Nitrogen-containing ligands for asymmetric homogeneous and heterogeneous catalysis have been highly developed.[1] Enantioselective reactions of olefins and diazoacetates catalyzed by a variety of metal complexes are also well known.[2,3] *N,N*-donor ligands led to remarkable *ee* values with copper complexes of bis-oxazolines[4,5] and semicorrins.[6] Chiral bipyridines were used for the first time by Katsuki[7,8] and very recently, Kwong and Lee[9] reported good enantioselective cyclopropanation with chiral C_2-symmetric terpyridine ligands.[10,11] Herein, we report a convenient synthesis of new chiral bi- and terpyridine ligands derived from the Kröhnke's method,[12] by using solvent-free microwave irradiation. Although microwave irradiation has been used for Suzuki coupling reactions of heterocycles,[13] to the best of our knowledge this is the first utilisation of microwave irradiation to form pyridyl rings. We also report the preparation and the characterisation of the corresponding Cu^{II} and Zn^{II} complexes, and the preliminary results of the catalytic activities of the terpyridine copper complex in asymmetric cyclopropanation.

Results and Discussion

Synthesis of polypyridine ligands usually requires a Stille coupling[14] or a Krönke reaction.[12] We used the latter, and carried out the preparation of the ligands in an expedient three-step synthesis: (−)-β-Pinene [(−)-**1**] was ozonolized to produce enantiomerically pure (+)-nopinone [(+)-**2**],[15,16] which was converted into the corresponding Mannich base **3** with the ratio 92:8 (determined by ^{1}H NMR) in favour of the (1*R*,3*R*,5*R*) diastereoisomer (Scheme 1). Condensation of the mixture of the two diastereoisomers of **3** with one equivalent of **4**[17] or **5**, or with half an equivalent of **6** under

the usual conditions (AcOH or formamide, NH_4OAc, 100 °C) led to **7**, **8**, or **9**, respectively, in very low yields (traces).

The polar solvents used for this reaction absorb microwaves very efficiently,[18] so we decided to carry out Kröhnke's synthesis under microwave irradiation. The yields increased to 10% (130 W, 5−15 min.), but the high temperatures decomposed most of the reactants or intermediates. In order to decrease the temperature dramatically, we tested solvent-free alumina-supported reaction conditions under microwave irradiation.[19] The alumina was mixed with ammonium acetate as an ammonia source. We expected that the strong affinity between alumina and salt reactants would provide a cleaner chemical conversion into the intermediate 1,5-diketone. Indeed, the microwave irradiation of this solvent-free mixture at 260 W for a few minutes led to the expected ligands **7**, **8**,[20] and **9** with good yields (45%, 50%, and 33%, respectively). Thus, the microwave irradiation eliminated the necessity of heating the reaction under reflux in the aggressive solvent (AcOH) that is required under the standard procedure, and the reaction time was reduced from approximately 4 hours to only a few minutes. Ligand **7** is particularly interesting for further study as it is a key product for the synthesis of polypyridines (by homocoupling to C2-symmetrical chiral quaterpyridines, or, after heterocoupling, to non-symmetrical chiral quaterpyridines).

Crystals suitable for X-ray crystallography were obtained by slow evaporation of a solution of **9** in chloroform. The molecular structure of **9**, as determined by X-ray analysis, is shown with its atom labelling scheme in Figure 1. Important bond lengths and bond angles are given in Table 1.

The main part of the molecule is roughly planar with the largest deviation being 0.211 Å at C(25). However, the external pyridine rings are slightly twisted with respect to the central one, resulting in dihedral angles of 10.95° and 6.32° for rings 2 and 3, respectively. Consequently, the C atoms of the pinene fragment are not symmetrically distributed with respect to the main plane of the terpyridine fragment, C(243) and C(343) being twisted away from it by 1.622 Å and −0.712 Å, whereas C(245) and C(345) are located −0.468 Å and 1.428 Å on each side of this plane. As observed in the related dipineno-[4,5:4′′,5′′]-fused 2,2′:6′,2′′-terpyridine[11] and in other terpyridine systems,[21] the nitrogen atoms are in the trans position with respect to each other in order to minimise the interactions between the nitrogen lone pairs.

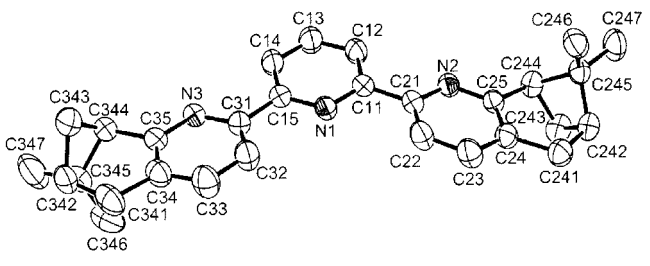

Figure 1. Molecular view of **9** with atom labelling scheme; ellipsoids represent 30% probability

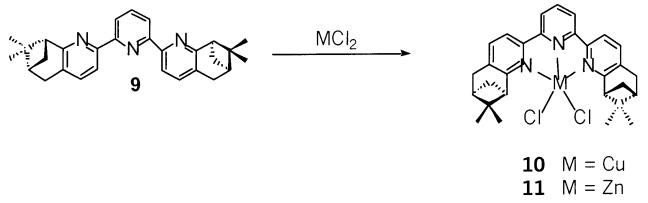

Scheme 2. Synthesis of the complexes

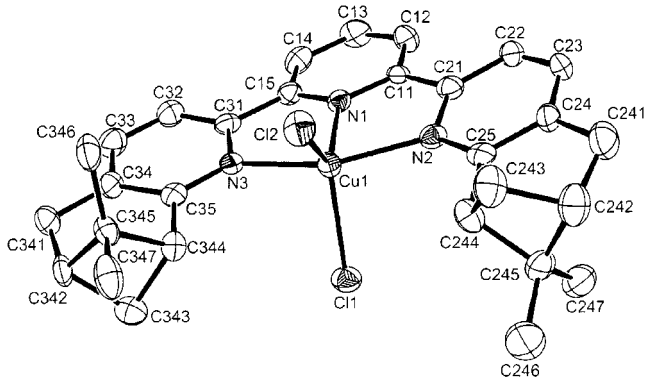

Figure 2. Molecular view of complex **10** with atom labelling scheme; ellipsoids are drawn at 30% probability

In order to investigate the coordination chemistry of this new terpyridine **9**, its copper complex was synthesised. Heating ligand **9** with $CuCl_2{\cdot}H_2O$ in EtOH for 3 hours under reflux resulted in the formation of **10** (Scheme 2). Crystals suitable for X-ray crystallography were obtained by recrystallization from dichloromethane/ether. The zinc complex **11** was also synthesised by reacting ligand **9** with $ZnCl_2$ in refluxing THF for 3 hours. Crystals suitable for X-ray crystallography were obtained by recrystallization from dichloromethane/ether. As the two complexes **10** and **11** are isostructural, only the copper one is shown, along with its atom labelling scheme, in Figure 2. Selected bond lengths and bond angles are given in Table 2.

In both complexes, the metal atom is surrounded by the three nitrogens of the terpyridine ligand and the two chlorine atoms in a distorted trigonal bipyramidal geometry (Table 2). The axial positions are occupied by two nitrogen atoms N(2) and N(3) [N(2)−Cu−N(3) = 157.2(2)° and 150.9(1)° for the Cu and Zn complexes, respectively]. The equatorial plane is made up of the two chlorine atoms and the nitrogen N(1) of the terpyridine moiety. The two M−Cl bonds are identical within experimental errors [M−Cl(1)= 2.317(1), 2.250(1) Å and M−Cl(2) = 2.314(1), 2.258(1) Å for the Cu and Zn complexes, respectively]. Although such a geometry has been observed for related five-coordinate $ZnCl_2$ species,[22] it is unusual for five-coordinate $CuCl_2$ complexes, which normally prefer square pyramidal conformations.[23] However, a similar pseudo trigonal-bipyramidal geometry has been observed in [Cu(terpy)X_2] (X= Br, I, NCS) complexes.[24] The occurrence of a trigonal bipyramidal geometry might be related to the presence of the bulky pinene substituents.

Owing to some hydrogen interactions occurring between the H attached to carbon C(12) and Cl(1)[20] [C−H···Cl: C−H = 0.95 Å, C···Cl = 3.501(5) Å, H···Cl = 2.568(1) Å, C−H···Cl= 167.6(1)°] the packing in the cell displays a right-handed helix arrangement of the complexes around the 6_1 axes (Figure 3). Such an arrangement explains the long *c* axes relative to *a* and *b*. The crystallisation in this space group is certainly induced by the shape and the (*R*,*R*) configuration of the terpyridine ligand.

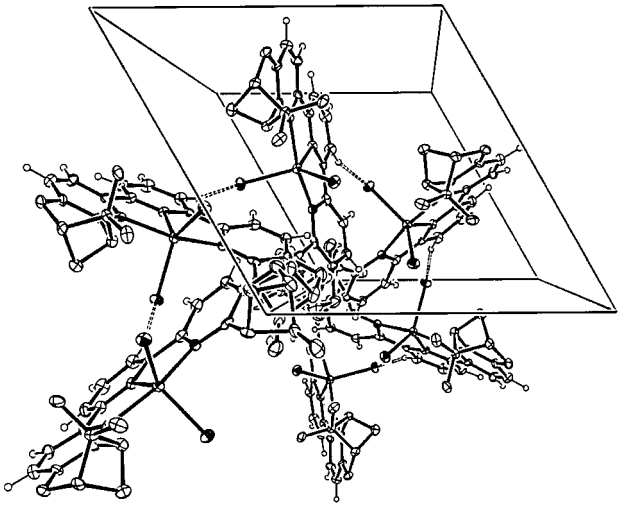

Figure 3. View along the 0 0 1 axis showing the right handed helix packing of the complexes around the 6_1 axes

To explore the catalytic potential of the copper terpyridine we examined the well-investigated cyclopropanation of various olefins with ethyl diazoacetate (Scheme 3). This commercially available diazoester, which is neither chiral nor a bulky reactant, has a very poor effect on the asymmetric induction, and allows one to evaluate the inherent capacity of the terpyridine to be a chiral controller. The reactions were carried out in the presence of 2mol % copper(II)triflate (2 mol % chiral ligand) in dichloromethane at ambient temperature. The use of other solvents such as toluene or THF led to much lower catalytic efficiency. The complex was found to be an efficient catalyst, converting alkenes and ethyldiazoacetate to optically active cyclopropanes (Table 3). Reaction of the mono-substituted olefins showed excellent yields of chiral cyclopropanes with good *trans*-selectivity, but moderate levels of enantioselectivity (6−66% *ee*) were observed. When ethyl diazoacetate was changed for the bulkier commercially available trimethylsilyldiazomethane, the diastereoselectivity increased slightly to a *trans*/*cis* ratio of 90:10, which has been observed with other copper catalysts.[7,8,25] Styrene derivatives bearing electron-donating groups showed lower enantioselectivity than those with electron-withdrawing groups, but higher reactivity (shorter reaction time). This result indicates that the active catalyst species is a strong electrophilic carbene copper complex.

N.D.: absolute configuration not determined

Based on the results and the sense of asymmetric induction, the metal carbenoid attack could be compared to the model previously reported by Pfaltz for *N,N*-bidentate ligands,[6] and by Kwong for *N,N,N*-tridentate ligands.[9] Using 1,1′- or 1,2-disubstituted olefins led to better results, showing that the steric interaction between the ligand and these olefins increased with respect to monosubstituted ones. For instance, a good *ee* of up to 87% was observed

with *trans*-stilbene. In contrast to the other substrates, *trans*-β-methylstyrene showed a remarkable reversed *cis*-selectivity, as already observed by Katsuki[8] with chiral bipyridine. The ratio *cis*/*trans* = 93:7 is of the same order as the results described by Nishiyama[26] with hydroxymethyl derivative of pybox and (+)-menthyl diazoacetate.

Conclusion

We have successfully synthesised new chiral ligands by microwave irradiation. The copper complex of the terpyridine derivative is an active catalyst for cyclopropanation and *ee*s up to 87% were observed. Cyclopropanation of *trans*-β-methylstyrene showed a very high *cis*-selectivity with ethyl diazoacetate. Further studies on other disubstituted olefins are under investigation.

Experimental Section

General: All reactions were carried out under an inert argon atmosphere. Chemicals were of reagent-grade quality and were obtained commercially. NMR spectra were recorded with a Bruker AM-250 (250 MHz) or AMX-400 (400 MHz) spectrometer for ^1H and ^{13}C and chemical shifts are reported in ppm downfield from Me_4Si in $CDCl_3$ or in CD_2Cl_2. All melting points are uncorrected and were measured on a SMP1 Stuart Scientific melting point apparatus. CI mass spectra and FAB mass spectra (*m*-nitrobenzyl alcohol matrix) were recorded with a quadrupolar Nermag R10−10H instrument. Optical rotations were measured on a Perkin−Elmer 241 polarimeter. Elemental analyses were performed by LCC (Laboratoire de Chimie de Coordination) Microanalytical Service. Column chromatography purifications were performed with Merck aluminum oxide (70−230 mesh ASTM), deactivated with 8% water. (+)-Nopinone was obtained from ozonolysis of (−)-β-pinene.[15]

Mannich Base of the Nopinone 3: *N*,*N*-dimethylmethyleneiminium chloride (6.8 g) was added to nopinone (**2**; 9 g) in 135 mL of dry acetonitrile. After stirring at room temperature for four days the white precipitate was filtered off and rinsed with acetonitrile. The filtrate was concentrated and more of the product was recovered (9.1 g, 60% yield). − M.p. 188 °C − ^1H NMR ($CDCl_3$): δ = 12.12 (m, 1 H), 3.5 (dd, ^2J = 12.8, ^3J = 3.6 Hz, 1 H), 3.23 (dd, ^2J = 12.8, ^3J = 10.0 Hz, 1 H), 2.92 (s, 6 H), 2.87 (m, 1 H), 2.66 (m, 2 H), 2.54 (m, ^2J = 14.0, ^3J = 2.4 Hz, 1 H), 2.34 (m sept, ^3J = 2.8 Hz, 1 H), 2.23 (ddd, ^2J = 14.0, ^3J = 3.6, ^3J = 3.6 Hz, 1 H), 1.34 (s, 3 H), 1.29 (d, ^2J = 10.8 Hz, 1 H), 0.94 (s, 3 H). − ^{13}CNMR ($CDCl_3$): δ = 211.9, 64.0, 58.4, 41.0, 40.7, 40.4, 29.7, 27.1, 26.2, 22.9. − MS (DCI, NH_3): *m*/*z* (%) = 196 (100), 197 (15). − $C_{12}H_{24}ClNO_2$·0.25H_2O: calcd. General Procedure for the Synthesis of Ligands 7 to 9 Under Microwave Irradiation: The aluminium oxide was prepared by mixing 10 g of aluminium oxide 90, 5 g of ammonium acetate, and 1 mL of AcOH in a mortar.

Freshly prepared aluminium oxide (3 g) was then added to a solution of **3** (1 mmol) and the pyridinium salt (1 mmol) in MeOH (30 mL). The solvent was evaporated and the resulting mixture was irradiated in the microwave oven for 4 min. at 260 W. After cooling, the ligand was extracted with CH_2Cl_2 and purified by column chromatography on aluminium oxide (eluent: 3% AcOEt in pentane)

Ligand 7: Following the above procedure with **4**, and the usual workup, gave **7** (0.142 g, 43%). − $[\alpha]_D^{20}$ = + 23.0 (*c* = 1, CH_2Cl_2). − M.p. 122 °C. − ^1H NMR ($CDCl_3$): δ = 8.33 (dd, ^3J = 7.5, ^4J = 1.0 Hz, 1 H), 8.15 (d, ^3J = 7.5 Hz, 1 H), 7. 60 (t, ^3J = 7.5 Hz, 1 H), 7.51 (d, ^3J = 7.5 Hz, 1 H), 7.41 (dd, ^3J = 7.5, ^4J = 1.0 Hz, 1 H), 3.04 (t, ^3J = 5.5 Hz, 1 H), 2.97 (d, ^3J = 2.5 Hz, 2 H,), 2.73 (td, ^2J = 9.5, ^3J = 5.5 Hz, 1 H), 2.33 (m sept, ^3J = 2.8 Hz, 1 H), 1.43 (s, 3 H), 1.32 (d, ^2J = 9.5 Hz, 1 H), 0.67 (s, 3 H). − ^{13}C NMR ($CDCl_3$): δ = 165.9, 158.0, 150.3, 141.3, 139.0, 135.9, 131.4, 127.2, 119.5, 119.2, 50.5, 40.0, 39.2, 31.3, 30.8, 26.0, 21.2. − MS (DCI, NH_3): *m*/*z* (%) = 317 (98), 319 (100) $[MH^+]$. − $C_{17}H_{17}BrN_2$ (329.24): calcd. Ligand 9: Following the above procedure with half an equivalent of **6**, and the usual workup, gave **9** (0.080 g, 38%) − $[\alpha]_D^{20}$ = − 8.4 (*c* = 1, CH_2Cl_2). − M.p. 255 °C. − ^1H NMR ($CDCl_3$): δ = 8.38 (d, ^3J = 3.8 Hz, 2 H), 8.35 (d, ^3J = 3.8 Hz, 2 H), 7.86 (t, ^3J = 7.8 Hz, 1 H), 7.56 (d, ^3J = 7.8 Hz, 2 H), 3.09 (dd, ^3J = 5.6, ^3J = 5.6 Hz, 2 H), 2.99 (d, ^3J = 2.5 Hz, 4 H), 2.74 (td, ^2J = 9.7, ^3J = 5.9 Hz, 2 H), 2.35 (m sept, ^3J = 2.8 Hz, 2 H), 1.44 (s, 6 H), 1.35 (d, ^2J = 9.7 Hz, 2 H), 0.70 (s, 6 H). − ^{13}C NMR ($CDCl_3$): δ = 165.7, 155.7, 152.3, 137.6, 135.9, 130.5, 120.2, 118.8, 50.5, 40.1, 39.2, 31.3, 30.9, 26.0, 21.3. − MS (DCI, NH_3): *m*/*z* (%) = 422 $[MH]^+$. − $C_{29}H_{31}N_3$ (421.58): calcd. C 82.11, H 7.63, N 10.26; found C 82.51, H 7.28, N 9.55.

Synthesis of Copper Complex 10: Complex **10** was synthesized by mixing ligand **9** (0.1 mmol) and copper(II) chloride dihydrate (0.05 mmol) in absolute EtOH (6 mL). The mixture was heated under reflux for 3 hours and the precipitate then collected. The green-yellow complex crystallised by slow diffusion of ether into a solution of **10** in dichloromethane (16 mg, 58% yield). − Positive ion FAB-MS: *m*/*z* = 519 $[M - Cl]^+$, 484 $[M - 2Cl]^+$.

Synthesis of Zinc Complex 11: Complex **11** was synthesised by adding ligand **9** (0.1 mmol) in THF (20 mL) to a stirred solution of zinc(II) chloride (0.1 mmol) in THF (10 mL). The mixture was then heated under reflux for 3 hours. After cooling, the solvent was evaporated and the white solid was recrystallized from a mixture of dichloromethane and ether (38 mg, 70% yield). − ^1H NMR (CD_2Cl_2): δ = 8.16 (m, 3 H), 7.98 (d, ^3J = 7.9 Hz, 2 H), 7.73 (d, ^3J = 7.9 Hz, 2 H), 4.25 (dd, ^3J = 5.5, ^3J = 5.5 Hz, 2 H), 3.10 (d, ^3J = 2.5 Hz, 4 H), 2.89 (m, 2 H), 2.39 (m sept, ^3J = 2.8 Hz, 2 H), 1.55 (s, 6 H), 1.41 (d, ^2J = 10.1 Hz, 2 H), 0.76 (s, 6 H). − ^{13}C NMR (CD_2Cl_2): δ = 169.1, 151.5, 144.1, 142.4, 138.4, 136.6, 121.4, 119.5, 49.6, 40.2, 39.9, 32.5, 30.8, 26.3, 21.8. − Positive ion FAB-MS: *m*/*z* = 520 $[M - Cl]^+$, 484 $[M - 2Cl]^+$.

X-ray Crystallographic Study: Suitable crystals of ligand **9** were grown by slow evaporation of a chloroform solution. Suitable crystals of complexes **10** and **11** were grown by dissolving each of them in dichloromethane and allowing diethyl ether to diffuse into the solution. Data for **9**, **10**, and **11** were collected on a Stoe IPDS diffractometer. The final unit cell parameters were obtained by the least-squares refinement of 8000 reflections. Only statistical fluctuations were observed in the intensity monitors over the course of the data collections.

All the structures were solved by direct methods (SIR97[27]) and refined by least-squares procedures on F^2. All H atoms were introduced in calculated idealised positions [d(CH) = 0.96 Å] and treated as riding models with isotropic thermal parameters related to the carbon to which they are attached. Least-squares refinements were carried out by minimising the function $\Sigma w(F_o^2 - F_c^2)^2$, where F_o and F_c are the observed and calculated structure factors. The absolute structure for **10** and absolute configuration for **11** were determined by refining the Flack enantiopole parameter.[28] The weighting scheme used in the last refinement cycles was $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = (F_o^2 + 2F_c^2)/3$ Models reached convergence with $R = \Sigma (||F_o| - |F_c||)/\Sigma(|F_o|)$ and $wR2 = \{\Sigma w(F_o^2 - F_c^2)^2/\Sigma w (F_o^2)^2\}^{1/2}$ with the values listed in Table 2. The calculations were carried out using the SHELXL-97 program[29] running on a PC. Molecular views were realised with the help of ORTEP32.[30] Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-158858 (**9**), -158859 (**10**) and -158860 (**11**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Procedure for Copper-Catalysed Cyclopropanation: A solution of 0.2 mmol of ligand and 0.2 mmol of $Cu(OTf)_2$ in dichloromethane (2 mL) under argon was stirred for 2 hours at room temperature. The alkene (4 mmol) and the ethyl diazoacetate (0.2 mmol) were then added and the mixture was stirred for 30 min. The reduction of Cu^{II} to Cu^{I} could also be activated by gentle heating of the solution (the colour of the solution changing from green to reddish). Slow addition of 2 mL of a 0.5 mM solution of the diazo compound in CH_2Cl_2 was carried out over a period of 3 hours, using a syringe pump. The mixture was allowed to stir overnight at room temperature then worked up by removing the solvent and purifying the crude product by column chromatography (pentane/ethyl acetate). All isolated cyclopropanes were known compounds and were characterised by ^1H and ^{13}C NMR spectroscopy, and mass spectrometry.

Kinetics of the Oxidative Addition of *ortho*-Substituted Aryl Halides to Palladium(0) Complexes

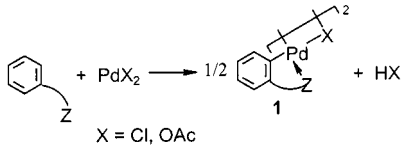
Mouad Alami,[a] Christian Amatore,*[b] Samia Bensalem,[b,c] Abdelharim Choukchou-Brahim,[c] and Anny Jutand*[b]

Keywords: Palladium / Oxidative addition / Kinetics / P ligands / P, P ligands

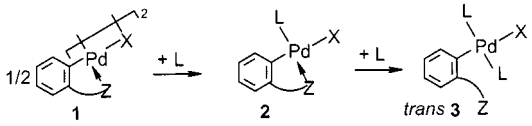
The rate constant of the oxidative addition of *ortho*-substituted aryl halides, *o*-ZCH_2–C_6H_4–X [X = I, Br; Z = OMe, NEt_2, $N(CH_2)_5$] to $Pd^0(PPh_3)_4$ or to Pd^0(dba)(dppp) generated from $Pd^0(dba)_2$ and 1 equiv. of dppp is determined. The oxidative addition is slower for *ortho*-substituted aryl halides than for the corresponding nonsubstituted or *meta*-substituted aryl halides. The *ortho* substituents investigated here do not participate in the oxidative addition by a preliminary complexation of the active $Pd^0(PPh_3)_2$ or Pd^0(dppp) complex. The observed decelerating effect induced by the *ortho* substituents is due to steric hindrance and electronic donor effects and is less important for aryl bromides than for aryl iodides; *ortho*-substituted aryl iodides remain more reactive than *ortho*-substituted aryl bromides for both ligands PPh_3 and dppp. The *cis*-(*o*-ZCH_2–C_6H_4)PdX(dppp) complexes are formed in the oxidative addition whereas an equilibrium takes place between *trans*-(*o*-ZCH_2–C_6H_4)$PdX(PPh_3)_2$ and (*o*-ZCH_2–C_6H_4)$PdX(PPh_3)$(*Z*–*Pd*) complexes.

Introduction

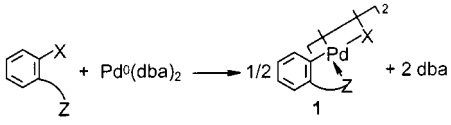
Dimeric *ortho*-palladated complexes **1** are synthesized by reaction of a Pd^{II} salt and a substituted arene, in which the substituent may be a ligand for the Pd^{II} centers [Equation (1)].[1–7] This reaction is regarded as a preliminary complexation of the Pd^{II} salt by the substituent of the arene, followed by an intramolecular electrophilic aromatic substitution of the Pd^{II} center.[8] When the coordinated atom Z (Z = N, O) is linked to the arene through one atom (C or N) the resulting five-membered palladated complexes **1** are quite stable.[1–7] Monomeric complexes **2** and **3** are generated from dimeric complexes **1** by addition of 1 or 2 equiv. of L per Pd, respectively [Equation (2)];[9,10] *ortho*-palladated complexes **1** are also generated by an oxidative addition of an *ortho*-substituted aryl halide to a Pd^0 complex, $Pd^0(dba)_2$ [Equation (3)], with subsequent formation of complexes **2** and **3** after addition of a ligand [Equation (2)].[9–10]



(1)

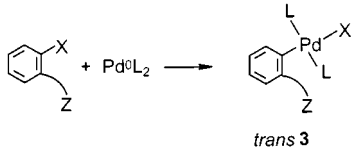


(2)



(3)

A recent paper[11] reports the synthesis of phosphane-bis(ligated) complexes **3** by oxidative addition of aryl bromides, substituted in the *ortho* position by CHO or C(O)Me, to Pd^0 complexes ligated by PPh_3 [Equation (4)]. Phosphane-monoligated complexes **2** are formed in the case of a bulky ligand L = P(*o*-tolyl)$_3$ and a C(O)Me substituent, which is able to coordinate the Pd^{II} center by the O atom.



(4)

Whereas reactions of *ortho*-substituted aryl halides with nucleophiles (alkynes,[12,13] alkenes,[13,14] organometallic reagents[6,15]) are catalyzed by Pd^0 complexes, reactions involving substituted arenes cannot be catalyzed by Pd^{II} complexes able to activate the initial substituted arene, unless the Pd^0 complex generated in the last step[4,7,16] is oxidized back to a Pd^{II} complex. To the best of our knowledge, the recycling of the Pd^{II} catalyst by oxidation has not yet been realized.[7]

Pd^0-catalyzed cross-coupling reactions of nucleophiles with *ortho*-substituted aryl halides are usually slower than with the corresponding nonsubstituted or *para*/*meta*-substituted aryl halides.[6,15] The three main steps involved in the catalytic cycle (oxidative addition, transmetallation, and reductive elimination) may be affected by the *ortho* substitution of the aryl derivatives,[15] due to steric hindrance around the metal center and to electronic effects consecutive to potential intramolecular complexation of the substituent for the metal centers. Nonsubstituted or *para*/*meta*-substituted aryl iodides are usually more reactive than the corresponding aryl bromides.[6,15] This is rationalized by considering that the oxidative addition becomes rate-determining when considering aryl bromides, which indeed are less reactive with Pd^0 complexes than aryl iodides in oxidative additions.[17,18] In the case of *ortho*-substituted aryl halides, the situation is much more complex in the sense that the *ortho* substituent may induce a steric hindrance, which is expected to slow down the oxidative addition. However, *ortho*-substituted aryl bromides become globally less bulky than *ortho*-substituted aryl iodides due to the smaller size of the Br atom compared to that of the I atom. On the other hand, the Pd^0L_2 (L = phosphane) complex, active in the oxidative addition step, is usually present at low concentration because it is involved in an endergonic equilibrium with a major but unreactive Pd^0L_2L' complex (L = phosphane, L′ = phosphane[19] or dba[20]). A preliminary complexation of the active Pd^0L_2 complex by the *ortho* substituents of the aryl halides should result in an intramolecular oxidative addition step with a consequently faster overall reaction.

These antagonist effects prompted us to investigate the kinetics of the oxidative addition of *ortho*-substituted aryl iodides and bromides with Pd^0 complexes ligated by a monodentate ligand as in $Pd^0(PPh_3)_4$ or by a bidentate ligand as in Pd^0(dba)(dppp). The latter was generated by treating $Pd^0(dba)_2$ with 1 equiv. of dppp [dppp = $Ph_2P-(CH_2)_3-PPh_2$].[21,22] The *ortho* substituents are either $-CH_2-NR_2$ or $-CH_2-OR$ groups so that potentially five-membered palladated complexes might be generated.

Results and Discussion

Characterization of the (Aryl)palladium(II) Complexes Formed in the Oxidative Addition of *ortho*-Substituted Aryl Iodides and Bromides to Palladium(0) Complexes

Before discussing kinetic data on the comparative reactivity of *ortho*-substituted aryl iodides and bromides with Pd^0 complexes, the (aryl)palladium(II) complexes formed in the

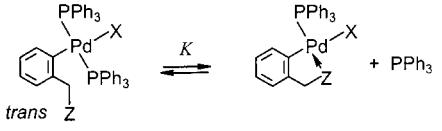
[a] Determined in [D_1]chloroform vs. H_3PO_4 as an external standard at 293 K. – [b] *cis*-PhPdI(dppp).[36] – [c] A minor singlet for PPh_3 at δ = −5.1 was also observed. – [d] Data in square brackets are indicative of the relative integration of the ^{31}P NMR signals. – [e] A broad singlet for PPh_3 at δ = −5.2 was also observed, integrating for 32%. – [f] n.o.: not observed.

oxidative addition were first characterized. The reactions were performed by treating the aryl halides (in large excess) with either $Pd^0(PPh_3)_4$ or with a mixture $Pd^0(dba)_2$ + 1 equiv. of dppp in toluene. The complexes were isolated and characterized by ^{31}P NMR spectroscopy (Table 1).

The oxidative addition of PhI or the *meta*-substituted aryl iodide **4** to $Pd^0(PPh_3)_4$ gave the expected *trans*-$PhPdI(PPh_3)_2$ and *meta*-**4a** complexes, respectively as unique complexes. (Table 1, Entries 1,2). The *ortho*-substituted aryl iodide **5** and bromide **6** gave a major complex **5a** and **6a**, respectively, characterized by a narrow singlet at $\delta \approx 22$ in the ^{31}P NMR spectra (Table 1, Entries 3,4), which is indicative of two equivalent PPh_3 moieties ligated to the Pd^{II} center.[11] The two PPh_3 groups are in a *trans* position, in agreement with the recently published X-ray structure of a related complex with X = Br and CHO as the *ortho* substituent.[11] The complex is slightly distorted square-planar. The two triphenylphosphane ligands (δ = 23.2) are in a *trans* position, and are magnetically equivalent because the plane of the *ortho*-substituted aryl group is perpendicular to the plane of P, Pd, P, and Br.

In both cases, besides a minor signal for PPh_3 at $\delta = -5$, another minor narrow singlet was detected at $\delta \approx 41$ and assigned to complexes **5b** and **6b** (Table 1). In these complexes the Pd^{II} center is ligated by only one PPh_3, the fourth coordination site being occupied by the amine substituent. Indeed, the singlets at δ = 41.1 and 41.7 disappeared after addition of PPh_3, which is evidence of an equilibrium between the complexes **5a/5b** or **6a/6b** and PPh_3 [Equation (5)]. Moreover, the values of δ = 41.1 and 41.6 assigned to **5b** and **6b**, respectively, are very similar to those reported for related cyclopalladated complexes where the Pd^{II} center is ligated by only one PPh_3.[11,23]



(5)

This is also in agreement with literature results, which report that phosphane-bis(ligated) (aryl)palladium(II) complexes are formed after addition of a second ligand to phosphane-monoligated complexes [Equation (2)].[9,10]

Stronger evidence for the equilibrium [Equation (5)] was provided upon treating the aryl iodide **7** with $Pd^0(PPh_3)_4$. Indeed, three broad signals ($\Delta\nu_{1/2}$ = 152 Hz) of very similar integration were observed in the ^{31}P NMR spectrum at δ = 41.7, 21.7, and −5.2, and these were assigned to complexes **7b**, **7a**, and PPh_3, respectively (Table 1, Entry 5). Addition of PPh_3 shifted the equilibrium [Equation (5)] towards its left-hand side, and complex **7a** was then observed as the major complex. The equilibrium constant *K* between **7a**, **7b**, and PPh_3 [Equation (5)] was estimated from the ^{31}P NMR spectroscopic data to K/c_0 = 0.6 (in $CDCl_3$ at 25 °C for $c_0 \approx$ 20 mM). The oxidative addition of aryl halides **8** or **9**, substituted in *ortho* position by a $-CH_2-OMe$ group, to $Pd^0(PPh_3)_4$ generated the phosphane-bis(ligated) complexes **8a** or **9a**, respectively (Table 1, Entries 6,7).

The oxidative addition of *ortho*-substituted aryl iodides or bromides to the Pd^0 complex generated from $Pd^0(dba)_2$ + 1 equiv. of dppp always gave the corresponding *cis*-ArPdX(dppp) complexes without any intramolecular coordination by the *ortho* substituent (Table 1, last column). In all cases, the ^{31}P NMR spectrum exhibited two doublets caused by the coupling of two nonequivalent P atoms ligated to the Pd^{II} center in a *cis* position. Moreover, the observed chemical shifts were very similar to those of the complexes generated by oxidative addition of PhI or *meta*-substituted phenyl iodide **4** (Table 1, Entries 1 and 2, last column), in which no internal coordination by the substituent may occur, by construction.

Therefore, in almost every case, the oxidative addition generates a major *trans*-(aryl)palladium(II) complex ligated by two phosphane ligands, without any intramolecular coordination of the *ortho* substituent. It is only with a monophosphane ligand (PPh_3) that an intramolecular complexation of the substituent may occur (Table 2, Entry 5),

Table 2. Comparative reactivity of ArX (X = I, Br) in their oxidative addition to $Pd^0(PPh_3)_4$ and to [$Pd^0(dba)_2$ + 1 equiv. of dppp] in DMF

involving decomplexation of one PPh_3 through an endergonic equilibrium [Equation (5)]. This does not occur with the bidentate ligand dppp considered here because the decomplexation of one phosphorus atom of a bidentate P,P ligand possessing a small bite angle is not favored.[24]

Comparative Reactivity of *ortho*-Substituted Aryl Iodides and Bromides in Their Oxidative Addition to Palladium(0) Complexes in DMF

Oxidative Addition to $Pd^0(PPh_3)_4$

The mechanism of the oxidative addition of aryl halides to $Pd^0(PPh_3)_4$ is now well established and proceeds according to Scheme 1 (S = solvent).[19,25] The kinetics of the oxidative addition was monitored by amperometry performed at a rotating disk electrode, polarized at +0.3 V vs. SCE, on the plateau of the oxidation wave of $Pd^0(PPh_3)_3$ (c_0 = 2 mM in DMF containing nBu$_4$NBF$_4$, 0.3 M). The decay of the oxidation current intensity, proportional to the Pd^0 concentration, was recorded versus time, after addition of the aryl halide in excess.[25]

$$Pd^0(PPh_3)_4 \rightleftharpoons Pd^0(PPh_3)_3 + PPh_3$$

$$Pd^0(PPh_3)_3 \overset{K_0}{\rightleftharpoons} SPd^0(PPh_3)_2 + PPh_3$$

$$SPd^0(PPh_3)_2 + ArX \xrightarrow{k} ArPdX(PPh_3)_2$$

Overall reaction:

$$Pd^0(PPh_3)_4 + ArX \xrightarrow{k_{app}} ArPdX(PPh_3)_2 + 2PPh_3 \quad (6)$$

Scheme 1. Mechanism of the oxidative addition of aryl halides to $Pd^0(PPh_3)_4$; S = solvent

The plot of $2\ln(i/i_0) + 1 - i/i_0 = 2\ln([Pd^0]/[Pd^0]_0) + 1 - [Pd^0]/[Pd^0]_0$ versus time was linear (Figure 1) (i: oxidation current intensity at t; i_0: initial oxidation current intensity).

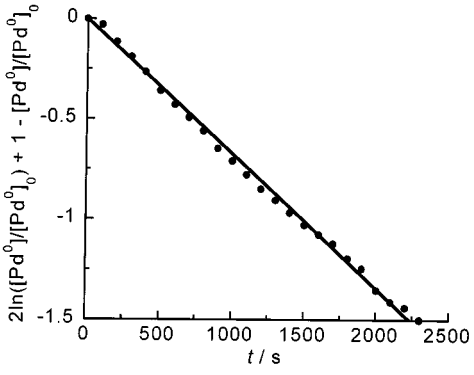

Figure 1. Oxidative addition of the aryl bromide **6** [0.2 M in DMF containing nBu$_4$NBF$_4$ 0.3 M)] to $Pd^0(PPh_3)_4$ (2 mM) at 40 °C, monitored by amperometry at a rotating gold disk electrode (i.d. 2 mm, ω = 105 rad·s^{-1}) polarized at + 0.35 V; plot of $2\ln(i/i_0) + 1 - i/i_0 = 2\ln([Pd^0]/[Pd^0]_0) + 1 - [Pd^0]/[Pd^0]_0$ versus time (i: oxidation current intensity at t; i_0: initial oxidation current intensity) [see Equation (7)]

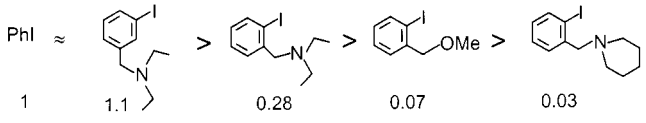
Note that the kinetic law [Equation (7)] is not strictly logarithmic due to the PPh_3 release during the reaction (Scheme 1).[25]

$$2\ln([Pd^0]/[Pd^0]_0) + 1 - [Pd^0]/[Pd^0]_0 = -kK_0[ArX]t/c_0 = -k_{app}[ArX]t \quad (7)$$

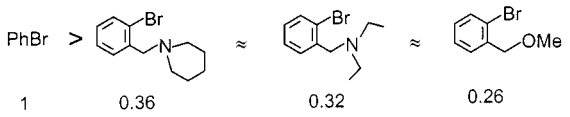
The apparent rate constant k_{app} of the overall oxidative addition [Equation (6)] was determined from the slope of the regression lines [Equation (7), Figure 1]. From the results gathered in Table 2, one observes the following order of reactivity: ArI >> ArBr, for identical *ortho* substituents, even when considering that the experimental temperature was generally lower for ArI (25 °C) than for ArBr (40 °C). This is consistent with the higher reactivity of nonsubstituted (Table 2, Entries 1−4) or *para*/*meta*-substituted aryl iodides when compared to the related aryl bromides as observed by Fitton and Rick.[17]

In the aryl iodides series (Scheme 2), the *meta* substitution does not significantly affect the rate of the oxidative addition. This rules out a preliminary complexation of the active $Pd^0(PPh_3)_2$ by the substituent, which would have affected the rate of the oxidative addition by decreasing the active $Pd^0(PPh_3)_2$ concentration. The *ortho* substitution slows down the oxidative addition. Since no precomplexation of the $Pd^0(PPh_3)_2$ complex by the *ortho* substituent occurs before the oxidative addition step, the mechanism of the oxidative addition (Scheme 1) is still valid. The decelerating effect is then rationalized by the cumulative influence of steric hindrance and electron-donating property of the substituent efficient in the *ortho* position, which both decrease the reaction rate. Electron-donating groups are indeed known to slow down oxidative additions of aryl derivatives to $Pd^0(PPh_3)_4$ complexes.[17−19] However, although the $-CH_2-OMe$ substituent is less electron-donating and less bulky than $-CH_2-NEt_2$, the corresponding aryl iodide is significantly less reactive, a fact which is difficult to rationalize. Some stabilization may occur in the transition state en route to the Pd^{II} center.



Scheme 2. Relative reactivity of aryl iodides in their oxidative addition to $Pd^0(PPh_3)_4$ at 25 °C

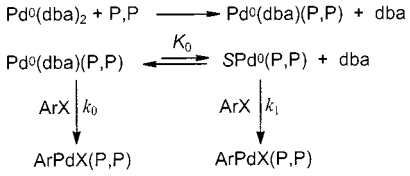
In the aryl bromides series (Scheme 3), the decelerating effect of the *ortho* substituent is less important than the corresponding one in the aryl iodide series (Scheme 2). This is consistent with the smaller size of the Br atom compared to that of the I atom, which globally decreases the steric constraint imposed by an *ortho* substituent in the aryl bromide compared to that in the corresponding aryl iodide.



Scheme 3. Relative reactivity of aryl bromides in their oxidative addition to $Pd^0(PPh_3)_4$ at 40 °C

Oxidative Addition to $Pd^0(dba)_2$ + 1 equiv. of dppp

As already reported, a major complex $Pd^0(dba)(P,P)$ is formed from $Pd^0(dba)_2$ and 1 equiv. of bidentate P,P ligands.[21,22] The mechanism of the oxidative addition of aryl halides has been established for P,P ligands (Scheme 4). The most reactive complex is the minor complex $SPd^0(P,P)$ but the major complex $Pd^0(dba)(P,P)$ is also reactive ($k_1 > k_0$).[22]



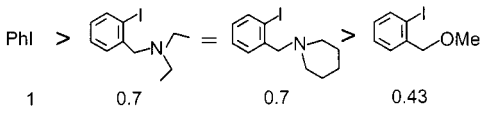
Scheme 4. Mechanism of the oxidative addition of aryl halides to the Pd^0 complexes generated from $Pd^0(dba)_2$ and 1 equiv. of bidentate P,P ligand.

In DMF, the formation of the major complex $Pd^0(dba)(dppp)$ from $Pd^0(dba)_2$ and 1 equiv. of dppp is a slow reaction because of the formation of the intermediate complex $Pd^0(dppp)_2$.[22] Therefore, the reactivity of aryl iodides or bromides in oxidative addition to $Pd^0(dba)(dppp)$ was investigated at least 90 min after mixing $Pd^0(dba)_2$ (2 mM in DMF) and dppp (2 mM) at room temperature, to ensure the total formation of $Pd^0(dba)(dppp)$. The apparent rate constant k_{app} of the overall oxidative addition [Equation (8)] was determined as explained above for $Pd^0(PPh_3)_4$, except that the rotating disk electrode was polarized at +0.7 V vs. SCE because $Pd^0(dba)(dppp)$ is less easily oxidized than $Pd^0(PPh_3)_3$.

(8)

The reactions were considerably slower compared to that of $Pd^0(PPh_3)_4$. They were then performed at 40 °C even for aryl iodides (Table 2). It has already been observed that $Pd^0(PPh_3)_4$ is generally considerably more reactive than $Pd^0(dba)_2$ + 1 equiv. of P,P,[20,22] despite the fact that P,P ligands are usually more basic and possess a smaller P−Pd−P angle than PPh_3. This arises from the fact that the concentration of $SPd^0(PPh_3)_2$ in the equilibrium with $Pd^0(PPh_3)_3$ (Scheme 1) is higher than that of $SPd^0(P,P)$ in the equilibrium with $Pd^0(dba)(P,P)$ (Scheme 4).[20]

As observed above for $Pd^0(PPh_3)_4$, PhI is more reactive than PhBr (Table 2, Entries 2, 4). The kinetics of the oxidative addition was only investigated for *ortho*-substituted aryl iodides, because reactions with *ortho*-substituted aryl bromides were too slow, even in the presence of ArBr in very large excess. The concomitant decomposition of the Pd^0 complex could not be excluded. In the aryl iodides series (Scheme 5), the *ortho* substitution slows down the oxidative addition, but the decelerating effect is less important than that observed with $Pd^0(PPh_3)_4$ (Scheme 2).



Scheme 5. Relative reactivity of aryl iodides in their oxidative addition to the Pd^0 complexes generated in the mixture $Pd^0(dba)_2$ and dppp at 40 °C

Conclusion

Determination of the rate constant of the oxidative addition of *ortho*-substituted aryl halides *o*-$ZCH_2-C_6H_4-X$ [X = I, Br; Z = OMe, NEt_2, $N(CH_2)_5$] with $Pd^0(PPh_3)_4$ or with the Pd^0 complexes generated from $Pd^0(dba)_2$ and 1 equiv. of dppp shows that the oxidative addition is slower for *ortho*-substituted aryl halides than for the corresponding nonsubstituted or *meta*-substituted aryl halides. This means that the *ortho* substituents do not participate in the oxidative addition by a preliminary complexation of the active $Pd^0(PPh_3)_2$ or Pd^0(dppp) complex. Oxygen and nitrogen ligands are indeed poor ligands for Pd^0 centers, unless they are involved in a bidentate complexation as for P,O or P,N ligands.[26] The observed decelerating effect induced by the *ortho* substituent is due to steric hindrance and electronic effects caused by the electron-donor properties of the substituents. These effects are less important for *ortho*-substituted aryl bromides than for *ortho*-substituted aryl iodides. Considering the same substituent, *ortho*-substituted aryl iodides remain more reactive than *ortho*-substituted aryl bromides, whatever the ligand. No inversion of reactivity occurs in the oxidative addition due to the *ortho* substitution. Were an inversion of reactivity observed in a Pd-catalyzed cross-coupling reaction, it should then arise at the level of the transmetallation step, which follows the oxidative addition. This probably lies at the origin of the inversion of reactivity observed in the palladium-catalyzed coupling of organomanganese derivatives with aryl halides, for which *ortho*-substituted aryl iodides were found to be less reactive than *ortho*-substituted aryl bromides.[27]

In this respect, it is worth to emphasize that an equilibrium results between *trans*-(*o*-$ZCH_2-C_6H_4$)$PdX(PPh_3)_2$ complexes formed in the oxidative addition and (*o*-$ZCH_2-C_6H_4$)$PdX(PPh_3)$(*Z*−*Pd*) exhibiting an intramolecular complexation of the *ortho* substituent. Nitrogen ligands are indeed good ligands for Pd^{II} centers, and the intramolecular character of the complexation enhances this effect. The latter complex might be involved in reactions with nucleophiles (transmetallation step). The *cis*-(*o*-$ZCH_2-C_6H_4$)PdX(dppp) complexes are formed when the Pd^0 is ligated by a bidentate ligand such as dppp. The bidentate character of this P,P ligand with a small bite angle

makes the intramolecular complexation by the *ortho* substituent less probable.

Experimental Section

General: All experiments were performed using standard Schlenk techniques under argon. − DMF was distilled from calcium hydride under vacuum. Toluene was distilled from sodium. − Iodo- and bromobenzene were commercial (Acros) and used after filtration through alumina. The dppp was commercial (Aldrich) and used without purification. $Pd(PPh_3)_4$,[28] $Pd(dba)_2$,[29] and $PhPdI(PPh_3)_2$ [17] were synthesized according to published procedures, as well as compounds **5**,[30,31] **6**,[32] **7**,[31] **8**,[33] **9**,[34] and **10**.[32] − ^{31}P NMR spectra were recorded with a Bruker spectrometer (162 MHz) using H_3PO_4 as an external reference, ^1H NMR spectra with a Bruker spectrometer (250 MHz) using TMS as an internal reference.

Diethyl(3-iodobenzyl)amine (4): Synthesis according to a published procedure[32] by treating 3-iodobenzyl bromide with diethylamine in anhydrous diethyl ether at room temperature. − ^1H NMR (250 MHz, $CDCl_3$): δ = 0.86 (t, *J* = 7.0 Hz, 6 H, CH_3), 2.33 (q, *J* = 7.0 Hz, 4 H, CH_2-CH_3), 3.31 (s, 2 H, CH_2-N), 6.83 (t, *J* = 7.7 Hz, 1 H, 5-*H*), 7.13 (d, *J* = 7.7 Hz, 1 H, 6-*H*), 7.37 (d, *J* = 7.7 Hz, 1 H, 4-*H*), 7.57 (s, 1 H, 2-*H*).

General Procedure for the Oxidative Addition: Complexes *m*-**4a**, **5a**, **6a**, **7a**, **8a**, and **9a** were synthesized according to a Fitton procedure.[17] In a Schlenk flask containing a solution of the aryl halide (from $4\cdot10^{-3}$ mol for the aryl iodides **4**, **5**, **7**, and **8** to 0.05 mol for the aryl bromides **6** and **9**) in 5 mL of degassed toluene was added 0.58 g ($0.5\cdot10^{-3}$ mol) of $Pd(PPh_3)_4$. The solution was kept overnight at room temperature for aryl iodides and heated during 4 h for aryl bromides. After filtration, the toluene was removed under vacuum, and the crude mixture was triturated with diethyl ether to eliminate the excess phosphane and aryl halide. The solid complexes were then characterized by ^{31}P NMR spectroscopy (Table 1).

(*o*-$CH_3OCH_2-C_6H_4$)PdI(PPh_3)$_2$ (8a): ^1H NMR (250 MHz, $CDCl_3$): δ = 2.85 (s, 3 H, OCH_3), 4.14 (s, 2 H, CH_2), 6.18 (t, *J* = 7.0 Hz, 1 H, 5-*H*), 6.35 (d, *J* = 7.0 Hz, 1 H, 3-*H*), 6.45 (t, *J* = 7.0 Hz, 1 H, 4-*H*), 6.74 (d, *J* = 7.0 Hz, 1 H, 6-*H*), 7.1−7.4 (m, 30 H, *H* of PPh_3).

Complexes *m*-**4c**, **5c**, **8c**, and **9c** were synthesized according to an adapted version of the Herrmann procedure.[35] In a Schlenk flask, containing a solution of 0.28 g ($0.5\cdot10^{-3}$ mol) of $Pd(dba)_2$ in 5 mL of degassed toluene, was added 0.21 g ($0.5\cdot10^{-3}$ mol) of dppp. After 2 h, 0.05 mol of the aryl halide was added. The solution was heated during 4 h for aryl iodides **4**, **5**, **8** and 6 h for the aryl bromide **9**. After filtration, the toluene was removed under vacuum, and the crude mixture was triturated with diethyl ether to eliminate the excess aryl halide. The pale-yellow complexes were then crystallized from chloroform/petroleum ether and characterized by ^{31}P NMR spectroscopy (Table 1).

Electrochemical Set-up for Amperometry and Kinetic Measurements of the Oxidative Addition: Electrochemical experiments were carried out in a three-electrode cell connected to a Schlenk line. The cell was equipped with a double envelope to maintain a constant temperature (Lauda RC20 thermostat). The working electrode consisted of a gold disk (i.d. 2 mm, Tacussel EDI 65109). The counter electrode was a platinum wire of ca. 1 cm^2 apparent surface area. The reference was a saturated calomel electrode separated from the solution by a bridge filled with a solution of nBu_4NBF_4 (0.3 mol dm^{-3}) in 3 mL of DMF. 15 mL of DMF containing the same concentration of supporting electrolyte was poured into the cell followed by 34 mg ($0.03\cdot10^{-3}$ mol) of $Pd(PPh_3)_4$. The kinetic measurements were performed using the rotating gold disk electrode with an angular velocity of 105 rad s^{-1} (Tacussel controvit). The potential of the rotating disk electrode was set at +0.35 V on the oxidation plateau wave of $Pd^0(PPh_3)_4$. The suitable amount of the aryl halide was added and the decay of the oxidation current was then monitored as a function of time. − In other experiments, 17 mg ($0.03\cdot10^{-3}$ mol) of $Pd(dba)_2$ was added, followed by 12 mg ($0.03\cdot10^{-3}$ mol) of dppp. After 2 h, the potential of the rotating disk electrode was set at +0.70 V on the oxidation plateau wave of Pd^0(dba)(dppp). The decay of the oxidation current was monitored as a function of time after addition of the suitable amount of the aryl halide.

Bis[(3,5-dimethyl-1-pyrazolyl)methyl]ethylamine − A Versatile Ligand for Complexation in Rh^I Cationic Complexes

René Mathieu,*[a] Glòria Esquius,[a,b] Noël Lugan,[a] Josefina Pons,[b] and Josep Ros*[b]

Keywords: Rhodium / Aminopyrazole / Hemilabile ligands / Cationic complexes

The bis[(3,5-dimethyl-1-pyrazolyl)methyl]ethylamine ligand (**1**) reacts with $[Rh(COD)(THF)_2][BF_4]$ leading to $[Rh(COD)(\mathbf{1})][BF_4]$ ($[\mathbf{2}][BF_4]$) in which **1** is κ^3 bonded in the solid state. Because of the steric bulk of 1,5-cyclooctadiene, it prefers the κ^2 mode of bonding in solution. Substitution of 1,5-cyclooctadiene by carbon monoxide generates $[\mathbf{3}][BF_4]$ in which **1** is κ^3 bonded in solution and solid state. Variable temperature NMR spectroscopic studies give evidence of a $\kappa^3 \rightleftarrows \kappa^2$ equilibrium in solution. $[\mathbf{3}][BF_4]$ is easily decarbonylated to $[Rh(CO)(\mathbf{1})][BF_4]$ $[\mathbf{4}][BF_4]$ in which **1** is κ^3 bonded; however on bubbling carbon monoxide through, $[\mathbf{3}][BF_4]$ is regenerated. The single-crystal X-ray structures of $[\mathbf{2}][BF_4]$, $[\mathbf{3}][BPh_4]$, and $[\mathbf{4}][BPh_4]$ are reported.

Introduction

The readily available pyrazolyl group has allowed the construction of various bi- or polydentate ligands, thus furnishing metal complexes of varying coordination geometry and nuclearity.[1−4] One of the reasons for this success arises from the ability to change the nature, number, and position of substituents in the pyrazole ring, thus allowing a fine tuning of the reactivity of the metal centre to which they are bound. For instance, the most well-developed ligands, the poly(pyrazolyl)borates and their complexes, have found interesting applications in catalysis and bioinorganic chemistry.[1,5−8]

The bonding properties of another family of pyrazole-based chelating ligands, the pyrazole derivatives of simple amines, are also well documented.[4,9,10] They are considered to be hard donor ligands, and the studies of their bonding properties have focussed on cations in high oxidation states, essentially to provide routes to a variety of bioinorganic model systems, or to evaluate their extracting properties. Prompted by the increasing success in catalysis of complexes containing amino ligands,[11−13] it was thought interesting to probe the bonding properties of aminopyrazoles toward soft cations, such as Rh^I. In contrast to the well studied tris(pyrazolyl)borate/Rh^I systems,[14−16] these ligands contain two types of donating centres with different degrees of hardness which might be expected to exhibit different types of behaviour toward the soft Rh^I centre.

We here describe the interactions of a typical aminopyrazole, bis[(3,5-dimethyl-1-pyrazolyl)methyl]ethylamine (**1**) towards a series of cationic Rh^I complexes.

Results and Discussion

Bis[(3,5-dimethyl-1-pyrazolyl)methyl]ethylamine (**1**) reacts with $[Rh(COD)(THF)_2][BF_4]$ − generated in situ from the reaction of $[Rh(COD)Cl]_2$ and $AgBF_4$ in THF − to give the complex $[Rh(COD)(\mathbf{1})][BF_4]$ ($[\mathbf{2}][BF_4]$) in 90% yield. At room temperature, the proton NMR spectrum of $[\mathbf{2}]^+$ shows the presence of two isomers $[\mathbf{2a}]^+$ and $[\mathbf{2b}]^+$ in a 2:1 ratio. The most salient feature of the spectra, and the most significant for probing structural differences, is provided by the NEt resonances, where the ethyl group resonances of the minor isomer are more deshielded than those of $[\mathbf{2a}]^+$. This observation suggests that in $[\mathbf{2b}]^+$ the nitrogen of the amine group is bonded to rhodium, and that the two isomers differ in their coordination to rhodium, which can be either the κ^2 or κ^3 type.

To clarify this point, $[\mathbf{2}][BF_4]$ was structurally characterised by X-ray crystallography. The complex crystallises with three independent ion pairs per unit cell. The three cations of $[\mathbf{2}]^+$ present the same geometry, with the respective distances and angles being equal within experimental errors. A view of one of the three independent cations (cation A) appears as Figure 1; selected bond length and angle data are provided in Table 1. In the solid state, only isomer $[\mathbf{2b}]^+$ is observed. The nitrogen of the amino group N3 is 2.513(7) Å from Rh1; it is longer than the other two Rh−N distances but smaller than the sum of van der Waals radii (3.4 Å). The pyrazolyl-nitrogen to Rh distances are slightly different but are in the range found for hydridotris(pyrazolyl)borate rhodium complexes.[15,16] The N4−Rh1 bond is significantly longer than the N1−Rh1 bond, and this is certainly the consequence of the steric crowding around rhodium as there are no electronic reasons to justify this differ-

ence. This is evident if we consider the positioning of the 1,5-cyclooctadiene ligand. The atoms C15, C18, N1, and N4 lie in a plane, which is usually[16] defined by the pyrazolyl nitrogen atoms and the middle of the olefinic carbon-carbon bonds. The rhodium atom lies 0.1 Å out of that coordination plane. The position of the cyclooctadiene undoubtedly results from steric crowding attributable to the amino group. Indeed C7 is nearer to C18 carbon than to C15, and lengthening of the Rh1−N4 distance minimises the steric crowding of the ethyl group. Likewise, the C18−Rh1−N4 angle is 10° wider than that of the C15−Rh1−N1 angle. If we consider the pyrazolyl planes, the angle between the mean plane defined by the N4 pyrazolyl ring and the Rh−N4 vector is more acute (142.8°) than the angle between the Rh−N1 vector and the mean plane of the N1 pyrazolyl ring (163.9°). Because of the strain induced by the methylene bridges, the N1−Rh1−N3 and N4−Rh1−N3 angles are around 73°.

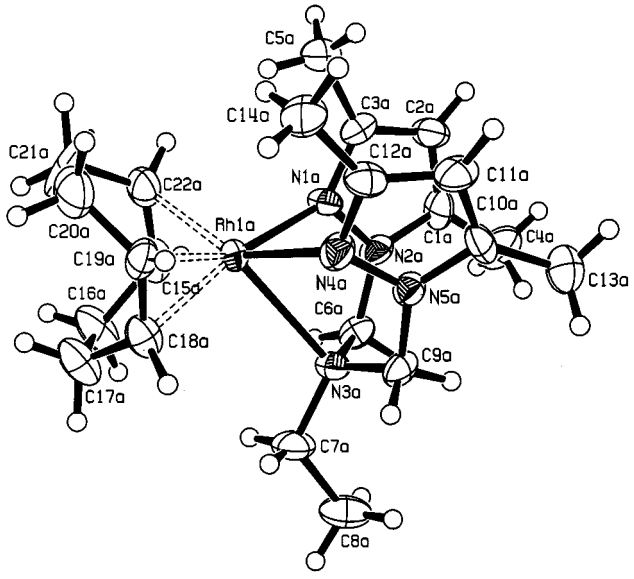

Figure 1. Structure of the cation $[\mathbf{2}]^+$ showing the numbering scheme; ellipsoids are drawn at the 50% probability level

To check whether the solid-state structure is maintained in solution, some crystals were dissolved in deuterated dichloromethane at −70 °C, and the solution was examined by ^{1}H NMR spectroscopy at this temperature. Initially, $[\mathbf{2b}]^+$ is the major component, but the concentration of $[\mathbf{2a}]^+$ slowly increases. When the temperature is raised to 20 °C, the previously observed 2:1 ratio of the isomers $[\mathbf{2a}]^+$/$[\mathbf{2b}]^+$ is rapidly restored, demonstrating the operation of a thermodynamic equilibrium which favours the less sterically encumbered isomer $[\mathbf{2a}]^+$, as summarised in Scheme 1.

We note that, as previously observed by several of the present authors, the reaction of **1** with $[Rh(COD)Cl]_2$ leads to $[Rh(COD)(\mathbf{1})]^+[Rh(COD)Cl_2]^-$.[17] However, in contrast to $[\mathbf{2}]^+$, the cationic part of this latter complex is characterised by broad ^{1}H NMR peaks assignable to ligand **1**, supporting the author's earlier hypothesis concerning the existence of an equilibrium in solution between the ionic

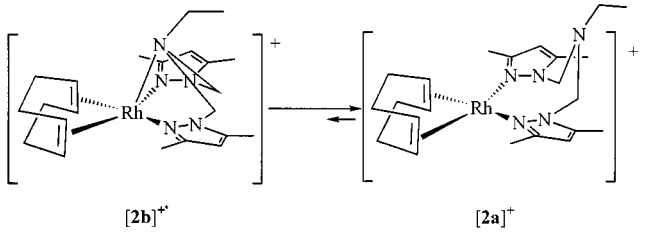

Scheme 1

form and a neutral one [Rh(COD)Cl][μ,η^2−(**1**)]-[Rh(COD)Cl].

In order to evaluate the influence of the 1,5-cyclooctadiene on the bonding capabilities of **1**, we replaced the diene by carbon monoxide. Bubbling carbon monoxide into a solution of $[\mathbf{2}]^+$ in dichloromethane at room temperature

produces $[Rh(CO)_2(\mathbf{1})][BF_4]$ ($[\mathbf{3}][BF_4]$) which can be isolated as a yellow solid in a nearly quantitative yield. The infrared spectrum in the νCO region shows two strong absorption bands at 2080 and 2011 cm^{-1}, and two weak peaks at 2100 and 2038 cm^{-1}, suggesting the presence of two complexes. This is corroborated by the ^1H NMR spectrum that, analogously to $[\mathbf{2a}]^+$ and $[\mathbf{2b}]^+$, exhibits ethyl resonances for two isomers $[\mathbf{3a}]^+$ and $[\mathbf{3b}]^+$, in the ratio 1:10. However, in contrast to $[\mathbf{2}]^+$, it is the isomer $[\mathbf{3b}]^+$, with the more deshielded ethyl resonances, that is the major compound in solution. For this complex, the methylene protons appear as a broad AB spectrum indicating the existence of a fluxional process in solution. As for $[\mathbf{2}]^+$, the NMR spectroscopic data reveals that there are two isomers where the aminopyrazole ligand can be κ^2 $[\mathbf{3a}]^+$ or κ^3 $[\mathbf{3b}]^+$ bonded. This is corroborated by the infrared data which shows that the minor isomer $[\mathbf{3a}]^+$ exhibits CO absorption at high frequencies, as expected for a 16 valence electron isomer compared to an 18 electron complex. To confirm this hypothesis an X-ray structure determination was undertaken on $[Rh(CO)_2(\mathbf{1})][BPh_4]$ ($[\mathbf{3}][BPh_4]$) obtained by metathesis with $NaBPh_4$, which was easier to crystallise than $[\mathbf{3}][BF_4]$.

Figure 2 depicts cation $[\mathbf{3}]^+$ and salient bond length and angle data are collected in Table 1. The cation has a distorted square pyramid geometry, in which the square plane is defined by the atoms C15, C16, N1, and N4, and the rhodium atom is out of that plane by 0.15 Å. As a consequence of the steric strain imposed by the methylene bridges, the N3 nitrogen atom is not perpendicular to this plane. The Rh−N3 bond is slightly longer than in $[\mathbf{2b}]^+$, but N3 remains within the bonding distance of rhodium. Thus, in the solid state, the structure corresponds to the major isomer $[\mathbf{3b}]^+$ observed in solution. The reduction of the steric crowding around rhodium induced by the replacement of 1,5-cyclooctadiene by two CO molecules is particularly evident if we consider the N1−Rh−N4 angle, which is 81.7(3)° in $[\mathbf{2b}]^+$ and 90.4(2)° in $[\mathbf{3b}]^+$. For the same reasons the Rh−N1 and Rh−N4 bond lengths are, as expected, equal within experimental error.

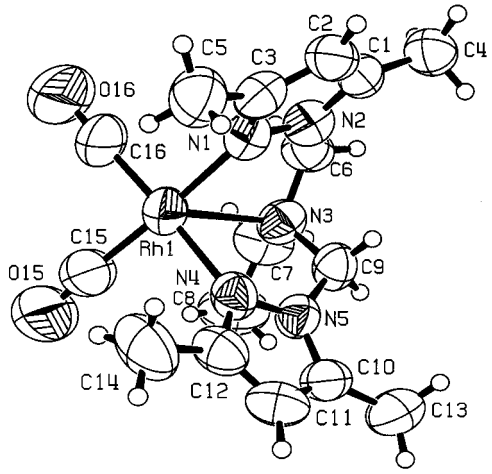

Figure 2. Structure of the cation $[\mathbf{3}]^+$ showing the numbering scheme; ellipsoids are drawn at the 30% probability level

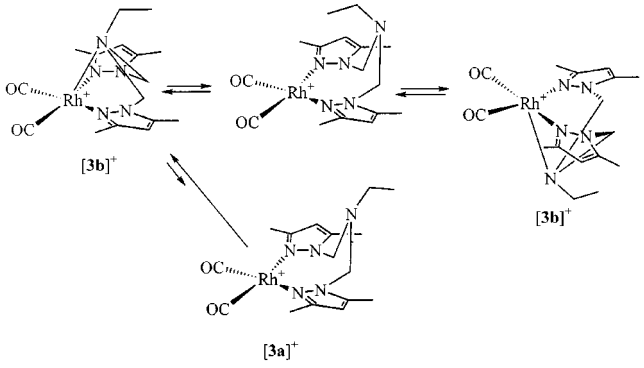
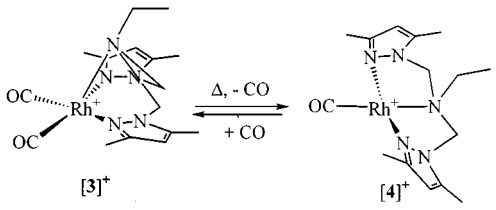
As mentioned above, we observed a broad ^1H NMR AB spectrum for the methylene groups of the isomer $[\mathbf{3b}]^+$, indicating fluxional behaviour in solution for this complex. For this reason we have carried out a variable-temperature ^1H NMR spectroscopic study on the mixture of $[\mathbf{3a}]^+$ and $[\mathbf{3b}]^+$ in $(CD_3)_2CO$ solution. For the $[\mathbf{3a}]^+$ spectrum no significant changes were observed during this study. At 253 K the methylene hydrogens of $[\mathbf{3b}]^+$ appear as a narrow AB spectrum, but lowering the temperature to 193 K induces no other significant changes, except for a slight broadening of the *N*-ethyl resonances. Raising the temperature to 333 K brings about coalescence of the AB spectrum to a broad singlet. (The solvent and the thermal stability of the complex did not allow acquisition of spectra above this temperature.) This corresponds to a $\Delta G^{\ddagger}$ value of ca. 70 $kJ \cdot mol^{-1}$, a value consistent with the mechanism proposed in Scheme 2 which implies an inversion of configuration of the nitrogen atom.[18] The initial step is the decoordination of N3, followed by inversion at the nitrogen atom, and subsequent coordination of N3 on the other face of the square plane.



Scheme 2

During the workup of $[\mathbf{3}]^+$, and especially after the evaporation of its solutions under vacuum, we observed the formation, in small quantities, of a new product characterised by a ν(CO) absorption at 1997 cm^{-1} in the infrared spectrum. This implies a decarbonylation of $[\mathbf{3}]^+$ and, indeed, refluxing a THF solution of $[\mathbf{3}]^+$ induces the nearly quantitative formation of the new complex $[Rh(CO)(\mathbf{1})][BF_4]$ ($[\mathbf{4}][BF_4]$) possessing a ν(CO) absorption at 1997 cm^{-1}. Bubbling carbon monoxide through a solution of $[\mathbf{4}]^+$ regenerates $[\mathbf{3}]^+$ immediately (Scheme 3).



Scheme 3

The ^{1}H NMR spectrum of $[\mathbf{4}]^+$ shows only the resonances of the coordinated ligand **1**. The solid-state structure of $[\mathbf{4}]^+$ was established by X-ray crystallography on the tetraphenylborate salt $[Rh(CO)(\mathbf{1})][BPh_4]$ ($[\mathbf{4}][BPh_4]$). A view of $[\mathbf{4}]^+$ is shown in Figure 3 and bond lengths and angles of interest are gathered in Table 1. The cation is square-planar, with the atoms N1, N3, N4, and C15 defining the plane, and the rhodium atom lying 0.02 Å above it. The Rh−N3 bond is longer than the other two Rh−N bonds, a consequence of the *trans* influence of the carbonyl ligand and of the different hybridisation of the nitrogen atom. Owing to the steric strain induced by the methylene bridges, the N1−Rh−N3 and the N3−Rh−N4 angles are less than 90°.

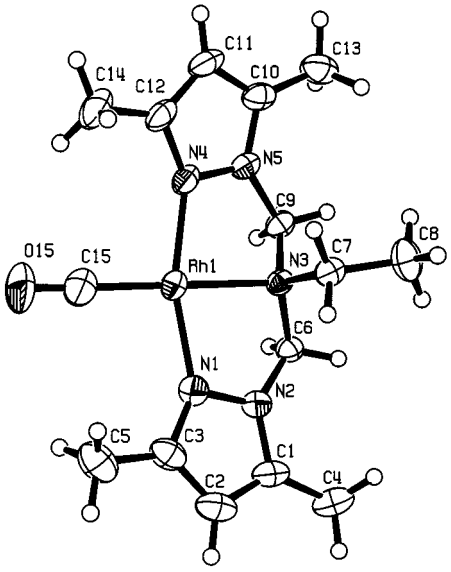


Figure 3. Structure of the cation $[\mathbf{4}]^+$ showing the numbering scheme; ellipsoids are drawn at the 50% probability level

All these structures reveal that **1** is a very flexible ligand that can accommodate, depending on the other ligands around rhodium, either a square-pyramidal geometry in a *fac* configuration or a square planar geometry in a *mer* configuration. Moreover, examination of the structures of other known complexes of bis[(3,5-dimethyl-1-pyrazolyl)methyl]-phenyl or ethylamine with Co^{II},[19,20] Ni^{II},[21] Cu^{I},[22] or Cu^{II},[19] salts shows that the most acute [81.7(3)°] N−M−N angles for the pyrazole ligands have been observed, in our case, with Rh^{I}. The smallest angle observed in the other complexes is 112.5° for the bis[(3,5-dimethyl-1-pyrazolyl)-methyl]phenylamine κ^3 bonded to the $Co(NO_3)_2$ salt[20] in a structure intermediate between a distorted trigonal bipyramid and a square pyramid. This shows that, for this family of ligands, the two pyrazolyl groups can equally adopt *cis*-positions in a square plane. In the other extreme of their bonding capabilities, i.e. in a *trans* configuration, 162° seems to be the maximum value these ligands can accommodate: 161.9(1)° for the N−M−N angle in $[\mathbf{4}]^+$ and 161.3° in an octahedral complex with the $Ni(NO_3)_2$ salt.[21]

Conclusion

This study provides further evidence of the flexibility of the ligand **1** which adapts its bonding mode to various electronic and steric situations around rhodium(I). For instance, for $[\mathbf{2}]^+$ to compensate the steric bulk of the cyclooctadiene ligand it prefers the κ^2 mode of bonding in solution. In the solid state, it adopts the κ^3 mode of bonding but minimises the steric bulk in the square plane by small variations of the length of the Rh−N (pyrazole) bonds. In the absence of steric strain, it adopts a κ^3 mode of bonding either in a *fac* (complex $[\mathbf{3}]^+$) or a *mer* (complex $[\mathbf{4}]^+$) configuration.

Experimental Section

General Remarks: All reactions were performed under a nitrogen atmosphere with the use of standard Schlenk techniques. Tetrahydrofuran and diethyl ether, used for the synthesis, were distilled under nitrogen from sodium benzophenone ketyl just before use. Other solvents were purified following the standard procedures and stored under nitrogen. − NMR spectra were recorded on Bruker AC 200, AC 250, or AMX 400 instruments. All chemical shift values are given in ppm and are referenced with respect to residual protons in the solvent for proton spectra, to solvent signals for ^{13}C spectra. − Elemental analyses were performed in our laboratory on a Perkin−Elmer 2400 CHN analyser. − The bis[(3,5-dimethyl-1-pyrazolyl)methyl]ethylamine[9] and $[Rh(COD)Cl]_2$[23] have been prepared according to published procedures.

Synthesis of [Rh(COD)(1)][BF$_4$] ([2][BF$_4$]): To a solution of 0.079 g (0.16 mmol) of $[Rh(COD)Cl]_2$ in 20 mL of THF was added 0.062 g (0.32 mmol) of $AgBF_4$ and the solution was stirred for half an hour at room temperature. The orange solution turned yellow and AgCl precipitated. The solution was then filtered through a pad of Celite and 0.084 g (0.32 mmol) of **1** was then added. After stirring for an hour, the solution was evaporated to dryness and the residue was crystallised in a dichloromethane/ether mixture to give 0.160 g (90%) of $[\mathbf{2}][BF_4]$ as yellow crystals. − $C_{22}H_{35}BF_4N_5Rh$ (559.3): C 47.24, H 6.32, N 12.52; found C 47.11, H 6.11, N 12.51. Isomer $[\mathbf{2a}]^+$: ^{1}H NMR ($CDCl_3$ solution, 250 MHz) δ = 6.58 (d, ^2J = 15.4 Hz, 2 H, CH_2N), 5.79 (s, 2 H, C*H* pyrazole), 5.42 (d, ^2J = 15.4 Hz, 2 H, pyrazole CH_2N), 3.99 (b, 4 H, C*H* cod), 2.76 (q, ^3J = 7.1 Hz, 2 H, CH_2CH$_3$), 2.68 (b, 4 H, CHH_{exo} cod), 2.61 (s, 6 H, CCH_3), 2.56 (b, 4 H, CHH_{endo} cod), 2.25 (s, 6 H, CCH_3), 0.64 (t, ^3J = 7.1 Hz, 3 H, CH$_2$CH_3). − ^{13}C{^{1}H} NMR ($CDCl_3$ solution, 50 MHz) δ: 150.8−137.3 (*C*CH$_3$), 107.5 (*C*H pyrazole), 85.2−83.6 (m, =*C*H cod), 69.4 (*C*H$_2$N), 44.8 (*C*H$_2$CH$_3$), 30.8−30.2 (*C*H$_2$ cod), 15.6−10.6 (CH$_2$*C*H$_3$, C*C*H$_3$). Isomer $[\mathbf{2b}]^+$: ^{1}H NMR ($CDCl_3$ solution, 250 MHz) δ = 5.68 (s, 2 H, C*H* pyrazole), 4.96 (d, ^2J = 12.2 Hz, 2 H, CH_2N), 4.87 (d, ^2J = 12.2 Hz, 2 H, CH_2N), 4.14 (q, ^3J = 7.2 Hz, 2 H, CH_2CH$_3$), 3.75 (b, 4 H, =C*H* cod), 2.68 (b, 4 H, CHH_{exo} cod), 2.60 (s, 6 H, CCH_3), 2.56 (b, 4 H, CHH_{endo} cod), 2.17 (s, 6 H, CCH_3), 1.56 (t, ^3J = 7.2 Hz, 3 H, CH$_2$CH_3);. − ^{13}C{^{1}H} NMR ($CDCl_3$ solution, 50 MHz)150.8−137.3 (*C*CH$_3$), 107.6 (*C*H pyrazole), 85.2−83.6 (m, =*C*H cod), 65.5 (*C*H$_2$N), 52.5 (*C*H$_2$CH$_3$), 30.8−30.2 (*C*H$_2$ cod), 15.6−10.6 (CH$_2$*C*H$_3$, C*C*H$_3$).

Synthesis of [Rh(CO)$_2$(1)][BF$_4$] ([3][BF$_4$]): Carbon monoxide was bubbled for 1 h through a solution of 0.168 g of $[\mathbf{2}][BF_4]$ dissolved in 20 mL of dichloromethane. The solution was then evaporated to dryness in vacuum leaving 0.124 g (80%) of **3** as a yellow powder.

Synthesis of [Rh(CO)$_2$(1)][BPh$_4$] ([3][BPh$_4$]): To a solution of 0.135 g (0.32 mmol) of [**3**][BF_4] in 10 mL of methanol was added 0.110 g (0.32 mmol) of $NaBPh_4$ and the solution was stirred for 1 h. A yellow precipitate appeared which was filtered and dried under vacuum. It was recrystallised in a dichloromethane/methanol mixture under a CO atmosphere. $C_{40}H_{43}BN_5O_2Rh$ (739.5): C 64.97, H 5.86, N 9.47; found C 64.52, H 6.01, N 9.20.

Synthesis of [Rh(CO)(1)][BF$_4$] ([4][BF$_4$]): A solution of 0.12 g of [**3**][BF_4] in 20 mL of THF was refluxed for 2 h. The solvent was evaporated to dryness in vacuum leaving 0.1 g of a yellow solid. − IR (CH_2Cl_2 solution) ν(CO): 1997 cm^{-1}. − ^1H NMR ($CDCl_3$ solution, 200 MHz) δ = 5.95 (s, 2 H, C*H*), 5.28 (AB system, ^2J = 12.1 Hz, 4 H, CH_2N), 2.93 (q, ^3J = 7.4 Hz, 2 H, CH_2CH$_3$), 2.37 (s, 6 H, CCH_3), 2.18 (s, 6 H, CCH_3), 0.98 (t, ^3J = 7.4 Hz, 3 H, CH$_2$CH_3). − $^{13}C\{^1H\}$ NMR ($CDCl_3$ solution, 50 MHz) δ = 188.3 (d, ^1J = 78.0 Hz, *C*O), 152.7 (*C*CH$_3$), 142.7 (*C*CH$_3$), 107.3 (*C*H), 68.7 (*C*H$_2$N), 51.6 (*C*H$_2$CH$_3$), 14.5−11.8, 11 (CH$_2$*C*H$_3$ + 2 C*C*H$_3$).

Synthesis of [Rh(CO)(1)][BPh$_4$] ([4][BPh$_4$]): To a solution of 0.1 g of [**4**][BF_4] in 10 mL of methanol was added 0.110 g (0.32 mmol) of $NaBPh_4$ and the solution was stirred for 1 h. A yellow precipitate appeared which was filtered and dried under vacuum. It was recrystallised in a dichloromethane/methanol mixture. $C_{39}H_{43}BN_5ORh$ (711.5): C 65.82, H 6.10, N 9.84; found C 65.67, H 5.79, N 9.63.

X-ray Crystallographic Study: Crystals of [**2**][BF_4], [**3**][BPh_4], and [**4**][BPh_4] suitable for X-ray diffraction were obtained through recrystallisation from a dichloromethane/ether mixture for [**2**][BF_4] and dichloromethane/methanol mixture for [**3**][BPh_4], and [**4**][BPh_4]. Data were collected on an STOE IPDS diffractometer at 160 K [**2**][BF_4] and [**4**][BPh_4], and at 298 K [**3**][BPh_4]. Full crystallographic data for the three complexes are gathered in Table 2. All calculations were performed on a PC-compatible computer using the WinGX system.[24] The structures were solved using the SIR92 program,[25] which revealed in each instance the position of most of the non-hydrogen atoms. All remaining non-hydrogen atoms were located by the usual combination of full-matrix least-squares refinement and difference electron density syntheses by using the SHELXS97 program.[26] Phenyl ring within the tetraphenylborate counter anion in the structure of [**4**][BPh_4] have been refined as rigid groups (D_{6h} symmetry; C−C = 1.39 Å; C−H = 0.93 Å). Atomic scattering factors were taken from the usual tabulations.[27] Anomalous dispersion terms for Rh were included in F_c.[28] All non-hydrogen atoms were allowed to vibrate anisotropically. All

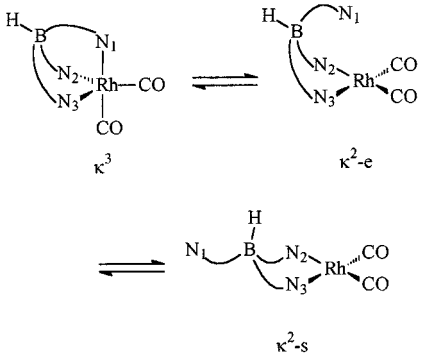
Keywords: Pyrazolylborato ligands / Rhodium / IR spectroscopy / Square-planar complexes / Fluxional behavior

Addition of 1 equiv. of a phosphane or phosphite ligand to the κ^3-bonded [Tp^{Me2}Rh(CO)$_2$] and [Tp^{Me2,4Cl}Rh(CO)$_2$] dicarbonyl precursors gives the monosubstituted complexes [TpRh(CO)L]. The X-ray crystal structures show that the three complexes [Tp^{Me2}Rh(CO)(PMe$_3$)], [Tp^{Me2}Rh(CO)(PMePh$_2$)], and [Tp^{Me2,4Cl}Rh(CO)(PMePh$_2$)] adopt square-planar geometries. The X-ray crystal structure of [Tp^{Me2}Rh(CO){P(OPh)$_3$}] is consistent with an interaction between the dangling pyrazolyl group and the rhodium centre, the Rh–N distance being 2.762(3) Å. Analysis of ν(BH) and ν(CO) stretching frequencies shows that all the phosphane-containing complexes are square planar in solution as well as in the solid state. According to infrared analyses, the phosphite complexes [Tp^{Me2,4Cl}Rh(CO){P(OPh)$_3$}] and [Tp^{Me2,4Cl}Rh(CO){P(OMe)$_3$}] adopt a pentacoordinated geometry both in the solid state and in solution. However, the infrared data for [Tp^{Me2}Rh(CO){P(OPh)$_3$}] and [Tp^{Me2}Rh(CO){P(OMe)$_3$}] indicate that the Tp^{Me2} ligand is in a κ^3 coordination mode in the solid state, as already evidenced by the X-ray crystal structure, but in a κ^2 mode in solution. We also describe an exchange phenomenon between dangling and coordinated pyrazolyl groups, as studied by NMR.

Introduction

Since the first report of pyrazolylborato ligands by Trofimenko in 1966,[1] hydrotris(pyrazolyl)borates have been extensively used as σ donor ligands in a wide variety of transition metal complexes.[2] They can provide stable complexes, e.g. by replacing the isoelectronic cyclopentadienyl and pentamethylcyclopentadienyl ligands, and offer greater flexibility. Indeed, these ligands can adopt various modes of coordination ranging from the ubiquitous κ^3 and κ^2 forms to the less common κ^1 coordination mode.[3,4] Even rarer is their recently recognized ability to act as counterions (i.e., a κ^0 form)[5] in transition metal salts. Venanzi and co-workers have studied the geometry adopted in solution by complexes of the type [{HB(3R,4R′,5R"-pyrazolyl)$_3$}Ir(η^4-C$_8$H$_{12}$)], or, using the nomenclature of Trofimenko,[2] of the type [Tp$^{3R,4R',5R''}$Ir(COD)].[6] In its κ^2 coordination mode, the ligand can have the non-coordinated pyrazolyl group either far from the iridium centre or dangling in such a position that the κ^3 mode can readily be achieved, as depicted in Scheme 1.



Scheme 1. The three coordination modes of Tp (adapted from ref.[3])

Electronic and steric effects of each pyrazolyl group play an important role in determining the equilibrium between the three different forms κ^2-e (the pyrazolyl in a pseudo-equatorial position), κ^2-s (scorpionate[6]), and κ^3. The nature of the substituent in the 3-position, i.e. adjacent to the potentially coordinating nitrogen atom, exerts a strong influence on this equilibrium. More specifically, steric hindrance between an R substituent in the 3-position and the hydrogen atoms of the two double bonds of the cyclooctadiene ligand in [Tp$^{3R,4R',5R''}$Ir(C$_8$H$_{12}$)] plays an important role.[6] Venanzi and co-workers,[6] as well as Akita, Moro-oka et al. for related [Tp^{iPr}Rh(diene)] complexes,[7] have used the wavenumber of the ν(BH) stretching vibration to assign a κ^2 or a κ^3 bonding mode for the Tp ligand. When ν(BH) is near to 2470 cm^{-1}, a square-planar complex in a κ^2 mode is observed, whereas a ν(BH) band at around 2540 cm^{-1} is indicative of a trigonal-bipyramidal structure with a κ^3 coordination mode.[7]

This class of complexes has become of particular interest since Ghosh and Graham demonstrated that [Tp^{Me2}Rh(CO)$_2$] photochemically activates one C–H bond of benzene or cyclohexane to afford the corresponding hydrido phenyl or cyclohexyl rhodium complexes.[8] This latter complex reacts with methane to afford

[Tp^{Me2}Rh(CO)(H)(CH_3)]. The mechanism of this photochemically induced C−H bond activation has been studied by Purwoko and Lees,[9] as well as by Bergman and coworkers.[10] The process is believed to involve a sequence of elimination of a CO ligand, coordination of the C−H bond in an η^2 mode, a change from κ^3 to κ^2 bonding of the Tp^{Me2} ligand to the rhodium, and finally oxidative addition of the alkane.[7] The observation of the intermediate [(κ^2-Tp^{Me2})Rh(CO)(η^2-RH)] has prompted us to report the preparation of a series of [Tp′Rh(CO)(PR_3)] complexes, which were designed to have a more nucleophilic centre with a view to enhancing their C−H activating ability. The present paper deals with the preparation and characterization of [Tp^{Me2}Rh(CO)L] and [$Tp^{Me2,4Cl}$Rh(CO)L] (L = phosphane, phosphite) complexes. We have performed a detailed study of their solid-state and solution structures, as probed by infrared and NMR spectroscopies, and by X-ray crystal structure determinations. While this project was in progress,[11] the synthesis of [Tp^{Me2}Rh(CO)(PPh_3)] was published.[12] Several [Tp^{Me2}Rh(CO)(PR_3)] complexes have been described in the Ph.D. thesis of C. K. Ghosh.[13]

Results and Discussion

Preparation of [Tp^{Me2}Rh(CO)(PR_3)] and [$Tp^{Me2,4Cl}$Rh(CO)(PR_3)] Complexes

Addition of one equivalent of a phosphane or a phosphite ligand PR_3 to [Tp^{Me2}Rh(CO)$_2$] (**1**) or [$Tp^{Me2,4Cl}$Rh(CO)$_2$] (**2**) at room temperature results in the substitution of one CO ligand to afford the corresponding [TpRh(CO)(PR_3)] complexes as shown in Equations (1) and (2).

$$[Tp^{Me2}Rh(CO)_2] + PR_3 \longrightarrow [Tp^{Me2}Rh(CO)(PR_3)] + CO \quad (1)$$

1

PR_3 = PMe_3: **3**; PMe_2Ph: **4**; $PMePh_2$: **5**; PPh_3: **6**; $P(OMe)_3$: **7**; $P(OPh)_3$: **8**

$$[Tp^{Me2,4Cl}Rh(CO)_2] + PR_3 \longrightarrow [Tp^{Me2,4Cl}Rh(CO)(PR_3)] + CO \quad (2)$$

2

PR_3 = PCy_3: **9**; PMe_3: **10**; PMe_2Ph: **11**; $PMePh_2$: **12**; PPh_3: **13**; $P(OMe)_3$: **14**; $P(OPh)_3$: **15**; $P(OiPr)_3$: **16**

The rate of this reaction is determined by the nature of the ligand. The more basic but sterically hindered tricyclohexylphosphane PCy_3 reacts with **2** within about 1 h to give **9**. The ligands PMe_3, PMe_2Ph, $PMePh_2$, and even $P(OMe)_3$ react within a few minutes, as monitored by infrared spectroscopy. The syntheses of **8**, **15**, and **16**, containing the less basic ligands $P(OPh)_3$ and $P(OiPr)_3$, require several hours. According to infrared data, these substitution reactions are quantitative and isolated yields are high (> 85%). In the case of complex **11**, PMe_2Ph in dichloromethane has to be added slowly at room temperature to avoid formation of the disubstituted complex [κ^1-$Tp^{Me2,4Cl}$Rh(CO)(PMe_2Ph)$_2$].[4] **11** can then be recrystallized at low temperature, leaving **2** and the bis-adduct in solution. All the complexes have been fully characterized by infrared, ^{1}H, and ^{31}P NMR, and in some cases by ^{13}C and ^{103}Rh NMR. The solid-state structures of **3**, **5**, **8**, and **12** have been confirmed by X-ray analyses.

Molecular Structures of the Complexes 3, 5, 8, and 12

X-ray crystal structures have been obtained for four complexes, two of which (**3** and **12**) have been described in brief in previous reports.[4,11] Salient data are presented in Table 1.

Table 1. Salient distances [Å] and angles [°] (SP = square plane) in complexes with PR_3: **3**, **5**, **8**, and **12**

	PMe_3: **3**	$P(OPh)_3$: **8**	$PMePh_2$: **5**	$PMePh_2$: **12**
Rh−C1	1.797(4)	1.802(4)	1.818(4)	1.810(2)
Rh−P1	2.2447(9)	2.1794(9)	2.2503(9)	2.258(5)
Rh−N1	2.113(3)	2.110(3)	2.097(3)	2.0923(15)
Rh−N3	2.101(3)	2.097(3)	2.095(3)	2.0911(16)
Rh−N5	3.632(3)	2.762(3)	3.661(4)	3.800(2)
Pz_3−SP angle	55.05	78.91	52.12	48.05
N6−B1−H1	109.9	111.7(20)	115.5(22)	113.3(14)

We first focus on the structures of **5** and **12**, which have the same $PMePh_2$ phosphane ligand. Both complexes show the same square-planar environment (see Figure 1 for **5** and Figure 2 for **12**), with two pyrazolyl groups bonded to the rhodium metal centre and the third one in a dangling position. The Rh−N5 distances of 3.661(4) and 3.800(2) Å in **5** and **12**, respectively, preclude any bonding interaction between these atoms. The difference between these distances is due to the rotation of the free pyrazolyl group, since the angle between the pyrazolyl and the square plane varies from 52.12° to 48.05°. The Rh−N1, Rh−N3, and Rh−P1 distances can be considered as being the same in these complexes. Within each complex, the Rh−N distances to the coordinated pyrazolyl groups, Rh−N1 and Rh−N3, are equal, irrespective of the ligand in the *trans* position (i.e. CO or $PMePh_2$). As usual, the ν(CO) stretching frequencies are more sensitive to the electronic modifications of the metal centre than the Rh−C, C−O, and Rh−O distances for the CO ligands. Indeed, the four Rh−O1 bond lengths for **3**, **5**, **8**, and **12** are 2.949 [ν(CO) = 1961 cm^{-1}], 2.954 (1984 cm^{-1}), 3.099 (1975 cm^{-1}), and 2.910 Å (1996 cm^{-1}), respectively. A square-planar environment is also found for **3** (Figure 3), and the Rh−N1 and Rh−N3 bond lengths are identical within experimental error.

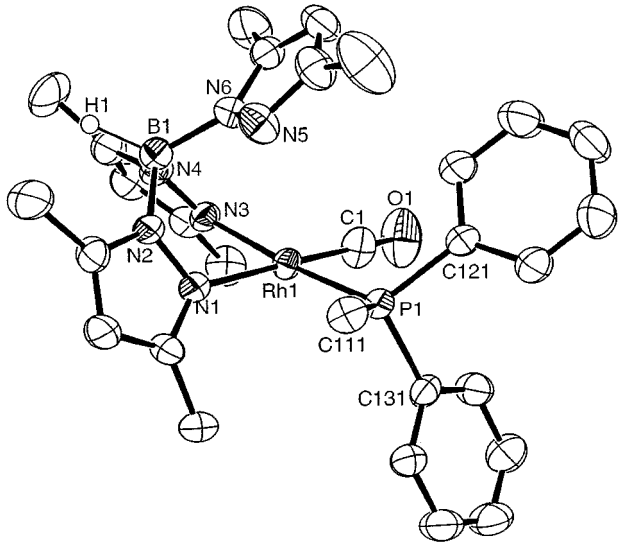

Figure 1. Molecular view of complex **5**; ellipsoids are drawn at a 30% probability level

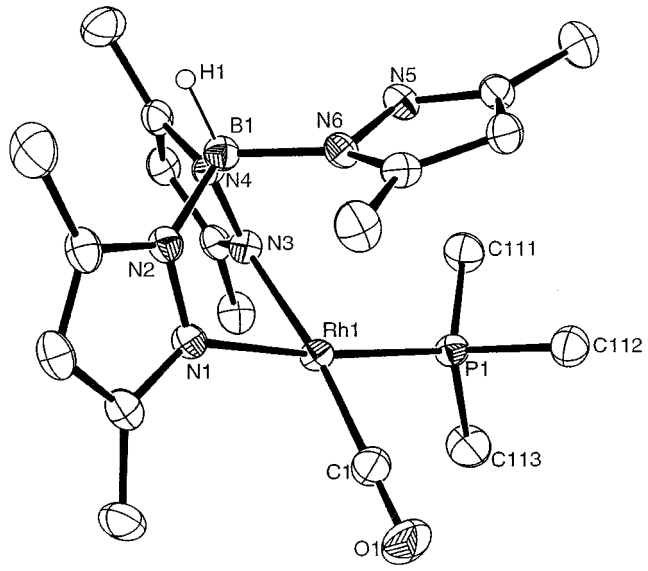

Figure 3. Molecular view of complex **3**; ellipsoids are drawn at a 30% probability level

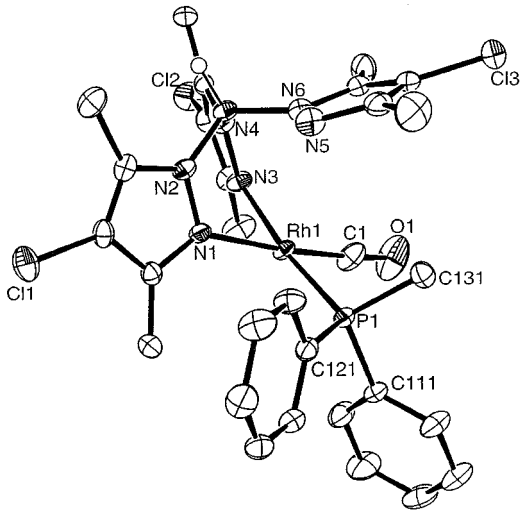

Figure 2. Molecular view of complex **12**; ellipsoids are drawn at a 30% probability level

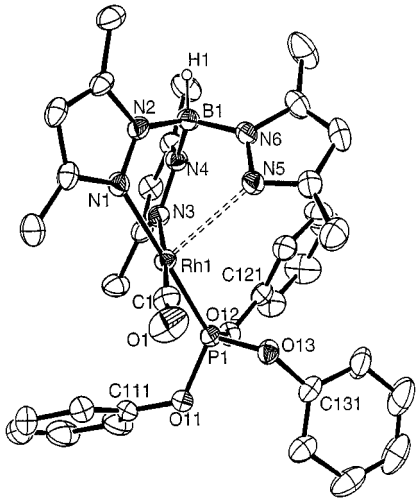

Figure 4. Molecular view of complex **8**; ellipsoids are drawn at a 30% probability level

Complex [Tp^{Me2}Rh(CO){P(OPh)$_3$}], **8**, has also been analysed by X-ray crystallography, in view of its unexpected infrared spectra (vide infra). The geometry about the rhodium is again square-planar (Figure 4). The most notable feature is an Rh−P1 distance of 2.1794(9) Å, which is significantly shorter than the Rh−P1 distances observed with PMe_3 in **3** (2.245 Å) or with $PMePh_2$ in **5** and **12** (2.250 Å and 2.258 Å, respectively). This is consistent with the better π-accepting properties of a phosphite as compared to a phosphane. A further feature deserves comment. The Rh−N5 distance is 2.762(3) Å, longer than that of a true coordination bond (ca. 2.1 Å), but shorter than the sum of the van der Waals radii (3.3 Å). Such a distance is thus consistent with an Rh−N5 interaction. Recently, Connelly et al. reported the X-ray structure of [Tp^{Me2}Rh(CO)(PPh$_3$)], which has a square-planar geometry with Tp^{Me2} adopting a κ^2 coordination mode.[12] One-electron oxidation results in the formation of [Tp^{Me2}Rh(CO)(PPh$_3$)]$^+$, X-ray analysis of which showed it to contain a κ^3-Tp^{Me2}. The rhodium(II) centre is then in a square-pyramidal environment, with the axial Rh−N5 bond length being 2.224(2) Å as opposed to 2.091(2) Å and 2.093(2) Å for the two other rhodium−nitrogen distances. Thus, the P(OPh)$_3$-containing complex **8** shows a lengthening of ca. 0.5 Å when compared to the rhodium(II) complex. Overall, we conclude that a κ^3 coordination mode is favoured by a decrease in the electron density at the metal centre.

Infrared Study of Complexes 3−15

Previous studies have shown that the ν(BH) stretching frequency offers a reliable means of ascertaining the coordination mode of tris(pyrazolyl)borato ligands.[6,7] Particularly

interesting are the absolute values of the ν(BH) frequencies determined by Moro-oka et al., which are ca. 2470 cm^{-1} for κ^2 coordination and 2540 cm^{-1} for κ^3 coordination.[7] The measured ν(BH) values for all the complexes are presented in Tables 2 and 3. Spectra were obtained from samples in both KBr and CH_2Cl_2. For the complexes bearing more basic phosphanes, i.e. those with PR_3 = PMe_3, PMe_2Ph, $PMePh_2$, and PPh_3 (**3−6** and **9−13**), the ν(BH) values are near to 2480 cm^{-1} and 2485 cm^{-1} in the solid state and in solution, respectively, irrespective of the Tp′ ligand. Figure 5 shows a plot of ν(BH) in CH_2Cl_2 as a function of the basicity of the phosphorus ligand on the Derencsényi scale;[14] ν(BH) is seen to be independent of the phosphane basicity, i.e. it is only weakly sensitive to the electron density at the metal centre. Thus, complexes **3−6** and **9−13** consistently show square-planar geometries, with Tp^{Me2} and $Tp^{Me2,4Cl}$ adopting the κ^2 coordination mode. The diagnostic criterion of Moro-oka et al., as established for [Tp^{Me2}Rh(diene)], is also valid here.

Table 2. ν(BH) and ν(CO) stretching frequencies for the complexes [Tp^{Me2}Rh(CO)(PR_3)] in KBr dispersions and in CH_2Cl_2 solutions

[Tp^{Me2}Rh(CO)(PR_3)]	ν(BH) [cm^{-1}] CH_2Cl_2	KBr	ν(CO) [cm^{-1}] CH_2Cl_2	KBr

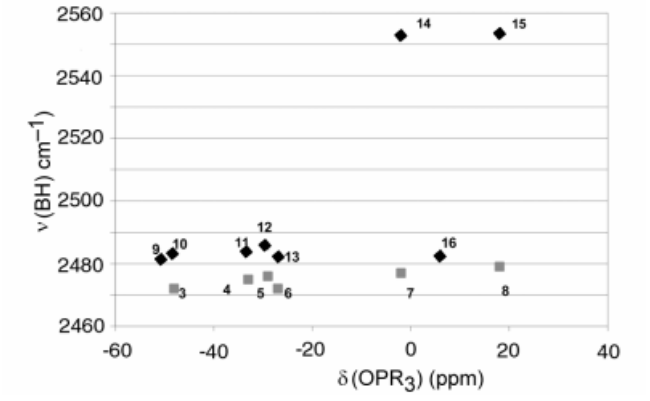

Figure 5. The ν(BH) values for complexes **3−16** in CH_2Cl_2 solution plotted as a function of phosphane basicity on the Derencsényi scale

The situation is slightly more subtle when the less basic phosphite ligands are considered. For complexes **14** and **15**, the ν(BH) values (Table 3 and Figure 5) suggest that the coordination mode of the $Tp^{Me2,4Cl}$ ligand is κ^3. Hence, although we have been unable to obtain X-ray quality crystals to confirm the proposal, complexes **14** and **15** would seem to exhibit a pentacoordinated geometry. Interestingly, for the Tp^{Me2}-based complexes **7** and **8**, which contain the same $P(OMe)_3$ and $P(OPh)_3$ phosphite ligands, the ν(BH) frequencies are only consistent with a κ^2 coordination mode in CH_2Cl_2 solution (2477 and 2479 cm^{-1}, respectively). In contrast, data obtained in KBr suggest that a κ^3 mode is preferred in the solid state (2508 and 2518 cm^{-1} for **7** and **8**, respectively). This is reminiscent of the weaker interaction between the third pyrazolyl group and the rhodium centre revealed by the X-ray crystal structure of **8** (vide supra). Consequently, the Tp^{Me2} ligand is not in a genuine κ^3 coordination mode in **8**, but the position of the third pyrazolyl substituent induces a geometry around the boron atom that results in a ν(BH) band at around 2510 cm^{-1}.

As a further representative of the phosphite family in the [$Tp^{Me2,4Cl}$Rh(CO)(PR_3)] complexes, we have introduced $P(OiPr)_3$, the basicity of which is intermediate between those of $P(OMe)_3$ and PPh_3. Table 3 and Figure 5 unambiguously show that the environment in complex **16** is square-planar, from which we conclude that the steric hindrance induced by the phosphite ligand is sufficiently strong to compensate the decrease in electron density at the metal centre that would favour the approach of the third pyrazolyl group.

The ν(CO) stretching frequencies were measured both in solution and in the solid state for all the complexes (Tables 2 and 3). Figure 6 shows a plot of ν(CO) as a function of the basicity of the PR_3 ligand (CH_2Cl_2 solution). The points representing those complexes having a κ^2-bonded Tp^{Me2} ligand lie on a straight line with a correlation coefficient of 0.98. As usual, the ν(CO) frequencies reliably reflect the electron density at Rh as the basicity of the ligand is varied.

For complexes **9−16**, the situation is less straightforward. A straight line can clearly be seen in Figure 6 for complexes **9−13** and **16**, which exhibit a κ^2 coordination mode in solution. This is in agreement with the conclusions drawn from the analysis of the ν(BH) frequencies. However, the ν(CO) values for complexes **14** and **15** lie at higher frequencies. The corresponding points in the plot do not fall on the previous straight line, but the line plotted between these two points is parallel to the first one. Thus, Figure 6 shows the monotonous variations in the electron density in [κ^2-$Tp^{Me2,4Cl}$Rh(CO)(PR_3)] (lower line) and [κ^3-$Tp^{Me2,4Cl}$Rh(CO){$P(OR)_3$}] (upper line). It is important to note that we might have expected a decrease in the ν(CO) stretching frequency due to the coordination of the third pyrazolyl group, i.e. a line in the plot lower than the κ^2

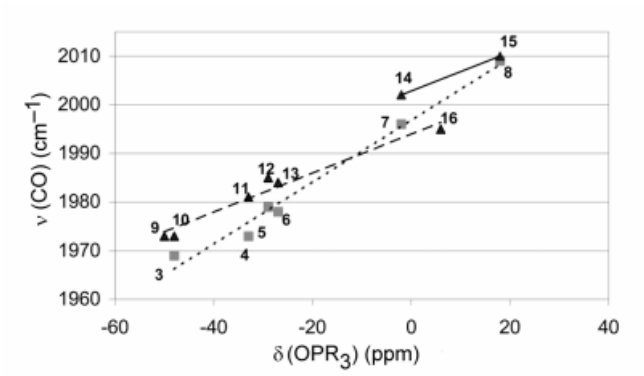

Figure 6. The ν(CO) frequencies for complexes **3**−**16** in CH_2Cl_2 solution plotted as a function of phosphane basicity on the Derencsényi scale

straight line. In fact, this coordination leads to a pentacoordinated geometry, in which the CO force constant is no longer comparable to that for a square-planar geometry.

NMR Studies; Fluxionality of Complexes 3−15

Most of the complexes have been studied by ^{1}H, ^{13}C, ^{31}P, and ^{103}Rh NMR, and in some cases at variable temperature as they are fluxional. We were particularly interested in the PMe_2Ph-containing complex **4** since, in its square-planar environment and with the third pyrazolyl group in a dangling position, as a result of which the plane of symmetry is lost, two diastereotopic methyl groups are to be expected. However, the ^{1}H NMR spectrum recorded at room temperature (Figure 7) features a doublet due to the Me groups of the PMe_2Ph ligand (J_{PH} = 9 Hz) and two singlets at δ = 2.15 and 2.21 due to the Tp^{Me2} methyl substituents. At 183 K (Figure 8), the signal due to the phosphane methyl protons is broader, two methyl groups of a pyrazolyl group give rise to signals at δ = 2.32 and 2.75, while the four remaining Tp^{Me2} methyls give rise to two signals at δ = 1.88 (broad) and 2.05. Thus, the NMR spectra show a non-rigidity for this complex, although the slow-exchange limit was not reached.

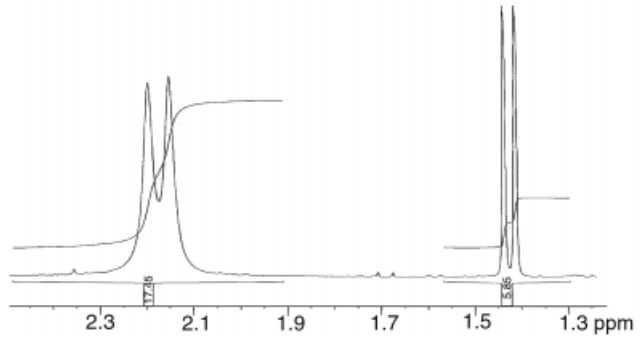

Figure 7. ^{1}H NMR spectrum of complex **4** at 293 K

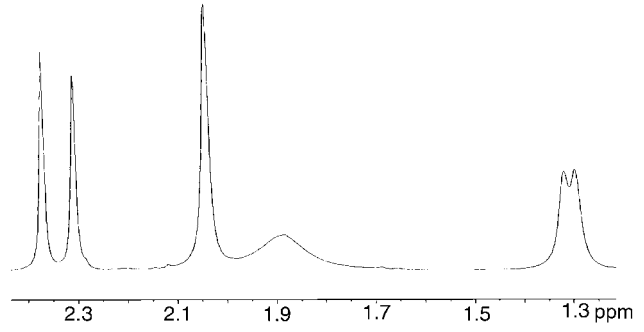

Figure 8. ^{1}H NMR spectrum of complex **4** at 183 K

In order to assign the signals in a situation in which the stereochemical non-rigidity of the complex would be avoided, we protonated **4** with 1 equiv. of HBF_4, a reaction yielding [{κ^2-HB(Pz^{Me2})$_2$(HPz^{Me2})}Rh(CO)(PMe$_2$Ph)][BF$_4$] (**4H$^+$**).[15] The infrared spectrum of **4H$^+$** in KBr shows ν(CO) and ν(BH) bands at 1987 and 2502 cm^{-1}, respectively, close to those of **4** (1968 and 2464 cm^{-1}). Direct protonation at the rhodium centre would have led to a shift in the position of the ν(CO) band of between 50 and 100 cm^{-1}. No ν(Rh−H) band was observed. These data are consistent with a square-planar environment for the rhodium atom and a κ^2 coordination mode for the Tp^{Me2} ligand. No spectroscopic evidence for a hydrido ligand was found, but a ^{1}H NMR signal at δ = 11.84 is consistent with the presence of an NH group. Thus, protonation of **4** occurs on the free pyrazolyl arm as expected. The methyl region of the ^{1}H NMR spectrum shown in Figure 9 confirms the absence of a symmetry plane in **4H$^+$**. The two methyls of PMe_2Ph are diastereotopic and six Tp^{Me2} methyl signals are observed. An Rh−H coupling (1.6 Hz) is apparent from the higher field doublet. With the aid of {^{1}H,^{1}H}, {^{1}H,^{13}C} HMQC, and HMBC measurements and {^{1}H,^{1}H} NOESY experiments, all the ^{1}H NMR signals have been assigned, as shown in Figure 10. It is worth noting that the two lower field methyl peaks at δ = 2.38 and 2.48 are attributable to the 3-Me and 5-Me groups of the pyrazolyl group *trans* to the CO ligand, respectively. Moreover, there is no exchange between the two pyrazolyl groups bonded to rhodium.

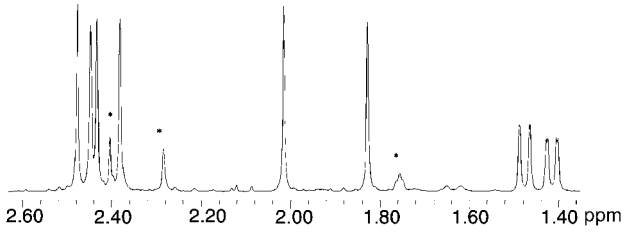

Figure 9. ^{1}H NMR spectrum of complex **4H$^+$**; *peaks attributable to the starting material **4**

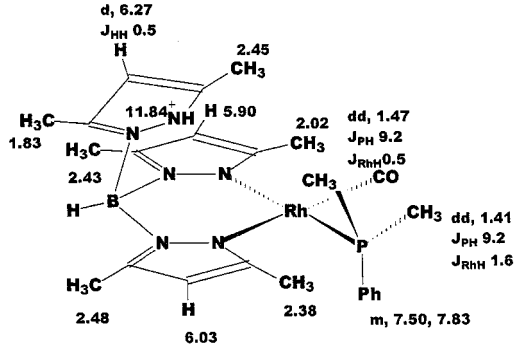

Figure 10. ^{1}H NMR signal assignments for complex **4H$^+$**

Study of the Exchange Phenomenon in 4

For complex **4** at 183 K (Figure 8), the two methyl proton signals observed at δ = 2.32 and 2.75 are assigned to the pyrazolyl *trans* to the CO ligand, these chemical shifts being very close to those of the pyrazolyl ligand *trans* to CO in **4H**$^+$. Hence, the methyl signal at δ = 1.88 is attributable to the dangling pyrazolyl, while that at δ = 2.05 is due to the pyrazolyl *trans* to the phosphane. The exchange rate for the former is slightly higher than the rate corresponding to the coalescence temperature. At low temperature, the latter pyrazolyl methyl groups undergo exchange with a low activation energy. Since the pyrazolyl *trans* to CO is not involved in the exchange phenomenon, we propose a square-pyramidal transition state, as shown in Figure 11. In a trigonal-bipyramidal transition state, the apical pyrazolyl group would exchange at the same rate with either of the two equatorial groups. When the temperature is raised, the third pyrazolyl *trans* to CO is also exchanged, so that the fast-exchange limit is reached at room temperature.

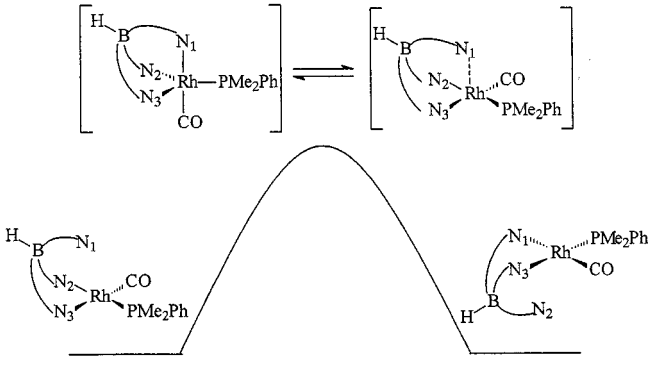

Figure 11. Proposed transition-state geometry for the exchange phenomenon between two square-planar isomers of **4**

This study shows that in a square-planar complex the pendant pyrazolyl group readily coordinates. Decoordination of the pyrazolyl *trans* to PMe_2Ph then provides the free pyrazolyl, as indicated in Figure 11. This phenomenon places the free pyrazolyl group either above or below the plane, such that the magnetic environments of the two methyl groups of PMe_2Ph become identical on the NMR time scale.[10]

The same exchange phenomenon has been observed for $[Tp^{Me2}Rh(CO)(PMe_3)]$,[11] $[Tp^{Me2,4Cl}Rh(CO)(PMePh_2)]$, and $[Tp^{Me2}Rh(CO)(PMePh_2)]$. For $[Tp^{Me2}Rh(CO)\{P(OPh)_3\}]$, however, the three pyrazolyl groups are still in fast exchange at 183 K. This is reminiscent of the results of the X-ray diffraction analysis, where the pendant pyrazolyl group and the rhodium centre were found to be in close proximity, and is consistent with the proposed geometry of the transition state and a low activation energy for the exchange between the square-planar isomers.

Conclusion

The complexes $[Tp^{Me2}Rh(CO)(PR_3)]$ and $[Tp^{Me2,4Cl}Rh(CO)(PR_3)]$ can readily be prepared by addition of one equivalent of the appropriate phosphane ligand to $[Tp^{Me2}Rh(CO)_2]$ and $[Tp^{Me2,4Cl}Rh(CO)_2]$, respectively. As shown by the X-ray crystal structures of four complexes and by an infrared study in the solid state and in solution, these complexes adopt a square-planar structure. In the case of a phosphite ligand, the dangling pyrazolyl group resides near the rhodium. The bonding mode is then intermediate between κ^2 and κ^3. NMR studies have shown a fluxional behaviour for all the $[Tp'Rh(CO)(PR_3)]$ complexes indicating that the more stable geometries are square-planar and that the transition state is close to square-pyramidal. Similar complexes have been prepared by Jones et al. with isocyanide ligands, while Carmona et al. have prepared iridium complexes with the general formula $[Tp'Ir(C_2H_4)(L)]$.[16,17]

Experimental Section

General Remarks: All experiments were carried out under argon. Reactions were performed using standard Schlenk techniques. Solvents were HPLC quality and were distilled under dinitrogen, toluene from sodium/benzophenone and dichloromethane from $CaSO_4$. They were frozen and degassed in vacuo, and were stored over molecular sieves under argon. Pentane was purified according to the method of Perrin and Armarego,[18] distilled from CaH_2 under argon, frozen, and degassed in vacuo. Commercial phosphites and phosphanes were used without purification. − NMR spectra were recorded with Bruker AC 200, WM 250, or AMX 400 spectrometers. − A Perkin−Elmer 1710 FT-IR spectrometer was used to record the infrared spectra. Solid samples were analysed in KBr and liquid samples were analysed between CaF_2 windows (vs: very strong, s: strong, m: medium, w: weak, vw: very weak, sh: shoulder). − X-ray analyses were performed with Enraf-Nonius CAD 4 or STOE IPDS diffractometers.

$HPz^{Me2,4Cl}$: This material[19] was prepared by the slow addition of hydrazine hydrate (20 mL, 412 mmol) to 3-chloro-2,4-pentanedione (49 mL, 411 mmol) in ethanol (600 mL) at 80 °C. The mixture was stirred for 3 h at 80 °C. After evaporation of the ethanol, the product was dissolved in CH_2Cl_2. The resulting solution was stirred with a small amount of $MgSO_4$ for 2 h and then filtered through Celite. The solvent was evaporated until crystallization commenced and then hexane (300 mL) was added. The solution was kept at 0 °C, whereupon white crystals were deposited. The crystals were washed with hexane (3 × 20 mL) at 0 °C and were then sublimed at 110 °C to yield 48.2 g (90%) of $HPz^{Me2,4Cl}$. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 2.24 (s, 6 H, CH_3). − IR (KBr): $\tilde{\nu}$ = 1588 cm^{-1} [ν(C=N)].

$KHBPz_3^{Me2,4Cl}$: This ligand[20] was prepared by the addition of 3,5-dimethyl-4-chloropyrazole (40.0 g, 307.2 mmol) to potassium tetrahydroborate (3.686 g, 68 mmol). The mixture was slowly heated to 120 °C. When the evolution of hydrogen had subsided, the temperature was raised to 220 °C. The reaction was seen to be complete when hydrogen evolution had ceased. Then, toluene (20 mL) was quickly added to avoid agglomeration of the product. The solution was concentrated to three-quarters of its original volume and then hexane (50 mL) was added. The resulting solution was kept at 0 °C. White crystals were deposited, which were washed with hexane (3 × 30 mL) at 0 °C. The crystals were freed of excess $HPz^{Me2,4Cl}$ by sublimation to yield 27.11 g (90%) of $KHBPz_3^{Me2,4Cl}$. − ^{1}H NMR ($CDCl_3$, 25 °C): δ = 2.00 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 2.14 [s, 9

H, CH_3(Pz^{Me2,4Cl})]. − IR (KBr): $\tilde{\nu}$ = 2468 cm^{-1} [ν(BH)], 1541 cm^{-1} [ν(C=N)].

KHBPz$_3^{Me2}$: This ligand[21] was prepared by the addition of 3,5-dimethylpyrazole (15.0 g, 117.2 mmol) to potassium tetrahydroborate (1.405 g, 28 mmol). The mixture was slowly heated to 110 °C. When the evolution of hydrogen had subsided, the temperature was increased to 190 °C. The reaction was seen to be complete when the hydrogen evolution had ceased. Then, toluene (20 mL) was quickly added to avoid agglomeration of the product. The solution was concentrated to three-quarters of its original volume and then hexane (50 mL) was added. The resulting solution was kept at 0 °C. White crystals were deposited, which were washed with hexane (3 × 30 mL) at 0 °C. The crystals were freed of excess HPz^{Me2} by sublimation to yield 8.47 g (85%) of KHBPz$_3^{Me2}$. − ^{1}H NMR (CDCl$_3$, 25 °C): δ = 2.00 [s, 9 H, CH_3(Pz^{Me2})], 2.14 [s, 9 H, CH_3(Pz^{Me2})]. − IR (KBr): $\tilde{\nu}$ = 2438 cm^{-1} [ν(BH)], 1538 cm^{-1} [ν(C=N)].

[Rh(μ-Cl)(CO)$_2$]$_2$: This complex was prepared by bubbling CO through a solution of RhCl$_3$·3H$_2$O (3.0 g, 11.4 mmol) in methanol (100 mL) at 65 °C for 20 h. The methanol was then slowly evaporated by passing nitrogen through the solution. Red crystals were obtained, which were sublimed in vacuo at 50 °C to yield 4.21 g (95%) of the product. − IR (KBr): $\tilde{\nu}$ = 2102 m, 2082 s, 2020 s cm^{-1} [ν(CO)].

[Tp^{Me2}Rh(CO)$_2$] (1): Compound **1** was prepared by adding KHBPz$_3^{Me2}$ (1.89 g, 4.15 mmol) to a solution of [Rh(μ-Cl)(CO)$_2$]$_2$ (1.0 g, 2.57 mmol) in CH_2Cl_2 (60 mL). The mixture was stirred for 4 h, in the course of which it turned from yellow-orange to brown. The reaction was monitored by infrared spectroscopy. KCl formed during the reaction was filtered off and washed with CH_2Cl_2. The combined filtrate and washings were concentrated in vacuo, yielding 1.9 g (90%) of **1** as a yellow-orange solid. − ^{1}H NMR (C_6D_6, 25 °C): δ = 2.31, 2.37 [s, 6 H, CH_3(Pz^{Me2})], 5.77 [s, 3 H, CH(Pz^{Me2})]. − IR (KBr): $\tilde{\nu}$ = 2512 [ν(BH)], 2054 s, 1973 s cm^{-1} [ν(CO)]. − UV/Vis (pentane): λ_{max} = 355 nm.

[Tp^{Me2,4Cl}Rh(CO)$_2$] (2): Addition of solid KHBPz$_3^{Me2,4Cl}$ (2.26 g, 5.15 mmol) to a yellow-orange solution of [Rh(μ-Cl)(CO)$_2$]$_2$ (1.00 g, 2.57 mmol) in CH_2Cl_2 (60 mL) yielded a brown slurry after 4 h. The progress of the reaction was monitored by IR. The solution was then filtered and the removed solid was washed with CH_2Cl_2. The combined filtrate and washings were concentrated in vacuo, yielding 1.3 g (90%) of **2** as a yellow-orange solid. − ^{1}H NMR (C_6D_6, 25 °C): δ = 2.12, 2.41 [s, 6 H, CH_3(Pz^{Me2,4Cl})]. − IR (KBr): $\tilde{\nu}$ = 2544 [ν(BH)], 2088 w, 2059 s, 2020 w, 1984 s cm^{-1} [ν(CO)]. − UV/Vis (pentane): λ_{max} = 361 nm.

[Tp^{Me2}Rh(CO)(PMe$_3$)] (3): Complex **3** was prepared by adding PMe$_3$ (0.96 mL, 0.96 mmol, 1 M in toluene) to a solution of [Tp^{Me2}Rh(CO)$_2$] (0.4 g, 0.88 mmol) in CH_2Cl_2 (20 mL). The reaction was immediate, as indicated by a ν(CO) band at 1969 cm^{-1} in the IR spectrum. The solvent was then evaporated and the residue was washed with hexane at 0 °C and dried in vacuo at 40 °C for 6 h to yield 0.36 g (85%) of **3**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 0.91 (d, 9 H, PMe$_3$, $^2J_{P-H}$ = 3 Hz), 1.75 [s, 9 H, CH_3(Pz^{Me2})], 2.15 [s, 9 H, CH_3(Pz^{Me2})]. − ^{31}P NMR (C_6D_6, 25 °C): δ = 5.02 (d, 1 P, $^1J_{Rh-P}$ = 145 Hz). − IR (KBr): $\tilde{\nu}$ = 2443 [ν(BH)], 1961 cm^{-1} [ν(CO)].

[Tp^{Me2}Rh(CO)(PMe$_2$Ph)] (4): Complex **4** was prepared by adding PMe$_2$Ph (62.4 μL, 0.44 mmol) to a solution of [Tp^{Me2}Rh(CO)$_2$] (0.20 g, 0.44 mmol) in CH_2Cl_2 (15 mL). The reaction was immediate, as shown by a ν(CO) band at 1973 cm^{-1} in the IR spectrum. The solvent was evaporated and the product was washed at 45 °C for 6 h, yielding 0.21 g (80%) of **4**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.43 (d, 6 H, PMe$_2$, $^2J_{P-H}$ = 9 Hz), 2.15 [s, 9 H, CH_3(Pz^{Me2})], 2.21 [s, 9 H, CH_3(Pz^{Me2})], 5.83 [s, 3 H, CH(pz)], 7.82 (m, 5 H, PPh). − ^{31}P NMR (C_6D_6, 25 °C): δ = 20.13 (d, 1 P, $^1J_{Rh-P}$ = 151 Hz). − IR (KBr): $\tilde{\nu}$ = 2464 [ν(BH)], 1968 cm^{-1} [ν(CO)]. − $C_{24}H_{33}BN_6OPRh$ (566.3): calcd. C 50.91, H 5.87, N 14.84; found C 50.31, H 5.96, N 14.62.

[Tp^{Me2}Rh(CO)(PMePh$_2$)] (5): Complex **5** was prepared by adding PMePh$_2$ (89.7 μL, 0.48 mmol) to a solution of [Tp^{Me2}Rh(CO)$_2$] (0.20 g, 0.44 mmol) in CH_2Cl_2 (20 mL). The reaction was complete within 15 min, as shown by IR [ν(CO) = 1979 cm^{-1}]. The solution was filtered and the filtrate was concentrated to dryness. Crystallization of the residue from toluene/heptane at −18 °C yielded 0.23 g (85%) of yellow crystals of **5**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.60 (dd, 3 H, P*Me*Ph$_2$, $^2J_{P-H}$ = 10, $^3J_{Rh-H}$ = 1 Hz), 2.05 [s, 9 H, CH_3(Pz^{Me2})], 2.32 [s, 9 H, CH_3(Pz^{Me2})], 5.71 [s, 3 H, CH(Pz^{Me2})], 7.42 (m, 10 H, PPh$_2$). − ^{31}P NMR (C_6D_6, 25 °C): δ = 30.60 (d, 1 P, $^1J_{Rh-P}$ = 155 Hz). − IR (KBr): $\tilde{\nu}$ = 2463 [ν(BH)], 1975 cm^{-1} [ν(CO)]. − UV/Vis (pentane): λ_{max} = 357 nm. − $C_{29}H_{35}BN_6OPRh$ (628.3): calcd. C 55.44, H 5.61, N 13.37; found C 52.40, H 5.16, N 12.34.

[Tp^{Me2}Rh(CO)(PPh$_3$)] (6): Complex **6** was prepared by adding solid PPh$_3$ (0.16 g, 0.48 mmol) to a solution of [Tp^{Me2}Rh(CO)$_2$] (0.20 g, 0.44 mmol) in CH_2Cl_2 (15 mL). The reaction was monitored by IR and was seen to be complete after 2 h [ν(CO) = 1978 cm^{-1}]. The solution was then filtered and the filtrate was concentrated to dryness. Crystallization of the residue from toluene/heptane at −18 °C yielded 0.24 g (80%) of yellow crystals of **6**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.75 [s, 9 H, CH_3(Pz^{Me2})], 2.15 [s, 9 H, CH_3(Pz^{Me2})], 5.70 [s, 3 H, CH(Pz^{Me2})], 7.3 (m, 15 H, PPh$_3$). − ^{31}P NMR (C_6D_6, 25 °C): δ = 42.86 (d, 1 P, $^1J_{Rh-P}$ = 161 Hz). − IR (KBr): $\tilde{\nu}$ = 2468 [ν(BH)], 1965 cm^{-1} [ν(CO)]. − $C_{34}H_{37}BN_6OPRh$ (690.4): calcd. C 59.15, H 5.40, N 12.17; found C 59.48, H 5.47, N 11.90.

[Tp^{Me2}Rh(CO){P(OMe)$_3$}] (7): Complex **7** was prepared by adding P(OMe)$_3$ (52 μL, 0.44 mmol) to a solution of [Tp^{Me2}Rh(CO)$_2$] (0.20 g, 0.44 mmol) in CH_2Cl_2 (15 mL). The reaction was immediate, as shown by IR [ν(CO) = 1996 cm^{-1}]. The solvent was evaporated and the residue was washed with hexane at 0 °C and dried in vacuo to yield 0.19 g (85%) of **7**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.92 [s, 9 H, CH_3(OMe$_3$)], 1.75 [s, 9 H, CH_3(Pz^{Me2})], 2.15 [s, 9 H, CH_3(Pz^{Me2})]. − ^{31}P NMR (C_6D_6, 25 °C): δ = 142.8 (d, 1 P, $^1J_{Rh-P}$ = 266 Hz). − IR (KBr): $\tilde{\nu}$ = 2508 [ν(BH)], 1963 cm^{-1} [ν(CO)].

[Tp^{Me2}Rh(CO){P(OPh)$_3$}] (8): Complex **8** was prepared by adding P(OPh)$_3$ (253 μL, 0.96 mmol) to a solution of [Tp^{Me2}Rh(CO)$_2$] (0.40 g, 0.87 mmol) in CH_2Cl_2 (20 mL). The reaction was complete within 2 h, as shown by IR [ν(CO) = 2009 cm^{-1}]. The solvent was then evaporated and the residue was washed with hexane at 0 °C and dried in vacuo at 45 °C for 6 h to yield 0.21 g (80%) of **8**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 2.23 [s, 9 H, CH_3(Pz^{Me2})], 2.28 [s, 9 H, CH_3(Pz^{Me2})], 5.70 [s, 3 H, CH(Pz^{Me2})], 7.20 [m, 15 H, P(OPh)$_3$]. − ^{31}P NMR (C_6D_6, 25 °C): δ = 126.40 (d, 1 P, $^1J_{Rh-P}$ = 279 Hz). − IR (KBr): $\tilde{\nu}$ = 2518 [ν(BH)], 1984 cm^{-1} [ν(CO)]. − $C_{34}H_{37}BN_6O_4PRh$ (738.4): calcd. C 55.91, H 5.05, N 10.05; found C 55.30, H 5.04, N 11.38.

[Tp^{Me2,4Cl}Rh(CO)(PCy$_3$)] (9): Complex **9** was prepared by adding solid PCy$_3$ (0.16 g, 0.58 mmol) to a solution of [Tp^{Me2,4Cl}Rh(CO)$_2$] (0.30 g, 0.54 mmol) in toluene (30 mL). The mixture was stirred for

4 h. The solvent was then evaporated in vacuo and the yellow residue was washed three times with hexane at 0 °C and dried in vacuo to yield 0.39 g of **9**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.75 (m, 33 H, PCy_3), 2.15 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 2.30 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$]. − ^{31}P NMR (C_6D_6, 25 °C): δ = 47.70 (d, $^2J_{Rh-P}$ = 152 Hz). − IR (KBr): $\tilde{\nu}$ = 2477 [ν(BH)], 1963 cm^{-1} [ν(CO)]. − UV/Vis (pentane): λ_{max} = 350 nm.

[Tp^{Me2,4Cl}Rh(CO)(PMe$_3$)] (10): Complex **10** was prepared by adding PMe_3 (0.4 mmol, 0.4 mL of a 1 M solution in toluene) to a solution of [Tp^{Me2,4Cl}Rh(CO)$_2$] (0.20 g, 0.37 mmol) in pentane (30 mL). The orange solution immediately turned yellow. The pentane was evaporated in vacuo to leave 0.20 g of **10** as a yellow solid. − ^{1}H NMR (C_6D_6, 25 °C): δ = 0.87 (d, 9 H, PMe_3, $^2J_{P-H}$ = 3 Hz), 2.09 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 2.21 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$]. − ^{31}P NMR (C_6D_6, 25 °C): δ = −9.66 (d, $^1J_{P-H}$ = 116 Hz). − IR (KBr): $\tilde{\nu}$ = 2477 [ν(BH)], 1963 cm^{-1} [ν(CO)]. − UV/Vis (pentane): λ_{max} = 350 nm.

[Tp^{Me2,4Cl}Rh(CO)(PMePh$_2$)] (12): Complex **12** was prepared by adding $PMePh_2$ (74 μL, 0.40 mmol) to a solution of [Tp^{Me2,4Cl}Rh(CO)$_2$] (0.20 g, 0.36 mmol) in pentane (30 mL) at 0 °C. A yellow solid was immediately precipitated, which was collected by filtration and dried in vacuo to afford a yellow powder. This powder was washed three times with hexane at 0 °C and dried in vacuo yielding 0.25 g of **12**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.56 (dd, 3 H, P*Me*Ph$_2$, $^2J_{P-H}$ = 9, $^3J_{Rh-H}$ = 1 Hz), 2.09 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 2.12 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 7.08 (m, 10 H, PMe*Ph*$_2$). − ^{31}P NMR (C_6D_6, 25 °C): δ = 27.38 (d, 1 P, $^1J_{Rh-P}$ = 157 Hz). − IR (KBr): $\tilde{\nu}$ = 2477 [ν(BH)], 1996 cm^{-1} [ν(CO)]. − UV/Vis (pentane): λ_{max} = 352 nm.

[Tp^{Me2,4Cl}Rh(CO)(PPh$_3$)] (13): Complex **13** was prepared by adding solid PPh_3 (0.95 g, 0.36 mmol) to a solution of [Tp^{Me2,4Cl}Rh(CO)$_2$] (0.20 g, 0.36 mmol) in toluene (25 mL). The reaction was complete within 2 h. The solvent was then evaporated in vacuo yielding 0.25 g of a yellow solid. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.75 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 2.15 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 7.3 (m, 15 H, PPh_3). − ^{31}P NMR (C_6D_6, 25 °C): δ = 42.86 (d, 1 P, $^1J_{Rh-P}$ = 161 Hz). − ^{13}C{^{1}H} NMR (C_6D_6, 25 °C): δ = 9.86, 11.81 [s, $CH_3(Pz^{Me2,4Cl})$], 107.52 [s, $CH(Pz^{Me2,4Cl})$], 129.66 [s, $C(Pz^{Me2,4Cl})$], 127.60 (d, J_{P-C} = 10 Hz, PPh_3), 133.6 (d, J_{PC} = 12 Hz, PPh). − IR (KBr): $\tilde{\nu}$ = 2477 [ν(BH)], 1988 cm^{-1} [ν(CO)].

[Tp^{Me2,4Cl}Rh(CO){P(OMe)$_3$}] (14): Complex **14** was prepared by adding $P(OMe)_3$ (0.077 mL, 0.03 mmol) to a solution of [Tp^{Me2,4Cl}Rh(CO)$_2$] (0.15 g, 0.27 mmol) in CH_2Cl_2 (20 mL). The reaction was complete within 1 h (IR monitoring). The solvent was then evaporated to leave a yellow powder, which was washed three times with hexane at 0 °C and dried in vacuo to yield 0.16 g of **14**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.80 [s, 9 H, $(OCH_3)_3$], 2.05 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 2.41 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$]. − ^{31}P NMR (C_6D_6, 25 °C): δ = 142.24 (d, 1 P, $^1J_{Rh-P}$ = 262 Hz). − IR (KBr): $\tilde{\nu}$ = 2536 [ν(BH)], 1998 cm^{-1} [ν(CO)].

[Tp^{Me2,4Cl}Rh(CO){P(OPh)$_3$}] (15): Complex **15** was prepared by adding $P(OPh)_3$ (0.155 g, 0.591 mmol) to a solution of [Tp^{Me2,4Cl}Rh(CO)$_2$] (0.30 g, 0.54 mmol) in CH_2Cl_2 (30 mL). The reaction mixture was stirred for 4 h. The CH_2Cl_2 was then evaporated to leave a yellow powder, which was washed three times with hexane at 0 °C and dried in vacuo yielding 0.39 g of **15**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 2.06 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 2.37 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 7.04 [m, 15 H, $P(OPh)_3$]. − ^{31}P NMR (C_6D_6, 25 °C): δ = 123.05 (d, 1 P, $^1J_{Rh-P}$ = 279 Hz). − IR (KBr): $\tilde{\nu}$ = 2494 [ν(BH)], 2007 cm^{-1} [ν(CO)]. − UV/Vis (pentane): λ_{max} = 345 nm

[Tp^{Me2,4Cl}Rh(CO){P(O*i*Pr)$_3$}] (16): Complex **16** was prepared by adding $P(OiPr)_3$ (0.145 mL, 0.59 mmol) to a solution of [Tp^{Me2,4Cl}Rh(CO)$_2$] (0.30 g, 0.54 mmol) in CH_2Cl_2 (30 mL). The volatiles were evaporated to leave a yellow powder, which was washed three times with hexane at 0 °C and dried in vacuo yielding 0.36 g of **16**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.10 [d, 6 H, $OCH(CH_3)_2$, $^3J_{H-H}$ = 6 Hz], 2.09 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 2.37 [s, 9 H, $CH_3(Pz^{Me2,4Cl})$], 4.51 [m, 1 H, $OCH(CH_3)_2$]. − ^{31}P NMR (C_6D_6, 25 °C): δ = 126.53 (d, 1 P, $^1J_{Rh-P}$ = 243 Hz). − IR (KBr): $\tilde{\nu}$ = 2469 [ν(BH)], 1996 cm^{-1} [ν(CO)].

[{κ^2-HB(Pz^{Me2})$_2$(HPz^{Me2})}Rh(CO)(PMe$_2$Ph)]$^+$[BF$_4$]$^-$ (4H$^+$): Complex **4H$^+$** was prepared by adding HBF_4 (25 μL, 54% in diethyl ether) to a solution of [Tp^{Me2}Rh(CO)(PMe$_2$Ph)] (0.10 g, 0.18 mmol) in diethyl ether (10 mL) at −78 °C. The solution was stirred for 15 min at this temperature and was then allowed to slowly warm to 25 °C, whereupon a white product precipitated. This solid was collected by filtration, washed with diethyl ether, and dried in vacuo yielding 0.08 g of **4H$^+$**. − ^{1}H NMR (C_6D_6, 25 °C): δ = 1.41 [dd, 3 H, J_{P-H} = 9, J_{Rh-H} = 1.6 Hz, (P*Me*$_2$Ph)], 1.47 (dd, 3 H, J_{P-H} = 9, J_{Rh-H} = 0.5 Hz, P*Me*$_2$Ph), 1.83, 2.02, 2.38, 2.43, 2.45, 2.48 [s, 3 H, *Me*(Pz^{Me2})], 7.50 (m, 5 H, PPh). − ^{31}P NMR (C_6D_6, 25 °C): δ = 15.86 (d, J_{Rh-P} = 151 Hz). − IR (KBr): $\tilde{\nu}$ = 2502 [ν(BH)], 1987 cm^{-1} [ν(CO)].

X-ray Crystal Structure Determinations: For compound **5**, data were collected at room temperature with a STOE IPDS diffractometer equipped with a graphite-oriented monochromator using Mo-K_α radiation (λ = 0.71073 Å). The final unit cell parameters were obtained by the least-squares refinement of 5000 reflections. An Enraf-Nonius CAD4F diffractometer was used for the data collection of compound **8**. For both compounds, only statistical fluctuations were observed in the intensities of standard reflections monitored throughout the course of the data collections. The structures were solved by direct methods (SIR-97)[22] and refined by least-squares methods on *F*. All H atoms attached to carbon were introduced in calculated positions [*d*(CH) = 0.96 Å] and their atomic coordinates were recalculated after each cycle. They were given isotropic thermal parameters 20% higher than those of the carbon to which they were attached. H atoms attached to boron were located by difference Fourier syntheses and their atomic and isotropic thermal parameters were refined. The absolute configuration of **5** was determined by careful examination of the sensitive reflections and refinement of Flack's enantiopole parameter.[23] Least-squares refinements were carried out by minimizing the function $\Sigma w(|F_o| - |F_c|)$, where F_o and F_c are the observed and calculated structure factors. The weighting scheme used in the final refinement cycles was $w = w'[1 - \{\Delta F/6\sigma(F_o)\}^2]^2$; here, $w' = 1/\Sigma \cong_1^n A_r T_r(x)$ with three coefficients A_r for the Chebyshev polynomial $A_r T_r(x)$, where $x = F_c/F_c(\max)$.[24] Models reached convergence with $R = \Sigma(||F_o| - |F_c||)/\Sigma(|F_o|)$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2]^{1/2}$, giving the values listed in Table 4. The calculations were carried out with the CRYSTALS program package[25] run on a PC. Graphical representations were generated using ORTEP.[26] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-149636 (**5**) and -149637 (**8**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Improved Preparations of Molybdenum Coordination Compounds from Tetrachlorobis(diethyl ether)molybdenum(IV)

François Stoffelbach,[a] Dirk Saurenz,[a] and Rinaldo Poli*[a]

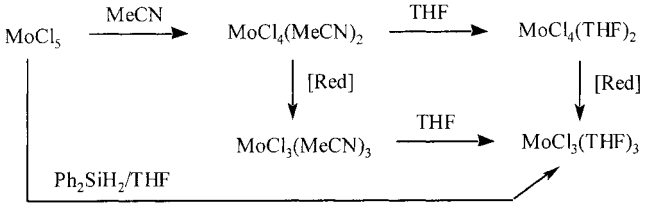
Keywords: Reduction / Molybdenum / Halides / Synthetic methods

The reduction of $MoCl_5$ with metallic tin in diethyl ether provides a rapid and convenient entry to $[MoCl_4(OEt_2)_2]$ This compound can be transformed easily and in high yields into a variety of other useful synthons. The loss of ether in the solid state affords a new and reactive form of $MoCl_4$. Treatment with THF, PMe_3 or Li*O*t*Bu affords $[MoCl_4(THF)_2]$, $[MoCl_4(PMe_3)_3]$ or $[Mo(O\,t\,Bu)_4]$ in high isolated yields. Treatment with metallic tin in THF affords $[MoCl_3(THF)_3]$ All of these reactions can be carried out under simple experimental conditions and represent significant improvements relative to previously reported syntheses of the same compounds.

Introduction

The element molybdenum displays a very rich chemistry in low, intermediate and high oxidation states. Research with this metal is intense in the organometallic/catalysis, coordination, bioinorganic, cluster, and solid state/materials fields. However, all this activity stems from a very limited amount of commercially available Mo-containing starting materials, the most convenient ones being elemental Mo, $Mo(CO)_6$, MoS_2, MoO_3 and $MoCl_5$. Some transformations require long, multiple-step procedures, resulting in a considerable investment of time and, perhaps more importantly, in considerable product losses due to the compounding of imperfect reaction yields. The improvement of known synthetic methods and the search for alternative procedures allowing a reduction of reaction times, the simplification of isolation and purification procedures, and an increase of overall yields are continuous goals of the synthetic chemist.

The situation is perhaps best illustrated by the example of $[MoCl_3(THF)_3]$, a useful intermediate for a wide variety of inorganic synthetic applications. Following the first reported preparation by a carbonyl route,[1] the compound was subsequently obtained by a reductive procedure starting from $MoCl_5$. This pentachloride compound is a strong Lewis acid and also a powerful oxidant and its direct reduction in THF is complicated by the acid-catalysed ring opening polymerization of THF, a problem which is circumvented by using other solvents. The most commonly employed synthetic procedure (Scheme 1) starts with the interaction of $MoCl_5$ with a nitrile RCN to afford $[MoCl_4(RCN)_2]$, followed by replacement of the nitrile with THF and final reduction to the Mo^{III} product. A variety of improvements of this procedure have been published over the years including three reports in Inorganic Synthesis, replacing propionitrile with acetonitrile, zinc with tin as the reducing agent, and modifying the reaction conditions and product separation procedures.[2–7] Nevertheless, this three-step procedure remains rather long and requires, in our hands, isolation of both $[MoCl_4(MeCN)_2]$ and $[MoCl_4(THF)_2]$ intermediates in order to obtain a product of sufficient quality. With individual step yields of 63–86%, the overall yield from $MoCl_5$ is 46% at best with a time investment of more than two days. Another variation on the same theme (Scheme 1) is the reduction of $[MoCl_4(MeCN)_2]$ to $[MoCl_3(MeCN)_3]$, followed by solvent exchange.[8] A direct and rapid one-step, high-yield (85%) procedure has been published more recently, but this requires the use of Ph_2SiH_2 as a reducing agent and a controlled, slow addition of the $MoCl_5$ solid to the silane-containing THF solution.[9] A reverse addition of the silane to $MoCl_5$ is possible only in pentane as solvent, prolonging the reaction time to 48 h.



Scheme 1

Our continued interest in the coordination and organometallic chemistry of middle-valent molybdenum continuously pushes us to improve the preparative procedures of our required synthetic intermediates. Our attention has been attracted by $[MoCl_4(OEt_2)_2]$, whose high yield synthesis was reported a few years ago from $MoCl_5$ and either norbornene[10] or allyltrimethylsilane[11] as reducing agents. However, only a limited use of this compound in sub-

sequent synthetic work was described. In this contribution, we shall show that $[MoCl_4(OEt_2)_2]$ can also be conveniently prepared by tin reduction of $MoCl_5$, and that it is a versatile intermediate for the preparation of a variety of other molybdenum compounds. In particular, $[MoCl_3(THF)_3]$ is now accessible in a half-day, two-step, single-flask procedure (no isolation of intermediates is required) in greater than 80% overall yields from $MoCl_5$ and the common reagents ether, THF, and metallic tin.

Results and Discussion

While the high Lewis acidity of $MoCl_5$ makes this compound incompatible with the THF solvent, causing its cationic ring-opening polymerization, non-cyclic ethers do not suffer from this decomposition pathway. Ethereal solutions of $MoCl_5$ are stable and are rapidly reduced by metallic tin to yield a fine, orange, crystalline powder of $[MoCl_4(OEt_2)_2]$ [Equation (1)]. The reaction is fast but controlled at room temperature, and is usually complete within 0.5 h as evident from the visual appearance of the powdery orange precipitate. No wild exothermic behavior has been observed during this reductive process, which therefore does not require any special precautions. In addition, the tin chloride co-product is ether-soluble while $[MoCl_4(OEt_2)_2]$ is only sparingly soluble. Therefore, the Mo^{IV} product is easily purified by washing with ether with only minimal product loss. The yields of this preparation are consistently greater than 80% for quantities of product greater than a gram. These yields and the product purity are comparable with those of the previously reported syntheses, which used more exotic reducing agents such as allyltrimethylsilane or norbornene.[10,11] It should be noted that a possible by-product, $[MoOCl_3(Et_2O)_2]$,[12] may form when wet ether and/or partially hydrolyzed $MoCl_5$ starting compound are employed. This compound, however, is green and soluble in ether,[10] while the $[MoCl_4(Et_2O)_2]$ product is orange and sparingly soluble. Thus, minor impurities of the molybdenyl species may be easily eliminated. In our work, we found no evidence for the formation of this by-product.

$$2\ MoCl_5 + Sn \xrightarrow{Et_2O} 2\ MoCl_4(OEt_2)_2 + SnCl_2 \quad (1)$$

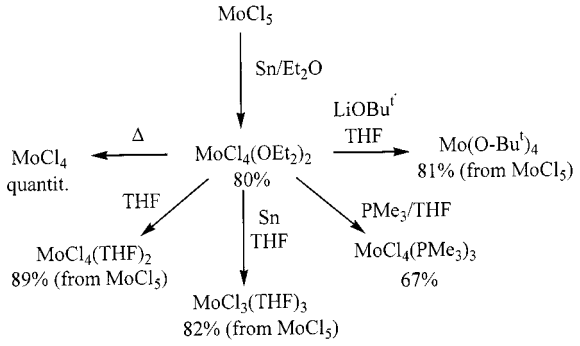
We have not investigated in detail the nature of the oxidized tin product. The literature reports that $SnCl_2$ is capable of reducing $[MoCl_4(THF)_2]$ in THF to afford $[MoCl_3(THF)_3]$ and $[SnCl_4(THF)_2]$.[9] Metallic tin is equally capable of carrying out the same reduction and to even over-reduce the metal below the +3 level. In ether, however, any further reduction by Sn (which may be used in excess) must be extremely slow since we found no NMR evidence for the formation of Mo^{III}, after isolation of the solid material and exchange with THF (vide infra). On the basis of this observation, we assume that $SnCl_2$ is probably also a poorer reductant in ether than in THF. Thus, the tin/ether combination seems ideal, giving rise to a rapid, controlled and selective reduction.

Although $[MoCl_4(OEt_2)_2]$ is only sparingly soluble in ether, it is readily soluble in aromatic hydrocarbons. In this respect, it resembles its sulfur congener $[MoCl_4(SEt_2)_2]$.[13] Besides elemental analysis and IR, no additional characterization was shown in the previous reports. The magnetic moment ($\mu_{eff} = 2.33\ \mu_B$) is significantly lower than the spin-only value for two unpaired electrons because of the expected spin-orbit coupling for the triplet ground state derived from the pseudo-t_{2g}^2 configuration. This value is in the range observed for other $[MoCl_4L_2]$ complexes (L = THF, MeCN, PPh_3, etc.), namely 2.2−2.5 μ_B.[14] The ^1H NMR spectrum in C_6D_6 shows only one resonance for the methyl and one for the methylene protons. These resonances are broad as may be expected for a paramagnetic complex. However, they are not significantly contact-shifted from the position of free ether (cf. the highly shifted resonances of the bis-THF adduct, vide infra, or those of the sulfur congener $[MoCl_4(SEt_2)_2]$[13]). We attribute this behavior to the rapid dissociation equilibrium of Equation (2), as proposed previously.[10] Thus, the broad lines would be the time-averaged signals of the methylene and methyl protons of the diamagnetic free ether and the paramagnetic complexes, at the fast exchange limit. In comparison with the related bis-SEt_2 complex, the NMR spectrum shows that diethyl ether is a much more labile ligand than the sulfur congener, as might be expected.

$$MoCl_4(OEt_2)_2 \rightleftharpoons MoCl_4(OEt_2) + Et_2O \quad (2)$$

The only available crystal structure for a $[Mo^{IV}X_4L_2]$ complex with monodentate ligands appears to be that of $[MoCl_4(SEt_2)_2]$ which is trans.[13] $[MoCl_4(CH_3OCH_2CH_2OCH_3)]$ has a cis arrangement enforced by the chelating dimethoxyethane ligand.[15] For this reason, it is likely that $[MoCl_4(OEt_2)_2]$ also adopts a trans configuration. Most related Mo^{III} anions $[Mo^{III}X_4L_2]^-$ also adopt a trans arrangement,[16−18] although examples having a cis configuration are also known.[19,20] In spite of numerous attempts under a variety of conditions, we have not been able to grow single crystals of this compound.

The synthetic utility of $[MoCl_4(OEt_2)_2]$ has been investigated in some detail and the results are summarized in Scheme 2. Because of the facile ether loss shown by the NMR study above, it is best to use a freshly prepared sample for the purpose of further synthetic applications. Heating the isolated $[MoCl_4(OEt_2)_2]$ solid under vacuum leads to the complete loss of the ether ligands at a relatively low temperature, leaving amorphous (by X-ray powder diffraction) $MoCl_4$. Darkening of the solid already occurs at about 55 °C, while at 80 °C the powder is totally black. Samples of ether-free $MoCl_4$ have been obtained by operating at temperatures up to 130 °C. This procedure is considerably more practical and time efficient than the literature preparations (see below) and leads to a more chemically reactive material.



Scheme 2

Three different crystalline forms of $MoCl_4$ have been described in the literature, namely α-$MoCl_4$,[21] β-$MoCl_4$,[22,23] and γ-$MoCl_4$.[24] The α form was obtained from $MoCl_5$ by reflux with tetrachloroethylene in carbon tetrachloride; a reflux time shorter than two days is said to leave unchanged pentachloride.[21] The β form was obtained by comproportionation of $MoCl_5$ and $MoCl_3$ in a temperature gradient,[22] while the γ form was prepared by heating a mixture of MoO_2 and carbon with a nitrogen stream saturated with CCl_4 vapors.[24] The observed magnetic moment of 1.6 μ_B for our amorphous $MoCl_4$ does not compare with any of those reported for the three crystalline phases (i.e. 0.85 μ_B for α-$MoCl_4$,[21] 2.31−2.54 μ_B for β-$MoCl_4$,[22] and 1.91 μ_B for γ-$MoCl_4$ [24]), although it is closest to that of the γ phase. An additional and significant difference is observed in the temperature behavior. A disproportionation process occurs at temperatures above 140 °C to generate $MoCl_5$ and $MoCl_3$. This process is also observed for the β phase, but only at about 288 °C.[24] On the other hand, the γ phase was shown to transform at ca. 140 °C into the α phase, which in turn converts into the β phase at ca. 240 °C. Our evidence for the disproportionation of amorphous $MoCl_4$ at 140 °C is clear: volatile $MoCl_5$ sublimes and the solid residue transforms into a reddish material which is no longer soluble in ethanol, indicating the formation of lower chlorides. Furthermore, the signals of $MoCl_3$ in this material have been detected by powder X-ray diffraction. On the basis of this evidence, it seems obvious that amorphous $MoCl_4$ is a labile and reactive form, leading directly to the thermodynamic mixture of Mo^{III} and Mo^{V} chlorides at relatively low temperature, while the crystalline α, β and γ phases are more inert.

The lability of amorphous $MoCl_4$ is further shown by its high chemical reactivity. Addition of THF leads to the rapid and exothermic formation of $[MoCl_4(THF)_2]$, and treatment of the resulting mixture with other reagents (for instance, Li*O*t*Bu*) affords the expected Mo^{IV} products in excellent yields (vide infra). The conversion of $MoCl_4$ to the bis-THF adduct is quantitative and is best accomplished by addition of THF to a pentane suspension of the tetrachloride, in order to evacuate the reaction heat.

$[MoCl_4(THF)_2]$, however, is more conveniently obtained by direct substitution of the ether in $[MoCl_4(OEt_2)_2]$, which may be obtained in situ from $MoCl_5$ (overall 89% isolated yields). This route appears to give a cleaner $[MoCl_4(THF)_2]$ product relative to the previously described synthesis from $[MoCl_4(MeCN)_2]$. It is possible that the ligand-exchange equilibrium is further shifted toward the bis-THF product when the less coordinating Et_2O ligand is bonded to the metal center. As for the bis-Et_2O analogue, no NMR spectroscopic data seem to be available in the literature for $[MoCl_4(THF)_2]$. The NMR spectrum in $CDCl_3$ shows highly shifted (12.5 and −32.8 ppm) but relatively sharp ($w_{1/2}$ = 12 and 15 Hz, respectively) resonances, indicating the presence of a single isomer in solution. These chemical shifts compare relatively well with those of the bis-thioether complex $[MoCl_4(SEt_2)_2]$.[13] As for the bis-Et_2O analogue, we were unable to grow single crystals of this compound. Substitution of the ether in $[MoCl_4(OEt_2)_2]$ with PMe_3 leads to the previously reported compound $[MoCl_4(PMe_3)_3]$.[25]

Besides substitution reactions of the ether ligand, the chlorides can also be easily replaced. This metathesis process provides a convenient entry to the tetrakis(*tert*-butoxy) derivative $[Mo(O\mathit{t}Bu)_4]$. The previous synthesis of this compound involves metathesis from $[Mo(NMe_2)_4]$,[26] a compound that is available only in low yields from $MoCl_5$.[27] After its first report, this compound does not appear to have been used for further investigations, possibly because of the laborious and low-yield synthetic procedure. It is now available, however, in a practical half-day procedure in greater than 80% yields from $MoCl_5$. As such, it may constitute a new useful synthon for Mo^{IV} chemistry. Previous physical characterization of $[Mo(O\mathit{t}Bu)_4]$ comprised IR, UV/Visible and mass spectra, and magnetic susceptibility. The compound was reported as having an intermediate magnetic moment between those expected for a magnetically diluted compound with two unpaired electrons and a diamagnetic compound (μ_{eff} = 1.38 μ_B in toluene or 1.37−1.40 μ_B in the solid state).[26] In our hands, the compound is diamagnetic by solid-state magnetic susceptibility and by NMR and EPR spectroscopy. In this respect, it appears perfectly homologous to the corresponding thiolato derivative $[Mo(S\mathit{t}Bu)_4]$.[28] Other MoX_4 compounds with π-donor X ligands, namely $[Mo(NMe_2)_4]$,[29] $[Mo(2\text{-}MeC_6H_4)_4]$,[30] and other mixed amido-phosphido derivatives[31] are mononuclear and diamagnetic, while compounds with π-neutral X ligands such as $[Mo(2\text{-}MeC_6H_4)_4]$[32] and $[Mo(norbornyl)_4]$[33] are paramagnetic with two unpaired electrons.

When $[MoCl_4(OEt_2)_2]$ was exposed to THF in the presence of metallic tin, a smooth reduction to $[MoCl_3(THF)_3]$ occurred. This is not surprising as the transformation of $[MoCl_4(OEt_2)_2]$ to $[MoCl_4(THF)_2]$ in a THF slurry has been established above, and the reduction of the latter to $[MoCl_3(THF)_3]$ by tin in THF is a well-established process. However, we found that this reaction gives excellent results without the need to isolate either the $[MoCl_4(OEt_2)_2]$ product after the first reductive step or the second $[MoCl_4(THF)_2]$ intermediate. Thus, it suffices to use enough tin reagent to reduce Mo^{V} to Mo^{III} and to replace

the solvent after completion of the first reduction step, in order to achieve a convenient high-yield synthesis of $[MoCl_3(THF)_3]$, in half a day, from $MoCl_5$.

Conclusion

In conclusion, we have developed a new, simple and time-efficient preparation of $[MoCl_4(OEt_2)_2]$, and demonstrated its synthetic utility with the improved preparation of a few key materials such as $[MoCl_4(THF)_2]$, $[MoCl_3(THF)_3]$, $[Mo(O\mathit{t}Bu)_4]$, and a new and reactive form of $MoCl_4$.

Experimental Section

General: All manipulations were carried out under an atmosphere of dry and oxygen-free argon with standard Schlenk techniques. Solvents were dried and deoxygenated by refluxing over suitable reagents (THF and ether over sodium benzophenone ketyl, toluene over sodium) and distilled under argon before use. ^1H NMR measurements were carried out on a Bruker AC 200 spectrometer. The peak positions are reported with positive shifts in ppm downfield of TMS as calculated from residual solvent peaks. The magnetic susceptibility measurements were carried out with a Johnson−Matthey magnetic balance, which operates by a modified Gouy method. The molar susceptibilities for the calculation of the magnetic moments were corrected for the diamagnetism of the ligands by using Pascal's constants. Elemental analyses were performed with a Fisons EA 1108 apparatus. $MoCl_5$, PMe_3 (1 M in THF) and Sn (fine grains, 20 mesh) were purchased from Aldrich Chemical Co. and used as received.

Synthesis of $[MoCl_4(Et_2O)_2]$: $MoCl_5$ (1.20 g, 4.39 mmol) and coarse tin powder (1.04 g, 8.76 mmol) were suspended in 30 mL of Et_2O at room temperature. The mixture was then stirred for 30 min. to form an orange solution and orange solid. The latter was separated mechanically from the excess tin taking advantage of the large difference in density between the two solids. Under gentle stirring with a magnetic stirring bar, the metallic tin remained at the bottom of the flask and the supernatant suspension of the $[MoCl_4(Et_2O)_2]$ product was transferred into a new flask through a medium size (G15) cannula. The product was then collected by filtration, washed with Et_2O (5 × 5 mL) and dried under vacuum. Yield: 1.36 g, 80%. The compound has a marked tendency to lose diethyl ether (see Results and Discussion) and samples dried without special precautions systematically gave low C,H analyses; a freshly prepared sample which was dried at −20 °C gave a correct analysis ($C_8H_{20}Cl_4MoO_2$: calcd. C 24.89, H 5.22; found C 25.31, H 5.23). The IR spectrum (Nujol mull) is identical with that reported in the literature.[11] ^1H NMR (C_6D_6, 25 °C): δ = 1.1 (broad, $w_{1/2}$ = 23 Hz, CH_3) ca. 3.5 ppm (broad, $w_{1/2}$ = 200 Hz, CH_2). μ_{eff} = 2.33 μ_B (diamagnetic correction: $\chi = -196.22 \cdot 10^{-6}$ c.g.s. units).

Synthesis of $MoCl_4$: In a typical reaction, orange $[MoCl_4(Et_2O)_2]$ was placed in a dry, air-free Schlenk tube and slowly heated under vacuum in an oil bath. First darkening occurred at about 55 °C. At 80 °C the powder was totally black. The yield of $MoCl_4$ produced is quantitative. Two experiments, carried out at 120° for 5 h and at 130° for 2 h gave materials with the same properties. Elemental analysis of the black material confirmed the absence of C and H. μ_{eff} = 1.60 μ_B and 1.61 μ_B, respectively (diamagnetic correction: $\chi = -80.4 \cdot 10^{-6}$ c.g.s. units). The product dissolves completely in ethanol. When the reaction temperature is raised above 140 °C, sublimation of $MoCl_5$ is observed and the resulting reddish solid residue ($MoCl_3$) is no longer soluble in ethanol. This decomposition process is also observed for isolated $MoCl_4$ in vacuum and under an argon atmosphere in a sealed ampoule.

Synthesis of $[MoCl_4(THF)_2]$. (a) From Isolated $[MoCl_4(Et_2O)_2]$: Compound $[MoCl_4(Et_2O)_2]$ (1.26 g, ca. 3.26 mmol) was suspended in 15 mL of THF. The mixture was then stirred for 3 h at room temperature to form an orange-yellow solid. The supernatant liquid was decanted off and the solid was washed with THF (10 mL), then ether (10 mL), and finally dried under vacuum. Yield: 0.99 g (79%). − $C_8H_{16}Cl_4MoO_2$ (381.96): calcd. C 25.16, H 4.22; found C 24.99, H 4.76. − ^1H NMR ($CDCl_3$, 25 °C): δ = 12.5 ($w_{1/2}$ = 12 Hz), −32.8 ($w_{1/2}$ = 15 Hz) (intensity ratio: 1.1).

(b) From $MoCl_5$: $MoCl_5$ (1.156 g, 4.23 mmol) and coarse tin powder (1 g, 8.42 mmol) were suspended in 20 mL of Et_2O at room temperature. The mixture was stirred for 30 min. to form $[MoCl_4(Et_2O)_2]$. Then, the excess metallic tin was eliminated by transferring the supernatant suspension of $[MoCl_4(Et_2O)_2]$ into a new flask through a medium-sized cannula. The solid was washed with Et_2O (3 × 10 mL) and 20 mL of THF was subsequently added. The mixture was then stirred for 3 h at room temperature to form an orange-yellow solid. The supernatant liquid was then decanted off and the residue was washed with 10 mL of THF and then with 10 mL of ether, and finally dried under vacuum. Yield: 1.438 g, 89%. The color and ^1H NMR spectrum of this material are identical with the analyzed product obtained as described in the previous section.

(c) From $MoCl_4$: Black $MoCl_4$ (553 mg, 2.33 mmol) was suspended in 5 mL of pentane. After addition of 5 mL THF on top of the pentane layer the mixture was allowed to stir for two minutes. The reaction occurred very rapidly to produce an orange precipitate. The colorless supernatant liquid was removed by cannula and the residue was dried in vacuo leaving 890 mg of $[MoCl_4(THF)_2]$ (quantitative yield).

Synthesis of $[MoCl_3(THF)_3]$: $MoCl_5$ (3.18 g, 11.64 mmol) and coarse tin powder (2.77 g, 23.33 mmol) were suspended in 30 mL of Et_2O. The mixture was then stirred for 30 min. at room temperature to form an orange solution and orange solid. The supernatant liquid was decanted off and 30 mL of THF was added. The mixture was then stirred for 3 h at room temperature. The pale orange-brown crystalline product $[MoCl_3(THF)_3]$ was separated from excess tin as described above for the synthesis of $[MoCl_4(Et_2O)_2]$. The product was then washed with Et_2O (2 × 15 mL) and dried under vacuum. Yield: 3.99 g, 82%. − $C_{12}H_{24}Cl_3MoO_3$ (418.62): calcd. C 34.43, H 5.78; found C 34.04, H 5.51. The ^1H NMR properties of this material correspond with those previously described for $[MoCl_3(THF)_3]$.[34]

Synthesis of $[MoCl_4(PMe_3)_3]$: A THF solution of PMe_3 (1 M, 8 mL, 8 mmol) was slowly added to a magnetically stirred suspension of $[MoCl_4(Et_2O)_2]$ (0.96 g, ca. 2.5 mmol) in THF (10 mL). The orange suspension rapidly transformed into a deep violet suspension. The mixture was stirred for 4 h at room temperature, then the supernatant liquid was decanted off and the solid was washed with THF (2 × 5 mL) and dried under vacuum. Yield: 0.78 g, 67%. − $C_9H_{27}Cl_4MoP_3$ (465.99): calcd. C 23.20, H 5.84; found C 23.04, H 5.62. The ^1H NMR spectrum [broad band at δ = −17 ($w_{1/2}$ = 130 Hz) in $CDCl_3$ at 25 °C] corresponds to that reported in the literature.[25]

Synthesis of $[Mo(O\mathit{t}Bu)_4]$. (a) From $MoCl_4$: THF (15 mL) was added to 330 mg (1.39 mmol) of black $MoCl_4$ causing a slight warm-

ing and precipitation of the orange THF adduct. The suspension was cooled in an ice bath and a 1 M LiO*t*Bu solution in THF/hexane (5.55 mL, 5.55 mmol) was added with a syringe. The reaction mixture was stirred for one hour at 0 °C, then slowly warmed to room temperature and stirred overnight to complete the reaction. The THF was removed in vacuo from the dark brown solution. The brown solid was extracted with 20 mL of pentane, then with 10 mL of CH_2Cl_2. After filtration, the combined extracts were evaporated in vacuo to dryness, leaving crude $[Mo(OtBu)_4]$ as a brown solid (540 mg, quantitative yield). The product can be recrystallized in low yields (ca. 25%) from cold pentane. – $C_{16}H_{36}MoO_4$ (388.40): calcd. C 49.48, H 9.34; found C 49.58, H 9.29. – ^{1}H NMR: δ =1.55 (s) in C_6D_6, 1.66 (s) in $C_6D_5CD_3$ and 1.12 (s) in $[D_6]$acetone. All these solutions are EPR-silent, but a strong signal rapidly develops upon exposure to air. $\mu_{eff} = 0.72\ \mu_B$ (diamagnetic correction: $\chi = -219.92 \cdot 10^{-6}$ c.g.s. units).

(b) From $[MoCl_4(Et_2O)_2]$: $[MoCl_4(Et_2O)_2]$ was obtained in situ from $MoCl_5$ (3.06 g, 11.2 mmol) and tin as described above. After separation from the excess tin and the ether, it was suspended in 40 mL of THF and the suspension was cooled in an ice bath. After addition of LiO*t*Bu (40 mL of a 1 M solution in THF/hexane, 40 mmol) the reaction mixture was stirred at 0 °C for 2 h, then slowly warmed to room temperature and stirred overnight to complete the reaction. Removal of the solvent in vacuo left a brown residue which was extracted with 35 mL of CH_2Cl_2 and filtered. After total removal of the solvent in vacuo, a gummy brown-black residue was left which became an almost black powdery solid over a period of two days. The yield of crude $[Mo(OtBu)_4]$ was 3.517 g (81% from $MoCl_5$).

Dinuclear Cobalt(II) Complexes of an Acyclic Phenol-Based Dinucleating Ligand with Four Methoxyethyl Chelating Arms − First Magnetic Analyses in an Axially Distorted Octahedral Field

Hiroshi Sakiyama,* Rie Ito, Hitoshi Kumagai, Katsuya Inoue, Masatomi Sakamoto, Yuzo Nishida, and Mikio Yamasaki

Eur. J. Inorg. Chem. **2001**, 2027−2032

In the paper, we used the effective spin s when the magnetic exchange was considered, thus we should have used (5/3)$\boldsymbol{s}$ instead of $\boldsymbol{S}$. At this stage the Hamiltonian will be $\boldsymbol{H} = -(3/2)\kappa\ \lambda\ \boldsymbol{L}\cdot\boldsymbol{S} + \beta[-(3/2)\kappa\ \boldsymbol{L} + g_e\boldsymbol{S}]\cdot\mathrm{H} - (25/9)\ J\ \boldsymbol{s}_1\cdot\boldsymbol{s}_2$, and the magnetic susceptibility equation will be as follows:

$$\chi_A = \frac{\chi_z + 2\chi_x}{3}$$

$$\chi_{z(x)} = N\frac{\sum_{n=\pm1}\left(\frac{E^{(1)}_{z(x),n}}{kT}\right)^2 - 2E^{(2)}_{z(x),n}\exp\left[\frac{-E^{(0)}_n + \frac{25J}{36}}{kT}\right] + \sum_{n\neq\pm1}\left(\frac{E^{(1)}_{z(x),n}}{kT}\right)^2 - 2E^{(2)}_{z(x),n}\exp\left[\frac{-E^{(0)}_n}{kT}\right]}{\frac{1}{4}\sum_{n=\pm1}\exp\left[\frac{-E^{(0)}_n - \frac{75J}{36}}{kT}\right] + \frac{3}{4}\sum_{n=\pm1}\exp\left[\frac{-E^{(0)}_n + \frac{25J}{36}}{kT}\right] + \sum_{n\neq\pm1}\exp\left[\frac{-E^{(0)}_n}{kT}\right]}$$

Magnetic parameters were calculated based on the equation set, and Table 3 should be changed as shown below.

Table 3. Magnetic data for complexes **1** and **2**

Complex	κ	λ/cm^{-1}	Δ/cm^{-1}	J/cm^{-1}	g_z	g_x	D/cm^{-1}	$R(\chi_A)/10^{-3}$	$R(\mu_{eff})/10^{-4}$
1	0.98	−134	749	−0.55	2.18	4.99	120	0.12	0.89

On the Mechanism of the Hydroxycarbonylation of Styrene with Palladium Systems

Inmaculada del Río,[a] Carmen Claver,*[a] and Piet W. N. M. van Leeuwen[b]

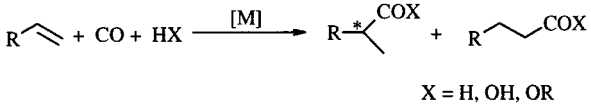
Keywords: Carbonylation / Palladium / Reaction mechanisms / Regioselective catalysis / P ligands

We present a review concerning the mechanism involved in the hydroxycarbonylation of styrene. We discuss the intermediates proposed in the literature, the effect of the acidic medium, the reactivity and kinetics, as well as the results of theoretical calculations on hydroxycarbonylation and related reactions. We have performed an in situ high-pressure NMR study to obtain more insight into the mechanisms that control the regioselectivity and have assessed how this is affected by the phosphorus ligand and the catalyst precursor. We observed palladium hydride and palladium acyl species and we suggest a catalytic cycle involving palladium hydride, palladium alkyl, and palladium acyl intermediates.

Introduction

Transition-metal-catalysed transformations of alkenes play a major role in synthesizing products of industrial importance. The catalytic routes are a safer and more selective alternative to conventional methods involving stoichiometric organic syntheses that lead to considerable amounts of by-products.[1]

Particularly useful are reaction sequences in which an alkene is inserted into a metal hydride and then CO is inserted to form new C−C bonds. Some of the most successful reactions, such as hydroformylation, alkoxycarbonylation, and hydroxycarbonylation, belong to this class of reaction (Scheme 1). In general, carbonylations are important processes since they lead to the production of oxygenated products from petrochemical hydrocarbons.



Scheme 1. General scheme for catalysed carbonylation reactions

Among the carbonylation reactions, hydroformylation using Co^{I} or Rh^{I} is now the largest industrial application of homogeneous catalysis by transition metal complexes for producing aldehydes and alcohols.[2,3] In hydroformylation chemistry, much progress has been made in recent years in

Inmaculada del Río (left) received her Ph.D. in 2000 from the University Rovira i Virgili working on mechanistic aspects of hydroformylation and hydroxycarbonylation reactions.

Carmen Claver (right) is Professor of Inorganic Chemistry at the University Rovira i Virgili in Tarragona (Spain), a position she has held since 1991. She received her Ph.D. in 1978 from the University of Zaragoza (Spain) working in the field of organometallic chemistry with Prof. Luis A. Oro. Her present research is focused on fundamental aspects of homogeneous catalysis with transition metals, especially in asymmetric catalysis.

Piet W. N. M. van Leeuwen is Professor of Homogeneous Catalysis at the University of Amsterdam, a position he has held since 1989. He has spent much of his career at Shell Research in Amsterdam working in the area of homogeneous catalysis and organometallic chemistry. His present research is aimed at the development of novel transition metal homogeneous catalysts, using the full range of available tools and techniques.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

controlling the regioselectivity and understanding the mechanism of the process.[4]

Palladium systems have been used as catalysts in many carbonylation reactions, and their use in hydroxycarbonylation and alkoxycarbonylation reactions has been widely studied.[5] They have also been used as catalysts in many other carbonyl-based processes of industrial interest. The hydroxycarbonylation of butadiene, the dicarboxylation of alkenes, the carbonylation of alkenes, the carbonylation of benzyl and aryl halides, and oxidative carbonylations have recently been reviewed.[6]

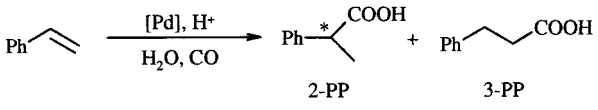
In the palladium-catalysed reactions, products such as alcohols, aldehydes, ketones, and oligoketones can be prepared by modifying the palladium complexes with different phosphorus ligands. The selective formation of ketones by the carbonylation of higher alkenes using Pd^{II} complexes has been reported.[7,8]

A major breakthrough regarding the activity of this type of catalyst was the discovery that palladium complexes modified with *cis*-diphosphanes can be used in the alternating copolymerization of ethene or propene with carbon monoxide. This is another Pd^{II}-catalysed process that has attracted the interest of industry in the last two decades.[9]

In hydroxycarbonylation, alkoxycarbonylation, and the amidocarbonylation of alkenes, the use of a palladium carbonylation catalyst to synthesize propionic and other acids has been widely studied. The catalysts were mainly designed for the carbonylation of alkenes in the presence of alcohols in order to prepare carboxylic esters, but were also found to work well in the synthesis of carboxylic acids and anhydrides.[10]

It seems appropriate to distinguish between aliphatic alkenes and functionalized vinylic substrates, including vinyl aromatics. The carbonylation of vinyl aromatics is important for the synthesis of 2-phenylpropionic acids/esters, a class of non-steroidal anti-inflammatory drugs.[11] Also, the linear products, i.e. 3-phenylpropionic acid and its esters, have found application as speciality chemicals. In view of the synthetic importance of the preparation of phenylpropionic acids, styrene was selected as a model substrate for use in carbonylation studies.

The palladium-catalysed hydroxycarbonylation of alkenes has attracted considerable interest in recent years as a means of obtaining carboxylic acids. In general, in acidic media, palladium salts in the presence of mono- or bidentate phosphanes afford mixtures of linear and branched acids (Scheme 2).[6]

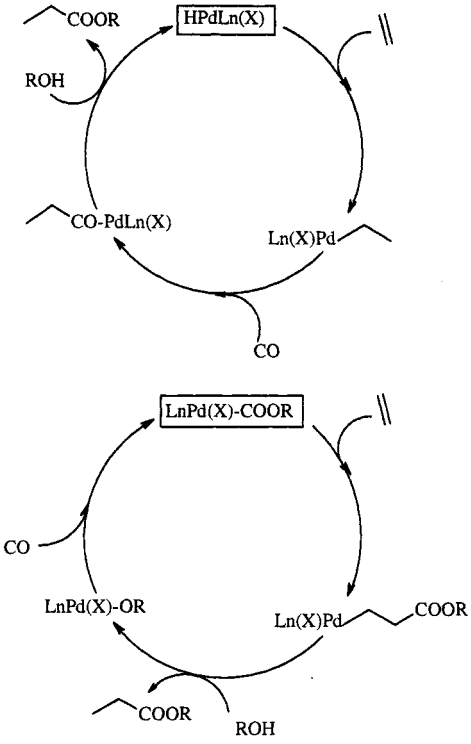


Scheme 2. Hydroxycarbonylation of styrene with palladium salts in acidic medium

This reaction has a number of associated problems, the most important of which is that metallic Pd^0 forms if the palladium species is not sufficiently well stabilized. Secondly, it is difficult to perform the reaction in an enantioselective fashion since the use of *cis*-chelate ligands provides linear acids. Also, because of the absence of a suitable nuclear spin on palladium, the characterization of its phosphane complexes in situ is more difficult than that of the corresponding rhodium or platinum complexes.

Although reports on the hydroxycarbonylation reaction with palladium systems have been published and several aspects of the mechanism have been discussed in the last few years, a review summarising the results and findings concerning the mechanism of this reaction is still lacking.

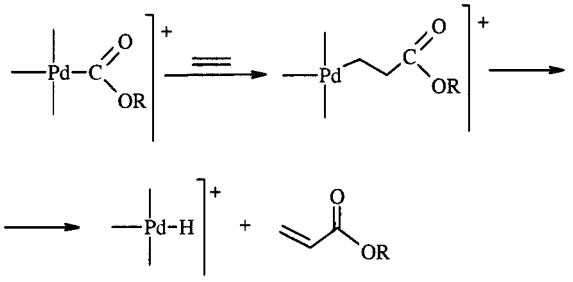
The related alkoxycarbonylation reaction has been studied in much greater detail[12–16] and two mechanisms have been suggested (Scheme 3).[17–21] One starts the cycle with a hydrido-metal complex.[19] In this cycle, an alkene inserts into a Pd–H bond, and then migratory insertion of CO into an alkyl–metal bond produces an acyl–metal complex. Alcoholysis of the acyl–metal species regenerates the palladium hydride and yields the ester. In the second mechanism, the crucial intermediate is an alkoxycarbonyl–metal complex.[20] Here, the insertion of the alkene into a Pd–carbon bond of the alkoxycarbonylmetal species is followed by alcoholysis to produce the ester and the alkoxymetal complex. The insertion of CO into the alkoxymetal species regenerates the alkoxycarbonylmetal complex.



Scheme 3. Mechanisms proposed for the alkoxycarbonylation of alkenes

Most researchers currently agree that the hydrido mechanism is more common than the alkoxycarbonyl path in the alkoxycarbonylation of alkenes with palladium systems. However, alkoxycarbonyl complexes may be plausible intermediates in carbonylation reactions of alcohols or in the

formation of succinates and polyketone diesters with metals such as Co, Rh, or Pd.[7] The unifying mechanistic theme of these diverse reactions may be the generation of an alkoxycarbonylmetal intermediate, M−COOR.[20] Moreover, palladium alkoxycarbonyl complexes can produce the palladium hydride species in situ after insertion of the alkene and β-elimination of the unsaturated ester (Scheme 4), as was shown by Otsuka.[22]



Scheme 4. Formation of Pd-hydride species from Pd-methoxycarbonyl species

The regioselectivity in the hydroxycarbonylation of styrene with palladium precursor systems under appropriate reaction conditions was controlled by modifying the auxiliary phosphorus ligand.[23] When monophosphanes are used as ligands, the major product is 2-phenylpropanoic acid with practically total regioselectivity. In contrast, the use of diphosphanes as auxiliary ligands switches the regioselectivity in favour of the linear product. Moreover, the activity and regioselectivity in the hydroxycarbonylation of styrene are both sensitive to the nature of the counteranion of the acid. The regioselectivities obtained for mono- and diphosphanes are generally strongly dependent on the nature of the anion.[24] In spite of several studies of the regioselectivity of the reaction, a satisfactory explanation for the regioselectivity is not yet available.

The aim of this Microreview is to provide a systematic overview of the mechanistic aspects and kinetic studies that have been published, as well as to provide some insight into the regioselectivity by means of a mechanistic study. We have performed in situ high-pressure NMR studies to obtain information about the resting state of the catalyst depending on the reaction conditions, the catalyst precursor, and the phosphorus ligands. Finally, we have compared the results of these studies with those of the catalytic experiments in order to arrive at a proposal for a catalytic cycle.

Reactivity and Characterization of the Palladium Species Involved in the Hydroxycarbonylation Reaction

The reactivity of Pd−H species towards the coordination and insertion of the substrate, as well as the subsequent coordination and insertion of carbon monoxide to form the palladium acyl species, have been studied for stoichiometric as well as catalytic alkoxycarbonylation reactions. Not all of these experiments, however, have been performed under the same conditions as the hydroxycarbonylation reaction; they are nevertheless useful for discussing the hydroxycarbonylation mechanism. Similarly, studies of the reactivity of Pd^0 species towards CO or phosphanes or acids are of interest to us. We will start the discussion with Pd^0 complexes.

Pd^0 carbonyl phosphane complexes are believed to be intermediates in the palladium-catalysed hydroxycarbonylation of alkenes, although they do not necessarily participate in the catalytic cycle (vide infra). $[Pd(CO)(PPh_3)_3]$ was isolated from the reaction mixture that arose from the hydroxycarbonylation of cyclohexene with $[PdCl_2(PPh_3)_2]$ as the precursor. This complex was also prepared by the direct reaction of $[Pd(PPh_3)_4]$ with CO in benzene. For the $[Pd(CO)(PPh_3)_3]$ complex, ^{31}P and ^{13}C NMR spectra suggest a rapid dissociation of PPh_3 at room temperature and a tetrahedral structure in solution at −70 °C.[25] $[Pd(CO)(PPh_3)_3]$ proved to be inactive in the hydroxycarbonylation of alkenes, like $[Pd(PPh_3)_4]$. However, the addition of traces of hydrochloric acid promoted the formation, under carbon monoxide pressure, of a catalytically active system.[26]

The Pd^0 complexes can be produced from mixtures of Pd^{II} complexes with phosphanes. Thus, stable Pd^0 complexes were generated in situ from the cationic Pd^{II} complex $[Pd(PPh_3)_2](BF_4)_2$ when water and triphenylphosphane were present in solution. Triphenylphosphane was able to reduce the Pd^{II} metal centre to Pd^0, and was itself oxidized to triphenylphosphane oxide. This reduction was performed on a Pd^{II} complex in which the palladium ion was most likely ligated by a hydroxy group.[27]

The reduction of Pd^{II} to Pd^0 has also been investigated in the presence of both monodentate PPh_3 and bidentate dppp [1,3-bis(diphenylphosphanyl)propane]. ^{31}P NMR measurements showed that triphenylphosphane can reduce $Pd(OAc)_2$ to Pd^0 in toluene. Bidentate dppp is mainly responsible for the reduction in DMF, which results in dppp hemioxide and dppp dioxide. Both mono- and bidentate coordination of dppp in intermediate species were proposed on the basis of in situ NMR studies.[28]

The key intermediates, namely palladium hydride, palladium alkyl, and palladium acyl, were detected and characterized by ^1H, ^{13}C, and ^{31}P NMR spectroscopy for the homogeneous water-gas shift reaction and for the carbonylation of ethene to diethyl ketone catalysed by the $Pd(OAc)_2$/PPh_3/CF_3COOH/H_2O system. The key palladium intermediate in both catalytic reactions was the hydride complex $[Pd(H)(PPh_3)_3]^+$. This cationic palladium hydride complex $[Pd(H)(PPh_3)_3]^+$ was formed by the oxidative addition of H^+ when the Pd^0 phosphane complex $[Pd(PPh_3)_4]$ was dissolved in an aqueous CF_3COOH solution. When the experiments were carried out starting with a Pd^{II} complex, it was shown that this complex was first reduced by CO (Scheme 5), giving CO_2 in the rate-determining step of the water-gas shift reaction.[8] Treating a solution of the hydride complex with CO at 25 °C resulted in a rapid rearrangement of a PdH^+ (a Pd^{II} species) and a Pd^0 species into the cationic dinuclear complex $[Pd_2(PPh_3)_4(\mu\text{-}H)(\mu\text{-}CO)]^+$.

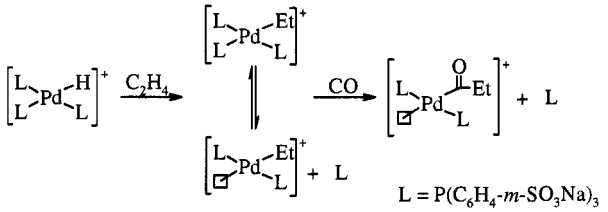
When a solution of the hydride complex was treated with ethene at −25 °C, a palladium alkyl complex formulated as $[Pd(Et)(PPh_3)_2]^+$ was formed. Similarly, exposure of a solution of the hydride complex to a CO/C_2H_4 (3:1) gas mixture at 25 °C led to a rapid, quantitative formation of the palladium propionyl complex *trans*-$[Pd\{C(O)Et\}(PPh_3)_2]^+$.[8] The cationic hydride, ethyl, and propionyl palladium complexes are relatively stable as a result of the polar solvent and the non-coordinating anion.

$$PdL_2X_2 + CO + H_2O \xrightarrow[\text{slow}]{-CO_2,\ -HX} PdL_n(H)X$$

$$PdL_n(H)X \underset{\text{fast}}{\rightleftharpoons} L_4Pd^0 + HX$$

Scheme 5. Formation of palladium hydride species in the presence of CO and water

A similar involvement of palladium hydride, palladium alkyl, and palladium acyl complexes as intermediates in the catalytic cycle of the palladium-catalysed hydroxycarbonylation of alkenes was demonstrated for the analogous reaction in the aqueous phase. When a solution of $Pd(OAc)_2$ and tppts (tppts = trisulfonated triphenylphosphane) in aqueous trifluoroacetic acid was placed under a CO atmosphere, the cationic hydride $[Pd(H)(tppts)_3]^+$ was formed by reduction of the Pd^{II} complex with CO and H_2O to $[Pd(tppts)_3]$ and subsequent protonation in the acidic medium. The reaction of the hydride complex with ethene produced an equilibrium mixture of two new compounds, $[Pd(Et)(tppts)_3]^+$ and $[Pd(Et)(tppts)_2]^+$. The fourth coordination site in the latter is presumably occupied by a solvent molecule. The mixture of the palladium alkyl complexes reacted readily with CO to afford *trans*-$[Pd\{C(O)Et\}(tppts)_2]^+$ (Scheme 6).[29] Once again, the stability of the cationic intermediates may be attributed to the ionic medium and the non-coordinating nature of the anion, which is even enhanced by the aqueous solvent. The authors showed that in the stoichiometric reaction the hydrolysis of the acyl species giving propionic acid is the slowest step in the sequence.



Scheme 6. The stepwise aqueous-phase hydroxycarbonylation of ethene

The intermediates involved in the palladium-catalysed methoxycarbonylation of ethene have also been characterized. The complex [Pd(L−L)(dba)] [L−L = 1,2-$(CH_2PtBu_2)_2C_6H_4$] reacts with HBF_4 or CF_3SO_3H in MeOH to produce a new compound that can be formulated as either the neutral complex [Pd(L−L)HX] or the solvated cation [Pd(L−L)H(MeOH)]X. This hydride complex reacts immediately with ethene at room temperature to form the cationic species [Pd(L−L)Et(MeOH)]X. On adding one equivalent of CO to the alkyl complex, the species [Pd(L−L){C(O)Et}(MeOH)]X is formed. Subsequent addition of a trace of MeOH to the solution leads to an immediate reaction regenerating the palladium hydride complex and forming EtCOOMe. It should be noted that the palladium hydride complex is stable even in the presence of oxidants (benzoquinone or oxygen) under these conditions. There was no evidence for the formation of any methoxycarbonyl complex.[30] For other systems, the formation of methoxycarbonyl palladium species is a well-documented process.[31,32] It should be noted, however, that the formation of methoxycarbonyl complexes under these conditions requires anhydrous conditions; in the presence of traces of water a hydroxycarbonyl-palladium species form, which rapidly loses carbon dioxide to give palladium hydride.[33] Thus, in the presence of water, hydride species will invariably be formed, which will initiate the catalytic cycle. This side reaction was efficiently suppressed by the addition of trimethyl orthoformate, which, under acidic conditions, transforms water into methanol.[34]

In the case of styrene, the mechanism of the methoxycarbonylation using $[Pd(OTs)_2(PPh_3)_2]$ formed in situ from $Pd(OAc)_2$, PPh_3, and TsOH in methanol has been investigated by isolating and characterising the intermediates. From the reaction mixtures, palladium hydridocarbonyl and palladium acyl complexes were isolated, and, accordingly, a palladium hydride mechanism has been proposed. Following exposure of the catalyst precursor system $Pd(OAc)_2$/$4PPh_3$/10HOTs to CO at 75 °C for 30 min., the complex $[Pd(H)CO(PPh_3)_2](OTs)$ was characterized. When the methoxycarbonylation was performed with $PdCl_2$ as the catalyst precursor, the acyl complex *trans*-$[PdCl(COCH_2CH_2Ph)(PPh_3)_2]$ was isolated.[35] The observation and isolation of the hydride, alkyl, and acetyl palladium species is, of course, strongly suggestive that they form part of the productive catalytic cycle; nonetheless, kinetic measurements are desirable to obtain further proof.

Palladium Hydride Complexes

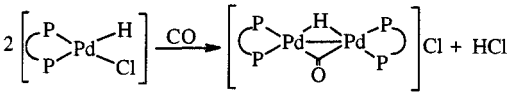
Palladium hydrides are of special interest due to their exceptional relevance to catalysis. Indeed, several hydrido complexes of palladium have been proposed as key intermediates in a number of palladium-catalysed reactions.[36−38] Also, the study of palladium hydride species has been the subject of some interesting reports and reviews.[39,40] However, the reactivity of palladium hydrido complexes has still not been adequately explored. Despite the exceptionally high affinity of palladium metal for hydrogen,[41] soluble molecular hydrides of palladium are rather unstable and in many cases they cannot be isolated but only generated and characterized in solution at low temperature. The stability of analogous hydrides increases dramatically on going from palladium to platinum; for instance, $[Pt(H)Cl(PPh_3)_2]$ is stable to air and moisture and has been fully characterized.[42]

Over the last few years, the chemistry of palladium hydrides has developed significantly and a number of neutral and cationic hydrido complexes of palladium have been prepared and characterized by a variety of techniques. In fact, all known general methods for synthesising transition metal hydrides can be used to prepare palladium hydride complexes.[40]

Neutral palladium hydride complexes of the type $[PdHCl(PPh_3)_2]$ can be synthesized by oxidative addition of strong acids, as in the oxidative addition of HCl to Pd^0 complexes such as $[Pd(CO)(PPh_3)_3]$ or $[Pd(PPh_3)_4]$.[43] Related hydride complexes have been synthesized using other monophosphanes such as PEt_3,[44,45] PCy_3,[43] and PBu_3.[46] The nature of the phosphane is important, since the more basic phosphanes stabilize the product of the oxidative addition, i.e. the hydride complex.

The cationic hydrido complexes of palladium can be prepared by several methods, for example by replacing an anionic ligand in neutral palladium hydrides with a neutral ligand,[47] or by the protonation of zero-valent palladium complexes.[45,48] There have been reports of the formation of palladium cationic hydrides with H_2O, CH_3CN, or other coordinated solvents.[49−51]

With diphosphane ligands, the hydride complexes of palladium *cis*-[PdHCl(P−P)] are apparently highly unstable and numerous attempts to synthesize such species have failed; instead, cationic dinuclear complexes of palladium $[(P-P)_2Pd_2(\mu\text{-}H)(\mu\text{-}CO)]^+$ are readily formed during carbonylation reactions (vide supra and Scheme 7). These dinuclear complexes have been isolated and characterized, and their reactivity towards alkenes under CO atmosphere has been studied. Apparently, it is important to stabilize the systems with CO and to create a bridging instead of a terminal hydride *trans* to the phosphane.[52−54]



Scheme 7. Formation of the dinuclear $[(P-P)_2Pd_2(\mu\text{-}H)(\mu\text{-}CO)]^+$ in the reaction of [(P−P)PdHCl] under a CO atmosphere

The fact that palladium hydride species are stabilized under CO pressure can favour the catalysis through the intermediacy of a palladium hydride species. Moreover, it is interesting that in the alkoxycarbonylation of alkenes catalysed by a $[PdCl_2(PPh_3)_2]/PPh_3$ system, the catalytic activity is higher in the presence of molecular hydrogen. This is most likely attributable to the formation of a Pd−H intermediate through the heterolytic splitting of H_2. This represents an alternative pathway for the formation of the initial hydride species. This route does not require the reduction of Pd^{II} prior to oxidative addition of H^+. The occurrence of heterolytic splitting of hydrogen rather than oxidative addition is further substantiated by the fact that no aldehyde has been detected in the reaction products.[8,55−57] The latter reaction would require oxidative addition of dihydrogen to a palladium(II) acyl species.

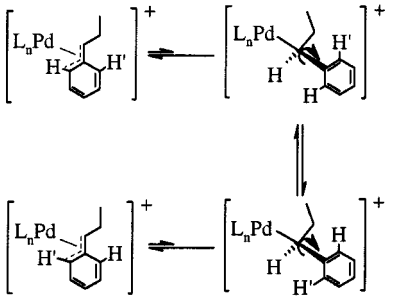
Palladium Alkyl Complexes

Palladium alkyl derivatives have also been synthesized and characterized, especially the benzyl derivatives, which are stabilized as η^3-benzylic species. Since one of the most interesting palladium−styrene intermediates is the palladium η^3-benzylic species, it is useful to discuss species of this type.

The benzyl palladium complexes *trans*-$[Pd(CH_2Ph)Cl(PPh_3)_2]$ have been synthesized by the oxidative addition of benzyl chloride to Pd^0 complexes such as $[Pd(PPh_3)_4]$.[58] However, these complexes proved to be unstable and the dinuclear complex $[Pd_2(CH_2Ph)_2(PPh_3)_2(\mu\text{-}Cl)_2]$ was formed.[59] Other palladium alkyl derivatives have been obtained by adding halogenated hydrocarbons to a suspension of $[Pd(PPh_3)_4]$.[60,61]

The structures of the arylpalladium complexes of the type *trans*-$[Pd(Ph)X(PPh_3)_2]$ (X = F, Cl, Br, I) were studied by single-crystal X-ray diffraction analysis and the relative affinities of the halide anions for the metal centre were studied using ^{31}P NMR spectroscopy.[62]

Palladium η^3-benzyl complexes have also been prepared by the insertion of styrene into the Pd−Me bond of the solvated cation [PdMe(L−L)S]. This η^3-coordination of the benzyl ligand has been elucidated by X-ray structure determination and NMR spectroscopy. NMR studies showed that the palladium η^3-benzyl complexes undergo two dynamic processes in solution, namely η^3-η^1 coordination of the benzyl group, and ligand exchange of coordination sites.[63] Kinetic and isotopic labelling experiments have been employed to determine the mechanism of this benzyl exchange reaction (Scheme 8).[64] These complexes are highly prone to β-hydride elimination.[33]



Scheme 8. An η^3-η^1-η^3 rearrangement mechanism that accounts for the observed exchange of the *ortho* hydrogens in $[(phen)Pd\{\eta^3\text{-}CH(CH_2CH_3)Ph\}]^+$

Palladium Acyl Complexes

Since the 1970s, a key question has been the involvement of either acylpalladium or alkoxycarbonylpalladium species in the reaction cycle. In the 1970s, supporting evidence for both mechanisms was put forward.[18,20] A comparative study of the reactivity and catalytic activity in the alkoxycarbonylation of alkenes using the isolated palladium acyl complex $[PdCl(COR)(PPh_3)_2]$ (R = Et, *n*-Hex) (a key inter-

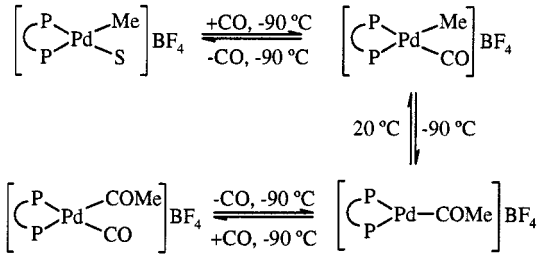
mediate in the palladium hydride mechanism) and the palladium methoxycarbonyl complex [PdCl(COOMe)(PPh_3)$_2$] (an active species in the alkoxycarbonyl mechanism) was carried out by Cavinato and Toniolo.[19] With regard to the reactivity, the palladium acyl complex was found to react with an alkanol R′OH in the presence of added PPh_3 to yield the ester RCOOR′ and a mixture of [$PdCl_2(PPh_3)_2$] and [Pd(PPh_3)$_{3,4}$]. This was considered to be the slowest step of the hydride mechanism. When the isolated methoxycarbonyl complex [PdCl(COOMe)(PPh_3)$_2$] was treated with 1-hexene in methanol, under nitrogen and in the absence of carbon monoxide, the ester was not formed and the starting complex was recovered almost quantitatively, thus confirming that the step presumed to be the slowest in this cycle was indeed very slow. As regards the catalytic activity of these complexes, use of the acyl palladium complex as the catalyst precursor in the alkoxycarbonylation of ethene yielded almost stoichiometric amounts of the ester. When [PdCl(COOMe)(PPh_3)$_2$] was used as the catalyst precursor in the alkoxycarbonylation of 1-hexene in methanol, in the absence of added PPh_3 and in the presence of NEt_3 or carboxylate anions (to favour the formation of the methoxycarbonyl complex), no catalytic activity was seen and the precursor was recovered in the form of Pd^0-carbonylphosphane complexes. Only after prolonged reaction times was some of the methoxycarbonyl complex observed.[19]

Other acyl species of palladium have been synthesized and characterized. White crystals of *trans*-[Pd(CO*n*Pr)Cl(PPh_3)$_2$] were isolated in 70% yield after allowing the solution obtained following the alkoxycarbonylation of propene to stand for several hours at room temperature. This complex was found to be active in the alkoxycarbonylation of propene.[65] In situ IR spectroscopic studies were performed during the hydroxycarbonylation of ethene with [$PdCl_2(PPh_3)_2$], by which the intermediate species [Pd(COEt)Cl(PPh_3)$_2$] was observed. A mechanism involving Pd−H active species has been proposed.[66]

In favour of the participation of alkoxycarbonylpalladium species, the following two observations may be mentioned. The cationic complexes [(P−P)PdC(O)OCH_3(PPh_3)]$^+$ (P−P = dppe, dppp, dppb) undergo slow insertion of reactive alkenes such as norbornadiene.[33] The formation of diester[67][68] and diester end-group polyketones indicates that, under anhydrous conditions, cationic species may allow the insertion of alkenes into alkoxycarbonylpalladium species.[69]

As regards diphosphanes, the insertion of CO was studied for both neutral palladium chlorides and ionic triflate complexes containing the bidentate phosphanes dppe, dppp, dppb, and dppf.[70] Half-life times for the neutral complexes were between 18 and 36 min at 235 K and 25 bar of CO and the rates decreased in the order dppb > dppp > dppf >> dppe (170 min at 305 K). The ionic complexes were found to react with rates one or two orders of magnitude higher, even though acetonitrile was used as the solvent. Thus, carbon monoxide insertion should indeed be a fast step in the hydroxycarbonylation cycle.

High-pressure NMR spectroscopy was also used to follow the synthesis of the chiral ionic square-planar [Pd(Me)CO(BDPP)]BF_4 compound [BDPP = (2*S*,4*S*)-2,4-bis(diphenylphosphanyl)pentane], an intermediate in CO insertion into the Pd−Me bond. This compound was formed in situ by the reaction of the solvated [Pd(Me)S(BDPP)]BF_4 with ^{13}CO and in a high-pressure NMR tube. Concomitant with the decomposition of [Pd(Me)CO(BDPP)]BF_4, the complex [Pd(COMe)CO(BDPP)]BF_4 was formed and CO insertion was followed by the coordination of another CO ligand. This reaction was found to be completely reversible at room temperature. Several experiments were carried out to investigate whether the methyl(carbonyl) complex was also an intermediate in the formation of the methoxycarbonyl compound [Pd(Me)(COOMe)(BDPP)], but this compound could not be obtained in this way (Scheme 9).[71] [Pd(Me)(COOMe)(BDPP)] has been reported previously as the product of insertion of CO into [Pd(Me)(OMe)(BDPP)] at low temperatures.[72] Low temperatures are imperative as otherwise β-hydride elimination would take place. Interestingly, insertion takes place in the Pd−O bond rather than the Pd−C bond, as has been reported previously for platinum.[73] There are no indications that this reaction is relevant to alkoxycarbonylation since in cationic alkyl palladium species the insertion of CO into the palladium alkyl bond is very fast.[70]



Scheme 9. Formation of palladium acyl complexes with diphosphane ligands under CO

Phosphorus-nitrogen ligands have been used for the study of the insertion of carbon monoxide into both ionic and neutral complexes.[74] In such complexes, the preferred structures have the methyl and acetyl groups *cis* to the phosphane ligand, as one would expect according to the *trans* influence. As a result, the insertion reaction for such P−N ligands is slower than those for either P−P or N−N ligands, because, in the first instance, migration leads to a less-stable isomer with the acetyl group *trans* to phosphorus. The details of such migration reactions in dissymmetric P−P* ligand complexes have been reported previously.[75][76]

A similar study has been performed concerning the reactivity of a cationic complex [(P,N)Pd(Me)(CO)]$^+$ towards CO and norbornene. Luinstra showed that in the presence of both an alkene and CO, the *trans* effect could be advantageously used to give faster reactions in some instances.[77] The same effect was reported by Mul et al.[78] This effect of ligand equilibria seems most relevant to polyketone synthesis, but similar effects can be envisaged for hydroxycar-

bonylation, casting some doubts on the rate measurements of stepwise stoichiometric reactions.

Benzylpalladium and (phenylacetyl)palladium complexes with two PMe_3 or PPh_3 ligands or a dppe ligand have been prepared as models for studying the mechanisms of carbonylation reactions by which benzyl halides are converted into singly and doubly carbonylated products.[58] The monodentate ligands give rise to *trans*-benzyl$PdX(L)_2$ structures containing η^1-benzyl fragments. When non-coordinating anions are used, η^3-benzyl species are formed. Insertion of CO is a fast and reversible process. Examination of the reactions of the (phenylacetyl)palladium complexes with secondary amines and alcohols provided evidence for the operation of different types of mechanisms leading to amides and esters. Amide formation proceeds more rapidly when more basic amines are used. The amines coordinate first to the palladium, and then attack the acyl moiety, which is assisted by another molecule of base. Ester formation proceeds more rapidly when more acidic alcohols are used. It was suggested that after coordination to palladium the alcohols are deprotonated by the base, and then the oxygen attacks the acyl carbon atom. In cationic diphosphane acylpalladium complexes, in the absence of base, the order of reactivity is $H_2O > MeOH > EtOH > 2\text{-PrOH}$, showing that the more acidic species react more rapidly.[79]

Effect of the Acidic Medium on Hydroxycarbonylation

The effect of the counteranion involved in the catalytic system has been studied, although its role is not yet fully understood. In the carbonylation of aliphatic and functionalized alkenes by cationic palladium complexes in the presence of hydrogen to give alcohols, aldehydes, ketones, or oligoketones, a selectivity control by the neutral ligand and anion was found. Non-coordinating anions primarily produce oligoketones, and increasing anion coordination strength shifts the selectivity towards aldehydes and alcohols.[7] For the latter, the heterolytic cleavage of hydrogen assisted by the more basic anions was proposed.

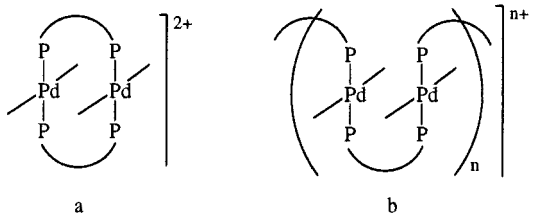
The regioselectivity of the alkoxycarbonylation of 1-arylethanols catalysed by Pd/acid systems is highly sensitive to the nature of the counteranion of the acid. Chloride anions favour branched products while weakly coordinating tetrafluoroborate and sulfonate anions favour linear products; the latter also enhance product yields.[80]

In the regioselective synthesis of ibuprofen by the $PdCl_2$/PPh_3/HCl-catalysed hydroxycarbonylation of 1-(4-isobutylphenyl)ethanol, the rate and selectivity of the reaction proved to be dependent on the concentration and nature of the halide ion used. It has been reported that hydrochloric acid plays a dual role in this reaction, firstly providing a proton, which promotes the dehydration of the alcohol, and secondly providing a chloride ion, which promotes the carbonylation step.[81]

In the asymmetric alkoxycarbonylation of alkenes catalysed by chiral palladium bis(dibenzophosphole) complexes, halide salts, such as LiCl or bis(triphenylphosphane)iminium chloride, and hydrogen at low pressure, were found to dramatically increase the extent of conversion without significantly decreasing the optical yield. Palladium species coordinated by halide are thought to prevent the aggregation of reduced palladium species.[82] In the asymmetric alkoxycarbonylation of styrene with palladium catalysts, both the degree of conversion and the asymmetric induction were found to be very low when acids such as MeCOOH, HCOOH, HCl, HBr, etc. were used instead of CF_3COOH.[83]

Finally, studies on the effect of the counteranion on the hydroxycarbonylation reaction have been performed. The effect of mineral acids as additives in the hydroxycarbonylation of 4-methylstyrene with $PdCl_2$/$CuCl_2$/PPh_3 has been studied. Efficient hydroxycarbonylation was only achieved after a halogen compound had been added; the addition of HCl improved the reaction rate significantly. This improvement was due to the effect of chloride ions rather than protons, as was proved by adding either other acids or other chloride salts.[84] Some reports have shown that the hydroxycarbonylation reaction also takes place if water is used instead of acid.[85,86]

In the course of a study on the use of palladium systems in the hydroxycarbonylation of styrene, we also explored how the counteranion of the acid affects this reaction when the Pd bears monophosphane and diphosphane ligands. To prevent the palladium precursor from introducing counteranions, we chose to perform a series of experiments using the catalyst precursor $[Pd_2(dba)_3]$ in the presence of acids. We showed that activity and regioselectivity in the hydroxycarbonylation of styrene are sensitive to the nature of the counteranion of the acid. The regioselectivities obtained for monophosphanes and diphosphanes (branched and linear, respectively) can be changed by judicious choice of the counteranion. When a monophosphane such as PPh_3 was used as the ligand, coordinating anions such as halides were found to favour the formation of branched acids. However, weakly coordinating anions such as sulfonic acids were found to favour the formation of linear acids. On the other hand, the regioselectivity for the systems formed with the diphosphane dppb in the presence of Br^- and I^- was found not to favour the linear acid as other diphosphanes do.[23] It has been suggested that the diphosphane could be monocoordinated depending on the nature of the counteranion, but it might also suggest that dinuclear species with the diphosphane bridging between two different palladium centres are formed (Scheme 10).[70,74] A similar behaviour



Scheme 10. Dimeric and oligomeric palladium complexes with diphosphane ligands

has recently been reported in Pd-diphosphane systems used in carbonylation processes, where differences in catalytic activity and selectivity can be rationalized in terms of monodentate coordination of the diphosphane.[87,88]

Regioselectivity in the Palladium-Catalysed Carbonylation Reactions

In spite of the reported studies, which have compared systems showing opposite regioselectivities in the palladium-catalysed alkoxycarbonylation and hydroxycarbonylation reactions, the issue of regioselectivity is still far from understood.

Since the 1970s, regioselectivity in the alkoxycarbonylation of alkenes has been shown to depend on the nature of the phosphorus ligand. Pd/monophosphane catalytic systems produce mainly the branched ester, whereas Pd/diphosphane systems produce mainly the linear one.[89,90]

In 1976, Sugi and Bando reported an interesting study of the ethoxycarbonylation of styrene with carbon monoxide and ethanol in the presence of diphosphane palladium complexes [$PdCl_2\{Ph_2P(CH_2)_nPPh_2\}$] ($n$ = 1−6, 10).[91] When diphosphanes with n = 3, 4, 5 were used, ethyl 3-phenylpropionate was obtained in significant amounts. With dppe, n = 2, however, no conversion was found. Phosphanes with n = 1, 6, 10 gave ethyl 2-phenylpropionate as the predominant isomer, in the same way as monodentate phosphanes do. The conversion increased with n, but proved to be highest for monodentate phosphanes. These results were rationalized in terms of the stability of the chelate ring under the reaction conditions, assuming the formation of monophosphane complexes for ligands with high n, similar to those with the monophosphane ligands. The current explanation is based on *cis* complexes for bidentate ligands of lower n, and *trans* complexes for ligands having higher n and monodentate ligands, at least for the resting states of the catalysts. The highest selectivity in favour of the branched ester (99.5%) was obtained using PBu_3.[91]

In several studies, monophosphanes and diphosphanes have been used together. In the asymmetric alkoxycarbonylation of α-methylstyrene using the Pd/DIOP system, the addition of PPh_3 was found to increase the amount of the branched ester.[92] In the hydroxycarbonylation of alkenes, PPh_3 was added to the $Pd(OAc)_2$/dppb system; this improved the yield without significantly affecting the product distribution.[93]

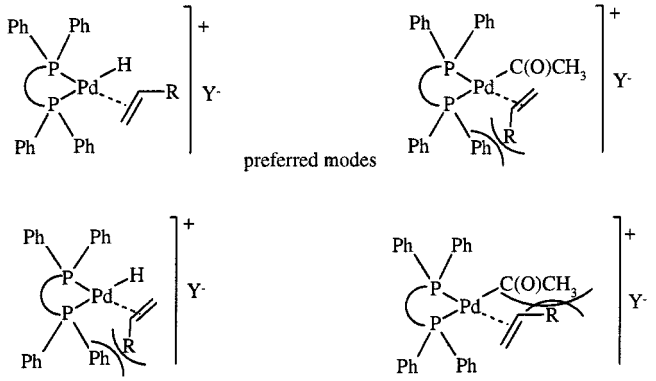
In some cases, a co-catalyst was added to the Pd/phosphane system, as in the hydroxycarbonylation of 1-heptene with [$HPdCl(PPh_3)_2$]/$SnCl_2$[94] and [$PdCl_2(PPh_3)_2$]/$Co_2(CO)_8$,[95] the hydroxycarbonylation of styrene with the [$PdCl_2(PPh_3)_2$]/$Co_2(CO)_8$ system,[96] and alkoxycarbonylation with the [$PdCl_2L_2$]/$SnCl_2$ or $GeCl_2$ systems (L = monophosphane).[48,55] In general, the co-catalyst increased the regioselectivity in favour of the linear product and decreased the rate of the reaction. In the asymmetric alkoxycarbonylation of styrene with the precursor $PdCl_2$ and chiral diphosphanes, the addition of $CuCl_2$ as a co-catalyst favoured the formation of the branched ester in good yield and with high enantiomeric excess.[97] In this case, however, the rigid structure of the iditol-derived ligand might have led to a non-chelating coordination, this being responsible for the high chiral induction. Monodentate coordination would be consistent with the high regioselectivity obtained in favour of the branched product.[98] A role of the MCl_2 salts that is frequently overlooked is that they may act as "chloride acceptors", thus assisting in the formation of weakly coordinating anions.

Interestingly, regioselectivity is seen to depend on the nature of the substrate. With aliphatic alkenes, the differences in isomeric composition are not as great as they are with vinyl arenes.[88] This can be explained in terms of π-benzylic stabilization of styrene in the styrylpalladium fragment obtained after insertion.[52,53] The steric bulk of the substrate is also important, as illustrated by the hydroxycarbonylation of simple and functionalized alkenes with $Pd(OAc)_2$/dppb/HCOOH. Control of the regioselectivity of the reaction depends in part on the effective bulk of the substituent group on the alkene; more hindered alkenes produce higher yields of the linear acid.[99] No pronounced influence of the electronic effects of the substrate on regioselectivity has been found in the alkoxycarbonylation and hydroxycarbonylation of 3,3,3-trifluoropropene and pentafluorostyrene catalysed by phosphane-palladium systems. When monophosphanes were used as ligands, the major product was the branched one, whereas when diphosphanes were used it was the linear one.[100] Thus, the fluoroalkenes follow the normal trend, although a higher preference for branched ones might have been expected.

Regioselectivity is often explained in terms of the following two mechanisms: (1) when styrene inserts into a metal−acyl bond, branched products are formed, and (2) when it inserts into a metal hydride, linear products are formed.[93][101] The regioselectivity of styrene insertion has been studied for the palladium-catalysed oligomerization of styrene and carbon monoxide. With diphosphanes, the insertion of the first styrene into the palladium hydride complex leads to the formation of a linear palladium alkyl species. This can be attributed to steric hindrance between the phenyl group of the styrene and the phosphane coordinated to the palladium centre. Insertion of styrene into the acyl palladium intermediate gives a branched insertion product.[100]

According to this interpretation, the different regioselectivities have a steric origin. In the first step, the hydride attacks the α-carbon of styrene, but the acyl species formed after insertion of CO attacks the styrene molecule at the β-carbon atom, as in our reaction (Scheme 11).[33] While this has proved to be correct for cationic complexes that act as polymerization or oligomerization catalysts, for hydroxycarbonylation this has yet to be confirmed (vide infra).

We have previously reported a systematic study into how palladium precursor systems and the phosphorus ligand affect the hydroxycarbonylation of styrene. Monophosphanes and diphosphanes behave differently when used as ligands in this reaction. Using monophosphanes, only Pd^{II} pre-



Scheme 11. Effect of steric hindrance on the stereochemistry of insertion of an alkene into a Pd−H bond and a Pd−C(O)CH_3 bond

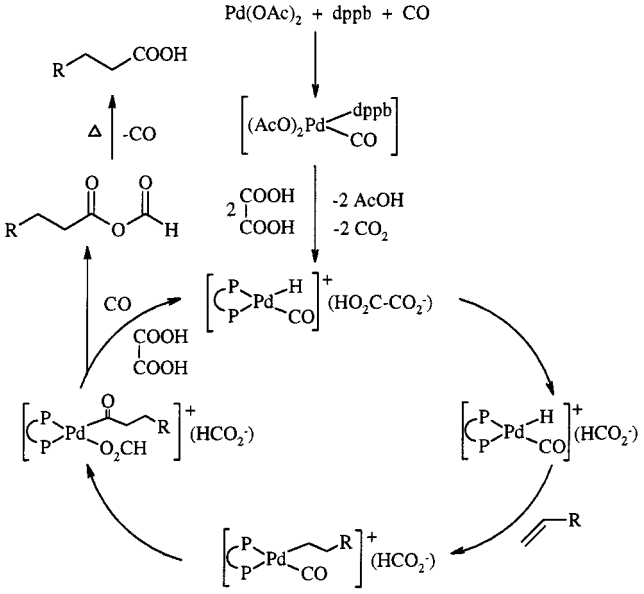
cursors containing chloride give reasonable activity. When diphosphanes are used as auxiliary ligands, the results obtained with Pd^0 and Pd^{II} precursors are similar. As far as regioselectivity is concerned, the branched acid is the major product with monophosphanes, while the linear acid is the major product with diphosphanes. Also, monophosphanes afford much faster catalysts. It has been suggested that different intermediates are involved in the catalytic cycle for monophosphanes and diphosphanes; the association/dissociation of counteranions and phosphanes may account for the differences between the two systems.[23]

Studies of the Mechanism of Palladium-Catalysed Carbonylations

The understanding of a catalytic process requires a combination of several techniques, such as kinetic studies, deuteration experiments, determination of the intermediates, and theoretical studies. Here, we review significant studies of hydroxycarbonylation or related reactions that have contributed to the understanding of the palladium hydroxycarbonylation mechanism.

In several instances in the literature, no experimental support is presented for proposed catalytic cycles, and it should be borne in mind that these proposals are often speculative and include at best circumstantial evidence. In general, in catalytic alkene carbonylation reactions involving palladium species, a palladium hydride is proposed as the species that starts the cycle. Subsequently, coordination and insertion of the substrate occurs, which is followed by the coordination and insertion of carbon monoxide, which leads to the proposed palladium intermediates (Scheme 3).[102]

A mechanism has also been proposed for the Pd^{II} acetate/oxalic acid systems used in the presence of a chelating phosphorus ligand in the hydroxycarbonylation of alkenes. The system consisting of oxalic acid in 1,2-dimethoxyethane (DME) allows relatively mild conditions and gives high regioselectivity in favour of the linear acid when 1,4-bis(diphenylphosphanyl)butane, dppb, is used.[97] A catalytic cycle was proposed for the hydroxycarbonylation reaction starting with a $[Pd(OAc)_2(dppb)(CO)]$ complex that reacts with two equivalents of oxalic acid to afford an ionic complex $[Pd(H)CO(dppb)]^+$. For subsequent steps, palladium alkyl and palladium acyl intermediates are proposed. Finally, the linear acid is formed by decarbonylation (Scheme 12).[103]

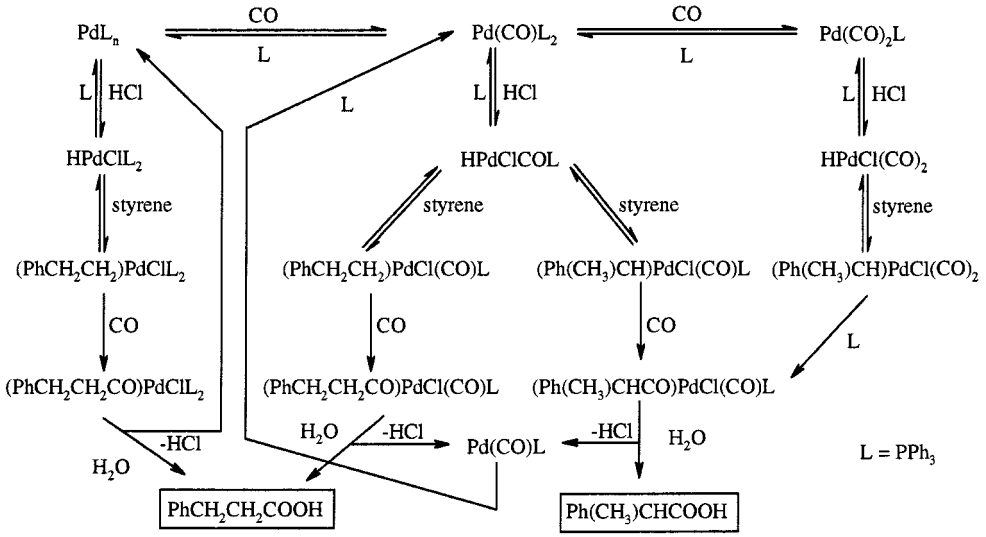


Scheme 12. Catalytic cycle proposed for the hydroxycarbonylation of alkenes with the $Pd(OAc)_2$/dppb/$H_2C_2O_4$ system

Kinetic Studies

A number of studies on the kinetics of the hydroxycarbonylation reaction with palladium systems have been reported.[104−106] These generally focus on how the carbon monoxide pressure, the concentration of styrene, the palladium precursor, the phosphane ligands, and water affect the activity and regioselectivity of the reaction.

The kinetics and mechanism of styrene hydroxycarbonylation catalysed by the complex $[PdCl_2(PPh_3)_2]$ have been reported. When water was added to the catalytic system up to $[H_2O]$ = 2 M, the rate of formation of the linear acid increased. Higher CO pressures were found to favour the formation of the branched acid. This can be attributed to the formation of species containing coordinated CO as a result of displacement of the bulkier PPh_3 ligand.[103] The rates of linear and branched acid formation both show a linear dependence on the concentration of the catalyst. Triphenylphosphane decreases the rate of formation of the branched acid more than that of the linear one; the inhibiting effect of PPh_3 is enhanced by increasing $[H_2O]$. As the styrene content increases, the rate of formation of the linear acid remains virtually constant, while the rate of formation of the branched acid increases markedly.[105] These relationships are consistent with the hydride mechanism, which involves four routes for the formation of phenylpropionic acids and three types of catalyst precursors $[Pd(H)Cl(CO)_n(PPh_3)_{2-n}]$ (n = 0−2) in equilibrium, depending on the CO pressure and the concentration of the



Scheme 13. Proposed mechanism for the hydroxycarbonylation of styrene with the $[PdCl_2(PPh_3)_2]/PPh_3$ system, involving $[Pd(H)Cl(CO)_n(PPh_3)_{2-n}]$ ($n = 0-2$) species

ligand. The regioselectivity of the intermediates with respect to 3-phenylpropionic acid drops from 100 to 0% as n increases from 0 to 2 (Scheme 13).[105]

More recently, a kinetic study of how the addition of $SnCl_2$ to the $[PdCl_2(PPh_3)_2]/PPh_3$ system affects the hydroxycarbonylation of styrene has been reported.[106] Adding an equimolar amount of $SnCl_2$ to $[PdCl_2(PPh_3)_2]$ increases the selectivity in favour of the linear acid from 30 to 70%, which stems from an increase in the rate of formation of this product. Kinetic and spectroscopic data were used to explain the effect of $SnCl_2$. It was proposed that it involves the displacement of CO ligands from Pd^{II}-containing intermediates by the π-acceptor $SnCl_3^-$, and leads to a higher concentration of phosphane hydride complexes that selectively afford the linear acid (Scheme 13).[107]

A kinetic study of the hydroxycarbonylation of 1-heptene catalysed by $[PdCl_2(PPh_3)_2]/PPh_3$ complexes has also been reported. The rates of formation of the acids increased as the carbon monoxide pressure was increased and as the water concentration was increased up to $[H_2O] = 2$ M. The same mechanism as that for styrene was suggested (Scheme 13).[107]

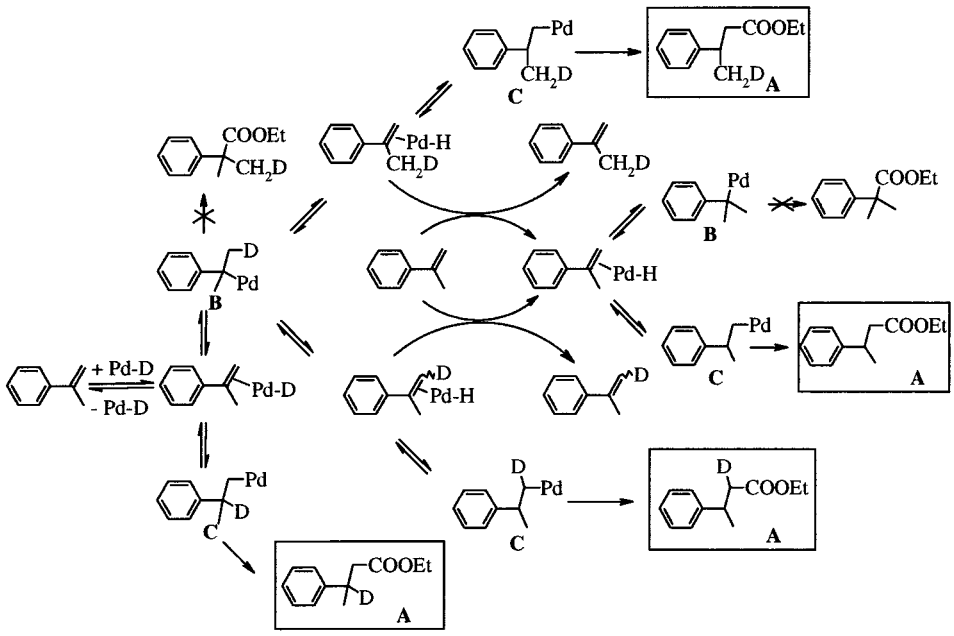
The kinetics of the alkoxycarbonylation of styrene have been studied using the $Pd(OAc)_2/PPh_3/TsOH$ catalyst system. The reaction was found to be first order with respect to the catalyst concentration and zero order with respect to styrene up to 3.8 mol·dm^{-3}. At high concentrations of styrene (3.8−6.7 mol·dm^{-3}), the rate increased significantly. Water was found to promote the alkoxycarbonylation of styrene, although beyond $9.2 \cdot 10^{-2}$ mol·dm^{-3} this effect was negligible. The rate increased when P_{CO} was below 3.4 MPa, but was not affected by higher partial pressures. A rate equation was proposed and the kinetic parameters were evaluated. A reaction mechanism involving palladium hydride, palladium alkyl, and palladium acyl species as intermediates has been proposed.[108]

In the $Pd(OAc)_2$/tppts-catalysed aqueous-phase hydroxycarbonylation of ethene, kinetic studies have shown that the conversion of a palladium acyl to a palladium hydride complex is a rate-determining, pseudo first-order reaction.[29]

Deuterium Labelling Experiments

Deuterium labelling has provided important information about the pathways that are operative in several catalytic reactions. A detailed investigation of the alkoxycarbonylation of styrene has been performed at various temperatures and conversions with the $[PdCl_2(PPh_3)_2]/SnCl_2$ system using labelled species, the content and distribution of deuterium in which was determined by mass spectral analysis and NMR (^1H, ^2H, ^{13}C) techniques. The large number of labelled species observed supports the assumption that the hydrido (Pd−H) route is the mechanism followed by this system. Significant deuteration of the unconverted styrene and the ester isomers formed was found in the alkoxycarbonylation of styrene with EtOD at low temperature (60 °C). Under more severe conditions, oligodeuterated species were formed in a less selective manner. The presence of deuterium in the unconverted alkene confirms the reversibility of the reaction (alkyl−metal intermediates readily undergo β-hydride elimination) and suggests that dissociation of the palladium alkyl intermediate occurred. Reversible alkene insertion/β-hydride elimination prior to carbonylation was deemed responsible for the incorporation of multiple deuterium atoms.[109]

A comparative study of the regioselectivity in styrene and α-methylstyrene alkoxycarbonylation in the presence of $[PdCl_2(PPh_3)_2]$ and $[PdCl_2(PPh_3)_2]/SnCl_2$ catalyst precursors has been reported. When styrene was transformed with $[PdCl_2(PPh_3)_2]/SnCl_2$ as the precursor, the linear ethyl 3-phenylpropanoate was the major product. The formation of both the linear and branched palladium alkyls was reversible, so that deuterium labelling occurred at all carbon



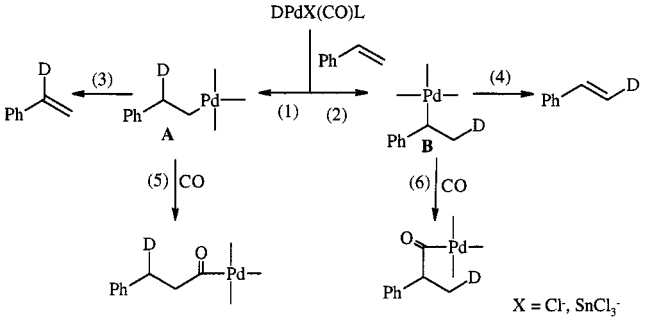
Scheme 14. Pathways for deuteration of α-methylstyrene and the derived deuterated isomeric esters

atoms of the side chains of the substrate and esters. In the absence of $SnCl_2$, the branched ethyl 2-phenylpropanoate was formed regioselectively and no deuterium was found adjacent to the phenyl rings. These results show that the routes leading to the linear metal-alkyls must be blocked.

When α-methylstyrene was used as the starting material, ethyl 3-phenylbutanoate (A) was predominantly obtained with both catalytic systems and there was no significant difference in the deuterium distributions obtained with the $[PdCl_2(PPh_3)_2]$ and $[PdCl_2(PPh_3)_2]/SnCl_2$ systems (Scheme 14). For the first time, this provides evidence for the formation of tertiary palladium alkyl species (B) with α-methylstyrene. These tertiary palladium alkyl species (B), although favoured over their primary counterparts (C), overwhelmingly underwent β-hydride elimination and, probably due to steric hindrance, the branched ester was not formed. Therefore, these intermediates undergo a slow migration of CO versus β-elimination. These results show that the different behaviour of primary, secondary, and tertiary palladium alkyl intermediates under alkoxycarbonylation conditions may account for the different regioselectivities.[110]

In the hydroxycarbonylation of styrene, the addition of $SnCl_2$ to the $[PdCl_2(PPh_3)_2]$ system also increases the selectivity in favour of the linear acid from 30 to 70%. Kinetic and spectroscopic data seem to indicate that this occurs through the displacement of a CO ligand from Pd^{II}-containing intermediates by the π-acceptor $SnCl_3^-$, as discussed above (Scheme 15).[104]

Scheme 15 shows that in systems containing chloride, when $X = Cl^-$, deuterium exchange occurs only at the β-position of the vinyl group; i.e. the rate of decomposition of species B (4) is higher than the rate of its carbonylation (6). The decomposition of species A (3) did not occur under the experimental conditions. Therefore, styrene insertion



Scheme 15. Study of the regioselectivity in the hydroxycarbonylation of styrene with deuterium labels

into a Pd−H bond was considered to be an equilibrium step in route (2) and an irreversible step in route (1). In the presence of $SnCl_2$, extensive deuterium exchange occurs at both the α and β positions; i.e. the rates of steps (3) and (4) become similar. This is consistent with the data on the ability of the $SnCl_3^-$ moiety to assist the β-elimination of hydrogen from hydrocarbon groups in transition metal complexes[111,112] and allowed the authors to suggest that the formation of an intermediate of type A according to route (1) with $X = SnCl_3^-$ is an equilibrium step (Scheme 15).[106]

These studies prove that β-elimination takes place in the carbonylation reaction with the palladium catalyst. This was previously demonstrated for hydroformylation with a rhodium catalyst by means of deuterium labelling experiments.[113,114] However, the occurrence of β-elimination had already been deduced for other systems. In the hydroxycarbonylation of 1-octene with Pd/monophosphane systems at temperatures above 150 °C, dehydratocarbonylation was observed, this being the inverse reaction of hydroxycarbonylation. The acids formed reverted to the alkene, carbon

monoxide, and water. Both the forward and reverse reactions proceeded with appreciable rates.[85]

Recently, deuterium labelling experiments have been used in the hydroxycarbonylation of acenaphthylene with the $[PdCl_2(MeCN)_2]$ system in the presence of monophosphanes with different electronic properties. Deuteriocarboxylation of this substrate is, owing to the structure of the product, useful for determining the diastereoselectivity of the *cis*-addition of Pd−D to the alkene.[115]

Theoretical Studies

In an attempt to ascertain whether palladium hydride species or palladium alkoxycarbonyl species are the key intermediates in the Pd^{II}-catalysed alkoxycarbonylation of ethene, ab initio calculations were carried out to provide information on the transition state barriers of the elementary steps. The palladium hydride species was shown to be preferable to the palladium alkoxycarbonyl species as the key intermediate.[19] However, comparison of different routes remains a difficult task in view of the present state of the art. It can merely be concluded that the calculations are consistent with the experiments in that there is no prohibitive barrier for either route.[21]

In situ High-Pressure NMR Experiments

We have performed in situ high-pressure NMR studies of the hydroxycarbonylation of styrene using several palladium systems in order to obtain insight into the mechanisms that control the regioselectivity and the effects of the phosphorus ligand and the catalyst precursor. Similar in situ HPNMR studies have been performed for the rhodium hydroformylation[116,117] and palladium copolymerization reactions.[118] In particular, in the case of rhodium hydroformylation, this approach proved very useful for determining the intermediate species involved in the catalytic cycle.

In this study, the HPNMR spectroscopic investigations were carried out using $Pd(OAc)_2$ and $[PdCl_2(PhCN)_2]$ as palladium precursors, which were modified with PPh_3 as a monophosphane or dppb as a diphosphane [dppb = 1,4-bis(diphenylphosphanyl)butane]. $H_2C_2O_4$ was used as the acid under CO atmosphere with $[D_8]$THF as the solvent. The system was stirred under pressure to favour the diffusion of the gas. The experimental conditions were chosen according to previous hydroxycarbonylation catalytic experiments.[23,24]

The System $Pd(OAc)_2/PPh_3/H_2C_2O_4$

HPNMR experiments were carried out at 30 bar CO and molar ratios of P/Pd = 4 and H^+/Pd = 25 with the $Pd(OAc)_2/PPh_3/H_2C_2O_4$ system. The system was heated to 100 °C to allow the catalytic species to form. The $^{31}P\{^1H\}$ NMR spectrum of the solution showed a sharp singlet at δ = 14.4. The resonance of the oxidized phosphane was observed at δ = 32. At room temperature, the same solution exhibited a broad signal at δ = 15.0, together with the signal of the oxidized phosphane. When the temperature was lowered to −60 °C, the signal shifted downfield to δ = 23.6; a second signal of low intensity simultaneously appeared at δ = −5.0, which was assigned to the free PPh_3 ligand. Despite the acidic medium, no hydride signal was observed in the ^1H NMR spectra (Figure 1; Table 1).

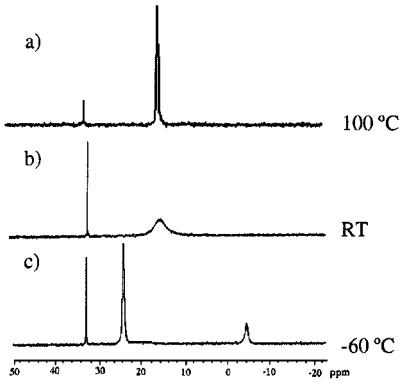


Figure 1. $^{31}P\{^1H\}$ NMR spectra for the reaction of $Pd(OAc)_2$ with PPh_3 under hydroxycarbonylation conditions at different temperatures: (a) 100 °C, (b) room temp., (c) −60 °C

In agreement with previously reported NMR spectroscopic data,[25] this behaviour may be rationalized in terms of ligand dissociation and a rapid ligand exchange according to an equilibrium between $[PdCO(PPh_3)_3]$ and $[PdCO(PPh_3)_2] + PPh_3$. At low temperatures, $[PdCO(PPh_3)_3]$ and free PPh_3 are observed.[27,28]

The HPNMR tube was then depressurized at room temperature and styrene (0.05 mL) was added under nitrogen (substrate/Pd = 4). The $^{31}P\{^1H\}$ NMR spectrum seen at 30 bar CO and room temperature remained unchanged. The temperature was then increased to 100 °C so as to reach carbonylation conditions. The formation of the acids was observed in the ^1H NMR spectrum, indicating the occurrence of hydroxycarbonylation. The major acid was the branched one, as reported previously for palladium systems with monophosphane ligands.[23] Simultaneously, the species observed in the $^{31}P\{^1H\}$ NMR spectra were those that had previously been observed when no substrate was added at these temperatures (Figure 1). When the system was cooled to −60 °C, decoalescence occurred in the same way as when there was no substrate. No hydride species were observed in the ^1H NMR spectra in the course of the experiment.

The System $[PdCl_2(PhCN)_2]/PPh_3/H_2C_2O_4$

Similar HPNMR experiments were performed for $[PdCl_2(PhCN)_2]/PPh_3/H_2C_2O_4$ at 30 and 10 bar CO, P/Pd = 4, and H^+/Pd = 25. The $^{31}P\{^1H\}$ NMR spectrum of the solution at 30 bar CO and 100 °C showed four broad signals: the signal of the oxidized monophosphane at δ = 33, two minor signals at δ = 24.5 and 22.9, and a major singlet at δ = 6.7. A broad hydride signal was observed in the ^1H NMR spectrum at δ = −13. At room temperature, the $^{31}P\{^1H\}$ NMR spectrum showed four sharp singlets at δ =

Table 1. NMR spectroscopic data for the [Pd]/PPh_3/$H_2C_2O_4$ systems under hydroxycarbonylation conditions

Complex	$\delta^{31}P\{^1H\}$ (ppm)	δ^1H (ppm)	Ref.

32.2, 24.9, 23.0, and 22.8 and a broad signal at δ = 6.8. When the system was cooled to −70 °C, the broad signal was shifted downfield to δ = 23 and a new signal appeared at δ = −6; this was assigned to free PPh_3. No hydride signal was observed in the ^1H NMR spectrum either at room temperature or at −70 °C (Figure 2; Table 1).

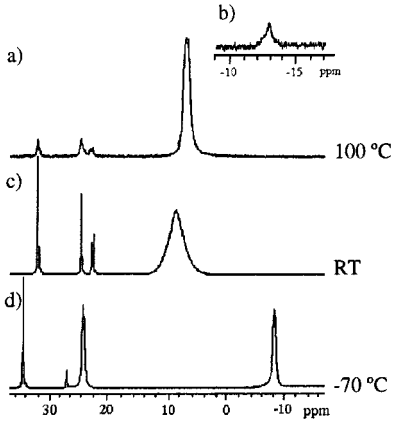

Figure 2. $^{31}P\{^1H\}$ and ^1H NMR spectra for the reaction of $[PdCl_2(PhCN)_2]$ with PPh_3 under hydroxycarbonylation conditions at different temperatures: (a) $^{31}P\{^1H\}$ NMR spectrum at 100 °C; (b) ^1H NMR spectrum at 100 °C; (c) $^{31}P\{^1H\}$ NMR spectrum at room temp.; (d) $^{31}P\{^1H\}$ NMR spectrum at −70 °C

As previously shown for the $Pd(OAc)_2/PPh_3$ system, a fast ligand exchange occurs at room temperature as well as at higher temperatures. However, the integrals of the phosphorus signals were different from those with the $Pd(OAc)_2/PPh_3$ system (Figure 1). These integrals may be indicative of the presence of a palladium complex with two monophosphanes coordinated as the $[Pd(H)Cl(PPh_3)_2]$ species.[43−46] These coordinated monophosphanes were responsible for the signal at δ = 23 in the $^{31}P\{^1H\}$ NMR spectrum and the corresponding hydride signal was observed at δ = −13 in the ^1H NMR spectrum. This hydride species is only observed at temperatures at or above 100 °C and under CO pressure.

The minor sharp singlets observed at room temperature at δ = 24.9 were attributed to the formation of $[Pd(PPh_3)_3]$ and those at δ = 23.0 and 22.8 to *cis*/*trans*-$[PdCl_2(PPh_3)_2]$. These complexes have previously been prepared in our laboratory for NMR assignment.

After cooling and depressurizing the HPNMR tube, styrene was added under nitrogen (substrate/Pd = 4). The solution was then pressurized with 30 bar CO and in the room temperature $^{31}P\{^1H\}$ NMR spectrum six sharp signals were observed at δ = 32.2 (oxidized monophosphane), 25.0, 23.1, 22.8, 20.6, and 19.8, together with a broad signal at δ = 0 (Figure 3, a). The singlets at δ = 25.0, 23.1, and 22.8 were assigned to the species previously observed in the absence of styrene, namely $[Pd(PPh_3)_3]$ and $[PdCl_2(PPh_3)_2]$. Two new singlets appeared at δ = 20.6 and 19.8 after the substrate was added, which were attributed to the palladium acyl complexes $[PdCl(PPh_3)_2(COCH_2CH_2Ph)]$ and $[PdCl(PPh_3)_2\{COCH(CH_3)Ph\}]$ (Table 1).[35] In the ^1H NMR spectrum, these palladium acyl complexes give rise to signals at δ = 1.4 and 2.2 due to the CH_2 of the linear isomer and at δ = 0.8 and 2.8 due to the CH_3 and CH of the branched acyl species, respectively. The major species was the linear palladium acyl species.

The broad signal observed at δ = 0 in the $^{31}P\{^1H\}$ NMR spectrum may be attributed to the species $[Pd(H)Cl(PPh_3)_2]$ that was previously observed in the absence of styrene at δ = 6.8 (Figure 2, c), despite there being no hydride signal in the ^1H NMR spectrum (Figure 3, a).

When the temperature was increased to 50 °C and 100 °C, hydroxycarbonylation was observed and in the $^{31}P\{^1H\}$ NMR spectrum the palladium acyl signals became broader (Figure 3, b,c). An exchange of PPh_3 between the palladium hydride and the palladium acyl species was observed.

The $^{31}P\{^1H\}$ NMR spectrum recorded after 24 hours was unchanged (Figure 3, d) and the ^1H NMR spectrum showed only 60% conversion to the acids with 64% regioselectivity in favour of the branched acid. When the temperature was increased to 120 °C (Figure 3, e), the rate of the reaction increased considerably and there was a faster phosphorus exchange between the palladium hydride and the palladium acyl species. After a few minutes, conversion reached 92% and the regioselectivity decreased to just 51% in favour of the branched acid. A dependence of the regioselectivity on the temperature was observed.

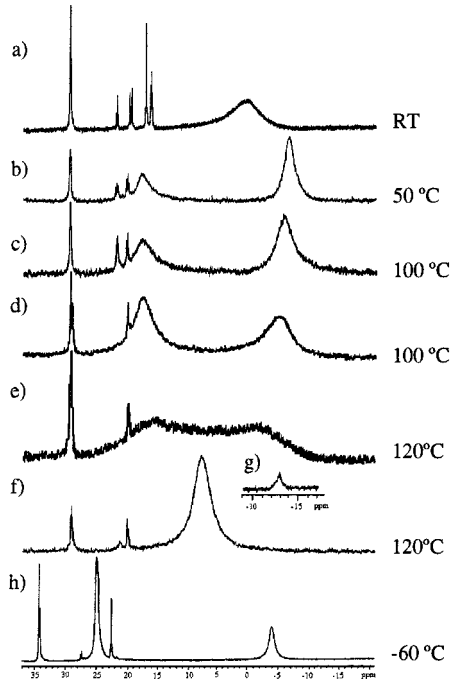

Figure 3. $^{31}P\{^1H\}$ and ^1H NMR spectra for the reaction of $[PdCl_2(PhCN)_2]$ with PPh_3 in the hydroxycarbonylation of styrene at different temperatures: (a) $^{31}P\{^1H\}$ NMR spectrum at room temp.; (b) $^{31}P\{^1H\}$ NMR spectrum at 50 °C; (c) $^{31}P\{^1H\}$ NMR spectrum at 100 °C; (d) $^{31}P\{^1H\}$ NMR spectrum after 1 day at 100 °C; (e) $^{31}P\{^1H\}$ NMR spectrum at 120 °C; (f) $^{31}P\{^1H\}$ NMR spectrum after 30 min at 120 °C; (g) ^1H NMR spectrum after 30 min at 120 °C; (h) $^{31}P\{^1H\}$ NMR spectrum at −60 °C

After 30 min, the hydroxycarbonylation was seen to be complete since the styrene and the palladium acyl complexes were no longer observed. A new hydride signal appeared at $\delta = -13$ (Figure 3, g). This signal was not observed in the course of the hydroxycarbonylation, possibly because it was below the detection level. The $^{31}P\{^1H\}$ NMR spectrum (Figure 3, f) was similar to that in the absence of styrene (Figure 2, a). Oxidized PPh_3, giving a signal at $\delta = 32$, and minor species such as $[Pd(PPh_3)_3]$ ($\delta = 25$) and $[PdCl_2(PPh_3)_2]$ ($\delta = 24$) were observed.

The solution was then cooled to −60 °C and, as previously observed in the absence of styrene (Figure 2, d), a broad signal appeared in the $^{31}P\{^1H\}$ NMR spectrum at $\delta = 24$ due to the complex $[Pd(H)Cl(PPh_3)_2]$, along with a signal due to the free phosphane at $\delta = -4$ (Figure 3, h).

To confirm the presence of the acyl species, we performed an experiment with the same $[PdCl_2(PPh_3)_2]/PPh_3/H_2C_2O_4$ system at 11 bar using a mixture of CO and ^{13}CO (10:1). Before the styrene was added, the species present were the same as those seen at 30 bar CO (Figure 2). After the addition of styrene at room temperature, the carbonyl signals of the palladium acyl complexes were observed in the ^{13}C NMR spectrum at $\delta = 234$ and 232. The temperature was then increased to 100 °C so as to reach hydroxycarbonylation conditions. This pressure favoured the formation of the linear acid and the ^1H NMR spectrum showed the presence of the hydride ($\delta = -13$) and the palladium acyl species.

During the hydroxycarbonylation, the temperature was lowered to −90 °C in an attempt to freeze out the intermediates of the reaction. The $^{31}P\{^1H\}$ spectrum was the same as that recorded without styrene (Figure 2, d; Figure 3, h), featuring signals due to the acyl complexes at $\delta = 19$ and 20. The temperature was then increased to 120 °C and at the end of the reaction the major product was the linear acid.

In conclusion, in the Pd/monophosphane systems, the palladium hydride species was only observed at high temperatures in the presence of carbon monoxide. Chloride ions favour the formation of this species. No hydrides were observed with the $Pd(OAc)_2/PPh_3$ system. With the $[PdCl_2(PhCN)_2]/PPh_3$ system at 30 bar CO, palladium acyl complexes were observed during the hydroxycarbonylation. At lower CO pressures, palladium hydride and palladium acyl species were observed. Similarly, the regioselectivity of the system was found to be dependent on the temperature and pressure; high temperatures and low pressures favoured the linear acid.

The System $Pd(OAc)_2/dppb/H_2C_2O_4$

Similar HPNMR experiments were performed with the $Pd(OAc)_2/dppb/H_2C_2O_4$ system at 60 and 20 bar CO, P/Pd = 4, and $H^+/Pd = 25$. At 60 bar CO, the system was heated to 120 °C to form the active species. The $^{31}P\{^1H\}$ NMR spectrum of the solution showed two broad signals at $\delta = 16$ and −6. Two resonances, corresponding to the oxidized diphosphane, were present at $\delta = 37$. A sharp hydride signal was seen in the ^1H NMR spectrum at $\delta = -5.6$. The $^{31}P\{^1H\}$ NMR spectrum of the same solution at room temperature showed a minor signal at $\delta = 27$ and a broad signal at $\delta = 14$, along with two signals due to the oxidized phosphane. On cooling to −70 °C, three broad signals were observed at $\delta = 27$, 16, and −14, the last of which was assigned to free dppb (Figure 4; Table 2).

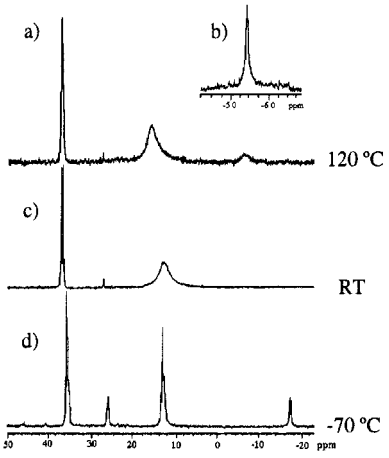

Figure 4. $^{31}P\{^1H\}$ and ^1H NMR spectra for the reaction of $Pd(OAc)_2$ with dppb under hydroxycarbonylation conditions at different temperatures: (a) $^{31}P\{^1H\}$ NMR spectrum at 120 °C; (b) ^1H NMR spectrum at 120 °C; (c) $^{31}P\{^1H\}$ NMR spectrum at room temp.; (d) $^{31}P\{^1H\}$ NMR spectrum at −70 °C

Table 2. NMR spectroscopic data for the [Pd]/dppb/$H_2C_2O_4$ systems under hydroxycarbonylation conditions

Complex	$\delta^{31}P\{^1H\}$ (ppm)	δ^1H (ppm)	Ref.
dppb[a]	−14	–	–
oxidized dppb[a]	37	–	–
[Pd(dppb)$_2$]	27 (−70 °C)	–	[119]
[Pd(OAc)$_2$dppb]	16 (−70 °C)	–	[28]
[(dppb)$_2$Pd$_2$(μ-H)(μ-CO)]OAc	23	−6.4 (μ-H)	[52,53]
[PdCl$_2$dppb][a]	28	–	–

[a] NMR spectroscopic data from experimental results.

These spectra may be explained in terms of ligand dissociation and a rapid ligand exchange at high temperatures. The signal at δ = 27 may be attributed to the complex [Pd(dppb)$_2$],[119] and that at δ = 16 to the species [Pd(OAc)$_2$dppb].[28] These species can undergo exchange of free dppb at high temperatures, thereby accounting for the broad signal at δ = 16. There may also be a dinuclear species with two bridging chelate diphosphanes coordinated to two palladium centres, with a hydride and carbon monoxide or acetate in a *trans* arrangement (Scheme 10, a). One of the two signals at δ = 37 can be attributed to monooxidized monocoordinated diphosphane. The species [Pd(P−P)(P−P=O)] or [Pd(OAc)$_2$(P−P=O)] may be formed, as has previously been suggested for the reduction of Pd^{II} species to Pd^0 as a means of initiating the catalytic cycle.[28] The sharp signal in the ^1H NMR spectrum at high temperatures did not show the expected large coupling constant for a hydride and a *trans* phosphorus atom (about 180 Hz). Therefore, the palladium hydride species did not have a hydride and the phosphane in a mutual *trans* arrangement. This species may correspond to the previously proposed dinuclear species.

The HPNMR tube was then depressurized at room temperature and styrene was added under nitrogen (substrate/Pd = 4). The $^{31}P\{^1H\}$ NMR spectrum at 60 bar CO and room temperature remained unchanged. The temperature was then increased to 120 °C so as to reach carbonylation conditions, and the formation of acids was observed in the ^1H NMR spectrum during the hydroxycarbonylation. As was previously reported for palladium systems with diphosphane ligands, the major product was the linear acid.[23] The species observed in the $^{31}P\{^1H\}$ NMR spectrum of the same solution were those that had previously been observed when no substrate was added at these temperatures (Figure 4). Furthermore, when the system was cooled to −70 °C, the behaviour was the same as that when no substrate was added. The hydride species was observed in the ^1H NMR spectrum only at high temperatures under carbon monoxide pressure. No palladium acyl species were observed.

An experiment was performed with the same system Pd(OAc)$_2$/dppb/$H_2C_2O_4$ at 20 bar CO with 1 bar of ^{13}CO. Prior to the addition of styrene, the species seen in the $^{31}P\{^1H\}$ NMR were the same as those seen at 60 bar CO (Figure 4) at the different temperatures, with only a minor singlet appearing at δ = 23. In the ^1H NMR spectrum, the sharp hydride signal was also present at δ = −5.6 and another minor broad signal was present at δ = −6.4. This palladium hydride signal and the $^{31}P\{^1H\}$ singlet at δ = 23 may be attributed to the dinuclear palladium species [(dppb)$_2$Pd$_2$(μ-H)(μ-CO)]OAc.[52,53]

When styrene was added and the system was heated to 120 °C, the $^{31}P\{^1H\}$ and ^1H NMR spectra were unchanged. In the ^{13}C NMR spectrum, however, a broad carbonyl signal due to a palladium acyl complex appeared at δ = 234. During the hydroxycarbonylation, formation of the linear acid was seen to be preferred. The system was cooled to −70 °C and the $^{31}P\{^1H\}$ NMR spectrum recorded at this temperature was the same as that when no styrene was added (Figure 4, d). The temperature was then increased to 120 °C once more and the reaction went to completion giving mainly the linear acid.

The System [PdCl$_2$(PhCN)$_2$]/dppb/$H_2C_2O_4$

Similar HPNMR experiments were performed with the [PdCl$_2$(PhCN)$_2$]/dppb/$H_2C_2O_4$ system at 60 bar CO, P/Pd = 4, and H^+/Pd = 25. The $^{31}P\{^1H\}$ NMR spectrum of the solution at 120 °C showed only free and oxidized dppb and a small signal due to the sparingly soluble [PdCl$_2$dppb] complex at δ = 28. When styrene was added to the system, no activity was observed. After one week, a small broad signal had appeared at δ = 16 in the room temperature $^{31}P\{^1H\}$ NMR spectrum. This signal was similar to that for the Pd(OAc)$_2$ system (Figure 4, c), where a small amount of the linear acid was observed. This may explain the fact that the [PdCl$_2$(PhCN)$_2$]/dppb system requires high pressures and temperatures in the catalytic experiments.

In conclusion, for the Pd(OAc)$_2$/dppb system palladium hydride species have been observed at high temperatures in the presence of carbon monoxide. On the other hand, monophosphane systems need chloride ions to stabilize the hydride species. At 20 bar CO, an acyl complex and the hydride species were observed by ^{13}C NMR spectroscopy. In the presence of palladium species, the occurrence of monooxidized, monocoordinated diphosphanes cannot be discarded, but the regioselectivity has invariably been found to favour the linear acid. The fact that some enantiomeric excess was seen with chiral diphosphanes means that some diphosphane remained coordinated as a chelate.[23]

Discussion of the Catalytic Cycle

The key questions to be answered concerning the catalytic cycle, focussing on the hydroxycarbonylation of styrene, are:

− Is the starting point a palladium hydride or a palladium alkoxycarbonyl species?

− How does the regioselectivity relate to the ligand, anion, and solvents?

Of the two proposed mechanisms, most researchers agree that the hydride mechanism is more common than the alkoxycarbonyl path in the alkoxycarbonylation of alkenes

with palladium systems. However, the involvement of alkoxycarbonyl species cannot be discarded as they are stable intermediates.[20] We must distinguish between hydroxycarbonylation and alkoxycarbonylation, as these reactions may have different characteristics. The prevailing mechanism for methoxycarbonylation is the hydride mechanism, but firm evidence has been presented for the occurrence of the methoxycarbonyl species as well. As examples, we mention double methoxycarbonylation leading to succinates,[67,68] the formation of methyl methacrylate from propyne,[120] and the formation of diesters during polyketone formation.[69] In two of these cases there is no choice, and the methoxycarbonyl species is the putative starting point. On the other hand, as pointed out by Sperrle and Consiglio,[121] it is difficult to present direct experimental evidence for either mechanism for the reactions producing monoesters or acids. For the very fast methoxycarbonylation of propene in methanol using alkyl diphosphanes, it was suggested[122,123] that palladium hydrido species were the starting points of the catalytic cycle as they were observed besides alkyl and alkanoyl species in separate NMR spectroscopy studies. Similar results have been reported[29] for the hydroxycarbonylation of propene in water using palladium complexes of tppts. However convincing it might seem though, it should be borne in mind that, strictly speaking, this remains circumstantial evidence. As we will discuss below, even kinetic measurements may not necessarily lead to clear-cut experimental evidence.

In the present study, like previous authors, we have observed palladium hydride intermediates and palladium acyl intermediates in the HPNMR experiments. The presence of hydroxycarbonyl species (or alkoxycarbonyl species[122,123]) below the detection limit responsible for the activity of the system is less likely because previous reactivity studies have shown that the alkoxycarbonyl species is less reactive than the hydride species.[16,87] This brings us to an important difference between alkoxycarbonylation and hydroxycarbonylation. The latter involves the PdCOOH fragment, which is highly unstable and rapidly degrades to palladium hydride and carbon dioxide. In the presence of oxidizing agents, divalent palladium dominates during the methoxycarbonylation, which leads to methoxycarbonyl species as the initiating group, provided that the system is anhydrous.[33,123] Tooze et al. reported an exception to this, a hydride being central to the catalytic cycle in the presence of an oxidizing agent, but it was not explicitly mentioned that this system was anhydrous. In the presence of water, the hydroxycarbonyl palladium species forms and hence palladium hydride will start the sequence.[16,122,123]

There are many other ways by which the palladium hydride species can be formed: (a) by β-elimination from the [PdCH(Ph)CH_2COOH] intermediate,[21] (b) by the formation of diacids, i.e. double carbonylation (the absence of minute amounts of these by-products in our experiments, as previously reported in catalytic experiments,[23] is incompatible with the presence of metal−carboxylic acid intermediates), (c) by reduction of phosphanes, (d) by addition of H_2, and (e) by β-elimination from [PdOCH_2R] species.[9,121] The deuterium exchange between the alkene and ROD found during the alkoxy- and hydroxycarbonylation[106,109,110] can only occur through reversible alkene insertion into a Pd−D bond, which strongly supports a reaction mechanism involving this step as well. The reversibility has implications for the regio- or enantioselectivity, as we will see below.

The regioselectivity and stereoselectivity have previously been discussed by Consiglio.[101,121] From the regioselectivity, it was concluded that the insertion of styrene into a metal−acyl bond leads to branched products, while its insertion into a metal hydride leads to linear products.[94,101,112] It is tempting to apply this finding to hydrocarboxylation as well. For the present systems, this is not the case as both the monodentate ligand systems, leading to mainly branched acid, and the bidentate ligand based systems, leading to mainly linear acid, imply insertions of styrene into a palladium hydride fragment. It has been argued[121] that insertion into a palladium hydride causes less steric constraints than insertion into a palladium alkoxycarbonyl species, and thus a lower stereospecificity can be obtained for the former. Indeed, high enantioselectivities were obtained in the formation of succinate.[67] This would make stereoselective hydroxycarbonylation difficult to accomplish. On the other hand, insertion of styrene into a palladium hydride bond may bring the aryl substituent in close proximity to a *cis* ligand, if this were a bulky and/or chiral ligand. We have previously reasoned that this steric interaction would stimulate the formation of linear products, which indeed seems to be the case for *cis* bidentate phosphane catalysts. A second problem arises from the reversibility of the insertion reactions. Alkene insertion is reversible, but so may be the insertion of carbon monoxide. If this were so, and the nucleophilic attack of water on the acyl group were to play a role in determining the overall rate, the selectivities under Curtin−Hammett conditions would be determined by all the rates and concentrations. In other words, the selectivities are determined by the differences in the overall final barriers. This may explain the low enantioselectivities obtained in many instances. It also complicates the discussion of the regioselectivity, as one pathway may involve complete equilibration while another may not.

Insertion reactions of alkenes and carbon monoxide using cationic palladium catalysts in alcohols and water may give rates of tens of thousands of turnovers per hour at 100 °C or even below.[29,87] The oxalic acid based systems are several orders of magnitude slower, for which there may be a number of reasons. Firstly, sites may be blocked by coordinating anions or by excess phosphanes. Secondly, low concentrations of alkenes may be found, especially in biphasic reactions.[29] Thirdly, palladium may be present in a state other than the required PdH^+ species, for example as Pd^0 species or as inactive dimers. Populating resting states of the latter two types diminishes the reactivity of the system, as we reported above. Stable palladium hydrides are obtained when two phosphanes occupy *cis* positions with respect to the hydride. We found that monophosphanes do indeed provide the fastest catalysts and the diphosphanes

provide much slower catalysts in the oxalic acid system.[23] In line with this, bidentate phosphanes having wide bite angles, which can also form *trans* complexes, give the most effective catalysts amongst the group of bidentate ligands.[23] Alkylphosphanes should give more stable hydride species as well, but in this system they show no activity and other side reactions must be followed, such as phosphonium salt formation perhaps.

Strong acids and polar media shift the equilibrium (Scheme 5) between Pd^0 and PdH^+ to the right. Indeed, high activities can be obtained[29,102] in water when soluble alkenes such as ethene and propene are used, but naturally this is not the case for styrene. Non-coordinating anions (i.e. the conjugate bases of strong acids) are also preferred in order to enhance coordination of alkenes and CO. Nevertheless, chloride has often been found to give the best results,[40] which may perhaps be ascribed to the higher stability of palladium hydrides when chloride anions are present. Acidic systems have an intrinsic drawback. If the nucleophilic attack on the acyl-palladium species is indeed rate determining, the strongest nucleophile present is water itself rather than the more nucleophilic hydroxide. This may be compared the very fast reaction of acyl palladium species and methoxy anions observed by Tóth.[16]

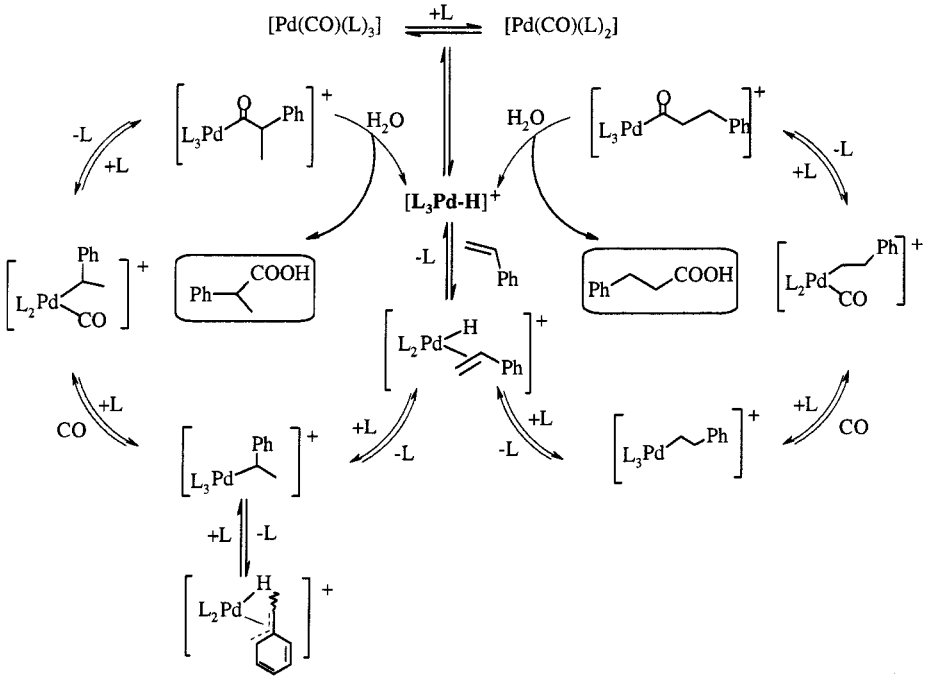
In an attempt to bring together the previously discussed reports and our in situ HPNMR study, we have summarized the catalytic cycle for the hydroxycarbonylation of styrene in Scheme 16.

A pre-equilibrium between different Pd^0 species bearing phosphane and carbon monoxide ligands is proposed; the stabilities of these species depend on the nature of the acidic medium and the phosphorus ligands, as demonstrated in the HPNMR spectra of the $Pd(OAc)_2/PPh_3/H_2C_2O_4$ system (Figure 1). This Pd^0 species can be formed by the methods discussed above, by oxidation of the phosphane,[27,28] or in the presence of CO and H_2O.[8,29] Because the acid used (AcOH) is not very strong, little hydride will be formed.

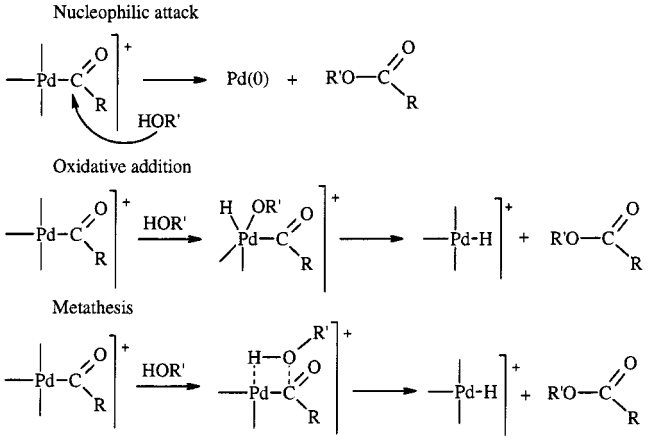
The insertion of styrene into the palladium hydride bond leads to two alkyl isomers, which can interconvert through β-elimination. Previous catalytic experiments,[85] kinetic studies,[106] and deuterium labelling methods[109,110] have demonstrated the occurrence of this β-elimination reaction.

For the branched palladium alkyl intermediate, stabilization through the formation of π-benzylic species[53,63] must also be taken into account. Thus, the regioselectivity may not yet be determined at this stage. The alkyl-alkanoyl equilibrium may reside on the side of the alkyl species, particularly for those π-benzylic species for which the insertion may be relatively slow, as has also been found for allyl palladium species.[124] The palladium acyl intermediates are formed by the insertion of carbon monoxide into the palladium−alkyl bond. The equilibrium between the palladium hydride species and palladium acyl species proposed in this catalytic cycle is in agreement with the reversibility of the CO insertion in the palladium alkyl bond, which was also verified by catalytic experiments.[71,77] Equilibration may even extend all the way between Pd^0 species and palladium acyl intermediates during hydroxycarbonylation (Scheme 17). Depending on the conditions, it seems likely that linear alkyl formation is irreversible whereas branched alkyl formation is reversible, even further down to alkanoyl formation. At least the trend will be in this direction.

Indeed, in the hydroxycarbonylation of styrene, kinetic and deuterium labelling studies have demonstrated that for the branched alkyl intermediate β-elimination is faster than



Scheme 16. Proposed catalytic cycle for the hydroxycarbonylation of styrene



Scheme 17. Different proposals for the final step in the palladium carbonylation reactions

CO insertion, but that for the linear alkyl intermediate carbonylation is faster than β-elimination.[106,109,110]

In the HPNMR experiments using ^{31}P as the probe, we could not establish whether or not equilibration was operative all the way from the hydride to the alkanoyl, because exchange of the phosphane ligand probe between the free and complexed species proved to be the fastest reaction, thus prohibiting the observation of exchange of CO or styrene. Phosphane exchange occurs on the NMR time scale and if reversible insertions were to have rates of only a few percent of that of this exchange, they would still be faster than the overall catalytic process.

We consider next the regioselectivity. The HPNMR experiments and the previously described kinetic studies[104,105,108] have shown that regioselectivity is dependent on the pressure and temperature. High temperatures and low CO pressures favour formation of the linear acid as these conditions favour β-elimination from the stabilized π-benzylic species to give the linear palladium alkyl species.

Previously, we have offered a tentative explanation for the different regioselectivities of monophosphanes and diphosphanes. The reason for the high degree of linearity achieved with diphosphane catalysts is not the higher temperatures used. Catalytic experiments performed under identical conditions (20 bar CO, 150 °C, and P/Pd ratio = 4) with PPh_3 as the monophosphane led to a branched/linear ratio of 73:27, while the ratio was 28:72 for the diphosphane dppb.[23] We surmise that *cis*-coordinated diphosphanes versus *trans*-coordinated monophosphanes could be the key to regioselectivity control. In a *cis*-diphosphane complex, a strong interaction between the moieties on the phosphane and the aryl group of styrene leads to the formation of linear alkyl-palladium species. Reversibility plays an important role and we still have insufficient knowledge about this. Branched alkanoyl species are probably slightly more stable than linear ones, but nucleophilic attack on the latter may be faster and thus the regioselectivity under Curtin−Hammett conditions is hard to predict.

Complexes containing fewer phosphanes coordinated to the palladium form more of the branched acid.[104,105] Similarly, more hindered alkenes afford the linear acid.[99] In conclusion, the regioselectivity remains an extremely delicate issue. It is still difficult to predict given the complex kinetics involved, with rates depending on the pressure, temperature, counteranion, and phosphorus ligand.

Finally, the mechanism of the last step is not so clear and is often neglected. For the palladium carbonylation reactions, nucleophilic attack of $R'O^-$ would generally lead to Pd^0 and H^+, with oxidative addition occurring as the next step. Alternatively, the oxidative addition of R′OH to Pd^{II}, in other words a sort of α-bond metathesis, may be considered (Scheme 17).

All evidence for the recently published, fast catalyst points to the fact that the hydrolysis step is rate determining. For the many systems mentioned above, the rates vary by many orders of magnitude. On the one hand, this may be due to the intrinsic effects of the ligands, anions, and solvents on the rate, but on the other hand it may also be due to the effects these factors have on the resting states, including those outside of the catalytic cycle. Monodentate ligands give the fastest reactions.

Polyketone catalysis employing a variety of *cis*-chelating bidentate ligands shows that insertion reactions are fast (several thousands of insertions per hour), while termination at 80−100 °C occurs only several times per hour. The latter depends on the time that the growing chain end exists as an alkyl or an acyl species, but at high CO pressures appreciable amounts of acyl palladium chain ends are present.[78] Thus, an acyl species *trans* to a phosphane ligand reacts relatively slowly[79] with water or an alcohol as the nucleophile, whereas insertion reactions are fast. In monophosphane systems, the group *trans* to acyl is a solvent molecule and in this case insertion reactions are slower and the acyl group is more susceptible to nucleophilic attack due to the smaller *trans* influence.

Conclusion

The reports that we have reviewed herein have shown that the hydroxycarbonylation reaction involves a palladium hydride mechanism and that palladium hydride, palladium alkyl, and palladium acyl are the intermediates of this reaction.

Previous kinetic and deuterium labelling studies proved the involvement of a β-elimination reaction. We have now performed in situ HPNMR experiments on different systems. Pd^0, palladium hydride, and palladium acyl species were observed during the hydroxycarbonylation reaction. We propose an equilibrium between the Pd^0 and the palladium acyl species in a catalytic cycle.

Control of the regioselectivity of the hydroxycarbonylation has proved to be dependent on the phosphorus ligand, the counteranion, the pressure, and the temperature. The regioselectivity remains a complicated issue and equilibration between several intermediates seems likely to play a major role, except in the case of diphosphane systems, where steric hindrance leads to predominantly irreversible, linear alkyl formation.

Rational Design of Open-Framework Coordination Solids − Synthesis and Structure of $[Co_5(OH)_2\{1,2,4,5\text{-}(O_2C)_4C_6H_2\}_2(H_2O)_4]\cdot xH_2O$

Siegfried O. H. Gutschke,[a] Daniel J. Price,[b] Annie K. Powell,[a] and Paul T. Wood*[c]

Keywords: Synthesis design / Cobalt / Carboxylate ligands / Mesoporous materials

A strategy for preparing open-framework coordination solids by hydrothermal synthesis has been developed and tested by the synthesis of a new porous cobalt carboxylate which can be dehydrated by heating to give a material with coordinatively unsaturated metal ions.

A number of groups are developing methods for synthesising open framework materials incorporating transition metals. These strategies include methods which aim to modify premade materials[1−8] as well as ones designed to construct the framework with the transition metal already incorporated.[9−19] Amongst the first class are syntheses in which the transition metal is substituted into a preformed zeolite,[1−3] or a metal complex is encapsulated within zeolite channels (ship-in-a-bottle catalysts)[4−7] and chemical modification of mesoporous (e.g. MCM-41) materials.[8] The second class includes the synthesis of molybdenum and vanadium phosphates,[9,10] zeolite-like cobalt (alumino) phosphate networks[11] and metal-organic coordination frameworks.[12−20] It is hoped that these materials will have the stability of zeolites with enhanced catalytic activity.

Our recent synthesis[20] of $[Co_3(OH)_2(C_4O_4)\cdot 3H_2O]$ has shown that microporous transition-metal-containing species can be produced based on metal hydroxide structural members joined together by anionic ligands. These materials can be viewed as being made up from assemblies of tubes with rectangular or diamond-shaped cross sections in which the ligands are the walls of the tube and the metal hydroxide chains form the corners. From the isolation of this material we postulated that the formation of open framework materials could be encouraged by a number a factors and we have now illustrated the usefulness of this theory by the preparation of the title compounds.

The factors which are important in the rational synthesis of open framework coordination solids relate to both the types of structural members (i.e. ligands) which can be used and also the way in which the voids can be stabilised during synthesis. The ligand should be capable of forming part of the metal hydroxide backbone and it should have a central portion which will act as part of the channel wall (Figure 1). Therefore we should be able to control the dimensions of the channel by choosing ligands with different distances between the donor groups. The channel structure can be stabilised by filling the lacunae with water molecules held in place by hydrogen bonds, particularly to bridging hydroxide ligands but also to coordinated water. The formation of species containing bridging hydroxide ligands is therefore encouraged by the use of high pH conditions for these reactions.

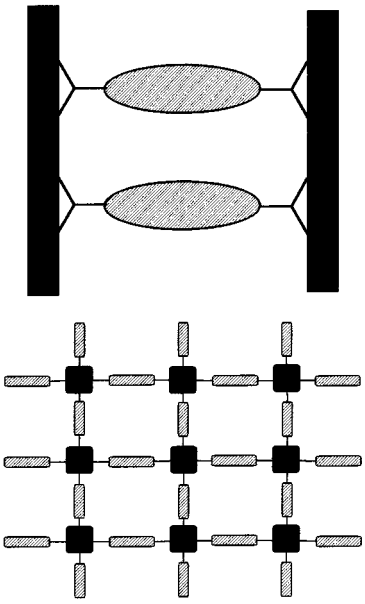

Figure 1. Schematic view of the construction of open-framework materials; black areas represent metal-oxo strips, shaded areas represent ligand "spacer" regions

The structure[21] (Figure 2) of the title compound is built around a $Co_5(\mu_3\text{-}OH)_2$ "bow-tie" cluster in which two metal triangles have a common vertex. Each triangle has a μ_3-OH at its centre and is held together by 1,3-bridging carboxylates around the periphery in a manner similar to the well-known $[M_3(O)(O_2CR)_6L_3]$ compounds. The two carboxylate functions responsible for the Co(1)−Co(2) and

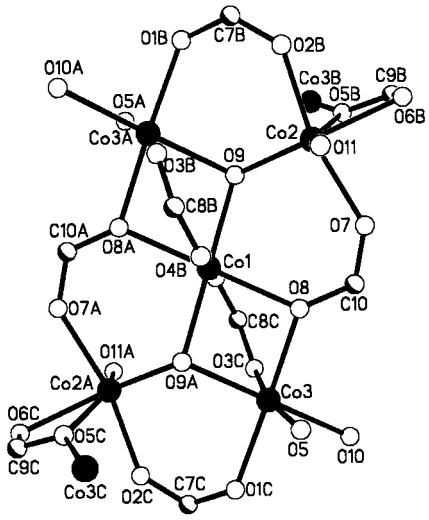

Figure 3. One of the $CO_5(OH)_2$ clusters with associated carboxylate groups; cobalt atoms from neighbouring clusters (Co3B and Co3C) have also been included

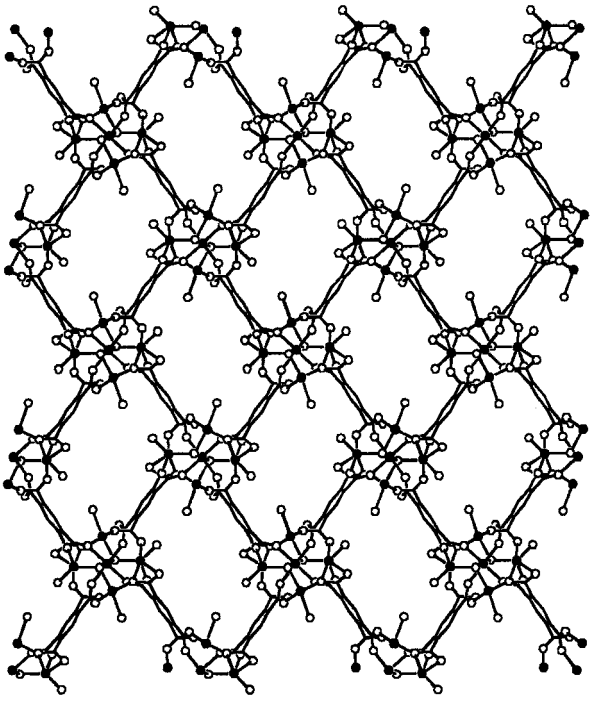

Figure 4. Packing diagram parallel to [100] with the non-coordinated water molecules omitted

Co(2)−Co(3) bridges lie close to the Co_3 plane whilst the third, Co(1)−Co(3), lies perpendicular to it. There is a further 1,1-carboxylate bridge between Co(1) and Co(3) which is common to the two fused triangles. The different types of bridging between metal atoms leads to triangles which are close to isosceles. The two edges with only OCO bridges are similar in length whereas the edge with two single-atom bridges is significantly shorter. The three crystallographically distinct metal atoms within each triangle have significantly different coordination environments. The ligand lacks any symmetry, two carboxylates on one side are 1,3-bridging and the other two acid groups together bridge four metals in a more complex arrangement. The Co_5 units are joined to adjacent clusters by four 1,1-carboxylate bridges to form a metal hydroxide-carboxylate backbone (Figure 3) running along the crystallographic *a* axis. The metal hydroxide-carboxylate rods are connected to one another by the ligand to form channels with an approximately rectangular cross-section (Figure 4). The dimensions of the rectangle are defined by the crystallographic *b* and *c* axes i.e. 16.5 × 14.6 Å. Allowing for the van der Waals radius of carbon this gives maximum dimensions of the channel of approximately 13 × 11 Å. A calculation using the PLATON[22] suite of programs shows that the framework occupies only 54.4% of the volume of the unit cell and therefore 45.6% is available for occupation by water. This compares with a free volume of 36.6% for $[Co_3(OH)_2(C_4O_4)_2{\cdot}3H_2O]$ showing that the use of larger spacer ligands not only leads to larger cavities but also to a cavity occupying a greater proportion of the material's volume. There is significant encroachment of the metal backbone into the channels, particularly for the water ligands O(10) and O(11), which hydrogen bond to some of the water molecules within the channels. There are five crystallographically distinct sites within the channels giving a maximum of 10 equivalents of

water for each Co_5 unit. At room temperature the thermal parameters of the oxygen atoms suggest that most of these sites are not fully occupied. Refinement of the X-ray data was most successful using a model which has 7.5 molecules of lattice water per Co_5 unit giving a total of 11.5 molecules of water (coordinated plus uncoordinated) per formula unit. This is in reasonable agreement with calculations using the "Squeeze" subroutine in PLATON which gives a value of 171 electrons per unit cell which corresponds to 8.5 molecules of lattice water and a total of 12.5 molecules per formula unit.

TGA studies show a gradual loss of 18% of the original mass from just above room temperature to 130 °C corresponding to 10.8 mol of water per formula unit. This suggests loss of at least half of the coordinated water, producing coordinatively unsaturated cobalt ions lining the channels which are then available as catalytic sites. The change in coordination number of cobalt is confirmed by a distinct colour change from red to blue on dehydration. The dehydrated material does not give good powder diffraction patterns showing that crystallinity is lost; however the connectivity of the lattice is maintained. When the compound is re-exposed to the atmosphere the colour change is reversed very rapidly to give a material with an IR spectrum identical to the original material and an X-ray powder diffraction pattern consistent with the single crystal structure.

In conclusion we have shown that this is a sound strategy for preparing open-framework solids and we are now applying it to other systems.

Experimental Section

Sodium hydroxide (100 mg, 2.5 mmol) was dissolved in H_2O (6 mL). A 4 mL portion of this solution was added to a solution of $CoCl_2{\cdot}6H_2O$ (250 mg, 1.9 mmol) in H_2O (2 mL) to give a blue precipitate of cobalt hydroxide. Solid 1,2,4,5-$(HO_2C)_4C_6H_2$ (100 mg, 0.4 mmol) was added to the remaining 2 mL of alkali solution. The two slurries were combined to give a molar ratio metal:ligand:base of 8:3:19 and a pH of 8.5. The mixture was placed in a 23 mL Teflon-lined autoclave and heated to 190 °C for 48 hours. The reaction vessel was cooled over a period of 4 hours and the product isolated by filtration and purified by repeated cycles of treatment of an aqueous slurry in an ultrasonic bath followed by decanting.

$[Co_5(OH)_2\{1,2,4,5\text{-}(O_2C)_4C_6H_2\}_2(H_2O)_4]{\cdot}xH_2O$ was obtained as red needles in a yield of 85 mg (39% based on ligand). – $C_{20}H_{34}Co_5O_{32}$: calcd. C 22.2, H 3.2; found C 21.7, H 2.7. Isostructural materials containing nickel (green microcrystalline powder) and zinc (colourless crystals) may also be prepared in the same way.

Acknowledgments

[^{1}H, ^{15}N] NMR Studies of the Platination of Phosphorothioate Nucleotides – Monofunctional Sulfur Adducts versus Macrochelation

Nicole A. Kratochwil,[a] John A. Parkinson,[a] Cheryl Sacht,[a][‡] Piedad del Socorro Murdoch,[a] Tom Brown,[b] and Peter J. Sadler*[a]

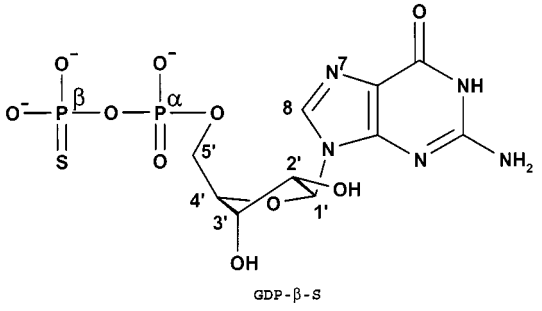
Keywords: Chelates / Drug research / Nucleotides / Sulfur / Platinum

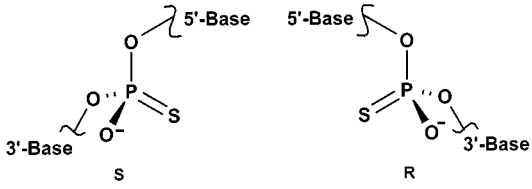
cis-[$PtI_2(^{15}NH_3)_2$] reacts rapidly with guanosine-5′-*O*-(2-thiodiphosphate) (GDP-β-S) to form a macrochelate in which Pt bridges the phosphorothioate S and guanine N7 atoms. Phosphorothioate(α-S)-containing self-complementary decamer oligonucleotides give rise to relatively long lived S-bound monofunctional adducts, the fate of which is sequence dependent.

Platinum complexes are now widely used in cancer chemotherapy.[1,2] In order to reduce toxic side effects it would be advantageous to target Pt to specific DNA base sequences on specific genes. Such a strategy is currently being explored by Lippert, Leng et. al.[3] using oligonucleotides labelled with *trans*-Pt^{II} diam(m)ine complexes, which subsequently cross-link guanine bases on the two strands. Since Pt^{II} drugs are known to have a high affinity for sulfur ligands[4] an alternative strategy might involve antisense or antigene recognition of the target gene using phosphorothioate-labelled oligonucleotides.[5–8] Phosphorothioate nucleotides are already of much clinical interest in view of their activity against HIV, for example.[9] One of our own interests is in targeting photoactivatable prodrugs to specific sites on DNA for potential photodynamic therapy.[10,11]

In the present work, we have studied the pathways and products from reactions of ^{15}N-labelled *cis*-[$PtI_2(^{15}NH_3)_2$] with the phosphorothioate guanosine-5′-*O*-(2-thiodiphosphate) [GDP-β-S, Chart 1] and three decamer oligonucleotides by NMR spectroscopy.

GDP-β-S was chosen for the study because of its ready availability. The oligonucleotides possess the self-complementary sequence 5′-TATGGCCATA-3′ (**I**) containing one phosphorothioate group either between the GG sequence 5′-TAT**GsG**CCATA-3′, **Is**, or between the CC sequence 5′-TATGG**CsC**ATA-3′, **IIs**. For comparison we also investigated the reaction of the diiodo Pt^{II} complex with the unmodified decamer **I**. Iodoplatinum complexes are also of interest because of their potential photoreactivity.[10,11]





Reactions of *cis*-[$PtI_2(^{15}NH_3)_2$] (0.8 mM) with guanosine-5′-*O*-(2-thiodiphosphate) [GDP-β-S] in a 1:1 molar ratio were investigated by ^{1}H NMR spectroscopy at pH 6.94 and 310 K for a period of 24 h. Within minutes, the ^{1}H NMR signals for *cis*-[$PtI_2(^{15}NH_3)_2$] and H8 of GDP-β-S decreased in intensity. After 5 h the reaction was finished and one major product was formed, giving rise to a singlet at δ = 8.99, which was assigned to H8 of Pt-bound GDP-β-S. A high-frequency shift for the H8 resonance of 5′-GMP is typical of metal coordination to the N7 of 5′-GMP (free 5′-GMP: δ = 8.17; Pt-bound 5′-GMP: δ = 8.52). The large high-frequency shift of 0.82 ppm observed for the H8 resonance is notable. The doublet for H1′ shifted to higher frequency from δ = 5.93 to 6.06 and the ^3J(H1′-H2′) coupling constant was dramatically reduced from 6.05 to 2.75 Hz. This suggested a major change in the sugar conformation. The signal for H2′, however, shifted to low fre-

quency from δ = 4.84 to 4.52. The assignments of the sugar proton resonances were confirmed by homonuclear ^{1}H-^{1}H-{^{15}N}-DQF-COSY NMR spectroscopy (Table S1 in the Supporting Information). The 2D [^{1}H, ^{15}N] HSQC NMR spectrum of the final product showed the presence of two cross-peaks with ^{15}N/^{1}H shifts of δ = −67.85/4.18 and −46.35/4.00, compatible with NH_3 *trans* to N and S, respectively, in square-planar Pt^{II} complexes.[12] The 1D ^{1}H-{^{15}N} NOE NMR difference spectrum of this product showed that irradiation of H8 increased the signal intensity of H3′ by ca. 5% and H2′ by ca. 4%, which suggested that the flexible sugar ring of free GDP-β-S changed to a more rigid structure with a C3′-endo sugar geometry in the Pt-bound GDP-β-S product. A model that is consistent with all of these observations is shown in Figure 1.

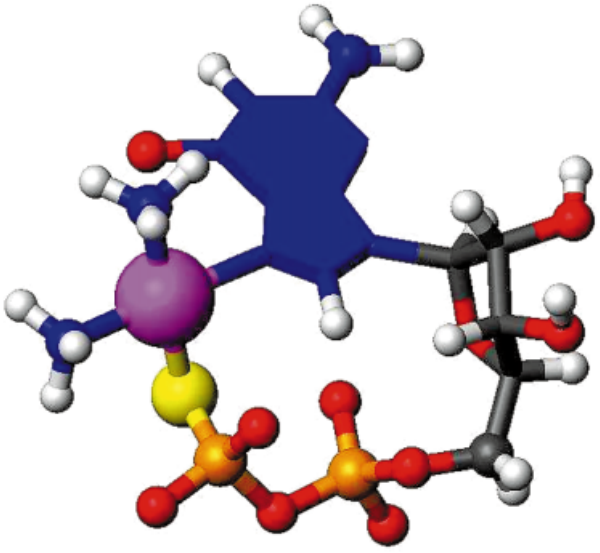

Figure 1. Model of the macrochelate complex *cis*-[$Pt(NH_3)_2$(GDP-β-S)-*N7,S*], the major adduct from the reaction of *cis*-[$PtI_2(NH_3)_2$] with the phosphorothioate GDP-β-S as deduced from NMR spectroscopic data; the macrochelate is formed by Pt binding to the S and N7 atoms of GDP-β-S

The model contains a square-planar *cis*-{$Pt(NH_3)_2$}$^{2+}$ centre bound to *N*7 and the S of GDP-β-S, thereby forming a 13-membered macrochelate ring. The composition was confirmed by ESI-MS analysis of the product of the reaction between *cis*-[$PtI_2(^{15}NH_3)_2$] and GDP-β-S (1:1 molar ratio, 100 μM) after 4 h incubation at 295 K. The negative ion electrospray mass spectrum of the product showed a cluster of ions related to the isotopic distribution of Pt, P and N at *m*/*z* = 687.1 associated with the molecular ion [$Pt(^{15}NH_3)_2C_{10}H_{12}N_5O_{10}P_2S]^-$ (calcd. 687.0) (Figure S1 in the Supporting Information), which corresponds to the macrochelate [$Pt(^{15}NH_3)_2$(GDP-β-S)*S,N*7].

Studies were also carried out to investigate the course of the reactions of *cis*-[$PtI_2(^{15}NH_3)_2$] with oligonucleotide duplexes containing a phosphorothioate group. The self-complementary oligonucleotides **I**, **Is** and **IIs** were shown to exist as duplexes in solution by the presence of imino-proton ^{1}H NMR resonances between δ = 12.00 and δ = 14.00. Reactions of *cis*-[$PtI_2(^{15}NH_3)_2$] (0.5 mM) with **Is** or **IIs** duplexes in a 1:1 molar ratio were studied by 2D [^{1}H, ^{15}N] HSQC NMR spectroscopy in 10 mM KH_2PO_4, 100 mM $KClO_4$, at pH 6.1 and 310 K for a period of 24 h. In this case the sulfur is located on the α-phosphate in contrast to the β-phosphate in GDP-β-S.

For the reactions with **Is**, the ^{15}N/^{1}H cross-peak at δ = −52.12/3.99 of *cis*-[$PtI_2(^{15}NH_3)_2$] in the 2D [^{1}H, ^{15}N] HSQC NMR spectrum had already disappeared after 4 h and four new major cross-peaks were observed (Figure 2). These peaks had ^{15}N/^{1}H chemical shifts of δ = −54.92/4.07 (**1**) and δ = −54.33/4.04 (**2**) consistent with NH_3 *trans* to I in square-planar Pt^{II} complexes, and δ = −45.97/4.24 (**3**) and δ = −46.05/4.22 (**4**), which are characteristic of NH_3 *trans* to S.[12] The intensities of cross-peaks **1**/**3** and **2**/**4** increased simultaneously and were comparable at all times, suggesting that they were due to the formation of two diastereomeric mono-iodo, mono-sulfur Pt^{II} oligonucleotide adducts, {$Pt(^{15}NH_3)_2$}-**Is**A and {$Pt(^{15}NH_3)_2$}-**Is**B, respectively. Interestingly, the cross-peaks for {$Pt(^{15}NH_3)_2$}-**Is**A, **1**/**3**, were about twice as intense as the cross-peaks **2**/**4** for {$Pt(^{15}NH_3)_2$}-**Is**B, indicating that {$Pt(^{15}NH_3)_2$}-**Is**A is the favoured product.

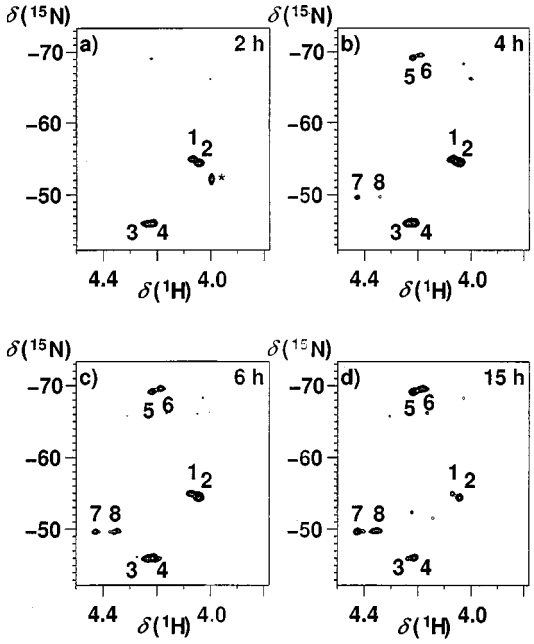

Figure 2. 2D [^{1}H, ^{15}N] HSQC NMR spectra showing the time course of the reaction between *cis*-[$PtI_2(^{15}NH_3)_2$] and **Is** at 310 K, pH 6.1: a) after 2 h; b) after 4 h; c) after 6 h; d) after 15 h; the cross-peak corresponding to the starting material is highlighted by an asterisk in a)

After 6 h, the intensities of peaks **1**/**3** and **2**/**4** decreased by ca. 27% and four new cross-peaks appeared, with intensities equivalent to the loss for signals **1**/**3** and **2**/**4**. The ^{15}N/^{1}H chemical shifts of δ = −68.98/4.22 (**5**) and δ = −69.45/4.19 (**6**) are consistent with NH_3 *trans* to N in Pt^{II} complexes, and those of the other two cross-peaks of δ = −49.69/4.43 (**7**) and δ = −49.80/4.35 (**8**) are compatible with NH_3 *trans* to S (Table S2 in the Supporting Information). These observations suggest that the mono-Pt adduct

with Pt^{II} bound to S is converted into a bifunctional-Pt adduct in which *cis*-$\{Pt(^{15}NH_3)_2\}^{2+}$ is bound to the phosphorothioate S and to N7 of a guanine base. Interestingly, the mono-iodo, mono-S Pt adducts (cross-peaks **1/3** and **2/4**) were still observable after several days, and are therefore long-lived.

We also studied the above reaction of *cis*-$[PtI_2(^{15}NH_3)_2]$ with **Is** by ^{31}P NMR spectroscopy. Oligonucleotide **Is** gave rise to two close ^{31}P NMR peaks at $\delta = 54.948$ and 54.446 due to the presence of two diastereomers (chiral P). These resonances decreased in intensity after the addition of the diiodo Pt^{II} complex, and a broad new multiplet appeared at $\delta = 41.06$. The large, low-frequency shift of the phosphorothioate ^{31}P resonance ($\delta = -13.8$) can be attributed to the direct coordination of P=S to Pt, as observed previously.[13,14] Any ^{195}Pt satellites appeared to be broadened beyond detection (by chemical shift anisotropy). The ^{31}P NMR chemical shifts of the resonances for the phosphate ^{31}P atoms of **Is** were little affected by the binding of Pt to the oligonucleotide.

The 2D [^{1}H, ^{15}N] HSQC NMR cross-peak for *cis*-$[PtI_2(^{15}NH_3)_2]$ had almost disappeared within 2 h of reaction with the oligonucleotide **IIs**, which contains the phosphorothioate group between the two cytosine residues (Figure S2 in the Supporting Information). Four new cross-peaks, **9/10** and **11/12** were then observed (^{15}N/^{1}H chemical shifts listed in Table S3 in the Supporting Information). The ^{15}N/^{1}H shifts of cross-peaks **9/10** and **11/12**) were similar to the intermediates giving rise to cross-peaks **1/3** and **2/4** in the reaction of *cis*-$[PtI_2(^{15}NH_3)_2]$ with **Is**. This suggested that two diastereomeric mono-iodo, mono-sulfur Pt^{II} adducts are also formed from **IIs** in a 2:1 (**9/10:11/12)** ratio. Surprisingly, the intermediates giving **9/10** and **11/12** for **IIs** were not as long-lived as they were during the reaction with **Is**. In particular the intermediate with cross-peaks **11/12** was short-lived compared to that with cross-peaks **9/10**. The rate of further reactions of these intermediates therefore appears to depend on the chirality at P. Cross-peaks **11** and **12** had disappeared completely after 12 h. After 8 h, five cross-peaks with ^{15}N/^{1}H shifts consistent with NH_3 *trans* to S (peaks **13**−**17**) and five cross-peaks with ^{15}N/^{1}H shifts consistent with NH_3 *trans* to N (peaks **18**−**22**; Table S3 in the Supporting Information) appeared simultaneously. This suggests that **9/10** and **11/12** undergo further reactions to form bifunctional Pt adducts in which *cis*-$\{Pt(^{15}NH_3)_2\}^{2+}$ is bound to S of the phosphorothioate and N from a base. After 12 h, two further species (cross-peaks **23**−**26**) were observed. These cross-peaks had similar ^{15}N chemical shifts to those for the products from the reaction of **Is**, indicating that *cis*-$\{Pt(^{15}NH_3)_2\}^{2+}$ is also bound to N and S. In all, about seven products appeared to form in this reaction, all of which were stable for 24 h (Table S3 in the Supporting Information) and contain Pt coordinated to S/N of the oligonucleotide. Over a longer period of time, it might be expected that some loss of coordinated NH_3 *trans* to S could occur.

For comparison, we followed the reaction of *cis*-$[PtI_2(^{15}NH_3)_2]$ with the unmodified oligonucleotide duplex **I** by 2D [^{1}H, ^{15}N] HSQC NMR spectroscopy (Figure S3 in the Supporting Information). After 10 h, three cross-peaks with similar ^{15}N/^{1}H shifts of $\delta = -68.19/4.50$, $-67.93/4.57$ and $-68.24/4.52$ were observed, consistent with NH_3 *trans* to N. This suggested that a bifunctional adduct was formed in which *cis*-$\{Pt(^{15}NH_3)_2\}^{2+}$ was bound to the N7 atoms of the two adjacent guanine bases. This is consistent with reported observations for *cis*-$\{Pt(^{15}NH_3)_2\}^{2+}$ binding to similar oligonucleotides.[15,16]

cis-$[PtI_2(^{15}NH_3)_2]$ reacts relatively rapidly with nucleotide phosphorothioates, initially at sulfur. In the case of the mononucleotide GDP-β-S, further reaction to form the S,N7 macrochelate was relatively rapid, whereas for the oligonucleotide **Is**, the *S*-bound monofunctional adducts were very long lived. Such macrochelation by Pt in phosphorothioate oligonucleotide duplexes appears to be at least partially stereoselective. Molecular modelling studies (Figure S4 in the Supporting Information) support the proposal of chelate formation by the duplex. Studies of the platination of phosphorothioate nucleotides have been reported previously,[8,13,14] but our work appears to provide the first evidence for Pt-S,N7 macrochelation. NMR evidence for O,N7 macrochelation has been reported for unmodified mono- and oligo-nucleotides.[17−19] The reaction pathways for phosphorothioate oligonucleotides appear to be highly dependent on the position of the sulfur atom. Our finding that monofunctional adducts of phosphorothioate oligonucleotides have considerable stability suggests that this might be a useful approach for the introduction of photo-active Pt−I centres into DNA and for antisense strategies.

Experimental Section

Materials: Guanosine-5′-*O*-(2-thiodiphosphate), GDP-β-S, was purchased from Aldrich and used without further purification. The oligonucleotides 5′-d(TATGGCCATA)-3′, **I**, 5′-d(TAT**Gs**G**C**CATA)-3′, **Is** and 5′-d(TATGG**Cs**CATA)-3′, **IIs**, were supplied by Oswel. *cis*-$[PtI_2(^{15}NH_3)_2]$ was synthesised according to previously described procedures[10] and was fully characterised by elemental analysis, NMR spectroscopy and FAB-MS.

ESI-MS: Atmospheric pressure ionization (API) negative ion electrospray mass spectrometry (ESI-MS) was performed using a Platform II mass spectrometer (Micromass, Manchester, UK). The mass spectra were obtained by injecting samples (concentration 100 μM in water) using an infusion pump with a flow rate of 0.48 mL/h. A source temperature of 65 °C and a drying gas flow rate of 450 $L \cdot h^{-1}$ were found to be suitable parameters for analysis. A potential of −3.17 kV was applied to the probe capillary and a cone voltage of −20 V over 100−1000 Da was used. The quadrupole was scanned at 100 $amu \cdot s^{-1}$. The acquisition and deconvolution of data were performed on a Mass Lynx (version 2.3) for Windows NT data system using the maximum entropy (MaxEnt) software algorithm. The mass accuracy of all measurements was within 0.1 *m/z* units.

NMR Spectroscopy: NMR spectroscopic data were acquired using a 500 MHz Bruker DMX NMR spectrometer according to previously described methods.[15] Typically 2D [^{1}H, ^{15}N] HSQC NMR spectra were acquired over a ^{1}H frequency width of 2 kHz and a

^{15}N frequency width of 3.55 kHz centred at δ = −55 relative to external $^{15}NH_4Cl$. 16 transients were acquired into 1024 data points for each of 256 t_1 increments. The total experiment time was typically 2 h for the acquisition of each 2D [^{1}H, ^{15}N] HSQC NMR spectroscopic data set. This was extended to 4 h (32 transients per t_1 increment) at later reaction times. $^{31}P\{^1H\}$ NMR spectra were acquired with 4096 transients over a frequency width of 50 kHz into 41662 data points (acquisition time 0.413 s). All NMR spectroscopic data were processed using Xwin-NMR version 2.0 (Bruker Ltd.).

pH Measurements: pH Measurements were made using a Corning 145 pH meter equipped with an Aldrich micro-combination electrode calibrated with Aldrich buffer solutions of pH 4, 7 and 10. Values of pH were adjusted with 1 M $HClO_4$ or NaOH as appropriate.

Synthesis and Chemistry of the 16-Electron Osmium Complex [OsBr(η^5-C_5Me_5)(P*i*Pr$_3$)]

Paul B. Glaser[a] and T. Don Tilley*[a]

Keywords: Osmium / Cyclopentadienyl ligands / Oxidative addition / Coordinative unsaturation

The isolable 16-electron half-sandwich Os complex [OsBr(η^5-C_5Me_5)(P*i*Pr$_3$)] has been synthesized and structurally characterized. This unsaturated complex binds N_2 reversibly at low temperature as determined by IR and multinuclear NMR spectroscopy. The reactions of the title complex with CO, H_2, $PhSiH_3$, and its thermolysis in C_6H_6 are reported.

The stable 16-electron complexes [RuClCp*(PR$_3$)] (Cp* = η^5-C_5Me_5; R = *i*Pr, Cy) were reported in 1988.[1] These complexes, prepared by addition of the appropriate phosphane in one step from the tetrameric ruthenium species [RuClCp*]$_4$,[2] have proven to be valuable starting materials for the synthesis of various silyl,[3] silene,[4] and metallacyclic[5] complexes. Analogous 16-electron complexes of osmium are also expected to be useful synthons, but they have yet to be reported. The synthesis of coordinatively unsaturated [OsXCp*(PR$_3$)] species would seem to require a method other than that used to prepare the related ruthenium complexes, as the osmium analog of [RuClCp*]$_4$ is not known. However, Esteruelas and co-workers have recently reported[6] the preparation of an 18-electron complex, [OsClCp(P*i*Pr$_3$)$_2$], which dissociates a phosphane ligand in solution to form an unsaturated species that activates E−H bonds (E = C, Si, Ge, Sn).[7,8]

Addition of two equiv. of triisopropylphosphane to a stirred CH_2Cl_2 solution of [$Os_2Br_4Cp^*_2$][9] effected a rapid color change from dark brown to black-cherry red. Removal of all volatile components of the mixture, washing with ether, and drying under vacuum afforded a pale pink-red solid which was soluble in toluene and dichloromethane. Three broad, featureless resonances spread over a range of greater than 30 ppm in the ^{1}H NMR spectrum (CD_2Cl_2, room temperature) were consistent with a paramagnetic 17-electron complex formulated as [OsBr$_2$Cp*(P*i*Pr$_3$)] (**1**); however, a CH_2Cl_2 solution of **1** gave no detectable EPR signal at room temperature, and only below 100 K was an extremely broad signal (with no detectable hyperfine coupling) observed. A Signer molecular weight determination[10,11] (room temperature, CH_2Cl_2 solution) confirmed the monomeric nature of the complex in solution.

Treatment of a THF solution of **1** with a stoichiometric amount of 0.3% Na/Hg amalgam resulted in a striking color change from red-black to purple. Removal of all volatile materials and recrystallization from pentane at −78 °C provided dendritic, translucent, red-orange crystals. Upon isolation and warming to room temperature, these crystals became purple and opaque. Repeated attempts to obtain X-ray diffraction data on these purple crystals failed. However, multinuclear NMR spectroscopy and combustion analysis allowed characterization of this compound as the 16-electron species [OsBrCp*(P*i*Pr$_3$)] (**2**).

To characterize the origin of the temperature-dependent color change associated with **2**, a [D_8]toluene solution of **2** was cooled to −78 °C under an atmosphere of nitrogen. This resulted in a color change from purple to red-orange. Variable temperature NMR spectroscopy experiments with **2** in [D_8]toluene under N_2 revealed disappearance of the ^{31}P{^{1}H} resonance for **2** as the temperature was lowered, and the appearance of two resonances at δ = 8.71 and 8.10. After this sample was thoroughly degassed with a series of freeze-pump-thaw cycles, cooling to −78 °C did not afford a color change. The NMR spectroscopic properties of this degassed sample were essentially invariant from room temperature to −80 °C. On the basis of these observations, it was postulated that **2** reversibly binds N_2 at low temperature to give the terminal and bridging dinitrogen complexes **3** and **4**, respectively. The appearance of a relatively strong band at 2074 cm^{-1} in the low-temperature solution IR spectrum acquired under an N_2 atmosphere confirmed the presence of the end-on bound N_2 species **3**.[12] This diagnostic band did not appear when the solution was cooled under an argon atmosphere. When a sample of **2** in [D_8]toluene was cooled and sealed under an atmosphere of $^{15}N_2$, three resonances were observed in the ^{15}N NMR spectrum at low temperature, consistent with both terminal binding (δ = −47.9 and −112.4) and a bridged structure (δ = −133).[13,14] The ^{31}P{^{1}H} resonances associated with these structures also exhibited coupling to ^{15}N.

Concentration and cooling of a diethyl ether solution of **2** under argon afforded large purple-black crystals suitable for an X-ray diffraction study. The solid-state structure of **2** is shown in Figure 1. The Cp*(centroid)−P−Os−Br unit is planar within experimental error and there is no evidence for agostic C−H interactions or close intermolecular contacts. It is noteworthy that samples of **2** obtained by recrystallization under N_2 had a completely different morphology to those crystallized under argon.

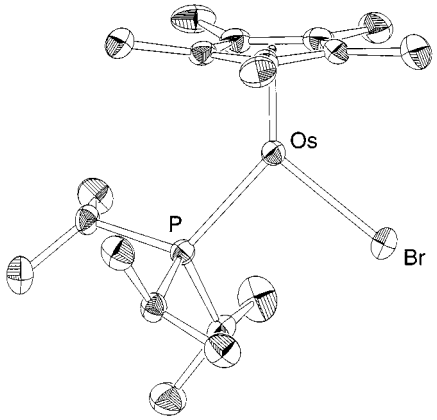

Figure 1. ORTEP diagram of **2** with 50% probability ellipsoids; hydrogens have been removed for clarity; selected bond lengths and angles (Cp^* = C_5Me_5 centroid): Os–Br 2.4785(6) Å, Os–P 2.349(2) Å, Os–Cp* 1.7898(2) Å, Br–Os–P 93.52(4)°, P–Os–Cp* 137.13(4)°, Br–Os–Cp* 129.34(2)°

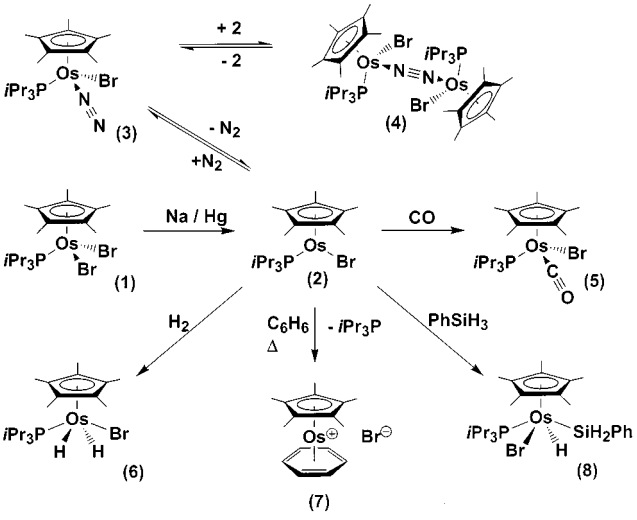
Exposure of a stirred pentane solution of **2** to an atmosphere of CO resulted in a rapid color change from purple to yellow. The resulting compound, [OsBrCp*(CO)(P*i*Pr$_3$)] (**5**), exhibited a CO stretching frequency of 1896 cm^{-1} (Nujol mull). This value compares to 1908 cm^{-1} for the closely related ruthenium complex [RuClCp*(CO)(P*i*Pr$_3$)][1] and is consistent with the more basic nature of the osmium center. Coordination of CO to the osmium center destroys the effective C_s symmetry of **2**, as indicated by NMR spectroscopy. Thus, the methyl groups of the triisopropylphosphane ligand in **5** are inequivalent in the ^{1}H NMR spectrum, appearing as two virtual quadruplets integrating to nine protons each.

Compound **2** reacted under an atmosphere of hydrogen in pentane solution, as indicated by a rapid color change of the solution from purple to yellow. The ^{1}H NMR spectrum of a C_6D_6 solution of the resulting pale yellow product contained a new doublet at $\delta = -10.7$ consistent with oxidative addition of dihydrogen to the Os center to give a product formulated as [OsH$_2$BrCp*(P*i*Pr$_3$)] (**6**). $T_{1(min)}$ measurements made by the null method revealed a value of 475 ms at −81 °C for the two hydrides of **6**, demonstrating that they are "classical" in nature. The ^{1}H NMR spectrum of **6** exhibited only one set of peaks for the isopropyl methyl groups, consistent with a *trans* disposition for the hydride ligands in a "four-legged piano stool" complex. A *cis* geometry for the hydride ligands would render the isopropyl methyl groups diastereotopic and can therefore be ruled out. It is interesting to note that [RuClCp*(PR$_3$)] complexes do not react with H_2 under comparable conditions.[1]

In an experiment intended to probe the thermal stability of **2**, an NMR tube fitted with a PTFE valve was charged with a benzene solution of **2** and heated in an oil bath at 80 °C. Colorless crystals were deposited on the bottom of the tube after a few days. Although insoluble in aliphatic hydrocarbons and benzene, the crystals were soluble in CD_2Cl_2 and were determined to be the arene complex [OsCp*(η^6-C_6H_6)]Br (**7**) by ^{1}H and ^{13}C{^{1}H} NMR spectroscopy. The formation of this species presumably involves thermal dissociation of the phosphane ligand from the osmium center followed by coordination of the arene solvent to the metal center with displacement of the halide substituent. Characterization of **7** as an arene complex is supported by a comparison with the related species [RuCp*(η^6-toluene)]Cl which has been synthesized and fully characterized in these laboratories by crystallographic and spectroscopic techniques.[15]

The reaction of **2** with 1 equiv. of PhSiH$_3$ in pentane caused an immediate color change from purple to yellow. The resulting compound, [Os(H)(Br)Cp*(SiH$_2$Ph)(P*i*Pr$_3$)] (**8**), was isolated as a yellow microcrystalline solid from pentane. The ^{1}H NMR spectrum includes two resonances at $\delta = 6.60$ and 4.71 for the diastereotopic silicon-bound protons. The stereochemistry of **8** depicted in Scheme 1 was assigned based on comparison to similar ruthenium complexes[1,4] and the structurally characterized analogue [Os(H)(Br)Cp*(SiHPh$_2$)(P*i*Pr$_3$)].[11]



Scheme 1

We are currently probing the utility of **2** as a synthon in osmium chemistry, especially its use in generating unsaturated metal–ligand interactions. We believe that the isolable nature of **2** makes it an ideal starting material for a series of studies involving the electron rich OsCp*(R$_3$P)$^+$ fragment.

Experimental Section

All solvents were distilled under N_2 from appropriate drying agents and stored in PTFE-valved flasks. Synthetic manipulations were performed under an atmosphere of purified N_2 or argon using standard Schlenk techniques. P*i*Pr$_3$ was obtained from Strem Chemicals, Inc. and was used as received. CO was obtained from Mattheson Gas and used without further purification. [Os$_2$Br$_4$Cp*$_2$] was prepared by the published method.[8] PhSiH$_3$ was made by the reduction of PhSiCl$_3$ with LiAlH$_4$ in ether and purified by fractional distillation under N_2. ^{1}H (500.1 MHz), ^{13}C{^{1}H} (124.7 MHz), ^{31}P{^{1}H} (202.4 MHz), ^{29}Si{^{1}H} (99.3 MHz), and ^{15}N{^{1}H} (50.7 MHz) NMR spectra were ac-

quired on a Bruker DRX-500 spectrometer equipped with a BBI probe. Spectra were recorded at room temperature in C_6D_6 unless otherwise noted and were referenced to protic impurities in the deuterated solvent for ^1H, solvent peaks for ^{13}C, $SiMe_4$ for ^{29}Si, neat $MeNO_2$ for ^{15}N, and 85% H_3PO_4 for ^{31}P. Elemental analyses were performed by the University of California, Berkeley College of Chemistry Microanalytical Facility. IR absorptions are reported in units of cm^{-1} and were recorded with a Mattson Infinity 60 MI FTIR spectrometer as Nujol mulls for room temperature measurements and with an ASI React-IR apparatus for low-temperature measurements.

[$OsBr_2Cp^*(P\mathit{i}Pr_3)$] (1): A stirred CH_2Cl_2 solution of [$Os_2Br_4Cp^*_2$] (1.23 g, 1.27 mmol) was treated with 2.1 equiv. of neat $P\mathit{i}Pr_3$ at room temperature. The solution was stirred for 60 minutes, by which time it turned from brown to deep black-red. All volatile components of the mixture were removed in vacuo, and the resulting black-red solid was washed with Et_2O at 0 °C (2 × 20 mL) and dried in vacuo to give a red-pink powder. 1.36 g (83%) isolated, m.p. 205−210 °C. ^1H NMR (CD_2Cl_2): δ = −2.26 [fwhh 205 Hz, 18 H, PCH($\mathit{CH_3}$)$_2$], 6.6 [fwhh 420 Hz, 3 H, PCH(CH_3)$_2$], 23.9 [fwhh 350 Hz, 15 H, $C_5\mathit{Me_5}$). − μ_{eff} = 1.37 B.M (Evans' method,[16] CH_2Cl_2, room temperature.) Solution molecular weight (CH_2Cl_2, Signer method) 580 (645 ideal). − $C_{19}H_{36}Br_2OsP$ (645.48): calcd. C 35.35, H 5.62; found, C, 35.19, H 5.76.

[$OsBrCp^*(P\mathit{i}Pr_3)$] (2): A solution of **1** (4.1 g, 6.36 mmol) in THF was added to a flask containing a stirred Na/Hg amalgam (0.3% Na, 1 equiv.) and THF at room temperature. The solution became violet after a few minutes of vigorous stirring, and a white precipitate formed. The reaction mixture was allowed to settle after approximately 60 minutes. The supernatant was filtered away from the amalgam and precipitated solids, then was pumped dry to give a black-purple solid. Extracting the solid with pentane (5 × 20 mL) gave a purple solution, which afforded red-orange crystals of the dinitrogen adduct after concentrated cooling to −78 °C under N_2. 2.3 g (64%) isolated, m.p. 132−136 °C. X-ray quality crystals were grown from a concentrated diethyl ether solution of **2** under argon at −78 °C. ^1H NMR: δ = 1.15−1.09 [vq, 18 H, PCH($\mathit{CH_3}$)$_2$], 1.45 (s, 15 H, $C_5\mathit{Me_5}$), 2.54 [m, 3 H PCH(CH_3)$_2$]. − $^{13}C\{^1H\}$ NMR: δ = 13.4 ($C_5\mathit{Me_5}$), 20.5 [PCH($\mathit{CH_3}$)$_2$], 25.7 [d, $^1J_{PC}$ = 24.3 Hz, PCH(CH_3)$_2$], 72.8 ($\mathit{C_5}Me_5$). − $^{31}P\{^1H\}$ NMR: δ = 42.63. − $^{15}N\{^1H\}$ NMR (220 K): δ = −47.0. − $C_{19}H_{36}BrOsP$ (565.57): calcd. C 40.35, H 6.42; found C 40.45, H 6.10.

[$OsBrCp^*(^{15}N_2)(P\mathit{i}Pr_3)$] (3-$^{15}N_2$) and [$OsBrCp^*(P\mathit{i}Pr_3)]_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}^{15}N_2$) (4-$^{15}N_2$): A [$D_8$]toluene solution of **2** in a 5 mm O.D. PTFE-valved NMR tube was degassed by several freeze-pump-thaw cycles, exposed to 2 atm. of $^{15}N_2$ (Aldrich, 98%), and slowly cooled to −78 °C. The tube was then sealed and carefully brought to room temperature. $^{15}N\{^1H\}$ NMR spectra were recorded as the sample was cooled in the spectrometer. At 220 K, resonances assignable to **3**-$^{15}N_2$ [δ = −72.4 (dd, $^2J_{NP}$ = 2.5 Hz, $^1J_{NN}$ = 4.5 Hz, Os−NN), −47.9 (d, $^1J_{NN}$ = 5 Hz, Os−NN)] and **4**-$^{15}N_2$ [δ = −133.6 (d, $^2J_{NP}$ = 2.0 Hz)] were observed. − $^{31}P\{^1H\}$ NMR: (220 K): **4**-$^{15}N_2$ δ = 8.10 (d, $^2J_{NP}$ = 2.0 Hz); **3**-$^{15}N_2$ δ = 8.71 (d, $^2J_{NP}$ = 2.5 Hz).

[$OsBrCp^*(CO)(P\mathit{i}Pr_3)$] (5): A flask containing a stirred pentane solution of 125 mg of **2** (0.220 mmol) was briefly evacuated, and then filled with an atmosphere of CO. The solution changed color from purple to yellow-orange within 20 seconds at room temperature. The solution was filtered, concentrated, and cooled to −78 °C, affording a crop of well-formed orange crystals of **5**. 97 mg (75%) isolated, m.p. 209−212 °C. ^1H NMR: δ = 0.96−1.00 [vq, 9 H, PCH($\mathit{CH_3}$)$_2$], 1.29−1.24 [vq, 9 H, PCH($\mathit{CH_3}$)$_2$], 1.63 (s, 15 H, $C_5\mathit{Me_5}$), 2.30 [m, 3 H, PCH(CH_3)$_2$]. − $^{13}C\{^1H\}$ NMR: δ = 10.4 ($C_5\mathit{Me_5}$), 19.6 [d, $^2J_{PC}$ = 23 Hz, PCH($\mathit{CH_3}$)$_2$], 20.8 [PCH($\mathit{CH_3}$)$_2$], 27.2 [d, $^1J_{PC}$ = 27 Hz, PCH(CH_3)$_2$], 92.2 (d, J_{PC} = 2 Hz, $C_5\mathit{Me_5}$), 190.1 (d, $^1J_{PC}$ = 12 Hz, Os−CO). − $^{31}P\{^1H\}$ NMR: δ = 16.3. − IR: ν_{CO} = 1896 s. − $C_{20}H_{36}BrOOsP$ (593.58): calcd. C 40.47, H 6.11; found C 40.51, H 6.01.

[$OsH_2BrCp^*(P\mathit{i}Pr_3)$] (6): A flask containing a stirred pentane solution of 100 mg (0.176 mmol) of **2** was briefly evacuated, and then filled with an atmosphere of H_2. The solution changed color from purple to very pale yellow within 50 seconds at room temperature. The solution was filtered, concentrated and cooled to −78 °C, affording solid **6** as feathery, pale yellow crystals. 62 mg (62%) isolated, m.p. 152 °C (color change) 172 °C melting complete. ^1H NMR: δ = −10.7 [d, 2 H, $^2J_{PH}$ = 34.8 Hz, Os−H; $T_{1(ambient\ T)}$ = 1.73 s, $T_{1(min)}$ = 475 ms, CD_2Cl_2, −81 °C), 1.12−1.03 [vq, 18 H, PCH($\mathit{CH_3}$)$_2$], 1.80 (s, 15 H, $C_5\mathit{Me_5}$), 2.07 [m, 3 H, PCH(CH_3)$_2$]. − $^{13}C\{^1H\}$ NMR: δ = 11.3 ($\mathit{C_5}Me_5$), 19.2 [PCH($\mathit{CH_3}$)$_2$], 28.2 [d, $^1J_{PC}$ = 31 Hz, PCH(CH_3)$_2$], 90.2 ($C_5\mathit{Me_5}$). − $^{31}P\{^1H\}$ NMR: δ = 42.63. − IR: ν_{SiH} = 2105 ws, 2042 s. − $C_{19}H_{38}BrOsP$ (567.59): calcd. C 40.35, H 6.42; found C 40.45, H 6.10.

[$OsCp^*(\eta^6\text{-}C_6H_6)$]Br (7): A 5 mm O.D. PTFE-valved NMR tube was charged with a C_6H_6 solution of **2**, degassed, sealed, and immersed in an oil bath maintained at approximately 80 °C. After 1 week, several crystals were deposited at the bottom of the tube. The crystals were removed from the tube inside the drybox, washed with a little pentane at ambient temperature and dried. ^1H NMR: δ = 2.19 (15 H, $C_5\mathit{Me_5}$), 5.90 (6 H, $C_6\mathit{H_6}$). − $^{13}C\{^1H\}$ NMR: δ = 11.7 ($C_5\mathit{Me_5}$), 78.1 ($\mathit{C_5}Me_5$), 94.4 ($\mathit{C_6}H_6$). Compound **7** was not prepared on a large enough scale to facilitate further characterization.

[$Os(H)(Br)Cp^*(SiH_2Ph)(P\mathit{i}Pr_3)$] (8): A stirred pentane solution of **2** (202 mg, 0.356 mmol) was treated with 1.1 equiv. of $PhSiH_3$ dissolved in pentane. The solution immediately changed color from purple to yellow. The solution was filtered, concentrated, and cooled to −78 °C, affording a crop of polycrystalline **8**. 195 mg (81%) isolated, m.p. 163−165 °C. ^1H NMR: δ = 8.16 (d, 2 H, *o*-Ph), 7.33 (t, 2 H, *m*-Ph), 7.21 (t, 1 H, *p*-Ph), 6.60 (d, $^1J_{SiH}$ = 189 Hz, $^2J_{HH}$ = 4 Hz, 1 H, SiH), 4.71 (vq, $^1J_{SiH}$ = 182 Hz, 1 H, SiH), 2.49 [m, 3 H, PCH(CH_3)$_2$], 1.52 (s, 15 H, $C_5\mathit{Me_5}$), 1.04−1.08 [vq, 9 H, PCH($\mathit{CH_3}$)$_2$], 0.97−1.00 [vq, 9 H, PCH($\mathit{CH_3}$)$_2$], −14.8 (d, 1 H, $^2J_{PH}$ = 32 Hz, Os−H). − $^{13}C\{^1H\}$ NMR: δ = 143.39, 136.42, 127.53, 93.9 (d, $^2J_{PC}$ = 2.1 Hz, $\mathit{C_5}Me_5$), 28.04 [d, $^1J_{PC}$ = 26.7 Hz, PCH(CH_3)$_2$], 20.50 [PCH($\mathit{CH_3}$)$_2$], 19.79 [d, $^2J_{PC}$ = 3 Hz, PCH($\mathit{CH_3}$)$_2$], 10.35 ($C_5\mathit{Me_5}$). − $^{31}P\{^1H\}$ NMR: δ = 8.98. − $^{29}Si\{^1H\}$ NMR: δ = −26.0 (d, $^2J_{PSi}$ = 17 Hz). − IR: ν_{SiH} = 2061 s, 2081 s. − $C_{19}H_{38}BrOsP$ (567.59): calcd. C 44.56, H 6.58; found C 44.66, H 6.66.

X-ray Crystallographic Study: Data were collected on a Siemens SMART system using Mo-K_α graphite monochromated radiation. Structure solution and refinement was performed with the TeXsan software package.[17] $C_{19}H_{36}BrOsP$ mol. weight 565.57, purple block, cryst. size 0.35 × 0.12 × 0.20 mm, a = 16.1302(2), b = 15.5831(2), c = 16.7732(3) Å, α = β = γ = 90°, V = 4216.09(9) Å^3, orthorhombic, *Pbca*, Z = 8, $d_{calcd.}$ = 1.782 Mg m^{-3}, F_{000} = 2208.00, index ranges: $0 < h < 19$, $-17 < k < 17$, $-20 < l < 20$; 2Θ range 3.5−45.0°, T = −115 °C; refl. collected: 19152; refl. unique: 4124; R_{int} = 0.055, no. variables: 199, GOOF = 0.62, R = 0.019, R_w = 0.020, R_{all} = 0.052. Largest residual peak/hole = 0.080/−0.39 e/Å^3.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication

no. CCDC-158416. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

New Types of Complexes Based on Re_4 Chalcocyanide Clusters − Syntheses and Crystal Structures of $[Ni(NH_3)_5]_2[Re_4Te_4(CN)_{12}]\cdot 3.4H_2O$ and $[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]\cdot 4H_2O$

Yuri V. Mironov,[a] Oliver Oeckler,[b] Arndt Simon,*[b] and Vladimir E. Fedorov[a]

Keywords: Rhenium / Clusters / Transition metals / Solid-state structures

Two new tetrahedral rhenium chalcocyanide cluster compounds $[Ni(NH_3)_5]_2[Re_4Te_4(CN)_{12}]\cdot 3.4H_2O$ (**1**) and $[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]\cdot 4H_2O$ (**2**), exhibiting molecular (**1**) and chain-like polymeric structures (**2**), have been synthesized by treatment of the salt-like cluster compound $K_4Re_4Te_4(CN)_{12}\cdot 5H_2O$ with solutions of nickel acetate and cadmium sulfate, respectively, in aqueous ammonia. Both compounds have been characterized by single-crystal X-ray diffraction analysis. Compound **1** crystallizes in the monoclinic space group $P2_1/c$ [a = 19.572(3), b = 14.849(2), c = 23.576(3) Å, β = 145.97(1)°, Z = 4, V = 3834.4(9) Å^3], while compound **2** crystallizes in the triclinic space group $P\bar{1}$ [a = 12.726(2), b = 13.408(2), c = 13.918(2) Å, α = 111.31(2), β = 116.77(2), γ = 90.17(2)°, Z = 2, V = 1935.3(5) Å^3].

Introduction

The chemistry of transition metal chalcocyanide cluster compounds, existing as either discrete or interconnected clusters, has been extensively developed in recent years.[1−14] One of the most interesting features of CN ligands is their ability to form cyano-bridged complexes with transition metals. In the past few years, many such complexes incorporating cluster chalcocyanide anions have been obtained, most of them based on the cluster anions $[Re_6Q_8(CN)_6]^{4-}$ (Q = S, Se) with an octahedral core.[9−14] In these polymeric compounds, all or some of the CN^- ligands may be bridging, thus allowing the formation of structures of different dimensionalities, i.e. 1D, 2D, or 3D. In recent publications,[6,15] we have reported the syntheses of the layered compound $[Cu_4(\mu_3\text{-}OH)_4][Re_4Te_4(CN)_{12}]$, obtained at pH ≈ 7, and three 3D-polymeric compounds $Mn_2[Re_4Se_4(CN)_{12}]\cdot 6H_2O$, $Cd_2[Re_4Te_4(CN)_{12}]\cdot 6H_2O$, and $Cu_2[Re_4Te_4(CN)_{12}]\cdot 4H_2O$, obtained at pH ≈ 1−5. We have now extended our studies to aqueous ammonia. Our findings demonstrate the significant dependence of the nature of the product on the reaction conditions used. In the present work, we have prepared one molecular complex $[Ni(NH_3)_5]_2[Re_4Te_4(CN)_{12}]\cdot 3.4H_2O$ (**1**) and one chain-like complex $[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]\cdot 4H_2O$ (**2**). Compound **1** contains only terminal $[Ni(NH_3)_5]^{2+}$ cations, while compound **2** contains both bridging $[Cd(NH_3)_3]^{2+}$ and terminal $[Cd(NH_3)_5]^{2+}$ cations.

Results

The treatment of $K_4Re_4Te_4(CN)_{12}$ with transition metal salts in aqueous solution leads to the formation of cyano-bridged cluster complexes, in which the transition metal atom may be coordinated by one, two, or three N atoms of CN ligands of the cluster anion $[Re_4Te_4(CN)_{12}]^{4-}$. In our earlier investigations in this area, it became clear that the preparation of single crystals of such complexes requires a very slow diffusion of the starting components. Mixing of aqueous solutions usually results only in powders, the structures of which are often different from those of the compounds obtained by slow diffusion. In the studied reactions, the transition metal adducts are aquo complexes $[M(H_2O)_6]^{n+}$. The M−(OH_2) bonds in these complexes are weaker than M−(NC) bonds and hence ligand exchange occurs.

We now extend our investigations in this area to complexes of the transition metals with ammonia. In the adduct complexes $[M(NH_3)_6]^{n+}$, the metal−ligand bonds are stronger than those in aquo complexes. Thermodynamic as well as kinetic factors may affect both the compositions of the products and the rates of their formation. Indeed, we have obtained some new types of Re_4 cluster complexes with transition metals starting from ammine complexes. Here we present two new cluster compounds with transition metals, namely $[Ni(NH_3)_5]_2[Re_4Te_4(CN)_{12}]\cdot 3.4H_2O$ (**1**) and $[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]\cdot 4H_2O$ (**2**). Both compounds were prepared under similar conditions by treating an aqueous solution of $K_4Re_4Te_4(CN)_{12}$ with the ammine complexes of the corresponding transition metals.

The structures of both complexes were solved by single-crystal X-ray analysis. Both compounds contain the $[Re_4Te_4(CN)_{12}]^{4-}$ cluster anion, the structure of which is similar to that found in other complexes containing this anion. It contains an $[Re_4Te_4]$ cubane-like core formed from an almost regular tetrahedron of Re atoms in oxidation

state IV with all triangular faces symmetrically capped by μ_3-Te ligands. The Re−Re bond lengths are in the ranges 2.8540(6)−2.8767(7) Å (**1**) and 2.8676(14)−2.8775(11) Å (**2**), the Re−Te bond lengths are in the ranges 2.6230(8)−2.6469(8) Å (**1**) and 2.6224(14)−2.6454(14) Å (**2**), and the Re−C distances are 2.09(1)−2.13(1) Å (**1**) and 2.03(2)−2.08(2) Å (**2**), respectively.

In the molecular structure of compound **1**, two $[Ni(NH_3)_5]^{2+}$ cations are coordinated to the N atoms of CN ligands of the $[Re_4Te_4(CN)_{12}]^{4-}$ anion (Figure 1). Each Ni atom is coordinated by the five N atoms of the NH_3 ligands with Ni−N distances ranging from 2.081(9) to 2.150(9) Å, and by one N atom from a CN ligand of the cluster with Ni−N distances of 2.067(8) and 2.097(8) Å. Interestingly, both cations are coordinated to the same Re atom. This is the first example of a chalcocyanide complex with a transition metal that exhibits a discrete molecular structure.

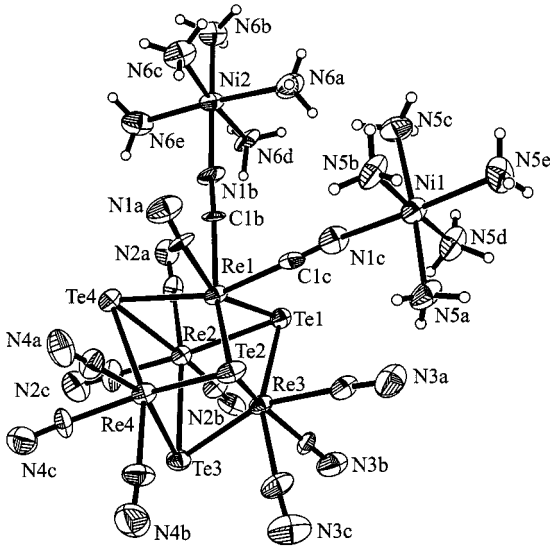

Figure 1. Crystal structure of $[Ni(NH_3)_5]_2[Re_4Te_4(CN)_{12}]\cdot 3.4H_2O$; thermal ellipsoids are drawn at a 75% probability level

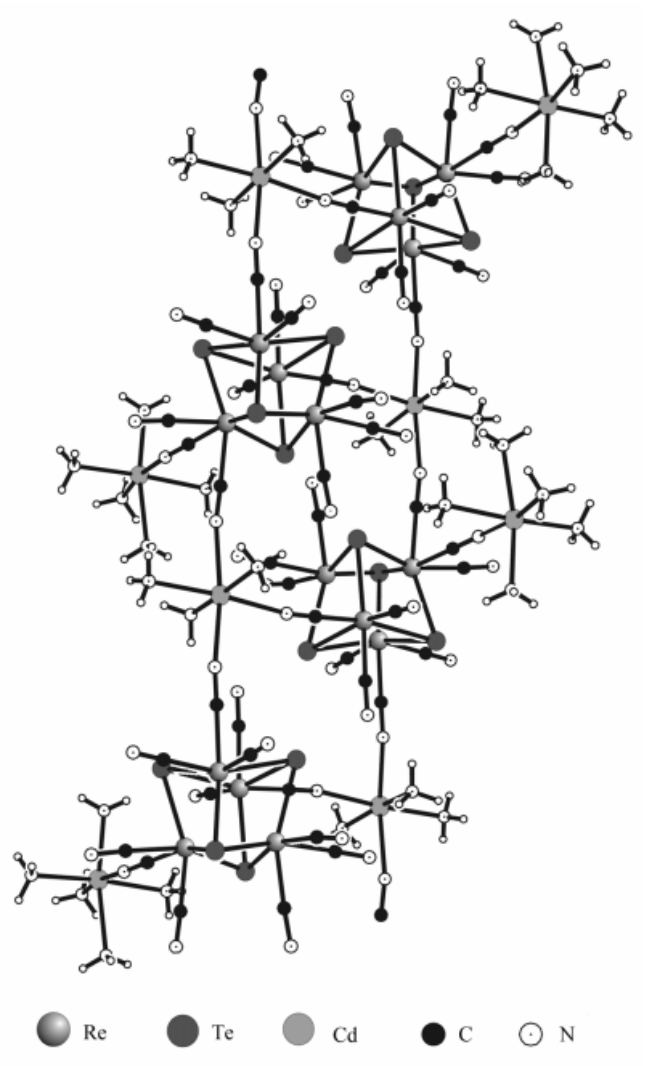

Figure 2. A fragment of the crystal structure of $[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]\cdot 4H_2O$

The second compound $[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]$ (**2**) contains two types of cations, namely terminal $[Cd(NH_3)_5]^{2+}$ and bridging $[Cd(NH_3)_3]^{2+}$ cations (Figure 2). The Cd atom of each $[Cd(NH_3)_5]^{2+}$ cation is coordinated by the five N atoms of the NH_3 ligands [Cd−N distances in the range 2.29(3)−2.47(4) Å] and one N atom of a CN ligand of the cluster. The Cd−N distance [2.43(3) Å] is similar to the Ni−N distance found in the Ni salt. The Cd atom of each bridging $[Cd(NH_3)_3]^{2+}$ cation is coordinated by the three N atoms of the NH_3 ligands with Cd−N distances ranging from 2.25(2) to 2.39(2) Å, and by three N atoms of CN ligands of different clusters with Cd−N distances in the range 2.36(2)−2.42(2) Å, thereby forming a chain-like structure. Each $[Re_4Te_4(CN)_{12}]^{4-}$ anion is coordinated by one terminal $[Cd(NH_3)_5]^{2+}$ group.

In the infrared spectra, two bands at 2169 and 2133 cm^{-1} (compound **1**), or at 2163 and 2133 cm^{-1} (compound **2**), can be assigned to the bridging and terminal CN groups, respectively. For both complexes, four additional bands are seen, due to coordinated ammonia molecules. Two of these, at 3345 and 1615 cm^{-1} (compound **1**) and 3340 and 1605 cm^{-1} (compound **2**), coincide with vibrations of water.

Comparison of the interaction of aqueous solutions of $[Re_4Te_4(CN)_{12}]^{4-}$ cluster anions with transition metal aquo $[M(OH_2)_6]^{2+}$ and ammine $[M(NH_3)_6]^{2+}$ complexes demonstrates that the formation of cyano-bridged complexes is dependent on the strength of the M−X (X = OH_2, NH_3, NC) bonds. In the case of aquo complexes, the weaker M−OH_2 bonds can be cleaved under formation of the thermodynamically more favourable M−NC bonds. As a result, polymeric complexes are formed, often with the maximum number of M−NC bonds. Starting from the ammine complexes $[M(NH_3)_6]^{2+}$, we observed the formation of the molecular complex **1** with only one substituted NH_3 ligand, and of the chain-like complex **2** with two types of cations, namely $[Cd(NH_3)_5]^{2+}$, from which one NH_3 molecule has been substituted, and $[Cd(NH_3)_3]^{2+}$, from which three NH_3 molecules have been substituted. This difference between these two compounds may have a kinetic origin. Under similar conditions, compound **1** is formed within 24 h, whereas

compound **2** only forms within 48 h. The compounds described herein may possibly represent the first and second steps in the formation of cyano-bridged polymeric complexes.

Experimental Section

General: All experimental manipulations were performed in air. $K_4Re_4Te_4(CN)_{12}\cdot 5H_2O$ was prepared by the reaction of $Re_4Te_4(TeCl_2)_4Cl_8$ with KCN.[5] All other reagents were used as received from commercial sources. − FT-IR: Bruker IFS-85. − Elemental analyses: Carlo Erba 1106.

$[Ni(NH_3)_5]_2[Re_4Te_4(CN)_{12}]\cdot 3.4H_2O$ (1): A solution of $Ni(CH_3COO)_2$ (20 mg) in concentrated aqueous ammonia (3 mL) was mixed with a solution of $K_4Re_4Te_4(CN)_{12}\cdot 5H_2O$ (10 mg) in water (2 mL). At ambient temperature, the resulting solution was transferred to a crystallizing dish, which was then covered by a watch glass. After 24 h, black crystals had formed, which were collected by filtration and dried on filter paper. Yield: 10 mg (95%). − $C_{12}H_{30}N_{22}Ni_2Re_4Te_4\cdot 3H_2O$ (1909.19): calcd. C 7.55, H 1.90, N 16.14; found C 7.22, H 1.41, N 15.54; the solvent content probably varies to a certain extent. − IR (KBr): $\tilde{\nu}$ = 3345 (m), 2169 (w), 2133 (s), 1615 (m), 1219 (m), 667 cm^{-1} (m). − μ_{eff} = 2.96 μ_B (298 K), 2.80 μ_B (78 K).

$[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]\cdot 4H_2O$ (2): A solution of $CdSO_4\cdot 8H_2O$ (20 mg) in concentrated aqueous ammonia (3 mL) was mixed with a solution of $K_4Re_4Te_4(CN)_{12}\cdot 5H_2O$ (10 mg) in water (2 mL). At ambient temperature, the resulting solution was transferred to a crystallizing dish, which was then covered by a watch glass. After 2 days, black crystals of **2** had formed, which were collected by filtration and dried on filter paper. Yield: 10 mg (91%). − $C_{12}H_{32}Cd_2N_{20}O_4Re_4Te_4$ (2000.58): calcd. C 7.20, H 1.61, N 14.00; found C 7.26, H 0.88, N 13.65. − IR (KBr): $\tilde{\nu}$ = 3340 (w), 2163 (m), 2133 (s), 1605 (m), 1204 (m), 612 cm^{-1} (m).

X-ray Structural Analyses: Stoe IPDS diffractometer, graphite monochromator, Mo-K_α radiation (λ = 0.71073 Å); the SHELX-97 program package[16] was used for structure solution by direct methods and for refinement by full-matrix least-squares techniques.[17]

$[Ni(NH_3)_5]_2[Re_4Te_4(CN)_{12}]\cdot 3.4H_2O$ (1): M_r = 1918, monoclinic, space group $P2_1/c$, a = 19.572(3), b = 14.849(2), c = 23.576(3) Å, β = 145.97(1)°, V = 3834.4(9) $Å^3$, Z = 4, $D_{calcd.}$ = 3.32 $g\cdot cm^{-3}$, μ = 16.58 mm^{-1}, T = 93(2) K. Crystal size 0.18 × 0.07 × 0.01 mm; $2\theta_{max}$ = 53° ($-25 \le h \le 25$, $-17 \le k \le 17$, $-30 \le l \le 30$), 8390 symmetry-independent reflections from 52895 collected reflections (R_{int} = 0.078); max./min. transmission: 0.83/0.28; 439 parameters refined; $R1$ = 0.0333, $wR2$ = 0.0655 [$I > 2\sigma(I)$]; $R1$ = 0.0624, $wR2$ = 0.0737 (all reflections), GoF = 0.932; $\Delta\rho_{max}$ = 1.84 $e\cdot Å^{-3}$, $\Delta\rho_{min}$ = −1.57 $e\cdot Å^{-3}$.

$[Cd(NH_3)_5][Cd(NH_3)_3][Re_4Te_4(CN)_{12}]\cdot 4H_2O$ (2): M_r = 2000.58, triclinic, space group $P\bar{1}$, a = 12.726(2), b = 13.408(2), c = 13.918(2) Å, α = 111.31(2), β = 116.77(2), γ = 90.17(2)°, V = 1935.3(5) $Å^3$, Z = 2, $D_{calcd.}$ = 3.433 $g\cdot cm^{-3}$, μ = 16.543 mm^{-1}, T = 293(2) K. Crystal size 0.20 × 0.15 × 0.11 mm; $2\theta_{max}$ = 50° ($-15 \le h \le 15$, $-15 \le k \le 15$, $-16 \le l \le 16$), 5626 symmetry-independent reflections from 18453 collected reflections (R_{int} = 0.089); max./min. transmission: 0.288, 0.937; 423 parameters refined; $R1$ = 0.0634, $wR2$ = 0.1677 [$I > 2\sigma(I)$]; $R1$ = 0.0742, $wR2$ = 0.1753 (all reflections), GoF = 1.052; $\Delta\rho_{max}$ = 3.57 $e\cdot Å^{-3}$, $\Delta\rho_{min}$ = −2.12 $e\cdot Å^{-3}$.

Derivatives of Bis(2,2′-bipyridyl)dicyanoiron(II) with Long Alkyl Chains – Versatile Solvatochromic Probes that Form Metalloaggregates in Water-Rich Media

Paula Gameiro,*[a] Eulália Pereira,[a] Paula Garcia,[a] Sónia Breia,[a] John Burgess,[b] and Baltazar de Castro[a]

Keywords: Aggregation / Iron / Surfactants / Solvatochromism

We report on the preparation, characterisation, and solvatochromic behaviour of four new $[FeL_2(CN)_2]$ complexes, where L is the ligand 4,4′-diisobutyl-2,2′-bipyridine, 4,4′-di-*n*-pentyl-2,2′-bipyridine, 4,4′-di-*n*-heptyl-2,2′-bipyridíne, or 4-*n*-heptyl-4′-methyl-2,2′-bipyridine. The solvatochromic properties of these complexes show that the hydrophobicity imposed by the alkyl chains controls the response of the complexes towards the solvent, and that they are ideal to use as solvation probes in heterogeneous/organised media. An interesting result emerging from this work is the demonstration of the self-aggregating properties of the complexes *cis*-$[Fe(Pe_2bpy)_2(CN)_2]$, *cis*-$[Fe(He_2bpy)_2(CN)_2]$, and *cis*-$[Fe(Hebpy)_2(CN)_2]$ which are, without doubt, metallosurfactants.

Introduction

Iron(II) cyanide complexes such as *cis*-$[FeL_2(CN)_2]$, with L = 2,2′-bipyridyl, *o*-phenanthroline, or one of various Schiff base diimines, are strongly solvatochromic.[1–3] This property makes them suitable for the monitoring of their local solvation environment, not only in pure solvents, but also in binary media where they are used to assess preferential solvation and to study possible synergic solvation effects.[4,5] By varying the nature of the diimine, it is possible to control the hydrophilicity or lipophilicity of the complex. They have also been used to probe solvation in organised aqueous media, such as micelles and microemulsions.[6–9]

These inorganic complexes can complement E_T dyes, the most widely used organic solvatochromic polarity probes, since most of these dyes are not very soluble in water and are not ideal for investigating solvation in water-rich binary aqueous solvent mixtures.[10] Since systematic changes in the electrostatic/hydrophobic properties of the probes are necessary to investigate solvation in a wide range of solvents, metal complexes have proved to be particularly versatile. These metal complexes can be tuned by varying the inner coordination sphere of the metal centre while maintaining (or not) the overall charge of the probe molecule, or by appending aliphatic chains to the ligands and retaining the inner coordination sphere of the metal centre. As a result, the electrostatic or hydrophobic interactions of the complexes can be varied. This approach allows the construction of a set of solvation probes that may be used to analyse the relative importance of electrostatic/hydrophobic interactions in binary aqueous media, and also in organised media.

The most common inorganic solvatochromic probes, *cis*-$[FeL_2(CN)_2]$, with L = 2,2′-bipyridyl or 1,10-phenanthroline, are soluble in water and other protic solvents, but sparingly soluble or insoluble in nonpolar solvents. On the other hand, iron(II) complexes with lipophilic Schiff base diimines are soluble in some nonpolar solvents, and are much less sensitive to solvent polarity than those with 2,2′-bipyridyl and 1,10-phenanthroline.[3] The use of substituted 2,2′-bipyridyl ligands, containing one or two hydrophobic chains of varying length, seems a good route to isolate the changes in the inner coordination sphere of the metal centre from the changes in the hydrophobicity of the complexes. These compounds with substituted 2,2′-bipyridyl ligands combine the sensitivity of the bipyridyldicyanoiron(II) complex and the solubility of Schiff base diimines in nonpolar solvents.

In a recent paper we reported on the solvatochromic properties of the complex *cis*-$[Fe(PeMebpy)_2(CN)_2]$, where PeMebpy is bis(4-methyl-4′-*n*-pentyl-2,2′-bipyridyl).[12] This complex represents the first example of a solvatochromic compound which is soluble in water and in *n*-alkanes, and which is as sensitive to its solvent environment as the parent complex *cis*-$[Fe(bpy)_2(CN)_2]$. The solvatochromic behaviour of this complex has shown that attaching aliphatic chains to 2,2′-bipyridyl can lead to the development of versatile inorganic solvatochromic indicators for a wide range of solvent media.

In this paper we report on the preparation, characterisation and solvatochromic behaviour of four new $[FeL_2(CN)_2]$ complexes, where L is the ligand Bu_2bpy, Pe_2bpy, Hp_2bpy, or HpMebpy (Scheme 1).

Their solvatochromism was studied in pure solvents and in mixed solvents (water/methanol, water/acetonitrile, and

water/acetone). Their solvatochromic characteristics are compared with those of the Reichardt dyes (E_T scale), as well as with those of *cis*-[Fe(bpy)$_2$(CN)$_2$], which is the most common solvatochromic inorganic probe, and of *cis*-[Fe(PeMebpy)$_2$(CN)$_2$], which is the first solvatochromic inorganic probe to be soluble in water and *n*-alkanes.

The results obtained demonstrated that complexes **1**−**4** combine the sensitivity of the bipyridyldicyanoiron(II) complexes with the solubility of the analogous, but less sensitive, complexes of Schiff base diimines in nonpolar solvents. On the other hand, the response of complexes **2**−**4** to solvent polarity in nonpolar solvents was found to be completely different from that observed for the Reichardt dyes. Finally, in water-rich media, it must be stressed that the hydrophobicity imposed by the alkyl tails clearly controls the response of the complexes to solvent polarity, and thus gives access to the synthesis of complexes for probing solvation in heterogeneous/organised solvent media.

An interesting result of complexes **2**−**4** is that they form metalloaggregates in the water-rich region of the mixed solvents used. The water content at which aggregation starts is dependent on the length and number of the alkyl chains.

Results and Discussion

Solutions of complexes **1**−**4** are violet in polar solvents, but blue in nonpolar solvents. The solvatochromic properties of these complexes were studied by visible spectrophotometry in several pure solvents, ranging from water to paraffins, and in the following mixed solvents: water/methanol, water/acetonitrile and water/acetone. The electronic absorption spectra of all complexes are identical to that reported for *cis*-[Fe(bpy)$_2$(CN)$_2$],[13] and the solvatochromic behaviour presented in this work is based on the wavenumber of the maximum absorption of the lowest-energy metal-to-ligand charge-transfer band, $\tilde{\nu}_{max}$(MLCT).

Solvatochromic Behaviour in Water and in Non-Aqueous Solvents

Table 1 includes the values of $\tilde{\nu}_{max}$(MLCT), in water and in a wide range of non-aqueous solvents, for each complex, and the values of the Reichardt parameter E_T,[14,15] and of Gutmann's acceptor number (*AN*),[16] for the solvents used. Solvatochromic data in water are restricted to *cis*-[Fe(*i*Bu$_2$-bpy)$_2$(CN)$_2$], the only complex that is water-soluble.

Comparison of solvent sensitivity of the *cis*-[FeL$_2$(CN)$_2$] complexes prepared in this work (**1**−**4**) with that of *cis*-[Fe(bpy)$_2$(CN)$_2$], the inorganic species whose solvatochromic behaviour has been most extensively studied, can be made by plotting their $\tilde{\nu}_{max}$(MLCT) values against those of *cis*-[Fe(bpy)$_2$(CN)$_2$], for solvents in which they are soluble. These plots gave straight lines, with correlation coefficients higher than 0.99±0.02, and with slopes close to unity (the average for complexes **1**−**4** is 1.05±0.05). Thus, it is possible to conclude that these complexes are as sensitive as *cis*-[Fe(bpy)$_2$(CN)$_2$] to the solvent environment, and that they also extend the range of solvents in which they can be used as probes. However, since *cis*-[Fe(bpy)$_2$(CN)$_2$] is not soluble in nonpolar solvents, it is of interest to note that a comparison of plots of $\tilde{\nu}_{max}$(MLCT) values for complexes **1**−**4** against those of the similar complex *cis*-[Fe(MePebpy)$_2$(CN)$_2$], which is soluble in solvents ranging from water to paraffins,[12] reveals that they have the same sensitivity, within experimental error (average slope: 1.00±0.02). All these results indicate that alkyl chains appended to 2,2′-bipyridine allow for a fine tuning of complex solubility, without changing the solvatochromic sensitivity of the "*cis*-[Fe(bpy)$_2$(CN)$_2$]" moiety.

It is also important to assess the solvatochromic response of complexes **1**−**4** against the E_T scale, the most widely used for empirical measurements of solvent polarity. The plots of $\tilde{\nu}_{max}$(MLCT) for similar inorganic complexes versus the solvent E_T values found in the literature typically exhibit two correlation lines, which correspond to hydroxylic and non-hydroxylic solvents.[1,17,18] Such plots for complexes **1**−**4** exhibit roughly the same behaviour, but with a novel feature: a third correlation line is observed for nonpolar solvents. This feature is absent from the plots reported in the literature, since the complexes were not soluble in nonpolar solvents. This effect is observed more clearly for the more hydrophobic complexes **3** and **4**. Figure 1 shows such a plot for *cis*-[Fe(Hp$_2$bpy)$_2$(CN)$_2$].

A comparison with Gutmann's acceptor number *AN*[16,19] (another empirical solvent polarity scale) was also carried out. For complexes **1**−**4**, plots of $\tilde{\nu}_{max}$(MLCT) against *AN* values, for all polar solvents for which this value is available, show one reasonable correlation line (average correlation coefficient: 0.90±0.05). However, as with the comparison of $\tilde{\nu}_{max}$(MLCT) with E_T data, a different line is also obtained for nonpolar solvents.

Before suggesting a possible explanation for the difference in behaviour of complexes **1**−**4** with that of the Reichardt dyes, it is important to recall that Reichardt defines solvent polarity as "the overall solvation capability of sol-

[a] E_T values are in kcal mol^{-1}. − [b] AN = acceptor number. − [c] $\tilde{\nu}_{max}$ for the lowest energy MLCT band for [Fe(CN)$_2$(bpy)$_2$] cm^{-1}. − [d] Not soluble. − [e] Not determined.

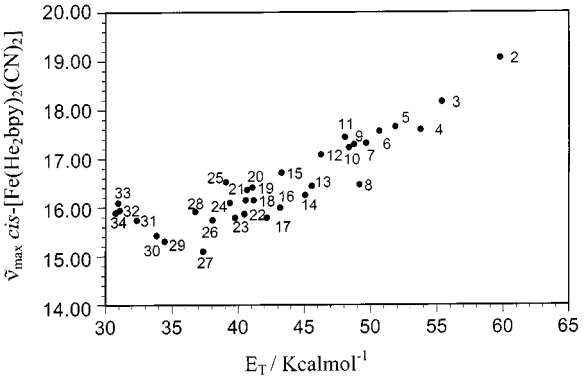

Figure 1. Wavenumber of the maximum absorption ($\tilde{\nu}_{max}$/10^3 cm^{-1}) for the lowest-energy MLCT band of *cis*-[Fe(Hp$_2$bpy)$_2$(CN)$_2$], plotted versus Reichardt E_T values; the numbering of the points corresponds to the numbering of solvents in Table 1

vents, which in turn depends on the action of all possible, non-specific and specific intermolecular interactions between solute ions or molecules and solvent molecules".[15,20] From this definition it is clear that the solvatochromic band of the Reichardt dyes (the lowest-energy charge-transfer absorption band) is not related to properties of the solvent considered as a non-structured continuum.

As the response of complexes **2**−**4**, and **5** correlates in a different manner with the E_T values, they must be responding to a different solvent property, probably to a physical property of the solvent considered as non-structured continuum. In fact a reasonable correlation is obtained when $\tilde{\nu}_{max}$(MLCT) is plotted against the dipole moment of the nonpolar solvents (correlation coefficient = 0.92).

Solvatochromic Behaviour in Binary Aqueous Solvent Mixtures

The solvatochromic behaviour of complexes **1**−**4** was also studied in three binary solvents; water/methanol, water/acetone, and water/acetonitrile. The first co-solvent is protic, and although the other two are non-protic, acetonitrile is also known as a protogenic solvent since a strongly basic solute induces the formation of hydrogen bonds with the hydrogen atoms from the methyl group adjacent to the CN group.[19]

For complexes **1**−**4** in the three binary aqueous mixtures, $\tilde{\nu}_{max}$(MLCT) data can be divided into two sets. The behaviour of the complex *cis*-[Fe(*i*Bu$_2$bpy)$_2$(CN)$_2$] (**1**) is practically identical to that of *cis*-[Fe(PeMebpy)$_2$(CN)$_2$], and is similar to that observed for other inorganic iron(II) diimine cyanide complexes.[4,12,21] However, for complexes **2**−**4**, which have longer alkyl chains attached to the 2,2′-bipyridine moiety, the $\tilde{\nu}_{max}$(MLCT) dependence on solvent composition for regions of high water content is completely different. The $\tilde{\nu}_{max}$(MLCT) values become independent of solvent composition. This unexpected result is, to the best of our knowledge, unparalleled in the literature for diimine-iron(II) cyanide complexes.

cis-[Fe(iBu$_2$bpy)$_2$(CN)$_2$] (1)

In water/methanol, plots of $\tilde{\nu}_{max}$(MLCT) against volume content (v/v) of methanol are linear, which indicates similar solvation by water and methanol in the full composition range. Analogous plots for acetone and acetonitrile as the co-solvents indicate strong preferential hydration in acetonitrile or acetone-rich media, but similar solvation by water and co-solvent in water-rich media (Figure 2). A comparable behaviour is observed for *cis*-[Fe(bpy)$_2$(CN)$_2$] in the first two solvent mixtures, but in water/acetone preferential solvation by water occurs over the full composition range, as has been reported in the literature.[4]

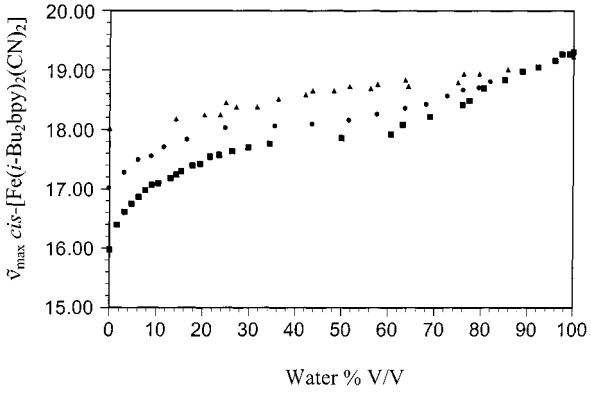

Figure 2. Wavenumber of the maximum absorption ($\tilde{\nu}_{max}/10^3$ cm^{-1}) for the lowest-energy MLCT band of *cis*-[Fe(*i*Bu$_2$bpy)$_2$(CN)$_2$] in methanol (▲), acetonitrile (●) and acetone (■) solvent mixtures

It is also of interest to compare the results for complex **1** and *cis*-[Fe(bpy)$_2$(CN)$_2$] with those for *cis*-[Fe(PeMebpy)$_2$(CN)$_2$].[12] In water/methanol and water/acetonitrile mixtures all these complexes exhibit the behaviour described above for **1**: (a) similar solvation by water and methanol in the full composition range; (b) preferential solvation by water in acetonitrile-rich media and similar solvation by water and acetonitrile in water-rich media. However, in the acetone-rich region of the water/acetone media all complexes exhibit preferential solvation by water, but for regions of high water content they exhibit different solvatochromic properties; *cis*-[Fe(bpy)$_2$(CN)$_2$] is preferentially solvated by water, *cis*-[Fe(PeMebpy)$_2$(CN)$_2$] by acetone and *cis*-[Fe(*i*Bu$_2$bpy)$_2$(CN)$_2$] is similarly solvated by water and acetone (Figure 3). These different solvatochromic characteristics must be related not only to solvent polarity, but also to differences between the hydrophobicity of the complexes (see below).

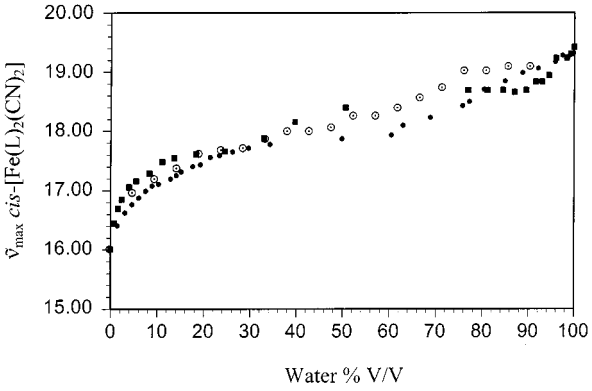

Figure 3. Wavenumber of the maximum absorption ($\tilde{\nu}_{max}/10^3$ cm^{-1}) for the lowest-energy MLCT band of *cis*-[Fe(*i*Bu$_2$bpy)$_2$(CN)$_2$] (●), *cis*-[Fe(PeMebpy)$_2$(CN)$_2$] (■) and *cis*-[Fe(bpy)$_2$(CN)$_2$] (⊙) in water/acetone mixtures; composition 0−100% H_2O, by volume before mixing, at 298 K

A plot of $\tilde{\nu}_{max}$(MLCT) of complex **1** against $\tilde{\nu}_{max}$-(MLCT) of *cis*-[Fe(bpy)$_2$(CN)$_2$] in water/acetone and water/acetonitrile mixtures is linear with a slope of 0.93±0.05. This indicates that both complexes have comparable sensitivities for these mixtures. In contrast, the slope in water/methanol is 0.78±0.05, an indication that complex **1** is less sensitive in methanol/water than *cis*-[Fe(bpy)$_2$(CN)$_2$]. This behaviour, which has already been found for *cis*-[Fe(PeMebpy)$_2$(CN)$_2$], indicates that the hydrophobicity, imparted by the presence of the aliphatic chains, renders the complexes less sensitive to small changes in the composition of a mixture of two very polar solvents.

Finally, a comparison with the Reichardt E_T scale can be made, as the E_T values are known for mixtures of water with methanol, acetone, or acetonitrile as the co-solvent.[21−23] When values of $\tilde{\nu}_{max}$(MLCT) were plotted against E_T, for all mixed solvents, linear correlations were obtained (average correlation coefficient: 0.98). This trend suggests that complex **1** is similarly affected by the mixed solvent components as is the organic betaine, upon whose spectra the E_T scale is based.

Complexes with Longer Alkyl Chains − *cis*-[Fe(Pe$_2$bpy)$_2$-(CN)$_2$] (2), *cis*-[Fe(Hp$_2$bpy)$_2$(CN)$_2$] (3), and *cis*-[Fe(HeMebpy)$_2$(CN)$_2$] (4)

Plots of $\tilde{\nu}_{max}$(MLCT) against water content for complexes **2**−**4** can be divided into two regions, co-solvent-rich and water-rich media (Figure 4).

In the co-solvent-rich region, all complexes exhibit a behaviour analogous to that of *cis*-[Fe(PeMebpy)$_2$(CN)$_2$], *cis*-[Fe(*i*Bu$_2$bpy)$_2$(CN)$_2$], and *cis*-[Fe(bpy)$_2$(CN)$_2$]: similar solvation by water and methanol in water/methanol, and preferential solvation by water in water/acetone and water/acetonitrile. Plots of $\tilde{\nu}_{max}$(MLCT) for complexes **2**−**4** versus $\tilde{\nu}_{max}$(MLCT) of *cis*-[Fe(bpy)$_2$(CN)$_2$] are linear, with an average slope of 1.02±0.05 in water/acetone and water/acetonitrile, but with a slope of 0.78±0.05 in water/methanol.

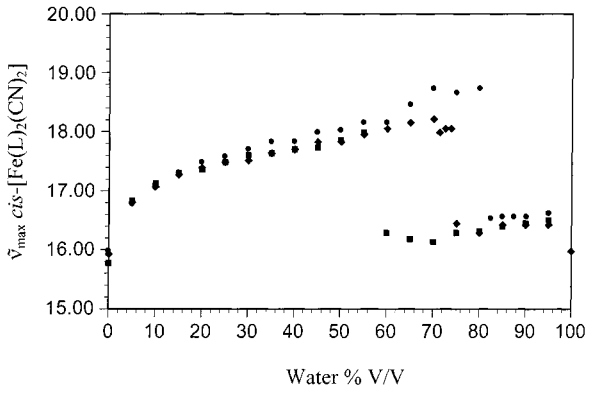

Figure 4. Wavenumber of the maximum absorption ($\tilde{\nu}_{max}/10^3$ cm^{-1}) for the lowest-energy MLCT band of *cis*-[Fe(Pe$_2$bpy)$_2$(CN)$_2$] (♦), *cis*-[Fe(Hp$_2$bpy)$_2$(CN)$_2$] (■), and *cis*-[Fe(HpMebpy)$_2$(CN)$_2$] (•) in water/acetone mixtures; composition 0−100% H_2O, by volume before mixing, at 298 K

This indicates less sensitivity to solvent polarity in this latter mixture. This situation is identical to that found for *cis*-[Fe(PeMebpy)$_2$(CN)$_2$] and *cis*-[Fe(*i*Bu$_2$bpy)$_2$(CN)$_2$] in water/methanol, and must reflect the reduced ability of hydrophobic complexes to discriminate between very polar complexes.

However, in regions of high water content and for all co-solvents, the solvatochromic behaviour of complexes **2**−**4** is completely different. An unexpected and abrupt bathochromic shift in $\tilde{\nu}_{max}$(MLCT) to the same final value of $\tilde{\nu}_{max}$(MLCT) for each complex is observed at a specific co-solvent volume content. This shift implies that nonpolar molecules must surround the complexes, since the final value of $\tilde{\nu}_{max}$(MLCT) is very similar to that observed in pure non-protic solvents. This is a very strange occurrence since the complexes are in water-rich media. This abrupt change in $\tilde{\nu}_{max}$(MLCT) is not only dependent on the complex, but also on the co-solvent (Table 2). The volume fraction of water at which the abrupt change occurs is: (a) for each complex roughly the same for acetonitrile and acetone as the co-solvents, and lower for methanol, and (b) increases in the order *cis*-[Fe(HpMebpy)$_2$(CN)$_2$] > *cis*-[Fe(Pe$_2$bpy)$_2$(CN)$_2$] > *cis*-[Fe(Hp$_2$bpy)$_2$(CN)$_2$]. For water contents above this critical value, the resulting solutions are blue and show a slight turbidity; however, the scattering does not prevent the observation of the lowest-energy MLCT band. Obviously, complexes **2**−**4** can only be used as probes for water concentrations smaller than that at which the abrupt change in $\tilde{\nu}_{max}$(MLCT) occurs, and in this region their sensitivity is similar to that of other bipyridyldicyanoiron(II) complexes.

Metalloaggregate Formation

A possible explanation for the anomalous solvatochromic behaviour of complexes **2**−**4** can be given by the formation of aggregates. These complexes have hydrophobic tails that not only have a reasonably strong affinity for themselves, but are also segregated from the polar liquid, largely due to the hydrogen bonding between the polar molecules. These factors lead to an exclusion of water molecules from the immediate environment of the complexes which sense a non-protic environment.

Solutions of complexes **2**−**4** (concentration ca. $1.5\cdot10^{-5}$ M) have been prepared in water/co-solvent mixtures with a water mol fraction higher than that at which the abrupt change in $\tilde{\nu}_{max}$(MLCT) occurs. Light-scattering analysis of these mixtures showed the existence of aggregates with a mean diameter of 1000±250 nm, and with very large polydispersion (1.00).

This observation supports the assumption that the abrupt change in $\tilde{\nu}_{max}$(MLCT) may be ascribed to the formation of metalloaggregates in regions of high water content. Formation is clearly solvent-dependent, and in the more polar water/methanol mixtures it occurs at a lower water content than in the less polar mixtures with acetone or acetonitrile (Figure 4). This is an expected result since the tails of the complexes render the monomers less soluble in the more polar mixtures. Obviously, the alkyl chains markedly control complex hydrophobicity, and the ease of formation of metalloaggregates is related to the size and number of the aliphatic chains. For complex **4**, which has four chains with seven carbon atoms, aggregation starts at a smaller water content than that for complex **2**, which has four alkyl chains with five carbon atoms each. Finally, the monomers of complex **3**, which have only two alkyl chains with seven carbon atoms each, are more soluble in water-rich media than either complex **2** or **4**.

Concluding Remarks

The complexes prepared in this work have been shown to be solvatochromic probes as sensitive to solvent polarity as [Fe(bpy)$_2$(CN)$_2$], the most studied inorganic probe, but with the added advantage of being soluble in a wider range of solvents. The hydrophilic-lipophilic balance, which in turn depends on the length of the alkyl chain, controls their solvation behaviour; short chains make the complexes insoluble in nonpolar solvents, whereas long chains render them insoluble in water. The complex [Fe(PeMebpy)$_2$(CN)$_2$], already reported in the literature, is still the only complex of this type with a hydrophilic-lipophilic balance that makes it soluble in both water and in *n*-alkanes.[12] The use of

Table 2. Water molar percent at which there is an abrupt change in the wavenumber of the maximum absorption

Solvent	[Fe(Pe$_2$bpy)$_2$(CN)$_2$]	[Fe(He$_2$bpy)$_2$(CN)$_2$]	[Fe(Hebpy)$_2$(CN)$_2$]
Acetone	92%	85%	95%
Acetonitrile	89%	84%	95%
Methanol	77%	70%	90%

iron(II) complexes with substituted 2,2′-bipyridyl ligands, which contain one or two hydrophobic chains of varying length, as solvatochromic probes combines the sensitivity of the bipyridyldicyanoiron(II) complexes with the solubility of the analogous, but less sensitive, complexes of Schiff base diimines in nonpolar solvents.

In binary mixtures the results obtained show that in co-solvent rich media, all new complexes exhibit similar behaviour: in acetone and acetonitrile, they are as sensitive as $[Fe(bpy)_2(CN)_2]$ to hydration, but less sensitive in methanol to changes in solvent polarity. In water-rich media, the hydrophobicity imposed by the alkyl tails clearly controls the behaviour of the complexes. With these new complexes we have begun the construction of a good basic set of solvation probes that seem to be ideal for the analysis of the relative importance of electrostatic/hydrophobic interactions in binary aqueous media. These complexes are very versatile solvation probes and may well prove to be valuable in assessing solvent polarity in a variety of novel heterogeneous/organised solvent media.

Finally, an interesting result emerging from this work is the demonstration of the self-aggregating properties of the complexes *cis*-$[Fe(Pe_2bpy)_2(CN)_2]$, *cis*-$[Fe(He_2bpy)_2(CN)_2]$, and *cis*-$[Fe(Hebpy)_2(CN)_2]$ which are, without doubt, metallosurfactants. Surfactants containing transition metal ions have only recently begun to be investigated. The use of a transition metal ion in the head-group permits the incorporation of useful properties such as colour, paramagnetism, variable charge, and pH sensitivity. Moreover, as transition metal complexes possess a wide range of reactivity, such as redox behaviour and catalytic activity, they can provide a good method of localising this kind of activity at interfaces.

Experimental Section

Instrumentation: Elemental analyses (C, H N) were performed by the Micro Analytical Laboratory, Department of Chemistry, University of Manchester (UK). No elemental analyses were performed for the complexes since compounds with cyanides always give unreliable results. − IE and FAB mass spectra at "Unidade de Espectrometria de Masas, Facultad de Química, Universidade de Santiago de Compostela" (Spain), using 3-nitrobenzyl alcohol (NBA) as the matrix. − ^{1}H NMR spectra were recorded with a Bruker AC 200 at 200 MHz (298 K). Chemical shifts are reported in ppm referred to TMS, used as an internal standard. − UV/Vis spectra were recorded in the 800−200 nm range with a Unicam UV-2, at room temperature, using quartz cells with 1 cm optical path. Light-scattering measurements were performed with a Malvern Instruments ZetaSizer 5000, using the 633-nm line of a He-Ne 5-mW laser.

Solvents and Reagents: All solvents were from Merck and all chemicals from Aldrich, except for 4,4′-dimethyl-2,2′-bipyridyl and the *n*-bromoalkanes which were from Fluka; all were used as received.

Ligand Synthesis

4,4′-Diisobutyl-2,2′-bipyridine (*i*Bu$_2$bpy): The ligand was prepared according to a published procedure[24] with 4,4′-dimethylbipyridine (Me_2bpy; 5.0 g; 27 mmol) and 2-bromopropane (7.7 ml; 82 mmol). All other reagents and solvents were used in the amounts described for the synthesis of the symmetric bipyridine derivatives.[24] Purification by chromatography on silica gel 60 (70−230 mesh ASTM) using 1,4-dioxane as the eluent afforded a pale yellow oil (yield: 58%, 4.20 g). − ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.91 (t, 3 H), 1.36 (m, 2 H), 1.70 (m, 4 H), 2.44 (s, 3 H), 2.69 (t, 2 H), 7.13 (m, 2 H), 8.22 (s, 2 H), 8.54 (m, 2 H). − $C_{18}H_{24}N_2$ (268.4): C 80.55, H 9.01, N 10.44; found C 80.55, H 9.01, N 10.38.

4,4′-Di-*n*-pentyl-2,2′-bipyridine (Pe$_2$bpy): A procedure similar to that described above was applied using 1-bromobutane (8.8 ml; 82 mmol). Purification by basic alumina column chromatography (3 × 20 cm, activity grade 1) using dichloromethane as the eluent, followed by chromatography of the appropriate fraction on silica gel (3 × 20 cm, 230−400 mesh) with a gradient starting with 10% up to 40% diethyl ether in petroleum ether, afforded the pure compound as a pale yellow oil (yield: 60.0%, 4.80 g). − ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.78−0.88 (m, 6 H, 2 × -CH_3), 1.25−1.34 [m, 8 H, 2 × -$(CH_2)_2$-CH_3], 1.60−1.67 (m, 4 H, 2 × Ar-CH_2-CH_2), 2.63 (t, $J_{H,H}$ = 7.79 Hz, 4 H, 2 × Ar-CH_2-), 7.06 (dd, $J_{H,H}$ = 4.99, 1.28 Hz, 2 H, 2 × Ar-5-H), 8.30 (s, 2 H, 2 × Ar-3-H), 8.55 (d, $J_{H,H}$ = 5.02 Hz, 2 H, 2 × Ar-6-H). − ^{13}C NMR (300 MHz, $CDCl_3$): δ = 13.5 (2 × -CH_3), 34.9 (2 × Ar-CH_2), 120.7, 123.3 (Ar-C3, Ar-C5), 148.4 (Ar-C4), 152.1 (Ar-C6), 155.6 (Ar-C2). − MS (70 eV, EI): *m*/*z* (%) = 296 (9) [$M^{+\cdot}$]. − $C_{20}H_{28}N_2$ (296.5): C 81.03, H 9.52, N 9.45; found C 80.92, H 9.81, N 9.58.

4,4′-Di-*n*-heptyl-2,2′-bipyridine (Hp$_2$bpy): A similar procedure was applied using 1-bromohexane (11.5 ml; 81.9 mmol). Purification by column chromatography (3 × 35 cm) with dichloromethane as the eluent afforded a white powder that was further purified by recrystallisation from ethanol (yield: 66.1%, 6.28 g), m.p. = 32−34 °C. − ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.88 (t, *J* = 6.81 Hz, 6 H, 2 × -CH_3), 1.24−1.37 [m, 16 H, 2 × -$(CH_2)_4$-CH_3], 1.66−1.72 (m, 4 H, 2 × ArCH_2-CH_2), 2.69 (t, $J_{H,H}$ = 7.80 Hz, 4 H, 2 × Ar-CH_2), 7.13 (dd, $J_{H,H'}$ = 5.0, 1.64 Hz, 2 H, 2 × Ar-5-H), 8.22, 8.23 (s, 2 H, 2 × Ar-3-H), 8.56 (d, $J_{H,H}$ = 5.13 Hz, 2 H, 2 × Ar-6-H). − ^{13}C NMR (300 MHz, $CDCl_3$): δ = 14.1 (2 × -CH_3), 35.5 (2 × Ar-CH_2), 121.3, 123.9 (2 × Ar-C3, 2 × Ar-C5), 148.9 (Ar-C4), 152.9 (Ar-C6), 156.1 (Ar-C2). − MS (70 eV, EI): *m*/*z* (%) = 352 (14) [$M^{+\cdot}$]. − $C_{24}H_{36}N_2$ (352): C 81.76, H 10.29, N 7.94; found C 81.66, H 10.39, N 8.26.

4-*n*-Heptyl-4′-methyl-2,2′-bipyridine (HpMebpy): 4,4′-Dimethylbipyridine (5.0 g; 27 mmol) and 1-bromohexane (11.5 ml; 81.9 mmol) were used. All other reagents and solvents were used in the amounts described for the synthesis of the asymmetric bipyridine derivatives.[24] Purification of the cream solid obtained was performed by recrystallisation from ethanol (yield: 32.0%, 2.32 g), m.p. 36−38 °C. − ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.84−0.91 (m, 6 H, 2 × -CH_3), 1.27−1.33 [m, 8 H, 2 × -$(CH_2)_4$-CH_3], 1.65−1.79 (m, 2 H, 2 × ArCH_2-CH_2), 2.44 (s, 3 H, Ar-CH_3), 2.69 (t, $J_{H,H}$ = 8.0 Hz, 2 H, Ar-CH_2), 7.13 (d, $J_{H,H}$ = 5.0 Hz, 2 H, 2 × Ar-5-H), 8.22 (s, 2 H, 2 × Ar-3-H), 8.54 (d, $J_{H,H}$ = 4.8, 2 H, 2 × Ar-6-H). − ^{13}C NMR (200 MHz, $CDCl_3$): δ = 14.0 (-CH_3), 31.7 (Ar-CH_3), 35.51 (Ar-CH_2), 121.3, 122.0, 123.9, 124.6(2 × Ar-C5, 2 × Ar-5), 148.0, 148.9 (2 × Ar-C4), 152.9 (Ar-C6), 156.1 (Ar-C2). − MS (70 eV, EI): *m*/*z* (%) = 268 (10) [$M^{+\cdot}$]. − $C_{18}H_{24}N_2$ (268.4): C 80.55, H 9.01, N 10.44; found C 79.95, H 9.04, N 10.99.

Synthesis of Iron(II) Complexes

***cis*-Dicyanobis(4,4′-diisobutyl-2,2′-bipyridine)iron(II) [Fe(*i*Bu$_2$bpy)$_2$(CN)$_2$]:** The complex was prepared by Schilt's method,[13] with mi-

nor modifications. A stoichiometric amount of $(NH_4)_2$-$FeSO_4 \cdot 6H_2O$ in water (5 mL) was added to a solution of *i*Bu_2bpy (0.371 g; 1.38 mmol) in refluxing methanol (25 mL). After full development of the characteristic red colour, a stoichiometric amount of KCN was added. On standing at room temperature, a blue solid formed which was washed with petroleum ether (10 × 20 mL) and recrystallised from a mixture of 1:5 v/v dichloromethane/petroleum ether (yield: 74.7%, 0.22 g), m.p. > 300 °C. − ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS). δ = 0.85−0.97 (m, 6 H, 2 × -CH_3), 1.27−1.43 [m, 8 H, 2 × -$(CH_2)_2$-CH_3], 1.57−1.76 (m, 4 H, 2 × Ar-CH_2-CH_2-), 2.61, 2.77 (t, $J_{H,H}$ = 7.79, $J_{H,H}$ = 7.76 Hz, 4 H, 2 × Ar-CH_2-), 6.86, 7.20 (dd, $J_{H,H}$ = 5.71, 1.28 Hz, $J_{H,H}$ = 5.76, 1.27 Hz, 2 H, 2 × Ar-5-H), 7.12, 9.81 (d, $J_{H,H}$ = 5.75 Hz, $J_{H,H}$ = 5.80 Hz, 2 H, 2 × Ar-6-H), 7.82 (s, 2 H, 2 × Ar-3-H). − ^{13}C NMR (200 MHz, $CDCl_3$): δ = 14.0 (2 × -CH_3), 35.28 (2 × Ar-CH_2), 121.1, 125.0 (Ar-C5, Ar-C3), 150.1, 158.3 (2 × Ar-C6), 151.2, 151.4 (2 × Ar-C4), 157.7, 161.6 (2 × Ar-C2). − MS (10 keV, FAB+): *m*/*z* (%) = 700 (5) [$M^{+\cdot}$], 674 (44) [M^+ − CN], 648 (29) [M^+ − $(CN)_2$].

***cis*-Dicyanobis(4,4′-di-*n*-pentyl-2,2′-bipyridine)iron(II) [Fe(Pe_2bpy)$_2$-$(CN)_2$]:** A similar procedure was followed using Pe_2bpy (1.35 g; 4.57 mmol). The blue solid formed was washed with petroleum ether (10 × 20 cm^3) and recrystallised from a mixture of 2:10 v/v dichloromethane/petroleum ether (yield: 74.7%, 0.80 g), m.p. > 300 °C. − ^{1}HNMR (300 MHz, $CDCl_3$, 25 °C, TMS). δ = 0.85−0.97 (m, 6 H, 2 × -CH_3), 1.27−1.43 [m, 8 H, 2 × -$(CH_2)_2$-CH_3], 1.57−1.76 (m, 4 H, 2 × Ar-CH_2-CH_2-), 2.61, 2.77 (t, $J_{H,H}$ = 7.79, $J_{H,H}$ = 7.76 Hz, 4 H, 2 × Ar-CH_2-), 6.86, 7.20 (dd, $J_{H,H}$ = 5.71, 1.28 Hz, $J_{H,H}$ = 5.76, 1.27 Hz, 2 H, 2 × Ar-5-H), 7.12, 9.81 (d, $J_{H,H}$ = 5.75 Hz, $J_{H,H}$ = 5.80 Hz, 2 H, 2 × Ar-6-H), 7.82 (s, 2 H, 2 × Ar-3-H). − ^{13}C NMR (200 MHz, $CDCl_3$): δ = 14.0 (2 × -CH_3), 35.28 (2 × Ar-CH_2), 121.1, 125 (Ar-C5, Ar-C3), 150.1, 158.3 (2 × Ar-C6), 151.2, 151.4 (2 × Ar-C4), 157.7, 161.6 (2 × Ar-C2). − MS (10 keV, FAB+): *m*/*z* (%) = 700 (5) [$M^{+\cdot}$], 674 (44) [M^+ − CN], 648 (29) [M^+ − $(CN)_2$].

***cis*-Dicyanobis(4,4′-diheptyl-2,2′-bipyridine)iron(II) [Fe(Hp_2bpy)$_2$-$(CN)_2$]:** A similar procedure was applied using Hp_2bpy (1.00 g; 2.84 mmol). Recrystallisation of the product from a mixture of 1:50 v/v dichloromethane/petroleum ether, afforded a dark blue solid (yield: 63.3%, 0.49 g), m.p. > 300 °C. − ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.84−0.94 (m, 6 H, 2 × -CH_3), 1.19−1.40 [m, 16 H, 2 × -$(CH_2)_4$-CH_3], 1.59−1.75 (m, 4 H, 2 × $ArCH_2$-CH_2), 2.61, 2.77 (t, $J_{H,H}$ = 7.77, $J_{H,H}$ = 7.77 Hz, 4 H, 2 × $ArCH_2$), 6.86, 7.21 (d, $J_{H,H}$ = 5.19, $J_{H,H}$ = 4.89 Hz, 2 H, 2 × Ar-5-H), 7.12, 9.81 (d, $J_{H,H'}$ = 5.76 Hz, $J_{H,H}$ = 5.8 Hz, 2 H, 2 × Ar-6-H), 7.80, 7.81 (s, 2 H, 2 × Ar-3-H). − ^{13}C NMR (200 MHz, $CDCl_3$): δ = 14.10 (2 × CH_3), 35.32 (2 × $ArCH_2$), 121.2, 125.2 (Ar-C3, Ar-C5), 150.1, 158.4 (2 × Ar-C6), 151.2, 151.4 (2 × Ar-C4), 157.8, 161.6 (2 × Ar-C2). − MS (10 keV, FAB^+): *m*/*z* (%) = 812 (6) [$M^{+\cdot}$], 786 (50) [M^+ − CN], 760 (30) [M^+ − $(CN)_2$].

***cis*-Dicyanobis(4-*n*-heptyl-4′-methyl-2,2′-bipyridine)iron(II) [Fe(HpMebpy)$_2$$(CN)_2$]:** A similar procedure was applied using HpMebpy (0.912 g; 3.40 mmol). The dark blue solid was purified twice by column chromatography (3 × 20 cm, silica gel 230−400 mesh) using a gradient of acetone/methanol as the eluent. The complex was further purified by recrystallisation from acetone/ethanol (yield 24.7%, 0.18 g), m.p. > 300 °C. − ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): δ = 0.83−0.91 (m, 3 H, -CH_3), 1.20−1.36 [m, 8 H, -$(CH_2)_4$-CH_3], 1.52−1.61 (m, 2 H, $ArCH_2$-CH_2), 2.35−2.37 (m. 2 H, Ar-CH_2), 2.53 (s, 3 H, $ArCH_3$), 6.84, 7.19 (d, $J_{H,H}$ = 6.0 Hz, $J_{H,H}$ = 5.6 Hz, 2 H, 2 × Ar-5-H), 7.10, 9.77 (t, $J_{H,H}$ = 6.6 Hz, $J_{H,H}$ = 5.8 Hz, 2 H, 2 × Ar-6-H), 7.83, 7.88 (s, 2 H, 2 × Ar-3-H). − ^{13}C NMR (200 MHz, $CDCl_3$): δ = 14.0 (-CH_3), 31.6 (Ar-CH_3), 35.23 (Ar-CH_2), 121.3, 122.15, 125.28, 126.31(2 × Ar-C5, 2 × Ar-C3), 146.0, 151.6(2 × Ar-C4), 150.0, 158.3 (2 × Ar-C6), 157.6, 162.0 (2 × Ar-C2). − MS (10 keV, FAB^+): *m*/*z* (%) = 644 (3) [$M^{+\cdot}$], 618(32) [M^+ − CN], 592(24) [M^+ − $(CN)_2$].

Structural and Electronic Properties of Neutral Phosphoniobenzo[*c*]phospholides

Stefan Häp,[a] Laszlo Szarvas,[a] Martin Nieger,[a] and Dietrich Gudat*[a]

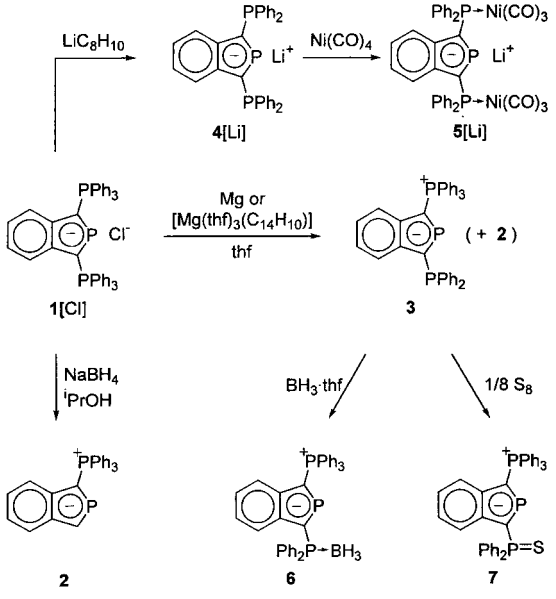
Keywords: Phosphorus / Phosphorus heterocycles / Electronic structure / Conjugation / Zwitterions

The neutral monophosphoniobenzo[*c*]phospholides **2** and **3** were selectively prepared by reduction of bis(triphenylphosphonio)benzophospholide chloride **1**[Cl]. Compound **3** was further converted into the borane adduct **6** and the thioxophosphorane **7**. All products were characterised by spectroscopic methods and X-ray diffraction. The most notable features of the molecular structures are the significantly different distances of the two P–C bonds adjacent to the two-coordinate phosphorus atom (P2–C1 175.0–176.6, P2–C3 171.7–173.5 pm), and a short exocyclic C–P(phosphonio) bond (C1–P1 172.5–173.7 pm) relative to cationic derivatives such as **1**. Structure comparisons revealed further variations in the bond lengths, which can be related to the changes in the inductive electron-withdrawing power of the substituents in the 3-position of the fused ring system. Computational studies of monophosphoniobenzophospholides, as well as the corresponding anions with no phosphonio substituents, and cations with two phosphonio substituents, allowed for the interpretation of the special properties of the neutral species in terms of a partial π-bond localisation. This, in terms of a VB picture, is equivalent to the prominence of a single resonance structure that can best be described as an ylide-substituted cyclic phosphaalkene. The analysis of these results allows important predictions for the chemical properties of these compounds.

Introduction

Bis(phosphonio)benzo[*c*]phospholide [bis(phosphonio)-2-phosphaindenide] cations such as **1**[1] exhibit a very special bonding situation that has been described in terms of a benzophospholide anion with a delocalised heteronaphthalenic 10π-electron system, and two positively charged phosphonio substituents.[2,3] Although electron delocalisation over the phosphonio groups and the π-electron system is low,[2,4] the electrostatic influence of the substituents still induces a marked reduction in nucleophilicity relative to the anionic phospholide derivatives, and polarises the π-electron distribution in the ring.[2–4] As a consequence of these effects, bis(phosphonio)benzophospholides display a very balanced nucleophilic and electrophilic reactivity, which is the primary reason for their remarkable stability towards solvolysis and addition reactions,[1,3,5] and their preference to coordinate to transition metal atoms through the phosphorus lone-pair[3,6] rather than the π-electron system as most other phospholide-type ligands.[7]

In the course of the investigation of the chemical properties of bis(phosphonio)benzophospholides, we established that reduction of **1** gives easy access to both neutral, zwitterionic phosphoniobenzophospholides **2**, **3**, and phosphanylbenzophospholide anions **4** (see Scheme 1).[8] Although a structural study of the carbonylnickel complex **5** revealed that the endocyclic bond lengths and angles are very similar to those of cation **1**,[8] one can expect that an increasing electrostatic polarisation by positively charged substituents should induce a concomitant modification of the π-electron distribution in the fused ring system. This view is, in principle, supported by the results of a comparative theoretical study of the parent benzo[*c*]phospholide anion and the corresponding bis(phosphonio)-substituted cation.[2] However, a concise investigation with regard to this issue is still lacking.



Scheme 1

In the present work we present a combined experimental and computational study of the molecular and electronic structures of the neutral 1-(triphenylphosphonio)enzo[*c*]-

phospholides **2** and **3**, the borane adduct **6**, and the thioxophosphorane derivative **7** (Scheme 1). The studied compounds were selected for two main reasons. Firstly, comparison of the bonding situation in **2** and **3** with that in the "symmetrically" substituted ions **1** and **4**, should allow us to see if the polarisation by a *single* charged phosphonio moiety leads to an imbalance in the π-electron distribution, which may result in partial bond localisation. Secondly, comparison of the bonding situation in **3** with that in the borane adduct **6**, thioxophosphorane **7**, and the phosphonium salt **1** should allow for the monitoring of the differential effects which accompany the increasing local positive charge on the phosphorus atom of the substituent in the 3-position. The understanding of both effects is considered important for an improved understanding of the chemical properties of the studied benzo[*c*]phospholide derivatives, and, in particular, of their behaviour in complexation reactions. The latter issue is of special interest in light of the fact that aromatic phosphorus heterocycles have gained recent attention as ligands in catalysis, because of their unusual electronic properties.[9]

Results and Discussion

Syntheses and Spectroscopic Investigations

3-Diphenylphosphanyl-1-triphenylphosphoniobenzo[*c*]-phospholide (**3**) was prepared as described previously,[8] by reduction of bis(triphenylphosphonio)benzo[*c*]phospholide chloride (**1**[Cl]) with active magnesium, which was generated by the decomposition of [Mg(THF)$_3$(anthracene)][10] in boiling toluene (Scheme 1). Further investigation of this reaction revealed that direct use of Mg/anthracene as a reducing agent gave slightly lower yields of the product, but required less effort for the preparation of the reagent and shorter induction times. 1-Triphenylphosphoniobenzo[*c*]-phospholide (**2**) was formed as a by-product in all the reactions, but could not be isolated as it decomposed during the workup procedure. However, the specific formation of compound **2** was observed when the reduction of **1**[Cl] was carried out with $NaBH_4$ in 2-propanol.[11] Under these conditions the product precipitated from the reaction mixture. It was easily separated from the formed PPh_3 and borate salts by filtration, and was isolated in good yield after recrystallisation from THF/*i*PrOH.

Having shown that quaternisation of the phosphane functionality in **3** with alkyl halides provides easy access to various side-chain-functionalised bis(phosphonio)benzo[*c*]-phospholide cations,[6] we anticipated that this compound should similarly undergo other typical phosphane reactions such as oxidation or formation of adducts with Lewis acids. In agreement with this assumption, treatment of **2** with equimolar amounts of borane−THF or sulfur afforded quantitative yields (based on ^{31}P NMR spectroscopic investigation of the reaction mixtures) of the corresponding borane adduct **6** and thioxophosphorane **7**, respectively. Use of excess reagents or prolonged reaction times gave no evidence for the quaternisation of the endocyclic phosphorus atom, and both products were isolated in good yields after evaporation of the volatiles and recrystallisation from THF/hexane.

The isolated zwitterionic phosphoniobenzophospholides are bright yellow to colourless solids, which are reasonably stable towards air and moisture. All products are readily soluble in polar aprotic solvents (CH_2Cl_2, MeCN, THF), very sparingly soluble in toluene, and insoluble in hexane.

The purities and identities of all compounds were unequivocally established by analytical and multinuclear (^{1}H, ^{11}B, ^{13}C, ^{31}P) NMR spectroscopic data. The ^{31}P{^{1}H} NMR spectra display characteristic AMX (**3**, **6**, **7**) or AX patterns (**2**) (Table 1). The chemical shifts of the exocyclic phosphorus nuclei fall in the expected ranges associated with the different types of functionalities. The resonance of the endocyclic phosphorus atom in **2** appears more upfield than that in **3**, whereas the corresponding resonances in **6**, **7** are more downfield and exhibit similar chemical shifts as the bis(methyldiphenylphosphonio)benzo[*c*]phospholide cation ($\delta^{31}P = 229.0$[8]). Besides the resonances of the C_6H_5 groups, the ^{1}H NMR spectra of all the compounds display the expected ABCD patterns for the protons of the benzophospholide moiety. For **2**, the signal assigned to 3-H is buried under other resonances in the aromatic region; however, it can clearly be seen in a two-dimensional ^{1}H,^{31}P-HMQC spectrum. The ^{1}H and ^{11}B NMR spectra of **6** show the expected broad multiplets assigned to the BH_3 moiety. The ^{13}C NMR spectra of all zwitterionic benzophospholides reveal close similarities with those of the bis(phosphonio)-substituted cations.[1−4,6] However, major differences are observed predominantly for the resonances of the two carbon atoms adjacent to the endocyclic phosphorus atom (cf. Table 1). In comparison with **1**, the signals of the

C-1 atoms adjacent to the exocyclic Ph_3P moiety are shifted upfield by about 10−20 ppm and approach the typical values observed for stable phosphonium ylides,[12] whereas the resonances of the C-3 atoms are deshielded by about 25−35 ppm and are similar to the chemical shifts for phosphinines.[12] On the whole, although the average chemical shift of both resonances (δ = 112.4−121.5) changes little relative to that of the cation **1** (δ = 109.0[1]), their large difference provides the first evidence for a marked polarisation of the π-electrons.

The UV/Vis spectra of the neutral benzo[*c*]phospholides display four major absorption bands whose positions and intensities are similar to those of the cation **1**[13] (Table 2). All observed electronic transitions display the characteristically high extinction coefficients of π−π* transitions and are much stronger than π−σ* transitions which are typical for ylides.[14] The two bands between 235 and 265 nm are assigned to π−π* transitions within the peripheral phenyl rings of the Ph_2P and Ph_3P^+ moieties, and the two bands at the lowest wavelengths are assigned to transitions of the benzophospholide chromophore. Absorption bands assigned to n−π* transitions are not observed and are presumably obscured by the much more intense π−π* transitions. The position of the energetically lowest absorption is comparable with those in 2-phosphanaphthalenes.[15] Examination

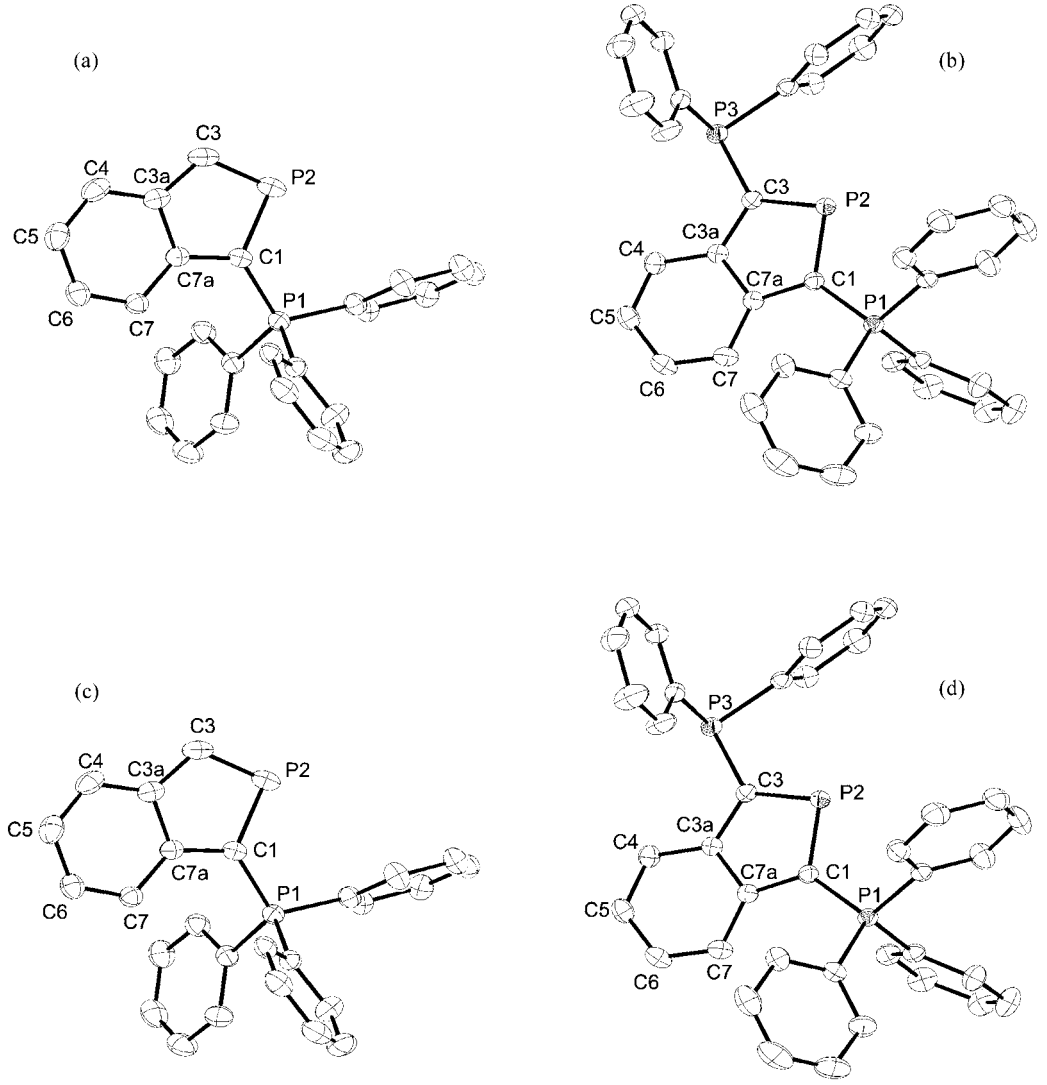

Figure 1. ORTEP-style view of the molecular structures of **2** (a), **3** (b), **6** (c), and **7** (d) with thermal ellipsoids drawn at the 50% level; hydrogen atoms are omitted for clarity, selected bond lengths are given in Table 3; in order to obtain a unique scheme, the crystallographic numbering was changed and a numbering scheme consistent with IUPAC rules used for the ring atoms; exocyclic phosphorus atoms are labelled as P1 (phosphonio group in the 1-position of the ring) and P3 (substituent in the 3-position of the ring)

of the spectra of the 3-substituted neutral compounds **3**, **6**, **7** and the cation **1**, reveals a continuous blue-shift of the energetically lowest absorption band with increasing electron-withdrawing power of the substituent in the 3-position, and an opposite trend for the second lowest absorption band.

Crystal Structure Studies

Suitable single crystals of **2**, **6**, and **7** were grown by slow evaporation of saturated THF solutions. Single crystals of **3** were obtained by cooling a saturated solution in toluene to −30 °C. The molecular structures are shown in Figure 1, and selected bond lengths are given in Table 3. The corresponding data of the cation **1**[16] and the anionic complex **5**[8] were included for comparison.

The results of the X-ray structure analyses reveal that the benzophospholide moieties in compounds **2** and **3** are planar, whereas in **6** and **7** the atoms in the benzene unit are slightly twisted around the long axis of the fused ring system. The origin of this distortion presumably arises from crystal packing effects; this effect is not considered significant and therefore will not be discussed further. The exocyclic phosphorus atoms in all compounds are located in the ring planes. The phenyl substituents at the exocyclic P2 and P3 atoms in **3** display a staggered conformation when observed along the P2−P3 axis, and those in **6** and **7** are eclipsed. As in the cation **1**,[16] the endocyclic phosphorus atom is always confined between two phenyl rings so that the P−B and P−S bonds (in **6** and **7**), or the hypothetical axis of the lone-pair (in **3**) at the exocyclic P3 atom, form angles of approx. 60−70° with the ring plane.

The lengths of all C−C bonds in the benzophospholide moiety (136−144 pm) lie in a range which is typical for aromatic systems and match those of corresponding bonds in indoles and indolyl anions.[17] Endocyclic and exocyclic P−C distances in the zwitterions **2**, **3**, **6** and **7** are similar to those in the ions **1** and **5**,[8,16] and are intermediate between pure single and double bond lengths. Comparison of the C1−P2 and P2−C3 bond lengths in the same molecule reveals the former to be significantly longer than the latter in all zwitterions. The effect is largest for **2** [Δr_{P-C} = 4.9(3) pm] and decreases continuously for **3** [Δr_{P-C} = 3.3(3) pm] and **6**, **7** [$\Delta r_{P-C} \approx$ 1.9(4) pm]. This effect is not observed in **1** and **5**, which have identical substituents at the C1 and C3 atoms, and in "asymmetric" bis(phosphonio)benzophospholides[6] with two different phosphonio groups. No similar asymmetry of the C−C bonds on opposite sides of the ring system is observed in any compound.

Comparison of corresponding bond lengths and angles in the fused rings of the disubstituted compounds **1**, **3** and **5**−**7** reveals that the C−C bonds and all bond angles are indistinguishable within experimental error. Insignificant variations were also found for the P2−C3 and the exocyclic P1−C1 bonds, whereas the C1−P2 bond lengths increase slightly but systematically in the series **3** < **6** ≈ **7** < **1**. The endocyclic P2−C3, C1−C7a, and C3−C3a bonds in the monosubstituted zwitterion **2** are shorter than the corresponding bonds in **3** by approx. 1 pm. A similar shortening is also observed for the exocyclic P1−C1 bond, and might suggest a slight increase in the ylidic nature of the phosphonio group. However, it must be noted that although the discussed differences and trends are significant when compared with the estimated standard deviations, it cannot be ruled out that these differences may have arisen from crystal packing effects or other intermolecular interactions (cf. the bond length differences between crystallographically independent molecules of **5** which are of similar magnitude). A further interpretation of these effects is thus, in our opinion, only meaningful when linked with the results of computational studies (see below).

The more pronounced variation of the C3−P3 distances in the studied zwitterions is easily explained in terms of the different substitution patterns at the P3 atom. Both the P3−B bond in **6** [193.15(19) pm] and the P3−S bond in **7** [196.90(7) pm] are longer than those in the corresponding triphenylphosphane derivatives (P−B in Ph_3P-BH_3 190.1 pm,[18] P−S in $Ph_3P{=}S$ 195.2 pm[19]), and lie near the upper limit of the known expected ranges for borane adducts and

sulfides of tertiary phosphanes (P−B 192.2±2.7, P−S 195.4±0.5 pm[17]). This suggests a comparatively low nucleophilicity of the exocyclic phosphane moiety in the studied molecules.

Computational Studies

In order to carry out a meaningful discussion of the changes in structure and bonding in the studied phosphoniobenzophospholides, and to gain a reliable basis for the interpretation of rather small structural distortions, we performed a comprehensive computational study using the B3LYP density functional method,[20] employed in the GAUSSIAN 98[21] suite of programs. To minimise computation times, the calculations were performed on the model compounds **1-H**−**4-H**, **6-H**, **7-H**, in which all peripheral phenyl rings of **1**−**4**, **6**, **7** had been replaced by hydrogen atoms, and any interaction of ionic species with the appropriate counter-ion was neglected.[22] The molecular structures of all compounds were obtained from energy optimisations at the B3LYP/6-31+g* level, and were shown to be local minima on the energy hypersurface by means of vibrational analyses. The results revealed that in the most stable conformers of compounds **3-H**, **6-H**, and **7-H**, the P−X axes of the PH_2X units (X = BH_3, S, lone-pair) form an angle of approx. 60° with the ring plane. This is in agreement with the experimentally observed conformations of **3**, **6**, **7** and implies a molecular C_1 symmetry. The molecular structures of **1-H** and **4-H** display C_{2v} symmetry, in agreement with the results of earlier computational studies of **1-H** at a different theoretical level,[2] and with the experimentally observed conformations of **1**[16] and complex **5**.[8] As the molecular structures of **3-H**, **6-H**, **5-H**, and **7-H** allow no clear-cut separation between orbitals of σ- and π-symmetry, we re-optimised the structures of these species under the constraint of C_s symmetry. The resulting molecular structures are local minima on the energy hypersurface whose energies (at the B3LYP/6-31+g* + ZPE level, see Table 4) and metric parameters (apart from the different torsion angles of the PH_2X groups) do not differ significantly from those of the C_1-symmetric conformers. Relevant structural parameters of the "symmetric" (C_s or C_{2v}) conformers, together with π-orbital populations and Wiberg bond indices (WBI), which were computed from NBO population analyses,[23] are given in Figure 2.[24] For further discussion we will refer only to the properties of the "symmetric" conformers.

Comparison of the computed bond lengths in the model compounds with the experimental data of **1**−**3**, **6**, and **7** shows a close agreement for all endocyclic C−C bonds and P1−C9 bonds (using the same numbering scheme as in Figure 1). The differences in the bond lengths are less than 1 pm. The computed lengths of the endocyclic C1−P2 bonds are generally about 3 pm longer than the experimental values, and those of the exocyclic C1−P1 bonds are shorter by the same amount. However, the variation of the individual computed bond lengths in different molecules reproduces the same trends that have been found in the experimental studies. This finding strongly suggests that the small structural variations detected reflect real differences in the electronic structures, rather than being a result of intermolecular interactions in the crystal.

Table 4. Computed absolute energies (at the B3LYP/6-31+g* level), zero-point energies, molecular point groups, and relative energies of different conformers (at the B3LYP/6-31+g* + zpe level) for the model compounds **1-H**−**4-H**, **5-H**, **6-H**

The results of NBO population analyses (cf. Figure 2b) reveal that the total π-electron population in the atoms of the annulated rings (9.75−9.86 electrons) is close to the theoretical value of 10 in all compounds. The small electron loss is attributed to weak hyperconjugation with antibonding P−H orbitals in the peripheral substituents (see below), and is almost independent of the substituent pattern. Inspection of individual atomic π-orbital population indicates a shift of π-electron density from the P2 phosphorus atoms and the remote C5/C6 carbon atoms in the six-membered ring, towards the C1/C3 carbon atoms. This shift increases with the total positive charge and, for **2-H**, **3-H**, **5-H**, and **6-H**, with the electron-withdrawing capability of the substituent on C3. In the neutral compounds, the π-electron density accumulates predominantly at the C1 atom adjacent to the strongly electron-withdrawing PH_3^+ moiety, thus introducing further pronounced "asymmetry" in the π-electron distribution. This effect is weakened in the series **2-H** > **3-H** > **5-H** ≈ **6-H**, by the growing electron-withdrawing effect of the C-9 substituents.

Inspection of the Wiberg bond indices reveals that the bond orders in the six-membered ring are essentially independent of the substituents in the 1- and 3-positions (Figure 2c). Beginning with the symmetrically substituted ions, both the C1−P2/P2−C3 and the C1−C7a/C3−C3a bond orders in the five-membered ring of the anion **4-H** are higher than those in the cation **1-H**, whereas the opposite trend is found for the C3a−C3a bonds. Interestingly, these variations result in appropriate changes in bond lengths only in the case of the C−C bonds; presumably, lower covalent P−C bond orders in **1-H** are counterbalanced by a larger electrostatic polarisation. For the betaines **2-H**, **3-H**, **6-H**, and **7-H**, the uneven distribution of π-electrons between C1 and C3 coincides with a concomitant polarisation of the P−C bond orders. The P2−C3 bonds display WBIs between 1.37 and 1.49, which are in the range between those of phosphinine (1.38) and methylenephosphane (1.94), and indicate pronounced double-bond char-

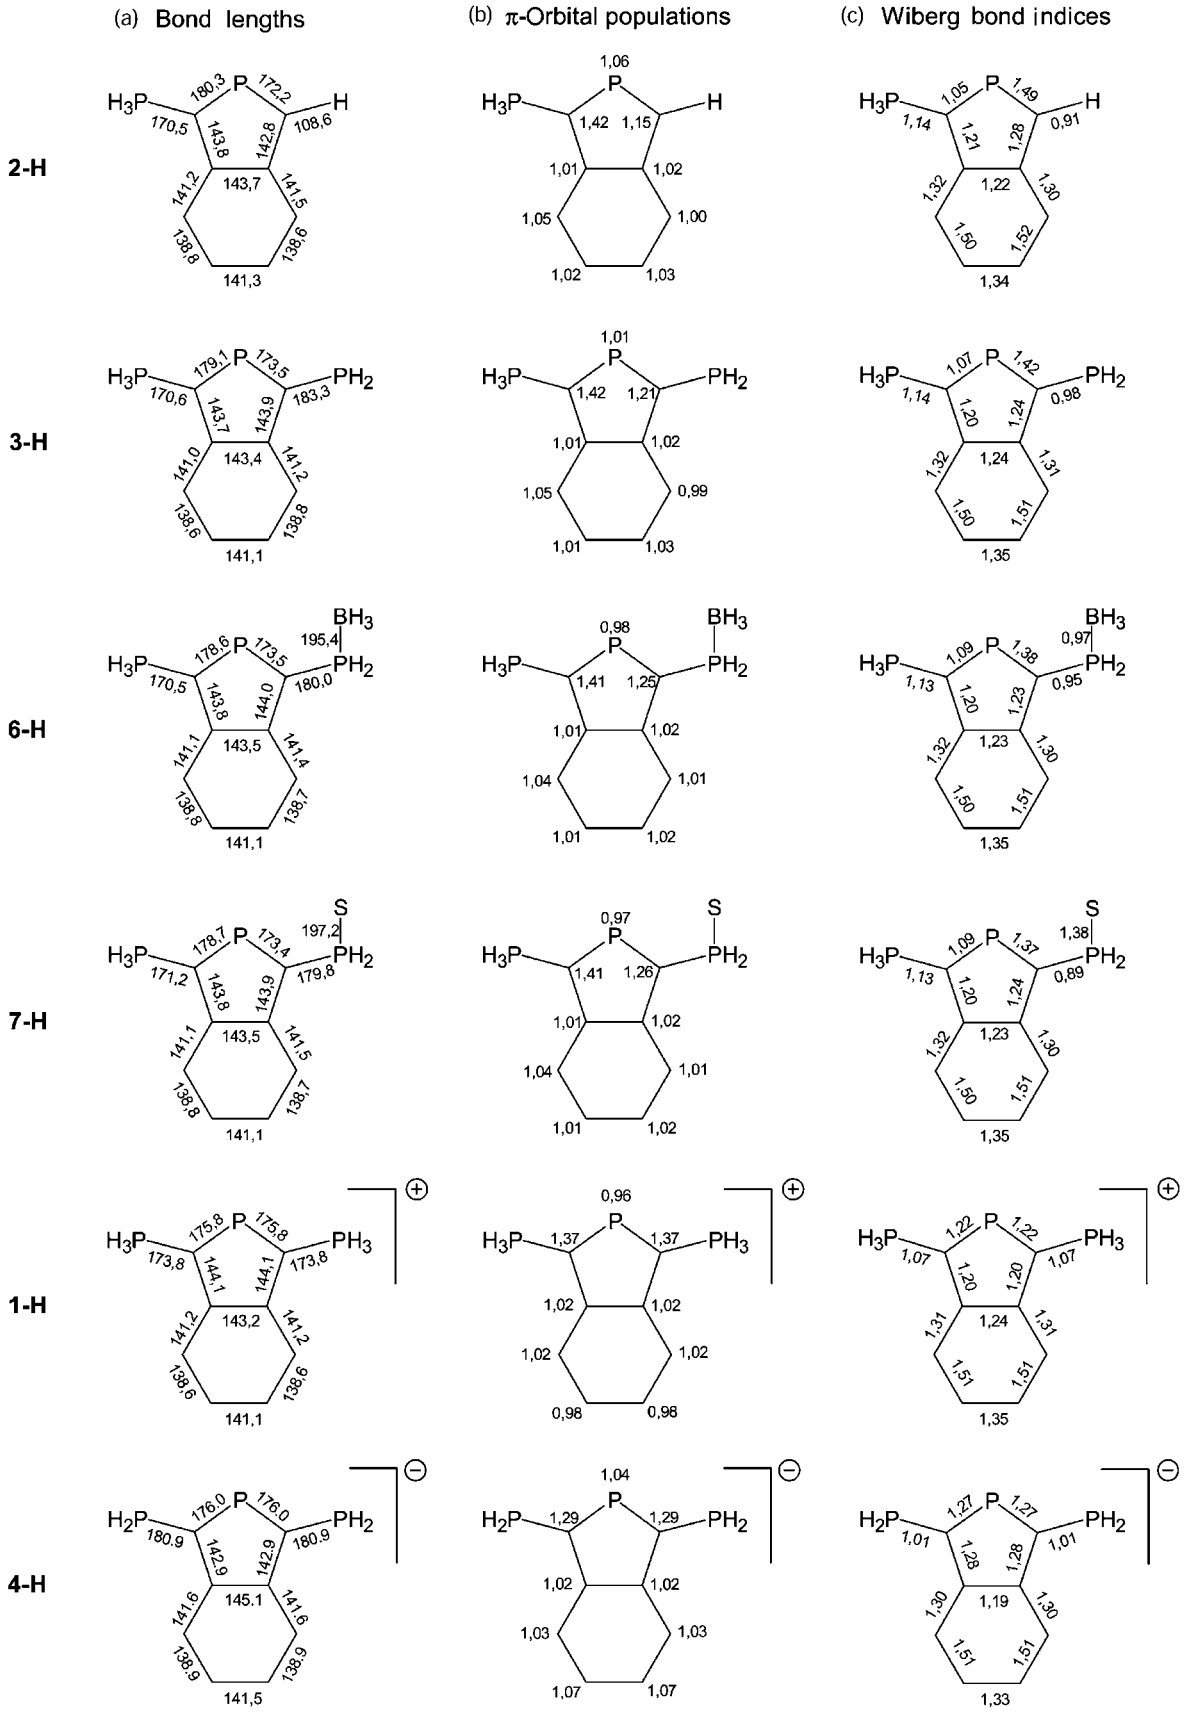

Figure 2. (a) Computed bond lengths, (b) π-orbital populations, and (c) Wiberg bond indices for the model compounds **1-H**−**4-H**, **5-H**, **6-H**; distances were obtained from energy-optimised molecular structures computed at the B3LYP/6-31+g* level, and orbital populations and bond indices from NBO population analyses[23] at the B3LYP/6-31 g*//B3LYP/6-31+g* level of theory

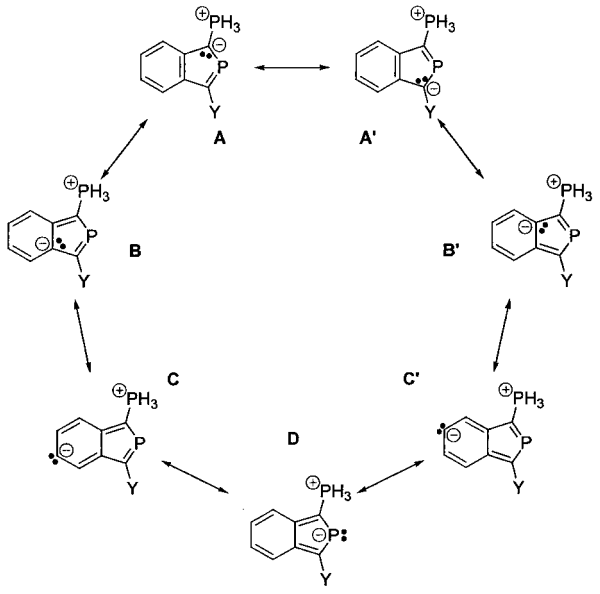
acter. The adjacent C1−P2 bonds display lower bond orders (WBI = 1.05−1.09), whose values nonetheless still exceed those of pure single bonds (cf. 0.98−1.01 for the exocyclic C3−P3 bonds in **2-H** and **4-H**). A less pronounced weakening of the bond (see Figure 2c) is also noted for the C1−C7a bond as compared with the C3−C3a bonds. The differences in the bond indices within each pair of P−C and C−C bonds in a single compound decreases slightly with increasing electron-withdrawing character of the substituent at C3. The higher WBIs for the exocyclic C1−P1(phosphonio) bonds in betaines (1.14) relative to the symmetrical ions **1-H** (1.07) and **4-H** (1.01), suggest a more pronounced ylide character of this bond. The exocyclic C3−P3 bonds (WBI = 0.89−0.98) are single bonds.

In the frame of a VB picture, a consistent interpretation of the changes in the bonding situation in the studied benzophospholide systems can be given in terms of a superposition of the canonical structures shown in Scheme 2. The results of the NBO analyses suggest that the dominating resonance structures in the cation **1-H** are **A**, **A′**, whose weightings are equal due to symmetry reasons.[2] For the betaines **2-H**, **3-H**, **6-H**, and **7-H**, the dominant canonical structure is **A**, even though the results of the perturbational analysis of the Fock matrix and the residual delocalisation of NLMOs suggest that the contribution of **A′** increases slightly with the growing electron-withdrawing capability of the substituent Y. The contribution of the canonical structure **B** is greater in these compounds than in the cation **I**−**H**. For the anion **4-H**, the NBO analysis suggests that the contribution of resonance structures **A**, **A′** (with H_2P instead of H_3P^+) decreases relative to that of the remaining alternatives **B**−**D**. This effect reflects a more efficient π-delocalisation along the ring perimeter and a shift of the excess charge in the π-system towards the P2 and C5, C6 atoms. The dominance of the 1,2-dipolar canonical structures **A** (and **A′**) in the phosphonio-substituted species can be understood since the charge separation is smallest. It also emphasises the fact that the shift in π-electron distributions between species with different overall charge can be understood mainly by electrostatics as the charges are in close proximity to each other.[25]

In light of the discussed results it can be concluded that all studied benzophospholides may be described as delocalised 10π-electron systems, which formally involve the interaction of a benzene (6π) and a phosphaallylic (4π) fragment.[2] The conjugation between both units (as expressed by increasing contributions of the canonical structures **B**−**C′** in Scheme 2) increases when the sum of the positive charges on the substituents decreases, and is thus most pronounced in the genuine anion **4-H**. Furthermore, substitution by a single positively charged substituent at the C2 atom in **2-H**, **3-H**, **6-H**, **7-H** lifts the degeneracy between canonical structures **A** and **A′**. The resulting essentially single resonance structure (**A**) brings a "phosphaalkene−benzylidene ylide" structure to the fore, and is equivalent to a partial π-electron localisation.



Scheme 2

With regard to the recent interest in the use of benzophospholide systems as ligands,[3,6,11] a short account of the nature and energies of frontier orbitals is of interest; this should allow some predictions on the coordination behaviour of these compounds to be made. The energies of selected molecular orbitals are listed in Table 5. As in the cation **1-H**, both HOMOs and LUMOs in the betaines **2-H**, **3-H**, **6-H**, and **7-H** have a′′ symmetry, and can be described as the 5π and 6π* orbitals of a heteronaphthalenic 10π-electron system.[2] The highest a′-type orbital in **2-H** and **6-H** lies approx. 2 eV below the HOMO and is assigned to a non-bonding pair of electrons centred at the endocyclic P1 phosphorus atom. In **3-H** and **7-H**, this orbital is best described as a "lone-pair" centred at the exocyclic P3 phosphorus or sulfur atoms, respectively. The energies of the phosphorus "lone-pair" orbitals in **2-H** and **6-H** (−7.3 to −7.5 eV) are similar to those calculated for phosphinine (−7.3 eV) or PH_3 (−7.5 eV) at the same level of theory. As expected, the energies of both occupied and unoccupied orbitals are stabilised with increasing overall positive charge of the system, but the HOMO−LUMO gap in all compounds remains essentially unchanged. Even if this finding allows a qualitative rationalisation of the observed similarity of the lowest π−π*-transition energies, a more detailed interpretation of the electronic spectra is not feasible in the frame of this simple one-electron model. Based on the computed orbital energies it can be predicted that the donor capability of benzo[*c*]phospholide ligands will decrease and their π-acceptor capability will increase with the number of positively charged phosphonio groups, whereas further modifications within the substituents will play a minor role. Furthermore, coordination of a transition metal via a phosphorus lone-pair in **3-H** and **4-H** should take place at the exocyclic three-coordinate rather than the endocyclic two-coordinate phosphorus atom, which is in agreement with

Conclusion

Our experimental and computational investigations have shown that the π-electron structures of neutral monophosphoniobenzo[*c*]phospholides are closely related to those of both bis(phosphonio)-substituted cations and genuine benzo[*c*]phospholide anions. However, on the other hand they have also highlighted characteristic deviations, which can be associated with the effects of π-electron polarisation by the charged phosphonio groups. Two major trends emerge from the results: (a) an increasing number of phosphonio substituents in the five-membered ring reduces π-conjugation between the fused rings; (b) a single phosphonio substituent in the 1-position of the fused ring system acts as a π-electron "trap" and induces a strong concentration of π-electron density on the adjacent ring carbon atom, and a concomitant π-bond localisation. Differential tuning of this effect is achieved by varying the inductive electron-withdrawing power of a substituent in the 3-position. With regard to the concomitant increase in ylidic character of the P(phosphonio)−C bond, the π-bond localisation brings a phosphaalkene ylide type of structure to the fore, which is most pronounced in **2**. Interestingly, a careful comparison of the computational results revealed that the observed variations in the bonding situation were only in part reflected in appropriate structural changes, thus emphasising that great care has to be taken during attempts to interpret the bonding situation exclusively on the basis of structural parameters.

The computational results further allow a number of predictions on the chemical properties of phosphoniobenzophospholides to be made. A comparison of frontier orbital energies suggests that the neutral species should behave as better σ/π-donors and weaker π-acceptors than cation **1**, which is in agreement with the conclusions drawn from a recent preliminary study of the complex chemistry of **2**.[11] In contrast to **2**, which binds a $Cr(CO)_5$ fragment via the endocyclic two-coordinate phosphorus atom,[11] complexation of **3** to a 16e-metal complex fragment is expected to occur at the exocyclic phosphane moiety, as in the anion **4**.[8] More importantly, the π-bond localisation in neutral phosphoniobenzophospholides towards a phosphaalkene−benzylidene ylide electronic structure, suggests that these compounds should also display an increased susceptibility towards addition [such as addition of reactive E−H bonds which have been found to occur for less reactive bis(phosphonio)-substituted cations[5]], or even cycloaddition reactions at the P−C double bond, or Wittig reactions at the ylide moiety. Investigations aiming at the verification of these reaction schemes for **2**, where the largest degree of π-bond localisation is observed, are currently in progress.

Experimental Section

General Remarks: NMR spectra were recorded at 30 °C with a Bruker AMX 300 spectrometer (300.13, 121.50, 96.3 and 75.46 MHz for ^1H, ^{31}P, ^{11}B and ^{13}C). Chemical shifts are referred to external TMS (^1H, ^{13}C), $Et_2O{\cdot}BF_3$ or 85% H_3PO_4. The atoms of the benzophospholide moiety are denoted C-1 to C-7a, 4-H to 7-H, and P-1 to P-3, using the numbering scheme given in Figure 1; carbon atoms of the phenyl groups by C_{para}, C_{meta} etc. − UV/Vis spectra: Kontron Uvikon 860. − FAB-MS: Kratos Concept 1 H, Xe-FAB. − Elemental analysis: Heraeus CHNO-Rapid.

3-(Diphenylphosphanyl)-1-(triphenylphosphonio)benzo[*c*]phospholide (3): 1,3-Bis(triphenylphosphonio)benzo[*c*]phospholide chloride (**1**[Cl]) (8.6 g, 12.5 mmol) and magnesium/anthracene·3THF (10.0 g, 24 mmol) were suspended in 50 mL of THF. The mixture was stirred for 8 h, filtered, and water-saturated Et_2O was added to the dark red solution until it turned yellow-orange. The mixture was filtered once more, the filtrate concentrated to dryness, and the orange residue suspended in a mixture of 20 mL of dry Et_2O and 50 mL of DME. Addition of 50 mL of MeOH gave the crude product as a yellow solid. Residual anthracene was removed by extraction with boiling hexane, and recrystallisation from DME/MeOH finally afforded 1.5 g (47%) of **2**, m.p. 179 °C. − Analytical and spectroscopic data are identical to those published in ref.[8]

1-(Triphenylphosphonio)benzo[*c*]phospholide (2): Solid $NaBH_4$ (2.5 g, 66 mmol) was added to a stirred suspension of **1**[Cl] (13.75 g, 19.9 mmol) in 150 mL of 2-propanol. It was stirred for 12 h until no starting material (^{31}P NMR control) was left. The mixture was then filtered, the precipitate washed three times with 2-propanol, and the filtrate concentrated to dryness. The yellow solid residue was extracted with 100 mL of THF and insoluble $NaBH_4$ was filtered off. After concentration of the filtrate in vacuum to a total

volume of 30−40 mL, 2-propanol was added until the precipitation of solid material started (approx. 20−30 mL). Cooling of the solution to 4 °C gave bright yellow crystals of **3**; yield 4.94 g (63%). − ^{1}H NMR ($CDCl_3$): δ = 6.71−7.63 (m, 4 H, 4-H to 7-H), 7.42−7.84 (m, 15 H, C_6H_5), 8.20 (dd, $^2J_{H,P-2}$ = 42.3 Hz, $^4J_{H,P-1}$ = 6.6 Hz, 1 H, 3-H). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 86.4 (dd, $^1J_{P-2,C}$ = 54.8 Hz, $^1J_{P-1,C}$ = 102.8 Hz, C-1), 118.1 (d, $J_{P,C}$ = 0.9 Hz, C-6/5), 119.1 (d, $J_{P,C}$ = 3.9 Hz, C-5/6), 119.6 (d, $J_{P,C}$ = 4.1 Hz, C-7/4), 121.3 (dd, $J_{P,C}$ = 9.0, 1.1 Hz, C-4/7), 125.6 (dd, $^1J_{P-1,C}$ = 89.5 Hz, $^3J_{P-2,C}$ = 2.2 Hz, C_{ipso}), 129.5 (d, $^3J_{P-1,C}$ = 12.3 Hz, C_{meta}), 133.9 (dd, $^2J_{P-1,C}$ = 10.2 Hz, $^4J_{P-2,C}$ = 1.4 Hz, C_{ortho}), 134.6 (d, $^4J_{P-1,C}$ = 2.9 Hz, C_{para}), 138.3 (dd, $^1J_{P-2,C}$ = 36.8 Hz, $^3J_{P-1,C}$ = 13.5 Hz, C-3), 142.4 (dd, $J_{P,C}$ = 9.5, 2.0 Hz, C-3/3a, 145.2 (dd, $J_{P,C}$ = 17.6, 9.5 Hz, C-3/3a). − FAB-MS: *m*/*z* (%) = 394 (100) $[M]^+$ − $C_{26}H_{20}P_2$ (394.39): calcd. C 79.18, H 5.11; found C 78.17, H 5.88.

3-[(Diphenylphosphanyl)borane]-1-(triphenylphosphonio)benzo[*c*]-phospholide (6): Compound **2** (0.4 g, 0.69 mmol) was dissolved in 10 mL of THF. After 0.7 mL of a 1 M solution of BH_3·THF in THF had been added, the mixture was stirred for 10 min and then concentrated to dryness. The yellowish residue was recrystallised from THF/hexane; yield 0.41 g (100%), m.p. 227 °C. − ^{1}H NMR ($CDCl_3$): δ = 6.70−7.00 (m, 4 H, 4-H to 7-H), 7.20−8.50 (m, 25 H, C_6H_5). − $^{11}B\{^1H\}$ NMR ($CDCl_3$): δ = −28.5 (s, broad). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 98.3 (ddd, $^1J_{P-2,C}$ = 58.1 Hz, $^1J_{P-1,C}$ = 98.6 Hz, $^3J_{P-3,C}$ = 11.6 Hz, C-1), 119.5 (s, C-6/5), 120.1 (s, C-5/6), 120.7 (d, $J_{P,C}$ = 3.8 Hz, C-7/4), 122.4 (d, $J_{P,C}$ = 3.9 Hz, C-4/7), 124.8 [d, $^1J_{P-1,C}$ = 89.8 Hz, $C_{ipso}(PPh_3)$], 128.6 [d, $^3J_{P-3,C}$ = 9.9 Hz, $C_{meta}(PPh_2)$], 129.7 [d, $^3J_{P-1,C}$ = 12.4 Hz, $C_{meta}(PPh_3)$], 130.5 [d, $^4J_{P-3,C}$ = 1.9 Hz, $C_{para}(PPh_2)$], 132.7 [d, $^1J_{P-3,C}$ = 4.4 Hz, $C_{ipso}(PPh_2)$], 133.4 [d, $^2J_{P-3,C}$ = 9.5 Hz, $C_{ortho}(PPh_2)$], 133.7 [d, $^4J_{P-1,C}$ = 2.7 Hz, $C_{para}(PPh_3)$], 134.4 [d, $^2J_{P-1,C}$ = 10.3 Hz, $C_{ortho}(PPh_3)$], 144.8 (dd, $^1J_{P-3,C}$ = 9.4 Hz, $^1J_{P-2,C}$ = 11.7 Hz, C-3), 145.6 (m, C-3a/7a). − FAB-MS: *m*/*z* (%) = 592 (20) $[M]^+$, 578 (100) $[M - BH_3]^+$ − $C_{38}H_{32}BP_3$ (592.40): calcd. C 77.05, H 5.44; found C 78.07, H 5.24.

3-(Diphenylthioxophosphoranyl)-1-(triphenylphosphonio)benzo[*c*]-phospholide (7): Compound **2** (0.5 g, 0.86 mmol) and sulphur (30 mg, 0.94 mmol) were dissolved in 10 mL of THF, and the resulting solution was stirred for 12 h. Subsequent addition of 20 mL of hexane produced a precipitate which was collected by filtration, washed with 5 mL of Et_2O/hexane (1:1), and dried in vacuum to give 0.46 g (87%) of a colourless solid, m.p. > 280 °C. − ^{1}H NMR ($CDCl_3$): δ = 6.70−6.93 (m, 4 H, 4-H to 7-H), 7.25−7.97 (m, 25 H, C_6H_5). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 98.4 (ddd, $^1J_{P-2,C}$ = 58.8 Hz, $^1J_{P-1,C}$ = 97.5 Hz, $^3J_{P-3,C}$ = 14.1 Hz, C-1), 119.8 (s, C-6/5), 120.3 (d, $J_{P,C}$ = 1.7 Hz, C-5/6), 120.5 (d, $J_{P,C}$ = 3.6 Hz, C-7/4), 122.8 (d, $J_{P,C}$ = 4.4 Hz, C-4/7), 124.7 [d, $^1J_{P-1,C}$ = 89.7 Hz, $C_{ipso}(PPh_3)$], 128.3 [d, $^3J_{P-3,C}$ = 12.4 Hz, $C_{meta}(PPh_2)$], 129.6 [d, $^3J_{P-1,C}$ = 12.4 Hz, $C_{meta}(PPh_3)$], 130.8 [d, $^4J_{P-3,C}$ = 2.9 Hz, $C_{para}(PPh_2)$], 132.8 [d, $^2J_{P-3,C}$ = 10.1 Hz, $C_{ortho}(PPh_2)$], 133.6 [d, $^4J_{P-1,C}$ = 2.9 Hz, $C_{para}(PPh_3)$], 135.7 (ddd, $^1J_{P-2,C}$ = 59.1 Hz, $^3J_{P-1,C}$ = 13.2 Hz, $^1J_{P-3,C}$ = 88.1 Hz, C-3), 134.5 [d, $^2J_{P-1,C}$ = 10.3 Hz, $C_{ortho}(PPh_3)$], 136.3 [d, $^1J_{P-3,C}$ = 85.5 Hz, $C_{ipso}(PPh_2)$], 144.7 (m, C-3a/7a). − FAB-MS: *m*/*z* (%) = 611 (100) $[M]^+$ − $C_{38}H_{29}P_3S$ (610.63): calcd. point vibrational energies (ZPE) were calculated at the same level. All structures reported here are minima on the potential energy surface (only positive eigenvalues of the Hessian matrix). Population analyses were carried out with the NBO module[23] included in the Gaussian 98 package. Due to problems with the handling of diffuse basis functions which occurred for some molecules in the NBO module, all population analyses were carried out using 6-31 g* wave functions with the molecular structures obtained at the 6-31(+)g* level. Comparison of the results of NBO analyses using both a 6-31 g* or a full 6-31(+)g* wave function was feasible for **2** and showed no significant differences between both approaches.

X-ray Crystallographic Study: Crystal structure determinations were carried out for **2**, **3**, **6**, **7**. All data were collected with a Nonius Kappa CCD diffractometer at −150 °C using Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods (SHELXS-97[26]). The non-hydrogen atoms were refined anisotropically, H atoms were refined using a riding model [full-matrix least-squares refinement on F^2 (SHELXL-97[27])]. Details of data collection and refinement are given in Table 6. A complete list of bond lengths and angles, thermal parameters, and positions of hydrogen atoms is available as Supporting Information. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-161501 (**2**), -161502 (**3**), -161503 (**6**), -161504 (**7**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

First Crystallographic Investigation of Complexes of *cis*-VO_2^+, *cis*-MoO_2^{2+}, and *trans*-UO_2^{2+} Species with Schiff-Base Molecules Derived from 4,6-*O*-Ethylidene-β-D-glucopyranosylamine

Keywords: Vanadium / Molybdenum / Uranium / Schiff bases / Structure elucidation

The interaction of Schiff-base ligands derived from 4,6-*O*-ethylidene-β-D-glucopyranosylamine with *cis*-VO_2^+, *cis*-MoO_2^{2+}, and *trans*-UO_2^{2+} species have been studied by isolating and characterizing the corresponding products. The structures of one complex of each type of species have been established by single-crystal X-ray diffraction analysis. In all the complexes, the saccharide moiety adopts a chair conformation and has a β-anomeric form. A gradual increase in coordination number (5, 6, and 7) and a gradual variation in the geometry (distorted trigonal-bipyramidal, distorted octahedral, and pentagonal-bipyramidal) are observed on going from the complexes of *cis*-VO_2^+ (mononuclear) to *cis*-MoO_2^{2+} (mononuclear) to *trans*-UO_2^{2+} (dinuclear). A variation in the binding mode of the ligand towards these dioxometal species is also observed. Intermolecular interactions of the type O–H···O, C–H···O, and N–H···O present in the lattices of these complexes lead to the formation of interesting structures.

Introduction

About two-thirds of the carbon in the biosphere is present in various forms of carbohydrates.[1] Carbohydrates not only act as the major source of energy for living beings, but also as building blocks for the formation of polysaccharides, nucleic acids, and antibiotics. The coexistence of saccharides and metal ions was established in the context of biological systems.[2] Although the metal ion−saccharide interactions were recognized long ago, the early literature was mainly concerned with solution studies, primarily with metal ions of the alkali and alkaline earth groups and of main group elements, as well as their adducts.[3] Only during the past decade have such interactions been delineated in the case of transition metal ions by isolation and characterization of the products.[4] In order to improve the binding affinities towards metal ions, as well as to isolate the metal ion−saccharide products in crystalline form, new strategies for saccharide modification have been developed. One such attempt of ours in this context recently resulted in the synthesis and characterization of complexes of *N*-(*o*-carboxyphenyl)-4,6-*O*-ethylidene-β-D-glucopyranosylamine with alkali and alkaline earth metal ions and the crystal structure of its potassium complex.[5] In this new strategy, the study of metal−saccharide interactions is attempted using the products of condensation of 4,6-*O*-ethylidene-β-D-glucopyranosylamine with salicylaldehyde and its derivatives as ligands suitable for metal ion binding. The results of these efforts are reported herein. Thus, the present studies are in continuation of our ongoing interest in establishing the interaction of OH-containing ligands with oxometal ion species, such as *cis*-VO_2^+, *cis*-MoO_2^{2+}, and *trans*-UO_2^{2+}. Studies of such oxometal ion species are also important with regard to the stereochemical preferences in binding to these new types of saccharide−Schiff-base ligands.

Therefore, we report herein the synthesis, characterization, and crystal structure determination of *cis*-VO_2^+, *cis*-MoO_2^{2+}, and *trans*-UO_2^{2+} metal ion complexes with salicylidene Schiff-base ligands derived from a glycosylamine, 4,6-*O*-ethylidene-β-D-glucopyranosylamine. The products have been characterized on the basis of their FT-IR- and NMR-spectroscopic data, FAB mass spectra, and single-crystal X-ray structural data. To the best of our knowledge, the three crystal structures of the saccharide−Schiff-base complexes of *cis*-VO_2^+, *cis*-MoO_2^{2+}, and *trans*-UO_2^{2+} reported herein are the first of their kind.

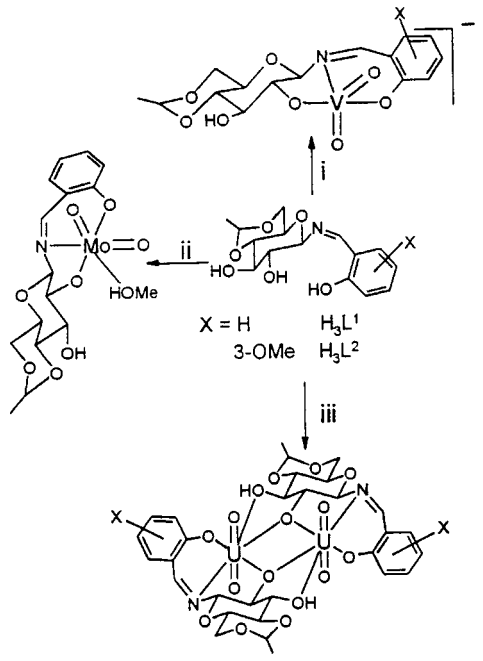
Results and Discussion

The ligands derived from 4,6-*O*-ethylidene-β-D-glucopyranosylamine and their complexes with dioxometal species of V, Mo, and U are shown in Scheme 1. While the reactions of *cis*-MoO_2^{2+} and *trans*-UO_2^{2+} gave the products in

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/1111−2773 $ 17.50+.50/0

high yields, those with *cis*-VO_2^+ resulted in rather low yields. This is attributable to the formation of a second product in the case of the vanadium reactions, which could not be isolated in pure form. Evidence for this was provided by UV/Vis studies. The products with V and Mo were found to be mononuclear, while those with U were dinuclear. All exhibited a 1:1 metal-to-ligand ratio.



Scheme 1. Syntheses of the *cis*-VO_2^+, *cis*-MoO_2^{2+}, and *trans*-UO_2^{2+} complexes in methanol using the ligands $\mathbf{H_3L^1}$ and $\mathbf{H_3L^2}$: (i) $VO(acac)_2$, (ii) *cis*-$MoO_2(acac)_2$, and (iii) *trans*- $UO_2(OAc)_2{\cdot}2H_2O$

FT-IR

Comparison of the FT-IR spectra of all the complexes with those of their precursor ligands supported the formation of the respective complexes through the observation of substantial spectral changes. Characteristic vibrational bands corresponding to the M=O groups are observed for all the complexes. The ligand exhibits two distinct bands in the ν_{OH} region, whereas only one broad signal is observed for the corresponding complexes, indicating the loss of some hydroxy protons during complexation. This conclusion was further supported by the ^{1}H NMR spectra as well as by the crystal structure determinations. The ν_{OH} is generally shifted to higher frequencies by about 100 cm^{-1} for the uranium complexes as compared to the position of this band for their vanadium and molybdenum counterparts; this can be attributed to the fact that 3-OH is involved in metal ion binding in the former, whereas it is free in the latter.

^{1}H NMR

The spectra of all the complexes are indicative of the presence of a single anomeric form. However, upon addition of a small amount of D_2O to the respective solutions, spectral peaks corresponding to a second anomer appear with time. Upon complexation, only a single hydroxy proton signal remains in the alkyloxy region, indicating the loss of the phenolic and one of the alcoholic protons. The signals of the skeletal protons of the saccharide moiety are subject to an overall downfield shift upon complexation, this shift being more pronounced in the case of the uranium complex as compared to the vanadium and molybdenum complexes. Thus, the downfield shift of the signals of the skeletal protons is in the order *trans*-UO_2^{2+}complex >> *cis*-MoO_2^{2+} complex > *cis*-VO_2^+ complex. This may be attributed to the additional involvement of 3-OH (in addition to 2-OH) in the complexation in the case of the UO_2^{2+} species. The same trend was observed for the the HC=N and 1-H proton signals of the complexes. The $J_{C1\text{-}H}$ values were found to be 8.79 and 7.69 Hz for $VO_2(HL^1)$ and $VO_2(HL^2)$, respectively, supporting the presence of the saccharide moiety in the β-anomeric form.[16] The β-anomeric form of the saccharide moiety was unequivocally established on the basis of the crystal structures of the three complexes.

FAB MS

FAB MS studies supported the mononuclear nature of the V^V and Mo^{VI} complexes and the dinuclear nature of the U^{VI} complexes through exhibiting molecular ion peaks. Furthermore, the spectra of the vanadium complexes revealed the formation of the monooxo dinuclear species shown in Figure 1.

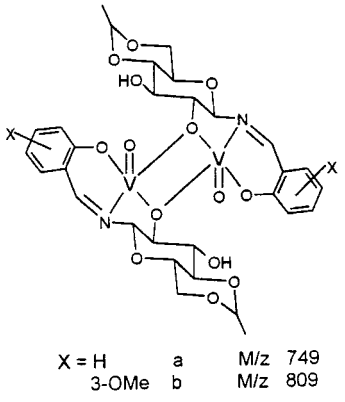


Figure 1. The dimeric species of monooxo V^V identified in the mass spectra

UV/Vis

Electronic spectra of all the complexes were recorded using freshly prepared solutions in DMSO at concentrations of 10^{-2} and 10^{-4} M; the corresponding spectra are shown in Figure 2. While the complexes of molybdenum and uranium (Figures 2b, 2c) proved to be stable in DMSO solution even after 36 h, those of vanadium underwent some cleavage and some free ligand was liberated (Figure 2a). An additional band was observed at 530−540 nm in the spectra, indicating the formation of some new oxovanadium species.

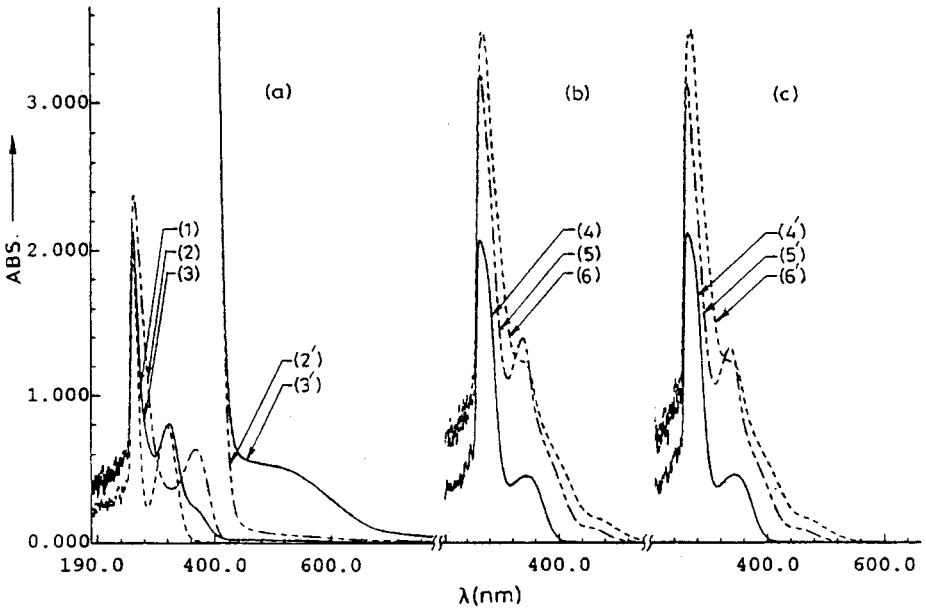

Figure 2. UV/Vis absorption spectra in DMSO: (a) spectrum (1) corresponds to H_3L^1, spectra (2, 2′) correspond to a freshly prepared solution of *cis*-$VO_2(HL^1)$, and spectra (3, 3′) correspond to the same complex analysed 36 h after dissolution; (b) and (c) spectra (4, 5, 6) correspond to freshly prepared solutions of the *cis*-$[MoO_2(HL^1)]$, *trans*-$[\{UO_2(HL^1)\}_2]$, and *trans*-$[\{UO_2(HL^1)\}_2]$ complexes, respectively, while spectra (4′, 5′, 6′) correspond to the same solutions after 36 h

Optical Rotation

The mononuclear complexes of *cis*-VO_2^+ and *cis*-MoO_2^{2+} showed a substantial change in specific rotation as compared with the specific rotations of the corresponding ligands.

Molecular and Crystal Structure of $VO_2(HL^1)$

Slow evaporation of the solvent from a concentrated methanolic solution of the complex resulted in single crystals in the monoclinic system. The crystal structure revealed the presence of a *cis*-dioxo mononuclear V^V complex, which is rather rare in vanadium−saccharide chemistry. Earlier reports dealt with either dioxo dinuclear homoleptic[7,8] or monooxo complexes of mixed ligands.[9] In the complex **$VO_2(HL^1)$**, the saccharide derivative is bound as a tridentate dianionic ligand, where 2-OH of the saccharide moiety extends coordination in its deprotonated form resulting in an ONO core, and where the other two ligations are extended by the salicylidene moiety. This results in the formation of one five- and one six-membered chelate. In order to compensate for the negative charge present on the complex, a dimethylammonium cation is present in the crystal lattice. Thus, the dioxo-V^V center exhibits a distorted trigonal-bipyramidal geometry (the *trans* angle is 156.8°), with both the oxo groups and the imine nitrogen donors occupying the basal plane. The basal plane accommodates the vanadium center without any deviation. An ORTEP view of the complex is shown in Figure 3, while crystallographic data are given in Table 1 and some selected bond lengths and angles are given in Table 2. All the metric data are well within the expected ranges and are consistent with the reported values for similar coordinations.[10] In the complex, the saccharide and aromatic moieties are arranged in a *trans* geometry with respect to the C=N bond. The dihedral angles of the saccharide moiety revealed a β-anomeric form, as was also indicated by the proton NMR study. In the solid state, both the six-membered rings of the saccharide moiety, i.e. the pyranose and the 4,6-protected part, were found to adopt a chair conformation.

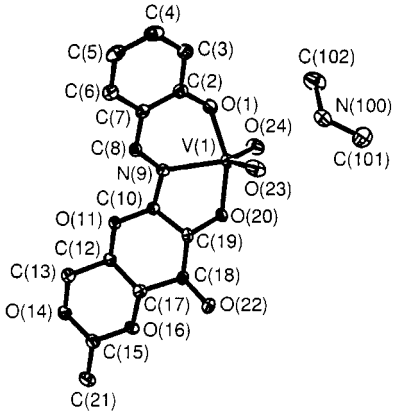

Figure 3. Molecular structure of **$[VO_2(HL^1)](Me_2NH_2)$**; thermal ellipsoids are drawn at a 50% probability level using ORTEP

Each NH group of the dimethylammonium ion is involved in one strong hydrogen bond interaction. One of the N−H bonds exhibits an additional weak interaction. These N−H protons are accepted by the oxo groups of the vanadium center (V=O) and 2-O of the saccharide moiety; 3-OH of the saccharide moiety acts as a hydrogen donor towards a second V=O group, exhibiting a strong O−H···O interaction.

In addition, there are at least five C−H···O-type intermolecular interactions, for which the metric data are well within the ranges reported for such interactions in the literature.[11] The CH groups in these arise from phenyl, 3-H of saccharide, and both the methyl groups of the countercation. The acceptor oxygen atoms for these interactions are ether oxygen atoms, 2- and 3-O of the saccharide moiety, the phenolic oxygen atom, and V=O. Thus, in the lattice, each molecule is connected to four other neighbouring molecules through weak interactions, thereby forming a three-dimensional network.

Molecular and Crystal Structures of $MoO_2(HL^1)$

Slow diffusion of methanol into a concentrated solution of the complex in DMSO resulted in single crystals in the monoclinic space group. Even in this case, the ligand moiety acts as a tridentate dianion bound to a *cis*-MoO_2 unit, giving rise to one five- and one six-membered chelate, similar to the situation observed in the case of the vanadium complex. The sixth coordination site is occupied by MeOH and an additional MeOH molecule is present in the lattice. Both the molybdenum mixed-ligand complexes reported in the literature were derived from the simple protected saccharide 1,2:5,6-di-*O*-isopropylidene-D-glucofuranose.[12,13] While the complex reported by Floriani was *cis*-dioxo−Mo^{VI}, that reported by McCleverty was non-oxo−Mo^{VI}; in both the cases the saccharide acts as a monodentate ligand. To the best of our knowledge, the present structure is the first example of one in which a saccharide-based Schiff-base ligand is complexed with oxo−Mo^{VI} that has been established by single-crystal X-ray diffraction analysis. An ORTEP view of the complex is shown in Figure 4 and some selected bond lengths and bond angles are given in Table 3. All the values are consistent with earlier reports for similar coordination.[14] The crystallographic studies clearly indicate a highly distorted octahedral geometry around the molybdenum center, with the saccharide derivative binding meridionally and the metal ion deviating from the mean plane formed by O1 (phenolic), N9 (imine), O17 (saccharide 2-O), and O30 (Mo=O) by 0.305(1) Å. The *trans* angles range from 150.9(1) to 167.2(1)° and all the other angles from 75 to 107°. The remaining binding features are similar to those of the *cis*-VO_2^+ structure reported herein. The crystal structure of the Mo complex also revealed the presence of the

β-anomeric form of the saccharide moiety based on the dihedral angles. Both the six-membered rings of the saccharide moiety were found to adopt a chair conformation.

As a result of the extensive intermolecular involvement of both the free and bound MeOH units in the molybdenum compound, the lattice exhibits a layered structure (Figure 5), in which extended motifs, having intermolecular O−H···O and C−H···O-type interactions, are present. Both the lattice CH_3OH and 3-OH of the saccharide moiety connect the molecules present in the lattice through intermolecular O−H···O-type interactions, where the OH groups of both these moieties are involved in two such interactions by acting as both hydrogen donors and hydrogen acceptors. Thus, in effect, the molecules in the lattice are connected through zig-zag-type O−H···O interactions, as shown in Figure 6a. Similarly, the bound methanol unit is also involved in two intermolecular H-bonds, one O−H···O-type and one C−H···O-type interaction, acting as a hydrogen donor in both cases. The acceptors in these two cases are Mo=O and 6-O of the saccharide. The (metal-bound methanol)C−H···O=Mo-type interaction results in the formation of a linear chain of complex units connecting the layers, as shown in Figure 6b. Perpendicular to this chain, Ar−C−H···O=Mo type interactions extend by a connection of the molecules present in each layer, as shown in Figure 6c. Thus, the lattice consists of layers of molybdenum compounds, these being connected through extensive H-bond interactions. Furthermore, in each layer, the molecules are interconnected through H-bond interactions.

Molecular and Crystal Structures of $[UO_2(HL^2)]_2$

Slow diffusion of a methanol/ethanol mixture into a concentrated solution of the complex in dichloromethane resulted in single crystals of the hexagonal system. A structural study of the product showed it to be a dinuclear *trans*-dioxo−U^{VI} complex, unlike the mononuclear complexes observed with *cis*-VO_2^+ and *cis*-MoO_2^{2+}. This is the only complex in which both the available hydroxy groups of the saccharide moiety, 2-OH and 3-OH, are involved in metal ion binding; 2-OH of the saccharide binds in its deprotonated form (2-O^-) and bridges the two metal centers giving rise to a four-membered U_2O_2 rhomb, whereas 3-OH binds to the metal ion without losing its proton. Thus, the ligand exhibits tetradentate binding plus one bridging interaction. Nevertheless, the metal-to-ligand ratio was found to be 1:1 in this complex as well. An ORTEP view of the complex is shown in Figure 7; selected bond lengths and bond angles are given in Table 4. All the values are consistent with earlier reports for a similar coordination.[15] The U_2O_2 rhomb exhibits a center of symmetry and has distances of 2.327 and 2.386 Å and angles of 113.5° and 64.9°. In addition, each asymmetric unit cell includes an ethanol and a water molecule. Even in this case, the C=N bond exhibits *trans* geometry and the saccharide moiety adopts the β-anomeric form. Both the six-membered rings of the saccharide moiety are found to adopt a chair conformation. In this complex, the *trans*-dioxo−uranium center exhibits a pentagonal-bipyramidal geometry, with the uranium ion showing almost no deviation from the basal plane [0.026(6) Å]. Thus, the *trans*-dioxo geometry of U^{VI} influences the binding characteristics of the saccharide−Schiff-base ligand.

The *trans*-UO_2^{2+} complex crystallizes with a free ethanol and a water molecule; these do not exhibit any extended interactions, showing only discrete H-bond interactions. While the water molecule in the lattice acts as an acceptor for one O−H···O and one C−H···O interaction, the ethanol molecule acts as donor for such interactions. Thus, in the lattice, the water molecule interacts with both the ethanol molecule and 3-OH of the saccharide moiety, while the ethanol molecule is connected to 5-O of the saccharide moiety within the same molecule. In addition, the lattice contains four other C−H···O-type intermolecular interactions, which are responsible for the formation of a layer-type structure. The donors for such interactions are 4-, 5-, and 6-H of the saccharide moiety and the methoxy C−H of the salicylidene moiety, while the acceptors are 4-, 3-OH, U=O, and the phenolic O, respectively, of the neighbouring molecules in the lattice. The layer-type structure that results from these interactions is shown in Figure 8.

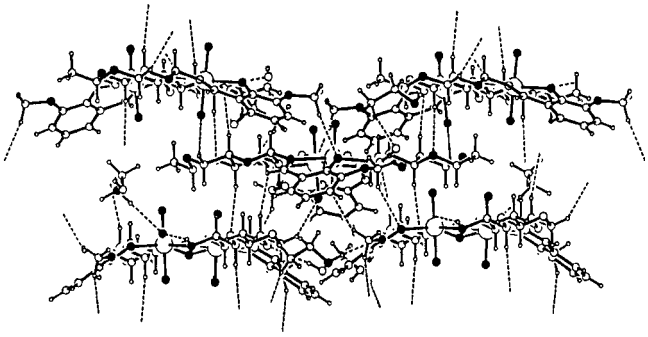

Figure 8. Layers of molecules in the lattice of the complex **[{UO_2(HL^2)}$_2$](EtOH)$_2$(H_2O)$_2$**; H-bond interactions are shown by dashed lines; large, open circles: metal ions; filled circles: oxygen atoms; circles with a line: nitrogen atoms

Conclusions

Saccharide−Schiff-base complexes of *cis*-VO_2^+, *cis*-MoO_2^{2+}, and *trans*-UO_2^{2+} have been synthesized and characterized using various analytical and spectroscopic techniques, as well as by single-crystal X-ray diffraction analysis. The NMR spectra of freshly prepared solutions in [D_6]DMSO show the saccharide moiety to be in the β-anomeric form. With *cis*-dioxo−metal ions, the ligand is tridentate, whereas with *trans*-dioxo ions it shows tetradentate coordination with an additional bridging interaction. A dianion results due to the loss of a phenolic as well as an alcoholic (2-OH of saccharide) proton. In the *trans*-UO_2^{2+} complex, 2-O^- of the saccharide moiety bridges the two uranyl centers, resulting in a dinuclear complex exhibiting a U_2O_2 rhomb, whereas 3-OH is involved in coordination without losing its proton. Metal ion binding results in the formation of one six- and two five-membered chelates. X-ray diffraction studies of the metal ion complexes revealed an increase in coordination number around the metal ion from 5 to 6 to 7 on going from *cis*-VO_2^+ to *cis*-MoO_2^{2+} to *trans*-UO_2^{2+}, corresponding to trigonal-bipyramidal, octahedral, and pentagonal-bipyramidal geometries, respectively. The dimeric structure seen in the case of the UO_2^{2+} ion complex may be attributed to the large size of the uranyl ion as well as the *trans* orientation of the oxo groups. In all the complexes, the saccharide unit adopts a chair conformation. In the lattice, weak interactions of the type O−H···O, N−H···O, and C−H···O were found to number 9, 5, and 7 for the vanadium, molybdenum, and uranium complexes, respectively. Some important features of these complexes are compared in Figure 9. As a result of these interactions, the molybdenum and uranium complexes exhibit interesting layer-type lattice structures, while the vanadium complex exhibits a three-dimensional network of hydrogen bonds. Thus, both the molecular and lattice features differ on going from *cis*-VO_2^+ to *cis*-MoO_2^{2+} to *trans*-UO_2^{2+} species, as demonstrated in this work by using saccharide-based Schiff-base ligands.

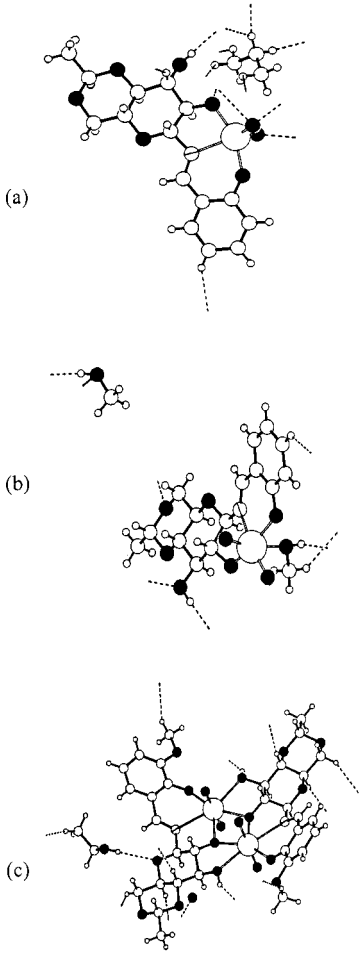

Figure 9. Coordination unit and H-bond interactions extended from each unit, as obtained from the crystal structures of (a) **[VO_2(HL^1)](Me$_2$NH_2)**, (b) **[MoO_2(HL^1)(MeOH)]MeOH**, and (c) **[{UO_2(HL^2)}$_2$](EtOH)$_2$(H_2O)$_2$**; donor/acceptor centers of H-bond interactions are indicated by dashed lines; large, open circles: metal ions; filled circles: oxygen atoms; circles with a line: nitrogen atoms

Experimental Section

General Remarks: Uranyl acetate was procured from BDH, England; the other precursors $[VO(acac)_2$ [16] and $MoO_2(acac)_2$ [17]] and 4,6-*O*-ethylidene-α-D-glucopyranose[5] and its 1-NH_2 derivative were synthesized according to reported procedures.[18] The glycosylamines $\mathbf{H_3L^1}$ and $\mathbf{H_3L^2}$ were synthesized by the condensation of 4,6-*O*-ethylidene-β-D-glucopyranosylamine with salicylaldehyde or 3-methoxysalicylaldehyde in a 1:1 ratio in ethanol, and were used after recrystallization. The solvents were procured from local sources and were purified and dried immediately prior to use. Microanalyses were carried out with a Carlo−Erba elemental analyser. − FT-IR spectra were recorded with a Nicolet Impact 400 spectrometer with samples in KBr. − UV/Vis absorption spectra were recorded with a Shimadzu UV2101PC spectrophotometer. − ^{1}H NMR spectra were recorded with Bruker Avance DRX 500 or Varian XL-300 spectrometers with samples in [D$_6$]DMSO. − FAB mass spectra were recorded with a JEOL SX 102/DA-600 mass spectrometer/data system using argon/xenon (6 kV, 10 mA) as the FAB gas and *m*-nitrobenzyl alcohol as the matrix. The accelerating voltage was 10 kV and the spectra were recorded at room temperature. − Optical rotations were measured with a JASCO model DIP-370 digital polarimeter. The abbreviations Sac, Prot, and Ar are used in the spectral assignments to denote saccharide, protecting, and aromatic groups, respectively. The ligands used and the complexes reported in this paper are shown in Scheme 1.

$[VO_2(HL^1)](Me_2NH_2)$: To a solution of $\mathbf{H_3L^1}$ (0.62 g, 2.01 mmol) in methanol (10 mL) containing dimethylamine, $VO(acac)_2$ (0.53 g, 2.00 mmol) was added and the reaction mixture was stirred at room temperature. After 10 h, oxygen was bubbled through it for 2 h and the resulting solid product was collected by filtration. The residue was washed with a small quantity of cold methanol and then with diethyl ether, and then dried in vacuo. Yield: 0.35 g (40%). − $C_{17}H_{25}N_2O_8V$ (436.33): calcd. C 46.80, H 5.77, N 6.42; found C 46.70, H 5.89, N 5.98. − ^{1}H NMR ([D$_6$]DMSO): δ = 8.50 (s, 1 H, HC=N), 7.46 (d, 1 H, ArH), 7.30 (t, 1 H, ArH), 6.67 (m, 2 H, ArH), 5.15 (br., 1 H, Sac OH), 4.75 (q, 1 H, Prot CH), 4.51 (d, 1 H, Sac 1-H), 4.18 (m, 1 H, Sac 5-H), 3.33−3.75 (m, 5 H, Sac H), 2.57 (s, 6 H, amine CH_3), 1.26 (d, 3 H, Prot CH_3). − FAB MS: *m*/*z* (%) = 391 [M + H$^+$] (95).

$[VO_2(HL^2)](Me_2NH_2)$: This compound was prepared by adopting the procedure described for **$[VO_2(HL^1)](Me_2NH_2)$**, but using $\mathbf{H_3L^2}$ (0.34 g, 1.00 mmol) and $VO(acac)_2$ (0.26 g, 0.98 mmol) in methanol (12 mL) containing dimethylamine. Yield: 0.08 g (17%). − $C_{18}H_{27}N_2O_9V$ (466.36): calcd. C 46.36, H 5.84, N 6.01; found C 46.20, H 5.56, N 6.15. − ^{1}H NMR ([D$_6$]DMSO): δ = 8.48 (s, 1 H, HC=N), 7.06 (d, 1 H, ArH), 6.93 (d, 1 H, ArH), 6.58 (t, 1 H, ArH), 5.32 (br., 1 H, Sac OH), 4.75 (q, 1 H, Prot CH), 4.51 (d, 1 H, Sac 1-H), 4.18 (m, 1 H, Sac 5-H), 3.73 (s, 3 H, $ArOCH_3$), 3.00−3.70 (m, 5 H, Sac H), 2.58 (s, 6 H, amine CH_3), 1.26 (d, 3 H, Prot CH_3). − FAB MS: *m*/*z* (%) = 418 [M − 2 H$^+$] (90).

$[MoO_2(HL^1)(H_2O)]$: To a solution of $\mathbf{H_3L^1}$ (0.62 g, 2.01 mmol) in methanol (30 mL), $MoO_2(acac)_2$ (0.65 g, 1.99 mmol) was added and the reaction mixture was stirred at room temperature for 13 h. The resulting solid product was collected by filtration, washed first with methanol and then with diethyl ether, and dried in vacuo. Yield: 0.65 g (72%). − $C_{15}H_{19}MoNO_9$ (453.25): calcd. C 39.75, H 4.22, N 3.09; found C 40.51, H 3.97, N 2.57. − ^{1}H NMR ([D$_6$]DMSO): δ = 8.55 (s, 1 H, HC=N), 7.75 (d, 1 H, ArH), 7.50 (dt, 1 H, ArH), 6.97 (t, 1 H, ArH), 6.92 (d, 1 H, ArH), 5.61 (d, 1 H, Sac OH), 4.75 (m, 2 H, Prot CH and Sac 1-H), 4.19 (m, 1 H, Sac 5-H), 3.30−3.80 (m, 5 H, Sac H), 1.27 (d, 3 H, Prot CH_3). − FAB MS: *m*/*z* (%) = 438 [M + 3 H$^+$] (40).

$[\{UO_2(HL^1)\}_2]$: This complex was prepared by adopting the procedure described for **$MoO_2(HL^1)$**, but using $\mathbf{H_3L^1}$ (0.93 g, 3.01 mmol) and $UO_2(OAc)_2{\cdot}2H_2O$ (1.27 g, 2.99 mmol) in methanol (40 mL). Yield: 1.05 g (57%). − $C_{30}H_{42}N_2O_{20}U_2$ (1226.72): calcd. C 29.37, H 3.45, N 2.28; found C 29.76, H 3.18, N 2.46. − ^{1}H NMR ([D$_6$]DMSO): δ = 9.05 (s, 1 H, HC=N), 7.50 (m, 2 H, ArH), 6.96 (d, 1 H, ArH), 6.61 (t, 1 H, ArH), 5.23 (m, 3 H, Sac OH, Sac 1-H, and Sac 3-H), 4.80 (q, 1 H, Prot CH), 4.26 (m, 1 H, Sac 5-H), 3.79 (m, 2 H, Sac H), 3.29 (m, 2 H, Sac H), 1.31 (d, 3 H, Prot CH_3). − FAB MS: *m*/*z* (%) = 1155 [M + H$^+$] (82).

$[\{UO_2(HL^2)\}_2]$: This complex was prepared by a procedure similar to that adopted for **$MoO_2(HL^1)$**, but using $\mathbf{H_3L^2}$ (1.02 g, 3.01 mmol) and $UO_2(OAc)_2{\cdot}2H_2O$ (1.27 g, 2.99 mmol) in methanol (40 mL). Yield: 1.40 g (73%). − $C_{32}H_{46}N_2O_{22}U_2$ (1286.77): calcd. C 29.86, H 3.61, N 2.17; found C 29.61, H 3.41, N 2.56. − ^{1}H NMR ([D$_6$]DMSO): δ = 9.02 (s, 1 H, HC=N), 7.13 (m, 2 H, ArH), 6.53 (t, 1 H, ArH), 5.22 (m, 3 H, Sac OH, Sac 1-H, and Sac 3-H), 4.80 (q, 1 H, Prot CH), 4.26 (m, 1 H, Sac 5-H), 3.94 (s, 3 H, $ArOCH_3$), 3.74 (m, 3 H, Sac H), 3.10−3.50 (m, 1 H, Sac H), 1.31 (d, 3 H, Prot CH_3). − FAB MS: *m*/*z* (%) = 1214 [M$^+$] (92).

X-ray Crystallography: Standard procedures were used for mounting the crystals. The diffraction data were collected with a Nonius Kappa CCD diffractometer in the φ scan + ω scan mode using Mo-K_α radiation. Single crystals of **$[VO_2(HL^1)](Me_2NH_2)$**, **$[MoO_2(HL^1)(MeOH)]MeOH$**, and **$[\{UO_2(HL^2)\}_2](EtOH)_2(H_2O)_2$** were obtained. The data were corrected for absorption by empirical methods. The structures were solved using the SHELXS-97 program package and refined using SHELXL-97.[19] The diagrams were generated using ORTEP III[20] and PLUTON-98.[21] Full-matrix least-squares refinement with anisotropic thermal parameters was used for all non-hydrogen atoms. The hydrogen atoms were treated as riding atoms with fixed thermal parameters. Other details of the data collection and structure refinement are presented in Table 1. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-162681 for **$[VO_2(HL^1)](Me_2NH_2)$**, -162679 for **$[MoO_2(HL^1)(MeOH)]MeOH$**, -162680 for **$[\{UO_2(HL^2)\}_2](EtOH)_2(H_2O)_2$**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of Oligometallic Compounds from *tripod*Iron(II) Species Using Cyano Bridging Ligands − Electronic Coupling of Two Metal Termini Through Metal Dicyano and Diisocyano Entities

Volker Jacob,[a] Gottfried Huttner,*[a] Elisabeth Kaifer,[a] Peter Kircher,[a] and Peter Rutsch[a]

Dedicated to Professor Henri Brunner on the occasion of his 66th birthday

Keywords: Cyanides / Cyclic voltammetry / Tripod ligands / Iron

Organometallic monocyanometalates $[M–CN]^-$ (**1**$^-$) [M = $Cr(CO)_5$ **1a**$^-$, $Cr(\eta^6\text{-}CF_3C_6H_5)(CO)_2$ **1b**$^-$, $Mn(\eta^5\text{-}CH_3C_5H_4)(CO)_2$ **1c**$^-$] produce tetrametallic (**2**$^-$) and trimetallic (**3**) aggregates upon reaction with *tripod* and iron(II) salts [*tripod* = $CH_3C(CH_2PPh_2)_3$]. The tetranuclear compound [*tripod*Fe{NC–M}$_3$]$^-$ (**2**$^-$) [M = $Cr(CO)_5$] or the trinuclear species [*tripod*Fe(CO){NC–M}$_2$] (**3**) [M = $Cr(CO)_5$ **3a**, $Cr(\eta^6\text{-}CF_3C_6H_5)(CO)_2$ **3b**, $Mn(\eta^5\text{-}CH_3C_5H_4)(CO)_2$ **3c**] can be selectively formed by following the appropriate reaction protocols. Organometallic dicyanometalates $[NC–M'–CN]^-$ (**4**$^-$) [M′ = $Mn(CO)_4$ **4a**$^-$, CpFe(CO) **4b**$^-$, CpCo(CN) **4c**$^-$] react in a similar manner to give pentanuclear species [*tripod*Fe{NC–M′–CN}$_3$Fe*tripod*]$^+$ (**5**$^+$). – In compounds **2**$^-$ and **3**, two easily oxidizable organometallic groups are linked through a *tripod*Fe$(NC)_2$ unit, while in **5**$^+$ two *tripod*iron(II) entities are linked through a less readily oxidizable M′$(CN)_2$ unit. For both types of compound, at least two distinct reversible oxidations are observed by cyclic voltammetry. The potentials at which these oxidations occur are characteristic of the terminal groups in each case. The potentials of the two consecutive oxidation steps are separated by between 150 and 350 mV. The oxidation products of compounds **2**$^-$, **3**, and **5**$^+$ can hence be classified as class III mixed-valence species with comproportionation constants K_C of between 10^2 and 10^6. The extent of electronic coupling mediated by the M′$(CN)_2$ or M′$(NC)_2$ bridging entities is thus similar to that mediated by $[RC(CN)_2]^-$ bridging ligands in otherwise analogous compounds, for which K_C values of around 10^4 are observed. All the aforementioned compounds have been characterized by analytical and spectroscopic techniques, including cyclic voltammetry and UV/Vis spectroscopy. In addition, X-ray crystallographic data are reported for **2**$^-$, **3a**, **3b**, **3c**, and **5a**$^+$.

Introduction

Dinitrile ligands are efficient building blocks for the synthesis of oligonuclear coordination compounds.[1] Anionic geminal dinitrile ligands [$RC(CN)_2^-$, $N(CN)_2^-$] have been found to lead to efficient electronic coupling between the terminal metal centers in the corresponding M−NC−X−CN−M arrangements.[2] It would appear that the nature of the linking unit X has little influence on the efficiency of this coupling, since the separation between the first and second oxidation potentials of the corresponding compounds is relatively constant, irrespective of the nature of X.[2] Even the replacement of RC^- by N^- as X does not greatly affect this separation.[2] The distance between the two metal centers in compounds of the type M−NC−X−CN−M (X = RC^-, N^-) is around 700 pm, which is rather similar to the distance between two metal centers linked by *cis*-dicyano complexes M′$(CN)_2$.[3] Compounds of this type have been extensively studied by Vahrenkamp,[4] who showed that these inorganic bridging ligands are quite effective in mediating electronic coupling between the two terminal metal centers in an M−(μ-CN)−M′−(μ-CN)−M arrangement.

As the efficiency of electronic coupling is easily measured by cyclic voltammetry, and since the electrochemical behavior of dinuclear *tripod*iron compounds [*tripod* = $CH_3C(CH_2PPh_2)_3$] in which the two iron centers are linked through X$(CN)_2$ entities [X = RC^-, N^-] is well known,[2] it was tempting to synthesize *tripod*iron derivatives having the two iron(II) centers linked by M′$(CN)_2$ bridging units (Scheme 1, **A**). We report herein the synthesis of such compounds (**5**$^+$) and the measurement of their degree of electronic coupling. Moreover, *tripod*iron(II) templates may also serve to address the same type of problem in an inverted version. Compounds of the type [*tripod*FeL{NC−M}$_2$] contain the *tripod*Fe^{II}L unit in a central position (Scheme 1, **B**).

In these compounds, the terminal metal centers are bridged by a CN−Fe−NC ligand entity. Cyclic voltammetry of such compounds should reveal the ability of this type of linker to electronically couple the two terminal metal centers. The synthesis of such compounds (**2**$^-$ and **3**; Scheme 2) and the efficiency of electronic coupling through the *tripod*Fe$(NC)_2$ linker are described herein.

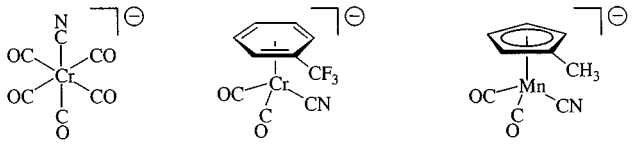
Results and Discussion

It has been shown that the N-termini of nitrile groups in organometallic cyano compounds are quite nucleophilic.[5] The nucleophilicity of metal-bonded cyano groups has been known since the early days of organic chemistry.[6] This appears to be a general property of anionic coordination compounds containing cyano ligands and has been amply demonstrated for species of type **1**$^-$ by their reactions with main-group-[7] or transition-metal-centered[8] electrophiles. Compounds **1a**$^-$ and **1c**$^-$ (Scheme 3) are easily accessible as their sodium or potassium salts by published procedures.[9]

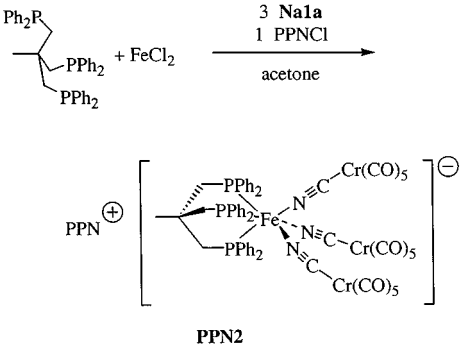


Scheme 3. Organometallic monocyanometalate ligands **1**$^-$

Compound **1b**$^-$ could be obtained by irradiation of the parent (arene)tricarbonyl species[10] in methanol in the presence of excess potassium cyanide[11] as its intensely orange-colored potassium salt. Its composition was unequivocally confirmed by its analytical and spectroscopic data (see Exp. Sect.).

K1b shows an irreversible oxidation wave in its cyclic voltammogram at $E_{pa} = -100$ mV (CH_3CN, vs. SCE). It is thus easily oxidized and is similar in this respect to **Na1a**.[12a] No data are available for **K1c** itself, but the parent compound $Na[CpMn(CO)_2CN]$ is reversibly oxidized at 40 mV vs. SCE[4][12b] and the oxidation potential of **1c**$^-$ can be expected to be of the same order. All compounds **1**$^-$ are thus oxidized at much lower potentials than the *tripod*iron(II) entity in a coligand environment of nitrile groups. The oxidation of $[tripodFe(CH_3CN)_3]^{2+}$ occurs at 1400 mV (CH_3CN, vs. SCE)[13] and oxidation of this entity in the dinuclear compounds $[tripodFe\{\mu\text{-}NC\text{-}C(R)\text{-}CN\}_3Fetripod]^+$ requires a minimum of 900 mV vs. SCE.[2c] This combination of facts makes compounds **1**$^-$ ideal ligands for testing the electronic coupling properties of a *tripod*$Fe(NC)_2$ unit linking two redox-active metal centers (Scheme 1, **B**).

The reaction of equimolar amounts of *tripod* and $FeCl_2$ with three equivalents of **Na1a** in acetone gives a red solution, from which, after cation exchange with PPNCl and crystallization, **PPN2**·0.75 CH_2Cl_2 is obtained in the form of red needle-shaped crystals (Scheme 4).



Scheme 4. Synthesis of **PPN2**

The constitution of the tetranuclear anion **2**$^-$ was unequivocally proven by the spectroscopic and analytical data of **PPN2** (Table 2). The signals of the axial and equatorial carbonyl groups as well as of the nitrile groups are clearly resolved in the ^{13}C NMR spectrum of **PPN2** (Table 3), while its infrared spectrum shows weak bands attributable to ν_{CN} absorptions at 2126 cm^{-1} and 2135 cm^{-1}. The ν_{CO} band pattern (Table 2) is consistent with the presence of $Cr(CO)_5$ groups, although the pattern is somewhat more complicated than that generally observed for $LCr(CO)_5$ compounds with undisturbed local C_{4v} symmetry. This indicates some deviation of these groups from this local symmetry in the tetranuclear anion. The structure of **PPN2**·0.75 CH_2Cl_2, as determined by single-crystal X-ray analysis (Figure 1; Tables 1 and 8), shows an overall close to C_3-symmetric arrangement for the anion **2**$^-$. The rotational

positions of the phenyl groups, as well as those of the $Cr(CO)_5$ entities, are close to this idealized symmetry (Table 1; torsion angles τ, φ, and χ).

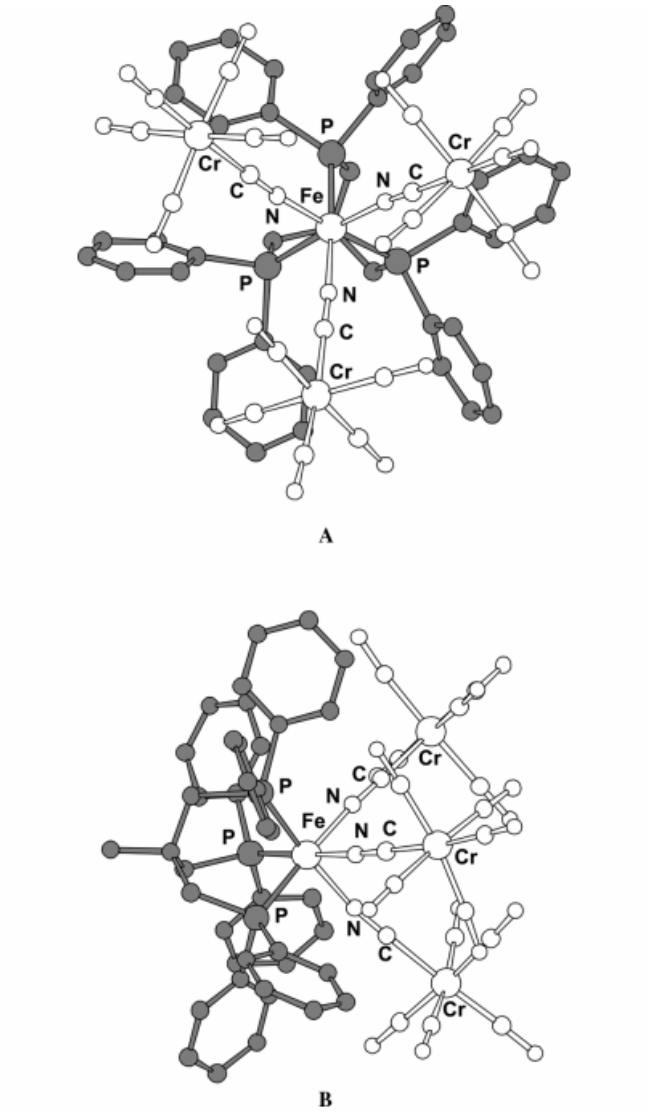


Figure 1. Two views of the structure of the tetranuclear anion **2**$^-$

Short O···H contacts are seen between some of the equatorial carbonyl groups and the protons of the phenyl rings. Each pentacarbonylchromium group is involved in at least one such contact with H···O distances in the range 260−300 pm (Table 1). Even though this is not indicative of hydrogen bonding, it shows that the *tripod*iron entity and the $Cr(CO)_5$ groups are in steric interference with one another. Disturbance of the local C_{4v} symmetry of the $Cr(CO)_5$ groups, as inferred from the IR-spectroscopic data, is thus consistent with the observed structure.

When equimolar mixtures of *tripod* and $FeCl_2$ in acetone are treated with 2 equiv. of either **Na1a**, **K1b**, or **K1c**, orange-red solutions result. On bubbling CO through these solutions, they undergo a color change to orange-brown.

The trinuclear compounds **3** were isolated as red-brown crystalline materials in yields of around 80%. The identities

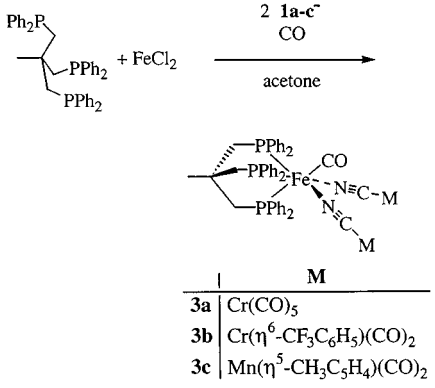
[a] The values in parentheses are standard deviations in units of the last decimal listed. − [b] τ denotes the torsion angles Fe−P−C−C within the chelate cage. − [c] The suffixes a and b refer to the two classes of aryl groups, which would be equivalent under exact C_3 symmetry (Figure 1, **A**). − [d] φ designates a torsion angle $C_{ortho}-C_{ipso}-P-Hz$, where Hz is the end point of a vector vertical to the plane spanned by the three phosphorus nuclei and fixed to one phosphorus center, pointing in the direction of the observer with respect to Figure 1, **A**. − [e] χ denotes the torsional arrangement of the $Cr(CO)_5$ groups. It is defined as the torsion angle $Hx-Fe-Cr-O_{CO,eq}$, where Hx is the end point of a vector radiating from the iron center along the idealized C_3 axis in a direction away from the observer with respect to Figure 1, **A**. − [f] Shortest distance between a carbonyl oxygen atom of any of the three pentacarbonylchromium units and a hydrogen atom of a *tripod* phenyl substituent.

of the compounds **3a**, **3b** ($FeCr_2$), and **3c** ($FeMn_2$) (Scheme 5) were unequivocally established from their spectroscopic data (Tables 2 and 3) and X-ray analyses (Tables 4 and 8; Figure 2).



Scheme 5. Synthesis of compounds **3**

The infrared spectra of compounds **3** each feature a band at around 2030 cm^{-1} (Table 2), attributable to the iron-bonded carbonyl group. The ν_{CN} vibrations are observed as one band envelope at around 2100 cm^{-1}. The ν_{CO} vibrations of the $Cr(CO)_5$ groups in **3a** produce the expected pattern (Table 2). The CO groups of the $Cr(\eta^6\text{-}CF_3C_6H_5)(CO)_2$ entities in **3b** give rise to two bands of equal intensity, as do those of the $Mn(\eta^5\text{-}CH_3C_5H_4)(CO)_2$ entities in the $FeMn_2$ compound **3c** (Table 2). The ^{31}P NMR spectra of compounds **3** each show a doublet of higher intensity and a

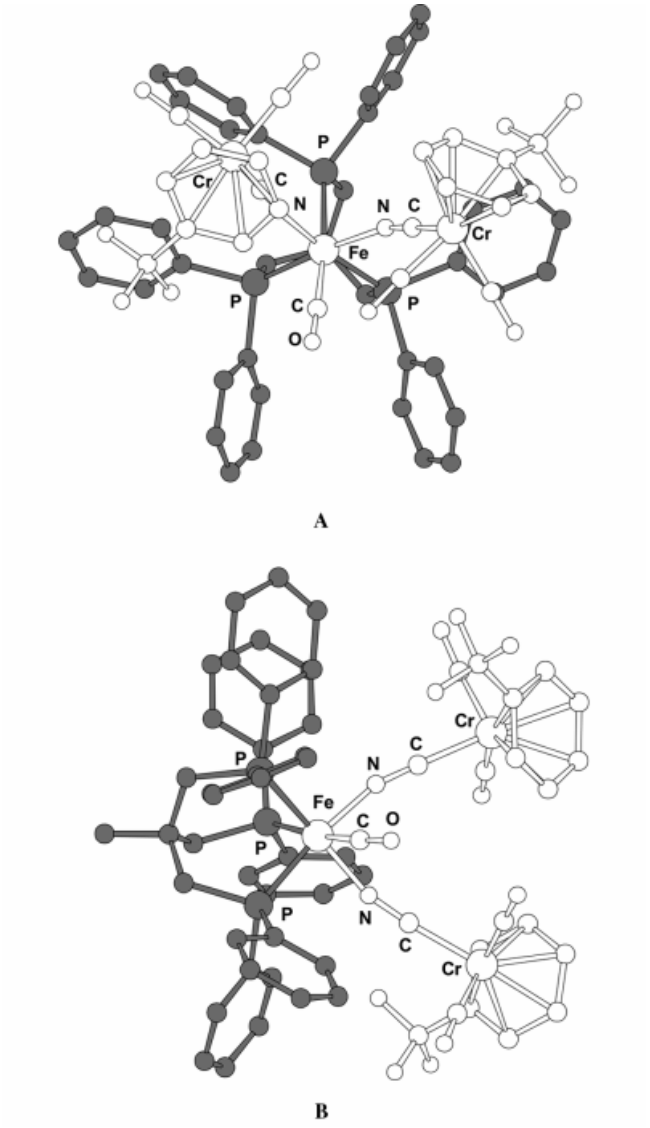

Figure 2. Two views of the structure of complex **3b**

triplet of lower intensity (Table 3). This is consistent with the static idealized octahedral coordination geometry around the iron centers, with two phosphorus nuclei lying *trans* to the nitrile ligands and the third being *trans* to the iron-bonded carbonyl group (Scheme 5, Figure 2). The coupling between these two types of phosphorus nuclei is $^2J_{PP} \approx 70$ Hz in each case (Table 3). The C_s symmetry of the coordination polyhedron around the iron center is corroborated by the ^{1}H NMR spectroscopic data of compounds **3**; two types of methylene groups are observed for the tripodal framework in the $^1H\{^{31}P\}$ NMR spectra of compounds **3** (Table 3). While the signal with a relative intensity of *two* would be expected to be a singlet, the other one with the observed relative intensity of *four* might be expected to show a more complicated pattern due to the diastereotopicity of the relevant methylene protons. However, the differentiation between these two types of protons is evidently too small to be observable with the resolution of our experiment and only an apparent singlet signal is observed for these protons (Table 3). The ^{13}C NMR spectra of the trinuclear complexes **3** show signals due to the iron-bonded carbonyl group, the carbonyl groups bonded to the chromium ($FeCr_2$ compounds **3a** and **3b**) or manganese centers ($FeMn_2$ compound **3c**), and the bridging cyanide groups (Table 3).

The presence of the (η^6-$CF_3C_6H_5$) moieties in **3b** is evident from their NMR signature. The ^{1}H NMR signals observed for this group in the spectrum of the potassium salt **K1b** are also observed in that of **3b**, with only very slight shift differences (Table 3). The ^{13}C NMR spectrum of **3b** shows signals due to the $CF_3C_6H_5$ ligands in the same spectral region as observed for **K1b**. In the ^{13}C NMR spectrum of **3b**, the CF_3 groups give rise to a quadruplet, which is partly obscured by the group of signals due to the *tripod* aryl carbon atoms. The arene carbon atoms of the $CF_3C_6H_5$ ligands, giving one signal each for the *ipso*, *ortho*, *meta*, and *para* carbon atoms in the spectrum of **K1b**, appear in part as pairs of signals in the spectrum of **3b** (Table 3). The reason for this side differentiation is not clear. It appears improbable that the two Cr(η^6-$CF_3C_6H_5$)$(CO)_2$ units would be fixed in **3b** such as to have different time-averaged chemical environments. A loss of the C_s symmetry of the environment due to the chirality of the {*tripod*Fe(CO)−NC−(η^6-$CF_3C_6H_5$)Cr$(CO)_2$} residue would appear to offer a more probable explanation.

The presence of the π-bonded $CH_3C_5H_4$ group in the $FeMn_2$ compound **3c** is evident from its characteristic ^{1}H NMR signals (Table 3). The methyl substituent gives rise to a signal at δ = 2.0, while the C_5H_4 fragment gives a partly

[a] The ^1H NMR resonances of the ligands are found at δ = 4.5–5.1 (**K1b**, $[D_6]$acetone) and δ = 4.4 (C_5H_4), 1.9 (CH_3) (**K1c**, $[D_6]$acetone)[9b,12b]. – [b] The ^{13}C NMR resonances of the ligands are found at δ = 221.5, 218.5 (CO) and 153.8 (CN) (**Na1a**, CD_3CN)[12]; δ = 241.3 (s, CO), 168.0 (s, CN), 126.4 (q, CF_3; $^1J_{FC}$ = 270 Hz), 89.6 (s, C_{ar}), 86.5 (q, C_{ipso}; $^2J_{FC}$ = 35 Hz), 86.3 (s, C_{ar}), 84.3 (s, C_{ar}) (**K1b**, $[D_6]$acetone). – [c] The signals are split due to $^3J_{CF}$ coupling.

resolved multiplet. In the spectrum of **K1c**, the expected A_2B_2 multiplet is unresolved,[12b] as is often observed for compounds of this type. The form of this signal seen for **3c**, like that observed for **3b**, is suggestive of side differentiation induced by the prochirality of the compound. The structures of the trinuclear complexes **3** have been elucidated by X-ray crystallography (Tables 4 and 8). The basic molecular arrangement is the same in all three compounds, hence only the representative structure of **3b** is shown in Figure 2. The coordination around the iron center is idealized octahedral with the *tripod* ligand occupying one face of the octahedron. The organometallic ligands are consequently in a mutually *cis* arrangement with the coordination octahedron being completed by the iron-bonded carbonyl ligand (Figure 2).

All three organometallic ligands have at least two mutually *cis*-carbonyl groups that are also *cis* to the cyano bridging group. These carbonyl groups show roughly the same orientation with respect to the *tripod*iron(II) entity in all three cases (Table 4). The torsion angles χ defined by the rotational position of the carbonyl groups around an Fe–M axis [M = Cr (**3a** and **3b**), Mn (**3c**)] with respect to the idealized trigonal axis of the *tripod*iron entity are very similar for these four groups in the three compounds **3**. This means that three of the carbonyl groups of the pentacarbonylmetal entities in **3a** are formally replaced by η^6-arene units ($FeCr_2$ compound **3b**) or η^5-cyclopentadienyl units ($FeMn_2$ compound **3c**) without a significant change in the position of the two remaining carbonyl groups. These carbonyl groups, like those in $\mathbf{2}^-$, show short contacts to some of the phenyl protons of the *tripod* entity (Table 4). Geometrically, these contacts are again rather similar for all three compounds. Thus, the rotational positions of the aryl groups (Figure 2) of the *tripod*iron entity are also rather similar for all three species (Table 4). Overall, in fact, the crystals of **3a**, **3b** ($FeCr_2$), and **3c** ($FeMn_2$) are isotypic (Table 8). The Fe–P bond lengths are in the normal range, with the bonds to the phosphorus atom *trans* to the carbonyl groups being longer than the other two Fe–P bonds (Table 4). The Fe–N bond lengths are in the range 195.7(3)–198.5(4) pm (Table 4) and are distinctly longer than the $Fe-C_{CO}$ bonds [179.5(5)–180.5(2) pm] in each case. The Fe–N–C entities deviate from linearity, as is generally observed for *tripod*iron(II) nitrile compounds.[1,2,13] The deviation is smaller in **3a** than in **3b** or **3c** (Table 4), reflecting the lower symmetry of the organometallic termini

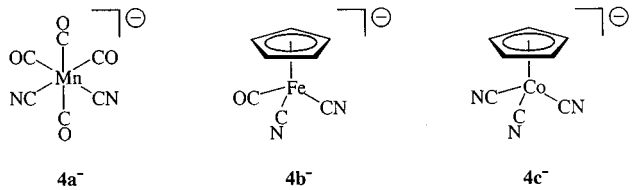
in the latter compounds. The geometries of the organometallic termini themselves are unremarkable (Table 4).

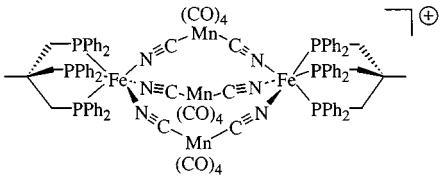
While compounds $\mathbf{2}^-$ ($FeCr_3$) and **3** ($FeCr_2$, $FeMn_2$) contain organometallic groups linked by a *tripod*-iron−diisocyano group (Scheme 1, **B**), the reaction of *tripod*iron(II) entities with organometallic dinitriles should lead to compounds containing two *tripod*iron(II) entities linked by a metal−dinitrile species (Scheme 1, **A**). Quite a number of anionic organometallic dinitriles are known and some of them have been shown to be suitable building blocks for the construction of oligometallic cage compounds.[3b,3c,14] The dicyanometalates $\mathbf{4}^-$ (Scheme 6) are obtained by standard procedures.[15]



4a⁻ **4b⁻** **4c⁻**

Scheme 6. Dicyanometalate ligands $\mathbf{4}^-$

When an equimolar solution of *tripod* and $FeCl_2$ in acetone is treated with an equimolar amount of **K4a**, the initially faintly yellow solution immediately turns red. Whereas we had hoped to obtain a tetrametal square with two *tripod*FeL entities and two $Mn(CO)_4$ constituents at its corners by applying this stoichiometry, compound $\mathbf{5a}^+$ (Scheme 7) was obtained as the only characterizable product in very low yield (see Exp. Sect.).



$\mathbf{5a}^+$

Scheme 7. The constitution of the pentanuclear cation $\mathbf{5a}^+$

$\mathbf{5a}^+$ was identified by X-ray crystallography of its $FeCl_4^-$ salt, which was serendipitously found to crystallize. $\mathbf{5a}^+$ is a pentanuclear Fe_2Mn_3 compound[16] composed of two *tripod*iron(II) entities, which are bridged by the *cis*-dicyano-

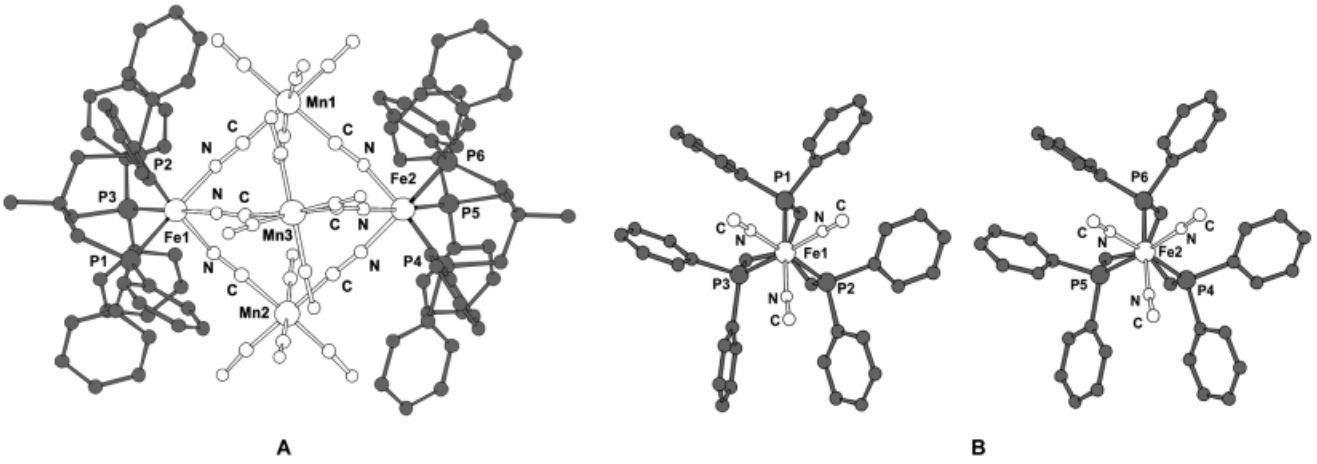


Figure 3. Structure determination of **5aFeCl$_4$**: **A**: view of the pentanuclear cation **5a**$^+$; **B**: standardized view of the two *tripod*iron(II) centers

manganese parts of three (tetracarbonyl)dicyanomanganese bridging units (Figure 3).

5a$^+$ has approximate C_2 symmetry (C_2 axis along the bisector of Fe1−Mn3−Fe2 in Figure 3, **A**). This symmetry is not imposed by crystal symmetry, but is evident from inspection of Figure 3, **A**, as well as from the values of the geometric parameters, pairs of which should be equal under this symmetry (Table 5).

Table 5. Bond lengths and angles in the pentanuclear cation **5a**$^+$

Fe−P	226.1(2)−228.4(2)[a]	Fe···Mn	507−511

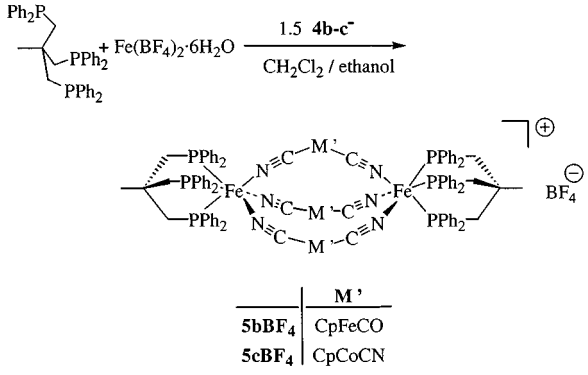
Mn−C−N	172.2(7)−177.3(7)	φ_{III}	−61.6/−53.7
P−Fe−P	85.8(1)−91.4(1)	φ_{IV}	−43.2/−42.8
N−Fe−N	83.8(3)−85.5(3)	φ_V	+9.6/−34.5
C−N	114(1)−116(1)	φ_{VI}	−16.3/−28.0

[a] The values in parentheses are standard deviations in units of the last decimal listed. − [b] The τ values refer to the torsion angles Fe−P−C−C within the chelate cages; they are arranged in pairs to reflect the approximate C_2 symmetry of the cation **5a**$^+$. − [c] φ describes the torsion of the phenyl rings of the *tripod*iron entities. The torsion relates to the rotation around the corresponding P−C_{ipso} axis with the idealized trigonal axis of the *tripod*iron fragment as the reference axis. The first value φ_I describes the rotation of the phenyl group at P1, which points towards the observer in Figure 3, **A**, with the companion phenyl group at P6 again pointing towards the observer. Starting from this phenyl group at P1, the six pairs of values φ_I−φ_{VI} are listed in a counterclockwise sequence, when looking at Fe1 from the location of Fe2 (Figure 3, **A** and **B**).

Thus, even the torsion angles φ describing the orientation of the phenyl groups at the two *tripod*iron entities, as well as the twist angles τ describing the skew of the chelate cage, are in good pairwise agreement (Figure 3, **B**; Table 5). The Fe−N−C angles deviate from linearity in a systematic way. If, as initially expected, only two sites at each *tripod*iron entity were to be coordinated by the cyano groups of two (tetracarbonyl)dicyanomanganate units, a strain-free square arrangement with linear Fe−N−C groups would result, with the vacant coordination site at each *tripod*iron entity being perpendicular to the plane of this square. These coordination sites have to be brought into an arrangement that allows them to be spanned by the additional $Mn(CN)_2$ unit. This induces some strain in the scaffolding, which results in a bending of the Fe−N−C angles. As is well known, these angles are rather tolerant to this type of deformation (Figure 3; Table 5).

In view of the fact that pentanuclear compounds such as the Fe_2Mn_3 complex **5a**$^+$ are formed even under stoichiometric conditions, which should favor the formation of square tetranuclear aggregates, the stoichiometry was changed to *tripod*/Fe^{II}/$M'(CN)_2^-$ = 2:2:3. According to this protocol, the pentanuclear compounds **5bBF$_4$** (Fe_5) and **5cBF$_4$** (Fe_2Co_3) were prepared (Scheme 8).

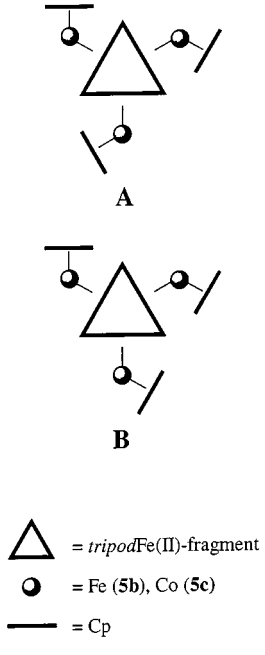


Scheme 8. Synthesis of **5bBF$_4$** and **5cBF$_4$**

Upon work-up of the respective reaction mixtures, microcrystalline red powders were obtained, which were shown by NMR spectroscopy to contain different diastereomers. With **5b**$^+$ (Fe_5), the reaction product showed four signals in the cyclopentadienyl region of the ^{1}H NMR spectrum. By repeated recrystallization, a product was obtained that showed one of these Cp peaks with 95% of the total intens-

ity. The cyclopentadienyl resonance of the crude product is clearly composed of two sets of signals, one being a sharp singlet at $\delta = 4.1$ and the other one being composed of three signals of equal intensity (see Exp. Sect.).

The intensity ratio of these two sets of signals is initially 2:1, whereas it becomes 19:1 following the recrystallization process. These observations may be explained as follows: There are two possible basic arrangements for the mutual orientation of the Cp groups in a compound of type **5b**$^+$ (Fe_5). One of them conforms to the constitutional C_3 symmetry (Scheme 9, **A**), while in the other this symmetry is lost (Scheme 9, **B**). There are six different possibilities for creating this unsymmetrical type of arrangement (Scheme 9, **B**), whereas there are only two possibilities for generating a C_3-symmetric arrangement (Scheme 9, **A**). The statistical probability of formation of the C_3-symmetric species is hence 0.25. The C_3-symmetric species will give rise to just one single Cp resonance, while for the unsymmetrical species three Cp signals of equal intensity can be expected. This is indeed what is observed in the ^{1}H NMR spectrum of crude **5b**$^+$. The ratio of the symmetrical to the unsymmetrical diastereomers is initially 2:1, which is quite different from the ratio expected on statistical grounds. This suggests that the C_3-symmetric product is formed under considerable diastereoselective control. Crystallization enriches the sample in the symmetrical product (Scheme 9, **A**), which is present to an extent of 95% after three recrystallizations.



Scheme 9. Diastereomers of **5b**$^+$ and **5c**$^+$

Diastereoselectivity is also observed in the formation of **5c**$^+$ (Fe_2Co_3). In this case, the C_3-symmetric isomer is isolated as the sole product in 40% yield after just one recrystallization step. **5cBF$_4$** (Scheme 9, **A**) shows only one sharp Cp signal at $\delta = 4.7$ in its ^{1}H{^{31}P} NMR spectrum. The protons of the methylene groups of the *tripod* ligands are diastereotopic and give rise to a doublet-of-doublets signal in the ^{1}H{^{31}P} NMR spectrum (see Exp. Sect.). Likewise, the phenyl groups of the PPh_2 donors of the *tripod* ligands are diastereotopic. The ^{13}C NMR signals fall into two well-separated groups, consisting of a multiplet due to the *ortho*, *meta*, and *para* carbon atoms and a well-resolved signal due to the *ipso* carbon atoms (see Exp. Sect.). The pentanuclear structure of **5**$^+$ was unequivocally established from these findings, as were the structures of **5a**$^+$ (Fe_2Mn_3), **5b**$^+$ (Fe_5), and **5c**$^+$ (Fe_2Co_3) by the aforementioned combination of analytical methods.

The FAB$^+$ mass spectra show peaks due to the molecular ion **5**$^+$ in each case, accompanied by peaks originating from [**5** − *tripod*]$^+$ (Table 6). The infrared spectrum of **5a**$^+$ (Table 6) shows the presence of the organometallic $(CO)_4Mn(CN)_2$ building blocks through the characteristic patterns of its ν_{CO} and ν_{CN} bands, which are similar to those seen for **K4a**. Although the ν_{CO} absorptions are seen at wavelengths similar to those found for **K4a**, they show a somewhat more complicated structure than in the case of this starting material (Table 6). This observation may be similarly explained as previously proposed for the pair of compounds **Na1a** and **PPN2** ($FeCr_3$). **5bBF$_4$** shows ν_{CN} bands at 2140 cm^{-1} and 2106 cm^{-1}, positions not dissimilar from those of the bands reported for **K4b**.[17] The ν_{CO} band of **5bBF$_4$** is observed at 1961 cm^{-1}, and is thus shifted to higher energies relative to the ν_{CO} absorption of **K4b**. The (cyclopentadienyl)tricyanocobalt(III) units of **5cBF$_4$** (Fe_2Co_3) give rise to a band at 2168 cm^{-1}, which is broader and more intense than a second band at 2126 cm^{-1}. This latter band is attributed to the ν_{CN} vibrations of the terminally bonded cyano ligands, while the former is interpreted as being the envelope of the two ν_{CN} vibrations of the bridging cyano groups.

Electrochemistry and UV/Vis Spectroscopy

All compounds **PPN2**, **3**, and **5BF$_4$** contain the *tripod*iron(II) entity coordinated to at least two nitrile functions. A band at $\lambda \approx 20000$ cm^{-1} appears to be characteristic of iron(II) compounds of this type (Table 7). Irrespective of whether the nitrile functions originate from bridging cyano groups or from organic nitriles, this is a constant signature for all [*tripod*Fe^{II}(NCR)$_3$]$^{n+}$ species and obviously for all [*tripod*Fe^{II}(NCR)$_2$L]$^{n+}$ species as well. The energy of this transition is fairly constant for all compounds of this type.[2,13] A band at shorter wavelengths at $\lambda \approx 25000$ cm^{-1} is somewhat more variable with respect to its energy and extinction coefficient (Table 7), but also appears to be characteristic of compounds containing a *tripod*Fe^{II}(NCR)$_3$ or a *tripod*Fe^{II}(NCR)$_2$L (**3a**) moiety.[2,13] Based on the intensities of the relevant bands, the underlying electronic transitions must involve some charge-transfer character. At the short wavelength side, a band is present at $\lambda \approx 30000$ cm^{-1}, although it is not always observable as it may be obscured by the steep rise of shorter wavelength bands. A band in this position has also been observed for other *tripod*-Fe^{II}(NCR)$_2$L compounds.[2,13]

[a] Equilibrium constants K_C for the comproportionation reaction (Scheme 10) calculated from $K_C = \exp\{\Delta E_{1/2}/25.69\}$; $\Delta E_{1/2}$ in mV. – [b] $\delta\Delta G_{298}$ calculated from the differences $\Delta E_{1/2}$ between the oxidation potentials of the first and second oxidation steps. – [c] The negative charge of **2$^-$** leads to a value for the first oxidation potential about 400 mV lower than that observed for **3a**. – [d] The extent of electronic coupling is greatest for the negatively charged complex **2$^-$**. – [e] Band is obscured by the steep rise of shorter wavelength bands. – [f] The $Cr(CO)_5CN$ groups of **2$^-$** and **3a** are less easily oxidized than the $Cr(CF_3C_6H_5)(CO)_2CN$ group of **3b**: E_{pa}{K[Cr(η^6-$CF_3C_6H_5$)(CO)$_2$CN], **K1b**} = −100 mV (vs. SCE, CH_3CN), $E_{1/2}${Na[Cr(CO)$_5$CN], **Na1a**} = +690 mV (vs. SCE; reversible, CH_3CN).[12] – [g] The oxidation potentials of the dinuclear compounds increase with the estimated electronegativity of the central atom (right column) in the bridging moieties.

Cyclic voltammetry shows a minimum of two reversible one-electron oxidation steps for compounds **PPN2**, **3**, and **5BF$_4$**. Compounds **PPN2** ($FeCr_3$) and **3** ($FeCr_2$) contain a *tripod*Fe^{II}L entity at the bridging position between two organometallic cyano compounds. [*tripod*Fe^{II}(NCMe)$_3$]$^{2+}$ [13] is only oxidized at 1400 mV (CH_3CN; reversible vs. SCE), while the organometallic nitriles bonded to this bridging group in **3** are more easily oxidized [$E_{1/2}${Na[(CO)$_5$CrCN]; **Na1a**} = +690 mV (CH_3CN; reversible vs. SCE);[12] E_{pa}{K[(η^6-$CF_3C_6H_5$)Cr(CO)$_2$CN]; **K1b**} = −100 mV (CH_3CN; vs. SCE; see Exp. Sect.)]. The oxidation waves observed for **3a** and **3b** (Table 7) are thus in the characteristic range for the one-electron oxidations of the terminal groups. Compared to the corresponding alkali metal salts, the oxidation potentials of the iron-coordinated organometallic nitriles are shifted to higher potentials by around 200 mV (Table 7), as would be expected for the oxidation of a neutral compound compared with the oxidation of an anion. The appearance of two well-separated one-electron oxidation steps for **3a** and **3b** implies electronic conjugation between the two organometallic termini. Purely electrostatic coupling cannot account for the difference in $\Delta E_{1/2}$ of around 165 mV observed between these two cases[18] (Table 7) for two centers about 600 pm apart as they are in **3**.

The comproportionation constant (Scheme 10) for the reaction is 6×10^2 for both $FeCr_2$ compounds **3a** and **3b** (Table 7). It is thus in a range characteristic of class III mixed-valence compounds[19] and may be taken as proof of

$$M\sim\sim M + M^{ox}\sim\sim M^{ox} \overset{K_C}{\rightleftharpoons} 2\ M\sim\sim M^{ox}$$

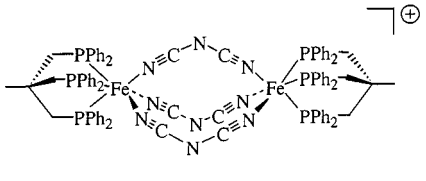
Scheme 10. Comproportionation equilibrium

a conjugative interaction between the termini through the *tripod*Fe(NC)$_2$ linking groups.

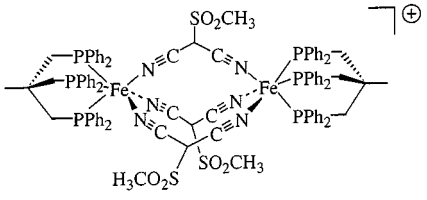
Compound **PPN2** ($FeCr_3$) undergoes three reversible one-electron oxidation steps, which is consistent with its composition. The three $Cr(CO)_5CN$ entities are oxidized in a stepwise manner $2^- \rightarrow 2$, $2 \rightarrow 2^+$, and $2^+ \rightarrow 2^{2+}$ (Table 7). Oxidation of the first $Cr(CO)_5CN$ entity occurs at $E^1_{1/2} = 425$ mV and is thus about 400 mV easier to oxidize than with the corresponding neutral $FeCr_2$ species **3a**. The second and third one-electron oxidation steps are found at $E^2_{1/2} = 780$ mV and $E^3_{1/2} = 900$ mV and are thus in a range well below the potential needed for the oxidation of *tripod*$Fe^{II}(NCR)_3$ entities.[13] The occurrence of three one-electron oxidation steps in the observed range leaves no doubt that the individual oxidations occur at the organometallic termini. Here again, the separation between the oxidation potentials can only be explained by assuming electronic conjugation between the organometallic termini through the *tripod*Fe(NC)$_3$ linker. The comproportionation constant deduced from the first two oxidation steps of **2**$^-$ ($K_c = 10^6$) is the largest for the series of compounds analyzed (Table 7). The comproportionation constant deduced from the second and third oxidation potentials is still $K_c = 10^2$ (Table 7). Both constants are characteristic of conjugated systems, and it appears that increasing the negative charge of the molecule tends to increase conjugation.

Compounds **5bBF$_4$** (Fe_5) and **5cBF$_4$** (Fe_2Co_3) contain two *tripod*iron(II) termini coupled through organometallic dicyano linkers M′(CN)$_2$. Two reversible one-electron oxidation steps are observed for these compounds (Table 7). The oxidation potentials are well below that observed for [*tripod*Fe(NCMe)$_3$]$^{2+}$, as would be expected for a reduction of the charge of a compound containing two [*tripod*Fe(NCR)$_3$]$^{2+}$ entities by three units in **5**$^+$. The separation between the oxidation potentials is again rather large and the comproportionation constants indicate strong conjugation between the *tripod*iron(II) termini through the organometallic dicyanometalate bridges. Thus, in all examples of **2**$^-$, **3**, and **5**$^+$, the mixed-valence species are definitely of type III.[19]

A comparison can now be made between the conjugation capacities of dicyanometalate bridges and main-group-based anionic dicyano bridges. Several compounds containing two *tripod*iron(II) entities coupled by dicyanamido or dicyanomethanido ligands are known[2] (Scheme 11; **A**$^+$, **B**$^+$). Their electrochemical properties are very similar to those observed for **5b**$^+$ and **5c**$^+$ (Table 7). The relevant comproportionation constants resulting from conjugation through the organic linkers are $K_C \approx 10^4$ and are thus not significantly different from the values observed with either organometallic dicyanometalate or *tripod*$Fe^{II}(CN)_2$ linking groups. It appears that the HOMO of such compounds does not have a large orbital coefficient at the central atom of the bridging group, be it a main-group element or a transition metal. In each case studied, this central group is far more difficult to oxidize than the termini.



A$^+$



B$^+$

Scheme 11. Dinuclear *tripod*iron(II) complexes **A**$^+$ and **B**$^+$ (Table 7)

Conclusion

With monocyanometalates [M−CN]$^-$ (**1**$^-$), the *tripod*iron(II) template selectively forms tetranuclear species [*tripod*Fe{NC−M}$_3$]$^-$ (**2**$^-$) or trinuclear entities [*tripod*Fe(CO){NC−M}$_2$] (**3**) under the appropriate stoichiometric control. Dicyanometalates [M′(CN)$_2$]$^-$ (**4**$^-$) form pentanuclear compounds [*tripod*Fe{NC−M′−CN}$_3$-Fe-*tripod*]$^+$ (**5**$^+$). The organometallic termini M in compounds **2**$^-$ and **3** [e.g. $Cr(CO)_5$] are more easily oxidizable than the *tripod*iron(II) entity. Cyclic voltammetry reveals stepwise one-electron oxidation of these termini with potential differences characteristic of conjugative coupling between them. In compounds **5**$^+$, with M′ being CpFe(CO) (**5b**$^+$) or CpCo(CN) (**5c**$^+$), the *tripod*iron(II) entities are more easily oxidized than the organometallic bridging units. Cyclic voltammetry shows two well-separated, reversible, one-electron oxidation steps, which is consistent with strong conjugative coupling of the iron centers through the organometallic M′(CN)$_2$ linkers. It has been observed that the coupling efficiency of M′(CN)$_2^-$ is similar to that of [RC(CN)$_2$]$^-$ in structurally analogous compounds.

Experimental Section

General Remarks: All manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods[20] and distilled under argon. Silica gel and kieselguhr used for filtrations and chromatography were degassed at 1 mbar for 24 h and saturated with argon. The compounds **Na1a**,[9] **K1c**,[9] *tripod*,[21] **K4a**,[15a] **K4b**,[15b] **K4c**,[15c] and $Fe(BF_4)_2 \cdot 6H_2O$[22] were prepared according to or by adaptation of literature procedures. All other chemicals were obtained from commercial suppliers and were used without further purification. − NMR: Bruker Avance DPX200 spectrometer operating at 200.13 MHz (^{1}H), 50.323 MHz (^{13}C), 81.014 MHz (^{31}P); T = 303 K; chemical shifts (δ) in ppm with respect to CD_2Cl_2 (^{1}H: δ = 5.32; ^{13}C: δ = 53.5), [D$_6$]acetone (^{1}H: δ = 2.05; ^{13}C: δ = 20.8,

206.1), or [D$_6$]DMSO (^{1}H: δ = 2.50; ^{13}C: δ = 39.4) as internal standards; ^{31}P chemical shifts (δ) in ppm with respect to 85% H_3PO_4 (^{31}P: δ = 0) as an external standard; CD_2Cl_2, [D$_6$]acetone, and [D$_6$]DMSO used for NMR-spectroscopic measurements were degassed by three successive freeze-pump-thaw cycles and dried with 4 Å molecular sieves. − IR: Biorad Excalibur FTS 3000 spectrophotometer (samples in CsI discs or as solutions between CaF_2 windows). − UV/Vis spectra: Perkin−Elmer Lambda 9 UV/Vis spectrophotometer; ca. 10^{-3} M solutions in CH_2Cl_2. − MS: Finnigan MAT 8320 operated in FAB mode (xenon; matrix: 4-nitrobenzyl alcohol). − Cyclic voltammetry: EG&G Princeton Applied Research model 273 potentiostat; potentials in mV versus SCE at a glassy carbon electrode at 25 °C; sample solutions: ca. 10^{-3} M in 0.1 M Bu_4NPF_6 in CH_3CN or CH_2Cl_2. − Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg.

Potassium [Dicarbonyl(cyano)(η^6-trifluoromethylbenzene)chromate(0)] (K1b): Tricarbonyl(η^6-trifluoromethylbenzene)chromium (1.72 g, 6.1 mmol) and potassium cyanide (1.14 g, 17.5 mmol) were dissolved in methanol (200 mL) in an irradiation vessel. The vessel was cooled to 0 °C and the solution was irradiated for 3 h with UV light from a high-pressure mercury lamp (Hanau TQ 150). After allowing the dark-brown reaction mixture to warm to room temperature, it was filtered and the filtrate was concentrated to dryness. The residue was washed with diethyl ether (100 mL) and filtered through 5 cm of kieselguhr with tetrahydrofuran (100 mL). Evaporation of the solvent from the orange-red filtrate and subsequent crystallization of the residue from acetone/petroleum ether (boiling range 40−60 °C) yielded **K1b** as a microcrystalline solid with an intense orange color (900 mg, 46%). − $C_{10}H_5CrF_3KNO_2$ (319.2): calcd. C 37.62, H 1.58, N 4.39; found C 36.93, H 1.89, N 4.48. − ^{1}H NMR ([D$_6$]acetone): δ = 4.5−5.1 (m). − ^{13}C NMR ([D$_6$]acetone): δ = 241.3 (s, CO), 168.0 (s, CN), 126.4 (q, CF_3, $^1J_{FC}$ = 270 Hz), 89.6 (s, C_{ar}), 86.5 (q, $C_{ar}CF_3$, $^2J_{FC}$ = 35 Hz), 86.3 (s, C_{ar}), 84.3 (s, C_{ar}). − IR (CH_3OH): $\tilde{\nu}$ = 2041 w, br (CN), 1910 s, 1856 s (CO). − MS (FAB$^-$): *m*/*z* = 280.0 [M]$^-$. − CV (CH_3CN, SCE): E_{pa} = −100 mV (irrev. ox.).

PPN[*tripod*Fe{NC−Cr(CO)$_5$}$_3$] (PPN2): To a solution of $FeCl_2$ (0.29 mmol, 34 mg) and *tripod* (0.29 mmol, 184 mg) in acetone, a solution of **Na1a** (216 mg, 0.90 mmol) in acetone was added dropwise by means of a syringe. An immediate color change from pale-yellow to red was observed. After the addition of bis(triphenylphosphanyl)iminium chloride (PPNCl; 176 mg, 0.31 mmol), the reaction mixture was concentrated to dryness in vacuo. The red residue was redissolved in dichloromethane (20 mL) and the resulting red solution was stirred for 2 h at room temperature to complete the cation exchange. Filtration through 3 cm of kieselguhr gave a red solution, which was concentrated to a volume of 5 mL and layered with ethanol (20 mL). **PPN2**·0.75 CH_2Cl_2 was obtained as red needle-shaped crystals (280 mg, 52%). For analytical and spectroscopic data of **PPN2**, see Tables 2 and 3.

[*tripod*Fe(CO){NC−M}$_2$] (3); M = Cr(CO)$_5$ (3a), Cr(η^6-CF$_3$C$_6$H$_5$)(CO)$_2$ (3b), Mn(η^5-CH$_3$C$_5$H$_4$)(CO)$_2$ (3c): To a solution of $FeCl_2$ (0.65 mmol, 34 mg) and *tripod* (0.65 mmol, 184 mg) in acetone, a solution of the alkali metal salt **Na1a** (**3a**), **K1b** (**3b**), or **K1c** (**3c**) (1.30 mmol) in acetone was added dropwise by means of a syringe. An immediate color change from pale-yellow to orange-red was observed. After bubbling carbon monoxide through the reaction mixture for 5 min, the turbid brown solution was concentrated to dryness in vacuo leaving a brown-red solid residue. This was redissolved in dichloromethane and the resulting solution was filtered through 3 cm of kieselguhr. The products were isolated in the form of brown microcrystalline powders by addition of petroleum ether (boiling range 40−60 °C) to the concentrated brown-red filtrates. Crystals of **3a**, **3b**, and **3c** suitable for X-ray analyses were grown by layering dilute solutions in acetone with petroleum ether (boiling range 40−60 °C) at room temperature. For analytical and spectroscopic data of compounds **3a**, **3b**, and **3c**, see Tables 2 and 3.

[(*tripod*Fe)$_2${NC−M′−CN}$_3$]BF$_4$ (5BF$_4$); M′ = Fe(η^5-C$_5$H$_5$)(CO) (5bBF$_4$), Co(η^5-C$_5$H$_5$)(CN) (5cBF$_4$): To a solution of $Fe^{II}aq(BF_4)_2$ (1.0 mmol, 338 mg) and *tripod* (1.0 mmol, 625 mg) in dichloromethane/ethanol (1:1, 40 mL), the potassium salt of the appropriate ligand, **K4b** (**5bBF$_4$**) or **K4c** (**5cBF$_4$**) (1.5 mmol), was added as a solid in a single portion. A color change from pale-yellow to red was observed. After stirring for 1 h at room temperature, the reaction mixture was concentrated in vacuo. The red residue was filtered through 1 cm of kieselguhr with dichloromethane. Evaporation of the solvent from the red filtrate and subsequent washing of the residue with diethyl ether left a red microcrystalline solid. The C_3-symmetric isomers (Scheme 9, **A**) of the pentanuclear complexes were purified by recrystallization from dichloromethane/ethanol. Yields: **5bBF$_4$**: 42% (crude product), ca. 10% (symmetric isomer of **5bBF$_4$**, three recrystallizations); **5cBF$_4$**: 67% (crude product), 40% (symmetric isomer of **5cBF$_4$**, one recrystallization).

5bBF$_4$: ^{1}H{^{31}P} NMR (CD_2Cl_2): δ = 1.53 (s, CH_3), 2.00−2.35 (m, CH_2), 4.10 (s, C_5H_5), 6.9−7.8 (m, H_{ar}). − ^{31}P NMR (CD_2Cl_2): δ = 37.4 (s). − The unsymmetrical isomer of **5bBF$_4$** was not isolated in pure form. Its Cp resonances were seen as singlets at δ = 4.14, 4.04, and 3.86 in the ^{1}H{^{31}P} NMR spectrum of the crude product.

5cBF$_4$: ^{1}H{^{31}P} NMR (CD_2Cl_2): δ = 1.43 (s, CH_3), 2.0−2.4 (m, CH_2), 4.7 (s, C_5H_5), 7.0−7.8 (m, H_{ar}). − ^{31}P NMR (CD_2Cl_2): δ = 39.1 (s). − ^{13}C NMR ([D$_6$]DMSO): δ = 138.6 (dd, PC_{ar}), 136.9 (dd, PC_{ar}), 134.5−128.0 (m, C_{ar}), 133.7 (s, Co−CN−Fe), 117.9 (s, Co−CN), 88.9 (s, C_5H_5), 37.6 (m, CH_3), 36.4 (m, C_q), 32.8 (m, CH_3). − For further analytical and spectroscopic data of compounds **5bBF$_4$** and **5cBF$_4$**, see Tables 6 and 7.

Crystals of compound **5aFeCl$_4$** suitable for an X-ray crystallographic structure determination were obtained in very low yield (15 mg) from the reaction of $FeCl_2$ (135 mg, 1.07 mmol), *tripod* (680 mg, 1.09 mmol), and potassium tetracarbonyl(dicyano)manganate(I) (280 mg, 1.08 mmol) in acetone. After concentrating the reaction solution to dryness and filtration of the residue through 1 cm of kieselguhr with dichloromethane, the red filtrate was concentrated to dryness. Red parallelepiped-shaped crystals of **5aFeCl$_4$** were grown by vapor diffusion of diethyl ether into a solution of the crude product in tetrahydrofuran/ethanol at room temperature. − ^{1}H{^{31}P} NMR (CD_2Cl_2): δ = 1.5 (br. s, CH_3), 2.3 (br. m, CH_2), 7.0−7.8 (m, H_{arom}); all signals are broad because of the paramagnetism of the $FeCl_4^-$ anion. − ^{31}P NMR (CD_2Cl_2): δ = 32.7 (s). − For further analytical and spectroscopic data, see Tables 5, 6, and 7.

Salts of **5a$^+$** with counteranions other than tetrachloroferrate(III) could not be obtained in analytically pure form, neither by the procedure described above for **5bBF$_4$** and **5cBF$_4$** nor under strictly anhydrous conditions. This is mainly due to problems associated with the purification of these compounds, which could not be effected by means of crystallization and chromatography.

X-ray Crystallographic Studies: Suitable crystals were taken directly from the mother liquor, immersed in perfluorinated polyether oil, and fixed to a glass capillary. Data were collected with a Nonius−Kappa CCD diffractometer (low-temperature unit, graph-

ite-monochromated Mo-K_α radiation). The data were processed by the standard Nonius software.[23] All calculations were performed using the SHELX software package. Structures were solved by direct methods using the program SHELXS-97[24] and refined using the program SHELXL-97.[24] Graphical handling of the structural data during solution and refinement was performed with XPMA.[25] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data relating to the structure determinations are compiled in Table 8. Figures 1, 2, and 3 were generated using WinRay-32 and WinRay-GL.[26] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-156056 to -156060. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are indebted to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support. We are very grateful to Mr. D. Günauer for performing the cyclic voltammetric measurements. The scientific assistance of Dr. J. Groß and coworkers of the mass spectrometry department and the help of the microanalytical laboratory of the Organisch-Chemisches Institut der Universität Heidelberg are gratefully acknowledged.

Anion Conformation and Physical Properties in BETS Salts with the Nitroprusside Anion and its Related Ruthenium Halide (X = Cl, Br) Mononitrosyl Complexes: θ-$(BETS)_4[Fe(CN)_5NO]$, $(BETS)_2[RuBr_5NO]$, and $(BETS)_2[RuCl_5NO]$

Keywords: Sulfur heterocycles / Ruthenium / Halides / Conducting materials / Electronic structure

θ-$(BETS)_4[Fe(CN)_5NO]$ (**1**), $(BETS)_2[RuBr_5NO]$ (**2**), and $(BETS)_2[RuCl_5NO]$ (**3**) [BETS = bis(ethylenedithio)tetraselenafulvalene] have been prepared by electrocrystallisation of BETS using $[Fe(CN)_5NO]^{2-}$ or $[RuX_5NO]^{2-}$, X = Cl or Br, as supporting electrolytes and 1,1,2-TCE/ethanol (10 vol%) for **1**, nitrobenzene/1,2-DCE (40 vol%)/ethanol (10 vol%) for **2**, and benzonitrile/ethanol (10%) solutions for **3** as solvents. Compound **1** exhibits a metallic behaviour down to 40 K, **2** behaves as a semiconductor and **3** as an insulator. The crystal structures of **1**, **2**, and **3** were determined by X-ray diffraction methods. BETS molecules in **1** crystallised in a θ-type mode. By contrast, the crystal structures of **2** and **3** show a packing of BETS molecules consisting of slipped, stacked $(BETS)_2$ dimers. The dimerisation is much stronger in **3** than in **2**. The physical behaviours of the three phases were investigated by means of molecular and band structure calculations and are shown to be directly related to the $[MX_5NO]$ (M = Fe, X = CN; M = Ru, X = Cl, Br) structural conformations.

Introduction

A recent new development in the research on molecular conductors concerns the possibility of creating solids in which conductivity (or superconductivity) coexists with other physical phenomena. This novel class of multifunctional materials should provide a unique opportunity to study the competition and mutual influence of, and better still a possible interplay between two properties in the same crystal lattice. Until recently, attention along this line has been primarily directed towards magnetic conductors.[1]

A parallel approach involving conducting radical cation salts with photochromic anions has been explored even more recently. The interest in the synthesis and characterisation of new molecular conductors containing photochromic anions is to analyse the influence of the electronic excitation of the anions over the conducting (superconducting) electrons. For example, one can imagine the design of a photochromic molecular conductor (or even a superconductor) in which the conducting properties can be tuned by light. In this context, the use of the photochromic nitroprusside $[Fe(CN)_5NO]^{2-}$ anion and related mononitrosyl transition-metal complexes as counter-anions in radical cation salts of BEDT-TTF [BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene] and its analogues has been contemplated.[2,3] These anions are highly interesting because they possess extremely long-living metastable excited states at low temperatures that can be generated by laser irradiation.[4] Two-dimensional salts in which BEDT-TTF or its oxygen-substituted analogue BEDO-TTF [BEDO-TTF = bis(ethylenedioxy)tetrathiafulvalene] is associated with the $[Fe(CN)_5NO]^{2-}$ anion have been already reported, as well as salts with the TTF molecule.[2]

The BETS molecule [BETS = bis(ethylenedithio)tetraselenafulvalene] is a modification of BEDT-TTF obtained by substituting selenium for sulfur in the central tetrathiafulvalene fragment (Figure 1).[5] A strikingly large number of metal-like and superconducting BETS-based salts have been recently reported.[6] Thus, BETS-based conducting salts incorporating photochromic anions also seem to be promising candidate systems for the preparation of photochromic conductors and superconductors.[3]

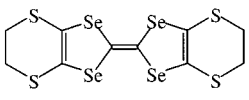

Figure 1. Atomic scheme for BETS

We report here on the preparation, the crystal and electronic structures, and the solid state properties of three phases namely, θ-$(BETS)_4[Fe(CN)_5NO]$ (**1**), $(BETS)_2[RuBr_5NO]$ (**2**), and $(BETS)_2[RuCl_5NO]$ (**3**), obtained when using the appropriate $[Fe(CN)_5NO]^{2-}$, $[RuBr_5NO]^{2-}$, $[RuCl_5NO]^{2-}$ anions.

Results and Discussion

Synthesis and Electrical Properties

Three different phases are obtained when the BETS molecule is associated with the $[Fe(CN)_5NO]^{2-}$ anion and its substituted mononitrosylruthenium halide $[RuX_5NO]^{2-}$ (X = Cl or Br) complexes. All these phases have been obtained electrochemically and characterised by X-ray structure determination and energy-dispersive X-ray spectrometry (EDS).[3b]

The different molecular arrangements of **1**, **2**, and **3** lead to different physical behaviours. The single-crystal room-temperature conductivity of **1** is 0.01 $S\cdot cm^{-1}$. As depicted in Figure 2, the temperature-dependent resistance shows a weakly metallic behaviour down to ca. 40 K ($\sigma_{40\,K}$ = 0.07 $S\cdot cm^{-1}$). Below this temperature, the compound undergoes a metal-to-semiconductor phase transition. By contrast, **2** is a semiconductor (0.2 $S\cdot cm^{-1}$) with a very small activation energy (E_a = 0.03 eV), whereas **3** behaves as an insulator, its resistivity at room temperature being larger than $4\cdot10^3$ $\Omega\cdot cm$.

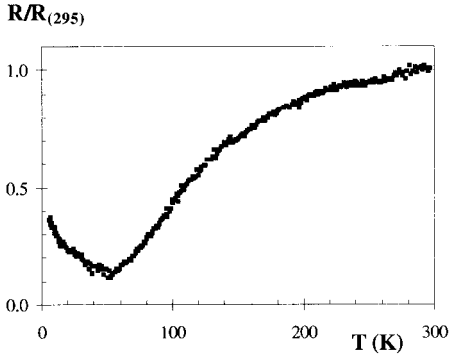

Figure 2. Temperature dependence of the resistance in **1**

X-ray Structure of 1, 2, and 3

θ-(BETS)$_4$[Fe(CN)$_5$NO] (1)

The asymmetric unit contains half a BETS molecule lying on a centre of inversion and 1/8 $[Fe(CN)_5NO]$ entity lying on a twofold rotation axis. The complete determination of the anion has not been possible because of a strong disorder: Two Fe atoms [Fe(1) and Fe(2)] are located at about 2 Å from each other along the twofold axis. This leads to a very low electronic density for the C, N, and O atoms whose positions could not be determined. Only one crown of electron density is evidenced from the Fourier map, which leads to the representation of the anion shown in Figure 3, a. A similar, not resolved disorder of the nitroprusside anion has also been observed in (BEDO-TTF)$_4$[Fe(CN)$_5$NO].[2c]

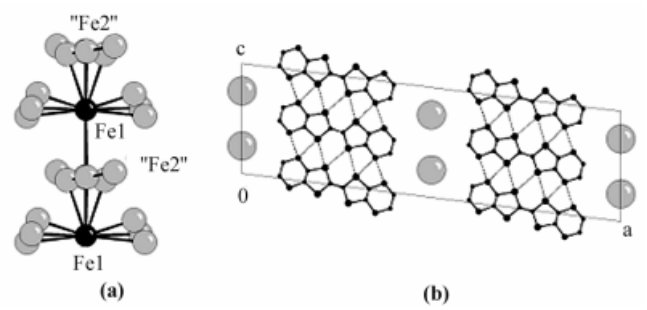

Figure 3. Cameron view of the anion in **1** along the *b* axis (a); projection in the *ac* plane of the cationic layer of **1** (b); the grey circles represent the electronic densities of the nitroprusside anion, H atoms are omitted for clarity

The crystal structure of **1** consists of sheets of adjacent columns in the *bc* plane alternating with layer of anions along the *a* direction (Figure 3, b). Two equivalent $(BETS)_2$ layers occur in the unit cell. Within each layer, the BETS molecules stack in a θ-type mode (Figure 4).[7] They form chains of parallel BETS molecules, running along the *b* direction and connected to adjacent chains through short chalcogen···chalcogen contacts (Table 1). The dihedral

angle between two BETS molecules belonging to adjacent chains is 133.82°.

$(BETS)_2[RuBr_5NO]$ (2)

The asymmetric unit contains two BETS molecules and one $[RuBr_5NO]$ entity. As shown in Figure 5, the packing consists of chains of dimerised BETS molecules (the distance between the averaged planes of two BETS molecules belonging to one dimer is 0.512 Å shorter than the distance between two dimeric entities) stacking along the *a* direction with Se···Se and Se···S contacts shorter than the van der Waals distances (Figure 5, a). The crystal structure of **2** can be described as a pseudo-hexagonal columnar architecture made of short intra- and intermolecular chalcogen···chalcogen contacts. The anionic complexes are located in the centre of each hexagon and repeat infinitely along the *a* direction (Figure 5, b).

In this phase, the anionic complex is pseudo-octahedral with averaged Ru−Br distances of 2.466(7) Å and

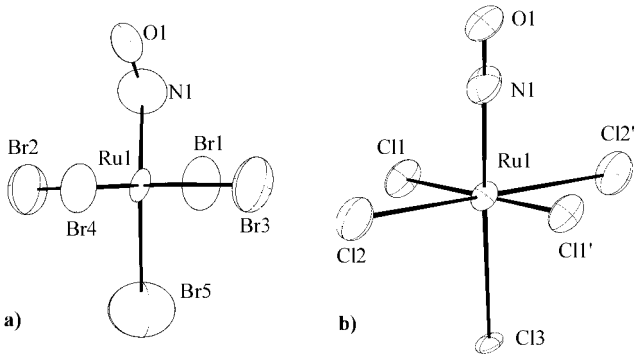

Figure 6. Cameron view of the anionic part in **2** (a) and **3** (b)

Br−Ru−Br angles close to 90° for the planar (Ru1Br1Br2Br3Br4) entity. The Ru−Br5 apical bond is almost perpendicular to the $Ru(Br)_4$ plane (89.20°). On the other hand, the Ru−N−O angle is 160.0(5)° (Figure 6, a). As already studied, this non-linearity can be connected with

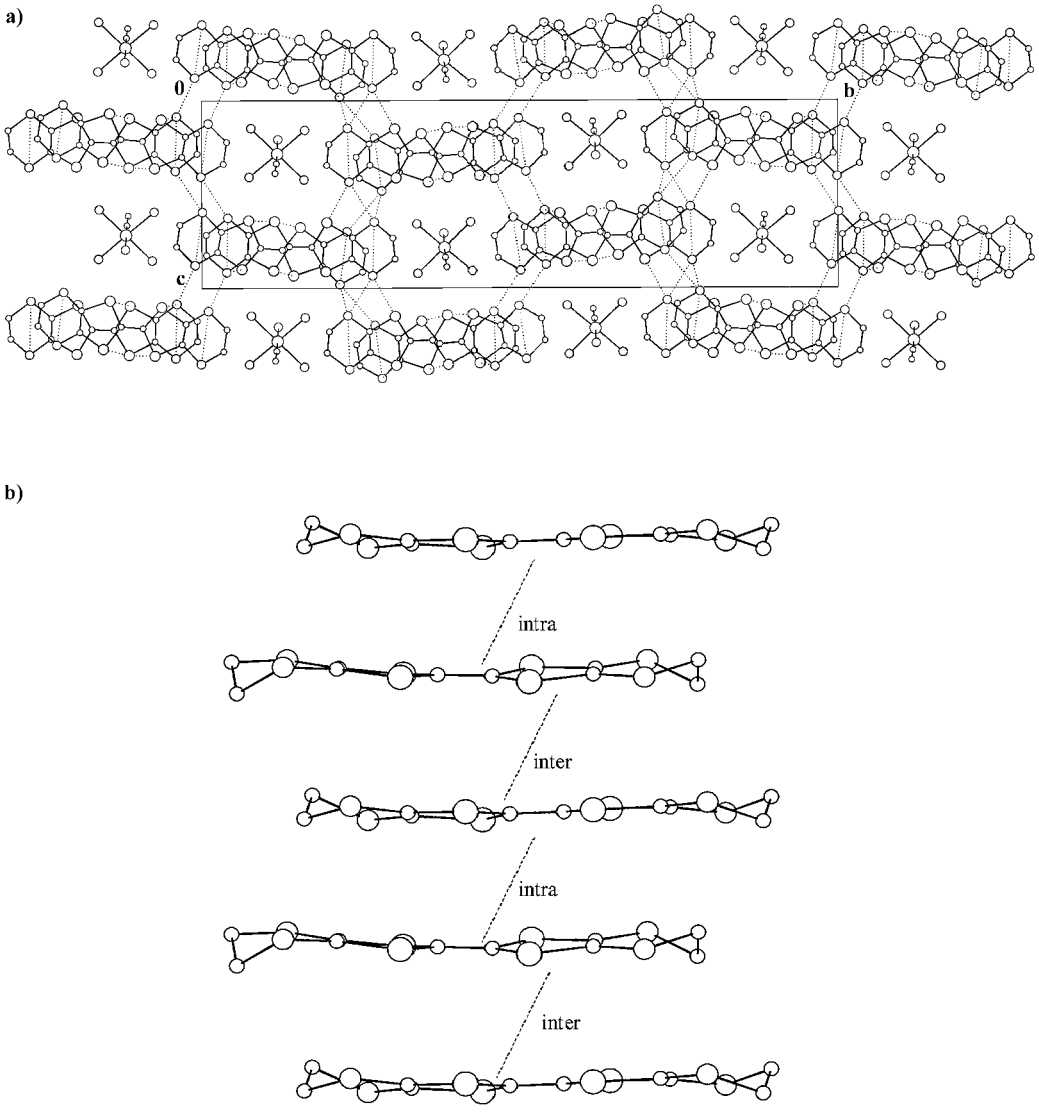

Figure 5. Projection in the *bc* plane of **2** (a); chain of BETS molecules along the *a* axis (b); H atoms are omitted for clarity

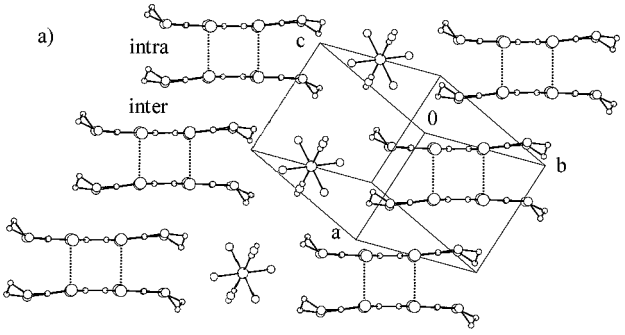
the formal charge on the nitrosyl ligand.[8] This will be discussed later in the discussion of the electronic structure.

$(BETS)_2[RuCl_5NO]$ (3)

The asymmetric unit contains one BETS molecule and half a $[RuCl_5NO]$ entity lying on a centre of inversion. Due to this special position, the nitrosyl ligand and the Cl(3) atom have an occupancy of 0.5 and are equally distributed on both sides of the Ru atom. The BETS molecule adopts a chair conformation, as shown in Figure 7, a. The crystal structure of **3** consists of chains of strongly slipped dimerised BETS molecules (built from two eclipsed BETS molecules connected through short Se···Se contacts, Table 1) stacking along the *a* direction and alternating with the anion along the *b* direction. Several chalcogen···chalcogen contacts shorter than the van der Waals distances occur between dimers belonging to the adjacent stacks (Figure 7, b). Thus, the structure can be regarded as sheets in the $(01\bar{1})$ plane of interconnected chains of isolated BETS dimers separated by $RuCl_5NO$ anions along the $[01\bar{1}]$ direction.



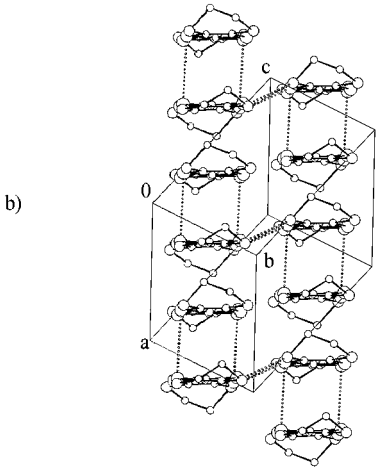


Figure 7. Projection in the $(01\bar{1})$ plane of **3** (a); projection of the cationic layer of **3** along the BETS central C=C bond (b); H atoms are omitted for clarity

As in **2**, the anionic complex presents a pseudo-octahedral configuration with averaged equatorial Ru−Cl distances of 2.381(2) Å and angles between Ru, Cl atoms, and NO ligand close to 90°. Contrary to **2**, Ru−N−O is almost linear [178.0(3)°] (Figure 6, b). This linearity will be discussed in the next part and compared to the bent conformation of $RuBr_5NO$ in **2**.

Electronic Structure of 1, 2, and 3

$(BETS)_2[RuX_5NO]$ (X = Br, Cl) (2, 3)

The intermolecular interaction energies calculated between the highest occupied molecular orbital (HOMO) of two adjacent BETS molecules are reported in Table 1. They confirm that **2** and **3** are characterised by strongly dimerised BETS chains running along the *a* direction of the crystal lattice, all inter-chain interactions being smaller by at least one order of magnitude. It is in agreement with the non-metallic properties of the BETS layers in **2** and **3**.

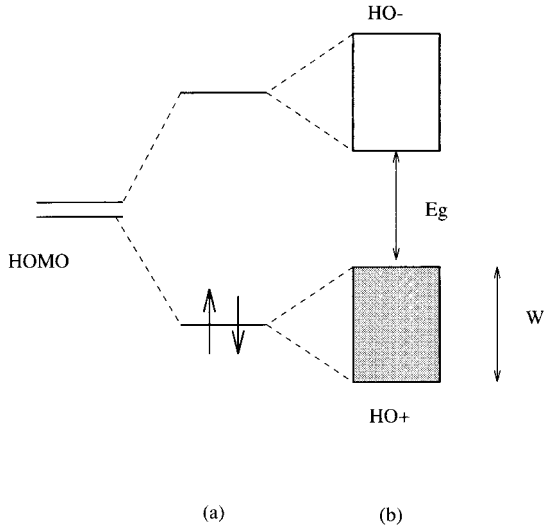

Figure 8. Qualitative electronic band structure of a strongly dimerised one-dimensional molecular solid; (a) and (b) correspond to the dimer and solid electronic structures, respectively; W and E_g stand for the bandwidths and the energy band gap, respectively

As depicted in Figure 8, the band structure of a dimerised chain consists of a fully occupied low-lying band (HO^+) and an empty high-lying band (HO^-). These two bands originate from the molecular orbitals $\Psi \cong^{+}_{HOMO}$ and $\Psi \cong^{-}_{HOMO}$ of the dimer, i.e. from the symmetric and the antisymmetric linear combinations between the HOMOs of the two interacting monomers.

The HO^+ and HO^- bandwidths (W) as well as the energy gap (E_g) between these two bands are governed by the inter-dimer and the intra-dimer interaction energies, namely β_{inter} and β_{intra}. In the case of **2** and **3**, the strong dimerisation observed in the BETS layers results in rather high band gaps ($E_g \approx 0.6$ eV for **2** and $E_g \approx 1.2$ eV for **3**) and small bandwidths, supporting their non-metallic behaviours.

However, whereas a large band gap is in agreement with the insulating behaviour of **3**, it is not consistent with the very small experimental activation energy $E_a = 0.03$ eV determined for **2**. To understand this discrepancy between experimental and theoretical results, it may be useful to pay

closer attention to the electronic structure of the anions, from which the following explanation may be proposed.

As previously mentioned, the main difference between the $[RuBr_5NO]^{2-}$ and the $[RuCl_5NO]^{2-}$ anions concerns the Ru−N−O angle α (see Figure 5). Whereas NO is linearly bonded to the ruthenium metal centre for X = Cl [α = 178.0(3)°], it is bent with an angle α = 160.0(5)° for X = Br. The subtle π-electron transfers occurring between the ruthenium atom and a bent or a linear NO ligand are well known and have been shown to depend on the nature of the ancillary ligands.[8] In particular, it has been shown that the Ru−N−O angle can be correlated to the π-donor character of the remaining ligands through a three-centre four-electron interaction, and that the nitrosyl formal charge can thus be treated as negative NO^- for a bent NO (α = 120°) and positive NO^+ for a linear one.[8] As a consequence, different Ru−N−O angles may result in different formal oxidation states for the transition metal atom. It is therefore tempting to associate the bending angle observed in the $(BETS)_2[RuBr_5NO]$ salt with a more pronounced π-donor character of Br^- compared to that of Cl^-. However, the nature of X (X = Cl or Br) does not seem to be the only factor that governs the nitrosyl conformation. Indeed, the Ru−N−O bending angles in $K_2[RuBr_5NO]$ and $K_2[RuCl_5NO]$ are nearly equivalent [α = 174.4(1)° for X = Br and α = 176.7(5)° for X = Cl].[9] Thus, the different bending angles in **2** and **3** raise the possibility that the BETS layers may interact with the anions, at the very least in **2**.

Considering further the Ru−N−O bending angles reported in the $(BETS)_2[RuBr_5NO]$ (X = Cl, Br) salts, a positive NO^+ may be conceived for X = Cl (α = 178°) and an intermediate charge between NO^+ and NO^- for X = Br (α = 160°). This would result in different oxidation states for the transition metal in the two compounds. Whereas for X = Cl, the $[Ru^{II}Cl_5^{5-}NO^+]^{2-}$ formal electron count is fully consistent with the insulating properties of a strongly dimerised $(BETS)_2^{2+}$ cationic layer, it may be envisioned that for X = Br some of the electron density missing around the transition metal (Ru^{+n}; $n > 2$) is retained by the cationic layers.

This hypothesis leads to the presence of some few electrons in the weakly dispersive HO^- band of the BETS layers, and is consistent with the very small activation energy experimentally measured for **2**. Hence, the different physical properties of $(BETS)_2[RuCl_5NO]$ and $(BETS)_2[RuBr_5NO]$ are proposed to originate from different BETS−RuX_5NO interactions, leading to different BETS→RuX_5NO electron transfers and therefore to different Ru oxidation states. EPR measurements are in progress to obtain more insight along this line. It should be noticed, however, that preliminary results have already shown a large and asymmetric signal centred at $g = 2.037$ for **2**, and no EPR signal for **3**. Such a large signal for **2** is unlikely to be the signature of isolated $BETS^+$ radicals, but is in turn consistent with our hypothesis of a Ru^{n+} ($n > 2$) oxidation state in the $(BETS)_2[RuBr_5NO]$ salt.

$(BETS)_4[Fe(CN)_5NO]$ (1)

Unlike Cl^- and Br^-, CN^- is a strong π-acceptor ligand. Consequently, the metal-like molecular orbitals of a $[Fe(CN)_5NO]$ pseudo-octahedron are expected to be less occupied, for an equivalent NO bending angle, than in the analogous $[RuX_5NO]$ (X = Cl, Br) complexes. The nitrosyl ligand most likely adopts a linear conformation to compensate (at least partially) for the lack of electron density around the transition metal centre. This seems to be corroborated by the strong disorder reported for the $[Fe(CN)_5NO]$ anions, since X-ray diffraction techniques often encounter difficulties in distinguishing close atoms such as C, N and O. Hence, to stabilise an Fe^{II} formal oxidation state,[10] the anions of **1** should require a larger electron density from the BETS layers than in the other Ru-based phases, in agreement with the 4:1 stoichiometry observed for that salt.

Since no accurate information on the anionic layers is available, the electron transfer cannot be accurately determined here. The electronic band structure and the Fermi surfaces associated with different oxidation states of the $(BETS)_2^{\rho+}$ ($\rho = 1, {}^3/_2$) cationic slabs are presented in Figure 9. Although $BETS^{+1/2}$ corresponds to the usual oxidation state found in BETS-based metal-like salts, it appeared interesting to check whether a larger oxidation state ($BETS^{+3/4}$) could alter the Fermi surface of the salt.

The electronic structures of Figure 9 are very similar to those previously reported for the homologous θ-type BETS phase associated with $[Cu_2Cl_6]^{2-}$ anions.[11] According to the topology of the intermolecular interactions (see Table 1), the Fermi surface associated with ρ = 1 exhibits a two-dimensional character (2D). This is consistent with the observed metallic behaviour of **1** at room temperature but cannot explain the first-order phase transition observed

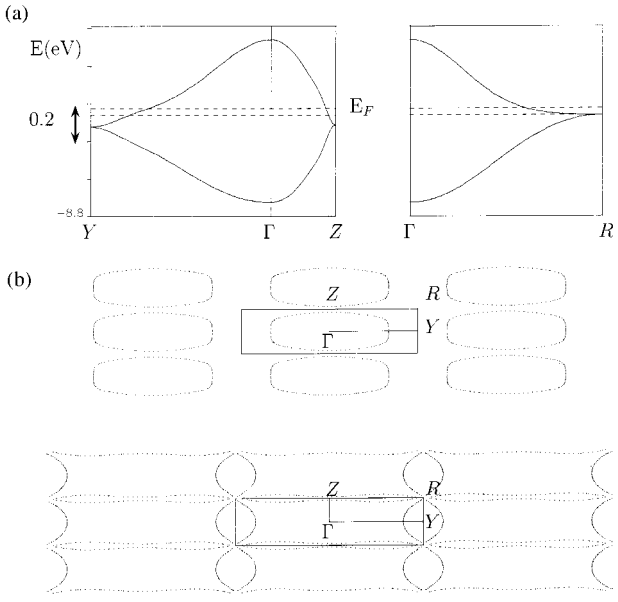

Figure 9. Electronic band structure of **1** (a), the dotted lines refer to the Fermi levels for ρ = 1 and ρ = ${}^3/_2$; Fermi surfaces of one $(BETS)_2^{\rho+}$ layer of **1** (b) for ρ = 1 (top) and ρ = ${}^3/_2$ (bottom); Γ, Y, Z and R correspond to the wave vectors (0,0), (b*/2,0), (0,c*/2) and (b*/2,c*/2), respectively

around 40 K, since such a 2D character of the Fermi surface would suggest a stable metallic state for this compound down to low temperatures. Should a larger electron transfer ($\rho = {}^{3}/_{2}$) be considered, then the Fermi level would approach the two degenerated HOMOs (see Figure 9, a).

As already suggested in a previous work,[11b] slight changes in the donor slab could occur at low temperature due to a modification of the donor−acceptor interactions. Such structural changes could be responsible for the change in the resistivity behaviour around 40 K. Let us note, however, that among all presently known BETS and BEDT-TTF cation radical based organic conductors, it is not rare that a first-order phase transition cannot be rationalised in terms of electronic instabilities of the Fermi surface. In a very recent work,[12] Canadell et al. suggested that the first-order phase transition observed in the κ-$(BETS)_2C(CN)_3$ salt mainly involves the anionic slabs and that the electronic structure of the donor slabs is only slightly altered by the transition. To obtain more insights into the mechanism of the transition observed for **1**, low-temperature X-ray investigations as well as magnetoresistance measurements could be of interest. The former may help in determining which of the cationic or/and anionic slabs is affected by the transition, and the latter may allow us to properly determine the electron transfer occurring from the donor slabs to the $[Fe(CN)_5NO]$ species, for this charge transfer is directly related to the area of the 2D Fermi surface.

Conclusions

The use of the nitroprusside $[Fe(CN)_5NO]^{2-}$ anion and its related mononitrosylruthenium halide complexes $[RuX_5NO]^{2-}$ (X = Cl, Br) in the preparation of BETS-based salts led to a number of different phases with different stoichiometries, **1**, **2**, and **3**. These various phases exhibit different interesting structures and properties. Compound **1** exhibits a metallic behaviour down to 40 K where it undergoes a first-order metal-to-semiconductor phase transition. Compound **2** is a small activated semiconductor ($E_a = 0.03$ eV) and **3** is an insulator. Molecular and band structure calculations have been carried out to rationalise the physical properties of the three salts. The results suggest a direct role of the anionic slabs on the electronic properties of the BETS layers. The different physical behaviours of **2** and **3**, corresponding to the same 2:1 stoichiometry, have been correlated to the conformation of the $[RuX_5NO]$ (X = Cl, Br) species. Depending on the Ru−N−O bending angle, different oxidation states are expected for the ruthenium atom and therefore different electron transfers from the BETS layers to the $[RuX_5NO]$ species. When NO is linearly bonded to the transition metal centre, the stabilisation of an $[Ru^{II}Cl_5NO^+]^{2-}$ anion dictates an integral oxidation state for the BETS molecules, in agreement with the insulating behaviour of **3**. When NO bends, a formal intermediate charge between NO^+ and NO^- may be considered, yielding an Ru^{n+} ($n > 2$) oxidation state. The lack of electron density around the transition metal centre is thus proposed to be retained by the BETS layers, in agreement with the small activation energy of **2**. Due to the 2D character of the $(BETS)_2^{1+}$ Fermi surface calculated for **1**, it is likely that the phase transition occurring in this compound mainly involves the anionic slabs. Nevertheless, low-temperature crystallographic data are required to check whether the donor slabs are, or are not affected by the phase transition.

In conclusion, this work has revealed possible relationships between the anion conformation and the physical properties of **1**, **2**, and **3**. We have shown that the presence of the radical cation salts affects the geometry of the nitroprusside anion and its related mononitrosylruthenium halide complexes $[RuX_5NO]^{2-}$ (X = Cl, Br). Further studies are currently in progress to investigate the photochromic properties of these systems, including DSC measurements to detect the existence of long-lived metastable states in the nitrosyl complexes, and Mössbauer experiments as well as conductivity measurements under irradiation.

Experimental Section

Syntheses: $(PPh_4)_2[Fe(CN)_5NO]$ was obtained by reaction of $Na_2[Fe(CN)_5NO]$ (Aldrich) with $(Ph_4P)Cl$ in water. $K_2[RuX_5NO]$ (X = Cl or Br) were synthesised according to the method of Mercer.[13] $(NH_4)_2[RuBr_5NO]$ was obtained by reaction of $K_2[RuBr_5NO]$ and NH_4Cl. − Crystals of **1** were obtained by electrocrystallisation from BETS solutions in 1,1,2-trichloroethane/ethanol (10 vol%) at 50 °C. $(Ph_4P)_2[Fe(CN)_5NO]$ was used as supporting electrolyte. The donor ($4\cdot10^{-4}$ M) and the electrolyte ($3\cdot10^{-3}$ M) were introduced into the different compartments of an H-shaped electrochemical cell. Oxidation of the donor was performed electrochemically (constant current density, $i = 0.5$ μA·cm^{-2}). Within 5 d, black crystals of **1** (thick blocks) grew on the anode, together with some few other diamond- and hexagonal-plate-shaped phases. − Crystals of **2** and **3** were obtained by using the same general procedure adding 18-crown-6 ($4\cdot10^{-3}$ M for **2** and $7\cdot10^{-3}$ M for **3**, respectively) with concentrations of the donor of $3\cdot10^{-4}$ M for **2** and $6\cdot10^{-4}$ M for **3**, respectively. $(NH_4)_2[RuBr_5NO]$ ($2\cdot10^{-3}$ M) and $K_2[RuCl_5NO]$ ($7\cdot10^{-3}$ M) were used as supporting electrolytes in nitrobenzene/1,2-dichloroethane (40 vol%)/ethanol (10%) for **2** and in benzonitrile/ethanol (10%) solutions for **3**. Crystals of **2** grew on the anode within 20 d (50 °C, $i = 0.5$ μA·cm^{-2}) while crystals of **3** (38 °C, $i = 1.5$ μA·cm^{-2}) grew within one month. − Conductivity measurements were performed using the standard four-probe method between room temperature and 4 K. Electrical contacts were achieved by mounting crystals on a Motorola printed circuit and gluing four gold wires on the sample with gold paint.

X-ray Crystallographic Studies: The experimental details and crystal data are listed in Table 2. The structures were solved using direct methods (SHELXS 97)[14] (**1** at 160 K, **2** at 160 K, and **3** at 193 K) and refined using full-matrix least squares on F^2. The calculations were carried out with the CRYSTALS[15] and WINGX[16] package programs running on a PC. The drawings of the molecular structures were obtained with the help of CAMERON.[17] The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[18] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-158312 (**1**), -158313 (**2**), -158314 (**3**). Copies of the data can be obtained free of charge on applica-

Band-Structure Calculations: The electronic band structures of the cationic layers were investigated using full tight-binding calculations based upon the effective one-electron Hamiltonian of the extended Hückel model.[19] The off-diagonal matrix elements of the Hamiltonian β_{ij} were calculated according to the modified Wolfsberg−Helmholz formula.[20] All valence electrons were explicitly treated in the calculations and the basis set, consisting in double-ζ Slater-type orbitals for C, S, Se and single-ζ Slater-type orbitals for H were taken from previous work.[11b]

Keywords: O ligands / N ligands / Platinum / Nitrile complexes / Structure elucidation

The reaction of *trans*-$[PtCl_4(EtCN)_2]$ and two equivalents of the formamides RR′NCHO (R/R′ = Me/Me, Me/H, *t*Bu/H) in CH_2Cl_2 led to the formation of the compounds *cis*-$[PtCl_4\{(O=)CHNRR'\}_2]$, two of which (R/R′ = Me/H, *t*Bu/H) were characterized by X-ray single-crystal diffractometry, as well as by elemental analysis, FAB$^+$-MS, and IR, ^{1}H, ^{13}C and ^{195}Pt NMR spectroscopy (including NOE, HMQC and INEPT experiments). The X-ray structures and IR spectroscopic data indicate the coordination of the formamides through the O atom and significant contribution of the bipolar structure $^-$O–C(H)=$^+$NHR in the resonance hybrid of the ligands. The complexes *cis*-$[PtCl_4\{(O=)CHNRR'\}_2]$ represent the first example of (formamide)Pt^{IV} species and also a rare case of platinum(IV) complexes with neutral O-donor ligands.

Introduction

Complexes containing weak donor ligands are essential as synthons for synthetic studies and as efficient homogeneous catalysts.[1] In recent years they have become a subject of paramount importance for the construction of multi homo- and heterometallic systems[2] with application in materials science.[3,4] Ideally, the complexes with weak donor ligands utilized in these branches of chemistry must be soluble, readily available and contain ligands which are easily replaced.[1]

As far as platinum complexes are concerned, an approach for developing compounds with weak donors includes the generation of complexes with antisymbiotic soft platinum centers and hard donor ligands, which interact only poorly and thus the weakly bound donors can be replaced by better ligands.[1,5–7] Complexes of both Pt^{II} and Pt^{IV} with *anionic* monodentate hard O-donors, for example $MeCO_2^-$, NO_2^-, NO_3^-, OH^-, SO_4^{2-}, or bidentate *anionic* hard O,O- or O,N-donors, for example carboxamidates and acetylacetonates, are common.[5] In contrast, platinum species with *neutral* O-donors are quite scarce due to the soft character of the metal centers. Moreover, if platinum(II) complexes with ligated H_2O,[5] ROH,[8] $R_2S{=}O$,[9,10] THF[11] or O-bonded formamides and amides[12] are rare, to the best of our knowledge compounds of platinum(IV) containing *neutral* O-donors are even more scarce. Indeed, apart from (aqua)Pt^{IV} [13] species only acetone[14] and (2-pyridyldiphenylphosphane oxide)platinum(IV) complexes[15] with a Pt–O interaction are known. We report herein the first representatives of O-bonded formamide-based platinum(IV) complexes and their X-ray structural characterization.

Results and Discussion

Our interest in the preparation of (formamide)Pt^{IV} complexes was twofold. First, this work was performed within the framework of an on-going project devoted to the search for new starting materials for platinum chemistry,[10,16] and second, we hoped to prepare new materials for the extension of our previous work on nucleophilic additions to ligands bearing double[17] and triple bonds.[2,18–20]

The reaction between *trans*-$[PtCl_4(EtCN)_2]$ and the formamides RR′NCHO in dichloromethane led to the formation of isomerically and analytically pure *cis*-$[PtCl_4\{(O=)CHNRR'\}_2]$ (R/R′ = Me/Me, Me/H, *t*Bu/H) isolated from the reaction mixture in moderate yields (ca. 40%; Scheme 1).

More *cis*-[$PtCl_4${(O=)CHNRR′}$_2$] can be obtained by the addition of diethyl ether to the filtrate, although in all three cases the solids isolated in this way were contaminated with other products which are formed, in particular, by a facile platinum(IV)-mediated hydrolysis, in the presence of traces of water to give amide[21] and ammonia species,[20,22] of the highly reactive starting nitrile complex. We also anticipate that some admixtures may be derived from the coupling of nitriles and the amines HNRR′, the latter being formed from the uncontrolled degradation of formamides, which is a well-known reaction. It is also worthwhile to mention that an attempt to perform a similar reaction between *trans*-[$PtCl_4(EtCN)_2$] and the unsubstituted formamide H_2NCHO failed due to the formation of a mixture of highly soluble products.

The structures of *cis*-[$PtCl_4${(O=)CHNHR}$_2$] (R = Me, *t*Bu) were determined by X-ray single-crystal diffraction. The coordination polyhedra of the complexes are slightly distorted octahedra (Figure 1 and 2) and the two formamide species are mutually *cis*.

An inspection of the bond lengths in the formamide ligands shows that coordination results in an increased contribution of the bipolar structure $^-O-C(H)=^+NHR$ in the resonance hybrid of the ligand, as previously observed for (dimethylformamide)Pt^{II} complexes.[11] Indeed, the C−O bond lengths [1.258(5) Å for R = Me and av. 1.271 Å for R = *t*Bu, Table 1 and 2] are longer than the C=O bond in amides (1.234 Å[24]) or in aldehydes (1.192 Å[24]), while the C−N bond [1.309(6) Å for R = Me and av. 1.305 Å for R = *t*Bu, Table 1 and 2] is shorter than that in the free amides (1.334 Å[24]).

In the IR spectra, the decrease of ν(C=O) by ca. 30−50 cm^{-1} with respect to the free ligands (see Exp. Sect.) also indicates[25] a coordination through the O atom and the contribution of the bipolar structure. It should be noted that the *cis*-geometry of the formamide compounds seems to be unusual for platinum(IV) chemistry, where in the vast majority of cases the substitution of the ligands in starting materials with a *trans* configuration gives rise to the appropriate *trans* products. Moreover, it has been reported that octahedral complexes of metals in a high oxidation state trend to isomerize from *cis* to *trans* irrespective of the nature of the ligated species.[26] In *cis*-[$PtCl_4${(O=)CHNHR}$_2$] (R = Me, *t*Bu), however, the formamides shorten the Pt−Cl

(*trans* to O) bonds [av. 2.28 Å] substantially relative to those *trans* to Cl [av. 2.31 Å]. Perhaps the *trans* Pt−O bonds do not stabilize each other to the same extent and this might be a reason for the formation of the complexes in the *cis* configuration.

The ^{1}H NMR spectra of the monoalkyl complexes *cis*-[$PtCl_4${(O=)CHNHR}$_2$] (R = Me, *t*Bu) display a =CH proton doublet resonance due to indirect coupling with the NH protons (proved by a double resonance ^{1}H{NH} experiment) with typical ^{195}Pt satellites. In both cases, NOE difference experiments showed a strong through-space interaction between the CH and NH protons of the ligated species, thus indicating the dominance of their *E*-conformation in solution. The positions of the signals in the ^{195}Pt NMR spectra of these complexes are in the normal range for other platinum(IV) compounds.

The complexes *cis*-[$PtCl_4${(O=)CHNRR′}$_2$] represent the first example of (formamide)Pt^{IV} species and also a rare case of platinum(IV) complexes with neutral O-donor ligands. Useful properties of these complexes are their good solubilities (*cis*-[$PtCl_4${(O=)CHNMe_2}$_2$], however, has a low solubility) in a number of organic solvents and also the solubility of *cis*-[$PtCl_4${(O=)CHNHMe}$_2$] in water, and these features indicate that the formamide complexes can be used for synthesis in a homogeneous liquid phase. In conclusion, it is worthwhile to mention that the (formamide)platinum(IV) complexes may be important as precursors for further synthetic work by substitution, or by addition of nucleophiles to the O=C double bond activated by the quadruply charged platinum(IV) ion; these studies are underway in our group. We hope that the useful properties of these (formamide)platinum(IV) complexes, combined with their facile synthesis, will extend the range of reactions possible in synthetic platinum(IV) chemistry.

Experimental Section

Materials and Instrumentation: The formamides were obtained from Aldrich and used as received. *trans*-[$PtCl_4(EtCN)_2$] was prepared according to a published method.[2,18] C, H and N elemental analyses were carried out by the Microanalytical Service of the Instituto Superior Técnico. Positive-ion FAB mass spectra were obtained on a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (NBA) matrices of the samples with 8 keV (ca. 1.28×10^{15} J) Xe atoms. Mass calibration for data system acquisition was achieved using CsI. Infrared spectra (4000−400 cm^{-1}) were recorded on a BIO-RAD FTS 3000MX instrument in KBr pellets. All NMR spectra were recorded at ambient temperature on a Varian UNITY 300 [299.95, 75.42 and 64.48 MHz for ^{1}H, ^{13}C and ^{195}Pt NMR, respectively] and/or Bruker DPX−300 [300.13 and 75.47 MHz for ^{1}H and ^{13}C NMR, respectively]. An irradiating field power of 30 Hz for selective decoupling from the NH proton in double resonance experiment and a presaturation time of 1.0 s were used in the NOE-difference experiments. ^{1}H and ^{13}C chemical shifts are given relative to DMSO (δ = 2.50 and 39.5, respectively). ^{195}Pt chemical shifts are given relative to $Na_2[PtCl_6]$ ($K_2[PtCl_4]$, δ = −1630, as a standard) and the half-height line width is given in parentheses. No other sets of signals, besides those indicated below, were observed in the NMR spectra measured in [D_6]DMSO; in addition, the complexes were recovered intact from [D_6]DMSO solutions after the measurements by addition of diethyl ether, thus indicating the absence of any substitution reaction in [D_6]DMSO. This is consistent with the weak donor properties of Me_2SO towards a platinum(IV) center,[27] even though it is a good ligand for the platinum(II) ion.[28]

The inverse detection HMQC method with the BIRD sequence during the preparation period[29] was used to determine the heteronuclear spin-spin coupling constants J^{195}_{Pt}-$^{13}_{C}$. HMQC spectra were measured with a 128 × 1024 data matrix size with 256 scans per t_1 value (the delay for the creation of anti-phase magnetization was 3.5 ms and the relaxation delay was 1.0 s) and broadband ^{13}C decoupling with GARP-1[30] was applied during the acquisition (^{13}C: 90° pulse of 60 ms). The data were zero-filled in the t_1 dimension and a sine-bell filter was applied in both dimensions before the Fourier transformation. The J^1_H-$^{13}_C$ coupling constants and ^{13}C chemical shifts were obtained from the INEPT and DEPT-135 spectra.

Synthesis and Characterization. General Procedure: A solution of the formamide (0.14 mmol) in CH_2Cl_2 (0.5 mL) was added to solid *trans*-[$PtCl_4(EtCN)_2$] (0.03 g, 0.07 mmol) and the reaction mixture was heated at 35 °C for 1−2 h, whereupon crystals started to form. At this point the mixture was cooled to 15−17 °C and left to stand at this temperature for 2 days. The dark-orange crystals were filtered off, washed with three 2-mL portions of CH_2Cl_2 and dried in air at room temperature. Yields were ca. 40%.

[$PtCl_4${(O=)CHNMe_2}$_2$]: $C_6H_{14}Cl_4N_2O_2Pt$ (483.09): calcd. C 15.03, H 2.92, N 5.85; found C 15.07, H 3.16, N 5.66. − FAB$^+$-MS: *m*/*z* = 482 [M − H]$^+$. − TLC on Merck 60 F_{254} SiO_2 plates: R_f = 0.51 (eluent Me_2CO/CH_2Cl_2, 1:1). − IR (KBr; selected bands): $\tilde{\nu}$ = 3065 w, 3005 w, and 2960 mw ν(C−H), 1638 s ν(C=O) cm^{-1} [in the free ligand ν(C=O) is found at 1687 cm^{-1} in CCl_4 [25]]. − ^{1}H NMR ([D_6]DMSO): δ = 3.07 and 3.31 (s, 3 H each, Me), 8.12 (s + d, J_{PtH} = 21.2 Hz, 1 H, =CH). The solubility of the compound is insufficient to measure ^{13}C{^{1}H} and ^{195}Pt NMR spectra even at high accumulation times.

X-ray Structure Determination: X-ray diffraction data were collected with a Nonius KappaCCD diffractometer using Mo-K_α radi-

ation (λ = 0.71073 Å). The Denzo and Scalepack[31] programs were used for cell refinements and data reduction. The structures of *cis*-[$PtCl_4${(O=)CHNHMe}$_2$] (**1**) and *cis*-[$PtCl_4${(O=)CHNH*t*Bu}$_2$] (**2**) were solved by direct methods using SIR97[32] and SHELXS-97[33] programs, respectively, with the WinGX[34] graphical user interface. The structure refinements were carried out with SHELXL-97.[35] A multi-scan absorption correction, based on equivalent reflections (XPERP in SHELXTL v5.1),[36] was applied to the data of both structure **1** (T_{max}/T_{min} 0.3812/0.2199) and structure **2** (T_{max}/T_{min} 0.2921/0.2100). In both structures the hydrogen atoms were constrained to ride on their parent atom. Selected bond lengths and angles are given in Table 1 and 2 and crystallographic data is summarized in Table 3. The crystal structures are shown in Figure 1 and 2.

Diamond-Shaped Heterometallic Complexes of Iron(II) and Copper(I) Bridged by Cyanide Groups Containing Monodentate or Bidentate Phosphanes Bound to Copper(I), Including an Alternative Structure Based on the Nature of the Bidentate Phosphane Ligand

Donald J. Darensbourg,*[a] Way-Zen Lee,[a] M. Jason Adams,[a] and Jason C. Yarbrough[a]

Keywords: Copper / Iron / P ligands / Cyanides / Bridging ligands

The diamond-shaped heterometallic cyanide-bridged complex of iron(II) and copper(I), $[CpFe(CO)(\mu\text{-}CN)_2Cu(CH_3CN)_2]_2$ (**1**), has been synthesized from the reaction of $K[CpFe(CO)(CN)_2]$ and $[Cu(CH_3CN)_4][BF_4]$ in acetonitrile. Upon the addition of 2–4 equivalents of phosphane ligands to complex **1**, the coordination geometry of the copper centers can be varied from trigonal planar as in $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)]_2$ (**2**), to tetrahedral as found in $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_2]_2$ (**3**). Analogous derivatives containing other phosphane ligands, namely PMe_3, P(*p*-tolyl)$_3$, PMe_2Ph, and PPh_2Me have been synthesized as well. Prolonged exposure of complex **3** in CH_2Cl_2 to excess PCy_3 has provided the bimetallic complex $[CpFe(PCy_3)(CN)(\mu\text{-}CN)Cu(PCy_3)_2]$ (**4**), where the metal aggregate is disrupted and PCy_3 has displaced CO at the iron center. Bidentate phosphane analogs of complex **3** have been prepared by adding two equivalents of dcpe [bis(dicyclohexylphosphanyl)-ethane] or dcpp [bis(dicyclohexylphosphanyl)propane] to complex **1**. The solid-state structures of several of these diamond-shaped derivatives, in addition to complex **4**, have been determined by X-ray crystallography. The overlapping diamond-shaped $[Fe_2(CN)_4Cu_2]$ cores, which form channels within the solids, are blocked by bulky, copper-bound phosphane ligands such as PCy_3. However, in the case of the small phosphane PMe_3, or the chelating phosphanes dcpe and dcpp, these channels are not blocked by the phosphane ligands; solvent molecules occupy the channels created by the overlapping metal cores instead. Alternatively, the complex $[CpFe(CO)(CN)(\mu\text{-}CN)Cu(dcpm)]_2$ (**13**), derived from bis(dicyclohexylphosphanyl)methane(dcpm), possesses two copper(I) centers, each in a distorted trigonal coordination geometry, bridged by two dcpm ligands to form an eight-membered metallacycle with a short $Cu^I\cdots Cu^I$ separation of 2.844 Å. The third ligand completing each copper's coordination sphere is a nitrogen-bound bridging cyanide group from a $CpFe(CO)(CN)_2^-$ anion.

Introduction

The use of linkage groups for assembling multinuclear complexes has been extensively investigated. A variety of polygons of transition metal complexes has been created using different linkage groups.[1] Among these, molecular squares are the most common of the metallacyclic polygons which have been prepared and structurally characterized. Included in these are one-, two-, and three-dimensional complexes which have been synthesized employing bridging cyanide groups of $M_x(CN)_y$ building blocks.[2–25] Recently, the research groups of Rauchfuss,[26] and Long[27] have reported remarkable molecular boxes, cages, and clusters made from $M(CN)_3$ or $M_6Q_6(CN)_6$ (Q = S, Se, or Te) building blocks. Other studies ranging from the electronic communication between metal atoms, i.e. electron transfer, mixed-valence, and magnetic interactions,[28] to the understanding of cyanide's role as a respiratory inhibitor in heme-copper oxidases, involve the investigation of metal cyanide complexes.[29]

Recently, we have communicated our initial investigations of the synthesis and characterization of diamond-shaped heterometallic cyanide-bridged complexes of iron(II) and copper(I) with tricyclohexylphosphane ligands coordinated to the copper(I) centers.[30] These studies showed that the coordination geometries of the copper(I) centers in the complexes $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_n]_2$ (Cp = η^5-C_5H_5; n = 1 or 2) vary from trigonal planar (n = 1) to tetrahedral (n = 2) upon the addition of a phosphane ligand. Herein we elaborate upon these investigations employing a variety of monodentate and bidentate phosphanes. Hopefully, these results will yield the necessary knowledge to allow us to expand our studies to dimeric cyanide-bridged complexes of iron(II) and zinc(II), the latter of which may serve to mimic the double metal cyanide (DMC) catalysts employed in the homopolymerization of epoxides or the copolymerization of CO_2/epoxides.[31]

Results and Discussion

Synthesis and Infrared Spectroscopy

Upon reacting $K[CpFe(CO)(CN)_2]$ (Cp = η^5-C_5H_5) with $[Cu(CH_3CN)_4][BF_4]$ in acetonitrile at ambient temperature, a clear yellow solution of $[CpFe(CO)(\mu\text{-}CN)_2Cu(CH_3CN)_2]_2$ (**1**) and a fine pale gray solid of KBF_4 were formed immediately. Two CN and one CO absorption bands in the infrared spectrum of complex **1** were observed at higher frequencies [2125 sh, 2118**s** (ν_{CN}); 1974 vs cm^{-1}

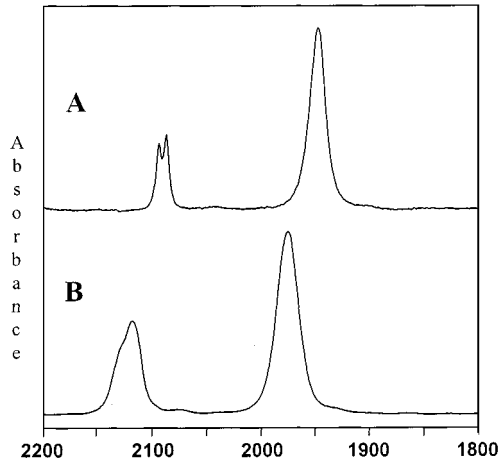

Figure 1. Infrared spectra of: **A**: [K][CpFe(CO)$(CN)_2$], and **B**: $[CpFe(CO)(\mu\text{-}CN)_2Cu(CH_3CN)_2]_2$

(ν_{CO}), Table 1] than in the parent anion $CpFe(CO)(CN)_2^-$. The absolute intensity of the ν_{CN} bands vs. that of the CO stretching vibration of **1** was increased by a factor of 2.1 times that of the corresponding bands in the parent anion (Figure 1).

The greater intensities and higher frequencies of the CN bands are evidence that the CN groups of the $CpFe(CO)(CN)_2^-$ unit are ligated to Cu^I centers in complex **1**. Two acetonitrile molecules are expected to complete each copper's coordination sphere. When the reaction was carried out in dichloromethane, free acetonitrile was observed in the infrared spectrum of the resulting solution, with the CN and CO bands being shifted to higher frequencies (Figure 2). These observations indicate that the acetonitrile molecules are dissociated from the copper(I) centers in dichloromethane solution, thereby making the metal more electron deficient. This in turn leads to a significant withdrawal of electron density from the nitrogens of the bridging cyanides to the Cu^I centers, and the frequencies of the CN and CO vibrational modes are shifted to significantly higher frequencies than those seen in complex **1**. Nevertheless, it is most likely that in this instance there are weak Cu···Cl interactions with dichloromethane. In the absence of strongly coordinating solvents, the complex was unstable under an argon atmosphere and decomposed within 3−4 h.

A turbid solution resulted immediately upon adding triphenylphosphane to an acetonitrile solution of **1**, with subsequent formation of a yellow solid after several minutes of stirring at ambient temperature. The isolated yellow solid was found to be insoluble in all common organic solvents. However, the solid-state infrared spectrum of this material (**1a**) exhibited ν_{CN} and ν_{CO} vibrational modes of lower frequencies than those observed in complex **1**, and hence indicate the binding of PPh_3 ligands at the copper(I) centers. In order to obtain an analogous complex which was soluble in organic solvent, complex **1** was reacted with tricyclohexylphosphane. In this manner, two complexes, $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)]_2$ (**2**) and $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_2]_2$ (**3**), were synthesized by the reaction of **1** with two or four equivalents of PCy_3, respectively.[30] Whereas, complex **2** precipitated directly from the acetonitrile reaction solution,

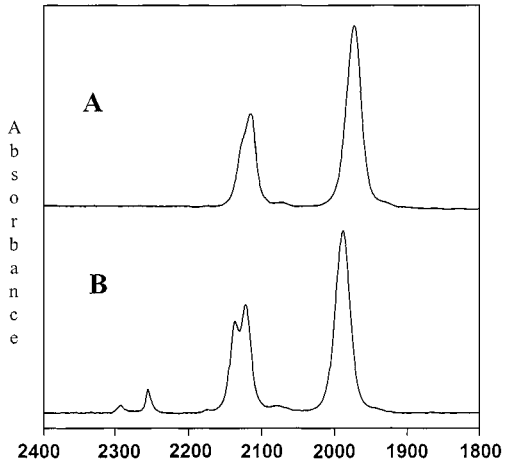

Figure 2. Infrared spectra of: **A** $[CpFe(CO)(\mu\text{-}CN)_2Cu(CH_3CN)_2]_2$, and **B**: $[CpFe(CO)(\mu\text{-}CN)_2Cu]$

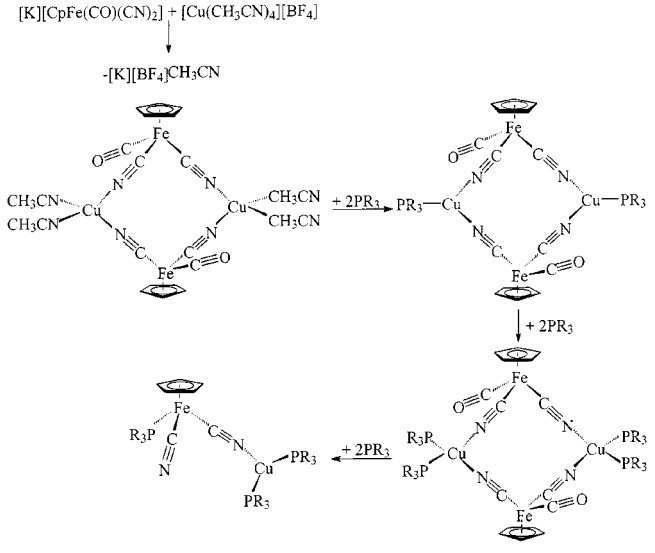
complex **3** remained in solution; both derivatives were readily soluble in dichloromethane. As seen in Table 1, the ν_{CN} and ν_{CO} bands progressively shift to lower frequencies in proceeding from complex **1** to **2** and **3**, consistent with one and two equivalents of PCy_3 binding to the Cu^I centers. The subsequent addition of PCy_3 to complex **3** in dichloromethane with stirring over a period of time affords a complex devoid of any CO ligand which has been characterized as $[CpFe(PCy_3)(CN)(\mu\text{-}CN)Cu(PCy_3)_2]$ (**4**) (vide infra). Scheme 1 summarizes the sequence of reactions employed in the synthesis of **2** and **3** and other phosphane analogs, along with further reaction pathways of these derivatives.



Scheme 1

In an effort to prepare soluble derivatives containing a phosphane ligand that closely mimics the electronic and steric properties of PPh_3, we synthesized the $P(p\text{-tolyl})_3$ derivatives. Upon adding two equivalents of $P(p\text{-tolyl})_3$ to complex **1** in acetonitrile, a yellow solution of $[CpFe(CO)(\mu\text{-}CN)_2Cu\{P(p\text{-tolyl})_3\}]_2$ (**5**) was obtained. Unfortunately, complex **5** was unstable in acetonitrile or dichloromethane solution, even when maintained at 10 °C. In contrast, the addition of four equivalents of $P(p\text{-tolyl})_3$ to **1** in acetonitrile resulted in the formation of a precipitate of $[CpFe(CO)(\mu\text{-}CN)_2Cu\{P(p\text{-tolyl})_3\}_2]_2$ (**6**), which was stable when redissolved in either THF or dichloromethane. The conversion of complex **6** to the bimetallic complex $[CpFe\{P(p\text{-tolyl})_3\}(CN)(\mu\text{-}CN)Cu\{P(p\text{-tolyl})_3\}]_2$, in the presence of added equivalents of $P(p\text{-tolyl})_3$ in dichloromethane (ν_{CN} = 2086 sh, 2073 s cm^{-1}) proceeded more rapidly (only four days) than the corresponding process involving **3** and PCy_3. In addition the reaction of two or four equivalents of the series of phosphanes PMe_nPh_{3-n} (n = 1, 2, or 3) with complex **1** in dichloromethane have similarly provided the mono- and bisphosphane-substituted copper(I) derivatives **7**, **9**, **11**, and **8**, **10**, **12**, respectively. As is evident from the vibrational data in Table 1, the basicity of the phosphane ligand, which varies significantly from PMe_3 to PPh_2Me, has a negligible effect on the ν_{CN} and ν_{CO} values observed. Complexes **8**, **10**, and **12** were found to react more rapidly with added equivalents of the corresponding phosphane ligand to provide the bimetallic complex than previously observed for other complexes. For example, complex **12** was quantitatively converted in the presence of PMe_3 into $[CpFe(PMe_3)(CN)(\mu\text{-}CN)Cu(PMe_3)_2]$ in two days. When eight equivalents of PMe_nPh_{3-n} (n = 1, 2, or 3) were added directly to complex **1** in dichloromethane, the infrared spectra of the products were consistent with complete disruption of the parallelogram structures with concomitant formation of the $[Cu(PMe_nPh_{3-n})_4]$-$[CpFe(CO)(CN)_2]$ salts.

In studies designed to examine the nature of the complex formed when the monodentate tricyclohexylphosphane is replaced by its bidentate analogs $Cy_2P\text{-}(CH_2)_n\text{-}PCy_2$, we synthesized the derivatives where n varies from 1 to 4 in an identical manner. Infrared spectroscopic data in the ν_{CO} and ν_{CN} regions for the derivatives of dcpm [bis(dicyclohexylphosphanyl)methane] (**13**), dcpe [1,2-bis(dicyclohexylphosphanyl)ethane] (**14**), and dcpp [bis(dicyclohexylphosphanyl)propane] (**15**) are quite similar (Table 1). Furthermore, these derivatives were shown by elemental analysis to be stoichiometrically of the same composition. The most distinguishing spectral feature noted between complex **13** and complexes **14** and **15** is the magnitude of the downfield shift of the ^{31}P NMR resonance of the bisphosphane ligand upon complexation to copper(I): whereas the ^{31}P NMR shift is significantly different from that of the free phosphane in complex **13** (by 16 ppm), in complexes **14** and **15** the chemical shift difference is only 0.9−1.2 ppm (see Table 2).

X-ray Crystal Structures

X-ray quality crystals of **2** were obtained upon the slow diffusion of acetonitrile into a dichloromethane solution of the complex over several days at 10 °C. Under similar conditions, yellow or yellow-orange crystals of complexes **3**, **6**, **12**, and **15** were obtained from THF/hexane, and orange crystals of **4**, **13**, and **14** from dichloromethane/diethyl

ether. The solid-state structures of **2**, **3**, **4**, **6**, and **12**−**15** were determined by X-ray crystallographic analysis. Selected bond lengths and angles of **2**, **3**, **4**, **6**, **12**−**15** are listed in Table 3. Figure 3 presents a crystal packing diagram of complex **2**, and Figure 4 shows a thermal ellipsoid drawing of complex **3**. Complexes **2** and **3** possess a diamond-shaped motif composed of two $\eta^5\text{-}C_5H_5Fe(CO)$ fragments, two Cu^I centers, and four bridging CN groups. Due to the addition of phosphane ligands, the coordination geometry about the copper(I) centers of **2** and **3** are trigonal planar and tetrahedral, respectively. As anticipated, upon increasing the coordination number of the copper centers from three to four, i.e., proceeding from complex **2** to **3**, the average Cu−P and Cu−N bond lengths are lengthened by about 0.1 Å. As seen in Figure 4, the diamond-shaped core of complex **3** was found to be partially blocked by the cyclohexyl groups from phosphane ligands. This steric hindrance is not observed in complex **2** or in the chelated bisphosphane derivatives (vide infra). Figure 3 shows the packing diagrams for complex **2**, where solvent molecules (CH_2Cl_2) lie between the overlapping diamonds that form channels within the solids. Complex **2** is the only structurally characterized of these species that has a trigonal Cu^I center. Presumably due to the sterically encumbering PCy_3 ligand, which has a cone angle of 179°,[32] complex **2** is stabilized by filling up the coordination space of the copper centers with PCy_3. We were not able to crystallize other derivatives from solution. The insert in Figure 4 illustrates another interesting feature of the solid-state structure of **3**: the disorder of the $\eta^5\text{-}C_5H_5Fe$ fragments. This type of disorder is also found in the solid-state structure of complex **6**. This is illustrated in Figure 5, which shows that complex **6** has a structure similar to complex **3**; the ball-stick drawing of the $\eta^5\text{-}C_5H_5Fe$ disorder of complex **6** is provided as the insert of Figure 5.

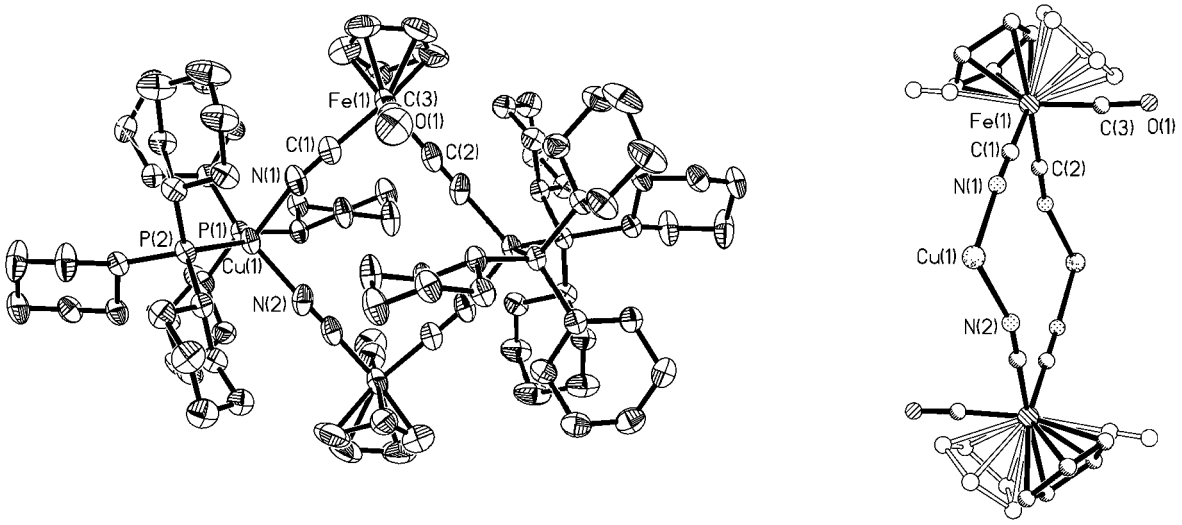

Figure 4. Thermal ellipsoid representation of $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_2]_2$ (**3**)

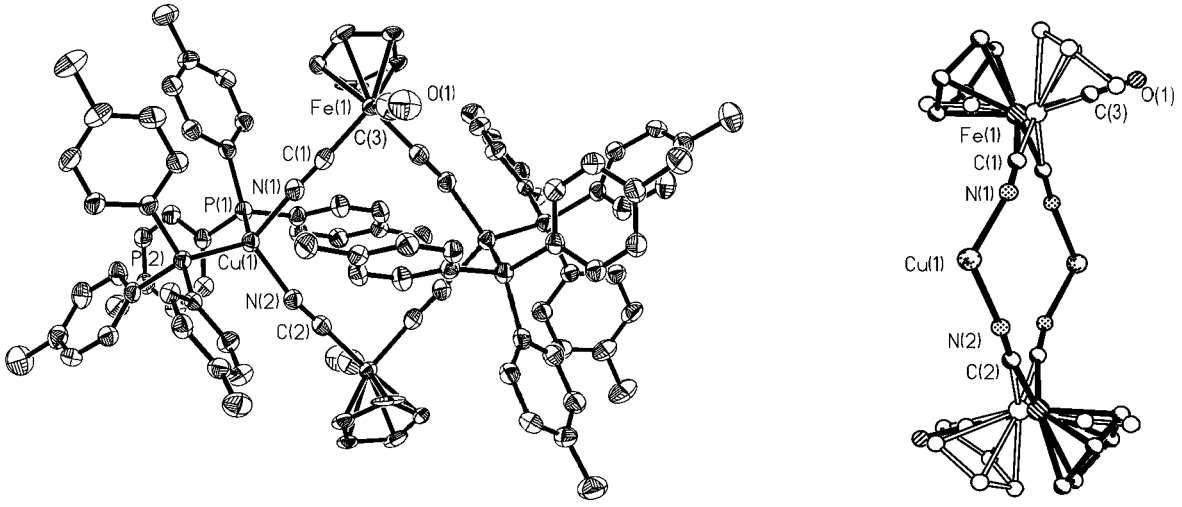

Figure 5. Thermal ellipsoid representation of $[CpFe(CO)(\mu\text{-}CN)_2Cu(P\text{-}p\text{-}totyl_3)_2]_2$ (**6**)

As previously mentioned, the prolonged exposure of complex **3** to PCy_3 in CH_2Cl_2 affords the bimetallic complex **4**, which does not contain a CO ligand bound to iron. The thermal ellipsoid representation of complex **4** is depicted in Figure 6. A tricyclohexylphosphane, a terminal CN ligand, and the bridging CN group occupy the remaining coordination sites of the CpFe moiety. The coordination geometry about the Cu^I center is trigonal, and the copper's coordination sphere is completed by the bridging CN group and two PCy_3 ligands. Apparently, complex **4** is synthesized by the substitution of CO with PCy_3 on the iron centers of **3** and the cleavage of one Cu^I-N bond on each copper center of complex **3**. The average Cu−P bond length in complex **4** (2.235 Å) is slightly shorter than those found in complex **3** (2.279 Å). Similarly, the Cu−N bond length of 1.943(9) Å is shorter than the average Cu−N bond length in **3** (2.028 Å). These bond length trends are the same as those observed in proceeding from **2** to **3**, that is, when the coordination number of copper increases from three to four. By comparing the two trigonal Cu^I centers of complexes **2** and **4**, the average Cu−P bond length in **4** (2.235 Å) is slightly longer than that in **2** [2.206(2) Å], whereas, the Cu−N bond length in **4** [1.943(9) Å] is shorter than that in **2** (1.955 Å on average). As expected, the P(I)−Cu−P(2) bond angle in complex **4** [139.54(11)°] is much larger than that found in **3** [127.75(4)°]. The bonding mode of Fe−C≡N−Cu in complex **4** is nonlinear, with Fe−C(1)−N(1) and C(1)−N(1)−Cu bond angles of 172.9(10) and 166.5(9)°, respectively.

Figure 7 shows a thermal ellipsoid drawing of $[CpFe(CO)(\mu\text{-}CN)_2Cu(PMe_3)_2]_2$ (**12**), where the basic metal cyanide core structure is similar to those seen in the other bis-bimetallic derivatives. However, in this instance the Cp and carbonyl ligands were not disordered about the $[Fe(CN)_2Cu]_2$ plane.

Furthermore, unlike the bis tricyclohexylphosphane and $P(p\text{-tolyl})_3$ analogs, the sterically less demanding PMe_3 ligands do not block the entrance to the diamond-shaped core. Instead, solvent molecules are able to occupy the channels created by the overlapping diamonds as in com-

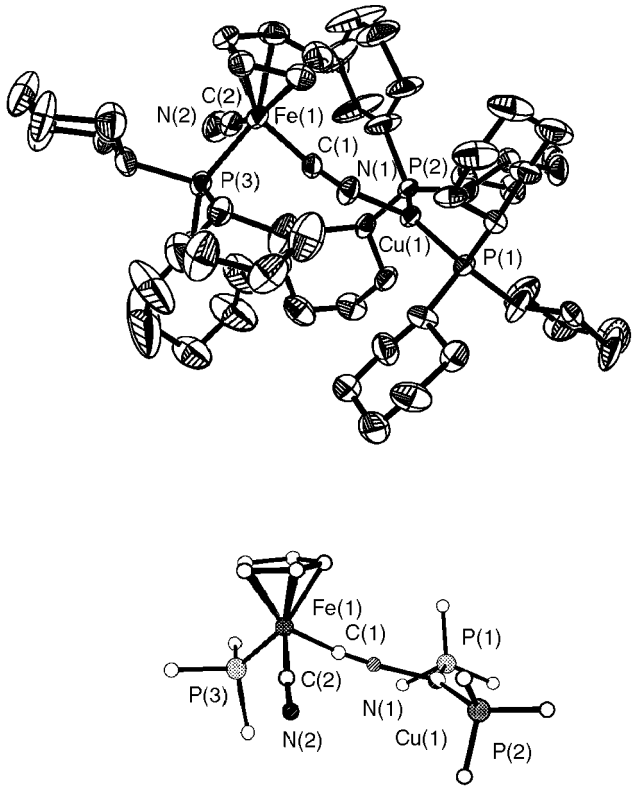

Figure 6. Thermal ellipsoid representation of $CpFe(PCy_3)(CN)(\mu\text{-}CN)Cu(PCy_3)_2$ (**4**)

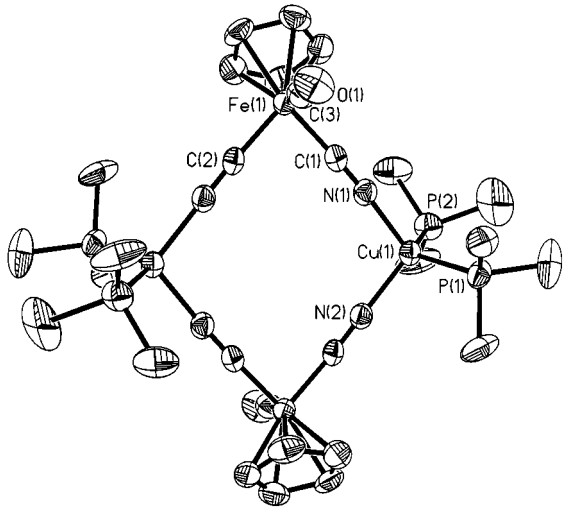

Figure 7. Thermal ellipsoid representation of $[CpFe(CO)(\mu\text{-}CN)_2Cu(PMe_3)_2]_2$ (**12**)

plex **2**. It is noteworthy that in this complex the C≡N−Cu bond angles are close to being linear, with an average bond angle of 174.7°. The corresponding average C≡N−Cu bond angles in the other crystallographically determined derivatives (complexes **2**, **3**, and **6**) cover a range of 160.4−166.7°. Although complexes **3**, **6**, and **12** have similar structures, the P−Cu−P angles and Cu−P bond lengths respond to the steric requirements of the phosphane ligands, that is, the P−Cu−P angles become more obtuse and the Cu−P bond lengths become longer with increasing phosphane cone angles (see Table 4).

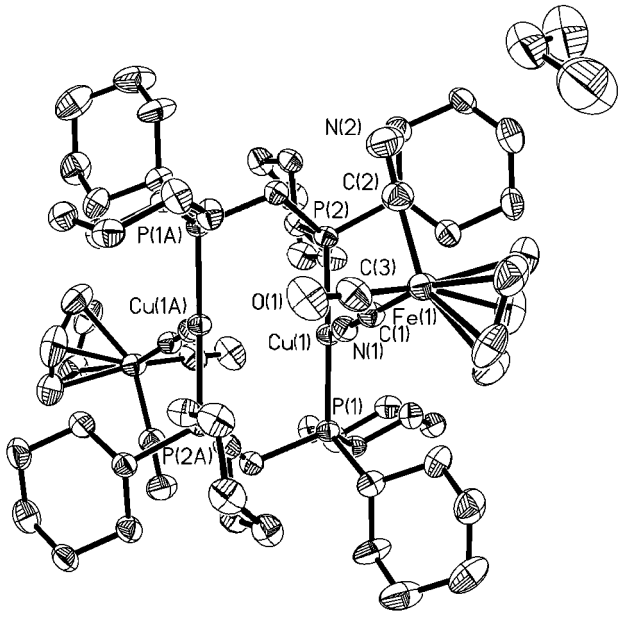
A thermal ellipsoid representation of complex **13** is shown in Figure 8, and a list of selected bond lengths and angles is provided in Table 3. Unlike the bis(tricyclohexylphosphane) derivative, complex **13** consists of two Cu^I centers, each in a distorted trigonal environment, separated by 2.844 Å and bridged by the two dcpm ligands. The third ligand completing each copper center's coordination sphere is a nitrogen atom of a bridging CN group from the $CpFe(CO)(CN)_2^-$ anion. The insert in Figure 8 illustrates the distorted T-shape about the copper centers, where the P(1)−Cu(1)−P(2) angle is 144.26(4)°. Hence, like the CO ligand, one cyanide ligand of the $CpFe(CO)(CN)_2^-$ units is terminal.

As seen in Figure 8, the two $CpFe(CO)(CN)_2^-$ moieties are on opposite sides of the eight-membered metallacycle afforded by the two copper(I) atoms and the two bisphosphane ligands. The Cu−P bond lengths in complex **13** [2.2473(11) and 2.2626(11) Å] are slightly shorter than those found in the diamond-shaped bis(tricyclohexylphosphane) derivative (2.28 Å on average), where the geometry about the copper is tetrahedral with two bridging CN ligands. Similarly, the Cu−N bond length of 1.994(3) Å is shorter than the average Cu−N bond length in the bis-PCy_3 analog. These observations are to be expected in proceeding from three- to four-coordinate copper, and are also observed in the mono- and bis-tricyclohexylphosphane complexes. Interestingly, the C−N−Cu bond angle in **13** [158.3(3)°] is more acute than that found in the geometrically constrained diamond-shaped derivatives (vide infra).

Again, in an effort to conclusively define the structures of complexes **14** and **15** we have resorted to X-ray crystallography. This is of particular importance since the spectroscopic data for complexes **13**−**15** are so similar. Thermal ellipsoid drawings of complexes **14** and **15** are found in Figures 9 and 10, respectively, and lists of selected bond lengths and angles are provided in Table 3.

Table 4. Cone angles, P−Cu−P bond angles, and Cu−P bond lengths of **3**, **6**, and **12**

Compound	Cone angle (deg)	P−Cu−P (deg)	Cu−P (Å)
$[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_2]_2$ (**3**)	179	127.75	2.264
$[CpFe(CO)(\mu\text{-}CN)_2Cu\{(P\text{-}p\text{-}tolyl)_3\}_2]_2$ (**6**)	145	121.21	2.279
$[CpFe(CO)(\mu\text{-}CN)_2Cu(PMe_3)_2]_2$ (**12**)	118	118.71	2.241



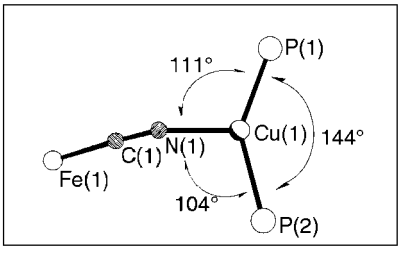


Figure 8. Thermal ellipsoid representation of complex **13**; the insert illustrates the coordination sphere about the copper(I) center

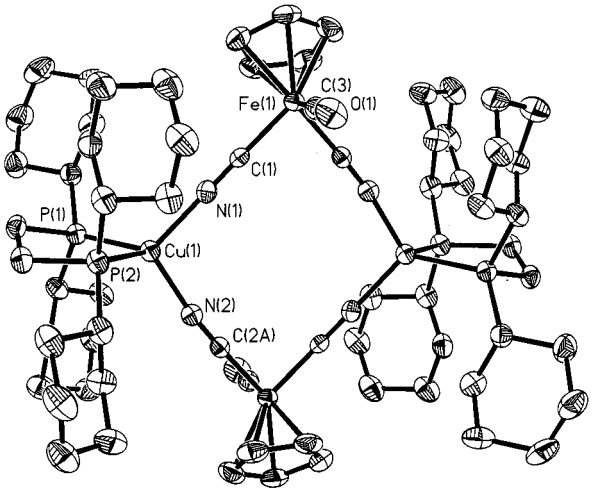

Figure 9.Thermal ellipsoid representation of complex **14**

Complex **14** crystallized with two molecules each of CH_2Cl_2 and CH_3CN, whereas complex **15** crystallized with five molecules of THF. Both derivatives possess the diamond-shaped structure previously observed in the analogous complexes containing monodentate tricyclohexylphosphane ligands. The diamond or parallelogram is formed by two iron(II) and two copper(I) atoms linked by four bridging cyanide ligands, where the carbon end of the CN group is bound to iron and the nitrogen end to copper. The coppers' coordination spheres are completed by a chelating bisphosphane ligand. Hence, upon changing the number of methylene groups between the two PCy_2 donors from one to two or three, the bisphosphanes switch from bridging to chelating with regard to their binding to the copper(I) centers. The two iron-bound terminal CO ligands lie on opposite sites of the plane defined by the four metal atoms.

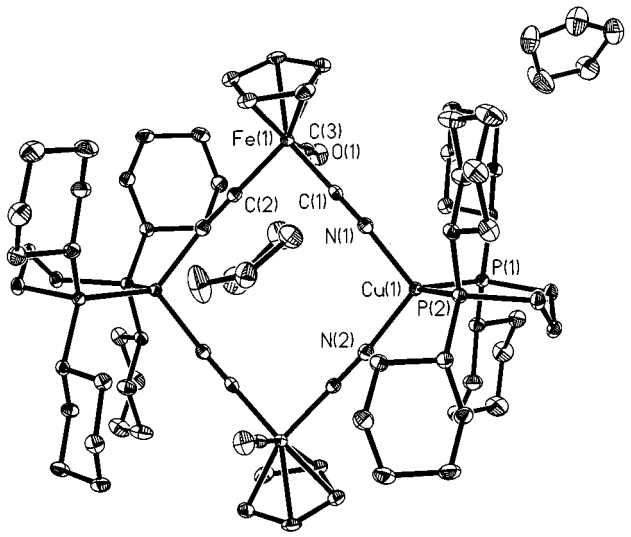

Figure 10. Thermal ellipsoid representation of complex **15**

The average Cu−N and Cu−P bond lengths were found to be 1.975(5) and 2.247(2) Å in **14**, and 1.998(3) and 2.252(1) Å in **15**, respectively. These bond parameters are quite similar to those found in complex **13**. The P−Cu−P angle in **14** at 92.49(6)° is, as expected, more acute than that seen in complex **15** [104.69(4)°] due to the change in going from a five-membered chelate ring to a six-membered chelate ring. On the other hand, the N−Cu−N angles are quite similar in the two diamond-shaped complexes at 103.93(19) and 101.93(12)°, in **14** and **15** respectively. Similarly, the C−Fe−C angles in the two parallelograms differ only slightly, 87.0(2) in **14** and 87.99(14)° in **15**. In contrast to complex **13**, where the Cu−N−C−Fe linkage is highly nonlinear, in complexes **14** and **15** which contain C−N−Cu average angles of 175.8(5) and 172.0(3)° and N−C−Fe average angles of 177.3(5) and 179.2(3)°, this unit is fairly linear.

The geometric dimensions of the Fe_2Cu_2 diamond-shaped core in complexes **14** and **15** are summarized in Figure 11. The internal area of the diamond is approximately 25 $Å^2$. As is seen in the space-filling model of **15** (Figure 12) access to the internal void space, which can accommodate a sphere with a radius up to approximately 1.04 Å, is ready available in the case of the chelated cyclohexylphosphane ligands. This is *not* the case in the analogous bis PCy_3 derivative where the cyclohexyl rings partially block the opening. Figure 13 displays a packing diagram for complex **14**, where

between the layers of overlapping diamonds, which form channels in the solids, there are solvate molecules of CH_3CN.

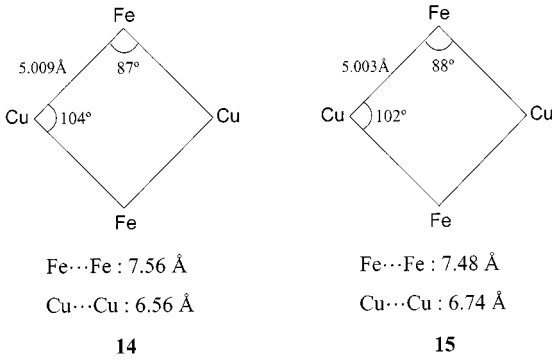

Figure 11. Metric parameters of the $Fe_2Cu_2(CN)_4$ cores of complexes **14** and **15**

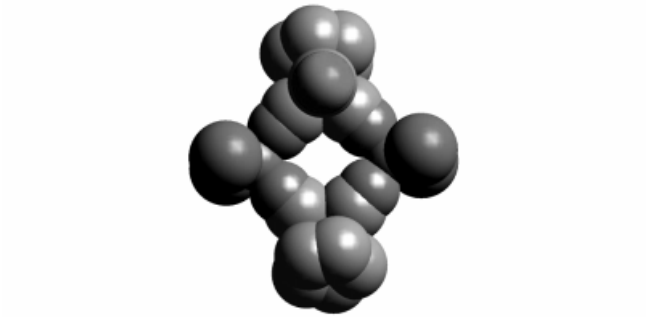

Figure 12. Space-filling model of complex **15**

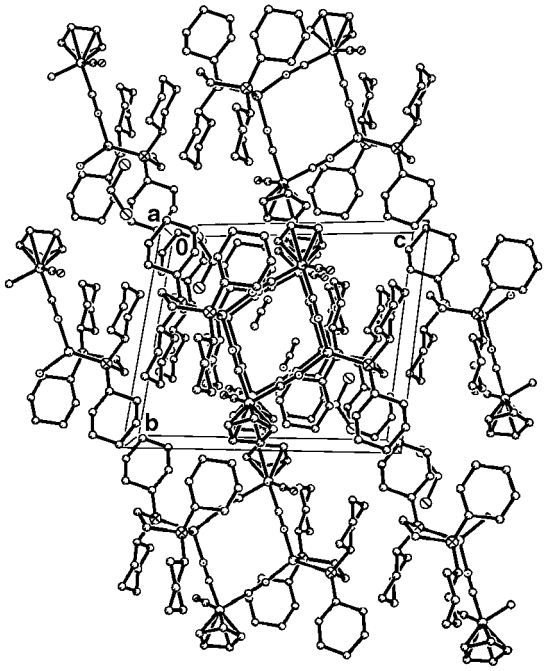

Figure 13. Packing diagram for complex **14**, indicating solvent molecules between the layers of the stacked diamond-shaped complexes

Since we have observed $[CpFe(CO)(\mu\text{-}CN)_2CuPCy_3]_2$, where the copper(I) center is trigonal, to be quite stable, it was of interest to examine the effect of extending the number of methylene units in the $Cy_2P(CH_2)_nPCy_2$ ligand to four. In this instance the bisphosphane ligand may have a greater propensity for affording linked chains of diamond-shaped moieties as opposed to chelating to a single copper(I) center. Hence, the synthesis of the derivative with $Cy_2P(CH_2)_4PCy_3$ (dcpb) (**16**) was performed in a completely analogous manner to that employed for complexes **14** and **15**. Unfortunately, we have yet to obtain X-ray quality crystals of **16**, and therefore have not been able to definitively identify its structure. However, based on the close spectral resemblance of complex **16** to complexes **14** and **15** (see Table 1), coupled with its ready solubility, we suggest it to be the seven-membered chelate bisphosphane derivative.

Solution ^{31}P NMR Spectroscopy

Table 2 lists the ^{31}P NMR spectra in CH_2Cl_2 of the heterobimetallic complexes synthesized and structurally characterized in this report. As seen in Table 2 and Figures 14A and 14B, the ^{31}P NMR resonances for complexes **2** and **3**, the mono- and bis-tricyclohexylphosphane derivatives of $[CpFe(CO)(\mu\text{-}CN)_2Cu]_2$, at ambient temperature are shifted slightly downfield from the free ligand at $\delta = 15.16$ and 11.74, respectively, and are somewhat broadened with frequency width half-height (fwhh) values of 106 and 65 Hz, respectively. This is presumably due to line broadening by

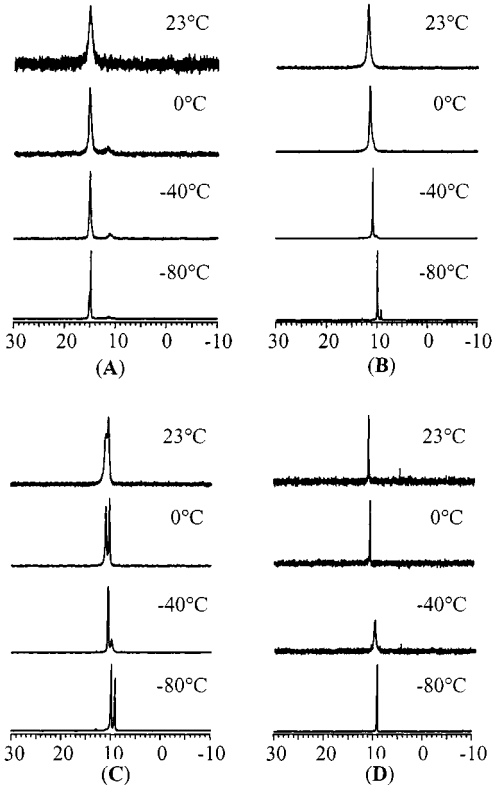

Figure 14. Variable temperature ^{31}P NMR spectra of $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)]_2$ (**A**), $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_2]_2$ (**B**), $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_2]_2 + PCy_3$ (**C**), and PCy_3 (**D**)

the quadrupolar nuclei ^{63}Cu and ^{65}Cu. By way of contrast, the free PCy_3 ligand has a resonance at $\delta = 10.86$ with a fwhh of only 11 Hz at ambient temperature. Nevertheless, there is a temperature dependence of the free PCy_3 ligand with broadening being noted around −40 °C; this can be attributed to the conformation exchange of the chair and boat forms of the cyclohexyl rings (see Figure 14D).

Upon the addition of two equivalents of PCy_3 to complex **3** in dichloromethane the ^{31}P NMR spectrum exhibits resonances for both complex **3** and free PCy_3. These ^{31}P NMR signals display the same temperature behavior noted for the individually determined spectra, i.e., the sum of the spectra in Figure 14B and 14D afford that seen in Figure 14C. These ^{31}P NMR spectral results are indicative of *slow phosphane exchange* between complex **3** and PCy_3 ($<<100$ sec^{-1}). Furthermore, the infrared spectra of complexes **2** and **3** clearly indicate that there is only one principal species in pure solutions of these two derivatives, as can be seen from the overlapping spectra in the ν(CN) region in Figure 15. As previously indicated prolonged standing of the reaction solution containing complex **3** and PCy_3 affords complex **4**, where the phosphorous resonance for PCy_3 bound to iron is observed at $\delta = 80.2$.

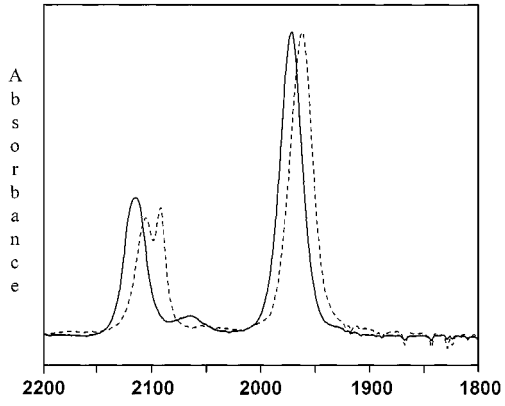

Figure 15. Superimposition of the infrared spectra of complexes **2** (——) and **3** (- - - -)

There is a trend noted in the ^{31}P NMR resonance of the methyl(phenyl)phosphane derivatives. That is, the more basic phosphane derivative shows an increased downfield shift in the complex compared to that of the free phosphane ligand (Table 2). These differences in chemical shift range from the most basic PMe_3 derivative (**9**; $\delta = 13.48$) to the least basic PPh_2Me derivative (**7**; $\delta = 4.04$). In addition, the ^{31}P NMR resonances of the derivatives containing two phosphanes per copper center all fall downfield from their one-phosphane-bound counterparts by about 2 ppm.

Concluding Remarks

Encompassed in this report are contributions to the growing body of work on the synthesis and structural characterization of metallacyclic polygons,[1] in particular those containing cyanide bridges.[2−27] Among the iron(II)/copper(I) cyanide-bridged bimetallic complexes we have synthesized, **13** is the only complex composed of an eight-membered metallacycle with a short $Cu^{I}\cdots Cu^{I}$ distance in the solid-state due to dcpm bridging the two copper(I) centers. As the number of methylene groups between the PCy_2 donors of the bisphosphane ligand is increased, the bisphosphane changes its bonding mode from bridging to chelating. Hence, the X-ray structures of complexes **14** and **15**, which contain the bisphosphane ligands dcpe and dcpp, respectively, show an Fe_2Cu_2 diamond-shaped core as seen in the monodentate phosphane derivatives **2**, **3**, **6**, and **12**, e.g., $[CpFe(CO)(\mu\text{-}CN)_2(PCy_3)_2]_2$, where the copper(I) centers are four coordinate. The diamond-shaped core can readily accommodate a sphere with a radius of up to 1.04 Å. In contrast to the bis(tricyclohexylphosphane) derivative, the cores of **12**, **14** and **15** are not blocked by cyclohexyl groups. Therefore, solvent molecules are able to occupy the channels created by the overlapping diamonds in the solids. In general the Cu−N−C−Fe linkage is nonlinear, with the Cu−N−C and Fe−C−N angles covering a range of 158.3 to 178.9° and 171.1 to 179.1°, respectively.

Experimental Section

Methods and Materials: All manipulations were performed under argon using standard Schlenk and glovebox techniques. Acetonitrile was distilled once from CaH_2 and once from P_2O_5 and then freshly distilled from CaH_2 immediately before use. Dichloromethane was dried and distilled over P_2O_5. Hexane, diethyl ether, and THF were dried in sodium benzophenone stills prior to use. The following reagents were used as received without further purification: Cyclopentadienylirondicarbonyl dimer, tetrafluoroboric acid, dimethylphenylphosphane (Aldrich); bromine (EM Science); potassium cyanide, cuprous oxide, triphenylphosphane (Fisher Scientific); tricyclohexylphosphane, trimethylphosphane, methyldiphenylphosphane, tri-*p*-tolylphosphane (Strem), bis(dicyclohexylphosphanyl)methane, dcpm (Strem), 1,2-bis(dicyclohexylphosphanyl)ethane, dcpe (Strem), 1,3-bis(dicyclohexylphosphanyl)-propane, dcpp (Aldrich), 1,4-bis(dicyclohexylphosphanyl)butane, dcpb (Aldrich). $[Cu(CH_3CN)_4][BF_4]$[33] and $K[CpFe(CO)(CN)_2]$[34] salts were prepared according to published literature procedures.

Infrared spectra were recorded on a Mattson 6021 FTIR using a 0.1 mm CaF_2-sealed cell for solutions and KBr pellets for solid samples. All ^{31}P NMR spectra were recorded on a Varian Unity Plus 300 MHz spectrometer (121.4 MHz ^{31}P) using non-deuterated dichloromethane as solvent. The magnetic field was locked with deuterium oxide, and a tube with an 85% phosphoric acid solution was used as an external reference. Variable temperature ^{31}P NMR spectra were recorded every 20 °C from +20 to −80 °C using liquid N_2 as coolant. Elemental analyses were carried out by Canadian Microanalytical Service, Ltd., Canada.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2Cu(CH_3CN)_2]_2$ (1): Acetonitrile (10 mL) was added to a mixture of $K[CpFe(CO)(CN)_2]$ (0.2 mmol, 0.048 g) and $[Cu(CH_3CN)_4][BF_4]$ (0.2 mmol, 0.0628 g) in a 50 mL Schlenk flask. After 30 min. of stirring at ambient temperature a pale gray solid of KBF_4 precipitated from the yellow reaction mixture. The KBF_4 salt was separated from the yellow solution of **1** by filtration. The acetonitrile solution of **1** was used immediately in the following syntheses.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)]_2$ (2): An acetonitrile solution of **1** prepared as described above was added to a 50 mL Schlenk flask containing 0.2 mmol of tricyclohexylphosphane (0.056 g). The crude product precipitated out as a yellow solid. Upon removal of the solvent by cannula and vacuum, the remaining solid was isolated in ca. 91% yield. X-ray quality crystals of **2** were obtained upon slow diffusion of acetonitrile into a dichloromethane solution of **2** maintained at 10 °C for several days. − $[CpFe(CO)(CN)_2Cu(PCy_3)]_2 \cdot 1.5CH_2Cl_2$: calcd. C 52.79, H 6.54, N 4.60; found C 52.90, H 7.21, N 4.36.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2Cu(PCy_3)_2]_2$ (3). Method I: Complex **3** was synthesized as described above for complex **2** employing 0.4 mmol of PCy_3 (0.112 g). A clear yellow solution of **3** was obtained in acetonitrile. Upon removal of the solvent by vacuum, a crude product of **3** was obtained as a yellow solid (yield 92%). Yellow orange crystals of **3** were obtained by slow diffusion of hexane into a THF solution of **3**. − $[CpFe(CO)(CN)_2Cu(PCy_3)]_2 \cdot 2THF$: calcd. C 64.24, H 8.87, N 3.12; found C 63.60, H 10.13, N 2.43.

Method II: Complex **3** could also be synthesized by adding two equivalents of PCy_3 to complex **2** in dichloromethane.

Synthesis of $[CpFe(PCy_3)(CN)(\mu\text{-}CN)Cu(PCy_3)_2]$ (4): A 5 mL dichloromethane solution of PCy_3 (0.2 mmol, 0.056 g) was added to a 10 mL dichloromethane solution of complex **3** (0.1 mmol, 0.165 g). An olive solution was formed along with some gray precipitate after two weeks of stirring. The gray precipitate was separated by filtration, and complex **4** was isolated by recrystallization. X-ray quality crystals of **4** were obtained by slow diffusion of diethyl ether into a dichloromethane solution of **4**.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2Cu(P\text{-}p\text{-}Tol_3)]_2$ (5): The synthesis of complex **5** was carried out exactly as described above for complex **2** employing tri-*p*-tolylphosphane (0.2 mmol, 0.061 g). A yellow solution of **5** resulted; unfortunately, complex **5** decomposes at ambient temperature.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2Cu(P\text{-}p\text{-}Tol_3)_2]_2$ (6): An acetonitrile solution of **1** as described above was added to a 50 mL Schlenk flask containing 0.4 mmol of tri-*p*-tolylphosphane (0.122 g). The reaction solution was stirred for 30 min., and **6** formed as a yellow precipitate. Upon removing the solvent by cannula and vacuum, the yellow solid was isolated in 90% yield. Yellow crystals of **6** were obtained upon slow diffusion of hexane into a THF solution of **6** at 10 °C for several days. − Calcd. C 68.77, H 5.42, N 3.21; found C 68.23, H 5.50, N 3.13.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2CuL]_2$ [L = $PMePh_2$ (7), PMe_2Ph (9), PMe_3 (11)]: A 5 mL acetonitrile solution of phosphane (0.2 mmol, 0.015 g for PMe_3, 0.028 g for PMe_2Ph, and 0.040 g for $PMePh_2$) was slowly added to a yellow acetonitrile solution of **1**. A yellow-orange solution was obtained for each phosphane derivative. Upon removing the solvent by vacuum, yellow-orange solids were isolated.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2CuL_2]_2$ [L = $PMePh_2$ (8), PMe_2Ph (10), PMe_3 (12)]: The syntheses of complexes **8**, **10**, and **12** were carried out as described above for **7**, **9**, and **11** with 0.4 mmol of phosphane (0.030 g for PMe_3, 0.056 g for PMe_2Ph, and 0.080 g for $PMePh_2$). X-ray quality crystals were obtained by slow diffusion of hexane into a THF solution of **12**.

Synthesis of $[CpFe(CO)(CN)(\mu\text{-}CN)Cu(dcpm)]_2$ (13): A 10 mL dichloromethane solution of dcpm (0.20 mmol, 0.081 g) was added to an acetonitrile solution of **1** prepared as described above. The reaction solution was stirred for 30 min. at ambient temperature, followed by removal of the mixed solvent under vacuum to afford a yellow residue in 92% yield. Yellow-orange crystals of **13** were obtained by slow diffusion of diethyl ether into a dichloromethane solution of **13** maintained at 10 °C for several days. − $C_{66}H_{102}Cu_2Fe_2N_4O_2P_4$ (1346.24): calcd. C 58.88, H 7.64, N 4.16; found C 58.10, H 8.00, N 3.98.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2Cu(dcpe)]_2$ (14): The synthesis of this derivative was carried out exactly as described above for complex **13** employing 0.20 mmol (0.084 g) of dcpe. The yellow-orange product was recovered upon removing the mixed solvent under vacuum. Orange crystals of **14** were obtained from CH_2Cl_2/diethyl ether maintained at 10 °C over several days. − $C_{68}H_{106}Cu_2Fe_2N_4O_2P_4 \cdot 2CH_2Cl_2$: calcd. C 54.45, H 7.18, N 3.63; found C 55.29, H 7.97, N 3.97.

Synthesis of $[CpFe(CO)(\mu\text{-}CN)_2Cu(dcpp)]_2$ (15): Alternatively, the reaction between $K[CpFe(CO)(CN)_2]$ (0.20 mmol, 0.048 g) and $[Cu(CH_3CN)_3][BF_4]$ (0.20 mmol, 0.063 g) was carried out directly in dichloromethane for 30 min. followed by filtration to remove the KBF_4 salt. Subsequently, dcpp (0.20 mmol, 0.087 g) in 10 mL of dichloromethane was added dropwise to the yellow filtrate and the solution stirred at room temperature for 30 min. to yield a yellow solution. Upon removal of the solvent under vacuum, the yellow solid was redissolved in THF for recrystallization. Yellow crystals of **15** were obtained upon slow diffusion of hexanes into a THF solution of **15** maintained at 10 °C for several days.

X-ray Crystallography: A yellow or yellow-orange crystal of **2**, **3**, or **4** was mounted on a glass fiber with epoxy cement and placed in a cold nitrogen stream at 193 K. X-ray crystallographic data of **2**, **3**, and **4** were obtained on a Siemens R3m/V single-crystal X-ray diffractometer operating at 55 kV and 30 mA, Mo-K_α (λ = 0.71073 Å) radiation equipped with a Siemens LT-2 cryostat. Diffractometer control software P3VAX 3.42 was supplied by Siemens Analytical Instruments, Inc. Crystals of **6** and **12**−**15** were coated by mineral oil and mounted on a glass fiber with apiezon grease at room temperature. The mounted crystal was then placed in a cold nitrogen stream (Oxford) maintained at 110 K on a Bruker SMART 1000 three-circle goniometer. X-ray data of **6** and **12**−**15** were obtained on a Bruker CCD diffractometer and covered more than a hemisphere of reciprocal space by a combination of three sets of exposures.

Crystal data and details of data collection for complexes **2**, **3**, **4, 6,** and **12**−**15** are provided in Table 5. The structures were solved by direct methods. Full-matrix least-squares anisotropic refinement for all non-hydrogen atoms yielded $R(F)$ and $wR(F^2)$ values as indicated in Table 5 at convergence. Hydrogen atoms were placed in idealized positions with isotropic thermal parameters fixed 1.2- or 1.5-times the value of the attached atom. Neutral atom scattering factors and anomalous scattering factors were taken from the International Tables for X-ray Crystallography Vol. C.

For complexes 2, 3, 4, 6, and 12−15, program(s) used to solve the structure: SHELXS-86 (Sheldrick[35]); program(s) used to refine the structure: SHELXL-97 (Sheldrick[36]); program(s) used for molecular graphics: SHELXTL version 5.0 (Bruker[35]); software used to prepare material for publication: SHELXTL version 5.0 (Bruker[37]).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-118334 (**2**), -168366 (**3**), -168367 (**4**), -168368 (**6**),

Synthesis and Crystal Structure of a Novel Binucleating Symmetrical μ-Bis(tetradentate) Schiff Base Ligand: Syntheses and Redox Properties of Dimanganese(III/III) Complexes

Uday Mukhopadhyay,[a] Larry R. Falvello,[b] and Debashis Ray*[a]

Keywords: Chelates / Redox chemistry / Manganese / Schiff bases / NMR spectroscopy / Cyclic voltammetry

A family of dinuclear manganese(III/III) complexes $[Mn_2^{III}(\mu\text{-}X)(\mu\text{-}L)(Y)_2](Z)_2$ (X = Cl, OMe, OEt; Y = H_2O; Z = Cl) (**6a**–**c**) of a new μ-bis(tetradentate) ligand, H_3L, derived from the stepwise Schiff base condensation of triethylenetetramine, acetylacetone, and salicylaldehyde has been reported for the first time. NMR spectral and single crystal X-ray structural characterizations of the ligand confirm the formation of a five-membered imidazolidine ring as a backbone to have a new type of doubly bridging binucleating ligand system. In methanol solutions both the $Mn^{III}Mn^{IV}/Mn^{III}Mn^{III}$ and $Mn^{II\text{-}I}Mn^{III}/Mn^{III}Mn^{II}$ couples are observable for the chloro-bridged complex with $E_{1/2}$ in the range of +0.49 to –0.13 V vs. saturated calomel electrode (SCE). The calculation of the comproportionation constant (K_c) from the $E_{1/2}$ values clearly point towards the role of the Mn–O(phenolate)–Mn core for thermodynamic stability of the parent dimanganese(III/III) complex.

Introduction

The field of binucleating ligands and their metal complexes has been receiving considerable attention in recent years.[1] These ligands can coordinate two of the same, or different, metal ions at a suitable predetermined distance to bind and activate a small molecule[2] between the metal centres. Such systems of transition metal complexes may be of interest in relating structures to interesting magnetic behaviours in homo- and hetero-dimetallic complexes,[3] and may mimic aspects of two-metal biosites in various proteins and enzymes.[4] Dinuclear complexes containing manganese centres in close proximity have been the subject of recent extensive investigations due to their involvement in a variety of important biochemical processes like catalytic disproportionation of H_2O_2 to H_2O and O_2 in Mn-catalase[5] and several others,[6] where the Mn_2^{III} unit is present as a redox core in the enzymatic cycle.[7] The Mn^{III}/Mn^{III} oxidation states are believed to participate in the catalytic cycle of Mn-catalase.[8] Furthermore, manganese model-compounds with Cl−Mn bonding have potential applications to the oxygen evolving complex (OEC) in Photosystem II (PSII).[9−13] Insight into the redox properties of Mn-catalase systems and the role of the Mn_2^{III} unit can be obtained from electrochemical studies of new synthetic dimanganese(III/III) complexes. Herein we describe a detailed synthetic account of the preparation of a novel binucleating ligand, its spectroscopic and X-ray structural characterisation, and synthesis of its dimanganese(III/III) complexes and their electron transfer properties.

Results and Discussion

The precursor hexadentate Schiff base ligand (**1**), formed from salicylaldehyde and triethylenetetramine, usually binds to a single metal ion in an octahedral (**2**) geometry, using two tridentate meridional (ONN) halves. However, incorporation of a seventh donor site (D) as a spacer bridging group inside this ligand framework, via an imidazolidine ring formation with a pendent salicylaldehyde group, resulted in a compartmentally fused μ-bis (tetradentate) ligand system (**3**). Here we report the synthesis and structural characterization of one such acyclic binucleating ligand and its binding property towards manganese(III) ions. This novel synthetic strategy for binucleating ligand systems is applicable to all meridionally spanning hexadentate ligands having an ethylenediamine backbone. A new symmetrical binucleating ligand, H_3L, having unsymmetrical compartments containing 1-methyl-3-oxobut-1-enyl end groups and its dimanganese(III/III) complexes are reported.

We have taken advantage of the known[14−19] imidazolidine ring formation reaction as shown in Scheme 1 to prepare the N_4O_3 Schiff base ligand. The ligand is potentially heptadentate, but has its chelating arms spread wide to allow bridging of two metal ions. Though free H_3L exits in the keto form (**4**) in the solid state, it can coordinate two metal ions in the enol form.[1a,20] The unsymmetrical "salenacac" (**5**)-winged ligand (**4**) could take up one metal ion in each wing and fold along the spacer backbone with the help of monoatomic (Cl or OR) exogenous bridging. Reaction of H_3L with $MnCl_2{\cdot}4H_2O$ in the absence or presence

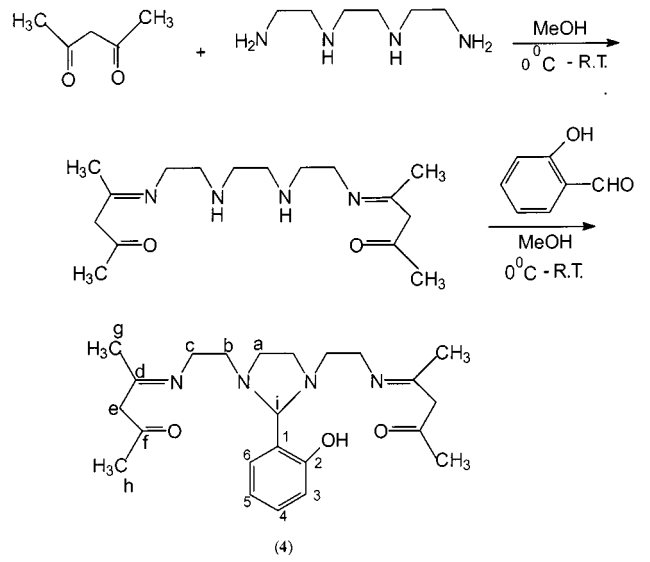
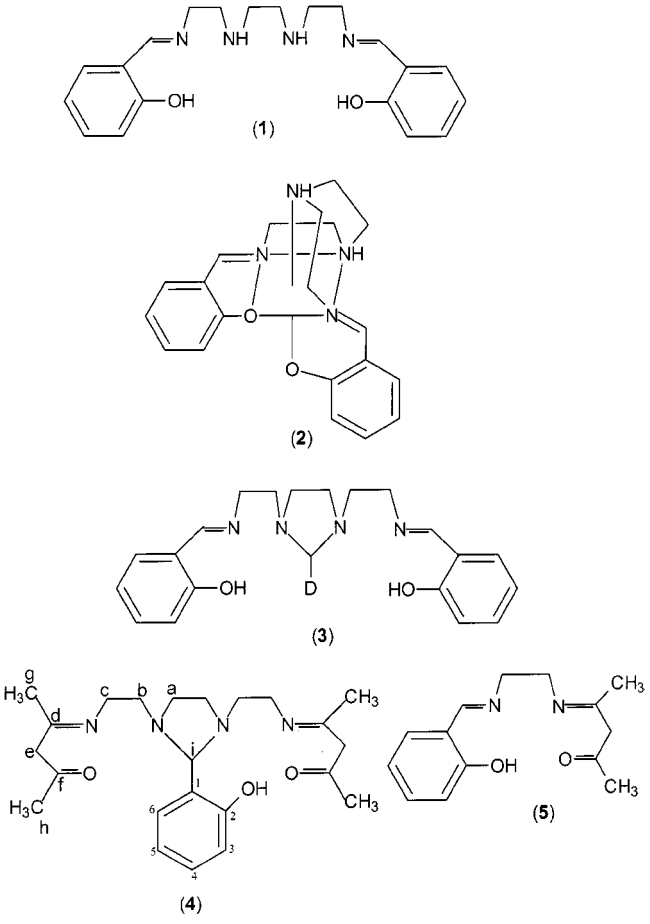
of NaOR (R = Me, Et) afforded complexes of the type $[Mn_2(\mu\text{-}L)(\mu\text{-}X)(H_2O)_2]Cl_2$ (X = Cl, OMe, OEt), where the potentially heptadentate ligand H_3L is coordinated as a μ-bis (tetradentate) N_2O_2-donor ligand with endogenous imidazolidine nitrogen and phenolic oxygen bridging.



Scheme 1



The complexation reaction in the presence of O_2 (from air) oxidizes all the Mn^{2+} centres to Mn^{3+}. During complex formation all the three protons from the phenol and enol functions are removed. The flexibility of the imidazolidine ring and the tendency of the manganese (III) centres to attain octahedral geometry appear to be the driving force for this overall non-planar arrangement of the complex. The potentially heptadentate, but functionally μ-bis (tetradentate), Schiff base ligand H_3L was prepared by a stepwise condensation reaction of trien with two equivalents of acetylacetone and salicylaldehyde in a 1:2:1 molar ratio in 78% yield (Scheme 1). The five-membered imidazolidine ring was formed at the ethylenediamine backbone with salicylaldehyde. The imidazolidine bridging-arm was therefore unique (compared to the other two ketoimine arms), as is clearly shown in the ^1H NMR spectra. ^1H and ^{13}C NMR spectral assignments for the H_3L were consistent with the proposed formulations. The infrared spectrum of the ligand showed peaks around 1605 cm^{-1}, which is characteristic of imine C=N functions. The phenolic OH resonance was observed as a broad signal at about δ = 10.7. This downfield signal can be explained by the intermolecular hydrogen bond of the phenolic OH with solvent ($CDCl_3$), water, or water of crystallization in the solid state (shown in the X-ray structure determination, vide infra). No enolic OH resonance was observed within the 20 ppm range, confirming the diketone form of H_3L in solution.

The molecular structure of H_3L was determined by X-ray crystallography. A view of the dinucleating ligand is shown in Figure 1, and selected bond lengths and angles are listed in Table 1. The ligand molecule is rendered quite rigid by the formation of a five-membered imidazolidine ring and by the presence of three very weak intermolecular hydrogen bonds with a water of crystallization [O(2)−H(2)···O(11) = 2.647 Å; O(11)−H(11A)···O(1) = 2.730 Å; O(11)−H(11B)···O(3) = 2.739 Å]. The water molecule in $H_3L{\cdot}H_2O$ sits comfortably, with the help of these hydrogen-bonding interactions, within the intermolecular hydrophilic pocket created by the keto and phenol functionalities of the ligand. Both N(1)−C(6)−C(7)−N(2) and N(3)−C(17)−C(18)−N(4) adopt gauche conformations [torsion angles: N(1)−C(6)−C(7)−N(2) = 57.5 (6) °; N(3)−C(17)−C(18)−N(4) = −55.5 (6) °]. The whole ligand structure resembles a big Y. Among the three intermolecular hydrogen bonds the bond length between phenolic hydrogen [H(2)] on one ligand molecule and oxygen [O(11)] of the water molecule is lowest 2.65 Å, and results in a highly ordered packing (Figure 2).

The molecular structure clearly shows two tetradentate non-planar compartments suitable for binding two of the same, or different, metal ions. The phenoxy hydrogen of the middle phenolate arm is not intramolecularly hydrogen bonded to one of the imidazolidine nitrogen as is the case with the H_3api ligand.[19] The observed >C=O distances of terminal acetylacetone arms are quite normal[21] for the purely keto tautomeric form in the crystalline state. The similar C−C distances within keto-imine framework also support this observation. The C=N distances also corre-

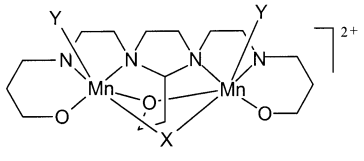
spond to a formal double bond.[19] The C−C and C−N distances within the imidazolidine ring are in the1.457−1.496 Å range.

Homodinuclear manganese(III) complexes with the formulation $[Mn_2^{III}(\mu\text{-}X)(\mu\text{-}L)(Y)_2](Z)_2$ (X = Cl, OMe, OEt; Y = H_2O; Z = Cl) (**6**) were prepared from reactions of Mn^{2+} with the ligand H_3L in presence and absence of bases (alkoxide), following oxidation by air. The homodinuclear complexes contain two manganese(III) ions, each coordinated by the N_2O_2 donor set of one half of the ligand. The phenolate O atom from the middle arm of the ligand acts as an endogenous bridge between the two metal centres. The exogenous alkoxide bridge and terminal Y groups complete the coordination sphere and the bi-octahedral structure. The binucleating ligand provides four donor points around each manganese(III) centre. We have so far been unable to synthesize any mononuclear complex of manganese(III) using H_3L. Those complexes could have been used as controls in comparing the change in spectral and magnetic behaviour through dinuclear complex formation. Single-crystal X-ray structure determination of a heterodinuclear assembly of copper(II)-zinc(II) inside the compartments of a similar type of ligand recently[22] established distorted square-pyramidal geometries around each metal centre. Microanalysis data for complexes **6a**−**c** (See Exp. Sect.) confirm their composition. The complexes are highly soluble in polar solvents such as methanol, dimethylformamide, and dimethyl sulfoxide, and are moderately soluble in non-polar solvents like dichloromethane and tetrahydrofuran.

The IR spectra of the complexes show strong C=N stretching frequencies of the imine functions at around 1612 cm^{-1}. The complexes have characteristic μ_2-bridging phenolic ν_{C-O} vibrations in the range 1509−1536 cm^{-1}. The terminal C−O and alkoxide bridging C−O stretching frequencies are observed at around 1295 and 1145 cm^{-1} respectively. The electronic spectra of the intimate dimanganese(III/III) complexes in methanol solutions show several intense absorptions in the near UV region (Table 2, Figure 3).



(**6**)

a : X = Cl

b : X = OMe

c : X = OEt

The moderately intense UV band near 360 nm is typical for the 2-hydroxyphenylimino chromophore.[23] The bands near 300 nm for the present complexes are due to the overlap of the azomethine transition with the charge-transfer band from bridging phenolic oxygen to the d-orbital of Mn^{III}. Absence of any inter-valence band in the 1170 nm region eliminates the possibility for a $Mn^{III}Mn^{II}$ species.[24]

In methanol solutions the complexes behave as 1:2 electrolytes (conductivity values, 180−210 $ohm^{-1}cm^2$ mol^{-1}).The complexes are paramagnetic and correspond to the trivalent states of the metals (high-spin d^4, S = 2) in these complexes. Magnetic studies of powdered samples of

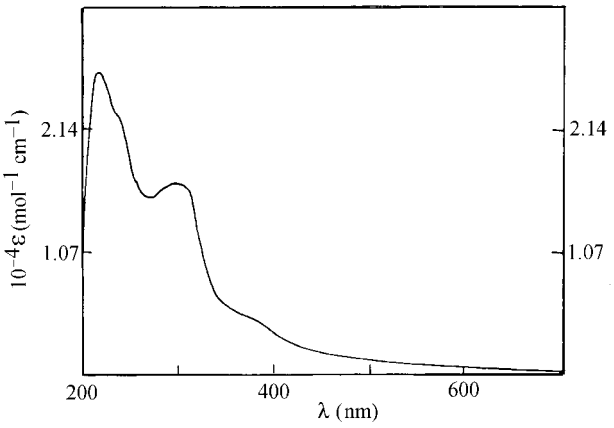

Figure 3. Electronic spectrum of $[Mn_2(\mu\text{-}L)(\mu\text{-}OEt)(H_2O)_2]Cl_2$ (**6c**) in DMF at 298 K

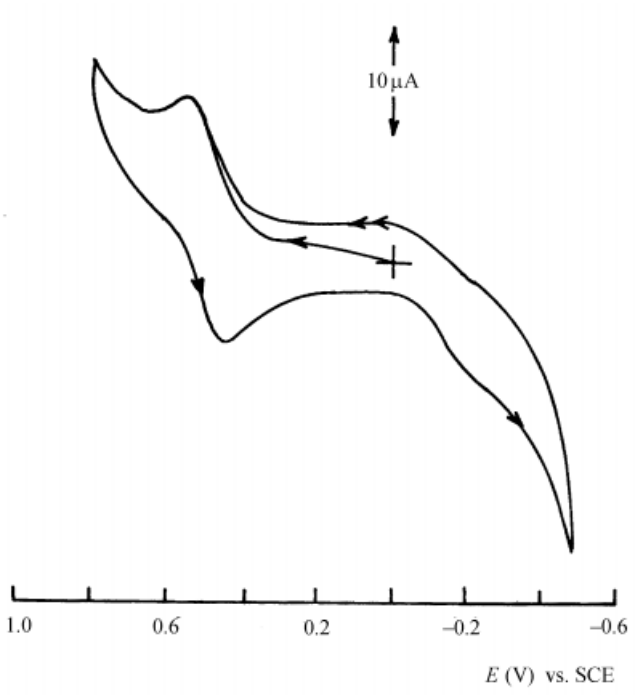

Figure 4. Cyclic voltammogram (scan rate 50 mVs^{-1}) of 10^{-3} M solutions of $[Mn_2(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]Cl_2$ (**6a**) in MeOH at a Pt electrode at 298 K

the complexes were carried out at room temperature using a Gouy balance. The room temperature magnetic moments (μ_{eff}) of the complexes were in the range of 4.24−4.39 μ_B per Mn at 298 K (total μ_{eff} 5.99−6.21 μ_B). The dependence of the room temperature magnetic moments on exogenous bridging is in the order Cl > OMe > OEt, clearly indicating the role of the single exogenous bridging group in varying the magnetic interactions.

The electron-transfer properties of complexes **6a**−**c** were studied in aqueous and methanol solutions by cyclic voltammetry (CV) using a platinum working-electrode. The complexes are electroactive with respect to the metal centres and exhibited two redox processes in the potential range +1.0 V *versus* a saturated calomel electrode (SCE) (tetraethylammonium perchlorate as supporting electrolyte, at 298 K). The chloro-bridged complex showed one oxidative and one reductive response on the positive and negative side of SCE, respectively (Figure 4).

The cathodic and anodic peak heights(i_{pc} and i_{pa}) are equal, and vary as the square root of the scan rate; E_{pc} and E_{pa} are virtually independent of the scan rate. The measured oxidation and reduction potentials were lower in aqueous solutions than in non-aqueous solutions. Both the processes are assumed to be metal-centred. The first quasi-reversible response on the positive side of SCE is due to the one-electron oxidation of Equation (1).

$$[Mn^{III}Mn^{IV}(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]^{3+} \rightleftarrows [Mn^{III}Mn^{III}(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]^{2+} \quad (1)$$

On further scan reversal on the negative side, the one-electron reductive couple in Equation (2) was observed.

$$[Mn^{III}Mn^{III}(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]^{2+} \rightleftarrows [Mn^{III}Mn^{II}(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]^{+} \quad (2)$$

Constant-potential coulometric- and cyclic-voltammetric current height (i_{pa}) data suggest the one-electron nature of these couples. From the separation of $E_{1/2}$ (oxidative response) and $E_{1/2}$ (reductive response) values for $[Mn_2(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]Cl_2$, the comproportionation constant (K_C at 298 K) of the reaction in Equation (3) was calculated to be 5.77×10^{10}, indicating that the Mn_2^{III} complex is considerably stabilized with respect to the $Mn^{III}Mn^{IV}$ and $Mn^{III}Mn^{II}$ species.

$$[Mn^{III}Mn^{IV}(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]^{3+} + [Mn^{III}Mn^{II}(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]^{+} \rightleftharpoons 2\,[Mn^{III}Mn^{III}(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]^{2+} \quad (3)$$

Thus, the cyclic voltammetric study gives an idea of the stability of the parent dimanganese(III/III) complexes with respect to disproportionation. A similar behaviour was reported for other binuclear manganese(III/III) complexes.[25] The reduction potential for $Mn_2^{III/IV}$ species is low compared to the other fully exogenous $(\mu\text{-O})(\mu\text{-OAc})_2$ triply bridged complexes.[26,27] The mixed-valence complexes are stable on the cyclic-voltammetric time scale. A reduction potential in acetonitrile of $E_{1/2} \approx +1.05$ V was measured for a functional model of Mn catalase possessing an alkoxo-bridged core structure.[28] The results described in this section indicate that the $Mn^{II}Mn^{III}$, Mn_2^{III} and $Mn^{III}Mn^{IV}$ oxidation states are accessible for complex **6a** in methanol.

Variation of the terminal arms of the ligand and the single exogenous bridging group to get different homo- and heterodinuclear complexes is currently under investigation. To suppress the deviation in redox potentials for successive electron transfers, charge neutralization within the complex, perhaps by proton release (from coordinated H_2O) or uptake of Cl^- (replacement of coordinated H_2O), might provide the requisite adjustment in redox potentials. Studies in that direction are also in progress.

Conclusion

It has been shown that the nitrogen-oxygen donor Schiff base ligand H_3L, with imidazolidine bridging groups, can be easily synthesized in high yields in a step-wise condensation reaction from the hexadentate precursor ligand with ethylenediamine back-bone. The ligand forms an interesting class of dimanganese complexes, and can serve as multi-electron reservoir showing stepwise electron transfer behaviour. The stability of the dimanganese(III/III) complexes of different but similar types of parent ligand such as H_3L could be compared with respect to the electrochemically generated $Mn^{III}Mn^{IV}$ and $Mn^{III}Mn^{II}$ species.

Experimental Section

Physical Measurements: Microanalyses (C, H N) were performed using a Perkin−Elmer 240 C elemental analyser. IR spectra were obtained on a Perkin−Elmer 883 spectrometer (200−4000 cm^{-1}) prepared as KBr pellets. Electronic spectra were recorded on a Shimadzu UV/Vis/NIR 3100 (190−3200 nm) (MeOH, 1 cm quartz cell) spectrometer. Magnetic susceptibilities were measured using a home built Gouy balance fitted with a polytronic DC power supply. Diamagnetic corrections for ligand susceptibilities were made using Pascal's constants. ^1H and ^{13}C NMR spectra were obtained on a Bruker AC 200 NMR spectrometer using TMS as the internal standard. Electrochemical measurements were made using a PAR model 173 potentiostat/galvanostat, 175 universal programmer, 178 electrometer, and 377-cell system. A planar Beckaman 39273 platinum-disk working-electrode, a platinum-wire auxiliary-electrode, and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. A digital series 2000 Omni Graphic recorder was used to trace the voltammograms. Electrochemical measurements were made under a dinitrogen atmosphere. All chemical data were collected at 298 K and are uncorrected for junction potentials. Solution electrical conductivity was measured using a Unitech type UI31C digital conductivity meter with a solute concentration of about 10^{-3}.

Materials: Triethylenetetramine (trien) was obtained from S.D. Fine Chem, India. Salicylaldehyde and 2,4-pentanedione were purchased from SRL, India and S.D. Fine Chem, India, respectively. All other chemicals and solvents were reagent grade materials and were used as received without further purification. Purification of methanol and preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work was performed as reported in the literature.[29]

1,3-Bis[3-aza-3-(1-methyl-3-oxobut-1-enyl)-prop-3-en-1-yl]-2-(2-hydroxyphenyl)-1,3-imidazolidine (H_3L): A solution of trien (7.00 g, 47.8 mmol) in methanol (50 mL) was added to an ice-cold solution of acetylacetone (9.57 g, 95.6 mmol) in methanol (100 mL). The resulting pale-yellow solution was stirred for ca. 15 min. at 0 °C. The hexadentate precursor diketone is a yellow oily product and was not isolated for the synthesis of **4**. In the next step, a solution of salicylaldehyde (5.84 g, 47.8 mmol) in methanol (50 mL) was added to the previous solution of diketone. The yellow solution was then stirred, initially at 0 °C for 15 min., and finally at ambient temperature (30 °C) for 23 h. The solution was then evaporated to dryness to give a yellow crystalline compound. The product was isolated by filtration, washed with water and hexane, and finally dried in vacuo over fused $CaCl_2$ for a total yield of 15.46 g (78%), m.p. 85−87 °C. − $C_{23}H_{34}N_4O_3$ (414.55): calcd. C 66.64, H 8.27, N 13.52; found C 66.52, H 8.16, N 13.57. − MS (EI): *m/z* = 414 [M^+]. − IR (KBr): $\tilde{\nu}$ = 1605 cm^{-1} (vs, $\nu_{C=N}$), 1546, 1443 (s, $\nu_{C=C}$). − ^1H NMR (200 MHz, $CDCl_3$): δ = 1.76 (s, 6 H, g), 2.65 (m, 4 H, a), 2.77 (m, 8 H, b, c), 6.79 (m, 2 H, 3,5), 10.73(H, b, phenolic OH). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 18.55 (g), 28.65 (h), 42.17 (a), 50.95 (b), 52.04 (c), 89.33 (i), 95.62 (e), 116.87 (3), 118.82 (5), 120.34 (1), 130.35 (6), 130.80 (4), 158.03 (2), 162.70 (d), 194.99 (f).

Preparation of the Dimanganese(III/III) Complexes: All manipulations were carried out under aerobic conditions. Since many of the syntheses are similar, a detailed procedure is given only for a representative example.

$[Mn_2(\mu\text{-}L)(\mu\text{-}Cl)(H_2O)_2]Cl_2$: Solid $MnCl_2{\cdot}4H_2O$ (0.477 g, 2.41 mmol) was added in portions during 15 min. to a solution of H_3L (0.5 g, 1.206 mmol) in methanol (20 mL). The resulting brown solution was stirred with a magnetic stirrer in air for 1 h at ambient temperature for complete oxidation of all Mn^{2+} centres to Mn^{3+}. The solution was then evaporated to dryness to give a brown gummy mass. A solid brown powder was obtained from this mass after trituration with hexane, collection by filtration, washing thoroughly with a little cold water to remove the produced NaCl, and washing with hexane. The compound was finally dried in vacuo over P_4O_{10}. Yield 0.714 g (89%). − $C_{23}H_{35}Cl_3Mn_2N_4O_5$ (663.79): calcd. C 41.62, H 5.31, N 8.44, Mn 16.55; found C 41.55, H 5.28, N 8.50, Mn 16.59. − IR (KBr): $\tilde{\nu}$ = 3394 cm^{-1} (b), 1612 (vs), 1536 (s), 1441 (s), 1386 (s), 1298 (s).

$[Mn_2(\mu\text{-}L)(\mu\text{-}OMe)(H_2O)_2]Cl_2$: Solid $MnCl_2{\cdot}4H_2O$ (0.477 g, 2.41 mmol) was added in portions during 15 min. to a solution of H_3L (0.5 g, 1.206 mmol) and NaOMe (0.07 g, 1.30 mmol) in methanol (30 mL). The resulting brown solution was stirred with a magnetic stirrer in air for 1 h at ambient temperature. The solution was then evaporated to dryness to yield a brown gummy mass. A solid brown powder was obtained after trituration with hexane, collection by filtration and washing thoroughly with hexane. The compound was finally dried in vacuo over P_4O_{10}. Yield 0.692 g (87%). − $C_{24}H_{38}Cl_2Mn_2N_4O_6$ (659.37): calcd. C 43.72, H 5.81, N 8.49, Mn 16.66; found C 43.66, H 5.86, N 8.52, Mn 16.72. − IR (KBr): $\tilde{\nu}$ = 3400 cm^{-1} (b), 1612 (vs), 1509 (s), 1440 (s), 1385 (s), 1296 (s).

$[Mn_2(\mu\text{-}L)(\mu\text{-}OEt)(H_2O)_2]Cl_2$: This compound was prepared following the above procedure, except that ethanol was used as solvent and stirring was continued for 1 h. − $C_{25}H_{40}Cl_2Mn_2N_4O_6$ (673.39): calcd. C 44.59, H 5.99, N 8.32, Mn 16.32; found C 44.51, H 6.01, N 8.37, Mn 16.41. − IR (KBr): $\tilde{\nu}$ = 3394 cm^{-1} (b), 1610 (vs), 1510 (s), 1438 (s), 1390 (s), 1296 (s).

X-ray Crystallography: Orange prismatic crystals of ligand **1** were obtained by slow diffusion of hexane into a dichloromethane solution of H_3L. Selected crystal data and data collection parameters are given in Table 3. The unit cell parameters were determined by the usual procedure of random searching followed by indexing. The plate-like yellow crystal selected for data collection was mounted at the end of a quartz fibre and covered with a thin layer of epoxy resin. Data were collected on an Enraf−Nonius CAD-4 diffractometer with PC control,[30] using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) by ω scans within the angular range 4.0−45.0°. The structure was solved by direct methods[31] in the monoclinic space group $P2_1/c$, which is the only space group in either the orthorhombic or monoclinic system consistent with the systematic absences found in the data. All non-hydrogen atoms were refined anisotropically. All data were used in the least-squares calculations[32] and the structure was refined to F_o^2. There was no significant residual electron density in a final difference Fourier map. The detailed experimental write-up and comments on the structure determination are given as Supplementary Material.

Fluorine Route Synthesis of Montmorillonites Containing Mg or Zn and Characterization by XRD, Thermal Analysis, MAS NMR, and EXAFS Spectroscopy

Marc Reinholdt,*[a,b] Jocelyne Miehé-Brendlé,[a] Luc Delmotte,[a] Marie-Hélène Tuilier,[b] Ronan le Dred,[a] Robert Cortès,[c] and Anne-Marie Flank[c]

Keywords: Montmorillonite / Clays / Synthesis / Fluorine / Solid-state NMR / EXAFS spectroscopy

EXAFS spectroscopy, combined with X-ray powder diffraction, chemical and thermal analysis, scanning electronic microscopy, ^{29}Si, ^{27}Al, and ^{19}F MAS NMR spectroscopy, are used in the structural analysis of montmorillonites, synthesised in an acidic fluoride medium. Hydrothermal synthesis performed under mild conditions (493 K, autogenous pressure) enables the formation of montmorillonite clays, containing Al and Zn or Mg in the octahedral sheet. It is shown that montmorillonites can only be synthesized in a narrow range of compositions. An accurate value of the Al for Si substitution rate in the tetrahedral sheet is determined by using ^{27}Al MAS NMR spectroscopy performed under definite conditions. Some interatomic distances are determined by EXAFS spectroscopy (R_{Mg-O} = 2.11 Å, R_{Zn-O} = 2.08 Å, R_{Zn-Al} = 2.98 Å, R_{Zn-Zn} = 3.11 Å) which reveals strong local distortions in the octahedral sheet with respect to the ideal montmorillonite structure. Lengthening of the out-of-plane Zn–Si(Al) distances also shows the swelling of the whole layer in the neighbourhood of Zn. Moreover, the combination of EXAFS and ^{19}F MAS NMR spectroscopic data reveals a clustering of the divalent elements of the octahedral sheet, which is related to a possible local trioctahedral character of these materials.

Introduction

Smectites present in soils and sediments are one of the largest and most important classes of the phyllosilicate clay minerals group. Their ability to swell upon contact with water and other solvents is extensively used in two fields of application. The first one is related to the properties of adsorption (use in the selective adsorption of toxic compounds from water, detergents, organic chemistry, etc.).[1] The other one concerns pillared clays which are commonly used in the field of catalysis.[2,3] The 2:1 structure of smectites consists of two sheets of distorted SiO_4 tetrahedra connected by a sheet of $Al(M)(OH)_2O_4$ octahedra, M being a divalent element (Figure 1a). The silicon and metal atoms occupy the centre of the tetrahedra or the octahedra, with the oxygen atoms and hydroxy groups (OH) located at the corners. Smectites are divided into two groups: the dioctahedral smectites for which the octahedral sheet contains two Al(M) elements in the centre of two out of three octahedra, the third one being vacant; and the trioctahedral smectites which contain only divalent elements in the octahedral sheet without vacancies. Montmorillonite, which belongs to the former group, has been extensively studied. Among the dioctahedral smectites, the distinctive feature of montmorillonite is that transition elements are included in the octahedral sheet whereas Al can be split into the tetrahedral (Al_{IV}) and octahedral (Al_{VI}) sheets. The Al atoms are partially replaced by either Mg or Fe atoms, thereby creating a charge deficiency within the unit structure. This results in a small negative charge on the basal plane of the silica tetrahedra which is balanced by exchangeable cations present in the interlayer spacing. In natural montmorillonites these cations are usually calcium or sodium according to the weather agent associated with the formation of the mineral. The crystal structure of montmorillonite has a *C*2*mm* symmetry.

The ideal formula per half a unit cell, without tetrahedral substitution, is $R_{2x}(Al_{2(1-x)}M_{2x}\ \square)Si_4O_{10}(OH)_2$, where R represents the interlayer cations and x the layer charge ranging from 0.05 to 0.54. Natural montmorillonites usually present isomorphic substitutions in both tetrahedral and octahedral layers. Moreover, depending on the deposits, various structural compositions and particle sizes can be found. These drawbacks, combined with the presence of impurities, limit their use in some applications. One way to avoid these disadvantages is to synthesize such compounds; this enables the control of the chemical composition by fine tuning the preparative methods. Many studies have been performed in this field, as recently mentioned by Kloprogge et al., but only four papers mentioned the synthesis of pure montmorillonite.[4] The first one, by Otsubo and Kato, described Zn for Al partially substituted montmorillonite in the $ZnO-Al_2O_3-SiO_2$ system,[5] the Zn and Al atoms being located in the octahedral sheet and the Si atoms in the tetrahedral sheet. The clay has been prepared under hydrothermal conditions in an alkali medium at temperatures

ranging from 423 to 573 K, over 5 to 20 h. The second synthesis, described by Harder, was carried out on the basis of the precipitation of hydroxides, in the $MgO-Al_2O_3-SiO_2$ system in an alkali to neutral medium at 276 and 293 K.[6] The same system was studied by Nakazawa et al., but syntheses were performed on magnesium aluminosilicate glass under a hydrothermal pressure of 100 Mpa.[7] A more recent work was also performed in an alkali medium, by Nagase et al., in the $MgO-Fe_2O_3-SiO_2$ system under hydrothermal conditions at 373 and 473 K for 24 h.[8] Samples were characterised by X-ray diffraction (XRD), thermal and chemical analyses, electronic microscopy, or X-ray photoelectron spectroscopy (XPS). None of these studies have brought any information about the distribution of the elements in the structure and their local environment.

The present paper deals with the synthesis of montmorillonites in the $MgO-Al_2O_3-SiO_2$ and $ZnO-Al_2O_3-SiO_2$ systems. Starting from the previously mentioned ideal formula per half a unit cell, we introduced an increasing amount of divalent element (x ranging from 0 to 1) in the hydrogel in order to establish the best conditions to obtain montmorillonite. Samples were labelled Mg($10 \times x$) or Zn($10 \times x$) (Table 1). Syntheses were performed in acidic and fluoride media. Similarly, mild conditions were previously used for the preparation of dioctahedral smectites, such as beidellite,[9,10] and trioctahedral smectites, such as stevensite.[11] In the present work, samples were characterised by XRD, thermal, and chemical analyses. Some of them were selected for further structural investigation by solid-state nuclear magnetic resonance spectroscopy (NMR) and X-ray absorption spectroscopy (XAS), in order to study the local environment of the metallic elements. An explanation of the process of formation of montmorillonite is suggested.

Table 1. Labels of the samples

Sample[a]	x	Theoretical formula[b]
M01	0.1	$Na_{0.2}(Al_{1.8}M_{0.2}\,\square)Si_4O_{10}(OH)_2$
M02	0.2	$Na_{0.4}(Al_{1.6}M_{0.4}\,\square)Si_4O_{10}(OH)_2$
M03	0.3	$Na_{0.6}(Al_{1.4}M_{0.6}\,\square)Si_4O_{10}(OH)_2$

[a] M represents Mg or Zn. – [b] □ Represents the vacancy.

Results

X-ray Powder Diffraction

XRD patterns of the two series of samples are characteristic of clays (Figure 2). Each diffractogram exhibits *hkl* bands at 4.45–4.48 Å (020, 110), 2.52–2.58 Å (130, 200) and 1.67–1.70 Å (210), which are typical features of smectites.[12] One or two peaks are also observed between 1.48 and 1.53 Å; they correspond to the (060) and (330) reflections. Their relative intensity is related to the dioctahedral (peak at about 1.49 Å) or trioctahedral (peak at about 1.52 Å) nature of the product, i.e. a dioctahedral compound has vacancies in the octahedral sheet and a trioctahedral one has none. The position of the (001) peak gives information about the basal spacing (d_{001}). The basal spacing is equal to the sum of the interlayer spacing and the thickness of the silicate layer, which is about 9.6 Å for a 2:1 phyllosilicate. The usual value of d_{001} is about 15 Å for natural montmorillonites under a relative humidity of $P/P_0 = 80\%$ (P represents the saturated vapour pressure over the sample at 298 K and P_0 the saturated aqueous vapour pressure at 298 K).

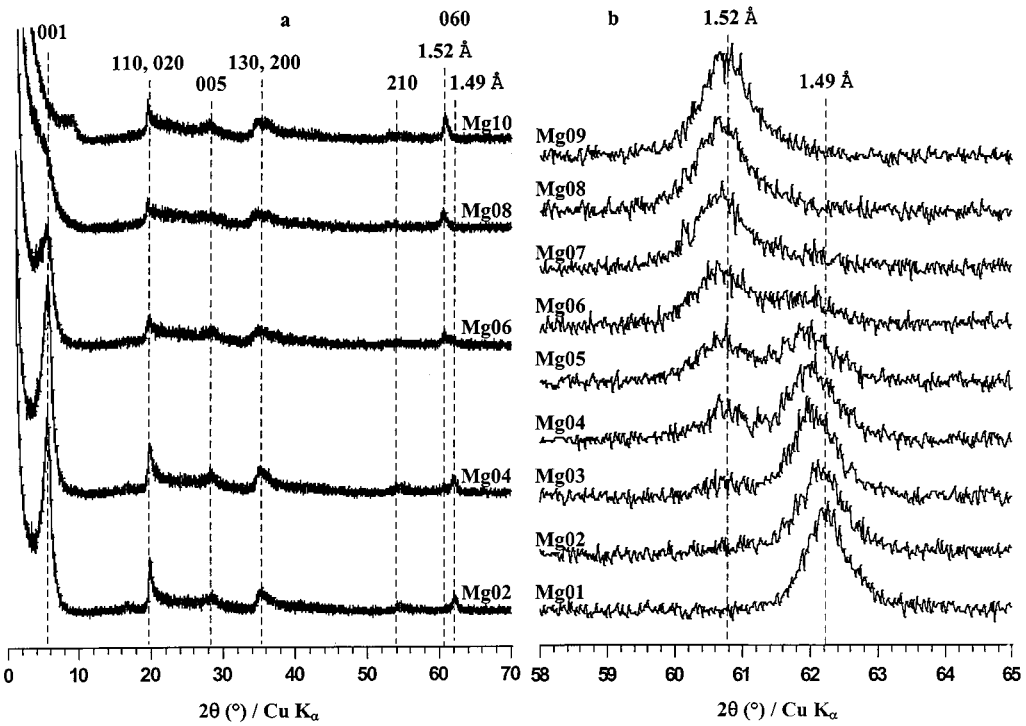

Figure 2. Comparison of the XRD patterns of synthetic clays containing various amount of Mg (P/P_0 = 80%) (a) and evolution of the position of the (060) peak with this amount (b)

A sample which has $x = 0.0$ is unambiguously identified as kaolinite (DRX and TGA-DTA). The Mg01 sample is a dioctahedral clay (d_{060} = 1.49±0.01 Å, Table 2) and the Mg02 sample could have a small trioctahedral component (see next section). Samples Mg03 to Mg06 are mixtures of di- and trioctahedral compounds. Their XRD patterns present two (060) bands, one at 1.49±0.01 Å and a second at 1.52±0.01 Å. For samples Mg07 to Mg09, d_{060} is equal to 1.52±0.01 Å. This value corresponds to trioctahedral compounds. The Mg10 sample is identified as a talc-type clay (probably stevensite) which is trioctahedral, with silicon in the tetrahedral sheet and magnesium in the octahedral sheet. The (001) peak is observed for each sample, except Mg08 and Mg09. This is characteristic of a higher disorder and a lower crystallinity of the samples. The Zn01 sample has the position of the (060) peak corresponding to a dioctahedral compound (d_{060} = 1.49±0.01 Å, Table 2). The Zn02 sample could have a little trioctahedral component (see next section). Similarly to the Mg series, the Zn03 to Zn06 samples are mixtures of di- and trioctahedral clays and the Zn07 to Zn09 samples have the structure of trioctahedral compounds (d_{060} = 1.52±0.01 Å). Each diffractogram of Zn(10 × x) samples exhibits a (001) peak, contrary to some of the Mg(10 × x) samples. The Zn10 sample is identified as a mixture of an amorphous phase and willemite (Zn_2SiO_4). The investigation of samples containing a mixture of clays was not carried out beyond this preliminary characterisation. Trioctahedral products are also dismissed because of the presence of amorphous silica, observed by NMR spectroscopy (see the paragraph about solid-state NMR spectroscopy). Consequently, only the Mg01, Mg02, Zn01, and Zn02 samples will be further characterised. Their diffractograms exhibit the characteristic *hk* bands of montmorillonite.[12] The position of the (060) peak indicates the dioctahedral nature of the sample, i.e. the presence of vacancies in the octahedral sheet, except for the Mg02 and Zn02 samples, which can have a weak trioctahedral component at 1.52 Å (Figures 2 and 3 and discussion section). As a comparison, Figure 3 (inset) shows the diffractogram of a natural clay from Camp Berteau which contains quartz. The study of the (001) peak position was performed on samples which were previously placed under a controlled humidity (P/P_0 = 80%). The d_{001} values are listed in Table 2. These values are in good agreement with those indexed in the literature for natural Na-exchanged montmorillonites (d_{001} = 15−16 Å).[13−15] The (001) peaks are more symmetrical and intense than they are for samples containing Mg.

Scanning Electronic Microscopy

The micrographs of the Mg01 sample are presented in Figure 4. The picture shows crumpled platelets that look like gypsum flower. More compact aggregates are also observed. Natural montmorillonites present this typical morphology.[16−18] The samples of Mg01, Zn01, and Zn02 have a similar morphology.

Table 2. X-ray diffraction, and thermal analysis data of samples Mg01, Mg02, Zn01, and Zn02

Sample	XRD		TGA-DTA[a]		
	d_{001} [A]	d_{060} [A]	Dehydration [K]	Dehydroxylation [K] First peak	Second peak
Mg01	16.5	1.49	350	750	930
Mg02	16.1	1.49	360	–	930
Zn01	17.4	1.49	360	750	950
Zn02	16.4	1.49	365	730	940

[a] Temperatures are taken at the inflexion point of the weight losses on the TGA curves.

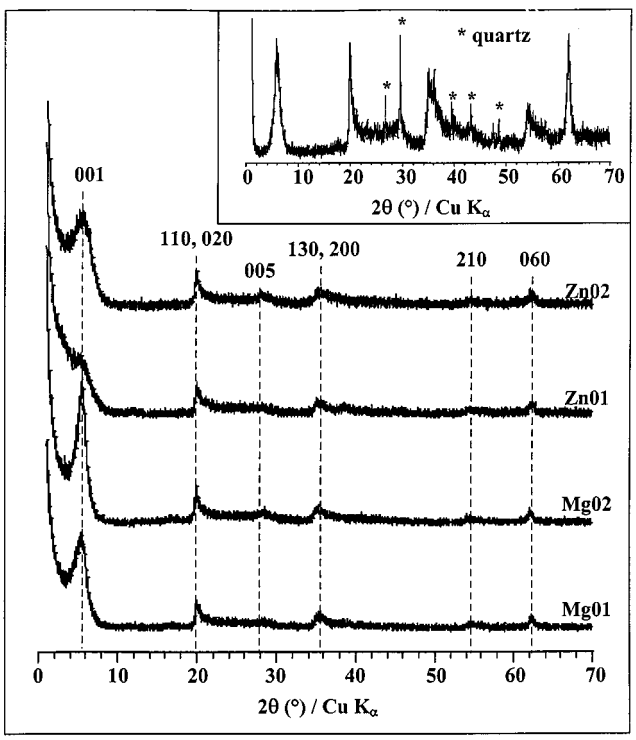

Figure 3. XRD patterns of synthetic montmorillonites containing Mg or Zn (P/P_0 = 80%); inset: diffractogram of natural montmorillonite from Camp Berteau

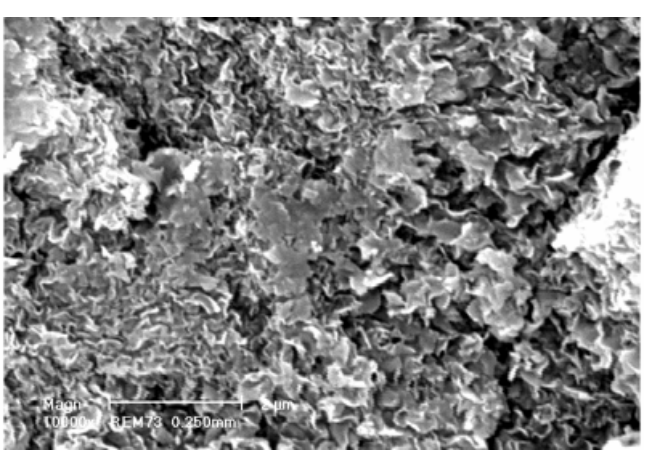

Figure 4. SEM micrograph of Zn02 sample

TGA-DTA

The curves of weight loss and heat flow versus temperature are shown in Figure 5. Each sample exhibits a main peak at 370 K corresponding to dehydration. Moreover, the Mg01, Zn01, and Zn02 samples exhibit two peaks, at about 720−760 K and 920−960 K, which are attributed to the dehydroxylation. The peaks of dehydroxylation are observed at 750 and 930 K for the Mg01 sample, 750 and 950 K for the Zn01 sample, and 730 and 930 K for the Zn02 sample (Figure 5). In the case of the Mg02 sample, only one dehydroxylation peak is observed at 930 K. The peak ranging from 920 to 960 K was already reported in the literature.[19−23] It is characteristic of natural montmorillonites. The peak ranging from 720 to 760 K was observed by Cuadros et al.[20] on DTA curves of samples coming from the deposit of "Los Trancos" in Almeria (SE Spain) and by Frost et al.[23] on ferruginous montmorillonite SWa-1 (Clay Mineral Society standard).

Chemical Analysis

The results of elemental analyses are listed in Table 3. Na and divalent element contents are higher, whereas the Al content is lower, in samples of Mg02 and Zn02 than in the Mg01 and Zn01 samples. The content of divalent element has roughly doubled in Mg02 (Zn02) with respect to Mg01 (Zn01). This is in good agreement with the theoretical compositions. It should be noted that there is a small amount of fluorine in each sample, so this element could only be considered as a local probe. The half unit cell formula was calculated for the four selected samples (last column of Table 3) on the basis of twenty two negative charges of the layer. However, chemical analysis does not enable one to determine whether Al is only in the octahedral sheet or if there is some Al in the tetrahedral sheet.

Solid-State NMR Spectroscopy

^{29}Si NMR spectroscopy, using the magic-angle spinning technique (^{29}Si MAS NMR), gives information on the Al-for-Si substitution in the tetrahedral sheet. In the case of trioctahedral products, the presence of a small quantity of amorphous silica was revealed by ^{29}Si MAS NMR spectroscopy. The ^{29}Si MAS NMR spectra of Mg01, Mg02, Zn01, and Zn02 samples (Figure 6) show signals corresponding to Si(nAl) (n ranges from 0 to 3) environments where n represents the number of tetrahedral Al atoms that are next-nearest neighbours of Si. The main peak, which appears at a chemical shift (δ) of $\delta \approx -93$ is assigned to the Si(0Al) environment, i.e. Si surrounded by three Si in the tetrahedral sheet.[24,25] The shoulder observed at $\delta \approx -90$ is attributed to the Si(1Al) environment, i.e. Si surrounded by one Al and two Si in the tetrahedral sheet. The presence of these signals indicates that Al is substituted for Si in the tetrahedral sheet, which could not be observed by chemical analysis. The shielding of the Si(0Al) site increases with the amount of Mg. The same behaviour is observed for the Zn01 and Zn02 samples but with an enhanced effect. These phenomena can be correlated to the increase of the average

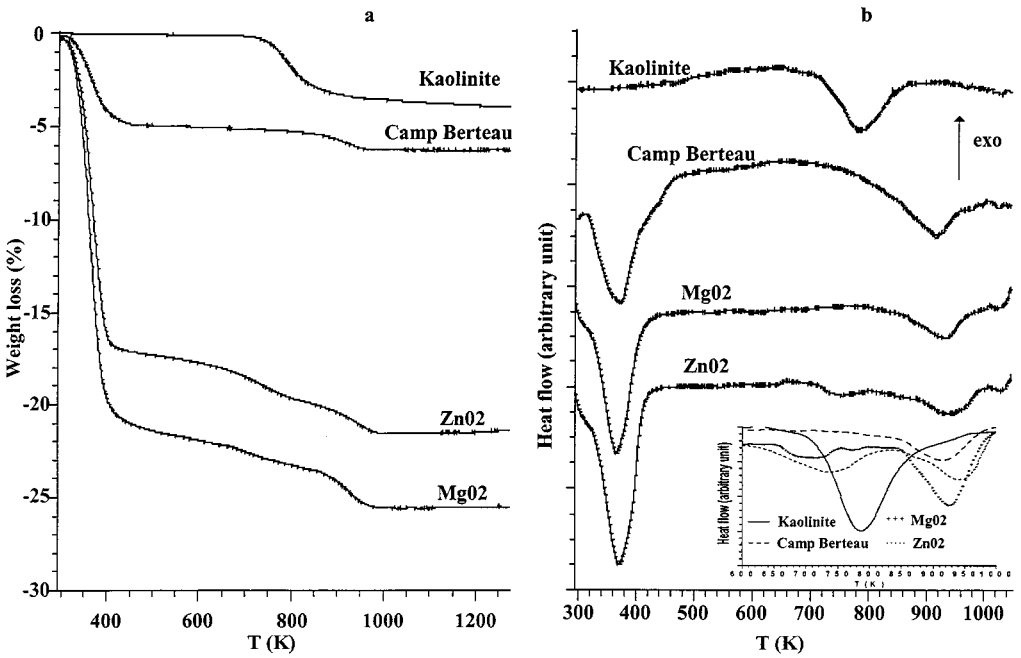

Figure 5. TG patterns of natural and synthetic clays (a) and ATD curves of the same samples (b); inset: comparison of the dehydroxylation peaks of each sample between 600 to 1000 K

Table 3. Half a unit cell formula calculated from chemical analysis for samples Mg01, Mg02, Zn01, and Zn02

Sample	Elemental analyses (mass-%)								Half a unit cell formula[a]
	Na_2O	MgO	ZnO	Al_2O_3	SiO_2	F	H_2O	sum	
Mg01	2.03	1.63	–	22.53	55.54	0.23	17.90	99.86	$Na_{0.28}[Al_{1.81}Mg_{0.18}\,\square_{1.01}]$-$[Si_{3.93}Al_{0.07}]O_{10}(OH_{1.95}F_{0.05})\cdot 3.3H_2O$
Mg02	2.34	3.40	–	19.02	55.00	0.20	19.95	99.91	$Na_{0.34}[Al_{1.64}Mg_{0.37}\,\square_{0.99}]$-$[Si_{4.00}]O_{10}(OH_{1.95}F_{0.05})\cdot 4.0H_2O$
Zn01	1.36	–	3.21	22.21	57.58	0.28	15.77	100.41	$Na_{0.17}[Al_{1.83}Zn_{0.17}\,\square_{1.00}]$-$[Si_{4.00}]O_{10}(OH_{1.94}F_{0.06})\cdot 2.8H_2O$
Zn02	1.98	–	6.90	18.30	55.70	0.20	19.25	102.33	$Na_{0.3}[Al_{1.64}Zn_{0.39}\,\square_{0.97}]$-$[Si_{4.00}]O_{10}(OH_{1.95}F_{0.05})\cdot 4.0H_2O$

[a] □ Represents the vacancy.

Si−O−Si bond angle[26] that was previously observed by Sanz and Serratosa.[24]

^{19}F MAS NMR spectroscopy confirms the substitution of fluoride ions for hydroxy groups, and reveals their environment.[11,27] Spectra (Figure 7) show several peaks with chemical shifts corresponding to various fluorine environments. In the spectrum of the Mg01 sample, two peaks are observed at δ = −133.3 and −153.0 which correspond to Al−Al−□ and Mg−Al−□ fluorine environments, respectively (□ represents a vacancy in the octahedral sheet). For the spectrum of the Mg02 sample, only the Mg−Al−□ peak is conserved at δ = −153.0 and another appears at δ = −177.0 which is characteristic of an Mg−Mg−Mg fluorine environment. The latter was previously observed for trioctahedral compounds like natural hectorite and synthetic mica-montmorillonite clay.[27] The two chemical shifts in the Zn01 and Zn02 samples are assigned to Al−Al−□ (δ = −132.8) and Zn−Al−□ (δ = −142.0 for Zn01 and δ = −142.4 for Zn02) fluorine sites, respectively.[11] The intensity of the former decreases whereas that of the latter increases as the Zn content increases. Consequently, ^{19}F MAS NMR spectroscopy shows the presence of Mg or Zn in the octahedral sheet and the presence of vacancies in the octahedral sheet.

^{27}Al MAS NMR spectroscopy indicates the localisation of Al in the structure.[24,28] The presence of Al_{VI} (δ = 2−3) and Al_{IV} (δ = 64−67) aluminium is observed in the structure (Figure 8). This is further proof for the Al-for-Si substitution in the tetrahedral sheet. The chemical shifts of Al_{VI} and Al_{IV} increase with the content of divalent element.

X-ray Absorption Spectroscopy (XAS)

The Zn *k*-edge extended X-ray absorption fine structure (EXAFS) spectra recorded from Zn01 and Zn02 montmorillonites are shown in Figure 9a, after background subtraction and conversion to *k*-space. There are no major differences between the data except for a slight enhancement of

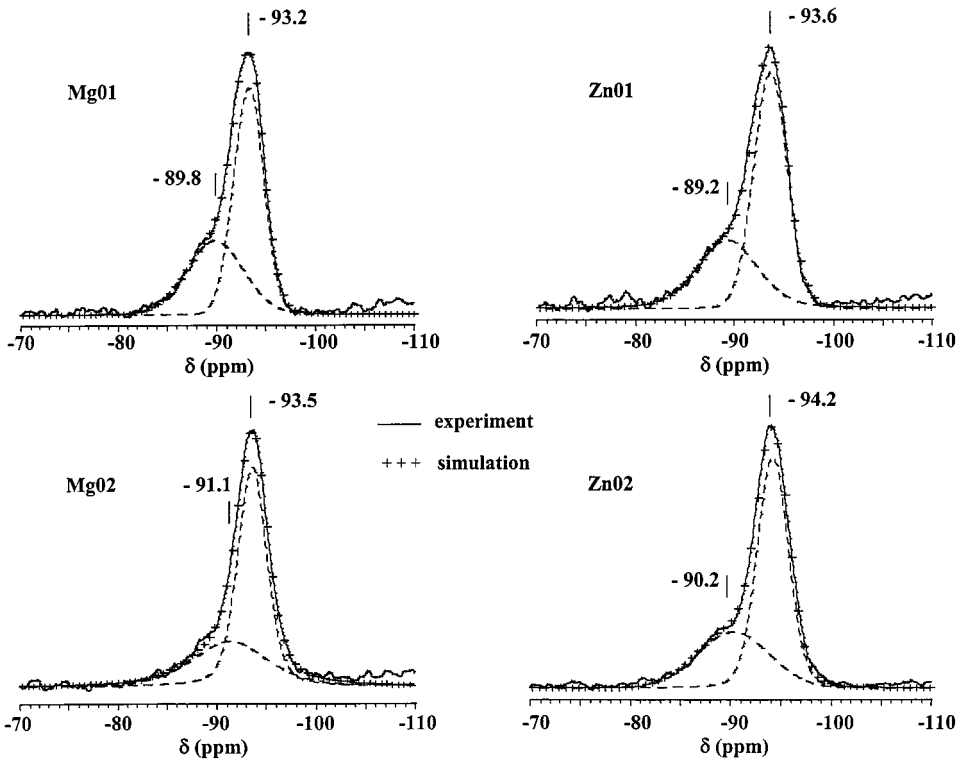

Figure 6. ^{29}Si MAS NMR spectra [standard reference $Si(CH_3)_4$] and corresponding simulations of the studied synthetic montmorillonites

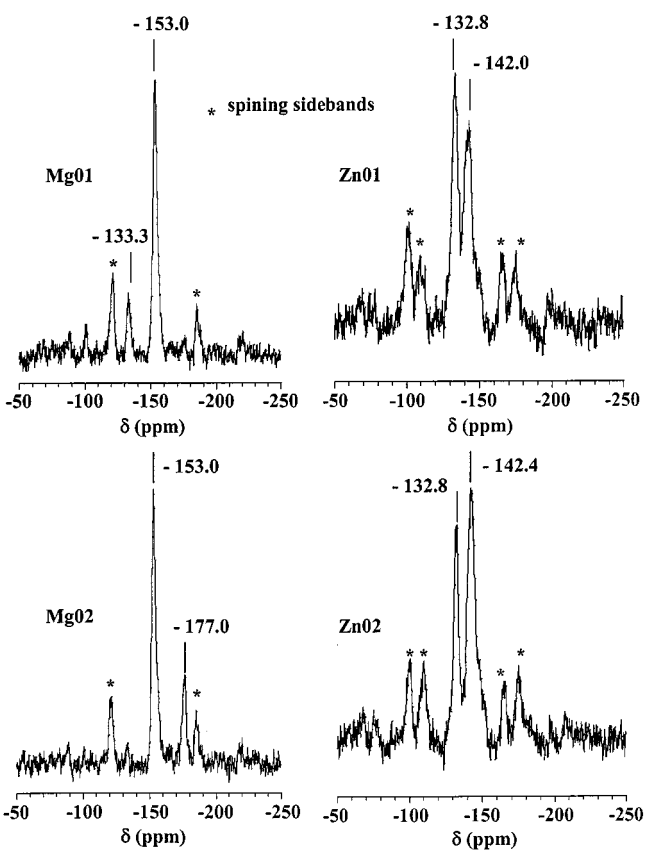

Figure 7. ^{19}F MAS NMR spectra of samples Mg01, Mg02, Zn01, and Zn02 (standard reference $CFCl_3$)

the high frequency oscillation for Zn02. The corresponding Fourier transforms (FT) between 0 and 8 Å are presented in Figure 9b. The main peak, which is assigned to the oxygen atom's nearest neighbours (NN), has the same position and amplitude for both samples. The structural parameters, derived from the simulation of the Fourier-filtered contribution of the NN peak, are reported in Table 4. Figure 10a compares the experimental and calculated curves. Zn is formed in octahedral coordination with O in agreement with the other characterisations; the average bond length is found to be 2.08 Å. The second and third peaks observed between 2 and 3.5 Å in FT (Figure 9 b) are not well separated and are related to Al and Zn next-nearest neighbours (NNN) in the octahedral sheet on one hand, and Si(Al) belonging to the tetrahedral sheets on the other hand. Some preliminary considerations have to be made before giving the results of the simulations. In the ideal montmorillonite lattice, the shortest metal−metal distance within the octahedral sheet is 2.99 Å, whereas the distance from sixfold-coordinated metal to fourfold-coordinated Si(Al) is 3.11−3.18 Å.[29] On the other hand, the average number of metallic neighbours inside the octahedral sheet is assumed to be four from the rate of vacancies (see next section), whereas the number of Si(Al) neighbours remains equal to 4 (2 per tetrahedral sheet) as in the theoretical structure. The Fourier-filtered contributions of the 2−3.5 Å region in FT are presented in Figure 10b, together with their best fits using the structural parameters of Table 4. They exhibit strong differences in the low *k*-range, which involves mainly Al and Si backscatterers. Indeed it is well known that Al's and Si's backscattering (BS) amplitudes, which are very

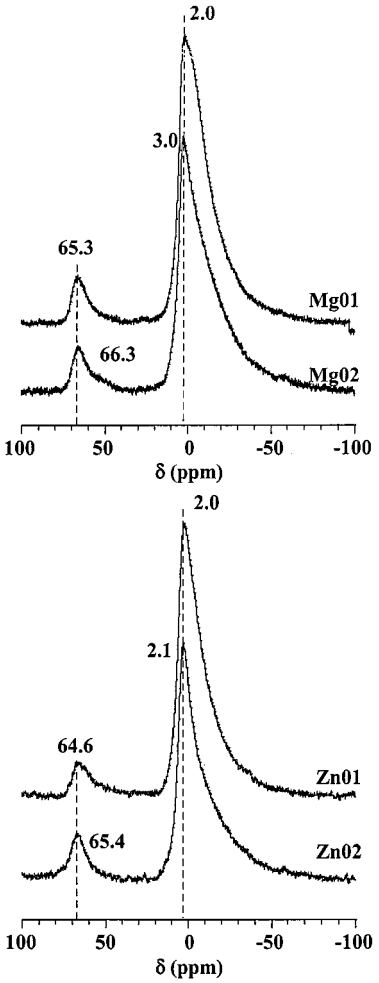

Figure 8. ^{27}Al MAS NMR spectra [standard reference $Al(H_2O)_6^{3+}$] of the studied synthetic montmorillonites

close together, present a maximum around 3−4 $Å^{-1}$ and are strongly dampened above 9−10 $Å^{-1}$ (ref.[30] and references therein). The behaviour of the Zn BS amplitude is quite different, with a minimum at low k and a maximum around 8−9 $Å^{-1}$. Therefore the high k-range of the data (Figure 10b) involves the Zn neighbours of Zn almost exclusively. The positions of the oscillations above 8 $Å^{-1}$, which are the same for Zn01 and Zn02, reveal that the metal−metal distances within the octahedral sheet do not depend on the Zn content in montmorillonite. However, the amplitude of the Zn contribution is enhanced by a factor of about one third in Zn02 with respect to Zn01. Coming back to the Si and Al contributions, the differences observed between Zn01 and Zn02, around 3−8 $Å^{-1}$, are attributed to a variation of the distance from Zn to Si(Al) belonging to the tetrahedral sheets. Following these considerations, the fits were performed by keeping the number of Si(Al) that are underneath and beyond the Zn, located in the plane of the octahedral sheet, constant and equal to four. The number of metallic neighbours inside the octahedral sheet was also kept constant and equal to four. The preferential orientation of the crystallites has not been considered in this preliminary treatment of the Zn k-edge data. An accurate determination of the absolute coordination numbers requires a careful texture analysis which has not yet been carried out.[31] Consequently, only an evaluation of the N_{Zn}/N_{Al} ratio can be deduced from the data treatment at this stage. After the interatomic distances and Debye−Waller parameters were roughly determined (with initial values of the Al and Zn coordination numbers taken to be 3 and 1, respectively) the Al/Zn ratio was varied step by step until the lowest value of the residue was obtained. In the octahedral sheet, the Zn−Al and Zn−Zn distances are found to be 2.98 and 3.11 Å for Zn01 and Zn02, respectively (Table 4). The values of 2.0 and 2.3 Zn neighbours of Zn are consistent with the amplitude of the data in the high k-range. The Zn−Si(Al) distances are found to be 3.17 and 3.25 Å in Zn01 and Zn02, respectively. The latter value is longer than the mean Al−Si distance in the ideal structure (3.15 Å). This main result clearly demonstrates that the montmorillonite lattice is submitted to more and more distortions as the Zn content is increased.

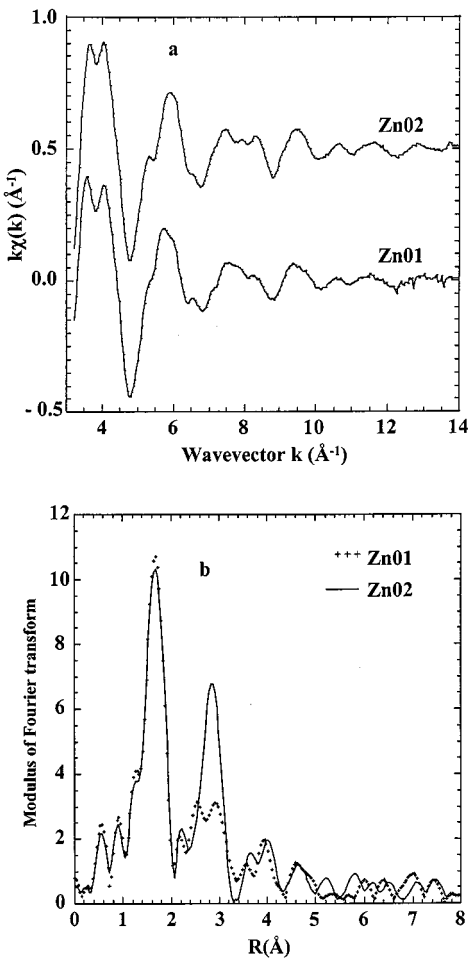

Figure 9. EXAFS data (a) and RDF (b) of synthetic montmorillonites containing Zn (samples Zn01 and Zn02)

The Mg k-edge spectra of samples Mg01 and Mg02 are presented in Figure 11a and the corresponding FT in Figure 11b. The results of the fits give a value of the Mg−O distance of 2.11 Å (Table 5) similar to the Zn−O distance.

Table 4. Structural parameters derived from Zn *K*-edge EXAFS analysis

	Sample	Shell	*N*	*R* [Å]	σ^2 [Å^2]

Due to the short-range data (2−8 Å^{-1}) the NNN shell has not yet been investigated.

Discussion

XRD and ^{29}Si MAS NMR spectroscopic studies of the $MgO-Al_2O_3-SiO_2$ and $ZnO-Al_2O_3-SiO_2$ systems demonstrate that montmorillonite can only be synthesized in a narrow range of compositions ($x = 0.2$). The XRD patterns of Mg01, Mg02, Zn01, and Zn02 selected samples (Figure 3) are unambiguously assigned to smectites and exhibit the typical *hkl* bands of montmorillonite.[12] Moreover, the morphology of the crystal particles observed by SEM (Figure 4) are similar to those of natural montmorillonites.[16−18]

The TGA-DTA analysis (Figure 5), which gives information about the octahedral sheet, confirms this result since the dehydroxylation peak characteristic of natural montmorillonite is observed between 920 and 960 K.[19−23] The additional dehydroxylation peak, which appears in the 720−760 K range, was assigned by Cuadros et al. to the presence of kaolinite.[20] However, the characteristic exothermic contribution of kaolinite above 1173 K is not ob-

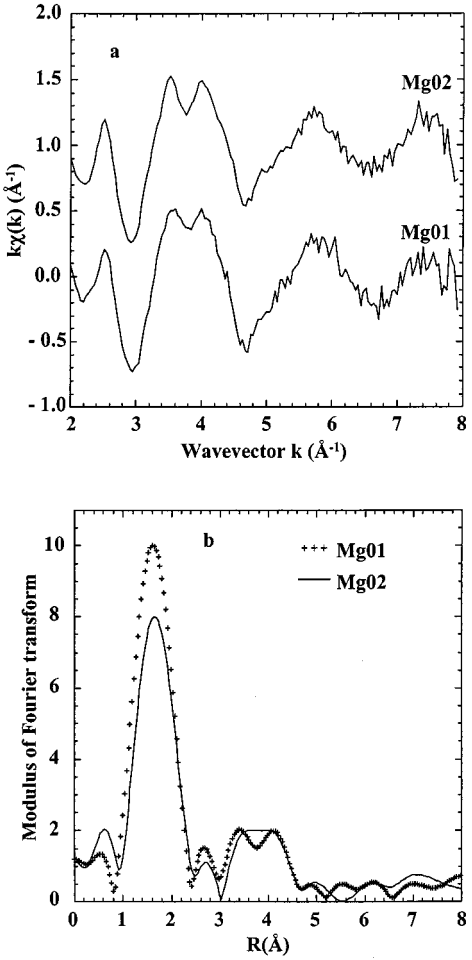

Figure 11. EXAFS data (a) and RDF (b) of synthetic montmorillonites containing Mg (samples Mg01 and Mg02)

Table 5. Structural parameters derived from Mg *K*-edge EXAFS analysis

	Sample	Shell	*N*	*R* [Å]	σ^2 [Å^2]
NN shell	Mg01	Mg−O	6	2.12±0.02	0.006
	Mg02		6	2.10±0.02	0.007

served for the four synthetic clays.[32] On the other hand, the endothermic peak observed at 720−760 K cannot be assigned to the presence of a small amount of kaolinite, because the typical endothermic contribution of kaolinite appears at higher temperatures.[20] The endothermic peak observed in our case (Figure 5) is attributed to hydroxy groups which have different octahedral metallic neighbours. In this way, Frost et al. have assigned the low-temperature dehydroxylation endotherm of a ferruginous montmorillonite to hydroxy groups associated with Fe−Fe pairs and the higher one to hydroxy neighbour Fe−Al pairs.[23] Therefore, the presence of extraneous kaolinite can be ruled out in the four analysed synthetic montmorillonites. The deviation of a random distribution of metallic atoms inside the montmorillonite lattice will be discussed below.

Both ^{29}Si and ^{27}Al MAS NMR spectroscopy gave proof that Al is partially substituted for Si in the tetrahedral sheets. Chemical analysis is not accurate enough to probe such a kind of substitution. It appears that whatever the synthetic conditions, the incorporation of small amounts of aluminium in the tetrahedral sheet (Al_{IV}) cannot be avoided. The Si/Al_{IV} ratio could not be determined by ^{29}Si MAS NMR spectroscopy because of the deviation of the statistic distribution pointed out below. Sanz and Serratosa have indeed shown that other factors exist besides the rule of Loewenstein (no Al−O−Al bond in the structure), which governs the Si and Al distribution in the tetrahedral sheet, when atoms are not randomly distributed in the layer.[24] Working on natural pyrophyllite (talc-type clay), muscovite and margarite (mica-type clays) as dioctahedral clays which have only tetrahedral substitutions, Sanz and Serratosa have reported a poor agreement between the Al_{VI}/Al_{IV} ratio determined by using ^{27}Al MAS NMR spectroscopy and those calculated from the chemical analysis and ^{29}Si MAS NMR spectroscopy.[26] Later, Goodman and Stucki noticed that ^{27}Al MAS NMR spectroscopy can be used to obtain the Al_{VI}/Al_{IV} ratio and probably, in precise experimental conditions, have accurate quantitative results in the case of natural montmorillonite.[28] The presence of paramagnetic elements in the samples of Sanz and Serratosa and the fact that the spinning rate was lower for the MAS at this time, could explain the poor agreement for ^{27}Al MAS NMR spectroscopy in their study.[24] Nowadays, the knowledge about ^{27}Al MAS NMR spectroscopic technology has improved, particularly that concerning the quantitative analysis.[33−35] The determination of the absolute Al contents in Mg01, Mg02, Zn01, and Zn02 by ^{27}Al MAS NMR spectroscopy can now be achieved. The calibration was made using well-known synthetic beidellites.[9,10] However, the determination of the Al_{VI}/Al_{IV} ratio by this technique requires complementary measurements that are currently in progress.[36]

The EXAFS study provides a determination of the NN and NNN shell distances. NN shell distances are very similar for samples Zn01 and Zn02 (2.08 Å and 2.07 Å, respectively) and for samples Mg01 and Mg02 (2.12 Å and 2.10 Å, respectively). These values have to be compared to those of an ideal montmorillonite lattice, where two types of octahedral sites exist: the first one, here called M_1, and the second one called M_2.[29] Only the M_2 octahedral site is occupied by an atom and the value of the M_2−O distance is 1.94 Å. These deviations indicate a strong distortion of the coordination polyhedron with respect to the ideal structure. In the case of the NNN shell, the values of the out-of-plane Zn−Si distance increases with the quantity of Zn contained in the octahedral sheet (3.17 Å for Zn01 and 3.25 Å for Zn02, as a comparison d_{M-Si} = 3.15 Å in the ideal lattice). The values of the Zn−Al distance deduced for samples Zn01 and Zn02 (2.98 Å and 2.97 Å, respectively) are close to those of the ideal montmorillonite lattice (2.99 Å), whereas the values deduced for the Zn−Zn distance are longer (3.11 Å for both Zn01 and Zn02). This observation confirms that the distance between two elements in the structure strongly depends on their nature.

Finally, let us consider the distribution of tri- and divalent elements within the octahedral sheet. The simulation of the backscattered contribution of the NNN of Zn reveals a surprisingly high value of the Zn/Al_{VI} ratio, which reaches 1.0/1.0 in Zn01 and 1.4/1.0 in Zn02 (Table 4). The projection of the octahedral sheet onto the (*ab*) plane has the form of a two-dimensional hexagonal network whose every third apex is vacant (Figure 1b). If we consider various arrangements of vacancies within this plane, the average coordination number of an element is four (at least 3, at most 5). Consequently, the coordination number of Zn was kept constant and equal to 4 in the simulations. The value of the octahedral substitution, which could be determined by using ^{27}Al MAS NMR spectroscopy and chemical analyses, indicates 1.8 Al for 0.2 Zn in Zn01 and 1.6 Al for 0.4 Zn in Zn02, i.e. one octahedral site out of 15 and two octahedral sites out of 15 are occupied by Zn atoms in Zn01 and Zn02, respectively. For a random distribution of the elements in the sheet, the number of Zn neighbours of Zn would be much less than one in both Zn01 and Zn02. On the other hand, the TGA-DTA study has also demonstrated a possible deviation from a random distribution of metallic atoms inside the montmorillonite lattice. The deviation from the statistical distribution and the clustering of divalent elements is also confirmed by ^{19}F MAS NMR spectroscopy that reveals unambiguously the presence of Mg−Mg−Mg arrangement around fluorine atoms in the Mg02 sample. The existence of a Mg−Mg−Mg environment and the absence of a Zn−Zn−Zn one could also be explained by a higher affinity of fluorine for Mg than Al or Zn due to the difference between the electronegativity of the elements. The clustering induces strong local distortions within the octahedral sheet that are balanced by the tetrahedral sheet substitutions. This behaviour was already observed in the octahedral sheet of a natural montmorillonite from Camp Berteau by EXAFS measurements at the Ni *k*-edge.[37]

Conclusion

Montmorillonites containing Al and exclusively Zn or Mg as divalent elements in the octahedral sheet were syn-

thesized in acidic and fluoride medium. The substitution of Al in the octahedral sheet was obtained for a narrow range of Mg or Zn contents. The elemental analysis (XRD, TGA-DTA, chemical analysis) of the synthesized materials demonstrates their major dioctahedral character. Beyond these fundamental characterisations, ^{27}Al MAS NMR spectroscopy gives an accurate value of the substitution rate of the Al for Si in the tetrahedral sheet and demonstrates that elemental analyses are not sufficient to establish the half unit cell formula. EXAFS reveals substantial increases of the bond lengths (R_{Mg-O} = 2.11 Å, R_{Zn-O} = 2.08 Å, R_{Zn-Al} = 2.98 Å, R_{Zn-Zn} = 3.11 Å) in the octahedral sheet with respect to the ideal structure. The distortions of the coordination polyhedra of divalent elements could be related to a local trioctahedral character of these materials. This interpretation can be connected with the clustering of divalent elements revealed by EXAFS and ^{19}F MAS NMR spectroscopy. It appears that the substitution and the clustering of the divalent elements induce a mismatch between the octahedral and the tetrahedral sheets, and finally a local undulation of the layer which could be compensated by Al for Si substitutions in the tetrahedral sheet. This could be the reason why montmorillonite clays without tetrahedral substitutions are seldom observed in nature. The relevant phenomena may influence the physical and the chemical properties of these clays (adsorption, catalytic efficiency, etc.).

Experimental Section

Synthesis: Two series of syntheses were performed on $MgO-Al_2O_3-SiO_2$ and $ZnO-Al_2O_3-SiO_2$ systems. The compositions of hydrogel are based on a theoretical formula of montmorillonite: $Na_{2x}[(Al_{2(1-x)}M_{2x}\ \square)Si_4O_{10}(OH,F)_2]\cdot nH_2O$. M represents the divalent element (Mg or Zn), and x ranges from 0.0 to 1.0. Samples were synthesized in an acidic fluoride medium under hydrothermal conditions using hydrogels with the following molar composition:

$$1SiO_2 : (1 - x)/4\cdot Al_2O_3 : x/2\cdot MO : x/4\cdot Na_2O : 0.05\cdot HF : 96\cdot H_2O$$

Water, hydrofluoric acid, and silicon oxide contents are the same for each synthesis. Reactants were mixed in the following order: deionized water, hydrofluoric acid (HF, 40%; BDH), sodium acetate ($NaCOOCH_3$, 99%; Fluka), zinc acetate [$Zn(COOCH_3)_2$, $2H_2O$, 98%; Prolabo] or magnesium acetate [$Mg(COOCH_3)_2\ 4H_2O$, 99%; Fluka], boehmite (Al_2O_3, 75−78%, Pural SB1; Condea), and silica (SiO_2, 99.5%, Aerosil 130; Degussa). Hydrogels were matured over 2 h at room temperature and the pH was measured (pH = 4.5−6) before hydrothermal treatment in a PTFE-lined stainless steel autoclave at 493 K for 72 h under autogeneous water pressure. After crystallisation, the autoclaves were cooled to room temperature. The pH of the supernatant was 3.5−4.5. Products were then separated by filtration, washed thoroughly with distilled water and dried at 333 K for 12 h. The samples were then ground to a fine powder form and placed under controlled humidity. This was made by keeping samples under a relative pressure P/P_0 = 80%, by using a saturated solution of NH_4Cl salt.

X-ray Powder Diffraction (XRD): The X-ray powder diffraction patterns were recorded with two diffractometers: the first one employing Cu-K_α radiation was equipped with automatic divergence slits (Philips PW1800), the second one employing either Cu-K_α or Cr-K_α radiation with fixed divergence slits (Philips PW1100). The latter enables patterns to be recorded under controlled humidity (P/P_0 = 80% RH). In both cases diffractograms were performed on powders which were only pressed on sample carriers. Information about the phase and d_{001} spacing was obtained with the APD 1700 software (Philips).

Scanning Electronic Microscopy (SEM): Starting materials were first examined by SEM with a Philips XL30 microscope in order to determine their morphology. An ethanolic suspension of the sample was left on a support covered by graphite and then evaporated. Samples were then metallized (10 or 20 nm of gold) under vacuum by sputtering.

Thermal Analysis (TGA-DTA): Measurements were carried out on samples which were previously placed under controlled humidity (P/P_0 = 80%), with a heating rate of 5 K·min^{-1} obtained by using a Setaram Labsys apparatus under a mixture of N_2 and O_2 (1 and 0.5 bars, respectively).

Chemical Analysis: A part of each sample was Na-saturated to be sure that only Na^+ cations balanced the charge. Na-saturated products were prepared as follows: 5 mL of 1 M NaCl solution was added to 0.5 g of synthetic product. The mixture was stirred at room temperature for 1 h before it was filtered. The exchange process was repeated twice. The samples were then washed with distilled water until the product was chloride-free (this was tested using $AgNO_3$ solution). The resultant product was then dried at 333 K for 12 h. Elemental analysis of Na-saturated clays was then performed by the Service Central d'Analyse of the Centre National de la Recherche Scientifique (Vernaison, France) for the following elements: Mg, Zn, Al, Si, and F.

Solid-State Nuclear Magnetic Resonance (NMR) Spectroscopy

Experiments: ^{29}Si MAS NMR spectra were obtained with a Bruker MSL-300 spectrometer at 59.63 MHz with 4 kHz spinning speed, 2 μs excitation pulses (π/2 pulse width of 4 μs) and 95 s recycle time. Chemical shifts of Si were referenced to tetramethylsilane (TMS) using a secondary standard of trimethylsilyl ester of cubic octameric silicate (Q8M8) at δ = −109.7 (the more shielded signal). ^{27}Al MAS NMR spectra were obtained with a Bruker MSL-300 spectrometer at 78.21 MHz with 10 kHz spinning speed, 0.7 μs excitation pulses (π/2 pulse width of 9 μs for an aqueous solution) and 1 s recycle time. Chemical shifts of aluminium were referenced to a 1 M $Al(NO_3)_3$ aqueous solution with a chemical shift of δ = 0. ^{19}F MAS NMR spectra were obtained with a Bruker DSX-400 spectrometer at 379.23 MHz with a Hahn echo pulse sequence (π/2 pulse − τ − π pulse − τ − acquisition),[38] 10 kHz spinning speed, π/2 pulse width of 7 μs and 20 s recycle time.

Data Analysis: After their collection, free-induction decay (FID) signals were treated following a standard procedure using the software WIN NMR (Bruker software). The FID signals were smoothed in order to reduce the background noise. Base-lines were also corrected when necessary. The ^{29}Si MAS NMR spectra were simulated with the WINFIT software.[39] The Al_{VI}/Al_{IV} ratio was calculated by determining the area of each component of the ^{27}Al MAS NMR spectra. Furthermore, the aluminium content was determined accurately by using quantitative ^{27}Al MAS NMR spectroscopic conditions.[33−36]

Extended X-ray Absorption Fine Structure (EXAFS)

Experiments: The X-ray absorption experiments were performed at the Laboratoire pour l'Utilisation du Rayonnement Electromagnétique (LURE, Orsay, France). Samples studied by EXAFS were named Mg01, Mg02, Zn01, and Zn02, see below for their selection. The Zn01 and Zn02 samples were mixed with cellulose (0.122 g of Zn01 and 0.006 g of cellulose, 0.121 g of Zn02 and 0.005 g of cellulose), and pressed (1 T and 1.5 T, respectively) in the form of pellets (less than 1 mm thickness), that were maintained between two Kapton windows. Measurements were performed on the D21 beam line of the DCI storage ring. The X-rays were monochromatized by an Si(311) two-crystal spectrometer. The X-ray absorption spectra were recorded at the Zn-*K* edge (9659 eV) from 9400 to 10900 eV (1 eV step; 1 s^{-1} per point) in transmission mode at 20 K. Measurements for the Mg (1305 eV) and Al (1559 eV) *K* edges were performed on the SA32 beam line of the Super−Aco storage ring. Powdered Mg01, Mg02, Zn01, and Zn02 samples were directly pressed on indium films deposited on a copper sheet used as a support. The X-ray absorption spectra were collected at the Mg-*K* edge between 1250 and 1560 eV (1 eV step; 4 s^{-1} per point) in fluorescence mode. X-rays were monochromatized by a spectrometer using beryl crystals. All the spectra were collected with the samples perpendicular to the beam path. Measurements were performed at room temperature in a chamber at a pressure of 10^{-9} bar.

Data Analysis: The raw data were analysed following the standard procedure by using the software designed by Michalowiz.[40] First the pre-edge and post-edge backgrounds were removed from the raw data. After conversion to *k*-space, the EXAFS spectra were k^3-weighted and Fourier-transformed using a Kaiser apodization window. The nearest neighbours (NN) and next-nearest neighbours (NNN) peaks in the Fourier transforms (FT) were assigned to the oxygen and metal backscatterers. The Fourier-filtered (FF) contribution of oxygen was simulated using a squares fit by the standard EXAFS formula in order to derive the structural parameters: the interatomic distances *R*, coordination numbers *N* and Debye−Waller (DW) parameters σ. The amplitude and phase shifts are extracted either from reference samples or theoretical calculation.[30] The Fourier-filtered contribution of the metallic NNN of Zn in the 2.0−3.3 Å range (Figure 9 b) were simulated with amplitude and phase shifts calculated by using the FEFF software.[30]

Acknowledgments

The authors are grateful to Jean-Marc Le Meins for the interesting and helpful discussions concerning crystallography and for providing Figure 1. We also thank Anne-Catherine Faust for SEM micrographs.

Structure and Magnetism of a Polycrystalline Transition Metal Soap – $Co^{II}[OOC(CH_2)_{10}COO](H_2O)_2$

Jean-Michel Rueff,[a] Norberto Masciocchi,*[b,c] Pierre Rabu,*[a] Angelo Sironi,[b] and Antoine Skoulios[a]

Keywords: Carboxylate ligands / Cobalt / Layered compounds / Magnetic properties / X-ray powder diffraction

Diaquacobalt(II) *n*-dodecane-α,ω-dioate (**2**) has been synthesized by metathesis of the corresponding potassium soap **1** and has been fully characterized by chemical and spectroscopic analysis. The crystal structure of **2** has been established by X-ray powder diffraction techniques combined with electron diffraction experiments. It crystallizes in a monoclinic cell [$P2_1/a$; a = 9.6558(8), b = 7.4793(6), c = 19.8936(2) Å, β = 95.648(9)°, V = 1429.7(3) Å^3; Z = 2] and consists of stacked layers of cobalt(II) ions connected by carboxylato bridges, thus forming chains that extend along the a axis. These layers are separated by alkyl chains arranged quasi-perpendicularly to the polar sheets. Structure analysis reveals a rare *anti-anti* conformation of the Co–OCO–Co fragments, which is thought to be responsible for the weak antiferromagnetism of the Co^{II} chains. The exchange coupling constant between the magnetic centres has been estimated as J = –2.08 K.

Introduction

Low-dimensional magnetic compounds, in which the magnetic centres are arranged in well-separated, one-dimensional rows or two-dimensional layers, for instance, may be fully understood and quantitatively analysed on theoretical grounds.[1–5] Their systematic investigation is therefore expected to provide useful information on the relationship between their properties and their chemical and crystal structures, and thus to help towards the design of novel magnetic materials, hopefully with high T_C values.

In this respect, lamellar transition metal soaps[6,7] are very appealing model compounds. As shown by systematic investigations of their X-ray powder diffraction (XRPD) fingerprints,[6,8,9] it has long been known that, like micelles[10] and liquid-crystalline phases,[11–13] these materials can adopt ordered structures, although the details of these structures have been only rarely established owing to the difficulty in growing suitable single crystals.

As established previously, grafting of dicarboxylates onto parallel metal-containing layers is expected to afford highly crystalline powders, for which a complete 3D structure may be determined,[14] and to permit control over the spin coupling if suitable magnetic metal ions are employed.[15] Accordingly, the aims of the present paper are: (i) to outline the synthesis of one long-chained cobalt(II) soap, $Co^{II}[OOC(CH_2)_{10}COO](H_2O)_2$, i.e. diaquacobalt(II) *n*-dodecane-α,ω-dioate (**2**), (ii) to describe its crystal structure in detail, as elucidated by XRPD methods combining ab initio techniques (a method recently promoted by us in the field of coordination chemistry[16]) with electron diffraction analysis, and (iii) to discuss its magnetic behaviour in terms of its chemical bonding and crystal structure.

Results and Discussion

Compound **2** was prepared as a pink powder by metathesis of the corresponding potassium soap **1** with a stoichiometric amount of cobalt(II) acetate tetrahydrate, according to the precipitation method generally used in the synthesis of heavy metal soaps.[17,18] To ensure its chemical (and magnetic) purity and the coordination state of the cobalt atoms, special care was taken in choosing the operating conditions (high purity of reactants and solvents, low concentration and temperature, strict stoichiometry). The chemical nature of the product was ascertained by a set of complementary analytical techniques and was fully confirmed by XRPD.

The room-temperature diffraction pattern of **2** contains a subset of low-angle, equidistant, sharp reflections (00*l*), indicative of a lamellar structure with a spacing of ca. 19.9 Å. This value, which is larger than that determined for *n*-dodecane (17.2 Å[19]), suggests parallel, all-*trans*-alkyl chains oriented perpendicularly to the layers. Moreover, the overall complexity of the XRPD pattern is indicative of a well-developed three-dimensional crystalline arrangement. Although too intricate to be interpreted straight away in terms of a 3D crystal lattice (using conventional cell determination procedures), the pattern was eventually indexed

with the aid of additional information provided by electron-diffraction experiments. Indeed, SEM observations (Figure 1) showed that **2** apparently consists of single-crystalline platelets, thus permitting electron diffraction (ED) experiments on isolated platelets oriented perpendicularly to the electron beam. A typical ED pattern contains an extended set of sharp reflections (*hk*0; all present in the XRPD trace), consistent with a rectangular two-dimensional lattice of cell parameters $a \approx 9.6$ Å and $b \approx 7.5$ Å. Using this information, along with the knowledge of the lamellar period, the XRPD pattern of **2** was indexed on the basis of a monoclinic lattice with cell parameters $a = 9.6558(8)$ Å, $b = 7.4793(6)$ Å, $c = 19.8936(2)$ Å, and $\beta = 95.648(9)°$.[20] Systematic absences pointed to $P2_1/a$ as the probable space group, which was later confirmed by a successful crystal structure determination. Interestingly, the centred rectangular sublattice ($a' = a/2 \approx 4.8$ Å, $b' = b \approx 7.5$ Å) built-up from reflections 400, 210, 020, 420, 230, 040 of the electron-diffraction patterns (Figure 2) is identical to the two-dimensional crystal lattice that describes the lateral packing of linear paraffins in the orthorhombic form,[21] and suggests a similar packing for the alkyl chains in the crystals of soap **2**. Incidentally, the intensities of these particular reflections are especially strong, as expected from the upright orientation of the alkyl chains in the platelets.

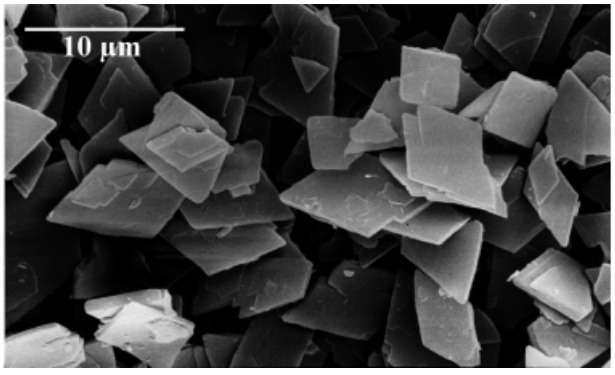

Figure 1. Morphology of powdered compound **2** as observed by scanning electron microscopy

The detailed crystal structure of **2** was established by an ab initio analysis and a Rietveld refinement of the intensity distribution in the powder X-ray diffraction patterns (see Exp. Sect.). As shown in Figure 3, the structure incorporates octahedral cobalt(II) ions *cis*-coordinated by two water molecules, as well as by one chelating [η^2-*O*,*O*] and two bridging [μ-*O*,*O*] carboxylato groups. Connected by OCO bridges in an *anti-anti* conformation (see Scheme 1), the Co atoms form $(-OCO-Co-)_n$ chains that extend in a zigzag fashion along *a*. Due to the glide symmetry operation, the chiral configuration of the Co atoms alternates along the chains. Arranged in slabs (with hydrophobic cores and polar surfaces), slightly tilted with respect to *c* and lying virtually perpendicular to the (*a*,*b*) planes, the fully extended dodecanedioato groups (bearing a chelating carboxylato

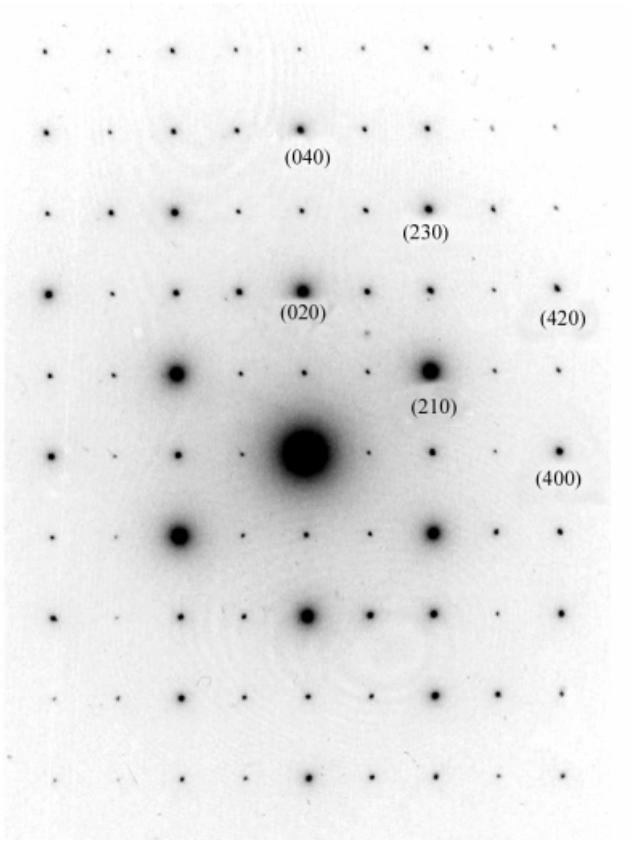

Figure 2. Electron diffraction pattern of **2** as recorded with the platelets oriented perpendicularly to the electron beam

group at one end and a bridging one at the other) connect Co atoms of opposite surfaces. These slabs are held together by hydrogen bonds between the water molecules and the carboxylic oxygen atoms, which are separated by about 2.70 Å. The separation of the Co atoms is 5.93 Å within the $(-OCO-Co-)_n$ chains, and only 5.07 Å between metal atoms of adjacent slabs (Co−O−H···O−Co).

The IR and UV data collected for **2** were readily analysed on the basis of the crystal structure. The IR spectrum features the characteristic bands of the alkyl chains in a fully stretched all-*trans* conformation. The frequency difference between the symmetric and antisymmetric carboxylate vibrations, $\Delta\nu = 128$ cm^{-1}, is smaller than that observed for the corresponding ionic potassium soap ($\Delta\nu_i \approx 150$ cm^{-1}), as befits the bidentate coordination mode of the carboxylic groups; because of the band widths, it is not possible to distinguish the chelating from the bridging mode in the structure.[22] The two broad ν(O−H) bands in the range 3200−3400 cm^{-1} can be assigned to the two hydrogen-bonded aqua ligands. The UV spectrum corroborates the quasi-regular octahedral geometry about the Co^{II} ions.[23,24] The values of Dq (950 cm^{-1}) and Racah's parameter B (846 cm^{-1}) deduced from the observed absorption bands indicate a low crystal field ($Dq/B = 1.1$), favouring the high-spin configuration observed for the metal centre (see below).

The magnetic behaviour of **2** was investigated using a SQUID magnetometer. The susceptibility χ (suitably cor-

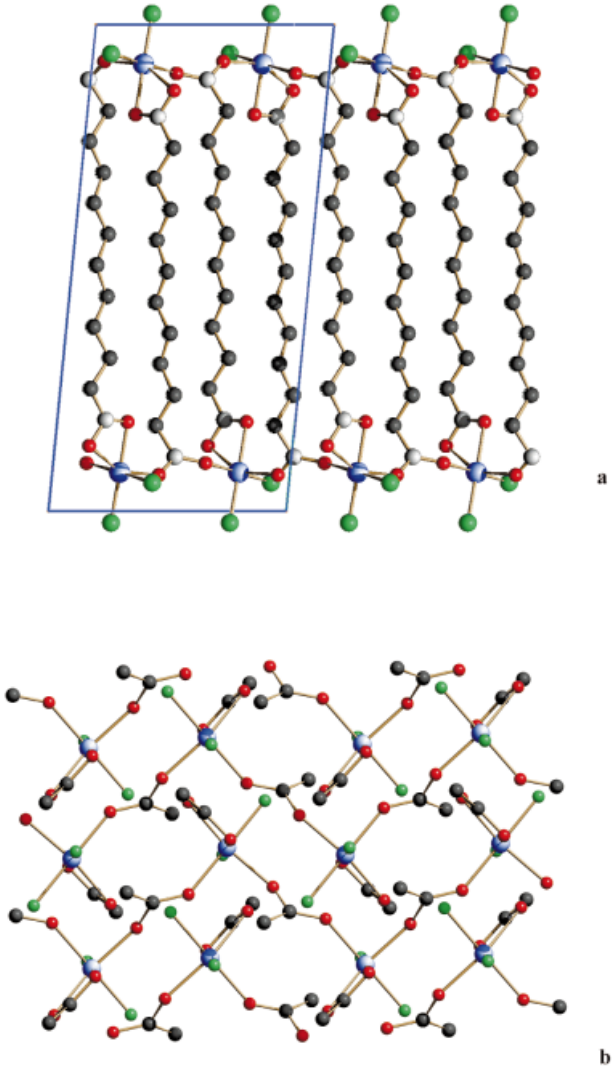

Figure 3. (a) Schematic plot (viewed down the *b* axis; horizontal axis = *a*) of the crystal structure of $Co(C_{10}H_{20}C_2O_4)(H_2O)_2$ showing the elongated organic ligands interconnecting parallel layers of octahedrally coordinated Co^{II} ions (see text); (b) a top view of the *ab* plane showing the Co^{II} chains extending along the *a* axis (horizontal) within the layers; cobalt atoms in blue; oxygen atoms of coordinated water molecules in green; for the sake of simplicity, a number of aliphatic carbon atoms have been omitted in (b)

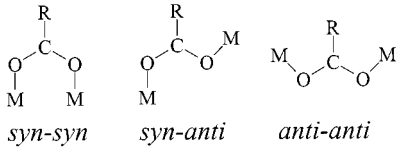

Scheme 1

rected for sample and holder diamagnetism) grows smoothly with decreasing temperature (Figure 4), according to the Curie–Weiss law $\chi = C/(T - \theta)$ at temperatures in excess of 200 K. The value of the Curie constant, $C = 3.0$ $cm^3\ K\ mol^{-1}$, is consistent with the presence of hexacoordinated high-spin Co^{II} ions ($C \approx 2.8-3.4$ $cm^3\ K\ mol^{-1}$)[25] and the negative sign of the Weiss temperature, $\theta = -19.7$ K, points, phenomenologically, to the existence of antiferromagnetic exchange interactions (also supported by the decrease of χT from 2.76 $cm^3\ K\ mol^{-1}$ at 295 K to 1.08 $cm^3\ K\ mol^{-1}$ at 2 K). The effect of spin-orbit coupling, known to be operative for Co^{II} ions,[5,25,26] most certainly also contributes to the decay of χT upon cooling; however, on no account does it explain entirely the observed decay. Firstly, the temperature dependence of the effective magnetic moment deduced from the experimental data differs from that calculated for isolated Co^{II} ions[26] (Figure 4); in particular, the χT value measured at 2 K (1.08 $cm^3\ K\ mol^{-1}$) is significantly smaller than expected (1.8 $cm^3\ K\ mol^{-1}$) for isolated Co^{II} magnetic centres. Secondly, the magnetization curve $M(H)$, saturating at $M_S = 2.2$ $\mu_B mol^{-1}$ as expected ($2-3$ $\mu_B mol^{-1}$),[5,25] is significantly lower than that predicted by Brillouin's law[25] (Figure 5).

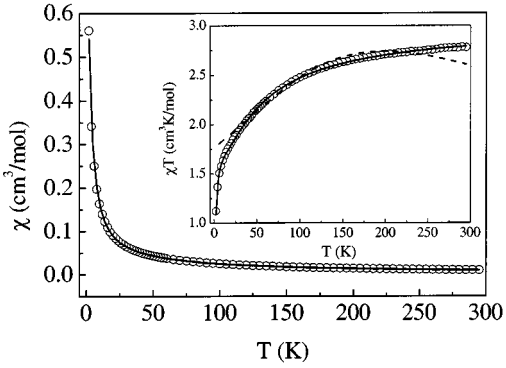

Figure 4. Temperature variation of the magnetic susceptibility of compound **2**; inset: χT vs. T variation; full lines correspond to the best fit of the experimental data with the relationship given in the text; the dashed line in the inset corresponds to the variation of $\mu_{eff}^2/8 = \chi T$ calculated from the expression given in ref.[26] for the effective moment of isolated Co^{II} ions in a weak octahedral field

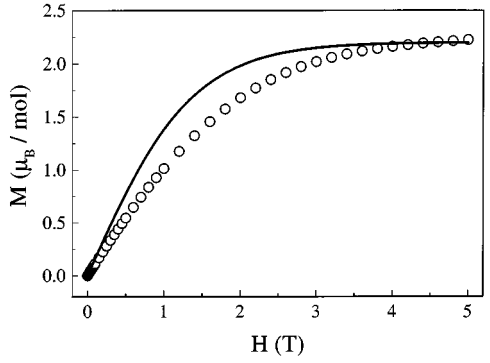

Figure 5. Magnetization vs. field curve at 2 K for compound **2**; the full line corresponds to the best fit to Brillouin's function

However weak, the antiferromagnetic coupling suggested by the experimental data most likely occurs through the carboxylato bridges along the $(-OCO-Co-)_n$ chains; although shorter, the exchange pathway through the hydrogen bonds appears to be less effective. No analytical expression is available in the literature to describe the temperature dependence of χT for chains of Co^{II} ions with spin-orbit coupling. Considering, however, that below 30 K the Co^{II}

ions generally behave as anisotropic $S = 1/2$ pseudo spins,[5,25,26] one may attempt to calculate the susceptibility by using the relationship given for Ising chains:[5,25]

$$\chi = 1/3(\chi_z + 2\chi_x)$$

with

$$\chi_z = \frac{Ng_z^2\mu_B^2}{4kT}\exp(J/2kT)$$

and

$$\chi_x = \frac{Ng_x^2\mu_B^2}{2J}\left[\tanh(J/2kT) + (J/4kT)\sec h^2(J/4kT)\right]$$

In the present case, this model turned out to be unsatisfactory as the antiferromagnetic exchange interaction is too weak to show up clearly against the spin-orbit coupling (see below) and, ultimately, because the anisotropy of the ion g tensor is too small.[5]

Nevertheless, in order to obtain an estimate of the strength of the antiferromagnetic exchange interaction, one may use the following simple phenomenological equation:[27]

$$\chi T = A\exp(-E_1/kT) + B\exp(-E_2/kT)$$

Here, $A + B$ equals the Curie constant, and E_1, E_2 represent the "activation energies" corresponding to the spin-orbit coupling and the antiferromagnetic exchange interaction. This equation adequately describes the spin-orbit coupling, which results in a splitting between discrete levels, and the exponential low-temperature divergence of the susceptibility [$\chi T \propto \exp(\alpha J/2kT)$]. Moreover, it is in excellent agreement with the experimental data obtained in the present work (Figure 4). The obtained values of $A + B = 3.0$ $cm^3\,K\,mol^{-1}$ and $E_1/k = +56.6$ K (using a least-squares fitting method) are consistent with those given in the literature for the Curie constant ($C \approx 2.8-3.4$ $cm^3\,K\,mol^{-1}$) and for the effect of spin-orbit coupling and site distortion (E_1/k of the order of $+100$ K).[25] As for the value found for the antiferromagnetic exchange interaction, it is very weak indeed ($-E_2/k = -1.03$ K), corresponding to $J = -2.06$ K according to the Ising chain approximation [see above; $\chi T \propto \exp(+J/2kT)$].

Although rare, several examples of one-dimensional systems of transition metal(II) ions have been reported in the literature,[28−32] in which the exchange effectively occurs through carboxylato bridges of various geometries (see Scheme 1). In Cu^{II} complexes, for instance, the exchange coupling is strongly antiferromagnetic with a *syn-syn* conformation,[33] very weakly so (eventually ferromagnetic[34]) with a *syn-anti* conformation,[35−37] and weak to moderately antiferromagnetic with an *anti-anti* conformation.[38] In the present work, the *anti-anti* geometry of the diaquacobalt(II) dicarboxylate appears to favour very weak antiferromagnetic interactions.

Conclusions

The cobalt compound investigated in the present work is, to the best of our knowledge, the first example of a carboxylate-bridged chain complex of Co^{II} featuring an uncommon *anti-anti* conformation to have been fully characterized both magnetically and structurally. Indeed, this *rare* coordination mode of the μ-RCOO group was only discovered thanks to XRPD, which has allowed the determination of the complete 3D structure of a transition metal soap for the first time.[39−41] The XRPD method that we used combined the power of ab initio techniques with that of selected area electron diffraction. Such coupling of complementary techniques, eventually assisted by further computational modelling,[42−44] is expected to allow the solution of more complex crystal structures in the near future, leading to the extensive use of these methods in materials science.[27,45,46] Furthermore, the magnetic properties of **2** have been analysed in detail on the basis of its crystal structure. The weak antiferromagnetism of the carboxylato-bridged Co^{II} chains (with a *cis* coordination mode of the cobalt atoms) is attributed to an *anti-anti* configuration of the bridges.

Experimental Section

General Remarks: Thermogravimetric experiments were performed using a Setaram TG92 instrument (heating rate 2 °C/min; air stream). − Mass-spectrometric measurements were performed using a Micro Mass Trio 2000 instrument (degassing of quartz crucible at 100 °C, desolvation of soap at 200 °C). − Scanning electron microscopy was performed using a JEOL JSM-840 instrument coupled with a KEVEX energy dispersion spectrometer. − Electron diffraction experiments were performed with a Philips CM12 transmission instrument equipped with a PW6594 goniometer (120 kV). − FT-IR studies were performed with an ATI Mattson Genesis computer-driven instrument (0.1 mm thick powder samples in KBr). − UV/Vis/NIR studies were performed with a Perkin−Elmer Lambda 19 instrument (spectra recorded by reflection with a resolution of 4 nm and a sampling rate of 480 nm/min). − Magnetic studies were carried out using a Quantum Design XMPMS SQUID magnetometer. Susceptibilities were measured at 0.2 T in the temperature range 1.7−295 K. The magnetization curve was determined at 2 K with an applied field ranging from 0 to 5 T. − For the powder X-ray diffraction experiments, the powder samples were cautiously deposited in the hollow of a side-loaded holder. Data were collected with a Siemens D500 diffractometer equipped with Soller slits, a primary-beam curved quartz monochromator (Co-$K_{\alpha 1}$, $\lambda = 1.78897$ Å), an Na(Tl)I scintillation detector, and a pulse height amplifier discriminator. The generator was operated at 35 kV and 30 mA. Slits used: divergence 1.0°, antiscatter 1.0°, and receiving 0.15 mm. Long overnight scans were performed in the range $2° < 2\theta < 130°$ with a $\theta/2\theta$ step-scanning mode ($\Delta 2\theta = 0.02°$ and $t = 10$ s). The indexing procedure is described in the text.

Potassium *n*-Dodecane-α,ω-dioate, $C_{12}H_{20}K_2O_4$ (1): A 0.1 N aqueous solution of KOH (5.611 g, 0.1 mol; Titrisol, Fluka) was diluted with acetone (150 mL; Carlo Erba, analytical grade) and added dropwise to a stirred solution of *n*-dodecane-α,ω-dioic acid (11.515 g, 0.05 mol; Lancaster, 99%) in acetone (500 mL) and the

mixture was refluxed for 3 h (56.5 °C). After cooling to room temperature, a white precipitate of the potassium soap had formed, which was collected by filtration, washed repeatedly with hot acetone, and dried in vacuo at room temperature for 12 h.

Diaquacobalt(II) *n*-Dodecane-α,ω-dioate, $C_{12}CoH_{24}O_6$ (2): Pure **1** (1.96 g, 6.4 mmol) was dissolved in a mixture of demineralized water (18.2 MΩcm; Millipore) and ethanol (purum; Carlo Erba) (300 mL, 1:1, v/v). The resulting solution was added dropwise to a stirred solution of $(CH_3COO)_2Co{\cdot}4H_2O$ (1.59 g, 6.4 mmol; Aldrich, 99.999%) in demineralized water (40 mL) at 20 °C. After stirring for 3 h, a pink precipitate of the diaquacobalt dicarboxylate had formed, which was collected by filtration, washed repeatedly with aqueous ethanol (1:1, v/v), and dried in vacuo at room temperature for 24 h (yield 82%). The presence of water molecules was detected by thermogravimetry (TGA) (10.8% weight loss at about 90 °C) and confirmed by mass spectrometry. The purity of the product was confirmed by elemental analysis (EA) $\{Co[OOC(CH_2)_{10}COO](H_2O)_2$: calcd. C 44.6, H 7.5; found C 44.3, H 7.5}, oxidative pyrolysis (OP) (heating in air from 20 to 700 °C at 2 °C/min, maintaining at 700 °C for 30 min to transform cobalt into Co_3O_4,[47,48] and cooling to 20 °C at 10 °C/min: calcd. Co 18.2; found 18.4), and Karl Fischer (KF) titration of water (calcd. 11.2; found 12.5) (water molecules per Co atom: 1.9 by TGA, 2.2 by KF, 1.9 by OP, and 2.1 by EA). − IR (KBr pellet): $\tilde{\nu}$ = 3401 [ν(OH−O)], 3262 [ν(OH−O)], 1670 [$\delta_b(H_2O)$], 2919 [$\nu_{as}(CH_2)$], 2850 [$\nu_s(CH_2)$], 1542 [$\nu_{as}(C{=}O)$], 1470 [$\delta_s(CH_2)$], 1414 [$\nu_s(C{-}O)$], 723 cm^{-1} [$\rho(CH_2)$]. − UV/Vis (reflectance for octahedral coordination of Co^{II}): λ = 1316 nm ($^4T_{1g} \rightarrow {}^4T_{2g}$), 714 nm ($^4T_{1g} \rightarrow {}^4A_{2g}$), 543 nm [$^4T_{1g} \rightarrow {}^4T_{1g}$(P)].

X-ray Crystallographic Study: The structure solution of **2** was initiated using EXPO,[49,50] which revealed the positions of the cobalt atom and of a few oxygen atoms bound to it. With the help of difference Fourier syntheses and geometrical modelling, approximate coordinates for *all* the remaining non-hydrogen atoms were subsequently obtained. All refinements were performed with the aid of the GSAS suite of programs,[51] by imposing steric restraints on the organic fragments, which were idealized with average literature values (C−C 1.54 Å; C−C−C 109.5°). Soft restraints were also applied to Co−O distances and C−O interactions in order to maintain plausible Co−O−C and O−C−O angles. The peak shapes were best described by the Thompson/Cox/Hastings formulation[52] of the pseudo Voigt function, with GV and LY set to zero. The experimental background was modelled by a cosine Fourier series, while systematic errors were corrected with the aid of sample-displacement angular shifts and preferred orientation corrections [with (001) pole]. Metal atoms were given a refinable isotropic displacement parameter of $U_{iso}(M)$ = 0.028(2) $Å^2$, while the *U* values of lighter atoms were arbitrarily given values of $U_{iso}(M)$ + 0.02 $Å^2$. The contribution of the hydrogen atoms to the scattered intensity was neglected. Scattering factors, corrected for real and imaginary anomalous dispersion terms, were taken from the GSAS internal library. The final Rietveld refinement plot is shown in Figure 6. Crystal Data: $C_{12}H_{24}CoO_6$, M_r = 323.25 g mol^{-1}, monoclinic, $P2_1/a$; *a* = 9.6558(8), *b* = 7.4793(6), *c* = 19.8936(2) Å, β = 95.648(9)°, *V* = 1429.7(3) $Å^3$; *Z* = 2; μ = 100.48 cm^{-1}; ρ = 1.502 g cm^{-3}. The final R_p, R_{wp}, and R_F agreement factors, for 6001 data collected in the 4−124° range (1442 reflections), were 0.125, 0.163, and 0.067, respectively. Full pattern decomposition resulted in R_p and R_{wp} values of 0.108 and 0.146, respectively. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-156267. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

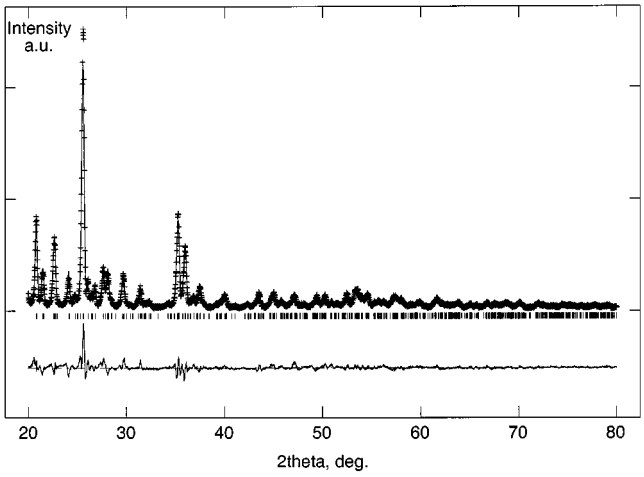

Figure 6. Rietveld refinement plot of compound **2** in the 20−80° (2θ) range, with difference plot and peak markers at the bottom; the low-angle section, dominated by the strong (001) peak, has been omitted in order to highlight the agreement at intermediate angles

Acknowledgments

Heptacoordinate Dimethyltin(IV)cupferronato Complexes − X-ray and Solid-State NMR Structural Analysis − Hydrogen Bond Supramolecular Self-Assembly

Andrea Deák,[a] Lajos Radics,*[a] Alajos Kálmán,*[a] László Párkányi,[a] and Ionel Haiduc*[b]

Keywords: Chelates / Hypervalent compounds / N ligands / Self assembly / Tin

Reaction of the dimeric dimethyltin(IV)cupferronato complex $[Me_2Sn(O_2N_2Ph)_2]_2$ (**1**) with 4,4′-bipyridine (bipy), pyridine (py), and 2,6-diamino-4-phenyl-1,3,5-triazine (dpt) afforded three new hepta-coordinated derivatives, [μ-(4,4′-bipy){$Me_2Sn(O_2N_2Ph)_2$}$_2$]·MeOH (**2**), $Me_2Sn(O_2N_2Ph)_2$(py) (**3**), and $[Me_2Sn(O_2N_2Ph)_2(MeOH)]$·dpt (**4**). These were characterised by X-ray structural analysis and solid-state ^{119}Sn, ^{13}C CP MAS NMR-, and multinuclear solution NMR spectroscopy. Single-crystal X-ray diffraction analysis of **2**–**4** showed that in all three compounds tin was hepta-coordinated, and the cupferronato anions were chelated to the Me_2Sn^{IV} centre in a nearly symmetrical arrangement. Compound **4** contained supramolecular self-assembled ribbons, formed by hydrogen bonds between Me_2SnO_5 moieties and pairs of dpt molecules.

Introduction

Recently, we reported the synthesis and structural characterisation of *N*-nitroso-*N*-phenylhydroxylaminato (cupferronato, $PhN_2O_2^-$, hereinafter cupf) tin(IV) complexes, such as $[Me_3Sn(cupf)]_4$ (**5**),[1] $Ph_2Sn(cupf)_2$ (**6**), $[Me_2Sn(cupf)_2]_2$ (**1**), and $Sn(cupf)_4$ (**7**).[2] We found that, depending on the number (0, 2, 3) and the nature (Me, Ph) of the substituents at the Sn^{IV} atom, the cupferronato anion displays various coordination patterns in these molecules: chelating (**6**, **1**, **7**), bridging (**5**), and bridging-chelating (**1**). As a consequence of this, the central Sn^{IV} atom assumes a penta- (**5**), hexa- (**6**), hepta- (**1**), or octacoordinate (**7**) state, respectively, and the resulting complexes display different coordination geometries at the central Sn^{IV} atom.[1,2] Bridging-chelating coordination of the cupferronato ligand to Me_2Sn^{IV} gives the dimeric species **1** (Scheme 1),[2] whereas a bridging coordination affords the tetrameric complex **5** (Scheme 2).[1]

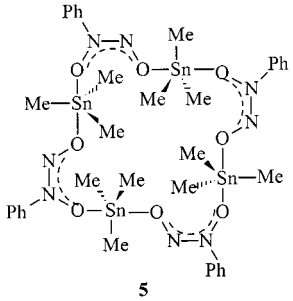
Scheme 1



5

Scheme 2

Compound **5** seemed an attractive starting material for building supramolecular structures based upon chains of alternating trigonal planar $SnMe_3$ units with rigid linear spacers, such as 4,4′-bipyridine (4,4′-bipy). The reaction of **5** with 4,4′-bipy, however, afforded a dimethyltin derivative **2**, following tin−carbon bond redistribution (vide infra). This led us to investigate the reactions of the dimethyltin derivative **1** with 4,4′-bpy and with pyridine (py) as a model. Formation of **2** and **3** suggested that a nitrogen-donor base coordinates easily to the tin atom of a $Me_2Sn(cupf)_2$ moiety and we decided to use 2,6-diamino-4-phenyl-1,3,5-triazine (dpt) as a coordinated ligand able to participate in intermolecular hydrogen bond interactions and thus to connect the tin coordination centres into supramolecular architectures. This approach is well documented by several examples of hydrogen bond self-assembled supramolecular structures formed by interactions between amino substituents and heteroatoms.[3] From our previous experience with cobalt and nickel cupferronato adducts of dpt[4] we knew that metalcupferronates could form supramolecular structures based upon this strategy. Although only in its

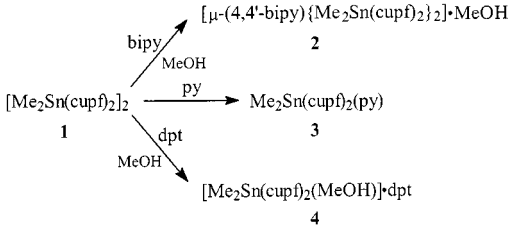
infancy, the combination of coordination dative and hydrogen bonds in the construction of supramolecular architectures opens a wide area of investigation, and has already provided some interesting results.[4] On the other hand, some organotin supramolecular assemblies based on hydrogen bonds are known,[6] opening a potentially broad field for novel materials of this type.

The reactions investigated in this research are illustrated in Scheme 3. The structural analyses of the products thus obtained, [μ-(4,4′-bipy){$Me_2Sn(cupf)_2$}$_2$]·MeOH (**2**), $Me_2Sn(cupf)_2(py)$ (**3**), and [$Me_2Sn(cupf)_2$(MeOH)]·dpt (**4**), are reported here. To this end, X-ray analyses of **2**−**4** were carried out and the resulting structures compared with those of **1** and **5** reported previously.[1,2]



Scheme 3

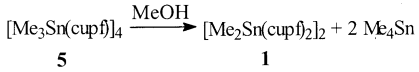
Solid-state ^{119}Sn NMR spectroscopy is known to give insight into the local symmetry properties of the central tin(IV) atom, and, combined with solution ^{119}Sn NMR spectroscopic data, provides information about the structural changes occurring upon dissolution of the organotin compounds.[7] The availability of X-ray data on a set of structurally related organotin(IV) molecules (**1**−**5**) prompted us to complement the present work with the solid-state and solution NMR spectroscopic data.

Results and Discussion

Synthesis of the Complexes

The reaction of **5**, a tetrameric complex, with bipy in methanol, and the reaction of dimer **1** in *n*-heptane with bipy, followed by recrystallisation from MeOH, both yielded the solvated binuclear complex **2** (Scheme 3).

Mössbauer spectroscopic studies[8] have shown that in concentrated methanolic solution, **5** undergoes a redistribution[9] involving Sn−Me bond cleavage (Scheme 4).



Scheme 4

Slow evaporation of a pyridine solution of **1** afforded mononuclear **3** as colourless crystals after several days. Addition of a methanolic solution of dpt to **1** in methanol readily gave **4** as a crystalline compound.

X-ray Analyses

Molecular Structures

The molecular structures of **2**−**4**, established by single-crystal X-ray diffraction, are shown in Figures 1−3, with the atom numbering schemes. The relevant geometric parameters are collected in Table 1. The data obtained for **2** reveal that the Sn^{IV} centres are heptacoordinate and located

[a] *L* = *A* and *L* = *B* represent the two different cupferronato ligands chelated to tin.

in a nearly pentagonal bipyramidal environment, with the equatorial plane defined by the O_4N donor set of the cupferronato and the bipy ligands, and the two methyl groups in the apical positions. The formation of **2** occurs through the cleavage of the dative Sn←O bonds of the dimer **1**, with the bipy ligands acting as spacers that link the two Me_2Sn^{IV} centres. One should note that the four-membered Sn_2O_2 ring, typical for all structurally characterised pentagonal bipyramidal C_2SnO_4N cores of Me_2Sn^{IV} dimers,[10] is absent in **2**. Consequently, each half of **2** contains two SnO_2N_2 units as five-membered chelate rings (*A* and *B*) with O(1*L*)−Sn(1)−O(2*L*) bite angles of 67.51(4)° (*A*) and 66.87(4)° (*B*). The lengths of the two Sn−O bond formed in ligands *A* are nearly equal (Δ = 0.009 Å), while those in ligands *B* are slightly different (Δ = 0.054 Å). It should be mentioned here that the chelating cupferronato anions in the parent **1** are isobidentate when coordinated to the dimethyltin(IV) centre (Δ = 0.076 Å), whereas the triconnective cupferronato ligands exhibit different Sn−O bond lengths (Δ = 0.148 Å). In a manner similar to the tridentate aminodicarboxylato anions in dimethyltin(IV) dimers,[10] the latter finding may be ascribed to the triconnective coordination of the cupferronato O atoms. The Sn−N bond length of 2.4450 (1) Å in **2** is slightly longer than the 2.402(2) Å observed in the polymeric $[Me_2SnCl_2(4,4'\text{-bipy})]_n$ complex.[11] There are two positionally disordered MeOH molecules in the unit cell (space group $P2_1/n$) with their O atoms in special positions (inversion centres).

Dissolution of **1** in anhydrous pyridine affords **3**, the "monomeric" form of **2**. Consequently, each tin(IV) centre retains its nearly pentagonal bipyramidal coordination. To the best of our knowledge this is the first reported case where a Me_2Sn^{IV} complex is built from C_2SnO_4N core, despite the fact that this core is known to be ubiquitous in multinuclear complexes.[7,10] The structural similarity between **3** and **2** is reflected by the practically unaltered O(1*L*)−Sn(1)−O(2*L*) bite angles [67.53(5)° for *A* and 67.71(5)° for *B*] and differential Sn−O distances (Δ = 0.052 Å for *A*, Δ = 0.086 Å for *B*). The Sn−N distance is somewhat longer than those found for dimer **2** and Me_2SnCl_2·2py (2.39 Å).[12] In a manner similar to **2**, the nitrosohydroxylaminato groups of the cupferronato anions are essentially planar in **3**, while the phenyl ring is nearly coplanar with the plane of the N(O)NO group, although the O(1*L*)−N(1*L*)−C(1*L*)−C(6*L*) and O(1*L*)−N(1*L*)−C(1*L*)−C(2*L*) torsion angles show some variation (Table 1).

The crystal lattice of **4** contains the complex $Me_2Sn(cupf)_2(MeOH)$ (**4a**) and dpt molecules. The coordination geometry of the Sn^{IV} atom in **4** was found to be closely similar to that in **2** and **3**. Coordination of the bulky dpt unit to the Me_2Sn^{IV} centre via the pyridyl nitrogen atoms is sterically hindered by the likewise bulky cupferronato ligands. Therefore, only one MeOH molecule may occupy the vacant seventh position of the coordination sphere. In this arrangement, the O atom of the MeOH molecule occupies the position of the N atom of bipy (**2**) or py (**3**). This results in a pentagonal bipyramidal C_2SnO_5 core, like the one found for the parent **1**. The latter core is known to occur both in mononuclear[13] and dinuclear[2,14] Me_2Sn^{IV} complexes, although **4** represents the first structurally characterised compound containing methanol coordinated to a dimethyltin(IV) centre.

In complex **4**, the cupferronato *A* and *B* ligands display fairly similar coordination, but remarkably different hydrogen bonding. Both *A* and *B* form five-membered inorganic SnO_2N_2 rings that assume different O(1*L*)−Sn(1)−O(2*L*) bite angles [66.12(3)° for *A* and 69.43(4)° for *B*] and unequal differential Sn−O bond lengths: Δ = 0.064 Å in ligand *A* and Δ = 0.079 Å in ligand *B*. Finally, in anion *B*, the plane of the phenyl group is markedly twisted away from the plane of the N(O)NO group with the O(1*B*)−N(1*B*)−C(1*B*)−C(6*B*) torsion angle taking a value of −145.1(1)°.

Crystal Packing and Supramolecular Organisation

The data collected in Table 2 reveal that the crystal lattices of the complexes reported in this work are supramolec-

ular architectures involving more than just van der Waals interactions. Thus, molecules **2** and **3** form crystal lattices stabilised by weak C−H···π intermolecular interactions. An additional interaction via weak C−H···O hydrogen bonding between individual molecules can also be observed in the crystal lattice of **2**.

Compound **4** forms an infinite supramolecular structure (Figure 4) where units of **4a** and dpt molecules are interconnected by regular N−H···O and O−H···N hydrogen bonds, mediated in part by the MeOH molecules. On the one hand, this is achieved in such a way that the MeOH molecules form short (1.96 Å) O−H···N hydrogen bonds with the neighbouring dpt units. In competition with the MeOH molecules, the dpt units, in their turn, interact with the two oxygen atoms of cupferronato anions of the **4a** complex via N−H···O hydrogen bonds (2.11 Å and 2.46 Å). The intermolecular O−H···N and N−H···O hydrogen bonds together assemble the units **4a** and dpt in infinite chains. These chains then become cross-linked to their respective symmetry-related neighbouring chains through N−H···O and N−H···N hydrogen bonds (2.32 Å and 2.18 Å, respectively) to form infinite one-dimensional double-chains (ribbons). In the supramolecular structure thus formed, the Sn···Sn separation between neighbouring **4a** units amounts to ca. 6.8 Å. It may be noted that the N−H···N hydrogen bonds between neighbouring dpt units lead to the formation of eight-membered $(N-C-N-H\cdots)_2$ rings (see Figure 4), while, using the hydrogen atoms of their NH_2 groups, the dpt units also formed N−H···O hydrogen bonds with the cupferronato O atoms of **4a** in the adjacent chain.

Alternatively, the supramolecular arrays can be described as containing pairs of hydrogen-bonded dpt molecules (via N−H···N bonds), interconnected through two separate **4a** molecules, via N−H···O bonds (to the chelate rings) and N···H−O bonds (to the coordinated methanol molecules). Therefore, the supramolecular architecture is a result of the co-operative use of hydrogen bonds and dative coordinate bonds (provided by the methanol ligand).

The neighbouring supramolecular sheets are ordered by C−H···π (Table 2) and π···π interactions. These weak C−H···π and π···π interactions influence the nature of hydrogen-bonding and vice versa.[15]

Structure Determination by NMR Spectroscopy

The structurally relevant NMR spectral parameters for **1**−**5** are collected in Table 3. (For the fully assigned, solution, ^1H, ^{13}C, and ^{119}Sn NMR parameters see the Exp. Sect. and ref.[2]).

Within a given set of related organotin complexes, the chemical shift of the ^{119}Sn nuclei has been shown to reflect the coordination number, the size of the chelate ring, and the nature of the donor atom directly bonded to the central tin(IV) atom: higher coordination numbers, larger ring sizes, and lower electronegativities of the donor atoms shift the ^{119}Sn resonance to lower frequencies.[3,16] Although an exact separation of the various contributions to the nuclear shielding is beyond current theoretical knowledge, the ^{119}Sn chemical shift values in Table 3 do, in general, follow the expected trends. The highest value of the chemical shift of tetrameric (**5**) clearly reflects its pentacoordinated geometry,[1] while the nuclear shielding found for **1**−**4** falls in the range typical of hexa- and heptacoordinated organotin complexes.[3,12] One may tentatively assume that the rela-

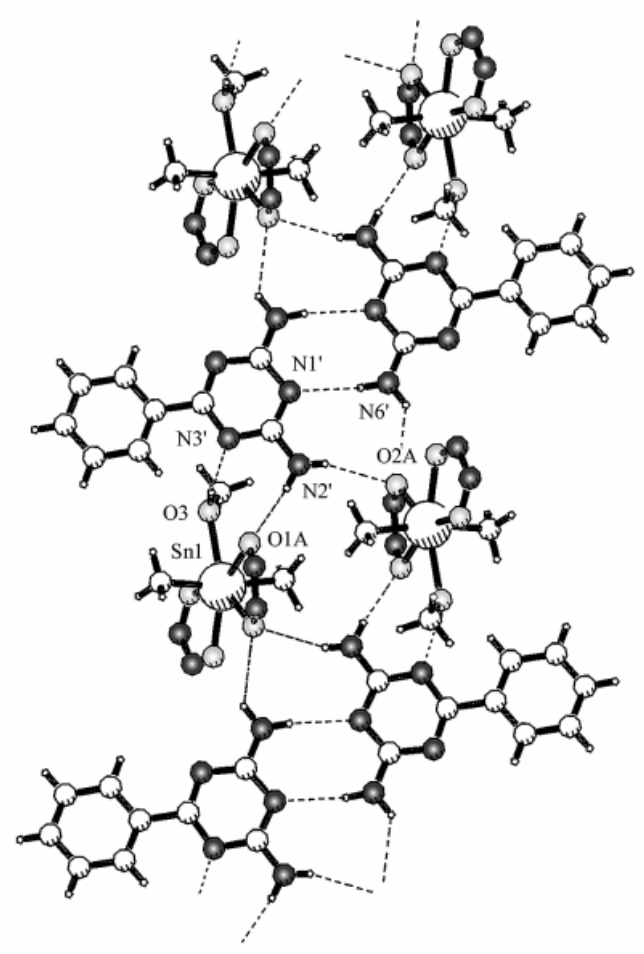

Figure 4. Section of the crystal structure of **4** showing the infinite one-dimensional double-chains (ribbons) formed through O−H···N and N−H···X (X = O, N) hydrogen bonds; the phenyl groups were omitted for clarity.

tively lower δ_i^{Sn} values observed for solid **1** and **4** are due to the higher electronegativity of the directly bonded oxygen atom as compared to the N-linkage in **2** and **3**.[16]

The chemical shift anisotropy, $\Delta\sigma$, for **1**−**4** varies in the range between +383 and +532 ppm, while it becomes negative (−262 ppm) in **5**. An analogous dissimilarity can be seen in the case of the asymmetry parameter, η: it is zero, or nearly zero, in complexes **1**−**4** while it has a substantial value (0.6) in **5**. Low values of η are known to reflect axial symmetry of the tin(IV) centre,[17] an expectation fully supported by X-ray results showing pentagonal bipyramidal coordination geometry for **1**−**4**. By contrast, the asymmetry parameter measured for **5** may be rationalised by considering the X-ray structure of this molecule.[1] It has been found that a weak, secondary, nonbonded Sn···O interaction removes the axial symmetry of the Sn^{IV} centre, which then assumes a distorted trigonal bipyramidal (TBP), pseudo hexagonal, geometry.

The magnitude of the solid state one bond tin−carbon scalar coupling, $^1J(^{119}Sn-^{13}C)$, (measured here as the frequency difference between ^{119}Sn satellite signals in the ^{13}C CP MAS spectra) can be used for estimating the Me−Sn−Me angle.[7] The coupling data obtained for **1**−**4** fall in the range ≈ 1060−1160 Hz (Table 3), and according to the Lockhart−Manders approximation,[7] give a value of 170−179°, in good overall agreement with X-ray observations. It should be noted, however, that the slight changes in the Me−Sn−Me angles show opposite trends according to whether the angles were inferred from X-ray or $^1J(^{119}Sn-^{13}C)$ coupling data (see Table 4). The value of 520 Hz measured for **5** gives 122°, in excellent agreement with the X-ray-derived average value, 120°.

Table 4. Values of Me−Sn−Me angles(°) from X-ray and from ^1J and ^2J[7a]

Compd.	Me−Sn−Me (°) X-ray	^1J(solid)[a]	^1J(solution)[a]	^2J(solution)[b]
1	173.6(1)[2]	171.6	136.3	127.3
2	177.91(7)	173	142.8	135.6
3	174.30(9)	173.8	151	145.8
4	170.75(6)	181.5	175.8	191.7
5	119.91(12)[1] [c]	121.3	110.4	109.5

[a] Me−Sn−Me (°) = ($|^1J|$ + 778)/10.7 [b] Me−Sn−Me (°) = 0.0161 ($|^2J|)^2 - 1.32(|^2J|)$ + 133.4 [c] average value

Some additional features of the ^{13}C CP MAS spectra deserve attention. Mirroring the slight changes in the steric environments of the two Sn^{IV}-bonded Me carbon atoms, the ^{13}C spectra of **1**−**4** display two methyl signals separated by 1.3−2.7 ppm (Table 3). No such effect could be resolved (at 100 MHz) in the spectrum of **5** having three, equatorially oriented, methyl groups attached to the central Sn^{IV} atom. The ^{13}C CP MAS spectrum of **4** also displays a sharp resonance at δ = 49.5 attributable to the methanol Me signal.

Dissolution of the complexes results in several changes in the spectral parameters (see Table 3) that suggest differences between the molecular conformations in the solid and solution states. The solution ^{119}Sn chemical shifts, δ^{Sn}(sol.), for **1**−**3** are fairly close to their isotropic values, δ_i^{Sn}, found in the solid state, suggesting that the coordination geometry of these complexes remains unaffected by dissolution. The marked shift to lower frequency of the ^{119}Sn resonance in **4** may be tentatively rationalised by assuming that due to the presence of DMSO in the solvent (which may replace the coordinated methanol molecule), the coordination pattern of the complex undergoes some modifications. In contrast to the near-constancy of the overall molecular geometry in the two states, as mirrored by the ^{119}Sn chemical shifts, $^1J(^{119}Sn-^{13}C)$ and in part $^2J(^{119}Sn-^1H)$, couplings suggest that the solvent-solute interactions may, in reality, give rise to some changes in the molecular geometry. As attested by the coupling data, these are highest in **1** while practically absent in **4**. For **1** we find that the Me−Sn−Me angle assumes a value of approx. 130° in solution as opposed to 170° (X-ray: 173.6°) in the solid-state (see Table 4). It seems justified to assume that so significant a decrease of the bond angles at the Sn^{IV} centre of the complex should entail further changes in the molecular conformation. However, at this stage of our work we cannot suggest a plausible correlation between the extent of solvent-induced geometrical changes and the structure of the complexes.

The δ = 1.5 measured for δ_i^{Sn} in **5** is in accordance[18] with the *trans*-TBP pentacoordinated structure of this complex (see above).[1] The ^{119}Sn resonance was shifted to higher frequency (δ = 95.9) in solution, which is best understood by assuming that the tetrameric complex dissociates into monomeric species featuring *cis*-TBP coordination geometry. This expectation seems to be supported by the reduction of the Me−Sn−Me angle from its original value of 120°, typical of planar Me_3Sn groups, to the value of 110° (see Table 4) characteristic for the pyramidal Me_3Sn arrangement as in the proposed monomer.[19]

Conclusion

Coordination of N- and O-donor molecules to the Me_2Sn^{IV} centre of dimeric **1** results in the cleavage of the stanoxanic dative Sn←O bonds, and subsequent formation of novel heptacoordinated dimethyltin(IV)cupferronato complexes (**2**−**4**). In these, the cupferronato ligands assume their typical chelating coordination pattern and are nearly symmetrically bound to the Me_2Sn^{IV} centre. An X-ray diffraction study of **4** revealed that the pentagonal bipyramidal C_2SnO_5 moiety might interact with dpt molecules through hydrogen-bonding interactions. Multinuclear solid- and solution NMR spectroscopic data of the novel complexes provide useful complementary information about structural changes accompanying the dissolution of the crystalline complexes.

Experimental Section

General Remarks: All reagents and solvents were purchased from commercial suppliers. The preparation and purification of the complexes were carried out in the open air or in a dry atmosphere, as indicated. The syntheses of **1**[2] and **5**[1] were reported previously. All other starting materials were obtained from commercial sources as pure compounds and used as received. − FT-IR spectra were recorded with a Jasco FT/IR 615 spectrometer. − NMR spectroscopy: A Varian Associates model Unity-Inova 400 NMR spectrometer was used to run the NMR spectra using TMS as the internal reference for ^{1}H, ^{13}C, and external $SnMe_4$ for ^{119}Sn spectra. Solution spectra were recorded at 30 °C using solutions of ca. 5% in $CDCl_3$. For solubility reasons, spectra for **4** were taken in a [D_6]DMSO/$CDCl_3$ (1:1) solvent mixture. Assignment of the resonances to individual sites in the molecules was inferred from ^nJ(H−H) and ^nJ(C−C) coupling patterns and, when needed, verified through standard, gradient-enhanced, homo-, and heteronuclear 2D (gDQFCOSY,[20] gHSQC[20]) experiments. − Solid-state ^{119}Sn and ^{13}C CP MAS spectra were recorded at room temperature using 7 mm rotors. Typically, two ^{119}Sn CP-MAS spectra were recorded at significantly different spinning rates, ca. 2000 and 4500 rps, respectively. The π/2 pulse width for ^{119}Sn had a value of 4.1 μs (61 kHz). A recycle delay of 20 s and a CP time of 1 ms were used, and from 30000 to 36000 transients were co-added to obtain the fits. Solid-state ^{119}Sn line-widths varied between 250 to 500 Hz. Solid-state spectral parameters (see Table 3) were inferred by iterative fitting of simulated spectra to the side band manifold of the experimental spectra. The r.m.s. errors of the fitting procedures varied between 0.12 and 0.18 suggesting a 10 to 15 ppm probable error in the values of δ_i and Δσ. However, due to limited pulse power for the uniform excitation of the wide (5000−8000 ppm) ^{119}Sn spectral range, the real errors of these parameters may be larger. ^{13}C CP MAS spectra were taken at spinning rates 3000−4000 rps using a pw90 = 4.1μs (61 KHz) carbon pulse, 5 s recycle delay, 1 ms CP time, and from 4000 to 8000 transients. In alternative runs the TOSS sequence[21] was used to remove the spinning side bands. Solids-state ^{13}C line-widths varied between 100 and 150 Hz.

(μ$_2$−4,4′-Bipyridyl)-bis[di-*N*-nitroso-*N*-phenyl-(hydroxylaminato)-dimethyltin(IV)] Methanol Solvate (2). − Method A: To a solution containing **1** (0.41 g, 0.47 mmol) in 5 mL of *n*-heptane was added a solution of bipy (0.10 g, 0.64 mmol, 35% excess) in 2 mL of *n*-heptane while stirring. Precipitation of the complex occurred immediately. After stirring for one hour at room temperature the precipitate was filtered off and washed with cold MeOH and dried in air. Yield 0.385 g, 81%. The product was recrystallized from MeOH under ambient conditions as large colourless block crystals.

Method B: To a solution containing **5** (0.3 g, 0.25 mmol) in 3 mL of MeOH was added a solution of bipy (0.156 g, 1 mmol, 300% excess) in 2 mL of MeOH while stirring. The mixture was stirred for 4 hours. After 2−3 days the compound was separated as large colourless block crystals. The crystals were filtered off, washed with cold MeOH and dried in air. Yield 0.14 g, 53%, melting point 125−126 °C. − FT-IR (KBr): $\tilde{\nu}$ = 3483 cm^{-1} (O−H) (m b), 3104−2823 (m b), 1606 (O−H) (m), 1482 (Ph) (m), 1461 (Ph) (ms), 1415(m), 1337 (N−N) (ms), 1285 (vs), 1215 (N=O) (s), 1166 (N=O) (ms), 1060 (ms), 921 (ONNO) (s), 812 (m), 761 (Ph) (s), 691 (Ph) (s), 627 (ms), 576 (SnC_2) (m), 523 (Sn−C) (m), 395 (Sn−O) (vs). − ^{1}H NMR ($CDCl_3$, 399.10 MHz, 30 °C): δ = 0.79 [m, 6 H, CH_3, $^1J(^{13}C-^1H)$ = 132.3 Hz, $^2J(^{119}Sn-^1H)$ = 83.6 Hz, $^2J(^{117}Sn-^1H)$ = 80.0 Hz, $^2J(^{115}Sn-^1H)$ = 73.6 Hz], 7.46 (m, 3 H, Ph−H3, −H4, −H5), 7.59 (m, 2 H, Py−H3, −H5), 7.96 (m, 2 H,

X-ray Crystallographic Study: Crystal data and refinement parameters are summarised in Table 5. Intensity data were collected on an Enraf−Nonius CAD-4 diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) using the ω-2θ scan technique. Three standard reflections were monitored every hour; these remained constant within experimental error. The structures were solved by direct methods (SHELXS-97)[22a] and refined by full-matrix least-squares (SHELXL-97).[22b] All non-hydrogen atoms were refined anisotropically in F^2 mode. Hydrogen atomic positions were generated from assumed geometries. The riding model was applied for the hydrogen atoms. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication nos. CCDC-162624 (**2**), CCDC-162625 (**3**) and CCDC-162626 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44(1223)336−033; E-mail: deposit@ccdc.cam.ac.uk].

1D Zigzag Coordination Polymers of Copper(II) and Nickel(II) with Mixed Ligands − Syntheses and Structures

Han Woong Park,[a] Soo Mi Sung,[a] Kil Sik Min,[a] Hyochoon Bang,[b] and Myunghyun Paik Suh*[a]

Keywords: Magnetic properties / N ligands / Polymers / Copper / Nickel / Self assembly

The one-dimensional coordination polymers $[Cu(NO_3)_2(2,2'\text{-bipy})(4,4'\text{-bipy})]_n{\cdot}2nCH_3OH$ (**1**) and $[Ni(tren)(4,4'\text{-bipy})]_n(ClO_4)_{2n}$ (**2**), have been synthesized by the self-assembly of a copper(II) complex of 2,2′-bipy and a nickel(II) complex of tren with 4,4′-bipy (2,2′-bipy = 2,2′-bipyridine, 4,4′-bipy = 4,4′-bipyridine, and tren = tris-(2-aminoethyl)amine). Their X-ray crystal structures show that the metal ions in **1** and **2** display a distorted octahedral coordination geometry to bind two 4,4′-bipy ligands at the *cis* positions. Each 4,4′-bipy links two $[Cu(NO_3)_2(2,2'\text{-bipy})]$ units in **1** and two $[Ni(tren)]^{2+}$ units in **2** to form 1D zigzag chains. In the structure of **1**, these chains are linked by offset π–π interactions through 2,2′-bipy ligands, giving rise to a 2D network. The pyridine rings in the 4,4′-bipy ligand are coplanar in **1** but twisted in **2**. The coordination polymer **1** shows a weak antiferromagnetic interaction between copper(II) ions with $J = -0.53$ cm^{-1} ($H = -J\sum_{i=1}^{n-1} S_{Ai}S_{A(i+1)}$).

Introduction

The construction of coordination polymers based on metal and organic building blocks is a rapidly developing area of research.[1] Coordination polymers with diverse architectures, such as linear or zigzag chains, helices, honeycombs, square grids, ladders, brick walls, and interwoven diamondoids have been extensively developed.[2] These coordination polymers attract a great deal of attention because of their interesting structural properties and potential applications to magnetism,[1f,3] electrical conductivity,[4] ion exchange,[5] separation,[1h,6] and catalysis.[7] Many important properties of coordination polymers arise from their structures and topology, and thus the rational design and construction of specific architectures are particularly important. To construct the desired framework, rigid organic building blocks are most often used.[8]

Here we report the synthesis and crystal structures of two 1D zigzag coordination polymers $[Cu(NO_3)_2(2,2'\text{-bipy})(4,4'\text{-bipy})]_n{\cdot}2nCH_3OH$ (**1**) and $[Ni(tren)(4,4'\text{-bipy})]_n(ClO_4)_{2n}$ (**2**), where the $[Cu(NO_3)_2(2,2'\text{-bipy})]$ units and $[Ni(tren)]^{2+}$ units are linked by a 4,4′-bipy ligand. The bidentate ligand 4,4′-bipy was chosen as the rigid organic building block that connects the metal ions because of its rod-like shape.[9] The coordination polymer **1** shows an antiferromagnetic interaction between the copper(II) ions.

Results and Discussion

Synthesis and Properties

The 1D zigzag coordination polymer $[Cu(NO_3)_2(2,2'\text{-bipy})(4,4'\text{-bipy})]_n{\cdot}2nCH_3OH$ (**1**) was synthesized in high yield by the self-assembly of $[Cu(NO_3)_2(2,2'\text{-bipy})]$ and 4,4′-bipy in MeOH. Similarly, the 1D zigzag polymer $[Ni(tren)(4,4'\text{-bipy})]_n(ClO_4)_{2n}$ (**2**) was obtained by the self-assembly of $[Ni(CH_3CO_2)_2{\cdot}4H_2O]$, 4,4′-bipy, and tren in MeOH. Although the assemblies could have resulted in compounds with a square architecture (Schemes 1 and 2),[10] we were only able to isolate the zigzag polymers. The IR and UV/Vis spectroscopic data of **1** and **2** are summarized in Table 1.

The coordination polymer **1** is purple in the solid state, and forms a blue solution upon addition of H_2O, DMF, or DMSO as it dissociates into the building blocks. It is insoluble in most other organic solvents. The UV/Vis spectrum of **1** in the solid state shows a band at 597 nm; an aqueous solution of **1** shows λ_{max} at 678 nm ($\varepsilon = 39.9$ M^{-1}cm^{-1}), which is similar to the absorption of $[Cu(NO_3)_2(2,2'\text{-bipy})]$.[11] Compound **1** shows an OH stretching band at 3468 cm^{-1} and C=C stretching bands for the bipy rings at 1612, 1569, and 1535 cm^{-1}. By comparison with the IR spectrum of $[Cu(NO_3)_2(2,2'\text{-bipy})]$,[11] the peaks at 1612 and 1569 cm^{-1} can be assigned to those of 2,2′-bipy and the peak at 1535 cm^{-1} to that of 4,4′-bipy.

The coordination polymer **2** is pale violet in the solid state. It is soluble in H_2O, MeCN, $MeNO_2$, DMF, or DMSO, but insoluble in most other organic solvents. The diffuse reflectance spectrum of **2** shows a maximum absorption at 495 nm. When **2** is dissolved in MeCN/H_2O (1:1 v/v), however, the absorption band (λ_{max}) shifts to 552 nm ($\varepsilon = 10.6$ M^{-1}cm^{-1}), which is similar to that of $[Ni(tren)(H_2O)_2]^{2+}$ in MeCN/H_2O ($\lambda_{max} = 555$ nm, $\varepsilon = 9.3$

$[Ni(tren)(4,4'\text{-bipy})]_n(ClO_4)_{2n}$ (**2**)	ν_{tren} 3344, 3296, 1608 ν_{py} 1535 ν_{ClO_4} 1089	495[d] 552(10.6)[f]

[a] Measured as a Nujol mull. − [b] Ref.[9] − [c] Measured in water. − [d] Diffuse reflectance spectrum. − [e] Measured with an MeCN/water solution containing 1 equiv. of $[Ni(OAc)_2 \cdot 4H_2O]$ and 1 equiv. of tren. − [f] Measured in MeCN/water.

$M^{-1}cm^{-1}$). We assume that the $[Ni(tren)]^{2+}$ moiety coordinates two water molecules in water according to the X-ray crystal structure of $[Ni(tren)(H_2O)_2]SO_4$ previously reported.[12] It is obvious that the polymeric structure decomposes into discrete units of $[Ni(tren)(H_2O)_2]^{2+}$ and 4,4′-bipy in $MeCN/H_2O$. The infrared spectrum of **2** shows strong absorption bands at 3344 cm^{-1} and 3296 cm^{-1}, which are attributed to the N−H stretching modes of the tren ligand. The NH_2 bending mode of tren appears at 1608 cm^{-1} and the C=C stretching of 4,4′-bipy at 1535 cm^{-1}.

X-ray Crystal Structure of 1

An ORTEP view of **1** is shown in Figure 1a. Table 2 shows the selected bond lengths and angles. In the structure, the copper(II) ion shows a distorted octahedral coordination geometry by binding a 2,2′-bipy and two 4,4′-bipy ligands in the equatorial positions and two nitrate anions at the axial sites. The average $Cu-N_{2,2'\text{-bipy}}$ and $Cu-N_{4,4'\text{-bipy}}$ bond lengths are 2.013(1) and 2.034(1) Å, respectively. The average Cu−O bond length involving nitrate li-

[a] Marked atoms are generated by the symmetry operation $2.5 - x$, $-0.5 + y$, $1.5 - z$. − [b] Marked atoms are generated by the symmetry operation $2.5 - x$, $0.5 + y$, $1.5 - z$.

gands is 2.505(1) Å, which is significantly longer than the equatorial Cu−N bond lengths because of a Jahn−Teller distortion. The angles N1−Cu1−N3 and N2−Cu1−N4 between 2,2′-bipy and 4,4′-bipy are greater than 90° because the chelate angle of 2,2′-bipy and the angle between two 4,4′-bipy ligands are less than 90°. The copper(II) ion lies 0.025(1) Å out of the square-coordination plane toward O4. Each 4,4′-bipy ligand links two copper(II) ions to form a zigzag chain which extends parallel to the *c* axis. The 4,4′-bipy unit is perfectly coplanar, with a dihedral angle of 0.0° between the two pyridyl ring planes. The dihedral angles between a 2,2′-bipy plane and the pyridine ring planes of 4,4′-bipy involving N3 and N4 are 87.4(1)° and 87.0(1)°, respectively. These perpendicular orientations must be attributed to the steric hindrance between the α-hydrogen atoms of the two different bipyridine ligands located at the *cis* positions. The dihedral angle between the two coordinating pyridyl ring planes involving different 4,4′-bipy ligands is 79.2(1)°. The distances Cu1···Cu2 and Cu1···Cu3 within a chain are 11.144(1) and 11.172(1) Å, respectively. The shortest interchain Cu···Cu distance is 6.980(1) Å. There are offset π−π interactions involving 2,2′-bipy groups between the zigzag chains. The centroid separation and the dihedral angle between the interacting 2,2′-bipy groups are 3.911 Å and 0.0°. The interactions propagate along the *b*−*a* direction, which leads to a 2D network structure (Figure 1b). The methanol guest molecule is involved in a hy-

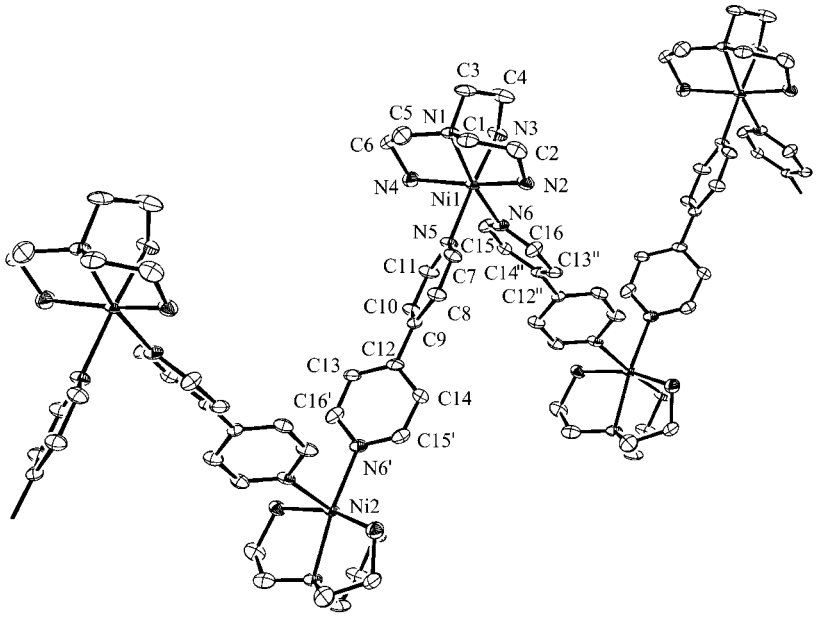

Figure 2. ORTEP drawing of **2** with atomic numbering scheme ($' = 2.5 - x, -0.5 + y, 1.5 - z$; $'' = 2.5 - x, 0.5 + y, 1.5 - z$); thermal ellipsoids are shown at the 40% probability level

drogen-bonding interaction with the oxygen atom of the coordinated nitrate anion [O5···O7($-1+x$, y, z): 2.796 Å; O5···H7A−O7: 165.5°].

X-ray Crystal Structure of 2

An ORTEP view of **2** is shown in Figure 2. Table 3 shows the selected bond lengths and angles. In the structure, the nickel(II) ion is coordinated to one tertiary and three secondary nitrogen atoms of a tren and two 4,4′-bipy ligands to form a distorted octahedral geometry. The average $Ni-N_{tren}$ and $Ni-N_{4,4'\text{-bipy}}$ bond lengths are 2.123(2) and 2.164(2) Å, respectively. The bite angles of tren are in the range 81−83°. Two 4,4′-bipy ligands coordinate a nickel(II) ion at the *cis* positions and each 4,4′-bipy ligand links adjacent $[Ni(tren)]^{2+}$ units, which gives rise to a 1D zigzag chain extending parallel to the *b* axis. In contrast to the structure of **1**, the 4,4′-bipy ligand is not planar. The dihedral angle between the two pyridyl ring planes in a 4,4′-bipy ligand is 37.9(3)°. This distortion is not unusual and has been observed with other complexes bridged by 4,4′-bipy ligands.[13] The dihedral angle between two pyridyl ring planes involving N5 and N6 is 76.8(3)°. This angle is lower than that in the structure of **1**, which must be attributed to steric hindrance with the tren ligand. The shortest Ni···Ni distance within a chain is 11.371(2) Å, and the shortest interchain Ni···Ni distance is 7.936(1) Å.

Magnetic Properties of 1

The effective magnetic moment of **1** measured at 300 K is 1.75 μ_B, in good agreement with the spin-only value of copper(II) (1.78 μ_B). The temperature dependence of the magnetic susceptibility of **1** is shown in Figure 3. The susceptibility data in the temperature range 20−300 K follow the Curie−Weiss law, where $\chi_M = C/(T - \theta)$ and $\theta = -1.8$ K. The value of $\chi_M T$ decreases as the temperature is lowered, indicating that an antiferromagnetic interaction exists between the copper(II) ions. To obtain the magnetic parameters, the magnetic susceptibility data were fitted to Equation (1), where N, β, and k are the Avogadro number, the Bohr magneton, and the Boltzmann constant, respectively.[14−15] For the simple chain made by an array of equally spaced copper(II) ions with $S = 1/2$ local spins, the spin Hamiltonian in zero-field describing the isotropic interaction between the nearest neighbor ions is expressed as Equation (2) and the magnetic susceptibility is expressed as Equation (1).[14]

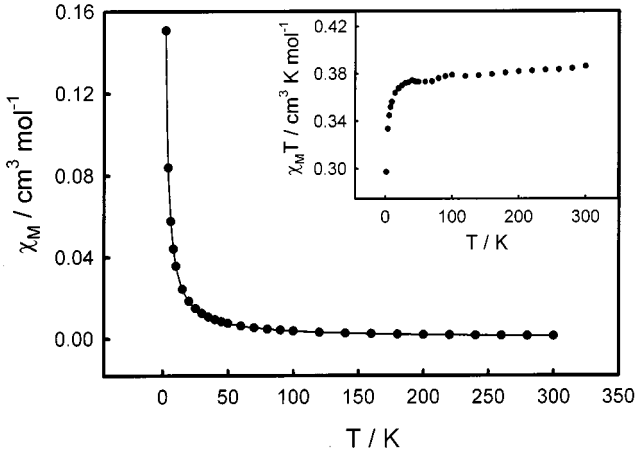

Figure 3. Plots of χ_M vs. T and $\chi_M T$ vs. T (inset) for **1**; the solid line represents the best-fit curve to Equation (1)

Table 4. Magnetic properties of various compounds bridged by 4,4′-bipy

Compounds[a]	θ [K]	J [cm^{-1}]	g	ref.
$[Cu(NO_3)_2(2,2'\text{-bipy})(4,4'\text{-bipy})]_n \cdot 2nCH_3OH$	−1.8	−0.53	2.01	This work
$[Cu_2(ClO_4)_2(dien)_2(4,4'\text{-bipy})](ClO_4)_2$	−0.4	−0.3	2.03	16
$[Cu_2(tren)_2(4,4'\text{-bipy})](BPh_4)_4$		< 1.0		17
$[Ni(Bu\text{-}dtp)_2(4,4'\text{-bipy})]_n$	−32			20

[a] Abbreviations used: dien = diethylenetriamine; Bu-dtp = dibutyldithiophosphate.

$$\chi = \frac{Ng^2\beta^2}{kT}\,\frac{0.25 + 0.074975x + 0.075235x^2}{1.0 + 0.9931x + 0.172135x^2 + 0.757825x^3}\,,\ \text{where}\ x = \frac{|J|}{kT} \quad (1)$$

$$H = -J\sum_{i=1}^{n-1} S_{Ai}S_{Ai+1} \quad (2)$$

The solid line in Figure 3 represents the best fit of the data to Equation (1), which provides $g = 2.01$ and $J = -0.53$ cm^{-1} with $R = 4.0 \times 10^{-6}$. The data are compared with those of other complexes bridged by a 4,4′-bipy ligand in Table 4. It is known that compounds bridged by 4,4′-bipy show almost no, or very weak, magnetic interactions because of the long distance of 4,4′-bipy (almost 11 Å)[16] and the weak Cu−N bond with the weak base 4,4′-bipy.[17] In addition, the C−C bond connecting two pyridine rings in 4,4′-bipy has a single bond character [the bond length of C13−C13′ is 1.484(6) Å], which breaks the conjugation of the 4,4′-bipy molecules. This also interrupts the magnetic interactions. The weak antiferromagnetic interaction in **1** must be attributed to the unfavorable π-type exchange pathway as well as the long σ-type exchange pathway for the 4,4′-bipy bridging ligand.

Experimental Section

General: All chemicals and solvents used in the syntheses were of reagent grade and were used without further purification. Infrared spectra were recorded with a Perkin−Elmer 2000 FT-IR spectrophotometer. Electronic spectra were measured with a CARY 300 Bio UV/Vis spectrophotometer. Magnetic susceptibility was measured on a Quantum Design MPMS superconducting quantum interference device (SQUID). Elemental analyses were performed by the analytical laboratory of the Seoul National University.

Safety Note: Although we have experienced no problem with the compounds reported in this work, perchlorate salts of metal complexes with organic ligands are often explosive and should be handled with great caution.

$[Cu(NO_3)_2(2,2'\text{-bipy})]$: An EtOH solution (10 mL) of $[Cu(NO_3)_2 \cdot 3H_2O]$ (4.82 g, 0.02 mol) was mixed with an EtOH solution (10 mL) of 2,2′-bipy (3.2 g, 0.02 mol). The blue precipitate formed was filtered, washed with EtOH, and dried in air. Yield: 6.19 g, 90%. − $C_{10}H_8CuN_4O_6$ (343.74): calcd. C 34.94, H 2.346, N 16.30; found C 34.78, H 2.055, N 16.35.

$[Cu(NO_3)_2(2,2'\text{-bipy})(4,4'\text{-bipy})]_n \cdot 2nCH_3OH$ (1): $[Cu(NO_3)_2(2,2'\text{-bipy})]$ (0.068 g, 0.20 mmol) was dissolved in MeOH (1 mL) in a test tube. A MeOH solution (1 mL) of 4,4′-bipy (0.031 g, 0.20 mmol) was then carefully added to the top of this blue solution, without disturbing it. A violet solid precipitated immediately at the interface of the two solutions, and violet crystals were formed over 10 days as the diffusion proceeded. These crystals were filtered, washed with MeOH, and dried in air. Yield: 0.089 g, 80%. − $C_{22}H_{24}CuN_6O_8$ (564.01): calcd. C 46.85, H 4.289, N 14.90; found C 45.28, H 3.30, N 15.93.

$[Ni(tren)(4,4'\text{-bipy})]_n(ClO_4)_{2n}$ (2): A methanol solution (10 mL) of tris-(2-aminoethyl)amine (0.63 g, 4.3 mmol) and a methanol solution (1 mL) of 4,4′-bipy (0.64 g, 4.3 mmol) were added dropwise to a methanol solution (10 mL) of $[Ni(CH_3CO_2)_2 \cdot 4H_2O]$ (1.04 g, 4.2 mmol). The solution was stirred for about 30 min. at room temperature and then a methanol solution (5 mL) of $LiClO_4$ (1.81 g, 17 mmol) was added. A pale violet precipitate formed immediately, which was filtered off, washed with methanol, and dried in vacuo. Yield: 2.07 g, 86%. The single crystals used for the X-ray diffraction study were obtained by the recrystallization of the product from a 1:1 mixture of water and MeCN. − $C_{16}H_{26}Cl_2N_6NiO_8$ (560.01): calcd. C 34.32, H 4.68, N 15.01; found C 34.34, H 4.42, N 15.36.

X-ray Diffraction Measurements: Single crystals of **1** and **2** were sealed in glass capillaries containing their mother liquor. X-ray

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. − [b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

data were collected at room temperature using graphite monochromated Mo-K_α radiation on a Siemens CCD diffractometer for **1** and on an Enraf−Nonius CAD4 diffractometer for **2**. The orientation matrix and unit cell parameters were determined from 25 machine-centered reflections with $22.76° < 2\theta < 25.18°$. Axial photographs were used to verify the unit cell choice. Data were corrected for Lorentz and polarization effects. An absorption correction was made for **1**, but not for **2**. The crystal structures were solved by a Patterson synthesis[18] and refined by full-matrix least-squares refinement using the SHELXL-97 computer program.[19] All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were positioned geometrically and refined using a riding model. The detailed crystallographic data of **1** and **2** are summarized in Table 5.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-160921 (**1**) and -160922 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Pendant Functionalised Triphosphamacrocycles

Peter G. Edwards,*[a] Florent Ingold,[a] Sudantha S. Liyanage,[a] Paul D. Newman,[a] Wai-Kwok Wong,[b] and Yang Chen[b]

Keywords: Macrocyclic ligands / Phosphanes / Molybdenum / Chromium

The selective functionalisation of a single phosphorus atom in the parent $[Mo(CO)_3(12aneP_3H_3)]$, where $12aneP_3H_3$ is 1,5,9-triphosphacyclododecane, has been achieved by deprotonation and subsequent reaction with an ether containing an alkyl halide group. Yields of the monosubstituted products are very sensitive to the reaction conditions, which must be carefully controlled in order to achieve reasonable selectivity. In addition, trisubstitution of $[M(CO)_3(12aneP_3H_3)]$ with carbon chains containing pendant donors such as ethers, thioethers, amines and phosphanes has been achieved by both deprotonation/addition ($M = Mo^0$) and hydrophosphination ($M = Cr^0$) protocols. The new compounds have been characterised by spectroscopic and analytical techniques, including X-ray crystallography, and a selection of the P_3 macrocycles released from their templates by oxidation and base digestion.

Introduction

We have previously reported the template synthesis and P-atom functionalisation of 1,5,9-triphosphacyclododecane to give a number of tritertiary derivatives ($12aneP_3R_3$), which can be liberated from their Mo^0 and Cr^0 templates by oxidation of the metal centre followed by base digestion.[1] Unlike the only other triphosphorus macrocycle known as the free ligand,[2] our synthetic procedure is stereospecific (for the *syn-syn* isomer) producing ligands with identical bridging backbone functions and hence achiral phosphorus atoms. A feature of these ligands is that they are ideally suited to coordinating a trigonal face in metal coordination polyhedra; the phosphorus atoms are clearly restricted to a mutually all *cis* arrangement which in turn locates the remaining active sites at the metal to also be mutually *cis* (at least for coordination numbers of six or less). Although a number of complexes which approximate to octahedral and tetrahedral geometries are now known for the $12aneP_3R_3$ ligand, there are others which show considerable distortions from idealised geometries as noted for the four coordinate Ni^0 [3] and five-coordinate Co^{II} systems.[4]

The enhanced stability of the metal-ligand unit formed by these macrocycles is in itself of value in the stabilisation of lower coordinate transients formed during reactions (e.g. resulting from a reductive elimination). Such reduced species might not prefer facially capping ligands and it is of interest in this context to study ligand systems that may be able to further stabilise transition states or intermediates by temporary coordination of an intrinsically labile donor, i.e. hemilabile ligands. We have previously studied acyclic phosphanes containing pendant ethers[5] and are interested to extend this approach to strongly bound ligands with a macrocyclic core, such that a section of the ligand will be bound tightly with reduced lability whilst an intrinsically labile function may provide freedom for reaction at the remaining sites and transient stabilisation. Within this theme, it is desirable to be able to selectively synthesise ligands with a chosen number of pendant functions; in this paper, we present the selective stereospecific synthesis of functionalised 1,5,9-triphosphacyclododecanes having one or three pendant ether functions, as well as related trisubstituted pendant thioether, amine or phosphane macrocycles.

Results and Discussion

Following our previous work[6] on the synthesis of tritertiary 1,5,9-triphosphacyclododecane ligands, the introduction of one ether function may be performed by the deprotonation of one secondary phosphane by a strong base (*n*BuLi), followed by the reaction of the resultant coordinated phosphide with the corresponding ether-functionalised alkyl halides (Scheme 1). The temperature at which the deprotonation is performed is critical for success in the synthesis of the mono-substituted derivative **3a**. Thus, when the reaction of the coordinated phosphide (generated in situ) with 2-bromoethyl methyl ether is performed at −78 °C the desired $[Mo(CO)_3\{12aneP_3H_2(CH_2CH_2OCH_3)\}]$ (**3a**) is formed in low yield and is difficult to isolate pure from the reaction mixture. However, when the reaction is performed at −30 °C, **3a** can be obtained in good yield (70%). Monitoring (by ^{31}P NMR spectroscopy) of the reaction mixture after addition of the alkyl halide shows resonances assignable to mono-, di- and trisubstituted macrocycles, with the undesired di- and tri- by-products being far more prevalent in the mixture at −78 °C than at −30 °C.

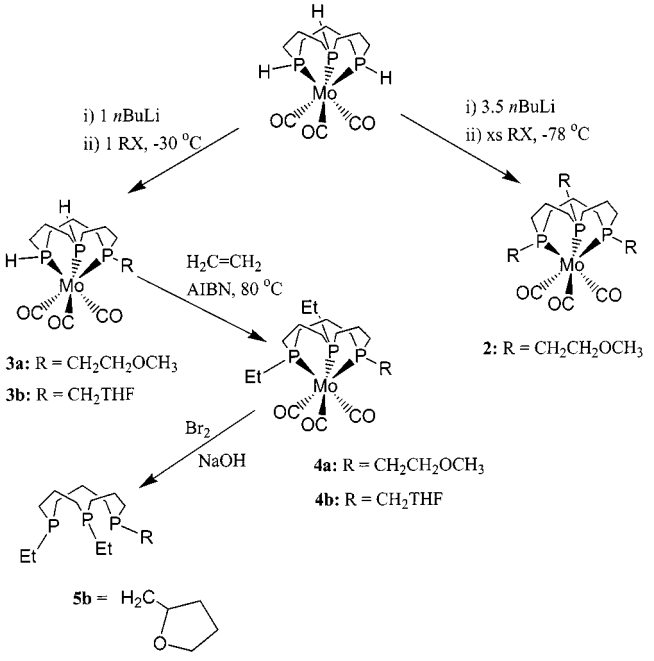
This may reflect incomplete solubility of the lithiated complex at the lower temperature. It should be noted that these yields (70%) are only obtainable with very careful control of the stoichiometry and the reaction temperature. Indeed, reproducibility is a problem and in a series of repeat reactions, yields of less than 20% were typical. Hydrophosphination of the monoether **3a** with ethene in the presence of AIBN gave the diethyl analogue **4a**. The related reaction with tetrahydrofurfuryl chloride was less successful, and although complex **3b** could be characterised by ^{31}P NMR spectroscopy and mass spectrometry, it proved impossible to isolate the complex in a pure form — the compound was invariably contaminated with unsubstituted starting material and/or further substitution (bi- and tri-) products — and it was convenient to prepare the crude diethyl derivative (**4b**) and liberate the free macrocycle **5b**, which could then be isolated pure.



Scheme 1

The $^{31}P\{^1H\}$ NMR spectrum of **3a** appears as a first order AX_2 pattern with the two equivalent secondary phosphorus centres resonating at $\delta_P = -32$ (t, $J = 32.0$ Hz) and the unique tertiary phosphorus at $\delta_P = 3$ (d, $J = 32.0$ Hz). When the two secondary phosphanes are converted into tertiary centres on ethylation to give **4a**, the $^{31}P\{^1H\}$ NMR spectrum approximates to an AM_2 pattern with signals at $\delta_P = 5.9$ (d, $J = 31.0$ Hz, $2 \times R_2PEt$) and 4.3 (t, $J = 31.0$ Hz, $R_2PCH_2CH_2OCH_3$). A similar AM_2 pattern is observed for the tetrahydrofurfuryl macrocycle complex **4b** with $\delta_P = 5.0$ (d, $J = 30.0$ Hz, $2 \times R_2PEt$) and 4.5 (t, $J = 30.0$ Hz, R_2PCH_2THF).

In the infrared spectrum of **3a** there are two bands assignable to P−H stretches at 2355 and 2323 cm^{-1} and two bands with a shoulder for the ν(C−O) stretches reflecting the lower symmetry of **3a**.

The molecular structure of **3a** is shown in Figure 1, with significant bond lengths and angles presented in Table 1. The geometry about the Mo^0 centre is octahedral, with the major source of distortion from ideal being the disparate metal−donor bond lengths [$Mo-P_{av} = 2.491(2)$ and $Mo-C_{av} = 1.989(4)$ Å]. The average Mo−P bond length is closer to that in $[Mo(12aneP_3H_3)(CO)_3]$ [2.476(1) Å][7] than in $[Mo(12aneP_3iPr_3)(CO)_3]$ [2.527(1) Å].[8] There are no significant differences in the Mo−P bond lengths for the secondary and tertiary phosphorus donors; the $M-P_{tert}$ bond being just 0.01 Å longer than the $M-P_{sec}$ bonds. Indeed, comparison with the related C_{3v} complexes above reveals less Mo−P and Mo−C bond variation in **3a** than in these higher symmetry systems. The methoxyethyl pendant group projects over one of the carbonyl groups (C3−O3) with the result that the P1−Mo−C3 angle is expanded significantly [95.99(13)°] compared to the other *cis* angles. As is typical for $12aneP_3$ complexes of Mo^0, the P−Mo−P angles are close to, but slightly less than, 90°. This contrasts with comparable Cr^0 complexes[9] and $[CpFe(12aneP_3R_3)]^+$ [10] species, where expanded angles of greater than 90° are observed; this was anticipated as the M−P bond lengths decrease along the series $Mo^0 > Cr^0 > Fe^{II}$. As in all other structurally characterised complexes of $12aneP_3$ macrocycles, two of the chelate rings have a pseudo-chair conformation whilst the third is pseudo-boat. Other deviations from idealised geometry are small and the data are comparable to other Mo^0 complexes of this type.

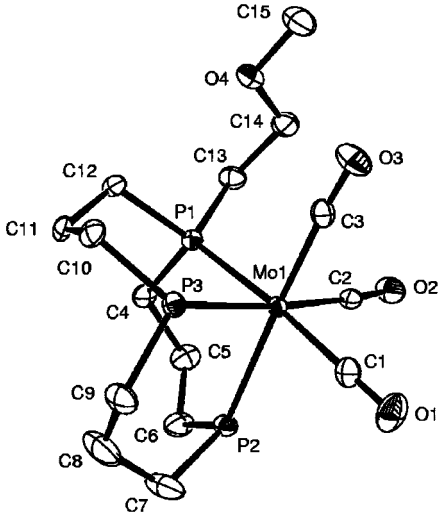


Figure 1. ORTEP representation of complex **3a**

When 3.5 mol equivalents of *n*BuLi are used followed by excess 2-bromoethyl methyl ether, the trisubstituted tertiary derivative **2** is isolated in high yield. As expected, the $^{31}P\{^1H\}$ NMR spectrum consists of a singlet at $\delta_P = 3$. The structure of the trisubstituted molybdenum complex **2** is shown in Figure 2 with selected bond lengths and angles presented in Table 2. All the bond lengths are very similar to those for complex **3a**, but, as expected for this higher symmetry complex, the angular distortions about the metal

centre are generally less than those observed in **3a**. Most notably, the large *cis* angle observed in the mono-pendant derivative is not a feature in this C_3 symmetric complex. All the features are similar to those of previously reported structures of this type, including the ubiquitous chair/chair/boat conformation of the three chelate rings.

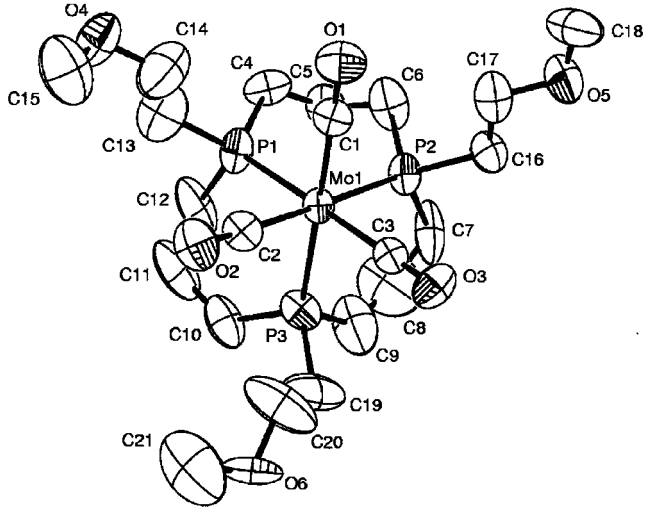

Figure 2. ORTEP representation of complex **2**

The C_3-symmetric trisubstituted macrocycles are also readily formed by radical-initiated hydrophosphinations of appropriate alkenes with $[M(CO)_3(12aneP_3H_3)]$ [M = Mo or Cr]. This method allows the direct incorporation of a range of hydrocarbyl or functionalised substituents including pendant ethers, amines, phosphanes or thioethers in high yield (Scheme 2). We have previously reported the synthesis of these pendant-donor-functionalised chromium compounds[11] although not the synthesis of the free ligands. Thus, the reaction of the coordinated secondary phosphane macrocycle with either vinyl ethyl ether or allyl methyl ether gives rise to the β- or γ-functionalised tris-ether derivatives **6a** and **6b**, respectively. These reactions may be performed readily using either $[Mo(CO)_3(12aneP_3H_3)]$ or $[Cr(CO)_3(12aneP_3H_3)]$, but are generally more efficient with the latter. The reaction of $[Cr(CO)_3(12aneP_3H_3)]$ with excess vinyl ethyl ether in toluene proceeds smoothly to the tritertiary phosphane derivative **6a**. This reaction appears to proceed by a radical-initiated mechanism as might be expected; yields are high when a radical initiator is included but are poor when performed in its absence or in the presence of a base catalyst alone. The same reaction with allyl methyl ether provides the methoxypropyl macrocycle complex, **6b**, in excellent yield.

The tris(methoxyethyl), diethyltetrahydrofurfuryl and tris(methoxypropyl) macrocycles were freed from their Mo and Cr templates by the established procedure of halogen oxidation and base digestion.[1b] As established previously, the liberation proceeds stereoselectively to give the *syn,syn* isomer exclusively; this conclusion is based on the ^{31}P NMR spectra which show singlets for both **7a** and **7b** and is confirmed by the relatively simple ^1H and ^{13}C NMR spectra. The coordination chemistry of these and the other functionalised macrocycles will be explored subsequently and will be reported at a later date. In conclusion, the versatility of the synthetic approaches described in this paper

enables access to a range of pendant-donor-functionalised macrocyclic triphosphanes, including selectively functionalised examples.

Experimental Section

All reactions were carried out under an atmosphere of dry nitrogen. All solvents were dried by boiling at reflux over standard drying agents. Petroleum ether had b.p. 40−60 °C. The compounds [Mo(CO)$_3$(12aneP$_3$H$_3$)] and [Cr(CO)$_3$(12aneP$_3$H$_3$)],[2] and **6a** and **6b**[11] were prepared as previously described. All other chemicals were obtained from the Aldrich Chemical Company and used without further purification, except alkyl halide reagents, which were dried over molecular sieves and deoxygenated by freeze-thaw degassing. NMR spectra were recorded on a Bruker WM400 instrument operating at 400 MHz (^{1}H), 100.6 MHz (^{13}C) or a Jeol FX-90Q instrument operating at 36.23 MHz (^{31}P). All NMR spectra were recorded in $CDCl_3$ solution unless otherwise stated, ^{1}H and ^{13}C NMR chemical shifts are quoted in ppm relative to tetramethylsilane ($\delta = 0$), ^{31}P NMR chemical shifts are quoted in ppm relative to external 85% H_3PO_4 ($\delta = 0$). All chemical shifts are positive to low field of the standards. Infrared spectra were recorded in Nujol on a Perkin−Elmer 783 infrared spectrometer. Magnetic susceptibilities were measured by the Gouy method on a Johnson−Matthey magnetic susceptibility balance, an experimental diamagnetic correction was measured for *cyclo*-(HPC$_3$H$_6$)$_3$ and applied. Mass spectra (EI) were recorded on a VG Platform II Fisons mass spectrometer. Melting points were obtained in sealed capillaries and are uncorrected.

[Mo(CO)$_3${12aneP$_3$(CH$_2$CH$_2$OCH$_3$)$_3$}] (2): *n*BuLi (3.5 equiv.) was added dropwise to a cooled (−78 °C) solution of [Mo(CO)$_3$(12aneP$_3$H$_3$)] (**1**; 2.5 g, 5.5 mmol) in THF (35 mL). The reaction mixture was allowed to warm up to −30 °C, whereupon 2-bromoethyl methyl ether (2.5 mL, 26.6 mmol) was added dropwise to the recooled (−78 °C) yellow solution and the whole allowed to warm to 20 °C. The product was purified by chromatography on silica (200 mesh) with dichloromethane as eluent. The solvent was removed to give a white solid which was crystallised from CH_2Cl_2/Et_2O. Yield: 2.63 g (83%) − ^{1}H NMR ($CDCl_3$): δ_H = 1.52 (m, 6 H, PCH$_2$C*H*$_2$CH$_2$P), 1.84 (dt, *J* = 10 and 7 Hz, 6 H, PC*H*$_2$CH$_2$OCH$_3$), 1.91 (m, 12 H, PC*H*$_2$CH$_2$C*H*$_2$P), 3.29 (s, 9 H, PCH$_2$CH$_2$OC*H*$_3$), 3.70 (dt, *J* = 13 and 7 Hz, 6 H, PCH$_2$C*H*$_2$OCH$_3$). − ^{13}C NMR ($CDCl_3$): δ_C = 20.5 (t, *J* = 7 Hz, PCH$_2$*C*H$_2$CH$_2$P), 25.6 (dd, *J* = 8 and 4 Hz, P*C*H$_2$CH$_2$*C*H$_2$P), 30.0 (m, P*C*H$_2$CH$_2$O), 58.4 (s, O*C*H$_3$), 70.2 (d, *J* = 7 Hz, *C*H$_2$O), 231.5 (m, *C*O). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ_P = 3 (s). − IR (Nujol): $\tilde{\nu}$ = 1922s, 1825s cm^{-1}. − Positive-ion EI-MS: *m*/*z* = 577 [M$^+$], 549 [M − CO]$^+$. − $C_{21}H_{39}MoO_6P_3$ (576.40): calcd. C 43.75, H 6.83; found C 43.9, H 7.0.

[Mo(CO)$_3${12aneP$_3$H$_2$(CH$_2$CH$_2$OCH$_3$)}] (3a): One equivalent of *n*BuLi was added dropwise to a cooled (−78 °C) solution of [Mo(CO)$_3$(12aneP$_3$H$_3$)] (2.5 g, 5.5 mmol) in THF (35 mL). The reaction mixture was allowed to warm up to −30 °C whereupon 2-bromoethyl methyl ether was added dropwise to the yellow solution and the whole allowed to warm to room temperature (20 °C). The product was purified by chromatography on silica (200 mesh) with toluene as eluent and the resultant white solid crystallised from CH_2Cl_2/Et_2O. Yield: 0.5 g (20%). − ^{1}H NMR ($CDCl_3$): δ_H = 1.52 (m, 4 H, HPCH$_2$CH$_2$C*H*$_2$PR), 1.74 (m, 6 H, PCH$_2$C*H*$_2$CH$_2$P), 1.86 (dt, *J* = 9 and 6 Hz, 2 H, PC*H*$_2$CH$_2$OCH$_3$), 1.93 (m, 8 H, HPC*H*$_2$CH$_2$CH$_2$PR), 3.29 (s, 3 H, PCH$_2$CH$_2$OC*H*$_3$), 3.70 (dt, *J* = 13 and 7 Hz, 2 H, PCH$_2$C*H*$_2$OCH$_3$), 4.86 (d, *J* = 323 Hz, 2 H, P*H*). − ^{13}C NMR ($CDCl_3$): δ_C = 21.8 [d, *J* = 14 Hz, HPCH$_2$-*C*H$_2$CH$_2$P(CH$_2$CH$_2$OCH$_3$)], 22.1 (d, *J* = 11 Hz, HPCH$_2$*C*H$_2$-CH$_2$PH), 24.5 [dd, *J* = 40 and 9 Hz, HP*C*H$_2$CH$_2$-CH$_2$P(CH$_2$CH$_2$OCH$_3$)], 24.6 (d, *J* = 24 Hz, HPCH$_2$*C*H$_2$*C*H$_2$PH), 31.3 [d, *J* = 24 Hz, HPCH$_2$*C*H$_2$CH$_2$P(CH$_2$CH$_2$OCH$_3$)], 35.4 (d, *J* = 26 Hz, P*C*H$_2$CH$_2$OCH$_3$), 58.9 (s, PCH$_2$CH$_2$O*C*H$_3$), 69.6 (d, *J* = 9 Hz, PCH$_2$*C*H$_2$OCH$_3$). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ_P = 3 (t, *J* = 32 Hz, R$_3$P), −32 (d, *J* = 32 Hz, 2 × R$_2$PH). − IR (Nujol): ν(P−H) = 2355m, 2323m; ν(C−O) = 1916s, 1831sh, 1821s cm^{-1}. − Positive-ion EI-MS: *m*/*z* = 460 [M$^+$], 432 [M − CO]$^+$. − $C_{15}H_{27}MoO_4P_3$ (460.24): calcd. C 39.14, H 5.92; found C 39.0, H 5.7.

[Mo(CO)$_3${12aneP$_3$H$_2$(CH$_2$THF)}] (3b): The complex was prepared in an analogous fashion to that for **3a** above, with tetrahydrofurfuryl chloride. The complex was not isolated pure and was used as such for the preparation of **4b**.

[Mo(CO)$_3${12aneP$_3$Et$_2$(CH$_2$CH$_2$OCH$_3$)}] (4a): A solution of **3a** (200 mg, 0.43 mmol) was placed in an autoclave with ca. 1% AIBN and the reaction mixture charged with ethene to 90 psi. After 12 h stirring at 90 °C, the autoclave was cooled to 20 °C and the excess of ethene removed. The solution was dried ($MgSO_4$) and the product purified by chromatography column on silica (200 mesh) with CH_2Cl_2 as eluent. Yield: 0.22 g (100%). − ^{1}H NMR ($CDCl_3$): δ_H = 1.08 (m, PCH$_2$*C*H$_3$), 1.7−1.2 (m, 20 H), 1.90 (q, *J* = 8 Hz, 4 H, PC*H*$_2$CH$_3$), 3.28 (s, 3 H, PCH$_2$CH$_2$OC*H*$_3$), 3.69 (dt, *J* = 11 and 7 Hz, 2 H, PCH$_2$C*H*$_2$OCH$_3$). − ^{13}C NMR ($CDCl_3$): δ_C = 8.1 (s, *C*H$_3$), 20.8 (s, PCH$_2$*C*H$_2$CH$_2$P), 23.2 (s, PCH$_2$*C*H$_2$CH$_2$P), 27.6 (dd, *J* = 13 and 9 Hz, P*C*H$_2$CH$_2$*C*H$_2$P), 29.1 (m, P*C*H$_2$CH$_2$*C*H$_2$P), 30.6 (d, *J* = 17 Hz, P*C*H$_2$CH$_3$), 34.8 (d, *J* = 20 Hz, P*C*H$_2$CH$_2$OCH$_3$), 58.3 (s, PCH$_2$CH$_2$O*C*H$_3$), 69.1 (d, *J* = 2 Hz, PCH$_2$*C*H$_2$OCH$_3$). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ_P = 4.3 (t, *J* = 32 Hz, R$_2$PCH$_2$CH$_2$OCH$_3$), 5.9 (d, *J* = 32 Hz, 2 × R$_2$PEt). − IR (CH_2Cl_2): ν(C−O) = 1923s, 1825s cm^{-1}. − Positive-ion EI-MS: *m*/*z* = 516 [M$^+$], 488 [M − CO]$^+$. − $C_{19}H_{35}MoO_4P_3$ (516.35): calcd. C 44.18, H 6.84; found C 44.0, H 6.7.

[Mo(CO)$_3${12aneP$_3$Et$_2$(CH$_2$THF)}] (4b): Prepared as for **4a** using crude **3b** (≈70%). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ_P = 4.5 (t, *J* = 31 Hz, R$_2$PCH$_2$CH$_2$THF), 5.0 (d, *J* = 31 Hz, 2 × R$_2$PEt). The

resultant material was used directly for the liberation and isolation of **5b**.

12aneP$_3$Et$_2$(CH$_2$THF) (5b): The ligand was released using the method defined previously.[1] It was purified by crystallisation from petroleum ether. Yield: 40%. – ^{1}H NMR ($CDCl_3$): δ_H = 2.0–0.7 (m, 34 H), 3.68 (m, $PCH_2CHCH_2CH_2CH_2O$), 3.83 (m, 2 H, PCH_2THF). – ^{13}C NMR ($CDCl_3$): δ_C = 9.9 (d, J = 12 Hz, CH_3), 19.3 (m, $PCH_2CH_2CH_2P$), 25.8 (s, CH_2-THF), 27.2 (m, $PCH2$), 29.5 (s, CH_2-THF), 33.9 (m, PCH_2CHO), 67.6 (s, $CHOCH_2$), 80.0 (d, J = 16 Hz, $CHOCH_2$). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ_P = –40.4 (t, J = 16 Hz, R_2PCH_2THF), –31.9 (d, J = 16 Hz, 2 × R_2PEt).

7a: Released from the metal as previously described.[1b] Yield = 55%. – ^{1}H NMR ($CDCl_3$): δ_H = 1.10 (t, J = 7 Hz, 9 H, CH_3), 1.46 (br. m, 6 H, $PCH_2CH_2CH_2P$), 1.65 (m, 12 H, $PCH_2CH_2CH_2P$), 1.90 (br. m, 6 H, $PCH_2CH_2OCH_2CH_3$), 3.45 (q, J = 7 Hz, 6 H, $PCH_2CH_2OCH_2CH_3$), 3.72 (t, J = 7 Hz, 6 H, $PCH_2CH_2OCH_2CH_3$). – ^{13}C NMR ($CDCl_3$): δ_C = 14.0 (s, CH_3), 18.4 (m, $PCH_2CH_2CH_2P$), 27.5 (dd, J = 14 and 9 Hz, $PCH_2CH_2CH_2P$), 32.8 (m, PCH_2CH_2O), 64.1 (s, OCH_2CH_3), 65.2 (s, PCH_2CH_2O). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ_P = –42.0 (s). – Positive-ion EI-MS: m/z = 438 [M^+], 365 [$M - EtOC_2H_4]^+$.

7b: Released from the metal as previously described.[1b] Yield = 68%. – ^{1}H NMR ($CDCl_3$): δ_H = 1.35 (br. m, 12 H, $PCH_2CH_2CH_2P$, $PCH_2CH_2CH_2OCH_3$), 1.58 (q, J = 8 Hz, 6 H, $PCH_2CH_2CH_2OCH_3$), 1.69 (m, 12 H, $PCH_2CH_2CH_2P$), 3.26 (s, OCH_3), 3.34 (t, J = 7 Hz, 6 H, $PCH_2CH_2CH_2OCH_3$). – ^{13}C NMR ($CDCl_3$): δ_C = 19.2 (br, $PCH_2CH_2CH_2P$), 23.2 (d, J = 7 Hz, $PCH_2CH_2CH_2O$), 27.1 (dd, J = 14 and 9 Hz, $PCH_2CH_2CH_2P$), 29.5 (d, J = 14 Hz, $PCH_2CH_2CH_2O$), 58.4 (s, OCH_3), 73.4 (d, J = 13 Hz, $PCH_2CH_2CH_2O$). – ^{31}P{^{1}H} NMR ($CDCl_3$): δ_P = –39.7 (s). – Positive-ion EI-MS: m/z = 438 [M^+], 365 [$M - EtOC_2H_4]^+$.

Crystal Data for Complex 2: $C_{21}H_{34}MoO_6P_3$, M = 571.33, T = 150(2) K, monoclinic, space group $P2_1/c$, a = 12.5069(9), b = 14.561(3), c = 15.4095(14) Å, β = 111.990(8)°, (by least-squares refinement of the setting angles for 250 reflections within θ = 1.76–24.74°), V = 2602.1(6) Å^3, Z = 4, D = 1.458 g cm^{-3}, μ(Mo-K_α) = 0.971cm^{-1}, F(000) = 1180, crystal size = 0.3 × 0.2 × 0.2 mm. All crystallographic measurements were made on an Enraf Nonius FAST area detector diffractometer. The structure was solved by direct methods[12] and refined on F_o^2 by full-matrix least-squares[13] using all unique data after correction for Lorentz and polarisation factors. All non-hydrogen atoms were refined with anisotropic thermal parameters. O6 was disordered between two half-occupied positions. Atoms C8, C13 and C14 were refined with the restraint ISOR = 0.0075. The hydrogen atoms were inserted in idealised positions with U_{iso} set at 1.5 times the U_{eq} of the parent. The weighting scheme used was $w = 1/[\sigma^2(F_o)^2 + (0.0739P)^2]$, where $P = [\mathrm{Max}(F_o)^2 + 2(F_c)^2]/3$; this gave satisfactory agreement analyses. Final R_1 (on F) and wR_2 (on F_o^2) values were 0.0789 and 0.1441 for all 3656 data and 291 parameters. The corresponding R values were 0.0543 and 0.1361 for 2467 data with $I > 2\sigma(I)$. Sources of scattering factors as given in ref.[13]

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-159939. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Crystal Data for Complex 3a: $C_{15}H_{27}MoO_4P_3$, M = 460.22, T = 150(2) K, monoclinic, space group $P2_1/c$, a = 10.453(19), b = 12.300(3), c = 15.777(8) Å, β = 108.41(5)°, (by least-squares refinement of the setting angles for 250 reflections within θ = 2.05–24.8°), V = 1924.7(36) Å^3, Z = 4, D = 1.588 g cm^{-3}, μ(Mo-K_α) = 0.971cm^{-1}, F(000) = 944, crystal size = 0.25 × 0.22 × 0.18 mm. All crystallographic measurements were made on an Enraf Nonius FAST area detector diffractometer. The structure was solved by direct methods[12] and refined on F_o^2 by full-matrix least-squares[13] using all unique data after correction for Lorentz and polarisation factors. All non-hydrogen atoms were anisotropic. The hydrogen atoms were inserted in idealised positions with U_{iso} set at 1.5 times the U_{eq} of the parent. The weighting scheme used was $w = 1/[\sigma^2(F_o)^2 + (0.0566P)^2]$, where $P = [\mathrm{Max}(F_o)^2 + 2(F_c)^2]/3$; this gave satisfactory agreement analyses. Final R_1 (on F) and wR_2 (on F_o^2) values were 0.0365 and 0.0834 for all 2943 data and 217 parameters. The corresponding R values were 0.0315 and 0.0790 for 2615 data with $I > 2\sigma(I)$. Sources of scattering factors as in ref.[13] Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-159940. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Formation and Stereochemistry of Octahedral Cationic Hydride-Azavinylidene Osmium(IV) Complexes

Ricardo Castarlenas,[a] Miguel A. Esteruelas,*[a] Yves Jean,[b] Agustí Lledós,*[c] Enrique Oñate,[a] and Jaume Tomàs[c]

Keywords: Vinylidene ligands / Osmium / Hydrides / Density functional calculations

The complexes $[OsHCl_2(=N=CR_2)(P\textit{i}Pr_3)_2]$ [CR_2 = CMe_2 (**1**), $C^a(CH_2)_4C^bH_2(\textit{C}^a\text{-}\textit{C}^b)$ (**3**)] react with $Ag(CF_3SO_3)$ in the presence of ligands L [H_2O, $P(OMe)_3$, CO]. The reactions in the presence of water lead to $[OsHCl(=N=CR_2)(H_2O)(P\textit{i}Pr_3)_2][CF_3SO_3]$ [CR_2 = CMe_2 (**2**), $C^a(CH_2)_4C^bH_2(\textit{C}^a\text{-}\textit{C}^b)$ (**4**)], which exist as 1:1 equilibrium mixtures of the isomers **2a**/**4a** (hydride *trans* to Cl) and **2c**/**4c** (hydride *trans* to water) in the solid state and in solution. The structure of **2c** has been determined by an X-ray diffraction study. The geometry around the metal center can be described as a distorted octahedron with *trans* phosphane ligands at opposite sites of an ideal coordination plane defined by the other four ligands. The reactions in the presence of $P(OMe)_3$ afford $[OsHCl(=N=CR_2)\{P(OMe)_3\}(P\textit{i}Pr_3)_2][CF_3SO_3]$ [CR_2 = CMe_2 (**5a**), $C^a(CH_2)_4C^bH_2(\textit{C}^a\text{-}\textit{C}^b)$ (**6a**)], with the hydride and chlorine ligands *trans* disposed. Complexes **5a** and **6a** can be also obtained starting from the equilibrium mixtures of **2a** and **2c** or **4a** and **4c**, respectively, and phosphite. Compounds **5c** and **6c**, with $P(OMe)_3$ *trans* to hydride, are formed initially, and subsequently isomerize to **5a** and **6a**. Reactions under carbon monoxide give $[OsHCl(=N=CR_2)(CO)(P\textit{i}Pr_3)_2][CF_3SO_3]$ [CR_2 = CMe_2 (**7a**), $C^a(CH_2)_4C^bH_2(\textit{C}^a\text{-}\textit{C}^b)$ (**8a**)], which also contain the chlorine *trans* to the hydride ligand. A theoretical study on $[OsHCl(=N=CH_2)L(PH_3)_2]^+$ [L = H_2O, $P(OH)_3$ and CO] model complexes shows that these stereochemical preferences arise from the properties of the ligands in the plane perpendicular to the P–Os–P axis. Although the structure with the H and Cl *trans* disposed is not the most favorable when the related pentacoordinate $[OsHCl(=N=CR_2)(P\textit{i}Pr_3)_2]^+$ model complex is considered, it maximizes the interaction energy between the pentacoordinate complex and L ligand, and thus it is the most stable as a whole.

Introduction

Transition metal azavinylidene complexes have attracted a great deal of attention in recent years.[1,2] Some of them have been proposed as intermediates in the catalytic and stoichiometric reduction of nitriles[1s][1y,3] and in the ammoxidation of propylene.[1o] However, only two mononuclear hydride-azavinylidene compounds had been reported before 2000: the five-coordinate d^6 species $[MH(=N=CPh_2)(CO)(P\textit{i}Pr_3)_2]$ (M = Ru,[4] Os[5]). These hydride complexes are prepared by reaction of the corresponding chloro-hydrides $[MHCl(CO)(P\textit{i}Pr_3)_2]$ with $LiN=CPh_2$. In agreement with the strong basicity of the imido group, these compounds undergo hydrolysis in methanol or in the presence of traces of water and evolve into the orthometallated benzophenone imine derivatives $[M^aH\{NH=C(Ph)C^b_6H_4\}(CO)(P\textit{i}Pr_3)_2(\textit{M}^a\text{-}\textit{C}^b)]$ (M = Ru, Os) by a similar process to the orthopalladation.[4]

We have recently shown that the dihydride-dichloro complex $[OsH_2Cl_2(P\textit{i}Pr_3)_2]$ reacts with acetone oxime and cyclohexanone oxime to give the six-coordinate d^4 hydride-azavinylidene derivatives $[OsHCl_2(=N=CR_2)(P\textit{i}Pr_3)_2]$,[6] via the oximate intermediates $[OsH_2Cl\{\kappa\text{-}\textit{N},\kappa\text{-}\textit{O}[ON=CR_2]\}(P\textit{i}Pr_3)_2]$ [CR_2 = CMe_2, $C^a(CH_2)_4C^bH_2(\textit{C}^a\text{-}\textit{C}^b)$].[7] In contrast to $[MH(=N=CPh_2)(CO)(P\textit{i}Pr_3)_2]$, these $[OsHCl_2(=N=CR_2)(P\textit{i}Pr_3)_2]$ complexes are stable in methanol and in the presence of significant amounts of water. Despite the *cis* disposition of the hydride and azavinylidene ligands, they are also stable towards intramolecular reductive elimination to afford d^6-imine species.[6]

The N−H oxidative addition/reductive elimination equilibrium is proposed to be one of the fundamental steps in the hydroamination of olefins and alkynes catalyzed by electron-rich late transition metal centers [Equation (1)]. The $MH(NR_2)$ species are considered the key intermediates of the process.[8]

$$M + H\text{-}NR_2 \rightleftharpoons MH(NR_2) \quad (1)$$

A homogeneous catalyst must have free coordination sites that allow it to bind the substrates *cis* disposed to the reactive points of the metallic center. However, the complexes $[OsHCl_2(=N=CR_2)(P\textit{i}Pr_3)_2]$ are saturated. So, from the hydroamination point of view, the creation of a coordination vacancy stabilizing the resulting metallic fragment, without producing the intramolecular reductive elimination to Os-imine species, is by itself an objective. This fact prompted us to investigate the reactivity of $[OsHCl_2(=N=$

$CR_2)(PiPr_3)_2]$ towards $Ag(CF_3SO_3)$ in the presence of water (a usual impurity in amines), trimethylphosphite and carbon monoxide (which are π-acceptor ligands as the olefins and alkynes) and to study the relative stability of the possible isomers resulting from the reactions.

In this paper, we report: *i*) the complexes $[OsHCl(=N=CR_2)L(PiPr_3)_2]^+$ [L = H_2O, $P(OMe)_3$, CO] and their stereochemistries, and *ii*) the factors determining the formation of these stereochemistries.

Results and Discussion

Reactions in the Presence of Water

The treatment of dichloromethane solutions of $[OsHCl_2(=N=CMe_2)(PiPr_3)_2]$ (**1**) with 1.0 equiv. of $Ag(CF_3SO_3)$ in the presence of 2.0 equiv. of water leads to blue solutions and AgCl. The solutions afford a blue solid after the solvent is removed. According to the elemental analysis and MS, the solid corresponds to the complex $[OsHCl(=N=CMe_2)(H_2O)(PiPr_3)_2][CF_3SO_3]$ (**2**). The IR, ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra indicate that complex **2** exists as a 1:1 equilibrium mixture of two isomers in the solid state and in solution.

The IR spectrum in KBr shows the ν(Os−H) band of both isomers, at 2164 and 2156 cm^{-1}, along with the characteristic stretching bands of the free $CF_3SO_3^-$ anion (see Exp. Sect.),[9] in agreement with the salt character of the complex. At −90 °C in [D_2]dichloromethane, the $^{31}P\{^1H\}$ NMR spectrum contains two singlets at δ = −10.3 and −3.7, corresponding to each isomer. Raising the sample temperature leads to a slight broadening of both resonances, although they show no signs of coalescence at temperatures below 35 °C. The ^1H NMR spectrum at −90 °C agrees well with the $^{31}P\{^1H\}$ NMR spectrum. In the high-field region, it contains two hydride resonances at δ = −3.85 and 0.56, which appear as triplets with H−P coupling constants of 14.1 and 13.2 Hz, respectively. In the low-field region, the spectrum contains two singlets due to the water protons at about δ = 4.9 and four singlets corresponding to the methyl protons of the azavinylidene ligand between δ = 4.6 and 3.4, in addition to the phosphane resonances. The behavior of the resonances due to the hydride and water ligands at this temperature is the same as that of the resonances observed in the $^{31}P\{^1H\}$ NMR spectrum. However, the behavior of the resonances corresponding to the methyl groups of the azavinylidene ligand is significantly different. At −70 °C, the coalescence of two of them is observed, whereas the coalescence of the other two occurs at −30 °C.

The above-mentioned spectra indicate that both isomers have an octahedral structure, with the phosphanes occupying *trans* positions and the C=N group and the carbon atoms bonded to this group lying in a plane that is perpendicular to the P−Os−P axis. In solution, the coordination polyhedron is rigid, although the azavinylidene ligand rotates around the Os−N−C axis.

Three stereochemistries are consistent with the spectroscopic data obtained for **2** (Scheme 1): hydride *trans* to chlorine (**a**), hydride *trans* to azavinylidene (**b**), and hydride *trans* to water (**c**). In order to obtain information about the stereochemistries of the isomers of **2**, we carried out its slow crystallization in dichloromethane/diethyl ether. Unfortunately, the crystals obtained from numerous attempts were in all cases not suitable for an X-ray crystallographic study. The $CF_3SO_3^-$ counterion was therefore exchanged for BF_4^-, and in a crop we obtained a suitable crystal. The remaining crystals of the crop showed the same NMR spectra as **2**.

A view of the molecular geometry of the obtained isomer is shown in Figure 1. Selected bond lengths and angles are listed in Table 1. Although the hydride ligand could not be properly refined, the X-ray study clearly indicates that the isomer formed has the stereochemistry **c**. Thus, the coordination geometry around the osmium atom can be rationalized as being derived from a distorted octahedron, with the triisopropylphosphane ligands occupying *trans* positions [P(1)−Os−P(2) = 168.59(4)°] at opposite sites of an ideal coordination plane defined by the hydride ligand *trans* disposed to the water molecule and the chlorine *trans* disposed to the azavinylidene group [Cl−Os−N = 178.59(12)°].

The most conspicuous feature of the structure is the very short Os−N bond length of 1.829(4) Å, which is fully consistent with an Os−N double bond formulation and agrees well with the Os−N(azavinylidene) bond lengths previously reported [between 1.789(2)[6] and 1.882(6)[2d] Å]. The C−N distance [1.285(6) Å] is similar to those found in other azavinylidene transition metal complexes (about 1.30 Å)[1,2] and also agrees with the N−C bond lengths found in organic azaallenium cations (between 1.23 and 1.33 Å)[10] and in the 2-azaallenyl complexes $[Cr\{C(OEt)=N=CtBu_2\}(CO)_5]$ [1.272(5) and 1.264(5) Å],[11] $[Cr\{C(Ph)=N=CHPh\}(CO)_5]$ [1.260(4) and 1.265(4) Å],[12] and $[Ru(\eta^5\text{-}C_5H_5)\{C(CH=$

$CPh_2)=N=CPh_2\}(CO)(P\textit{i}Pr_3)]^+$ [1.283(9) and 1.252(9) Å].[13]

The Os−N−C chain is almost linear [Os−N−C(1) = 176.5(4)°] and, in agreement with the ^1H and $^{13}C\{^1H\}$ NMR spectra at low temperatures, forms a plane with C(2) and C(3) perpendicular to the best plane containing the phosphorus atoms of the phosphane ligands and the osmium atom [angle: 89.0(2)°]. A similar disposition of the azavinylidene ligand has also been found in the complex $[OsHCl_2\{=N=C^a(CH_2)_4C^bH_2)(P\textit{i}Pr_3)_2(C^a\text{-}C^b)]$ (**3**), where the azavinylidene group is also *trans* disposed to a chlorine ligand.[6]

Since experimental methods have been shown to be ineffective in solving the problem of the determination of the stereochemistry in the other isomer of **2**, we have carried out DFT geometry optimizations on the **a**, **b** and **c** isomers of the model complex $[OsHCl(=N=CH_2)(H_2O)(PH_3)_2]^+$ (**2t**). Single point CCSD(T) calculations on the B3LYP optimized geometries have also been carried out in order to refine further the obtained energetic differences between the three isomers. The results (Table 2) indicate that the stereochemistries **a** (hydride *trans* to chlorine) and **c** (hydride *trans* to water) are clearly more stable (about 20 kcal·mol^{-1}) than stereochemistry **b** (hydride *trans* to azavinylidene) and, in agreement with the spectroscopically observed 1:1 ratio between the isomers, that the difference in stability between **a** and **c** is negligible. Thus, our discussion will be focused on these two isomers. Their main geometrical parameters are listed in Table 3, and their structures are depicted in Figure 2.

Table 2. B3LYP relative energies of the **a**, **b** and **c** isomers of the $[OsHCl(=N=CH_2)L(PH_3)]^+$ (L = H_2O, $P(OH)_3$, CO) model complexes; CCSD(T)//B3LYP single point energies are given in parentheses, where available

	L = H_2O	L = $P(OH)_3$	L = CO
Isomer **a**	0.0(0.0)	0.0	0.(0.0)
Isomer **b**	19.6(21.0)	11.4	3.2(2.2)
Isomer **c**	1.1(0.4)	5.5	7.7(5.4)

A good agreement is found when the optimized structure for isomer **c** of $[OsHCl(=N=CH_2)(H_2O)(PH_3)_2]^+$ and the available X-ray structure of **2c** are compared. The coordination geometry around the Os atom is essentially well reproduced, although the Os−P distances are somewhat shorter (between 0.04 and 0.05 Å) when real phosphanes are substituted by model PH_3 phosphanes. Another minor discrepancy arises from the modeling of the azavinylidene ligand: the substitution of $N=CMe_2$ by $N=CH_2$ decreases the N−Os−O angle in complex **2t**. Our theoretical calculations do, however, allow the determination of the hydride position. The short Os−H distance, similar to that found in the pentacoordinate $[OsHCl(=N=CH_2)(PH_3)_2]^+$ complex (1.601 Å in the former vs. 1.590 Å in the latter) is noteworthy. This reflects the large *trans* influence exerted by the hydride ligand, which is also mirrored by the long Os−O distance (2.341 Å).

Structure **a** shows a distorted octahedral geometry, with almost strictly *trans* arranged phosphanes (P−Os−P = 178.1°) and the angles in the perpendicular plane ranging from 73.8° to 115.0°. The different arrangement of ligands induces some changes in the osmium−ligand distances with regard to structure **c**. Thus, with the chlorine and the strong σ-donor hydride *trans* disposed, the Os−Cl and Os−H distances are significantly longer than in isomer **c** (2.431 Å and 1.622 Å respectively). On the other hand, the Os−N and Os−O distances are shorter (1.792 Å and 2.264 Å), the former being among the smallest Os−N distances found in the literature for Os-azavinylidene complexes. The linearity

Figure 2. B3LYP optimized structures of the most stable isomers (**a** and **c**) of the $[OsHCl(=N=CH_2)(H_2O)(PH_3)_2]^+$ complex

of the Os-azavinylidene moiety (Os−N−C = 179.5°) should also be noted. In addition, it should be mentioned that in the calculated structures, the azavinylidene ligand is perpendicular to the P−Os−P axis, in agreement with the ^1H and $^{13}C\{^1H\}$ NMR spectra of **2** and the X-ray structure shown in Figure 1.

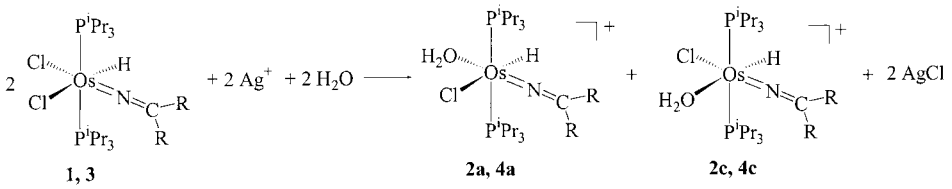
The spectroscopic data of **2** together with the results of the theoretical calculations strongly support that the reaction of **1** with $Ag(CF_3SO_3)$ and water leads to an equimolar mixture of the isomers shown in Equation (2). Similarly, the treatment of **3** with $Ag(CF_3SO_3)$ and water gives $[OsHCl\{=C=C^a(CH_2)_4C^bH_2\}(H_2O)(P\textit{i}Pr_3)_2(\textit{C}^a\text{-}\textit{C}^b)][CF_3SO_3]$ (**4**), which according to the IR, ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra is a 1:1 mixture of the isomers **4a** and **4c**.

The IR spectrum of **4** in KBr contains two ν(Os−H) bands at 2145 and 2135 cm^{-1}. In the ^1H NMR spectrum, the hydride resonances appear at δ = −4.40 and 0.43 as triplets, with H−P coupling constants of 13.8 and 13.2 Hz, respectively. The $^{31}P\{^1H\}$ NMR spectrum shows two singlets at δ = −10.9 and 4.8.

Reactions in the Presence of Trimethylphosphite

The treatment of dichloromethane solutions of **1** at −40 °C with 1.0 equiv. of $Ag(CF_3SO_3)$ and 1.1 equiv. of trimethylphosphite leads, after 2 h at this temperature, to brown solutions and AgCl. The solutions afford a brown-orange solid after the solvent is removed. According to the elemental analysis and MS, the solid corresponds to the complex $[OsHCl(=N=CMe_2)\{P(OMe_3)\}(P\textit{i}Pr_3)_2][CF_3SO_3]$ (**5**).

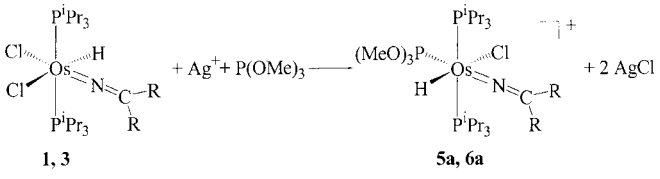
In contrast to **2** and **4**, the IR spectrum of **5** in KBr shows only one ν(Os−H) band, at 2155 cm^{-1}, suggesting that in the solid state this complex exists as only one isomer. The ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra in $[D_2]$dichloromethane at −40 °C also indicate that there is also only one isomer in solution. Thus, the $^{31}P\{^1H\}$ NMR spectrum contains a triplet at δ = 57.5 [$P(OMe_3)$] and a doublet at δ = 47.6 ($P\textit{i}Pr_3$). The multiplicity of the signals and the value of the P−P coupling constant (19.4 Hz) strongly support the *trans* disposition of the phosphanes, which lie *cis* to the phosphite. In the ^1H NMR spectrum the hydride ligand appears as a doublet of triplets at δ = −7.20, with



(2)

H−P coupling constants of 39.6 and 13.8 Hz, indicating that the hydride is *cis* to the phosphorus donor ligands. At temperatures higher than room temperature the decomposition of **5** to $[HP{i}Pr_3]^+$ and unidentified products is observed.

The above-mentioned spectroscopic data are consistent with the stereochemistries **a** and **b** shown in Scheme 1. In order to determine the most stable isomer of **5** DFT calculations on the model complex $[OsHCl(=N=CH_2)\{P(OH)_3\}(PH_3)_2]^+$ (**5t**) were also carried out. In this case, the results of the B3LYP calculations (Table 2) indicate that the stereochemistry **a** (hydride *trans* to chlorine) is again favored, while **b** and **c** lie higher in energy (11.4 kcal·mol^{-1} and 5.5 kcal·mol^{-1} respectively). This excludes the possibility of an equilibrium similar to that found in the previous case. So, the spectroscopic data of **5** together with the results of the theoretical calculations support that the reaction of **1** with $Ag(CF_3SO_3)$ in the presence of trimethylphosphite leads to **5a** [Equation (3)]. Similarly the treatment of **3** with $Ag(CF_3SO_3)$ and trimethylphosphite affords **6a**.



(3)

The spectroscopic data of **6a** agree well with those of **5a**. The IR spectrum in KBr shows the ν(OS−H) band at 2154 cm^{-1}. In the ^{1}H NMR spectrum in $[D_2]$dichloromethane at −40 °C, the resonance corresponding to the hydride ligand appears at δ = −7.07 as a doublet of triplets with H−P coupling constants of 40.0 and 13.2 Hz. The $^{31}P\{^1H\}$ NMR spectrum shows a triplet at δ = 59.2 and a doublet at δ = 49.1. The value of the P−P coupling constant is 12.3 Hz.

The geometrical parameters for isomer **a** of the $[OsHCl(=N=CH_2)\{P(OH)_3\}(PH_3)_2]^+$ model complex are listed in Table 3 and its structure is depicted in Figure 3. This complex can be described as a distorted octahedron with *trans* phosphanes (P−Os−P = 178.9°). In the perpendicular plane, the angles N−Os−P and Cl−Os−H are 160.6° and 151.5°, respectively. The Os−N (1.839 Å) and N−C (1.261 Å) distances and Os−C−N angle (169.7°) are consistent with the azavinylidene formulation. In agreement with the structures shown in Figure 1, the azavinylidene lies in the plane containing the osmium atom, the hydride, the chlorine and the phosphorous atom of the phosphite ligand.

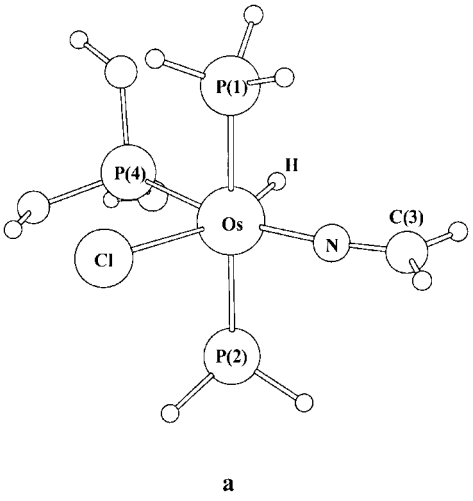


Figure 3. B3LYP optimized structure of the most stable isomer of the $[OsHCl(=N=CH_2)\{P(OH)_3\}(PH_3)_2]^+$ complex

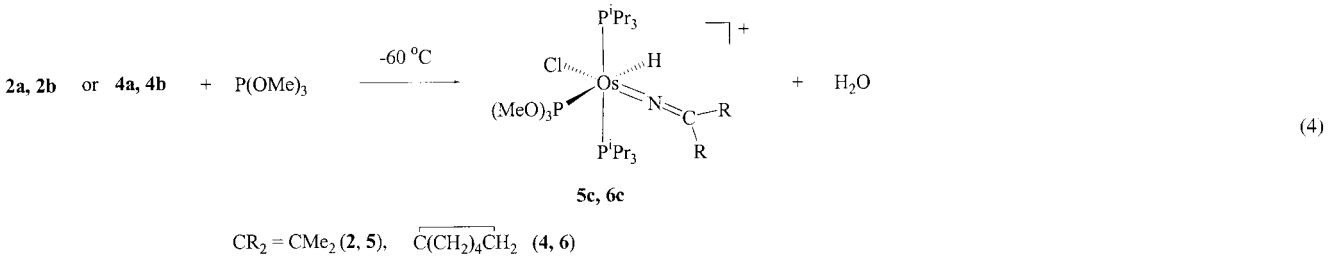
Theoretical results also indicate that the stability of the stereochemistry of **c** (hydride *trans* to phosphite) is between those of the stereochemistries of **a** and **b**. The corresponding isomers **5c** and **6c** can be isolated from $[D_2]$dichloromethane solutions at −60 °C. Thus, the addition of 1.0 equiv. of trimethylphosphite to $[D_2]$dichloromethane solutions of the equilibrium mixtures of **2a** and **2c** or **4a** and **4c** at −60 °C gives rise to the immediate and selective formation of **5c** or **6c** [Equation (4)] (in quantitative yield, in both cases). Under these conditions the isomers **5c** and **6c** are moderately stable and slowly isomerize to **5a** or **6a**. At −20 °C, about 50% of conversion is observed after 10 min. Isomers with **b** stereochemistry are not observed during the isomerization process, in agreement with the higher energy of this stereochemistry.

The *trans* disposition of the hydride and phosphite ligands in **5c** and **6c** is strongly supported by the ^{1}H NMR



(4)

spectra of these compounds, which show a doublet of triplets at $\delta = 0.95$ (**5c**) and $\delta = 0.65$ (**6c**) with H−P coupling constants of 125.0 and 16.3 Hz (**5c**) and 122.7 and 17.7 Hz (**6c**).

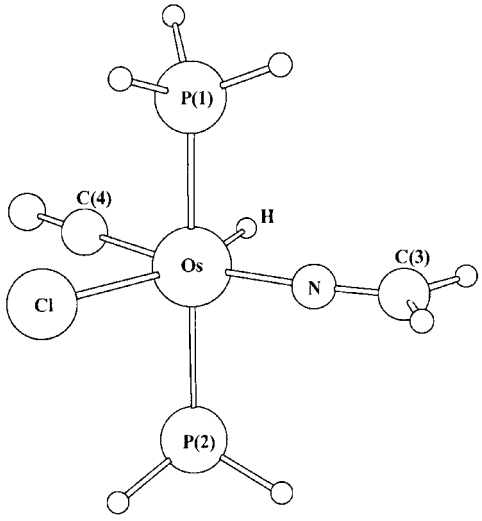
Reactions Under a Carbon Monoxide Atmosphere

The reaction of **1** with $Ag(CF_3SO_3)$ under a carbon monoxide atmosphere affords only one isomer of the carbonyl derivative $[OsHCl\{=N=C(CH_3)_2\}(CO)(P\textit{i}Pr_3)_2][CF_3SO_3]$ (**7**), according to the IR, ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra of the yellow solid obtained.

In the IR spectrum, the most noticeable features are the presence of a ν(Os−H) band at 1951 cm^{-1} and a ν(CO) vibration at 1981 cm^{-1}. In the high field region of the ^1H NMR spectrum, the hydride ligand appears as a triplet at $\delta = -5.74$, with an H−P coupling constant of 34.5 Hz. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at $\delta = 63.0$.

The chemical shift of the hydride ligand of **7** is similar to that of both **5a** and **6a**. At first glance, this suggests that the stereochemistry of **7** is the same as that of **5a** and **6a** (hydride *trans* to chloride), since the chemical shift of a hydride ligand is highly dependent on the *trans* effect of the ligand located *trans* to the hydride. In order to corroborate this, DFT calculations were also carried out on the model complex $[OsHCl(=N=CH_2)(CO)(PH_3)_2]^+$ (**7t**). As expected, the results of the single point CCSD(T) calculations on the B3LYP optimized geometries (Table 2) indicate that the stereochemistry **a** is the most stable. The spectroscopic data of **7** together with the results of the theoretical calculations both suggest that the reaction of **1** with $Ag(CF_3SO_3)$ under carbon monoxide atmosphere leads to **7a** [Equation (5)]. Similarly, the treatment of **3** with $Ag(CF_3SO_3)$ under a carbon monoxide atmosphere gives **8a**. These isomers are also the species formed by the reaction of **2** or **4** with carbon monoxide at −60 °C in $[D_2]$dichloromethane as solvent.

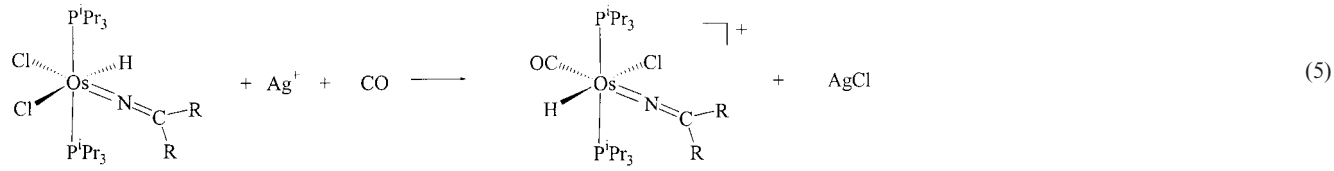
The spectroscopic data of **8a** agree well with those of **7a**. The IR spectrum of **8b** in KBr shows the ν(Os−H) band at 1940 cm^{-1} and the ν(CO) vibration at 1977 cm^{-1}. In the ^1H NMR spectrum in $[D_2]$dichloromethane, the hydride ligand appears as a triplet at $\delta = -5.56$, with an H−P coupling constant of 34.5 Hz. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at $\delta = 63.2$.



a

Figure 4. B3LYP optimized structure of the most stable isomer of the $[OsHCl(=N=CH_2)(CO)(PH_3)_2]^+$ complex

Figure 4 shows the optimized geometry at the B3LYP level for the **a** isomer of the $[OsHCl(=N=CH_2)(CO)(PH_3)_2]^+$ model complex; its main geometrical parameters are listed in Table 3. This isomer exhibits similar patterns to the $[OsHCl(=N=CH_2)(H_2O)(PH_3)_2]^+$ and



(5)

$[OsHCl(=N=CH_2)\{P(OH)_3\}(PH_3)_2]^+$ model complexes i.e. a distorted octahedral geometry where the P−Os−P angle is almost linear, although the angles between the ligands in the plane containing the H, Cl, N and C atoms clearly deviate from ideality (H−Os−Cl = 151.5°, N−Os−Cl = 162.7°). As in the $[OsHCl(=N=CH_2)\{P(OH)_3\}(PH_3)_2]^+$ complex, the Os−azavinylidene axis is slightly tilted (Os−N−C = 169.9°). The Os−N distance is the longest of our family of complexes (1.846 Å). As in the previous cases the azavinylidene ligand lies in the plane perpendicular to the P−Os−P axis.

Stereochemical Preferences of $[OsHCl(=N=CH_2)L(PH_3)_2]^+$ [L = H_2O, $P(OH)_3$ and CO] Complexes

In octahedral hexacoordinate complexes containing ligands with different electronic properties, as in $[OsHCl(=N=CH_2)L(PH_3)_2]^+$ [L = H_2O, $P(OH)_3$ and CO] model complexes, the presence of a strong σ-donor hydride will have a pronounced influence on the rest of the ligands, and the ability of a given ligand to remain *trans* to the hydride will govern the stereochemistry of the complex. To illustrate this general idea, a DFT theoretical study on $[OsHCl(=N=CH_2)(PH_3)_2]^+$ and $[OsHCl(=N=CH_2)L(PH_3)_2]^+$ [L = H_2O, $P(OH)_3$ and CO] complexes is offered in this section.

Pentacoordinate Complexes

To begin our study the parent pentacoordinate $[OsHCl(=N=CH_2)(PH_3)_2]^+$ model complex, from which the hexacoordinate $[OsHCl(=N=CH_2)L(PH_3)_2]^+$ complexes are obtained, is analyzed in some detail. The structures of the related hexacoordinate complexes (i.e. phosphanes must be equivalent by symmetry), with available NMR spectroscopic data, have been fully optimized at the DFT level of theory using the B3LYP functional. Regular square-planar pyramids and trigonal bipyramids have been taken as starting points and no symmetry constraints have been imposed in order to allow free rotation of the azavinylidene ligand. The seven initial structures that were obtained are depicted in Scheme 2.

After geometry optimization, no trigonal bipyramid is found to be stable, and they all revert to a square-planar pyramid structure. Within the square-planar pyramid's family, only two isomers are obtained (**B** and **C** according to our labelling), although **B** lies much higher in energy than **C** (by 33.8 kcal·mol^{-1}). Thus, it is obvious that despite the apparent possibility of isomerism, there is only one available structure for the pentacoordinate complex. This result agrees perfectly with the ligand site preferences in a square-planar pyramid, where the stronger σ-donor ligand tends to occupy the apical position.[14] The geometrical parameters of complex **C** are listed in Table 4, and its structure is depicted in Figure 5.

Table 4. Selected bond lengths (Å) and angles (deg) for the most stable isomer of the B3LYP optimized $[OsHCl(=N=CH_2)(PH_3)]^+$ model complex

Os−P(1)	2.411	Os−P(2)	2.411

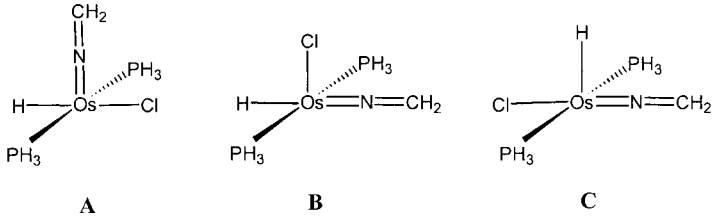
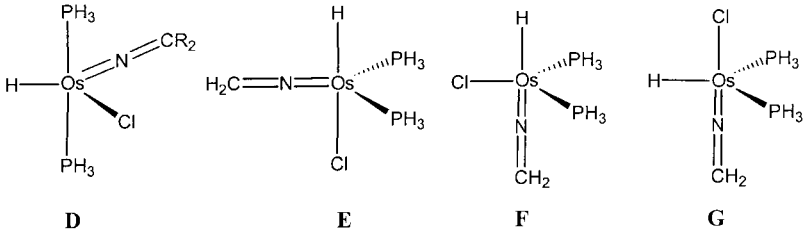
Square Planar Pyramids



Trigonal Bipyramids



Scheme 2

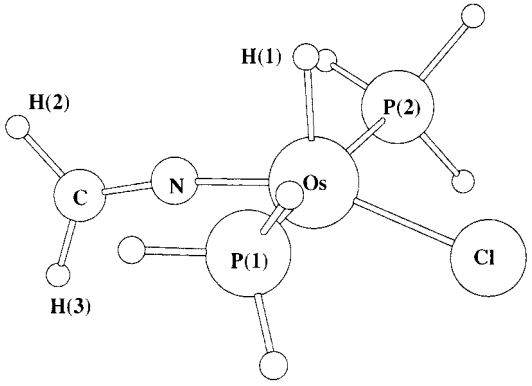


Figure 5. B3LYP optimized structure of the most stable isomer of the $[OsHCl(=N=CH_2)(PH_3)]^+$ complex

Complex **C** can be described as a slightly distorted square-planar pyramid with the strongest σ-donor hydride occupying the apical position *trans* to the vacant site. The phosphanes are located almost strictly *trans* to each other (P−Os−P = 174.0°), and the other ligands of the basal plane (azavinylidene and chloride) form an angle of 156.5°, thus making the whole structure somewhat distorted. It is noteworthy that the $Os=N=CH_2$ plane is perpendicular to the P−Os−P axis. As a matter of fact, the structure with the azavinylidene plane parallel to the P−Os−P axis, which would correspond to the transition state for the azavinylidene ligand rotation process, was found to be 9.2 kcal·mol^{-1} higher in energy than the minimum at the B3LYP// CCSD(T) level of theory.

Hexacoordinate Complexes

From the structural data and the calculated relative energies for the different isomers of $[OsHCl(=N=CH_2)L(PH_3)_2]^+$ complexes (Table 2), some initial trends may be drawn: (a) No matter what the electronic character of L (from a σ-donor H_2O ligand to a strong π-acceptor CO ligand), the structure with H *trans* to Cl turns out to be the most stable. (b) If the **b** and **c** structures are taken into account, opposite trends are found when the π-acceptor character of L is enhanced i.e. **b** is stabilized and **c** is destabilized. For the $[OsHCl(=N=CH_2)(H_2O)(PH_3)_2]^+$ complex the relative energies of **a** and **c** are similar (a difference of only 0.4 kcal·mol^{-1} is found at the CCSD(T)// B3LYP level of theory), but **c** is 5.4 kcal·mol^{-1} higher in energy than **a** in $[OsHCl(=N=CH_2)(CO)(PH_3)_2]^+$. At the same time, structure **b** is 21.0 kcal·mol^{-1} higher in energy than **a** in $[OsHCl(=N=CH_2)(H_2O)(PH_3)_2]^+$, although the difference between them is lowered to 2.2 kcal·mol^{-1} for the $[OsHCl(=N=CH_2)(CO)(PH_3)_2]^+$ complex. It should be noted at this point that even on purely thermodynamic grounds this difference might be somewhat large to allow an equilibrium between these two isomers. However, it should be possible in principle for **a** and **b** to exist simultaneously by using an even stronger π-acceptor ligand. (c) The addition of a sixth ligand to the most favorable pentacoordinate isomer (H *trans* to the empty coordination site) would lead to the **c** isomer. As a consequence, it is reasonable to suppose that this is the isomer that would be obtained under kinetic control conditions; structure **c** is indeed observed for L = $P(OMe)_3$ (**5c**, **6c**) and rapidly evolves into the isomer **a**.

To give a simple explanation of these facts, it has been assumed that, starting from the most stable pentacoordinate isomer, the corresponding hexacoordinate complexes can be obtained in two steps (of course, this has nothing to do with the actual mechanism; it is only a theoretical way of thinking). In a first step, the pentacoordinate complex is distorted towards the geometry that it would have in the hexacoordinate complex. The energy related to this distortion (ΔE_{dist}) is evaluated by simply removing the L ligand from the optimized hexacoordinate structure and calculating the B3LYP energy of the resulting fragment. In the second step, a crude interaction energy (ΔE_{int}) of the $[OsHCl(=N=CH_2)(PH_3)_2]^+$ fragment with the L ligand fragment is obtained as the difference between the sum of the energies of both fragments and the energy of the optimized hexacoordinate structure. The results of this decomposition are shown in Figures 6 and 7.

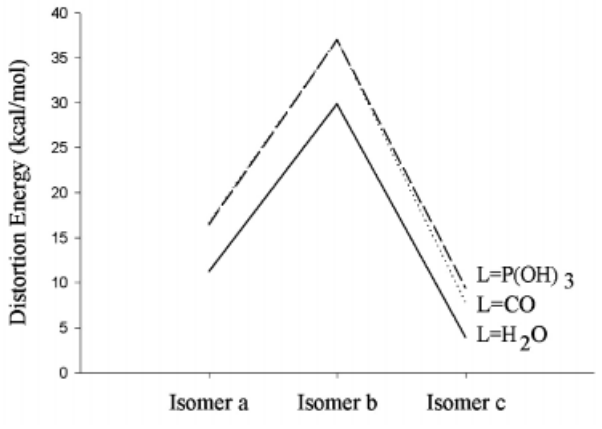

Figure 6. Distortion energies of the $[OsHCl(=N=CH_2)(PH_3)_2]^+$ fragments calculated at the B3LYP level of theory

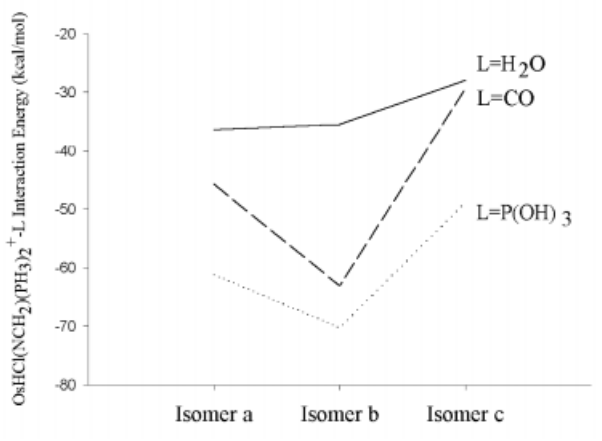

Figure 7. Interaction energies between $[OsHCl(=N=CH_2)(PH_3)_2]^+$ distorted fragments and L ligands (L = H_2O, $P(OH)_3$, CO) calculated at the B3LYP level of theory

The distortion term (Figure 6) is in fact related to the stability of the pentacoordinate fragment. This term is clearly smaller for isomer **c**, which is related to the best pentacoordinate structure previously described. The highest distortion energy arises from isomer **b**. In this fragment, the chloride ligand occupies the apical position *trans* to the vacant site, which is a very unfavorable arrangement for a square-planar pyramid. As a consequence, this would, in principle, be a factor that works against this hexacoordinate isomer. The distortion energy of isomer **a** lies in between the **b** and **c** isomers. Another interesting fact is that although the distortion energy is smaller for L = H_2O (as we shall see later, this is a consequence of the weaker interaction of water with the pentacoordinate fragment), the trends are almost identical in all cases [for L = $P(OH)_3$ and L = CO, the distortion term is not only parallel, but practically coincident]. Thus, the same consequences for the three isomers would be drawn if only this term is considered, and the energetic ordering of the hexacoordinate isomers would be **c** < **a** < **b**. It is obvious that the different behavior arises from the interaction term. Just looking at the shapes of the lines in Figure 7, it is clear that H_2O, $P(OH)_3$ and CO interact very differently with the distorted $[OsHCl(=N=CH_2)(PH_3)_2]^+$ fragment. Our theoretical results show that water interacts only weakly with the metallic fragment; the long Os−O distance in **2c** confirms this. The strongest interaction would correspond to the phosphite ligand, and carbonyl lies in between both of these. It is evident that in all cases isomer **c** is clearly disfavored, because this isomer is obtained by adding a σ-donor or a π-acceptor ligand *trans* to the strong σ-donor hydride. The strong *trans* influence exerted by this hydride would then destabilize the bond between Os and the L ligand, and this would lead to a small interaction energy. The next isomer in our ordering of interaction energies is isomer **a**. For this isomer, an equilibrium is reached between interaction and distortion, and the immediate consequence is that this is the most stable isomer as a whole. Lastly, isomer **b** exhibits a large interaction energy except for L = H_2O, but this energy is in general not enough to compensate the distortion term.

The relative interaction energies within each group (see the slope of the lines in Figure 7) follow a definite trend in enhancing the π-acceptor character of L: taking the most stable isomer **a** as the reference, the interaction energy due to isomer **b** increases, while that due to isomer **c** decreases. Again, this is a consequence of the electronic nature of the ligands, because in isomer **b** the L ligand is trans to a π-donor chloride, while in isomer **c** L is trans to a hydride. Thus, for L = H_2O, the interaction energy of isomer **c** is not very small and the distortion term can compensate nicely for the disadvantage of having an H_2O ligand *trans* to the hydride. This compensation leads to the observed equilibrium between **a** and **c**. For L = $P(OH)_3$, both hexacoordinate isomers **b** and **c** are far more unstable than isomer **a**, because in isomer **b** the interaction cannot compensate for the distortion and in isomer **c** the distortion cannot compensate for the interaction. Finally, for L = CO, the interaction term is so small for isomer **c** that the corresponding hexacoordinate structure is highly unstable, while the interaction term in **b**, although bigger than in the other cases, does not compensate for the distortion.

Concluding Remarks

Although the imido groups [$R_2C=N$] are strong bases, this study has revealed that the azavinylidene ligand of the complexes $[OsHCl_2(=N=CR_2)(P\mathit{i}Pr_3)_2]$ are stable towards hydrolysis when they are treated with $Ag(CF_3SO_3)$ in the presence of water. The reactions lead to the six-coordinate hydride-azavinylidene-osmium(IV) derivatives $[OsHCl(=N=CR_2)(H_2O)(P\mathit{i}Pr_3)_2]^+$, which are the first cationic species of this type.

Hydride-azavinylidene-osmium(IV) compounds are stable, not only towards hydrolysis of the azavinylidene, but also towards reductive elimination into imino species. It is well-known that the oxidative addition/reductive elimination equilibrium is governed by the amount of electron density at the metal. Electron-rich donor ligands favor the oxidized species, while π-acceptor ligands favor the reduced one. However, the extraction of a strong π-donor chlorine from $[OsHCl_2(=N=CR_2)(P\mathit{i}Pr_3)_2]$ and the coordination of π-acceptor ligands [i.e. CO, $P(OMe)_3$] does not induce a reductive elimination to afford the corresponding d^6-imine derivatives, but results in the formation of $[OsHCl(=N=CR_2)L(P\mathit{i}Pr_3)_2]^+$ [L = $P(OMe)_3$, CO].

Three stereochemistries are possible for complexes $[OsHCl(=N=CR_2)L(P\mathit{i}Pr_3)_2]^+$ [L = H_2O, $P(OMe)_3$, CO]: hydride *trans* to chlorine (**a**), hydride *trans* to azavinylidene (**b**) and hydride *trans* to L (**c**). Theoretical calculations indicate that structure **a** is the most favored in all cases from a thermodynamic point of view, whereas structure **c** is kinetically favored. The relative stability of structures **b** and **c** depends upon the electronic character of L. When the π-acceptor character of L increases, **b** is stabilized and **c** is destabilized; however, even with L=CO, the **b** isomer is never observed.

Experimental Section

All reactions were carried out with rigorous exclusion of air using Schlenk-tube techniques. Solvents were dried by the usual procedures and distilled under argon prior to use. The starting materials $[OsHCl_2(=N=CMe_2)(P\mathit{i}Pr_3)_2]$ (**1**) and $[OsHCl_2\{=N=C^a(CH_2)_4C^bH_2\}(P\mathit{i}Pr_3)_2(C^a\text{-}C^b)]$ (**3**) were prepared by the published method.[6] ^1H NMR spectra were recorded at 300 MHz and chemical shifts are expressed in ppm downfield from Me_4Si. $^{13}C\{^1H\}$ NMR spectra were recorded at 75.4 MHz and chemical shifts are expressed in ppm downfield from Me_4Si. $^{31}P\{^1H\}$NMR spectra were recorded at 121.4 MHz and chemical shifts are expressed in ppm downfield from 85% H_3PO_4. Coupling constants, *J* and *N*, are given in Hertz.

Preparation of $[OsHCl\{=N=C(CH_3)_2\}(H_2O)(P\mathit{i}Pr_3)_2][CF_3SO_3]$ (2a,c): A pale green solution of **1** (200 mg, 0.313 mmol) in 10 mL of acetone was treated with 81 mg (0.315 mmol) of $Ag(CF_3SO_3)$ and 12 μL (0.666 mmol) of water. The suspension was stirred for 3

hours and was filtered through Celite to remove the AgCl formed. After the solvent was removed, addition of diethyl ether yielded a blue precipitate that was washed (2 × 2 mL) with diethyl ether and dried in vacuo. The resulting blue microcrystalline solid was a mixture of two isomers with an **a**:**c** ratio of 1:1. Yield: 180 mg (74%). − $C_{22}H_{51}ClF_3NO_4OsP_2S$ (770.30): calcd. C 34.30, H 6.67, N 1.82, S 4.16; found C 34.51, H 6.52, N 1.73, S 3.99. − MS (FAB^+): *m*/*z* = 604 [$M^+ - H_2O$].

Reaction of an Equilibrium Mixture of 4a and 4c with CO at −60 °C: CO was bubbled through a solution of an equilibrium mixture of **4a** and **4c** (30 mg, 0.037 mmol) in 0.5 mL of [D$_2$]dichloromethane in an NMR tube at −60 °C for 5 minutes. Then, the NMR tube was sealed under argon and measurements were made immediately. A mixture of **4a**, **4c**, and **8a** was obtained.

X-ray Structure Analysis of Complex 2: Crystals suitable for X-ray diffraction analysis were mounted onto a glass fiber and transferred to a Bruker-Siemens P4 automatic diffractometer (173 K, Mo-K_α radiation, graphite monochromator, λ = 0.71073 Å). A summary of crystal data and refinement parameters is reported in Table 5. Accurate unit cell parameters were determined by least-squares fitting from the setting of high angle reflections. Data were collected by the ω/2θ scan method. Lorentz and polarization corrections were applied. Measuring three standards throughout the data collection monitored the decay. Corrections for decay and absorption (semiempirical psi-scan method) were applied.

Table 5. Crystal data and data collection and refinement for complex [OsHCl{=N=C(CH$_3$)$_2$}(H$_2$O)(P*i*Pr$_3$)$_2$][BF$_4$]·CH$_2$Cl$_2$ (**2c**)

[a] $R_1(F) = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. − [b] $wR_2(F^2) = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. − [c] Goof = S = $\{\Sigma[w(F_o^2 - F_c^2)^2]/(n - p)\}^{1/2}$, where n is the number of reflections, and p is the number of refined parameters.

The structure was solved by Patterson methods and refined by full-matrix least-squares on F^2.[16] Non-hydrogen atoms were anisotropically refined and the hydrogen atoms were observed or included at idealized positions. The hydride ligand H(01) was observed in the difference Fourier maps as a peak of adequate intensity and expected geometry, but does not support an appropriate refinement, and was not included in the atom list. However, the water hydrogen atoms H(02) and H(03) were located and refined as isotropic atoms with the same distance to the O atom.

Computational Details: DFT[17] optimizations without any symmetry constraint were carried out with the Gaussian94 series of programs[18] using the B3LYP functional.[19] Furthermore, for [OsHCl(=N=CH$_2$)(PH$_3$)$_2$]$^+$, [OsHCl(=N=CH$_2$)(H$_2$O)(PH$_3$)$_2$]$^+$, [OsHCl(=N=CH$_2$){P(OH)$_3$}(PH$_3$)$_2$]$^+$ and [OsHCl(=N=CH$_2$)-(CO)(PH$_3$)$_2$]$^+$ complexes CCSD(T)[20] single-point calculations on the DFT-optimized structures were performed in order to obtain more reliable energies. A quasi-relativistic effective core potential operator was used to represent the 60 innermost electrons of the osmium atom.[21] The basis set for the osmium atom was that associated with the pseudopotential[21] with a standard valence double-ζ LANL2DZ contraction.[18] The 6-31G(d) basis set[22c] was used for all the atoms directly attached to the metal, except for the hydride atom, which was described using a 6-31G(p) basis set.[22a,22b] For the oxygen atom in the carbonyl ligand a 6-31G(d) basis was used.[22c] The rest of the atoms were described with a 6-31G basis set.[22a]

Bimetallic Titanocene or Zirconocene/Aluminium Complexes as Active Catalysts in Lactone Polymerization Reactions

Perdita Arndt,*[a] Anke Spannenberg,[a] Wolfgang Baumann,[a] Sigurd Becke,[b] and Uwe Rosenthal[a]

Keywords: Lactones / Sandwich complexes / Titanium / Zirconium / Aluminum / Ring-opening polymerization

The metallocene alkyne complexes [$Cp_2M(L)(\eta^2$-$Me_3SiC_2R)$] react with diisobutylaluminium hydride at room temp. by addition of $HAl(iBu)_2$ to yield the heterobimetallic complexes [{Cp_2M}(μ-η^1:η^2-$RCCSiMe_3$)(μ-H){$Al(iBu)_2$}] [{Cp_2M}: (η^5-$C_5H_5)_2Ti$, R = Ph **1**, R = $SiMe_3$ **2**; {Cp_2M}: (η^5-$C_5H_5)_2Zr$, R = $SiMe_3$ **3**; {Cp_2M}: (ebthi)Zr, R = $SiMe_3$ **4**] {ebthi: *rac*-[1,2-ethylene-1,1′-bis(η^5-tetrahydroindenyl)]}. Complexes **1**–**4** were characterized by NMR spectroscopy and **1**, **2** and **4** investigated by X-ray crystal structure analysis. Compounds **1**–**4** were tested as initiators in the ring-opening polymerization of lactones. The results are discussed in comparison to the corresponding monometallic titanocene and zirconocene alkyne complexes.

Introduction

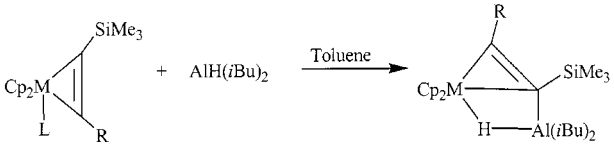
Group 4 metallocene complexes react with organoaluminium compounds to give highly active Ziegler-type catalyst systems.[1] Nevertheless, these catalysts present some disadvantages, such as the necessity of very large amounts of MAO. An approach to overcome this problem resides in the development of new activation methods to extend these active systems to other catalytic reactions. The generation of single-component catalysts, or their direct precursors, is therefore of great current interest.[2]

The reaction of metallocene-alkyne and -alkene complexes with aluminium or boron organic compounds has been intensively investigated by Erker and Binger[3] and leads to bimetallic systems of the type [{Cp_2M^1}(μ-η^1:η^2-RCCR)(μ-X){$M^2R_2^2$}] (M^1 = Zr, Hf, X = Cl, H, M^2 = Al, Ga; M^1 = Ti, X = H, M^2 = B) containing a planar tetracoordinate carbon atom bridging between a group 4 transition metal and a main group element; [$Cp_2M(PMe_3)$(alkyne)] complexes give [{Cp_2M}(μ-η^1:η^2-RCCR)(μ-H){$Al(iBu)_2$}] with diisobutylaluminium hydride.[3f] These compounds are of current interest and have been studied extensively, although compounds with a desired activation for catalytic processes were not obtained.[4]

We report here the easy synthesis of bimetallic titanium or zirconium/aluminium compounds, starting from (η^2-alkyne) metallocene complexes (alkyne = Me_3SiC_2R, R = Ph, $SiMe_3$) and their polymerization capability in the ring-opening polymerization (ROP) of lactones in comparison to the corresponding monometallic (η^2-alkyne)compounds.[11,12]

Results and Discussion

In the reaction of [$Cp_2M(L)(\eta^2$-$RC_2SiMe_3)$] {[Cp_2M]: (η^5-$C_5H_5)_2Ti$, R = Ph, $SiMe_3$, without L; [Cp_2M]: (η^5-$C_5H_5)_2Zr$, R = $SiMe_3$, L = Py; [Cp_2M]: *rac*-(ebthi)Zr, R = $SiMe_3$, without L} with diisobutylaluminium hydride in toluene (2 h) at ambient temperature, corresponding to the investigations by Erker,[3f] the bimetallic complexes [{Cp_2M}(μ-η^1:η^2-$RCCSiMe_3$)(μ-H){$Al(iBu)_2$}] **1**–**4** are formed [Equation (1)].



1 - 4

Cp_2M	R	L
(η5-$C_5H_5)_2Ti$	Ph	-
(η5-$C_5H_5)_2Ti$	$SiMe_3$	-
(η5-$C_5H_5)_2Zr$	$SiMe_3$	Py
rac-(ebthi)Zr	$SiMe_3$	-

Cp_2M	R	
(η5-$C_5H_5)_2Ti$	Ph	**1**
(η5-$C_5H_5)_2Ti$	$SiMe_3$	**2**
(η5-$C_5H_5)_2Zr$	$SiMe_3$	**3**
rac-(ebthi)Zr	$SiMe_3$	**4**

rac-(ebthi) = *rac*-[1,2-Ethylene-1,1'-bis(η5-tetrahydroindenyl)]

(1)

Complex **1** crystallizes from *n*-hexane as yellow prisms (m.p. 150–152 °C) and is stable in solution for some days even at higher temperatures. The corresponding bis(trimethylsilyl)-substituted compound **2** (brown-yellow crystals, m.p. 136 °C dec.) is less stable, it regenerates the starting

compound [$Cp_2Ti(\eta^2$-$Me_3SiC_2SiMe_3)$] in solution at higher temperatures (80 °C, 5 h). The stable analogous zirconocene complexes **3** (light yellow needles, m.p. 142 °C) and **4** (deep yellow prism, m.p. 157−158 °C) are obtained in a similar reaction. All the above complexes were characterized by NMR spectroscopy and **1**, **2** and **4** by X-ray crystal structure analysis.

Spectroscopic Data

The most characteristic proton NMR spectroscopic feature of the compounds **1**−**4** is the high-field resonances of the bridging hydrido ligands (Table 1). The resonance signals are located in the range expected for a hydrogen atom bridging the aluminium and the transition metal center[7] [broad singlets at: δ = −3.79 (**1**), δ = −4.87 (**2**), δ = −2.46 (**3**), δ = −1.27 (**4**)].

Table 1. Selected NMR spectroscopic data of complexes **1**−**4**

	1	**2**	**3**	**4**
^{1}H NMR (δ [ppm])				
Cp	5.15	5.10	5.35	
H	−3.79	−4.87	−2.46	−1.27
^{13}C NMR (δ [ppm])				
C_α, C_β (alkyne)	230.1	234.3	240.4	243.4
	105.0	123.7	138.5	149.5

The methylene groups at aluminium give broad signals in the ^{13}C NMR spectrum which become sharper upon cooling the sample, especially for complex **2**. Besides that, no changes in the NMR spectra were observed. The ^{13}C resonances of the planar-tetracoordinated carbon atom are in the expected olefinic range [δ = 105.0 (**1**), δ = 123.7(**2**), δ = 138.5 (**3**), δ = 149.5 (**4**)]. The methylene group at the aluminium is found in the ^{13}C NMR spectrum as a broad signal at room temp.

These data of complexes **1**−**4** are in good agreement with the zirconocene/aluminium complexes [{Cp_2Zr}(μ-η^1:η^2-RCCR)(μ-H){Al(*i*Bu)$_2$}] from Erker,[3a−3f,4] and the titanocene complexes [{Cp_2Ti}(μ-η^1:η^2-$RCCSiMe_3$)(μ-H)-{Al(*i*Bu)$_2$}] described by Binger[4] and show the same structural features.

X-ray Crystal Structure Analysis of Bimetallic Ti or Zr and Aluminium Compounds

It turned out that an unambiguous characterization of the compounds **1**, **2** and **4** cannot be revealed by NMR spectroscopy as the structural element of the square-planar carbon coordination geometry does not cause any remarkable features in the NMR spectra. Compounds **1**, **2** and **4** were therefore crystallized from *n*-hexane solution by cooling to −30 °C.

The X-ray crystal structures of the titanium complexes exhibit planar, bicyclic five-membered ring systems consisting of the metal atom, the hydridic hydrogen H, Al, C_β and C_α (Figure 1−3 and Table 2). The most remarkable structural element is the coordination geometry of the carbon atom C_β, which is bonded to C_α, M, Al and the Si atom of the $SiMe_3$ group, with all four bonds lying in one plane (mean deviation from the best plane through Ti, Al, Si, C_α **1**: 0.057 Å, **2**: 0 Å). The zirconium complex **4** shows a similar bicyclic ring system as the titanium complexes but in this case the planarity is distorted because of the steric hindrance of the ebthi ligand. The values found for the M−C_β bond lengths are in the expected range for such structural features.[3−5]

Catalytic ROP of Lactones with Complexes 1−4 as Catalysts

The ROP of ε-caprolactone provides a convenient route to the synthesis of polylactones which are important for medical applications and as plastic modifiers.[6] These applications require polyesters with predictable molecular weights and low polydispersity indices, which is only possible with initiators having selectivity in terms of initiation, propagation and termination reactions.[7] For example, alkali metal alkyls or alkoxides give very fast polymerization of lactones, but inter- and intramolecular side reactions often lead to a broadening of the molecular weight distribution of the products. When aluminium alkoxides are used as initiators, the ROP has been reported to be living and generates polyesters with narrow polydispersity indices that are free of macrocycles.[8a−8c] Recently, well characterized transition metal and lanthanoid complexes containing cyclopentadienyl ligands (metallocenes) have emerged as a new class of initiators.[9] The polymerization activity (for polar monomers) was tested using mono(cyclopentadienyl)-titanium,[9] rare earth[7a] and heterobimetallic lanthanocene[7a,10a−10c] compounds. Organolanthanide complexes in general seem to be highly active and well suited as initiators for the ROP of lactones due to their Lewis acidity.[7a]

Recently, we described how (alkyne)zirconocene and titanocene complexes are capable of polymerizing ε-caprolactone with living characteristics and high yield.[11,12] (Table 3, runs 1 and 4)

The heterobimetallic complexes **1−4** are of interest in the context of the activation of catalytic systems. Polymerization reactions were carried out under the same conditions as described before;[11,12] for a high conversion it is necessary to start with a mixture of ε-caprolactone/catalyst in toluene at room temp. and add a second portion of substrate/toluene at 75 °C (Table 3, runs 2, 3 and 5). The poly-ε-caprolactone (PCL) was isolated as a colorless solid and characterized by GPC and NMR spectroscopy. The polymers formed by **1−4** are generally of high molecular weight and of moderate polydispersities ($M_w/M_n < 2.7$). The efficiency depends on the experimental conditions, with the highest value being observed for **3**.

The heterobimetallic complexes show an increase of molecular weights (runs 2 and 3, Ti) by a factor of 10 for titanium compared to their monometallic derivatives and are dependent on the metal in the metallocene unit. The lower yield of run 2 might be explained by the instability of complex **2**: as mentioned above, it forms the monometallic compound [$Cp_2Ti(\eta^2$-$Me_3SiC_2SiMe_3)$] in solution at higher temperatures (80 °C, 5 h).

The results of NMR studies of the ROP with titanocene initiators were disappointing. All subsequent steps of the catalytic cycles such as initiation, propagation and chain termination are very fast on the NMR time scale, and could not be detected. This is consistent with the results we obtained in the case of (alkyne)zirconocene catalysts (for propagation and termination)[12] and those obtained by other groups in monitoring lactone polymerization by NMR spectroscopy.[10b] Furthermore, no end-group signals were found.[12] This has been explained in other reports by the formation of a cyclic polymer as the termination step.[10a,10d] The corresponding heterobimetallic zirconocene(alkyne)/aluminium derivatives (**3**, **4**) (Table 3, runs 5, 7) show no significant changes in comparison to their monometallic example in the ROP. The NMR investigation of the ROP of ε-caprolactone with initiator **4** shows the formation of a five-membered metallacyclic spirozirconadihydrofuran complex, which was already described as the first step in the ROP of lactones by the monometallic

Table 3. Polymerization of ε-caprolactone (CL) in toluene at 75 °C by complexes **1**−**4** in comparison to the corresponding monometallic (η^2-alkyne) compounds (75 °C, toluene)

[a] Efficiency is defined as the fraction of active initiators, calculated from the observed number of polymer chains relative to the theoretical ones, assuming that each metallocene initiates one polymer chain.

(zirconocene) alkyne complexes;[12] it is followed by a rapid polymerization. No influence of the HAl(*i*Bu)$_2$ was found. A control experiment with HAl(*i*Bu)$_2$ as catalyst gave no polymerization. This is in agreement with the fact that Al(*i*Bu)$_3$ has no catalytic activity for the ROP of ε-caprolactone.[13b]The catalytic activity of the titanocene heterobimetallic compounds can be explained by an interaction between the active species and the monomer by coordination of the exo- or endocyclic oxygen of ε-caprolactone to different metal units (Al, Ti). This could cause the increased rate of polymerization and high molecular weights of the resulting polylactones. Such an activation was demonstrated by Sheng[13a,13b] for rare-earth coordination initiators obtained in situ by adding trialkylaluminium to Ln compounds. Also, heterobimetallic lanthanide/lithium complexes have been found to be active in the polymerization of ε-caprolactone, as reported by Okuda.[10a] In this case, however, another activation mechanism involving an amide nitrogen atom was proposed.

Experimental Section

General: All operations were carried out under argon with standard Schlenk techniques. Solvents were freshly distilled prior to use from sodium tetraethylaluminate and stored under argon. Deuterated solvents were treated with sodium or sodium tetraethylaluminate, distilled and stored under argon. ε-Caprolactone (Aldrich) was dried over molecular sieves and degassed before use. − The following spectrometers were used: Mass spectra: AMD 402. − NMR spectra: Bruker ARX 400. Chemical shifts referenced to signals of the used solvents: [D_6]benzene (δ_H = 7.16, δ_C = 128.0). The spectra were assigned with the help of DEPT experiments. − Melting points: sealed capillaries, Büchi 535 apparatus. − Elemental analyses: Leco CHNS-932 elemental analyzer. − Gel permeation chromatographic (GPC) analyses of the polymers were performed using a Liquid Chromatograph 1090 HP [column: SDV 10^4 Å + 10^3 Å +100 Å (Polymer Standard Service), eluent: THF]. Molecular weights were corrected by universal calibration relative to polystyrene standards.

Preparation of 1: 1.2 mL (1.2 mmol) of a 1.0 M solution of AlH(*i*Bu)$_2$ in *n*-heptane was added to a solution of [$Cp_2Ti(\eta^2$-$PhC_2SiMe_3)$] (375 mg, 1.18 mmol) in 10 mL of toluene. The mixture was stirred for 2 h at room temp. and the color changed to brown. After evaporation of the solvents to dryness, the residue was washed twice with 2 mL of *n*-pentane and dissolved in *n*-hexane (60 °C). The solution was filtered, and after 12 h at room temp. yellow crystals formed. The crystals were washed with cold *n*-pentane and dried in vacuo to give 435 mg (75%) of **1**. M.p. 150 −152 °C. − ^{1}H NMR (C_6D_6, 297 K): δ = −3.79 (br., 1 H, μ-H), 0.11 (2 s, 9 H, $SiMe_3$), 0.47, 0.62 (m, 4 H, CH_2), 1.34, 1.36 (2 d, ^3J = 5.9/5.8 Hz, 12 H, CH_3), 2.35 (m, 2 H, CH), 5.13 (d, 2 H, Ph), 5.15 (s, 10 H, Cp), 6.83 (d, 2 H, Ph), 6.98 (t, 1 H, Ph). − ^{13}C{^{1}H} NMR (C_6D_6, 297 K): δ = 3.8 ($SiMe_3$), 26.8 (br., CH_2), 27.3 (CH), 28.8, 29.0 (CH_3), 104.9 (Cp), 123.8, 125.1, 128.0 (CH, Ph), 150.4 (*ipso-C*, Ph), 105.0(*C*-$SiMe_3$), 230.1 (*C*-Ph). − MS (70 eV): *m*/*z* (%) = 352 [$Cp_2Ti(\eta^2$-$PhC_2SiMe_3)]^+$, 178 [Cp_2Ti^+], 173 [$PhC_2SiMe_3]^+$, 141 [Al(*i*Bu)$_2]^+$. − $C_{29}H_{43}AlSiTi$ (494.61): calcd. C 70.42, H 8.76; found C 70.10, H 8.59.

Preparation of 2: 1.2 mL (1.2 mmol) of a 1.0 M solution of AlH(*i*Bu)$_2$ in *n*-heptane was added to a solution of [$Cp_2Ti(\eta^2$-$Me_3SiC_2SiMe_3)$] (405 mg, 1.16 mmol) in 10 mL of toluene. The mixture was stirred for 2 h at room temp. and the color changed to green-brown. After evaporation of the solvents to dryness, the oil was washed twice with 1 mL of cold *n*-pentane and dissolved in a small amount of *n*-hexane. After filtration the solvent was removed in vacuo until the first yellow-brown crystals formed. Upon cooling to −78 °C for 12 h a brown precipitate formed which was filtered off, washed with cold *n*-pentane and dried in vacuo to give 400 mg (76%) of **2**. M.p.: 136 °C (dec.). − ^{1}H NMR (C_6D_6, 297 K): δ = −4.87 (br., 1 H, μ-H), 0.29, 0.33 (2 s, 18 H, $SiMe_3$), 0.46, 0.60 (m, 4 H, CH_2), 1.30, 1.35 (2 d, ^3J = 6.5 Hz, 12 H, CH_3), 2.31 (m, 2 H, CH), 5.10 (s, 10 H, Cp). − ^{13}C{^{1}H} NMR (C_6D_6, 297 K): δ = 2.0, 3.6 ($SiMe_3$), 25.8 (br, CH_2), 25.7 (CH), 27.4, 27.5 (CH_3), 102.5 (Cp), 123.7, 234.3 (*C*-$SiMe_3$). − ^{1}H NMR ([D_8]toluene, 192 K): δ = −5.05 (br., 1 H, μ-H), 0.18, 0.18 (2 s, 18 H, $SiMe_3$), 0.43, 0.56 (br., 4 H, CH_2), 1.32, 1.40 (2 d, 12 H, CH_3), 2.30 (m, 2 H, CH), 5.10 (s, 10 H, Cp). − ^{13}C{^{1}H} NMR ([D_8]toluene, 192 K): δ = 2.0, 3.6 ($SiMe_3$), 26.5 (br., CH_2), 27.0 (CH), 28.8, 28.9 (CH_3), 103.5 (Cp), 123.7, 234.3 (*C*-$SiMe_3$). − MS (70 eV): *m*/*z* (%) =348 [$Cp_2Ti(\eta^2$-$Me_3SiC_2SiMe_3)]^+$, 178 [Cp_2Ti^+], 173 [$Me_3SiC_2SiMe_3]^+$, 141 [Al(*i*Bu)$_2]^+$. − $C_{26}H_{47}AlSi_2Ti$ (490.69): calcd. C 63.64, H 9.65; found C 63.09, H 9.23.

Preparation of 3: 1.1 mL (1.1 mmol) of a 1.0 M solution of AlH(*i*Bu)$_2$ in *n*-heptane was added to a solution of [$Cp_2Zr(Py)(\eta^2$-$Me_3SiC_2SiMe_3)$] (503 mg, 1.07 mmol) in 10 mL of toluene. The

mixture was stirred for 2 h at 40 °C and the color changed to light green. After evaporation of the solvents to dryness. the residue was solved in a small amount of *n*-hexane. Upon cooling to −78 °C for 12 h light yellow-green crystals were formed which were filtered off, washed with cold *n*-pentane and dried in vacuo to give 410 mg (71%) of **3**. M.p.: 142 °C. − ^{1}H NMR (C_6D_6, 297 K): δ = − 2.46 (br., 1 H, μ-H), 0.34, 0.35 (2 s, 18 H, $SiMe_3$), 0.39, 0.60 (m, 4 H, CH_2), 1.29, 1.34 (2 d, ^3J = 6.4 Hz, 12 H, CH_3), 2.28 (m, 2 H, CH), 5.35 (s, 10 H, Cp). − $^{13}C\{^1H\}$ NMR (C_6D_6, 297 K): δ = 3.5, 4.7 ($SiMe_3$), 26.8 (br., CH_2), 27.2 (CH), 28.6, 28.9 (CH_3), 104.6 (Cp), 138.5, 240.4 (*C*-$SiMe_3$). − MS (70 eV): *m*/*z* (%) = 534 [M^+], 220 [Cp_2Zr^+], 170 [$Me_3SiC_2SiMe_3]^+$. − $C_{26}H_{47}AlSi_2Zr$ (534.03): calcd. C 58.48, H 8.87; found C 58.23, H 8.60.

Preparation of 4: 0.7 mL (0.7 mmol) of a 1.0 M solution of $AlH(iBu)_2$ in *n*-heptane was added to a solution of [(ebthi)Zr(η^2-$Me_3SiC_2SiMe_3$)] (378 mg, 0.72 mmol) in 10 mL of toluene were added of $AlH(iBu)_2$ as a solution in *n*-heptane (1.0 M). The light yellow solution was stirred for 2 h at room temp. After evaporation to dryness. the residue was dissolved in 5 mL of *n*-hexane. After filtration and cooling to −40 °C for 12 h crystals formed, which were filtered off and dried in vacuo to give 234 mg (48%) of **4**. M.p.: 157−158 °C. − ^{1}H NMR (C_6D_6, 297 K): δ = −1.27 (br., 1 H, μ-H), 0.48, 0.50 (2 s, 18 H, $SiMe_3$), 0.63−0.72 (m, 4 H, CH_2), 1.20, 1.29, 1.38, 1.43 (4 d, ^3J = 6.4 Hz, 12 H, CH_3), 2.23 (m, 2 H, CH), 4.38, 5.51, 5.54, 6.35 (4 d, *J* = 2.5 Hz, 4 H, CH ebthi). − $^{13}C\{^1H\}$ NMR (C_6D_6, 297 K): δ = 3.5, 4.7 ($SiMe_3$), 26.8 (br., CH_2), 27.1 (CH), 28.6, 28.9 (CH_3), 99.2, 100.46, 103.0, 104.8 (CH, ebthi), 116.7, 119.2, 122.1, 124.0, 126.4, 126.2 (q-C, ebthi) 149.5, 243.4 (*C*-$SiMe_3$). − $C_{36}H_{61}AlSi_2Zr$ (668.25): calcd. C 64.71, H 9.20; found C 63.99, H 9.02.

Polymerization of ε-Caprolactone: A stirred 5 M solution of the monomer in toluene (5 mL) was heated to 75 °C and an appropriate amount of the initiator complex dissolved in toluene was added. Ten minutes later a further amount of lactone dissolved in toluene was added. After one hour the reaction mixture was worked up by dropwise addition of a tenfold volume of methanol. The poly(ε-caprolactone)s were filtered off and dried in vacuo until the weight remained constant.

PCL: ^{1}H NMR (C_6D_6, 297 K): δ = 1.5, 1.41, 1.17 (3 m, 6 H, CH_2); 2.11, 3.98 (2 t, 4 H, CH_2).

X-ray Crystallographic Study of Complexes 1, 2 and 4: Diffraction data were collected on a STOE-IPDS diffractometer using graphite-monochromated Mo-K_α radiation. Crystal data, details of the data collections and structure refinement are compiled in Table 4. The structures were solved by direct methods (SHELXS-86: G. M. Sheldrick, *Acta Crystallogr., Sect. A* **1990**, *46*, 467) and refined by full-matrix least-squares techniques against F^2 (SHELXL-93: G. M. Sheldrick, University of Göttingen, Germany, **1993**).
Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-157428 (**1**), -157429 (**2**), -157430 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax (internat.): +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

On the d^6-Transition Metal Complex Formation of Electron-Rich Methylenephosphanes, a Quantum Chemical Investigation

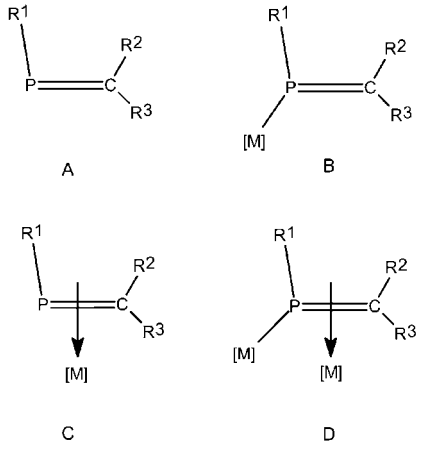
Wolfgang W. Schoeller,*[a] Alexander B. Rozhenko,[a] and Sonja Grigoleit[a]

Keywords: Ab initio calculations / Density functional theory / Methylenephosphanes / Carbonyl complexes

d^6-Transition metal fragments $M(CO)_5$ (M = Cr, Mo, W) form mono- and binuclear complexes with methylenephosphanes. In the mononuclear complexes the metal fragment adds to the lone pair at the phosphorus atom without considerable geometrical change of the original phosphaalkene moiety. Amino substitution at the phosphorus atom yields a slightly more stable complex than amino substitution at the carbon atom. The latter substitution pattern causes an *inverse polarization* of the P–C π-bond. As a further consequence, in the corresponding transition metal complexes, the phosphorus atom is slightly pyramidalized. In the binuclear complexes the transition metal atoms tend to adopt a distorted bipyramidal arrangement at the phosphorus atom with concomitant lengthening of the P–C bond. The stretching of the P–C π-bond is required to form a second lone pair for coordination at the phosphorus atom. However, the longest P–C bonds are achieved by *C*-diamino-substituted methylenephosphanes with overall bulky alkyl groups at the phosphorus and nitrogen atoms. It has the effect of not only extending the P–C bond but also widening the angle at the phosphorus atom.

Introduction

While the earliest reports of compounds containing a P=C double bond originated from Dimroth and Hoffmann,[1] its first stable acyclic species with a localized P=C bond was described in the pioneering work of Becker and co-workers,[2] type **A**. It opened an exciting chapter in modern phosphorus chemistry and is now documented in various review articles.[3−8] It has been stated that phosphorus is related to carbon by the diagonal relationship in the periodic table of elements[8] and typical reactions of organic chemistry may well be found also in organophosphorus chemistry[9] (Scheme 1).



Scheme 1

An archetypal reaction of phosphaalkenes **A** is the formation of transition metal complexes,[10] as η^1-complexes, type **B** {[M] = $Cr(CO)_5$,[11] $Fe(CO)_4$,[12] $Pt(PPh_3)_2$[13]}. The X-ray crystal structure of the solid indicated that for the latter, the ligand was η^1-bonded, whereas in solution η^2-coordination, type **C**, was favoured. A rationalization for this experimental observation was not given. It was also suggested that the ligation modes are a delicate balance of various effects.[14] Other η^2-bonded complexes with Ni, Rh, and W were subsequently reported.[15] A series of η^2-ligated nickel(0) species were prepared.[16] It has been shown that for an η^2-bonded ligand, the P−C bond is longer than it is in the comparable η^1-complexes or the free ligand systems.[17,18] An η^1,η^2-complex of a phosphaalkene with two coordinated transition metal atoms {[M] = $Fe(CO)_4$}, type **D**, was first recorded by Appel et al.[19] (see also ref.[15]). Phosphaalkenes acting as an η^1-(μ_2)-four-electron donor have also been reported {[M] = $Cr(CO)_5$,[20] $CpFe(CO)_2$[21]}. In these complexes the transition metal fragments are linked to the same phosphorus atom.

It is obvious that the experimental results obtained for transition metal coordination of phosphaalkenes is very rich. Besides the η^1- and η^2-mode of coordination, bridged metal centres in an η^1-(μ_2-P) or η^2-(μ_3) manner are also known. This material has been recorded in detail in reviews.[8,15] In the present publication we analyze the principal bonding features of transition metal coordination, i.e., the η^1- and η^2-modes, for methylenephosphanes. Particular attention is given to amino-substituted methylenephosphanes, since their coordination abilities are somewhat different and they can also be considered as electron rich π-systems. We considered mono- and binuclear transition metal complex formation at the phosphorus atom. The d^6-ML_5 (L = CO; M = Cr, Mo, W) species were chosen as the transition metal fragments. Our analysis is based on the results of quantum chemical investigations at a density functional level (DFT). We note that in this instance DFT calculations are the appropriate choice for the cases studied

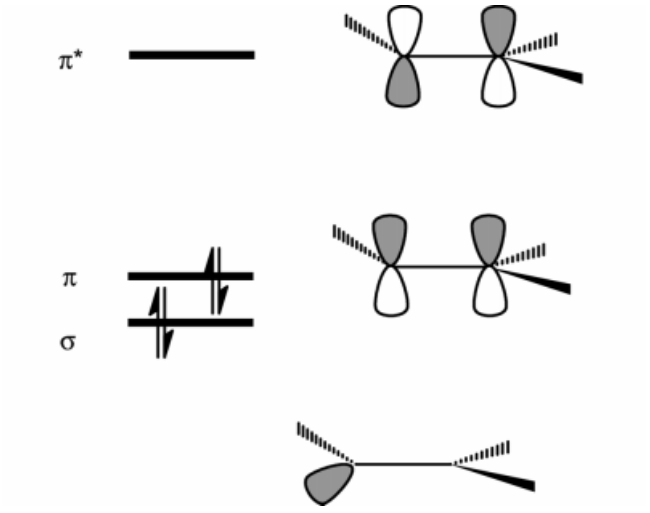
at hand, due to the large size of these structures. Recent investigations on a variety of transition metal complexes with phosphorus compounds were skilfully performed by Creve et al.[22,23] These studies show that the results of density functional calculations (at the B3LYP level) are comparable to those obtained at the more elaborate CCSD(t) level. Details of the used quantum chemical methodology are given in the Theoretical Section.

Results and Discussion

a. Various Modes of Complexation

We first discuss the qualitative bonding features of the P−C π-bond. The parent methylenephosphane possesses two closely spaced frontier orbitals,[24,25] shown schematically in Scheme 2.



Scheme 2

In general the HOMO is the π- and the LUMO the π*-orbital. Slightly below the HOMO is the σ-orbital, constituted from the nonbonding lone pair orbital at the phosphorus atom. On the contrary in the related iminophosphanes[26,27] the HOMO is the σ- and the HOMO-1 is the π-orbital, thus the orbital sequence is reversed. This gives rise to a different chemical behaviour of methylene- vs. iminophosphanes. The latter class of compounds reveals a pseudo-carbenic behavior.[24] The levelling of frontier orbitals in the methylene- and iminophosphanes is in agreement with detailed photoelectron-spectroscopic investigations[27,28−31] and the assignment of the orbital character (σ vs. π) is performed by supplementary investigations of the UV spectra.[26,27]

The P−C π-bond (in methylenephosphane) is essentially weaker than a C−C or an N−C π-bond,[32−34] thus it can be more easily distorted by other potential π-donors, e.g., an amino group at the carbon atom. It causes a polarization of the P−C π-bond, in terms of canonical valence bond structures best described as quasi-allylic resonance, under accumulation of negative charge at the phosphorus atom.[25] Since phosphorus and carbon atoms possess comparable electronegativities,[35] the P−C π-bond is unpolarized in the parent methylenephosphane. With this we mean the coefficient at the HOMO is almost the same for both the carbon and the phosphorus atom. However, substitution by an amino group at the carbon atom causes the formation of a strong N−C π-bond, with concomitant weakening of the P−C π-bond. As a consequence negative π-charge is accumulated at the phosphorus atom by allylic resonance. In terms of frontier orbital considerations the π-bond coefficient becomes enlarged at the phosphorus atom and diminished at the carbon atom. The effect is rather strong since an N−C π-bond is stronger than a P−C π-bond. This aspect was first noted some time ago[25] and was coined as *inverse π bond polarization*, in the studies on phosphatriafulvenes.[36−38] Thus, while parent methylenephosphane possesses an unpolarized π-bond (phosphorus and carbon have similar electronegativities), in *C*-amino-substituted species the π-bond is *inversely polarized*. This concept explains the large variation in the cycloaddition behavior of the P−C double bond[39,40] and was recently summarized in a review article.[41]

What effect does it have on transition metal complex formation? This is the aim of our present study. In order to reveal the effect of π-bond polarization we included in our work the transition metal complexes of (a) the parent compound and an amino group attached (b) to the phosphorus or (c) to the carbon atom. Thus, the DFT calculations probe the various alternatives. For mononuclear transition metal complexation with a d^6-$M(CO)_5$ (M = Cr, Mo, W) fragment the bonding parameters as shown in Figure 1 were obtained.

For completeness we include the bonding parameters for the (substituted) methylenephosphanes. The transition metal fragment in our study refers to the d^6-$M(CO)_5$ fragment. In qualitative terms it possesses the frontier orbital system[42] as shown in Scheme 3.

Two doubly occupied orbitals at the transition metal centre (d_{xz}, d_{yz}) can provide electron density for the formation of a π-bond while the d_z^2-orbital can accept electrons. In more detail, on a qualitative basis this extends the common view on bonding in Fischer-type complexes[43] to the diagram in Scheme 4, with **II** referring to donation and **I** to back-donation of electron density. One expects that the amount of back-donation $\pi(ML_5)\rightarrow\pi^*(PC)$ is less compared to (phosphanyl)carbenes,[44] due to the energetically higher (antibonding) π*-orbital in methylenephosphane as compared with the corresponding empty (nonbonding) p-orbital in methylene.

The calculations indicate that the mononuclear transition metal coordination does in essence only slightly alter the geometry of the methylenephosphane. The transition metal variation insignificantly changes the bonding parameters of the (free) methylenephosphane moieties. It is in contrast to the phosphanylcarbene complexes in which complexation requires substantial changes in the geometries of the free

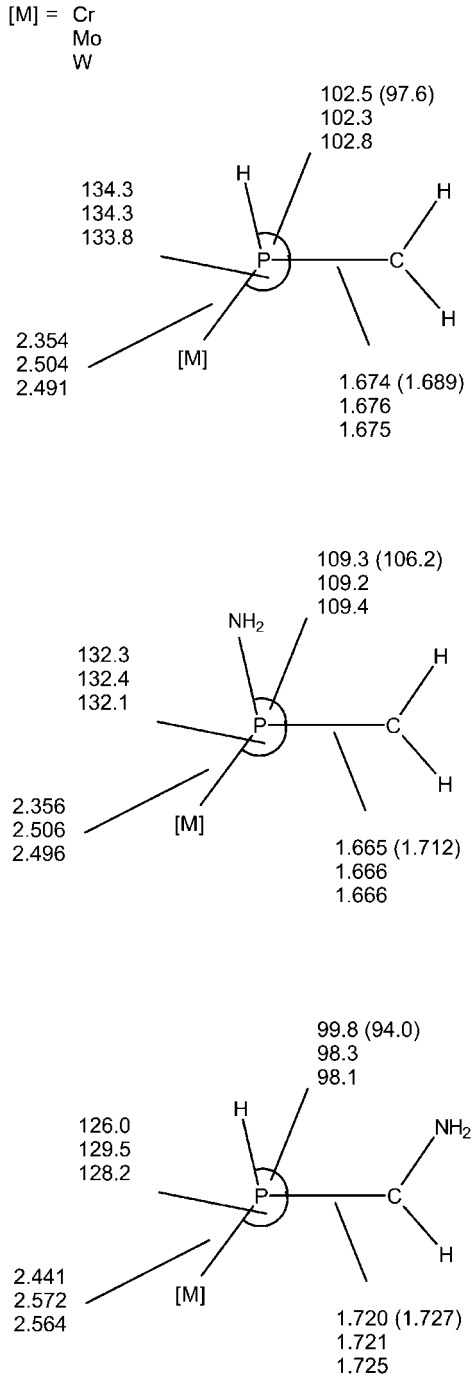


Figure 1. Relevant bonding parameters (bond lengths [Å], bond angles [°]) of η^1-transition metal complexes of methylenephosphanes

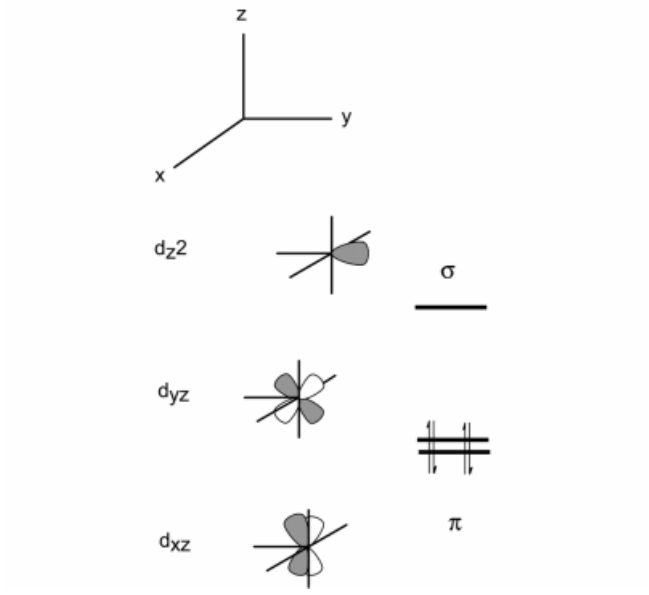
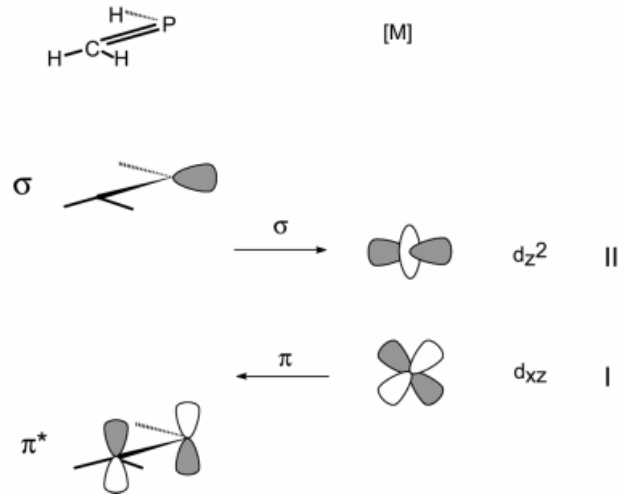
carbenes.[44] The situation for η^1-coordination is more deeply analyzed by an inspection of the energies for bonding of the transition metal fragments (Table 1). They are defined by the reactions according to Equations (1) and (2).

$$R^1P{=}CR^2R^3 \rightarrow [R^1P{=}CR^2R^3]^{\ddagger} \quad (1)$$

$$[R^1P{=}CR^2R^1]^{\ddagger} + ML_5 \rightarrow (ML_5)(R^1P{=}CR^2R^3 \quad (2)$$



Scheme 3



Scheme 4

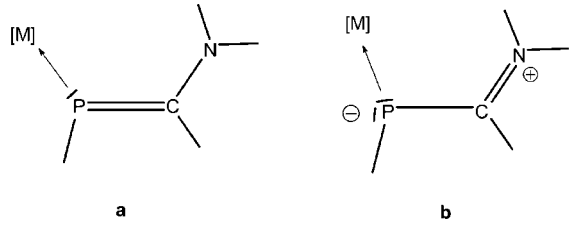
The first process [Equation (1)] refers to the energy (E_{prep}) needed to bring the free ligand (methylenephosphane) towards the structure for complexation.[45] Overall the preparation energies are in the range of 1−2 kcal/mol, thus fairly small. The second process [Equation (2)] corresponds to the energy gained in the formation of the transition metal complex from its standard state. The table includes the electronic energies (ΔE, with zero-point vibrational energy correction) and the free energies (ΔG, at room temperature) for complexation. The binding energies (as given by ΔE and ΔG) are throughout exothermic and strongly superimpose the (endothermic) preparation energies. We note here that the free energies also include the entropy contributions and were determined by standard thermodynamic formulae (see Theoretical Section). The bonding situation for transition-metal complexation contrasts that of the phosphanylcarbene complexes, where both

Table 1. Energies for η^1-coordination of d^6-$M(CO)_5$ fragments

Ligand	Metal	$-\Delta E$ [kcal/mol]	$-\Delta G$ [kcal/mol]	ΔE_{prep} [kcal/mol]
$HP{=}CH_2$	Cr	26.5	16.0	1.0
	Mo	27.7	17.5	0.9
	W	31.8	21.5	1.0
$H_2N{-}P{=}CH_2$	Cr	28.2	17.2	0.7
	Mo	29.4	18.8	0.7
	W	33.5	22.9	0.7
$HP{=}CH{-}NH_2$	Cr	25.3	15.1	1.4
	Mo	27.7	18.0	1.1
	W	30.8	21.6	1.4

quantities are comparable in magnitude.[44] Overall the free energies (ΔG) are smaller in magnitude than the electronic energies (ΔE + zero-point vibrational energy corrections). There is a continuous trend in that the binding energies increase slightly from Cr to W.

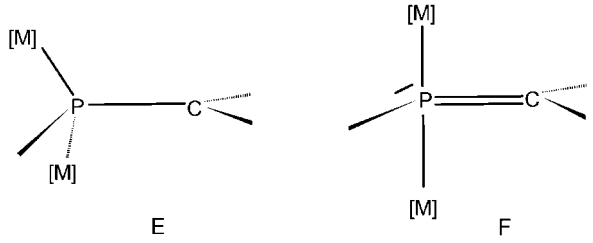
The structures of the methylenephosphanes are to a degree preserved by the coordination. Amino substitution at the phosphorus atom does not essentially alter the geometry of the parent compound, the P−C bond is only slightly elongated, as compared with the parent compound. In terms of π-conjugation, the amino group at the phosphorus atom acts only as a weak π-donor toward the P−C π-bond. The case is different for amino substitution at the carbon atom. Here the P−C bond is sizeably elongated, due to effects of *inverse* π *bond polarization*. In the coordinated compounds the phosphorus atom adopts for **a** the parent methylenephosphane and **b** for its $P{-}NH_2$-substituted congener a trigonal planar arrangement. The situation is different for the $C{-}NH_2$ substitution. After coordination, the phosphorus atom becomes slightly pyramidal, in agreement with the experiments.[31,41] The sum of valence angles for *C*-amino substitution are as follows: Cr 348.9°, Mo 353.9°, W 350.9°. This matter can be touched on in the limiting structures shown in Scheme 5.



Scheme 5

In **a** the transition metal centre coordinates to the lone pair at the phosphorus atom while in **b** the transition metal fragment occupies one lone pair of the phosphorus atom which is obtained by shifting electron density from the amino group towards the P−C π-bond. In this case one lone pair is available for complexation while the other becomes stereochemically active and causes pyramidalization at the phosphorus atom.

For the *binuclear coordination*, the various modes for complexation at the phosphorus as shown in Scheme 6 are possible.



Scheme 6

In **E** the phosphorus atom adopts a tetrahedral coordination with equal bond angles [M]−P−C. In **F** the phosphorus atom adopts a trigonal bipyramid with one lone pair in an equatorial position. In principle, the stereochemical activity of the phosphorus lone pair can lead to such conformations.[46] However, the electropositive transition metal fragment would occupy the axial rather than the equatorial positions. This would be uncommon for a trigonal bipyramid. In any case, one expects for all three alternatives, **D** to **F**, a longer P−C bond than for the mononuclear cases since the phosphorus atom has now to provide a second lone pair for coordination. It becomes only available by adopting the limiting structure **b**.

A binuclear chromium complex of $F_3CP{=}C(F)NMe_2$ has been reported recently.[20] The P−[M] distances are 2.459, 2.457 Å, with Cr−P−Cr = 127.5° and Cr−P−C = 113.5, 104.6°. Thus, this structures has been addressed as a (η^1-μ_2)-4e-complex. Concomitantly the P−C bond results in a value of 1.859 Å, which is in the range of the length of a P−C single bond (exp. 1.82−1.86 Å).[47]

We have studied the binuclear case for [M] = $Cr(CO)_5$ at (*C*-amino)methylenephosphane. A Molden plot[48] of the resulting equilibrium geometry is shown in Figure 2.

Only the case where the transition metal fragment was situated *trans* to the amino group at the carbon atom was studied, in order to mimic the situation with the least steric hindrance. The P−C bond here is sizeably longer (1.784 Å) than in the parent compound or in the mononuclear congener (see Figure 1), however also essentially shorter than in the experiment.[20] Interestingly, the angles [M]−P−C are

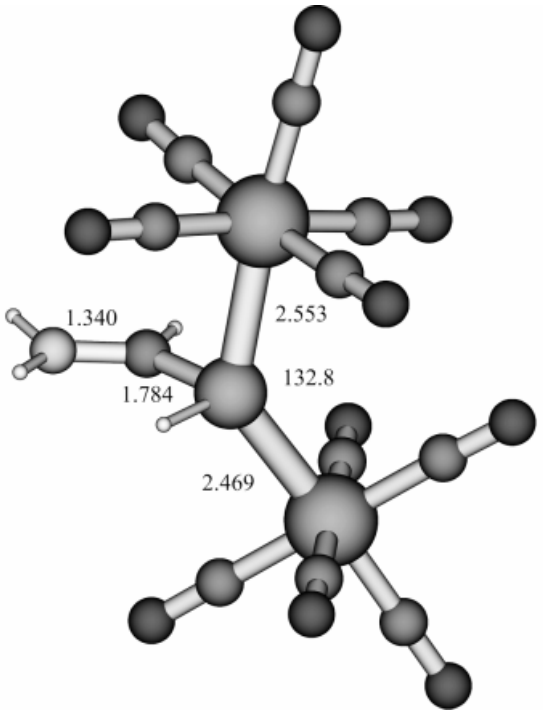


Figure 2. Molden plot of the chromium binuclear complex of *C*-aminomethylenephosphane

different (112.8, 88.2°), also the Cr−P distances are not equal (2.469, 2.553 Å) (see Figure 2). This indicates that the structure does not adopt type **D**, rather it prefers a bonding situation between **E** and **F**. In other words, the first transition metal fragment can easily coordinate to the lone pair of the phosphorus atom, however, the second transition metal fragment cannot bind strongly enough, such as to emphasise the limiting structure of **b** over **a**. It will be shown in the following section that steric effects also contribute to a further lengthening of the P−C bond in methylenephosphanes.

Accordingly, an amino group at the phosphorus atom shortens the [M]−P bond. It can be attributed to an increase of the p-character of the lone pair. On this basis the phosphorus atom changes from p^3-hybridization[32,49] (R−P−C = 90°) to sp^2-hybridization (R−P−C = 120°). This is already witnessed in the structures of the transition metal free methylenephosphanes. The amino substitution at the phosphorus atom causes an opening of the angle at P, as compared with the parent methylenephosphane. In the experimentally reported structure of the binuclear chromium complex the M−Cr distances as well as the angles of the transition metal centres with the P−C bond are almost equal. Thus, our investigations make it likely that the crucial structural effect on bicoordination is exerted by the electron-withdrawing substituent at the phosphorus atom. The energy quantities for coordination of a second $Cr(CO)_5$ fragment in addition to the η^1-complex of *C*-aminomethylenephosphane are: $\Delta E = -20.8$, $\Delta G = -8.0$, $\Delta E_{prep} = 1.4$ kcal/mol. Hence the second metal coordination is essentially less favored than the first metal coordination. The preparation energy, i.e., the energy mainly required to stretch the P−C π-bond is rather small. It is evident that the η^1/η^2- or η^1/η^1-coordination will preferentially take place for inversely polarized methylenephosphanes, since the energy contributions ΔE_{prep}, i.e., the energy to stretch the P−C π-bond can be expected to be small. Our analysis is in agreement with the wealth of experimental data available on transition metal coordination of the P−C systems.[8]

There is a further aspect that must be considered here, that is the electron distribution in the various coordination compounds. In the η^1-complexes, the $M(CO)_5$ fragments are only weakly bound to the phosphorus atom. The Wiberg bond indices yield a result for the [M]−P bond of approximately 0.5 which indicate a rather weak bond. These values are almost independent on the nature of the transition metal (Cr, Mo, W). Overall −0.4 e flow from the ligand (methylenephosphane) into the $M(CO)_5$ fragment. In other words, the latter acts only as a poor electron acceptor. Again, it is not essentially effected by the nature of the transition metal, e.g., for η^1-coordination at the *C*-aminomethylenephosphane the following Wiberg bond orders and flow of electron densities result: Wiberg bond order (Δ charge) Cr 0.411 (−0.438), Mo 0.437 (−0.374), W 0.434 (−0.376). Thus, the $Cr(CO)_5$ fragment is the slightly stronger electron acceptor, although the $W(CO)_5$ fragment binds slightly stronger to the methylenephosphanes. With respect to the electron distribution in the transition metal complexes we will now report our results on the Laplacians (Figure 3).

Figure 3 (top) views the Laplacian of the electron density of Cr bound to the phosphorus atom as well as in plane with the carbon atom. The bond-critical point is at the phosphorus atom that indicates a bond of the lone pair at P towards the transition metal centre. In comparison to the coordination of the second transition metal fragment, an essentially different electronic structure results (Figure 3, bottom). The bond-critical point is located within the triangle spanned by the atoms C, P, and Cr. It indicates that the second transition metal fragment binds simultaneously to the phosphorus and the carbon atom. Whether the second transition metal fragment coordinates according to type **E** or **F** thus depends largely on the preparation energy required to stretch the P−C π-bond.

b. Steric Effects

While it seems clear that monocoordination does not effect the P−C bond length, this, however, is the case for the addition of a second transition metal fragment, since a second lone pair at the phosphorus atom has to be provided. Alternatively in the coordination **C** to **F** the P−C π-bond is weakened. In practise the methylenephosphanes are substituted by bulky groups in order to kinetically protect the central π-bond. It is well established that the "naked" methylenephosphanes tend to undergo immediate reactions after generation.[50] To further analyze this aspect we performed quantum chemical calculations on a variety of differently substituted methylenephosphanes, at times utilizing the B3LYP/6-31g* level of approximation (see following Theoretical Section). The most important bonding para-

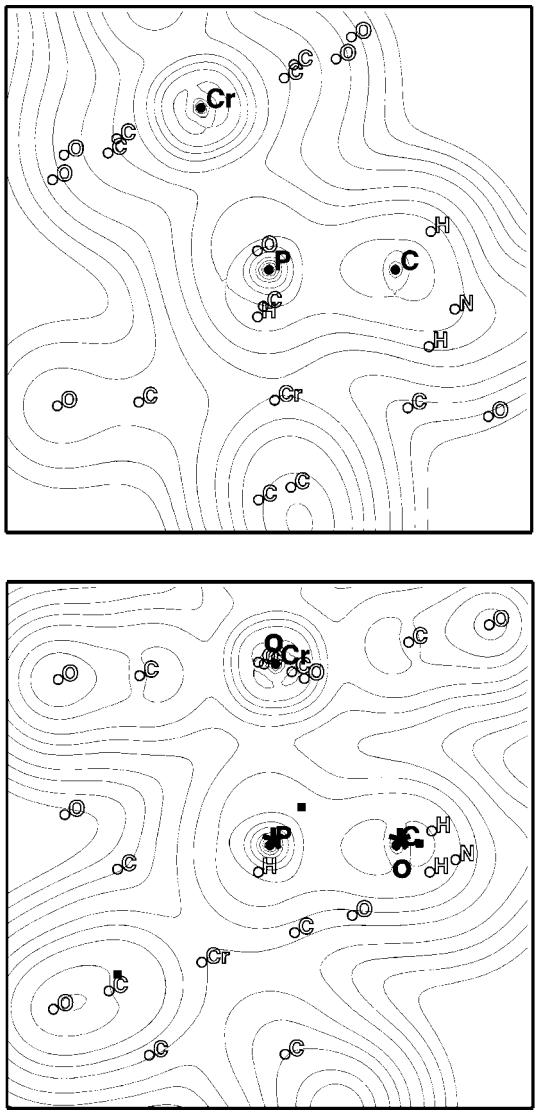

Figure 3. Laplacian of the electron density distribution for $Cr(CO)_5$ complex formation with *C*-aminomethylenephosphane; top: first transition metal fragment (with a large angle bound to the phosphorus atom); bottom: second transition metal fragment (with a small angle bound to the phosphorus atom)

meters are the P−C bond lengths and the R−P−C angles; these are collected in Table 2.

The amino groups at the carbon atom sizeably extend the P−C bond lengths. The effect is largely electronic. Two amino groups increase the P−C distance to 1.742 Å, but the further substitution by sterically demanding isopropyl groups does not essentially continue this tendency. Still the resulting equilibrium bond lengths are shorter than the largest value (1.805 Å) obtained for the binuclear metal complex.[20] According to our investigations the stretching of the P−C bond does not require much energy. Consequently the actual P−C bond lengths are determined by the bonding state in the crystal.

The alkyl substitution in the phosphaalkenes has a further effect, it induces a twisting of the π-bond. The matter is illustrated for the case R^1 = *i*Pr and $R^2 = R^3 = NiPr_2$ in a Molden plot of the computed equilibrium geometry

Table 2. Relevant bonding parameters of various alkyl-substituted phosphaalkenes (bond lengths [Å], bond angles [°]), computed at B3LYP/6-31 g(d) level

(Figure 4). The substituents at the phosphorus and carbon atoms exert considerable mutual steric hindrance, such as to induce rotation at the amino groups (Figure 4, top). As a further consequence, the P−C π-bond starts rotating (Figure 4, bottom).

Conclusion

The results of our investigations can be summarized as follows:

(1) For π-conjugation of an amino group with the π-bond in methylenephosphane an essential lengthening of the P−C bond is observed for the case of substitution of an amino group at the carbon atom. It is due to the stronger N−C π-bond compared with the P−C π-bond that makes the stronger N−C π-conjugation feasible. This refers to the case of *inverse polarized* PC π-bonds.

(2) The mononuclear transition metal coordination causes only slight changes in the equilibrium geometries of the free ligands, resulting in small preparation energies required for coordination. The phosphorus atom remains essentially planar. However, for the case of amino substitution at the carbon atom, the phosphorus atom accumulates negative charge. As a consequence the latter are slightly pyramidal in the coordinated compounds and [M]−P is also slightly longer compared to the other cases.

(3) For the binuclear complexes the first transition metal fragment is coordinated to the phosphorus lone pair and the second fragment to the P−C π-bond. Consequently, the second fragment is weaker bound than the first fragment. The second fragment can easily slip from η^1- to η^2-coordination.

(4) Sterically demanding alkyl groups cause a further lengthening of the P−C π-bond. Concomitantly a twisting of the P−C π-bond is induced.

Theoretical Section

All structures were fully optimized at the B3LYP[51,52] level. For the description of the metal complexes the effect-

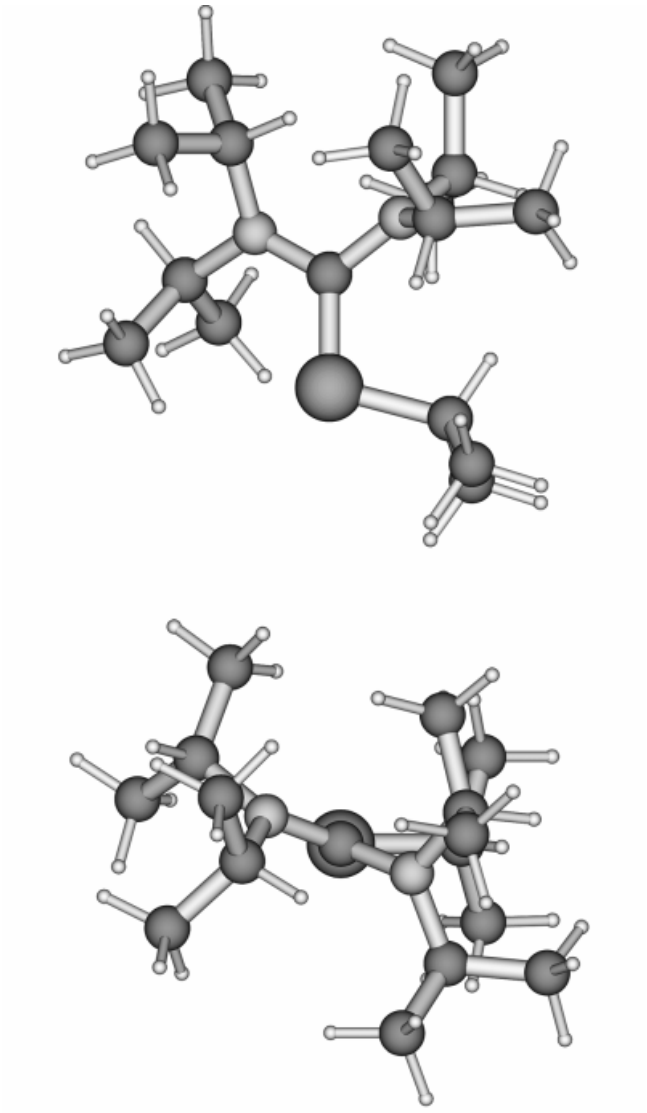

Figure 4. Molden plot of a substituted phosphaalkene (R^1 = *i*Pr; $R^2 = R^3$ = N*i*Pr$_2$)

ive core potential basis sets of Stevens, Basch, and Krauss,[53,54] were augmented by one set of polarization functions (of d-type) for the heavy (non-hydrogen) main group elements [SBK(d) basis]. The use of polarization functions is imperative to obtain a correct description of the polar [M]−P bond. All stationary points were characterized as local minima by inspection of the eigenvalues of the corresponding Hessian matrices calculated at the DFT level. The free energy contributions were evaluated using standard thermodynamic formulae and refer to contributions at 25° C (room temperature). For the cases of the uncomplexed methylenephosphanes which are substituted by bulky substituents [see Section (b)] we employed the 6-31g(d) basis set.[55] For the population analyses the NBO partitioning scheme[56] was used. Further investigations of the electron density distributions were performed with the method of "atoms in molecules".[57] All calculations were performed using the Gaussian 98 package of programs.[58]

Reactivity of $[Ru_3(\mu_3\text{-NPh})(\mu_3\text{-CO})(CO)_9]$ towards Activated Alkynes and Diynes − Isolation of a Trinuclear Intermediate During the Formation of Bi- and Tetranuclear Products

Javier A. Cabeza,*[a] Ignacio del Río,[a] Santiago García-Granda,[b] Marta Moreno,[a] Víctor Riera,[a] María de Jesús Rosales-Hoz,[c] and Marta Suárez[a]

Keywords: Ruthenium / Imido complexes / Cluster compounds / Alkynes / Diynes

Treatment of the trinuclear imido-bridged cluster compound $[Ru_3(\mu_3\text{-NPh})(\mu_3\text{-CO})(CO)_9]$ (**1**) with activated alkynes (methyl propynoate and methyl phenylpropynoate) and diynes (diphenylbutadiyne, 2,4-hexadiyne, 1,6-diphenyloxy-2,4-hexadiyne, and 1-trimethylsilyl-1,4-pentadiyne) in hexanes at reflux temperature leads to separable mixtures of the tetranuclear and binuclear derivatives $[Ru_4(\mu_4\text{-NPh})(\mu_4,\eta^2\text{-RC}{\equiv}\text{CR}')(\mu\text{-CO})_2(CO)_9]$ and $[Ru_2\{\mu,\eta^3\text{-RC=CR}'\text{C(O)NPh}\}(CO)_6]$, respectively. While the former complexes feature a phenylimido ligand in a rather rare μ_4-coordination mode, the binuclear compounds contain acrylamido ligands that result from the coupling of a CO ligand and the original phenylimido ligand of **1** with the incoming alkyne or diyne. Surprisingly, all the products derived from diynes contain a pendant (non-coordinated) alkyne functionality. The isolation of the trinuclear derivative $[Ru_3(\mu_3\text{-NPh})(\mu_3,\eta^2\text{-PhC}{\equiv}\text{CC}{\equiv}\text{CPh})(CO)_9]$ (**9**) in the reaction of **1** with diphenylbutadiyne and the fact that its thermolysis leads to a mixture of $[Ru_4(\mu_4\text{-NPh})(\mu_4,\eta^2\text{-PhC}{\equiv}\text{CC}{\equiv}\text{CPh})(\mu\text{-CO})_2(CO)_9]$ and $[Ru_2\{\mu,\eta^3\text{-C(C}{\equiv}\text{CPh)=C(Ph)C(O)NPh}\}(CO)_6]$ support the proposal that trinuclear species containing coordinated alkyne or diyne ligands, similar to **9**, are intermediates in the synthesis of all the bi- and tetranuclear products. Only one of the two possible regioisomers of each product (that might have arisen from the asymmetry of the alkyne or diyne reagents used) is formed. The origin of this regioselectivity is also discussed.

Introduction

Carbon−nitrogen bond formation assisted by metal cluster complexes has emerged as a powerful tool for the synthesis of novel organic fragments.[1−12] The cluster precursors often contain amido (NR_2)[1,2] or imido (NR)[4−12] ligands, which constitute the nitrogen source for the synthesis of new N-containing organic fragments. In other cases, C−N bond-forming reactions have been achieved by attack of nitrogen nucleophiles (e.g. RNH_2, R_2NH) on coordinated unsaturated hydrocarbyls such as alkynyls, allenyls, etc.[3] In some cases, these assemblies have been successfully separated from the metallic core, yielding interesting heteronuclear organic molecules.[4−8]

Interesting reactions of face-capping organoimido ligands (μ_3-NR) in cluster complexes have been reported. These ligands can easily combine with a variety of other ligands such as hydrides,[13] carbenes,[5,14] acyls,[5,8] carbonyls,[7,10] methoxycarbonyls,[5] or alkynes[4,11] to give organic compounds such as imidates, amides, amines, carbamates, isocyanates, pyridinones, or ureas. In this context, Geoffroy et al. have reported on the reactivity of the trinuclear imido cluster $[Ru_3(\mu_3\text{-NPh})(\mu_3\text{-CO})(CO)_9]$ (**1**) with the internal alkynes diphenylacetylene and methylphenylacetylene.[4] These reactions afforded, among other noteworthy products, binuclear metallapyrrolidone complexes from which pyridinone or maleimide derivatives could subsequently be obtained by treating them with further alkyne or CO, respectively.[4]

Recently, our group has been paying attention to the reactivity of diynes with ruthenium carbonyl cluster complexes containing N-donor ligands.[2,15] To date, only a few reactions of ruthenium clusters with diynes have appeared in the literature,[2,15−17] though these ligands are expected to be more reactive than monoalkynes and, therefore, to offer a richer derivative chemistry.

The interesting results obtained by Geoffroy et al. in the reactions of **1** with non-activated internal alkynes[4] prompted us to study its reactivity towards activated alkynes and diynes, the aim being to prepare new derivatives made accessible by the enhanced reactivity expected for these unsaturated molecules as compared to simple non-activated monoalkynes.

We report herein the synthesis and structural characterization of a series of new bi-, tri-, and tetranuclear ruthenium cluster complexes derived from **1** and activated alkynes or diynes. The regioselectivity of the reactions, which

give only one of the two possible regioisomers of each product (that might arise from the asymmetry of the alkyne or diyne reagents used) is discussed. This work also demonstrates that trinuclear alkyne or diyne complexes are intermediates in the synthesis of the final bi- and tetranuclear products.

Results and Discussion

Synthesis and Characterization of the Compounds

It has been reported that compound **1** can be prepared following different synthetic procedures, i.e. by treating $[Ru_3(CO)_{12}]$ with phenyl isocyanate,[18] nitrobenzene,[18,19] or nitrosobenzene,[20] or by treating the more reactive $[Ru_3(MeCN)(CO)_{11}]$ with nitrosobenzene.[8] However, the first three methods afford compound **1** in only moderate to low yields and it is invariably accompanied by considerable amounts of the diimido derivative $[Ru_3(\mu_3\text{-}NPh)_2(CO)_9]$. In our hands, the best yields (up to 40%) were obtained starting from $[Ru_3(MeCN)(CO)_{11}]$ and nitrosobenzene, following a modification of the published method (see Exp. Section).[8]

Treatment of a solution of **1** with an excess of methyl propynoate in refluxing hexanes afforded a mixture of compounds, from which the derivatives $[Ru_4(\mu_4\text{-}NPh)\{\mu_4,\eta^2\text{-}C(CO_2Me)\equiv CH\}(\mu\text{-}CO)_2(CO)_9]$ (**2**) and $[Ru_2\{\mu,\eta^3\text{-}C(CO_2Me)=CHC(O)NPh\}(CO)_6]$ (**3**) could be isolated by column chromatography (Scheme 1). In an analogous reaction, the compounds $[Ru_4(\mu_4\text{-}NPh)\{\mu_4,\eta^2\text{-}C(CO_2Me)\equiv CPh\}(\mu\text{-}CO)_2(CO)_9]$ (**4**) and $[Ru_2\{\mu,\eta^3\text{-}C(CO_2Me)=C(Ph)C(O)NPh\}(CO)_6]$ (**5**) were obtained by reaction of compound **1** with methyl phenylpropynoate.

Scheme 1

The ^1H NMR spectra of the tetranuclear compounds **2** and **4** clearly indicate the absence of hydride ligands and confirm that only one molecule of alkyne is present per phenylimido ligand. Both compounds display the same pattern in the carbonyl stretching region of their IR spectra, showing the presence of terminal and bridging CO ligands. This IR pattern is analogous to that reported previously for the compounds $[Ru_4(\mu_4\text{-}NR)(\mu_4,\eta^2\text{-}PhC{\equiv}CPh)(\mu\text{-}CO)_2(CO)_9]$ (R = Ph,[21] H[22]), which were structurally characterized by X-ray diffraction methods.

As the alkyne ligands in **2** and **4** are asymmetric, an X-ray diffraction study was carried out on a single crystal of **4** in order to determine the ligand arrangement within the clusters. A molecular plot is shown in Figure 1. Selected bond lengths are listed in Table 1.

Table 1. Selected interatomic distances [Å] in compounds **4** and **8**

C(1)−C(2)	1.427(5)	1.424(7)
C(2)−C(3)	1.496(6)	1.427(4)
C(3)−C(4)	−	1.193(7)
C(3)−O(1)	1.190(5)	−
C(3)−O(2)	1.335(6)	−
C(4)−O(2)	1.444(7)	−

The four Ru atoms of **4** define a distorted square, forming a dihedral Ru(1)−Ru(3)−Ru(4)−Ru(2) angle of 19.5°. The Ru−Ru distances range from 2.695 to 2.795 Å. Two CO ligands span the Ru(1)−Ru(3) and Ru(1)−Ru(4) edges. The phenylimido ligand bridges the four metal atoms, while the alkyne ligand is positioned on the opposite face of the metal core, binding the four Ru atoms in an η^2-fashion, in such a way that it is σ-bonded to Ru(1) and Ru(2) and π-bonded to Ru(3) and Ru(4). The C(2) atom of the alkyne ligand, which bears the CO_2Me group, is attached to the three Ru atoms that bear the bridging carbonyl ligands, while the CPh fragment is bonded to Ru(2), Ru(3), and Ru(4). The cluster shell is completed by nine terminal CO ligands. The structure of **4** resembles those reported previously for the complexes $[Ru_4(\mu_4\text{-}NR)(\mu_4,\eta^2\text{-}PhC{\equiv}CPh)(\mu\text{-}CO)_2(CO)_9]$ (R = Ph,[21] H[22]), which contain a symmetrical alkyne ligand.

The μ_4-coordination mode adopted by the phenylimido ligand in **2** and **4** is rather rare. Apart from the compounds mentioned above, a series of ruthenium compounds containing μ_4-imido ligands has been prepared by Wong et al.

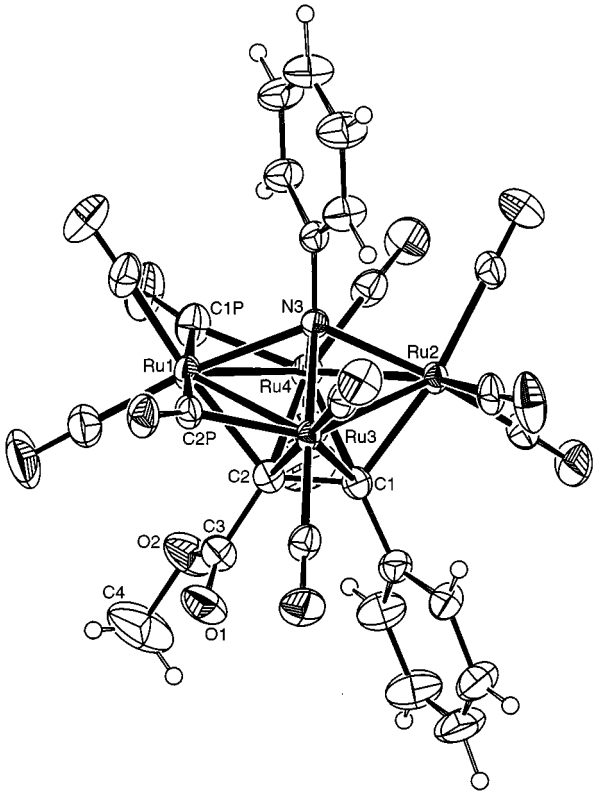

Figure 1. Molecular structure of compound **4**; ellipsoids are drawn at a 50% probability level

by deoxygenation reactions of the methoxyimido precursor $[Ru_3(\mu_3\text{-NOMe})(\mu_3\text{-CO})(CO)_9]$.[12] Further examples of μ_4-imido complexes are the heteronuclear derivative $[WO(\eta^5\text{-}C_5H_5)(\mu\text{-O})Ru_4(\mu_4\text{-NPh})(\mu_4,\eta^2\text{-CCPh})(CO)_{10}]$[23] and the iron complex $[Fe_4(\mu_4\text{-NEt})(\mu,\eta^2\text{-ONEt})(CO)_{11}]$.[24]

The other two complexes isolated from the reactions of **1** with monoalkynes are the binuclear derivatives **3** and **5**. Their elemental analyses and mass spectra clearly indicate their binuclear nature, while their ^1H NMR spectra show the incorporation of only one molecule of alkyne per phenylimido ligand. A comparison of the ^1H and ^{13}C NMR spectra of both compounds with those of other related binuclear metallapyrrolidone complexes[9,11,12a] also indicates that the CO_2Me group is attached to the C_α carbon atom. Both compounds display the same IR pattern in the carbonyl stretching region, suggesting an analogous ligand arrangement. This IR pattern is similar to that reported previously for other binuclear metallapyrrolidone ruthenium[4,11,12a] and iron[9,25] compounds. All these data are in accordance with the structures proposed for **3** and **5** in Scheme 1, and are also supported by an X-ray structural characterization of a related compound (vide infra).

Similar coupling reactions of imido ligands with CO and alkynes to give binuclear metallapyrrolidone compounds have also been reported for rhodium,[26] although in this case the coordination sphere of the metal atoms is not completed by carbonyl but by cyclopentadienyl ligands.

The reactivity of **1** towards 2,4-hexadiyne, diphenylbutadiyne, 1,6-diphenyloxy-2,4-hexadiyne, and 1-trimethylsilyl-1,4-pentadiyne was studied. To our surprise, the diyne ligands exhibited the same reactivity pattern as the monoalkynes, leading to mixtures of the tetranuclear cluster compounds $[Ru_4(\mu_4\text{-NPh})(\mu_4,\eta^2\text{-RC}\equiv\text{CR}')(\mu\text{-CO})_2(CO)_9]$ (R = C≡CMe, R′ = Me, **6**; R = C≡CPh, R′ = Ph, **8**; R = $C\equiv CCH_2OPh$, R′ = CH_2OPh, **11**; R = $CH_2C\equiv CSiMe_3$, R′ = H, **12**; Scheme 1) and the binuclear metallapyrrolidones $[Ru_2\{\mu,\eta^3\text{-RC}{=}\text{CR}'\text{C(O)NPh}\}(CO)_6]$ (R = C≡CMe, R′ = Me, **7**; R = C≡CPh, R′ = Ph, **10**; R = $CH_2C\equiv CSiMe_3$, R′ = H, **13**; Scheme 1), which could be separated by chromatographic methods. In the case of 1,6-diphenyloxy-2,4-hexadiyne, only the tetranuclear derivative **11** could be satisfactorily isolated, while the corresponding binuclear compound could not be separated from uncharacterized impurities.

Interestingly, in the reaction of **1** with diphenylbutadiyne, a novel trinuclear derivative, subsequently characterized as $[Ru_3(\mu_3\text{-NPh})(\mu_3,\eta^2\text{-PhC}\equiv\text{CC}\equiv\text{CPh})(CO)_9]$ (**9**), could be isolated in addition to the aforementioned tetranuclear and binuclear compounds **8** and **10**.

The IR spectra of the tetranuclear compounds **6**, **8**, **11**, and **12** are reminiscent of those of compounds **2** and **4**, indicating a similar ligand arrangement. This was confirmed by an X-ray diffraction study carried out on a single crystal of **8**. A molecular plot is shown in Figure 2 and selected bond lengths are listed in Table 1. For quick comparison purposes, and as far as possible, similar numbering schemes have been used for **4** and **8**. The structure of **8** is entirely analogous to that of compound **4**. Again, the car-

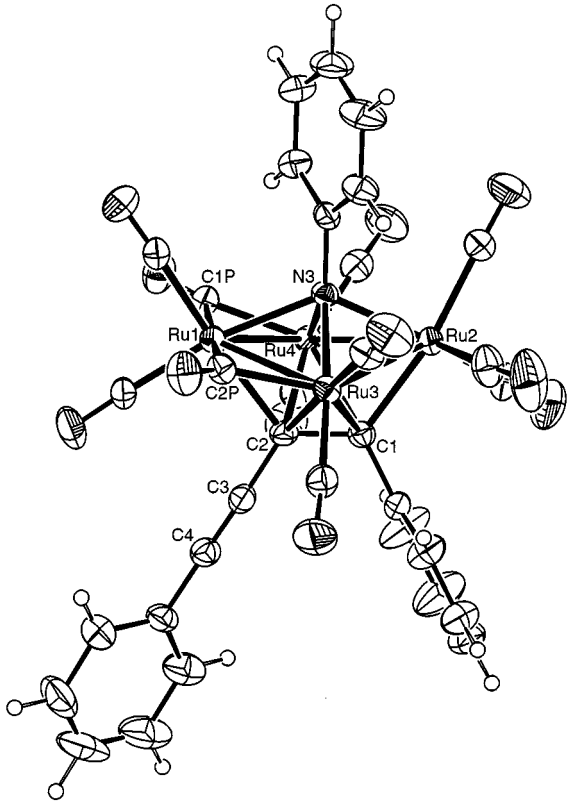

Figure 2. Molecular structure of compound **8**; ellipsoids are drawn at a 50% probability level

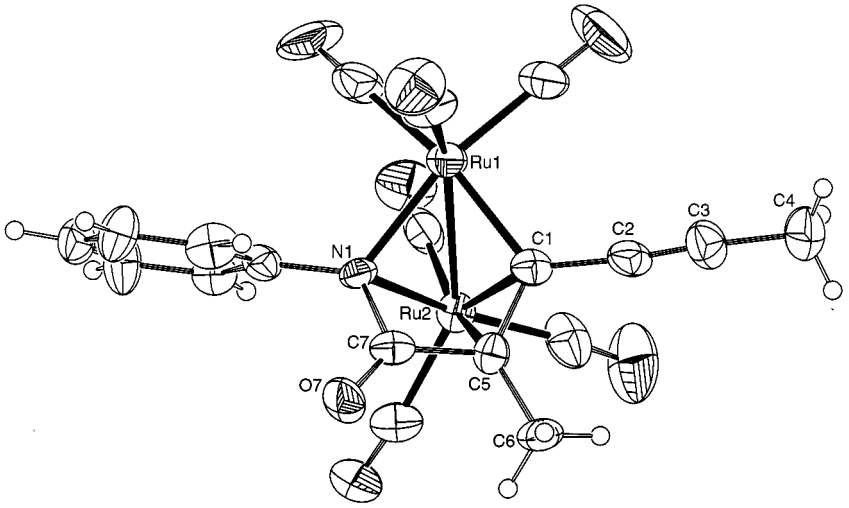

Figure 3. Molecular structure of compound **7**; ellipsoids are drawn at a 50% probability level

bon atom bearing the most electron-withdrawing substituent of the coordinated alkyne, the C≡CPh group, is bonded to the three metal atoms that bear the bridging carbonyl ligands.

The structures of the binuclear ruthenapyrrolidones **7**, **10**, and **13** are analogous to those described above for compounds **3** and **5**. The positions of the substituents attached to the C_α and C_β carbon atoms of the metallapyrrolidone fragments were unambiguously determined on the basis of their ^{13}C and ^{1}H NMR spectra (Scheme 1). These data also compare well with those reported previously for related iron[9] and ruthenium[11,12a] compounds. This structural assignment was also supported by an X-ray structure determination carried out on a single crystal of **7**.

The structure of **7** is shown in Figure 3. Selected bond lengths are listed in Table 2. The compound consists of two ruthenium atoms bridged by an acrylamido ligand, which stems from the coupling of the original imido ligand, one of the C≡C bonds of the incoming diyne, and a carbonyl ligand. The molecule can be described as a ruthenapyrrolidone fragment attached to a ruthenium atom through the Ru, N, and both C atoms of the double bond, C(1) and C(5). The carbon atom C(1), bearing the noncoordinated C≡CMe group, is also σ-bonded to Ru(1). The coordination sphere of each metal atom is completed by three terminal CO ligands. The C(1)−C(5) distance, 1.42(2) Å, is within the range typical of coordinated double bonds, while the C(1)−Ru(1) bond length, 2.05(2) Å, is shorter than that corresponding to C(1)−Ru(2), 2.26(2) Å, reflecting σ- and π-interactions, respectively. The Ru(1)−Ru(2) distance, 2.682(2) Å, is appropriate for a single metal−metal bond.

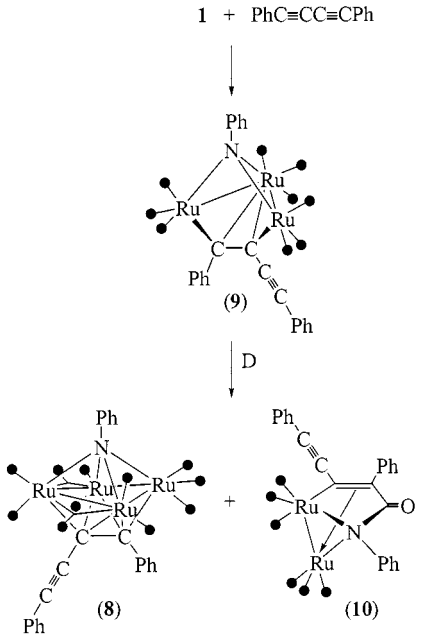
The ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra of the trinuclear compound **9** show the presence of the imido ligand and indicate the incorporation of one molecule of diyne into the cluster shell. Its trinuclear nature was revealed by its elemental analysis and mass spectrum, which shows the appropriate molecular ion isotopomers. The presence of nine carbonyl ligands was also deduced from its $^{13}C\{^{1}H\}$ NMR spectrum. The 50-electron count of the cluster is consistent with the presence of only two metal−metal bonds. Unfortunately, despite many attempts, we could not obtain crystals of **9** suitable for an X-ray diffraction study and the coordination mode of the diyne could not be unambiguously determined. However, its IR spectrum compares well with that reported previously for the imido-bridged cluster $[Ru_3(\mu_3\text{-}NOPh)(\mu_3,\eta^2\text{-}PhC{\equiv}CH)(CO)_9]$,[12a] which was structurally characterized by X-ray diffraction methods and which features the same ligand arrangement as that depicted for **9** in Scheme 2.

Regioselectivity of the Products

In all the reactions reported in this article, the use of asymmetric alkynes could have led to the formation of two regioisomers for each compound. However, *only one of the two possible regioisomers is selectively formed.* Diynes can also be considered as asymmetric alkynes, since all the isolated products derived from them contain a pendant (noncoordinated) alkyne fragment.

For the metallapyrrolidone complexes, electronic rather than steric effects seem to govern the exclusive formation



Scheme 2

of one of the two possible isomers in each case, since the group attached to the pyrrolidone C_α atom is always more electron-withdrawing than that attached to C_β, regardless of their volumes. This proposal is also in agreement with the results obtained by Geoffroy et al. for analogous derivatives, for which no explanations were given.[4]

In the case of the tetranuclear derivatives, again only one of the two possible isomers was observed in each case. In these complexes, the two alternative coordination modes of the alkynes or diynes are not expected to lead to marked differences in the spectroscopic data, and only in the compounds studied by X-ray diffraction methods could the ligand disposition be unambiguously determined. For the X-ray-characterized compounds **4** and **8**, it is found that the ruthenium atom that bears the two bridging CO ligands is attached to the carbon atom of the alkyne moiety that bears the most electron-withdrawing group, but, coincidentally, this group is also the smallest one in each case. It is also unfortunate that the two previously reported structures of related compounds are of complexes containing a symmetrical alkyne ligand, $[Ru_4(\mu_4\text{-NR})(\mu_4,\eta^2\text{-PhC}{\equiv}\text{CPh})(\mu\text{-CO})_2(CO)_9]$ (R = Ph,[21] H[22]). However, careful examination of the X-ray structures of all these tetranuclear complexes indicates that there is sufficient space at both ends of the C≡C moiety to accommodate the bulkier substituent. Therefore, electronic rather than steric effects must account for the observed regioselectivity. Accordingly, the assignment of the substituents shown in Scheme 1 for the tetranuclear derivatives is such that the most electron-withdrawing substituent of the alkyne is close to the ruthenium atom that bears the two bridging CO ligands, as found in the structurally characterized compounds **4** and **8**.

Insights into the Formation of the Bi- and Tetranuclear Compounds

The synthesis of the bi- and tetranuclear complexes appears to be initiated by coordination of the alkyne or diyne reagents to compound **1**, to generate trinuclear intermediates analogous to complex **9**. These 50-electron trimetallic intermediates seem to be highly unstable as they could only be isolated in the reaction with diphenylbutadiyne. In subsequent steps, the alkyne coordination must be followed by cluster fragmentation and C−C and C−N bond formations to afford the corresponding binuclear ruthenapyrrolidone complexes. The $Ru(CO)_x$ fragments arising from this cluster degradation would be readily trapped by the remaining trimetallic intermediates to afford the corresponding tetranuclear derivatives (Scheme 2).

This proposal is supported by the fact that compound **9** is readily converted into an approximately 1:1 mixture of compounds **8** and **10** upon heating in hexanes or after long periods in solution at room temperature. In fact, all attempts to obtain single crystals of **9** afforded compound **8** as the only crystallized species, while the IR spectrum of the remaining solution indicated the presence of the binuclear derivative **10** as the major product.

Concluding Remarks

The present work describes the synthesis of a series of bi- and tetranuclear ruthenium derivatives by treatment of a trinuclear imido-bridged compound with activated alkynes and diynes. In each case, only one of the two possible regioisomers of the product is formed. This selectivity has been rationalized on the basis of electronic effects of the groups attached to the C≡C moiety. The μ_4-coordination mode adopted by the imido ligand in the tetranuclear compounds reported herein is rather rare for ligands of this type, the number of examples hitherto reported being very limited.[12,21−24]

Surprisingly, the diynes studied in the present work invariably behaved as simple monoalkynes, leading to metal complexes containing a pendant, non-coordinated alkyne fragment. These results are to some extent at variance with those found for other triruthenium clusters in their reactions with diynes, where these ligands lead to a richer derivative chemistry than that of simple monoalkynes.[2,15−17] The isolation, characterization, and observed reactivity of the trinuclear derivative **9** has shed light on the general reaction pathway followed by trinuclear imido-bridged cluster complexes in their reactions with alkynes and diynes since compounds analogous to **9** are intermediates in the formation of the final bi- and tetranuclear products.

Experimental Section

General Remarks: Solvents were dried withn sodium diphenyl ketyl (THF, hydrocarbons) or calcium hydride (dichloromethane, acetonitrile) and were distilled under nitrogen prior to use. The reactions were carried out under nitrogen using Schlenk vacuum line techniques and were routinely monitored by solution IR spectroscopy

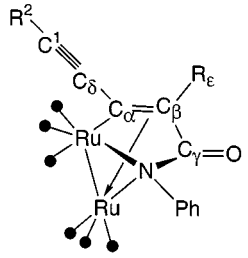


Figure 4. Carbon atom labeling scheme for the binuclear derivatives

(carbonyl stretching region) and by spot TLC (silica gel). − All reagents were purchased as analytically pure samples, except for anhydrous Me_3NO, which was obtained by azeotropic distillation of $Me_3NO{\cdot}2H_2O$ in toluene. − IR: Perkin−Elmer Paragon 1000 FT. − NMR: Bruker AC-200, AC-300, or DPX-300, room temperature, $SiMe_4$ as internal standard; carbon atom labeling scheme see Figure 4. − Microanalyses were obtained from the University of Oviedo Analytical Service. − FAB-MS were obtained from the University of Santiago de Compostela Mass Spectrometric Service; data given refer to the most abundant molecular ion isotopomer.

Synthesis of $[Ru_3(\mu_3\text{-NPh})(\mu_3\text{-CO})(CO)_9]$ (1): A solution of Me_3NO (70 mg, 0.936 mL) in dichloromethane (50 mL) was added dropwise to a solution of $[Ru_3(CO)_{12}]$ (500 mg, 0.782 mmol) in dichloromethane/acetonitrile (400 mL:15 mL) at −78 °C. An instantaneous color change from yellow to brown was observed. Once the addition was complete, the mixture was allowed to warm to room temperature and a solution of nitrosobenzene (100 mg, 0.934 mmol) in dichloromethane (10 mL) was added dropwise. After stirring for 15 min, the mixture was concentrated under reduced pressure to a volume of ca. 2 mL and the residue was transferred to a column of silica gel (10 × 2 cm). Elution with hexanes afforded first a yellow band, which contained some unchanged $[Ru_3(CO)_{12}]$, followed by a second yellow band containing 210 mg (40%) of complex **1**. − $C_{16}H_5NO_{10}Ru_3$ (674.46): calcd. C 28.50, H 0.75, N 2.08; found C 28.70, H 0.80, N 1.99. − FAB-MS: *m*/*z* = 675 [M^+]. − IR (CH_2Cl_2): ν(CO) = 2102 (d), 2070 (vs), 2029 (m), 1721 (w, br) cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 7.20−7.00 (m, 5 H, Ph).

General Procedure for the Reactions of 1 with Alkynes and Diynes: In a typical reaction, a solution of **1** in hexanes (30 mL) was stirred at reflux temperature with an excess of the appropriate alkyne or diyne until complete consumption of the starting material **1** (IR monitoring). The color of the solution changed from yellow to brown. The solution was then transferred to a column of silica gel (2 × 15 cm). In each case, elution with hexanes afforded a first band that contained some unchanged starting material **1**. Subsequent elution with the appropriate eluent gave the products.

$[Ru_4(\mu_4\text{-NPh})\{\mu_4,\eta^2\text{-C(CO}_2\text{Me)}{\equiv}\text{CH}\}(\mu\text{-CO})_2(CO)_9]$ (2) and $[Ru_2\{\mu,\eta^3\text{-C(CO}_2\text{Me)}{=}\text{CHC(O)NPh}\}(CO)_6]$ (3): Reactants: **1** (52 mg, 0.077 mmol); methyl propynoate (50 μL, 0.562 mmol). Reaction time: 2 h.

Thermolysis of 9: A solution of **9** (40 mg, 0.047 mmol) in hexanes (20 mL) was heated at reflux temperature for 3 h, whereupon the color changed from yellow to brown. It was then concentrated under reduced pressure to a volume of ca. 2 mL and applied to the top of a column of silica gel. Elution with hexanes/diethyl ether (30:1) afforded 13 mg (27%) of compound **8** as an orange solid. Subsequent elution with hexanes/diethyl ether (3:1) afforded a pale-green band, which was found to contain 10 mg (31%) of compound **10**.

X-ray Crystallographic Studies: Crystal data and refinement details are summarized in Table 3. Single crystals of compounds **4**, **7**, and **8** were analyzed on a Nonius CAD4 diffractometer, equipped with a graphite crystal monochromator, using the $\omega-2\theta$ scan technique with a variable scan rate and a maximum scan time of 60 s per reflection. In all cases, Lorentz and polarization corrections were applied and data were reduced to F_o^2 values. A semiempirical absorption correction was applied based on ψ scans,[27] with correction factors in the range 0.53 to 0.40 for **4**, 0.977 to 1.011 for **7**, and 0.987 to 0.995 for **8**. The structures were solved by Patterson interpretation using the program DIRDIF-96.[28] Isotropic and full-matrix anisotropic least-squares refinements were carried out using SHELXL-97.[29] All non-H atoms were refined anisotropically. Hydrogen atom positions were geometrically calculated and refined as riding on their parent atoms. Molecular plots were generated with the EUCLID program package.[30]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-164215 (**4**), CCDC-164216 (**7**), and CCDC-164217 (**8**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

A New Highly Active Diphosphane-Palladium(II) Complex as a Catalyst Precursor for the Heck Reaction

Sven Sjövall,[a] Maria H. Johansson,[a] and Carlaxel Andersson*[a]

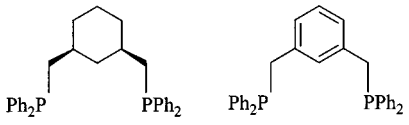
Keywords: Palladium / Phosphanes / Catalysis / Heck reaction

The new diphosphane ligand *cis*-1,3-bis[(diphenylphosphanyl)methyl]cyclohexane (**4**) has been prepared and has allowed the synthesis of the palladium complex *cis*-[Pd(**4**)$(CO_2CF_3)_2$] (**6**). To obtain *cis* complexation of the diphosphane in **6** the cyclohexane skeleton adopts a chair conformation with a diaxial orientation of the substituents, a structure that has been verified by an X-ray structure determination. This complex efficiently catalyses the vinylation of iodo- and bromobenzenes in high yields. For the best reaction, with methyl acrylate and iodobenzene, a yield of >98% was obtained with an average turnover frequency of 11 760 h^{-1} and a turnover number of 1 176 000.

Introduction

Novel or improved homogeneous catalytic reactivities are continuously being achieved with a large variety of organometallic complexes. The main method of controlling and directing the reactivity of a metal in such a compound is by modifying the steric and/or electronic properties of the coordinated ligands.[1] The effect of using different "fine-tuned" ligands in catalysis is perhaps best illustrated by the widely studied Heck reaction,[2] the generation of sp^2-sp^2 carbon−carbon bonds by palladium-catalysed arylation of olefins with aryl halides.[3] In order to increase the catalyst efficiency in this potentially industrially important reaction a great deal of efforts have been made recently and this has led to the development of improved palladium catalysts in terms of both stability and activity.[4−10] A variety of different ligands have been investigated for these high-performing catalysts, such as sterically hindered, highly basic phosphanes,[4] carbenes,[5] cyclometallated phosphanes,[6] phosphites,[7] mono- and bis-chelating diphosphanes[8] and imines,[9] as well as more traditional Heck coupling catalysts combined with additives such as $[PPh_4]Cl$ or $PtBu_3$.[10] A key feature of several of these systems is the stabilisation of the active catalyst by either ligand chelation or steric shielding of the transition metal centre. This confers a high thermal stability on the catalyst allowing long reaction times and high reaction temperatures without noticeable catalyst deactivation. Intrigued by the delicate ligand effects in the Heck reaction we have initiated a general program aimed at the development and catalytic investigation of bidentate phosphane ligands that can potentially cyclometallate at an sp^3 carbon.

In this paper we report the synthesis of the stereospecific diphosphane *cis*-1,3-$(Ph_2PCH_2)_2C_6H_{10}$ (**4**), which is the fully aliphatic analogue to the well-known tridentate PCP ligand 1,3-$(Ph_2PCH_2)_2C_6H_4$ (**4′**).[11] Thus, by changing the ring carbons from sp^2 to sp^3, the different electronic properties of ligand **4** relative to **4′** should modify the reactivity of the resulting complex. However, when we first investigated the coordination chemistry of ligand **4** we found a totally different coordination mode, as evidenced by X-ray crystallography, from the analogous aromatic diphosphane. We also describe some preliminary results on the catalytic vinylation of aryl halides by the Pd^{II} complex synthesised herein.



4 **4′**

Results and Discussion

Ligand Synthesis

Based on the fact that the sterically demanding substituents of *cis*-1,3-cyclohexanedicarboxylic acid (**1**) prefer an equatorial orientation,[12] we have chosen **1** as the starting material for the preparation of *cis*-1,3-bis[(diphenylphosphanyl)methyl]cyclohexane (**4**) following the procedure depicted in Scheme 1. In the initial step, **1** was reduced with an excess of BH_3 in THF yielding *cis*-1,3-bis(hydroxymethyl)cyclohexane (**2**). A good leaving group was introduced in **2** by treating it with a stoichiometric amount of trifluoromethanesulfonic anhydride in the presence of a base, giving *cis*-1,3-bis[(trifluoromethylsulfonyloxy)methyl]cyclohexane (**3**). This colourless oil undergoes decomposition within hours, even when it is stored below −18 °C, and was therefore used immediately after isolation. The reaction of **3** with 2 equiv. of $LiPPh_2$ in THF furnished phosphane **4**. An NMR spectroscopic analysis showed the phosphane to be essentially pure and, because of its high air-sensitivity, it was used without further purification. However, sulfuriz-

[a] Inorganic Chemistry, Centre for Chemistry and Chemical Engineering, Lund University,

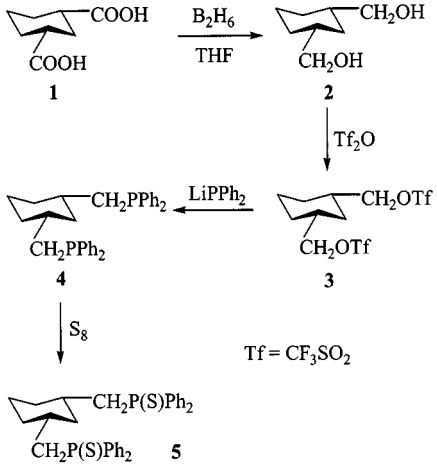
ation of the phosphane, by treating it with an excess of elementary sulfur, results in the air-stable compound *cis*-1,3-bis[(diphenylphosphane sulfide)methyl]cyclohexane (**5**), which was fully characterised including elemental analysis. Clean removal of the sulfur atoms in **5** with Raney-Nickel or trichlorosilane,[13] was unsuccessful and sulfurization therefore does not provide a simple route to analytically pure **4**.

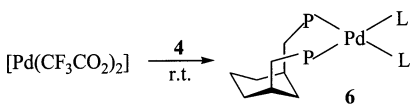


Scheme 1

The $^{13}C\{^1H\}$ NMR spectra of compounds **2**−**5** imply C_s symmetry and thus confirm the *cis* arrangement of the functional groups in the 1,3-positions of the cyclohexane ring. Hence, the respective cyclohexane skeletons give rise to four sets of signals: those of the chemically equivalent methine groups and three chemically different sets of methylene groups. Furthermore, the triflate substituents in **3** cause a significant downfield shift (to δ = 81.2) for the α-methylene group, which is in accordance with its good leaving group capacity.

Complexation

Our initial studies revealed that the choice of palladium precursor was of importance, since attempts to synthesise a monomeric palladium complex using a dihalide precursor failed. Hence, when $[PdCl_2(NCPh)_2]$ was stirred overnight with 1 equiv. of **4** in CH_2Cl_2 a yellow insoluble material was isolated in high yield. Shaw and co-workers have earlier described similar results, which they explained with the formation of a large-ring polynuclear palladium compound.[14] Instead, the preparation of a monomeric palladium complex was achieved by reacting $[Pd(CO_2CF_3)_2]$ with 1 equiv. of **4** in THF, yielding **6** as air-stable crystals in reasonable yield (Scheme 2).



Phenyls on P omitted for clarity
L = CF_3CO_2

Scheme 2

The integral sum in the ^1H NMR spectrum of **6** suggests no displacement of hydrogen from ligand **4**. In addition, one of the protons in the cyclohexane ring is substantially shifted downfield to δ = 4.46, implying a through-space interaction with the metal centre. The $^{31}P\{^1H\}$ NMR spectrum displays a singlet, which is consistent with a mirror-plane symmetry of **6**, and the position at δ = 16.5 is in accordance with other Pd *cis*-diphosphane complexes.[15] In the $^{13}C\{^1H\}$ NMR spectrum, the C2 signal occurs as a triplet in the normal aliphatic region (δ = 28.6, $^3J_{PC}$ = 6.6 Hz). Hence, the NMR spectroscopic data is consistent with the structure shown in Scheme 2, i.e. the ligand binds to the metal centre in a *cis*-diphosphane fashion with a diaxial arrangement of the substituents on the cyclohexane ring. This energetically more demanding conformation of the cyclohexane ring, relative to the diequatorial counterpart, was not expected.[12] Moreover, the coordination mode of **4** also deviates substantially from the fully aromatic analogue 1,3-bis[(diphenylphosphanyl)methyl]benzene, which coordinates as a tridentate PCP ligand in a *trans*-configuration.[11] The reason for the reluctance of ligand **4** to activate a C−H bond, even though the spacing between its phosphorous atoms is sufficiently large for *trans*-coordination when diequatorially oriented, must be due to an improper arrangement of its C−H bonds with respect to the palladium metal centre.

An X-ray crystallographic investigation has confirmed the structure of **6**. Yellow blocks were obtained upon crystallisation by layering Et_2O onto a THF solution of **6**. A perspective view of the molecular structure is shown in Figure 1 including selected bond lengths and angles.

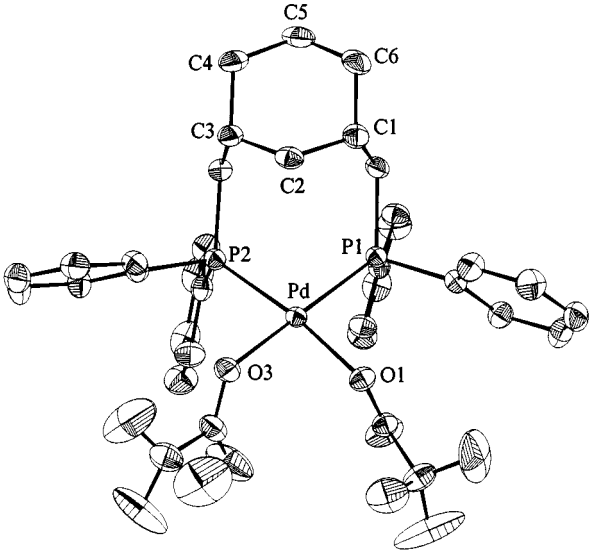


Figure 1. Perspective view (DIAMOND) of **6** (thermal ellipsoids at 30% probability); bond lengths (Å) and angles (deg) with estimated standard deviations: Pd−O1 2.086(2), Pd−O3 2.074(2), Pd−P1 2.261(1), Pd−P2 2.252(1), O1−Pd−O3 83.36(10), P1−Pd−P2 93.81(4), P1−Pd−O1 93.36(8), P1−Pd−O3 173.83(7)

Complex **6** exhibits a *cis* square-planar geometry. The congested conformation of the cyclohexane ring causes the chelate to distort the complex slightly away from an ideal geometry by widening the P1−Pd−P2 angle [93.81(4)°]. Small deviations in the bond lengths, for example for Pd−P1 [2.261(1) Å] and Pd−P2 [2.252(1) Å], illustrate the pseudo-symmetric property of **6**. The diaxial disposition of the substituents on the cyclohexane ring causes the ring to lie well above the plane of the complex (Figure 2). Note the correlation of the position of the equatorial hydrogen on C2 (Figure 2) and its downfield shift in the ^{1}H NMR spectrum of **6** (vide supra). The strained cyclohexane ring adopts the chair conformation, where the endocyclic bond angles deviate substantially from free cyclohexane (111.5°).[16]

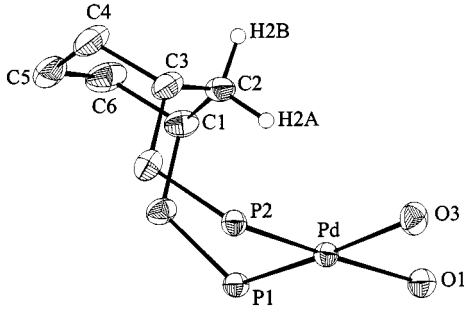

Figure 2. A plot showing the chair conformation of the cyclohexane skeleton in **6** including the hydrogens on C2; bond angles (deg) with estimated standard deviations: C1−C2−C3 115.2 (3), C2−C3−C4 109.0(3), C3−C4−C5 113.3(3), C4−C5−C6 112.2(4), C5−C6−C1 = 112.9(3), C6−C1−C2 108.8 (3)

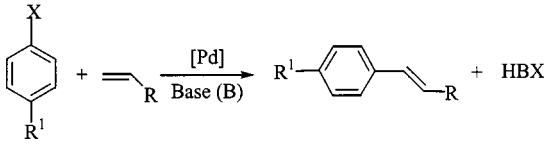
Catalysis

As mentioned in the introduction, some chelating diphosphane-palladium(II) complexes are high-performing precatalysts for the vinylation of aryl halides (Scheme 3), as recently communicated by Shaw et al.[8a]



Scheme 3

Until then, the prevailing belief was that diphosphanes were unsuitable ligands in Heck catalysis.[17] Intrigued by this observation we decided to investigate complex **6** as a precatalyst for the same reaction.

As shown in Table 1, complex **6** is indeed very active in the arylation of a variety of olefins with aryl iodides and bromides. The reaction of methyl acrylate with iodobenzene is by far the most active system in the present study where a TON of 1.2×10^6 was achieved (TOF up to 1.2×10^4, Table 1, entry 2). This TON is the highest observed so far for a chelating palladium-diphosphane catalyst,[18] and also among the highest reported overall for a phosphane-containing catalyst in a high-yielding Heck reaction.[19] The screening of different bases (Na_2CO_3, NaOAc, lutidine, NBu_3 and DABCO) revealed that **6** performs best with NBu_3 as base. Of the polar solvents tested, *N*-methylpyrrolidone (NMP) was found to be superior in terms of reaction rate (entry 1), relative to *N*,*N*-dimethylformamide or *N*,*N*-dimethylacetamide, when using the same reaction conditions. The reaction can also be carried out in semi-polar and non-polar solvents, although at lower rates. However, as far as we are aware, the TONs in dioxane (333 000, entry 5) and mesitylene (320 000, entry 6) are unsurpassed.[20] The catalyst system is sensitive and to ensure high catalytic activity the efficient exclusion of air was necessary, as well as the use of pure solvents and starting materials. Complex **6** is thermally stable up to at least 140 °C, presumably due to the stabilising chelate effect, but the reactions were routinely performed at 120 °C for comparative purposes.[8a] To further verify the thermal stability of the complex we intentionally left some reactions for prolonged times: some reaction times could probably be reduced, and in no case was any noticeable formation of palladium metal observed. The catalyst remains highly active after the reaction is completed, and upon addition of more substrates the catalytic reaction resumes at essentially the same rate using the reaction conditions described (Table 1, entry 1).

As expected, both the electronic properties of the reacting olefin and steric hindrance are decisive factors for the efficiency of the catalyst: methyl acrylate gave a higher average reaction rate than styrene or *n*-butyl acrylate regardless of the aryl halide employed. However, the TONs for the arylation of *n*-butyl acrylate (495 000, entry 3) and styrene (490 000, entry 4) with iodobenzene are again among the highest reported.[6a] Complex **6** was also capable of catalysing the vinylation of relatively unreactive bromobenzenes in excellent yields (entry 7−10). Here it is also evident that an electron-withdrawing group on the aryl ring increases the reaction rate. Unfortunately, **6** is not able to convert the relatively cheaper aryl chlorides to any degree, although the effect of adding expensive promoters like [NBu_4][Br] was not tested.[21]

The trend of reactivity for iodo-, bromo- and chlorobenzenes indicates that an oxidative addition of the aryl halide to the catalyst is involved in the rate-determining step for the Heck reaction. Whether this mechanism involves a Pd^{II}/Pd^{IV} catalytic cycle, as previously suggested for other palladium-diphosphane catalysts,[8a] or not, is unclear for the moment. However, the greater efficiency of the eight-membered chelate complex **6** in catalysing the Heck reaction, compared to the previously reported four- to seven-membered ones,[8a] suggests that chelate-opening is involved in the catalytic cycle. A similar striking chelate effect on catalytic activity has been reoported by Milstein and coworkers.[4b]

In summary, ligand **4** coordinates as a normal *cis*-diphosphane, which is opposed to its fully aromatic analogue. This is made possible by the diaxial orientation of the substituents in the cyclohexane skeleton. An investigation of the catalytic activity of the resulting diphosphane-palladium

[a] mac = methyl acrylate, bac = *n*-butyl acrylate, sty = styrene. – [b] 4-bba = 4-bromobenzaldehyde. – [c] TON = Turnover number (mol product/mol catalyst). – [d] GC yield using 2-methylnaphthalene as internal standard. – [e] TOF = Turnover frequency (mol product/mol catalyst × time). – [f] *trans*-stilbene/*cis*-stilbene = 9. – [g] Dioxane as solvent. – [h] Mesitylene as solvent.

complex **6** has shown it to be by far the most active chelating diphosphane-Pd^{II} catalyst reported for the Heck reaction, and it shows an exceedingly high catalytic activity including reactions of non-activated aryl bromides. Huge TONs are also found in semi-polar or non-polar solvents, and **6** should be placed amongst the most active phosphane-containing catalysts overall for vinylation of aryl halides. We believe that the catalytic cycle is assisted by a labile chelate.

Experimental Section

All experiments with metal complexes and phosphane ligands were carried out under an atmosphere of argon or nitrogen in a Braun glovebox equipped with an inert gas purifier, or by using standard Schlenk and vacuum-line techniques. All non-deuterated solvents, reagent grade or better, were freshly distilled under a nitrogen atmosphere: Et_2O, THF, toluene, *n*-hexane, and *n*-pentane from sodium/benzophenone ketyl; CH_2Cl_2 and $CHCl_3$ from CaH_2. Deuterated solvents were used as received. Commercially available reagents was purchased from Aldrich and used without purification. The *cis*-1,3-cyclohexanedicarboxylic acid (**1**) was isolated from the commercially available *cis,trans* mixture according to a literature procedure.[22] The lithium phosphide $LiPPh_2$ was prepared by the drop-wise addition of *n*BuLi to an equimolar amount of PPh_2Cl below −60 °C, allowed to age for 2 h at room temperature, and thereafter used in situ for further reaction.

NMR spectra were recorded either on a Varian Unity 300 MHz instrument (^1H, ^{31}P, ^{19}F) or a Bruker ARX 500 MHz spectrometer (^{13}C). A ^{13}C DEPT NMR spectrum was routinely recorded for each compound. The NMR spectroscopic measurements were performed in $CDCl_3$ unless stated otherwise. ^1H and ^{13}C NMR chemical shifts are reported in ppm downfield from tetramethylsilane but were measured relative to the residual ^1H in the deuterated solvent. ^{31}P NMR chemical shifts are reported in ppm downfield from an external 85% solution of phosphoric acid. ^{19}F NMR chemical shifts are reported in ppm downfield from an external sample of $CClF_3$ in $CDCl_3$ v = virtual. NMR multiplicities are abbreviated as follows: s = singlet, d = doublet, t = triplet, q = quadruplet, m = multiplet, br = broad. Fast Atom Bombardment (FAB) mass spectroscopic data were obtained on a JEOL SX-102 spectrometer using 3-nitrobenzyl alcohol as matrix and CsI as calibrant. Gas chromatographic analyses were performed on a Varian 3300 instrument equipped with a 12-m BP-10 fused silica capillary column (0.22 ID). Elemental analyses were performed by MikroKemi AB, Uppsala, Sweden.

Except for the workup of reaction mixtures, all Heck reactions were carried out under argon. Stock solutions of catalyst were used due to low concentrations. These were freshly prepared under anaerobic conditions for each reaction and used only once. The solvents, aryl halides and bases were distilled when possible and used immediately. The olefin substrates were carefully deoxygenated by at least three freeze-pump-thaw cycles.

General Procedure for the Heck Reactions: The solvent (10 mL), aryl halide, base, olefin, 2-methylnaphthalene (internal standard) and a magnet were placed in a Schlenk tube with a screw cap. Three freeze-pump-thaw cycles were performed before the addition of an appropriate volume of the catalyst stock solution. The Schlenk tube was sealed and placed in a pre-heated, temperature-controlled oil-bath. The mixture was stirred vigorously for the desired time. Workup was achieved by pouring the cooled reaction mixture into an excess of 5% HCl (aq) and extracting with CH_2Cl_2 or Et_2O. The combined organic phases were neutralised with 10% $NaHCO_3$ (aq) and dried with $MgSO_4$. After removal of the solvent the products were analysed by ^1H NMR spectroscopy and MS; the yields were determined by GC. All of the products are known compounds.[23]

Preparation of *cis*-1,3-Bis(hydroxymethyl)cyclohexane (2): Over a period of 1.5 h, BH_3 (100 mL, 2.2 equiv. as a 1.0 M THF solution) was slowly added to an ice-cooled, stirred solution of **1** (7.75 g, 45.0 mmol) in 20 mL of THF. After the addition was completed the suspension was stirred at room temperature for an additional 2 h, and the excess hydride was thereafter carefully decomposed by the addition of 20 mL of 2 M HCl (aq). The water phase was neutralised with NaOH and about 8−10 g of K_2CO_3 was added in order to transfer the water-soluble diol to the organic phase. The organic phase was isolated and the water phase was further extracted with 2 × 10 mL of $CHCl_3$; the combined organic phases were then dried over silica. Filtration and removal of the organic solvent resulted in a highly viscous, colourless oil which solidified upon standing. Yield: 5.71 g (88%). – ^1H NMR (D_2O): δ = 0.45 (q, $^2J_{HH}$, $^3J_{HH}$ = 12.0 Hz, 1 H, CH_eH_a), 0.71 (m, 2 H, CH_2), 1.15 (m, 1 H, CH_eH_a), 1.39 (m, 2 H, CH), 1.62 (m, 4 H, CH_2), 3.41 (d, $^3J_{HH}$ = 6.3 Hz, 4 H, CH_2OH). – $^{13}C\{^1H\}$ NMR (D_2O): δ = 25.1

(s, $CH_2CH_2CH_2$), 29.3 (s, $CHCH_2CH_2$), 32.3 (s, $CHCH_2CH$), 39.4 [s, $(CH)_2CHCH_2$], 67.9 (s, CH_2OH). − MS (FAB^+): *m*/*z* = 142 [$C_8H_{14}O_2^+$]. − $C_8H_{16}O_2$ (144.21): calcd. C 66.6, H 11.2; found C 66.5, H 11.4.

Preparation of *cis*-1,3-Bis[(trifluoromethylsulfonyloxy)methyl]cyclohexane (3): A stirred suspension of **2** (1.00 g, 6.93 mmol) and pyridine (1.15 mL, 14.2 mmol) in 15 mL of CH_2Cl_2 was cooled in an ice-bath. Dropwise addition of trifluoromethanesulfonic anhydride (2.40 mL, 14.2 mmol), diluted with 10 mL of CH_2Cl_2, resulted in a yellow-tinted solution. After 30 min., the ice-bath was removed and the solution was allowed to age for an additional hour. The suspension was then filtered through a short plug of silica on a G3 glass frit and the plug was rinsed with additional CH_2Cl_2. Removal of the organic solvent on a rotary evaporator resulted in a colourless oil. The compound is too unstable for microanalysis. Yield 2.29 g (82%). − ^{1}H NMR: δ = 0.89 (q, $^2J_{HH}$, $^3J_{HH}$ = 12.0 Hz, 1 H, CH_eH_a), 1.03 (m, 2 H, CH_2), 1.37 (m, 1 H, CH_eH_a), 1.97−1.83 (m region, 6 H, CH and CH_2), 4.36 (d, $^3J_{HH}$ = 6.0 Hz, 4 H, CH_2OTf). − ^{13}C{^{1}H} NMR: δ = 24.6 (s, $CH_2CH_2CH_2$), 28.4 (s, $CHCH_2CH_2$), 31.1 (s, $CHCH_2CH$), 37.2 [s, $(CH)_2CHCH_2$], 81.2 (s, CH_2OTf), 119.0 (q, $^1J_{FC}$ = 320 Hz, CF_3). − ^{19}F NMR: δ = 51.5 (s, CF_3).

Preparation of *cis*-1,3-Bis[(diphenylphosphanyl)methyl]cyclohexane (4): A solution of **3** (2.33 g, 5.71 mmol) in 15 mL of THF was carefully added to a cooled (−60 °C) and stirred deep-red solution of $LiPPh_2$ (2.14 g, 11.4 mmol) in 15 mL of THF. The solution was allowed to reach room temperature over a period of 1 h, and stirred for an additional 18 h. The orange solution was then quenched with 5 mL of degassed water and the colourless organic phase was isolated. The water phase was further extracted with 2 × 10 mL of Et_2O and the combined organic phases were dried over silica. Filtration and removal of the solvent resulted in a viscous, almost colourless oil which partly solidified upon standing. NMR spectroscopic analysis showed the product to be essentially pure. The air-sensitivity precluded further purification and the phosphane was therefore not subjected to microanalysis. Yield: 2.52 g (92%). − ^{1}H NMR: δ = 1.41−0.84 (m region, 6 H, CH_2), 1.72 (m, 1 H, CH_2), 1.93 (m, 2 H, CH), 2.02 (d, $^3J_{HH}$ = 6.9 Hz, 4 H, CH_2P), 2.24 (m, 1 H, CH_2), 7.33 (m, 12 H, Ar), 7.43 (m, 8 H, Ar). − ^{13}C{^{1}H} NMR: δ = 26.0 (s, $CH_2CH_2CH_2$), 34.5 (d, $^3J_{PC}$ = 9.7 Hz, $CHCH_2CH_2$), 35.3 [d, $^2J_{PC}$ = 13.6 Hz, $(CH)_2CHCH_2$], 36.7 (d, $^1J_{PC}$ = 13.1 Hz, CH_2P), 43.5 (t, $^3J_{PC}$ = 9.6 Hz, $CHCH_2CH$), 128.3 (br. s, CH), 132.8 (m, CH), 133.9 (m, CH), 134.1 (m, CH), 139.4 (m, CH). − ^{31}P{^{1}H} NMR: δ = −21.3 (s).

Preparation of *cis*-1,3-Bis[(diphenylphosphane sulfide)methyl]cyclohexane (5). Sulfur (1.76 g, 6.86 mmol) was added to a solution of **4** (827 mg, 1.72 mmol) in 15 mL of toluene and the mixture was stirred for 16 h. The solution was decanted and removal of the toluene resulted in a pale yellow solid. The crude compound was loaded on a column of silica of 10 cm height. Eluting with *n*-hexane removed the remaining elementary sulfur and the white solid **5** was recovered by washing the column with CH_2Cl_2 and removing the solvent under vacuum. Yield: 759 mg (81%). − ^{1}H NMR: δ = 0.74 (m, 2 H, CH_2), 0.87 (q, $^2J_{HH}$, $^3J_{HH}$ = 11.6 Hz, 1 H, CH_eH_a), 1.12 (m, 1 H, CH_eH_a), 2.01−1.42 (m region, 6 H, CH and CH_2), 2.32 (m, 4 H, CH_2P), 7.43 (m, 12 H, Ar), 7.82 (m, 8 H, Ar). − ^{13}C{^{1}H} NMR: δ = 25.6 (s, $CH_2CH_2CH_2$), 33.0 (br. s, $CHCH_2CH_2$), 34.0 [d, $^2J_{PC}$ = 6.9 Hz, $(CH)_2CHCH_2$], 39.2 (d, $^1J_{PC}$ = 55.1 Hz, CH_2P), 43.5 (t, $^3J_{PC}$ = 10.2 Hz, $CHCH_2CH$), 128.5 (m, CH), 130.9 (m, CH), 131.3 (br. s, CH), 133.2 (d, J_{PC} = 28.2 Hz, CH), 134.2 (d, J_{PC} = 28.9 Hz, CH). − ^{31}P{^{1}H} NMR: δ = 37.1 (s). − MS (FAB^+): *m*/*z* = 544 [$C_{32}H_{34}P_2S_2^+$]. − $C_{32}H_{34}P_2S_2$ (544.69): calcd. C 70.6, H 6.3, S 11.8; found C 70.4, H 6.1, S 11.6.

Reaction of 4 with $[Pd(CO_2CF_3)_2]$. Formation of $[Pd(4)(CO_2CF_3)_2]$ (6): Phosphane **4** (25.1 mg, 52.2 μmol) and $[Pd(CO_2CF_3)_2]$ (17.4 mg, 52.2 μmol) were dissolved in 3 mL of THF. After stirring for 3 h, 12 mL of Et_2O was layered on top of the red THF solution. After 3 days yellow air-stable crystals were harvested. Yield: 20.5 mg (48%). − ^{1}H NMR (CD_2Cl_2): δ = 1.89−1.54 (m region, 7 H, CH_2), 2.25 (m, 4 H, CH_2P), 2.81 (m, 2 H, CH), 4.46 (br. d, $^2J_{HH}$ = 15.3 Hz, 1 H, CH_eH_a), 7.39 (m, 16 H, Ar), 7.82 (m, 4 H, Ar). − ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 28.3 (s, $CH_2CH_2CH_2$), 28.6 (t, $^3J_{PC}$ = 6.6 Hz, $CHCH_2CH$), 33.5−33.0 (m region, CH and CH_2), 116.4 (q, $^1J_{FC}$ = 291 Hz, CF_3), 129.0 (vt, J_{PC} = 11.1 Hz, CH), 129.7 (vt, J_{PC} = 11.1 Hz, CH), 131.9 (s, CH), 132.5 (s, CH), 132.9 (vt, J_{PC} = 10.0 Hz, CH), 133.8 (vt, J_{PC} = 11.1 Hz, CH), 160.8 (q, $^2J_{FC}$ = 36.2 Hz, C=O). − ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 16.5 (s). − ^{19}F NMR (CD_2Cl_2): δ = 52.8 (s). − MS (FAB^+): *m*/*z* = 812 [$C_{36}H_{34}F_6O_4P_2Pd^+$] (correct isotope pattern). − $C_{36}H_{34}F_6O_4P_2Pd$ (813.00): calcd. C 53.2, H 4.2; found C 53.2, H 4.2.

X-ray Crystal Structure Determination of Complex 6:[24] Crystal data and details of the data collection and refinement are given in Table 2. The intensity data were collected at 293 K with a Bruker Smart CCD system using ω scans and a rotating anode with Mo-K_α radiation (λ = 0.710 73 Å).[25] The intensities were corrected for Lorentz, polarisation and absorption effects with SADABS.[26]

Table 2. Crystallographic data

	Complex **6**

(Δ/σ) max	0.002
ρ max/min (e$^-$/Å^3)	1.482/−0.958

[a] $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$. − [b] $wR = [\Sigma w(|F_o| - |F_c|)^2/\Sigma|F_o|^2]^{1/2}$. − [c] $S = [\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$.

The first 50 frames were collected again at the end to check for decay. No decay was observed. All reflections were merged and integrated with SAINT.[27] The structure was solved by direct methods and refined by a full-matrix least-squares calculation on F^2.[28] Non-H atoms were refined with anisotropic displacement parameters. The hydrogen atoms were constrained to their parent sites using a riding model.

Acknowledgments

We thank Mr David Dominguez-Guiteéres for helpful assistance in the laboratory. Financial support by the TFR (The Swedish Research Council for Engineering Sciences) and the NFR (The Swedish Natural Science Research Council) is gratefully acknowledged.

Characterization and Reactivity of Triperoxo Vanadium Complexes In Protic Solvents

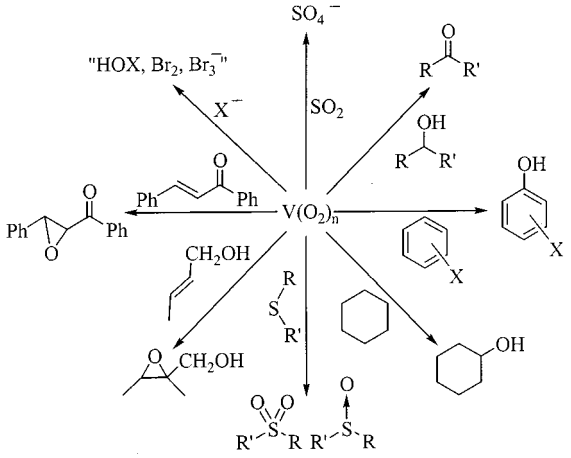
Marcella Bonchio,[a] Olga Bortolini,*[b] Valeria Conte,*[c] and Stefano Moro[d]

Keywords: Mass spectrometry / Ab initio calculations / Peroxo complexes / Vanadates

ESI-MS and ^{51}V NMR techniques have been used to detect the formation of vanadium triperoxo complexes in protic solvents. RHF/6-311++G(d,p) ab initio calculations were also carried out to address the structure and the energy requirements of vanadium peroxo species formed from vanadates and hydrogen peroxide. Such studies point to a step-by-step decomposition process involving the triperoxo vanadium complex, as highlighted by ESI-MS^n experiments. The reactivity of the triperoxo compound has been examined in an alcohol/water mixture with the aim of elucidating its oxidative behavior; evidence for the formation of the HOO^- anion as an active oxidant in solution has been obtained.

Introduction

The relevance of peroxo transition metal compounds either in oxidation chemistry[1,2] or in biochemical systems[3,4] is well established. Vanadium peroxides, in particular, are effective oxidants, as demonstrated by their reactions with different inorganic and organic substrates, viz. halides, sulfur dioxide, thioethers, alkenes, alcohols and aromatic or aliphatic hydrocarbons (Scheme 1).[5,6]



Scheme 1. Reactivity of vanadium peroxides with inorganic and organic substrates

These processes, whether stoichiometric or catalytic, where the oxidant can be hydrogen peroxide or an alkyl hydroperoxide, are usually carried out under very mild conditions with good selectivities and chemical yields.

The oxidation of halides with peroxo vanadates is the rate-determining step in the peroxidative halogenation of organic substrates [Equation (1)]:[7]

$$X^- + H_2O_2 + RH + H^+ \xrightarrow{\text{V(V)-peroxides}} RX + 2H_2O \quad (1)$$

Such a process is actually a chemical model of the activity of vanadium-dependent haloperoxidases enzymes.[8,9] Recent studies have shown that in the natural haloperoxidase systems the active peroxidic intermediate for the oxidation of bromide ion is a monoperoxo vanadate stabilized by a histidine residue contained in the active site pocket.[8,9] Conversely, mimicking systems reported in the literature are usually based either on monoperoxo vanadium [10] or on divanadium triperoxo species.[11]

Monoperoxo vanadium compounds are also catalysts for the aerobic oxidation of alcohols to carbonyl compounds [Equation (2)]:

$$R_2CHOH + O_2 \xrightarrow{\text{catalyst}} R_2C{=}O + H_2O_2 \quad (2)$$

In particular, it has been observed[12] that an accumulation of hydrogen peroxide takes place during the course of the oxidation of *i*PrOH with $n Bu_4NVO_3$ in the presence of $HClO_4$ and excesses of H_2O_2 and H_2O, carried out at 40 °C under a pressure of one atmosphere of oxygen. Interestingly, the kinetic profile of this process is characterized by the presence of a periodic pattern, where the concentration of H_2O_2 oscillates as the result of a balance between subsequent production and decomposition phases. Under certain experimental conditions the efficiency of the process, defined as $([H_2O_2]t_{max} - [H_2O_2]_0)/[cat]_0$ where t_{max} is the reaction time for detection of the first maximum in the H_2O_2 concentration kinetic profile, reaches values higher than 4000.[13] Such a reaction compares well with the re-

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, 2001 1434−1948/01/1111−2913 $ 17.50+.50/0

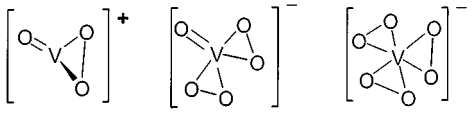
cently reported Pd^{II}-catalyzed process,[14,15] one of the most effective and environmentally friendly methods for the production of hydrogen peroxide.

It should be noted that most of the reactivity data cited above refer to mono- and diperoxo-vanadates. These species are easily formed in neutral or acid solutions upon addition of hydrogen peroxide to V^V precursors according to the equilibria in Equations (3) and (4):[16]

$$VO_2^+ + H_2O_2 \overset{K_1}{\rightleftharpoons} VO(OO)^+ + H_2O \quad (3)$$

$$VO(OO)^+ + H_2O_2 \overset{K_2}{\rightleftharpoons} VO(OO)_2 + 2\,H^+ \quad (4)$$

Nevertheless, together with mono- and diperoxo complexes, other peroxo vanadates may be formed depending upon the pH, and relative concentrations of vanadate and H_2O_2. The nature of the different complexes formed has been studied by ^{17}O and ^{51}V NMR,[17−22] Raman,[23] UV/Vis[24] spectroscopy and, more recently, by electrospray ionization mass spectrometry (ESI-MS).[25−27] The most important monomeric peroxo species are collected in Scheme 2. For the sake of simplicity throughout the paper the peroxo vanadium derivatives will be reported without the solvent molecules bound to the metal center in the first coordination sphere.



1 2 3

Scheme 2. Monomeric peroxo vanadium species with ligands or solvent molecules in the coordination sphere omitted for clarity

The spectroscopic studies cited above provided several details concerning the true structure in solution of the vanadium peroxides,[21,25] even though the actual coordination number for all of them is still uncertain. Further information on the structure of vanadium peroxo derivatives has also been obtained from theoretical calculations. As already reported, considering the coordination ability of the vanadium(V) metal center, the maximum stabilization energy for the naked monoperoxo derivative has been calculated (from both HF and DFT calculations) with three molecules of solvent (H_2O) coordinated to the metal center.[28] Moreover, particular attention has been paid to the identification of the protonation sites for complexes **1** and **2** of Scheme 2. As an example, results obtained for the diperoxo species from RHF/3-21G(*) and B3LYP/LANL2DZ DFT calculations, have indicated that between the two most favorite protonation sites, i.e. the oxo oxygen and one of the peroxidic oxygens, protonation at the latter position is by far the most favored.[29]

It should be noted that very little information, from both experimental and theoretical[30] points of view, is available on species with more than two peroxo ligands.

It has already been mentioned that mono- and diperoxo complexes are well-known as electrophilic oxygen-transfer reagents or as radical oxidants.[5,6] However, the few papers[31,32] present in the literature reporting the reactivity of triperoxo vanadates claim that these species behave as nucleophilic oxidants. In particular, the triperoxo vanadium complexes $M[V(O_2)_3]\cdot 3H_2O$ (M = Na or K) are proposed[32,33] to be efficient oxidants of α,β-unsaturated ketones to the corresponding epoxide, benzonitrile to benzamide and benzil to benzoic acid, reactions which are usually carried out with alkaline hydrogen peroxide.

In the course of our studies on the mechanism[12,13] of the aerobic vanadium-catalyzed oxidation of *i*PrOH cited above [see Equation (2)], we were faced with the possible occurrence in solution of triperoxo vanadium derivatives caused by the high concentration of hydrogen peroxide that accumulates during the reaction. Hence, we decided to analyze alcoholic solutions of vanadates in the presence of high excesses of hydrogen peroxide in more detail in order to ascertain the presence of triperoxo species, and possibly to characterize them. We have also performed reactivity studies in the same media with preformed triperoxo vanadates with the aim of elucidating their oxidative behavior. The results obtained are presented and discussed below.

Results and Discussion

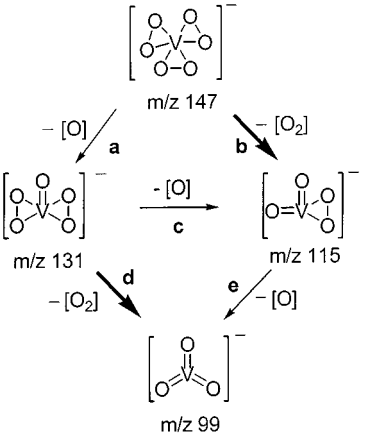
Characterization

Vanadium derivatives undergo fast and favorable addition reactions with hydrogen peroxide producing peroxo complexes whose nature depends on the concentration of the reagents and on the pH. The negative-ion mode ESI mass spectra of $n Bu_4NVO_3$ (5×10^{-4} molL^{-1}) solutions in *i*PrOH containing 0.5 molL^{-1} H_2O and increasing amounts of H_2O_2 from 0.025 up to 0.35 molL^{-1}, are characterized and increasing amounts of H_2O_2 from 0.025 up to 0.35 mol·L^{-1}, are characterized by the presence of two major ions at m/z = 131 and 147. Less intense, but equally important, ionic species are found at m/z = 99, 115, 133, 149 and 165. For relatively low excesses of H_2O_2 over V^V (50−150 equivalents) the m/z = 131 ion, corresponding to the oxo diperoxo derivative,[26] is dominant, however it is progressively overtaken by the species centered at m/z = 147 as the hydrogen peroxide concentration is increased. By analogy with previous studies carried out using either ethanol or *i*PrOH as mobile phases, the system under investigation was studied in both solvents and no significant dependence on the alcohol used was observed.

The different species were identified on the basis of labeling experiments and MS^n spectra[25−27] and are summar-

ized in the inset of Figure 1. Among them, the species at m/z = 147, identified as the vanadium triperoxo derivative $[V(O_2)_3]^-$, and that at m/z = 115, assigned to the unprecedented dioxo monoperoxo compound $[O_2V(O_2)]^-$, are of particular interest. Labeling experiments were used to confirm this assignment. As expected, the replacement of water with $H_2{}^{17}O$ (ca. 50% isotope content) has no effect on the triperoxo anion, whereas formation of new peaks at m/z = 116 and 117 is observed next to the species at m/z = 115. In agreement with literature data,[5] this evidence indicates a fast exchange of the two oxo oxygens.

When the triperoxo derivative is mass selected within the ion-trap analyzer and allowed to decompose by increasingly higher tickling voltages, the CID decompositions observed are the fragmentations of one and two of the three peroxidic bridges, thus affording the oxo diperoxo derivative $[OV(O_2)_2]^-$ (m/z = 131, path **a**), and the dioxo monoperoxo



Scheme 3. Decomposition patterns of mono-, di- and triperoxo derivatives as obtained by MS^n experiments; wate-r or alcohol-containing adducts of ions at m/z = 131, 115 and 99 are not shown

derivative $[O_2V(O_2)]^-$ (m/z = 115, path **b**) of Scheme 3, including its water- and alcohol-containing homologues

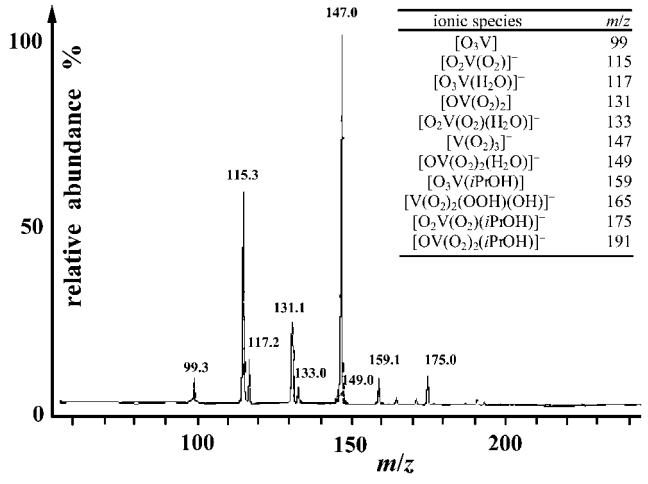


Figure 1. Negative-ion mode ESI-MS full scan spectrum of solutions of 5×10^{-4} mol·L^{-1} nBu$_4$NVO$_3$ in iPrOH-0.5 mol·L^{-1} H_2O and H_2O_2 (0.25 mol·L^{-1}); the identification of the different ions is reported in the inset

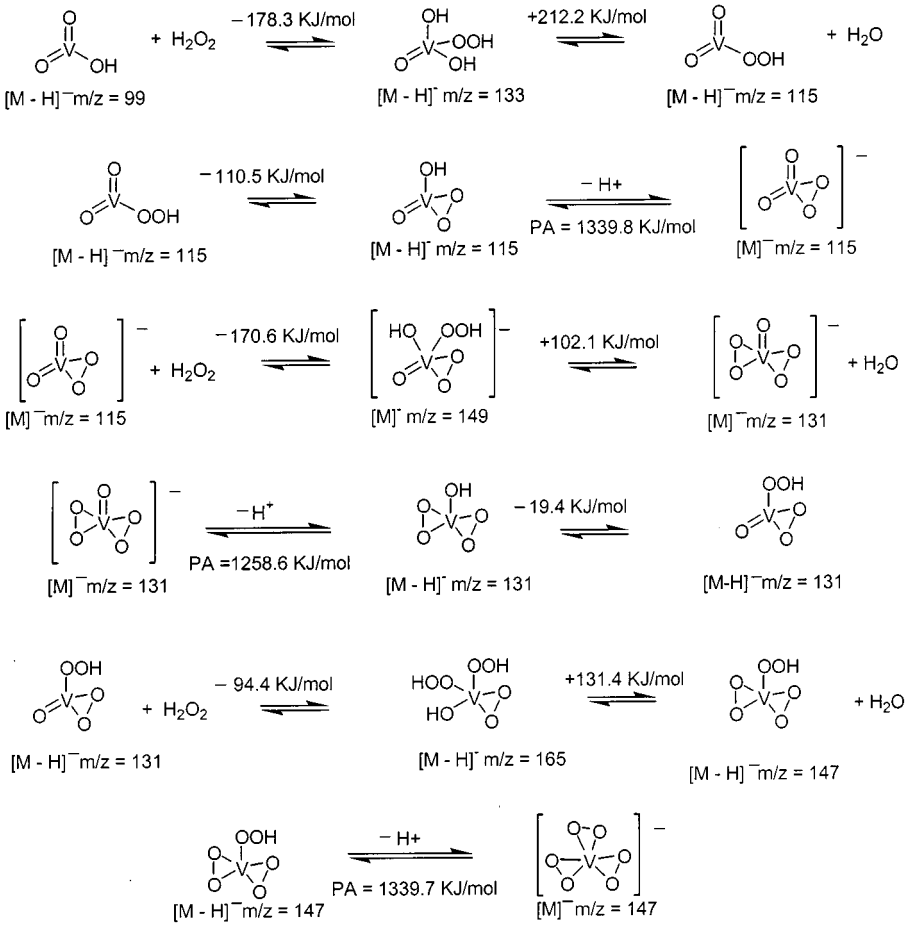
$[O_2V(O_2)(ROH)]^-$ (R=H, Et, iPr). The decomposition implicating two peroxo moieties is the most favorable pattern. This fragmentation is also the major decomposition observed with the oxo diperoxo derivative $[OV(O_2)_2]^-$, path **d** of Scheme 3.

The direct decomposition of both peroxidic bridges, formally corresponding to the expulsion of an O_2 molecule (pathways **b** and **d** of Scheme 3) probably occurs by a two-step mechanism consisting of two subsequent oxygen atom losses; this has been confirmed by experiments at increasing tickling energies.

Ab initio calculations have been carried out in order to address the structure and the energy requirements for the various intermediates detected by MS^n experiments and outlined in Scheme 3. Calculations have been carried out at the RHF/6-311++G(d,p) level of theory,[34–39] and the fully optimized species are collected in Scheme 4. The formation of all the peroxidic species results from a sequence of addition of H_2O_2, release of H_2O and proton transfer equilibria. In particular, proton-transfer processes are thermodynamically connected with the corresponding proton affinity (PA) of vanadium peroxo species, defined as the standard heat of ion dissociation to form a proton and the conjugate base in the gas phase (see Scheme 4).

The theoretical calculations showed that the addition of one molecule of hydrogen peroxide to vanadate, to form the hydroxo-monoperoxo derivative, is a favorable process with an energy balance of −76.6 kJ/mol. Similarly, the coordination of hydrogen peroxide to such a monoperoxidic adduct to produce the oxo-diperoxo species is an exothermic process by −68.5 kJ/mol. Such theoretical evidence agrees well with the experimental studies carried out on the complexation of vanadate by hydrogen peroxide, where an almost quantitative formation of mono and diperoxo vanadium complexes is observed under a range of conditions.[5]

Interestingly, the further reaction of protonated diperoxo vanadates with hydrogen peroxide yielding the triperoxo complex is clearly endothermic (see Scheme 4). In fact, the protonated triperoxo species lies 33.5 kJ/mol higher in energy than the diperoxo precursor. The capped trigonal prismatic geometry expected for the triperoxo complex[30,33] does not retain the V=O bond originally present in all mono and diperoxo vanadium complexes, and this probably destabilizes the triperoxo structure. However, the hydroperoxy-diperoxo vanadium complex can be formed in solution by protonation of the triperoxo derivative, and it could also represent one of the predominant structures of the triperoxo vanadate in alkaline solution. Moreover, the structure of this hydroperoxy-diperoxo vanadium complex may explain the peculiar oxidative behavior of vanadium species formed in highly basic solutions in the presence of large excesses of hydrogen peroxide (seebelow). The optimized structures of both protonated and unprotonated triperoxo vanadium complexes are shown in Figure 2. It should be noted that all the minimized species shown in Scheme 4 have been observed experimentally, as anions or as $[M - H]^-$ if neutrals, in the full scan ESI mass spectrum of Figure 1.



Scheme 4. Calculated relative energies (kJ/mol) for the formation of peroxo species from hydrogen peroxide and vanadate derived by RHF/6-311++G(d,p) ab initio calculations; calculated proton affinities (PA) for vanadium peroxo species, defined as the standard heat of ion dissociation to a proton and the conjugate base in the gas phase, are also included; all the species reported here have been observed experimentally, either as anions or as $[M - H]^-$ if neutrals, in the full scan ESI mass spectrum of Figure 1

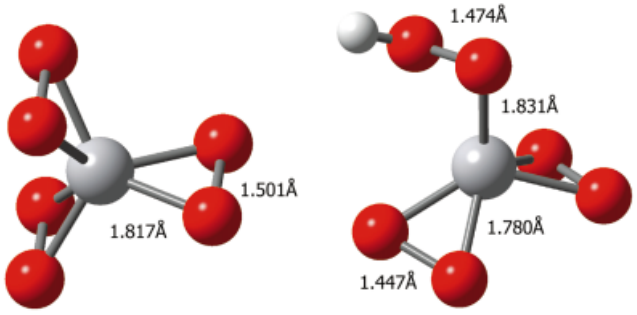


Figure 2. Structures of $[V(O_2)_3]^-$ (*left*) and of $[V(O_2)_2OOH]$ (*right*) optimized at the RHF/6-311++G(d,p) level; atomic distances are reported in Å

As pointed out in previous paragraphs, ESI-MS experiments were conducted to investigate the possible direct relationship occurring between diperoxo and triperoxo species as a function of hydrogen peroxide excess. The full-scan mass spectra of the system under investigation, recorded at different initial concentration of hydrogen peroxide, (5×10^{-4} molL^{-1} nBu$_4$NVO$_3$ in iPrOH containing 0.5 molL^{-1} H_2O, $[H_2O_2]$ from 0.025 up to 0.35 mol·L^{-1}, apparent pH ca. 7), showed that, as the concentration of H_2O_2 is increased, the vanadium diperoxo derivatives are progressively replaced by the triperoxo species. In addition, the ratio of the relative abundances of the diperoxo compounds (and related fragments) with the relative abundances of the triperoxo compounds (and related fragments) correlates linearly with the hydrogen peroxide concentration. Such a linear behavior suggests a direct equilibrium between the two peroxo species, even though a quantitative measure of the related K_{eq} is hampered by the non-equilibrium, low-pressure and solvent free conditions that pertain to ion traps.

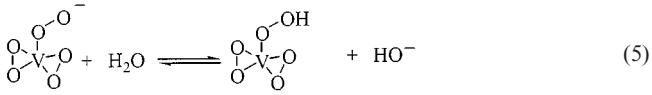
Tracey et al.[40] have reported a thermodynamic measure of a pH dependent K_{eq} (9.4 L·mol^{-1}) in water measured in ^{51}V NMR experiments (1.0 mol·L^{-1} KCl, 2×10^{-2} mol·L^{-1} HEPES buffer, pH 6.7), referring to the equilibrium $Vl_2 + l \rightleftarrows Vl_3$ (l = peroxide). We have tried to determine the equilibrium constant for the formation of triperoxo derivatives in experimental conditions as close as possible to those employed for ESI experiments by recording ^{51}V NMR spectra in mixed solvents (alcohol/water) in the absence of buffers and without controlling the ionic strength. Under our experimental conditions, in contrast to Tracey's results, the presence of an alcohol-containing diperoxo derivative (signal at $\delta = -642$, $W_{1/2} = 240$ Hz) is

detected irrespective of the excesses of hydrogen peroxide. Furthermore, upon increasing the water content in the solvent a second signal ($\delta = -663$, $W_{1/2} = 260$ Hz) appears, probably due to a water-containing diperoxo complex. The occurrence of a slow equilibrium between these species was confirmed previously by the coalescence of these two signals at 348 K.[12] It should be noted that the high ionic strength of the solutions (buffers and/or KCl as used in Tracey's experiments) is compelling for the formation of triperoxo vanadium complexes.[41]

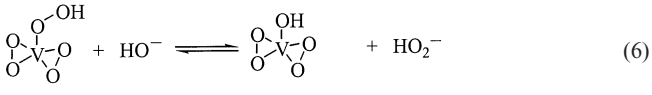
The observation, during ESI-MS experiments in almost neutral solutions, of the triperoxo derivative as the major ionic species in the presence of large excesses of hydrogen peroxide may be explained by the particular conditions that pertain to the electrospray ionization technique. The electrospray process of aqueous or mixed alcohol-water solutions of various analytes has been reported to produce a marked pH change in the nebulized droplets with respect to the bulk.[42,43] In particular, droplets formed under the ESI negative-ion mode may undergo a considerable pH increase, favoring the formation of the triperoxo derivative, which is stable under fairly basic conditions, as discussed below.

Reactivity

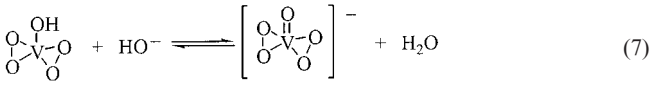
The blue-violet complex $Na[V(O_2)_3]$ has been synthesized by using a slightly modified literature procedure[31−33] (see Experimental section for details). $Na[V(O_2)_3]\cdot 3H_2O$ is not stable in aqueous solution at millimolar concentrations. Accordingly, a fast change of color from blue-violet (triperoxo vanadate) to yellow (diperoxo vanadate) is observed while preparing the solutions. The yellow solution thus obtained has a pH of about 11 due to the hydrolysis of the triperoxo derivative.[31−33] Such equilibria may be indicated schematically as in Equation (5)−(7), where the triperoxo species is reported with one end-on peroxy anion in order to unravel the hydrolysis equilibria. Indeed, the structural data available[7] indicate that such a species contains three side-on peroxo moieties. Similarly, the theoretical calculations reported above indicate that the triperoxo complex has a capped trigonal prismatic geometry with three side-on peroxo moieties.



(5)



(6)



(7)

The formation of the yellow diperoxo complex from the blue triperoxo derivative has been further confirmed by ^{51}V NMR spectroscopy.[17−22] When $Na[V(O_2)_3]\cdot 3H_2O$ (1×10^{-3} mol·L^{-1}) is dissolved in aqueous solution (giving a solution of pH 11), the triperoxo complex quickly decomposes to form the diperoxo vanadium derivative identified by a signal at $\delta = -764$. On the other hand, when strongly basic water (pH 14) is used to dissolve the same amount of $Na[V(O_2)_3]\cdot 3H_2O$, the decomposition reaction described above is slowed down, although not blocked. In fact, in the ^{51}V NMR spectrum a peak is observed at $\delta = -847$ due to the triperoxo derivative together with the signal at $\delta = -764$.

The scarce data present in the literature[31,32] regarding the reactivity of triperoxo vanadium complexes indicate that they react as nucleophilic oxidants. Correspondingly, the oxidation of benzonitrile to benzamide by $Na[V(O_2)_3]\cdot 3H_2O$ and Baeyer−Villiger-type oxidations of benzil to benzoic acid, as well as the epoxidation of (*E*)-chalcone, have been reported. These authors also reported that the reduction product of the triperoxo derivative is the anionic diperoxo vanadate $[OV(O_2)_2(H_2O)]^-$.[32]

In the present work the behavior of the complex $Na[V(O_2)_3]\cdot 3H_2O$ toward cyclobutanone was studied. The triperoxo complex is almost insoluble in most organic solvents therefore its oxidative ability toward the selected substrate was examined in mixed alcohol/water solvents, even though the oxidant was still not completely dissolved at the desired concentration in this medium (see below).

When 0.45 mmol of $Na[V(O_2)_3]\cdot 3H_2O$ was allowed to react with 0.3 mmol of cyclobutanone in 2.5 mL of *i*PrOH/H_2O (2:1, heterogeneous conditions) at room temperature, complete consumption of the substrate and the formation of 4-hydroxy butyric acid as the main product were observed in about four days. It has also been confirmed that the initially formed γ-butyrolactone is not stable in the basic reaction conditions. By a careful GC check of the reaction mixture, it was observed that oxidation of *i*PrOH to acetone occurs as well as oxidation of the cyclobutanone. Thus, in order to simplify the system under analysis the solvent was changed to a mixture of CH_3OH/H_2O (1:2), where a similar oxidation of cyclobutanone to 4-hydroxy butyric acid takes place.

It is well-known that Baeyer−Villiger-type oxidations are carried out by the hydroperoxy anion.[44] It is conceivable that in the hydrolytic equilibria of Equation (5)−(7), the triperoxo vanadium species may act as a source of HOO^-. Therefore a more detailed analysis of the oxidation of cyclobutanone with $Na[V(O_2)_3]\cdot 3H_2O$ was required in order to elucidate the nature of the active nucleophilic oxidant.

Figure 3 shows the disappearance of cyclobutanone (0.12 mol·L^{-1}) as a function of time, observed under different experimental conditions. A very fast reaction (•) is observed when the substrate is reacted with basic H_2O_2 [CH_3OH/H_2O (1:2), pH 11]. On the other hand, slower processes have been observed with the triperoxo complex in CH_3OH/H_2O (1:2) (○) or in CH_3OH/H_2O (1:2; pH 11) (▲).

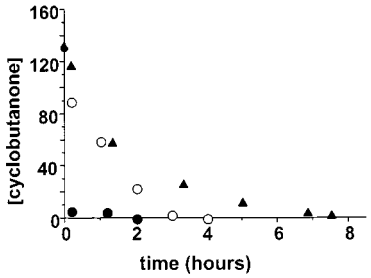


Figure 3. Behavior of cyclobutanone concentration as a function of time: (•) reaction with basic H_2O_2 in CH_3OH/H_2O (1:2), pH 11, room temp.; (○) reaction with $Na[V(O_2)_3]\cdot 3H_2O$ in CH_3OH/H_2O (1:2), room temp.; (▲) reaction with $Na[V(O_2)_3]\cdot 3H_2O$ in CH_3OH/H_2O (1:2), pH 11 (NaOH) room temp.

The behaviors detected can be explained by taking into consideration that, in all cases, the real oxidant is the hydroperoxy anion. Indeed, when the oxidant is $[V(O_2)_3]^-$, HOO^- is slowly released in solution upon hydrolysis of the vanadium triperoxide. This process [see Equation (5)−(7)] is in fact inhibited in the presence of added base. Accordingly the reaction performed at pH 11 (▲) is the slowest.

In order to verify this hypothesis further, two reactions with $Na[V(O_2)_3]\cdot 3H_2O$ in basic water (pH 14) were performed in the presence and in the absence of cyclobutanone. These processes were monitored by UV/Vis spectroscopy by measuring the decrease of the absorbance of the triperoxo vanadium complex at 561 nm. Interestingly, an identical kinetic behavior is observed both in the presence and in the absence of cyclobutanone, which is clear evidence that the substrate is not involved in the rate-determining step of the oxidation. Furthermore, taking into account that $[V(O_2)_3]^-$ decomposes to form $[OV(O_2)_2]^-$, and that the acid-base equilibria reported in Equation (5) and (7) are fast, it is likely that the ligand exchange process HO^-/HOO^- [Equation (6)], where the hydroperoxy anion is released in solution, is the rate determining step in the oxidation of cyclobutanone.

At variance with literature data,[32] our reactivity studies provide conclusive evidence that the triperoxo anion is a mere precursor of the hydroperoxy anion, which is the active species in the Baeyer−Villiger-type oxidation here examined. Furthermore, this result fits in well with the accepted knowledge that nucleophilic reactivity for d^0 metal peroxides is rarely observed.[45]

Conclusion

In summary, the association of ESI-MS spectrometry with ^{51}V NMR spectroscopy and ab initio calculations has allowed the definition of the nature and the speciation of peroxidic vanadium compounds, and in particular, of the triperoxo vanadium derivative that is formed in highly basic protic solutions in the presence of large excesses of hydrogen peroxide. Furthermore, the oxidation of cyclobutanone to 4-hydroxy butyric acid carried out with the preformed triperoxo compound in alcohol/water mixtures clearly indicates that the triperoxo complex does not itself act as a nucleophilic oxidant, but only as a source of the HOO^- anion.

Experimental Section

The synthesis of $n Bu_4NVO_3$ has been reported previously.[27,46] $Na[V(O_2)_3]$ was synthesized by using a slightly modified literature procedure:[31,33] V_2O_5 (2.6 mmol) was suspended in 1 mL of water and stirred. A large excess of hydrogen peroxide (ca. 50 equivalents, 14.8 mL of 30% v/v solution) was then added slowly and the solution stirred at 0° C until it turned dark red. Subsequently, 11 equivalents of NaOH (1.144 g) were slowly added whilst stirring at 0 °C. The reaction mixture changed color from red to yellow and, finally, to blue-violet, thus indicating the formation of the triperoxo derivative. The reaction was left at 0 °C for 30 min. and the precipitation of the complex was obtained by addition of cold ethanol (10 mL). The product was collected by filtration, washed twice with cold ethanol, dried and characterized as $Na[V(O_2)_3]\cdot 3H_2O$ (86% yield). IR (KBr): ν_{O-O} 854 cm^{-1}, ν_{V-O_2} 617 and 565 cm^{-1}. − UV/Vis: λ'_{max} = 192 nm, λ''_{max} = 560 nm (ε = 230). The active oxygen content was determined quantitatively by cerimetric titration.

The ESI-MS measurements were obtained using an LCQ instrument (Thermoquest, San Jose, CA). The peroxovanadium solutions were prepared by dissolving $n Bu_4NVO_3$ (5×10^{-4} mol·L^{-1}) in *i*PrOH (or EtOH for the experiments conducted in this solvent) in the presence of increasing amounts of H_2O_2 from 0.025 up to 0.35 mol·L^{-1}. The concentration of water was adjusted to 0.5 mol L^{-1}. The apparent pH for these solutions is about 7. For labeling experiments, $H_2{}^{17}O$ with an isotope content of ca. 50% was used ($H_2{}^{18}O$ less than 4%). Solution flow rate: 8μL min^{-1}; capillary temperature: 80 °C; spray voltage: 2.2 kV; capillary voltage: −5 to −10 V; tube lenses offset: −55 V; nebulizing gas: N_2 (40 units flow rate). The parameters related to the octapoles and detector were achieved by the automatic set-up procedure. Collision-induced decompositions of selected ions were obtained by applying a supplementary r.f. voltage (tickle voltage) to the end-cap electrodes of the ion trap (resonance activation).

All calculations were carried out with Gaussian 98,[34] running on an SGI O2 R10000 workstation. Hartree−Fock calculations were run with the 6-311++G(d,p) basis set. The latter includes the Wachters−Hay all-electron basis set for vanadium,[34,35] and the standard triply split valence basis set for H and O.[36,37] Only singlet states were considered. Harmonic vibrational frequencies were obtained from RHF/6-311++G(d,p) calculations and used to characterize local energy minima (all frequency real). Atomic charges were calculated by fitting to electrostatic potential maps (CHELPG method).[38]

Oxidation Reactions: The desired amount of cyclobutanone was dissolved in the alcoholic solvent (*i*PrOH or CH_3OH, typically 0.3 mmol in 1.5 mL *i*PrOH or CH_3OH). Subsequently, the appropriate amount of an aqueous (natural pH or basic pH obtained with NaOH) solution of $Na[V(O_2)_3]\cdot 3H_2O$ (typically 0.45−0.6 mmol) was slowly added. The reaction mixture was stirred at room temperature. The consumption of the substrate was followed by quantitative GC analysis [external standard n-C14 on a Carbowax 20M 15% on Chromosorb WAW-DMCS (1.8 m × 2 mm) column, FID detector]. Identification of the products was accomplished by ^1H NMR spectroscopy of the solid material isolated from the reaction mixtures.

A Model for Trivalent Actinides in Media Containing High Carbonate Concentrations − Structural Characterization of the Lanthanide Tetracarbonate $[Co(NH_3)_6][Na(\mu\text{-}H_2O)(H_2O)_4]_2[Ho(CO_3)_4]\cdot 4H_2O$

Keywords: Actinides / Lanthanides / Carbonate / Coordination chemistry / Structural elucidation

The identity of the limiting Ho^{III} species in aqueous solutions with high carbonate concentrations has been determined to be $Ho(CO_3)_4^{5-}$. Single crystals of $[Co(NH_3)_6][Na(\mu\text{–}H_2O)(H_2O)_4]_2[Ho(CO_3)_4]\cdot 4H_2O$ were obtained by the addition of $[Co(NH_3)_6]^{3+}$ to an aqueous 0.04 M solution of Ho^{III} in 2.1 M Na_2CO_3. The asymmetric unit contains the anion, $[Ho(CO_3)_4]^{5-}$, a $[Co(NH_3)_6]^{3+}$ cation and two Na^+ cations, which are bound to H_2O molecules in an edge-sharing bioctahedral geometry. The $[Ho(CO_3)_4]^{5-}$ anion is eight coordinate with four bidentate carbonate ligands bound to the Ho atom. The molecule has essentially C_{2v} symmetry with two coplanar carbonates making a vane, which is perpendicular to a similar vane produced by the other two carbonate ligands. An alternative way to this view molecule is through the geometry of the C atoms, which are found in a distorted tetrahedron. The average Ho–O distance was determined to be 2.361(5) Å, while the average Ho–C distance was 2.784(6) Å. The IR and Raman spectra were determined in both the solid state and solution in order to confirm the solution speciation. The Raman data show a single CO_3^{2-} stretch for the solid at 1062 cm^{-1}. The solution data show multiple peaks with the most prominent being at 1048 cm^{-1}, which is consistent with the literature reports of an equilibrium mixture. The IR data for the solids confirm the X-ray results showing bidentate carbonate ligands by the splitting of the ν_3 band of the CO_3^{2-}. The crystal data for $[Co(NH_3)_6][Na(\mu\text{-}H_2O)(H_2O)_4]_2[Ho(CO_3)_4]\cdot 4H_2O$ are as follows: monoclinic space group $P2/n$, a = 8.7091(5) Å, b = 10.8744(6) Å, c = 15.7971(9) Å, β = 93.117(1)°, Z = 2, $R1$ = 0.0307, $wR2$ = 0.0756.

Introduction

Carbonate is commonly found in groundwater environments and has a high affinity for metal cations such as lanthanide and actinide ions; thermodynamic formation constants can often be as high as 10^{50}.[1,2] Unlike many metal ions, whose carbonate salts are relatively insoluble, carbonate complexation of the lanthanides and actinides can actually enhance solubility through the formation of highly charged anionic complexes. This enhancement of the solubility of the actinides in carbonic solutions is a serious concern for modeling the transport of these materials through the environment.[1−3] As an example, we note that there are conflicting reports on the nature of the limiting complex in trivalent lanthanide/actinide carbonate system. Recent spectroscopic studies of Cm^{III} in carbonate solution indicate that the tetra-carbonato complex $[Cm(CO_3)_4]^{5-}$ is the limiting species in the An^{III} carbonate system.[4] Other workers who have examined trivalent lanthanide systems have argued that the tris-carbonato complex $[Nd(CO_3)_3]^{3-}$ is the limiting species in the Ln^{III} carbonate system.[5] As a result, it is important to identify the structural models which could have spectroscopic tags for the environmentally relevant complexes formed in the equilibria.

Despite the reported synthesis of a number of materials, there are limited structural data for either the lanthanide or actinide metals with lower carbonate stoichiometries. The proposed lanthanide materials include: $Ln_2(CO_3)_3$, $Ln_2(CO_3)_3\cdot xH_2O$ (x = 2, 3, 8),[6−15] $M_6[Ce(CO_3)_5]\cdot xH_2O$ (M = Na, x = 12; M = $C(NH_2)_3$, x = 4),[16] $M_4[Ce(CO_3)_4]\cdot xH_2O$ (M = Na, x = 7; M = $C(NH_2)_3$, x = 6),[17] $M[Ln(CO_3)_2]$ (M = Li,[18] Na,[19,20] K,[21] Cs,[11] Tl[22]), and $M_5[Ln(CO_3)_4]$ (M = Na,[21] Tl[22]). Typically, the characterization of these materials involved X-ray powder diffraction, vibrational spectroscopy and thermogravimetric analysis. Recently, one of the first examples of a single crystal X-ray determination of a monomeric Ln^{III} tetra-carbonato complex, $[C(NH_2)_3]_5Nd(CO_3)_4(H_2O)$ was re-

ported.[23] We have also structurally characterized by single crystal X-ray techniques, $[Co(NH_3)_6][Sm(CO_3)_3(H_2O)]\cdot 4H_2O$[24] and $[Co(NH_3)_6]_6[K_2(H_2O)_{10}][Nd_2(CO_3)_8]_2\cdot 20H_2O$.[25] We sought to extend these studies by structurally characterizing additional carbonato anions, which could be found in the equilibrium systems described above. Studies were initiated with the lanthanides due to the ease of handling, the oxidation state stability and greater resistance to hydrolysis. Since the ionic radii of the lanthanides decrease across the series, we reasoned that the heavier lanthanides would be most likely to produce a mononuclear eight-coordinate tetracarbonate anion. We describe here our efforts in the synthesis and structural characterization of the limiting Ho^{III} tetracarbonate anion $[Ho(CO_3)_4]^{5-}$.

Results and Discussion

Synthesis and Electronic Spectra

The study of the holmium carbonate system is complicated by the precipitation of mineral phase carbonates of the form $Ho_2(CO_3)_3\cdot xH_2O$. The formation of this phase can be avoided by a judicious choice of metal carbonate, for example M_2CO_3 (M = Na, K, Cs, etc.), as well as controlling the total lanthanide and carbonate concentrations. The solutions were prepared by addition of $Ho(NO_3)_3\cdot xH_2O$ to 2.5 M Na_2CO_3, resulting in a yellow 0.1 M Ho^{III} solution. The Ho^{III} solution was analyzed by UV/Vis spectroscopy to identify any shift or change in intensity of the *f-f* transition compared to the Ho^{III} aquo ion. The electronic absorption spectrum was measured from 350 to 800 nm. The five most intense peaks were found at 360, 419, 450, 489, and 539 nm, with optical densities of 8.1, 2.9, 28, 1.9, and 3.5 $M^{-1}cm^{-1}$, respectively. It should be noted that the peaks at 360 and 450 nm are more intense than those of the aquo ion (ε = 1.3 and 3.1 $M^{-1}cm^{-1}$, respectively), indicating a possible lowering of the molecular symmetry.

Single Crystal X-ray Diffraction

Single crystals of $[Co(NH_3)_6][Na(\mu\text{-}H_2O)(H_2O)_4]_2[Ho(CO_3)_4]\cdot 4H_2O$ were obtained by addition of $[Co(NH_3)_6]Cl_3$ to a 0.04 M solution of Ho^{III} in 1.7 M Na_2CO_3, from which yellow orange crystals were obtained after two weeks of slow evaporation at room temperature. The data collection and crystallographic parameters are summarized in Table 1, and the selected bond lengths and angles are given in Table 2. A thermal ellipsoid drawing of $[Co(NH_3)_6][Na(\mu\text{-}H_2O)(H_2O)_4]_2[Ho(CO_3)_4]\cdot 4H_2O$ is shown in Figure 1, which also provides the atom-numbering scheme used in the tables. Figure 2 depicts the crystal matrix down the *b*-axis and shows the extensive hydrogen bonding network within the crystal.

The asymmetric unit contains the anion $[Ho(CO_3)_4]^{5-}$, a $[Co(NH_3)_6]^{3+}$ cation, two Na^+ cations, and 14 H_2O molecules, which are either bound to the Na^+ cations or found in the lattice. The metrical parameters for the $[Co(NH_3)_6]^{3+}$ ion are all within normal ranges. The $[Ho(CO_3)_4]^{5-}$ anion is eight coordinate, with four bidentate carbonate ligands bound to the Ho atom. The molecule has essentially C_{2v} symmetry with two coplanar carbonates making a vane, which is perpendicular to a similar vane produced by the other two carbonate ligands. Another view of this molecule is obtained through the geometry of the C atoms, which are found in a severely distorted tetrahedral geometry. The

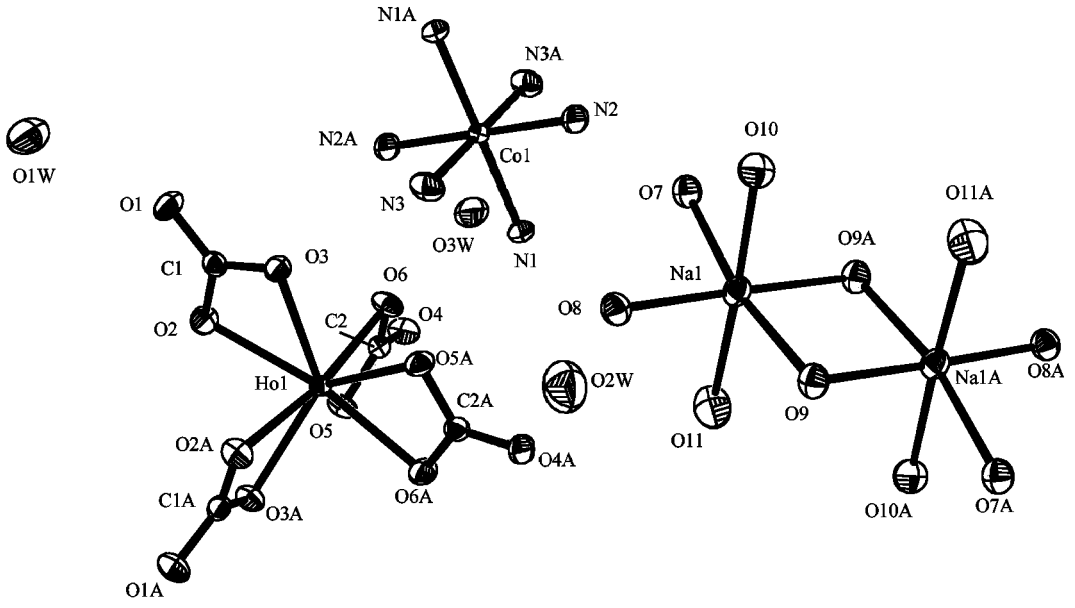

Figure 1. Thermal ellipsoid plot (50% probability) of $[Co(NH_3)_6][Na_2(H_2O)_{10}][Ho(CO_3)_4]\cdot 4H_2O$, giving the atom numbering scheme used in the tables

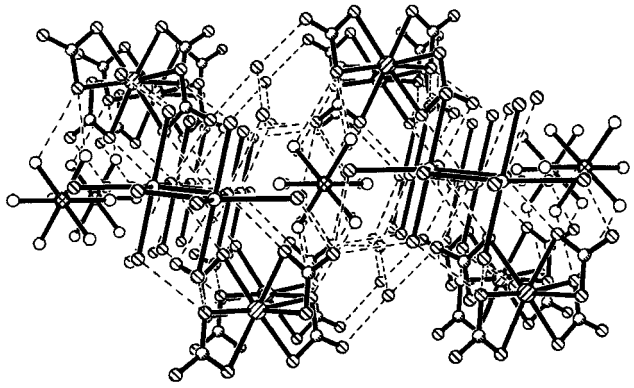

Figure 2. Ball and stick drawing depicting the crystal matrix of $[Co(NH_3)_6][Na_2(H_2O)_{10}][Ho(CO_3)_4]\cdot 4H_2O$ down the *b*-axis; the hydrogen bonding within the complex is shown by the dashed lines

average Ho−O distance was determined to be 2.361(5) Å, while the average Ho−C distance was 2.784(6) Å. As was previously stated, this is the first structural characterization of a mononuclear homoleptic carbonato complex of a trivalent lanthanide. In fact, the only structurally well characterized homoleptic lanthanide carbonate molecules are $[C(NH_2)_3]_6[Ce(CO_3)_5]\cdot 4H_2O$,[26] $La_2(CO_3)_3\cdot 8H_2O$,[27] $(La,Ce)_2(CO_3)_3\cdot 8H_2O$,[28] and $M[Ln(CO_3)_2]$ (M = K, Ln = Nd, Dy; M = Cs, Ln = Pr).[11,29,30] A comparison of the bond lengths may be made with $[Ho(oxam)_3(H_2O)_3]_4\cdot 2.75H_2O$ (**I**),[31] Ho(2,6-dihydroxybenzoato-*O*)$_2$(2,6-dihydroxybenzoato-*O*,*O*)$(H_2O)_4\cdot 2H_2O$ (**II**),[32] and $Ho(HCO_3)_3(H_2O)_4\cdot 2H_2O$ (**III**).[33] These complexes all contain terminal aquo ligands and carbonate or carboxylate groups with the Ho−O bond lengths being slightly different for Ho−$O_{(aquo)}$ and Ho−$O_{(O\text{-}R)}$. For **I** the average Ho−$O_{(aquo)}$ bond length is 2.37(1) Å, while the average for Ho−$O_{(O\text{-}R)}$ is 2.42(1) Å with values ranging from 2.362(8)−2.535(8) Å.[31] For **II** the average Ho−OH_2 distance is 2.37(1) Å, with a range for all Ho−O distances of 2.297(3)−2.486(3) Å.[32] Lastly, the average Ho−OH_2 distance in **III** is 2.36(1) Å, while the bond lengths of the bicarbonate ligands range from 2.442(9)−2.557(9) Å.[33] Clearly the bond lengths for the $Ho(CO_3)_4^{5-}$ ion are reasonable relative to other known Ho complexes. There are three main O−Ho−O angles of interest. The first type is the "bite" angle of the carbonate ligands, for example O(3)−Ho(1)−O(2), whose average is 55.5 (1)°. The other two angles are based on those between the carbonate ligands: O(3)−Ho(1)−O(5A) at 76.99(9)° and O(2)−Ho(1)−O(6A) at 169.77(9)°. An indication of the planarity between the two sets of carbonate ligands can be obtained by addition of the angles, which gives 358(1)°, quite close to the theoretical 360°. The C−Ho−C angles come in pairs and range from 132.26(11) to 97.42(15)° with the average being 107.5(2)°. The large range in the angles indicates the severe distortion from a tetrahedral geometry. The average distal C−O distance, 1.265(4) Å, is significantly shorter than the average metal-bound C−O distance, 1.301(5) Å. The O−C−O angles of the carbonate ligand deviate from the ideal value of 120°. The O−C−O angle between O atoms bound to Ho (the bite angle) averages 115.4(3)° while the remaining two O−C−O angles have opened up somewhat to 122.3(6)°. These distortions are typically found within carbonate ligands that are complexed to metal centers. The carbonate ligands are also involved with an extended hydrogen-bonding network. There are close contacts between the O atoms of the Ho carbonate ligands to the N atoms of the $[Co(NH_3)_6]^{3+}$ [average O···N is 3.09(1) Å]. The carbonate O atoms also have close contacts with the H_2O molecules in the lattice and those bound to the Na atoms [average O···O is 2.81(1) Å]. These dis-

tances are all well within the range expected for weak H-bonding interactions.[34]

Another interesting structural feature is the sodium aquo ion dimer $[Na_2(H_2O)_{10}]^{2+}$. Each of the Na atoms is six-coordinate, with four terminal and two bridging H_2O molecules; the overall geometry is best described as an edge-shared bioctahedron. The two Na atoms are separated by a reasonable 3.555(3) Å. The average Na−O distance is 2.43(1) Å with values ranging from 2.388(3) Å to 2.503(3) Å. The octahedra are distorted by an approximate 5° tilt of the axial ligands towards the center of the molecule. This distortion is further indicated by the average $O(11)-Na-O_{(cis)}$ angle of 91.7(1)°, while the average $O(10)-Na-O_{(cis)}$ angle is 88.5(1)°.

Vibrational Spectroscopy

Metal-carbonate complexation results in the splitting of the doubly degenerate e′ and e′′ modes of the free carbonate (D_{3h} symmetry). The extent of this splitting can be used to indicate whether the complexation is mono- or bidentate in nature.[35−37] This is especially true of the e′ ν_3 carbonate band composed of the asymmetric stretch of the free ligand. For bidentate complexation to a trivalent metal, the higher frequency stretch is pushed to over 1500 cm^{-1}, and the splitting between this band and the lower stretch is greater than 100 cm^{-1}. Conversely, monodentate complexation shifts the higher stretch to less than 1500 cm^{-1} and results in a splitting of less than 100 cm^{-1}. Another vibrational mode of interest, the metal−oxygen stretch, gives information on the strength of the bonding. For carbonate complexes with trivalent metals, this peak is typically in the 300−400 cm^{-1} region.[36]

Both Raman and infrared absorption (IR) measurements were performed to aid the characterization of the mode of carbonate complexation to Ho^{III}. The Raman spectrum from a single crystal of Ho^{III} carbonate is dominated by bands due to the $Co(NH_3)_6^{3+}$ moiety, with the only clear carbonate mode due to the symmetric stretch at 1062 cm^{-1}(Figure 3). The spectrum of the crystal differs from that of the parent solution, in which peaks at 1048 and 1066 cm^{-1} are observed. The latter feature is due in large part to free carbonate and obscures any measure of the tetracarbonato species, while the former demonstrates that a significant amount of the Ho in solution is a lower carbonato complex. This is consistent with earlier work that indicated an equilibrium mixture of complexes even up to 2.0 M CO_3^{2-}.[38] No Raman feature due to the Ho−O stretch could be observed, perhaps due to it being obscured by the cobalt hexaammine peak at 295 cm^{-1}, but also possibly due to the lack of covalent character of the holmium-carbonate bonding.

More carbonate bands for the $Ho(CO_3)_4^{5-}$ solid are found in the IR spectrum obtained from a ground sample prepared as a KBr pellet (Figure 4). In contrast to the Raman spectrum, the cobalt hexaammine peaks do not mask large areas of the spectral region: peaks are observed at 826, 1328 (shoulder), and 1653 cm^{-1},[36] with the latter also receiving any contribution from H_2O absorption. The remaining IR peaks are similar to those found for a holmium carbonate complex previously postulated to be the tetracarbonato species.[39] The coincidence of the IR peaks shown in the earlier work and the peaks reported here confirm that the holmium carbonato species is the same in both reports. While the nature of the species was postulated in the earlier work, water molecules directly bonded to the holmium had been postulated to sterically force the carbonates to bond in a monodentate fashion.[39] The crystal structure here shows that these water molecules are not bonded to holmium but rather to sodium, and that the carbonate bonds are indeed bidentate. The IR peaks support this bidentate bonding scheme.[35−37] Specifically, there is clearly a high frequency carbonate peak at 1519 cm^{-1}, consistent

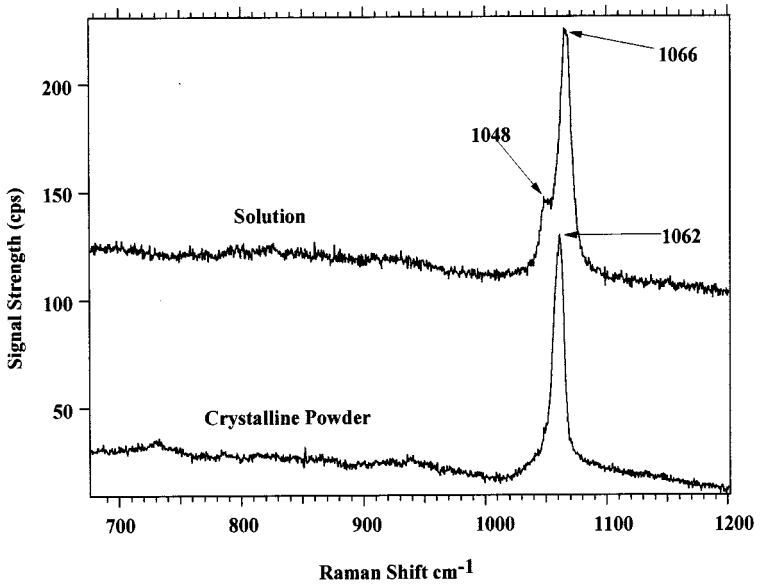

Figure 3. Raman spectra of 0.01 M Ho^{III} in 2.5 M Na_2CO_3 (upper) and solid $[Co(NH_3)_6][Na_2(H_2O)_{10}][Ho(CO_3)_4]\cdot 4H_2O$ (lower)

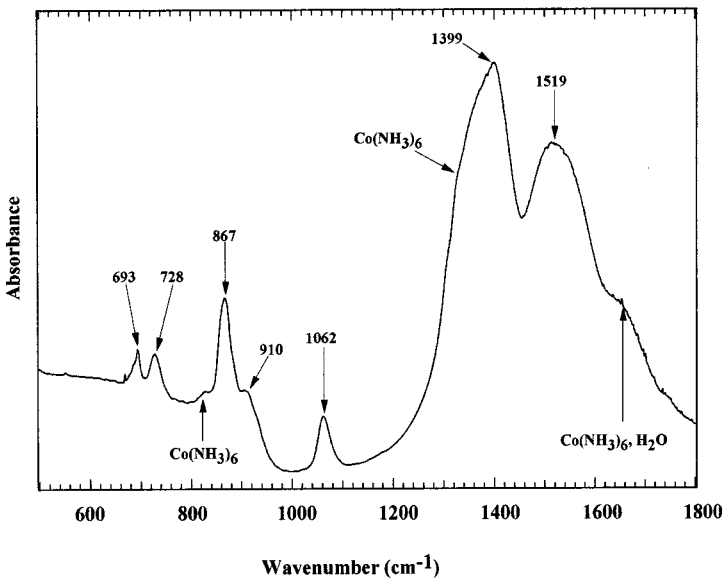

Figure 4. Infra-red spectrum of solid $[Co(NH_3)_6][Na_2(H_2O)_{10}][Ho(CO_3)_4]\cdot 4H_2O$ in a KBr matrix

with the higher asymmetric stretch from bidentate carbonate complexation. The other partner to this split e′ mode is observed at 1399 cm^{-1}, yielding a 120 cm^{-1} splitting of these peaks, consistent with bidentate complexation. To complete the vibrational description, the two peaks at 694 and 729 cm^{-1} are the result of splitting the ν_4 e′′ free carbonate bending mode upon complexation, the 867 cm^{-1} peak is the trampoline π mode, and the symmetric stretching mode can be seen at 1062 cm^{-1}, consistent with the Raman spectrum, and very close to the value observed in solution for the free carbonate ion. Therefore, the Raman and IR spectra are consistent with bidentate carbonate complexation with little covalent character.

Conclusion

The identification of the limiting complex in the Ho^{III} carbonate system under high carbonate concentration has been determined using a combination of single-crystal X-ray diffraction, electronic absorption and vibrational spectroscopy. It has been shown that the limiting complex is the mononuclear $[Ho(CO_3)_4]^{5-}$ ion. The solution from which the solid tetracarbonate was isolated was confirmed to contain an equilibrium mixture of complexes. This molecule can now be used as a structural and spectroscopic model for tetracarbonates of other Ln^{III} as well as $An^{III/IV}$ ions. However, it should be noted that this is only one structure type, and other expanded coordination environments could be observed in the larger lanthanide and actinide ions. Similar studies to determine the identity of the other species in the Ln^{III}, An^{III} and Pu^{IV} carbonate systems of importance to nuclear waste isolation and disposal programs are currently in progress.

Experimental Section

General: All operations were carried out in an open atmosphere and at room temperature. $Co(NH_3)_6Cl_3$, Na_2CO_3, and $Ho(NO_3)_3\cdot 5H_2O$ (Aldrich) were all used as received. The solution electronic absorption measurements were obtained in 1.0 cm matched quartz cells on a Perkin−Elmer Lambda 19 or Cary Model 5 spectrophotometer. Complete spectra in the range from 400 to 1000 nm as well as absorbance values at selected wavelengths were obtained. Measurements were made at 23 ± 1 °C. Raman vibrational spectra were obtained using near-infrared excitation obtained from a Ti-sapphire CW laser (752 nm, Spectra Physics Model 3900s) with detection accomplished through a CCD detector (Princeton Instruments). The Raman scattering was dispersed with a single-stage monochromator (diffraction gratings blazed at 1150 nm, 4 cm^{-1} resolution) after being prefiltered through an interference filter designed to remove Rayleigh-scattered laser light. The Raman samples were recorded in sealed 5 mm glass NMR tubes or mounted on a glass plate with silicon grease. Elemental analyses were performed with a Perkin−Elmer Series II CHNS/O Analyzer.

Preparation of Ho^{III} Carbonate Solutions: A solution of Ho^{III} (1.0 mL, 0.08 M) was prepared by dissolving $Ho(NO_3)_3\cdot 5H_2O$ (0.707 g, 1.60 mmol) in 20 mL of H_2O. The carbonate solution was then prepared by the addition of 1.0 mL of the Ho^{III} stock solution to 1.0 mL of a 4.1 M Na_2CO_3 solution. The resulting solution concentrations were 0.04 M Ho^{III} and 2.1 M Na_2CO_3.

Preparation of $[Co(NH_3)_6][Na_2(H_2O)_{10}][Ho(CO_3)_4]\cdot 4H_2O$: $Co(NH_3)_6Cl_3$ (0.4 mL, 0.2 M) was added to a solution of Ho^{III} (2.0 mL, 0.04 M) in 2.1 M Na_2CO_3. The mixture was allowed to sit open to the atmosphere for two weeks, during which time yellow-orange blocks formed. Raman: $\tilde{\nu}$ = 1064 cm^{-1}. − IR: $\tilde{\nu}$ = 694, 727, 827, 867, 907 1062, 1399 (CO_3^{2-}), 1520 (CO_3^{2-}), 1646 cm^{-1}. − $C_4H_{46}CoHoN_6Na_2O_{26}$ (864.3): calcd. C 5.56, H 5.36, N 9.12; found C 5.83, H 5.07, N 10.16.

X-ray Crystallography: A yellow-orange, irregular shaped crystal was attached to a glass fiber with a spot of silicone grease. The crystal was mounted from a matrix of mineral oil. The crystal was immediately placed on a Bruker P4/CCD/PC diffractometer, and cooled to 203 K using a Bruker LT-2 temperature device. The data were collected using a sealed, graphite monochromatized Mo-K_α X-ray source. A hemisphere of data were collected using a combination of and ω scans, with 20 second frame exposures and 0.3° frame widths. Data collection, initial indexing and cell refinement was handled using SMART[40] software. Frame integration and final cell parameter calculation were carried out using SAINT[41] software. The data were corrected for absorption using the DIFABS[42] program. Decay of reflection intensity was not observed.

The structure was solved in the space group *P*2/*n* using Direct methods and difference Fourier techniques. The initial solution revealed the holmium, cobalt, and the majority of all non-hydrogen atom positions. Several lattice water molecules were discovered during subsequent Fourier synthesis [atoms labeled O(1W) to O(3W)]. The hydrogen atoms were fixed (N−H= 0.89 Å) on the amine groups, which were allowed to rotate in order to maximize electron density at the hydrogen atom positions, and were refined with isotropic temperature factors set to 1.5 times the equivalent isotropic U of the atoms to which they are bound. The hydrogen atom positions associated with the water molecules were not considered in the structural model. The final refinement included anisotropic temperature factors on all non-hydrogen atoms, and converged to $R1 = 0.0267$ and $wR2 = 0.0741$. Structure solution, refinement, graphics, and creation of publication materials were performed using SHELXTL/NT.[43] Additional details of the data collection and structure refinement are listed in Table 1.

Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-411045.

Synthesis, Spectroscopic and Structural Studies on Six- and Eight-Coordinate Phosphane and Arsane Complexes of Titanium(IV) Halides

Richard Hart,[a] William Levason,[a] Bhavesh Patel,[a] and Gillian Reid*[a]

Keywords: Titanium / Halides / Phosphanes / Arsanes / Structure elucidation

The six-coordinate complexes [TiX_4(L-L)] [X = Cl or Br; L-L = $Ph_2PCH_2PPh_2$, $Ph_2P(CH_2)_2PPh_2$, $Ph_2P(CH_2)_3PPh_2$, *o*-$C_6H_4(PPh_2)_2$, *o*-$C_6H_4(PMe_2)_2$, $Ph_2As(CH_2)_2AsPh_2$, *o*-$C_6H_4(AsMe_2)_2$ or $MeC(CH_2AsMe_2)_3$] and the eight-coordinate complexes [TiX_4(L-L)$_2$] [L-L = *o*-$C_6H_4(PMe_2)_2$ or *o*-$C_6H_4(AsMe_2)_2$] have been prepared and characterised by solution ^1H and $^{31}P\{^1H\}$ NMR spectroscopy, IR and UV/Visible spectroscopy and microanalyses. The crystal structures of [$TiCl_4${*o*-$C_6H_4(PMe_2)_2$}], [$TiCl_4${*o*-$C_6H_4(PMe_2)_2$}$_2$], [$TiBr_4${*o*-$C_6H_4(PMe_2)_2$}$_2$], [$TiBr_4${*o*-$C_6H_4(AsMe_2)_2$}$_2$] and [$TiBr_4${$MeC(CH_2AsMe_2)_3$}] are described and permit detailed comparisons to be made between the six- and eight-coordinate species and between the phosphane and arsane species. The crystal structure of the zwitterionic [$TiCl_5(Ph_2PCH_2PHPh_2)$] is also reported.

Introduction

Recently we have been investigating the chemistry of the early transition metal ions, particularly Ti^{IV}, with thio-, seleno- and telluroether ligands. Part of the impetus for this work arises from the potential of the resultant complexes as single-source precursors for transition metal chalcogenides through CVD processes. Thus, we have reported the preparation of a wide range of six-coordinate, distorted octahedral complexes of the form [TiX_4(E-E)] (E-E = dithio- or diselenoether).[1] We have also isolated six- and seven-coordinate species involving trithio- and triselenoether ligands.[2] In the course of this work we attempted to generate eight-coordinate species of the form [TiX_4(E-E)$_2$]; however we saw no evidence at any stage for their existence either in solution or in the solid state. This prompted us to examine in some more detail the literature describing eight-coordinate Ti^{IV} complexes involving diphosphane and diarsane ligands. While a number of references to such species have been made, including, for example, [$TiCl_4${*o*-$C_6H_4(PMe_2)_2$}$_2$], [TiX_4{*o*-$C_6H_4(AsMe_2)_2$}$_2$] (X = Cl or Br) and [$TiCl_4${$Me_2P(CH_2)_2PMe_2$}$_2$],[3−8] the literature is in fact very patchy and single crystal X-ray structural data are only available for two examples: an early report by Nyholm and co-workers on [$TiCl_4${*o*-$C_6H_4(AsMe_2)_2$}$_2$],[3,4] and [$TiCl_4${$Me_2P(CH_2)_2PMe_2$}$_2$], which was reported by Cotton and co-workers in 1998.[6] The synthesis of [$TiCl_4${*o*-$C_6H_4(PMe_2)_2$}$_2$] has been reported, but structural information is limited to an X-ray powder photograph, indicating the same structure as [$TiCl_4${*o*-$C_6H_4(AsMe_2)_2$}$_2$].[5] This lack of structural data and the absence of any detailed solution studies on either the six- or eight-coordinate systems has prompted us to conduct more thorough studies on the synthesis and properties of phosphane and arsane complexes of Ti^{IV}. Our specific aims were to investigate the possibility of forming other complexes with coordination numbers greater than six and to establish the structural consequences of changing from six- to eight-coordination. In this paper we report the results of our studies, including the preparations and spectroscopic characterisation of six- or eight-coordinate Ti^{IV} halide complexes involving $Ph_2PCH_2PPh_2$, $Ph_2P(CH_2)_2PPh_2$, $Ph_2P(CH_2)_3PPh_2$, *o*-$C_6H_4(PPh_2)_2$, *o*-$C_6H_4(PMe_2)_2$, $Ph_2As(CH_2)_2AsPh_2$, *o*-$C_6H_4(AsMe_2)_2$ and $MeC(CH_2AsMe_2)_3$. The crystal structures of [$TiCl_4${*o*-$C_6H_4(PMe_2)_2$}], [$TiCl_4${*o*-$C_6H_4(PMe_2)_2$}$_2$], [$TiBr_4${*o*-$C_6H_4(PMe_2)_2$}$_2$], [$TiBr_4${*o*-$C_6H_4(AsMe_2)_2$}$_2$] and [$TiBr_4${$MeC(CH_2AsMe_2)_3$}] are also described and permit the details of the structural changes incurred upon changing the Ti^{IV} coordination to be examined. The crystal structure of the unusual zwitterionic species [$TiCl_5(PPh_2PCH_2PHPh_2)$], which was obtained as a decomposition product from a solution of [$TiCl_4(Ph_2PCH_2PPh_2)$], is also presented.

Results and Discussion

Compounds TiX_4 (X = Cl or Br) react with one molar equivalent of L-L [L-L = $Ph_2P(CH_2)_nPPh_2$ (n = 1−3), *o*-$C_6H_4(PMe_2)_2$, *o*-$C_6H_4(PPh_2)_2$, *o*-$C_6H_4(AsMe_2)_2$ or $Ph_2As(CH_2)_2AsPh_2$] in rigorously anhydrous CH_2Cl_2 solution under an N_2 atmosphere to afford the 1:1 species [TiX_4(L-L)] as orange- or red-coloured solids in good yield; the tripodal ligand $MeC(CH_2AsMe_2)_3$ gives [TiX_4{$MeC(CH_2AsMe_2)_3$}] also in high yield. The 1:2 complexes [TiX_4{*o*-$C_6H_4(PMe_2)_2$}$_2$] and [TiX_4{*o*-$C_6H_4(AsMe_2)_2$}$_2$] were obtained in good yield by similar reactions using two molar equivalents of ligand. The compounds are relatively stable as solids when stored under N_2 in a dry glove-box. However, in solution they are very susceptible to hydrolysis, rapidly decolourising. The powdered solids are also readily hydrolysed in moist air. For these

reasons all measurements were conducted using solutions freshly prepared in rigorously anhydrous solvents. IR spectra were recorded as nujol mulls and the complexes $[TiX_4(L\text{-}L)]$ show, in addition to peaks due to the coordinated phosphane or arsane ligand, up to four bands around 420−350 cm^{-1} (X = Cl) or 320−280 cm^{-1} (X = Br), consistent with the presence of the *cis*-octahedral species (theory $2a_1 + b_1 + b_2$ for C_{2v} symmetry). Similar frequencies were observed for the tetrahalo-titanium thio- and selenoether species reported earlier.[1] For the complexes $[TiX_4(L\text{-}L)_2]$ [L-L = *o*-$C_6H_4(PMe_2)_2$ or *o*-$C_6H_4(AsMe_2)_2$], IR spectroscopy shows two peaks around 315 cm^{-1} for the chloro species and ca. 290 cm^{-1} for the bromo species (theory $b_2 + e$ for D_{2d} symmetry). The frequencies for the eight-coordinate species are generally significantly lower than for their six-coordinate analogues. These data are in good agreement with the literature.[5]

Electronic spectra were recorded by diffuse reflectance owing to the highly sensitive nature of the compounds in solution. For the six-coordinate d^0 complexes $[TiCl_4(L\text{-}L)]$, two broad features are present at ca. 21,000 and ca. 28,000 cm^{-1}, which may be assigned as $\sigma(P,As) \rightarrow Ti(t_{2g})$ and $\pi(Cl) \rightarrow Ti(t_{2g})$ LMCT transitions, respectively. Although the actual symmetry at Ti is C_{2v} rather than O_h, the lifting of the degeneracy of the Ti t_{2g} orbitals does not result in resolved splittings, although it may contribute to the broadness of the bands. The spectra of the $[TiBr_4(L\text{-}L)]$ complexes are less well resolved, but features at ca. 20,000 and 23,000 cm^{-1} are assigned similarly as $\sigma(P,As) \rightarrow Ti(t_{2g})$ and $\pi(Br) \rightarrow Ti(t_{2g})$ transitions. The $\sigma(P,As) \rightarrow Ti(t_{2g})$ transition appears at slightly lower energy when X = Br than when X = Cl, an effect often observed with later transition metals.[9] The eight-coordinate $[TiX_4(L\text{-}L)_2]$ complexes have broad features at similar energies to their six-coordinate analogues, which are similarly assigned to LMCT transitions. For a D_{2d} metal centre, taking the z-axis as the principle inversion (S_4) axis, the lowest d-level is b_1 and thus the transitions are L (or X) $\rightarrow$ Ti(b_1). A careful comparison of the diffuse reflectance spectra of the corresponding $[TiCl_4(L\text{-}L)]$ and $[TiCl_4(L\text{-}L)_2]$ complexes shows two differences: (i) the bands are broader in the eight-coordinate than in the six-coordinate complexes, and (ii) the $\sigma(P,As) \rightarrow Ti$ transitions are relatively more intense than the $\pi(X) \rightarrow Ti$ transition in the former, which is reasonable since the number of P/As donors has doubled. The bands in the spectra of $[TiBr_4(L\text{-}L)_x]$ (x = 1 or 2) are very broad, but appear to show a similar trend. Whilst the six- and eight-coordinate complexes can be distinguished by their diffuse reflectance spectra when the spectra for both species are compared; the differences do not appear to be sufficiently large to assign the coordination number to a $TiX_4(L\text{-}L)_x$ complex on the basis of the spectrum of only one or the other with any confidence.

Solution NMR studies

The $^{31}P\{^1H\}$ NMR spectrum of $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ in CH_2Cl_2 at room temperature is a singlet at δ = 31.5, whereas that of the poorly soluble $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ has δ = 29.5. The corresponding ^1H NMR spectra show second order multiplets for the PMe_2 groups at δ = 1.88 ($[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$) and 1.90 ($[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$) and the spectra are essentially unchanged on cooling the solution to −90 °C. We therefore conclude that neither complex dissociates ligand under these conditions. Similar studies on $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ reveal a single $^{31}P\{^1H\}$ NMR resonance at δ = 24.5, and addition of *o*-$C_6H_4(PMe_2)_2$ to this solution produces, in addition to a free ligand resonance at δ = −55, a new species at δ = 22.2. The $^{31}P\{^1H\}$ NMR spectrum of $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ at ambient temperatures contains three resonances at δ = 24.5, 22.2 and −54, from which it is clear that $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ is partially dissociated in solution into the 1:1 complex and *o*-$C_6H_4(PMe_2)_2$, and that exchange between either complex and *o*-$C_6H_4(PMe_2)_2$ is slow on the ^{31}P NMR time-scale at ambient temperatures. The ^1H NMR spectra lead to similar conclusions, although the coordinated PMe_2 resonances overlap. The $^{31}P\{^1H\}$ NMR spectrum of $[TiCl_4\{o\text{-}C_6H_4(PPh_2)_2\}]$ shows a sharp singlet at δ = 34.2, and that of $[TiCl_4\{Ph_2P(CH_2)_2PPh_2\}]$ a singlet at δ = 24.6. The spectra of the corresponding bromides and of $[TiX_4\{Ph_2P(CH_2)_3PPh_2\}]$ show only very broad resonances at lower frequency which remain broad even at −90 °C; we attribute this to reversible ligand dissociation.

For the *o*-$C_6H_4(AsMe_2)_2$ complexes only ^1H NMR spectroscopic data were available (attempts to study ligand exchange in solution by $^{13}C\{^1H\}$ NMR were unsuccessful due mainly to poor solubility). At room temperature the complex $[TiCl_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$ showed a singlet $AsMe_2$ resonance at δ = 1.75, whereas $[TiCl_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ contained three resonances at δ = 1.8, 1.74 and 1.2. The δ = 1.2 resonance is due to free *o*-$C_6H_4(AsMe_2)_2$, and thus the spectrum shows that $[TiCl_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ is partially dissociated into the 1:1 complex and *o*-$C_6H_4(AsMe_2)_2$. Attempts to record spectra at −90 °C were unsuccessful due to the poor solubility of the complex at low temperatures. The spectrum obtained from $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$ in CD_2Cl_2 at room temperature shows an $AsMe_2$ singlet at δ = 1.9 (assigned to the complex) and some free *o*-$C_6H_4(AsMe_2)_2$ at δ = 1.2. The spectrum of $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ contained broad lines at δ = 1.9 and 1.2 attributable to the 1:1 complex and free ligand; a weaker peak at δ = 1.6 is tentatively attributed to the 2:1 complex. These resonances sharpened on cooling.

Comparison of these results show that whilst the $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_n]$ (n = 1 or 2) and $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ complexes are stable in solution, the $[TiCl_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ and $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ complexes are partially dissociated in solution into the corresponding 1:1 complex and free ligand. Greater dissociation is observed with the weaker Lewis acid $TiBr_4$: $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$ appears to be partially dissociated into $TiBr_4$ and *o*-$C_6H_4(AsMe_2)_2$ in solution. Of the complexes of the phenyl-substituted diphosphanes, only the $[TiCl_4(L\text{-}L)]$ [L-L = $Ph_2P(CH_2)_2PPh_2$ or *o*-$C_6H_4(PPh_2)_2$] show sharp ^{31}P NMR spectra; in the corresponding brom-

ides or in $[TiCl_4\{Ph_2P(CH_2)_3PPh_2\}]$, only very broad lines, typical of rapidly exchanging systems are observed.

The $[TiX_4\{MeC(CH_2AsMe_2)_3\}]$ systems were difficult to study in solution due to their very poor solubility in chlorocarbons, and attempts to obtain $^{13}C\{^1H\}$ data were unsuccessful. However, the ^1H NMR spectroscopic data are consistent with the six-coordinate structure established crystallographically for the bromide. Both show an uncoordinated $AsMe_2$ resonance at $\delta = 0.95$, coordinated $AsMe_2$ groups (broad singlet at $\delta = 1.71$ for X = Br, and two lines of 1:1 intensity $\delta = 1.59$, 1.61 X = Cl) and corresponding CH_2 resonances near $\delta = 2.0$ (coord) and $\delta = 1.7$ (free). The spectra show that exchange between the free and coordinated arms of the tridentate arsane is slow at ambient temperatures, which contrasts with the behaviour in the trithioether analogues.[2] These conclusions are at odds with an early literature report[10] which concludes from ^1H NMR spectroscopy that $[TiCl_4\{MeC(CH_2AsMe_2)_3\}]$ is seven-coordinate with tridentate triarsane coordination. This was subsequently questioned by McAlees and co-workers[11] who reinterpreted the original NMR spectroscopic data and suggested six-coordination, with one arm of the tripod uncoordinated. Our conclusions are also supported by a single crystal X-ray structure determination (see below).

X-ray Crystallographic Studies

Crystals of $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$, $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$, $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$, $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ and $[TiBr_4\{MeC(CH_2AsMe_2)_3\}]$ were obtained from CH_2Cl_2 solution. The structure of $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ (Figure 1) shows a discrete distorted octahedral geometry at Ti^{IV}, with the $o\text{-}C_6H_4(PMe_2)_2$ ligand chelating. The Ti−P bond lengths of 2.5733(13) and 2.5600(12) Å are in agreement with those in $[TiCl_4\{Me_2P(CH_2)_2PMe_2\}]$ [2.574(2) − 2.590(2) Å] and other six-coordinate phosphane complexes of Ti^{IV}.[12,13] The Ti−Cl distances *trans* to Cl are longer than those *trans* to P by ca. 0.2 Å, consistent with a *trans* influence on Ti^{IV} of Cl > P. A similar trend was observed for $[TiX_4(E\text{-}E)]$ (E-E = dithioether or diselenoether), where the *trans* influence was X > E, and $[TiCl_4\{Me_2P(CH_2)_2PMe_2\}]$ and $[TiCl_4\{Et_2P(CH_2)_2PEt_2\}]$.[12,13] The axial Cl(3)−Ti(1)−Cl(4) unit is tilted to lie over the $o\text{-}C_6H_4(PMe_2)_2$ ligand, with an angle of 164.25(6)°. The P−Ti−P angle in the five-membered chelate ring is constrained to be 76.05(4)°.

Crystals were also obtained for the directly comparable eight-coordinate species $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$, although the crystal quality was less good, resulting in higher residuals. However, the structure of this complex (Figure 2) shows crystallographic 4bar symmetry and adopts a dodecahedral stereochemistry. The Ti−Cl distance [2.503(3) Å] is 0.20−0.25 Å longer than in the six-coordinate $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$. This is substantially greater than the increase in d(Ti−P) which is ca. 0.1 Å on going from a six- to an eight-coordinate geometry. Normally one would expect an increase in coordination number to be accompanied by an increase in Ti−donor atom bond length. Indeed,

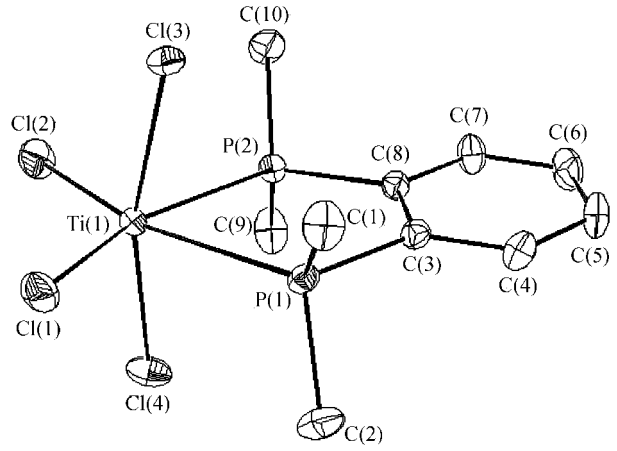

Figure 1. View of the structure of $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ with atom numbering scheme; ellipsoids are shown at the 40% probability level; selected bond lengths (Å) and angles (°): Ti(1)−Cl(1) 2.2748(12), Ti(1)−Cl(2) 2.253(1), Ti(1)−Cl(3) 2.2975(13), Ti(1)−Cl(4) 2.2938(13); Ti(1)−P(1) 2.5733(13), Ti(1)−P(2) 2.5600(12); Cl(1)−Ti(1)−Cl(2) 114.58(5), Cl(1)−Ti(1)−Cl(3) 93.88(5), Cl(1)−Ti(1)−Cl(4) 94.23(5), Cl(1)−Ti(1)−P(1) 84.39(5), Cl(1)−Ti(1)−P(2) 160.39(5), Cl(2)−Ti(1)−Cl(3) 94.42(5), Cl(2)−Ti(1)−Cl(4) 94.44(5), Cl(2)−Ti(1)−P(1) 161.00(5), Cl(2)−Ti(1)−P(2) 84.96(5), Cl(3)−Ti(1)−Cl(4) 164.25(6), Cl(3)−Ti(1)−P(1) 82.80(4), Cl(3)−Ti(1)−P(2) 82.39(4), Cl(4)−Ti(1)−P(1) 84.59(5), Cl(4)−Ti(1)−P(2) 85.45(5), P(1)−Ti(1)−P(2) 76.05(4)

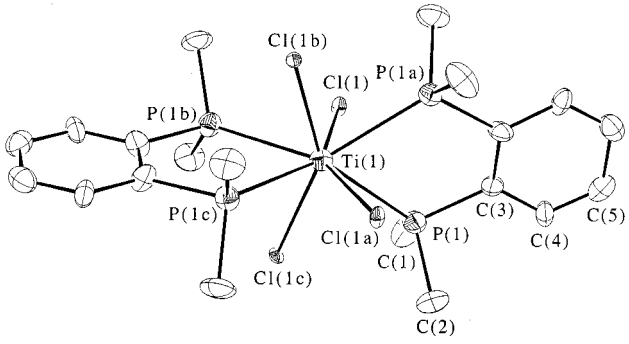

Figure 2. View of the structure of $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ with atom numbering scheme; ellipsoids are shown at the 40% probability level; symmetry operators $-x, -y, z$; $1/2 - y, 1/2 + x, 1/2 - z$; $1/2 + y, 1/2 - x, 1/2 - z$; selected bond lengths (Å) and angles (°): Ti(1)−Cl(1) 2.503(3), Ti(1)−P(1) 2.654(4); Cl(1)−Ti(1)−Cl(1b) 95.23(3), Cl(1)−Ti(1)−Cl(1a) 144.85(11), Cl(1)−Ti(1)−P(1) 75.97(12), Cl(1)−Ti(1)−P(1a) 75.88(12), Cl(1)−Ti(1)−P(1b) 71.22(10), Cl(1)−Ti(1)−P(1c) 143.93(10)

this is clearly true for these systems, although the increase in bond length is different for Ti−P than for Ti−Cl. In the six-coordinate species the high *trans* influence of Cl on Ti^{IV} lengthens the Ti−P bond and indeed shortens the Ti−Cl *trans* P bond length (above). In the eight-coordinate flattened dodecahedron, however, the P−Ti−Cl angles are all less than 145°, and this will reduce the magnitude of the *trans* influence of the Cl ligands, thus accounting for some of the disparity. The P−Ti−P angle in the chelate ring is reduced to 72.7(2)° upon increasing the coordination number, a direct consequence of the longer Ti−P bond lengths.

The same geometry has been identified for $[TiCl_4\{Me_2P(CH_2)_2PMe_2\}_2]$, although in this case there is twofold crystallographic symmetry [d(Ti−P) = 2.648(1), 2.654(1) Å; d(Ti−Cl) = 2.446(1), 2.451(1) Å].[6] $[TiCl_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$[3,4] is probably isostructural with the $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ complex reported here, although few details of the crystallographic information are presented in the early reports [d(Ti−As) = 2.71(2) Å; d(Ti−Cl) = 2.46(2) Å].

The only other case where both the six- and eight-coordinate Ti^{IV} complexes of a single phosphane or arsane ligand have been structurally characterised involves $Me_2P(CH_2)_2PMe_2$. The structures of $[TiCl_4\{Me_2P(CH_2)_2PMe_2\}]$ and $[TiCl_4\{Me_2P(CH_2)PMe_2\}_2]$ were both reported by Cotton and co-workers,[6,12] although in the former the phosphane ligand is disordered, making direct comparison of the structural details more difficult.

The crystals of $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ (Figure 3) and $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ (Figure 4) are isostructural with $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ above, although the crystal quality was significantly better in these, leading to better structure definition and lower esd's on the geometric parameters. The Ti−Br and Ti−P distances in $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ are 2.5776(9), 2.672(2) Å, respectively. The latter is in agreement with the Ti−P distance in $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$. The Ti−As distance in $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ is 2.7324(13) Å, similar to the value of 2.71(2) Å reported for $[TiCl_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$.[3,4] A comparison of the Ti−P and Ti−As distances in $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ and $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ shows an increase of 0.06 Å upon changing from phosphane to arsane. This is slightly less than the differences observed for some other transition metal complexes of $o\text{-}C_6H_4(PMe_2)_2$ and $o\text{-}C_6H_4(AsMe_2)_2$. For example, $[NiCl_2\{o\text{-}C_6H_4(PMe_2)_2\}_2]^+$ has a Ni−P bond length of 2.255(3) Å and $[NiCl_2\{o\text{-}C_6H_4(AsMe_2)_2\}_2]^+$ Ni−As bond lengths of 2.339(3), 2.345(3) Å,[14,15] while $[CoCl_2(o\text{-}C_6H_4(PMe_2)_2\}_2]^+$ has an average Co−P bond length of 2.261 Å and $[CoCl_2\{o\text{-}C_6H_4(AsMe_2)_2\}_2]^+$ an average Co−As bond length of 2.334 Å.[15,16]

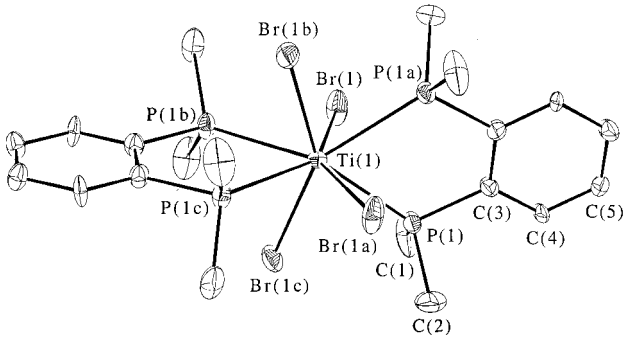

Figure 3. View of the structure of $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ with atom numbering scheme; ellipsoids are shown at the 40% probability level; symmetry operators $-x, -y, z$; $y, -x, -z$; $-y, x, -z$; selected bond lengths (Å) and angles (°): Ti(1)−Br(1) 2.5776(9), Ti(1)−P(1) 2.672(2); Br(1)−Ti(1)−Br(1a) 144.70(4), Br(1)−Ti(1)−Br(1b) 95.276(13), Br(1)−Ti(1)−P(1) 75.89(7), Br(1)−Ti(1)−P(1a) 75.86(7), Br(1)−Ti(1)−P(1b) 71.22(6), Br(1)−Ti(1)−P(1c) 144.08(5)

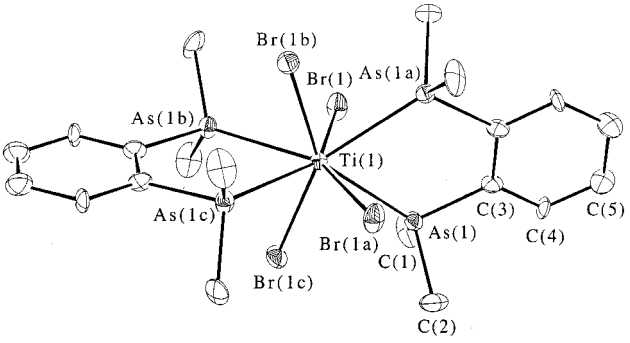

Figure 4. View of the structure of $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ with atom numbering scheme; ellipsoids are shown at the 40% probability level; symmetry operators $-x, -y, z$; $y, -x, -z$; $-y, x, -z$; selected bond lengths (Å) and angles (°): Ti(1)−Br(1) 2.5869(12), Ti(1)−As(1) 2.7324(13); Br(1)−Ti(1)−Br(1a) 144.77(6), Br(1)−Ti(1)−Br(1b) 95.26(2), Br(1)−Ti(1)−As(1) 75.98(5), Br(1)−Ti(1)−As(1a) 75.92(5), Br(1)−Ti(1)−As(1b) 70.94(4), Br(1)−Ti(1)−As(1c) 144.29(4)

The Ti^{IV} tetrahalo complexes of the tripodal $MeC(CH_2AsMe_2)_3$ were prepared in an attempt to obtain seven-coordinate species. NMR studies (above and ref.[11]) indicate that these species in fact adopt six-coordinate geometries in solution with one arm of the $MeC(CH_2AsMe_2)_3$ ligand remaining uncoordinated. A crystal structure determination was also undertaken on $[TiBr_4\{MeC(CH_2AsMe_2)_3\}]$ to establish the solid state structure. This shows that the complex adopts a distorted octahedral coordination environment at Ti^{IV}, derived from four Br ligands and two mutually *cis* As atoms from the bidentate tripodal $MeC(CH_2AsMe_2)_3$ ligand (Figure 5). The remaining As atom is uncoordinated. Hence the structures adopted in solution and in the solid state are the same. The Ti−Br distances in this species exhibit similar trends to the Ti−Cl distances in the six-coordinate $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ complex above, with the Ti−Br(*trans*-Br) distances significantly longer than those *trans* to the *trans* As atom. Also, the Ti−Br distances in this six-coordinate species are significantly shorter than in the eight-coordinate $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ complex above, while the Ti−As distances [2.680(3), 2.686(2) Å] are ca. 0.05 Å shorter than in $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$. These observations parallel the differences described above for the six- and eight-coordinate $TiCl_4/o\text{-}C_6H_4(PMe_2)_2$ systems.

A small number of crystals of $[TiCl_5(Ph_2PCH_2PHPh_2)]$ were produced by partial decomposition of $[TiCl_4(Ph_2PCH_2PPh_2)]$ in CH_2Cl_2 solution, probably by hydrolysis and subsequent HCl addition. Although there was insufficient sample to permit full spectroscopic characterisation (ν_{Ti-Cl} = 360 sh, 356, 344 sh), a crystal structure was obtained. The structure shows the phosphane ligand to be coordinated to a $TiCl_5$ fragment through a single phosphorus atom (Figure 6). A proton on the other P atom (giving a phosphonium function) was located in the difference map and is also inferred to achieve charge balance. Thus this species is an unusual zwitterionic complex with a distorted octahedral Ti^{IV} coordination geometry. The Ti−P

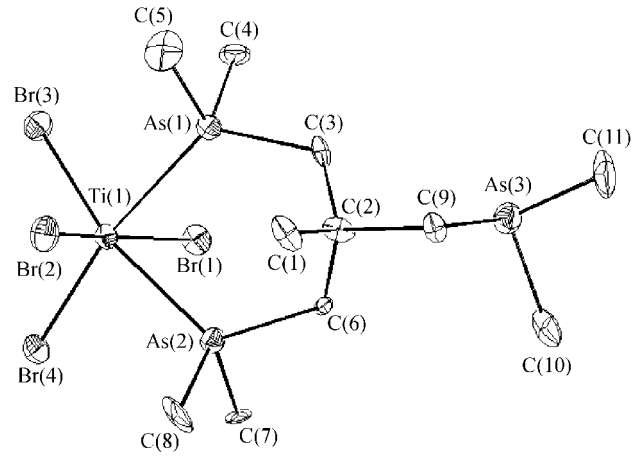

Figure 5. View of the structure of $[TiBr_4\{MeC(CH_2AsMe_2)_3\}]$ with atom numbering scheme; ellipsoids are shown at the 40% probability level; selected bond lengths (Å) and angles (°): Br(1)−Ti(1) 2.471(3), Br(2)−Ti(1) 2.445(3), Br(3)−Ti(1) 2.407(3), Br(4)−Ti(1) 2.403(3), As(1)−Ti(1) 2.680(3), As(2)−Ti(1) 2.688(3); Br(1)−Ti(1)−Br(2) 162.3(1), Br(1)−Ti(1)−Br(3) 95.93(11), Br(1)−Ti(1)−Br(4) 95.97(11), Br(1)−Ti(1)−As(1) 82.57(10), Br(1)−Ti(1)−As(2) 81.53(10), Br(2)−Ti(1)−Br(3) 94.84(12), Br(2)−Ti(1)−Br(4) 93.93(11), Br(2)−Ti(1)−As(1) 84.78(10), Br(2)−Ti(1)−As(2) 84.70(10), Br(3)−Ti(1)−Br(4) 108.29(13), Br(3)−Ti(1)−As(1) 83.36(10), Br(3)−Ti(1)−As(2) 166.30(13), Br(4)−Ti(1)−As(1) 168.4(1), Br(4)−Ti(1)−As(2) 85.39(10), As(1)−Ti(1)−As(2) 82.97(9)

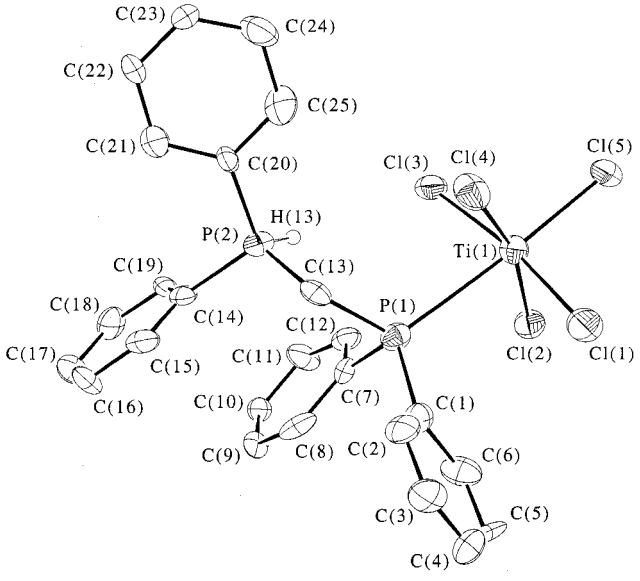

Figure 6. View of the structure of $[TiCl_5(Ph_2PCH_2PHPh_2)]$ with atom numbering scheme; ellipsoids are shown at the 40% probability level; selected bond lengths (Å) and angles (°): Ti(1)−Cl(1) 2.276(3), Ti(1)−Cl(2) 2.283(3), Ti(1)−Cl(3) 2.320(3), Ti(1)−Cl(4) 2.333(3), Ti(1)−Cl(5) 2.291(3), Ti(1)−P(1) 2.732(4); Cl(1)−Ti(1)−Cl(2) 95.67(12), Cl(1)−Ti(1)−Cl(3) 96.82(12), Cl(1)−Ti(1)−Cl(4) 93.02(13), Cl(1)−Ti(1)−Cl(5) 98.94(12), Cl(1)−Ti(1)−P(1) 176.52(13), Cl(2)−Ti(1)−Cl(3) 87.87(13), Cl(2)−Ti(1)−Cl(4) 171.2(1), Cl(2)−Ti(1)−Cl(5) 89.1(1), Cl(2)−Ti(1)−P(1) 87.62(12), Cl(3)−Ti(1)−Cl(4) 89.70(12), Cl(3)−Ti(1)−Cl(5) 164.18(13), Cl(3)−Ti(1)−P(1) 82.15(11), Cl(4)−Ti(1)−Cl(5) 90.92(12), Cl(4)−Ti(1)−P(1) 83.66(11), Cl(5)−Ti(1)−P(1) 82.20(10), P(1)−C(13)−P(2) 113.7(5)

distance in this species [2.732(4) Å] is considerably longer (by about 0.2 Å) than *d*(Ti−P) *trans* X in other six-coordinate complexes such as $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$, above, and $[TiCl_4\{Me_2P(CH_2)_2PMe_2\}]$.[12] This substantial lengthening of *d*(Ti−P) in the zwitterionic complex may arise from deactivation of the P-based lone pair on the phosphane function upon quaternization of the adjacent P centre, leading to a weaker Ti−P interaction. Notably, the Ti−Cl distance *trans* to P is not very different to the other Ti−Cl distances, unlike the examples above, $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ and $[TiBr_4\{MeC(CH_2AsMe_2)_3\}]$, where *d*(Ti−X) *trans* P/As is significantly shorter than *d*(Ti−X) *trans* X. The angles at Ti indicate a distorted octahedral geometry, but with the Cl(1)−Ti(1)−Cl angles all greater than 90° and, correspondingly, the P(1)−Ti(1)−Cl(x) ($x = 2-5$) angles all less than 90°. The consequence of this is that the Cl atoms in the $TiCl_4$ plane are displaced towards the phosphane ligand.

Conclusions

These results show that both six- and eight-coordinate Ti^{IV} complexes of $o\text{-}C_6H_4(PMe_2)_2$ and $o\text{-}C_6H_4(AsMe_2)_2$ may be isolated. Solution NMR studies show that the six-coordinate phosphane and arsane species do not undergo fast ligand exchange. On the other hand, the eight-coordinate complexes generally dissociate a ligand and exist in solution as an equilibrium mixture of $[TiX_4(L\text{-}L)_2]$, $[TiX_4(L\text{-}L)]$, TiX_4 and L-L. Attempts to prepare seven-coordinate Ti^{IV} complexes with $MeC(CH_2AsMe_2)_3$ yielded only the six-coordinate species, with the tripodal ligand functioning as a bidentate chelate. The six- and eight-coordinate complexes $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ and $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$ have been crystallographically characterised and the structural consequences of converting from six- to eight-coordinate Ti^{IV} have been established.

Experimental Section

Infrared spectra were measured as Nujol mulls between CsI plates using a Perkin−Elmer 1710 spectrometer over the range 220−4000 cm^{-1}. ^1H NMR spectra were recorded in $CDCl_3$ or CD_2Cl_2 using a Bruker AM300 or DPX400 spectrometer. $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded at 300 K unless otherwise stated, using a Bruker DPX400 spectrometer operating at 100.6 and 162.0 MHz, respectively, and are referenced to TMS or external 85% H_3PO_4. UV/Visible spectra were recorded by diffuse reflectance using a Perkin−Elmer Lambda19 spectrometer. Samples were diluted with $BaSO_4$. Titanium halides were obtained from Aldrich and used as received. The ligands $o\text{-}C_6H_4(PMe_2)_2$, $o\text{-}C_6H_4(PPh_2)_2$, $Ph_2As(CH_2)_2AsPh_2$, $o\text{-}C_6H_4(AsMe_2)_2$ and $MeC(CH_2AsMe_2)_3$ were prepared by literature methods,[17−20] while the other phosphane ligands were obtained from Aldrich. Dichloromethane and chloroform were dried by distillation from CaH_2 and hexane was dried by distillation from the sodium ketyl of benzophenone. Deuterated solvents were dried over molecular sieves. All preparations used rigorously anhydrous solvents and inert atmosphere techniques.

(i) [$TiCl_4(Ph_2PCH_2PPh_2)$]: $Ph_2PCH_2PPh_2$ (0.35 g, 0.91 mmol) was dissolved in dry, degassed hexane (20 cm^3) in a Schlenk flask under an atmosphere of dry N_2. $TiCl_4$ (0.1 cm^3, 0.91 mmol) was added with a syringe, resulting in immediate precipitation of a bright orange solid. The solution was stirred for ca. 30 min. and the solid filtered and dried in vacuo. Yield 0.45 g, 88%. $C_{25}H_{22}Cl_4P_2Ti$ (574.11): calcd. C 52.3, H 3.8; found C 52.0, H 3.7. − IR: ν_{Ti-Cl} = 419, 398, 385, 375 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 20.7, 28.5sh, 34.8. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.0−8.0 (m, Ph), 4.0 (t, $^2J_{H-P}$ = 10 Hz, CH_2).

(ii) [$TiCl_4(Ph_2P(CH_2)_2PPh_2)$]: Method as for (i) above, orange solid, yield 0.43 g, 80%. $C_{26}H_{24}Cl_4P_2Ti$ (588.14): calcd. C 53.0, H 4.1; found C 53.7, H 4.4. − IR: ν_{Ti-Cl} = 420, 398, 385, 376 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 20.7, 26.1sh, 34.8. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.1−7.9 (*m*, Ph), 3.0 (*d*, CH_2, $^2J_{H-P}$ = 13 Hz). − $^{31}P\{^1H\}$ NMR (CH_2Cl_2/CD_2Cl_2): δ = 24.6.

(iii) [$TiCl_4\{Ph_2P(CH_2)_3PPh_2\}$]: Method as for (i) above, orange solid, yield 0.49 g, 91%. $C_{27}H_{26}Cl_4P_2Ti$ (602.16): calcd. C 53.8, H 4.3; found C 53.6, H 4.4. − IR: ν_{Ti-Cl} = 417, 394, 369 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 20.7, 27.8 sh, 37.7. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.2−7.8 (m, Ph), 2.7 (t, CH_2), 2.2 (q, CH_2). − $^{31}P\{^1H\}$ NMR (CH_2Cl_2): 2.3 (very broad).

(iv) [$TiCl_4\{o\text{-}C_6H_4(PPh_2)_2\}$]: Method as for (i) above, orange solid, yield 0.69 g, 81%. $C_{30}H_{24}Cl_4P_2Ti$: calcd. C 56.6, H 3.8; found C 56.3, H 3.9. − IR: ν_{Ti-Cl} = 420, 408, 386, 375 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 21.3, 26.0sh, 32.3. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.0−8.2 (m, Ph). − $^{31}P\{^1H\}$ NMR ($CH_2Cl_2/CDCl_3$): δ = 34.1.

(v) [$TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}$]: Method as for (i) above, pale yellow solid, yield 0.10 g, 57%. $C_{10}H_{16}Cl_4P_2Ti$ (387.90): calcd. C 31.0, H 4.2; found C 31.2, H 4.3. − IR: ν_{Ti-Cl} = 420, 410, 382 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 22.7, 28.6, 33.0. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.6 (m, *o*-C_6H_4), 1.9 (m, Me). − $^{31}P\{^1H\}$ NMR ($CH_2Cl_2/CDCl_3$): δ = 29.5.

(vi) [$TiCl_4\{Ph_2As(CH_2)_2AsPh_2\}$]: Method as for (i) above, red solid, yield 0.26 g, 86%. $C_{26}H_{24}As_2Cl_4Ti$ (676.03): calcd. C 46.2, H 3.6; found C 46.0, H 3.7. − IR: ν_{Ti-Cl} = 401, 385, 377 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 20.0, 21.7, 25.0, 32.3. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.7−7.3 (m, Ph), 3.1 (s, CH_2).

(vii) [$TiCl_4\{o\text{-}C_6H_4(AsMe_2)_2\}$]: Method as for (i) above, pale orange solid, yield 0.16 g, 62%. $C_{10}H_{16}As_2Cl_4Ti$ (475.79): calcd. C 25.2, H 3.4; found C 25.4, H 3.5. − IR: ν_{Ti-Cl} = 422, 409, 384 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 21.9, 29.1, 33.0. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.6 (m, *o*-C_6H_4), 1.75 (s, Me).

(viii) [$TiCl_4\{MeC(CH_2AsMe_2)_3\}$]: Method as in (i), orange solid, yield 0.22 g, 86%. $C_{11}H_{27}As_3Cl_4Ti$ (573.81): calcd. C 23.0, H 4.7; found C 23.0, H 4.9. − IR: ν_{Ti-Cl} = 400, 375, 368 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 21.1, 25.3, 27.2, 34.5. − ^1H NMR (CD_2Cl_2, 300 K): δ = 0.95 (AsMe, free), 1.23 (MeC), 1.58, 1.61 (AsMe, coordinated), 1.74 (CH_2, free), 2.15 (m, CH_2, coordinated).

(ix) [$TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2$]: Method as in (i), using two molar equivalents of *o*-$C_6H_4(PMe_2)_2$, golden yellow solid, yield 0.22 g, 85%. $C_{20}H_{32}Cl_4P_4Ti$ (586.08): calcd. C 41.0, H 5.5; found C 40.6, H 5.3. − IR: ν_{Ti-Cl} = 314, 302 sh cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 20.8, 22.5, 24.0, 28.0. − ^1H NMR (CD_2Cl_2, 300 K): δ = 7.5−7.7 (m, *o*-C_6H_4), 1.88 (Me); (183 K): 7.7 (br, *o*-C_6H_4), 1.92 (m, Me). − $^{31}P\{^1H\}$ NMR ($CH_2Cl_2/CDCl_3$): δ = 31.5.

(x) [$TiCl_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2$]: Method as in (i), using two molar equivalents of *o*-$C_6H_4(AsMe_2)_2$, bright orange solid, yield 0.30 g, 89%. $C_{20}H_{32}As_4Cl_4Ti$ (761.87): calcd. C 31.5, H 4.2; found C 31.4, H 4.0. − IR: ν_{Ti-Cl} = 323 sh, 317 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 21.6, 27.6. − ^1H NMR (CD_2Cl_2, 300 K): δ = 7.6 (m, *o*-C_6H_4), 1.8, 1.74, 1.2 (s, Me).

(xi) [$TiBr_4\{Ph_2P(CH_2)_3PPh_2\}$]: $TiBr_4$ (0.15 g, 0.41 mmol) was dissolved in refluxing, dry, degassed CH_2Cl_2 (≈30 cm^3) in a Schlenk flask under an atmosphere of N_2. After cooling to room temperature, $Ph_2P(CH_2)_3PPh_2$ (0.17 g, 0.41 mmol) in CH_2Cl_2 (5 cm^3), was added to the stirring solution with a syringe, resulting in a dark red solution. The solution was stirred for ca. 30 min., and then the solvent volume was reduced in vacuo to ca. 5 cm^3. Dry, degassed hexane (20 cm^3) was added to afford a red/orange solid. This solid was filtered, washed with hexane and dried in vacuo. Yield 0.23 g, 73%. $C_{27}H_{26}Br_4P_2Ti$ (779.97): calcd. C 41.5, H 3.3; found C 42.0, H 3.5. − IR: ν_{Ti-Br} = 313, 298, 293 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 22.5, 32.7. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.2−8.3 (m, Ph), 3.0−3.6 (br, CH_2). − $^{31}P\{^1H\}$ NMR (CH_2Cl_2/CD_2Cl_2): δ = 3.5 (broad).

(xii) [$TiBr_4\{Ph_2P(CH_2)_2PPh_2\}$]: Method as for (xi) above, red solid, yield 0.26 g, 65%. − IR: ν_{Ti-Br} = 309, 299, 292 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 20.6, 25.5, 34.5. − ^1H NMR ($CDCl_3$, 300 K): δ = 6.8−7.9 (m, Ph), 4.4−4.8 (m, CH_2). − $^{31}P\{^1H\}$ NMR ($CH_2Cl_2/CDCl_3$, 300 K): δ = 13.0 (s); (200 K): δ = 15.4.

(xiii) [$TiBr_4\{o\text{-}C_6H_4(PPh_2)_2\}$]: Method as for (xi) above, red/orange solid, yield 0.26 g, 72%. $C_{30}H_{24}Br_4P_2Ti$ (813.98): calcd. C 44.2, H 2.9; found C 44.6, H 3.0. − IR: ν_{Ti-Br} = 315, 310, 304, 301 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 20.5. − ^1H NMR ($CDCl_3$, 300 K): δ = 7.0−8.3 (m, Ph, *o*-C_6H_4). − $^{31}P\{^1H\}$ NMR (CH_2Cl_2/CD_2Cl_2): δ = −10.3 (broad).

(xiv) [$TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}$]: Method as for (xi) above, orange/brown solid, yield 0.16 g, 55%. $C_{10}H_{16}Br_4P_2Ti$ (565.70): calcd. C 21.2, H 2.8; found C 21.6, H 2.9. − IR: ν_{Ti-Br} = 325 sh, 321 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 21.0, 23.3, 27.7. − ^1H NMR (CD_2Cl_2, 300 K): δ = 7.6 (m, *o*-C_6H_4), 2.03 (m, Me). − $^{31}P\{^1H\}$ NMR (CH_2Cl_2/CD_2Cl_2): δ = 24.5.

(xv) [$TiBr_4\{Ph_2As(CH_2)_2AsPh_2\}$]: Method as for (xi) above, red solid, yield 0.33 g, 78%. $C_{26}H_{24}As_2Br_4Ti$ (853.83): calcd. C 36.6, H 2.8; found C 36.3, H 3.0. − IR: ν_{Ti-Br} = 304, 295, 291, 285 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 18.9, 22.2, 28.6, 32.3. − ^1H NMR (CD_2Cl_2, 300 K): δ = 7.7−7.4 (m, Ph), 3.1 (s, CH_2).

(xvi) [$TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}$]: Method as for (xi) above, bright red solid, yield 0.17 g, 53%. $C_{10}H_{16}As_2Br_4Ti$ (653.60): calcd. C 18.4, H 2.5; found C 18.4, H 2.5. − IR: ν_{Ti-Br} = 327, 323 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 20.0, 22.6, 27.2. − ^1H NMR (CD_2Cl_2, 300 K): δ = 7.6 (m, *o*-C_6H_4), 1.9 (s, Me), 1.2 (s, Me).

(xvii) [$TiBr_4\{MeC(CH_2AsMe_2)_3\}$]: Method as in (xi), red solid, yield 0.27 g, 72%. $C_{11}H_{27}As_3Br_4Ti$ (751.62): calcd. C 17.6, H 3.6; found C 18.1, H 3.7. − IR: ν_{Ti-Br} = 326, 313, 284 cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 19.7, 21.5, 26.7, 32.3. − ^1H NMR (CD_2Cl_2, 300 K): δ = 0.96 (AsMe, free), 1.26 (MeC), 1.71 (br, AsMe, coordinated), 1.75 (CH_2, free), 2.2 (m, CH_2, coordinated).

(xviii) [$TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2$]: Method as in (xi), using two molar equivalents of *o*-$C_6H_4(PMe_2)_2$, bright orange solid, yield 0.16 g, 55%. $C_{20}H_{32}Br_4P_4Ti$ (763.88): calcd. C 31.4, H 4.2; found C 31.2, H 4.0. − IR: ν_{Ti-Br} = 280 br cm^{-1}. − UV/Vis ($\lambda_{max} \times 10^3$ cm^{-1}): 18.9, 21.5, 25.8, 29.0. − ^1H NMR (CD_2Cl_2, 300 K): δ = 7.6−7.8 (m, *o*-C_6H_4), 2.02 (m, Me); (−90 °C): 7.6−7.9 (m, Ph), 2.04−2.00 (m, Me), 1.32 (m, Me). − $^{31}P\{^1H\}$ NMR (CH_2Cl_2/

X-ray Crystallography: Details of the crystallographic data collection and refinement parameters are given in Table 1. Crystals of $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$, $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$, $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$, $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$ and $[TiBr_4\{MeC(CH_2AsMe_2)_3\}]$ were obtained by slow evaporation from a solution of the appropriate complex in CH_2Cl_2. The crystals of $[TiCl_5(Ph_2PCH_2PHPh_2)]$ were obtained as a hydrolysis product from $[TiCl_4(Ph_2PCH_2PPh_2)]$ in CH_2Cl_2. Data collection was performed with an Enraf–Nonius Kappa CCD diffractometer operating at 150 K, with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). Structure solution and refinement were routine.[21–24] Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-162704–162709. -162704: $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$, -162705: $[TiCl_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$, -162706: $[TiBr_4\{o\text{-}C_6H_4(PMe_2)_2\}_2]$, -162707: $[TiBr_4\{o\text{-}C_6H_4(AsMe_2)_2\}_2]$, -162708: $[TiBr_4\{MeC(CH_2AsMe_2)_3\}]$, -162709: $[TiCl_5(Ph_2PCH_2PHPh_2)]$. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the EPSRC for support and Professor M. B. Hursthouse for access to the Nonius Kappa CCD diffractometer.

Two-Step Spin Crossover in a Mononuclear Compound $[Fe(DPEA)(bim)](ClO_4)_2 \cdot 0.5\,H_2O$[DPEA = (2-Aminoethyl)-bis(2-pyridylmethyl)amine, bim = 2,2-Bisimidazole] − Crystal Structure, Magnetic Properties, Mössbauer Spectroscopy, and Photomagnetic Effects

Dedicated to the memory of André Collet and Olivier Kahn

Keywords: Iron / N ligands / Spin crossover / Mössbauer spectroscopy / Photomagnetism

The synthesis and characterization of the new spin crossover mononuclear complex $[Fe^{II}(DPEA)(bim)](ClO_4)_2 \cdot 0.5\,H_2O$, where DPEA = (2-aminoethyl)bis(2-pyridylmethyl)amine and bim = 2,2-bisimidazole, are reported. Variable-temperature magnetic susceptibility measurements (77–295 K) reveal the occurrence of a two-step spin transition. Two steps on the magnetic curve are separated by an inflection point at 200 K, corresponding to about 50% of the complexes that have undergone a thermal spin transition. The first step is centered at 171 K and the second one at 218 K. Mössbauer spectroscopy and X-ray analysis show that the profile of the magnetic curve is a consequence of the presence of two inequivalent iron(II) molecules in the crystal lattice. The crystal structure was resolved at 293 K (high-spin form) and at 123 K (low-spin form). Both spin-state isomers belong to the monoclinic space group $P2_1/c$ ($Z = 4$). The main differences between high-spin and low-spin isomers are found in the geometry of the $[FeN_6]$ core, the shorter Fe–N distances are seen at lower temperatures. Two inequivalent HS molecules at lattice sites **1** and **2** successively undergo a thermal spin transition. The analysis of the mean Fe–N distances for functionally different nitrogen donor atoms show that the two steps of the spin transition can be assigned to the inequivalent lattice sites. The gradual character of the spin transition at both lattice sites is accounted for in terms of intermolecular H-bonding via the perchlorate ions. At 10 K the light-induced excited spin state trapping (LIESST) effect is observed within the SQUID magnetometer cavity. Two critical temperatures T_c(LIESST) were recorded (36 K and 21 K) and are attributed to the lattice sites **1** and **2**.

Introduction

During the last few decades coordination chemistry has provided many examples of new iron(II) compounds exhibiting high-spin (HS, $^5T_2$) ↔ low-spin (LS, $^1A_1$) transitions, which have been extensively studied using various techniques.[1] The proximity of HS and LS electronic states in an isolated molecule, governed by the interplay between the electron-pairing energy and the ligand field, is a prerequisite for the occurrence of a spin transition. The change of the molecular equilibrium geometry accompanying a spin transition in the solid state occurs through intermolecular interactions, leading to more or less pronounced cooperative effects. Different intermolecular interactions such as H-bonding, π-stacking, van der Waals interactions can act as the communication link between neighboring molecules. Several theoretical models have been proposed to account for cooperativity in spin transition.[2]

The crystal structure plays an important role in the shaping of spin transition. Packing effects appear as a small perturbation on the interplay between the ligand field and the interelectronic interactions. Besides this they determine the propagation pattern of the cooperative interactions in the solid. The influence of packing effects on the spin-state of the complex is neither predictable, nor controllable and can

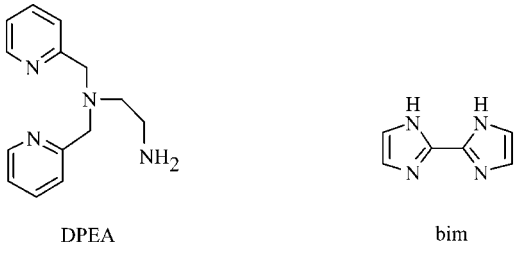
lead to different situations. One such situation involves the existence of several polymorphic modifications with differing magnetic behavior for a single compound.[3,4] Recently, we have isolated, under the same experimental conditions, three polymorphic modifications of the [Fe(DPPA)$(NCS)_2$] complex, where DPPA = (3-aminopropyl)bis(2-pyridylmethyl)amine.[4] A detailed study has revealed that one polymorph undergoes a gradual spin transition, the second remains high-spin at temperatures down to 4.5 K and the third exhibits a spin transition with hysteresis. Another situation arises when several crystallographically independent iron(II) sites co-exist in the same unit cell. The structural distinctions among iron(II) complexes can result in their different magnetic behavior. In the iron(II) complex $[Fe(mtz)_6](BF_4)_2$ (mtz = 1-methyl-1*H*-tetrazole), one site remains in the HS form until 4.2 K and the second undergoes a thermal spin transition.[5] Two lattice sites can be selectively converted into their spin isomers at low temperature by irradiating light at different frequencies. A similar feature was observed for $[Fe(etz)_6](BF_4)_2$ (etz = 1-ethyl-1*H*-tetrazole).[6] In the crystal of the iron(II) complex of C_3-cyclotriveratrylene ligand,[7] one site is occupied by LS species, whereas the other shows a temperature-independent mixture of HS and LS states. In the spin-equilibrium complex $[Fe(tren)](ClO_4)_2 \cdot {}^2/_3H_20$ [tren = tetrakis(2-pyridylmethyl)ethylendiamine)], one of two cation sites has a greater HS content, and both sites act quasi independently in the HS $\leftrightarrow$ LS conversion.[8] In the recently reported compound $[Fe(btr)_3](ClO_4)_2$ (btr = 4,4′-bis-1,2,4-triazole), the presence of two slightly different Fe^{II} sites generates the two-step spin transition with a plateau.[9] Another case of the two-step transition is represented by [Fe(5-NO_2-sal-N(1,4,7,10)] (the ligand results from the Schiff base condensation of 5-nitrosalicylaldehyde with tetraazadecane), in which two inequivalent lattice sites appear as a result of the structural phase transition on cooling.[10]

Here we report on the detailed characterization of a new spin transition complex $[Fe(DPEA)(bim)](ClO_4)_2 \cdot 0.5\ H_2O$, with DPEA = (2-aminoethyl)bis(2-pyridylmethyl)amine and bim = 2,2-bisimidazole (Scheme 1). The single-crystal X-ray structure at 293 K (HS form) and 123 K (LS form), magnetic susceptibility, Mössbauer spectra and photomagnetism of this complex are investigated. The presence of two inequivalent molecules in the crystal lattice both undergoing thermal spin conversion results in a two-step magnetic behavior. The LIESST (light-induced excited spin state trapping)[11] experiments reveal a partial conversion of the LS state into the HS state for both sites.



DPEA bim

Results

Description of the Structure

The crystal structures of $[Fe(DPEA)(bim)](ClO_4)_2 \cdot 0.5\ H_2O$ in both HS and LS states were resolved by X-ray crystallography at 293 K and 123 K, respectively. The X-ray analysis did not reveal a change in the space group over the temperature range 123−293 K, and both spin-state forms belong to the monoclinic space group $P2_1/c$ (Z = 4). The unit cell contains two crystallographically independent iron(II) sites **1** and **2** (Figure 1), occurring in equal amounts in general positions. Selected bond lengths and angles are given in Table 1 and Table 2, respectively. The $[FeN_6]$ core is formed by two imino nitrogen atoms of 2,2-bisimidazole and by four nitrogen atoms of the tetradentate DPEA ligand. The latter is coordinated to the iron(II) atom via two pyridine nitrogen atoms in apical positions and by two aliphatic amino groups in adjacent positions. Thus, due to the meridionally arranged DPEA pyridine rings, both inequivalent iron(II) complexes represent the achiral *mer* isomer, as was also observed for $[Fe(DPEA)(NCS)_2]$.[12] Despite some

[a] Estimated standard deviations in the least significant digits are given in parentheses.

differences in the corresponding bond lengths and angles of the two inequivalent $[FeN_6]$ octahedrons, their configurations are the same at both temperatures.

(a) High-Spin Complex Structure (T = 293 K)

The similar $[FeN_6]$ octahedrons in the two inequivalent molecules are strongly distorted. The two Fe−N distances involving the 2,2-bisimidazole ligand are rather different [site **1**: Fe1−N101 = 2.130(4) Å, Fe1−N102 = 2.233(4) Å; site **2**: Fe2−N201 = 2.134(4) Å, Fe2−N202 = 2.253(4) Å]. The Fe−N(DPEA) bond lengths also differ considerably for the aromatic and aliphatic nitrogen donor atoms within each site and between both sites (see Table 1). The corresponding N−Fe−N angles at both lattice sites are rather similar (Table 2). They fall within 75.6(2)−107.9(2)° for adjacent nitrogen atoms and 152.8(2)−178.5(2)° for opposite nitrogen atoms, instead of 90 and 180° that would be observed in an ideal octahedron. The largest deviations from 90° are observed in the five-membered chelate rings (see Table 2). Evidently, this severe distortion of the $[FeN_6]$ core from O_h symmetry is due to the steric constraints caused by the coordination of the tetradentate and bidentate ligands.

The large values of the equivalent isotropic displacement parameter at room temperature reflect a disorder of the perchlorate anions and the solvent water molecules in the crystal. The disordered character of the packing of the ClO_4 groups is also displayed in the variation of the distances and angles. The Cl−O bond lengths in four ClO_4 groups arising from two sites are in the range 1.277(6)−1.420(5) Å. The angles Cl−O−Cl fall within the range 98.4(5)−120.6(6)°, instead of 109° for an ideal tetrahedron. It has not been possible to split the atom positions into several different orientations.

The crystal packing of [Fe(DPEA)(bim)]$(ClO_4)_2$·0.5 H_2O consists of alternate layers originating from the Fe1 and Fe2 molecule sets parallel to the *bc* plane. Figure 2 shows a projection of the structure along the *b* axis. Each layer can be considered as being formed by the columns of complex cations along the *b* direction. The columns of the complex cations at lattice sites **1** and **2** result from the symmetry operations ($-x$, $-{}^1/_2 + y$, ${}^1/_2 - z$) and ($1 - x$, $-{}^1/_2 + y$, ${}^1/_2 - z$), respectively. The nearest complexes in the columns are linked by π-stacking interactions resulting from a par-

tial overlap of the pyridine rings of the DPEA ligand, which can be illustrated by the corresponding C···C intermolecular contacts (see Table 3). The dihedral angles between the stacked pyridine planes of the adjacent molecules are 9.6(4) and 20.2(4)° at lattice sites **1** and **2**, respectively. Each column is surrounded by perchlorate anions, yielding the electrically neutral layers of molecules. The solvent water molecules are inserted between the layers. The cohesion within a layer, as well as between neighboring layers is achieved by numerous H-bonds involving the oxygen atoms of the perchlorate ions. Moreover, these indirect H-bonds are realized either by means of the same oxygen atom of the perchlorate ion, or by the different ones. Detailed information on the hydrogen-bonding interactions is listed in Table 4.

(b) Low-Spin Complex Structure (T = 123 K)

The comparison of the HS and LS complex structures shows that the molecular configuration of the two forms essentially remains unchanged. The main difference between them involves the variation of the octahedral geometry of the $[FeN_6]$ core. The HS → LS transition is accompanied by the shortening of the Fe−N bond lengths, the degree of which is dependent on the chemical nature of the nitrogen atoms. In the LS complex two Fe−N(bim) distances are shorter by 0.134 Å (Fe1−N101) and 0.193 Å (Fe1−N102) at lattice site **1**, relative to 0.141 Å (Fe2−N201) and 0.193 Å (Fe2−N202) at lattice site **2**. The reduction of the Fe−N(DPEA) mean distances to the aromatic and aliphatic nitrogen atoms at both lattice sites are 0.211 Å (Fe1−N_{arom}) and 0.190 Å (Fe1−N_{aliph}), and 0.190 Å (Fe2−N_{arom}) and 0.195 Å (Fe2−N_{aliph}). The N−Fe−N angles, which are significantly distorted in the HS complex, are closer to 90° and 180° in the LS complex. The range of the N−Fe−N angles for both lattice sites in the LS $[FeN_6]$ core is 80.5(1)−99.5(1)° and 165.0(1)−179.6(1)°. Clearly, the HS → LS transition is followed by the rearrangement of the $[FeN_6]$ octahedron into a more regular geometry.

The perchlorate anion positions, which are disordered at high temperatures, are far less perturbed at low temperature. The Cl−O distances are in the range 1.372(4)−1.445(3) Å. The Cl−O−Cl angles range from 104.9(2) to 113.4(4)°, and approach the regular tetrahedron value. The disordered nature of the solvent water molecules, which is noted at room temperature, is also reduced at low temperatures.

The crystal packing in the LS complexes is similar to that in the HS state, but more compact. This is consistent with the decrease in the volume of the unit cell by 5.66% and the increase in the density from 1.600 to 1.696 g/cm^3 on lowering the temperature to 123 K. In the columns of the

cation complexes, the interplanar distances between the overlapping pyridine rings of the DPEA ligand are slightly reduced relative to the HS structure, as can be seen from the C···C intermolecular distances (Table 3). The dihedral angles between the adjacent stacked pyridine rings in the LS structure are reduced to 5.7(4) and 15.3(4)° at lattice sites **1** and **2**, respectively. It appears that in the LS structure the overlap between pyridine rings is more effective. As in the case of the HS form, no direct intermolecular interactions between the complexes from the different columns have been detected. The cohesion between the columns of complexes within a layer, as well as between the columns from neighboring layers, is maintained by numerous H-bonds. Data on the hydrogen-bonding interactions are listed in Table 4.

Magnetic Susceptibility Data

Variable-temperature magnetic susceptibility data were collected in both cooling and warming modes in the temperature range 290−77 K and are presented as $\chi_M T$ versus T plots in Figure 3. This magnetic behavior indicates a gradual spin transition between high-spin ($S = 2$) and low-spin ($S = 0$) electronic states. At 290 K, the magnitude of $\chi_M T$ is 3.13 $cm^3 \cdot mol^{-1} \cdot K$ ($\mu_{eff} = 5.01\ \mu_B$) which corresponds to a quintet spin-state. This value continuously decreases on cooling to 77 K, to reach a value of 0.02 $cm^3 \cdot mol^{-1} \cdot K$ ($\mu_{eff} = 0.40\ \mu_B$), which is close to the expected temperature-independent paramagnetism value for singlet spin state iron(II) complexes. Furthermore, the absence of residual paramagnetism at low temperatures, as confirmed by Mössbauer spectroscopy (vide infra), suggests that the spin transition is practically complete. Examination of the shape of the magnetic curve reveals that the spin transition takes place in two steps, separated by an inflection point at about 200 K. Approximately 50% of the complexes undergo a thermal spin transition at this temperature. The high-temperature and low-temperature steps are centered at about 218 and 171 K, respectively.

Mössbauer Spectroscopy

The temperature-dependent ^{57}Fe Mössbauer spectra of [Fe(DPEA)(bim)]$(ClO_4)_2 \cdot 0.5\ H_2O$ were recorded between 80 and 295 K. Figure 4 shows six relevant spectra obtained in the cooling mode. Fitting parameters for all spectra are given in Table 5. The low- and high-temperature spectra are characteristic for the LS and HS states of iron(II). According to the X-ray study (vide supra), the crystal lattice of [Fe(DPEA)(bim)]$(ClO_4)_2 \cdot 0.5\ H_2O$ incorporates two inequivalent iron(II) molecules with slightly different $[FeN_6]$ core geometries. The Mössbauer spectra also clearly agree with the presence of two spin crossover sites in the system.

The thermal variations of the quadrupole splitting and the isomer shift of the HS and LS doublets are shown in Figure 5. The thermal variation of the isomer shift of the LS and HS1 doublets is linear and follows the classical 2nd order Doppler shift law. The isomer shift of the HS2 doublet remains approximately constant between 80 and 295 K. The range of values (2.00−1.81 $mm \cdot s^{-1}$ for the first site and 2.4−2.0 $mm \cdot s^{-1}$ for the second site) of the quadrupole splitting ΔE_Q(HS) between 170 and 295 K is indicative of a strong distortion from cubic symmetry. This is also seen from the X-ray data, and suggests that the orbital levels are not degenerate. The orbital energy splittings can be obtained through the analysis of the thermal variation of the quadrupole splitting.[13] The ratio of the average energy splittings between the fundamental and first excited orbital states for the two sites ($\Delta E1$ and $\Delta E2$) gives a rough estimate of the relative degree of their distortion and can be evaluated from both the Ingalls's model[13] and ref.[10] and ref.[14] The ratio $\Delta E2/\Delta E1 = 0.74$ is obtained {$\Delta E = 570$ and 420 cm^{-1} and $\Delta E_Q(0\ K) = 2.06$ and 2.59 mm/s for sites **1** and **2**, respectively} when the thermal variation of the quadrupole splitting is fitted to the Ingalls's model[13] {$\Delta E_Q(T) = \Delta E_Q(0\ K) \times \tanh[\Delta E/2K_BT]$}. The same value for the ratio $\Delta E2/\Delta E1 = p_1/p_2 = 0.7$ was obtained from the slopes ($p_1 = 2 \cdot 10^{-3}$ $mm \cdot s^{-1} \cdot K^{-1}$ and $p_2 = 1.36 \cdot 10^{-3}$ $mm \cdot s^{-1} \cdot K^{-1}$) of the thermal variation of ΔE_Q(HS).[10,14] In systems with two non-equivalent Fe^{II} sites, the Mössbauer spectra would be expected to reveal two clearly separated quadrupole doublets. However, because of the temperature variation of the quadrupole splitting[10,14] and the similar

symmetries of the sites **1** and **2**, the two complexes cannot be easily separated. At high temperatures, the quadrupole splittings for the two sites with similar geometry almost merge, resulting in essentially one doublet.

On cooling, the $[Fe(DPEA)(bim)](ClO_4)_2 \cdot 0.5\ H_2O$ complex undergoes the HS → LS transition. On spin conversion the spectra show the co-existence of the HS and LS isomers, with strongly temperature-dependent relative intensities. At 80 K, the spectrum consists of one quadrupole doublet with typical parameters for the iron(II) LS state (Table 5), and the HS → LS transition at both **1** and **2** sites is complete, as seen by the absence of a residual HS fraction. The temperature at which 50% of the complexes undergo thermal spin transition is found to be close to 200 K. Curves showing the thermal variation of the total high-spin fraction n_{HS}, as determined from Mössbauer measurements and independently from magnetic susceptibility data, are in reasonable agreement as shown in the inset of Figure 5. In order to confirm the two-step character of the spin crossover, DSC measurements were carried out (Figure 6). Two peaks around 170 and 220 K are observed, which corresponds to the transition temperatures found from the thermal variation of the high-spin fraction for the two sites of the system obtained by Mössbauer spectroscopy (Figure 6). This confirms the two-step character of the spin transition in the present complex.

Photomagnetic Properties

The LIESST experiments were performed at 10 K on a very thin layer of powder sample. The weight was estimated by comparing the thermal spin crossover curve with the curve recorded with a heavier and accurately weighed sample. The sample was irradiated using different wavelengths accessible with the Laser-Diode (830±15 nm) and with the Kr^+ Laser; i.e. single-line 530.9 nm, multi-lines 647.1−676.4 nm and 752.3−799.3 nm.

At 10 K, the magnetic response of the sample without irradiation was diamagnetic (LS state). Irradiation with the wavelengths accessible with the Kr^+ Laser or the Laser-Diode resulted in a rapid increase of the magnetic response (Figure 7). This peculiar behavior may be assigned to a conversion into the HS state, according to the well-known LIESST effect.[11] It is worth noting that independent of the wavelengths used, the power applied and the irradiation time, the highest LS → HS conversion reached was about 40%. The optimal conversion was obtained with the multilines 647.1−676.4 nm at a power of 20 mW/cm^2 and after 2 hours of irradiation. In contrast, the irradiation of the compound at 830 nm induced only 5% of HS state, whereas tetrazole iron(II) derivatives exhibited a reverse-LIESST ef-

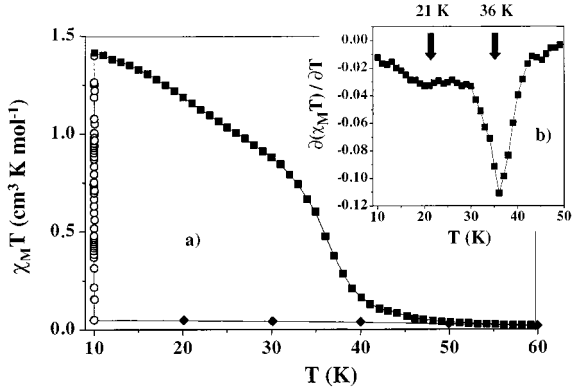

Figure 7. a) Temperature-dependence of $\chi_M T$ for [Fe(DPEA)(bim)]$(ClO_4)_2$·0.5 H_2O: (◆) data recorded in the cooling mode without irradiation; (○) data recorded with irradiation for 2 h at 10 K; (■) data recorded in the warming mode (0.3 K min^{-1}) after light irradiation was applied for two hours, then turned off. b) Derivative $\partial(\chi_M T)/\partial T$

fect instead.[15][11b] The most straightforward explanation for this difference is that the weak $^5T_2 \rightarrow {}^5E$ absorption band is totally overlapped by the intense ^{1}MLCT band involving the aromatic rings of the organic ligand.

We have recently proposed that the capacity of a compound to retain the light-induced HS information may be estimated through the determination of the T_c(LIESST) value.[16] By using the same procedure, we recorded the photomagnetic properties of [Fe(DPEA)(bim)]$(ClO_4)_2$·0.5 H_2O. After 2 hours of irradiation at 10 K, a photostationary limit was reached. The light was turned off and the temperature was slowly increased (0.3 K·min^{-1}). Figure 7 shows the temperature dependence of $\chi_M T$, which gradually decreases until 30 K and then rapidly drops to a value close to zero around 50 K. The $\partial(\chi_M T)/\partial T$ versus T plot reveals a clear minimum at a temperature of 36 K and also a second minimum is present around 21 K. This suggests that for both sites **1** and **2** the LS → HS conversion occurs under light-irradiation. The shape of the $\partial(\chi_M T)/\partial T$ vs. T plot nevertheless indicates a more effective LS → HS conversion for the site with the T_c(LIESST) at 36 K than for the site at 21 K.

Figure 8 shows the HS → LS relaxation curve recorded at 10 K. These data reveal a strong deviation from the single exponential law. The time-dependence of the high-spin fraction γ_{HS} is fast at first and then slows down. This behavior has been previously reported[17] and attributed to the local non-homogeneities of the iron(II) environment in the [FeN_6] core. Hauser et al.[17a] have proposed an analysis of the $\gamma_{HS}(t)$ curves based upon a distribution of relaxation rates $k_{HL}(T)$ and a corresponding repartition of the activation energy. In the [Fe(DPEA)(bim)]$(ClO_4)_2$·0.5 H_2O case, the situation is more complicated due to the population of sites **1** and **2**; i.e. each site may possess an exponential decay and hence the HS → LS relaxation curves may follow the bi-exponential law [Equation (1)].

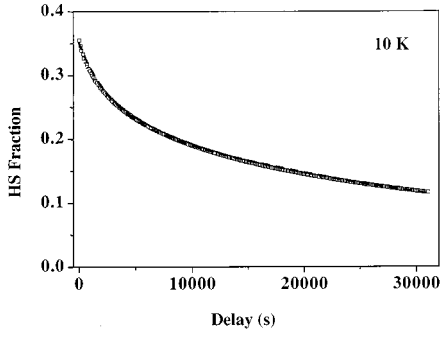

Figure 8. The HS → LS relaxation curve recorded at 10 K. The dashed line represents the fitted curve

$$\gamma_{HS} = A_1 \exp(-k_{HL}^1 t) + A_2 \exp(-k_{HL}^2 t) \quad (1)$$

The solid line shown in Figure 8 results from the least-squares fit of the relaxation data to Equation (1). It can be seen that a good fit of the data has been found with the biexponential law. The numerical fit results in values of $2.3 \cdot 10^{-5}$ s^{-1} and $3.4 \cdot 10^{-4}$ s^{-1} for k_{HL}, and of 0.24 and 0.11 for pre-exponential factors. Note that this relaxation curve can also be fitted by using a Gaussian distribution of activation energy centered at 50 cm^{-1} with a standard deviation of 12 cm^{-1} and a pre-exponential factor of $6.5 \cdot 10^{-2}$ s^{-1}. This gives a k_{HL} value of $5 \cdot 10^{-5}$ s^{-1}. However, the large standard deviation that arises in the latter case suggests that the bi-exponential analysis related to the two independent lattice sites is the more likely scenario.

Discussion

Relation Between the Structure and Spin Transition Properties

The synthesis and investigation of the title complex were undertaken with the aim of modifying the spin transition properties of the complex *mer*-[Fe(DPEA)$(NCS)_2$].[12] The latter manifests a sharp spin conversion close to the first-order transition. We expected that the replacement of two NCS groups by a bidentate ligand more predisposed to the intermolecular H-bonding, might enhance the cooperativity and eventually lead to a spin transition with hysteresis. The 2,2-bisimidazole molecule, containing two NH groups, was selected for this purpose. To the best of our knowledge, there are no data regarding iron(II) spin transition complexes with 2,2-bisimidazole in the literature. Contrary to expectation, the [Fe(DPEA)(bim)]$(ClO_4)_2$·0.5 H_2O complex exhibits a very gradual two-step spin transition which was revealed by the magnetic measurements, Mössbauer spectroscopy and differential scanning calorimetry. To date, there have been three reports in the literature describing the two-step behavior in spin crossover systems. The first one arises from the static density waves of HS complexes in the crystal lattice with a unique crystallographic Fe^{II} site.[18] The second one relates to binuclear complexes.[19] It is known that 2,2-bisimidazole can act not only as a bidentate chelating ligand but also as a bridging tetradentate one.[20] The third reason for the two-step behavior may be due to the presence of two inequivalent sites in the crystal lattice.

The X-ray analysis of [Fe(DPEA)(bim)]$(ClO_4)_2$·0.5 H_2O shows that the unit cell contains two inequivalent molecules with analogous configurations. The average Fe−N distances at both lattice sites **1** and **2** are almost identical and equal to 2.189 and 2.185 Å at 293 K, and 2.001 and 2.002 Å at 123 K, respectively. The closeness of the mean Fe−N distances in both inequivalent HS molecules does not allow the two steps of the spin transition, which arise on cooling, to be attributed to lattice sites **1** and **2**. In order to address this question we must analyze separately the bond lengths for three pairs of functionally distinct nitrogen atoms, which form the first coordination sphere of iron(II), namely, imidazolic imine, pyridinic imine and aliphatic amine types. In the HS state, the mean Fe−N(imidazole), Fe−N(pyridine), and Fe−N(amine) distances are 2.182, 2.195, and 2.191 Å, respectively at lattice site **1**, compared with 2.194, 2.160, and 2.203 Å, respectively at lattice site **2**. In other words, the mean Fe−N(pyridine) distance is shorter by 0.035 Å at site **2**, whereas the mean Fe−N(imidazole) and Fe−N(amine) distances at this same site are both longer by 0.012 Å. The occurrence of the spin transition depends on the magnitude of the ligand field strength, and the ligand field strength depends on the metal−ligand distance (as $\approx 1/r^5$) and on the nature of the donor atoms. Three functionally distinct types of nitrogen donor atoms contribute, in differing degrees, to the overall magnitude of the ligand field.[1d] The main contribution arises from the aromatic pyridine ligands, participating in both σ- and π-bonding interactions and favoring the LS state in iron(II) complexes. The contribution of the imine nitrogen atoms of 2,2-bisimidazole is much weaker due to the lack of aromaticity. Indeed, the $[Fe(bim)_3]SO_4$ complex is paramagnetic.[21] The ligand field produced by the aliphatic amine nitrogen atoms is still weaker and is entirely determined by σ interactions. It is clear that the spin transition sequence at lattice sites **1** and **2** is dependent on the difference in the Fe−N(pyridine) distances. The shorter mean Fe−N(pyridine) distance at lattice site **2** (by 0.035 Å) ensures a stronger overall ligand field and can be regarded as favoring the higher temperature spin conversion. However, it is unlikely that the inflection point near 200 K separates two successive and independent spin transitions. As it follows from the Mössbauer data, it results from the overlap of two gradual spin processes with close transition temperatures. Under such conditions the X-ray study near the inflection point, which proved to be useful in the case of the two sharp steps separated by a plateau,[9,10] cannot distinguish spin states at two lattice sites.

It could be noted that the order-disorder transition of both the solvent molecules and the perchlorate anions on cooling might also be a reason for the different change in spin state for the two sites. However, the intrinsic structural distinction of the two Fe^{II} sites found from the X-ray data, and resulting in the difference in the overall ligand field (also displayed by the two values of the crystal field distortion parameter) seems to be a more likely explanation for the two-step transition behavior.

The X-ray analysis confirms that our goal of generating a branched network of intermolecular links in the crystal lattice has been attained (Table 3 and Table 4). Nevertheless, the spin transition is rather gradual. Let us consider the structural features responsible for cooperative interactions in [Fe(DPEA)(bim)]$(ClO_4)_2$·0.5 H_2O. The layers of Fe1 and Fe2 molecules alternate parallel to the *bc* plane, forming two similar interpenetrating sublattices (Figure 2). The cooperativity within a sublattice is assured by two different types of intermolecular interactions. The pyridine rings of the DPEA ligand of neighboring complexes partially overlap resulting in the columns of π-stacked molecules extended along the *b* direction. The Fe−Fe distances in columns for two HS sublattices, 7.455(1) and 7.417(1) Å, are rather short in comparison with the values for several other spin-crossover systems.[22] At 123 K, the C···C intermolecular contacts become shorter and some new contacts appear (Table 3), probably due to a more parallel arrangement of the pyridine rings. The second type of intermolecular interactions is represented by hydrogen-bonds (Table 4), forming a branched network. The H-bonds propagate preferentially in the *a* and *c* directions where they link the complexes of neighboring columns from the same or from different sublattices. The H-bonds between the molecules within the columns are less numerous. All hydrogen-bonds between the complexes are indirect and pass through the oxygen atoms of the perchlorate anions. As a result, the corresponding Fe−Fe distances are rather long and vary in the range 9.764(2)−14.936(3) Å within the HS sublattices and 9.466(2)−20.234(5) Å between them. The majority of the H-bonds involve the atoms belonging to the second coordination sphere of the Fe^{II} ion. Only four of the sixteen hydrogen-bonds include the nitrogen atoms directly linked to Fe^{II} and can be represented schematically as N−H···O(ClO_4) or N−H···O(ClO_4)···H−C. At 123 K, several new H-bonds appear but the overall network essentially does not change relative to the HS state. The indirect character of the hydrogen-bonds and the non-branched one-dimensional system of the intermolecular π-stacking do not provide a good basis for a strong cooperativity resulting in a gradual spin transition in [Fe(DPEA)(bim)]$(ClO_4)_2$·0.5 H_2O. It can reasonably be concluded that the various ways referred to above of propagating intermolecular interactions are responsible for the anisotropy in the unit cell contraction (2.15, 0.03, and 1.94% for the *a*, *b*, and *c* axes, respectively) on cooling.

Two distinct iron(II) lattice sites are also manifested in the LIESST process. The HS conversion after light irradiation at 10 K results in the two minima in the $\partial(\chi_M T)/\partial T$ versus T plot (Figure 7). The corresponding T_c(LIESST) values are 21 K and 36 K, with a less pronounced minimum for the first temperature. This shows that the relaxation at one of the two lattice sites is faster than at the other. The lifetime of the HS species at 10 K was recorded over a 10-hour period. As has already been reported for other spin crossover compounds exhibiting a LIESST effect, the HS → LS relaxation curves deviate markedly from single exponential behavior. The numerical data can be fitted both by

using a Gaussian distribution of activation energy and with a biexponential decay that considers two independent lattice sites. In this latter case, the numerical analysis shows that one of the two lifetimes is very short. This may explain why the HS conversion does not exceed 40%. In fact, the photostationary point reached after irradiation is due to a critical balance between light population and HS → LS relaxation.

According to the theory of nonadiabatic multiphonon relaxation,[23] the characteristic features of the relaxation rate constant are a temperature-independent tunneling rate at low temperatures and a thermally activated process at elevated temperatures. At low temperatures, the lifetimes of the HS species depend on both the Huang−Rhys factor, S, which is a measure of the horizontal displacement of the potential wells of the HS and LS states, and the energy gap $\Delta E°_{HL}$ HL between the lowest vibronic levels of the HS and LS states. Hauser et al.[24] proposed that S does not vary to a large extent within the series of $[FeN_6]$ compounds, whereas the energy difference and thus the reduced energy gap $p = \Delta E°_{HL}/h\omega$ varies from $p < 1$ for samples with $T_{1/2}$ below 100 K to $p > 10$ for LS compounds. The thermal spin transitions in $[Fe(DPEA)(bim)](ClO_4)_2 \cdot 0.5\ H_2O$ located at 171 K for lattice site **1** and at 218 K for site **2** correspond to a higher $\Delta E°_{HL}$ HL (and thus p) value for site **2**. Note that the Δr_{HL} values recorded by X-ray diffraction are similar for the two lattice sites (0.188 and 0.183 Å), and hence S can be assumed to be quasi constant. According to the inverse energy-gap law reported for $[FeN_6]$ core compounds, the increase in the p factor between the two lattice sites enables the faster relaxation to be attributed to lattice site **2**. Consequently, T_c(LIESST) around 21 K corresponds to the relaxation of site **2**, and that at 36 K to site **1**. The relaxation rates estimated at 10 K with both the biexponential fit and the Gaussian distribution are in the range $10^{-4}-10^{-5}\ s^{-1}$. These values, as well as those observed recently for other $[FeN_6]$ compounds[17b] exceed the values predicted by the inverse energy-gap law[24] with $S \approx 50$. Generally, this discrepancy can be accounted for by large changes in the Fe−N bond lengths, which do not agree with the theoretical approximations. The Δr_{HL} change (≈ 0.19 Å) for $[Fe(DPEA)(bim)](ClO_4)_2 \cdot 0.5\ H_2O$ is in the same range as for other $[FeN_6]$ core compounds (0.16−0.21 Å). It is clear that the LIESST effect is controlled by many parameters, which are not all identified yet. More extensive studies should be carried out.

Experimental Section

Materials: All reagents and solvents used in this study are commercially available and were used without further purification. All syntheses involving Fe^{II} species were carried out in deoxygenated solvents under an inert atmosphere of N_2 using glovebox techniques. (2-Aminoethyl)bis(2-pyridylmethyl)amine (DPEA) was obtained according to the procedure we have recently reported.[12] 2,2-Bisimidazole (bim) was prepared as described previously.[25] ^1H NMR spectra were recorded in $CDCl_3$ on a Bruker AC200 spectrometer operating at 200 MHz. Elemental analyses (C, H N, Cl, and Fe determination) were performed at the Service Central de Microanalyse du CNRS in Vernaison.

Caution: The perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small quantities of the compound should be prepared and handled with much care!

Synthesis of the Iron(II) Complex: $Fe(ClO_4)_2 \cdot 6\ H_2O$ (72.6 mg, 0.2 mmol) was dissolved in 8 mL of ethanol/methanol (5:1 mixture) and 2,2-bisimidazole (26.8 mg, 0.2 mmol) was added to it. A yellow solution was formed. After the addition of (2-aminoethyl)bis(2-pyridylmethyl)amine (48.4 mg, 0.2 mmol) in 2 mL of the same mixture of alcohols, the solution turned red-brown. The solution was filtered and allowed to stand overnight at room temperature, affording yellow-brown crystals of $[Fe(DPEA)(bim)](ClO_4)_2 \cdot 0.5\ H_2O$ which were collected by filtration, washed with ethanol, and dried in vacuum. The crystal used in the X-ray structure determination was selected from this sample. Yield: 56%. − $C_{20}H_{25}Cl_2FeN_8O_{8.5}$ (640.2): calcd. C 37.52, H 3.94, N 17.50, Cl 11.08, Fe 8.72; found C 37.68, H 3.98, N 17.74, Cl 11.22, Fe 8.77.

Magnetic Properties: Magnetic susceptibility measurements were carried out using two instruments: (i) A Manics DSM-8 fully automated Faraday-type magnetometer equipped with an DN-170 Oxford Instruments continuous-flow cryostat and a BE 15f Bruker electromagnet operating at ca. 0.8 Tesla and in the 80−300 K temperature range; (ii) a MPMS-55 QuantumDesign SQUID magnetometer operating at ca. 2 Tesla in the 2−300 K temperature range. Data were corrected for the magnetization of the sample holder and for diamagnetic contributions.

LIESST experiments were realized using a Spectra-Physics series 2025 Ker^+ laser system coupled through an optical fiber to the cavity of a MPMS-55 Quantum Design SQUID magnetometer. The wavelengths at 830±15 nm were generated using a Laser Diode SDS-2360-L2. The measurements were performed on a very thin layer of powder sample. The weight was estimated by comparing the thermal spin crossover curve with that for a heavier and accurately weighed sample.

Mössbauer Spectra: The variable-temperature Mössbauer measurements were obtained on a constant-acceleration spectrometer with a 50 mCi source of ^{57}Co (Rh matrix). The isomer shift values (δ) are given with respect to metallic iron at room temperature. The absorber was a sample of microcrystalline powder enclosed in a 2 cm diameter cylindrical plastic sample holder, the size of which had been determined to optimize the absorption. The variable-temperature spectra were obtained in the range 80−305 K, using a MD306 Oxford cryostat, the thermal scanning was monitored by an Oxford ITC4 servocontrol device (±0.1 K). Fitting parameters for all spectra (Table 5) were obtained by using a least-squares computer program.[26] The standard deviations of statistical origin are given in parentheses. As a Mössbauer fitting criteria, in order to get correct parameters of the Mössbauer spectra components for the present compound, it was important to find a good starting point for the fitting procedure. The spectrum at 210 K was selected for this goal, since it is the only case where two components of the HS state can be separated, even visually. Once this spectrum fits well, the starting points of the fitting procedure for other spectra were obtained smoothly and continuously varying the Mössbauer parameters.

Differential Scanning Calorimetry (DSC): Calorimetric measurements were obtained with a NETZSCH DSC-204 differential scanning calorimeter. The instrument was calibrated at solid cyclohexane transition and melting temperatures, and at the mercury melt-

ing temperature. 27 mg of the sample was used in an aluminium sample-holder. An identical aluminium holder was used as a reference. The scan rate of the measurements in the cooling and heating modes was 10 K·min^{-1}. The temperature values are measured with a ±0.4 K accuracy and the uncertainty on the enthalpy values is ±2%. All results were analyzed with an integrated PROTEUS Analysis computational program.

Solution and Refinement of the X-ray Structure: A Nonius Kappa CCD diffractometer was used for data collection. The selected crystal was mounted on a thin glass fiber. Two collections were made: one at the room temperature and the second at 123 K after a very slow decrease of the temperature with a cold nitrogen gas flow at a rate of 0.3 K·min^{-1}. From 10 frames with 1° steps, the initial set of cell parameters was obtained for each measurement. A total of 42881 reflections were collected at room temperature, of which 12124 unique reflections were used for the structure determination. The second collection at 123 K involved 45394 measured reflections of which 11793 unique reflections were used for the hypothesis and refinement. The structures were solved by direct method using the SHELXS-97 program.[27] The structures were then refined by the least-squares method using the SHELXL-97[28] with anisotropic temperature factors for all non-H atoms. The hydrogen atoms were introduced at calculated positions and refined riding on their carrier atoms. The final R factor [with $I > 2\sigma(I)$] has a value of 0.077 and 0.056 for both structures. Crystal data and refinement results are summarized in Table 6. The perspective view of the asymmetric unit containing two complex cations (Figure 1) has been calculated with PLATON.[29]

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC- 162786 for structure at 293 K and CCDC-162787 for structure at 123 K. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44−1223/336-033; E-mail:deposit@ccdc.cam.ac.uk].

Acknowledgments

We deeply thank Professor J. J. McGarvey for his helpful suggestions to the present work. We are grateful for financial support from the European Commission for granting the TMR-Network "Thermal and Optical Switching of Spin States (TOSS)", Contract No. ERB-FMRX-CT98−0199. We thank J.-F. Meunier for technical assistance in the Mössbauer spectroscopy, magnetic and DSC measurements.

Silylimido Complexes of Niobium and Tantalum at the Limit of π-Bond Saturation

Andrea Schorm[a] and Jörg Sundermeyer*[a]

Dedicated to Professor Ernst-G. Jäger on the occasion of his 65th birthday

Keywords: Niobium / Tantalum / N ligands / Cyclopentadienyl ligands / Rearrangements

Convenient strategies towards the synthesis of silylimido niobium and -tantalum complexes of the metallocene and half-sandwich type are reported. Bent metallocenes [(η^5-C_5H_5)$_2$M(NSiMe$_3$)Cl] (M = Nb: **1a**; Ta: **1b**) and [(η^5-C_5H_5)$_2$M(NSiMe$_3$)(η^1-C_5H_5)] (M = Nb: **2a**; Ta: **2b**) are synthesized by reaction of [M(NSiMe$_3$)Cl$_3$(py)$_2$] with 2 or 3 equiv. NaCp, respectively. Half-sandwich type silylimido complexes [(η^5-C_5Me_5)M(NSiMe$_3$)Cl$_2$] (M = Nb: **3a**; Ta: **3b**) cannot selectively be obtained from the (pyridine)(silylimido) precursor complexes. However, their synthesis is accomplished by reaction of [(η^5-C_5Me_5)MCl$_4$] with LiN(SiMe$_3$)$_2$. On the other hand pyridine silylimido complexes are perfect starting materials for the synthesis of the related hydridotris(pyrazolyl)borato complexes [Tp*M(NSiMe$_3$)Cl$_2$] [M = Nb: **4a**; Ta: **4b**; Tp* = κ^3-HB(3,5-Me$_2$pz)$_3$]. A comparative study of the σ,π-donor capability of isoelectronically related *tert*-butyl- and trimethylsilylimido ligands in complexes [(η^5-C_5H_5)$_2$Ta(NR)(η^1-C_5H_5)] (R = SiMe$_3$: **2b**; *t*Bu: **2c**) is presented. With respect to solid-state structural investigations and solution variable-temperature NMR-spectroscopic studies on the dynamic exchange process of η^5- and η^1-bonded cyclopentadienyl rings in **2b**,**c**, *tert*-butlyimido ligands are better donors than silylimido ligands, and both are better donors towards a d^0 metal center than an η^5-C_5H_5 ligand.

Introduction

The last two decades have witnessed an increasing interest in the organometallic chemistry of transition metal complexes containing imido ligands [NR]$^{2-}$.[1] Half-sandwich imido complexes of group-5 metals containing the fragment [(η^5-$C_5R'_5$)M(NR)] have been investigated in their relationship with bent metallocenes of group-4 metals.[2] The concept of the cyclopentadienyl imido ligand analogy[3] was introduced to explain the surprising similarities in structural features and reactivity of both complex classes and led to new catalytic systems.[4] Variation of the ancillary substituent R at the imido function [NR]$^{2-}$ offers a tool for the fine tuning of the steric demand and electronic properties of these ligands. In previous studies we and others have established the chemistry of organoimido complexes (R = alkyl, aryl) of type [(η^5-$C_5R'_5$)M(NR)X$_2$],[2,5] [(η^5-$C_5R'_5$)$_2$M(NR)X][5a,5k,6] and [Tp*M(NR)Cl$_2$][7,22] (M = Nb, Ta, X = anionic ligand). Less reports are available, by far, for corresponding silylimido complexes of niobium and tantalum:[8] the key compounds are [M(NSiMe$_3$)Cl$_3$(py)$_2$] reported by Doherty et al.[9], [Nb{(η^5-C_5H_4)CMe$_2$(η^5-C_5H_4)}(NSiMe$_3$)Cl], a representative of a silylimido *ansa*-metallocene complex reported by Green and co-workers[10] and [Cp*Ta(NSi*t*Bu$_3$)Cl$_2$], which was synthesized and tested by Stryker et al.[4b] as an interesting catalyst for olefin polymerization reactions. Our interest in developing silylimido compounds stems from their potential to act as precursors for heterobimetallic complexes containing bridging nitrido ligands.[11] We believe that electronic saturation of all empty d orbitals of a d^0-metal center by interaction with a set of strong σ- and, especially, π-donor ligands might be a good strategy in order to direct the attack of a nucleophile, for example fluoride or chloride, towards the silicon atom of the silylimido ligand instead of the d^0-metal center. We anticipate that π-bond saturation of a Lewis-acidic metal center might increase the selectivity in condensation reactions with other reactive metal compounds. Therefore we set out to systematically synthesize a series of new silylimido complexes of half-sandwich, bent metallocene and tris(pyrazolyl)borate types. Furthermore we intended to receive experimental data from crystal structure analyses and variable-temperature NMR-spectroscopic studies in order to compare the donor capability of *tert*-butyl- and silylimido ligands in isoelectronically related compounds.

Results and Discussion

Preparative Studies

The starting compounds [M(NSiMe$_3$)Cl$_3$(py)$_2$] (M = Nb, Ta) are readily prepared from the metal pentachlorides and (Me$_3$Si)$_2$NH.[9] All our attempts to synthesize half-sandwich complexes by treatment of these pyridine complex precursors with an equimolar amount of NaCp or LiCp* in THF or toluene failed. This is in contrast to the results of Otero et al. who recently described that [(η^5-C_5H_5)Nb(N*t*Bu)Cl$_2$] can be obtained in 80% yield by reaction of [Nb(N*t*Bu)Cl$_3$(py)$_2$] with NaCp in THF[12]. In agree-

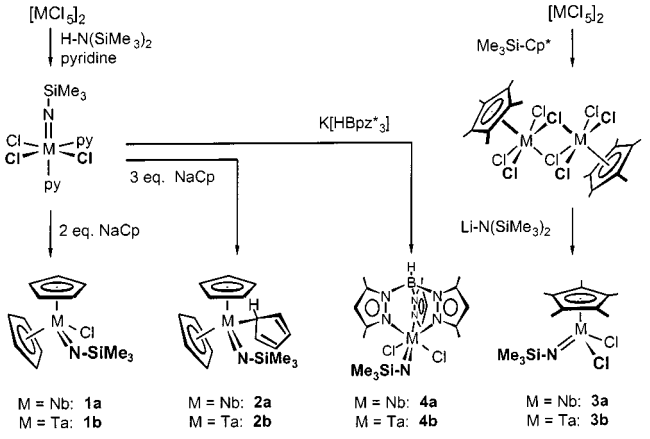
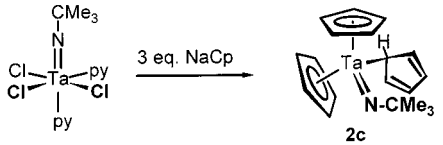
ment with our report on this class of cyclopentadienyl imido complexes[5a] the selectivity of the reaction is increased, when 2 equiv. of NaCp are treated with the pyridine silylimido precursors. We were able to synthesize the corresponding bent metallocenes $[(\eta^5\text{-}C_5H_5)_2M(NSiMe_3)Cl]$ (M = Nb: **1a**; Ta: **1b**), which were isolated as yellow powders in good yields (Scheme 1). The cyclopentadienyl protons in silylimido complex **1a** (δ = 6.14) are less shielded compared to the corresponding (*tert*-butylimido)niobium complex (δ = 5.74)[5a]. A similar trend is found for the silylimido tantalum complex **1b** and its *tert*-butylimido derivative. This is the first experimental evidence, that the donor strength of $NCMe_3$ is superior to that of $NSiMe_3$.



Scheme 1

In previous work Green and co-workers examined the reaction of $[(\eta^5\text{-}C_5H_5)Nb(N\textit{t}Bu)Cl_2]$ with NaCp in THF at room temperature leading to the blue d^0-metal compound $[(\eta^5\text{-}C_5H_5)_2Nb(N\textit{t}Bu)(\eta^1\text{-}C_5H_5)]$. The latter was structurally characterized and the dynamic exchange between σ- and π-bonded cyclopentadienyl rings was examined.[13] We prepared the corresponding silylimido niobium and -tantalum complexes $[(\eta^5\text{-}C_5H_5)_2M(NSiMe_3)(\eta^1\text{-}C_5H_5)]$ (M = Nb: **2a**; Ta: **2b**) by reaction of $[M(NSiMe_3)Cl_3(py)_2]$ (M = Nb, Ta) with 10 equiv. of NaCp. The large excess is needed for complete conversion to the highly π-bond-saturated products. Their variable-temperature NMR-spectroscopic study is described below.

In order to have two isoelectronically and structurally related complexes for a comparative study of the σ,π-donor capability of $NCMe_3$ vs. $NSiMe_3$ ligands, the alkylimido complex $[(\eta^5\text{-}C_5H_5)_2Ta(N\textit{t}Bu)(\eta^1\text{-}C_5H_5)]$ (**2c**) was synthesized by reaction of $[(\eta^5\text{-}C_5H_5)_2Ta(N\textit{t}Bu)Cl]$[5a] with 1 equiv. of NaCp or by reaction of $[Ta(N\textit{t}Bu)Cl_3(py)_2]$ with 3 equiv. of NaCp in THF.



Finally we intended to obtain hitherto unknown silylimido complexes of the half-sandwich type $[(\eta^5\text{-}C_5Me_5)M(NSiMe_3)Cl_2]$ (M = Nb: **3a**; Ta: **3b**) as well as their related tris(pyrazolyl)borato derivatives $[Tp^*M(NSiMe_3)Cl_2]$ [M = Nb: **4a**; Ta: **4b**; Tp* = κ^3-HB(3,5-Me_2pz)$_3$]. It was found that a silylimido ligand may be introduced to preformed half-sandwich complexes $[(\eta^5\text{-}C_5Me_5)MCl_4]$[14] (M = Nb, Ta). By applying ultrasound the reaction of $[(\eta^5\text{-}C_5H_5)MCl_4]$ (M = Nb, Ta) with $LiN(SiMe_3)_2$ in toluene (40 °C) leads to the pale yellow condensation products **3a** and **3b**. Bis(trimethylsilyl)amido complex intermediates[15] were not observed spectroscopically under these conditions.

EHMO calculations support the statement that the monoanionic 6-electron donor ligands Tp and Tp* [Tp = κ^3-HBpz$_3$; Tp* = κ^3-HB(3,5-Me_2pz)$_3$] possess similar σ,2π-bonding interactions with metal d orbitals as an η^5-cyclopentadienyl group.[16] Therefore these ligands can be envisaged as cyclopentadienyl ligand equivalents with a very high steric demand.[17] According to our procedure developed for the synthesis of $[Tp^*M(N\textit{t}Bu)Cl_2]$ (M = Nb, Ta)[7] we treated $[M(NSiMe_3)Cl_3(py)_2]$ (M = Nb, Ta)[9] with 1 equiv. of KTp* in THF and isolated $[Tp^*M(NSiMe_3)Cl_2]$ (M = Nb: **4a**, Ta: **4b**) in good yields. The 2:1 ratio of chemically equivalent ^{1}H and ^{13}C nuclei of the Tp* ligand reflects the C_s symmetry of complexes **4a** and **4b**. Because of the quadrupole moment of the ^{93}Nb nucleus (I = 9/2, 100%) ^{29}Si NMR signals of all niobium complexes described in this paper are too broad to be detected under standard conditions. The corresponding silylimido tantalum complexes reveal ^{29}Si NMR signals in the range of δ_{Si} = −4.9 (**2b**), −2.4 (**3b**), −2.3 (**1b**) and −1.5 (**4b**). As expected, by increasing the strength and number of σ,π-donor ligands the ^{29}Si nucleus becomes more shielded. In oscillators with a linear M=N−Si backbone the ν(M=N) and ν(N−Si) vibrational modes are probably coupled.[18] Therefore in most literature reports, assignments of the stretching modes ν(M=N−Si) of imido niobium or -tantalum complexes are not reported. By synthesis of the analogous *tert*-butyl- and silylimido complexes and by comparing their IR absorptions in the region 900−1300 cm^{-1} we were able to assign the stretching frequencies ν_{sym}(M=N−E) (E = C, Si). Vibrational absorptions are shifted towards lower wavenumbers due to the higher atomic mass of silicon versus carbon. Because of the coupling of vibrational modes IR data seems to be too insignificant to compare the donor strength via bond orders of the silyl- and *tert*-butylimido ligands.

Molecular Structures

In order to evaluate the σ,π-donor strength of the two imido ligands, $NCMe_3$ and $NSiMe_3$, single crystals of two isoelectronically related complexes $[(\eta^5\text{-}C_5H_5)_2Ta(NEMe_3)(\eta^1\text{-}C_5H_5)]$ (E = Si **2b**; C **2c**) were grown. Yellow needles of **2b** crystallized from a saturated hexane solution at −30 °C whereas cubic crystals of **2c** were obtained from acetonitrile. The results of the X-ray analyses are shown in Figure 1 and Figure 2.

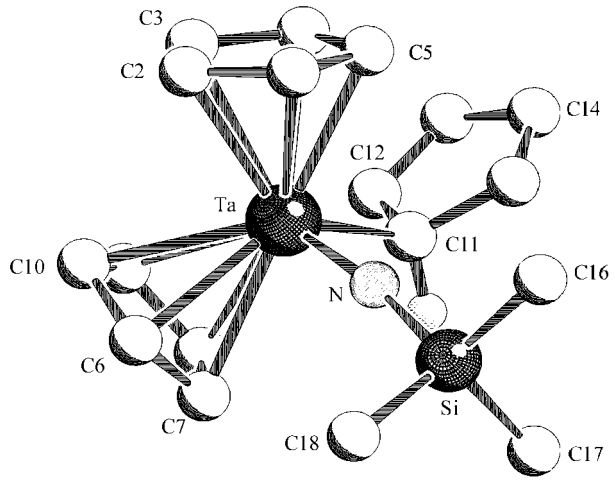


Figure 1. Molecular structure of **2b**; selected bond lengths [Å] and angles [°]: Ta−N(1) 1.796(7), Ta−C(11) 2.291(8), N(1)−Si 1.701(8), Ta−X(1) 2.168, Ta−X(2) 2.185, Ta−C(1) 2.449(9), Ta−C(2) 2.461(10), Ta−C(3) 2.523(9), Ta−C(4) 2.500(9), Ta−C(5) 2.438(9), Ta−C(6) 2.410(9), Ta−C(7) 2.457(9), Ta−C(8) 2.530(9), Ta−C(9) 2.547(10), Ta−C(10) 2.485(10), Ta−C(11) 229.1(8); Ta−N(1)−Si 171.9(5), X(1)−Ta−X(2) 125.9, X(1)−Ta−N(1) 111.7, X(1)−Ta−C(11) 117.0, X(2)−Ta−N(1) 111.3, X(2)−Ta−C(11) 102.8; X(1) is the centroid of the ring C(1)−C(5); X(2) is the centroid of the ring C(6)−C(10)

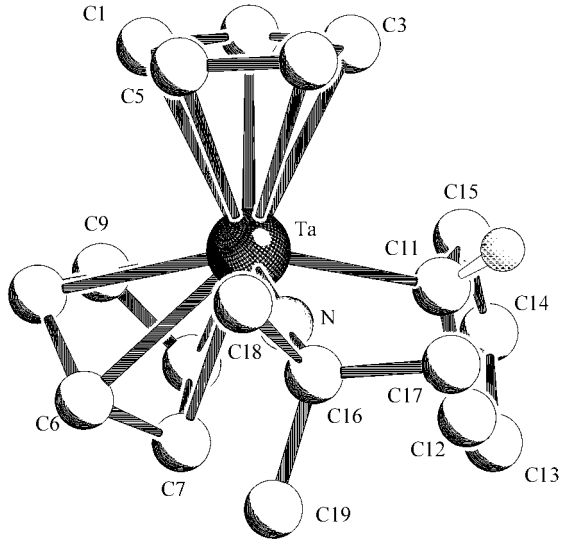

Figure 2. Molecular structure of **2c**; selected bond lengths [Å] and angles [°]: Ta−N(1) 1.761(5), Ta−C(11) 2.308(6), N(1)−C(16) 1.450(9), Ta−X(1) 2.199, Ta−X(2) 2.192, Ta−C(1) 2.510(7), Ta−C(2) 2.573(7), Ta−C(3) 2.525(6), Ta−C(4) 2.474(8), Ta−C(5) 2.417(8), Ta−C(6) 2.444(6), Ta−C(7) 2.447(7), Ta−C(8) 2.518(7), Ta−C(9) 2.570(7), Ta−C(10) 2.483(7), Ta−C(11) 2.308(6), Ta−N(1)−C(16) 175.2(5), X(1)−Ta−X(2) 124.2, X(1)−Ta−N(1) 113.1, X(1)−Ta−C(11) 102.3, X(2)−Ta−N(1) 112.3, X(2)−Ta−C(11) 107.2; X(1) is the centroid of the ring C(1)−C(5); X(2) is the centroid of the ring C(6)−C(10)

Both complexes **2b** and **2c** reveal a pseudotetrahedral coordination sphere at the tantalum atom defined by the centroids of two η^5-bonded cyclopentadienyl ligands X(1) and X(2), C(11) of the η^1-bonded cyclopentadienyl ring and the nitrogen atom N(1) of the imido ligand. They crystallize in different conformers with respect to the rotation about the Ta−C(11) bond. It is evident that the silylimido ligand, being less basic and also sterically less demanding than its carbon counterpart, forms a longer bond to the metal center: Ta−N(1)$SiMe_3$ 179.6(7) pm versus Ta−N(1)*t*Bu 176.1(5) pm. This is in agreement with the view that the dianion $[NSiMe_3]^{2-}$ is a weaker donor than $[NCMe_3]^{2-}$. The shorter Ta−N(1) bond of *tert*-butylimido complex **2c** corresponds with a longer distance Ta−C(11) 230.8(6) pm and longer distances of the tantalum atom to the centroids Ta−X(1) 219.9 and Ta−X(2) 219.2 pm of both η^5-C_5H_5 rings, whereas a longer Ta−N(2) bond of the silylimido complex **2b** corresponds with shorter distances Ta−C(11) 229.1(8), Ta−X(1) 216.8 and Ta−X(2) 218.5 pm. Steric ligand repulsion, but also the stronger σ,π-donor capability of the more π-basic alkylimido ligand, seem to be responsible for this trend. Due to the strong *trans* influence of the imido ligands Ta−C, the distances of the η^5-C_5H_5 ligands are not equivalent, the ones *trans* to Ta−N are longer. This is a typical structural feature of the imido half-sandwich complexes.[19] The angle between the ring centroids X(1)−Ta−X(2) of **2c** (124.2°) and **2b** (125.9°) are significantly smaller than in other bent tantalocenes.[6] This is probably due to steric repulsion. In both compounds **2b** and **2c** four ligands, with a potential for one σ- and two π-bonds and a maximum electron count of 6, are competing for π-interactions with a limited set of empty metal s, p and d orbitals. Orbital-symmetry restrictions are limiting the number of π-type interactions in a tetrahedral transition metal complex to five: two strong π-bonds are generated by the *e* set and three weaker π-bonds by the t_2 set of metal orbitals.[20] Four σ- and five π-bonding electron pairs would also be in agreement with the 18 valence electrons rule. If in a π-bond-saturated pseudo-tetrahedral molecule more than five orbitals of π-symmetry (p orbitals at N atoms or e_1-group orbitals of η^5-C_5H_5 rings) are available at the 4 ligands, electron density essentially remains in nonbonding orbitals (lone pairs) centered at the ligands, and only the strongest π-interactions dominate the π-bond regime.[21] Our structural data indicates that both dianionic $[NR]^{2-}$ ligands (R = $SiMe_3$, CMe_3) possess a stronger π-donor capability towards the relatively hard d^0-metal center than the more polarizable, softer and sterically more demanding ligand $[C_5H_5]^-$ that is released into a σ-bonding mode.

In π-bond-saturated complexes **2b**,**c** the Ta−N bond order, based on its length, is about 2. With respect to orbital symmetry and electron count considerations a higher Ta−N bond order is expected for the octahedral complex **4b**. In order to check this proposal, colorless cubic crystals of **4b** were grown from acetonitrile and submitted for an X-ray structural analysis. The molecular structure of **4b** is presented in Figure 3.

The tantalum center is octahedrally coordinated by three *fac*-binding nitrogen atoms of the Tp* ligand, by two chlorine atoms and one nitrogen atom of the silylimido ligand. The tantalum−imido bond Ta−N(1) 176.7(6) pm in **4b** is short compared with Ta−N(1) 179.6(7) pm in **2b**. This is in agreement with the assumption, that the silylimido ligand

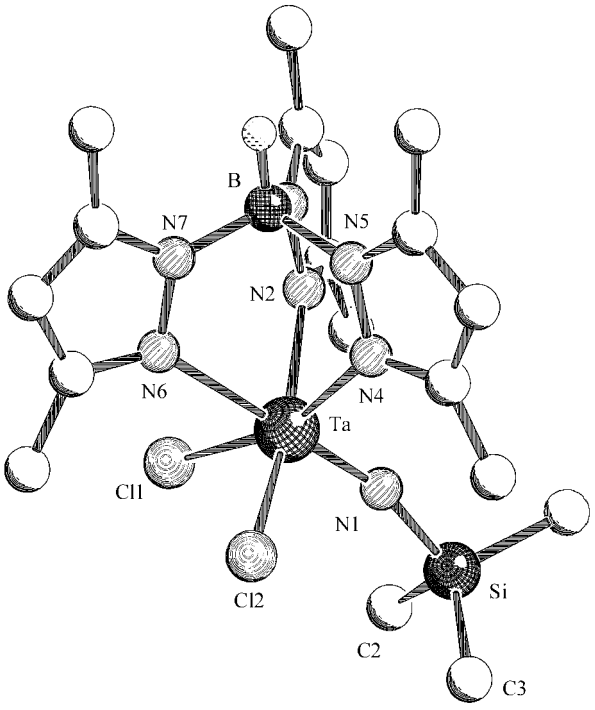

Figure 3. Molecular structure of **3b**; selected bond lengths [Å] and angles [°]: Ta−N(1) 1.767(6), Ta−N(2) 2.176(6), Ta−N(4) 2.201(6), Ta−N(6) 2.387(6), Ta−Cl(1) 2.373(2), Ta−Cl(2) 2.367(2), Si−N(1) 1.742(6), B−N(3) 1.550(11), B−N(5) 1.527(11), B−N(7) 1.515(12); Ta−N(1)−Si 164.8(4), N(1)−Ta−N(2) 97.9(3), N(1)−Ta−N(4) 97.8(3), N(1)−Ta−N(6) 179.5(3), N(1)−Ta−Cl(1) 96.8(2), N(1)−Ta−Cl(2) 96.29(19)

of [Tp*Ta(NSiMe$_3$)Cl$_2$] is more involved in π-bonding to the metal center than **2b**. The higher Ta−N bond order is a consequence of the lower π-bond saturation due to a weaker set of donor ligands in **4b**. It is worth noting that a shorter Ta−N bond corresponds with a longer N−Si bond: N(1)−Si 174.2(6) pm in **4b** vs. N(1)−Si 170.1(8) pm in **2b**. This is a result of an unequal competition of the electrophilic centers, the d^0-metal atom and the SiMe$_3$ substituent, for the electron density at the nitrogen atom of the nitrido bridge. The Ta−N−Si axis 164.8(4)° of **4b** deviates considerably from linearity, presumably a result of the steric requirement imposed by the bulky trimethylsilyl group and the Tp* ligand. Deviations from M−N−C linearity in the range 160−180° are not specific for the evaluation of bond orders.[21] There is no correlation of bond order and angle; e.g. the more π-saturated **2b** has a lower Ta−N bond order but a higher angle Ta−N(1)−Si(1) 171.9(5)°. The strong *trans* influence of the imido ligand is evident in the longer tantalum−pyrazol distance Ta−N(6) 238.7(6) pm *trans* to the imido ligand when compared with the *cis*-bonded pyrazol groups Ta−N(2) 217.6(6) pm and Ta−N(4) 220.1(6) pm. This is in agreement with other structurally characterized tris(pyrazolyl)borato complexes [Tp*Ta(NDip)Cl$_2$][22] and [Tp*Mo(N*t*Bu)$_2$Cl].[7]

Variable-Temperature NMR-Spectroscopic Studies

In solutions of π-bond-saturated complexes with σ- and π-bonded enyl ligands of the same type, ligand fluxionality is expected. The potential of the electronically flexible imido ligand to act as either a 4- or 6-electron donor [NR]$^{2-}$ should support the fluxional rearrangement of the σ- and π-bonded cyclopentadienyl ligands by lowering the energy barriers between the η^1-, η^3- and η^5-coordination modes. In agreement with the experiments of Green et al. on the related complex [(η^5-C$_5$H$_5$)$_2$Nb(NCMe$_3$)(η^1-C$_5$H$_5$)][13] variable-temperature ^{1}H-NMR spectroscopic studies, which are shown in Figure 4 and Figure 5, reveal the dynamic behavior of the cyclopentadienyl ligands in complexes **2b** and **2c**.

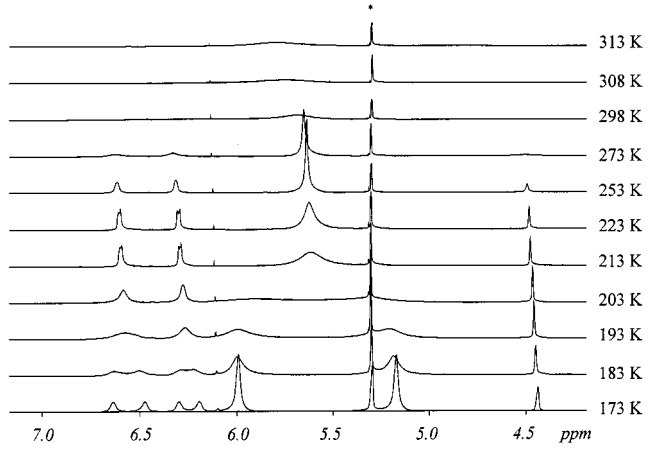

Figure 4. Variable-temperature ^{1}H NMR spectra of [(η^5-C$_5$H$_5$)$_2$Ta(NSiMe$_3$)(η^1-C$_5$H$_5$)] (**2b**) (400 MHz, CD$_2$Cl$_2$), showing the dynamic behavior of the C$_5$H$_5$ ligand; the asterisk denotes the solvent resonance

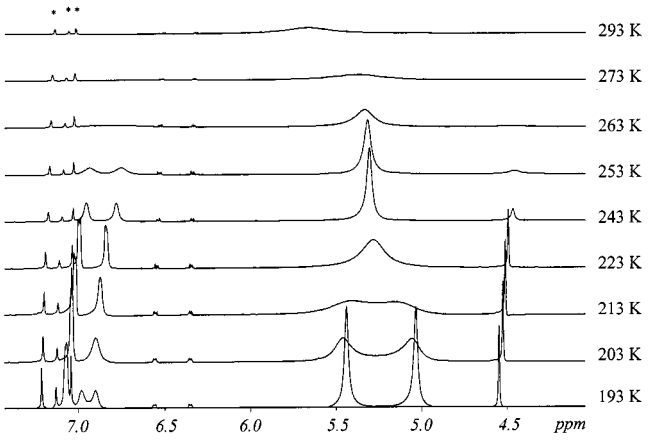

Figure 5. Variable-temperature ^{1}H NMR spectra of [(η^5-C$_5$H$_5$)$_2$Ta(N*t*Bu)(η^1-C$_5$H$_5$)] (**2c**) (400 MHz, [D$_8$]toluene), showing the dynamic behavior of the C$_5$H$_5$ ligand; the asterisks denote the solvent resonances

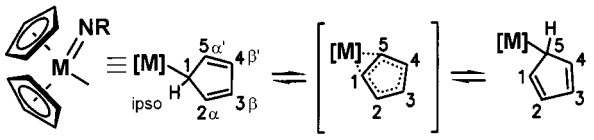
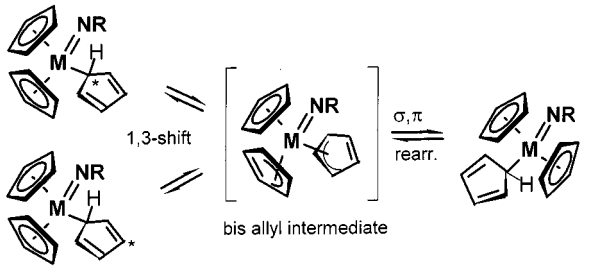
Three fluxional processes shown in Scheme 2 and Scheme 3 are observed for **2b** and **2c**: The rotation of the σ-C$_5$H$_5$ ligand about the Ta−C$_{ipso}$ bond, the metallotropic migration of the tantalum center between the σ-C$_5$H$_5$ ring

carbon atoms, and the σ,π-exchange of the cyclopentadienyl ligands.



Scheme 2. 1,2-Metallotropic rearrangement by 1,5-sigmatropic shift of [M] (M = Nb, Ta)



Scheme 3. 1,3-Shift of [M] and σ,π-rearrangement via the allyl intermediate (M = Nb, Ta)

In the slow-exchange-limiting ^{1}H NMR spectrum of **2b** at 173 K two resonances of the η^5-C_5H_5 ligands at δ = 6.02 and 5.20 and five resonances of the σ-C_5H_5 ligand at δ = 6.66, 6.50, 6.32, 6.22, 4.46 are separated. This is consistent with a hindered rotation about the Ta−C_{ipso} bond on the NMR time scale. The same separation is observed for *tert*-butylimido complex **2c** but at a higher coalescence temperature. Upon raising the temperature a pairwise coalescence of the signals of both η^5-C_5H_5 ligands and of the σ-C_5H_5 olefinic protons H_α, $H_{\alpha'}$, H_β, $H_{\beta'}$ is observed, while H_{ipso} remains unchanged, as expected for a system with free rotation about the Ta−C_{ipso} bond. Experimental data of dynamic exchange processes and their coalescence temperatures for complexes **2b** and **2c** are listed in Table 1. The assignment of H_α and $H_{\alpha'}$ is based on the assumption that due to their closer position to the tantalum center, their chemical shift difference will be larger than between H_β and $H_{\beta'}$.

There is a trend in that the three exchange processes originating from a hindered rotation about the Ta−C_{ipso} bond, have higher coalescence temperatures for *tert*-butylimido complex **2c** than for the silylimido complex **2b**. This is probably due to the higher degree of RN→M π-donation and to the greater steric demand of the *tert*-butylimido versus silylimido ligand. The free activation enthalpy of rotation about the Ta−C_{ipso} bond reveals $\Delta G^{\neq}(T_C)$ values in the range 37.5−40.6 kJmol^{-1} (**2b**) and 40.7−41.9 kJmol^{-1} (**2c**) depending on the type of exchanging nuclei chosen for this estimation (Table 1). These barriers are slightly lower than 43.4 kJ mol^{-1} reported by Green for the sterically slightly more hindered complex $[(\eta^5\text{-}C_5H_5)_2Nb(NCMe_3)(\eta^1\text{-}C_5H_5)]$.[13] It is evident that in the sterically less hindered silylimido complex **2b**, rotation is less hindered. On the other hand, the lower coalescence temperatures for the σ,π-exchange of silylimido complex **2b** suggests that the stronger donor $[NCMe_3]^{2-}$ promotes the ring slippage into an η^3- and finally the η^1-cyclopentadienyl bonding mode more readily than the weaker donor $[NSiMe_3]^{2-}$. In our complexes the migration of the tantalum atom between the carbon atoms of σ-C_5H_5 could occur by either a metallotropic 1,3-shift via such η^3-allyl intermediates or by a concerted 1,2-shift, a process that could also be envisaged as a symmetry-allowed 1,5-sigmatropic rearrangement. According to Cotton et al. a 1,2-shift mechanism will lead to a faster initial broadening of the resonances assigned to the H_α and $H_{\alpha'}$ resonances relative to the *ipso* hydrogen atom, while initial broadening of the resonances assigned to H_β and $H_{\beta'}$ would be indicative of a 1,3-shift mechanism. In agreement with our variable-temperature NMR spectra we favor the 1,2-shift mechanism. We are facing the same problem discussed for $[(\eta^5\text{-}C_5H_5)_2Nb(NCMe_3)(\eta^1\text{-}C_5H_5)]$[13] since we are not able to fully resolve the coupled fluxional processes associated with the Ta−C_{ipso} rotation on our NMR time scale in order to obtain quantitative results of the rate constants of the metallotropic migration.

Conclusion

A series of new silylimido niobium and -tantalum complexes of half-sandwich and metallocene type has been synthesized. To the best of our knowledge the donor strength of isoelectronically related trimethylsilyl- and *tert*-butylimido complexes has not been evaluated by experimental methods before. M−N bond lengths and, in a less pronounced manner, dynamic exchange of η^1- and η^5-coordinated cyclopentadienyl ligands in isoelectronic compounds of the formula $[(\eta^5\text{-}C_5H_5)_2M(NEMe_3)(\eta^1\text{-}C_5H_5)]$ (M = Nb, Ta; E = C, Si) indicate that *tert*-butylimido ligands are stronger donors than their silylimido counterparts. This might have been expected from the standpoint of N-basicity or proton affinity of the corresponding amines that is, to a certain extent, reflecting the donor strength of the ligand.

Table 1. Coalescence temperatures T_c, rate constants k and free activation enthalpies $\Delta G^0(T_C)$ for the Ta−C_{ipso} bond rotation process in **2b** and **2c**

By this study we extend the series of isolobal, highly π-bond-saturated organometallic complexes of group-4 −7 metals with a set of competing cyclopentadienyl and imido ligands. The isolobal relationship among the complexes shown in Scheme 4 is based on the cyclopentadienyl imido ligand analogy.[3]

Experimental Section

Materials and Methods: All manipulations were performed under dry argon 4.8. Solvents were rigorously dried, distilled and stored over 3 Å and 4 Å molecular sieves before use. All air-sensitive compounds were stored in glove boxes MB 150B-G-II and Lab Master 130 (MBraun) under nitrogen. − Melting points (uncorrected) were determined with a melting point apparatus Büchi-SMP 20. − The ^{1}H, ^{13}C and ^{29}Si NMR spectra were recorded with a Bruker ARX200, a Bruker AMX300 and a Bruker DRX400 at 25 °C if not indicated otherwise. All ^{13}C NMR spectra are proton-decoupled. The signals of solvents were used as internal standards for the ^{1}H and ^{13}C NMR spectra: CD_2Cl_2 (δ = 5.32; 54.2), $CDCl_3$ (δ = 7.24; 77.0), C_6D_6 (δ = 7.15; 128.0) and C_7D_8 (δ = 2.03; 20.4). Tetramethylsilane served as an external standard for the ^{29}Si NMR spectra. − The IR spectra were recorded with a Nicolet 510 M FT spectrometer. All solids were recorded as Nujol mulls between KBr plates. − Elemental analyses were performed in the microanalytical laboratories of the Chemistry Department at Marburg University. − EI mass spectra were recorded with a Varian MAT CH7 (70 eV) and APCI mass spectra were recorded with a Hewlett Packard HP 5989 B spectrometer. − The X-ray structure analyses were performed with an Enraf Nonius CAD4 diffractometer. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-132475 (**2b**), -132476 (**2c**), and -132477 (**4b**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. Starting materials: Niobium and tantalum pentachloride were products of H. C. Starck GmbH & Co. KG. The following compounds were prepared as described in the literature: $Na(C_5H_5)$,[26] $Li(C_5Me_5)$,[27] $Me_3Si(C_5Me_5)$,[28] $LiN(SiMe_3)_2$,[29] KTp*,[30] $[(\eta^5\text{-}C_5Me_5)MCl_4]$,[14] $[M(NSiMe_3)Cl_3(py)_2]$ (M = Nb, Ta)[9].

$[(\eta^5\text{-}C_5H_5)_2Nb(NSiMe_3)Cl]$ (1a): A mixture of $[Nb(NSiMe_3)Cl_3(py)_2]$ (250 mg, 0.56 mmol) and NaC_5H_5 (104 mg, 1.18 mmol) was dissolved in 20 mL of THF at −78 °C. After 1 h, the temperature was allowed to reach 25 °C and the color of the mixture turned from yellow to brown. After 2 h of stirring, the volatiles were removed in vacuo. The brown residue was extracted into 25 mL of toluene and the solution was filtered. Part of the solvent of the filtrate was evaporated to leave 10 mL, which was layered with 7 mL of hexane and stored at −30 °C to afford **1a** as a yellow powder. Yield: 65 mg (0.19 mmol, 30%); m.p. 156 °C. − ^{1}H NMR (300 MHz, C_6D_6): δ = 0.02 [s, 9 H, $Si(CH_3)_3$], 5.81 (s, 10 H, C_5H_5). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = − 0.03 [s, 9 H, $Si(CH_3)_3$], 6.14 (s, 10 H, C_5H_5). − ^{13}C NMR (75 MHz, C_6D_6): δ = 0.5 [s, $Si(CH_3)_3$], 112.5 (s, C_5H_5). − IR (Nujol): $\tilde{\nu}$ = 3086 vw, 1634 vw ν(C=C), 1377 s, 1262 m, 1246 s, 1078 vs ν(Nb=N−Si), 1067 vs, 951 w, 835 vs, 812 vs, 793 vs, 748 m, 687 w, 633 w cm^{-1}. − $C_{13}H_{19}ClNNbSi$ (345.75): calcd. C 45.16, H 5.54, N 4.05; found C 44.36, H 5.60, N 3.74. − EI-MS (70 eV, EI): *m/z* (%) = 346 (74) [M^+], 311 (12) [M^+ − Cl]. − APCI-MS (CH_3CN): *m/z* (%) = 346 (100) [M^+].

$[(\eta^5\text{-}C_5H_5)_2Ta(NSiMe_3)Cl]$ (1b): A mixture of $[Ta(NSiMe_3)Cl_3(py)_2]$ (250 mg, 0.47 mmol) and NaC_5H_5 (87 mg, 0.99 mmol) was dissolved in 25 mL of THF at −78 °C. After 2 h, the temperature was allowed to reach 25 °C and the color of the mixture turned brown. After 2 h of stirring, the volatiles were removed in vacuo. The brown residue was extracted into 30 mL of *n*-hexane, the solution was filtered and reduced in volume. **1b** was obtained at −30 °C as a yellow powder. Yield: 100 mg (0.23 mmol, 45%); m.p. 145 °C. − ^{1}H NMR (200 MHz, C_6D_6): δ = − 0.09 [s, 9 H, $Si(CH_3)_3$], 5.78 (s, 10 H, C_5H_5). − ^{1}H NMR (300 MHz, $CDCl_3$): δ = − 0.06 [s, 9 H, $Si(CH_3)_3$], 6.13 (s, 10 H, C_5H_5). − ^{13}C NMR (75 MHz, $CDCl_3$): δ = 1.5 [s, $Si(CH_3)_3$], 111.4 (s, C_5H_5). − ^{29}Si NMR (78 MHz, C_6D_6): δ = −2.3 [s, $Si(CH_3)_3$]. − IR (Nujol): $\tilde{\nu}$ = 3137 vw, 3122 w, 3082 w, 1638 vw, 1611 m ν(C=C), 1528 m, 1456 vs, 1435 vs, 1395 w, 1377 s, 1368 s, 1261 s, 1244 s, 1113 vs ν(Ta=N−Si), 1080 vs, 1026 vs, 920 m, 855 br, 801 br, 745 vs, 706 vs, 631 vs, 606 m cm^{-1}. − $C_{13}H_{19}ClNSiTa$ (433.79): calcd. C 35.99, H 4.41, N 3.23; found C 35.99, H 4.98, N 3.01. − EI-MS (70 eV): *m/z* (%) = 433 (55) [M^+], 418 (100) [M^+ − CH_3].

$[(\eta^5\text{-}C_5H_5)_2Nb(NSiMe_3)(\sigma\text{-}C_5H_5)]$ (2a): A mixture of $[Nb(NSiMe_3)Cl_3(py)_2]$ (300 mg, 0.68 mmol) and an excess of NaC_5H_5 (595 mg, 6.75 mmol) was dissolved in 25 mL of THF at −78 °C. After 2 h, the temperature was allowed to reach 25 °C. After 2 h of stirring at 25 °C, the volatiles of the light-brown reaction mixture were removed completely and the residue was extracted into 30 mL of *n*-hexane. The solution was filtered and reduced in volume to 7 mL and stored for 1 week at −30 °C to give **2a** as a yellow, microcrystalline solid. Yield: 100 mg (0.27 mmol, 30%); m.p. 132 °C. − ^{1}H NMR (400 MHz, CD_2Cl_2, 298 K): δ = 0.01 [s, 9 H, $NSi(CH_3)_3$], 5.64 (br. s, 10 H, $\eta^5\text{-}C_5H_5$), 6.27 (br. s, 5 H, $\eta^1\text{-}C_5H_5$). − ^{1}H NMR (400 MHz, CD_2Cl_2, 173 K): δ = −0.11 [s, 9 H, $NSi(CH_3)_3$], 5.09 (br. s, 5 H, $\eta^5\text{-}C_5H_5$), 5.14 (br. s, 1 H, C-H_{ipso}), 5.99 (br. s, 5 H, $\eta^5\text{-}C_5H_5$), 6.26 (m, br, 2 H, C-$H_{\beta,\beta'}$), 6.49 and 6.61 (m, 2 H, C-$H_{\alpha,\alpha'}$). − ^{13}C NMR (75 MHz, CD_2Cl_2, 298 K): δ = 1.5 [s, $NSi(CH_3)_3$], 111.0 (s, $\eta^5\text{-}C_5H_5$), 132.9 (br. s, $C_{\beta,\beta'}$), 133.9 (br. s, $C_{\alpha,\alpha'}$), C_{ipso} is not observed. − ^{13}C NMR (100 MHz, CD_2Cl_2, 173 K): δ = 0.3 [s, $NSi(CH_3)_3$], 55.5 (s, C_{ipso}), 109.0 and 110.7 (br. s, $\eta^5\text{-}C_5H_5$), 121.15 and 119.4 (br. s, $C_{\beta,\beta'}$), 136.3 and 141.0 (br. s, $C_{\alpha,\alpha'}$). − IR (Nujol): $\tilde{\nu}$ = 3102 m, 3079 m, 3065 w, 1624 vw, 1607 m ν(C=C), 1383 s, 1366 m, 1300 w, 1262 vs, 1244 vs, 1128 vw, 1080 vs ν(Nb=N−Si), 1030 vs, 972 m, 909 vw, 883 s, 835 vs, 801 vs, 752 s, 737 vs, 714 s, 693 w, 685 w, 633 m, 625 m, 611 vw cm^{-1}. − $C_{18}H_{24}NNbSi$ (375.39): calcd. Synthesis and Host−Guest Properties of Multi-Crown Dendrimers towards Sodium Pertechnetate and Mercury(II) Chloride

Holger Stephan,*[a] Hartmut Spies,[a] Bernd Johannsen,[a] Karsten Gloe,*[b] Marius Gorka,[c] and Fritz Vögtle*[c]

Dedicated to Prof. Peter Mühl (Dresden) on the occasion of his 70th birthday

Keywords: Dendrimers / Crown compounds / Pertechnetate / Mercury / Solvent extraction

Multi-crown dendrimers of four different generations have been synthesized by grafting 4, 8, 16, and 32 benzo[15]-crown-5 units at the periphery of POPAM dendrimers. The binding of sodium pertechnetate and mercury(II) chloride by the multi-crown dendrimers has been studied by liquid-liquid extraction using the radioactive probes $^{22}Na^+$, $^{99}TcO_4^-$, and $^{203}Hg^{2+}$. The third- and fourth-generation dendrimers **3** and **4**, in particular, are capable of extracting mercury(II) with high efficiency (ca. 12 Hg^{II} ions per dendrimer molecule, even at low generation). It has been shown that the guest molecules investigated are preferentially encapsulated inside the dendrimers.

Introduction

Due to their unique topology, dendrimers show unusual guest-binding behaviour,[1] and there are almost unlimited possibilities for the structural modification of dendritic hosts. In principle, dendrimers can accommodate different kinds of guests, such as anionic species,[2] metal ions,[3] and neutral substrates,[4] either within the porous interior or at the exterior of the multifunctional periphery. Furthermore, there is an almost infinite variability regarding the solubility behaviour. Thus, water-soluble unimolecular micelles have been developed, having a hydrophobic interior and hydrophilic shells, which are capable of encapsulating hydrophobic guests.[5] Recently, oligoethyleneoxy-modified polypropyleneamine dendrimers (POPAM dendrimers) possessing hydrophilic interiors and exteriors were shown to function as water-soluble hosts for hydrophilic xanthene dyes.[6] On the other hand, hydrophilic guests can be transported from water into an organic phase or liquid carbon dioxide by the use of inverted unimolecular micelles based on a POPAM skeleton with grafted aliphatic and fluorinated chains.[7] Such hydrophobic dendrimers have been discussed as a new generation of extractants.[8] This stems mainly from the unique ability of dendrimers to encapsulate a multitude of guests. In this context, dendritic hosts have been propagated as nanoscopic reactors for environmental remediation.[9] Additionally, dendrimers are gaining in importance in the development of novel diagnostic and therapeutic agents with high specific activities.[10] For both applications, dendrimers based on multiple 1,4,7-triazacyclononane derivatives seem to be very promising.[11] These molecules coordinate multiple Cu^{2+} and Ni^{2+} ions, whereby each triazacyclononane unit can be loaded with the metal ions under investigation. Likewise, cascade molecules having up to 21 diaza[18]crown-6 moieties have been reported.[12] These dendrimers were shown to extract alkali metal ions in a generation-independent manner. The experimental results indicated only 1:1 complexes of the crown subunits with Cs^+, without any sandwich species.

Herein, we present the synthesis of multi-crown dendrimers having a different structure. Specifically, benzo[15]-crown-5 units have been grafted onto the periphery of four generations of POPAM dendrimers (Scheme 1). The combination of protonated amine nitrogen atoms in the dendrimer core, which can bind anions, together with cation-active crown ether moieties, represents an approach for the simultaneous binding of cations and anions. The host−guest properties of these dendrimers **1**−**4** have been investigated by liquid-liquid extraction. Sodium pertechnetate, as a typical contaminant of nuclear waste,[13] and mercury(II) chloride, as a pollutant of chloride-containing effluents of incineration processes,[14] were selected as guests for our studies.

Results and Discussion

The new dendritic family consists of four different generations of benzo-crown-modified polypropyleneamine

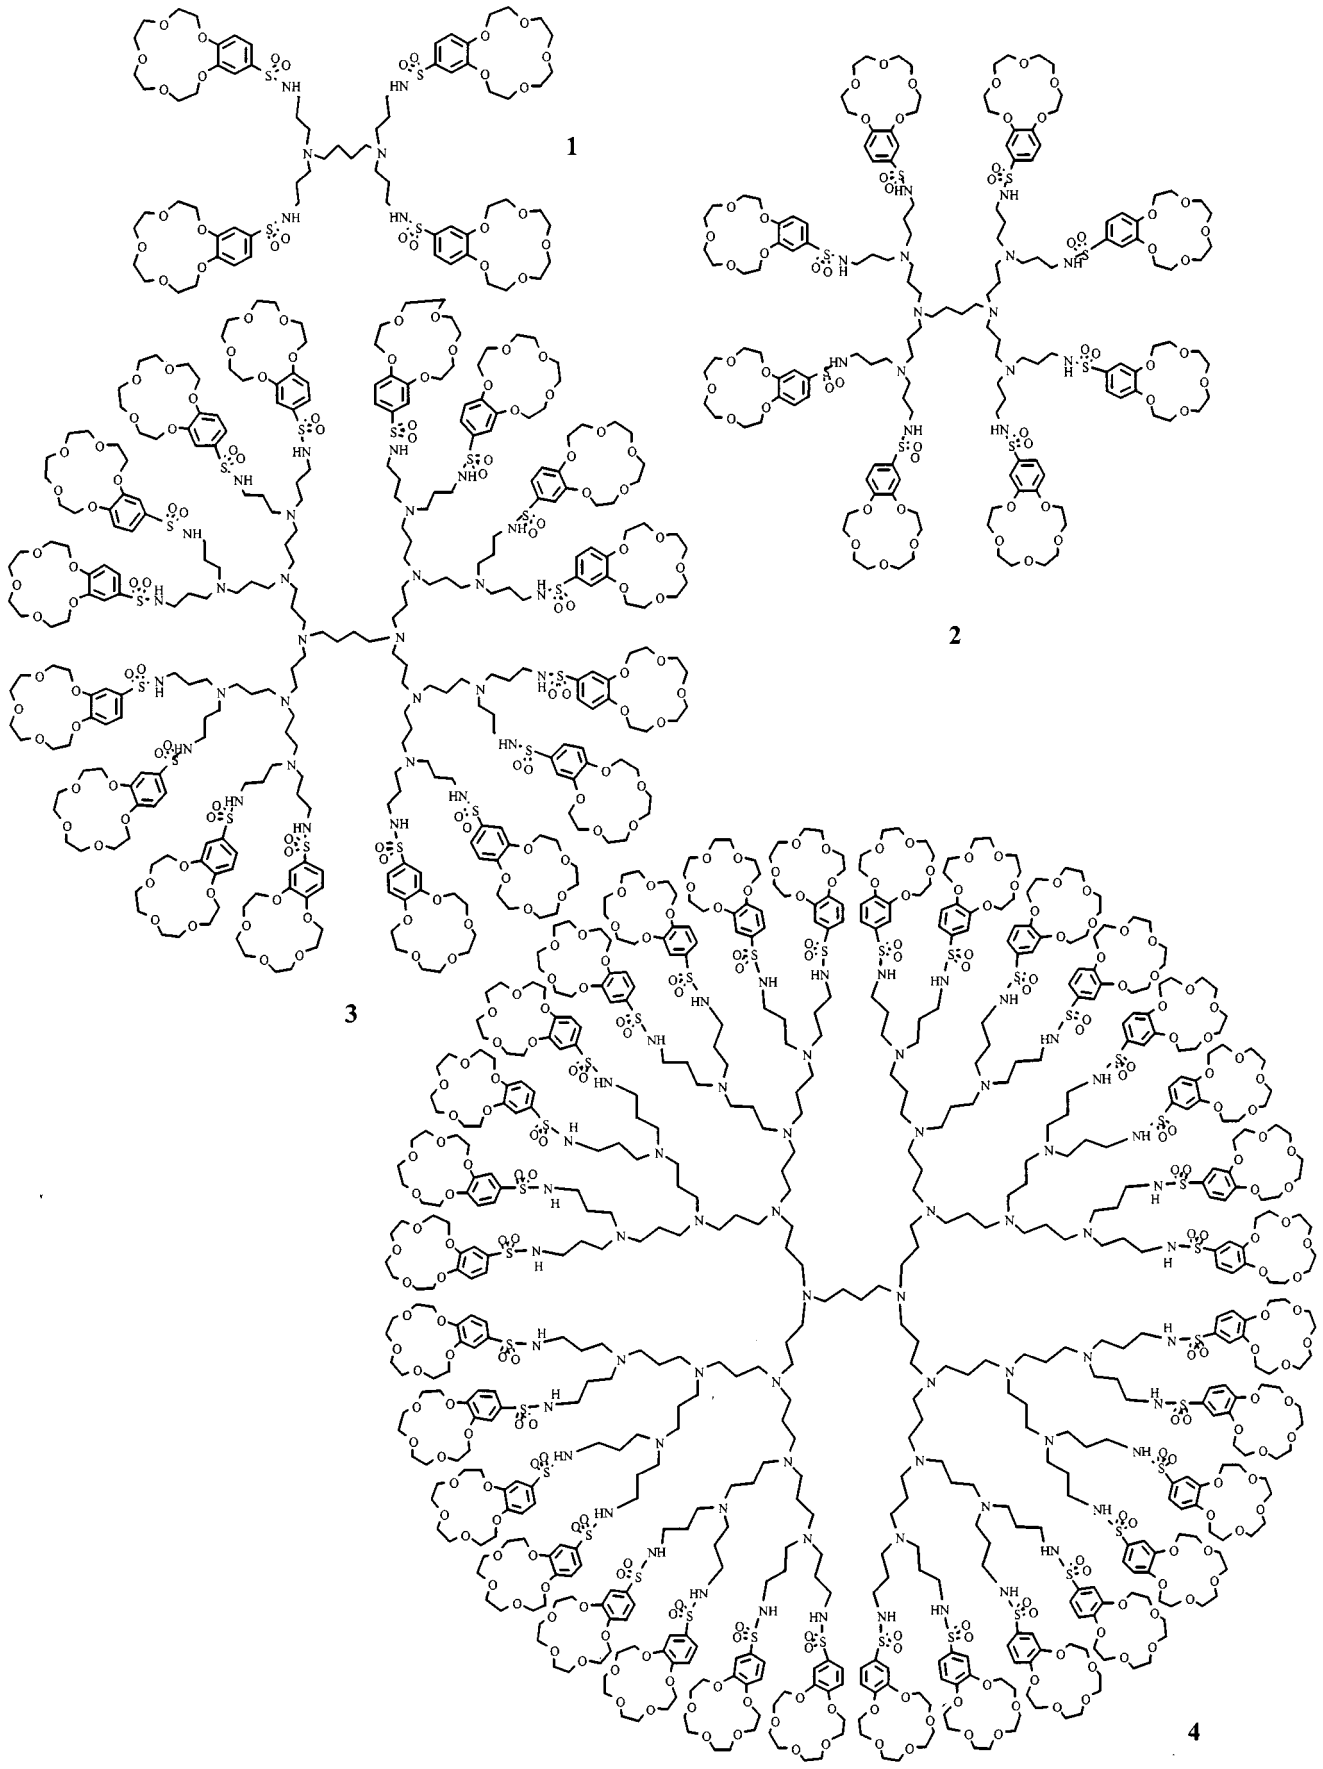
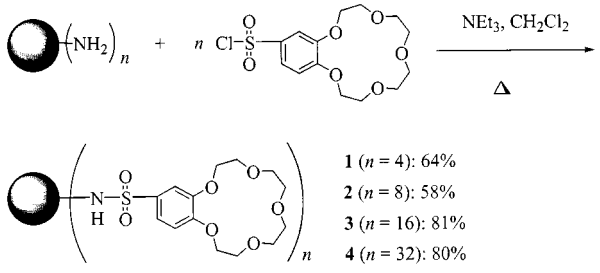


Scheme 1. Constitutions of the investigated multi-crown dendrimers

(POPAM, PPI) dendrimers. They were synthesized by treating amine-functionalized POPAM dendrimers with 1 equiv. (with respect to the primary amino groups of the dendrimer) of benzo[15]crown-5-4′-sulfonyl chloride in the presence of triethylamine (Scheme 2). The monofunctionalized multi-crown dendrimers **1**−**4** were characterized by ^1H and ^{13}C NMR spectroscopy as well as by MALDI-TOF mass spectrometry.[15] Dendrimers **1**−**4** were found to be soluble in common organic solvents but not in water. The melting points of the products ranged from 74 °C (**1**) to 85 °C (**4**).



Scheme 2. Preparation of multi-crown dendrimers

The synthesized multi-crown dendrimers were found to exhibit good solubility in solvents of low polarity, such as dichloromethane and chloroform, making them attractive as extractant and carrier molecules for separation processes. Solvent extraction was thus chosen to characterize the host−guest properties. In all cases, the experimental parameter of interest was the distribution ratio *D*, defined as the quotient of the relative amounts of the species present in the organic and aqueous phases. Aqueous solutions of sodium pertechnetate and mercury(II) chloride were extracted with solutions of the multi-crown dendrimers in chloroform. Excellent coalescence behaviour and the rapid attainment of extraction equilibria (within a few minutes) was observed.

The extraction of pertechnetate by the multi-crown dendrimers was investigated as a function of dendrimer concentration at pH = 7.5 (see Figure 1). As expected, the extraction efficiency increases with increasing dendrimer generation.[16] This finding is consistent with the results of pertechnetate extraction studies using urea- and methyl-orange-functionalized dendrimers,[10c,10d] confirming that the anion is bound by protonated tertiary amine groups in the interior of the dendrimer. Analysis of the organic phase revealed that no sodium ions were co-extracted, indicating that the crown ether moieties at the periphery of the dendrimer were not involved under the experimental conditions used.[17] Further insight into the extraction mechanism was gained by studying the effect of pH on the distribution ratio D_{TcO_4}.

Figure 2 summarizes the extraction of pertechnetate by the third-generation crown-ether dendrimer **3** as a function of pH and dendrimer concentration. The highest efficacy was obtained at pH = 5.4,[18] at which most of the tertiary amine groups should be protonated.[19] Increasing the pH led to a decrease in the efficiency of the pertechnetate extraction, in agreement with the decreasing degree of protonation of the dendrimer. It is worth mentioning that the buffer composition plays only a minor role. Likewise, the presence of a competing anion such as chloride[20] has only a small influence on the extraction of pertechnetate. At pH < 11, sodium ions were not extracted into the organic phase. Thus, we conclude that in this pH range the binding of pertechnetate occurs mainly by electrostatic attraction of the protonated amine groups. The peripheral groups play only a minor role. This was corroborated by the results of control experiments using dendrimers bearing 3,4-dimethoxybenzenesulfonamide peripheral groups.[21] Only at pH > 12 was the co-extraction of sodium ions observed. We found that the extraction efficacy of sodium pertechnetate from sodium hydroxide solution using dendrimer **3** was rather poor (Figure 2). However, it is known that benzo[15]-crown-5 shows only a weak affinity in the binding and extraction of sodium ions.[22] Despite this, the multi-benzo[15]crown-5 dendrimers investigated show considerable sodium uptake when the dendrimer concentration is increased and the hydrophobic picrate counterion is used (see Figure 3). As expected, the sodium uptake increases with increasing dendrimer generation. The introduction of more suitable crown ether units such as cyclohexano[18]-

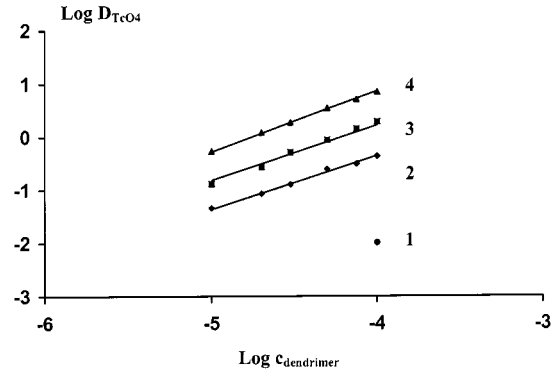


Figure 1. Variation of log D_{TcO_4} with dendrimer concentration for the extraction of pertechnetate with dendrimers **1**−**4**; c_{NaTcO_4} = 1×10^{-5} M, pH = 7.5 (TRIS/HCl buffer), $c_{dendrimer} = 1 \times 10^{-5}$ to 1×10^{-4} M in $CHCl_3$

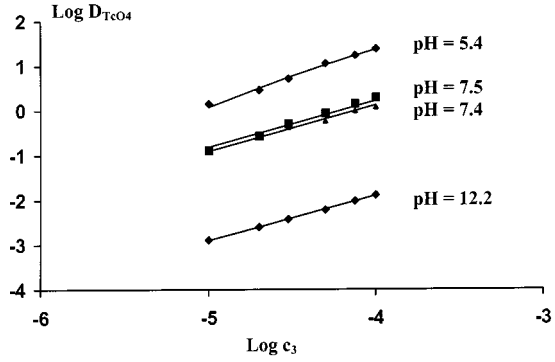

Figure 2. Variation of log D_{TcO_4} with pH for the extraction of pertechnetate with **3**; $c_{NaTcO_4} = 1 \times 10^{-5}$ M, pH = 5.4 (MES/NaOH), 7.4 (HEPES/NaOH), 7.5 (TRIS/HCl), 12.2 (1.5×10^{-2} M NaOH), $c_3 = 1 \times 10^{-5}$ to 1×10^{-4} M in $CHCl_3$

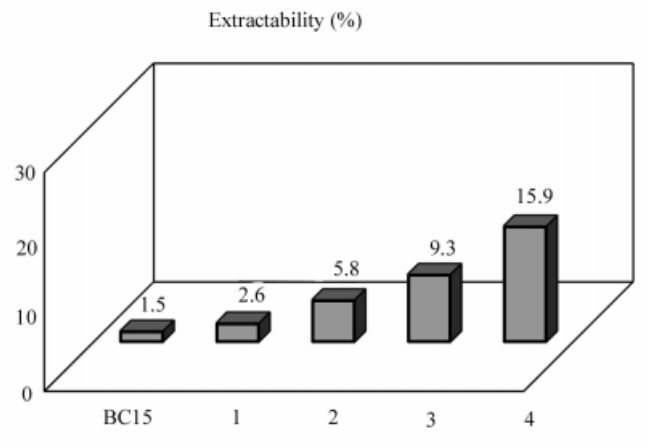

Figure 3. Extractability of sodium ions by benzo-15-crown-5 (BC15) and dendrimers **1**−**4**; $c_{NaOH} = 1.5 \times 10^{-2}$ M, $c_{HPic} = 1.5 \times 10^{-2}$ M, $c_{ligand} = 1 \times 10^{-3}$ M in $CHCl_3$

crown-6[23] at the periphery of the dendrimers can be expected to lead to higher sodium ion extraction efficiency.

Interestingly, in all cases, the slopes of the lines in the log D_{TcO_4}/log $c_{dendrimer}$ plots (Figures 1 and 2) were unity, indicating a clean 1:1 composition (pertechnetate:dendrimer) of the extracted complexes.[24] This finding is mainly attributable to the experimental conditions used. The concentration of the dendrimer was equimolar or in excess with respect to the pertechnetate concentration, which is a prerequisite for obtaining reliable information about the stoichiometries of the extracted complexes.[25] On the other hand, an excess of the dendrimer with respect to the pertechnetate concentration favours the formation of some partially loaded host−guest species. This is clearly evident from Figure 4.

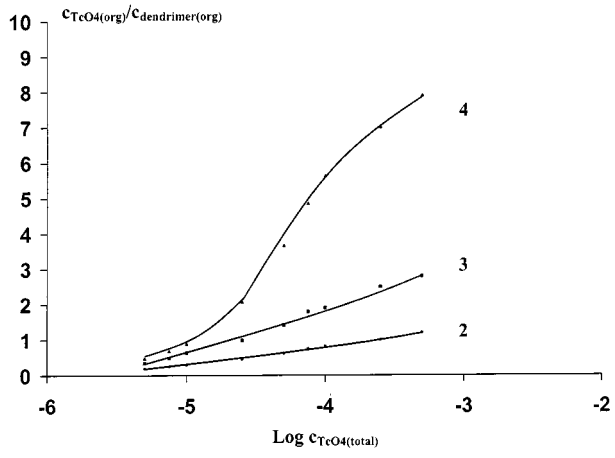

Figure 4. Variation of ratio $c_{TcO_4(org)}/c_{dendrimer(org)}$ with log $c_{TcO_4(total)}$ for the extraction of pertechnetate with dendrimers **2**−**4**; $c_{TcO_4} = 5 \times 10^{-6}$ to 5×10^{-4} M, pH = 5.4 (MES/NaOH), $c_{dendrimer} = 1 \times 10^{-5}$ in $CHCl_3$

Thus, at low pertechnetate concentration, the ratio $c_{TcO_4(org)}/c_{dendrimer(org)}$ is ≤ 1. The higher the generation of the dendrimer and the concentration of pertechnetate, the higher the loading capacity of the dendrimer with pertechnetate. At a total pertechnetate concentration of 5×10^{-4} M, approximately eight pertechnetate anions are extracted into the organic phase per fourth-generation dendrimer **4**.

Multi-crown dendrimers are also capable of extracting mercury(II) ions from chloride-containing solutions. The same trends were observed as in the case of pertechnetate extraction. As shown in Figure 5, the extraction efficiency of mercury(II) ions increases with increasing dendrimer generation. Benzo[15]crown-5 shows only a poor ability to transfer mercury(II) ions into an organic phase.

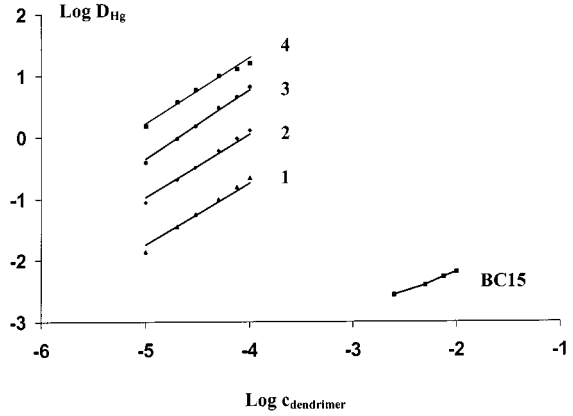

Figure 5. Variation of log D_{Hg}^{II} with dendrimer concentration for the extraction of mercury(II) with dendrimers **1**−**4** and benzo-15-crown-5 (BC15); $c_{HgCl_2} = 1 \times 10^{-5}$ M, pH = 7.5 (TRIS/HCl buffer), $c_{dendrimer} = 1 \times 10^{-5}$ to 1×10^{-4} M in $CHCl_3$, c_{BC15} 1×10^{-3} to 1×10^{-2} M in $CHCl_3$

The different extraction behaviour of multi-crown dendrimers as compared to benzo[15]crown-5 is not caused by a dendritic effect. Apparently, it is determined by the binding mode. Benzo[15]crown-5 is known as a weak extraction agent for $HgCl_2$.[22b] In general, mercury(II) prefers nitrogen and sulfur as donor atoms.[26] Hence, POPAM dendrimers are ideally suited to the binding and extraction of mercury(II) in the presence of chloride. Both neutral undissociated $HgCl_2$ as well as anionic $HgCl_3^-$ and $HgCl_4^{2-}$ may be bound by unprotonated and protonated tertiary amine groups, respectively.[27] The third- and fourth-generation dendrimers **3** and **4** in particular were found to be capable of extracting mercury(II) ions with high efficiency. Furthermore, these dendrimers can be loaded with a multitude of mercury(II) species. Thus, we found that the third-generation dendrimer **3** could accommodate approximately 12 Hg^{II} guests per molecule when mercury(II) was extracted from an aqueous solution ($c_{HgCl_2} = 5 \times 10^{-2}$ M; pH = 7.5; TRIS/HCl buffer) using only a low dendrimer concentration ($c_{\mathbf{3}} = 5 \times 10^{-5}$ M in $CHCl_3$).

Conclusion

It has been demonstrated that novel multi-crown dendrimers are easily accessible by grafting benzo[15]crown-5 units at the periphery of POPAM dendrimers. These multi-

crown dendrimers of four different generations, having 4, 8, 16, and 32 crown moieties at the exterior, are most soluble in organic solvents of low polarity and may serve as a new kind of carrier molecules for transport processes. Extraction studies performed with sodium pertechnetate and mercury(II) chloride have shown that the guest molecules are mainly bound in the interior of the polyamine skeleton. The crown ether units are rather inferior in terms of their complexation behaviour. Replacing the benzo[15]crown-5 units by more suitable [18]crown-6 moieties would seem to be an interesting line of future research, not only with regard to binding metal salts, but also for the complexation of biologically relevant substrates such as amino acids in their zwitterionic forms.

Experimental Section

General Remarks: All synthetic experiments were routinely carried out under dry nitrogen. Starting materials (POPAM dendrimers, generations 1 to 4) were purchased from Aldrich. Benzo[15]crown-5-4′-sulfonyl chloride was prepared according to a published procedure.[28] − NMR-spectroscopic data were obtained at 400 MHz with a Bruker AM 400 spectrometer (for ^{1}H and ^{13}C NMR spectra, the $CDCl_3$ signals were used as an internal reference; shifts are quoted with respect to TMS). − MALDI-TOF mass spectra were obtained with a TofSpec E & SE instrument from Micromass, Manchester.

General Synthetic Procedure for the Multi-Crown Dendrimers 1−4: 1/*n* equiv. of the starting polypropyleneamine dendrimer-$(NH_2)_n$ and 1.1·*n* equiv. of triethylamine were dissolved in dry dichloromethane (150 mL) (where *n* is the number of primary amino groups on the dendrimer). The mixture was heated to reflux, whereupon a solution of *n* equiv. of benzo[15]crown-5-4′-sulfonyl chloride in dichloromethane (50 mL) was added dropwise. The reaction mixture was stirred for 3−5 d under reflux under argon. The solvent was then removed in vacuo, the residue was taken up in dichloromethane, and the resulting solution was thoroughly washed with water, aq. sodium hydrogen carbonate solution, and again water (three times). After drying the organic phase with sodium sulfate and evaporation of the solvent, the multi-crown dendrimers were obtained as bright-yellow solids.

4-Cascade:1,4-diaminobutane[4-*N*,*N*,*N*′,*N*′]:(1-azabutylidene)^1: benzo[15]crown-5-4′-sulfonamide (1): Reaction procedure as described above. Amounts of reagents used to obtain the 4-cascade: 1,4-diaminobutane[4-*N*,*N*,*N*′,*N*′]:(1-azabutylidene)^1:aminopropane (0.20 g, 0.63 mmol), triethylamine (0.28 g, 2.77 mmol), benzo[15]crown-5-4′-sulfonyl chloride (0.93 g, 2.53 mmol). We obtained 0.66 g (0.40 mmol, 64%) of a bright-yellow solid; m.p. 74−76 °C. − ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.39−1.65 (br, 12 H, CH_2), 2.25−2.43 (br, 12 H, CH_2N), 2.79−2.92 (br, 8 H, CH_2NHSO_2), 3.61−3.75 (m, 32 H, OCH_2), 3.76−3.91 (m, 16 H, OCH_2), 4.01−4.21 (m, 16 H, OCH_2), 6.82−6.92 (d, 4 H, CH_{ar}), 7.25−7.32 (s, 4 H, CH_{ar}), 7.35−7.45 (d, 4 H, CH_{ar}). − ^{13}C NMR (62.9 MHz, $CDCl_3$, 25 °C): δ = 25.1 ($CH_2CH_2NHSO_2$), 25.6 (CH_2CH_2N), 42.9 (CH_2NHSO_2), 53.1, 53.5 (CH_2N), 68.9, 69.0, 69.2, 70.2, 70.3, 71.2, 71.2 (OCH_2), 111.1, 111.9, 121.9, 135.9, 149.1, 154.9 (CH_{ar}). − MALDI-TOF MS (matrix: 2,5-DHB; $CHCl_3$/EtOH, 3:1): *m*/*z* (%) = 1659.2 (100) $[M + Na]^+$, 1636.1 (60) $[M]^+$, 1306.6 (8) [M − crown]$^+$, 846.1 (37) $[M/2 + 2CH_2]^+$. − $C_{72}H_{112}N_6O_{28}S_4$: 1638.0.

8-Cascade:1,4-Diaminobutane[4-*N*,*N*,*N*′,*N*′]:(1-azabutylidene)^2: benzo[15]crown-5-4′-sulfonamide (2): Reaction procedure as described above. Amounts of reagents used to obtain the 8-cascade: 1,4-diaminobutane[4-*N*,*N*,*N*′,*N*′]:(1-azabutylidene)^2:aminopropane (0.23 g, 0.30 mmol), triethylamine (0.26 g, 2.64 mmol), benzo[15]-crown-5-4′-sulfonyl chloride (0.88 g, 2.40 mmol). We obtained 0.58 g (0.17 mmol, 58%) of a bright-yellow solid; m.p. 79−80 °C. − ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.32−1.61 (br, 28 H, CH_2), 2.21−2.41 (br, 36 H, CH_2N), 2.75−2.92 (br, 18 H, CH_2NHSO_2), 3.55−3.75 (br, 64 H, OCH_2), 3.80−3.92 (br, 32 H, OCH_2), 4.00−4.20 (m, 32 H, OCH_2), 6.82−6.93 (d, 8 H, CH_{ar}), 7.25−7.32 (s, 8 H, CH_{ar}), 7.35−7.43 (d, 8 H, CH_{ar}). − ^{13}C NMR (62.9 MHz, $CDCl_3$, 25 °C): δ = 24.0 ($CH_2CH_2NHSO_2$), 25.9 (CH_2CH_2N), 42.6 (CH_2NHSO_2), 51.7, 51.9, 52.6 (CH_2N), 68.9, 69.0, 69.19, 70.2, 70.3, 71.16, 71.19 (OCH_2), 111.05, 111.86, 121.91, 135.89, 149.12, 154.89 (CH_{ar}). − MALDI-TOF MS (matrix: 2,5-DHB; $CHCl_3$/EtOH, 3:1): *m*/*z* (%) = 3434.3 (100) $[M + Na]^+$, 3411.7 (47) $[M + H]^+$, 3082.2 (9) [M − crown]$^+$, 1734.7 (32) $[M/2 + 2\ CH_2]^+$. − $C_{152}H_{240}N_{14}O_{56}S_8$: 3413.4.

16-Cascade:1,4-Diaminobutane[4-*N*,*N*,*N*′,*N*′]:(1-azabutylidene)^3: benzo[15]crown-5-4′-sulfonamide (3): Reaction procedure as described above. Amounts of reagents used to obtain the 16-cascade: 1,4-diaminobutane[4-*N*,*N*,*N*′,*N*′]:(1-azabutylidene)^3:aminopropane (0.23 g, 0.14 mmol), triethylamine (0.25 g, 2.46 mmol), benzo[15]-crown-5-4′-sulfonyl chloride (0.82 g, 2.24 mmol). We obtained 0.77 g (0.11 mmol, 81%) of a bright-yellow solid; m.p. 80−82 °C. − ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.45−1.65 (br, 60 H, CH_2), 2.21−2.58 (br, 84 H, CH_2N), 2.78−2.95 (br, 32 H, CH_2NHSO_2), 3.65−3.81 (br, 128 H, OCH_2), 3.82−3.97 (br, 64 H, OCH_2), 4.03−4.21 (br, 64 H, OCH_2), 6.82−6.92 (d, 16 H, CH_{ar}), 7.25−7.32 (s, 16 H, CH_{ar}), 7.35−7.45 (d, 16 H, CH_{ar}). − ^{13}C NMR (62.9 MHz, $CDCl_3$, 25 °C): δ = 24.3 ($CH_2CH_2NHSO_2$), 26.1 (CH_2CH_2N), 42.6 (CH_2NHSO_2), 51.8−52.5 (CH_2N), 68.9, 69.0, 69.2, 70.2, 70.3, 71.2, 71.2 (OCH_2), 111.1, 111.9, 121.9, 135.9, 149.1, 154.9 (CH_{ar}). − MALDI-TOF MS (matrix: THAP; $CHCl_3$/EtOH, 3:1): *m*/*z* (%) = 6969.9 (87) $[M]^+$, 6992.6 (69) $[M + Na]^+$, 3512.1 (40) $[M/2 + CH_2]^+$. − $C_{312}H_{496}N_{30}O_{112}S_{16}$: 6973.0.

32-Cascade:1,4-diaminobutane[4-*N*,*N*,*N*′,*N*′]:(1-azabutylidene)^4: benzo[15]crown-5-4′-sulfonamide (4): Reaction procedure as described above. Amounts of reagents used to obtain the 32-cascade: 1,4-diaminobutane[4-*N*,*N*,*N*′,*N*′]:(1-azabutylidene)^4:aminopropane (0.24 g, 0.07 mmol), triethylamine (0.25 g, 2.46 mmol), benzo[15]-crown-5-4′-sulfonyl chloride (0.82 g, 2.24 mmol). We obtained 0.77 g (0.06 mmol, 80%) of a bright-yellow solid; m.p. 84−85 °C. − ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.41−1.72 (br, 124 H, CH_2), 2.19−2.67 (br, 180 H, CH_2N), 2.79−2.92 (br, 64 H, CH_2NHSO_2), 3.49−3.75 (br, 256 H, OCH_2), 3.76−3.91 (m, 128 H, OCH_2), 4.01−4.21 (br, 128 H, OCH_2), 6.72−6.92 (br, 32 H, CH_{ar}), 7.23−7.32 (br, 32 H, CH_{ar}), 7.35−7.45 (br, 32 H, CH_{ar}). − ^{13}C NMR (62.9 MHz, $CDCl_3$, 25 °C): δ = 26.0 ($CH_2CH_2NHSO_2$), 26.0 (CH_2CH_2N), 42.4 (CH_2NHSO_2), 51.7−52.8 (CH_2N), 68.9, 69.0, 69.2, 70.2, 70.3, 71.2, 71.2 (OCH_2), 111.1, 111.9, 121.9, 135.9, 149.1, 154.9 (CH_{ar}). − $C_{632}H_{1008}N_{62}O_{224}S_{32}$: 14085.

Liquid-Liquid Extraction Procedure: Extraction studies were performed at 25 ± 1 °C in 2-mL microcentrifuge tubes by mechanical shaking.[29] The phase ratio $V_{(org)}/V_{(w)}$ was 1:1 (0.5 mL each); the shaking period was 30 min. The extraction equilibrium was attained within this period. All samples were centrifuged after extraction. The pertechnetate and metal concentrations in both phases

were determined radiometrically using β-emission ($^{99}TcO_4^-$; Beckman LS 6000 LL liquid scintillation counter) and γ-radiation [^{22}Na, ^{203}Hg; Cobra II/Canberra Packard NaI(Tl) scintillation counter]. The pH of the aqueous solution was adjusted using 0.05 M 2-(*N*-morpholino)ethanesulfonic acid (MES)/NaOH (pH = 5.4), *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid) (HEPES)/NaOH (pH = 7.4), and tris(hydroxymethyl)aminomethane (TRIS)/HCl buffer (pH = 7.5).

Acknowledgments

We thank the Sächsisches Ministerium für Wissenschaft und Kunst (project no. 7533-844-98/4) and the BMBF ("Funktionelle supramolekulare Systeme für diagnostische Anwendungen") for support of this work, and Roche Diagnostics GmbH, Penzberg (Dr. H.-P. Josel, Dr. J. Herrmann) for co-operation.

[15] MALDI-TOF spectra of multi-crown dendrimers **1**−**3** are available as Supporting Information; see footnote on the first page of this article.

[16] The extractability of pertechnetate using benzo[15]crown-5 ($c = 1 \times 10^{-2}$ M in $CHCl_3$) was lower than 1% under the experimental conditions used.

[17] Co-operative pertechnetate anion−sodium cation binding has been described for a tripodal tris(amidobenzo[15]crown-5) ligand; see: P. D. Beer, P. K. Hopkins, J. D. McKinney, *Chem. Commun.* **1999**, 1253−1254.

[18] At pH < 5, the solubility of lipophilic POPAM dendrimers in the aqueous phase is noticeably increased. This is obviously due to the higher hydrophilicity of the higher protonation state. Thus, dendrimers incorporating amino groups are rather unsuitable as extractants in more acidic media.

[19] For the protonation mechanism of POPAM dendrimers, see: [19a] G. J. M. Koper, M. H. P. van Genderen, C. Elissen-Roman, M. W. P. L. Baars, E. W. Meijer, M. Borkovec, *J. Am. Chem. Soc.* **1997**, *119*, 6512−6521. − [19b] R. C. van Duijvenbode, M. Borkovec, G. J. M. Koper, *Polymer* **1998**, *39*, 2657−2664.

[20] In the case of TRIS/HCl buffer (pH = 7.5), the chloride concentration is 4.2×10^{-2} M, which represents a huge excess over the pertechnetate concentration (ratio Cl^-/TcO_4^- = 4200:1).

[21] Dendrimers bearing 3,4-dimethoxybenzene peripheral groups extract pertechnetate with comparable efficiency as multi-crown dendrimers. Thus, at pH = 7.4, the third-generation 3,4-dimethoxybenzene-functionalized dendrimer ($c_{dendrimer} = 1 \times 10^{-4}$ M) extracts 42.1% of the pertechnetate into the or-

ganic phase. The analogous multi-crown dendrimer **3** extracts 54.1% of the pertechnetate under the same experimental conditions.

Platinum(II) Complexes of 2-(Dimethylamino)ethylselenolate − Donor−Acceptor Inter-Ligand Interactions as Evident from Experimental and TD-DFT Computational Analysis

Sandip Dey,[a] Vimal K. Jain,*[a] Axel Knoedler,[b] Wolfgang Kaim,[b] and Stanislav Zalis[c]

Keywords: Platinum / Selenium / NMR spectroscopy / Density functional calculations

Several platinum(II) complexes of 2-(dimethylamino)ethaneselenolate with the formulae, $[PtCl(SeCH_2CH_2NMe_2)(PR_3)]$ (**1**), $[PtPh(SeCH_2CH_2NMe_2)(PnBu_3)]$ (**2**), $[Pt_2Ph_2(Cl)(SeCH_2CH_2NMe_2)(PnBu_3)_2]$ (**3**), $[Pt_2Cl_3(SeCH_2CH_2NMe_2)(PR_3)_2]$ (**4**), $[Pt(SeCH_2CH_2NMe_2)_2(P–P)]$ (**5**), $[Pt_2(SeCH_2CH_2NMe_2)_2(P–P)_2]^{++}$ (**6**), and $[Pt(SeCH_2CH_2NMe_2)(PPh_3)]_n[PF_6]_n$ (**7**) have been synthesized and characterized by elemental analysis, UV/Vis and NMR (^1H, ^{31}P, ^{77}Se, ^{195}Pt) spectroscopy. The stereochemistry of these complexes (**1**–**7**) has been deduced from NMR spectroscopic data. A weak absorption in the UV/Vis spectrum of **1** has been assigned to a ligand (Se)-to-ligand (PR_3) charge transfer (LLCT), supported by TD-DFT calculations. The structures of $[PtCl(SeCH_2CH_2NMe_2)(PPh_3)]$ and $[Pt_2Ph_2(Cl)(SeCH_2CH_2NMe_2)(PnBu_3)_2]$ have been established by single crystal X-ray diffraction analysis. Each platinum atom in the latter is coordinated to four different ligands and $Me_2NCH_2CH_2Se$ behaves as μ_2-bridging and is also simultaneously chelated to one of the platinum atoms.

Introduction

Platinum group metal chalcogenolates have attracted considerable attention during the last 15 years or so due to their wide structural diversity[1] and relevance in catalysis,[2−5] and as a result of being precursors for the synthesis of metal chalcogenides[6−8] for electronic devices.[9] The area of metal chalcogenolates has been dominated by molecules containing the M−SR linkage.[1] In most cases these molecules have been isolated as non-volatile, insoluble (or sparingly soluble) polymers, thus making them inconvenient as precursors for the synthesis of metal chalcogenides. Although several strategies have been adopted to suppress polymerisation, the use of hybrid ligands containing both soft chalcogen and hard N donor atoms has been quite successful, such as pyridine-2-thiolate[10] or aliphatic mercapto amines.[11−14] The continued current interest in selenium containing inorganic materials[15] and in pursuance of our program on the design and development of molecular precursors, we explored some chemistry of internally functionalized selenolates, viz. pySe[16] and $Me_2NCH_2CH_2Se^-$.[8] Herein we now report the synthesis, spectroscopy, electrochemistry, structures, and DT-DFT calculations of platinum complexes derived from the latter ligand.

Results and Discussion

Synthesis and Spectroscopy

Treatment of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ with two equivalents of $NaSeCH_2CH_2NMe_2$, prepared by the reductive cleavage of the Se−Se bond in $(Me_2NCH_2CH_2Se)_2$ with sodium borohydride, afforded dimethylaminoethylselenolate complexes of the type $[PtCl(\eta^2\text{-}SeCH_2CH_2NMe_2)(PR_3)]$ (**1**) [PR_3 = PEt_3 (**1a**), $PnPr_3$ (**1b**), $PnBu_3$ (**1c**), PMe_2Ph (**1d**), or $PMePh_2$ (**1e**)] (Scheme 1). The analogous triphenylphosphane complex, $[PtCl(SeCH_2CH_2NMe_2)(PPh_3)]$ (**1f**) can be readily prepared by the reaction of $PtCl_2(PPh_3)_2$ with one equivalent of $NaSeCH_2CH_2NMe_2$.

The ^1H NMR spectra of **1** showed the expected integration and peak multiplicities. The selenolate proton resonances, i.e., $SeCH_2$, NMe_2, NCH_2 were flanked with platinum satellites with ^3J(Pt-H) being 24−27, 14−18, and 36−42 Hz, respectively. The observed magnitudes of ^3J(Pt-H) can be compared with platinum complexes containing neutral $RSeCH_2CH_2NMe_2$ ligands.[17,18] The ^{31}P NMR spectra of **1** exhibited single resonances flanked with ^{195}Pt satellites. The magnitude of ^1J(Pt-P), (3434−3662 Hz) indicates that the phosphane ligand is *trans* to the nitrogen atom of the chelated $[SeCH_2CH_2NMe_2]^-$ group.[16,19,20] The $^{195}Pt\{^1H\}$ NMR spectra of these complexes displayed a doublet due to coupling with a single ^{31}P nucleus. The doublet appeared in a narrow range of δ = −4266 to −4308. As is evident from Table 1, there is shielding of the ^{195}Pt resonances as the phosphane ligand is changed from PMe_2Ph to $PMePh_2$ through PPh_3. A similar trend is evident for ^{77}Se and ^{31}P chemical shifts which, however, showed deshielding. The ^{77}Se NMR resonances for **1** appeared as a triplet owing to the coupling with the ^{195}Pt nucleus. The resonance for **1f**, however, appeared as a broad signal and

hence platinum coupling could not be resolved. The magnitude of $^1J(^{195}Pt\text{-}^{77}Se)$ is comparable to that of the values reported for mononuclear platinum selenolates.[16,21,22] The appearance of a single resonance in ^{77}Se NMR spectra suggests that the phosphane is *cis* to the selenium atom as the $^2J(^{77}Se\text{-}^{31}P)_{cis}$ couplings are usually small (> 10 Hz).[22,23] However, such couplings are slightly larger for **1d** and **1e** (24 and 30 Hz, respectively) and could thus be resolved in the ^{77}Se NMR spectra.

Reaction of [Pt$_2$Ph$_2$(μ-Cl)$_2$(P*n*Bu$_3$)$_2$] with two equivalents of NaSeCH$_2$CH$_2$NMe$_2$, affords a mixture of products, [PtPh(SeCH$_2$CH$_2$NMe$_2$)(P*n*Bu$_3$)] (**2**) and [Pt$_2$Ph$_2$(Cl)-(SeCH$_2$CH$_2$NMe$_2$)(P*n*Bu$_3$)$_2$] (**3**). Compound **3** appears to be an intermediate product in the reaction, which on further reaction with NaSeCH$_2$CH$_2$NMe$_2$ yields **2**. The calculated values of C, H, and N for the two are not significantly different, hampering an unambiguous identification of **2** and **3**. The two can, however, be separated by repeated

recrystallization. The NMR spectroscopic data for **2** can be compared with **1** as described above. Although the magnitude of ^1J(Pt-P) is greater (418 Hz) than that of **1c**, it is in compliance with $ArPt^{II}$ complexes in which the phosphane is *trans* to nitrogen, e.g. $[Pt_2R_2(\mu\text{-}N{-}N)_2(PR_3)_2]$ (R = Me or aryl, N−N = pyrazole).[24] The ^{31}P and ^{195}Pt NMR spectra of **3** exhibited two separate resonances attributable to "$PtPhCl(PnBu_3)$" and "$PtPh(Se{-}N)(PnBu_3)$" fragments. The magnitude of ^1J(Pt-P) suggests that the phosphane ligand is *trans* to Cl in the former and *trans* to N in the latter fragment.[25] This stereochemistry is unambiguously established by X-ray structural analysis (see later).

The chloro analogue of **3**, $[Pt_2Cl_3(SeCH_2CH_2NMe_2)(PR_3)_2]$ (**4**) [PR_3 = PEt_3 (**4a**), PMe_2Ph (**4b**)] can be obtained readily by treatment of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ with **1** in 1:2 molar ratio. The ^{31}P NMR spectra of a freshly prepared solution exhibited two singlets each flanked with platinum satellites. The signal of lower frequency may be attributed to the phosphane attached to the metal atom containing the chelating Se−N ligand. The magnitude of ^1J(Pt-P) coupling associated with this signal is reduced (≈ 90 Hz) relative to that of the corresponding mononuclear complex. The second resonance at higher frequency may be assigned to the phosphane coordinated to the metal atom containing two chlorines and the selenium atom. Similar NMR spectroscopic data have been reported for $[Pt_2Cl_3(\mu\text{-}Sepy)(PR_3)_2]$.[16] Although the spectra of **4b** did not change with time, **4a** slowly isomerised in solution to establish an equilibrium with another species **4a′**. Thus, a $CDCl_3$ solution of **4a**, after 2 h, displayed four resonances (δ = 5.1, 3.4, 3.1, 2.4), each showing platinum satellites, the intensity of which changed with time until an equilibrium is reached after two days. No change occurs after a week. It is likely that the "$PtCl_2(PR_3)$" fragment of **4a** isomerises from *cis*-"$PtCl_2$" to the *trans*-"$PtCl_2$" configuration, a structure observed for palladium complex, $[Pd_2Cl_3(Sepy)(PR_3)_2]$.[16] Thus, the second set of resonances (δ = 3.1, ^1J(Pt-P) = 3504 Hz; δ = 2.4, ^1J(Pt-P) 3218 Hz) may be attributed to **4a′** in which "$PtCl_2$" has a *trans* configuration.

Reaction of $PtCl_2(P{-}P)$ with two equivalents of $NaSeCH_2CH_2NMe_2$ yields, mononuclear $[Pt(SeCH_2CH_2NMe_2)_2(P{-}P)]$ (**5**) [P−P = dppm (**5a**), dppe (**5b**), dppp (**5c**)] as yellow crystalline solids. The NMR spectra (^{31}P, ^{77}Se, ^{195}Pt) (Table 1) are similar to several organochalcogenolates $[Pt(ER)_2(P{-}P)]$ reported by us.[16,21,23,26] These complexes have been assigned a *cis* configuration. Unlike **1**, the $Me_2NCH_2CH_2Se$ in **5** acts in monodentate fashion i.e., binding through selenium only. This mode of binding can readily be identified from ^1H NMR spectra. The NMe_2 protons in **5** appear at δ ≈ 2.0 with the absence of ^{195}Pt couplings whereas in **1** they appear at δ ≈ 2.7 with ^{195}Pt couplings. When the reaction is carried out in 1:1 stoichiometry in the presence of $NaBPh_4$ (Scheme 1), a new series of binuclear complexes, $[Pt_2(SeCH_2CH_2NMe_2)_2(P{-}P)_2][BPh_4]_2$ (**6**) [P−P = dppm (**6a**), dppe (**6b**), dppp (**6c**)] could be isolated. Complex **6** can also be prepared, as pale yellow fibrous crystals, by the reaction of **5** with $[Pt(solvent)_2(P{-}P)][BPh_4]_2$. The ^{77}Se NMR spectra exhibited single resonances suggesting that two bridging selenolate ligands are equivalent. The signals are deshielded with increased ^1J(Pt-Se) in comparison to the corresponding resonance for **5**. However the $^{31}P\{^1H\}$ (Figure 1) and $^{195}Pt\{^1H\}$ (Figure 2) spectra showed two sets of resonances, and doublet of doublets, respectively; a pattern indicative of non-equivalence of phosphorus nuclei of the P−P ligand. The spectra of **6a** and **6c** further showed phosphorus coupling, thus each signal appeared as a doublet (Figure 1). The X-ray structures of several mononuclear compounds $[M(ER)_2(P{-}P)]$ (E = S or Se, M = Pd or Pt) have been reported.[13,23] The structures reveal that in thiolates the two M−S distances are nearly identical,[13,23] but for selenolates the two M−Se distances differ markedly[21,23,26] (e.g. $Pt(Sepy)_2(dppe)$ Pt−Se = 2.498, 2.433 Å).[26] Similar differences in Pt−E distances in binuclear complexes $[Pt_2X_2(\mu\text{-}ER)_2(PR_3)_2]$ (ER = SeEt, $SeCH_2Ph$)[19,27] are reported. The selenolato ligands form an asymmetric Pt_2Se_2 ring[19,27] whereas the thiolates give a symmetrical Pt_2S_2 fragment.[28] On chelation of $M(ER)_2(P{-}P)$ with another metal centre, binuclear complexes such as $[M_2(ER)_2(P{-}P)_2]^{++}$ [11,13] (M = Pd or Pt) are formed when E = S a symmetrical M_2E_2 bridge forms as shown by the X-ray structure of $[M_2(\mu\text{-}SC_5H_9NMe)_2(dppe)_2][BPh_4]_2$[13] where M−S distances are nearly equivalent. Accordingly all phosphorus nuclei become chemically equivalent and display only one ^{31}P NMR resonance.[11,13,21,23] In case of binuclear cationic selenolate complexes, as observed for $[Pt_2Cl_2(\mu\text{-}SeR)_2(PR_3)_2]$,[19,27] the M−Se bridge may be asymmetric (**I**) due to different M−Se distances consequently making the

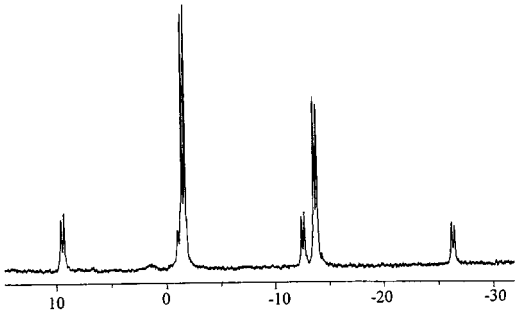

Figure 1. $^{31}P\{^1H\}$ NMR spectrum of $[Pt_2(SeCH_2CH_2NMe_2)_2(dppp)_2][BPh_4]_2$ (**6c**) in $CDCl_3$

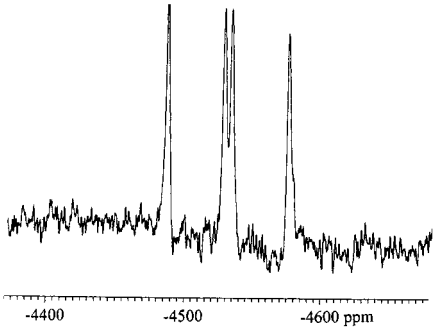

Figure 2. $^{195}Pt\{^1H\}$ NMR spectrum of $[Pt_2(SeCH_2CH_2NMe_2)_2(dppp)_2][BPh_4]_2$ (**6c**) in $CDCl_3$

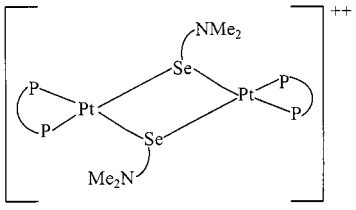
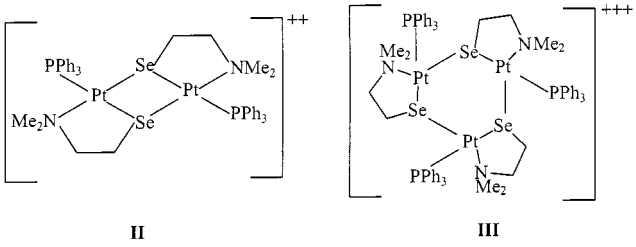
phosphorus nuclei magnetically different. The two inequivalent phosphorus nuclei are coupled together to give doublets in the ^{31}P NMR spectra of **6a** and **6c**. The magnitude of ^{2}J(P-P) couplings are in accordance with the literature values.[29] The absence of ^{2}J(P-P) in **6b** might be due to different signs of ^{3}J(P-P), ^{2}J(P-P) coupling operating through P−C−C−P and P−Pt−P routes, respectively.[30] The intensity of two resonances (Figure 1) is significantly different. This can be attributed to the difference in the magnitude of T_1 of two sites, as reported earlier.[30]



I

Treatment of **1f** with $AgPF_6$ affords $[Pt(SeCH_2CH_2NMe_2)(PPh_3)]_n[PF_6]_n$ (**7**). The ^{31}P, ^{77}Se, and ^{195}Pt spectra exhibited two separate resonances in approximately a 2:1 ratio. The ^{1}J(Pt-P) in ^{31}P and ^{195}Pt NMR spectra are comparable, indicating that both the species have similar configuration. Recently we have reported the structure of $[\{Pd(SeCH_2CH_2NMe_2)Cl\}_n]$ which is a trimer ($n = 3$) in which the chelated Se−N ligand bridges another palladium atom through Se.[8] The observed two signals may be interpreted for dimeric (**II**) and trimeric (**III**) forms in which each platinum is bonded to two Se atoms, one N and one PPh_3 in nearly similar environments.



II **III**

Absorption Spectra and Electrochemistry

The absorption spectra of the complexes $[PtCl(SeCH_2CH_2NMe_2)(PR_3)]$ in CH_2Cl_2 solution are characterised by a very weak band at 400−430 nm (Figure 3, Table 2). The band is hypsochromically shifted on replacing the phenyl substituents on the PR_3 group by donating alkyl groups. As will be confirmed by TD-DFT calculations (see below) this absorption is due to a ligand (Se)-to-ligand (PR_3) charge transfer (LLCT) transition. The geometry obviously allows only rather poor orbital overlap, resulting in very weak yet well discernible bands (Figure 3). A similar band with $\varepsilon = 80\ mol^{-1}\cdot dm^3\cdot cm^{-1}$ at 514 nm has been reported for the palladium analogue $[PdCl(SeCH_2CH_2NMe_2)(PPh_3)]$.[8] Allowed transitions occur only at higher energies with $\lambda_{max} < 300$ nm, in agreement with theory. The dinuclear species $[Pt_2Ph_2(Cl)(SeCH_2CH_2NMe_2)(PnBu_3)_2]$ does not allow a detectable Se-to-P*n*Bu$_3$ transition in the visible or near UV region(Table 2).

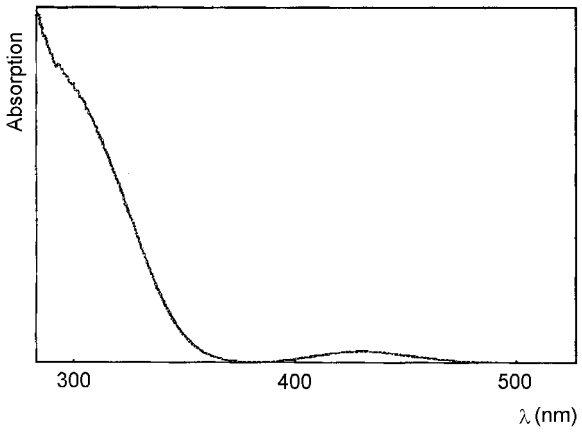


Figure 3. UV/Vis spectrum of $[PtCl(SeCH_2CH_2NMe_2)(PPh_3)]$ (**1f**) in CH_2Cl_2

Table 2. UV/Vis absorption data of some platinum complexes recorded in CH_2Cl_2

$[PtCl(SeCH_2CH_2NMe_2)(PMePh_2)]$ (**1e**)	266 sh, 273 sh, 293 sh, 418
$[PtCl(SeCH_2CH_2NMe_2)(PPh_3)]$ (**1f**)	268 sh, 275 sh, 300 sh, 430

According to cyclic voltammetry in CH_2Cl_2/0.1 $mol\cdot dm^{-3}$ Bu_4NPF_6 the Pt^{II} complexes **1** and **3** are oxidised irreversibly. The peak potentials for **1** show little variation (0.83−0.89 V vs. ferrocene/ferrocenium), confirming that it is primarily the selenolate part (HOMO) which loses an electron and not the PR_3^- ligating platinum centre. The bridging selenolate in compound **3** is hard to oxidise as illustrated by the anodic peak potential of 1.13 V for irreversible oxidation.

Electronic Structure Calculations on 1f

The ADF/BP calculated one-electron scheme of the $[PtCl(SeCH_2CH_2NMe_2)(PPh_3)]$ complex is schematically given in Figure 4. The composition of important molecular

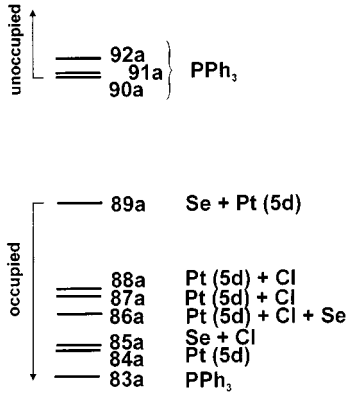

Figure 4. ADF/BP calculated qualitative MO scheme of **1f**

Table 3. ADF/BP calculated one-electron energies and percentage composition of selected highest occupied and lowest unoccupied molecular orbitals of [PtCl($SeCH_2CH_2NMe_2$)(PPh_3)] (**1f**) expressed in terms of composing fragments

MO	*E* [eV]	Prevailing Character	Pt	PPh_3	Se	Cl	N
Unoccupied							
92a	−1.87	PPh_3	3 (d)	90	2	2

83a	−6.60	PPh_3	6 (d)	72	10	3	2

orbitals is summarised in Table 3. The highest molecular orbital 89a is formed mainly from a Se *p* orbital with some additional metal contribution. Pt 5*d* and Cl 3*p* orbitals contribute significantly to the next lower lying occupied MOs. The set of the lowest lying unoccupied molecular orbitals, 90a, 91a, and 92a, is to a large extent located on the PPh_3 fragment. The composition of the occupied MOs of the [PtCl($SeCH_2CH_2NMe_2$)(PH_3)] model (Table 4) corresponds to those of the PPh_3 complex. The lowest lying molecular orbital is delocalised; PH_3 localised unoccupied MOs lie at a rather high energy. The excitation energies listed in Table 5 were calculated for the [PtCl($SeCH_2CH_2NMe_2$)(PH_3)] model with different DFT program configurations. In agreement with the experiments, there is one very weak transition (HOMO→LUMO, oscillator strength $< 10^{-3}$) at low energy, set apart by more than 1 eV from the following singlet transitions (Table 5). The calculated excitation energies of about 2.4 eV (corresponding to ca. 500 nm) are in broad agreement with the 400−430 nm observed for various substituted derivatives (Table 2). This conspicuous absorption must be formulated mainly as ligand (Se)-to-ligand (PR_3) charge transfer, as has been proposed previously for palladium analogues.[8]

Table 4. ADF/BP calculated one-electron energies and percentage composition of selected highest occupied and lowest unoccupied molecular orbitals of model complex [PtCl($SeCH_2CH_2NMe_2$)(PH_3)] expressed in terms of composing fragments

Crystal Structures of 1f and 3

An ORTEP plot of **1f** with the crystallographic numbering scheme is shown in Figure 5, and Table 6 summarises essential data. The geometry around the platinum atom is essentially square planar with the atoms P, Cl, Se, and N defining the coordination sphere. The phosphane ligand is *trans* to the nitrogen atom of the chelating selenolate group as inferred from the NMR spectroscopic data. The five-membered chelate ring (Pt−Se−C−C−N) exists in a puckered conformation with the carbon atoms C(19) and C(20) lying on opposite sides of the mean plane. The structure of **1f** is isomorphous to its palladium analogue, [PdCl($SeCH_2CH_2NMe_2$)(PPh_3)][8] and various bond lengths and angles in the two structures are comparable.

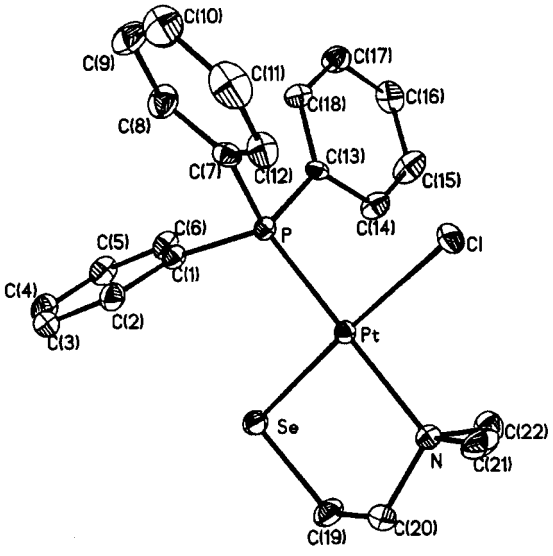

Figure 5. Molecular structure of [PtCl($SeCH_2CH_2NMe_2$)(PPh_3)] (**1f**) with crystallographic numbering scheme

Table 5. Selected calculated lowest TD DFT singlet excitation energies (eV) for [PtCl($SeCH_2CH_2NMe_2$)(PH_3)]

State	Main character	ADF/BP		G98/B3LYP	
		Transition energy [eV]	Oscillator strength	Transition energy [eV]	Oscillator strength
$^1A_1$	HOMO → LUMO	2.24	0.0004	2.53	0.0006
$^1A_1$	HOMO → LUMO +1	3.55	0.001	3.71	0.002
$^1A_1$	HOMO − 1 → LUMO	3.58	0.002	3.95	0.005
$^1A_1$	HOMO → LUMO + 2	3.67	0.010	4.08	0.012
$^1A_1$	HOMO −4 → LUMO	4.71	0.082	5.09	0.190

Table 6. Selected bond lengths [Å] and bond angles [°] with esd's for [PtCl(SeCH$_2$CH$_2$NMe$_2$)(PPh$_3$)] (**1f**)

Pt−N	2.161 (5)	N−C(20)	1.501 (8)
Pt−P	2.2292 (15)	N−C(21)	1.485 (8)

Pd−Se−C(19)	95.9 (2)	N−C(20)−C(19)	112.2 (5)
		Se−C(19)−C(20)	108.9 (4)

The molecular structure of [Pt$_2$Ph$_2$(Cl)(SeCH$_2$CH$_2$NMe$_2$)(P*n*Bu$_3$)$_2$] (**3**), established by the X-ray diffraction method, is illustrated in Figure 6. Selected bond lengths and bond angles are given in Table 7. The structure consists of two distorted square planar platinum atoms which are held together by a bridging selenolate centre. The two square planes of the platinum atoms are inclined to each other through a Pt(1)−Se−Pt(2) angle of 111.69 (5)°. Each platinum atom is coordinated to four different ligand atoms. The Pt(1) centre is coordinated to Ph, Cl, PBu$_3$, and the selenium atom, the latter being mutually *trans*. The Pt(2) atom is bound to the chelating Me$_2$NCH$_2$CH$_2$Se ligand and to the other PBu$_3$ and Ph groups. The phosphane is *trans* to the nitrogen atom whereas Se is *trans* to Ph. The Pt−Se distances in **1f** [2.3788(15) Å] and **3** [2.4793(14) and 2.4562(12) Å] are significantly different, although these distances are in agreement with the standard values. The longer Pt−Se distances in **3** compared with that of **1f** reflect greater *trans* influence of Ph and PBu$_3$ than the chloride.

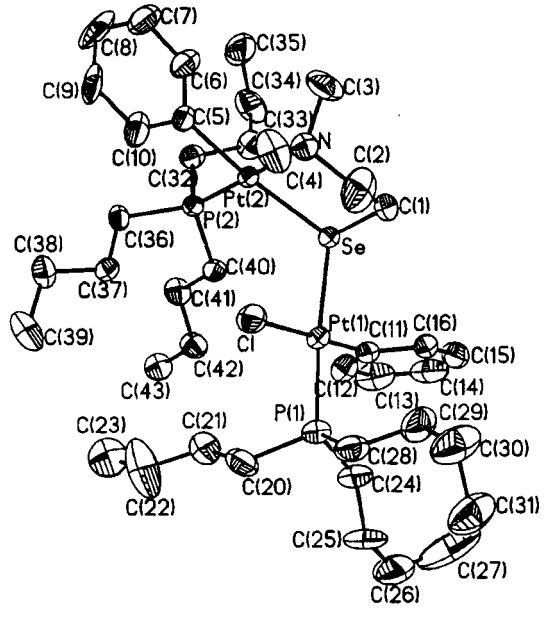

Figure 6. ORTEP plot of [Pt$_2$Ph$_2$Cl(SeCH$_2$CH$_2$NMe$_2$)(P*n*Bu$_3$)$_2$] (**3**) with crystallographic numbering scheme

Table 7. Selected bond lengths [Å] and bond angles [°] with esd's for [Pt$_2$Ph$_2$(Cl)(SeCH$_2$CH$_2$NMe$_2$)(P*n*Bu$_3$)] (**3**)

Pt(1)−Se	2.4793(14)	Pt(2)−Se	2.4562(12)
Pt(1)−P(1)	2.235(3)	Pt(2)−P(2)	2.227(2)
Pt(1)−Cl	2.432(3)	Pt(2)−N	2.177(9)
Pt(1)−C(11)	2.010(10)	Pt(2)−C(5)	2.039(10)
Se−C(1)	1.931(12)	N−C(2)	1.542(18)
C(11)−Pt(1)−P(1)	92.1(3)	C(5)−Pt(2)−N	90.7(3)
C(11)−Pt(1)−Cl	178.4(3)	C(5)−Pt(2)−P(2)	88.5(3)
P(1)−Pt(1)−Cl	88.20(11)	P(2)−Pt(2)−N	178.9(2)
C(11)−Pt(1)−Se	85.1(3)	C(5)−Pt(2)−Se	174.0(3)
P(1)−Pt(1)−Se	175.23(8)	N−Pt(2)−Se	87.2(2)
Cl−P(1)−Se	94.69(8)	P(2)−Pt(2)−Se	93.64(7)
Pt(1)−Se−Pt(2)	111.69(8)	Pt(2)−N−C(2)	109.2(7)
Pt(1)−Se−C(1)	101.7(4)	Se−C(1)−C(2)	110.7(9)
		Pt(2)−Se−C(1)	95.3(4)

The comparable *trans* influence of PBu$_3$ and Ph groups is evident from the ^1J(Pt-P) values from NMR spectra. Other distances, Pt−P, Pt−Cl, Pt−N, and Pt−C are well in agreement with those reported in the literature.[16,21,23,26]

Experimental Section

All the reactions were carried out under a nitrogen atmosphere in dry, distilled analytical grade solvents to prevent oxidation of the oxygen sensitive selenolate ions. The complexes K$_2$[PtCl$_4$], *cis*-[PtCl$_2$(PPh$_3$)$_2$], *cis*-[PtCl$_2$(P−P)], *trans*-[Pt$_2$Cl$_2$(μ-Cl)$_2$(PR$_3$)$_2$], and the mixture of *cis*- and *trans*-[Pt$_2$Ph$_2$(μ-Cl)$_2$(P*n*Bu$_3$)$_2$] (P−P = dppm, dppe, dppp; PR$_3$ = PEt$_3$, P*n*Pr$_3$, P*n*Bu$_3$, PMe$_2$Ph, PMePh$_2$) were prepared by the literature methods.[31,32,33] Melting points were determined in capillary tubes and are uncorrected. Microanalyses were performed by the Analytical Chemistry Division of B.A.R.C. ^{1}H, ^{31}P{^{1}H}, ^{77}Se{^{1}H}, and ^{195}Pt{^{1}H} NMR spectra were recorded on a Bruker DPX-300 NMR spectrometer operating at 300, 121.49, 57.31, 64.52 MHz, respectively. Chemical shifts are relative to internal chloroform peak (δ = 7.26) for ^{1}H, external 85% H$_3$PO$_4$ for ^{31}P, Me$_2$Se for ^{77}Se, and Na$_2$PtCl$_6$ for ^{195}Pt. UV/Vis absorption spectra were recorded on a Bruins Instruments Omega 10 spectrophotometer. Cyclic voltammetry was carried out at 100 mV/s scan rate in dichloromethane/0.1 M Bu$_4$NPF$_6$ using a three electrode configuration (glassy carbon working electrode, Pt counter electrode, Ag/AgCl reference) and a PAR 273 potentiostat and function generator. The ferrocene/ferrocenium couple served as internal reference.

Ground state electronic structure calculations on [PtCl(SeCH$_2$CH$_2$NMe$_2$)(PPh$_3$)] have been done by density-functional theory (DFT) methods using the ADF2000.01[34,35] and Gaussian 98[36] program packages. The lowest excited states were calculated by the time dependent DFT (TD-DFT) method (both ADF and G98 programs) for the model system [PtCl(SeCH$_2$CH$_2$NMe$_2$)(PH$_3$)]. Within the ADF program, Slater type orbital (STO) basis sets of double-ζ quality with polarisation functions within the phenyl rings and triple-ζ for the rest of the system were employed. The inner shells were represented by the frozen core approximation (1s for C, N 2p for Cl, 3p for Se, and 1s−4d for Pt were kept frozen). The following density functionals were used within ADF: The local density approximation (LDA) with VWN parameterisation of electron gas data or the functional including Becke's gradient correction[37] to the local exchange expression in conjunction

with Perdew's gradient correction[38] to the LDA expression (ADF/BP). The scalar relativistic (SR) zero order regular approximation (ZORA) was used within the study. Within Gaussian-98 Dunning's polarized valence double-ζ basis sets[39] were used for C, N, Cl, and H atoms; quasirelativistic effective core pseudopotentials and a corresponding optimized set of basis functions was employed for Pt[40] and Se.[41] Becke's three parameter hybrid functional with the Lee, Yang, and Parr correction functional (B3LYP)[42] was used in Gaussian 98 calculations (G98/B3LYP). The calculation on the model system $[PtCl(SeCH_2CH_2NMe_2)(PH_3)]$ was done with the experimental geometry of the PPh_3 complex with an optimized structure of the PH_3 ligand.

1. Preparation of $[PtCl(SeCH_2CH_2NMe_2)(PEt_3)]$ (1a): To a freshly prepared methanolic solution (5 cm^3) of $NaSeCH_2CH_2NMe_2$ [prepared from $(Me_2NCH_2CH_2Se)_2$ (99.7 mg, 0.32 mmol) and $NaBH_4$ (25.4 mg, 0.67 mmol)] was added a dichloromethane solution (20 cm^3) of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PEt_3)_2]$ (247.7 mg, 0.32 mmol). The reaction mixture was stirred at room temperature for 4 h. The solvents were evaporated under reduced pressure and the residue was extracted with dichloromethane (3×7 cm^3), the solution was passed through a Florisil column and the solvent removed in vacuo. The residue was recrystallised from hexane (yield 210 mg, 65%). All other mononuclear complexes $[PtCl(SeCH_2CH_2NMe_2)(PR_3)]$ (PR_3 = P*n*Pr$_3$, P*n*Bu$_3$, PMe_2Ph, $PMePh_2$) were prepared in a similar manner. Pertinent data are summarized in Table 8.

2. Preparation of $[PtCl(SeCH_2CH_2NMe_2)(PPh_3)]$ (1f): Prepared analogously as described in method **5** by using $[PtCl_2(PPh_3)_2]$ (268.8 mg, 0.34 mmol) $NaSeCH_2CH_2NMe_2$ [prepared from $(Me_2NCH_2CH_2Se)_2$ (54.4 mg, 0.18 mmol) and $NaBH_4$ (14.0 mg, 0.37 mmol)]. The residue was washed thoroughly with diethyl ether to remove liberated triphenylphosphane and then recrystallised from CH_2Cl_2/acetone mixture as yellow-orange crystals (yield 158 mg, 72%).

3. Preparation of $[PtPh(SeCH_2CH_2NMe_2)(PnBu_3)]$ (2) and $[Pt_2Ph_2Cl(SeCH_2CH_2NMe_2)(PnBu_3)_2]$ (3): Prepared analogously

Table 8. Physical, analytical and ^1H NMR spectroscopic data for dimethylaminoethaneselenolate complexes of platinum(II)

as described in method **1** from $[Pt_2Ph_2(\mu\text{-}Cl)_2(PnBu_3)_2]$ (99.5 mg, 0.10 mmol) and $NaSeCH_2CH_2NMe_2$ [prepared from $(Me_2NCH_2CH_2Se)_2$ (32 mg, 0.11 mmol) and $NaBH_4$ (8.9 mg, 0.23 mmol)]. The ^{31}P and ^{195}Pt NMR spectra of this product exhibited three resonances. The product on recrystallization from hexane gave colourless crystals of $[PtPh(SeCH_2CH_2NMe_2)(PnBu_3)]$ (yield 29 mg, 24%). The supernatant solution on repeated recrystallization from hexane containing ≈ 5% benzene afforded $[Pt_2Ph_2(Cl)(SeCH_2CH_2NMe_2)(PnBu_3)_2]$ (54 mg, 48%).

4. Preparation of $[Pt_2Cl_3(SeCH_2CH_2NMe_2)(PEt_3)_2]$ (4a): Solid $[PtCl(SeCH_2CH_2NMe_2)(PEt_3)]$ (17.7 mg, 0.04 mmol) was mixed with $[Pt_2Cl_2(\mu\text{-}Cl)_2(PEt_3)_2]$ (13.5 mg, 0.02 mmol) in $CDCl_3$ (0.5 cm^3) in an NMR tube. After a few days the solution was dried in vacuo, the pale yellow product was washed with hexane and dried in vacuo (yield 25.0 mg, 80%).

5. Preparation of $[Pt(SeCH_2CH_2NMe_2)_2(dppe)]$ (5b): To a stirred methanolic solution (5 cm^3) of $NaSeCH_2CH_2NMe_2$ [prepared from $(Me_2NCH_2CH_2Se)_2$ (92.8 mg, 0.31 mmol) and $NaBH_4$ (23.8 mg, 0.63 mmol)] solid $[PtCl_2(dppe)]$ (201.5 mg, 0.30 mmol) was added. To this mixture dry acetone (20 cm^3) was added whereupon a yellow solution formed which was stirred for 3 h at room temperature. The solvents were stripped off under vacuum and the residue was extracted with acetone (3×7 cm^3) and filtered. The filtrate was reduced to a minimum volume (5 cm^3), a few drops of hexane were added to yield yellow crystals of the title complex (yield 163 mg, 60%).

The complexes $[Pt(SeCH_2CH_2NMe_2)_2(P-P)]$ (P−P = dppm, dppe) were prepared in an analogous manner.

6. Preparation of $[Pt_2(SeCH_2CH_2NMe_2)_2(dppm)_2][BPh_4]_2$ (6a): a) A dichloromethane suspension of (20 cm^3) of $[PtCl_2(dppm)]$ (248.9 mg, 0.38 mmol) was added to a stirred methanolic solution (5 cm^3) of $NaSeCH_2CH_2NMe_2$ [prepared from $(Me_2NCH_2CH_2Se)_2$ (59.2 mg, 0.20 mmol) and $NaBH_4$ (15.5 mg, 0.41 mmol)]. After 1 h of stirring a methanolic solution of $NaBPh_4$ (133.5 mg, 0.39 mmol) was added and the whole mixture was stirred for 3 h. Solvents were evaporated in vacuo and the residue was extracted with dichloromethane and passed through a Florisil column. The solvent was evaporated in vacuo, the residue was washed with hexane and recrystallised from a CH_2Cl_2/hexane mixture (yield 261 mg, 65%). Other cationic complexes $[Pt_2(SeCH_2CH_2NMe_2)_2(P-P)_2][BPh_4]_2$ (P−P = dppe, dppp) were prepared in a similar way.

b) To a methanolic suspension (8 cm^3) of $[PtCl_2(dppm)]$ (215.7 mg, 0.33 mmol) a methanolic solution (3 cm^3) of $NaBPh_4$ (114.2 mg, 0.33 mmol) was added and stirred for 1 h whereupon a pale yellow solution formed. To this a freshly prepared methanolic solution of $NaSeCH_2CH_2NMe_2$ [prepared from $(Me_2NCH_2CH_2Se)_2$ (51.4 mg, 0.17 mmol), $NaBH_4$ (13.2 mg, 0.35 mmol)] and 20 cm^3 of dichloromethane was added and stirred. After 3 h the solvents were stripped off under vacuum. The residue was extracted with dichloromethane (3×7 cm^3) and passed through a Florisil column. The volume of the solution was reduced to 5 cm^3. Recrystallisation from CH_2Cl_2/hexane mixture gave yellow solid (yield 216 mg, 62%).

7. Preparation of $[Pt(SeCH_2CH_2NMe_2)(PPh_3)]_n[PF_6]_n$ (7): An acetone solution (15 cm^3) of $AgPF_6$ (51 mg, 0.21 mmol) was added to solid $[PtCl(SeCH_2CH_2NMe_2)(PPh_3)]$ (116 mg, 0.20 mmol) with stirring. Silver chloride immediately precipitated with concomitant colour change from orange to pale yellow. The reactants were stirred at room temperature for 4 h. Precipitated AgCl was filtered through celite and the solvent was evaporated in vacuo. The yellow residue was examined by NMR spectroscopy.

Crystallography: X-ray data of an orange crystal of $[PtCl(SeCH_2CH_2NMe_2)(PPh_3)]$ (**1f**) (0.2×0.2×0.2 mm) and a colourless crystal of $[Pt_2Ph_2Cl(SeCH_2CH_2NMe_2)(PnBu_3)_2]$ (**3**) (0.3×0.3×0.3 mm) were collected at 173(2) K on a Siemens P3 diffractometer using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å), employing the ω-2θ scan technique. The unit cell parameters (Table 9) were determined from 25 reflections each, measured by random search routine. The intensity data were

corrected for Lorentz polarisation and absorption effects. The structures were solved using direct methods, the mononuclear complex proved to be isostructural with the previously reported palladium analogue.[8] The non-hydrogen atoms were refined anisotropically except for the methyl carbon atoms C(23) and C(43). These two atoms were treated within a disorder model [0.62 and 0.38 for C(23) and C(23A), 0.93 and 0.07 for C(43) and C(43A)]; each of the adjacent methylene carbon atoms C(22) and C(42) was refined using two different sets of hydrogen atoms. Three of the n-butyl groups and the phenyl ligands exhibit high standard deviations, presumably due to thermal motion.

Acknowledgments

We thank Dr. J. P. Mittal and Dr. P. Raj for encouragement of this work. We are also grateful to Dr. P. K. Mathur, Head, Analytical Chemistry Division, BARC for providing the microanalysis of the compounds. Support for this work from BMBF (Project IND 99/060), the DFG, FCI (Frankfurt am Main), the Ministry of Education of the Czech Republic, and the DLR (Bonn) for KONTAKT Project CZE 00/013 is gratefully acknowledged.

Medium and Temperature Effects on the Redox Chemistry of Cytochrome *c*

Gianantonio Battistuzzi,[a] Marco Borsari,[a] and Marco Sola*[a]

Keywords: Cytochrome *c* / Electrochemistry / Thermodynamics / Ionic strength

Cytochromes *c* (cytc) are ubiquitous heme-containing metalloproteins that shuttle electrons in a variety of electron-transport chains, most often central to the production of the chemical energy necessary for cell life. The reduction potential ($E^{\circ\prime}$) of the $Fe^{3+/2+}$ couple is central to the physiological role of these species in that it influences the thermodynamic and kinetic features of electron-exchange reactions with redox partners. In the last two decades, voltammetric techniques exploiting the heterogeneous electron exchange between cytc and solid electrodes have proved to be particularly valuable for the determination of $E^{\circ\prime}$ values for these species and for characterizing the mechanistic and kinetic aspects of the redox process for the various cytc conformers under a variety of solution conditions. The understanding of how, and to what extent, different molecular factors control the $E^{\circ\prime}$ value in these species has been the subject of much debate. First coordination sphere effects on the heme iron and the interactions of the heme group with the surrounding polypeptide chain and the solvent are the main factors affecting $E^{\circ\prime}$ in cytc. These interactions are sensitive to medium effects such as the pH and the nature and ionic composition of the solvent. $E^{\circ\prime}$ is also strongly affected by the temperature. This article summarizes the authors' work on the effects on the selective stabilization of the two redox states of class I cytochromes *c* exerted by acid-base equilibria, general ionic strength effects, specific anion binding, the presence of non-aqueous solvents, and the temperature. The temperature dependence of $E^{\circ\prime}$ allows the determination of the enthalpy and entropy changes that accompany protein reduction. These parameters have proved to be informative with regard to the interplay between first coordination sphere effects and electrostatics at the heme–protein interface, including solvent dipoles, which mainly affect the reduction enthalpy, and solvent reorganization effects and differences in protein dynamics between the two oxidation states, which control the reduction entropy instead.

Introduction

Biological electron-transport (ET) chains in photosynthetic and aerobic and anaerobic respiratory processes are the main source of chemical energy in living systems.[1,2] Electron flow occurs among membrane-bound multi-com-

Gianantonio Battistuzzi obtained his Ph.D. in Chemistry from the University of Modena (Italy) in 1996, under the supervision of Prof. M. Sola, working on the purification and the characterization of the solution behavior of electron-transfer metalloproteins. After a period in the laboratories of Professors H. Witzel and B. Krebs at the University of Münster, he held a postdoctoral position at the University of Modena, where he was appointed Assistant Professor of Inorganic Chemistry in 1999. His main research interest lies in the understanding of the molecular and solution factors influencing the thermodynamics of the reduction of electron-transfer metalloproteins, in particular cytochromes c and blue copper proteins, through a combination of electrochemical and spectroscopic techniques.

Marco Borsari obtained his Ph.D. in Chemistry from the University of Modena (Italy) in 1992, working with Prof. G. Gavioli on the characterization of the electrochemical behavior of sulfur-containing organic molecules and the determination of the nature and stability of metal complexes in solution through voltammetric and polarographic techniques. In 1992, he was appointed Assistant Professor of Physical Chemistry at the University of Modena and Reggio Emilia (Italy) and started working on the electrochemistry of metalloproteins with Marco Sola. He also established collaborations with the groups of I. Bertini and H. B. Gray. His main research activity has been directed towards the study of the redox properties of electron-transport proteins and redox enzymes, with a particular focus on the thermodynamics of the electron-transfer processes in cytochromes, blue copper, and iron–sulfur proteins.

Marco Sola obtained his Ph.D. in Chemistry from the University of Parma (Italy) in 1987. Between 1985 and 1991 he was a member of the group of I. Bertini and C. Luchinat in Florence working on NMR of paramagnetic metalloproteins. He spent 1988 as a research associate at the California Institute of Technology, Pasadena, CA, with H. B. Gray, working on iron–sulfur proteins involved in biological electron transport. From 1992, he independently pursued the characterization of the redox properties of electron-transport proteins, and with M. Borsari initiated the bio-electrochemistry group at the University of Modena. In 1992, he was also appointed Associate Professor of Chemistry at the University of Basilicata, Potenza, Italy. He then moved to the University of Bologna (1994–1997) and afterwards returned to the University of Modena, where he became Full Professor of General and Inorganic Chemistry in 2000. His main research interests have focused on structure–function relationships in redox metalloproteins and, more recently, on the issue of how the protein matrix and medium effects control the reduction potentials of cytochromes, blue copper, and iron–sulfur proteins.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ponent protein complexes that feature a variety of mono- or polynuclear metal centers (heme, type I and type II copper, and Fe-S) capable of switching between two stable oxidation states. Electrons are shuttled between these complexes by mobile carriers, which may be either organic molecules (e.g. the ubiquinone/ubihydroquinone system) or small metalloproteins such as cytochromes *c*, blue copper proteins, and iron-sulfur proteins.[1,2]

Cytochromes *c* (cytc) are ubiquitous species: their remarkable stability in vitro and ease of purification[2−5] made them the system of choice for an impressive amount of biophysical research on biological ET.[4,5] In their native form, these monomeric proteins contain one or more heme groups covalently bound to the polypeptide chain through two thioether bonds involving two cysteines; in addition, two residues (either His,Met or His,His) serve as axial ligands to the heme iron. The latter thus resides in a six-coordinate (distorted octahedral) geometry and has a typical low-spin state. Cytochromes *c* can be classified into four subclasses on the basis of their structural properties.[4] The most widely studied species belong to class I, found in both eukaryotes and prokaryotes, which are small positively charged globular proteins (M_r = 10−15 kDa) possessing a His,Met pair of axial heme iron ligands and are characterized by a largely preserved polypeptide folding. These species constitute the main focus of this article. The mitochondrial species shuttle electrons between the last two membrane-bound components of the electron-transfer chain of oxidative phosphorylation, namely ubiquinol-cytochrome *c* reductase and cytochrome *c* oxidase, whereas the species from photosynthetic bacteria, generally denoted as cytochromes c_2, act as electron donors to the photooxidized photosynthetic reaction center.[2−5]

Class III cytochromes *c* are multiheme proteins of bacterial origin featuring bis(histidine) coordination.[4−6] Classes II and IV include cytochromes *c*′, in which the heme iron is high-spin pentacoordinate with an axial histidine ligand, and bacterial tetraheme proteins containing either bis(His) or His,Met-coordinated heme.[4,5]

As for any other redox protein, the reduction potential ($E^{\circ\prime}$) is a key property of cytc. On the one hand, it regulates the biological function influencing both the thermodynamic and kinetic aspects of electron-exchange reactions with redox partners, as a result of which extensive work has been devoted to unravelling the complex interplay of molecular factors and medium effects that modulate it. On the other hand, $E^{\circ\prime}$ can be profitably exploited as a tool for the investigation of several aspects of the solution chemistry of cytc. In fact, the reduction potential of cytc is remarkably sensitive to any changes in the properties of the heme and the protein matrix, and can nowadays be measured with relative ease thanks to the development of direct electrochemical (voltammetric) techniques for redox proteins.

This article summarizes the authors' work on both the above aspects, which are closely related, focusing mainly on how the $E^{\circ\prime}$ of cytc is influenced by the ionic composition and pH of the aqueous medium, by the presence of organic solvents, and on temperature effects. The temperature dependence of $E^{\circ\prime}$ allows the determination of the enthalpy and entropy changes that accompany reduction of oxidized cytc: these parameters have proved to be informative with regard to understanding the molecular factors that control the reduction potential in these species. This aspect will also be covered in detail. No details are given here of the theoretical and experimental aspects of the voltammetric techniques or of the operational conditions that allow the attainment of fast heterogeneous electron transfer between the freely diffusing protein in solution and the solid electrode, for which the reader is referred to the original literature.[7−11] It is worth mentioning, however, that under the conditions of variable pH, temperature, and solvent composition employed in these studies, the electrochemical processes involving cytc at surface-modified gold electrodes were invariably found to be one-electron, electrochemically reversible or quasi-reversible, and diffusion-controlled (as an example, a typical cyclic voltammogram of freely diffusing native cytochrome *c* obtained on a 4-mercaptopyridine surface modified gold electrode at pH = 7 is shown in Figure 1, a). These conditions warrant that the electron transfer between the protein and the electrode is fast and that no protein adsorption and denaturation occurs at the electrode surface. Therefore, the half-wave potentials obtained from the voltammograms can be confidently assumed to represent the thermodynamic $E^{\circ\prime}$ values.

I. The Reduction Potential of the Native Form of Class I Cytochromes *c*

The native His,Met-ligated form (state III) of class I cytochromes *c* from mitochondrial and bacterial sources has reduction potentials in the range of +0.2 to +0.38 V (vs. SHE) (all the potential values reported herein are referred to the standard hydrogen electrode, SHE).[4,12] Two main factors have been recognized as contributing to these remarkably positive $E^{\circ\prime}$ values. One is the π-electron accepting character of the thioether sulfur atom of the methionine axially bound to the iron, which stabilizes the reduced (Fe^{2+}) state.[12−14] The other is the poor accessibility of the solvent to the heme and its burial within a hydrophobic pocket, which induce a further significant enthalpic stabilization of the ferrous over the ferric state.[12] Against this background, electrostatic interactions of the charge at the redox center with net charges and polar groups on the protein and solvent dipoles are responsible for the fine-tuning of $E^{\circ\prime}$.[4,5,15−18] Theoretical and experimental approaches have been directed towards an understanding of how and to what extent these interactions modulate $E^{\circ\prime}$ in cytochromes *c*.[4,5] Models for the calculation of the electrostatic interaction energies of the heme with polar and charged residues and solvent dipoles were able to reproduce the differences in $E^{\circ\prime}$ among cytc from different sources.[18−20] Evidence has been obtained from experiments involving chemical modification, site-directed mutagenesis, and specific anion binding[4,21−25] that modification of internal net charges, such as those of the heme propionates, induces variations in $E^{\circ\prime}$ (50−65 mV per charge) that

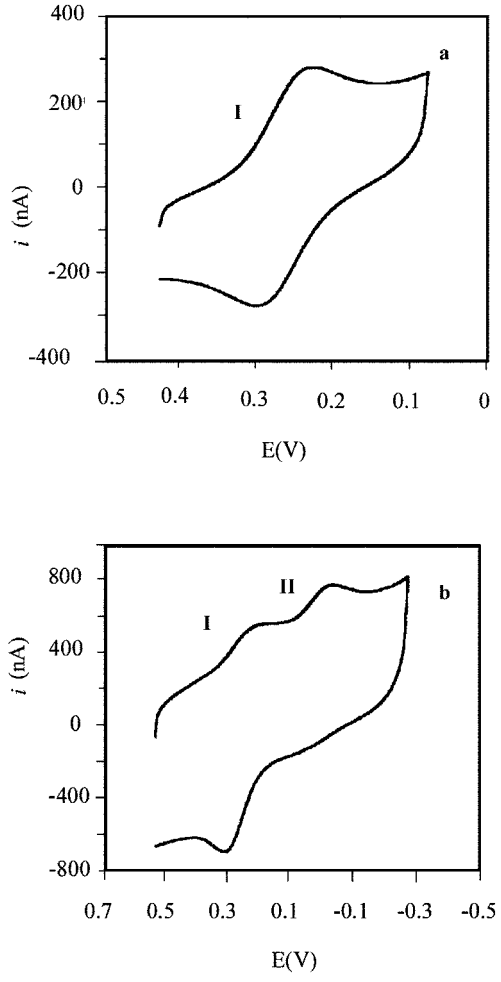

Figure 1. Cyclic voltammograms of beef heart cytochrome *c* at a 4-mercaptopyridine surface modified gold disc electrode: (a) pH = 7, $T = 293$ K, sweep rate 50 mV s^{-1}, protein concentration 0.17 mM; (b) pH = 9.13, $T = 293$ K, sweep rate 50 mV s^{-1}, protein concentration 0.25 mM; I and II refer to the waves of the native and alkaline conformers, respectively; supporting electrolyte 0.1 M sodium acetate (reproduced by permission from G. Battistuzzi et al., *Biochemistry* **1999**, *38*, 7900−7907; copyright American Chemical Society, 1999)

are more pronounced than those due to surface charges (10−30 mV per charge). The overall effect depends on several factors, such as the heme−charge distance and the dielectric properties of the intervening medium, which can be described by an "effective dielectric constant"; the latter is different for each particular interaction and involves contributions from both the solvent and the protein.[4,16,21−23,25]

Our recent work on the thermodynamics of cytc reduction, carried out by means of variable-temperature $E^{\circ\prime}$ measurements (see Section II), has elucidated the role of entropic effects in determining the reduction potential. Reduction entropy is likely to be largely controlled by differences in dynamic and solvation properties between the two redox states, although no detailed understanding of the factors involved at a molecular level has yet been achieved. However, it is clear that this thermodynamic contribution strongly affects $E^{\circ\prime}$[12] and may contribute to the differences in $E^{\circ\prime}$ between cytc from different sources, as found for other classes of electron-transport metalloproteins.[26,27]

A wealth of data is now available on the way in which the pH, temperature, ionic composition, and dielectric constant of the solvent influence the electrostatic interactions at the heme−protein/solvent interface, axial coordination to the heme iron, and the dynamic and solvation properties of both redox forms, and hence how they ultimately affect $E^{\circ\prime}$. These effects, which constitute the focus of this review, indicate that the properties of the medium exert a critical influence on the redox behavior of cytochrome *c* in vitro and, in principle, may also affect its function in vivo.

II. Temperature Dependence of $E^{\circ\prime}$: Reduction Thermodynamics

The redox behavior of class I cytochromes *c* is temperature-sensitive. The reduction potential of the conformers for which the voltammetric signal due to the Fe^{3+}/Fe^{2+} couple falls in the potential range accessible in diffusion-controlled direct electrochemistry experiments at surface-modified gold or graphite electrodes (from +1.3 to −0.60 V), namely the native His,Met-ligated form (state III) and the alkaline His,Lys-ligated form (state IV), invariably decreases with increasing temperature between 5 and 65 °C. However, the $E^{\circ\prime}/T$ profiles are pH-dependent and differ slightly for species from different sources.[12,28−37] In particular, the $E^{\circ\prime}$ of the native form of cytc from mammalian mitochondria shows a monotonic linear decrease with increasing temperature at slightly acidic and neutral pH values (Figure 2, a), whereas at higher pH values the $E^{\circ\prime}$ vs. T plot clearly becomes biphasic with a transition point at approximately 50 °C (Figure 2, b). This behavior has been ascribed to a reversible conformational transition between two states of the oxidized native form involving fractional proton loss on going from the low-T to the high-T conformer,[33] which is indeed consistent with the decrease in the transition point temperature observed with increasing pH.[12] Spectroscopic studies indicate that the low-T and high-T native conformers are not significantly different in the surroundings of the heme.[12] An additional effect of increasing temperature is a depression of the pK_a for the alkaline transition (see Section III.2).

The $E^{\circ\prime}/T$ profiles for the native form of class I cytc from plant mitochondria and photosynthetic bacteria are similar to those outlined above, but show some interesting differences (Figure 3).[12,28] In particular: (i) the transition between the low-T and high-T native forms occurs at lower pH values and lower temperatures (35−40 °C), (ii) the temperature of the transition point decreases with increasing pH, (iii) the T-induced decrease in the pK_a for the alkaline transition is more marked as compared to that of their mammalian analogues (for these species, formation of the alkaline form can be observed at pH values as low as 7−7.5 at temperatures of approximately 35−40 °C).[12,28]

The temperature dependence of $E^{\circ\prime}$ can be profitably exploited to measure the thermodynamic parameters of cytc

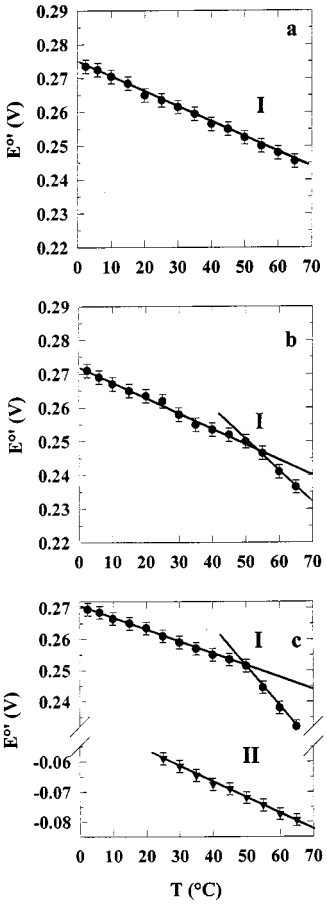

Figure 2. Temperature dependence of the reduction potential of beef heart cytochrome *c* at pH = 6.9 (a), 7.5 (b), and 8.3 (c); supporting electrolyte 0.1 M sodium chloride; solid lines are least-squares fits to the data points; I and II refer to the waves of the native and alkaline conformers, respectively (reproduced by permission from G. Battistuzzi et al., *Biochemistry* **1997**, *36*, 16247−16258; copyright American Chemical Society, 1997)

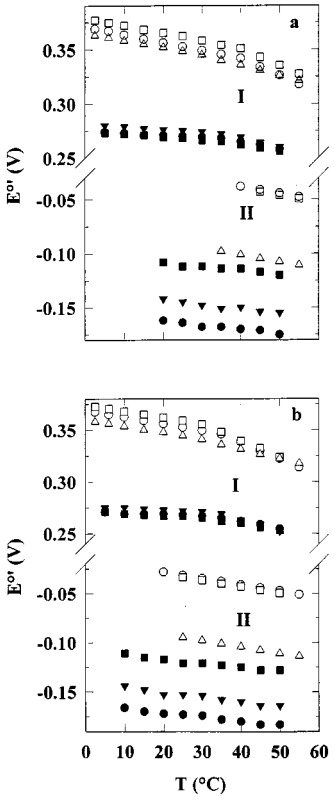

Figure 3. Temperature dependence of the reduction potentials of bacterial and plant cytochromes *c*: (a) pH = 7.5 (plant), 7 (bacterial); (b) pH = 8.5;[12,28] plant cytochromes *c*: spinach (■), cucumber (●), sweet potato (▲); bacterial cytochromes c_2: *Rps. palustris* (□), *Rb. sphaeroides* (○), *Rb. capsulatus* (Δ); supporting electrolyte 0.1 M NaCl in 10 mM phosphate buffer; least-squares fits to the data points are omitted for clarity; I and II refer to the reduction potentials of wave I (native cytc) and wave II (alkaline cytc), respectively

reduction. In particular, the use of a so-called "non-isothermal" electrochemical cell, in which the reference electrode (SCE) is kept at constant temperature while the half-cell containing the working electrode and the junction to the reference electrode is under thermostatic control,[38] allows determination of the standard entropy ($\Delta S^{\circ\prime}_{rc}$) and enthalpy ($\Delta H^{\circ\prime}_{rc}$) changes associated with reduction of the oxidized protein.[12,28,30−37] In particular, with this experimental configuration, the reaction entropy for reduction of the oxidized form is given by the following Equation.[34,38−40]

$$\Delta S^{\circ\prime}_{rc} = S^{\circ\prime}_{red} - S^{\circ\prime}_{ox} = nF\,(dE^{\circ\prime}/dT)$$

Thus, $\Delta S^{\circ\prime}_{rc}$ can be determined from the slope of the plot of $E^{\circ\prime}$ versus temperature, which turns out to be linear under the hypothesis that $\Delta S^{\circ\prime}_{rc}$ is constant over the limited temperature range investigated. With the same assumption, the enthalpy change ($\Delta H^{\circ\prime}_{rc}$) can be obtained from the Gibbs−Helmholtz equation, namely from the slope of the $E^{\circ\prime}/T$ versus $1/T$ plot.

Analysis of the thermodynamic parameters of protein reduction for several mitochondrial and bacterial class I cytochromes *c* (Table 1) allowed further insight to be gained into the interplay between the enthalpic and entropic contributions to the reduction potential (see ref.[12] for an overview on the available thermodynamic data for cytc reduction determined by several authors using a variety of techniques under different solution conditions). It can clearly be seen that the high reduction potentials of these species are largely enthalpic in origin, arising from the remarkably negative $\Delta H^{\circ\prime}_{rc}$ values, which can confidently be ascribed to the stabilization of the ferroheme by ligand binding interactions and the hydrophobicity of the heme environment.[12,28−30] Conversely, the entropic term invariably disfavors protein reduction ($\Delta S^{\circ\prime}_{rc} < 0$),[12,32] yielding a negative contribution to the $E^{\circ\prime}$ values. The entropic term is generally smaller than the enthalpic term, but it nevertheless plays an important role in the modulation of the reduction potential in these species.[12,28−30] Solvent reorganization effects and changes in protein flexibility, the latter expressed as the sum of the conformational (vibrational, torsional) degrees of freedom, associated with reduction of

cytc play a major role in determining the $\Delta S^{\circ\prime}_{rc}$ values.[3,12,28–31] In particular, the entropy loss upon reduction is consistent with the decreased flexibility of the reduced state as compared to the ferri form determined by NMR in solution.[41–45] However, it is still the case that the contribution of the reduction-induced changes in the H-bonding network within the hydration sphere of the molecule remains largely uncharacterized.

[a] Subscripts N and A denote native and alkaline forms, respectively. – [b] At 25 °C. Measurements were performed in 10 mM phosphate buffer, 0.1 M NaCl. Values in the upper and lower rows for the native species refer to the low-T (N_1) and high-T (N_2) conformers, respectively. Average errors in the $\Delta H^{\circ\prime}_{rc}$ and $\Delta S^{\circ\prime}_{rc}$ values are ±2 kJ·mol^{-1} and ±6 J·mol^{-1}·K^{-1}, respectively. – [c] $E_{1/2}$ value at 55 °C for an electrochemically quasi-reversible wave (ΔE_p = 0.07 V).

A similar balance between the enthalpic and entropic contributions to the $E^{\circ\prime}$ value of cytc has been observed for all the other classes of high-potential electron-transport metalloproteins, namely blue copper proteins and high-potential iron–sulfur proteins (HiPIPs).[26,27,46,47] Therefore, it is apparent that Nature uses the same strategy to control the reduction potential of these species; the reasons for this are still unclear and define a fascinating field for future investigations.

The alkaline conformer(s) of cytc are characterized by lower (negative) $E^{\circ\prime}$ values as compared to the native conformers (Table 1). This decrease in $E^{\circ\prime}$ is almost entirely enthalpic in origin, since the $\Delta S^{\circ\prime}_{rc}$ values for this form are found to be comparable to those for the native form, whereas the $\Delta H^{\circ\prime}_{rc}$ values are much less negative (Table 1) (see Section III.2.a for details).[12,48]

III. Acid-Base Equilibria

Acid-base equilibria involving ionizable groups such as axial ligands, heme propionates, and distal residues influence the electronic properties of the heme, axial heme ligation, and polypeptide folding. Therefore, the reduction potential of class I cytc is remarkably pH-dependent.[4,5,28,49,50]

III.1. Equilibria Occurring Between Acidic and Neutral pH Values

The native His,Met-ligated form (state III) transforms into a low-pH conformer (state II) with an apparent pK_a of 2.5. In this conformer, the axial ligands are protonated and are detached from the iron (which indeed becomes high-spin): the free coordination positions are most likely occupied by water molecules.[4,5] The $E^{\circ\prime}$ of this form cannot be determined owing to the worsening of the electrochemical response at low pH caused by protonation of the promoter adsorbed onto the electrode surface and the probable disruption of the adsorbed layer.[49]

At intermediate pH values (approximately from pH = 5 to 8), the pH dependence of the reduction potential of native cytc is species-dependent. In particular, no acid/base equilibria affect the redox properties of mitochondrial (mammalian and plant) cytc in this pH range. In fact, His26 (present in all eukaryotic cytc) and the heme propionate-7 are characterized by low pK_a values. In particular, the former residue, which controls the accessibility of the solvent to the hydrophobic core of cytc influencing the global protein stability and that of the ligating Met80,[51] has a pK_a value lower than 3.6 in horse heart cytc, probably due to its non-polar environment,[4,51,52] which is maintained also in the plant proteins.[53] The pK_a of the heme propionate-7 in oxidized mammalian cytochromes *c* is lower than 4.5.[4,50] In contrast, the $E^{\circ\prime}$ values of some bacterial cytochromes c_2 have been found to be sensitive to the pro-

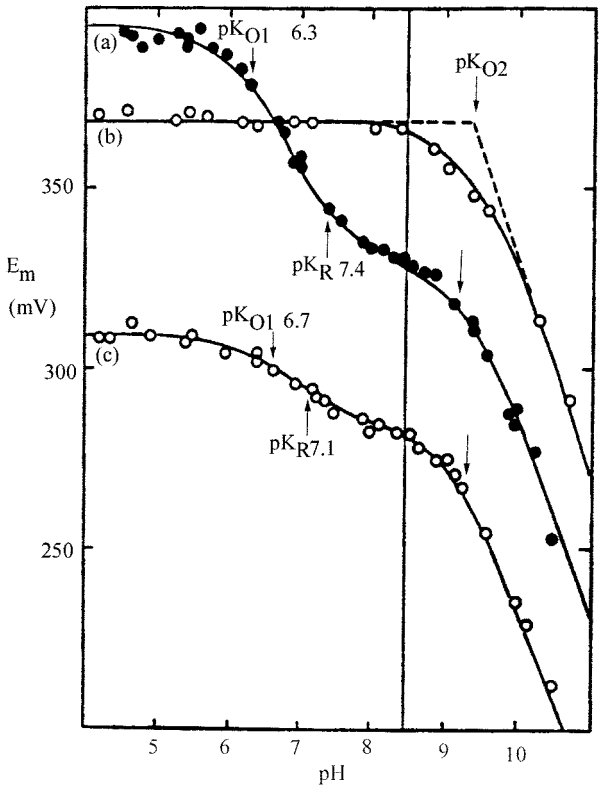

Figure 4. pH dependence of the reduction potentials of cytochromes c_2 from: (a) *Rm. vannielii*, (b) *Rps. viridis*, (c) *Rb. capsulatus* (reproduced by permission from G. R. Moore, G. W. Pettigrew *Cytochromes c: Evolutionary, Structural and Physicochemical aspects*, Springer-Verlag, Berlin, **1990**)

tonation state of a non-ligated histidine residue[4,16,22,50,54] or heme propionate, the pK_a of which falls in the range 6−8 (Figure 4).[4,50] The deprotonation of an ionizable residue induces the typical sigmoidal decrease in $E°'$ because of the electrostatic stabilization of the oxidized form due to the decrease of the overall positive charge of the protein: the extent of the change in $E°'$ depends on the solvation properties of the residue, the distance from the heme, and the properties of the intervening medium.

III.2. The Alkaline Transition

The moderate affinity of the axial methionine sulfur for the ferric ion in the native form of cytochrome *c* renders this residue susceptible to substitution by endogenous ligand(s) at high pH, leading to the "alkaline" isomer(s) (state IV), in which the iron retains the low-spin ferric state.[4,5,12,28−30,48,49,55−60] The spectroscopic and redox changes induced by this equilibrium have been exploited to determine the thermodynamics and kinetics of the isomerization, to identify the nature of the substituting ligands, and to determine the role of the residues neighboring the heme in the relative stabilization of the two conformers. The overall reaction turns out to be a two-step process, in which a fast residue deprotonation triggers a slow and thermodynamically favored conformational change leading to the replacement of the methionine by a surface lysine in axial heme ligation, with an apparent pK_a in the range 8.5−9.5 depending on the species.[4,5] The ionizable residue has not yet been unambiguously identified, and no information is available on the structural features of the alkaline conformers. The existence of two alkaline isomers in a pH-dependent ratio suggests that at least two Lys residues can replace the methionine at high pH.[28,30,48,56−59]

The alkaline conformers of cytc give rise to a single voltammetric wave (wave II) (Figure 1, b), which is diffusion-controlled and chemically irreversible at the potential sweep rates employed for detection of the voltammetric wave for native cytc (wave I) (20−200 mVs^{-1}). The reduction potentials of the alkaline isomers of various cytc's are lower than those of the native forms by 0.3−0.5 V (falling in the range −0.05 to −0.18 V) (Figure 2, c, and Figure 3).[12,28,29,48,49,55] It has been found that this remarkable decrease in the reduction potential is mainly due to the different coordination properties of methionine and lysine: the latter is a stronger donor ligand that selectively stabilizes the ferric form.[12] The chemical irreversibility of wave II is due to the fact that the reduced alkaline conformer is unstable and tends to transform rapidly into the reduced native form through the uptake of a proton. With increasing sweep rate, the reduced alkaline isomer has no time to transform prior to re-oxidation, and indeed the intensity of the anodic counterpart of wave II becomes comparable to that of the cathodic peak using scan rates higher than 0.6 V s^{-1} (for beef heart cytc).[12]

Upon increasing the pH in the range 7.5−10.5, the cathodic peak current of wave II increases to the detriment of that of native cytc, while the sum of the two currents remains constant. Moreover, at each pH value, the cathodic peak currents of both waves (as well as their $E°'$ values) are independent of the potential sweep rate in the range 0.02−1 Vs^{-1}.[48] Individual peak intensities simply depend on the root square of the scan rate, as expected for diffusion-controlled processes.[48] Thus, waves I and II turn out not to be "kinetic waves" (in the range of potential sweep rates used) and, at each pH value, their currents are those determined by the chemical equilibrium between the native and alkaline forms.[48,61] Therefore, the measured currents can be used to determine the apparent equilibrium constants. The current intensity (*i*) of the cathodic peak of wave I was measured as a function of pH at different temperatures from 5 to 65 °C.[48] The fit of the sigmoidal decrease of *i* with increasing pH to a one-proton equilibrium equation yields the apparent pK value (pK_{app}) for the alkaline transition at a given temperature (Figure 5). This value was found to decrease from 9.8 to 8.6 on increasing the temperature from 5 to 65 °C at 0.1 M ionic strength (acetate).[48] The latter effect is a direct consequence of the endothermicity of the overall process of the alkaline isomerization (see Section III.2.a).

It is worthy of note that the alkaline transition is also greatly influenced by the properties of the medium. The pK_{app} decreases with decreasing dielectric constant of the medium, as noted in mixed water/dimethyl sulfoxide solutions (see Section V).[29] This effect is of potential relevance

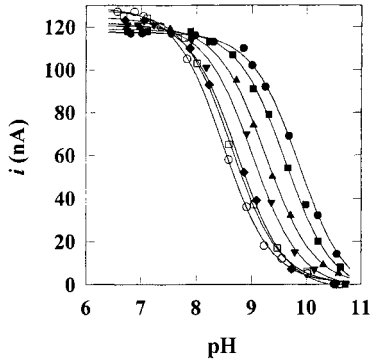

Figure 5. pH dependence of the current intensity of the cathodic peak (*i*) of wave I for beef heart cytochrome *c* at different temperatures in sodium acetate at I = 0.1 M; T [°C] = 5 (●), 10 (■), 20 (▲), 30 (▼), 40 (◆), 50 (□), and 60 (○); the pH values were corrected for temperature; solid lines are fits to a conventional one-proton equilibrium equation (reproduced by permission from G. Battistuzzi et al., *Biochemistry* **1999**, *38*, 7900−7907; copyright American Chemical Society, 1999).

from a physiological point of view since it has been reported that there is a decrease in the dielectric constant near the surface of phospholipid membranes and that the alkaline form of cytochrome *c* is involved in the interaction with synthetic anion phospholipid vesicles.[62,63] Interestingly, monoclonal antibody binding studies indicate that only the native form is present in live cells, where cytochrome *c* acts as an electron shuttle near the inner mitochondrial membrane, whereas the presence of the alkaline isomers has been detected in apoptotic and necrotic cells.[64] The alkaline isomers are formed in the early stages of apoptosis and necrosis, possibly as a result of the translocation of cytochrome *c* through the mitochondrial membrane (or of its association with membranes altered during the process of death). It is therefore possible that the phospholipid-induced conformational changes associated with the formation of the alkaline isomers are connected with the signaling role of cytochrome *c* during apoptosis, although experimental evidence seems to indicate that these isomers are not involved in the interaction with Apaf-1 to form apoptosomes.[63,64]

The pK_{app} for the alkaline transition also increases with increasing ionic strength (see Section III.2.a).[48] This is likely to be one of the factors that hampers separation of the alkaline form in the crystal state from the usually high ionic strength solutions (ammonium sulfate) used in the crystallization procedure.

Upon increasing the pH beyond 10, another state (state V) becomes accessible, in which a hydroxide ion is probably axially bound to the heme iron.[56] The remarkably low reduction potential of this species is outside the potential window accessible with the present techniques.

III.2.a The Thermodynamics of the Alkaline Transition

The thermodynamic parameters of the alkaline transition have been investigated in some detail.[48,65−67] We have measured the apparent equilibrium constant (K_{app}) of the alkaline transition (AT) of beef heart cytochrome *c* by means of pH titrations of the current intensities in cyclic voltammetry experiments. These were carried out at different temperatures (from 5 to 65 °C) and at different ionic strengths (I = 0.01−0.2 M).[48] The ionic strength of the solution was varied using acetate, which has been found not to bind specifically to beef (and horse) heart cytc, but rather to simply exert an ionic atmosphere effect (see Section IV).[23]

The temperature profile of the pK_{app} values was found to be biphasic (Figure 6). Two distinct sets of $\Delta H^{\circ\prime}_{AT}$ and $\Delta S^{\circ\prime}_{AT}$ values were obtained below and above approximately 40 °C (Table 2). In the low-temperature range, the process is endothermic and is accompanied by a small positive entropy change, whereas at higher temperatures it becomes less endothermic and involves a moderate entropy loss. Ligand substitution should not be responsible for the endothermicity of the process, given the higher affinity of the lysine nitrogen atom for the ferric ion as compared to the methionine sulfur atom. Therefore, other factors, such as transition-induced changes in the hydrogen-bond network (also including ordered water molecules on the protein surface) and in the electrostatic interactions between the metal site and the protein environment and the solvent must be responsible for the positive $\Delta H^{\circ\prime}_{AT}$ values. The slightly positive or negative $\Delta S^{\circ\prime}_{AT}$ values cannot be easily rationalized. In fact, this isomerization has been proposed to involve a number of processes, which would increase the number of degrees of freedom of the molecule, such as the net release of a proton, the formation of multiple conformers,[56−59] the opening of the heme crevice through the disruption of two key stabilizing interactions on the protein surface,[67] and the probable disruption of a hydrogen-bond network involving the internal water molecule and protein residues due to the detachment of Met80.[68] Therefore, other opposing (structure-making) processes must be operative, which most probably involve a rearrangement of the solvation sphere of the protein (in a way

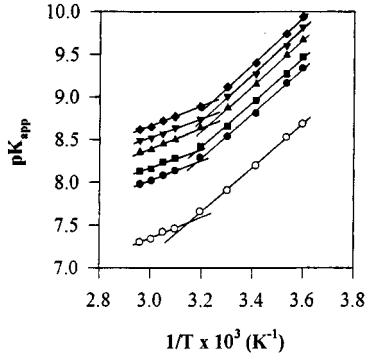

Figure 6. Apparent pK values for the alkaline transition of beef heart cytochrome *c* as a function of 1/T at various ionic strengths (sodium acetate); I = 0.01 M (●), 0.02 M (■), 0.05 M (▲), 0.1 M (▼), and 0.2 M (◆); the pK values extrapolated to I = 0 (○) are true thermodynamic equilibrium constants; solid lines are least-squares fits to the data points (reproduced by permission from G. Battistuzzi et al., *Biochemistry* **1999**, *38*, 7900−7907; copyright American Chemical Society, 1999)

[a] Sodium acetate. − [b] Average errors in the $\Delta H^{\circ\prime}_{AT}$ and $\Delta S^{\circ\prime}_{AT}$ values are ±2 kJ·mol^{-1} and ±6 J·mol^{-1}·K^{-1}, respectively. − [c] Enthalpy and entropy values in the low-T and high-T ranges refer to the N_1 and N_2 conformers, respectively (see text). − [d] Data obtained from the pK_a values extrapolated at $f(I) = 0$ at various temperatures (see Figure 6). These values are true standard thermodynamic parameters.

which is presently unknown, but that might involve formation of internally hydrogen-bonded ordered molecular arrays within the hydrophobic heme crevice or a net release of water molecules from the hydration sphere of the protein to the bulk solvent) and/or a suppression of vibrational, rotational, and torsional motions in the A form as compared to the N form. However, no clear definition of the molecular details of the processes underlying the entropy change is yet available.

The change in transition thermodynamics observed above approximately 40 °C is most likely the result of the thermal transition of native ferricytochrome *c* from a low-T to a high-T conformer, which occurs at alkaline pH values at a comparable temperature (see Section II). Thus, it is apparent that the transitions of the two native conformers to the corresponding alkaline forms are thermodynamically distinct processes. It is suggested that this difference either arises from peculiar transition-induced changes in the hydration sphere of the protein or is due to the preferential binding of different lysines to the heme iron in the two temperature ranges. Extrapolation of the K_{app} values at zero ionic strength allowed determination of the thermodynamic equilibrium constants (K_a) at each temperature, and hence of the "true" standard thermodynamic parameters of the transition. The pK_a value at 25 °C was found to be 8.0. A pK_{app} value of 14.4 was calculated for the alkaline transition of ferrocytochrome *c* at 25 °C and I = 0.1 M. The much greater relative stabilization of the native state in the reduced as compared to the oxidized form turns out to be almost entirely enthalpic in origin, and is most likely due to the greater affinity of the methionine sulfur for the Fe^{II} ion.[48]

The pK_{app} values for the alkaline transition of cytc are influenced by the ionic strength in a fashion that can be explained, at least qualitatively, by the finite-ion version of the Debye−Hückel theory,[48] analogously to the ionic strength dependence of the reduction potential (see Section IV). In particular, the pK_{app} values measured at different ionic strengths were found to conform to Equation (1).

$$pK_{app} = pK_a + 0.5(z^2_{cytH} - z^2_{cyt^-}) \cdot \frac{\sqrt{I}}{1+6\sqrt{I}} = pK_a + 0.5(z^2_{cytH} - z^2_{cyt^-}) \cdot f(I) \quad (1)$$

Here, z_{cytH} and z_{cyt^-} are the net charges of the neutral and alkaline forms, respectively (Figure 7).[4,69] The slope of the plots (approximately +10) is almost twice that expected from the net charges of the native and alkaline forms, namely $0.5\cdot(6^2 - 5^2) = +5.5$. This difference is most likely due to the intrinsic limits of the Debye−Hückel theory as applied to a complex electrolyte such as a protein (see below), although it might also be due to the specific binding of one acetate ion to a surface site of the alkaline form. In fact, although the acetate ion was shown not to interact specifically with neutral cytc, nothing is known about its interaction with the alkaline conformer.

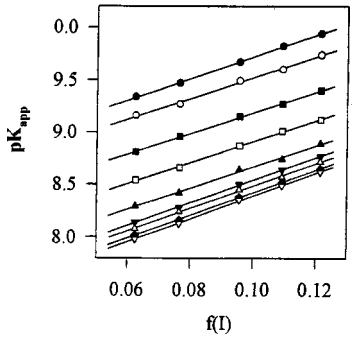

Figure 7. Apparent pK values for the alkaline transition of beef heart cytochrome *c* as a function of $f(I) = \sqrt{I}/(1 + 6\sqrt{I})$ at various temperatures; T [°C] = 5 (●), 10 (○), 20 (■), 30 (□), 40 (▲), 50 (▼), 55 (Δ), 60 (◆), 65 (▽); solid lines are least-squares fits to the data points (reproduced by permission from G. Battistuzzi et al., *Biochemistry* **1999**, *38*, 7900−7907; copyright American Chemical Society, 1999)

Comparison of the $\Delta H^{\circ\prime}_{AT}$ and $\Delta S^{\circ\prime}_{AT}$ values at different ionic strengths (Table 2) indicates that the increase in the pK_{app} values with increasing ionic strength is almost entirely entropic in origin. Thus, the expected selective stabilization of the native conformer (which has one more positive charge than the alkaline form) by the negative ionic atmosphere that surrounds the protein has little or no effect. This result cannot be readily rationalized at present owing to the uncertainty regarding the factors responsible for the transition entropy.

IV. The Effects of the Ionic Composition of the (Aqueous) Medium on $E^{\circ\prime}$

The ionic composition of the medium is known to affect the interaction of cytc with redox partners[70] and phospholipid membranes.[71] Salt-induced effects on the reduction potential of cytc are of two types: (i) changes in the activity coefficients of both redox states, known as "general" ionic strength effects; (ii) specific protein−anion interactions at surface sites (cytc is positively charged at neutral pH). The former effect is related to the shielding of the protein charge

by the surrounding "ionic atmosphere", which is greater for the oxidized state since it bears the greater positive charge. As a consequence, the oxidized state will be selectively stabilized with respect to the reduced state, leading to a decrease in the reduction potential with increasing ionic strength (see Section IV.2). A combination of the Nernst and extended Debye−Hückel equations, using a model in which the protein behaves as a low dielectric cavity bearing a net charge uniformly distributed on the surface, with no specific ion−protein interactions, yields Equation (2) for the changes in $E^{\circ\prime}$ of cytc induced by the ionic atmosphere.[4,72,73]

$$E^0 = E^0_{I=0} + 2.303 \cdot \frac{RT}{nF} \cdot \left[z^2_{red} - z^2_{ox}\right] \cdot \frac{0.5 \cdot \sqrt{I}}{1 + 0.33 \cdot a \cdot \sqrt{I}} \quad (2)$$

Here, I is the ionic strength, $E^\circ_{I=0}$ is the reduction potential extrapolated to zero ionic strength, z_{red} and z_{ox} are the charges of the reduced and oxidized protein, and a is the "ion-size parameter", defined as the mean distance of closest approach between the protein and an ion of opposite charge belonging to the ionic atmosphere. The value of a lies between the sum of the crystallographic radii and the sum of the solvated radii. An a value of 18 Å has been used for bovine ferricytochrome *c*. By defining Equation (3), Equation (2) becomes Equation (4) which predicts a linear decrease in E° with increasing $f(I)$, with a slope given by $0.059 \cdot (z^2_{red} - z^2_{ox})$.

$$f(I) = (0.5\sqrt{I})/(1 + 0.33a\sqrt{I}) \quad (3)$$

$$E^\circ = E^\circ_{I=0} + 0.059(z^2_{red} - z^2_{ox})f(I) \quad (4)$$

Despite the roughness of the model, especially regarding the dielectric properties of the polypeptide matrix, this approach proved to be surprisingly effective in describing the ionic strength dependence of $E^{\circ\prime}$ for native and chemically modified class I cytochromes *c*.[21−23,69,72−74] This might be ascribed, at least in part, to the facts that these species are roughly spherical, that there are only subtle oxidation state induced structural changes[42,46,75] (which fits with an implicit assumption of the model), and that the metal center is almost totally embedded in the protein matrix. Indeed, we found that the Debye−Hückel theory works less well for the cucumber basic protein (which possesses a type I copper center), in which the metal site is more exposed to the solvent (hence the dielectric constant of the metal environment can no longer be regarded as low and homogeneous) and which shows more pronounced oxidation state induced changes in solvation properties and a stronger asymmetry in charge distribution as compared to cytochrome *c*.[76,77]

Specific binding of anions to surface sites of cytc (intended as more or less localized surface regions of positively charged potential),[78] occurring either on one or both redox states, would result in a decrease in the net positive protein charge, related to the charge of the anion and the number of protein-bound anions. This would alter the slope of the $E^{\circ\prime}/f(I)$ profile as compared to the free protein. Therefore, the above equations were exploited to detect specific anion−cytc interactions and to determine the stoichiometry of binding for a wide variety of anions either occurring in biological systems in vivo (such as Cl^-, HPO_4^{2-}, HCO_3^-), or used as components of buffer systems in vitro (NO_3^-, SO_4^{2-}, citrate^{3-}, oxalate^{2-}).[21−23] Several anions were found to possess peculiar binding properties,[78,79] often including sequential binding due to the presence of multiple protein binding sites with different affinities for the anion.[21−23] In parallel, these studies allowed evaluation of the electrostatic effect on $E^{\circ\prime}$ resulting from anion-induced neutralization of net positive protein surface charge(s). In the following we will briefly illustrate some details of the binding properties of biologically important anions and the relationships between surface charges and $E^{\circ\prime}$ which were obtained with this approach.

IV.1. Specific Anion Binding Effects

IV.1.a. Anion−Protein Binding Stoichiometries

Some examples of the $E^{\circ\prime}$ vs. $f(I)$ plots obtained for bovine and horse heart cytochromes *c* interacting with different anions are shown in Figure 8. Linear plots are invariably obtained, according to Equation (4), showing either a constant slope or biphasic behavior. The latter plots, which yield two sets of protein charges at low and high anion concentrations, are interpreted as being indicative of sequential anion binding. The protein charges obtained from the slopes of the plots allowed an estimate to be made of the number of anions bound to the two redox states of bovine and horse heart cytc, which are listed in Table 3[23] [it is worth noting that evaluation of *two* unknowns, z_{red} and z_{ox}, from only *one* experimental parameter ($z^2_{red} - z^2_{ox}$) can only be achieved by introducing a number of constraints on the charge values, for which the reader is referred to the original literature].[21−23] The main results can be summarized as follows: (i) all anions other than acetate interact specifically with both proteins, (ii) in many cases, the number of anions bound per protein molecule increases with increasing anion concentration, indicating sequential anion binding due to the presence of low and high affinity sites, (iii) chloride and phosphate bind to both species to a greater extent as compared to the other anions and show different binding stoichiometries toward the two closely sequence-related proteins (97% identity). In particular, one less chloride ion binds to the bovine protein as compared to the equine species: it is tempting to attribute this effect to the presence of one less lysine residue in the bovine species as compared to the horse species (a Gly residue in the former replaces Lys60 in the latter). However, since Lys60 is proposed as not being directly involved in the anion binding sites,[69,80] the observed effect is likely to be due to a decrease in the overall positive charge of bovine cytc and to a change in the distribution of the surface electrostatic potential.

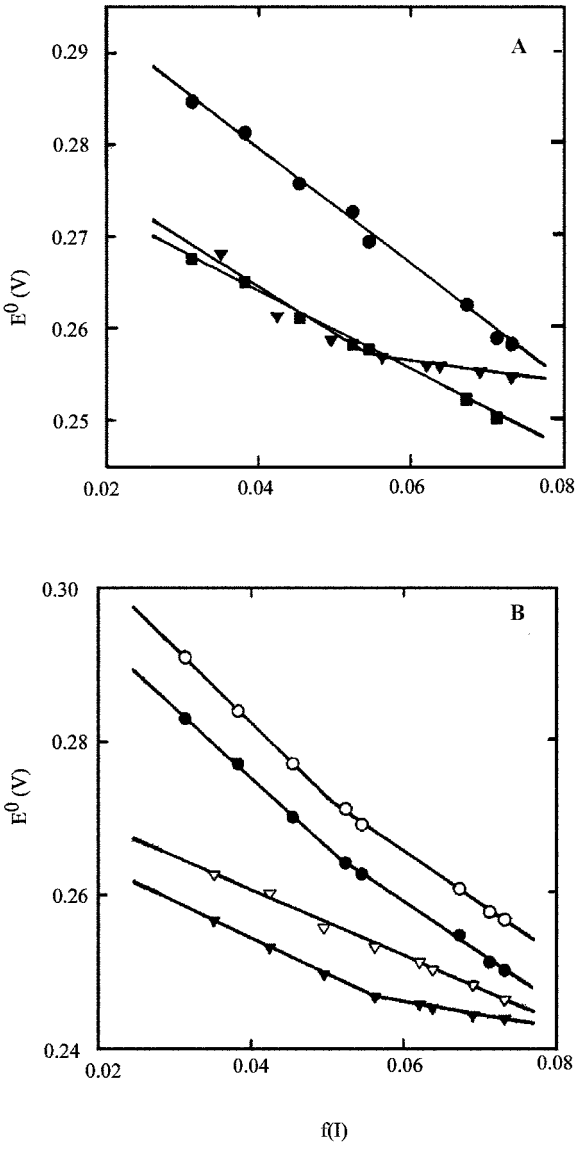

Figure 8. Selected $E^{\circ\prime}$ vs. $f(I)$ plots for horse and bovine heart cytochromes *c* in the presence of various anions: (A) bovine protein with acetate (●), sulfate (▼), bicarbonate (■); (B) bovine protein with chloride (●) and oxalate (▼); horse protein with chloride (○) and oxalate (▽); solid straight lines are fits to Equation (4) (reproduced by permission from G. Battistuzzi et al., *Eur. J. Biochem.* **1996**, *241*, 208−214; copyright Blackwell Science Ltd., 1996)

The presence of two phosphate binding sites on the horse protein at low anion/protein molar ratios was also indicated by different approaches, some of which involved chemical modification of surface lysines.[69,79,81−85] With increasing anion concentration, the electrochemical data indicate the binding of a third phosphate anion (except to the reduced horse protein). As also indicated by ion chromatography data,[69] phosphate displays a distinct binding preference toward the oxidized forms of both proteins as compared to the reduced forms. This is in contrast to chloride, which shows the opposite behavior. This indicates that for both proteins the lysine-based binding sites for the two anions are different and are subject to different reduction-induced changes that affect anion affinity. In addition, phosphate, unlike chloride, binds to a greater extent to the bovine cytochrome, in spite of the smaller positive charge as compared to the horse species. No obvious explanation for this effect can be offered at present. As noted elsewhere,[69] these facts demonstrate that even a few amino acid substitutions perturb the positive surface potential field of the protein in such a way as to significantly alter the number, magnitude, and/or location of the potential energy minima for anion interaction.

Only one bicarbonate ion binds to both of these proteins, in agreement with studies of chemical modification of surface lysines, from which it was proposed that lysines 72 and/or 73 and 86 and/or 87 are involved in anion binding.[79] It is possible that one of the nitrate binding sites corresponds to the bicarbonate site, in view of the structural similarity of the two anions.

Sulfate and citrate show the same binding properties. For both proteins and redox states, the number of anions bound per protein molecule increases from one to two with increasing anion concentration. This suggests the presence of two protein sites with different affinities for the two anions in both of the cytochromes, possibly corresponding to those for phosphate, given the close similarity of sulfate and phosphate in terms of geometry, dimensions, and charge. Consistently, citrate has previously been shown to have at least one binding site in common with phosphate.[67,79,86]

Given that a number of anions show different binding stoichiometries toward horse and bovine cytc, which are highly sequence-related, the anion binding data for a bacterial cytochrome c_2 from *Rps. palustris* (which shows only about 38% sequence identity with the mitochondrial species) were expected to be quite distinctive. However, it has been found that, although some anions such as chloride, phosphate (at concentrations below 0.06−0.08 M), acetate, and oxalate do indeed show peculiar binding properties toward different species (e.g. chloride does not bind to the bacterial species), many others, including perchlorate, bicarbonate, nitrate, phosphate (at concentrations above 0.06−0.08 M), sulfate, and citrate exhibit the same binding stoichiometries (Table 3).[21−23] These two groups of anions do not differ in their structural and charge characteristics, or in their ability to form hydrogen bonds, hence intrinsic anion properties are not responsible for this distinct behavior. Therefore, the invariance of the binding data for the latter group of anions is most probably a consequence of the fact that the binding sites are maintained in the different species: this would suggest the existence of (a) more or less extended region(s) of relatively conserved electrostatic potential in the three cytochromes. It is known that the distribution of lysines around the perimeter of the heme crevice at the "front" of the molecule is largely retained in eukaryotic cytochromes *c* and bacterial cytochromes c_2, which also share the main features of the overall polypeptide folding.[87−91] This also appears to be the case for *Rps. palustris* cytochrome c_2.[21] No other regions show analogous similarities in the location of lysine residues. As a consequence, the "frontside" region of these cytochromes,

Table 3. Number *n* of specifically bound anions for horse and bovine heart cytochromes *c* and *Rps. palustris* cyt c_2, determined from the ionic strength dependence of the redox potential in the presence of various anions, according to Equation (2); $T = 25$ °C; measurements for chloride, perchlorate, nitrate, and sulfate were carried out at pH = 7; for the basic anions the pH varied from 8 to 9.3 depending on anion concentration; in the case of sequential anion binding, values in the upper and lower rows refer to low and high anion concentrations, respectively (from refs.[21−23])

which has been proposed to correspond to the likely site of interaction with physiological oxidoreductases,[91−94] should also serve as a site of interaction with a number of anions. Accordingly, the proposed binding site for the bicarbonate ion to the horse protein[79] as well as the common binding site for phosphate and citrate (''Phosphate Site I'' formed by Lys86, Lys87, and Lys88)[79,81,82] fall in this region. As a consequence, the sites for chloride and acetate, as well as the additional low-affinity site(s) for phosphate, are probably located elsewhere.

IV.1.b. Relationships between Surface Charges and $E^{\circ\prime}$

The role of net surface charges in determining the reduction potential in redox metalloproteins has been the subject of much debate.[16,18,95−98] In the various protein families, net charges contribute to the $E^{\circ\prime}$ value only by approximately 10−30 mV per charge, depending on their location with respect to the metal center. These data were obtained through mutation or chemical modification of surface residues and pH titration studies. This moderate effect can mainly be attributed to the screening of the coulombic interaction by the dielectric effect of water. However, recent work from this laboratory[99] has shown that enthalpy-entropy compensation phenomena also contribute in minimizing the resulting $E^{\circ\prime}$ change.

Anion binding to specific surface sites of cytochrome *c* may be exploited as an additional tool to monitor the effect of changes in charge on the $E^{\circ\prime}$ value.[21−23] In fact, since NMR and X-ray data indicate that increasing anion concentrations induce only minor structural modifications, which leave the overall protein folding and conformational flexibility of the molecule largely unaffected,[44,100] it is reasonable to assume that the $E^{\circ\prime}$ change caused by specific anion binding is mainly electrostatic in origin, due to the partial neutralization of positive surface charges. The relationships between $E^{\circ\prime}$ and charge were obtained as follows.[21−23] When only one anion is bound per protein molecule, in both redox states, extrapolation of the linear $E^{\circ\prime}$ vs. $f(I)$ plot to $f(I) = 0$ allows determination of the $E^{\circ\prime}$ value at zero ionic strength ($E^{\circ\prime}_{I=0}$) for the protein, the surface charge of which is decreased by that of the bound anion. The value $E^{\circ\prime}_{I=0}$ for the ion-free protein is taken as that extrapolated in the plot for the non-binding anion (acetate and chloride for the mitochondrial and bacterial species, respectively). The difference between $E^{\circ\prime}_{I=0}$ for the ion-free and the electrostatically perturbed protein ($\Delta E^{\circ\prime}_{I=0}$) yields an estimate of the fall in reduction potential due to the neutralization of *n* positive surface charges (at zero ionic strength). The $\Delta E^{\circ\prime}_{I=0}$ and $dE^{\circ\prime}/dq \cdot (dE^{\circ\prime}/dq$ = change in $E^{\circ\prime}$ per unit charge) values obtained for the three cytochromes studied are listed in Table 4. A number of observations can be made. First, the $dE^{\circ\prime}/dq$ values for the multiply charged anions, such as sulfate, oxalate, and citrate, interacting with the mitochondrial species range from 14.6 to 16.5 mV. They are intermediate between the theoretical value of 12 mV predicted by the smeared charge model for a sphere of radius 1.5 nm in water[4] and 23 mV determined from a comparison of the reduction potentials of a series of proteins bearing different charges.[101] They compare very well with the $dE^{\circ\prime}/dq$ value at zero ionic strength of 11−14 mV determined from mutation of surface lysines,[102] while they appear to be somewhat higher than the 5−10 mV estimated from chemical modification and pH titration studies.[4] Second, the $dE^{\circ\prime}/dq$ values for the two monovalent anions, perchlorate and bicarbonate, are somewhat greater, especially those for the latter ion (24 and 25 mV for beef and horse heart cytc, respectively). This may be due to a closer approach of these anions to the heme, consistent with the existence of a specific ''bicarbonate site''.[79]

Table 4. $\Delta E^{\circ\prime}_{I=0}$ and $dE^{\circ\prime}/dq$ values (see text) for beef and horse heart cytochromes *c* and *Rps. palustris* cytochrome c_2 determined upon anion binding to one site in both redox states of the proteins (from refs.[21−23])

Anion	$\Delta E^{\circ\prime}_{I=0}$ [mV]			$dE^{\circ\prime}/dq$		
	horse	bovine	*Rps. palustris* cyt c_2	horse	bovine	*Rps. palustris* cyt c_2
ClO_4^-	21	20	23	21	20	23
HCO_3^-	25	24	33	25	24	33
SO_4^{2-}	31	31	31	15.5	15.5	15.5
$C_2O_4^{2-}$	33	33	–	16.5	16.5	–
$citrate^{3-}$	44	45	41	14.6	15	14
CH_3COO^-	–	–	28	–	–	28
HPO_4^{2-}	–	–	32	–	–	16

Overall, the $dE^{\circ\prime}/dq$ values determined using the present approach are in line with those previously estimated for mutated or chemically modified species. The picture that emerges is that the effect of alteration of one net surface charge of the protein on the reduction potential of the heme, although being small, as discussed above, is measurable and is also significant at physiological ionic strengths. Thus, besides the general ionic strength effects related to the charge shielding of the protein as a whole due to the surrounding ionic atmosphere, the ionic composition of the medium may also induce protein charge neutralization at specific site(s), which determines an additional alteration (decrease) in the reduction potential. Hence, the salt effects on the rate of electron transfer between cytochrome *c* and redox partners may not only be due to changes in orientation and/or distance of the redox centers in the complex, but a contribution may also arise from changes in the driving force.

IV.1.c. Effects on the Alkaline Transition

Recently, the thermodynamic parameters of the alkaline transition of beef heart ferricytochrome *c* have been measured using the procedure illustrated in Section II.2.a in the presence of various sulfate concentrations.[103] Sulfate is known to bind specifically to cytochrome *c* in a sequential manner at two surface sites.[23] It has been found that the effects of such a specific binding reflect the thermodynamics of the transition and can be satisfactorily interpreted within the frame of the Debye−Hückel theory with simple electrostatic considerations. In particular, the increase in the thermodynamic pK_a values (extrapolated to $I = 0$) upon sequential sulfate binding turns out to be a fully enthalpic effect, which can be accounted for, at least qualitatively, simply by considering the coulombic effects of charge modification due to the formation of ionic couple(s) on the protein surface. In particular, according to Equation (1), the pK_{app} values increase linearly with increasing $f(I)$ (Figure 9). It is worthy of note that: (i) the discontinuity in the pK_{app} vs. $f(I)$ plot corresponds to the sulfate concentration (0.08 M) above which the number of sulfate anions specifically bound to the protein is known to increase from one to two;[23] (ii) the measured slopes are in close agreement with those expected from the decrease in protein charge upon binding of one and two binegative anions to both the alkaline and neutral isomers. These two observations, taken together, clearly indicate that the biphasic profile of the pK_a values as a function of sulfate concentration is the result of the electrostatic effect of sequential anion binding to protein surface sites.

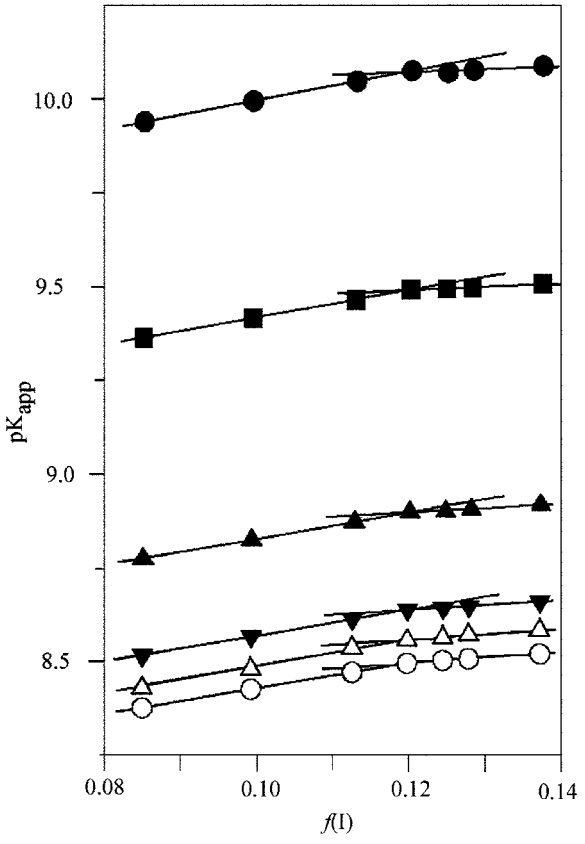

Figure 9. Apparent p*K* values for the alkaline transition of beef heart cytochrome *c* as a function of $f(I) = \sqrt{I}/(1 + 6\sqrt{I})$ (sodium sulfate) at various temperatures; *T* [°C] = 5 (●), 20 (■), 40 (▲), 50 (▼), 55 (Δ), 60 (○); solid lines are least-squares fits to the data points (reproduced by permission from G. Battistuzzi et al., *Arch. Biochem. Biophys.* **2001**, *386*, 177−122; copyright Academic Press, 2001)

IV.2. General Ionic Strength ("Ionic Atmosphere") Effects

The reduction potential of native beef heart cytochrome *c* has been measured as a function of the temperature in the presence of increasing concentrations of the non-binding

anion acetate, in order to quantify the influence of the general ionic strength effect, namely of non-specific electrostatic interactions due to the ionic atmosphere that surrounds the protein, on the thermodynamics of protein reduction.[30] Most of the previous investigations on salt-induced effects on the physicochemical properties of cytochromes *c* were carried out using either phosphate or chloride to adjust the ionic strength of the solution, which, as seen above, do in fact bind specifically to both redox states of cytochrome *c*.[21−23,69,79] The $E^{\circ\prime}/T$ profiles at different ionic strengths and the $E^{\circ\prime}/f(I)$ plots at different temperatures measured at three pH values (7, 8, and 9) are shown in Figure 10 and Figure 11, respectively. At pH = 7 and 8, the reduction enthalpy and entropy become less negative with decreasing ionic strength. The reduction entropy extrapolated to zero ionic strength is approximately zero, indicating that in the absence of the screening effects of the salt ions on the network of the electrostatic interactions at the protein−solvent interface, the solvation properties and the conformational flexibilities of the two redox states are comparable. At the same pH values, the reduction potential of cytc slightly decreases with increasing ionic strength at constant temperature (Figure 11). For example, $\Delta E^{\circ\prime}{}_{IS} = (E^{\circ\prime})_{I=0.1\,M} - (E^{\circ\prime})_{I=0\,M} = -0.035$ V at 25 °C, which corresponds to a $\Delta\Delta G^{\circ\prime}{}_{IS}$ value of +3.3 kJ·mol^{-1}.[30] Since X-ray and NMR studies have shown that salt effects do not alter the overall protein folding and the conformational flexibility of cytc,[100,104−106] the positive $\Delta\Delta G^{\circ\prime}{}_{IS}$ value can mainly be attributed to the selective stabilization of the ferri form by the exclusively electrostatic effects of the salt ions. Such a free energy change turns out to be composed of a $\Delta\Delta H^{\circ\prime}{}_{IS}$ [$= (\Delta H^{\circ\prime})_{I=0.1\,M} - (\Delta H^{\circ\prime})_{I=0\,M}$] term of −8.5 kJ·mol^{-1} and a $T\Delta\Delta S^{\circ\prime}{}_{IS}$ term of −11.8 kJ·mol^{-1} (analogous quantitative relationships between the enthalpic and entropic terms hold at the other pH values and temperatures).[30] Enthalpy-entropy compensation phenomena in the hydration of biopolymers[107−111] must be taken into account to identify the molecular effect responsible for the positive value of $\Delta\Delta G^{\circ\prime}{}_{IS}$. In particular, since the salt-induced changes in the hydration sphere of the two redox states of cytc are likely to be responsible for the negative $T\Delta\Delta S^{\circ\prime}{}_{IS}$ term, a compensating enthalpic effect of the same sign and magnitude should contribute to the measured $\Delta\Delta H^{\circ\prime}{}_{IS}$. Thus, once the compensating enthalpic and entropic effects of the change in solvation properties are factorized out, the measured $\Delta\Delta G^{\circ\prime}{}_{IS}$ value of +3.3 kJ·mol^{-1} turns out to be entirely due to a $\Delta\Delta H^{\circ\prime}$ term attributable to the electrostatic effect of the negatively charged ionic atmosphere that surrounds cytc, which should indeed stabilize the ferri form (which bears a greater positive charge than the reduced state). This would nicely explain why at pH = 7 the $E^{\circ\prime}$ vs. $f(I)$ plot follows the simple electrostatic model of the extended Debye−Hückel equation [Equation (4)], yielding a negative slope that at most temperatures is that expected for the unperturbed protein ($z_{red} = 5+$ and $z_{ox} = 6+$). Notably, at pH = 8, the gradient of such a slope decreases, and at pH = 9 it becomes positive (Figure 11, b, c).[30] We attribute this effect to the specific binding of the hydroxide ion to surface sites of the protein, which results in a decrease in the positive charge of both redox states. The positive slope at pH = 9 would indicate that such a binding occurs preferentially to the oxidized form, as observed elsewhere for a number of anions.[21−23,69]

V. The Effects of Non-Aqueous Solvents

Solvent−solute interactions play a significant role in determining the reduction potentials of redox metalloproteins, affecting both the enthalpic and entropic contributions to the free energy change of the reduction process.[26,27,29] Some theoretical models reproduce the experimental $E^{\circ\prime}$ values of families of homologous ET proteins reasonably well, treating the solvent as a dielectric continuum.[95,112−115]

It has been proposed that there is a decrease in the dielectric constant near the surface of the cell membrane, which induces conformational transitions in some proteins that are central to their physiological role.[116−118] The behavior of cytochrome *c* has been investigated in mixed water/alcohol solutions of low average dielectric constant and at low pH, conditions that, in principle, simulate those in the proximity of the inner mitochondrial membrane.[116,119,120] Two alcohol-induced conformational transitions have been detected at intermediate and high alcohol concentrations. The former leads to a compact species which retains most of the secondary structure of the native state but lacks most features of the tertiary structure (molten globular state), whereas the latter is a more helical state that differs from the extensively unfolded state obtained at high concentrations of strong denaturants such as guanidine hydrochloride or urea.[116] Much less is known about the effects of other organic solvents, or about the redox properties of cytochrome *c* in not purely aqueous media in general. We have investigated the redox behavior of bovine heart cytc in mixed water/dimethyl sulfoxide (DMSO) solutions containing up to 40% (v/v) DMSO. We used cyclic voltammetry, under varying conditions of temperature and pH, and we also monitored the effects on protein conformation by means of ^{1}H NMR and circular dichroism.[29] The main observations can be summarized as follows. The redox behavior of cytc in solutions containing less than 10% DMSO is very similar to that in water. An increase in the proportion of DMSO induces a number of effects, which are different for the native and alkaline forms. Regarding the native form, at constant temperature, its $E^{\circ\prime}$ decreases to a similar extent as that determined in aqueous solution following an increase in temperature reproducing the same dielectric constant as that of the mixed solvent. This indicates that the effect of DMSO on $E^{\circ\prime}$ is mainly determined by the decrease in the average dielectric constant of the solvent. It would appear that DMSO does not significantly alter the protein conformation, as indicated by the absence of appreciable DMSO-induced changes in the hyperfine-shifted ^{1}H NMR resonances and CD spectra of native cytc. Regarding

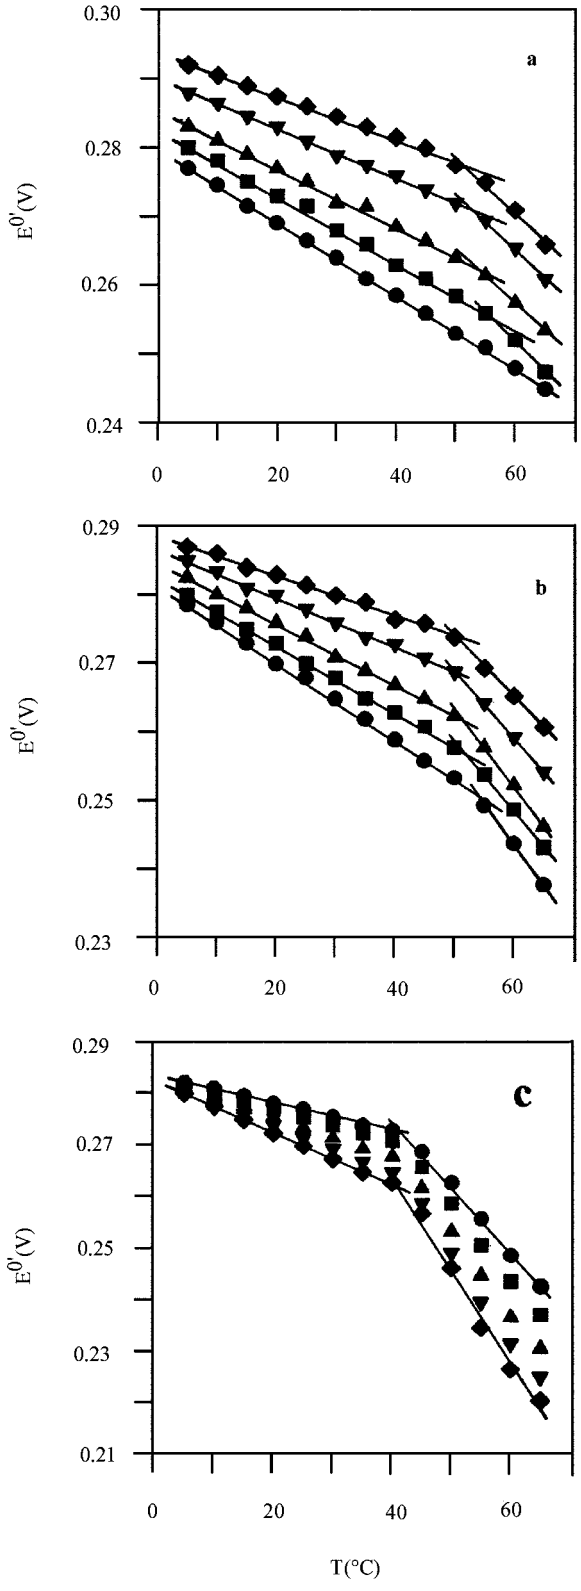

Figure 10. Temperature dependence of the reduction potential of beef heart cytochrome *c* at various ionic strengths (sodium acetate); I = 0.01 M (◆), 0.02 M (▼), 0.05 M (▲), 0.1 M (■), and 0.2 M (●); (a) pH = 7, (b) pH = 8, (c) pH = 9; solid lines are least-squares fits to the data points [those for intermediate ionic strength in (c) are omitted for clarity] (reproduced by permission from G. Battistuzzi et al., *J. Biol. Inorg. Chem.* **1999**, *4*, 601−607; copyright Springer, 1999)

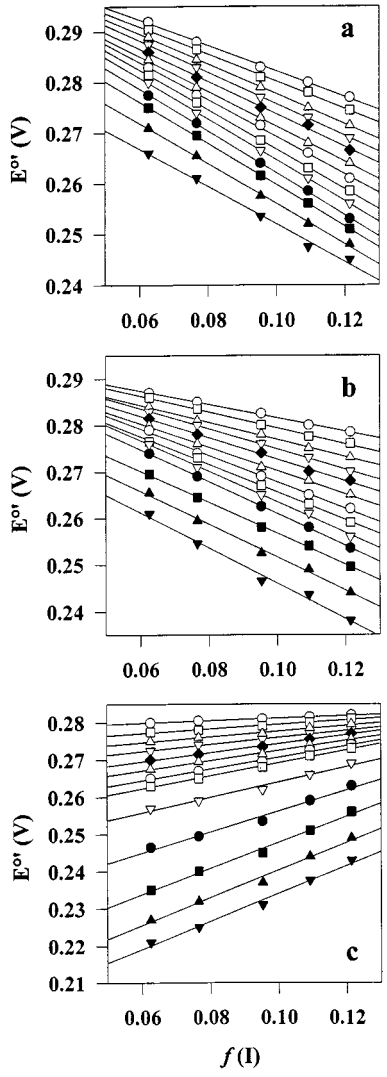

Figure 11. Reduction potential of beef heart cytochrome *c* as a function of $f(I) = \sqrt{I}/(1 + 6\sqrt{I})$ at various temperatures; T [°C] = 5 (○), 10 (□), 15 (Δ), 20 (▽), 25 (◆), 30 (Δ), 35 (○), 40 (□), 45 (▽), 50 (●), 55 (■), 60 (▲), 65 (▼); (a) pH = 7, (b) pH = 8, (c) pH = 9; solid lines are least-squares fits to the data points (reproduced by permission from G. Battistuzzi et al., *J. Biol. Inorg. Chem.* **1999**, *4*, 601−607; copyright Springer, 1999)

the alkaline form(s), at constant pH, the electrochemical wave corresponding to the alkaline conformer(s) of cytc (wave II) increases in intensity to the detriment of wave I (Figure 12). This is paralleled by a decrease in the apparent pK_a value for the transition of native cytc to the alkaline form, estimated from the pH dependence of the peak currents (not shown). Moreover, the electrochemical reversibility of wave II increases (Figure 12) and detectable changes are observed in the ^{1}H NMR and CD spectra of the alkaline form. These data indicate that, in contrast to the native form, DMSO affects to some extent the conformation of alkaline cytc and stabilizes both redox states of this form to the detriment of the native form. The latter effect is not unexpected since the alkaline species is less positively charged and therefore should be preferentially stabilized over the neutral species by a decrease in solvent polarity.

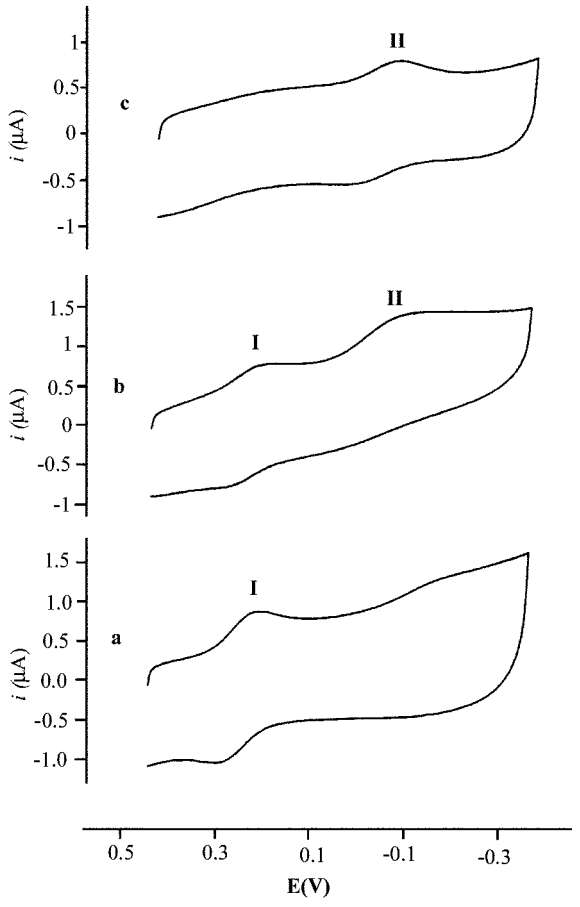

Figure 12. Cyclic voltammograms for bovine heart cytc at a 4-mercaptopyridine surface-modified gold electrode in (a) water, pH = 6.7; (b) 30% DMSO, pH* = 6.1; (c) 40% DMSO, pH* = 6.3; scan rate 50 mVs^{-1}; waves I and II are due to native and alkaline cytc, respectively; protein concentration 0.2 mM; T = 55 °C (this fairly high temperature allows the effects of DMSO on the current and reversibility of wave II to be better visualized) (reproduced by permission from G. Battistuzzi et al., *Inorg. Chim. Acta* **1998**, *272*, 168−175; copyright Elsevier Science S.A., 1998)

The highly homologous horse heart cytc was previously found to behave in a similar manner in water/methanol mixtures at pH = 6.[121]

Rhodium-Catalysed Carbonylation of Methanol Using a New Multifunctional Ligand − Isolation and Structural Characterisation of the Macrocycle $[Rh_2I_6(CO)_2(C_6H_4N_3CH_2CO_2C_4H_2SCO_2CH_2C_6H_4N_3)]_2$

Christophe M. Thomas,[a] Antonia Neels,[a] Helen Stœckli-Evans,[a] and Georg Süss-Fink*[a]

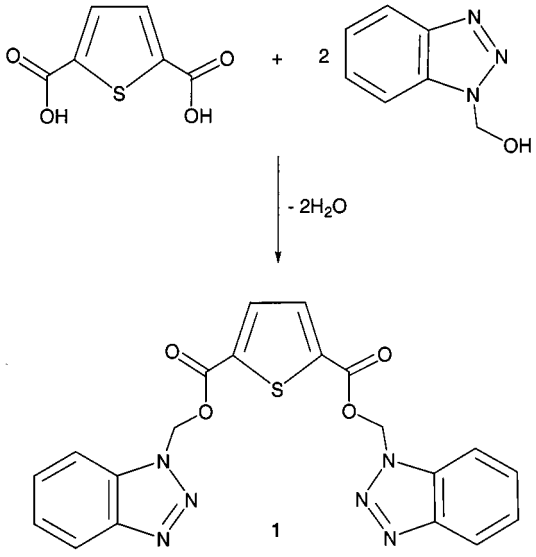
Dedicated in profound gratitude to Professor Max Herberhold on the occasion of his 65th birthday

Keywords: Rhodium / Nitrogen ligands / Macrocycles / Carbonylation

The new multifunctional ligand thiophene-2,5-bis(carboxylatomethylenebenzotriazole) (**1**) reacts with $[RhCl(CO)_2]_2$ to give the rhodium complex $[RhCl(CO)(\mathbf{1})]_2$ (**2**), which was found to catalyse efficiently the iodide-mediated carbonylation of methanol. The macrocyclic carbonyliodorhodium complex $[Rh_2I_6(CO)_2(\mathbf{1})]_2$ (**3**) was isolated from the catalytic mixture and structurally characterised.

The carbonylation of methanol to give acetic acid is one of the most important homogeneously catalysed industrial processes.[1] The catalytic reaction requires the use of iodide promoters which convert methanol, prior to carbonylation, into the actual substrate methyl iodide.[2] The classical Monsanto process is based on soluble rhodium catalysts.[3] It is well established that the anion $[RhI_2(CO)_2]^-$ is the active species in the catalytic process, the rate-determining step of which is the oxidative addition of CH_3I to give $[RhI_3(CH_3)(CO)_2]^-$.[4] There have been many attempts to modify the complex $[RhI_2(CO)_2]^-$ with suitable ligands which can increase the susceptibility of the Rh^I centre towards oxidative addition of methyl iodide.[5] Our approach consisted in developing multifunctional ligands based on benzotriazole and thiophene units in order to improve the catalytic activity of the rhodium catalyst.

The multifunctional ligand thiophene-2,5-bis(carboxylatomethylenebenzotriazole) (**1**) is easily accessible by classical condensation methods[6] from hydroxymethylbenzotriazole and 2,5-thiophene dicarboxylic acid (Scheme 1). It can be isolated in 62% yield as a white microcrystalline powder.



Scheme 1

Compound **1** was found to coordinate easily to rhodium through the 3-N atom of the triazole unit. The reaction of **1** with $[RhCl(CO)_2]_2$ in toluene at room temperature gives the rhodium(I) complex $[RhCl(CO)(\mathbf{1})]_2$ (**2**) quantitatively as an air-stable yellow solid (Scheme 2). This compound is moderately soluble in acetone and toluene, but only sparingly soluble in alcohols and insoluble in alkanes. Microanalytical and NMR spectroscopic data are consistent with the composition proposed, the dimeric nature of the molecule clearly follows from the ESI mass spectrum which shows the molecular peak at $m/z = 1220$. Complex **2** exhibits two

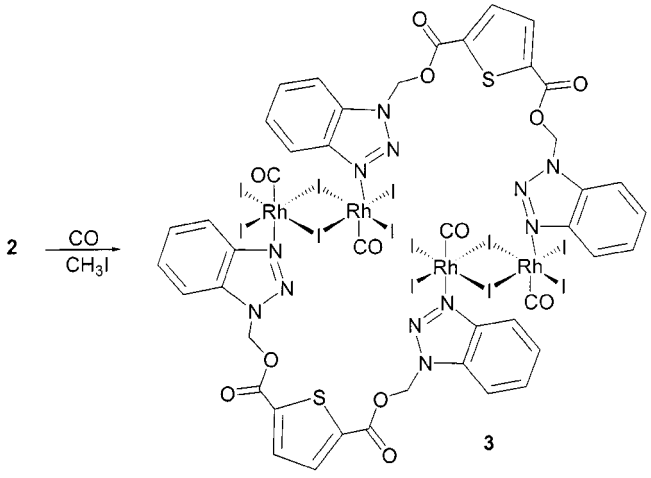
strong ν(CO) absorptions in the IR spectrum, as expected for a *cisoid* arrangement of the two terminal carbonyl ligands.[7] The yellow colour is indicative of square-planar, noninteracting rhodium centres.[8] Macrocycles of similar types, for example $[Rh_2Cl_2(CO)_2\{\mu\text{-}(Ph_2P)_2py\}_2]$[9] and $[Rh_2(CO)_2Cl_2\{Ph_2P(CH_2)P(S)Ph_2\}_2]$,[7] have been reported previously for rhodium but never used as catalysts.

Complex **2** catalyses the iodide-promoted carbonylation of methanol to give acetic acid and methyl acetate with much higher catalytic activities than that of the classical $[RhCl(CO)_2]_2$ catalyst. The catalytic reaction is performed with a methanol/methyl iodide/water (58%, 26%, 16%) mixture at 170 °C under a CO pressure of 25 bar, the catalyst/substrate ratio being 1:2000. After 20 min., the catalytic turnover number (mol CH_3COOH plus mol CH_3COOCH_3 per mol **2**) is found to be 700 (catalytic turnover frequency 35 min^{-1}). $[RhCl(CO)_2]_2$ gives a catalytic turnover number of 400 (catalytic turnover frequency 20 min^{-1}) under the same conditions. A similar increase of the catalytic activity with respect to that of $[RhCl(CO)_2]_2$ has been observed for the triethylphosphane complex $[RhCl(CO)(PEt_3)_2]$.[5f]

From the reaction mixture of the catalytic reaction we isolated the red-brown complex **3** by crystallisation of the organometallic residue from acetone. Compound **3** is directly accessible in high yield from the reaction of **2** with methyl iodide and carbon monoxide (1 bar) in acetone solution. It contains iodo ligands and a *transoid* dicarbonyl arrangement, giving rise to a single ν(CO) absorption in the infrared spectrum. It was suggested for complexes containing phosphane ligands that the dissociation of the phosphane may occurred during the catalytic process. In our case there is clearly a Rh−N bond cleavage. The facile conversion of **2** into **3** under ambient conditions demonstrates that fragmentation, ligand dissociation and rearrangement occur easily.

In the single-crystal X-ray structure analysis[10] **3** turns out to be a macrocycle containing two dinuclear iodo-bridged Rh^{III} units (Scheme 3). The four rhodium atoms have a distorted octahedral coordination geometry: they are coordinated to the 3-N atoms of the benzotriazole units of



Scheme 3

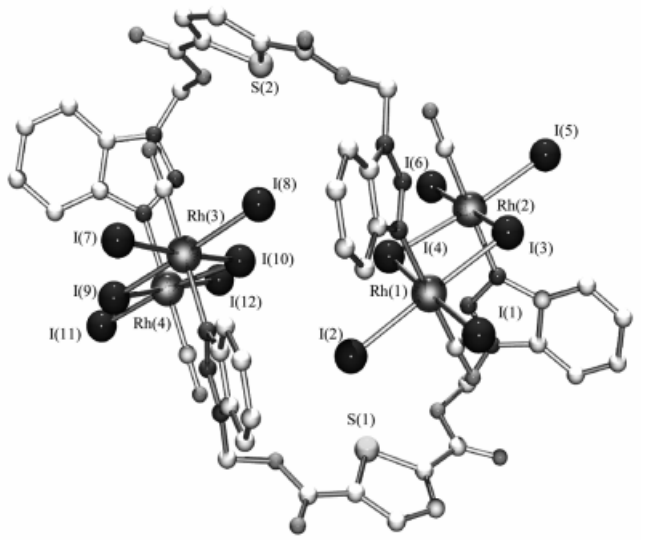


Figure 1. Molecular structure of complex **3** (hydrogen atoms and solvent molecules omitted for clarity); selected bond lengths [Å]: Rh(1)−N(12) 2.128(11), Rh(2)−N(1) 2.139(10), Rh(3)−N(6) 2.091(11), Rh(4)−N(7) 2.102(11), Rh(1)-(C1) 1.864(16), Rh(2)−C(2) 1.851(14), Rh(3)−C(3) 1.867(16), Rh(4)−C(4) 1.840(12), Rh(3)−I(8) 2.6056(14), Rh(3)−I(10) 2.6922(13), Rh(1)−Rh(2) 3.8854, Rh(3)−Rh(4) 3.9098

1 (Figure 1). The four rhodium−nitrogen bonds are almost equal in length. The two planar $Rh_2(\mu_2\text{-}I)_2$ rings are arranged perpendicular with respect to the cycle formed by the four rhodium atoms and the two ligands, Rh(1)−**1**−Rh(2)−Rh(3)−**1**−Rh(4). The bond lengths and angles for each Rh_2I_6 unit are similar to those reported by Forster[11] for $[Rh_2I_6(MeCO)_2(CO)_2]^{2-}$ and by Dilworth[12] for $[Rh_2I_6(Ph_2PC_6H_4SMe)_2]$.

In contrast to the rhodium(I) macrocycle **2**, the rhodium(III) macrocycle **3** does not catalyse the carbonylation of methanol: the low catalytic activity observed (TON 100 after 20 min., TOF 5 min^{-1}) when **3** is used as the catalyst precursor is due to a partial decomposition of **3** to give $[RhI_2(CO)_2]^-$. This is in line with what has been observed for other iodo-bridged dirhodium(III) complexes.[13]

To the best of our knowledge, **2** is the first macrocyclic dirhodium complex involved in the carbonylation of methanol. It is possible that the better catalytic performance of **2** with respect to that of the classical species $[RhI_2(CO)_2]^-$ is due to its macrocyclic nature.

Experimental Section

General: Solvents were dried and distilled under nitrogen prior to use. All reactions were carried out under nitrogen, using standard Schlenk techniques. All other reagents were purchased (Fluka) and used as received. Nuclear magnetic resonance spectra were recorded using a Varian Gemini 200 BB instrument or a Bruker AMX 400 spectrometer and referenced to the signals of the residual protons in the deuterated solvents. ^1H NMR: internal standard solvent, external standard TMS; ^{13}C NMR: internal standard solvent, external standard TMS. Infrared spectra were recorded with a Perkin−Elmer 1720X FT-IR spectrometer as KBr pellets. Micro-

analyses were carried out by the Laboratory of Pharmaceutical Chemistry, University of Geneva, Switzerland.

1: A solution of 2,5-thiophenedicarboxylic acid (1.72 g, 10 mmol), *N*,*N*-dicyclohexylcarbodiimide (2.3 g, 11 mmol), 4-(dimethylamino)pyridine (122 mg, 1 mmol), 4-pyrrolidinopyridine (148 mg, 1 mmol) and hydroxymethylbenzotriazole (3.3 g, 22 mmol) in CH_2Cl_2 (40 mL) was allowed to stand at room temperature under nitrogen, until the esterification was complete. The resulting solution was filtered to remove *N*,*N*-dicyclohexyl urea and the filtrate was concentrated under reduced pressure. The residue was chromatographed on silica gel (80 g), eluting with hexane/ether (1:1) to afford 2.7 g (62%) of **1** as a white solid. $C_{20}H_{14}N_6O_4S$ (434.4): calcd. C 55.29, H 3.25, N 19.35; found C 55.25, H 3.27, N 19.31. − FT-IR (4000−400 cm^{-1}): $\tilde{\nu}$ = 3029vw, 2979w, 1749s, 1709vs, 1532m, 1452m, 1280s, 1240s, 1159m, 1069s, 989m, 743s, 543m, 493m cm^{-1}. − FAB-MS (positive ion): *m*/*z* = 435 [M^+]. − ^{1}H NMR ([D$_6$]acetone): δ = 8.07 (m, 4 H), δ = 7.87 (s, 2 H), δ = 7.68 (t, 2 H), δ = 7.37 (t, 2 H), δ = 6.99 (s, 4 H). − ^{13}C NMR ([D$_6$]acetone): δ = 160.46, 146.31, 138.28, 134.73, 132.95, 128.94, 124.97, 120.44, 110.17, 68.82.

2: A solution of $[RhCl(CO)_2]_2$ (100 mg, 0.26 mmol) and **1** (248 mg, 0.57 mmol) in toluene (20 mL) was stirred at room temperature for 2 h. The solution was filtered then evaporated to dryness. The resulting yellow solid was washed with ether (10 mL) and dried under vacuum (240 mg, 77%). $C_{42}H_{28}Cl_2N_{12}O_{10}Rh_2S_2$ (1201.6): calcd. C 41.98, H 2.35, N 13.99; found C 42.25, H 2.27, N 13.81. − FT-IR (4000−400 cm^{-1}): $\tilde{\nu}$ = 3035vw, 2975w, 2086s, 2013vs, 1727vs, 1529m, 1455m, 1237s, 1159m, 1070s, 984m, 746s, 493m cm^{-1}. − ESI-MS: *m*/*z* = 1220 [M + H_2O]. − ^{1}H NMR ([D$_6$]acetone): δ = 8.35 (d, 4 H), δ = 8.20 (d, 4 H), δ = 7.91 (s, 4 H), δ = 7.80 (m, 4 H), δ = 7.67 (m, 4 H), δ = 7.09 (s, 8 H). − ^{13}C NMR ([D$_6$]acetone): δ = 183.52, 160.35, 145.89, 138.18, 135.74, 133.42, 129.58, 125.98, 120.09, 111.66, 70.16.

3: Complex **2** (100 mg, 0.08 mmol), ethanoic acid (1 mL) and iodomethane (1 mL) were dissolved in acetone (20 mL) under an atmosphere of carbon monoxide. After heating at reflux for 1 h, the resulting brownish solution was filtered and then the solvent was evaporated to dryness. The remaining red-brown solid was washed with ether and dried in vacuo (388 mg, 59%). Crystals suitable for X-ray diffraction analysis were grown by slow evaporation of an acetone solution. FT-IR (4000−400 cm^{-1}): $\tilde{\nu}$ = 3035vw, 2975w, 2059s, 1729vs, 1524m, 1455m, 1246s, 1076s, 746s, 519m cm^{-1}. − ^{1}H NMR ([D$_6$]DMSO): δ = 8.65 (d, 4 H), δ = 8.53 (d, 4 H), δ = 8.01−7.88 (m, 12 H), δ = 7.15 (s, 8 H). − ^{13}C NMR ([D$_6$]DMSO): δ = 192.53, 160.26, 147.04, 138.56, 134.93, 133.40, 129.21, 125.50, 120.11, 111.66, 70.28.

Catalytic Runs: In a typical experiment, $[RhCl(CO)_2]_2$ (24 mg, 0.06 mmol) and **1** (53 mg, 0.12 mmol) were dissolved in methanol (4.46 mL). Iodomethane (11 mmol) and water (200 mmol) were added to this solution, and the mixture was placed in a 100 mL stainless steel autoclave. After purging three times with CO, the autoclave was pressurised with carbon monoxide (25 bar) and heated to 170 °C with vigorous stirring of the reaction mixture (900 rpm). After 20 min., the autoclave was cooled to room temperature, and the pressure was released. The solution was filtered and analysed by GC.

Crystal Structure Determination of 3:[10] A black crystal of compound **1** was mounted on a Stoe Imaging Plate Diffractometer System (Stoe & Cie, 1995) equipped with a one-circle goniometer and a graphite-monochromator. Data collection was performed at −120 °C using Mo-K_α radiation (λ = 0.71073 Å). 190 exposures (3 min. per exposure) were obtained at an image plate distance of 70 mm with $0 < \theta < 190°$ and with the crystal oscillating through 1° in θ. The resolution was D_{min} − D_{max} 12.45−0.81 Å. Crystallographic data are reported in Table 1. The structure was solved by direct methods using the program SHELXS-97[14] and refined by full-matrix least-squares on F^2 with SHELXL-97.[15] The hydrogen atoms were included in calculated positions and treated as riding atoms using the SHELXL-97 default parameters. The compound crystallises with 7.5 molecules of acetone per asymmetric unit. The solvent molecule with an occupancy of 0.5 is strongly disordered and therefore all atom positions have been refined isotropically. An absorption correction using DIFABS in PLATON99[16] was applied (T_{min} = 0.185, T_{max} = 0.656). The figures were drawn with ORTEP-32.[17]

New Pyridine−Imidazoline Ligands for Palladium-Catalyzed Copolymerization of Carbon Monoxide and Styrene

Amaia Bastero,[a] Aurora Ruiz,[a] Carmen Claver,*[a] and Sergio Castillón[b]

Keywords: N ligands / Palladium / Copolymerization / Stereochemistry / Nitrogen heterocycles

C_1-symmetrical pyridine–imidazoline ligands have been synthesised and used in the preparation of Pd^{II} complexes of general formula [PdMe(NCMe)(N-N′)][BAr′$_4$] [Ar′ = 3,5-$(CF_3)_2C_6H_3$]. The introduction of electronically different substituents in the imidazoline moiety determines the coordination position of the methyl group in the cationic complexes, which are catalyst precursors for the copolymerization of carbon monoxide and 4-*tert*-butylstyrene (TBS). Interestingly, the use of a precatalyst with a different stereochemistry provides copolymers with a different stereoregularity.

Introduction

Chelating nitrogen ligands have been reported to be the most efficient for the Pd-catalyzed alternating copolymerization of carbon monoxide and styrene.[1−6] Catalysts containing planar, achiral ligands give syndiotactic copolymers with high stereocontrol.[3,7,8] This stereoregularity has been attributed to a chain-end control due to the interaction of the growing chain with the incoming styrene unit, which inserts exclusively in a 2,1-fashion.[3] Enantiomerically pure C_2-symmetrical N-N ligands yield highly isotactic copolymers due to the strict enantiomorphic site control provided by the chiral ligand.[9−11]

To the best of our knowledge there is only one example of a C_1-symmetrical bisnitrogen ligand. Surprisingly, the use of (*S*,*S*)-4,5-dihydro-4-methoxymethyl-3-phenyl-2-(2-pyridyl)oxazole provides a syndiotactic copolymer. It has been proposed that, due to a pronounced site-selective coordination of the olefin, the influence of the chirality of the growing chain is more efficient than the enantiosite control.[9,12,13] The related C_1-symmetrical phosphane−oxazoline ligands provide isotactic poly(styrene-*alt*-CO). It seems that with these ligands the enantioface discrimination is determined by the site-selective coordination of the olefin (*trans* to the P atom) and a secondary insertion of the incoming styrene units.[12]

Recently it has been reported that electronic effects in palladium catalysts modified with chiral ferrocenyldiphosphanes may increase the differentiation of the two coordinating P atoms and change the catalytic activity in the enantioselective copolymerization of carbon monoxide and propene dramatically.[14]

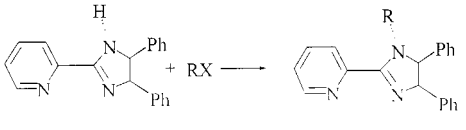
In this paper we show that the stereochemistry of the [PdMe(NCMe)(N-N′)][BAr′$_4$] complexes can be modified by changing the electronic properties of the C_1-symmetrical pyridine−imidazoline ligands. This fact influences the stereoregularity of the CO/TBS copolymers.

Results and Discussion

The pyridine−imidazoline ligand **1a** was prepared similarly to the oxazolines by reaction of 2-cyanopyridine with *meso*-1,2-diphenylethylenediamine but using $YbOTf_3$ as catalyst.[15,16] Further reaction of **1a** with BnBr, TsCl or Tf_2O, provided the 1-substituted-4,5-dihydro-4,5-diphenyl-2-(2-pyridyl)-imidazoles **1b**−**d**, respectively, in a racemic manner (Figure 1).[16] The neutral [PdClMe(N-N′)] complexes **2a**−**d** were isolated from the stoichiometric reaction of [PdClMe(cod)] (cod = 1,5-cyclooctadiene) and the ligands **1a**−**d** in anhydrous toluene.[17,18] The cationic palladium complexes [PdMe(NCMe)(N-N′)][BAr$_4$′] (**3a**−**d**) were prepared following reported procedures.[19]

The stereochemistry of the neutral complexes **2a**−**d** was assigned by means of NOE experiments at room temperature, showing that all the complexes have the methyl group coordinated *trans* to the pyridine ring. This is also confirmed by the downfield shift in the ^{1}H NMR spectra of the proton H_6, next to the N-pyridine atom, which is indicative of the presence of the chloride ligand in a *cis* position.[17] However, the cationic compounds [Pd(Me)(NCMe)(N-N′)][BAr′$_4$] (**3a**−**d**) show a different stereochemistry depending on the ligand. The ^{1}H NMR spectra of **3c**−**d** at



1a **1b** R = Bn
c R = Ts
d R = Tf

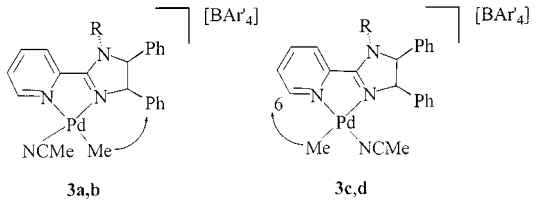

Figure 2. NOE difference experiments show the stereochemistry of the complexes

room temperature show a downfield shift of the Pd−Me signal to around δ = 1.[19] NOE difference experiments at room temperature allowed the determination of the stereochemistry of these complexes and showed that in the complexes **3a**−**b** the methyl group is *trans* to the pyridine moiety whereas it is *cis* in the complexes **3c**−**d** (Figure 2). Therefore the use of different substituents (R) with electron-donor or electron-withdrawing character results in an effective electronic determination in the methyl coordination. The methyl group is always coordinated *trans* to the less basic nitrogen of the ligand.

Under copolymerization conditions the coordination of carbon monoxide and the migratory insertion of the methyl group take place to form an acyl species; the styrene coordinates in the vacant position. The electronic effects of these ligands could therefore affect the steroregularity of the copolymer obtained with the catalytic precursors. The new Pd^{II} complexes with imidazoline-containing ligands were tested as catalysts for the alternating CO/TBS copolymerization. In a typical experiment **3a**−**d** were placed in chlorobenzene under 1 bar CO and TBS was added (Table 1).

Table 1. Alternating CO/TBS copolymerization catalysed by [PdMe(NCMe)(N-N′)][BAr′$_4$][a]

Entry	Precursor	Productivity[b] [g(gPd × h)$^{-1}$]	Stereoregularity (*l* diads) [%]	M_N (M_W/M_N)
1	**3a**	2	65	42200 (1.1)
2	**3b**	8.9	52	49750 (1.5)
3	**3c**	7	15	59250 (1.2)
4	**3d**	12.8	18	39700 (1.5)

[a] Reaction conditions: 0.0125 mmol catalyst, [TBS]/[cat] = 620, 5 mL chlorobenzene, p(CO) = 1 bar, 24 h at room temperature. [b] Productivity calculated from the isolated copolymer.

As Table 1 shows, introducing electron-withdrawing groups (entries 3 and 4) leads to a greater proportion of *u* diads giving highly syndiotactic copolymers. With the substituents H and Bn (entries 1 and 2 respectively) such a clear effect is not observed, probably due to the smaller electronic differentiation of the two rings (pyridine and imidazoline), although there is a bigger proportion of *l* diads. The degree of stereoregularity was evaluated from the ^{13}C NMR spectrum of the copolymers by integrating the signals in the region of the methylene carbon atom using the epimerized copolymer as reference (Figure 3). The molecular weights were high and similar in all the cases. In general, we did not find any relation between the nature of the R substituent and the activity of the catalytic systems.

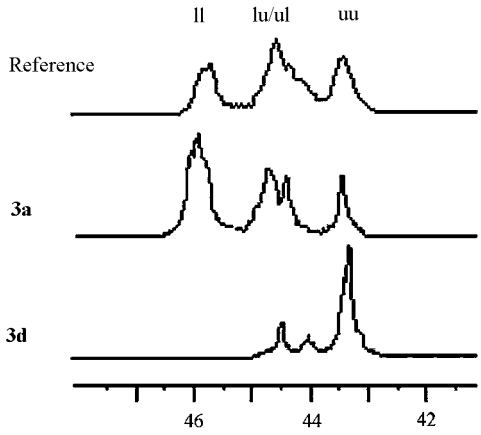

Figure 3. Comparative ^{13}C NMR spectrum of the copolymers in the region of the methylene carbon atom using the epimerized copolymer as reference

In conclusion, we have prepared pyridine−imidazoline ligands with several substituents in the imidazoline moiety and their related [Pd(Me)(NCMe)(N-N′)][BAr$_4$′] complexes. Interestingly, the nature of the substituents determines the stereochemistry of the complexes. The Pd^{II} complexes are active as catalysts in the CO/TBS copolymerization reaction and show that the electronic properties of the ligands strongly influence the stereoregularity of the copolymers. We are currently studying how this electronic discrimination affects the different steps of the catalytic reaction.

Bent Metallocenes of Germanium, Tin, and Lead with Aminoboratabenzene Ligands − Crystal Structures of E[3,5-$Me_2C_5H_3BN(SiMe_3)_2$]$_2$ (E = Ge, Sn, and Pb)[‡]

Xiaolai Zheng[a] and Gerhard E. Herberich*[a]

Keywords: Boron / Metallocenes / Sandwich compounds / Germanium / Tin / Lead

The reaction of GeI_2, $SnCl_2$, or $PbCl_2$ with two equivalents of lithium aminoboratabenzenes in diethyl ether affords the new sandwich compounds Pb(3,5-$Me_2C_5H_3BNMe_2$)$_2$ (**4**) and E[3,5-$Me_2C_5H_3BN(SiMe_3)_2$]$_2$ (**5:** E = Ge, **6:** E = Sn, **7:** E = Pb). While compound **4** undergoes a redox ligand coupling reaction at ambient temperature to give lead black and ligand dimers, the bis(trimethylsilyl)amino compounds **5**–**7** are thermally stable, and coupling products are only detected under the conditions of mass spectrometry. This difference in stability can be attributed to the different perturbation effects which the *B*-amino groups exert on the electronic properties of the boratabenzene rings. Crystal structure determinations reveal that the compounds **5**–**7** possess a monomeric bent-sandwich geometry in the solid state with facially bonded boratabenzenes. The E–C distances span rather large ranges [**5:** 2.320–2.939(4) Å; **6:** 2.519–3.033(9) Å; **7:** 2.632–3.054(7) Å]; the central element E is always particularly close to one of the two α-C atoms and displays intermediate E–B distances.

Introduction

Compared to sandwich complexes of the transition metals, group 14 metallocenes exhibit a more ionic bonding character of the metal−ligand interactions and minimal involvement of the metal d orbitals. These features give rise to loose electronic demands and flexible bonding situations, which have well been documented in recent years with the observation of great structural diversity in this family of compounds.[1−3]

In the solid state, group 14 metallocenes can essentially be classified into three types (Figure 1). Bridging μ-η^5:η^5 cyclopentadienyl ligands (type **A**) exist in all three polymorphic modifications of the parent plumbocene, Pb(C_5H_5)$_2$, with the structural motifs of a zigzag chain,[4] of a toluene/solvated sinusoidal chain,[5] and of a hexameric aggregate.[5] Utilization of lighter homologues[6,7] and/or of sterically demanding cyclopentadienyl ligands[8−10] affords the most frequently encountered bent sandwich structures (type **B**);[1] in some cases, extra short intermolecular interactions are present among neighboring molecules in the lattice.[11] Finally, high steric congestion may cause a parallel alignment of the two cyclopentadienyl rings, resulting in a linear sandwich geometry (type **C**).[12−15] The first group 14 metallocene with parallel ring ligands to be discovered was decaphenylstannocene Sn(C_5Ph_5)$_2$,[12] and the first linear germanocene and plumbocene were E[(C_5Me_4)($SiMe_2tBu$)]$_2$ (E = Ge, Pb).[13] Interestingly, in the case of decamethylsilicocene Si(C_5Me_5)$_2$ two independent isomers are observed in the crystal structure, one with parallel pentamethylcyclopentadienyl ligands and the other one with a bent geometry.[16]

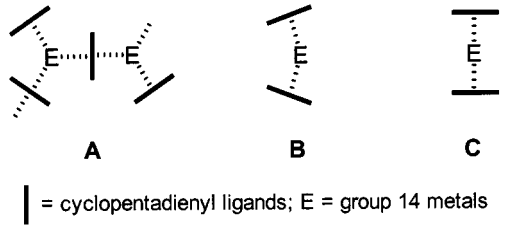

Figure 1. Three structural types of group 14 metallocenes

As aromatic anionic ligands with some similarity to cyclopentadienides, boratabenzenes have drawn substantial research interest recently.[17,18] However, boratabenzene compounds of p-block elements are still quite rare.[19−22] In previous work, we have synthesized the bis(1-methylboratabenzene) compounds E(C_5H_5BMe)$_2$ (**1**: E = Ge; **2**: E = Sn; **3**: E = Pb).[19] X-ray diffraction studies showed that the lead compound **3** possesses a bent geometry locally and forms a tetrameric packing aggregate with short intermolecular contacts which indicate a specific interaction between the lead atoms and the most negatively charged α-carbons of the boratabenzenes of neighboring molecules. In this paper, we describe the synthesis and characterization of the bis(aminoboratabenzene) compounds **4**−**7** using 1-(dimethylamino)-3,5-dimethylboratabenzene and 1-[bis(trimethylsilyl)amino]-3,5-dimethylboratabenzene as ligands. A comparison of their spectroscopic and structural data with those of the known 1-methylboratabenzene analogues provides insight into the electronic and steric effects of the *B*-bonded substituents on group 14 metal−boratabenzene complexes.

Results and Discussion

Syntheses

Salt-metathetical reactions were used in the present work to synthesize the bis(aminoboratabenzene) compounds of the group 14 elements. We had previously reported the synthesis of $Pb(C_5H_5BMe)_2$ (**3**) from lithium 1-methylboratabenzene and $PbCl_2$ in a 2:1 molar ratio.[19] The analogous reaction of lithium 1-(dimethylamino)-3,5-dimethylboratabenzene with $PbCl_2$ at −30 °C produced $Pb(3,5\text{-}Me_2C_5H_3BNMe_2)_2$ (**4**) as a red oil. The formation of the targeted compound was verified by ^1H, ^{11}B, and ^{13}C NMR spectroscopy. Unfortunately, **4** is thermally unstable at ambient temperature and decomposes completely within hours to give lead black as well as an oily mixture of ligand coupling products. To avoid thermal decomposition, all manipulations must be performed at temperatures lower than −20 °C. A similar oxidative coupling reaction had previously been observed when a pinene-fused aminoboratabenzene ion was treated with CuI.[23]

The different stabilities of **3** and **4** seem to arise from the different electronic perturbations of the *B*-amino substituents on the boratabenzene ligands.[24−27] In general, considerable π-interactions exist between the nitrogen and the boron for 1-(dialkylamino)boratabenzenes.[24] This B−N π-interaction is antibonding with respect to the intra-ring B−C π-conjugation, which consequently makes aminoboratabenzenes somewhat similar to the open pentadienyl ligand.[25] Using cyclopentadienide ions as reference, Ashe et al.[26] evaluated the pK_a values of several boracyclohexadienes (or dihydroborinines), the conjugate acids of the corresponding boratabenzene ions, in DMSO by means of NMR spectroscopic methods. The pK_a of 1-methylboracyclohexa-2,5-diene is lower than 12.5 whereas that of 1-(diisopropylamino)boracyclohexa-2,5-diene reaches 17.8 (cf. pK_a = 18.0 for CpH[28]). In other words, 1-(dimethylamino)-boratabenzene is considerably more basic than 1-methylboratabenzene, and hence should be more prone to oxidation and oxidative ligand coupling.

We then chose 1-[bis(trimethylsilyl)amino]-3,5-dimethylboratabenzene as the ligand. From the viewpoint of electronic effects, the polarizing positive Si centers stabilize the nitrogen lone-pair and weaken the B−N π-conjugation; as a consequence, this ligand is expected to be less basic and less nucleophilic than the *B*-(dimethyamino) analogue. The reduced π-conjugation is evidenced by the B−N bond length in the crystal structure of $ScCl[3,5\text{-}Me_2C_5H_3BN(SiMe_3)_2]_2$ [1.471(3) Å] which is considerably longer than that of the η^6-bonded 1-(dialkylamino) ligand in $[ScCl(3,5\text{-}Me_2C_5H_3BNMe_2)]_2$ [1.417(3) Å].[29] Further support comes from the ^{11}B NMR spectroscopic data of the relevant compounds as will be discussed in some detail below. From the viewpoint of steric effects, the bulky *B*-bis(trimethylsilyl)amino substituent of the ligand is expected to enhance the kinetic stability of its complexes.

The bis[1-bis(trimethylsilyl)amino-3,5-dimethylboratabenzene] compounds **5**−**7** can be obtained in good yields (63−85%) from a suitable dihalide (GeI_2, $SnCl_2$, or $PbCl_2$) and 2 equivalents of $Li[3,5\text{-}Me_2C_5H_3BN(SiMe_3)_2]$ using diethyl ether as the solvent. All three compounds can be crystallized from pentane at −30 °C as large prisms. Since the previously known 1-methyl compounds **1** and **2** are liquids, the new compounds **5** and **6** of germanium and tin are the first crystalline bis(boratabenzene) derivatives of these elements. While **5** and **6** are pale yellow, the lead compound **7** is orange red; they are thermally stable at room temperature but quite sensitive to moisture and oxygen.

Spectroscopic Data

The new compounds were characterized by multinuclear NMR spectroscopy and electron-impact mass spectrometry (EIMS). The ^{11}B NMR chemical shifts for **1**−**7** are collected in Table 1, together with data for the related lithium boratabenzenes. On going from germanium to lead, the chemical shifts $\delta(^{11}B)$ move to high field and are, for the lead−boratabenzene compounds, very close to the chemical shifts of the corresponding lithium boratabenzenes.[29,30] This increase (**5** < **6** < **7**) indicates an increasing electrostatic contribution to the metal−ligand interactions for the heavier homologues, which reduces the transfer of electron density from the ligand to the cationic center. Moreover, a survey of the ^{11}B NMR spectroscopic data also provides an insight into the influence of the *B*-bonded substituents on the electronic properties of the ligands. In the case of 1-[bis(trimethylsilyl)amino]-3,5-dimethylboratabenzene, the polarizing influence of the positive silicon centers, as well as the steric demand of the *B*-substituent, diminishes the π-interaction in the B−N bond.[29] Therefore, the ^{11}B chemical shifts of its compounds are located between those of

[a] Chemical shifts were measured in CD_2Cl_2 for group 14 metal compounds and in $[D_8]$THF for lithium boratabenzenes.

the 1-methylboratabenzene and those of the 1-(dimethylamino)-3,5-dimethylboratabenzene compounds.

The ^{119}Sn and ^{207}Pb NMR chemical shifts for the relevant compounds are listed in Table 2. $\delta(^{119}Sn)$ for **6** is located at $\delta = -1592$ and the $\delta(^{207}Pb)$ for **7** at $\delta = -2890$. Both values are slightly more negative than those of the 1-methylboratabenzene analogues [**2**: $\delta(^{119}Sn) = -1535$, **3**: $\delta(^{207}Pb) = -2579$],[19] and far less negative than those of the cyclopentadienyl analogues [e.g., $Sn(C_5H_5)_2$:[31] $\delta(^{119}Sn) = -2199$, $Pb(C_5H_5)_2$:[32] $\delta(^{207}Pb) = -5030$].[34] As discussed in our earlier paper, these dramatic differences can qualitatively be related to the different donor properties of the ligand anions (mainly influencing σ_{dia}) and to the different HOMO/LUMO gaps (influencing σ_{para}).[19]

The EIMS data for **5**−**7** are summarized in Table 3. All three compounds exhibit very weak parent peaks {$[EL_2 - 1]^+$, $I_{rel} < 1\%$; E = Ge, Sn, Pb; L = 3,5-$Me_2C_5H_3BN(SiMe_3)_2$} and feature two sequential losses of the boratabenzene ligands. The most abundant peaks belong to the cations EL^+ or L^+. It is interesting to note that the fragments L_2^+ and $[L_2 - Me]^+$ are also present in the mass spectra. This observation indicates that oxidative ligand coupling reactions are taking place under the conditions of mass spectrometry.

Crystal Structures of E[3,5-$Me_2C_5H_3BN(SiMe_3)_2]_2$ (E = Ge, Sn, Pb)

The crystal structures of the compounds **5**−**7** were determined by X-ray diffraction methods (Table 4 and 5). The germanium compound **5** (Figure 2) crystallizes in the monoclinic space group $P2_1/c$ ($Z = 4$) whereas the tin compound **6** and the lead compound **7** (both with an overall structure very similar to that of **5** and therefore not shown) adopt the triclinic space group $P\bar{1}$ ($Z = 4$) with two independent, but quite similar molecules per asymmetric unit. The latter two compounds are isomorphous in the solid state.

All three structures are of a bent-sandwich type, and no specific intermolecular interactions between neighboring molecules are observed. The two boratabenzene ligands are orientated in such a way that the two voluminous bis(trimethylsilyl)amino groups are related to each other with rotational angles of 147−162° so as to minimize repulsive interactions. The B−N bond lengths [1.46−1.49(1) Å] are comparatively long, and the interplanar angles between the best boratabenzene C_5B plane and the amino NSi_2 plane are quite large. Both observations indicate rather weak π-interactions between the boron and the nitrogen.

The central elements display a rather asymmetric bonding to the boratabenzene rings. This is evidenced by the fact that the metal-to-carbon/boron distances span a very large range, especially in the case of the germanium compound [**5**: 2.320−2.939(4) Å; **6**: 2.519−3.033(9) Å, **7**: 2.632−3.054(7) Å]. Note that the E−B distances are even slightly shorter than some of the E−C distances despite the larger covalent radius of the boron atom. In such a situation, a statement about ligand hapticity would seem quite arbitrary, but we may safely state that the ligand is facially coordinated to the central element.

Table 5. Structural data related to the best least-squares planes for **5**−**7**[a]

Compound	**5**	**6**	**7**
Max. deviation from C_5B planes [Å]	0.072 (C*n*2)	0.055 (C*n*2)	0.047 (C*n*2)
Tilt angle of the sandwich unit [°]	43	51	51
Metal distance to best C_5B plane [Å]	2.179	2.375	2.456
Rotational angle between ligands[b] [°]	162	148	147
Slip distortion[c] [Å]	0.56	0.51	0.43

[a] The data are averaged where applicable. − [b] The rotational angle of the two boratabenzene ligands A and B is defined as the angle between the projections of the two exocyclic B−N bond vectors onto the C_5B plane of the ligand A. − [c] The slip distortion is defined as the distance between the projection of the central metal onto the C_5B plane and the geometric center of the C_5B ring.

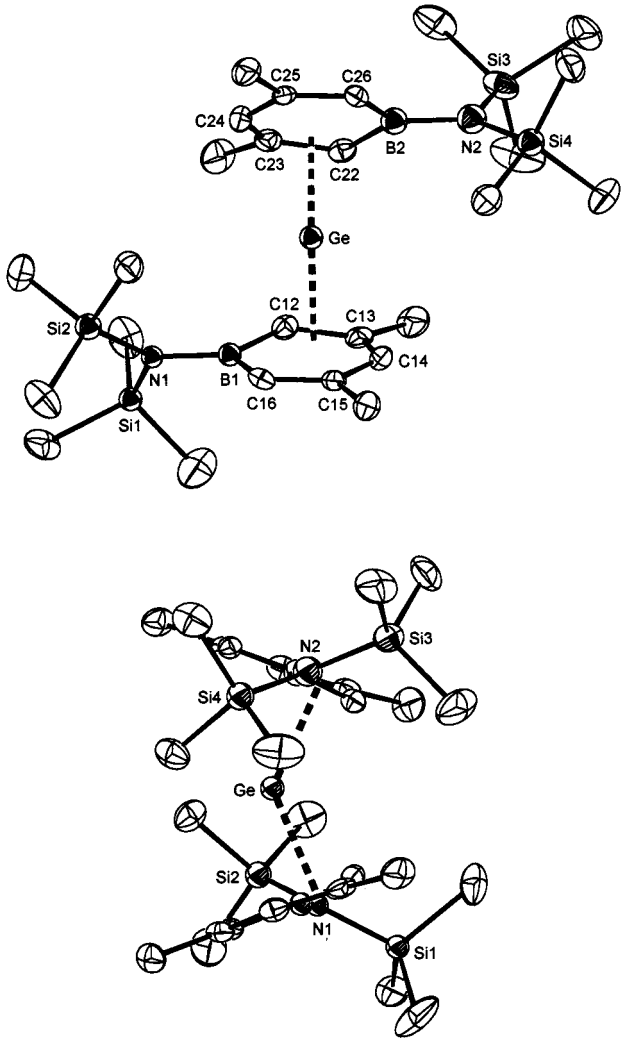

Figure 2. Front and side views (Platon plots[35] at the 30% probability level) of the molecular structure of **5**

The slip distortions, defined as the distances between the projections of the central metals onto the ligand C_5B planes and the geometric centers of the C_5B rings, are 0.56 Å for **5**, 0.51 Å for **6**, and 0.43 Å for **7** on average. These slip distortions are essentially directed toward one of the two ortho-carbon atoms (C*n*2), as can readily be seen from the extremely short E−C*n*2 and at the same time rather long E−C*n*6 distances. The rings also display substantial deviations from planarity. In all cases, the C*n*2 atoms show the largest vertical displacements [0.043−0.056 Å] from the best C_5B planes and toward the central elements.

The π-electron distribution of the boratabenzene ring and the intra-ring B−C bond polarization concentrate negative charge onto the α-carbons.[19−21,25] A symmetric slip toward the boron atom would indicate a largely ionic interaction as in the case of $Mg(C_5H_5BMe)_2$.[25] On the other hand, the combination of an asymmetric slip toward one of the two α-carbon atoms with a partial localization of the ring π-electron system would be expected in cases with significant covalent orbital interactions, as for instance for 2-$(Me_3Sn)C_5H_5BMe$.[20] The Ge compound **5** displays the most asymmetric coordination of the central atom, and the intra-ring bond lengths [cf. B1−C12 1.515(7), C12−C13 1.428(6), C13−C14 1.388(6), C14−C15 1.411(6), C15−C16 1.374(6), B1−C16 1.523(6) Å] show some localization of the π-electron system. The situation is still far from a fully localized diene system, but we may safely conclude that covalent orbital interactions contribute significantly to the bonding in this case. On the other hand, the Pb compound **7** shows a less asymmetric slip, and the intra-ring distances [cf. B1−C12 1.532(10), C12−C13 1.403(9), C13−C14 1.396(10), C14−C15 1.400(10), C15−C16 1.385(9), B1−C16 1.514(10) Å] show barely significant differences which exclude any pronounced localization of the π-electron system. Hence electrostatic interactions are more important in this case.

The tilt angles of the sandwich units are remarkably large in all three structures. For instance, an averaged interplanar angle of 51° is found for the lead compound **7**. In comparison, the sterically less demanding compound bis(1-methylboratabenzene)lead (**3**) possesses a smaller tilt angle of 44° despite the marked short intermolecular interactions in the structure.[19] Although it is generally accepted that steric congestion may cause a decrease of the bending angle of the group 14 sandwich compounds, a rationalization of the molecular geometries based solely on this line seems insufficient. Recent ab initio calculations on the parent stannocene and plumbocene predict very small energy gaps between the bent and linear forms.[36] In addition, accumulating experimental evidence tends to support the notion that the molecular shapes of this family of compounds are strongly affected by lattice forces, as one would expect for soft structural parameters. A pertinent example is the fact

that decaisopropylplumbocene $Pb(C_5Pri_5)_2$ [10a] is bent, whereas the less highly substituted hexaisopropyl analogue $Pb(C_5H_2Pri_3)_2$ [15] is linear.

Concluding Remarks

This paper presents work on bis(aminoboratabenzene) compounds of divalent group 14 elements. We found that the thermal stability of the plumbocene analogues decreases in the order **3** > **7** > **4**. This sequence parallels the basicity of the corresponding boratabenzene ligands and suggests that the stability is tunable by varying the *B*-bonded groups.

Crystal structure analyses reveal a monomeric bent-sandwich structure for the compounds **5**−**7**. The molecules possess rather large tilt angles, implying that the bulky substituents of the ligands do not necessarily result in less bent molecular geometries for group 14 metallocenes. In all three structures, the metal−ligand bonding is surprisingly asymmetric with large slip distortions. This observation, together with the synopsis of the ^{11}B NMR spectroscopic data, suggests that the metal−ligand interactions comprise large electrostatic contributions for this family of compounds which increase on going from Ge to Pb.

Experimental Section

General: All manipulations were carried out under an inert atmosphere of nitrogen by means of standard Schlenk techniques. Pentane was distilled from Na/K alloy, toluene from sodium, and Et_2O from sodium benzophenone ketyl solution. Anhydrous GeI_2, $SnCl_2$, and PbI_2 were used as received from commercial sources. The lithium salts $Li(3,5\text{-}Me_2C_5H_3BNMe_2)$[29,37] and $Li[3,5\text{-}Me_2C_5H_3BN(SiMe_3)_2]$[29] were prepared according to established procedures. Electron-impact mass spectra were recorded on a Finnigan MAT-95 at a nominal electron energy of 70 eV. Elemental analyses were performed at the Analytische Laboratorien, 51779 Lindlar, Germany.

NMR spectra were recorded on a Varian Unity 500 (^1H: 500 MHz; ^{13}C: 125.7 MHz; ^{11}B: 160.4 MHz; ^{119}Sn: 186.5 MHz; ^{207}Pb: 104.6 MHz), a Varian Mercury 200 (^1H: 200 MHz; ^{13}C: 50.3 MHz), or a PMR Firenze spectrometer (^{11}B: 27.9 MHz). Chemical shifts are given in ppm and are referenced to TMS for ^1H and ^{13}C, to $BF_3{\cdot}OEt_2$ for ^{11}B, to $SnMe_4$ for ^{119}Sn, and to $PbMe_4$ for ^{207}Pb. In the case of ^{207}Pb, a solution of $PbEt_4$ (17%, δ = 74.8)[38] in CD_2Cl_2 was used as external standard.

Synthesis of Bis(1-dimethylamino-3,5-dimethylboratabenzene)lead (4): $Li(3,5\text{-}Me_2C_5H_3BNMe_2)$ (0.53 g, 3.42 mmol) in ether (10 mL) was added to a suspension of $PbCl_2$ (0.48 g, 1.71 mmol) in ether (10 mL) at −30 °C. The reaction mixture was stirred at this temperature for 24 h to give a red solution. After removal of the solvent under high vacuum at −30 °C, cold pentane (15 mL, −78 °C) was injected to the residue and a precipitate of LiCl was filtered off quickly. All the solvent was pumped off from the filtrate to give **4** (ca. 0.6 g, 70%) as a red oil that can be stored at −78 °C for weeks. Upon standing at room temperature, compound **4** decomposes to give lead black and a pale yellow oil; this oil contains the ligand-coupling products and consists mainly (ca. 80%) of the 4,4′-isomer.

Data for 4: ^1H NMR (200 MHz, $CDCl_3$, −20 °C): δ = 2.10 (s, 2 × 3-/5-Me), 2.90 (s, 2 × NMe_2), 4.97 (s, 2 × 2-/6-H), 6.10 (s, 2 × 4-H). − $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$, −20 °C): δ = 24.3 (3-/5-Me), 39.0 (NMe_2), 109.3 (C-4), 114.1 (br, C-2,6), 148.5 (C-3,5). − ^{11}B NMR (28 MHz, $CDCl_3$, external $BF_3{\cdot}OEt_2$, −20 °C): δ = 32.

Data for the 4,4′-Isomeric Ligand-coupling Product: ^1H NMR (200 MHz, $CDCl_3$, 20 °C): δ = 1.91 (s, 3-/3′-/5-/5′-Me), 2.83 (s, 2 × NMe_2), 3.23 (s, 4-/4′-H), 5.96 (s, 2-/2′-/6-/6′-H). − $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$, 20 °C): δ = 26.6 (3-/5-Me), 39.1 (NMe_2), 52.5 (C-4,4′), 127.0 (br, C-2,2′,6,6′), 159.2 (C-3,3′,5,5′).

Synthesis of Bis[1-bis(trimethylsilyl)amino-3,5-dimethylboratabenzene]germanium (5): $Li[3,5\text{-}Me_2C_5H_3BN(NSiMe_3)_2]$ (0.64 g, 2.36 mmol) in ether (10 mL) was added dropwise to GeI_2 (0.39 g, 1.18 mmol) in ether (10 mL) at 0 °C. The system was allowed to warm to ambient temperature and stirring was continued for 6 h to give a yellow slurry. After the solvent had been completely removed under vacuum, pentane (30 mL) was added to the residue. A white precipitate of LiCl was removed by filtration and washed with pentane (2 × 5 mL). The combined filtrate was concentrated and cooled to −30 °C for 3 days to give **5** (0.52 g, 73%) as pale yellow crystals. The compound is extremely sensitive to moisture and air.

Data for 5: ^1H NMR (500 MHz, CD_2Cl_2, 20 °C): δ = 0.20 (s, 4 $SiMe_3$), 2.06 (s, 2 × 3-/5-Me), 5.32 (t, *J* = 1.5 Hz, 2 H, 4-H), 5.44 (d, *J* = 1.5 Hz, 2 × 2-/6-H). − $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2, 20 °C): δ = 4.7 ($SiMe_3$), 25.1 (3-/5-Me), 117.9 (C-4), 122.0 (br, C-2,6), 147.8 (C-3,5). − ^{11}B NMR (160 MHz, CD_2Cl_2, external $BF_3{\cdot}OEt_2$, 20 °C): δ = 37.8. − $C_{26}H_{54}B_2GeN_2Si_4$ (601.3): calcd. C 51.94, H 9.05, N 4.66; found C 51.69, H 9.23, N 4.55.

Synthesis of Bis[1-bis(trimethylsilyl)amino-3,5-dimethylboratabenzene]tin (6): $Li[3,5\text{-}Me_2C_5H_3BN(NSiMe_3)_2]$ (231 mg, 0.85 mmol) in ether (10 mL) was added dropwise to $SnCl_2$ (80 mg, 0.42 mmol) in ether (5 mL) at 0 °C. The system was allowed to warm to ambient temperature and stirring was continued for 6 h to give a yellow slurry. After the solvent had been completely removed under vacuum, pentane (20 mL) was added to the residue. A white precipitate of LiCl was removed by filtration and washed with pentane (5 mL). The combined filtrate was concentrated and cooled to −30 °C overnight to give **6** (0.17 g, 63%) as pale yellow crystals. The compound is sensitive to moisture and air.

Data for 6: ^1H NMR (500 MHz, CD_2Cl_2, 20 °C): δ = 0.21 (s, 4 × $SiMe_3$), 2.10 (s, 2 × 3-/5-Me), 5.32 (t, *J* = 1.2 Hz, 2 × 4-H), 5.51 (d, *J* = 1.2 Hz, 2 × 2-/6-H). − $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2, 20 °C): δ = 4.9 ($SiMe_3$), 24.9 (3-/5-Me), 113.7 (C-4), 123.8 (br, C-2,6), 148.1 (C-3,5). − ^{11}B NMR (160 MHz, CD_2Cl_2, external $BF_3{\cdot}OEt_2$, 20 °C): δ = 36.3. − ^{119}Sn NMR (186 MHz, CD_2Cl_2, external $SnMe_4$, 20 °C): δ = −1592. − $C_{26}H_{54}B_2N_2Si_4Sn$ (647.4): calcd. C 48.24, H 8.41, N 4.33; found C 48.14, H 8.40, N 4.17.

Synthesis of Bis[1-bis(trimethylsilyl)amino-3,5-dimethylboratabenzene]lead (7): $Li[3,5\text{-}Me_2C_5H_3BN(NSiMe_3)_2]$ (0.56 g, 2.06 mmol) in ether (20 mL) was added dropwise to a suspension of $PbCl_2$ (0.28 g, 1.02 mmol) in ether (10 mL) at −78 °C. The system was allowed to warm to ambient temperature and stirring was continued for 6 h to give an orange slurry. After the solvent had been completely removed under vacuum, pentane (30 mL) was added to the residue. A white precipitate of LiCl was removed by filtration and washed with pentane (2 × 5 mL). The combined filtrate was concentrated to ca. 5 mL and cooled to −30 °C to afford **7** (0.64 g, 85%) as large orange-red crystalline blocks which are sensitive to moisture and air.

Data for 7: ^{1}H NMR (500 MHz, CD_2Cl_2, 20 °C): δ = 0.20 (s, 4 $SiMe_3$), 2.19 (s, 2 × 3-/5-Me), 5.32 (t, J = 1.8 Hz, 2 × 4-H), 5.41 (d, J = 1.8 Hz, 2 × 2-/6-H). − $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2, 20 °C): δ = 5.0 ($SiMe_3$), 24.6 (3-/5-Me), 113.5 (C-4), 125.0 (br, C-2,6), 148.5 (C-3,5). − ^{11}B NMR (160 MHz, CD_2Cl_2, external $BF_3{\cdot}OEt_2$, 20 °C): δ = 35.2. − ^{207}Pb NMR (105 MHz, CD_2Cl_2, external $PbEt_4$, relative to $PbMe_4$, 20 °C): δ = −2890. − $C_{26}H_{54}B_2N_2PbSi_4$ (735.9): calcd. C 42.44, H 7.40, N 3.81; found C 41.27, H 7.51, N 3.72.

X-ray Crystal Structure Determinations of 5−7: Data collection was performed on an ENRAF-Nonius CAD4 diffractometer with Mo-K_α radiation (graphite monochromator, λ = 0.71073 Å) using the ω-2θ scan mode. Crystal data, data collection parameters, and convergence results are listed in Table 6. Empirical absorption corrections on the basis of azimuthal scans[39] were applied to the data sets of **5** and **7** before merging symmetry-related reflections. The structure of **5** was solved by direct methods whereas the solutions for compounds **6** and **7** were obtained by conventional heavy atom methods.[40] All three structures were refined on reflection intensities (F^2) with the SHELXL-97 program.[41] In the final structural models, non-hydrogen atoms were refined with the anisotropic displacement parameters while hydrogen atoms were included as riding with fixed displacement parameters [C−H = 0.98 Å, U_{iso}(H) = 1.3 U_{eq}(C)].[42]

Acknowledgments

We thank Dr. U. Englert for helpful advice with the X-ray structure determinations. This work was generously supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Reactivity of Coordinated Nitriles − Formation of the Acetamidine Complex *cis*-[$(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]^+$ from the 1-Methylthyminate Compound *cis*-[$(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]^+$ − Synthesis, Characterisation, and X-ray Structures

Bruno Longato,*[a,b] Giuliano Bandoli,[c] Adele Mucci,[d] and Luisa Schenetti[d]

Keywords: Platinum / Nucleobases / Phosphanes / N ligands

1-Methylthymine (1-MeTy) reacts reversibly with the hydroxo complexes *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2X_2$ ($X^- = NO_3$; ClO_4) in various solvents (S = CH_3CN, H_2O, DMSO) to give the thyminate derivatives *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(S)]X$ that have been isolated as pure compounds when S is CH_3CN. The single-crystal X-ray structure of *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]ClO_4$ shows that the N(3)-platinated nucleobase acts as a monodentate ligand and a molecule of CH_3CN completes the coordination sphere of the metal. Crystals of the acetamidine derivative *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]X$ were isolated from an acetonitrile solution of this complex, in the presence of small amounts of water, after several months at room temperature, separated in 5–10% yield. The X-ray analysis of the perchlorate salt shows a configuration of the amidine ligand consistent with a formal *trans* addition of NH_3 to the CN triple bond of the coordinated nitrile. The acetamidine complex was formed in high yield (70%), in a few weeks, when aqueous solution of NH_3 was added to *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]^+$ dissolved in CH_3CN. Side products of this reaction are the ammonia complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(NH_3)]^+$, which was also obtained as pure compound, acetamide, and other platinum containing species. All the isolated complexes were characterised by elemental analysis, IR, and multinuclear NMR spectroscopy.

Introduction

The coordination of nitriles to electron-withdrawing transition metals results in an enhanced electrophilicity of the nitrile carbon, making it susceptible to nucleophilic attack. Reactions of nitriles with protic nucleophiles such as water, alcohols, and ammonia (or amines) generate the corresponding amides, $H_2N-C(O)R$, imino esters (or imino ethers), $HN=C(OR')R$, and amidines, $HN=C(R)NH_2$, respectively.[1,2]

The products of the reactions of Pt^{II}-coordinated nitriles with water and alcohols have been investigated in details, whereas only a few reports deal with the characterization of amidine complexes.[3−5] The first example of structurally authenticated acetamidine [$HN=C(CH_3)NH_2$] complex of platinum was the dication *trans*-$[Pt(NH_3)_2\{CH_3C(NH)NH_2\}_2]^{2+}$, initially formulated as the octahedral species *trans*-$[Pt(NH_3)_4(CH_3CN)_2]^{2+}$.[6] Very recently, Bertani and co-workers have reported the characterisation of the bis-amidine *trans*-$[PtCl_2\{CH_3C(NH)NHMe\}_2]$, obtained by reacting the acetonitrile complex *trans*-$[PtCl_2(CH_3CN)_2]$ with the primary amine $MeNH_2$, under very mild conditions.[7]

Following our interest in the study of model nucleobases with phosphane analogues of *cis-platin*,[8−14] we came across the nitrile complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]^+$, **1**, containing the N(3)-deprotonated 1-methylthymine ligand [1-MeTy(−H)]. Complex **1** is formed by condensation of the dinuclear hydroxo compound *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2^{2+}$ with N(1)-substituted methylthymine (1-MeTy), in acetonitrile. We found that when this cationic acetonitrile complex was left in the reaction mixture for several months at room temperature, the acetamidine derivative *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]^+$, **2**, separated as pure colourless crystalline solid, whereas the solution became yellow. Such a transformation, which implies the formal addition of NH_3 to the coordinated acetonitrile, occurred in low yield (5−10%) and was accompanied by the formation, in addition to free acetamide, of the ammonia complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(NH_3)]^+$, **3**, and other platinum-containing products.

In this paper we report on the synthesis and the characterisation of these new thyminate complexes showing that the acetamidine derivative **2** can be conveniently prepared by addition of aqueous NH_3 to the acetonitrile complex **1**.

Along with a detailed multinuclear NMR analysis of the isolated compounds, the X-ray structures of *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]ClO_4$ and *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]ClO_4$ were obtained, defining the stereochemistry of the amidine ligand in solution as well as in the solid state.

Results and Discussion

Synthesis and Characterisation of the Thyminate Complexes *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]X$ ($X^- = ClO_4$, **1a**; NO_3, **1b**)

The dinuclear hydroxo complex *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2^{2+}$ reacted with a stoichiometric amount of 1-MeTy in H_2O, DMSO, or CH_3CN, to give the mononuclear species *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(S)]^+$ (S = solvent molecule), resulting from the deprotonation of the nucleobase, according to the following reaction [Equation (1)]:

$$^1/_2\ cis\text{-}[(PMe_3)_2Pt(\mu\text{-}OH)]_2^{2+} + 1\text{-}MeTy + S \rightleftarrows cis\text{-}[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(S)]^+ + H_2O \quad (1)$$

The reaction occurred at room temperature in a few hours and was essentially quantitative when anhydrous acetonitrile was used as the solvent, whereas it was incomplete in dimethylsulfoxide or water. The position of the equilibrium could be easily deduced from the ^{31}P NMR spectrum of the reaction mixture since the reagent is characterized by a sharp singlet at δ ca. −25, flanked by the ^{195}Pt satellites, which was substituted by an AB multiplet when the product was formed. The chemical shifts and the coupling constants are dependent on the solvent, as shown in Table 1.

Table 1. ^{31}P NMR spectroscopic data of *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(S)]^+$ (S = solvent molecule)

Solvent S	δ_P; $^1J_{PPt}$ (Hz)	δ_P; $^1J_{PPt}$ (Hz)	$^2J_{PP}$ (Hz)
CD_3CN	−31.10 (2944)	−29.59 (3809)	27.5
$[D_6]$DMSO	−23.16 (3169)	−29.12 (3892)	25.6
D_2O	−26.05 (3171)	−30.11 (3885)	26.4

Thus, the ^{31}P NMR spectrum of a $5\cdot10^{-2}$ M solution of the perchlorate salt *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ in CD_3CN containing the nucleobase in 1:2 molar ratio, after equilibration (a few hours at ambient conditions), showed the complete disappearance of the resonance at δ = −25.6, which was replaced by a sharp AB multiplet at δ = −29.6 ($^1J_{PPt}$ = 3810 Hz) and −31.1 ($^1J_{PPt}$ = 2944 Hz) with $^2J_{PP}$ 27.5 Hz, attributable to the thyminato complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]ClO_4$, **1a**.

When the reaction was carried out in $[D_6]$DMSO, at the equilibrium ca. 10% of the starting hydroxo complex remained unchanged, suggesting a relatively lower stability of the thyminate complex in this solvent. In line with the presence of different types of donor atoms *trans* to the PMe_3 ligands, the ^{31}P NMR spectrum of the product shows well separated doublets ($^2J_{PP}$ = 25.6 Hz), at δ = −23.1 ($^1J_{PPt}$ = 3169 Hz) and −29.1 ($^1J_{PPt}$ = 3892 Hz). The deprotonation of the nucleobase is evidenced in the proton spectrum by the disappearance of the N(3)H resonance at δ = 11.2 and the concomitant shift to higher field of the H(6) resonance, which is observed as a 1:3:3:1 quadruplet ($^4J_{HH} \approx 1$ Hz) at δ = 7.40, slightly shielded with respect to the free base (δ = 7.49).[9]

Although to a minor extent, the deprotonation of the thymine occurs also in aqueous solution. In this solvent, the perchlorate is insoluble and therefore the corresponding nitrato salt was used. The stoichiometric amount of 1-MeTy added to a $4.1\cdot10^{-2}$ M solution of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ in D_2O dissolved in 2.5 h at ambient temperature. The ^{31}P NMR spectrum of the resulting colourless solution exhibits an intense AB pattern (Table 1), tentatively attributed to the aqua complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(H_2O)]^+$, and the singlet of the unchanged hydroxo complex having an intensity of about 18% of the total resonances. In addition, at the equilibrium, very weak resonances in the range δ = −25 to −32 are detectable. Since the thyminate ion can also act as a bidentate ligand,[15] these signals could be due to the presence of small concentrations of polynuclear complexes of the type *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}]_n^{n+}$ or, alternatively, to other species related to the acidic character of the water molecule coordinated to the metal centre. It is worth noting that addition of a small amount of CH_3CN (1−2%) to the D_2O solution resulted in the immediate appearance of the multiplet due to the complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]^+$ as the only detectable species.

As anticipated, in anhydrous CH_3CN the reaction 1 was essentially complete and the solvent complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]^+$ could be isolated by addition of diethyl ether. The IR spectrum of the perchlorate salt, **1a**, shows the weak absorptions at 2332 and 2371 cm^{-1}, typical values for the η^1-coordinated CH_3CN in platinum(II) complexes, and the carbonyl bands of the thyminate ligand at 1653 and 1591 cm^{-1}. The $\{^1H\}$-^{31}PNMR spectrum (at 161 MHz) in CD_3CN shows an AB system at δ = −29.6 and −31.1 (Table 1), flanked by the ^{195}Pt satellites, due to the chemical non-equivalence of the phosphane ligands. In the corresponding ^1H NMR spectrum the PMe_3 resonances are observed as two doublets at δ = 1.78 ($^2J_{HP}$ = 11.3 Hz; $^3J_{HPt}$ = 30 Hz) and δ = 1.63 ($^2J_{HP}$ = 11.8 Hz; $^3J_{HPt}$ = 42 Hz). The first resonance is attributable to the methyl groups of the phosphane resonating at higher field, as deduced from inverse detection experiments. However, attempts to discriminate between the two PMe_3 ligands with respect to the nucleobase, through NOE experiments, were unsuccessful. The nitrile methyl resonance (δ = 2.03) does not differ significantly from the value of the free ligand indicating that replacement of the CH_3CN molecule by the solvent upon dissolution of compound had occurred. The lability of the acetonitrile ligand was confirmed by dissolving the complex in $[D_6]$DMSO. In this solvent the ^{31}P NMR spectrum of **1a** displays a main set of resonances due to the species *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(DMSO)]^+$ (Table 1) and a weak AB multiplet ($^2J_{PP}$ = 25.9 Hz) at δ = −29.4 ($^1J_{PPt}$ = 3960 Hz) and −30.9

($^1J_{PPt}$ = 2985 Hz), which accounts for ca. 5% of the mixture, attributable to the incomplete replacement of the nitrile molecule on the coordination sphere of the metal. Moreover, as a consequence of the reversibility of reaction (1), **1a** decomposes immediately in water with precipitation of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ that is, unlike the nitrate salt, insoluble in water.

The dissolution of the acetonitrile complexes **1a** and **1b** in [D_6]DMSO or D_2O (for **1b**) caused a remarkable shift to lower field of one of the two PMe_3 resonances in the ^{31}P NMR spectra, while the second one changed only slightly (Table 1). Whereas these changes are in agreement with the replacement of the labile CH_3CN ligand by the solvent, the attribution of the resonances is not obvious. It is generally assumed that in square-planar Pt^{II} complexes the phosphane *trans* to a labile ligand experiences the highest value of the one-bond $^{31}P-^{195}Pt$ coupling. For the complexes *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(S)]^+$ (Table 1) we found that the larger value of $^1J_{PPt}$ was associated with the less shielded phosphane in the case of CD_3CN (δ = 29.6, $^1J_{PPt}$ = 3809 Hz) but in [D_6]DMSO and D_2O the opposite was observed.

Characterisation of the Acetamidine Complexes *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]X$ (X = ClO_4, 2a; NO_3, 2b)

When the reaction mixture of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ (ca. 0.1 M) and 1-MeTy in CH_3CN [Equation (1)] was left at room temperature for several weeks, the colourless solution, became yellow, and colourless crystals started to precipitate. In some months (4−7) small amounts (5−10%) of the new complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]ClO_4$, **2a**, were formed as a crystalline solid that was characterised by elemental analysis, multinuclear NMR spectroscopy, and single-crystal X-ray diffraction methods. The compound was insoluble in acetonitrile and in chlorinated solvents, whereas it dissolved in DMSO and water. The proton spectrum (400 MHz) in [D_6]DMSO exhibits the resonances of the phosphane methyl groups as doublets (δ = 1.58 and 1.48, $^2J_{HP}$ = 11 Hz) with unresolved Pt-satellites and a single set of resonances for the thymine and the amidine ligands. The acetamidine resonances are observed as broad singlets at δ = 7.37 for the imino proton, at δ = 7.24 and 6.95 for the amino protons, and as a sharp singlet at δ = 1.93 for the CH_3 group. The assignments of the NH resonances were obtained through inverse detected $^1H,^{15}N$ heteronuclear multiple quantum coherence experiments (HMQC).[16]

As shown in Figure 1, a, the two NH resonances at higher field correlate with the same ^{15}N resonance at δ = −274 ($^1J_{NH}$ = 90 Hz), whereas that at δ = 7.37, partially overlapping with the thymine H(6) multiplet, correlates with a second ^{15}N resonance at δ = −241 ($^1J_{NH}$ = 80 Hz). This latter ^{15}N resonance displays (Figure 1, b) an additional splitting (ca. 60 Hz) due to the coupling with the ^{31}P nucleus in *trans* position. Moreover, the imino proton displays an H,H coupling (3 Hz) with the NH_2 proton at δ = 7.24, as confirmed through a COSY experiment. This finding suggests a *trans* relationship between the NH_2 group and the imino proton and, in particular, a zigzag arrangement between the imino proton and the NH_2 proton at δ = 7.24.

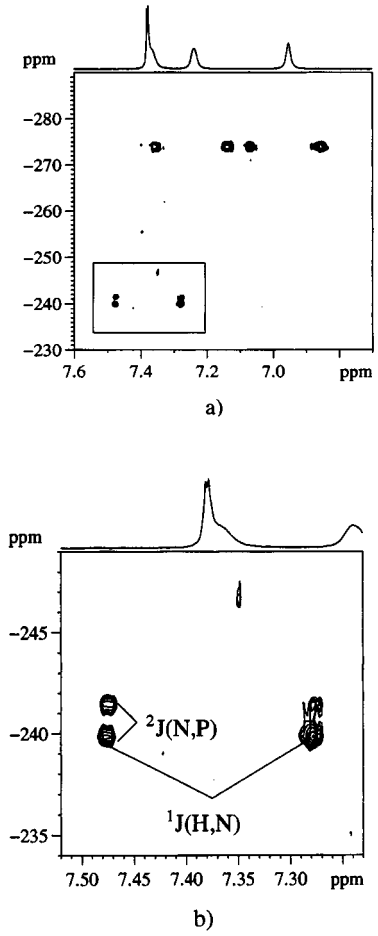

Figure 1. Inverse-detected $^1H,^{15}N$ shift-correlated spectrum of **2a** in [D_6]DMSO obtained with a HMQC experiment without decoupling during the acquisition: a) complete spectrum of the NH region; b) expanded region corresponding to the imino proton

In the inverse detected $^1H,^{195}Pt$ heteronuclear multiple bond correlation experiment (HMBC),[17] the imino proton at δ = 7.37 shows a correlation with the ^{195}Pt signal at δ = −4633 (Figure 2, a), confirming the involvement of the imino group in the coordination to the metal centre.

Figure 2, b, displays that the same ^{195}Pt resonance is also detected through the phosphane proton resonances, demonstrating that the imino nitrogen and the phosphane ligands are bonded to the same metal centre. The left trace in Figure 2 represents the $\{^1H\}$-^{195}Pt spectrum obtained by direct acquisition and, due to the low resolution used in the experimental conditions, the resonance appears as a triplet, whereas the $\{^1H\}$-^{31}P spectrum allowed us to detect two different $^1J_{PPt}$ coupling constants. The phosphane resonances exhibit, in fact, very similar chemical shifts and coupling constants (δ = −28.80 and −29.25; $^1J_{PPt}$ = 3088 and 3125 Hz, respectively) in agreement with the presence of similarly hybridized nitrogen atoms in a *trans* position. As shown in Figure 3, the ^{195}Pt satellites, in spite of the rela-

Figure 2. The upper trace corresponds to the proton spectrum and the left trace corresponds to the ^{195}Pt spectrum

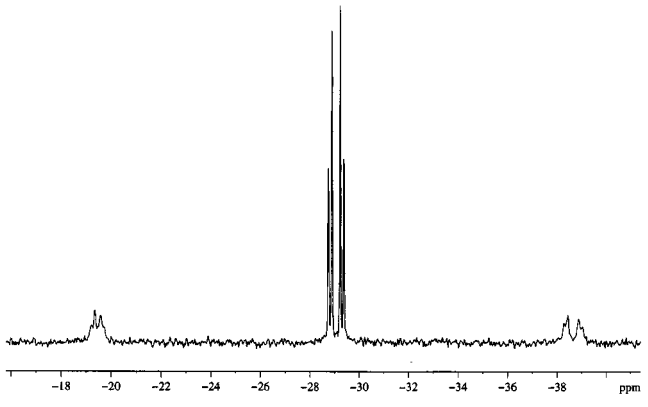

Figure 3. $\{^{1}H\}$-^{31}P NMR at 162 MHz of *cis*-[$(PMe_3)_2$Pt{1-MeTy(−H)}{$CH_3C(NH)NH_2$}]ClO_4 (**2a**) in [D_6]DMSO

tively high field used (162 MHz), were particularly well resolved.

X-ray Structure Analyses of *cis*-[$(PMe_3)_2$Pt-{1-MeTy(−H)}(CH_3CN)]ClO_4, 1a, and *cis*-[$(PMe_3)_2$Pt-{1-MeTy(−H)}{$CH_3C(NH)NH_2$}]ClO_4, 2a

The identification of the atoms and the molecular structures of **1a** and **2a** are depicted in Figure 4 and Figure 5,

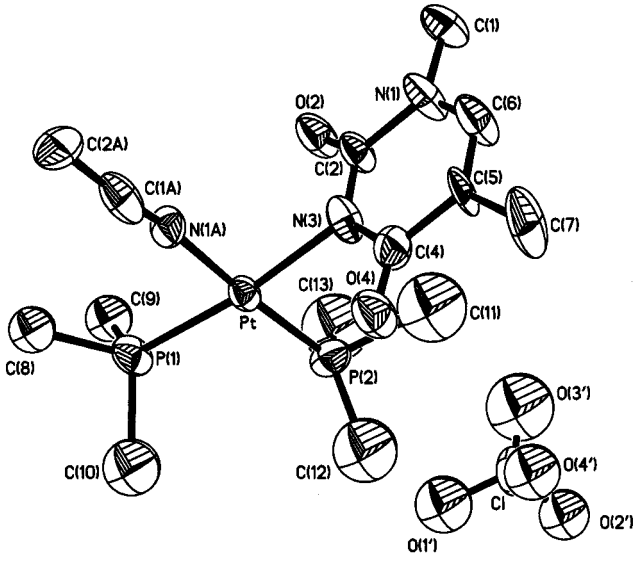

Figure 4. ORTEP drawing of the molecular structure of *cis*-[$(PMe_3)_2$Pt{1-MeTy(−H)}(CH_3CN)]ClO_4, **1a**, along with atomic numbering system. Non-hydrogen atoms are presented as thermal ellipsoids at 35% probability levels

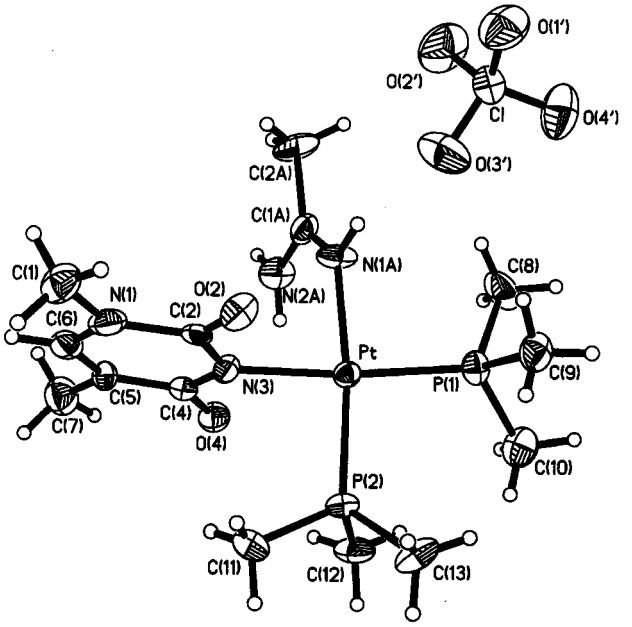

Figure 5. ORTEP drawing of the molecular structure of *cis*-[$(PMe_3)_2$Pt{1-MeTy(−H)}{$CH_3C(NH)NH_2$}]ClO_4 **2a**, along with atomic numbering system. Non-hydrogen atoms are presented as thermal ellipsoids at 35% probability levels, whereas hydrogen atoms are drawn as spheres of arbitrary size

Table 2. Selected bond lengths [Å], intramolecular separations [Å] and angles [°] in *cis*-[$(PMe_3)_2$Pt{1-MeTy(−H)}(CH_3CN)]ClO_4, **1a**, and *cis*-[$(PMe_3)_2$Pt{1-MeTy(−H)}{$CH_3C(NH)NH_2$}]ClO_4 **2a**. Standard deviations are given in parentheses

Compound	**1a**	**2a**
Pt−P(1)	2.268(5)	2.263(3)
Pt−P(2)	2.232(5)	2.259(3)
Pt−N(3)	2.12(1)	2.097(9)
Pt−N(1A)	2.05(1)	2.09(1)
P(1) ··· P(2)	3.347	3.361
P(2) ··· N(3)	3.04	3.07
N(3) ··· N(1A)	2.86	2.81
P(1)−Pt−P(2)	96.1(2)	95.2 (3)
P(1)−Pt−N(3)	173.2(5)	172.0(7)
P(1)−Pt−N(1A)	89.1(4)	90.5(3)
P(2)−Pt−N(3)	88.5(4)	92.6(7)
P(2)−Pt−N(1A)	174.3(4)	173.2(3)
N(3)−Pt−N(1A)	86.5(5)	84.1(5)

respectively, and the main bond lengths and angles are summarised in Table 2.

In both complexes the platinum exhibits a distorted square-planar coordination in which the bond angles around the metal range from 86.5(5) to 96.1(2)° in **1a** and from 84.1(5) to 95.2(3)° in **2a**, their sum being 360.2° and 362.4°, respectively. The common portion of the two structures are roughly superimposable, with an r.m.s. deviation (derived from the BMFIT program)[18] of 0.13 Å when the fitting is performed without the methyl groups. The thymine ring forms a dihedral angle of 89.3(4)° in **1a** and 103.0(3)° in **2a** with the coordination plane, and the acetamidine group in **2a** lies nearly orthogonal to the mean square plane [dihedral angle 111.2(3)°]. In both compounds no effective hydrogen bonds occur and the complexes are built up by the juxtaposition at van der Waals distances of well separated Pt^{II} monocations and perchlorate counter anions. This

[a] Refers to the atom in the position x, $y-1$, z.

is despite the fact that the shortest intramolecular (2.93 Å) and intermolecular (2.85 Å) separations in **2a** (Table 3 and Figure 6) seem to be of some significance.

The Pt−P distances are comparable to the mean value of 2.27(4) Å derived from 65 Pt−PMe_3 data retrieved from Cambridge Crystallographic Data Base,[19] while the Pt−N(3) distances [2.12(1) and 2.10(1) Å in **1a** and **2a**, respectively] are greater than the value of 2.03 Å found for Pt−N (thyminate or uracilate) distances in four mononuclear, but uncharged, Pt^{II} complexes.[20−23] Similarly, in **1a** the Pt−N(acetonitrile) distance [2.05(1) Å] is remarkably longer than the mean value [1.97(3) Å] derived from 12 X-ray determinations.[19] The Pt−N(acetamidine) distance of **2a** [2.09(1) Å] is also longer than the value of 1.96 Å found in the diamminebis(acetamidine)platinum(II) dichloride.[6]

Reactivity of the Coordinated Nitrile in the Cationic Complex *cis*-[$(PMe_3)_2$Pt{1-MeTy(−H)}(CH_3CN)]$^+$

Amidine complexes are formally derived by nucleophilic attack of amines on metal-coordinated nitriles. It has recently been reported that the neutral acetonitrile complex *trans*-$PtCl_2(CH_3CN)_2$ reacts with $MeNH_2$, under very mild conditions, to give the bis-amidine product *trans*-$PtCl_2${(*Z*)-N(H)=C(NHMe)CH_3}$_2$.[7] The X-ray structure shows that the organic ligands assume the (*Z*) configuration corresponding to the *trans*-addition of the amine fragments to the CN triple bond (Scheme 1).

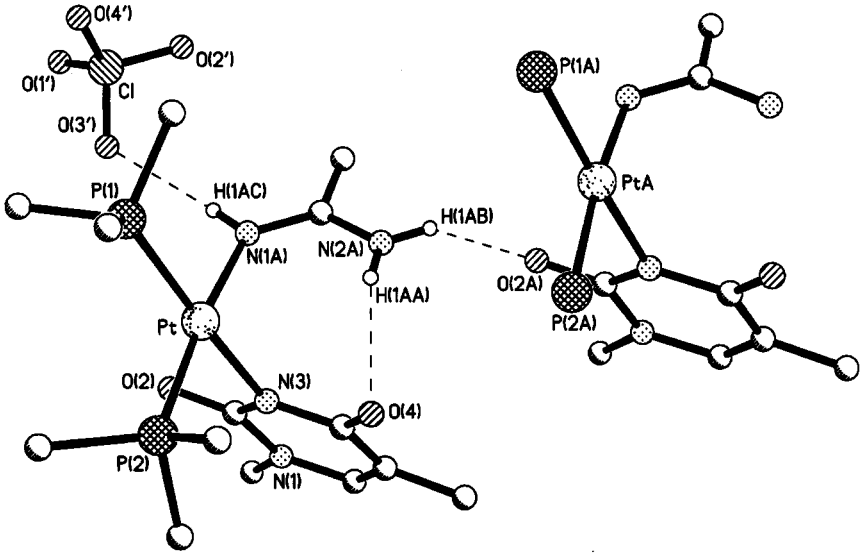

Figure 6. The interactions involving the acetamidine group in **2a**

Scheme 1

The same stereochemistry of the acetamidine groups was early established for the cationic amino complex *trans*-$[Pt(NH_3)_2\{CH_3C(NH)NH_2\}_2]^{2+}$ [6] and is now confirmed for complex **2a** in the solid state as well as in solution.

The separation of the acetamidine compound **2a** as crystalline colourless solid from the reaction mixture of 1-MeTy and *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2^{2+}$ in CH_3CN requires several months at ambient conditions, and the yield is poor. The NMR analysis of the solution, after separation of the solid, removal of the volatiles and dissolution of the yellow residue in $[D_6]$DMSO, indicates the formation of a very complex mixture of products among which acetamide is one of the main components.

Under the experimental conditions in which we observe the conversion of **1** into **2**, the formation of acetamide is easily predictable since the initial solution contains the nitrile molecule, activated through the coordination to the metal centre, and a stoichiometric amount of water resulting from the condensation reaction (1). The hydrolysis of the nitrile to acetamide, therefore, was expected to be the first step of the transformation of the CH_3CN complex into the amidine derivative. The resulting acetamide is likely the source of the ammonia required for the formation of the amidine ligand.

Comparative experiments in which variable amounts of water were added to solutions of **1a** in CH_3CN indicate an increased concentration of acetamide in the reaction mixture after a few weeks, whereas the conversion of complex **1** into **2** had occurred to a small extent (ca. 1−2%). This result is in line with expectations, if we consider the catalytic properties of platinum complexes on the hydrolysis of nitriles to amides.

Amides, in turn, can undergo hydrolysis with formation of free NH_3, or its conjugate acid, depending on the pH. Moreover, the coordination of acetamide to a metal centre, either in the neutral[24] or deprotonated form, is well documented, in particular in the case of platinum.[25] Preliminary experiments indicate that the hydroxo complex *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ does react with $CH_3C(O)NH_2$, leading to the deprotonation of the amide and the coordination of the resulting anion.[26]

Complex **2** can be obtained in relatively good yield by addition of aqueous NH_3 to the acetonitrile complex **1** in CH_3CN. Within a few weeks at room temperature, crystals of the pure **2a** (yield 44%) separated from a solution of *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]ClO_4$ containing an excess of NH_3. The NMR analysis of the colourless solution, after removal of the solid **2a**, indicated the complete conversion of **1a** into the amidine derivative **2a** (ca. 70% of the mixture of products, on the basis of the ^{31}P spectrum) together with the ammonia complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(NH_3)]^+$ (ca. 16%) and another species (ca. 14%) that has not yet been fully characterised.

This ammonia complex was isolated as a pure compound with the composition *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(NH_3)]NO_3\cdot H_2O$, **3**, and characterised by multinuclear NMR spectroscopy. It was isolated from a solution of **1b** after addition of excess aqueous NH_3. In the proton spectrum, in $[D_6]$DMSO, the NH_3 resonance is seen as a broad singlet at $\delta = 4.0$, with unresolved platinum satellites. The presence of ammonia in the coordination sphere of the metal was confirmed by means of $^1H,^{15}N$ HMQC experiments in which the ^{15}N signal at $\delta = -381.6$, attributable to the NH_3 ligand, correlates with the proton signal at $\delta = 4.0$, and shows couplings with protons ($^1J_{HN} = 70$ Hz) and ^{31}P nuclei ($^2J_{NP} \approx 50$ Hz; $^3J_{HP} = 5$ Hz). Moreover, in the $^1H,^{195}Pt$ HMBC spectrum the NH_3 and PMe_3 protons correlate with the ^{195}Pt resonance at $\delta = -4653$. The chemical non-equivalence of the phosphanes (in *trans* position to the nucleobase and to the NH_3 ligands, respectively) is proved by the presence of two distinct resonances in the proton spectrum (at $\delta = 1.48$ and 1.66), flanked by well-resolved (90 MHz) ^{195}Pt satellites ($^2J_{HP} = 11.2$; $^3J_{HPt} = 33$ Hz), and by the presence of an AB multiplet [at $\delta = -29.0$ ($^1J_{PPt} = 3237$ Hz) and −32.0 ($^1J_{PPt} = 3084$ Hz) with $^2J_{PP} = 25.6$ Hz] in the ^{31}P spectrum.

Conclusion

In this paper we have reported a further example of reactivity of a dinuclear hydroxo complex of platinum(II) stabilized by phosphanes towards model nucleobases. As previously shown for *N*(1)-methylcytosine,[8,12] *N*(9)-substituted adenine,[11] and guanine,[13] the dimeric species *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2^{2+}$ deprotonates the *N*(1)-substituted thymine, leading to the platination of the nucleobase at the N(3) position. In the isolated complex **1a** the thyminate moiety acts as monodentate ligand leaving the fourth position around the metal centre available for the coordination of a solvent molecule. A similar binding mode of the thymine was early shown in the interaction with the hydroxo complex *cis*-$[(dppf)Pt(\mu\text{-}OH)]_2^{2+}$ [dppf = 1,1′-bis(diphenylphosphanyl)ferrocene].[9]

Fortuitous circumstances of leaving the nitrile complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]ClO_4$ in the presence of small amounts of water for a long period of time, allowed the separation of X-ray quality crystals of the amidine derivative *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]ClO_4$. This reaction represents the first example of a direct (i.e. in absence of metal-coordinated[6] or added ammonia) conversion of a nitrile group into an amidine. Such a transformation occurred in low yield with the concomitant formation of a yellow solution containing several not fully characterised products. The ^{31}P NMR spectrum

exhibits a plethora of PMe_3 resonances among which only those of the amidine and ammonia complexes, **2** and **3**, have so far been attributed.

Both **2** and **3** were isolated as pure compounds by simple addition of aqueous NH_3 to acetonitrile solution of *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]^+$. The replacement of the acetonitrile ligand by NH_3 in **1** is immediate, and the formation of **3** appears to be quantitative (by ^{31}P NMR). In contrast, the formation of the amidine complex **2** from **1**, in the presence of added ammonia, is a slow process. At room temperature, in fact, the separation of crystals of *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]ClO_4$ requires several weeks (4−6). This is likely due to the high stability of the ammonia complex *cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(NH_3)]^+$. We observed that CD_3CN solutions of the isolated compound **3**, warmed at 50 °C for one week, appeared unchanged. Whether this complex is an intermediate in the transformation of the nitrile complex **1** into the acetamidine derivative **2** is, at the moment, an open question.

Experimental Section

Reagents and Chemicals: Reagent grade chemicals were used as received unless otherwise stated. The complex *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ was synthesized as previously reported.[8] 1-MeTy was purchased from Sigma Chemical Company.

Instrumentation: ^1H, ^{31}P, ^{13}C, ^{195}Pt, and ^{15}N NMR spectra were obtained with a Bruker AMX 400-WB spectrometer operating at 400.13, 161.98, 100.61, 85.88, and 40.56 MHz, respectively, and/or on a JEOL 90Q spectrometer. The external references are H_3PO_4 (85% w/w in H_2O) for ^{31}P, Na_2PtCl_4 in D_2O (adjusted to δ = −1628 from Na_2PtCl_6) for ^{195}Pt, CH_3NO_2 in $CDCl_3$ (50% v/v) for ^{15}N. Proton and carbon resonances are referred to internal TMS. The parameters used for HMQC and HMBC experiments are similar to those previously reported.[14] IR spectra in the range 4000−400 cm^{-1} were recorded as KBr pellets with a Perkin−Elmer 283 spectrophotometer.

Syntheses of the Complexes

Preparation of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$: Addition of $NaClO_4{\cdot}H_2O$ (0.20 g, 0.48 mmol) to a solution of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (0.410 g, 0.48 mmol) caused the immediate precipitation of a white solid, which was collected by filtration, washed with H_2O, and dried under vacuum. The yield of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ was 438 mg (98%). − $C_6H_{19}ClO_5P_2Pt$ (463.7): calcd. C 15.54, H 4.13; found C 15.6, H 4.15. The complex, insoluble in water, dissolved in DMSO and CH_3CN; it was slightly soluble in CH_2Cl_2 and $CHCl_3$. ^1H NMR in $[D_6]$DMSO: δ = 3.46 (s, 1 H, OH), 1.52 (d, $^2J_{HP}$ 11.7 Hz, $^3J_{HPt}$ 36 Hz, 18 H, PMe_3). − $\{^1H\}^{31}P$ NMR in $[D_6]$DMSO: δ = −24.4 (s, $^1J_{PPt}$ 3358 Hz); in CD_3CN −25.5 ($^1J_{PPt}$ 3416 Hz).

Caution: The perchlorate is a potential explosive!

***cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]ClO_4$ (1a):** A mixture of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ (263 mg, 0.283 mmol) and 1-MeTy (79.4 mg, 0.567 mmol) was dissolved in CH_3CN (12 mL) at room temperature and stirred for 24 h. The resulting solution was filtered to eliminate a trace amount of a black powder, and concentrated to a final volume of 2 mL. Addition of Et_2O afforded a white precipitate, which was recovered by filtration, and recrystallised from CH_3CN/Et_2O. The yield of the pure **1a** was 261 mg (74%). − $C_{14}H_{28}ClN_3O_6P_2Pt$ (626.9): calcd. C 26.82, H 4.47, N 6.70; found C 26.83, H 4.43, N 6.49. − ^1H NMR at 90 MHz in CD_3CN δ = [1-MeTy(−H) resonances] 7.15 [quadruplet, J_{HH} ca 1 Hz, 1 H, H(6)], 3.26 (singlet, 3 H, NCH_3), 1.72 (doublet, J_{HH} ca 1 Hz, 3 H, CH_3); 1.93 (s, 3 H, CH_3CN); 1.59 (d, $^2J_{HP}$ 11.7 Hz, $^3J_{HPt}$ 36 Hz, 9 H, PMe_3); 1.49 (d, $^2J_{HP}$ 11.7 Hz, $^3J_{HPt}$ 36 Hz, 9 H, PMe_3). − $\{^1H\}^{31}P$ NMR at 36.23 Mz in CD_3CN: δ = −29.7 ($^1J_{PPt}$ 3809 Hz) and −31.1 ($^1J_{PPt}$ 2944 Hz) with $^2J_{PP}$ 27 Hz. − ^1H NMR in $[D_6]$DMSO: [1-MeTy(−H) resonances] 7.40, [d $^4J_{HH}$ 1.2 Hz, H(6); 3.20, (s, NCH_3), 1.83 (d, $^4J_{HH}$ 1.2 Hz, $CH_3(5)$] 2.03 (s, 3 H, CH_3CN); 1.59 (d, $^2J_{HP}$ 11.7 Hz, 9 H, PMe_3); 1.53 (d, $^2J_{HP}$ 12 Hz, 9 H, PMe_3). $\{^1H\}^{31}P$ NMR at 36.23 Mz in $[D_6]$DMSO: δ = −23.1 ($^1J_{PPt}$ 3169 Hz) and −29.1 ($^1J_{PPt}$ 3892 Hz) with $^2J_{PP}$ 25.6 Hz. $\{^1H\}^{195}Pt$ in $[D_6]$DMSO: δ = −4695, dd.

***cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(CH_3CN)]NO_3$ (1b):** With the procedure described for **1a**, the nitrate derivative **1b** was prepared from *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (350 mg, 0.41 mmol) and 1-MeTy (115 mg, 0.82 mmol). The yield of the recrystallised product was 338 mg (70%). − $C_{14}H_{28}N_4O_5P_2Pt$ (589.4): calcd. C 28.53, H 4.79, N 9.50, found C 28.17, H 4.78, N 9.31. The spectroscopic data (^1H and ^{31}P NMR) are the same as those of **1a**. The elemental analysis and the ^{31}P NMR spectrum of the isolated solid indicate the presence of small amounts (ca. 3%) of unchanged *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$.

***cis*-$[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}\{CH_3C(NH)NH_2\}]ClO_4$ (2a). − a):** A suspension of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ (212 mg, 0.23 mmol) and 1-MeTy (64 mg, 0.45 mmol) in CH_3CN (10 mL) was stirred at room temperature for 12 h. The resulting colourless solution was left at room temperature in the dark for 6 months during which time a colourless solid was formed while the solution became yellow. The crystalline product, separated by filtration, washed with CH_3CN, and dried under vacuum, was 26 mg (yield 8.8%). − $C_{14}H_{31}ClN_4O_6P_2Pt$ (643.9): calcd. C 26.11, H 4.85, N 8.70; found C 26.02, H 4.68, N 8.73. − ^1H NMR (400 MHz) in $[D_6]$DMSO δ = [1-MeTy(−H) resonances] 7.38 [q, J_{HH} 1 Hz, 1 H, H(6)], 3.19 (s, 3 H, NCH_3), 1.72 (d, J_{HH} 1 Hz, 3 H, CH_3); [$CH_3C(NH)NH_2$ resonances] 7.37 (broad singlet, 1 H, NH), 7.24, (br. s, 1 H, NH_2), 6.95 (br. s, 1 H, NH_2), 1.93 (s, 3 H, CH_3); 1.58 (d, $^2J_{HP}$ 11 Hz, 9 H, PMe_3) and 1.48 (d, J_{HP} 11 Hz, 9 H, PMe_3). − $\{^1H\}^{31}P$ NMR at 162 MHz in $[D_6]$DMSO: δ = −28.82 ($^1J_{PPt}$ 3100 Hz) and −29.27 ($^1J_{PPt}$ 3119 Hz) with $^2J_{PP}$ 23 Hz. − $^{13}C\{^1H\}$ at 100.6 MHz, in $[D_6]$DMSO δ = [1-MeTy(−H) resonances] 171.0 C(4)O, 154.0 C(2)O, 140.0 C(6), 106.0 C(5); 35.9 NCH_3, 12.5 $CH_3(5)$; PMe_3 14.0 (d, J_{CP} ca 40 Hz); $CH_3C(NH)NH_2$ resonances: 167.0 and 20.8. $\{^1H\}^{195}Pt$: δ = −4633, apparent triplet.

b): A suspension of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ (228 mg, 0.245 mmol) and 1-MeTy (68.5 mg, 0.49 mmol) in CH_3CN (8 mL) was stirred at room temperature for a few hours. The resulting solution was then divided in 3 portions (labelled A, B, and C) the first of which was left as a reference. To the fraction B (1 mL) 25.2 mg of H_2O [molar ratio $(H_2O)/(Pt)$ = 20] was added. To the fraction C (2.0 mL) 62.7 mg of an aqueous solution of NH_3 {25% w/w; [molar ratio $(NH_3)/(Pt)$ = 7.5]} was added. After 6 weeks at ca. 20 °C samples A and B appeared as colourless solutions whereas fraction C contained well shaped prismatic crystals of pure **2a** that were separated, washed with CH_3CN and dried under vacuum (35 mg, yield 44%). The mother liquor was evaporated under vacuum, the residue dissolved in $[D_6]$DMSO and analysed by NMR. The ^{31}P spectrum of this residue showed major components to be

the species **2a** (ca. 60%), **3** (14%), and a third species characterised by a broad singlet (line width 8 Hz) at δ = −30.05, flanked by ^{195}Pt satellites ($^1J_{PPt}$ = 2963 Hz), whose relative intensity was 18% of the total resonances. Moreover, a number of very weak resonances in the range δ = −28 to −31 were also detectable. From the corresponding ^{1}H NMR spectrum, the presence of small amounts of free nucleobase and acetamide were also detected.

c): A solution of **1a**, obtained reacting *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(ClO_4)_2$ (137 mg; 0.147 mmol) and 1-MeTy (41 mg, 0.29 mmol) in CH_3CN (5 mL), was divided in 3 portions. One of them was left as reference sample (A), to the second (B) was added water (molar ratio H_2O/Pt = 34) and to the third sample (C) was added aqueous NH_3 (molar ratio: H_2O/Pt = 70; NH_3/Pt = 9.2). After 4 weeks at ca. 30 °C the resulting colourless solutions were evaporated under vacuum and the residues dissolved in [D$_6$]DMSO. The ^{31}P NMR analysis of the reference solution A indicated only a minor conversion of the initial species **1a** into **2a** (1−2%) and the presence of small amounts (a few %) of other platinum containing species. Trace amounts of acetamide were identified in the corresponding ^{1}H spectrum. In the sample B, free acetamide was the major component of the mixture whereas the molar ratio of the complexes **1a** and **2a** was approximately 1.3. Sample C contained the acetamidine complex **2a** as the dominant component (ca. 80%) of the mixture of products, whereas complex **1** appeared to have completely reacted.

***cis*-[(PMe$_3$)$_2$Pt{1-MeTy(−H)}(NH$_3$)]NO$_3$ (3):** A mixture of *cis*-$[(PMe_3)_2Pt(\mu\text{-}OH)]_2(NO_3)_2$ (161 mg, 0.19 mmol) and 1-MeTy (55 mg, 0.39 mmol) in DMSO (3.5 mL) was stirred at room temperature for 12 h, and the resulting colourless solution, containing trace amounts a black solid, was filtered. Addition of aqueous NH_3 (25% w/w, 50 μL, 0.67 mmol) gave **3** in quantitative yield (by ^{31}P NMR). The compound was isolated by addition of CH_3CN (6 mL) and precipitated with Et_2O (30 mL). The white solid recovered by filtration and dried under vacuum was purified by dissolution in the minimum volume of hot CH_3CN, filtered and left to crystallise at room temperature. The yield of colourless crystals, having the composition $[(PMe_3)_2Pt\{1\text{-}MeTy(-H)\}(NH_3)]NO_3\cdot H_2O$, was 175 mg, 79%. − $C_{12}H_{30}N_4O_6P_2Pt$ (583.4): calcd. C 24.70, H 5.18, N 9.60; found C 24.71, H 5.08, N 9.46. − ^{1}H NMR (90 MHz) in CD_3CN δ = [1-MeTy(−H)] 7.10 [q, $^4J_{HH}$ 1.4 Hz, 1 H, H(6)], 3.20 (s, 3 H, NCH_3), 1.74 (s, 3 H, CH_3); 3.7 (very broad singlet, 3 H, NH_3); 2.20 (s, 2 H, H_2O); 1.69 (d, $^2J_{PH}$ 11 Hz, $^3J_{HPt}$ 34 Hz, 9 H, PMe_3) and 1.23 (d, J_{PH} 11 Hz, $^3J_{HPt}$ 34.7 Hz, 9 H, PMe_3). − ^{1}H NMR at 400 MHz in in [D$_6$]DMSO: [1-MeTy(−H)] 7.35 [s, H(6)], 3.17 (s, NCH_3), 1.72 (s, CH_3); 4.03 (broad singlet, 3 H, NH_3); 3.31 (s, H_2O); 1.65 (d, $^2J_{PH}$ 11 Hz, 9 H, PMe_3) and 1.48 (d, J_{PH} 11 Hz, 9 H, PMe_3). − $\{^1H\}^{31}$P NMR at 162 MHz in [D$_6$]DMSO: AB multiplet at δ = −29.5 ($^1J_{PPt}$ 3342 Hz) and −32.5 ($^1J_{PPt}$ 3076 Hz) with $^2J_{PP}$ 26 Hz. $\{^1H\}^{195}$Pt NMR in [D$_6$]DMSO: δ = −4653.

X-ray Data Collection, Structure Solution, and Refinement of 1a and 2a:[27] The experimental X-ray data are summarized in Table 4 and some metrical parameters for both structures are reported in Table 2. Further details are provided in Supporting Information. The crystals [milk-white, opaque, wedged-shaped **1a**, and colourless, transparent cuboids **2a**] proved of sufficient size to collect data on a Nicolet R3m/V four-circle diffractometer, using the ω − 2θ technique. Unfortunately, the crystal quality of **1a** was poor and significant crystal decomposition was observed during the course of data collection (up to 20% in intensity). The structures were solved by Patterson methods using the SHELXTL/PC[28] and refined using the SHELXL-93 package.[29] Refinement of the crystal structure of **1a** was not satisfactory and it was hampered by some disorder of the ClO_4^- ions. No disorder model was found to be adequate and consequently some high residual electron density peaks (up to 1.2 e·Å^{-3}) lie in the vicinity of the Cl atom, as evidenced by the final Fourier map. In addition, the phosphane methyl

The $[M_2(CO)_8]$ Complexes of the Cobalt Group

Gabriel Aullón*[a] and Santiago Alvarez[a]

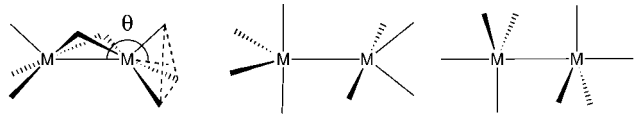
Keywords: Carbonyl complexes / Cobalt / Rhodium / Iridium / DFT calculations / Metal-metal interactions

A theoretical study of the carbonyl complexes $[M_2(CO)_8]$ of the group 9 metals (M = Co, Rh, Ir) is presented. Three isomers were found for each metal, with the relative stabilities and energies differing from one metal to another, and two transition states corresponding to their interconversion processes were identified. The minima in the potential energy surface have been fully characterized through a vibrational analysis and the Raman-active metal–metal stretching frequencies, as well as infrared-active carbonyl stretching frequencies. The combination of theoretical, structural, and vibrational data is expected to be useful for the correct characterization of the Rh and Ir complexes for which no experimental structural data have been reported so far.

Introduction

Transition-metal carbonyl complexes constitute a reference set of compounds that have played a crucial role in the development and understanding of modern transition metal chemistry.[1] Dinuclear carbonyls, for instance, are paradigmatic examples used to illustrate the predictive power of the electron counting rules in regard with the existence of metal−metal bonds. Those complexes also constitute the simplest possible realization of a metal cluster and have allowed us to theoretically analyze the effect of the ligands' orientation on metal−metal bonding and their influence in stability.[2,3]

In the particular case of the dicobalt complex $[Co_2(CO)_8]$, a structure with two bridging and six terminal carbonyl groups has been found in the solid state (**1a**).[4,5] The geometry around the metal may be described as square pyramidal with the basal plane comprising two bridging and two terminal carbonyls. With this arrangement, the metal atom obeys the 18-electron rule, completing a pseudo-octahedral coordination sphere with a so-called *bent* metal−metal bond,[5,6] consistent with its diamagnetic behavior.



C_{2v} D_{2d} D_{3d}

1a **1b** **1c**

Evidence for the existence of other structures for $[Co_2(CO)_8]$ was early reported by Bor and Noack, based on the study of the carbonyl region of its infrared spectrum, from which they proposed the presence of at least two isomeric forms.[7−9] The first form was associated with the same structure found in the solid state, namely a bridged form with idealized C_{2v} symmetry (**1a**). A second unbridged form with D_{3d} symmetry was proposed, analogous to that found for the isoelectronic $[Fe_2(CO)_8]^{2-}$ anion in the solid state. Later, the existence of a third isomer with eight terminal ligands was detected by infrared spectroscopy.[10−12] Raman spectroscopy also shows the presence of three forms in solution.[13] In summary, it is currently accepted that the vibrational spectra of $[Co_2(CO)_8]$ is consistent with the existence of three isomers: C_{2v} (**1a**), D_{2d} (**1b**), and D_{3d} (**1c**).

No crystal structure has been reported so far for the analogous compounds with other group 9 metals, although some interesting data have been reported in the literature. A bridged form **1a** was proposed for $[Rh_2(CO)_8]$ from its infrared[14−16] and electronic[17] spectra, which are consistent with the existence of two bridging carbonyls. In contrast, no bridging carbonyl groups appear in the infrared spectrum of $[Ir_2(CO)_8]$, for which the unbridged form has been proposed.[18] In both cases, the isomers seem to be unstable toward the formation of tetranuclear species.[19]

Substitution of carbonyls by ER_3 ligands [e.g., PR_3, $P(OR)_3$, or AsR_3] may provide some hints about the structures of the parent compounds. Hence, the $[Co_2(CO)_6(ER_3)_2]$ complexes appear in the D_{3d} structure (**1c**) in the solid state,[20−28] and their conversion in solution into the C_{2v} form has been observed by infrared spectroscopy.[29−31] A similar interconversion has been reported for $[Co_2(CO)_7(ER_3)]$ complexes.[29,32] Rhodium[15,33−35] and iridium[36] complexes of type $[M_2(CO)_{8-n}(ER_3)_n]$ also present an equilibrium between bridged and unbridged forms.

In this paper we present a systematic density functional (DFT) study[37,38] of the $[M_2(CO)_8]$ complexes (M = Co, Rh, or Ir) in an attempt to contribute to a better interpretation of the experimental data available for these complexes. We will focus not only on the calculation of molecular geometries, but also on the relative energies of the three isomers, and on the barriers for their interconversion. We also

intend to provide some hints for the characterization of the different tautomers from the vibrational spectra, mostly in the carbonyl stretching and metal-metal stretching regions.

Results

Molecular Structure

Density functional calculations were performed on complexes with the formula $[M_2(CO)_8]$ (M = Co, Rh, or Ir), considering in each case the three possible isomers corresponding to idealized symmetries C_{2v}, D_{2d}, and D_{3d} (**1**). The main structural parameters for the optimized structures are presented in Table 1.

Table 1. Calculated structural parameters for the three optimized isomers of $[M_2(CO)_8]$ complexes with M = Co, Rh, and Ir. All distances in Å, angles in degrees, mean experimental values (refs. [4,5]) in parentheses

[a] Notation: eq = equatorial (D_{2d} and D_{3d}) or basal (C_{2v}); ax = axial (D_{2d} and D_{3d}) or apical (C_{2v}); bg = bridge (C_{2v}).

The optimized geometry of the bridged form of $[Co_2(CO)_8]$ (**1a**) is in good agreement with the experimental data, such as the Co−Co distance (2.545 Å calculated, 2.536 and 2.539 Å experimental) and the pyramidality angle for the apical ligand (100.6° calcd., 100.1° exp.). These data are consistent with a description of the coordination sphere of the metal atom as a square pyramid. The structural parameters calculated here are very similar to those previously reported by Ziegler,[39] only a shorter Co−Co distance was found by us, in better agreement with the experimental value. The orientation of the terminal carbonyl triads (defined by an angle θ of 196.5°, **1a**) is slightly different from the experimental values (193.1±0.5°), but well within the range of experimental values found for the analogous $[Co_2(\mu\text{-}CO)_2(CO)_{6-n}L_n]$ complexes (188° < θ < 212°, Table 2). As predicted for the isoelectronic iron carbonylate,[3] the experimental data for the homoleptic complexes $[Co_2(\mu\text{-}CO)_2(CO)_6]$ and $[Co_2(\mu\text{-}CNR)_2(CNR)_6]$ present a linear correlation between the orientation angle θ and the Co−Co bond length (Figure 1, black circles), corresponding to Equation (1) (regression coefficient $r = 0.958$).

$$Co-Co = 4.187 - 0.00857\cdot\theta \quad (1)$$

It thus seems obvious that substitution of the carbonyls by the bulkier isocyanide ligands should favor a larger outward bending of the terminal ligands and shorten the Co−Co distance (which in turn would affect the Co−Co stretching vibration, see below). A similar behavior was found for the isoelectronic mixed ligand complexes $[Co_2(\mu\text{-}CO)_2(CO)_{6-n}L_n]$ (Figure 1, white circles), although some dispersion appears probably due to the bidentate nature of the non-carbonyl ligands. Although the available data is scarcer for Rh and Ir, their complexes follow a similar trend [Figure 1, squares, regression coefficient $r = 0.976$, Equation (2)].

$$M-M = 4.092 - 0.00697\cdot\theta \quad (2)$$

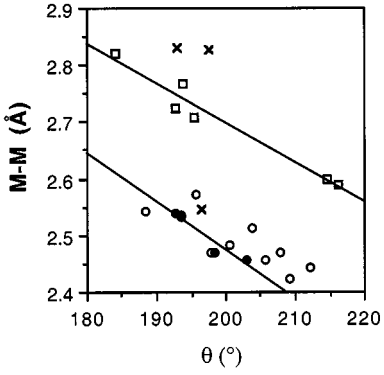

Figure 1. Scatterplot of the experimental values of the orientation angle of the terminal carbonyl groups (θ, see **1**) and the Co−Co distance for the family of $[Co_2(\mu\text{-}CO)_2(CO)_{6-n}L_n]$ complexes; the black circles and the solid line correspond to homoleptic complexes $[Co_2(\mu\text{-}CO)_2(CO)_6]$ and $[Co_2(\mu\text{-}CNR)_2(CNR)_6]$, white circles to the rest of Co complexes in Table 2, squares to Rh and Ir compounds, and crosses to calculated data (Table 1)

Two unbridged forms of symmetries D_{2d} and D_{3d} were also found to be minima in the potential energy surface. The Co−Co bond length in these two isomers is significantly longer than in the bridged one. In the D_{2d} isomer (**1b**), the axial ligands form angles of less than 90° with the equatorial plane, indicating the presence of a weak semibridging interaction (Co···C = 2.83 Å and $Co-Co-C_{ax}$ = 77.1°), similar to that observed in the optimized isoelectronic anion $[Fe_2(CO)_8]^{2-}$ (2.87 Å and 76° for the same parameters),[3] and in $[Mn_2(CO)_8]$ (2.74 Å and 82°).[58]

We have found no D_{2d} structures for carbonyl complexes in the chemical literature, but D_{2d} structures have been proposed for the isoelectronic compounds $[M_2(PF_3)_8]$ (M =

Rh, Ir) based on their ^{19}F- and ^{31}P NMR spectra. Also, an approximate Rh−Rh distance of ≈ 2.88 Å has been estimated from X-ray diffraction of a poor crystal,[59] in agreement with the calculated value of 2.882 Å for the corresponding carbonyl complex. In contrast, ^1H and ^{31}P NMR spectra of complexes with bulkier ligands, $[M_2\{P(OR)_3\}_8]$ (M = Co, Rh), suggest a D_{3d} symmetry.[60−62]

A third isomer of $[M_2(CO)_8]$ (D_{3d} symmetry, **1c**) with trigonal bipyramidal coordination around the metal atoms was also found to be a minimum in the potential energy surface. Such a structure is found in isoelectronic compounds of the type $[M_2(CO)_6(ER_3)_2]$ (M = Co,[20−28] Rh,[63] and Ir[64]), and the most relevant structural parameters are shown in Table 3. The metal−metal distances in the optimized structures agree well with the experimental data for Co (calcd.: 2.671, exp.: 2.639−2.671 Å) and Rh (calcd.: 2.851, exp.: 2.817−2.827 Å). The equatorial carbonyls are bent towards the second metal atom (i.e., $M-M-C_{eq}$ angles of less than 90°) for the three metals, and the calculated values are also in good agreement with the experimental ones. The present results for Co agree, within chemical accuracy, with those reported by Ziegler,[39] both in the Co−Co distance (2.634 Å) and the pyramidality angle (85.1°).

Energy Minima and Transition States

The relative energies of the minima and transition states of each metal are presented in Table 4. The three isomers shown in **1** correspond to minima in the potential energy surfaces of the three metals, according to the analysis of calculated vibrational frequencies (see below). As summarized in the introductory section, there is spectroscopic evidence for the coexistence, in solution, of different isomers of the compounds under study, in agreement with the similar energies found in our calculations. However, for such intramolecular reactions to occur thermally, a low activation-

Table 4. Calculated energies of the stationary points in the potential energy surfaces of $[M_2(CO)_8]$ (M = Co, Rh, Ir). All data are in kcal·mol^{-1}

Compound	Co	Rh	Ir
Minima			
C_{2v} (**1a**)	1.48	0.00	5.97
D_{2d} (**1b**)	0.00	2.78	0.00
D_{3d} (**1c**)	5.81	8.17	3.53
Transition states			
$C_{2v} \rightleftarrows D_{2d}$ (**2a**)	2.96	4.69	7.91
$D_{2d} \rightleftarrows D_{3d}$ (**2b**)	8.41	10.92	7.43

energy is needed. We have located only two transition states connecting the three minima, indicating two isomerization pathways: **1a** → **1b** and **1b** → **1c** (for schematic energy diagrams see Figure 2). No transition state could be located between C_{2v} and D_{3d} isomers (**1a** → **1c**), indicating that their interconversion must proceed through a D_{2d} intermediate **1b**.

The results of our calculations indicate that the unbridged D_{2d} (**1b**) structure is the most stable one for Co and Ir, but for Rh it is the C_{2v} isomer (**1a**), with **1b** ≈ 2.8 kcal·mol^{-1} above the minimum. Nevertheless, the energy differences between the three isomers are relatively small in most cases, as previously found for the isoelectronic $[Fe_2(CO)_8]^{2-}$ anion.[3] Noack studied the interconversion of bridged to unbridged forms of the cobalt complex in paraffin/alkane solutions between 69 and 295 K,[9] and estimated a reaction enthalpy of about −1.3±0.1 kcal·mol^{-1}, compared with a calculated value of −1.5 kcal·mol^{-1}. The isomerization was monitored through the infrared intensities of the 2044 (or 1857) and 2025 cm^{-1} absorption bands of the bridged and unbridged forms, respectively. A second isomerization ($D_{2d} \rightarrow D_{3d}$) process can be expected according to our results, with a reaction enthalpy of +5.8 kcal·mol^{-1} and low energy barriers (Table 4).

The ligand rearrangement that takes place along the $C_{2v} \rightleftarrows D_{2d}$ path is schematically illustrated in **2a**. Through such a pathway, the bridging and basal CO ligands of the C_{2v} structure (labeled 2, 3, and 4 in **2a**) occupy axial and equatorial positions of the trigonal bipyramid coordination spheres of the D_{2d} isomer. Since the apical ligand (labeled 1 in **2a**) of the C_{2v} isomer also occupies an equatorial position of the D_{2d} trigonal bipyramid, successive rearrangement steps result in exchange of the three types of CO ligands of the C_{2v} structure. Therefore, the $C_{2v} \rightleftarrows D_{2d}$ interconversion is consistent with the observation of a single NMR signal for the carbonyl ligands. This process has a tiny calculated energy barrier of 3.0 kcal·mol^{-1} for $[Co_2(CO)_8]$, lower than the upper limit measured by infrared spectroscopy in hexane matrices at 84 K where interactions with matrix molecules exist ($\Delta G^{\ddagger} \approx 6.4 \pm 0.4$ kcal·mol^{-1}).[12] The complex $[Co_2(CO)_8]$ has been observed to be fluxional at room temperature, even in the solid state, as seen by the equivalence of all carbonyl ligands in the ^{13}C NMR spectrum.[65] An activation energy for the exchange of bridging and terminal carbonyls has been estimated at 11.7±0.6 kcal·mol^{-1}. The $D_{2d} \rightleftarrows D_{3d}$ conversion (**2b**) for $[Co_2(CO)_8]$ has an energy barrier

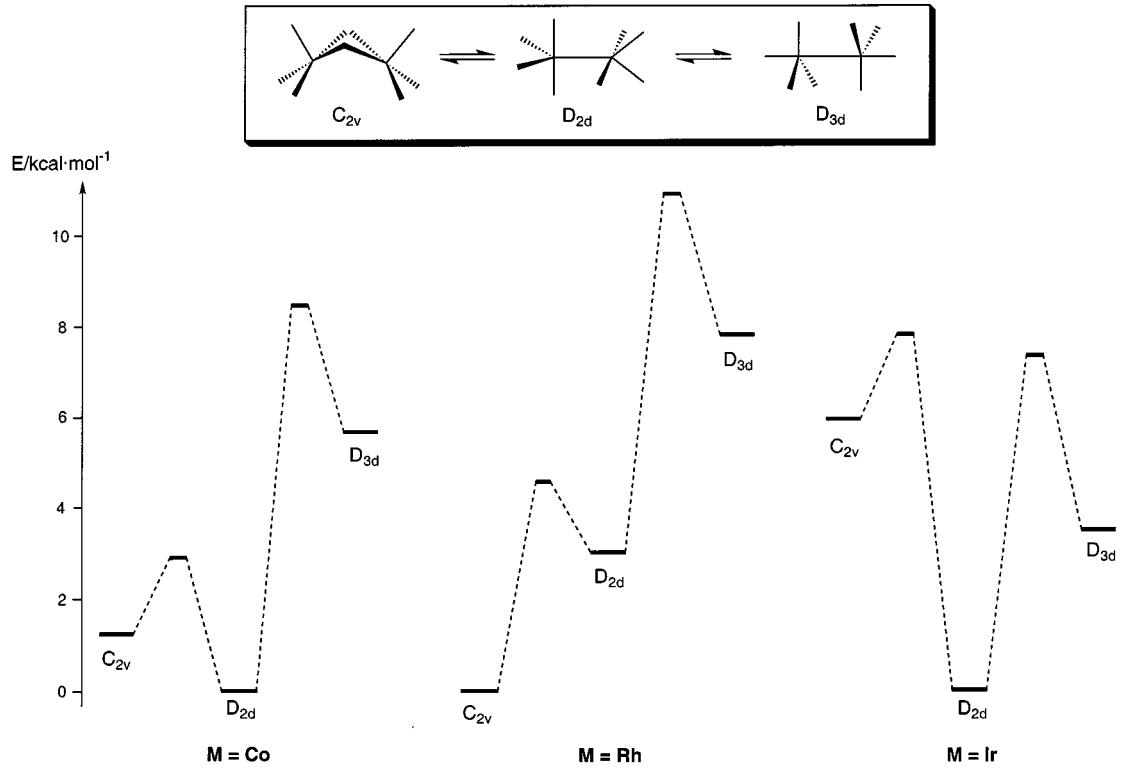

Figure 2. Diagram of the relative energies [in kcal·mol^{-1}] for the differents isomers of the $[M_2(CO)_8]$ complexes (M = Co, Rh, Ir)

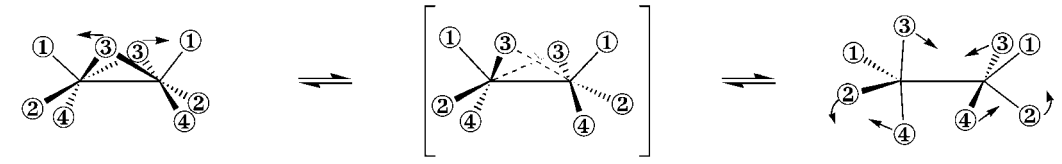
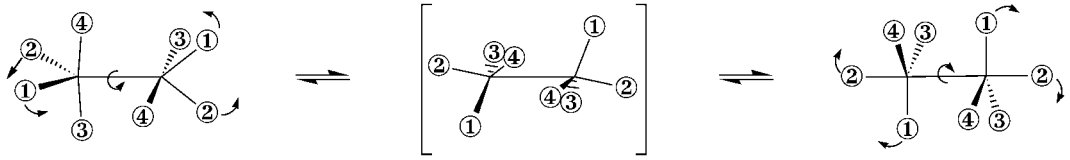


2a



2b

of 8.4 kcal·mol^{-1}, and the reverse process has an energy barrier of 2.6 kcal·mol^{-1}. The experimental observation is that this transformation is extremely facile in hexane at 84 K.[12]

For $[Rh_2(CO)_8]$, the most stable structure is that with the bridged C_{2v} symmetry, as previously suggested from infrared and UV/Visible spectroscopic data. In contrast, our calculations for the Ir complex clearly predict the unbridged D_{2d} structure to be the most stable one, in agreement with the absence of absorption bands in the bridging CO region of the infrared spectrum. According to our calculations, the Rh complex presents a low barrier for the $C_{2v} \rightarrow D_{2d}$ transformation (4.7 kcal·mol^{-1}), although this isomerization cannot be experimentally observed due the formation of larger clusters.[15,16,19] The $D_{2d} \rightarrow D_{3d}$ transformation presents a barrier of about 8.1 kcal·mol^{-1}. For the Ir complex, the larger stability of the intermediate D_{2d} structure and the calculated energy barriers of about 7−8 kcal·mol^{-1} allow us to predict that a fluxional process should be observable.

Vibrational Analysis

Metal−Metal Stretching Vibrations

We have studied the vibrational frequencies for the three isomers (**1**): C_{2v}, D_{2d}, and D_{3d}. In all cases they have no imaginary frequencies, and all three structures are minima in the potential energy surface, as found previously in studies on the isoelectronic dianion $[Fe_2(CO)_8]^{2-}$.[3] The calculated metal−metal stretching frequencies of the three isomers are shown in the Table 5. An interesting finding is the existence of a linear correlation between the optimized M−M distance and the corresponding stretching frequency for the three isomers in the case of the Co and Ir complexes [regression coefficients $r = 0.990$ and 0.992, Equation (3) and Equation (4), respectively]. The same trend is found for Rh but the correlation is poorer.

Table 5. Theoretical M−M stretching frequencies, ν_{MM} [cm^{-1}] for the three isomers of $[M_2(CO)_8]$, and experimental Raman values for M = Co (refs. [13,66])

Structure	$[Co_2(CO)_8]$ calcd.	$[Co_2(CO)_8]$ exp.	$[Rh_2(CO)_8]$ calcd.	$[Ir_2(CO)_8]$ calcd.
C_{2v}	221	235−239[a] 229−231[b]	183	163
D_{2d}	179	185−186[a]	150	128
D_{3d}	162	157−159[a]	148	131

[a] Solution. − [b] Solid state.

$$\tilde{\nu}_{CoCo} = 1392 - 450 \cdot d_{Co-Co} \quad (3)$$

$$\tilde{\nu}_{Ir-Ir} = 1261 - 389 \cdot d_{Ir-Ir} \quad (4)$$

For $[Co_2(CO)_8]$, the $\tilde{\nu}_{Co-Co}$ band in the solid state[13] appears at 229 cm^{-1}, a value that is consistent with a metal−metal bond supported by two carbonyl bridging ligands,[1] although it appears shifted to 235−239 cm^{-1} in solution. This band can be unequivocally assigned to the C_{2v} isomer, structurally characterized in the solid state, according to our calculated value (221 cm^{-1}), since the corresponding vibration for the two other isomers is expected at significantly lower wavenumbers. Two additional bands appear in solution,[13] at 185 and 158 cm^{-1}. The most intense peak, at 185 cm^{-1}, corresponds to the predominant species in solution, which can be assigned to a D_{2d} structure according to the present computational results (calculated value 179 cm^{-1}) and in excellent agreement with this being the most stable isomer in our calculations. The intensity of the band observed in solution at 158 cm^{-1} increases upon warming[13] and can be assigned to the D_{3d} structure according to the present results (calculated value 162 cm^{-1}). No Raman data have been reported for the analogous Rh and Ir compounds. The calculated frequencies in these cases allow for a clear-cut assignment of the Raman stretching bands that appear at different temperatures to the three isomers: C_{2v}, D_{2d}, and D_{3d} (see Table 5). The successive appearance of the C_{2v}, D_{2d}, and D_{3d} isomers upon warming is consistent with the theoretical finding that the two transition states located allow no direct conversion of the C_{2v} and D_{3d} isomers, but requires going through the D_{2d} intermediate.

Vibrational Spectra in the Carbonyl Region

The second part of our vibrational analysis focused on the carbonyl stretching frequencies (Table 6) since this region of the infrared spectrum is used as a diagnostic tool for carbonyl complexes. The main characteristic of this spectral zone is the number of infrared-active $\tilde{\nu}_{CO}$ modes, although group-theoretical predictions may be not fulfilled because of the existence of allowed bands with low-intensity. The presence of CO bands below 1850 cm^{-1} can be considered as a fingerprint of the presence of bridging carbonyl groups. This feature is clearly present in the calculated spectra for the three metals, as well as in the experimental data of the Co and Rh complexes. In the terminal carbonyl stretching region, two of the three intense bands expected for the C_{2v} isomer are practically coincident and only two peaks should be observed, whereas three bands seem to appear in the D_{2d} form, probably due to intensity stealing between the two B_2 modes. In summary, the three isomers can in principle be identified from the pattern of the CO stretching bands for any of the three metals. These patterns are as follows: (a) the C_{2v} isomer must present two bridging frequencies below 1850 cm^{-1} and three intense bands around 2000–2030 cm^{-1}; (b) the D_{2d} isomer does not present bands below 1900 cm^{-1} but three bands around 2000 cm^{-1} spanning a range of at most 29 cm^{-1}; (c) the D_{3d} isomer does not present bands below 1900 cm^{-1} but has two bands around 2000 cm^{-1}, separated by 37 (for Co) to 63 cm^{-1} (for Ir).

The infrared spectra reported for $[Co_2(CO)_8]$ and $[Rh_2(CO)_8]$ are assigned to the C_{2v} structure, because of the presence of two bridging carbonyl stretching bands between 1820 and 1870 cm^{-1}, together with a set of three strong bands in solid state between 2010 and 2090 cm^{-1}. A similar pattern is found in solution, except that only two terminal carbonyl bands are observed in the case of Rh. The spectra of $[Co_2(CO)_8]$ in an argon matrix at 8 K and in a hexane solution at 77 K, however, are consistent with the pattern expected for the D_{2d} isomer. The spectrum reported in the literature for $[Ir_2(CO)_8]$ can probably be assigned to the D_{2d} isomer, given the absence of bridging carbonyls and the relatively small splitting of the terminal CO bands (25 cm^{-1}, compared to a calculated range of 29 cm^{-1}). With the proposed assignments, deviations of the calculated frequencies relative to the experimental ones of less than 3% result. Interestingly, the isomers that best account for the experimental spectra of the Rh and Ir complexes, and for the Co complex at low temperatures, are those found in our calculations to be the most stable ones.

Conclusions

In the present theoretical work we have analyzed three structures of the dinuclear carbonyl complexes $[M_2(CO)_8]$ (M = Co, Rh, and Ir). The three isomers are stationary points in the corresponding energy surfaces, with the D_{2d} structure being the most stable one for Co and Ir, and C_{2v} the most stable for Rh. However, the other isomers are not very different in energy and are separated by relatively small energy barriers. The calculated structural parameters of the optimized structures are in good agreement with the available experimental data.

Two transition states are found for fluxional process and our calculations show a sequence of transformations $C_{2v} \rightarrow D_{2d} \rightarrow D_{3d}$ without direct pathway connecting the C_{2v} and D_{3d} structures. The conversion between the C_{2v} and D_{2d} isomers has smaller energy barriers for Co and Rh. For the Ir complex, slower processes are to be expected, given the higher calculated energy barriers.

The analysis of the M−M stretching region of the vibrational spectra for the three isomers shows a linear correlation between the M−M wavenumber and the distance for M = Co and Ir. For each of the three metals the M−M stretching of the C_{2v} isomer appears at higher frequencies than the D_{2d} and D_{3d} ones. The calculated peaks show an excellent agreement with the experimental Raman spectrum for Co. In the carbonyl stretching region, two bands are expected at low frequencies for the C_{2v} bridged isomer (1780−1840 cm^{-1}, characteristic of bridging carbonyls), together with three bands between 1995 and 2025 cm^{-1}. For the unbridged D_{2d} and D_{3d} isomers, very similar infrared spectra are expected between 1950 and 2100 cm^{-1}. In all cases, the calculated frequencies differ from the experimental ones by less than 3%.

Experimental Section

Computational Details: Density functional calculations were carried out using the GAUSSIAN94 package.[69] The hybrid B3LYP-DFT method was applied, in which the Becke three parameters exchange functional[70] and the Lee−Yang−Parr correlation functional[71] were used. The double-ζ basis set for the valence and outermost core orbitals combined with pseudo-potentials known as LANL2DZ were used for all the atoms.[72][73] The geometries were fully optimized using gradient techniques. The calculated frequencies shown in this paper are not corrected with any factor to reproduce experimental ones. The zero-point energies of minima and transition states were also calculated, but the relative energies change by less than 10%.

Structural Analysis: Structural data was searched through the Cambridge Structural Database (Version 5.19, February 2000).[74] Our search included compounds with several cores having metal atoms of group 9.

Supporting Information: Tables containing atomic coordinates of structures $[M_2(CO)_8]$ (M = Co, Rh, and Ir) for the three energy minima (**1a**, **1b**, and **1c**) and for the transition states (**2a**, **2b**). This material is available free of charge via the Internet, see also footnote on the first page of this article.

Magnesium Versus Zinc Coordination to Multidentate Schiff Base Ligands

Andrea Erxleben*[a] and Dinah Schumacher[a]

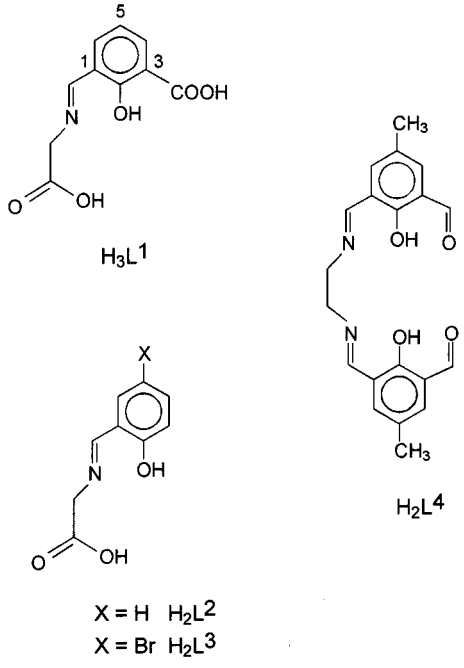
Keywords: Magnesium / Zinc / Schiff bases / N,O ligands

The reactions of two mononuclear zinc complexes, $[Zn(HL^1)(H_2O)_2]$, **1**, and $[ZnL^4(H_2O)]$, **7**, (H_3L^1 = Schiff base derived from 3-formylsalicylic acid and glycine, H_2L^4 = Schiff base derived from 2,6-diformyl-4-methylphenol and 1,2-diaminoethane), with Mg^{2+} has been studied. These complexes contain binucleating Schiff base ligands and have vacant coordination sites. For both compounds, substitution of zinc by magnesium has been observed in DMSO. Likewise, the Zn complex of H_2L^2 (Schiff base derived from salicylaldehyde and glycine) can be converted into the corresponding Mg compound. The following complexes were characterized by single-crystal X-ray analysis: $[MgL^3(H_2O)_3]$, **4**, $[MgL^2(H_2O)_2]_n$, **5**, $[Mg(sal)_2(H_2O)_2]$, **6**, and $[MgL^4(H_2O)(CH_3OH)]$, **8** (H_2L^3 = Schiff base derived from 5-bromosalicylaldehyde and glycine, Hsal = salicylaldehyde). The tri- and tetradentate *N,O* ligands H_2L^3 and H_2L^4 form discrete complex molecules in the solid state, while a carboxylate-bridged polymeric structure is formed by H_2L^2. In **4** and **8** the aqua ligands hydrogen bond with the deprotonated phenolate and carboxylate oxygen atoms, resulting in the formation of dimers. In **6** two aqua ligands, two phenolate oxygens and two aldehyde oxygens give rise to an O_6 coordination sphere.

Introduction

Magnesium and zinc are indispensable elements in biology. They are involved in several biochemical processes and are essential cofactors required for the activation of a variety of enzymes. To date, a large number of coordination compounds of Zn have been prepared, many of which represent low-molecular-weight model compounds for Zn enzymes.[1−11] By contrast, Mg complexes have received much less attention.[12−19] Relative to other biologically relevant cations, Mg is unique in that it possesses the smallest ionic radius and the highest charge density. Furthermore, Mg^{2+} shows a strong tendency to bind six water molecules in the inner coordination sphere as manifested by the wide range of crystal structures containing the octahedral $[Mg(H_2O)_6]^{2+}$ dication.[12] Consequently, the presence of hexahydrated Mg^{2+} as the counterion in the crystal structure of $[Mg(H_2O)_6][\{Zn_2L(CH_3CO_2)\}_2(\mu_3\text{-}OH)_2]\cdot 6H_2O$ (H_3L = Schiff base derived from 2,6-diformyl-4-methylphenol and glycine) previously reported by us was not unusual.[20] However, in nonaqueous solution (DMSO) substitution of zinc by magnesium was observed and the heteronuclear complex $[MgZnL]^+$ was identified in solution.

As part of our ongoing study on dinucleating Schiff base ligands[21] we have now investigated Zn and Mg coordination to H_3L^1, as well as to the salen derivative H_2L^4. The ability of the deprotonated phenolic oxygen atoms of *N,N*-ethylenebis(salicylideneimine), H_2salen, to bridge two metal ions has been known for a long time. Several examples of neutral salen complexes acting as bidentate oxygen-donor ligands, and forming adducts of the type $[(ML)M']^{n+}$ or $[(ML)_2M']^{n+}$ (M = transition metal ion, M′ = transition metal, alkali or alkaline earth metal ion) are documented in the literature.[22] Fukuhara et al. and Carbonaro et al. showed that Mg reacted with Cu(salpd), Ni(salpd)[23] and Ni(salen)[24] to give di- and trinuclear complexes [H_2salpd = *N,N*-propylenebis(salicylideneimine)]. Besides the formation of heteronuclear compounds, metal substitution has been observed for transition metal complexes of salen and related ligands: Co was replaced by Cu in [Co(salen)],[25] while Ni substituted Cu in [Cu(amben)] [H_2amben = *N,N′*-ethylenebis(2-aminobenzaldimine)].[26]



Here we report on the reaction of $[Zn(HL^1)(H_2O)_2]$, $[ZnL^2(H_2O)]$ and $[ZnL^4(H_2O)]$ with Mg^{2+}, leading to the conversion of the Zn complexes into the corresponding Mg compounds. The crystal structures of $[MgL^3(H_2O)_3]$,

$[MgL^2(H_2O)_2]_n$, $[Mg(sal)_2(H_2O)_2]$ (Hsal = salicylaldehyde) and $[MgL^4(H_2O)(CH_3OH)]$ are presented.

Results and Discussion

Reaction of $[Zn(HL^1)(H_2O)_2]$ and $[ZnL^2(H_2O)]$ with Mg^{2+}

Metal complexes of Schiff bases are generally easily accessible in high yields in a one-step synthesis, by condensation of an aldehyde with an amine in the presence of the metal ion. Despite the well-known susceptibility of imine bonds to hydrolysis, metal complexes of Schiff bases are usually resistant towards hydrolytic cleavage, and as a result the syntheses can be carried out in aqueous solutions.[27] Reaction of 3-formylsalicylic acid with glycine and $Zn(CH_3CO_2)_2$ in ethanol/water gave a pale yellow precipitate of $[Zn(HL^1)(H_2O)_2]$ (**1**). Formation of the Schiff base complex is seen by the ^1H NMR spectrum displaying a singlet for the azomethine proton at $\delta = 8.49$. In the infrared spectrum characteristic bands at 1653 and 1617 cm^{-1} which are assigned to CO and C=N vibrations are observed. In analogy to compound **4** (see below), the polydentate ligand is assumed to coordinate to Zn via the deprotonated phenolic oxygen, the imine nitrogen and the aliphatic carboxylate group. The aromatic carboxyl group is protonated and not coordinated, as deduced from the ^1H NMR spectrum featuring a sharp resonance at $\delta = 16.11$. The assignment of the aromatic carboxyl proton was confirmed by an HMBC experiment that indicated coupling between the proton and the ring carbon C2 at $\delta = 170.0$. Since **1** is only sparingly soluble in most common solvents, attempts to crystallize this compound were unsuccessful.

Complex **1** is potentially suitable to bind a second metal ion through the aromatic carboxyl group and the (bridging) phenolate oxygen. It was reacted with $MgCl_2 \cdot 6H_2O$ in DMSO and the reaction was monitored by ^1H NMR spectroscopy (Figure 1). On addition of increasing amounts of $MgCl_2$ new singlets appear at $\delta = 16.97$ and $\delta = 8.25$. By comparison with a genuine sample prepared by the reaction of 3-formylsalicylic acid with glycine and $Mg(CH_3CO_2)_2$, the new resonances can be assigned to the azomethine and carboxyl protons of the mononuclear magnesium complex of H_3L^1 (**2**).[28] Conversion of **1** into **2** is complete after addition of two equivalents Mg^{2+}. As in the case of **1**, crystallization of **2** is hampered by its low solubility, however, coordination through the chelating ligand side-arm and protonation of the aromatic carboxyl group is consistent with the NMR spectroscopic data and the X-ray structures of the related Mg compounds **4** and **5** (see below).

Metal ion exchange is also observed for the Zn complex of H_2L^2, **3**. Addition of one equivalent Mg^{2+} leads to ca. 30% conversion of **3** into the corresponding Mg compound.

The reaction of **1** and **3** with $MgCl_2 \cdot 6H_2O$ deserves some further comments. Obviously, in DMSO Mg^{2+} competes efficiently with Zn^{2+} for the binding sites of the chelate ligand. Mg coordination is probably supported by the use of a nonaqueous reaction medium. The dielectric properties of the solvent are known to have a crucial influence on the coordination behavior of metal ions. Recently, the dependence of water-(monodentate)ligand exchange reactions of Mg complexes on the dielectric constant has been studied theoretically by Lim and co-workers.[29] They demonstrated that water-carboxylate exchange can take place in media with a low ε, while it is thermodynamically unfavorable in aqueous solutions. In general, the basicity of negatively charged oxygen donors increases significantly with decreasing solvent polarity.[30] Consequently, M^{2+}/O^- binding is stabilized in a medium with a low dielectric constant. Unfortunately, the low solubilities of **1** and **3** prevent studies in other solvents (for the effect of small amounts of water added to the DMSO solution, see below).

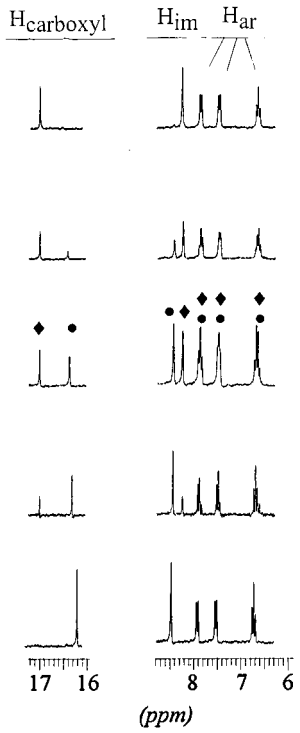

Figure 1. Reaction of **1** with Mg^{2+} in [D$_6$]DMSO. Proton NMR spectra ($\delta = 6-9$ and $\delta = 16-17$) of **1** (bottom) and after addition of 0.7, 1.0, 1.3 and 2.0 equiv. of $MgCl_2$ (top). **1** (•), **2** (◆).

Solid-State Structures of $[MgL^3(H_2O)_3]$, $[MgL^2(H_2O)_2]_n$ and $[Mg(sal)_2(H_2O)_2]$

Tridentate coordination of the Schiff base ligand via the deprotonated phenolic oxygen, the aliphatic carboxylate group and the imine nitrogen has been verified by X-ray crystallography for the magnesium complexes $[MgL^3(H_2O)_3]$ (**4**) and $[MgL^2(H_2O)_2]_n$ (**5**). A perspective view of the complex molecule of **4** is displayed in Figure 2, selected bond lengths and angles are listed in Table 1. Due to the narrow bite of the chelating Schiff base ligand, Mg assumes a distorted octahedral coordination geometry with the angles around Mg ranging from 76.7 to 98.9°. The bond lengths are normal, Mg−O(water) distances compare well with those found in other Mg aqua complexes. The ligand deviates significantly from the planar conformation that might be expected, the aromatic ring is inclined at 20.61(5)°

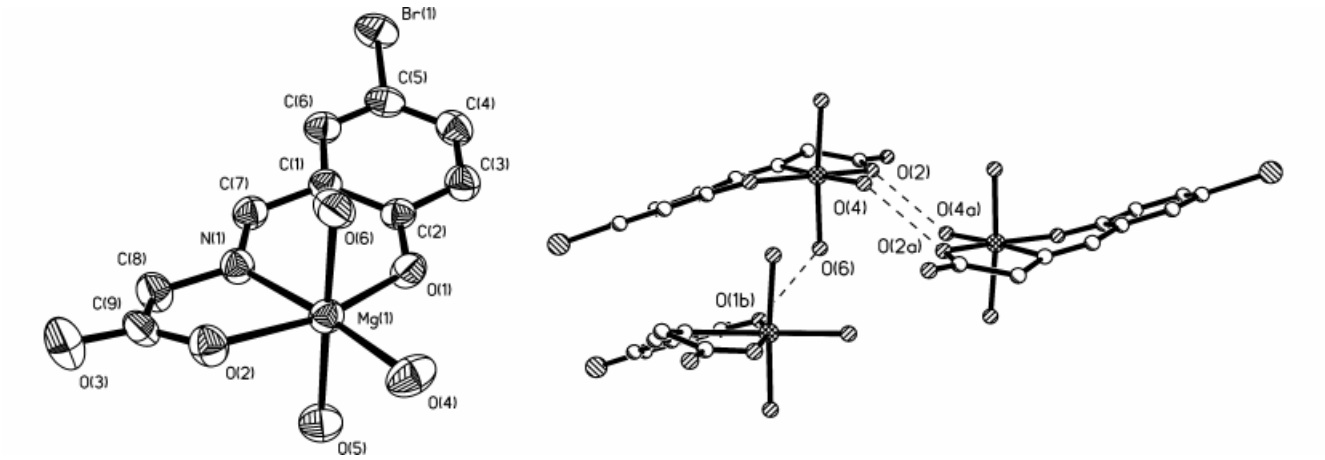

Figure 2. Molecular structure of **4** and details of intermolecular H-bonding interactions. Hydrogen atoms are omitted for clarity.

O(3)···O(5)[e]	2.954(3)	O(3)···O(6)[f]	2.786(3)

[a] $x, -y + 1/2, z + 1/2$. − [b] $x, -y + 1/2, z - 1/2$. − [c] $-x - 1, -y + 1, -z$. − [d] $-x - 1, y + 1/2, -z - 1/2$. − [e] $x, -y + 1/2 + 1, z + 1/2$. − [f] $x, -y + 1/2 + 1, z - 1/2$.

to the plane defined by the three donor atoms. In the crystal lattice two molecules dimerize via two hydrogen bonds involving the coordinating carboxylate oxygens O(2) and the aqua ligands O(4).

Adjacent dimers form stacks along the crystallographic z-axis that are stabilized by hydrogen-bonding interactions between the phenolate oxygen and the aqua ligands O(5) and O(6). The metal ions are indirectly bridged through the phenolate oxygen as H-bonding takes place between O(1) and the Mg-bound water molecules. Further H bonding occurs between the carboxylate oxygen O(3) and the water ligands O(4), (O5) and O(6).

In contrast to **4**, the Mg complex derived from the related ligand H_2L^2 is polymeric in the solid state. Figure 3 gives a view of the X-ray structure of $[MgL^2(H_2O)_2]_n$ (**5**), selected bond lengths, angles and hydrogen-bonding interactions are summarized in Table 2. The asymmetric unit comprises the Schiff base ligand that is bonded to Mg via the three donor sites and the two aqua ligands. Adjacent $MgL^2(H_2O)_2$ entities are linked through carboxylate bridges in a *syn-anti* fashion forming infinite chains extending in the z-direction. The C(9)−O(2) [1.264(3) Å] and C(9)−O(3) [1.256(3) Å] distances indicate full delocalization of the carboxylate negative charge. The Mg(1)−O(2) and Mg(1)−O(3) bond lengths differ only slightly [2.120(2) and 2.085(2) Å]. Again, the phenolic oxygen is involved in hydrogen-bonding interactions. Neighboring chains are connected through hydrogen bonds involving the aqua ligand O(5) and the phenolate oxygen O(1), as well as the carboxylate oxygens O(2) and O(3).

The X-ray structure of the bis(salicylaldehydato) complex $[Mg(sal)_2(H_2O)_2]$, **6**, is depicted in Figure 4. This complex was obtained as a by-product during the synthesis of **5**. As pointed out above, Schiff base formation is generally quantitative and the coordination of metal ions renders imine bonds resistant towards hydrolytic cleavage. Thus, in the case of the Zn complexes dissociation to the aldehyde and amine due to the presence of water was not observed. However, as for Mg, slow decomposition of the complex during crystallization results in hydrolysis of the ligand and the formation of the aldehyde complex. In the centrosymmetric molecule of **6**, the deprotonated salicylaldehydes act as chelating, bidentate ligands, and two water molecules complete the octahedral coordination sphere around the Mg atom. Salicylaldehyde and the metal ion are located on a mirror plane and the Mg−O(water) bond coincides with a crystallographic twofold axis of symmetry. Thus, except for O(1)−Mg(1)−O(2) and O(1)−Mg(1)−O(2a), ideal 90° values are observed for the valence angles around Mg. Due to the chelating coordination mode of the ligand, the O(1)−C(7)−C(1) bond angle involving the aldehyde carbon increases to 128.1(7)°. In the crystal lattice the neutral complex molecules form layers parallel to the crystallographic ac plane. Adjacent layers are linked through hydrogen bonds involving the water ligands, as well as the carbonyl and phenolate oxygens (Table 3). Thus, again the deprotonated phenolic oxygen acts as an H bond acceptor. The structure of **6** is in contrast with that of $[Mg(salicylate)_2(H_2O)_4]$ and [Mg(*p*-aminosalicylate)$(H_2O)_4$] reported in the literature.[18,19] In the latter complexes the salicylate ligands act as monodentate O-donors and bind to the Mg atom through one carboxylate oxygen, while the phenolic groups are protonated and do not take part in the coordination.

Substitution of Zn^{2+} by Mg^{2+} in a Salen-Type Complex

As outlined in the introduction, metal ion exchange and the formation of adducts are observed when first row transition metal complexes of salen are treated with hetero metals. The Zn[31] and Mg[32] complexes of salen have been known for a long time, however, no studies on the formation of adducts, or metal ion substitution have been carried out. We have used the mononuclear Zn complex of the salen derivative H_2L^4, $[ZnL^4(H_2O)]$,[33] **7**, and investigated its reaction with Mg^{2+}. In principle, **7** provides an O_4 coordination site to bind Mg to form a heteronuclear complex. As evident from the solid-state structure of **6**, chelation through the phenolate and aldehyde oxygens is a possible binding mode. However, in the ^1H NMR spectrum (Fig-

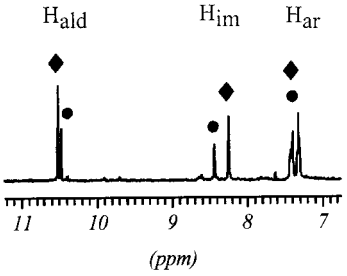

Figure 5. ^{1}H NMR spectrum (δ = 7−11) of **7** in [D_6]DMSO after addition of 2 equiv. of $MgCl_2$. **7** (•), **8** (◆). Peaks of very low intensity at δ = 10.39, 9.90, 9.70, 8.61 and δ = 7.63 result from hydrolysis of the imine ligand due to traces of water.

ure 5), the new set of signals that emerges after the addition of $MgCl_2 \cdot 6H_2O$ to a solution of **7** in DMSO is unambiguously assigned to the Mg complex [MgL^4] (**8**), resulting from metal ion exchange as found for complexes **1** and **3**. Complex **8** was identified by preparation of a genuine sample from H_2L^4 and $MgCl_2$. When two equivalents of $MgCl_2$ are added, approximately 62% of **7** is converted into **8**. Small amounts of water shift the equilibrium between **7** and **8** towards the formation of the Zn complex: on addition of 2.5% D_2O to the DMSO solution, the percentage of **8** is halved. The conversion of **8** back into **7** in the presence of water reflects the high affinity of Mg for aqua ligands.

It might be speculated that the substitution reaction proceeds via the heteronuclear Zn,Mg complex as an intermediate, although no evidence for its existence (or lack thereof) is seen from the NMR spectra. It is worth noting that **7** and **8** are nonlabile on the NMR time-scale, since mixtures of the respective complex and the "free" ligand give two distinct sets of resonances. Dissociation to the ligand and solvated metal ions was not observed in the spectra of pure **7** or **8** in DMSO.

The structure of **8** has been determined by single-crystal X-ray analysis. In the solid state the molecules of [$MgL^4(H_2O)(CH_3OH)$] form centrosymmetric dimers via hydrogen-bonding between the water ligand and the phenolic oxygen (Figure 6).

The hydrogen bonds are reinforced by stacking interactions of the aromatic rings (stacking distance ≈ 3.5 Å). As expected, the Schiff base ligand assumes an essentially planar configuration. The dihedral angles between the phenolic rings and the four donor atoms are 8.5(1) and 12.0(1) °. The rigid nature of the chelating ligand causes a significant distortion of the octahedral coordination geometry (range of valence angles around Mg: 78.5−107.9 °). Coordination of Mg^{2+} causes a shift of the $\tilde{\nu}$(C=O) and $\tilde{\nu}$(C=N) IR bands from 1688 and 1645 cm^{-1} [34] to 1655 and 1609 cm^{-1}, respectively.

Conclusions

In conclusion we have demonstrated that in complexes with *N,O* ligands, Zn is susceptible to substitution by Mg^{2+} when DMSO is used as the nonaqueous solvent. The presence of small amounts of water decreases the yield of the Mg complex significantly due to the high affinity of Mg for aqua ligands. The quantity of the Mg complex formed in DMSO is comparable for all ligand systems described here (ca. 30% Mg complex formed on addition of equimolar amounts of $MgCl_2$ to the respective Zn Schiff base complex).

Furthermore we have isolated and structurally characterized three Mg Schiff base complexes, namely [$MgL^4(H_2O)(CH_3OH)$], [$MgL^3(H_2O)_3$], and polymeric [$MgL^2(H_2O)_2]_n$. Schiff bases have been extensively used in transition metal chemistry, while main-group imine complexes are considerably less abundant. The coordination chemistry of alkaline earth metals has generally received far less attention than the coordination chemistry of transition metals. Thus, it is

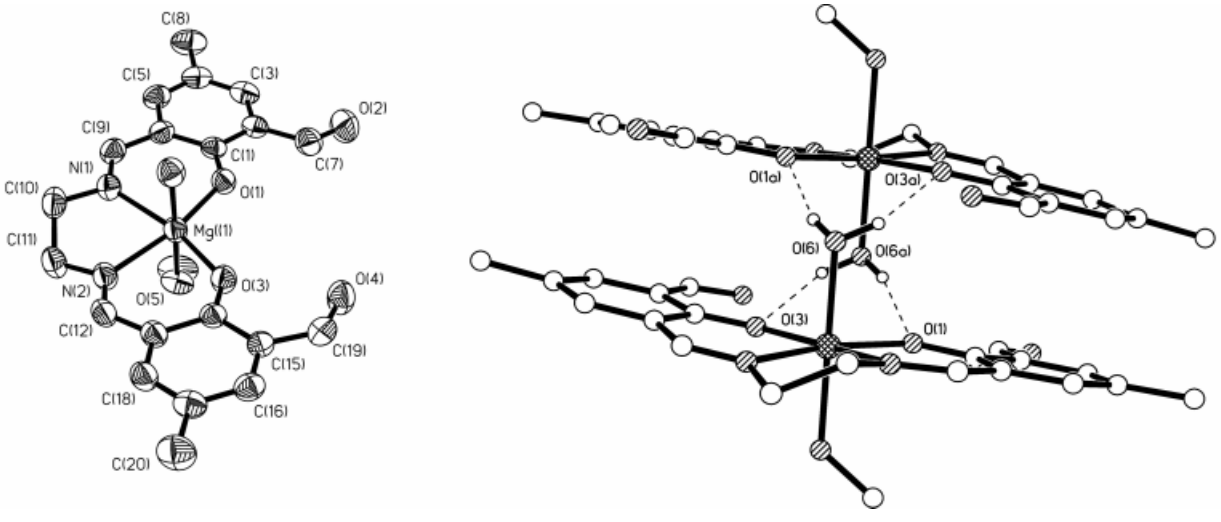

Figure 6. Molecular structure of **8** and arrangement of two molecules with H-bonding interactions indicated. Hydrogen atoms were located in the Fourier-difference map, but for clarity only the hydrogen atoms involved in H-bonding are shown.

our aim to further increase the number of Mg compounds by varying the versatile Schiff base ligands.

Experimental Section

Materials and Methods: 3-Formylsalicylic acid[35] and 2,6-diformyl-4-methylphenol[36] were prepared according to the literature procedures. H_2L^4 was prepared by reaction of 2,6-diformyl-4-methylphenol and 1,2-diaminoethane in $CHCl_3$ and subsequent evaporation of the solvent according to a slightly modified literature procedure.[34] All chemicals and solvents were of reagent grade and used without further purification. – ^{1}H NMR spectra were recorded on a Varian Mercury spectrometer at 200.13 MHz., the HMBC experiment on a Bruker DRX 400 spectrometer. – Infrared spectra of KBr pellets were measured on a Bruker IFS 28 FT-spectrometer.

Complex 1: 3-Formylsalicylic acid (84 mg, 0.51 mmol), glycine (34 mg, 0.45 mmol) and $Zn(CH_3CO_2)_2{\cdot}2H_2O$ (151 mg, 0.69 mmol) were stirred in ethanol/water (1:1, 30 mL) for 3 h. The resulting precipitate was filtered off, washed with ethanol and dried at 40 °C overnight to give $[Zn(HL^1)(H_2O)_2]$, **1** as a yellow powder (98 mg, 0.30 mmol, 68%). – IR (KBr): $\tilde{\nu}$ = 3071, 2925, 1653 (CO), 1617 (C=N), 1566, 1519, 1471, 1399, 1296, 1243, 1097, 1076, 1005, 959 cm^{-1}. – ^{1}H NMR [$(CD_3)_2SO$]: δ = 3.96 (s, 2 H, CH_2), 6.73 (t, J = 7.6 Hz, 1 H, CH_{arom}), 7.54 (d, J = 7.8 Hz, 1 H, CH_{arom}), 7.93 (d, J = 7.8 Hz, 1 H, CH_{arom}), 8.49 (s, 1 H, HC=N), 16.11 (s, 1 H, COOH). – ^{13}C NMR [$(CD_3)_2SO$]: δ = 59.5 (CH_2), 117.6 (C_{arom}), 121.6 (C_{arom}), 132.4 (C_{arom}), 147.3 (C_{arom}), 155.0 (C_{arom}), 167.7 (C=N), 170.0 (C_{arom}), 173.6 (COOH), 177.0 (Ar-COOH). – $C_{10}H_{11}NO_7Zn$ (322.56): calcd. C 37.2, H 3.4, N 4.3; found C 36.8, H 3.5, N 4.3.

Complex 2: 3-Formylsalicylic acid (83 mg, 0.50 mmol), glycine (38 mg, 0.51 mmol), $Mg(CH_3CO_2)_2{\cdot}4H_2O$ (107 mg, 0.50 mmol) and KOH (56 mg, 1.00 mmol) were reacted in ethanol/water (5:1, 30 mL). After 3 days a yellow precipitate of $[Mg(HL^1)(H_2O)_2]$, **2**, was filtered off, washed with ethanol and dried at 40 °C overnight (65 mg, 0.23 mmol, 46%). – IR (KBr): $\tilde{\nu}$ = 3395, 1659 (CO), 1613 (C=N), 1546, 1495, 1464, 1436, 1401, 1314, 1220, 1154 cm^{-1}. – $C_{10}H_{11}NO_7Mg$ (281.47): calcd. C 42.7, H 3.9, N 5.0; found C 42.3, H 3.8, N 4.9.

Complex 3: Salicylaldehyde (117 mg, 0.96 mmol), sodium glycinate hydrate (111 mg, 0.97 mmol) and $Zn(NO_3)_2{\cdot}6H_2O$ (900 mg, 3.03 mmol) were reacted in methanol (20 mL) for 6 h at room temperature and afforded a pale yellow precipitate of composition $ZnL^2{\cdot}1.5H_2O$, **3** (116 mg, 0.43 mmol, 45%). – IR (KBr): $\tilde{\nu}$ = 3277, 3064, 2909, 1654 (CO), 1611 (C=N), 1581, 1476, 1405, 1282, 1197, 1158, 1076, 1040, 796, 767 cm^{-1}. – ^{1}H NMR [$(CD_3)_2SO$]: δ = 3.88 (s, 2 H, CH_2), 6.41 (t, J = 7.2 Hz, 1 H, CH_{arom}), 6.59 (d, J = 8.5 Hz, 1 H, CH_{arom}), 7.12 (t, J = 7.2 Hz, 2 H, CH_{arom}), 8.34 (s, 1 H, HC=N). – $C_9H_{10}NO_{4.5}Zn$ (269.57): calcd. C 40.1, H 3.7, N 5.2; found C 40.0, H 3.5, N 5.1.

Complex 4: 5-Bromosalicylaldehyde (201 mg, 1.00 mmol), sodium glycinate hydrate (115 mg, 1.00 mmol) and $Mg(NO_3)_2{\cdot}6H_2O$ (769 mg, 3.00 mmol) were stirred in methanol (20 mL) for 3 h. Addition of water (10 mL) yielded a yellow precipitate that was filtered off and washed with Et_2O. Recrystallization from methanol/water (4:1, 50 mL) gave pale yellow needles of $[MgL^3(H_2O)_3]$, **4** (140 mg, 0.42 mmol, 42%). – IR (KBr): $\tilde{\nu}$ = 3410, 2911, 1657 (CO), 1607 (C=N), 1532, 1469, 1395, 1381, 1285, 1174 cm^{-1}. – ^{1}H NMR [$(CD_3)_2SO$]: δ = 3.79 (s, 2 H, CH_2), 6.34 (d, J = 8.9 Hz, 1 H, CH_{arom}), 7.05 (d, J = 8.9 Hz, 1 H, CH_{arom}), 7.17 (s, 1 H, CH_{arom}), 8.01 (s, 1 H, HC=N). – $C_9H_{12}BrMgNO_6$ (334.41): calcd. C 32.3, H 3.6, N 4.2; found C 32.3, H 3.7, N 4.1.

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. – [b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$; $w^{-1} = \sigma^2(F_o^2) + (aP)^2$; $P = (F_o^2 + 2F_c^2)/3$ with a = 0.0783 for **4**, 0.0393 for **5**, 0.1297 for **6** and 0.0522 for **8**.

Complex 5: 5 was prepared in an analogous manner to **4** from salicylaldehyde (117 mg, 0.96 mmol), sodium glycinate hydrate (111 mg, 0.97 mmol) and $Mg(NO_3)_2 \cdot 6H_2O$ (735 mg, 2.87 mmol). yield: 53%. X-ray suitable crystals of $[MgL^2(H_2O)_2]_n$ (**5**) were obtained by recrystallization from methanol. − IR (KBr): $\tilde{\nu}$ = 3383, 1658 (CO), 1574, 1539, 1471, 1452, 1406, 1334, 1298, 1193 cm^{-1}. − ^1H NMR [$(CD_3)_2SO$]: δ = 3.84 (s, 2 H, CH_2), 6.28 (t, J = 7.2 Hz, 1 H, CH_{arom}), 6.46 (d, J = 8.5 Hz, 1 H, CH_{arom}), 7.04 (t, J = 7.1 Hz, 2 H, CH_{arom}), 8.08 (s, 1 H, HC=N). − $C_9H_{11}MgNO_5$ (237.50): calcd. C 45.5, H 4.7, N 5.9; found C 45.8, H 4.7, N 5.9.

Complex 6: Salicylaldehyde (351 mg, 2.88 mmol), sodium glycinate hydrate (333 mg, 2.89 mmol) and $Mg(NO_3)_2 \cdot 6H_2O$ (2.20 g, 8.58 mmol) were stirred in methanol (36 mL) overnight. The solution was evaporated to dryness and complex **5** was extracted with water. The residue was dissolved in methanol. After a few days microcrystals of $[Mg(sal)_2(H_2O)_2] \cdot 0.5H_2O$, **6**·$0.5H_2O$ formed (82 mg, 0.26 mmol, 18%). − IR (KBr): $\tilde{\nu}$ = 3455, 2887, 2795, 1661 (CO), 1606 (ring), 1531, 1449, 1333, 1201, 1179, 1152, 1124 cm^{-1}. − ^1H NMR [$(CD_3)_2SO$]: δ = 6.34 (t, br, 1 H, CH_{arom}), 7.26 (t, br, 2 H, CH_{arom}), 7.45 (d, J = 8.5 Hz, 1 H, CH_{arom}), 9.19 (s, 1 H, HC=O). − $C_{14}H_{15}MgO_{6.5}$ (311.58): calcd. C 53.9, H 4.9; found C 53.7, H 4.7.

Recrystallization from methanol yielded pale yellow needles of $[Mg(sal)_2(H_2O)_2]$, **6** suitable for X-ray analysis.

Complex 7:[33] H_2L^4 (215 mg, 0.61 mmol), $NaOCH_3$ (66 mg, 1.22 mmol) and $ZnCl_2$ (83 mg, 0.61 mmol) were stirred in methanol (20 mL) at room temperature. After 10 min unchanged H_2L^4 was filtered off. Addition of water resulted in the precipitation of $[ZnL^4(H_2O)]$, **7** (110 mg, 0.25 mmol, 41%). − IR (KBr): $\tilde{\nu}$ = 3262, 2921, 1664 (CO), 1609 (C=N), 1532, 1449, 1389, 1231, 1029 cm^{-1}. − ^1H NMR [$(CD_3)_2SO$]: δ = 2.22 (s, 6 H, CH_3), 3.81 (s, 4 H, CH_2), 7.39 (s, 2 H, CH_{arom}), 7.48 (s, 2 H, CH_{arom}), 8.53 (s, 2 H, HC=N), 10.55 (s, 2 H, HC=O). − $C_{20}H_{20}N_2O_5Zn$ (433.78): calcd. C 55.4, H 4.7, N 6.5; found C 55.0, H 4.7, N 6.5.

Complex 8: 8 was prepared in an analogous manner to **7** from H_2L^4 (554 mg, 1.55 mmol), $NaOCH_3$ (168 mg, 3.11 mmol) and $MgCl_2 \cdot 6H_2O$ (315 mg, 1.55 mmol) in a 69% yield. Recrystallization from methanol afforded orange-yellow cubes of $[MgL^4(H_2O)(CH_3OH)]$ suitable for X-ray analysis. − IR (KBr): $\tilde{\nu}$ = 3438, 2900, 1655 (CO), 1609 (C=N), 1539, 1522, 1463, 1386, 1231, 1032 cm^{-1}. − ^1H NMR [$(CD_3)_2SO$]: δ = 2.19 (s, 6 H, CH_3), 3.70 (s, 4 H, CH_2), 7.32 (s, 2 H, CH_{arom}), 7.41 (s, 2 H, CH_{arom}), 8.26 (s, 2 H, HC=N), 10.53 (s, 2 H, HC=O). − $C_{21}H_{24}MgN_2O_6$ (424.74): C 59.3, H 5.7, N 6.6; found C 58.9, H 5.8, N 6.5.

Metal Ion Substitution: Solutions of **7** (10 mM), **1** and **3** (2 mM due to lower solubility) in $(CD_3)_2SO$ were treated with aliquots of a solution of $MgCl_2 \cdot 6H_2O$. NMR spectra were run 10 to 30 minutes after addition of $MgCl_2$. For a representative sample no change of the spectrum was observed over 24 h.

X-ray Crystallography: Crystal data for compounds **4, 5, 6** and **8** were collected at room temperature on an Enraf−Nonius-KappaCCD diffractometer[37] using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). For data reduction and cell refinement the programs DENZO and SCALEPACK were used.[38] The structures were solved by conventional Patterson (**4**) or direct (**5**, **6** and **8**) methods and subsequent Fourier syntheses, and refined by full-matrix least-squares on F^2 using the SHELXTL PLUS and SHELXL-93 programs.[39] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms of **4**, **5**, and **8** were located in the final Fourier-difference maps (except for those of the aqua ligands in **4**) and refined isotropically. For **6** carbon-bound hydrogen atoms were placed at calculated positions and given fixed isotropic temperature factors. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-161094 (**4**), -161095 (**5**), -161096 (**6**) and 161097 (**8**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Gas-Phase Structures and Acidities of the Sulfur Oxoacids $H_2S_nO_6$ (n = 2−4) and $H_2S_2O_7$[‡]

André H. Otto[a] and Ralf Steudel*[a]

Keywords: Sulfur oxoacids / Acidity / Superacidic systems / ab initio calculations / Thermodynamics

The gas-phase geometries, dipole moments, enthalpies, and Gibbs free energies of dithionic acid $H_2S_2O_6$, trithionic acid $H_2S_3O_6$, tetrathionic acid $H_2S_4O_6$, and disulfuric acid $H_2S_2O_7$ have been determined by ab initio MO calculations at various levels of theory. The most stable conformations of $H_2S_2O_6$ and $H_2S_2O_7$ are of C_2 symmetry, the other two acids are of C_1 symmetry. The gas-phase acidities defined as $\Delta G°_{298}$ of the deprotonation reaction obtained at the {MP2/6-311++ G(3df, 3pd)//MP2/6-31+ G(d) + ZPVE[HF/6-31+ G(d)]} level are as follows [kJ·mol^{-1}]: $H_2S_2O_6$ 1180, $H_2S_3O_6$ 1162, $H_2S_4O_6$ 1156, $H_2S_2O_7$ 1171. All four acids are much stronger than fluorosulfuric acid and chlorosulfuric acid in the gas phase. The decomposition of $H_2S_2O_7$ into SO_3 and H_2SO_4 is slightly endothermic and the same holds for the decomposition of $H_2S_3O_6$ into SO_3 and $H_2S_2O_3$, but the reaction of $H_2S_2O_6$ to SO_2 and H_2SO_4 is strongly exothermic. The structures of the monoanions $HS_2O_6^-$, $HS_3O_6^-$, $HS_4O_6^-$, and $HS_2O_7^-$ are characterized by intramolecular hydrogen bonds.

Introduction

Sulfur forms numerous ternary oxoacids $H_2S_mO_n$ where the oxidation numbers of the sulfur atom(s) are between −1 and +6.[1] Most of these compounds are unstable at ambient temperatures and have been detected only in aqueous solution (as anions) or in the vapour phase by mass spectrometry. Consequently, the structures and physical properties of almost all sulfur oxoacids have remained unknown for a long time.[2] More recently high-level ab initio MO calculations of a number of these compounds provided, for the first time, the gas-phase structures and, in some cases, the gas-phase acidities of H_2SO,[3] H_2SO_2,[3] H_2SO_3,[3] H_2SO_4,[3,4] H_2SO_5,[5] H_2S_2O,[6] $H_2S_2O_2$,[7] $H_2S_2O_3$,[5] $H_2S_2O_4$,[8] and H_2S_3O.[9] In this work we report on the gas-phase structures and acidities of three disulfonic acids $H_2S_nO_6$ (n = 2−4) and of disulfuric acid $H_2S_2O_7$.

Disulfuric acid is an industrial chemical prepared in huge amounts as an intermediate in the production of sulfuric acid from SO_3 and water. The sulfur trioxide from the contact process is absorbed into concentrated sulfuric acid with the formation of polysulfuric acids that are subsequently hydrolysed to give H_2SO_4:[10]

$$x\,SO_3 + H_2SO_4 \rightarrow H_2S_{x+1}O_{3x+4} \quad (1)$$

$$H_2S_{x+1}O_{3x+4} + x\,H_2O \rightarrow (x+1)\,H_2SO_4 \quad (2)$$

If x = 1, disulfuric acid is formed. Its structure is unknown but its gas-phase acidity has recently been determined by density functional calculations, at the B3LYP/6-311+ G(d, p) level of theory[11], as $\Delta G°_{298}$ = 1147 kJ·mol^{-1}. This enthalpy applies to the deprotonation reaction resulting in the gaseous monoanion $HS_2O_7^-$. The structure of this anion is known from X-ray crystallography of a number of salts, e.g. $[NO_2][HS_2O_7]$[12] and $[Se_4][HS_2O_7]_2$.[13] The connectivity of the anion is $HO-SO_2-O-SO_2^-$ but the structures of the two salts are characterized by strong intermolecular O−H···O hydrogen bonds.

The disulfonic acids $H_2S_nO_6$ with n = 2, 3, 4, ... occur in various natural habitats[14] as well as in industrial processes.[15] Consequently, they play a role in the global sulfur cycle. However, neither their structures nor their gas-phase acidities are known. The acidity of aqueous dithionic acid $H_2S_2O_6$ has recently been determined as pK_a = 1.9,[16] but no data for the other acids are available. The structures of the monoanions $HS_nO_6^-$ are also unknown since no corresponding salts have ever been isolated. However, a number of salts containing the dianions $S_nO_6^{2-}$ have been analyzed by X-ray crystallography.[17] From these studies it follows that the acids should have the connectivities $HO-SO_2-S_{n-2}-SO_2-OH$ (n = 2−4). In other words, all these molecules contain at least one sulfur−sulfur bond.

Calculations

Ab initio molecular orbital calculations were performed with CBS-Q,[18] G2(MP2),[19] and an MP2 treatment[20] elaborated in our group. The G2(MP2) method is a modified version of G2[21] and is almost as accurate as the G2 method, but at a substantially reduced computational expense.

The Complete Basis Set (CBS) model CBS-Q utilizes the "dagger" 6-31G† basis set[22] trying to overcome some deficiencies in the standard 6-31G(d) basis set. CBS-Q consists

of the following steps: Geometry optimization at the HF/6-31G† level, thermal corrections using wavenumbers obtained at the same level and scaled by a factor of 0.918, reoptimization at the MP2/6-31G† level followed by energy calculations using a large basis set in combination with HF and MP2. The next steps are MP4(sdq) and QCISD(T) calculations applying medium size basis sets. Then the CBS extrapolation is made and empirical corrections are added to obtain the final thermodynamic data.

The excellent performance of both CBS-Q and G2(MP2) in predicting gas-phase acidities of small molecules is well established.[23]

For an effective estimation of Brønsted acidities, a special MP2 treatment is elaborated. This approach consists of MP2/6-31+ G(d) geometry optimizations followed by MP2/6-311++ G(3df, 3pd) energy calculations while the thermal corrections were obtained from HF/6-31+ G(d) wavenumbers scaled by 0.9.

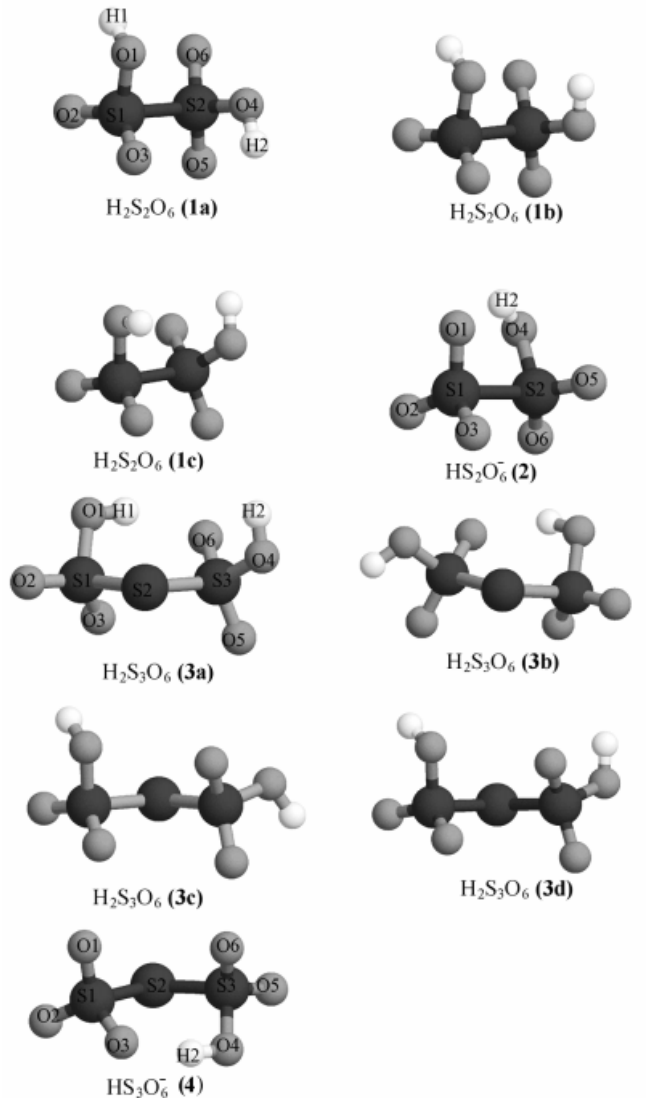

Figure 1. Conformations of the sulfur oxoacids $H_2S_nO_6$ (n = 2, 3) and of their anions as well as numbering of atoms in the most stable conformers

For details of the quantum chemical methods see ref.[24] To allow for the thermal corrections to the Gibbs free energy of the proton a value of −0.010654 hartree (−28 kJ·mol^{-1}) was used.

All calculations were carried out on a Cray J90 or on a Linux workstation using the GAUSSIAN program system.[25]

Results and Discussion

Molecular Structures

Dithionic Acid $H_2S_2O_6$

Three conformations of $H_2S_2O_6$ (**1a**−**1c**) were found to be minima on the potential energy surface (PES) of $(SO_3H)_2$. These structures are shown in Figure 1. Basically, they are rotational isomers which differ mainly by the signs and values of the torsion angles at the three axes H−O−S−S, (H)O−S−S−O(H), and S−S−O−H. The signs of these torsion angles, if one goes from one hydrogen atom to the other, are termed *motifs* which are used in the following tables to identify the different rotamers. In all three $H_2S_2O_6$ molecules the trigonal-pyramidal SO_3 groups are staggered. The conformers **1a** and **1b** are of C_2 symmetry while **1c** is of C_1 symmetry.

The geometrical parameters of the most stable isomer **1a** are listed in Table 1. The enthalpy and Gibbs energy differ-

ences between the three conformers calculated at various levels of theory are shown in Table 2.

At the highest level, conformer **1b** is 4 kJ·mol^{-1} less stable than **1a**, and **1c** is 13 kJ·mol^{-1} less stable. None of these molecules seem to contain intramolecular hydrogen bonds, since the shortest O···H contacts are 256 pm in **1a**, 252 pm in **1b**, and 246 pm in **1c**. These distances are roughly equivalent to the van der Waals distance between oxygen and hydrogen atoms. For comparison, the length of the weak hydrogen bond in the gaseous water dimer $(H_2O)_2$ is 200 pm.[1a] The calculated bond lengths O−H and S−O as well as the bond angles show the expected values. Interestingly, the S−S bond (219.2 pm) is considerably longer than the single bond length of 205 pm observed in H_2S_2 and in S_8. This fact is in line with the evidence that S−S distances depend on the coordination numbers (CNs) of the two atoms and increase with higher CNs. An even longer S−S bond of 226.6 pm is calculated for the monoanion $HS_2O_6^-$ (**2**) the structural parameters of which are also listed in Table 1. This anion is of C_1 symmetry and, in contrast to **1a**−**1c**, contains an O···H hydrogen bond of length 209.6 pm (O1···H2). For the anion of potassium dithionate ($K_2S_2O_6$) the S−S bond length has been determined by X-ray crystallography as 214 pm (S−O 145 pm, S−S−O 105°, O−S−O 114°).[17]

Trithionic Acid $H_2S_3O_6$

Trithionic acid is also termed as sulfane disulfonic acid since it is formally a derivative of sulfane H_2S as the following formula shows: $S(SO_3H)_2$. Four conformational isomers (rotamers) were located as minima on the PES. The structures of these isomers (**3a**−**3d**) are shown in Figure 1; they are all of symmetry C_1 and differ mainly by the values and signs of the four torsion angles H1−O−S−S, (H1)O−S−S−S, S−S−S−O(H2), and S−S−O−H2. The signs of these angles (*motifs*) are given in Table 3. The most stable species **3a** is characterized by a weak intramolecular hydrogen bond between O6 and H1 (length 201.0 pm). Isomer **3b** is 5 kJ·mol^{-1} less stable than **3a** and also contains a hydrogen bond (O3···H2) with a length of 200.6 pm. In contrast, the shortest intramolecular O···H contacts in **3c** and **3d** are 243 and 248 pm, respectively. These rotamers are 19 and 20 kJ·mol^{-1}, respectively, less stable than **3a** (Gibbs energies; see Table 3).

The geometrical parameters of the stable isomer **3a**, together with those of the monoanion $HS_3O_6^-$ (**4**), are given in Table 4.

While the O−H and S−O bond lengths as well as the bond angles show the normal values, the two S−S bonds of **3a** (212.2 and 214.4 pm) are not equivalent, probably as a result of the hydrogen bond which makes the two SO_3H groups inequivalent. An even larger difference between the two S−S bonds is calculated for the anion **4** (208.3 and 226.3 pm) which is characterized by a strong hydrogen bond that is 172.8 pm (O3···H2; see Figure 1) in length; this is about the same length as observed for the hydrogen bonds in ice I (176 pm).[1a] For the anion of potassium trithionate ($K_2S_3O_6$) the two S−S distances have been determined by X-ray crystallography as 215 pm.[17]

Attempts to optimize the geometry of the zwitterion $HO_3S-S^+(H)-SO_3^-$ at the MP2/6-31+G(d) level of theory led to the dissociation of this tautomer of trithionic acid into thiosulfuric acid, $H_2S_2O_3$, and sulfur trioxide.

Tetrathionic Acid $H_2S_4O_6$

Ten rotational isomers were located as minima on the PES of $H_2S_4O_6$. Seven of these species are of C_1 symmetry and three are of C_2 symmetry; their structures are shown in Figure 2. To characterize these rotamers we once again use the motif which in this case represents the signs of the five torsional angles H1−O−S−S, (H1)O−S−S−S, S−S−S−S, S−S−S−O(H2), and S−S−O−H2. The structures **5a**−**5d** as well as **5f** contain one intramolecular hydrogen bond each which are of the lengths 190.5 pm (**5a**), 187.8

pm (**5b**), 188.6 pm (**5c**), 201.2 pm (**5d**), and 191.5 pm (**5f**). For the other five species the shortest O···H contacts were calculated as 241 pm or longer.

At the highest level of theory employed, the three species **5a**−**5c** practically have identical Gibbs energies (see Table 5) while the other molecules are 8−22 kJ·mol^{-1} less stable.

The geometrical parameters of the most stable species **5a** are given in Table 6. The most interesting data are those of the S−S bonds. As expected, the central S−S bond (202.7 pm) is considerably shorter than the other two (212.9 and 216.5 pm) as a result of the higher CNs within the sulfonic groups. The S−S−S−S torsion angle of 80.9° is quite normal for sulfur chains.[26]

For the monoanion $HS_4O_6^-$, three rotational isomers of C_1 symmetry (**6a**−**6c**) were found as local minima on the PES. Their structures are shown in Figure 3 and their relative enthalpies are given in Table 7.

The more stable structures **6a** and **6b** contain hydrogen bonds of length 162.0 and 159.8 pm, respectively, while no such bond is present in isomer **6c**. The geometrical parameters of **6a** are given in Table 6. The lengths of the S−S bonds show an interesting pattern: while the central bond (203.6 pm) has changed little compared to the free acid **5a**

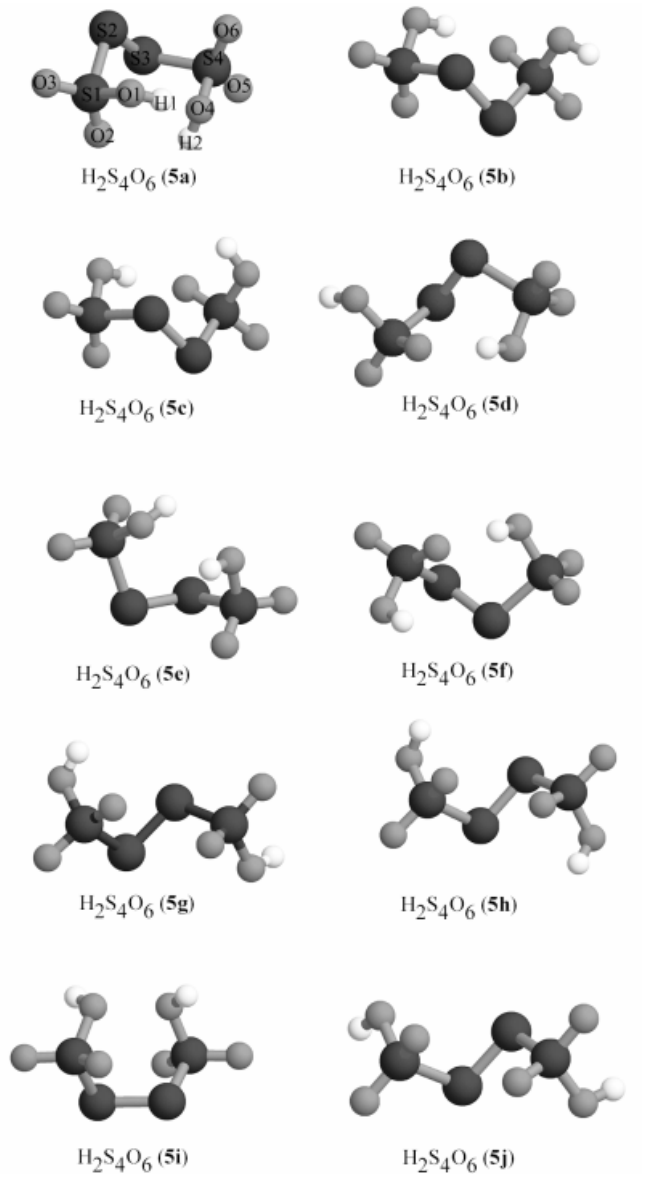

Figure 2. Conformations of the sulfur oxoacid $H_2S_4O_6$ as well as numbering of atoms in the most stable conformers

(202.7 pm), the bond in the S−SO_3H group (213.8 pm) has shortened by 2.7 pm and the bond S−SO_3^- (220.8 pm) has increased in length by 8 pm on deprotonation. For the anion of potassium tetrathionate the S−S bond lengths have been determined by X-ray crystallography as 202 pm (central bond) and 212 pm (terminal bonds); the S−S−S bond angles were found as 102° and 104°.[17]

Disulfuric Acid $H_2S_2O_7$

The structure of the disulfuric acid molecule **7** is of C_2 symmetry as shown in Figure 3. Only one minimum was located on the PES. This structure is stabilized by two hydrogen bonds of length 204.3 pm. The geometrical parameters of $H_2S_2O_7$ **7** as well as of its monoanion **8** are given in Table 8. The anion is characterized by a strong but asymmetric hydrogen bond of length 178.6 pm (symmetry C_1;

bond lengths of 160.2 pm and 184.1 pm and a bond angle of 120.5°; the experimental values are: 160(2) pm, 167(2) pm, 123(1)°.[13]

Acidities

The gas-phase acidities of the four acids investigated in this work are listed in Table 9. Only the most stable conformers were used. The acidities are defined as the enthalpies or Gibbs energies of the deprotonation reaction at 298 K. As a reference the acidity of gaseous sulfuric acid is used which has been calculated at the G2 level of theory[3] as $\Delta H°_{298} = 1305$ and $\Delta G°_{298} = 1268$ kJ·mol^{-1} in excellent agreement with experimental studies. Acids that have a higher acidity than sulfuric acid are termed superacids. The results in Table 9 demonstrate that both disulfuric acid and all the polythionic acids, including dithionic acid, are superacids that are stronger proton donors than HSO_3F, HSO_3Cl and $HClO_4$. They are surpassed only by a few extremely superacidic molecules like $HSO_3F{\cdot}SO_3$, $H_2S_3O_{10}$, and $HSO_3F{\cdot}SbF_5$.[11] Figure 4 shows a comparison of the acidities of sulfur-containing superacids.

It is obvious from this data that the acidity increases with increasing anion size. This may be rationalized by the better stabilization of the excess negative charge and this stabilization should be easier the larger the anion becomes with regard to the total number of electrons.[27] Similar observations have been made before with peroxosulfuric acid and chlorosulfuric acid.[5]

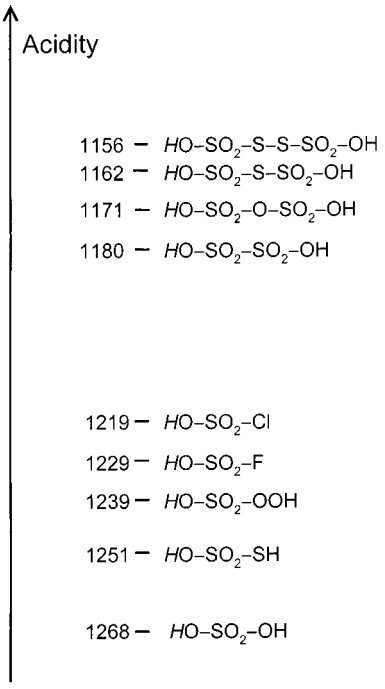

Figure 4. Gas phase acidities of the sulfur oxoacids $H_2S_nO_6$ (n = 2, 3, 4) and $H_2S_2O_7$ compared to the acidities of other superacidic proton donors. The values of $\Delta G°_{298}$ [kJ·mol^{-1}] for the deprotonation reaction are given

According to our previous experience[5] the acidities calculated at the CBS-Q level agree with those from the G2(MP2) level within 10 kJ·mol^{-1}. Therefore, we consider our acidity of disulfuric acid of 1169 kJ·mol^{-1} ($\Delta G°_{298}$) as

Table 9. Gas phase acidities [kJ·mol^{-1}] and dipole moments [Debye] of the polythionic acids HO−SO_2−S_n−SO_2−OH (n = 0, 1, 2) (**1**, **3**, **5**) and disulfuric acid HO−SO_2−O−SO_2−OH (**7**)

more reliable than the literature value[11] of 1147 kJ·mol^{-1} obtained by B3LYP calculations. It has been shown[28] that B3LYP provides accurate Brønsted acidities only in combination with large basis sets.

Stabilities

Since heating can easily decompose all the acids investigated in this work, we have calculated the Gibbs energies ($\Delta G°_{298}$) of some typical dissociation reactions. The data in Table 10 show that the decomposition of dithionic acid to sulfuric acid and sulfur dioxide is exothermic. This reaction has in fact been observed in aqueous solution.[29] The decomposition of trithionic acid into sulfur trioxide and thiosulfuric acid is slightly endothermic. This also holds for the decomposition of disulfuric acid into sulfuric acid and SO_3. However, in the case of $H_2S_3O_6$ other redox reactions are also possible.

Table 10. Stabilities ($\Delta G°_{298}$) of the polythionic acids HO−SO_2−S_n−SO_2−OH (n = 0, 1) (**1**, **3**) and disulfuric acid (**7**) HO−SO_2−O−SO_2−OH with respect to the decomposition into lower acids and SO_2 or SO_3

Decomposition	MP2[a]	CBS-Q	G2(MP2)
$H_2S_2O_6$ (**1a**) → H_2SO_4 + SO_2	−121	−116	−122
$H_2S_3O_6$ (**3a**) → $H_2S_2O_3$ + SO_3	21		
$H_2S_2O_7$ (**7**) → H_2SO_4 + SO_3	15	32	

[a] MP2/6-311++ G(3df, 3pd)//MP2/6-31+ G(d) + ZPVE[HF/6-31+ G(d)].

The calculated enthalpies $H°$ and Gibbs energies $G°$ of the 24 conformers corresponding to the four sulfur oxoacids and their anions are given in Table 11S while Table 12S contains the data from which the stabilities have been determined. These Tables are available as Supplementary Information (see also first page of this article).

Conclusions

The four sulfur oxo acids HO−SO_2−SO_2−OH (**1**), HO−SO_2−S−SO_2−OH (**3**), HO−SO_2−S−S−SO_2−OH (**5**), and HO−SO_2−O−SO_2−OH (**7**), as well as their monoanions, were investigated by ab initio MO calculations at various levels to obtain their structures as well as their enthalpies and Gibbs energies from which the thermodynamics of the deprotonation reactions, at 298 K, were calculated. In most cases several different conformations were located as minima on the PES. The monoanions and some of the acid molecules are stabilized by intramolecular hydrogen bonds. The sulfonic acid groups are always staggered to each other. The S−S bonds are scattered over the range 202.7−226.6 pm with long distances occurring between sulfur atoms of CN = 4 and short distances with sulfur of CN = 2. All other structural parameters show normal values. Unexpectedly, the gas-phase acidities of these acids are much higher than that of sulfuric acid. Therefore, these species may be termed as superacids. The decomposition of dithionic acid **1** to sulfur dioxide and sulfuric acid is strongly exothermic. Tetrathionic acid is even stronger than disulfuric acid.

$[(C_9H_7)YbI(DME)_2]$, the First Indenyl Half-Sandwich Complex of Divalent Ytterbium

Alexander A. Trifonov,*[a] Eugenii N. Kirillov,[a] Sebastian Dechert,[b] Herbert Schumann,*[b] and Mikhail N. Bochkarev[a]

Keywords: Indenyl complexes / Structure determination / Ytterbium / Sandwich complexes

The reaction of the naphthalene ytterbium(II) complex $(\mu\text{-}C_{10}H_8)[YbI(DME)_2]_2$ (**1**) with indene proved to be a convenient synthetic route to the novel indenyl half-sandwich ytterbium(II) complex $[(C_9H_7)YbI(DME)_2]$ (**2**), which is a monomer in the solid state and stable in DME solution, although it rearranges in THF to give the symmetric derivatives $[(C_9H_7)_2Yb(THF)_2]$ and $[YbI_2(THF)_2]$. The reaction of **2** with equimolar amounts of C_5H_5Na in DME yields $[(C_5H_5)_2Yb(DME)]$ and $[(C_9H_7)_2Yb(DME)]$.

Introduction

Although the first tris(indenyl)lanthanide complexes were synthesized more than 30 years ago,[1] the interest in indenyllanthanide compounds, especially concerning the nature of the metal-ligand bond and the characteristics of their molecular structures, still continued in the following decades. In the last years, a new wave of interest in this class of compounds was caused by the numerous reports on the high catalytic activity of analogous complexes of the early d-transition metals in α-olefin polymerization.[2,3]

Despite the attention which Ln^{II} complexes with η^5-bonded aromatic carbocyclic ligands attracted as prospective catalysts for the polymerization of both non-polar and polar monomers,[4−7] the number of indenyllanthanide(II) complexes is still very limited and their catalytic potential only scarcely investigated.

Although the synthesis of the first indenyl complex of divalent ytterbium, $[(C_9H_7)_2Yb(THF)_2]$, obtained by ligand exchange between $(C_6F_5)_2Yb$ and indene was described in 1985,[8] the structure of this complex was not determined until 1993.[9] The corresponding DME-coordinated complex $[(C_9H_7)_2Yb(DME)]$ was isolated as an unexpected product in 98% yield from the reaction of $[(CH_3)_2C(1\text{-}C_9H_6)_2]Na_2$ with $YbCl_3$, although the authors were actually intending to synthesize the $(CH_3)_2C$-bridged *ansa*-bis(indenyl) complex $[(CH_3)_2C(1\text{-}C_9H_6)_2YbCl]$.[10] The ethylene-bridged *ansa*-bis(indenyl) complexes *rac*-$[(CH_2)_2(1\text{-}C_9H_6)_2Yb(THF)_2]$ and *rac*-$[(CH_2)_2\{1\text{-}(4,7\text{-}(CH_3)_2C_9H_4\}_2\text{-}Yb(THF)_2]$ have been isolated in poor yields starting from $YbCl_3$ and $[(CH_2)_2(1\text{-Ind})_2]Li_2$ [Ind = C_9H_6, 4,7-$(CH_3)_2C_9H_4$], and subsequent reduction of the product by sodium metal.[10] The ytterbocenes $[\{1\text{-}(HSiR_2)\text{-}2\text{-}R'\text{-}C_9H_5\}_2Yb(L)_2]$ (R = Me, Ph; R′ = H, Me; L = donor ligand), obtained by a silylamine elimination reaction from $HSiR_2$-substituted indenes and $Yb[N(SiMe_3)_2]_2(THF)_2$ as well as their fluxional behaviour in solution have also been described.[11] A structurally characterized bisindenyl complex of divalent samarium, $[(C_9H_7)_2Sm(THF)]$, was prepared in high yields by metathesis of $SmI_2(THF)_2$ and C_9H_7K.[12] The Yb^{II} and Sm^{II} derivatives, $(Me_2NCH_2CH_2C_9H_6)_2Ln$ (Ln = Sm, Yb) containing the donor-functionalized 2-dimethylaminoethylindenyl ligands were synthesized by Qian et al.[13]

Halogen-functionalized half-sandwich complexes of Yb^{II} are of essential practical interest since they might serve as suitable precursors for the synthesis of mixed-ligand derivatives. Up to now, only very few compounds of this type such as $[Cp^*YbI(THF)_2]$[14] and $[(1,2\text{-}Me_2NCH_2CH_2)_2\text{-}C_5H_3]YbI(THF)_2$ [15] are known, probably due to the pronounced tendency of heteroleptic Ln^{II} compounds to equilibrate in solution to the corresponding symmetric derivatives.[16] Since half-sandwich indenyllanthanide(II) halide complexes are still unknown, we tried to synthesize the mixed indenyl iodide complex of divalent ytterbium.

Results and Discussion

Naphthalene complexes of ytterbium[17,18] proved to be suitable precursors for the preparation of various Yb^{II} and Yb^{III} derivatives. In particular, these complexes readily react with CH and EH acidic compounds affording the corresponding derivatives of divalent ytterbium in good yields.[17] Thus, the reaction of $(\mu\text{-}C_{10}H_8)[YbI(DME)_2]_2$ (**1**) with indene was proposed as a convenient method for the preparation of indenylytterbium(II) iodide. In contrast to a metathetical pathway, the formation of an alkali halide, which very often hampers the synthesis of organolanthanide complexes, is avoided.

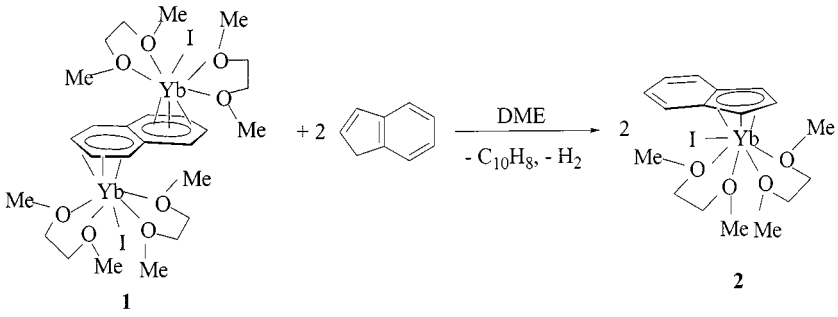

Scheme 1

The reaction of (μ-$C_{10}H_8$)[YbI(DME)$_2$]$_2$ (**1**) with indene in DME occurs at room temperature with progressive dissolution of **1**, evolution of hydrogen and formation of free naphthalene, and is complete within ca. 4 hours. Ruby-red diamagnetic crystals of [C_9H_7YbI(DME)$_2$] (**2**) separate at 0 °C from the filtered and concentrated reddish-brown DME solution with yields of 76% (Scheme 1).

Complex **2** has been characterized by elemental analysis, IR spectroscopy, magnetic measurements and by single crystal X-ray diffraction. It dissolves in DME, THF and pyridine, but is stable only in DME solution. A ligand rearrangement occurs in THF or pyridine yielding equimolar amounts of the symmetric compounds [(C_9H_7)$_2$Yb(THF)$_2$] and YbI$_2$(THF)$_4$ [Equation (1)].

$$2\,(C_9H_7)YbI(DME)_2\,(\mathbf{2}) \rightarrow (C_9H_7)_2Yb(THF)_2 + YbI_2(THF)_2 \qquad (1)$$

Complex **2** is diamagnetic corresponding to the Yb^{2+} oxidation state.[19] The ^{1}H and ^{13}C NMR spectra recorded in [D_8]THF or [D_5]pyridine show a complex pattern of signals due to simultaneous or exclusive presence of the ligand exchange products.

The single crystal X-ray diffraction study of complex **2** − the crystal and structure refinement data are listed in Table 1 − shows monomeric molecules (Figure 1) with the ytterbium atom coordinated in a distorted octahedral fashion to one iodine atom, the five-membered ring part of the indenyl ligand, and the four oxygen atoms of the two DME molecules. The fact that the distances of the ytterbium atom to three of the carbon atoms [C(1), C(2), and C(3)] forming the coordinating cyclopentadienyl part of the indenyl ligand are shorter than the remaining two Yb−C(4) and Yb−C(9) distances, indicate a certain transition from an η^5- to an η^3-bonding mode. This is also consistent with a ring slippage of 0.27 Å. In contrast to **2**, the bis(indenyl) complexes [(C_9H_7)$_2$Yb(DME)][9] and [(C_9H_7)$_2$Yb(THF)$_2$][10] show a distorted tetrahedral ligand arrangement with slightly shorter Yb−ring centroid and Yb−O distances (Yb−C_g: 2.43/2.45 Å; Yb−O: 2.41/2.38 Å).

To examine the utility of complex **2** for the synthesis of mixed ligand complexes of divalent ytterbium, we reacted **2** in DME with equimolar amounts of sodium cyclopentadienide, which did not result in the formation of the expected [(C_5H_5)Yb(C_9H_7)], but instead gave a mixture of the two ligand-exchanged products [(C_5H_5)$_2$Yb(DME)] and [(C_9H_7)$_2$Yb(DME)]. This result corresponds to that reported by Roesky et al.,[21] who isolated [Li(THF)$_3${μ^2−η^8−C_8H_8)}Sm(C_8H_8)] after the reaction of [(C_8H_8)SmI(THF)$_2$] with (1,4-$R_2C_8H_6$)Li$_2$ [R = 2-(dimethylsilyl)-*N*,*N*-dimethylaniline], formed by ligand rearrangement, instead of a heteroleptic complex. Both examples demonstrate a facile transfer of multi-η-bonded anionic carbocyclic ligands from one lanthanide centre to another, a chemical behaviour which already has been observed with cyclopentadienyl complexes of the lanthanides [Equation (2)].[22−24]

$$2\,(C_9H_7)YbI(DME)_2\,(\mathbf{2}) + 2\,C_5H_5Na \rightarrow (C_9H_7)_2Yb(DME) + (C_5H_5)_2Yb(DME) + 2\,NaI \qquad (2)$$

Experimental Section

All experiments were performed in evacuated tubes using standard Schlenk techniques, thus excluding traces of air and water. THF, DME, and toluene were purified by distillation from sodium/benzophenone ketyl. [D_5]pyridine was dried with CaH_2 and condensed in vacuum prior to use. Commercially available indene (Dalhim Ltd.) was used after drying with CaH_2 and subsequent distillation. Compound **1** was prepared from $YbI_2(THF)_2$, $C_{10}H_8$ and Li according to literature methods.[18] IR spectra were recorded as Nujol mulls on a Specord M80 spectrophotometer. NMR spectra were recorded in [D_8]THF or [D_5]pyridine at 298 K using a Bruker DPX 200 spectrometer. Chemical shifts for ^1H and ^{13}C spectra were referenced internally using the residual solvent resonances and reported relative to tetramethylsilane.

[(C9H7)YbI(DME)2] (2): A solution of indene (1.91 g, 16.44 mmol) in DME (10 mL) was slowly added to a suspension of **1** (8.92 g, 8.19 mmol) in DME (50 mL) at room temperature with vigorous stirring. The suspended **1** disappeared within 4 h. The resulting solution was filtered and slowly concentrated in vacuum at room temperature until crystallization started. The concentrate was then cooled to 0 °C and left overnight. The mother liquor was decanted from ruby-red crystals of **2**, which were washed with cold DME and dried in vacuum. Yield: 3.70 g (76%). − IR (Nujol): $\tilde{\nu}$ = 3060 (w), 1340 (s), 1320 (m), 1250 (m), 1200 (m), 1125 (s), 980 (m), 870 (s), 750 (s), 720 (s), 700 cm^{-1} (s). − $C_{17}H_{27}IO_4Yb$ (595.34): calcd. C 34.30, H 4.57, I 21.33, Yb 29.07; found C 33.84, H 4.11, I 20.95, Yb 29.50.

Ligand Exchange of 2 in THF: Compound **2** (0.78 g, 1.31 mmol) was dissolved in THF (15 mL) at room temperature. Within 1 h a pale yellow precipitate formed. The precipitate was separated by filtration, washed with cold THF and dried in vacuo yielding $YbI_2(THF)_2$ (0.33 g, 88%). Hexane (5 mL) was then slowly added to the mother liquor, and the resulting solution was cooled to 0 °C and left overnight. Ruby-red crystals of [$(C_9H_7)_2Yb(THF)_2$] (0.30 g, 83%) were isolated after filtration. − ^1H NMR (200 MHz, [D_8]THF): δ = 5.74 [d, ^3J(H,H) = 3.2 Hz, 2 H, aryl-H^1,H^3], 6.20 [t, ^3J(H,H) = 3.2 Hz, 1 H, aryl-H^2], 6.62−6.67 (m, 2 H, aryl-H^5, H^6), 7.29−7.34 (m, 2 H, aryl-H^7, H^8). − ^{13}C NMR (50.3 MHz, [D_8]THF) δ = 94.0 (aryl-C^1, C^3), 116.6 (aryl-C^2 and aryl-C^5,C^6), 120.4 (aryl-C^4,C^7), 127.1 (aryl-C^8,C^9).

Reaction of 2 with NaCp: A solution of NaC_5H_5 (0.33 g, 3.75 mmol) in DME (15 mL) was slowly added to a solution of **2** (2.26 g, 3.79 mmol) in DME (30 mL) precooled to 0 °C with vigorous stirring. The reaction mixture was allowed to warm up to room temperature, was then stirred for 12 h and filtered. The resulting brown solution was concentrated in vacuum until the growth of green crystals started and was then cooled to 0 °C. 0.4 g (54%) of [$(C_5H_5)_2Yb(DME)$] was isolated. The IR and ^1H NMR spectra as well as the microanalytical data were in agreement with those given previously.[25] Long term cooling or condensation of hexane into the solution decanted from the precipitated [$(C_5H_5)_2Yb(DME)$] resulted in the simultaneous growth of both green and ruby-red crystals. Parts of the red crystals were separated manually and found to be [$(C_9H_7)_2Yb(DME)$]. − ^1H NMR (200 MHz, [D_8]THF): δ = 3.26 (s, 6 H, OCH_3, DME), 3.49 (s, 4 H, CH_2O, DME), 5.73 [d, ^3J(H,H) = 3.3 Hz, 2 H, aryl-H^1,H^3], 6.19 [t, ^3J(H,H) = 3.2 Hz, 1 H, aryl-H^2], 6.62−6.68 (m, 2 H, aryl-H^5,H^6), 7.30−7.35 (m, 2 H, aryl-H^4,H^7). − ^{13}C NMR (50.3 MHz, [D_8]THF): δ = 59.3 (OCH_3, DME), 72.8 (CH_2O, DME), 94.0 (aryl-C^1, C^3), 116.6 (aryl-C^2 and aryl-C^5,C^6), 120.4 (aryl-C^4,C^7), 127.1 (aryl-C^8,C^9).

Crystal Structure Determination: Data were collected on a Siemens SMART CCD diffractometer (graphite monochromated Mo-K_α radiation, λ = 0.71073 Å) with area-detector by use of ω scans at 173 K. The structure was solved by direct methods using SHELXS-97[26] and refined on F^2, using all reflections, with SHELXL-97.[27] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in calculated positions and assigned to an isotropic displacement parameter of 0.08 $Å^2$. The idealized methyl groups were allowed to rotate about their X−C bond. The absolute structure parameter was determined according to Flack[28] with SHELX-97. SADABS[29] was used to perform area-detector scaling and absorption corrections. The maximum and minimum transmission factors are summarized in Table 1. The PLATON program[30] was used for the geometric analysis of the structure.

Crystallographic Data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no CCDC-164375 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

New Carbaalanes − $(AlMe)_8(CCH_2Me)_5(C{\equiv}C{-}Me)$ and the THF Adduct $(AlMe)_8(CCH_2Me)_5H{\cdot}2THF$

Werner Uhl,*[a] Frank Breher,[a] Alphonse Mbonimana,[a] Jürgen Gauss,[b] Detlev Haase,[c] Arne Lützen,[c] and Wolfgang Saak[c]

Keywords: Aluminium / Carbaalanes / Clusters / Quantum-chemical calculations / NMR spectroscopy

The hydroalumination of $Me_2Al{-}C{\equiv}C{-}Me$ with a large excess of Me_2AlH afforded the *arachno*-carbaalane $(AlMe)_8(CCH_2Me)_5H$ (**4**) by the release of $AlMe_3$. **4** is almost insoluble in noncoordinating solvents and could not be purified by recrystallization. On an attempt to recrystallize **4** from a THF solution, the adduct $(AlMe)_8(CCH_2Me)_5H{\cdot}2THF$ (**5**) was isolated as the first stable ether adduct of a carbaalane. Crystal structure determination revealed a cube of eight aluminium atoms, five faces of which are bridged by $C{-}CH_2Me$ groups. The sixth face is μ_2-bridged by a hydrogen atom, and two opposite aluminium atoms of this face are coordinated by one THF ligand each. When the excess of dimethylaluminium hydride was reduced and the starting compounds were employed in a 1:2.1 molar ratio, an incomplete hydroalumination reaction led to the formation of the carbaalane $(AlMe)_8(CCH_2Me)_5(\mu\text{-}C{\equiv}C{-}Me)$ (**6**), in which the bridging hydrogen atom of **4** is replaced by an alkynido group. ^{27}Al NMR spectroscopic data of all the characterized carbaalanes are reported and supplemented by ^{27}Al NMR chemical shift calculations.

Introduction

Carbaalanes[1] constitute a new class of compounds containing clusters of aluminium and carbon atoms. They are easily obtained by hydroalumination of dialkylaluminium alkynides using an excess of the corresponding dialkylaluminium hydride.[2−4] Two completely different structure types have so far been observed. One may be described by a cube of eight aluminium atoms (**1**, Scheme 1), the six faces of which are occupied by five $C{-}CH_2{-}R$ groups and one hydrido or alkynido ligand. Compound **2** (Scheme 1) may be derived from this cubic arrangement, but it has a unique structure with one vertex unoccupied and possesses only seven aluminium atoms. The three remaining Al_4 faces are still occupied by $C{-}CH_2{-}R$ groups, while the open site of the cluster is coordinated by one hydrogen atom and two alkenido ligands containing C=C double bonds. This structure results from an incomplete hydroalumination reaction, and the formal addition of one equivalent of ethylaluminium dihydride to complete the Al_8 cube is missing. The second principal type of carbaalane has a *closo*-configuration on the basis of its structure and electron count (**3**; Scheme 1) and is a remarkable analogue of the *closo*-borate anion $[B_{11}H_{11}]^{2-}$.[5] The bonding situation in the carbaalanes has been studied by quantum-chemical calculations.[4] They revealed a delocalized multi-centre bonding with only weak direct Al−Al interactions. We report herein on the synthesis and structure of further carbaalane derivatives and their characterization by ^{27}Al NMR spectroscopy.

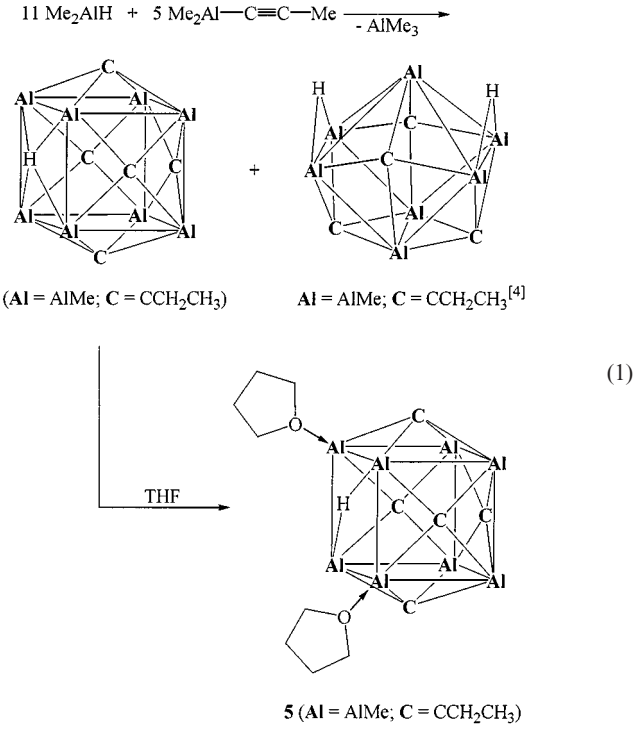
ported by our group only recently.[4] As a main product, we isolated the heptaaluminium carbaalane $(AlMe)_7(CCH_2Me)_4H_2$ in 63% yield, which possesses the *closo*-structure **3** shown in Scheme 1. In all of these reactions, we observed the formation of a hitherto uncharacterized by-product [**4**; Equation (1)], which is almost insoluble in nonpolar solvents such as pentane or toluene and could not be purified by recrystallization. It was isolated as an amorphous and highly pyrophoric powder in about 30% yield. Owing to its insolubility and unknown purity, **4** was characterized only by its ^1H NMR spectrum, which was recorded from a very dilute solution in $[D_6]$benzene. The data obtained were clearly indicative of an *arachno*-type structure similar to compound **1** in Scheme 1. Two resonances of equal intensity were observed for the methyl groups attached to aluminium in a quite normal range ($\delta = -0.20$ and -0.15). The signal of the hydrogen atom bridging an Al_4 face of the cluster is shifted downfield ($\delta = 5.68$) compared to that in dialkylaluminium hydrides containing μ_2-bridging hydrogen atoms in four- or six-membered heterocycles.[6] A similar shift has been observed in all carbaalanes isolated to date. Two triplets ($\delta = 1.04$ and 1.33) and two quadruplets ($\delta = 1.93$ and 2.33), each pair with an intensity ratio of 4:1, were observed for the ethyl substituents of the cluster carbon atoms. These observations are in accordance with the proposed *arachno* structure, in which four of these substituents are adjacent to the hydrogen-bonded face, while one is opposite to this face.



(1)

All attempts to recrystallize **4** from dilute solutions in noncoordinating solvents failed. In some cases, we were able to successfully recrystallize carbaalanes from THF, in which they are usually quite soluble and they do not form any kind of stable THF adduct. Clearly, the aluminium atoms of the carbaalanes are such weak Lewis acids that the coordination of THF molecules even at the open faces of these clusters has never previously been observed. Upon treatment of **4** with THF and slow evaporation of the solvent at room temperature, we obtained colourless crystals. However, an X-ray structure determination (see below) showed that a THF adduct of compound **4** had been formed in which two opposite aluminium atoms of the hydrogen-bonded face of the cluster were each coordinated by one THF molecule [**5**; Equation (1)]. The ether molecules are tightly bound to the aluminium atoms, and no dissociation was observed upon storing of the crystals in vacuo at 10^{-3} Torr and 50 °C. Compound **5** is thermally very stable and does not decompose at temperatures below 260 °C. The NMR spectroscopic characterization in $[D_8]$THF at room temperature showed two quite narrow singlets due to the methyl groups attached to aluminium, two triplets and two quadruplets (each pair with an intensity ratio of 4:1) due to the ethyl substituents bound to the cluster carbon atoms, and one singlet due to the bridging hydrogen atom. The chemical shift of the latter ($\delta = 4.19$) shows the most significant deviation from the resonances of the starting compound **4** and is closer to the shifts normally observed for alkylaluminium hydrides. The cluster carbon atoms exhibit chemical shifts of $\delta = 20.5$ and 21.5, which are strongly downfield shifted compared to the resonances normally observed with coordinatively saturated aluminium atoms ($\delta = -8.8$ and -9.4 for the terminal methyl groups) and may be caused by the particular delocalized bonding situation in these clusters. Two resonances were observed in the ^{27}Al NMR spectrum ($\delta = 155$ and 56), which are discussed in more detail below. Two THF molecules were detected for each formula unit of **5**, in accordance with the result of the crystal structure determination. More complicated NMR spectra were expected in view of the molecular symmetry detected in the solid state, indicating a fast exchange process in THF solution at room temperature. This process is frozen only at very low temperatures, and at -110 °C a splitting of both methyl resonances was observed [$\delta = -0.41$ and -0.56 (coalescence at about 225 K) and $\delta = -0.49$ and -0.51 (coalescence at about 202 K)]. The activation barrier was estimated[7] from these data to be about 45 kJ mol^{-1}.

A crystal structure determination of **5** revealed a structure similar to that of **1**[2,4] (Figure 1) with a cube of eight aluminium atoms. However, two opposite aluminium atoms of the hydrogen-bonded face are coordinated by a THF molecule. The Al−C distances to the terminal methyl groups (average 196.8 pm) do not depend on the coordination sphere of the aluminium atoms and are shorter than those within the cluster (203.8 to 213.3 pm). The Al−Al separations are 293.4 pm at the hydrogen-bonded face and 258.3 pm for the remaining eight edges of the Al_8 cube. The latter are similar to those observed for 3c−2e Al−X−Al interactions (X = H, CH_3)[8] and are shorter than those of Al−Al single bonds in tetraalkyldialuminium(4) derivatives $R_2Al-AlR_2$.[9] All these parameters were similarly determined in carbaalanes of type **1**.[2,4] The most notable devi-

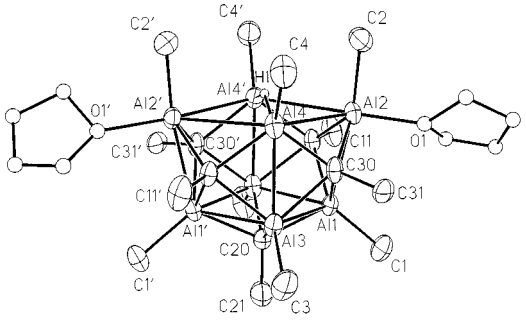


Figure 1. Molecular structure and numbering scheme for compound **5**; thermal ellipsoids are drawn at a 40% probability level; methyl groups have been omitted for clarity; hydrogen atoms are drawn with arbitrary radii; selected bond lengths (pm): Al-1−C-1 196.8(3), Al-2−C-2 197.5(4), Al-3−C-3 196.4(3), Al-4−C-4 196.3(3), Al-1−C-10 210.7(3), Al-1−C-20 205.7(2), Al-1−C-30 209.4(3), Al-2−O-1 197.9(2), Al-2−C-10 204.4(3), Al-2−C-30 205.5(3), Al-3−C-20 203.8(2), Al-3−C-30 211.5(3), Al-3−C-10′ 213.3(3), Al-4−C-30 204.8(3), Al-4−C-10′ 205.7(3), Al-4−H-1 173(1), Al-1−Al-2 259.3(1), Al-1−Al-3 258.4(1), Al-1−Al-3′ 258.4(1), Al-2−Al-4 293.0(1), Al-2−Al-4′ 293.7(1), Al-3−Al-4 257.1(1); C-10′ and Al-3′ were generated by $-x + 3/2$, y, $-z + 1/2$

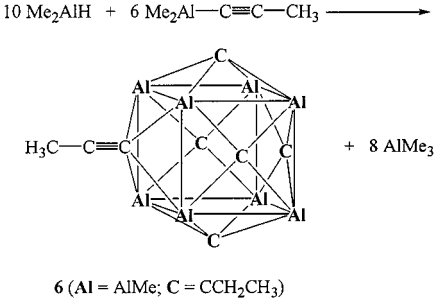
ation from these recently published structures is a greater distortion of the hydrogen-bonded face with strongly differing transannular Al−Al distances of 483.2 pm (Al2−Al2′, unsupported) and 331.8 pm (Al4−Al4′, hydrogen bonded). The latter distance resembles that in the trimeric compound $[(Me_3C)_2AlH]_3$ containing a six-membered Al_3H_3 heterocycle with three μ_2-bridging hydrogen atoms.[10] The THF molecules are bound to the aluminium atoms Al2 and Al2′ with relatively long Al−O "dative" distances of 197.9 pm.[11] The oxygen atoms of the ether molecules lie slightly below the plane spanned by the four aluminium atoms of the hydrogen-bonded face of the cluster (37.6 pm; angle Al2′···Al2−O1 9.6°). Owing to this lateral coordination of THF, the Al(2)−C bonds are almost perpendicular to this plane (angle Al2′···Al2−C2 94.5°; for comparison Al4′···Al4−C4 54.4°).

Synthesis of $(AlMe)_8(CCH_2Me)_5(\mu\text{-}C{\equiv}C{-}Me)$ (6)

In a further reaction, we reduced the excess of dimethylaluminium hydride from about 6:1 required for the synthesis of **4** and **5** according to Equation (1) to a molar ratio of only 2.1:1. Once again, a strongly exothermic reaction was observed on stirring a mixture of the hydride and the alkynide at room temperature without a solvent and a bright-yellow solid precipitated. After 1 h at room temperature, all volatile components ($AlMe_3$) were distilled off in vacuo and the yellow residue was recrystallized from warm toluene. Bright-yellow crystals of compound **6** were isolated in 39% yield after cooling to −30 °C [Equation (2)]. According to the NMR spectra, the mother liquors still contained considerable quantities of **6**, but in all cases we were unable to isolate a second pure fraction. Compound **6** was identified as the carbaalane $(AlMe)_8(CCH_2Me)_5(\mu\text{-}C{\equiv}C\text{-}Me)$, which is similar to compound **4** but has a bridging propynido group instead of the bridging hydrogen atom. The formation of **6** according to Equation (2) requires a stoichiometric ratio of the starting compounds of 1 (alkynide) to 1.7 (hydride). Thus, we still employed a slight excess of the hydride, but further reduction of the hydride concentration did not result in an improved yield of **6**.



(2)

An absorption at 2019 cm^{-1} was detected in the IR spectrum due to the stretching vibration of the C≡C triple bond. Compared to the corresponding vibration of the starting compound $Me_2Al{-}C{\equiv}C{-}Me$ (2109 cm^{-1}),[4] a shift of about 90 cm^{-1} to lower wavenumbers was observed. An even lower value (1957 cm^{-1}) was found for a similar compound with benzyl instead of ethyl groups bound to the cluster carbon atoms.[4] In this case, the weakening of the C≡C triple bond, which may be caused by the particular μ_4-bridging arrangement in the cluster, was also verified by an increased C−C bond length and by quantum chemical calculations.[4] NMR spectroscopic characterization proved quite difficult owing to the very low solubility of **6** in organic solvents. In contrast to compound **4**, small quantities of **6** could be dissolved and handled in THF at room temperature without the formation of a stable ether adduct; thus, all spectra were recorded in dilute $[D_8]$THF solutions. The terminal methyl groups attached to aluminium exhibit two equivalent resonances in the expected ranges of the ^1H and ^{13}C NMR spectra ($\delta = -0.36$, -0.44 and $\delta = -7.7$, -8.9, respectively). The cluster carbon atoms resonate at $\delta = 21.5$ and 17.5, which, as discussed above, is further downfield than expected, and a shift of $\delta = 88.2$ was observed for the bridging carbon atom of the propynido ligand ($\delta = 117.0$ in the benzyl compound cited above).[4] Only one resonance was observed in the ^{27}Al NMR spectrum ($\delta = 153$); a shoulder may be present at $\delta \approx 130$ owing to a marked asymmetry of this signal (see below). A crystal structure determination of **6** revealed a strong disorder of the propyne group, which partially occupies all faces of the Al_8 cube (not shown). As a result of this disorder, an almost undistorted cube of eight aluminium atoms is obtained, with an average Al−Al distance of 265.8 pm; this represents a reasonable mean value between the three different distances expected for a regular structure, as discussed previously for compound **5** and the corresponding benzyl derivative.[4]

In contrast to the dimethylaluminium starting compounds, the sterically slightly more shielded ethyl derivatives diethylaluminium hydride and diethylaluminium propynide do not react exothermically at room temperature. The mixture was heated to 50 °C without a solvent for 18 h

to complete the reaction. As expected, triethylaluminium was formed, which was distilled off in vacuo. An orange residue remained, which, according to its ^{1}H NMR spectrum, contained a carbaalane cluster accompanied by a considerable amount of impurities. However, we did not succeed in isolating a pure component by recrystallization or sublimation. Moreover, the sterically more shielded diisopropyl derivatives did not react exothermically at room temperature and had to be stirred at 50 °C for 18 h to complete the reaction. Owing to the low volatility of triisobutylaluminium, the mixture was subsequently heated in vacuum to 80 °C for 2 h to completely remove this by-product. The oily, light-yellow residue was redissolved in diisopropyl ether. After several weeks at −70 °C, only trace amounts of a colourless solid (**7**) were isolated. On the basis of the results of the NMR spectroscopic characterization (see Exp. Sect.), we suppose that **7** has a *closo*-type structure (Scheme 2) with two opposite Al−Al edges bridged by hydrogen atoms. As required by such a structure, we observed three clearly resolved ^{27}Al NMR resonances (see below). Single crystals suitable for a crystal structure determination were not obtained. A concentrated solution of bis(*tert*-butyl)aluminium hydride and the corresponding propynylaluminium compound in toluene was heated for 20 h at 50 °C. NMR spectroscopic monitoring of the reaction showed the complete consumption of the starting compounds, but no evidence was found for the formation of a carbaalane cluster. Despite many attempts to recrystallize the crude product from various solvents, we did not succeed in isolating any pure component of the mixture.

Scheme 2

^{27}Al NMR Spectra of Carbaalanes

For the first time, we have investigated the ^{27}Al NMR spectra of carbaalanes in a systematic manner. ^{27}Al NMR shifts are known to be very sensitive to the coordination sphere at the central aluminium atoms, and coordination numbers of three, four, five, or six give characteristic shifts of $\delta \approx 270$, 170, 120, and 0, respectively.[12] Furthermore, ^{27}Al NMR chemical shifts, in combination with quantum chemical NMR shift calculations, have previously been shown to be useful for the identification and characterization of aluminium cluster compounds.[13−15] However, the unequivocal interpretation of ^{27}Al NMR spectra is difficult owing to the quadrupole moment of aluminium and the usually broad line width of the resonances. The overlap of signals often prevents a clear assignment, especially in those cases in which chemically different aluminium atoms are present, as in the carbaalanes.

To facilitate the interpretation of the experimental spectra, we performed quantum chemical ^{27}Al NMR shift calculations for most of the carbaalanes under consideration and in this way investigated the usefulness of ^{27}Al NMR spectroscopy for the identification and characterization of carbaalanes. The results of the experimental and the computational investigations are summarized in Table 1. Experimentally, only one broad resonance is observed for most carbaalanes; this is in line with the calculations, which yield values within the rather narrow range of $\delta = 150$ to 210 for the ^{27}Al chemical shifts of all the considered carbaalanes. In some cases, shoulders could be identified, but it seems that in most cases these result from strong anisotropies of the main resonances.

As expected, the *arachno*-type compounds exhibit two Al NMR signals, which are found experimentally at around $\delta = 80$ and 140, while the calculations predict values around $\delta = 160$ and 180 to $\delta = 210$. According to the calculations, the ^{27}Al signal at lower field corresponds to the aluminium atoms close to either the bridging hydrogen atom or the bridging CCR group. The signal shows a slight, though not very pronounced, dependence on the bridging group. The resonances at higher field on the other side are due to the remaining aluminium cluster atoms. They appear to be rather insensitive to the nature of the bridging group and the substituents at the carbon atoms in the cluster.

In principle, the more open alkenido derivatives have five distinct aluminium atoms. The calculations predict ^{27}Al NMR signals for these in the range $\delta = 155$ to 172. Only for the F-containing derivative are higher values of $\delta = 184$ and 200 found for the aluminium atoms close to the bridging fluorine atom. Experimentally, very broad resonances with one (R = H) or two maxima (R = F) are observed. One of the resonances of the fluorine derivative has quite an unusual chemical shift of $\delta = -28$.

For the *closo* form, the calculations again predict values in the range of $\delta = 150$ to 170. The experimental value of $\delta = 157$ for one of the carbaalanes seems to be in satisfactory agreement with the theoretical predictions. However, three clearly resolved resonances ($\delta = 145$, 79, and −38) are observed for **7**.

Overall, it appears that the ^{27}Al NMR spectra of carbaalanes typically consist of one broad resonance, for which a clear assignment, even with the aid of quantum chemical shift calculations, is rather difficult. Our experimental and computational results also suggest that the sensitivity of the ^{27}Al NMR shifts to structural features of the carbaalanes is not very pronounced and that ^{27}Al NMR spectroscopy is not a particularly promising tool for future investigations of such compounds.

Experimental Section

General: All procedures were carried out under purified argon in dried solvents (toluene and THF over Na/benzophenone; *n*-pent-

ane and *n*-hexane over $LiAlH_4$). The compounds $Me_2Al-C\equiv C-CH_3$,[4] Me_2Al-H,[17] Et_2Al-H,[17] iPr_2Al-H,[17] tBu_2Al-H,[10] Et_2Al-Cl,[17] iPr_2Al-Br,[17] and tBu_2Al-Cl[18] were synthesized according to literature procedures. – ^1H and ^{13}C NMR shifts were assigned on the basis of ^1H, ^{13}C, HH-COSY, HMQC, and HMBC spectra. Shifts are reported on the δ scale in ppm relative to residual nondeuterated solvent signals (^1H) or the signals of the deuterated solvent (^{13}C) as internal standards, or relative to $[Al(H_2O)_6]^{3+}$ (^{27}Al) as an external standard.

Synthesis of $(AlMe)_8(CCH_2Me)_5H$ (4): Dimethylpropynylaluminium (0.604 g, 6.29 mmol) was dissolved in excess dimethylaluminium hydride (2.301 g, 39.6 mmol) and the solution was stirred at room temperature. A strongly exothermic reaction occurred after some minutes and a colourless solid precipitated. After stirring for 2 h, all volatile components were distilled off in vacuo. The vessel containing the residue was thoroughly evacuated to 10^{-3} Torr and then the dried product was redissolved in toluene (40 mL). After filtration and cooling to −30 °C, an amorphous, extremely pyrophoric precipitate of the product **4** was deposited. The mother liquor contained a *closo*-carbaalane derivative similar to **3**, the isolation and characterization of which has been reported previously. Owing to its low solubility, **4** could not be purified by recrystallization from noncoordinating solvents. Yield of the crude product: 0.201 g (29% based on propynylaluminium). – ^1H NMR (very dilute solution in C_6D_6, 200 MHz, 298 K): δ = −0.20 and −0.15 (2 s, 12 H each, AlMe), 1.04 (t, 12 H, $^3J_{HH}$ = 7.3 Hz, CH_3 of ethyl), 1.33 (t, 3 H, $^3J_{HH}$ = 7.5 Hz, CH_3 of ethyl opposite to bridging H), 1.93 (q, 8 H, $^3J_{HH}$ = 7.3 Hz, CH_2 of ethyl), 2.33 (q, 2 H, $^3J_{HH}$ = 7.5 Hz, CH_2 of ethyl opposite to bridging H), 5.68 (s, 1 H, AlH).

Synthesis of $(AlMe)_8(CCH_2Me)_5H{\cdot}2THF$ (5): Compound **4** was dissolved in THF. The solution was slowly concentrated under slightly reduced pressure at room temperature over several weeks to yield single crystals of the THF adduct **5**. M.p. (argon, sealed capillary): 260 °C (dec.). – ^1H NMR ([D$_8$]THF, 500 MHz, 300 K): δ = −0.44 (s, 12 H, methyl at Al-1, Al-3), −0.43 (s, 12 H, methyl at A-l2, Al-4 of the hydrogen-bonded face), 1.04 (t, 12 H, $^3J_{HH}$ = 7.3 Hz, CH_3 of ethyl), 1.05 (t, 3 H, $^3J_{HH}$ = 7.3 Hz, CH_3 of ethyl opposite to the bridging hydrogen atom), 1.99 (q, 8 H, $^3J_{HH}$ = 7.3 Hz, CH_2 of ethyl), 2.05 (q, 2 H, $^3J_{HH}$ = 7.3 Hz, CH_2 of ethyl opposite to the bridging hydrogen atom), 4.19 (s, 1 H, AlH); coordinated THF: δ = 1.77 and 3.62 (each m), part of the THF was replaced by [D$_8$]THF and was detected as free THF in solution. – ^1H NMR ([D$_8$]THF, 400 MHz, 165 K): δ = −0.49 and −0.51 (2 s, 6 H each, methyl of Al-1, Al-3), −0.41 and −0.56 (2 s, 6 H each, methyl of Al-2, Al-4), 3.98 (s, 1 H, AlH), broad resonances of the ethyl groups at δ = 1.0 and 1.9. – ^{13}C NMR ([D$_8$]THF, 125.8 MHz, 300 K): δ = −9.4 and −8.8 (AlMe); 20.5 (cluster carbon atom C-20, see Figure 1), 21.5 (cluster carbon atoms C-10 and C-30), 23.1 (CH_3 of ethyl, C-12 and C-32), 24.35 (CH_2 of ethyl, C-11 and C-31), 24.40 (CH_3 of ethyl, C-22), 24.5 (CH_2 of ethyl, C-21), 68.2 (CO of coordinated THF), 26.4 (C_β of THF). – ^{13}C NMR ([D$_8$]THF, 100.6 MHz, 202 K): δ = −10.6, −10.3, −8.5, and −7.8 (AlMe). – ^{27}Al NMR: See Table 1. – IR (CsBr, paraffin): $\tilde{\nu}$ = 1616 m (νAlH), 1458 vs, 1376 vs paraffin; 1314 s, 1269 m (δCH_3), 1196 m, 1176 s, 1078 m, 1066 m, 1025 s, 1004 s, 920 m, 874 s, 801 s (νCC, νCO, δCH_3) 721 vs, 679 vs [br. νAlC(Me)] 465 m, 426 m, 388 m, 344 m, 301 m, 275 m (νAlC, δCC). – $C_{31}H_{66}Al_8O_2$ (686.7): calcd. Al 31.4; found Al 31.2.

Synthesis of $(AlMe)_8(CCH_2Me)_5(\mu\text{-}C\equiv C-Me)$ (6): Dimethylpropynylaluminium (1.665 g, 17.3 mmol) was treated with dimethylaluminium hydride (2.102 g, 36.2 mmol, 2.1 equiv.) without a solvent at room temperature. After about 1 min, a strongly exothermic reaction occurred and a bright-yellow solid precipitated. The mixture was stirred for 1 h and then all volatile components were re-

moved in vacuo. The yellow residue was redissolved in warm toluene (50 mL). The yellow, air-sensitive product was isolated after cooling the solution to −30 °C. Yield: 0.654 g (39%), m.p. (argon, sealed capillary): 240 °C (dec.). − ^{1}H NMR ([D$_8$]THF, 500 MHz, 300 K): δ = −0.44 (s, 12 H, methyl groups of the aluminium atoms at the bottom of the cluster), −0.36 (s, 12 H, methyl groups of the aluminium atoms of the propynido-bridged face), 1.03 (t, 12 H, $^3J_{HH}$ = 7.3 Hz, CH$_3$ of ethyl), 1.08 (t, 3 H, $^3J_{HH}$ = 7.3 Hz, CH$_3$ of the ethyl group opposite to the bridging propynido group), 1.99 (q, 8 H, $^3J_{HH}$ = 7.3 Hz, CH$_2$ of ethyl), 2.07 (q, 2 H, $^3J_{HH}$ = 7.3 Hz, CH$_2$ of the ethyl group opposite to the bridging propynido group), 2.41 (s, 3 H, CH$_3$ of the propynido ligand). − ^{13}C NMR ([D$_8$]THF, 125.8 MHz, 300 K): δ = −8.9 and −7.7 (AlMe), 8.8 (CH$_3$ of the propynido ligand), 17.5 (cluster carbon atom opposite to the bridging propynido ligand), 21.5 (remaining cluster carbon atoms), 23.5 (CH$_3$ of ethyl), 24.1 (CH$_2$ of ethyl opposite to the propynido bridge), 24.3 (CH$_3$ of the ethyl group opposite to the propynido bridge), 25.0 (CH$_2$ of ethyl)*, 88.2 (bridging C of the C≡C triple bond), 162.3 (β-C of C≡C triple bond); *obscured by solvent signal. − ^{27}Al NMR: See Table 1. − IR (CsBr, paraffin): ṽ = 2019 m, 2010 m (νC≡C, splitting possibly caused by Fermi resonance) 1460 vs, 1377 vs (paraffin) 1322 s, 1186 vs, 1082 m, 1067 m, 1031 vs, 879 vs, 788 m (νCC, δCH$_3$), 663 vs [br. νAlC(Me)] 437 m, 402 w, 344 w (νAlC). − $C_{26}H_{54}Al_8$ (582.6): calcd. Al 37.1; found Al 37.2.

Synthesis of Et$_2$Al−C≡C−Me:[19] A mixture of *n*-butyllithium (15.0 mL, 1.6 M solution in *n*-hexane, 24.0 mmol) and *n*-pentane (20 mL) was cooled to −70 °C. Dried (P_4O_{10}) gaseous propyne was then passed over the solution for half an hour. A colourless solid precipitated. The resulting suspension was allowed to warm to room temperature and stirred until the gas evolution had ceased. A solution of diethylaluminium chloride (2.601 g, 21.6 mmol, 0.9 equiv.) in *n*-pentane (20 mL) was then added dropwise at room temperature. The mixture was stirred for 1 h and filtered. The solvent was removed in vacuo and the oily residue was employed directly for further reactions without purification. Yield: 1.955 g (73% based on Et$_2$AlCl). − ^{1}H NMR (C_6D_6, 300 MHz, 300 K): δ = 0.43 (q, 4 H, $^3J_{HH}$ = 8.1 Hz, CH$_2$), 1.25 (s, 3 H, C≡C−CH$_3$), 1.39 (t, 6 H, $^3J_{HH}$ = 8.1 Hz, CH$_3$ of ethyl). − ^{13}C NMR (C_6D_6, 75.5 MHz, 300 K): δ = 2.4 [AlC(Et)], 5.3 (CH$_3$ of propyne), 9.6 (CH$_3$ of ethyl), 86.3 and 134.5 (C≡C). − ^{27}Al NMR (C_6D_6, 104.3 MHz, 300 K): δ = 146 ($W_{1/2}$ = 4000 Hz). − IR (CsBr, paraffin): ṽ = 2149 s, 2101 vs (νC≡C), 1463 vs (paraffin), 1407 s, 1393 s (δCH$_3$), 1375 s (paraffin) 1303 vw, 1227 w, 1194 w, 1167 w, 1101 w, 1056 s, 988 vs, 974 sh, s, 951 s, 919 m, 899 s, 868 m, 808 m, (br. νCC, δCH$_3$) 656 vs (br. νAlC), 541 s, 469 sh, s, 406 s, br., 346 s, 312 m (νAlC, δCC).

Synthesis of *i*Pr$_2$Al−C≡C−Me: A solution of *n*-butyllithium (15.6 mL, 1.6 M in *n*-hexane, 25.0 mmol) and *n*-hexane (20 mL) was cooled to −70 °C. Dried (P_4O_{10}) gaseous propyne was passed over the solution for half an hour. A colourless solid precipitated. The mixture was then allowed to warm to room temperature and stirred until the gas evolution (butane, excess propyne) had ceased. A solution of diisopropylaluminium bromide (4.568 g, 23.7 mmol, 0.95 equiv.) was then added dropwise at room temperature. The resulting suspension was stirred for 3 h, then filtered, and all volatile components were removed from the filtrate in vacuo. The waxy residue was employed without further purification. Yield: 2.179 g (61% based on *i*Pr$_2$AlBr). − ^{1}H NMR (C_6D_6, 200 MHz, 300 K): δ = 0.76 (septet, 2 H, $^3J_{HH}$ = 7.5 Hz, AlCH), 1.32 (s, 3 H, C≡C−CH$_3$), 1.41 (d, 12 H, $^3J_{HH}$ = 7.5 Hz, CH$_3$ of isopropyl). − ^{13}C NMR (C_6D_6, 50.3 MHz, 300 K): δ = 5.9 (CH$_3$ of propyne), 12.1 [br., AlC(*i*Pr)], 21.1 (CH$_3$ of isopropyl), 136.8 (C≡C); only one resonance of the C≡C triple bond was detected. − ^{27}Al NMR (C_6D_6, 104.3 MHz, 300 K): δ = 138 ($W_{1/2}$ = 5000 Hz). − IR (CsBr, paraffin): ṽ = 2149 w, 2098 vs (νC≡C), 1461 vs, 1377 vs (paraffin), 1305 w, 1261 m, 1206 w, 1169 sh, w, 1120 m, 1055 s, 1028 sh, m, 972 s, 957 s, 910 w, 873 s, 835 w, 801 m, (br. νCC, δCH$_3$), 723 m,

Reaction of *i*Pr$_2$Al−H with *i*Pr$_2$Al−C≡C−Me: Diisopropylpropynylaluminium (1.090 g, 7.17 mmol) was treated with diisopropylaluminium hydride (3.466 g, 30.4 mmol) and the resulting mixture was heated to 50 °C for 18 h. In order to distil off triisopropylaluminium, the mixture was heated in vacuo to 80 °C for 2 h. The oily, light-yellow residue was treated with diisopropyl ether. After filtration, the solution was cooled to −70 °C to furnish a small quantity of a colourless solid (**7**) after several weeks. Yield: <1%. − ^{1}H NMR (C_6D_6, 500 MHz, 300 K, the numbering scheme is given in Scheme 2): ethyl groups at C-1 and C-2: δ = 1.19 (t, 6 H, $^3J_{HH}$ = 7.4 Hz, CH_3)*, 2.18 (q, 4 H, $^3J_{HH}$ = 7.4 Hz, CH_2); ethyl groups at C-3 and C-4: δ = 1.19 (t, 6 H, $^3J_{HH}$ = 7.4 Hz, CH_3)*, 2.18 (q, 4 H, $^3J_{HH}$ = 7.4 Hz, CH_2); isopropyl groups at Al-1 and Al-2: δ = 0.90 (m, 2 H, $^3J_{HH}$ = 7.7 Hz, AlCH), 1.46 (d, 12 H, $^3J_{HH}$ = 7.7 Hz, CH_3); isopropyl groups at Al-3, Al-4, Al-5, and Al-6: δ = 0.85 and 0.95 (2 m, each 2 H, $^3J_{HH}$ = 7.7 Hz, AlCH), 1.37 and 1.38 (2 d, each 12 H, $^3J_{HH}$ = 7.7 Hz, CH_3); isopropyl group at Al-7: δ = 0.46 (septet, 1 H, $^3J_{HH}$ = 7.7 Hz, AlCH), 1.41 (d, 6 H, $^3J_{HH}$ = 7.7 Hz, CH_3); 4.53 (s, 2 H, AlH) (*assignments may be interchanged). − ^{13}C NMR (C_6D_6, 125.8 MHz, 300 K): ethyl groups at C-1, C-2, C-3, and C-4: δ = 21.2 and 23.1 (CH_2), 23.9 and 25.3 (CH_3); cluster carbon atoms C-1 to C-4: δ = 18.0 and 27.0; isopropyl groups at Al-1 and Al-2: δ = 13.0 or 13.3 (AlC, uncertain), 21.0 (CH_3); isopropyl groups at Al-3, Al-4, Al-5, Al-6: δ = 6.2 and 10.3 (AlC), 21.6 and 21.8 (CH_3); isopropyl group at Al-7: δ = 9.8 (AlC), 21.7 (CH_3). − ^{27}Al NMR: See Table 1.

Synthesis of (Me$_3$C)$_2$Al−C≡C−Me: Li−C≡C−Me was synthesized as described above (5.3 mL of a 1.6 M solution of *n*-butyllithium in *n*-hexane, 8.48 mmol). A solution of bis(*tert*-butyl)aluminium chloride (1.490 g, 8.44 mmol) in *n*-hexane (20 mL) was added and the mixture was stirred at room temperature for 3 h. After filtration and concentration, a colourless solid was obtained upon cooling the solution to −30 °C. The product was further purified by recrystallization from *n*-hexane. Yield: 1.172 g (77%, based on *t*Bu$_2$AlCl); m.p. (argon, sealed capillary): 96 °C (dec.). − ^{1}H NMR (C_6D_6, 200 MHz, 300 K): δ = 1.31 (s, 18 H, CMe_3), 1.49 (s, 3 H, C≡C−CH_3). − ^{13}C NMR (C_6D_6, 100.6 MHz, 300 K): δ = 5.6 (CH_3 of propyne), 18.4 [br., AlC(*t*Bu)], 31.8 (CH_3 of *tert*-butyl), 135.6 (C≡C); only one resonance of the C≡C triple bond was detected. − ^{27}Al NMR (C_6D_6, 104.3 MHz, 300 K): δ = 130 ($W_{1/2}$ = 5000 Hz). − IR (CsBr, paraffin): $\tilde{\nu}$ = 2092 vs, 2058 w, 2047 w (νC≡C), 1464 vs, 1378 vs (paraffin), 1308 m, 1262 m, 1178 m, 1127 w, 1043 m, 1002 s, 966 s, 939 s, 891 w, 846 w, 812 vs (νCC, δCH$_3$), 722 s, 663 vw, 631 w, 587 vs (νAlC), 541 s, 442 vs, 418 vs, 356 vs (νAlC, δCC).

Crystal Structure Determinations: Single crystals of compounds **5** and **6** were obtained by very slow concentration of solutions in THF at room temperature over several weeks. Crystal data and structure refinement parameters are given in Table 2.[22] The carbon atoms of the THF molecules and one ethyl group (C-31, C-32) of compound **5** showed a disorder; these atoms were refined in split positions. Compound **6** is severely disordered and the propynido group is distributed over all six faces of the cluster.

Quantum Chemical Calculations: The structures of the carbaalanes **1** (with Al = AlMe and R = CCPh as well as H, respectively), **2**, **3** (with Al = AlMe and AlEt, respectively), **4**, and **6** were optimized at the density-functional theory (DFT) level[23] employing the Becke−Perdew (BP86) functional[24] together with an auxiliary basis set approximation for the Coulomb energy (RI-DFT).[25] A polarized split-valence basis SV(P)[26] was used in all calculations, with the parentheses indicating that polarization functions have been considered only for non-hydrogen atoms as well as the hydrogen bonds.

^{27}Al NMR chemical shifts were computed employing the gauge-including atomic orbital (GIAO) Hartree−Fock self-consistent-field (HF-SCF) method[27] using a polarized double-zeta (dzp) basis[28] for Al, C, and F and a DZ basis for all nonbridging hydrogen atoms. Relative shifts were obtained with $[AlH_4]^-$ as an internal reference and a δ(^{27}Al) value for $[AlH_4]^-$ of δ = 101 [28] (the absolute shielding computed for $[AlH_4]^-$ at the GIAO-HF-SCF/dzp level is 517.1 ppm). For the parent system of **5** (all ethyl and methyl groups replaced by hydrogens), the accuracy of the calculated shifts was checked in GIAO-HF-SCF calculations using a larger polarized triple-zeta (TZP) basis,[26] as well as in electron-correlated calculations using second-order Møller−Plesset perturbation theory, i.e. GIAO-MP2.[29] According to these calculations, the accuracy of the computed shift can be estimated to be in agreement with previous ^{27}Al NMR chemical shift calculations on aluminium cluster compounds within δ = 20−30.[13,14] All calculations were carried out with the TURBOMOLE program package.[30]

Structural Investigations of Sulfite-Bridged Binuclear Complexes of Platinum(II) and Palladium(II)

Roland Krieglstein,[a] Dietrich K. Breitinger,*[a] and Günther Liehr[a]

Keywords: Palladium / Platinum / O,S ligands / Structure elucidation / Vibrational spectroscopy

Although analogous platinum(II) and palladium(II) compounds usually show similar chemical behaviour, different reaction products have been obtained on reaction of ethane-1,2-diamine bissulfitometallates(II) with the diaqua ethane-1,2-diamine metal(II) complexes of Pt and Pd. – The crystal structures of bis(μ-sulfito-1κS:2κO)bis[(ethane-1,2-diamine)-platinum(II)] trihydrate $[(en)Pt(SO_2O)_2Pt(en)]\cdot 3\,H_2O$ (**1**) with parallel μ-(S:O) sulfite bridges, and of bis[(ethane-1,2-diamine)-μ-(S:O)-sulfitopalladium(II)] trihydrate $[(en)Pd(SO_2O)(OO_2S)Pd(en)]\cdot 3\,H_2O$ (**2**) with antiparallel bridges, have been determined by single-crystal X-ray structure analyses. In both compounds the complex units are held together mainly by a complicated network of hydrogen bonds including the hydrate water molecules. – In contrast to the complex molecules in **1** with parallel bridges, the complex units of **2** possess an inversion centre. As a result the mutual exclusion rule reduces the number of bands in each of the vibrational spectra of **2** to half that in the spectra of **1**. This effect is most clearly seen in the number of the valence vibrations $\nu(MN_2)$; the Raman spectrum of **1** displays four relatively strong bands, whereas the Raman spectrum of **2** shows only two, as expected. Further, features of the vibrational spectra are in agreement with the findings of the crystal and molecular structures. Thus, the *trans*-influence exerted by the *S*-coordinated sulfites onto the M–N bonds in the *trans*-position induces a significant lengthening and weakening of these bonds relative to the M–N bonds *trans* to oxygen. In the Raman spectrum of **1** the valence vibrations of the PtN_2 group *trans* to sulfur are clearly lowered in frequency.

Introduction

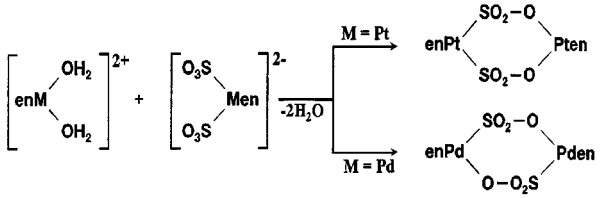
Our group has been involved with the syntheses, crystal structures, and vibrational spectra of the sulfito complexes of the platinum-group metals for some time. In these studies particular attention has been paid towards the effects of the *trans*-influence of the sulfite ligands.

It has been shown by X-ray structure analysis and vibrational spectroscopy that the anions in the compounds $K_2[M^*(SO_3)_2]$ (M* = Pd and Pt) are coordination polymers in which the metal atoms are connected by pairs of sulfite groups forming parallel μ-(S:O) bridges.[1,2]

After the preparation of a non-polymeric trinuclear cobalt complex with triple parallel μ-(S:O) bridges,[3] it seemed feasible to form related dinuclear sulfite-bridged complexes of the platinum-group metals involving the isolated repeat units in the above mentioned coordination polymers. A possible synthetic pathway would be the condensation of the cation *cis*-$[L_2M^*(OH_2)_2]^{2+}$ and the anion *cis*-$[L_2M^*(SO_3)_2]^{2-}$ to yield the neutral complex $[L_2M^*(SO_2O)_2M^*L_2]$. It was not possible to use a complex with $L = NH_3$ as a terminating ligand for this purpose (as in the case of the above cobalt complex), since it was previously found that the anion *cis*-$[Pd(SO_3)_2(NH_3)_2]^{2-}$ undergoes *cis*-*trans*-isomerisation in aqueous solution.[1a] Hence, the chelating ligand ethane-1,2-diamine (en), which prevents this rearrangement, was chosen as terminating ligand. The preparation of the complexes $[(en)M^*(OH_2)_2]^{2+}$ and $[(en)M^*(SO_3)_2]^{2-}$ are well-documented (see ref.[4]).

Based on limited IR[5] and Raman spectra,[6] the existence of a palladium complex with antiparallel double sulfite bridges has already been suggested.

Although analogous platinum and palladium compounds usually show similar chemical behaviour in their reactions of the aqua complexes $[(en)M^*(OH_2)_2]^{2+}$ with the disulfitometallates $[(en)M^*(SO_3)_2]^{2-}$, different final reaction products are obtained. For M* = Pt, the complex bis(μ-sulfito-1κS:2κO)bis[(ethane-1,2-diamine)platinum(II)] trihydrate $[(en)Pt(SO_2O)_2Pt(en)]\cdot 3\,H_2O$ (**1**) with parallel bridges is formed, and for M* = Pd, the species bis[(ethane-1,2-diamine)-μ-(S:O)-sulfitopalladium(II)] trihydrate $[(en)Pd(SO_2O)(OO_2S)Pd(en)]\cdot 3\,H_2O$ (**2**) with antiparallel bridges is formed (see Scheme 1).



Scheme 1

Results and Discussion

Crystal Structure Analyses

Both complexes **1** and **2** could be obtained as single crystals by recrystallisation from aqueous media, under care-

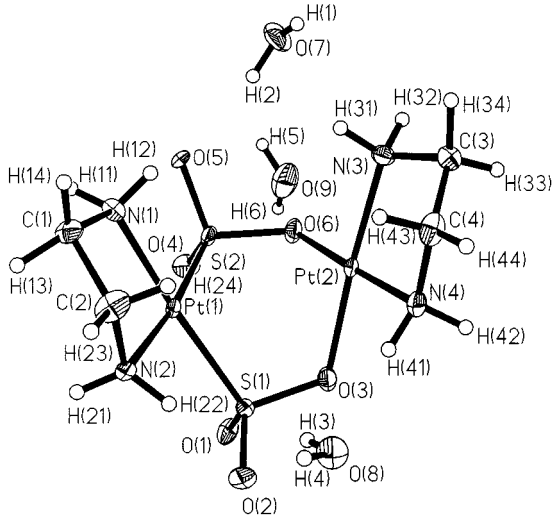

Figure 1. ORTEP plot of the dinuclear complex unit of **1**

fully controlled conditions (see Exp. Sect.). Table 4 lists the relevant crystallographic data.

Figure 1 shows the molecular structure of the dinuclear complex unit of **1**, including one set of the three independent water molecules.

Bond lengths and angles for both compounds are presented in Table 1 and Table 2.

All bond lengths and angles in the complex unit $[(en)Pt(SO_3)_2Pt(en)]$ of **1** (with no crystallographically imposed symmetry) are as expected. Thus, the chemically equivalent Pt−N bonds in each of the two different chelate rings, as well as the chemically equivalent Pt−S and Pt−O bonds are the same within their e.s.d's. However, the averaged Pt(1)−N bonds [$\bar{r}$ = 2.09(1) Å] are significantly longer than the Pt(2)−N bonds [$\bar{r}$ = 2.02(1) Å], clearly showing the differences in the *trans*-influence of sulfite when coordinated through sulfur and oxygen. Further, the angles N−Pt(1)−N [81.9(4)°] and N−Pt(2)−N [84.2(5)°] deviate substantially from 90°. This is also suggested by the sequences $\nu_s > \nu_{as}$ of the valence frequencies of the two PtN_2 entities in the Raman spectrum of **1**.[7]

The S(1)−O(3) and S(2)−O(6) bonds, which form part of the sulfite bridges in **1**, are clearly longer [$\bar{r}$ = 1.533(8) Å] relative to the four terminal S−O bonds [$\bar{r}$ = 1.468(9) Å], which do not deviate significantly from each other. This is similar to the findings in the structure of $K_2[Pd(SO_3)_2]\cdot H_2O$.[1b] The bonding data of these μ-(S:O) bridging sulfite ligands are similar to those in the less precisely determined structure of a dinuclear organometallic complex $[Pt_2(\mu\text{-}SO_3)(\mu\text{-}SO_2)(COD)_2]$ (COD = cycloocta-1,5-diene).[8]

Both μ-(S:O)-bridged platinum atoms display an approximately square-planar environment comprising pairs of nitrogen atoms *cis* to one another, and pairs of sulfur and oxygen atoms at Pt(1) and Pt(2), respectively. The five atoms in each of these groups deviate from the respective least-squares plane by a maximum of 0.099 Å for the $Pt(1)N_2S_2$ group, and by a maximum of 0.025 Å for the $Pt(2)N_2O_2$ group (see Table 3).

The central ring $Pt(1)(S-O)_2Pt(2)$ in **1** adopts a boat conformation in contrast to the chair conformation in **2**.

In **1** two molecules are arranged around an inversion centre such that their Pt(2) atoms are 3.0441(9) Å apart (Figure 2). This is a remarkably short distance. The conformations of the two en ligands within one molecule are different. However, due to the inversion centre between the two molecules, their symmetry-related en-rings adopt δ- and λ-conformations, respectively.

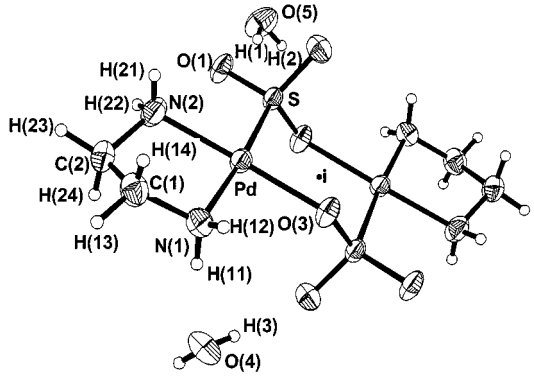

Figure 3. ORTEP plot of the dinuclear complex unit of **2**

Table 3. Deviation from the least-square planes through the metal atoms and their environments in **1** and **2**

$Pt(1)N_2S_2$ plane of **1**		$Pt(2)N_2O_2$ plane of **1**		PdN_2SO plane of **2**	
Pt(1)	−0.049(3)	Pt(2)	−0.025(4)	Pd	0.021(1)
N(1)	0.099(4)	N(3)	0.016(5)	N(1)	0.045(2)
N(2)	−0.072(4)	N(4)	−0.004(5)	N(2)	−0.053(2)
S(1)	0.083(4)	O(3)	0.016(5)	S	0.037(1)
S(2)	−0.061(4)	O(6)	−0.003(5)	O(3)	−0.050(2)

The above-mentioned short intermolecular Pt···Pt distance may suggest that metal-to-metal interactions could contribute to the cohesion of the molecules in the lattice. Square-planar complexes of d^8-metals that are stacked in columns or chains, with overlapping d_{z^2} orbitals, are well-known. Thus, chain-structured Krogmann salts (obtained by partial oxidation of $K_2[Pt(CN)_4]$) show Pt−Pt distances between 2.87 and 2.96 Å, in comparison with the distance of 2.78 Å in platinum metal.[9] In the structure of **1** there are no such chain-like arrangements, but only isolated pairs of close Pt atoms in antiparallel (inversion correlated) N_2PtO_2 groups. A situation similar to that in **1** is found in $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2]CO_3{\cdot}2\,H_2O$, where an intermolecular metal-to-metal distance of 3.167(1) Å is found.[10] In this case, the authors precluded attractive interactions between the platinum atoms, since they deviate from the least-squares planes, containing the atoms coordinated to the Pt atoms, such that the Pt···Pt distance increases. Consequently, the cohesion within a pair of complex units is attributed to four hydrogen bonds N−H···O.

Similarly, in **1** the platinum atom Pt(2) is shifted from the least-squares plane through the ligand atoms N(3), N(4), O(3) and O(6) by 0.031(5) Å, such that the Pt···Pt distance increases again. Once more, four hydrogen−bonds, N−H···O, apparently hold the two molecules together. Although these individual hydrogen−bonds, with O···N distances of 2.98(1) and 2.99(1) Å, and unfavourable bond angles are considered to be weak, their cooperation effects the cohesion in these pairs of molecules.

Thus, a complex network of these hydrogen bonds, and of further hydrogen bonds involving the water molecules, hold the constituents of this crystal structure together.

The remarkably poor stability of the crystals in air under ambient conditions can be attributed to the fewer appropriate partners available for hydrogen bonding with the lattice water molecule $H_2O(9)$. Further, one of the two hydrogen bonds [N(4)···O(9)] with a distance of 2.96(1) Å is weak. These facts are in accordance with the findings of the TGA/DTA analysis of the substance. They show that the loss of just one water molecule per formula unit occurs at a temperature as low as 30 °C; the further loss of two lattice water molecules occurs by about 140 °C.

The molecular structure of **2** is shown in Figure 3. The respective bond lengths and angles are presented in Table 2.

The two palladium centres in **2** are μ-(S:O) bridged by two sulfite groups in an antiparallel arrangement. The coordination around these equivalent Pd atoms is square-planar, with two non-equivalent nitrogen atoms *cis* to one another, one oxygen atom and one sulfur atom. The five atoms deviate from the ideal plane by a maximum of 0.05 Å (see Table 3). The $(Pd-S-O)_2$ ring adopts a chair conformation, in contrast to the central ring in the platinum compound **1** (see above). Since the molecules in **2** are centrosymmetric, their equivalent Pd(en) rings adopt opposite δ- and λ-conformations, respectively. While the oxygen atom O(4) of one lattice water molecule is located on a C_2-axis (Wyckoff 4e), the second water molecule and all the other atoms are distributed on general sites (Wyckoff 8f).

The Pd−N(2) bond [2.019(4) Å] is significantly shorter than Pd−N(1) bond [2.079(4) Å]. It is also shorter than the analogous Pd−N bonds in $Na_2[Pd(SO_3)_2en]\cdot 4\,H_2O$ [2.084(2) Å].[11] Both these examples serve to emphasise the effect of the *trans*-influence of the sulfite ligands, albeit to a different extent (dependent on the total charge and coordination mode). As discussed for **1**, this is as a result of the lower *trans*-influence of the bridging oxygen atom, as compared with sulfur, on the Pd−N(2) bond in the position *trans* to it.

The influence of the ligand in the *trans*-position also affects the Pd−O bond. Here, this bond, with the less efficient nitrogen atom *trans* to it, is significantly shorter [2.043(3)

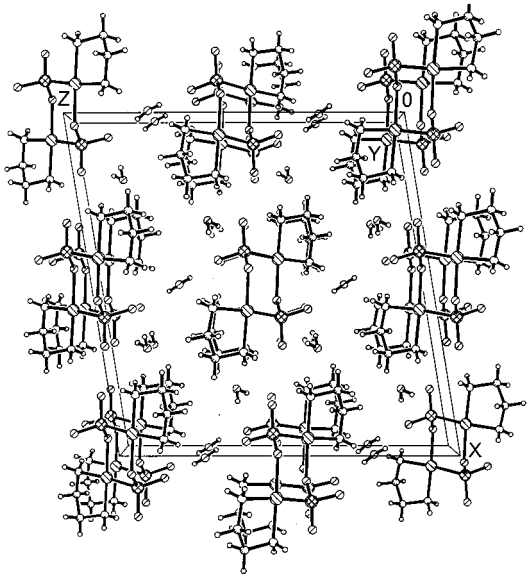

Figure 4. Molecular packing in the crystal structure of **2**

Å] than that in $K_2[Pd(SO_3)_2]\cdot H_2O$ where a sulfur atom is in the *trans*-position [2.121(3) Å].[1b]

As expected, the Pd−S bond in **2** is clearly shorter [2.229(1) Å] than that in the complex $Na_2[Pd(SO_3)_2(en)]\cdot 4\,H_2O$ [2.269(1) Å],[11] involving monodentate *S*-coordinated sulfite ligands in an anionic complex species. After the bond-valence approach,[12] weakening of one bond causes an increase of the bond orders and hence the decrease of the bond lengths in adjacent bonds. Thus, lowering of the bond order on going from almost S−O double bonds in $Na_2[Pd(SO_3)_2(en)]\cdot 4\,H_2O$ to S−O single bonds in the sulfite bridges of **2**, leads to the shortening of the Pd−S bonds. In $K_2[Pd(SO_3)_2]\cdot H_2O$, with bidentate bridging sulfite ligands, the Pd−S bonds are similarly short [2.241(1) Å].[1b]

The overall arrangement of the chair-shaped molecules in the crystal lattice of **2** is such that the hydrophilic regions of the complexes (NH_2 and SO_2 groups) approach each other. Thus, a complicated network of hydrogen bonds between these hydrophilic segments of the dinuclear complex units, and between the complexes and water molecules can be formed. Also, the intermolecular distances between the hydrophobic parts of the complexes (CH_2 groups) are short (see Figure 4).

Spectrometry

UV/Vis Spectra: The reaction between $[Pd(en)(OH_2)_2]^{2+}$ and $[Pd(SO_3)_2(en)]^{2-}$ was followed by UV/Vis spectrometry (see Figure 5). However, from the spectra it is not certain whether the dinuclear complex $[(en)Pd(SO_2O)_2Pd(en)]$ is formed first, followed by the isomerisation to $[(en)Pd(SO_2O)(OO_2S)Pd(en)]$, or whether the mononuclear complex $[(en)Pd(SO_3)(H_2O)]$ is formed (generated by the partial dissociation of the anion and recoordination of the released sulfite to the cation), which condenses prior to the crystallisation of **2**.

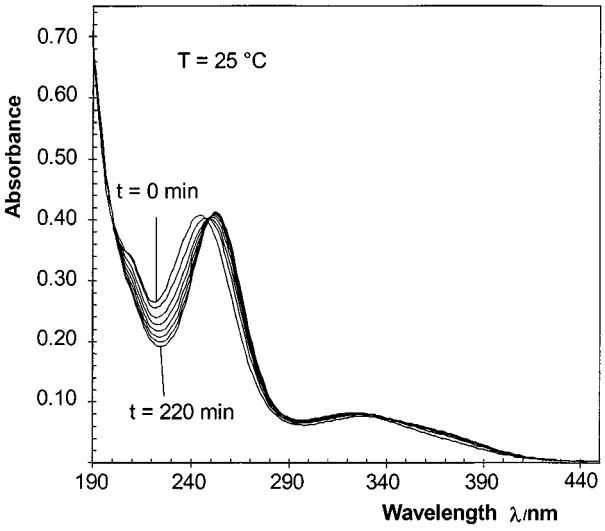

Figure 5. Time-dependent UV spectra of the reaction mixture yielding **2**

IR and Raman Spectra: The molecule of **2** (crystallographic symmetry $\bar{1}$ − C_i) has an inversion centre, in contrast to the complex unit in **1** on a general position. As a result, the mutual exclusion rule reduces the number of bands in each of the vibrational spectra of **2** to one half of that in **1**, i.e. both IR and Raman spectra of **2** are simpler. This fact is most clearly seen in the region of the valence vibrations $\nu(MN_2)$. Thus, the Raman spectrum of **1** displays four rather strong bands [two interpenetrating $\nu_s(MN_2)$/$\nu_{as}(MN_2)$ doublets] around 500 cm^{-1}, whereas the spectrum of **2** shows only two bands (see Figure 6). With respect to the differences in the Pt−N bond lengths at Pt(1) and Pt(2) (*trans*-influence), the higher doublet (574/490 cm^{-1}) is assigned to the valence vibrations of the $Pt(2)N_2$ group *trans* to oxygen and the lower one (517/442 cm^{-1}) to the $Pt(1)N_2$ fragment *trans* to sulfur. Since the angles in both PtN_2 groups are substantially smaller than 90° [81.9 and 84.2° at Pt(1) and Pt(2), respectively], the frequency sequence of their valence vibrations is always $\nu_s(PtN_2) > \nu_{as}(PtN_2)$ (cf. the reasoning in ref.[7]).

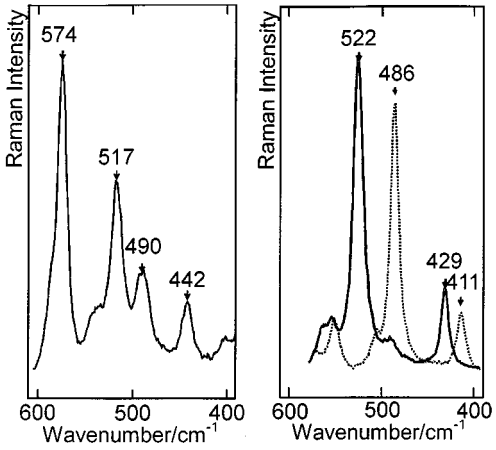

Figure 6. Raman spectra of the $\nu(MN_2)$ ranges of **1** (left), and of **2** (right) and its N-deuterated isotopomer (dotted)

In the IR spectra the result of these structural features are by far less obvious since the valence vibrations $\nu(MN_2)$ are weak. Further, these vibrations are obscured by the complex system of intense bands originating from the splitting of the deformation vibrations $\delta_{as}(SO_3)$ by the present bonding mode, with concomitant symmetry lowering, and by correlation coupling. In addition, librational modes of the three different water molecules contribute to the complexity of this spectral region. The special bonding mode also leads to three regions of valence vibrations $\nu(SO_3)$; $\nu_{as}(SO_2)$ (coarsely around 1150 cm^{-1}), $\nu_s(SO_2)$ (1050 cm^{-1}) and ν(SO) (ca. 900 cm^{-1}); for details see ref.[7] The latter vibrations are very strong in both the IR and Raman spectra of **1** and **2.** However, the bands of the SO_2 fragments are strong and broad in the IR spectra, but are of different intensity in the Raman spectra. It should be mentioned that the valence vibrations ν(CC) and ν(CN), as well as the wagging modes $\omega(NH_2)$ and $\omega(CH_2)$ of the chelate rings are expected to be in the same spectral region. Hence, a definite assignment of all the bands is difficult.

Due to the low solubilities of **1** and **2** in H_2O under ambient conditions, and its almost insoluble nature in common organic solvents, it was not possible to obtain Raman and NMR spectra of solutions.

Conclusion

On reaction of the cations $[(en)M^*(OH_2)_2]^{2+}$ and anions $[(en)M^*(SO_3)_2]^{2-}$, the expected dinuclear complex $[(en)M^*(SO_2O)_2M^*(en)]$ (in **1**) with two parallel μ-(S:O) sulfite bridges really forms in the case of M* = Pt. Thus, the repeat unit $M^*(SO_2O)_2M^*$, previously found in polymeric complexes of the type $K_2[M^*(SO_3)_2]$, is now available in an isolated stabilised form. In the case of M* = Pd, the kinetically labile starting materials probably symmetrise in two steps to form $[(en)Pd(SO_3)(OH_2)]$, prior to the condensation to the dinuclear unit $[(en)Pd(SO_2O)(OO_2S)Pd(en)]$ (in **2**) with antiparallel μ-(S:O) sulfite bridges. Seemingly, the latter is the thermodynamically controlled product, whereas in the reaction of the inert platinum(II) complexes the kinetically controlled product is formed.

These findings also raise the question of the existence of coordination polymers $^1_\infty[M^*(SO_2O)(OO_2S)]^{2-}$, with these antiparallel bridged repeat units, and also of polymers with counter-current bridges of each type, for instance $^1_\infty[M^*(SO_2O)_2M^*(OO_2S)_2]^{4-}$.

The molecular structures clearly reveal the differences of the *trans*-influence of S- and O-coordinated sulfite ligands in the same complex species. These differences and the different symmetries (non-centrosymmetric **1** vs. centrosymmetric **2**) also imprint the vibrational spectra.

Experimental Section

General Remarks: Elemental analyses for C, H, N, and S were performed using the analyser Carlo Erba Model 1108. Platinum and palladium were determined as residues after simultaneous TGA/DTA runs using the thermal analyser TA Instruments Model SDT 2960 (reference Al_2O_3).

Time-dependent UV/Vis spectra were scanned using the spectrometer HP 8452 A.

IR spectra on KBr pellets were taken with the FTIR spectrometer ATI Mattson Infinity controlled by the soft-ware package WinFirst 3.0.

Raman spectra of the pure substances in capillaries, excited with a Spectra Physics Stabilite 2014 Ar^+ laser (514.5 nm, 100 to 150 mW), were recorded using the spectrometer DILOR XY (multichannel detection) controlled by the software system XY 2.0.

X-ray structure determinations were performed with data sets collected on a four-circle diffractometer Enraf−Nonius CAD4 Mach 3, after the determination of the space groups on the basis of Weissenberg photographs. Details of the data collections for the compounds **1** and **2** are compiled in Table 4. The structures were solved with Patterson techniques and refined on F^2 using the program SHELX97.[13] In the last step of the structure refinement of **1**, the H atoms were considered with restraints for the bond lengths r(O−H), r(N−H), and r(C−H) (0.85, 0.90, and 0.96 Å, respectively), and for the bond angles in H_2O and in the H_2N groups (107 and 109°, respectively). The isotropic displacement factors of the H atoms were taken as the 1.2-fold of the equivalent U_{eq} values of the respective neighbouring atoms O, N, and C. In the case of **2** the H atoms were included in the refinement without restraints and with individual isotropic displacement factors, with the exception of the H_2O molecules (restraints 0.85 Å and 107°). − Due to the instability and the strong absorption of **1**, its structure is less accurate than that of **2**.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-148274 and CCDC-148275. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

$[(en)Pt(SO_2O)_2Pt(en)]\cdot 3\,H_2O$ (1): $[PtCl_2(en)]$ (0.326 g, 1.00 mmol) was dissolved in 10 mL of H_2O whilst heating. After cooling to about 30 °C, $AgNO_3$ (19.9 mL of a 0.1 M solution, 1.99 mmol) was added. The mixture was stirred at room temperature in the dark for at least 8 h in order for the reaction to reach completion. The precipitated AgCl was then filtered off and washed twice with 10 mL of H_2O. The combined filtrates must be completely clear and colourless. The resulting solution of $[Pt(en)(OH_2)_2]^{2+}$ was combined with a solution of $K_2[Pt(SO_3)_2(en)]\cdot 2\,H_2O$[4] (0.519 g, 0.980 mmol) in 10 mL of H_2O and kept in a refrigerator for 3 h. The reaction product deposited as a lemon-yellow, microcrystalline precipitate. To complete precipitation, 200 mL of acetone was added; the product was filtered off, washed with 20 mL of acetone, dried in an air flow, and recrystallised from 15 mL of boiling water. Yield: 0.415 g (0.587 mmol), 60.0% of the dihydrate. − $C_4H_{20}N_4O_8S_2Pt_2$: calcd. C 6.80, H 2.85, N 7.93, S 9.08, Pt 55.22; found C 7.03, H 2.77, N 7.75, S 8.82, Pt 56.4.

In order to grow single crystals, about 200 mg of the compound was dissolved in 8 to 10 mL of hot H_2O. This solution was placed in an appropriate vial and put into a well-isolated Dewar flask, so that slow cooling could take place over several days; after about a week lemon-yellow crystal platelets of the trihydrate **1**, with edge lengths of 0.2 to 1.0 mm had grown. − $C_4H_{22}N_4O_9S_2Pt_2$: calcd. C 6.63, H 3.06, N 7.73, S 8.85, Pt 53.76; found C 6.72, H 2.87, N 7.70, S 8.64, Pt 55.2.

$[(en)Pd(SO_2O)(OO_2S)Pd(en)]\cdot 3\,H_2O$ (2): $[PdCl_2(en)]$ (0.2373 g, 1.000 mmol) was dissolved in 10 mL of boiling H_2O; after cooling

The Hydrothermal Synthesis, Crystal Structures and Thermal Stability of the Novel One- and Two-Dimensional Thioantimonate(III) Compounds $[Co(tren)]Sb_2S_4$ and $[Ni(tren)]Sb_2S_4$

Ralph Stähler[a] and Wolfgang Bensch*[a]

Keywords: Sulfur / Antimony / Solvothermal synthesis / Crystal structure / Thermoanalytical measurements

Two novel thioantimonate(III) compounds $[Co(C_6H_{18}N_4)]Sb_2S_4$ (**1**) and $[Ni(C_6H_{18}N_4)]Sb_2S_4$ (**2**) were synthesised under solvothermal conditions by reacting the transition metal, Sb and S in a 50% solution of tris(2-aminoethyl)amine (tren). The use of a tetradentate amine yields incompletely shielded transition metal cations which in turn are able to form bonds to the sulfur atoms of thioantimonate(III) anions. Compound **1** crystallises in the orthorhombic space group *Pbca*, a = 13.886(3) Å, b = 11.452(2) Å, c = 20.549(4) Å, V = 3268(1) Å^3, Z = 8 and compound **2** crystallises in the monoclinic space group $P2_1/n$, a = 6.906(1) Å, b = 22.822(5) Å, c = 10.347(2) Å, β = 103.17(3)°, V = 1587.9(6) Å^3, Z = 4. The $^2_\infty[Sb_2S_4^{2-}]$ anion in compound **1** is formed by an SbS_3 and an SbS_4 unit sharing a common corner. Two SbS_4 units have a common edge to form an Sb_2S_2 heterocycle. Four such Sb_2S_2 rings are at the corners of a two-dimensional square-like net. Interconnection of the rings by SbS_3 pyramids yields $Sb_{10}S_{10}$ rings with pores measuring 10·8.4 Å in diameter. The pores are filled by the $[Co(tren)]^{2+}$ cations. The $[Co]^{2+}$ cation is in a trigonal bipyramidal environment of four N atoms of the tren ligand and one S atom of the SbS_3 pyramid. The one-dimensional $^1_\infty[Sb_2S_4^{2-}]$ chain anion in **2** is built by two corner-sharing SbS_3 units. The $[Ni]^{2+}$ cation is in an octahedral environment consisting of four N atoms of the tren ligand and two S atoms of the anion. An $NiSb_2S_3$ heteroring in a twist conformation is formed with an unusually large Ni–S(1)–Sb(1) angle of 121.73(3)°. For the $[Co]^{2+}$ (d^7) cation no significant energy differences can be expected for the trigonal bipyramidal and octahedral coordination, and due to the geometrical requirements of the tetradentate ligand the former environment is preferred. In contrast, for $[Ni]^{2+}$ (d^8) an octahedral environment is energetically favoured over the trigonal bipyramidal arrangement. Both compounds start to decompose under an Ar atmosphere at about 250 °C. For **1** two not well resolved steps are observed, whereas **2** decomposes in one step. In the X-ray powder patterns of the grey products Sb_2S_3, Co/NiSbS and Co/NiS could be identified.

Introduction

Compared to the large number of thioantimonate(III) compounds with A^+ (A = alkali metal), EA^{2+} (EA = earth alkali metal) or organic ammonium cations as charge balancing ions only a few compounds are known in which a transition metal is integrated within the anionic framework of the main group thiometallates. In $[M(NH_3)_6]Cu_8Sb_3S_{13}$ the Cu_8S_{13} cores are linked by Sb atoms resulting in the formation of channels that are occupied by transition metal hexamine complexes.[1] Adamantane-like $[Ge_4S_{10}]^{4-}$ units have been linked by tetrahedral Mn^{II},[2] copper[3] or dimers like $[Ag_2]^+$ and $[Cu_2]^+$.[4] Other examples are copper antimony sulfides prepared at elevated temperatures such as $Cu_{12}Sb_4S_{13}$,[5] Cu_3SbS_4,[6] Cu_3SbS_3,[7–9] $CuSbS_2$,[10] and $[Cu_2SbS_3]\cdot(en)_{0.5}$ synthesised by the solvothermal route.[11] Applying solvothermal conditions it was also possible to incorporate a complex cation $[Co(en)_3]^{2+}$ into a thioantimonate(III) framework.[12] During the last few years we have synthesised and characterised layered thioantimonates(III) with general formula $Mn_2Sb_2S_5\cdot L$ (L = methylamine, ethylamine, 1,3-diaminopropane, *N*-methyl-1,3-diaminopropane and diethylenetriamine) with Mn^{II} being part of the Sb_2S_5 network.[13–15]

For syntheses using elements as starting materials very basic solutions are needed to dissolve and mobilise the elements. Organic amines are useful solvents with high pH values. However, the amines usually coordinate to the transition metal cations (TM^{n+}) preventing their incorporation into the thioantimonate(III) network. A way of enhancing the probability that the TM^{n+} ions are integrated into the thiometallate network is the use of multidentate amines which coordinate the TM^{n+} ion but leave one or two coordination sites free for bonds to the S atoms of the M_xS_y moieties (M = main group element). According to this idea the tetradentate amine tris(2-aminoethyl)amine (tren) seems to be a good candidate: transition metal cations that prefer an octahedral environment are coordinated by the four N atoms of the tren ligand leaving two coordination sites to form bonds to the S atoms of the thiometallate framework. Such ligated $[TM(tren)]^{n+}$ complexes may be described as geometrically constrained structure-directing agents.

Based on these considerations we synthesised and characterised two novel thioantimonate(III) compounds, two-dimensional $[Co(tren)]Sb_2S_4$ and one-dimensional $[Ni(tren)]Sb_2S_4$, both exhibiting new and exciting thioantimonate(III) networks.

Results and Discussion

In the new compound $[Co(tren)]Sb_2S_4$ (**1**) the $[Co]^{2+}$ ion is coordinated by four N atoms of the tren ligand, with Co−N distances ranging from 2.077(2) to 2.263(2) Å (see Table 1) and by one S atom of the $^2_\infty[Sb_2S_4^{2-}]$ anion yielding a trigonal bipyramidal environment (Figure 1). As expected the longer Co−N(1) bond is *trans* to the Co−S(1) bond [distance: 2.3539(7) Å].[14] The $^2_\infty[Sb_2S_4^{2-}]$ anion is built up from the Sb(1) and Sb(2) atoms, each being in a different geometrical environment of S atoms. The Sb(1) atom has bonds to three S atoms [S(1) to S(3)] forming the typical SbS_3 trigonal pyramid. The Sb(1)−S bond lengths are between 2.3899(7) and 2.4655(6) Å, indicating single bonds. The S(1) atom of the $Sb(1)S_3$ pyramid has a bond to the $[Co]^{2+}$ ion and the two other S atoms are bound to the Sb(2) atom. The Sb(2) atom has a shorter bond to S(3) [2.4577(7) Å] and a longer bond of 2.8784(8) Å to S(2a). The environment of Sb(2) is completed by S(4) at a distance of 2.3991(8) Å and the symmetry related S(4b) atom at 2.7084(7) Å yielding an $Sb(2)S_4$ unit. The two long Sb(2)−S distances are longer than expected for single bonds, which usually lie between about 2.4 and 2.6 Å, but they are significantly shorter than the typical so-called secondary bonds with Sb−S distances above about 2.9 Å. The two long Sb(2)−S bonds are in *trans* position to each other [angle: S(2a)−Sb(2)−S(4b): 174.95(2)°]. Taking into account the Sb^{III} $6s^2$ lone pair the environment may be described as distorted trigonal bipyramidal. We note that SbS_4 units are not uncommon and Sb−S distances between 2.4 and 2.85 Å were reported, for example, for $Cs_2Sb_8S_{13}$,[17] $(CH_3NH_3)_2Sb_8S_{13}$,[18] $Cs_5Sb_8S_{18}(HCO_3)$,[19] and $[Fe(C_4H_{13}N_3)_2]Sb_6S_{10}\cdot 0.5H_2O$.[20]

Two $Sb(2)S_4$ units share a common edge to form an Sb_2S_2 heteroring. Four such Sb_2S_2 heterorings are at the corners of a square-like net and are each joined by four $Sb(1)S_3$ pyramids yielding a two-dimensional thioantimonate(III) layer within the *ab* plane (Figure 2). The interconnection of the Sb_2S_2 rings and the pyramids yields large $Sb_{10}S_{10}$ rings with pores having a diameter of 10.19 × 8.388 Å (shaded area in Figure 2) measured between symmetry related Sb(1) atoms. The cavities of the rings are filled by the $[Co(tren)]^{2+}$ cations.

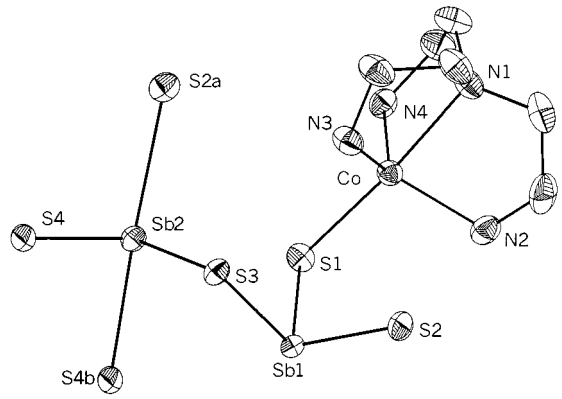

Figure 1. View of the $[Co(tren)]Sb_2S_4$ unit with labelling and displacement ellipsoids drawn at the 50% probability level; the symmetry codes are given in Table 1; hydrogen atoms are omitted for clarity

The layers are stacked parallel to the *c* axis to form channels containing the cations, with H···S contacts between 2.566 and 2.723 Å and angles N−H···S ranging from 150.24 to 164.63° indicating weak hydrogen bonding (Table 2).

The Sb atoms complete their coordination spheres by so-called secondary bonds to S atoms: one contact is observed for Sb(1) [3.6103(8) Å to S(4b)] and one for Sb(2) [3.4765(9) Å to S(1)] (Figure 3: A and B; Table 1). Taking these contacts into account the environment of Sb(1) may be viewed as a ψ-trigonal bipyramid (Figure 3, A) and that of Sb(2) as a distorted ψ-octahedron (Figure 3, B).

In $[Ni(tren)]Sb_2S_4$ the $[Ni]^{2+}$ ion is coordinated by four N atoms of the tren ligand with Ni−N distances ranging between 2.085(2) and 2.115(2) Å (see Table 3) and by two S atoms of the $^1_\infty[Sb_2S_4^{2-}]$ anion, yielding an octahedral coordination (Figure 4). The Ni−N bond lengths lie within the range reported in the literature.[21−23] The Ni−S bond lengths are 2.4306(8) Å for Ni−S(1) and 2.642(1) Å for Ni−S(4). An analysis of the geometry about the cation reveals why the Ni−S(4) distance is elongated: the S(1) and S(4) atoms have neighbouring N atoms at a distance of about 3.2−3.5 Å. A shortening of the Ni−S(4) bond to about 2.4 Å would bring the S(4) atom in closer contact to the N atoms leading to strong repulsive interactions. To avoid these repulsive forces the geometry at the $[Ni]^{2+}$ centre, as well as that of the anion, must be distorted, which is energetically unfavourable.

The thioantimonate(III) anion acts as a bidentate ligand to form an $NiSb_2S_3$ heteroring exhibiting the twist conformation (Figure 4). An interesting feature within the ring is the relatively large Ni−S(1)−Sb(1) angle of 121.73(3)°. In the overwhelming number of cases the angles around the

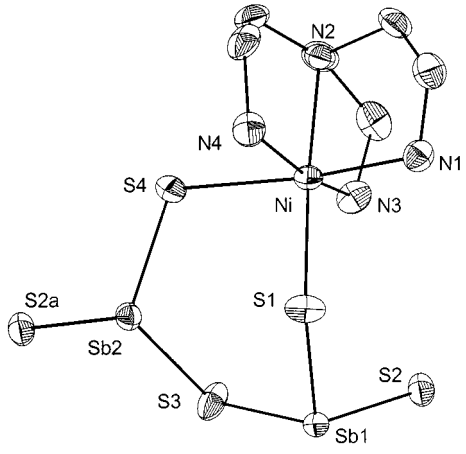

Figure 4. $[Ni(tren)]Sb_2S_4$ with the $NiSb_2S_3$ heteroring, labelling and displacement ellipsoids drawn at the 50% level; the hydrogen atoms are omitted for clarity

S atoms are between about 90 and 110°. For silicates, strong deviations of the Si−O−Si angles from the strain-free angle of about 140° are accompanied by an enhanced isotropic (U_{eq}) and/or anisotropic displacement parameter.[24] For S(1) the U_{eq} is comparable with those of the other atoms, but the U_{11} parameter is more than twice the U_{22} and U_{33} components. However, it should be noted that the U_{22} of S(3) is also large despite a relatively "normal" Sb(1)−S(3)−Sb(2) angle of 98.34(3)°, hence a straightforward relationship as for silicates is not obvious, and a rigorous analysis of many such thioantimonates(III) is required to establish such a relationship.

The anionic part of the structure, $^1_\infty[Sb_2S_4^{2-}]$, is composed of two corner-sharing SbS_3 pyramids formally yielding an Sb_2S_5 unit. The Sb−S distances are between

2.3549(8) and 2.486(1) Å, typical for single bonds. The Sb_2S_5 unit is interconnected via the S(2) atom into one-dimensional chains running parallel to the *a* axis (see Figure 5). These chains are arranged in a simple hexagonal rod packing. The coordination sphere of Sb(2) is completed by a secondary bond to S(1) of 3.405(1) Å forming a distorted ψ-trigonal bipyramid (Figure 3, C; Table 3). For the Sb(1) atom no S atoms are found at distances less than 4 Å. Three short intermolecular H···S distances (Table 2) with distances ranging from 2.594 to 2.834 Å and N−H···S angles between 146.62° and 166.86° are observed, which may indicate weak hydrogen bonding.

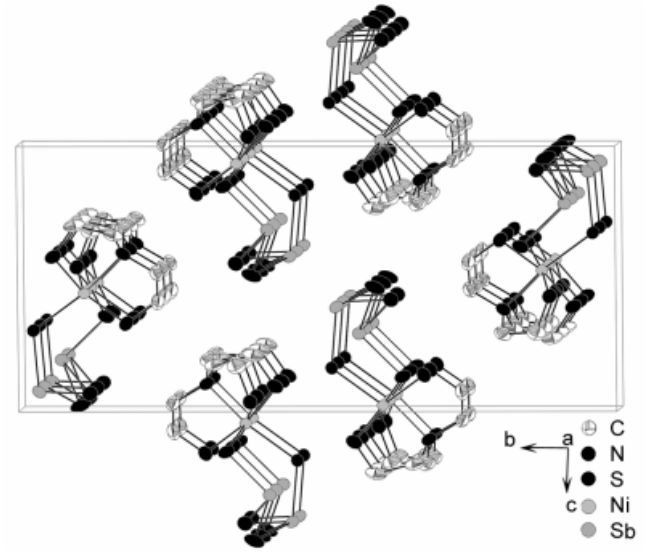

Figure 5. Crystal structure of [Ni(tren)]Sb_2S_4 viewed along [100]; the probability ellipsoids are drawn at the 50% level; hydrogen atoms are omitted for clarity

The $[Co]^{2+}$ cation has a d^7 electronic configuration. Simple considerations suggest that the energy differences between the trigonal bipyramidal and octahedral coordination should be negligible. Therefore, it can be assumed that the geometrical requirements of the tetradentate ligand force the formation of the trigonal bipyramidal environment. For $[Ni]^{2+}$, with a d^8 electronic configuration, the octahedral environment is energetically favoured over the trigonal bipyramidal arrangement.

Thermal Investigations

[Co(tren)]Sb_2S_4: The DTA-TG curve is shown in Figure 6. Decomposition starts at T_{onset} = 262 °C. A weight loss occurs in two steps on heating. These steps are accompanied by two strong endothermic signals in the DTA curve with peak temperatures T_p = 270 °C and T_p = 295 °C. The total loss of weight amounts to $-\Delta m_{1+2}$ = 23.8% ($-\Delta m_1$ = 15.8%, $-\Delta m_2$ = 8%). If the tren ligand is extruded during thermal decomposition a value of $-\Delta m_{theo(tren)}$ = 25.3% is expected. C, H and N were all found in the grey residue (C: 0.4%; H: 0.5%; N: 0.2%; CHN_{sum} = 1.1%) suggesting that the decomposition reaction is more complex. In the decomposition product Sb_2S_3, CoS and CoSbS was identified by X-ray powder diffraction (XRD).

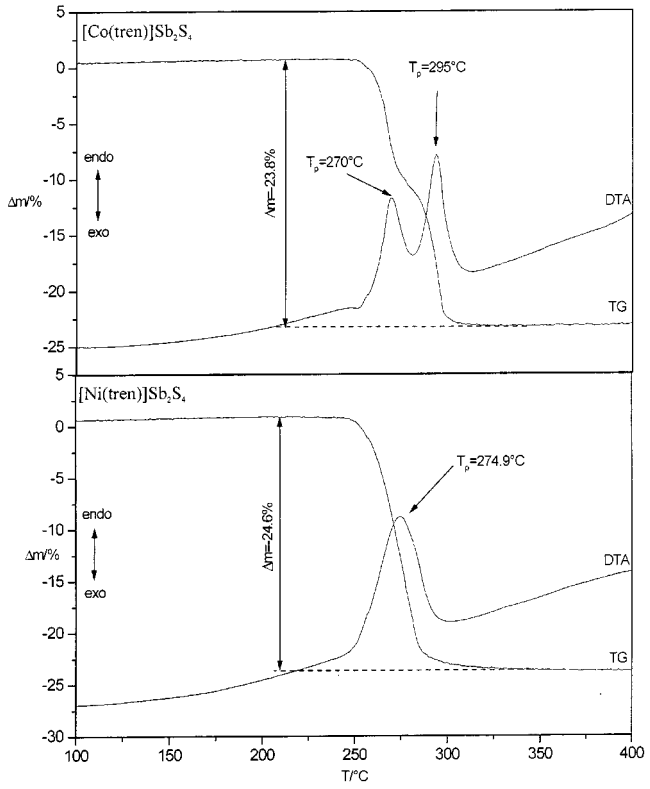

Figure 6. DTA and TG curves of [Co(tren)]Sb_2S_4 (atmosphere: argon; weight: 75.10 mg powdered crystals; heating rate: 3 °C/min) and [Ni(tren)]Sb_2S_4 (atmosphere: argon; weight: 68.50 mg; heating rate: 3 °C/min; T_p = peak temperature)

In a further experiment the decomposition was stopped at 270 °C. In the X-ray powder pattern Sb_2S_3, CoS, CoSbS and a small amount of a fourth phase were identified. The weight loss between T_p = 270 °C and T_p = 295 °C may be attributed to the decomposition of the unknown phase accompanied by the emission of C, H and N as well as S (C: 5.061%; H: 0.876%; N: 3.242%; CHN_{sum} = 9.179%). In the IR spectrum of the residue no C−H, C−N, C−C or N−H vibrations could be detected.

[Ni(tren)]Sb_2S_4: A significantly different behaviour is observed for the Ni compound. As can be seen in Figure 6 the sample decomposes in one step with an endothermic signal in the DTA curve at T_p = 274.9 °C (T_{onset} = 254 °C). The loss of weight is $-\Delta m$ = 24.6% which is similar to the value calculated for the emission of the tren ligand ($-\Delta m_{theo(tren)}$ = 25.4%). In the black residue small amounts of C, H and N could be found (C: 0.3%; H: 0.3%; N: 0.2%; CHN_{sum} = 0.8%). No C−H, C−N, C−C or N−H vibrations could be detected in the IR spectrum. NiS, Sb_2S_3 and NiSbS could be identified by X-ray powder diffraction.

Raman Spectroscopy

The changes of the bonding properties of a lone pair atom are best detected from changes in the bond angles, as interatomic bond lengths are only affected slightly.[25,26]

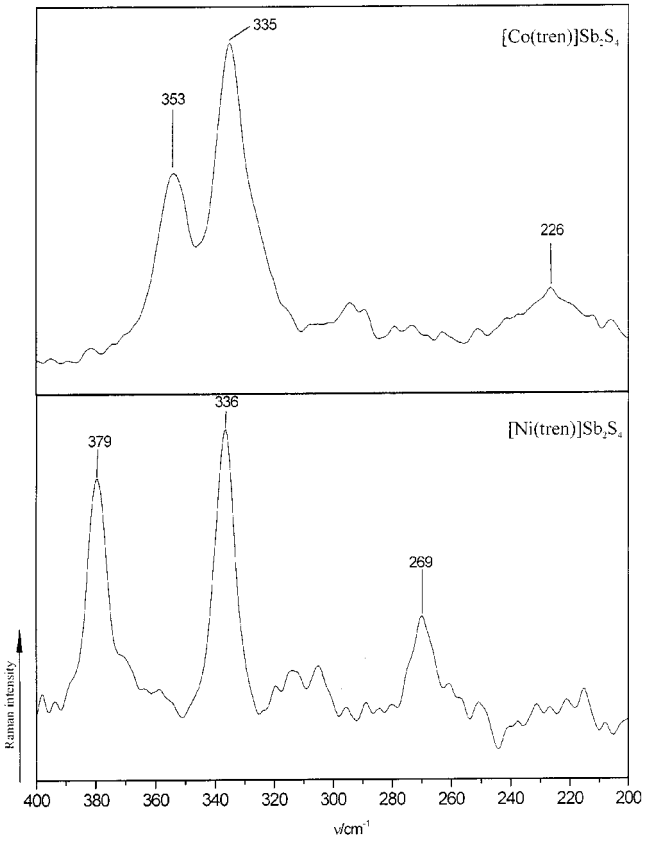

Figure 7. Raman spectra of $[Co(tren)]Sb_2S_4$ and $[Ni(tren)]Sb_2S_4$

This means that the local environment of the Sb^{III} ions does not lead to significant alterations of the Sb−S distances. In the Raman spectra, however, the different bonding properties of the two title compounds become apparent (Figure 7). For $[Co(tren)]Sb_2S_4$ two intense bands located at 353 and 335 cm^{-1} are observed, in accordance with the observation that all Sb^{III} ions have a $(3 + n)$ coordination [$n = 1$ for Sb(1) and $n = 2$ for Sb(2)]. For the Ni compound one Raman band is located at 379 cm^{-1} which can be assigned to $Sb(1)S_3$; a band at lower frequency of 336 cm^{-1} is due to the $Sb(2)S_4$ unit. The lower Raman frequencies obtained for the Co compound reflect the decreased bonding interactions within the $[SbS_3^{3-}]$ units. The Raman bands at 226 cm^{-1} (Co compound) and 269 cm^{-1} (Ni compound) are assigned to Co−S/Ni−S vibrations. The assignment of the Sb−S modes is in accordance with the results reported by Pfitzner for Cu_3SbS_3 and $(CuI)_2Cu_3SbS_3$.[27] In the former compound two maxima were observed at 321 and 290 cm^{-1} reflecting the weaker bonding interaction due to the (3 + 5) environment. In the latter compound the $[SbS_3^{3-}]$ anion has no next-nearest S atoms, yielding Raman bands at 362 and 339 cm^{-1}. For $Mn_2Sb_2S_4$ with one Sb^{III} atom in a sixfold and the other Sb^{III} atom in a sevenfold environment of S atoms the Raman bands occur at even lower frequencies and are located between about 280 and 310 cm^{-1}.[28]

Experimental Section

Synthesis: $[Ni(tren)]Sb_2S_4$ was first prepared by reacting elemental Ni, Sb and S in an aqueous solution of tren under solvothermal conditions in a Teflon-lined steel autoclave (inner volume: 30 mL). In a typical synthesis 1 mmol of Ni (0.0586 g), 1 mmol of Sb (0.1217 g) and 3 mmol of S (0.0962 g) were added to 10 mL of a 50% aqueous tren solution. The mixture was heated at 140 °C for 8 days then cooled to room temperature within 3 h. The reaction mixture was filtered, washed with water and acetone and cleaned in an ultrasonic bath. The product consists of green square-like crystals of the title compound as the major phase and a grey microcrystalline powder as the minor phase which is amorphous to X-rays. In the by-product the elements Ni, S, and Sb were identified by an EDAX analysis. Stirring the reaction mixture during the synthesis gave a phase-pure product using the same ratio of starting materials as under static conditions. C, H N analysis: calcd. C 12.49, H 3.15, N 9.72; found C 12.24, H 3.05, N 9.60.

$[Co(tren)]Sb_2S_4$: Dark black squares of $[Co(tren)]Sb_2S_4$ were prepared by reacting a mixture of elemental Co (0.059 g, 1 mmol), Sb (0.121 g, 1 mmol) and S (0.096 g, 3 mmol) in an aqueous solution of 50% tren (10 mL) (Merck Chemical). The synthesis was performed in a Teflon-lined steel autoclave, which was heated to 140 °C, held at this temperature for 7 days and then cooled to room temperature within 3 h. The products were filtered off, washed with water and dried under vacuum. The yield was 70% based on Co. Stirring the solution during the synthesis gave nearly 100% yield based on Co (Co/Sb/S = 1:1:3) in an aqueous solution of 10 mL tren (50%) at 140 °C. Calcd. C 12.49, H 3.14, N 9.71; found C 12.14, H 3.14, N 9.17. NB The differences between the applied starting material ratio and the 1:2:4 ratio in the solid products is due to unknown antimony sulfide species dissolved in the solution.

Structure Determination: Intensities were collected on a STOE Imaging Plate Diffraction System (IPDS) and a STOE AED-II four-circle diffractometer using monochromated Mo-K_α radiation (λ = 0.71073 Å). The intensities were corrected for Lorentz, polarisation and absorption effects. Structure solution was performed using SHELXS-97.[29] Refinement was done against F^2 using SHELXL-97.[30] All heavy atoms were refined anisotropically. The hydrogen atoms were positioned with idealised geometry and refined with fixed isotropic displacement parameters using a riding model. Technical details of data acquisition and refinement results are summarised in Table 4.

Thermoanalytical Measurements: Thermoanalytical measurements were performed using a DTA-TG device STA 429 from Netzsch. All measurements were performed under an argon atmosphere (flow rate 50 mL min^{-1}) with Al_2O_3 crucibles and heating rates of 3 K min^{-1}.

Raman Spectroscopy: Raman spectra were measured in the region from 100 to 3500 cm^{-1} with a Bruker IFS 66 Fourier transform Raman spectrometer (wavelength: 514.5 nm, 20 K).

X-ray Powder Diffractometry: The X-ray powder patterns were recorded on a STOE Stadi-P diffractometer (Co-$K_{\alpha 1}$, Cu-$K_{\alpha 1}$ radiation, λ = 1.788965 and 1.540598 Å, respectively) in transmission geometry.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-162040 for $[Ni(tren)]Sb_2S_4$ and CCDC-162041 for $[Co(tren)]Sb_2S_4$. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge

Speciation of Al^{III} in Blood Serum − The Al^{III}−Citrate−Phosphate Ternary System

Andrea Lakatos,[a] Ferenc Evanics,[b] György Dombi,[b] Roberta Bertani,[c] and Tamás Kiss*[d]

Keywords: Aluminium / Citric acid / Inorganic phosphate / Speciation of blood serum / NMR spectroscopy / Bioinorganic chemistry

Time-dependent speciation studies have been carried out on the ternary Al^{III}–citrate (A)–phosphate (B) system in order to clarify the solution state of Al^{III} in blood serum. The potentiometric results indicate that ternary complexes predominate both in freshly prepared mixtures and at equilibrium. The ternary species AlAB and $AlABH_{-1}$ and the binary species $AlAH_{-1}$ and $AlBH_{-1}$ are present at physiological pH. As the solution ages the amount of the trinuclear species $[Al_3(AH_{-1})_3(OH)]^{4-}$ increases at the expense of the mononuclear binary and ternary complexes. ^{31}P NMR spectra measured at neutral pH provide corroborating evidence of the formation of the ternary complexes AlAB and $AlABH_{-1}$ and binary species $AlBH_{-1}$ and Al_2BH_{-3} found potentiometrically. Time-dependent ^1H NMR measurements show that monodentate phosphate can slowly displace citrate from the otherwise very stable structure of the trinuclear species $[Al_3(AH_{-1})_3(OH)]^{4-}$. At blood serum concentrations [$c(Al^{III})$ = 3 μM], Al^{III} is mostly bound to citrate either in binary species or in the ternary species formed with phosphate. However, with increasing Al^{III} concentrations binding to phosphate becomes more important.

Introduction

The toxicity of aluminium is recognized as the cause of various neurological disorders, including dialysis dementia and other skeletal and haematological disorders.[1,2] Its involvement in Alzheimer's disease (AD) is rather controversial, although it is largely accepted that Al^{III} is not a causative agent but may serve as a risk factor by inducing conformational changes in neuropeptides, leading to the enhanced formation of plaques and tangles, the common markers of AD.[3,4] To understand the toxic effects of Al^{III}, it is important to know the chemical forms in which Al^{III} can enter the organism or in which it is present in natural waters, soil waters, biological fluids, and tissues. The absorption, excretion, tissue retention, and deposition of Al^{III} depend on the properties of the Al^{III} complexes formed with exogenous and endogenous biological ligands. After absorption in the body, Al^{III} is transported via the blood stream to the target organs. The main carrier of Al^{III} in blood serum is transferrin;[3−5] albumin, the other high molecular mass (h.m.m.) protein, is not an efficient aluminium binder.[6] Transferrin binds about 80% of the total Al^{III}; the remaining 20% is complexed by the low molecular mass (l.m.m.) bioligands present in blood serum.[7] As regards the most important l.m.m. Al^{III} binders, the picture is rather controversial. Dayde et al.,[8] Jackson,[9] and Harris[7] propose inorganic phosphate, while Clevette and Orvig,[10] Duffield et al.,[11] and Öhman and Martin[12,13] suggest that citrate is the main Al^{III} binder. The main reasons for the divergent results are the kinetically rather sluggish equilibration of the Al^{III}−citrate system and the very slow ligand-exchange processes of the citrate complexes of Al^{III}.[14−16] In freshly prepared solutions of Al^{III} and citrate, 1:1 mononuclear species are present; these polymerize to the trinuclear complex $[Al_3(AH_{-1})_3OH]^{4-}$ in rather slow processes. In the presence of a large excess of the ligand, 1:2 complexes predominate and the trinuclear species is of less importance. At pH 7.4 and a metal ion-to-ligand ratio of 1:1, besides the aforementioned trinuclear complex, the mononuclear species $[Al(AH_{-1})]^-$ and $[Al(AH_{-1})OH]^{2-}$ are present in solution; at higher ligand excesses, the bis complexes $[Al(AH_{-1})(A)]^{4-}$ and $[Al(AH_{-1})_2]^{5-}$ are formed.[14−17]

The Al^{III}−phosphate system can only be studied directly in a fairly acidic pH range, because at pH > 4 $AlPO_4$, or, more precisely, a mixed hydroxo-phosphato complex precipitates. To estimate the binding constants of Al^{III}−phosphate species at physiological pH, linear free-energy relationships (LFER) have been used. Harris[7] and Atkari et al.[18] concluded that the predominant species at pH

7.4 is the mixed hydroxo complex $Al(PO_4)(OH)^-$, but they obtained values differing by approximately an order of magnitude for the binding constant of this species.

All the models proposed for the biological speciation of Al^{III} only take into account binary species of Al^{III} with l.m.m. bioligands. However, biological systems invariably contain many potential binder ligands and hence the formation of ternary complexes may also be very important. Since the main potential l.m.m. Al^{III} binders in blood serum are citrate and phosphate, the formation of their ternary species would seem to be a very logical assumption. For this reason, we have studied the Al^{III}−citrate (A)−phosphate (B) ternary system. As a consequence of the slow oligomerization processes, time-dependent speciation measurements could be carried out. The time-dependent species distribution can give a more accurate description of the Al^{III} speciation in blood serum as Al^{III} does not generally attain thermodynamic equilibrium in biological fluids because of its very sluggish ligand-exchange reactions.

Results and Discussion

Time-Dependent Potentiometric Study

Potentiometric titrations were carried out in order to determine the protonation constants of the two ligands and the concentrations of their solutions. The proton complex formation constants obtained in this way are reported in Table 1.

For the Al^{III}-containing samples, as for the binary Al^{III}−citrate system,[16] very sluggish electrode responses were observed in the slightly acidic and neutral pH ranges. Thus, instead of carrying out normal titrations, the Al^{III}-containing samples were analysed using the batch method described in the Exp. Sect.. The time course of the pH changes proved to be dependent on the starting pH of the samples: starting at pH < 5.6, the hydrogen ion concentration increases with time, while above this pH it decreases. Similar behaviour was observed for the binary Al^{III}−citrate system[16] and was explained in terms of the slow oligomerization of the mononuclear complexes with formation of the trinuclear species $[Al_3(AH_{-1})_3OH]^{4-}$. While the oligomerization of the semi-protonated mononuclear complexes is accompanied by the release of protons in the acidic pH range, at basic pH the mixed hydroxo species oligomerize with the liberation of hydroxide ions.[16] This explanation seems to be applicable to the ternary system as well (vide supra). For each sample, the zero-time data (the pH values corresponding to the time of mixing of the components) were extrapolated from the first three minutes of the pH changes.

Through a combination with the potentiometric data obtained at the same time, a series of titration curves was created. Some selected curves obtained at an Al^{III}−citrate−phosphate ratio of 1:1:1 are depicted in Figure 1. The main differences between the titration curves relating to different times are seen in the pH range 3−5.6, the range of formation of the trinuclear citrato complex. At higher pH, in contrast to the results obtained for the Al^{III}−citrate system, no measurable time dependence was observed. The titration curve obtained after 30 h represents the equilibrium state. At an Al^{III}−citrate−phosphate ratio of 1:1:4, the time-induced changes are not so spectacular, due to the large excess of phosphate, which may partly suppress the oligomerization processes and also buffer the pH effect of the oligomerization.

In the evaluation of the titration curves corresponding to the equilibrium state, the stability constants of the binary complexes in the Al^{III}−citrate system were regarded as known values; we used the results obtained earlier in a time-dependent speciation study of the binary Al^{III}−citrate system.[16] For the binary Al^{III}−phosphate species, our basis was the speciation model proposed by Atkari.[19] For this system, pH equilibrium could be attained in less than 5 min for each point and thus normal titrations were carried out for speciation description. The applied model, however, gives practically no information on the species formed at pH > 4, since the formation of a precipitate of alumi-

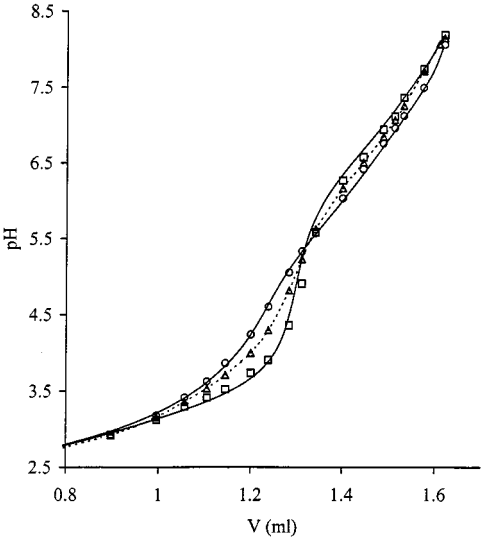

Figure 1. Titration curves (plotted as mL titrant KOH versus pH) of the Al^{III}−citrate−phosphate system at a ratio of 1:1:1, c_{Al} = 0.004 M and at different times after mixing of the reactants: (O) immediately after mixing (zero time), (Δ) 40 min after mixing, (□) at equilibrium (after 30 h); the solid curve was calculated using the stability constants reported in Table 1; the intermediate dashed curve serves only to join the titration points and does not represent any theoretical model

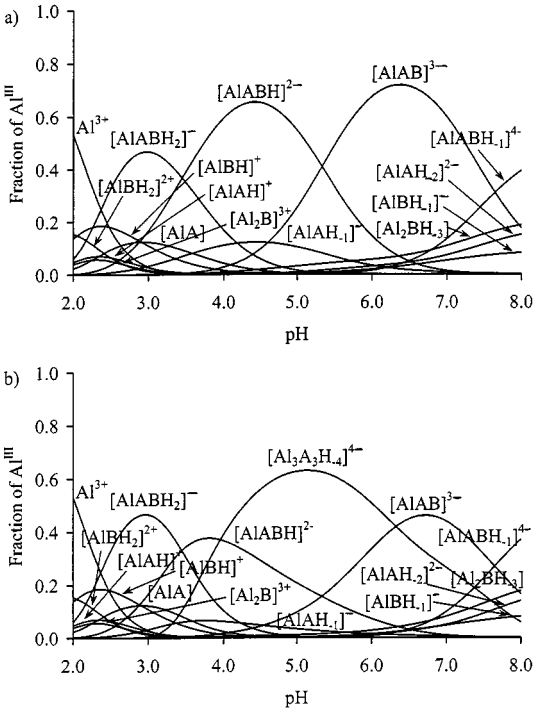

Figure 2. Species distribution curves as a function of pH for the Al^{III}−citrate−phosphate system at a 1:1:4 ratio, c_{Al} = 0.004 M and at different times after sample preparation: (a) immediately after mixing, (b) at equilibrium (after 30 h)

nium(III) phosphate does not allow potentiometric studies above this pH. For data evaluation in the neutral and slightly basic pH ranges, the stability constants of the Al^{III}−phosphate complexes [AlB] (log β = 13.50) and $[AlBH_{-1}]^-$ (log β = 7.20) estimated by LFER calculations[18] were used. In addition to the binary citrato and phosphato complexes, the formation of ternary Al^{III}−citrate−phosphate species was assumed in the speciation calculations. The species distribution calculated using the stability constants obtained for the ternary system at equilibrium showed that the amount of the Al^{III}−phosphate complex $[AlBH_{-1}]^-$ was negligible. In contrast, NMR spectroscopy indicated the presence of a considerable amount of this binary Al^{III}−phosphate complex at neutral pH (see later). This led to the conclusion that the stability constant of the complex $[AlBH_{-1}]^-$ (log β = 7.2) obtained by means of LFER calculations[18] may be underestimated. It should be noted here that Harris[7] suggested a stability constant one order of magnitude higher (log β = 8.37) for this species. When this value was used in the model calculations, the fitting of the experimental titration data were slightly improved. The speciation model obtained and the stability constants of the complexes are listed in Table 1. The titration curves corresponding to the zero-time data were fitted well if the sole formation of mononuclear complexes was assumed and the trinuclear complex $[Al_3(AH_{-1})_3OH]^{4-}$ was excluded from the speciation model. Speciation curves of the complexes formed on mixing of the components and in the equilibrium state are depicted in Figure 2.

Both immediately after mixing and at equilibrium, the ternary complexes $[AlABH_2]^-$, $[AlABH]^{2-}$, $[AlAB]^{3-}$, and $[AlABH_{-1}]^{4-}$ predominate in the system over the entire pH range. In addition to these complexes, as Figure 2 indicates, the concentration of the trinuclear species $[Al_3(AH_{-1})_3OH]^{4-}$ increases with time at the expense of the initially formed mononuclear binary and ternary complexes. In fresh solutions, the trinuclear species is hardly formed, while at equilibrium it is the predominant complex over a wide pH range. It can also be seen that at physiological pH (7−7.4) most of the Al^{III} is bound in the ternary complexes $[AlAB]^{3-}$ and $[AlABH_{-1}]^{4-}$, but that significant amounts of the binary phosphato complexes $[Al_2BH_{-3}]$ and $[AlBH_{-1}]^-$ are also present. Because of the excess of phosphate, the mononuclear and trinuclear binary citrato complexes are somewhat less important at an Al^{III}−citrate−phosphate ratio of 1:1:4. In the absence of citrate, Al^{III}−phosphate precipitates under neutral to alkaline conditions as a solid of variable composition, $Al(PO_4)_f(OH)_{3(1-f)}$, where the value of f varies from 1 to 0 as a function of the pH and concentration of the solution.[13] Detailed solubility measurements led Martin and Öhman[13] to conclude that $f = 0.75$ at pH 7.4; thus, the precipitate may be described as $Al(PO_4)_{0.75}(OH)_{0.75}$ and characterized by $\log K_{SO} = [Al^{3+}][PO_4^{3-}]^{0.75}/[H]^{0.75} = -11.1$. In the presence of citrate (at Al^{III}−citrate ratios of at least 1:1 and up to a maximum tenfold phosphate excess), the solutions are clear even at higher concentrations (0.04 and 0.1 M).[13] However, besides the proposed soluble Al^{III}−phosphate complexes $[Al_2BH_{-3}]$ and $[AlBH_{-1}]^-$, this Al^{III}−hydroxide−phosphate precipitate dissolves to form not only ternary Al^{III}−citrato−phosphato−hydroxo complexes, but probably also outer-sphere complexes with the

binary Al^{III}−citrate species through electrostatic and/or hydrogen-bonding interactions. This interpretation may explain our observation that potentiometry indicates the formation of a greater amount of ternary complexes than is suggested by NMR spectroscopy (vide infra).

As regards the ternary complexes, the complexation starts with the formation of $[AlABH_2]^-$ in acidic solution. In this complex, both ligands are coordinated to Al^{III}, probably each in a monoprotonated form. Thus, the complex should be written as $[AlCitH(HPO_4)]^-$. Here, the citrate binds to Al^{III} as a tridentate ligand through one terminal and the central carboxylate group and also the protonated hydroxy group (as in the binary species $[AlAH]^+$ [16]) and the hydrogen phosphate coordinates to Al^{III} as a monodentate ligand. The other terminal carboxylic group of the citrate ion is protonated and unbound. Further deprotonations occur on the coordinated hydroxy group and the unbound terminal carboxylate group with formation of the complexes $[Al(Cit)(HPO_4)]^{2-}$ and $[Al(CitH_{-1})(HPO_4)]^{3-}$. The ternary species $[AlABH_{-1}]^{4-}$ eventually formed can exist in two microforms: $[Al(CitH_{-1})(PO_4)]^{4-}$, with the phosphate coordinated to Al^{III} as a trivalent ligand with all hydroxy groups in deprotonated form, and $[Al(CitH_{-1})(HPO_4)(OH)]^{4-}$, which is a mixed hydroxo species.

NMR Spectroscopic Measurements

The formation of ternary Al^{III}−citrate−phosphate species was also unambiguously demonstrated by NMR spectroscopy. For correct NMR signal assignment, we first studied the Al^{III}−phosphate system. Figure 3, a, shows the ^{31}P NMR spectrum recorded at pH ≈ 2.2 and an Al^{III}−phosphate ratio of 1:2. The intense sharp signal at δ = 1.03 is due to free phosphate, while the other resonances can be attributed to the complexed ligand. Although a number of authors have investigated the Al^{III}−phosphate system, the assignment of the ^{31}P NMR signals remains uncertain. Akitt et al.[20,21] attributed these signals to differently protonated mononuclear 1:1 and 1:2 species and a polynuclear complex. Feng and Waki[22] assumed the presence of coordination isomers. The authors generally agree that, in the presence of excess ligand, the signal at δ = −6.37, which is the closest to the signal of the free ligand, is due to a bis-Al^{III}−phosphate complex. Our results for an Al^{III}−phosphate solution at a metal ion-to-ligand ratio of 1:4 and pH ≈ 2.2 support this assumption, since the intensity of the signal in question is increased compared to that in the spectrum recorded at a metal ion-to-ligand ratio of 1:2 and also relative to the other signals in the spectrum (not shown). For the ternary Al^{III}−citrate−phosphate system, the formation of binary Al^{III}−citrate species results in a higher phosphate excess than in the citrate-free solution under the same conditions, which favours formation of the bis-Al^{III}−phosphate complex. This is reflected in an increased intensity of the resonance at δ = −6.37 (Figure 3, b). Akitt et al.[21] also detected this signal at more acidic pH, and assigned it to a highly protonated 1:2 complex, AlB_2H_6. However, the formation of this species with the phosphate in fully protonated form is highly questionable, especially at pH ≈ 2. No similar bis complex has been found at acidic pH in any potentiometric study. As regards the other signals in the spectrum (see Figure 3, a), by analogy with the Al^{III}−phosphinate system, Feng and Waki[22] established that the coordination mode of the ligand (proceeding from the signal of the free ligand to higher fields) varies in the following order: monodentate, bidentate, and bridged coordination. To summarize the literature results and those from our own experiments, and additionally taking into account our potentiometric findings, the signals in the spectrum depicted in Figure 3, a, could be assigned as follows: free phosphate: δ = 1.03; highly protonated bis complex with monodentate phosphate coordination: δ = −6.37; monodentate phosphate-coordinated species $[AlBH_2]^{2+}$ and $[AlBH]^+$: δ = −6.91; the complex $[AlBH]^+$ with the ligand coordinated in a bidentate fashion and the binuclear phosphate and/or hydroxide-bridged complex $[Al_2B]^{3+}$: δ = −11.42 (the shape of the resonance suggests the presence of two overlapping signals belonging to two different species). The signal at δ = −16.42 was assigned by Akitt et al.[21] to another polynuclear (most probably trinuclear) complex. Feng and Waki[22] could not detect this latter species in less concentrated solution (0.025 M). At the millimolar concentrations employed in our potentiometric study, the formation of this polynuclear complex is probably negligible.

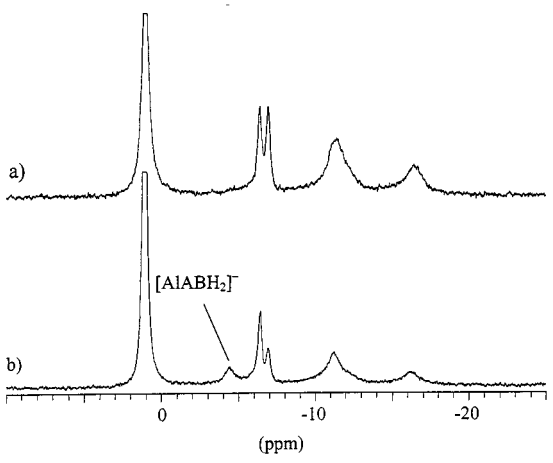

Figure 3. ^{31}P NMR spectra measured at pH ≈ 2.2 in a solution of (a) Al^{III}−phosphate at a 1:2 ratio and (b) Al^{III}−citrate−phosphate at a 1:1:2 ratio; c_{Al} = 0.04 M

Besides the aforementioned signals, in the spectrum of the citrate-containing solution at pH ≈ 2.2 a new ^{31}P resonance is seen at δ = −4.41; this could clearly be assigned to the ternary complex $[AlABH_2]^-$. On the basis of the chemical shift of this signal in the complex $[AlABH_2]^-$, the phosphate group must be coordinated in a monodentate fashion. On increasing the pH of the samples, the resonance of the ternary complexes is shifted downfield, which indicates that there is a rapid proton-exchange between the differently protonated ternary species. At pH ≈ 3, the resonances corresponding to the ternary complexes $[AlABH_2]^-$ and $[AlABH]^{2-}$ (δ = −4.2) and the monodentate phosphate-

coordinated binary complex $[AlBH]^+$ ($\delta = -5.64$) can be assigned unambiguously, but a small amount of the complex $[Al_2B]^{3+}$ is also present, giving a broad signal centred at around $\delta = -11$. At higher pH, due to the poor resolution of the spectra (the signals are broad and merged) the signals are extremely difficult to assign. This is well-illustrated by the spectrum recorded at pH ≈ 7.4 (Figure 4), where the very broad signals at $\delta = -3.7$, -9.3, and -13.9 were attributed to the ternary complexes $[AlAB]^{3-}$ and $[AlABH_{-1}]^{4-}$, the mononuclear 1:1 complex $[AlBH_{-1}]^-$, and the dinuclear complex $[Al_2BH_{-3}]$, respectively. Since no spectra of the binary Al^{III}−phosphate system could be recorded because of precipitation at this pH, signals were assigned on the basis of their relative intensities, taking into account the potentiometric speciation results and the spectra measured in the acidic pH range. The pattern of the signals, however, may suggest the presence of coordination isomers, possibly including the bidentate phosphate-coordinated isomer of the ternary complex and the proposed outer-sphere complexes of the Al^{III}−hydroxide−phosphate precipitate formed with the binary Al^{III}−citrate species (vide supra).

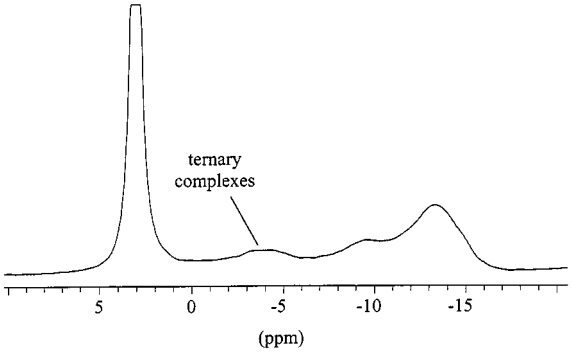

Figure 4. ^{31}P NMR spectrum recorded for the Al^{III}−citrate−phosphate system at a metal ion-to-ligand ratio of 1:1:2 and pH ≈ 7.4; $c_{Al} = 0.04$ M

In the ^1H NMR spectra of the same solutions, only the AB quadruplet of free citrate can be unambiguously assigned. The resonances of the other complexes present are merged into one very broad signal in the chemical shift range $\delta = 3.0-2.4$, probably as a consequence of the quadrupole effect of ^{27}Al nuclei and the relatively fast exchange reactions between these complexes. The resolution of the spectra was not improved even at low temperatures (5−10 °C). In the pH range of formation of the trinuclear complex $[Al_3(AH_{-1})_3OH]^{4-}$, its signals are well-separated and easily discerned as a result of its rigid structure and slow proton- and ligand-exchange reactions.[23] Figure 5 shows the ^1H NMR spectrum obtained at pH ≈ 7.4, which clearly indicates the slow formation of the trinuclear complex.

Since the primary aim of this work was to characterize the behaviour of the Al^{III}−citrate−phosphate system under physiological conditions, we attempted to obtain quantitative information from ^1H and ^{31}P NMR measurements. For a quantitative evaluation of the spectrum, a known amount of dioxane was added to a solution of the

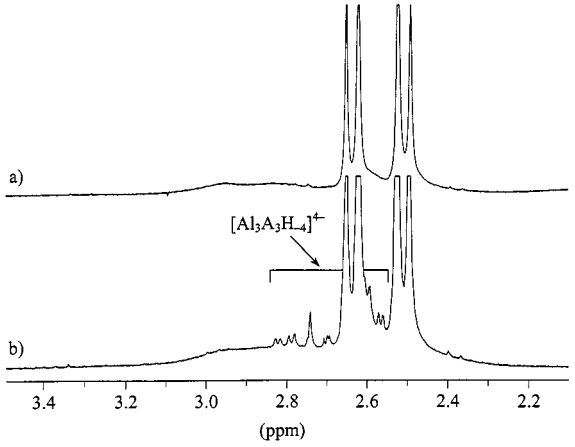

Figure 5. ^1H NMR spectra of the Al^{III}−citrate−phosphate system at a metal ion-to-ligand ratio of 1:1:2 and pH ≈ 7.4: (a) in freshly prepared solution, (b) at equilibrium; $c_{Al} = 0.04$ M

Al^{III}−citrate−phosphate 1:1:2 system under thermodynamic equilibrium at pH ≈ 7.4 and the amount of free citrate was calculated from the ^1H NMR spectrum using the deconvolution method. About 43% of the citrate was found to be free, while 57% was complexed in binary and ternary species. Since the ratio of Al^{III}−citrate in these solutions was 1:1, and since potentiometry indicates that only 1:1 Al^{III}−citrato species exist in the system, an amount of Al^{III} equivalent to the free citrate (43%) should be complexed in the binary Al^{III}−phosphato species. We should mention here that the ^{27}Al NMR spectrum of this solution featured one very broad resonance centred at $\delta \approx 3$, suggesting the formation of complexes containing Al^{III} in an octahedral environment, and gave no indication of the presence of free $[Al(OH)_4]^-$ (no signal at $\delta = -80$), i.e. no uncomplexed Al^{III} in the sample. Integration of the signals due to the free and the complexed phosphate in the ^{31}P NMR spectrum of the same solution revealed that ca. 65% of the phosphate was free and ca. 35% was in complexed form. This means that about 70% of the Al^{III} was bound in phosphate-containing complexes (including the ternary species), as the ratio of Al^{III}−phosphate in the sample was 1:2. The ^1H and ^{31}P NMR spectra revealed that ca. 43% of the total Al^{III} was bound in binary Al^{III}−phosphato species, ca. 30% in binary Al^{III}−citrato complexes, and ca. 27% in ternary complexes. In contrast, the speciation calculations indicate 58% in ternary complexes. This difference in the results of NMR and potentiometry may be explained partly by the relatively high degree of error in the percentage values calculated from the NMR measurements due to the rather poor quality of the spectra, and partly by the assumption of the formation of outer-sphere complexes (vide supra), which cannot be clearly observed by NMR spectroscopy.

These results indicate that (although a full quantitative speciation description of the Al^{III}−citrate−phosphate system could not be given) under the conditions (concentrations and metal ion-to-ligand ratios) of our NMR measurements, the binding abilities of the ligands citrate and phos-

phate to complexed Al^{III} are practically the same at physiological pH.

Reaction of the Trinuclear Species in the Presence of Inorganic Phosphate

The most characteristic species of the Al^{III}–citrate speciation is the trinuclear complex $[Al_3(AH_{-1})_3OH]^{4-}$. This is the predominant complex in equimolar Al^{III}–citrate solution between pH 4 and 9, i.e. in the range including physiological pH. The solid-state structure of the complex has been determined by X-ray crystallography[24] and the same rather asymmetric binding mode was confirmed by solution ^1H and ^{13}C NMR studies.[23] This raises the question as to what happens to this very stable and kinetically rather inert species in the presence of phosphate. Is phosphate able to decompose the trinuclear species? To answer this question, a twofold excess of phosphate (pH 7.4) was added to a 0.1 M solution of the trinuclear complex adjusted to pH 7.4. A slight increase ($\approx$ 0.2 pH unit) in the pH of the solution was observed and the spectral changes over time were monitored by ^1H, ^{31}P, and ^{13}C NMR. The ^1H NMR spectrum shows that the very characteristic proton spectrum (Figure 6, a) of the trinuclear complex collapses in the presence of phosphate (Figure 6, b), and that citrate is slowly partially displaced by phosphate as the AB quadruplet of free citrate clearly appears in the spectrum recorded after five days (Figure 6, c).

In the ^{31}P NMR spectrum of the same sample, a sharp signal initially appeared at $\delta = -1.8$, besides the resonance of the free phosphate. The intensity of this signal slowly decreased and it disappeared completely at equilibrium.

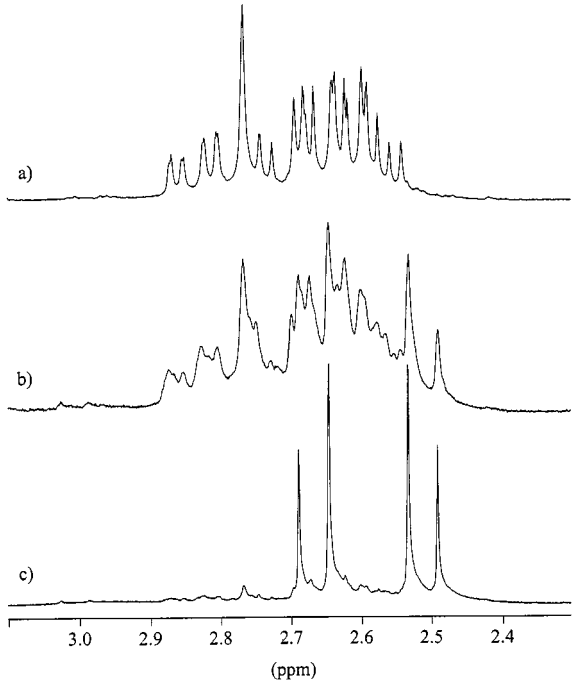

Figure 6. Decomposition of the trinuclear Al^{III}–citrate complex in the presence of a twofold excess of phosphate as monitored by ^1H NMR spectroscopy: (a) spectrum of the trinuclear species, (b) 10 h and (c) 5 days after the addition of phosphate; $c_{complex}$ = 0.1 M

The pattern of the equilibrium spectrum was the same as that obtained when Al^{III} was added to a solution of a mixture of citrate and phosphate (see Figure 4). The signal at $\delta = -1.8$ may presumably be assigned to a mixed-ligand complex formed as an intermediate species during decomposition of the trinuclear complex. The signals of this intermediate complex can easily be recognized in the ^{13}C NMR spectrum of the above solution. Besides the signals of the trinuclear complex (δ = 41.80, 42.90, 43.67, 44.98, 45.95, 46.24, 73.37, 75.51, 75.68, 177.18, 177.64, 177.89, 177.92, 178.19, 178.45, 180.78, 182.75, and 182.89),[16] 14 new resonances appear at δ = 41.83, 43.77, 45.51, 46.10, 46.46, 73.10, 75.25, 177.43, 177.73, 177.91, 178.88, 179.44, 180.85, and 183.29, which suggests that the intermediate species is most probably an oligonuclear mixed-ligand complex with a relatively asymmetric structure. During the formation of this complex, phosphate may be incorporated into the structure of the trinuclear complex $[Al_3(AH_{-1})_3OH]^{4-}$, replacing one or more of the coordinated donor groups of one of the citrate molecules. The ligand exchange between the trinuclear complex $[Al_3(AH_{-1})_3OH]^{4-}$ and the intermediate species is slow on the NMR time scale.

Modelling of Blood Serum

As one of the aims of the work was to determine whether citrate or phosphate is the primary l.m.m. Al^{III} binder in blood serum, we constructed the species distribution at plasma concentrations by using the speciation model and the stability constants obtained from the potentiometric measurements (Figure 7). For the calculations, the serum model suggested by Harris[7] was used: c(phosphate) = 1.1 mM, c(citrate) = 99 μM; the other l.m.m. constituents of blood serum, such as lactate, oxalate, amino acids, etc.,[7] have significantly lower affinities for Al^{III} and their participation in Al^{III} binding can therefore be neglected. This was assumed in all previous modelling calculations.[8–13] The total Al^{III} concentration was taken as 3 μM, which is in the range of serum concentrations observed for patients on haemodialysis.[7] In the calculations, we also took into account the fact that only ca. 20% of the total Al^{III} in the serum is bound to l.m.m. biomolecules while ca. 80% is bound to the h.m.m. components, mostly to transferrin[7] (vide supra). Figure 7 shows that at biologically relevant Al^{III} concentrations ($c_{Al}^{III} \approx$ 3 μM, of which only 0.6 μM is bound to l.m.m. components) the mononuclear complexes predominate and ternary species are formed in significant amounts. The oligomerization processes are strongly suppressed. At physiological pH, 51% of the Al^{III} is bound to citrate in the complex $[AlAH_{-2}]^{2-}$, ca. 28% is bound in the ternary species $[AlAB]^{3-}$ and $[AlABH_{-1}]^{4-}$, and ca. 21% is bound in the binary species with phosphate, $[AlBH_{-1}]^{-}$. If, however, we envisage an Al overload case, when the serum Al^{III} level can increase up to 100 μM, assuming a complete saturation of transferrin the distribution of Al^{III} between the h.m.m. and l.m.m. fractions of serum is 26:74%. The distribution of Al^{III} between citrate, phosphate binary, and citrate–phosphate ternary complexes becomes ca. 32%, 51%, and 17%, respectively. Interestingly, at increasing Al^{III}

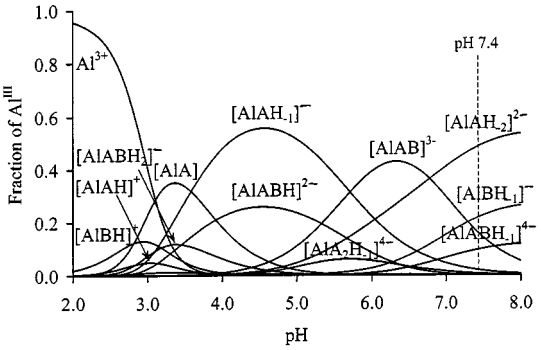

Figure 7. Species distribution curves for complexes formed in the Al^{III}−citrate−phosphate system at serum concentrations ($c_{Al} = 6 \times 10^{-7}$ M, $c_{citrate} = 99 \times 10^{-6}$ M, $c_{phosphate} = 1.1 \times 10^{-3}$ M, see text)

concentrations, phosphate becomes the more important binder.

Citrate-bound Al^{III} (either in binary or in ternary species) has been observed directly in blood plasma by Sadler et al. by means of ^1H NMR spectroscopy.[25] In a more recent study, Bantan et al.[26] investigated the speciation of l.m.m. Al^{III} complexes in human serum taken from eight healthy volunteers by means of fast liquid chromatography and electrospray techniques. In agreement with our results, they found that the main l.m.m. Al^{III} species present in the serum were binary Al^{III}−citrate and Al^{III}−phosphate and ternary Al^{III}−citrate−phosphate complexes. The distribution of these complexes varied from individual to individual.

Conclusions

This work has clearly demonstrated that the assumption of ternary complex formation may be of great importance in the modelling of biological systems. In the ternary Al^{III}−citrate−phosphate system under model conditions, the ternary species dominate, especially in freshly prepared solutions. Gradual increases in the concentrations of the trinuclear species over time are observed. This has been confirmed by time-dependent NMR spectral measurements. At physiological pH and millimolar concentrations, most of the Al^{III} is bound in the ternary complexes $[AlAB]^{3-}$ and $[AlABH_{-1}]^{4-}$, but some Al^{III} is also bound in the binary species involving citrate or phosphate. The trinuclear species $[Al_3(AH_{-1})_3OH]^{4-}$ slowly decomposes in the presence of excess phosphate, indicating that monodentate phosphate is not a negligible Al^{III} binder and that the trinuclear citrato species is not completely stable under these conditions. The latter is nevertheless relatively inert as the partial citrate replacement by excess phosphate reaches equilibrium only after several days.

At normal blood serum concentrations and physiological pH, Al^{III} is bound partly in mononuclear ternary complexes but mostly in the mixed Al^{III}−citrate−hydroxo complex $[AlAH_{-2}]^{2-}$.

Experimental Section

Reagents: Citric acid of the highest available purity was purchased from Sigma; the phosphate used was the highest quality monopotassium salt from Fluka. The ligands were used without further purification. Their purities were checked and the precise concentrations of their solutions were determined by the Gran method.[27] An Al^{III} stock solution was prepared from recrystallized $AlCl_3 \cdot 6H_2O$; its metal concentration was determined gravimetrically following conversion into the oxinate. The stock solution contained 0.1 M HCl to prevent hydrolysis of the aluminium.

Potentiometric Measurements: The stability constants of the proton complexes of the ligands were determined by pH-potentiometric titrations of 10.0 cm^3 samples. The ligand concentration was 0.004 M. The titrations were performed using 0.2 M carbonate-free KOH solution of known concentration under a purified argon atmosphere. The ionic strength of all solutions for potentiometric measurements was adjusted to 0.2 M with KCl and the samples were thermostatted at 25.0 ± 0.1 °C.

In this work, only the Al^{III}−citrate−phosphate ternary system was analysed; stability constants for the binary systems were taken from our previous studies.[16,18,19] The time-dependent speciation measurements were performed using the batch technique, in a similar manner as described for the Al^{III}−citrate binary system.[16] After appropriate amounts of stock solutions of the ligand and base had been mixed with the Al^{III} solution, the pH of the resulting mixture was recorded at given times until thermodynamic equilibrium of the system had been obtained (ca. 30 h). The procedure was repeated for different starting pH values, whereby titration curves relating to different times were obtained. The measurements were carried out at Al^{III}−citrate−phosphate ratios of 1:1:1 and 1:1:4 in 10.0 cm^3 solutions with intense stirring under argon atmosphere. The pH range studied was 2−8. For each ratio, the time-dependent changes were monitored for 20 different samples. However, in order to increase the reliability of the speciation description of the system at thermodynamic equilibrium and to reduce the uncertainties in the calculated stability constants, twice as many samples were prepared, but every second one was only analysed 30 h after mixing, when pH equilibrium had been attained. The stability constants listed in Table 1 were calculated from the total number of batch points (40 points for each metal ion ligand composition). In the case of the Al^{III}−phosphate binary system,[18,19] pH equilibrium could be attained within 5 min for each point and the normal titration procedure was used to obtain the stability constants for the complexes formed. The pH was measured with an Orion 710A precision digital pH-meter with a Metrohm combined glass electrode, which was calibrated for hydrogen ion concentration according to Irving et al.[28]

The concentration stability constants $\beta_{pqrs} = [M_pA_qB_rH_s]/[M]^p[A]^q[B]^r[H]^s$ were calculated with the aid of the computer program PSEQUAD.[29] The stability constants used for the hydroxo species of Al^{III} were taken from ref.[30] and corrected to $I = 0.2$ M using the Davies equation: −5.49 for $[AlH_{-1}]^{2+}$, −13.54 for $[Al_3H_{-4}]^{5-}$, −97.2 for $[Al_{13}H_{-32}]^{7-}$, and −23.40 for $[AlH_{-4}]^{-}$.

NMR Spectroscopy: ^1H, ^{31}P, and ^{13}C NMR spectra were recorded at 25 °C on Bruker AM360 and DMX500 spectrometers. For the ^1H and ^{13}C NMR spectra, chemical shifts were referenced to the signal of TMS as an external standard, while for the ^{31}P NMR spectra 85% orthophosphoric acid was used as an external standard. The samples were prepared in D_2O and the pH was adjusted with concentrated NaOD and DCl, using the relationship pH =

pD + 0.4. The concentrations of the solutions were 0.04−0.1 M in Al^{III}; samples with Al^{III}−phosphate ratios of 1:1, 1:2, and 1:4 and Al^{III}−citrate−phosphate ratios of 1:1:1, 1:1:2, and 1:1:4 were investigated. Unless otherwise stated, all NMR measurements were made on thermodynamically equilibrated samples. − ^{27}Al NMR spectra were measured on a Bruker AM200 instrument at 25 °C. Chemical shifts were recorded with respect to $Al(H_2O)_6^{3+}$. Solutions containing 0.1 M Al^{III} and having a metal ion-to-ligand ratio of 1:1:2 were prepared in water, to which 10% D_2O was added to provide a lock signal.

Thermodynamics of Complexation of Cadmium(II) by Open-Chain N-Donor Ligands in Dimethyl Sulfoxide Solution

Clara Comuzzi,[a] Michela Grespan,[a] Andrea Melchior,[a] Roberto Portanova,[a] and Marilena Tolazzi*[a]

Keywords: Cadmium / Ammine complexes / Solvent effects / Calorimetry / Thermodynamics

Thermodynamic parameters for the complexation of Cd^{II} by the amines *n*-butylamine (*n*-but), ethylenediamine (en), *N*,*N*′-dimethylethylenediamine (dmen), *N*,*N*,*N*′-trimethylethylenediamine (trmen), *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmen), diethylenetriamine (dien), *N*,*N*′′-dimethyldiethylenetriamine (dmdien), and *N*,*N*,*N*′,*N*′′,*N*′′-pentamethyldiethylenetriamine (pmdien) have been determined in dimethyl sulfoxide (DMSO) solution by potentiometric and calorimetric techniques at 298 K and 0.1 mol dm^{-3} ionic strength (NEt_4ClO_4). Only mononuclear complexes are formed, in which the polyamines act predominantly as chelating agents. All the complexes are enthalpy-stabilized, whereas the entropy changes counteract the complexation. The steric requirements of the donors have a strong influence on the stoichiometry and nature of the Cd^{II} complexes formed. Comparisons are made with data reported for some of these systems in water and with available data on silver(I) complexation by the same amines in DMSO, the latter showing that the selectivity of the ligands towards metal ions is also influenced by *N*-alkylation.

Introduction

In the last few years, many papers have been published concerning the complexation of transition and f-block metal ions by a number of multidentate polyamines.[1−9] The aim of this work has been to improve knowledge on the coordination chemistry of hard and soft metal ions with N-donor ligands in aprotic solvents of varying donating ability, as well as to investigate the strong influence of the basicities and steric properties of the ligands on the thermodynamic stability and nature of the complexes formed. These studies have also attracted renewed interest as the coordination properties of open-chain polyamines towards different cations have been used as models allowing direct comparison with the corresponding macrocyclic systems.[10]

In particular, the papers published by our group concerning complexation of the transition metal ions silver(I) and cobalt(II)[3a−3f] have shown that the coordination properties of polyamines towards these ions may be modulated through adjustment of the alkyl chain length between the donor atoms or through nitrogen functionalization. Methylation of nitrogens leads to a decrease in the thermodynamic stability of the corresponding metal complexes due to the decreased σ-donor ability of *N*-methylated groups. Nitrogen functionalization may also lead to molecular crowding and to an increase in the radii of the complexes; such steric effects may strongly affect the selectivity pattern in metal coordination. As far as cobalt(II) complexes are concerned, different *N*-alkylation of polyamines has important effects on the dioxygen affinity of these complexes.[3f,10]

In this context, and as an extension of previous work, we have now undertaken an investigation on the complexation of Group 12 dications by a series of open-chain and cyclic polyamines in aprotic solvents. Especially interesting comparisons should be possible between the monovalent d^{10} acceptor silver(I), with very soft character, and the divalent very soft Hg^{2+} or moderately soft Cd^{2+}. Moreover, despite the fact that complexation of Group 12 dications has been extensively studied in the past[11−14] and in more recent years,[15] scant thermodynamic data are available concerning their coordination by simple, open-chain N-donor ligands.[13h,14]

In this paper, we report the first results concerning the complexation of Cd^{II} by the differently *N*-methylated mono- and polyamines *n*-butylamine (*n*-but), ethylenediamine (en), *N*,*N*′-dimethylethylenediamine (dmen), *N*,*N*,*N*′-trimethylethylenediamine (trmen), *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmen), diethylenetriamine (dien), *N*,*N*"-dimethyldiethylene triamine (dmdien), and *N*,*N*,*N*′,*N*′′,*N*′′-pentamethyldiethylenetriamine (pmdien) in the aprotic solvent dimethyl sulfoxide (DMSO).

In order to investigate both the influence of the solvent on Cd^{II} complexation as well as the selectivity of these ligands toward metal ions, comparisons are made with available data for the same systems in water[14] and with previously obtained data concerning Ag^{I} complexation by some of these polyamines.[3a−3e]

Potentiometric and calorimetric measurements have been used to obtain the free energies and enthalpies of the reactions, respectively. All measurements were performed at 298 K in an ionic medium adjusted to 0.1 mol dm^{-3} with NEt_4ClO_4 as the neutral salt. FT-IR spectroscopy has been used to provide insight into the coordination modes of the ligands.

Results

Computer treatment of the potentiometric experimental data shows that for all the systems the best fit is obtained when the formation of successive mononuclear complexes is taken into account. The overall stability constants obtained from the potentiometric data minimization procedures, with the corresponding error limits, are listed in Table 1 for the reactions $Cd^{2+} + jL \rightleftarrows CdL_j^{2+}$ ($j = 1-3$ for L = *n*-but, en, dmen; $j = 1,2$ for L = trmen, dien, dmdien; $j = 1$ for L = tmen and pmdien).

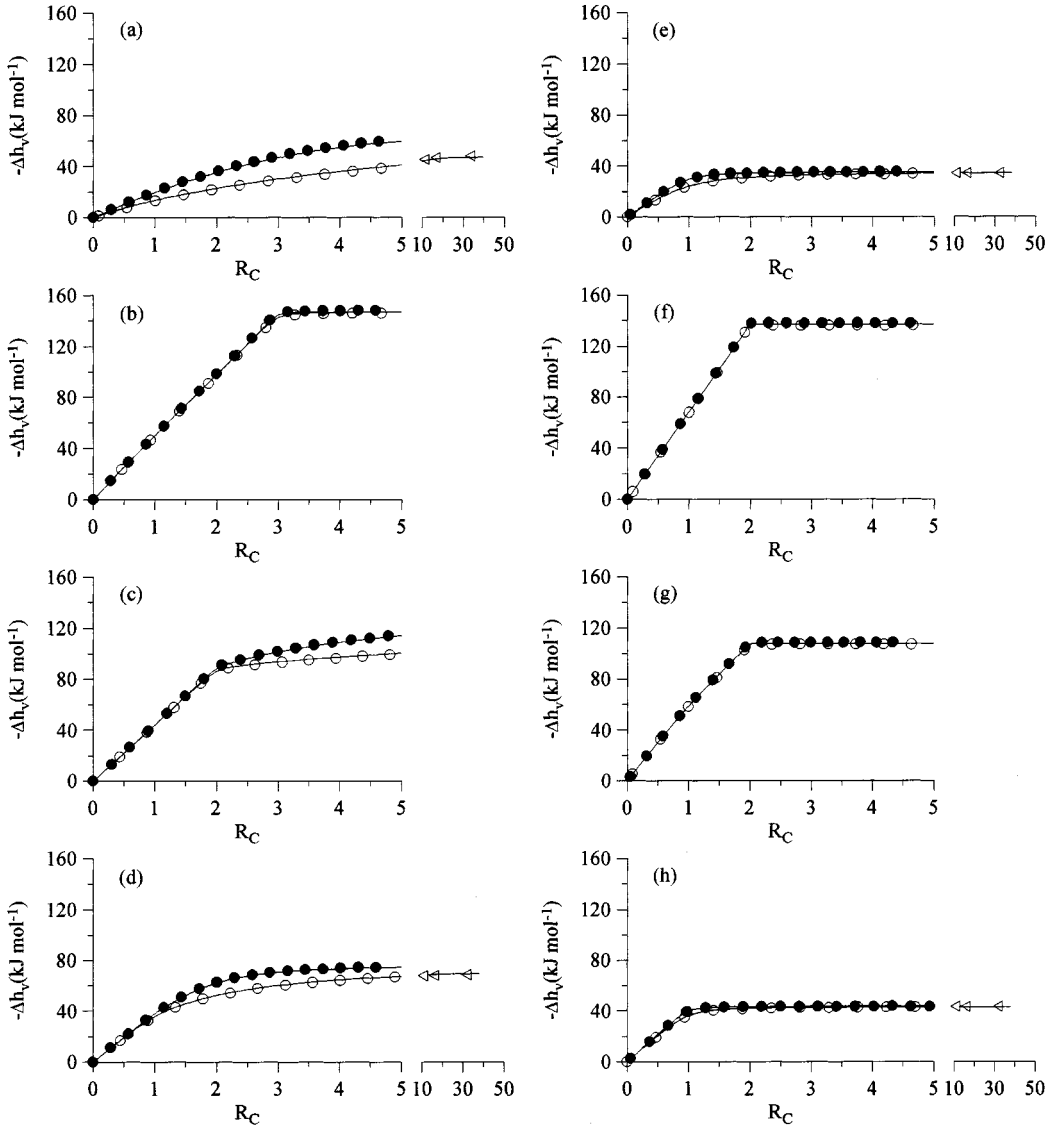

Figure 1. The total molar enthalpy changes, Δh_v, as a function of $R_c = C_L/C_M$ for Cd^{II}- polyamine systems in DMSO: (a) *n*-but (○) 5.05, (•) 19.90 mmol dm^{-3} in Cd^{2+}; (b) en, (○) 5.05, (•) 19.90 mmol dm^{-3} in Cd^{2+}; (c) dmen, (○) 5.10, (•) 19.98 mmol dm^{-3} in Cd^{2+}; (d) trmen, (○) 5.10, (•) 19.98 mmol dm^{-3} in Cd^{2+}; (e) tmen, (○) 5.05, (•) 19.90 mmol dm^{-3} in Cd^{2+}; (f) dien, (○) 5.05, (•) 19.98 mmol dm^{-3} in Cd^{2+}; (g) dmdien, (○) 5.10, (•) 20.05 mmol dm^{-3} in Cd^{2+}; (h) pmdien, (○) 5.05, (•) 20.05 mmol dm^{-3} in Cd^{2+}; the open triangles represent part of the "reverse" titrations; only some of the experimental points, chosen at random, have been plotted; the solid lines have been calculated from the values of β_j and $\Delta H^\circ_{\beta j}$ in Table 1

From an examination of the shape of the curves reproduced in Figure 1, some conclusions can be drawn about the coordinated species formed, which are fully consistent with the information obtained from analysis of the potentiometric data.

For the diamine en, the shape of the thermogram is consistent with the formation of three successive complexes of high stability. For the dmen system, the calorimetric curves indicate the formation of a third complex of lower stability in addition to two highly stable mononuclear species. The overlapping of the complexation curves up to $R_c = 2$ for the triamines dien and dmdien is indicative of the formation of two successive complexes of high stabilities and the lack of heat evolution at $R_c > 2$ clearly indicates that no more complexes are formed beyond the second one. The fit between the experimental and calculated curves is quite good.

Figure 2 depicts the FT-IR spectra of a series of solutions containing the same concentration (about 50 mmol dm^{-3}) of Cd^{2+} and different ligand-to-metal ratios R_c for the Cd^{II}-dmen system, chosen as a representative example.

Figure 3 shows log β_{jCd} plotted as a function of log β_{jAg} to allow better visualization of the comparison between the behaviour of the two ions.

Discussion

All the complexation reactions are strongly exothermic whereas the entropy terms oppose the reactions (Table 1).

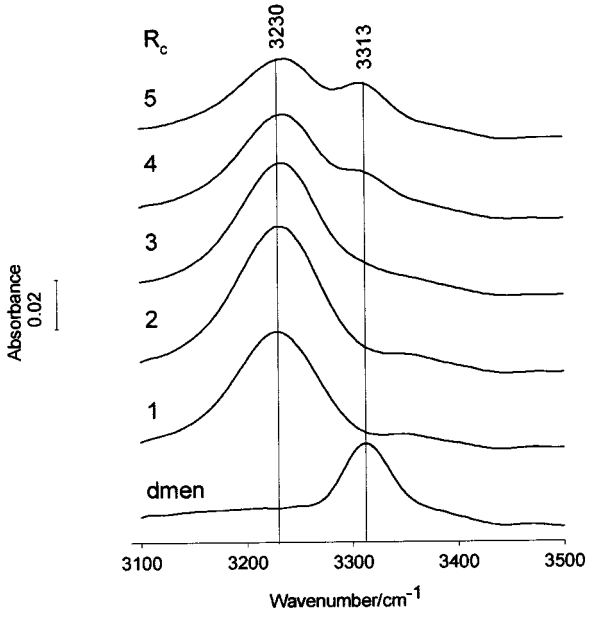

Figure 2. FT-IR spectra of solutions containing 50 mmol dm^{-3} cadmium(II) and different dmen/metal ratios, R_c

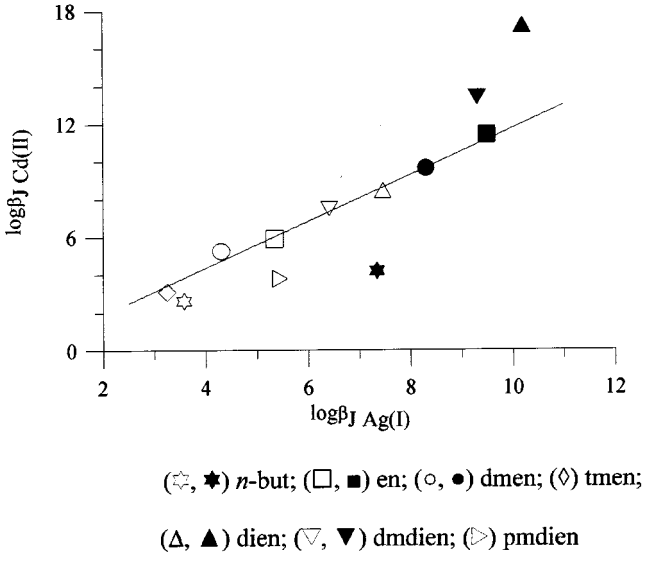

Figure 3. The log β_j relationship of the complexation of cadmium(II)- and silver(I)-amines; open symbols refer to ML, filled symbols to ML_2 species

The negative enthalpy values are typical of reactions involving the complexation of metal ions by neutral ligands in aprotic solvents.[3,5] The negative entropy values are in line with the fact that the release of solvent molecules from the coordination sphere of the metal ions does not compensate the decrease in internal entropy of the ligand and the negative entropy change due to the loss of translational entropy of the reagents upon complexation.[16] Data are available for a few of these species in aqueous solution.[14] Cd^{2+} is hexasolvated in both DMSO and water with the solvent molecules in a regular octahedral arrangement.[16]

The complexes are characterized by lower stabilities in water than in DMSO when primary and secondary amines are involved. Moreover, the complexes are always more enthalpy-stabilized in DMSO than in water, while in the latter solvent the entropy terms are favourable or, when negative, much less unfavourable. This trend is at variance with what might be expected on the basis of the thermodynamic parameters for the transfer of Cd^{2+} from water to DMSO ($\Delta G^{\circ}_{\text{transfer water}\rightarrow\text{ DMSO}} = -60.4$ kJ mol^{-1} [17]) and may be attributed to a greater solvation, through hydrogen bonding, of amines in water than in DMSO.[16] For the complexes with the tertiary amines trmen and tmen the opposite is observed as they are more stable in water than in DMSO; hydrogen bonds are only formed to a limited extent (for trmen) or not at all (for tmen) and therefore the greater solvation of the metal ion in DMSO prevails in governing the trend in the stabilities.

Cd^{II}-*n*-but System: The upper limit of Cd^{II} complexation is the fourth complex in both water and aprotic solvents when charged halides and thiocyanate ligands are involved.[15c,16] With these ligands, the behaviour of which has been extensively studied, a switch from an octahedral to a tetrahedral configuration has been shown to take place in DMSO as well as in water, which occurs at the second or third step of complexation, respectively.[16] The only data available in the literature for Cd^{II} monoamine systems in water relate to methylamine[14] and show that four successive mononuclear complexes are also formed in this case. In DMSO, only three successive mononuclear complexes are detected for the Cd^{II}-*n*-but system, despite the fact that the mildly soft character of Cd^{II} becomes hard in DMSO[16] and its affinity towards the hard N-atom is enhanced accordingly. Evidently, the steric requirements of this bulky ligand prevent the monodentate *n*-but from forming higher Cd^{II} complexes.

The only available data concerning Cd^{II} complexation by uncharged amines in DMSO do not allow suitable comparisons as they refer to the very bulky tri-*N*-butylamine,[13f] which is only able to form one mononuclear complex, whereas data relating to secondary monoamines show that they are able to form three successive complexes with the Group 12 dication Hg^{II} in DMSO.[13i] Interesting features emerge on analyzing the values of the thermodynamic functions. The more exothermic stepwise enthalpy value of the second complexation step, $\Delta H\,(K_2)$, as compared with $\Delta H\,(K_1)$, is probably due to the occurrence of particularly extensive desolvation in the first step of complexation: the enthalpy needed for desolvation causes $\Delta H\,(K_1)$ to be less exothermic than $\Delta H\,(K_2)$ in spite of the greater exothermicity associated with Cd^{II}-amine bond formation in the first step.

A switch in the coordination seems to take place at the third complexation step; indeed, the rupture of the solvate shell generally results in the liberation of more solvent molecules than would occur in the case of a simple substitution. Consequently, this step will be characterized by an abnormally large entropy gain while, on the other hand, the

extensive desolvation will absorb extra energy thereby resulting in an abnormally unfavourable enthalpy change.[16]

The low enthalpy gain and the slight counteracting effect of the entropy term associated with the third complexation step are consistent with this hypothesis.

Cd^{II}-diamine Systems: The $[CdL]^{2+}$ complexes of the various primary, secondary, and tertiary diamines are all more stable than the corresponding *n*-but complex. Furthermore, their enthalpies and entropies of formation are more exothermic and more negative, respectively, than the corresponding ΔH°_1 and ΔS°_1 values with the unidentate amine. This indicates the formation of chelate complexes with all the investigated diamines.

It can be seen in Table 1 that the $\log \beta_1$ values decrease smoothly as the number of methyl groups is increased on going from primary to secondary diamines (and triamines; see below), while the decrease in both stability and exothermicity is much more evident when tertiary groups are present. Evidently, for primary and secondary diamines, the decrease in stability is primarily due to the different basicities of the N-atoms, which decrease in the order $NH_2 > -NHR > -NR_2$.[18] The huge decrease in the thermodynamic stability and exothermicity shown by Cd^{II}-trmen and, in particular, -tmen systems can readily be explained in terms of the greater steric crowding resulting from complete *N*-methylation leading to decreased strength and marked elongation of the M−N bonds.[19] The steric requirements of the ligands evidently play an important role in determining the nature and stoichiometry of the complexes formed; this is even more clearly evidenced by the absence of higher complexes beyond the first one using the bulky tmen (or pmdien when triamines are considered).

The stability constants available in the literature relating to Cd^{II} complexation by dmen, trmen, and tmen in water at $\mu = 1.0$[14] are listed in Table 1. It should be noted that steric requirements also strongly influence the stoichiometry of the species formed in water as dmen and trmen form three successive mononuclear complexes while only two species are formed by the bulkier tmen.

The high values of the stability constants relating to the formation of the second complex and the high exothermicities of the reactions $ML + L \rightleftarrows ML_2$ suggest that both ligands are bidentate in these complexes. A reasonable question about this assumption may be raised in view of the high K_1/K_2 value associated with the Cd^{II}-trmen system. The highly exothermic value of the stepwise $\Delta H\,(K_2)$ favours chelation; in fact, if rough values of $-22\ kJ\ mol^{-1}$ and $-18\ kJ\ mol^{-1}$, respectively, are calculated for the formation of one $Cd^{II}-NHR$ and one $Cd^{II}-NR_2$ bond of a diamine chelate (on the basis of the mean enthalpy values relating to Cd^{II}-dmen and Cd^{II}-tmen complex formation), then the stepwise value of $\Delta H\,(K_2) = -39.6\ kJ\ mol^{-1}$ found for the Cd^{II}-trmen system [calculated: $-22 + (-18) = -40\ kJ\ mol^{-1}$] is wholly consistent with the hypothesis that both the $-NR_2$ and $-NHR$ groups coordinate to the metal ion in the formation of the $[Cd(trmen)_2]^{2+}$ complex.

Chelation is certainly also achieved when the $[Cd(en)_3]^{2+}$ complex is formed. For the $[Cd(dmen)_3]^{2+}$ system, the abrupt decrease in K_3 might be viewed as an indication of a possible rearrangement of the ligands in this third complexation step. In reality, this is an example illustrating the fact that a determination of the complete thermodynamics of complexation is necessary in order to ensure a reliable interpretation of the reactions involved; the values of the enthalpy and entropy terms are, in fact, in line with a bidentate behaviour of dmen in the $[Cd(dmen)_3]^{2+}$ complex.

Independent FT-IR spectroscopic measurements were carried out in order to corroborate the conclusions drawn from thermodynamic data. The interactions of the amino groups with the metal ions were studied by observing the bathochromic shift of the NH stretching modes of primary (at 3360 and 3300 cm^{-1}) and secondary (at 3313 cm^{-1}) groups in DMSO when Cd^{II} ions were added to amine solutions.[3g] Figure 2 shows the spectra of a series of solutions containing Cd^{II} and different dmen-to-metal ratios, R_c. It can be seen that up to $R_c = 3$ only the band due to the bonded amine (at 3230 cm^{-1}) is present, while the band due to the free amino group is present only when $R_c > 3.0$, clearly indicating that all the $-NH$ groups are coordinated to the Cd^{II} ion in each of the complexation steps. Similar measurements were also carried out for the other diamine (and triamine, see below) systems and confirmed the hypotheses suggested on the basis of the thermodynamic data.

Cd^{II}-triamine Systems: The higher values of the stability constants and the higher exothermicities associated with the formation of the $[CdL]^{2+}$ complexes of the triamines dien and dmdien, compared with those of the corresponding diamines, indicate that these ligands are tridentate, forming two fused five-membered chelate rings. The same arguments discussed in detail for the Cd^{II}-diamine systems can also be applied to the Cd^{II}-triamine systems to account for the decrease in stability and exothermicity observed on going from primary to tertiary triamines. In particular, it should be stressed that in this case as well, and to an even greater extent, the values of the stability constants and enthalpy gains for Cd^{II}-pmdien differ greatly from the values found for the secondary dmdien, further supporting the statement that, in addition to the decreased basicity of the amino groups, steric crowding plays a very important role in determining the coordinating abilities of the amines. The thermodynamic parameters for the Cd^{II}-pmdien system show better agreement with a bidentate coordination for this ligand; no additional information could be obtained by independent spectroscopic measurements.

The Cd^{II} ion is certainly hexacoordinated ion in the ML_2 complexes with the other triamines. This is unequivocally indicated by the thermodynamic parameters and was confirmed by independent FT-IR measurements run on the Cd^{II}-dien and -dmdien systems, which did not show the presence of uncoordinated amino groups up to $R_c > 2$ (see above for details). Evidently, a certain "preorganization" of the diamines and triamines is responsible for their ability to saturate the coordination sphere of the Cd^{II} ion, which is not achieved using monoamines.

It should be noted that $[Cd(dien)_2]^{2+}$ is formed alongside $[Cd(dien)]^{2+}$ as a result of the higher stability constant relating to the second complexation step ($\log K_2 = 8.74$), which is not seen in water. This result may be explained by considering that in Cd^{II} complexation by dien the desolvation of the species involved occurs mainly in the first step of complexation; this is confirmed by the lower enthalpy gain and the unfavourable entropy term associated with the formation of the ML complex as compared to the stepwise terms relating to the formation of the ML_2 species [$\Delta H(K_2) = -72$, $T\Delta S(K_2) = -22.3$ kJ mol^{-1}].

Cd^{II}- vs. Ag^{I}-amines Complexation: In Figure 3, the stabilities of the 1:1 and 1:2 Cd^{II}-amine complexes are plotted against the corresponding stabilities of the $[AgL]^+$ and $[AgL_2]^+$ species[3a−3e] in DMSO. The positive slope (1.2) of the line, calculated by taking into account the $\log \beta_1$ values for all the amines except *n*-but and pmdien (for the reasons discussed below), indicates that the stabilities of the 1:1 Cd^{II}-amine complexes are invariably greater than those of the corresponding Ag^{I} complexes (although almost of the same order of magnitude in the case of tmen); this probably reflects the higher affinity of the N atom for the soft-hard borderline divalent acceptor Cd^{II} than for the very soft univalent Ag^{I} ion. The linearity evident in Figure 3 seems to indicate that the different coordination structures of the two metal ions in DMSO, octahedral for Cd^{II} and tetrahedral for Ag^{I},[16] does not play a significant role in the ML complexation by the polyamines en, dmen, tmen, dien, and dmdien.

In the case of the bulkier *n*-but and pmdien, however, the selectivity of the ligands changes and Ag^{I} complexation becomes more favourable than Cd^{II} complexation. The steric hindrance of the ligands, together with the different structures of the metal ion solvates, is likely to be responsible for this behaviour. In fact, the environment of a tetrahedrally coordinated metal ion is less crowded compared with an octahedral structure[15c] and may allow enough space for the steric bulk of the *n*-but or pmdien molecules to no longer be significant.

In line with this hypothesis is the fact that pmdien is able to act as a terdentate ligand in the $[AgL]^+$ complex,[3e] while bidentate ligation is more reasonable in the $[CdL]^{2+}$ species (see the above discussion).

Furthermore, the $\log \beta_2$ values for the dmen and en systems fall on the line shown in Figure 3, indicating that the same arguments invoked to explain the trends observed for their ML (M = Cd, Ag) species can also be applied in rationalizing the behaviour of their ML_2 complexes.

Considering the dien and dmdien ML_2 compounds, the huge increase in stability of the Cd^{II} complexes with respect to their Ag^{I} counterparts certainly stems from the fact that terdentation is also achieved in the second complexation step using Cd^{II}. This is not possible in the case of $[AgL_2]^+$ as the maximum coordination number of silver(I) in solution is usually four.[20]

Conclusions

Cd^{II} complexes with open-chain N-donors in DMSO have been shown to be stable. Hexacoordination of the metal ion is achieved with primary and secondary polyamines. Complexation by primary and secondary amines is favoured in DMSO compared to that in water due to the less extensive hydrogen bonding of the amines in the aprotic solvent. The greater solvation of the metal ion in DMSO prevails in governing the stability trend in the case of the Cd^{II}-trmen and -tmen systems, the complexes being more stable in water than in DMSO.

The *N*-functionalization of the ligands has a strong influence not only on the stoichiometry and the nature of the Cd^{II} complexes formed but, very interestingly, on the selectivity of the ligands towards metal ions as well, as shown by a comparison with the available data on silver(I) complexation by the same amines.

Experimental Section

Warning! Although metal perchlorates solvated by DMSO are generally explosive under certain conditions,[11,21] no problems were encountered when handling $Cd(ClO_4)_2 \cdot 6DMSO$. Nevertheless, as a precaution, the salt should only be prepared in small quantities. Great caution has been exercised when handling DMSO solutions of poisonous cadmium salts, since they are easily carried through the skin by DMSO, which penetrates lipid tissues at an astonishing rate. Moreover, DMSO dissolves many natural and synthetic polymers.[11,21] These solvent properties were, of course, taken into account when designing the apparatus (e.g. the ion-selective cadmium electrode was externally covered by Teflon), particularly so as to ensure good personal and environmental protection.

General Remarks: $Cd(ClO_4)_2 \cdot 6DMSO$ was prepared by precipitation from an almost saturated solution of the hydrated salt (Aldrich; 98%) in dimethyl sulfoxide by the addition of diethyl ether. It was collected by filtration and dried in vacuo for several days at 50 °C. The compound was characterized as $Cd(ClO_4)_2 \cdot 6DMSO$ by elemental analysis and by titration of Cd^{II} with EDTA[22] using Eriochrome Black T as indicator. The molar conductivity of a 1.00 mmol dm^{-3} solution of $Cd(ClO_4)_2$ in DMSO (about 75 Ω^{-1} M^{-1} cm^2) was measured with a Metrohm 712 conductometer and was found to be in good agreement with the accepted value for 1:2 elecrolytes in DMSO.[23] Dimethyl sulfoxide (Fluka, > 99%) was purified by distillation according to the described procedure[3a] and stored over 4 Å molecular sieves. The ligands *n*-but, en, dmen, trmen, tmen, dien, and pmdien (Aldrich, >97%) were purified by fractional distillation.[24] The ligand dmdien was synthesized and purified as described previously.[25,26] Its purity (> 99%) was checked by GC mass spectrometry and ^{1}H NMR measurements. Cd^{II} perchlorate stock solutions were prepared by dissolving weighed amounts of the adducts in anhydrous DMSO and their concentrations were checked by titration with EDTA.[22] The supporting salt NEt_4ClO_4 was recrystallized twice from methanol and dried at 110 °C. The solutions of the ligands were prepared by dissolving weighed amounts in DMSO and were standardized by thermometric titration with standard $HClO_4$ solutions. All standard solutions were prepared and stored in an MB Braun 150 glove box under a controlled atmosphere containing less than 1 ppm of

water. The water content in the solutions, typically 10−20 ppm, was determined using a Metrohm 684 KF coulometer.

Potentiometric Measurements: All measurements were carried out in the aforementioned MB Braun 150 glove box in a thermostatted cell maintained at 298.0 ± 0.1 K. The experimental data required for the determination of the stability constants of the Cd^{II}-polyamine complexes were the equilibrium concentrations of the cadmium ion, which were obtained from the e.m.f. data of a galvanic cell. For this purpose, a Weiss WCDIOOI Cd ion selective electrode with a Teflon body was used as the working electrode and a Metrohm 6.0718.000 silver electrode was used as the reference. To Cd^{II} solutions in the concentration range $2.00 < c^0_{Cd} < 20.00$ mmol dm^{-3}, ligand solutions of known concentration were added and the free cadmium(II) concentration was measured after each addition of titrant. Some titrations were carried out in duplicate to verify the reproducibility of the systems. Equilibrium was typically reached in 2−5 minutes. The Nernstian response of the Cd electrode was checked in the range $10^{-2} < [Cd^{II}] < 10^{-6}$ mmol dm^{-3}. The computer program Hyperquad[27] was used to calculate the stability constants.

Calorimetric Measurements: A Tronac model 87−558 precision calorimeter was employed to measure the heats of reaction. The calorimeter was calibrated by titrating tris(hydroxymethyl)aminomethane (tham) with a standard solution of HCl in water. The experimental value of the heat of neutralization of tham was found to be $\Delta H° = -47.59$ kJ mol^{-1}, in good agreement with the accepted value of -47.53 ± 0.13 kJ mol^{-1}.[14]

The calorimetric titrations were performed at 298.00 ± 0.02 K by adding known volumes of ligand solutions ($50 < c^0_L < 200$ mmol dm^{-3}) to 20 mL of cadmium(II) solution ($2.00 < c^0_{Cd} < 20.0$ mmol dm^{-3}). In order to reach higher ligand-to-metal ratios so as to confirm that no higher complexes beyond the reported ones were formed by *n*-but, trmen, tmen, and pmdien, "reverse" calorimetric titrations were carried out for the relevant systems. In these titrations, Cd^{II} ion solutions (100 mmol dm^{-3}) were added to solutions of ligand (≈ 30 mmol dm^{-3}).

For each titration run, *n* experimental values of the total heat produced in the reaction vessel ($Q_{ex,j}$ $j = 1$ to n) were calculated as a function of the amount of titrant added. These values were only corrected for the heat of dilution of the titrant ($Q_{dil,j}$), which was determined separately. The heat of dilution of the titrate was found to be negligible in the metal ion concentration range used. The net heat of reaction at the *j*th point ($Q_{r,j}$) was obtained from the difference $Q_{r,j} = Q_{ex,j} - Q_{dil,j}$.

The quantity Δh_v, the total heat per mol of metal ion, was defined and calculated by dividing the net heat of reaction by the number of mol of metal ion in the calorimetric vessel. The enthalpy and entropy changes of the identified complexes were calculated using a Fortran program, MQ90,[28] with $q_{r,j}$ ($= Q_{r,j} - Q_{r,j-1}$) or Δh_v as the error-carrying variables.

FT-IR Measurements: The FT-IR measurements were made using a Bio-Rad FTS40 spectrometer (maximum resolution 4 cm^{-1}; 16 scans). A cell with barium fluoride windows (thickness of 32 μm) was used. The cell was filled and sealed in a glove box and then transferred to the spectrometer.

Nucleophilic Attack of Carbanions on Cationic Platinum(II) Nitrile Complexes Affording Stable η^1-Imine Enol and η^1-Enamine Coordinated Fragments

Maria E. Cucciolito,*[a] Vincenzo De Felice,[b] Federico Giordano,[a] Ida Orabona,*[a] and Francesco Ruffo[a]

Keywords: Platinum / Carbanions / Nucleophilic addition / Nitrile complexes / Enaminodiones

Cationic nitrile platinum(II) complexes of formula [PtMe(RCN)(bipy)]$^+$ undergo nucleophilic addition of carbanions $^-$CH(COX)(COY) (X, Y= Me, OMe), $^-$CH(CO_2Me)CN and $^-$CH$(CN)_2$ to afford neutral products. According to the nature of the nucleophile, the organic ligand fragment displays either an imino enol or an enamine isomeric structure. The Pt–N bond can be cleaved upon reaction with acids with formation of the corresponding β-enaminodione.

Introduction

Nucleophilic attack on coordinated nitriles is an agile way for the formation of several organic functions.[1,2] For example, the addition of water,[1] alcohols,[1] amines,[1] nitrones[3] and oximes[4] to metal-bonded nitriles gives rise to the corresponding amidato, imidoester, amidine, oxadiazoline and iminoacylated oxime groups. With several metals (e.g. W, Co, Ir, Rh, Ru, Pt) stable complexes can be isolated.[1]

Within this field of research, d^8 ions exhibit a very rich chemistry. For example, Michelin[1,5] and Natile[6] have carried out extensive studies on the attack of amines and alcohols to Pd^{II} and Pt^{II} nitrile complexes, with important implications for asymmetric synthesis[7] and medicine.[8]

On the other hand, a correspondingly thorough investigation of the species involved in the addition of carbanions to d^8 metal-bound nitriles has not been developed, although this is a convenient catalytic route to β-enaminodiones.[1,2] As far as we know, only one group has investigated the attack of carbanions, for example $^-$CH$(COMe)_2$, on platinum(II) nitrile complexes.[9] The reaction was generally accompanied by acyl migration and the formation of neutral products containing a bidentate *N,O*-chelated moiety, such as [Pt{N(COMe)C(Ph)CHC(Me)O^a}(*Pt*−*O*^{a})]. The acyl migration could be prevented with retention of the chelated fragment [Pt{NHC(Ph)C(COMe)C(Me)O^a}(*Pt*−*O*^{a})]. Similar Pd^{II} and Ni^{II} complexes were also prepared[10] by an alternative method, the addition of β-enaminodiones, for example $H_2NC(Et)=C(COMe)_2$, to suitable metal precursors.

Aiming to extend the knowledge within this field, we investigated the reaction of carbanions with complexes of formula [PtMe(RCN)(bipy)]$^+$. As described below, in all cases the nucleophile easily attacks the coordinated nitrile, and different structural types are obtained according to the nature of the carbanions.

The solid-state characterisation of a representative product, as well as reactions involving the functionalised coordinated fragment, have also been carried out.

Results and Discussion

Addition of Carbanions to [PtMe(RCN)(bipy)]BF_4 Complexes. Characterisation of the Products

Five carbanions of general formula $^-$CH(COX)(COY) were used, $^-$CH$(COMe)_2$ (**a**), $^-$CH(COMe)(CO_2Me) (**b**), $^-$CH$(CO_2Me)_2$ (**c**), $^-$CH(CO_2Me)(CN) (**d**) and $^-$CH$(CN)_2$ (**e**). In most cases the cationic platinum(II) precursor was [PtMe(MeCN)(bipy)]BF_4 (**1,** bipy = 2,2′-bipyridine), although in some experiments the related complexes [PtMe(PhCN)(bipy)]BF_4 (**2**), [PtMe(MeCN)(phen)]BF_4 (**3**, phen = 1,10-phenanthroline) and [PtMe(MeCN)(dmphen)]BF_4 (**4**, dmphen = 2,9-dimethyl-1,10-phenanthroline) were used. The latter was chosen in order to see the effect of the steric hindrance of the chelating ligand.

When an acetonitrile suspension of the Pt^{II} complexes was allowed to react with an excess of the appropriate nucleophile, the colour of the reaction mixture turned from yellow to orange-red within a few minutes. The metal products could be isolated in good yields as microcrystalline powders according to standard procedures. Only when the chelate was the hindered dmphen was the yield low, possibly due to the pronounced crowding in the square-planar coordination plane.

The new complexes are soluble in chlorinated solvents, although very poorly in the case of the cyano derivatives derived from **d** and **e**. Characterisation was carried out by IR and NMR spectroscopy, elemental analysis and, in one representative case, by X-ray diffractometry.

In principle, nucleophiles can react with cationic nitrile-containing platinum(II) complexes either by substitution or

by attacking the ligand, with formation of a corresponding metal-bonded organic fragment. The following NMR spectroscopic features allow us to confirm that all the reactions involved the attack of the anion on the nitrile with formation of a square-panar product:

i) the presence of a peak for the σ-bonded Pt−Me group with ^{195}Pt satellites of the appropriate intensities ($^{2}J_{Pt-H}$ = 80−85 Hz).[11]

ii) a singlet weakly coupled to ^{195}Pt around δ = 2.3 attributable to the methyl group of a Me−C−N−Pt fragment ($^{4}J_{Pt-H}$ = 8 Hz) in the case of the acetonitrile precursor. When benzonitrile was used, the aromatic region contained the expected Ph pattern.

iii) the presence of other singlets attributable to CO_2Me and COMe groups, when present in the reacting nucleophile. In the case of symmetric carbanions, i.e. X = Y, these groups are equivalent even at 213 K.

iv) the non-equivalence of the two halves of the chelating ligand, according to the absence of a mirror plane orthogonal to the square-planar coordination plane. The $^{3}J_{Pt-H}$ coupling constants of the protons H6 (12−16 Hz) and H6′ (45−50 Hz) of bipy are significantly different. On the grounds of the higher trans influence of Me groups with respect to N atoms, these values are compatible with the presence of a Me and an N atom trans to N1 and N1′ respectively. Analogously, the H2 and H9 protons of phen split to a different extent, and the smaller coupling is attributable to the hydrogen trans to Me.

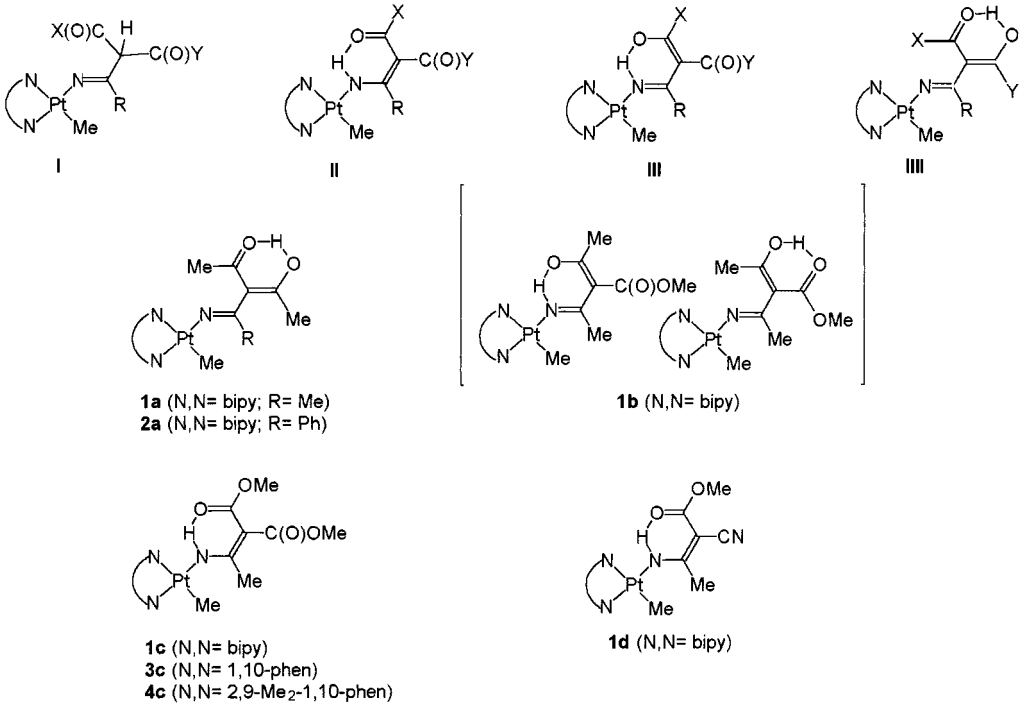
When the nucleophile contains at least one carbonyl function (**a**−**d**), the product resulting from the addition can exist in an equilibrium between the following isomers:[12] keto enamine (**I**), enamine with N−H···O hydrogen bonds (**II**) and imino enol (with either O−H···N, **III**, or O−H···O hydrogen bonds, **III′**), as depicted in Scheme 1.

Structures such as **I** seem to contribute little to our products since the ^{1}H NMR spectra lack a signal attributable to the CH proton that was originally present in the nucleophiles. Instead, a broad singlet is present at very low field (δ = 9.5−12), which disappears in a couple of hours when a few drops of CD_3OD are added to a $CDCl_3$ solution of the complexes. The position of this peak is typical of a proton involved in a hydrogen bond,[13] as is found in isomers of types **II**, **III** and **III′**.

Further structural information was obtained from the IR spectra of the complexes in chloroform solution. More precisely, in the products derived from acetylacetone (X= Y= Me, **1a** and **2a**), the COMe signals were found below 1570 cm^{-1}. A similarly significant lowering of the carbonyl frequencies suggests that an imino enol (isomer **III′**) is present, which forms an O−H···O chelating moiety. An IR band at 2500 cm^{-1} is in agreement with this linkage. The electronic delocalisation within the dicarbonyl moiety would account for the equivalence of the carbonyl functions in the NMR spectra (see point iii, above).

Analogously, the COMe stretching in **1b** (X= Me, Y= OMe) is found at 1568 cm^{-1}, while the CO_2Me signal lies at 1670 cm^{-1}. This suggests that an imino enol isomer is favoured here as well, even though a distinction between **III** and **III′** appears to be quite difficult. In fact, the lowering of the CO_2Me stretching mode at 1670 cm^{-1} can also be ascribed to the conjugation in the organic fragment, rather than to the possible formation of a hydrogen bond.[10]

It should be noted that the organic moiety present in complexes **1a, 1b** and **2a** is strongly related to the above-



Scheme 1

mentioned chelated fragments [M{NHC(R)C(COMe)-C(Me)O[a]}(*M-O[a]*)].[1,2,9,10] In the latter cases, the ligand binds the metal by forming a six-membered ring. In **1a, 1b** and **2a** the lack of an easily accessible coordination site prevents chelation through the oxygen atom, which therefore binds the mobile proton. As far as we know, these are the first examples of β-imino enols bonded to a d^8 ion in an η^1 fashion.

When the carbonyl group does not belong to a ketonic function (**c**,**d**), an enolic form of the product is no longer possible,[13] and hence the isomeric forms **III** and **III′** can be ruled out. In keeping with this hypothesis, the IR spectra of **1c**, **1d 3c**, and **4c** (Scheme 1) show N−H bands in the range 3230−3320 cm^{-1}. This band disappears upon addition of deuterium oxide to a chloroform solution of the complexes. The two carbonyl stretchings in **1c** appear at 1670 and 1610 cm^{-1}. The difference of ca. 60 cm^{-1} can be attributed to the fact that only one of them is involved in a hydrogen bond N−H···O[13] according to a type **II** structure (Scheme 1). The carbonyl groups are equivalent on the NMR time scale, as expected by site exchange through conformational rearrangements.

Analogous considerations hold true for **3c** and **4c**, which contain phen and dmphen as chelating ligands, respectively.

For complex **1d**, derived from the attack of $^{-}CH(CO_2Me)CN$, an enamine type **II** isomer seems favoured in chloroform solution. In addition to the above-mentioned N−H band (3250 cm^{-1}) and to a sharp signal at 2180 cm^{-1} (CN), the IR spectrum also displays the carbonyl stretching shifted to 1640 cm^{-1}. This frequency is in agreement with the involvement of this moiety in a N−H···O hydrogen bond.

Finally, when the nucleophile does not contain a carbonyl group, i.e. $^{-}CH(CN)_2$ (**e**), the formation of a hydrogen bond in the product **1e** (Scheme 2) is obviously not possible. In this case the absence of a methinic -$CH(CN)_2$ signal in the ^1H NMR spectrum rules out a keto enamine form (**I** in Scheme 2). The presence of a broad signal at δ = 6.5, which slowly disappears upon addition of CD_3OD, suggests the presence of an N−H bond,[5] which is confirmed by the corresponding IR stretching at 3316 cm^{-1}. Furthermore, the two non-equivalent nitriles give rise to two strong signals at 2195 and 2167 cm^{-1}, respectively. Thus, in this case the most stable structure is the enamine (type **II** in Scheme 2).

N(1)−C(12)−C(13)	118(2)	O(2)−C(15)−C(17)	120(2)
N(1)−C(12)−C(18)	123(2)	C(13)−C(15)−C(17)	119(2)
C(13)−C(12)−C(18)	119(1)		

The metal complex displays a square-planar geometry with the platinum lying out of the plane defined by the coordinated atoms by 0.05 Å.

The distances Pt−N(2) [2.01(2) Å] and Pt−N(3) [2.08(3) Å] are different and reflect the higher *trans* influence of Me with respect to the nitrogen function.

The most relevant feature of the structure is the electronic distribution within the ligand fragment resulting from the addition. It should be noted that: (i) atoms C(12), C(13), C(14) and C(15) are hybridised sp^2; (ii) N(1)−C(12) [1.29(3) Å] is a double bond, while C(12)−C(13) [1.53(4) Å] is a single bond; (iii) the atoms C(12), C(13), C(14), C(15), C(16), C(17), O(1) and O(2) lie in the same plane within 0.02 Å. This plane forms an angle of 76.3(5)° with the plane Pt−N(1)−C(12)−C(13)−C(18); (iv) C(13)−C(14) and C(13)−C(15) are intermediate between a single and a double bond; (v) the C(14)−O(1) and C(15)−O(2) bond lengths are characteristic of the carboxyl group.

These features, which indicate π-electron delocalisation within the planar dicarbonyl moiety, allow us to state that an imino enol isomer is also present in the solid state, al-

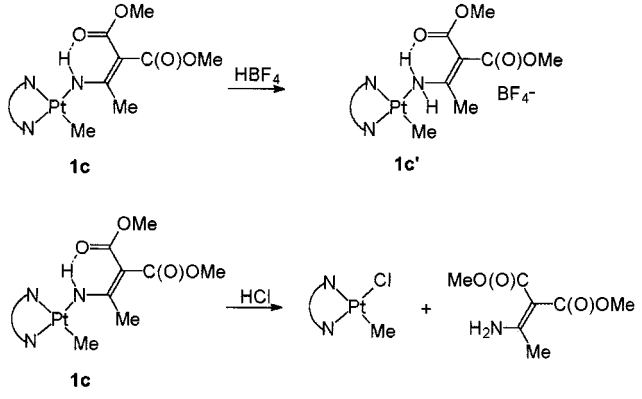
though not of type **III**, which implies the complete planarisation of the whole fragment including N(1) and C(18). This conformation seems in any case to be ruled out by the presence of a short methyl−methyl contact. The crystal structure shows a *transoid* conformation of the oxygen atoms, which makes it different also from the *cisoid* form **III′** found in solution, where an intramolecular hydrogen bond is present. In the solid state, the enolic H is statistically shared by O(1) and O(2). One of these positions is stabilised by the formation of the H bond O(2)−H···Cl [O(2)−Cl 2.86 Å] with a Cl atom of the solvent molecule CH_2Cl_2 in one of the two alternative sites of occupancy (see Exp. Sect.). On the other hand, when the hydrogen is linked to O(1), an intermolecular hydrogen bond is established with N(1) [O(1)−H···N(1), O(1)−N(1) 2.91 Å], and in this case the solvent lies far from the complex in order to minimise the steric contacts.

In conclusion, crystal forces stabilise a molecular structure in the solid state which is different from that found in solution, even though the main bonding properties are retained.

Reactions of 1c

The reaction of **1c** with protic acids were examined. Reaction with $HBF_4{\cdot}Et_2O$, which contains a non-coordinating anion, was very fast. The spectroscopic features of the product are similar to those displayed by the parent complex, except for a new signal at δ = 4.89 integrating for one proton. This evidence can be interpreted as the protonation of **1c**, with formation of a cationic product. Actually, in a type **II** structure (Scheme 3) the nitrogen atom has a lone pair, which can be protonated to form **1c′**. The large difference in chemical shift (5 ppm) between the hydrogen atoms bound to N can be ascribed to the fact that only one is involved in a hydrogen bond. It should be noted that **1c′** can be obtained independently by reacting $H_2NC(Me)=C(CO_2Me)_2$ with [PtClMe(bipy)] in the presence of one equivalent of $AgBF_4$.

The β-enaminodione can be liberated by reacting **1c** with HCl, which contains a coordinating anion. In this case, the formation of an intermediate product was followed by cleavage of the organic molecule and coordination of the chloride anion affording the stable complex [PtCl(Me)(bipy)] (Scheme 3).



Scheme 3

Conclusion

In this study we have demonstrated that nitriles (RCN) coordinated to square-planar cationic Pt^{II} complexes easily undergo nucleophilic attack by carbanions. The structure of the resulting organic ligand moiety can be controlled by varying the nature of the nucleophile. When it contains a ketonic function, imino enoles coordinated in an η^1 fashion are attained. In the other cases, an enamine structure is favoured.

It should also be noted that the same nucleophiles react with five-coordinated olefin complexes of formula $[PtMe(RCN)(N,N\text{-chelate})(olefin)]^+$ by simply substituting the axial nitrile.[14] This finding confirms once again the great influence of the coordination environment on the stability and reactivity of Pt^{II} complexes.

The reaction of a protic acid HX affords the corresponding β-enaminodione, which is either still coordinated to the metal centre or is obtained free, according to the coordinating ability of the X^- anion.

Experimental Section

All experiments were carried out under a nitrogen atmosphere using standard Schlenk techniques. Solvents and reagents were of AnalaR grade and were used without further purification, unless otherwise stated. THF was dried and distilled from Na/benzophenone. The carbanions,[15] [PtClMe(*N*,*N*-chelate)][16,17] and $[PtMe(MeCN)(N,N\text{-chelate})]BF_4$ [18] were prepared according to literature procedures.

^{1}H NMR spectra were recorded on a Varian XL-200 spectrometer. $CDCl_3$, CD_3NO_2 and $C_2D_2Cl_4$ were used as solvents and $CHCl_3$ (δ = 7.26), CD_2HNO_2 (δ = 4.33) and C_2DHCl_4 (δ = 5.98) as internal standard. ^{13}C NMR spectra were recorded on a Varian XL-200 (^{13}C: 50.3 MHz). $^{13}CDCl_3$ (δ = 77) and $^{13}CD_3NO_2$ (δ = 62.8) were used as internal standard. The following abbreviations are used for describing NMR multiplicities: s, singlet; d, doublet; dd, doublet of doublets; t, triplet; m, multiplet; br, broad signal. Infrared spectra were recorded on a JASCO FT/IR 430 spectrometer.

[PtMe(PhCN)(bipy)]BF_4 (2): $AgBF_4$ (0.107 g, 0.550 mmol) and benzonitrile (0.100 mL, 1.00 mmol) were added to a cooled dichloromethane solution (10 mL) of [PtClMe(bipy)] (0.201 g, 0.500 mmol). After 1 h of stirring AgCl was removed by filtration and the solvent was evaporated under vacuum. The residue was washed with diethyl ether (2 × 5 mL) and dried. The yield was almost quantitative (0.270 g, 97.1%). − $C_{18}H_{16}BF_4N_3Pt$ (556.24): calcd. C 38.87, H 2.90, N 7.55; found C 39.03, H 2.95, N 7.52. − ^{1}H NMR (200 MHz, CD_3NO_2): δ = 1.11 (s, $^2J_{Pt-H}$ = 75 Hz, 3 H, Pt-Me), 7.73 (m, 3 H, PhCN), 7.90 (m, 2 H, PhCN), 8.07 (dd, 2 H, H5 and H5′-bipy), 8.40 (m, 4 H, H3,H3′,H4 and H4′-bipy), 8.98 (d, $^3J_{Pt-H}$ = 16 Hz, 1 H, H6-bipy), 8.98 (d, $^3J_{Pt-H}$ = 60 Hz, 1 H, H6′-bipy). − ^{13}C NMR (CD_3NO_2): δ = −13.1 ($^1J_{Pt-C}$ = 678 Hz, Pt-Me), 110.9 (C1-PhCN), 120.7 (C≡N), 124.8 (C3-bipy), 125.4 ($^3J_{Pt-C}$ = 33 Hz, C3′-bipy), 129.0 ($^3J_{Pt-C}$ = 55 Hz, C5′-

bipy), 130.0 (C5-bipy), 131.1 (C3 and C5-PhCN), 135.0 (C2 and C6-PhCN), 136.8 (C4-PhCN), 141.9 and 142.4 (C4 and C4′-bipy), 149.4 ($^2J_{Pt-C}$ = 25 Hz, C6-bipy), 150.8 ($^2J_{Pt-C}$ = 51 Hz, C6′-bipy), 154.8 and 159.9 (C2 and C2′-bipy).

Complexes 1a−e, 3c, 4c. − General Procedure: A THF suspension (6 mL) of the appropriate carbanion (2.0 mmol) was added to an acetonitrile solution (2 mL) of [PtMe(MeCN)(*N*,*N*-chelate)]BF_4 (0.200 mmol). The mixture was stirred for 30 min. The solvent was then removed under vacuum and the residue extracted with dichloromethane (4 × 5 mL). The extracts were filtered through Celite, then concentrated to 1−2 mL. An orange-red crystalline product was obtained by adding diethyl ether (yield: 80−90%).

Complex 1c′: (a) HBF_4·Et_2O (0.016 g, 0.10 mmol) was added to a chloroform solution (5 mL) of **1c** (0.054 g, 0.10 mmol). The colour of the solution turned from orange to yellow, and the solvent was removed under vacuum affording the product **A** in quantitative yield (0.062 g).

(b) A deuteronitromethane solution (1 mL) of $AgBF_4$ (0.010 g, 0.050 mmol) and $NH_2C(Me)=C(COMe)_2$ (0.010 g, 0.059 mmol) was added to solid [PtClMe(bipy)] (0.020 g, 0.050 mmol). After one hour of stirring AgCl was removed by filtration through a short column of Celite, and the filtrate transferred into an NMR tube. The spectrum was identical to that of the product **1c′** obtained as in (a) above. ^{1}H NMR (CD_3NO_2): δ = 0.82 (s, 3 H, $^2J_{Pt-H}$ =

80 Hz, Pt-Me), 2.57 (s, $^4J_{Pt-H}$ = 12 Hz, 3 H, MeCN), 3.92 (s, 6 H, MeOCO), 4.89 (s, 1 H, NH), 7.8 (m, 2 H, H5 and H5′-bipy), 8.4 (m, 4 H, H3,H3′,H4 and H4′-bipy), 8.59 (d, 1 H, H6-bipy,), 9.01 (d, $^3J_{Pt-H}$ = 52 Hz, 1 H, H6′-bipy), 11.1 (br, 1 H, NH).

X-ray Crystallographic Determination of 1a: Details of the structure analysis are listed in Table2. The compound was recrystallised from dichloromethane/toluene. X-ray data were collected at room temperature on an Enraf−Nonius CAD4-F automatic diffractometer using Mo-K_α graphite-monochromated radiation and operating in the ω/θ scan mode. The unit cell parameters were obtained by a least-squares fitting of the setting values of 25 reflections in the θ range 12°≤ θ ≤14°. Three monitoring reflections, measured every 500 reflections, showed an intensity decay of about 12% for which a linear correction was applied. In addition to the corrections for Lorentz and polarisation factors, a semiempirical correction for absorption was applied[19] (max and min. values of the transmission factor were 1.3 and 1.0). The structure was solved by routine application of the Patterson and Fourier techniques and refined by a full-matrix least-squares procedure minimising the quantity $\Sigma w(|F_o| - |F_c|)^2$ with $w^{-1} = [\sigma^2(F_0)+(0.02F_0)^2+4]$, where σ is derived from counting statistics. A molecule of CH_2Cl_2 per molecule of complex allowed the calculated density to fit the measured value (by flotation). However, scrutiny of the Fourier difference map showed the solvent molecule to be distributed over two different sites and only the position of the four Cl atoms could be located and refined with isotropic thermal parameters. All non-hydrogen atoms were refined anisotropically. The H atoms were placed in calculated positions and included, but not refined, in the last refinement cycles with isotropic thermal parameters equal to those of the carrier atoms. The final Fourier difference map showed no peaks greater than 1.5 e·Å^{-3}. All calculations were performed with the Enraf−Nonius SDP set of programs.[20]

Relaxivity Studies on a Gadolinium(III) Complex of a Macrocyclic DTPA Derivative

Emrin Zitha-Bovens,[a] Luce Vander Elst,[b] Robert N. Muller,[b] Herman van Bekkum,[a] and Joop A. Peters*[a]

Keywords: Chelates / Contrast agents / Gadolinium / Macrocyclic ligands / NMR spectroscopy

The dinuclear Gd^{3+} complex of the 30-membered cyclic DTPA derivative, cy(DTPA-en-DTPA-en), was studied by various NMR spectroscopic techniques in order to evaluate the parameters governing its relaxivity. The values obtained were compared with those for Gd(DTPA-BMA), which is an acyclic mononuclear analogue. Because of the increase in molecular weight the relaxivity r_1 =5.25 $s^{-1}mM^{-1}$ (20 MHz, 37 °C) is higher than that of the monomeric analogue (4.2 $s^{-1}mM^{-1}$). The rotational correlation time at 298 K, τ_R^{298} was determined to be 175–188 ps, which is significantly higher than that expected, based on the increase in the molecular volume of the acyclic compared to the cyclic compound. Possibly, the cyclic nature of the ligand induces steric constraints in Gd[cy(DTPA-en-DTPA-en)], which reduce the local mobility. The water exchange rate for this complex (k_{ex}^{298} = 2.9×10^5 s^{-1}) is somewhat smaller than that of Gd(DTPA-BMA) (k_{ex}^{298} = 4.5×10^5 s^{-1}), which suggests that the water exchange rates are different in the various isomers of acyclic Gd-DTPA-bisamides.

Introduction

Chelates of Gd^{3+} have found widespread application as contrast agents for MRI (Magnetic Resonance Imaging).[1−3] The paramagnetic Gd^{3+} ion in these compounds has an enhancing effect on the relaxation rate of the water protons in its proximity, which may lead to an increase in the quality of the images and a decrease of the recording time. The encapsulation of Gd^{3+} into a strongly chelating ligand is necessary, since the Gd^{3+} aquo ion is highly toxic, whereas the chelates are not. The currently commercially available MRI contrast agents are derivatives of either the acyclic DTPA (DTPA = diethylenetriamine-*N*,*N*,*N*′,*N*′′,*N*′′-pentaacetate) or the macrocyclic ligand DOTA (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetate). Both types of Gd^{3+} complexes have been shown to be very suitable for this application, because of their high in vivo thermodynamic and kinetic stabilities. It is important that the chelating ligand leaves enough space on the Gd^{3+} ion for the coordination of a water molecule, which exchanges with the bulk to provide an overall reduction of the water proton relaxation rate.

The overwhelming success of the MRI contrast agents and the rapid development of the MRI technique have given rise to a continuing demand for new generations of contrast agents that are more effective and selective. Extensive studies in this field have shown that higher relaxivities, r_1 (enhancement of the water proton relaxation rate, expressed in $s^{-1}mM^{-1}$ Gd^{3+}), may be achieved, for example, by: (i) the design of the environment of the water coordination site, so that the water exchange rate will not limit the overall relaxivity ($\tau_m < T_{1m}$, with τ_m being the residence time of a water molecule in the first coordination sphere, and T_{1m} its proton longitudinal relaxation time), or (ii) an increase of the molecular weight of the compounds, in order to increase τ_R and thus the relaxivity, or (iii) by attaching substituents onto the ligand so that a higher tissue specificity is obtained.

Here, we report on a comprehensive study of the parameters that govern the relaxivity of the dinuclear Gd^{3+} complex of the 30-membered macrocycle cy(DTPA-en-DTPA-en),[4,5] also referred to as L (see Figure 1), using variable temperature ^{17}O and ^2H NMR spectroscopic measurements, and ^1H NMR longitudinal relaxation rate measurements at variable magnetic fields (NMRD profiles).

Ligand L can be considered as a cyclic dimer of DTPA-bis(methylamide) (DTPA-BMA) and features several interesting aspects which may be of relevance to its relaxivity: (i) the distance between the two Gd^{3+} ions in the dinuclear complex is relatively small (7.1 Å),[6] which might result in magnetic coupling and a concomitant effect on the electronic relaxation, (ii) Gd_2L has a higher molecular weight than Gd(DTPA-BMA), which may result in a smaller tumbling rate and (iii) intramolecular fluctuations are reduced due to the cyclic nature of the ligand. Furthermore, the number of diastereomeric pairs is reduced from 4 to 2 upon the 'cyclization' of DTPA-BMA[5] and, therefore, this compound may afford information on possible differences in water exchange rates between the various diastereomers of Gd^{3+} complexes of DTPA derivatives. Recently, it has been shown that subtle differences in the coordination geometry of the lanthanide ion in chelates, with macrocyclic derivatives of cyclen, has a profound effect on the rate of exchange between the bound water and the bulk.[7–12]

Results and Discussion

NMRD Measurements

The complex Gd_2L was investigated by water ^1H longitudinal relaxation time measurements at several temperatures (5, 15, 25, 37, and 45 °C) and magnetic field strengths varying between 2.5×10^{-4} T and 1.2 T (NMRD) in order to assess the relaxation processes in this system (see Figure 2). The profiles were fitted using the Solomon–Bloembergen–Morgan equations, to obtain the inner-sphere relaxation, along with the Freed equations for the outer-sphere contribution. Using these well-established procedures[13] may afford the values of the parameters that determine the overall relaxivity of Gd_2L. Since the NMRD curves are rather featureless and the number of parameters is large, first τ_m and τ_R were determined independently using other techniques. Previous studies have shown that variable temperature ^{17}O NMR spectroscopy is a very suitable technique for evaluating accurate values for water exchange rates.[13] Discrepancies often exist between τ_R values obtained from ^{17}O NMR spectroscopy and those obtained from NMRD. Therefore, these values were determined independently with the use of ^2H longitudinal relaxation rates. The advantage of ^2H relaxation for the determination of τ_R is that it is fully controlled by quadrupolar interactions (see below), while for the ^{17}O longitudinal relaxation, a dipole-dipole contribution also has to be taken into account.[14]

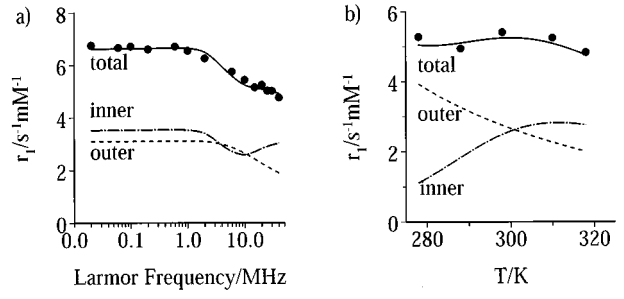

Figure 2. (a) NMRD profile of Gd_2L at 310 K. The lines are calculated using the values for the parameters as mentioned in Table 1. (b) Temperature dependence of the relaxivity of Gd_2L at 20 MHz

Variable Temperature ^2H NMR Spectroscopy

The cyclic ligand L deuterated at the methylene moieties of the acetate groups was synthesized in a similar manner to the unlabeled compound[4] which is by condensation of the bisamide of DTPA and ethylenediamine with DTPA-bisanhydride. However, deuterated DTPA was now used as the starting compound. The latter was obtained by refluxing a solution of DTPA in D_2O at pD 10.6 for 24 hours.[15] Subjecting the cyclic ligand L to similar reaction conditions leads to the hydrolysis of the amide bonds.[16]

The ^2H longitudinal relaxation time T_1 of La_2L, the diamagnetic analogue of the Gd^{3+} complex under study, was measured at different temperatures (see Figure 3). The rotational correlation time (τ_R) was calculated from the data using Equation (1), where χ is the quadrupolar coupling constant ($\chi = 1.06\times10^6$ rad s^{-1}) and η is an asymmetry factor which is negligible for the C-^2H bond. From the temperature dependence of the rotational correlation times, the values of $\tau_R^{298} = 175$ ps and an activation energy $E_R = 22.1$ kJ mol^{-1} were calculated using Equation (2).

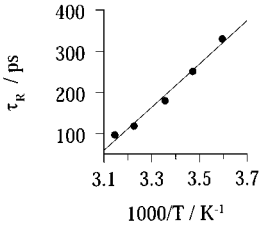

Figure 3. Temperature dependence of τ_R of La_2L, as determined from ^2H longitudinal relaxation rates as calculated from the experimental T_1 values using Equation (1)

$$\frac{1}{T_1}\left(^2H\right) = \frac{3\pi^2}{10}\frac{2I+3}{I^2(2I-1)}\chi^2\left(1+\eta^2/3\right)\tau_R \quad (1)$$

$$\tau_R = \tau_R^{298}\exp\left(\frac{E_R}{R}\left(\frac{1}{T}-\frac{1}{298.15}\right)\right) \quad (2)$$

Variable Temperature ^{17}O NMR Spectroscopy

The water exchange rate ($k_{ex} = \tau_m^{-1}$) of Gd_2L was determined from a variable temperature ^{17}O NMR spectroscopic study (chemical shifts and longitudinal and transversal relaxation rates). The total set of data (see Figure 4) enables the determination of a number of parameters including the rotational correlation time (τ_R), the hyperfine coupling constant ($A/\hbar$), and parameters concerning the electronic relaxation, τ_V (the correlation time for the zero-field splitting),

E_V (the activation energy for the latter process) and Δ^2 (the trace of the square of the zero-field splitting tensor).

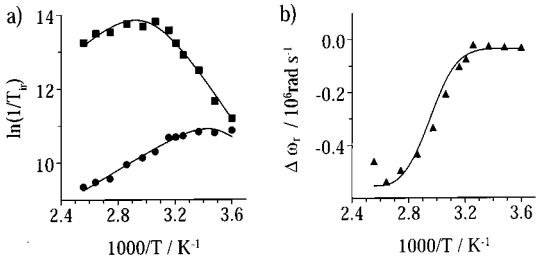

Figure 4. Temperature dependence of the reduced ^{17}O (a) transverse (filled squares) and longitudinal (filled circles) relaxation rates, expressed as $\ln(1/T_{ir})$, and (b) chemical shifts (filled triangles), $\Delta\omega_r$.

Simultaneous Fitting of NMRD and ^{17}O NMR Spectroscopic Data

The NMRD data of Gd_2L (Figure 2) together with the ^{17}O NMR spectroscopic data (Figure 4) was submitted for a least-squares fitting procedure. The advantage of a simultaneous fitting is that it puts constraints on the common parameters. Additional constraints were introduced by fixing the water hydration number (q) of each Gd^{3+} at 1, the quadrupolar coupling constant $[\chi(1 + \eta^{2/3})^{1/2}]$ at 7.58 MHz, the distance of closest approach of a water proton to a Gd^{3+} center (a_{GdH}) at 3.5 Å, and the inner sphere Gd−H distance (r_{GdH}) at 3.1 Å. In Table 1, the parameters as determined from the multiparameter fit are compared with those of the acyclic complexes $Gd(DTPA)^{2-}$ and Gd(DTPA-BMA).[17] Three parameters for the cyclic dinuclear complex Gd_2L differ significantly from those of its acyclic mononuclear counterparts, namely, $A/\hbar$, τ_R, and k_{ex}^{298}.

The relatively low value found for the scalar coupling constant ($A/\hbar = -3.2\times10^6$ rad s^{-1}, see Table 1) may indicate that there is effectively less water bound to the paramagnetic center. The hydration number, q, is an average taken over the different isomers, which are characterized by their respective lifetime in aqueous solution. Because of the crowding in the cyclic ligand, it is very well possible that the averaged value of q is smaller than one. Overestimation of the (fixed) hydration number in the fitting procedure can result in a lower value for $A/\hbar$. Assuming that $A/\hbar = -3.9\times10^6$ rad s^{-1} for a Gd^{3+}-bound ^{17}O nucleus,[13,15] the data would indicate that $q = 0.8$, which is in good agreement with previous results based on Dy^{3+} induced water ^{17}O shifts.[5]

Table 1. Comparison of parameters obtained from simultaneous fitting of ^{17}O NMR spectroscopic and NMRD data with some literature data

	DTPA[17]	DTPA-BMA[17]	L

$\chi(1+\eta^2/3)^{1/2}$ (MHz)	7.58	7.58	7.58[a]

[a] Parameter fixed in fitting procedure. – [b] Parameter that determines the spin rotation contribution of the longitudinal electronic relaxation.[13]

The value of the rotational correlation time (τ_R^{298}) follows the general trend of the relative molecular masses of the complexes. The value found from the simultaneous fitting was in good agreement with the value determined by ^2H NMR spectroscopy (see above). It should be noted that the ^1H water relaxation rate of Gd_2L solutions at 200 MHz was linearly dependent on the concentration of the paramagnetic compound in solution. Over the concentration range in which the ^{17}O and ^2H NMR spectroscopic measurements and the NMRD profiles were recorded (200, 50 and 1 mM of Gd^{3+}, respectively), a correlation coefficient of 0.99 was calculated for T_1 as a function of the concentration. This justifies the use of the data that were obtained via the different techniques in a simultaneous fitting procedure.

It is surprising that the increase of τ_R^{298} upon going from Gd(DTPA-BMA) to GdL_2 is not linearly proportional with the increase in molecular weight. The molecular mass of the dimeric compound is two times higher than that of the DTPA-BMA complex, and the molar volume, as estimated from molecular mechanics using the HyperChem program on the Gd_2L complex (1857 Å^3) is 1.7 times higher than that of Gd(DTPA-BMA) (1084 Å^3). Based on these data, and the Debye−Stokes−Einstein relationship, a value for τ_R^{298}, of about 112 ps would be expected for Gd_2L. The value of 175 ps for τ_R^{298} as found by ^2H NMR spectroscopy that is in agreement with the results of the fitting of the ^{17}O NMR spectroscopic data, is significantly higher. Therefore, features other than the molar volume must be involved in the rotational correlation time of these complexes. Possibly, the τ_R^{298} value of Gd(DTPA-BMA) is not only determined by the global rotation, but has an additional contribution of relatively fast local motions. It may be expected that the mobility decreases upon going from the acyclic Gd(DTPA-BMA) to its macrocyclic dimer Gd_2L, which may explain the unexpectedly high τ_R^{298} value for the latter compound. This is in line with the ratio of the τ_R values for $Gd(DOTA)^-$ and $Gd(DTPA)^{2-}$, which is 1.3, whereas the molecular volumes of these complexes are about equal (982 Å^3 and 937 Å^3, respectively).

The water exchange rate k_{ex}^{298} for the dimeric Gd_2L ligand is somewhat smaller than for DTPA-BMA. The cyclic nature of the ligand limits the number of isomers that are existing in solution.[5] Recently, it was shown that for Ln^{3+} complexes of cyclen derivatives the water exchange rate can vary significantly for the different isomers of a complex in solution.[7−11] So, the reduction of the number of isomers

in the present case may explain a different overall water exchange rate than was observed for the acyclic monomeric counterpart.

The relatively low exchange rate of the inner sphere water molecules in Gd_2L limits the transfer of inner sphere relaxation towards the bulk solution. This effect is manifested clearly in Figure 2, b, which displays the relaxivity at 20 MHz as a function of the temperature. The inner and outer sphere contributions to the relaxivity have an opposite temperature dependence; the outer sphere term increases with a decrease in the temperature. Upon decreasing the temperature below 30 °C the relaxivity levels off, because the effect of the increase in τ_R is quenched by slow water exchange. The water exchange is slowed down (and the inner sphere relaxivity decreases) to the extent where the outer sphere relaxivity, which increases on lowering the temperature, becomes predominant.

Finally, the NMRD profile recorded from an aqueous solution of the Gd_2L compound containing 4% Human Serum Albumin (HSA), at 37 °C, was identical to the curve obtained in the absence of HSA, indicating that there is no interaction with albumin.

Conclusion

The 'cyclo-dimerisation' of Gd(DTPA-BMA) towards Gd_2L has some particular effects on the relaxivity properties. First, the increase in molar volume (with a factor of 1.7) resulted in a much higher increase in the rotational correlation time (factor of 2.7), suggesting a reduction in the local mobility of the complex as induced by the cyclic nature of the ligand. Moreover, the water exchange rate, k_{ex}^{298} is somewhat smaller for Gd_2L than for Gd(DTPA-BMA), which may be due to a difference in the isomer distribution in aqueous solution. The exchange rate of the inner sphere water molecule with the bulk, limits the relaxivity to such an extent that, at low temperature (5 °C), the outer sphere term becomes predominant. The electronic relaxation does not seem to be influenced by the cyclo-dimerization. Apparently, the interaction between the neighboring Gd^{3+} ions is negligible. Finally, it can be stated that the design of rigid cyclic ligands can lead to an increase in τ_R, which is favorable for higher relaxivity values. A drawback is that the water exchange can become so slow, that the effect of τ_R is counteracted. The challenge is to find an optimum for both parameters.

Experimental Section

General Remarks: All chemicals were purchased from ACROS Chimica, except the lanthanide chlorides that were purchased from Aldrich Chemical Co. All compounds were used without further purification.

NMR Spectroscopy: The ^1H and ^{13}C NMR spectra were recorded on a Varian INOVA-300 or a Varian VXR-400 spectrometer. *Tert*-butyl alcohol was used as an internal standard (methyl signal at $\delta = 1.2$ (^1H NMR) and $\delta = 31.2$ (^{13}C NMR). The variable temperature ^{17}O NMR spectroscopic measurements were performed with H_2O solutions at a magnetic field of 7.05 T on a Varian INOVA 300 spectrometer. The samples were enclosed in a sealed NMR tube under argon atmosphere. The ^1H signal of *tert*-butyl alcohol was used as an internal reference, to correct the ^{17}O NMR chemical shift for the Bulk Magnetic Susceptibility (BMS) shift contribution. The BMS shift had to be taken into account since the measurements were performed in an unlocked configuration.

Longitudinal relaxation rates, $1/T_1$, were measured using the inversion-recovery method, and transversal relaxation rates, $1/T_2$, were obtained via the Carr−Purcell−Meiboom−Gill spin-echo technique. At each temperature, the spectral parameters were measured for both a sample with 0.1 M dinuclear Gd^{3+} complex and a sample of acidified water (pH 5.2) under exactly the same conditions.

^2H longitudinal relaxation rates were measured at 4.7 T on a Bruker MSL-200−15 spectrometer using a broadband probe. The solvent (water) was deuterium depleted. The 90° and 180° pulse lengths were 9 and 18 μs, respectively.

The exact Gd^{3+} contents of the NMR samples were determined by ICP. The pH values of the NMR samples were measured at room temperature with a calibrated micro-combination probe (Aldrich Chemical Co.) and a Corning 125 pH meter. No corrections were made for deuterium isotope effects.

Relaxivity Measurements: The $1/T_1$ NMRD (Nuclear Magnetic Relaxation Dispersion) profiles were recorded at different temperatures on a FCS Research Relaxometer using the field cycling method, covering a continuum of magnetic fields from 2.5×10^{-4} to 1.2 T (corresponding to a proton Larmor Frequency range of 0.01−50 MHz). The absolute uncertainty in the $1/T_1$ values for the NMRD measurements was about 2%. The spin-lattice relaxation rates at 20 MHz were also measured on a Minispec Bruker PC-20 spin analyzer.

Computer Calculations: Experimental variable-temperature ^{17}O NMR spectroscopic and NMRD data were fitted with a computer program written by Dr. É. Tóth and Dr. L. Helm (University of Lausanne, Switzerland) using the Micromath Scientist program version 2.0 (Salt Lake City, UT, USA). Molecular volumes were calculated with the use of the HyperChem program (version 6.0, HyperCube Inc., Gainsville FL, USA).

Synthesis of the Ligands: The ligand L was synthesized following Carvalho et al.[4] Purification was done via ion exchange chromatography (DOWEX 1×8−200, OAc^- form, elution with a gradient of HOAc).[5] Ligand L with deuterated methylene groups in the acetate functions was synthesized in an analogous way starting from DTPA, deuterated at the corresponding positions. The latter was obtained using the procedure of Wheeler and Legg.[15] H_5DTPA (0.42 g) was dissolved in 15 mL D_2O, and the pD was adjusted to 10.6 by addition of solid K_2CO_3. The solution was refluxed for 24 h. After cooling, the reaction mixture was acidified to pD 2 using concentrated HCl. The solution obtained was concentrated under reduced pressure, and the solid KCl was filtered off. Upon addition of 2-propanol to the filtrate, the deuterated compound precipitated, and was filtered off. The yield of $[D_{10}]H_5DTPA$ was 0.27 g (67%). The degree of acetate methylene deuteration (>99%) was determined from the integrals in the ^1H NMR spectrum. The compound was converted into the bis-anhydride compound by reflux in an acetic anhydride/pyridine mixture.

Preparation of the Dinuclear Gd_2L Complex: The gadolinium complex of the macrocyclic ligand L was prepared by adding an aque-

ous solution of $GdCl_3 \cdot 6H_2O$ dropwise to a solution of the ligand in water (molar ratio $GdCl_3$:L = 2:1) while keeping the pH at about 6. Salts were removed by ultrafiltration over a UTC-60 membrane (Toray Industries, Tokyo, Japan) under a pressure of 20 bar N_2. Finally, the aqueous solution was freeze dried. The complex was tested for the absence of free lanthanides using an arsenazo III indicator.

Acknowledgments

3,7,10-Trichalcogenaoctasila[3.3.3]propellanes

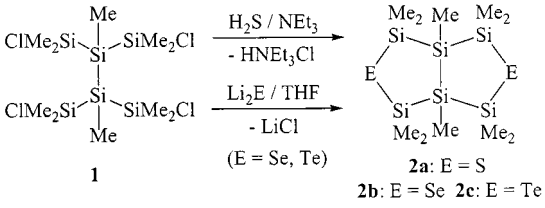
U. Herzog*[a] and G. Rheinwald[b]

Keywords: Silanes / Sulfur / Selenium / Tellurium / Polycycles

The reaction of hexakis(trimethylsilyl)disilane with acetyl chloride and aluminum chloride yields hexakis(chlorodimethylsilyl)disilane (**5a**) under carefully controlled reaction conditions. Treatment of **5a** with either H_2S/NEt_3 or Li_2E (E = Se, Te) gives the dodecamethyl-3,7,10-trichalcogenaoctasila-[3.3.3]propellanes $Si_2(SiMe_2)_6E_3$ (**6a** E = S, **6b** E = Se, **6c** E = Te). The products have been characterized by multinuclear NMR spectroscopy (^1H, ^{13}C, ^{29}Si, ^{77}Se, ^{125}Te). The central silicon atoms are very deshielded in comparison with other compounds containing an $Si(Si)_4$ unit due to their incorporation into three five-membered rings. The molecular structures of **5a** and **6a** are reported revealing an elongated central Si–Si bond in **5a** of 2.3865(11) Å and three different spatial orientations of the $SiMe_2Cl$ groups in each $Si(SiMe_2Cl)_3$ unit. In **6a** all three five-membered rings Si_4S adopt *envelope* conformations with the four silicon atoms in one plane. A view of the Si_8S_3 skeleton along the central silicon–silicon bond of **6a** resembles a three-blade propeller.

Introduction

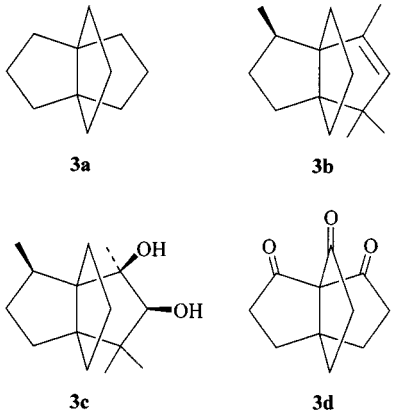
In previous investigations we have shown that the reaction of 1,1,2,2-tetrakis(chlorodimethylsilyl)dimethyldisilane (**1**) with either H_2S/NEt_3 or Li_2E (E = Se, Te) yields exclusively the 3,7-dichalcogenahexasilabicyclo[3.3.0]octanes [**2a**–**c**; Equation (1)].[1]



(1)

The formation of these compounds underlines the general observation that the formation of five-membered heterocycles is preferred in the systems silicon-sulfur, -selenium and -tellurium.[2,3] The facile formation of the bicyclic systems tempted us to apply these reactions to the synthesis of the corresponding tricyclic ring systems, which can be described as [3.3.3]propellanes (**3a**, Scheme 1).

It should be mentioned that carbon-based [3.3.3]propellanes have been known for some time[4,5] and even a naturally occurring sesquiterpene, modhephene (**3b**),[6,7] containing this tricyclic skeleton has been described. Molecular structures have been reported for modhephenediol (**3c**, 2,3-dihydroxy-2,4,4,8-tetramethyl[3.3.3]propellane,[6]) and [3.3.3]-propellane-2,8,9-trione (**3d**).[8]



Scheme 1

Results and Discussion

Formation and Structure of Hexakis(chlorodimethylsilyl)disilane (5a)

The formation of 3,7,10-trichalcogenaoctasila[3.3.3]propellanes requires an octasilane skeleton with six chlorodimethylsilyl units connected to a central disilane. This compound, hexakis(chlorodimethylsilyl)disilane (**5a**), can be prepared in three steps starting from tetrakis(trimethylsilyl)-silane by the formation of hypersilylpotassium developed by Marschner[9] [Equation (2)] and a subsequent oxidative dimerization of the hypersilanyl anion [Equation (3)].

(4)

The molecular structure of the formed hexakis(trimethylsilyl)disilane (**4**) has been reported previously[10,11] revealing an elongated central Si−Si bond of 2.40 Å.

The treatment of **4** with acetyl chloride and aluminum chloride in hexane yields the desired hexachlorinated octasilane **5a** under optimized reaction conditions. Slightly higher reaction temperatures also led to the formation of the higher chlorinated octasilanes **5b** and **5c** [Equation (4)].

The molecular structure of **5a** is shown in Figure 1 and 2 and selected bond lengths and angles are summarized in Table 1. The structure of **5a** is a rare example of a successful crystal structure determination of a methylchlorooligosilane because most compounds of this class are liquids or low melting solids which are highly soluble in all organic solvents. The central silicon−silicon bond of **5a** (Si1−Si5) is, at 2.3865(11) Å, longer than the other Si−Si bonds but slightly shorter than that in **4**. In both $Si(SiMe_2Cl)_3$ units one chlorine substituent occupies a more axial position with respect to the central Si−Si bond (Cl3, Cl4) while the other two are equatorial. This reduces the steric overcrowding resulting in a slightly shorter central Si−Si bond than in **4**. A closer look reveals that in each $Si(SiMe_2Cl)_3$ unit there are three different $SiMe_2Cl$ groups which can be distinguished by their different dihedral angles Cl−Si−Si−Si (see Table 1). A comparison of the two $Si(SiMe_2Cl)_3$ units shows that the silyl units containing Si(2) and Si(8) have a similar orientation, as is the case for Si(3) and Si(7) and Si(4) and Si(6). A look at the Si−Si−Si angles shows that all the Si−Si(1)−Si(5) ands Si(1)−Si(5)−Si angles are larger than the tetrahedral angle of 109.5°, while all the Si−Si−Si angles within each $Si(SiMe_2Cl)_3$ unit are smaller. This is a result of the mutual repulsion of the two $Si(SiMe_2Cl)_3$ units connected by the central Si−Si bond. By comparing the angles C−Si−C (107.93−112.18°, average 109.68°) and C−Si−Si (112.18−117.41°, average 114.30°) with the angles C−Si−Cl (104.94−107.03°, average 106.00°) and Cl−Si−Si (102.97−109.18°, average 105.68°) it can be clearly seen that a methyl group occupies more space than a chlorine substituent.

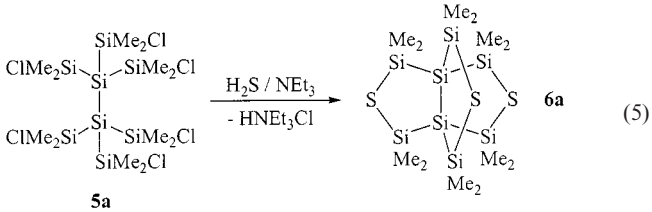
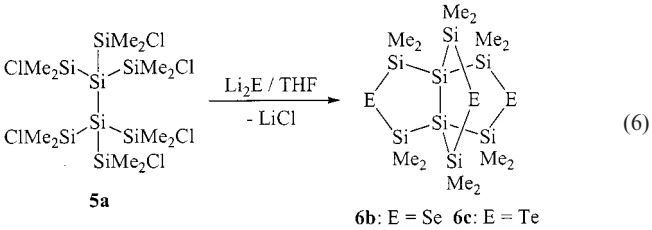
3,7,10-Trichalcogenaoctasila[3.3.3]propellanes

The reaction of **5a** with either H_2S/NEt_3 in hexane or Li_2E (E = Se, Te) prepared in situ from the chalcogens and $LiBEt_3H$ in THF yielded the expected dodecamethyl-3,7,10-trichalcogenaoctasila[3.3.3]propellanes **6a−c** [Equation (5) and (6)]:



(5)



(6)

The NMR spectroscopic data of the propellanes **6a−c** are given in Table 2. While the δ_{Si} values of the $SiMe_2$ units are similar to those in the corresponding monocyclic five-membered rings $(SiMe_2)_4E$[12] and the bicyclo[3.3.0]octanes **2a−c**, the NMR chemical shifts of the central Si atoms are remarkable. Compared with other compounds containing $Si(Si)_4$ units like $Si(SiMe_3)_4$ (δ_{Si} = −135.5[13]), $Si_2(SiMe_3)_6$ (**4**, δ_{Si} = −129.5[9]) or even chloro-substituted derivatives like $Si(SiMe_2Cl)_4$ (δ_{Si} = −113.9[14]) and $Si_2(SiMe_2Cl)_6$ (**5a**, δ_{Si} = −111.62) the chemical shifts found in the propellanes **6a−c** are shifted significantly to lower field, especially in the cases of the heavier chalcogens (Se, Te; see Figure 3).

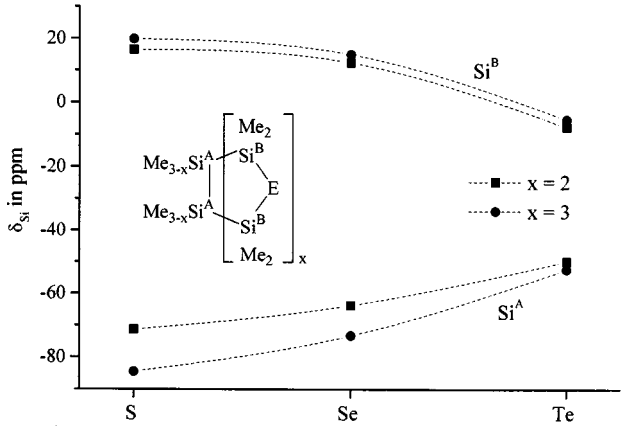


Figure 3. ^{29}Si NMR chemical shifts in bicyclo[3.3.0]octanes (**2a−c**) [1] and [3.3.3]propellanes (**6a−c**) for E = S, Se, Te

It has been observed before that the formation of five-membered rings in the silicon chalcogen systems is always accompanied by a strong low-field shift of the ^{29}Si NMR signals, which increases from sulfur to tellurium in the case of oligosilanyl units.[3] In the cases of the central silicon atoms in the propellanes **6a−c** these atoms are incorporated into three five-membered rings causing these unusual low-

field shifts. Furthermore, compared to the bicyclo[3.3.0]octanes **2b**−**c**[1] the ^{77}Se and the ^{125}Te NMR signals of the propellanes **6b**−**c** are shifted to lower field by 89 ppm (Se) and 114 ppm (Te), despite the same first and second coordination sphere around the chalcogen atoms.

Compound **6a** was characterized by its mass spectrum and also by an X-ray structure analysis. Figure 4 shows the molecular structure of **6**, and some bond lengths and angles are given in Table 3.

In contrast to **5a** all the Si−Si bond lengths are in the usual range. All three five-membered rings adopt almost ideal envelope conformations with dihedral angles Si−Si(1)−Si(5)−Si of −4.8 to −5.2° and envelope angles of 44.57(6)° [Si_4S ring including S(1)], 46.52(6)° [Si_4S ring including S(2)] and 45.28(8)° [Si_4S ring including S(3)]. This is slightly more than in the organic [3.3.3]propellane modhephenediol (**3c**) with envelope angles of 37−42°[6] and close to the envelope angles in the bicyclo[3.3.0]octane derivative **2a** [42.34(4)° and 44.35(3)° [1]]. In contrast to the structure of **2a**, however, all three five-membered rings in **6a** are folded in the same rotatory sense resembling an almost ideal three-blade propeller (Figure 5). The angles at the sulfur atoms in **6a** are, at 101.5−102.4°, close to the values in **2a**. The same holds for the Si−Si and the Si−S bond lengths. Due to the formation of the five-membered rings all Si−Si−Si angles including the Si(1)−Si(5) bond are smaller than the tetrahedral angle (101.5−102.6°) resulting in Si−Si−Si angles of more than 109.5° within the $Si_3Si(1)$ and $Si_3Si(5)$ units (in the range of 115.1−116.4°).

Experimental Section

General: All NMR spectra were recorded on a Bruker DPX 400 in $CDCl_3$ solution and TMS as internal standard for ^{1}H, ^{13}C and ^{29}Si. External Ph_2Se_2 (δ_{Se} = 460) and Ph_2Te_2 (δ_{Te} = 422) in $CDCl_3$ were used as standards for ^{77}Se and ^{125}Te. In order to obtain a sufficient signal-to-noise ratio of ^{29}Si NMR spectra for obtaining $^1J_{SiC}$, $^1J_{SiSi}$, $^{1,2,3}J_{SiSe}$ or $^1J_{SiTe}$ satellites ^{29}Si INEPT spectra were also recorded. ^{77}Se and ^{125}Te spectra were determined using an IGATED pulse program.

Mass spectra were measured on a Hewlett Packard 5971 (ionization energy: 70 eV, column: 30 m × 0.25 mm × 0.25 μm, phenylmethylpolysiloxane, column temperature: 80 °C (3 min)/20 K/min, flow: He 0.5 mL/min).

Starting Materials: H_2S (N25, Air Liquide), Se, Te, triethylamine, 1 M $LiBEt_3H$ in THF (Super Hydride), were commercially available. $Si(SiMe_3)_4$ was prepared as described in ref.[21] THF was distilled from sodium/potassium alloy prior to use. The other solvents were dried over KOH or sodium wire. All reactions were carried out under argon using standard Schlenk techniques.

Crystal Structure Analysis: X-ray structure analysis measurements were performed on a Bruker SMART CCD. Crystal data of **5a** and

6a as well as data collection and refinement details are given in Table 4. The unit cell dimensions were determined with the program SMART.[15] The program SAINT[15] was used for data integration and refinement of the unit cell parameters. The space group was determined with the aid of the programs ABSEN[16] (**5a**) and XPREP[15] (**6a**). All data were corrected for absorption using SADABS.[17] The structures were solved using direct methods [SIR97[18] (**5a**), SHELX97[19] (**6a**)], refined using least-squares methods (SHELX-97) and drawn using Diamond.[20] The ellipsoids of the non-hydrogen atoms are at the 50% probability level. The hydrogen atoms on the methyl groups in **6a** were refined as constrained groups, whereas all hydrogen atoms in **5a** could be located from the difference map and fully refined.

Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-164379 (**5a**) and -164380 (**6a**). Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Hexakis(trimethylsilyl)disilane, $Si_2(SiMe_3)_6$ (4): $Si(SiMe_3)_4$ was reacted in THF with KO*t*Bu and the resulting $KSi(Me_3Si)_3$ solution was treated with $C_2H_4Br_2$ as described in ref.[9] After removal of the solvent the product was a mixture of **4** and approximately 25% $Si(SiMe_3)_4$. The two compounds were separated by sublimation in vacuo at 130 °C for 6 h. The residue of the sublimation was almost pure **4** in 72% yield, which could be used without further purification. ^{1}H NMR: δ = 0.274; ^{13}C NMR: δ = 4.38 ($^1J_{SiC}$ = 42.3 Hz); ^{29}Si NMR: δ = −9.55 ($SiMe_3$, $^1J_{SiSi}$ = 53.0 Hz), −130.13 ($SiSi_4$). − GC/MS: *m*/*z* (%) = 494 (4) [M$^+$], 479 (4) [M − Me], 421 (3) [$Me_{15}Si_7$], 406 (5) [$Me_{14}Si_7$], 305 (2) [$Me_{11}Si_5$], 273 (11) [Me_7Si_6], 247 (22) [Me_9Si_4], 232 (100) [Me_8Si_4], 199 (15), 173 (12) [$Me_5Si_3CH_2$], 131 (13) [Me_5Si_2], 73 (62) [Me_3Si].

Hexakis(chlorodimethylsilyl)disilane, $Si_2(SiMe_2Cl)_6$ (5a): Compound **4** (1.36 g, 2.75 mmol) was dissolved in 20 mL hexane and anhydrous aluminum chloride (3.00 g, 22.5 mmol) was added. Acetyl chloride (1.6 g, 20 mmol) was slowly added to this stirred mixture. After stirring overnight the reaction mixture was heated to 40 °C for one hour and the hexane phase was separated. Removal of the solvent in vacuo yielded 0.70 g (1.13 mmol, 41%) of pure crystalline **5a**, m.p.: 257 °C; ^{1}H NMR: δ = 0.845; ^{13}C NMR: δ = 8.05 ($^1J_{SiC}$ = 48.7 Hz); ^{29}Si NMR: δ = 29.06 ($SiMe_2Cl$, $^1J_{SiSi}$ = 56.9 Hz), −111.62 ($SiSi_4$). − GC/MS: *m*/*z* (%) = 601 (2) [M − Me], 581 (1) [M − Cl], 523 (44) [$Me_{10}Cl_5Si_7$], 488 (21) [$Me_{10}Cl_4Si_7$], 395 (9) [$Me_8Cl_3Si_6$], 380 (15) [$Me_7Cl_3Si_6$], 309 (13) [$Me_6Cl_3Si_4$], 272 (42) [$Me_6Cl_2Si_4$], 209 (18) [Me_6ClSi_3], 174 (13) [Me_6Si_3], 131 (26) [Me_5Si_2], 93 (37) [Me_2ClSi], 73 (100) [Me_3Si].

If the reaction mixture was heated to 70 °C, a mixture of **5a** (52%), $(ClMe_2Si)_3Si-Si(SiClMe_2)_2(SiCl_2Me)$ (**5b**; 43%) and

$(Cl_2MeSi^C)(ClMe_2Si^B)_2Si^A-Si^A(Si^BClMe_2)_2(Si^CCl_2Me)$ (**5c**; 5%) was obtained after removal of the solvent hexane.

$(ClMe_2Si^C)_3Si^A-Si^B(Si^DClMe_2)_2(Si^ECl_2Me)$ (5b): ^{13}C NMR: δ = 8.03 (Si^CMe_2), 7.69 (Si^DMe_2), 13.02 (Si^EMe); ^{29}Si NMR: δ = −111.23 (Si^A), −104.08 (Si^B), 28.88 (Si^C), 27.85 (Si^D), 36.98 (Si^E). − GC/MS: *m*/*z* (%) = 623 (2) [M − Me], 543 (27) [$Me_9Cl_6Si_7$], 508 (28) [$Me_9Cl_5Si_7$], 415 (10) [$Me_7Cl_4Si_6$], 400 (24) [$Me_6Cl_4Si_6$], 309 (31) [$Me_6Cl_3Si_4$], 272 (13) [$Me_6Cl_2Si_4$], 209 (19) [Me_6ClSi_3], 159 (22) [Me_5Si_3], 131 (29) [Me_5Si_2], 93 (61) [Me_2ClSi], 73 (100) [Me_3Si].

$(Cl_2MeSi^C)(ClMe_2Si^B)_2Si^A-Si^A(Si^BClMe_2)_2(Si^CCl_2Me)$ (5c): ^{29}Si NMR: δ = −111.23 (Si^A), 27.75 (Si^B), 36.21 (Si^C).

Dodecamethyl-3,7,10-trithiaoctasila[3.3.3]propellane, $Si_2(SiMe_2)_6S_3$ (6a): Compound **5a** (0.23 g, 0.37 mmol) was dissolved in 30 mL hexane and NEt_3 (0.35 mL, 2.5 mmol) was added while a stream of dried H_2S was bubbled through the stirred solution. After stirring overnight the reaction mixture was filtered. Removal of the solvent from the filtrate yielded 0.14 g (0.28 mmol, 76%) of pure **6a** as a colorless crystalline residue. Single crystals of **6a** were grown from a solution in hexane, m.p.: 225 °C (decomp.).

6a: GC/MS: *m*/*z* (%) = 500 (25) [M^+], 485 (6) [M − Me], 441 (8) [$Me_9Si_7S_3CH_2$], 427 (29) [$Me_9Si_7S_3$], 395 (3) [$Me_9Si_7S_2$], 351 (6) [$Me_7Si_6S_2CH_2$], 337 (7) [$Me_7Si_6S_2$], 293 (6) [$Me_5Si_5S_2CH_2$], 277 (10) [Me_7Si_5S], 262 (8) [Me_6Si_5S], 247 (15) [Me_5Si_5S], 233 (11) [$Me_5Si_4SCH_2$], 189 (11) [Me_7Si_3], 131 (13) [Me_5Si_2], 73 (100) [Me_3Si].

Dodecamethyl-3,7,10-triselenaoctasila[3.3.3]propellane, $Si_2(SiMe_2)_6Se_3$ (6b) and Dodecamethyl-3,7,10-tritelluraoctasila[3.3.3]propellane, $Si_2(SiMe_2)_6Te_3$ (6c): A solution of **5a** (0.31 g, 0.50 mmol) in 1 mL THF was slowly added to a suspension of Li_2E (E = Se, Te) prepared from 1.5 mmol elemental E and 3 mL of a 1 M solution of $Li[BEt_3H]$ in THF. In the case of the tellurium compound the reaction was carried out at −30 °C to prevent Si−Si bond cleavage reactions. After stirring for 30 min the solvent was removed in vacuo and replaced by 10 mL hexane. Filtration from precipitated lithium salts and removal of the solvents yielded the propellanes **6b** and **6c** as colorless crystalline residues in 62 and 25% yield, respectively.

Photoinduced C−H Activation and Catalytic Carbonylation of Benzene − New Features of a Tris(pyrazolyl)methanesulfonato (Tpms) Rhodium(I) Complex

Wolfgang Kläui,*[a] Daniel Schramm,[a] and Wilfried Peters[a]

Keywords: Rhodium / Tripodal ligands / N ligands / C−H activation / Carbonylation / Homogeneous catalysis / Aldehydes

Irradiation of [(Tpms)Rh(CO)(PMe_3)] (**1**) in benzene or [D_6]benzene affords the rhodium(III) compounds [(Tpms)Rh(H)(C_6H_5)(PMe_3)] (**2**) and [(Tpms)Rh(D)(C_6D_5)(PMe_3)] (**2-d_6**) respectively. The k_H/k_D ratio for the formation of **2** and **2-d_6** was found to be 1.1. The complexes **2** and **2-d_6** are stable in protic solvents. When a solution of **1** in benzene is irradiated under carbon monoxide pressure, benzaldehyde is formed catalytically with turnover numbers of up to 20. The formation of **2** and [(Tpms)Rh(H)(COC_6H_5)(PMe_3)] (**4**) under catalytic conditions allows the proposal of a catalytic cycle.

Introduction

Since the first reports on C−H bond activation in 1965,[1] the transition-metal-catalysed activation of alkanes and arenes has become one of the most challenging fields of organometallic chemistry.[2] Bergman was the first to observe the oxidative addition of cyclohexane to the Cp*Rh(PMe_3) fragment in 1982,[3] which led to the development of similar complexes with ligands such as tris(pyrazolyl)borates (Tp, Tp*).[4,5] So far none of the above-mentioned complexes has been reported to catalytically functionalize hydrocarbons or arenes by C−H activation. Until now carbonylation reactions based on tripodal rhodium(I) systems like [Tp*Rh(CO)(C_2H_4)] only produced stoichiometric amounts of insertion products.[5b] The catalytic carbonylation of arenes and alkanes is, however, known with Vaska-type catalysts like [RhCl(CO)(PPh_3)$_2$][6] and analogous compounds.[7,8]

We have recently reported[9] the synthesis of the novel tris(pyrazolyl)methanesulfonate ligand (Tpms), a monoanionic tripodal nitrogen ligand. TpmsRh^I compounds show a coordination chemistry which resembles that of analogous tris(pyrazolyl)borato compounds. Moreover, they are hydrolytically stable and soluble in polar protic solvents.[10]

We describe here the C−H activation of benzene and [D_6]benzene with [(Tpms)Rh(CO)(PMe_3)] leading to the rhodium(III) complexes [(Tpms)Rh(R)(C_6R_5)(PMe_3)] (R = H, D) that catalyse the formation of benzaldehyde from benzene and carbon monoxide.

Results and Discussion

Photoactivation of [(TpmsRh(CO)(PMe_3)] (1)

The photolysis of the bright yellow [(TpmsRh(CO)(PMe_3)] (**1**) offers a convenient method for the generation of a coordinatively unsaturated intermediate which can then undergo the oxidative addition of C−H bonds. Although **1** is only moderately soluble in benzene, irradiation leads to a quantitative conversion into the C−H activation product [(TpmsRh(H)(C_6H_5)(PMe_3)] (**2**). However, due to its low solubility in less polar solvents we have not yet found the correct reaction conditions for the C−H activation of saturated hydrocarbons.

Preparation of [(TpmsRh(H)(C_6H_5)(PMe_3)] (2) and [(TpmsRh(D)(C_6D_5)(PMe_3)] (2-d_6)

The UV/Vis spectrum of [(TpmsRh(CO)(PMe_3)] (**1**) shows a band at 232 nm (ε = 17000 L·mol^{-1}·cm^{-1}), which is typical for the Tpms ligand, and a charge transfer band at 355 nm (ε = 2000 L·mol^{-1}·cm^{-1}). In order to prevent possible photochemical reactions of the pyrazoles, **1** is irradiated in Pyrex vessels ($\lambda > 290$ nm) which serve as a cut-off filter. The yellow suspension of **1** in benzene gradually clears as the reaction proceeds leading to the whitish hydrido compound [(TpmsRh(H)(C_6H_5)(PMe_3)] (**2**) (Figure 1). The reaction is complete within one hour. When the reaction is performed in a 1:1 mixture of benzene/[D_6]benzene, **2** and [(TpmsRh(D)(C_6D_5)(PMe_3)] (**2-d_6**) are formed in a ratio of 1:0.9 (i.e. k_H/k_D = 1.1). This indicates that there is only a very small kinetic isotope effect.[11]

Both **2** and **2-d_6** are soluble in benzene, toluene, and in polar organic solvents like THF and acetone. In wet solvents like acetone no decomposition is observed within hours at ambient temperatures. However, the hydrido compound **2** reacts with a stoichiometric amount of CCl_4 to

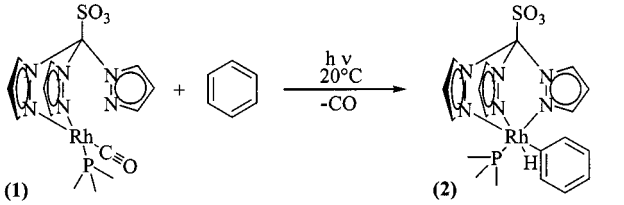

Figure 1. C−H activation of benzene with [(TpmsRh(CO)(PMe_3)] (**1**)

give the corresponding chloro compound [(TpmsRh(Cl)(C_6H_5)(PMe_3)] (**3**) and chloroform within a few hours.

The ^{1}H NMR spectrum of the benzene activation product **2** shows a signal pattern consistent with a compound of C_1 symmetry. The most prominent signal is a doublet of doublets found at $\delta = -16.30$ for the hydride bound to the rhodium atom. The coupling constants to rhodium ($^1J_{RhH} = 26.0$ Hz) and phosphorous ($^2J_{PH} = 32.3$ Hz) are within the range found for similar Cp*[12] and Tp*[13] compounds. All the pyrazole protons (see Figure 2 for numbering scheme) show coupling to the hydride and the phosphorous. Due to limitations of the spectral resolution ($\approx$ 0.2 Hz) only the *trans* couplings are observable. This allows a complete assignment of all protons by selective decoupling, COSY and NOESY-experiments (see Exp. Sect.).

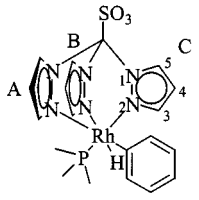

Figure 2. Schematic structure of the C_1 symmetrical complex [(TpmsRh(H)(C_6H_5)(PMe_3)] (**2**)

The deuteride bound to the rhodium in the [D_6]benzene activation product **2-*d*$_6$** can be found as a doublet of doublets in the ^{2}H NMR spectrum at $\delta = -16.1$. Due to the differences in the magnetogyric ratio, the coupling constants are smaller by a factor of 6.5 ($^1J_{RhD} = 4$ Hz, $^2J_{PD} = 5$ Hz). Therefore no H−D coupling can be resolved in the ^{1}H NMR spectrum.

In the IR spectra of **2** and **2-*d*$_6$** the characteristic $\nu_{(Rh-H)}$ band is found at $\tilde{\nu} = 2085$ cm^{-1}, whereas the $\nu_{(Rh-D)}$ band can be observed at $\tilde{\nu} = 1500$ cm^{-1}. The frequency ratio caused by the different masses of H and D is close to the theoretical value of $\approx$1.41.

The mass spectra show peaks at $[M - 1]^+$ for **2** and $[M - 2]^+$ for **2-*d*$_6$**. This indicates that the hydrido and deuterido ligands are lost under FAB conditions.

Catalytic Carbonylation of Benzene

A suspension of [(TpmsRh(CO)(PMe_3)] (**1**) in benzene was irradiated with a 125 W medium pressure mercury arc. The reaction was conducted in a Pyrex ($\lambda > 290$ nm) vessel equipped with Teflon seals and valves allowing us to maintain a carbon monoxide pressure of three to four atmospheres. The carbonylation proceeds without a significant induction period (Figure 3). This indicates that the primary photoprocess is fast under catalytic conditions. In the beginning the turnover frequency (TOF) is about 3 h^{-1}, which is in the same range as found for the Vaska-type compound [RhCl(CO)(PMe_3)$_2$] under similar conditions.[7a] The analogous complex [Tp*Rh(CO)(PMe_3)][14] produces only sub-

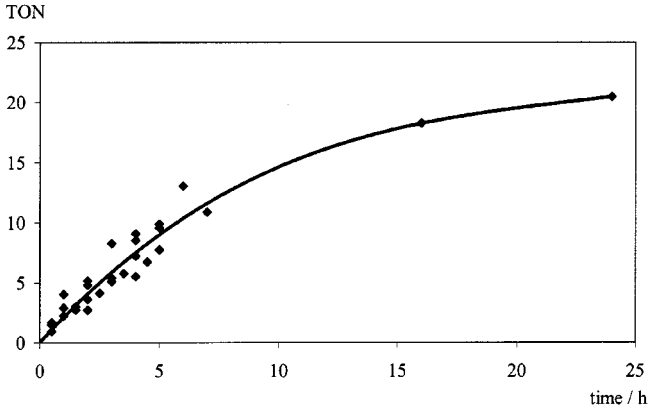

Figure 3. Time-dependence of the catalytic carbonylation of benzene

stoichiometric amounts of benzaldehyde within 5 hours under similar conditions.

The maximum turnover of 20 is reached after about 24 h. At that point only small amounts of the catalytically active hydride species can still be found in the reaction mixture. In addition secondary photoreactions of the benzaldehyde take place. This was also observed in the analogous reaction with [RhCl(CO)(PMe_3)$_2$] as catalyst.[8]

Intermediates and Mechanism

After a short time the benzene activation product **2** and the carbon monoxide insertion product [(TpmsRh(H)(COC_6H_5)(PMe_3)] (**4**) can be identified by NMR spectroscopy. The most characteristic signal of **4** is a doublet of doublets for the hydrido ligand found at $\delta = -14.88$. The coupling constants as well as the spectral appearance are almost identical to those found for **2** indicating the structural relationship between **2** and **4**. This allows us to propose a catalytic cycle for the carbonylation of benzene with [(TpmsRh(CO)(PMe_3)] (**1**) as precursor (Figure 4).

The irradiation of the carbonyl compound **1** probably results in the formation of an unsaturated 14-electron complex, which reacts with benzene to give the hydridophenyl compound **2**. We exclude an associative mechanism as we could show that **1** does not undergo oxidative addition without irradiation. For the Vaska-type compound [RhCl(CO)(PMe_3)$_2$] an associative mechanism was proposed to be more likely than a dissociative one.[7d]

The next step, leading to the CO insertion product **4**, again does not happen without irradiation. When complex **2** is stirred under carbon monoxide pressure without irradiation, the rhodium(I) compound **1** is recovered and no traces of **4** or benzaldehyde are observed. The reason for this is that **2** is a coordinatively saturated complex where one of the ligands has to be abstracted in order to add and insert CO. This is most likely to occur by a change of the tripod's denticity, as Tpms is known to act as a bi- or tridentate ligand in rhodium chemistry.[10]

^{1}H and ^{31}P NMR studies of the reaction mixture show that **2** and **4** exist in a ratio of 3:1 throughout the catalysis,

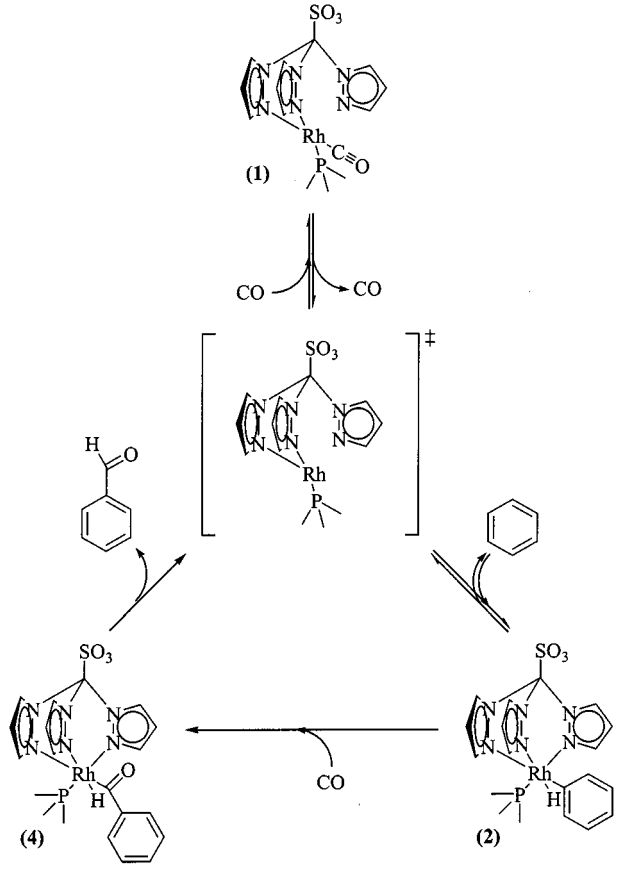

Figure 4. Proposed catalytic cycle for the photoinduced carbonylation of benzene

while only traces of **1** are found. This indicates that the Tpms ligand stabilises the catalytic intermediates **2** and **4** in a steady state at ambient temperatures. This is in clear contrast to the $[RhCl(CO)(PMe_3)_2]$ catalyst where the intermediates of the catalytic cycle revert thermally to the starting material.[15]

Conclusions

The compound $[(TpmsRh(CO)(PMe_3)]$ (**1**) readily activates benzene under irradiation to give $[(TpmsRh(H)(C_6H_5)(PMe_3)]$ (**2**), which is the first example of a $TpmsRh^{III}$ complex. The analogous reaction with $[D_6]$benzene affords $[(TpmsRh(D)(C_6D_5)(PMe_3)]$ **(2-*d*$_6$)**. Both compounds are stable in protic solvents. The kinetic isotope effect (k_H/k_D = 1.1) is similar to that found for the [Cp*Rh(PMe_3)] fragment.[11a]

To the best of our knowledge, $[(TpmsRh(CO)(PMe_3)]$ (**1**) is the only known catalyst with a tripodal ligand which is active in the catalytic carbonylation of benzene. The low steric bulk of the tripod and the phosphane help to keep the metal centre accessible while inhibiting intramolecular C−H activation. Therefore **1** produces efficiencies which are similar to those observed for the Vaska-type catalyst $[RhCl(CO)(PMe_3)_2]$.

Compound **1** provides a push-pull system of a highly basic phosphane and the weakly donating Tpms, which can act as a bi- or tridentate ligand. This unique blend allows the stabilisation of both planar Rh^I and octahedral Rh^{III} complexes. This is the main reason why the hydridophenyl complex **2** and the hydridobenzoyl compound $[(TpmsRh(H)(COC_6H_5)(PMe_3)]$ (**4**) are stable enough to be identified from the catalytically active reaction mixture.

Experimental Section

General Remarks: The compound $[(TpmsRh(CO)(PMe_3)]$ (**1**), was synthesised as previously reported.[10] All other reagents were commercial samples and were used as received. All reactions were carried out under nitrogen using standard Schlenk techniques unless stated otherwise. All solvents were purified and degassed by standard procedures. Filtration was done with 1 μm membrane filters (regenerated cellulose, Schleicher & Schuell). Reactions under 3−4 atm. pressure were performed in glass tubes equipped with Teflon seals and valves. All operations in glass vessels at elevated pressures should be done using effective body and face protection! Irradiation was done with a medium pressure mercury arc Philips HPK 125 (125 W, $\lambda > 230$ nm). Turnover numbers (TON) and turnover frequencies (TOF) are based on the molar ratio of benzaldehyde/catalyst. One dimensional ^1H, ^{31}P, and ^{13}C NMR spectra were recorded with Bruker DRX 200 (at 296 K) or Bruker DRX 500 (at 300 K) spectrometers. Two dimensional NOESY and COSY as well as one dimensional ^2H, ^1H $\{^1H\}$and ^1H $\{^{31}P\}$ NMR spectra were recorded with a Bruker DRX 500 spectrometer. The chemical shifts (δ) are given in ppm referenced to the solvent $[D_6]$benzene at δ = 7.16.[16] Infrared spectra were recorded using a Bruker IFS 66 FT spectrometer. FAB mass spectra were recorded on a Finnigan MAT 8200 using a NBA matrix with addition of NaI. Elemental analyses were performed using a Perkin−Elmer CHN-2400/II elemental analyser. GC analysis was done with a HP-5890 series II chromatograph with a FID-detector and a MSD 5970 integrator. All concentrations were determined by comparison to calibration curves obtained with actual samples of benzaldehyde in benzene.

Hydridophenyltrimethylphosphane[tris(pyrazol-1-yl)methanesulfonato]rhodium(III), $[(TpmsRh(H)(C_6H_5)(PMe_3)]$ (2): A suspension of **1** (10 mg, 0.020 mmol) in 10 mL of benzene was stirred in a Pyrex vessel in a water bath at room temperature. The mixture was irradiated for one hour. Addition of pentane precipitated 12 mg of a light grey solid. − ^1H NMR (500 MHz, C_6D_6): δ = −16.30 (dd, $^1J_{RhH}$ = 26.0 Hz, $^2J_{PH}$ = 32.3 Hz, 1 H, hydrido-*H*), 0.65 [dd, $^2J_{PH}$ = 10.1 Hz, $^3J_{RhH}$ = 1.2 Hz, 9 H, $P(CH_3)_3$], 5.31 (ddd, $^3J_{HH}$ = 3.0 Hz, $^3J_{HH}$ = 2.0 Hz, $^4J_{PH}$ = 1.1 Hz, 1 H, C-pyrazolyl C^4H), 5.56 (dd, $^3J_{HH}$ = 3.0 Hz, $^3J_{HH}$ = 2.0 Hz, 1 H, A-pyrazolyl C^4H), 5.69 (ddd, $^3J_{HH}$ = 3.0 Hz, $^3J_{HH}$ = 2.0 Hz, $^4J_{HH}$ = 0.4 Hz, 1 H, B-pyrazolyl C^4H), 6.85 (db, $^3J_{HH}$ = 2.0 Hz, 1 H, A-pyrazolyl C^3 *H*), 6.96 (db, $^3J_{HH}$ = 2.0 Hz, 1 H, C-pyrazolyl C^3H), 7.05 (m, 5 H, C_6H_5), 7.10 (db, $^3J_{HH}$ = 2.0 Hz, 1 H, B-pyrazolyl C^3H), 9.36 (ddd, $^3J_{HH}$ = 3.0 Hz, $^4J_{RhH}$ = 0.7 Hz, $^5J_{PH}$ = 1.5 Hz, 1 H, C-pyrazolyl C^5H), 9.52 (dd, $^3J_{HH}$ = 3.0 Hz, $^4J_{RhH}$ = 0.7 Hz, 1 H, A-pyrazolyl C^5H), 9.64 (ddd, $^3J_{HH}$ = 3.0 Hz, $^4J_{RhH}$ = 0.6 Hz, $^5J_{HH}$ = 0.6 Hz, 1 H, B-pyrazolyl C^5H). − ^{13}C $\{^1H\}$ NMR (500 MHz, C_6D_6): δ = 15.8 [d, $^1J_{PC}$ = 35 Hz, $P(CH_3)_3$], 90.3 (s, *C*-SO_3), 104.7 (s, A-pyrazolyl C^4), 104.8 (s, C-pyrazolyl C^4), 105.0 (s, B-pyrazolyl C^4), 121.5, 126.0, 126.1 (s, phenyl *C*), 126.2 (d, J_{RhC} = 2 Hz, phenyl *C*), 135.0 (s, C-pyrazolyl C^5), 135.3 (s, A-pyrazolyl C^5), 135.5 (s, B-pyrazolyl C^5), 141.2 (s, B-pyrazolyl C^3), 143.0 (s,

Determination of the k_H/k_D Ratio: A suspension of **1** (20 mg, 0.040 mmol) in a mixture of benzene (10 mL) and [D$_6$]benzene (10 mL) was stirred in a Pyrex vessel in a water bath at room temperature. The mixture was irradiated for 100 minutes. After the solution was evaporated, the residue was dissolved in [D$_6$]benzene and analysed by ^{1}H NMR spectroscopy. The integration ratios of the hydrido signal of **2** at δ = −16.30 (1.0 H) and the signals of the protons bound to the pyrazoles of the ligand allows the calculation of the ratio k_H/k_D to be 1.1. The ratio did not change within 12 hours, which rules out a thermal equilibration of **2** with [D$_6$]benzene.

Chlorophenyltrimethylphosphane[tris(pyrazol-1-yl)methanesulfonato]rhodium(III), [(TpmsRh(Cl)(C_6H_5)(PMe_3)] (3): Tetrachloromethane (1 mL) was added to a solution of **2** (22 mg, 0.040 mmol) in 15 mL of benzene. The reaction mixture was stirred overnight and the solvents evaporated to dryness to yield **3** as a light grey solid (23 mg). − ^{1}H NMR (200 MHz, C_6D_6): δ = 0.62 [dd, $^2J_{PH}$ = 10.8 Hz, $^3J_{RhH}$ = 0.8 Hz, 9 H, P(C*H*$_3$)$_3$], 5.31 (ddd, $^3J_{HH}$ = 3.0 Hz, $^3J_{HH}$ = 2.3 Hz, $^4J_{PH}$ = 1.8 Hz, 1 H, pyrazolyl C^4*H*), 5.50 (dd, $^3J_{HH}$ = 3.0 Hz, $^3J_{HH}$ = 2.5 Hz, 1 H, pyrazolyl C^4*H*), 5.63 (dd, $^3J_{HH}$ = 3.0 Hz, $^3J_{HH}$ = 2.2 Hz, 1 H, pyrazolyl C^4*H*), 6.60 (db, $^3J_{HH}$ = 2.5 Hz, 1 H, pyrazolyl C^3*H*), 7.04 (m, 5 H, C_6H_5), 7.21 (m,1 H, pyrazolyl C^3*H*), 7.44 (dd, $^3J_{HH}$ = 2.2 Hz, $^3J_{RhH}$ = 0.7 Hz, 1 H, pyrazolyl C^3*H*), 9.24 (ddd, $^3J_{HH}$ = 3.0 Hz, $^4J_{RhH}$ = 0.8 Hz, $^5J_{PH}$ = 1.8 Hz, 1 H, pyrazolyl C^5*H*), 9.44 (dd, $^3J_{HH}$ = 3.0 Hz, $^4J_{RhH}$ = 0.8 Hz, 1 H, pyrazolyl C^5*H*), 9.58 (dd, $^3J_{HH}$ = 3.0 Hz, $^4J_{RhH}$ = 0.8 Hz, 1 H, pyrazolyl C^5*H*). − ^{13}C {^{1}H} (500 MHz, C_6D_6): δ = 12.8 [d, $^1J_{PC}$ = 35 Hz, P(*C*H$_3$)$_3$], 90.0 (s, *C*-SO$_3$), 105.5 (s, pyrazolyl *C*^{4}), 105.6 (s, pyrazolyl *C*^{4}), 105.7 (s, pyrazolyl *C*^{4}), 122.6, 124.2, 125.8 (s, phenyl *C*), 126.1 (db, J_{RhC} = 3 Hz, phenyl *C*), 135.0 (s, pyrazolyl *C*^{5}), 135.4 (s, pyrazolyl *C*^{5}), 135.5 (s, pyrazolyl *C*^{5}), 142.3 (s, pyrazolyl *C*^{3}), 143.4 (s, pyrazolyl *C*^{3}), 143.6 (s, pyrazolyl *C*^{3}). − ^{31}P {^{1}H} NMR (200 MHz, C_6D_6): δ = 7.6 (d, $^1J_{RhP}$ = 127 Hz). − IR (KBr): $\tilde{\nu}$ = 3171 cm^{-1} (m, pyrazolyl C−H), 3059 (w, phenyl C−H), 2962, 2910 [w, P(CH)$_3$ C−H], 1569 (m, phenyl), 1522 (s, C=C), 1422 (s, P−C), 1099, 1070, 1054, 1021 (s, S=O). − MS (FAB$^+$): *m*/*z* (%) = 607 (7.1) [M + Na]$^+$, 549 (1.3) [M − Cl]$^+$. − $C_{19}H_{23}ClN_6O_3PRhS$ (584.8): calcd. Keywords: S ligands / Charge transfer / Nickel / Cyclic voltammetry / Magnetic properties

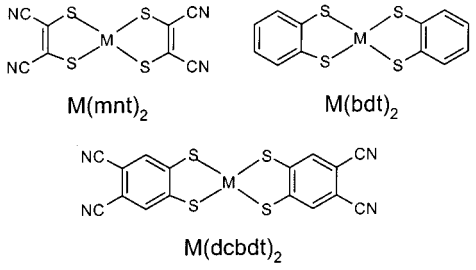
The synthesis and characterization of the new aromatic *ortho*-dithiol, 4,5-dicyanobenzene-1,2-dithiol (**3**) is reported. This compound was used to prepare tetrabutylammonium salts of novel nickel complexes; the nickel(II) salt $(n\mathrm{Bu_4N})_2[Ni(dcbdt)_2]$ (**4**), the nickel(III) salt $(n\mathrm{Bu_4N})_2[Ni(dcbdt)_2]_2$ (**5**), and the partially oxidized $Ni^{III/IV}$ salt $(n\mathrm{Bu_4N})_2[Ni(dcbdt)_2]_5$ (**6**). (dcbdt = 4,5-dicyanobenzene-1,2-dithiolate). The Ni^{II} complex presents a square-planar coordination geometry and is diamagnetic, while in the paramagnetic Ni^{III} complex the $Ni(dcbdt)_2$ units are strongly dimerized with the metal atom in a square-pyramidal coordination geometry and its magnetic susceptibility follows a singlet-triplet model with an antiferromagnetic coupling J = 897 K. The partially oxidized $Ni^{III/IV}$ complex **6** presents a weakly temperature-dependent paramagnetism of $5–6\cdot10^{-4}$ emu/mol and a room-temperature electrical conductivity of 0.15 S/cm following a semiconducting regime.

Introduction

Bis(dithiolene) transition metal complexes, showing a variety of coordination geometries and oxidation states, have been extensively studied since the 1960s,[1] and they have been widely used as building blocks for molecular compounds with conducting and or magnetic properties.[2] Among the simple examples of such complexes are the $M(mnt)_2$ complexes based on the ligand mnt = 1,2-dicyanoethene-1,2-dithiolate, also known as maleonitriledithiolate (Scheme 1), first prepared in 1955 by Bähr and Schleitzer.[3] These simple $M(mnt)_2$ complexes have provided the basis of compounds with very interesting properties such as metallic conductivity,[4] magnetic chains in compounds also having conducting chains based on other donor species,[5] and even ferroelectric behaviour.[6] However, it is believed that more extended and delocalized π-ligands of this type would make the different oxidation states more accessible, favouring electron transport in the solid, and offering a richer variety of structures. Indeed, other bis(dithiolene) complexes with delocalized sulfur-rich ligands have provided the bases for many other metallic and even superconducting systems.[2]



Scheme 1

In order to explore chemical modifications on electron charge-transfer solids containing the $M(mnt)_2$ complexes, we decided to prepare analogous dicyanodithio complexes with the more extended and aromatic ligand 4,5-dicyanobenzene-1,2-dithiol (**3**), (H_2dcbdt), whose preparation was not previously described. Preliminary data on a gold complex with this ligand, $(n\mathrm{Bu_4N})_2[Au(dcbdt)_2]_5$, was recently reported by us.[7] In this paper we report the synthesis of the ligand and the preparation and characterization of the tetrabutylammonium salts of three different nickel complexes, $[Ni(dcbdt)_2]^{z-}$ (z = 0.4, 1, 2).

Results and Discussion

The key compound for the synthesis of the ligand is 4,5-dichloro-1,2-dicyanobenzene (**1**) that can be obtained from 4,5-dichlorophthalic anhydride,[8] and is actually commercially available. The followed synthetic procedure involved the preparation of the aromatic dibenzyl sulfide,[9] 1,2-bis(*S*-benzylthio)-4,5-dicyanobenzene (**2**), in 71% yield (m.p. 189–190 °C), followed by a mild cleavage with the assistance of anhydrous aluminium chloride[10] (Scheme 2) to obtain **3** in 53% yield [m.p. 100 °C (dec.)].

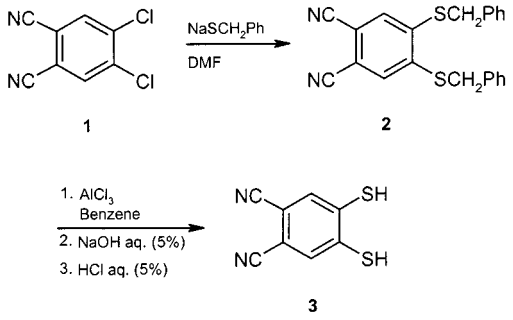

Scheme 2

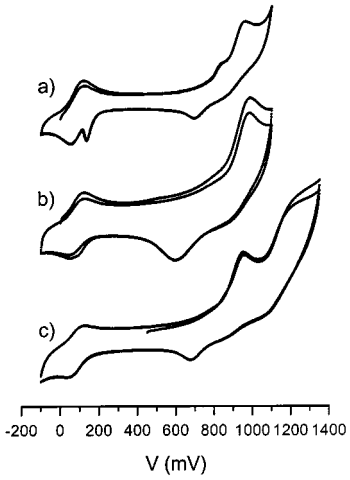

Figure 1. Cyclic voltammograms of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_2$ (**5**) in acetonitrile solution (ref. $Ag/AgNO_3$) at different scan rates: a) 50 mV/s; b) 500 mV/s; c) 100 mV/s

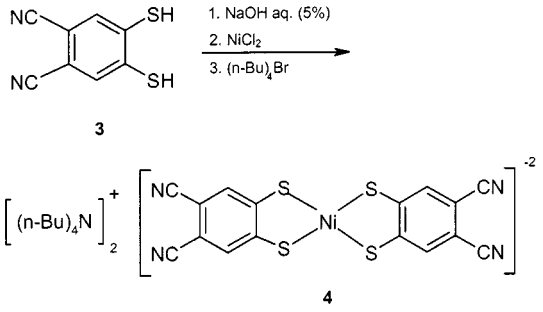
The nickel(II) complex of the ligand 4,5-dicyanobenzene-1,2-dithiol was obtained by the reaction of the dithiolate with nickel chloride, in an aqueous/alcoholic solvent mixture, and precipitated in the form of the tetrabutylammonium salt $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]$ (**4**) (Scheme 3), following the usual procedure for other bis(dithiolene) complexes.[11] This complex could be oxidized to Ni^{III}, $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_2$ (**5**), with iodine in acetone solutions (yield 44%, m.p. 244−245 °C). Further electrochemical oxidation of **5** led to a mixed Ni^{III}/Ni^{IV} compound $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5$ (**6**).



Scheme 3

The cyclic voltammetry of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_2$ (**5**) in acetonitrile showed different redox processes (Figure 1). One pair of reversible waves at 0.08 V vs. $Ag/AgNO_3$ was always present, as in $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]$ (**4**), and it was ascribed to the couple Ni^{II}/Ni^{III}. This value should be compared with the corresponding one for the compound with the unsubstituted benzodithiolate ligand (bdt), $Ni(bdt)_2$ (−1.05 V),[12] showing that the two cyano groups stabilize the dianionic state. In fact, while the $Ni(bdt)_2^-$ complex was obtained by oxidation of the dianion in air, obtaining $Ni(dcbdt)_2^-$ from the dianion required iodine as the oxidizing agent.

At more positive potentials a series of irreversible waves were observed with oxidation peaks at 0.83, 0.94, and 1.2 V, and reductions at 1.08, 0.89, and 0.68 V. The first oxidation wave became less prominent at higher scan rates (above 100 mV/s), while the corresponding reduction wave changed position from 0.70 to 0.50 V as the rate increased from 50 to 3000 mV/s. For slow scanning rates (50−100 mV/s) with amplitudes above 0.9 and below 1.2 V, there was an additional reduction peak at 0.120 V, typical of the formation upon oxidation of adsorbed species on the electrode (Figure 1, a). This peak was no longer observed at a scan rate of 500 mV/s and above (Figure 1, b) or for sweeps of 1.2 V or above (Figure 1, c).

This suggests that the process at 0.94/0.89 V led to the formation of insoluble $[\mathrm{Ni(dcbdt)_2}]_5^{2-}$ at the electrode. In fact from dichloromethane solutions of the monoanionic complex $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_2$ (**5**), crystals of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5$ (**6**) were obtained by electrocrystallization, using similar conditions to those previously described to obtain the gold analogue.[7] The higher potential process is probably the full oxidation to Ni^{IV}, while the waves at 0.83/0.68 with a very rate-sensitive reduction peak were associated with the process $[\mathrm{Ni(dcbdt)_2}]_2^{-2}/[\mathrm{Ni(dcbdt)_2}]_2^-$, coupled to some other reaction.

The direct comparison of this with cyclic voltammetry data obtained with $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]$ (**4**) was not possible due to the much lower solubility of compound **4**. The results for compound **4** present the same pair of reversible waves at 0.086 V, and the two similar pairs of waves at higher oxidation potentials. However, the waves at 0.83/ca. 0.68 V and the reduction wave ascribed to electrode deposition were not observed. This may be due only the lower solubility of **4**.

Compound **5** probably exists in solution as the dimer $[\mathrm{Ni(dcbdt)_2}]_2^{2-}$ as suggested by the solid-state X-ray structure with quite short dimerization bonds (see below). This

proposal is also supported by the comparison of the conductivity of **4** and **5** in acetonitrile solutions. If compound **5** were fully dissociated, the conductivity of an equimolar solution of **4** should have been twice that of **5**, but we found values of 57.5 and 22.7 μS/cm, respectively, for 0.2 mM solutions at 18 °C, giving a higher ratio and denoting the presence of the less mobile dimer.

The crystals obtained for compounds **4** and **5** enabled the crystal-structure determination by X-ray diffraction, but those of **6** were of insufficient quality for diffraction work. An ORTEP view of the complex anions in **4** and **5** is depicted in Figure 2, showing the atomic labelling scheme. Selected bond lengths for these compounds are presented in Table 1.

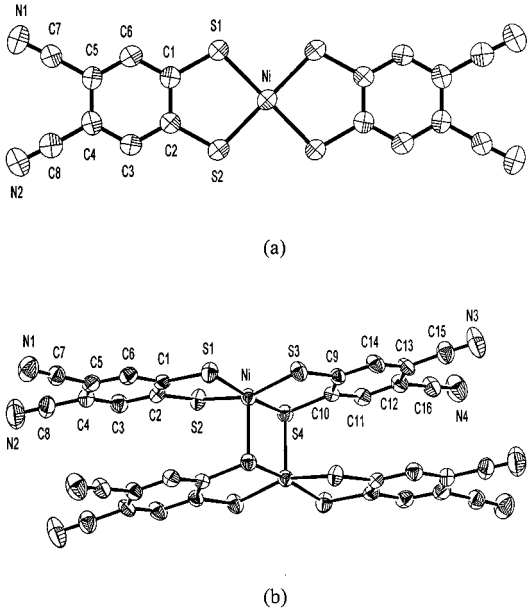


Figure 2. ORTEP diagrams and atomic numbering scheme of the complexes; a) $[Ni(dcbdt)_2]^{2-}$ in **4** and b) $[Ni(dcbdt)_2]^{-}$ in **5**, with thermal ellipsoids at 40% probability level

In complex **4** the Ni atom is located at an inversion centre, and the dianion $[Ni(dcbdt)_2]^{2-}$ presents a perfectly planar geometry, since all atoms lie in a mirror plane. The Ni−S bond lengths, Ni−S(2) 2.1736(15) Å and Ni−S(1) 2.1658(16) Å, are in the typical range, 2.16−2.18 Å, of other bis(dithio)Ni^{II} complexes,[13−16] namely for $Ni(bdt)_2$ where the distances are 2.166−2.172 Å.[16] The crystal structure of **4** shows $[Ni(dcbdt)_2]^{2-}$ layers with the complex in mirror planes at $y = 0$ and $y = 1/2$, which are separated by cation layers (Figure 3) preventing any short anion−anion interactions.

In **5** the Ni^{III} complex presents a strong dimerization of the $[Ni(dcbdt)_2]^{-}$ units that are related by an inversion centre (Figure 2) between the two nickel atoms. In the $[Ni(dcbdt)_2]_2^{2-}$ units, besides the equatorial Ni−S bonds at distances Ni−S(1) 2.2050(17) Å, Ni−S(2) 2.2023(16) Å, Ni−S(3) 2.1993(16) Å, Ni−S(4) 2.1792(16) Å, there are two Ni−S(4)* bonds at 2.3965(16) Å.

As shown by the side view of the dimer $[Ni(dcbdt)_2]_2^{2-}$ in Figure 4, the ligand where one sulfur atom is coordinating two metal atoms is almost planar [the largest deviations being the S(3) 0.072 Å and S(4) 0.083 Å] and the Ni atom lies only 0.08 Å from its average plane. In contrast, the other ligand presents a more considerable distortion with the coordinating sulfur atoms S1 and S2 deviated in opposite directions (0.063 and −0.127, respectively) and the Ni atom −0.39 Å from its average plane. Thus the four coordinating sulfur atoms are not coplanar and present a significant tetrahedral distortion with deviations of ±0.137 Å from their average plane, while the Ni atom deviates 0.286 Å from the average plane of the four sulfur atoms. The average plane of the two ligands makes a dihedral angle of 9.39(17)°.

[a] $-x,-y,-z+1$.

The dimerization of bis(dithiolene)metal(III) complexes, with the metal atom presenting a square-pyramidal coordination geometry, is frequent in similar complexes of other metals such as Fe and Co.[1,17,18] For bis(dichalcogenato)-nickel complexes such a clear dimeric structure was only found in a few bis(diselenolato)Ni complexes, as the neutral $Ni^{IV}(ddds)_2$ complex (ddds = 5,6-dihydro-1,4-dithiin-2,3-diselenolate),[19] the partially oxidised $Me_4N[Ni(dsise)_2]_2^{+}$ (dsise = 1,3-dithio-2-selenenido-4,5-diselenolate),[20] and the Ni^{III} complex $nBu_4N[Ni(dsit)_2]$ (dsit = 1,3-dithiole-2-thione-4,5-diselenolate).[21] With complex $Ni(mnt)_2^{-}$ a much weaker tendency towards a metal-over-sulfur packing has been reported in the compounds $(pet)_3[Ni(mnt)_2]_2$,[22] $(PPh_3Me)[Ni(mnt)_2]$,[23] and $NEt_4[Ni(mnt)_2]$,[24] where the

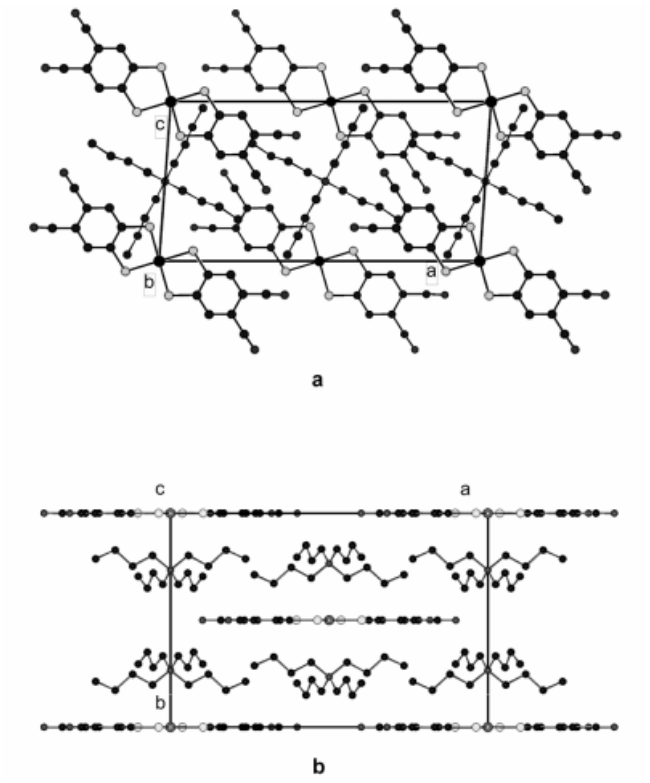

Figure 3. Crystal structure of $(n\mathrm{Bu_4N})_2\mathrm{Ni(dcbdt)_2}$ (**4**): (a) viewed along the *b* axis, and (b) viewed along the *c* axis

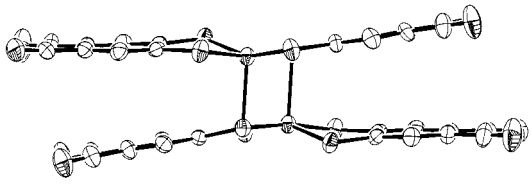

Figure 4. Side view of the dimer $[\mathrm{Ni(dcbdt)_2}^-]_2$ in **5**

apical Ni−S distances are much larger, 3.85, 3.59, and 3.69 Å, respectively, and the $\mathrm{Ni(mnt)_2}$ units remain almost planar. To the best of our knowledge, this is the first time that a clearly dimerized structure was found in a bis(dithio)$\mathrm{Ni^{III}}$ complex. Furthermore, it should be noticed that in this case, when compared with other dimerized bis(dichalcogenide) complexes, the apical bond is quite short and almost comparable to the equatorial ones.

The crystal structure of **5** is shown in Figure 5. Along the axes *c* and *b* the dimerized anions and the cations are alternating. However, along *a* the $[\mathrm{Ni(dcbdt)_2}]_2^{2-}$ dimers are arranged in chains, due to several weak interactions, connecting two $[\mathrm{Ni(dcbdt)_2}]^-$ units of adjacent dimers side by side, namely the hydrogen bonds N(3)···H(3*) and N(3*)···H(3) at 2.612 Å and 156.6°, and S(1)···H(11) at 3.188 Å and 149.9°, and a short contact S(3)···S(3*) at 3.784 Å, (see Figure 6).

While the dianionic complex **4** is diamagnetic, the monoanionic complex **5**, with $\mathrm{Ni^{III}}$, is expected to be paramagnetic with $S = {}^1/_2$. However, the strong dimerization

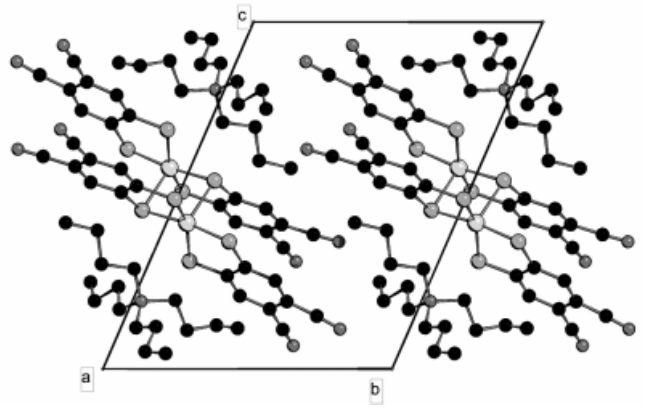

Figure 5. Crystal structure of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_2$ (**5**) viewed along the *a* axis

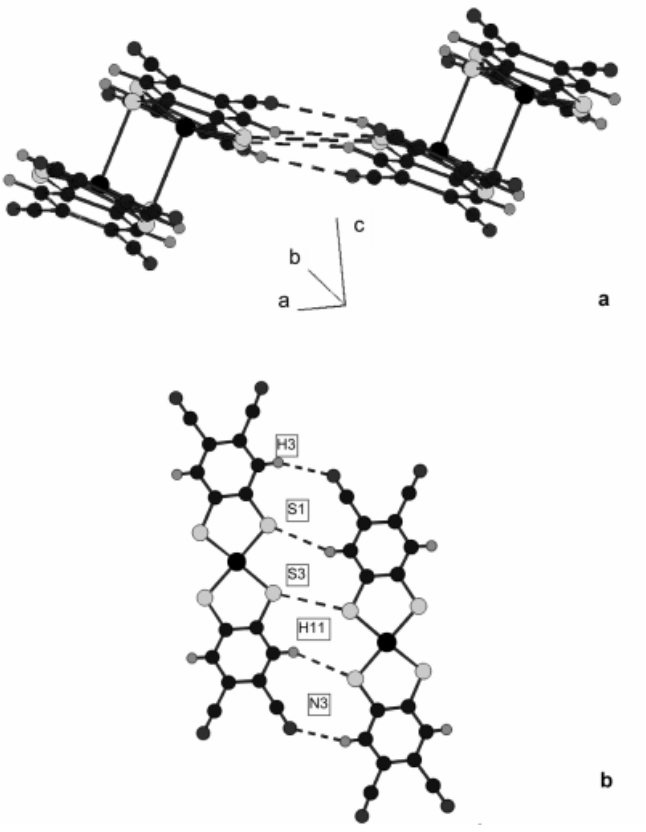

Figure 6. Chain of $[\mathrm{Ni(dcbdt)_2}^-]_2$ dimers in **5** connected along *a* by S···S contacts and N···H and S···H hydrogen bonds: a) side view; b) detail of two $[\mathrm{Ni(dcbdt)_2}]^-$ units of adjacent dimers viewed perpendicularly to their average plane with indication of the short contacts connecting them

of the $[\mathrm{Ni(dcbdt)_2}]^-$ units, as frequently observed in other dimerized Fe complexes, can lead to a strong antiferromagnetic coupling of the $S = {}^1/_2$ states expected for a isolated square planar coordination.[17,22,25]

The EPR spectra of **5**, both as a powder or as a frozen solution, show rhombic symmetry, with *g* values of 2.210, 2.0421, and 2.0064, for acetone solution at 110 K.

$(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5^{-2}$ also shows an EPR signal, as expected for a partially oxidized $Ni^{III/IV}$ compound, but this signal is visible only at low temperature, as an almost isotropic broad signal, 300G wide and centred at $g = 2.025$ at 8 K.

The paramagnetic susceptibility of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_2$, obtained from raw data after a correction for diamagnetism estimated from tabulated Pascal constants as $4.2\cdot10^{-4}$ emu/mol, was ca. $5\cdot10^{-4}$ emu/mol at room temperature and showed a strong decrease upon cooling, reaching a minimum around 100 K (Figure 7). At lower temperatures the magnetic susceptibility became dominated by a Curie tail of impurities and increased again. The paramagnetic susceptibility data could be accurately fitted by a model, considering in addition to the Curie tail and a temperature-independent term a contribution due to the dimers of $S = {}^1/_2$ spins, following a singlet-triplet law as given by the Bleaney−Jones equation.[26]

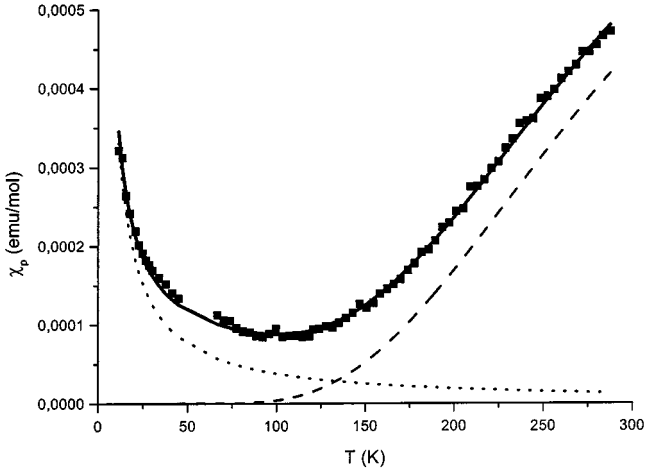

Figure 7. Paramagnetic susceptibility χ_p of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_2$ (**5**) as a function of the temperature T: the continuos line is a fit by Equation (1), the dotted line being the Curie tail contribution, corresponding to ca. 0.9% of $S = {}^1/_2$ spins and the dashed line the singlet-triplet contribution of the dimers (see text)

$$\chi_P = A + C/T + (Ng^2\mu_B^2/k_BT)[\exp(-2J/k_BT) + 3]^{-1} \quad (1)$$

with $A = 50(2)\cdot10^{-6}$ emu/mol, $J = 447(4)$ K, $g = 2.79(4)$, and $C = 0.00339(5)$ emu/mol·K corresponding to approximately 0.90% of $S = {}^1/_2$ spins (see Figure 7).

As it can be seen in Figure 7, the fit to our data is very good, but it is worth noting that the g value obtained is too high compared with known isolated Ni^{III} complex, and is above the EPR value obtained for this compound. However, the EPR signal that was visible only at low temperature, where the contribution was negligible, was due to the isolated Ni^{III} species associated with the Curie tail, rather than with the triplet state for which there are no EPR data in dimers of Ni^{III} species.

The J value obtained is quite large and can be compared to those reported for other $Ni(mnt)_2^-$ compounds such as $Cs[Ni(mnt)_2]\cdot H_2O$,[4c] $(pet)_3[Ni(mnt)_2]_2$,[22] $(PPh_3Me)[Ni(mnt)_2]$,[27] and $NEt_4[Ni(mnt)_2]$,[27] where the susceptibility data were also fitted to a similar singlet-triplet model with J values of 197, 226, 352, and 446 K, respectively. It is worth noting that the g values obtained by the fit in the last three compounds are also significantly larger than typical ones for similar isolated Ni^{III} complexes.

The paramagnetic susceptibility of **6**, obtained after a correction for diamagnetism, estimated from tabulated Pascal constants as $6.8\cdot10^{-4}$ emu/mol, is ca. $7\cdot10^{-4}$ emu/mol at room temperature and shows an almost temperature-independent behaviour down to ca. 70 K (Figure 8). Below this temperature there is an increase of susceptibility upon cooling that is ascribed to a Curie tail of impurities (or most likely defects). As shown in Figure 8, this Curie tail is relatively large and corresponds to ca. 5.6% $S = {}^1/_2$ spins. Subtracting this Curie tail from our experimental data an intrinsic susceptibility contribution was obtained that remained almost constant at least above 20 K with values in the range $5-7\times10^{-4}$ emu/mol. This behaviour is comparable to that previously found also in the partially oxidised gold analogue $(n\mathrm{Bu_4N})_2[\mathrm{Au(dcbdt)_2}]_5$ where the susceptibility was smaller (ca. $3-4\times10^{-4}$ emu/mol) as well as the Curie tail (ca. 0.7% of $S = {}^1/_2$ spins).

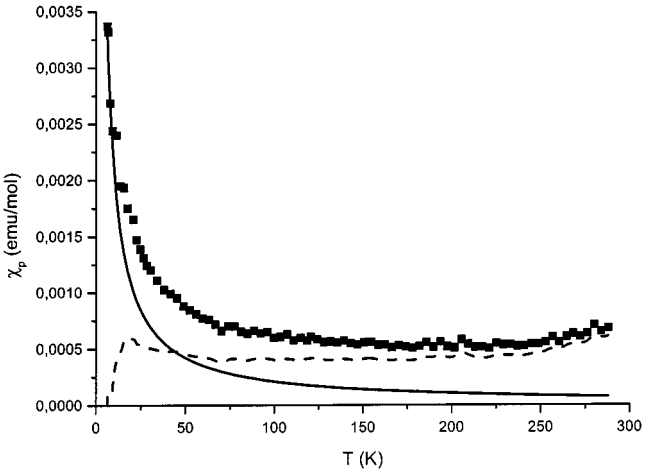

Figure 8. Paramagnetic susceptibility χ_p of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5$ (**6**) as a function of the temperature T: the lines are a decomposition in a Curie tail, corresponding to ca. 5.6% of $S = {}^1/_2$ spins (full line) and the intrinsic susceptibility (− − −)

Although this behaviour of the paramagnetic susceptibility is reminiscent of a Pauli contribution, such a possibility is ruled out by the relatively low electrical resistivity as discussed below, and instead it should be seen as the result of complex antiferromagnetic interactions between the Ni^{III} states. The electrical conductivity, σ, of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5$ (**6**), measured in single crystals is $\sigma_{rt} \approx 0.15$ S/cm at room temperature, following a thermally activated

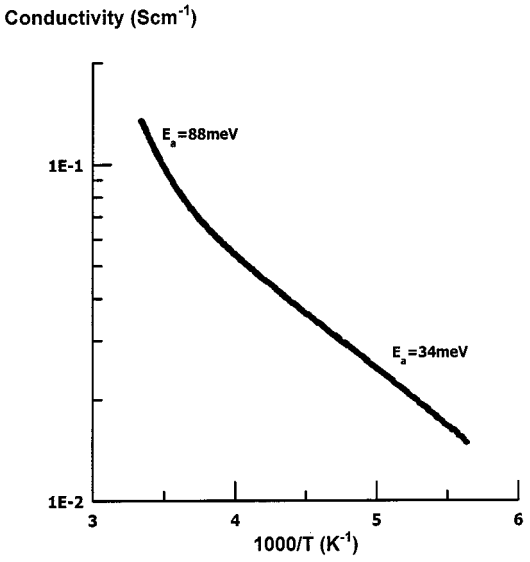

Figure 9. Electrical conductivity of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5$ (**6**) single crystals as a function of the inverse temperature

semiconducting behaviour (Figure 9). The plot of logσ versus $1/T$ shows an activation energy of 88 meV at higher temperatures that decreases upon cooling, and was reduced to 34 meV below 250 K. This variation could be attributed to a change from an intrinsic to an extrinsic semiconducting regime upon cooling. The electrical conductivity of this compound was not as large as that of the gold analogue $(n\mathrm{Bu_4N})_2[\mathrm{Au(dcbdt)_2}]_5$, where the room-temperature value was $\sigma_{rt} \approx 11$ S/cm, with a smaller activation energy of 13.5 meV.[7] The thermoelectric power measurements in crystals of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5$ indicated a value of $S_{rt} = -170$ μV/K at room temperature, also following a semiconducting behaviour with more negative values upon cooling in contrast to the gold analogue where the room-temperature thermopower value was rather small, $S_{rt} = -6$ μV/K, and slowly increased upon cooling, reaching a maximum of 20 μV/K at 120 K.[7] It was not possible to solve the crystal structure of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5$ due to the poor diffracting quality of the crystals, and in the absence of the structure it was only possible to speculate about the reason for this difference in the electrical properties of the Ni and Au compounds. However, besides a possible stacking of the $\mathrm{Ni(dcbdt)_2}$ units in a more irregular way than in the Au analogue, but in a similar structure, the smaller conductivity and the larger activation energy observed in the Ni compound most probably reflects the different band filling.

Conclusion

In summary, we synthesized a new aromatic *ortho*-arenedithiol, which allowed the preparation of a new bis(dithiolate)nickel complex, that could exist in a broad range of oxidation states, dianionic, monoanionic, or mixed between monoanionic and neutral. The monoanionic complex presents a dimerisation of the $\mathrm{Ni(dcbdt)_2}$ units, the strongest found so far in an $\mathrm{Ni^{III}}$ complex. The partially oxidised compound $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]_5$ behaves as a semiconductor. This new dcbdt ligand opens the way for the preparation of a new family of transition metal complexes with other metallic elements such as Au, Pt, Pd, Cu, Co, and Fe. The use of the nickel complex as an electron acceptor in the preparation of different new charge-transfer salts is presently under way.

Experimental Section

General: Elemental analyses were performed by the analytical services of IST and ITN. − ^{1}H and ^{13}C NMR: Varian (300 MHz), [D$_6$]DMSO as solvent, TMS as internal standard. − IR: Perkin-Elmer 1330. − UV/Vis/NIR: Cary 5G Varian spectrophotometer. − MS: Fourier Transform Ion Cyclotron Resonance apparatus (EXTREL FTMS 2001) operated with a YAG laser source. − 4,5-Dichloro-1,2-dicyanobenzene was synthesized by literature methods.[8] DMF, acetonitrile, and dichloromethane were distilled from phosphorus pentoxide, while benzene was distilled from sodium. All other reagents were used without purification.

Synthesis of 1,2-Bis(*S*-benzylthio)-4,5-dicyanobenzene (2): To a suspension of sodium hydride (1.2 g, 51 mmol) in dry DMF (80 mL), phenylmethanethiol (6 ml, 51 mmol) was added under argon while keeping the temperature between 10 and 15 °C. At room temperature, **1** (5 g, 25 mmol) (Aldrich, TCI) was then added in small portions. The reaction mixture was left overnight under argon with stirring. The product was collected by filtration and recrystallized from $CHCl_3$/MeOH to give **2** as pale yellow needles. Yield 71%, m.p. 189−190 °C. − $C_{22}H_{16}N_2S_2$ (372.50): calcd. C 70.94, H 4.34, N 7.52, S 17.21; found C 70.28, H 4.44, N 7.42, S 16.91. − IR (KBr): $\tilde{\nu}$ = 3080 cm^{-1}, 2220, 1560, 1490, 1455, 1340, 1235, 1110. − ^{1}H NMR (CD_2Cl_2): δ = 7.47 (s, 2 H), 7.34 (m, 10 H), 4.24 (s, 4 H). − ^{13}C NMR (CD_2Cl_2): δ = 144.2, 135.0, 130.4, 129.3, 128.4, 115.8, 112.2, 37.9. − MS (EI, 70 eV): *m*/*z* (%) = 372 (13) [M$^+$], 281 (15), 203 (25), 91 (100), 83 (58).

Synthesis of 4,5-Dicyanobenzene-1,2-dithiol (3): A solution of **2** (3.0 g, 8.05 mmol) in dry benzene (100 mL) was added dropwise to a suspension of finely powdered anhydrous $AlCl_3$ (4.3 g, 32.2 mmol) in dry benzene (50 mL) and the mixture was stirred under argon at room temperature for 96 h. Ice/water was added (120 mL) and the organic layer was separated and washed successively with water and 5% aq. NaOH (3 × 80 mL). Upon acidification with 5% aq. HCl a yellowish solid precipitated that was filtered to give **3**. Yield 53%, m.p. 100 °C (dec.). − $C_8H_4N_2S_2$ (192.25): calcd. C 49.97, H 2.10, N 14.57, S 33.36; found C 50.78, H 2.02, N 13.93, S 32.76. − IR (KBr): $\tilde{\nu}$ = 3080 cm^{-1}, 2540, 2230, 1570, 1460, 1340, 1220. − ^{1}H NMR ([D$_6$]acetone): δ = 8.05 (s, 2 H), 3.84 (s, 2 H). − ^{13}C NMR ([D$_6$]acetone): δ = 141.0, 134.0, 116.1, 112.3.

Synthesis of $(n\mathrm{Bu_4N})_2[\mathrm{Ni(dcbdt)_2}]$ (4): Compound **3** (0.2 g, 1.04 mmol) was dissolved in 5 mL of NaOH aq. (5%). A solution of $n\mathrm{Bu_4NBr}$ (0.34 g, 1.05 mmol) in EtOH/H_2O (1:1) (5 mL) was added, followed by a solution of $NiCl_2{\cdot}6H_2O$ (0.12 g, 0.5 mmol) in the same solvent. The mixture was cooled and filtered, and the precipitate was washed with EtOH. The crude material was recrystallized from EtOH to give **4** as red needles. Yield 17%, m.p. 261−262 °C. − $C_{48}H_{76}N_6NiS_4$ (924.11): calcd. C 62.37, H 8.30, N 9.09, S 13.88; found C 62.38, H 8.28, N 8.92, S 13.62. − UV/Vis (CH_2Cl_2): λ (ε [Mcm^{-1}]) = 251.9 (31800), 281.6 (50700), 319.8 (52200), 406.0 (28700). − IR (KBr): $\tilde{\nu}$ = 3060 cm^{-1}, 2960−2860,

2220, 1530, 350. − ^{1}H NMR ([D$_6$]DMSO): δ = 7.24 (s, 4 H), 3.19 (t, 16 H, *J* = 8.5, *J* = 8.5), 1.57 (m, 16 H), 1.31 (m, 16 H), 0.93 (t, 24H *J* = 7.2, *J* = 7.2). − ^{13}C NMR ([D$_6$]DMSO): δ = 128.7, 120.8, 118.0, 101.6, 57.5, 23.0, 19.1, 13.4.

Synthesis of (*n*Bu$_4$N)$_2$[Ni(dcbdt)$_2$]$_2$ (5): To a solution of **4** (0.17 g, 0.18 mmol) in acetone (100 mL) was added a solution of I_2 (70.1 mg, 0.28 mmol) in 5 ml of the same solvent. EtOH was added and the solution was slowly concentrated to give **5** as dark green needles. Yield 44%, m.p. 244−245 °C. − $C_{64}H_{80}N_{10}Ni_2S_8$ (1363.28): calcd. C 56.35, H 5.93, N 10.28, S 18.83; found C 55.85, H 6.03, N 10.13, S 18.39. − UV/Vis (CH_2Cl_2): λ (ε [mcm]) = 274.5 (7400), 319.8 (6000), 352.3 (4900), 854.3 (1400). − IR (KBr): $\tilde{\nu}$ = 3070 cm^{-1}, 2970, 2220, 1530, 420. − ^{1}H NMR ([D$_6$]acetone): δ = 7.98 (s, 4 H), 3.44 (t, 8 H, *J* = 7.8, *J* = 7.8), 1.85 (m, 8 H), 1.46 (m, 8 H), 0.99 (t, 12 H, *J* = 7.1, *J* = 7.1). − ^{13}C NMR ([D$_6$]acetone): δ = 135.5, 128.4, 123.9, 102.8, 47.1, 24.5, 20.5, 13.9. − MS: *m*/*z* (%) = 437.86 (100), 438.89 (14.9), 439.87 (48.83), 440.89 (9.49) 441.88 (10.63) 442.90 (1.82), 443.91 (2.02) [Ni(dcbdt)$_2^-$], 685.88 (4.33) 687.89(5.31) 689.89 (2.80) [Ni$_2$(dcbdt)$_3$]$^-$.

Synthesis of (*n*Bu$_4$N)$_2$[Ni(dcbdt)$_2$]$_5$ (6): A solution of **5** (19.4 mg, 28.4 μmol) in dichloromethane (20 mL) was placed in a two-compartment electrocrystallisation cell, separated by a glass frit, with platinum electrodes. Employing galvanostatic conditions (ca. 1.5 μA/cm^2) for 5 d, dark brown thin needle-shaped crystals, with typical dimensions up to 2 × 0.1 × 0.05 mm, grew on the anode surface. The product was collected and washed with dichloromethane. M.p. > 240 °C. − $C_{112}H_{92}N_{22}Ni_5S_{20}$ (2680.81): calcd. C 50.18, H 3.46, N 11.49, S 23.92; found C 50.31, H 3.38, N 11.47, S 23.52.

Electrochemical Measurements: Cyclic voltammetry data were obtained using an EG&G Princeton Applied Research Electrochemical workstation. The measurements were performed at 20 °C in acetonitrile containing 0.1 M tetra-*n*-butylammonium perchlorate as supporting electrolyte with platinum working and counter-electrode and either a 0.1 M Ag/AgNO$_3$ or a calomel reference electrode and scan rates in the range 50−3000 mV s^{-1}.

X-ray Crystallographic Study: Data collection for both crystals of **4** and **5** was performed with an Enraf Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069) at room temperature. Intensities were collected by the ω-2θ scan technique. The structures were solved by directed methods using SHELXS86[28] and refined with SHELXL97.[29] All non-hydrogen atoms were anisotropically refined by a full-matrix least-squares method. The hydrogen atoms were placed at calculated positions riding on the parent carbon atoms. Details of data collection and refinement are presented in Table 2. Molecular and crystal graphics were prepared with ORTEPIII[30] and SCHAKAL-97.[31] Crystallographic data (excluding structure factors) for the structures reported in this manuscript have been deposited with the Cambridge Crystallographic Data Centre. The deposition numbers are CCDC-154018 and -154019 for (*n*Bu$_4$N)$_2$[Ni(dcbdt)$_2$] and (*n*Bu$_4$N)[Ni(dcbdt)$_2$], respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

EPR Measurements: EPR spectra in the range 4−300 K were obtained with an X-Band Bruker ESP 300E spectrometer equipped with a microwave bridge ER041XK, a rectangular cavity operating in T102 mode, a Bruker variable-temperature unit, an Oxford ESR-900 cryostat, and a field controller ER 032M system. The modulation amplitude was kept well below the line-width and the microwave power well below saturation.

Magnetic Susceptibility Measurements: Magnetic susceptibility measurements in the range 4−300 K were performed using a longitudinal Faraday system (Oxford Instruments) with a 7 T superconducting magnet under a magnetic field of 5 T and forward and reverse field gradients of 1 T/m. Polycrystalline samples (8−12 mg) were placed inside a previously calibrated thin-wall Teflon bucket. The force was measured with a microbalance (Sartorius S3D-V). Under these conditions the magnetisation was found to be proportional to the applied magnetic field.

Electrical Transport Measurements: Electrical conductivity and thermoelectric power measurements of selected single crystals were performed in the range 120−320 K, using a measurement cell attached to the cold stage of a closed-cycle helium refrigerator. In a first step, thermopower was measured using a slow AC (ca. 10^{-2} Hz) technique,[32] by attaching to the extremities of an elongated sample, with platinum paint (Demetron 308A), two 60 μm diameter 99.99% pure Au wires (Goodfellow Metals) thermally anchored to two quartz reservoirs, in a previously described apparatus,[33] operated by computer control.[34] In a second step, electrical resistivity measurements of the same sample were performed using a four-probe technique. Two extra Au wires were placed on the sample, in order to achieve a four-in-line contact configuration. Measurements were done imposing through the sample a current of 1 μA at low frequency (77 Hz) and measuring the voltage drop with a lock-in amplifier.

Keywords: S ligands / Coordination chemistry / Magnetic properties / Nickel

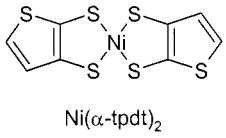
The nickel complex nBu$_4$N[Ni(α-tpdt)$_2$] (**2**) (α-tpdt = 2,3-thiophenedithiolate) has been prepared and characterized. A salt of this monoanionic paramagnetic complex, [Fe(Cp*)$_2$][Ni(α-tpdt)$_2$] (**3**), was obtained with decamethylferrocene, crystallizing in the monoclinic space group $P2_1/a$ with a = 15.443(3), b = 10.237(1), c = 20.360(2) Å, β = 107.54(1)°, V = 3069.1(7) Å^3, Z = 4. Its structure consists of alternating cationic and anionic layers, with short interlayer contacts defining alternating cation–anion chains. Magnetic characterization of **3** at low applied magnetic fields revealed an antiferromagnetic transition at T_N = 2.56 K. Below T_N, **3** displays a metamagnetic behaviour with a critical field of 0.07 T at 1.6 K. The magnetic properties of this compound are compared with those of the analogous salts with diamagnetic gold dithiolate [Fe(Cp*)$_2$][Au(α-tpdt)$_2$] (**4**), and diamagnetic decamethylcobaltocenium, [Co(Cp*)$_2$][Ni(α-tpdt)$_2$] (**5**), which are also reported. This comparison shows that the ferromagnetic interactions observed in **3** are due to cation–anion intrachain interactions.

Introduction

Square-planar bis(dithiolene) transition metal complexes have attracted considerable interest, essentially in their use as building blocks for constructing molecular materials. They are versatile units that can have a wide range of oxidation states, coordination geometries, and magnetic moments.[1] To date they have been used to generate several interesting and unusual properties, such as metallic behaviour[2] or even superconductivity,[3,4] third-order nonlinear optical properties, and cooperative magnetic properties such as ferromagnetism[5] or metamagnetism.[6]

In a recent paper, we reported the preparation of gold complexes based on three different thiophenedithiolate ligands.[7] They were viewed as the first members of a new larger family of complexes with different transition metals. These complexes have a high potential for use as building blocks in the preparation of novel molecular materials with interesting conducting or magnetic properties.

In this paper, we report the synthesis and characterization of the first nickel complex belonging to this series in the form of a tetrabutylammonium salt, nBu$_4$N[Ni(α-tpdt)$_2$], where α-tpdt = 2,3-thiophenedithiolate (Scheme 1). The synthesis, crystal structure, and magnetic properties of the decamethylferrocenium charge-transfer (CT) salt are also reported and are compared with those of the analogous salts with the diamagnetic acceptor (A) [Fe(Cp*)$_2$][Au(α-tpdt)$_2$] and the diamagnetic donor (D) [Co(Cp*)$_2$][Ni(α-tpdt)$_2$].



Ni(α-tpdt)$_2$

Scheme 1

Results and Discussion

The synthesis of nBu$_4$N[Ni(α-tpdt)$_2$] was carried out following a procedure (Scheme 2) similar to that described previously for the gold analogue.[7] The thiophenedithiolate ligands were obtained from 5,6-thieno[2,3-*d*]-1,3-dithiol-2-one (**1**) in methanol solution by cleavage with potassium methoxide. The ligand solution thus obtained, without isolation of the intermediate, was immediately added to a solution of nickel dichloride in methanol to give the nickel species, which precipitated as the green tetrabutylammonium salt nBu$_4$N[Ni(α-tpdt)$_2$] (**2**) upon treatment with nBu$_4$NI followed by stirring in air at ice-bath temperature. The precipitate was washed with methanol and purified by recrystallization from acetone/2-propanol to give air-stable crystals. The final yield was 89%. Elemental analysis results

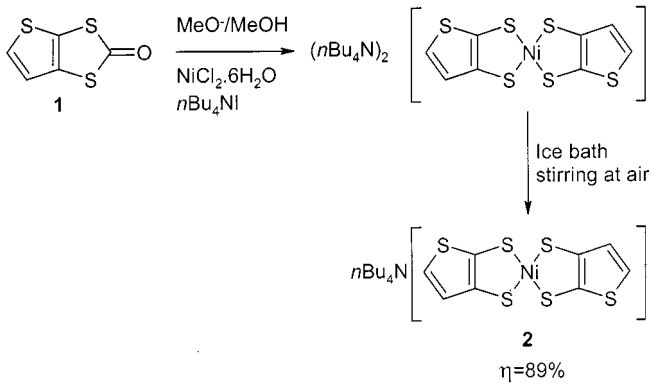

Scheme 2

correspond to a 1:1 stoichiometry for the nBu$_4$N salts of the nickel complex, thus indicating that Ni^{II} is oxidized during the synthesis.

Cyclic voltammetry of **2** in acetonitrile shows a pair of symmetric reversible redox waves at $E_{1/2} = -0.562$ V vs. Ag/AgCl, corresponding to the couple [Ni(α-tpdt)$_2$]$^{2-}$/[Ni(α-tpdt)$_2$]$^-$. At higher potentials, a pair of reversible waves is seen at $E_{1/2} = 0.253$ V, corresponding to the couple [Ni(α-tpdt)$_2$]$^-$/[Ni(α-tpdt)$_2$]. Similar voltammograms and almost identical potentials are observed in dichloromethane solution.

Oxidation potentials indicate that it is easier to obtain the neutral species in the case of the nickel complex than for the gold analogue, for which the couples Au^{II}/Au^{III} and Au^{III}/Au^{IV} were found under the same conditions at −1.62 V and 0.456 V, respectively.[7] In fact, solutions of compound **2** are rather unstable in air and decompose to give a fine precipitate, faster than in the case of the Au analogue.

In spite of the fact that well-formed single crystals are easily obtained, the crystal structure of **2**, with cell parameters $a = 9.4801(19)$, $b = 18.7867(24)$, $c = 9.6185(20)$ Å, $\beta = 119.336(23)°$, $V = 1493(1)$ Å^3, could not be solved due to severe twinning problems.

Ni^{III}, having a d^7-electronic configuration, in the square-planar coordination anticipated for [Ni(α-tpdt)$_2$]$^-$, is expected to be paramagnetic with $S = {}^1/_2$. This was confirmed by EPR and magnetization measurements.

The powder EPR spectrum of salt **2** at 7.5 K is shown in Figure 1, a. The spectrum observed in frozen acetone solutions, as shown in Figure 1, b, gives similar g values, with a structure corresponding to a rhombic anisotropy with

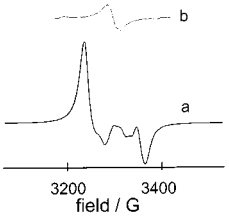

Figure 1. EPR spectra of compound **2**: (a) powder at 7.5 K, (b) acetone solution at 60 K

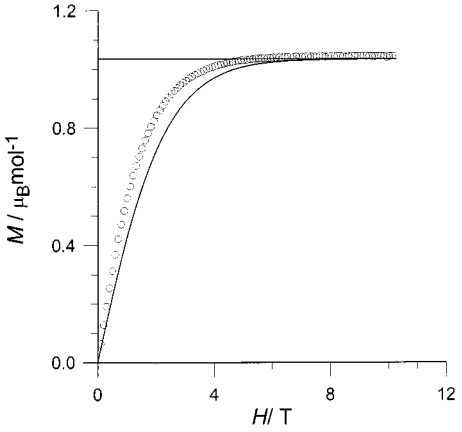

Figure 2. Magnetization of compound **2** as a function of the field at 1.6 K

values of $g_1 = 2.11492$, $g_2 = 2.04992$, $g_3 = 1.99611$. Single-crystal data show a single line of width 20 G at 8 K.

The static paramagnetic susceptibility of compound **2** follows the Curie−Weiss law with $\theta = 2.1$ K and indicates an effective magnetic moment, μ_{eff}, of 1.76 μ_B. The presence of slight ferromagnetic interactions in this compound, as denoted by the small positive θ value, is confirmed by the magnetization field dependence at 1.6 K (Figure 2), which shows a saturation magnetization of 1.04 $N\mu_B$. This is approached more rapidly than predicted by the Brillouin function for an $S = {}^1/_2$ spin system with an average $<g> = 2.06$ (thin solid curve). In most cases, the salts of metal-bis(dichalcogenide) monoanionic complexes with diamagnetic cations exhibit antiferromagnetic interactions, while in the case of compound **2** the coupling between the complexes is ferromagnetic. However, the absence of a crystal structure precludes a discussion of the contacts that give rise to the ferromagnetic interactions. In view of this, efforts towards the determination of the structure of compound **2** will be made.

The CT salt **3** and the corresponding analogues with decamethylcobaltocenium, [Co(Cp*)$_2$][Ni(α-tpdt)$_2$] (**4**), and gold-bis(thiophenedithiolate), [Fe(Cp*)$_2$][Au(α-tpdt)$_2$] (**5**), were obtained as small crystals by addition of equimolar solutions of a decamethylmetallocene salt and nBu$_4$N-[M′(α-tpdt)$_2$], respectively, under anaerobic conditions. Single crystals suitable for structural and physical studies were obtained by slow evaporation of the solvent from saturated acetonitrile solutions.

The crystal structure of compound **3** was solved. It crystallizes in the monoclinic space group $P2_1/a$ with $Z = 4$. Crystal and experimental data are summarized in Table 2. The systematic absences confirm the space group as $P2_1/a$. In the asymmetric unit, we found two half-[Fe(Cp*)$_2$]$^+$ fragments, the Fe atoms lying in special positions (centres of symmetry), and one acceptor molecule, [Ni(α-tpdt)$_2$], the Ni atom residing far from any special position. A significant disorder was observed in the methyl groups of the Cp* fragments; several disorder models were tried but none seemed to bring any improvement in the structure refine-

ment, not by lowering the e.s.d. in the bond lengths and angles nor by lowering the *R* values. Thus, the Me groups were allowed to refine anisotropically with an ISOR restraint of 0.02.

The Cp rings of the donor adopt a staggered conformation, as is commonly found. The $[Ni(\alpha\text{-tpdt})_2]^-$ anion adopts only a *trans* (*E*) configuration in the crystal, in analogy with the salt of a gold complex with the similar non-aromatic ligand dtpdt, $n Bu_4N[Au(dtpdt)_2]$.[7] The Ni−S bond lengths observed in the Ni complex, with average values of 2.156 Å (see Table 1), are in a good agreement with the values reported for other Ni^{III} dithiolates.[8−10] The $[Ni(\alpha\text{-tpdt})_2]^-$ anion is almost planar with a small chair-type distortion (Figure 3).

The crystal structure of **3** consists of alternating layers of donors, $[Fe(Cp^*)_2]^+$, and acceptors, $[Ni(\alpha\text{-tpdt})_2]^-$, extending parallel to the *a*,*b* plane. This is illustrated in Figure 4, which shows a projection of the crystal structure along the *a* axis. Unlike the donor layers, in which the cations are quite isolated from each other, in the acceptor layers relatively short interionic AA distances are found involving S atoms of the central NiS_4 fragment and a C atom of the thiophenic fragment of the ligand, as shown in Figure 5. The S···C separations are 3.723 and 3.751 Å, exceeding the sum of the van der Waals radii (3.450 Å) by 8 and 9%, respectively. Short interlayer interionic DA distances are also seen, involving C atoms of the Cp rings and the S atom of the thiophenic fragment from the acceptors, as shown in Figure 4 (dashed lines). These S···C distances are 3.530 and 3.610 Å, exceeding the sum of the van der Waals radii by 2 and 5%, respectively. These contacts form another set of layers composed of parallel alternating DA chains, as shown in Figure 6, and the chains in adjacent layers are almost perpendicular to each other, extending along directions alternating from $2\boldsymbol{b} + \boldsymbol{c}$ to $2\boldsymbol{b} - \boldsymbol{c}$ (Figure 7).

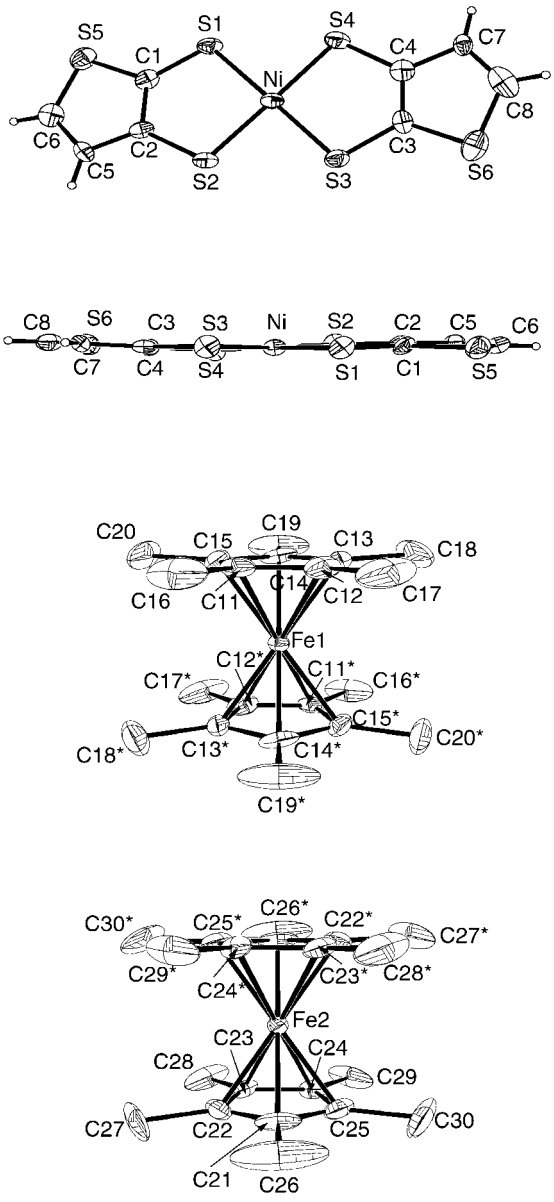

Figure 3. ORTEP diagram and atomic numbering scheme of compound **3** with thermal ellipsoids drawn at a 20% probability level; the high thermal vibration of the methyl groups is due to the disorder referred to in the text

The linear chain-based layers, extending parallel to the *b*,*c* plane (*bc* layers) are connected by the acceptor−acceptor interactions shown in Figure 5 forming a 3D network. Two chains from adjacent layers are shown in Figure 7 along with one anionic *ac* layer. The S···C contacts are slightly shorter in the *b*,*c* layers than in the *a*,*b* layers. However, in this case it is not possible to predict which ones dominate the magnetic interactions, as this also depends on the spin densities of the atoms involved in the contacts.

In view of this crystal structure, if the *ab* intralayer (AA) and *bc* intralayer (DA) contacts are different in nature, a complex magnetic behaviour can be expected for compound **3**, where both the donor and acceptor units are paramag-

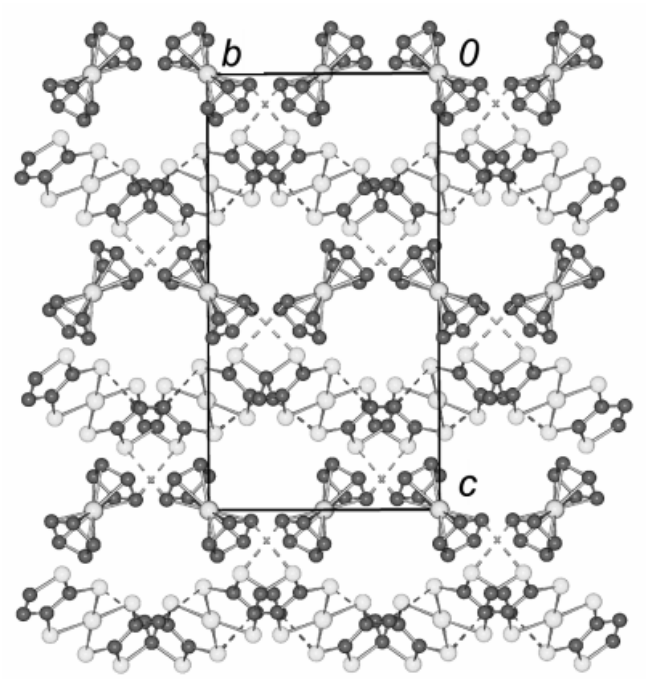

Figure 4. Crystal structure of **3** viewed along the *a* axis showing alternating layers of donors, $[Fe(Cp^*)_2]^+$, and acceptors, $[Ni(\alpha\text{-tpdt})_2]^-$, extending parallel to the *a*,*b* plane

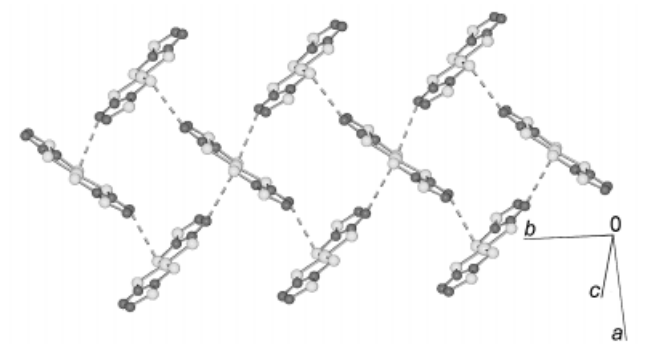

Figure 5. Layers of $[Ni(\alpha\text{-tpdt})_2]^-$ in **3** showing the closest S···C contacts

netic species with localized $S = {}^1/_2$ spins. The nature of these interactions can be better understood through studying the magnetic properties of the two other analogous CT salts **4** and **5**, in which one of the species, either the donor, as $[Co(Cp^*)_2]^+$, or the acceptor, as $[Au(\alpha\text{-tpdt})_2]^-$, is diamagnetic.

For compound **4**, the crystal structure could not be refined due to lower quality of the crystals, but the X-ray diffraction data reveal a monoclinic unit cell with parameters of $a = 15.370(3)$, $b = 10.233(2)$, $c = 20.450(3)$ Å, $\beta = 108.41(3)°$, indicating that it is isostructural with **3**. In the case of **5**, it was not possible to determine the unit cell parameters.

The temperature dependence of the product of the static paramagnetic susceptibility χ_P and the absolute temperature T, $\chi_P T$, for compounds **3**, **4**, and **5** is shown in Figure 8. In the latter two cases, $\chi_P T$ decreases upon cooling

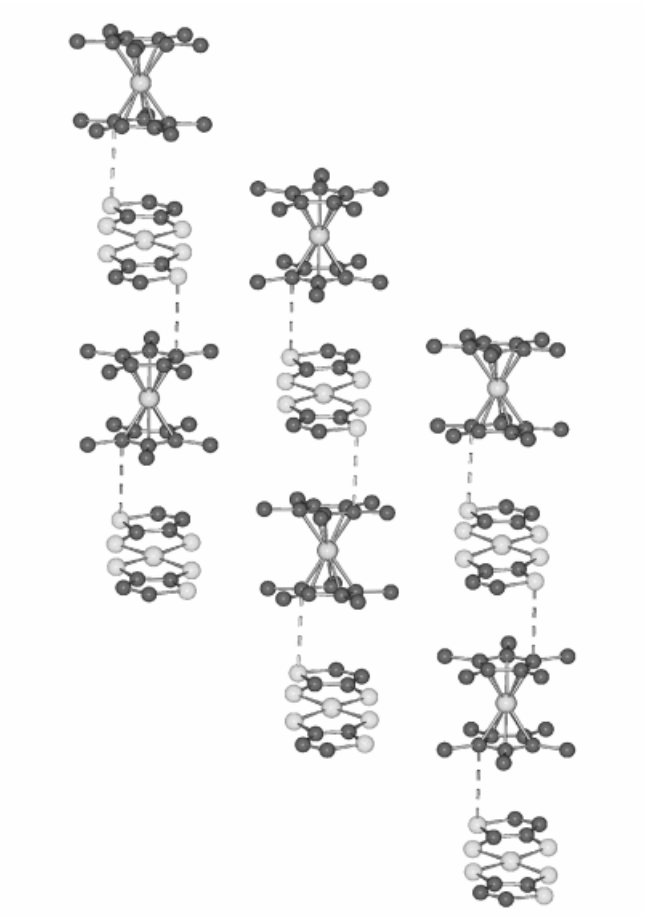

Figure 6. Partial view of the crystal structure of **3** showing the parallel alternating DA chains

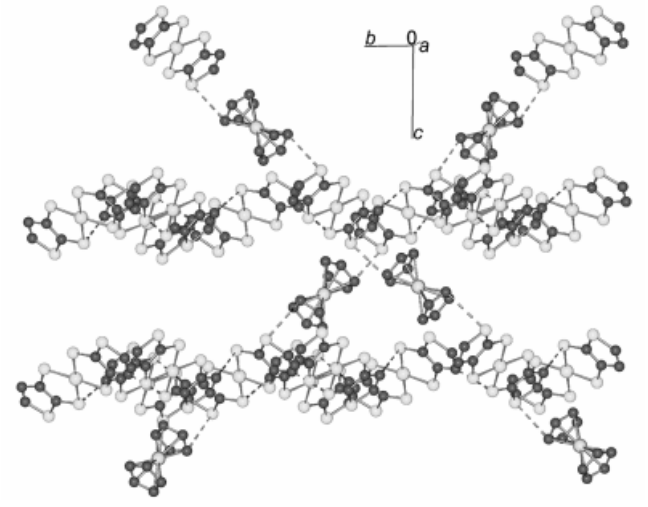

Figure 7. Partial view of the crystal structure of **3** illustrating the orthogonal DA chain directions

indicating that for the CT salt **4** the AA interactions are antiferromagnetic and that for compound **5** the DD interactions are antiferromagnetic. In the case of **3**, a broad minimum was observed at 130 K, and at lower temperatures a faster increase upon cooling was detected, indicating that

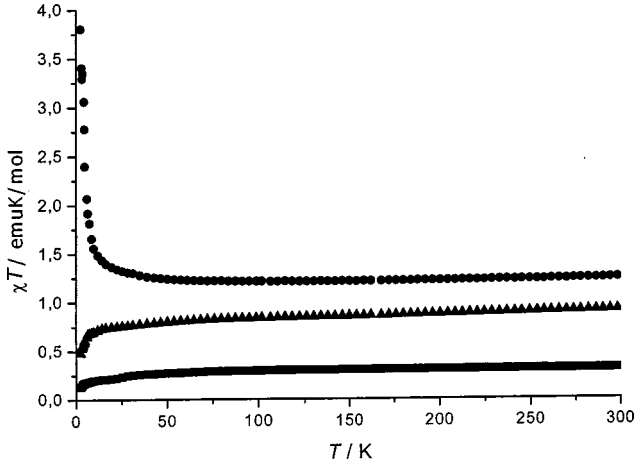

Figure 8. Temperature dependence of the product of the absolute temperature, T, with the static paramagnetic susceptibility, χ_P, for salts **3** (circles), **4** (triangles), and **5** (squares)

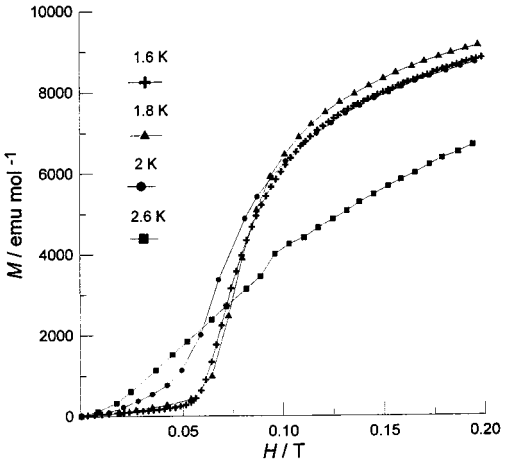

Figure 10. Magnetisation field dependence of compound **3**, at different temperatures indicated

under these conditions the dominant interactions are ferromagnetic.

At low temperatures, a field-dependent behaviour was observed in the magnetization temperature dependence of compound **3**, as shown in Figure 9. At low fields, e.g. at 15 mT, a maximum in the magnetization was observed at 2.5 K, indicating the existence of an antiferromagnetic transition. On increasing the applied magnetic field, the maximum shifts towards lower temperatures and at 30 mT it occurs at 2.35 K. At fields of greater than 70 mT the maximum is suppressed, suggesting a metamagnetic behaviour. The Neél temperature of the antiferromagnetic transition in this compound was determined by low-field (1 Oe) AC magnetic susceptibility measurements through the observation of a sharp maximum at $T_N = 2.56$ K (inset in Figure 9). Below 2.6 K, the isothermal magnetization (Figure 10) shows a sigmoidal field dependence, confirming the existence of a metamagnetic transition. At 1.6 K, the critical field H_C, defined as the maximum of dM/dH, is 70 mT. Above 7 T, the magnetization becomes almost saturated, attaining a value of 2.45 μ_B/mol at 12 T. This value is close to the predicted value of 2.44 $N\mu_B$, with $g_{Ni} = 2.07$[1a] and $g_{Fe} = 2.81$.[11] The different measurements of DC magnetization as a function of temperature at several magnetic field strengths and of AC susceptibility as a function of field and temperature led to the tentative phase diagram shown in Figure 11.

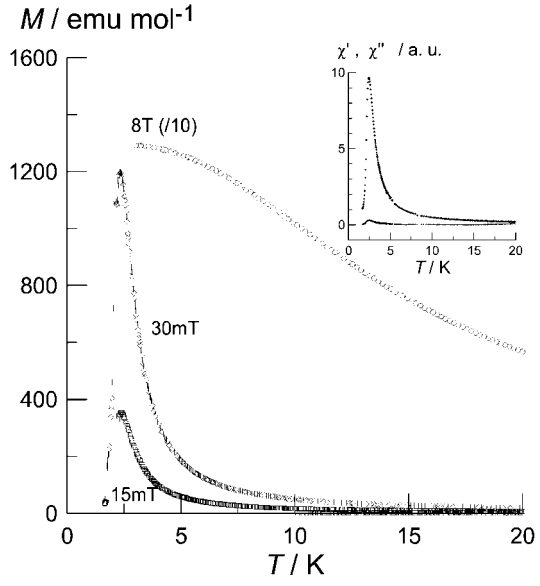

Figure 9. Magnetization temperature dependence of compound **3** under different applied magnetic fields as indicated; the inset shows the AC susceptibility, χ_{AC}, vs. T

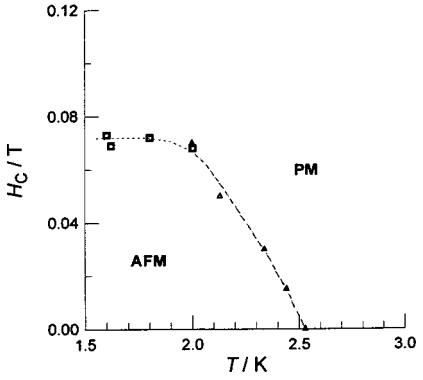

Figure 11. Critical field temperature dependence for compound **3**

Metamagnetism results from the existence of magnetic anisotropy. For compound **3**, this anisotropy can only be assigned to a different magnetic nature of the S···C contacts in the *b*,*c* layers, corresponding to DA contacts from the alternating 1D DA chains, and in the *a*,*b* layers, corresponding to the AA contacts in the acceptor layers. The negative θ value obtained for the isostructural CT salt **4** suggests that in the *a*,*b* layers the AA interactions are antiferromagnetic, which would imply that the DA interactions from the *b*,*c* layers are ferromagnetic. It is envisaged that this could be confirmed by single-crystal experiments, since if the linear chains in the *b*,*c* plane show a ferromagnetic coupling, then an antiferromagnetic behaviour should be observed along a perpendicular direction. Unfortunately,

however, it has not yet been possible to grow crystals large enough to perform such experiments.

In order to achieve a better understanding of the magnetic behaviour of the CT salt **3**, efforts will be made to obtain large single crystals. This should also allow a more detailed study of the phase diagram, which we hope to report in a subsequent publication along with the analogous salts with the donors $[Mn(Cp^*)_2]^+$ ($S = 1$) and $[Cr(Cp^*)_2]^+$ ($S = {}^3/_2$).

Conclusion

In conclusion, we have prepared and characterized a new nickel complex $[Ni(\alpha\text{-tpdt})_2]^-$, based on a thiophenedithiolate ligand that was previously described as coordinating a gold atom. The nBu$_4$N$^+$ salt of this complex shows ferromagnetic interactions, a full understanding of which will require a crystal structure determination. From this complex, decamethylmetallocenium-based CT salts have been obtained. $[Fe(Cp^*)_2][Ni(\alpha\text{-tpdt})_2]$ displays a metamagnetic behaviour with $T_N = 2.56$ K and a critical field of 70 mT at 1.6 K. Comparison of the magnetic properties of this compound with those of analogous salts with the diamagnetic acceptor $[Au(\alpha\text{-tpdt})_2]^-$ and the diamagnetic donor $[Co(Cp^*)_2]^+$ indicates that the metamagnetism is associated with the existence of ferromagnetically coupled alternating DA chains, forming layers in the *b*,*c* plane, together with antiferromagnetically acceptor-coupled layers in the perpendicular *a*,*b* plane.

The possibility of combining this complex with suitable donors to prepare conducting materials with paramagnetic anions as well as new magnetic materials is currently being explored and will be reported in due course.

Experimental Section

General Remarks: All manipulations were carried out with the exclusion of air under nitrogen or argon (CV), unless stated otherwise. The starting ketone, 5,6-thieno[2,3-*d*]-1,3-dithiol-2-one, and the tetrabutylammonium salt of gold(III) bis(2,3-thiophenedithiolate), nBu$_4$N[Au(α-tpdt)$_2$], were prepared following the method used in ref.[7] All solvents were purified following standard procedures. Other chemicals were obtained commercially and were used without further purification. − Column chromatography was carried out on silica gel S (0.063−0.2 mm). − UV/vis spectra were recorded on a Cary 5G spectrophotometer (Varian). − IR spectra were recorded on a Perkin−Elmer 577 spectrophotometer. − ^{1}H NMR: Bruker Aspect 3000 (300 MHz for ^{1}H), CD_2Cl_2 as solvent, TMS as internal reference. − MALDI mass spectra were obtained in time-of-flight linear mode on a Kratos Kompact MALDI 2 K probe apparatus (Kratos Analytical) operated through pulsed extraction of the ions. − Cyclic voltammetry data were obtained using an EG&G PAR 263A potentiostat galvanostat on a cell equipped with a double KCl (3 M) bridge. Measurements were made at room temperature in dichloromethane and acetonitrile solutions containing nBu$_4$NPF$_6$ as the supporting electrolyte at a scan rate of 100 mV/s, using platinum wire working and counterelectrodes and an Ag/AgCl reference electrode.

Tetrabutylammonium Salt of Nickel(III) Bis(2,3-thiophenedithiolate), nBu$_4$N[Ni(α-tpdt)$_2$] (2): To a stirred solution of potassium methoxide in methanol (10 mL, 2 M) was added 5,6-thieno[2,3-*d*]-1,3-dithiol-2-one (**1**) (100 mg, 0.57 mmol). The resulting yellow solution was filtered and the filtrate was added to a solution of nickel dichloride (107.7 mg, 0.29 mmol) in methanol (2 mL) yielding a red mixture. The inorganic precipitate was removed and the supernatant was added to a solution of tetrabutylammonium iodide (207.4 mg, 0.58 mmol) in methanol (1 mL). No visible change occurred while the solution was kept under an inert atmosphere. When it was stirred open to the air in an ice bath, the colour changed to green and a dark-green crystalline precipitate appeared. This solid was collected by filtration and recrystallized from acetone/2-propanol to afford dark-green, plate-like crystals. Stirring was maintained in all steps until no further modification was observed. Yield 151 mg (89%). − $C_{24}H_{40}NNiS_6$ (593.7): calcd. C 48.56, H 6.79, N 2.36, S 32.40; found C 49.01, H 6.51, N 2.38, S 32.93. − UV/vis (CH_3CN): $\lambda_{max.}$ = 672, 989 nm. − M.p. 130 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 380, 390 (m, Ni−S), 500 (m), 700 (m), 780 (m), 875 (m), 1140 (s), 1345 (s), 1460 (m), 3035−3085 (m, C−H arom.). − MS: *m*/*z* (%) = 243 [M$^+$], 350 [M$^-$].

Decamethylferrocinium Salt of Nickel(III) 2,3-Thiophenedithiolate, [Fe(Cp*)$_2$][Ni(α-tpdt)$_2$] (3): Saturated solutions of nBu$_4$N[Ni(α-tpdt)$_2$] (30.8 mg, 52 μmol) and $[Fe(Cp^*)_2]BF_4$ (58.1 mg, 0.14 mmol) in acetonitrile were mixed under an inert atmosphere with stirring. Almost immediately, a dark-green crystalline precipitate appeared. This microcrystalline powder was then recrystallized from acetonitrile to afford dark-green plates. Crystals suitable for X-ray measurements were obtained by slow evaporation of the solvent from acetonitrile solutions. Yield 24 mg (69%). − $C_{28}H_{34}FeNiS_6$ (677.5): calcd. C 49.64, H 5.06, S 28.39; found C 49.71, H 6.00, S 28.16.

Decamethylferrocinium Salt of Gold(III) 2,3-Thiophenedithiolate, [Fe(Cp*)$_2$][Au(α-tpdt)$_2$] (4): This compound was obtained according to the same method as used to prepare **3**, using nBu$_4$N[Au(α-tpdt)$_2$] instead of nBu$_4$N[Ni(α-tpdt)$_2$]. Yellow-gold needle-shaped crystals were obtained in 76% yield. − $C_{28}H_{34}AuFeS_6$ (815.8): calcd. C 41.23, H 4.20, S 23.58; found C 40.72, H 4.28, S 23.51.

Decamethylcobaltocinium Salt of Nickel(III) 2,3-Thiophenedithiolate, [Co(Cp*)$_2$][Ni(α-tpdt)$_2$] (5): This compound was obtained according to the same method as used to prepare **3**, using $[Co(Cp^*)_2]PF_6$ instead of $Fe(Cp^*)_2BF_4$. Dark-green, plate-like crystals were obtained in 34% yield. − $C_{28}H_{34}CoNiS_6$ (680.6): calcd. C 49.42, H 5.04, S 28.26; found C 49.03, H 5.13, S 27.91.

EPR Spectroscopy: EPR spectra in the range 4−300 K were obtained with an X-band Bruker ESP 300E spectrometer equipped with an ER041XK microwave bridge, a rectangular cavity operating in T102 mode, a Bruker variable-temperature unit, an Oxford Instruments ESR-900 cryostat, and an ER 032M field controller system. The modulation amplitude was kept well below the line width and the microwave power well below saturation.

Magnetic Susceptibility: Magnetic measurements were performed using either a longitudinal Faraday system (Oxford Instruments) with a 7 T superconducting magnet for static susceptibility measurements in the range 2−300 K, or a Maglab 2000 system (Oxford Instruments) for DC magnetization and AC susceptibility at fields of up to 12 T at temperatures down to 1.5 K. The Faraday system was used with a magnetic field of 2 T and forward and reverse field gradients of 5 T/m. A polycrystalline sample (10−15 mg) was placed inside a previously calibrated thin-walled Teflon® bucket. The force was measured with a microbalance (Sartorius S3D-V). The Maglab 2000 system was used for magnetization measurements

of similar polycrystalline samples at different magnetic fields using an extraction technique, and for AC susceptibility measurements using an AC field of 1 Oersted.

X-ray Crystallographic Study: The crystal structure was solved by direct methods.[12] Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions and refined as riding on their parent carbon atoms. Further details of the crystal structure determination are given in Table 2. Graphical representations were generated using ORTEP III[13] (Figure 4) and SCHAKAL-97[14] (Figure 5−Figure 7). Experimental details such as atomic coordinates, bond lengths, and angles are available as Supporting Information. Crystallographic data (excluding structure factors) for the structure of $Fe(Cp^*)_2[Ni(\alpha\text{-tpdt})_2]$ reported in this paper have been deposited with the Cambridge Crystallographic Data Centre under the depository number CCDC-152949. Copies of the data can be obtained free of charge upon application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-(0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Oxo ligands / Vanadium / N ligands / NMR Spectroscopy / Cluster compounds

A new trinuclear oxovanadium(V) complex with the anionic dmpp ligand (Hdmpp = 3-hydroxy-1,2-dimethyl-4-pyridinone), $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$, was isolated from the reaction of Hdmpp, KOH and sodium metavanadate at pH 4.5. The solid state structure of the $[V_3O_6(H_2O)(dmpp)_3](H_2O)_2$ complex, investigated by X-ray diffraction methods, was found to contain a cyclic trinuclear metal cluster. This complex crystallises in the monoclinic system: $P2_1/n$, a = 9.5324(7) Å, b = 16.4107(11) Å and c = 18.0638(12) Å, β = 91.1010(10)°, V = 2825.3(3) Å^3, Z = 4 and $R_1(wR_2)$ = 0.0704 (0.2025). Two of the vanadium atoms (V1 and V3) are six-coordinated, with distorted octahedral geometries, and the other one (V2) is five-coordinated with a distorted square pyramidal geometry. The cyclic V_3O_4 framework has one oxygen atom bridging two vanadium atoms in two V–O–V groups, V1–O4–V2 and V2–O5–V3, and two oxygens bridging the V1–V3 atoms, V1–O6–V3 and V1–O12–V3. IR data confirm the crystallographic results, showing the characteristic V=O band in the 973–935 cm^{-1} frequency range. This compound has three bands corresponding to V=O stretching, indicative of different chemical environments around the vanadium atoms in the solid state. The ES mass spectrum in aqueous solution displays an intense peak corresponding to the $[V_3O_6(dmpp)_3(H_2O)+2H^+]^{2+}$ fragment. ^{51}V and ^1H NMR spectroscopy were used to study this complex in aqueous solution. The dissolution of the crystalline $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$ compound in water, under aerobic conditions at pH 4.2, gave one intense broad signal at δ = –490 in the ^{51}V NMR spectrum, which is attributed to a major species present in solution. The observation of only one ^{51}V NMR signal, instead of the three expected from the different chemical environments of each vanadium atom present in the solid, is consistent with a fast (in the NMR timescale) dynamic equilibrium equalising their environments. This involves a fast exchange between O8, O10 and O12 as mono- or bifunctional oxygen atoms, as well as the H_2O molecule, which acts in another fast equilibrium coordinating the vanadium atom that has a dmpp ligand with one bifunctional oxygen atom. The trinuclear oxovanadium(V) complex is relatively stable in water in the pH range 2.5–5.0. However, dissociation of the complex occurs at higher pH, leading to various hydrolysis products, which include mononuclear complex species with 1:1 and 1:2 metal-to-ligand stoichiometries, and monomeric and oligomeric species of free vanadium(V).

Introduction

Vanadium inorganic salts like sodium metavanadate and vanadyl sulfate have demonstrated insulino-mimetic effects in a variety of tissues.[1] However, due to their poor absorption, high doses of these salts are required and toxicity occurs. For this reason, they are not used in the treatment of diabetes, although some recent clinical studies were carried out with oral administration of these compounds in very low concentrations.[2–4] The insulino-mimetic properties exhibited by vanadium (V^{IV} and V^V) have led to an intensive search for a vanadium complex to be used as an effective oral substitute of insulin. The complex bis-maltolato-oxovanadium ^{IV} (BMOV)[5,6] seems to be, at present, one of the most promising compounds in this field. The ligand 3-hydroxy-1,2-dimethyl-4-pyridinone (Hdmpp) (see chemical structure in Scheme 1), currently used in the treatment of iron-overload under the name deferiprone,[7] forms a V^{IV} complex which, although not as soluble as BMOV, allows the optimization of the lipophylic-hydrophylic balance by changing the substituent group at the N atom, thus controlling its absorption into the cells.[8,9]

Oxovanadium complexes are attracting interest due to their biological relevance[10,11] as insulino-mimetics, as models of the vanadium coordination modes in biological systems (haloperoxidases, amavadine, tunichrome),[12] due

to their effects on the activity of several enzymes,[13,14] and also due to their application as catalysts.[15]

Vanadium(IV) and vanadium(V) coordinate polydentate ligands, with N and O donor atoms in most cases, resulting in complexes of different stoichiometries and structures depending on ligand design, pH, metal-to-ligand ratio and total vanadium concentration.[16–18] The vanadium(V) species present in solution have been largely identified by potentiometric[19,20] and combined potentiometric/^{51}V NMR spectroscopic[21] studies, and vanadium(IV) species have been studied by EPR spectroscopy as well.[22] The solid state structures of vanadium complexes have been determined by using X-ray crystallography[23] and EXAFS.[8] Vanadium(V), in particular, has stereochemically flexible coordination geometries ranging from tetrahedral and octahedral to trigonal pyramidal and pentagonal bipyramidal, which are thermodynamically plausible.[24] It can also form mono- and polynuclear[25] oxovanadium complexes.

The biological properties of vanadium complexes are strongly dependent on their solution structures. The examination of the structural and chemical selectivity of complexes with di- or polyfunctional ligands[26–34] is an important contribution to understanding the modes of action of vanadium in biological systems.[35,36] Thus, the study of their behaviour in an aqueous medium at different pH values is necessary to obtain the structures of the different species, as well as their thermodynamic and kinetic stabilities.[37] In this work, we report the synthesis and structural characterisation, both in the solid state and in aqueous solution, of a new oxovanadium(V) complex containing three anionic dmpp ligands and a cyclic trinuclear cluster.

Results and Discussion

Synthesis of the Complex $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$

3-Hydroxy-1,2-dimethyl-4-pyridinone (0.174 g, 1.25 mmol) in 5 mL of water was added to KOH (0.07 g, 1.25 mmol) in 5 mL of water and sodium metavanadate (0.169 g, 1.25 mmol)in 5 mL of water. The pH was raised to 4.5 with a solution 2 M HCl. The black crystals, which came out of solution, were isolated by filtration and dried under *vacuum*. The yield was 0.160 g (48% based on V). Anal. Calcd. (found) for $C_{21}H_{30}O_{15}N_3V_3$: calcd. C 35.2 (34.9), H 4.2 (4.1), N 5.9 (5.8). ES mass spectrum, $[V_3O_6(C_7H_9O_2N)_3(H_2O) + 2\,H^+]^{2+}$: $m/z = 342$.

IR Spectroscopic Data

The IR spectrum of the complex $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$ obtained in KBr pellets showed the characteristic V=O band in the frequency range 973–935 cm^{-1}. This compound exhibits three bands corresponding to V=O stretching, indicative of a different chemical environment around the vanadium atoms in the solid state. In addition, the V–O–V stretching modes were observed at about 640–510 cm^{-1}, in agreement with those reported in the literature.[38] The spectrum exhibits a set of four bands in the 1625–1450 cm^{-1} range, characteristic of pyridinones.[39]

IR spectroscopy provides information on the ligands chelated to the vanadium atoms but is less informative about the nuclearity of the complex.

Crystallographic Results

The X-ray crystal structure with an atomic numbering scheme for the crystalline $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$ complex is shown in Figure 1 and the bond lengths and angles are in Table 2. It contains a cyclic trinuclear oxovanadium(V) complex, $[V_3O_6(dmpp)_3(H_2O)]$, with three anionic dmpp ligands, three oxo groups, three oxygen atom bridges and one H_2O molecule. The other two H_2O molecules are included in the asymmetric unit. Oxygen atom bridges link the three vanadium atoms and each one is coordinated to one oxo group. Two vanadium atoms (V1 and V3) are six-coordinated, exhibiting a distorted octahedral geometry and one (V2) is five-coordinated with a distorted square pyramidal geometry, with the vanadium atom (V2) 0.4197 Å from the basal plane defined by O4, O5, O9 and O10 (Figure 2). In addition to the oxo group, V1 is chelated by three dmpp oxygen atoms (O7, O8 and O12, this one acting as a bridging atom between V3 and V1), V2 and V3 are chelated by two dmpp oxygen atoms (V2 by O9 and O10, V3 by O11 and O12). The V3 atom is also coordinated to one H_2O molecule.

All the vanadium atoms have a strong V=O bond, and the values for the V1–O1, V2–O2 and V3–O3 distances are compatible with those found in other similar structures.[23] This complex has a dmpp oxygen atom (O12 in V3) that is *trans* and five dmpp oxygen atoms (O7 and O8 in V1, O9 and O10 in V2, and O11 in V3) that are *cis* relative to the strong V=O bond in each vanadium atom.[25,40–42] The dmpp oxygen atoms belonging to the enolic groups are deprotonated (O7, O9 and O11). The V3–O12 bond is longer than the V–O bonds to the other

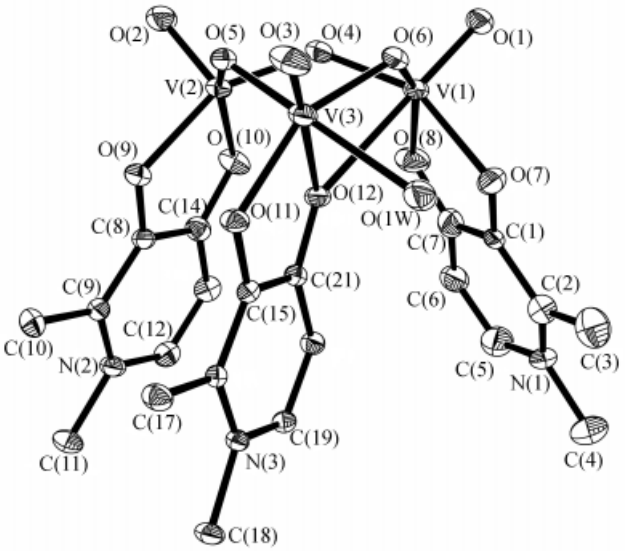

Figure 1. X-ray crystal structure of the complex $[V_3O_6(dmpp)_3(H_2O)]$ showing the atomic numbering scheme. Hydrogen atoms have been omitted for simplicity. The ORTEP plot is at the 30% probability level.

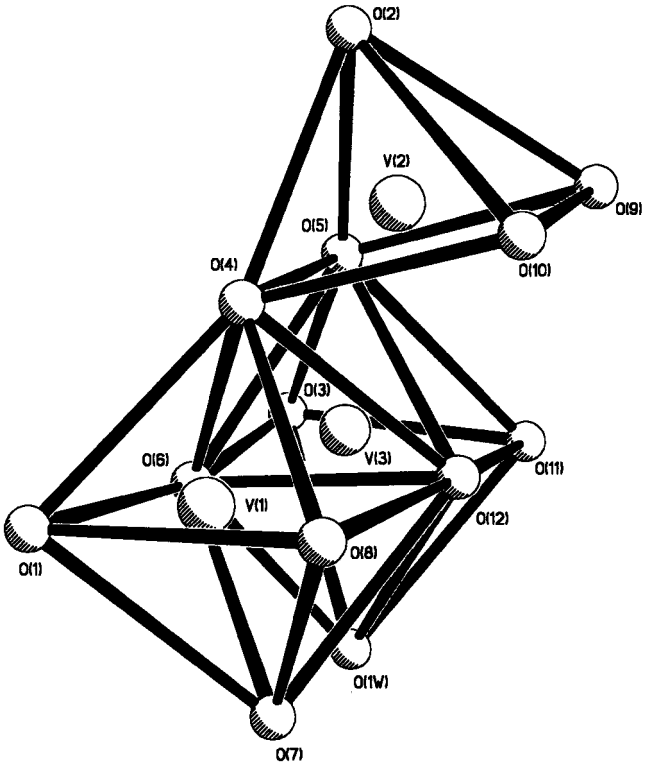

Figure 2. Coordination polyhedron in the crystal structure of the vanadium cluster in trimeric species $[V_3O_6(dmpp)_3(H_2O)]$.

ketonic groups, V1−O8 and V2−O10, (V1−O8 [2.008(4) Å], V2−O10 [2.004(4) Å] and V3−O12 [2.204(4) Å]. In addition, all these V−O bond lengths are longer than those to the enolate groups (V1−O7 [1.980(4) Å], V2−O9 [1.962(3) Å] and V3−O11 [1.909(3) Å].[43] These bond length values are all in the range of the bond lengths reported in the literature for other known polynuclear vanadium(V) complexes.[25,40−43]

The trinuclear complex contains the cyclic V_3O_4 framework.[23] This framework exhibits only one oxygen bridging two vanadium atoms in two V−O−V groups, V1−O4−V2 and V2−O5−V3, and two oxygens bridging the V1−V3 atoms, the oxo bridge V1−O6−V3 and the formal ketonic oxygen atom O12 of one dmpp. From the X-ray results one could not unambiguously distinguish between a keto-O12 and an enolate-O12 structure for this bifunctional binding group, as the C−O bond lengths to the formal keto and enolate oxygens in each C−O−V−O−C cycle are almost the same (eg. C21−O12 [1.309(5) Å], C15−O11 [1.336(5) Å], for the V3 cycle). It is possible that the π electronic cloud is delocalized among all the atoms that form each C−O−V−O−C cycle, giving an intermediate character to all the formal ketonic and enolic oxygen atoms of each dmpp. As expected, the doubly bridging dmpp oxygen atom (O12) gives V−O bond lengths [2.204(3), 2.450(3) Å] longer than the V−O distance for the bridging oxygen atoms (O6) [1.794(3), 1.857(3) Å]. The average value of the V−O−V bond lengths (V1−O4−V2, V2−O5−V3 and V3−O6−V1) is 1.82(3) Å, which is similar to that obtained for other polynuclear vanadium compounds.[44−46]

The three V−O−V bond angles, in the cyclic V_3O_4 framework, involving single bridging oxygen atoms are very similar (V1−O4−V2 = 125.61(18)°, V2−O5−V3 = 120.39(17)° and V1−O6−V3 = 119.22(17)°]. The V−O−V bond angle in the V1−O12−V3 fragment [84.98(10)°] is quite different.

Figure 3 shows an upper view of the complex along an axis perpendicular to the pseudo-plane defined by the three vanadium atoms, illustrating how the complex has lost C_{3v} symmetry. The anionic dmpp ligand bound to V3 has rotated relative to the equivalent positions of the other two ligands in the cluster, becoming almost parallel to the dmpp ligand at V2 and perpendicular to the one at V1. Its O12 oxygen binds to V1, and V3 binds a water molecule in a *cis* position relative to V3=O3, pointing outwards. V2 keeps the five coordination, as an extra water molecule *trans* to V2=O2 would be sterically hindered by the opposing dmpp ring. The methyl group at V3 points outwards, and those at V1 and V2 point t*rans* to one another.

Solution Studies

The behaviour of the crystalline compound $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$ in aqueous solution and in the presence of oxygen was investigated using ^{51}V and ^{1}H NMR and EPR spectroscopy. A freshly prepared 2 mM aqueous solution of the crystalline complex, with pH = 4.2, was grey in colour. Immediately after its preparation, this solution gave no EPR signal (data not shown), showing that all three the vanadium atoms present in the crystalline structure were in the +5 oxidation state. The ^{51}V NMR spectrum of this solution (Figure 4b) shows one single

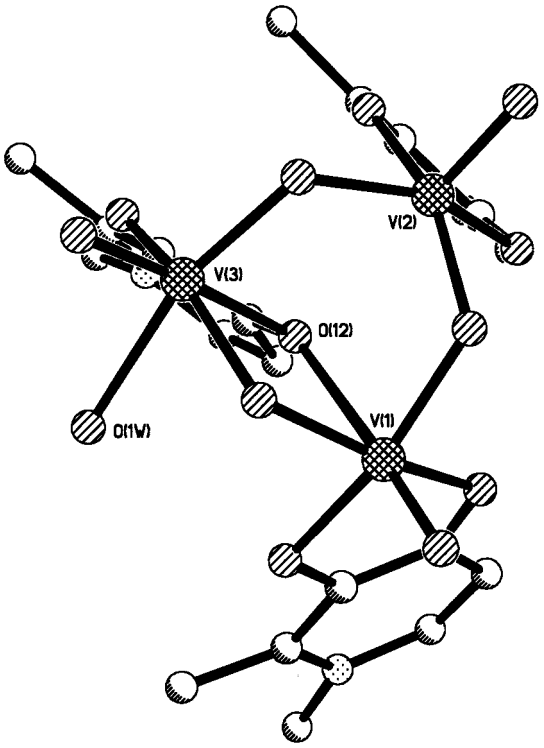

Figure 3. Upper view of the complex $[V_3O_6(dmpp)_3(H_2O)]$.

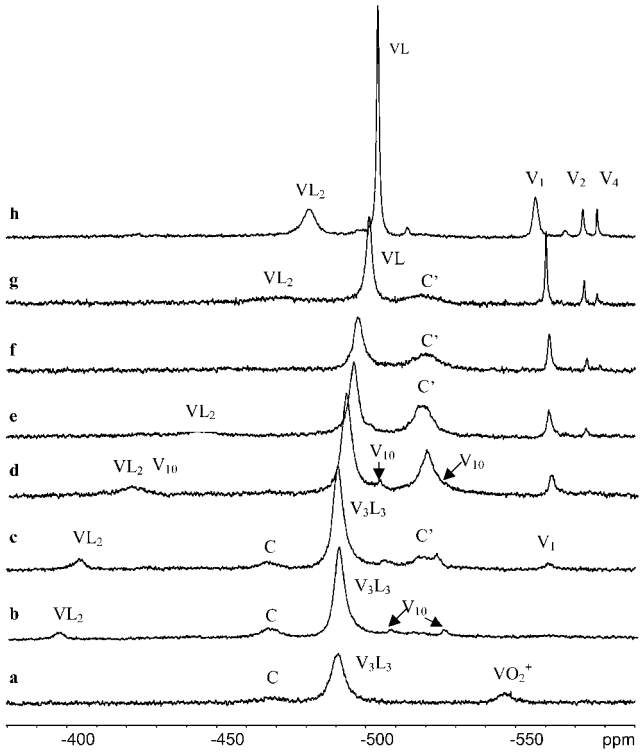

Figure 4. ^{51}V NMR spectra, at 22.0 ± 0.5 °C, of a freshly prepared 2 mM aqueous solution of the crystalline complex $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$ under aerobic conditions at a) pH = 2.8; b) pH = 4.2; c) pH = 4.7; d) pH = 5.6; e) pH = 6.1; f) pH = 6.4; g) pH = 6.9; h) pH = 7.8.

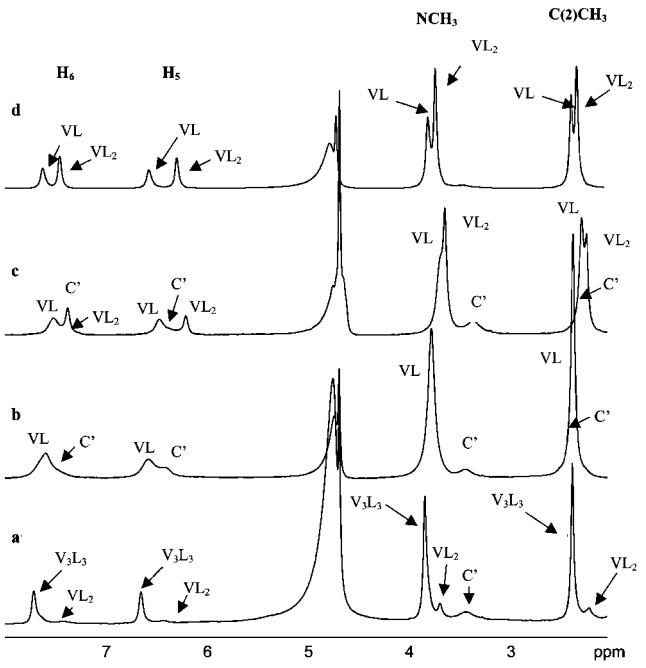

Figure 5. ^{1}H NMR spectra, at 22.0 ± 0.5 °C, of a freshly prepared 2 mM D_2O solution of the crystalline complex $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$ under aerobic conditions at a) pH = 3.6; b) pH = 5.3; c) pH = 6.8; d) pH = 8.4.

broad signal at δ = −490 (line width of 525 Hz), assigned to the cyclic trimer $[V_3O_6(dmpp)_3(H_2O)]$ (V_3L_3) as the major species present in solution. The observation of only one ^{51}V NMR signal, instead of the three expected from the different chemical environments of each V-dmpp unit present in the crystal structure, reflects the increased effective symmetry acquired by the cyclic trimer species in solution. The equivalence of its three monomer units should result from the presence of a dynamic equilibrium in solution in fast exchange conditions (in the NMR timescale). In this equilibrium, the dmpp ligand oxygen atoms bridging between two vanadium atoms of the cluster (O12 bridge between V1 and V3, O8 between V1 and V2 and O10 between V2 and V3) change their coordination between mono- and bifunctional when the compound is dissolved in water. On the other hand, the H_2O molecule acts in another fast equilibrium, coordinating the vanadium atom that has a dmpp ligand with one bifunctional oxygen atom. Thus, the presence of the polydentate oxygen donor anionic ligand (dmpp) allows the oxygen atoms to act as monofunctional or bifunctional donors.[23] The ES spectrum of the trimer in aqueous solution at pH = 4.3 exhibits an intense peak *m*/*z* = 342, corresponding to the cationic complex $[V_3O_6(dmpp)_3(H_2O)+2H^+]^{2+}$.

Additional studies of the trinuclear oxovanadium(V) complex in solution were carried out in order to investigate its stability as a function of pH, using ^{51}V (Figure 4) and ^{1}H (Figure 5) NMR spectroscopy. These spectra were compared with ^{51}V and ^{1}H NMR spectra of aqueous solutions of vanadate and dmpp at different pH and metal-to-ligand ratios (see illustrative examples at Figure 6). Figure 4 shows ^{51}V NMR spectra of a 2 mM aqueous solution of the crystalline complex at different pH values. These spectra were assigned by comparison with the ^{51}V NMR spectra of the vanadate/ dmpp aqueous solutions at the same pH values, as well as on the basis of literature data.[9,21c,27] The spectral features indicate that in the pH range 2.8−5.3 the major species present in solution is the trimer $[V_3O_6(dmpp)_3(H_2O)]$, corresponding to the dominant ^{51}V NMR peak, with very small shift changes with pH, from δ = −488 (pH 2.8−3.6) to δ = −490 (pH 3.9−5.3). Some low intensity signals are also present in the ^{51}V NMR spectra in this pH range (see Figure 4a−c), which correspond to very minor species in solution. Some of these are free vanadium(V) species: dioxovanadium(V) cation (VO_2^+), δ = −543 [21c] at pH 2.8, the monovanadate (V_1), δ = −560[21c] at pH 4.7, and two of the three decavanadate (V_{10}) signals, δ = −506 and δ = −523 [27] at pH 4.2 and 4.7. At pH < 3.9, the cyclic trimer is practically the only complex present in solution (besides the species C). However, above this pH value, a small signal of the mononuclear 1:2 complex (VL_2) is also seen at high frequency (δ = −396 and δ = −405 at pH 4.2 and 4.7, respectively). According to previous studies, this complex occurs at this pH range predominantly in its monoprotonated form $[VO_2H(dmpp)_2]$.[9] At these pH values a small resonance (VL) of the mononuclear 1:1 $[VO_2(dmpp)(H_2O)_2]$ complex, if present, is hidden by the signal of the trinuclear cationic complex.[9] Its ^{51}V shift at pH 2.8−4.7 is δ = −491, and at pH 5.3 is δ = −494 (see Figure 6a). A broad signal at δ = −468 is also

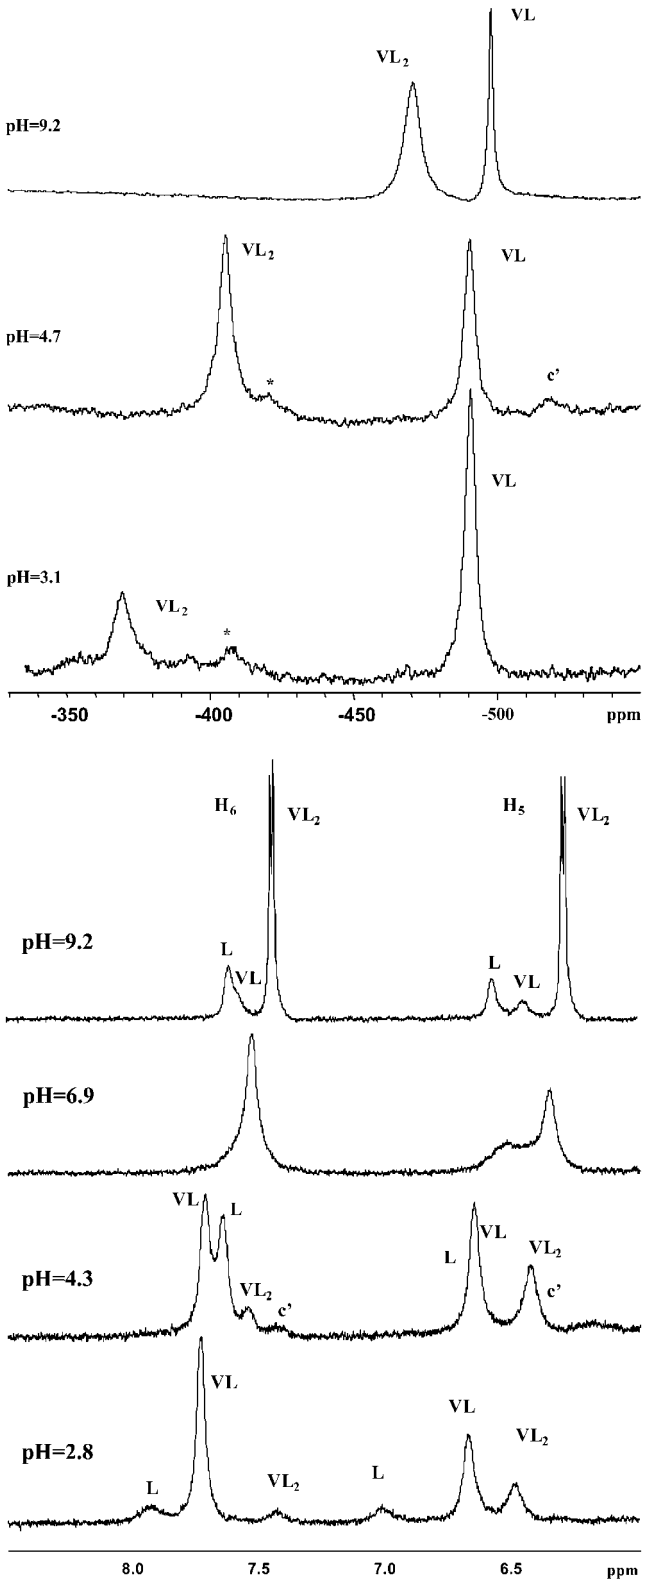

Figure 6. ^{51}V (top) and ^{1}H (bottom) NMR spectra, at 22.0 ± 0.5 °C, of a 3 mM: 6 mM vanadate-dmpp solution at different pH values.

seen between pH 2.8 and 5.3, corresponding to another complex labelled as C, and a new signal at δ = −519 appears at pH > 3.9, corresponding to another complex, labelled as C′. Both complexes C and C′ were not characterised.

Above pH 5.3 (Figure 4d−h), decomposition of the trinuclear oxovanadium(V) complex takes place, which is replaced by the two mononuclear complexes VL and VL_2, whose ^{51}V NMR resonances are shifted to lower frequency when the pH increases, as they become deprotonated.[9] From pH 5.6 to 7.8, the ^{51}V shifts of VL and VL_2 change from δ = −493 and δ = −424 to δ = −504 and δ = −480, respectively. The signal of complex C disappears at pH 5.6 and the signal at δ = −519, corresponding to complex C′, reaches a maximum intensity at pH ≈ 6 and disappears at pH 7.8. The signals of decavanadate stay very small (Figure 4d,e) and new resonances corresponding to other free vanadium(V) oligomeric species also appear: the divanadate V_2 (δ = −572) and tetravanadate V_4 (δ = −578) (Figure 4f−h). Above pH 7 the colour of the solution changes to yellow and at pH 7.8 only the signals corresponding to the mono- (δ = −556), di- (δ = −572) and tetravanadate (δ = −577) species, and those assigned to the two mononuclear complexes VL (δ = −504) and VL_2 (δ = −480) are observed. According to previous studies, these complexes occur at this pH in their deprotonated forms $[VO_2(dmpp)(H_2O)(OH)]^-$ and $[VO_2(dmpp)_2]^-$, respectively.[9]

^{51}V NMR spectra of aqueous solutions of vanadate and dmpp were obtained as a function of pH in the 2.3 to 9.2 range, at 3 mM vanadate concentrations and at 1:1, 1:2 and 1:5 metal-to-ligand ratios. Figure 6 (top) shows a few illustrative examples at the 1:2 ratio. VL and VL_2 predominate over the entire pH and metal-to-ligand ranges studied, and their shifts change with pH in accordance with what was found in the trimer solution. In the pH range 2.3−6.9, their intensities are much higher in the spectra of the vanadate-dmpp mixtures than in those of the trimer. Complex C′ (at δ = −519) is also present between pH 4.0 and 6.4, but complex C (at δ = −468) is not, as it is only present in vanadate/dmpp mixtures with excess vanadate (data not shown). Although this observation points to the possibility that C may be a dimeric complex, the characterisation of complexes C and C′, as well as of the signals at δ = −420 to −405 and at δ = −350, observed at acid pH [see Figure 6 (top)], and the detailed interpretation of the pH dependence of the ^{51}V shifts of the VL and VL_2 complexes in terms of the species previously observed by potentiometry[9] will be the subject of a future publication.

^{1}H NMR spectra were also obtained from a 2 mM D_2O solution of the crystalline complex at different pH values (Figure 5). These spectra were assigned by comparison with those of solutions of vanadate and dmpp, at 3 mM vanadate concentrations and at 1:1 and 1:2 metal-to-ligand ratios, obtained as a function of pH [see Figure 6 (bottom), for some representative spectra] and by comparison of the intensities of the ^{51}V and ^{1}H signals of the different complexes. The spectrum at pH 3.6 (Figure 5a) shows four intense signals (H_6 at δ = 7.72, H_5 at δ = 6.66, N−CH_3 at δ = 3.86 and C(2)−CH_3 at δ = 2.40, data not shown) from the trinuclear complex V_3L_3, the major species in solution. The symmetry

of the spectrum again reflects the equivalence of the three monomer units in solution. These signals are in slow exchange on the NMR timescale with the very weak signals from the complexes VL_2 and C. The signals of the V_3L_3 complex are shifted to higher frequencies relative to the respective signals of the free Hdmpp ligand at pH 7 (H_6 at $\delta = 7.53$, H_5 at $\delta = 6.41$, $N-CH_3$ at $\delta = 3.68$ and $C(2)-CH_3$ at $\delta = 2.30$, data not shown), due to complexation. However, the trimer has very similar shifts to the 1:1 monomer VL [see Figure 6 (bottom)], possibly because the coordination of the V^V ion is similar in both compounds and the relative orientations of the pyridinone rings in the trimer, near the edge of their respective dipolar shift cones, lead to negligible intramolecular ring current effects. At pH 5.3, the signals broaden and the spectrum (Figure 5b) is quite similar to that of a 1:1 vanadate/ dmpp solution, except for the relative intensities of the complexes present, in agreement with dissociation of the complex and the presence of the mononuclear complexes resulting from its hydrolysis, with relative intensities $VL > C' >> VL_2$. At pH 6.8 (Figure 5c) the signals of the complexes present, $VL > VL_2 >> C'$, start to sharpen and at pH 8.4 (Figure 5d) only the VL and VL_2 complexes are present. The protons of the VL_2 complex are shifted to lower frequency relative to those of the VL complex, due to the mutual effect of the pyridinone ring currents in an octahedral complex. Comparison with the ^1H NMR spectra of free Hdmpp solutions at the same pH values showed that no free ligand could be detected at any pH studied. The results from ^1H NMR spectroscopy are, therefore, in good agreement with those obtained by ^{51}V NMR spectroscopy.

Figure 6 (bottom) shows the aromatic region of the ^1H NMR spectra of a 3 mM:6 mM vanadate-dmpp solution at some of the pH values between 2.8 and 9.2. At this metal-to-ligand ratio of 1:2, it was found that, while at pH 2 to 2.8 the relative concentrations of the species are $VL >> VL_2 \approx L$, at pH 4 to 5 VL decreases and L increases, so that $VL \approx L > VL_2 >> C'$. Above pH 5, L and VL decrease and VL_2 becomes the dominant species. The complex C′ is only present in the range of pH 4.0 to 5.6, and complex C is not detected at low pH. For a 1:1 metal-to-ligand ratio (3 mM: 3 mM vanadate-dmpp, data not shown), VL is the dominant species at pH 2 (92%), with $VL >> VL_2$, and VL slowly decreases its percentage up to pH 5 (80% VL), with $VL >> VL_2 > C'$. Above pH 5, VL continues to decrease, VL_2 increases more sharply and C′ disappears. The detailed interpretation of the pH dependence of the distribution of the VL and VL_2 species by NMR spectroscopy and potentiometry[9] will be presented in a future publication.

Thus, the differences observed in the ^{51}V and ^1H NMR spectra of a V_3L_3 solution and a vanadate-dmpp 1:1 solution in the pH range of 2.5−5.0, where the trimer is stable in solution, can be summarised as follows: slightly different ^{51}V shifts of V_3L_3 and VL, sharper proton resonances of VL at the same pH values, smaller relative intensity of VL_2 and larger relative intensity of C′ in the trimer solution, and presence of species C at low pH in the trimer solution, which is not present in the vanadate-dmpp 1:1 solution.

The stability of the solution structure of the trinuclear complex at pH 4.2 with time was also studied by ^{51}V NMR spectroscopy. The spectra obtained (see Supporting Information, Figure 1S) show that there are no changes in the signal corresponding to the $[V_3O_6(dmpp)_3(H_2O)]$ complex (see Figure 4b), even 5 days after the dissolution of the crystalline compound in water and in the presence of oxygen, which indicates that the structure of the trinuclear oxovanadium(V) complex is stable in solution at this pH. The low intensity signals also present decrease their intensity somewhat.

Thus, we can conclude that the major species resulting from the dissolution of the crystalline compound in water, under aerobic conditions and at pH 2.5−5.0, is a trinuclear oxovanadium(V) cationic complex, which is relatively stable in this pH range. However, when the pH increases above 5.0, dissociation of the complex takes place with the appearance in solution of various hydrolysis products, including free V^V oligomeric species and the mononuclear V^V species with metal to ligand ratios of 1:1 and 1:2.

Experimental Section

Reagents: Sodium metavanadate, $NaVO_3$, and the ligand 3-hydroxy-1,2-dimethyl-4-pyridinone (Hdmpp) were purchased from Sigma and ACROS Organics, respectively, and used without further purification. D_2O (99.9 atom% D), DCl and NaOD were obtained from Cambridge Isotope Laboratories. All the experiments were carried out in aqueous solution and under aerobic conditions.

Methods: IR Spectroscopy: Vibrational spectra were obtained in potassium bromide pellets on a Bruker Vector 22 MIR spectrometer. − Elemental Analysis: Analyses for C, H and N were performed using a Carlo Erba EA 1108 elemental analyser. − Mass Spectrometry: A mass spectrum was obtained in aqueous solution on a LC/NS Mass Spectrometer Finnigan Navigator with ES(+) ion mode and direct injection. − NMR Spectroscopy: ^{51}V and ^1H NMR spectra were recorded on a Varian Unity-500 Spectrometer operating at 131.404 MHz and 499.824 MHz, respectively, using a 5 mm broad band probe, at 22.0±0.5 °C. The pH of the D_2O solutions was adjusted with DCl and CO_2-free NaOD using a Crison MicropH 2002 pH-meter with an Ingold 405-M5 combined electrode. ^{51}V NMR chemical shifts were externally referenced to a $VOCl_3$ solution at $\delta = 0$. The ^{51}V NMR acquisition parameters were: 33 KHz spectral width, 25 μs pulse width, 0.5 s acquisition time and 10 Hz line broadening. A pre-saturation pulse sequence was used for ^1H NMR spectra to eliminate the residual water signal. − EPR Spectroscopy: The EPR spectrum of the freshly prepared aqueous solution of the crystalline compound $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$ was obtained at room temperature on a Bruker ESP300E spectrometer, operating at 9.77 GHz. The frequency was calibrated with diphenylpycryl-hydrazyl (dpph) and the magnetic field using Mn^{2+} in MgO.

X-ray Crystallography: Selected crystallographic data are shown in Table 1. Three dimensional X-ray data were collected at low temperature (173 K) in the range $1.68 < 2\theta < 28.32°$ on a Siemens SMART 1000 CCD diffractometer by the Ω-scan method. Complex scattering factors were taken from the program package

Table 1. Crystallographic data for the complex $[V_3O_6(Hdmpp)_3(H_2O)](H_2O)_2$

Empirical formula	$C_{21}H_{30}N_3O_{15}V_3$
Formula mass	717.30

No. of reflns collected	19434
No. of indep reflns.	6989
R_1 [a]	0.0704
wR_2(all data)	0.2025
Largest diff peak and hole (e·Å^{-3})	2.04, −0.887

[a] $R_1 = \Sigma||F_0| - |F_c||/\Sigma[|F_0|$, $wR_2 = \{\Sigma[w(||F_0|^2 - |F_c|^2|)^2]/\Sigma[w(F_0^4)]\}^{1/2}$.

SHELXTL.[48] The structure was solved by direct methods and refined by using full-matrix least-squares methods on F^2. The data were processed and corrected for Lorentz and polarisation effects and for absorption (semi-empirical method). The non-hydrogen atoms were refined with anisotropic thermal parameters in all cases. The hydrogen atoms of the H_2O molecules were refined with isotropic thermal parameters. The other hydrogen atoms were refined to carbon, which were placed in idealised positions and refined by using a riding mode. A final difference Fourier map showed no residual density outside −0.887 to +2.041; the highest peaks in this case suggested the presence of a residual density in the middle of one pyridinone group but its assignment was not possible. Selected bond lengths and bond angles appear in Table 2.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-160778. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information: ^{51}V NMR spectra (131.404 MHz, 22.0 ± 0.5 °C) of $[V_3O_6(dmpp)_3(H_2O)](H_2O)_2$ in aqueous solution (2 mM, pH = 4.2) in the presence of oxygen, as a function of time (10 minutes to 5 days) (Figure 1S).

Acknowledgments

We thank Fundação para a Ciência e Tecnologia, Portugal (Project SAPIENS QUI/35368/99) for financial support. Servicios Generales de Apoyo a la Investigación (SXAIN) de la Universidad de A Coruña are also thanked for carrying out the elemental analysis, IR spectra and X-ray crystallographic data and Xunta de Galicia and University of A Coruña for two grants to F.A. to visit the University of Coimbra. This work was carried out within the Working Group "Vanadium Compounds as Insulin-Mimetic Agents" of the COST D8 Action of the E. U.

The Role of the Apical Donor in the Decomposition of Copper(II) Benzoate under DOW-Phenol Conditions

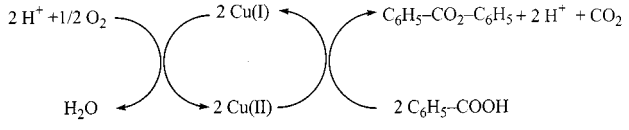
Wim Buijs,[a] Peter Comba,*[b] Danny Corneli,[b] Ynze Mengerink,[a] Hans Pritzkow,[b] and Martina Schickedanz[c]

Keywords: DOW-phenol process / Methylated pyridines / Halogenated pyridines / Pyrolysis / Paddle-wheel / Aniline

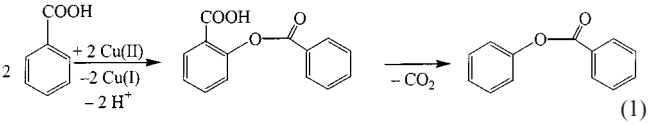
The synthesis and characterization of copper(II) benzoates with the apical donors pyridine, 2-CH_3-pyridine, 2,4-$(CH_3)_2$-pyridine, 2,6-$(CH_3)_2$-pyridine, 2-fluoropyridine, 2-chloropyridine, 2-bromopyridine, 3-bromopyridine, 2,5-dibromopyridine, 3,5-dibromopyridine, and aniline, starting from copper(II) benzoate, is reported. Single-crystal X-ray structures of the products with four apical ligands show the usual paddle-wheel structure of copper(II) carboxylates; in the case of aniline no paddle-wheel dicopper(II) benzoate could be isolated. The products of thermal decomposition of the pure copper(II) compounds were analyzed by HPLC, LC-MS, and GCFID, and the expected DOW-phenol products were found in all cases other than that of aniline. This supports the assumption that a paddle-wheel dicopper(II) benzoate is required for the DOW-phenol reaction. Generally, high *ortho*-selectivities (to phenyl benzoate and phenol; the selectivity increases with increasing basicity) are obtained, in good agreement with earlier findings on the role of the base. Small but significant steric effects are observed in the series of methylated pyridine donors and the monohalogenated pyridine donors used as apical ligands; with the two dibromopyridine donors there are large steric effects and the DOW-phenol reaction is partially suppressed. With halogenated pyridine donors as apical ligands, a $Cu^{[I]}$-catalyzed process occurs, leading to dehalogenation.

Introduction

The selective oxidation of hydrocarbons in the liquid phase is a major challenge in fundamental and applied research.[1−3] Generally, free-radical chain mechanisms dominate, and only in a few cases (xylene and toluene derivatives) is a high selectivity towards the corresponding acids obtained. Various approaches have been proposed to overcome these problems but, so far, these have led to only limited success. We have tried to avoid unselective free-radical chain oxidation reactions by adopting an approach that utilizes oligonuclear metal complexes in the oxygenation of hydrocarbons. The starting point for our studies was the DOW-phenol process. This converts benzoic acid into phenol under copper(II) catalysis and this reaction may be considered as a regioselective hydroxylation.[4] In the DOW-phenol process (Scheme 1), benzoic acid is oxidized at $T >$ 180 °C with moist air and copper(II) to give phenyl benzoate and CO_2; the reduced copper(I) is reoxidized by dioxygen; hydrolysis of the phenyl benzoate then yields the desired phenol and benzoic acid [Equations (1)−(5)].[4]



Scheme 1



(1)

$$2\,Cu^{II} + 2\,ArCOOH \rightarrow ArCO_2Ar + 2\,H^+ + CO_2 + 2\,Cu^{I} \quad (2)$$

$$2\,Cu^{I} + 1/2\,O_2 + 2\,H^+ \rightarrow 2\,Cu^{II} + H_2O \quad (3)$$

$$ArCO_2Ar + H_2O \rightarrow ArOH + ArCOOH \quad (4)$$

Overall:

$$ArCOOH + 1/2\,O_2 \rightarrow ArOH + CO_2 \quad (5)$$

The main reaction in the catalytic process (Scheme 1) is the thermal decomposition of copper(II) benzoate to *o*-benzoyloxybenzoic acid. Rapid decarboxylation leads to phenyl benzoate [Equation (1)]. The amount of CO_2 produced is directly proportional to the amount of copper(II) involved in the stoichiometric decomposition and its quantification can be used to study the kinetics of the process. Phenyl benzoate is hydrolyzed with steam to yield phenol [Equation (4)]. The overall reaction is sensitive to solvents. In anhydrous benzoic acid solutions, the *ortho*-selectivity of the benzoyloxybenzoic acid formation is only about 50% (45% *meta*-benzoyloxybenzoic acid, 5% *para*-benzoyloxybenzoic acid).[5]

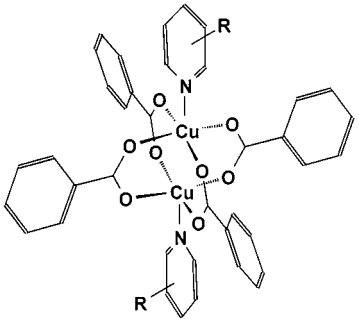
Results and Discussion

Thermal Decomposition of Copper(II) Benzoate with Substituted Pyridine Donors or Aniline at the Apical Sites of the Paddle-Wheel Dicopper(II) Compounds

The influence of substituted pyridine donors bearing electron-withdrawing or electron-donating groups was studied to investigate the role of the donors at the apical sites of the paddle-wheel dicopper(II) complexes in the DOW-phenol process (see Scheme 2). Copper(II) benzoate with various pyridine donors (different substitution patterns) and with aniline was pyrolyzed in a sealed silica tube (stoichiometric reaction; see Exp. Sect.). Table 1 summarizes the identified DOW-phenol products recovered following the pyrolyses of the copper(II) compounds.



Scheme 2

An important observation is that all the apical donors studied show high *ortho*-selectivities, except for 2,5-dibromopyridine. This is in line with earlier observations on the effect of base in the DOW-phenol reaction.[5] In the series pyridine, 2-methylpyridine, 2,4-dimethylpyridine, and 2,6-dimethylpyridine, both the conversion and the *ortho*-selectivity decrease, from 40.9% to 3.8% and from 99.9% to 95.7%, respectively. Since the basicity in this series of pyridines follows the order pyridine < 2-methylpyridine < 2,4-dimethylpyridine ≈ 2,6-dimethylpyridine, both the conversion and the *ortho*-selectivity might have been expected to increase, as was observed with Mg^{II} benzoate.[5] However, the pyridine donors coordinate to Cu^{II} whereas Mg^{II} benzoate merely acts as a simple base. The electronic effect of the pyridine donors influences the thermal stability and hence the reactivity: the more electron-donating the pyridine donor is, the less effectively Cu^{II} will be able to abstract electrons from benzoate. If, however, the electrophile resulting from a benzoate is formed, the steric effect of the methylated pyridine donors may slightly decrease the probability of an *ortho*-attack at the corresponding pyridinium benzoate.

The halogenated pyridine donors constitute another interesting series. Unfortunately, their conversion cannot be compared directly with that of the methylated pyridine donors because they are also subject to reduction, which produces additional Cu^{II}.[6] This reaction seems to be comparable to the reduction of halogenated hydrocarbons.[7] The scope and limitations of the catalytic reduction are reported separately.[6]

The use of 2-fluoropyridine did not lead to any reaction at 230 °C. However, at 250 °C a fast substitution reaction of benzoate on the fluoride was observed prior to the DOW-phenol reaction. The resulting *ortho*-selectivity of approximately 89% cannot be assigned to 2-fluoropyridine, but mainly to 2-benzoyloxypyridine and HF instead.[6]

The other halogenated pyridine donors show *ortho*-selectivities of 66.7% (2,5-dibromopyridine), 94.8% (2-chloropyridine), 95.1% (2-bromopyridine), 98.1% (3-bromopyridine), and 99.2% (3,5-dibromopyridine). We believe that in these cases, both electronic and steric effects play a similar role to that observed with the methylated pyridine donors, albeit to a less pronounced extent. Despite the increasing size of the substituents, a chloro or a bromo substituent in the 2-position of the pyridine has a similar effect on the *ortho*-selectivity as two methyl groups in the 2,6-positions. This

might be due to the fact that only one side of the benzoate in a pyridinium benzoate is accessible for the coupling reaction. Moreover, a bromo substituent in the 3-position of pyridine has a similar effect as a methyl group in the 2-position. Comparing the pyridine donors with two bromo substituents in the 2,5- and 3,5-positions, a large steric effect on the *ortho*-selectivity due to the second bromine in the 2-position is evident.

For the series of monohalogenated pyridine donors, the relative amount of reduced material (given as mol % of additional copper benzoate; see Table 1) is comparatively small with respect to the observed conversion, but it is high for the dibromopyridine donors. For the latter, this correlates with the observed conversion ratios. The total conversion may therefore be interpreted as follows. The steric demand of dibromo-substituted pyridine donors in the apical positions leads to a slow DOW-phenol reaction; the resulting $Cu^{[I]}$ leads to a comparably high reduction and substitution rate to yield reduced and substituted pyridine donors and Cu^{II}; the DOW-phenol reaction then also proceeds with pyridine and benzoate-substituted pyridines. The observed selectivities for the two dibromopyridine ligands support this. With 3,5-dibromopyridine, a comparatively large amount of pyridine is formed and the observed *ortho*-selectivity is 99.2%, similar to that seen with pyridine itself. With 2,5-dibromopyridine, the major product is a pyridine substituted at the 2-position and reduced at the 5-position. This secondary ligand still leads to substantial steric hindrance, and the resulting *ortho*-selectivity of 66.7% is close to that observed for Cu^{II} benzoate in the absence of base and water.[5]

The apical donor aniline blocks the DOW-phenol reaction completely. Phenyl benzoate was not detected. Instead, the quantitative formation of *N*-phenyl benzamide was observed. Since this co-elutes with phenyl benzoate in the HPLC procedure used, LC-MS, including a peak purity check, was applied to enable a quantitative determination. On adding pyridine donors to a Cu^{II} benzoate solution in acetone, the paddle-wheel structure remained intact, whereas with aniline a distinct color change was observed and no paddle-wheel dicopper(II) compound could be isolated. The failure to observe DOW-phenol chemistry with aniline supports the interpretation that paddle-wheel structures of copper(II) benzoate are a requirement for the DOW-phenol reaction.[5]

With three donors, namely 2,6-dimethylpyridine, aniline, and 2-fluoropyridine, benzene was detected as an additional product of the stoichiometric DOW-phenol reactions. Benzene is a common by-product in the DOW-phenol process, but its formation is generally attributed to $Cu^{[I]}$, reaction at the reactor wall, and high temperatures ($\geq$ 250 °C). However, in the three cases where benzene was found (Table 1), $[Cu^{[I]}]$ is low and no metal reactor wall was present. With 2,6-dimethylpyridine and aniline, the reaction temperature was as low as 230 °C. Therefore, apart from in the case of 2-fluoropyridine, our interpretation of the benzene production is that a relatively strong base must be present.[8] In the case of 2-fluoropyridine, the elevated temperature might be the most important factor.

Molecular Structures of Copper(II) Benzoates with Apical Donors

For all the apical donors studied, except for aniline, dicopper(II) species with stoichiometries in agreement with the expected paddle-wheel structures were isolated. The X-ray crystal structures of the four structurally characterized dicopper(II) benzoates (see Figure 1, Table 2) are essentially identical and, as expected for copper(II), do indeed represent paddle-wheel compounds. They consist of centrosymmetric dicopper(II) units, in which each copper(II) ion is coordinated by four oxygen atoms of the four bridging carboxylate groups (see Figure 1, Scheme 2, and Table 2). The copper−copper distances range from 2.626 Å to 2.678 Å. The angle between the two planes through the two copper(II) centers and two benzoates ranges from 88.92° to 89.80°. The two pyridine rings are parallel, except in compound **2**, where their ring planes intersect at an angle of 79.23°. No paddle-wheel-type copper(II) benzoate could be isolated with aniline. Aniline seems to destroy the copper(II) benzoate fragment and this leads to the formation of unidentified mononuclear copper(II) species.

CO_2 Measurements

The pyrolyses of copper(II) benzoate in sealed silica tubes in the absence of oxygen, with all the pyridine derivatives used in this study, produce CO_2. The cumulative formation of CO_2 as a function of time with copper(II) benzoate alone reaches a constant value of approximately 66% with respect to the stoichiometrically expected amount (Figure 2; approximately 50% *o*-selectivity in the formation of the benzoyloxybenzoic acid, see above[5]). With the methylated and halogenated pyridine donors, the production of CO_2 increases significantly [see Figure 2; with pyridine 109% and with 3-bromopyridine 108% was obtained; 100% CO_2

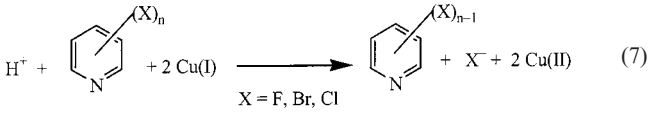
corresponds to the stoichiometric amount of copper(I) generated in one reduction cycle (see Scheme 1)].

There are various explanations for this behavior. An important observation is that after the pyrolysis with pyridine, elemental copper is found in the reaction vessel. This indicates that copper(I), formed during the reduction of the halogenated pyridines and the ensuing DOW-phenol process, undergoes disproportionation to copper(0) and copper(II) [Equation (6)]. The resulting copper(II) leads to additional CO_2 production [Equation (1) and Scheme 1].

$$2\,Cu^{I} \rightarrow Cu^{0} + Cu^{II} \qquad (6)$$

Moreover, pyridine catalyzes the decarboxylation of aromatic acids.[8] The copper(II) compound with 3-bromopyridine leads to an even larger excess of CO_2, although no elemental copper could be found after the reaction. This may be related to the detection of reduced pyridines by HPLC. After the usual decomposition of copper(II) benzoate, copper(I) is re-oxidized to copper(II) by the halopyridines [Equation (7)]. The complete reduction of halogenated pyridine derivatives in a catalytic reaction is prohibited by the precipitation of copper(I) halides.[7] These processes are described in detail in a separate publication.[6]



(7)

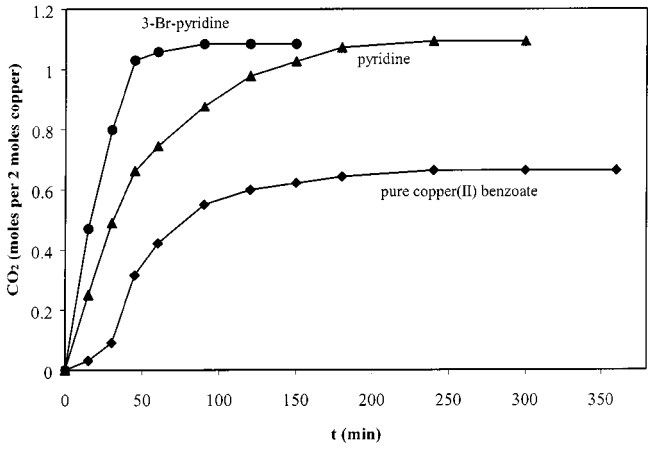


Figure 2. Cumulative CO_2 formation during the pyrolysis of various copper(II) benzoates with apical donors (stoichiometric reaction under argon; for conditions, see Exp. Sect.)

Experimental Section

Materials: Copper(II) benzoate was obtained from DSM and was used without purification. All other compounds were purchased from Sigma or Aldrich and were used without further purification. The purity ranges were 97−99%.

Syntheses of the Copper(II) Compounds

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4(3,5\text{-}Br-C_5H_3N)_2]$ (1): 3,5-Dibromopyridine (1.00 g, 4.22 mmol) was added to a solution of copper(II) benzoate (1.37 g, 2.12 mmol) in dry acetone (50 mL). After 24 h, the turquoise-green precipitate was collected by filtration, washed with Et_2O, and dried in vacuo. Yield: 1.55 g (67.4%). − IR (KBr): $\tilde{\nu}$ = 3060 [ν(C−H)], 1626 [ν(C=N)], 1600 [ν(C=C)], 1574 [$\nu_{asym.}$ (C=O, COO^-)], 1406 [$\nu_{sym.}$ (C=O, COO^-)], 1022 [ν(aryl-Br)] cm^{-1}. − $C_{38}H_{26}Br_4Cu_2N_2O_8$ (1085.34): calcd. C 42.03, H 2.41, N 2.58; found C 42.09, H 2.61, N 2.51.

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4(3\text{-}Br-C_5H_4N)_2]$ (2): 3-Bromopyridine (1.50 g, 9.81 mmol) was added to a solution of copper(II) benzoate (2.05 g, 3.17 mmol) in dry acetone (50 mL). The reaction mixture was heated at 60 °C for 24 h. The turquoise-green precipitate was then collected by filtration, washed with Et_2O, and dried in vacuo. Yield: 2.13 g (72.4%). − IR (KBr): $\tilde{\nu}$ = 3066 [ν(C−H)], 1628 [ν(C=N)], 1616 [ν(C=C)], 1572 [$\nu_{asym.}$ (C=O, COO^-)], 1402 [$\nu_{sym.}$ (C=O, COO^-)], 1028 [ν(aryl-F)] cm^{-1}. − $C_{38}H_{28}Cu_2Br_2N_2O_8$ (927.54): calcd. C 49.21, H 3.04, N 3.02, Br 17.23; found C 49.19, H 3.37, N 2.87, Br 16.47.

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4(2,5\text{-}Br-C_5H_3N)_2]$ (3): 2,5-Dibromopyridine (2.00 g, 8.44 mmol) was added to a solution of copper(II) benzoate (2.74 g, 4.43 mmol) in dry acetone (50 mL). The reaction mixture was heated at 60 °C for 24 h. The solvent was then removed under reduced pressure, and the residue was washed with petroleum ether (30 mL) and dried in vacuo. Yield: 2.59 g (56.3%). − IR (KBr): $\tilde{\nu}$ = 3063 [ν(C−H)], 1625 [ν(C=N)], 1600 [ν(C=C)], 1570 [$\nu_{asym.}$ (C=O, COO^-)], 1410 [$\nu_{sym.}$ (C=O, COO^-)], 1070 [ν(aryl-Br)] cm^{-1}. − $C_{38}H_{26}Br_4Cu_2N_2O_8$ (1085.34): calcd. C 42.03, H 2.41, N 2.58, Br 29.45; found C 42.48, H 2.72, N 2.57, Br 28.50.

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4(2\text{-}Cl-C_5H_4N)_2]$ (4): 2-Chloropyridine (2.00 g, 17.61 mmol) was added to a solution of copper(II) benzoate (3.71 g, 5.72 mmol) in dry acetone (100 mL). The reaction mixture was heated at 60 °C for 24 h. The solvent was then removed under reduced pressure, and the residue was washed with petroleum ether (30 mL) and dried in vacuo. Yield: 2.46 g (51.25%). − IR (KBr): $\tilde{\nu}$ = 3062 [ν(C−H)], 1626 [ν(C=N)], 1616 [ν(C=C)], 1572 [$\nu_{asym.}$ (C=O, COO^-)], 1406 [$\nu_{sym.}$ (C=O, COO^-)], 1270 [ν(aryl-Cl)] cm^{-1}. − $C_{38}H_{28}Cu_2Cl_2N_2O_8$ (838.65): calcd. C 54.42, H 3.37, N 3.34; found C 54.48, H 3.50, N 3.13.

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4(2\text{-}Br-C_5H_4N)_2]$: 2-Bromopyridine (2.70 g, 17.09 mmol) was added to a solution of copper(II) benzoate (5.00 g, 7.72 mmol) in dry acetone (100 mL). The reaction mixture was heated to 60 °C for 24 h. The solvent was then removed under reduced pressure, and the residue was washed with petroleum ether (30 mL) and dried in vacuo. Yield: 4.7 g (65.64%). − IR (KBr): $\tilde{\nu}$ = 3063 [ν(C−H)], 1625 [ν(C=N)], 1600 [ν(C=C) =], 1570 [$\nu_{asym.}$ (C=O, COO^-)], 1410 [$\nu_{sym.}$ (C=O, COO^-)], 1070 [ν(aryl-Br)] = cm^{-1}. − $C_{33}H_{24}BrCu_2NO_8$ (769.55): calcd. C 51.50, H 3.14, N 1.82, Br 10.38; found C 51.52, H 3.46, N 1.84, Br 10.11.

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4(2\text{-}F-C_5H_4N)_2]$: 2-Fluoropyridine (1.00 g, 10.30 mmol) was added to a solution of copper(II) benzoate (2.34 g, 5.16 mmol) in dry acetone (50 mL). The reaction mixture was heated at 60 °C for 24 h. The solvent was then removed under reduced pressure, and the residue was washed with petroleum ether (30 mL) and dried in vacuo. Yield: 2.53 g (53.73%). − IR (KBr): $\tilde{\nu}$ = 3070 [ν(C−H)], 1628 [ν(C=N)], 1610 [ν(C=C)], 1574 [$\nu_{asym.}$ (C=O, COO^-)], 1404 [$\nu_{sym.}$ (C=O, COO^-)], 1270 [ν(aryl-F)] cm^{-1}. − $C_{38}H_{28}Cu_2F_2N_2O_8$ (805.74): calcd. C 56.64, H 3.50, N 3.48; found C 56.58, H 3.87, N 3.10.

$[Cu(\mu_2\text{-}O_2C-C_6H_5)_2(H_2N-C_6H_5)]_n$: To a suspension of copper(II) benzoate (1.00 g, 1.54 mmol) in petroleum ether (30 mL) was added aniline (0.29 g, 3.11 mmol). After 24 h, the green precipitate was collected by filtration, washed with Et_2O, and dried in vacuo. Yield: 1.10 g (80.65%). − IR (KBr): $\tilde{\nu}$ = 3312 [ν(N−H)], 3066 [ν(C−H)], 1596 [ν(C=C)], 1548 [$\nu_{asym.}$ (C=O, COO^-)], 1490 [$\nu_{sym.}$ (C=O, COO^-)] cm^{-1}. − $C_{40}H_{34}Cu_2N_2O_8$ (797.81): calcd. C 60.22, H 4.30, N 3.51; found C 59.16, H 4.59, N 3.72.

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4(C_5H_5N)_2]$: Pyridine (1.22 g, 15.42 mmol) was added to a solution of copper(II) benzoate (5.00 g, 7.72 mmol) in dry acetone (100 mL). The reaction mixture was heated at 60 °C for 24 h. The green precipitate was then collected by filtration, washed with EtOH, and dried in vacuo. Yield: 3.6 g (60.60%). − IR (KBr): $\tilde{\nu}$ = 3063 [ν(C−H)], 1628 [ν(C=N)], 1600 [ν(C=C)], 1572 [$\nu_{asym.}$ (C=O, COO^-)], 1405 [$\nu_{sym.}$ (C=O, COO^-)] cm^{-1}. − $C_{38}H_{30}Cu_2N_2O_8$ (769.76): calcd. C 59.29, H 3.93, N 3.64; found C 59.05, H 4.01, N 3.43.

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4(2\text{-}CH_3-C_5H_4N)_2]$: 2-Methylpyridine (1.44 g, 15.44 mmol) was added to a solution of copper(II) benzoate (5.00 g, 7.72 mmol) in dry acetone (100 mL). The reaction mixture was heated at 60 °C for 24 h. The green precipitate was then collected by filtration, washed with Et_2O, and dried in vacuo. Yield: 3.55 g (57.63%). − IR (KBr): $\tilde{\nu}$ = 3066 [ν(C−H)], 2932 [ν(C−H, CH_3)], 1630 [ν(C=N)], 1600 [ν(C=C)], 1574 [$\nu_{asym.}$ (C=O, COO^-)], 1404 [$\nu_{sym.}$ (C=O, COO^-)] cm^{-1}. − $C_{40}H_{34}Cu_2N_2O_8$ (797.81): calcd. C 60.22, H 4.30, N 3.51; found C 60.27, H 4.38, N 3.46.

$[Cu_2(\mu_2\text{-}O_2C-C_6H_5)_4\{2,4\text{-}(CH_3)_2-C_5H_3N\}_2]$: 2,4-Dimethylpyridine (1.65 g, 15.44 mmol) was added to a solution of copper(II) benzoate (5.00 g, 7.72 mmol) in dry acetone (100 mL). The reaction mixture was heated at 60 °C for 24 h. The green precipitate was then collected by filtration, washed with Et_2O, and dried in vacuo.

$[Cu_2(\mu_2\text{-}O_2C{-}C_6H_5)_4\{2,6\text{-}(CH_3)_2{-}C_5H_3N\}_2]$: 2,6-Dimethylpyridine (1.65 g, 15.44 mmol) was added to a solution of copper(II) benzoate (5.00 g, 7.72 mmol) in dry acetone (100 mL). The reaction mixture was heated at 60 °C for 24 h. The solvent was then removed under reduced pressure, and the residue was washed with petroleum ether (30 mL) and dried in vacuo. Yield: 3.24 g (58.38%). − IR (KBr): $\tilde{\nu}$ = 3062 [ν(C−H)], 2928 [ν(C−H, CH_3)], 1632 [ν(C=N)], 1598 [ν(C=C)], 1574 [$\nu_{asym.}$ (C=O, COO^-)], 1402 [$\nu_{sym.}$ (C=O, COO^-)] cm^{-1}. − $C_{35}H_{29}Cu_2NO_8$ (718.52): calcd. C 58.50, H 4.68, N 1.95; found C 58.69, H 4.63, N 1.98.

Pyrolyses: The pure copper(II) benzoate salts with the apical donors (150 mg in each case) were heated for 7 h at 230 °C in sealed silica tubes. The tubes were filled under argon. Since in the case of copper(II) benzoate with 2-fluoropyridine no reaction occurred at 230 °C, this experiment was repeated at 250 °C. After cooling to ambient temperature, the tubes were opened and the products were analyzed by HPLC. In the case of the halogenated pyridines, the products were also analysed by LC-MS.

Positive-ion ESI-MS data were obtained on an HP1100 quadrupole LC-MS system (Agilent Technologies, Waldbronn, Germany). Mass spectra were obtained in full scan mode from m/z = 50−1000 amu at a fragmentor voltage of 70 V and a capillary voltage of 3000 V. The drying gas flow was 10 L/min and the drying gas temperature was 350 °C.

For reversed-phase HPLC, the black solids produced were dissolved in acetonitrile (2 mL) and then injected into an HP 1090 chromatograph with a Nucleosil 120−5 C18 column (500 × 4 mm) at 50 °C. The products were eluted with a gradient made up of different mixtures of eluents A and B [eluent A: 1 M H_3PO_4 (45 mL), conc. acetic acid (2 mL), and 1 M NaOH (35 mL) were added to water (1500 mL) and the pH of the solution was adjusted to 3.2 with 1 M NaOH; after the addition of acetonitrile (200 mL), the mixture was made up with water to give 2000 mL of eluent A; eluent B: 1 M H_3PO_4 (20 mL), conc. acetic acid (2 mL), and 1 M NaOH (60 mL) were added to water (60 mL) and the pH of the solution was adjusted to 6.6 with 1 M NaOH; after the addition of acetonitrile (1200 mL), the mixture was made up with water to give 2000 mL of eluent B]. A DAD (L-3000 Hitachi) was used for detection at 254 nm.

GC analyses were performed using a Hewlett−Packard series 5890 gas chromatograph, equipped with a 30 m fused silica Megabore column (G. & W. Scientific) with a 5 μm DBI stationary phase. The products were identified with an FID detector; nitrogen was used as the carrier gas. − Elemental analyses were obtained from the microanalytical laboratory of the chemical institutes of the University of Heidelberg. Infrared spectra (KBr pellets) were measured with a Perkin−Elmer 16PC FT-IR instrument.

X-ray Crystallography: Crystallographic data are presented in Table 3; all structural data have been deposited with the Cambridge Crystallographic Data Centre (CCDC) as supplementary publication nos. CCDC-152937−152940. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (1223) 336-033; E-mail: deposit@ccdc.cam.ac.uk]. Crystal data

were collected on a Bruker AXS SMART 1000 diffractometer with a CCD area detector (Mo-K_α radiation, graphite monochromator, $\lambda = 0.71073$ Å) at −100 °C, using the SMART suite of programs.[7] The reflection intensities were integrated using SAINT and corrected for absorption using SADABS.[9,10] The structures were solved by direct methods and refined by full-matrix least-squares methods based on F^2 with all reflections, using the SHELXTL programs.[11]

Catalytic Dehalogenation of Halogenated Pyridine Donors under DOW-Phenol Conditions

Wim Buijs,[a] Peter Comba,*[b] Danny Corneli,[b] Ynze Mengerink,[a] and Ron Peters[a]

Keywords: DOW-phenol process / Halogenated pyridines / Reductions / Nucleophilic substitutions

Various halogenated pyridines (2-fluoropyridine, 2-chloropyridine, 2-bromopyridine, 3-bromopyridine, 2,5-dibromopyridine, and 3,5-dibromopyridine) are subject to catalytic reduction and substitution under DOW-phenol conditions; copper(I) benzoate is shown to play a key role in these processes. In the absence of copper(I), the halogenated pyridines do not react with benzoic acid, while after precipitation of copper(I) halide the dehalogenation process stops. Marked differences are observed between the copper(I)-catalyzed dehalogenation of the halopyridines and the previously reported dehalogenation of halogenated aromatics. While the copper(I)-catalyzed substitution of haloaryl compounds by benzoate makes only a minor contribution to the overall dehalogenation process, substitution of halopyridine compounds is at least as important as the reduction reaction. Furthermore, the reaction with halopyridine compounds is regioselective, in contrast to that with halogenated aryl compounds.

Introduction

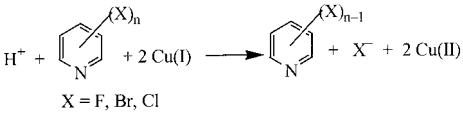
Many halogenated hydrocarbons are hazardous due to their tendency to accumulate in the body and the resultant damage of nerves and hepar.[1] Halogenated hydrocarbons are widely used as solvents and monomers for polymer production. Furthermore, halogenated compounds are produced in various combustion processes, including (natural) wood burning and the combustion of waste. TCDD, 2,3,7,8-tetrachlorodibenzo[1,4]dioxin, known as the "Seveso dioxin", is a well-known representative of the latter group.[1] Halogenated compounds have also played a role in parasite control (DDT).[2] The transformation of halogenated hydrocarbons into less harmful compounds is still a challenge in chemistry. Among the methods currently used industrially, electrochemical dehalogenation and decomposition by iron catalysts are well-known processes.[3,4] A recent discovery was that chlorinated and brominated hydrocarbons can be catalytically reduced under DOW-phenol conditions,[5] and this was confirmed in our investigation of the role of different apical donors on the DOW-phenol process.[6] We have investigated this process in some detail and report here the scope of this novel catalytic reaction.

Results

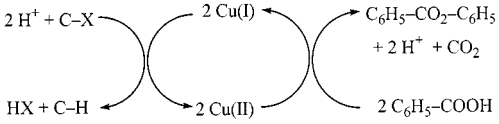
The catalytic reduction of halogenated hydrocarbons under DOW-phenol conditions consists of two steps:

(i) Copper(I) is oxidized by the halogenated pyridines to copper(II) [Equation (1)].

(ii) Copper(II) is reduced to copper(I) during the thermal decomposition of copper(II) benzoate (DOW-phenol reaction) [Equation (2)].

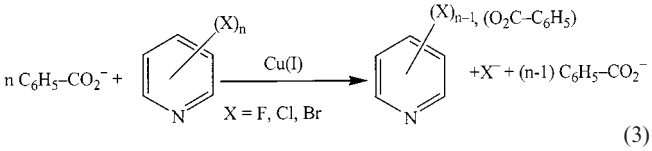


(1)



(2)

Another possible route for the dehalogenation of the halogenated pyridines is the nucleophilic substitution of a halogen atom by a benzoate [Equation (3)].



(3)

During a catalytic cycle, a halogen in a carbon−halogen bond is substituted by a benzoate and, in acidic solution, one molecule of HX is produced. The reaction stops when all halogenated substrates are reduced or substituted, or when the copper catalyst has completely precipitated as the $Cu^{[I]}$ halide.

Table 1 gives an overview of the results obtained in the thermal decomposition of the copper(II) benzoates with apical donors. Apart from the expected DOW-phenol product, i.e. phenyl benzoate, pyridine, *ipso*-benzoate substituted

[a] 250 °C (no reaction occurred at 230 °C); 3.4% of benzene was also produced. – [b] No phenyl benzoate was observed, but a mixture of the precursor *o*-, *p*-, and *m*-benzoyloxybenzoic acids; *ortho*-selectivity: 66.7%.

pyridines, and hydroxypyridine are obtained. Dehalogenation appears to be essentially complete in these experiments. The results demonstrate the scope of the reaction: F-, Cl-, and Br-substituted pyridine ligands undergo reduction and substitution by benzoate under DOW-phenol conditions. Substitution follows the order F > Cl > Br in the series of 2-halopyridine ligands, with relative molar amounts of the substituted products amounting to 99%, 94%, and 87%, respectively. The reduction shows an opposite trend, with relative amounts of pyridine of 1%, 6%, and 13%, respectively. In the case of 3-bromopyridine, the reduction and substitution processes both account for approximately 50% of the overall reaction. Similar behavior is observed for the dibromopyridine donors: the observed monobenzoyloxypyridine compounds are the result of a reduction and substitution cycle. A double reduction process yields pyridine, while a double substitution yields dibenzoyloxypyridine. Both are observed by LC-MS, albeit at very low levels. Hydroxypyridine products, resulting from hydrolysis, are also detected. Phenol, i.e. the hydrolysis product of phenyl benzoate, is not observed. In the case of 2-fluoropyridine, a significant amount of benzene is also obtained, which is probably formed as a decomposition product due to the relatively high temperature (250 °C).

Discussion

Comparing the different pyridine substrates, three issues need clarification: 1) the order of the halogens in both substitution and reduction, 2) the order of reactivity in the series of brominated pyridines with respect to their regiochemistry, and 3) the observation that phenol, the hydrolysis product of phenyl benzoate, is not present in the reaction mixtures, while the hydroxypyridines are present in all the mixtures.

A possible explanation for these issues emerges from the proposed mechanism.[5] One electron is donated by Cu^I to the carbon–halogen bond, possibly involving the temporary formation of a cuprate. A second Cu^I donates an electron to the carbon, leading formally to a carbanion stabilized by two Cu^{II} centers. The resulting halide might form a Cu^{II}·X·Cu^{II} bridge. The Cu^{II}-stabilized carbanion is then protonated by benzoic acid and eliminated from the Cu^{II} coordination sphere. Alternatively, a benzoate might act as a nucleophile after the donation of the first electron to the carbon–halogen bond, leading to net overall nucleophilic substitution of the original halogen by a benzoate. In this case, the role of Cu^I is to improve the leaving group ability of the halogen. The tentative mechanism is shown in Figure 1.

Important features are the properties of the reactive intermediates and transition states, i.e. the radicals and carbanions derived from the substrates. Quantum mechanical calculations are a useful tool for the investigation of the properties of such species. Semi-empirical calculations (PM3) were used for an efficient comparison of the entire series. DFT calculations (BP level) on the series of monohalogenated pyridines gave essentially the same results. Computational details are given in the Exp. Sect.. Table 2 lists the computed electrostatic charges on the corresponding C-atoms of the 2- and 3-halogenated pyridines.

2-Fluoropyridine has by far the highest positive charge, +0.858, on the C2 atom, followed by 2-chloro- and 2-bromopyridine, with charges of +0.504 and +0.305. 3-Bromopyridine, on the other hand, has a negative charge on the C3 atom (−0.634). If the nucleophilic substitution can be correlated with the positive charge on the relevant carbon atoms, the proposed order by PM3 would be: 2-fluoropyridine > 2-chloropyridine > 2,5-dibromopyridine (2) > 2-bromopyridine > 3-bromopyridine > 2,5-dibromopyridine (5) > 3,5-dibromopyridine. This order is indeed observed for the series of 2-halopyridines. 2,5-Dibromopyridine is a special case with its two different carbon–bromine bonds. The C2 atom is positively charged, this charge being roughly equal to that on the C2 atom of 2-bromopyridine, while its C5 atom is even more negatively charged than the C3 atom of 3-bromopyridine. Therefore, 2,5-dibromo- and 3,5-dibromopyridine fit well in this sequence, being intermediate between the 2-bromo- and 3-bromopyridines.

If the reduction can be correlated with the negative charge on the corresponding pyridine anion, then the order predicted by PM3 calculations would be: 3-pyridine anion (−1.489) ≈ 5-bromo-3-pyridine anion (−1.467) ≈ 2-bromo-5-pyridine anion (−1.464) > 2-pyridine anion (−0.893) ≈ 5-bromo-2-pyridine anion (−0.840). This order

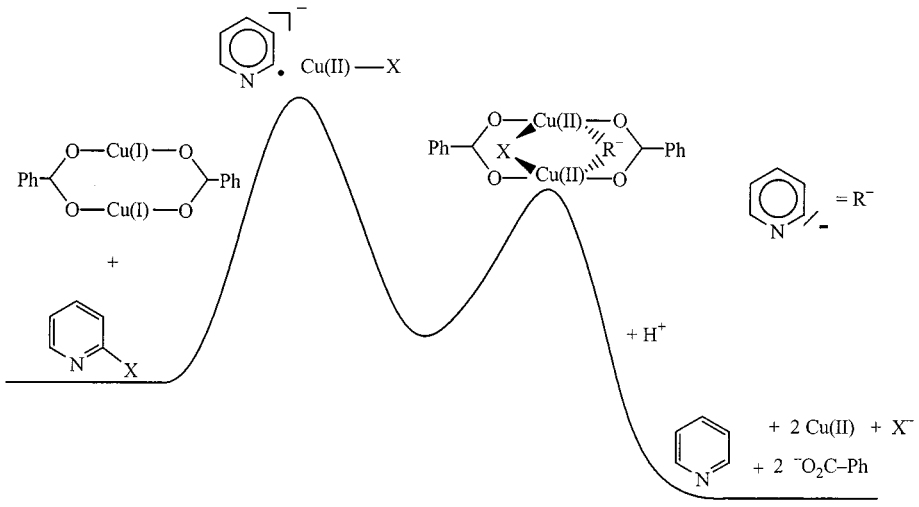

Figure 1. Proposed mechanism for the reduction of halogenated pyridines under DOW-phenol conditions

Table 2. Electrostatic charges of the halogenated pyridines, pyridyl radicals, and pyridine anions; computations were carried out at the PM3 and BP levels

pyridine substrate	PM3 electrostatic charge	BP electrostatic charge
2-fluoropyridine	+0.858	+0.718
2-chloropyridine	+0.504	+0.437
2-bromopyridine	+0.305	+0.413
3-bromopyridine	−0.634	−0.299
2,5-dibromopyridine 2-position 2,5-dibromopyridine 5-position	+0.338	
−0.651		
3,5-dibromopyridine	−0.747	
2-pyridyl radical	−0.089	+0.038
3-pyridyl radical	−0.439	−0.299
2-bromo-5-pyridyl radical	−0.428	
5-bromo-2-pyridyl radical	+0.084	
5-bromo-3-pyridyl radical	−0.497	
2-pyridine anion	−0.893	−0.793
3-pyridine anion	−1.489	−1.188
2-bromo-5-pyridine anion	−1.464	
5-bromo-2-pyridine anion	−0.840	
5-bromo-3-pyridine anion	−1.467	

indeed explains the different reduction yields, i.e. of 9.3% for 3-bromopyridine and of 2.2% for 2-bromopyridine. A similar pattern is observed for 2,5-dibromopyridine (0.5%) and 3,5-dibromopyridine (1.4%), although the double reduction yields are rather low. This also leads to speculation concerning the major product derived from the two dibromopyridines; that arising from 2,5-dibromopyridine should be 2-benzoyloxypyridine (28.6%), whereas the corresponding product from 3,5-dibromopyridine should be 3-benzoyloxypyridine (25.2%).

Conclusion

(i) Semi-empirical quantum chemical calculations are an excellent tool for interpreting the observed order of the halogens in the substitution reaction of 2-halopyridines; the opposite order for the reduction might be a simple consequence of the preference for substitution, while the next steps (pyridyl radical, pyridine anion) become increasingly independent of the leaving group in the proposed mechanism.

(ii) The difference between the regioisomers 2-bromo- and 3-bromopyridine can be adequately explained, both in terms of substitution and reduction.

(iii) At first sight, it might seem surprising that the hydrolysis products hydroxypyridines are observed, while phenol is not. However, with the benzoyloxypyridines intramolecular base hydrolysis is possible, whereas with phenyl benzoate it is not.

Finally, we would like to comment on the behavior of the halopyridines as compared with that of the haloaromatics. With the latter, no indication was found for a major contribution of the nucleophilic substitution reaction and no regioselectivity was observed.[5] An appealing explanation is that the benzene ring is an electron-rich aromatic system in comparison with the pyridine ring. Therefore, nucleophilic

substitution is more likely to occur on the electron-poor pyridine system than on benzene. Moreover, the reaction mixtures composed of benzoic acid, Cu^{I} benzoate, and a haloaryl compound are rather acidic, whereas the mixtures composed of benzoic acid, Cu^{I} benzoate, and a halopyridine are basic, at least locally. The final step in the reduction requires a proton. Therefore, the reduction should be easier in the more acidic environment. Fortunately, halogenated pyridines are not produced in very large quantities because the observed regioselectivity has to be considered as a disadvantage for an environmental technology.

Experimental Section

Materials and Analytical Procedures: Copper(II) benzoate was prepared from copper(II) sulfate and sodium benzoate. All other compounds were purchased from Sigma or Aldrich and were used without further purification. − **Pyrolyses:** The pure copper(II) benzoate salts with the apical donors (150 mg in each case) were heated for 7 h at 230 °C in sealed silica tubes. The tubes were filled under argon. Since in the case of copper(II) benzoate with 2-fluoropyridine no reaction occurred at 230 °C, this experiment was repeated at 250 °C. After cooling to ambient temperature, the tubes were opened and the products were analyzed by HPLC. In the case of the halogenated pyridines, the products were also analyzed by LC-MS. − **Electrospray MS:** Positive-ion ESI-MS data were obtained on an HP1100 quadrupole LC-MS system (Agilent Technologies, Waldbronn, Germany). Mass spectra were obtained in full scan mode from m/z = 50−1000 amu at a fragmentor voltage of 70 V and a capillary voltage of 3000 V. The drying gas flow was 10 L/min and the drying gas temperature was 350 °C. − **Reversed-Phase HPLC:** For reversed-phase HPLC, the black solids produced were dissolved in acetonitrile (2 mL) and then injected into an HP 1090 chromatograph with a Nucleosil 120−5 C18 column (500 × 4 mm) at 50 °C. The products were eluted with a gradient made up of different mixtures of eluents A and B [eluent A: 1 M H_3PO_4 (45 mL), conc. acetic acid (2 mL) and 1 M NaOH (35 mL) were added to water (1500 mL) and the pH of the solution was adjusted to 3.2 with 1 M NaOH; after the addition of acetonitrile (200 mL) the mixture was made up with water to give 2000 mL of eluent A; eluent B: 1 M H_3PO_4 (20 mL), conc. acetic acid (2 mL), and 1 M NaOH (60 mL) were added to water (60 mL) and the pH of the solution was adjusted to 6.6 with 1 M NaOH; after the addition of acetonitrile (1200 mL) the mixture was made up with water to give 2000 mL of eluent B]. A DAD (L-3000 Hitachi) was used for detection at 254 nm.

Computational Details

All calculations were carried out using the Titan molecular modeling suite of programs.[8] All molecules and fragments were geometry-optimized using the semi-empirical PM3 method. These structures were used as input data for a geometry optimization at the BP level (DFT), using the LACVP* basis set for Br and 6−31 G* for all other elements. DFT calculations were carried out only for the monohalogenated pyridines. The DFT results were in full accord with the PM3 results.

A Tripodal Triaminostannate as a Metal Nucleophile: Synthesis of Transition Metal−Tin Heterodimetallic Complexes

Matthias Lutz,[a,b] Bernd Findeis,[a] Matti Haukka,[b] Tapani A. Pakkanen,*[b] and Lutz H. Gade*[a]

In memoriam Sallaraisa Pulkkinen

Keywords: Tin / Metal−metal interactions / N ligands / Transition metals

The coordination capability of the previously reported triamidostannate [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$SnLi($OEt_2$)] (**1**) as a precursor for transition metal–tin heterodimetallic complexes is presented. Whereas reaction with CH_3I, Me_3SiCl, or Me_3SnCl yielded the derivatives [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$Sn–R] (R = Me, **2**; Me_3Si, **3**; Me_3Sn, **4**), demonstrating the nucleophilic properties of the stannate(II), its complexation to transition metal centres was achieved by halide substitution with [$CuCl(PPh_3)]_4$, [$CpM(CO)_2X$] (M = Fe, X = Cl; M = Ru, X = Br), [$CpM(CO)_3Cl$] (M = Mo, W) and *trans*(Cl)-[$RuCl_2(bpy)(CO)_2$] to give [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$-Sn–$Cu(PPh_3)$] (**5**), [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$Sn–$M(CO)_2Cp$ (M = Fe: **6**; Ru: **7**)], [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$Sn–$M(CO)_2Cp$] (M = Mo: **8**; W: **9**) and [(MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$Sn)$_2$Ru(bpy)$(CO)_2$] (**10**), of which **6**, **9** and **10** were characterized by X-ray diffraction.

Introduction

Transition metal−tin heterodimetallic complexes were among the first metal−metal bonded compounds to be studied in detail,[1] and since the pioneering work of the 1960's a great number of such complexes have been synthesized and characterized.[2] Apart from the fundamental aspect of bonding between transition metals and main group metals, the fact that the formation and transformation of transition metal−main group metal bonds are crucial steps in a variety of catalytic processes as well as semiconductor growth has created a great deal of interest.[4,5] In spite of the multitude of known transition metal−tin compounds, some transition metal complex fragments, notably the more highly oxidizing species, do not form stable dimetallic complexes with tin fragments. In order to suppress degenerative intramolecular redox reactions, an appropriate ligand shell for the group 14 element has to be chosen.

The tripodal amido ligands developed by us[6] were found to be ideally suited for the synthesis of group 14 triamidometallates, in particular triamidostannates.[7−9] These triamidostannates were found to bind to potentially highly oxidizing metal centres such as the tetravalent group 4 metals[10] as well as Ag^{I}, Au^{II} and Au^{III} to give thermally stable heterometallic compounds.[11−13] The electronegative nitrogen substituents at divalent group 14 metal centres thus appear to stabilize the metals with respect to oxidation by a heterometal centre to which they are bonded.

In view of the relative chemical inertness to oxidation by transition metals of the triamidostannates and the facile variability of their peripheral tripodal amido unit, we have recently begun to explore their properties as monoanionic "ligands" in transition metal chemistry, along with their isoelectronic neutral group 15 analogues.[14] In this work we present a detailed study of the coordination capability of the previously reported triamidostannate [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$SnLi($OEt_2$)] (**1**).[11]

Results and Discussion

The properties of the amidostannate complex [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$SnLi($OEt_2$)] (**1**)[11] as a metal nucleophile were initially tested by reaction with CH_3I, Me_3SiCl, and Me_3SnCl. Stirring the reagents in toluene whilst warming the reaction mixture from −20 °C to ambient temperature gave the corresponding coupling products as thermally stable solids in moderate to high yields (Scheme 1).

Elemental analyses and the ^1H, ^{13}C and ^{29}Si NMR spectroscopic data are in agreement with their formulation as [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$Sn−R] (R = Me, **2**; Me_3Si, **3**; Me_3Sn, **4**); the molecular structures are depicted in Scheme 1. All three compounds display the expected threefold symmetry in solution as indicated by the signal patterns in the NMR spectra.

Reaction of **1** with 0.25 molar equivalents of [$CuCl(PPh_3)]_4$ in toluene at room temperature immediately gave the Sn−Cu complex [MeSi{$SiMe_2N(4\text{-}CH_3C_6H_4)$}$_3$Sn−

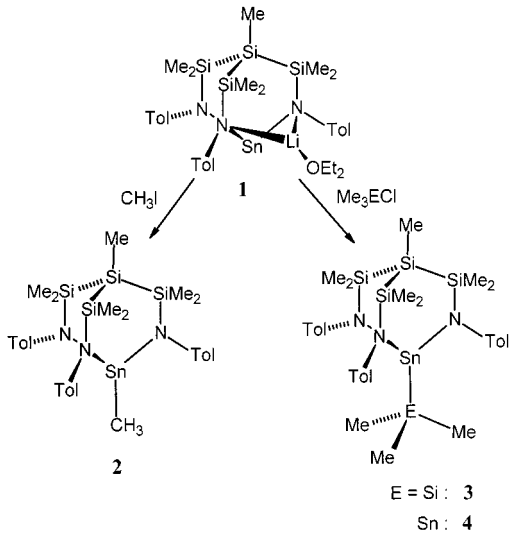
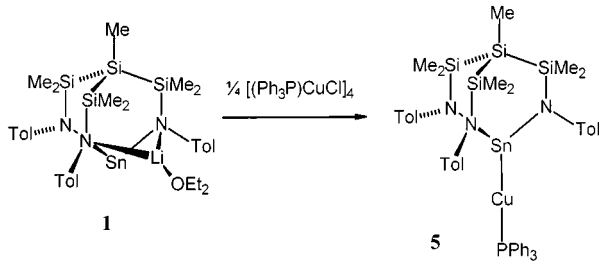


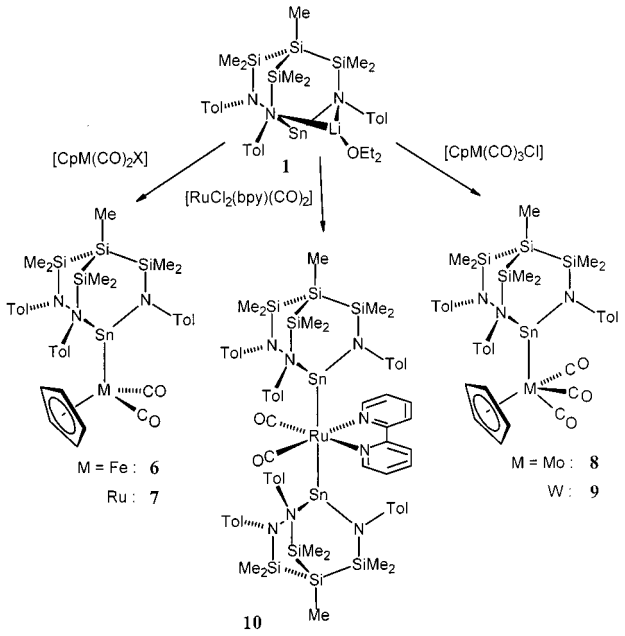
Scheme 1. Reaction of the triaminostannate with metal and non-metal electrophiles to give Sn−element bonds



Scheme 2. Synthesis of the Cu−Sn compound **5**

Cu(PPh$_3$)] (**5**) (Scheme 2).[15] The formation of a Sn−Cu bond in this complex is supported by the observation of $^{117/119}$Sn satellites in the ^{31}P NMR spectra, which appear at room temperature as an averaged $^2J(^{117/119}\text{Sn-}^{31}\text{P})$ coupling satellite pattern associated with the ^{31}P NMR resonance at $\delta = 0.7$. The characteristic $^{117/119}$Sn-^{31}P splitting pattern [$^2J(^{117/119}\text{Sn-}^{31}\text{P})$ = 634.2 Hz/662.8 Hz] could be observed upon lowering the temperature to 205 K. The Cu−Sn compound apparently does not undergo detectable redistribution reactions in solution and thus resembles more closely the previously characterized analogous Au−Sn complex[12] than the Ag−Sn compound bearing the same triamidostannate unit.[11]

As we have previously performed studies of group 4/8 heterodimetallic complexes[16] in which the early transition metal is coordinated by the amido tripod employed in the synthesis of **1**, it was of interest to find out whether the corresponding group 14 derivatives are accessible and how their structures and properties are related to the early transition metal derivatives. [MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$SnLi(OEt$_2$)] (**1**) reacts with [CpM(CO)$_2$X] (M = Fe, X = Cl; M = Ru, X = Br) to afford the corresponding heterodimetallic complexes [MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$Sn−



Scheme 3. Synthesis of transition metal−tin heterodimetallic complexes **6**−**10**

M(CO)$_2$Cp] (M = Fe: **6**; Ru: **7**; Scheme 3). They were characterized by ^{1}H, ^{13}C, and ^{29}Si NMR spectroscopy, infrared spectroscopy, and elemental analysis. The NMR spectra recorded at 295 K established the effective threefold symmetry of the heterodinuclear complexes in solution and thus indicated a rapid internal rotation of the molecules around the metal−metal axis. Cooling of these solutions led to the broadening of the resonances at 200 K but it was not possible to reach the low temperature limit corresponding to a frozen internal rotation on the NMR time scale. In the CO stretching region of the IR spectrum, [MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$Sn−M(CO)$_2$Cp] exhibits two bands of approximately equal intensity (**6**: 2016 and 1971 cm^{-1}; **7**: 2031 and 1981 cm^{-1}). These values are lower than those of CpM(CO)$_2$X (M = Fe, X = Cl: 2050, 2004 cm^{-1} in toluene; M = Ru, X = Br: 2049, 1999 cm^{-1} in toluene) (see Table 1), due to coordination of the two strongly σ-donating and weakly π-accepting amidostannyl ligands causing an increased π back-donation to the CO ligands.

In order to establish the details of the molecular structure of the type of group 8-tin complex discussed above, a single crystal X-ray structure analysis of compound **6** was carried out. The molecular structure of **6** is shown in Figure 1, along with the principal bond lengths and angles. The tripod amide-tin unit is characterized by its rigid cage structure as found in related tin complexes previously characterized by us. The peripheral tolyl groups adopt a "lampshade" arrangement to make space for the CpFe(CO)$_2$ fragment bonded through a metal−metal bond. The Sn−Fe bond length found in **6** [2.5146(3) Å] is similar to those found in structurally related Fe−Sn heterodimetallics, such as [Cp(CO)$_2$Fe−SnPh$_3$] (2.533 Å),[17] [Cp(CO)$_2$Fe−SnCl$_3$] [2.467(1) Å],[18] [Cp(CO)$_2$Fe−SnBr$_3$] [2.462(2) Å],[19]

[$Cp(CO)_2Fe]_2SnCl_2$ [2.492(8) Å],[20] [$Cp(CO)_2Fe$−Sn{N*t*Bu)$_2$SiMe}$_2$Me] [2.532(2) Å],[21] [$Cp(CO)_2$Fe{Sn(N*t*Bu)$_2$SiMe}$_2$] [2.605(2) Å],[21] [$Cp(CO)_2Fe]_2Sn(N_3)_2$ [2.504(1) Å][22] and [$Cp(CO)_2Fe$−Sn($SiMe_3NCH_2)_3CCH_3$] [2.539(1) Å].[24] The Sn−Fe−C(carbonyl) bond angles are nearly perpendicular [89.46(8)° and 94.37(7)°] and resemble those in [$Cp(CO)_2Fe$−Sn($SiMe_3NCH_2)_3CCH_3$].[24]

In analogy to the formation of the Fe−Sn and Ru−Sn complexes, compound **1** reacts with the group 6 metal complexes [CpM(CO)$_3$Cl] (M = Mo, W) to afford the corresponding heterodimetallic complexes [MeSi{$SiMe_2$N(4-$CH_3C_6H_4$)}$_3$Sn−M(CO)$_2$Cp] (M = Mo: **8**; W: **9**) (Scheme 3). However, their NMR spectral patterns recorded at room temperature differ considerably from those found for the Fe and Ru analogues. The ^{1}H NMR spectrum exhibits two singlets for the $SiMe_2$ groups (**8**: δ = 0.58, 0.62; **9**: δ = 0.54, 0.62), two singlets for the $CH_3(C_6H_4)$ groups (**8**: δ = 2.17, 2.19; **9**: δ = 2.12, 2.15), and four doublets for the aromatic protons (**8**: δ = 6.94, 7.05, 7.18, 7.21; **9**: δ = 6.88, 7.03, 7.14, 7.20). In addition, two ^{13}C NMR carbonyl resonances (**8**: δ = 224.7, 230.0; **9**: δ = 213.5, 217.4) and three ^{29}Si NMR signals [**8**: δ = −89.0 (SiMe), 1.9, 2.4 ($SiMe_2$); **9**: δ = −89.1 (SiMe), 1.7, 2.2 ($SiMe_2$)] have been detected at room temperature. It is thus clear that the internal rotation around the metal−metal bond axis is frozen out on the NMR time scale at 295 K. This is a consequence of the sterically more encumbered coordination sphere around the group 6 metal bearing an additional carbonyl ligand with respect to **6** and **7**.

In a series of high temperature ^{1}H NMR spectra of **8** and **9** coalescence of the proton resonances was observed and the high temperature limit attained at 340 K for **8** and at 350 K for **9**. At these temperatures the ^{1}H NMR spectra of both compounds show one singlet for the $SiMe_2$ groups (**8**: δ = 0.52; **9**: δ = 0.51), one singlet for the $CH_3(C_6H_4)$ groups (**8**: δ = 2.16; **9**: δ = 2.17), and two doublets for the aromatic protons (**8**: δ = 6.94, 7.13; **9**: δ = 6.94, 7.14), whereas only one ^{13}C NMR carbonyl resonance (**8**: δ = 224.9; **9**: δ = 213.7) has been observed. Coalescence of the $SiMe_2$ and $CH_3(C_6H_4)$ resonances is observed at T_c = 313 K (**8**), and T_c = 316 K (**9**), and an activation enthalpy for the rotation around the Sn−M bond of $\Delta G^{\neq}$ = 67.8 ± 1.0 kJ·mol^{-1} (**8**) and 68.3 ± 1.0 kJ·mol^{-1} (**9**) may be estimated based on these data.

The different dynamic behaviour in solution of the group 6 tricarbonyl derivatives in comparison with the group 8 dicarbonyl complexes made a detailed structural characterization desirable. To this end a single crystal X-ray diffraction study of compound **9** was carried out. The molecular structure of **9** is depicted in Figure 2 along with the principal bond lengths and interbond angles.

The overall molecular structure resembles that of **6**, the triamidotin unit being structurally very similar. The Sn−W bond length in **9** [2.7826(2) Å] is comparable to those found in structurally related W−Sn heterodimetallics, such as [$Cp(CO)_3W-SnCl_2$(*t*Bu)] (2.752 Å),[25] [(Ph_2Si−O−$SiPh_2$)O_2Sn(*t*Bu)−W(CO)$_3$Cp] (2.779 Å and 2.761 Å),[26] [$Cp(CO)_3W-SnCl_2-${Os(CO)$_4$}$_2$Os(CO)$_4$Cl] (2.756 Å),[27] [$Ph_3Sn-W(Cp)_2-SnCl$(*t*Bu)$_2$] (2.811 Å and 2.794 Å)[28] and [IHg−W(Cp)$_2$−SnPh$_3$] (2.768 Å).[17] The Sn−W−C(carbonyl) bond angles are 75.79(9)°, 74.83(9)°, and 126.44(10)° and reflect the steric hindrance around the W centre. The W−C distances of the two carbonyl ligands pointing towards the tin fragment are virtually identical [C(50)−W(1): 1.996(4) Å; C(51)−W(1): 1.987(3) Å] to that of the carbonyl pointing away from the W−Sn bond [C(52)−W(1): 2.002(3) Å].

In the synthesis of complexes **6**−**9** the triamidostannate was reacted with transition metal monohalide complexes to

Figure 2. form a single metal−metal bond. To extend this synthetic approach, a coupling with a "difunctional" transition metal complex (bearing two displaceable halide ligands) was attempted. Reaction of *trans*(Cl)-[$RuCl_2(bpy)(CO)_2$][30] with two molar equivalents of **1** in THF afforded the trinuclear complex **10** in moderate yield (Scheme 3). Its NMR spectroscopic data (^1H, ^{13}C, ^{29}Si) indicate a local threefold symmetry of the stannate fragment in solution. The IR spectrum of **10** shows two equally intense bands in the CO stretching region at 2039 and 1990 cm^{-1}, which can be assigned to $\nu_s(CO)$ and $\nu_{as}(CO)$, respectively. The strongly σ-donating and weakly π-accepting amidostannyl ligands shift the wavenumbers to smaller values than those of *trans*(Cl)-[$RuCl_2(bpy)(CO)_2$] (2065, 2004 cm^{-1} in CH_2Cl_2) (see Table 1). It is noteworthy that the reaction of *trans*(Cl)-[$RuCl_2(bpy)(CO)_2$] with one molar equivalent of **1** instantaneously yields **10** and 0.5 molar equivalent of unchanged *trans*(Cl)-[$RuCl_2(bpy)(CO)_2$]. The substitution of the second chloro ligand therefore appears to be accelerated by the strong trans effect of the triamidostannate bonded to the ruthenium centre upon the first substitution step. This trinuclear complex is the first of its type using the triamidostannate cages and was therefore structurally characterized by X-ray diffraction.

The molecular structure of **10** is depicted in Figure 3, along with the principal bond lengths and angles. The two $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn]^-$ ligands are bonded to the Ru centre in a nearly linear fashion [Sn(1)−Ru−Sn(2): 174.26(2) °] and are staggered with respect to their tolyl groups. The Ru−Sn bond lengths of 2.7085(5) and 2.7324(5) Å are slightly longer than the typical values for Ru−Sn bonds (2.55−2.69 Å).[31] Similar structural parameters have been recently described in the closely related compound $[Ru(SnPh_3)_2(CO)_2(i\text{Pr-DAB})]$ (*i*Pr-DAB = *N*,*N*′-diisopropyl-1,4-diaza-1,3-butadiene),[32] where Ru−Sn bond lengths of 2.686(2) and 2.691(2) Å, and an Sn−Ru−Sn bond angle of 173.45(7)° were found. The shorter carbonyl C−O bond lengths [1.133(22) and 1.123(20) Å] in the precursor complex *trans*(Cl)-[$RuCl_2(bpy)(CO)_2$][30] compared to those of **10** [1.148(6) and 1.148(5) Å] may be due to the strong σ-donation of the stannyl ligands in the latter and confirm the results obtained by IR spectroscopy. The pyridine rings in the bpy subunit are slightly twisted with respect to each other, probably due to the steric demand of the tolyl groups [torsional angles: N(1)−C(14)−C(15)−N(2): 1.1(6)° and C(13)−C(14)−C(15)−C(16): 2.8(8)°].

Conclusion

This study has not only established new types of transition metal−tin complexes but introduced the monoanionic triamidostannate $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn]^-$ as a "ligand" in transition metal chemistry. This system is isoelectronic to the neutral group 15 analogues but, due to its charge, gives access to structures which are complementary to those of phosphane, arsane or stibane complexes. A particularly interesting aspect of its chemistry is the *trans* effect of the stannate established for the substitution of the two *trans* disposed chloro ligands in the synthesis of **10**. Along with further aspects of the structural chemistry it is this point which we are currently studying in the context of the potential of the stannates in homogeneous catalysis.

Experimental Section

General: All manipulations were performed under argon (desiccant P_4O_{10}, Granusic®, J.T. Baker) on a high vacuum line using standard Schlenk techniques, or in a glovebox. All reaction flasks were heated prior to use using three evacuation-refill cycles. Solvents and solutions were transferred by needle-septa techniques. Solvents were dried according to standard methods and saturated with argon. The deuterated solvents used for the NMR spectroscopic measurements were degassed by three successive "freeze−pump−thaw" cycles and stored over 4 Å molecular sieves. Solids were separated from suspensions by filtration through dried Celite. The ^1H, ^{13}C, ^{29}Si and ^{31}P NMR spectra were recorded on a Bruker AC 200, a Bruker Avance 250 and a Bruker AMX 400 FT NMR spectrometer, respectively. ^1H and ^{13}C data are listed in parts per million [ppm] relative to tetramethylsilane and were referenced using the residual protonated solvent peak (^1H) or the carbon resonance (^{13}C). ^{29}Si data are listed in ppm relative to tetramethylsilane as an external standard. ^{31}P data are listed in ppm relative to 85% H_3PO_4 as an external standard. Infrared spectra were recorded on a Nicolet Magna IRTM 750 spectrometer. Elemental analyses were carried out with a Leco CHNS-932 microanalyzer and a CE-instruments EA 1110 CHNS-O microanalyzer, respectively. The compounds $[CpFe(CO)_2Cl]$,[33] $[CpRu(CO)_2Br]$,[34] *trans*-$[RuCl_2(bpy)(CO)_2]$,[35] $[CpMo(CO)_3Cl]$,[36] $[CpW(CO)_3Cl]$,[36] $[CuCl(PPh_3)]_4$ [37] and $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3SnLi(OEt_2)]$[11] were prepared according to published procedures. All other chemicals used as starting materials were obtained commercially and used without further purification.

Preparation of $[MeSi\{SiMe_2N(p\text{-Tol})\}_3SnCH_3]$ (2): Methyl iodide (30 μL, 67.4 mg, 0.475 mmol) was added to a solution of $[MeSi\{SiMe_2N(p\text{-Tol})\}_3SnLi(OEt_2)]$ (**1**) (348 mg, 0.474 mmol) in 15 mL of toluene at −20 °C. The reaction mixture was subsequently warmed to ambient temperature, centrifuged, and the filtrate evaporated to dryness. The colourless, microcrystalline residue was washed twice with cold pentane and then dried in vacuo. Yield: 307 mg (97%). − ^1H NMR (200.13 MHz, C_6D_6, 295 K): δ = 0.03 (s, 3 H, $SnCH_3$), 0.20 (s, 3 H, $SiCH_3$), 0.57 [s, 18 H, $Si(CH_3)_2$], 2.10 (s, 9 H, $CH_3C_6H_4$), 6.88 (d, $^3J_{H,H}$ = 8.1 Hz, 6 H, Tol-$H^{2,6}$), 6.98 (d, 6 H, Tol-$H^{3,5}$). − $^{13}C\{^1H\}$ NMR (50.32 MHz, C_6D_6, 295 K): δ = −15.0 ($SiCH_3$), −9.3 ($SnCH_3$), 3.4 [$Si(CH_3)_2$], 20.7 ($CH_3C_6H_4$), 125.9 (Tol-$C^{2,6}$), 130.1 (Tol-$C^{3,5}$), 130.9 (Tol-C^4), 147.6 (Tol-C^1). − $^{29}Si\{^1H\}$ NMR (39.76 MHz, C_6D_6, 295 K): δ = −91.3 ($SiCH_3$), 4.3 [$Si(CH_3)_2$]. − $C_{29}H_{45}N_3Si_4Sn$ (666.73): calcd. C 52.24, H 6.80, N 6.30; found C 52.57, H 6.97, N 6.41.

Preparation of $[MeSi\{SiMe_2N(p\text{-Tol})\}_3Sn-SiMe_3]$ (3) and $[MeSi\{SiMe_2N(p\text{-Tol})\}_3Sn-SnMe_3]$ (4): Me_3SiCl or Me_3SnCl (0.475 mmol) was added to a solution of $[MeSi\{SiMe_2N(p\text{-Tol})\}_3SnLi(OEt_2)]$ (**1**) (365 mg, 0.490 mmol) in 15 mL of toluene at −20 °C. The reaction mixture was subsequently warmed to ambient temperature, centrifuged, and the filtrate evaporated to dryness. The colourless, microcrystalline residue was washed twice with cold pentane and then dried in vacuo. Yields: **3**: 341 mg, 96%; **4**: 388 mg, 97%.

3: ^1H NMR (200.13 MHz, C_6D_6, 295 K): δ = −0.34 [s, 9 H, $SnSi(CH_3)_3$], 0.21 (s, 3 H, $SiCH_3$), 0.59 [s, 18 H, $Si(CH_3)_2$], 2.10 (s, 9 H, $CH_3C_6H_4$), 6.91 (d, $^3J_{H,H}$ = 8.1 Hz, 6 H, Tol-$H^{2,6}$), 7.05 (d, 6 H, Tol-$H^{3,5}$). − $^{13}C\{^1H\}$ NMR (50.32 MHz, C_6D_6, 295 K): δ = −14.4 ($SiCH_3$), 0.3 [$Si(CH_3)_3$], 3.4 [$Si(CH_3)_2$], 20.7 ($CH_3C_6H_4$), 125.2 (Tol-$C^{2,6}$), 130.0 (Tol-$C^{3,5}$), 130.2 (Tol-C^4), 150.3 (Tol-C^1). − $^{29}Si\{^1H\}$ NMR (39.76 MHz, C_6D_6, 295 K): δ = −87.0 ($SiCH_3$), 2.1 [$Si(CH_3)_2$], 9.6 [$Si(CH_3)_3$]. − $C_{31}H_{51}N_3Si_5Sn$ (724.88): calcd. C 51.37, H 7.09, N 5.80; found C 51.86, H 7.24, N 5.91.

4: ^1H NMR (200.13 MHz, C_6D_6, 295 K): δ = −0.26 [s, 9 H, $SnSn(CH_3)_3$], 0.22 (s, 3 H, $SiCH_3$), 0.60 [s, 18H, $Si(CH_3)_2$], 2.10 (s, 9 H, $CH_3C_6H_4$), 6.91 (d, $^3J_{H,H}$ = 8.4 Hz, 6 H, Tol-$H^{2,6}$), 6.98 (d, $^3J_{H,H}$ = 8.4 Hz, 6 H, Tol-$H^{3,5}$). − $^{13}C\{^1H\}$ NMR (50.32 MHz, C_6D_6, 295 K): δ = −8.4 ($SiCH_3$), 3.5 [$Si(CH_3)_2$], 15.6 [$Sn(CH_3)_3$], 20.7 ($CH_3C_6H_4$), 124.9 (Tol-$C^{2,6}$), 130.1 (Tol-$C^{3,5}$), 130.2 (Tol-C^4), 150.0 (Tol-C^1). − $^{29}Si\{^1H\}$ NMR (39.76 MHz, C_6D_6, 295 K): δ = −87.3 ($SiCH_3$), 2.0 [$Si(CH_3)_2$]. − $C_{31}H_{51}N_3Si_4Sn_2$ (815.49): calcd. $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn-Cu(PPh_3)]$ (5): Precooled (−40 °C) toluene (10 mL) was added to a mixture of solid $[MeSi\{SiMe_2N(p\text{-Tol})\}_3SnLi(OEt_2)]$ (**1**) (376 mg, 0.51 mmol) and solid $[CuCl(PPh_3)]$ (186 mg, 0.51 mmol). The stirred solution was subsequently warmed to ambient temperature, the LiCl which precipitated removed by filtration and the concentrated filtrate (1 mL) stored for several days at −30 °C. The colourless crystals of compound **5** were collected after decanting of the mother liquor and dried in vacuo. Yield: 349 mg (43%). − ^1H NMR (250.13 MHz, C_6D_6, 295 K): δ = 0.38 (s, 3 H, $SiCH_3$), 0.73 [s, 18 H, $Si(CH_3)_2$], 2.05 (s, 9 H, $CH_3C_6H_4$), 6.52 (d, $^3J_{H,H}$ = 8.3 Hz, 6 H, $H^{2,6}$ of $CH_3C_6H_4$), 6.85−6.96 (m, 15 H, PPh_3), 7.02 (d, $^3J_{H,H}$ = 8.3 Hz, 6 H, $H^{3,5}$ of $CH_3C_6H_4$). − $^{13}C\{^1H\}$ NMR (62.89 MHz, C_6D_6, 295 K): δ = −13.9 ($SiCH_3$), 4.2 [$Si(CH_3)_2$], 20.9 ($CH_3C_6H_4$), 125.7, 126.7, 128.6, 129.3, 129.8, 132.9, 134.0, 152.6 (all tol and PPh_3). − $^{29}Si\{^1H\}$ NMR (49.69 MHz, C_6D_6, 295 K): δ = −88.7 ($SiCH_3$), −3.4 [$Si(CH_3)_2$]. − $^{31}P\{^1H\}$ NMR (81.03 MHz, C_6D_6, 295 K): δ = 0.70 (br, PPh_3). − $^{31}P\{^1H\}$ NMR (81.03 MHz, [D_8]toluene, 205 K): δ = 6.6 [$^2J(^{117/119}Sn-^{31}P)$ = 634.2/662.8 Hz, PPh_3]. $C_{46}H_{57}CuN_3PSi_4Sn$ (984.68): calcd. C 56.52, H 5.88, N 4.30; found C 56.19, H 5.73, N 4.29.

$[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn-Fe(\eta^5\text{-}C_5H_5)(CO)_2]$ (6): A mixture of solid $[(\eta^5\text{-}C_5H_5)Fe(CO)_2Cl]$ (116 mg, 0.55 mmol) and $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3SnLi(OEt_2)]$ (**1**) (400 mg, 0.55 mmol) was dissolved at room temperature in toluene (15 mL) and stirred for 3 h. The solution was filtered through Celite and the residue was extracted with toluene (10 mL). After complete removal of the solvent, a bright yellow, crystalline solid was obtained, which was subsequently washed with pentane (10 mL) and dried in vacuum (yield: 308 mg, 68%). Suitable crystals for the structure determination could be obtained from a saturated solution of **6** (100 mg) in benzene (0.5 mL) at room temperature. − ^1H NMR (200.13 MHz, C_6D_6, 295 K): δ = 0.28 (s, 3 H, $SiCH_3$), 0.62 [s, 18 H, $Si(CH_3)_2$], 2.16 (s, 9 H, $CH_3C_6H_4$), 3.43 (s, 5 H, C_5H_5), 7.01 (d, $^3J_{H,H}$ = 8.0 Hz, 6 H, $H^{2,6}$ of $CH_3C_6H_4$), 7.19 (d, $^3J_{H,H}$ = 8.0 Hz, 6 H, $H^{3,5}$

of $CH_3C_6H_4$). – $^{13}C\{^1H\}$ NMR (50.32 MHz, C_6D_6, 295 K): δ = −14.6 (Si*C*H$_3$), 3.8 [Si(*C*H$_3$)$_2$], 20.8 (*C*H$_3$C$_6$H$_4$), 81.8 (*C*$_5$H$_5$), 128.9 (C^{2,6}), 129.7 (C^{3,5}), 131.4 (C^4), 149.7 (C^1), 212.8 (CO). – $^{29}Si\{^1H\}$ NMR (39.76 MHz, C_6D_6, 295 K): δ = −90.0 (*Si*CH$_3$), 0.8 [*Si*(CH$_3$)$_2$]. – IR (toluene): ν(CO) = 2016, 1971 cm^{-1}. – $C_{35}H_{47}FeN_3O_2Si_4Sn$ (828.65): calcd. C 50.73, H 5.72, N 5.07; found C 50.83, H 5.91, N 5.23.

[MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$Sn−Ru(η^5-C$_5$H$_5$)(CO)$_2$] (7): An analogous procedure described to prepare **6**, with 61.8 mg (0.21 mmol) of [(η^5-C$_5$H$_5$)Ru(CO)$_2$Br] and 150 mg (0.21 mmol) of [MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$SnLi(OEt$_2$)] (**1**) dissolved in 10 mL of toluene, afforded compound **7** (100 mg, 56%) as a yellow, crystalline solid. – ^{1}H NMR (250.13 MHz, C_6D_6, 295 K): δ = 0.29 (s, 3 H, SiC*H*$_3$), 0.63 [s, 18 H, Si(C*H*$_3$)$_2$], 2.16 (s, 9 H, C*H*$_3$C$_6$H$_4$), 3.88 (s, 5 H, C$_5$*H*$_5$), 7.01 (d, $^3J_{H,H}$ = 7.8 Hz, 6 H, H^{2,6} of CH$_3$C$_6$H$_4$), 7.16 (d, $J_{H,H}$ = 7.8 Hz, 6 H, H^{3,5} of CH$_3$C$_6$H$_4$). – $^{13}C\{^1H\}$ NMR (62.89 MHz, C_6D_6, 295 K): δ = −14.6 (Si*C*H$_3$), 3.8 [Si(*C*H$_3$)$_2$], 20.8 (*C*H$_3$C$_6$H$_4$), 84.6 (*C*$_5$H$_5$), 128.8 (C^{2,6}), 129.7 (C^{3,5}), 130.5 (C^4), 149.9 (C^1), 199.4 (CO). – $^{29}Si\{^1H\}$ NMR (49.69 MHz, C_6D_6, 295 K): δ = −89.7 (*Si*CH$_3$), 0.7 [*Si*(CH$_3$)$_2$]. – IR (toluene): ν(CO) = 2030, 1981 cm^{-1}. – $C_{35}H_{47}N_3O_2RuSi_4Sn$ (873.88): calcd. C 48.11, H 5.42, N 4.81; found C 48.39, H 5.80, N 4.46.

[MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$Sn−Mo(η^5-C$_5$H$_5$)(CO)$_3$] (8): A solution of [(η^5-C$_5$H$_5$)Mo(CO)$_3$Cl] (38.3 mg, 0.14 mmol) in toluene (2 mL) was added at −78 °C to a vigorously stirred solution of [MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$SnLi(OEt$_2$)] (**1**) (100 mg, 0.14 mmol) in toluene (2 mL). The solution was slowly warmed up to room temperature over a period of 12 h and subsequently filtered through Celite. The solvent was removed under reduced pressure and the resulting residue was washed with pentane (1 mL). Compound **8** (74.6 mg, 61%) was obtained as a pale orange, microcrystalline solid. – ^{1}H NMR (400.13 MHz, [D$_8$]toluene, 290 K): δ = 0.26 (s, 3 H, SiC*H*$_3$), 0.58 [s, 12 H, Si(C*H*$_3$)$_2$], 0.62 [s, 6 H, Si(C*H*$_3$)$_2$], 2.17 (s, 6 H, C*H*$_3$C$_6$H$_4$), 2.19 (s, 3 H, C*H*$_3$C$_6$H$_4$), 4.07 (s, 5 H, C$_5$*H*$_5$), 6.94 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, H^{2,6} of CH$_3$C$_6$H$_4$), 7.05 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, H^{2,6} of CH$_3$C$_6$H$_4$), 7.18 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, H^{3,5} of CH$_3$C$_6$H$_4$), 7.21 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, H^{3,5} of CH$_3$C$_6$H$_4$). – ^{1}H NMR (400.13 MHz, [D$_8$]toluene, 340 K): δ = 0.24 (s, 3 H, SiC*H*$_3$), 0.52 [s, 18 H, Si(C*H*$_3$)$_2$], 2.16 (s, 9 H, C*H*$_3$C$_6$H$_4$), 4.19 (s, 5 H, C$_5$*H*$_5$), 6.94 (d, $^3J_{H,H}$ = 7.8 Hz, 6 H, H^{2,6} of CH$_3$C$_6$H$_4$), 7.13 (d, $^3J_{H,H}$ = 7.8 Hz, 6 H, H^{3,5} of CH$_3$C$_6$H$_4$). – $^{13}C\{^1H\}$ NMR (100.63 MHz, [D$_8$]toluene, 290 K): δ = −14.2 (Si*C*H$_3$), 4.1, 4.2 [Si(*C*H$_3$)$_2$], 20.9 (*C*H$_3$C$_6$H$_4$), 89.7 (*C*$_5$H$_5$), 117.1, 117.2 (C^4), 129.0, 129.1 (C^{2,6}), 130.8, 131.0(C^{3,5}), 148.3, 149.8 (C^1), 224.7, 230.0 (CO). – $^{13}C\{^1H\}$ NMR (100.63 MHz, [D$_8$]toluene, 340 K): δ = −14.6 (Si*C*H$_3$), 4.1 [Si(*C*H$_3$)$_2$], 20.6 (*C*H$_3$C$_6$H$_4$), 89.6 (*C*$_5$H$_5$), 117.8 (C^4), 129.8 (C^{2,6}), 131.4(C^{3,5}),149.8 (C^1), 224.9 (CO). – $^{29}Si\{^1H\}$ NMR (49.69 MHz, [D$_8$]toluene, 295 K): δ = −89.1 (*Si*CH$_3$), 1.9, 2.4 [*Si*(CH$_3$)$_2$]. – IR (toluene): ν(CO) = 2021 (s), 1954 (m), 1937 (s) cm^{-1}. – $C_{36}H_{47}MoN_3O_3Si_4Sn$ (896.76): calcd. [(MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$Sn)$_2$−Ru(bpy)(CO)$_2$] (10): A solution of [MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}$_3$SnLi(OEt$_2$)] (200 mg, 0.27 mmol) in THF (30 mL) was added at −40 °C to solid [*trans*-RuCl$_2$(bpy)(CO)$_2$] (52.4 mg, 0.14 mmol), resulting in an immediate change of colour from pale yellow to deep orange. The reaction mixture was warmed up to ambient temperature over a period of 4 h and subsequently filtered through Celite. Removal of the solvent in vacuum, extraction of the residue with toluene (30 mL), and concentration of the solution to about 3 mL yielded a microcrystalline powder after storage at −50 °C. The supernatant solution was removed by decantation and the solid was washed with pentane (5 mL) and dried in vacuum to yield **10** (147 mg, 66%) as a deep orange solid. Suitable crystals for the structure determination could be obtained from a saturated solution of **10** (80 mg) in benzene (0.5 mL) at room temperature. – ^{1}H NMR (250.13 MHz, [D$_8$]THF, 295 K): δ = −0.08 (s, 6 H, SiC*H*$_3$), −0.04 [s, 36 H, Si(C*H*$_3$)$_2$], 2.39 (s, 18 H, C*H*$_3$C$_6$H$_4$), 6.29 (dt, $^3J_{H,H}$ = 5.7, $^4J_{H,H}$ = 1.1 Hz, 2 H, H$^{5,5'}$ of bipy), 6.47 (d, $^3J_{H,H}$ = 8.2 Hz, 12 H, H^{2,6} of CH$_3$C$_6$H$_4$), 6.71 (d, $^3J_{H,H}$ = 8.2 Hz, 12 H, H^{3,5} of CH$_3$C$_6$H$_4$), 7.04 (dd, $^3J_{H,H}$ = 5.7, $^4J_{H,H}$ = 1.1 Hz, 2 H, H$^{6,6'}$ of bipy), 7.32 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, H$^{3,3'}$ of bipy), 7.45 (dt, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.6 Hz, 2 H, H$^{4,4'}$ of bipy). – $^{13}C\{^1H\}$ NMR (62.89 MHz, [D$_8$]THF, 295 K): δ = −13.7 (Si*C*H$_3$), 4.2 [Si(*C*H$_3$)$_2$], 21.3 (*C*H$_3$C$_6$H$_4$), 117.5 (bipy), 123.0 (bipy), 124.6 (bipy), 128.2 (tol), 130.1 (tol), 137.7 (bipy), 151.1 (tol), 153.8 (tol), 154.4 (bipy), 199.1 (CO). – $^{29}Si\{^1H\}$ NMR (49.69 MHz, [D$_8$]THF, 295 K): δ = −81.4 (*Si*CH$_3$), 3.0 [*Si*(CH$_3$)$_2$]. – $^{119}Sn\{^1H\}$ NMR (149.21 MHz, [D$_8$]THF, 295 K): δ = −123.9 (N$_3$*Sn*Ru). – IR (toluene): ν(CO) = 2039, 1990 cm^{-1}. – $C_{68}H_{92}N_8O_2RuSi_8Sn_2$ (1616.66): calcd. C 50.52, H 5.74, N 6.93; found C 50.15, H 5.64, N 6.49.

X-ray Crystallographic Study of 6, 9 and 10: The X-ray diffraction data were collected with a Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å) and the Collect[38] data collection program. The Denzo and Scalepack[39] programs were used for cell refinements and data reduction. The structures were solved by Patterson methods using the DIRDIF-99[40] and the WinGX graphical user interface.[41] A multi-scan absorption correction based on equivalent reflections (XPREP in SHELXTL v. 5.1)[42] was applied to **6** and **9** (T_{max}/T_{min} were 0.2529/0.2166 and 0.2766/0.2206, respectively). Structural refinements were carried out with the SHELXL-97 program.[40] All hydrogens were placed in an idealised position and constrained to ride on their parent atom. The crystallographic data are summarised in Table 2. The molecular structures of the complexes along with principal bond lengths and angles are presented in Figure 1−3.

Synthesis, Structural Characterization, Solvatochromism, and Electrochemistry of Tetra-Osmium Carbonyl Clusters Containing Azo-Ligands

Yat Li,[a] Zhen-Yang Lin,[b] and Wing-Tak Wong*[a]

Keywords: Electrochemistry / Solvatochromism / Azo-compounds / Osmium / Cluster compounds

The reaction of $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ with 4-(2-pyridylazo)-*N*,*N*-dimethylaniline (PNNDA) in dichloromethane afforded the new clusters $[Os_4(\mu\text{-}H)_4(CO)_{11}\{NC_5H_4(N{=}N)C_6H_4NMe_2\}]$ (**1**) and $[Os_4(\mu\text{-}H)_4(CO)_{10}\{\eta^2\text{-}NC_5H_4(N{=}N)C_6H_4NMe_2\}]$ (**2**) in 34% and 15% yields, respectively. Upon heating in toluene under reflux, compound **1** converted into **2** in 80% yield. The MLCT transition of compound **2** shows strong solvent dependency, displaying unusually large positive solvatochromism in different organic solvents. Treatment of $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ with 2-(5-bromo-2-pyridylazo)-5-(diethylamino)-phenol (Br-PADAP) in dichloromethane gives $[Os_4(\mu\text{-}H)_3(CO)_{10}\{\mu\text{-}\eta^3\text{-}Et_2NC_6H_3(O)(N{=}N)C_5NH_3Br\}]$ (**3**). The O–H bond activation is observed and the azo-ligand behaves as a five-electron donor. The clusters $[Os_4(\mu\text{-}H)_2(CO)_{10}\{\mu\text{-}\eta^3\text{-}NC_5H_4(N{=}N)C_5H_4N\}]$ (**4**) and $[Os_4(\mu\text{-}H)_4(CO)_{10}\{\mu\text{-}\eta^2\text{-}NC_5H_4(N{=}N)C_5H_4N\}]_2$ (**5**) were isolated from the reaction of $[Os_4(\mu\text{-}H)_4(CO)_{10}(NCMe)_2]$ with 2,2′-azopyridine and 3,3′-azopyridine, respectively. In compound **4**, both pyridine and azo nitrogen atoms were found to coordinate to the cluster core. Dehydrogenation was also observed in this compound. For compound **5**, two tetra-osmium metal cores were connected by two azo ligands through their pyridyl nitrogen atoms to form a novel cyclic structure. The redox properties of the compounds described herein were investigated by means of cyclic voltammetry and controlled potential coulometry. Both compound **2** and **5** exhibit a reversible cathodic wave, which indicates that they undergo addition of one electron without significant structural changes. Furthermore, compound **5** displays an electronic interaction between two redox centers, the extra electrons are believed to delocalize throughout the cyclic structure.

Introduction

The activation of strong multiple-bonded organic substrates using polynuclear metal complexes is an interesting facet of cluster reactivity. The cleavage of N=N bond in organic diazenes to give metal imido (nitrene) complexes is an important chemical transformation.[1−5] Metal imido complexes have been shown to be potential intermediates for metal-prompted organic transformations involving the formation of nitrogen-carbon bonds. As a result, the chemistry of carbonyl clusters containing azo ligands has been extensively studied in recent years.[6−18] Previously, we reported that $[Os_3(CO)_{10}(NCMe)_2]$ reacts with 2-(5-bromo-2-pyridylazo)-5-(diethylamino)phenol at room temperature to give $[Os_3(CO)_{10}\{\mu\text{-}N(H)(C_5H_3NBr)\}\{\mu\text{-}N(C_{10}H_{13}NO)\}]$,[19] containing two types of amido moieties, in which N=N cleavage of the azo ligand was observed. In an attempt to synthesize tetra-osmium imido complexes by the N=N cleavage of azo ligands, we were able to prepare some new tetra-osmium carbonyl clusters containing azo ligands. However, no cleavage of the N=N bond of these compounds by thermal or photochemical methods was observed. These compounds exhibit interesting solvatochromism and electrochemistry. The redox behavior of the clusters $M_3(CO)_{12}$ (M = Fe, Ru, Os) has been extensively studied.[20−23] To the best of our knowledge, the electrochemical behavior of tetra-osmium carbonyl clusters is rarely reported. The correlation between the structure and the redox properties of these compounds was also described.

Results and Discussion

The preparation of compounds **1**−**5** is summarized in Scheme 1 and Scheme 2. These compounds have been fully characterized by elemental analyses, infrared, ^{1}H NMR, and mass spectroscopic methods. The infrared spectra of compounds **1**−**5** revealed that only terminal carbonyl ligands were present, and the mass spectra exhibit molecular ion envelopes that agree with the formulae of the compounds, with stepwise loss of terminal carbonyl ligands. Their molecular structures were established by single crystal X-ray diffraction analyses.

The molecular ion peak was not observed in the mass spectrum of **1** due to fragmentation during the ionization process. However, it exhibits an intense daughter peak at m/z = 1073 attributed to $[M^+ - PNNDA]$, and is followed by peaks corresponding to the successive loss of carbonyl groups. The chelation of the azo ligand is supported by the ^{1}H NMR spectroscopic data. The ^{1}H NMR spectrum of **1** shows two sets of multiplets for the aromatic protons at δ = 6.84−8.01. Two sets of singlets at δ = 2.04 and 1.67 correspond to the methylene protons of the azo-ligand. The

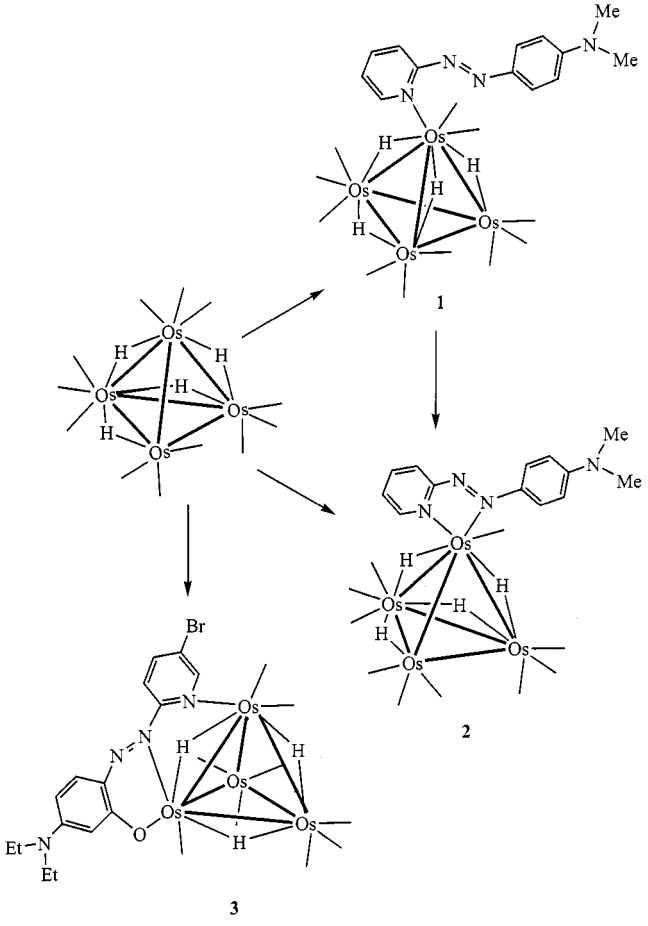
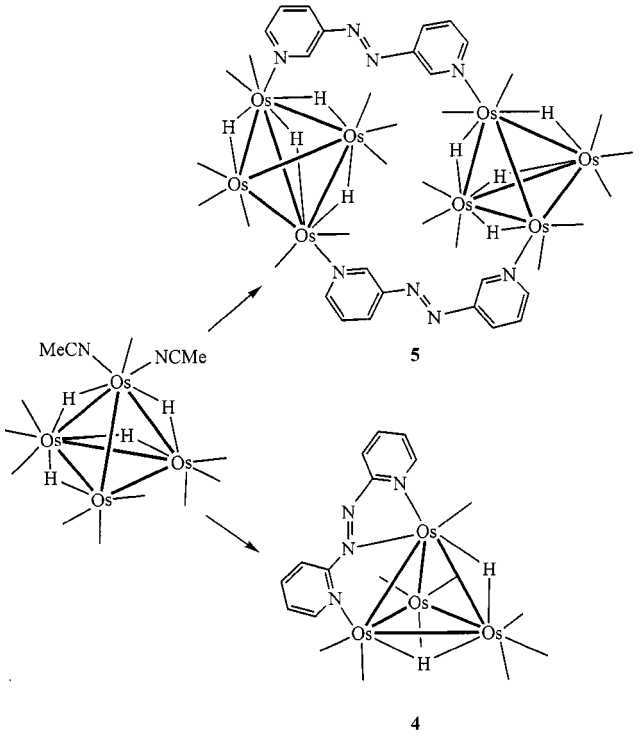


Scheme 1



Scheme 2

^{1}H NMR cannot give a clear assignment of four hydrides in the tetra-osmium core due to the fluxional behavior of hydrides at room temperature, which is common in tetra-osmium systems.[24−25] Therefore, a variable-temperature ^{1}H NMR study from 233 to 298 K was conducted for **1**. At 233 K, the broad hydride peaks resolved into two sets of sharp singlet peaks at $\delta = -18.10, -18.63, -24.01$ and at $\delta = -16.93, -17.95, -18.86, -25.53$, with an integral ratio of 2:1:1 and 1:1:1:1, respectively. This indicates the presence of two possible isomers in solution, namely **1a** and **1b**, due to a different bridging hydride disposition. As the temperature is raised to 253 K, the ratio of **1b** to **1a** gradually increases from 0.4 to 0.5. This suggests that isomer **1a** is more favored in solution at a higher temperature.

The molecular structure of **1** is depicted in Figure 1 and selected bond lengths, and angles are summarized in Table 1. Four osmium atoms define a distorted tetrahedron with eleven carbonyl ligands terminally bonded to the metal centers. The Os(2)−Os(3) and Os(2)−Os(4) [2.819(1) and 2.809(1) Å] lengths of compound **1** are comparable to the corresponding values observed in the parent cluster $[Os_4(\mu\text{-}H)_4(CO)_{10}(NCMe)_2]$.[26] The hydride bridged Os−Os bonds are significantly elongated,[27] within the range [2.928(1)-3.022(1) Å]. The hydrides bridging the Os(1)−Os(3) and Os(1)−Os(4) are chemically equivalent, which give a sharp singlet with double integral value in low temperature ^{1}H NMR spectra. Hence, it is believed that the solid-state structure of **1** obtained by X-ray crystallography is the structure of isomer **1a**. The azo-ligand terminally coordinated to Os(1) through the pyridyl nitrogen N(1) with a mirror plane bisects along the azo ligand and Os(1) atom. The Os(1)−N(1) bond length [2.17(2) Å] is not significantly different from the equivalent Os−N distance found in other osmium-pyridine containing complexes.[28] The N(2)−N(3) bond [1.26(2) Å] is slightly lengthened compared to other azo ligands in the tri-osmium system[29] due to the electron donating aniline group, consistent with its assignment as a N−N double bond. The torsion angle defined by C(16)−N(2)−N(3)−C(17) is 178(2)°, indicating that the *trans* configuration of the ligand remains almost intact upon coordinating to the cluster framework. The dihedral angle between the pyridyl and phenyl rings is 8.08°.

Upon heating under reflux in toluene, compound **1** converted into **2** in 80% yield. Substitution of a carbonyl ligand on Os(1) by azo nitrogen was observed. The ^{1}H NMR of **2** is similar to **1**, with three broad peaks in hydride region. A variable-temperature ^{1}H NMR study was conducted for **2** from 223 to 298 K. At 223 K, the broad peaks resolved into four sets of sharp hydride signals, each with the relative intensity 1:1:1:1, indicating the presence of four isomers (namely **2a**, **2b**, **2c**, and **2d**) in solution, see Figure 2. The ratio of **2a/2b/2c/2d** is 1:2:5:8. The molecular structure of compound **2** is illustrated in Figure 3 and the relevant bond parameters are listed in Table 1. A chloroform molecule, as a solvent of crystallization, is present in the crystal lattice. The basic metal architecture of **1** is retained in compound **2**. The azo ligand coordinated to Os(1) through the pyridyl nitrogen N(1) and the azo nitrogen N(3) atom.

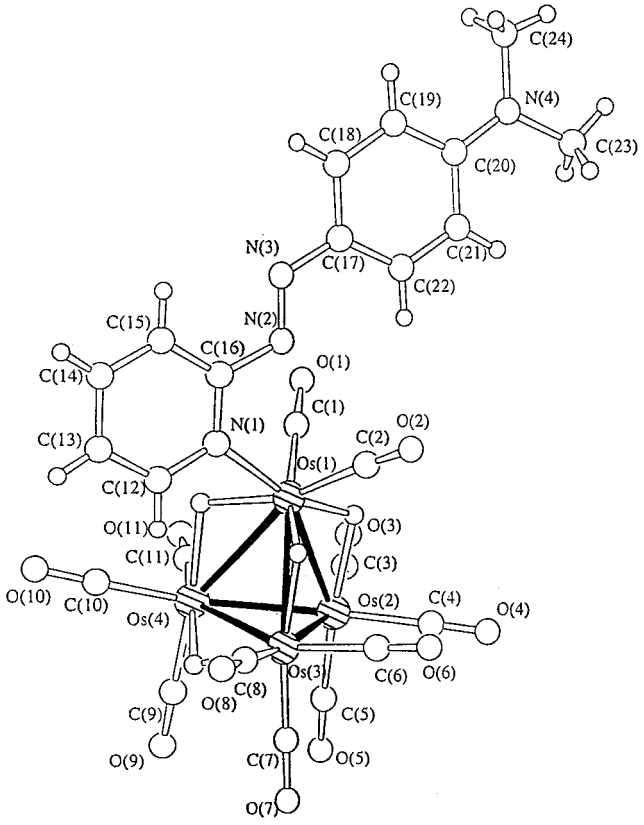


Figure 1. The molecular structure of clusters $[Os_4(\mu\text{-}H)_4(CO)_{11}\{NC_5H_4(N{=}N)C_6H_4NMe_2\}]$ (**1**) showing the atom numbering scheme

Os(1)−N(1)−C(15)−N(2)−N(3) form a metallacyclic five-membered ring with a mean deviation of 0.022Å from the least-square plane. The N(1)−Os(1)−N(3) coordination is asymmetric, with Os(1)−N(1) and Os(1)−N(3) bond lengths of 2.078(6) Å and 2.111(7), respectively, and a N(1)−Os(1)−N(3) angle of 75.0(3)°. The N(2)−N(3) length [1.290(9) Å] is almost identical to **1**, indicating a retained double bond character. Upon coordination of azo nitrogen, the pyridyl and phenyl rings are twisted with respect to each other to a greater extent, with a dihedral angle of 11.8°.

The molecular structure of **3** is shown in Figure 4 and some important bond lengths and angles are listed in Table 1. The azo-ligand was found to bridge the edge Os(1)−Os(2) of the Os_4 distorted tetrahedron, affording a five-membered ring containing Os(1), Os(2), N(2), C(15), and N(1) and a six-membered ring containing Os(2), O(11), C(21), C(16), N(3), and N(2), respectively. These rings had a maximum deviation of 0.205 Å and 0.192 Å from the least-square planes, respectively. The dihedral angle between two metallacyclic rings is 25.5°. The Os(1)−Os(2) bond [2.7816(6) Å] is slightly shorter than the hydride bridged Os−Os bonds. The O−H bond cleavage is observed in **3**. This bonding mode of the azo ligand is very similar to that found in the tri-osmium cluster $[(\mu\text{-}H)Os_3(CO)_9\{\mu\text{-}\eta^3\text{-}Et_2NC_6H_3(O)(N{=}N)C_5NH_3Br\}]$.[29] The N(2)−N(3) bond length [1.32(1) Å] is comparable to the N=N bonds in **1** and **2**, indicating no involvement of the π-electrons of the N=N bond. The pyridyl and phenyl rings are highly twisted with respect to each other, with a dihedral angle of 60.3° due to the bond strain. The characteristic 60 cluster-valence electron count was observed with the azo-ligand acting as a five-electron donor. Only three bridging hydrides were found in the metal core, confirmed by ^{1}H NMR spectroscopy, with three sharp peaks of equal intensity observed in the hydride region.

The molecular structure of **4** is depicted in Figure 5 and the relevant bond lengths and angles are listed in Table 1. It has a structure similar to compound **2** in terms of ligand coordination, however, the involvement of the other pyridyl ring was observed. The coordination of the azo-ligand, acting as a six-electron donor, resulted in a pair of hydrides being eliminated rather than a carbonyl ligand being substituted. Such elimination is not commonly observed in osmium chemistry. The presence of only two hydrides on the metal core is supported by ^{1}H NMR spectroscopic data, with two sharp singlets of equal intensity observed in hydride region. The ligand bridged Os(1)−Os(3) bond length [2.8145(8) Å] is slightly shorter than the hydride bridged Os−Os bonds. Os(1)−Os(3)−N(4)−C(16)−N(3) and Os(1)−N(1)−C(15)−N(2)−N(3) form two metallacyclic five-membered rings, with a mean deviation of 0.034Å and 0.159Å, respectively, from the least square planes. The Os(3)−N(4) bond [2.18(1) Å] is significantly lengthened compared to Os(1)−N(1) bond [2.06(1) Å] and Os(1)−N(3) bond [2.05(1) Å], owing to the bond strain. The two pyridyl rings are not coplanar, with a dihedral angle upon coordination to the metal framework of 16.2° between them. The bite angle N(1)−Os(1)−N(3) of chelating azo-ligand is 75.3(5)°, which is comparable to **2** [N(1)−Os(1)−N(3) 75.0(3)°] and $[Os_3(CO)_{10}(bipy)]$ [N−Os−N 75.6(9)°].[30]

Although the ligand system of **5** is very similar to **4**, they have totally different reaction pathways towards the tetra-osmium cluster. The molecular structure of **5** is illustrated in Figure 6 and the relevant parameters are listed in Table 1. Four tetrahydrofuran molecules, as a solvent of crystallization, were found in the crystal lattice. Two tetra-osmium metal cores are connected by two azo-ligands through their pyridyl nitrogen atoms N(1) and N(4) to form a novel cyclic structure. A similar cyclic structure was observed in the tri-osmium cluster system.[31] Cluster **5** possesses a C_i symmetry, with the center of inversion at the central point of the square involving Os(3), Os(4), Os(3)*, and Os(4)*. The Os(1)−N(1) [2.18(2) Å] and Os(2)−N(4)* [2.13(2) Å] bond lengths are lengthened relative to other Os−N dative bonds because of the large steric hindrance in the cyclic structure. The two pyridyl rings are twisted with a dihedral angle of 24.5°. The two tetra-osmium sets of atoms with their associated carbonyl ligands do not approach each other very closely; the nearest contact is O(3)···O(3)* [5.48(3) Å] and the shortest Os···Os distance between clusters is Os(2)···Os(2)* [7.940(2) Å]. This novel cyclic structure opens the possibility of encapsulating some alkali or oxophilic metal ions. The supramolecular system so formed will be useful for the studies of redox active host towards metal ion sensing applications. The steric effect may be the main

Solvatochromism

Compounds **1**−**5** show a variety of intense colors in the solid state, which prompted us to examine them by optical spectroscopy. Based on the experimental geometry, molecular orbital calculations at the B3LYP level of density functional theory were carried out for these compounds to examine the characteristics of the molecular orbitals in the frontier region. Similar to trinuclear osmium clusters,[32−33] the highest occupied molecular orbital (HOMO) of these compounds is mainly metal based, and the lowest unoccupied molecular orbital (LUMO) mostly based on the organic moiety.[34] The intense color of these compounds undoubtedly arises from a strong absorption due to metal-to-ligand charge transfer (M.L.C.T.) transitions.[32,34] These compounds exhibit solvatochromic absorptions in the visible region, contributed by changes in the metal-ligand bond polarity between the ground and excited states and specific solvent-solute and induced dipolar interaction.[35−40] The optical spectral parameters for a range of solvents are summarized in Table 2.

Compounds **1**−**3**, demonstrated a positive solvatochromism,[41−42] where the dipole moment of ground state (μ_g) is smaller than the excited state (μ_e). On MLCT transition, polar solvents were found to be better at stabilizing the excited state of the molecule. The red shift in absorption energies from *n*-hexane to dichloromethane was due to the increasing polarity of the organic solvents. The exceptionally large solvatochromism was observed in compound **2** (Figure 7), due to the smaller energy gap of HOMO−LUMO electronic transition. The contour plots of the lowest unoccupied (LUMO) and the highest occupied (HOMO) molecular orbitals of **2** are illustrated in Figure 8. The molecular orbital calculations showed that N(2) has a

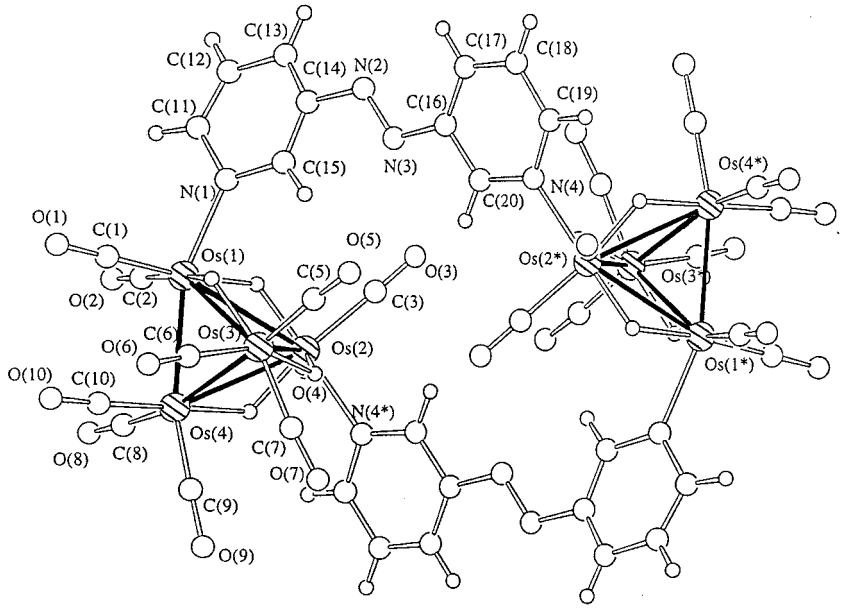

Figure 6. The molecular structure of clusters $[Os_4(\mu\text{-}H)_4(CO)_{10}\{\mu\text{-}\eta^2\text{-}NC_5H_4(N{=}N)C_5H_4N\}]_2$ (**5**) showing the atom numbering scheme

lone pair of electrons whose maximum electron density points away from the central cluster unit. This lone pair is greatly affected by the solvent environment. The interac-

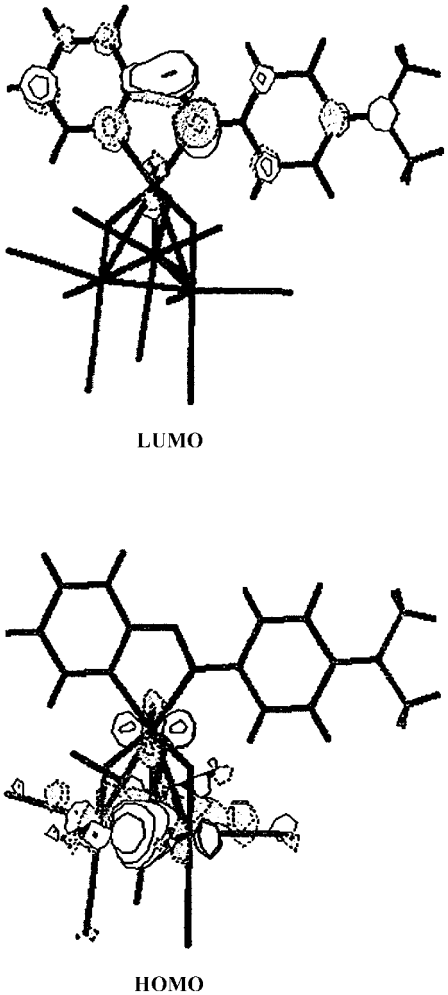

Figure 8. The contour plots of the lowest unoccupied- (LUMO) and the highest occupied (HOMO) molecular orbitals calculated for $[Os_4(\mu\text{-}H)_4(CO)_{10}\{\eta^2\text{-}NC_5H_4(N{=}N)C_6H_4NMe_2\}]$ (**2**)

tions with the polar solvents pull the electron density away from the N(2) center, lowering the orbital energy of the LUMO, which contains significant N(2)−N(3) π* character. As a result, the MLCT transition will shift to a lower energy (red shift) in polar solvents. Compound **2** has a much lower energy MLCT absorption than compound **1**. It is believed that more extensive ligand coordination to the cluster core leads to a smaller HOMO−LUMO energy gap.

Compound **4** showed some degree of solvent dependence; however, it was random with respect to the solvent polarity. Compound **4** had a low energy absorption band at around 600 nm due to the extensive coordination of ligand. Compound **5** exhibited a strong featureless intraligand π→π* absorption band at around 300 nm, along with an analogous band observed in the absorption spectrum of free ligand 3,3′-azopyridine under the same conditions. As shown in Table 1, some degree of negative solvatochromism shift was detected for **5**. Apart from π→π* transition, no indication of a low-energy band was attributed to an MLCT transition.

Electrochemistry

In order to investigate the redox properties of these new azo-ligands containing tetra-osmium compounds, the electrochemistry of compounds **1−5** was examined. Cyclic voltammetry and controlled potential coulometry were carried out at 298 K in a standard three-electrode system (glassy carbon/carbon cloth working electrode, platinum auxiliary electrode, and $Ag/AgNO_3$ reference electrode)[43] using a 0.1 M tetrabutylammonium hexafluorophosphate/dichloromethane solution as supporting electrolyte. The results of voltammetric experiments are summarized in Table 3.

Table 3. Electrochemical data for compounds **1−5**

Compounds[a]	Oxidation E_{pa2} [V][b]	E_{pa1} [V][b]	Reduction E_{pc1} [V][b]	E_{pc2} [V][b]
1	−	0.64	−1.25	−
2	0.93	0.49	(−0.94)[c]	−1.27
3	−	0.72	−1.17	−
4	−	0.52	−	−
5	−	0.55	(−1.06)[c]	−1.68

[a] ca. 10^{-3} M cluster in 0.1 M TBAHFP in dichloromethane at 298 K, the working electrode was a glassy carbon electrode, the auxiliary electrode and the reference electrode were a platinum wire and $Ag/AgNO_3$ (0V) under the same conditions, calibrated with ferrocene. Scan rate was 100 mVs^{-1}. − [b] E_{pa} and E_{pc} are the anodic and cathodic potentials, respectively. − [c] Values in parentheses are $E_{1/2}$, half-wave potential values.

Compound **1** exhibits an irreversible cathodic wave (E_{pc}) and anodic wave (E_{pa}) at −1.25 and 0.64 V vs. $Ag/AgNO_3$ in dichloromethane, respectively. Applying a working potential (E_w) at −1.4 V, controlled potential coulometry showed that two faraday/mole of **1** was involved in this reduction step. On the basis of the relative peak currents of the cathodic and anodic waves, the oxidation process is assigned as a one-electron step. Two-electron addition to compound **1** is believed to afford a 62e compound, which would be unstable, with consequent metal−metal bond cleavage, leading to metal carbonyl fragments of lower nuclearity. It conforms to a ECEC or EEC mechanism.[44]

Compounds **1** and **2** have the same ligand system, their cyclic voltammograms were expected to be similar. Interestingly, the incorporation of the azo group in the cluster framework led to great changes in the electrochemical behavior of **2**. The cyclic voltammograms of **2** consist of a reversible and an irreversible cathodic wave at −0.94 and −1.27 V, respectively. Controlled potential coulometry at the first reduction step (E_w = −1.09 V) indicates that this cathodic process consumes 1 faraday/mole of **2**. Analysis of the cyclic voltammetric responses relating to the cathodic peak of **2**, with scan rate varying from 50 to 500 mVs^{-1}, indicates that the peak current ratio i_{pa}/i_{pc} remains close to unity. The current function (proportional to $i_{pc}/v^{1/2}$) is essentially constant and the peak-to-peak separation lies between 80−100 mV. This trend is parallel with the ferrocene under the same experimental conditions. Thus, we assume that the first reduction step proceeds by an essentially reversible electron transfer process. This implies that any structural change of **2** accompanying the single-electron transfer is chemically reversible and rapid with respect to the time scale of the electrochemical experiment. The irreversible nature of the second cathodic wave showed that the reduction of compound **2** followed an EEC mechanism. In addition, two anodic waves at 0.49 and 0.93 V were found. The similarity of the relative peak heights for the waves within a given voltammogram points to the same number of electrons being involved in the oxidation and reduction of **2**. Two irreversible one-electron oxidations in **2** were assigned to follow the ECEC process. There is a 310 mV positive and 150 mV negative shift upon coordination of azo group in cathodic and anodic wave values, respectively. It shows that both reduction and oxidation processes are more likely to occur. It is believed that the extensive ligand coordination lowers the HOMO−LUMO energy gap and hence gives a lower redox potential for compound **2**. This is consistent with the UV/Vis spectroscopic data. Furthermore, it is reasonable to suggest that the reversible step of **2** is due to the presence of a metallacyclic five-membered ring unit.

The cyclic voltammograms of **3** contained an irreversible cathodic wave at E_{pc} = −1.17 V vs. $Ag/AgNO_3$, along with a small return oxidation at −0.56 V. The region where the weak oxidation wave appears was initially empty, with the wave appearing after the cathodic wave was traversed. The ΔE_p values remained virtually unchanged on varying the scan rates from 50 to 1000 $mV \cdot s^{-1}$. An irreversible anodic wave is also located at E_{pa} = 0.72 V. The irreversible nature of both oxidation and reduction presumably derives from an irreversible chemical reaction that follows the redox reaction (EC process). Controlled potential coulometry was run at 0.87 V for **3**, showing that one electron is removed for each molecule. Based on the relative peak heights, the cathodic wave is tentatively assigned to have consumed two electrons. For compound **4**, only one irreversible anodic wave was located at E_{pa} = 0.54 V vs. $Ag/AgNO_3$ within the

solvent limit. Controlled potential coulometry at the oxidation step (E_w = 0.67 V) shows that the anodic process consumes one electron per molecule. Compounds **3** and **4** have a similar ligand disposition, however, the former is much harder to oxidize than the latter due to the presence of a strong electron-withdrawing bromine ligand. Moreover, although compound **4** is extensively coordinated by the azo-ligand, the oxidation potential is comparable to **2**. This suggested that the aniline is an effective electron-donating ligand that makes oxidation easier.

Compound **5** is a cyclic structure consisting of two tetra-osmium metal cores connected by two azo-ligands. Although compounds **1** and **5** have a similar ligand system, they show different redox behavior. It is believed that there is an electronic interaction between two redox centers. The cyclic voltammogram of **5** is shown in Figure 9. A quasi-reversible and an irreversible cathodic wave were observed at E_{pc} = −1.06 and −1.68 V vs. $Ag/AgNO_3$. In addition, an irreversible anodic wave occurred at E_{pa} = 0.55 V. Applying a working potential at 0.8 V, controlled potential coulometry indicates that two faraday/mole of **5** is involved in the oxidation step. The other redox waves were assumed to involve one electron per molecule according to the relative peak heights in the voltammogram. The large potential difference between the first and second reduction peaks (over 600 mV) implies that there is good electronic interaction between the two tetra-osmium metal cores, through the azo-ligand in this novel cyclic structure. This kind of electronic interaction also appears in some organometallic dimers.[45−50]

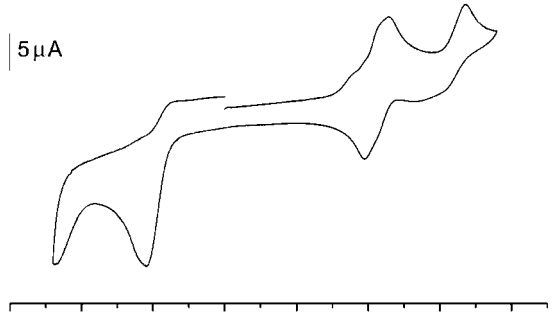

Figure 9. Cyclic voltammogram of $[Os_4(\mu\text{-}H)_4(CO)_{10}\{\mu\text{-}\eta^2\text{-}NC_5H_4(N{=}N)C_5H_4N\}]_2$ (**5**) in CH_2Cl_2 containing 0.1 mol·dm^{-3} Bu_4NPF_6; glassy carbon working electrode, platinum auxiliary electrode and $Ag/AgNO_3$ reference electrode (Ag^+ 0.1 mol·dm^{-3}; scan rate, 100 mV·s^{-1})

There is a completely charged delocalization over two redox centers, while the azo-ligand acts as a conductor. As one metal core receives one electron, the cyclic structure become more electron rich, making the second reduction of another metal core more difficult. The cyclic structure exhibits remarkably flexible redox behavior comparable to **2**, able to accommodate the addition of one electron without gross structural changes. Furthermore, it shows that both reduction and oxidation are more likely to occur in compound **5** than in compound **1**, as the extra charge is shared by two metal cores through the bridging azo-ligands. This is consistent with the 190 mV positive and 90 mV negative shift in cathodic and anodic wave values in comparison to the corresponding value observed in **1**.

Experimental Section

General: All reactions and manipulations were carried out under argon using standard Schlenk techniques, except for the chromatographic separations. Solvents were purified by standard procedures and distilled prior to use.[51] Reactions were monitored by both IR spectroscopy and analytical thin-layer chromatography (Merck Kieselgel 60 F_{254}) and the products were separated by thin-layer chromatography on plates coated with silica (Merck Kieselgel 60 F_{254}).

Materials: All chemicals, unless otherwise stated, were purchased commercially and used as received. $[Os_4(\mu\text{-}H)_4(CO)_{12}]$,[52−54] $[Os_4(\mu\text{-}H)_4(CO)_{10}(NCMe)_2]$,[26] ligand 2,2′-azopyridine,[55] and 3,3′-azopyridine[55] were prepared by literature methods.

Instrumentation: Infrared spectra were recorded on a Bio-Rad FTS-135 IR spectrometer, using 0.5 mm calcium fluoride solution cells. − ^{1}H NMR and ^{1}H-^{1}H COSY spectra were obtained on a Bruker DPX300 spectrometer using CD_2Cl_2 and referenced to $SiMe_4$ (δ = 0), variable-temperature ^{1}H NMR spectra on a Bruker DPX500 spectrometer. − Positive ionization fast atom bombardment (FAB) mass spectra were recorded on a Finnigan MAT 95 mass spectrometer, using *m*-nitrobenzyl alcohol as matrix solvent. − Electronic absorption spectra were obtained with a Hewlett−Packard 8453 diode array UV/Vis spectrophotometer, using quartz cells, with 1 cm path length at room temperature. − Microanalyses were performed by Butterworth Laboratories, UK.

Reaction of $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ with 4-(2-Pyridylazo)-*N*,*N*-dimethylaniline: The complex $[Os_4(\mu\text{-}H)_4(CO)_{12}]$ (110 mg, 0.1 mmol) was dissolved in dichloromethane (50 cm^3) and stirred with one equivalent of 4-(2-pyridylazo)-*N*,*N*-dimethylaniline (22.6 mg, 0.1 mmol) at 0 °C. Two equivalent of trimethylamine *N*-oxide (Me_3NO) were added dropwise over 20 min. After the reaction had proceeded at ambient temperature for 18 h, the initial yellow solution changed to dark brown. The solvent was removed under reduced pressure and the residue subjected to TLC with *n*-hexane/dichloromethane (1:1, v/v) as eluent. Two new products were isolated, in the following order of elution: dark red $[Os_4(\mu\text{-}H)_4(CO)_{11}\{NC_5H_4(N{=}N)C_6H_4NMe_2\}]$ (**1**, R_f = 0.85, 44 mg, 0.034 mmol, 34%). IR [ν(CO)/cm^{-1}, *n*-hexane]: $\tilde{\nu}$ = 2091 w, 2060 s, 2051 m, 2032 m, 2005 m, 1985 m. − ^{1}H NMR (CD_2Cl_2): at 298 K δ = −24.06 (s, 1 H, Os−H), −18.65 (s, 1 H, Os−H), −18.06 (s, 2 H, Os−H), 1.67 (s, 3 H, methyl), 2.04 (s, 3 H, methyl), 6.84 (m, 4 H, pyridyl), 8.01 (m, 4 H, phenyl); at 233 K, **1a:** δ = −24.01 (s, 1 H, Os−H), −18.63 (s, 1 H, Os−H), −18.10 (s, 2 H, Os−H); **1b:** δ = −25.53 (s, 1 H, Os−H), −18.86 (s, 1 H, Os−H), −17.95 (s, 1 H, Os−H), −16.93 (s, 1 H, Os−H). − MS (positive FAB): *m*/*z* (%) = 1073 [M$^+$ − PNNDA]. − $C_{24}H_{18}N_4O_{11}Os_4$ (1299.3): calcd. with a glassy carbon working electrode (Bioanalytical), a platinum wire auxiliary electrode (Aldrich), and an $Ag/AgNO_3$ reference electrode (Bioanalytical) at room temperature; 0.1 mol·dm^{-3} *n*-tetrabutylammonium hexafluorophosphate (TBAHFP) in anhydrous deoxygenated CH_2Cl_2 was used as a supporting electrolyte. Ferrocene was added at the end of each experiment as an internal standard. Potential data (vs. $Ag/AgNO_3$) were checked against the ferrocene (0/+1) couple; under the actual experimental conditions the ferrocene/ferrocenium couple is located at +0.13 V. Bulk electrolyses were carried out in a gas-tight cell consisting of three chambers separated at the bottom by fine frits, with a carbon cloth (80 mm^2) working electrode in the middle, and $Ag/AgNO_3$ reference and Pt gauze auxiliary electrodes in the lateral chambers. The working potentials (E_w) for reduction and oxidation processes were ca. 0.15 V more negative and more positive than the corresponding electrode potential (E_p), respectively; all coulometric experiments were performed in duplicate.

Crystallography: Crystals suitable for X-ray analyses were glued on glass fibers with epoxy resin or sealed in a 0.3 mm glass capillary. Intensity data were collected at ambient temperature using a Bruker SMART CCD 1000 diffractometer with graphite monochromated Mo-K_α radiation using ω scan type. Details of the intensity data collection and crystal data are given in Table 4. The data were corrected for Lorentz and polarization effects. The structure were solved by direct methods[56] and expanded using Fourier techniques.[57] Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically. Hydrogen atoms were included but not refined. All calculations were performed by using the teXsan[58] crystallographic software package of Molecular Structure Corporation.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-163743 to CCDC-163747. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK. Reactivity of Sterically Unencumbered Transient Nitrilium Phosphanylide Complexes Towards 1-Piperidinocarbonitrile: A Case Study[‡]

Rainer Streubel,*[a] Udo Schiemann,[a] Ngoc Hoa Tran Huy,[b] and François Mathey*[b]

Dedicated to Professor Hans-Georg Schnöckel on the occasion of his 60th birthday

Keywords: Nitrogen heterocycles / NMR spectroscopy / Phosphorus heterocycles / P ligands / Tungsten

The thermal decomposition of the 7-phosphanorbornadiene complexes **6a**,**b** in xylene at 120 °C in the presence of two equivalents of 1-piperidinocarbonitrile yielded the 2*H*-1,3,2-azaphosphole complexes **11a**,**b** and the 2*H*-1,4,2-azaphosphole complexes **12a**–**c** in ratios of 7:4 (**11a**:**12a**) and 1:5 (**11b**:**12b**). Remarkably, the two atropisomers **12b** and **12c** were obtained (ratio: 5:1) in the case of the *P*-phenyl-substituted 2*H*-1,4,2-azaphosphole complex. Interestingly, the product ratios of both reactions were approximately the same if neat 1-piperidinocarbonitrile was used as the solvent. The reaction of complexes **6a,b** with $Cu^{I}Cl$ and 1-piperidinocarbonitrile, with exclusion of light, also furnished the 2*H*-1,3,2-azaphosphole complexes **11a,b** as the main products. In the case of complex **6a**, a by-product was detected by ^{31}P NMR spectroscopy but could not be isolated. Complexes **11a,b**, **12a** and **13** were purified by column chromatography at low temperature and characterized by NMR and MS spectroscopic means and elemental analysis, whereas only a 1:1 mixture of **12b** and **12c** could be characterized.

Introduction

Nitrilium phosphanylide complexes with bulky substituents at the phosphorus have recently become established as new building blocks in N,P-heterophosphole synthesis and their reactivity towards different trapping reagents such as alkynes,[2] nitriles[3] or phosphaalkynes[4] has been explored. So far, their generation has relied on the use of the 2*H*-azaphosphirene complexes **1a,b** and can be achieved either thermally or photochemically;[5] the mild reaction conditions of the latter being synthetically very useful. The majority of these three-component reactions profit from transylidation reactions yielding the *P*-bis(trimethylsilyl)methyl- and *P*-pentamethylcyclopentadienyl-substituted nitrilium phosphanylide tungsten complexes **2a**,**b** as transient species.[3] Of special interest are those cases where dialkylamino-substituted nitriles such as 1-piperidinocarbonitrile were used as trapping reagent and solvent (**i**; Scheme 1), thus affording selectively the 2*H*-1,3,2-diazaphosphole complexes **3a**[3b] and **3b**;[3c] if toluene solutions were used (**ii** and **iii**; Scheme 1) then intramolecular reactions also took place. Depending on the substituent at the phosphorus center two different by-products were thus formed: the 2*H*-azaphosphirene complex **4**[3b] in the case of **2a** (route **ii**) or the C,N,P-cage compound **5**[3c] in the case of **2b** (route **iii**). So far, no dimerization of complexes **2a**,**b** has been observed in solution, although we obtained a dimer by melting the 2*H*-azaphosphirene complex **1a**.[6]

Very recently we demonstrated that transient nitrilium phosphanylide complexes with less bulky substituents at the phosphorus, such as **9a**,**b**, are accessible by thermal decomposition of the 7-phosphanorbornadiene complexes **6a**,**b** in the presence of 1-piperidinocarbonitrile; the reactive intermediates **9a**,**b** were trapped with dimethylacetylene dicarboxylate, thus yielding the 2*H*-1,2-azaphosphole complexes **10a**,**b** as the main products (Scheme 2).[1] Remarkably, in these reactions no Δ^3-oxazaphospholene complexes were formed from the [3+2] cycloaddition of **9a**,**b** with the C−O π-system of DMAD, as observed earlier for **2a**,**b**.[7,8] This finding provided the first evidence for the different reactivities of sterically unencumbered and encumbered nitrilium phosphanylide complexes.

Because of our interest in exploiting the chemistry of nitrilium phosphanylide complexes using this new and easy access, we decided to study the reactions of the 7-methyl- and 7-phenyl-phosphanorbornadiene complexes **6a**,**b** with 1-piperidinocarbonitrile, which should be a good model system. The quest for the generation of transient 2*H*-azaphosphirene complexes will also be discussed.

Results and Discussion

The thermal decomposition of the 7-phosphanorbornadiene complexes **6a**,**b**[9] in xylene in the presence of two

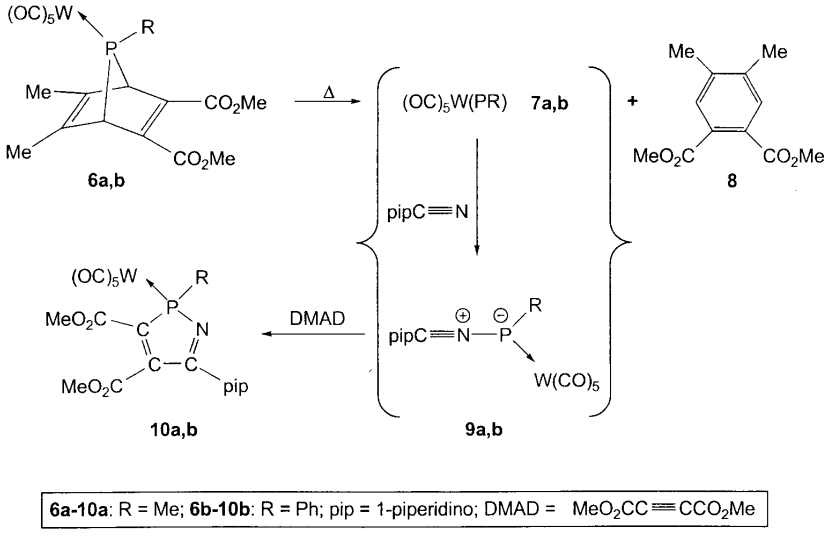
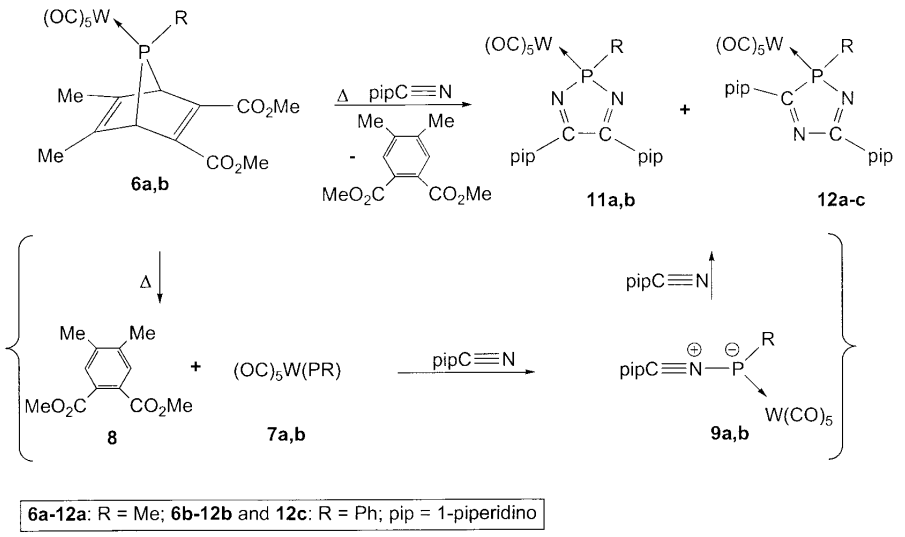


Scheme 2. Trapping reaction of nitrilium phosphanylide complexes **9a**,**b** with DMAD

equivalents of 1-piperidinocarbonitrile at 120 °C yielded the 2*H*-1,3,2-azaphosphole complexes **11a**,**b** and, surprisingly, the 2*H*-1,4,2-azaphosphole complexes **12a**,**b** *and* **12c** (Scheme 3). The ratios of the two regioisomers **11** and **12** were 7:4 (**11a**:**12a**) and 1:5 (**11b**:**12b**), as determined by ^{31}P NMR spectroscopy. Remarkably, the *P*-phenyl-substituted 2*H*-1,4,2-azaphosphole complex was obtained as a mixture of two atropisomers **12b**,**c** (5:1 ratio), in contrast to the methyl derivative **12a**. The complexes **11a,b** and **12a** were separated by double low-temperature column chromatography, whereas only a 1:1 mixture of **12b**,**c** could be isolated. According to the spectroscopic data of complexes **12b**,**c** we propose that the atropisomerism originates from differently orientated C(2)-bonded pyramidal piperidino nitrogen centers, which can be *cisoid* or *transoid* with respect to the pentacarbonyltungsten group and which have a hindered rotation around the C(2)−N bond (Figure 1). According to monitoring of the reaction by ^{31}P NMR spectroscopy, 2*H*-azaphosphirene complexes were not formed under these conditions.

Astonishingly, the deviation from the formerly observed product ratios was less than 5% if neat 1-piperidinocarbonitrile was used as solvent. The appropriate *P*-phenyl-substituted 2*H*-azaphosphirene complex was eventually de-



Scheme 3. Thermal decomposition of 7-phosphanorbornadiene complexes **6a**,**b** in neat 1-piperidinocarbonitrile or 1-piperidinocarbonitrile toluene solutions

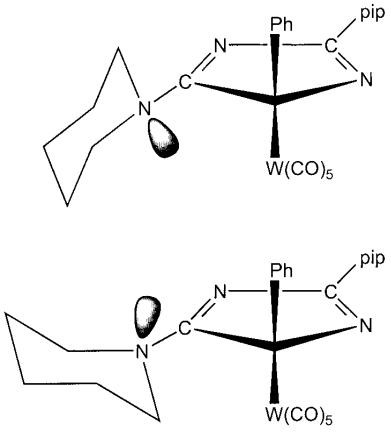


Figure 1. Proposed structures for the atropisomeric 2*H*-1,2,4-diazaphosphole complexes **12b**,**c**

tected in very small amounts (< 3% according to the ^{31}P NMR spectrum; δ = −47.9) only in the case of complex **1b**; the related *P*-bis(trimethylsilyl)methyl-substituted 2*H*-azaphosphirene complex was observed at δ = −70.3.[3b]

Because of the known thermal instability of 2*H*-azaphosphirene complexes, we decided to carry out a preliminary study on the use of Cu^{I}Cl as catalyst for the decomposition,[10] and were thus able to lower the temperature substantially to 65−70 °C. Although we performed the reaction of the complexes **6a**,**b** with 1-piperidinocarbonitrile — with and without exclusion of light[11] — the ^{31}P NMR spectra showed no further evidence for 2*H*-azaphosphirene complexes. Remarkably, the reaction of complex **6b** with 1-piperidinocarbonitrile and catalytic amounts of Cu^{I}Cl in toluene at 70 °C and with exclusion of light furnished the 2*H*-1,3,2-azaphosphole complex **11b** selectively. In the case of complex **6a** the 2*H*-1,3,2-azaphosphole complex **11a** and a complex **13** were formed in a 6:4 ratio (Scheme 4). Unfortunately, the latter complex could not be isolated by column chromatography due to decomposition. Nevertheless, a comparison of the ^{31}P NMR spectroscopic data of complex **13** [δ = 73.2, $J(^{31}P,^{31}P)$ = 25.6, $^{1}J(^{183}W,^{31}P)$ = 217.9 Hz; δ = 68.7, $J(^{31}P,^{31}P)$ = 25.6, $^{1}J(^{183}W,^{31}P)$ = 259.7 Hz] with {2,5-bis[bis(trimethylsilyl)methyl]-4,6-diphenyl-2,5-dihydro-1,3-diaza-2,5-diphosphinine-κP^2]}pentacarbonyltungsten(0)[6] [δ = 79.9, $J(^{31}P,^{31}P)$ = 15.3, $^{1}J(^{183}W,^{31}P)$ = 266.1 Hz; δ = −0.6, $J(^{31}P,^{31}P)$ = 15.3 Hz] provides some evidence for the constitution of complex **13** as the head-to-tail dimer of complex **9a**.

As expected, the ^{13}C NMR spectra of the 2*H*-1,3,2-azaphosphole complexes **11a,b** showed one resonance for the PN*C* imino carbon atoms of the ring between δ = 160.7 and 161.6 with coupling constant magnitudes $|J(^{31}P,^{13}C)|$ of ca. 2.5−6.4 Hz; the data of the complexes **14a**[3b] and **14b**[3c] are also listed in Table 1 for comparison. Three resonances were observed for the methylene carbon atoms of the 1-piperidino substituent, as expected for such 2*H*-1,3,2-azaphosphole complexes.[3b,3c] More surprising were the ^{13}C NMR spectra of the 2*H*-1,4,2-azaphosphole complexes **12a**−**c** (Table 2). Here the resonances for both types of imino carbon atoms were observed in a comparably narrow range between δ = 160 and 185 and the coupling constant magnitudes $|J(^{31}P,^{13}C)|$ were also considerably smaller (ca. 2−15 Hz) than those observed for the derivatives **15a**,[3b] **15b**[5] and **15c**[12] [values between δ = 195 and 200 (P*C*N) and δ = 163 and 170 (PN*C*); $|J(^{31}P,^{13}C)|$ ca. 1−30 Hz]. Therefore, we could only make tentative assignments in the present study. As expected, each 1-piperidino substituent of **12a**−**c** shows more than three resonances for the methylene carbon atoms, although in some cases only collapsed signals were observed.

Within each class of compounds the bulky substituted derivatives **14** and **15** tend to have ^{31}P resonances at significantly lower field; for example, the resonances of **15a**,[3b] and **15b**[5] are observed in the range δ = 110−123 with characteristic coupling constants $|J(^{183}W,^{31}P)|$ of 228−234 Hz, whereas **12a**−**c** were observed in the range δ = 70−80 with

coupling constants $|J(^{183}W,^{31}P)|$ of 248−258 Hz. These differences in the chemical shifts and the tungsten-phosphorus couplings seem to be mainly caused by different steric interactions of the organic substituents at the phosphorus center and the pentacarbonyltungsten group.

EI mass spectrometric experiments revealed that these 2*H*-1,3,2-azaphosphole and 2*H*-1,4,2-diazaphosphole complexes preferentially lose carbon monoxide and show cleavage of the C−N bonds between the different heterocyclic ring systems subsequent to the ionisation process; this behavior has also been observed for the bulky substituted derivatives **14**[3b,3c] and **15**.[3,5,12]

In conclusion, we have shown that the chemistry of nitrilium phosphanylide complexes can be further exploited using 7-methyl- and 7-phenyl-phosphanorbornadiene complexes and 1-piperidinocarbonitrile, thus providing a new access to 2*H*-1,3,2-azaphosphole and 2*H*-1,4,2-diazaphosphole complexes. Furthermore, we obtained new insights into the reactivity of nitrilium phosphanylide complexes that are sterically unencumbered at phosphorus, and we provide first evidence for the transient formation of a *P*-phenyl-substituted 2*H*-azaphosphirene complex.

Experimental Section

General Procedures: All reactions and manipulations were carried out under an atmosphere of deoxygenated dry nitrogen, using standard Schlenk techniques with conventional glassware, and solvents were dried according to standard procedures. NMR spectra were recorded on a Bruker AC-200 spectrometer (200 MHz for ^1H; 50.3 MHz for ^{13}C; 81.0 MHz for ^{31}P) with [D]chloroform and

[D_6]benzene as both solvent and internal standard; shifts are given relative to external tetramethylsilane (^{1}H, ^{13}C) or 85% H_3PO_4 (^{31}P). Mass spectra were recorded on a Finnigan Mat 8430 (70 eV); apart from the *m*/*z* values of the molecule ions, only *m*/*z* values with intensities of more than 20% are given. Infrared spectra were recorded on a Biorad FT-IR 165 (selected data given). Melting points were obtained on a Büchi 535 capillary apparatus. Elemental analyses were performed by using a Carlo Erba analytical gas chromatograph. The κ*P* notation differentiates between *P*- and *N*-coordination of the appropriate heterocycle to the metal.

Procedure for the Synthesis of the Diazaphosphole Complexes 11a,b and 12a−c: Compound **1a** (0.45 g, 0.85 mmol) or **1b** (0.56 g, 0.85 mmol) and 1-piperidinocarbonitrile (0.2 mL, 1.7 mmol), dissolved in 5 mL of xylene, were heated for 3.5−4 h at 120 °C with slow stirring. When the reaction was complete (as monitored by ^{31}P NMR spectroscopy), the solution was evaporated to dryness in vacuo (ca. 0.01 mbar), and the residue subjected to low-temperature column chromatography on silica (−32 °C, *n*-hexane/diethyl ether, 10:1). The eluates were evaporated to dryness in vacuo (ca. 0.01 mbar), and the residues recrystallised from *n*-pentane at −20 °C.

Cationic Five-Coordinate Bis(butadiene)iridium(I) Complexes from the Highly Labile *cis*-$[Ir(\eta^2\text{-}C_8H_{14})_2(acetone)_2]^+$ Cation as the Precursor

Marco Bosch,[a] Kerstin Ilg,[a] and Helmut Werner*[a]

Dedicated to Professor Rudolf Taube on the occasion of his 70th birthday

Keywords: Acetone complexes / Alkene ligands / Iridium / P ligands / Arsenic / Antimony

The cation *cis*-$[Ir(\eta^2\text{-}C_8H_{14})_2(acetone)_2]^+$, which is generated in situ from $[Ir(\mu\text{-}Cl)(\eta^2\text{-}C_8H_{14})_2]_2$ (**1**) and $AgPF_6$ in acetone, reacts with butadiene at room temperature to give the five-coordinate complex $[Ir(s\text{-}cis\text{-}\eta^4\text{-}C_4H_6)_2(\eta^2\text{-}C_8H_{14})]PF_6$ (**3**). The cyclooctene ligand of **3** is only weakly coordinated and easily displaced by P*i*Pr$_3$, As*i*Pr$_3$ and Sb*i*Pr$_3$ to afford the compounds $[Ir(s\text{-}cis\text{-}\eta^4\text{-}C_4H_6)_2(E\textit{i}Pr_3)]PF_6$ (**5**–**7**) in excellent yields. Alternatively, **5**–**7** can be prepared from $[IrCl(s\text{-}cis\text{-}\eta^4\text{-}C_4H_6)_2]$ (**4**) by stepwise treatment with $AgPF_6$ and E*i*Pr$_3$ (E = P, As, Sb). The X-ray crystal structure analysis of **5** revealed a square-pyramidal geometry of the cation with the phosphane ligand in the apical position.

Introduction

In the course of our investigations on the ability of sulfonatorhodium(I) compounds to catalyze C−C coupling reactions of olefins and other unsaturated substrates,[1] we recently found that the monomeric triflatorhodium(I) complex $[Rh\{\eta^2\text{-}O_2S(O)CF_3\}(P\textit{i}Pr_3)_2]$ is an active catalyst for the polymerization of butadiene.[2] Moreover, we observed that if instead of the bis(phosphane) compound the dimeric bis(cyclooctene) derivative $[Rh\{\mu\text{-}O_2S(O)CF_3\}(\eta^2\text{-}C_8H_{14})_2]_2$ is treated with C_4H_6, the five-coordinate bis(butadiene) complex $[Rh\{\eta^1\text{-}OS(O)_2CF_3\}(\eta^4\text{-}C_4H_6)_2]$ is formed, and this complex reacts with bulky phosphanes to give the corresponding cations $[Rh(\eta^4\text{-}C_4H_6)_2(PR_3)]^+$ in excellent yields by ligand displacement.[3] Since these cations readily undergo intramolecular C−C coupling reactions and are intermediates in the formation of the unusual cyclotetramer *cis*,*cis*,*trans*,*trans*-1,5,9,13-$C_{16}H_{24}$,[4] we became interested to find out whether analogous bis(butadiene)iridium(I) compounds would be accessible and what their reactivity compared to the rhodium counterparts is. In this paper we report the generation of the highly reactive bis(cyclooctene)iridium(I) cation *cis*-$[Ir(\eta^2\text{-}C_8H_{14})_2(acetone)_2]^+$ and its smooth conversion into cationic five-coordinate bis(butadiene) derivatives.

Results and Discussion

Our attempts to start the stepwise synthesis of the target compounds $[Ir(\eta^4\text{-}C_4H_6)_2(PR_3)]^+$ from the preparation of $[Ir\{\mu\text{-}O_2S(O)CF_3\}(\eta^2\text{-}C_8H_{14})_2]_2$, the analogue of the above-mentioned rhodium complex $[Rh\{\mu\text{-}O_2S(O)CF_3\}(\eta^2\text{-}C_8H_{14})_2]_2$, failed. Treatment of a suspension of $[Ir(\mu\text{-}Cl)(\eta^2\text{-}C_8H_{14})_2]_2$ (**1**) in acetone with two equivalents of AgO_3SCF_3 afforded a mixture of products which could not be separated either by fractional crystallization or chromatographic techniques.

Following earlier work by Schrock[5] and Muetterties,[6] we therefore used the dimeric chloro derivative **1** as the starting material. This compound reacts with $AgPF_6$ (molar ratio 1:2) in acetone to give an orange solution from which, even by evaporation of the solvent under very mild conditions, no analytically pure compound could be isolated. If, however, [D$_6$]acetone was used as the solvent, both the ^{1}H and the ^{13}C NMR spectra of the solution indicated that a bis(cyclooctene)iridium(I) cation had been generated. Although the NMR spectroscopic data did not allow us to determine the number of [D$_6$]acetone molecules coordinated to the metal center, we assume, in analogy to the more stable, isolated complex *cis*-$[Rh(\eta^2\text{-}C_8H_{14})_2(acetone)_2]PF_6$,[7] that the coordination geometry corresponds to a square plane with the cyclooctene and the [D$_6$]acetone ligands in *cis* positions (see Scheme 1). We note that in the ^{13}C NMR spectrum of **2** there is only one signal for the C=O moiety and one signal for the CH_3 carbon indicating that, at room temperature, a fast exchange between free and coordinated [D$_6$]acetone takes place.

Passing a slow stream of butadiene through a solution containing the in situ generated cation **2** for ten seconds, in the presence of excess cyclooctene, led to a quick change of color from orange to pale-yellow. After addition of pentane, a white, moderately air-sensitive solid precipitated which analyzed as $[Ir(s\text{-}cis\text{-}\eta^4\text{-}C_4H_6)_2(\eta^2\text{-}C_8H_{14})]PF_6$ (**3**). The ^{1}H NMR spectrum of **3** displays three well-separated resonances for the butadiene protons at δ = 6.10, 3.50 and 1.48 of which those for the *exo* and *endo* protons of the terminal CH_2 groups are split into doublets of doublets. The signal for the olefinic protons of the coordinated cyclooctene appears at δ = 5.66 and is thus shifted about 2.2 ppm down-

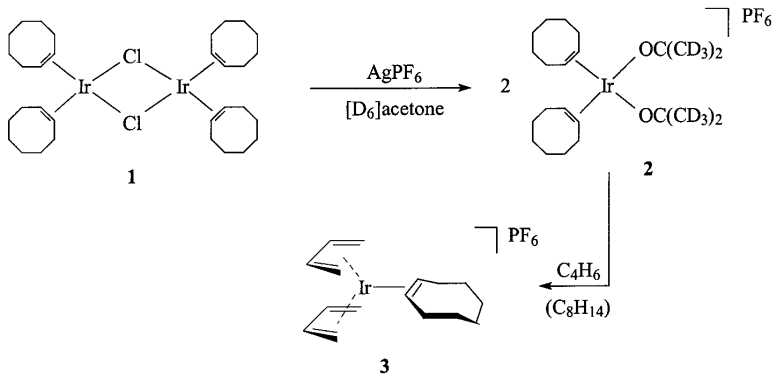

Scheme 1

field relative to **2**. A similar downfield shift is also observed in the ^{13}C NMR spectrum for the signal of the CH=CH carbon atoms of C_8H_{14}, which appears at $\delta = 81.9$ for **3** but at $\delta = 62.7$ for **2**. The increased electron density at the five-coordinate iridium(I) center of **3** could explain these observations.

The cyclooctene ligand of **3** is not strongly coordinated and can therefore be displaced by a better donor such as P*i*Pr$_3$ (Scheme 2). However, treatment of a solution of **3** in dichloromethane with *one* equivalent of the phosphane did not lead to a complete conversion and, after removal of the solvent, afforded a 1:1 mixture of **3** and **5**. An almost quantitative yield of the substitution product **5** could be achieved upon the addition of a second equivalent of P*i*Pr$_3$ to the 1:1 mixture of **3** and **5**. An alternative procedure to prepare **5** consists of the stepwise reaction of the mononuclear precursor **4**[8] with $AgPF_6$ and an equimolar amount of P*i*Pr$_3$. The yield here is also excellent. Compound **5** is a white solid that can be handled in air for a short period of time and can be stored under argon for weeks without decomposition. Similarly to **3**, the ^1H NMR spectrum of **5** displays three signals of equal intensity for the C_4H_6 protons and the ^{13}C NMR spectrum shows two resonances for the butadiene carbon atoms, one of which is split into a doublet due to ^{13}C-^{31}P coupling.

The molecular structure of the triisopropylphosphane complex **5** was determined by X-ray crystallography. There are two independent molecules, **5a** and **5b**, in the unit cell, of which **5a** is shown in Figure 1. The coordination geometry around the iridium center is square-pyramidal with the CH_2 groups of the butadiene ligands at the base of the pyramid. The apical position of the cationic species is occupied by the phosphorus atom of the P*i*Pr$_3$ ligand. The C−C bond lengths of the C_4H_6 moieties together with the bond angles C(1)−C(2)−C(3), C(4)−C(3)−C(2), C(5)−C(6)−C(7) and C(8)−C(7)−C(6) (all ≈120°) clearly indicate an η^4-coordination mode for the diene molecules. The distances between the metal and the CH and CH_2 units lie in the ranges 2.215(11)−2.205(11) and 2.184(11)−2.167(12) Å, respectively, and are quite similar to those found in other

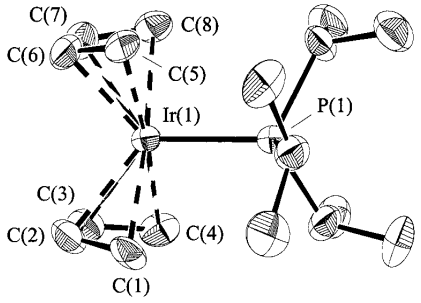

Figure 1. Molecular structure of **5a** (hydrogen atoms and anionic ligand omitted for clarity; there are two independent molecules **5a** and **5b** in the unit cell, the data for **5b** are given after the diagonal lines); principle bond lengths [Å] and angles [°] with estimated standard deviations in parentheses: Ir(1)−C(1) 2.206(11)/2.224(13), Ir(1)−C(2) 2.167(12)/2.166(12), Ir(1)−C(3) 2.184(11)/2.179(12), Ir(1)−C(4) 2.215(11)/2.216(11), Ir(1)−C(5) 2.205(11)/2.219(12), Ir(1)−C(6) 2.161(12)/2.187(13), Ir(1)−C(7) 2.178(13)/2.178(13), Ir(1)−C(8) 2.209(12)/2.212(12), C(1)−C(2) 1.424(18)/1.419(19), C(2)−C(3) 1.448(19)/1.436(19), C(3)−C(4) 1.414(18)/1.384(19), C(5)−C(6) 1.381(18)/1.418(19), C(6)−C(7) 1.430(19)/1.435(19), C(7)−C(8) 1.389(19)/1.388(18), Ir(1)−P(1) 2.394(3)/2.389(3); C(1)−Ir(1)−P(1) 90.4(3)/90.5(4), C(4)−Ir(1)−P(1) 94.4(4)/94.9(4), C(5)−Ir(1)−P(1) 91.1(3)/90.3(3), C(8)−Ir(1)−P(1) 95.1(4)/95.3(4), C(1)−C(2)−C(3) 116.8(12)/119.2(12), C(2)−C(3)−C(4) 117.5(12)/118.4(12), C(5)−C(6)−C(7) 118.4(12)/119.2(12), C(6)−C(7)−C(8) 118.5(12)/117.3(12)

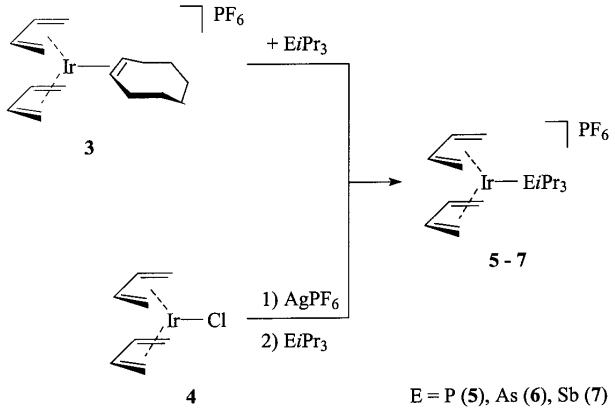

Scheme 2

bis(diene)iridium(I) compounds.[9] Both butadiene ligands are nearly planar, as indicated by the torsional angles of −1.7(17)° for the plane [C(1)−C(2)−C(3)−C(4)] and 1.9(18)° for [C(6)−C(7)−C(8)−C(9)]. However, the two planes of the butadienes are not parallel to each other but tilted by 14.6(3)° which could be due to steric repulsion between the bulky phosphane and the diene systems. The Ir−P distance of 2.394(3) Å in **5a** is relatively long compared with the distances of [IrH(s-cis-η⁴-C_4H_6)(PiPr$_3$)$_2$] (2.30−2.32 Å)[10] and several square-planar iridium(I) compounds containing $trans$-[Ir(PiPr$_3$)$_2$] (average Ir−P distance 2.34 Å) as a molecular building block.[11]

The cycloocteneiridium(I) complex **3** also reacts with two equiv. of AsiPr$_3$ or SbiPr$_3$ in dichloromethane at room temperature. The substitution products **6** and **7** (see Scheme 2) can also be formed from **4**, $AgPF_6$ and triisopropylarsane or -stibane in the molar ratio of 1:1:1. Compounds **6** and **7** are white solids, with properties that are quite similar to those of the triisopropylphosphane analogue **5**. With regard to the ^{1}H NMR spectroscopic data of **6** and **7**, we note that the signal of the *endo* protons H_a (for assignment see Figure 2) appears at lower field than that of **5** while the resonances for the protons H_b and H_c are observed slightly upfield compared with the triisopropylphosphane counterpart.

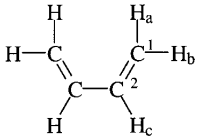

Figure 2. Assignment of the diene protons and carbon atoms in compounds **3**, **5**−**7**

The cations [Ir(s-cis-η⁴-C_4H_6)$_2$(EiPr$_3$)]$^+$ (E = P, As, Sb) are not only thermally quite stable (the PF_6^- salts decompose at about 150 °C) but, in contrast to the rhodium analogue [Rh(s-cis-η⁴-C_4H_6)$_2$(PiPr$_3$)]$^+$, they do not react upon heating by coupling of the two diene units to give an isomeric octadienediyliridium(III) derivative. We have already mentioned that the cationic bis(butadiene)rhodium(I) complex readily undergoes an intramolecular C−C coupling process in refluxing dichloromethane leading to [Rh(η³:η³-C_8H_{12})(PiPr$_3$)]$^+$, which is an intermediate in the rhodium-catalyzed cyclotetramerization of butadiene.[4] However, under the same conditions the iridium cations are completely inert and, even after stirring solutions of **5**, **6** or **7** in refluxing CH_2Cl_2 or CH_3NO_2 for 10−12 h, the starting materials could be quantitatively re-isolated. This inert behavior of the five-coordinate iridium(I) species is not only different to that of [Rh(s-cis-η⁴-C_4H_6)$_2$(PiPr$_3$)]$^+$ but also in contrast to the reactivity of some bis(butadiene)molybdenum and -ruthenium compounds which, in the presence of a Lewis base, undergo an intramolecular C−C coupling reaction.[12] Finally, we note that unlike [Rh(s-cis-η⁴-C_4H_6)$_2$(PiPr$_3$)]$^+$ the iridium counterpart does not react with excess PiPr$_3$ by either displacement of one of the diene ligands or attack of the phosphane at the coordinated butadiene to give a phosphoniumbutenylmetal cation.[3] The chemistry of diolefinrhodium(I) and diolefiniridium(I) compounds really is, as shown by several other examples,[13] not the same at all.

Experimental Section

All experiments were carried out under an atmosphere of argon by Schlenk techniques. The commercially available starting materials AgO_3SCF_3, $AgPF_6$ and butadiene were used without further purification. PiPr$_3$ was purchased from Strem Chemicals. The complexes [Ir(μ-Cl)(η²-C_8H_{14})$_2$]$_2$ (**1**)[14] and [IrCl(s-cis-η⁴-C_4H_6)$_2$] (**4**)[8] were prepared as described in the literature. The preparation of AsiPr$_3$ and SbiPr$_3$ was carried out as described for the n-propyl analogues.[15] NMR spectra were recorded at room temperature on Bruker AC 200 and Bruker AMX 400 instruments, unless otherwise stated. Abbreviations used: s, singlet; d, doublet; t, triplet; quin, quintet; sept, septet; m, multiplet; br, broadened signal. Melting and decomposition points were measured by differential thermal analysis (DTA).

Generation of cis-[Ir(η²-C_8H_{14})$_2$([D$_6$]acetone)$_2$]PF$_6$ (2): A suspension of **1** (60 mg, 0.07 mmol) in [D$_6$]acetone (1 mL) was treated with $AgPF_6$ (34 mg, 0.13 mmol) and stirred for 1 h at room temperature. A white solid precipitated, which was removed by filtration, and the clear orange solution was investigated by NMR spectroscopy. ^{1}H NMR (400 MHz, [D$_6$]acetone): δ = 2.57 (br. s, 4 H, CH of C_8H_{14}), 2.06 (br. s, 4 H, =CHCH_2 of C_8H_{14}), 1.61 (m, 4 H, CH_2 of C_8H_{14}), 1.42 (m, 12 H, CH_2 of C_8H_{14}), 1.24 (m, 4 H, CH_2 of C_8H_{14}); ^{13}C NMR (100.6 MHz, [D$_6$]acetone): δ = 206.6 (s, C=O of [D$_6$]acetone), 62.7 (s, CH of C_8H_{14}), 29.8 [sept, ^1J(D,C) = 19.3 Hz; CD_3 of [D$_6$]acetone], 29.6, 28.3, 26.7 (all s, CH_2 of C_8H_{14}); ^{19}F NMR (376.4 MHz, [D$_6$]acetone): δ = −72.3 [d, ^1J(P,F) = 709.4 Hz]; ^{31}P NMR (162.0 MHz, [D$_6$]acetone): δ = −144.1 [sept, ^1J(F,P) = 709.4 Hz].

Preparation of [Ir(s-cis-η⁴-C_4H_6)$_2$(η²-C_8H_{14})]PF$_6$ (3): A suspension of **1** (207 mg, 0.23 mmol) in acetone (10 mL) was treated with $AgPF_6$ (117 mg, 0.46 mmol) and stirred for 1 h at room temperature. The solution was filtered, and cyclooctene (100 μL, 0.77 mmol) was added to the filtrate. After stirring for 2 min, a slow stream of butadiene was passed through the solution for 10 s. The gaseous diene was replaced by argon, the pale-yellow solution was stirred for 30 min at room temperature and then concentrated to ca. 2 mL in vacuo. Addition of pentane (20 mL) resulted in the precipitation of a white solid, which was separated from the mother liquor, washed with pentane (3 × 5 mL) and dried in vacuo; yield 114 mg (89%); m.p. 103 °C (decomp); ^{1}H NMR (200 MHz, [D$_6$]-acetone): δ = 6.10 (m, 4 H, H_c), 5.66 (m, 2 H, CH of C_8H_{14}), 3.50 [dd, ^3J(H,H) = 8.0, ^2J(H,H) = 1.8 Hz, 4 H, H_b], 2.50 (m, 2 H, CHCH_2 of C_8H_{14}), 2.17, 1.97, 1.87, 1.78, 1.57 (all m, 10 H, CH_2 of C_8H_{14}), 1.48 [dd, ^3J(H,H) = 9.0, ^2J(H,H) = 1.8 Hz, 4 H, H_a]; for the assignment of the butadiene protons and carbon atoms see Figure 2; ^{13}C NMR (100.6 MHz, [D$_6$]acetone, 308 K): δ = 87.9 (s, C^2), 81.9 (s, CH of C_8H_{14}), 49.8 (s, C^1), 32.6, 29.6, 26.8 (all s, CH_2 of C_8H_{14}); ^{19}F NMR (376.4 MHz, [D$_6$]acetone, 308 K): δ = −72.2 [d, ^1J(P,F) = 705.5 Hz]; ^{31}P NMR (162.0 MHz, [D$_6$]acetone, 308 K): δ = −144.1 [sept, ^1J(F,P) = 705.5 Hz]; $C_{16}H_{26}F_6IrP$ (555.6): calcd. C 34.59, H 4.72; found C 34.34, H 4.56.

Preparation of [Ir(s-cis-η⁴-C_4H_6)$_2$(PiPr$_3$)]PF$_6$ (5): a) A solution of **3** (87 mg, 0.16 mmol) in CH_2Cl_2 (10 mL) was treated with PiPr$_3$ (30 μL, 0.16 mmol) and stirred for 1 h at room temperature. After removal of the solvent in vacuo, the colorless solid residue was

washed with pentane (5 mL) and dried in vacuo. Since the ^1H and ^{13}C NMR spectroscopic data showed that the product is a 1:1 mixture of **3** and **5**, the residue was dissolved in CH_2Cl_2 (10 mL) and treated again with P*i*Pr$_3$ (30 μL, 0.16 mmol). After stirring for 30 min, pentane (20 mL) was added to afford a colorless suspension. The solvent was decanted, the residue was washed with pentane (3 × 5 mL) and dried in vacuo. White solid; yield 88 mg (91%).

b) A suspension of **4** (125 mg, 0.37 mmol) in acetone (15 mL) was treated with $AgPF_6$ (94 mg, 0.37 mmol) and the mixture stirred for 1 h at room temperature. After removal of the solvent in vacuo, the residue was suspended in CH_2Cl_2 (10 mL). The resulting suspension was treated with P*i*Pr$_3$ (72 μL, 0.37 mmol) and stirred for 1 h at room temperature. Filtration of the mixture afforded a clear orange-yellow solution which was concentrated to ca. 2 mL in vacuo. Addition of pentane (10 mL) led to the precipitation of a white solid, which was separated from the mother liquor, washed with pentane (3 × 5 mL) and dried in vacuo. Yield 206 mg (92%); m.p. 152 °C (decomp); ^1H NMR (400 MHz, [D$_3$]nitromethane): δ = 5.64 (m, 4 H, H$_c$), 3.25 [dd, ^3J(H,H) = 7.8, ^2J(H,H) = 2.3 Hz, 4 H, H$_b$], 2.78 (m, 3 H, PC*H*CH$_3$), 1.43 [dd, ^3J(P,H) = 14.1, ^3J(H,H) = 7.4 Hz, 18 H, PCHC*H*$_3$], 1.09 [ddd, ^3J(H,H) = ^3J(P,H) = 8.9, ^2J(H,H) = 2.3 Hz, 4 H, H$_a$]; for the assignment of the butadiene protons and carbon atoms see Figure 2; ^{13}C NMR (100.6 MHz, [D$_3$]nitromethane): δ = 82.2 (s, C^2), 39.8 [d, ^2J(P,C) = 4.1 Hz, C^1], 29.1 [d, ^1J(P,C) = 27.5 Hz, P*C*HCH$_3$], 20.7 [d, ^2J(P,C) = 2.0 Hz, PCH*C*H$_3$]; ^{19}F NMR (376.4 MHz, [D$_3$]nitromethane): δ = −72.6 [d, ^1J(P,F) = 706.9 Hz]; ^{31}P NMR (162.0 MHz, [D$_3$]nitromethane): δ = 11.2 (s, P*i*Pr$_3$), −144.6 [sept, ^1J(F,P) = 706.9 Hz, PF_6^-]; $C_{17}H_{33}F_6IrP_2$ (605.6): calcd. C 33.72, H 5.49; found C 33.56, H 5.21.

Preparation of [Ir(*s-cis*-η^4-C$_4$H$_6$)$_2$(As*i*Pr$_3$)]PF$_6$ (6): This was prepared as described for **5** (method a), from **3** (93 mg, 0.17 mmol) and two portions of As*i*Pr$_3$ (33 μL, 0.17 mmol). White solid; yield 98 mg (90%). Alternatively, **6** could also be prepared as described for **5** (method b), from **4** (125 mg, 0.37 mmol), $AgPF_6$ (94 mg, 0.37 mmol) and As*i*Pr$_3$ (73 μL, 0.37 mmol) as starting materials. White solid; yield 229 mg (95%); m.p. 156 °C (decomp); ^1H NMR (400 MHz, [D$_3$]nitromethane): δ = 5.58 (m, 4 H, H$_c$), 3.21 [dd, ^3J(H,H) = 7.8, ^2J(H,H) = 2.3 Hz, 4 H, H$_b$], 2.90 [sept, ^3J(H,H) = 7.1 Hz, 3 H, AsC*H*CH$_3$], 1.47 [d, ^3J(H,H) = 7.1 Hz, 18 H, AsCHC*H*$_3$], 1.22 [dd, ^3J(H,H) = 7.9, ^2J(H,H) = 2.3 Hz, 4 H, H$_a$]; for the assignment of the butadiene protons and carbon atoms see Figure 2; ^{13}C NMR (100.6 MHz, [D$_3$]nitromethane): δ = 81.0 (s, C^2), 37.0 (s, C^1), 29.6 (s, As*C*HCH$_3$), 21.0 (s, AsCH*C*H$_3$); ^{19}F NMR (376.4 MHz, [D$_3$]nitromethane): δ = −73.3 [d, ^1J(P,F) = 706.4 Hz]; ^{31}P NMR (162.0 MHz, [D$_3$]nitromethane): δ = −144.6 [sept, ^1J(F,P) = 706.4 Hz]; $C_{17}H_{33}AsF_6IrP$ (649.6): calcd. C 31.43, H 5.12; found C 31.19, H 5.45.

Preparation of [Ir(*s-cis*-η^4-C$_4$H$_6$)$_2$(Sb*i*Pr$_3$)]PF$_6$ (7): This was prepared as described for **5** (method a), from **3** (76 mg, 0.14 mmol) and two portions of Sb*i*Pr$_3$ (27 μL, 0.14 mmol). White solid; yield 85 mg (89%). Alternatively, **7** could also be prepared as described for **5** (method b), from **4** (203 mg, 0.60 mmol), $AgPF_6$ (153 mg, 0.60 mmol) and Sb*i*Pr$_3$ (120 μL, 0.60 mmol) as starting materials. White solid; yield 388 mg (93%); m.p. 150 °C (decomp); ^1H NMR (400 MHz, [D$_3$]nitromethane): δ = 5.54 (m, 4 H H$_c$), 3.07 [dd, ^3J(H,H) = 7.6, ^2J(H,H) = 2.2 Hz, 4 H, H$_b$], 2.92 [sept, ^3J(H,H) = 7.4 Hz, 3 H, SbC*H*CH$_3$], 1.55 [d, ^3J(H,H) = 7.4 Hz, 18 H, SbCHC*H*$_3$], 1.29 [dd, ^3J(H,H) = 7.6, ^2J(H,H) = 2.2 Hz, 4 H, H$_a$]; for the assignment of the butadiene protons and carbon atoms see Figure 2; ^{13}C NMR (100.6 MHz, [D$_3$]nitromethane): δ = 79.0 (s, C^2), 32.4 (s, C^1), 22.0 (s, SbCH*C*H$_3$), 21.6 (s, Sb*C*HCH$_3$); ^{19}F NMR (376.4 MHz, [D$_3$]nitromethane): δ = −73.3 [d, ^1J(P,F) = 706.4 Hz]; ^{31}P NMR (162.0 MHz, [D$_3$]nitromethane): δ = −144.6 [sept, ^1J(F,P) = 706.4 Hz]; $C_{17}H_{33}F_6IrPSb$ (696.4): calcd. C 29.32, H 4.78; found C 29.14, H 5.17.

Thermolysis Experiments: Solutions of **5** (45 mg, 0.07 mmol), **6** (50 mg, 0.08 mmol) and **7** (63 mg, 0.09 mmol) in [D$_3$]nitromethane (0.5 mL) were stirred for 6 h at 60 °C. During this time no change of color of the solutions could be observed. The ^1H and ^{31}P NMR spectra revealed that in all cases no reaction had taken place.

Determination of the X-ray Crystal Structure of 5: Single crystals were grown by slow diffusion of pentane (10 mL) into a saturated solution of **5** in acetone (2 mL) at room temperature. The white crystalline product was washed with pentane (2 × 2 mL) and dried under a stream of argon. Crystal data (from 23 reflections, 10.00° < Θ < 15.00°): triclinic; space group $P\bar{1}$ (No. 2); a = 9.929(2), b = 12.295(3), c = 17.370(4) Å, α = 89.91(3)°, β = 89.92(3)°, γ = 89.92(3)°; V = 2120.7(7) Å^3, Z = 4; $d_{calcd.}$ = 1.897 g cm^{-3}; μ(Mo-K_α) = 6.497 mm^{-1}; crystal size 0.19 × 0.16 × 0.15 mm; Enraf−Nonius CAD4, Mo-K_α radiation (0.71073 Å), graphite monochromator; T = 193(2) K; ω/Θ-scan, max. 2Θ = 44.92°; 5964 reflections measured, 5508 independent ($R_{int.}$ = 0.0435), 4470 with $I > 2\sigma(I)$. Intensity data were corrected for Lorentz and polarization effects and an empirical absorption correction was applied. The structure was solved by direct methods (SHELX-97).[16] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares method on F^2 (program package SDP (Enraf−Nonius) and SHELXL-97).[17] The asymmetric unit of **5** contains two formula units, each consisting of two moieties: a cationic iridium complex and a PF_6^- counterion. Both the PF_6^- ions are disordered occupying in both cases two geometrically independent positions. The site occupancy factors were refined with restrains on U_{ij} to values of 0.49:0.51 and 0.48:0.52, respectively. The positions of all hydrogen atoms were calculated according to ideal geometry and refined by using the riding method. Conventional R = 0.0461 [for 4470 reflections with $I > 2\sigma(I)$], and weighted wR_2 = 0.1342 for all 5964 located reflections; reflection/parameter ratio 10.0; residual electron density +1.997/−2.739 eÅ^{-3}.

Crystallographic data (excluding structure factors) for **5** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-169995. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347), BASF AG, and the Fonds der Chemischen Industrie. We are also grateful to the latter in particular for a PhD grant (to K. I.). Moreover, we thank Mrs. R. Schedl and Mr. C. P. Kneis (DTA and elemental analysis), Mrs. M.-L Schäfer and Dr. W. Buchner (NMR spectra), and Dr. J. Wolf for helpful advice.

Seven-Coordinate d^0 and d^{10} Ions − Computational and Experimental Studies on Tris(tropolonato)metal(III)−TOPO Adducts

Jerzy Narbutt,*[a] Marian Czerwiński,[b] and Jadwiga Krejzler[a]

Keywords: Chelates / Thallium / Yttrium / Coordination chemistry / Density-functional calculations / Hypervalent compounds

The stabilities of molecular adducts between tris(tropolonato)metal(III) chelates of some tripositive ions of Groups 3 and 13 and trioctylphosphane oxide (TOPO) were studied using both theoretical and experimental methods. Density-functional calculations were used to optimise the structure and characterise tris(tropolonates) of scandium and yttrium, a series of model chelates of gallium, indium, thallium, scandium, and yttrium, as well as the 1:1 adducts of these chelates with trimethylphosphane oxide. The calculated energy of adduct formation decreased in the order: Y > Sc > Tl > In. Stability constants of the 1:1 (and some 1:2) TOPO adducts in solution, determined by synergistic solvent extraction of metal tropolonates, decreased in the same order. Both methods show that gallium does not increase its coordination number (CN) above six. The chelates of d^{10} ions (CN 6) and their adducts (CN 7) are less stable than the corresponding d^0 species, because the former are hypervalent compounds with no higher-lying metal *n*d orbitals participating in bonding, while the latter have easily accessible vacant $(n-1)$d orbitals. A significant distortion of the chelate structure makes the adducts of smaller ions less stable. Examination of bonding molecular orbitals in the adducts shows an unusual origin of the metal–TOPO bond, which may be due to a contribution from π-bonding. Differences in some characteristics of indium and thallium compounds can be explained by relativistic properties of thallium.

Introduction

Metal ions with high coordination numbers (CN) continue to attract interest,[1,2] and the reason is not purely academic. The ability of a metal ion in a complex to increase its CN makes it possible to form inner-sphere adducts, to exchange ligands by an associative mechanism, to affect catalytic properties of the compound, etc. Inner-sphere solvation of metal complexes influences their behaviour in solution, which is of importance in different fields such as e.g. metal ion controlled biological processes and processes of separation of metal ions.

The coordination stereochemistry of metal complexes depends on the relations between geometrical and electrostatic factors on one side, and the electronic configuration of the metal ions on the other.[3] Geometrical models consider not only the size of the metal ion and ligand atoms, but also the ligand structure.[3,4] For example, the bite in rigid bidentate ligands and the intraligand strain affect the coordination environment of the ion.[3,5,6] Electrostatic metal−ligand attraction and ligand−ligand repulsion in the coordination polyhedron, which depend on the charges on the ion and on the ligand atoms, also affect the geometry of the complex and the strength of metal−ligand bonds. Generally, the weaker and longer the bonds, i.e. the easier the deformation of the coordination polyhedron, the greater the tendency to increase the CN by coordination of (an) additional ligand(s).[7] For less stable metal chelates, the role of ligand structure, in particular of bite size, is less pronounced.[6] The electronic configuration of the metal ion is also important in this connection. The effect of d-orbital population in transition metal ions on their CN was recently discussed in terms of the angular overlap model.[2]

The major objective of this work was to explain how the tendency to increase CN of a central metal ion in neutral chelates with bidentate ligands is influenced by properties of the ion, in particular its radius and electron configuration. Particularly interesting in this respect was the comparison of d^{10} and d^0 ions whose $(n-1)$d orbitals were either completely filled or vacant. We expected that d^0 ions with $(n-1)$d orbitals easily accessible for hybridisation would attain CN = 7 more readily than d^{10} ions with distant vacant *n*d orbitals.[8]

The metal ions selected were trivalent gallium, indium, and thallium from Group 13, as well as scandium and yttrium from Group 3. The tropolonate anion, $C_7H_5O_2^-$ − a short-bite bidentate ligand − made it possible for the ions to reach CN > 6.[6] Trioctylphosphane oxide (TOPO) − a very strong electron donor − was an auxiliary neutral monodentate ligand. Practical interest in studying such systems stemmed from the application of indium tropolonates and other α-diketonates for labelling blood cells with radioindium to be used in nuclear medicine,[9] while gallium tro-

polonate was not effective in this respect.[10] Other reasons for our interest were relativistic properties of thallium and scarcity of data on its mixed-ligand complexes.[1,11,12]

Both quantum chemistry calculations and an experimental technique were used in our studies. Theoretical calculations based on Density-Functional Theory (DFT), particularly suitable for studying metal complexes,[13] were carried out for the chelates and adducts. We obtained information on their structure, energy and charge distribution, and verified our hypothesis on the role of electronic configuration of the ion. The calculated (DFT) energies of adduct formation correlate well with the experimental stability constants of the metal tropolonate − TOPO adducts in solution, determined by solvent extraction, and considered as a measure of the tendency of a metal ion to increase its CN over six.

Computational Details

Density-functional calculations were carried out both on the metal(III) tris(chelates) (CN = 6) and on their 1:1 adducts (CN = 7). To save computer resources, only two tris(-tropolonato)metal(III) structures were optimised, and then the whole system was modelled. In order to reproduce symmetry of chelate rings in tris(chelato)metal(III) complexes, as well as their quasi-aromatic character (in the original complex they are coupled with the seven-membered ring of tropolone) the simple bidentate anionic ligand O−CH=CH−O$^-$ (denoted as αdik)[14] was selected as a model for tropolonate, while trimethylphosphane oxide (denoted as TMPO or B) replaced TOPO. Additionally, to check the reliability of the model with the radical anionic ligand another system was studied consisting of Sc and Y chelates (and their TMPO adducts) with a molecular ligand, O=CH−CH$_2$−O$^-$. All the calculations were based on the DFT method as implemented in the GAUSSIAN-94 program.[15] The Lanl2dz double-ζ basis set,[16] Becke three-parameter functional (B3LYP),[17] and Berny geometry-optimisation algorithm[18] were used. The charge density was obtained from Mulliken overlap and bonding population analysis.[19] The calculations were performed by using relativistic effective core potential, which retained the outer shells (e.g. $5d^{10}6s^26p^1$ shells of the Tl atom) in the valence space, replacing the rest of electrons by relativistic effective potentials. The basis sets for the metals were supplemented with polarisation functions taken from Andzelm et al.[20]

CAS SCF Calculations

In order to evaluate the tendency of the d^0 and d^{10} ions to reach a valence state corresponding to CN = 7, we carried out multi-configurational self-consistent-field calculations with the complete active space self-consistent-field (CAS SCF)[21] approach. Promotion energies, defined as differences between the calculated energies of the ground and excited states, were calculated for single isolated atoms. The active space with seven electrons distributed over eight orbitals was taken for the CAS SCF calculations; this led to 2352 configuration states. The calculations were carried out for the ground state and the two lowest excited states of the atoms, of total multiplicity two. All the numerical calculations were carried out using supercomputers: Cray T3E, Cray J90, and Cray Y-MP.

Results

Geometry Optimisation and Charge Distribution

Firstly the optimisations of geometry of the chelates [ML$_3$] (where L = trop or αdik; Table 1), of a free TMPO molecule, and of their adducts [ML$_3$·TMPO] (Table 2) were performed. The coordination polyhedra of the chelates were D_3-twisted trigonal antiprisms (Figure 1a).

Optimisation of systems consisting of [ML$_3$] and TMPO, starting with the previously optimised structures, resulted in stable [ML$_3$·TMPO] adducts with CN = 7, of significantly distorted structures for Sc, Y, In, and Tl^{III} ions (Figure 1b). The smallest Ga^{III} ion preserved a CN = 6 in the adduct by breaking one of the six Ga−O^L bonds (Table 2).

Formation of the M−O^B bond was accompanied by a charge (electron density) transfer from TMPO to [ML$_3$]. Its magnitude is given by the Δq value (Table 2), which is equal to the total charge on each of the two components in the

adduct. The dipole moments of the adducts were much greater than that of TMPO alone, and the TMPO molecule in the adduct was strongly polarised. In the Supporting Information the computed coordinates and total charges of all atoms in the Sc, Y, (Ga), In, and Tl^{III} chelates and adducts studied, the dipole moments, and other data are reported.

Energy Calculations

Energies of Chelate Formation and Adduct Formation and Their Components

The respective ΔE_{ch} and ΔE_{ad} values were calculated after full optimisation of all the components, and computing their total energies with the same Lanl2dz basis set. The use of polarisation functions had little effect on the results of the calculations (Table 3, footnote c).

The bond analysis developed by Ziegler and Rauk[24] made possible an insight into the character of metal−ligand interactions in the complexes studied. The energy of adduct formation could be separated into contributions related to the energy of structure distortion, ΔE_d, for both components of the adduct, and the energy of interaction, ΔE_{int}, between the distorted components. In our system, $\Delta E_{d,ch}$ reflects significant changes in the chelate structure upon adduct formation, involving rearrangement of the first coordination sphere of the metal ion, and $\Delta E_{d,B}$ − a slight deformation of the TMPO structure when in the adduct. Further separation of the ΔE_{int} term is also possible into orbital interaction energies (charge transfer) and steric interactions (Pauli repulsion and Coulomb electrostatic terms), the former being the main stabilising factor in some adducts [Equation (1)].[25]

$$\Delta E_{ad} = \Delta E_{d,ch} + \Delta E_{d,B} + \Delta E_{int} \quad (1)$$

The values $\Delta E_{d,ch}$ and $\Delta E_{d,B}$ were calculated (Table 3) as the differences between the total bond energies of the [M(αdik)$_3$] (and TMPO) molecules in their distorted and optimised structures.[26] The ΔE_{int} values were obtained with the use of Equation (1). However, because these values might be in error due to calculating their components with the use of different basis sets, we independently calculated another set of $\Delta E_{int}'$ values, equal to the differences between the total energies of the adduct and of its subunits −

Table 3. Calculated (GAUSSIAN 94 with potential B3LYP in the basis Lanl2dz) formation energies of chelates and adducts [M(αdik)$_3$·TMPO], distortion energies of the chelates and TMPO, and the energy of interaction between the components of the adducts

Chelate	ΔE_{ch}	ΔE_{ad} [a]	$\Delta E_{d,ch}$	$\Delta E_{d,B}$	ΔE_{int}	$\Delta E_{int}'$	E^{σ} [b]	E^{π} [c]

chelate and TMPO − all in the same structure, optimised for the adduct.[27] The results, except for thallium where the procedure was not convergent, are presented in Table 3. The reasonable agreement between both sets of data makes the ΔE_{int} values convincing.

Promotion Energies

Data were calculated for the metal atoms by using the CAS SCF method. The ground and excited states of each atom are well represented by single determinants (the coefficients of the SCF configurations being greater than 0.8). The ground state was characterised by the $s^2p^3d^2$ configuration, the excited states by $s^2p^2d^3$. High values of ca 330 kJ mol^{-1}, corresponding to the transfer of one electron from the ground-state p orbital to the lowest excited-state d orbital, were obtained for isolated atoms of In and Tl. In contrast, the respective values for the Group 3 atoms were either much lower (ca 100 kJ mol^{-1} for Sc), or even negative (−5 kJ mol^{-1} for Y). In our opinion, the difference between the above data obtained for the d- and p-block metal atoms well characterises the change CN = 6 → CN = 7, which relates to the formation of the 1:1 TOPO adducts by the respective chelates.

Molecular Orbitals

In order to characterise the [ML$_3$]−TMPO bonds by the electron density localised in the bond region, i.e. between the O^B and M atoms (q_{M-O^B} Table 2), the population and the energy of all occupied molecular orbitals (MO) in the adducts were calculated after full optimisation of the structures. To find the original MOs of [M(αdik)$_3$] and TMPO, which contribute to formation of the adduct bond, the respective data including some vacant MOs were also calculated for TMPO and the chelates. All the calculated MOs of the chelates and TMPO (Supporting Information), and of the adducts (Figure 2) were examined with the use of MOLDEN,[28] a program for visualisation. Tables 1 and 2 show M−O bond populations in the chelates and adducts, respectively, and Table 3 shows the average energies of bonding MOs (σ and π) in the adducts.

Solvent Extraction Studies

Solvent extraction is a technique particularly useful for characterising molecular adducts formed in solution by amphiphilic neutral metal chelates and neutral hydrophobic ligands, e.g. TOPO.[6] If a metal ion, M^{m+}, and a bidentate organic ligand in the anionic form, L^-, in aqueous solution combine, the neutral chelate formed, ML_m, may then be transferred to an immiscible organic phase on bringing the solutions into contact. The equilibrium can be described by an extraction constant, where square brackets denote the molar concentrations[29] of the given species, and subscripts "org" and "aq" refer to the organic and aqueous phase, respectively [Equation (2)].

$$K_{ex} = \frac{[ML_m]_{org}[H^+]^m_{aq}}{[M^{m+}]_{aq}[HL]^m_{org}} \quad (2)$$

The transfer can be enhanced by formation (in the organic phase; the subscripts omitted) of molecular adducts [ML_m·iB] where B denotes an auxiliary neutral hydrophobic ligand, e.g. TOPO [Equation (3)].

$$ML_m + iB \rightleftarrows ML_m \cdot iB \quad (3)$$

The stability constants, $\beta_{m,i}$, of the adducts, equal to the equilibrium constants of reactions (3), are expressed in terms of molar concentrations, assuming the solution to be ideal associated. This assumption is reasonable in view of trace concentration of the chelate. The distribution ratio of the metal is given by Equation (4).

$$D = \frac{[ML_m]_{org} + \sum_i [ML_m \cdot iB]_{org}}{[M^{m+}]_{aq} + \sum_j [ML_j^{m-j}]_{aq}} \quad (4)$$

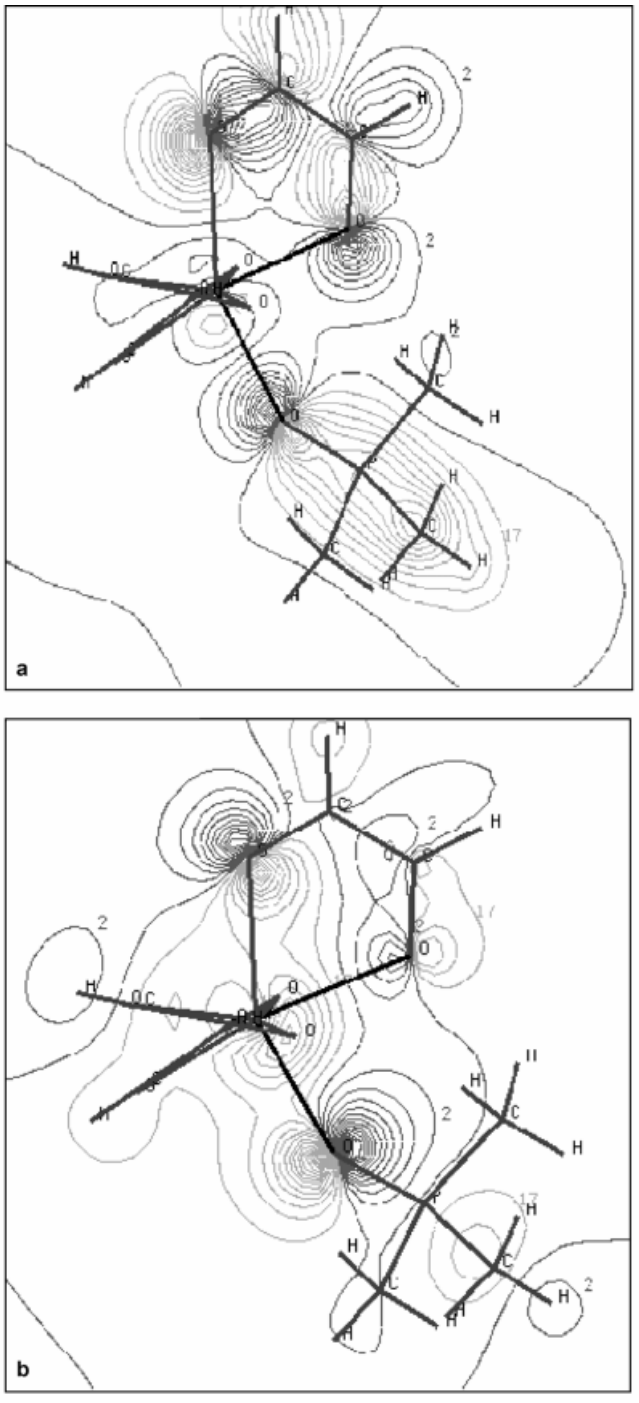

Figure 2. 3D contours of selected bonding molecular orbitals in the [Y(αdik)$_3$·TMPO] adduct: (a) σ symmetry, $E = -0.4006$ a.u.; (b) π symmetry, $E = -0.2874$ a.u.

In the case of two adducts ML_m·B and ML_m·2B predominating in the organic phase Equation (4) can be rearranged to Equation (5), where D_0 denotes the distribution ratio in the absence of TOPO in the system, and [B] − the molar concentration of free TOPO in the organic phase at equilibrium.

Only in the case of gallium, which is extracted from HCl solutions as solvates, $Ga(TOPO)_nCl_3$, D_0 denotes the distribution ratio at the same TOPO concentration, but in the absence of tropolone in the system. In the cases when D was independent of pH and of the concentration of HL (plateau region, when the only form of the metal in the aqueous phase was the uncharged chelate, ML_m), D_0 was equal to partition constant, P, defined as the ratio of molar concentrations of ML_m in both phases. The chelate partition constants were determined directly for Sc and Y, and indirectly for Tl as specified below. The distribution ratio D of thallium(III) has been found to decrease with time. After a fast decrease during the first few minutes, reflecting the transfer of Tl(trop)$_3$ from the organic to the aqueous phase, a further continuous, but rather slow drop in D was observed, with the rate practically constant (the half-time being 13−16 min) in the pH range studied (2.0−4.6). This slow decrease was presumably due to the hydration of the uncharged chelate molecule in the aqueous phase, followed by fast hydrolysis of the hydrated thallium(III) species. The hydration is a first-order reaction, followed by further fast transfer of Tl(trop)$_3$ from the organic to the aqueous phase to sustain the transient equilibrium described with the equilibrium constant $P = [Tl(trop)_3]_{org}\,[Tl(trop)_3]_{aq}^{-1}$. The transfer is thus a first-order reaction as well, and the organic phase concentration of the chelate is (in the interval of the continuous slow drop in D) a function of time (t): $[Tl(trop)_3]_{org} = C^0 \cdot e^{-\lambda t}$, where C^0 is an extrapolated value equal to a hypothetical concentration of the chelate in the organic phase at time zero, assuming the hydration had not started, but the transfer equilibrium had already been established. Provided that the volumes of the organic and aqueous phases are equal to each other, $P = C^0(C_{tot} - C^0)^{-1}$, where C_{tot} denotes the real initial concentration of the chelate in the organic phase. Extrapolation of the experimental $\log[Tl(trop)_3]_{org}$ values to $t = 0$ from the time interval where the dependence was found linear, made it possible for us to evaluate the partition constant for [Tl(trop)$_3$], and the "true" distribution constants when TOPO was present in the system.

$$\frac{D}{D_0} = 1 + \beta_{m,1}[B] + \beta_{m,2}[B]^2 \quad (5)$$

Figure 3 shows the logarithms of the relative distribution ratios, $\log(D/D_0)$ or $\log(D/P)$, of metal tropolonates studied, plotted against the total TOPO concentration (C_B). The solid curves are the best-fit functions (weighted least squares), except for the highest C_B values for Tl and Y. The observed increase in D with increasing TOPO concentration means that the chelates, except for [Ga(trop)$_3$],[30] formed adducts with TOPO. However, because of significant tropolone−TOPO association in the organic phase:

$$HL + B \xrightarrow{K_{as}} HL \cdot B \quad (6)$$

where K_{as} denotes the association constant, $[B] < C_B$ and therefore, to calculate adduct stability constants, we must

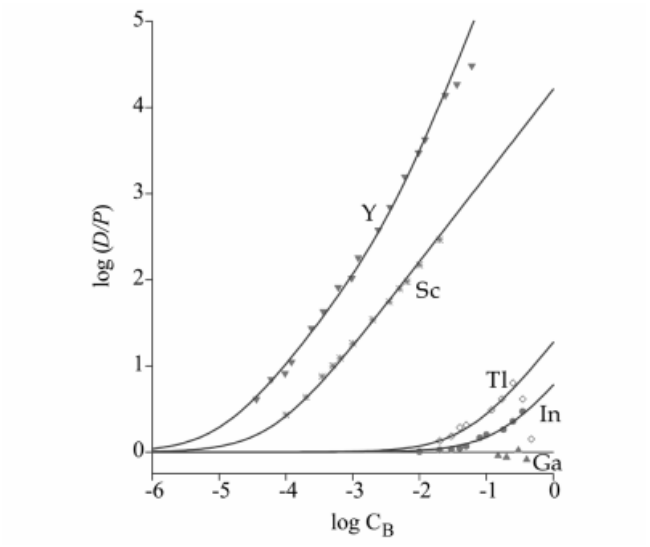

Figure 3. Effect of total molar concentration of TOPO, C_B, on the distribution of tropolonates of gallium, indium, and thallium(III) between carbon tetrachloride and various aqueous phases, and tropolonates of scandium and yttrium between toluene and water at 298.2 K (see Exp. Sect.); in the case of In and Ga, P denotes the distribution ratio, D_0, determined in the absence of either TOPO or tropolone, respectively; the solid lines are the best-fit curves

account for this effect. In contrast, we may neglect a decrease in TOPO concentration due to adduct formation, because of the large excess of TOPO with respect to the metal ions. Thus, the actual [B] values can be calculated[31] as a function of C_{HL}, C_B, K_{as}, and P_{HL}, where C_{HL} denotes the total concentration of tropolone, and P_{HL} – its partition constant (at low experimental pH the dissociation of tropolone in the aqueous phase is negligible). The P_{HL} values were either determined spectrophotometrically (3.9 for the CCl_4/water system), or evaluated (10 for toluene/water). The association constants of the tropolone–TOPO adduct were either determined from the distribution data[32] of tropolone in the solvent–TOPO/water system at pH = 2 (K_{as} = 2.7 ± 0.3 mol^{-1} dm^3 in CCl_4), or estimated based on the former value and on the data of ref.[32] (K_{as} = 5 mol^{-1} dm^3 in toluene).

Equation (5) correctly describes the system when the changes in the concentration of B do not affect the $M^{n+} \rightleftarrows ML_n$ equilibrium, i.e. where $D_0 = P$, which is the case for Sc, Y, and Tl. The decrease in the concentration of free tropolone, [HL], in the experiments with In(trop)$_3$ results (at low pH) in some dissociation of the chelate, accompanied by a decrease in the D values. That is because at sufficiently low pH, when the concentration of any charged chelate, $[ML_j]^{m-j}$, in the aqueous phase is negligible in relation to M^{m+}, the extraction equilibrium can be described with the Equation (7) obtained by the transformation of Equation (2).

$$D = K_{ex}[HL]_{org}^{m}[H^+]_{aq}^{-m} \quad (7)$$

The TOPO–tropolone association decreases the original $[HL]_{org,0}$ value to $[HL]_{org}$, therefore the values $D[HL]_{org}^{-m}[H^+]_{aq}^{m}$ and $D_0[HL]_{org,0}^{-m}[H^+]_{aq,0}^{m}$, are to be substituted for D and D_0, respectively, in Equation (5).[31] With this substitution, and assuming that (1) D and D_0 were measured at the same pH, (2) only one TOPO–tropolone associate (1:1) was formed in the organic phase, and (3) a large excess of HL existed with respect to M^{m+}; we could rearrange Equation (5) to Equation (8).

$$\frac{D}{D_0}\left(\frac{C_{HL}}{C_{HL} - C_B + [B]}\right)^m = 1 + \beta_{m,1}[B] + \beta_{m,2}[B]^2 \quad (8)$$

The stability constants (Table 4) were calculated in this way by putting free TOPO concentrations for [B], and by weighted least-squares fitting, Equation (5) for Sc^{3+}, Y^{3+}, and Tl^{3+} ions; and Equation (8) for In^{3+}.

Discussion

Reliability of the Model

The αdik ligand has 23 valence electrons, but their number on the four atoms (O and C) in the 5-membered chelate ring, 21, is the same as that in the tropolonate ligand which has the even number of all valence electrons. The αdik ligand has a high symmetry in the optimised chelate structure, the same as the tropolonate ligand. Although the optimised structures of [M(αdik)$_3$] and [M(trop)$_3$] chelates (M = Sc, Y) and the charge distribution on their atoms had appeared similar (Table 1), a question arose, as to whether the αdik ligand, a radical, was a reliable model for tropolonate. Additional calculations were thus carried out for scandium and yttrium chelates with another similar ligand, O=CH–CH$_2$–O$^-$ (L′), which has an even number of electrons. However, the optimised 5-membered chelate rings formed by L′ appeared asymmetric, with the M–O$^{L'}$ distances differing by ca. 20% from each other, and also with two different C–O distances. Two hydrogen atoms at one of the carbon atoms were located out-of-plane of the ligand rings. Also some other differences between [ML′$_3$] and [M(trop)$_3$], greater than those between [M(αdik)$_3$] and [M(trop)$_3$], allowed us to conclude that the αdik ligand, although a radical, is a good model for tropolonate, and is better than L′.

Another question concerns the possible inadequacy of the computation method used for thallium, the heavy relativistic metal. In fact, the DFT calculations with the use of pseudo-relativistic potentials can hardly be considered as fully relativistic, and their use for heavy metal compounds may result in, e.g. overestimated metal–ligand distances.[33] At the moment, the quality of the computation method used can be verified indirectly (see below). As long as fully relativistic calculations in such extensive systems are extremely troublesome and time consuming, we have to accept the results obtained.

Table 4. Experimental values of partition constants of metal tropolonates, stability constants of their adducts with TOPO, and Gibbs free energies of the 1:1 adducts formation (25 °C, molar concentration scale; energies in kJ mol^{-1}; the uncertainties are equal to two standard deviations)

Chelate	Solvent	P	log $\beta_{3,1}$ [a]	log $\beta_{3,2}$ [a]	ΔG_{ad} (1:1)
$Sc(trop)_3$ [b]	toluene	0.381 ± 0.007	4.27 ± 0.03	− [c]	−24.4 ± 0.2
$Y(trop)_3$	toluene	0.0020 ± 0.0003	4.99 ± 0.05	7.39 ± 0.08	−28.5 ± 0.3
$Ga(trop)_3$	CCl_4	38 ± 3	no adduct	−	−
$In(trop)_3$	CCl_4	39 ± 3	0.97 ± 0.10	1.86 ± 0.10	−5.5 ± 0.6
$Tl(trop)_3$	CCl_4	6.8 ± 0.7	1.35 ± 0.08	(0.3 ± 5.9)[c]	−7.7 ± 0.4

[a] Calculated using Equation (5) for Sc, Y, and Tl, and Equation (8) for In. [b] The data from ref.[6], corrected for TOPO−tropolone association. [c] The $\beta_{3,2}$ value could not be determined because of either insufficient TOPO concentration in the experiment (Sc) or the antagonistic effect in solvent extraction at higher TOPO concentrations (Tl).

Structures

The optimised distances and angles in $[Sc(trop)_3]$ correspond very well with the experimental data for the crystalline complex (Table 1). A good agreement was also found between the parameters calculated for $[M(\alpha dik)_3]$ chelates (M = Sc, Ga, In) and the experimental data for crystalline tropolonates[22] and other α-diketonates.[34] Because of no experimental data are available for α-diketonates of thallium(III) (and Y), their aqua complexes can be used for comparison. The $Tl^{III}-O$ distance calculated for $[Tl(\alpha dik)_3]$ is greater (by 4%) than the experimental values in octahedral hexahydrates, both in solution and in the solid (221 to 225.5 pm[35]), while the corresponding differences for Sc,[36] Ga, and In[37] (Y forms octahydrates) are smaller, below 2%.

The analysis of the optimised coordination polyhedra in the adducts (CN = 7)[5] shows that TMPO attacks the chelate molecule (CN = 6; D_3) from the side of its open trigonal face. The coordination of the seventh ligand is accompanied by significant rearrangements in the chelate structure (Table 2). To make room for this ligand, the three αdik ligands have to be contracted, turned, and spread apart (Figure 1b), followed by a decrease in their bite angles and an elongation of the $M-O^L$ bonds. The chelate rings are nonsymmetrically deformed, the three $M-O^L$ bonds adjacent to the $M-O^B$ bond being elongated much more than those opposite the bond were. The extent of distortion of chelate molecules depends on the metal ion radius. The smallest distortion has been found for chelates of large Tl^{3+} and Y^{3+}; the angle between two αdik ligands (medians) adjacent to the $M-O^B$ bond increased by ca 15% in relation to the original one (120°) in the chelates. There are three short (290−320 pm) O^B-O^L distances, one intermediate (330−336 pm), and two long (390−450 pm) in the distorted structures (intermediate between C_{3v} and C_{2v}). For the intermediate-size In^{3+} and Sc^{3+}, the angle between the two αdik ligands increased by ca 22%. There are three or four short (280−310 pm) O^B-O^L distances, one or two intermediate (340−365 pm), and one long (ca 415 pm) in the distorted structures (intermediate between C_{2v} and D_{5h}).

According to the calculations, binding of TMPO by the smallest Ga^{3+} ion in $[Ga(\alpha dik)_3]$ is accompanied by breaking one $Ga-O^L$ bond and opening the chelate ring. Such a picture has not been experimentally confirmed for $[Ga(trop)_3]$, but has been confirmed for another, less stable chelate $[Ga(tta)_3]$ (Htta = 2-thenoyltrifluoroacetone), which forms a TOPO adduct.[31] In no case Ga^{3+} increases its CN to seven. The nonexistence of $[Ga(trop)_3]$−TOPO adducts may explain the difference in the ability of tris(tropolonates) of gallium and indium to label blood cells[9,10] by an associative reaction within the cell.

Energies

We expected the energy of $[ML_3]$ formation to be affected by two factors: (1) the charge-to-radius ratio of the metal ion, and (2) the availability of vacant d orbitals of the metal ion for hybridisation to a valence state corresponding to CN = 6. The order of decreasing ΔE_{ch} values calculated for the $[M(\alpha dik)_3]$ chelates, Sc > Y > Ga > In > Tl (Table 3), shows that the d^0 ions form much more stable chelates than d^{10} ions, while the expected decrease in chelate stability with increasing ionic radius can be observed only within each group. Thus, the effect of electron configuration prevails over that of radius.

The calculated ΔE_{ad} values give the following order of adduct stability in the gas phase: In < Tl < Sc < Y. This sequence reproduces the experimental order of Gibbs free energies of adduct formation in solution,[38] $\Delta G_{ad} = -RT \ln \beta_{3,1}$. The differences between the ΔE_{ad} and ΔG_{ad} values result from the differences in the reaction media, temperature (0 and 273.2 K), and above all from the entropy term that contributes to ΔG_{ad} only, and can be large.[39] With all these differences, the correlation between ΔE_{ad} for $[M(\alpha dik)_3]$ and ΔG_{ad} for $[M(trop)_3]$ (Tables 3 and 4) is quite reasonable. Moreover, the differences between the values for the two tropolonates (of yttrium and scandium), $\Delta(\Delta E_{ad}) = -5.5$ kJ mol^{-1} and $\Delta(\Delta G_{ad}) = -4.2$ kJ mol^{-1}, are fairly similar.

The experimental data on the 1:1 and 1:2 TOPO adducts of metal tropolonates (CN = 7 and 8) correspond well with the data on anionic $[M(trop)_4]^-$ complexes;[6,40] more stable for Y and Sc, and less stable for In.[40] Much greater stability of the adducts of the d-block than p-block metal ions betokens the primary importance of electron config-

uration of the metal center. Only further, in each group, is the adduct stability differentiated according to the radii of metal ions. Moreover, the sequences of ΔE_{ad} values are reversed when compared with those of ΔE_{ch}, i.e. the effect of ionic radius on the stability of the adducts (CN = 7) is opposite to that observed for the chelates (CN = 6).[41] This can be explained in terms of differences in distortion energies of the chelates formed by small and large ions of the same charges upon coordination of the seventh ligand. These differences are due to stronger $M-O^L$ bonds and the lesser flexibility of ligands in the chelates of small ions.[6] Greater distortion energies observed for the chelates of small ions (Sc, In) compared to those of large ions (Y, Tl) (Table 3) overcompensate the stronger attraction of the ligand by the small cations.

Character of the M−O Bonds; Hypervalence

Less stable $[ML_3]$ chelates and $[ML_3{\cdot}TMPO]$ adducts of the d^{10} ions do not necessarily imply that the high-lying (cf. the calculated promotion energies) virtual *n*d orbitals of the $(n-1)d^{10}$ ions participate in bonding. General considerations suggest that the use of these distant *n*d orbitals in bonding is unlikely.[42] Molecular orbitals of such a complex with e.g. six ligands can be formed using only four orbitals of the central ion (s and p) and six ligand orbitals. Thus, four bonding and four antibonding MOs are formed, and the two ligand orbitals remain nonbonding. This results in a lowering of the average bond order and a decrease in the electron population in the $M-O^L$ bond region, therefore in less stable hypervalent (or hypercoordinate) complexes.[42] The binding of the seventh ligand to the hypervalent chelate should additionally decrease the electron population of the $M-O^L$ bonds in the adduct by $^1/_7$. This has been observed for In and Tl, where the $M-O^L$ populations in the TMPO adducts are about 14% less than those in the corresponding chelates (Tables 1 and 2), in contrast to the Sc and Y adducts, where the $M-O^L$ populations remain practically the same as those in the chelates. Therefore, we suppose that the adducts formed by In and Tl chelates are also hypercoordinate, with their bonding MOs formed only from the *n*s and *n*p orbitals of the d^{10} ions, with no participation of either filled $(n-1)$d or virtual *n*d orbitals. In contrast, Sc and Y chelates form stronger "normal" adducts with seven bonding MOs in which the vacant $(n-1)$d orbitals of the metal do participate. Indeed, the analysis of charge distribution on the metal ions (q_M in Tables 1 and 2) shows that the d-block ions accept some electron density from TMPO in the adducts, in contrast to the p-block metals that increase their positive charge in the adducts. Also, the analysis of the electron population of basis metal AOs contributing to bonding ($M-O^L$) MOs in the chelates betokens a contribution from the d orbitals of scandium and yttrium, but none from those of indium and thallium. The same has been observed in the case of the adducts ($M-O^B$ bonding). The expansion coefficients of the bonding MOs show that the d orbitals of Sc and Y in the adducts accept practically the whole charge equal to the difference (ca. 0.03 a.u.) between the Δq values calculated for the adducts of d-block and p-block metals (Table 2).

Rather high electron population in the $In-O^L$ bonds (the population on the $Tl-O^L$ bonds is low, as expected) can be explained in terms of incomplete screening from nuclear charge by the filled d^{10} shell, which increases the effective charge on the p-block ion, and also the population of the bonds. This is in line with the high negative $\Delta E_{d,ch}$ and ΔE_{int} values for In (Table 3). The lack of unoccupied $(n-1)$d indium orbitals able to accept the electron density makes the $M-O^L$ charge separation in $[In(\alpha dik)_3]$ the highest (Table 1), i.e. the smallest shift of electron density from the ligands to the metal ion. On the other hand, particularly strong stabilisation of thallium 6s and $6p_{1/2}$ orbitals, due to the presence of filled 4f shell and relativistic effects,[43] should result in a greater shift of electron density from the ligands to these orbitals, which is the reason for the low positive charge on the Tl^{III} ion in the chelate, and for the small electron population of the $Tl-O^L$ bonds.

In all the adducts, the $M-O^B$ bond is significantly shorter than the $M-O^L$ bonds, though this is not reflected in the bond populations (Table 2). A possible reason for shortening the $M-O^B$ bond is its partially π-bond character, as discussed below. Its lower electron population can be due in turn to the lack of charge on the TMPO ligand, whereas the αdik ligands are negatively charged. In any case, the In and Tl adducts studied give us an interesting case of hypervalent bonding strengthened by π-bonding.

Molecular Orbitals

The examination of the system, by means of MOLDEN, shows that there exist sets of lower lying multi-centred bonding MOs of σ symmetry, responsible for the formation of TMPO adducts of yttrium and scandium chelates. In the yttrium adduct, these strongly bonding MOs (ca. −1.0 a.u.) are formed from the MOs of the chelate (−0.957 a.u.) and TMPO (−0.923 a.u.), with the contribution from AOs of the metal (s and p, ca. 25%) and oxygen atoms only. In the scandium adduct, these MOs (ca. −1.3 a.u.) are weakly bonding because they are formed almost entirely from the metal orbitals. The indium and thallium adducts have no bonding MOs in the region of lower energies. The only orbitals in the latter (ca. −0.75 a.u.) are practically pure, occupied AOs (d) of thallium, while there is no contribution from indium AOs in the former.

In all the adducts there are higher lying (ca. −0.41 a.u.) bonding MOs of σ symmetry (Figure 2a). They are more strongly delocalised (apart from mainly the O atoms, they also extend to the C atoms), and are formed with the participation of occupied orbitals of σ symmetry, the HOMO (ca. −0.22 a.u.) of the chelates and the HOMO−2 (−0.3317 a.u.) of TMPO. Unexpectedly, the latter does not describe a lone electron pair on the O^B atom, but the σ-electron pair of the O=P bond. The energy gain is due to redistribution of the electron densities of both MOs over the delocalised orbitals. This rather unusual picture can be explained assuming that (1) the lone electron pairs on the O^B atom participate in another bonding, and (2) the O^B

atom changes its valence state and hybridisation from sp^2 in the free TMPO molecule to sp^3 or rather sp^m in the adduct (*m* is a fractional value smaller than 3). The former assumption is in line with the short O^B-O^L distances. The latter explains why the shift of electron density from the P=O to the $M-O^B$ bond region is large (Table 2). The most important, however, is the observation that the contribution from the metal AOs to these multi-centred bonding MOs in the adducts is quite different for the d- and p-block metals. This contribution is equal to about 7% from the d orbitals of Sc and Y, but none from those of In and Tl, in line with the hypothesis of hypervalent character of their adducts.

The expected additional bonding between TMPO and the chelates has been exemplified by another set of bonding MOs found in each adduct, higher lying (ca. −0.29 a.u.), of symmetry typical for π-type interactions (Figure 2b). These MOs are greatly delocalised; their electron density extends over the whole adduct molecule, in particular the O^B and O^L atoms. These MOs are formed from orbitals of the same symmetry, presumably with the chelate LUMO localised mainly on the O^L atoms (ca. −0.13 a.u.), and the TMPO doubly degenerate HOMO (−0.2336 a.u.) that accommodates two lone electron pairs localised on the TMPO oxygen atom. This π-type interaction between the two lone electron pairs and the αdik ligands enhances the deformation of the adduct molecule and increases the MOP angle to 130−140°, as calculated.

The energies of both σ- and π-type bonding MOs in the adducts (Table 3) are closer to the energies of the original MOs in TMPO, not in the chelates. This is in line with the earlier conclusion (based on Δq values) that the TMPO electrons are mainly responsible for the TMPO − chelate bonding. The moderate asymmetry of this bond together with the results of bond population analysis (Table 2) shows that both the extent of covalence and of the ionic character determine the bond character.

Conclusions

Both density-functional calculations and experimental data show that the coordination number of the central metal ion in the studied neutral chelates with bidentate ligands increases from six to seven (or even eight) upon formation of inner-sphere molecular adducts with a monodentate strong electron-donor ligand. Noteworthy is a good correspondence between the computational and experimental data both in structural parameters of the chelates and in the energies of adduct formation. The method used permits not only the calculation of reasonable values of the energies, but also their separation into contributions related to mutual interactions of electron clouds of both components, and to the structural distortion of the components that accompany adduct formation.

The tendency to increase the CN from 6 to 7 depends strongly on the metal ion, in particular on its radius and electron configuration − the larger the radius, i.e. the larger the space accessible to the seventh donor atom, the smaller the energy required for distortion of the chelate structure, and in consequence the greater the tendency to form adducts. The energy of chelate distortion strongly differentiates the metal ions with respect to adduct stability. If the ion is too small, the chelate does not form adducts at all, as exemplified by gallium tropolonate.

On the other hand, much greater tendency to increase the CN by metal ions of d-block than those of p-block points out the problem of high energy gaps between the *n*s, *n*p, and *n*d orbitals, which is not the case with empty $(n-1)$d orbitals in the d^0 ions. High promotion energy makes it rather unlikely that the distant virtual *n*d orbitals could be used for hybridisation, corresponding to CN = 5 and more. Instead, the assumption on the formation by p-block metal ions of hypervalent compounds, with no participation in bonding of metal d orbitals, satisfactorily explains why the chelates (CN = 6) of d^{10} metal ions and their TOPO adducts (CN = 7 or 8) are less stable than the related compounds of d^0 ions.

The analysis of the molecular orbitals calculated for the adducts and for their components allows the identification of the orbitals contributing to adduct formation, and the description of the bond between the components as having both σ- and π-type character. The σ-type bond is formed with no participation of the lone electron pair on the donor oxygen atom in the TOPO molecule but of another pair already engaged in double bonding, therefore, in order to form the bond, the oxygen atom must change its original hybridisation. The π-type bonds are formed by transferring electron density from the lone electron pairs of the TOPO oxygen atom to the vacant orbitals on the donor oxygen atoms of the bidentate ligands. This additional π-bonding strengthens the bond and stabilises the adduct.

Some unexpected characteristics calculated for the compounds of d^{10} ions, especially of indium, are probably due to the occupancy of the metal $(n-1)$d orbitals, which hinder the transfer of electron density to the metal ions, in contrast to the compounds of d^0 ions. Quite effective transfer of electron density to the thallium(III) ion can be explained in terms of the relativistic properties of this heavy metal.

Experimental Section

General Remarks: Distribution ratios were calculated from direct measurements of specific radioactivity of both phases using an NaI(Tl) well-type detector (^{72}Ga and ^{114m}In), and a Geiger−Müller counter (^{90}Y, ^{204}Tl). The radiotracers were supplied by the Centre for Isotope Production at Swierk, Poland. Tropolone, 1-hydroxycyclohepta-3,5,7-trien-2-one, Htrop (98%, Aldrich), was used as received. TOPO (p.a., Merck) was purified[6] by repeated (up to six times) washing its concentrated stock solutions in heptane or toluene with 5% aqueous sodium carbonate solution and water. Carbon tetrachloride (p.a., POCh Gliwice) was washed and distilled. Toluene (p.a., POCh Gliwice) was used as received. Doubly distilled water was used throughout. Distribution of tropolone between water (pH = 2) and carbon tetrachloride (+ TOPO) was studied by shaking the solutions followed by absorbance measurements of

dilute aqueous solutions of tropolone (original and at equilibrium) in quartz cells at 345 nm at pH = 1. − pH: Orion 720A with a glass-calomel combination electrode calibrated against standard reference buffers. UV/Vis: Beckman DU-68.

Solvent Extraction Procedure: The organic phase was prepared immediately before extraction. After the radiotracer was added to the equilibrated aqueous phase, the pH was adjusted with either H_2SO_4 (Tl: pH = 2.6) or HCl (Ga: 2 mol dm^{-3}; In: pH = 1.5; Y: pH = 4.5) and the system was re-equilibrated. Thallium(I) was previously oxidised in 2 mol dm^{-3} H_2SO_4 with $Na_2S_2O_8$ (10^{-3} mol dm^{-3} Ag^+).[44] The concentration of indium and thallium carriers was kept in the range 10^{-5}−10^{-4} mol dm^{-3}, that of scandium and gallium in the range 10^{-6}−10^{-5} mol dm^{-3}, and ^{90}Y was carrier-free. The initial concentration of tropolone in carbon tetrachloride was either 0.1 mol dm^{-3} (Tl) or 0.01 mol dm^{-3} (Ga and In), and in toluene either 0.01 mol dm^{-3} (Y) or 0.02 mol dm^{-3} (Sc). The phases were shaken for 30 min until the distribution equilibrium was attained, separated, and then the specific activities of aliquots were measured. The loaded (Sc, In) organic phase was contacted again with a freshly pre-equilibrated aqueous phase containing no metal and the procedure was repeated. The *D* values (see Supporting Information) determined in both extraction and back-extraction steps differed from each other by less than 5%.

The partition constant and "true" distribution ratios for Tl(trop)$_3$ were determined in back-extraction experiments with the thallium-loaded organic phase and fresh, no thallium-containing, aqueous phase of pH ≈ 2.6. The phases were continually shaken and the aliquot samples were collected at ca. 5−10 min intervals in the range from 10 to 45 min (see Supporting Information). Partition constants of the other tropolonates have been determined independently in the plateau regions,[6] i.e. $4 < pH < 6$. The data for scandium are taken from our recent paper.[6] The extraction experiments were carried out at 298.2 ± 0.2 K.

Acknowledgments

We thank Professor J. Konarski (Poznan) and Dr. J. Burgess (Leicester) for their critical reading of the manuscript and for valuable comments. The research was supported in part originally by the Polish Committee for Scientific Research (KBN) under grant nr. 3 T09A 016 09 and then by the Institute of Nuclear Chemistry and Technology. The numerical calculations were carried out at the Interdisciplinary Centre for Mathematical and Computational Modelling, Warsaw, and the Poznan Supercomputing & Networking Centre. We acknowledge obtaining access to the computer resources and the kind cooperation of the staff.

[14] Neither the double bond nor the negative charge was fixed on the ligand; the electron density was distributed on the atoms of the chelate in the course of the optimisation procedure.

[26] The total energies of the distorted structures were calculated for both components of the same geometry as they had in the adduct with the optimised structure. This means that all the atoms belonging to one of the adduct components were removed, preserving the interatomic distances and angles in the other, and then the energy was calculated for the remaining system of total charge equal to zero. Then the same procedure was repeated for the other component.
[27] The total energies of the adduct components (subunits − chelate and TMPO) were calculated after moving away the subunits (the distance of 600 pm was thought sufficient to neglect the effects of all interactions between the two components − electrostatic, charge transfer etc.) In this new system the M−O^B bond was broken, but the geometry of the subunits was maintained the same as that in the adduct. The total charges (Δq) on all the atoms of the separated subunits were equal to zero, contrary to the case when in the adduct.

[29] This concentration extraction constant correctly describes the system, provided the concentrations are low enough and the activity coefficients are close to one.
[30] Under the conditions of the experiment with gallium (2 mol dm^{-3} HCl as the aqueous phase) not only [Ga(trop)$_3$], but also solvated chloride, [$GaCl_3$·3TOPO], was extracted into the organic phase at higher TOPO concentrations. After deducting the contribution from the latter from the *D* values, we obtained

a set of corrected D values for gallium, each very close to D_0 (equal to 0.905) over the whole range of TOPO concentrations studied (Figure 2). This shows that [Ga(trop)$_3$] formed no TOPO adducts.

[38] The differences in log$\beta_{3,1}$ caused by the use of either toluene (when studying Sc and Y chelates) or CCl_4 (In and Tl chelates) may be neglected because the expected corrections are probably less than 0.2 unit (see ref.[32]).

[41] This inverse relationship between the stability of the chelates (CN = 6) and of their adducts (CN = 7) is in line with the general empirical rule "the stronger chelate the weaker its adduct", well known in solvent extraction (ref.[7]).
