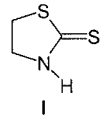
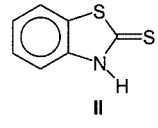
The adduct bond formation between a donor (sulfur atom in the present case) and diiodine stabilizes the lone pair of electrons of the donor by mixing its orbital with the σ* anti-bonding orbital of I_2.[20] As a result a sulfur−iodine dative bond forms and the double bond of the thione group and also the iodine−iodine bonds[4,6] are lengthened. A direct relationship was found to exist between these three bond lengths: if *d*(S−I) is short, then *d*(C−S) and *d*(I−I) will be long and the donation is considered strong; for weak complexes, the situation is reversed.[4,6] In addition the ν(I−I) frequencies are linearly correlated with *d*(I−I) bond lengths.[12]

It is also worth noting that a partial positive charge is imparted to the rest of the molecule by the lengthening of the double bond of the thione group *d*(C−S).[4] Therefore, thioamides are particularly good donors; the positive charge is easily supported by nitrogen atoms (especially if it contains alkyl groups). Generally, the greater the stabilizing ability of the *N*-alkyl or -aryl groups, the stronger the resulting diiodine complex will be.[4] Similar behavior is expected in the case of molecules containing 1,3-dithiole sulfur atoms, such that the positive charge is delocalized over the S−C−S fragment of the ring, forming a 6π pseudo-aromatic system.[7]

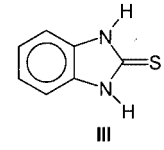
In this paper, we report the structural and spectroscopic characterization of four new diiodine complexes with the heterocyclic thioamides, thiazolidine-2-thione or mercaptothiazoline (tzdtH, **I**), benzothiazole-2-thione (bztzdtH, **II**) and benzimidazole-2-thione (bzimtH, **III**) of formulae $[\{(tzdtH)_2I^+\}\cdot I_3^-\cdot 2I_2]$ (**1**), $[\{(bztzdtH)I_2\}\cdot I_2]$ (**2**), $[(bztzdtH)I_2]$ (**3**) and $[\{(bzimtH)I_2\}_2\cdot I_2\cdot 2H_2O]$ (**4**).



I



II



III

TzdtH (**I**) has been used in the treatment of hyper-thyroidism and our aim was to investigate its behavior in the reaction with diiodine. The ligands bztzdtH (**II**) and bzimtH (**III**), on the other hand, were also used for comparison purposes. Formation constant measurements of all these ligands with diiodine have been reported previously[8,9,21,22] in organic solvents, but always assuming the formation of 1:1 complexes in solution. No structural and/or spectroscopic studies have ever been reported previously. The structure of compound **1** shows that the ligand tzdtH, with anti-thyroidal activity, easily forms iodonium salts and is able to retain a total of four diiodine molecules per ligand molecule, thus acting as an iodine sponge. This is the first anti-thyroidal agent ever reported which contains an I_3^- counterion and interacts and retains two more diiodine molecules.

2. Results and Discussion

2.1. General Aspects

Studies on the interaction of thione donors with diiodine have established three types of adducts in the solid state, as proposed by Deplano et al.[5,10,23] These are type D···I−I (**A**) with long D···I and short I−I bond lengths,[24,25] type D−I−I (**B**) with comparable D−I and I−I distances[14,26] and type $D-I^+\cdots I^-$ (**C**) with short D−I and long I···I distances.[16] In type **A**,[5,10] the UV/Vis spectra show both the known charge-transfer band and the blue-shifted diiodine and donor bands, while the Raman ν(I−I) band appears in the range 180−140 cm^{-1}. In type **B**,[5,10] two peaks due to ν_{asym}(I−I) and ν_{sym}(I−I) are observed in the Raman spectra while in type **C** there is only one peak due to the ν(D−I) vibration.

In addition, reduction of iodine to polyiodides by electron transfer to the diiodine from the donor may also take place, together with the formation of iodonium salts with I^+ linearly bound to two donor molecules.[11,12,17] D·*n*I_2 complexes may also form where the bonded I_2 molecule interacts with the other diiodine molecules.[11,16,27,28]

In our case, thiazolidine-2-thione causes the heterolytic cleavage of the I−I bond resulting in the formation of the $S-I^+-S$ and I_3^- as a counter anion. This is a rather rare structure and the second according to the best of our knowledge of an anti-thyroidal agent, the first being the one with thiourea (tu).[29] The two other ligands, benzothiazole-2-thione and benzimidazole-2-thione form compounds of stoichiometry DI_2 and $(DI_2)I_2$ (D is the thione donor) of **B** and **C** types.

Thiazolidine-2-thione could be considered as a strong donor towards diiodine, while benzothiazole-2-thione or benzimidazole-2-thione as weaker such donors. This is expected,[8] since in the last two cases, the sulfur atom is part of an aromatic system.

The formulae of the synthesized complexes **1**, **2**, **3** and **4** were first deduced from elemental analyses and spectroscopic data. All complexes were highly soluble in organic solvents and their crystals were stable in air but were stored in darkness in a refrigerator.

2.2. Crystal and Molecular Structures

[{(tzdtH)$_2$I$^+$}·I$_3^-$·2I$_2$] (1)

An ORTEP diagram of compound **1** is shown in Figure 1 while selected bond lengths and angles are given in Table 1. There are only a few crystal structures reported in the literature containing $S-I^+-S$ dimers. These include 1,3-dimethyl-2-thiourea (dmtu), ethylenethiouria (etu) thiourea (tu) and *N*-methylbenzothiazole-2-thione (mbzttH).[4,12,16,29]

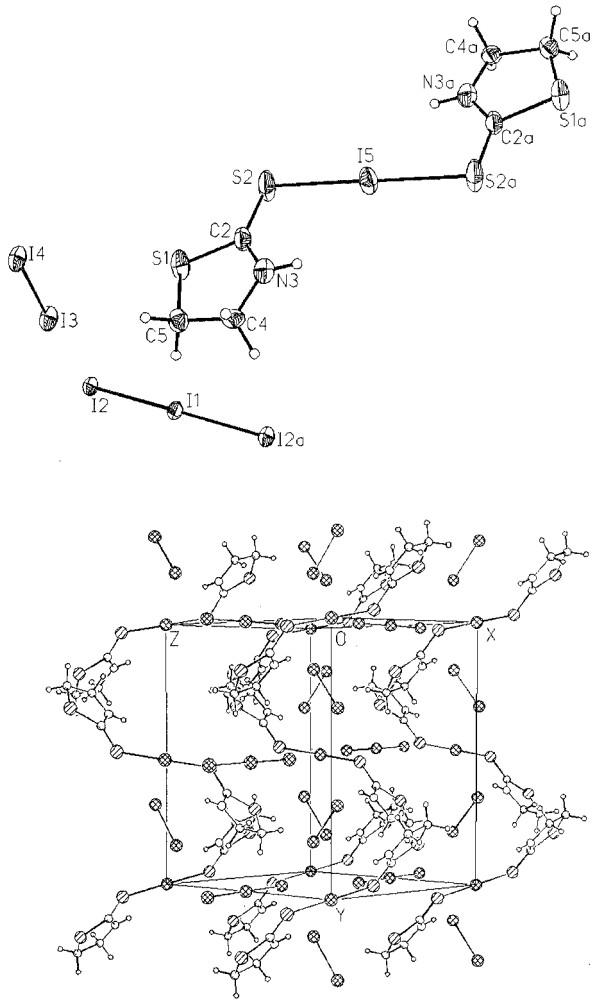


Figure 1. ORTEP diagram and unit cell of **1** together with the atomic numbering scheme

Table 1. Selected bond lengths [Å] and angles [°] for **1** with e.s.d. values in parentheses

Bond lengths:	
I(1)−I(2)	2.9195(14)
I(3)−I(4)	2.741(2)
I(5)−S(2)	2.654(6)
N(3)···I(4)[a]	3.82(2)
N(3)−H(3)	0.860(19)
H(3)[N(3)]···I(5)	2.9336(6)
N(3)···I(5)	3.495(19)
Bond angles:	
I(2)−I(1)−I(2)[b]	180.0
S(2)−I(5)−S(2)[c]	180.0
N(3)−H(3)···I(4)[a]	140

[a] $x + 1, y, z$. [b] $-x, -y, -z + 1$. [c] $-x + 1, -y + 1, -z + 1$.

The structure of compound **1** consists of three residues, one cationic $\{(tzdtH)_2I^+\}$, containing the linear S−I$^+$−S linkage, one I_3^- counter anion and two independent diiodine molecules, shown only in the packing diagram of Figure 1. More similar structures including metal complexes have also been reported.[12] Comparison of various structural parameters of known iodonium complexes are reported in Table 2.

Both S−I bond lengths are equal to 2.654(6) Å. These bond lengths compare well with the corresponding distances found in $\{[(dmtu)_2I]\}$ [2.602(4) and 2.654(4) Å],[4] in $[(tu)_2I^+]$ 2.629 Å [29] and in $[(mbzttH)_2I^+]$ [I−S = 2.600(2) and 2.634(2) Å].[12] They are, however, significantly longer than the ones in (etu)·I$^+$ of 2.487(3) Å.[16] The S(2)−C(2) bond length of the complex **1** (Figure 1) is only 1.65(3) Å which is among the shortest such distances ever reported (Table 2).

The N(3)−C(2)−S(2)−I(5) torsion angle (Figure 1) is 9(3)° indicating an almost co-planar arrangement of the iodine atom towards the plane of N−C=S bond. The corresponding torsion angle found in $\{[(tu)_2I^+]I^-\}$ is 17°, again almost co-planar, presumably due to the short intramolecular I···H or I···N distances.[29]

An intramolecular hydrogen bond between the imino NH proton and the sulfur atom coordinated to the iodine atom is formed in **1** (Figure 1) {H(3)[N(3)]···I(5) = 2.9336(6) and N(3)···I(5) = 3.495(19) Å}.[30] This hydrogen bonding favors the planar structure.[9]

The I(1)−I(2) bond length (Figure 1) of the linear I_3^- counter anion is 2.9195(14) Å, slightly longer than the corresponding bond lengths measured in $\{[(dmtu)_2I][I_3^-]\}$ [I−I = 2.8874(14) and 2.9082(14) Å[4]]. Two diiodine mole-

[a] This work. [b] dmtu = 1,3-dimethyl-2-thiourea, etu = ethylenethiourea, tu = thiourea, mbzttH = *N*-methylbenzothiazole-2-thione.

cules are also co-crystallized with an I(3)−I(4) bond length of 2.741(2) Å (Figure 1). Weak intermolecular interactions ($I_3^-\cdots I_2$), shorter than the sum of iodine van der Waals radii have been measured[30] between I(3)···I(2) (3.4220 Å) and I(4)···I(2) (3.4120 Å) and are longer than the corresponding $I^-\cdots I$ interactions between I^- and I_2 species found in $\{[(mbzttH)_2I^+][I^-\cdot 3I_2]\}$ [3.237(1), 3.260(1) and 3.242(1) Å].[12]

[{(bztzdtH)I_2}·I_2] (2), [(bztzdtH)I_2] (3) and [{(bzimtH)I_2}$_2$·I_2·H_2O] (4)

ORTEP diagrams of molecules **2**, **3** and **4** are shown in Figures 2−4, respectively, while selected bond lengths and angles are given in Tables 3−5.

The crystal structures of molecules **2**, **3** and **4** consist of a thione ligand, bonded with a diiodine atom through a sulfur atom with S−I = 2.587(5) Å in **2** (Figure 2), S−I = 2.728(6) Å in **3** (Figure 3) and 2.571(6) Å in **4** (Figure 4), respectively. The corresponding I−I bonds are lengthened with values of I−I = 2.969(2) Å in **2** (Figure 2), I−I = 3.077(2) Å in **3** (Figure 3) and I−I = 2.989(2) Å in **4** (Figure 4) as compared with the I−I distances in the gas phase (2.677 Å),[14,31] or in crystalline diiodine (2.717 Å at 110 K),[14,32] as a result of the S···I interaction. Table 6 compares structural parameters of compounds **2**, **3** and **4** with other compounds of similar structures.

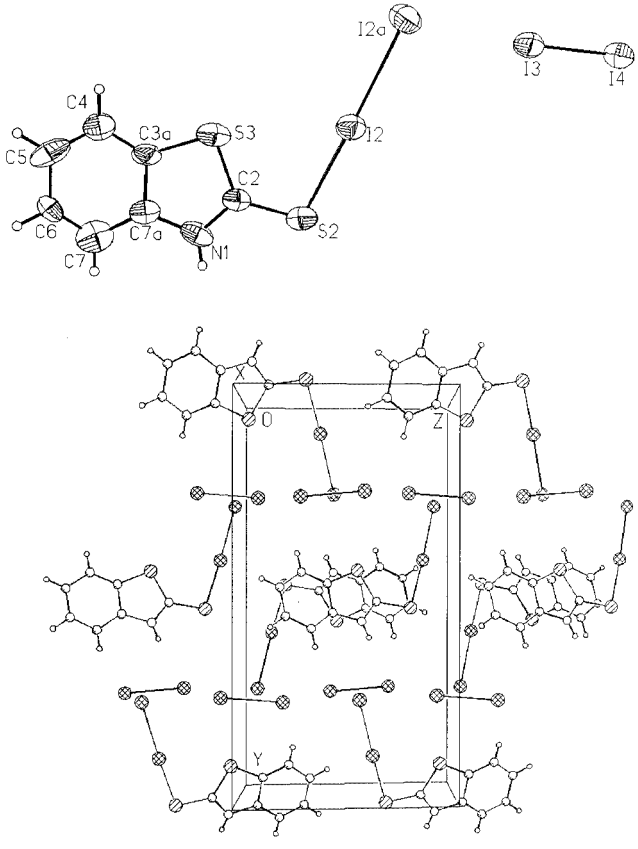

Figure 2. ORTEP diagram and unit cell of **2** together with the atomic numbering scheme

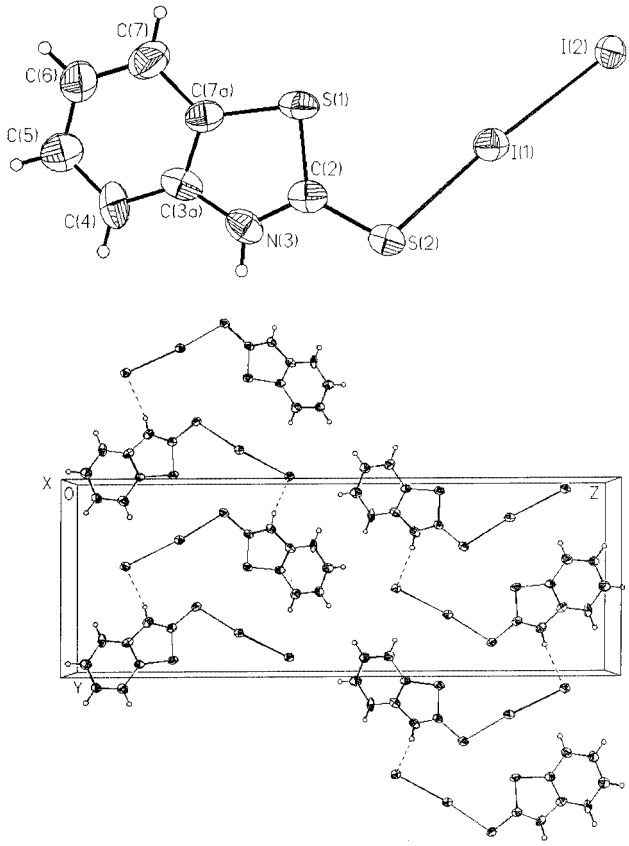

Figure 3. ORTEP diagram and unit cell of **3** together with the atomic numbering scheme

All bond lengths are within the expected ranges, however, the S−I bond length of molecule **2** is the shortest ever reported. The ligand donation leads to the formation of a neutral complex. The I−I bond lengths, all longer than the corresponding distance in free diiodine, are the longest ever measured for compounds **3** and **4**.

An extended intramolecular hydrogen bonding H(3)[N(3)]···I(2) = 2.7865(16) with N(3)···I(2) = 3.597(19) Å (Figure 3) is also formed in complex **3**. In the case of complex **4**, an intramolecular I(2)···H(4)[C(4)] = 3.2540 Å interaction[30] (Figure 4) leads to the formation of dimers, while an extended hydrogen-bonding network H(12w)[O(12)w]··· N(3) = 1.9033 Å, O(1w)··· N(3) = 2.846(19) Å[30] (Figure 4) links the alternate parallel dimers forming a supramolecular assembly.

The X−C=S···I torsion angles for the complexes were S(3)−C(2)−S(2)−I(2) = −2.3(12)° for **2** , S(1)−C(2)−S(2)−I(2) = −15.6(14)° for **3** and N(1)−C(2)−S(1)−I(3) = 3.0(19)° for **4**. Thus, all compounds, including **1** can be considered of almost coplanar arrangements of iodine atoms towards the N−C=S bond planes.

Finally, the values for the S−I−I angles (Table 6) also imply an almost linear arrangement.

2.3. Spectroscopy

UV/Vis

The visible spectra of the thione−diiodine adducts in dichloromethane or chloroform exhibit one distinct absorption band at 495−505 nm which is assigned to the "blue-shift" band of I_2,[18] which occurs at 504 nm in free I_2 in CH_2Cl_2.[14] A shoulder in the range of 310−360 nm could be assigned to a charge-transfer band from the HOMO of the donor to the diiodine LUMO (σ_π*)[5,8−10,17]. Complex **1** exhibits a c.t. band at 317 nm, while complex **4** shows a c.t. band at 356 nm. It should be noted that the c.t. bands are not recognizable for complexes **2−3**, most probably as a result of interference from the intraligand transitions occurring at almost the same wavelength. The bands, however, are enhanced in intensity, increasing their coefficients, in the complexes.

Table 5. Selected bond lengths [Å] and angles [°] for **4** with e.s.d. values in parentheses

Bond lengths:	
I(1)−I(1)[a]	2.767(3)
I(2)−I(3)	2.989(2)
I(3)−S(1)	2.571(6)
N(1)···I(3)	3.471(8)
O(1)W···O(1)W[b]	2.78(2)
O(1)W···N(3)[c]	2.77(3)
Bond angles:	
S(1)−I(3)−I(2)	176.76(14)
C(2)−S(1)−I(3)	102.3(8)
N(1)−H(1)···I(3)	119
O(1)W−H(1)W(1)···O(1)W[b]	171
O(1)W−H(1)W(2)···N(3)[c]	170

[a] $-x, -y+1, -z+1$. [b] $1-x, -1/2+y, 3/2-z$. [c] $x, 3/2-y, 1/2+z$.

According to the assumption of Laurence et al.,[9] c.t. absorption bands of I_2−thioamide complexes have been correlated with an in-plane or a perpendicular arrangement of the I_2 moiety towards the plane of N−C=S and this hypothesis is also followed by the thiocarbonyl−I_2 adduct studied by Essefar et al.[3] Thus, complexes of thiocarbonyl−I_2 or I_2−thioamide with in-plane conformation, where the X−C=S···I torsion angle was close to 0°, have shown the c.t. band at 295−305 nm while those with perpendicular arrangements with the angle near 90° have shown this band around 320−350 nm.[3,9] Generally, perpendicular complexes are expected when the substituents around the thiocarbonyl group are bulky[9] while a planar arrangement is expected when an NH group *cis* to the thiocarbonyl group exists.[3] Thus, for all our complexes coplanar arrangements are expected since they all contain the *cis*-NH group, able to form hydrogen bonds with I_2.

Since the X−C=S···I torsion angle for compound **1** is 9(3)° and for **4** is 3.0(19)°, the results of Laurence et al.[9] as well as Esseffar et al.[3] seem to be confirmed for **1** but unexpectedly not for **4**. The absorption band at 283 nm in the spectrum of complex **1**, at 329 nm in the case of complex **2**, at 329.5 nm for **3** and at 309.5 nm for **4** are attributed to intraligand (π→π*) transitions.

Vibrational Spectroscopy

Characteristic infrared bands of the complexes and the ligands are listed in Table 7. The spectra of the complexes

[a] This work.

show distinct vibrational bands between 1520−1480 and 1330−1210 cm^{-1}, which can be assigned to ν(CN) vibrations (thioamide I and II bands) and 1020−990 and 850−740 cm^{-1}, which can be attributed to the ν(CS) vibrations (thioamide III and IV bands). Amide N−H bond vibrations were observed at 3434−3204 cm^{-1} in CH_2Cl_2. According to Laurence et al.,[9] the ν(NH) band of I_2−thioamide complexes in CH_2Cl_2 shifts to lower wavenumbers and it is more intense in the planar complexes than in the perpendicular ones (torsion angle X−C=S···I). This is due to the amphoteric behavior of I^+, which can simultaneously accept electrons from the sulfur atom and offer electrons to the hydrogen atom of the N−H group, thus forming an intramolecular hydrogen bond.[9]

In our case, N−H···I hydrogen bonds exist in complexes **1**, **3** and **4**. In CH_2Cl_2 solutions, the band assignable to ν(N−H) appears in the IR spectrum of complex **1** at 3325 cm^{-1}, while the ligand tzdtH shows also two bands for the same vibration at 3396, and 3233 cm^{-1} assigned to its free and associated forms.[9] The band of the free form shifts by 71 cm^{-1} to lower wavenumbers in **1**. In **4** the shift of 55 cm^{-1} is towards lower wavenumbers (3379 cm^{-1} for **4**, 3434 cm^{-1} for bzimtH), in accordance with its structure. However, the ν(N−H) band of the free form of the ligand bztzdtH at 3379 cm^{-1} ν(N−H) appears as a unique band at 3372 cm^{-1} in both **2** and **3** complexes shifted again to lower wavenumbers (7 cm^{-1}) in accordance with the literature.[9] In the solid state the situation is even more complicated, since all bands shift to higher wavenumbers on passing from the free ligands to the complexes.

New bands appearing at 155 cm^{-1} in the far-IR spectra of the compounds may be assigned to the ν(I−I) stretching vibration modes.[34] The corresponding ν(I−S) bond vibration for the dithian−I_2 complex, was observed at 212 cm^{-1}.[34] In our compounds, new bands appear around 281−280 cm^{-1} and 255−254 cm^{-1} which can be similarly assigned (Figure 5).

Characteristic Raman frequencies of the compounds are also included in Table 7. Diiodine vapor gives a strong band at 216 cm^{-1} ν(I−I) which appears at 180 cm^{-1} in the solid state.[35] This shifts to lower wavenumbers upon coordination to a donor atom, reflecting the reduction in the I−I bond order and the strengthening of the complex formed.[5,10,12]

Thus, the Raman spectrum of complex **1**, recorded in the 300−50 cm^{-1} region, shows a doublet at 181.5 and 178.0

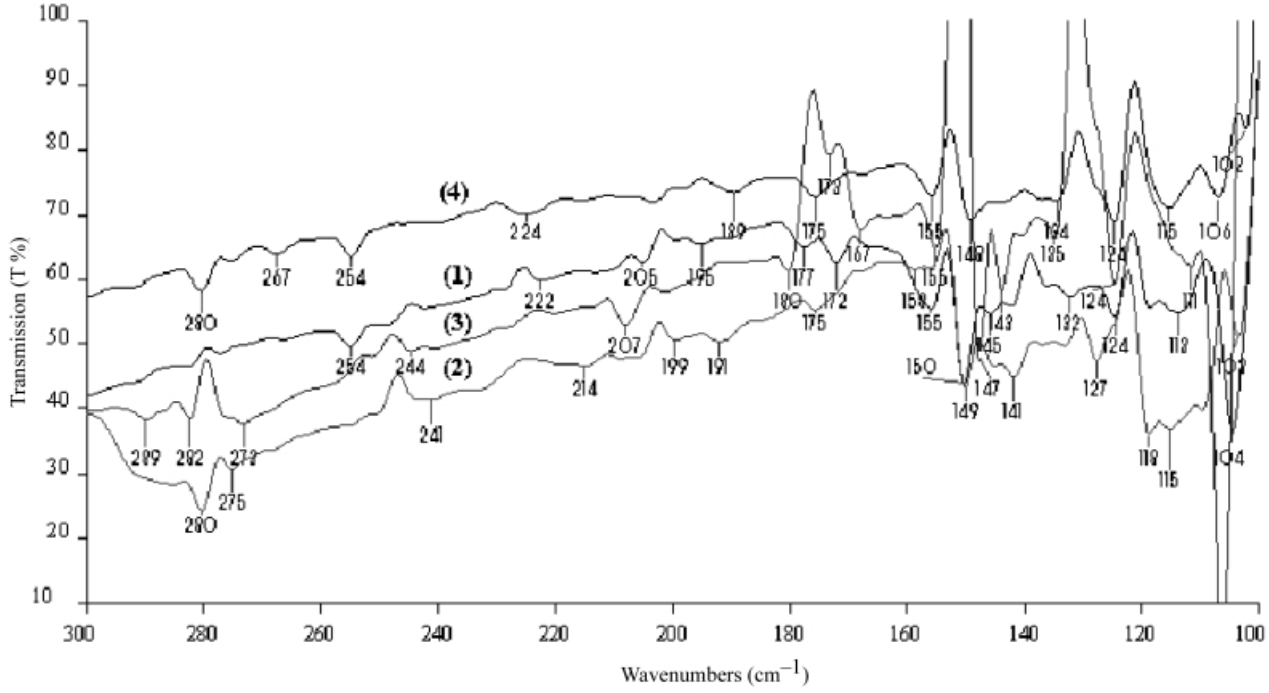

Figure 5. Far-IR spectra of the complexes

cm^{-1}, very close to that usually reported for the symmetric stretching [ν_1(I−I)] of I_2 in the solid state, which may be attributed to the uncoordinated I_2 that cocrystallizes. The I−I bond length of 2.715 Å, measured in free diiodine,[32] is slightly lengthened to 2.741 Å in **1**, justifying this shifting (Table 2). It is worth mentioning that bands around 110 cm^{-1} are normally attributed to the ν_1 symmetric stretching of I_3^-, which being a symmetrical ion normally exhibits only one Raman-active band. Antisymmetric stretching and bending is only infrared-active. When a distortion of I_3^- occurs, the antisymmetric stretching may become Raman-active and additional bands of medium intensity near 140−130 and 80−70 cm^{-1} can be observed, assigned to antisymmetric stretching (ν_3) and ν_2 deformation, respectively.[24,26] Thus, the intense band at 116.8 cm^{-1} is indicative of the presence of I_3^- ions. Similar assignments have also been reported in the literature: 172 cm^{-1} [strong, ν(I−I)], 150 (medium) and 105cm^{-1} [strong, $\nu(I_3^-)$][15,36] for interacting I_3^- and I_2 units. Furthermore the shoulder at 153.3 cm^{-1} might be attributed to the δ(C−S−I) bend, which has already been reported at 150 cm^{-1}.[37] Moreover, δ(C−S−I) bends are reported to be less intense than [ν_1(I−I)]. Therefore, it is very likely that the shoulder at 153.5 cm^{-1} might also be attributed to I, bridging both of the (tzdtH) moieties, in our case.

The Raman spectrum of complex **2** is characterized by an intense band at 172.8 cm^{-1}, attributed to ν_1(I−I) of the I_2 counterpart [I(3)−I(4), Figure 2]. The band at 143.7 cm^{-1} may also be attributed, to coordinated I_2 moieties (Figure 2). Structural assignments from Raman spectra indicate that complex **2** follows the pattern of the D−I−I (**B**-type) adducts[5] which is also in agreement with the relatively shorter S−I and longer I−I bonds measured for **2** by X-ray crystallography (see section 2.2).

The Raman spectrum of complex **3** shows a band at 147 cm^{-1} which can be attributed to ν_1(I−I) symmetric stretching. Considering the magnitude of the shift from free I_2 of 33 cm^{-1} for complex **3** and of 36.3 cm^{-1} for complex **2**, it can be said that the species generated in adduct formation are much effective.

Bands around 150 cm^{-1} were also reported in the literature for I_2 adducts: 152 cm^{-1} (5,5-dimethylimidazolidine-2,4-dithionediiodine),[24] 147 cm^{-1} {4,5,6,7-tetrathiocino[1,2-*b*:3,4-*b'*]diimidazolyl-1,3,8,10-tetraethyl-2,9-dithionebis(diiodine)},[38] 158 cm^{-1} (5,5-dimethyl-4-oxoimidazolidine-2-thionediiodine),[24] 152 and 158 cm^{-1} (5,5-dimethylimidazoline-2,4-dithione and 5,5-dimethyl-4-oxo-2-thioxoimidazolidium, respectively).[24] Finally, the presence of free I_2 is detected in the Raman spectrum of complex **4** as a shoulder at 170 cm^{-1}.

Resonance Raman (RR) uses visible laser excitation sources − which may induce fluorescence, sample pyrolysis, and photoreactions − and spurious peaks, could appear in the spectrum.[39a] Studies comparing FT-Raman and RR spectroscopy have shown remarkable advantages of the former since it eliminates or strongly reduces the pyrolysis of the samples.[39b]

The RR spectra of complex **1** were obtained, using laser sources, 488.0 and 514.5 nm. Bands at 220 cm^{-1} observed in RR have been attributed to I_2 in the gas phase arising from decomposition.[39c] The band observed in the present case (256.8 cm^{-1}) at a much higher frequency, is attributed to I_2 (vapor).

The large band centered at 100 cm^{-1} can be attributed to I_3^- species. In the case of the 514.5 nm line, the spectrum is dominated by a peak at 112.6 cm^{-1} (I_3^-). A large band centered at 167.9 cm^{-1} might be attributed to an I_2 interacting species. The high intensity observed for the 112.6 cm^{-1} band could be due to I_2 disproportionation. Nevertheless, enhancement of this band has already been reported in the literature and attributed to the resonance effect.[39c]

The RR spectra of complex **2** at 488.0 nm showed very low intensity, presenting a cut-off below 50 cm^{-1}. At 514.5 cm^{-1}, we observed an enhancement of the peak at 107 cm^{-1} ($2\nu = 212$ cm^{-1}), and a shoulder at 158.2 cm^{-1}. Once again, the detection of a band relating to I_3^- could either be considered as an RR effect or as the generation of I_3^- species by decomposition. As in the previous case, the RR spectrum using the 488.0-nm line led to a very low intensity spectrum in the case of complex **3**, presenting a cut-off below 50 cm^{-1}. In the case of 514.5-nm excitation, bands at 172 cm^{-1} and 107 cm^{-1} dominate the spectrum in the low-frequency region. It is worth noting the presence of the band at 172 cm^{-1} attributed to I_2, which was absent when an NIR source was used. For this system, the ν(C−H) region as well as the skeleton region (not shown) seemed to be unaffected. The spectra of complex **4** showed no band in the case of the 488.0-nm source. With the 514.5-nm line, an intense band was observed at 107.0 cm^{-1} ($2\nu = 214.9$ cm^{-1}; $3\nu = 328.3$ cm^{-1}), attributable to an I_3^- species which may be generated by the decomposition of complex **4**. As in the previous case, a cut-off below 50 cm^{-1} was shown in the case of 663 nm line.

2.4. Correlations

The S−I bond strength of the iodine charge transfer complexes could be classified by the graphical plots of *d*(C=S) vs. *d*(S−I) [see (a) in Figure 6] or *d*(I−I) vs. *d*(S−I) [see (b) in Figure 6].[4] Ionic complexes exhibit short S−I bond lengths, due to the strong interaction between the iodine and sulfur atoms [see (a) in Figure 6], which seems to be independent from the C=S bond length. For charge transfer complexes with an S−I−I structure, a hyperbolic correlation between *d*(S−I) vs. *d*(I−I) has been proposed[16] which is also confirmed for the complexes **2** and **4** but not for **3** [see (b) in Figure 6]. Additionally *d*(I−I) is linearly correlated to the FT-Raman ν(I−I) frequencies[24] confirmed for complexes **2** and **3** (Figure 7).

According to the value of the I−I bond order (*n*) defined by the Pauling Equation,[31] where d_o is the I−I bond length of I_2 in the gas phase, which is 2.67 Å,[40] Deplano et al.[24] and Bigoli et al.[5] classified I_2 adducts in three classes, type **A** (D···I−I), **B** (D−I−I) and **C** (D−I···I).[10,24]

$$d(\mathrm{I{-}I}) = d_o - 0.85\cdot\log(n)$$

If the value of the I−I bond order $n \geq 0.6$ [d(I−I) < 2.85 Å] the adduct could be classified as a type **A**, while if $n \leq 0.4$ [d(I−I) > 3.01 Å] as a type **C**. The I−I bond order values calculated for the complexes studied in this work are 0.445, 0.332 and 0.421 for the complexes **2**, **3**, and **4**, re-

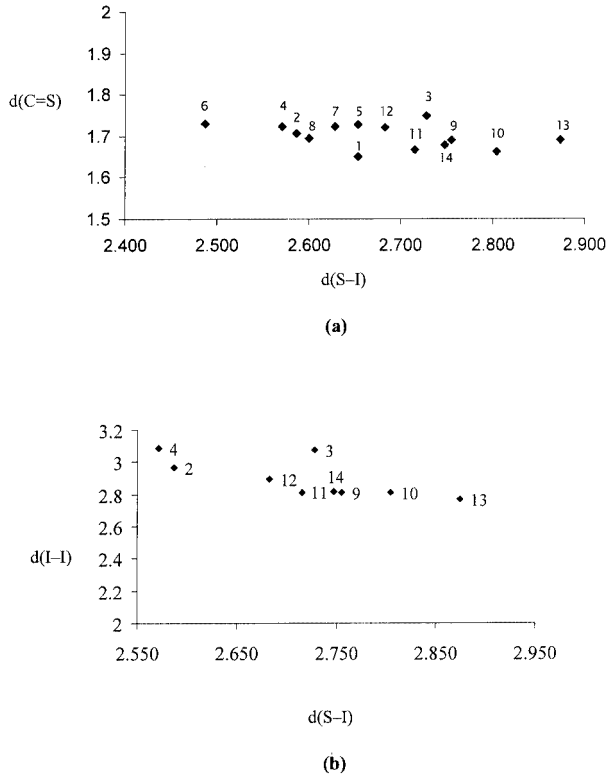

Figure 6. Plot of *d*(S−C) against *d*(S−I) (a) and *d*(I−I) against *d*(S−I) (b) for thione−iodine adducts **5** [{(dmtu)$_2$·I^+}·I_3^-][4] (dmtu = 1,3-dimethyl-2-thiourea), **6** [{(etu)·I^+}·I_3^-][16] (etu = ethylenethiouria), **7** [{(tu)$_2$$I^+$}·$I^-$][29] (tu = thiourea), **8** [(mbzttH)$_2$$I^+$·$I^-$·3$I_2$][12] (mbzttH = *N*-methylbenzothiazole-2-thione), **9** [ptc·I_2][5] (ptc = 1,3-dithiacyclohexane-2-thione), **10** [ttb·I_2],[5] (ttb = 4,5-ethylenedithio-1,3-dithiole-2-thione), **11** [mdtt·I_2][7] [mdtt = 4,5-bis(methylsulfanyl)-1,3-dithiole-2-thione], **12** [mbit·I_2][10] [mbit = 1,1-methylenebis(3-methyl-4-imidazoline-2-thione)], **13** [bzoxtH·I_2][11] (bzoxtH = benzoxazole-2-thione), **14** [dmimdtH·I_2][13] (dmimdtH = 5,5-dimethylimidazoline-2,4-dithione), including our compounds **1**−**4**

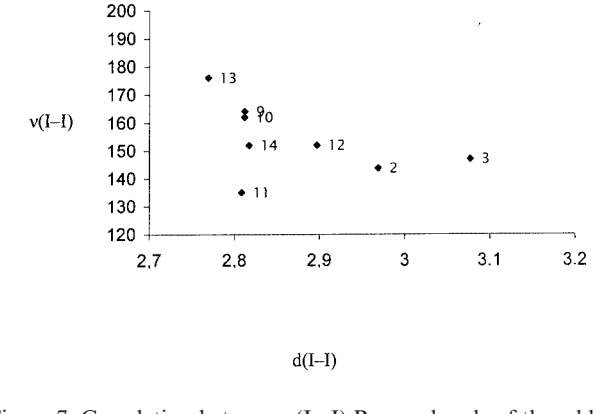

Figure 7. Correlation between ν(I−I) Raman bands of the adducts **9** [ptc·I_2][5] (ptc = 1,3-dithiacyclohexane-2-thione) [ν(I−I) = 164 cm^{-1}], **10** [ttb·I_2][5] (ttb = 4,5-ethylenedithio-1,3-dithiole-2-thione) [ν(I−I) = 162 cm^{-1}], **11** [mdtt·I_2][7] [mdtt = 4,5-bis(methylsulfanyl)-1,3-dithiole-2-thione] [ν(I−I) = 136 cm^{-1}], **12** [mbit·I_2][10] [mbit = 1,1-methylenebis(3-methyl-4-imidazoline-2-thione] [ν(I−I) = 152 cm^{-1}], **13** [bzoxtH·I_2][11] (bzoxtH = benzoxazole-2-thione) [ν(I−I) = 176 cm^{-1}], **14** [dmimdtH·I_2][13] (dmimdtH = 5,5-dimethylimidazoline-2,4-dithione) [ν(I−I) = 152 cm^{-1}], including compounds **2**−**4**

spectively. Therefore, complex **3** could be classified as a type **C** adduct, and complexes **2** and **4** as types **B**.

3. Conclusions

Using the anti-thyroidal agent thiazolidine-2-thione, together with benzothiazole-2-thione or benzimidazole-2-thione, we have tried to compare their behavior towards I_2 coordination and possibly throw some light on the anti-thyroidal activity and mechanism of reaction of these types of molecules. The structure of compound **1** is the second such example of an anti-thyroidal agent.

Laurence et al.[9] also tried to reach similar conclusions by using the anti-thyroidal drugs methimazole, carbimazole and propylthiouracil. No crystal structure of their I_2 adducts was reported, however.[9,41] These authors[9,41] concluded that the action of the anti-thyroidal drugs involved diiodine sponges trapping I_2, I^+ or HOI[42] which were produced during the oxidation of iodide ions taken up by the thyroid. Thus, the agents should be able to form stable complexes with diiodine, diverting iodides from their second oxidation step ($I_2 \rightarrow 2\ I^+ + 2\ e^-$) and in this way prevent the electrophilic substitution of I^+ on the tyrosine residue of thyroglobulin.[2c,43]

This conclusion seems to be substantiated in our work, because (i) like methimazole,[9] thiazolidine-2-thione forms the most stable complexes with I_2 in CH_2Cl_2 solution, compared with the other two ligands[8,9,22] assuming the formation of 1:1 complexes; (ii) the data shows that thiazolidine-2-thione can be classified as a strong donor ligand, in contrast to the non-anti-thyroidal activity of the two other ligands; (iii) thiazolidine-2-thione is such a strong donor that it causes heterolytic cleavage of the diiodine molecule to form $[\{D_2I^+\}I_3^-\cdot 2I_2]$ species and is able to carry two more neutral I_2 molecules in the solid state, which the two other ligands cannot.

Therefore, new anti-thyroidal agents might be found among the strong donors towards diiodine, having the ability to absorb as many molecules of diiodine as possible. Also, these agents should be able to reduce iodine to polyiodides by causing cleavage of the I−I bond.

4. Experimental Section

4.1. Materials and Instruments: All solvents used were reagent grade. Diiodine (Aldrich), thiazolidine-2-thione, benzothiazole-2-thione and benzimidazole-2-thione (Merck) were used with no further purification. Elemental analyses for C,H,N,S were carried out with a Carlo−Erba EA model 1108 elemental analyzer. Melting points were measured in open tubes with a Stuart scientific apparatus and are uncorrected. Infra-red spectra in the region of 4000−370 cm^{-1} were obtained from KBr discs while far-infrared spectra in the region of 400−50 cm^{-1} were obtained from polyethylene discs, with a Perkin−Elmer Spectrum GX FT-IR spectrophotometer. A Jasco UV/Vis/NIR V 570 series spectrophotometer was used to obtain the electronic absorption spectra. The ^1H NMR spectra were recorded with a Bruker AC250 MHFT NMR instrument in $CDCl_3$ solutions. Chemical shifts δ are given in ppm referenced to internal TMS (^1H).

4.2. Synthesis and Crystallization of the Molecules: Complexes $[\{(tzdtH)_2I^+\}\cdot I_3^-\cdot 2I_2]$ (**1**), $[\{(bztzdtH)I_2\}\cdot I_2]$ (**2**), $[(bztzdtH)I_2]$ (**3**) and $[\{(bzimtH)I_2\}_2\cdot I_2\cdot 2H_2O]$ (**4**) were prepared by mixing dichloromethane solutions of diiodine with dichloromethane solution of the appropriate thione in molar ratios of 2:1 in the case of complexes **1**, **2** and **4** or 1:1 for complex **3** in air at 0 °C under continuous stirring for 2−3 h. The solutions were then filtered and the resulting clear solutions were kept in the refrigerator for several days. Dark crystals of the complexes suitable for single-crystal analysis by X-ray crystallography were then grown and filtered off.

Complex 1: Yield 0.060 g, (20%); m.p. 50−52 °C. UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 497 (3.59), 283 (4.50), 227.5 (4.39). ^1H NMR ($CDCl_3$): δ = 7.9441 [s, 1 H, HN−C(5)], 4.1884−4.1481 [t, CH_2−C(4)], 3.7081−3.6688 [t, 2 H, CH_2−C(5)]. $C_6H_{10}IN_2S_4\cdot I_3\cdot 2I_2$ (1253.60): calcd. C 5.75, H 0.80, N 2.23, S 10.23; found C 5.57, H 0.50, N 2.09; S 9.46.

Complex 2: Yield 0.105 g (30%); m.p. 112 °C. UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 503 (2.82), 329 (3.90), 229 (3.92). ^1H NMR ($CDCl_3$): δ = 10.542 [s, 1 H, HN−C(2) of bztzdtH], 7.597−7.384 (m, 4 H, bz of bztzdtH). $C_7H_5I_2NS_2\cdot I_2$ (674.84): calcd. C 12.46, H 0.75, N 2.08, S 9.50; found C 12.96, H 0.47, N 1.91, S 6.28.

Complex 3: Yield 0.256 g (61%), m.p. 110 °C. UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 506.5 (3.02), 329.5 (4.46), 229 (4.30). ^1H NMR ($CDCl_3$): δ = 10.6 [br, 1 H, HN−C(2) of bztzdtH], 7.935−7.379 (m, 4 H, bz of bztzdtH). $C_7H_5I_2NS_2$ (421.06): calcd. C 19.97, H 1.20, N 3.33; S 15.23; found C 19.78; H 1.12, N 3.19, S 15.68.

Complex 4: Yield 0.045 g (12%); m.p. 165 °C. UV/Vis ($CHCl_3$): λ_{max} (log ε) = 499, (3.56), 309.5, (4.91), 239 (4.60). ^1H NMR ($CDCl_3$): δ = 7.4055−7.3099 (m, 4 H, bz of bzimtH). $C_{14}H_{12}I_6N_4S_2\cdot 2H_2O$ (1097.83): calcd. C 15.32, H 1.47, N 5.10, S 5.84; found C 15.91, H 0.94, N 5.11, S 6.74.

4.3. Raman Measurements: Micro FT-Raman measurements were carried out by using near-infrared laser radiation (Nd^{3+}:YAG, 1064.1 nm). FT-Raman spectra (2.6 cm^{-1} resolution) were recorded with a Bruker IFS-88 FT-IR/FRA-105 Raman module fitted with a Ge proprietary detector and coupled via two 1.0-m photooptic cables to a Nikon Optiphot-II optical microscope equipped with a Nikon 20X, super long-range objective. Near-IR laser radiation was directed onto the sample through the objective and collected along the same optical pathway in a 180° backscattering mode. Samples were measured as solid powders dispersed on a glass slide. Resonance Raman spectra were measured by means of a Renishaw 3000 Ramanscope spectrometer. A typical acquisition time was 10 s, with a slit of 25 μ. Measurements were performed using 488.0- and 514.5-nm sources.

4.4. X-ray Structure Determination: Data were collected by the ω-scan technique in the range $3° < 2\theta < 23°$ for **1** and **4**, and $3° < 2\theta < 25°$ for **2** and **3** with a KUMA KM4CCD four-circle diffractometer[44a] with CCD detector, using graphite-monochromated Mo-K_α (λ = 0.71073Å) at −103 °C (**1**), 20 °C (**2** and **3**) and −168 °C (**4**). Cell parameters were determined by a least-squares fit[44b] of 655, 444, 807, and 3156 reflections for **1**, **2**, **3** and **4**, respectively. All data were corrected for Lorentz-polarization effects and absorption.[44b] Totals of 4672 (**1**), 5771 (**2**), 4699 (**3**) and 6939 (**4**) reflections were collected of which 1603, 2207, 1484 and 1691, respectively, were unique; of these 1175, 1159, 1311 and 1631 were observed [$I > 2\sigma(I)$]. The structures were solved with direct

methods using SHELXS97[45] and refined by full-matrix least-squares procedures on F^2. All non-hydrogen atoms were refined anisotropically, hydrogen atoms were located at calculated positions and refined as a "riding model" with isotropic thermal parameters fixed at 1.2 times the U_{eq} values of the appropriate carrier atom. Selected crystal data are listed in Table 8. Bond lengths and angles for the complexes are given in Tables 2−5, while the displacement ellipsoid representation of the complexes and their unit cell diagrams are shown in Figures 1−4. CCDC-172151 (**1**), -172154 (**2**), -172153 (**3**) and -172152 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was carried out in partial fulfillment of the requirements for an M.Sc. thesis of V. D. within the graduate program EPEAEK in Bioinorganic Chemistry financed by the Ministry of Education of Greece and coordinated by N. H. The NATO grant awarded to N. H. and I. S. B. is also acknowledged.

Reactions of Pentafulvene Complexes of Titanium with Carbonyl Compounds − Diastereoselective Synthesis of σ,π-Chelate Complexes with Cp~O Ligands

Jörg Stroot,[a] Rüdiger Beckhaus,*[a] Wolfgang Saak,[a] Detlev Haase,[a] and Arne Lützen[a]

Keywords: Titanium / Fulvene complexes / Reaction mechanism / Substituent effects / Stereoselectivity / O ligands / Cyclopentadienyl ligands

The compound Cp*Ti[η^6-$C_5H_4C(H)(t$Bu)]Cl (**1**) reacts with ketones, aldehydes, and esters to give σ,π-chelate complexes with Cp~O ligands through insertion of the carbonyl group into the Ti–C(H)(*t*Bu) bond. Starting from diastereomerically pure **1**, the reaction with symmetric ketones R_2CO led to the formation of two diastereomeric products. The diastereomeric ratio could be controlled by steric and electronic properties of the substituent R. Thus, this procedure provides an easy approach to complexes with Cp~O ligands where new chiral centres are formed directly in the coordination sphere of the metal atom through a side-differentiated attack of the carbonyl compound at the titanium atom. All products were thoroughly characterized. Crystal structure determinations were carried out on **2a**, **3a**, **5**, **6b**, and **9a**.

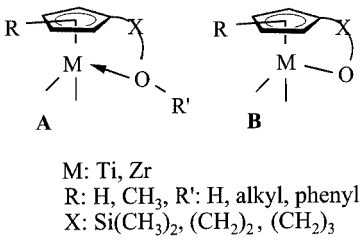
Introduction

Complexes with functionalized cyclopentadienyl chelate ligands have gained great importance in organo transition metal chemistry because they have been demonstrated to be useful catalysts (or precatalysts) in different kinds of reactions.[1] Generally, chelating Cp~O ligands can be classified as two principal types, ligands functionalized with a neutral O donor (mostly an ether group) (**A**) − forming a hemilabile ligand − and ligands with an anionic O donor (**B**) − leading to cyclopentadienylalkoxide σ,π-chelate complexes (Scheme 1). Diels−Alder reactions,[2] hydrogenations,[3] or the polymerization of olefins[4] and dienes,[5] as well as ring-opening metathesis polymerization reactions[6] are described for complexes of early transition metals exhibiting Cp~O ligands. However, in comparison to related *N*-functionalized cyclopentadienyl complexes, which proved to be remarkably successful in catalytic applications,[7] the use of *O*-functionalized species still seems to be underdeveloped.

Usually these complexes are available by two synthetic routes. Either a suitable transition metal ion is complexed by an already preformed *O*-functionalized cyclopentadienyl ligand,[8] or the ligand is prepared directly in the coordination sphere of the metal centre from a suitable precursor ligand. While the first route is well described,[4b,9] examples for the second one are rather rare.[10] Here we report on new titanium complexes with Cp~O ligands of the alkoxide type (**B**), which we were able to synthesize very efficiently by treating the diastereomerically pure pentafulvene complex Cp*Ti(η^6-$C_5H_4C(H)(t$Bu)]Cl (**1**) with various carbonyl compounds. This approach offers the opportunity to control the stereochemistry of the desired coordination compounds by steric and electronic effects of the carbonyl species, and that can be explained by a proposed mechanism.



Scheme 1

Results and Discussion

The reaction of diastereomerically pure Cp*Ti[η^6-$C_5H_4C(H)(t$Bu)]Cl (**1**)[11] with benzophenone in *n*-hexane at room temperature proceeded smoothly to give complex **2** as a mixture of diastereomers (Scheme 2), which could easily be separated by a simple filtration since diastereomer **2b** precipitated as a yellow nacreous solid, whereas **2a** proved to be well soluble and remained in solution. Thus, **2b** could be obtained as a yellow powder (81%) by washing the precipitate with a small amount of *n*-hexane. Complex **2a** was isolated as yellow-orange cube-shaped crystals (18%) by

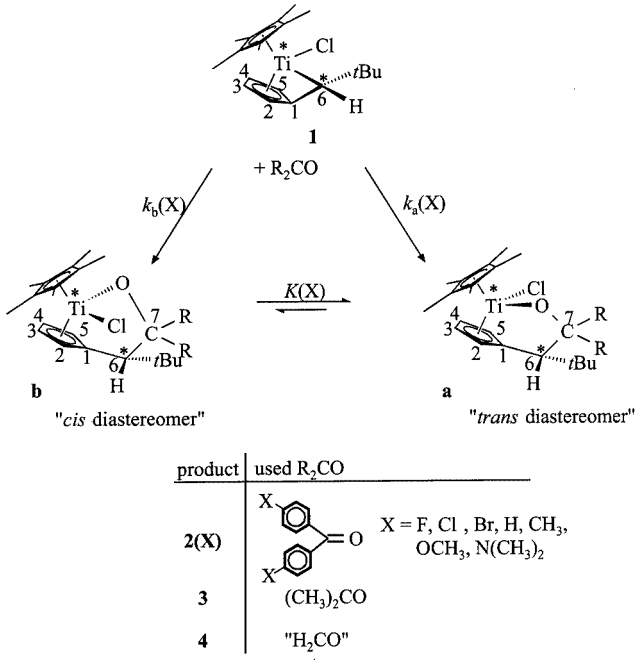
concentrating the filtrate and cooling to −20 °C. Complexes **2a** and **2b** differ in the relative arrangement of the exocyclic fulvene proton (6-H) to the titanium-bonded chlorine atom; **2a** was found to have a *trans*-arrangement and is therefore called the "*trans* diastereomer" and **2b** a *cis* arrangement and therefore named the "*cis* diastereomer".



Scheme 2

The two diastereomeric products were thermally stable and could be exposed to air for several hours. However, diastereomerically pure **2a** or **2b** underwent a very slow rearrangement upon storing as a solution in [D_6]benzene for several weeks to give noticeable amounts of the other diastereomer, respectively. After about 12 months these solutions of **2a** and **2b** had equilibrated. However, this equilibrium could be reached considerably faster in the presence of Lewis acids such as $AlMe_3$ or $B(C_6F_5)_3$.

X-ray Crystal Structure Analysis of Complex 2a

Crystals of **2a** suitable for X-ray structural analysis were obtained from a concentrated solution of **2a** in *n*-hexane at 0 °C, and the results are depicted in Figure 1. Two crystallographically independent, but remarkably similar, molecules of **2a** are present within the asymmetric unit. Due to this similarity only one molecule will be discussed in the following section.

The crystal structure reveals a characteristically bent metallocene arrangement of the ligands around the titanium atom. Distances from the metal atom to the ring centroids are 2.050 Å for the functionalized cyclopentadienyl group and 2.111 Å for the Cp* ring. The angle between the geometrical centres of both rings and the titanium atom is 132.9°. These data are in good agreement with those reported for other titanium complexes.[12] The distance Ti−O1 is 1.881(2) Å, similarly as short as those reported

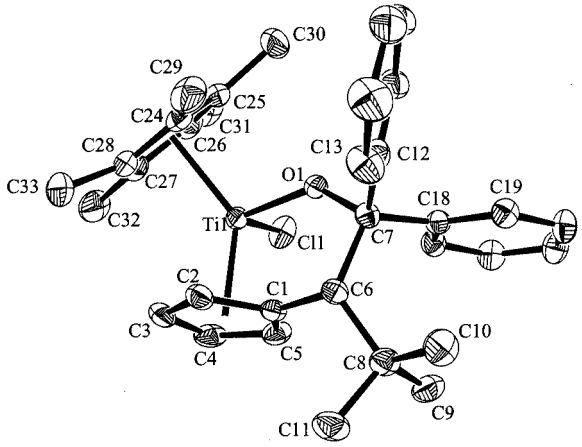


Figure 1. Molecular structure of **2a**; hydrogen atoms have been omitted for clarity; ORTEP ellipsoids represent 50% probability; selected bond lengths [Å] and angles [°]: Ti1−Cl1 2.398(1), Ti1−O1 1.881(2), O1−C7 1.439(3), C6−C7 1.601(3), C1−C6 1.515(3), Ti1−Ct1 2.050, Ti1−Ct2 2.111; Ti1−O1−C7 137.1(1), O1−C7−C6 106.8(2), C1−C6−C7 107.8(2), O1−Ti1−Cl1 100.1(1), Ct1−Ti1−Ct2 132.9; Ct1 = ring centroid of C1 to C5, Ct2 = ring centroid of C24 to C28)

for Ti−OH bonds in titanocene hydroxides,[13] and indicates metal−oxygen double-bond character caused by $O(p_\pi)\rightarrow Ti(d_\pi)$ interactions.[14] It is known from other *x*-membered metallacycles that a general correlation exists between the Ti−O bond length, the Ti−O−C angle, and the ring size. This is due to the attractive interaction between the oxygen lone pairs (located in the p_z orbital) and the lowest unoccupied molecular orbital (LUMO) of the metal atom, which increases with increasing Ti−O−C angle. In the case of the five-membered metallacycle **2a**, with its Ti−O bond length of 1.881(2) Å and its Ti−O−C angle of 137.1(1)°, there is a good agreement with these findings.[15] Furthermore, the significant elongation of the Ti−Cl distance in **2a** [2.398(1) Å] compared with the one found in **1** [2.354(1) Å][11] is noticeable, because it indicates a weakening of $Cl(d_\pi)\rightarrow Ti(d_\pi)$ interactions caused by a raised electron density at the titanium atom by $O(p_\pi)\rightarrow Ti(d_\pi)$ interactions. Whereas the O−C7 and C1−C6 distances are close to typical O−C and C−C single bonds, respectively,[16] the new C6−C7 bond shows a length [1.601(3) Å] that is significantly larger than a typical C−C single bond. This most probably indicates a higher ring strain. The hypothesis that this elongation of the C6−C7 bond is induced rather by ring strain than by steric effects of the substituents at the C6 and C7 atoms is further supported by the reaction products of **1** with several other ketones and aldehydes bearing substituents of varying steric bulkiness (Table 2). In all cases this C−C bond was significantly elongated.

Complex **2b** crystallised from all the usual solvents as fine needles, unsuitable for X-ray structure analysis. However, it could be identified unambiguously by NMR and MS data as well as elemental analysis.

Diastereoselectivity of the Insertion Reaction

In order to obtain an idea about the sense of the stereochemical induction and the underlying mechanism we

studied the reactions shown in Scheme 2 more closely by ^{1}H NMR spectroscopy. Benzophenone proved to be an especially suitable substrate for our purposes, because the proton signals of the pentamethylcyclopentadienyl ligand of **1** and the two diastereomeric products (**2a** and **2b**) were well separated from each other (Figure 2) and the reaction with **1** proceeded sufficiently slowly when we used starting concentrations of $c_{\mathbf{1}} = c_{\text{benzophenone}} = 0.071$ mol L^{-1}.[17] Thus, the concentration of all species involved in the reaction (**1**, **2a**, and **2b**) could be determined at any point during the reaction.

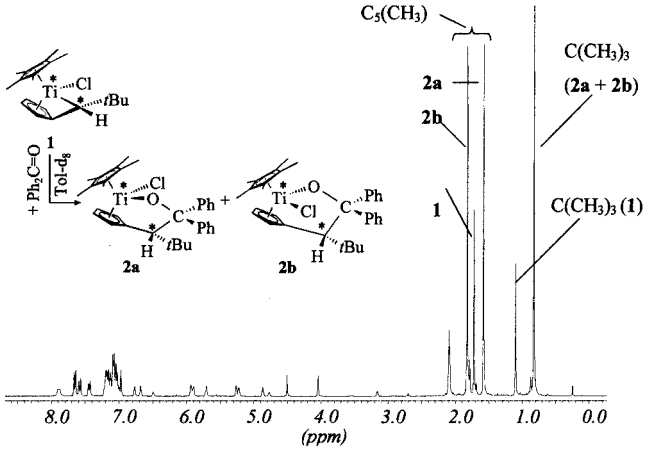

Figure 2. ^{1}H NMR spectra (300 MHz, [D$_8$]toluene) of the reaction of **1** with benzophenone after about 24 h

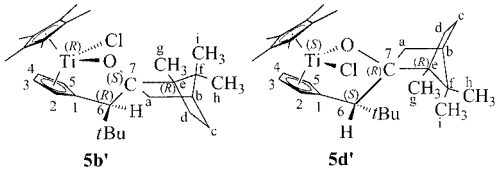
Furthermore, it was possible to insert activating (electron-donating) or deactivating (electron-accepting) substituents at the phenyl rings in the *para* position to the carbonyl group to study the influence of electronic effects on the reaction. As a preliminarily result,[18] the quotients of rate constants $k_b(X)/k_a(X)$ (cf. Scheme 2) for several disubstituted benzophenones [X = F, Cl, Br, (H), CH_3, OCH_3, $N(CH_3)_2$], which indicate the quantities of obtained "*cis* diastereomer" **2b(X)** and "*trans* diastereomer" **2a(X)**, are listed in Table 1.

Table 1. Ratio of single rate constants k_a and k_b at 300 K for the reactions shown in Figure 1 leading to "*trans* and *cis* diastereomers" **2a(X)** and **2b(X)**, respectively, and difference of the Gibbs energies between **2a(X)** and **2b(X)** [kJ mol^{-1}] at 298 K, showing the dependence on the benzophenone *para* substituent X

	F	Cl	Br	H	CH_3	OCH_3	$N(CH_3)_2$
$k_b(X)/k_a(X)$	3.67	1.74	–	1.39	0.95	0.69	0.23
$\Delta\Delta G_{(b-a)}$	−4.65	−4.85	−4.97	−4.90	−5.04	−5.11	−6.18

As mentioned above, **2a(X)** and **2b(X)** equilibrate after about 12 months with **2b(X)** being the thermodynamically more stable diastereomer in all cases. From equilibrium constant K ($K = c_{\mathbf{2b(X)},\infty}/c_{\mathbf{2a(X)},\infty}$) at 298 K the difference of free Gibbs energies between **2a(X)** and **2b(X)** could be calculated as given in Table 1. The *para* substituents in Table 1 are arranged in a manner that the activating effect increases to the right.

These data suggest two possible pathways for controlling the diastereomeric ratio, namely thermodynamic and kinetic control. While the thermodynamic effect is relatively small − the equilibrium between **2a(X)** and **2b(X)** shifts towards **2b(X)** with rising electron-donating effect of the *para* substituent − the kinetic effect is distinctively larger. The insertion, for example, of a benzophenone derivative with fluorine substituents, which remove electron density from the carbonyl group, led mainly to the "*cis* diastereomer" **2b(F)** ($k_{\mathbf{2b(F)}}/k_{\mathbf{2a(F)}} = 3.67$, according to Table 1), whereas the reaction with a benzophenone carrying the electron-donating Me_2N group yielded the "*trans* diastereomer" **2a(N(CH$_3$)$_2$)** as the major product ($k_{\mathbf{2b(NMe2)}}/k_{\mathbf{2a(NMe2)}} = 0.23$, according to Table 1). However, the diastereomeric ratio could be influenced, not only by electronic, but also by steric effects. In this context, reaction of **1** with small carbonyl compounds like acetone and formaldehyde led exclusively to "*trans* diastereomers" **3a** and **4a**, respectively. The "*cis* diastereomers" **3b** and **4b** could not be detected until the equilibration reaction was performed. However, the reaction with bulky *R*-(+)-camphor gave rise to the "*cis* diastereomers" **5b′** and **5d′** only (Scheme 3), and the "*trans* diastereomers" were not observed, even under the conditions mentioned above to reach equilibrium of the other insertion products.



Scheme 3

Structural analyses of three of these insertion products (**3a**, **5b′**, and **5d′**) revealed the bond lengths and angles of the metallacycle to be similar to those found for **2a** (Table 2). Corresponding ORTEP plots are depicted in the Supporting Information.

According to these results, the reaction of **1** with methyl isobutyrate, which has a significantly reduced electron density at the carbonyl oxygen atom, gave exclusively the "*cis* diastereomer" **6b** after β-elimination of MeOH (Scheme 4).

However, released MeOH also reacted with **1** to form compound **11**. Furthermore, since the primary insertion step of the carbonyl group into the Ti−C6 bond is comparatively slow, while the following β-elimination is very fast, the primary product was not observed, even in a ^{1}H NMR experiment. However, both products **6b** and **11** could be isolated by fractional crystallization.

Mechanistic Reflections

In pseudo-tetrahedral bent metallocene complexes of the Cp_2MR_2 type, eight out of the nine metal valence orbitals are used for coordinating the ligands. Two opposed spatial arrangements for the remaining ninth orbital, which determines the chemical reactivity of such complexes to a considerable content, have been discussed in a number of previous

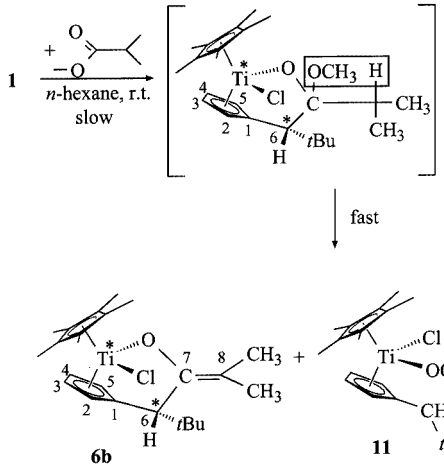
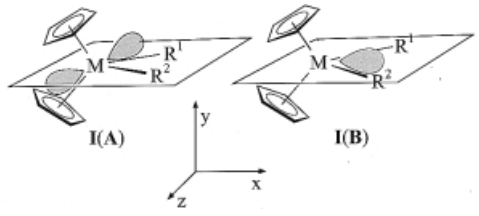


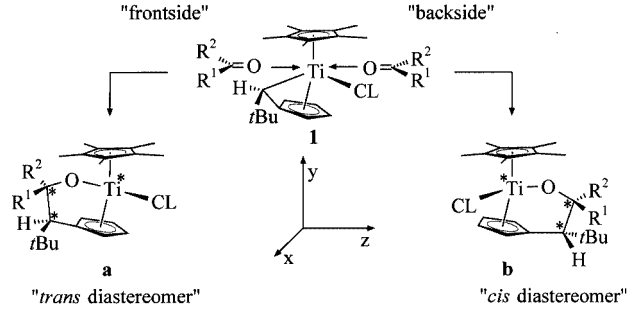
Scheme 4

publications (Scheme 5). Whereas Ballhausen and Dahl favoured a central position between the σ ligands R (**IB**),[19] Alcock et al. postulated a lateral position aligned along the *z* axis (**IA**).[20] Nowadays, recent results from several spectroscopic and theoretical studies unanimous support the lateral arrangement.[21]



Scheme 5

In case of metallocenes of group-IV metals (16 electron species) this "ninth" orbital is unoccupied (acceptor orbital). Assuming that the spatial arrangement of the acceptor orbital of **1** (16-electron species) is also in the lateral position, the nucleophilic attack of the lone pairs of the carbonyl oxygen atom at the titanium centre and the resulting interactions with the acceptor orbital can in principle proceed from two different sites (Scheme 6). Whereas the "frontal" attack leads to the "*trans* diastereomer", the "backside" attack results the "*cis* diastereomer".



Scheme 6

Calculations of the electrostatic potential[22] of **1** indicate a high electron density at the "backside" induced by the lone pairs of the chlorine atom (Figure 3). This suggests that from the electronic point of view the nucleophilic attack of the carbonyl oxygen atom from the "backside" is strongly disfavoured compared with the "frontal" attack, because the lone pairs of the oxygen and chlorine atoms should repel each other.

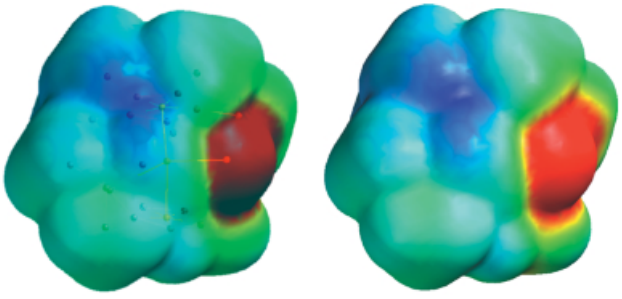


Figure 3. Electrostatic potential, molecular surface of **1** in colour-code form, red representing the negative, blue the positive maximum in charge density in relative terms (left hand semitransparent illustration)

On the other hand, the crystal structure of **1**[11] shows a slight deviation of both rings with respect to each other, and in consequence the titanium centre is sterically shielded from the "front" (Figure 4).

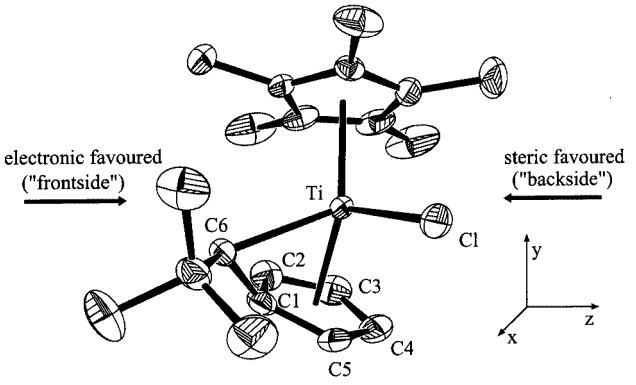

Figure 4. Molecular structure of **1**; hydrogen atoms have been omitted for clarity; ORTEP ellipsoids represent 50% probability

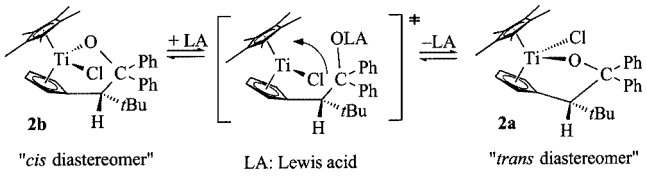
In solution (C_6D_6) strong NOE contacts between the pentamethylcyclopentadienyl protons and the protons at C2 and C3 atoms are observed,[11] indicating a similar deviation in solution. In consequence, an attack from the "front" should be disfavoured from a steric point of view. Thus, **1** is characterized by an electronically favoured "frontal" and a sterically favoured "backside". Therefore, benzophenone derivatives with activating (electron-donating) *para* substituents, e.g. X = NMe_2, attack mainly from the electronically favoured "front", whereas derivatives with deactivating (electron-accepting) substituents, e.g. F, attack from the sterically favoured "backside" [cf. $k_b(X)/k_a(X)$, Table 1]. Likewise, bulky carbonyl compounds like *R*-(+)-camphor approach the titanium centre from the sterically favoured, but electronically disadvantageous "backside", while small carbonyl compounds like acetone or formaldehyde from the electronic favoured "front". The "medium-sized" benzophenone attacks from both sides. According to these results, methyl isobutyrate, which has a considerably lower electron density at the carbonyl oxygen atom, reacts in terms of a "backside" attack exclusively to the "*cis* diastereomer" **6b**.

In order to further corroborate our proposed mechanism, we substituted the chlorine atom in **1** with a methyl group, which led to Cp*Ti[η^6-$C_5H_4C(H)(t\text{Bu})$]Me (**7**). If our mechanism is correct, this should eliminate the electronic disadvantages of the sterically favoured "backside", and in consequence the "*cis* diastereomer" **8b**, resulting from the "backside" attack, should be the main product of the reaction with "medium-sized" benzophenone. Indeed, only **8b** was found and **8a** could only be observed later as a consequence of the equilibration reaction. Insertion products in the Ti−Me bond of **7** were not observed.

Even the stereochemistry of the products, resulting from the reaction of **1** with asymmetric (prochiral) benzaldehyde, could be explained by our proposed mechanism if we take a pre-coordination[10b] of the carbonyl compound (Scheme 6 with R^1 = phenyl, R^2 = H) into account, which has already been suggested by Erker et al. Due to the deviation of the rings in **1**, the orientation of the benzaldehyde phenyl group out of the front of the *xz* plane is very likely, and thus leads to "*trans* and *cis* diastereomers" **9a** and **9b**, respectively.

Rearrangement of Diastereomers

As mentioned above all insertion products, except complexes **5b′** and **5d′**, slowly rearranged to give the corresponding diastereomer and finally reached an equilibrium after about 12 months. However, addition of stoichiometric as well as catalytic amounts of Lewis acids like $AlMe_3$ or $B(C_6F_5)_3$ made this equilibration reaction become considerably faster.[23] We found kinetics of pseudo-first order for the reaction **2b** → **2a** in the presence of $AlMe_3$, suggesting that the Lewis acid (LA) acts as a catalyst whose concentration does not change with time (Scheme 7). Furthermore, ^{1}H NMR spectra indicated that all involved species (**2a**, **2b**, and $AlMe_3$) existed unchanged in solution − since we did not see any permanent agglomeration products of $AlMe_3$. Also, the difference in the Gibbs free energy between the diastereomers [$\Delta\Delta G_{(b-a)}$] did not change.



Scheme 7

In principle, one could think of two different mechanisms for this rearrangement. An intramolecular rearrangement involving only a temporary cleavage of the Ti−O bond or an intermolecular exchange of carbonyl compounds between two titanium complexes which would need the permanent cleavage of the Ti−O bond and a C−C bond. Although the latter one seemed unlikely anyway, we further proved this assumption through cross-over experiments with **2a** or **2b** and **7**, as well as with **8a** or **8b** and **1**, which clearly showed, that there was no exchange of carbonyl compounds between two titanium complexes because all complexes remained unchanged even after several months.

However, we were able to confirm the kinetic lability of the Ti−O bond in **2a** and **2b**, respectively, which is the key factor for the probability of the intramolecular rearrangement mechanism proposed in Scheme 7. This was determined by ^{1}H NMR experiments made with **11**-type complexes and free alcohols. A fast exchange of the alkoxy group (methoxy versus ethoxy group) was observed upon addition of stoichiometric amounts of ethyl alcohol to a solution of **11** in [D_6]benzene.[24] Furthermore, no chloride/alkoxy exchange was observed, neither in experiments described above nor in a mixture of Cp*Ti($C_5H_4CH_2t\text{Bu}$)Cl_2 (**15**)[25] and EtOH, hence, also supporting the proposed mechanism.

Conclusion

A simple approach to complexes with Cp~O ligands has been presented, starting from diastereomerically pure Cp*Ti[η^6-$C_5H_4C(H)(t$Bu)]Cl (**1**) and several carbonyl compounds, and it has been demonstrated how the diastereomeric ratio of the product complexes could be controlled in a rather sensitive manner by the nature, nucleophilicity, and steric properties of the utilized carbonyl compounds. In all cases, the stereochemical outcome of this insertion could be explained by a side-differentiated attack of the carbonyl compound at the titanium atom. Thus, this procedure provides a convenient access to complexes with Cp~O ligands where the new chiral centres are formed directly in the coordination sphere of the metal atom in a well-defined manner.

Experimental Section

General Remarks: All operations were performed in nitrogen with rigorous exclusion of oxygen and moisture using glove-box or Schlenk techniques. Solvents were thoroughly dried and saturated with nitrogen. ^{1}H NMR and ^{13}C NMR spectra were recorded with a Bruker AVANCE 500 spectrometer (^{1}H, 500.1 MHz; ^{13}C, 125.8 MHz) or a Bruker AVANCE 300 spectrometer (^{1}H, 300.1 MHz; ^{13}C, 75.8 MHz), chemical shifts were referenced to residual protons or carbon atoms of the solvent. The notation of the nuclei follows the numbering in Scheme 2 and 3. Electron impact (EI) mass spectra were taken with a Finnigan-MAT 95 spectrometer. IR spectra were recorded with a BIO-RAD FTS-7 Spectrometer using KBr pellets. Elemental analyses were carried out by the Analytische Laboratorien in Lindlar (Germany). The complexes Cp*Ti[η^6-$C_5H_4C(H)t$Bu]Cl (**1**)[11] and Cp*Ti[η^6-$C_5H_4C(H)t$Bu]Me (**7**)[26] were prepared according to reported procedures. All carbonyl compounds were purchased from Aldrich and used as received. Diastereomers **3b**, **4b**, and **8a** resulted from the described equilibration reaction between the corresponding diastereomers and could not be isolated, but were characterized by NMR spectroscopy of the respective diastereomeric mixtures.

Complex 2: A solution of benzophenone (0.911 g, 5.0 mmol) in *n*-hexane (10 mL) was added dropwise to a stirred solution of Cp*Ti[η^6-$C_5H_4C(H)t$Bu]Cl (**1**) (1.764 g, 5.0 mmol) in *n*-hexane (20 mL) at room temperature. A yellow nacreous solid began to precipitate after about 8 h. After stirring for additional 52 h, the suspension was filtered. Washing the residue with *n*-hexane (4 × 10 mL) and drying in vacuo led to **2b** as a yellow powder (2.167 g, 81%). Concentration of the filtrate to 10 mL and cooling to −20 °C resulted in the isolation of **2a** as yellow-orange, cube-shaped crystals (0.321 g, 18%).

2a: M.p. 104 °C. ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = 0.84 [s, 9 H, $C(CH_3)_3$], 1.57 [s, 15 H, $C_5(CH_3)_5$], 4.03 (s, 1 H, 6-H), 5.21 (m, 1 H, C_5H_4), 5.24 (m, 1 H, C_5H_4), 6.01 (m, 1 H, C_5H_4), 6.78 (m, 1 H, C_5H_4), 7.00−7.24 (m, 6 H, *m*-H_{Ph}, *p*-H_{Ph}), 7.47 (m, 2 H, *o*-H_{Ph}), 7.68 (m, 2 H, *o*-H_{Ph}). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 12.5 [$C_5(CH_3)_5$], 30.1 [$C(CH_3)_3$], 34.5 [$C(CH_3)_3$], 58.0 (C6), 109.3 (C_5H_4), 110.8 (C_5H_4), 112.8 (C7), 117.1 (C_5H_4), 121.2 (C_5H_4), 124.8 [$C_5(CH_3)_5$], 127.0, 127.1, 127.3, 128.3, 130.2, 131.2 (CH_{Ph}), 149.0, 149.4 (*i*-C_{Ph}), 152.2 (C1). IR (KBr): ṽ = 3047 (m), 2957 (m), 2907 (m), 2894 (m), 1729 (s), 1660 (s), 1443 (s), 1261 (vs), 1095 (vs), 1024 (s), 995 (vs), 815 (s), cm^{-1} 801 (vs). EI MS: *m*/*z* (%) = 534 (5) [M$^+$], 399 (100) [M$^+$ − Cp*], 352 (6) [M$^+$ − $(Ph)_2CO$], 316 (36) [M$^+$ − $(Ph)_2CO$ + HCl], 218 (38) [M$^+$ − ($C_{10}H_{14}$ + Ph_2CO)], 182 (22) [Ph_2CO^+], 135 (30) [Cp*$^+$]. $C_{33}H_{39}ClOTi$ (534.99): calcd. C 74.09, H 7.35; found C 72.45, H 7.42 (lower carbon value due to e.g. TiC formation).

2b: Decomposition without melting at 244 °C. ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = 0.84 [s, 9 H, $C(CH_3)_3$], 1.81 [s, 15 H, $C_5(CH_3)_5$], 4.56 (s, 1 H, 6-H), 4.87 (m, 1 H, C_5H_4), 5.71 (m, 1 H, C_5H_4), 5.86 (m, 1 H, C_5H_4), 6.89 (m, 1 H, C_5H_4), 7.04−7.31 (m, 8 H, H_{Ph}), 7.68 (m, 2 H, H_{Ph}). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 12.8 [$C_5(CH_3)_5$], 30.4 [$C(CH_3)_3$], 30.2 [$C(CH_3)_3$], 59.3 (C6), 102.9 (C_5H_4), 109.5 (C_5H_4), 109.8 (C7), 117.9 (C_5H_4), 124.7 [$C_5(CH_3)_5$], 135.8 (C_5H_4), 126.6, 127.0, 127.5, 128.3, 129.2, 130.2 (CH_{Ph}), 139.1 (C1), 148.8 (both *i*-C_{Ph}). IR (KBr): ṽ = 3052 (m), 2955 (m), 2905 (m), 2892 (m), 1493 (s), 1488 (s), 1445 (s), 1393 (s), 1007 (vs), 1000 (vs), 899 (s), 880 (s), 824 (vs), 799 (vs), 783 (s), 764 (vs), 716 (vs), 698 (vs), cm^{-1} 687 (vs). Complex 3: A mixture of acetone (0.290 g, 5.0 mmol) in *n*-hexane (10 mL) was added dropwise to a stirred solution of Cp*Ti[η^6-$C_5H_4C(H)t$Bu]Cl (**1**) (1.764 g, 5.0 mmol) in *n*-hexane (20 mL) at room temperature. After 5 min, the colour of the solution turned from dark green to orange. After stirring for an additional 2 h, the solution was concentrated to 10 mL and cooled to −20 °C, **3a** was isolated as yellow-orange, cube-shaped crystals (1.397 g, 68%). M.p. 104 °C. ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = 0.97 [s, 9 H, $C(CH_3)_3$], 1.29 (s, 3 H, CH_3), 1.53 (s, 3 H, CH_3), 1.81 [s, 15 H, $(C_5(CH_3)_5$], 2.35 (s, 1 H, 6-H), 4.97 (m, 1 H, 2-H), 5.34 (m, 1 H, 3-H), 5.54 (m, 1 H, 4-H), 6.72 (m, 1 H, 5-H). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 12.6 [$C_5(CH_3)_5$], 27.1 (CH_3), 30.4 [$C(CH_3)_3$], 33.1 [$C(CH_3)_3$], 37.6 (CH_3), 63.6 ($^1J_{C,H}$ = 124.5 Hz, C6), 105.4 (C7), 109.5 (C2), 111.8 (C3), 114.3 (C4), 119.0 (C5), 123.9 [$C_5(CH_3)_5$], 148.3 (C1). IR (KBr): ṽ = 3088 (m), 2969 (m), 2911 (m), 2870 (m), 1478 (s), 1452 (s), 1437 (s), 1375 (s), 1358 (s), 1146 (s), 1123 (vs), 1020 (m), 974 (s), 826 cm^{-1} (vs). EI MS: *m*/*z* (%) = 410 (10) [M$^+$], 352 (22) [M$^+$ − $(CH_3)_2CO$], 316 (22) [M$^+$ − $(CH_3)_2CO$ + HCl], 275 (100) [M$^+$ − Cp*], 218 (90) [M$^+$ −$C_{10}H_{14}$ + $(CH_3)_2CO$], 135 (16) [Cp*$^+$]. $C_{23}H_{35}ClOTi$ (410.86): calcd. C 67.24, H 8.59; found C 67.06, H 8.47.

3b: ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = 0.95 [s, 9 H, $C(CH_3)_3$], 1.25 (s, 3 H, CH_3), 1.40 (s, 3 H, CH_3), 1.81 [s, 15 H, $C_5(CH_3)_5$], 3.12 (s, 1 H, 6-H), 4.94 (m, 1 H, 4-H), 5.18 (m, 1 H, 2-H), 5.67 (m, 1 H, 3-H), 6.85 (m, 1 H, 5-H). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 12.6 [$C_5(CH_3)_5$], 29.6 (CH_3), 30.1 [$C(CH_3)_3$], 33.3 [$C(CH_3)_3$], 33.7 (CH_3), 62.7 (C6), 103.5 (C4), 103.7 (C7), 106.0 (C2), 116.3 (C3), 123.9 [$C_5(CH_3)_5$], 134.6 (C5), 139.6 (C1).

Complex 4: Powdered paraformaldehyde 0.300 g, 10.0 mmol) was added to a solution of Cp*Ti[η^6-$C_5H_4C(H)t$Bu]Cl (**1**) (1.764 g, 5.0 mmol) in THF (20 mL). The suspension was stirred under reflux. After 2 h, the colour of the solution turned from dark green to orange. The reaction mixture was stirred for an additional 2 h. After the THF had been removed, the residue was dissolved in 20 mL of *n*-hexane and separated from insoluble excessive paraformaldehyde by filtration. The filtrate was concentrated to 10 mL and cooled to −20 °C. Complex **4a** could be isolated as a yellow-orange, microcrystalline solid (1.340 g, 70%). **4a:** M.p. 108 °C. ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = 0.88 [s, 9 H, $C(CH_3)_3$], 1.83 [s, 15 H, $C_5(CH_3)_5$], 2.37 (dd, $^3J_{H6,H7}$ = 11.8, $^3J_{H6,H7'}$ = 6.1 Hz, 1 H, 6-H), 4.71 (dd, $^2J_{H7,H7'}$ = −9.1 Hz, 1 H, 7′-H), 5.10 (m, 1 H,

2-H), 5.34 (m, 1 H, 3-H), 5.50 (dd, 1 H, 7-H), 5.62 (m, 1 H, 4-H), 6.78 (m, 1 H, 5-H). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 12.5 [$C_5(CH_3)_5$], 29.0 [$C(CH_3)_3$], 32.3 [$C(CH_3)_3$], 55.7 (C6), 91.3 (C7), 109.6 (C2), 111.8 (C3), 115.8 (C4), 120.5 (C5), 124.5 [$C_5(CH_3)_5$], 148.2 (C1). C 71.35, H 8.98; found C 71.36, H 8.97.

Complex 6: A solution of methyl isobutyrate (0.106 g, 2.5 mmol) in *n*-hexane (10 mL) was added dropwise to a stirred solution of Cp* Ti[η^6-$C_5H_4C(H)tBu$]Cl (**1**) (1.764 g, 5.0 mmol) in *n*-hexane (20 mL) at room temperature. After 12 h, the colour of the solution turned from dark green to claret red. After stirring for additional 48 h, the solution was concentrated to 10 mL and cooled to 0 °C; **6b** could be isolated diastereomerically pure as ruby coloured, acicular crystals (0.655 g, 62%). M.p. 139 °C. ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = 1.02 [s, 9 H, $C(CH_3)_3$], 1.71 (s, 3 H, CH_3), 1.78 (s, 3 H, CH_3), 1.83 [s, 15 H, $C_5(CH_3)_5$], 3.86 (s, 1 H, 6-H), 5.35 (m, 1 H, 2-H), 5.37 (m, 1 H, 4-H), 5.53 (m, 1 H, 3-H), 6.46 (m, 1 H, 5-H). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 12.6 [$C_5(CH_3)_5$], 17.7 (CH_3), 20.7 (CH_3), 29.8 [$C(CH_3)_3$], 35.2 [$C(CH_3)_3$], 51.5 (C6), 99.0 (C8), 107.1 (C2), 112.4 (C4), 114.7 (C3), 124.9 [$C_5(CH_3)_5$], 127.1 (C5), 145.6 (C1), 169.9 (C7). IR (KBr): ṽ = 2962 (m), 2948 (m), 2903 (m), 1653 (s), 1493 (s), 1480 (s), 1464 (s), 1438 (s), 1383 (s), 1169 (s), 1138 (vs), 1099 (s), 1022 (s), 937 (s), 827 (vs), 809 cm^{-1} (vs). EI MS: *m*/*z* (%) = 422 (80) [M$^+$], 386 (22) [M$^+$ − HCl], 352 (8) [M$^+$ − C_4H_6O], 329 (100) [M$^+$ − HCl + $C(CH_3)_3$], 316 (18) [M$^+$ − (C_4H_6O + HCl)], 218 (34) [M$^+$ − ($C_{10}H_{14}$ + C_4H_6O)], 135 (16) [Cp*$^+$]. $C_{24}H_{35}ClOTi$ (422.87): calcd. C 68.17, H 8.34; found C 68.08, H 8.26.

Complex 8: A solution of benzophenone (0.456 g, 2.5 mmol) in *n*-hexane (10 mL) was added dropwise to a stirred solution of Cp* Ti[η^6-$C_5H_4C(H)tBu$]Me (**7**) (0.831 g, 2.5 mmol) in *n*-hexane (10 mL) at room temperature. After 2 h, a yellow nacreous solid began to precipitate. After stirring for an additional 58 h, the suspension was filtered. Washing of the residue with *n*-hexane (4 × 10 mL) and drying in vacuo led to **8b** as a yellow powder (0.836 g, 65%).

8a: ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = 0.66 (s, 3 H, CH_3), 0.93 [s, 9 H, $C(CH_3)_3$], 1.48 [s, 15 H, $C_5(CH_3)_5$], 4.05 (s, 1 H, 6-H), 4.64 (m, 1 H, C_5H_4), 5.36 (m, 1 H, C_5H_4), 5.58 (m, 1 H, C_5H_4), 6.54 (m, 1 H, C_5H_4), 7.01−7.24 (m, 8 H, H_{Ph}), 7.43 (m, 2 H, H_{Ph}). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 11.7 [$C_5(CH_3)_5$], 30.4 [$C(CH_3)_3$], 34.5 [$C(CH_3)_3$], 37.4 (CH_3), 58.6 (C6), 106.5 (C_5H_4), 113.6 (C_5H_4), 114.6 (C_5H_4), 116.2 (C_5H_4), 108.2 (C7), 119.4 [$C_5(CH_3)_5$], 125.6, 126.7, 126.9, 128.3, 128.5, 130.3 (CH_{Ph}), 136.8 (C1), 149.6, 152.6 (*i*-C_{Ph}).

8b: Decomposition without melting at 235 °C. ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = −0.05 (s, 3 H, CH_3), 0.91 [s, 9 H, $C(CH_3)_3$], 1.72 [s, 15 H, $C_5(CH_3)_5$], 4.32 (s, 1 H, 6-H), 4.53 (m, 1 H, C_5H_4), 5.39 (m, 1 H, C_5H_4), 5.86 (m, 1 H, C_5H_4), 6.41 (m, 1 H, C_5H_4), 7.04−7.24 (m, 8 H, H_{Ph}), 7.59 (m, 2 H, H_{Ph}). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 12.1 [$C_5(CH_3)_5$], 30.5 [$C(CH_3)_3$], 34.4 [$C(CH_3)_3$], 34.7 (CH_3), 59.4 (C6), 102.4 (C_5H_4), 106.7 (C7), 107.3 (C_5H_4), 113.6 (C_5H_4), 119.2 [$C_5(CH_3)_5$], 128.9 (C_5H_4), 126.5, 126.8, 126.9, 128.7, 128.9, 130.2 (CH_{Ph}), 136.8 (C1), 149.1, 150.5 (*i*-C_{Ph}). IR (KBr): ṽ = 3053 (m), 2943 (m), 2908 (m), 2889 (m), 1492 (s), 1477 (s), 1443 (s), 1392 (s), 1035 (s), 1013 (vs), 808 (vs), 800 (vs), 763 (vs), 713 (vs), 700 (vs), 686 cm^{-1} (vs). EI MS: *m*/*z* (%) = 514 (24) [M$^+$], 261 (100), 135 (20) [Cp*$^+$]. $C_{34}H_{42}OTi$ (514.58): calcd. C 79.36, H 8.23; found C 79.09, H 8.09.

Complex 9: A mixture of benzaldehyde (0.531 g, 5.0 mmol) in *n*-hexane (10 mL) was added dropwise to a stirred solution of Cp* Ti[η^6-$C_5H_4C(H)tBu$]Cl (**1**) (1.764 g, 5.0 mmol) in *n*-hexane (20 mL) at room temperature. After 15 min, the colour of the solution turned from dark green to orange. After stirring for an additional 4 h, the solution was concentrated to 10 mL and cooled to −20 °C. A mixture of diastereomers **9a** and **9b** was isolated as a yellow-orange, microcrystalline solid (1.308 g, 57%; **9a/9b** = 25:75).

9a: ^{1}H NMR (500 MHz, C_6D_6, 300 K): δ = 0.82 [s, 9 H, $C(CH_3)_3$], 1.76 [s, 15 H, $C_5(CH_3)_5$], 3.22 (d, $^3J_{H6,H7}$ = 8.5 Hz, 1 H, 6-H), 5.23 (m, 1 H, 2-H), 5.24 (m, 1 H, 3-H), 6.01 (m, 1 H, 4-H), 6.38 (d, 1 H, 7-H), 6.84 (m, 1 H, 5-H), 6.96−7.24, 7.89 (m, 5 H, H_{Ph}). ^{13}C NMR (125 MHz, C_6D_6, 300 K): δ = 12.4 [$C_5(CH_3)_5$], 29.3 [$C(CH_3)_3$], 33.5 [$C(CH_3)_3$], 61.0 (C6), 107.2 (C7), 109.7 (C3), 111.1

Crystal Structure Determinations. Single crystals of **2a**, **3a**, **5**(**b**′+**d**′), **6b**, and **9a** were obtained from saturated *n*-hexane solutions upon cooling to 0 °C. The crystal data were collected with a STOE-IPDS diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073). Intensity measurements were performed at 193(2) K on crystals in sealed glass capillaries. The structures of all complexes were solved by direct phase determination (SHELXS-97) and refined on F^2 (SHELXS-97)[27] with anisotropic thermal parameters for all non-hydrogen atoms. All hydrogen atoms in **2a**, **3a**, **5**(**b**′+**d**′), and **6b** were calculated and refined as riding atoms; hydrogen atoms in **9a** refined freely. Details of data collection parameters and refinements results are listed in Table 3. CCDC-174560 (**2a**), -174562 (**3a**), -174561 (**5**), -174559 (**6b**) and -174563 (**9a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structural and Chiroptical Properties of Acyclic and Macrocyclic 1,5-Bis(oxazoline) Ligands and Their Copper(I) and Silver(I) Complexes

Miklos Hollosi,[a] Zsuzsa Majer,[a] Elemér Vass,[a] Zlata Raza,[b] Vladislav Tomišić,[c] Tomislav Portada,[b] Ivo Piantanida,[b] Mladen Žinić,[b] and Vitomir Šunjić*[b]

Keywords: Circular dichroism / Conformation analysis / Copper / Silver / Bis(oxazoline) ligands / Macrocyclic ligands

C_2-symmetric acyclic ligands **1a**–**1e**, macrocyclic ligands **2a**–**2d** and **3**, and their copper(I) and silver(I) complexes were studied by UV, NMR and CD spectroscopy. The stability constants of the metal–**1a** and –**1b** complexes with 1:1 and 1:2 stoichiometries in acetonitrile were determined by spectrometric titrations. Evidence of tetrahedral coordination for complex $[Ag(\mathbf{1a})_2]^+$ was obtained from the complexation induced shifts (CIS) and NOEs, and corroborated by molecular modeling. Ligands with phenyl rings on the stereogenic centers (**1a**,**c** and **2**) exhibit a strong Cotton effect (CE) in the region of the ^1B_b band, which is absent in the ligands with benzyl groups on the stereogenic center (**1b**, **3**). This effect is ascribed to the exciton coupling (EC) of two aromatic chromophores on the stereogenic center. For ligands **1a** and **2a** the EC changes the sign on complexation to Cu^+, revealing opposite helicity of the free and complexed ligand.

Introduction

Chiral bis(oxazoline)−metal complexes have received a great deal of attention through their use in various asymmetric catalytic processes.[1−4] Among them the complexes with 1,5-bis(oxazoline) ligands having one carbon spacer between the oxazoline rings and able to form six-membered metal chelates, are the most frequently utilized as chiral catalytic complexes in various enantioselective transformations.

The most explored catalytic complexes are those of copper(I)[5−14] (enantioselective cyclopropanation of alkenes,[5−11] aziridation of olefins[12] and imines,[13] allylic oxidation of cycloalkenes[14]), copper(II)[15−24] (Diels−Alder reaction,[15−19] Mukaiyama aldol reaction,[20] Mukaiyama−Michael addition reaction,[21,22] Friedel−Crafts reaction,[23] Canizzaro reaction[24]), palladium(II)[25−27] (allylic substitution reaction), and zinc(II)[28−30] (allylation reaction). We have recently reported on very high cumulative enantio- and diastereoselectivity in cyclopropanation of styrene catalyzed by copper(I) complexes of macrocyclic ligands **2a**−**2c** (Figure 1).[31] These results are in line with our previous observation,[32,33] that enantioselectivity enhancement can be achieved by restricting conformational mobility of the ligand by repulsive or attractive π−π interactions.[34−36]

Structural studies of the ligand−metal complexes often provide valuable information regarding transition state assembly in the catalytic transformation. Already, the solid-state structures of various bis(oxazoline)−metal complexes have been elucidated on the basis of X-ray diffraction analysis,[5,9,19,26,27,37−44] but only a few were determined in solution based on NMR[26,38,43−45] and CD[44,45] spectroscopic investigations. To the best of our knowledge, the spectroscopic study of 1,5-bis(oxazoline)−copper(I) and −silver(I) complexes in solution, aimed at elucidating their structure and stability, has not been performed to date. Herewith we report the results of the combined achiral (UV, fluorimetric, ES-MS, NMR) and chiroptical (CD) spectroscopic studies of the acyclic (**1**) and macrocyclic ligands (**2**, **3**) (Figure 1) as well as their Cu^+ and Ag^+ complexes, corroborated by molecular modeling of some selected complexes. The study was expected to give insight into the topology of the free ligands and complexes, identify the stoichiometry, stability and structure of the complexes, and consequently to shed more light on the origin of stereoselectivity exhibited by this type of bisoxazoline ligands.

After this study was completed, a paper of Walsh et al.[46] appeared reporting on the study of the conformation of flexible macrocyclic catalysts in solution. The results support that bis(sulfonamido) ligands, derived from (*R*,*R*)-1,2-

Results and Discussion

Spectrometric Studies of Copper(I) and Silver(I) Complexes of 1a and 1b

The copper(I) and silver(I) complexing properties of ligands **1a** and **1b** have been investigated by spectrometric (UV, NMR, and fluorimetric) titrations. The obtained spectrometric data were processed using the SPECFIT program.[47] The addition of Cu^+ into the MeCN solutions of both **1a** and **1b** caused a hyperchromic effect in the corresponding UV spectra (Figure 2). Among several chemically reasonable speciations used in the fitting of the spectrophotometric data, two (set by assuming the presence of $[CuL]^+$ and $[CuL_2]^+$ or $[CuL_2]^+$ and $[Cu_2L_2]^{2+}$; L standing for either **1a** or **1b**) gave satisfactory results. However, the electrospray mass spectrometry (ES-MS) experiments indicated formation of $[CuL]^+$ and $[CuL_2]^+$ complexes and no evidence of the presence of $[Cu_2L_2]^{2+}$ species was observed. The mass spectra of MeCN solutions of Cu^+/**1a** with various $c(Cu^+)/c(\mathbf{1a})$ ratios showed peaks at m/z = 678 $\{[Cu(\mathbf{1a})(MeCN)]_n^{n+}\}$ and 1212 $\{[Cu(\mathbf{1a})_2]^+\}$, while in the case of Cu^+/**1b** peaks were observed at 665 $\{[Cu(\mathbf{1b})]_n^{n+}\}$ and 1268 $\{[Cu(\mathbf{1b})_2]^+$, a very weak signal, presumably due to the fragmentation in the mass spectrometer$\}$. The isotopic abundances of the peaks at m/z = 678 and 665 showed peak separation of 1 Da, supporting the presence of singly charged species, i.e. $[CuL]^+$. The stability constants of the Cu^+ complexes calculated from the spectrophotometric titration data are collected in Table 1. Both, **1a** and **1b** form quite stable 1:1 ($K_{CuL} \approx 10^5$ M^{-1}) and 1:2 ($K_{CuL2} \approx 10^4$ M^{-1}) complexes with Cu^+ in MeCN.

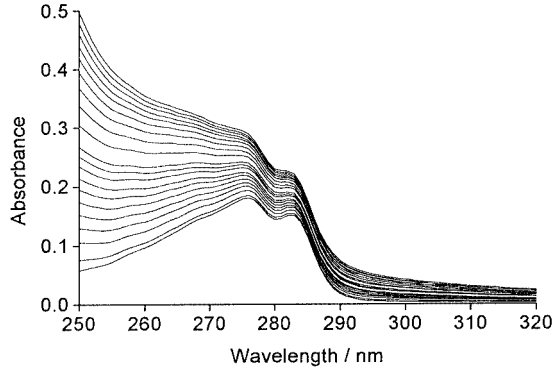

Figure 2. Spectrophotometric titration of **1a** ($c = 5\cdot10^{-5}$ mol·dm^{-3}) with $[(CH_3CN)_4Cu]PF_6$ in MeCN; l = 1 cm; φ = 25 °C; $c(Cu^+)$ = 0 (bottom curve) to $1.7\cdot10^{-4}$ mol·dm^{-3} (top curve); the spectra are corrected for dilution

Table 1. Stability constants of Cu^+ and Ag^+ complexes with **1a** and **1b** in MeCN determined by UV, ^{1}H NMR, and fluorimetric titrations; numbers in parentheses are estimated errors of the last digit

Species	log K[a] UV	^{1}H NMR	Fluorimetry
Cu(**1a**)	5.23(5)		
Cu(**1a**)$_2$	4.2(2)		
Cu(**1b**)	5.07(3)		
Cu(**1b**)$_2$	4.2(1)		
Ag(**1a**)		3.49(7)	3.45(6)
Ag(**1a**)$_2$		3.27(8)	
Ag(**1b**)		3.92(7)	3.63(4)
Ag(**1b**)$_2$		3.1(2)	

[a] $K = [ML_n]/([ML_{n-1}][L])$; M standing for Cu^+ or Ag^+ and L for **1a** or **1b**; n = 1, 2.

The UV spectral changes recorded during the titrations of **1a** and **1b** with Ag^+ in MeCN had qualitatively the same trend as in the case of Cu^+, but were insufficient to enable accurate analysis. Therefore, the formation of Ag^+ complexes was studied by means of ^1H NMR and fluorimetric titrations. The ^1H NMR spectra of **1a** and **1b** in [D$_3$]MeCN are concentration-independent in the range of $2\cdot10^{-3}$ to $2\cdot10^{-2}$ mol·dm^{-3}. The addition of $AgBF_4$ to **1a** up to the ratio $c(Ag^+)/c(\mathbf{1a}) = 0.5$ induced shielding of all protons except that of C(5)−H$_{trans}$ (Figures 3 and 4, a). Further addition [$c(Ag^+)/c(\mathbf{1a}) = 0.5-2.0$] resulted in a deshielding effect. The shielding/deshielding effect changed at the ratio $c(Ag^+)/c(\mathbf{1a}) = 0.5$ indicating the initial formation of $[Ag(\mathbf{1a})_2]^+$ species. Accordingly, the titration data were best fitted with a model including $[Ag(\mathbf{1a})]^+$ and $[Ag(\mathbf{1a})_2]^+$ complexes. The addition of Ag^+ to the solution of **1b** caused deshielding of all proton signals except for those of the methyl groups, which were shielded. However, the data were again best fitted with the model including two complex species, $[Ag(\mathbf{1b})]^+$ and $[Ag(\mathbf{1b})_2]^+$. Comparison of the determined stability constants of Ag^+ complexes with those of Cu^+ complexes (Table 1) shows that the former are more than one order of magnitude less stable for both ligands **1a** and **1b**.

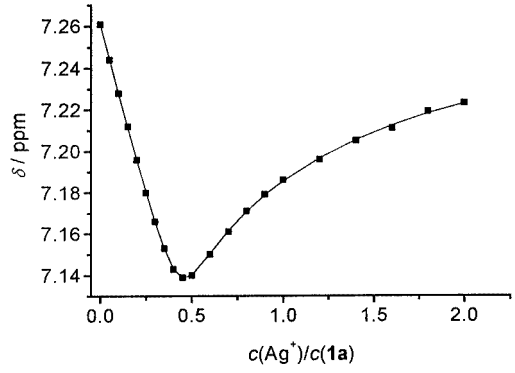

Figure 3. Experimental (dots) and calculated (line) chemical shifts of C(2′)−H of **1a** induced by addition of $AgBF_4$ (solvent: [D$_3$]MeCN)

The stabilities of the **1a**− and **1b**−Ag^+ complexes were also determined by means of fluorimetry. In MeCN ligands **1a** and **1b** exhibited a concentration-independent fluorescence up to the concentration of $2\cdot10^{-5}$ mol·dm^{-3}. The addition of Ag^+ quenched the fluorescence of **1a** and **1b** for ca. 90%. Processing of the titration data gave good fits when only the $[AgL]^+$ complex formation was taken into account for both compounds. The absence of $[AgL_2]^+$ could be explained assuming that fluorimetric properties of this species are similar to those of the free ligand causing insignificant spectral changes. On the other hand, the $[AgL]^+$ complexes exhibit a much weaker emission than free **1a** and **1b**. Consequently, titration data were collected mostly under conditions preferable for 1:1 stoichiometry and only the formation of $[Ag(\mathbf{1a})]^+$ and $[Ag(\mathbf{1b})]^+$ was observed. As can be seen in Table 1, the stability constants of these complexes determined by fluorimetric and ^1H NMR titrations are in

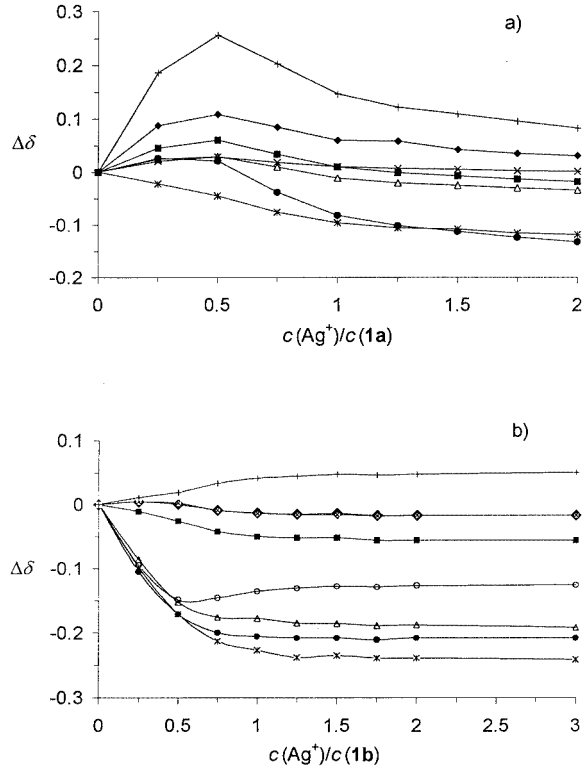

Figure 4. Complexation-induced shifts for **1a**− and **1b**−Ag^+ complexes; a): (+) CH_3; (◆) C(2′)−H; (×) C(4′)−OCH_2; (■) C(3′)−H; (Δ) C(4)−H; (*) C(5)−H$_{trans}$; (•) C(5)−H$_{cis}$; b): (O) C(4)−CH_2

rather good agreement. The stoichiometries of the Ag^+ complexes were additionally confirmed by electrospray mass spectrometry which showed peaks at m/z = 683 $\{[Ag(\mathbf{1a})]_n^{n+}\}$, 1258 $\{[Ag(\mathbf{1a})_2]^+\}$ and 711 $\{[Ag(\mathbf{1b})]_n^{n+}\}$. The exception was the absence of the signals of the $[Ag(\mathbf{1b})_2]^+$ species that could be attributed to the fragmentation in the mass spectrometer and to the equilibrium in solution (see next paragraph and Figure 6). The isotopic abundances of the peaks at m/z = 683 and 711 showed peak separation of 1 Da, corresponding to the singly charged species $[Ag(\mathbf{1a})]^+$ and $[Ag(\mathbf{1b})]^+$, respectively.

Complexation-Induced Shifts (CIS) and NOEs in the ^1H NMR Spectra of the Ag−1a,b Complexes

Structure of Complex $[Ag(1a)_2]^+$

Addition of Ag^+ to **1a** produced significant shifts of all the resonances of **1a**, without line broadening. This indicates fast equilibrium kinetics on the NMR time scale. The observed complexation induced shifts of **1a**, expressed as $\Delta\delta = \delta H i_{lig} - \delta H i_{compl}$ (ppm), were plotted against the $c(Ag^+)/c(\mathbf{1a})$ ratio (Figure 4, a). Ag^+ was added until a ratio of 0.5 was reached for the induced upfield shifts of all **1a** resonances except that of C(5)−H$_{trans}$; further additions of the cation produced downfield shifts of all resonances. A clear maximum at a $c(Ag^+)/c(\mathbf{1a})$ value of 0.5 suggests initial formation of the Ag^+−**1a** complex in a 1:2 stoichiometry which at higher ratios transforms to the 1:1 com-

plex. The methyl groups at the bis(oxazoline) bridge as well as the aromatic C(2′)−H and C(3′)−H groups experience the strongest shielding effects in the $[Ag(\mathbf{1a})_2]^+$ complex, which strongly suggests formation of the tetrahedral Ag^+ complex with the cation bound to 4 nitrogen atoms of the two orthogonally oriented bis(oxazoline) units of the **1a** molecules. The molecular models (see next paragraph and Figure 7, a) shows that in such a complex each bis(oxazoline) unit is located between two phenyl groups of the second ligand molecule. The C(4)-phenyl groups of two ligands end up close to one another, which results in the shielding of C(2′)−H and C(3′)−H. The methyl groups and the C(4)−H and C(5)−H_{cis} atoms of each bis(oxazoline) unit are also shielded by C(4)-phenyl groups of the second ligand. Additional support for the occurrence of such a 1:2 complex comes from the analysis of the NOESY spectrum at a $c(Ag^+)/c(\mathbf{1a})$ ratio of 0.5. The observed NOE interactions are shown in Figure 5. The molecular model of **1a** shows that the majority of the observed NOE crosspeaks could be explained by the favorable distances between respective hydrogen atoms in a single **1a** molecule. However, a clear crosspeak corresponding to NOE interactions between C(4′)−OCH_2 and methyl protons of the bis(oxazoline) bridge is observed. The closest possible distance between these protons in the model of **1a** is ca. 8 Å, well exceeding the limiting value of 4−5 Å, necessary for observation of NOE interactions. The additional proof for the structure of the $[Ag(\mathbf{1a})_2]^+$ complex is also provided by the observed trend of the complexation induced shifts in the $c(Ag^+)/c(\mathbf{1a})$ range of 0.5 and 2.0 (Figure 4, a), where all ligand resonances underwent downfield shifts. This trend could be explained by the disappearance of the $[Ag(\mathbf{1a})_2]^+$ complex and predominant formation of the $[Ag(\mathbf{1a})]^+$ complex. The ligand protons close to the metal center [C(4)−H, C(5)−H and C(2′)−H] of the 1:1 complex should be more deshielded by Ag^+ coordination through bond effects than those in the 1:2 complex, where these effects are distributed between two bis(oxazoline) units. Indeed, deshielding effects were observed for the C(4)−H and C(5)−H protons on going from a 1:2 to a 1:1 complex. However, the strongest deshielding experienced was of the methyl groups on the bridge, being four bonds away of the Ag^+ coordination site (Figure 4, a). Therefore, the latter effect must come from the shielding of the methyl groups in the 1:2 complex by the π-system of the C(4)-phenyl groups of the second molecule of the ligand **1a**.

In contrast to **1a**, the addition of Ag^+ to a CD_3CN solution of **1b** produced deshielding of all proton resonances but only slight shielding of the methyl protons; no clear indication of a 1:2 complex could be observed (Figure 4, b). However, processing of the NMR titration data gave the best fit for the formation of Ag^+−**1b** complexes of 1:2 and 1:1 stoichiometries (see previous paragraph). Comparison of the stability constants determined for Ag^+−**1a** and −**1b** complexes (Table 1) shows that the 1:1 complex of **1b** is around seven times more stable than the 1:2 complex, whereas the equivalent complexes of **1a** are of approximately the same stability, with the 1:1 complex being marginally more stable. This is reflected in the distribution diagrams of Ag^+−**1b** and Ag^+−**1a** systems shown in Figure 6, a, b. At a $c(Ag^+)/c(\mathbf{1b})$ ratio of 0.5 in the first system the concentration of the 1:1 complex is close to twice that of the 1:2 complex (Figure 6, a). For Ag^+−**1a** at this concentration ratio, a 1:2 complex is present in approximately four times higher concentration than the 1:1 complex (Figure 6, b). Consequently, the presence of an Ag^+−**1a** 1:2 complex can be detected through pronounced shielding effects. However, this is not the case for an Ag^+−**1b** system where the complexation induced shifts are dominated by the prevailing 1:1 complex at low and high $c(Ag^+)/c(\mathbf{1b})$ ratios. Nevertheless, the observation of shielding effects of methyl groups on the bridge in **1b** indicates similar structures of 1:2 Ag^+−**1a** and Ag^+−**1b** complexes.

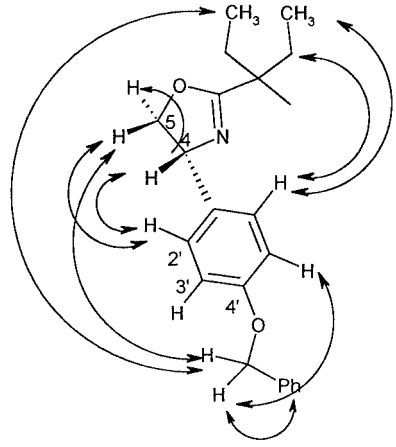

Figure 5. NOE interactions observed in the NOESY spectrum of $[Ag(\mathbf{1a})_2]^+$

Molecular Modeling

The $[Ag(\mathbf{1a})_2]^+$ complex was modeled[48] using 3−5 Å distance constrains between Me and OCH_2Ph protons in accordance with observed NOE interactions. The fully minimized final structure gives N−Ag^+ distances of 1.700, 1.704, 1.704, and 1.710 Å, Me to C(4)−Ph centroid distances of 3.12 Å and Me−OCH_2Ph C−C distances of 3.89 Å, in agreement with observed strong Me shielding and NOEs in the ^1H NMR spectra. The planes containing two bis(oxazoline) units form an angle of 71°, showing pseudotetrahedral coordination (Figure 7, a). The conformational space of the $[Ag(\mathbf{1a})]^+$ complex was then searched using the systematic search procedure at 30° increments for rotations of 8 rotatable bonds of PhO−CH_2Ph fragments. Five different low-energy conformations with energies within 5 kcal/mol were selected and each was fully minimized (Figure 7, b). The calculated structure reveals high conformational mobility of C(4′)−OCH_2Ph fragments and the absence of possible intramolecular aromatic π−π interactions between terminal phenyl groups, is in complete accordance with all experimental results.

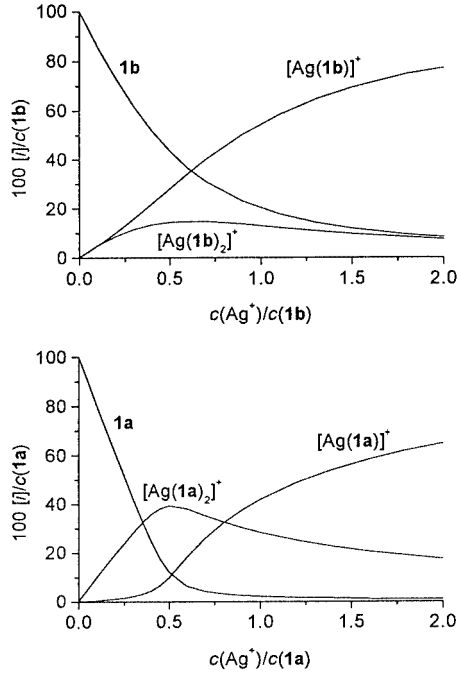

Figure 6. Distribution diagrams of the Ag^+/**1a** and Ag^+/**1b** systems in MeCN; *c* denotes total concentration, while [*i*] stands for equilibrium concentration of *i* = L (**1a** or **1b**), $[ML]^+$ and $[ML_2]^+$ species, respectively

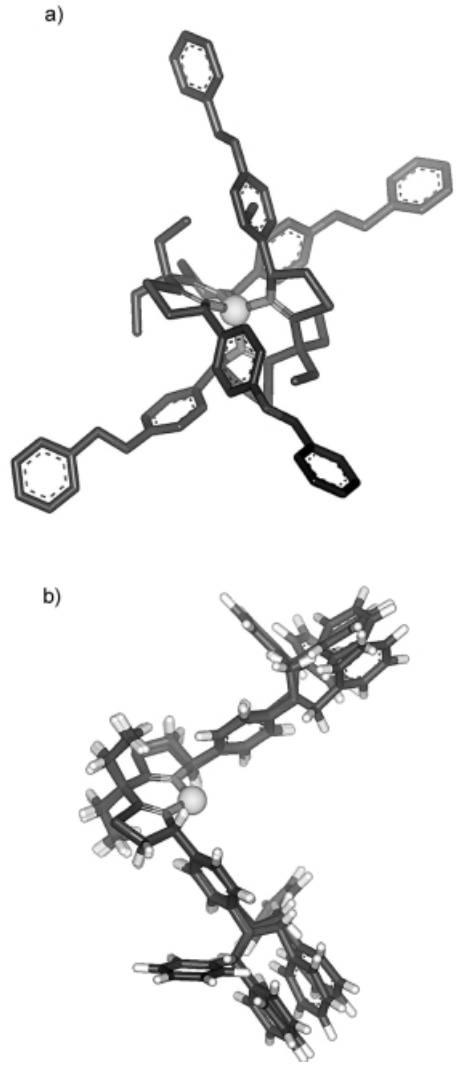

Figure 7. a) Structure of $[Ag(\mathbf{1a})_2]^+$ generated by molecular modeling; hydrogen atoms are omitted for the sake of clarity; b) five superpositioned low-energy conformations of $[Ag(\mathbf{1a})]^+$ generated by the systematic search of the conformational space

Chiroptical (CD) Study of the Acyclic and Macrocyclic Ligands and Their Copper(I) and Silver(I) Complexes

UV and CD Spectra of Acyclic Bis(oxazolines) 1

The short-wavelength band (λ_{max} = 194 nm) can be assigned to the $\pi_{C=N}-\pi^*_{C=N}$ transition in C_2-symmetric **1e**, whereas in **1d** it (λ_{max} = 190 nm) comprises superimposed ^1L_a bands of the phenyl chromophore. The weak long-wavelength band at λ_{max} = 264 nm in the UV spectrum of **1e** is assigned to the conjugated $\pi-\pi^*$ transition, based on the ab initio 6-31G* calculations and analysis of photoelectronic spectra;[49] **1a** and **1b** show similar UV spectra. However, the spectrum of **1d** is strikingly different showing much less intense bands at 264, 258, and 252 nm corresponding to phenyl substituents. The much more intense band observed at 275 nm for **1a** (ε = 4700 $M^{-1}\cdot cm^{-1}$) as compared to the band at 264 nm for **1d** (ε = 360 $M^{-1}\cdot cm^{-1}$), belongs to the phenoxy group on the stereogenic center.

Absolute configuration of acyclic bis(oxazolines) are (*R*,*R*) for **1a**,**c**,**d** and (*S*,*S*) for **1b**,**e**. In the CD spectra of **1a** and **1c** the intense positive band at 205 nm and 204 nm, respectively, is accompanied by a negative band near 192 nm as a sign of exciton interaction between the ^1B_b transitions. Ligand **1c** with an $O(CH_2)_4O$ bridge between the *para*-phenylene and phenyl rings shows some blue-shift and decreased intensity, presumably due to the increased conformational mobility of the side chains. The third ligand with a phenyl group attached to a stereogenic center (**1d**) shows a ca. 10 times decreased negative band at 190 nm ($\Delta\varepsilon < -5\ M^{-1}\cdot cm^{-1}$), and a positive band at 198 nm ($\Delta\varepsilon$ = 46.2 $M^{-1}\cdot cm^{-1}$), only ca 50% less intense then the positive 205-nm band of **1a** and **1c** (Table 2). One can argue that this shift in position and intensity is because of the absence of electron-donating *para*-alkoxy groups in **1d**. In the CD spectra of chiral bis(oxazolines) **1b** and **1e**, having no aromatic substituent at the stereogenic center the bands at 204 and 190 nm, respectively, belong to the π-π^* transition of the C=N chromophore (Table 2). The possibility of a weak exciton interaction between the ^1B_b transitions of the phenyl chromophores cannot be excluded either.

CD Spectra of Macrocyclic Bis(oxazolines) 2 and 3

As expected, in the CD spectrum of (*R*,*R*)-**2a** with oppositely configured chiral centers, as compared to **1b** and **3**, the ^1L_a band (ca. 230 nm) is positive. However, instead of one, there are two extremely strong bands of opposite sign in the ^1B_b region of the spectrum. In the UV spectrum a strong absorption was measured at 195 nm that supports the above

[a] Continuous spectral changes up to $r_{Ag,L} \approx 5$. [b] No band could be measured even with a 1-cm cell.

assignment. Clearly, the strong bands at 204 and 194 nm are due to the *para*-substituted phenyl chromophores attached to the stereogenic centers (Table 3). Notably, a couplet in the ^1B_b band spectral region was observed for **1a** with *para*-alkoxyphenyl substituents but not for **1b** with *para*-alkoxylbenzyl groups.

Regardless of the length of the alkyl chain (n = 2−5), the macrocyclic ligands **2a**−**d** with *para*-alkoxy-substituted phenyl groups attached to the stereogenic centers show CD spectra marked by an almost symmetric exciton couplet in the ^1B_b region. The most intense bands turn up in the spectrum of (*R*)-**2b** (n = 3) [204 nm (90.5 м$^{-1}$·cm^{-1}) and 193 nm (−73.0 м$^{-1}$·cm^{-1}), respectively]. The positive sign of the couplet is compatible with the orientation of the ^1B_b electric transition moment vectors, as discussed in the final section. On the basis of the increased intensity of the ^1L_a bands, a weaker exciton interaction between the ^1L_a transitions cannot be excluded either. However, instead of the expected negative band near 220 nm, the spectra of all macrocycles of type **2** have a positive CD (mostly two positive shoulders) between 225 and 205 nm. The lack of an exciton couplet in the ^1L_a region can be attributed to the nearly parallel orientation of the electric transition vector (Table 3). A positive band appears in the spectrum of **2b** at 220 nm. The complexity of the spectrum clearly indicates that the CD contribution of the "lower half" of the molecule cannot be completely neglected. Because of the increased flexibility, this part of the molecule likely occurs as a mixture of conformers but the dominant one(s) are expected to have the same sign of helical twist of the *para*-alkoxyphenyl rings attached to the $C(Et)_2$ bridge.

The CD spectrum of (*S*,*S*)-**3** is dominated by two negative bands at 203.5 and 228 nm which can be assigned to the ^1B_b and ^1L_a band, respectively, of the *para*-alkoxybenzyl chromophores attached to stereogenic centers. A weak positive and some weaker negative bands are seen in the ^1L_b region of the spectrum (Table 3). In the spectrum of the related acyclic analog (*S*,*S*)-**1b** (R = Bzl−O−Bzl) the cor-

responding bands turn up at 204 nm (-16.8 $M^{-1}\cdot cm^{-1}$), 229 nm (sh) and 282 nm. The lack of exciton splitting in the far-UV spectral region of **1b** and **3** is attributed to the difference in geometry and the greater conformational freedom of the *para*-alkoxybenzyl chromophores.

CD Spectra of Copper(I) and Silver(I) Complexes

In order to study their complexation by CD, acyclic ligands **1a−c** as well as the corresponding macrocyclic analogs **2a−d** and **3** were titrated with Ag^+ and Cu^+ ions.

In the spectrum of the acyclic ligand **1a** the exciton couplet of the ^1B_b transition was destroyed by Cu^+ complexing. A strong negative and a weaker positive band replaced the positive ^1L_a band at 229.5 nm (Figure 8). The spectrum showed only small changes between $r_{Cu,\mathbf{1a}} = 1$ and 2 [$r_{M,L} = c(M)/c(L)$] that suggests formation of a 1:1 complex of significant stability, in accordance with the results of the UV titration. Titration of **1a** with Ag^+ ions gave rise to a gradual decrease of the band intensities of the couplet. Significant spectral changes were observed also in the ^1L_a band region: a relatively strong negative band appeared at $r_{Ag,\mathbf{1a}} \geq 1$, while position and intensity of the band at 205 nm in the spectrum of **1a** varied gradually up to $r_{Ag,\mathbf{1a}} = 5$ (Figure 9). This spectral behavior can be explained by the formation of a 1:1 complex of lower stability compared to $[Cu(\mathbf{1a})]^+$. Ligand **1c** showed a similar spectral response to Ag^+ as **1a**. Cu^+ broke the positive couplet at $r_{Cu,\mathbf{1c}} \geq 0.75$ and the titration data indicated formation of a stable 1:1 Cu^+ complex.

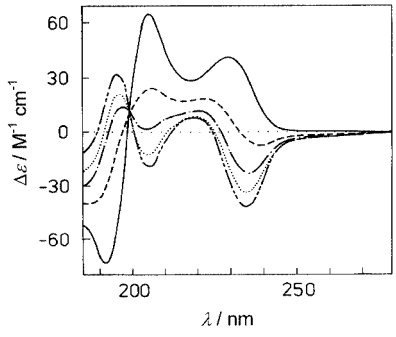

Figure 8. CD spectra of free (*R*,*R*)-**1a** (—), and on addition of Cu^+; 1:0.5 (− − −), 1:0.75 (— · —), 1:1 (·····) and 1:2 (— - - —)

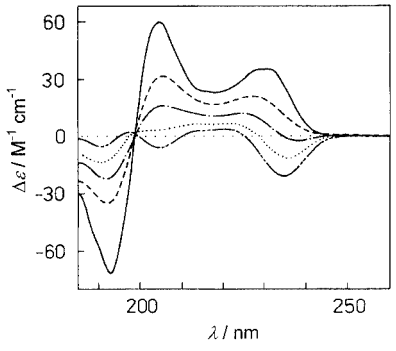

Figure 9. CD spectra of free (*R*,*R*)-**1a** (—), and on addition of Ag^+; 1:0.5 (− − −), 1:1 (— · —), 1:2 (·····), and 1:5 (— - - —)

Titration of **1b** with Ag^+ resulted in gradual spectral changes up to $r_{Ag,\mathbf{1b}} = 5$ (Figure 10). The formation of a 1:1 complex of exceeding stability could not be detected (Table 2). No definite spectral changes were seen between $r_{Ag,\mathbf{1b}} = 5$ and 10. Addition of Cu^+ caused marked spectral changes in the ^1L_a band region. Above $r_{Cu,\mathbf{1b}} = 1$ the main feature of the spectra is a positive band at ca. 230 nm. The formation of no dominant 1:1 complex could be detected (Figure 11).

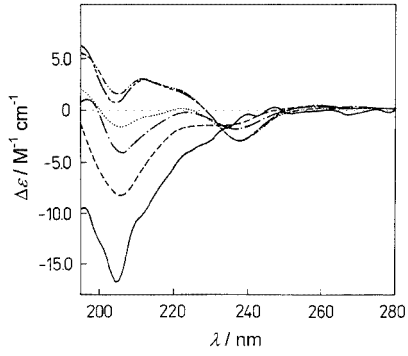

Figure 10. CD spectra of free (*S*,*S*)-**1b** (—), and on addition of Ag^+; 1:0.5 (− − −), 1:1 (— · —), 1:2 (·····), 1:5 (— - - —), and 1:10 (− · · − · ·−)

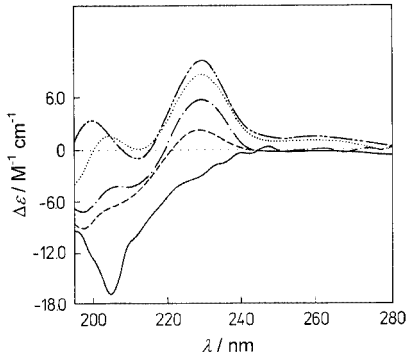

Figure 11. CD spectra of free (*S*,*S*)-**1b** (—), and on addition of Cu^+; 1:0.5 (− − −), 1:1 (— · —), 1:2 (·····), and 1:5 (— - - —)

Macrocyclic ligands **2a−d** showed a similar behavior against Ag^+. The couplet was completely destroyed at an $r_{Ag,\mathbf{2}} \geq 2$ ratio in the case of $n = 2$ and 5 (Figure 12); Cu^+ proved to be a more efficient breaker of the couplet. The spectra reflected no exciton interaction at $r_{Cu,\mathbf{2}} \geq 1$ for ligands **2**, $n = 2$ and 4. At $r_{Cu,\mathbf{2}} > 1$ the ^1L_a band appeared as a pair of negative and positive bands. The ^1B_b couplet, characteristic for the spectra of ligands **2a−d**, was replaced by a shoulder at ca. 210 nm and a pair of weaker blue-shifted oppositely signed bands (Figure 13) at $r_{Cu,\mathbf{2}} > 1$. Increasing the amount of Cu^+ gave rise to further spectral shifts, both below and above 250 nm. This spectral behavior can be interpreted as the consequence of the formation of a 1:1 complex of lower stability. However, the occurrence of complexes of other stoichiometry cannot be excluded either.

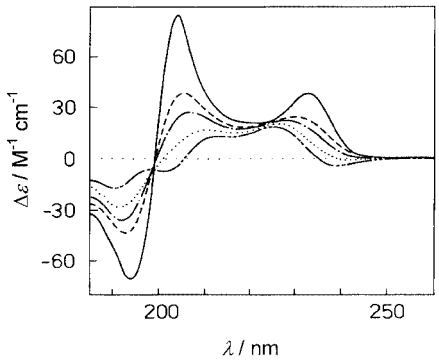

Figure 12. CD spectra of free (*R*,*R*)-**2a** (—), and on addition of Ag^+; 1:0.5 (– – –), 1:1 (— · —), 1:2 (·····), and 1:5 (— - - —)

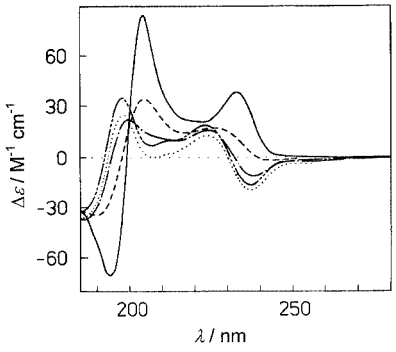

Figure 13. CD spectra of free (*R*,*R*)-**2a** (—), and on addition of Cu^+; 1:0.5 (– – –), 1:1 (— · —), 1:2 (·····), and 1:5 (— - - —)

Addition of Ag^+ to the macrocyclic ligand **3** resulted in an almost continuous spectral change (Figure 14). The position and intensity of the ^1L_a band at 228 nm were less influenced than that of the more intense ^1B_b band at 203.5 nm. Interestingly, the weak negative band at 299.5 nm of **3** with vibrational fine structure changed only to a small extent, while the weak positive band at 282.5 nm of **3** was blue-shifted, changed sign and appeared with increased intensity upon addition of Ag^+ (Table 3). Accordingly, the latter band can be assigned to the n–π* transition of the C=N groups, the nitrogen atoms of which coordinate to a central cation. Addition of Cu^+ to **3** changed the spectrum continuously up to a 2:1 metal/ligand molar ratio ($r_{Cu,3}$ = 2) (Figure 15). Complexing of Cu^+ by **3** gave rise to an increase in the intensity of both long-wavelength bands. The negative band showed a red-shift while the positive one a more definite (> 20 nm) blue-shift (Table 3). The weak negative band at ca. 310 nm of the 1:1 Cu^+ complex likely belongs to the complexed Cu^+ ion. In the far-UV region, both bands showed definite intensity and wavelength shifts up to $r_{Cu,3}$ = 2.

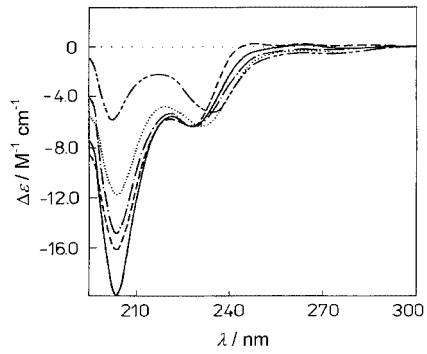

Figure 14. CD spectra of free (*S*,*S*)-**3** (—), and on addition of Ag^+; 1:0.5 (– – –), 1:1 (— · —), 1:2 (·····), and 1:7.8 (— - - —)

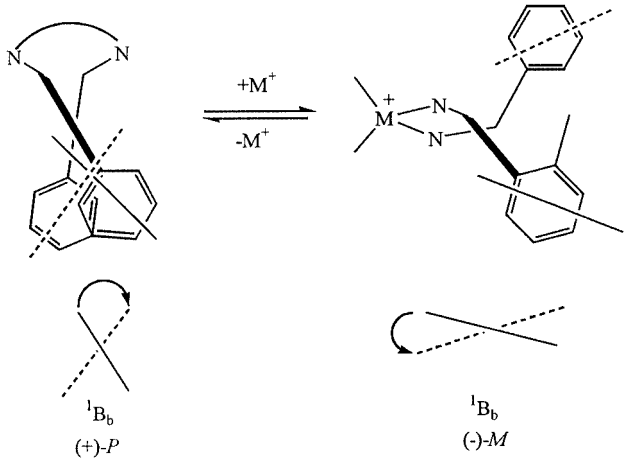
Conformations of Free Ligand 1a and Its Copper(I) and Silver(I) Complexes in Solution

There are few reports on comparative spectroscopic study of (poly)nitrogen ligands and their metal complexes. In an early study Bosnich has observed the split of π–π* transitions and the nearly equal positive and negative CD bands (couplet) for Zn^{2+} complexes with 1,4-*N*,*N*-bidentate ligands derived from salicylaldehyde (salene), comprising strong conjugated chromophores, and the presence of exciton interaction was demonstrated;[50,51] *transoid* conformation of the free ligand was observed in solution of 6,6′-disubstituted 2,2-bipyridine,[52,53] and its rotation into a *cisoid* conformer on complexation with Co^{2+}, affording a complex of C_2 symmetry, is documented by X-ray analysis of the complex.[54] Williams et al. have recently reported on the enantiopure helicates, complexes of chiral 2,6-bis(oxazolyl)pyridines as tridentate nitrogen ligands and an Ag^+ ion.[44,45] They had observed large changes in the CD spectrum of the ligand upon complex formation. The free ligand shows a weak negative band in the UV region of the spectrum ($\Delta\varepsilon_{296} = -0.4\ M^{-1}\cdot cm^{-1}$), whereas the complex shows a strong positive band ($\Delta\varepsilon_{301} = 10.15\ M^{-1}\cdot cm^{-1}$, for one metal center), corresponding to a new shoulder in the UV/Vis spectrum ($\varepsilon = 1547\ M^{-1}\cdot cm^{-1}$). This CD activity was attributed to a fixed helical conformation of the ligand in the complex, whereas free ligands may adopt different con-

formations that cancel out each other in the CD spectrum. Similar phenomena have been observed for several ligands[55−57] and metal complexes,[44][58][59] and explained by the exciton theory.

For the free bis(oxazoline)-type ligands, the conformation in solution is not known. We have therefore performed MM calculations[48] for an analog of **1a** (for better visualization methyl substituents are attached instead of benzyl), and the most stable conformation found was the helically twisted *transoid* one. In this conformation two phenyl groups form a positive (*P*) twist, and therefore a positive CE for the ^1B_b band is expected, (Scheme 1, Figure 16). In the 1:1 complex Cu^+−**1a** two halves of bis(oxazoline) are fixed in the nearly coplanar *cis* position with two large groups on the stereogenic centers forming a "picket-fence" topology, important for high enantioselectivity in catalytic reactions.[60]



Scheme 1. Schematic presentation of interacting chromophores in **1a** and **1a**−metal complex, and position of their ^1B_b transition vectors in the free ligand and in the complex

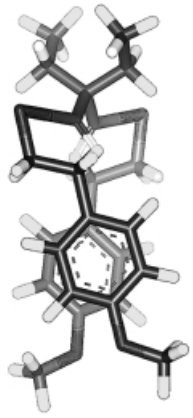


Figure 16. Ball-and-stick model of the non-hydrogen atoms of an analog of **1a** based on MM2 calculations

It is interesting that no such straight-forward change of the CD of **1a** is observed on titration with Ag^+ ions (Figure 9). The inflection point at ca. 195 nm is maintained, revealing formation of an $[Ag(\mathbf{1a})_2]^+$ complex, as confirmed by the NMR titration, but only partial inversion of the sign of the two bands of the couplet is observed. This reveals different influence of Cu^+ and Ag^+ on conformational change of **1a** upon complexation.

Generally, diminished intensity of the short-wavelength band on complexation of **1a** and **1b** is presumably raised by depleting π- and n-electron density in the C=N group on coordination to the metal ion. Since any stronger exciton coupling between two C=N chromophores, which are nonplanar in the free ligand, seems to be absent, coplanarization of the 4π system on complexation should result in an enhanced intramolecular charge transfer, and consequently could influence only the long-wavelength transition band at ca 280 nm.

Conclusion

Combined achiral and chiral spectroscopic study of 1,5-dinitrogen ligands with C_2-symmetic **1a** and **1b** and their copper(I) and silver(I) complexes has shown that they form stable 1:2 metal/ligand complexes, which transform on ulterior addition of metal ions to 1:1 complexes. Modeling experiments indicate pseudotetrahedral arrangement of coordinating N atoms around the central metal ion in the $[Ag(\mathbf{1a})_2]^+$ complex. The stability constants (Table 1) were determined for Cu^+− and Ag^+−**1a** and −**1b** complexes of 1:2 and 1:1 stoichiometries. At low cation/ligand molar ratios, 1:2 complexes are formed with Cu^+. The stabilities of 1:1 complexes exceed those of 1:2 complexes for one order of magnitude. The catalytic 1:1 Cu^+ complexs of **1a** and **1b** used in stereoselective cyclopropanations have stability constants of ca. 10^5 M^{-1} in acetonitrile. A ^1H NMR study of the **1a**−Ag^+ complexation reveals the formation of an $[Ag(\mathbf{1a})_2]^+$ complex with a stability constant of ca. 10^3 M^{-1}. The observed complexation induced shifts and NOEs together with molecular modeling suggest formation of a pseudotetrahedral complex. The comparative CD study of free acyclic (**1a−e**) and macrocyclic (**2a−d**, **3**) ligands and their Cu^+ and Ag^+ complexes provided insight into conformational changes occurring upon formation of the complexes. For free ligands **1a**, **1c** and **2a−d** strong exciton coupling in the ^1B_b region was observed and explained by a positive helicity of the alkoxyphenyl substituents on the stereogenic centers. Addition of a Cu^+ ion destroys the couplet and leads to opposite CE. The latter is the consequence of the ligand conformational change from *transoid* in the free ligand to *cisoid* in the Cu^+ complex and formation of a negative helicity between two alkoxyphenyl substituents. Such spectral properties are not observed for **1b** and **3** possessing more flexible benzyl substituents at the stereogenic centers.

Experimental Section

General: Compounds **1d** and **1e** are commercially available. Preparation of the compounds **2a−d** is reported in ref.[31] and the pre-

paration of the compounds **1a−c** and **3** will be published elsewhere. Reagents were purchased from Aldrich or Fluka and were used without further purification. All solvents were purified and dried according to standard procedures.

Spectrometric Titrations: UV titrations were performed at (25±0.1) °C by means of a Varian Cary 5 spectrophotometer equipped with a thermostating device. The spectral changes of **1a** and **1b** solutions ($c = 5{\cdot}10^{-5}$ mol·dm^{-3}) in MeCN were recorded upon stepwise addition of copper(I) ions directly into the measuring quartz cell (1 cm). Copper(I) ions were added as $[(CH_3CN)_4Cu]PF_6$ solution ($c = 2.6{\cdot}10^{-4}$ mol dm^{-3}) in MeCN. Spectra were sampled at 1-nm intervals. Fluorimetric titrations (λ_{exc} = 277 nm, λ_{em} = 285−330 nm, filter = 290 nm) were carried out using a Perkin−Elmer LS-50 spectrofluorimeter at ambient temperature. The MeCN solutions of **1a** and **1b** ($c = 1.32{\cdot}10^{-5}$ mol·dm^{-3}) were placed in the measuring quartz cell (1 cm) and titrated with an MeCN solution of $AgBF_4$ (c = 0.0116 mol·dm^{-3} and 0.116 mol·dm^{-3}). ^{1}H NMR titrations of **1a** and **1b** were performed at ambient temperature in CD_3CN (data taken as Δδ/ppm according to the signal of solvent used as internal standard) with Varian Gemini 300 MHz [c(**1a**) = 0.02 mol·dm^{-3}, V_0 = 0.5 mL, $c(AgBF_4)$ = 0.1 mol·dm^{-3}] and a Bruker 500 MHz instruments [c(**1b**) = 0.001 mol·dm^{-3}, V_0 = 0.5 mL, $c(AgBF_4)$= 0.005 mol·dm^{-3}]. Aliquots of the metal ion solution were added into the solution of the ligand in an NMR probe with Hamilton syringes. The obtained spectrometric data were processed using the SPECFIT program.[47] CD titrations: UV/Vis and CD spectra were recorded in acetonitrile with a Jobin−Yvon VI dichrograph calibrated with epiandrosterone. The ligands were titrated with $AgBF_4$ and $[(CH_3CN)_4Cu]PF_6$, respectively, in both the long-wavelength (> 240 nm) and short-wavelength UV regions. Measurements were performed at room temperature in 0.02- and 0.1-cm cells. The spectral changes of ligand solutions ($c = 4.5{-}6.0{\cdot}10^{-4}$ mol·dm^{-3}) in MeCN were recorded upon addition of silver(I) ($c = 2.0{\cdot}10^{-2}$ mol·dm^{-3}) and copper(I) ($c = 8.0{\cdot}\ 10^{-3}$ mol·dm^{-3}) solutions in MeCN, respectively.

Molecular Modeling: The metal-free bis(oxazoline) ligand was docked on the complex Ag^+/**1d** and the low-energy structure obtained modified by adding two additional N−heavy atom bonds to obtain the tetracoordinated complex. The metal−N bonds of 2.18 Å were used as distance constraints and the complex was fully minimized. In the next step, a benzyloxy group was attached in the *para* position to the stereogenic center of each phenyl ring to generate the 1:2 Ag^+/**1a** complex. The molecular modeling of the 1:2 Ag^+/**1a** complex and the search of the conformational space of the 1:1 Ag^+/**1a** complex was performed using the SYBYL molecular modeling software, version 6.3 of TRIPOS Inc. 4,4′-Diphenylbis(oxazoline) complex **1d**−Ag^+ was constructed using the Builder module. Instead of the Ag^+ ion, a heavy atom parameter available in the SYBYL package was used together with N−heavy atom distance constraints of 2.18 Å corresponding to an N−Ag^+ bond length found in the X-ray structure of some tetracoordinated Ag^+−bis(oxazoline) helicates.[44] The Gasteiger−Hückel charges were used with +1 formal charge of the heavy atom and the complex was minimized.

Vanadium(IV/V) Complexes Containing $[VO]^{2+}$, $[VO]^{3+}$, $[VO_2]^+$ and $[VO(O_2)]^+$ Cores with Ligands Derived from 2-Acetylpyridine and *S*-Benzyl- or *S*-Methyldithiocarbazate

Mannar R. Maurya,*[a] Shilpa Khurana,[a] Wenjian Zhang,[b] and Dieter Rehder[b]

Keywords: Malonate / Oxo transfer / Sulfur ligands / Hydrazones / Vanadium

Vanadium complexes containing $[VO]^{2+}$, $[VO]^{3+}$, $[VO_2]^+$ and $[VO(O_2)]^+$ cores with ligands (LH) derived from 2-acetylpyridine and *S*-benzyldithiocarbazate (Hacpy-sbdt, **I**) or *S*-methyldithiocarbazate (Hacpy-smdt, **II**) are introduced. The dioxovanadium(V) complexes $[VO_2L]$ [HL = **I** (**2**), **II** (**5**)] were isolated from the reaction between LH and $[VO(acac)_2]$ in the presence of air and KOH in dry methanol. Treatment of **II** with aerated $[VO(acac)_2]$ in *wet* methanol yielded the malonato complex [VO(acpy-smdt)mal] (**6**), with the malonate ligand originating from acetylacetonate. Under anaerobic reaction conditions, LH replaced one of the acac(1−) ligands to yield the oxovanadium(IV) complexes [VO(acac)L] [HL = **I** (**1**), **II** (**4**)]. Treatment of these complexes with H_2O_2, catechol or benzhydroxamic acid gave rise to oxo(peroxo)vanadium complexes $[VO(O_2)L]$ [HL = **I** (**3**), **II** (**7**)], catecholato complexes [VOL(cat)] [HL = **I** (**8**), **II** (**9**)] or benzhydroxamato complexes [VOL(bha)] [HL = **I** (**10**), **II** (**11**)]. Compounds **3** and **7** were capable of transferring an oxo group to PPh_3. In the presence of L-ascorbic acid under aerobic conditions, **8** and **11** were converted into **2** and **5**, possibly through intermediate reduction. Acidification of **2** with HCl in methanol afforded a hydroxo(oxo) complex. The crystal and molecular structures of **2** and **6** were determined, confirming the *NNS* (enethiolate) binding mode of L^-, and the bidentate coordination of the malonate ligand in **6**. The geometrical arrangement of the ligand set in **2** is intermediate between a trigonal bipyramid and a tetragonal pyramid.

Introduction

The coordination chemistry of oxovanadium(IV), oxovanadium(V) and dioxovanadium(V) has acquired new interest as these complexes can serve as good models for vanadium-containing biomolecules.[1−3] Potential therapeutic applications,[4−6] studies on the metabolism and detoxification of vanadium compounds under physiological conditions,[7] and the stability and speciation of vanadium complexes in biofluids[8] have further influenced the study of the coordination chemistry of vanadium. In this context, vanadium complexes containing thiofunctional ligands have received less attention.[9−11] Complexes with *OS* coordination [such as bis(1-oxy-2-pyridinethiolato)oxovanadium(IV)] have been found to be orally active insulin mimetic agents in the treatment of diabetic model animals.[12] In addition, coordination of a sulfur atom to the vanadium centre has been well established in vanadium nitrogenase found in nitrogen-fixing bacteria of the genus *Azotobacter*.[13,14] Vanadium complexes that model parts of the structure of the enzyme have been designed (cf. ref.[9]). Vanadium−sulfur coordination is also of interest for the inhibition of phosphatases (interaction between the vanadium centre and the active site cysteinate)[15,16] and the enantioselective oxidation of prochiral thioethers to sulfoxide by vanadate-dependent haloperoxidases.[17,18]

Unless bulky groups are attached to the ligand to provide sufficient steric hindrance, interaction between monobasic tridentate ligands and $[VO(acac)_2]$ under aerobic conditions generally produces dimeric, pseudo-octahedral complexes with the $[VO_2]_2$ core.[19−22] In the current work, we have employed less bulky ligands (cf. Scheme 1) with an *NNS* donor set, which stabilise monomeric dioxovanadium(V) ($[VO_2]^+$) complexes with the vanadium centre in a tetragonal-pyramidal array, strongly distorted towards a trigonal bipyramid. Other complexes, with $[VO]^{2+}$, $[VO]^{3+}$ and $[VO(O_2)]^+$ cores, have also been prepared. The hitherto unknown coordination of malonate to oxovanadium(V) has been achieved by the unprecedented preparation of the complex [VO(acpy-smdt)mal] by oxidative removal of the methyl groups from one of the acetylacetonates in $[VO(acac)_2]$ in the presence of the supporting *NNS* ligand. In all cases reported here, the ligands coordinate from their thioenolate form; cf. refs.[23−31] for other examples of stable oxo- and dioxovanadium(V) complexes with this coordination mode. Apart from their interesting coordination beha-

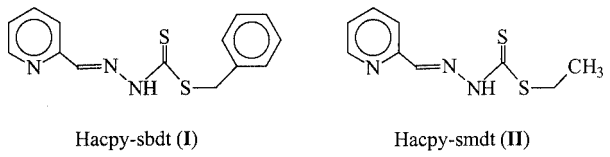
viour, our motivation to use these particular ligands (**I** and **II**, Scheme 1) also arises from the recently assessed antiamoebic activity of their ruthenium(II) and palladium(II) complexes against *Entamoeba histolytica* (strain HK-9).[32,33]

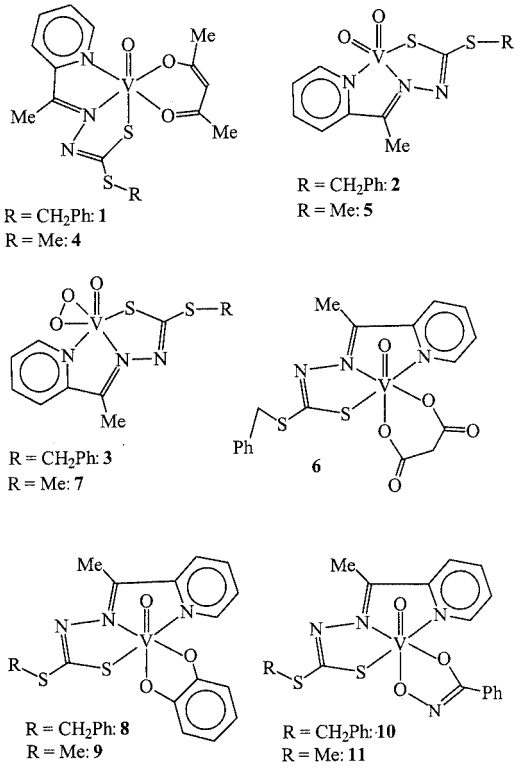


Scheme 1

Results and Discussion

Synthesis, Reactivity and Solid-State Characteristics

Direct treatment of the ligands Hacpy-sbdt (**I**) and Hacpy-smdt (**II**) (Scheme 1) with methanolic solutions of $[VO(acac)_2]$ in equimolar amounts under anaerobic conditions provided the oxovanadium(IV) complexes [VO(acac)L] [**1** and **4**, Scheme 2, Equation (1)].



Scheme 2

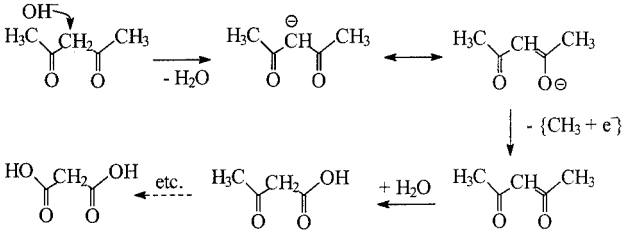
Solutions of $[VO(acac)_2]$ in organic solvents undergo rather slow oxidation under aerobic conditions.[34] In methanolic KOH, however, oxidation occurred within 8−10 h, possibly to a complex of composition $K[VO_2(acac)_2]$ [Equation (2a)]. Treatment of **I** or **II** with this species, generated in situ, under aerobic conditions yielded the monomeric pentacoordinated dioxovanadium(V) complexes **2** and **5**, respectively [Scheme 2, Equation (2b)]. A pentacoordinated vanadium(V) complexes with the dioxo groupe may have either tetragonal-pyramidal or trigonal-bipyramidal coordination geometry. The former tend to dimerise through oxo bridges to produce pseudo-octahedral coordination environments.[19] With bulky substituents on the ligand, the formation of tetragonal-pyramidal species, and thus dimerisation, can be circumvented, and trigonal-bipyramidal species can be stabilised.[20−22] The procedure employed here, refraining from bulky substituents, directly provided monomeric, square-pyramidal complexes.

$$\underset{\mathbf{1,4}}{[VO(acac)_2]} + HL \rightarrow \underset{\mathbf{1,4}}{[VO(acac)L]} + Hacac \quad (1)$$

$$2[VO(acac)_2] + 2KOH + \tfrac{1}{2}O_2 \rightarrow \text{“}2K[VO_2(acac)_2]\text{”} + H_2O \quad (2a)$$

$$K[VO_2(acac)_2] + HL \rightarrow \underset{\mathbf{2,5}}{[VO_2L]} + Hacac + Kacac \quad (2b)$$

On addition of a few drops of water to solutions of $[VO(acac)_2]$ in methanol plus KOH, followed by addition of Hacpy-smdt in the presence of air, the malonato(oxo)vanadium(V) complex **6** was obtained. This unprecedented formation of malonate from acetylacetonate was apparently a consequence of oxidative removal of the methyl groups from acetylacetone, activated by coordination, and catalysed by OH^-, as depicted in Scheme 3. The malonic acid thus formed ultimately reacted with the oxidised vanadium species in the presence of Hacpy-smdt to give **6**.



Scheme 3

Complexes **1**, **2**, **4** and **5** served as good starting materials for the preparation of other oxovanadium(V) complexes. For example, **1** and **4** were oxidised in the presence of the strong oxidant H_2O_2 to give the corresponding oxo(peroxo)vanadium(V) complexes, as shown by Equations (3) and (4).

$$\underset{\mathbf{1}}{2[VO(acac)(acpy\text{-}sbdt)]} + 3H_2O_2 \rightarrow \underset{\mathbf{3}}{2[VO(O_2)(acpy\text{-}sbdt)]} + 2Hacac + 2H_2O \quad (3)$$

$$\underset{\mathbf{4}}{2[VO(acac)(acpy\text{-}smdt)]} + 3H_2O_2 \rightarrow \underset{\mathbf{7}}{2[VO(O_2)(acpy\text{-}smdt)]} + 2Hacac + 2H_2O \quad (4)$$

These complexes could also be prepared from the corresponding dioxo species as shown for **3** by Equation (5).

$$\underset{\mathbf{2}}{[VO_2(acpy\text{-}sbdt)]} + H_2O_2 \rightarrow \underset{\mathbf{3}}{[VO(O_2)(acpy\text{-}sbdt)]} + H_2O \quad (5)$$

Treatment of catechol or benzhydroxamic acid with **1** and **4** under aerobic conditions resulted in the formation of the mixed chelate oxovanadium(V) complexes **8**, **9**, **10** and **11**, as represented by the general Equations (6) and (7). For proposed structures, cf. Scheme 2.

$$2[VO(acac)L] + 2H_2cat + \tfrac{1}{2}O_2 + 2H^+ \rightarrow 2[VO(cat)L] + 2Hacac + H_2O \quad (LH = \mathbf{I}: \mathbf{8}; LH = \mathbf{II}: \mathbf{9}) \quad (6)$$

$$2[VO(acac)L] + 2H_2bha + \tfrac{1}{2}O_2 + 2H^+ \rightarrow 2[V^{V}OL(bha)] + 2Hacac + H_2O \quad (LH = \mathbf{I}: \mathbf{10}; LH = \mathbf{II}: \mathbf{11}) \quad (7)$$

Analytical and IR spectroscopic data of the complexes are included in the Exp. Sect. All complexes were fairly soluble in CH_3CN, DMF and DMSO; peroxo complexes were sparingly soluble in CH_3CN only. Complexes **1** and **4** were paramagnetic with magnetic moments of $\mu = 2.10$ and 2.16 BM, respectively, while all other complexes were diamagnetic, as to be expected for $3d^0$ systems.

Thermogravimetric Studies

The mixed-ligand complexes **1**, **4** and **8**−**11** lost about 1−3% weight (due to residual water of crystallisation) between 80 and 135 °C. The weight loss in the temperature range 195−225 °C corresponded to the loss of acac, cat or bha, minus one oxygen atom, thus giving rise to the formation of dioxo intermediates as shown by Equation (8) for **1** and **4**.

$$[V^{IV}O(acac)L] \rightarrow [V^{V}O_2L] + \{acac - O\} \quad (8)$$

The peroxo complexes **3** and **7** lost some weight (about 3%) below 150 °C. The main decomposition process took place above 180 °C, and corresponded to the simultaneous loss of an oxygen atom plus part of the ligand, possibly forming $[VO_2L']$ and $[VOL']$ intermediates, where L′ is a fragment of L. The dioxo complexes **2** and **5** decomposed in three major steps. Between 190 and 330 °C the weight loss corresponded to $SCH_2C_6H_5$ (in **2**) or SCH_3 (in **5**), followed by a second step between 330 and 500 °C corresponding to the loss of the SCN group. On further heating, the remaining residue decomposed to yield V_2O_5 as the end product. The final residue always weighed a little more than expected, probably due to incomplete oxidation of the end-product.

Structure Descriptions

The molecular structure of $[VO_2(acpy\text{-}sbdt)]$ (**2**) together with the atom-numbering scheme is shown in Figure 1, with selected bond lengths and angles in Table 1. The geometry of this neutral, five-coordinated mononuclear complex can be described either in terms of a trigonal bipyramid, distorted towards a tetragonal pyramid, or in terms of a tetragonal pyramid, distorted towards a trigonal bipyramid. The τ value, which is 0 for ideal tetragonal and 1 for ideal trigonal arrangements, amounts to $\tau = (N1-V-S1 - O2-V-N2)/60 = 0.47$. This is significantly more than in the related thiohydrazone complex [VO(OEt)(*ONS*)], in which $\tau = 0.27$.[31] The two alternative views are depicted in Scheme 4. In both views, the distortion comes about from the steric requirements resulting from the small bite angles of the bicyclic structure constituted by the two five-membered chelate rings.

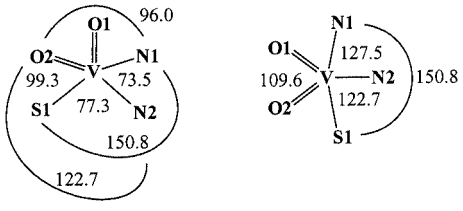

Scheme 4

The N_2SO_2 coordination in **2** is supplied by the pyridine nitrogen, the imine nitrogen and the thiolate sulfur atom of the monobasic tridentate ligand acpy-sbdt(1−), and by the two oxo groups. If viewed as a tetragonal pyramid, O1 is at the apex, while the three ligand functions and O2 form the tetragonal plane. If viewed as a trigonal bipyramid, N1 and S1 are in axial positions (N1−V−S1 = 150.8°), with the remaining ligand function (N2) plus the two doubly bonded oxygen atoms in the trigonal plane. This arrangement is similar to that reported for other $[VO_2L]$ compounds in which LH is a Schiff base derived from 2-hydroxy-1-naphthaldehyde and 8-aminoquinoline (Hsal-amq)[21] or *N*-anisoyl-*N′*(picolinylidene)hydrazine (Hpic-anh).[22] The V=O distance of 1.615(1) Å (for both oxo groups) is typical of V=O groups not involved in hydrogen bonding and other weak intermolecular contacts.[35] Furthermore, the bond lengths *d*(V1−N1) [2.1038(14) Å], *d*(V1−N2) [2.1454(14) Å] and *d*(V1−S1) [2.3852(5) Å] are in agreement with literature values for aromatic ring and imine nitrogen atoms[36] and for thioamide sulfur atoms coordinating to the vanadium centre.[29−31] The bond lengths *d*(N2−N3) [1.3904(17) Å], *d*(N3−C8) [1.294(2) Å] and *d*(S1−C8) [1.7273(17) Å] are consistent with the enethiolate mode of coordination.

For the structures of the closely related complex **5** and the peroxo complexes **3** and **7**, we assume a ligand arrangement corresponding to that in **2**; cf. Scheme 2.

The ORTEP drawing of $[VO(acpy\text{-}smdt)\{CH_2(COO)_2\}]$ (**6**) along with its atom-labelling scheme is presented in Figure 2, with selected structure parameters in Table 2. The coordination environment around vanadium is distorted octahedral, with malonate(2−) in axial/equatorial and the tridentate acpy-smdt(1−) in equatorial positions. The second axial position is occupied by the oxo group. The vanadium atom is displaced from the equatorial plane defined by N1, N2, S1 and O2 by 0.2415(9) Å towards the oxo ion O1. At 176.79(8)°, the O=V−O(malonate) axis is almost linear. Because of the strong *trans* influence of the oxo group, *d*(V−O3) [2.1387(17) Å] is significantly elongated with respect to the second, equatorial V−carboxylate bond, *d*(V−O2) = 1.9933(18) Å. Such elongation has previously been observed in other complexes with similar structures.[37−40] Bond lengths *d*(V1−N1) [2.125(2) Å] and *d*(V1−N2) [2.068(2) Å] are well within the common range.[37] The range of V−S bond length generally reported in the literature for oxovanadium(V) complexes of ligands derived from *S*-benzyldithiocarbazate is 2.343−2.365 Å.[29−31] The bond length *d*(V1−S1) = 2.4364(7) Å found here is somewhat longer. The distances *d*(N3−C8) [1.306(3) Å] and *d*(S1−C8) [1.736(3) Å] again support thioenolisation in the coordinated ligand. The bite angles in the two five-membered rings formed by the tridentate ligand are 75.77(7)° (N1−V1−N2) and 79.70(6)° (S1−V1−N2), and thus compare with the bite angles in **2**. The two "open" angles N1−V1−O2 and S1−V1−O2 amount to 95.43(8) and 106.05(6)°, respectively.

From the structural evidence provided for **6**, with the bidentate, dianionic malonato ligand occupying an axial and an equatorial position, the structures for other mixed-ligand complexes containing dianionic oxygen-functional ligands, [VO(cat)L] (**8** and **9**) and [VO(bha)L] (**10** and **11**) have been formulated accordingly in Scheme 2. For the complexes [VO(acac)L] (**1** and **4**), an axial coordination of the sulfur atom has been assumed on the basis of EPR results (see below).

IR Spectra

IR spectra of the ligands exhibited two bands at 3175 and 1064 cm^{-1} (in Hacpy-sbdt, **I**) and at 3150 and 1062 cm^{-1} (in Hacpy-smdt, **II**) due to ν(NH) and ν(C=S) stretches. The presence of both bands in the ligands was indicative of their thionic nature [−NHC(=S)− functionality] in the solid state. Absence of these bands in the spectra of the complexes indicates that the tautomeric enethiol form of the ligand [−N=C(SH)− functionality] is the preferred one on coordination to vanadium. A strong ligand band in the 1579−1600 cm^{-1} region was assigned to the ν(C=N) azomethine stretch, and this band underwent a shift to higher wave numbers by 5−42 cm^{-1} on complexation, indicating the participation of the azomethine nitrogen atom in coordination.[32,33] A sharp band appearing at ca. 1020 cm^{-1} was within the 990−1050 cm^{-1} range commonly observed for monodentate coordination of the >N−N< residue, though this band could not be located unequivocally in the ligands.[41] The band due to the coordinated pyridine nitrogen atom could not be assigned because of the strong absorption of ν(C=N) in this region. The coordination of the pyridine nitrogen atom has, however, been confirmed by single-crystal X-ray studies of, for example, $[VO_2(pic\text{-}anh)]_2$,[16] and in the complexes **2** and **6** reported here.

All of the monooxo complexes displayed one sharp band in the 945−967 cm^{-1} region, due to the ν(V=O) mode, while the dioxo compounds **2** and **5** showed two sharp bands at 930−939 and 947 cm^{-1}, corresponding to the $\nu_{sym}(O=V=O)$ and $\nu_{antisym}(O=V=O)$ modes. The existence of two sharp bands in the dioxo complexes suggested a *cis*-VO_2 arrangement, as verified by the structure results of **2**. The peroxo complexes **3** and **7** showed three IR-active vibrational modes associated with the peroxo moiety at ca. 928, 775 and 620 cm^{-1} and assigned to the O−O intrastretch (ν_1), the antisymmetric $V(O_2)$ stretch (ν_3), and the symmetric $V(O_2)$ stretch (ν_2), respectively.[42] These bands confirmed the η^2-coordination of the peroxo group.

Solution Studies

NMR and EPR Studies

The typical ^1H NMR chemical shifts of the ligands and complexes are shown in Table 3. The Schiff bases each exhibited a signal due to the NH proton at δ = 9.90−9.95, indicating their presence as their thionic tautomers. The absence of this signal in the complexes further supported the thioenolisation of the thione group and consequent replacement of H by the metal ion. A downfield shift of the signal for the methyl protons of the acetylpyridine residue from

δ = 2.55−2.60 in the ligand to δ = 2.73−2.79 in the complex indicated coordination of the azomethine nitrogen atom. The aromatic protons of the coordinated catecholate groups (in **8** and **9**) resonated as two multiplets between δ = 6.59 and δ = 6.72, while the aromatic protons of the benzylhydroxamate groups (in **10** and **11**) appeared along with other aromatic protons (Table 3). Signals due to the methyl protons of the *S*-methyldithiocarbazate and methylene protons of the *S*-benzyldithiocarbazate residue all appeared well within the expected ranges and did not shift significantly with respect to those of the free ligands. Complexes **8**, **9**, **10** and **11** exhibited two signals both for the methyl and for the methylene protons. One set of signals corresponded to the complexes of composition [VO(cat/bha)L], while the other set belonged to the dioxo complexes $[VO_2L]$, which formed by slow decomposition in the DMSO solvent (see also below).

The ^{13}C NMR spectra of the dioxo complexes and ligands (Table 4) provided a useful diagnostic tool for the elucidation of the structures of the complexes. Assignments were based on the chemical shift and intensity patterns, and on the coordination-induced shift δΔ = δ(complex) − δ(free ligand) of the signals for the carbon atoms in the vicinity of the coordinating atoms.[43] A large coordination shift was observed for the signal of the carbon atom (C7) bearing the enethiolate sulfur atom, and for the azomethine carbon atom (C1). Even the methyl carbon signals associated with the azomethine group experienced some downfield shift.

To characterise the compounds further in solution, ^{51}V NMR spectra of **2**, **5**, **6**, **8**, **9**, **10** and **11** were also recorded; for data see Table 5. The resonances were somewhat broadened as a consequence of the nuclear quadrupole moment of the spin 7/2 nucleus ^{51}V; line widths at half height were approximately 200 Hz, which is still considered narrow in ^{51}V NMR spectroscopy.[44−46] Each dioxo complex showed one strong resonance at δ = −444.0 (**2**) or −442.5 (**5**). The ^{51}V nucleus was thus less shielded than commonly observed with dioxovanadium(V) complexes with a mixed *ON* donor set; the chemical shifts, however, were well within the range expected for coordination of a soft (thio) function in addition to *O* and *N*.[31,48−50] The catecholato complexes **8** and **9** displayed two resonances: the lowfield signals at δ = +368.4 (**9**) and +373.7 (**8**) (peak 1) were indicative of catecholate coordination and thus belonged to the mixed-ligand complexes [VO(cat)L], while the signal at δ = −434.0 (peak 2) corresponded to the decomposition product $[VO_2L]$. Similarly, the hydroxamate complexes **10** and **11** each exhibited a lowfield resonance at δ = +135.6 (**11**) or +143.0 (**10**) along with a signal in the upfield region

at δ = −430 and −434, again due to dioxo species [VO_2L] formed by decomposition. An additional decomposition band at δ = −508 indicated either an oxo- or a dioxovanadium(V) complex with only *O*/*N* coordinating functions. The substantial downfield shift of the ^{51}V resonances (peak 1) in the catecholate and benzhydoxamate complexes has been reported previously and traced back to strong ligand-to-metal charge transfer (LMCT);[47] cf. also the UV/Vis spectra. The downfield shift of peak 2 (the resonance corresponding to the decomposition product) by ca. 10 ppm with respect to solutions containing authentic **2** or **5** is a medium effect, imparted by the presence of catechol in the solution in contact with [VO^2L].

Room-temp. EPR spectra of the two vanadium(IV) (d^1) complexes [VO(acac)L] (**1** and **4**) in DMSO provided a g_0 value of 1.965, and a comparatively large hyperfine coup-

ling constant $A_0 = 93 \cdot 10^{-4}$ cm^{-1}. For the anisotropic spectrum at 97 K, the following parameters were obtained: $g_{zz} = 1.938$, $g_{xy} = 1.978$; $A_{zz} = 178.5$, $A_{xy} = 50.3 \cdot 10^{-4}$ cm^{-1}. These values were essentially in the expected range.[48] The large A_{zz} component accounts for the diminished delocalisation of electron density into the ligand system, which may be a consequence of steric strains in the bicyclic chelate structure, and of a weak bonding contribution in the axial position, provided by coordination of the thio function subjected to the *trans* influence of the oxo group.

Electronic Absorption Spectra

The UV/Vis spectroscopic data of the ligands and complexes recorded in acetonitrile are presented in Table 6. All of the complexes displayed a medium to intense electronic spectral band at $\lambda = 410.5-416$ nm, attributable to LMCT arising from the N_2S^- ligand. Coordinated benzhydroxamate and catecholate induce strong charge transfer to the metal centre in complexes with high-valent metal ions. Thus, a strong band at $\lambda = 565$ nm for **10** and **11**, and two intense bands at $\lambda \approx 500$ and 766 nm for **8** and **9** were assigned to LMCT originating from lone-pair p orbitals on the hydroxamato[49] and catecholato oxygen atoms,[50] respectively, into an empty d orbital of the vanadium ion. As vanadium(V) complexes are d^0 systems, d−d bands were not expected in these complexes. In the oxovanadium(IV) complexes **1** and **4**, however, a weak band at $\lambda \approx 590$ nm was probably due to a d−d transition, as this band slowly disappeared on oxidation of **1** and **4** to the corresponding peroxo complexes by H_2O_2 (vide infra). Other spectral features of the complexes (intraligand bands in the UV region) were nearly identical to those of the free ligands.

Stability and Reactivity Studies

The stabilities of the complexes **8**, **9**, **10** and **11** were studied in various solvents. Complexes **9**, **10** and **11** were stable in solvents such as CH_2Cl_2, MeOH and CH_3CN, while they slowly decomposed in DMF and DMSO. A rather slow loss of coordinated catechol followed by conversion into the respective dioxo species has been noticed in dry solvents, while addition of few drops of water facilitated this conversion, as observed by electronic absorption spectroscopy (Figure 3). Addition of 1 drop of water to 5 mL of a ca.10^{-4} M solution of [VO(acpy-sbdt)cat] (**8**) in DMSO caused the gradual loss of the LMCT bands belonging to coordinated catecholate, which disappeared within 8 h. Complexes **10** and **11** gave comparable results. Similar observations have also been noted for [VO(sal-amq)cat].[21] The suggested reaction is formulated in Equation (9).

$$[VOL(cat)] + H_2O \rightarrow [VO_2L] + H_2cat \quad (9)$$

Oxovanadium(V) complexes generally undergo redox reactions with reducing agents such as L-ascorbic acid, cysteine and cysteine derivatives.[51,52] A model redox reaction with L-ascorbic acid was carried out for complexes **8** and **11**. In a typical reaction, 9 mL of a 10^{-4} M solution of **8** or **11** was treated with 1 mL of a 10^{-1} M solution of L-ascorbic acid in acetonitrile, and the reaction was monitored by electron absorption spectroscopy (Figure 4). The absorption bands at $\lambda = 765.5$ and 501.5 nm for complex **8** slowly disappeared. The band at $\lambda = 410.5$ shifted to $\lambda = 415$ nm with a marginal reduction in intensity, while the band at $\lambda = 338$ nm underwent a blue shift to appear at $\lambda = 331$ nm with a marginal increase in intensity. An additional new band appeared at $\lambda = 277$ nm. For complex **11** (not shown), the bands at $\lambda = 564.5$ and 257 nm slowly disappeared. The band at $\lambda = 411.5$ nm remained unchanged, while the band at $\lambda = 338$ nm shifted to $\lambda = 331$ nm with a slight increase in intensity. As L-ascorbic acid has reducing properties, reduction of **8** and **11** might be anticipated along with the removal of coordinated catecholate/benzhydroxamate. However, the match of the spectral features with those of solutions of **2** and **5**, with only minor deviations in the UV region, indicated that the reduced species was rapidly reoxidised to the dioxo complex $[VO_2L]$, and not to the original mixed ligand compound. The slight deviations in the UV were probably due to factors arising from the presence of uncoordinated catecholate or hydroxamate. L-Ascorbic acid was thus simply involved in electron transfer, without formation of any long-lived complex with **8** or **11**.

Treatment of complexes **1** and **4** with H_2O_2 around 0 °C yielded the oxo(peroxo)vanadium(V) complexes **3** and **7** (cf. Exp. Sect.). These reactions, involving dropwise addition of 30% H_2O_2 to 10 mL of ca. 10^{-4} M solutions of **1** or **4** in acetonitrile at ca. 10 ° C, were also monitored by electron absorption spectroscopy. The spectral changes during the reaction are shown in Figure 5 for complex **4**. In each case, the band appearing at $\lambda = 410.5$ nm slowly disappeared, while a red shift to $\lambda = 350.5$ nm was observed for the band at $\lambda = 338.5$ nm of **1**, with a corresponding red shift for the band at $\lambda = 336.5$ nm to $\lambda = 345.5$ nm in the case of **4**. The features of the final spectra were similar to those of the corresponding isolated peroxo complexes **3** and **7**.

The peroxo complexes underwent oxygen transfer with PPh_3 in CH_3CN to give the corresponding dioxovanadium(V) complexes **2** and **5**. During the reaction, PPh_3 possibly inserts directly into one of the metal−peroxo bonds, followed by the transfer of an oxo group from the peroxo

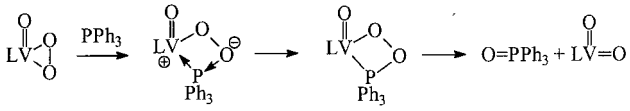

Scheme 5

λ = 585 nm. We preliminarily interpret these results in terms of the formation, on acidification, of a hydroxo complex of composition $[VO(OH)(acpy\text{-}sbdt)]^+$, similar to the hydroxo(oxo) complex $[VO(OH)(LH)]^+$, where LH_2 = *N*-[{(*o*-hydroxyphenyl)methyl}-*N*′-(2-hydroxyethyl)ethylenediamine][53] or *N*-salicylidene-*N*′-(2-hydroxyethyl)ethylenediamine,[54] generated in a similar manner from the respective dioxyvanadium(V) dimer. {See also [VO(OH)Tp(H_2O)] [Tp = tris(3,5-diisopropyl-1-pyrazolyl)borate][55] and [VO(OH)(8-oxyquinolinato)$_2$][56] for other characterised oxo-hydroxovanadium complexes.} On allowing the above solution to stand overnight, or on addition of KOH dissolved in acetonitrile, the solution reacquired its original character; the reaction was hence reversible and gave the spectrum of **2**. The reversibility of such reactions is an important observation in the context of the vanadate-dependent haloperoxidases, for which a hydroxo group in an apical position has been confirmed by X-ray diffraction analysis.[57]

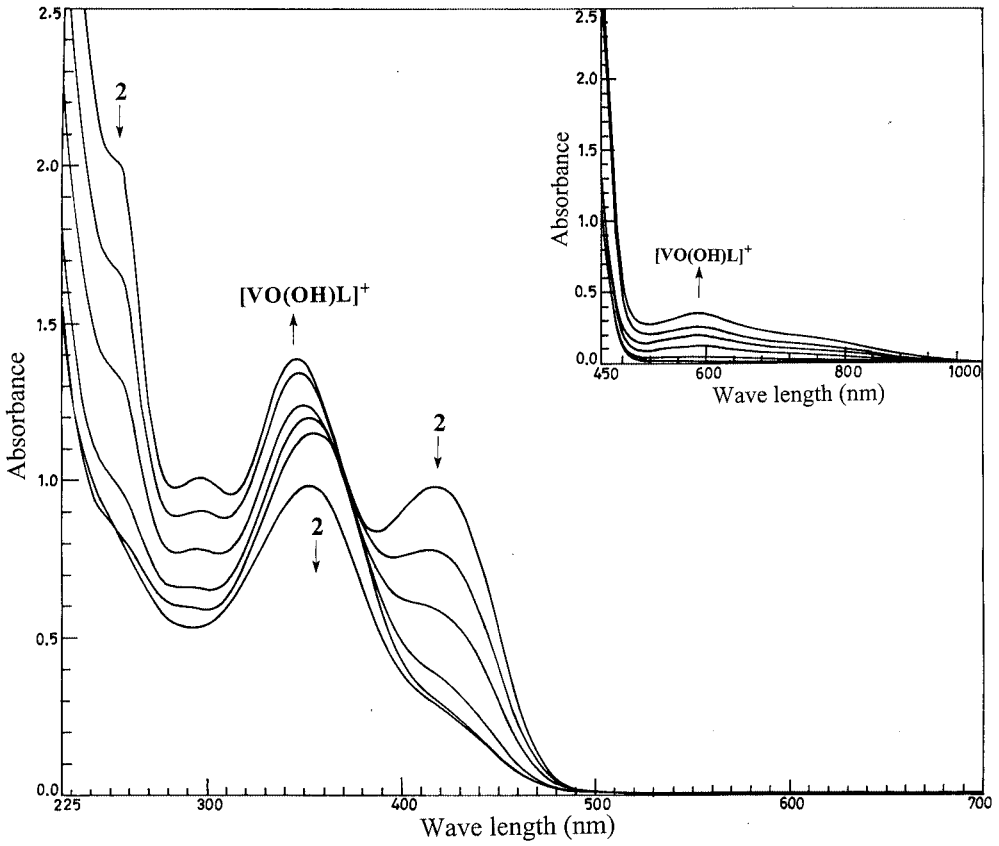

Figure 6. Titration of $[VO_2(acpy\text{-}sbdt)]$ (**2**) with a saturated solution of HCl in CH_3CN; spectra were recorded after the addition of 3 drops of CH_3CN/HCl to 10 mL of a ca. 10^{-4} M CH_3CN solution of **2**

Conclusion

The preparation and characterisation of monomeric dioxovanadium(V) complexes with a structure between a square-pyramidal and a trigonal-bipyramidal ligand arrangement is described, together with octahedral monooxovanadium complexes. A tridentate N_2S^- ligand system derived from acetylpyridine and dithiocarbazine, acpy-sbdt and acpy-smdt, was used. These complexes model part of the structure of vanadium nitrogenase and the active site of vanadate-dependent haloperoxidases. The model includes intermediate species with $[VO(OH)]^{2+}$ and $[VO(O_2)]^+$ cores, as postulated for catalytic turnover by the peroxidases, and which have been generated and characterised in this work. Additional reactions − such as the reversibility of the formation of a hydroxo(oxo) complex from a dioxo complex, the transfer of a peroxo oxygen atom from the (oxo)peroxo complex to triphenylphosphane, and the role of water or ascorbic acid in the conversion of monooxo- to dioxovanadium(V) complexes − are of interest from the perspective of vanadium speciation under physiological conditions, the mechanism by which vanadate-dependent haloperoxidases catalyse oxo transfer to halide and thioethers, and also a possible general role of vanadium in oxotransferases. The oxidative conversion of acetylacetonate in $[VO(acac)_2]$ to malonate, and concomitant oxidation of V^{IV} to V^V under mild basic conditions and in the presence of Hacpy-sbdt afforded the complex [VO(acpy-sbdt)malonate], underlining the versatile reaction patterns accompanying this interesting ligand system.

Experimental Section

Materials and Methods: V_2O_5 (Loba Chemie, India), methyl iodide (Spectrochem, India), benzhydroxamic acid (Merck, Germany), catechol (s. d. fine chemicals, India), acetylacetone and 2-acetylpyridine (Aldrich, U.S.A.) were used as obtained. Other reagents and solvents used were of AR grade. *S*-Benzyldithiocarbazate,[58] *S*-methyldithiocarbazate [59] and $[VO(acac)_2]$ [60] were prepared according to methods reported in the literature. The Schiff bases Hacpy-sbdt (**I**) and Hacpy-smdt (**II**) (cf. Scheme 1) were prepared as reported in a previous paper.[32,33] Elemental analyses were carried out by The Central Drug Research Institute, Lucknow, India. UV/Vis spectra were recorded in acetonitrile and methanol with a UV-1601 PC UV/Vis spectrophotometer. IR spectra were recorded as KBr pellets with a Perkin−Elmer model 1600 FT-IR spectrometer. EPR spectra of the paramagnetic complexes were measured with a Bruker ESP 300E spectrometer at ca. 9.6 GHz (X-band) in ca. 2 mM DMSO solution. Magnetic susceptibilities of oxovanadium(IV) complexes were measured by the Scientific Instrumentation Centre of the Indian Institute of Technology, Roorkee. ^1H NMR spectra were obtained with a Bruker 200 MHz spectrometer, ^{13}C and ^{51}V NMR spectra with a Bruker AM 360 spectrometer at 90.56 and 94.73 MHz, respectively, in $[D_6]$DMSO with the usual parameter settings. The $\delta(^{51}V)$ values have been referenced and are

quoted relative to $VOCl_3$. Thermogravimetric analyses of the complexes were carried out on a simple, manually operated thermobalance as described by us previously. Crystal Structure Determinations: Data were collected with a Siemens/Bruker SMART Apex CCD diffractometer with a graphite monochromator and Mo-K_α radiation (λ = 0.71073 Å) at 153(2) K. Hydrogen atoms were placed in calculated positions and included in the last cycles of refinement. Crystal data and details of the data collection and refinement are collected in Table 7. The programme systems SHELXS 86 and SHELXL 93 were used throughout.[61] CCDC-177111 (**2**) and -177112 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of Complexes

[VO(acac)(acpy-sbdt)] (1): [VO(acac)$_2$] (0.53 g, 2 mmol) was added to a stirred solution of Hacpy-sbdt (0.60 g, 2 mmol) in 20 mL of dry methanol, and the resulting mixture was refluxed for 4 h. On cooling the reaction flask to ambient temperature, a dark green solid separated and was filtered off, washed with methanol and dried in vacuo to give 0.84 g (90%) of **1**. $C_{20}H_{21}N_3O_3S_2V$ (466.47): calcd. C 51.50, H 4.51, N 9.01; found C 51.42, H 4.54, N 9.20. IR: $\tilde{\nu}$ = 1586 (C=N, C=C), 1022 (N−N), 947 (V=O), 440, 410 cm^{-1} (V−O, V−N).

[VO$_2$(acpy-sbdt)] (2): [VO(acac)$_2$] (0.53 g, 2 mmol) was dissolved in 40 mL of dry methanol, and KOH (0.11 g, 2 mmol) was added. The resulting solution was stirred for 2 h and then left for ca. 10 h in air. The solution slowly changed to red-brown. A solution of Hacpy-sbdt (0.60 g, 2 mmol) in 15 mL of methanol was added slowly, and the mixture was stirred magnetically for 4 h. A lustrous yellow solid separated; it was filtered off, washed with methanol and dried in vacuo to give **2**. Yield 0.42 g (55%). X-ray quality single crystals were grown by slow concentration of an acetonitrile solution of the complex in air. $C_{15}H_{14}N_3O_2S_2V$ (383.36): calcd. C 47.0, H 3.66, N 10.96; found C 47.0, H 3.54, N 10.83. IR: $\tilde{\nu}$ = 1600, 1580, 1557 (C=N, C=C), 1019 (N−N), 947, 939 (O=V=O sym and antisym), 461, 422 cm^{-1} (V−O, V−N).

[VO(O$_2$)(acpy-sbdt)] (3). Method A: Compound **2** (0.192 g, 0.5 mmol) was dissolved in 30 mL of acetonitrile while heating on a water bath, and filtered. The filtrate was treated with H_2O_2 (30%, 4 mL) while stirring and maintaining the reaction mixture at 10 °C. The colour changed from yellow to dark red. After 4 h, the solution was refrigerated (ca. 10 °C) overnight, whereupon orange-red crystalline **3** separated. The product was filtered off and dried in vacuo at ambient temperature. Yield: 70 mg (35%). $C_{15}H_{14}N_3O_3S_2V$ (399.36): calcd. C 45.11, H 3.51, N 10.53; found C 45.20, H 3.63, N 10.68. IR: $\tilde{\nu}$ = 1632, 1580, 1569 (C=N, C=C), 1023 (N−N), 951 (V=O), 929 (O−O), 777 (VO_2 antisym), 617 (VO_2 sym), 435, 414 cm^{-1} (V−O, V−N). **Method B:** Compound **1** (0.466 g, 1 mmol) was dissolved in 60 mL of acetonitrile, and H_2O_2 (30%, 8 mL) was added while stirring. The reaction mixture was stirred for 4 h at 10 °C and then left overnight at the same temp. The orange-red crystals that had separated were filtered and dried in vacuo. Yield: 0.16 g (40%). IR and electronic spectroscopic data matched well with **3** prepared according to method A.

[VO(acac)(acpy-smdt)] (4): Complex **4** was prepared in 85% yield by the procedure described for **1**. $C_{14}H_{17}N_3O_3S_2V$ (390.37): calcd. C 43.07, H 4.36, N 10.77; found C 43.13, H 4.47, N 10.91. IR: $\tilde{\nu}$ = 1588 (C=N, C=C), 1021 (N−N), 951 (V=O), 440, 409 cm^{-1} (V−O, V−N).

$[VO_2$(acpy-smdt)] (5): An oxidized red-brown methanolic solution of $[VO(acca)_2]$ (0.53 g, 2 mmol) was produced as described for complex **2**. A solution of Hacpy-smdt (0.23 g, 2 mmol), dissolved in 15 mL of methanol, was added with stirring. Workup was carried out as described for **2**. Yield: 0.31 g (50%). $C_9H_{10}N_3O_2S_2V$ (307.26): calcd. C 35.18, H 3.26, N 13.68; found C 35.36, H 3.31, N 13.70. IR: $\tilde{\nu}$ = 1583, 1561 (C=N, C=C), 1033(N−N), 947, 930 (O=V=O sym and antisym), 461, 424 cm^{-1} (V−O, V−N).

[VO(acpy-smdt)malonate] (6): $[VO(acac)_2]$ (0.53 g, 2 mmol) was dissolved in 30 mL of methanol, and two drops of water and KOH (0.11 g, 2 mmol) were added. The resulting solution was stirred for 2 h and then left for ca. 10 h in air. The solution slowly changed to red-brown with the deposition of some white solid on the wall of the flask. A solution of Hacpy-smdt (0.23 g, 2 mmol) in 15 mL of methanol was added, and the mixture was stirred for 2 h. A light green product that gradually precipitated was redissolved by heating the reaction mixture on a water bath, and the mixture was then left in air at ambient temperature. Over ca. 5 h, a light red solid precipitated and was filtered off, washed with methanol and dried. The product was recrystallised from hot acetonitrile. Orange crystals were obtained within 2−3 d on slow evaporation of the solvent in air. Yield: 0.24 g (30%). The elemental analysis showed that the bulk product was a mixture of **6** and **4**. The S/N ratio was reproduced correctly, indicating that the ligand had remained intact.

$[VO(O_2)$(acpy-smdt)] (7): Complex **7** was prepared from **4** and from **5** with H_2O_2 as described for **3**, in ca. 50% yield. $C_9H_{10}N_3O_3S_2V$ (323.26): calcd. C 33.44, H 3.09, N 13.0; found C 33.52, H 3.24, 13.0. IR: $\tilde{\nu}$ = 1628, 1580 (C=N, C=C), 950 (V=O), 928 (O−O), 775 (VO_2 antisym), 620 (VO_2 sym), 435, 410 cm^{-1} (V−O, V−N).

[VO(acpy-sbdt)cat] (8): Compound **1** (0.47 g, 1 mmol) was dissolved in hot methanol (40 mL). After the mixture had cooled to room temp., catechol (0.11 g, 1 mmol) was added and the reaction mixture was stirred for 6 h. The volume of the solvent was reduced to ca. 10 mL and the mixture was kept in the refrigerator overnight, whereupon brown-black solid **7** separated. This was filtered off, washed with cold methanol and dried in vacuo at ambient temp. Yield: 0.19 g (40%). $C_{21}H_{18}N_3O_3S_2V$ (475.45): calcd. C 53.05, H 3.79, N 8.84; found C 53.19, H 3.83, N 8.82. IR: $\tilde{\nu}$ = 1600, 1576 (C=N, C=C), 1020 (N−N), 950 (V=O), 460, 414 cm^{-1} (V−O, V−N).

[VO(acpy-smdt)cat] (9): Complex **9** was prepared analogously to **8** in 52% yield, by replacing **1** with **4**. $C_{15}H_{14}N_3O_3S_2V$ (399.36): calcd. C 45.11, H 3.51, N 10.52; found C 45.38, H 3.56, N 10.47. IR: $\tilde{\nu}$ = 1600, 1577 (C=N, C=C), 1030 (N−N), 950 (V=O), 460, 441, 415 cm^{-1} (V−O, V−N).

[VO(acpy-sbdt)bha] (10): Compound **1** (0.47 g, 1 mmol) was dissolved in 40 mL of hot methanol, and after the reaction flask had cooled to room temp., benzohydroxamic acid (0.137 g, 1 mmol) was added. The resulting reaction mixture was stirred for 6 h. After reduction of the volume to ca. 10 mL, the solution was kept at 10 °C overnight, during which brown solid **10** separated. This was filtered off, washed with methanol, and dried in vacuo. Yield: 0.19 g (38%). $C_{22}H_{20}N_4O_3S_2V$ (503.49): calcd. C 52.48, H 3.97, N 11.13; found C 52.53, H 4.11, N 11.05. IR: $\tilde{\nu}$ = 1600, 1580 (C=N, C=C), 1031 (N−N), 967 (V=O), 473, 420 cm^{-1} (V−O, V−N).

[VO(acpy-smdt)bha] (11): Compound **11** was prepared in 42% yield analogously to **10**, by replacing **1** by **4**. $C_{16}H_{16}N_4O_3S_2V$ (427.39): calcd. C 44.96, H 3.76, N 13.11; found C 45.0, H 3.91, N 13.23. IR: $\tilde{\nu}$ = 1585, 1562 (C=N, C=C), 1025 (N−N), 963 (V=O), 463, 414 cm^{-1} (V−O, V−N).

Treatment of 3 and 7 with PPh_3: PPh_3 (0.195 g, 0.75 mmol) was added to a suspension of **3** or **7** (0.05 mmol) in 15 mL of hot CH_3CN, and the reaction mixture was refluxed on an oil bath for 4 h, during which the complex slowly dissolved. After reduction of the solvent volume to ca. 10 mL, the heating was discontinued, and the flask was kept at ca. 10 °C overnight, whereupon a crystalline solid separated out within 5−6 h. This was filtered off and dried in vacuo. Yield 45%. Analytical and spectroscopic data of the complexes thus obtained matched well with **2** and **5**, respectively

Gold(I) Thiolates as Metalloligands for the Synthesis of the First Zirconocene−Gold Complexes

Barbara Wenzel,[a] Peter Lönnecke,[a][‡] and Evamarie Hey-Hawkins*[a]

Dedicated to Professor Dr. Peter Welzel on the occasion of his 65th birthday

Keywords: Metallocenes / Zirconium / Gold / O,S ligands / Bridging ligands

The reactions of the mercaptocarboxylic acids $HOOC(CH_2)_nSH$ (n = 1, 2) with $H[AuCl_4]$ followed by treatment with PMe_2Ph led to the (phosphane)gold thiolates $[Au\{S(CH_2)_nCOOH\}(PMe_2Ph)]$ [n = 1, (**1**) 2 (**2**)], which can act as metalloligands towards complex fragments of a second metal. Compounds **1** and **2** react with $[Cp^\circ{}_2ZrMe_2]$ (Cp° = C_5EtMe_4) to give the trinuclear Zr/Au complexes $[Cp^\circ{}_2Zr\{\kappa^1O\text{-}OOC(CH_2)_nSAu(PMe_2Ph)\}\{\kappa^2O,O'\text{-}OOC(CH_2)_n\text{-}SAu(PMe_2Ph)\}]$ [n = 1 (**3**), n = 2 (**4**)]. Complexes **1**–**4** were characterized by ^1H, ^{13}C, ^{31}P NMR and IR spectroscopy. The crystal structure of **4** shows mono- and bidentate coordination of two metalloligands to one zirconocene fragment. In solution at room temperature **3** and **4** are dynamic, and the carboxylato groups alternate between the mono- and bidentate bonding modes. Complex **4** shows catalytic activity in the oxidation of PPh_3 with O_2.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Research in early/late heterobimetallics (ELHBs) has grown in the last few years and has been the subject of numerous reports.[1−4] The reasons for the interest include their relevance to bioinorganic bimetallic systems and their potential in homogeneous catalysis. The pairing of two electronically different metals in a single compound may lead to cooperative interactions between them, such as those observed in heterogeneous catalysis, and there is also the possibility for stereo- or regioselective catalysis. Heterogeneous catalysts in which late transition metals are dispersed on a Lewis acid (TiO_2 or Al_2O_3) support often show increased catalytic activity.[5−9] Such strong metal−support interactions (SMSI) are not well understood but have been attributed to the electronic communication between the metals and cooperative activation of substrates by the different metal centers.[10,11]

For the synthesis of related homogeneous systems we have used an early transition metal complex of a bifunctional ligand as a so-called metalloligand for a late transition metal. For example we reported on the synthesis of a monomeric (mercaptoacetato)zirconocene complex that acted as metalloligand to form heterobimetallic Zr/Ni and Zr/Pd complexes.[12] Furthermore, we described the synthesis of macrocyclic, dimeric zirconocene complexes as metalloligands by using thioglycolates as bridging ligands, and the formation of a tetranuclear Zr/Mo complex.[13] In the present study, we prepared Au^I-based metalloligands. Thus, we describe the synthesis of phosphanylgold thiolates from mercaptoacetic and mercaptopropionic acid and their reactions with $[Cp^\circ{}_2ZrMe_2]$ to give trinuclear Zr/Au complexes. The formation of linearly coordinated thiolato complexes is a well-known property of Au^I that is also important for our purposes, since an attempt to prepare a related bis(phosphane)nickel thiolate as a metalloligand led only to formation of the energetically stable chelate complex.[14]

Results and Discussion

Gold(I) Thiolates $[Au\{S(CH_2)_nCOOH\}]$ (n = 1, 2)

Gold(I) thiolates are well known.[15] Their preparation usually starts from gold(III), in the form of sodium tetrachloroaurate(III) or the corresponding acid, which then requires a reduction step. Bishop et al.[16] described the synthesis of $[Au(SCH_2COOH)]$ using ethyl 2-hydroxyethyl sulfide as reducing agent. We found that $HSCH_2COOH$ and $HS(CH_2)_2COOH$ also function as reductants to give nearly quantitative yields of the thiolates $[Au(SCH_2COOH)]$ and $[Au(SCH_2CH_2COOH)]$.

(Phosphane)gold(I) Thiolates $[Au\{S(CH_2)_nCOOH\}(PMe_2Ph)]$ [n = 1 (1), n = 2 (2)]

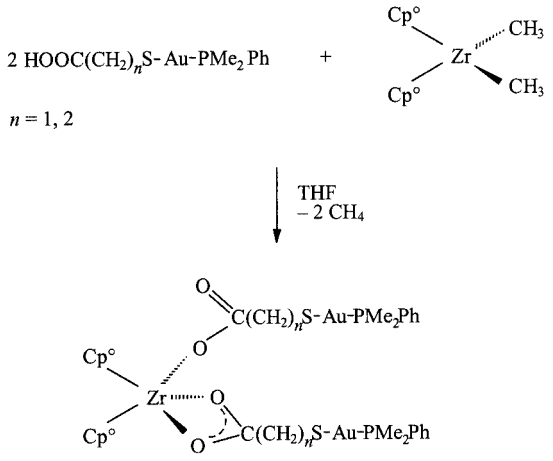
Bishop et al.[16] also reported the synthesis of $[Au(SCH_2COOH)(PPh_3)]$, which is only sparingly soluble in ethanol.

[a] Institut für Anorganische Chemie der Universität Leipzig
Johannisallee 29, 04103 Leipzig, Germany
[‡] Crystal structure determinations

To increase the solubility in common solvents, which is important for the introduction of the second metal in subsequent reactions, we used PMe_2Ph instead of PPh_3. $[Au(SCH_2COOH)(PMe_2Ph)]$ (**1**) and $[Au(SCH_2CH_2COOH)(PMe_2Ph)]$ (**2**) were obtained by treating the gold(I) thiolates $[Au(SCH_2COOH)]$ and $[Au(SCH_2CH_2COOH)]$ with 1 equiv. of PMe_2Ph in ethanol at room temperature; **1** was obtained as a pale yellow solid, but **2** was only obtained as a yellow oil. Both complexes are soluble in THF and were characterized by ^1H, ^{31}P, ^{13}C NMR and IR spectra. In the ^1H NMR spectra the protons of the carboxyl groups were observed as very broad signals in a range of δ = 10−12 ppm owing to exchange processes. The IR spectrum of **1** shows two strong bands at 1690 and 1303 cm^{-1} for the C=O and C−O stretching vibrations of the COOH group.

Trinuclear Gold(I)−Zirconocene Complexes $[Cp^\circ_2Zr\{\kappa^1O\text{-}OOC(CH_2)_nSAu(PMe_2Ph)\}\{\kappa^2O,O'\text{-}OOC(CH_2)_n\text{-}SAu(PMe_2Ph)\}]$ [n = 1 (3), n = 2 (4)]

The trinuclear Zr/Au complexes **3** and **4** were obtained by reaction of the metalloligands **1** and **2** with $[Cp^\circ_2ZrMe_2]$ in a molar ratio of 2:1 (Scheme 1). Both complexes were obtained as pale yellow solids, and X-ray quality crystals of **4** were grown from a concentrated solution in THF at room temperature.



Scheme 1

Structural Studies on 4

An ORTEP plot of **4** is shown in Figure 1. The trinuclear complex crystallizes in the triclinic space group $P\bar{1}$ with two molecules of the complex and three THF molecules in the unit cell. One of the THF molecules is disordered and lies on the inversion center. The zirconium atom is coordinated by two η^5-cyclopentadienyl rings, as well as one monodentate and one bidentate carboxylato group, so that the Zr atom has 18 valence electrons. This bonding mode was also observed in related zirconocene bis(carboxylates)[17−19] and in a zirconocene mercaptoacetate[12] and the Zr−O bond lengths and O−Zr−O bond angles are similar to these complexes. Both Au atoms are almost linearly coordinated by one P and one S donor [S1−Au1−P1 174.63(6), S2−Au2−P2 176.83(6)°]. The Au−S and Au−P bond lengths are similar to those in related Au^I complexes, e.g., $[Au(SCH_2COOH)(PPh_3)]$, $[Au(SCMe_2COOH)(PPh_3)]$[16] and $[Au(SPh)(PPh_3)]$.[20] The Au1−Au2 distance of 3.2992(4) Å suggests intramolecular gold−gold interaction. Intermolecular Au−Au contacts are very common and are also found for other gold(I) complexes with sulfur-containing ligands; the distances observed range from 2.9 to 3.5 Å[21] and are attributed to relativistic effects in the valence orbitals of gold atoms,[22] e.g., $[Au(SPh)(PPh_3)]$ [Au−Au 3.1355(3) Å].[20] To facilitate this interaction the S−Au−P fragments in **4** have an almost perpendicular arrangement [torsion angles: P1−Au1−Au2−P2 116.5(3), S1−Au1−Au2−S2 118.9(3)°; see Figure 2]. This arrangement is similar to that in $[Au(SPh)(PPh_3)]$, in which torsion angles of 96.1 and 110.8° were observed.[20] Depending on the structural properties of the ligands, in other complexes the "head-to-head" or "head-to-tail" arrangements were found.

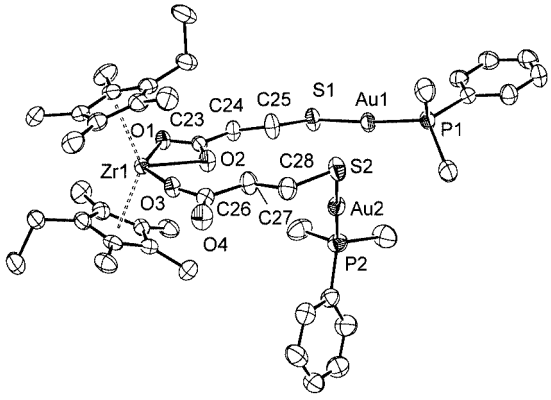


Figure 1. ORTEP plot of **4** (50% probability thermal ellipsoids are shown; hydrogen atoms are omitted for clarity); selected bond lengths [Å] and angles [°]: Zr1−O1 2.352(4), Zr1−O2 2.213(4), Zr1−O3 2.067(4), Au1−S1 2.302(2), Au1−P1 2.265(2), Au2−S2 2.306(2), Au2−P2 2.268(2), O1−C23 1.260(7), O2−C23 1.279(6), O3−C26 1.291(7), O4−C26 1.226(7); O1−Zr1−O2 56.5(1), O2−Zr1−O3 78.9(1), S1−Au1−P1 174.63(6), S2−Au2−P2 176.83(6), O1−C23−O2 117.0(5), O3−C26−O4 123.2(6)

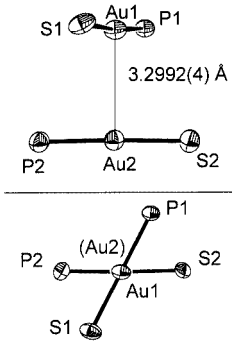

Figure 2. Front and top view of the S−Au−P fragments in **4**

Spectroscopic Studies on 3 and 4

The IR spectra of **3** and **4** exhibit two strong bands for the C=O and C−O stretching vibrations of the monodentate ligand, and two strong bands for the asymmetric and symmetric vibrations of the bidentate ligand. Compared to the free carboxyl group in **1**, the C=O and C−O vibration bands in the heterobimetallic complexes are shifted to lower wavenumbers owing to coordination to the Lewis acidic zirconium atoms.

In the NMR spectra of **3** and **4** the CH_2 groups of the two metalloligands next to the carboxylate groups were observed as one signal for both complexes. On the basis of the molecular structure of **4** in the solid state, we would expect at least two signals for these CH_2 groups owing to the different bonding mode of the ligands. Therefore the NMR spectroscopic data suggest a rapid dynamic process in which the carboxylato groups alternate between mono- and bidentate bonding. Such dynamics are well known and were observed for most zirconocene bis(carboxylates)[17−19] and in a zirconocene mercaptoacetate[12] and dimeric zirconocene thioglycolates.[13] Low-temperature NMR experiments on **3** and **4** down to −70 °C failed to freeze out this dynamic process, and we only observed slight broadening of the signals.

Preliminary catalytic investigations in oxidation reactions were performed with **4**. We used the model system O_2/PPh_3, and the ratio PPh_3/PPh_3O was determined by ^{31}P NMR spectroscopy. Complex **4** catalyzes the oxidation of PPh_3 in a molar ratio of 1:10 without apparent decomposition (only the PMe_2Ph ligands are partly oxidized) over 1.5 h at 50 °C. On the basis of earlier investigations on the catalytic properties of a similar zirconocene mercaptoacetato complex,[12] we assume that the catalytic activity of **4** is due to the Lewis acidic Zr atom, which is coordinatively unsaturated in solution. Investigations on possible interactions between the two metals in these complexes are in progress.

Experimental Section

General Details: All operations except the synthesis of the gold thiolates were carried out under dry nitrogen using standard Schlenk techniques. The reagents and solvents were purified by standard procedures. The ^1H, ^{13}C and ^{31}P NMR spectra were recorded with an AVANCE DRX 400 spectrometer. The IR spectra were recorded with an FT-IR spectrometer Perkin−Elmer System 2000 in the range 400−4000 cm^{-1}. [Cp°$_2$ZrMe$_2$][23] was prepared by a literature procedure. Mercaptoacetic and mercaptopropionic acid were purchased from Fluka. $H[AuCl_4]$ was donated by Degussa.

[Au{S(CH$_2$)$_n$COOH}] (n = 1, 2): An aqueous solution of $H[AuCl_4]$ was treated with an aqueous solution of a mercaptocarboxylic acid ($HOOCCH_2SH$, $HOOCCH_2CH_2SH$) in a molar ratio of 1:3. Both gold thiolates were obtained as pale yellow solids in nearly quantitative yields and were characterized by elemental analyses.

[Au(SCH$_2$COOH)(PMe$_2$Ph)] (1): 0.31 mL (2.2 mmol) of PMe_2Ph was added to a suspension of 0.64 g (2.2 mmol) of [Au(SCH$_2$COOH)] in 20 mL of ethanol. After about 30 min, the yellow solution became clear. Complete removal of the solvent gave a yellow oil, which was dissolved in 10 mL of THF. At −20 °C, **1** was obtained as a nearly colorless precipitate. Yield: 0.70 g (73%); m.p. 134−136 °C. ^1H NMR ($CDCl_3$, 25 °C, 400 MHz): δ = 1.81 [d, $^2J_{H,P}$ = 9.7 Hz, 6 H, P(CH_3)$_2$Ph], 3.68 (s, 2 H, SCH_2COOH), 7.49 (br. m, 3 H, $PMe_2C_6H_5$), 7.51 (m, 2 H, $PMe_2C_6H_5$) ppm, OH signal not observed. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C, 100.6 MHz): δ = 16.3 [d, $^1J_{C,P}$ = 35.9 Hz, P(*C*H$_3$)$_2$Ph], 32.1 (s, S*C*H$_2$COOH), 130.0 (d, $^3J_{C,P}$ = 11.3 Hz, *m*-C of PC_6H_5), 132.3 (br. s, *p*-C of PC_6H_5), 132.5 (s, *o*-C of PC_6H_5), 132.6 (d, $^1J_{C,P}$ = 57.3 Hz, *ipso*-C of PC_6H_5), 176.5 (s, SCH$_2$*C*OOH) ppm. Signals for THF are observed in the ^1H and ^{13}C NMR spectrum. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 25 °C, 162 MHz): δ = 11.2 (s, *P*Me$_2$Ph). IR (KBr pellet): $\tilde{\nu}$ = 1690 (C=O), 1303 (C−O) cm^{-1}. $C_{10}H_{14}AuO_2PS\cdot1/4THF$ (444.25): calcd. C 29.7, H 3.6, S 7.2; found C 29.1, H 4.3, S 6.9.

[Au(SCH$_2$CH$_2$COOH)(PMe$_2$Ph)] (2): 0.21 mL (1.4 mmol) of PMe_2Ph was added to a suspension of 0.44 g (1.4 mmol) of [Au(SCH$_2$CH$_2$COOH)] in 20 mL of ethanol. After about 30 min, the yellow solution became clear. Complete removal of the solvent gave a yellow oil which was dissolved in 20 mL of THF. However, in contrast to **1**, complex **2** could only be isolated as an oil. Yield: 0.45 g (85%). ^1H NMR ($CDCl_3$, 25 °C, 400 MHz): δ = 1.75 [d, $^2J_{H,P}$ = 8.8 Hz, 6 H, P(CH_3)$_2$Ph], 2.70 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, SCH_2CH$_2$COOH), 3.07 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, SCH$_2$CH_2COOH), 7.44 (br. s, 3 H, $PMe_2C_6H_5$), 7.62 (m, 2 H, $PMe_2C_6H_5$) ppm, OH signal not observed. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C, 100.6 MHz): δ = 16.4 [d, $^1J_{C,P}$ = 32.8 Hz, P(*C*H$_3$)$_2$Ph], 23.4 (s, S*C*H$_2$CH$_2$COOH), 42.0 (s, SCH$_2$*C*H$_2$COOH), 129.7 (d, $^3J_{C,P}$ = 10.8 Hz, *m*-C of PC_6H_5), 131.9 (d, $^4J_{C,P}$ = 1.8 Hz, *p*-C of PC_6H_5), 132.2 (d, $^2J_{C,P}$ = 13.5 Hz, *o*-C of PC_6H_5), 133.8 (d, $^1J_{C,P}$ = 51.3 Hz, *ipso*-C of PC_6H_5), 177.2 (s, SCH$_2$*C*OOH) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 25 °C, 162 MHz): δ = 7.2 (s, *P*Me$_2$Ph) ppm.

[Cp°$_2$Zr{κ^1*O*-OOCCH$_2$SAu(PMe$_2$Ph)}{κ^2*O*,*O*′-OOCCH$_2$SAu(PMe$_2$Ph)}] (3): A solution of 0.08 g (0.2 mmol) of [Cp°$_2$ZrMe$_2$] in 5 mL of THF was added to a solution of 0.17 g (0.4 mmol) of **1** in 5 mL of THF. The reaction mixture was stirred overnight at room temperature. Concentration of the solution to about half of its volume and addition of 10 mL of petroleum ether gave a pale yellow precipitate of **3** at −20 °C. Yield: 0.21 g (85%); m.p. 163−169 °C. ^1H NMR ($CDCl_3$, 25 °C, 400 MHz): δ = 0.84 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, $C_5Me_4CH_2CH_3$), 1.82 [d, $^2J_{H,P}$ = 10.0 Hz, 12 H, P(CH_3)$_2$Ph], 1.88 [s, 12 H, $C_5Et(CH_3)_4$], 1.90 [s, 12 H, $C_5Et(CH_3)_4$], 2.38 (q, $^3J_{H,H}$ = 7.6 Hz, 4 H, $C_5Me_4CH_2CH_3$), 3.74 (s, 4 H, SCH_2COO), 7.46 (br. m, 6 H, $PMe_2C_6H_5$), 7.77 (m, 4 H, $PMe_2C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C, 100.6 MHz): δ = 11.7, 11.9 [s, $C_5Et(CH_3)_4$], 15.0 (s, $C_5Me_4CH_2CH_3$), 16.6 [d, $^1J_{C,P}$ = 35.1 Hz, P(*C*H$_3$)$_2$Ph], 19.7 (s, $C_5Me_4CH_2CH_3$), 32.9 (s, S*C*H$_2$COO), 121.4, 122.2, 127.1 (s, C_5EtMe_4), 129.7 (d, $^3J_{C,P}$ = 11.1 Hz, *m*-C of PC_6H_5), 132.0 (s, *p*-C of PC_6H_5), 132.5 (d, $^2J_{C,P}$ = 13.1 Hz, *o*-C of PC_6H_5), 133.6 (d, $^1J_{C,P}$ = 55.3 Hz, *ipso*-C of PC_6H_5), 183.1 (s, SCH$_2$*C*OO) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 25 °C, 162 MHz): δ = 10.7 (s, *P*Me$_2$Ph) ppm. IR (KBr pellet): $\tilde{\nu}$ = 1635 (C=O), 1523, 1323 (O−C−O), 1191 (C−O) cm^{-1}. $C_{42}H_{60}Au_2O_4P_2S_2Zr$ (1240.15): calcd. C 40.6, H 4.8, S 5.1; found C 38.2, H 4.9, S 4.2.

[Cp°$_2$Zr{κ^1*O*-OOC(CH$_2$)$_2$SAu(PMe$_2$Ph)}{κ^2*O*,*O*′-OOC(CH$_2$)$_2$SAu(PMe$_2$Ph)}] (4): A solution of 0.16 g (0.39 mmol) of [Cp°$_2$ZrMe$_2$] in 10 mL of THF was added to a solution of 0.35 g (0.79 mmol) of **2** in 10 mL of THF. The reaction mixture was stirred overnight at room temperature. Concentration of the solution to about half of its volume gave a pale yellow precipitate of **4** at −20 °C. Suitable crystals for a structure analysis were obtained from a saturated THF solution at room temperature. Yield: 0.38 g (77%); m.p. 95−98 °C. ^1H NMR ($CDCl_3$, 25 °C, 400 MHz): δ =

Syntheses, Characterization, X-ray Crystal Structure, Redox and Photophysical Properties of Polypyridylruthenium(II) Complexes Containing Carboxylate-Substituted Pyridyltriazoles

Bedri Mehmetaj,[a][‡] Jaap G. Haasnoot,*[a] Luisa De Cola,[b] Gerard A. van Albada,[a] Ilpo Mutikainen,[c] Urho Turpeinen,[c] and Jan Reedijk[a]

Keywords: Ruthenium / N ligands / Crystal structure / Photophysical properties / Redox potentials

The syntheses and properties of two novel $[Ru(bpy)_2(L–L')]^{n+}$ complexes with **L–L′** = 3-carboxy-5-(pyrid-2′-yl)-1,2,4-triazole (**H_2cpt**) or 3-(ethoxycarbonyl)-5-(pyrid-2′-yl)-1,2,4-triazole (**Hcept**) ligands are described. Previous publications on Ru^{II} complexes containing (pyrid-2′-yl)-1,2,4-triazoles revealed that their coordination is possible via N1 and N4 of the triazole ring. ^{1}H NMR spectroscopic data and the crystal structure of $[Ru(bpy)_2(cept)]PF_6{\cdot}H_2O$ (**2**) indicate that the coordination of the **Hcpt**$^-$ and **cept**$^-$ occurs via N1 of the triazole ring. The crystals of **2** are monoclinic and belong to the space group $P2_1/n$ with a = 12.339(7), b = 16.512(7), c = 16.802(8) Å, β = 110.29(4)°, and Z = 4. A water molecule is hydrogen-bonded to the carbonyl oxygen atom of the ethoxycarbonyl group with an O···O distance of 2.891 Å. Spectroscopic measurements reveal that **H_2cpt** and **Hcept** are strong σ-donor ligands. When coordinated to a ruthenium(II) centre, both triazole ligands reported in this study lost their acidic triazole hydrogen atoms and became negatively charged, resulting in even stronger σ-donor ligands, as demonstrated by a negative shift of their redox potentials compared to the complexes containing the neutral ligand. The complexes reported in this study showed ^{3}MLCT-based luminescence emission, both at room temperature and at 77 K.

Introduction

A considerable number of $[Ru(bpy)_2(L\text{-}L')]^{n+}$ systems with **L−L′** = substituted (pyrid-2′-yl)-1,2,4-triazole ligands have been reported by Hage et al.[1−14] Electrochemical, absorption, and emission measurements revealed that triazoles are strong σ-donor and weak π-acceptor ligands, thus lowering the oxidation potential of the metal ion. Additionally, due to a higher π* level of the triazole compared with the π* level of the **bpy** ligand, both the first reduction and the lowest exited states of these complexes are **bpy**-based.[1] Therefore, a study towards the related ligands with a variety of substituents is relevant.

In this paper the synthesis and properties of a $Ru(bpy)_2$ moiety with 3-carboxy-5-(pyrid-2′-yl)-1,2,4-triazole (**H_2cpt**) and 3-(ethoxycarbonyl)-5-(pyrid-2′-yl)-1,2,4-triazole (**Hcept**) ligands is described. The selection of the **H_2pct** and **Hpcet** ligands was made to study the effect of electron-withdrawing groups in the photophysical and electrochemical properties of the ruthenium(II) complexes. Previous publications, mainly from our laboratory[1−14] of a number of ruthenium(II) complexes containing (pyrid-2′-yl)-1,2,4-triazoles showed that coordination is possible via N1 and via N4 of the triazole ring. A crystal structure of the $Ru(bpy)_2(cept)](PF_6){\cdot}H_2O$ (**2**) revealed that the triazole ring is coordinated to ruthenium(II) via N1. This coordination mode was also observed for the 3-methyl-5-(pyrid-2′-yl)-1,2,4-triazole (**3Meptz**),[1] and is predicted for the **H_2cpt**-based complex. The structure and properties of the complexes were investigated with the use of ^{1}H NMR spectroscopy, ESI MS, CV measurements, UV/Vis absorption, and time-resolved emission spectroscopy.

Results and Discussion

Ligand Syntheses

Synthesis of the ligands (structures given in Figure 1) was straightforward by starting from pyridylamidrazone and diethyl oxalate, in a ratio 1:4 to avoid possible formation of a dimer, and heating under reflux in absolute ethanol for 1 h (modified procedure[15]). However, contrary to the results reported in the literature, two different products were obtained. The ratio was found to be close to 1:1. The first fraction appeared to be a hydrolysed ester (acid), while the second fraction was the ester itself.

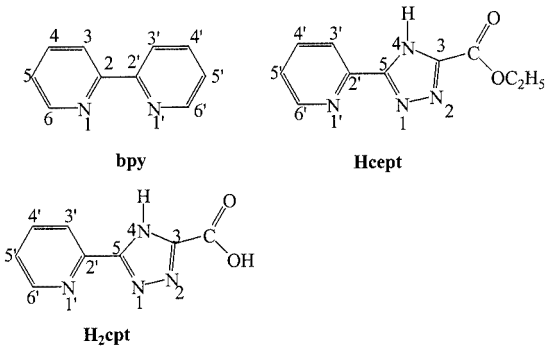

Figure 1. Structural formula of the ligands used in this study

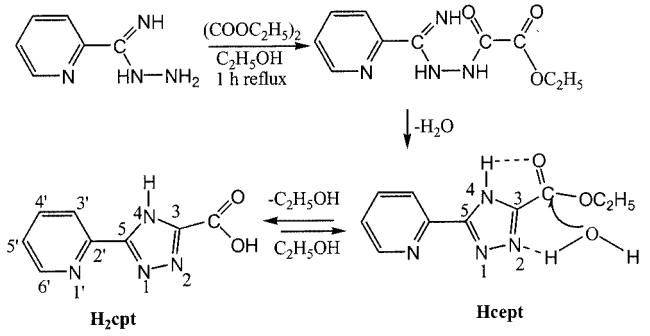
The chemistry of amidrazones is diverse,[15−28] and offers the possibility of obtaining different products with a slight change in the experimental conditions. It is not clear how the reaction for obtaining the hydrolysed ligand may proceed. A possible reaction route is shown in Scheme 1. The triazole hydrogen atom forms a hydrogen bond to the free oxygen atom of the ethoxycarbonyl group, reducing the electron density in its carbon centre. The water molecule then attacks the partially positive carbon atom, followed by the hydrolysis of the ester. A supporting factor could be the activation of a water molecule by hydrogen-bonding to N2 of the triazole (see Scheme 1). In order to testify to these hypotheses, the same reaction was performed with an *N*-substituted triazole. The reaction was unsuccessful, and no products could be isolated. However, there are several possible routes for the hydrolysis of the ester, and more experiments would be needed to prove this mechanism.



Scheme 1. Reaction route and mechanism for the **H_2cpt** and **Hcept** ligand syntheses

Syntheses and Characterization of the Complexes

The synthesis of the metal complexes was achieved by using an excess of one of the ligands and *cis*-Ru(bpy)$_2$Cl$_2$. The **Hcept** ligand lost its triazole hydron and acquired a negative charge upon coordination to the ruthenium(II) centre. This phenomenon was known from previous studies[1,10,14] and has been attributed to the increased acidity of the coordinated triazole ligands. In the **H_2cpt**-based complex, both triazole and carboxylic hydrons were found to be ionised.

The mass of the complexes was determined using mass spectrometry. Both complexes reported showed mono-positively charged complex ions [M$^+$].

Another important technique for elucidating the structure of the ruthenium(II) complexes is ^{1}H NMR spectroscopy. The chemical shifts of complex **2** are shown in Table 1. For the sake of comparison the ^{1}H NMR chemical shifts of [Ru(bpy)$_2$(3Meptz)]$^+$ are also presented. The assignment of the ^{1}H NMR spectra of the complex presented in Table 1 was made based on literature data of the related pyridyltriazole complexes,[1,14] and the difference in coupling constants (^3J) of 3-H and 6-H of the pyridine ring.

The ^{1}H NMR spectrum of [Ru(bpy)$_2$(Hcpt)]$^+$ is rather complex and the assignment is difficult. There are two sets of peaks with the same coupling constants, but different intensities (approximately 3:1 for the ones with higher chemical shifts), which suggests that the **H_2cpt** ligand is partially dehydronated (higher chemical shift). Such a claim is also supported by CV data (see next section).

Description of the X-ray Structure of [Ru(bpy)$_2$(cept)]-(PF$_6$)·H$_2$O (2)

A projection of the structure of the title compound, the atom numbering, and the position of the hydrogen bonds is presented in Figure 2. Selected bond lengths and angles, and hydrogen-bond information are presented in Table 2. The ruthenium(II) ion coordinates to two **bpy** molecules in the *cis* configuration and one **cept**$^-$ ion. The "bite angles" of the coordinated ligands are 78−79°, similar to the chelating angles observed for similar complexes.[1,10,12] The Ru−N distances, 2.04−2.06 Å, are in the normal range for this type of ruthenium(II) complexes.[1,13,29] The relatively long distance between the ruthenium(II) centre and the nitrogen atom of the pyridine ring of the **cept**$^-$ ligand might be caused by the limited π backbonding of the pyridyltriazole-containing ruthenium(II) complexes. Steric factors might also play a role in these bond lengths. Similar distances were found for the analogous mononuclear **bpt**$^-$-containing ruthenium complex.[13]

As can be seen in Figure 2, the **cept**$^-$ ligand is coordinated to ruthenium(II) via N111 and N121. This coordination mode was observed for other pyridyltriazoles containing bulky groups bound to the remaining carbon atom of the triazole ring.[1] A water molecule is relatively strongly hydrogen-bonded via H1 to O2 with an O1···O2 distance of 2.89 Å, and via H2 to F1 and F2 of a neighbouring PF$_6^-$ ion with an O1···F1 distance of 2.91 Å (see Table 2). No

hydrogen bonds were found in which N123 and N125 of the triazolate ring were involved.

Electrochemical Properties

The highest occupied molecular orbitals (HOMOs) of most of the polypyridylruthenium(II) complexes are metal-centred, while their lowest unoccupied molecular orbitals (LUMOs) are known to be ligand-centred.[30] The oxidation of these complexes leads to the formation of the low-spin ruthenium(III) complexes $[\pi_M\ (t_{2g})^5]$, while the reduction primarily takes place in the π* orbital of the polypyridine ligands.[30]

The redox potentials of the studied complexes and of some similar complexes taken from the literature are reported in Table 3. The complexes were hydronated by addition of a drop of 1 M $HClO_4$ solution in acetonitrile. The oxidation potentials of the hydronated species occurred at higher potentials. This increase in the oxidation potential was caused by the decreased σ-donor capacity of the hydronated triazoles, which led to the stabilisation of the dπ metal orbitals.

The redox behaviour of **2** is similar to complexes of analogous pyridyltriazoles reported in the literature,[1,14] with a small shift to higher values. The reason for that is a decreased σ-donor ability of the **Hcept** ligand. This is due to the presence of an electron-withdrawing group ($COOC_2H_5$) at C-3 of the triazole ring. The cyclic voltammogram of **2** is shown in Figure 3 (**2** and **2a**). The first reduction potentials are attributed to **bpy** ligands.

The redox behaviour of **1** is rather complicated. Both, triazole ring and acid hydrons of the **H_2cpt** ligand are partially dehydronated (see **1** in Figure 3). When a drop of 1 M $HClO_4$ was added to a solution, the first oxidation peak disappeared (see **1a** in Figure 3) and the carboxy group be-

came hydronated. Due to the presence of an electron-withdrawing group (COOH) at C-3 of the triazole ring, the remaining triazole hydrogen atom will only be partially ionized (see **1a** in Figure 3, the smaller peak at 1.33 V). The reduction parts of the voltammograms are not clear and an accurate assignment is quite difficult and was not attempted.

The fine-tuning of the electrochemical properties of **1** was possible by changing the pH of the solution. It is anticipated that in a strong acidic environment **H_2cpt** becomes a stronger π-acceptor than **bpy**, and the first reduction poten-

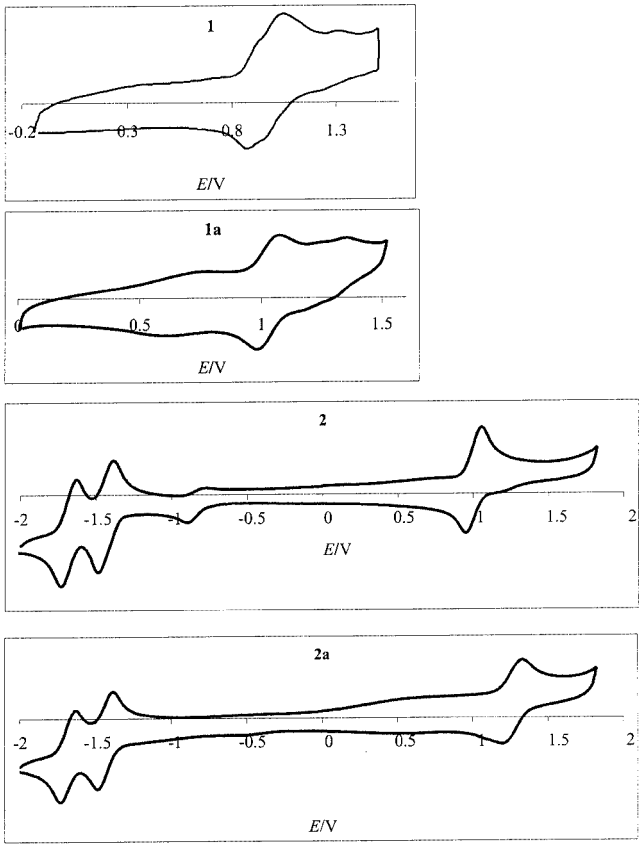

Figure 3. Cyclic voltammograms of the $[Ru(bpy)_2(cpt)]^+$ (**1**), $[Ru(bpy)_2(Hcpt)]^+$ (**1a**) $[Ru(bpy)_2(cept)]^+$ (**2**), and $[Ru(bpy)_2(Hcept)]^{2+}$ (**2a**) referenced against Ag/AgCl

tial, as well as the lowest exited state of **1** could be located at the **H_2cpt** ligand.

Absorption and Emission Spectra

The absorption and emission spectra of **1** and **2** in acetonitrile at room temperature are shown in Figure 4. The wavelengths and extinction coefficients of the lowest energy absorption maxima at 298 K, the wavelengths of the emission maxima at 77 K and 298 K, the luminescence lifetimes at 77 K and 298 K and the luminescence quantum yields at 298 K are summarized in Table 4, where the luminescence properties of the $[Ru(bpt)(bpy)_2]^+$ complex,[7] taken as model compound, are also displayed for comparison.

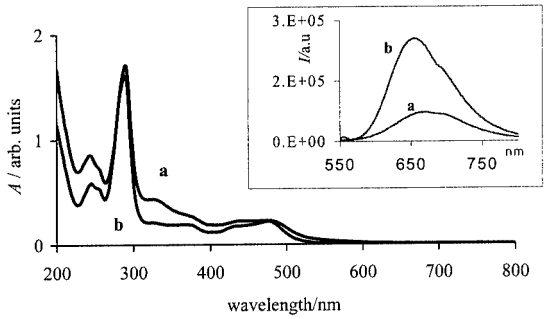

Figure 4. Absorption spectra in acetonitrile solutions at 298 K of $[Ru(bpy)_2(Hcpt)]^+$ (**a**) and $[Ru(bpy)_2(cept)]^+$ (**b**); inset: emission spectra measured at room temperature in acetonitrile approximately 2 10^{-5} M

For the complexes examined, the intense absorption bands in the UV region are due to ligand−centre transitions, and the moderately intense broad bands in the visible region (Figure 4) can be assigned to metal-to-ligand charge-transfer (^{1}MLCT) transitions. When deprotonated, both **H_2cpt** and **Hcept** are expected to be better donors and worse acceptors than **bpy**. The absorption and emission spectra of the two complexes are in agreement with this expectation. Replacement of a **bpy** ligand of $[Ru(bpy)_3]^{2+}$ by an **L−L′** ligand to give $[Ru(L-L')(bpy)_2]^+$ caused an increase in the electronic charge of the metal atom with a consequent red shift of the metal-to-ligand charge-transfer (Ru→bpy) absorption and emission band (Figure 4 and inset). A similar behaviour has been observed for complexes containing imidazole-type bridging ligands.[1,7,10,14]

The luminescence intensity was found to exhibit a mono-exponential decay in all cases. The state responsible for luminescence is likely the lowest ^{3}MLCT excited state, which corresponds to a spin-forbidden (Ru→bpy) transition. Experiments have also been performed in butyronitrile rigid matrix at 77 K and the results obtained are also summarized in Table 4.

All the photophysical properties for the reported compounds are pH-sensitive, and can be tuned by hydronation and dehydronation of the ligands.

Conclusion

In this paper ruthenium(II) mixed-ligand complexes with the newly synthesized ligands **H_2cpt** and **Hcept** are described. The crystal structure of $[Ru(bpy)_2(cept)](PF_6)\cdot H_2O$ has revealed that the **cept$^-$** ligand is coordinated to ruthenium(II) via N1 of the triazole ring. The coordination mode of the related **Hcpt$^-$** ligand is likely to take place via N1 as well. Such a coordination mode results from the presence of the bulky groups at C-3 of the triazole ring, generating steric hindrance to the N4 binding site of the triazole ring.

The CV measurements revealed that the redox potentials for the complexes discussed in this paper are altered with changing pH. The redox potentials of the complexes shift to lower values after dehydronation, which is attributed to the increased σ-donor capacity of the negatively charged ligands. Both photophysical and electrochemical data for the above-mentioned complexes suggest that **Hcpt$^-$** and **cept$^-$** are stronger σ-donor ligands than **bpy**, and that the first reduction processes involve the late ligands. **Hcpt$^-$** and **cept$^-$** play a role of spectator ligands. Both complexes show a moderate emission, which occurs from the lowest-lying triplet excited state ^{3}MLCT.

Experimental Section

Synthesis of the Ligands: A mixture of diethyl oxalate (43 g, 0.29 mol) and 2-pyridylamidrazone (10 g, 0.07 mol) in ethanol (50 mL), prepared as reported by Hage,[1] was heated under reflux for 1 h (modified procedure[15]). Two fractions were obtained in an approximate 1:1 ratio. The first fraction, 3-carboxy-5-(pyrid-2′-yl)-1,2,4-triazole (**H_2cpt**), precipitated immediately, while the second, 3-(ethoxycarbonyl)-5-(pyrid-2′-yl)-1,2,4-triazole (**Hcept**), precipitated after standing for one night at −20 °C. The second fraction was purified by recrystallisation from a acetone/methanol mixture (2:1, v/v). The yield (including both fractions) based on 2-pyridylamidrazone was 4.8 g, 30%.

Synthesis of the Ruthenium Complexes

[Ru(bpy)$_2$(Hcpt)]PF$_6$ (1): *cis*-[Ru(bpy)$_2$Cl$_2$]·2H$_2$O (520 mg, 1 mmol), prepared as reported in the literature,[31] and **H_2cpt** (380 mg) were added to a 50 mL ethanol/water (1:1, v/v) mixture. The mixture was heated under reflux for 4 h. After cooling, the solvent was removed by rotary evaporation. The remaining solid was dissolved in 10 mL of water and added to a saturated NH_4PF_6 (4 mmol) solution. The precipitate was filtered off and dried. The solid was recrystallised from a 50 mL acetone/water (1:1, v/v) mixture. The yield based on *cis*-[Ru(bpy)$_2$Cl$_2$]·2H$_2$O was 0.5 g (65%). The complex was purified further by column chromatography using neutral alumina and acetone followed by ethanol as eluents. MS: *m/z* = 603 [M^+].

[Ru(bpy)$_2$(cept)](PF$_6$)·H$_2$O (2): This complex was prepared and purified as with **1**, except that for column chromatography acetone was used as eluent. The yield based on *cis*-[Ru(bpy)$_2$Cl$_2$]·2H$_2$O was 0.75 g (90%). Crystals of [Ru(bpy)$_2$(cept)](PF$_6$)·H$_2$O, suitable for X-ray structural determination, were obtained by slow concentration at room temperature of a diluted solution of **2** in a mixture of methanol/water (1:1, v/v). MS: *m/z* = 632 [M^+].

Physical Measurements: Infrared spectra of the compounds in the region 4000−200 cm^{-1} were measured with a Perkin−Elmer Paragon 1000 FTIR spectrophotometer using pressed KBr pellets. ^1H NMR spectra were recorded with a Bruker WM 300 MHz NMR spectrometer. The ^1H NMR spectra of the ligands were obtained in $(CD_3)_2SO$ solvent, while those of the ruthenium(II) complexes were recorded in $(CD_3)_2CO$. The peak positions are relative to TMS. Mass spectra were obtained with a Finnigan MAT TSQ-70 equipped with a custom-made electrospray interface (ESI). Spectra were collected by constant infusion of the analyte, dissolved in a methanol/water (80:20) solution with 1% acetic acid. Elemental C, H, N analyses were carried out with a Perkin−Elmer 2400 Series II analyser. Cyclic voltammograms were recorded using an Autolab PG Stat10 potentiostat controlled by a GPES4 software. A home-made three-compartment cell was used, containing an Ag/AgCl electrode as a reference electrode, a platinum wire as counter electrode, and a glassy carbon electrode as working electrode. All the CV measurements were carried out in spectroscopic grade acetonitrile, using 0.1 M tetrabutylammonium hexafluorophosphate as a supporting electrolyte. The scan rate was 100 mV/s. Prior to each run the solution was purged with argon for 30 s. Absorption and emission spectra at room temperature were performed in air-equilibrated spectroscopic grade acetonitrile solutions in 1-cm quartz cells using a Perkin−Elmer Lambda 900 spectrophotometer and Fluorolog equipment, respectively. The standard compound used for determining the emission quantum yields of the complexes was $[Ru(bpy)_3]^{2+}$ in an aerated water solution (φ_{em} = 0.028).[32] The quantum yields were calculated according to Equation (1).[33,34]

$$\phi_{em} = \phi'_{em} * \left(\frac{I}{I'}\right) * \left(\frac{A'}{A}\right) * \left(\frac{\eta}{\eta'}\right)^2 \quad (1)$$

In Equation (1), I (sample) and I' (standard) are the integrated emission intensities, A and A' the absorptions at the excitation wavelength, and η and η′ the refractive indices of the solvents. Time-resolved emission spectra were obtained using a Hamamatsu C-5680 streak camera equipped with an M 5677 sweep unit. Excitation at 337 nm was achieved by a pulsed (fwhm 600 ps) nitrogen laser (LTB, MGS 405 TD) operating at a repetition rate of 20 Hz. The time resolution of this set was ca. 200 ps, as limited by the laser pulse width. For measurements at 77 K in a rigid matrix, freshly distilled butyronitrile as a solvent was used. All the values for emission maxima are uncorrected for the phototube response. Estimated errors are as follows: band maxima, ±2 nm; relative luminescence intensity ±20%; lifetimes, ±10%.

X-ray Crystallographic Study of [Ru(bpy)$_2$(cept)](PF$_6$)·H$_2$O (2): A red needle-shaped crystal was selected and mounted on a glass fibre using the oil-drop method.[35] X-ray data were collected with a Rigaku AFC-7S diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å, ω-2θ scans). The intensity data were corrected for Lorentz and polarisation effects, for absorption (ψ-scan absorption correction) and extinction. All non-H atoms were refined anisotropically. The water H atoms were located from a Fourier-difference map. All other H atoms were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms. The structure was solved by direct methods. The programs TEXSAN,[36] SHELXS-97,[37] and SHELXL-97[38] were used for data reduction, structure solution, and structure refinement, respectively. Refinement of F^2 was done against all reflections. The weighted R factor, wR, and goodness of fit, S, are based on F^2. Conventional R factors, R, are based on F, with F set to zero for negative F^2. Selected crystal data and numerical details of the structure determination are given in Table 5. The supple-

Peralkylated Four- and Five-Membered Cyclosilanes Containing a Heteroatom: Synthesis, Structure, and Properties

Hamao Watanabe,*[a] Hideo Suzuki,[a] Syuji Takahashi,[a] Kiichiro Ohyama,[a] Yuji Sekiguchi,[a] Hideki Ohmori,[a] Michio Nishiyama,[a] Michihiro Sugo,[a] Minoru Yoshikawa,[a] Nobuo Hirai,[a] Yoichi Kanuma,[a] Takahiro Adachi,[a] Masami Makino,[a] Katsura Sakata,[b] Kentaro Kobayashi,[b] Takako Kudo,*[b] Haruo Matsuyama,[c] Nobumasa Kamigata,[c] Michio Kobayashi,[c] Masashi Kijima,*[d] Hideki Shirakawa,[d] Kazumasa Honda,[e] and Midori Goto*[e]

Keywords: HOMO−LUMO interactions / Photolysis / Small ring systems / Silicon / Strained molecules

Seventeen peralkylated four- and five-membered heteroatom-containing silacycles $[R^1R^2Si]_nX$ [R^1 = *i*Pr and/or R^2 = *t*BuCH$_2$; *n* = 3; X = CH$_2$ (**1a**, **1b**), NR^3 (R^3 = C_6H_{11}) (**3a**–**d**), O (**5a**–**c**), and *n* = 4; X = CH$_2$ (**2a**, **2b**), NR^3 (R^3 = C_6H_{11} or Pr) (**4a**–**d**), and O (**6a**, **6b**)] have been synthesized and characterized. The structural features of twelve compounds – **1b**, **3a**–**d**, and **5b** (Si_3X) and **2a**, **4a**–**c**, **6a**, and **6b** (Si_4X) – determined by X-ray analysis have been investigated and geometrical differences between the silacycles bearing neopentyl groups and those with isopropyl groups as bulky substituents on silicon atoms have been identified. The ring strain energies for the compounds $[R_2Si]_nX$ [*n* = 3, 4; R = Me, *i*Pr; X = CH$_2$, N(*i*Pr), NMe, O, SiH$_2$], estimated by theoretical calculations at the PM3 level, are discussed in relation to experimentally ascertained structural features of the silacycles $[R_2Si]_nX$ (*n* = 3, 4; R = *i*Pr; X = CH$_2$, NC_6H_{11}, O, SiR$_2$). ^{29}Si NMR spectra for **1**–**6** showed that the resonances for the α-silicon atoms attached to the heteroatoms X in the two ring-size series were shifted downfield by a deshielding effect due to an electronegative atom X; larger electronegativity (*En*) of X caused this effect at lower field. The chemical shifts of the Si^{α} atoms showed a good linear correlation with the electronegativities of the heteroatoms X in the $[R_2Si]_nX$ cycles. In the UV spectra for **1**–**6**, little difference in the longest-wavelength absorption (LWA) maxima was observed for $[(iPr)_2Si]_nX$ and $[(tBuCH_2)_2Si]_nX$ of the same ring size. The LWA bands for **1**–**6** and related compounds could be roughly classified into four groups: (a) $[R_2Si]_3X$ (X = SiR$_2$, GeR′$_2$) λ = 286–300 nm; (b) $[R_2Si]_3X$ (X = CH$_2$, NR^3, O) (**1**, **3**, **5**), λ = 230–250 nm; (c) $[R_2Si]_4X$ (X = SiR$_2$, GeR′$_2$) λ = 274–280 nm; (d) $[R_2Si]_4X$ (X = CH$_2$, NR^3, O) (**2**, **4**, **6**), λ = 250–260 nm. With the aid of the ionization potentials and the transition energies (E_T), the HOMO and LUMO levels for the series of compounds and the related ones were experimentally evaluated. The HOMO and LUMO levels thus obtained for $[R_2Si]_3X$ and $[R_2Si]_4X$ (R = *i*Pr and *t*BuCH$_2$; X = SiR$_2$, GeR′$_2$, CH$_2$, NC_6H_{11}, O) are discussed in terms of the calculated values and frontier orbitals on the basis of PM3 levels. The theoretical prediction for bond scission in the silacycles $[(iPr)_2Si]_nX$ (*n* = 3, 4; X = CH$_2$, NMe, O) in which the HOMOs and LUMOs have Si–Si bonding and antibonding character, respectively, was corroborated by the good agreement with experimental results from photolysis of the silacycles $[R_2Si]_nX$ (*n* = 3, 4; R = *i*Pr and *t*BuCH$_2$; X = CH$_2$, NC_6H_{11}, O), with bond scission occurring only at the Si–Si bonds, and not at the Si–X bonds.

Introduction

The chemistry of silacycles containing a heteroatom such as oxygen, nitrogen, etc. comprises an intriguing subject worthy of study regarding their properties. Although a large number of studies of homosilacycles Si_n[1] and of heteroatom-containing silacycles such as Si_nGe,[2] Si_nC,[3] Si_nN,[4] and Si_nO[5] have appeared, there are only limited systematic studies focusing on the series of heteroatom-containing silacycles Si_nX from the perspective of properties arising from the presence of X as a heteroatom.[6] We have previously studied some properties of various peralkylated cyclosilanes $[R^1R^2Si]_n$ ($n = 3-7$)[7] and have also reported

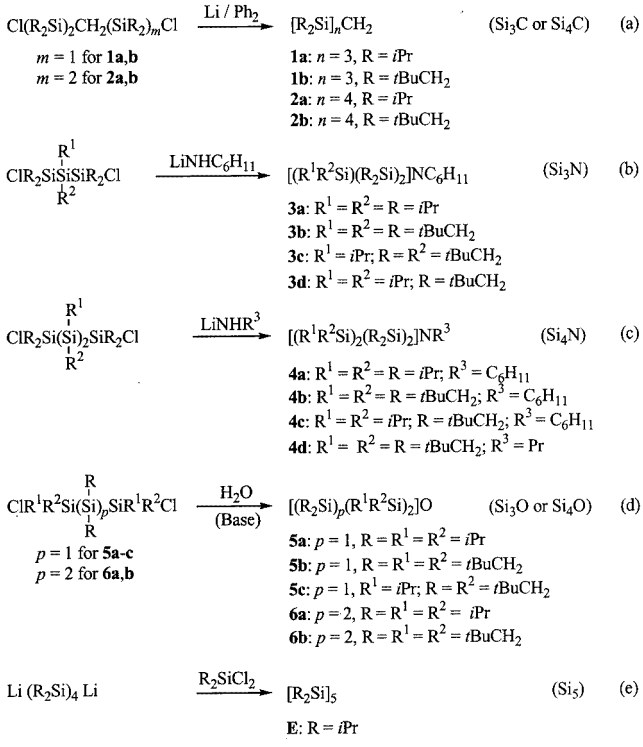
preliminary results for $[R_2Si]_3O$.[8] Recently, we described the synthesis, molecular structure, and photolysis of the $[R_2Si]_nGeR'_2$ series [n = 2: R = tBuCH$_2$, R′ = Me$_3$SiCH$_2$;[9] n = 3: R = iPr, tBuCH$_2$, R′ = Me$_3$SiCH$_2$ (**C**, **D**);[10] and n = 4: R = iPr, tBuCH$_2$, R′ = Me$_3$SiCH$_2$, Ph (**G**−**I**)[11]].

This paper deals with a full account of the series of heteroatom-containing four- and five-membered cyclosilanes $[R^1R^2Si]_nX$ [n = 3, 4; R^1, R^2 = iPr, tBuCH$_2$; X = CH$_2$ (**1**, **2**), NR^3 (R^3 = C$_6$H$_{11}$ or Pr) (**3**, **4**), O (**5**, **6**)], as shown in Scheme 1, including molecular structures determined by X-ray crystal analysis, some properties such as ^{29}Si NMR and UV spectra, and oxidation and ionization potentials. We have performed semiempirical PM3[12] molecular orbital calculations for a series of heterosubstituted silacycles $[R_2Si]_nX$ [n = 3, 4; R = Me, iPr; X = SiH$_2$, CH$_2$, NMe, N(iPr), O] in order to estimate the ring strain energies. The energy levels and character of their frontier orbitals are also discussed in relation to their molecular structures, oxidation and ionization potentials, and photochemical reactions of the series of heterosilacycles obtained experimentally in the current study.

Results and Discussion

Synthesis

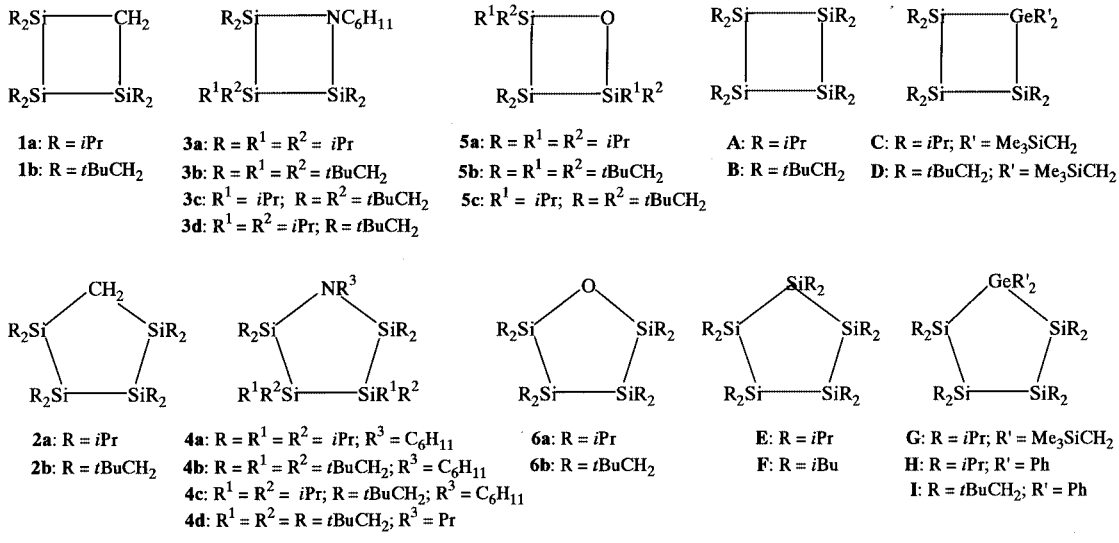
Compounds **1** and **2** were synthesized in good yields (72−92%) by reductive coupling of the corresponding α,ω-dichlorocarbosilanes with lithium in THF at room temperature [Scheme 2, (a)]. Compounds **3** and **4** were synthesized in moderate yields (35−69%) by treatment of the corresponding α,ω-dichlorosilanes with lithium alkylamides [Scheme 2, (b) and (c)]. Compounds **5** and **6** were synthesized by hydrolytic cyclization with the corresponding α,ω-dichlorosilanes, in good yields (88−96%) except in the case of **5a** (28%) [Scheme 2, (d)]. Compound **E** was also prepared from the corresponding 1,4-dilithiotetrasilane and dichlorosilane in a reasonable yield [Scheme 2, (e)]. All the compounds **1**−**6** obtained were found to be air- and moisture-stable liquids (**1a**, **5c**) or crystals (the others) and were identified in the usual manner (NMR, IR, and MS data, as well as elemental analysis), while $[Me_2Si]_3CH_2$[3a] and $[Ph_2Si]_4X$ (X = NMe, NEt, O)[6e] have been reported to be air- and moisture-sensitive compounds.



Scheme 2. (a−e) Synthetic methods for heteroatom-containing silacycles Si_nX [n = 3, 4; X = CH$_2$, NR^3 and O; n = 4, X = Si(iPr)$_2$]

Molecular Structures

Except for Si_3C[3a] and Si_4O,[5g] there are no precedents for structural studies on the ring systems Si_4C, Si_nN (n = 3, 4), and Si_nO (n = 3, 4). The molecular structures of **1b**,



Scheme 1. Molecular formula of heteroatom-containing silacycles and related compounds

2a, **3a−d**, **4a−c**, **5b**, **6a**, and **6b** were determined by X-ray crystal analysis; structural data for **1a** and **5a** could not be obtained by X-ray analysis. Selected bond lengths and bond and torsion angles for these compounds are listed in Tables 1−12, and the pertinent geometrical data needed for structural discussion of $[R_2Si]_3X$ and $[R_2Si]_4X$ (X = C, N O) and the related compounds **A**−**E**, **H**, and **I** are summarized in Tables 13 and 14.

(1) Bond Lengths and Angles

The Si_3C ring of **1b** was found to be moderately puckered, with a dihedral angle of 25.5°, and the Si_4C ring of **2a** to be a slightly deformed envelope conformation. The structural data for four known Si_3C ring compounds[3b−3d]

have been reported previously (dihedral angles: 0−14°, Si−Si−Si: 77.2−82.9°, Si−C−Si: 100.8−107.8°, Si−Si distances: 2.389−2.500 Å, Si−$C_{(ring)}$ distances: 1.936−1.983 Å). If the data listed in Tables 1 and 13 for **1b** are compared with those for the known compounds,[3b−3d][6a] the dihedral angle in **1b** is seen to be the largest, and both the Si−Si−Si angle and Si−$C_{(ring)}$ distance in **1b** are the smallest. The Si−Si bond length (2.394 Å) in **1b** is in the range between the known Si_3C cycles.[3b−3d] Among the four inner angles for the Si_3C ring of **1b**, Si−Si−Si (75.9°) is the smallest and Si−C−Si (102.3°) the largest. A similar trend was also observed for the five inner angles of the Si_4C ring of **2a**. The bond lengths of Si−Si (2.393 Å) and Si−$C_{(ring)}$ (1.888 Å)[13] in the Si_4C of **2a** are within the normal ranges.

The four-membered Si_3N cycles of **3a−d** are planar or puckered structures (dihedral angles 21−23°). The five-membered Si_4N cycles of **4a−c** are in distorted half-chair or envelope conformations. The Si−Si bond lengths in **3a−d** are 2.370−2.384 Å. Compound **3a** has nearly the same distance as in cyclotetrasilane **A** (2.373 Å), while those in compounds **3b−d** (average 2.381 Å) are shorter than those in cyclotetrasilane **B** (2.409) by 0.028 Å. On the other hand, the Si−Si bond lengths (2.397−2.402 Å) in the five-membered compounds **4a−c** are, except for the Si^2-Si^3 bond (2.372 Å) in **4c**, very close to each other. The three distances are longer than those in the corresponding four-membered compounds **3a−d**, but shorter than that (2.422 Å) in the related homosilacycle **E**.[14] The Si−N bond lengths in the two sets Si_3N (**3a−d**, 1.757−1.768 Å) and Si_4N (**4a−c**, 1.760−1.775 Å) are comparable with the typical value of 1.70−1.76 Å,[13] those involving neopentyl groups on the silicons being longer than those with isopro-

[a] Average value of the distances of Si(1)−Si(2) and Si(3)−Si(4). [b] Distance Si(2)−Si(3). [c] Average value from molecules A and B. [d] Ref.[14] [e] Ref.[11]

pyl groups in each set. Comparison of the four angles between the two ring sets identifies some interesting features. The sizes of the corresponding angles fall in the order: Si−N−Si (109.5°, **3a**; 108.7−109.3°, **3b−d**) > Si−Si−N (88.0°, **3a**; 85.9−86.5°, **3b**) > Si−Si−Si (74.5°, **3a**; 74.0−74.3°, **3b−d**). This trend is also observed in the five-membered Si_4N rings of **4a−c**. Interestingly, it could be shown that all the nitrogen atoms in **3** and **4** were of almost sp^2 geometry, from the sums (359.8−360°) of the three angles around the nitrogen atoms, as has also been shown in various silylamines[13] and a calculated cycle $[H_2Si]_3NH$.[6a]

The Si_3O cycle in **5b** and the Si_4O cycles in **6a** and **6b** are almost planar (dihedral angle 3°) and a slightly distorted envelope (dihedral angle 23°−25°), respectively, but **6b** has a distorted half-chair form. The Si−Si bond length in **5b** is 2.433 Å, which is the longest in all the Si_3X rings and considerably longer than that (2.409 Å) in the related cyclotetrasilane **B**. The long Si−Si distance in the small-membered rings is reminiscent of the fact that the presence of the bulky substituents on the highly strained planar Si_3O ring should result in remarkably stretched Si−Si distances, as has been discussed previously for cyclosilanes $[R_2Si]_n$ (n = 3, 4) bearing bulky substituents such as Me_3Si and *t*Bu groups.[7f] The Si−Si bond lengths in **6a** and **6b** are 2.392−2.414 Å, which is comparable with those (2.393−2.402 Å) in the other Si_4X rings of **2** and **4** in Table 14. It is of interest to note that the longer Si−Si bond length in **6b**, relative to those in **6a** and in the other heterosilacyles Si_3X, is similar to the situation in the five-membered rings **E**, **H**, and **I**. The Si−O bond lengths in **5b**, **6a**, and **6b** are in the 1.631−1.656 Å range, around the typical values of 1.64±0.03 Å.[13] The distance (1.656 Å) in **5b** is slightly short relative to those (1.663−1.721 Å) in the similar four-membered compounds cyclo-1,3-disiloxanes $[R_2SiO]_2$.[15] The Si−Si−Si bond angles in **5b**, **6a**, and **6b** are 68.2, 95.3, and 92.9°, respectively, and are the smallest in each set of the two types of rings (68.2−90.4°, Si_3X; 92.9−106.0°, Si_4X), as seen in Tables 13 and 14. Surprisingly, the angle (68.2°) in **5b**, with a planar structure, is unusually small and much closer to the inner angle (60°) of a three-membered ring rather than that (90°) of a planar four-membered one. This compound may thus have quite large angular and Pitzer strains, for which supporting results were obtained by theoretical calculations of the ring strain energies by the PM3 method (vide infra). The Si−O−Si bond angle in **5b** (111.1°) is comparable with those (106.3 and 112.1°) of the calculated $[H_2Si]_3O$,[6a] respectively. However, the Si−O−Si bond angles (133.6 and 132.3°) for **6a** and **6b** are significantly large compared to those (119.9−124.6°) in calculated $[R_2Si]_4O$ (R = H, Me).

Finally, the Si−Si bond lengths in **A−I** (except for **F**) and **1−6** in Tables 13 and 14 fall in the 2.370−2.433 Å range, and are considerably longer than the sums of the covalent

radii (2.34 Å), suggesting that the four- and five-membered rings are fairly strained because of steric repulsion between the bulky substituents (*i*Pr or *t*BuCH$_2$) on the silicons and the angular strains.

(2) Geometries

Firstly, the geometrical features show the following behavior with increasing bulkiness of substituent from an isopropyl to a neopentyl group in each pair of heterosilacycles [R$_2$Si]$_n$X (R = *i*Pr, *t*BuCH$_2$; X = CH$_2$, NC$_6$H$_{11}$, O, SiR$_2$, GeR′$_2$) (Tables 13 and 14):

i. The dihedral angles in the four-membered cycles increase (**3a**, **3b**; **A**, **B**; **C**, **D**).

ii. In the five-membered cycles, the ring torsion angles increase (**4a**, **4b**; **6a**, **6b**; **H**, **I**), whereas the sums of the internal angles decrease (**4a**, **4b**; **6a**, **6b**; **H**, **I**).

iii. In all cases, the Si−Si and Si−X bond lengths increase, except for Si−Ge in Si$_3$Ge, Si−Si in Si$_4$N, and Si−X in Si$_4$O cycles.

iv. The Si−Si−Si, Si−Si−X, and Si−X−Si bond angles decrease, except for Si−Si−O in the Si$_4$O cycle.

Consequently, the above results probably reflect the fact that the compounds bearing neopentyl groups release the steric repulsions between the bulky substituents through elongation of the bond lengths and expansion of the dihedral angles or torsion angles, while the compounds carrying isopropyl groups avoid steric repulsion (Pitzer strains) through expansion of the internal bond angles and distortion of the molecular shape. The bond elongation with increasing bulkiness of the substituents on the silicon atoms was also confirmed by the fact that the Si−Si bond lengths in the four- and five-membered [R$_2$Si]$_3$X and [R$_2$Si]$_4$X are longer − except in only one case (X = SiR$_2$)[14,16] − than those in the corresponding calculated cycles [R$_2$Si]$_3$X (R = H, Me, etc., X = SiH$_2$, CH$_2$, NH, O).[6a]

Secondly, the types of heteroatoms X in the four- and five-membered cycles [R$_2$Si]$_n$X also affect the geometrical parameters as follows:

i. The dihedral angles vary depending on the different combinations of heteroatom X, substituent R, and ring size; that is, Si$_n$X rings with NC$_6$H$_{11}$ or O as X prefer planar conformations (**3a**, **5b**), while the other silacyles have puckered (n = 3) or distorted conformations (n = 4).

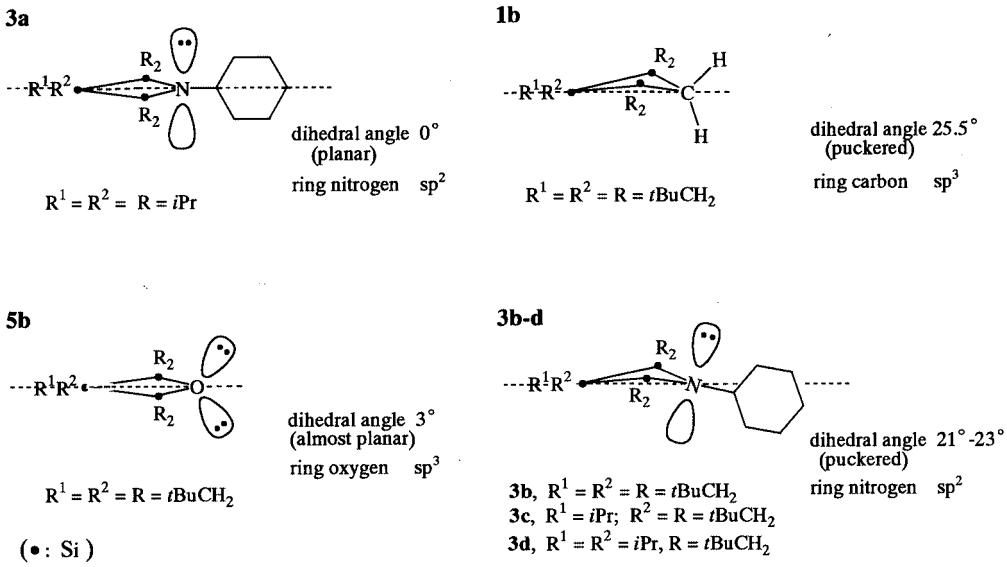
ii. For heterosilacycles [R$_2$Si]$_n$X [n = 3, 4; R = *i*Pr, *t*BuCH$_2$; X = Ge(CH$_2$SiMe$_3$)$_2$, CH$_2$, NC$_6$H$_{11}$, O], as can be seen in Tables 13 and 14, the Si−Si−Si bond angles and Si$^{\alpha}$···Si$^{\alpha'}$ nonbonding distances in Si$_3$X decrease with decreasing atomic radii of the heteroatoms X and Si−X bond lengths, whereas the Si−X−Si bond angles increase. Alternatively, with increasing electronegativity[18] of X, decreases in the Si−Si−Si angles and the Si$^{\alpha}$···Si$^{\alpha'}$ nonbonding distances and increases in the Si−X−Si angles were observed. Interestingly, similar results from calculations for [H$_2$Si]$_3$X (X = SiH$_2$, PH, S, CH$_2$, NH, O) have previously been reported by another group of workers,[19] who explained their results in terms of a concept, the σ-bridged-π-bonding concept, by which the structural properties were correlated with the electronegativities[18] of the heteroatoms X in the rings. Thus, if this idea is applicable to the current systems for explaining the geometrical properties of such types of small rings, the results shown in Tables 13 and 14 seem virtually to substantiate this concept for the relationship between parameters such as the electronegativity of X, the Si−X bond length, and the Si−X−Si angle.

In terms of the molecular structures of heterosilacycles [R$_2$Si]$_n$X (n = 3, 4; R = *i*Pr, *t*BuCH$_2$; X = CH$_2$, NC$_6$H$_{11}$, O) (**1**−**6**), it is of considerable interest to discuss the molecular shapes on the basis of the steric repulsions arising from the bulky substituents on the ring silicon atoms and the steric requirements around the heteroatoms X, including their atomic sizes. Scheme 3 shows schematic diagrams of four-membered silacycles consisting of X = CH$_2$, NC$_6$H$_{11}$, O (see Table 13). Silacycles **3a** (X = NC$_6$H$_{11}$; R = *i*Pr) and **5b** (X = O; R = *t*BuCH$_2$) are planar rings, while **1b** (X = CH$_2$; R = *t*BuCH$_2$) and **3b**−**d** (X = NC$_6$H$_{11}$; R = *t*BuCH$_2$) are folded ones. The results show that when bulky neopentyl groups (steric substituent constant, *Es* = −1.74)[17] are attached to the two α-silicon atoms (**1b**, **3b**−**d**, **5b**), heterosilacycle **5b** containing (the smallest) oxygen (covalent atomic radius, 0.66 Å) as X (or X group), is planar, whereas the other silacycles, containing nitrogen (0.70 Å; **3b**−**d**) and carbon (0.77 Å; **1b**), are folded. However, in **3a**, which contains the medium-sized nitrogen (0.70 Å) as X and less bulky isopropyl substituents (*Es* = −0.47[17]) on the α-silicon atoms, the ring shape is also planar. In addition, the strongly electronegative X atoms, such as X = O (*En* = 3.50[18]) and N (*En* = 3.07[18]) in silacycles **3a**−**d** and **5b** strongly attract the neighboring silicon atoms (*En* = 1.74[18]) to produce an Si−X bond length shorter than that calculated on the basis of the normal covalent radii of silicon and X when there is a large electronegativity difference between them.[19] Furthermore, so-called (p−d)π bonding produced by back-donation of the lone-pair electrons from X to the d-orbitals of α-silicon atoms is also possible. From these observations, it is thus reasonable to consider that the ring shapes of the heterosilaycles may be attributable to the result of a compromise between parameters: steric repulsions due to the congestion imposed by the bulky substituents on the silicon atoms, especially α-silicon atoms, the steric requirement around the heteroatoms X (or X groups) in Si−X−Si systems, the ring strain energies, and the electronegativity differences between heteroatom X (or heteroatom group) and silicon.

For five-membered rings (R$_2$Si)$_n$X (n = 4; R = *i*Pr; *t*BuCH$_2$) (**2**, **4**, **6**), on the other hand, detailed investigation of the molecular shapes is apparently necessary to explain their structural features in Table 14 fully.

^{29}Si NMR Spectra

The ^{29}Si NMR spectroscopic data for **1**−**6** are summarized in Table 15, together with those for the related compounds **A**−**I** (except for **F**). Various features relating to variation in ring size, heteroatom X, silicon atom (Si$^{\alpha}$ or Si$^{\beta}$), and substituents on the silicon atoms [see Scheme 1, (a)−(e)] are observed, as follows:



Scheme 3. Schematic diagrams of four-membered heteroatom-containing silacycles **1b**, **3a**−**d**, and **5b** (side views)

1) The resonances for the α-silicon atoms attached to the heteroatoms X are shifted downfield by a deshielding effect due to the electronegative atom X, and − as shown in Figure 1 − the larger the electronegativity (*En*)[18] of X, the lower the field of the chemical shifts.

2) The resonance for the β-silicon atoms generally occurs at higher fields than those for the α-silicon atoms, and there is no relationship between the chemical shift of the β-silicon atoms and the electronegativity[18] of X.

3) In the $[(i\mathrm{Pr})_2\mathrm{Si}]_n\mathrm{X}$ and $[(\mathrm{R^1R^2Si})_n\{(t\mathrm{BuCH_2})_2\mathrm{Si}\}_2]\mathrm{X}$ types (n = 1, 2), the resonances for the α- and β-silicon atoms appeared at higher fields with increasing ring size, due to a shielding effect with decreasing ring strain, as has previously been shown in various cyclosilanes.[20]

4) In each system of $\mathrm{Si}_n\mathrm{X}$ cycles, the resonances for both α- and β-silicon atoms of the compounds bearing neopentyl groups are shifted to higher fields than those bearing isopropyl groups, since the silicon atom at the γ-position from the terminal methyl carbon atom in an $\mathrm{SiCH_2C(CH_3)_3}$ group is subject to a high-field shielding effect due to the terminal carbon atom.[21]

Interestingly, it can be seen from Table 15 that the trend towards an increasing deshielding effect on the Si^α chemical shifts with increasing electronegativity[18] of X is substantially present, regardless of the presence or absence of a substituent on the heteroatom X. Indeed, as shown in Figure 1, the chemical shifts of the Si^α atoms in each series showed a good linear correlation with the electronegativity[18] of the heteroatom X, with good correlation coefficients (γ = 0.95−0.99). This is the first example in which a good linear correlation of $\delta\mathrm{Si}^\alpha$ with the electronegativity[18] of X in the $[\mathrm{R_2Si}]_n\mathrm{X}$ cycles has been found.

Electronic Spectra

The UV spectra for $[\mathrm{R_2Si}]_n\mathrm{CH_2}$ (**1**, **2**), $[\mathrm{R^1R^2Si}]_n\mathrm{NR^3}$ ($\mathrm{R^3}$ = $\mathrm{C_6H_{11}}$ or Pr) (**3**, **4**), and $[\mathrm{R^1R^2Si}]_n\mathrm{O}$ (**5**, **6**) are listed in Table 16. In the UV spectra of **1a** and **1b** and of **2a** and **2b**, the longest-wavelength absorptions occur at λ = 234, 231 and 261, 254 nm, respectively, with varying extinction coefficients. The absorption maxima for the $\mathrm{Si_3C}$ cycles (**1**) consisting of peralkylated ring silicon atoms are substantially different from those (λ = 502−538 nm) for known $\mathrm{Si_3C}$ cycles with rather particular substituents,[3b][3c] such as trisilacyclobutaimines $[t\mathrm{Bu_2Si}]_3\mathrm{C{=}NAr}$. The absorption maxima of $\mathrm{Si_4C}$ (**2**) occur in almost the same region as that (λ = 258 nm) of peralkylated compound $[\mathrm{Me_2Si}]_4\mathrm{CH_2}$[3j] and are fairly different from that (λ = 443 nm) of perphenylated tetrasilacyclopentaimine $[\mathrm{Ph_2Si}]_4\mathrm{C{=}NPh}$[3f] and that (λ = 325 nm) of partially phenylated allenic tetrasilacy-

[a] In *c*-C_6H_{12}. [b] Ref.[7d] [c] Ref.[16] [d] Ref.[10] [e] See also ref.[14] [f] Our data. [g] Ref.[7d]

The *N*-substituted four- and five-membered cycles **3** and **4** showed the longest-wavelength absorption bands at λ = 233−240 nm and 252 nm (sh), respectively. The absorption (252 nm) for **4** occurred at a longer wavelength region than that (235 nm) for $[Me_2Si]_4NMe$,[6b−6d] but shorter than that (282 nm) for $[Ph_2Si]_4NR^3$ (R^3 = Me, Et).[6e]

In the UV spectra of the *O*-substituted four- and five-membered compounds **5** and **6**, the longest-wavelength absorption bands occurred at λ = 245−250 and 255−260 nm, respectively. The absorption maxima for the Si_4O cycles (**6**) are comparable with those (λ = 253−258 nm) for $[Me_2Si]_4O$,[6d] $[Ph_2Si]_4O$,[6e] and $[Me(tBu)Si]_4O$.[5d] The UV data for the four-membered compounds **3** and **5** are the first examples for the Si_3N and Si_3O ring systems, respectively.

The UV data for **1**−**6** in Table 16, together with those for the related compounds **A**−**I**, showed various interesting features, as follows:

i. Little difference was observed in the UV data for $[iPr_2Si]_nX$ and $[(tBuCH_2)_2Si]_nX$ of the same ring size.

ii. With respect to the longest-wavelength absorption bands, compounds **1**−**6** and **A**−**I** could be roughly classified by a combination of ring size and heteroatom X into four groups: (a) $[R_2Si]_3X$ [X = SiR_2, $Ge(CH_2SiMe_3)_2$] (**A**−**D**), λ = 280−300 nm; (b) $[R_2Si]_3X$ (X = CH_2, NC_6H_{11}, O) (**1**, **3**, **5**), λ = 230−250 nm; (c) $[R_2Si]_4X$ (X = SiR_2, GeR'_2; R′ = CH_2SiMe_3, Ph) (**E**, **G**−**I**), λ = 270−300 nm; (d) $[R_2Si]_4X$ [X = CH_2, NR^3 (R^3 = C_6H_{11}, Pr), O] (**2**, **4**, **6**), λ = 250−260 nm. Compounds belonging to the same group showed absorption bands in almost the same region with nearly the same molar extinction coefficients, regardless of the nature of X and the substituents on the silicon atoms.

iii. As the ring size increased, the absorption maxima for the *Ge*-substituted compounds **C**−**D** and **G**−**I** hypsochromically shifted by 8−10 nm with increased extinction coefficients, as expected by analogy with the peralkylcyclosilanes such as $[R_2Si]_n$ (R = Me[22a,22b] and Et[22c]), while those for the *C*-, *N*-, and *O*-substituted compounds **1**−**6** bathochromically shifted by 10−20 nm with decreased extinction coefficients. This trend resembles that observed with increasing chain length for linear permethylpolysilanes $Me(Me_2Si)_nMe$,[23] rather than the cyclosilanes[22] mentioned above. Similarly, bathochromic shifts with increasing ring size have previously been observed for the *N*-substituted compounds $[Me_2Si]_nX$ (n = 4−6).[6b]

iv. The molar extinction coefficients (ε = 200−4100 $dm^3cm^{-1}mol^{-1}$) for compounds **A**−**I**, **2**, **4**, **6**, containing one germanium or four silicon atoms in the ring systems, were very small relative to those (ε = 8800−12000 $dm^3{\cdot}cm^{-1}{\cdot}mol^{-1}$) for **1**, **3**, and **5**, containing three silicon atoms. The large difference in the ε values between the two sets of ring systems may be due to differences in the forbidden σ−π* or allowed σ−σ* transitions[1a][3j] (vide infra).

Ring Strain Energies by Theoretical Calculation

The ring strain energies of homosilacycles or silicon cluster compounds are a very interesting subject, not only experimentally but also theoretically. We have previously experimentally determined the ring strain energies for a series of peralkylated homosilacycles $[R^1R^2Si]_n$ as 41, 23, 6, and 0 kcal/mol for n = 3−6, respectively.[7e] From the theoretical perspective, on the other hand, the homodesmotic ring strain energies for $(SiH_2)_4$ and $(SiH_2)_5$ at HF (Hartree−Fock) or MP2 levels with the basis sets of double

zeta plus polarization functions quality were calculated to be ca. 17.0 and 6.0 kcal/mol, respectively.[24] Similar results (18.7 and 5.7 kcal/mol) have been obtained at the higher MP4SDTQ/6-31G** level.[25] The calculated values thus seem to be slightly underestimated for the four-membered ring, although the data for the five-membered ring agree well with the above experimentally determined values.

Although some theoretical studies on the types of homosilacycles $(SiH_2)_n$[24,25] mentioned above and on $(SiH_2)_nX$ (X = PH and S)[19,26] are thus available, alkyl-substituted homosilacycles $(SiR_2)_n$ and alkyl-substituted heteroatom-containing silacycles have not so far been reported. In a preliminary study,[27] we estimated the ring strain energies for the alkylated four- and five-membered heterosilacyles $[R_2Si]_nX$ [R = Me, *i*Pr; *n* = 3, 4; X = CH_2, NMe, N(*i*Pr), O, SiH_2], on the basis of the homodesmotic reaction energies.[28] The magnitudes of the calculated strain energies for the series R = *i*Pr, listed in Table 17, were found to be in the order: *n* = 3: X = O (**5a**, 12.8 kcal/mol) > CH_2 (**1a**, 8.7) > SiH_2 (8.1) > N(*i*Pr) (6.4) > NMe (2.2); *n* = 4: X = N(*i*Pr) (11.4) > O (**6a**, 8.3) > SiH_2 (3.9) > CH_2 (**2a**, 3.1) > NMe (−2.1). In the four-membered cycle with SiH_2 as X, it was shown that the PM3 strain energy (8.1 kcal/mol) was much less than the above result (18.7 kcal/mol) obtained by the ab initio method,[25] and also the experimentally determined one (23 kcal/mol). The strain energies calculated for the four-membered rings are much larger than those for the five-membered rings for all kinds of heteroatom (or heteroatom group) X except for X = N(*i*Pr), in which the two kinds of silacycles are reversed in the magnitude of their strain energies. This may be explained in terms of the steric repulsions between the bulky groups including the Si−N(R^3)−Si system (R^3 = *i*Pr; see Table 17, footnote) in the Si_4N cycle, as such an effect is apparently more severe in the five-membered cycle than in the four-membered one, as shown and discussed previously for homosilacycles.[7f] This order of the magnitude in the two series of silacycles seems to be reasonable, although more advanced calculations are necessary.[27] In the four-membered rings, it is noteworthy that the strain energy (12.8 kcal/mol) for **5a** (X = O) is the largest and that the results agree well with prediction from the structural features of this molecule, that is, the highly strained conformation, as shown in Table 13 and discussed in the previous section. For the silacycles with X = CH_2 and SiH_2 as X, the strain energies of Si_3X (8.7, 8.1 kcal/mol) and Si_4X (3.1, 3.9) are fairly close to each other, while those for Si_3X and Si_4X cycles where X = NMe (2.2, −2.1, respectively) are the smallest. However, the considerable strain energy for Si_3X, X = N(*i*Pr) (6.4 kcal/mol) is of interest, because the conformation of the silacycle, including the steric requirements around the Si−N(R^3)−Si system, seems to be similar to that of X = NC_6H_{11} (**3a**, see also Table 17, footnote). The large strain energy calculated for Si_4X (X = O, **6a**) (8.3 k/cal) may also be in agreement with the experimental results shown in Table 2, in which the conformation, consisting of the relatively small angles Si−Si−Si (95°) and Si−Si−O (102°), the large angle Si−O−Si (134°), the short distance Si−O (1.65 Å), and the small ring-torsion angle (23°), would be a fairly strained molecule. It is worthwhile to note that a similar consideration may be applicable to the large strain energy (11.4 kcal/mol) for the heterosilacycles containing X = N(*i*Pr) if the X group can accommodate the NC_6H_{11} group of **4a** (see Table 17, footnote).

Table 17. Estimated strain energies [kcal/mol] of $[R_2Si]_nX$ at PM3 level

ring size	n	X	R: Me	R: *i*Pr
4	3	CH_2	7.9	8.7 (**1a**)
		NMe	9.0	2.2
		N(*i*Pr)[a]	...	6.4
		O	10.8	12.8 (**5a**)
		SiH_2	5.1	8.1
5	4	CH_2	0.9	3.1 (**2a**)
		NMe	-2.0	-2.1
		N(*i*Pr)[a]	...	11.4
		O	-0.9	8.3 (**6a**)
		SiH_2	0.5	3.9

[a] For convenience, the bulkiness of the two β-carbon atoms of the isopropyl group is assumed to be close to those of the cyclohexyl group; polar substituent constant σ*(*i*Pr) = −0.190, σ*(C_6H_{11}) = −0.15 (see ref.[17])

Oxidation Potentials

The oxidation potentials (E_{pa} vs. SCE) of the homo- and heterosilacycles were determined by cyclic voltammetry in MeCN or CH_2Cl_2. The results are summarized in Table 18[7h,29] and Table 19, respectively, together with those for the related compounds **A**−**I** (except for **E**). Firstly, it should be noted that this is the first report describing the oxidation potentials for silacycles containing a heteroatom in the ring system $[R_2Si]_nX$ (X = CH_2, O, NR^3, GeR'_2). The silacycles also gave irreversible voltammograms similar to those obtained for the homosilacycles, as shown in the previous work,[7h] suggesting the formation of their unstable cation-radicals produced from the starting silacycles. Interestingly, the oxidation potentials thus obtained from the four- and five-membered silacycles **1**, **3**, **5**, **A**−**D** and **2**, **4**, **6**, **F**−**I** roughly fall into nearly the same potential ranges as found for the homosilacycles Si_4 and Si_5[7h] in the two solvents. Thus, the potentials for the Si_3X rings were 0.8−1.0 V in MeCN and 0.96−1.24 V in CH_2Cl_2, while those for the Si_4X rings were 1.0−1.24 V in MeCN and 1.16−1.53 V in CH_2Cl_2. As described in the previous work,[7h] solvation of the cation radicals produced by the oxidations may account for the lower potentials in MeCN than in CH_2Cl_2 for **1**−**6**. Furthermore, it is also apparent from Table 19 that the potentials for the Si_3X system decreased relative to those for the Si_4X system in each solvent system. The results are in accord with the trend of the oxidation potentials in a series of homosilacycles $[R^1R^2Si]_n$ (*n* = 3−7).[7h,29] The silacycles of smaller ring size have larger ring strain energies and more strongly electron-donating natures than those with larger ring sizes.[7e] It was thus found that the oxidation potentials were primarily affected by the ring size, regardless of the types of heteroatom X and the substituents on the silicon

atoms, and − in addition − the presence or absence of a substituent on the heteroatom X.

[a] The first anodic peak potentials; scan rate, 250 mV/s; see also ref.[7h] [b] Values calculated using the regression line (Figure 2) obtained from the experimental data of the oxidation (E_{pa}, CH_2Cl_2) and ionization potentials (Table 18). [c] Values calculated by using the HOMO levels and the transition energies obtained from the longest-wavelength absorption bands (Table 16). [d] Transition energy. [e] Ref.[31]

Molecular Frontier Orbitals

Generally, it is well known that oxidation potentials obtained by cyclic voltammetry (CV) for various compounds are linearly correlated to their ionization potentials,[30] which are useful for evaluation of HOMO levels. Accordingly, the oxidation potentials for this series of heteroatom-containing silacycles are applicable to estimation of their HOMO levels, from which their LUMO levels can also be estimated.

(1) Observed Results

Firstly, in order to determine the HOMO levels for a series of homosilacyles, we obtained a regression line for the relationship, with a good correlation coefficient (γ = 0.86 in Figure 2), between the reported ionization potentials (eV) of some homosilacycles measured by photoelectron spectroscopy (PES)[31−33,35] and their oxidation potentials (E_{pa}, in V vs. SCE in CH_2Cl_2) determined by the CV method, as listed in Table 18 (numbers 1, 3, 5, 7, 10, and 16). Interestingly, it should be pointed out that, in the current study, the E_{pa} value of $(Me_2Si)_5$ was shown to be 1.26 V (number 10), whereas the reported value is 1.54 V.[29] Although a better correlation (γ = 0.92) can be obtained if the former value is disregarded, the reason why the relatively large discrepancy occurred could not be clarified and remains to be investigated.

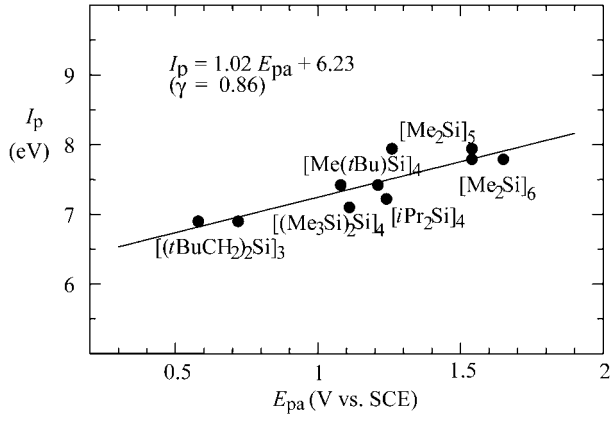

Figure 2. Correlation of the ionization potentials (PES) with the oxidation potentials (CV) of peralkylated homosilacycles $[R_2Si]_n$ (n = 3−7)

Next, with the aid of the regression line (Figure 2), the frontier HOMO levels of all the homosilacycles $(R_2Si)_m$ were estimated, from the oxidation potentials listed in Table 18, as approximately −6.8, −7.3, −7.7, −7.8, −7.6 eV for m = 3−7 (numbers 1−18), respectively. The

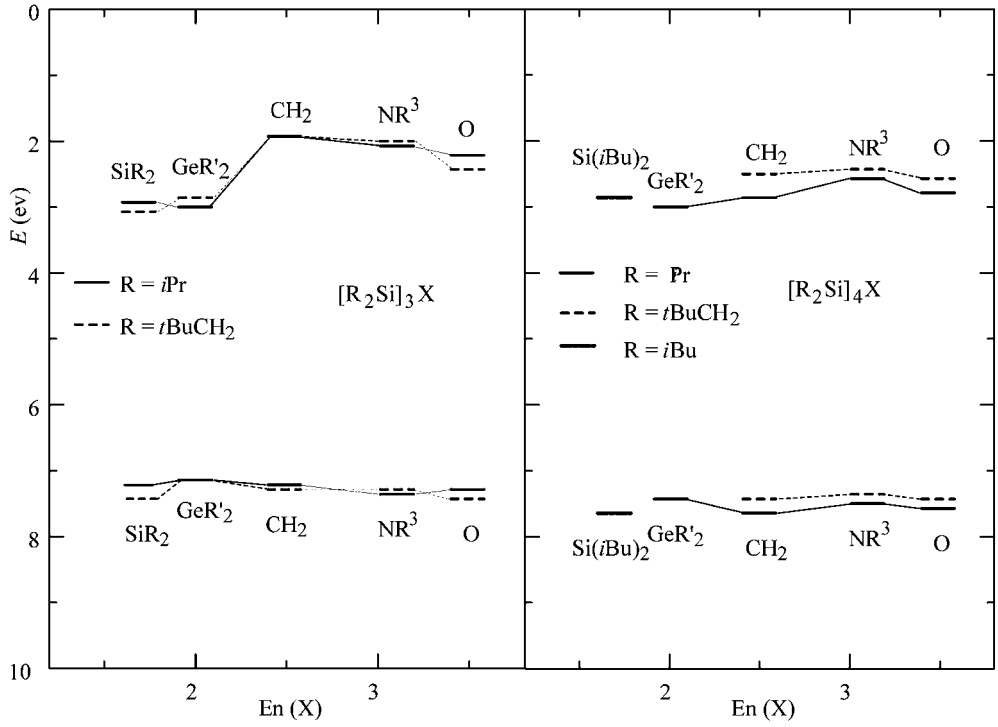

Figure 3. HOMO and LUMO levels for four- and five-membered heteroatom-containing silacycles $[R_2Si]_nX$ (n = 3, 4; R = *i*Pr, *t*BuCH$_2$)

results clearly exhibit decreasing levels with increasing ring size, except for m = 7, which is similar to that of m = 5. However, the LUMOs of m = 3−6 fall within a narrow range (numbers 1−17, −2.81 to −3.29 eV), and the level for the ring size m = 7 (number 18, −2.5 eV) appears to be slightly higher than those for m = 3−6.

In a similar manner, the two frontier levels for the series of heteroatom-containing silacycles $[R_2Si]_nX$ (R = *i*Pr, *t*BuCH$_2$; n = 3, 4; X = CH$_2$, O, NR^3, SiR$_2$, GeR′$_2$) were then estimated as listed in Table 19 and shown in Figure 3. Of interest is the fact that, in the four-membered cycles (n = 3), the HOMO levels were found to be very close to each other (ca. 7.2−7.4 eV), due to the close values of their oxidation potentials (E_{pa} = 0.96−1.24 V). The results suggest that the HOMOs of the $[R_2Si]_3X$ series lie at very close levels, probably arising from similar bonding character in the four-membered heterosilacycles at the HOMO levels. For the frontier orbitals of the five-membered cycles Si$_4$X, on the other hand, the HOMO levels are also very close to each other (Figure 3), but, as would be expected from their oxidation potentials, are at slightly lower levels than those for the Si$_3$X cycles.

With regard to the LUMO levels for the Si$_3$X cycles, the experimentally determined results can apparently be classified by the size of the energy gaps (E_T) into two groups: X = CH$_2$, NR^3, O (**1**, **3**, **5**) and X = SiR$_2$, GeR′$_2$ (**A**, **D**), as shown in Table 19 and Figure 3. Interestingly, as can be seen in Figure 4 at the LUMOs, including both the first LUMO and the second LUMO levels, which are in a very narrow range (vide infra), it is likely that the enhanced LUMO levels of the former group in comparison to those of the latter may be attributable to the contribution of the heteroatom (or heteroatom group) X to the frontier orbitals, especially the LUMOs, associated with the conformations due to the four-membered ring systems. In addition, the transition probabilities from the HOMOs to the LUMOs (ε = 8800−12000 dm^3·cm^{-1}·mol^{-1}for **1**, **3**, **5**; "allowed" transition[36]) for the former definitely appear different from those for the latter (ε = 200−590 dm^3·cm^{-1}·mol^{-1} for **A**−**D**; "forbidden" transition[36]), as shown in the longest-wavelength UV absorption bands in Table 16.

For the five-membered Si$_4$X (X = SiR$_2$, GeR′$_2$, CH$_2$, NR^3, O), on the other hand, the LUMOs are close to each other in all ring types, showing lower levels than those seen for the corresponding Si$_3$X, except for X = SiR$_2$. Thus, the contribution of the heteroatom (or heteroatom group) X to the LUMOs mentioned above cannot be observed in Figure 5 in the heterosilacycles containing X = CH$_2$, NR^3, O (**2**, **4**, **6**), which is related to their conformations. The values for the transition probabilities (ε = 1100−4100 dm^{3}cm^{-1}mol^{-1} for **2**, **4**, **6**, **E**, **F**, **G**; "partially allowed" transition[36]) in Table 16 fall in the mid-range between the two cases in the transitions, including compounds **H** and **I** (ε = 5700−7600 dm^{3}cm^{-1}mol^{-1}) which contain phenyl rings that provide resonance effects on the germanium atom in the rings.

From the above observations it should therefore be noted that the concept of a contribution through the heteroatom (or heteroatom group) X in the Si−X−Si systems to the LUMOs derived from theoretical calculations for the

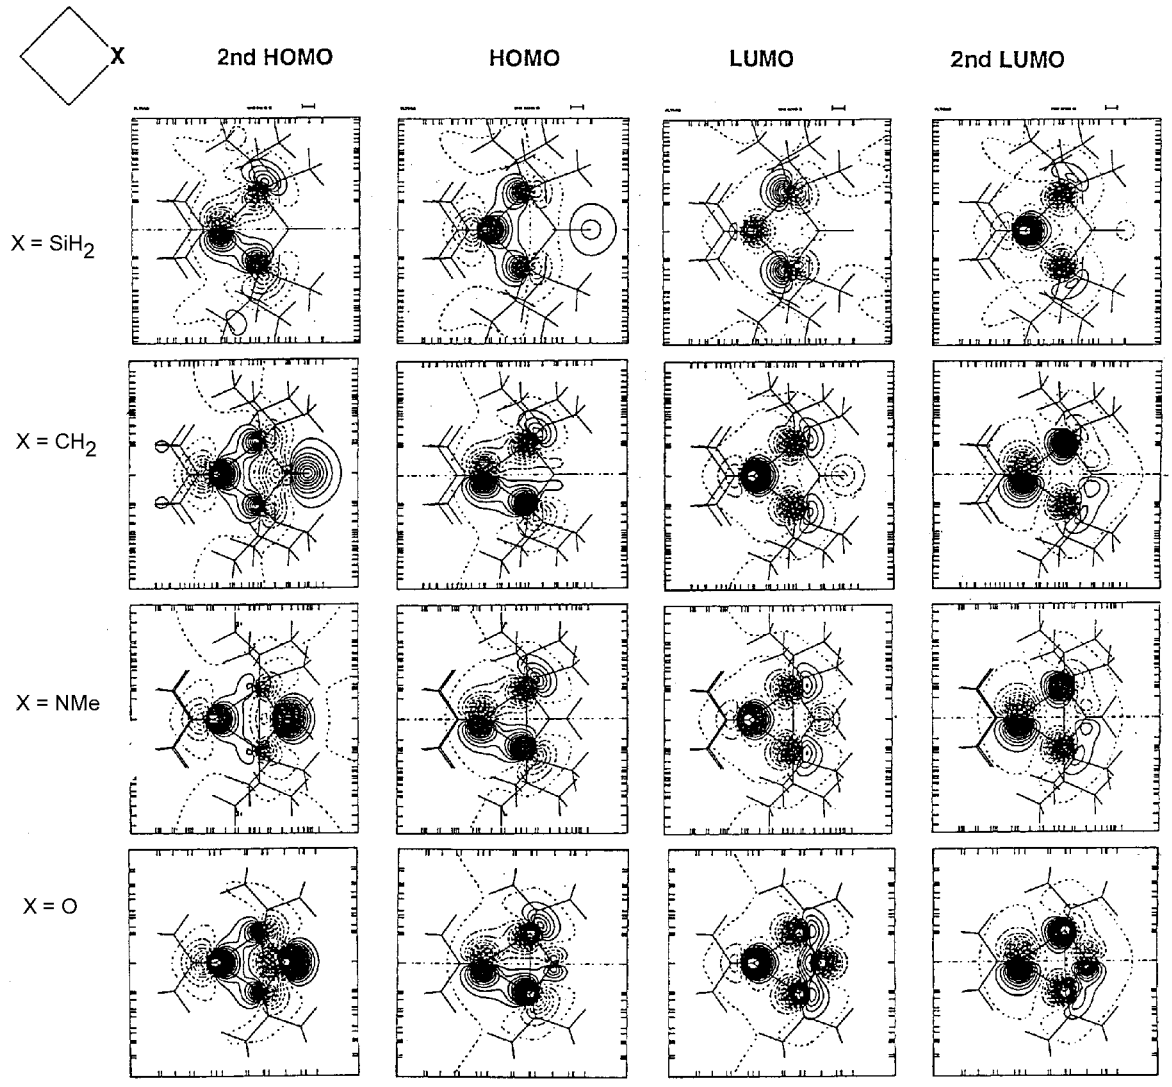

Figure 4. Orbital pictures of the frontier orbitals of $[(i\mathrm{Pr})_2\mathrm{Si}]_3\mathrm{X}$ (X = SiH_2, CH_2, NMe, and O)

HOMOs and LUMOs of the heterosilacycles Si_3X and Si_4X (X = CH_2, NR^3, O) may account for the above experimental results, although detailed studies are necessary.[27]

(2) Theoretical Calculations

The frontier orbital levels determined by PM3 are listed in Table 20. There seems to be no clear trend in the transition energies or energy gaps (E_T) of the molecules of interest. In the case of X = SiH_2, both HOMO and LUMO levels lie slightly lower in energy than in the other compounds with heteroatoms (or heteroatom groups). Both energy levels are almost the same in both sizes of rings, but the energy gaps seem to be slightly smaller in the five-membered rings than in the four-membered ones. Interestingly, the trend of the calculated E_T values in Table 20 for the series of compounds $[(i\mathrm{Pr})_2\mathrm{Si}]_n\mathrm{X}$ [n = 3, 4; X = CH_2, NMe, N(iPr), O, SiH_2] is in good agreement with those for the series of experimental results obtained from the corresponding (or similar) heterosilacycles $[R_2Si]_nX$ [n = 3, 4; X = CH_2 (**1a**; **2a**), NC_6H_{11} (**3a**; **4a**), O (**5a**; **6a**), SiR_2 (**A**; **E**)], respectively (see Table 19 and Figure 3).

The frontier orbitals for the four- and five-membered rings containing X = CH_2, NMe, SiH_2, and O are displayed in Figures 4 and 5, respectively. The orbital levels of the HOMO and the second HOMO, and the LUMO and second LUMO are very close to each other, so that the order of levels can vary depending on the kinds of heteroatom (or heteroatom group). However, the character of the orbitals is independent of the natures of X, as the HOMOs are almost localized on the ring frames. This is also true even if the kinds of substituents are changed. Interestingly enough, it was shown from Figures 4 and 5 that photochemical bond scission in the heteroatom-containing silacycles $[(i\mathrm{Pr})_2\mathrm{Si}]_n\mathrm{X}$ would occur at the Si−Si bonds and not at the Si−X bonds, as the HOMOs and LUMOs have Si−Si bonding and antibonding character, respectively.

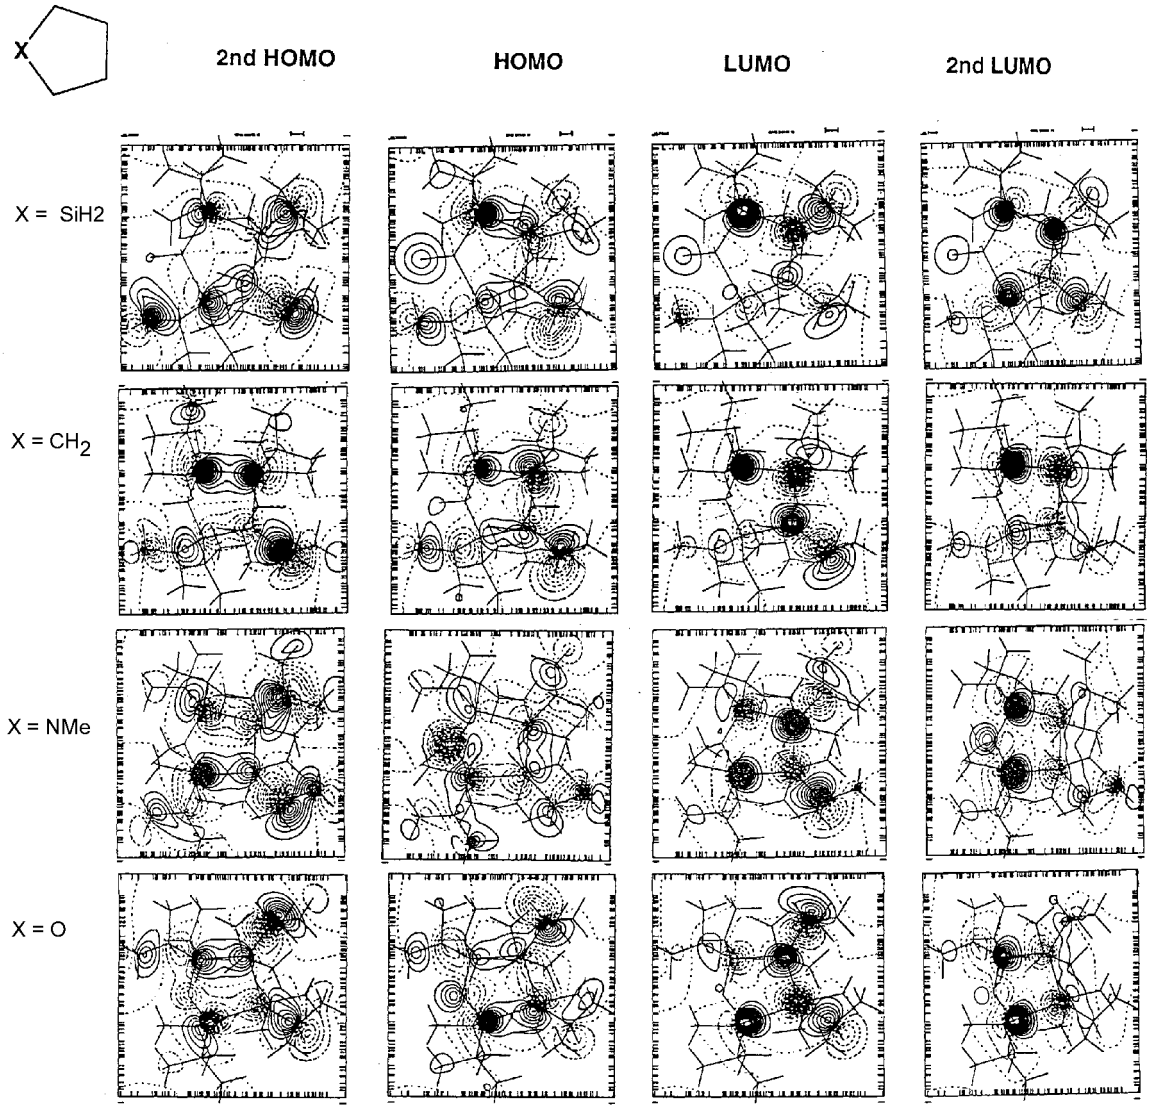

Figure 5. Orbital pictures of the frontier orbitals of $[(i\text{Pr})_2\text{Si}]_4\text{X}$ (X = SiH_2, CH_2, NMe, and O)

Table 20. Frontier orbital levels [eV] of $[(i\text{Pr})_2\text{Si}]_n\text{X}$ at PM3 level

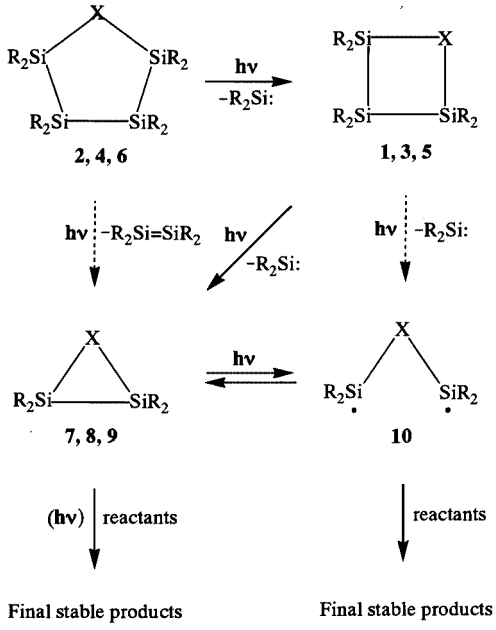
[a] Transition energy. [b] For convenience, the bulkiness of the two β-carbon atoms of the isopropyl group is assumed to be close to that of the cyclohexyl group; polar substituent constant σ*(*i*Pr) = −0.190, σ*(C_6H_{11}) = −0.15 (see ref.[17]).

It seemed quite interesting to compare the theoretical prediction with experimental results obtained by photochemical cleavage of the heteroatom-containing silacycles Si_nX (n = 3, 4; X = CH_2, NC_6H_{11}, O).[8,37] We therefore investigated photochemical decomposition of the series of silacycles in a hydrocarbon solvent at room temperature or at 77 K under various reaction conditions in the absence or presence of reactants to trap reactive intermediates produced during the reactions.[1b] With a low-pressure mercury lamp (λ = 254 nm light)[8,37a] or a halogen lamp (λ > 390 nm light) in the presence of a photosensitizer such as 9,10-dicyanoanthracene,[37b] various photochemical decompositions were carried out to give the corresponding products, which were characterized, identified, and quantitatively analyzed (**1**, **3**, **5**, **7**, **8**, **9**, **10**, and final products). The results, summarized in Scheme 4, clearly show that the bond scissions occurred exclusively at the Si−Si bonds, and not at the Si−X bonds, which indicated good agreements with the above predictions. Finally, it should be noted that the strain energies in the series of silacycles Si_nX (n = 3, 4; X = CH_2, NR^3, O, GeR'_2) probably affect the differences between their reaction rates, as has been previously shown for thermal reactions of homosilacycles.[1b,38]



Scheme 4. Photochemical decompositions of heteroatom-containing silacycles Si_nX (n = 3, 4; X = CH_2, NR^3, and O) to give products; the paths shown with a dotted arrow do not seem to exist

Experimental Section

General Procedure: All reactions were carried out in dry flasks under an inert gas (N_2 or Ar). A commercially available 30% lithium dispersion in mineral oil was employed and was usually washed with the same solvent as used in subsequent reactions unless otherwise noted. In all preparations, the progress of the reaction in each step was monitored by GLC analysis. All melting points (uncorrected) were determined in sealed tubes, and for high melting point measurements a block heating apparatus equipped with a microscope were used. ^{1}H NMR spectra were recorded with Varian EM 360 A (60 MHz) (for **3b** and **5**), Hitachi 90H (90 MHz) and Varian Gemini 200M (200 MHz) spectrometers (for **1**, **2**, **3a**, **3c**, **3d**, **4**, and **6**) in $CDCl_3$ or C_6D_6 with Me_4Si as an internal standard. ^{13}C NMR spectra were recorded with Hitachi 90H (for **3a**, **3b**, **5**, and **6**) and Varian Gemini 200M (for **1**, **2**, **3c**, **3d**, and **4**) spectrometers in $CDCl_3$ or C_6D_6 with Me_4Si as an internal standard. For convenience, some spectroscopic data signals include the multiplicities in parentheses determined by the off-resonance technique. ^{29}Si NMR spectra were recorded in $CDCl_3$ or C_6D_6 with Hitachi 90H (for **3**−**6**) and JEOL ALPHA 500 (for **1** and **2**) spectrometers. Mass spectra were recorded with a JEOL DX 302 spectrometer (Ip = 30 or 70 eV). UV spectra were obtained with a Hitachi 200-10 spectrometer. GLC analysis was performed with an Ohkura GC-103 gas chromatograph equipped with a glass column (1 m) packed with SE-30 (10%) on Celite 545-AW (60−80 mesh). Cyclic voltammetry was performed with a Hokuto Denko Model HB-107A function generator and a Hokuto Denko Model HA-101 potentiostat. A cyclic voltammogram obtained at a scan rate of 250 mV/s was recorded with a Rikadenki X-Y recorder Model BW 133. For high-speed recording, a two-channel wave memory (NF Model MW-812A) was employed.

Materials: Tetrahydrofuran and benzene used in synthesis were dried with sodium wire and then freshly distilled out from a flask containing benzophenone/ketyl radical before use. Hexane, cyclohexane, and pentane were dried with lithium aluminum hydride and freshly distilled before use. Butyllithium solution in pentane (ca. 1.78 M) was commercially available. Spectrochemical grade cyclohexane was used for the determination of UV spectra. For cyclic voltammetry, spectrochemical grade acetonitrile and dichloromethane were dried by heating under reflux with P_2O_5 and freshly distilled under nitrogen before use. Other solvents and materials were commercially available.

Synthesis of *C*-Substituted Compounds 1 and 2: Compounds **1** and **2** were synthesized by reductive coupling of the corresponding α,ω-dichlorocarbosilanes with lithium as shown in Scheme 2, (a).

Synthesis of 2,2,3,3,4,4-Hexaisopropyl-2,3,4-trisilacyclobutane (1a): Typically, a solution of 1,4-dichloro-1,1,2,2,4,4-hexaisopropyl-1,2,4-trisilabutane $Cl(R_2Si)_2CH_2SiR_2Cl$ (R = *i*Pr) (**1a-1**, 0.161 g, 0.38 mmol) in a solvent mixture of THF (1.9 mL) and hexane (10.1 mL) was slowly added over 8 min at room temperature with stirring to a green suspension of lithium (69 mg, 2.98 mmol) and biphenyl (23 mg, 0.15 mmol) in THF (3.8 mL). After 2 h of stirring and addition of hexane, the unchanged lithium was filtered off. Purification by short column chromatography (silica gel, hexane) gave **1a** (0.134 g, 93% purity by GLC) as a colorless liquid, which was isolated by preparative GLC. ^{1}H NMR ($CDCl_3$): δ = 0.03 (s, 2 H, $C_{(ring)}H_2$), 1.09−1.12 [m, 24 H, $Si^{\alpha}CH(CH_3)_2$], 1.24 [d, 12 H, $Si^{\beta}CH(CH_3)_2$], 1.13−1.20 (m, 4 H, $Si^{\alpha}CHMe_2$), 1.41−1.50 (m, 2 H, $Si^{\beta}CHMe_2$). ^{13}C NMR ($CDCl_3$) −4.0 ($C_{(ring)}H_2$), 13.6 ($Si^{\beta}CHMe_2$), 14.9 ($Si^{\alpha}CHMe_2$), 19.7 and 20.0 [$Si^{\alpha}CH(CH_3)_2$], 22.5 [$Si^{\beta}CH(CH_3)_2$]. MS: *m*/*z* (%) = 356 (100) [M^+], 313 (60) [M − (*i*Pr)]$^+$, 271 (80) [M − (*i*Pr) − C_3H_6]$^+$. $C_{19}H_{44}Si_3$: calcd. C 63.96, H 12.43; found C 64.18, H 12.63. The above 1,4-dichlorotrisilabutane (**1a-1**) was prepared by a method similar to that used for the preparation of the methyl analogue $Br(Me_2Si)_2CH_2SiMe_2Br$,[3a] starting from R_2SiHCl (R = *i*Pr) via HR_2SiCH_2Cl (GLC yield, 36%), $HR_2SiCH_2SiR_2Ph$ (74%), $ClR_2SiCH_2SiR_2Ph$ (100%), $PhR_2SiSiR_2CH_2SiR_2Ph$ (100%), and then $ClR_2SiSiR_2CH_2SiR_2Cl$ (**1a-1**) (70%) (overall yield based on R_2SiHCl used, 19%); Colorless liquid; b.p. 103−105 °C/0.2 Torr. ^{1}H NMR ($CDCl_3$): δ = 0.28 (s, 2 H, $SiCH_2Si$), 1.11−1.50 [m, 42 H, $SiCH(CH_3)_2$]. ^{13}C NMR ($CDCl_3$): δ = 7.6 ($SiCH_2Si$), 13.5 (Si^2CHMe_2), 16.5 (Si^1CHMe_2), 17.0 (Si^4CHMe_2), 17.7 [$Si^2CH(CH_3)_2$], 18.1 and 18.6 [$Si^1CH(CH_3)_2$], 19.6 [$Si^4CH(CH_3)_2$]. MS: *m*/*z* (%) = 383 (5) [M − (*i*Pr)]$^+$, 341 (3) [M − (*i*Pr) − C_3H_6]$^+$, 274 (100) [M − (*i*Pr)$_2$SiCl]$^+$. $C_{19}H_{44}Cl_2Si_3$: calcd. C 53.35, H 10.37; found C 53.27, H 10.36.

Synthesis of 2,2,3,3,4,4-Hexaneopentyl-2,3,4-trisilacyclobutane (1b): This compound was synthesized by a method similar to that used for **1a**, by treatment of 1,4-dichloro-1,1,2,2,4,4-hexaneopentyl-1,2,4-trisilabutane $Cl(R_2Si)_2CH_2SiR_2Cl$ (**1b-1**: R = *t*$BuCH_2$; 0.599 g, 1.00 mmol, THF 5 mL/hexane 15 mL) with lithium (0.220 g, 9.5 mmol) and biphenyl (33 mg, 0.21 mmol, THF 10 mL) for 2.5 h. Compound **1b** (recrystallized from ethanol/pentane): 0.379 g, 72% yield; m.p. 138−140 °C. ^{1}H NMR ($CDCl_3$): δ = 0.44 (s, 2 H, $C_{(ring)}H_2$), 1.05 [s, 18 H, $Si^{\beta}CH_2C(CH_3)_3$], 1.06 [s, 36 H, $Si^{\alpha}CH_2C(CH_3)_3$], 1.15−1.19 [m, 12 H, $SiCH_2(t$Bu)]. ^{13}C NMR ($CDCl_3$) δ = −6.7 ($C_{(ring)}H_2$), 29.5 [$Si^{\beta}CH_2(t$Bu)], 31.4 ($Si^{\beta}CH_2CMe_3$), 32.0 ($Si^{\alpha}CH_2CMe_3$), 33.6 [$Si^{\alpha}CH_2(t$Bu)], 33.8 [$Si^{\alpha}CH_2C(CH_3)_3$], 33.9 [$Si^{\beta}CH_2C(CH_3)_3$]. Synthesis of *N*-Substituted Compounds 3 and 4: Compounds **3** and **4** were synthesized by treatment of the corresponding α,ω-dichlorosilanes with lithium alkylamide as shown in Scheme 2, (b) or (c).

Synthesis of 1-Cyclohexyl-2,2,3,3,4,4-hexaisopropyl-1-aza-2,3,4-trisilacyclobutane (3a) [Scheme 2, (b)]**:** Typically, a pentane solution of butyllithium (1.59 mL, 2.83 mmol) was added dropwise to a solution of cyclohexylamine (0.25 mL, 2.18 mmol) in THF (11 mL) at −75 to −60 °C. With stirring at the same temperature, the reaction progress was monitored by GLC for the peak intensity of the amine. When the intensity had decreased to a minimum, a solution of 1,3-dichloro-hexaisopropyltrisilane[5a] (0.50 g, 1.21 mmol) in THF (1 mL) was added to the reaction mixture at the same temperature. After additional stirring for 1 h at that temperature, 1 h at room temperature, and then heating under reflux for 10 h, the solvents were evaporated to give a solid, to which cyclohexane was added. After filtration, the resulting solution was concentrated, treated with water, and extracted with cyclohexane. The extracts were dried with calcium chloride, filtered, and concentrated to give a solid product, which was recrystallized from ethanol to afford colorless crystals of **3a** (0.36 g, 57% based on the dichlorotrisilane used); m.p. 208−213 °C. ^{1}H NMR ($CDCl_3$): δ = 1.08−1.15 [m, 24 H, $Si^{\alpha}CH(CH_3)_2$], 1.29−1.32 [m, 12 H, $Si^{\beta}CH(CH_3)_2$], 1.50−1.77 (m, 6 H, $SiCHMe_2$), 0.7−2.0 (m, 10 H, $C^{2-5}H_2$ in C_6H_{11}), 2.7−2.9 (m, 1 H, C^1H in C_6H_{11}). ^{13}C NMR ($CDCl_3$): δ = 14.8 (d, $Si^{\beta}CHMe_2$), 17.0 (d, $Si^{\alpha}CHMe_2$), 19.2 [q, $Si^{\alpha}CH(CH_3)_2$], 19.8 [q, $Si^{\alpha}CH(CH_3)_2$], 23.3 [q, $Si^{\beta}CH(CH_3)_2$]; 25.9 (t, C^4 in C_6H_{11}), 26.7 (t, $C^{3,5}$ in C_6H_{11}), 37.8 (t, $C^{2,6}$ in C_6H_{11}), 57.6 (d, C^1 in C_6H_{11}). The 1,3-dichlorotrisilane (**3d-1**) mentioned above was prepared by chlorination of the corresponding trisilane HSiR$_2$SiR′$_2$SiR$_2$H (**3d-2**: R = *t*BuCH$_2$, R′ = *i*Pr; 0.52 g, 1.13 mmol) with phosphorus pentachloride (1.67 g, 7.97 mmol) in benzene (7 mL). Compound **3d-1**: viscous liquid; 0.55 g, 92% yield. MS: *m*/*z* (%) = 481 (4) [M − (*i*Pr)]$^+$, 453 (20) [M − (*t*BuCH$_2$)]$^+$, 319 (100) [M − (*t*BuCH$_2$)$_2$SiCl]$^+$. The trisilane **3d-2** was prepared by lithium-mediated (0.62 g, 89 mmol in 13 mL of THF) cross-coupling with chlorodineopentylsilane (5.71 g, 28 mmol) and dichlorodiisopropylsilane (2.38 g, 13 mmol) in THF (15 mL). Compound **3d-2** (recrystallized from ethanol): 2.37 g, 40% yield; m.p. 67−68 °C. ^{1}H NMR (CDCl$_3$): δ = 1.02 [s, 36 H, CH$_2$C(C*H*$_3$)$_3$], 0.78−1.50 [m, 22 H, C*H*(CH$_3$)$_2$, C*H*$_2$(*t*Bu)], 4.10−4.17 (m, 2 H, Si*H*). ^{13}C NMR (CDCl$_3$): δ = 14.7 (*C*HMe$_2$), 23.0 [CH(*C*H$_3$)$_2$], 31.8 [*C*H$_2$(*t*Bu)], 33.2 (CH$_2$*C*Me$_3$), 34.5 [CH$_2$C(*C*H$_3$)$_3$]. MS: *m*/*z* (%) = 456 (3) [M$^+$], 413 (6) [M − (*i*Pr)]$^+$, 385 (8) [M − (*t*BuCH$_2$)]$^+$, 285 (100) [M − (*t*BuCH$_2$)$_2$SiH]$^+$. $C_{26}H_{60}Si_3$: calcd. C 68.33, H 13.23; found C 68.39, H 13.39.

Synthesis of 1-Cyclohexyl-2,2,3,3,4,4,5,5-octaisopropyl-1-aza-2,3,4,5-tetrasilacyclopentane (4a): This compound was synthesized by a method similar to that used for **3a** [Scheme 2, (c)], by treatment of 1,4-dichloro-1,1,2,2,3,3,4,4-octaisopropylcyclotetrasilane[11] Cl(R$_2$Si)$_4$Cl (R = *i*Pr; 1.4 g, 2.6 mmol) with lithium cyclohexylamide, prepared from cyclohexylamine (0.9 mL, 7.9 mmol in 5 mL of THF) and butyllithium (6.5 mL, 10.2 mmol in hexane). Compound **4a** (recrystallized from 2-propanol): 0.51 g, 35% yield; m.p. 346−350 °C. ^{1}H NMR (δ, C$_6$D$_6$) 1.22−1.34 [m, 24 H, Si$^{\alpha}$CH(C*H*$_3$)$_2$], 1.36−1.48 [m, 24 H, Si$^{\beta}$CH(C*H*$_3$)$_2$], 1.60−1.76 (m, 8 H, SiC*H*Me$_2$), 1.2−2.0 (m, 10 H, C$^{2-6}$*H*$_2$ in C$_6$H$_{11}$), 3.0−3.2 (m, 1 H, C^1*H* in C$_6$H$_{11}$). ^{13}C NMR (C$_6$D$_6$) δ = 15.2 (Si$^{\beta}$*C*HMe$_2$), 17.8 (Si$^{\alpha}$*C*HMe$_2$), 20.4 and 20.6 [Si$^{\alpha}$CH(*C*H$_3$)$_2$], 24.1 and 24.4 [Si$^{\beta}$CH(*C*H$_3$)$_2$]; 26.3 (C^4 in C$_6$H$_{11}$), 27.9 (C^{3,5} in C$_6$H$_{11}$), 38.9 (C^{2,6} in C$_6$H$_{11}$), 59.0 (C^1 in C$_6$H$_{11}$). MS: *m*/*z* (%) = 559 (7) [M$^+$], 510 (100) [M − (*i*Pr)]$^+$, 468 (20) [M − (*i*Pr) − C$_3$H$_6$]$^+$, 446 (20) [M − (*i*Pr) − (C$_3$H$_6$)$_2$]$^+$. $C_{30}H_{67}NSi_4$: calcd. C 65.01, H 12.19; found C 64.50, H 11.98.

Synthesis of 1-Cyclohexyl-2,2,3,3,4,4,5,5-octaneopentyl-1-aza-2,3,4,5-tetrasilacyclopentane (4b): This compound was synthesized by a method similar to that used for **3a**, by treatment of 1,4-dichloro-1,1,2,2,3,3,4,4-octaneopentyltetrasilane[11] Cl(R$_2$Si)$_4$Cl (R = *t*BuCH$_2$; 0.58 g, 0.77 mmol) with lithium cyclohexylamide, prepared from cyclohexylamine (1.4 mL, 12.3 mmol in 3 mL of THF) and butyllithium (10.1 mL, 16.0 mmol in pentane). Compound **4b** (recrystallized from 2-propanol): 0.23 g, 38% yield; m.p. 379−383 °C. ^{1}H NMR (CDCl$_3$): δ = 1.12 (s), and 1.13 (s) [72 H, SiCH$_2$C(C*H*$_3$)$_3$], 0.7−1.0 (m), 1.15−1.30 (m), and 1.30−2.2 (m) [26 H, C$^{2-6}$*H*$_2$ in C$_6$H$_{11}$, SiC*H*$_2$(*t*Bu)$_3$], 3.0−3.2 (m, 1 H, C^1*H* in C$_6$H$_{11}$). ^{13}C NMR (CDCl$_3$) (tentative) δ = 30.3 [t, Si$^{\beta}$*C*H$_2$(*t*Bu)], 31.7 (s, Si$^{\beta}$CH$_2$*C*Me$_3$), 32.1 (s, Si$^{\alpha}$CH$_2$*C*Me$_3$), 34.4 [q, Si$^{\beta}$CH$_2$C(*C*H$_3$)$_3$], 34.5 [q, Si$^{\alpha}$CH$_2$C(*C*H$_3$)$_3$], 36.9 [t, Si$^{\alpha}$*C*H$_2$(*t*Bu)], 26.0 (t, C^4 in C$_6$H$_{11}$), 27.1 (t, C^{3,5} in C$_6$H$_{11}$), 37.8 (t, C^{2,6} in C$_6$H$_{11}$), 59.5 (d, C^1 in C$_6$H$_{11}$). MS: *m*/*z* (%) = 777 (3) [M$^+$], 706 (100) [M − (*t*BuCH$_2$)]$^+$, 536 (30) [M − (*t*BuCH$_2$)$_3$Si]$^+$. $C_{46}H_{99}NSi_4$: calcd. C 70.78, H 12.82; found C 70.96, H 12.82.

Synthesis of 1-Cyclohexyl-3,3,4,4-tetraisopropyl-2,2,5,5-tetraneopentyl-1-aza-2,3,4,5-tetrasilacyclopentane (4c): This compound was synthesized by a method similar to that used for **3a**, by treatment of 1,4-dichloro-2,2,3,3-tetraisopropyl-1,1,4,4-tetraneopentyltetrasilane ClSiR$_2$(SiR′$_2$)$_2$SiR$_2$Cl (**4c-1**: R = *t*BuCH$_2$, R′ = *i*Pr; 0.59 g, 0.90 mmol) with lithium cyclohexylamide, prepared from cyclohexylamine (3.46 mL, 28.7 mmol in 8 mL of THF) and butyllithium (17.1 mL, 27.9 mmol in pentane). Compound **4c** (recrystallized from 2-propanol): 0.28 g, 47% yield; m.p. 364−366 °C. ^{1}H NMR (C$_6$D$_6$) δ = 1.09 [s, 36 H, CH$_2$C(C*H*$_3$)$_3$], 0.78−2.10 [m, 51 H, C*H*(CH$_3$)$_2$, C*H*$_2$(*t*Bu), C$^{2-6}$*H*$_2$ in C$_6$H$_{11}$], 3.10−3.25 (m, 1 H, C^1*H* in C$_6$H$_{11}$). ^{13}C NMR (CDCl$_3$): δ = 14.5 (Si*C*HMe$_2$), 23.3 and 23.8 [SiCH(*C*H$_3$)$_2$], 31.7 (CH$_2$*C*Me$_3$), 34.1 [CH$_2$C(*C*H$_3$)$_3$], 36.7 [*C*H$_2$(*t*Bu)], 26.0 (C^4 in C$_6$H$_{11}$), 27.0 (C^{3,5} in C$_6$H$_{11}$), 37.6 (C^{2,6} in C$_6$H$_{11}$), 60.0 (C^1 in C$_6$H$_{11}$). MS: *m*/*z* (%) = 665 (3) [M$^+$], 622 (10) [M − (*i*Pr)]$^+$, 594 (100) [M − (*t*BuCH$_2$)]$^+$. $C_{38}H_{83}NSi_4$: calcd. C 68.49, H 12.55; found C 68.49, H 12.46. The 1,4-dichlorotrisilane (**4c-1**) mentioned above was prepared by chlorination of the corresponding tetrasilane HSiR$_2$(SiR′$_2$)$_2$SiR$_2$H (**4c-2**: R = *t*BuCH$_2$, R′ = *i*Pr; 1.00 g, 1.75 mmol) with phosphorus pentachloride (1.30, 6.19 mmol) in benzene (15 mL). Compound **4c-1** (recrystallized from hexane): 0.53 g, 47% yield; m.p. 65−66 °C. MS: *m*/*z* (%) 569 (10) [M − (*t*BuCH$_2$)]$^+$, 433 (100) [M − (*t*BuCH$_2$)$_2$SiCl]$^+$. The tetrasilane **4c-2** was prepared by lithium-mediated (1.51 g,

270 mmol in 80 mL of THF) cross-coupling with 1,2-dichlorotetraisopropyldisilane (7.36 g, 24.6 mmol) and chlorodineopentylsilane (14.24 g, 68.3 mmol) in THF (20 mL). Compound **4c-2** (recrystallized from pentane/ethanol): 10.6 g, 69% yield; m.p. 94−95 °C. ^{1}H NMR ($CDCl_3$): δ = 1.04 [s, 36 H, $CH_2C(CH_3)_3$], 0.82−1.50 [m, 36 H, $CH(CH_3)_2$, $CH_2(t$Bu)], 4.20−4.28 (m, 2 H, Si*H*). ^{13}C NMR ($CDCl_3$): δ = 13.9 (*C*HMe_2), 22.2 [$CH(CH_3)_2$], 29.8 (CH_2CMe_3), 31.5 [$CH_2(t$Bu)], 32.7 [$CH_2C(CH_3)_3$]. MS: *m*/*z* (%) = 570 (1) [M^+], 527 (10) [M − (*i*Pr)]$^+$, 499 (20) [M − (tBuCH_2)]$^+$, 399 (100) [M − (tBuCH_2)$_2$SiH]$^+$. $C_{32}H_{74}Si_4$: calcd. C 67.28, H 13.06; found C 67.06, H 13.07.

Synthesis of 1-Propyl-2,2,3,3,4,4,5,5-octaneopentyl-1-aza-2,3,4,5-tetrasilacyclopentane (4d): This compound was synthesized by a method similar to that used for **3a**, by treatment of 1,4-dichlorooctaneopentyltetrasilane[11] $Cl(R_2Si)_4Cl$ (R = tBuCH_2; 0.52 g, 0.69 mmol) with lithium propylamide, prepared from propylamine (0.44 g, 5.34 mmol in 3 mL of THF) and butyllithium (4.0 mL, 7.01 mmol in pentane). Compound **4d** (recrystallized from 2-propanol): 0.18 g, 35% yield; m.p. 396−399 °C. ^{1}H NMR ($CDCl_3$): δ = 0.83 (t, 3 H, $NCH_2CH_2CH_3$), 1.07 [s, 36 H, $Si^{\alpha}CH_2C(CH_3)_3$], 1.12 [s, 36 H, $Si^{\beta}CH_2C(CH_3)_3$], 1.17 (s), 1.24 (s), 1.31 (s), 1.38 (s), 1.43 (s), and 1.46−1.75 (m) [18 H, $NCH_2CH_2CH_3$, $Si^{\alpha}CH_2(t$Bu), $Si^{\beta}CH_2(t$Bu)], 2.90−3.10 (m, 2 H, $NCH_2CH_2CH_3$). ^{13}C NMR ($CDCl_3$): δ = 30.0 [$Si^{\beta}CH_2(t$Bu)], 31.6 ($Si^{\alpha}CH_2CMe_3$), 32.0 ($Si^{\beta}CH_2CMe_3$), 34.2 [$Si^{\beta}CH_2C(CH_3)_3$], 34.4 [$Si^{\alpha}CH_2C(CH_3)_3$], 36.5 [$Si^{\alpha}CH_2(t$Bu)], 11.7 (C^3 in C_3H_7), 27.8 (C^2 in C_3H_7), 51.6 (C^1 in C_3H_7). MS: *m*/*z* (%) = 737 (3) [M^+], 666 (100) [M − (tBuCH_2)]$^+$, 497 (15) [M − (tBuCH_2)$_4$Si$_2$]$^+$. $C_{43}H_{95}NSi_4$: calcd. C 69.93, H 12.96; found C 69.57, H 12.80.

Synthesis of *O*-Substituted Compounds 5 and 6: Compounds **5** and **6** were synthesized by treatment of the corresponding α-ω-dichlorosilanes with H_2O or NaOH as shown in Scheme 2, (d).

Synthesis of 2,2,3,3,4,4-Hexaisopropyl-1-oxa-2,3,4-trisilacyclobutane (5a): Typically, H_2O (1 mL, 56 mmol) was added at 53 °C with stirring to a solution of 1,3-dichlorohexaisopropyltrisilane[5a] (3.50 g, 8.5 mmol) in degassed triethylamine (20 mL). After the mixture had been stirred for 1 h at this temperature, degassed cyclohexane was added, and the mixture was extracted and dried with calcium chloride. After filtration, the filtrate was concentrated to give a solid product, which was recrystallized from methanol to afford colorless crystals of **5a** (see also ref.[8]) (0.85 g, 28%); m.p. 100−103 °C. ^{1}H NMR (C_6D_6) δ = 1.0−1.6 [m, 42 H, $SiCH(CH_3)_2$, $SiCH(CH_3)_2$]. ^{13}C NMR (C_6D_6) δ = 13.7 (d, $Si^{\beta}CHMe_2$), 16.6 (d, $Si^{\alpha}CHMe_2$), 17.9 [q, $Si^{\alpha}CH(CH_3)_2$], 22.7 [q, $Si^{\beta}CH(CH_3)_2$]. MS: *m*/*z* (%) = 358 (40) [M^+], 315 (100) [M − (*i*Pr)]$^+$, 273 (35) [M − (*i*Pr) − C_3H_6]$^+$. $C_{18}H_{42}OSi_3$: calcd. C 60.26, H 11.80; found C 59.58, H 11.72.

Synthesis of 2,2,3,3,4,4-Hexaneopentyl-1-oxa-2,3,4-trisilacyclobutane (5b): 1,3-Dichlorohexaneopentyltrisilane[10] $Cl(R_2Si)_3Cl$ (R = tBuCH_2; 0.59 g, 1.0 mmol in 10 mL of THF) was added to a mixture of NaOH (0.16 g, 4.0 mmol), THF (5 mL), and EtOH (5 mL). The mixture was stirred for 20 min at room temperature. After addition of hexane and filtration, the filtrate was concentrated and cyclohexane was then added. The solution was washed with dilute hydrochloric acid solution and water, dried, and then concentrated to give a crude product. Compound **5b** (recrystallized from ethanol/pentane) (see also ref.[8]): 0.41 g, 77% yield; m.p. 151−153 °C. ^{1}H NMR (C_6D_6) δ = 0.97 [s, 18 H, $Si^{\beta}CH_2C(CH_3)_3$], 1.03 [s, 36 H, $Si^{\alpha}CH_2C(CH_3)_3$], 1.22 [s, 4 H, $Si^{\beta}CH_2(t$Bu)], 1.28 [s, 8 H, $Si^{\alpha}CH_2(t$Bu)]. ^{13}C NMR ($CDCl_3$): δ = 29.0 [t, $Si^{\beta}CH_2(t$Bu)], 31.5 (s, $Si^{\alpha}CH_2CMe_3$), 31.8 (s, $Si^{\beta}CH_2CMe_3$), 33.7 [q, $Si^{\alpha}CH_2C(CH_3)_3$], 34.0 [q, $Si^{\beta}CH_2C(CH_3)_3$], 36.5 [t, $Si^{\alpha}CH_2(t$Bu)]. MS: *m*/*z* (%) = 526 (30) [M^+], 511 (25) [M − Me]$^+$, 455 (90) [M − (tBuCH_2)]$^+$, 399 (80) [M − (tBuCH_2) − C_4H_8]$^+$. $C_{30}H_{66}OSi_3$: calcd. C 68.36, H 12.62; found C 68.24, H 12.63.

Synthesis of 2,4-Diisopropyl-2,3,3,4-tetraneopentyl-1-oxa-2,3,4-trisilacyclobutane (5c): This compound was synthesized by a method similar to that used for **5a**, by hydrolysis of 1,3-dichloro-1,3-diisopropyltetraneopentyltrisilane ClSiRR′SiR_2SiRR′Cl (**5c-1**: R = tBuCH_2, R′ = *i*Pr; 0.50 g, 0.95 mmol) with H_2O (1 mL) in triethylamine (15 mL), followed by workup of the resulting mixture. Compound **5c**: 0.39 g (purity: 92%) 87% yield, liquid; analytical samples were isolated by GLC purification. ^{1}H NMR (C_6D_6) δ = 1.05−1.30 (m) (composed of four peaks at 1.16, 1.19, 1.22, 1.25) [48 H, $SiCH(CH_3)_2$, $SiCH_2C(CH_3)_3$], 1.48 (broad s, 2 H, $SiCHMe_2$), 1.60 [broad s, 8 H, $SiCH_2(t$Bu)]. $C_{26}H_{58}OSi_3$: calcd. C 66.30, H 12.41; found C 66.10, H 12.42. The 1,3-dichlorotrisilane (**5c-1**) mentioned above was prepared by chlorination of the corresponding trisilane HSiRR′SiR_2SiRR′H (**5c-2**: R = tBuCH_2, R′ = *i*Pr; 6.5 g, 14 mmol/CCl_4 30 mL) by chlorine gas bubbling. Compound **5c-1**: b.p. 185−195 °C/3 Torr; 3.8 g, 52% yield. ^{1}H NMR (C_6D_6) δ = 1.16 (s), and 1.18 (s) [48 H, $CH(CH_3)_2$, $CH_2C(CH_3)_3$], 1.35 [m, 4 H, $Si^{1,3}CH_2(t$Bu)], 1.50 [broad s, 4 H, $Si^2CH_2(t$Bu)], 1.73 (m, 2 H, $CHMe_2$). $C_{26}H_{58}Cl_2Si_3$: calcd. C 59.38, H 11.12; found C 59.41, H 11.15. The trisilane **5c-2** was prepared by lithium-mediated (fine cut, 0.4 g, 58 mmol in 40 mL of THF) cross-coupling with dichlorodineopentylsilane (2.4 g, 10.0 mmol) and chloro(isopropyl)-(neopentyl)silane (4.2 g, 23.6 mmol) in THF (15 mL). Compound **5c-2**: b.p. 124−127 °C/5 Torr; 1.8 g, 39% yield. ^{1}H NMR ($CDCl_3$):

C 60.29, H 11.90; found C 60.94, H 11.93.

Synthesis of 2,2,3,3,4,4,5,5-Octaneopentyl-1-oxa-2,3,4,5-tetrasilacyclopentane (6b): This compound was synthesized by a method similar to that used for **5a**, by treatment of 1,4-dichlorooctaneopentyltetrasilane[11] Cl(R_2Si)$_4$Cl (R = *t*BuCH_2; 0.58 g, 0.77 mmol) with NaOH (ca. 1 mL of 1 M aq. solution) in THF (15 mL) at 50−60 °C for 20 h. Compound **6b** (recrystallized from hexane/ethanol): 0.5 g, 93% yield; m.p. 377−380 °C. ^{1}H NMR ($CDCl_3$): δ = 1.08 [s, 36 H, Si$^{\beta}$CH$_2$C(CH_3)$_3$], 1.10 [s, 36 H, Si$^{\alpha}$CH$_2$C(CH_3)$_3$], 1.16 [s, 8 H, Si$^{\beta}$CH_2(*t*Bu)], 1.29 [s, 8 H, Si$^{\alpha}$CH_2(*t*Bu)]. ^{13}C NMR ($CDCl_3$): δ = 29.6 [t, Si$^{\beta}$*C*H$_2$(*t*Bu)], 31.8 (s, Si$^{\alpha}$CH$_2$*C*Me$_3$), 32.0 (s, Si$^{\beta}$CH$_2$*C*Me$_3$), 34.0 [q, Si$^{\alpha}$CH$_2$C(*C*H_3)$_3$], 34.3 [q, Si$^{\beta}$CH$_2$C(*C*H_3)$_3$], 36.0 [t, Si$^{\alpha}$*C*H$_2$(*t*Bu)]. MS: *m*/*z* (%) = 696 (100) [M$^+$], 625 (65) [M − (*t*BuCH_2)]$^+$, 525 (50) [M − (*t*BuCH_2)$_3$Si]$^+$, 340 (70) [(*t*BuCH_2)$_4$Si$_2$]$^+$. $C_{40}H_{88}OSi_4$: calcd. C 68.88, H 12.72; found C 68.58, H 12.81.

Synthesis of Decaisopropylpentasilane E: This compound was synthesized (not optimized) by treatment of 1,4-dilithiooctaisopropyltetrasilane (in place of 1,4-dipotassiooctairopropyltetrasilane[14] with dichlorodiisopropylsilane [Scheme 2, (e)]. Freshly distilled anhydrous HMPA (1.1 mL) was added to a mixture of octaisopropylcyclotetrasilane **A** (168 mg, 0.368 mmol) and lithium (51 mg, 0.735 mmol). The mixture was stirred at room temperature for 2 h to afford a dark red-brown solution containing 1,4-dilithiooctaisopropyltetrasilane, to which benzene (5 mL) was then added. This solution, containing the 1,4-dilithiotetrasilane, was added dropwise by hypodermic syringe to a separate flask containing dichlorodiisopropylsilane (70 μL, 0.401 mmol) in benzene (2.5 mL) in an ice/water bath. After stirring at 0 °C for 30 min, the reaction mixture was mixed well with hexane (60 mL) and water (80 mL). After separation of the organic layer, it was washed well with water, dried with calcium chloride, and then filtered. The solution obtained was concentrated to give a solid product mixture, from which the reaction product, decaisopropylcyclopentasilane **E**, was isolated by repeated fractional recrystallization from a mixture of pentane/ethanol to afford 40 mg, 19% yield, m.p. 357−366 °C. It was found

Oxidation Potentials: Measurements of the oxidation potentials[7h,41] for **1**−**6** (10^{-3} M) by cyclic voltammetry were performed under N_2 (purified) in an anhydrous solvent (MeCN or CH_2Cl_2) containing Bu_4NClO_4 (TBAP, 0.1 M) as supporting electrolyte with a specially devised cell equipped with a working electrode (Pt inlay type, Beckmann 32273), counterelectrode (Pt wire), and saturated calomel electrode as a reference, connected to the cell through two salt bridges (saturated KCl solution), and the acetonitrile or dichloromethane solution of the sample. All runs were made at room temperature after a 15 min purge with N_2 and within 30 min of preparing the solution, experimental error ±0.02 V. All the results are summarized in Tables 18 and 19, together with those for the related compounds **A**−**D**, **F**−**I**.

Methods of Theoretical Calculations for Geometries, Frontier Molecular Orbitals, and Ring Strain Energies: Geometries of all molecules considered here were fully optimized at the PM3 level with the Gaussian 98 program.[42] They were then characterized as minima or transition states by calculation and diagonalization of the Hessian matrix of energy second derivatives at the same level of theory. The orbital pictures were drawn with the Gamess program.[43] The optimized structures for all four-membered rings are found to have C_s symmetry with a σ plane involving one silicon atom and heteroatom, except for X = N(*i*Pr) which is in a C_1 conformation. On the other hand, none of the five-membered rings have a symmetry higher than C_1. The ring strain energies for the four- and five-membered ring compounds (R = *i*Pr) were estimated on the basis of the homodesmotic reaction energies[28] [Equations (1) and (2)].

$$Si^1R_2{-}X{-}SiR_2Si^3R_2(Si^1\text{-}Si^3) + 2\,SiHR_2{-}SiHR_2 + 2\,SiHR_2{-}XH \rightarrow SiHR_2{-}X{-}SiHR_2 + SiHR_2{-}SiR_2{-}SiHR_2 + 2\,SiHR_2{-}SiR_2{-}XH \quad (1)$$

$$Si^1R_2{-}X{-}SiR_2SiR_2{-}Si^4R_2(Si^1\text{-}Si^4) + 3\,SiHR_2{-}SiHR_2 + 2\,SiHR_2{-}XH \rightarrow SiHR_2{-}X{-}SiHR_2 + 2\,SiHR_2{-}SiR_2{-}SiHR_2 + 2\,SiHR_2{-}SiR_2{-}XH \quad (2)$$

X-ray Crystal Analysis of 1−6: Crystals obtained from alcohols such as methanol, ethanol, and 2-propanol were used for X-ray analysis. Intensity data were obtained with an Enraf−Nonius CAD-4 diffractometer equipped with graphite-monochromated Cu-K_α (λ = 1.5418 Å) or Mo-K_α (λ = 0.7107 Å) radiation and by the ω-2θ scan technique. Structures of **1**−**6** were solved by direct methods with the MULTAN 78 program[39] and refined by full-matrix least squares. All the calculations were performed with the UNICS III system.[40] The molecular structures of **1b**, **2a**, **3a**−**d**,

4a−**c**, **5b**, **6a**, and **6b** are given in the electronic supporting information. Selected bond lengths and bond and torsion angles are given in Tables 1−12, respectively. The crystallographic data for twelve four- and five-membered compounds are summarized in Tables 21−24. CCDC-169794 (**1b**), -169795 (**2a**), -169796 (**3a**), -169797 (**3b**), -169798 (**3c**), -169799 (**3d**), -169800 (**4a**), -169801 (**4b**), -169802 (**4c**), -169803 (**5b**), -169804 (**6a**), and -169805 (**6b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information: Supporting information for this article (Figures 6−17 with ORTEP drawings of molecular structures for **1**−**6**, and Figures 18−21 with UV spectral curves for **1**−**6**) is available (see also footnote on the first page of this article).

Acknowledgments

The authors are grateful to Toshiba Silicone Co., Ltd., and Shin-Etsu Chemical Co., Ltd., for a generous gift of chlorosilanes. The authors express their deep gratitude to the late Professor Yoichiro Nagai for helpful discussions at the early stage of this work, and also express thanks to Professors Hiroshi Hiratsuka and Shigefumi Tobita for helpful suggestions from the photochemical viewpoint. This work was partially supported (for H. W.) by Sansen Co., Ltd., Colcoat Co., Ltd., and the Gunma University Foundation for Promotion of Science and Technology.

Phase Diagram and Impedance Spectroscopy Study of the $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ System

M.-L. Martínez-Sarrión,*[a] L. Mestres,[a] M. Herráiz,[a] O. Maqueda,[a] A. Bakkali,[a] and N. Fernández[b]

Keywords: Phase diagrams / Perovskite phases / Conducting materials / Lanthanides

The phase diagram of the system $Li_2O/La_2O_3/TiO_2/Bi_2O_3$ has been studied. Using powder X-ray diffraction, five distinct areas have been found in the triangle $Bi_{0.5}Li_{0.5}TiO_3/La_{2/3}TiO_3/La_{0.5}Li_{0.5}TiO_3$. A region of perovskite-like solid solutions was obtained when the bismuth content in the general formula $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ was less than y = 0.10. Two two-phase regions, one of them consisting of a perovskite-like phase and $La_2Ti_2O_7$, and the other a perovskite-like phase and Li_2TiO_3, were obtained. One four-phase region, consisting of a perovskite-like phase, Li_2TiO_3, $Bi_4Ti_3O_{12}$ and $La_4Ti_3O_{12}$, was also obtained. The fifth area corresponds to the melting of the initial mixtures. The microstructures of these phases were studied by SEM/EDS. The compounds of general formula $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ are ionic conductors. Their ionic conductivity increases when the amount of lithium rises up to x = 0.075, and decreases when the amount of bismuth increases.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

With the development of advanced materials in which the fine-tuning of composition is often required in order to optimize properties, phase diagrams take on the increasingly important role of representing phase stoichiometries. The phase diagram contains qualitative structural information as well as quantitative compositional information, and together they provide a powerful basis for understanding and optimising relationships between stoichiometry, structure and properties.

Research into solid ionic conductors and lithium cathodes is important for the development of solid-state lithium batteries. Some time ago, fast ion conductors with the general formula $RE_{0.5+x}Li_{0.5-3x}TiO_3$, where RE = La, Pr, Nd, and Sm, were reported.[1−3] The maximum bulk conductivity was found in the lanthanum system, with a value of 1.1×10^{-3} S·cm^{-1} for $x = 0.07$, although the total conductivity (bulk and grain boundary conductivity), was less than 10^{-6} S·cm^{-1}. More recently, the phase diagram, crystal chemistry and ion conductivity of the systems $RE_{0.5+x}Li_{0.5-3x}TiO_3$, (RE = La, Pr, Nd),[4−7] which show a similar total conductivity, have been reported.

In recent years, the phase diagrams, crystal chemistry and conductivity study of $Pr_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$,[8] $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Mn_{3y}O_3$,[9] and $La_{0.5+x+y}Li_{0.5-3x}Ti_{1-3y}Cr_{3y}O_3$,[10] have been reported.

Systems containing Bi_2O_3 are now becoming increasingly important in the technology of new materials used by the electronics industry. Levin and Roth[11] studied 33 systems with bismuth oxide as one of the components. The content of the other components was never higher than 10−15 mol %. The binary systems Bi_2O_3/Li_2O, Bi_2O_3/TiO_2, and Bi_2O_3/La_2O_3 were described.

Bi_2O_3 has two stable crystalline forms: a low-temperature monoclinic form and a high-temperature cubic form, and the conversion of one form into the other takes place at 730 °C. Many systems typically form solid solutions based on bismuth oxide.

Doped $Bi_4V_2O_{11}$ materials are currently under intensive study in several laboratories because of their attractive electrical properties. They are, however, complex materials both structurally and compositionally as the $Bi_4V_2O_{11}$ phase has a variable Bi:V ratio.[12−14]

The aim of the present work was to investigate the synthesis and the stoichiometry range of the new compounds of general formula $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ and to establish the phase diagram at room temperature of the system $La_{2/3}TiO_3$-$Bi_{0.5}Li_{0.5}TiO_3$-$La_{0.5}Li_{0.5}O_3$. The substitution of lanthanum by bismuth in $La_{0.5+x}Li_{0.5-3x}TiO_3$ may affect the ionic conductivity of these compounds, therefore changes in the electric behaviour of the

$La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ system are expected, even though bismuth is only a minority element.

Results and Discussion

Phase Diagram

The triangle $Bi_{0.5}Li_{0.5}TiO_3$-$La_{2/3}TiO_3$-$La_{0.5}Li_{0.5}TiO_3$ in the Li_2O-La_2O_3-TiO_2-Bi_2O_3 system was chosen for detailed study since the $La_{2/3}TiO_3$-$La_{0.5}Li_{0.5}TiO_3$ join has been reported previously.[3,15] This triangle was studied by synthesizing compounds of general formula $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ by heating, as described in the Exp. Sect. More than 50 different compositions were prepared. The results of X-ray powder diffraction and the results of ICP analysis (Table 1), were used to construct the composition diagram (Figure 1).

Five distinct areas were found on this triangle. A region, (A), resulting from the melting of the initial mixture, a region, (D), of perovskite-like solid solutions (Figure 2a), and three mixed-phase regions (B, C, E). Region C is a mixture of the perovskite-like phase and peaks belonging to $La_2Ti_2O_7$ (identified from PDF 28-517; Figure 2b). Region E is a mixture of the perovskite-like phase and peaks which belong to Li_2TiO_3 (identified from PDF 33-0831; Figure 2c). Region B is a mixture of the perovskite-like phase and peaks identified as Li_2TiO_3 (from PDF 33-0831), $Bi_4Ti_3O_{12}$ (PDF 73-2181) and $La_4Ti_3O_{12}$ (PDF 33-727; Figure 2d) (PDF compiled by JCPDS).

Table 2 shows the X-ray powder diffraction data for $La_{0.51}Bi_{0.047}Li_{0.25}TiO_3$ (region D). This compound has an orthorhombic perovskite-type structure. Table 3 shows the X-ray diffraction data for $La_{0.56}Bi_{0.047}Li_{0.08}TiO_3$ (region C), containing reflections corresponding to an orthorhombic perovskite-type structure, reflections corresponding to $La_2Ti_2O_7$ and some peaks associated with a superstructure.

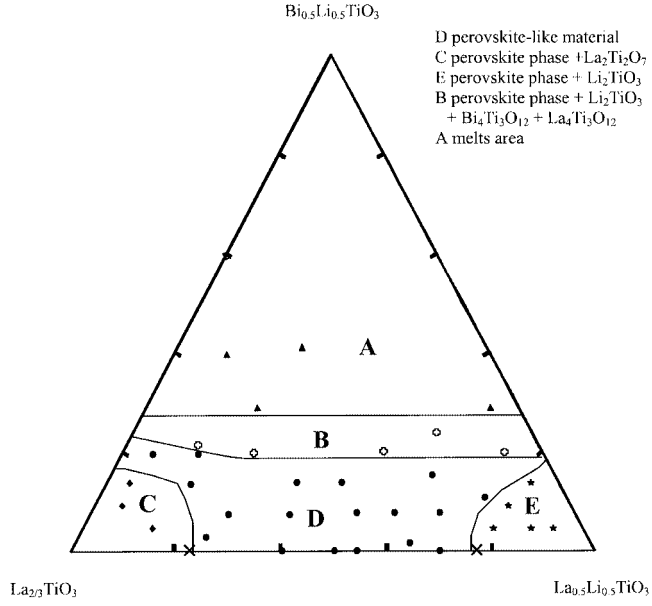

Figure 1. Composition triangle of the system $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$ at 1250 °C; the samples marked with × are taken from the literature[4]

This superstructure depends on the lithium content and is related to the lanthanum and vacant A-sites that alternates along the *c*-axis. This ordering becomes progressively disordered when the lithium content increases.[16]

Table 4 shows the X-ray powder diffraction data for $La_{0.48}Bi_{0.023}Li_{0.43}TiO_3$ (region E). We observed reflections corresponding to a cubic perovskite-type structure and reflections corresponding to Li_2TiO_3. Finally, Table 5 shows X-ray powder diffraction data for $La_{0.40}Bi_{0.112}Li_{0.47}TiO_3$ (region B). In this region reflections corresponding to a cubic perovskite-type structure, Li_2TiO_3, $Bi_4Ti_3O_{12}$, and $La_4Ti_3O_{12}$ appear.

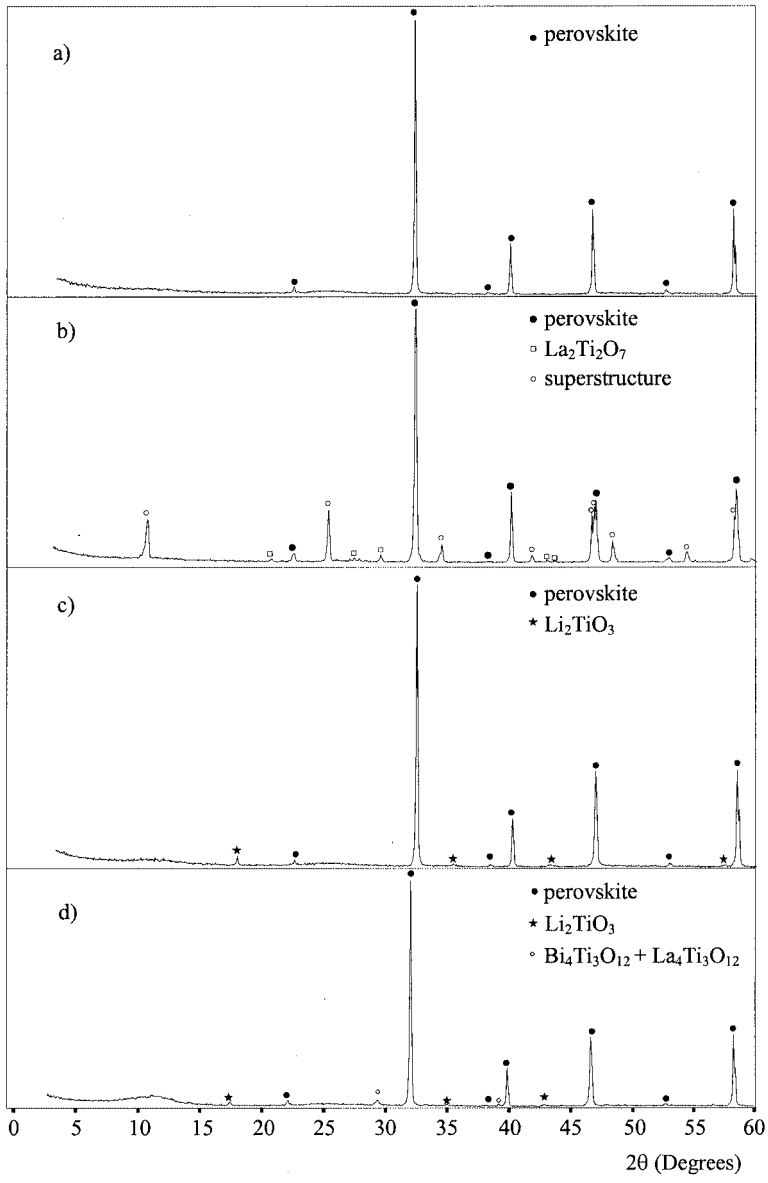

Figure 2. XRD patterns of the five regions on the composition triangle

Table 2. Indexed powder pattern of the single phase $La_{0.51}Bi_{0.047}Li_{0.25}TiO_3$; orthorhombic system: a = 5.487(2) Å, b = 5.472(1) Å, c = 7.739(2) Å, V = 232.38(5) Å^3, Z = 4

hkl	d_{obs}/Å	d_{calc}/Å	I/I_0
002	3.862	3.869	3
200	2.740	2.744	100
112	2.736	2.738	26
103	2.326	2.333	1
202	2.239	2.238	19
022	2.237	2.234	8
004	1.930	1.935	64
222	1.728	1.732	1
114	1.727	1.731	1
204	1.578	1.583	23
132	1.577	1.581	33

Some melting occurs in the compositions in area A. These compositions have a greater content of bismuth (as Bi_2O_3), and as bismuth oxide melts at about 830 °C the formation of the perovskite-like phase is prevented. Some systems containing Bi_2O_3 reported in the literature, such as Bi_2O_3-Li_2O, Bi_2O_3-TiO_2, and Bi_2O_3-La_2O_3, show the *liquidus* area at about 900 °C.[11]

Perovskite-like phases mixed with titanium compounds are obtained in the areas C and E. In the area close to the vertex $La_{2/3}TiO_3$ (area C), $La_2Ti_2O_7$ is segregated along with the perovskite-like phase. On progressing towards the join $La_{2/3}TiO_3$/$La_{0.5}Li_{0.5}TiO_3$ the lithium content increases and Li_2TiO_3 is segregated along with the perovskite-like phase near the $La_{0.5}Li_{0.5}TiO_3$ vertex (area E).

In area B, on increasing the lithium content, the number of species mixed with the perovskite-like phase increases, as

do their relative amounts. For instance, the maxima of Li_2TiO_3 are not observed and the reflections of the $Bi_4Ti_3O_{12}$ and $La_4Ti_3O_{12}$ components are very weak in the sample of starting composition $La_{0.45}Bi_{0.10}Li_{0.35}TiO_3$. On increasing the lithium content, for example for starting composition $La_{0.41}Bi_{0.10}Li_{0.48}TiO_3$, the perovskite-like phase is mixed with Li_2TiO_3, $Bi_4Ti_3O_{12}$ and $La_4Ti_3O_{12}$, with an increase in the relative intensities.

The cell volume was obtained for two joins on the composition triangle. Along join 1, $La_{0.46+x}Bi_{0.04}Li_{0.5-3x}TiO_3$, the amount of bismuth remained constant, while along join 2, $La_{0.57-y}Bi_yLi_{0.29}TiO_3$, the amount of lithium was constant. The cell volume was measured against the amount of lanthanum along these two joins (Figure 3). For the same

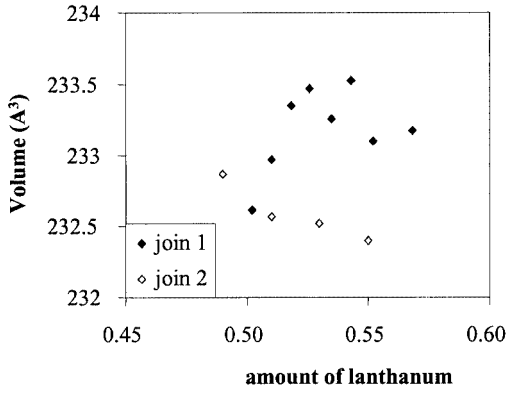

Figure 3. Cell volume vs. La content along the two joins on samples quenched from 1250 °C

amount of bismuth, the cell volume decreases as the lanthanum content decreases, due to the substitution of lanthanum by a smaller cation such as lithium in the 12-coordinate sites. Along join 2, the substitution of lanthanum by bismuth leads to a small increase in the cell volume because of the different ionic radii.

The composition with the highest conductivity in the join $La_{2/3}TiO_3$-$La_{0.5}Li_{0.5}TiO_3$ is $La_{0.57}Li_{0.29}TiO_3$.[1−3] The new conductors should occur in the join $La_{0.57}Li_{0.29}TiO_3$-$Bi_{0.5}Li_{0.5}TiO_3$. The compositions of the new phases containing bismuth should have lanthanum and lithium contents close to $La_{0.57}Li_{0.29}TiO_3$, with low bismuth contents. This is indeed the case, since the only one-phase compositions with the perovskite structure are those with bismuth contents less than 0.10 in the general formula $La_{0.5+x-y}Bi_yLi_{0.5-3x}TiO_3$.

Scanning Electron Microscopy (SEM, EDS)

A selection of ceramic samples from both within and outside the perovskite single-phase region was analysed by

SEM/EDS. Elemental analyses were carried out with a fixed beam of 10 kV and 20 nA over different points of the sample surface.

Scanning electron micrographs were obtained for samples from each of the four regions observed in the composition triangle, and in all the phases we checked the presence of the different elements by SEM and EDS.

Figure 4a shows the back-scattered electron image (BEI) of the sample $La_{0.51}Bi_{0.047}Li_{0.25}TiO_3$. In this case, homogeneous crystals were observed, which agrees with the XRD pattern shown in Figure 2a. The EDS spectrum of this zone (Figure 5a) shows the presence of lanthanum, bismuth and titanium in a perovskite-like phase for this composition obtained when different crystals of the sample are analysed. Figure 4b shows the BEI of the sample $La_{0.56}Bi_{0.047}Li_{0.08}TiO_3$. In this case we observed similar crystals to Figure 4a (area 1 in the picture) and new gray crystals (area 2 in the picture).

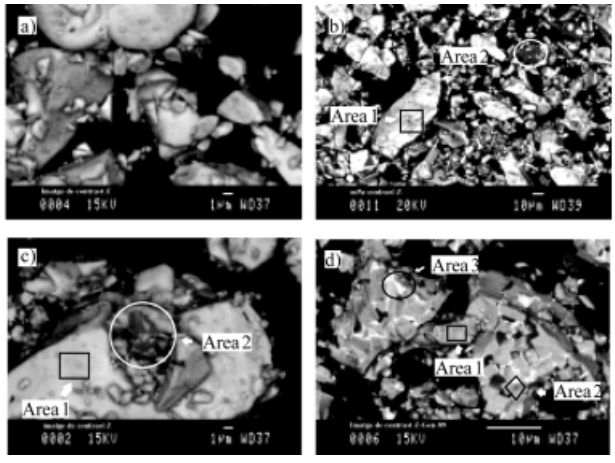

Figure 4. Scanning electron micrographs of: a) perovskite-like single-phase solid solution region; b) perovskite-like phase + $La_2Ti_2O_7$; c) perovskite-like phase + Li_2TiO_3 region; d) perovskite-like phase + Li_2TiO_3, + $Bi_4Ti_3O_{12}$ + $La_4Ti_3O_{12}$ region

The EDS spectrum of area 1 (grey line in Figure 5b) is similar to the spectrum of the previous sample. However, the EDS spectrum of area 2 does not show the peaks of bismuth (black line in Figure 5b). This confirms the results of XRD, which shows the presence of $La_2Ti_2O_7$ (Figure 2b). Figure 4c shows the BEI of the sample $La_{0.48}Bi_{0.023}Li_{0.43}TiO_3$ where two different phases co-exist. The light crystals (area 1 in the picture) correspond to the perovskite-like phase with the same distribution of the elements as in the previous cases (grey line in Figure 5c). The dark ones (area 2) belong to a titanium-rich phase, and the lines of lanthanum and bismuth do not appear in the EDS spectrum (black line in Figure 5c). This agrees with the results of XRD, which show the presence of Li_2TiO_3 (Figure 2c). Finally, Figure 4d shows the BEI of the sample $La_{0.40}Bi_{0.112}Li_{0.47}TiO_3$. We can see three zones. The greyish crystals (area 1 in the picture) belong to a perovskite-like phase with the EDS spectrum shown in Figure 5d (grey line). The dark crystals (area 2 in the picture) correspond to a titanium-rich phase with a similar EDS spectrum

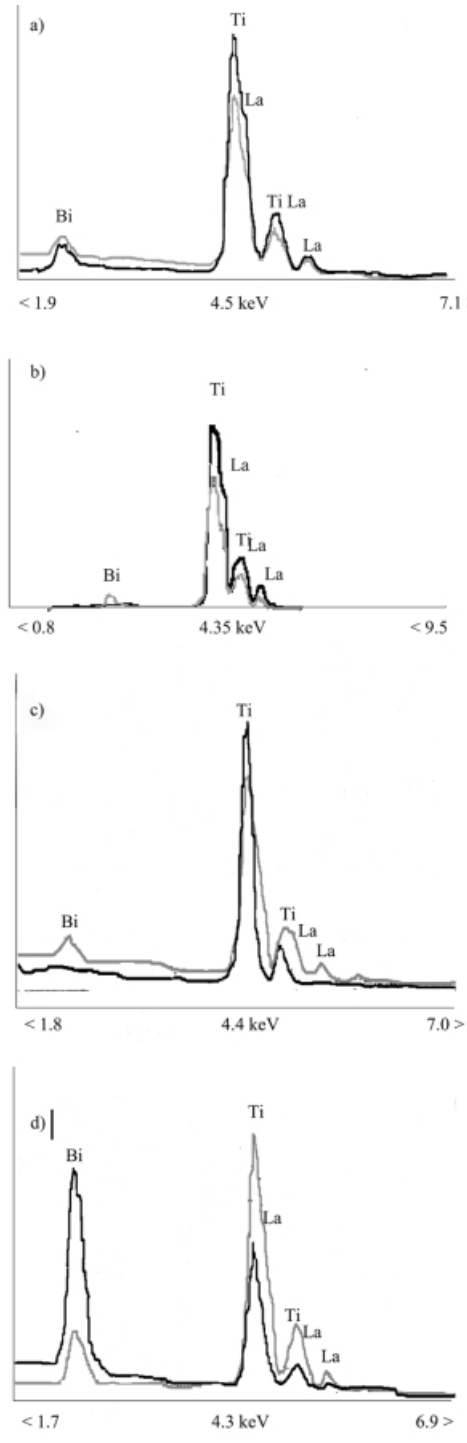

Figure 5. EDS of: a) perovskite-like single-phase solid solution region; b) perovskite-like phase + $La_2Ti_2O_7$ phase; c) perovskite-like phase + Li_2TiO_3 region; d) perovskite-like phase + Li_2TiO_3, + $Bi_4Ti_3O_{12}$ + $La_4Ti_3O_{12}$ region

(black line in Figure 5c and Li_2TiO_3 in the XRD pattern of Figure 2d). The white crystals (area 3 in the picture) are rich in bismuth and titanium but hardly contain lanthanum, as we can see from the EDS spectrum (black line in Figure 5d). This confirms the results of XRD, which showed $Bi_4Ti_3O_{12}$ (Figure 2d). The lanthanum peaks may be due to $La_4Ti_3O_{12}$, as we can see from the XRD pattern (Fig-

ure 2d), or a nearby zone corresponding to the perovskite-like phase.

ICP Analysis

ICP analyses were carried out. We assume that the oxygen content in all the samples is near to 3. For all compositions, the experimental values of Li and Bi were lower than those expected from the starting composition. The results of elemental analyses on mixed regions (Table 1) for different spots matched those for the proposed compounds in Figure 2.

Electrical Measurements (AC)

An HP 4192A Impedance Analyzer was used for AC measurements. These measurements were carried out from 25 °C to 100 °C for compounds on joins $La_{0.46+x}Bi_{0.04}Li_{0.5-3x}TiO_3$ ($0.04 < x < 0.11$) and $La_{0.57-y}Bi_yLi_{0.29}TiO_3$ ($y \leq 0.08$). Two semicircles and a spike were observed in the impedance complex plane plots in all the samples; the second semicircle becomes higher on increasing the amount of bismuth (Figure 6).

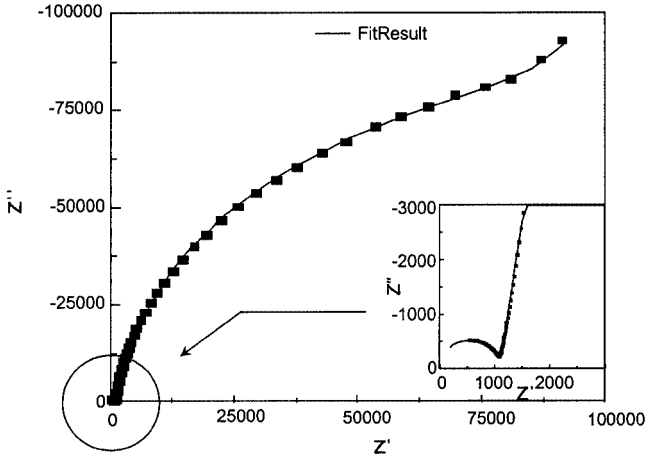

Figure 6. Impedance response at 25 °C for $La_{0.55}Bi_{0.018}Li_{0.29}TiO_3$

The centre of the semicircles was clearly depressed below the baseline, indicating a non-Debye response, which is usual in ionic conductors.[17,18] An equivalent circuit (Figure 7) with two RC and two constant phase elements (CPE)[19] has been used to fit the high frequency data; these elements are assigned to bulk and grain boundary responses with capacities around 20 $pFcm^{-1}$ and 5 $nFcm^{-1}$, respectively. An additional CPE element was used to model the low frequency spike with a capacity around 50 $nFcm^{-1}$.

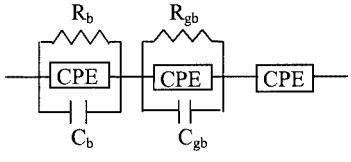

Figure 7. Equivalent circuit for fitting AC data

This value, which is too low for an electrode, has previously been reported for high Na^+ and Li^+ ion conductors,[17,5] and it is attributed to the presence of a Na^+ or Li^+ free layer on the crystal surface. All fitting used the ZView software package.[20]

Bulk conductivity data extracted from the impedance complex plane plots are shown in Arrhenius format for both joins in Figure 8 and Figure 9. Along the join $La_{0.46+x}Bi_{0.04}Li_{0.5-3x}TiO_3$, where the amount of bismuth remains constant, the conductivity is highest when $x = 0.075$, with a conductivity value at 25 °C of 7.59×10^{-4} Scm^{-1}, although the variation in conductivity with composition is quite small (Figure 10). The activation energy increased from 0.310 eV to 0.344 eV. The presence of a maximum in Figure 10 agrees with earlier results for the La system,[2] which report a conduction mechanism based on the A-site vacancies. Along the join $La_{0.57-y}Bi_yLi_{0.29}TiO_3$, where the amount of lithium remains constant, the conductivity decreases when the amount of bismuth increases (Figure 8). However, the substitution of La by Bi is not accompanied by a significant change in the cell volume of the perovskite, so this behaviour does not seem to be related to any change in the "bottleneck" size. However, it could be related to the existence of the lone-electron pair of bismuth.[21,22] Future neutron diffraction studies are underway

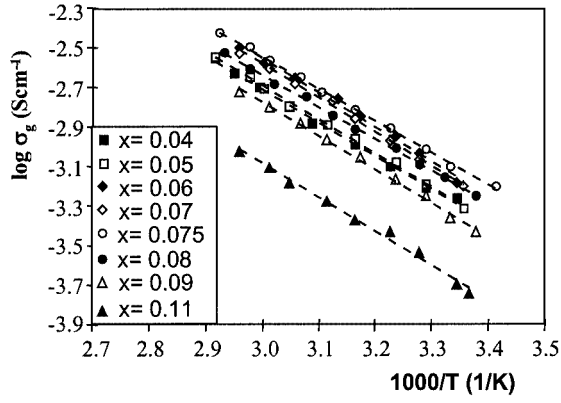

Figure 8. Arrhenius ionic conductivity plots for the join $La_{0.46+x}Bi_{0.04}Li_{0.5-3x}TiO_3$

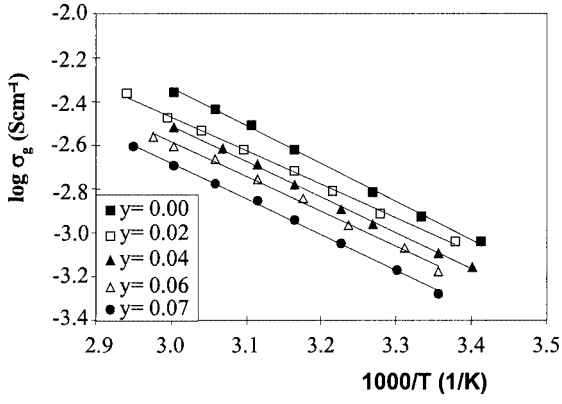

Figure 9. Arrhenius ionic conductivity plots for the join $La_{0.57-y}Bi_yLi_{0.29}TiO_3$

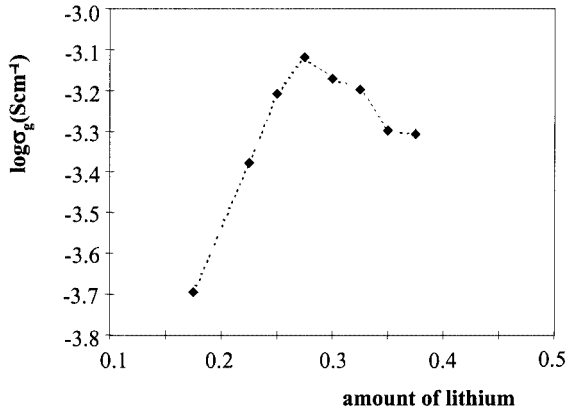

Figure 10. Plot of log σ_b vs. amount of lithium along join $La_{0.46+x}Bi_{0.04}Li_{0.5-3x}TiO_3$

which will give more information about the structure of these compounds and allow us to explain this effect better.

In spite of the good values of bulk conductivity in this system, the samples present significant boundary resistances that are three orders of magnitude higher than the resistances of the bulk, and higher activation energies, around 0.56 eV, which limit the overall conductivity.

Conclusions

Solid solutions with general formula $La_{0.5+x-y}Bi_y$-$Li_{0.5-3x}TiO_3$ have been studied and the results represented on a diagram with corners $La_{2/3}TiO_3$/$La_{0.5}Li_{0.5}TiO_3$/$Bi_{0.5}$-$Li_{0.5}TiO_3$.

Five distinct areas have been found in the diagram. Region A is a melts area, resulting from the melting of the initial mixture. Region B is a mixture of the perovskite-like compound and Li_2TiO_3, $Bi_4Ti_3O_{12}$ and $La_4Ti_3O_{12}$. Region C is a mixture of perovskite-like compounds and $La_2Ti_2O_7$. Region D is a region of perovskite-like solid solutions and region E is a mixture of perovskite-like compound and Li_2TiO_3.

The compounds of general formula $La_{0.5+x-y}Bi_y$-$Li_{0.5-3x}TiO_3$ are ionic conductors. Their ionic conductivity increases when the amount of lithium rises to $x = 0.075$, and the ionic conductivity decreases when the amount of bismuth increases.

Experimental Section

Synthesis: La_2O_3 (99.9% Fluka), TiO_2 (Aldrich 99 +%), Bi_2O_3 (99.9% Aldrich), and Li_2CO_3 (Aldrich >99%) were used as starting materials. La_2O_3 and TiO_2 were dried overnight at 900 °C prior to weighing. These chemicals were weighed, mixed in an agate mortar with acetone, dried, and heated to between 600 and 700 °C for 2 h to drive off CO_2. After grinding, the samples were pressed into pellets and covered with powder of the same composition to avoid loss of lithium and bismuth during the thermal treatment. The pellets were fired at 1100 °C for 12 h giving whitish products which were reground, re-pelleted, and fired at 1200 °C for a further 12 h. Finally, the samples were reground and re-pelleted, fired at 1250 °C for 4 h and quenched to room temperature.

X-ray Diffraction: The solid solution range, crystalline phase identification, and lattice parameters were obtained by powder X-ray diffraction on a Siemens D-500 diffractometer in reflection mode with a detector and a graphite monochromator, using Cu-K_α radiation. Lattice parameters were obtained using a silicon internal standard.

SEM and EDS: Scanning electron microscopy and EDS were obtained with an AN10000 EDS coupled to a JEOL JSM-840 microscope. Stoichiometry was obtained by ICP with a JOVIN IVON instrument.

Electrical Measurements: AC measurements were carried out using an HP 4192A Impedance Analyzer over the range 5 Hz−13 MHz, only in the single phase region. Data correction were carried out in order to avoid the stray capacitance of the jig and the stray inductance and series lead resistance associated with the leads, although data above 5×10^6 Hz were discarded.

Synthesis and Characterization of a New Aurivillius Phase

M.-L. Martínez-Sarrión,*[a] L. Mestres,[a] M. Herraiz,[a] A M. Balagurov,[b] A. I. Beskrovniy,[b] S. G. Vasilovskij,[b,c] and L. S. Smirnov[b]

Keywords: Aurivillius phase / Neutron diffraction / Solid-state structures / Perovskite phases

Several new Aurivillius phases with the general formula $Bi_{2.5+x}Li_{0.5-3x}Nb_2O_9$ ($0.04 < x < 0.08$) were synthesized. The crystal structure of the compound with $x = 0.04$ was studied by X-ray powder diffraction at room temperature, and by neutron powder diffraction in temperature intervals from 10 to 290 K. A single-phase compound was obtained. The crystal structure can be described by a space group, $Cmc2_1$, with lattice parameters of an orthorhombic unit cell: $a = 24.840(5)$ Å, $b = 5.449(6)$ Å, $c = 5.450(9)$ Å. The atomic positions were refined by a profile method. The conductivity of $Bi_{2.53}Li_{0.29}Nb_2O_9$ ranges from 1.35×10^{-8} S/cm at 543 K to 1.46×10^{-4}S/cm at 1013 K
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Aurivillius phases are described by the common formula $A_2O_2(A'_{n-1}B_nO_{3n+1})$,[1] where n denotes the thickness of the perovskite layers in terms of BO_6 octahedra. Currently, compounds are known with $n = 1$, 2, 3, 4, 5 and 8. Structures of this type show a great variability in their physical properties upon substitution of different metal cations.[2] This opens up great possibilities in the synthesis of new materials.

Some Aurivillius phases exhibit pseudo-tetragonal symmetry crystallizing in orthorhombic space groups. A large number of Aurivillius phases have been structurally characterized and all of them have tetragonal or pseudo-tetragonal symmetry, with a_o ranging between 3.85 and 3.95 Å ($a_{orthorhombic} = 5.45-5.58$ Å).[3]

The Aurivillius phases Bi_2WO_6, $Bi_2SrTa_2O_9$ and $Bi_4Ti_3O_{12}$ have been known as ferroelectric materials since the work of Smolenski et al.[4] and Subbarao,[5] who extensively studied their ferroelectrical properties as a function of composition. Thin films of $Bi_2SrTa_2O_9$ have been used in the recent developments in nonvolatile computer memory applications, such as an information storage medium.

The work of Withers and co-workers[6,7] has suggested that the major cause of spontaneous polarisation in the two-layer materials is the displacement of the A site cation in the perovskite block along the *a*-direction in the polar space group $A2_1am$ and not the movement of the B site cation away from the octahedral centre. A further important question regards the possibility of anti-site defects in the cation sublattice, Bi on the A site and A on the Bi site in the system $Bi_2ATa_2O_9$ (A = Ba, Sr, Ca; B = Nb, Ta). Recent work by Ismunandar et al.[8] using powder neutron diffraction data suggests that there is no cation-site disordering in these systems, although a similar study of $Bi_2PbNb_2O_9$ by Srikanth[9] suggests that some disorder may be present.

Blake et al.[10] used simultaneous X-ray and neutron powder refinements to obtain accurate models of the structure of $Bi_2BaNb_2O_9$, which is tetragonal with space group $I4/mmm$, and the structures of $Bi_2SrNb_2O_9$ and $Bi_2CaNb_2O_9$, which are orthorhombic with space group $Cmc2_1$. All the compounds exhibit disorder between the bismuth and A sites, increasing as the A-site cation size increases. The cause of this disorder may be explained by a combination of cation size considerations and bond valence sum analysis. It is possible that the two-layer Aurivillius structure may prefer a trivalent cation on the A site.

Durán-Martín and co-workers[11] have synthesised and characterised solid solutions $Bi_{2-x}Te_xSrNb_{2-x}B_xO_9$ (B = Zr, Hf) ($0 < x < 0.5$) and $Bi_{2-y}Te_ySr_{1-y}A_yNb_2O_9$ (A = K), ($0 < y < 0.25$). These materials are stable up to 800 °C for $y = 0.25$ and 750 °C for $x = 0.5$. All compositions are ferroelectric at room temperature. The AC electric conductivity shows anomalies at temperatures close to those where the remnant polarisation disappears.

In the last few years, some Aurivillius phases have been used as cathode materials in lithium batteries.[12,13] The aim of the present work is to investigate new Aurivillius phases with the general formula $Bi_{2.5+x}Li_{0.5-3x}Nb_2O_9$. These com-

pounds have vacancies in the A-sites of the perovskite blocks that could promote the lithium mobility. The stoichiometry range, crystal structure and electrical behaviour have been studied.

Results and Discussion

Four compositions with general formula $Bi_{2.5+x}Li_{0.5-3x}Nb_2O_9$ ($0.04 < x < 0.08$), corresponding to an Aurivillius phase, were prepared. The use of powder XRD at room temperature confirmed that all the samples are monophasic with orthorhombic symmetry. Table 1 shows the formula and cell parameters for the new phases.

Table 1. Sample composition and cell parameters

	a (Å)	b (Å)	c (Å)	V (Å^3)
$Bi_{2.53}Li_{0.29}Nb_2O_9$	24.82(2)	5.440(6)	5.448(9)	735.59
$Bi_{2.54}Li_{0.24}Nb_2O_9$	24.81(1)	5.442(2)	5.457(1)	736.78
$Bi_{2.56}Li_{0.22}Nb_2O_9$	24.81(1)	5.444(2)	5.460(1)	737.46
$Bi_{2.59}Li_{0.20}Nb_2O_9$	24.81(1)	5.448(4)	5.458(2)	737.73

In order to understand these compounds better, $Bi_{0.53}Li_{0.29}Nb_2O_9$ was studied by neutron diffraction at different temperatures. Figure 1 shows the X-ray and neutron powder diffraction patterns at room temperature and also shows the initial indexing of the peaks. The figure shows that only the space group $Cmc2_1$ describes all the observed peaks. The atomic positions determined for $Bi_2CaNb_2O_9$ and $Bi_2SrNb_2O_9$ [10] were used as an initial model for Rietveld refinement.

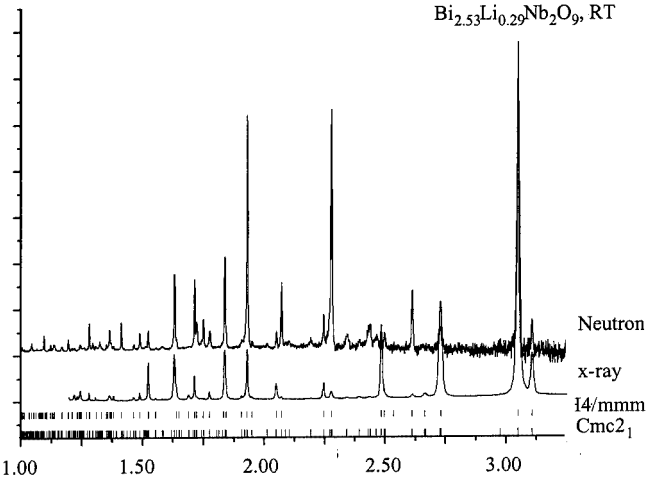

Figure 1. X-ray and neutron diffraction patterns at room temperature and initial indexing of the peaks for tetragonal *I*4/*mmm* and orthorhombic $Cmc2_1$ symmetry

Table 2 and 3 show the determined elementary cell parameters, the position of the atoms in the structure, the sites and the thermal factors in the isotropic approach, at 10 K and 290 K respectively.

At T = 10 K all the B_{iso} values are fixed. The results of the Rietveld refinement are shown in Figure 2. The observed neutron diffraction data are shown as a dotted line and the calculated profile as a solid line. A mark below the profile indicates the position of an allowed reflection. The lowest line near zero corresponds to the differences between observed and calculated intensities.

The possible variant of the replacement of bismuth by lithium in the bismuth oxide layer was checked during specification of the crystal structure. According to our calculations, the population of lithium in the bismuth oxide layer was nil. The bismuth oxide layer is much more inert with regard to substitution than the perovskite layer.[14,15] These data provide a basis for assuming that replacement of a bivalent ion in $Bi_2SrNb_2O_9$ or $Bi_2BaNb_2O_9$ by trivalent bismuth results in the formation of structural vacancies in the perovskite layer. The partial occupation of these vacancies

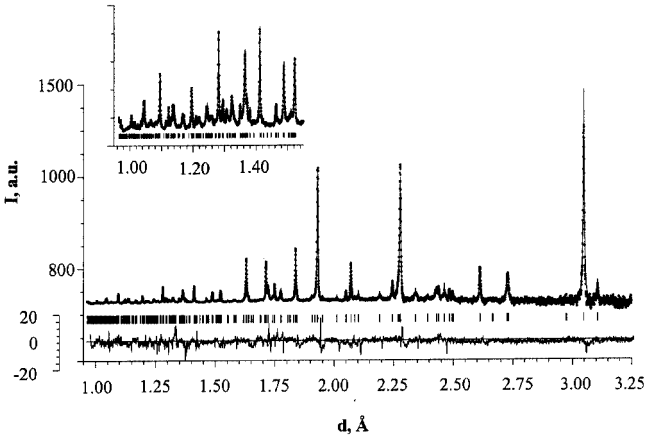

Figure 2. Observed, calculated (upper curve) and difference (lower curve) neutron profiles for $Bi_{2.53}Li_{0.29}Nb_2O_9$ obtained with an HRFD diffractometer at 290 K

by lithium ions can create favourable conditions for the development of ionic conductivity on structural vacancies.

The valences V_{ij} of the different cations were calculated from the atomic coordinates and Equation (1) (bond valence method):

$$V_{ij} = \sum_{i}^{v} s_{ij}\left(R_{ij}\right) \quad (1)$$

where v is the coordination number.

The dependence of valence strain s_{ij} on the bond length R is determined as:

$$s_{ij} = \exp\left[\left(R_{1j} - R_{ij}\right)/b\right] \quad (2)$$

where R_1 is the bond length of the individual valence, and the empirical parameter b is 0.37 Å (Table 4).

Table 4. Calculated valency for cations

Atom	Bond valence		
	T = 10 K	T = 290 K	Model
Bi	3.03	2.89	3
(Bi/Li)	1.89	1.81	1.88
Nb	4.94	5.14	5

The arrangement of octahedra in the structure is distorted. There is also a noticeable distortion of their form. Table 5 gives the bond lengths between atoms that fall into an octahedral configuration.

Table 5. Bond lengths in the NbO_6 octahedra

Bond type	L, Å	
	T = 10 K	T = 290 K
Nb−O(1)	2.131	2.136

	2.019	2.039
Nb−O(5)	1.957	1.992
	2.054	2.085

In order to gain a better understanding of this compound powder neutron diffraction data were collected at high temperature on a DN-2 diffractometer. On the basis of these data, the dependence of the parameters of an elementary cell on the temperature were deduced (Figure 3). From the given dependences it may be seen that orthorhombic distortion of the structure increases with temperature. This is not consistent with the data, which are given for $Bi_2(Sr, Ca)Nb_2O_9$.[10]

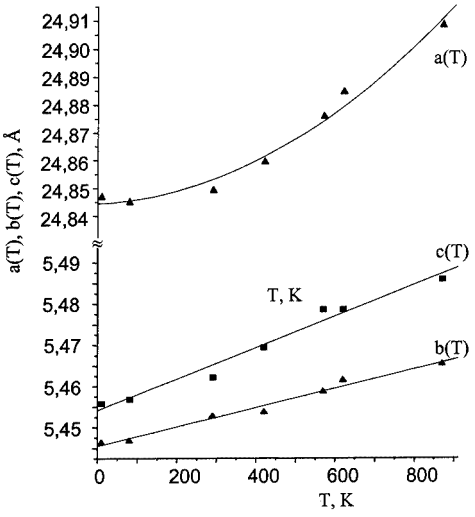

Figure 3. Dependence of the elementary cell parameters of $Bi_{2.53}Li_{0.29}Nb_2O_9$ vs. temperature

The plot of the parameters against temperature in Figure 3 shows a possible phase transition between 600 and 650 K. The small structure distortion due to the presence of lithium in the 12-coordinated positions of the perovskite part would lead to a possible phase transition at high temperature, in agreement with the small change in the slope observed in the plot.

Analysis of the results of TG and DSC analysis did not show the presence of a phase transition of these compounds in our experimental conditions, although one has to take into account that not all phase transitions carry an enthalpy variation detectable by DSC.

Figure 4 shows the structure of the new Aurivillius phase $Bi_{2.53}Li_{0.29}Nb_2O_9$, which may be described structurally as intergrowths of fluorite-like $Bi_2O_2^{2+}$ layers with perovskitic $(A'_{n-1}B_nO_{3n+1})^{2-}$ layers (n = 2). The $Bi_2O_2^{2+}$ layers are composed of a square planar net of oxygen anions with Bi^{3+} in an alternating sequence above and below, forming BiO_4-pyramids. Double perovskite layers are inserted between $Bi_2O_2^{2+}$ layers. Nb^{5+} cations are on the B-site, and Bi^{3+}, Li^+ and vacancies can be found on the A′ positions. NbO_6 octahedra in the structure are partially collapsed as a result of a cooperative tilting and rotating due to the presence of Bi^{3+}, Li^+ and vacancies placed on the larger A′ sites of the perovskite structure.

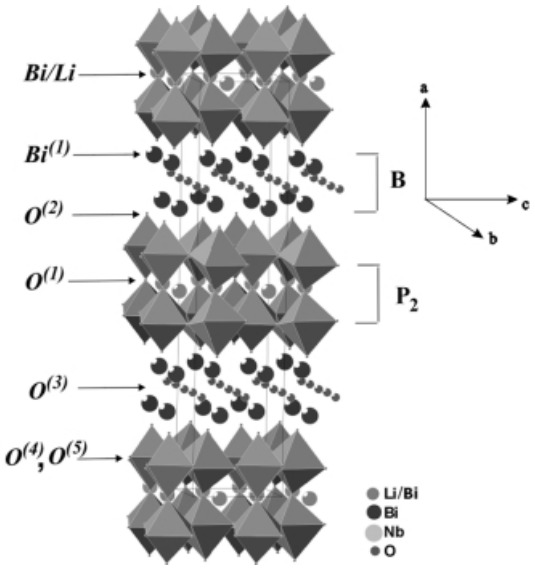

Figure 4. Crystal structure of $Bi_{2.53}Li_{0.29}Nb_2O_9$; octahedra NbO_6: large black spheres, Bi: small grey spheres O; large grey balls are Bi, Li or vacancies

AC impedance measurements were carried out on sintered pellets (diameter ≈ 6 mm and thickness ≈ 2 mm) of the sample $Bi_{2.53}Li_{0.29}Nb_2O_9$, using gold electrodes. The conductivity was measured up to 750 ΘC, the maximum temperature allowed by our sample holders. An almost perfect semicircle associated with the bulk conductivity (C ≈ 40pF) was observed (Figure 5) and the conductivity was determined from the intercepts on the real axis.

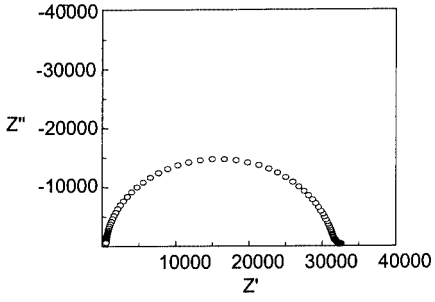

Figure 5. Impedance spectra for $Bi_{2.53}Li_{0.29}Nb_2O_9$ at 953 K

Figure 6 shows the variation of the dielectric constant (ε′) as a function of the temperature for different frequencies during the heating run. As can be seen, there are two anomalies in the behaviour of this constant; the first one at approximately 573 K and the second one at 873 K. The maximum corresponding to the first one shifts to lower temperatures with decreasing frequency. This kind of behaviour of the dielectric constant is typical of materials with a diffuse phase transition, and is also found for different ferroelectric materials.[17,18] For temperatures above 873 K a further increase of the dielectric constant was observed as the increasing electric conductivity leads to a dielectric breakdown.[19]

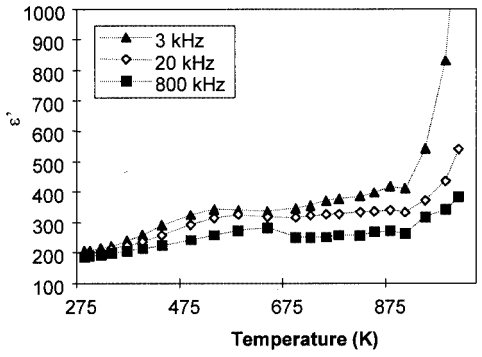

Figure 6. Dielectric constant ε′ of $Bi_{2.53}Li_{0.29}Nb_2O_9$ vs. temperature for different frequencies

Conductivity data from the impedance complex plane plots are shown in Arrhenius format in Figure 7. The plot is not linear and the slope changes around the same temperatures where the dielectric permittivity plots show anomalies that may be attributed to a phase transition. The activation energy changes from 0.57 eV to 0.93 eV, and finally 1.43 eV.

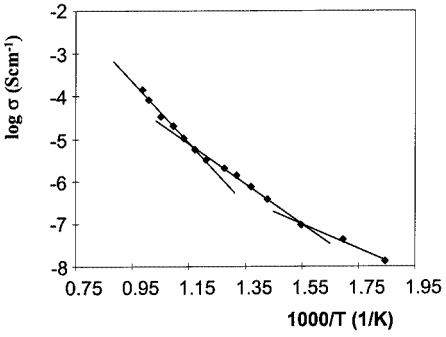

Figure 7. Arrhenius plots of conductivity for $Bi_{2.53}Li_{0.29}Nb_2O_9$

Experimental Section

Synthesis: Samples were prepared in 10 g quantities from Bi_2O_3 (Aldrich 99.9%), Li_2CO_3 (Aldrich, purity > 99.0%) and Nb_2O_5 (Aldrich 99.9%). Nb_2O_5 was dried overnight at 950 °C prior to weighing. These chemicals were weighed, mixed in an agate mortar with acetone, dried and heated to 650 °C for 3 h to drive off CO_2. After grinding, samples were pressed into pellets and covered with powder of the same composition to avoid loss of lithium during thermal treatment. The pellets were fired at 950 °C for 4 h yielding white products, which were reground, re-pelleted and fired at 1025 °C for 12 h and at 1100 °C for 6 h.

Analysis: Lithium, bismuth and niobium stoichiometries were obtained by ICP with a Jovin Ivon instrument.

X-ray Diffraction: Phase purity was checked by X-ray powder diffraction with a Siemens D-500 diffractometer in reflection mode and a secondary monochromator using Cu-K_α radiation. The program FULLPROF was used for Rietveld refinements.[20]

Neutron Diffraction: Neutron diffraction experiments were carried out in the FLNP, JINR at the IBR-2 pulse reactor using two different diffractometers. On the DN-2 diffractometer, the neutron dif-

fraction data were measured in the range from 1.5 Å to 12 Å at medium resolution. On the HRFD diffractometer, neutron diffraction data were recorded in the range from 1 Å to 3.2 Å at high resolution. The unit-cell parameters were determined using the AUTOX program for automatic indexing.[21] The atomic positions were refined by the Rietveld profile analysis using the MRIA program.[22]

Thermal Analysis: The thermal analysis for the temperature range 298−1173 K by thermogravimetry (TG), and from 123−873 K by differential scanning calorimeter (DSC) was carried out in a Mettler Toledo Star System. With TG the warming rate was 10 K/min, and the weight of the sample, was 27.4027 mg. In the DSC study the weight of the sample was 12.2430 mg from 298 K to 873 K, and 12.8800 mg, from 123 K to 298 K. The measurements were made during both heating and cooling. The reference material was alumina.

Electrical Measurements: AC measurements were carried out using a HP 4192A Impedance Analyser over the range100 Hz $< f <$ 1.3 $\times$ 10^7 Hz. Data corrections were carried out in order to avoid the stray capacitance of the jig and the stray inductance and series lead resistance associated with the leads; data above 5 $\times$ 10^6 Hz were discarded.

Monomeric and Dimeric Iron(III) Complexes of 5-Hydroxy-10,15,20-triphenylporphyrin: Formation of Cyano and Pyridine Complexes of (5-Oxo-10,15,20-triphenylphlorin)iron

Jacek Wojaczyński,[a] Marcin Stępień,[a] and Lechosław Latos-Grażyński*[a]

Keywords: Porphyrinoids / Oxophlorins / Iron / Electronic structure / NMR spectroscopy

The reaction of $[(TrPP)Fe^{II}(py)_2]$ (TrPP = dianion of 5,10,15-triphenylporphyrin) with hydrogen peroxide results in oxygenation of the (porphyrin)iron and the formation of (10,15,20-triphenyl-5-oxophlorin)iron $[(5\text{-}O\text{-}TrPP)Fe(py)_2]$. Coupled oxidation of $[(TrPP)Fe^{III}Cl]$ in the presence of ascorbic acid and potassium cyanide in methanol leads to oxidative hydroxylation of the porphyrin ring to form a cyclic dimer $[(5\text{-}O\text{-}TrPP)Fe^{III}]_2$. Three out of four pyrrole ^{1}H NMR resonances of the dimeric complex present the characteristic displacement with respect to the typical position for the high-spin (tetraphenylporphyrin)iron(III) complexes. The linewidths of the β-H pyrrole resonances correlate with specific locations of the respective protons within the dimeric structure. Addition of HCl to $[(5\text{-}O\text{-}TrPP)Fe^{III}]_2$ results in cleavage of the dimer producing $[(5\text{-}OH\text{-}TrPP)Fe^{III}Cl]$. $[(5\text{-}O\text{-}TrPP)Fe^{III}]_2$ is also split with acetic anhydride to give (5-acetoxy-10,15,20-triphenylporphyrin)iron(III). In the presence of $[D_5]$pyridine or a large excess of cyanide ion, $[(5\text{-}O\text{-}TrPP)Fe^{III}]_2$ undergoes cleavage to form air-sensitive $[(5\text{-}O\text{-}TrPP)Fe(py)_2]$ or $[(5\text{-}O\text{-}TrPP)Fe(CN)_2]^{2-}$. The pyrrole pattern observed for $[(5\text{-}O\text{-}TrPP)Fe(py)_2]$ is similar to that determined on the basis of an analysis carried out for four (oxophlorin)-iron regioisomers obtained from hemes. For comparison, the characteristic ^{1}H NMR features of the typical (5-substituted-10,15,20-triphenylporphyrin)iron(III) complexes have been investigated for the series of high-spin and low-spin complexes. The spin-density distribution in the (oxophlorin)iron skeleton is dominated by the radical-like electronic structure. (© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Coordinating properties of porphyrins, widely used in biomimetic chemistry and catalytic studies, can be remarkably modified by the introduction of some additional metal ion coordinating centers at the porphyrin periphery. Such substituents are suitable for coordination of the metal ion of the same or other molecular systems.[1−3] These ''hybrid'' bifunctional ligands combine properties of the porphyrin macrocycles with those of the peripheral coordinating moiety.

The hydroxy-substituted octaethylporphyrin and tetraphenylporphyrin are representative examples of polyfunctional ligands related to porphyrins. They are able to coordinate through the tetranitrogen macrocyclic center and/or through an ionized hydroxy group at the periphery. Three structurally distinct locations of the hydroxy substituents for the originally highly symmetrical model porphyrins $OEPH_2$ and $TPPH_2$ were attainable synthetically, a *meso* position for $OEPH_2$, and β-pyrrole or phenyl positions for $TPPH_2$.[4−7] Insertion of an iron ion into 5-(2-hydroxyphenyl)-10,15,20-tritolylporphyrin ($TTOPH_2$) or 5-hydroxy-octaethylporphyrin (octaethyloxophlorin, $OEPOH_2$) resulted in the formation of the high-spin doubly oxo-bridged iron(III) head-to-tail dimers $[(TTOP)Fe^{III}]_2$ and $[(OEPO)Fe^{III}]_2$, respectively.[8−10] Dimerization through phenoxide $\{[(TTOP)Fe^{III}]_2\}$ or the *meso*-oxygen atom $\{[(OEPO)Fe^{III}]_2\}$ rather than μ-oxo bridging was preferred in both cases.

The structure of $[(TTOP)Fe^{III}]_2$ was determined by X-ray crystallography and the retention of the dimeric structure in solution was demonstrated by ^{1}H NMR spectroscopy.[8,9] Goff et al. characterized the manganese(III) dimer $[(TTOP)Mn^{III}]_2$ and detected, by means of ^{1}H NMR spectroscopy, the diphenoxo-bridged heteronuclear complex $[(TTOP)Fe^{III}(TTOP)Mn^{III}]$.[9]

(Oxophlorin)iron complexes are significant in the context of their involvement as intermediates in the conversion of (porphyrin)iron to biliverdin in the oxidative heme destruction.[11,12] Masuoka and Itano characterized the (oxophlorin)iron(III) dimer $[(OEPO)Fe^{III}]_2$ by a range of spectroscopic techniques.[10] The presence of two paramagnetic centers produced marked changes of the ^{1}H NMR spectral parameters compared to monomeric analogs, including variation of the linewidths for the methylene protons.[13] The formation of $[(OEPO)Mn^{III}]_2$ has been demonstrated,[14] and the unique structure of the related indium complex determined by X-ray crystallography.[15]

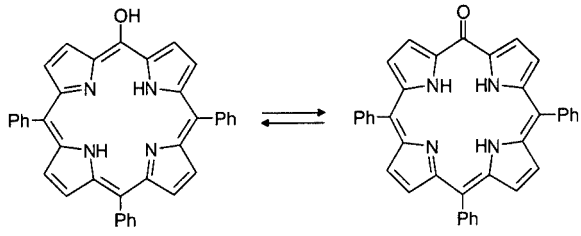
2-Hydroxy-5,10,15,20-tetraphenylporphyrin is the tetraphenylporphyrin derivative hydroxylated at a β-position. The cyclic trimers $[(2\text{-O-TPP})Fe^{III}]_3$, $[(2\text{-O-TPP})Ga^{III}]_3$, and $[(2\text{-O-TPP})Mn^{III}]_3$ were generated in a self-assembly process of monomeric (2-hydroxy-5,10,15,20-tetraphenylporphyrin)iron(III), -gallium(III), or -manganese(III).[16−18] The trivalent metal ion coordinated in the porphyrin crevice seems to be a prerequisite for the trimer formation. The paramagnetic heterometallic head-to-tail cyclic trimers of general formula $[(2\text{-O-TPP})M^{III}]_n[(2\text{-O-TPP})M_1^{III}]_{3-n}$ (M, M_1: Fe^{III}, Ga^{III}, Mn^{III}) have also been identified.[19]

In this project we introduce a new hybrid bifunctional ligand, namely 5-hydroxy-10,15,20-triphenylporphyrin (5-OH-$TrPPH_2$) which is formally derived from tetraphenylporphyrin. The molecule is "constructed" by replacement of a single *meso*-phenyl group with a hydroxy group.

5-OH-$TrPPH_2$ and the previously investigated 5-hydroxyoctaethylporphyrin contain the identical structural motif of 5-hydroxyporphyrin.[20] In analogy to 5-OH-$OEPH_2$, the coordinating properties of 5-OH-$TrPPH_2$ can be related to two tautomers, 5-hydroxyporphyrin and 5-oxophlorin, presented in Scheme 1.



Scheme 1

In order to determine the influence of the *meso*-hydroxy group on (porphyrin)iron properties in a broader scope, a representative group of low-spin and high-spin iron(III) complexes of 5-substituted-10,15,20-triphenylporphyrin (5-X-$TrPPH_2$; X = NO_2, Br, *n*Bu, H, OMe) have been investigated in parallel. The 5-X substituents vary in their electron-donating/-withdrawing properties as measured by Hammett constants. Considering the biochemical aspects, the electronic structure and reactivity of the (5-oxo-10,15,20-triphenylphlorin)iron complex $[(5\text{-O-TrPP})FeL_2]$ (L = py, CN^-) are of particular interest.

The related (octaethyloxophlorin)Fe(pyridine)$_2$ complex {$[(OEPO)Fe(py)_2]$} has been studied extensively.[21−26] It has been found that a mechanism of coupled oxidation of $[(OEP)Fe^{II}(py)_2]$ in pyridine solution includes a *meso*-hydroxylation step producing $[(OEPO)Fe(py)_2]$.[12,27] It is widely accepted that the first step in heme degradation by heme oxygenase results in the *meso* hydroxylation of heme.[12,23,26,28,29] Direct spectroscopic evidence has been presented showing that *meso*-hydroxylated heme is formed by heme oxygenase.[30]

^{1}H NMR spectroscopy provides a uniquely useful probe for studying the structure of (porphyrin)iron complexes in solution.[31,32] The hyperfine shift patterns are particularly sensitive to the ligation, oxidation and spin state of the metal ion. For instance, the (porphyrin)iron(III) complexes bridged by ligands containing one or more oxygen atoms present ^{1}H NMR spectroscopic patterns unequivocally explainable in terms of their dimeric[8,9,13] or trimeric[16−19] structures. In this contribution our investigations have been focused on (5-hydroxy-10,15,20-triphenylporphyrin)- and (5-oxo-10,15,20-triphenylphlorin)iron(III) complexes. Four inequivalent pyrrole resonances of TrPP complexes and their *meso*-substituted derivatives provided the direct probe of the spin density around the porphyrin macrocycle, and allowed the detection of a cyclic dimeric structure.

Results and Discussion

Synthesis of [(5-X-TrPP)Fe^{III}Cl]

5,10,15-Triphenylporphyrin, $TrPPH_2$, was synthesized by the condensation of pyrrole, benzaldehyde, and paraformaldehyde. The procedure followed the methodology typically used for synthesis via a mixed aldehyde−pyrrole condensation.[33] Alternatively, $TrPPH_2$ was obtained by phenylation of 5,15-diphenylporphyrin with phenyllithium.[34]

$TrPPH_2$ was characterized by X-ray crystallography (Figure 1); the bond lengths and angles are within the range expected for a porphyrin.[35] The porphyrin macrocycle is practically flat. In the crystal, a 2_1 axis (along the *c* direction) generates a ribbon of molecules (Figure 1), which demonstrate a characteristic set of close CH−π contacts (with CH−centroid distances of 2.58 and 3.05 Å) involving Ph(5)···Ph(10)···Ph(15) *meso*-phenyl rings from adjacent triphenylporphyrins. An analogous structural motif has been observed for $TPPH_2$-based porphyrin sponges.[36,37] The periphery of $TrPPH_2$ presents a blending of structural features that are typical for $TPPH_2$ and $OEPH_2$ as the 5-*meso* position and two pyrrole rings are exposed.

5-Bromo-10,15,20-triphenylporphyrin (5-Br-$TrPPH_2$) was obtained from the reaction of $TrPPH_2$ with *N*-bromosuccinimide as described previously.[38] 5-Nitro-10,15,20-triphenylporphyrin (5-NO_2-$TrPPH_2$) was obtained by nitration of triphenylporphyrin with $AgNO_2$ in the presence of I_2 by modification of the method applied for the nitration of 5,15-diphenylporphyrin.[39]

Reaction of $[(TrPP)Zn^{II}]$ with sodium methoxide in the presence of air yielded (5-methoxy-10,15,20-triphenylporphyrin)zinc(II), which was subsequently demetallated with acid to give 5-MeO-$TrPPH_2$.

Iron insertion into 5-X-$TrPPH_2$ produced the corresponding $[(5\text{-X-TrPP})Fe^{III}Cl]$ complexes. The $[(5\text{-Br-TrPP})Fe^{III}Cl]$ complex was characterized by X-ray crystallography (Figure 2). The iron ion is five-coordinate with bonds to the four pyrrole nitrogen atoms of nearly equal lengths [2.065(4), 2.065(4), 2.071(4), and 2.076(4) Å]. The metal ion lies 0.461(2) Å out of the mean plane of the macrocycle. The Fe−N distances and the displacement from the mean plane are characteristic of five-coordinate high-spin (S = 5/2) (porphyrin)iron(III) complexes.[40−42] The Fe−Cl distance is 2.209(2) Å, which is typical for chloro(porphyrin)iron(III) complexes.[40,41]

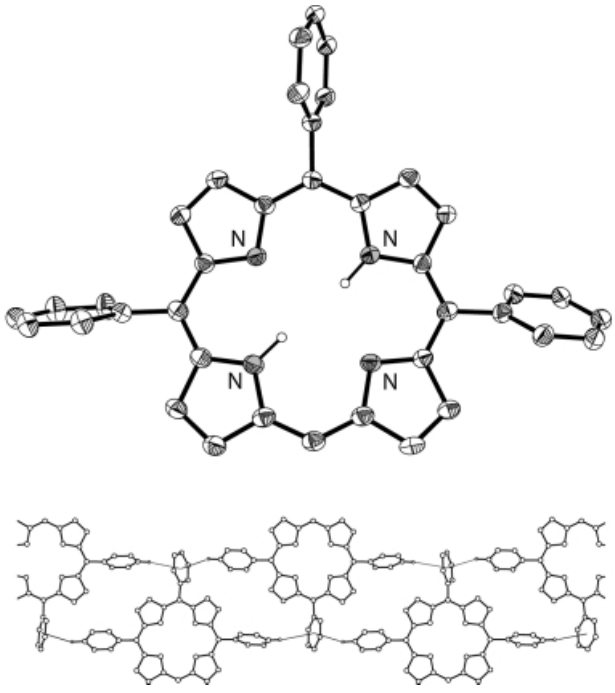


Figure 1. (top) The crystal structure of $TrPPH_2$; the vibrational ellipsoids represent 50% probability; (bottom) a view of the molecular packing demonstrating the ribbon arrangement and CH−π contacts of *meso*-phenyl rings from adjacent triphenylporphyrins

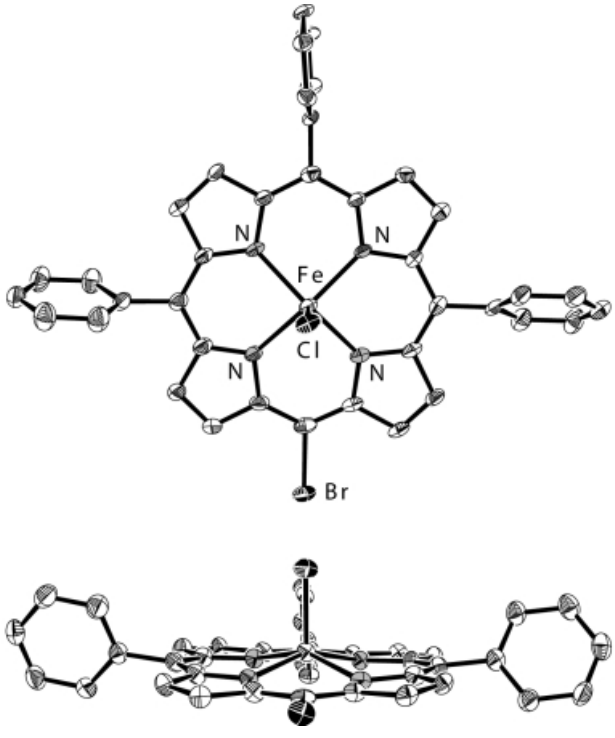

Figure 2. A perspective view of (5-Br-TrPP)$Fe^{III}Cl$ with 50% thermal contours

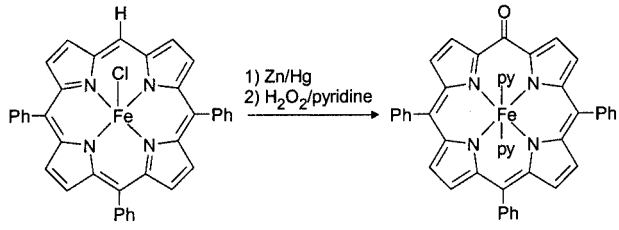
Reaction of Hydrogen Peroxide with [(TrPP)$Fe^{II}(py)_2$]

The standard hydroxylation procedure of $OEPH_2$ involves the reaction of [(OEP)Zn^{II}] with thallium(III) trifluoroacetate (TTFA) to produce (5-trifluoroacetoxyoctethylporphyrin)zinc(II) [(5-TFA-OEP)Zn^{II}].[4] Hydrolysis of this complex yields octaethyloxophlorin. Quite differently, the [(TrPP)Zn^{II}] complex undergoes a regiospecific C(5)−C(5′) coupling, mediated by TTFA acting solely as a two-electron oxidizing reagent to produce [5,5′-bi(10,15,20-triphenylporphyrin)]dizinc(II) [$(TrPP)_2Zn^{II}_2$].[43−45] Consequently, to obtain (5-hydroxy-10,15,20-triphenylporphyrin)iron(III), a different approach has been applied. We have taken into account that porphyrins themselves are not nearly as susceptible to initial *meso* oxygenation (hydroxylation) as are (porphyrin)iron complexes.[26,46,47] Consequently, the reaction of [(TrPP)$Fe^{II}(py)_2$] with hydrogen peroxide at −30 °C in the absence of dioxygen has been examined. Scheme 2 shows the structures and transformations involved.



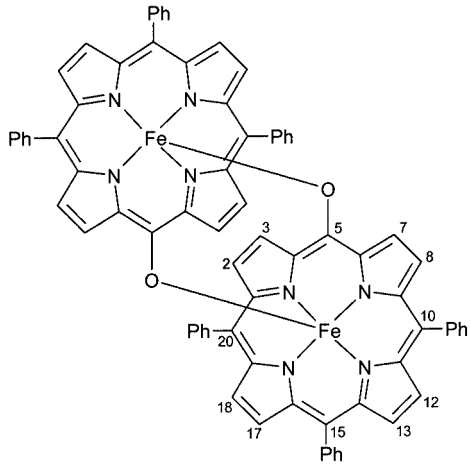
Scheme 2

A [D_5]pyridine solution of [(TrPP)$Fe^{II}(py)_2$] was prepared under dinitrogen to exclude any oxidation with dioxygen and cooled to −30 °C, at which point a dioxygen-free solution of hydrogen peroxide (30% in water)/[D_5]pyridine solution (1:60, v/v) was introduced into the sample in a stepwise manner. The red solution of [(TrPP)$Fe^{II}(py)_2$] turned brownish on addition of the hydrogen peroxide, and the ^1H NMR spectra showed the gradual growth of a new set of resonances accompanied by a lowering of the intensities of those assigned to the low-spin diamagnetic [(TrPP)Fe^{II}-$(py)_2$]. A paramagnetic product was identified as (5-oxo-10,15,20-triphenylphlorin)iron with two axially coordinated [D_5]pyridine ligands, [(5-O-TrPP)Fe$(py)_2$] (see below). Thus, the reaction had taken place exclusively at the unsubstituted *meso* position. Once formed, the solution of [(5-O-TrPP)Fe$(py)_2$] in [D_5]pyridine is stable as long as it is protected from dioxygen, the addition of which results in bleaching.

Extraction of the [D_5]pyridine solution of [(5-O-TrPP)Fe$(py)_2$] with 1 M aqueous HCl yielded high-spin [(5-OH-TrPP)Fe^{III}Cl]. Subsequently, the dichloromethane solution of [(5-OH-TrPP)Fe^{III}Cl] was subjected to chromatography on a silica column. In the course of the process the monomeric [(5-OH-TrPP)Fe^{III}Cl] complex was transformed into the cyclic dimer [(5-O-TrPP)$Fe^{III}]_2$ (Scheme 3).

Coupled Oxidation

Recently, a convenient method for the preparation of the dimeric [(OEPO)$Fe^{III}]_2$ complex has been reported in the course of coupled oxidation of [(OEP)Fe^{III}Cl] under pyridine-free conditions.[48] Herein, this procedure has been adopted with success to obtain [(5-O-TrPP)$Fe^{III}]_2$.



Scheme 3

Addition of [(TrPP)Fe^{III}Cl] to a methanolic solution of ascorbic acid and potassium cyanide leads to oxidative hydroxylation of the porphyrin ring to form [(5-O-TrPP)Fe^{III}]$_2$. Initially, the cyanide coordinates to [(TrPP)Fe^{III}Cl] producing [(TrPP)$Fe^{III}(CN)_2]^-$, a reaction substrate that is soluble in methanol. The reaction mixture was stirred overnight in the presence of air. In the course of the coupled oxidation we obtained [(5-O-TrPP)Fe^{III}]$_2$, which was subsequently separated using column chromatography. The yield of the process was ca. 20%. At the present stage of investigations, no effort has been made to optimize the yield and to characterize other feasible reaction products.

Characterization of [(5-O-TrPP)Fe^{III}]$_2$

The electronic spectrum of [(5-O-TrPP)Fe^{III}]$_2$ is presented in Figure 3 together with the spectrum of [(5-OAc-TrPP)Fe^{III}Cl] and [(5-O-TrPP)Fe$(CN)_2]^{2-}$ (see below). The electronic spectrum of [(5-OAc-TrPP)Fe^{III}Cl] resembles the spectra of high-spin (tetraphenylporphyrin)iron(III) complexes and other [(5-X-TrPP)Fe^{III}Cl] complexes. The electronic spectrum of [(5-O-TrPP)Fe^{III}]$_2$ is considerably different; all bands are broadened compared to [(5-OAc-TrPP)Fe^{III}Cl], and a new band is detected at 330 nm. These differences may be induced by the 5-oxygen axial ligand coordination[49] and/or from the porphyrin−porphyrin π interaction caused by the proximity of the porphyrin rings in the close-packed dimeric structure.[13,16,50−52]

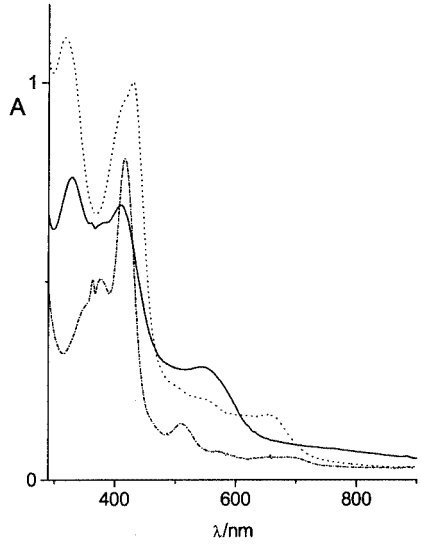


Figure 3. Electronic absorption spectra of [(5-O-TrPP)Fe^{III}]$_2$ (——), [(5-AcO-TrPP)Fe^{III}Cl] (-·-·-·) (both in CH_2Cl_2), and [(5-O-TrPP)Fe$(CN)_2]^{2-}$ (· · ·) (in methanol)

The electrospray ionization (ESI) mass spectrum of [(5-O-TrPP)Fe^{III}]$_2$ shows peaks due to the parent species [(5-O-TrPP)Fe^{III}]$_2$ at *m*/*z* (%) = 1215.4 (7) and its deoligmerization product [(5-OH-TrPP)$Fe^{III}]^+$ at *m*/*z* (%) = 608.3 (100). In our experiment the most intense peak corresponds to the monomeric unit because the technique used requires the addition of acid to the sample, which favors the formation of monomer.

^{1}H NMR Spectroscopic Studies of [(5-O-TrPP)Fe^{III}]$_2$

The downfield part of the ^{1}H NMR spectrum of [(5-O-TrPP)Fe^{III}]$_2$ is shown in Figure 4 (Trace A). The resonance assignments have been made on the basis of relative intensities and linewidth analysis. The ^{1}H NMR spectrum of [(5-O-TrPP)Fe^{III}]$_2$ shows a number of remarkable features that must arise from its unusual molecular structure. In particular, three β-pyrrolic signals are strongly displaced upfield relative to their typical position for the high-spin (tetraphenylporphyrin)iron(III) complexes at δ (linewidths in Hz) = 56.3 (400), 49.6 (650), 47.5 (2200) ppm ($CDCl_3$, 293 K). The deconvolution procedure (not shown) has been applied to this part of the spectrum in order to demonstrate that three resonances of remarkably different linewidths and identical intensities are required to reproduce the experimental spectrum. The fourth inequivalent pyrrole position produces the resonance at δ = 84.3 (linewidth 300 Hz) ppm. The phenyl resonances form a complex, unresolved pattern which is spread over the δ = 0−16 ppm range.

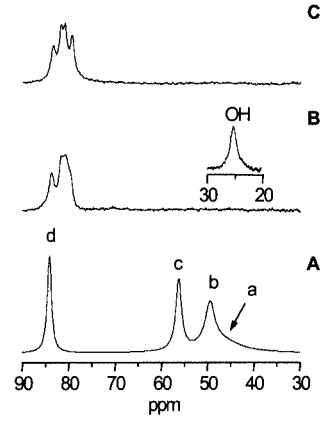

Figure 4. The downfield region of (A) 300 MHz ^{1}H NMR spectrum of [(5-O-TrPP)Fe^{III}]$_2$ at 291 K, (B) 500 MHz ^{1}H NMR spectrum of [(5-OH-TrPP)Fe^{III}Cl], (C) 500 MHz ^{1}H NMR spectrum of [(5-AcO-TrPP)Fe^{III}Cl]; resonance assignments: a: 3(7)-H; b: 2(8)-H; c: 12(18)-H; d: 13(17)-H

Molecular mechanics calculations have been used to visualize the structure of the dimer and to estimate the degree of the porphyrin distortion that is necessary to form this species. In the minimization procedure we used the standard MM+ parameterization of the HyperChem program, with the exception of the iron coordination surroundings where we imposed the constraints reflecting the high-spin state of the iron(III) ion. The characteristic features of the high-spin (tetraphenylporphyrin)iron(III) complexes and [(5-Br-TrPP)Fe^{III}Cl] included displacement of the iron ion from the plane of the four nitrogen atoms (0.45 Å), and relatively long Fe−N bonds (2.05 Å).[41−43] The spectroscopic evidence indicates that the iron(III) complex has a head-to-tail dimeric structure, with the *meso*-alkoxide groups forming the bridges from one macrocycle to the metal ion of the adjacent macrocycle. Such a dimeric structure accounts for the mass of the largest ion in the mass spectrum. The ^{1}H NMR spectrum clearly shows the equivalence of the two (porphyrin)iron(III) subunits. The upfield relocation of three β-H resonances can be explained only by the direct coordination of the O(5) atom to the external iron(III) ion, as required by the cyclic dimeric structure. Hence high-spin (5-hydroxytriphenylporphyrin)-iron(III) can be used as a building block in the dimerization.

A schematic view of the dimeric (porphyrin)iron(III) skeleton as obtained by molecular mechanics is presented in Figure 5. The closest contacts are in the range observed in the structures of other metalloporphyrins.[15,19,41]

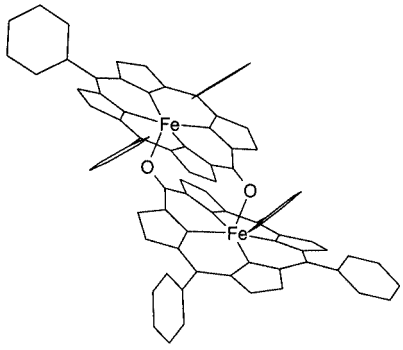

Figure 5. Drawing of the dimer [(5-O-TrPP)Fe^{III}]$_2$ obtained from the molecular mechanics calculations; hydrogen atoms have been omitted for the sake of clarity

The features of the ^{1}H NMR spectra of [(5-O-TrPP)Fe^{III}]$_2$ can be understood in the context of the presence of two high-spin iron(III) ions in the molecule. The 5-hydroxyporphyrin of each monomeric unit is coordinated simultaneously to the internal iron(III) ion through the four nitrogen atoms and to the external one by the 5-oxygen atom. The typical delocalization pathway for high-spin (tetraphenylporphyrin)iron(III) complexes shifts the pyrrole resonances downfield as a result of the dominating σ-contact contribution. Additionally, the π delocalization locates a considerable amount of the spin density at the *meso* positions,[16,31,53−55] and some at the pyrrole positions.[56] The π-spin density at the *meso*-carbon atoms produces sign alternation of the *meso*-phenyl resonances. The dipolar contribution, caused only by the ZFS effect in high-spin (porphyrin)iron complexes, is usually notably smaller than the contact contribution, and this observation has been applied in the further analysis of the hyperfine shifts.[55]

The characteristic features of the internal iron(III) ion influence are exemplified by the ^{1}H NMR spectra of [(5-X-TrPP)Fe^{III}I] (X = NO_2, Br, MeO, H; the choice of I^- as an axial ligand allowed better differentiation of the pyrrole resonances), [(5-OH-TrPP)Fe^{III}Cl], and [(5-AcO-TrPP)-Fe^{III}Cl], where the typical downfield sets of the four pyrrole resonances are found centered around δ = 80 ppm (as shown in traces B and C of Figure 4, and in Table 1). The presence of a second source of spin density in [(5-O-TrPP)Fe^{III}]$_2$, i.e., the external iron(III) ion, changes the hyperfine shifts for the β-H pyrrole protons considerably. Assuming simple additivity of contact contributions by two independent routes, we have estimated that such shifts require a downfield contribution similar to that found for [(5-OH-TrPP)Fe^{III}Cl], hence the upfield shift of ca. −30 ppm for 2(8)-H, −32 ppm for 3(7)-H, and −24 ppm for 12(18)-H. This upfield contribution to the β-H shift results mainly from the σ donation of the electron density of the 5-oxygen donor on the half-occupied d_{z^2} orbital of the iron(III) ion. The anticipated positive spin density on the σ orbital of the oxygen atom will be directly transferred into the π system of the pyrrole ring without any iron(III)−oxygen π bonding, spreading the effect up to the distant pyrrole position [12(18)-H] with respect to the coordinating oxygen atom. The σ orbital of the oxygen atom and the porphyrin π orbitals are not orthogonal, and consequently σ−π overlap permits the direct spin-density transfer.[57,58] We therefore suggest a similar delocalization mechanism to that proposed for [(2-O-TPP)Fe^{III}]$_3$, although with a different location of the external coordinating center.[16]

The linewidths of the β-H pyrrole resonances correlate with their specific locations within the dimeric structure. The dipolar contribution to linewidth broadening is presumed to be proportional to r^{-6}, where r is the distance from the paramagnetic iron(III) center to the proton in question when the ligand-centered dipolar relaxation is insignificant.[59,60] The contribution from the internal iron(III) ion by dipolar and scalar mechanisms has been approximated by the linewidths of the most downfield pyrrole resonance. The markedly larger linewidths of the β-H resonances can be split into two parts: the internal one, which is identical to the most downfield pyrrole position, and the remaining external one {100 Hz [12(18)-H], 350 Hz [2(8)-H], and 1900 Hz [3(7)-H]}. Most likely the external part derives mainly from the dominant dipolar relaxation of the neighboring external iron(III) ion. The respective $Fe_{external}$−β-H distances are estimated from the model to be: 3.5 Å (3/7-H), 5.5 Å (2/8-H), 9 Å (12/18-H), 10 Å (13/17-H). Thus, the pattern of pyrrole linewidths is qualitatively in agreement with the proposed molecular structure.

Table 1. ^{1}H NMR chemical shifts of the pyrrole resonances of *meso*-substituted high-spin (triphenylporphyrin)iron(III) complexes

Compound	δ [ppm][a]
[(5-NO_2-TrPP)Fe^{III}I]	80.0 (2 H), 80.2 (2 H), 84.5 (4 H)
[(5-Br-TrPP)Fe^{III}I]	81.1 (2 H), 82.2 (4 H), 85.3 (2 H)
[(5-MeO-TrPP)Fe^{III}I]	88.2 (2 H), 92.8 (2 H), 93.7 (2 H), 94.5 (2 H)
[(5-OH-TrPP)Fe^{III}Cl]	79.9 (2 H), 80.8 (2 H), 81.7 (2 H), 83.8 (2 H)
[(5-AcO-TrPP)Fe^{III}Cl]	79.4 (2 H), 80.9 (2 H), 81.9 (2 H), 83.5 (2 H)
[(5-O-TrPP)Fe^{III}]$_2$	47.5 (4 H), 49.6 (4 H), 56.3 (4 H), 84.3 (4 H)

[a] Conditions: T = 293 K, $CDCl_3$, 500 MHz or 300 MHz.

Cleavage of [(5-O-TrPP)Fe^{III}]$_2$

Addition of acids in excess to [(5-O-TrPP)Fe^{III}]$_2$ results in the cleavage of the dimer according to Equation (1).

$$[(5\text{-O-TrPP})Fe^{III}]_2 + 2\,HX \rightarrow 2\,[(5\text{-OH-TrPP})Fe^{III}X] \quad (X = Cl, TFA) \qquad (1)$$

Trace B of Figure 4 shows the spectrum of a [(5-O-TrPP)Fe^{III}]$_2$ sample to which gaseous HCl has been added. The spectrum is consistent with the formation of [(5-OH-TrPP)Fe^{III}Cl]. The β-H pyrrole resonances of [(5-O-TrPP)Fe^{III}]$_2$ centered at δ = 50 ppm disappeared. Four new pyrrole resonances were found (δ = 83.8, 81.7, 89.0, 79.9 ppm). They correspond to four pyrrole protons that are inequivalent because of the 5-substitution. The pyrrole resonances of [(5-OH-TrPP)Fe^{III}Cl] have similar linewidths (ca. 600 Hz). The differential broadening of the pyrrole resonances determined for the dimeric molecule is absent. A unique resonance at δ = 25.3 ppm for [(5-OH-TrPP)Fe^{III}Cl] has been assigned to the 5-hydroxy proton {the intensity of this resonance varies in the range 1−2 H depending on preparation, so the formation of [(5-H_2O-TrPP)FeCl]$^+$ remaining in the fast equilibrium with [(5-OH-TrPP)Fe^{III}Cl] seems to be of importance}. When a small amount of $CDCl_3$, saturated with deuterium oxide, was added to the solution of [(5-OH-TrPP)Fe^{III}Cl], the 5-OH resonance diminished in intensity. Addition of base to [(5-OH-TrPP)Fe^{III}Cl] caused its conversion into [(5-O-TrPP)Fe^{III}]$_2$. Actually, such a conversion was detected even when a $CDCl_3$ solution of [(5-OH-TrPP)Fe^{III}Cl] was saturated with water.

[(5-O-TrPP)Fe^{III}]$_2$ was also split with acetic anhydride into (5-acetoxy-10,15,20-triphenylporphyrin)iron(III). The relevant ^{1}H NMR spectrum of the resulting complex, [(5-AcO-TrPP)Fe^{III}Cl] is presented in trace C of Figure 4. The feasible formation of two isomeric forms, one with the carbonyl oxygen atom and the chloride ion on the same side of the porphyrin, and one with these groups on the opposite faces of the porphyrin plane cannot be excluded, although they have not been confirmed by ^{1}H NMR spectroscopy because the respective β-H resonances are not sufficiently resolved.

Cleavage of [(5-O-TrPP)Fe^{III}]$_2$ by Pyridine or Cyanide Anion

In the presence of [D_5]pyridine, [(5-O-TrPP)Fe^{III}]$_2$ undergoes a cleavage to form air-sensitive [(5-O-TrPP)Fe(py)$_2$]. Thus, treatment of a dioxygen-free chloroform solution of the dimeric complex with a 50-fold excess of [D_5]pyridine results in its immediate conversion. The overall pattern of resonances is similar to that generated in the hydroxylation of [(TrPP)Fe^{II}(py)$_2$]. The detected shift differences have been attributed to the solvent effect and/or a different concentration of the pyridine ligand remaining in equilibrium. The ^{1}H NMR spectrum of the [D_5]pyridine solution of [(5-O-TrPP)Fe(py)$_2$] is shown in Figure 6, and the chemical shifts are given in Table 2. Three of the four pyrrole resonances are found in the downfield region of the spectrum, while the other signal is located upfield. Sign alternation of isotropic shifts of *meso*-phenyl protons is also observed, with larger absolute shift values assigned to the 15-Ph position.

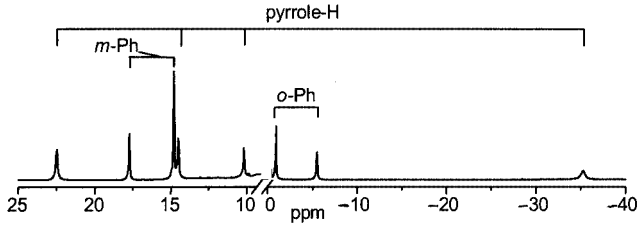

Figure 6. 500 MHz ^{1}H NMR spectrum of [(5-O-TrPP)Fe(py)$_2$] in a [D_5]pyridine solution; resonance assignment: pyrrole-H: pyrrole protons; *o*-Ph, *m*-Ph: *ortho*-, *meta*-phenyl protons

A ^{1}H NMR titration was carried out by addition of trifluoroacetic acid (solution in $CDCl_3$) to a solution of [(5-O-TrPP)Fe(py)$_2$] in [D_5]pyridine. Smooth changes of the chemical shifts in the whole titration range were observed. This fact can be attributed to a gradual protonation of the 5-oxygen atom and a fast proton exchange among two species in the system formed in the conditions of our experiment, as shown in Equation (2).

$$(5\text{-O-TrPP})Fe(py)_2 + H^+ \rightleftarrows [(5\text{-OH-TrPP})Fe^{III}(py)_2]^+ \qquad (2)$$

The direction of shift changes experienced by the pyrrole resonances indicates that protonation of the 5-O atom results in the formation of a low-spin complex [(5-OH-TrPP)Fe^{III}(py)$_2$]$^+$ with the usual $(d_{xy})^2(d_{xz},d_{yz})^3$ electronic ground state. Independently, this complex was observed in the course of [D_5]pyridine titration of [(5-OH-TrPP)Fe^{III}-(TFA)] conducted in $CDCl_3$, and is characterized by four

Table 2. ^{1}H NMR chemical shifts of bis(pyridine) and bis(cyanide) complexes[a]

Compound	δ [ppm] pyrrole-H 2(8)-H	3(7)-H	12(18)-H	13(17)-H	*ortho*-Ph 10(20)-H	15-H	*meta*-Ph 10(20)-H	15-H	*para*-Ph 10(20)-H	15-H	Solvent
[(5-O-TrPP)Fe(py)$_2$]	−35.4	22.6	10.2, 14.6[b]		−0.8	−5.5	14.9	17.8	2.2	−0.3	C_5D_5N
[(5-O-TrPP)Fe(py)$_2$]	−30.2	21.0	13.6, 14.6[b]		−0.7	−4.6	14.6	17.2	[b]	0.1	$CDCl_3$
[(5-O-TrPP)Fe(CN)$_2$]$^{2-}$	−6.0	12.9	8.1, 9.1[b]		2.2	0.2	12.9	13.7	4.1	3.0	CD_3OD
[(5-NO_2-TrPP)Fe^{III}(CN)$_2$]$^-$	−13.9	−9.6	−14.4	−15.1	6.0	4.6	7.3	6.7	6.7	6.3	CD_3OD
[(5-Br-TrPP)Fe^{III}(CN)$_2$]$^-$	−7.5	−6.9	−8.5	−7.9	5.6	5.4	8.2	8.0	6.5	6.4	CD_3OD
[(5-MeO-TrPP)Fe^{III}(CN)$_2$]$^-$ [c]	−6.6	−5.9	−7.0	−7.4	5.5	5.3	8.8	8.6	6.3	6.3	CD_3OD

[a] Conditions: T = 293 K, 500 MHz. Intensities: pyrrole resonances (2 H each); 10(20)-*ortho* and 10(20)-*meta*-Ph (4 H); 15-*ortho*, 15-*meta*, and 10-*para*-Ph (2 H); 15-*para*-Ph (1 H). [b] Not identified. [c] MeO resonance at δ = 2.9 ppm.

upfield pyrrole resonances [δ = −16.8, −19.8, −27.4, −27.8 ppm (293 K)].

In the presence of a large excess of the cyanide ion [(5-O-TrPP)Fe^{III}]$_2$, dissolved in [D_4]methanol, undergoes cleavage to form the air-sensitive [(5-O-TrPP)Fe(CN)$_2$]$^{2-}$. The ^{1}H NMR spectrum of the resulting solution is shown in Figure 7. The overall pattern of resonances with three downfield and one upfield pyrrole resonances [δ = 12.9, 9.1, 8.1, −6.0 ppm (293 K)] is similar to that of [(5-O-TrPP)Fe(py)$_2$]. The sign alternation of the isotropic shifts of the *meso*-phenyl resonances has also been detected. Since only two *ortho* resonances are observed, the axial ligation on both sides of the macrocycle is identical.

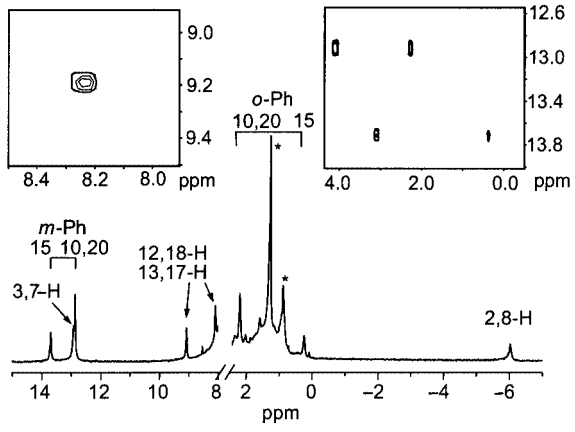

Figure 7. 500 MHz ^{1}H NMR spectrum of [(5-O-TrPP)Fe(CN)$_2$]$^{2-}$ in [D_4]methanol (293 K); the insets show the respective COSY maps; resonance assignments as in Figure 6

The insets in Figure 7 show fragments of a COSY spectrum that was obtained for [(5-O-TrPP)Fe(CN)$_2$]$^{2-}$. The individual *meso*-phenyl groups were identified by the respective cross-peaks between the *ortho*, *meta*, and *para* protons. The cross-peak detected between the pyrrole resonances at δ = 8.1 and 9.1 ppm confirms their location on the same pyrrole ring. Consequently, two other pyrrole resonances are assigned to a second scalar-coupled pair of pyrrole resonances.

The UV/Vis absorption spectrum of [(5-O-TrPP)Fe(CN)$_2$]$^{2-}$ is included in Figure 3. The spectrum displays the Soret band at 427 nm and a broad absorption at 659 nm.

Electronic Structure of [(5-O-TrPP)Fe(py)$_2$] and [(5-O-TrPP)Fe(CN)$_2$]$^{2-}$

Addition of an excess of potassium cyanide to a solution of [(5-X-TrPP)Fe^{III}Cl] in [D_4]methanol results in its conversion into the six-coordinate low-spin complex [(5-X-TPP)Fe^{III}(CN)$_2$]$^-$. The representative ^{1}H NMR spectra for [(5-X-TPP)Fe^{III}(CN)$_2$]$^-$ complexes (the pyrrole region) are shown in Figure 8, and the chemical shift values are gathered in Table 2. The characteristic sets of four upfield-shifted pyrrole resonances assigned by means of 2D NMR experiments have been observed for each compound. These resonances are accompanied by sets of upfield-shifted *ortho* and *para* proton resonances of the *meso*-phenyl groups and downfield shifted *meta* proton signals. The ^{1}H NMR spectra reflect features typical for low-spin (porphyrin)iron(III) complexes.[31,56]

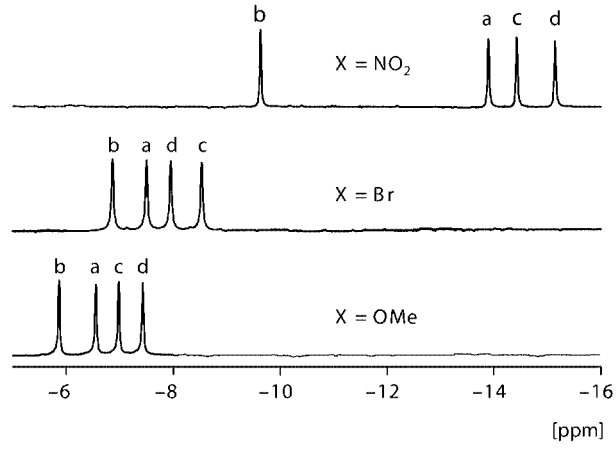

Figure 8. 500 MHz ^{1}H NMR spectra (pyrrole region) of [(5-X-TrPP)Fe^{III}(CN)$_2$]$^-$ complexes (X = NO_2, Br, MeO) in a [D_4]methanol solution at 293 K; resonance assignments follow those of Figure 4

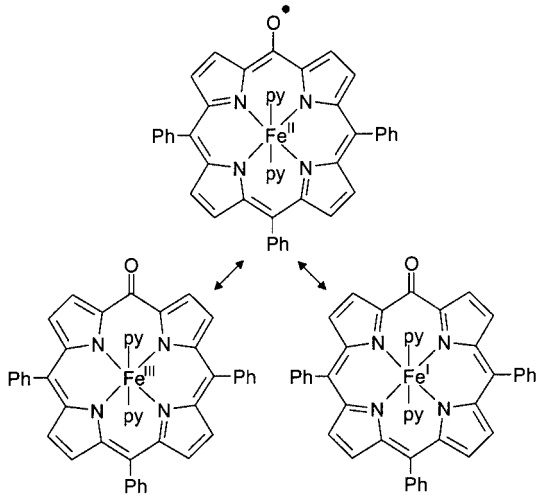
On the contrary, the ^{1}H NMR spectrum of [(5-O-TrPP)Fe(CN)$_2$]$^{2-}$ demonstrates the remarkably different pattern revealing the sign alternation detected for the pyrrole resonances (Figure 7). The overall oxidation level of

[(5-O-TrPP)Fe(py)$_2$] or [(5-O-TrPP)Fe(CN)$_2$]$^{2-}$ is consistent with the resonance structures presented in Scheme 4.[12,21−27,48]

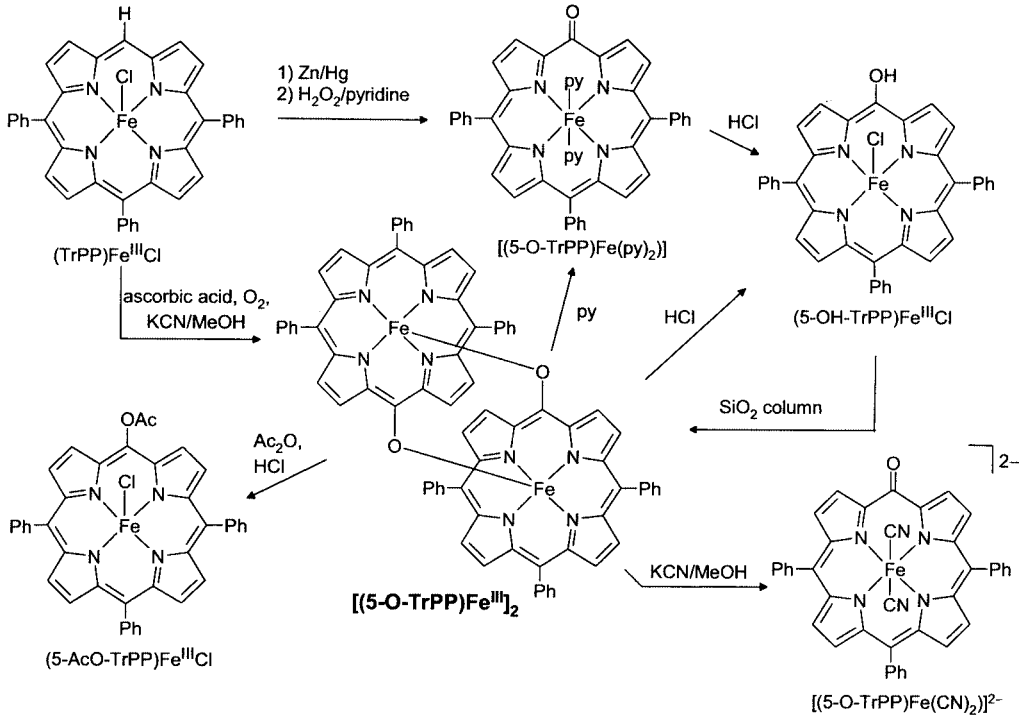


Scheme 4

The new (oxophlorin)iron complexes [(5-O-TrPP)Fe(py)$_2$] and [(5-O-TrPP)Fe(CN)$_2$]$^{2-}$ present ^{1}H NMR spectroscopic patterns that reveal a general similarity to the spectra of [(OEPO)Fe(py)$_2$], [(5-X-OEPO)Fe(py)$_2$], [(OEPO)Fe(CN)$_2$]$^{2-}$, [(Etio-I-PO)Fe(py)$_2$], [(DeuteroPO)Fe(py)$_2$], [(MesoPO)Fe(py)$_2$], and [(ProtoPO)Fe(py)$_2$] (OEPO, 5-X-OEPO, Etio-I-PO, DeuteroPO, MesoPO, and ProtoPO are trianions of oxophlorins obtained from octaethylporphyrin, 5-substituted octaethylporphyrin, etioporphyrin-I, deuteroporphyrin-IX dimethyl ester, mesoporphyrin-IX dimethyl ester, and protoporphyrin-IX dimethyl ester, respectively).[22,26,46]

Based on the chemical shifts measured for the four (deuterooxophlorin)iron isomers [(DeuteroPO)Fe(py)$_2$], the following values are anticipated for (5-oxophlorin)iron or its β-methylated derivative: pyrrole resonances: δ = −33 (2-H), 27 (3-H), 13 (12- and 13-H) ppm; methyl resonances: δ = 65 (2-CH$_3$), −14 (3-CH$_3$) ppm. Substitution of a methyl group by a proton is expected to give rise to a resonance that is subject to a hyperfine shift of opposite sign, but a magnitude similar to that of the corresponding methyl group if π-spin delocalization dominates the hyperfine shifts. Consequently, the pyrrole β-H resonances with the largest hyperfine shifts and the methyl resonances with the most upfield shift must originate from a common site (i.e., from a site with similar value and sign of the spin density) within the molecule as has been well documented for four regioisomers of [(DeuteroPO)Fe(py)$_2$].[26]

The four pyrrole protons of [(5-O-TrPP)Fe(py)$_2$] provide direct probes of the spin density around the oxophlorin macrocycle. In principle, this should allow the determination of the differences in the contact shifts for four pyrrole rings avoiding any differences due to the unsymmetrical substitution effect expected for natural porphyrins. The pyrrole pattern determined for [(5-O-TrPP)Fe(py)$_2$] was found to be very similar to that determined from the rather complex analysis carried out for four (oxophlorin)iron regioisomers obtained from hemes.[26] The relatively large paramagnetic shift of the *meso*-phenyl resonances dominated by the π-contact mechanism reflects the large spin density at the *meso* positions, as found previously for other (oxophlorin)-iron complexes. In conclusion, the spin-density distribution



Scheme 5

in the oxophlorin skeleton is dominated by the location of the oxygenated *meso* site and that this functional group imposes a basic twofold electronic symmetry that is only moderately perturbed by the presence of other functional groups.

Conclusion

The synthetic work of this contribution is summarized in Scheme 5. In particular, this work demonstrates considerable parallels in the properties of (10,15,20-triphenyl-5-oxophlorin)iron and (oxophlorin)iron complexes completely substituted at the β-positions. Potentially, an introduction of the *meso*-phenyl groups provides a suitable means for the control and exploration of the properties of this peculiar class of (porphyrin)iron-related systems. The electronic and steric factors can be conveniently adjusted by appropriate substitution of the *meso*-phenyl rings.

Experimental Section

General: ^{1}H NMR spectra were recorded with a Bruker AMX300 and a Bruker Avance 500 spectrometer operating at 300 and 500 MHz, respectively. The residual ^{1}H resonances of the deuterated solvents were used as internal references. Absorption spectra were recorded with a diode-array Hewlett Packard 8453 spectrometer. Mass spectra were recorded with a Finnigan MAT TSQ 700 spectrometer using the ESI technique. Molecular mechanics calculations using the HyperChem software (Autodesk) were carried out and displayed with a Pentium PC. The standard MM+ force field, with the constraints set on the coordination bonds to achieve a high-spin (porphyrin)iron(III) geometry, were used as described in the text. 5,10,15-Triphenylpophyrin ($TrPPH_2$) and 5-bromo-10,15,20-triphenylporphyrin (5-Br$TrPPH_2$) were synthesized as described previously.[35,36,38,45] 5-Nitro-10,15,20-triphenylporphyrin (5-NO_2-$TrPPH_2$) was obtained by nitration of $TrPPH_2$ with $AgNO_2$ in the presence of I_2 by modification of the method applied for nitration of 5,15-diphenylporphyrin.[39]

5-Methoxy-10,15,20-triphenylporphyrin: [(TrPP)Zn^{II}] (40 mg) was dissolved in 50 mL of toluene, and sodium methoxide (1−2 g) was added along with a small amount of methanol. The mixture was refluxed in the presence of air for 6 h and then concentrated to dryness under reduced pressure. The solid residue was extracted with a small volume of CH_2Cl_2, and the dissolved crude product was column-chromatographed on basic alumina with dichloromethane. [(5-MeO-TrPP)Zn^{II}] was eluted as the second band, directly after the unchanged [(TrPP)Zn^{II}]. The zinc complex of 5-methoxy-10,15,20-triphenylporphyrin was demetallated with hydrochloric acid to yield 5-MeO-$TrPPH_2$, which was used without further purification. ^{1}H NMR ($CDCl_3$): δ = −2.70 (s, 2 H, NH), 4.95 (s, 3 H, OCH_3), 7.7 (m, 9 H, *m*,*p*-Ph), 8.2 (m, 6 H, *o*-Ph), 8.76 (d, ^3J = 4.8 Hz, 2 H, H_β), 8.81 (d, ^3J = 4.8 Hz, 2 H, H_β), 8.88 (d, ^3J = 4.8 Hz, 2 H, H_β), 9.53 (d, ^3J = 4.8 Hz, 2 H, H_β) ppm. MS (ESI): *m*/*z* (%) = 569.5 (100) [MH^+].

Iron ion insertion according to a known route yielded the corresponding [(5-X-TrPP)Fe^{III}Cl] complexes.[16,56] Usually, the dicyano-ligated complexes of the investigated (porphyrin)iron(III) complexes were prepared by dissolution of 2−3 mg of the respective high-spin complex in 0.4 mL of [D_4]methanol saturated with KCN.

[Fe^{III}(OEPO)]$_2$: Potassium cyanide (43.7 mg, 0.67 mmol) and ascorbic acid (0.53 g, 3.0 mmol) were dissolved in 50 mL of methanol. [(TrPP)Fe^{III}Cl] (41 mg, 0.065 mmol) was added to the solution, and the reaction mixture was stirred in air for 12−20 h. The resulting solution was concentrated to a volume of 5 mL, diluted with 10 mL of dichloromethane, and washed 2−3 times with water. The organic layer was dried and the solvents were evaporated to dryness. The crude sample was column-chromatographed on silica gel (0.05−0.2 mm/70−270 mesh). The dimeric complex was eluted with an ethanol/dichloromethane mixture (2:98, v/v), and recrystallized from dichloromethane/hexane. Yield: 8 mg (20%). MS (ESI): *m*/*z* (%) = 1215.4 (7) [M^+], 608.3 (100) [(5-OH-TrPP)Fe^{III}]$^+$.

X-ray Crystallographic Study: Crystals of $TrPPH_2$ were grown by slow diffusion of *n*-hexane into a dichloromethane solution of the porphyrin. Diffraction data were collected with a Kuma KM4CCD diffractometer. The data were corrected for Lorentz and polarization effects. No absorption correction was applied. The structure was solved by direct methods (SHELXS-97) and refined by full-matrix least squares (SHELXL-97). All heavy atoms were refined anisotropically and the hydrogen atoms isotropically with no constraints. Crystals of [(5-Br-TrPP)Fe^{III}Cl]·C_6H_6 were obtained by slow concentration of a CH_2Cl_2/benzene solution. The specimen chosen for analysis was twinned but the diffraction patterns of the two domains did not overlap significantly. Data collection was carried out as for $TrPPH_2$. The structure was solved using heavy-atom methods (SHELXS-97) and refined by full-matrix least squares (SHELXL-97). Heavy atoms were refined anisotropically, and the hydrogen atoms by using a riding model. Empirical absorption correction assuming an ellipsoidal crystal was applied using the routine implemented in XPREP.[61] Crystal data and details of the data collection and refinement are presented in Table 3. CCDC-173923 and -173924 contain the supplementary crystallographic data for

Coordination Chemistry of 2,5,8-Trithia[9],(2,9)-1,10-phenanthrolinophane (L) toward Rhodium(III) at the Polarised Water/1,2-Dichloroethane Interface − A Possible New Approach to the Problem of Separating Rh^{III} from Chloride Media

Alexander J. Blake,[a] M. Helena M. Caçote,[b] Francesco A. Devillanova,[c] Alessandra Garau,[c] Francesco Isaia,[c] Vito Lippolis,*[c] Carlos M. Pereira,[b] Fernando Silva,[b] and Lorenzo Tei[c]

Keywords: Rhodium / Macrocyclic ligands / Interfaces / Cyclic voltammetry

The coordination chemistry involved in the assisted transfer of Rh^{III} by interfacial coordination with 2,5,8-trithia[9],(2,9)-1,10-phenanthrolinophane (L) has been studied at the water/1,2-dichloroethane interface by cyclic voltammetry. The dependence of the half-wave transfer potential on the ligand and metal concentrations suggests the $[Rh(L)Cl_2]^+$ formulation for the complex cation involved in the assisted transfer. In contrast, from the reaction of L in refluxing MeCN/water solution the $[Rh(L)Cl][BF_4]_2 \cdot 2MeCN$ compound has been isolated and structurally characterised. In the $[Rh(L)Cl]^{2+}$ complex cation L acts as an N_2S_3 donor encapsulating the metal centre within a cavity having a square-based pyramidal geometry. A chloride ligand completes the distorted octahedral coordination sphere around the Rh^{III} ion.

Introduction

The quest for new macrocyclic ligands capable of specific and effective molecular recognition of metal ions in carrier-assisted membranes or solid-state ion-selective electrodes is a topic of current interest.[1,2] Attention has mainly been focussed on the assisted transfer of group I and group II ions between two immiscible electrolyte solutions; different crown ether derivatives have been used as neutral carriers for the construction of ion-selective electrodes and for performing selective separations.[1−4] A smaller number of studies have been performed with transition and heavy metal ions, particularly precious metal ions, probably because of their greater inertness.[5,6] However, the recovery and removal of precious metals from aqueous solutions is of considerable economic and environmental concern. In particular, the separation and purification of rhodium from other platinum group metals in aqueous chloride solutions is made difficult by the complex chemistry that Rh^{III} exhibits in these media, which are largely employed because platinum group metals are usefully soluble in them. Mixed aquachloro complexes of the type $[RhCl_{6-n}(H_2O)_n]^{n-3}$ ($0 < n < 6$) are formed in different proportions depending primarily on the chloride concentration.[7] These species are highly hydrophilic and not easily isolated by direct solvent extraction. Some reagents such as $SnBr_2$, $SnCl_2$,[8,9] or SCN^- [10] can be used to enhance the extractability of the metal by forming Rh^{III} complexes with better solvent extraction properties, but once the metal is in the organic phase, the stripping process is not that easy. Despite these difficulties, the separation of Rh^{III} has been carried out by using different techniques such as solvent extraction,[11] ion exchange[9,12] and liquid membrane separation,[13−16] and particular attention is paid to research in this area is very guarded. Recently we have reported the synthesis of new mixed aza-thioether crowns containing the 1,10-phenanthroline (phen) unit as an integral part of the macrocyclic structure.[17−19] These ligands have shown a great affinity for heavier transition metal ions such as Pd^{II}, Pt^{II} and Rh^{III}, with coordination properties strictly dependent upon the conformational constraints imposed by the heteroaromatic moiety on the S-donor thioether linker of the ring. Herein we report a study by cyclic voltammetry of the assisted transfer of Rh^{III} by interfacial complexation with 2,5,8-trithia[9],(2,9)-1,10-phenanthrolinophane (L) at the polarised water/1,2-dichloroethane interface. The principal target of this work has been to study the coordination chemistry of L towards Rh^{III} at the water/1,2-dichloroethane junction; however, the results obtained could represent a useful start-

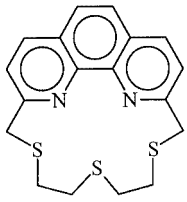
ing point for a novel way of approaching the problem of Rh^{III} separation and purification from aqueous solutions.



L

Results and Discussion

We reported previously[18] the reaction of L with $RhCl_3$ in refluxing MeCN/water to afford a yellow microcrystalline powder after addition of an excess of NH_4PF_6. The resulting complex was formulated as $[Rh(L)Cl][PF_6]_2 \cdot MeCN$ on the basis of elemental analysis data and IR and FAB mass spectrometry. ^{13}C NMR spectroscopic measurements in CD_3CN confirmed this formulation and indicated an octahedral stereochemistry at the Rh^{III} centre similar to that observed around Ni^{II} in $[Ni(L)Cl]^+$,[19] with all the five donor atoms of the macrocyclic ligand strongly coordinated and with a chloride completing the octahedral environment. After many attempts we have been able to grow crystals of $[Rh(L)Cl][BF_4]_2 \cdot 2MeCN$ suitable for X-ray diffraction studies by diffusion of Et_2O vapour into a MeCN solution of the complex. The structure determination confirms the rhodium(III) ion to be bound to the pentadentate macrocycle through two N-donors of the phen unit [Rh(1)−N: 2.001(3) and 1.996(3) Å] and three thioether S-donors of the thioether linker of the ligand [Rh(1)−S: 2.3361(9), 2.3219(9) (*trans* to phen) and 2.3033(9) Å (*trans* to Cl)] (Figure 1, Table 1). The octahedral coordination sphere is completed by a Cl^- ion [Rh(1)−Cl(1): 2.3456(8) Å]. The phenanthroline moiety and the two adjacent sulfur atoms S(1) and S(2) of the thioether linker lie approximately in an equatorial plane of the octahedron, with the third sulfur atom S(3) and the Cl^- ligand occupying the two apical positions [S(3)−Rh(1)−Cl(1): 178.10(3)°]. This structure demonstrates the ability of L to host the Rh^{III} ion within its ring cavity without any particular constraint of the organic framework; therefore, L is a possible candidate as a sequestering agent for the recovery of this precious metal ion from aqueous solutions.

In order to test the ability of L to assist the electrochemical extraction of Rh^{III} at the water/1,2-dichloroethane (1,2-DCE) polarised interface, we have made preliminary studies by cyclic voltammetry (CV) with an electrochemical cell as shown schematically below (Cell 1).

Cell 1

Ag	AgCl	NaCl (10 mM) NaTPB (10 mM) (H_2O)	L (0.025 mM) TOATPB (10 mM) (1,2-DCE)	$RhCl_3$ (2.8 mM) LiCl (10 mM) (H_2O)	AgCl	Ag

This type of cell has already been successfully employed to study the transfer of Cu^{II} assisted by 6,7-dimethyl-2,3-di(2-pyridyl)quinoxaline (DMDPQ),[20] and the transfer of Zn^{II}, Cd^{II} and Pb^{II} assisted by cyclic thioether ligands.[21] Previous work by Homolka,[22] Matsuda,[23] Kakiuchi and Senda,[24] and Reymond et al.[25,26] has provided a theoretical framework for the determination of parameters such as the complex stoichiometry involved in the transfer process. In the absence of L, there is no visible wave in the cyclic voltammogram within the potential window available, demonstrating the absence of any transfer process of Rh^{III} across the organic phase under these conditions (Figure 2a, dashed line). When the ligand L is present in the organic phase, the CV responses exhibit a well-defined single reversible wave (Figure 2a, full line) related to the transfer of an ionic species with $\Delta_o^w\phi_{1/2} = 30$ mV and a peak-to-peak separation of 60 mV; this is consistent with the assisted transfer of Rh^{III} by L across the water/1,2-dichloroethane interface. Measurement of the pH of the aqueous solution containing $RhCl_3$ (electrodic compartment on the right in cell 1) showed that the medium was acidic due to the hydrolysis of

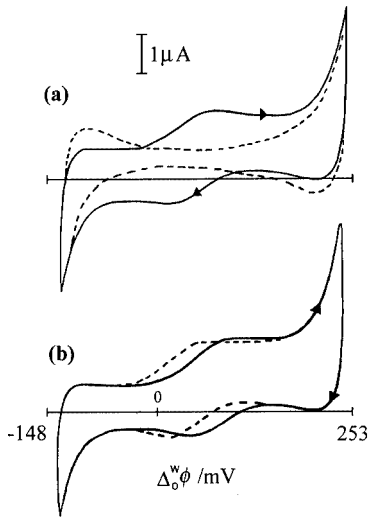

Figure 2. (a) Voltammetric responses in the absence (dashed line) and in the presence (full line) of L in the organic phase for the cell 1 system; (b) voltammetric responses for the cell 1 system in the case of acidic aqueous phase (dashed line) and neutralised aqueous phase by addition of LiOH (full line)

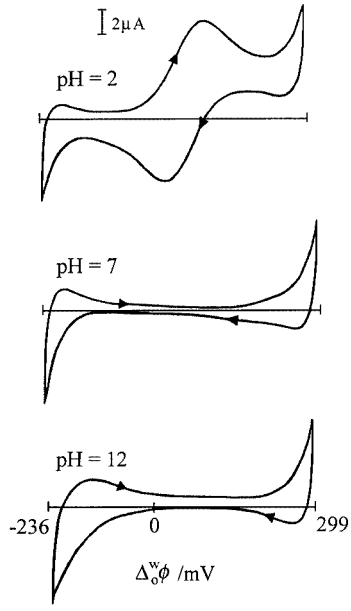

Figure 3. Voltammetric responses for the cell 2 system showing the effect of pH on the assisted transfer of H^+ by L across the water/1,2-DCE interface

Cell 2

X = HCl 10 mM (pH = 2); X = LiCl 10 mM (pH = 7); X = LiOH 10 mM + LiCl 10 mM (pH = 12)

Ag	AgCl	NaCl (10 mM) NaTPB (10 mM) (H_2O)	L (0.3 mM) TOATPB (10 mM) (1,2-DCE)		X (H_2O)	AgCl	Ag

Rh^{III} aquo/chloro complexes[7] and therefore the assisted transfer of H^+ by the ligand could also occur under these experimental conditions. The peak observed could then indicate either the facilitated transfer of the proton or the Rh^{III} ion by the ligand. In order to identify clearly the transfer of Rh^{III} assisted by L, LiOH was then added to the acidic aqueous phase containing Rh^{III} in order to neutralise it. The cyclic voltammogram recorded under neutral conditions resembles that obtained when the aqueous phase is acidic, with a single reversible wave observed at a slightly more positive $\Delta_o^w\phi_{1/2}$ (65 mV) with a peak-to-peak separation of 60 mV (Figure 2b).

We also decided to study the protonated ligand transfer across the water/1,2-DCE interface upon changing the pH of the aqueous phase. Figure 3 includes the voltammograms observed when the pH of the aqueous solution (electrodic compartment on the right in cell 2) changes from 2 to 12.

While a single well-defined peak appears in the voltammogram at pH 2, no transfer processes are observed at pH 7 and 12, indicating that the proton transfer facilitated by L across the water/1,2-DCE interface occurs only when acidic solutions are used. From the transfer potential at different pH of the aqueous phase, obtained by cyclic voltammetry using cell 2, an ionic partition diagram of the ligand was constructed as described by Reymond et al.[27] (Figure 4a). This diagram can be used to predict qualitatively the influence of the variation of the Galvani potential difference ($\Delta_o^w\phi_{1/2}$) and/or aqueous pH on the nature of the transferring species present at the water/1,2-DCE interface. Furthermore, the behaviour of the peak current on changing the pH of the aqueous phase in cell 2 (Figure 4b) allowed the assessment of the acidic constant (pK_a) in water for the ligand L, the value of which was estimated to be 4.3. This value is lower than those reported for 1,10-phenanthroline (pK_a = 4.97)[28] and 2,9-dimethyl-1,10-phenanthroline (pK_a = 5.85)[29] as determined potentiometrically in water solution. A direct pH-potentiometric determination of the pK_a of L was not possible because of the very low solubility of the ligand in water.

From these results it can be concluded that the rhodium(III)-assisted transfer by L at a polarised water/1,2-DCE interface is possible and that pH control of the aqueous phase is necessary to study the process.

The evaluation of the charge and stoichiometry of the complex involved in the transfer was carried out by studying the voltammetric behaviour of the transfer under neutral pH conditions for the aqueous phase, in the presence of excess metal with respect to the ligand in the organic phase. Cell 3 was used to carry out these studies: bis(triphenylphosphoranylidene)ammonium tetrakis(4-chlorophenyl)borate (BTPPATPBCl) was used as the organic electrolyte salt because it allows a larger potential window (and it has no effect on the voltammetric signal).

Figure 5a shows the change in mid-peak potential ($\Delta_o^w\phi_{1/2}$) when the concentration of excess metal is varied. From the slope of the line (-58 ± 6 mV) a charge of +1 for the complex is deduced.[20] The peak current (i_{pc}) is independent of the concentration of the metal. The effect on $\Delta_o^w\phi_{1/2}$ of the change of the concentration of the ligand (in the organic phase) in the presence of excess metal (in the aqueous phase) has also been monitored in order to

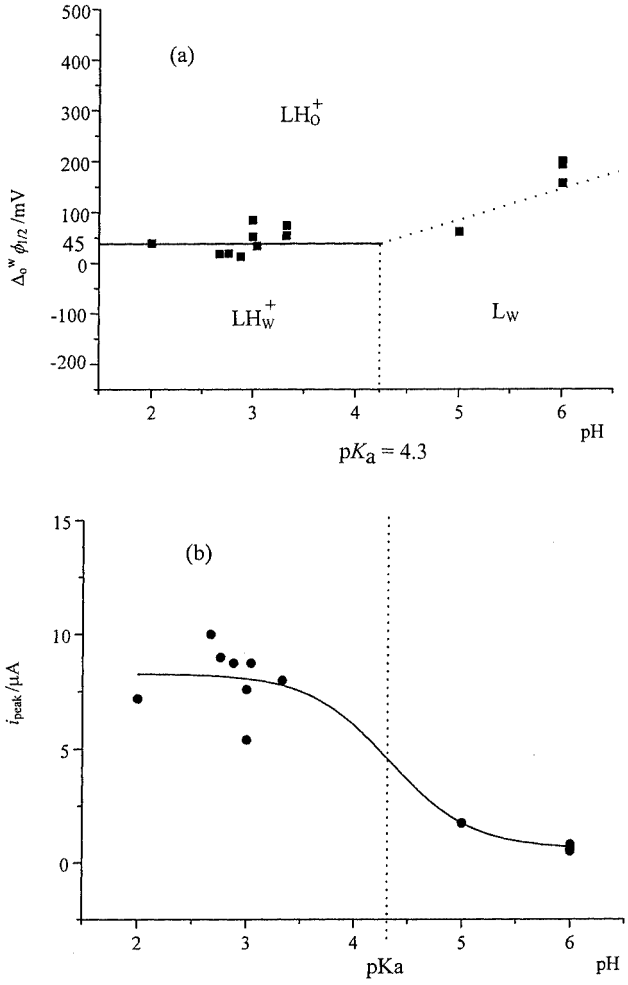

Figure 4. (a) Ionic partition diagram of L at room temperature; (b) change of the peak current upon variation of the pH of the aqueous phase in cell 2

Ag	AgCl	10 mM LiCl 1 mM BTPPACl (H_2O)	L 10 mM BTPPATPBCl (1,2-DCE)	$RhCl_3$ LiOH 10 mM LiCl (H_2O)	AgCl	Ag

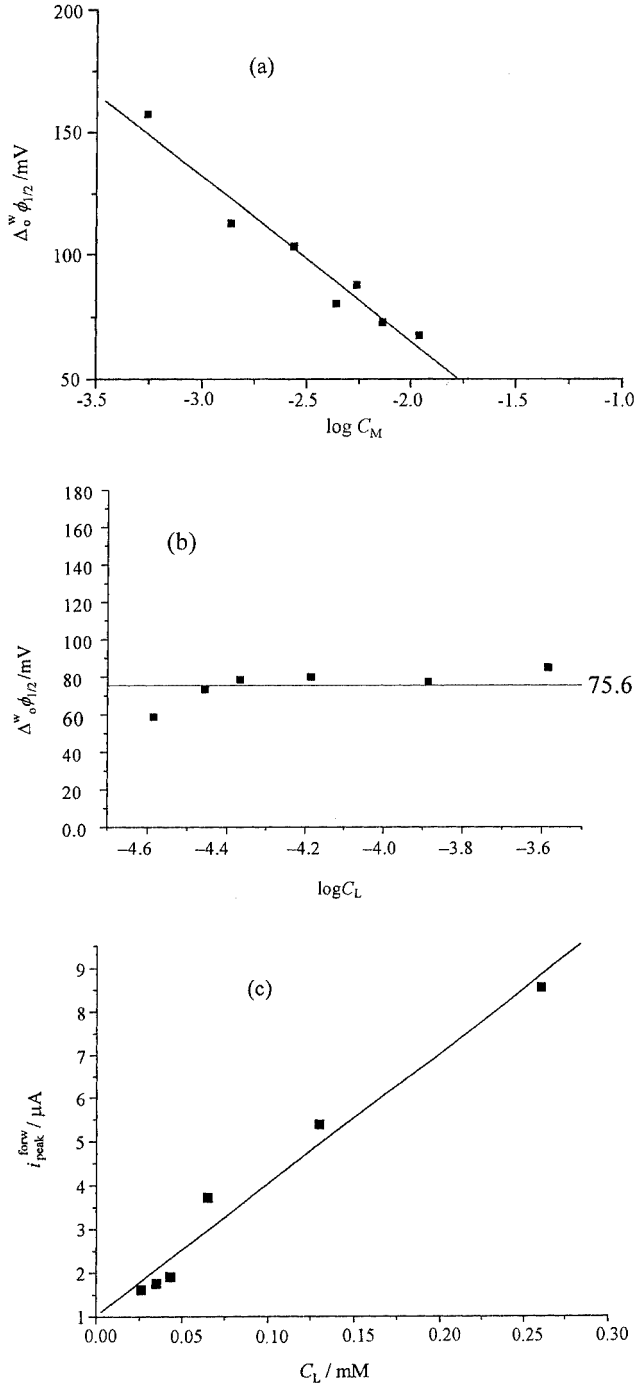

Figure 5. (a) Change in mid-peak transfer potential ($\Delta_o^w\phi_{1/2}$) when the concentration of excess metal in the aqueous phase is varied (log $C_L = -4$); (b) effect on $\Delta_o^w\phi_{1/2}$ of the change of the concentration of L in the organic phase in the presence of excess metal in the aqueous phase (log $C_M = -2.3$); (c) current forward peak intensity vs. the log of ligand concentration (C_L) (log $C_M = -2.3$, slope = 30 μA/mM); the system cell considered is cell 3

evaluate the stoichiometry of the complex.[20] Since there is no dependence of the half-wave transfer potential on log C_L (Figure 5b), according to Reymond et al.,[25,26] the stoichiometry of the complex must be 1:1. From the variation of the peak current intensity on changing the concentration of L on excess metal ion concentration (Figure 5c), and using the modified Randles−Sevcik expression,[26] it was possible to estimate the diffusion coefficient of the ligand in the organic phase (in fact, due to the metal excess, the current is limited by the diffusion of the ligand): $D_o = 5.1 \times 10^{-6}$ cm^2/s. This value is in good agreement with those reported in the literature for 1,10-phenanthroline (phen) and its bulky derivatives in 1,2-dichloroethane (D_o[phen] = 9.6×10^{-6}, D_o[4,7-diphenyl-phen] = 4.8×10^{-6} cm^2/s).[30]

As already pointed out, the studies reported so far have been conducted by cyclic voltammetry in cell 3, varying either the metal or the ligand concentration but keeping the metal-ion concentration in excess. If excess ligand is used and the metal concentration is varied, another voltammetric signal appears when $C_L > C_M$ (Figure 6), which can be assigned to the assisted transfer of a 1:2 Rh/L complex.

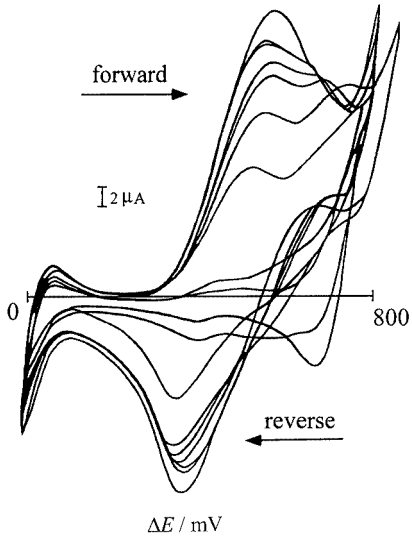

Figure 6. Cyclic voltammograms obtained for the Rh^{III} transfer assisted by L (C_L = 1.30 mM) for different metal concentrations (C_M ranging from 0.05 to 9.70 mM)

The plot of forward peak current (i_{pc}) vs. C_M for the voltammograms in Figure 6 clearly demonstrates the presence of a transition point between two limiting diffusion regimes (Figure 7). However, a study similar to that performed for the transfer of the 1:1 complex was not possible due to the poor definition of the two voltammetric signals.

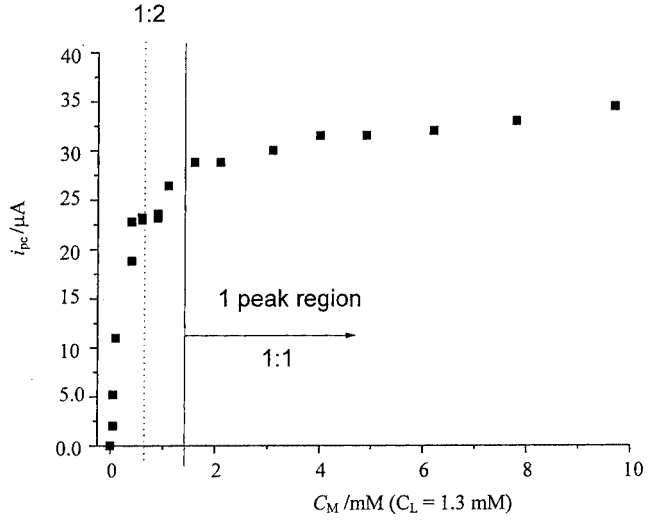

Figure 7. Plot of the forward peak current vs. C_M for the results in Figure 6

The 1:1 complex involved in the assisted transfer seems to have the formulation $[Rh(L)Cl_2]^+$. An analogous stoichiometry has been observed for the Rh^{III} complex with a structural analogue of L where S(3) (Figure 1) has been replaced by an oxygen atom. In this case, it has been shown by NMR spectroscopy that the O-donor of the ligand is not able to coordinate the octahedral metal centre and that the two chloride ligands are mutually *trans*.[31]

The unassisted transfer of Rh^{III} as $RhCl_2^+$ occurs at $\Delta_o^w\phi^{0'}$ $[RhCl_2]^+$ = 514 mV and was determined by applying the methodology proposed by Shao et al.[32] for determining the half-wave potential of the species limiting the potential window. The value of K_f^0, corresponding to the complexation of one $[RhCl_2]^+$ ion with one molecule of L, can therefore be estimated from the dependence of $\Delta_o^w\phi_{1/2}$ on the metal concentration (Figure 5a) using the methodology proposed by Reymond et al.,[26] which in the case of a metal ion excess is:

$$\Delta_o^w\phi_{1/2,ML_j^{z+}} = \Delta_o^w\phi^{0'}_{M^{z+}} - \frac{2.303RT}{zF}\log\left(\sum_{j=0}^{m} j\beta_j^0 C_{M_{init}}\left(\frac{C_{L_{init}}}{2}\right)^{j-1}\right)$$

For the case of a 1:1 complex between the $[RhCl_2]^+$ ion and L this expression can be rewritten as:

$$\Delta_o^w\phi_{1/2,ML^{z+}} = \Delta_o^w\phi^{0'}_{M^{z+}} - \frac{2.303RT}{zF}\log\left(\beta^0 C_{M_{init}}\right)$$

where j is the number of ligands in the complex, z the charge of the complex species involved in the assisted transfer, $\Delta_o^w\phi_{1/2,ML^{z+}_j}$ the half-wave Galvani potential for the transfer of the complex ML_j^{Z+}, $\Delta_o^w\phi^{0'}{}_M{}^{z+}$ the formal Galvani transfer potential for the metal ion, β_j^0 the stability constant for the complex ML_j^{z+}, and $C_{M_{init}}$, and $C_{L_{init}}$ the initial concentrations of metal ion and ligand, respectively. Taking $\Delta_o^w\phi^{0'}$ $[RhCl_2]^+$ to be 514 mV and using the intercept of Figure 5a (−69.7 mV), the value calculated for the formation constant of $[Rh(L)Cl_2]^+$ is $\log K_f^0$ = 9.7. This value, when compared with those obtained by cyclic voltammetry at the water/1,2-DCE interface for some 1:3 metal-phenanthroline complexes {$\log\beta_3^0$ $[Ca(phen)_3]^{2+}$ = 15.8, $\log\beta_3^0$ $[Sr(phen)_3]^{2+}$ =14.0},[33] clearly shows that, despite its steric hindrance, the thiacrown ring in L has an overall stabilising effect (in comparison with complexes having higher stoichiometries). This should be due to the donor properties of the S-donors in the ring.

Conclusions

The assisted transfer of Rh^{III} ion with 2,5,8-trithia[9],(2,9)-1,10-phenanthrolinophane (L) at the water/1,2-DCE interface has been demonstrated, thus pointing towards a new approach to the problem of separating Rh^{III} from chloride media. The nature of the Rh^{III} complex involved in the assisted transfer has been elucidated by cyclic voltammetry and it corresponds to the formulation $[Rh(L)Cl_2]^+$. This complex cation is different from that obtained by refluxing L with $RhCl_3$ in MeCN/water solution, which has the formulation $[Rh(L)Cl]^{2+}$, and has the same stoichiometry as the Rh^{III} complex obtained with a structural analogue of L having an O-donor instead of the S(3) atom.

Experimental Section

General Procedures and Chemicals: Cyclic voltammetry was performed using a four-electrode potentiostat (Solartron 1287) with ohmic drop compensation. The electrochemical cell was made from borosilicate glass and was of the same design as used previously;[21] with two Luggin reference probes and a geometrical area for the water/1,2-DCE interface of 0.22 cm^2. All the measurements were carried out at laboratory temperature (20 ± 3 °C), with scan rates ranging from 10 to 100 mV/s. For each experiment the addition of a fixed amount of ClO_4^- ($LiClO_4$ > 99.99% purity from Aldrich) provided a reference for all half-wave potential measurements The values measured were easily transposed to the Galvani potential scale taking into account the following relationship
$E_{1/2} - \Delta_o^w\phi^0 = E_{1/2}(ClO_4^-) - \Delta_o^w\phi^0(ClO_4^-)$
and the value of the transfer potential of perchlorate ion [$\Delta_o^w\phi^0(ClO_4^-) = -176$ mV].[34]

The organic electrolyte salts used in this study were tetraoctylammonium tetrakis(phenyl)borate (TOATPB), prepared as reported previously,[35] and bis(triphenylphosphoranylidene)ammonium tetrakis(4-chlorophenyl)borate (BTPPATPBCl), which was prepared by the metathesis of BTPPACl (Aldrich) and KTPBCl (Fluka). Rhodium(III) unassisted transfer in the absence of L was studied using 10 mM BTPPATPBCl as the supporting electrolyte in the organic phase. 2,5,8-Trithia[9],(2,9)-1,10-phenanthrolinophane (L) was synthesised according to the literature.[17] LiCl (>99% purity) and $RhCl_3 \cdot 3H_2O$ (38% Rh) were obtained from Merck. Aqueous solutions were prepared with purified water from Milli Q 185 system (Millipore). 1,2-Dichloroethane (1,2-DCE) (>99.5% purity, Merck) was used without further purification and was handled with all necessary precautions.

Crystal Structure Determination: Crystal data for $C_{22}H_{24}B_2ClF_8N_4RhS_3$, M = 752.61, orthorhombic, *Pccn*, a = 14.2317(13), b = 31.974(3), c = 12.4458(11) Å, V = 5663.4(9) $Å^3$, Mo-K_α radiation λ = 0.71073 Å, Z = 8, $D_{calcd.}$ = 1.765 g cm^{-3}, $F(000)$ = 3008. T = 150(2) K, μ(Mo-K_α) = 0.994 mm^{-1}. Yellow plate, 0.21 × 0.16 × 0.12 mm^3. Bruker SMART1000 CCD area detector diffractometer with Oxford Cryosystems open-flow cryostat,[36] ω scans, 6808 absorption-corrected reflections (SADABS,[37] T = 0.80−1.00), 5132 reflections with $I > 2\sigma(I)$. The structure was solved by direct methods using SHELXS-97[38] and full-matrix least-squares refinement on F^2 was performed using SHELXL-97.[39] All non-H atoms were refined anisotropically and H atoms were placed geometrically and thereafter allowed to ride on their parent atoms. One of the two BF_4^- anions exhibited disorder and the refinement was accomplished with restraints to the B−F distances and F−B−F angles, and to the total occupancy of the F atoms.

Control of Epoxidation Enantioselectivity by Axial Ligation in Manganese Chiroporphyrins with Diastereotopic Faces

Shu-Qing Liu,[a] Jacques Pécaut,[a] and Jean-Claude Marchon*[a]

Keywords: Porphyrins / Enantioselectivity / Ligand effects / Manganese

A manganese(III) chiroporphyrin with alternate pentafluorophenyl and chiral cyclopropyl meso-substituents in the αFαF conformation has been shown by X-ray crystallography to have its chloro axial ligand predominantly on the non-chiral β face. Epoxidation of 1,2-dihydronaphthalene by iodosylbenzene induced by the neat catalyst in dichloromethane solution shows a twofold increase in enantioselectivity relative to the same reaction in the presence of pyridine. These observations suggest that the location of the chloro ligand on the β face can block that face from participating in catalytic epoxidation, and direct the reaction to take place on the chiral α face.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Chiroporphyrins derived from (1*R*)-*cis*-hemicaronaldehydic acid (**1**) display an αβαβ conformation of the chiral *meso*-substituents which make their two faces equivalent.[1] Their manganese(III) complexes such as chloromanganese(III) tetramethylchiroporphyrin [MnCl(TMCP)] (**2**) are mild asymmetric catalysts in olefin epoxidation by iodosylbenzene, with *ee*'s in the range 60−86% for the epoxidation of 1,2-dihydronaphthalene.[2,3] With the aim of improving the reactivity of these catalysts, we have introduced electron-withdrawing pentafluorophenyl substituents in the two opposite *meso* positions.[4] We report here that the resulting chiroporphyrin free bases have a predominant conformation (labelled αFαF) in which two opposite chiral cyclopropyl substituents are located on the same face of the macrocycle (labelled α), leaving the other face (labelled β) devoid of stereogenic groups. The enantioselectivities of 1,2-dihydronaphthalene epoxidation induced by several catalysts of this type have been measured with or without added pyridine, and the results provide new insights into the stereochemistry of the active oxidant.

Results and Discussion

Methyl and benzyl esters were obtained by deprotonation of **1** with sodium hydride followed by nucleophilic attack on methyl iodide or benzyl iodide, respectively.[5] Mixed condensation of either aldehyde ester with pentafluorobenzaldehyde and pyrrole, catalysed by trifluoroacetic acid under standard reaction conditions,[6] afforded a mixture of porphyrins (Scheme 1) from which pure products could be isolated after several consecutive separations on TLC plates. Ten types of chiroporphyrin-free bases with mixed *meso*-substitution are expected in this case, of which seven were obtained in amounts sufficient for characterization by electrospray mass spectrometry and NMR spectroscopy. The stereochemistries of the seven compounds, depicted schematically in Scheme 2, were assigned on the basis of the observed ^{1}H and ^{13}C NMR spectral multiplicities. Among the chiroporphyrins with two pentafluorophenyl groups, those with identical orientations of the chiral substituents (αFαF and ααFF) were predominant for both ester derivatives (respective yields for H_2MeCP: 4% and 4%; respective yields for H_2BzCP: 0.2% and 0.2%). Compounds of the type αβFF and βαFF were obtained in minute amounts among the benzyl ester derivatives, but they could not be separated. The αFβF stereoisomer was obtained in 0.2% yield in the H_2BzCP mixture, but it was not detected in the H_2MeCP mixture. The αβαF chiroporphyrin was obtained in 3% yield among the methyl ester derivatives, but it was not detected among the benzyl ester derivatives. The chloromanganese(III) complexes shown in Figure 1 were obtained by standard metal insertion methods, and pure samples obtained by TLC were characterized by electrospray mass spectrometry and UV/Visible spectroscopy.

The X-ray structure of the catalyst [MnCl(αFαF)MeCP] (**3**) was solved, and a stick representation is shown in Figure 2. The porphyrin macrocycle of **3** is less ruffled than that of [MnCl(TMCP)] (**2**),[2] with average out-of-plane displacements of the C_{meso} atoms with respect to the 24-atom mean-planes of 0.43(1) Å for **3** and 0.73(1) Å for **2**, consistent with the absence of steric crowding on the β face of the former. The average $Mn-N_P$ bond length is therefore

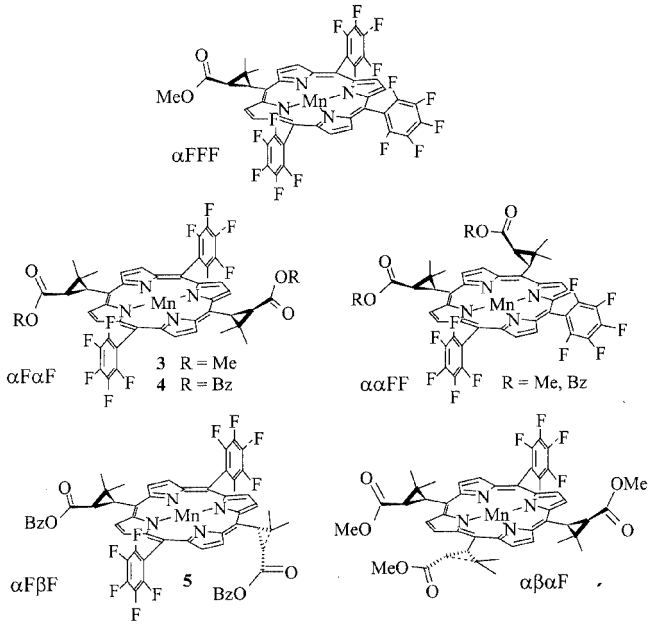

Figure 1. Stereochemistries of the five characterised types of chiroporphyrin catalysts with mixed substitution by pentafluorophenyl and chiral cyclopropyl groups

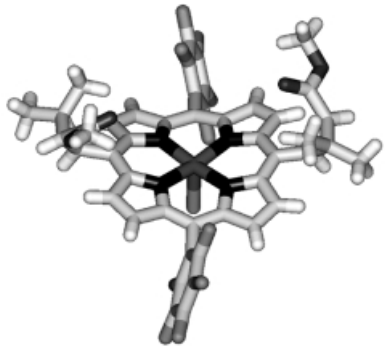

Figure 2. Stick representation of the structure of the major (90%) β-Cl conformer in the crystal lattice of [MnCl(αFαF)MeCP] (**3**), showing the moderate ruffling of the macrocycle; selected bond lengths (Å): [Mn−N_P] average 1.9972(7), Mn−Cl 2.3868(8); Mn is displaced from the porphyrin mean plane towards Cl by 0.14 Å; the C_{meso} atoms are displaced alternatively up [+0.46(1) Å] and down [−0.40(1) Å] with respect to the 24-atom mean plane

longer in **3** [1.9972(7) Å] than in **2** [1.974(2) Å], and the Mn−Cl bond length is also longer [2.3868(8) Å vs. 2.3475(9) Å]. The manganese atom of **3** is slightly displaced from the porphyrin mean plane by 0.14 Å (as compared to 0.44 Å in **2**). There is a small disorder of the chloro ligand of **3**, which is predominantly (ca. 90%) located on the open β face as shown in Figure 2 (β-Cl conformer). The presence of a small amount of α-Cl conformer in the samples of **3** (ca. 10% as indicated by the crystallographic disorder model) was confirmed by TLC on silica gel, which showed a minor, more polar spot very close to the major spot, and inseparable from it. The conformer composition of the chloromanganese(III) complex derived from the analogous benzyl ester derivative {noted [MnCl(αFαF)BzCP] (**4**)} has not been determined.

Asymmetric epoxidation of 1,2-dihydronaphthalene by iodosylbenzene with **3** as catalyst was faster than with the first-generation chiroporphyrin catalysts[3] and gave improved product yields. For example, epoxide yields obtained with **3** under our standard conditions with pyridine co-catalyst reached 96% after only 15 min, as compared to 83% after 60 min for **2** (Table 1). On the other hand, the *ee* lagged below 20% for **3**, as compared to 60% for **2**, indicating that epoxidation takes place at a significant rate on the non-chiral β face of **3**. Bulky bases such as 4-*tert*-butylpyridine, 1-(*tert*-butyldimethylsilyl)imidazole, 1,5-dicyclohexylimidazole, or diazabicyclo[2.2.2]octane had a similar effect to that of pyridine (Table 1). These observations led us to exclude the nitrogen bases and to use the neat chloromanganese(III) complexes **3** and **4** as catalysts. A remarkable improvement of the *ee* (which more than doubled from 18% to 43% for **3**, and from 17% to 35% for **4**) was obtained,

without affecting much the reaction rates and product yields, which remained satisfactory (Table 1).

Table 1. Catalytic asymmetric epoxidation of 1,2-dihydronaphthalene with manganese chiroporphyrins **3**−**5**

Axial ligand[a]	Epoxide yield (%)[b] [c]				*ee* (%, 60 min)[d]
	5 min	15 min	30 min	60 min	
	[MnCl(αFαF)MeCP] (**3**)				
py	62	96	>99	>99	18

[a] Axial ligands: py = pyridine; bp = 4-*tert*-butylpyridine; bsi = 1-(*tert*-butyldimethylsilyl)imidazole; dci = 1,5-dicyclohexylimidazole; dabco = 1,4-diazabicyclo[2.2.2]octane. [b] Reactions conditions: 1.0 μmol of catalyst, 100 μmol of iodosylbenzene, 250 μmol (or none) of axial ligand, and 1.00 mmol of 1,2-dihydronaphthalene in 2 mL of CH_2Cl_2, 1 h. [c] Based upon iodosylbenzene and determined by GC analysis with 20 μL of *n*-tridecane as internal standard. [d] Determined by GC (Cyclodex-B chiral capillary column). The major enantiomer had 1*S*,2*R* absolute configuration in all cases.

The detrimental effect of pyridine on enantioselectivity in this system is unexpected, since in most previous investigations the *ee* increases upon addition of a nitrogen base. A complete understanding of this effect is difficult because the nature of the active catalyst in the presence of pyridine, and that of the active oxidant, have never been established.[7,8] However, our results are consistent with a simple mechanism in which the presence of the chloro ligand on the β face favours the binding of added ligands on the vacant site of the α face. Pyridine binding on the chiral α face would, in turn, direct the formation of the active oxidant on the non-chiral β face, resulting in a poor *ee*, while iodosylbenzene binding on the α face in the absence of pyridine would generate the active oxidant on that same face and induce a good enantioselectivity. A rough calculation based on potential *ee* values of 60% for the α face (similar to that of **2**) and of 0% for the β face, and assuming equal reactivities on both faces, gives an overall *ee* value of about 50% for the mixture of conformers of **3** in a 90:10 β-Cl:α-Cl ratio. The reasonable agreement with the observed *ee* suggests that **2** and the β-Cl conformer of **3** have similar enantioselectivities.

Conclusion

In summary, although several elaborate synthetic routes to A_2B_2 porphyrins are available,[9] cross condensation is an expedient method to obtain the free-base precursors of active chiroporphyrin catalysts for a quick screening of their *ee*'s in a combinatorial sense. The two diastereotopic faces of a chiroporphyrin with mixed *meso*-substitution by pentafluorophenyl and chiral cyclopropyl groups in an αFαF conformation have widely different potential for enantiocontrol. The preference of the chloro ligand of manganese for the β face devoid of stereogenic groups in **3** directs the formation of the active oxo species on the α face and allows enantioselective olefin epoxidation. The electrophilicity of **3** allows the catalytic epoxidation to be carried out without exogenous ligand such as pyridine, which is advantageous since the latter can be a competitive substrate.[7]

Experimental Section

General Remarks: Solvents and chemicals were used without purification unless indicated. Dichloromethane was stabilized by ethanol (ACS for analysis, C_2H_5OH 0.1%). Pyrrole was purified by filtration through alumina before use. The methyl and benzyl esters of **1** (biocartol esters) were prepared according to previously published procedures.[1] Thin-layer chromatography was performed using Merck precoated silica plates 60F-254. Silica gel (230−400 mesh) and alumina (neutral, act. I) were used for column chromatography.

Spectroscopy: UV/Visible spectra were recorded on a Perkin−Elmer Lambda 9 instrument. Nuclear magnetic resonance spectra were obtained with Bruker AC 200, or Varian Avance 400 and 500 instruments. Spectra are tabulated in the following order: chemical shift (δ values), multiplicity (s = singlet, d = doublet, t = triplet, m = multiplet, br = broad singlet), number of protons, assignment [CH_{aro} (aromatic proton or carbon), $C_{aro\text{-}F}$ (pentafluorophenyl carbon), H_β (β pyrrolic protons of chiroporphyrins), C_α and C_β (α and β pyrrolic carbon of chiroporphyrins), C_{meso} (meso carbon of chiroporphyrins)]. The δ values of the C atoms connected to F atoms are not reported in the ^{13}C NMR spectra for some porphyrins because of high coupling constants.[10] Mass spectra were determined in the electrospray mode on a Finnigan MATLCQ instrument.

Typical Procedure For the Synthesis of Free Base Porphyrins: A 2.5 L commercial brown bottle filled with CH_2Cl_2 (containing 0.1% ethanol), equipped with a gas inlet, and shielded from ambient light by aluminium foil, was purged with argon for one hour. The flask was then charged with 6.4 mmol of biocartol methyl or benzyl ester, 6.4 mmol of pentafluorobenzaldehyde, and 15.4 mmol (1.2 equiv. relative to total aldehyde) of pyrrole under argon, followed 10 minutes later by the addition of 15.4 mmol (1.2 equiv.) of TFA. The resulting mixture was stirred at room temperature under gentle argon flow for 3 days. After this time, 12.8 mmol (1 equiv.) of DDQ was added to the reaction mixture which was stirred at room temperature for 4 hours. The solvents were then evaporated to dryness. The residue was chromatographed on alumina (neutral, act. I), eluting with CH_2Cl_2 containing 2% methanol under UV/Visible spectroscopic control, to afford a mixture of porphyrins. Pure compounds were obtained by preparative chromatography on successive TLC plates.

Selected Spectroscopic Data for H_2(αFαF)MeCP: ES-MS: *m*/*z* = 895.2 (calcd. 895.8 for [MH^+]). UV/Vis (CH_2Cl_2): λ_{max} = 421 nm, 519, 551, 595, 652. ^1H NMR (400 MHz, $CDCl_3$): δ = −2.26 (br, 1 H, NH), 0.99 (s, 6 H, CH_3i), 1.95 (s, 6 H, CH_3e), 2.85 [d, 2 H,

Facile Oxidative Addition of C−Cl Bonds to New Neutral and Cationic Rhodium(I)-Bipyridine Complexes

Reto Dorta,[a] Linda J. W. Shimon,[b] Haim Rozenberg,[b] and David Milstein*[a]

Keywords: Rhodium / N ligands / Oxidative addition / Peroxo complexes

Neutral and cationic Rh(dmbpy) systems (dmbpy = 4,4′-dimethyl-2,2′-bipyridine) were synthesized starting from different metal precursors. [RhCl(dmbpy)(DMSO)] (**3**) was obtained either from the ethylene precursor [RhCl(dmbpy)(C_2H_4)] (**1**) or directly from [$Rh_2Cl_2(COE)_4$] (COE = cyclooctene) in DMSO. The neutral isocyanide complex [RhCl(dmbpy){CNC(CH_3)$_3$}] (**4**) was obtained by reaction of **1** with *tert*-butyl isocyanide. Reaction of dmbpy with [Rh(DMSO)$_4$]PF_6 gave the corresponding cationic complex [Rh(dmbpy)(DMSO)$_2$]PF_6 (**5**), and the cationic system [Rh(dmbpy){CNC(CH_3)$_3$}$_2$]BF_4 (**6**) was prepared starting from [Rh(dmbpy)(HD)]BF_4 (**2**) (HD = 1,5-hexadiene). All of these complexes were found to activate the C–Cl bond in benzyl chloride leading to quantitative isolation of the corresponding Rh^{III} complexes [$RhCl_2$($CH_2C_6H_5$)(dmbpy)(DMSO)] (**7**), [$RhCl_2$($CH_2C_6H_5$)(dmbpy){CNC(CH_3)$_3$}] (**9**) [RhCl(CH_2-C_6H_5)(dmbpy)(DMSO)$_2$]PF_6 (**10**) and [RhCl($CH_2C_6H_5$)-(dmbpy){CNC(CH_3)$_3$}$_2$]BF_4 (**12**). Oxidative addition of dichloromethane by complexes **3** and **5** yielded the corresponding chloromethyl complexes [$RhCl_2$(CH_2Cl)(dmbpy)(DMSO)] (**8**) and [RhCl(CH_2Cl)(dmbpy)(DMSO)$_2$]PF_6 (**11**). The reactivity of **3** towards oxygen led to the isolation of the peroxo Rh^{III} complex [RhCl(O_2)(dmbpy)(DMSO)] (**13**). Complexes **6**, **8**, **9** and **12** were characterized by X-ray crystallography.

Introduction

The use of transition metal catalysts that employ nitrogen-donor ligands is expanding rapidly.[1] The most widely used nitrogen ligand is the bidentate 2,2′-bipyridine unit.[2] Rh^I-bipyridine systems and closely related derivatives have been extensively investigated as catalysts in the hydrogenation and hydrogen-transfer reactions of olefins and ketones.[3] In this context, the cationic complex [Rh(bpy)(L)$_2$]X (X = PF_6^-, BF_4^-, ClO_4^-; bpy = 2,2′-bipyridine, L = acetone) is believed to be the active species in the hydrogenation of olefins.[4] Such complexes with labile additional ligands have never been isolated, the only known complexes of this type being with L = CO,[5] or with chelating ligands such as dienes[6] or bipyridine.[7] Furthermore, oxidative addition to neutral or cationic precursors of this type has never been studied in detail, the only example reported involving oxidative addition of methyl iodide to [Rh(bpy)(CO)X] (X = Cl, Br, I; bpy = 2,2′-bipyridine).[8]

The oxidative addition of carbon halides to low-valent metal complexes is involved in numerous industrially important catalytic cycles and has therefore attracted considerable academic interest. Of particular interest is the activation of the relatively inert C−Cl bond, which is more challenging than that of the C−Br and C−I bonds. Oxidative addition of C−Cl bonds, especially of dichloromethane, requires an electron-rich rhodium center. Relatively few examples of simple oxidative addition of dichloromethane to Rh^I complexes have been reported. These systems incorporate mono- or polydentate phosphorous ligands,[9−11] mono- or polydentate nitrogen ligands,[12−14] sulfur macrocycles[15] or phosphorous-nitrogen hybrid ligands,[16−18] and in several cases the starting Rh^I species were not isolated.[12,14,17,18]

Herein we report the synthesis, characterization and oxidative addition chemistry of new Rh^I complexes with the bidentate ligand 4,4′-dimethyl-2,2′-bipyridine (dmbpy).[19] The nucleophilicity of the Rh^I can be controlled by the choice of the additional ligands. We chose the loosely bound DMSO ligand and the relatively strongly bound *tert*-butyl isocyanide ligand for our study. The oxidative addition of dichloromethane at room temperature takes place in the complexes stabilized by additional DMSO ligands. Oxidative addition of the C−Cl bond of benzyl chloride is observed in all of these complexes. Reaction of the neutral Rh^I-(dmbpy)-DMSO complex with O_2 leads to the isolation of a stable peroxo-Rh^{III} compound.

Results and Discussion

Synthesis of the Rh^I-dmbpy Complexes

The new complexes **1**−**6** were prepared from different precursors. The preparation of **1** was achieved following a

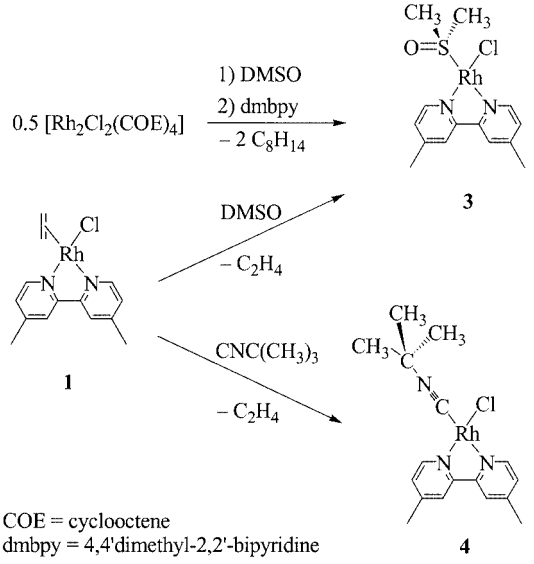
[b] Department of Chemical Services, The Weizmann Institute of Science,
Rehovot, 76100, Israel

literature method published for the corresponding 2,2′-bipyridine complex.[20] Complex **1** was found to be moderately stable in a dichloromethane solution but decomposed immediately when dissolved in either acetonitrile, pyridine or methanol. Surprisingly, dissolution of **1** in DMSO resulted in quantitative formation of **3**, which was isolated by pouring the concentrated DMSO solution into a large excess of diethyl ether. Direct synthesis of **3** was achieved by treating a DMSO solution of the rhodium dimer $[Rh_2Cl_2(COE)_4]$ (COE = cyclooctene) with an equimolar amount of 4,4′-dimethyl-2,2′-bipyridine. Subsequent precipitation from diethyl ether gave **3** as a brick-red solid in high yield (Scheme 1).



Scheme 1. Synthesis of the neutral Rh^I complexes **3** and **4**

The ^1H NMR spectrum of **3** showed six resonances in the aromatic region attributable to the nonequivalent parts of the ligand unit, one singlet at δ = 3.19 ppm for the coordinated DMSO (bound through the sulfur atom) and two singlets for the methyl groups of dmbpy at δ = 2.31 and 2.51 ppm . The corresponding neutral isocyanide complex **4** was synthesized in high yield by treating a suspension of **1** in THF with 1 equiv. of *tert*-butyl isocyanide as shown in Scheme 1. Starting with **3** and treating it with 1 equiv. of *tert*-butyl isocyanide led to a mixture of products. One of the by-products was isolated by precipitation from the solution mixture and identified by ^1H NMR spectroscopy to be the symmetrical species $[Rh(dmbpy)\{CNC(CH_3)_3\}_2]Cl$. This indicates that displacement of the DMSO molecule in **3** is much slower than that of ethylene leading to the displacement of the chloride and the formation of the more stable bis-isocyanide species. The ^1H NMR spectrum of **4** showed the expected peaks for the nonsymmetrical dmbpy ligand and a singlet at δ = 1.53 ppm for the coordinated *tert*-butyl isocyanide.

The corresponding cationic complexes, **5** and **6**, respectively, were also synthesized (Scheme 2). Compound **5** was obtained as a red solid after addition of dmbpy to a DMSO solution containing $[Rh(DMSO)_4]PF_6$.[21] As expected, the ^1H NMR spectrum in $[D_6]$DMSO showed only three peaks in the aromatic region for the ligand and one singlet for the two methyl groups of dmbpy. Complex **6** was obtained by treating a THF slurry of $[Rh(dmbpy)(HD)]BF_4$ (**2**) (HD = 1,5-hexadiene) with 2 equiv. of *tert*-butyl isocyanide. After precipitation from pentane, **6** was obtained as a deep-red solid. FT-IR spectroscopy, ^1H NMR spectroscopy and elemental analysis support its formulation, and the molecular structure of **6** was confirmed by an X-ray diffraction study of red single crystals obtained by slow evaporation of an acetone solution. An ORTEP drawing is shown in Figure 1 and the averages of selected bond lengths and angles are given in Table 1. The rhodium atom of complex **6** is located in the center of a square planar arrangement with the two

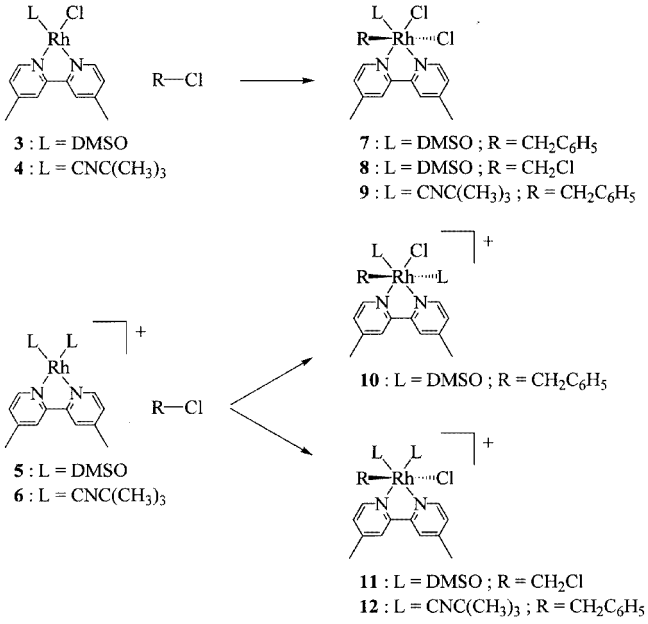
isocyanide ligands *trans* to the corresponding pyridine moieties of dmbpy.

Oxidative Addition of C−Cl Bonds

When an acetone or DMSO solution of **3** was treated with benzyl chloride, an immediate color change from deep red to yellow took place. The ^{1}H NMR spectrum showed clean oxidative addition of the C−Cl bond, and subsequent workup of the yellow solution gave complex **7** in high yield (Scheme 3). The benzylic CH_2 group is seen as two nonequivalent proton signals showing couplings with each other (6.8 Hz) and with the rhodium metal center (3.1 Hz). In the case of dichloromethane, oxidative addition was, as expected, much slower and took 15 h for completion, giving complex **8** in quantitative yield. Following the process by ^{1}H NMR spectroscopy showed the appearance of two signals at δ = 4.31 ppm (dd, J = 5.7, 3.0 Hz) and δ = 4.75 ppm (dd, J = 5.7, 3.0 Hz) for the CH_2Cl unit (Figure 2) together with a new set of peaks for the dmbpy unit. When the reaction was performed in [D_6]DMSO, minor amounts



Scheme 3. Reaction of the Rh^{I} complexes **3**−**6** with R−Cl to yield the Rh^{III} complexes **7**−**12**

(<10% by integration) of an isomeric species were also present. In this case, the ligand seems to be symmetrical with three signals in the aromatic region and one singlet for the methyl group of dmbpy. The chloromethyl moiety gives rise to one doublet at δ = 5.05 ppm (d, J = 3.1 Hz). These data indicate a species with the two chloride ligands *trans* to the

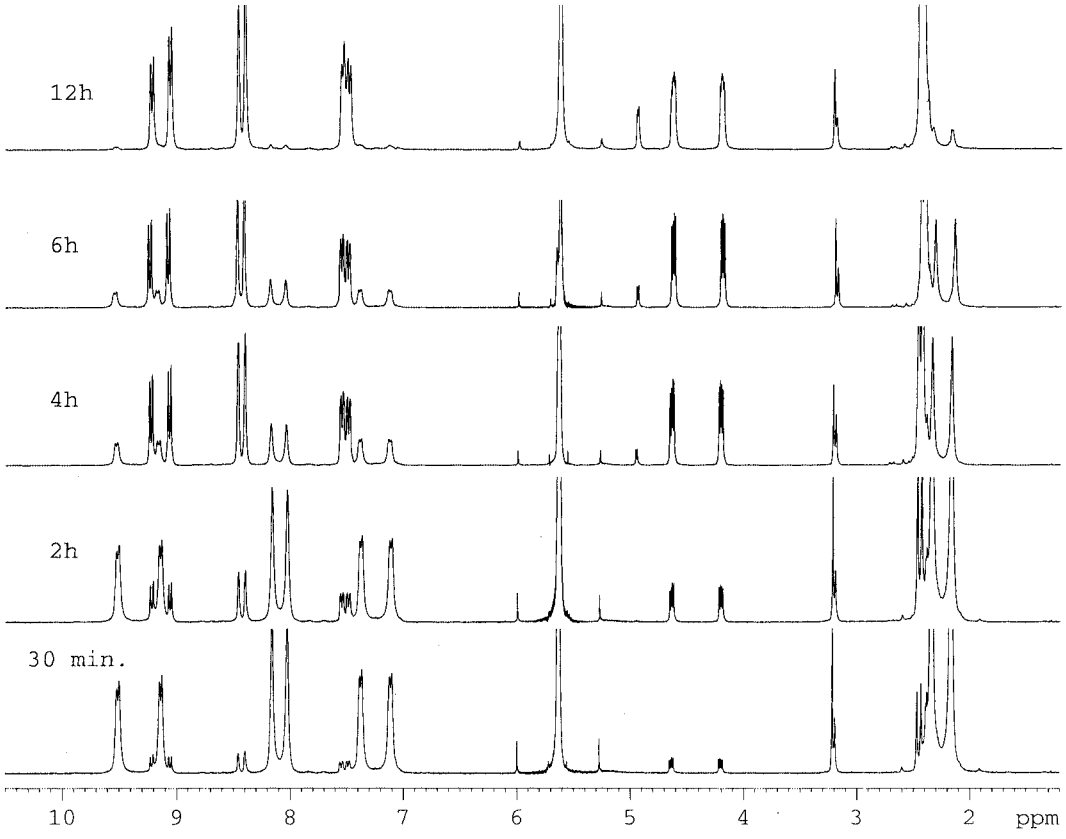


Figure 2. ^{1}H NMR follow-up experiment of the reaction between **3** and dichloromethane in [D_6]DMSO

bipyridine moiety and with the chloromethyl group and the DMSO ligand axially arranged. This compound could be removed during workup due to its higher solubility in diethyl ether. It was not observed when the reaction was performed in acetone. Trying to obtain this compound in pure form, an NMR tube sample of **8** in [D_6]DMSO was heated at 80 °C for 2 h. Indeed, the ^{1}H NMR spectrum showed 30% of this compound compared to **8** was formed.[22] Colorless single crystals of **8** suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into a concentrated DMSO solution. The geometry around the rhodium atom in this complex is distorted octahedral (Figure 3). In the equatorial plane, a chloride atom, the two N atoms of dmbpy and the S atom of DMSO are coordinated to the rhodium atom. The chloromethyl ligand and the second chloride atom occupy the axial positions. As expected, the two chloride atoms show quite different bond lengths to rhodium, the one *trans* to the N atom being significantly shorter than the chloride *trans* to the chloromethyl moiety [Rh(1)−Cl(3) = 2.3528(7) and Rh(1)−Cl(3) = 2.4891(7)] (Table 2). The Rh(1)−C(4) distance of 2.046(2) Å is very close to the value reported recently for [$RhCl_2(CH_2Cl)$\{2,6-(CH=N*i*Pr)$_2$-C_5H_3N\}].[13] The C(4)−Cl(4) bond length of 1.811(3) Å is longer than those found for other metal chloromethyl complexes, indicating a slightly higher carbene character of **8** ($Rh=CH_2^+Cl^-$).

The reactivity of the corresponding *tert*-butyl isocyanide complex **4** towards C−Cl bonds was checked next. As expected, complex **4** is much less reactive due to significantly higher backbonding from the rhodium center to the *tert*-butyl isocyanide ligand and the resulting lower nucleophilicity of the metal center. Treating a deep-red acetone solution of **4** with benzyl chloride for 12 h at room temperature led to a color change to yellow. The ^{1}H NMR spectrum showed that clean oxidative addition took place also in this case, leading to quantitative isolation of complex **9**. In contrast, oxidative addition of dichloromethane to complex **4** did not occur at room temperature. Even after stirring a solution of **4** with excess CH_2Cl_2 for several days the starting complex was recovered unchanged. The crystal structure of [$RhCl_2(CH_2C_6H_5)$(dmbpy)\{$CNC(CH_3)_3$\}] (**9**) has been determined (Figure 4) and found to adopt an octahedral geometry. In the equatorial plane, the rhodium center is bound to the dmbpy, the *tert*-butyl isocyanide and to one of the chloride atoms. The benzylic moiety together with the second chloride atom adopt the apical positions. As in the case of **8**, the Rh−Cl bond length of the chloride *trans* to the pyridine of dmbpy is significantly shorter than the one *trans* to the benzyl moiety [Rh(1)−Cl(3) = 2.3573(10) and Rh(1)−Cl(2) = 2.5391(9), respectively] (Table 3).

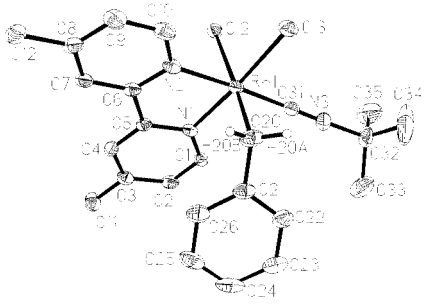

Figure 4. ORTEP drawing of a molecule of **9** (50% of probability); hydrogen atoms (except Rh−Ch_2R) are omitted for clarity

The cationic complexes **5** and **6** also undergo oxidative addition of the C−Cl bond of benzyl chloride (Scheme 3). In both cases, oxidative addition occurred somewhat slower than for the corresponding neutral complexes, leading to the cationic Rh^{III} complexes **10** and **12**, respectively. Surprisingly, the benzyl methylene group in **10** shows formation of the asymmetrical species with one DMSO molecule *trans* to the benzyl methylene, giving rise to two doublets of doublets for the methylene group. Oxidative addition to complex **6** does lead to the expected symmetrical species with the methylene group appearing as one doublet at δ = 3.12 ppm, the doublet signal arising from coupling to the

rhodium center. Slow diffusion of diethyl ether into an acetone solution of **12** led to colorless crystals suitable for X-ray diffraction. As shown in Figure 5, compound **12** adopts the expected octahedral arrangement around the metal center. The bond lengths between the rhodium atom and the *tert*-butyl isocyanide and dmbpy ligands are very close to the values observed in the starting complex **6** with marginally longer Rh(1)−C(40) and Rh(1)−C(30) bond lengths (Table 4). As observed in the neutral systems, also in the cationic case the DMSO stabilized complex **5** oxidatively added dichloromethane due to its higher nucleophilicity. Reaction of **5** with excess CH_2Cl_2 resulted in a gradual color change from deep-red to yellow when left standing at room temperature for two days and gave the symmetrical complex **11** in high yield (Scheme 3).

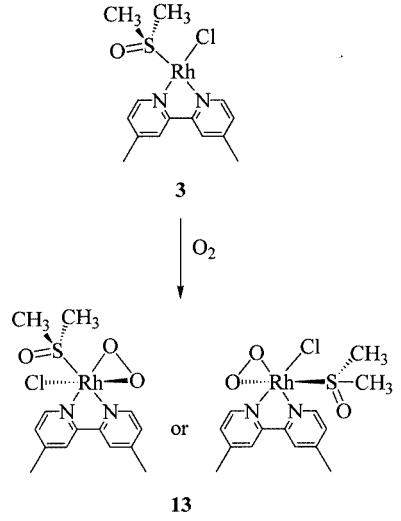
Oxidative Addition of Oxygen to 3

When a deep-red DMSO or acetone solution of **3** was treated with 1 equiv. or excess O_2, an immediate color change to yellow occurred. The product was identified as being the peroxo complex $[RhCl_2(O_2)(dmbpy)(DMSO)]$ (**13**) based on elemental analysis and the appearance of an IR band at $\tilde{\nu} = 870\ cm^{-1}$ for the peroxo ligand (Scheme 4). The ^1H NMR spectrum showed shifts for all the protons relative to the peaks observed for the starting complex **3**. As expected, the biggest difference is seen in one of the protons in the α-position to the nitrogen of the dmbpy ligand, the pyridine moiety being substantially more shielded by the presence of the oxygen atom *trans* to it. However, we could not determine whether the DMSO ligand or the chloride occupy the position *trans* to the second oxygen atom. With respect to the properties of **13**, we should note that O_2 is bonded strongly and did not dissociate under vacuum or by bubbling N_2 through a solution of **13**.[23] Complexes **4** and **5** also add oxygen and a detailed investigation of the reactivity of these complexes will be published in due course.



Scheme 4. Reaction of complex **3** with O_2 giving the peroxo complex **13**

Summary

New neutral and cationic rhodium complexes bearing the chelating 4,4′-dimethyl-2,2′-bipyridine (dmbpy) ligand and additional DMSO or *tert*-butyl isocyanide ligands were synthesized in high yield starting from various Rh^I precursors. These complexes underwent oxidative addition of the C−Cl bond of benzyl chloride at room temperature. The complexes bearing the additional DMSO ligands were shown to be more nucleophilic at the rhodium center and underwent C−Cl oxidative addition of dichloromethane. In addition, the oxidative addition of O_2 to one of the Rh^I complexes led to the quantitative isolation of a stable Rh^{III} peroxo species.

Experimental Section

General Procedures: All experiments were carried out under an atmosphere of purified nitrogen in a Vacuum Atmospheres glove box equipped with a MO 40-2 inert gas purifier. All solvents were reagent grade or better. All non-deuterated solvents were refluxed over sodium/benzophenone ketyl and distilled under argon atmosphere. Deuterated solvents were used as received. All the solvents were degassed with argon and kept in the glove box over molecular sieves. Commercially available reagents were used as received. The complexes $[Rh_2Cl_2(COE)_4]$,[24] $[Rh_2Cl_2(C_2H_4)_4]$,[25] and $[Rh(DMSO)_4]PF_6$ [21] were prepared according to literature procedures.

^1H NMR spectra were recorded at 250 MHz on a Bruker AMX-250 NMR spectrometer or on a Bruker AMX-400 NMR spectro-

meter. Chemical shifts are reported in ppm downfield from tetramethylsilane and are referenced to the residual hydrogen signal of the deuterated solvents (δ = 2.04 ppm, acetone; δ = 2.49 ppm, DMSO; δ = 5.32 ppm, dichloromethane). Abbreviations used in the description of NMR spectroscopic data are as follows: br., broad; s, singlet; d, doublet; t, triplet; m, multiplet. Elemental analyses were performed by H. Kolbe, Mikroanalytisches Laboratorium, 45470 Mülheim, Germany.

Synthesis of [RhCl(dmbpy)(C_2H_4)] (1): [$Rh_2Cl_2(C_2H_4)_4$] (241 mg, 0.620 mmol) was dissolved in toluene (35 mL) and filtered, affording an orange solution. 4,4′-dimethyl-2,2′-bipyridine (205 mg, 1.115 mmol) was dissolved in toluene (8 mL) and added dropwise. The color of the solution turned from orange to violet. Stirring at room temperature for 2 h resulted in the formation of a violet precipitate which was filtered off, washed with toluene and dried in vacuo. Yield: 346 mg, 89%. ^{1}H NMR (250 MHz, CD_2Cl_2, 298 K): δ = 2.27 (s, 3 H), 2.53 (s, 3 H), 3.62 (s, 4 H), 7.00 (d, *J* = 5.1 Hz, 1 H), 7.21 (d, *J* = 5.9 Hz, 1 H), 7.39 (d, *J* = 5.6 Hz, 1 H), 7.63 (s, 1 H), 7.84 (s, 1 H), 9.06 (d, *J* = 5.6 Hz, 1 H) ppm. $C_{14}H_{16}ClN_2Rh$ (350.7): C 47.95, H 4.60, N 7.99; found C 47.99, H 4.78, N 7.78.

Synthesis of [Rh(dmbpy)(HD)]BF_4 (2): A suspension of [$Rh_2Cl_2(COE)_4$] (140 mg, 0.196 mmol) in MeOH (7 mL) was treated with excess 1,5-hexadiene (1.1 mL) and the yellow suspension was stirred at room temperature for 1.5 h. Addition of a solution of 4,4′-dimethyl-2,2′-bipyridine (72 mg, 0.392 mmol) in dichloromethane (4 mL) resulted in a color change to deep red. After stirring the solution at room temperature for 1 h, a solution of $AgBF_4$ (76 mg, 0.392 mmol) in dichloromethane (4 mL) was added dropwise and the solution was stirred at room temperature for another hour. Filtration, followed by concentration of the red solution to 6 mL and addition of diethyl ether led to the precipitation of a red solid which was filtered, washed with additional diethyl ether and dried in vacuo. Yield: 173 mg, 97%. ^{1}H NMR (250 MHz, CD_2Cl_2, 298 K): δ = 1.94 (m, 2 H), 2.54 (m, 2 H), 2.61 (s, 6 H), 3.00 (d, *J* = 13.9 Hz, 2 H), 3.59 (d, *J* = 7.7 Hz, 2 H), 4.78 (m, 2 H), 7.47 (d, *J* = 5.7 Hz, 2 H), 7.66 (d, *J* = 5.8 Hz, 2 H), 8.15 (s, 2 H) ppm. $C_{18}H_{22}BF_4N_2Rh$ (456.1): C 47.40, H 4.87, N 6.14; found C 47.36, H 4.79, N 6.08.

Synthesis of [RhCl(dmbpy)(DMSO)] (3): [$Rh_2Cl_2(COE)_4$] (494 mg, 0.692 mmol, COE = cyclooctene) was dissolved in DMSO (16 mL) and the deep-orange solution was stirred at room temperature for 30 min. 4,4′-Dimethyl-2,2′-bipyridine (255 mg, 1.384 mmol) was then added as a solid in small portions resulting in a color change to deep red. The solution was stirred for 3 h at room temperature and then poured into diethyl ether (450 mL). The resulting brick-red solid was carefully decanted, washed with diethyl ether and pentane and dried in vacuo. Yield: 460 mg, 83%. ^{1}H NMR (250 MHz, [D_6]acetone, 298 K): δ = 2.31 (s, 3 H), 2.51 (s, 3 H), 3.19 (s, 6 H), 7.16 (d, *J* = 6.0 Hz, 1 H), 7.45 (d, *J* = 5.8 Hz, 1 H), 8.03 (s, 1 H), 8.18 (s, 1 H), 9.46 (d, *J* = 5.7 Hz, 1 H), 9.83 (d, *J* = 6.0 Hz, 1 H) ppm. $C_{14}H_{18}ClN_2ORhS$ (400.7): C 41.96, H 4.53, N 6.99; found C 41.78, H 4.46, N 7.06.

Synthesis of [RhCl(dmbpy){CNC(CH_3)$_3$}] (4): A solution of *tert*-butyl isocyanide (40 mg, 0.486 mmol) in THF (10 mL) was added dropwise to a violet slurry of **1** (170 mg, 0.486 mmol) in THF (14 mL). The resulting green-brown solution was stirred at room temperature for 2 h. Concentration of the THF solution to 10 mL and addition of diethyl ether (40 mL) caused the precipitation of a green-brown solid which was washed with diethyl ether and dried in vacuo. Yield: 162 mg, 83%. ^{1}H NMR (250 MHz, [D_6]acetone, 298 K): δ = 1.53 (s, 9 H), 2.23 (s, 3 H), 2.49 (s, 3 H), 7.10 (d, *J* = 5.9 Hz, 1 H), 7.46 (d, *J* = 5.7 Hz, 1 H), 7.98 (s, 1 H), 8.14 (s, 1 H), 8.85 (d, *J* = 5.6 Hz, 1 H), 9.37 (d, *J* = 5.7 Hz, 1 H) ppm. $C_{17}H_{21}ClN_3Rh$ (405.7): C 50.32, H 5.22, N 10.36; found C 50.21, H 5.29, N 10.26.

Synthesis of [Rh(dmbpy)(DMSO)$_2$]PF_6 (5): [$Rh(DMSO)_4$]PF_6 (65 mg, 0.115 mmol) and dmbpy (21 mg, 0.115 mmol) were dissolved in 4 mL DMSO and the resulting deep-red solution was stirred at room temperature for 2 h. The solution was then poured into diethyl ether (150 mL) and the brick-red precipitate was decanted, washed with additional diethyl ether and dried in vacuo. Yield: 61 mg, 90%. ^{1}H NMR (250 MHz, [D_6]DMSO, 298 K): δ = 2.52 (s, 6 H), 7.52 (d, *J* = 5.9 Hz, 2 H), 8.41 (s, 2 H), 8.70 (d, *J* = 5.8 Hz, 2 H) ppm. $C_{16}H_{24}F_6N_2O_2PRhS_2$ (588.4): C 32.66, H 4.11, N 4.76; found C 32.78, H 4.18, N 4.71.

Synthesis of [Rh(dmbpy){CNC(CH_3)$_3$}$_2$]BF_4 (6): A THF (3 mL) solution of *tert*-butyl isocyanide (33 mg, 0.401 mmol) was added dropwise to a red suspension of **2** (87 mg, 0.191 mmol) in THF (6 mL). The suspension was left stirring at room temperature for 2 h during which time the color turned deep-red with precipitation of a deep-red solid. Concentration to 3 mL, addition of pentane and subsequent washings with additional pentane afforded a deep-red solid which was dried in vacuo. Yield: 91 mg, 88%. ^{1}H NMR (250 MHz, [D_6]acetone, 298 K): δ = 1.62 (s, 18 H), 2.55 (s, 6 H), 7.56 (d, *J* = 5.6 Hz, 2 H), 8.39 (s, 2 H), 8.67 (d, *J* = 5.5 Hz, 2 H) ppm. $C_{22}H_{30}BF_4N_4Rh$ (540.2): C 48.91, H 5.60, N 10.37; found C 48.76, H 5.52, N 10.27.

Reaction of 3 with Benzyl Chloride. Formation of [$RhCl_2$-($CH_2C_6H_5$)(dmbpy)(DMSO)] (7): Complex **3** (70 mg, 0.175 mmol) was dissolved in an acetone/DMSO (3:1 mL) mixture and stirred at room temperature for 30 min giving a deep-red solution. Addition of benzyl chloride (44 mg, 0.348 mmol) led to an immediate color change to yellow. Leaving the solution at room temperature for 1 h resulted in the formation of a yellow precipitate which was carefully decanted, washed with diethyl ether and dried in vacuo. Yield: 77 mg, 84%. ^{1}H NMR (250 MHz, [D_6]DMSO, 298 K): δ = 2.39 (s, 3 H), 2.48 (s, 3 H), 3.51 (dd, *J* = 6.8 Hz and 3.0 Hz, 1 H), 4.02 (dd, *J* = 6.8 Hz and 3.1 Hz, 1 H), 6.17 (d, *J* = 6.9 Hz, 2 H), 6.50 (dd, *J* = 7.5 Hz, 2 H), 6.70 (dd, *J* = 7.3 Hz, 1 H), 7.42 (d, *J* = 5.0 Hz, 1 H), 7.52 (d, *J* = 5.0 Hz, 1 H), 8.01 (s, 1 H), 8.18 (s, 1 H), 9.12 (d, *J* = 5.9 Hz, 1 H), 9.41 (d, *J* = 5.7 Hz, 1 H) ppm. $C_{21}H_{25}Cl_2N_2ORhS$ (527.3): C 47.83, H 4.78, N 5.31; found C 47.35, H 4.76, N 5.22.

Reaction of 3 with Dichloromethane. Formation of [$RhCl_2$-(CH_2Cl)(dmbpy)(DMSO)] (8): Complex **3** (80 mg, 0.200 mmol) was dissolved in DMSO (2 mL) and five drops of CH_2Cl_2 were added. Leaving the solution at room temperature for one day led to the formation of pale yellow crystals. Addition of diethyl ether and subsequent washing with additional diethyl ether gave an off-white solid which was dried in vacuo. Yield: 82 mg, 85%. ^{1}H NMR (250 MHz, [D_6]DMSO, 298 K): δ = 2.53 (s, 3 H), 2.57 (s, 3 H), 4.31 (dd, *J* = 5.7 Hz and 3.0 Hz, 1 H), 4.75 (dd, *J* = 5.7 Hz and 3.0 Hz, 1 H), 7.60 (d, *J* = 5.0 Hz, 1 H), 7.65 (d, *J* = 5.0 Hz, 1 H), 8.51 (s, 1 H), 8.57 (s, 1 H), 9.17 (d, *J* = 5.9 Hz, 1 H), 9.33 (d, *J* = 6.0 Hz, 1 H) ppm. $C_{15}H_{20}Cl_3N_2ORhS$ (485.7): C 37.10, H 4.15, N 5.77; found C 37.27, H 4.06, N 5.71.

Reaction of 4 with Benzyl Chloride. Formation of [$RhCl_2$-($CH_2C_6H_5$)(dmbpy){CNC(CH_3)$_3$}] (9): Complex **4** (28 mg, 0.069 mmol) was dissolved in acetone (3 mL) giving a green-black solution. Addition of benzyl chloride (17 mg, 0.138 mmol) resulted in a color change to pale yellow after one day at room temperature.

Addition of diethyl ether led to the precipitation of an off-white solid which was washed with additional diethyl ether and dried in vacuo. Yield: 33 mg, 89%. ^{1}H NMR (250 MHz, [D$_6$]acetone, 298 K): δ = 1.61 (s, 9 H), 2.42 (s, 3 H), 2.48 (s, 3 H), 3.00 (dd, *J* = 7.8 Hz and 3.2 Hz, 1 H), 3.70 (dd, *J* = 7.8 Hz and 3.0 Hz, 1 H), 6.54 (m, 2 H), 6.73 (m, 3 H), 7.25 (d, *J* = 5.8 Hz, 1 H), 7.48 (d, *J* = 5.7 Hz, 1 H), 8.25 (br. s, 2 H), 8.31 (d, *J* = 5.9 Hz, 1 H), 9.35 (d, *J* = 5.7 Hz, 1 H) ppm. $C_{24}H_{28}Cl_2N_3Rh$ (532.3): C 54.15, H 5.31, N 7.89; found C 54.04, H 5.15, N 7.93.

Reaction of 5 with Benzyl Chloride. Formation of [RhCl(CH$_2$C$_6$H$_5$)(dmbpy)(DMSO)$_2$]PF$_6$ (10): Complex **5** (70 mg, 0.119 mmol) was dissolved in DMSO (2 mL) and stirred at room temperature for 30 min giving a deep-red solution. Upon addition of benzyl chloride (30 mg, 0.238 mmol) the solution turned yellow. After 12 h at room temperature, the solution was poured into diethyl ether (17 mL) and the resulting yellow precipitate was washed with additional diethyl ether and dried in vacuo. Yield: 77 mg, 91%. ^{1}H NMR (250 MHz, [D$_6$]DMSO, 298 K): δ = 2.44 (br. d, 6 H), 3.59 (dd, *J* = 6.8 Hz and 2.9 Hz, 1 H), 4.19 (dd, *J* = 6.8 Hz and 3.2 Hz, 1 H), 6.28 (d, *J* = 7.4 Hz, 2 H), 6.50 (dd, *J* = 7.5 Hz, 2 H), 6.74 (dd, *J* = 7.3 Hz, 1 H), 8.16 (s, 1 H), 8.26 (s, 1 H), 8.82 (br. s, 2 H), 9.09 (d, *J* = 5.9 Hz, 1 H), 9.30 (d, *J* = 5.9 Hz, 1 H) ppm. $C_{23}H_{31}ClF_6N_2O_2PRhS_2$ (715.0): C 38.64, H 4.37, N 3.92; found C 38.20, H 4.80, N 4.82.

Reaction of 5 with Dichloromethane. Formation of [RhCl(CH$_2$Cl)(dmbpy)(DMSO)$_2$]PF$_6$ (11): Complex **5** (80 mg, 0.136 mmol) was dissolved in DMSO (2 mL) and an excess of CH_2Cl_2 (five drops) was added. After two days at room temperature a pale yellow solution was formed. Addition of diethyl ether and subsequent washing with diethyl ether gave an off-white solid which was dried in vacuo. Yield: 71 mg, 78%. ^{1}H NMR (250 MHz, [D$_6$]DMSO, 298 K): δ = 2.59 (s, 6 H), 3.44 (br. d, 2 H), 7.66 (d, *J* = 6.0 Hz, 2 H), 7.87 (d, *J* = 6.0 Hz, 2 H), 8.89 (s, 2 H) ppm. $C_{17}H_{26}Cl_2F_6N_2O_2PRhS_2$ (673.3): C 30.33, H 3.90, N 4.16; found C 32.70, H 3.73, N 5.15.

Reaction of 6 with Benzyl Chloride. Formation of [RhCl(CH$_2$C$_6$H$_5$)(dmbpy){CNC(CH$_3$)$_3$}$_2$]BF$_4$ (12): A deep-red acetone solution (10 mL) of **6** (60 mg, 0.111 mmol) was treated with benzyl chloride (28 mg, 0.222 mmol). The color turned to orange within 1 h and leaving the solution overnight led to the precipitation of a yellow solid. Addition of diethyl ether and subsequent washing with diethyl ether gave a yellow powder which was dried in vacuo. Yield: 64 mg, 86%. ^{1}H NMR (250 MHz, [D$_6$]DMSO, 298 K): δ = 1.58 (s, 18 H), 2.57 (s, 6 H), 3.12 (d, *J* = 2.6 Hz, 2 H), 6.77 (m, 2 H), 7.00 (m, 3 H), 7.63 (d, *J* = 5.8 Hz, 2 H), 8.54 (d, *J* = 5.7 Hz, 2 H), 8.59 (s, 2 H) ppm. $C_{29}H_{37}BClF_4N_4Rh$ (666.8): C 52.24, H 5.60, N 8.40; found C 52.10, H 5.58, N 8.38.

Reaction of 3 with Oxygen. Formation of [RhCl$_2$(O$_2$)(dmbpy)(DMSO)] (13): A red DMSO solution (2 mL) of **3** (30 mg, 0.075 mmol) was treated with an equimolar amount of O_2 (1.7 mL). The solution turned yellow immediately and after 3 h at room temperature, it was poured into diethyl ether (17 mL). The pale-yellow precipitate was filtered, washed with diethyl ether and dried in vacuo. Yield: 30 mg, 93%. ^{1}H NMR (250 MHz, [D$_6$]acetone, 298 K): δ = 2.59 (s, 3 H), 2.62 (s, 3 H), 3.39 (s, 6 H), 7.53 (d, *J* = 5.9 Hz, 1 H), 7.58 (d, *J* = 5.6 Hz, 1 H), 8.38 (s, 1 H), 8.42 (s, 1 H), 8.57 (d, *J* = 5.6 Hz, 1 H), 9.56 (d, *J* = 5.5 Hz, 1 H) ppm. FT-IR (nujol): $\tilde{\nu}$ = 870 (O−O) cm^{-1}. $C_{14}H_{18}ClN_2O_3RhS$ (432.7): C 38.86, H 4.20, N 6.47; found C 38.30, H 4.26, N 6.55.

X-ray Crystal Structure Determination of 6, 8, 9 and 12: A single crystal of **6**, **8**, **9** or **12** were mounted on the nylon loop and flash frozen in a nitrogen stream at 120 K. Data were collected on a Nonius Kappa-CCD diffractometer mounted on a FR590 generator equipped with a sealed tube with Mo-K_α radiation (λ = 0.71073Å) and a graphite monochromator. The four structures were solved by direct methods with SHELXS-97 and refined by full-matrix least-squares techniques with SHELXL-97 based on F^2.[26]

Complex 6: $C_{22}H_{30}N_4Rh{\cdot}BF_4$, orange needles, 0.2 × 0.03 × 0.03 mm^3, orthorhombic, $Pmc2_1$ (No. 20), *a* = 6.861(1), *b* = 16.516(3), *c* = 21.825(4) Å, *V* = 2473.1(9) Å^3, *Z* = 4, fw = 540.22, D_c = 1.451 Mg/m^3, μ = 0.736 mm^{-1}. The final cycle of refinement based on F^2 gave an agreement factor *R* = 0.0252 for data with $I > 2\sigma(I)$ and *R* = 0.0294 for all data (2214 reflections) with a goodness-of-fit of 0.987. Idealized hydrogen atoms were placed and refined in a riding mode.

Complex 8: $C_{15}H_{20}Cl_3N_2OSRh$, yellow, thin parallelogram, 0.30 × 0.10 × 0.02 mm^3, monoclinic, $P2_1/c$ (No. 14), *a* = 7.5840(15), *b* = 10.636(2), *c* = 23.216(5) Å, β = 99.28(3)°, *V* = 1848.2(6) Å^3, *Z* = 4, fw = 485.65, D_c = 1.745 Mg/m^3, μ = 1.474 mm^{-1}. The final cycle of refinement based on F^2 gave an agreement factor *R* = 0.027 for data with $I > 2\sigma(I)$ and *R* = 0.040 for all data (4219 reflections) with a goodness-of-fit of 1.030. Idealized hydrogen atoms were placed and refined in a riding mode. Two hydrogen atoms on C4 were found and refined manually.

Complex 9: $C_{24}H_{28}N_3Cl_2Rh{\cdot}1/2(C_3H_6O){\cdot}H_2O$, yellow, bipyramidal prisms, 0.05 × 0.05 × 0.05 mm^3, tetragonal, $I4_1/a$ (No. 88), *a* = *b* = 20.722(3), *c* = 26.090(5) Å, *V* = 11203(3) Å^3, *Z* = 16, fw = 579.36, D_c = 1.374 Mg/m^3, μ = 0.824 mm^{-1}. The final cycle of refinement based on F^2 gave an agreement factor *R* = 0.0362 for data with $I > 2\sigma(I)$ and *R* = 0.0508 for all data (4291 reflections) with a goodness-of-fit of 1.054. Idealized hydrogen atoms were placed and refined in riding mode The acetone is disordered with 1/2 a molecule per asymmetric unit.

Complex 12: $C_{29}H_{37}N_4ClRh{\cdot}C_3H_6O{\cdot}BF_4$, colorless, prisms, 0.3 × 0.3 × 0.3 mm^3, monoclinic, $P2_1/n$ (No. 14), *a* = 12.623(3), *b* = 21.262(4), *c* = 14.011(3) Å, β = 105.84(3)°, *V* = 3617.7(13) Å^3, *Z* = 4, fw = 724.87, D_c = 1.331 Mg/m^3, μ = 0.596 mm^{-1}. The final cycle of refinement based on F^2 gave an agreement factor *R* = 0.0491 for data with $I > 2\sigma(I)$ and *R* = 0.0596 for all data (7146 reflections) with a goodness-of-fit of 1.035. Idealized hydrogen atoms were placed and refined in a riding mode. C32, C33 and C34 (one *tert*-butyl group) and the BF_4 are partially disordered and modeled with two alternative positions.

A Europium(II) Complex with Benzo-15-Crown-5

Przemysław Starynowicz*[a] and Krystyna Bukietyńska[a]

Dedicated to the memory of Mikołaj Starynowicz

Keywords: Europium / Crown compounds / X-ray diffraction / Luminescence / Lanthanides

The present paper reports the crystal structure and luminescent properties of bis(benzo-15-crown-5)europium(II) diperchlorate. The structure is composed of complex bis(benzo-15-crown-5)europium(II) cations and perchlorate anions. The complex cation is centrosymmetric, and the metal ion is surrounded by 10 oxygen atoms of two ligand molecules. The compound shows very bright luminescence at 23450 cm^{-1}. The emission parameters (wavelength and the average lifetime of the excited state) are compared to those previously reported for the analogous complex in methanol solutions.

Introduction

Complexes of divalent lanthanides (mainly Eu^{II}) with crown ethers have attracted much attention and the present state of the investigations on these complexes was excellently reviewed by Jiang et al.[1] The interest in these compounds is motivated both by the luminescent properties of the Eu^{2+} cation in the macrocyclic coordination environment and by the ligand's ability to stabilize the divalent state of the lanthanide. The luminescence quantum yield of the Eu^{II}-crown ether complexes in methanol solutions is increased relative to solutions of $EuCl_2$ and noncyclic polyethers because of encapsulation of the central ion, which in turn prevents the solvent OH groups from entering the first coordination sphere of the metal. This effect is particularly pronounced for 15-crown-5 and some of its derivatives. On the other hand the f^6d-state splittings in these systems, deduced from absorption and emission spectra, are smaller than for the $EuCl_2$-methanol system. The other interesting feature of the discussed complexes is their ability to shift the reduction potential of the Eu^{III}/Eu^{II} couple towards more positive values,[2] which may eventually lead to the application of these compounds or their derivatives as redox-sensitive shift agents in MRI tomography. It is therefore important and very interesting to gain information about the possible coordination behaviour of the macrocycles in compounds with Eu^{II} both in solution and in the solid state. Unfortunately, to the best of the authors' knowledge, there are no reports on the crystal structures of Ln^{II}-crown ether complexes, or attempts to correlate their spectroscopic properties in the solid state with their properties in solution. This work, which is an extension of our earlier work on Eu^{II} carboxylates, is intended to be such an attempt.

Results and Discussion

Crystal Structure

The crystals are built up from complex bis(benzo-15-crown-5)europium(II) cations and perchlorate anions, which are kept together by weak electrostatic and Van der Waals interactions. The metal ion is located at an inversion centre, between two symmetry-related ligand molecules, thus forming a sandwich-like complex cation. Such a coordination fashion for 15-crown-5-type ligands is common for K,[3] Rb,[4] Cs,[5] Sr[6] or Ba[7] (see also J. W. Steed[8] for a general review), whereas the trivalent lanthanide cations typically form 1:1 complexes.[9] The Eu^{2+} ion is accordingly surrounded by ten oxygen atoms, and the metal coordination environment may be described as a slightly distorted pentagonal antiprism with approximate point symmetry D_{5d}. The θ angles between the idealised C_5 axis and the Eu−O vectors are in the range 55.3−61.2°, with the average being 58.4°. The Eu−O distances, given in Table 1, although within the range observed in previously reported organic Eu^{II} compounds,[10] should be considered as rather long.

Table 1. The Eu−O distances (Å)

Eu−O(5)	2.662(3)
Eu−O(1)	2.688(3)
Eu−O(3)	2.694(3)
Eu−O(4)	2.718(4)
Eu−O(2)	2.728(4)

The shortest Eu−Eu distance is 9.774(2) Å. The whole macrocycle fragment is rather puckered and the aliphatic -CH_2-CH_2- chains in the macrocycle ring are disordered over two sets of positions (see the Exp. Sect.). The high values of the transversal principal components of the thermal ellipsoids may also indicate disorder within the benzo rings; however this could not be resolved during the refinement. The complex cation is drawn in Figure 1.

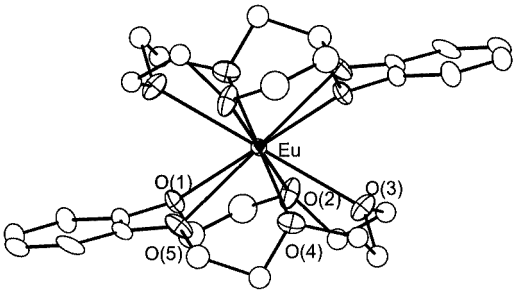

Figure 1. A DIAMOND[20] view of the complex cation; for the sake of clarity only symmetry-independent oxygen atoms have been labelled and the disordered carbon sites with the lower occupancy have been omitted

Spectroscopy

The compound shows very bright luminescence (to the point of gaining a violet hue in full daylight). The emission is observed in the form of a single peak with the maximum at 422 nm (23700 cm^{-1}) at room temperature, and at 426.5 nm (23450 cm^{-1}) at 77 K (see Figure 2). These values are slightly different from those reported for the Eu^{2+}-benzo-15-crown-5 system in methanol solution [417 nm (23980 cm^{-1})],[1,11] which may suggest a larger splitting of the excited $4f^65d^1$ state in the crystal. To identify the emitting level we decided to use the Jγ coupling method as described by Johnson and Sandoe.[12] Thus, it is commonly known that the lowest multiplet of the $4f^6$ core is ^7F, so only splitting of the 5d orbitals merits attention. To simplify our considerations we assumed that the degeneration of the 5d states is lifted by interaction with the ten oxygen atoms belonging to the first coordination sphere only, and the symmetry of the latter is D_{5d}. Following Gołębiewski,[13] the energy shift of the d orbitals in any crystal field is:

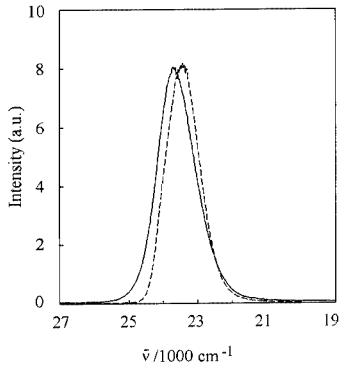

Figure 2. Emission spectrum of the complex at room temperature (solid line) and at 77 K (dashed line)

$$\Delta E(d_z2) = \frac{2}{7}L_{20}G_2+\frac{2}{7}L_{40}G_4;$$

$$\Delta E(d_{xz}) = \frac{1}{7}L_{20}G_2-\frac{4}{21}L_{40}G_4+\frac{1}{126}(9L_{22}G_2+2L_{42}G_4);$$

$$\Delta E(d_{yz}) = \frac{1}{7}L_{20}G_2-\frac{4}{21}L_{40}G_4-\frac{1}{126}(9L_{22}G_2+2L_{42}G_4); \quad (1)$$

$$\Delta E(d_x2_{-y}2) = -\frac{2}{7}L_{20}G_2+\frac{1}{21}L_{40}G_4+\frac{1}{504}L_{44}G_4;$$

$$\Delta E(d_{xy}) = -\frac{2}{7}L_{20}G_2+\frac{1}{21}L_{40}G_4-\frac{1}{504}L_{44}G_4;$$

where the L terms are angular factors in the form:

$$L_{20} = \frac{1}{2}\Sigma(3\cos^2\theta_i-1);$$

$$L_{40} = \frac{1}{8}\Sigma(35\cos^4\theta_i-30\cos^2\theta_i+3);$$

$$L_{22} = 3\Sigma\sin^2\theta_i\cos2\varphi_i; \quad (2)$$

$$L_{42} = 7\Sigma(7\cos^2\theta_i-1)\sin^2\theta_i\cos2\varphi_i;$$

$$L_{44} = 105\Sigma\sin^4\theta_i\cos4\varphi_i;$$

where θ_i and $_i$ are the angular coordinates of the i-th ligand, and the summation runs over all ligand positions. The G_2 and G_4 are (positive) radial integrals, as defined previously;[13] their detailed forms are not necessary for the reasoning below. Assuming that $\theta_i = \theta$ or $\pi-\theta$, and the φ_i angles span two regular pentagons, the last three L functions disappear. On substituting the previously obtained value of 58.4° for θ into the above equations, one gets:

$$\Delta E(d_z2) = -0.252G_2-0.928G_4 \quad (A_{1g});$$

$$\Delta E(d_{xz}) = \Delta E(d_{yz}) = -0.126G_2+0.619G_4 \quad (E_{1g}); \quad (3)$$

$$\Delta E(d_x2_{-y}2) = \Delta E(d_{xy}) = 0.252G_2-0.155G_4 \quad (E_{2g});$$

where the symbols of the relevant irreducible representations are given in parentheses.

Thus the d_{z^2} orbital will be the lowest, and the emitting states may be described as $4f^6(^7F)5d_{z^2}$. Furthermore, one may tentatively assume that the energy difference between the e_{1g} and e_{2g} orbitals will not be large because of different signs of the coefficients of G_2 and G_4; the ratio G_2/G_4 lies between 2 and 4.[13] The splitting of the $4f^6$ core must also be taken into consideration, which gives rise to a rather complicated structure of higher lying excited states that can be observed in the excitation spectra (Figure 3). The range in which the bands are observed is similar to the ranges observed in the excitation spectra of Eu^{2+} doped in $BaMg_2Si_2O_7$ [14] or MgF_2 matrices.[15] In our case the spectrum may be roughly divided into two parts: a more intense band between 270 and 400 nm (25000−37000 cm^{-1}; marked as band A in the Figure 3), and a weaker one between 220 and 270 nm (37000−45500 cm^{-1}; band B). The difference between their centres may be estimated as approximately 12000 cm^{-1}, which is similar to the energy difference between the ^7F and ^5D states in Eu^{3+} [16] or Sm^{2+}.[17] Considering this, and the earlier assumption of a small splitting of the e_{1g} and e_{2g} orbitals, one can conclude that the band B must reflect the positions of the $4f^6(^5D)5d$ states. The luminescence decay curves were monoexponen-

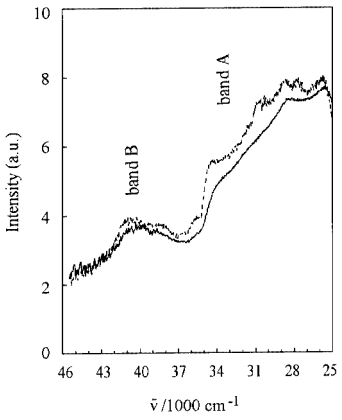

Figure 3. Excitation spectrum of the complex at room temperature (solid line) and at 77 K (dashed line)

tial, with a mean lifetime of the excited state of 0.65(2) μs at room temperature and 0.59(1) μs at 77 K. Comparison of these values with the value observed for methanol solutions (0.14 μs)[11] suggests additional relaxation processes, which could be caused by the presence of methanol OH oscillators in the first coordination sphere of the metal in solution.

Conclusion

A new complex of Eu^{II} with benzo-15-crown-5 has been obtained and characterized by X-ray diffraction and spectroscopic methods. Its properties, namely energy and the luminescence lifetime of the $4f^6 5d \rightarrow 4f^7$ transition, are different from those reported for the $EuCl_2$-benzo-15-crown-5 system in methanol solution. We can therefore conclude that the structure of the complex in the solid state is different from the labile species existing in the solution — in the latter case the solvent molecules probably enter the first coordination sphere of Eu.

Experimental Section

Preparation: Eu_2O_3 (0.663 g, 1.9 mmol) was dissolved in a small excess of 60% $HClO_4$, evaporated until white fumes appeared, cooled down and dissolved in a few millilitres of a 3:1 methanol/water mixture. To this benzo-15-crown-5 (1 g, 3.7 mmol) was added. The resulting mixture was placed in an H-shaped electrolyzer with a pool mercury cathode, platinum anode and a sintered glass diaphragm between the anode and cathode compartments. A dilute solution of $HClO_4$ in a 2:1 methanol/water mixture was the anolyte. Electrolysis was performed at a potential of −1 V with respect to the saturated calomel electrode. The first crystals appeared after half an hour. The compound is colourless, with a light violet hue in full daylight, and is rather stable in air at room temperature. $C_{28}H_{40}Cl_2EuO_{18}$: calcd. C 37.89, H 4.68, Cl 7.99, Eu 17.12; found C 37.21, H 4.54, Cl not analysed due to the explosive properties of the compound, Eu 16.30.

Spectroscopy: The luminescence and excitation spectra were measured on an SCL Aminco 500 spectrofluorimeter. The luminescence was excited with a lamp source with a wavelength of 330 nm, and the excitation spectra were recorded for the emission at 425 nm. The luminescence decay curves were detected on a device equipped with a Hamamatsu photomultiplier and Tektronix TDS-3052 digital oscilloscope. The sample was excited with the third harmonic of a neodymium laser (355 nm), and the registered output signal had a wavelength of 23460 cm^{-1}. All the measurements (luminescence, excitation and life times) were recorded at room temperature and at 77 K.

X-ray Crystallographic Study: An appropriate crystal was cut from a larger one and mounted on a Kuma KM4 diffractometer equipped with a CCD counter. The collected data were corrected for polarisation, Lorentz and absorption effects; the latter was calculated from the crystal habit captured from a photo scan. The position of Eu was found from a Patterson map, and the rest of the non-H atoms from difference Fourier maps. The positions of the hydrogen atoms were calculated geometrically. The refinement was full-matrix with all ordered atoms anisotropic. The carbon atoms belonging to the aliphatic fragment of the ligand were found to be disordered between two sets of positions [denoted with suffices A and B in the relevant atom names, with occupancies of 0.642(7) and 0.358(2), respectively], and therefore kept isotropic. The temperature factors of the H atoms were constrained to be 1.2-times the factors of the relevant C atoms.

The programs used were SHELXS-97[18] for the solution, and SHELXL-97[19] for the refinement. The data collection and refinement details are presented in Table 2.
CCDC-177469 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structures, and Redox Properties of Copper Complexes with Chiral and Achiral Amino Acid Derived Ligands

Nicole Niklas,[a] Frank Hampel,[b] Olaf Walter,[c] Günter Liehr,[a] and Ralf Alsfasser*[a]

Keywords: Amino acids / Chirality / Copper / Redox chemistry

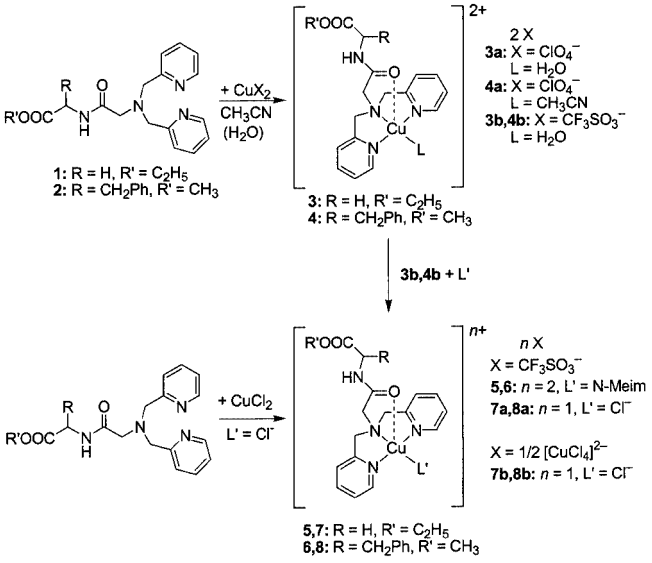
A series of copper(II) complexes containing the amino acid derived ligands bpaAc-Gly-OEt {**1**; [bis(picolyl)amino]acylglycine ethyl ester} and bpaAc-Phe-OMe {**2**; [bis(picolyl)amino]acylphenylalanine methyl ester} were synthesized and characterized in solution and in the solid state. This was done in order to evaluate the relevance of weak aromatic interactions between a metal center and amino acid side chains in square-pyramidal or octahedral coordination environments. The results showed that the structural, spectroscopic, and electrochemical properties of the copper(II) center are not affected by the amino acid side chain structure. This is in remarkable contrast to our previous investigations on zinc(II) complexes of the same ligands, which indicate close association of the metal center and the phenyl substituent of **2** in a trigonal-bipyramidal environment.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Aromatic rings are important structural and functional elements both in biological and in synthetic supramolecular architectures. They significantly contribute to the intramolecular stabilization of structures, as well as to the formation of intermolecular complexes.[1–6] This is achieved either through noncovalent ring stacking[7] or through π-cation interactions.[8,9] Furthermore, the redox-active aromatic amino acids tyrosine and tryptophan are known to participate in metalloenzyme-catalyzed substrate oxidations.[10]

The quest for synthetic metalloenzyme mimetics has stimulated much interest in the characterization of weak aromatic ring/cation interactions in small coordination complexes.[11–16] We have recently reported trigonal-bipyramidal zinc complexes of the amino acid derived ligands bpaAc-Gly-OEt (**1**) and bpaAc-Phe-OMe (**2**), shown in Scheme 1 {bpaAc = [bis(2-picolyl)amino]acyl; Gly-OEt = glycine ethyl ester; Phe-OMe = phenylalanine methyl ester}.[17] Intriguing features of the phenylalanine derivatives are: (i) the relatively short distance of 4.5 Å between the zinc ion and the center of the phenyl ring, and (ii) a rigid conformation of the benzyl side chain in solution. The latter is evidenced by analysis of the proton NMR chemical shifts and coupling constants.



Scheme 1. Copper(II) coordination chemistry of bpaAc-Gly-OEt (**1**) and bpaAc-Phe-OMe (**2**)

Here we report the synthesis and characterization of copper(II) complexes containing **1** and **2**. This was done in order to evaluate specific geometric requirements for the occurrence of weak aromatic interactions in complexes containing our tripodal N_3O ligand framework. In contrast to our findings for trigonal-bipyramidal zinc complexes, X-ray structure analyses together with electrochemical, EPR, and

circular dichroism measurements in solution demonstrated that the phenyl ring in **2** is flexible in square-pyramidal copper(II) compounds and does not efficiently interact with the metal center.

Results

Synthesis

All reactions are summarized in Scheme 1. The complexes [(bpaAc-Gly-OEt)(H_2O)Cu](ClO_4)$_2$ (**3a**), [(bpaAc-Gly-OEt)(H_2O)Cu](OTf)$_2$ (**3b**, OTf = CF_3SO_3), [(bpaAc-Phe-OMe)(CH_3CN)Cu](ClO_4)$_2$ (**4a**), and [(bpaAc-Phe-OMe)(H_2O)Cu](OTf)$_2$ (**4b**) were readily obtained from acetonitrile solutions containing stoichiometric amounts of the respective ligand and copper(II) salt. The *N*-methylimidazole complex [(bpaAc-Gly-OEt)(*N*-Meim)Cu](OTf)$_2$ (**5**) was similarly formed in one-pot reaction mixtures containing stoichiometric amounts of the ligand **1**, *N*-Meim, and Cu(OTf)$_2$. This was not the case for the sterically more demanding ligand **2**, with only [(*N*-Meim)$_5$Cu](OTf)$_2$ and bpaAc-Phe-OMe being isolated under the same conditions. However, the complex [(bpaAc-Phe-OMe)(*N*-Meim)Cu](OTf)$_2$ (**6**) was readily obtained by substitution of the labile aquo ligand from **4b**. This method worked equally well in the synthesis of **5** from **3b**.

Ligand exchange from **3b** and **4b** was also a convenient route to generate the chloro complexes [(bpaAc-Gly-OEt)Cu(Cl)](OTf) (**7a**) and [(bpaAc-Phe-OMe)Cu(Cl)](OTf) (**8a**) in situ for spectroscopic studies in solution. As we have reported earlier for the glycine derivative **7b**,[18] the cations [LCuCl]$^+$ may also be synthesized by treatment of the respective ligand with copper(II) chloride. This method always results in the formation of chlorocuprate anions, which severely complicate spectroscopic investigations. However, the tetrachlorocuprate salt [(bpaAc-Phe-OMe)Cu(Cl)]$_2$[$CuCl_4$] (**8b**) was the only copper(II) complex of ligand **2**, other than the acetonitrile diperchlorate derivative **4a**, to yield single crystals suitable for an X-ray structure determination.

Structures

We have characterized the glycine derivatives **3a**, **3b**, and **5**, as well as the phenylalanine derivatives **4a** and **8b**, by X-ray structure analyses. ORTEP plots of the cations containing **1** are shown in Figures 1−3, and the cations containing **2** are presented in Figures 4 and 5. Crystallographic details are summarized in Table 1; the structure of **7b** has been reported elsewhere.[18] All complexes show a similar first coordination sphere with a typical Jahn−Teller-distorted octahedral geometry around the copper(II) center. The three bpa nitrogen atoms of the tripodal ligands are bound in the equatorial plane and the amide oxygen atom occupies one of the axial positions. The equatorial plane is completed by the respective monodentate coligand − water (**3a**, **3b**), CH_3CN (**4a**), *N*-Meim (**5**), or chloride (**8b**) − and a weakly coordinating anion (Cu−L > 2.5 Å) is located at the respective second axial sites in the complexes **3a**, **3b**, **4a**, and **5**. Pairs of cations are formed by **8b**, with the coordinated chloro ligand of one complex above the copper center of the other at a nonbonding distance of ca. 3.1 Å. Bond lengths and angles are compared in Table 2. The first coordination spheres within our series are very similar, and all structural parameters agree well with those of the closely related complexes described by Nishida et al.[19,20]

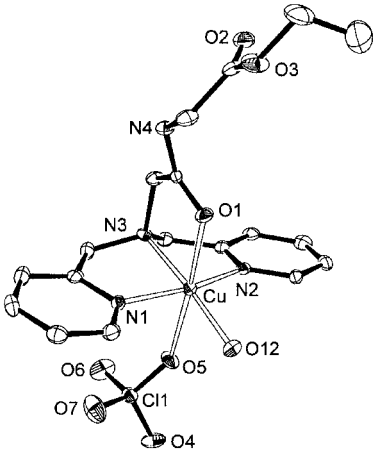

Figure 1. ORTEP plot (30% ellipsoids) of the cation [(bpaAc-Gly-OEt)(H_2O)Cu(ClO_4)]$^+$ (**3a**); hydrogen atoms are omitted for clarity

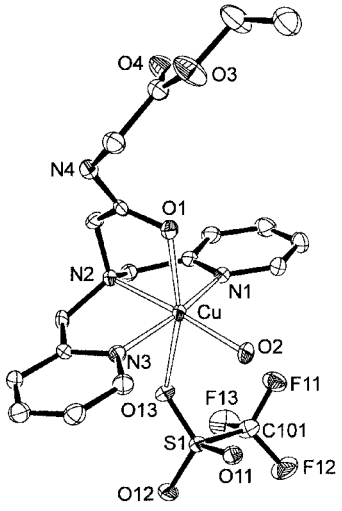

Figure 2. ORTEP plot (30% ellipsoids) of the cation [(bpaAc-Gly-OEt)(H_2O)Cu(CF_3SO_3)]$^+$ (**3b**); hydrogen atoms are omitted for clarity

Interesting are the different orientations adopted by the benzyl substituents in **4a** and **8b**. In both cases the structures are disordered. They refined best by assumption of two overlapping conformers with their phenyl rings in different orientations with respect to the equatorial plane defined by the first coordination sphere, as illustrated in Figures 4 and 5. The shortest distance between the copper(II) center and the phenyl ring center is observed in conformer B of **8b** (Figure 5; 7.24 Å). As a consequence of the disordered benzyl substituents and the disordered solvent mole-

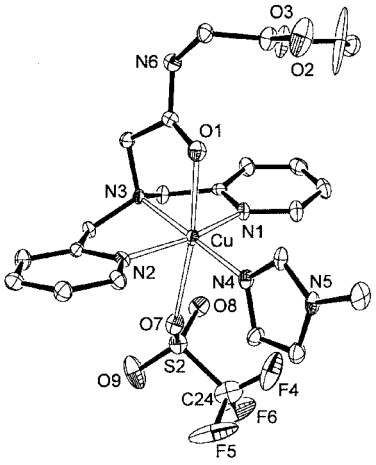

Figure 3. ORTEP plot (30% ellipsoids) of the cation [(bpaAc-Gly-OEt)(*N*-Meim)Cu(CF_3SO_3)]$^+$ (**5**); hydrogen atoms are omitted for clarity

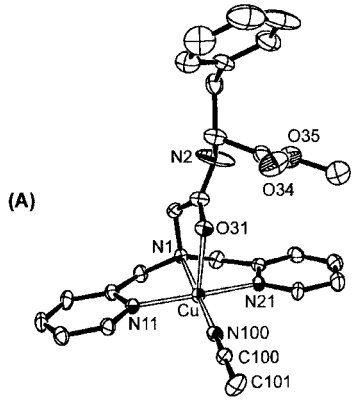

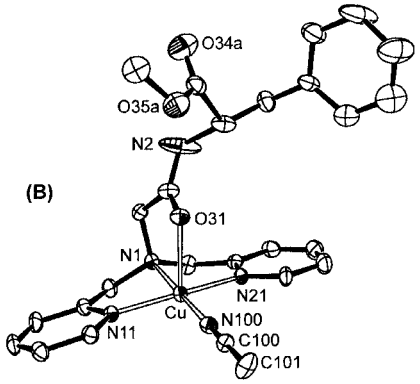

Figure 4. ORTEP plots (30% ellipsoids) of the two conformational isomers (A) and (B) of the cation [(bpaAc-Phe-OMe)(CH_3CN)Cu]$^{2+}$ (**4a**); hydrogen atoms have been omitted for clarity

cules in the asymmetric units (**4a**: CH_3CN; **8b**: 3 MeOH), both structures are of relatively poor quality. However, their similarity is striking and the data agree with the spectroscopic and electrochemical data reported below.

UV/Vis, EPR, and CD Spectroscopy

The UV/Vis spectra of our complexes in methanol were characterized by a weak metal-centered d-d band. Comparison showed that substitution of ligand **2** for ligand **1** did not significantly affect either λ_{max} or extinction coefficients. Differences were observed only between the various monodentate coligands. The spectra of the perchlorate and triflate salts **3a/3b** and **4a/4b** were very similar ($\lambda_{max} \approx 709$ nm, lg $\varepsilon \approx 1.86$), consistent with identical first coordination spheres around the copper(II) center. We therefore assume that the acetonitrile ligand in **4a** is rapidly exchanged in solution. This may also be true for the aquo ligands in **3a**, **3b**, and **4b**. With respect to the spectra of **3a**, **3b**, **4a**, and **4b**, the bands of the imidazole complexes were blue-shifted (**5**: $\lambda_{max} = 675$ nm, lg $\varepsilon = 1.93$; **6**: $\lambda_{max} = 681$ nm, lg $\varepsilon = 1.91$). The bands of the chloro complexes **7a** and **8a** appeared at longer wavelengths (**7a**: $\lambda_{max} = 725$ nm, lg $\varepsilon = 1.97$; **8a**: $\lambda_{max} = 732$ nm, lg $\varepsilon = 1.96$). Even larger red shifts and extinction coefficients were observed for the chlorocuprate salts **7b** and **8b** (**7b**: $\lambda_{max} = 757$ nm, lg $\varepsilon = 2.32$; **8b**: $\lambda_{max} = 755$, lg $\varepsilon = 2.30$). This behavior must be due to the anions, since the first coordination spheres are similar to those in **7a** and **8a**. Figure 6 illustrates the trend observed for the chloro complexes. Shown are the spectra of the aquo complexes **3b** and **4b**, their water/chloride exchange products **7a** and **8a**, and the chlorocuprate salts **7b** and **8b**.

The EPR spectra of our complexes were typical for copper(II) complexes with a $d_{x^2-y^2}$ ground state. All data obtained in frozen methanol solutions are summarized in Table 3. They confirmed that only the monodentate ligand had an effect on the *g* values and coupling constants,

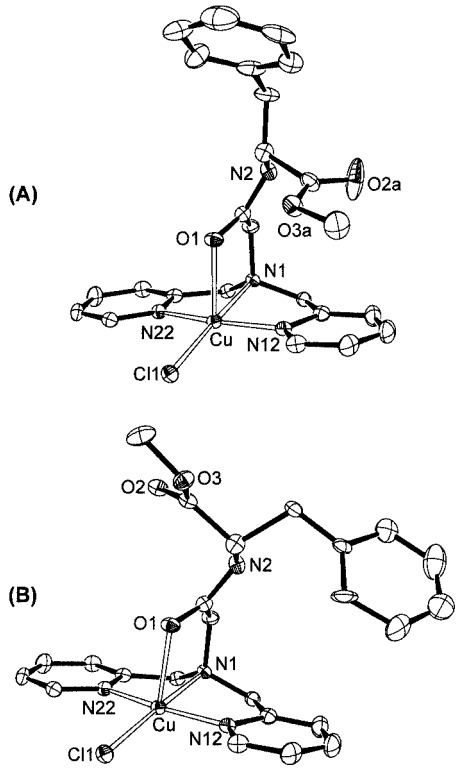

Figure 5. ORTEP plots (30% ellipsoids) of the two conformational isomers (A) and (B) of the cation [(bpaAc-Phe-OMe)Cu(Cl)]$^+$ (**8b**); hydrogen atoms have been omitted for clarity.

[a] N^{am} = amine nitrogen atom of the bpa ligand fragment. [b] N^{py} = pyridine nitrogen atom of the bpa ligand fragment. [c] O^{ad} = amide oxygen atom. [d] L^{eq} = equatorial ligand atom (monodentate coligand).

whereas changes in the amino acid structures did not register. The spectra of the *N*-methylimidazole complexes **5** and **6** and the chloro complexes **7a** and **8a** were rhombic, whereas axial patterns were found for the aquo and acetonitrile species **3a**, **3b**, **4a**, and **4b**. The spectra of **7b** and **8b** appeared to be rhombic but were not well resolved, due to complications arising from the presence of different chlorocuprate anions.[18] It was therefore not possible to determine an accurate value of g_y for these complex salts.

Circular dichroism spectra were collected for the chiral L-phenylalanine derivatives **4a**, **4b**, **6**, **8a**, and **8b**. The results are shown in Figure 7. In agreement with the similarity of the structures, there was no significant observed difference between the spectra of **4a**, **4b**, and **6**. They closely resembled

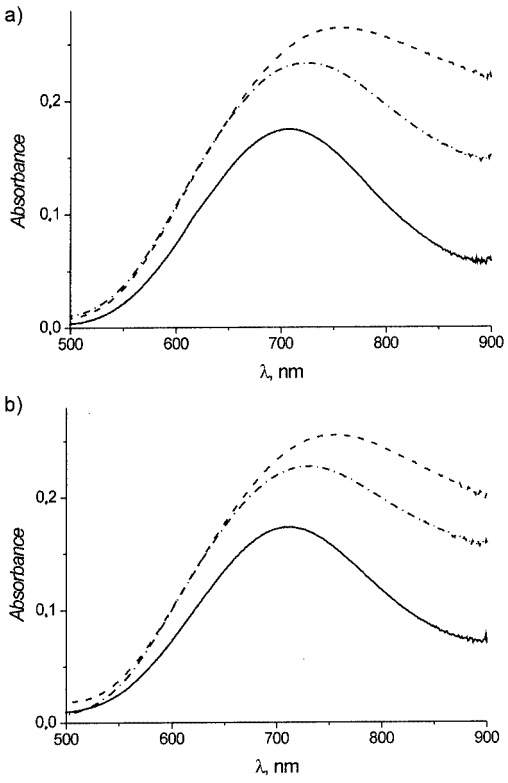

Figure 6. Vis spectra (0.002 M Cu^{2+} in methanol) of the triflate complexes **3b** (a) and **4b** (b) (——), the ligand exchange products **7a** (a) and **8a** (b) (–·–·), and the tetrachlorocuprate salts **7b** (a) and **8b** (b) (----)

Table 3. EPR spectra of the complexes in frozen methanol solutions (10^{-3} M Cu^{2+}; 120 K)

Compound	g_x	$g_\perp/g_y$	$g_\parallel/g_z$	$A_\parallel/A_z$ [10^{-4} cm^{-1}]
3a	–	2.06	2.27	170
3b	–	2.16	2.28	170
4a	–	2.05	2.26	169
4b	–	2.10	2.28	170
5	2.01	2.06	2.25	185
6	2.01	2.06	2.25	182
7a	1.94	2.03	2.23	170
7b	1.96	not resolved	2.25	175
8a	1.95	2.05	2.25	172
8b	1.96	not resolved	2.25	171

that of the free ligand **2**,[17] except for a 20 nm red shift of the pyridine ring π-π* transitions,[21] which appeared at 282 nm. In comparison, the corresponding free ligand signal is at 262 nm with a similar positive Cotton effect. Interestingly, the corresponding signal of $[(\mathbf{2})(H_2O)Zn](OTf)_2$ [17] exhibited a negative Cotton effect with a minimum at 270 nm. The chloro complexes **8a** and **8b** showed different behavior, exhibiting positive signals at ca. 289 nm significantly larger and broader than those of the other complexes studied. Though we cannot assign this band to a particular transition, it is interesting to note that the behavior is paralleled by a similar effect observed for the corresponding chlorozinc(II) complex.[22]

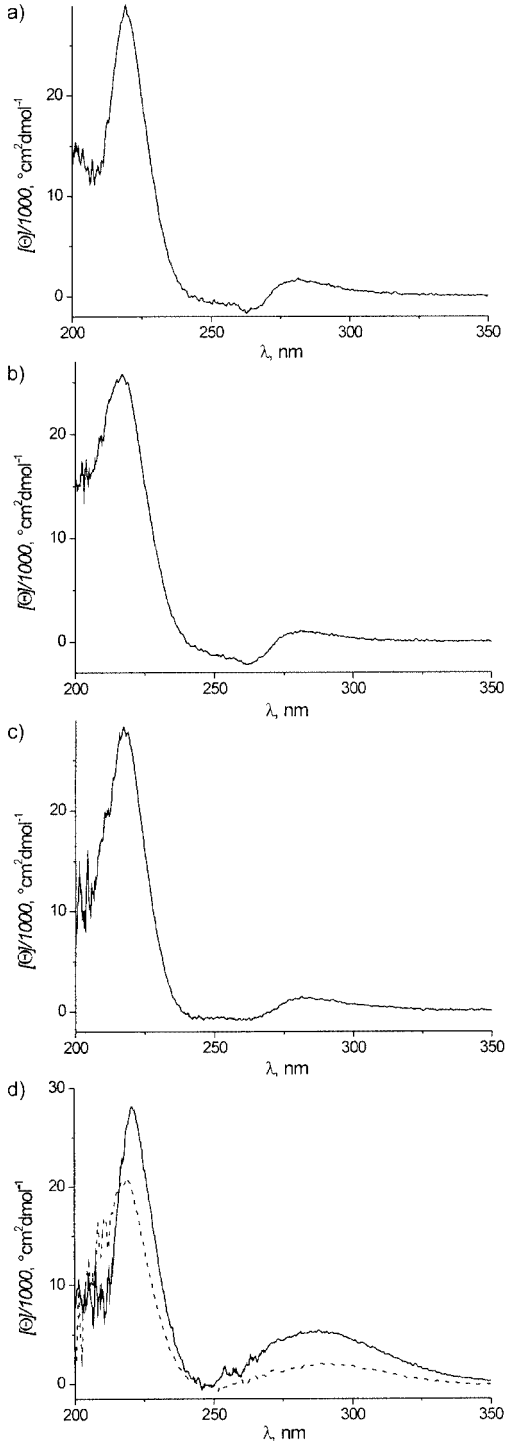

Figure 7. Circular dichroism spectra (0.001 M Cu^{2+} in methanol) of a) **4a**, b) **4b**, c) **6**, and d) **8a** (----) and **8b** (——)

Cyclic Voltammetry

The cyclic voltammograms of the complexes are shown in Figure 8 and the data are summarized in Table 4. In general, electrochemically quasireversible redox transitions were observed for all compounds. We assign these transitions to the Cu^{II}/Cu^{I} redox couple. The perchlorate and

triflate salts **3a/3b** and **4a/4b** exhibited broad shoulders at anodic potentials of ca. + 0.1 V. This feature is commonly encountered in copper(II) complexes and has been ascribed to adsorption processes at the glassy carbon working electrode.[23]

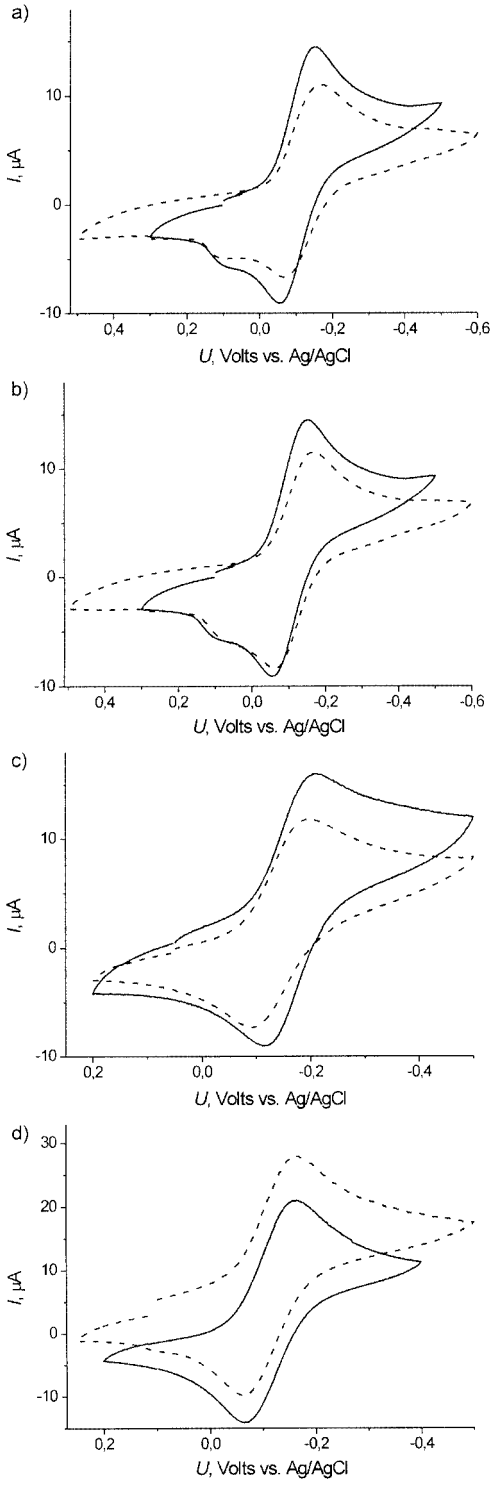

Figure 8. Cyclic voltammograms (0.1 M TBAH in methanol) of the complexes (10^{-3} M Cu^{2+}), a) **3a** and **4a**, b) **3b** and **4b**, c) **5** and **6**, d) **7b** and **8b** (——: bpaAc-Gly-OEt; ----: bpaAc-Phe-OMe)

Table 4. Electrochemical data ($E_{1/2}$ in V vs. Ag/AgCl; $\Delta E_{1/2}$ in mV) obtained for the complexes in 10^{-3} M methanol solutions at scan rates of 50 mV/s

Compd.	**3a**	**3b**	**4a**	**4b**	**5**	**6**	**7b**	**8b**
$E_{1/2}$	−0.10	−0.10	−0.10	−0.12	−0.16	−0.15	−0.11	−0.11
$\Delta E_{1/2}$	89	106	90	107	88	107	93	98

It is evident that no significant differences exist between complexes of the two ligands **1** and **2**. Considering the broad waves and the adsorption phenomena involved, the small shifts observed in $E_{1/2}$ for the triflate (**3a**, **4a**), perchlorate (**3b**, **4b**), and chloro (**7b**, **8b**) complexes are certainly well within the experimental errors. Small changes were only observed for the *N*-methylimidazole complexes **5** and **6**, which were reduced at potentials ca. −50 mV more negative than for the other compounds. In view of the accuracy of cyclic voltammetry, however, this shift may also not be significant.

Discussion

Our earlier investigations on zinc(II) complexes of ligand **2** demonstrated that a trigonal-bipyramidal coordination geometry resulted in an unusual conformational stability of the noncoordinating benzyl substituent.[17] We have now incorporated **2** in square-pyramidal copper(II) complexes. This was done in order to evaluate the effects of different geometries on the formation of noncovalent interactions between metal ions and aromatic amino acid side chains in tripodal ligand frameworks.

Both ligands **1** and **2** form copper complexes that are typical members of the tpa family [tpa: tris(picolyl)amine]. It has been generally observed that distorted square-pyramidal coordination geometries dominate when one pyridine arm of tpa is replaced by a thioether group[24] or oxygen donor ligands such as carboxylate[19] or phenolate.[25−27] In contrast, copper complexes of tris(picolyl)amine (tpa) itself are always trigonal-bipyramidal.[28−31] The amino acid side chain functionalities in **1** and **2** did not affect the structural properties of our complexes. The benzyl substituent, unlike that in the corresponding trigonal-bipyramidal zinc complexes,[17] is flexible and does not interact with the copper(II) center. This is indicated by the X-ray structure analyses of **4a** and **8b**. The distance between copper(II) and the center of the phenyl ring is always larger than 7 Å, whereas it is only 4.5 Å in $[(\mathbf{2})(H_2O)Zn]^{2+}$.

The circular dichroism spectra of **4a**, **4b**, and **6** supported these observations, no indication of a structural change affecting the chiral amino acid moiety in **2** upon copper complexation being found. This is evident on comparison with the spectra of the free ligand and its trigonal-bipyramidal zinc(II) complexes. However, there were unique features in the spectra of **8a** and **8b** that cannot yet be explained. EPR and UV/Vis spectra, as well as the cyclic voltammograms of the compounds, further confirmed that the first coor-

dination sphere was not affected by the benzyl substituent in ligand **2**. Only the monodentate coligand induced measurable changes. It is interesting to note that we did not observe an effect of the benzyl substituent on electrode processes in the electrochemical measurements. Such phenomena have been discussed with regard to a series of cobalt(III) complexes containing nitrilotriacetic acid ligands derived from different amino acids including phenylalanine.[32]

Conclusions

Our results have demonstrated that the coordination geometry of complexes with amino acid derived ligands is a crucial determinant for the occurrence of weak noncovalent interactions. The benzyl substituent in the chiral ligand **2** is closely associated with zinc(II) in trigonal-bipyramidal complexes, but does not interact at all with the copper(II) center in square-pyramidal or octahedral coordination environments. This is an important consideration for the development of synthetic chiral metal complexes intended to exhibit metalloenzyme-like properties such as the activation or recognition of substrates by interactions involving the second, noncoordinating ligand sphere.

Experimental Section

General Methods: Spectra were recorded with the following instruments: UV/Vis spectra: Varian Cary 1G spectrophotometer. Cyclic voltammetry: PAR potentiostat 263 equipped with a three-electrode cell containing a glassy carbon working electrode, an Ag/AgCl reference electrode, and a Pt counterelectrode. Methanol solutions (10^{-3} M) of the complexes containing tetrabutylammonium hexafluorophosphate (TBAH, 0.1 M) as supporting electrolyte were used. Solutions were deoxygenated by bubbling with dry nitrogen. The reported potentials have not been corrected for junction potential effects. Under the measurement conditions, the ferrocene/ferrocenium couple was observed at +0.40 V. EPR spectra: Bruker ESP 300 E spectrometer. All spectra were recorded at 120 K in frozen methanol solutions at 10^{-3} M copper concentrations. Circular dichroism: Jasco J710 Spectropolarimeter. IR: Mattson Polaris FTIR. All complexes were prepared and stored under dry nitrogen. The workup was performed under ambient laboratory conditions unless stated otherwise. Absolute solvents were purchased from Fluka and stored under nitrogen. Solvents were used without further purification. All other reagents were of commercially available reagent-grade quality. The syntheses of the ligands bpaAc-Gly-OEt (**1**) and bpaAc-Phe-OMe (**2**),[17] and of the copper complexes [(bpaAc-Gly-OEt)CuCl](OTf) (**7a**) and [(bpaAc-Gly-OEt)-$CuCl]_2[CuCl_3(MeOH)]Cl$ (**7b**)[18] are described elsewhere.

General Synthetic Procedure: The complexes **3a**, **3b**, **4a**, **4b**, and **5** were prepared by the same procedure described below. However, the subsequent workup and purification were slightly different for each compound and are therefore described separately. Solid Cu^{2+} salt was added in one portion to a stirred solution of 1 equiv. of the respective ligand in MeCN. In the case of [(bpaAc-Gly-OEt)(*N*-Meim)Cu]$(OTf)_2$ (**5**), *N*-methylimidazole was added after 15 min. Stirring was continued overnight at room temperature, followed by removal of all solvent in a vacuum.

[(bpaAc-Gly-OEt)(H_2O)Cu(ClO_4)](ClO_4)·H_2O (3a): This compound was prepared from **1** (243 mg, 0.71 mmol) and $Cu(ClO_4)_2$·$6H_2O$ (263 mg, 0.71 mmol) in MeCN (5 mL). The solid residue was suspended in a minimum of MeOH, and the resulting blue precipitate was separated from the green filtrate, dried in a vacuum, and completely dissolved in hot MeOH. The solution was left at 4 °C for several days, yielding **3a** as a blue solid that was isolated and dried in a vacuum. Single crystals suitable for an X-ray structure analysis where obtained by slow recrystallization from MeOH at 4 °C over a period of several weeks. Yield: 296 mg (0.46 mmol, 65%). $C_{18}H_{24}Cl_2CuN_4O_{12}$·$H_2O$ (640.9): calcd. C 33.74, H 4.09, N 8.74; found C 33.97, H 4.14, N 8.72. FAB-MS (nitrobenzyl alcohol): *m*/*z* = 504 [(bpaAc-Gly-OEt)Cu(ClO_4)]$^+$, 405 [(bpaAc-Gly-OEt)Cu]$^+$. IR (KBr): $\tilde{\nu}$ = 1723 cm^{-1} (COOEt), 1658 (amide I), 1105 (ClO_4). UV/Vis (MeOH): λ_{max} (lg ε) = 706 nm (1.88).

[(bpaAc-Gly-OEt)(H_2O)Cu(OTf)](OTf)·0.3CH_2Cl_2 (3b): This compound was prepared from **1** (483 mg, 1.41 mmol) and $Cu(OTf)_2$ (510 mg, 1.41 mmol) in MeCN (15 mL). The crude product was treated with CH_2Cl_2 (10 mL) and the mixture was cooled to −20 °C and filtered to remove insoluble impurities. The volume of the filtrate was reduced, and some diethyl ether was added. Storage of the solution at −20 °C and repeated addition of Et_2O afforded the product as blue needles, which were isolated by filtration and dried in a vacuum. Recrystallization from CH_2Cl_2 by slow evaporation of the solvent under dry nitrogen afforded blue crystals suitable for X-ray structure analysis. Yield: 593 mg (0.79 mmol, 56%). $C_{20}H_{24}CuF_6N_4O_{10}S_2$·0.3$CH_2Cl_2$ (747.6): calcd. C 32.62, H 3.32, N 7.49; found C 32.45, H 3.34, N 7.40. FAB-MS (nitrobenzyl alcohol): *m*/*z* = 554 [(bpaAc-Gly-OEt)Cu(OTf)]$^+$, 405 [(bpaAc-Gly-OEt)Cu]$^+$. IR (KBr): $\tilde{\nu}$ = 1749 cm^{-1} (COOEt), 1663 (amide I), 1287, 1254, 1171, 1032 (OTf). UV/Vis (MeOH): λ_{max} (lg ε) = 706 nm (1.85).

[(bpaAc-Phe-OMe)(MeCN)Cu](ClO_4)$_2$·H_2O (4a): This compound was prepared from **2** (508 mg, 1.21 mmol) and $Cu(ClO_4)_2$·$6H_2O$ (448 mg, 1.21 mmol) in MeCN (10 mL). CH_2Cl_2 (5 mL) was added to the crude product, and the resulting suspension was decanted. The residue was dried in a vacuum and dissolved in 10 mL of MeCN. Slow diffusion of Et_2O into this solution afforded the product as blue needles, which were isolated and dried in a vacuum. Some of these crystals were suitable for X-ray structure analysis. Yield: 772 mg (1.07 mmol, 88%). $C_{26}H_{31}Cl_2CuN_5O_{12}$ (740.0): calcd. C 42.20, H 4.22, N 9.46; found C 42.31, H 4.38, N 9.40. FAB-MS (nitrobenzyl alcohol): *m*/*z* = 580 [(bpaAc-Phe-OMe)Cu(ClO_4)]$^+$, 481 [(bpaAc-Phe-OMe)Cu]$^+$. IR (KBr): $\tilde{\nu}$ = 1749 cm^{-1} (COOEt), 1659 (amide I), 1103 (ClO_4). UV/Vis (MeOH): λ_{max} (lg ε) = 709 nm (1.85). CD (10^{-3} M in methanol): λ [nm] ([θ]/1000 [°cm^2dmol^{-1}]) = 219 (+28.2), 263 (−1.5), 282 (+1.6).

[(bpaAc-Phe-OMe)(H_2O)Cu](OTf)$_2$ (4b): This compound was prepared from bpaAc-Phe-OMe (713 mg, 1.70 mmol) and $Cu(OTf)_2$ (615 mg, 1.70 mmol) in MeCN (20 mL). The crude product was dissolved in 5 mL of CH_2Cl_2 and filtered. Cooling of the filtrate overnight at −20 °C yielded the complex as a blue precipitate. The suspension was decanted and the residue was dried in a vacuum. Yield: 1.133 g (1.42 mmol, 84%). $C_{26}H_{28}CuF_6N_4O_{10}S_2$ (798.2): calcd. C 39.12, H 3.54, N 7.02; found C 39.27, H 3.66, N 6.87. FAB-MS (nitrobenzyl alcohol): *m*/*z* = 630 [(bpaAc-Phe-OMe)Cu(OTf)]$^+$, 481 [(bpaAc-Phe-OMe)Cu]$^+$. IR (KBr): $\tilde{\nu}$ = 1746 (COOMe), 1657 (amide I), 1282, 1253, 1166, 1031 (OTf). UV/Vis (MeOH): λ_{max} (lg ε) = 713 nm (1.83). CD (10^{-3} M in methanol): λ [nm] ([θ]/1000 [°cm^2dmol^{-1}]) = 217 (+25.4), 262 (−2.2), 282 (+1.0).

[(bpaAc-Gly-OEt)(*N*-Meim)Cu](OTf)$_2$ (5): This compound was prepared from **1** (382 mg, 1.11 mmol), Cu(OTf)$_2$ (402 mg, 1.11 mmol), and *N*-Meim (91 mg, 1.11 mmol) in MeCN (5 mL). The residual solid was dissolved in 5 mL of CH_2Cl_2, cooled to −20 °C and filtered to yield a clear blue solution. After reduction of the filtrate, diethyl ether was added. The mixture was stored at −20 °C to precipitate the product, which was isolated by filtration and dried in a vacuum. X-ray quality crystals were grown by layering a solution of **5** in a minimum of CH_2Cl_2 with diethyl ether for several days at 4 °C. Yield: 703 mg (0.89 mmol, 80%). $C_{24}H_{28}CuF_6N_6O_9S_2$ (786.2): calcd. C 36.67, H 3.59, N 10.69; found C 36.73, H 3.78, N 10.60. FAB-MS (nitrobenzyl alcohol): *m/z* = 554 [(bpaAc-Gly-OEt)Cu(OTf)]$^+$, 405 [(bpaAc-Gly-OEt)Cu]$^+$. IR (KBr): $\tilde{\nu}$ = 1732 cm^{-1} (COOEt), 1666 (amide I), 1282, 1247, 1157, 1031 (OTf). UV/Vis (MeOH): λ_{max} (lg ε) = 675 nm (1.93).

[(bpaAc-Phe-OMe)(*N*-Meim)Cu](OTf)$_2$ (6): *N*-Methylimidazole (18 μL, 0.23 mmol) was added in one portion to a stirred solution of **4b** (187 mg, 0.23 mmol) in 10 mL of MeCN. Stirring was continued overnight at room temperature, followed by removal of all solvent in a vacuum. The resulting solid was dissolved in 5 mL of CH_2Cl_2 and stored at −20 °C overnight. After filtration, diethyl ether was added dropwise to cause a slight cloudiness. The mixture was stored again at −20 °C to afford a blue precipitate, which was isolated by decantation of the supernatant and dried in a vacuum. In order to maximize yields it was necessary to isolate the product quickly, because it redissolved at room temperature. Yield: 177 mg (0.20 mmol, 87%). $C_{30}H_{32}CuF_6N_6O_9S_2$ (862.3): calcd. C 41.79, H 3.74, N 9.75; found C 41.73, H 3.81, N 9.50. FAB-MS (nitrobenzyl alcohol): *m/z* = 630 [(bpaAc-Phe-OMe)Cu(OTf)]$^+$, 481 [(bpaAc-Phe-OMe)Cu]$^+$. IR (KBr): $\tilde{\nu}$ = 1744 (COOMe), 1661 (amide I), 1282, 1255, 1162, 1031 (OTf). UV/Vis (MeOH): λ_{max} (lg ε) = 681 nm (1.91). CD (10^{-3} M in methanol): λ [nm] ([θ]/1000 [°cm^{2}dmol^{-1}]) = 218 (+27.6), 282 (1.3).

[(bpaAc-Phe-OMe)CuCl]$_2$[CuCl$_4$]·MeOH (8b) and [(bpaAc-Phe-OMe)CuCl](OTf) (8a): Solid $CuCl_2 \cdot 2H_2O$ (189 mg, 1.11 mmol) was added in one portion to a stirred solution of **2** (309 mg, 0.74 mmol) in 20 mL of MeOH. Stirring was continued overnight at room temperature. The volume of the solution was reduced, and storage at −20 °C afforded the product as a green solid. The complex was redissolved in the minimum possible amount of MeOH and recrystallized by slow diffusion of Et_2O into the solution. Diamond-shaped, green crystals were obtained. C,H,N, elemental analysis indicated the formulation [(bpaAc-Phe-OMe)CuCl]$_2$[CuCl$_4$]·MeOH for this compound. Single crystals suitable for X-ray structure analysis were obtained by slow recrystallization from MeOH at −20 °C. It was necessary to isolate the crystals quickly, because they rapidly redissolved at room temperature. The X-ray structure analysis indicates that the single crystals contained 3 molecules of MeOH per copper complex. For spectroscopic studies, the complex salt **8a** was generated in situ by addition of aqueous NaCl (2.5 or 1 M: 10% excess; saturated solution: large excess) to a solution of **4b** in methanol. The reaction was monitored by UV/Vis, EPR, or circular dichroism spectroscopy and run to completeness. Spectroscopic data are reported for both salts **8a** and **8b**. Yield (**8b**): 405 mg (0.31 mmol, 84%). $C_{48}H_{54}Cl_6CuN_8O_7 \cdot MeOH$ (1290.4): calcd. C 45.61, H 4.53, N 8.68; found C 45.46, H 4.46, N 8.74. FAB-MS (nitrobenzyl alcohol): *m/z* = 516 [(bpaAc-Phe-OMe)CuCl]$^+$, 481 [(bpaAc-Phe-OMe)Cu]$^+$. IR (KBr): $\tilde{\nu}$ = 1743 (COOMe), 1654 (amide I). UV/Vis (MeOH): **8a:** λ_{max} (lg ε) = 732 nm (1.96); **8b:** λ_{max} (lg ε) = 755 nm (2.30). CD (10^{-3} M in methanol): **8a:** λ [nm] ([θ]/1000 [°cm^{2}dmol^{-1}]) = 216 (21.4), 289 (2.3); **8b:** λ [nm] ([θ]/1000 [°cm^{2}dmol^{-1}]) = 221 (27.6), 288 (5.3).

X-ray Data Collection and Structure Refinement Details: Crystal data and experimental conditions are listed in Table 1. The molecular structures are illustrated in Figures 1−5. Selected bond lengths and bond angles, with standard deviations in parentheses, are summarized in Table 2. Intensity data were collected with graphite-monochromated Mo-K_α radiation with a Nonius CAD MACH3 diffractometer (**3a**, **5**), with a Nonius Kappa CCD area detector (**4a**, **8b**), and with a Siemens SMART 5000 CCD-diffractometer (exposure time: 10 s/frame, Δω = 0.3°, **3b**). The collected reflections were corrected for Lorentz, polarization, and absorption effects.[33] All structures were solved by direct methods and refined by full-matrix, least-squares methods on F^2.[34−36] Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were calculated for idealized geometries and allowed to ride on their parent atoms with isotropic displacement parameters related to those of the adjacent atoms by a factor of 1.5. CCDC-172745 (**3a**), -173039 (**3b**), -173635 (**4a**), -172744 (**5**), and -173634 (**7b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK 8Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The $[Re(CO)_6]^+$ Cation as a Ligand-Transfer Reagent with Ferrocene Derivatives

Siden Top,*[a] Stéphane Masi,[a] and Gérard Jaouen*[a]

Keywords: Carbonyl(cyclopentadienyl)rhenium / Hexacarbonylrhenium / Ferrocene / Ligand transfer

The $[Re(CO)_6]^+$ cation is a stable compound, soluble in aqueous media. We show that it can be used as a reagent in the synthesis of tricarbonyl(cyclopentadienyl)rhenium complexes. $[Re(CO)_6]^+$ reacts with ferrocene derivatives, particularly acetylferrocene, in DMSO, DMF or a water/DMSO (1:1) mixture at 160 °C to give tricarbonyl(cyclopentadienyl)rhenium derivatives with high yields.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The $[Re(CO)_6]^+$ cation is a robust compound insensitive to air or moisture. It is normally prepared by one of two different standard preparation methods, either by reaction of $Re(CO)_5X$ with $AlCl_3$ under high pressure of CO gas,[1] or by treating ethyl chloroformate with $Re(CO)_5Na$ at normal atmospheric pressure, followed by addition of BF_3.[2] Unlike $Re_2(CO)_{10}$, $Re(CO)_5Br$ or $[Re(CO)_5]^-$, precursors that are often used as reagents in the synthesis of carbonyl complexes of Re, $[Re(CO)_6]^+$ is normally considered to be a relatively inert compound. To the best of our knowledge only a few rare studies have dealt with its reactivity. One example is the nucleophilic reaction with the azide ion or amines, leading to the formation of the isocyanate $Re(CO)_5(NCO)$ and of the amide $Re(CO)_5(CONRR')$, respectively.[3] The carbonyl ligands are labile in this cation, and up to three CO groups can be substituted by two-electron donor ligands, such as triphenylphosphane.[4] It is also known that $[Re(CO)_6]^+$ reacts with the metallate anions $[Fe(CO)_4]^{2-}$, $[Mn(CO)_5]^-$, $[W(CO)_5Cl]^-$ and $[W(CO)_5H]^-$ by an electron-transfer reaction to give $[Re(CO)_5]^-$, $(CO)_5MnRe(CO)_5$, $Re(CO)_5Cl$ and $HRe(CO)_5$, respectively.[5] $[Re(CO)_6]^+$ possesses several properties that are worth exploiting. Firstly, its solubility and stability allow it to be used in aqueous media. Secondly, it has been shown that hexacarbonyltungsten is accessible in its radioactive form $^{188}W(CO)_6$ and that its disintegration should lead to the formation of $[^{188}Re(CO)_6]^+$ and $[^{188}Re(CO)_5]^{\cdot}$.[6] This transformation is an important one, since ^{186}Re and ^{188}Re are now recognized as radionuclides with therapeutic applications.[7] At present, the radionuclide of rhenium is only available in the form of the perrhenate.[8] It is for this reason that rhenium-based radiopharmaceuticals have normally been prepared as chelates of the N_2S_2 or N_3S type.[9] The need for new radiopharmaceuticals with good stability has led us to consider the idea of using the tricarbonyl(cyclopentadienyl)rhenium group in place of the chelates, since it has the advantages of being lipophilic, less bulky and more robust.[10] The concept of using carbonyl organometallic compounds as radiopharmaceuticals is undergoing rapid expansion.[11] However, syntheses of cyclopentadienyl complexes of Re require multi-step reactions. The traditional methods are not available for radionuclides of rhenium. The search for an efficient preparation method has led us to propose a new synthesis for certain rhenium compounds, including $Re_2(CO)_{10}$ at normal atmospheric pressure,[12] and $(\eta^5\text{-}C_5H_4COOH)Re(CO)_3$ by a simple thermal reaction of $Re_2(CO)_{10}$.[13] Other synthetic advances have been made by Katzenellenbogen et al.[14] and by Alberto et al.[15] Recently, Alberto demonstrated the viability of preparing cyclopentadienyltechnetium complexes in aqueous media using the reagent $[Tc(CO)_3(H_2O)_3]^+$ obtained from radioactive pertechnetate.[16] However, this synthesis is limited for the moment to cyclopentadienyl compounds bearing a carbonyl substituent. There is therefore a clear need for a new source of radioactive rhenium to widen the range of organometallic radiopharmaceuticals. With this aim in mind, $[^{188}Re(CO)_6]^+$ could be generated by the decay of $^{188}W(CO)_6$, thus providing a solution to the problem and an interesting alternative to the $^{188}ReO_4^-$ generator based on $^{188}WO_3$.[8] $^{188}W(CO)_6$ decay should clearly be the most direct route to the production of the carbonyl rhenium reagent. It has already been clearly established that $[^{99m}Tc(CO)_6]^+$ can be obtained from $^{99}Mo(CO)_6$.[17] This β decay of ^{99}Mo is interesting owing to the imaging application of ^{99m}Tc as well as the recognized similarity between the chemistry of Re and Tc. We were therefore interested in examining the potential of $[Re(CO)_6]^+$ in the synthesis of

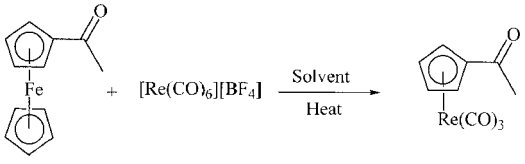
organometallic complexes. The double ligand-transfer reaction was a particular object of study with a view to preparing radiopharmaceuticals. This reaction, first reported by Wenzel,[18] has recently been enhanced by Katzenellenbogen et al.[14] We also showed that $Re_2(CO)_{10}$ can be used in ligand-transfer reactions with cyclopentadienyl complexes.[19] It may therefore be possible to use the $[Re(CO)_6]^+$ cation in this type of ligand transfer. We describe here the first results obtained with this cation.

Results and Discussion

Acetylferrocene was chosen for our first experiments with $[Re(CO)_6]^+$ since this complex has been found to give the best results in ligand-exchange reactions.[14]



Scheme 1. Ligand-transfer reaction between acetylferrocene and hexacarbonylrhenium cation

Scheme 1 shows the synthetic route that was used. Acetylferrocene, $[Re(CO)_6][BF_4]$ and methanol were placed in a sealed tube and heated to 170 °C. After heating for 1 h and purification by chromatography, $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ was obtained in 30% yield. We note that $CpRe(CO)_3$ is not formed under these reaction conditions. The low yield is probably due to the poor solubility of $[Re(CO)_6][BF_4]$ in methanol. Since this compound is very soluble in DMSO and DMF, the experiment was therefore repeated with DMSO in place of methanol as solvent. Owing to the high boiling point of DMSO, it was not necessary to use a sealed tube. A solution of acetylferrocene and $[Re(CO)_6][BF_4]$ in commercial DMSO was heated in an oil bath at 160 °C for 30 min. In this case, a 70% yield of $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ was obtained. DMSO was later replaced with DMF. Under the same conditions $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ was isolated in 64% yield. The choice of solvent has a clear influence on the outcome of the reaction. To elucidate this point, we carried out the experiments with other common solvents, such as acetonitrile, acetone, ethanol as well as water. Experimental conditions and yields obtained are summarized in Table 1.

$[Re(CO)_6][BF_4]$ is also soluble in acetonitrile. Heating a solution of the cation in acetonitrile at 95 °C for 27 h gave neither $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ nor $CpRe(CO)_3$. The experiment was repeated using a maximum temperature of 160 °C in a sealed tube. Again, no cyclopentadienylated complex was formed, and only $[Re(CO)_3(MeCN)_3]^+$ was isolated. Heating the solution to boiling point in acetone or ethanol also failed to give $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$.

We also tried to conduct the reaction in aqueous media, because this solvent is the most commonly used for radiopharmaceutical syntheses.[16] Heating a solution of the $[Re(CO)_6]^+$ cation and acetylferrocene in water at 95 °C for 2 h gave neither $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ nor $CpRe(CO)_3$. On the other hand, the same reaction carried out in a pressure tube gave rise to $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ in 13% yield. The result is even more promising in a pressure tube with a water/DMSO (1:1) mixture: in this case a yield of 60% of $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ was obtained. The use of the $[Re(CO)_6]^+$ cation in a water-based mixture of solvents could thus be envisaged. It is essential to consider this aspect when radioactive elements are handled.

The results reported below show that temperature also has a significant effect on the reaction. To study this effect, the exchange reaction was repeated using DMSO and DMF as solvents at different temperatures. The results obtained are listed in Table 2.

In DMSO, the yield of $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ drops from 70% to 58% and then to 16% when the temperature is lowered from 160 °C to 130 °C and then 90 °C, even when the reaction is allowed to proceed for a longer time. The same pattern is observed with DMF, in which case the yield drops from 64% to 23%, and finally to 0%. This result indicates that the reaction with $[Re(CO)_6][BF_4]$ requires heating to approximately 160 °C to obtain the rhenium tricarbonyl complex in good yield.

Table 1. Reaction of acetylferrocene with $[Re(CO)_6][BF_4]$ in a variety of solvents

Entry	Solvent	Quantity of acetylferrocene	Heating time	Temperature of heating bath	Yield of $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$
1	DMSO	3.12 equiv.	30 min	160 °C	70%
2	DMF	3.12 equiv.	30 min	160 °C	64%
3	MeOH[a]	3.12 equiv.	1 h	170 °C	30%
4	MeOH	3.12 equiv.	17 h	95 °C (reflux)	0%
5	H_2O	3.12 equiv.	2 h	110 °C (reflux)	0%
6	H_2O[a]	3.12 equiv.	1 h	160 °C	13%
7	H_2O/DMSO (1:1)[a]	3.12 equiv.	1 h	160 °C	60%

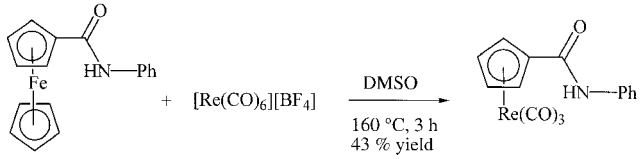
Table 3. Reaction of $(\eta^5\text{-}C_5H_4R)FeCp$ with $[Re(CO)_6][BF_4]$ in DMSO

Entry	R	Quantity of $(\eta^5\text{-}C_5H_4R)FeCp$	Heating time	Temperature of heating bath	Yield of $(\eta^5\text{-}C_5H_4R)Re(CO)_3$
1	COMe	1.05 equiv.	4 h 30	130 °C	58%
2	H	3.56 equiv.	5 h	180 °C	18%
3	COH	1.05 equiv.	30 min	160 °C	12%
4	COH	1.05 equiv.	3 h 20	130 °C	33%
5	COOEt	1.05 equiv.	2 h 30	160 °C	34%
6	C≡CH	1.05 equiv.	1 h 30	160 °C	0%

We also assessed how the nature of the ferrocene substituent might influence the reaction. Ferrocene, formylferrocene, ethyl ferrocenecarboxylate and ethynylferrocene were all tested in reactions in DMSO. Yields and experimental conditions are shown in Table 3.

Ferrocene gives 18% $CpRe(CO)_3$ after 5 h of heating at 180 °C. Formylferrocene and ethyl ferrocenecarboxylate give 33% and 34%, respectively of tricarbonyl(cyclopentadienyl)rhenium derivatives. Ethynylferrocene, however, gives $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ in 48% yield instead of the expected $(\eta^5\text{-}C_5H_4C{\equiv}CH)Re(CO)_3$. This type of transformation was also observed in the reaction with the perrhenate.[14] The reaction with $[Re(CO)_6][BF_4]$ was also tested with a fairly complex molecule such as *N*-phenylferrocenecarboxamide (Scheme 2).

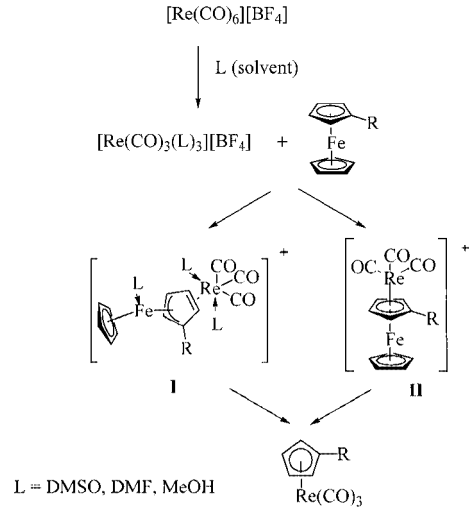


Scheme 2. Ligand-transfer reaction between *N*-phenylferrocenecarboxamide and hexacarbonylrhenium cation

Heating a solution of $[Re(CO)_6][BF_4]$ and *N*-phenylferrocenecarboxamide to 160 °C for 3 h gives tricarbonyl(*N*-phenylcyclopentadienylcarboxamide)rhenium in 43% yield.

The results obtained clearly show that $[Re(CO)_6][BF_4]$ does not react in the same way as the perrhenate.[14] The one-pot reaction between ReO_4^- and acetylferrocene in the presence of $Cr(CO)_6$ and $CrCl_2$ does not lead to the expected product in DMSO or in DMF. For this double ligand-transfer reaction, methanol was the only solvent that provided $(\eta^5\text{-}C_5H_4COMe)Re(CO)_3$ in acceptable yield (65%). This difference might be attributed to the fact that the reduction or the carbonyl transfer did not seem to proceed very well in DMSO or in DMF. By contrast, in our case, the best yields were obtained with DMSO or DMF, while methanol gave only mediocre results. It should be noted that $[Re(CO)_6][BF_4]$ is the only reagent that can react with ferrocene itself, while the perrhenate[14] and $Re_2(CO)_{10}$ [13] are inactive. To identify the real intermediate of the reaction, the $[Re(CO)_6][BF_4]$ solution in DMSO was heated to 80 °C for 3 h. The progress of the reaction was monitored using IR spectroscopy. A progressive disappearance of the peak at 2071 cm^{-1} of $[Re(CO)_6][BF_4]$ and concomitant progressive formation of two peaks at 2021 cm^{-1} and 1893 cm^{-1} were observed, characteristic of a molecule possessing C_{3v} symmetry. We postulate the formation of $[Re(CO)_3(DMSO)_3]^+$. The same transformation was also noted when $[Re(CO)_6][BF_4]$ was heated in DMF or acetonitrile under pressure. In this last case, it was possible to isolate the $[Re(CO)_3(MeCN_3)]^+$ cation which was identified by IR data.[20] Consequently, we propose that our reaction occurs in two stages (Scheme 3).

The first is the replacement of the three CO groups with solvent molecules. This exchange occurs at around 80 °C. The second step is the reaction between $[Re(CO)_3(L)_3]^+$ and the ferrocene derivative. This final reaction only begins around 130 °C and reaches full efficiency at 160 °C. Based on literature work, it has been suggested that the $\eta^5-\eta^3$ slippage of the Fe−cyclopentadienyl bond of the ferrocene



Scheme 3. Possible mechanism of cyclopentadienyl transfer reaction

derivative is responsible for its reaction with $[Re(CO)_3(MeO)(MeOH)_2]$.[14] It has also been observed that the ferrocene derivative reacts with $[(naphthalene)Mn(CO)_3]BF_4$ via the dimetallic intermediate $[Cp-Fe-Cp'-Mn(CO)_3]^+$.[21] Two mechanistic possibilities thus spring to mind for the reaction with $[Re(CO)_3(L)_3]^+$. The first is the $\eta^5-\eta^3$ slippage of the Fe−cyclopentadienyl bond, allowing the formation of the intermediate **I** which is converted into the tricarbonylrhenium compound. The second possibility is formation of the dimetallic intermediate **II**, followed by breaking of the Fe−Cp′ bond. Sweigart has shown that heating to 40 °C in dichloromethane is sufficient to cause $[(naphthalene)Mn(CO)_3]BF_4$ to react with a ferrocene derivative, leading to formation of tricarbonyl(cyclopentadienyl)manganese. Heating $[Re(CO)_3(L)_3]^+$ with the ferrocene compound to a high temperature is thus necessary to change the hapticity of the cyclopentadienyl ligand (intermediate **I**), or to drive off the three solvent molecules (intermediate **II**). Without proof of the formation of intermediates **I** and **II**, it is difficult at this stage to suggest a precise mechanism. However, the acetyl group on the cyclopentadienyl ring, acting as an electron-withdrawing group, should minimize the formation of the intermediate **II**. It is noteworthy that the reaction under pressure, using acetonitrile as the solvent, stops only at the point where $[Re(CO)_3(Me_3CN)_3]^+$ is formed indicating that this intermediate is not sufficiently reactive in the ligand-transfer reaction. To summarize, $[Re(CO)_3(Me_3CN)_3]^+$ is not an efficient intermediate, but its existence is a valuable mechanistic indicator suggesting future directions in the use of $[Re(CO)_6]^+$.

Conclusion

We have shown for the first time that the $[Re(CO)_6]^+$ cation reacts with ferrocene derivatives through a ligand-transfer reaction to give tricarbonyl(cyclopentadienyl)rhenium complexes. The reaction is rapid and in certain cases gives good yields. Due to its reactivity in water and its potential availability in a radioactive form, this reagent could be used for synthesis in water, and also in radiopharmaceutical syntheses. The reaction with $[Re(CO)_6]^+$ is both simpler and cleaner than that with the perrhenate, which requires a CO source and high pressure. We are continuing to study other types of reactions with this cation.

Experimental Section

General: The synthesis of all the compounds was performed under ambient atmospheric conditions. DMSO was used without any purification. TLC chromatography was performed on silica gel 60 GF254. Infrared spectra were obtained with an IR-FT BOMEM Michelson-100 spectrometer. ^1H and ^{13}C NMR spectra were recorded with 200 MHz and 400 MHz Bruker spectrometers. Mass spectrometry was performed with a Nermag R 10-10C spectrometer. Melting points were measured with a Kofler device. Elemental analyses were performed by the regional microanalysis department of the Université Pierre et Marie Curie.

Hexacarbonylrhenium: $[Re(CO)_6][BF_4]$ was prepared according to the procedure described in the literature.[2] IR (CH_3CN): $\tilde{\nu}$ = 2085 (ν_{CO}) cm^{-1}.

Synthesis of (Acetylcyclopentadienyl)tricarbonylrhenium in DMSO and in DMF: $[Re(CO)_6][BF_4]$ (0.073 g, 0.166 mmol) was dissolved in DMSO (1 mL) in a 5-mL round-bottom flask equipped with a magnetic stirrer bar. Acetylferrocene (0.040 g, 0.175 mmol) was added and the solution heated for 4 h 30 min at 130 °C. The mixture was allowed to warm to room temperature and then 10 mL of water was added. The product was extracted with dichloromethane (2 × 50 mL). The organic phase was washed, dried ($MgSO_4$), filtered and concentrated. The mixture was purified by chromatography on a silica gel plate (petroleum ether/ethyl acetate, 7:1) to give (acetylcyclopentadienyl)tricarbonylrhenium (0.036 g, 58%). ^1H NMR (200 MHz, $CDCl_3$): δ = 2.34 (s, 3 H, CH_3), 5.40 (t, J = 2.2 Hz, 2 H, 3,4-H of C_5H_4), 5.98 (t, J = 2.2 Hz, 2 H, 2,5-H of C_5H_4) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 2032 s, 1939 s (ν_{CO}), 1688 w ($COCH_3$) cm^{-1}. By using DMF as solvent and by applying the same procedure (heating time: 3 h), 23% yield of (acetylcyclopentadienyl)tricarbonylrhenium was obtained.

Synthesis of (Acetylcyclopentadienyl)tricarbonylrhenium under Pressure: $[Re(CO)_6][BF_4]$ (0.073 g, 0.166 mmol) and acetylferrocene (0.118 g, 0.519 mmol) were combined in a 20-mL pressure tube containing a magnetic stirrer bar. Methanol (1 mL) was added, and the tube was sealed and heated to 170 °C. After the heating period, the tube was cooled to room temperature. The solvent was evaporated, the mixture was dissolved in a minimum volume of CH_2Cl_2 and purified by chromatography on a silica gel plate (petroleum ether/ethyl acetate, 7:1) to give (acetylcyclopentadienyl)tricarbonylrhenium (0.020 g, 30%).

Ethyl Ferrocenecarboxylate: Ferrocenecarboxylic acid (0.500 g, 2.17 mmol) was dissolved in ethanol (12 mL) in a 25-mL round-bottom flask equipped with a magnetic stirrer bar. H_2SO_4 (0.15 mL) was added, and the solution heated under reflux for 12 h. The mixture was allowed to cool to room temperature and the solvent was partially evaporated. Cold water (10 mL) was added and the product was extracted with diethyl ether (3 × 100 mL). The organic phase was washed first with saturated K_2CO_3 solution, to

eliminate the excess acid, and then with water. The organic phase was dried ($MgSO_4$), filtered and concentrated. The mixture was purified by chromatography on a silica gel plate (petroleum ether/ethyl ether, 4:1) to give ethyl ferrocenecarboxylate (0.108 g, 19%). ^1H NMR (200 MHz, $CDCl_3$): δ = 1.37 (t, J = 7.1 Hz, 3 H, CH_3), 4.21 (s, 5 H, Cp), 4.29 (q, J = 7.1 Hz, 2 H, O−CH_2−), 4.40 (t, J = 1.9 Hz, 2 H, 3,4-H of C_5H_4), 4.82 (t, J = 1.9 Hz, 2 H, 2,5-H of C_5H_4) ppm. MS (EI): m/z = 258 $[M]^+$, 230 $[M - C_2H_4]^+$, 138, 121, 56 $[Fe]^+$.

***N*-Phenylferrocenecarboxamide:** The reaction was carried out under argon in a Schlenk tube equipped with a reflux condenser. Ferrocenecarboxylic acid (0.152 g, 0.66 mmol) was placed into the Schlenk tube and cooled with an ice bath. Oxalyl chloride (3 mL, 34 mmol) was then added and the solution was kept at room temperature for 2 h. The oxalyl chloride was evaporated. The acyl chloride formed was dissolved in anhydrous THF (4 mL), and aniline (0.186 g, 2 mmol) was added dropwise. The mixture was stirred for 3 h then separated by chromatography on a silica gel plate (petroleum ether/dichloromethane, 1:1) to give *N*-phenylferrocenecarboxamide (0.114 g, 57%) m.p. 211 °C. ^1H NMR (200 MHz, $(CD_3)_2CO$): δ = 4.24 (s, 5 H, Cp), 4.42 (dd, J = 1.9 Hz, 2 H, 3,4-H of C_5H_4), 4.97 (dd, J = 1.9 Hz, 2 H, 2,5-H of C_5H_4), 7.05 (m, 1 H, Ph), 7.31 (m, 2 H, Ph), 7.76 (m, 2 H, Ph), 8.84 (s, 1 H, NH) ppm. ^{13}C NMR (50 MHz, $(CD_3)_2CO$): δ = 73.7, 74.6, 75.5, 77.8, 120.8, 123.9, 129.4, 140.5, 168.9 (CO) ppm. MS (EI): m/z = 305 $[M]^+$, 213 $[CpFeC_5H_4CO]^+$, 185 $[FeCp_2]^+$, 65 $[Cp]^+$. $C_{17}H_{15}FeNO$ (305.16): calcd. C 66.91, H 4.95, N 4.59; found. C 66.70, H 5.27, N 4.39.

Reaction in Water and in Water/DMSO: $[Re(CO)_6][BF_4]$ (0.073 g, 0.166 mmol) and acetylferrocene (0.118 g, 0.519 mmol) were combined in a 20-mL pressure tube containing a magnetic stirrer bar. Water (1 mL) was added, then the tube was sealed and heated to 160 °C. After heating for 1 h, the tube was cooled to room temperature. 10 mL of water was added. The product was extracted with dichloromethane (2 × 50 mL). The organic phase was dried ($MgSO_4$), filtered and concentrated. The mixture was purified by chromatography on a silica gel plate (petroleum ether/ethyl acetate, 7:1) to give (acetylcyclopentadienyl)tricarbonylrhenium (0.008 g, 13%). By using a water/DMSO mixture (0.5 mL/0.5 mL) as solvent and by applying the same procedure, 60% yield of (acetylcyclopentadienyl)tricarbonylrhenium was obtained.

Reaction in Acetonitrile: $[Re(CO)_6][BF_4]$ (0.073 g, 0.166 mmol) and acetylferrocene (0.040 g, 0.175 mmol) were combined in a 20-mL pressure tube containing a magnetic stirrer bar. Acetonitrile (1 mL) was added, then the tube was sealed and heated to 170 °C. After the heating period, the tube was cooled to room temperature. The solvent was evaporated, the mixture was dissolved in a minimum volume of CH_2Cl_2 and purified by chromatography on a silica gel plate (petroleum ether/ethyl acetate, 7:1) to give $[Re(CO)_3(CH_3CN)_3]^+$ (0.042 g). IR (CH_2Cl_2): $\tilde{\nu}$ = 2053 s, 1953 s (ν_{CO}) cm^{-1}.

Reaction with Ferrocene: The procedure is similar to that of the synthesis of (acetylcyclopentadienyl)tricarbonylrhenium in DMSO. Ferrocene (0.110 g, 0.591 mmol) was used in a reaction heated for 5 h at 180 °C. The compound was purified on a silica gel plate (petroleum ether/ethyl acetate, 20:1) to give tricarbonyl(cyclopentadienyl)rhenium (0.010 g, 18%). ^1H NMR (200 MHz, $CDCl_3$): δ = 5.38 (s, 5 H, Cp) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 2024 s, 1926 vs (ν_{CO}) cm^{-1}.

Reaction with (*N*-Phenyl)ferrocenecarboxamide: The procedure is similar to that of the synthesis of (acetylcyclopentadienyl)tricarbonylrhenium in DMSO. *N*-phenylferrocenecarboxamide (0.054 g, 0.175 mmol)was used and the reaction mixture was heated for 3 h at 160 °C. The compound was purified by chromatography on a silica gel plate (ethyl acetate/petroleum ether, 2:1) to give tricarbonyl(*N*-phenylcyclopentadienylcarboxamide)rhenium (0.032 g, 43%), m.p. 179 °C. ^1H NMR (200 MHz, $(CD_3)_2CO$): δ = 5.72 (t, J = 2.3 Hz, 2 H, 3,4-H of C_5H_4), 6.41 (t, J = 2.3 Hz, 2 H, 2,5-H of C_5H_4), 7.10 (m, 1 H, Ph), 7.32 (m, 2 H, Ph), 7.67 (m, 2 H, Ph), 9.25 (s, 1 H, −NH−CO) ppm. ^{13}C NMR (100 MHz, $(CD_3)_2CO$): δ = 86.6 (C_{Cp}), 88.1 (C_{Cp}), 96.5 (C_{Cp}), 120.9 (C_{Ar}), 124.7 (C_{Ar}), 129.4 (C_{Ar}), 139.3 (C_{Ar}), 161.0 (NHC=O), 194.1 (CO) ppm. IR (CH_2Cl_2): $\tilde{\nu}$ = 2033 s, 1945 s (ν_{CO}) cm^{-1}. MS (EI): m/z = 455 $[M]^+$, 427 $[M - CO]^+$, 371 $[M - 3CO]^+$. $C_{15}H_{10}NO_4Re$ (454.45): calcd. C 39.64, H 2.22, N 3.08; found. C 40.05, H 2.00, N 3.00.

Reaction with Formylferrocene: The procedure is similar to that of the synthesis of (acetylcyclopentadienyl)tricarbonylrhenium in DMSO. Formylferrocene (0.038 g, 0.175 mmol) was used in a reaction that underwent 3 h 20 min of heating at 130 °C. The compound was purified by chromatography on a silica gel plate (petroleum ether/ethyl acetate, 5:1) to give tricarbonyl(formylcyclopentadienyl)rhenium (0.020 g, 33%). ^1H NMR (200 MHz, $CDCl_3$): δ = 5.5 (t, J = 2.4 Hz, 2 H, 3,4-H of C_5H_4), 6.0 (t, J = 2.4 Hz, 2 H, 2,5-H of C_5H_4), 9.59 (s, 1 H, −COH) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 2036 s, 1945 s (ν_{CO}), 1693 w (−CHO) cm^{-1}. IR (KBr): $\tilde{\nu}$ = 2031 s, 1920 s (ν_{CO}), 1690 w (−CHO) cm^{-1}. MS (EI): m/z = 364 $[M]^+$, 336 $[M - CO]^+$, 308 $[M - 2\ CO]^+$, 280 $[M - 3\ CO]^+$. Also isolated was $Re_2(CO)_{10}$ (0.005 g, 4%). IR ($CHCl_3$): $\tilde{\nu}$ = 2071 w, 2014 vs (ν_{CO}), 1971 w cm^{-1}.

Reaction with Ethyl Ferrocenecarboxylate: The procedure is similar to that of the synthesis of (acetylcyclopentadienyl)tricarbonylrhenium in DMSO. Ethyl ferrocenecarboxylate (0.045 g, 0.175 mmol) was used in a reaction that underwent 2 h 30 min of heating at 160 °C. The compound was purified by chromatography on a silica gel plate (petroleum ether/ethyl ether, 4:1) to give tricarbonyl(ethoxycarbonylcyclopentadienyl)rhenium (0.023 g, 34%). ^1H NMR (200 MHz, $CDCl_3$): δ = 1.32 (t, J = 7.1 Hz, 2 H, CH_3), 4.28 (q, J = 7.1 Hz, 2 H, OCH_2), 5.37 (t, J = 2.3 Hz, 2 H, 3,4-H of C_5H_4), 6.02 (t, J = 2.3 Hz, 2 H, 2,5-H of C_5H_4) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 2033 s, 1945 s (ν_{CO}), 1722 w (−CO−OEt) cm^{-1}. MS (EI): m/z = 408 $[M]^+$, 380 $[M - CO]^+$, 352 $[M - 2\ CO]^+$, 324 $[M - 3\ CO]^+$, 308, 268, 225.

Do Divalent [{HC(CR′NR′′)$_2$}E] Compounds Contain E(I) or E(III) (E = B, Al, Ga, In)? On the Correspondence of Formal Oxidation Numbers, Lewis Structures, and Reactivity

Markus Reiher*[a] and Andreas Sundermann[b]

Dedicated to Professor Jürgen Hinze on the occasion of his 65th birthday

Keywords: Oxidation number analysis / Group-13 carbene analogs / Density functional calculations

Very recently, carbene-analogous aluminum and gallium compounds have been obtained in beautiful synthetic work giving rise to interesting theoretical questions in the framework of qualitative MO theory. We analyze the concept of oxidation numbers and the stabilities of these [{HC(CR′NR′′)$_2$}E] compounds, **1(E)**, with E being boron, aluminum, gallium, and indium. Population analyses and the electron localization function are used as analytical tools for the elucidation of the electronic density distribution. Singlet-triplet splitting energies, and model reactions probing donor and acceptor properties of the atom E, yield criteria for the reactivity of the cyclic molecules. It is demonstrated that a unique class of Lewis structures can be selected from the large number of chemically reasonable Lewis structures in order to achieve a sufficiently good mapping of the quantum chemical results on simple chemical concepts. The analysis yields that **1(E)**, where E = In, is expected to have similar properties as the experimentally known compounds **1(Al)** and **1(Ga)**, while the boron homologue is expected to be highly reactive, such that its synthesis appears to be difficult. (© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

1. Introduction

Recently, Cui et al.[1] synthesized a new cyclic compound **1(E)** = [{HC(CR′NR′′)$_2$}E] containing an aluminum atom bound to two neighboring nitrogen atoms. At about the same time, the corresponding gallium compound was obtained.[2] The planarity of the ring resembles a benzene-like system. This observation led both groups of authors to the conclusion that the electronic structure of the molecule may be described as a carbene analog with Al and Ga, respectively, having the formal oxidation number +I. While **1(Al)** is the first carbene-analogous aluminum compound known, a carbene-analogous gallium compound has already been characterized[3] as predicted by quantum chemical calculations.[4] A divalent boron homologue has not yet been synthesized, and the question arises whether {HC(CR′NR′′)$_2$}B might be sufficiently stable to be obtainable in bulk.

Since Cui et al. utilized quantum chemical calculations to support their conclusions,[5] the interesting problem has arisen of when and how numerical results of elaborate quantum chemical calculations can be mapped on simple qualitative chemical descriptors in order to gain transferable knowledge about the electronic structure of a new class of compounds. Is it, in particular, possible at all to determine the formal oxidation state from quantum chemical calculations? A positive answer to this question would in turn attribute substantial meaning to the concept of oxidation numbers.

Jørgensen already tried to settle this question in his book about oxidation numbers,[6] in which he introduced five different oxidation number concepts in order to account for many different chemical situations. Unfortunately, the definitions given[6] are mainly phenomenological, their number exceeds the acceptable degree, and they do not meet concepts of contemporary quantum chemical methods. For instance, Jørgensen defined a spectroscopic and a conditional oxidation state based on *atomic* orbital occupation numbers (atomic configurations). But the atomic occupation number is neither an observable property nor a decisive concept in the light of *molecular* orbitals and *configuration interaction* approaches. Atoms are no longer well-defined entities in molecules, because in all but the simplest cases molecules are treated as collections of electrons and atomic nuclei rather than as clusters of polarized atoms. Actually, this is the fundamental reason why the oxidation number concept can hardly be obtained directly as an atomic "property" in quantum chemical calculations.

[b] hte Aktiengesellschaft, Kurpfalzring 104, 69123 Heidelberg, Germany

Some attempts have been made to circumvent this problem and to give a definition of the oxidation number concept based on quantum chemistry. Zhan et al. founded their definition on charge transfer within molecular orbital theory.[7] However, their approach appears useless since its ingredients are not well-defined quantities (from the viewpoint of the physical foundations) such as "charge in a local region of a given atom" or "charge in the bonding region". Additionally, some electronegativity values enter their definition neglecting the importance of using clearly defined electronegativity values for an atom in a particular valence state, which gives the best resemblance to its state in the molecule, as explicated in great detail 40 years ago by Hinze and Jaffe.[8–13]

In their analysis of the oxidation state and the possible carbene-analogous character of **1(Al)**, Cui et al. followed closely an earlier work on the electronic structure of Arduengo carbene analogs of group-13 elements.[4] Here, we extend and generalize the work of Cui et al. on the aluminum compound with respect to other group-13 elements to establish a thorough oxidation number classification and stability analysis of [{HC(CR′NR″)$_2$}E], **1(E)**, with E being boron, aluminum, gallium, and indium. This permits also an assessment of the possible stability of the divalent boron compound **1(B)**.

As we demonstrate in the sequel, it is difficult to assign a most suitable Lewis structure for **1(E)** on the grounds of (chemical) common sense. We will discuss possible candidates to conclude which class of Lewis structures is the best one for the representation of the electronic structure. These reasonable Lewis structures for **1(E)** are given in the following section and extended Hückel calculations are employed for a qualitative molecular orbital discussion of the electronic situation. The structures obtained from density functional calculations are discussed thereafter and the electronic density distribution is analyzed in terms of partial charges, the electron localization function, and the Laplacian of the electron density. A discussion of reactivity on the basis of singlet-triplet splitting energies and Lewis acid-base reactions follows in Section 5. Details on the quantum chemical methods employed are given in the Appendix.

2. Qualitative Picture

Nowadays, compounds of the size of **1(E)** can be analyzed on personal computers using quantum chemical methods with sufficiently large basis sets. The aim of a theoretical study should therefore be the gain of insight rather than a reproduction of experimentally obtained quantities. Consequently, the complete knowledge about the electronic density distribution obtained from the numerical calculation should be analyzed in order to assign a characteristic set of Lewis structures. The benefit is a simplified

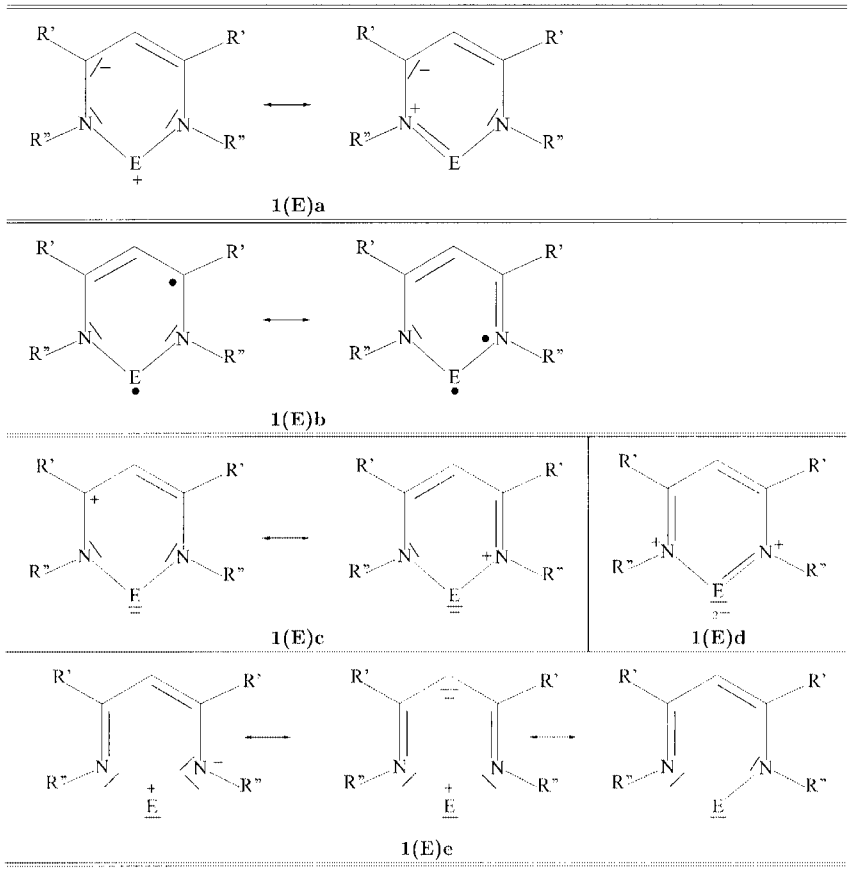

Figure 1. Three classes (the last one is subdivided into three sub-classes) of Lewis structures of [{HC(CR′NR″)$_2$E] compounds (E = B, Al, Ga, In); corresponding symmetric Lewis structures were omitted for the sake of brevity

graphical expression of the electronic structure with the most prominent features. Subsequent work should be possible on the back of an envelope rather than using large computer resources. Three different classes of Lewis structures can be constructed for **1(E)** (Figure 1).

• Class I: In **1(E)a** the element E bears a positive (formal) charge, while the corresponding negative charge is assigned to the ring carbon atoms resulting in an allyl-anion-type substructure. It is possible to delocalize the positive charge on the three-center N−E−N substructure by assuming an additional π interaction between E and the neighboring nitrogen atoms.

• Class II: The only possible electronic structure without charge separation is given by **1(E)b** yielding a diradical.

• Class III: This class is best discussed in terms of three subclasses. The structures in **1(E)c** show a similar bonding pattern like **1(E)a**, although the formal charges of the subsystems are reversed, i.e., a negatively charged atom E and an allyl cation substructure results or the positive charge is shifted towards the nitrogen atoms, respectively. Structure **1(E)d** builds up a separate subclass because a Hückel-aromatic 6π system can only be established at the cost of two negative charges localized on atom E and positive charges localized on the nitrogen atoms. Finally, the structures **1(E)e** generate the third subclass. A bidentate chelate ligand coordinates to the central atom E. Thus, **1(E)e** represents a donor-acceptor complex. This type of bonding has been extensively investigated by Schoeller and co-workers for group-13, -14, and -15 compounds with similar connectivities,[4,14−18] and others have also investigated this.[19−23]

All three classes of Lewis structures stress different qualitative aspects of the electronic structure and correspond to three different oxidation numbers. While Lewis structures and formal charges are well-defined concepts in the sense that they can be drawn without any arbitrariness, this does, in general, not hold for oxidation numbers as already discussed in the Introduction. However, in cases where electrons can be classified as "bonding" and "non-bonding" (such as in cases of lone pairs or non-bonding d electrons in transition metal complexes) the assignment of a formal oxidation number is possible. Since the Lewis structures suggest that we count 0 electron in **1(E)a**, 1 electron in **1(E)b**, and 2 electrons in **1(E)c−e** as non-bonding according to the lone-pair electrons at E [σ/π separation is possible (point group C_{2v})], we obtain the following oxidation number assignment: **1(E)c**, **1(E)d**, and **1(E)e** possess E in the formal oxidation number +I, while **1(E)b** contains E in the formal oxidation number +II and finally for **1(E)a** we have +III. This assignment is in accordance with the rules given by Pauling.[24] Pauling's rule no. 3, which states that the bonding electrons are assigned to the more electronegative atoms, leads to exactly the same oxidation number assignment. In our case, the nitrogen atoms are the more electronegative atoms when compared with E (in terms of Pauling's "averaged" electronegativity scale as well as in terms of the Mulliken−Jaffe electronegativity scale; see also ref.[8]).

The "oxidation number problem" has now been reduced to the analysis of the contribution of the Lewis structures in Figure 1 to the total electronic wavefunction. But a decision about which Lewis structure is most appropriate to describe the actual electronic structure is not straightforward. The standard textbook rules for the relative contribution of Lewis structures are difficult to apply because the stabilizing effect of several electronic and structural features (such as s−p separation in the valence shell of the isolated atom E, charge delocalization, and negative charge on electronegative atoms) is hard to estimate. Numerical results from quantum chemical calculations are needed to solve this puzzle and to achieve a better understanding and improvement of these formal concepts. It should be noted that counting the number of lone-pair electrons is complementary to counting the number of π electrons in the ring. We have 8π electrons in the case of **1(E)a** with oxidation number +III, and 6π electrons in the case of **1(E)c−d** with oxidation number +I. This gives a first hint, along the lines of Hückel's rule, which Lewis structures and thus which oxidation numbers are to be preferred.

The discussion of Lewis structures so far allows us to define descriptors for testing which of these structures are most appropriate. Firstly, we note that E^{III} always bears a positive charge while E^{II} is uncharged and E^{I} results in a more or less pronounced accumulation of negative charge on the group-13 atom. Therefore, population analyses yielding a formal separation of charges in areas of real or Hilbert space may be used to determine the partial charge on atom E.

Since a formal oxidation number of +I requires a lone-pair on atom E, approaches such as the electron localization function,[25] which are able to detect possible lone pairs, may contribute to the classification of the electronic structure in terms of the Lewis structures. Besides these methods for the direct analysis of the charge density, chemical measures for probing particular features of the electronic density distribution such as bond angles and distances, as well as reactivity-based approaches, can be considered. The latter appears to be promising because E^{I} and E^{III} compounds could be distinguished by their different affinity towards Lewis acids such as BF_3, and Lewis bases such as NH_3. Thus, the ability to form Lewis acid-base complexes could be utilized to probe for a lone-pair at the group-13 atom. Binding energies resulting from the analysis of such Lewis acid-base addition reactions are also accessible by quantum chemical calculations. A complication of this viewpoint comes from the so-called inert-pair effect: The larger the nuclear charge Z of atom E, the more important is this effect on reducing the donor property of E without changing the formal oxidation number.

To obtain a first qualitative picture of the electronic structure within molecular orbital theory, we performed Extended-Hückel Theory (EHT) calculations since they provide an *occupation number independent* view of the electronic structure. A representation of the molecular orbitals on the basis of fragment orbitals of cation E^+ and a negatively charged ligand $[HC(CR'NR'')_2]^-$ reveals some im-

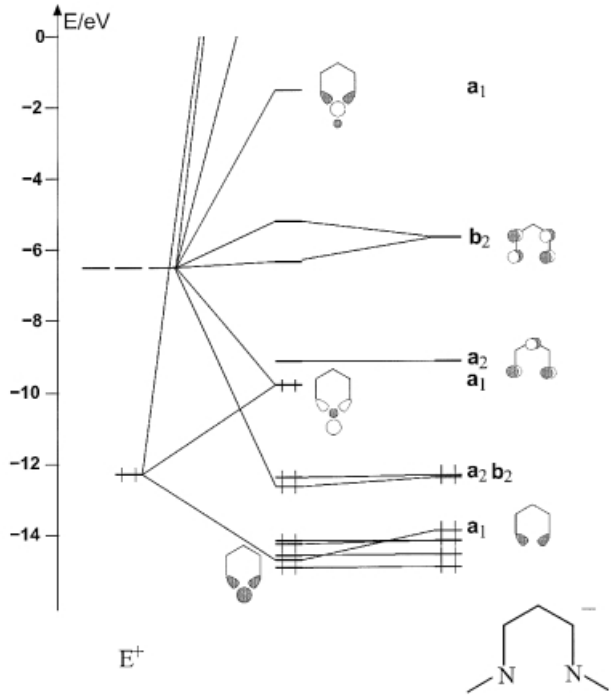

Figure 2. Simplified MO diagram from Extended-Hückel calculations; the left-hand side shows the valence atomic orbitals of the aluminum atom, whereby the highest occupied p-orbital is denoted by a small vertical line; the right-hand side gives the molecular orbitals of the remaining {HC(CR′NR′′)$_2$} chelate ligand; in the center the molecular orbitals for the total complex are depicted

portant aspects of the bonding situation (Figure 2). It should be noted that the ligand is σ- and weakly π-bonding, and element E^+ cannot back-donate.

The qualitative MO diagram from EHT calculations shows a rather small HOMO−LUMO energy splitting. The frontier orbitals can be classified as a metal−ligand nonbonding orbital of a_2 symmetry (point group C_{2v} assumed) being localized on the ligand and a weakly anti-bonding combination with nitrogen sp^2 and metal sp contributions. The latter MO has the character of a metal lone pair. Since the a_2 MO has no metal contributions for symmetry reasons, its energy is largely independent of the nature of E. The energy of the a_1 MO is expected to be the HOMO for the heavier group-13 elements, while at least for E = B a more pronounced antibonding character due to a larger π overlap may result in a_2 then becoming occupied. A decision about this ordering is beyond the scope of the qualitative EHT treatment.

3. Optimized Structures

The structures obtained with the pure density functional BP86 and the hybrid functional B3LYP are discussed in the following. For the sake of simplicity and computational efficiency and to arrive at substituent-independent conclusions we concentrate on generic models of **1(E)**. Therefore, we chose the model compound with R′ = R′′ = H. However, to test for substituent effects we also performed calculations

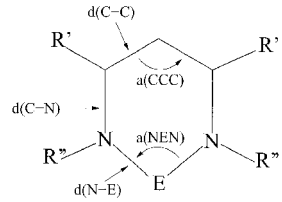

Figure 3. Definition of characteristic structural parameters

for R′′ = Me. The most important structural parameters are depicted in Figure 3 and given in Table 1. All optimized structures **1(E)** are found to be minima on the potential energy surface.

The optimized structures for the heavy elements of group-13 adopt C_{2v} symmetry in their singlet ground state, and they are thus planar. For the boron compound, a distortion to C_2 symmetry is observed, indicating a qualitatively different electronic structure of **1(B)** when compared to its higher homologues. In the triplet state, **1(Al)** and **1(B)** are planar, while the Ga and In atoms in **1(Ga)** and **1(In)**, respectively, may lie above the NCCN plane in an envelope-type structure (this depends on the density functional and on the R′′ substituent, indicating an electronic structure of the triplet state being too complicated to be accessible by density functional methods).

The C−C and N−C bond lengths deviate for Al to In slightly from the values found for the anionic $C_3H_5N_2^-$ ligand. These findings justify the fragmentation used in the qualitative EHT calculation and indicate that the Lewis structures **1(E)e** are a good representation for E = Al and an even better one for E = Ga and E = In. The heavier the group-13 element E is, the more the binding situation resembles a chelate complex.

In the case of E = B, the changes observed in the ligand are larger; the C−N bond is 5 pm longer while the C−C distance is shortened by 2.5 pm. It is interesting to note that similar values can be found for the lowest triplet states of the Al, Ga, and In complexes. This may be interpreted as an indicator for the orbital crossover discussed in the previous section.

In general, the substitution of hydrogen by a methyl group does not change the structure significantly and both compare very well with the experimental structures for E = Al and E = Ga, in which 2,6-*i*$Pr_2C_6H_3$ substituents are present, Only the N−E bond lengths deviate by 5−6 pm from the calculated distances.

4. Analysis of the Electronic Density

According to the charge separation suggested by the different Lewis structures, we calculated partial charges from two different population analyses. One was suggested by Cioslowski,[26] which is defined in real space, and the other one by Heinzmann and Ahlrichs,[27] which is defined in the Hilbert space of (modified) atomic orbitals. The two conceptually different population analyses are used since the partial charge of an atom in a molecule is not a well-defined

Table 1. Selected structural parameters of [{HC(CR′NR′′)$_2$}E] (R′ = H) for their singlet ground states (S = 0) and the lowest-lying triplet states (S = 1); the last data set contains structural parameters for the anionic ligand; distances d are given in pm and the angles a in °; the definition of parameters $a-d$ are given in Figure 3; the experimental bond lengths and angles for [{HC(CMeNAr)$_2$}E] (R′′ = Ar = 2,6-iPr$_2$C$_6$H$_3$) with E =Al, Ga are given for comparison (PG is an acronym for "point group")

quantum mechanical quantity. Any definition of this intuitive concept is affected by a certain degree of arbitrariness. However, we aim at qualitative results and these should be reproduced by both population analyses. The results of the calculations are given in Table 2.

Table 2. Partial charges q on atom E in fractions of the elementary charge in the singlet state of **1(E)** (R′ = H) according to population analyses by Cioslowski q_C[26] and by Ahlrichs and co-workers q_A[27] (q_A includes multi-center corrections); discrepancies occur for E = In, where the general trend is not maintained; this can be traced back to the use of the ECP for In

While Al and its higher homologues carry positive partial charges, the boron compound exhibits negative partial charges indicating that reactions of **1(B)** will be different from those of the higher homologues. The N−E bonds have substantial ionic character.

In order to visualize a potential electron-pair on element E we utilize the electron localization function (ELF).[25] The ELF is a measure for the spherically averaged Fermi-hole around a reference electron at position $\vec{r}$. As introduced by Becke and Edgecombe,[25] the function can be mapped onto an interval $0 < \mathrm{ELF} < 1$. ELF ≈ 1 indicates areas of a localized exchange potential. Such areas are occupied by electron pairs. For ELF ≈ 0 the exchange hole is strongly delocalized. The ELF reveals the presence of a lone pair at atom E for all group-13 elements (Figure 4). A polar nature of the N−E bonds is present for all heavier atoms E, i.e., E = Al, Ga, In, which is typical for donor−acceptor complexes.

In addition to ELF, we also calculated the Laplacian of the electron density in the framework of the Atoms-In-Molecules theory[28] but refrain from giving plots of the result because of the mapping which connects ELF and the Laplacian of the density.[29,30] [An advantage of ELF is that the corresponding Laplacian of the density, $\nabla^2\rho(\vec{r})$, is unbound, while ELF is not; ELF is therefore more suitable for graphical representations.] Since the Laplacian field $\nabla^2\rho(\vec{r})$ is a measure for local charge concentrations [$\nabla^2\rho(\vec{r}) < 0$] and for charge depletion [$\nabla^2\rho(\vec{r}) > 0$] in the electron distribution of a molecule, we find for the elements Al to In the N−E bonding electrons assigned to the valence shell of the nitrogen atoms as witnessed by the convex nature of the area of charge concentration/electron localization. Only for E = B is the situation less clear. Here, the bond exhibits a more covalent character.

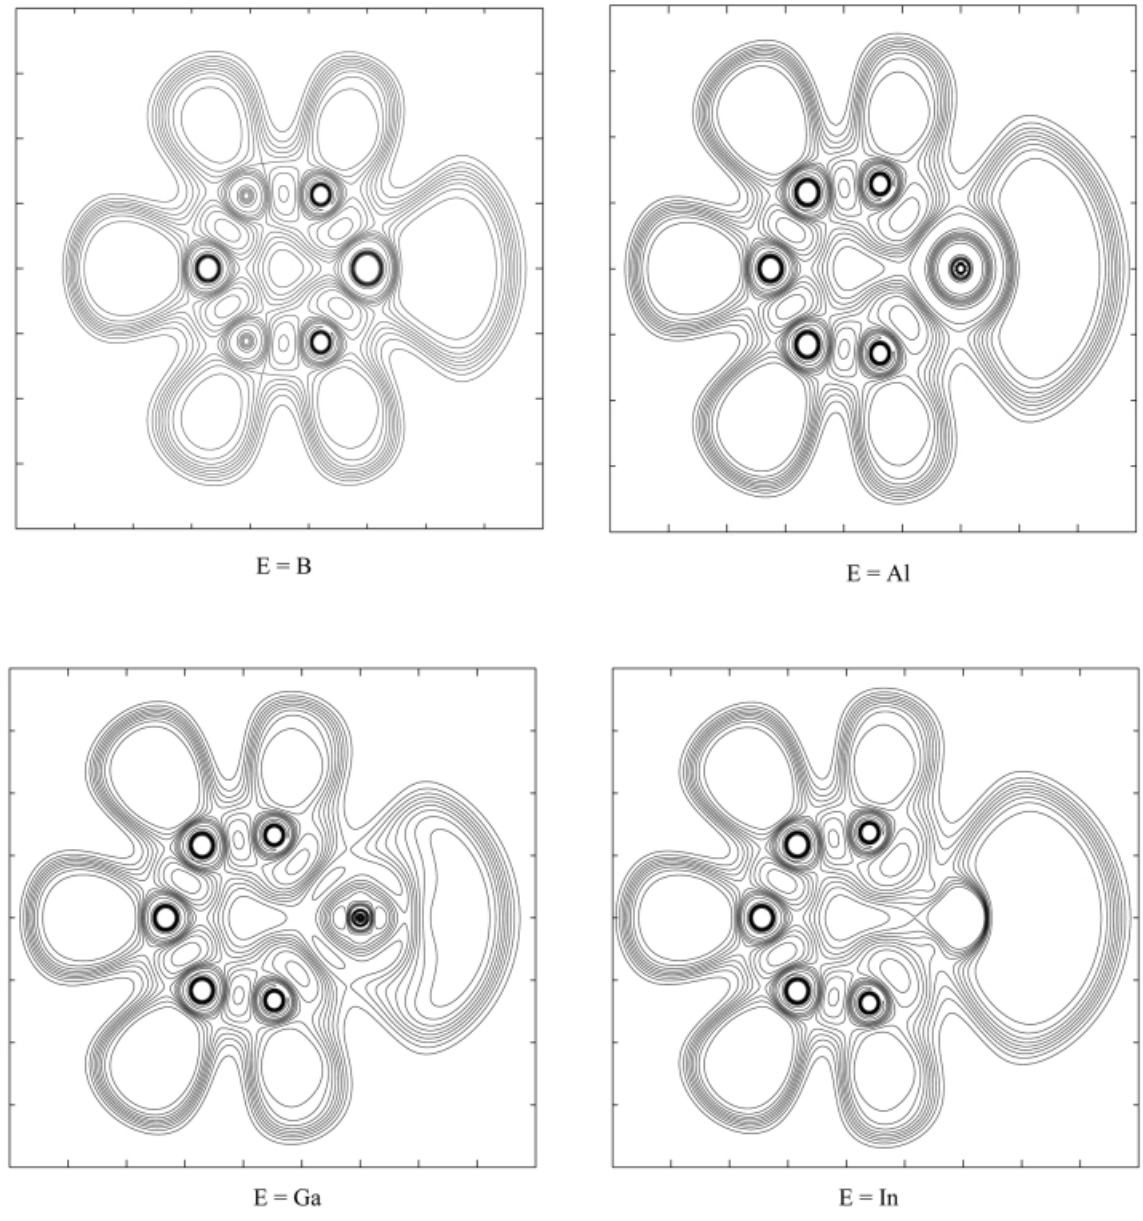

Figure 4. ELF plots for [{HC(CR′NR′′)$_2$}E], where R′ = R′′ = H; the contour lines give the increasing value for ELF in steps of 0.1 from 0.0 (no localization) outside the molecules to 1.0 (high localization) at the C−H and N−H bonds and at the lone pairs; the internal structure of the indium atom is not resolved because of the ECP

5. Reactivity − Singlet−Triplet Splittings and Addition of NH_3 and BF_3

We proceed by analyzing the singlet−triplet splitting energies given in Table 3. We find that for E = B and R′ = R′′ = H, the triplet state is almost as stable as the singlet state, indicating a high reactivity of **1(B)**. The B3LYP splitting energy favors the triplet state by about 20 kJ/mol, which is due to the fact that B3LYP always favors spin states of high multiplicities owing to the explicit consideration of Fermi correlation through exact exchange admixture.[31] If the hydrogen atoms on the ring nitrogen atoms are substituted by methyl groups, the situation becomes even less clear. DFT calculations are not sufficiently accurate to finally answer the question of the ground state multiplicity of **1(B)**. Since the knowledge of the ground state multiplicity is of minor importance to our study, we refrain from performing more elaborate calculations. The important result is that singlet and triplet states are energetically close for E = B, while this is not the case for the higher homologues, where the triplet states lie more than 150 kJ/mol above the singlet states.

This analysis of the singlet−triplet energy splittings reveals that the aluminum, gallium, and indium compounds have a similar electronic structure, while the boron compounds are different as they will exhibit a higher reactivity and are thus well represented by the Lewis structures of the biradical, **1(B)b**. This structure should also come to the fore

in a plot of the spin polarization, which is the "excess density" of the unpaired electrons. It is plotted for the triplet state of **1(B)** in Figure 5 and clearly shows a single electron at atom E and a "delocalized" electron over the four ring atoms exactly corresponding to Lewis structure **1(B)b**. It is thus most likely that the boron compound **1(E)** is not sufficiently stable to be "accessible in a flask".

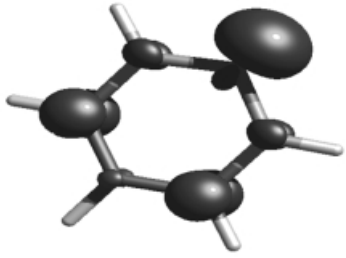

Figure 5. Spin polarization of the triplet state of **1(B)**

To analyze the electronic situation and reactivity of element E in **1(E)** further, we probe the potential lone pair or "electron-hole" on element E by addition reactions, in which an electron-pair donor such as NH_3 and an electron-pair acceptor such as BF_3 are added [Equations (1) and (2)].

Reaction (I): **1(E)** + NH_3 → **1(E)**−NH_3 (1)

Reaction (II): **1(E)** + BF_3 → **1(E)**−BF_3 (2)

Note that these addition reactions shall serve as model reactions to probe certain electronic features of **1(E)** rather than to find stable, experimentally accessible adducts. The addition of NH_3 occurs only perpendicular to the plane of the six-membered ring for E = Al, Ga, In, as one would expect for E bearing a lone-pair. An in-plane addition does not occur; the NH_3 is then rejected indicating that a lone-pair−lone-pair repulsion appears. In the case of E = B, the adduct rearranges to give a five-membered ring, where one N−H unit builds up an annulated B−C−N three-membered ring. Therefore, we restrict the discussion to the addition reactions for the higher homologues, which are all minimum structures on the potential energy surface. The general adduct structure is depicted for E = Al in Figure 6. Selected structural parameters are given in Table 4, and the reaction energetics can be found in Table 5.

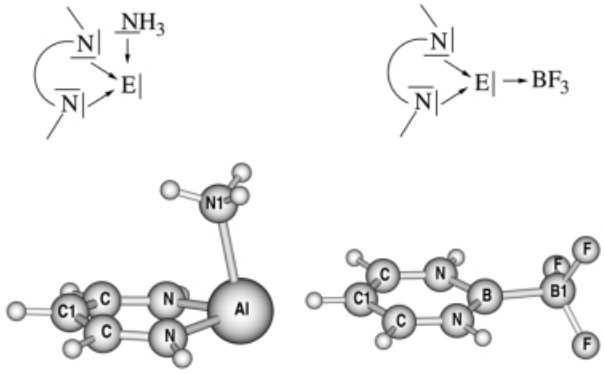

Figure 6. Structures for two possible adducts of NH_3 and BF_3 and the corresponding BP86/RI/TZVP-optimized structures for **1(Al)** + NH_3 and **1(B)** + BF_3

	BP86(/RI)				B3LYP			
	$\Delta\langle E\rangle$	ΔZPVE	ΔH	ΔG	$\Delta\langle E\rangle$	ΔZPVE	ΔH	ΔG
Al	−20.9	5.4	−14.0	23.0	−15.1	5.3	−8.1	29.1
Ga	−13.6	4.6	−6.5	27.1	−10.2	5.3	−2.7	32.7
In	−23.5	5.5	7.9	23.4	−21.4	6.2	8.3	28.9

All three reactions are energetically very similar. They are exothermic by about 15 kJ/mol, but endergonic by about 20 kJ/mol because of the model-inherent increase of vibra-

tional entropy from the quenching of translational and rotational degrees of freedom on adduct formation. These results are almost independent of the functional used and demonstrate that **1(E)** with E = Al, Ga, In react as Lewis acids if the Lewis base approaches from above the ring plane. Upon addition, the structure of the allyl system is not changed; the C−C and C−N bond lengths as well as the C−C−C angle do not change significantly. However, the donated lone-pair of ammonia lengthens the E−N bonds in the six-membered ring by 3.6 pm for E = Al and by about 5 pm for E = Ga, In. In all adducts, the E−NH_3 distances are 30 to 40 pm longer than the in-plane E−N distances, which may be an indication for a double-bond character of the E−N bond in the ring. However, the equatorial E−N distances should be shorter because of sp^2 hybridization and for steric reasons, while the axial E−NH_3 bond should be longer because of the larger repulsion in this position.

For reaction (II) [Equation (2)], i.e., the addition of the electron acceptor BF_3, stable addition products are found for all four molecules. The general structure of the adduct is shown for E = B in Figure 6 (selected parameters see Table 6). In contrast with the NH_3 addition, the addition of BF_3 occurs in the plane of the six-membered ring as would be expected in view of the Lewis base addition of **1(E)** to BF_3.

Table 6. Selected structural parameters of adducts [{HC(CR′NR′′)$_2$}E]BF_3 (R′ = R′′ = H) for their singlet ground state (S = 0): distances d are given in pm and the angles a in °; the definition of parameters a−d are according to the definition for the basis systems in Figure 3; the labelling C1 and B1 is according to Figure 6; an asterisk, *, indicates that the BF_3 ligand tends to dissociate; all calculations have been performed with the TZVP basis set

While the addition is about 140 kJ/mol exergonic for **1(B)** (Table 7) indicating that **1(B)** itself is unstable, reaction (II) is endergonic for the higher homologues, where the inert-pair effect becomes more and more important, such that the molecular orbital corresponding to the lone pair has an increased s character, which reduces the Lewis base character of the compound and reduces in turn the bond energy of the adduct. As a consequence, in the case of E = Ga and particularly for E = In, the Lewis acid BF_3 is rejected and thus does not build a donor−acceptor bond with the six-membered ring. In the case of E = B, Al, the allyl subsystem in the ring is again hardly distorted upon adduct formation, while the E−N bond lengths are shortened by about 7 pm, for aluminum it changes only little in the boron compound.

Table 7. Energetics for the addition of BF_3 [Equation (2)]: reaction energy $\Delta\langle E\rangle$ at 0 K without zero-point vibrational energy correction (ZPVE), difference of zero point energies ΔZPVE, reaction enthalpy ΔH and free reaction enthalpy ΔG (both at 298.15 K and 1013.25 hPa) obtained for BP86/RI and B3LYP with the TZVP basis set; ΔH and ΔG are not given in cases where the BF_3 tends to dissociate; all energies are given in kJ/mol

6. Conclusion

To conclude, we were able to identify the formal oxidation number of atom E in **1(E)** through various descriptors and could correspond the electronic structure, stability, and reactivity with one particular class of Lewis structures for each molecule **1(E)**. This is remarkable in view of the many different classes of reasonable Lewis structures, which can be thought of for **1(E)**. All higher homologues of **1(E)** are best represented by the donor−acceptor Lewis structure **1(E)e**. For these cases we find a formal oxidation number of +I while boron is in its formal oxidation state +II in **1(B)**.

Furthermore, **1(B)** differs largely from the higher homologues: The electronic structure of **1(B)** can be characterized by the diradical Lewis structures **1(B)b**, symbolizing the low-lying triplet state, which is an indicator of high reactivity. This is supported by the finding that **1(B)** reacts with NH_3 under rearrangement, and with BF_3 to give a stable adduct with a boron−boron bond. Unfortunately, it also implies that **1(B)** with divalent boron is not a valuable synthetic target in contrast to the Arduengo-analoguous boron compound studied previously.[4]

Appendix

Quantum Chemical Methodology: For all calculations we used the density functional programs provided by the TUR-

BOMOLE 5.1 suite.[32] The Becke−Perdew functional dubbed BP86[33,34] and the hybrid functional B3LYP[35,36] were employed as implemented in TURBOMOLE. For all molecules that do not contain In, all-electron calculations have been performed. In these cases the resolution of the identity (RI) technique[37,38] was used in combination with the BP86 functional calculation. All results were obtained from fully optimized Kohn−Sham calculations using Ahlrichs' TZVP basis featuring a valence triple-zeta basis set with polarization functions on all atoms.[39] For all compounds containing indium, we tested the 46-electron effective core potential (ECP) from the Stuttgart−Bonn (SB) group,[40] which allowed us to treat only 3 electrons explicitly. It turned out that such a large-core ECP does not describe the In atom properly (i.e., the core polarization is drastically underestimated). Therefore, a 28-ECP from the SB group[41] was used, which leaves 16 electrons to be treated explicitly. The double-zeta basis set optimized for this ECP and distributed by the SB group has been employed.[42] Up to date, no optimized auxiliary basis exists for the small-core 28-ECP, therefore we did not apply the RI technique for the indium complexes. The addition reactions have not been corrected for the basis-set superposition error because it is less than 7 kJ/mol for the addition of NH_3, and less than 5 kJ/mol for the BF_3 addition, and would not change the qualitative picture. In order to analyze the electron density of the compounds, we use the population analysis by Ahlrichs and co-workers[27] as implemented in TURBOMOLE. For the vibrational analysis, the second derivatives of the total electronic energy were computed as numerical first derivatives[43,44] of analytical energy gradients (obtained from TURBOMOLE) within the harmonic approximation. The Cioslowski charges have been computed with SNF[43] as well as the thermochemical data, which were obtained in the standard way from the frequency analysis using the partition function of the harmonic oscillator in combination with the vibrational frequencies. Translational and rotational degrees of freedom were treated classically. For the EHT calculations we used YAEHMOP.[45] The ELF calculations and the analysis of the Laplacian of the electron density have been performed using the program ELF.[46] The program MOLDEN[47] has been used for the visualization of structures.

Acknowledgments

We are grateful to Prof. B. A. Hess and Prof. W. W. Schoeller for generous support and discussions. We also would like to thank Dr. E. Dobbert and Dr. G. Dembeck for drawing our attention to the Al compound. All calculations have been performed at the Chair of Theoretical Chemistry at the University of Erlangen-Nürnberg, which is gratefully acknowledged.

Physicochemical Properties and Structural Refinement of Strontium-Lead Hydroxyapatites

Béchir Badraoui,[a] Adriana Bigi,*[b] Mongi Debbabi,[a] Massimo Gazzano,[b] Norberto Roveri,[b] and René Thouvenot[c]

Keywords: Hydroxyapatite / X-ray diffraction / IR spectroscopy / ^{31}P MAS NMR / Ionic substitution

Continuous series of solid solutions of strontium and lead apatite $Sr_{(10-x)}Pb_x(PO_4)_6(OH)_2$ ($0 \leq x \leq 10$), synthesized in aqueous media have been investigated by X-ray powder-pattern fitting, ^{31}P MAS NMR and IR spectroscopy. The lattice dimensions and the IR frequencies of the solid solutions vary linearly with the atom% of lead. The results of the Rietveld analysis indicated a clear preference of lead for the M(2) site of the apatitic structure, so that in the samples with low Pb content it is almost exclusively found in the M(2) site. ^{31}P MAS NMR spectra at 162 MHz show a unique isotropic signal at δ_{iso} between +2.9 (SrHA) and −0.7 ppm (PbHA). From the variation of δ_{iso} with the phase composition it appears that ^{31}P shielding in these mixed apatites is essentially governed by the nature of the metal in the M(1) site. The qualitative variation of the chemical shift anisotropy of the PO_4 group agrees with the deviation from ideal T_d symmetry shown by the Rietveld refinement analysis.

Introduction

Hydroxyapatites, $M_{10}(PO_4)_6(OH)_2$, crystallizing in the hexagonal lattice, are known for the bivalent metals M = Ca, Sr, Ba, Cd, and Pb.[1−5] Because of the high stability and flexibility of the apatitic structure, a great number of substitutions, both cationic and anionic are possible. In particular, substitution of the bivalent cations has a great influence on the structural, textural, and physical properties of these materials and justifies the increasing number of studies on this subject, which involves several research and application fields: dental and bone pathologies, bioceramics, luminescence, ionic conduction, water treatment by ionic exchange, catalysis, etc.[6−10]

A major contribution to these studies comes from the results of structural refinements of powder X-ray diffraction patterns (Rietveld methods) and of solid-state NMR spectroscopy investigations, performed at high resolution with magic-angle spinning (MAS NMR). Actually, these two methods are complementary and their combined use represents a powerful tool for investigating the localization of the substituted elements in the apatitic cell, as well as the resulting structural modifications.

The unit cell of stoichiometric crystalline apatite hosts ten cations arranged in two non-equivalent positions: four at the M(1) site aligned in the column, each surrounded by nine oxygen atoms, and six at the M(2) site arranged at the apexes of "staggered" equilateral triangles, each surrounded by seven oxygen atoms.[1,2,10]

Ca-Sr, Ca-Ba, Ca-Cd, and Ca-Pb hydroxyapatites have been widely investigated[11−15] (hereafter MHA and M′-M′′HA indicate pure or mixed-metal hydroxyapatites, respectively). The lattice parameters of these mixed apatites vary linearly with the composition, with the exception of the *c* axis of Pb-CaHA that displays a discontinuity at about 50 atom% of lead. The peculiar variation of the *c*-axis dimension has been ascribed to an inhomogeneous lead distribution in the two non-equivalent cation sites, on the basis of the results of powder pattern structure refinements of Pb-CaHA, which indicate a clear preference of lead for site M(2) of the hydroxyapatite structure.[9]

We have previously applied powder pattern fitting refinements and ^{31}P MAS NMR spectroscopy to the study of Cd-Pb and Cd-Sr systems.[16,17] CdHA and PbHA exhibit just a limited range of solubility; cadmium can replace up to 30% of the lead, whereas lead does not seem to "like" the incorporation into CdHA. The cadmium ion displays a

clear preference for the M(1) site of the apatite structure, in agreement with the shorter metal−metal distances in this site with respect to the M(2) site. On increasing the cadmium content, it begins to fill the M(2) site so that at the highest degree of substitution, two of the four metal ions in the M(1) site are Cd, whereas just one of the six metal ions in the equilateral triangles characteristic of site M(2) is Cd. Also $Sr_{(10-x)}Cd_xHA$ were obtained as a single phase in a limited range of composition ($x \leq 4$). In this system, in comparison with the Cd-Pb one, the relatively small Cd^{2+} ion is almost statistically distributed over both sites.

Here we report the results of a structural (Rietveld method) and spectroscopic (IR and ^{31}P MAS NMR spectroscopy) investigation carried out on strontium-lead hydroxyapatites in the whole range of lead substitution for strontium.

Results

X-ray Analysis

Preliminary structural analysis by X-ray diffraction (XRD) shows that all the samples correspond to pure apatitic phases, whatever the Sr/Pb ratio. This is confirmed by structural Rietveld refinements of six samples where the resulting formulae are: $Sr_{8.9}Pb_{1.1}HA$, $Sr_{6.9}Pb_{3.1}HA$, $Sr_{4.9}Pb_{5.1}HA$, $Sr_{4.0}Pb_{6.0}HA$, $Sr_{2.0}Pb_{8.0}HA$, and $Sr_{1.0}Pb_{9.0}HA$. From now onwards, the samples will be indicated as $Sr_{(10-x)}Pb_xHA$, where x corresponds to the stoichiometry resulting from chemical analysis.

Figure 1 displays the final plot for $Sr_{8.9}Pb_{1.1}HA$ and $Sr_{2.0}Pb_{8.0}HA$ samples, as typical comparisons between the observed and the calculated patterns. The refined structural parameters are reported in Table 1, and the data about cationic distribution are reported in Table 2.

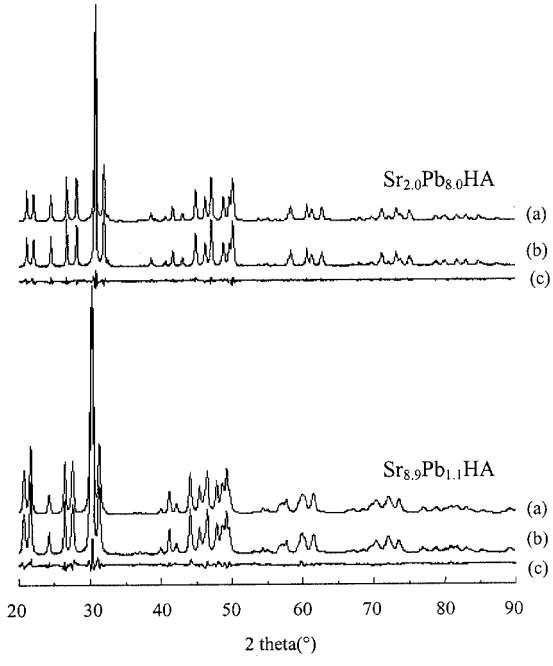

Figure 1. Comparison of the observed [curve (a)] and calculated [curve (b)] powder diffraction patterns of $Sr_{2.0}Pb_{8.0}HA$ and $Sr_{8.9}Pb1_{1.1}HA$ [curve (c)] is the difference profile

[a] Rietveld refinement. [b] Chemical analysis.

havior of Ca-Pb and Ca-Sr apatites.[11,14] The progressive substitution of lead for strontium results in a slight increase in the lattice parameters *a* and *c*; the variation of these sizes is appreciably linear and follows the Vegard law,[18] according to the following relations:

$a = (9.7729 + 0.0122x)$ Å; $\sigma(a) = 9.3 \cdot 10^{-3}$ Å
$c = (7.2761 + 0.0011x)$ Å; $\sigma(c) = 4.7 \cdot 10^{-2}$ Å

Despite this regular variation and the similarity of the ionic radii (coord. 7: Pb^{2+} = 1.37 Å, Sr^{2+} = 1.35 Å; coord. 9: Pb^{2+} = 1.49 Å, Sr^{2+} = 1.45 Å),[19] the variation of the average values of the M(1)−O and M(2)−O distances is someway irregular. In the mixed hydroxyapatites, the phosphate group is considerably distorted by comparison with the limiting phases. A table with M−O distances and distortion indexes is reported as Supporting Information.[20]

According to the similarity of the radii of the two cations the distribution of these ions in both the M(1) and M(2) sites, should be close to a statistical occupancy. However, the refinement shows that the occupancy factor of lead in the M(2) site is always higher than that corresponding to the statistical distribution (Table 3).

Thus, small lead contents (0.86 atom per cell) go almost exclusively into the M(2) site. The difference from the statistical distribution decreases when the lead content increases. We could attribute this behavior, as well as the preferential location of lead in the M(2) site, to the relatively high electronegativity of lead, which increases the polarization of the O−H bond and strengthens the hydrogen bonds, as well as the structural stability of the apatite.[21]

Finally, we observed a good agreement between the values of the Pb/(Pb + Sr) ratios deduced from structural refinements and those obtained by chemical analyses, except for the phase $Sr_{8.9}Pb_{1.1}HA$, which exhibits an appreciably smaller lead incorporation (see Table 2).

Table 3. Statistic distribution and refinement occupancy in the metal M(1) and M(2) sites of Sr-PbHA; the occupancy parameters are normalized to one unit cell content

Pb content [atom/cell]	Refinement distribution (A)		Statistic distribution (B)		(A − B)/B

Infrared Absorption Spectroscopy

The infrared spectra of various mixed apatites show the characteristic absorption bands of the $(PO_4)^{3-}$ groups and OH^- ions of the apatitic structure. Weak bands characteristic of HPO_4^{2-} and CO_3^{2-} ions[22] are also present, as it which can be seen from a typical plot (Figure 2).

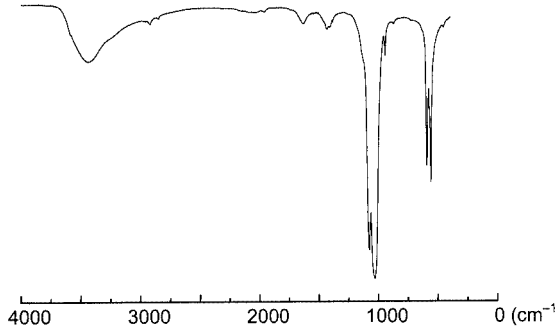

Figure 2. Infrared spectrum of $Sr_{6.9}Pb_{3.1}HA$

The progressive substitution of the lead ions for strontium induces a regular shift of the absorption bands towards smaller wavenumbers as shown in Figure 3.[20]

The shift of the absorption bands of the (PO_4) group can be attributed to the variation of the nature of the metal−oxygen interactions. The character of lead−oxygen interaction is more covalent than that of strontium−oxygen and furthermore a cation of larger mass is involved.[23] The more covalent character of the Pb−OH leads to a shift of the OH vibrational modes towards lower frequency. In particular the shift of the OH stretching mode when the Pb content increases is in agreement with the predominant role of the M−OH interaction with respect to the OH···O(PO_3) hydrogen bond.[24]

^{31}P Solid-State NMR Analysis

Table 4 shows the NMR spectroscopic data for the whole series of mixed Sr-PbHA, as well as that of the pure phases SrHA and PbHA, and Figure 4 shows parts of the 162 MHz MAS spectra obtained at relatively high spinning rates (ca. 5 kHz).

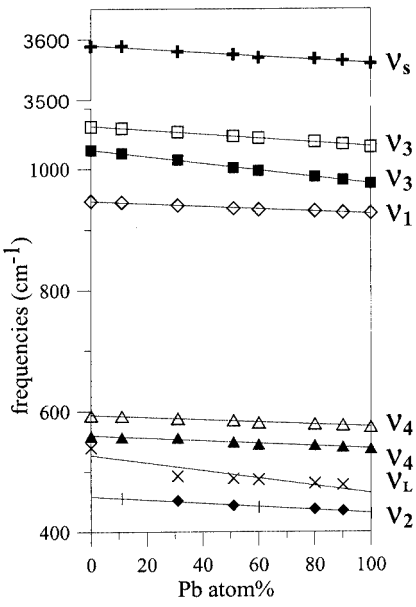

Figure 3. Infrared frequencies of the vibrational modes of strontium-lead hydroxyapatite solid solutions as a function of Pb content; ν_S, ν_L stretching and librational mode of the OH group; ν_1, ν_2, ν_3, ν_4 vibrational mode of the PO_4 group

[a] Position of the central line observed at a high spinning rate (about 5 kHz). [b] In ppm relative to 85% aqueous H_3PO_4 (±0.1 to ±0.2 ppm). [c] In ppm, with the values in Hz in parentheses. [d] Half-height bandwidth of the resonance for non-spinning sample; in kHz, with ppm values in parentheses.

The evolution of the isotropic chemical shift δ_{iso} and of the isotropic full width at half maximum (*fwhm*) as a function of the Pb content is depicted in Figures 5 and 6.

As shown in Figure 4, whatever the phase composition, only one isotropic signal is observed; however, for the samples with relatively high Pb contents, a shoulder is apparent, which cannot be resolved by resolution enhancement. This is not surprising when considering the small chemical shift difference between the limiting phases SrHA (δ_{iso} = +2.9 ppm) and PbHA (δ_{iso} = −0.7 ppm); $\Delta\delta_{iso}$ = 3.6 ppm amounts to only four times the smallest observed line width of SrHA (0.9 ppm, Table 4).

The δ_{iso} variation is far from linear; it does not vary significantly with increasing Pb content up to 60%, where it decreases abruptly, in agreement with a shielding effect of Pb^{2+} compared with Sr^{2+}. This peculiar variation has to be related to the nonstatistical distribution of Pb in both the M(1) and M(2) sites.

The isotropic signal is relatively narrow at low Pb content, it broadens significantly on increasing Pb substitution to reach a maximum value (about 5 ppm) for 70% Pb. This could also be related to the unequal site occupancy, as a

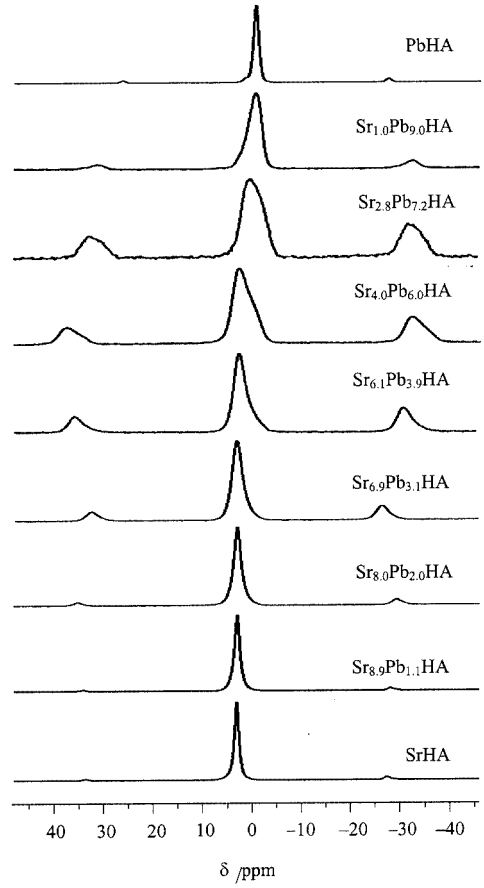

Figure 4. Part of the 162 MHz ^{31}P MAS spectra of the pure and mixed Sr-Pb hydroxyapatites, showing only the isotropic signal and the first (n = +1 and −1) spinning side bands; from bottom to top: SrHA (Ro = 5 kHz, NS = 24), $Sr_{8.9}Pb_{1.1}$ (Ro = 5.1 kHz, NS = 24), Sr_8Pb_2 (Ro = 5.2 kHz, NS = 24), $Sr_{6.9}Pb_{3.1}$ (Ro = 4.9 kHz, NS = 48), $Sr_{6.1}Pb_{3.9}$ (Ro = 5.4 kHz, NS = 48), Sr_4Pb_6 (Ro = 5.6 kHz, NS = 104), $Sr_{2.8}Pb_{7.2}$ (Ro = 5.2 kHz, NS = 72), Sr_1Pb_9 (Ro = 5.2 kHz, NS = 48), PbHA (Ro = 4.3 kHz, NS = 48)

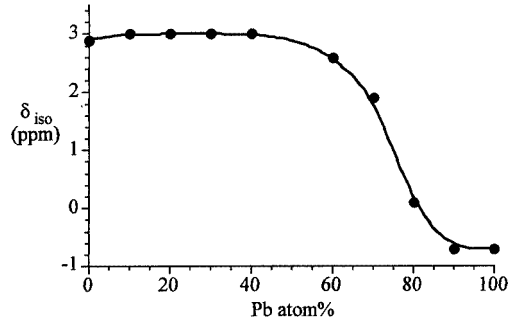

Figure 5. Variation of δ_{iso} as a function of Pb content (atom%)

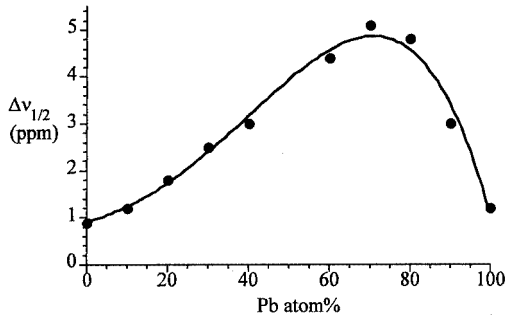

Figure 6. Variation of the full width at half maximum of the isotropic signal as a function of Pb content (atom%)

statistical distribution would have given a symmetrical shape for the $\Delta\nu_{1/2}$ variation.

The chemical shift anisotropy (CSA) of the PO_4 tetrahedron can be derived from the intensity of the spinning side bands (SSB) (see Exp. Sect.). Determination of the chemical shift tensor components and of the CSA is in principle feasible through analysis of the SSB at various spinning rates.[25] However, in the present case, this analysis is virtually impossible because of overlap of numerous unresolved resonances and because of the existence of dipolar interactions which contribute to the SSB intensity at a low spinning rate and significantly broaden the band observed in static spectra.[17] The trend in CSA variation can, however, be qualitatively appreciated from the relative intensity of the first pair of SSB depicted in Figure 4, taking into account that at any fixed spinning rate, the relative intensity of these spinning side bands increases with increasing anisotropy. It is apparent that the CSA of the PO_4 increases smoothly with increasing Pb content, reaching a maximum at around 70% Pb and decreases again with further Pb substitution. This explains the variation of the band width of the static spectra, which, in the absence of any dipolar interaction, would have allowed us a direct determination of the chemical shift anisotropy.

Discussion

The results of this study indicate that SrHA and PbHA form solid solutions over the whole range of composition. Lead substitution for strontium in the hydroxyapatite structure induces a linear expansion of the lattice constants in agreement with its slightly greater ionic radius. Furthermore, Pb is a soft acid and displays a greater tendency towards covalent interactions and directional bonding, whereas strontium can be considered a hard acid. The more covalent character of Pb−O interactions with respect to Sr−O interactions can be invoked to justify the shift of the infrared OH absorption modes towards lower frequencies when the Pb content increases.[24] The increase of lead content also induces a shift of the absorption bands, characteristic of the phosphate internal modes towards lower frequencies. This might either be due to the different ionic character of the metal or to the different anion−anion distances.[23]

The results of the powder fitting structure refinements indicate a clear preference of lead for the M(2) site of the apatitic structure, so that in the samples of low Pb content it is almost exclusively found in the M(2) site. The preference of lead for the M(2) site is in agreement with its slightly greater dimensions with respect to Sr, since in site M(2) the arrangement of the staggered equilateral triangles allows for the optimization of the packing of larger ions, in contrast to the M(1) site where the strict alignment in the columns causes a stronger repulsion. However, a contribution of the more covalent character of the M−O interaction to the cation site preference cannot be excluded, as suggested by the previous results obtained for Sr-Cd apatites[17] where cadmium displays a slight preference for the M(2) site in spite of its small dimensions which should have preferred the hexacoordination of site M(1). A clear preference of Pb for the M(2) site of the apatitic structure was previously reported on the basis of the results of the powder fitting refinements carried out on Ca-Pb apatites.[14] When substituting for calcium, lead almost exclusively fills the M(2) site, until, at Pb contents greater than 45%, it begins to fill the M(1) site, leading to a nonlinear variation of the *c* axis of the apatite structure. The ionic radii and the characters of the metal−oxygen interaction are not as different for Sr and Pb as they are for Ca and Pb. This can account for the minor modifications provoked by lead incorporation into the SrHA structure.

The preference of lead for the M(2) site becomes less evident on increasing the lead content of the solid phase. In agreement, the broadening of the NMR isotropic signal is quite small for the samples at low Pb content and increases when lead is more statistical distributed in the two cationic sites.

Numerous studies, experimental and theoretical, have shown that, among other effects, ^{31}P shielding in phosphate compounds increases − that is δ decreases − with increasing π-bond order between phosphorus and oxygen (p_π-d_π overlap) leading to shorter P−O distances.[26−31]

The shielding effect for pure PbHA (δ = −0.7 ppm) with respect to pure SrHA (δ = 2.9 ppm) can be correlated with the shortening of the mean P−O bond, which decreases from 1.54 Å in SrHA to 1.46 Å in PbHA (Table 1 in Supporting Information[20]).

For the mixed phases we have to consider the various cationic environments of the P atom, that is $PSr_{(9-y)}Pb_y$ (y = 0−9).[16,17] The isotropic resonance of each $PSr_{(9-y)}Pb_y$ environment should be observed between δ = +2.9 (PSr_9 in SrHA) and −0.7 (PPb_9 in PbHA), the shielding increasing with *y*. Accordingly, as we have already discussed for cadmium-lead hydroxyapatites,[16] the incidence in the ^{31}P MAS spectra of the progressive Pb for Sr substitution would have been in the case of a statistical distribution:

− a regular shielding of the isotropic resonance according to δ_{iso} (ppm) = [2.9·(10 − x) − 0.7·x]/10.

− a pseudo-Gaussian shape for the variation of the isotropic *fwhm*, with a maximum at $x = 5$.

On the contrary, both curves (Figures 5 and 6) present singularities for $x = 6-8$. Departure from the theoretical behavior can be accounted for by the results of the Rietveld analysis. At low Pb content, Pb is located almost exclusively in the M(2) site, this means that Sr almost exclusively occupies the M(1) site. The quasi invariance of δ_{iso} for SrPbHA up to 40% Pb could be the indication that in these series the shielding of the ^{31}P nucleus is primarily determined by the nature of the metal in M(1) and consequently influenced very little by the metal in the M(2) site. As can be seen in Table 2, more than 70% of the M(1) sites are occupied by Sr, for Pb contents of up to 60%. Therefore, the singularities observed for both δ_{iso} and $\Delta\nu_{iso}$ curves for around 60−80% Pb could easily be explained if we assume the predominant contribution of the metal in the M(1) site to the ^{31}P shielding.

Let us return to the variation of the chemical shift anisotropy, which reflects the distortion of the PO_4 tetrahedron. For the pure phases SrHA and PbHA, the geometry of the phosphate anion is quite regular and corresponds to a quasi T_d local symmetry with nearly identical P−O distances and all O−P−O angles approaching 109.47°. This explains the low intensity of the spinning side bands (Figure 4) characteristic of a small CSA. For the mixed hydroxyapatites, deviation from the T_d symmetry is evidenced by unequal bond lengths [DI(PO) > 1%] and bond angles [O−P−O between 102 and 116°, DI(O−P−O) up to 5%]. Maximal distortion occurs effectively for the mixed apatites with Pb contents around 60−80% [DI(O−P−O) ca. 0.04−0.05] which actually exhibit the largest chemical shift anisotropy (Figure 4, Table 4).

Experimental Section

Synthesis: The mixed strontium and lead hydroxyapatites with various Pb/(Pb + Sr) ratios, were obtained from a double decomposition method, in aqueous medium.[32,33] Concentrations of the solutions in lead, strontium and phosphate ions correspond to the stoichiometry of the desired apatite. 0.03 M ammonium dihydrogen phosphate [$(NH_4)H_2(PO_4)$, Merck 99%] solution (A solution) and a solution containing a mixture of lead acetate [$Pb(CH_3COO)_2{\cdot}3H_2O$, Fluka 99%] and strontium nitrate [$Sr(NO_3)_2$, Riedel−de Haën AG 98%], with a total concentration of metal cations of 0.05 M (B solution) were prepared. Solution (A) was added dropwise to solution (B), at boiling temperature under a nitrogen stream. The pH value of the slurry was maintained at approximately 12 by regular additions of small amounts of ammonia (Prolabo, $d = 0.89$; 28% aqueous solution). The resulting solid phase was kept in contact with the mother solution for 1 h, at boiling temperature. The precipitate was then filtered, washed with hot distilled water, in order to eliminate traces of ammonium, nitrate and acetate ions, dried at 100 °C for 12 h and calcined at 600 °C for 4 h to improve its crystallinity. Several B solutions, with lead cation fractions ranging from 0 to 1, were prepared and the procedure was repeated in order to obtain the mixed apatites. The compounds obtained were submitted for XRD, chemical analysis, IR spectroscopy, and ^{31}P MAS NMR spectroscopy analyses.

Characterizations: The XRD data were collected with a Philips PW1710 diffractometer, equipped with a copper anode and a graphite monochromator in the diffracted beam ($K_{\alpha 1}$ radiation, $\lambda = 1.5406$ Å). The investigated range was from 18 to 99.99° (2θ), with a step of 0.03° and a counting time of 13 s for each step. The FT-IR spectra (4000−400 cm^{-1}) were recorded with a Bio-Rad FTS 6000 spectrophotometer. 1 mg of the samples was crushed with 300 mg of KBr, and pelletized at 8 tons. The NMR experiments were performed on powdered samples at room temperature with a Bruker MSL400 spectrometer (9.4 T) operating at 162 MHz. A Doty probehead, equipped with 4-mm diameter rotors, was used for spinning rates of up to 6.5 kHz. The spinning rate was monitored by a Bruker pneumatic unit, allowing the control of bearing and drive-inlet nitrogen pressure. Because of unexpected failure of the spinning ratemeter, it was impossible to select and lock a precise spinning rate for all samples; however, bearing and drive pressures were sufficiently stable to avoid fluctuations in the spinning rate. Actually, by comparison with the isotropic signal, no significant broadening of the spinning side bands could be detected and the exact spinning rate was easily determined from the spacing of the spinning side bands. The spectra were acquired using a simple one-pulse sequence with phase cycling (CYCLOPS sequence). Pulse duration was 1 μs that corresponds to a 15° flip angle. The spectral width was 45 kHz (280 ppm). Preacquisition and interpulse delays were 22 μs and 5 s, respectively. The number of transients (NS) was chosen between 24 and about 1000, to obtain a good signal-to-noise ratio, depending on the spinning rate and of the linewidth of the signal. The 4 K free induction decay was zero-filled to the size of 8 K and Fourier-transformed after exponential multiplication of the free induction decay using a 20-Hz line-broadening factor: the final digital resolution of the real spectrum was 10 Hz (0.07 ppm). Chemical shifts are reported with respect to external 85% H_3PO_4 in the IUPAC convention, i.e. positive δ corresponds to a resonance at higher frequency (deshielding) than the reference. Chemical shift values are given with a precision ranging between ±0.1 ppm (narrow resonances) and ±0.2 ppm (broad resonances). The lead and strontium contents in the samples were determined with a Perkin−Elmer 3110 atomic absorption spectrophotometer. The phosphate ions were quantified by visible absorption spectrophotometry of the phosphovanadomolybdic complex. The measurement of the optical densities was carried out at 430 nm.[34] XRD shows that all the samples correspond to pure apatitic phases; according to the results of the chemical analyses the samples exhibit the following formulae: $Sr_{10}(PO_4)_6(OH)_2$, $Sr_{8.9}Pb_{1.1}(PO_4)_6(OH)_2$, $Sr_{8.0}Pb_{2.0}(PO_4)_6(OH)_2$, $Sr_{6.9}Pb_{3.1}(PO_4)_6(OH)_2$, $Sr_{6.1}Pb_{3.9}(PO_4)_6(OH)_2$, $Sr_{4.9}Pb_{5.1}(PO_4)_6(OH)_2$, $Sr_{4.0}Pb_{6.0}(PO_4)_6(OH)_2$, $Sr_{2.8}Pb_{7.2}(PO_4)_6(OH)_2$, $Sr_{2.0}Pb_{8.0}(PO_4)_6(OH)_2$, $Sr_{1.0}Pb_{9.0}(PO_4)_6(OH)_2$, $Pb_{10}(PO_4)_6(OH)_2$.

Structural Analysis: Rietveld full-profile refinements[35] of the mixed strontium-lead hydroxyapatites were carried out by means of the DBWS-9411 program.[36] The space group ($P6_3/m$, no. 176), the cell parameters, the atomic positions and the Debye−Waller factors of SrHA are introduced as the initial structural model for the hydroxyapatite with the lowest lead content. A five-order polynomial was used to simulate the background, while the peaks were fitted using a "pseudo-Voigt" function. Half width of the diffraction peaks as a function of 2θ was evaluated by the formulation of the Caglioti model.[37] Rietveld refinement was performed in several stages, the parameters obtained in each stage being deferred as follows. In the first cycles the scale factor and the background were refined. Refinement of the other parameters was in the following order: profile parameters, zero shift, asymmetry parameter and cell parameters. Refinement of the occupancy factors was done only

for Pb^{2+} and Sr^{2+} ions, with the assumption that these two cations were, initially, statistically located in the two cationic sites, the total contents answering to the stoichiometry obtained by chemical analysis. The apatitic structure comprises 7 independent atoms, corresponding to 21 atomic coordinates, 8 being fixed according to symmetry rules. The other 13 coordinates were refined, starting with those of the two metal sites. In the last refinement cycles, all 30 parameters were released. Then, the refined parameters were used like the initial model for apatite with the lead content immediately higher, and so on. Atomic positions, anisotropic thermal parameters, lattice parameters, reliability pattern factor R_p and weighted factor R_{wp} are gathered in Table 1. A Table in the Supporting Information[20] gives interatomic distances and distortion indices of the phosphate tetrahedron.[38] Lead ion distribution between the two metal sites and chemical analysis results are gathered in Table 3. Equivalent thermal parameters $B_{eq} = \sum_i \sum_j \beta_{ij} (\vec{a}.\vec{b})$ are calculated by the relation: $B_{eq} = 4 \cdot (a^2\beta_{11} + b^2\beta_{22} + c^2\beta_{33} + ab\beta_{12} \cdot \cos(\gamma)/3$.[4] A table with distances, angles and distortion indexes in Sr-PbHA is reported as Supporting Information.[20] Further details of the crystal-structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany on quoting the depository numbers CSD-412026 to -412031.

Keywords: Template reaction / Spin equilibrium / Recognition / Cooperative effects / Nickel / N ligands

Nickel(II) complexes of mono- and bis(macrocyclic) ligands are the products of a nickel(II)-assisted template reaction with 2,3,2-tet, melamine and formaldehyde [2,3,2-tet = bis–*N*,*N*′-(2-aminoethyl)propane-1,3-diamine; melamine = 2,4,6-triamino-1,3,5-triazine]. The structures of two four-coordinate, diamagnetic nickel(II) complexes (protonated and non-protonated form) and of a six-coordinated paramagnetic nickel(II) compound with the protonated ligand have been determined by X-ray crystallography. Electronic spectroscopy was used to analyze the equilibrium between the paramagnetic and diamagnetic forms, and the electrochemical properties have been studied extensively ($Ni^{III/II}$ and $Ni^{II/I}$ couples). The equilibrium between the paramagnetic and diamagnetic forms and the nickel(III/II) couple are strongly dependent on the electrolyte, and sulfate is found to be coordinated selectively to the apical positions of both the nickel(II) and nickel(III) centers of the dinuclear compound. The structural, thermodynamic and electrochemical studies suggest that cooperative effects, involving coordination of sulfate to one nickel center, assisted by hydrogen bonding to an axially coordinated water molecule of the other nickel center, is responsible for the recognition of this anion.

Introduction

Mannich-type, metal-ion-assisted condensation reactions of *cis*-disposed primary amines with formaldehyde and a nucleophile have been used extensively to prepare hexaamine cages, pendent-arm macrocyclic and open-chain ligands with N-, S-, Se- and O-donors, coordinated to copper, nickel, palladium, cobalt and a few other metal centers.[1−6] Due to the rigidity of the aromatic spacer groups and the possibility to obtain oligonuclear complexes in one-pot reactions, aromatic amines, melamine in particular (melamine = 2,4,6-triamino-1,3,5-triazine), are of interest as "capping" groups in metal-based template condensations. However, in the copper(II)-assisted condensation the poor nucleophilicity of the aniline-type amines results in low yields of the desired mono-, bis- and tris(macrocyclic) products,[7−9] and this is also the case for the nickel(II)-assisted Mannich reaction (see below). When the mono-(macrocyclic), melamine-substituted nickel(II) or copper(II) intermediates are used as capping groups in the template reactions mixed-metal oligonuclear systems may be obtained.[10]

The two factors which make the melamine-based oligomacrocyclic ligand complexes of particular interest are vacant or labile axial sites at the metal centers, with the possibility for cooperative binding and activation of substrates in the bis- and tris(macrocyclic) ligand systems, and the fact that melamine can be protonated. π-Stacking, hydrogen bonding and bonding to relatively labile axial sites of transition metal complexes have been described as important features for host-guest interactions.[11−16] Metal complex hosts which have been reported include trizinc(II) compounds and a tetrahedral tetragallium(III) complex.[17−19] A variety of possible applications, including crystal engineering, the preparation and stabilization of anionic metal complexes, as well as cooperativity and selectivity of anion binding have been described with melamine-based macrocyclic ligand complexes.[7−9,20]

Here, we present details on the syntheses and structures of nickel(II) complexes with melamine-based mono- and

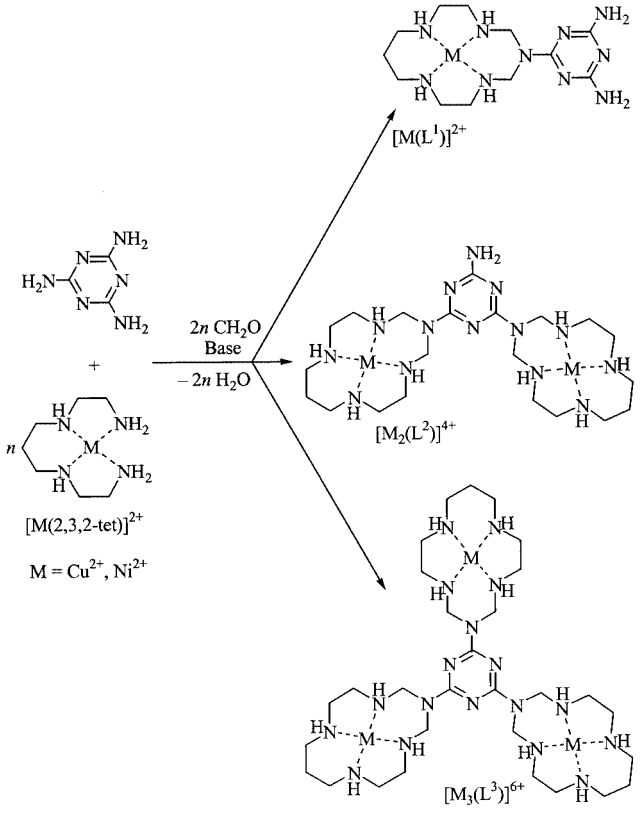
bis(macrocyclic) ligands and a thorough study of the equilibria between the paramagnetic and diamagnetic forms and electrochemical reduction and oxidation processes; this leads to a detailed understanding of the importance of cooperative effects in the recognition of sulfate by the dinickel(II) and the dinickel(III) complexes.

Results and Discussion

Synthesis

The macrocyclization reaction of the open-chain copper(II) complex $[Cu(2,3,2\text{-tet})]^{2+}$ with formaldehyde and melamine yields three possible compounds of different nuclearity, $[Cu(L^1)]^{2+}$, $[Cu_2(L^2)]^{4+}$ and $[Cu_3(L^3)]^{6+}$ (Scheme 1).[7−9] Only complexes with the mono- and bis(macrocyclic) ligands, $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$, can be isolated with $[Ni(2,3,2\text{-tet})]^{2+}$ as the template. These are separated by column chromatography, using 0.2 mol·L^{-1} and 0.4 mol·L^{-1} aqueous $NaClO_4$ as eluents. Melamine generally leads to lower yields of the macrocyclic ligand products than other locking groups in metal-ion-assisted Mannich condensations. The yields of the copper(II) complexes are 9%, 13% and 7% for the mono-, bis- and tris(macrocyclic) ligand complexes, respectively.[7−9] The yields of the nickel(II) compounds are even lower (see Exp. Sect.).

An aromatic nitrogen atom of melamine in $[M(L^1)]^{2+}$ and $[M_2(L^2)]^{4+}$ can be protonated (pK_{a1} = 4.2 for $[Cu(L^1)]^{2+}$ [7]). The resulting sites for hydrogen bonding are of importance for the stabilization of specific types of arrangements of the macrocyclic cations in the crystal lattices.[7−9,20]) However, since protonation does not result in significant changes of the solution spectroscopic and electrochemical properties of the nickel compounds (see below), we conclude that protonation alone does not lead to stable supramolecular assemblies in solution, similar to those observed in crystal lattices.



Scheme 1

Vibrational spectra of the complexes have features, which are characteristic for both the melamine fragment and the tetraazamacrocyclic ligand nickel(II) core. Similar to the copper(II) compounds,[9] the number of transitions which correspond to the out-of-plane vibrations of the aromatic amino groups [$\delta(NH_2)$, 1660 cm^{-1} in melamine] are related to the nuclearity of the complexes and, for complexes of L^1 and L^2, to the degree of protonation of the melamine fragment: three bands (1700, 1650, 1600 cm^{-1}) are observed in the nickel(II) compounds of the protonated mono(macrocyclic) ligand $(HL^1)^+$; two bands (1667 and 1600 cm^{-1}) are characteristic for complexes of the protonated bis(macrocyclic) ligand $(HL^2)^+$; one band is observed for complexes of the free bases ($[Ni(L^1)]^{2+}$, 1600 cm^{-1}; $[Ni_2(L^2)]^{4+}$, 1610 cm^{-1}).

Molecular and Crystal Structures

The structures of the mono(macrocyclic) ligand nickel(II) complexes with the non- and monoprotonated melamine fragment and diamagnetic or paramagnetic nickel(II) centers, i.e., four-coordinate nickel(II) complexes of two forms of L^1, $[Ni(L^1)](ClO_4)_2\cdot H_2O$ (**1**) and $[Ni(HL^1)](ClO_4)_2\text{-}Cl\cdot H_2O$ (**2**), and the six-coordinate complex of $(HL^1)^+$ $[Ni(HL^1)(OSO_3)(OH_2)]ClO_4\cdot 5H_2O$ (**3**) were determined by X-ray crystallography. Single crystals of the four-coordinate dinickel(II) compound $[Ni_2(L^2)](ClO_4)_4\cdot 2H_2O$ (**4**) were also obtained but were of poor quality, the preliminary data obtained were used to determine the overall conformation of the dinuclear cation. The variety of the structural data, together with the published structures of the corresponding copper(II) compounds, i.e., $[Cu(L^1)(OClO_3)_2]\cdot H_2O$ (**5**)[9] and **6**,[20] $[Cu(HL^1)(OClO_3)_2](ClO_4)\cdot H_2O$ (**7**),[9] $[Cu(HL^1)\text{-}(OClO_3)](ClO_4)_2\cdot 2H_2O$ (**8**),[7] and $\{[Cu(HL^1)(OH_2)(Cl)]\text{-}[Cu(HL^1)(OClO_3)(Cl)]\}(ClO_4)_3$ (**9**),[9] form a broad basis for a comparative analysis of the molecular and crystal structures of melamine-based macrocyclic ligand complexes [copper(II) compounds of L^2 and L^3, which have also been reported before [8,9] are not included in this analysis].

Molecular Structures

The geometries of the macrocyclic ligands L^1 and $(HL^1)^+$ in the nickel(II) complexes (Figure 1) and in the corresponding copper(II) compounds [7−9,20] are identical, i.e., *trans*-III (*RRSS*).[21] The distances and angles are typical for nickel(II) [and copper(II)] complexes of 14-membered tetraaza macrocycles.[22] The melamine rings are nearly planar (rms 0.01−0.02 Å), as observed in other 1,3,5-triazine derivatives.[23] The nickel(II) ions in **1** and **2** are coordinated in a planar chromophore to four nitrogen donors of

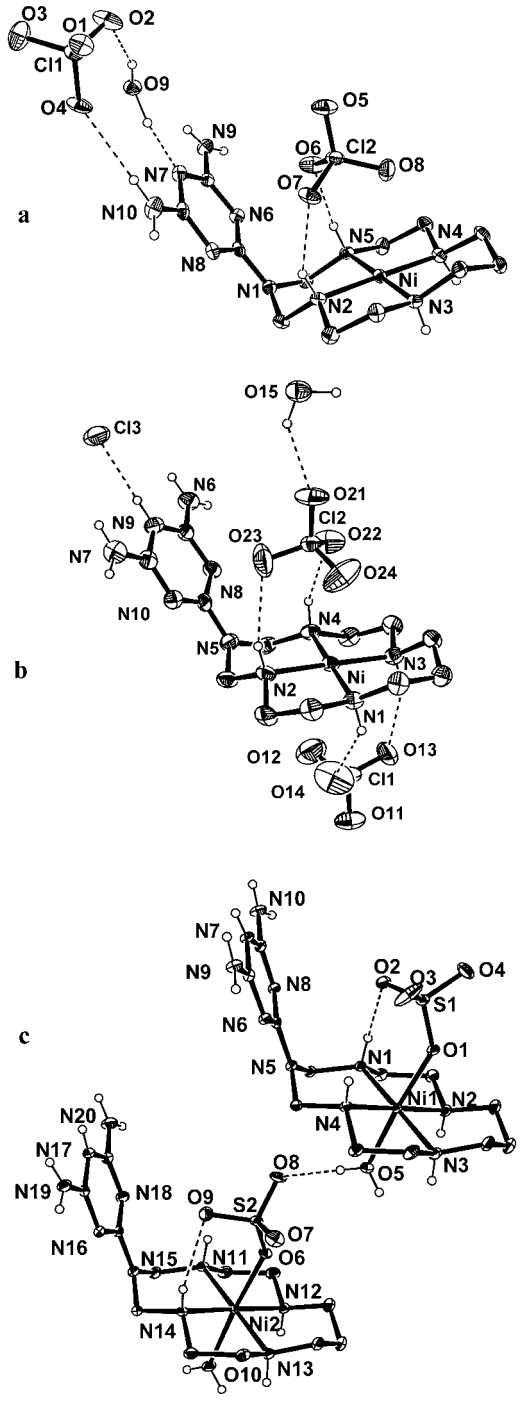


Figure 1. ORTEP[40] view (30% probability ellipsoids) of **1** (a), **2** (b) and **3** (c); C−H hydrogen atoms are omitted for clarity; selected hydrogen bond lengths are: **1**: O(4)···H−N(10) 3.278 Å, O(9)−H···O(2) 2.956 Å, O(9)−H···N(7) 2.747 Å, N(2)−H···O(7) 3.008 Å, N(5)−H···O(6) 3.047 Å; **2**: N(1)−H···O(14) 2.984 Å, N(3)−H···O(13) 3.116 Å, N(2)−H···O(23) 3.148 Å, N(4)−H···O(22) 3.071 Å, Cl(3)···H−N(9) 2.988 Å; **3**: O(5)−H···O(8) 2.680 Å, O(10)−H···O(4′) 2.630 Å O(2)···H−N(1) 2.938 Å; O(9)···H−N(14) 3.010 Å

the macrocycle with nearly identical metal−nitrogen distances, as expected for four-coordinate, diamagnetic nickel(II) compounds[22] (see Table 1). The paramagnetic nickel(II) ion in **3** is six-coordinate, with a sulfate anion and a water molecule completing the coordination sphere, in a nearly regular octahedral geometry with significantly longer metal−donor distances than observed in **1** and **2** (see Table 1).

From the structural parameters of the complexes of L^1 (see Table 1), it emerges that four-, five- or six-coordinate metal ions with a variety of metal donor distances [Ni−N < 1.95 Å in diamagnetic nickel(II); Cu−N ≈ 2.02 Å; Ni−N > 2.06 Å in paramagnetic nickel(II) complexes, 2.1 Å $<$ M−O^{ax} < 2.6 Å] are well accommodated in the macrocycle in *trans*-III configuration, with close to planar MN_4 chromophores and the expected N−M−N bite angles (ca. 95° for the six-membered and ca. 85° for the five-membered chelate rings). The flexibility in the orientation of the melamine rings with respect to the mean MN_4 planes (angles α, β, γ, see Figure 2) allows for a wide range of substrates to be stabilized (this is of specific importance for the bis- and tris(macrocyclic) compounds, see ref.[9]) and for the stabilization of specific crystal lattice patterns (see below).

In complexes with two or three macrocyclic ligands fixed on the melamine spacer group, as in L^2 and L^3, there are two possible conformations (*syn* or *anti* in L^2; *syn*,*syn* or *syn*,*anti* in L^3). Both are similar in energy[8,9] and the preference for a particular structure in a crystal lattice or in solution is a function of the substrates (or electrolytes) and the environment (lattice or solvent). Both structural types have been observed for $[Cu_3(L^3)]^{6+}$,[8,9] only the *anti* isomer was characterized structurally for the copper(II) complex with the bis(macrocyclic) ligand,[9] and the same is observed in the corresponding dinickel(II) system **4** discussed here. Also, host-guest complexation studies and preliminary computations indicate that the barrier for isomer interconversion (*syn*/*anti*) is relatively low.[9,24] The experimental structural data support this assumption (angles α, β, γ, see Table 1); there appears to be a large flexibility (shallow energy minimum) with an optimum structure of $10° < \alpha < 30°$ [planarity of the pendent amine groups of melamine would require $\alpha = 0°$, values of $\alpha > 2°$ have been observed in copper(II) complexes[9]], $70° < \beta < 90°$ and $40° < \gamma < 60°$. This flexibility is an advantage for the cooperative binding and activation of substrates at the axial sites of the metal chromophores.

Crystal Packing

Three main structural motifs have been found in crystal lattices of copper(II) complexes with the melamine-derived mono(macrocyclic) ligand,[7,9,20] i.e., infinite tapes of the molecular cations (hydrogen bonds between the free amino groups of the melamine substituents and water molecules or perchlorate anions, 5.0 Å $< d_2 <$ 5.7 Å, see Figure 3, Table 2), π-stacking interactions between the melamine rings, $d_4 \approx 3.5$ Å, $\delta \approx 0°$ (δ is the angle between the two melamine ring planes), and, for the copper(II) complexes **5** and **6** with the free-base ligand, the formation of double-stranded tapes, due to hydrogen bonding between self-complementary melamine groups (ADA, acceptor-donor-acceptor pattern). Two different types of stacked pairs are possible, depending on the orientation of the macrocyclic

Table 1. Structural parameters (distances in Å, angles in °) of metal(II) complexes with the melamine-derived macrocyclic ligand L^1

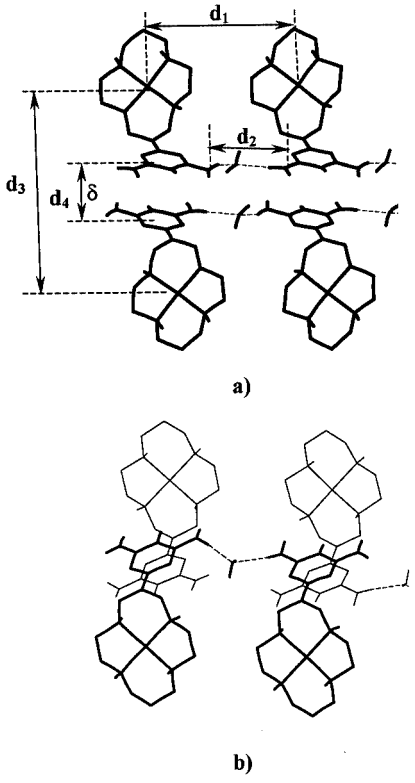

Figure 3. The two different types of stacked pairs of $[M(L^1)]^{n+}$ complexes

rings with respect to the neighboring melamine plane (see Figure 3a,b). The relevant structural parameters are given in Table 2, see Figure 3 for their definition.

Interestingly, in the crystal lattice of **1** the common features of all other structures are absent (see Figure 4a). This presumably is due to the specific location of a water molecule relative to the melamine residues; the hydrogen bonding patterns (see Figure 1a) do not allow the formation of the usual tapes and prevent a complementary hydrogen bonding interaction between pairs of melamine rings. Also, this indicates that the formation of the usually observed tapes, stabilized by hydrogen bonding and π-stacking, is, as expected, a relatively small contribution which may be overcome by other effects.

Similar to the copper(II) complexes **5**−**8**,[7,9,20] the macrocyclic cations in the crystal lattice of **2** form infinite hydrogen-bonded chains, bridged by water molecules and supported by π-interactions between the parallel and nearly coaxial melamine rings (see b in Figure 4). The metal−metal distance d_1 is slightly shorter than in the copper(II) analogues, and d_2 is intermediate between those observed in the copper(II) compounds.

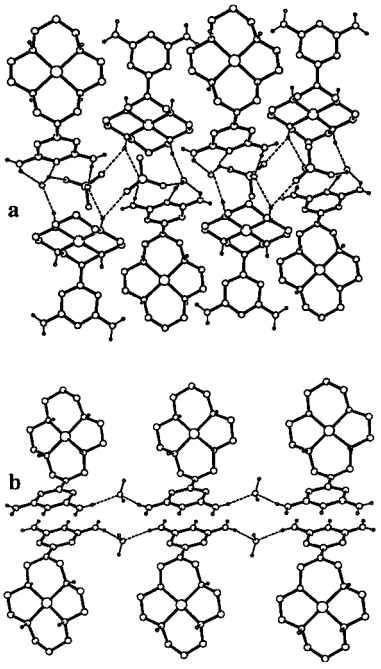

Figure 4. Crystal packing of **1** with intermolecular hydrogen bonds (a) and π-stacked cationic tapes in the crystal lattice of **2** (b)

The crystal lattice of **3** is unique, the tape structure has a "stair"-type arrangement (see a in Figure 5). This is due to the water molecule $H_2O(27)$, which not only bridges two neighboring cations in the tape but also forms a hydrogen bond to the aromatic nitrogen atom of the adjacent tape [O(27)−H···N(8), 2.988 Å]. In addition, the tape observed in **3** is not isotropic and consists of distinct hydrogen-bound dimers (d_1 = 9.32 Å, d'_1 = 9.12 Å); the distance between the melamine amino groups of the non-bonded adjacent cations is smaller than for those connected by hydrogen bonds (see Table 2). This tape interacts via π-stacking with another tape of the same structure but shifted by one macrocyclic unit, i.e., alternating hydrogen bonds hold the two tapes together (see b in Figure 5).

The melamine substituents in all examples form π-stacked pairs of cations; generally, the metal chromophores of the stacked cations are oriented at different sides of the

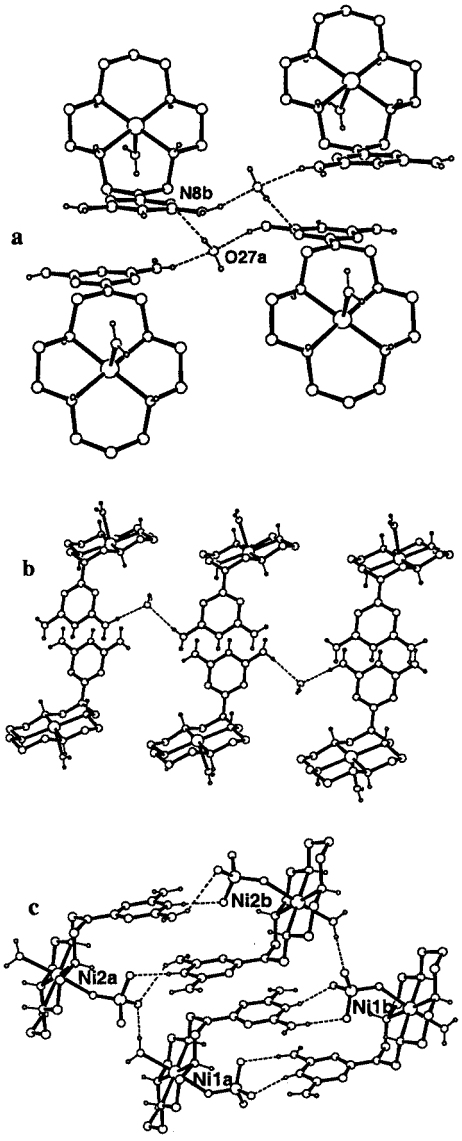

Figure 5. Pair of π-stacked cations (a), modulated tape (b) and modulated π-stacking in the crystal lattice of **3**

interaction plane (see Figure 3a, "open" stack). The only exception is the copper(II) complex **9** for which the π-π interaction plane bisects the metal chromophores (see Figure 3b, "closed" stack).[9] Both "open" [Ni(1a)−Ni(2b) pair] and "closed" stacks [Ni(na)−Ni(nb) pair] are present in the crystal lattice of **3** (Figure 5c), and the sulfate anions have the same dual function as the chloride anions in **9**, i.e., as axial donors they form strong hydrogen bonds to the acceptor centers of the protonated melamine [O(2)···H−N(9′), 2.835 Å; O(3)···H−N(7′), 2.708 Å; O(8)···H−N(19′), 3.114 Å; O(9)···H−N(17′), 2.695 Å]. Also, the stacks in **3** are not isolated and can be considered as modulated, extended chains of π-stacked molecules (see Table 2).

Solution Properties

Electronic Spectroscopy and Equilibria between Diamagnetic and Paramagnetic Compounds

Electronic spectra of the nickel(II) compounds with the mono- and bis(macrocyclic) ligands were measured in nitromethane, acetonitrile and water. The spectra in the UV region are characterized by a strong absorption centered at ca. 210 nm ($\varepsilon \approx 6\ 10^5$ L·mol^{-1}·cm^{-1}), which probably is a superposition of an MLCT band (shoulder at ca. 219 nm) and an intramolecular melamine transition (204 nm in melamine). Absorption spectra in the visible and near-infrared region consist of d-d bands at ca. 330, 455, 660 and > 910 nm, and are typical for nickel(II) complexes of tetraaza-macrocycles and for systems, where nickel(II) complexes with different electronic ground states persist simultaneously in solution [Equations (1) and (2)], i.e., a four-coordinate, planar diamagnetic form (455 nm) and a six-coordinate distorted octahedral paramagnetic form (330, 660 and > 910 nm).[25]

$$[Ni(L)]^{2+} + 2\ solv \rightleftarrows [Ni(L)(solv)_2]^{2+} \quad (1)$$

$$K_{ax} = (\varepsilon_{ls} - \varepsilon_{eff})/(\varepsilon_{eff} - \varepsilon_{hs}) \quad (2)$$

$$\varepsilon_{eff} = \{\varepsilon_{ls}[Ni(L)^{2+}] + \varepsilon_{hs}[Ni(L)(solv)^{2+}]\}/\{[Ni(L)^{2+}] + [Ni(L)(solv)^{2+}]\} \quad (3)$$

In nitromethane there is only a transition at 455 nm for $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$, with a molar absorption of 64 L mol^{-1} cm^{-1} per nickel(II) center (see Table 3). Therefore, in the weakly coordinating solvent nitromethane there is no coordination of axial donors, and this allows to determine the molar absorptivity of the diamagnetic form (ε_{ls}). The apparent molar absorption coefficients [ε_{eff}, Equation (3)] of the transition at 455 nm in acetonitrile and aqueous solutions of various electrolytes are lower (see Table 3), indicating the presence of significant amounts of the six-coordinate form in equilibrium with the four-coordinate compounds.

The strength of bonding of axial donors to the nickel(II) centers (increasing K_{ax}, decreasing η) is of similar magnitude for $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$ (see Table 3) and significantly higher than for $[Ni(cyclam)]^{2+}$ (cyclam = 1,4,8,11-tetraazacyclotetradecane; 0.1 mol·L^{-1} aqueous $NaClO_4$: $K_{ax} = 0.40$, η = 71%;[26] CH_3CN: η = 22% [27]). An interesting observation is that the thermodynamic parameters for the complexation to axial sites of $[Ni(Me\text{-}azacyclam)]^{2+}$ (Me-azacyclam = 3-methyl-1,3,5,8,12-pentaazacyclotetradecane) are similar to those of the cyclam complex (0.1 mol·L^{-1} aqueous $NaClO_4$: $K_{ax} < 0.5$; CH_3CN: η = 23% [28]), i.e., different to those of the structurally related azacyclam derivatives discussed here. The fact that the spectroscopic properties of all four nickel(II) complexes are similar to each other ($\lambda^{ls}_{max} \approx 455$ nm, $\lambda^{hs}_{max} \approx 330$, 670 and > 900 nm) indicates that metal-centered electronic factors are not the major reason for the drastic differences, and electronic, as well as steric factors related to the capping groups, and differences in solvation may be of importance.

A comparison of the thermodynamic parameters for the axial coordination of water (0.1 mol·L^{-1} $NaClO_4$) to $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$ (see Table 3; for details see Supporting Information) with those of $[Ni(cyclam)]^{2+}$ ($\Delta H^0 = -23$ kJ mol^{-1}, $\Delta S^0 = -84$ J mol^{-1} K^{-1}) [29] indicates that the strong axial binding to nickel(II) complexes with the melamine-based ligand is primarily due to an entropy effect (less negative ΔS^0), rather than differences in bond strength (similar ΔH^0). A possible interpretation is that one of the axial water donors [H_2O(A) in Scheme 2] is, upon decomplexation to the four-coordinate form, not released to the bulk solvent, but remains in the first solvation shell. A hydrogen bond similar to that proposed in Scheme 2 was observed in the crystal lattice of **3**.

The largest fraction of the paramagnetic nickel(II) form was observed in the presence of sulfate (see Table 3). There-

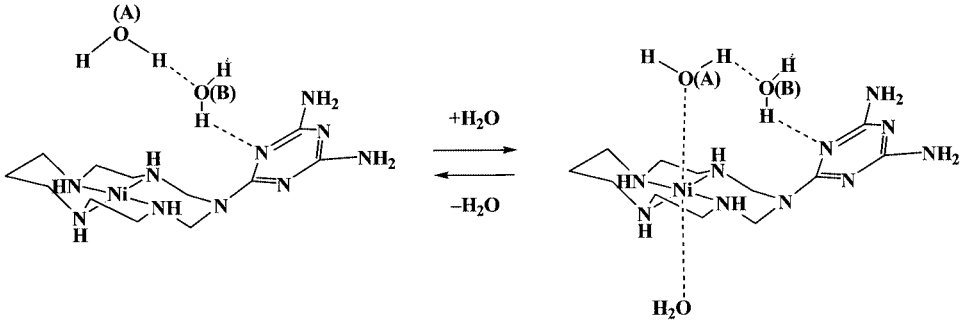

Scheme 2

fore, the stepwise complexation with sulfate was studied in aqueous solution (μ = 0.1 mol·L^{-1}; 0 mol·L^{-1} < [SO_4^{2-}] < 3.33 10^{-2} mol·L^{-1}), see Equation (4), where K_{ax}^{H2O} is the equilibrium constant in absence of sulfate [see Equation (2), 0.1 mol·L^{-1} $NaClO_4$; see Table 3) and K_{ax}^1 to K_{ax}^4 are the stepwise complexation constants with sulfate.

$$K_{ax} = K_{ax}^{H2O} + \sum_{i=1}^{4} [SO_4^{2-}]^i \prod_{j=1}^{i} K_{ax}^i \quad (4)$$

From the data analysis (see Supporting Information) it follows that K_{ax}^2 is ca. 0 for both $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$, and fits with higher terms (K_{ax}^3 and K_{ax}^4 for $[Ni_2(L^2)]^{4+}$) do not lead to a significant improvement, i.e., these can be ignored. It emerges that, in sulfate-containing solutions, the mono(sulfate) adduct [per nickel(II) ion] is the primary species, and K_{ax}^1 is significantly larger for $[Ni_2(L^2)]^{4+}$ than for $[Ni(L^1)]^{2+}$ (162 ± 6 L mol^{-1} and 79 ± 10 L mol^{-1}, respectively). Part of this effect may be due to differences in ion pairing [increasing electrostatic attraction with the higher charge of the dinickel(II) complex[30]] but the increasing axial bonding may also be attributed to cooperativity, involving both nickel(II) centers and hydrogen bonding between a coordinated sulfate and an axial water molecule (see Figure 6). Qualitative models suggest that this may lead to stabilization of the sulfate/$[Ni_2(L^2)]^{4+}$ adduct in the *syn* conformation of the dinickel(II) complex.[24] A preliminary structural analysis indicates that in the crystal lattice the dinuclear complex **4** has the *anti* conformation but recent studies on the corresponding copper(II) compounds indicate that the two conformations are similar in energy and that the barrier of interconversion is low.[9,24,31]

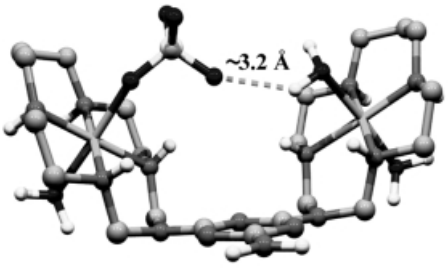

Figure 6. Model for the visualization of cooperativity in the axial bonding of sulfate

Electrochemical Properties and Recognition of Sulfate Anions

The electrochemical behavior of $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$ was studied in acetonitrile and aqueous solutions of various salts. In acetonitrile (0.1 mol·L^{-1} [Bu_4N]ClO_4) a quasi-reversible redox process, assigned to the nickel(III/II) couple is observed {$[Ni(L^1)]$: E_f = 1.084 V (ΔE = 87 mV); $[Ni_2(L^2)]$: E_f = 1.027 V (ΔE = 73 mV)}. An irreversible process {E_{cat} = −1.46 V and −1.40 V for $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$, respectively} is attributed to the nickel(II/I) couple; small additional peaks at ca. 0.6 V are assigned to adsorption effects and peaks at ca. 1.3 V may be assigned to ligand oxidation (see Figure 7). The data indicate that both metal centers in $[Ni_2(L^2)]^{4+}$ undergo the redox transformations independently and at the same potentials. Similar results are obtained with [Bu_4N]BF_4 as the electrolyte.

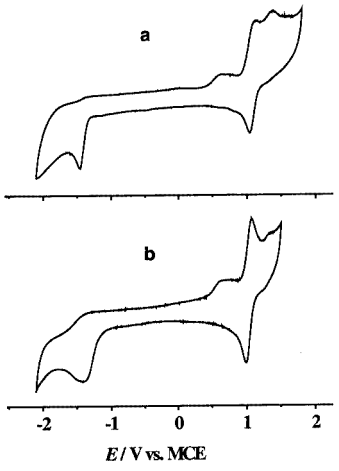

Figure 7. Cyclic voltammograms of 1 10^{-3} mol·L^{-1} solutions of $[Ni(L^1)]^{2+}$ (a) and $[Ni_2(L^2)]^{4+}$ (b) in acetonitrile (0.1 mol·L^{-1} [Bu_4N]ClO_4)

Protonation of non-coordinated nucleophiles in the ligand backbone are known to lead to a destabilization of the oxidized form of metal complexes.[32] As expected, there is approximately an inverse relationship between the destabilization of nickel(III) over nickel(II) and the distance between the nickel center and the site of protonation.[33] For [Ni(Me-azacyclam)] the change of the nickel(III/II) potential upon protonation is ca. 120 mV (0.790 V and

0.910 V in neutral solution and 9.5 mol·L^{-1} $HClO_4$, respectively).[33] The corresponding effects observed for $[Ni(L^1)]^{3+/2+}$ and $[Ni_2(L^2)]^{6+/4+}$ are much smaller (0.815 ± 0.020 V and 0.825 ± 0.010 V, respectively, 10^{-7} mol·L^{-1} < $[H^+]$ < 9.5 mol·L^{-1}). This indicates that, upon protonation of the aromatic fragment, the positive charge is delocalized over the melamine ring.

The electrochemical behavior of $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$ in aqueous solution with various electrolytes was studied by cyclic voltammetry (CV) and differential pulse voltammetry (DPV). These data are listed in Table 4, relevant DPV curves of the oxidation scans are collected in Figure 8 and Figure 9. The E_f value for the single quasi-reversible redox transformation of the mono(macrocyclic) ligand complex $[Ni(L^1)]^{2+}$ is strongly anion-dependent and decreases in the order $ClO_4^- > NO_3^- > Cl^- > HSO_4^- \approx H_2PO_4^- > SO_4^{2-} > HPO_4^{2-}$. This sequence is typical for nickel(III/II) couples of azamacrocyclic ligands and reflects the increasing stabilization of nickel(III) by electrostatic effects.[34–36] The poor reversibility observed in the experiments with HPO_4^{2-} is probably related to the high pH of the solutions which leads to a destabilization of the nickel(III) complex with respect to decomposition. This is supported by significantly lower currents observed in the corresponding CV and DPV experiments.

Table 4. Redox potentials (E_f in V vs. MCE, ΔE in mV in parentheses) of the $Ni^{III/II}$ couple of melamine-derived macrocyclic ligand complexes $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$ in aqueous solution, containing 0.1 mol·L^{-1} Na^+ salts (CV data, pH = 7.0, sweep rate 0.1 V s^{-1})

Anion of the electrolyte	$[Ni(L^1)]^{2+}$	$[Ni_2(L^2)]^{4+}$

The behavior of the bis(macrocyclic) ligand complex $[Ni_2(L^2)]^{4+}$ in the presence of perchlorate, nitrate and chloride is similar to that of $[Ni(L^1)]^{2+}$ (see Table 4 and Figure 8). In presence of sulfate or phosphate, however, there are two separate oxidation/reduction steps for $[Ni_2(L^2)]$ (Table 4, Figure 8 and Figure 9). These are reversible in sulfate but only poorly reversible or irreversible in phosphate (similar effects were observed with the mononuclear compound, see above). The fact that the currents for the two-electron oxidation processes in $[Ni_2(L^2)]^{4+}$ in perchlorate-containing solutions are nearly equal to the sum of the two separate single-electron steps in sulfate media indicates that both single-electron oxidation steps are related to the nickel(III/II) couple. Therefore, anion coordination leads to two structurally (and electronically) different nickel centers or to strong coupling of the two metal ions. Also, the reduction potentials of the nickel(III/II) couple in the dinuclear complex are more anodic (E_{f1}) and more cathodic (E_{f2}) than that of the mononuclear compound. For a thorough analysis of the redox processes, the dependencies of the E_f values on the sulfate concentration in neutral (pH = 7.0) and acidic (pH = 1.0) aqueous solutions were studied.

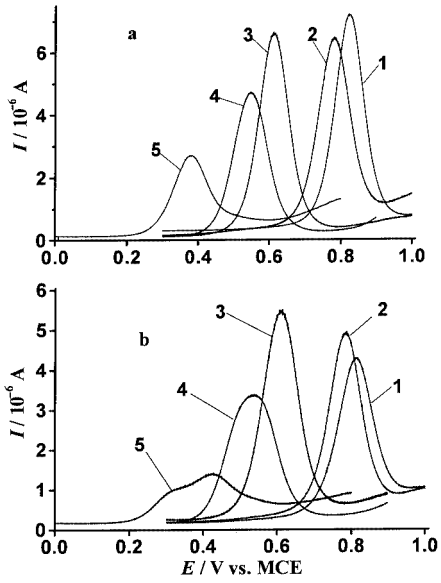

Figure 8. Differential pulse voltammograms of $1.0 \cdot 10^{-3}$ mol·L^{-1} $[Ni(L^1)]^{2+}$ (a) and $5 \cdot 10^{-4}$ mol·L^{-1} $[Ni_2(L^2)]^{4+}$ (b) in 0.1 mol·L^{-1} aqueous solutions of different electrolytes: 1: $NaClO_4$; 2: $NaNO_3$; 3: NaCl; 4: KH_2PO_4; 5: Na_2HPO_4; pulse amplitude 10 mV, potential scan rate 2 mV s^{-1}

The corresponding DPV curves are shown in Figure 9, the potentials are listed in Table 5 (CV curves are given as Supporting Information). The splitting of the redox potential depends on the concentration of the anions and, for a given concentration, it is larger for sulfate than for hydrogen sulfate. The shifts of E_{f1} and E_{f2} are also sensitive to the concentration of the anions. This indicates that sulfate forms adducts of different stability, depending on the nuclearity of the nickel(II) complex. The dependence of the reduction potential of the nickel(III/II) couple on the concentration of the anion X^{n-} is described by Equation (5), where X^{n-} is SO_4^{2-} or HSO_4^-, K_i^{II} and K_i^{III} are the stepwise stability constants of the nickel(II) and nickel(III) complexes with sulfate, and E_f^{aq} is the redox potential in absence of coordinating anions (i.e., in 0.1 mol·L^{-1} aqueous $NaClO_4$). The values of K_i^{II} are relatively small (see above); therefore Equation (5) transforms into Equation (6), where $\Delta E_f = E^X{}_f - E_f^{aq}$.[37]

$$E_f^x = E_f^{aq} - (RT/F) \ln \left(\frac{(1 + \sum_{i=1}^{4} [X^{n-}]^i \prod_{j=1}^{i} K_j^{III})}{(1 + \sum_{i=1}^{4} [X^{n-}]^i \prod_{j=1}^{i} K_j^{II})} \right) \quad (5)$$

$$\exp\{\Delta E_f(-F/RT)\} - 1 = \sum_{i=1}^{4} [X^{n-}]^i \prod_{j=1}^{i} K_j^{III} \quad (6)$$

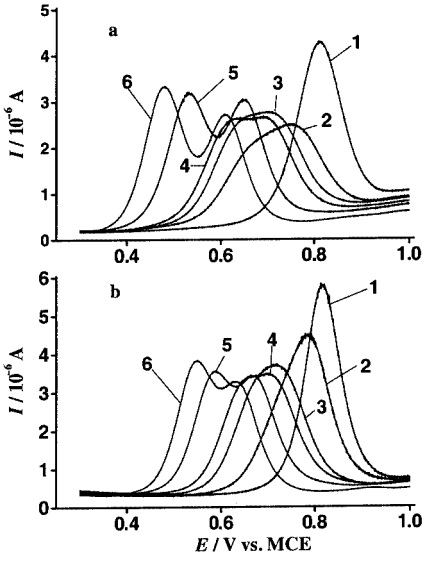

Figure 9. Differential pulse voltammograms of 5.0 10^{-4} mol·L^{-1} $[Ni_2(L^2)]^{4+}$ at various concentrations of Na_2SO_4 (a: pH = 7; 1: 0, 2: 5.0 10^{-4}, 3: 1.0 10^{-3}, 4: 1.5 10^{-3}, 5: 8.7 10^{-3}, 6: 3.3 10^{-2} mol·L^{-1}) and H_2SO_4 (b: pH = 1; 1: 0, 2: 5.0 10^{-4}, 3: 2.4 10^{-3}, 4: 4.6 10^{-3}, 5: 2.5 10^{-2}, 6: 1.0 10^{-1} mol·L^{-1}) (I = 0.1, pulse amplitude 10 mV, potential scan rate 2 mV s^{-1})

Plots of E_f^X vs. logC_X, where C_X is the total concentration of SO_4^{2-}, are linear (see Figure 10), and their slopes, divided by 0.059, give the average values of the number of anions coordinated to the metal center involved in the redox transformation (k in Table 6). Interpolation of the dependences of exp{$\Delta E_f(-F/RT)$} vs. C_X, using these values

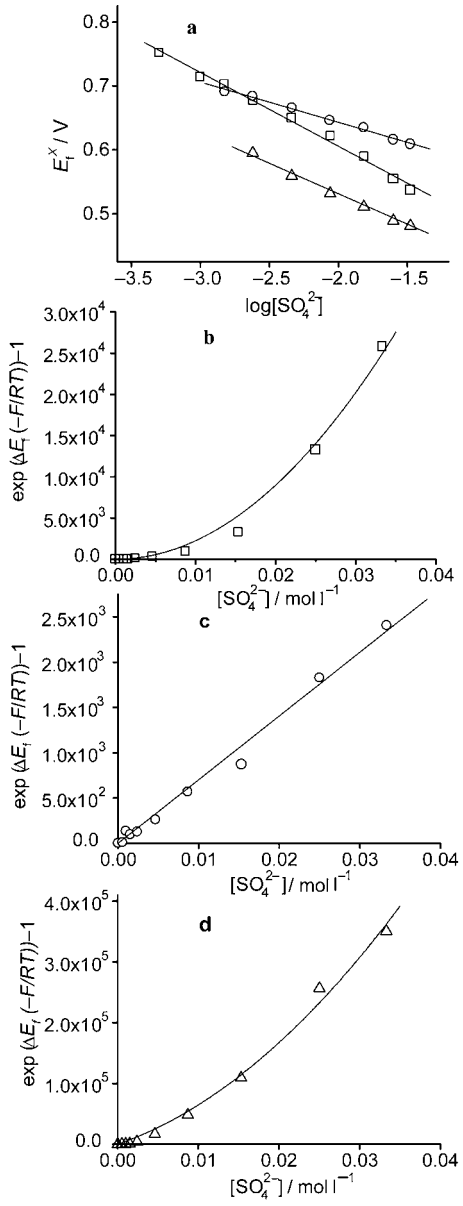

Figure 10. Plots used in the calculations of stoichiometric and thermodynamic parameters for the interaction of sulfate anion with $[Ni(L^1)]^{2+}$ (squares) and those for more anodic (E_{f1}, circles) and less anodic (E_{f2}, triangles) processes observed in $[Ni_2(L^2)]^{4+}$; the curves correspond to best fit lines based on the values presented in Table 6

of k, and assuming that $[SO_4^{2-}] = C_X$ (see Figure 10) allows to obtain values for the corresponding stability constants (see Table 6).

From Table 6 it emerges that the nickel(III) complex with the mono(macrocyclic) ligand forms a bis(sulfate) adduct, although the data analysis did not allow to separate the values of K_1^{III} and K_2^{III}. For $[Ni_2(L^2)]^{6+}$ two separate binding constants for one nickel(III) center (E_{f2}) are observed, the second nickel(III) center (E_{f1}) is coordinated to a single sulfate anion. These results agree well with the model proposed for the explanation of enhanced binding of sulfate to the nickel(II) complex with the bis(macrocyclic) ligand (see electronic spectroscopy, above, Scheme 2). Strong hydrogen

Table 6. Stoichiometric and thermodynamic parameters of the interaction of sulfate with the nickel(III) complexes with the macrocyclic ligands

Anion	$[Ni(L^1)]$	$[Ni_2(L^2)]$ E_{f2}	E_{f1}
SO_4^{2-}	$k = 1.95 \pm 0.01$ $K_1^{III} K_2^{III} = (2.25 \pm 0.02)\cdot10^7$	$k = 1.68 \pm 0.01$ $K_1^{III} = (4.59 \pm 0.02)\cdot10^6$ $K_2^{III} = 41 \pm 10$	$k = 1.06 \pm 0.01$ $K_3^{III} = (7.03 \pm 0.18)\cdot10^4$
HSO_4^-	$k = 1.82 \pm 0.01$ $K_1^{III} = (6.36 \pm 1.05)\cdot10^4$ $K_2^{III} = 28 \pm 10$	$k = 1.83 \pm 0.01$ $K_1^{III} = (2.83 \pm 0.25)\cdot10^5$ $K_2^{III} < 1$	$k = 1.02 \pm 0.01$ $K_3^{III} = (1.19 \pm 0.05)\cdot10^4$

bonding between the coordinated sulfate and an axially coordinated water molecule at the neighboring metal center leads to suppression of the substitution of the remaining water molecule by another sulfate anion. Therefore, one axial coordination site in $[Ni_2(L^2)]^{6+}$ is blocked and two independent reduction processes are observed, one with participation of the bis(sulfate) adduct (E_{f2}) and the other related to the (aqua)(sulfate) complex with the macrocyclic ligand (E_{f1}).

A similar behavior is observed for the nickel complexes in acidic media (pH = 1.0), where hydrogen sulfate is coordinated to the nickel(III) centers (see Table 6). However, the stability constants of the corresponding adducts are significantly lower. This is believed to be due to the smaller charge of the coordinating anion. All constants K_1^{III} for the complexes with the melamine-derived macrocyclic ligands are in the range expected for nickel(III) complexes with tetraaza macrocyclic ligands.[34−36]

Conclusion

The copper(II),[7−9] nickel(II) and nickel(III) complexes of the bis- and tris(macrocyclic) melamine-based ligands are versatile hosts for anionic guest molecules. This is due to the relatively labile coordination to the vacant axial sites, assisted by Jahn−Teller effects [copper(II), nickel(III)] or spin-equilibria [nickel(II)] and to some flexibility in the arrangement of the macrocyclic subunits (*syn-anti* conformations with respect to the melamine rings and relative geometry in the *syn* conformation, angles α, β, γ in Figure 2). In the case of the dinickel(II/III) complexes this leads to an enhanced stability of the coordination of sulfate to one of the axial sites, assisted by the second nickel center. With the di- and trimetal systems [nickel(II), nickel(III), copper(II) and mixed-metal] there is a variety of host systems which, in spite of or due to the limited flexibility are able to selectively bind, activate and/or stabilize anionic guest species.

Experimental Section

Syntheses: ***Caution!*** *Perchlorate salts of metal complexes with organic ligands are potentially explosive and should be handled with care.* $[Ni(2,3,2\text{-tet})](ClO_4)_2$ [2,3,2-tet = bis-*N*,*N*′-(2-aminoethyl)propane-1,3-diamine] was obtained as described,[38] all other AR grade chemicals and solvents were used as received. To a solution of $[Ni(2,3,2\text{-tet})](ClO_4)_2$ (2.0 g, 4.8 mmol) in 15 mL of water were added melamine (1.0 g, 7.9 mmol), triethylamine (5.0 mL, 35.9 mmol) and ethanol (100 mL). The resulting mixture was heated and aqueous formaldehyde (37%, 8.0 mL, 106.7 mmol) was added dropwise over a period of 1 h; refluxing of the solution was continued for an additional 24 h. The mixture was then cooled, and the dark brown precipitate that formed was removed by filtration. The resulting deep brown solution was diluted with water to 2 L and sorbed onto an SP-Sephadex C-25 cation exchange resin (Na^+ form). The column was washed with water (0.5 l) and the products were then eluted with aqueous $NaClO_4$ solutions. Two yellow bands were eluted with 0.2 mol·L^{-1} $NaClO_4$. The first contained unchanged $[Ni(2,3,2\text{-tet})](ClO_4)_2$ and was discarded. With 0.4 mol·L^{-1} $NaClO_4$ a third yellow fraction was obtained. The remaining products were eluted with NaCl or $NaNO_3$ (0.4−0.8 mol·L^{-1}) but did not contain any macrocyclic ligand products.

$[Ni(L^1)](ClO_4)_2\cdot H_2O$ (1): The second yellow band eluted with 0.2 mol·L^{-1} $NaClO_4$ was concentrated under reduced pressure to 25 mL and left cooling to room temperature. Yellow needles of the product were collected, washed with ethanol and dried under vacuum. Yield 0.38 g, 14%. $C_{12}H_{28}Cl_2N_{10}NiO_9$ (586.01): calcd. C 24.60, H 4.82, N 23.90; found C 24.51, H 4.73, N 23.94. Electronic absorption spectrum (H_2O, 0.1 mol·L^{-1} $NaClO_4$): λ_{max} (ε, L mol^{-1} cm^{-1}) = 658 (ca. 2), 455 (23), 330 sh (30), 209 nm (52000). Single crystals of **1**, suitable for X-ray analysis, were selected from the precipitate.

$[Ni(HL^1)](ClO_4)_2Cl\cdot2H_2O$: This complex was obtained with nearly quantitative yield by recrystallization of **1** from 2 mol·L^{-1} HCl. $C_{12}H_{31}Cl_3N_{10}NiO_{10}$ (640.49): calcd. C 22.50, H 4.88, N 21.87; found C 22.45, H 4.83, N 21.67. X-ray quality crystals of $[Ni(HL^1)](ClO_4)_2Cl\cdot H_2O$ (**2**) were obtained by slow concentration of an acidic aqueous solution of **1** containing NaCl.

$[Ni(HL^1)](ClO_4)SO_4\cdot3.5H_2O$: This complex was obtained in nearly quantitative yield by recrystallization of **1** from acidic 1 mol·L^{-1} Na_2SO_4. $C_{12}H_{33}ClN_{10}NiO_{11.5}S$ (627.66): calcd. C 22.96, H 5.30, N 22.32; found calcd. C 23.91, H 5.34, N 22.73. X-ray quality crystals of $[Ni(HL^1)(OSO_3)(OH_2)]_2(ClO_4)_2\cdot5H_2O$ (**3**) were obtained by slow concentration of an acidic solution of **1** containing Na_2SO_4.

$[Ni_2(HL^2)](ClO_4)_5\cdot nH_2O$: The third yellow band which contained the bis(macrocyclic) ligand complex was eluted with 0.4 mol·L^{-1} $NaClO_4$. The volume of the elute was reduced to approximately 25 mL and the hot solution was acidified to pH ≈ 1 with concentrated $HClO_4$ and then cooled. Large orange and small yellow crystals formed were collected, washed with ethanol and dried in air. Total yield: 0.08 g, 1.5%. The crystals were separated manually. Orange complex, $[Ni_2(HL^2)](ClO_4)_5\cdot6H_2O$. $C_{21}H_{59}Cl_5N_{14}Ni_2O_{26}$

(1218.42): calcd. C 20.70, H 4.88, N 16.09; found C 20.71, H 4.46, N 15.94. Yellow complex, $[Ni_2(HL^2)](ClO_4)_5\cdot 2H_2O$. $C_{21}H_{51}Cl_5N_{14}Ni_2O_{22}$ (1146.36): calcd. C 22.00, H 4.48, N 17.11; found C 22.06, H 4.65, N 16.78. Recrystallization from nitromethane (diffusion of diethyl ether) of either of these complexes results in the formation of yellow crystals of the composition $[Ni_2(L^2)](ClO_4)_4\cdot 2H_2O$.

$[Ni_2(L^2)](ClO_4)_4\cdot 2H_2O$: $C_{21}H_{50}N_{14}Cl_4Ni_2O_{18}$ (1045.90): calcd. C 24.12, H 4.82, N 18.75; found C 24.05, H 4.77, N 18.63. Electronic absorption spectrum (H_2O, 0.1 mol·L^{-1} $NaClO_4$): λ_{max} (ε, L mol^{-1} cm^{-1}) = 658 (5), 455 (48), 330 (14), 214 nm (62000). Single crystals of $[Ni_2(L^2)](ClO_4)_4\cdot 2H_2O$ (**4**) were grown by vapor diffusion of diethyl ether to a nitromethane solution of $[Ni_2(HL^2)](ClO_4)_5\cdot 2H_2O$.

Crystal Structure Determinations: Reflections of representative crystals were measured with Siemens P4 (**2**) or Bruker AXS SMART 1000 (**1**, **3** and **4**) diffractometers using Mo-K_α radiation (λ = 0.71073 Å) and operating in the ω-scan mode. The structures were solved by direct methods (SHELXS-86) and refined by full-matrix least-squares methods based on F^2 (SHELXL-97),[39] using anisotropic thermal parameters for all non-hydrogen atoms. The crystallographic parameters are given in Table 7. CCDC-172715 (**1**), -172712 (**2**) and -172716 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Physical Methods: Infrared spectra (KBr pellets) were recorded with a Specord 75 IR (Carl Zeiss) spectrophotometer. Electronic absorption spectra were measured with a Cary1E (Varian) or a Specord M40 (Carl Zeiss) spectrophotometer, equipped with thermostatted cells. The electrochemical experiments (cyclic voltammetry, CV, or differential pulse voltammetry, DPV) were carried out with an Autolab (EcoChemie) system. A standard three-electrode scheme, consisting of a glassy carbon working, a calomel (1 mol·L^{-1} NaCl) reference (MCE) and a Pt plate auxiliary electrode was used. All solutions were purged with argon before measurement. The values of E_f (vs. MCE) for reversible or quasi-reversible redox transformations were calculated as the midpoints between the anodic and cathodic peaks, the distances between peaks (ΔE) were used as parameters for the characterization of the reversibility of the electrochemical transformations (ΔE = 59 mV for thermodynamically reversible process). Analytical data were obtained from the microanalytical laboratory of the chemical institutes of the University of Heidelberg.

Equilibria between Diamagnetic and Paramagnetic Forms: These were measured spectrophotometrically in a thermostatted (± 0.1°) quartz cell (only freshly prepared solutions were used). For aqueous solutions the ionic strength was kept equal at 0.1 mol·L^{-1}; when variable concentrations of sulfate were used the ionic strength was adjusted to 0.1 with $NaClO_4$ and/or $HClO_4$. ε_{ls} = 64 L mol^{-1} cm^{-1} {$[Ni(L^1)]^{2+}$} and 128 L mol^{-1} cm^{-1} {$[Ni_2(L^2)]^{4+}$} were obtained from nitromethane solutions. The ε_{ls} values were obtained from data fitting and Gaussian analyses of the experimental spectra {5 and 9 L·mol^{-1}·cm^{-1} for $[Ni(L^1)]^{2+}$ and $[Ni_2(L^2)]^{4+}$, respectively}. Stability constants for the sulfate adduct formation were calculated by iterative procedures applied to the plots of K_{ax} vs. equilibrium concentrations of sulfate. In a first step the equilibrium concentration of sulfate was assumed to be equal to its total concentration. The values of K^1_{ax} and K^2_{ax} so obtained were then used for the calculation of the equilibrium concentration of sulfate. Iterations were stopped when the difference between two consecutive equilibrium concentrations of the anion was less than $1\cdot 10^{-5}$ mol·L^{-1}.

COVER PICTURE

The cover picture shows the pH-dependent coordination chemistry of the potentially ambidentate ligand 2,2′-bipyridine-3,3′-diamine. A dimeric 2:2 complex is formed with copper(II) chloride in which each copper ion is bound to two pyridine nitrogen atoms and two chloride ions in a distorted square-planar arrangement, with a long axial contact from a neighbouring amino group completing a distorted square-pyramidal geometry. Under acidic conditions, both pyridine nitrogen atoms are protonated preventing coordination to the copper(II) ion and as a consequence, the two amino groups together with four chloride ions are bound to the metal ion completing an octahedral coordination sphere. Details are discussed in the article by J. D. Wallis, M. Pilkington et al. on p. 1985ff.

RECRUITMENT

GROUP LEADER POSITIONS AT THE NEW INSTITUTE OF CHEMICAL RESEARCH OF CATALONIA (ICIQ)

AREAS: Homogeneous Catalysis Heterogeneous Catalysis Molecular Recognition Molecular Devices Mechanistic Organometallic Chemistry Theoretical Organometallic Chemistry

The Institute of Chemical Research of Catalonia (ICIQ), financially supported by the autonomous government of Catalonia (Generalitat de Catalunya) and sponsored by a group of chemical/petrochemical companies, has been recently created with the mission of contributting to a significant improvement of the scientific level of chemical research and of strengthening, by means of innovation and technological upgrade, competitiveness of the chemical and pharmaceutical industries in Catalonia (Spain).

Located in the town of Tarragona, 100 km south from Barcelona, nearby one of the most important chemical/petrochemical complexes in Southern Europe, the Institute will be based on a 7000 square meter building now under construction at the scientific campus of the Universitat Rovira i Virgili (URV) and will constitute, together with the Faculty of Chemistry and the School of Chemical Engineering of the URV, the nucleus of the Tarragona Research Cluster. The Institute will be equipped with highly functional laboratories and state-of-the-art scientific instruments. Research at ICIQ will be in the areas of Catalysis and Supramolecular Chemistry, with special focus on sustainable aspects of chemistry and on molecular nanotechnology. A combined theoretical/experimental approach will be followed, and dynamic collaborations for multidisciplinary approaches to relevant scientific/industrial problems will be favored.

For the start-up of research activities, planned for the 4th quarter of 2003, positions are available at ICIQ at the levels of Senior Group Leader and Junior Group Leader. The successful candidates will be responsible of leading and developing a research group of up to 16 people (Sr. group leader) or up to 8 people (Jr. group leader). Besides performing high-quality research, they should have a positive attitude towards the implication in multidisciplinary projects and in the solution of industrially relevant problems.

If you have built-up a scientific career with outstanding achievements in one of the following areas: Homogeneous Catalysis, Heterogeneous Catalysis, Molecular Recognition, Molecular Devices, Mechanistic Organometallic Chemistry, Theoretical Organometallic Chemistry

and you feel attracted by the possibility of participating in the ICIQ project from the early beginning, please submit a letter of application accompanied by a CV, a description of previous accomplishments (up to 5 pages), a brief plan of the research you would like to develop at ICIQ (up to 5 pages), and the names and contact addresses of three or more scientists willing to act as reference persons, to:

Miquel A. Pericàs, Director
Institut Català d'Investigació Química
Pg. Lluís Companys, 23
08028 Barcelona (Spain)
e-mail: mapericas@fcr.es

In addition, an electronic version of the above documents should be attached to a cover message e-mailed to: **positions@iciq.es** All the information relative to applicants will be treated confidentially. Only applications received before October 31st, 2002 will be considered, and pre-selected candidates will be notified before the end of 2002.

ICIQ
Institut Català d'Investigació Química

Young brilliant researchers now in post-doc: Tenure track positions to be announced soon.

η^1 to η^6 Ru−Arene π Complexation: New Bonding Modes and P−C Bond Cleavage Chemistry

Tilmann J. Geldbach[a] and Paul S. Pregosin*[a]

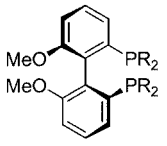
Keywords: P−C bond cleavage / π complexes / Unusual bonding / Stereospecific migration

Binap and MeOBiphep biarylbis(phosphane) complexes of Ru^{II} are shown to undergo a series of stereospecific P–C bond cleavage reactions. The products are novel cationic chiral arenebis(phosphane) compounds which contain stereogenic Ru centers. Upon further solvolysis in alcohols, additional P–C cleavage reactions lead to stereogenic P atoms. Several novel olefin π-bonding modes are recognised, including one in which only a single arene carbon atom i.e. an η^1 π-bond, weakly coordinates to Ru^{II}.

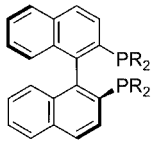
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

1. Introduction

There is an increasing interest in the area of enantioselective homogeneous catalysis[1] involving relatively small quantities of chiral catalytic materials that can produce substantial amounts of an enantiopure product. Although there are numerous examples of successful chiral nitrogen chelates,[2,3] as well as mixed P,N-ligands,[4] many auxiliaries are still based on chelating tertiary phosphanes.



1a R = 3,5-di-*t*Bu-phenyl
1b R = Ph
1c R = *p*-tolyl
1d R = *i*Pr



2a R = Ph
2b R = *p*-tolyl

The atropisomeric phosphanes MeO−Biphep **1**[5] and Binap **2**[6] are known to be excellent auxiliaries. These function exceptionally well in Ru-based homogeneous hydrogenation,[7,8] but can also be used in allylic alkylation,[9] and Heck reactions using palladium.[10] The syntheses of **1** and **2** are sufficiently flexible such that various R groups can be introduced and the backbone modified.[5,11] The catalyst precursor most often used in hydrogenation is the octahedral complex $Ru(OAc)_2$(**1**), $Ru(OAc)_2$(**2**), or a related trifluoroacetate complex.

Despite the widespread use of these biaryl ligands, not a great deal is known with respect to their fundamental organometallic chemistry. Several hydride compounds have been prepared,[12] e.g. $[RuH(i\text{PrOH})_2(\mathbf{1a})]BF_4$ (**3**),[13] however, olefin and alkyl compounds seem to have been neglected. Given the utility of **1** and **2**, it seems reasonable to ask how these might modify classical coordination behaviour. Moreover, if catalysts based on these ligands behave poorly or "die" in the course of the reaction, then perhaps knowledge of the possible decomposition pathways is important.

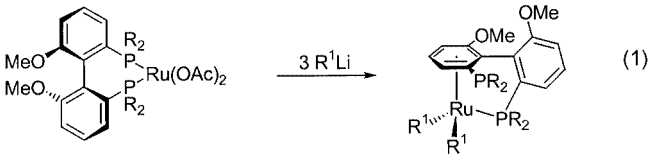
[a] Laboratorium für Anorganische Chemie, ETHZ, Hönggerberg, 8093 Zürich, Switzerland

Tilmann J. Geldbach (left) was born in Geislingen, Germany, in 1972. He began his chemistry studies in 1992 at the University of Konstanz, then spent a year at the University of Sussex at Brighton before graduating in 1998 at the Humboldt University in Berlin. He is currently preparing his PhD thesis at the ETH Zürich on the coordination chemistry of bis(phosphane)ruthenium complexes.

Professor P. S. Pregosin (right) received his PhD degree in New York City in 1970. After post-doctoral research studies at Queen Mary College, London and the University of Delaware, USA, he joined the faculty of the ETH Zürich in 1973, where he has remained. His research interests centre on NMR spectroscopy and organometallic chemistry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

As an example, reaction of [Ru(OAc)$_2$(**1a**)] with 3 equiv. of methyllithium or trimethylsilylmethyllithium affords the dialkyl complexes [RuR$_2$(**1a**)] (**4a** or **4b**) in good yields [see Equation (1)].[14]



R = 3,5-di-*t*Bu-phenyl

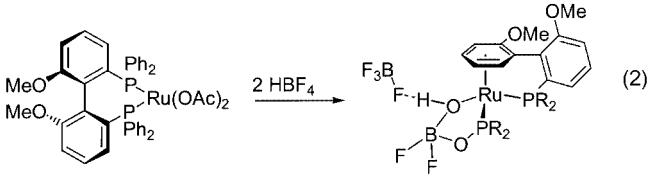
4a R^1 = Me
4b R^1 = CH_2SiMe_3

The molecule achieves this coordinatively saturated electronic structure by dissociating one tertiary phosphane donor, thereby making room (electronically) for an η^6-arene. This reduction from a bidentate to a monodentate ligand is hardly a common occurrence; however, we believe that this propensity for the Ru atom to complex one face of the biaryl ligand is related to the observation of facile P−C bond breaking. In this Microreview, we will focus on acid- and solvent-induced P−C bond cleavage in complexes containing the bidentate phosphane ligands **1** and **2**, and the array of arene−ruthenium bonding modes that are associated with these reactions.

2. P−C Bond Cleavage

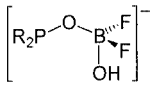
2.1 Acid-Induced Cleavage

As the starting compound in hydrogenation chemistry is often protonated to open one or more coordination positions, we begin with a discussion of the chemistry of Ru(OAc)$_2$(**1** or **2**) on addition of a strong acid. Reaction of Ru(OAc)$_2$(**1**) with 2 equiv. of HBF_4 in dichloromethane afforded product **5**, in which a P−C bond is cleaved [see Equation (2)].[15]



5a R = 3,5-di-*t*Bu-phenyl
5b R = Ph
5c R = *p*-tolyl

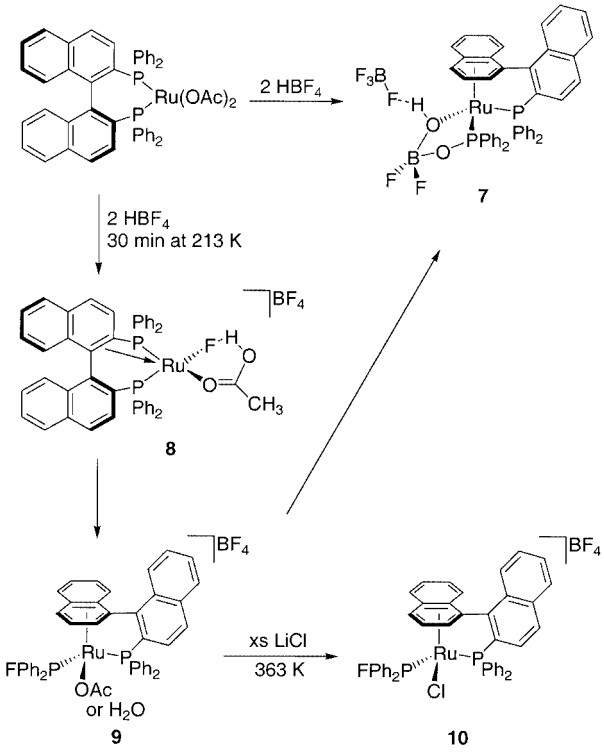
Complex **5** contains new P−O and B−O bonds, in addition to an unsymmetrical η^6 Ru−arene interaction, which arises from the complexation of the biaryl ring which loses the P-donor. The bis(phosphane) bidentate ligand has been cleaved affording two different chelating ligands.



6

Formally, **5** contains the new phosphinite anion **6**, which arises by a hydrolysis reaction. The second BF_4^- ion is held close by through a hydrogen bond. The major features of the structure of **5** were determined by one- and two-dimensional multinuclear NMR spectroscopy and X-ray crystallography.[15]

A more detailed NMR spectroscopic study of this protonation was carried out for the Binap analogue **7**, and these results are summarised in Scheme 1.[16] These reactions can be shown to involve an initial 6e$^-$ donor Ru−F complex **8** (and $BF_3{\cdot}Et_2O$), followed by P−C bond splitting, yielding the monofluoro(phosphane) intermediate, whose structure is assigned as **9**. The ^{31}P and ^{19}F NMR spectra of the PR_2F ligand in **9** clearly show the expected > 900 Hz one-bond $^1J_{P,F}$ values, as well as a very high-frequency ^{31}P chemical shift due to the strongly electronegative fluorine atom. Reaction of **9** with Cl$^-$ afforded the single diastereomeric chloro complex **10**. Obviously, this reaction produces Ru complexes that are sufficiently reactive to extract a fluoride from the BF_4^- anion. Apart from their surprising structure, these compounds are noteworthy in that they demonstrate an undesirable side reaction, the potential loss of axial chirality.

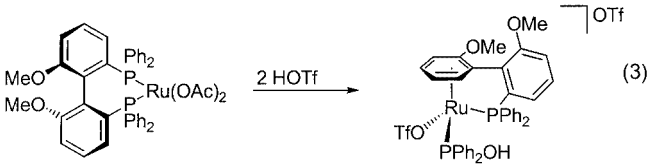


7 **8** **9** **10**

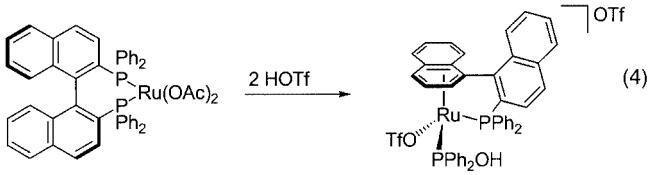
Scheme 1

The syntheses of the arene complexes **5** and **7** were complicated due to the slow, but concurrent BF_4^- anion hydrolysis. To avoid this complication, [Ru(OAc)$_2$(**1** or **2**)], was allowed to react with slightly more than 2 equiv. of wet CF_3SO_3H in 1,2-dichloroethane at 363 K [see Equations (3) and (4)].[16] These reaction conditions gave the MeO−Biphep product **11** and the Binap analogue **12** in less then 2 h and in good yields. Formally, the H$^+$ cation pro-

tonates the acetate anion and the water molecule adds across the P−C bond. Interestingly, we observed only one of the two possible diastereomers (the metal atom is a stereogenic centre), thus this reaction is stereospecific. The ligand $P(OH)Ph_2$ is not very common, but there are a number of such (and related) complexes reported in the literature.[17,18]

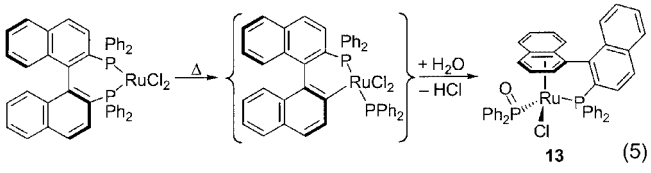


11 (3)



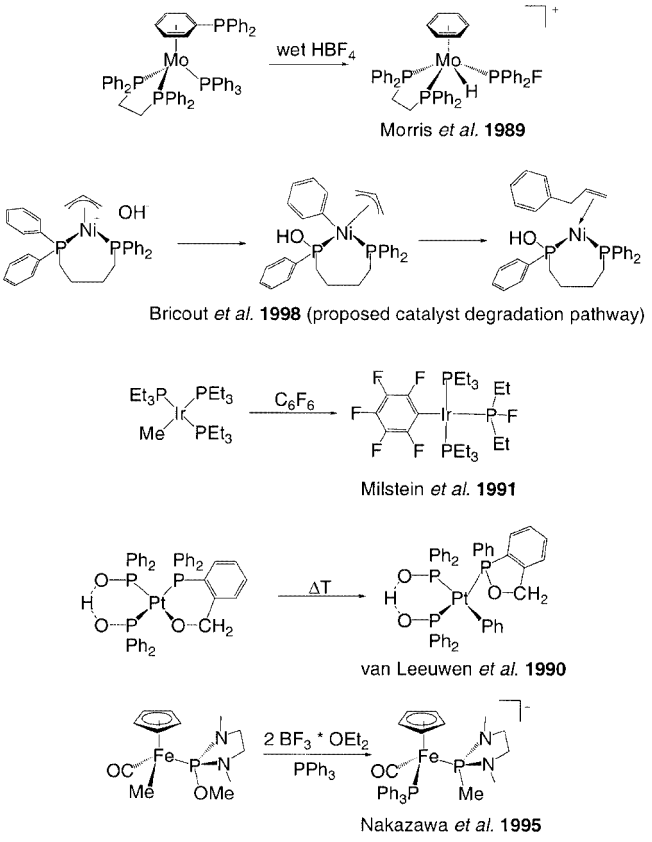
12 (4)

Apart from oxidative addition reactions,[19,20] there are not many examples of related P−C bond cleavage reactions in the literature and we show a selection of these in Scheme 2.[21−25] The first four examples involve the splitting of a P−C bond and the creation of a new P−X bond (X = electronegative group), whereas in the last reaction, a new P−C bond is formed at the expense of a P−O bond. Moreover, there are only a few examples of tethered phosphane−arene complexes,[26,27] e.g. **13** [see Equation (5)].[26a] Of course, lower valent Ru^0 clusters are also capable of cleaving P−C bonds.[28]



13 (5)

The structures of the new arene−phosphane compounds **11** and **12** were determined by X-ray diffraction and a view of the cation of **11** is shown in Figure 1. The six Ru−C(arene) bond lengths in both **11** and **12** are very different and seem to exist in three groups of two. Two bond lengths are relatively short [Ru−C1 and Ru−C6 (ca. 2.13−2.16 Å)] (but are fairly average),[29−33] two are slightly long [Ru−C4 and Ru−C5 (ca. 2.29−2.32 Å)], and two are quite long [Ru−C2 and Ru−C3 (ca. 2.35−2.48 Å)]. Inspection of the literature involving X-ray studies of arene complexes of Ru^{II} suggests that the usual Ru−C distances in a variety of substituted and simple Ru−arene complexes should be in the range 2.15−2.28 Å, with an average of



Scheme 2

ca. 2.23 Å. Specifically, the observed values of 2.480(5) and 2.477(5) Å for C2 and C3, respectively, in **11** suggest a weak interaction. The lengths of these bonds might be related to steric effects, since they involve the two sterically hindered fully substituted arene carbon atoms. We shall return to this theme in the discussion on possible flexible arene bonding in the next chapter.

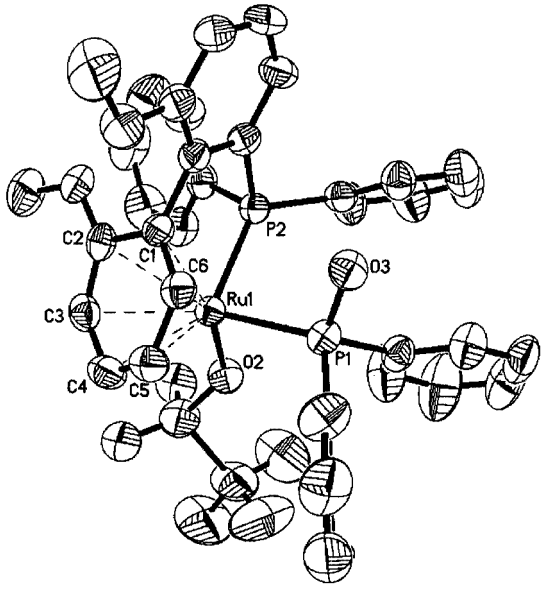


Figure 1. View of the cation of **11**

Although we reasoned that the presence of water was due to the wet triflic acid, there was another possible source. To test whether the acetate was a source of water, $Ru(OAc^*)_2(Binap)$ was synthesised containing > 98% ^{13}C-1 acetate (enriched at the carbonyl group).[34] The reaction of this complex with ca. 2.2 equiv. of high-purity (> 99%) triflic acid at 80 °C for 30 min in 1,2-dichloroethane was monitored by ^{13}C NMR spectroscopy (see Figure 2). The spectrum shows a coordinated acetate (δ ≈ 188 ppm), as well as acetic acid (δ ≈ 176 ppm) and acetic anhydride (δ ≈ 167 ppm). Clearly, the presence of acetic anhydride implies that water is produced.

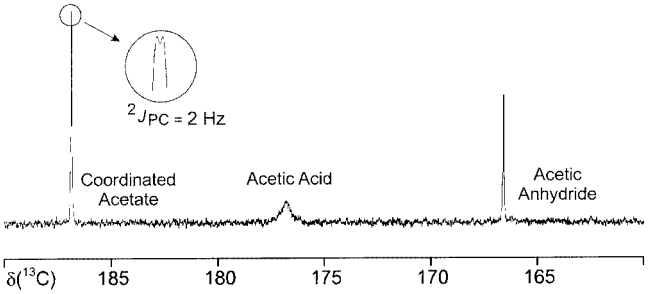

Figure 2. $^{13}C\{^1H\}$ NMR spectrum of the reaction solution after 30 min at 80 °C, with peaks for complexed acetate, acetic acid and acetic anhydride; the expanded section shows the P−C coupling, ^2J = 2.0 Hz (75 MHz, 1,2-dichloroethane with D_2O capillary as internal lock)

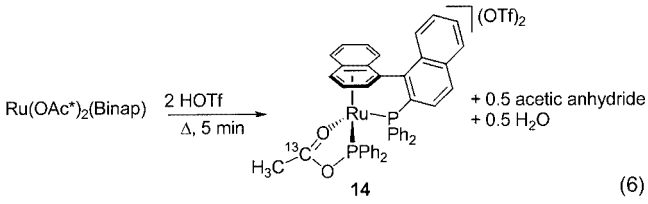
Warming of a fresh sample of the enriched starting material to 80 °C for 5 min afforded a small amount (< 10%) of product **12**, a parallel amount of acetic anhydride (and thus water), in addition to a large quantity of a new compound, **14** [see Equation (6)].

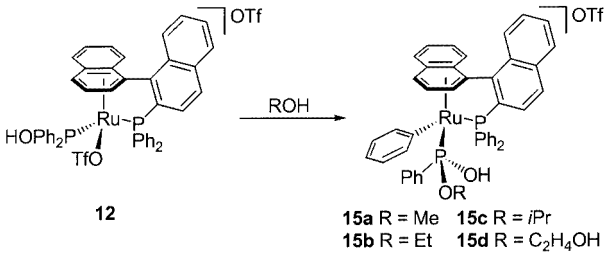


(6)

The ratio of **14** to **12** approaches unity after roughly 1 h. In the ^{31}P NMR spectrum of the new species, an AX ^{31}P spin system is seen, with one of the signals found at relatively high frequency (δ = 185.8 ppm). This new complex contains one acetate ligand as shown by ^1H and ^{13}C NMR spectroscopy. Interestingly, this intermediate species reacts quickly with water to form **12**. Indeed, workup of the NMR reaction solution, by simply pouring it into ether is sufficient to convert it immediately into **12**. The evidence for structure **14** is based on detailed NMR spectroscopic data.

2.2 Solvent-Induced Cleavage

We considered that the triflate compounds **11** and **12** might undergo solvolysis affording useful Lewis acids, so we treated these compounds with methanol. To our surprise we obtained good yields of the MeO−Biphep phenyl complex and its Binap analogue **15a**[35] [see Equation (7)].



(7)

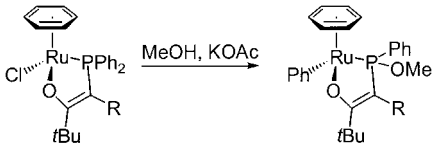
Additional compounds, **15b** and **15c**, have been prepared using EtOH and *i*PrOH, respectively. The new phenyl complexes are unique in that

a) they are produced in *only one diastereomeric form*, i.e. phenyl migration and P−O bond formation are specific,

b) they contain *three different forms of stereogenicity*: atropisomerism, from the biaryl moiety, a chiral transition metal atom and the newly formed stereogenic P atom, and

c) these are the first reported transition metal complexes of the ligands P(OH)(OR)Ph.

This kind of solvolysis and subsequent migration of a phenyl group from the phosphane group to the metal atom has been observed previously, see Equation (8).[36]



(8)

The solid-state structure of the *i*PrOH analogue **15c** was determined by X-ray diffraction methods and a view of the cation is shown in Figure 3. The immediate coordination sphere consists of the two phosphorus atoms, the π-arene and the η^1-phenyl ligand. While four of the Ru−C(arene) distances are fairly average and fall in the range

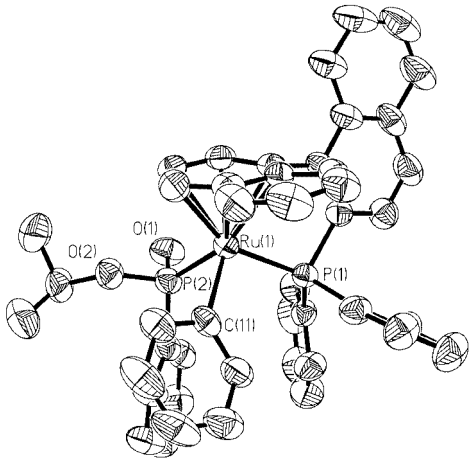


Figure 3. View of the cation of **15c**

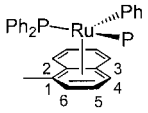
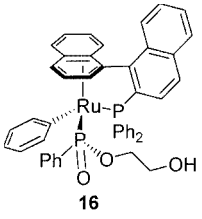
2.217(7)−2.272(8) Å, again, the remaining two distances, involving the bridgehead carbon atoms C(2) and C(3), are quite long and suggest that little or no bonding to the metal atom occurs.



Ru–C2 = 2.433(7) Å Ru–C3 = 2.419(8) Å

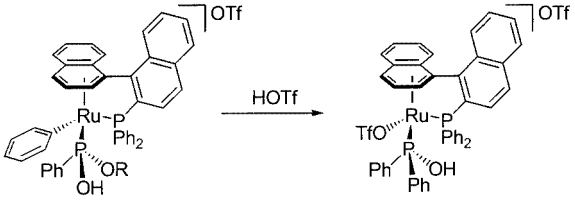
The Ru{P(OH)(OR)Ph} fragment is readily deprotonated and in some cases, e.g. the ethylene glycol derivative, **16**, rather than **15d**, was isolated.



16

2.3 Stereochemistry and Protonation Studies

With a view to preparing chiral complexes with an open coordination site, two of the Ru−{P(OH)OR)Ph} compounds (**15a**: R = Me; **15c**: R = *i*Pr; both with racemic phosphane ligands), were allowed to react with excess triflic acid in dichloromethane.

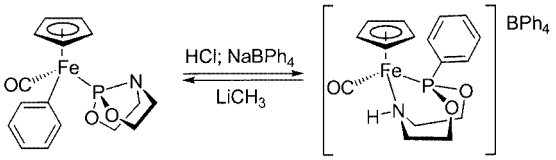


15a R = Me
15c R = *i*Pr

12

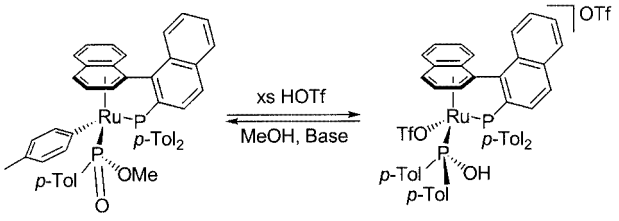
(9)

Instead of removing the Ru−phenyl ligand, the observed protonation product was either exclusively **12** (methoxy), or primarily **12** (isopropoxy).[37] For these acid reactions only a single diastereomer is observed, i.e. epimerisation at the Ru atom is not found. This type of migration reaction is known, but rare. A relevant example is shown in Equation (10).[38]



(10)

As an additional check on the stereospecificity of the transformation, we carried out several protonation reactions using the commercially available, optically pure (*S*)-(−)-*p*-tolyl−Binap **2b**. While only marginally different from **2a**, this ligand afforded yet another subset of complexes, **17**.



17 **18**

Addition of excess triflic acid to **17** immediately afforded only one diastereomeric form of **18**. Consequently, both the formation of the MeO analogue **15a** and the reformation of **12** proceeded stereospecifically. It was recognised that epimerisation at Ru can (but need not always) be facile.[39−41] Therefore, we repeated the protonation of **17** with excess triflic acid in dichloromethane at dry ice/acetone temperatures. After addition of HOTf to a precooled NMR probe at 220 K, we observed only a single product with a broad resonance at δ = 123.2 ppm and a sharp doublet at δ = 52.4 ppm. Slowly warming to 270 K using 10° increments, afforded a sharp peak in the ^{31}P NMR spectrum of the pure P(OH)(*p*-tolyl)$_2$ analogue of **12**. Since there is no evidence for a second diastereomer, we concluded that the reaction is very facile and, indeed, proceeds stereospecifically.

2.4 Kinetics of the Formation of 15a−c

The rates of reaction for **12** with ROH were not all identical. Consequently, these reactions were monitored by ^{31}P NMR spectroscopic methods. Reaction of **12** using either methanol or ethanol as the solvent proceeded essentially within mixing time to afford **15a** and **15b**, respectively. The difference in reaction rates as a function of the alcohol concentration becomes obvious when **12** is allowed to react using 4:1 alcohol/[D$_6$]benzene mixtures at 21 °C.

To reduce the reactivity of complex **12** with methanol and to obtain rate data at similar alcohol concentrations, 1:4 MeOH/[D$_6$]benzene mixtures were studied. The observed rate constant at 21 °C for the formation of **15a** is $k_{obs} = 6.4{\cdot}10^{-4}$ s^{-1}. For the reaction of **12** with ethanol under similar conditions, $k_{obs} = 5.6{\cdot}10^{-4}$ s^{-1}; therefore, for these somewhat more dilute alcohol solutions, the reactions with both MeOH and EtOH proceed at similar rates. In both cases, a new intermediate in the ^{31}P NMR spectrum is observed.[37] Due to its relatively slow rate, the reaction with 2-propanol was carried out at 27 °C, and not 21 °C. The major peaks observed are those of the starting material, together with a weak, unresolved resonance at δ ≈ 94 ppm. The product **15c** reacts slowly with traces of water to form a new species, which we believe to be a dinuclear complex. After 16 h, the two products are present in similar amounts. The observed reaction rate, $k_{obs} = 8.8{\cdot}10^{-5}$ s^{-1} (27 °C), was calculated using the disappearance of the substrate. Obviously, the reaction with 2-propanol can be considered to be one order of magnitude slower than with either methanol or ethanol.

We have recently managed to isolate two of the dinuclear species, **19** and **20**, and the crystallographic results for **19** are shown in Figure 4.[42]

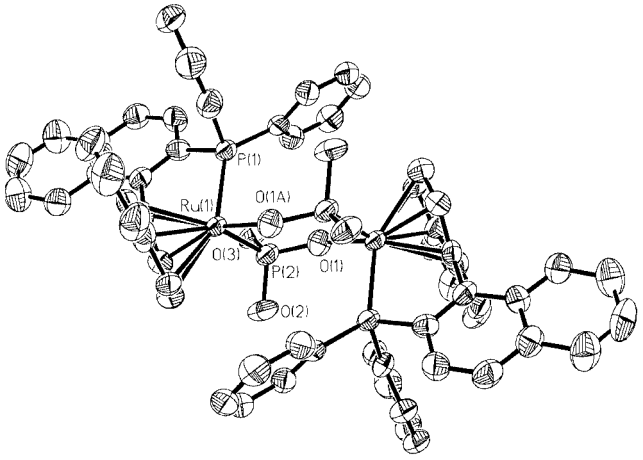


Figure 4. View of the dication of **19**

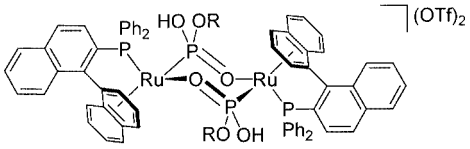
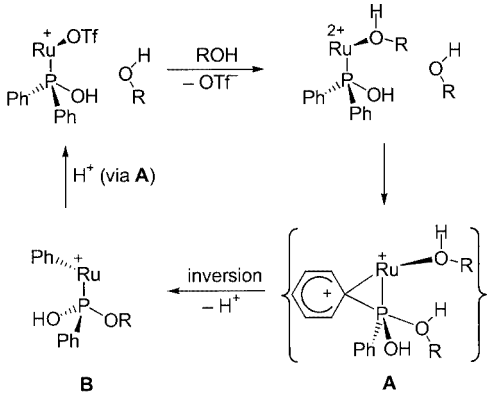


19 R = H
20 R = Me

The structures show that water from the alcohol competes favourably for the P atom, and indeed, one of these two species was prepared by a reaction involving *tert*-butyl alcohol, i.e. the *tert*-butyl alcohol reacts even more slowly than 2-propanol, relative to water.

The reaction of **12** with 2-propanol was also studied in the presence of an excess of sodium triflate. The starting material was consumed after 4 h, whereas in the same time, without added sodium triflate, ca 70% of substrate had reacted, i.e. addition of triflate increases the reaction rate. From a mechanistic point of view, if triflate dissociation was important, the rate should be slower. The kinetic data suggest that the reaction with 2-propanol, as well with methanol and ethanol, are first order with respect to complex **12**. A comparison of the values of k_{obs} obtained using different concentrations of ethanol supports a rate dependence on the concentration of the alcohol.

A possible reaction pathway, which rationalises the stereospecific transformation of complex **12** into the products is shown in Scheme 3 (only the reactive sites of these molecules are shown). Solvent substitution is followed by arene migration to afford a Ru−Ph complex. Protonation of the OR group in the Ru−Ph complex restores the $P(OH)Ph_2$ compound. Using the alcohol as the solvent favours the formation of the dicationic solvent complex (as might the presence of excess charged triflate). Presumably, these solvent complexes are the unknown compounds that appear in the ^{31}P NMR studies, when diluted with benzene. There is always solvent alcohol in close proximity, partially due to the hydrogen bonding to both the triflate anion and POH moieties (another possible source of an intermediate structure). In the transition state, the complexed solvent begins to dissociate. Simultaneously, the phenyl group bridges the Ru and P atoms and the proximate H-bonded solvent begins to form the new P−O bond through a pseudo-backside attack. Possibly, these steps occur sequentially, although the alcohol must be in the rate-determining step. This mechanism is reminiscent of the formation of a nonclassical arenium ion (a typical intermediate in 1,2 shifts of aryl rings), and would be consistent with the observed stereospecificity. Since the alcohol is involved in the transition state, it is reasonable that both its concentration and size affect the kinetics.



Scheme 3

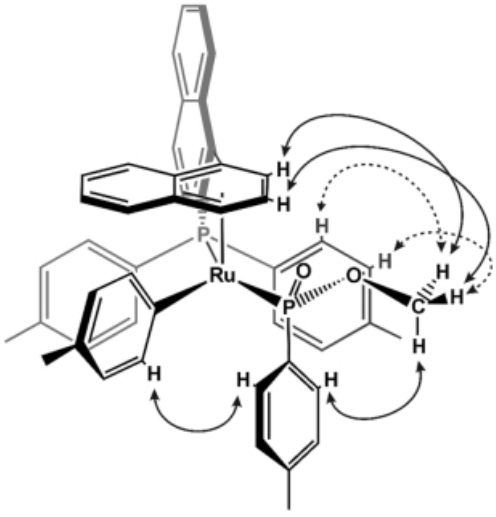
To support this mechanism we have determined the 3-D solution structure of {P(=O)(OMe)(*p*-tolyl)} complex **17** in dichloromethane, using NOE methods (see Scheme 4).[37,43,44] From these and additional NOE results, it can be seen that the Ru−aryl ring is positioned in an approximately antiperiplanar position relative to the methoxy group. This structural feature allows us to rationalise both the ease and specificity of the reactions indicated in Scheme 3. The positive charge which would develop from facile protonation of the P(OR) group by the strong acid, can be stabilised by the Ru−*p*-tolyl group, again in analogy with carbon cation chemistry (see structure **A**, Scheme 3). Complete transfer of the aryl group to the P atom is then accompanied by rapid triflate capture by the ruthenium cation affording the product, e.g. **15**. Since **A** and **B** are positively charged, in dichloromethane the triflate anion will be nearby. The excess triflic acid helps to facilitate rapid capture before epimerisation.

3. Flexible Arene Bonding

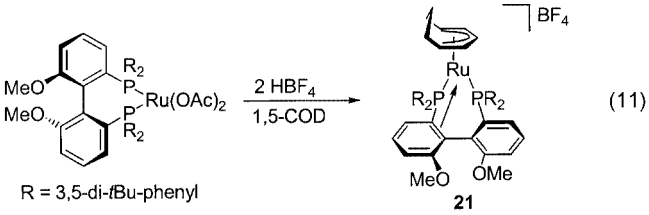
3.1. Olefin-Type Coordination

We noted above, without comment, that a proximate biaryl double bond can complex the Ru^{II} atom, e.g. the middle structure in Scheme 1. We believe this type of complexation to be surprisingly common.

In dichloromethane, $Ru(OAc)_2$(**1a**) reacts with 1,5-COD and HBF_4 to afford **21** in a good yield [see Equa-

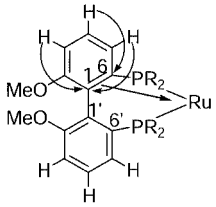


Scheme 4



(11)

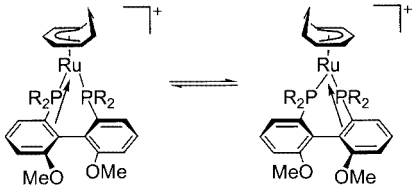
tion (11)].[45] The ^{31}P NMR spectrum shows a routine AX spin system; however, the chemical shifts at δ = 69.6 and −11.2 ppm (!) are unexpected, with the latter in a region often associated with uncoordinated phosphane. The nature of the organometallic ligand in **21** was not immediately obvious; however, a routine 2-D $^{13}C,^{1}H$-correlation showed only three aliphatic CH_2-type signals, and five CH absorptions in the region δ = 57−114 ppm. These ^{13}C chemical shift data are strongly suggestive of the cyclooctapentadienylruthenium fragment, Ru(η^6-C_8H_{11}).[46] At this point, we noted two ^{13}C resonances of *nonprotonated* carbon atoms at δ = 74.5 ppm as a strong doublet, and at δ = 95.1 ppm as a very weak triplet. A long-range $^{13}C,^{1}H$-correlation revealed connectivity between both of these nonprotonated carbon atoms and the proton *ortho* to the P atom, plus further $^{3}J(^{13}C,^{1}H)$ correlations, as indicated.



δ C(1) = 95.1 ppm δ C(6) = 74.5 ppm

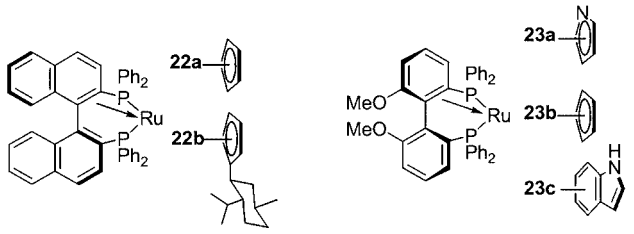
The ^{13}C signals for the noncomplexed analogous carbon atoms (C1′: δ = 139.7 ppm; C6′: δ = 135.4 ppm) are at a higher frequency. Given these assignments we conclude that the C1−C6 biaryl double bond is coordinated to the metal atom, thereby affording an 18e$^-$ coordinatively saturated complex, and thus making the ligand **1a** a six-electron donor to the metal atom. The low-frequency ^{31}P signal at δ = −11.2 ppm is associated with the unexpected coordination mode.

The ^{1}H phase-sensitive NOESY spectrum[44,45] for **21** at ambient temperature reveals a slow exchange process in which the two halves of the MeO−Biphep ligand are exchanged. Since the product has exactly the same structure, one observes only one set of resonances. Presumably, the biaryl double bond dissociates, thus making room for its counterpart in the second biaryl ring [see Equation (12)].

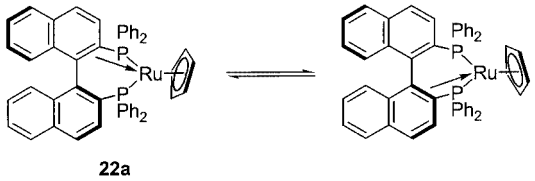


(12)

This new type of pseudo-allylic olefin bonding is unusual; however, White and co-workers reported[47] the solid-state structure for [Ru(Cp)(Binap)]CF_3SO_3, in which they found the same type of six-electron donation from the Binap ligand. They also noted widely dispersed ^{31}P chemical shifts at δ = 74.0 and 14.1 ppm. They were kind enough to provide us with samples of two Cp complexes, **22a** and **22b**, for NMR spectroscopic studies (see Scheme 5). These show both the typical ^{13}C shifts and exchange dynamics [see Equation (13)].[48]



Scheme 5



(13)

Subsequently, we prepared the complexes **23a**−**c**, and the solid-state structures of **23b** and **23c** are shown in Figure 5 and Figure 6, respectively. All of these compounds contain the complexed proximate double bond.

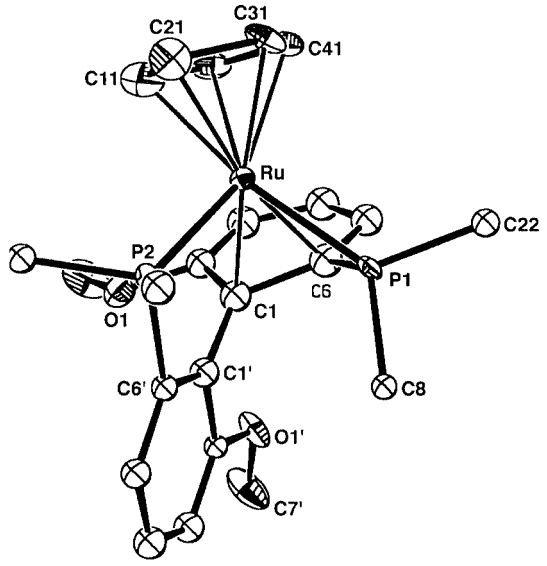


Figure 5. View of a part of the cation **23b**

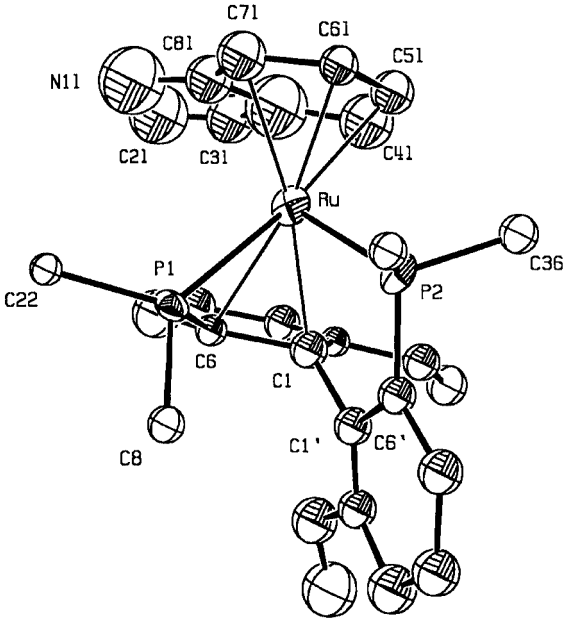

Figure 6. View of part of the cation **23c**

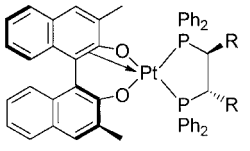
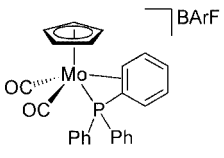
In recent literature reports, we found two related cases of this type of bonding: The Pt complex **24**[49] is clearly related, whereas the Mo complex **25**[50] might be of a more general nature due to the ubiquitous triphenylphosphane.

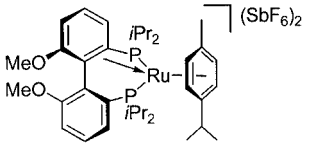


24



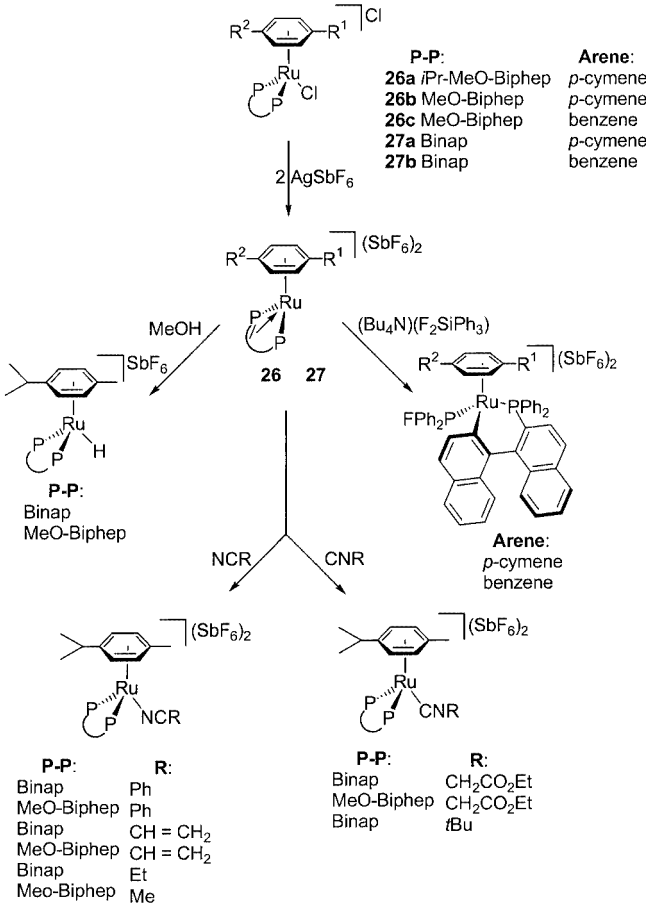
25

Once it is known that **21**−**23** are stable, then it is a relatively simple task to extend the known range of complexes showing this type of bonding by extracting chloride from [RuCl{bis(phosphane)}(arene)]Cl to afford the cymene complex **26a**.[51]



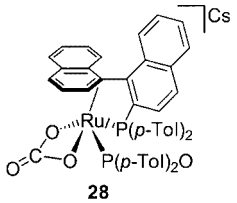
26a

Compound **26a** and related species are shown in Scheme 6, along with several other derivatives, and selected NMR spectroscopic data are given in Table 1.[51]



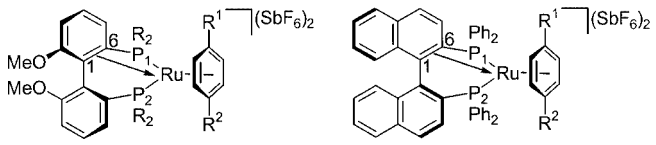
Scheme 6

Reaction of **12** with Cs_2CO_3 gave compound **28,** which also shows an η^2-olefin interaction, albeit of a different nature. Interestingly, the two carbon atoms complexed are those which can coordinate before P−C cleavage.



28

Table 1. Selected NMR chemical shifts for the carbon and phosphorus donors in Ru−arene complexes **26** and **27**



26a R = *i*Pr; *p*-cymene
26b R = Ph; *p*-cymene
26c R = Ph; benzene

27a *p*-cymene
27b benzene

	C1	C6	P1	P2
26a	102.5	79.1	27.3	82.6
26b	93.0	80.1	7.7	67.1
26c	90.9	86.0	15.4	64.7
27a	98.0	67.5	3.3	68.7
27b	101.7	73.0	19.0	64.0

A section of the ^{13}C long-range correlation for **28** is given in Figure 7 and reveals two "typical" chemical shifts for C1 and C6, the carbon atoms coordinated to the ruthenium atom. The four remaining ring carbon atoms show normal NMR characteristics.

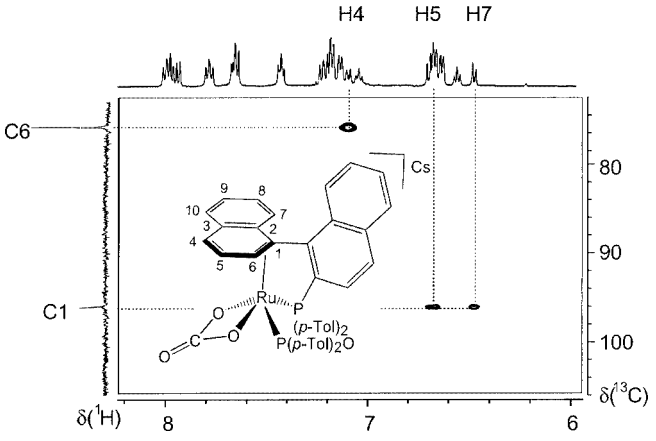


Figure 7. C,H long-range correlation for **28** showing the cross peaks for the two coordinated carbon atoms C6 and C1 stemming from the interaction of the *meta*-protons H4 and H5, and H7, respectively

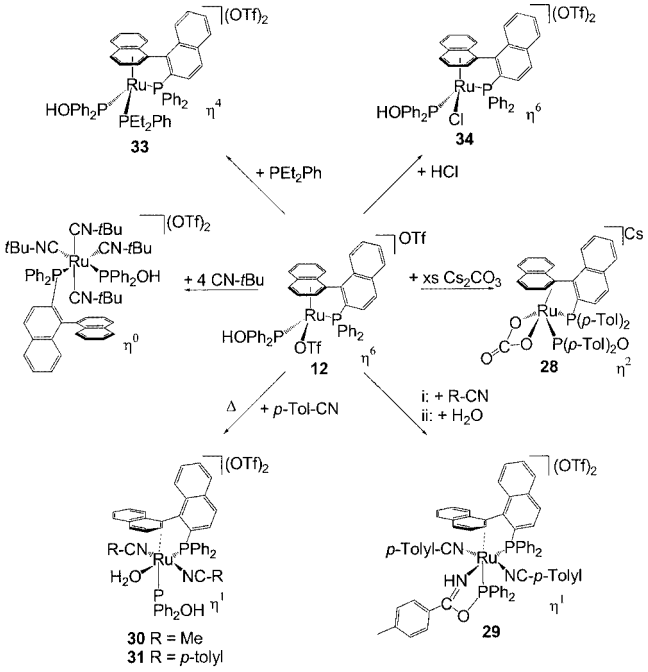
3.2. Coordination from a Single Arene Carbon Atom

A number of derivatives of the [Ru−P(OH)Ph_2] complexes **11** and **12**, containing nitrile, isocyanide and phosphane donors have been prepared (see Scheme 7).[52] In these compounds the arene has either been partially or fully displaced. On the surface, all of the apparent five-coordinate nitrile complexes appear to have structures in which the η^6-arene bonding has been completely displaced. However, these nitrile complexes contain an interesting and unexpected feature as shown by their ^{13}C NMR spectroscopic data. Just *one* of the (previously η^6-arene) biaryl carbon atoms (C6) remains situated in a pseudo-sixth coordination position, and its ^{13}C resonance is shifted to δ = 105−112 ppm from that of a "normal" arene hydrocarbon, which we estimate to be at δ ≈ 127−130 ppm.[53] This difference in carbon chemical shift is much too large to arise from local anisotropic effects. The signals of the adjacent carbon atoms C1 and C5 are found at δ ≈ 130−140 ppm, i.e. in rather typical positions, so that an η^2 description is not suitable for these molecules. The protons on C6 in these nitrile compounds (δ = 7.69−8.27 ppm) are also of a routine nature.



Scheme 7

Specifically, complex **29**, which arises from attack of the P−OH on a complexed nitrile ligand, shows this type of novel η^1 bonding.

One could consider the observed bonding as arising from a "remote agostic", i.e. weak, interaction of the metal atom with the biaryl C−H bond.[54,55] However, we do not believe this to be correct based on the normal observed values of $^1J_{C,H}$ (from the C,H correlations) and the H6 chemical shifts, both of which seem rather unaffected by the bonding. The most reasonable explanation involves a weak η^1-π bonding mode from a single CH biaryl arene carbon atom to the ruthenium atom. A strong interaction might induce larger coordination chemical shifts and shorter bond lengths.

Crystals of the two aquo(nitrile) complexes **30** and **31** were grown and their solid-state structures determined by X-ray diffraction. Figure 8 and Figure 9 show views of the cations and, although there is strong disorder in these crystals (the *R* values are not excellent), the coordination sphere around the ruthenium centre is clear.[52] Atom C(6) occupies the sixth position in both structures and P(2), possessing the P(OH) group, is in a pseudo-*trans* position to this arene carbon atom. The Ru−C(6) distances of 2.62 and 2.63 Å, for complexes **30** and **31**, respectively, are clearly too long for a routine σ-bond, but approach the upper end of what is known[56] for weak Ru−olefin interactions. The distances from the ruthenium atom to C(5) are both rather

long for a bonding interaction, ca 3.3 Å, which is consistent with the ^{13}C NMR results. Placing the H atom at a ca. 1 Å distance from C(6) affords Ru···H distances in the region of 2.69−2.70 Å, i.e. there is no reason to invoke a C−H agostic interaction.

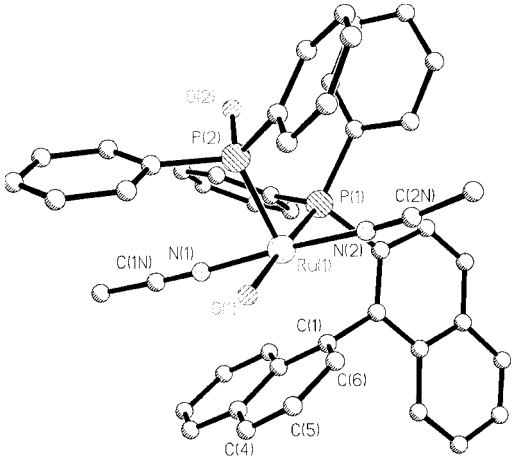


Figure 8. View of the cation **30**; note the position of C(6), occupying the 6th coordination site

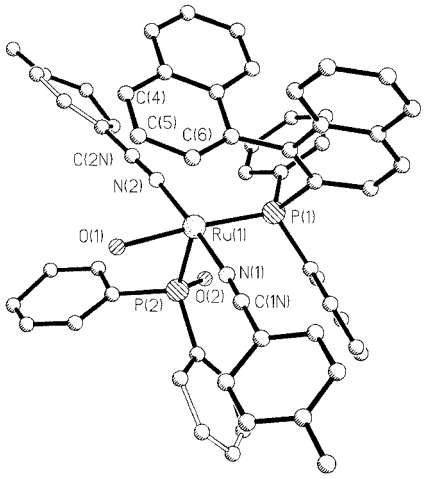

Figure 9. View of the cation **31**; note the position of C(6), occupying the 6th coordination site

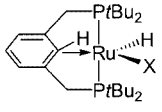
We are not aware of many examples of η^1 Ru−CH bonds; however, Gusev et al.[57] have recently assigned the Ru−CH interaction in **32** as a strong agostic interaction based on the short M−C distance, ca. 2.1 Å.



32

Indeed the reported *high frequency* carbon chemical shift of this Ru−CH carbon atom ($\delta \approx 152$ ppm) is consistent with a strong M−C σ-bond character.[58] This interaction is obviously different from those found in our Ru compounds.

3.3. η^4 or η^6 Bonding?

The PEt_2Ph complex **33** in the upper half of Scheme 7 is assigned to an η^4 diolefin structure. Although only slightly different from **12**, based on X-ray and NMR spectroscopic data, there are clearly two complexed double bonds and one remote, perhaps weak, interaction.

The question of η^6 vs. η^4 arene bonding in **12** and its derivatives is one that is discussed using ^{13}C NMR data. Despite the observed Ru−C distances (ca 2.4 Å or more), we believe that the bonding is best described as strongly asymmetric η^6. The ^{13}C chemical shifts for the two carbon atoms in question, C-2 and C-3, are shown together with three model compounds **28**, **33** and **34** (see Scheme 7).

	C-2	C-3	C-2'	C-3'
28	136.6	133.7	133.8	134.8
33	116.4	116.2	131.5	134.9
34	111.6	114.0	131.8	135.1

Assuming that a "normal" ^{13}C position (pure η^4 arene bonding) would be at $\delta \approx 130$ ppm, then both C-2 and C-3 experience some effect of the proximate Ru atom. Consequently, it is somewhat superficial to draw the line between the η^6 and η^4 description; however, as expected, the presence of stronger donating groups (e.g. phosphane vs. chloride), leads to a weaker arene−Ru interaction and thus to a shift towards higher frequency for the signals of C-2 and C-3.

4. Comments

The biaryl chelating phosphanes **1** and **2** do not display "routine" coordination/organometallic chemistry. In general, for Ru complexes of **1** and **2**, the nature of the other ligands bound to the ruthenium atom determines whether these bis(phosphanes) function as $4e^-$ or $6e^-$ donors. There is a definite propensity for this metal to "reach" for the electrons of the biaryl π-system (as in **21**−**27**) as soon as the electron count for ruthenium is only $16e^-$. In order to achieve this, the biaryl is severely twisted.[43,46] Once the Ru atom has complexed the double bond next to the P atom, it is reluctant to release it, and all of the X-ray data show that the Ru−C1 and Ru−C6 distances are the shortest. When the P−C bond has been broken, and a new π-ligand formed, the nature of the different donor ligands (phosphanes, nitriles, carbonate etc.) determines whether the ring of the biaryl ligand slips from a weak six- to a normal four-, and then down to a two-atom donor. Rather than

completely forsake this nearby π-system, these complexes can adopt the novel η^1-π bonding mode, as in **29**−**31**; the weakest interaction with the π-system manageable. This interest in holding the π-cloud may well be responsible for the observed ease of P−C bond breaking in bidentate biarylphosphane compounds. In any case, the chemistry of **1** and **2** affords a variety of novel, new chiral phosphane complexes of Ru^{II} in which arene complexation plays a major role.

The undesirable second and third P−C bond breaking reactions, i.e. the formation of **19** and **20**, prohibits a controlled synthesis of $16e^-$ intermediates. Nevertheless, both **19** and **20** are unique and offer opportunities for studying interactions of these with additional harder metal centres, e.g. the preparation of phosphorus-containing chiral complexes of metals in higher oxidation states.

Oxorhenium(V) Complexes of Carbohydrate Ligands[‡]

Peter Klüfers,*[a] Oswald Krotz,[a] and Martin Oßberger[a]

Keywords: Rhenium / Carbohydrates / Oxo ligands

The reaction of anhydroerythritol (AnEryt) and methyl-β-D-galactopyranoside (Me-β-D-Gal*p*) with dichloro[hydridotris(pyrazolyl)borato]oxorhenium(V) [(tpb)ReOCl$_2$] in methanol/triethylamine results in the formation of blue crystals of the diolato complexes [(tpb)ReO(AnErytH$_{-2}$)] (**1**) and [(tpb)ReO(Me-β-D-Gal*p*3,4H$_{-2}$)] (**2**). The amounts of *anti*-**1** and *syn*-**1** isomers are investigated by means of NMR spectroscopy and depend on the solvent chosen. For **2**, the generally rigid pyranoside ligand enters the complex in a conformation that is even more heavily strained than the corresponding isopropylidene sugar in terms of torsion angles. Though *anti* and *syn* isomers are also formed in non-aqueous media initially, various synthetic procedures are given to obtain pure *syn*-**2**.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Diolato complexes of the oxo-rhenium(V) moiety have attracted considerable interest in the past decade.[1−12] Most of this work has been directed towards ethylene glycol and catechol as the ligands. Unfortunately, there is no information on rhenium complexes of diol functions incorporated into a carbohydrate. A knowledge of the rules of rhenium binding to carbohydrates is of medical significance, since it would be of great advantage to couple radioactive rhenium isotopes, which are used both in tumour diagnosis and therapy, to biomolecules that specifically bind to receptor sites of a tumour. Among the biomolecules in question, glycopeptides provide carbohydrate functionalities.

In a first attempt to learn about the structural and spectroscopic properties of rhenium-carbohydrate complexes, several furanoidic and pyranoidic diols were investigated. With this work, we report on complexes of two ligands: anhydroerythritol (AnEryt), which provides the core of *cis*-configured furanosides, and methyl-β-D-galactopyranoside (Me-β-D-Gal*p*). The latter provides diol functions, which exhibit larger torsion angles as typical for pyranosides generally.

Results and Discussion

Preparation and Crystal Structures

The new compounds were prepared according to a modification of Brown and Mayer's method[7] by reaction of dichloro[hydridotris(pyrazolyl)borato]oxorhenium(V) [(tpb)ReOCl$_2$], triethylamine, and the carbohydrate in refluxing methanol (Scheme 1). To prevent formation of oligomeric rhenium complexes — obviously the main side reaction — a fourfold excess of carbohydrate over rhenium was used. Typical yields of 60% with respect to rhenium were obtained with this method. Attempts to obtain crystals were successful for both the ligands mentioned. Blue, monoclinic crystals of [(tpb)ReO(AnErytH$_{-2}$)] (**1**) are built up from equal amounts of two isomers, which differ in the orientation of the oxolanediolato ligand with respect to the (tbp)ReO fragment. Figure 1 shows the molecular structure of then *anti* isomer, highlighting an intramolecular hydrogen bond of the type C−H···O, with the ether-O atom of the ligand being the acceptor. In the *syn* isomer (Figure 2), the ligand is turned by 180° (the *syn* isomer has been defined as the one with the oxolane ring hinged towards the Re=O group). In the hydrogen-bonded *anti* form, the additional bond between the oxolanediolate and the (tpb)ReO residue results in a more perfect transfer of symmetry from the metal fragment to the ligand. Hence *anti*-**1** is close to C_s symmetry from which *syn*-**1** deviates markedly (cf. the diol torsion angles of both forms in the legends to Figure 1 and 2, the ideal angle for C_s symmetry being 0°). In the crystal structure, the ether-O atom of *syn*-**1** also acts as an acceptor in a hydrogen bond with a C−H donor; other oxygen atoms also establish weak contacts of this kind, all of which are intermolecular.

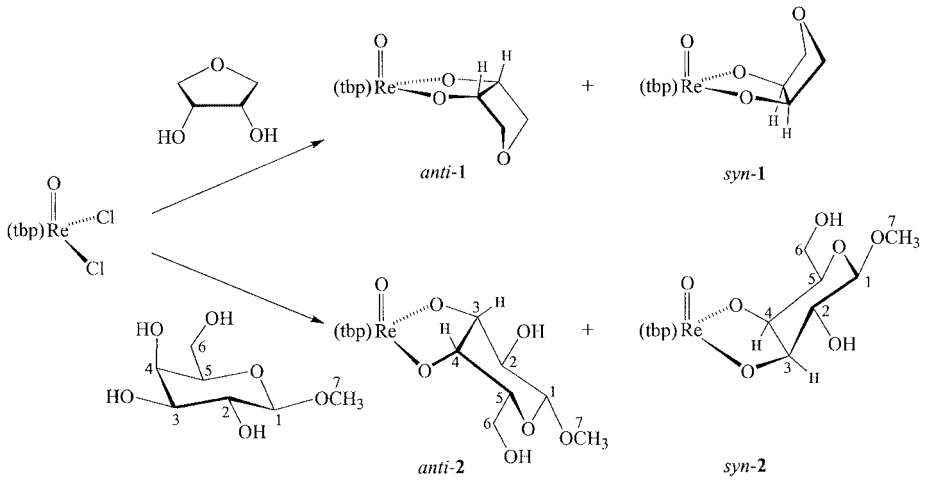

Scheme 1. Reaction scheme and numbering of carbon atoms in **2** [tpb = hydridotris(pyrazolyl)borate]

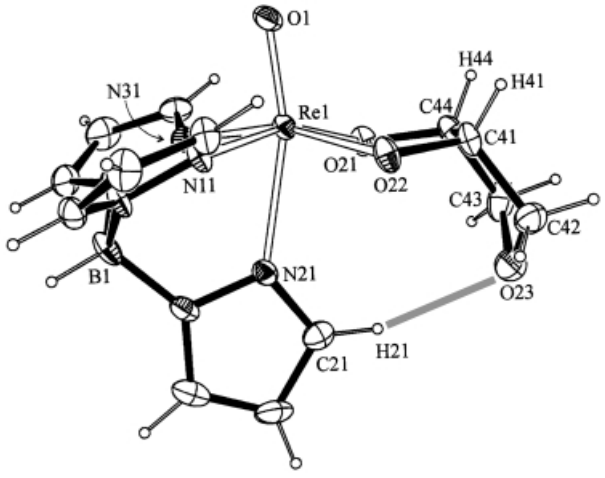

Figure 1. The structure of the H-bonded *anti* isomer of **1**; thermal ellipsoids are drawn at 40% probability; selected bond lengths (Å) and angles (°): Re1−O1 1.683(4), Re1−O21 1.929(4), Re1−O22 1.930(4), Re1−N11 2.095(4), Re1−N31 2.122(4), Re1−N21 2.291(4); O22−C41−C44−O21 −1.2(6); hydrogen bond C21−H···O23 23 3.218(7), H···O23 2.319 Å; C21−H···O23 157.8°; some of the H atoms are labelled to explain the result of an NOE experiment in the text

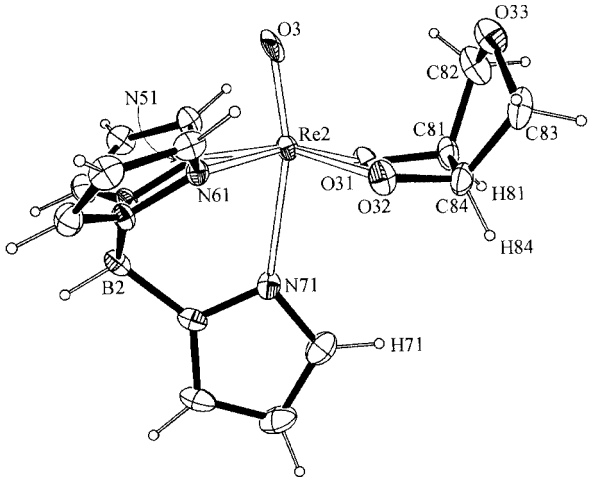

Figure 2. The structure of the *syn* isomer of **1**; thermal ellipsoids are drawn at 40% probability; selected bond lengths (Å) and angles (°): Re2−O3 1.660(4), Re2−O32 1.930(4), Re2−O31 1.932(4), Re2−N51 2.112(4), Re2−N61 2.119(4), Re2−N71 2.261(4); O31−C81−C84−O32 −19.3(6); some H atoms are labelled; in solution NMR studies, an NOE was analysed for these atoms (see text)

In a similar procedure using methyl-β-D-galactopyranoside as the polyol, blue crystals of the diolate complex [(tpb)ReO(Me-β-D-Gal*p*3,4H$_{-2}$)] (**2**) were obtained. Though the diol group with O2 and O3 is the most acidic one, a structure analysis reveals that the carbohydrate ligand binds in an O^3,O^4 bonding mode. Hence the *cis*-diol group of the pyranoside is engaged in complexation, which allows a smaller O−C−C−O torsion angle (Table 1). In **2**, the pyranose ring is found in the *syn* position (*syn* defined as in **1**). A closer inspection of the bonding parameters (Figure 3) shows the ligand to be in an unusual strained conformation. The diol torsion angles O2−C2−C3−O3 and O3−C3−C4−O4 show a 12.8° increase for the free and a 23.7° decrease for the ligating diol group with respect to the free galactoside. Hence the deviation from the unstrained conformation is much larger than would be expected from other galactopyranoside derivatives that have their O3−C3−C4−O4 fragment incorporated into a chelate ring (Table 1). For comparison, the values of the isopropylidene derivative of methyl-β-D-galactopyranoside are included in Table 1, where the differences in bond angles between metalla- (ca. 90°) and carbacycles (110−120°) are very noticeable.

The unexpectedly large distortion of the galactoside on rhenium complexation may be interpreted in terms of a mismatch between the binding sites of the metal and the diol moiety, which should result in a decreased stability of **2** with respect to **1**. In fact, **1** appears to be the product of higher stability: Batches with a 1:1 molar ratio of rhenium and galactoside hardly yielded product. On the other hand,

Table 1. Mean torsion angles τ in five-membered rings where a complex fragment L_nM (or an isopropylidene group in the last table entry) is chelated by a diolate entity derived from methyl-β-D-galactopyranoside; the torsion angles of the free galactoside are 62.9 and 56.0° for O2−C2−C3−O3 and O3−C3−C4−O4, resp.;[a] Δτ is the deviation from τ of the free galactoside; the bond length X−O (X = M or C) is given as a measure for the size of X

L_nM or Me_2C	bonding mode	X−O/Å	τ/°	Δτ/°	Ref.
(tpb)ORe^{V} (**2**)	O^3,O^4	1.944	32.3	−23.7	this work

Chem.* **1999**, *38*, 3283−3289; L-vsal is the salicylimide of L-valine; the galactoside ligand is the mono-anion of methyl-2,6-di-*O*-methyl-β-D-galactopyranoside, i.e. the ligand is di-*O*-methylated with respect to the other table entries. [c] P. L. Barili, G. Catelani, G. Fabrizi, D. Lamba, *Carbohydr. Res.* **1993**, *243*, 165−176.

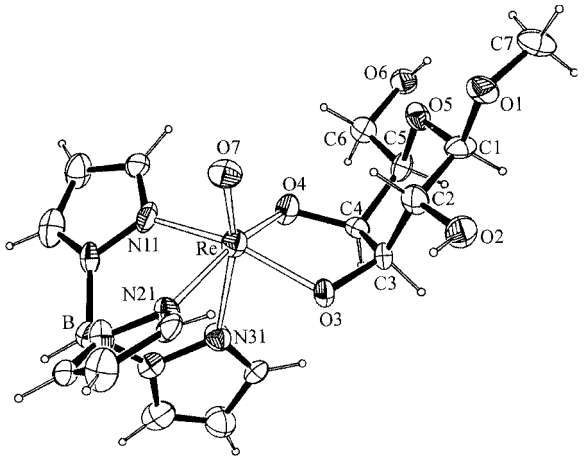

Figure 3. The molecular structure of **2**; thermal ellipsoids are drawn at 30% probability; selected bond lengths (Å) and angles (°): Re−O7 1.709(11), Re−O4 1.927(10), Re−O3 1.960(11), Re−N11 2.087(15), Re−N21 2.125(13), Re−N31 2.242(12); O3−C3−C4−O3 32.3(16), O2−C2−C3−O3 75.7(15); puckering parameters[14] of the pyranose ring: Q = 0.541(16) Å, θ = 20.3(17), φ_2 = 29(5)°

in the case of anhydroerythritol about 40% (instead of about 60% using a fourfold excess of diol) of product was obtained with the 1:1 ratio.

Solution Studies

Although *anti*-**1** and *syn*-**1** are present in equal parts in the asymmetric unit of **1**, they form in different quantities in the course of the reaction of [(tpb)$ReOCl_2$] and anhydroerythritol. After refluxing for two hours in methanol, the mixture consists of three parts of the major isomer and two parts of the minor isomer. Two sets of signals are observed in the ^1H and ^{13}C NMR spectra, and these could be assigned by means of 2D techniques as H21 and H41/H44 on one hand (Figure 1) and H71 and H81/H84 on the other (Figure 2) were well resolved. On irradiation at the frequency of the H81/H84 signal, resonance enhancement of the respective pyrazolyl-H atom (H71) was observed (the mean distance H71···H81 and H71···H84 is 3.0 Å in the crystal structure), and, likewise, irradiation at the frequency of the H71 signal resulted in resonance enhancement of the H81/H84 signal. Hence the *syn* isomer shown in Figure 2 is the minor component of the solution equilibrium. The molar ratio of the isomers depends on the solvent used. In acetonitrile, the solvent used by Brown and Mayer,[7] the *syn*/*anti* ratio increases to 4:1, whereas with water as the medium in a heterogeneous reaction, followed by dissolution of the product in dimethyl sulfoxide, a 5:1 *syn*/*anti* ratio is obtained. It should be noted, however, that due to the kinetic inertness of the complexes, these values obviously do not represent the equilibrium mixture. On prolonged heating of solutions for weeks, the isomer ratio still varies but at the same time decomposition reactions interfere with isomerization.

The ^{13}C NMR signals of both isomers were determined by a "coordination induced shift" ("CIS"), a mostly downfield shift of those carbon atoms that bear the metal-bonded oxygens. Due to the fact that rhenium(v) exhibits both a high valency and a partly filled d-shell, the CIS values are large at 28.1 ppm for *anti*-**1** and 27.1 ppm for the *syn* isomer (the methylene carbons of the oxolane ring are shifted by 3.4 and 3.0 ppm for *anti*- and *syn*-**1**, respectively).

In the case of **2**, the spectra of reaction mixtures from the methanol route consist of two signal sets, which can be assigned to *anti*-O^3,O^4- and *syn*-O^3,O^4-**2**. As with **1**, a large−although not so large−CIS is observed for C3 and C4 in the galactoside complex (Table 2). No signals have been observed that indicate O^2,O^3 isomers in solution, which are the main species in cationic complexes with the trivalent $(en)_2Co^{III}$ fragment (en = ethylenediamine).[13] An assignment of which signal set stems from the *syn* form depicted in Figure 2 was possible from NOE measurements of the same kind that have been described for **1**. These results are collected in Table 2. Despite the fact that *syn*/*anti* isomerism is also observed with **2**, all experiments support the view that no solution equilibria with significant amounts of both isomers are present for the galactoside, but instead the *syn* form is of considerably higher stability than *anti*-**2**.

Table 2. Signal positions of the methyl-β-D-galactopyranosidato(2−) ligand in ^{13}C NMR spectra of solutions of **2** in methanol; in the second and fourth numeric row Δδ, defined by $\delta_{complex} - \delta_{reference}$ is tabulated; the reference is an approximately 0.1 M solution of methyl-β-D-galactopyranoside in [D_4]methanol; Δδ values that indicate a "coordination induced shift" ("CIS") are in bold

		C1	C2	C3	C4	C5	C6	C7
syn-**2**	δ	106.0	72.4	94.8	93.0	78.0	63.7	57.5
	Δδ	−0.3	−0.4	**19.6**	**22.5**	1.1	0.9	0.0
anti-**2**	δ	105.4	71.8	94.9	91.6	78.9	62.7	57.2
	Δδ	−0.9	−1.0	**19.7**	**21.1**	2.0	−0.1	−0.3

Hence, the latter seems to be formed as an unstable intermediate only (note that *anti*-**2** is not stabilized by intramolecular hydrogen bonding). Pure *syn*-**2** is thus accessible and was obtained by several routes. Upon leaving the initial methanol solutions of both forms for about two weeks at room temperature, only *syn*-**2** is detected by NMR spectroscopy. On adding water to the reaction mixture prior to heating, only *syn*-**2** is obtained. Eventually, in a synthetic route using water as the only medium in a heterogeneous reaction, pure *syn*-**2** was also obtained. Solutions of pure *syn*-**2** in various solvents never showed formation of *anti*-**2** on heating.

Conclusion

Oxorhenium(V) complexes are kinetically inert. On reaction with a polyfunctional carbohydrate, many isomeric forms are possible in principle including isomers that are obtained by simple 180° rotation of the ligand normal to the Re=O axis (*syn*/*anti* isomers). Steric and energetic restrictions of the oxo-rhenium centre, however, reduce the number of actual species. In the case of **2**, equilibrium adjustment appears to be more rapid in aqueous media.

Experimental Section

Materials: Methyl-β-D-galactopyranoside (98%) was purchased from Fluka; anhydroerythritol was a gift from Eridania Bégin-Say; dichloro[hydridotris(pyrazolyl)borato]oxorhenium(V) was prepared according to Brown and Mayer's procedure.[7]

Spectroscopic Experiments: ^{1}H and ^{13}C NMR: Jeol EX-400. ^{1}H-^{13}C HMQC and NOE difference spectra: Jeol eclipse +500; mass spectra: Jeol JMS-700 (ionisation method: DEI$^+$). IR: Nicolet 520-FT-IR.

1: [(tpb)ReOCl$_2$] (97 mg, 0.20 mmol), anhydroerythritol (83 mg, 0.80 mmol), triethylamine (80 mg, 0.80 mmol) and 7 mL of methanol were placed in a 25 mL flask. The suspension was refluxed for 2 hours to give a dark blue solution. After cooling to room temperature, the solvent was evaporated and the residue was taken up in 3 mL of dichloromethane. The organic phase was washed

twice with 3 mL of water to remove triethylamine hydrochloride and unreacted anhydroerythritol, dried over magnesium sulfate and the solvents evaporated to dryness. The dark blue solid was recrystallised from toluene/*n*-pentane (ca. 1:1). Blue crystals formed within a few days at room temperature. NMR spectra of the equilibrium mixture of the two isomers of **1**: ^{1}H NMR (400 MHz, [D$_6$]DMSO, 25 °C): δ = 3.86 (m, 2 H, H82B, H83A), 4.02 (m, 2 H, H82A, H83B), 4.21 (m, 2 H, H42A, H43B), 4.51 (d, $^2J_{H,H}$ = 11 Hz, 2 H, H42B, H43A), 5.58 (m, 2 H, H41, H44), 5.67 (m, 2 H, H81, H84), 6.05 (dd, $^3J_{H,H}$ = 2 Hz, 1 H, H22), 6.06 (dd, $^3J_{H,H}$ = 2 Hz, 1 H, H72), 6.54 (m, 4 H, H12, H32, H52, H62), 7.58 (d, $^3J_{H,H}$ = 2 Hz, 1 H, H71), 7.66 (m, 2 H, H23, H73), 7.90 (m, 4 H, H11, H31, H51, H61), 8.28 (dd, $^3J_{H,H}$ = 2 Hz, 2 H, H53, H63), 8.30 (m, 3 H, H13, H21, H33) ppm. ^{13}C NMR (100.5 MHz, [D$_6$]DMSO, 25 °C): δ = 75.0 (C82, C83), 75.4 (C42, C43), 97.9 (C81, C84), 98.8 (C41, C44), 105.6 (C72), 105.7 (C22), 108.2 (C52, C62), 108.3 (C12, C32), 134.6 (C73), 134.8 (C23), 139.4 (C13, C33, C53, C63), 142.1 (C71), 142.5 (C21), 147.7 (C51, C61), 147.9 (C11, C31) ppm. MS (70 eV): *m*/*z* (%) = 518 (100) [M$^+$], 416 (27) [M$^+$ − C$_4$H$_6$O$_3$]. IR (KBr): $\tilde{\nu}$ = 967 cm^{-1} (s; Re=O). Decomposition on heating to 218−222 °C.

2: [(tpb)ReOCl$_2$] (97 mg, 0.20 mmol), methyl-β-D-galactopyranoside (155 mg, 0.80 mmol), triethylamine (80 mg, 0.80 mmol) and 7 mL of methanol were placed in a 25 mL flask. The suspension was refluxed for 2 hours to give a dark blue solution. After cooling to room temperature the solvent was evaporated and the residue was taken up in 3 mL of dichloromethane. The organic phase was washed twice with 3 mL of water to remove triethylamine hydrochloride and unreacted galactoside. Since the aqueous phase was slightly blue, it was extracted twice with 2 mL dichloromethane. The combined organic phases were dried over magnesium sulfate and the solvent was evaporated. The dark blue solid was recrystallised from chloroform/*n*-pentane (ca. 1:1). Blue crystals formed within a few days at room temperature. The crystal that was investigated by X-ray methods was obtained by this procedure.

Solutions of pure *syn*-**2** were produced by an alternative method using water as the reaction medium: [(tpb)ReOCl$_2$] (97 mg, 0.20 mmol), methyl-β-D-galactopyranoside (155 mg, 0.80 mmol), triethylamine (80 mg, 0.80 mmol) and 7 mL of deoxygenated water were placed in a 25 mL flask. The suspension was refluxed for 3 hours, its colour turning dark blue. The resulting dark blue precipitate was filtered, extracted three times with 5 mL of acetonitrile and the organic phase evaporated to dryness. NMR spectra taken from aqueous preparations: ^{1}H NMR (400 MHz, [D$_4$]MeOH, 25 °C): δ = 3.56 (dd, 2 × $^3J_{H,H}$ = 8 Hz, 1 H, H2), 3.57 (s, 3 H. C7H$_3$), 3.91 (dd, $^3J_{H,H}$ = 7, $^2J_{H,H}$ = 11 Hz, 1 H, H62), 4.01 (dd, $^3J_{H,H}$ = 5, $^2J_{H,H}$ = 11 Hz, 1 H, H61), 4.39 (d, $^3J_{H,H}$ = 8 Hz, 1 H, H1), 4.50 (ddd, $^3J_{H5,H62}$ = 7, $^3J_{H5,H61}$ = 5, $^3J_{H5,H4}$ = 2 Hz, 1 H, H5), 4.80 (dd, $^3J_{H3,H2}$ = 8, $^3J_{H3,H4}$ = 6 Hz, 1 H, H3), 5.20 (dd, $^3J_{H4,H3}$ = 6, $^3J_{H4,H5}$ = 2 Hz, 1 H, H4), 6.03 (dd, 2 × $^3J_{H,H}$ = 2 Hz, 1 H, H32), 6.45, 6.55 (dd, 2 × $^3J_{H,H}$ = 2 Hz, 2 H, H12, H22), 7.54 (d, $^3J_{H,H}$ = 2 Hz, 1 H, H33), 7.70 (d, $^3J_{H,H}$ = 2 Hz, 1 H, H31), 7.99 (d, $^3J_{H,H}$ = 2 Hz, 1 H, H21), 8.00, 8.23 (d, $^3J_{H,H}$ = 2 Hz, 2 H, H23, H13), 8.07 (d, $^3J_{H,H}$ = 2 Hz, 1 H, H11) ppm. ^{13}C NMR (100.5 MHz, [D$_4$]MeOH, 25 °C): δ = 106.7 (C32), 109.0, 109.6 (C12, C22), 136.3 (C33), 139.6, 141.0 (C13, C23), 143.0 (C31), 149.1 (C21), 149.5 (C11) ppm; the signals of the galactoside ligand are collected in Table 2. MS (70 eV): *m*/*z* (%) = 608 (97) [M$^+$], 416 (16) [M$^+$ − C$_7$H$_{12}$O$_6$]. IR (KBr): $\tilde{\nu}$ = 970 cm^{-1} (m; Re=O). Decomposition on heating to 227−235 °C. To obtain pure *syn*-**2** in a homogeneous reaction, the methanol route was slightly altered by replacing the 7 mL quantity of methanol by a mixture of 0.8 mL of water and 6.2 mL of methanol.

X-ray Structure Determinations: Details of the structure analyses are summarized in Table 3. CCDC-179747 (**1**) and CCDC-179738 (**2**) contain the supplementary crystallographic data for this paper. X-ray Structure of a Ruthenium Dinuclear Complex Incorporating 4,4′-Bis(cyanamidophenylethynyl)benzene as a Ligand, a Conjugated Bridge Two Nanometers in Length

Elodie Sondaz,[a] Joel Jaud,[a] Jean-Pierre Launay,[a] and Jacques Bonvoisin*[a]

Keywords: Ruthenium / Bridging ligands / N ligands / X-ray structure

The reaction of [Ru(bpy)(tpy)(Ipcyd)]$^+$ (bpy = 2,2′-bipyridine, tpy = 2,2′:6′,2′′-terpyridine, Ipcyd = 4-iodophenylcyanamide anion) with diethynylbenzene in a Sonogashira cross-coupling reaction gives an unprecedentedly long and conjugated dinuclear complex [{[Ru(bpy)(tpy)]$_2$(μ-dcpeb)}(BPh$_4$)$_2$]·4(PhCH$_3$) (dcpeb = dicyanamidophenylethynylbenzene dianion). The crystal structure data are as follows: crystal system monoclinic, space group $P2_1/c$, with a = 12.6960(3), b = 34.0960(10), c = 15.3540(4) Å, β = 110.7381(15)°, V = 6215.8(3) Å^3, and Z = 2. The structure was refined to a final R factor of 0.063. The metal ions are separated by a through-space distance of 24.9 Å.

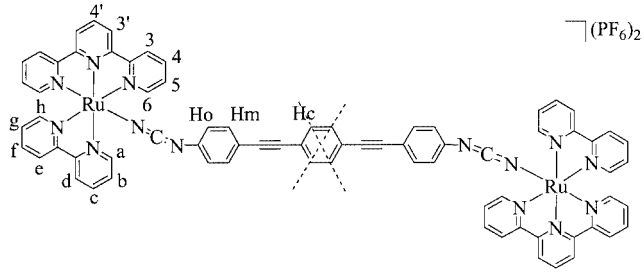
Introduction

This work concerns the general theme of long distance electronic communication, a topic that is very important in biology[1] and also in molecular electronics.[2] One of our major preoccupations is to find a way to measure the electronic communication between redox sites through a molecular bridge (molecular wire), when the distance between these sites is long enough (>25 Å). Several methods may be followed. One such method was proposed by Crutchley, who found that NCN groups can be very efficient in ensuring a good communication between ruthenium atoms,[3] either in the mixed-valence state, by measuring the electronic coupling parameter (V_{ab}) using optical absorption techniques,[4] or in the homovalent state, by the magnetic exchange parameter (J) using magnetic susceptibility or EPR spectroscopy.[5] Following this line, we recently synthesized a mononuclear ruthenium compound which can be viewed as a starting unit.[6] In this work, we present the use of this unit to make the dinuclear ruthenium compound [{[Ru(bpy)(tpy)]$_2$(μ-dcpeb)}(BPh$_4$)$_2$]·4(PhCH$_3$) (dcpeb = dicyanamidobiphenylethynylbenzene; Scheme 1).

Very few examples of dinuclear ruthenium complexes with long conjugated bridges are known in the literature, and even rarer are those whose X-ray structures have been solved.[5,7−9] We present here the X-ray structure of the first such dinuclear ruthenium complex with a long conjugated bridge, the through-space internuclear distance reaching 24.9 Å.



Scheme 1

Results and Discussion

The dinuclear compound was obtained by a Sonogashira cross-coupling reaction[10] adapted to the iodoruthenium complex. The use of the iodo complex was justified by its high reactivity in this kind of coupling (yield: 89%).[11]

The complex crystallises in the $P2_1/c$ space group (for crystallographic data see Table 1). The asymmetric unit consists of half a molecule of **2**, the central phenyl group lying on the inversion center. The tetraphenylborate anions are found near the angle of the bent phenylcyanamido unit, and toluene molecules fill the remaining voids of the structure.

The general shape of the molecule is a dumb-bell (see Figure 1). Interestingly, there are few reports of crystal structures containing such molecular shapes. Thus Crutchley has described the crystal structures of dinuclear complexes with dicyanamidobenzene as a bridging ligand and either [Ru(NH$_3$)$_5$]$^{3+}$,[5] *trans*-[Ru(NH$_3$)$_4$(py)]$^{3+}$ [12] or *mer*-[Ru(NH$_3$)$_3$(bpy)]$^{3+}$ [13] as terminal units (metal−metal distances 13.1, 10.9, and 13.1 Å, respectively). More recently, he has also reported the structure of [Ru(bpy)(tpy)-μ(adcp)-

Ru(bpy)(tpy)]·$(PF_6)_2$·DMF, where adpc is the 4,4′azodi-(phenylcyanamido) dianion (metal−metal distance 19.5 Å).[9] The present molecule is longer still, with a Ru−Ru distance of 24.9 Å.

The scarcity of crystal structures with dumb-bell molecules is probably due to the fact that it is impossible to densely pack molecules made up of bulky ends connected by a thinner spacer.[14] This is why our strategy was to attempt crystallisation in the presence of a large counterion (tetraphenylborate) and also of a large solvent (toluene). Our expectation was that the large counterion and solvent molecules could fill the voids and thus stabilise the crystal structure, as already observed by Jetti et al. in the case of the dimer of 4-(triphenylmethyl)benzoic acid in the presence of either xylene or chlorobenzene.[14]

The ruthenium moiety [Ru(bpy)(tpy)(cyanamido)] is at first sight similar to the mononuclear compound described elsewhere,[6] with the NCN group in the plane of the phenylene group to which it is linked (see Figure 2). This geometry ensures a good conjugation of their π systems. The bipyridine and terpyridine planes are perpendicular, with the bipyridine plane bisecting the terpyridine. The phenylcyanamido moiety makes a dihedral angle of 79° with the bipyridine plane (see Figure 2), while this value is 28° for the mononuclear compound[6] and 58° for [Ru(bpy)(tpy)-μ(adcp)-Ru(bpy)(tpy)]$^{2+}$.[9] Since the phenylcyanamido ligand and bipyridine are not coplanar, the Ru(bpy)(tpy)-(phenylcyanamido) group is *chiral*; the two enantiomers are present in the same molecule. In solution, on the other hand, it is likely that all possible isomers are present, although because of the length of the molecule, each of the extremities of a single molecule behaves as if it were isolated with regards to the NMR spectrum.

The Ru−N(6)−C(26) moiety is slightly bent (161.5°), suggesting that the π interaction is weaker than in Ru^{III}-cyanamide complexes, for which it is almost linear.[15] The Ru−N(6) bond is shorter (2.024 Å) than in the mononuclear compound (ca. 2.08 Å), and comparable to the one observed in the complex with adpc (2.046 Å). Concerning the cyanamido group itself, one notices a short distance between the terminal nitrogen and the central carbon [N(6)−C(26) = 1.136(7) Å], showing the preponderance of the cyanamide form [$^-$N−C≡N] over the carbodiimide [-N=C=N] form.

The cyanamido groups of the $(dcpeb)^{2-}$ ligand adopt a *trans* disposition, as generally observed in dinuclear bis-cyanamido complexes,[5] and free ligands $(dicyd)(AsPh_4)_2$ [16] and $(dcpib)(AsPh_4)_2$,[17] where dcpib = 4,4′-dicyanamidobiphenyl. The only exception is $[\{Ru(NH_3)_4(py)\}_2\mu\text{-}(dicyd)]^{4+}$ where the cyanamide groups are *cis*.[12] The C(33)−C(34)

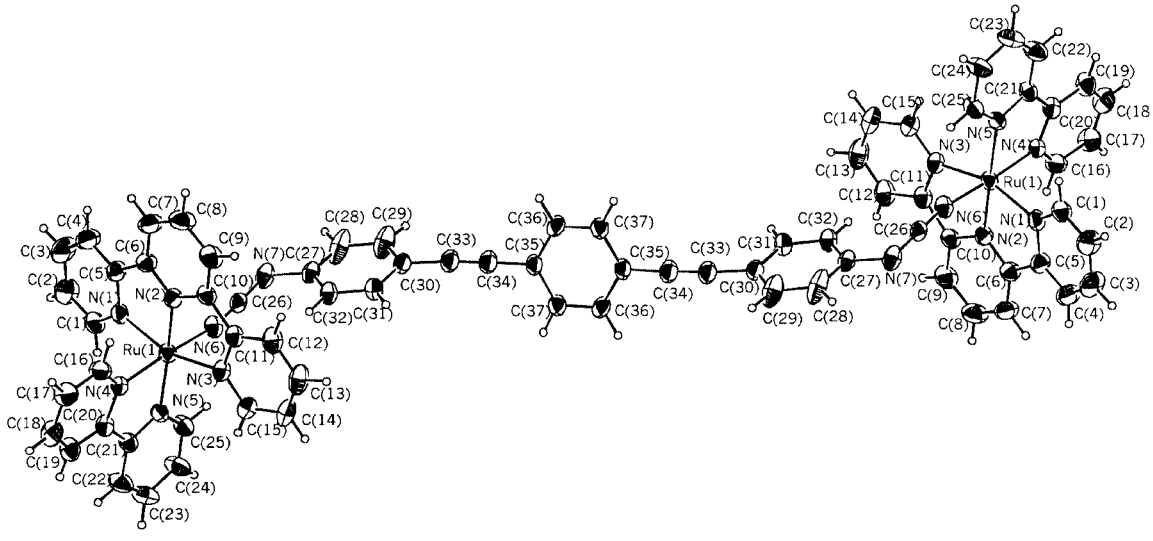

Figure 1. ORTEP drawing of the molecule of **2**

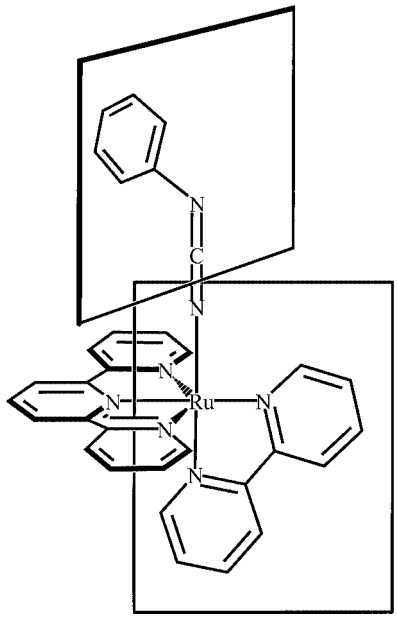

Figure 2. Coordination around ruthenium; definition of the dihedral angle between the bipyridine plane and the phenylcyanamido plane

triple bond length is 1.1863 Å, a value similar to the case of [Ru(bpy)(tpy)(pa)]$(PF_6)_2$·acetone (1.175 Å) and [Ru(bpy)(tpy)(ppa)]$(PF_6)_2$·acetone (1.187 Å) (pa = pyridylacetylene, and ppa = phenylpyridylacetylene).[18]

Of the three phenylene groups, the outer two are coplanar because of the inversion center. The dihedral angle with the central phenylene group is 65°. This value is probably not determined by intramolecular interactions, because it is known that torsion barriers around a phenylethynyl link are very small, ca. 1 kcal.[19] It is more likely determined by packing interactions. Thus, a detailed inspection of the structure shows many H···H Van der Waals contacts between the bulky Ru(bpy)(tpy) groups and tetraphenylborate and toluene molecules (H···H distances 2.60 to 2.80 Å, with an exceptionally short contact at 2.28 Å between a tpy H and a tetraphenylborate H). Consequently, the outer parts are locked in fixed positions. If free to rotate, the central phenylene group should prefer a coplanar disposition,[19] but this is prevented by a weak contact with a tetraphenylborate (H···H 2.51 Å and 2.70 Å) on one side, and with a toluene molecule on the other side.

Owing to the low torsional barrier, it is very likely that in solution there is a distribution of dihedral angles bearing on two independent torsions: between one terminal phenylene and the central one, and between the central one and the other terminal phenylene.

As far as physicochemical studies are concerned, UV/Vis spectroscopic studies of compound **1** in DMF shows two types of bands, one attributed to a $\pi\rightarrow\pi^*$ transition at 293 (94600) and 315 nm (86400 M^{-1} cm^{-1}) and the other attributed to metal-to-ligand charge-transfer bands at 397 (69800) and 493 nm (16800 M^{-1} cm^{-1}) as in similar compounds.[20,21] The cyclic voltammogram of **1** in dimethylformamide shows a quasi-reversible one-electron wave at 0.752 V vs. SCE which becomes irreversible in acetonitrile and dichloromethane. Attempts to prepare oxidized species did not lead to the appearance of any intervalence transition

Experimental Section

Physical Measurements. Electrospray (positive mode) mass spectra were obtained with a Perkin−Elmer Sciex (Nermag R10-R10) spectrometer. IR spectra were recorded as KBr pellets on a Perkin−Elmer FT-IR 1725 spectrometer. UV/Vis electronic spectra were obtained with a Shimadzu UV-3100 spectrometer. ^{1}H NMR spectra were recorded on a Bruker WF-250 spectrometer in CD_3CN solution. The solvent signal was used as internal reference at [δ_H = 1.96 ppm (CD_3CN)]. Cyclic voltammograms were obtained with an Autolab system (PGSTAT 100) (0.1 M tetrabutylammonium hexafluorophosphate, TBAH as supporting electrode) at 25 °C. A three-electrode cell was used comprising a 1 mm Pt-disk working electrode, a Pt-wire auxiliary electrode, and an aqueous saturated calomel (SCE) reference electrode.

{[Ru(bpy)(tpy)]$_2$(μ-dcpeb)}$(PF_6)_2$ (1): [Ru(bpy)(tpy)(Ipcyd)](PF_6)[6] (250 mg, 0.28 mmol) was placed in a small Schlenk tube together with [$PdCl_2(PPh_3)_2$] (4 mg, 0.007 mmol) and CuI (3 mg, 0.014 mmol). The powders were dissolved in a piperidine/DMF (1:1) mixture (3 mL) and carefully degassed under vacuum/argon several times. After stirring for 15 minutes, diethynylbenzene (18 mg, 0.14 mmol) was added to the solution. The reaction was continued all night at room temperature under argon. The solvents were then removed under vacuum and the product purified on an acidic alumina column (toluene/acetonitrile 60:40). The starting material was eliminated as a pink band, and a brown fraction of the dinuclear compound was then obtained. Recrystallisation was achieved by addition of toluene to an acetonitrile solution of **1**, which crystallised as long black needles (206 mg, 89%). IR (KBr disc): $\tilde{\nu}$ = 2160 cm^{-1} (N=C=N). ^{1}H NMR (250 MHz, CD_3CN, 20 °C, TMS): δ = 9.76 (d, *J* = 5.7 Hz, 2 H, H-a), 8.62 (d, *J* = 8.1 Hz, 2 H, H-d), 8.53 (d, *J* = 8.1 Hz, 4 H, H-3′), 8.42 (d, *J* = 8.1 Hz, 4 H, H-3), 8.32 (d, *J* = 7.9 Hz, 2 H, H-e), 8.28 (td, *J* = 8.1, 7.7 Hz, 2 H, H-c), 8.17 (t, *J* = 7.7, 8.5 Hz, 2 H, H-4′), 7.95 (t, *J* = 7.7, 8.1 Hz, 4 H, H-4), 7.95(m, 2 H, H-b), 7.73 (m, 6 H, H_{6+f}), 7.39 (s, 4 H), 7.37 (dq, *J* = 6.5 Hz, 2 H, H-h), 7.32 (dd, *J* = 5.5, 7.7 Hz, 4 H, H-5), 7.21 (d, *J* = 7.3 Hz, 2 H, H-g), 7.02 (d, *J* = 8.7 Hz, 4 H, H-m,m′), 6.07 (d, *J* = 8.7 Hz, 4 H, H-o,o′). (see Scheme 1 for atom numbering). MS (ES) for $C_{74}H_{50}F_6N_{14}PRu_2$ [M − PF_6]$^+$: *m*/*z*: calcd. 1483.2; found 1483.3; for [M − $2PF_6$]$^{2+}$/2: calcd. 669.3; found 669.1; for [M − $2PF_6$ − [Ru(bpy)(tpy)] + H^+]$^+$: calcd. 848.2; found 848.2. $C_{74}H_{50}F_{12}N_{14}P_2Ru_2(Al_2O_3)$ (1730.1): calcd. C 51.3, H 2.9, N 11.3; found C 51.4, H 2.8, N 11.0.

{[Ru(bpy)(tpy)]$_2$(μ-dcpeb)}$(BPh_4)_2$.4(Ph-CH_3) (2): Compound **1** was dissolved in acetonitrile. Subsequent addition of tetrabutylammonium bromide (in excess) precipitated the bromide salt of the complex, which was filtered and rinsed with ether. Dissolution of the bromide salt in methanol/water (1:1 mixture), followed by addition of sodium tetraphenylborate (excess) precipitated [{Ru(bpy)(tpy)]$_2$(μ-dcpeb)}]$(BPh_4)_2$. Slow diffusion of toluene into an acetonitrile solution of [{Ru(bpy)(tpy)]$_2$(μ-dcpeb)}]$(BPh_4)_2$ led to the desired complex **2**.

X-ray Crystallographic Study: Recrystallisation was performed by slow diffusion of toluene into an acetonitrile solution of the tetraphenylborate salt of the complex. Brown needles were obtained. A

single crystal was chosen to perform the X-ray diffraction measurements. Reflection data for the crystal were measured using a Nonius Kappa CCD diffractometer at room temperature, using graphite monochromated Mo-K_α radiation ($\lambda = 0.71074$ Å) at a detector distance of 4 cm and a swing angle of 20° (this type of crystal, being unfortunately very small, and showing poor quality of crystallinity, did not give observable spots at wider angles). To increase the quality of the collected data, we tried to perform measurements at low temperature, but the crystal broke due to the very poor mosaicity found at room temperature. The crystallographic cell was found by using HKL Scalepack.[22] The structure was solved using SIR92[23] and refined in the Maxus software package.[24]

The asymmetric unit contains a tetraphenylborate counteranion, and two toluene solvent molecules. The refinement was performed anisotropically for all the non-hydrogen atoms of the complex. The hydrogen atoms were localized by difference Fourier synthesis, recalculated and fixed at 0.96 Å, then their contributions were introduced in the calculations but not refined. For the toluene atoms, due to their high thermal vibration, they were refined in isotropic positions; nevertheless it was difficult to position them, so for the last refinement, they were left fixed at their last atomic positions in order not to disturb the overall geometry of the complex. 6468 reflections [$I > 3\sigma(I)$] were used for the 631 parameters and the R value dropped to 0.0634.

CCDC-179708 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Novel Ru^{III}-DMSO Complexes of the Antiherpes Drug Acyclovir

Iztok Turel,*[a] Milena Pečanac,[a] Amalija Golobič,[a] Enzo Alessio,[b] and Barbara Serli[b]

Keywords: Bioinorganic chemistry / Nucleoside analogues / Ruthenium / X-ray diffraction / Hydrogen bonds

Treatment of the anionic Ru^{III} precursor X[*trans*-$RuCl_4$(DMSO-*S*)$_2$] (X = protonated DMSO, Na^+, NH_4^+) and acyclovir (acv) in various solvents yields two new products *mer*-[$RuCl_3$(acv)(DMSO-*S*)(CH_3OH)]·0.5CH_3OH (**1**) and *mer*-[$RuCl_3$(acv)(DMSO-*S*)(H_2O)]·H_2O (**2**) in which hydrogen bonds between the acv purine oxygen and coordinated methanol or water, respectively, play an important role.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

The antitumor properties of simple ruthenium(III) coordination compounds were discovered over 30 years ago,[1] and since then several tumor-inhibiting ruthenium complexes have been isolated and characterized,[2] with DMSO-ruthenium-N donor ligand ternary complexes being amongst the most promising. The typical example of the group, NAMI-A, [ImH] [*trans*-$RuCl_4$(DMSO-*S*)Im] (Im = imidazole), has already entered clinical phase I trials.[3] The main advantages of ruthenium-DMSO complexes are the selectivity for solid tumor metastases and the lack of significant host toxicity.

Acyclovir [9-(2-hydroxyethoxymethyl)guanine, acv] is a well-known antiviral drug used in clinical practice. The crystal structures of acv complexes with Cu,[4] Pt,[5] Ni, Co, Cd and Zn,[6] have appeared in the literature. It was found that the coordination of acv to the metal occurs in most cases through N(7) only, whereas O(6) is not directly involved in the bonding. The sole exception is [$Cu(acv)_2(H_2O)_2$](NO_3)$_2$, in which a pseudo-chelate N(7)/O(6) bonding of a purine to the metal was found.[4c]

Recently, the interactions of two Ru^{II}-DMSO precursors, *cis*- and *trans*-[$RuCl_2$(DMSO)$_4$], with acv were studied by NMR spectroscopy in aqueous solution. The authors proposed the formation of mono and bis adducts with N(7) as the preferred binding site.[7]

Our basic idea was to prepare an NAMI-A type compound of acv with the formula [*trans*-$RuCl_4$(acv)(DMSO-*S*)]$^-$. The main chemical feature of the Ru^{III} anionic precursor of NAMI-A type complexes, X[*trans*-$RuCl_4$(DMSO-*S*)$_2$] (X = protonated DMSO, Na^+, NH_4^+), is the facile dissociation of one of the two *trans* S-bonded DMSOs, attributed to the relatively large *trans* effect of this ligand.[8] The coordination position set free by DMSO is easily replaced by a nitrogen donor ligand (L) and through this synthetic procedure a wide class of derivatives with the general formula X[*trans*-$RuCl_4$(DMSO-*S*)L] (NAMI-A type complexes) have been prepared from acetone or DMSO/acetone mixtures. In these reactions it has never been observed that chloride ions were substituted; nevertheless, stepwise chloride hydrolysis occurs after dissolution of these products at physiological pH and it is thus relevant for their in vivo mechanism of action.

The generally poor solubility of acv limits the choice of solvents in which the reaction with the Ru^{III} precursor could be performed. Surprisingly, we realized that, regardless of the solvent used, coordination of acv trans to DMSO-S was always accompanied by replacement of one chloride with a molecule of a hydrogen bond donor, either H_2O (adventitious or solvent) or methanol (solvent), to give neutral species. In this paper we report the synthesis and solid-state structures of two Ru^{III}-DMSO complexes of acv:

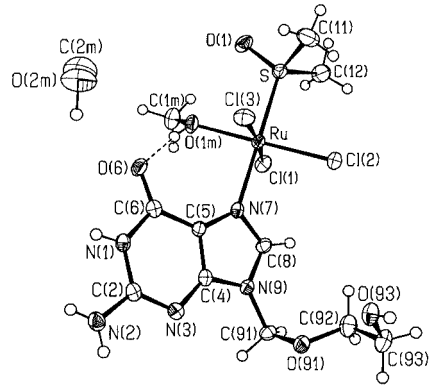

Figure 1. View of the asymmetric unit of **1**; selected bond lengths (Å): Ru−Cl(1) 2.309(2), Ru−Cl(2) 2.326(2), Ru−Cl(3) 2.362(2), Ru−S 2.270(2), Ru−O(1m) 2.072(6), Ru−N(7) 2.127(5), O(6)−C(6) 1.245(8)

mer-[$RuCl_3$(acv)(DMSO-*S*)(CH_3OH)]·0.5CH_3OH (**1**) and *mer*-[$RuCl_3$(acv)(DMSO-*S*)(H_2O)]·H_2O (**2**), which provide a new insight into the reactivity of the [*trans*-$RuCl_4(DMSO)_2]^-$ precursor and, in particular, show the important role of H bonds in these reactions.

Treatment of X[*trans*-$RuCl_4$(DMSO-*S*)$_2$] with acv in methanol yielded brown-red crystals of **1**; when the same reaction was performed in water or various nondried solvents (such as ethanol, propanol, acetone/DMSO mixtures, nitromethane) crystals of **2** were isolated instead. The structures of compounds **1** and **2** were determined by X-ray diffraction analysis; the asymmetric unit and selected bond lengths for each compound are reported in Figure 1 and 2, respectively, and the crystallographic data in Table 1.

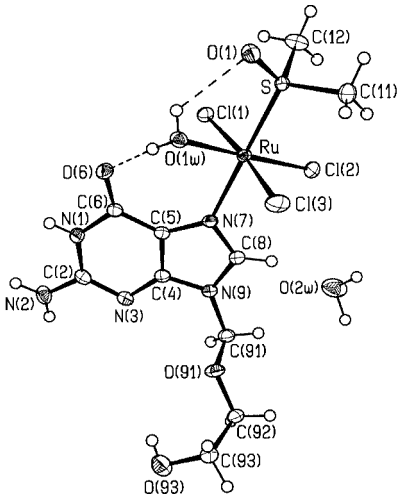

Figure 2. View of the asymmetric unit of **2**; selected bond lengths (Å): Ru−Cl(1) 2.3686(4), Ru−Cl(2) 2.3187(5), Ru−Cl(3) 2.3210(6), Ru−S 2.2677(5), Ru−O(1w) 2.077(1), Ru−N(7) 2.132(2), O(6)−C(6) 1.247(3)

In both complexes **1** and **2** the geometry about the Ru^{III} ion is distorted octahedral, as expected, with three chloride ions in a *mer*-configuration and DMSO (coordinated through S) *trans* to acv. An oxygen atom from methanol (in **1**) or water (in **2**) is additionally coordinated to ruthenium. The ruthenium-oxygen distances in both compounds are similar and are also similar to those found in the literature.[9] In both complexes one Ru−Cl bond is significantly longer than the remaining two since only that chloride ion is an acceptor of an intermolecular hydrogen bond. In **1**, Cl(3) is hydrogen bonded to an amino group of the symmetry related complex [contact distance N(2)···Cl(3) 3.298(6) Å], whereas in **2**, Cl(1) is hydrogen bonded to a noncoordinated water molecule [contact distance O(2w)···Cl(1) 3.291(2) Å] and to an amino group of the symmetry related complex [contact distance N(2)···Cl(1) 3.445(2) Å]. The shortening of the Ru−S bond in these complexes relative to the precursor (above 2.34 Å) has already been interpreted as being due to an increased π-back-bonding contribution from Ru^{III}.[8,10] All other bond lengths and angles in both compounds are also in an agreement with the corresponding data cited in the literature.[11]

Whereas the replacement of one DMSO-S molecule in the precursor with the N-donor ligand acv is to be expected, further replacement of one of the four chloride ions by the oxygen-bearing ligand is rare. We have tried to prevent the dissociation of the chloride ion from ruthenium by increasing the concentration of chloride in solution [by addition of $(CH_3)_4NCl$ or NaCl]. However one of the four chloride ions attached to ruthenium in the precursor was again substituted by water and the final product of this reaction was **2**. To date, syntheses performed in anhydrous solvents under inert atmosphere did not result in the isolation of the NAMI-A type acv analogue, which is another proof that such a reaction is not favourable in the case of acv.

Inspection of the crystal structures of both compounds suggests that the replacement of chloride with methanol (in **1**) or water (in **2**) is induced by the formation of intramolecular hydrogen bonds (marked with dashed lines in Figure 1 and 2). The oxygen atom O(6) from acv is hydrogen bonded to either coordinated methanol (**1**) or water (**2**). Both hydrogen bonds are strong: contact distance O(1m)···O(6) 2.517(7) Å in **1** and O(1w)···O(6) 2.573(2) Å in **2**. In **2**, the second hydrogen atom of water is additionally involved in hydrogen bonding to the oxygen atom of DMSO [contact distance O(1w)···O(1) 2.918(2) Å]. (In both structures there are additional intermolecular hydrogen bonds which are described in the CIF supplementary material deposited with the CCDC).

The neutral species **1** and **2**, which still maintain some solubility in aqueous solution, are thus good models for the first intermediate species that is expected to form upon stepwise chloride hydrolysis from NAMI-A type complexes in physiological solution. We are aware of only two examples where a similar chloride replacement was reported. The complex *mer*-[$RuCl_3(H_2O)$(DMSO-*S*)(dmtp)]·H_2O[12] was prepared by the dissolution of dmtpH[*trans*-$RuCl_4$(dmtp)(DMSO-*S*)] (dmtp = 5,7-dimethyl[1,2,4]triazolo[1,5-*a*] pyrimidine) in water, and strong hydrogen bonds between coordinated dmtp and coordinated water were also found in this case. Just recently it was reported that treatment of [$(dmso)_2H$][*trans*-$RuCl_4$(DMSO-*S*)$_2$] with 9-ethylguanine (9EtG) in methanol yielded *mer*-[$RuCl_3$(9EtG)(H_2O)(DMSO-*S*)] (**3**), in which the coordination sphere of ruthenium is very similar to that of **2**; the X-ray structure showed that the coordinated water molecule is involved in strong intramolecular hydrogen bonding with the oxygen atoms of guanine and DMSO-S.[13] The chemical difference between **3** and **2** is in the group bonded to N(9); instead of the ethyl group of **3** there is a 2-hydroxyethoxymethyl in **2** which, besides being bulkier, also acts as a donor and acceptor of intermolecular H bonds. Additionally, the crystals of **2** also contain noncoordinated water molecules and the consequence of this is that the packing of **3** and that of **2** are substantially different. In the structure of **3** there are N(1)−H···Cl(3) and N(2)−H···O(2) intermolecular H bonds, while in the structure of **2** intermolecular H bonds N(1)−H···O(1), N(2)−H···O(93), N(2)−H···Cl(1), O(93)−H···O(2w), O(2w)−H···N(3) and O(2w)−H···Cl(1) are present. Furthermore, in **3** the stacking of guanine residues was not observed. In contrast, in the structures of **1** and **2** we have observed pairs of symmetry-related acv residues for which the planes through their aromatic rings are nearly parallel. The distances between such planes are 3.25 Å in **1** and 3.50 Å in **2**, so the interactions between π electronic systems are possible.

The IR spectra of compounds **1** and **2** are very similar. In free acv the carbonyl stretching band is found at 1715 cm^{-1} whereas the bending frequency of the amino group falls at 1631 cm^{-1}.[4] Four bands are found in the spectra of both complexes in the range 1657−1630 cm^{-1}. According to the crystal structures, we assume that these absorptions can be ascribed to the stretching of the hydrogen bonded carbonyl group and to the bending of the hydrogen bonded amino group. A similar trend was previously observed in other N(7) metal-bonded complexes of acv.[4a,6]

The UV/Vis spectra of **1** and **2** were assigned according to the data of similar complexes reported in the literature.[8,12,14] The highest energy band found at 278 nm in both complexes was attributed to π-π* transitions of the ligand,[14] whereas the remaining absorptions are typical charge-transfer bands from three chlorides in a *mer*-geometry on Ru^{III}.[15]

Experiments to assess the possible cytotoxic and antiviral activity of compounds **1** and **2** are currently being planned in collaboration with other groups.

Experimental Section

***mer*-[$RuCl_3$(acv)(DMSO-*S*)(CH_3OH)]·$0.5CH_3OH$ (1):** X[*trans*-$RuCl_4$(DMSO-*S*)$_2$] (0.235 mmol) was dissolved in absolute methanol (30.0 mL) and acv (0.235 mmol) was added whilst stirring. The solution was heated at 50 °C until all acv had dissolved. The colour of the solution changed from orange to brown-yellow. Brown-red crystals appeared in the solution after one day of isothermal evaporation of the solvent in air (0.0723 g, 55.2% yield). The crystals were filtered off, washed with diethyl ether and dried in air. $C_{11.5}H_{23}Cl_3N_5O_{5.5}RuS$ (558.8): calcd. C 24.71, H 4.15, N 12.53; found C 24.61, H 4.08, N 12.59. Selected IR bands (Nujol): $\tilde{\nu}$ = 1657 cm^{-1} (s, sh), 1650 (s, sh), 1640 (vs), 1634 (vs), 1608 (s); 1082 (m, S=O for DMSO-*S*); 423 (w, Ru−*S*). UV (methanol): λ_{max} (ε) = 278 nm (6889 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$), 374 (3256), 438 (1124).

***mer*-[$RuCl_3$(acv)(DMSO-*S*)(H_2O)]·H_2O (2):** This complex was prepared from several solvents following similar reaction procedures. Initially it was prepared from aqueous solution: X[*trans*-$RuCl_4$(DMSO-*S*)$_2$] (0.235 mmol) was dissolved in distilled water (30.0 mL) and acv (0.235 mmol) was added. The mixture was stirred for two hours until all the acv had dissolved. The colour of the solution changed from orange to dark green. After three days the precipitation of free acv and of a very small amount of brown-red crystals of the product occurred from the solution. These crystals were filtered off, washed with diethyl ether and dried in air. It was later found that the yield was much higher if ethanol was used as solvent (the same procedure as for compound **1**, yield 43.5%). It was also realized that this product can be isolated from many other nondried solvents such as propanol, acetone/DMSO mixtures, nitromethane. $C_{10}H_{21}Cl_3N_5O_6RuS$ (546.8): calcd. C 21.97, H 3.87, N 12.80; found C 22.27, H 3.60, N 12.63. Selected IR bands

(Nujol): $\tilde{\nu}$ = 1657 cm^{-1} (s, sh), 1650 (s, sh), 1640 (vs), 1633 (vs), 1602 (s); 1081 (m, S=O for DMSO-*S*); 426 (w, Ru−S). UV (methanol): λ_{max} (ε) = 278 nm (7182 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$), 376 (3346), 438 (1138).

X-ray Crystallographic Study: X-ray diffraction data for compounds **1** and **2** were collected on a Nonius Kappa CCD diffractometer using graphite monochromated Mo-K_α radiation. Data were processed using DENZO-SMN program.[16] Both structures were solved by direct methods using SIR-97.[17] The positions of the hydrogen atoms were obtained from the difference Fourier map. Atom C(2m) from the noncoordinated methanol molecule in **1** lies on a twofold axis. The positions of three hydrogen atoms bonded to C(2m) were not determined. For both compounds we employed full-matrix least-squares refinement on *F* with anisotropic displacement factors for all non-hydrogen atoms using the Xtal3.4 program.[18] All observed and those "less than" reflections for which F_c was greater than F_0 were included in the final refinement. The hydrogen atom parameters of **1** were not refined. In the case of **2** only the coordinates of hydrogen atoms were refined while their displacement parameters were not. The resulting crystal data and details concerning data collection and refinement for both compounds are quoted in Table 1. ORTEP[19] was used for the preparation of the figures.

CCDC-178936 and CCDC-178937 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was performed within the framework of European COST Action D20, working groups D20/0001 and D20/ 0006. Coordinatively and Electronically Unsaturated Pentamethylcyclopentadienyliridium(III) Complexes with the Dianions of Biuret, of the Diamide of Malonic Acid and of an *N*-Acetyldipeptide Ester[‡]

Walter Ponikwar,[a] Peter Mayer,[a] and Wolfgang Beck*[a]

Dedicated to Professor Karl Wieghardt on the occasion of his 60th birthday

Keywords: Cyclopentadienyl ligands / Iridium / Biuret / Electron-deficient compounds

The dianions of biuret, of the diamide of malonic acid and of *N*-acetyl-L-alanyl-L-alanine methyl ester give the coordinatively unsaturated 16-electron *N*,*N*′-chelate complexes [Cp*Ir[NHC(O)NHC(O)NH)] (**1**), [Cp*Ir[NHC(O)CH_2C(O)NH)] (**2**) and {Cp*Ir[N($COCH_3$)CH(CH_3)C(O)NCH(CH_3)CO_2Me]} (**3**) upon reaction with $[Cp^*IrCl_2]_2$. From $[(R_3P)PdCl_2]_2$ (R = Et, Ph) and biuret the complexes $[(Cl)(R_3P)Pd(\eta^2\text{-biureto})Pd]^-Na^+$ were obtained. The X-ray structure determinations of **1** and **3** reveal that the almost planar chelate rings lie perpendicular to the Cp* ring.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The long and interesting history of biuret was reviewed by Kurzer in 1956.[2] The copper(II) complex of biuret was one of the first complexes of all,[3] and the biuret reaction, the formation of a red-violet copper compound with peptides was discovered even earlier in 1833.[4] Schiff[5] found later that the diamides of malonic acid and of oxalic acid form similar copper(II) complexes as with biuret, and the pioneers in coordination chemistry Tschugaeff[6] and Pfeiffer[7] proposed correct formulas for the biuret copper(II) chelate and analogous complexes, the structures of which were later confirmed by the X-ray diffraction studies of Freeman et al.[8]

Other chelate complexes with the dianion of biuret, including Cu^{III} and Ni^{III} complexes, have also been reported.[9] We thought it would be interesting to introduce the classical ligand biuret into organometallic chemistry. As shown below, the coordinatively unsaturated sixteen electron complexes Cp*Ir(L-L) **1**−**3** resulted from the reactions of the chloro-bridged complex $[Cp^*IrCl_2]_2$ with the dianions of biuret, its C analogue malodiamide and of an acetyldipeptide ester. Closely related to these new compounds are Grotjahn's Cp* complexes with the dianions of *N*-acyl and *N*-sulfonyl α-amino acids.[10] Other coordinatively unsaturated complexes are, for example, $[CpM(NO)R_2]$ and $[CpM(NO)L]$ (M = Mo, W),[11] $[CpMo(PR_3)_2Cl]$,[12] $[(arene)Ru(SR)_2]$,[13] [CpCo(1,2-ethylenedithiolato)],[14,15] $[Cp^*Ru(PR_3)OR]$,[16] $[Cp^*Ru(R_2NCH_2CH_2NR_2)]^+$,[17] $[M(CO)_3(O,S\text{-}C_6H_4)]^{2-}$ and $[(OC)_3MS_2C_6R_4]^{2-}$ (M = Cr, Mo, W).[18] Noyori's coordinatively unsaturated half-sandwich complex [(arene)RuNHCH(Ph)CH(Ph)-$NSO_2C_6H_4$Me] is an efficient catalyst for asymmetric hydrogen transfer to ketones.[19] The 16-electron complexes $[Cp^*M(L\text{-}L')]^+$ (M = Ru, Fe) with P,P- or P,O-donors have been studied by several groups as catalysts.[20] The geometry of coordinatively unsaturated two-legged piano-stool complexes with 16 valence electrons has been analysed theoretically.[21]

Results and Discussion

Reaction of the chloro-bridged iridium complex $[Cp^*IrCl_2]_2$ with biuret, malodiamide or *N*-acetyl-L-alanyl-L-alanine methyl ester in the presence of NaOMe gives the chelate complexes **1**−**3**.

The wine-red colour of these complexes is characteristic of 16-electron iridium complexes.[10] Addition of triphenylphosphane to **1** and **3** in methanol affords yellow solutions which show only one ^{31}P NMR signal (**1**: δ = 8.62 ppm; **3**: δ = 8.05 ppm) in the ^{31}P NMR spectra due to the corresponding 18-electron species.[10] The colour change from wine red to yellow can be explained by the π-donor function of the chelate ligands in the 16-electron complexes.[10,18]

[‡] Metal Complexes of Biologically Important Ligands, CXLV. Part CXLIV: Ref.[1]

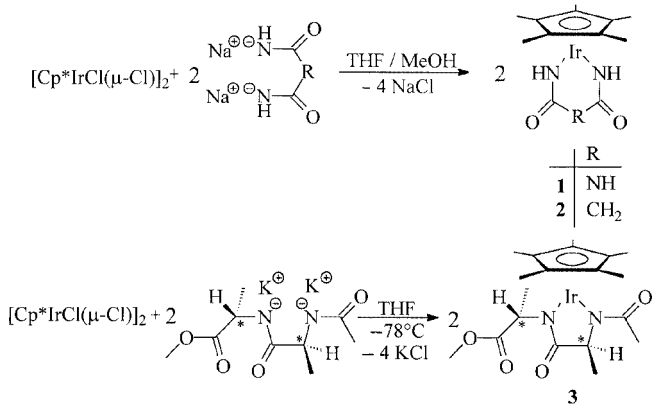
Butenandtstr. 5−13, 81377 München, Germany
E-mail: wbe@cup.uni-muenchen.de



The IR, ^1H and ^{13}C NMR spectra of **1**–**3** exhibit the expected data (see Exp. Sect.). In the ^1H and ^{13}C NMR spectra of **3** only one set of signals is detected which shows that diastereoisomers of **3** were not formed. Complex **2** could not be obtained analytically pure. In the mass spectra of the product from malodiamide the ions of dimers $\{Cp_2^*\text{-}Ir_2Cl_2[NHC(O)CH_2C(O)NH)]\}^+$ (*m/z* = 826; 6%), $\{Cp_2^*\text{-}Ir_2Cl[NHC(O)CH_2C(O)NH]\}^+$ (*m/z* = 789; 4%) and $\{Cp_2^*\text{-}Ir_2[NHC(O)CH_2C(O)NH]\}^{2+}$ (*m/z* = 378; 3%) were observed.

The X-ray structure analysis of **1** (Figure 1) and **3** (Figure 2) reveals the typical geometry of a two-legged pianostool half-sandwich complex, due to the coordinatively unsaturated nature of these compounds. Although water molecules were found in the unit cells of both compounds they definitely do not coordinate because of the large distance to the iridium atoms (**1**: ≥439.8 pm, **3**: 600.7 pm). The planes formed by the Cp* ligands in **1** and **3** are almost perpendicular (**1**: 91.8°; **3**: 93.3°) to the planes formed by the two coordinating nitrogen atoms and the two carbon atoms connected to them. This has also been found in other 16-electron half sandwich complexes with chelate ligands.[10,14,19] Of great interest are the observed bond lengths for the Ir–N bonds. In compound **1** those bond lengths are 195.1(8) pm [Ir(1)–N(1)] and 197.8(6) pm [Ir(1)–N(3)]. In compound **3** these bond lengths were found to be 198.3(2) pm [Ir(1)–N(2)] and 201.3(6) pm [Ir(1)–N(1)]. A comparison with the Ir–N bond lengths (ca. 210 pm) in 18-electron complexes with monosubstituted deprotonated amide ligands,[22] for example in [Cp*(Cl)Ir(Leu-LeuOMe-H$^+$)][23] shows a significant shortening of the Ir–N bond in compounds **1** and **3**. This decrease in the Ir–N bond length is in good agreement with the decline observed by Grotjahn and Noyori in their 16-electron half-sandwich chelate complexes.[10,14] The most reasonable explanation for this bond shortening is that besides the usual σ-symmetrical interaction of a filled ligand orbital with an empty metal orbital (σ-donation), an additional π-symmetrical interaction of another filled orbital of the anionic heteroatom ligand with an empty metal orbital of suitable symmetry (π-donation) is present.[10,18] The contribution of lone-pair electrons at the anionic heteratom ligand to the π-donation explains the exceptional stability of these compounds; the dark red colour results from LMCT in those compounds. The C–N bond lengths in **1** are 2–3 pm longer than in "free" biuret.[24]

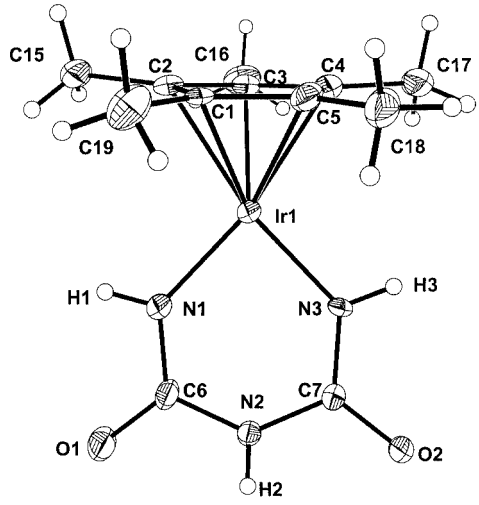


Figure 1. Molecular structure of **1** in the crystal

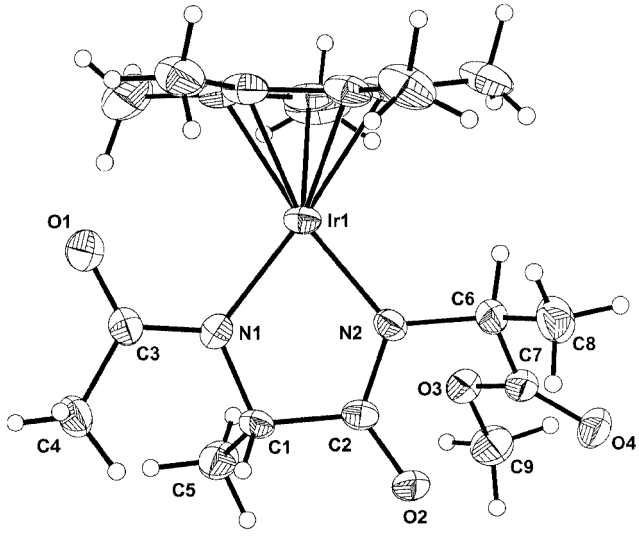

Figure 2. Molecular structure of **3** in the crystal

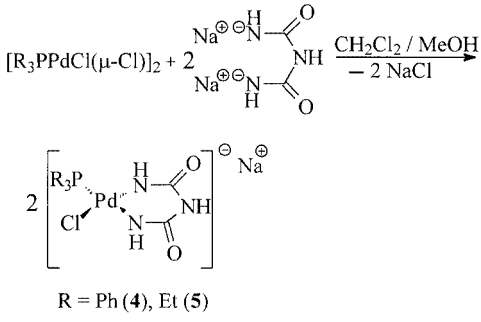
The chloro-bridged palladium(II) complexes $Pt_2(PR_3)_2Cl_4$ afforded the yellow anionic chelates **4** and **5** with the biuret dianion. They were characterised by their IR and NMR spectroscopic data (see Exp. Sect.). As for **1** and **2** the NH signals of CD_3OD solutions of **4** and **5** cannot be observed in the ^1H NMR spectra because of a rapid H/D exchange. The ^{31}P NMR spectra of **4** and **5** exhibit only one signal.



Experimental Section

The chloro-bridged complexes $[Cp^*IrCl_2]_2$ [25] and $[PdCl_2(PR_3)]_2$ [26] were obtained according to literature procedures. All reactions were carried out in Schlenk tubes under argon.

Cp*(η²-*N*,*N*-biureto)Ir^{III} (1): A solution of biuret (41.2 mg, 0.4 mmol) and 0.4 mmol of NaOMe in 10 mL of methanol was added dropwise to a suspension of $[Cp^*IrCl_2]_2$ (159.3 mg, 0.2 mmol) in 15 mL of methanol whilst stirring at room temperature. The solution turned dark red and was then stirred for 48 h. The solvent was then removed in vacuo. NaCl could not be separated from the product by chromatography. The dark red product was dried at 75 °C for 4 days. Yield 65 mg (77%). IR (KBr): $\tilde{\nu}$ = 3403 cm^{-1} s (NH sec. amide), 3294 s (NH prim. amide), 1650 vs (CO, amide I), 1635 m (NH-bending, amide II). ^{1}H NMR (270 MHz, CD_3OD): δ = 1.85 (s, 15 H, Cp*) ppm. ^{13}C NMR (67.9 MHz, CD_3OD): δ = 8.2 (s, Cp*), 88.7 (s, Cp*), 163.1 (s, CO) ppm. $C_{12}H_{18}IrN_3O_2$·2.25NaCl (559.98): calcd. C 25.74, H 3.24, N 7.50; found C 25.57, H 3.16, N 7.83.

Cp*(η²-*N*,*N*-malodiamine-2H$^+$)Ir^{III} (2): $[Cp^*IrCl_2]_2$ (159.3 mg, 0.2 mmol) in 15 mL of THF was added to a solution of malodiamide (40.8 mg, 0.4 mmol) and NaOMe (0.8 mmol) in 10 mL of methanol whilst stirring at room temperature. The solution became wine red. After stirring for 16 h at room temperature the solvent was removed in vacuo. Complex **2** was not analytically pure. Efforts to purify the compound by recrystallization from methanol led to decomposition. IR (KBr): $\tilde{\nu}$ = 3295 cm^{-1} s (NH), 2984 s (CH), 2944 s (CH), 2685 s, 2625 s, 2606 s ($HNEt_3^+$), 1676 vs (CO, amide I), 1620 m (NH-bending, amide II), 1586 w ($HNEt_3^+$), 1398 m (CH), 1384 m (CH). ^{1}H NMR (400.1 MHz, CD_3OD): δ = 1.61 (s, 15 H, Cp*), 3.35 (m, 2 H, CH_2) ppm. ^{13}C NMR (100.5 MHz, CD_3OD): δ = 5.8 (s, Cp*), 52.9 (s, CH_2), 85.2 (s, Cp*), 169.7 (s, CO, malodiamide) 178.3 (s, CO). FAB$^+$MS (*m*-NBA): *m*/*z* (%) = 429 (86) [M + H], 329 (52) [M − ligand].

Cp*(η²-*N*-acetyl-L-alanyl-L-alanine methyl ester-2H$^+$)Ir^{III} (3): [Cp*$IrCl_2]_2$ (159.3 mg, 0.2 mmol) in 15 mL of THF was stirred for 2 h at −78 °C (2-propanol/dry ice) and to this mixture was added a suspension of *N*-acetyl-L-Ala-L-Ala-OMe (86.5 mg, 0.4 mmol) and K_2CO_3 (165.8 mg, 1.2 mmol) in 15 mL of cold THF. The reaction mixture was allowed to warm to room temperature for 18 h and an almost clear wine-red suspension was formed. The solvent was then removed in vacuo and the residue treated with 15 mL of dichloromethane and stirred for 30 min. KCl and excess K_2CO_3 were centrifuged off and the solution concentrated to dryness to give a dark red microcrystalline product. Yield 88 mg (82%). IR (KBr): $\tilde{\nu}$ = 2924 cm^{-1} s (CH), 2851 s (−O-CH_3), 1738 vs (COOMe), 1630 s (CO amide I), 1375 s (−CO-CH_3). ^{1}H NMR (270 MHz, CD_2Cl_2): δ = 1.33 (d, $^3J_{H,H}$ = 10.27 Hz, 3 H, α-CH_3), 1.35 (d, $^3J_{H,H}$ = 9.99 Hz, 3 H, α-CH_3), 1.76 (s, 15 H, Cp*), 1.95 (s, 3 H, Ac-N), 3.70 (s, 3 H, Me-O), 4.50 (m, 2 H, α-H) ppm. ^{13}C NMR (67.9 MHz, CD_2Cl_2): δ = 9.9 (s, Cp*), 22.9 (s, β-C), 23.2 (s, β-C), 30.2 (s, $NCOCH_3$), 51.5 (s, $COOCH_3$), 61.4 (s, α-C), 62.6 (s, α-C), 88.9 (s, Cp*), 173.7 (s, $NCOCH_3$), 174.0 (s, $COOCH_3$), 190.5 [s, N-CO-$C(CH_3)$N] ppm. The analysed substance was recrystallised from methanol. $C_{19}H_{29}IrN_2O_4$·MeOH (573.69): calcd. C 41.87, H 5.80, N 4.88; found C 41.56, H 5.97, N 4.89.

[Cl(Ph$_3$P)(η²-biureto)Pd]$^-$Na$^+$ (4): A solution of biuret (41.2 mg, 0.4 mmol) and NaOMe (0.8 mmol) in 10 mL of methanol was added to $[(Ph_3P)PdCl_2]_2$ (176 mg, 0.2 mmol) in 10 mL of methanol whilst stirring at room temperature. After 1 h the solution turned yellow and was stirred for another 17 h at room temperature. The solvent was then removed in vacuo. The residue was treated with 15 mL of methanol, filtered over celite and the solvent was again removed in vacuo. The yellow product was washed with 10 mL of hexane , centrifuged and dried at 60 °C in vacuo for two days. IR (KBr): $\tilde{\nu}$ = 3373 cm^{-1} s (NH sec. amide), 3234 m (prim. amide), 1630 vs (CO amide I), 1601 m (NH-bending amide II). IR (PE): $\tilde{\nu}$ = 378 cm^{-1} m (Pd-Cl). ^{1}H NMR (270 MHz, CD_3OD): δ = 7.78 (m, 15 H, Ph_3P) ppm. ^{31}P NMR (109.4 MHz, CD_3OD): δ = 27.99 (s, PPh_3) ppm. $C_{20}H_{18}ClN_3NaO_2PPd$ (528.2): calcd. C 45.48, H 3.43, N 7.96; found C 45.88, H 3.66, N 8.05. FAB-MS (*m*-NBA): *m*/*z* (%) = 506 (75) [M]$^-$, 471 (24) [M − Cl], 405 (5) [M − biuret], 244 (18) [M − P(Ph)$_3$].

[(Cl)(Et$_3$P)(η²-*N*,*N*-biureto)Pd]$^-$Na$^+$ (5): A solution of biuret (20.8 mg, 0.2 mmol) and NaOMe (0.4 mmol) in 10 mL of methanol was added to a solution of $[(Et_3P)PdCl_2]_2$ (59.1 mg, 0.1 mmol) in 10 mL dichloromethane whilst stirring at room temperature. The dark red mixture turned yellow. After stirring for 30 min the solvent was removed in vacuo and the residue dissolved in 15 mL of methanol and filtered over celite. The solvent was again removed in vacuo and the residue was treated with 20 mL of *n*-pentane and stirred for 10 min. The product was then separated by centrifugation and dried in vacuo. IR (KBr): $\tilde{\nu}$ = 3429 cm^{-1} s (NH sec. amide), 3201 m (NH prim. amide), 1630 vs (CO amide I), 1597 s (NH-bending amide II). IR (PE): $\tilde{\nu}$ = 360 cm^{-1} m (Pd-Cl). ^{1}H NMR (270 MHz, CD_3OD): δ = 1.21 [m, 9 H, P(CH_2CH_3)$_3$], 1.78 [m, 6 H, P(CH_2CH_3)$_3$] ppm. ^{31}P NMR (109.4 MHz, CD_3OD): δ = 24.56 (s, Et_3P) ppm. $C_8H_{18}ClN_3NaO_2PPd$·0.75NaCl (427.90): calcd. C 21.71, H 4.10, N 9.49; found C 21.26, H 4.53, N 9.53. FAB-MS (*m*-NBA): *m*/*z* (%) = 361 (55) [M]$^-$, 325 (17) [M − Cl], 244 (16) [M − PEt_3].

Crystal Structure Determination of 1 and 3: Suitable crystals of both compounds for the X-ray structure determination were obtained by slow evaporation of a methanolic solution. The data collection for compound **1** was done on a Siemens P4 four circle X-ray diffractometer with a Single Point detector at 293 K. Compound **3** was measured on a Stoe IPDS with an Image Plate detector at 200 K. The structure solution of **1** was done with the XS program from Bruker Analytical X-ray Systems (1997 Ver. 5.10) and the structure solution of **3** with the SHELXS-97 program (Sheldrick, 1990). Structure refinement for compound **1** was done with the SHELXTL suite of programs (Bruker Analytical X-ray Systems 1997 Ver. 5.10) and for the refinement of **3** the SHELXL-97 program (G. M. Sheldrick. University of Göttingen, 97−2 version) was used. For both structure determinations graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. The hydrogen atoms H(1)−H(3) in compound **1** were found by difmap and refined freely. All other hydrogen atoms were inserted in idealised

The First Tetranuclear Complex with a (μ-CrO_4-*O*,*O*′,*O*″) Bridge: Crystal Structure and Ferromagnetic Behavior of [{$Cu(bpy)_2$}$_3$(μ-CrO_4)](ClO_4)$_4$·H_2O

Li-Hua Yin,[a] Wei-Hua Gu,[a] Peng Cheng,*[a] Lei Z. Zhang,[a] Dai-Zheng Liao,*[a] Jing Li,[a] Xiu-Lin Yang,[a] Xue-Qi Fu,[b] Shi-Ping Yan,[a] and Zong-Hui Jiang[a]

Keywords: Structure elucidation / Magnetic properties / Bridging ligands / Chromium / N,O ligands

A novel tetranuclear complex [{$Cu(bpy)_2$}$_3$(μ-CrO_4)](ClO_4)$_4$·H_2O (**1**) with a (μ-CrO_4-*O*,*O*′,*O*″) bridge has been synthesized by the reaction of K_2CrO_4 with $Cu(ClO_4)_2$·$6H_2O$ and bpy in CH_3CN/H_2O solution (bpy = 2,2′-bipyridine). A single crystal X-ray diffraction analysis showed that the chromate ion bridges three copper(II) ions showing a pesudo-C_{3v} symmetry. The coordination sphere of each copper(II) ion is best described as trigonal bipyramidal, implying that the magnetic orbital of copper(II) ion is d_{z^2}, which is also confirmed by the powder ESR spectra. Variable-temperature magnetic studies verify the validity of the chromate bridging unit to link the tricopper system with ferromagnetic coupling, with $2J = +1.8$ cm^{-1}.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

The magnetochemistry of polynuclear metal complexes has attracted considerable interest from both physicists and chemists due to the peculiar behavior derived from the nature of these magnetic ions.[1−3] Ferromagnetic interactions can be achieved if the magnetic orbitals are orthogonal to each other.[4−6] The chromate ion has been known to act as a bridging ligand and tends to bridge metal centers to form oligo- and polymetallic systems with zero-, one-, two-dimensional structures.[7−14] Many chromate-bridged polynuclear metal complexes have been structurally and magnetically characterized. Some of them show ferromagnetic interaction due to the magnetic orbital orthogonality through the chromate bridge. For example, the one-dimensional metal(II) complexes *catena*-(μ-CrO_4-*O*,*O*′)[Ni^{II}-(cyclam)]·$2H_2O$ (cyclam = 1,4,8,11-tetraazacyclotetradecane) and *catena*-(μ-CrO_4-*O*,*O*′)[M^{II}(L)]·$5H_2O$ (M = Ni^{II}, Cu^{II}; L = 3,14-dimethyl-2,6,13,17-tetraazatricyclo[14,4,$0^{1.18}$,$0^{7.12}$]docosane) revealed an octahedral geometry about each metal(II) ion and showed weak intrachain ferromagnetic interactions [$2J = +0.6(1)$, $+1.6(1)$ and $+0.10(1)$ cm^{-1}; $H = -2J\Sigma S_i \cdot S_{i+1}$] which is explained by means of an accidental degeneracy of the σ-type frontier orbitals.[8,10] In a dinuclear copper(II) complex [{Cu^{II}(acpa)}$_2$(μ-CrO_4)] (acpa = tridentate Schiff-base ligands), the coordination geometry about the copper(II) ions is square planar, and the ferromagnetic coupling has a $2J$ value of $+14.6$ cm^{-1} ($H = -2J\Sigma S_1 \cdot S_2$).[7] Metal complexes with chromate bridge have been known to contain one, two, and three (μ-CrO_4-*O*,*O*′) ions.[7−14] However, to the best of our knowledge, no polynuclear metal complexes bridged by a chromate ion in a (μ-CrO_4-*O*,*O*′,*O*″) mode have been reported. In this paper we report the crystal structure and magnetic properties of the first tetranuclear complex [{$Cu(bpy)_2$}$_3$(μ-CrO_4)](ClO_4)$_4$·H_2O (**1**) (bpy = 2,2′-bipyridine) with a (μ-CrO_4-*O*,*O*′,*O*″) bridge.

The structure of **1** has been elucidated by X-ray crystallography. The molecular structure of **1** is presented in Figure 1. The coordination geometry about the chromium atom is a slightly distorted tetrahedron with O−Cr−O bond angles in the range 108.0(2)−111.6(2)°. The Cr−O bonds where O is also coordinated to Cu [1.648(4), 1.648(4), and 1.669(4) Å for Cu(1), Cu(2), and Cu(3), respectively] are slightly longer than the "uncoordinated" Cr−O bond [1.605(4) Å]. As can be seen from the figure, the chromate ion bridges the copper(II) ions with a pesudo-C_{3v} symmetry, with a Cu−Cr separation of 3.173−3.504 Å. The Cu−O bond lengths are 1.996(4), 1.961(4), and 1.970(3) Å, respectively. In each $Cu(bpy)_2^{2+}$ unit, the axial coordination sites of the copper(II) ion are occupied by two nitrogen atoms from bpy and the equatorial sites are occupied by two nitrogen atoms from bpy and an oxygen atom from the chromate ion. The bond angle of each axial N−Cu−N unit is almost 180° [177.5(2), 176.6(2), and 178.27(19)° for Cu(1), Cu(2), and Cu(3), respectively]. The axial Cu−N bond lengths are shorter than those of the equatorial Cu−N bonds. Thus, the coordination sphere of each copper(II) ion is best described as a trigonal bipyr-

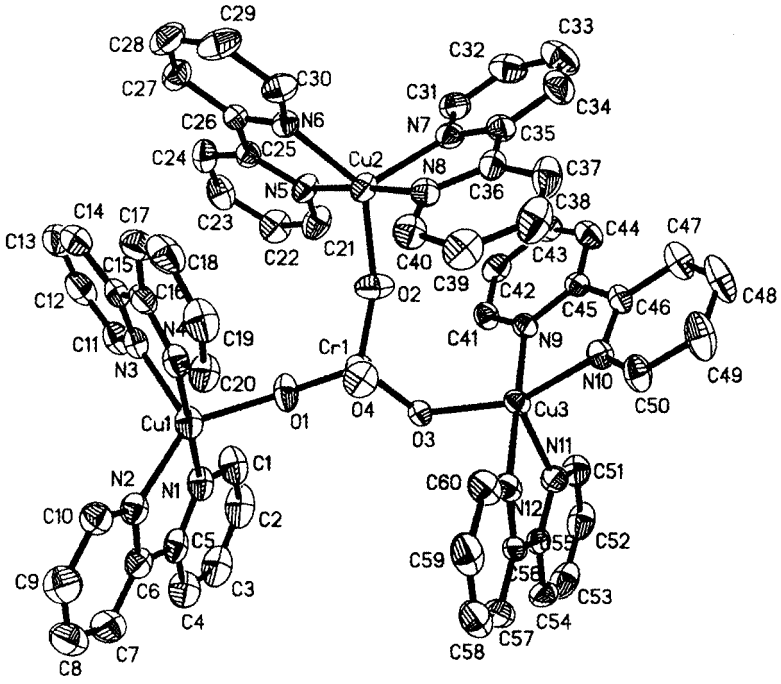

Figure 1. Molecular structure diagram of **1** (showing 30% probability ellipsoids; hydrogen atoms are omitted for clarity)

amid, which implies that the magnetic orbital of copper(II) ion is d_{z^2}.

The powder X-band ESR spectra of **1** was recorded at both room temperature and 77 K (Figure 2). The spectrum remains essentially the same down to 77 K, without any detectable alteration of the relative intensities of the peaks. The very weak ferromagnetic interaction between the copper(II) ions revealed by the magnetic measurements seems not to influence the powder ESR spectrum, where a quasi-isotropic signal centered at $g = 2.18$ is observed.

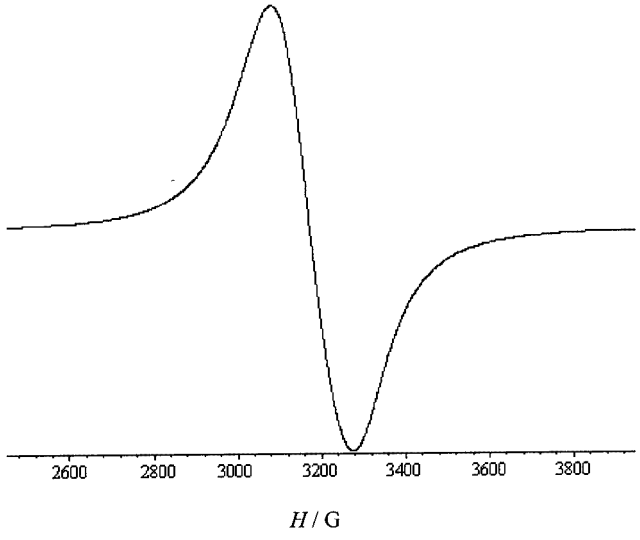

Figure 2. The powder X-band ESR spectrum of **1** at room temperature

A magnetic susceptibility measurement for **1** was carried out in the temperature range 5−300 K. The temperature dependence of the magnetic susceptibilities (χ_m) and the effective magnetic moments (μ_{eff}) versus T plot for **1** is shown in Figure 3. The tetranuclear complex has a room-temperature magnetic moment of 3.23 μ_B. The μ_{eff} value increases markedly below 20 K and reaches a maximum of 3.63 μ_B. This magnetic behavior suggests the operation of a ferromagnetic spin-exchange in the complex, which is probably due to the magnetic orbitals between copper(II) ions being orthogonal to each other through the bridging chromate ligand. The magnetic susceptibility data were fitted to the equation for a triangular unit of $S = 1/2$ spins. The parameters giving the best fit were $2J = +1.8$ cm^{-1}, $g = 2.15$, and $R = 1.4 \times 10^{-4}$ $\{R = [(\chi_m{}^{obs} - \chi_m{}^{calc})^2/(\chi_m{}^{obs})^2]\}$. These results confirmed that the spin coupling between copper(II) ions through the bridging chromate ligand is a ferromagnetic spin-exchange interaction.

Propagation of the ferromagnetic interaction in **1** can be understood from the orbital topology of the frontier orbitals (Figure 4). If we assume that the chromate ion has a tetrahedral geometry (the X-ray crystallographic analysis of **1** revealed a pesudotetrahedral symmetry), we would expect the d-orbitals of the chromium ion to be split into e- and t_2-type orbitals and the p-orbitals of the coordinated oxygen atoms to form a_1- and t_2-type orbitals.[7,8] The e pair of the d-orbitals has no matching combination of oxygen orbitals, hence these orbitals remain nonbonding. The t_2-type orbitals of the chromium ion, however, form triply degenerate bonding and antibonding orbitals with those of the oxygen p-orbitals and six electrons from the coordinated oxygen p-orbitals occupy the t_2-type bonding orbitals.

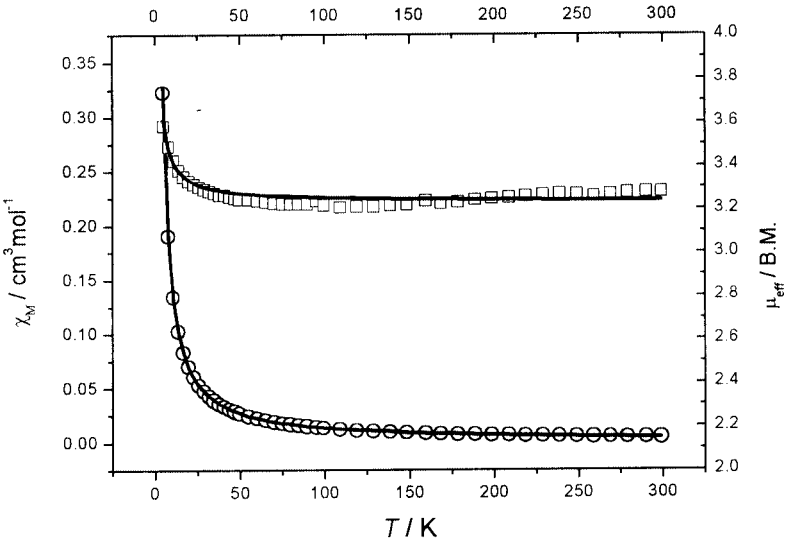

Figure 3. Plots of χ_m vs. T (O) and μ_{eff} vs. T (□) for **1**; the solid line represents the best fit of the experimental data using the parameters described in the text

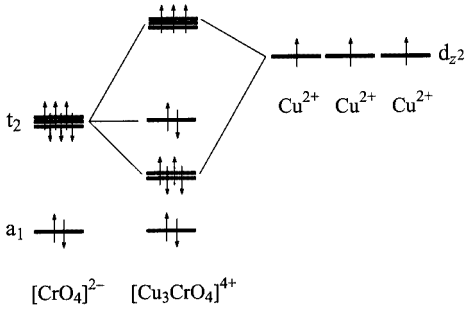

Figure 4. A proposed molecular orbital scheme for the $[Cu_3CrO_4]^{4+}$ chromophore

As revealed by previous measurements, the magnetic orbital of copper(II) ion is d_{z^2}. Thus, when the chromate anion bridges copper(II) ions, two of the t_2-type molecular orbitals of the chromate anion form two sets of σ-type bonding and antibonding orbitals with the d_{z^2} orbitals of the three copper(II) ions; the remainder of the t_2-type orbitals remains nonbonding. The d_{z^2} orbitals of the copper(II) ions and the oxygen p-orbitals interact to mix through the LMCT (O → Cu) interactions. Since the molecular geometry of the complex is pesudo-C_{3v}, orbitals do degenerate under C_{3v} symmetry. The three unpaired electrons from the d_{z^2} orbitals of copper(II) ions occupy three antibonding orbitals. The magnetic susceptibility measurement of **1** does show a ferromagnetic interaction between the copper(II) ions. Therefore, the three antibonding MOs with three spins must be energetically close enough to stabilize the high-spin state. It should be noted here that $[LFe^{III}(\mu\text{-}CrO_4)_3Fe^{III}L]$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane) shows an antiferromagnetic interaction ($2J = -15\ cm^{-1}$) between the high-spin iron(III) centers through the three chromate bridges.[12] The antiferromagnetic interaction in the iron(III) complex might be understood by an extra π-orbital overlap between $[CrO_4]^{2-}$ and Fe^{III} ions leading to the nondegenerate frontier orbitals of the $[Fe^{III}_2(\mu\text{-}CrO_4)_3]$ chromophore.

In conclusion, the first tetranuclear complex $[\{Cu(bpy)_2\}_3(\mu\text{-}CrO_4)](ClO_4)_4\cdot H_2O$ bridged by a chromate ion in a (μ-CrO_4-*O*,*O*′,*O*″) mode is reported in this paper. This complex was structurally analyzed by X-ray diffraction crystallography. Variable-temperature magnetic studies verify the validity of the chromate bridging unit linking the tricopper system with ferromagnetic interactions. These results enhance the fruitful research field of the magnetochemistry of polynuclear metal complexes.

Experimental Section

General: Infrared spectra were recorded as KBr discs on a Shimadzu IR-408 infrared spectrometer in the 4000−600 cm^{-1} region. UV/Vis absorption spectra were recorded on a Shimadzu UV-2101 spectrophotometer. The X-band ESR spectra of polycrystalline powders were collected on a Bruker ER 200 D-SRC ESR spectrometer at both room temperature and 77 K. Magnetic susceptibility data were collected in the 5−300 K range using a Quantum Design MPMS-7 SQUID magnetometer. The data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from Pascal's constants.[15]

Preparation of 1: A solution of K_2CrO_4 (97 mg, 0.5 mmol) in H_2O (5 mL) was added to a solution of $Cu(ClO_4)_2\cdot 6H_2O$ (186 mg, 0.5 mmol) and bpy (78 mg, 0.5 mmol) in CH_3CN (10 mL). The reaction mixture was then stirred for 30 min. Dark green single crystals suitable for X-ray analysis were obtained by slow evaporation at room temperature over several days. Yield: 70 mg (50%). $C_{60}H_{50}Cl_4CrCu_3N_{12}O_{21}$ (1659.54): calcd. C 43.39, H 2.89, N 10.16; found C 43.15, H 2.79, N 10.07. Important IR absorptions (KBr): $\tilde{\nu}$ = 3500 (br), 1610 (s), 1090 (br), 885 (s) cm^{-1}.

X-ray Crystallographic Analysis of 1:[16] A single crystal of **1** with approximate dimensions 0.20 × 0.25 × 0.30 mm was mounted on a glass fiber. A full data collection was performed with graphite monochromatized Mo-K_α radiation (λ = 0.71073 Å) on a Bruker SMART 1000 diffractometer equipped with a CCD camera. Cell parameters were determined from a least-squares refinement. The intensities of the ±hkl reflections were measured up to θ_{max} = 25.03° using a ω-2θ scan technique. The absorption correction was performed empirically.[17] The structure was solved by direct methods using SHELXS-97,[18] and refined by full-matrix least-squares on F^2 using SHELXL-97.[19] All non-hydrogen atoms were refined anisotropically, while hydrogen atoms were set in their calculated positions and treated as riding atoms with a common fixed isotropic thermal parameter. Further data of the X-ray structure analysis are given in Table 1.

Hydroxylation of Hexane Using Dioxygen and Trimethylhydroquinone: Biomimetic Catalysis by an Unsymmetrical Diiron-μ-Oxo Complex

Nathalie Raffard-Pons Y Moll,[a] Frédéric Banse,*[a] Keiji Miki,[b] Martine Nierlich,[c] and Jean-Jacques Girerd*[a]

Keywords: Bioinorganic chemistry / Iron / Dioxygen activation / Biomimetic catalysis / N ligands

An unusual unsymmetrical diiron(III) complex has been obtained with an amine/pyridine ligand. Its ability to catalyze the hydroxylation of *n*-hexane with O_2 and trimethylhydroquinone as reductant and proton donor, respectively, is reported in homogeneous and supported conditions. A spectroscopic study is reported to confirm the role of the reductant. A high-valent iron-oxo species is suggested.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Transforming alkanes into alcohols under environmentally friendly conditions (i.e. using O_2 at room temperature) is a challenge for chemists.[1] In the area of biomimetic chemistry, complexes with porphyrins[2] or amine/pyridine ligands[3] are extensively used to model the active site of mono- or dinuclear iron-containing biological systems capable of performing the above-mentioned reaction. Among nonheme metallobiomolecules able to hydroxylate a CH bond using O_2 and electrons, one can evoke two systems: the antitumoral drug Bleomycin (BLM),[4,5] which cleaves DNA oxidatively, or the metalloenzyme methane monooxygenase (MMO),[6,7] which catalyzes the conversion of methane into methanol. In both cases, the entity responsible for the oxidation of the CH bonds has been suggested to be a high valent iron-oxo compound. In the case of MMO, the active state is an $Fe^{IV}(\mu\text{-}O)_2Fe^{IV}$ intermediate (compound Q) derived from the peroxo form $Fe^{III}(\mu\text{-}1,2\text{-peroxo})Fe^{III}$ (compound P). It has been envisioned that the so-called "activated BLM" Fe^{III}-OOH dissociates to yield $Fe^{IV}O + OH^{\cdot}$ or $Fe^{V}O + OH^{-}$.

Most of the synthetic models that mimic the oxidation reactions catalyzed by these natural systems do not react directly with O_2 plus a reductant, but with H_2O_2 instead.[3] Although some peroxo models have been obtained by reacting Fe^{II} complexes with O_2,[8,9] only a few complexes have been reported to catalyze alkane oxidation reactions with dioxygen as oxidant.[3,10] In this communication, we report a new unsymmetrical dinuclear Fe^{III} complex obtained with the ligand *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridylmethyl)propane-1,3-diamine (L_4^3). This diiron(III) complex can be reduced to the Fe^{II} state to further react with dioxygen and converts *n*-hexane into *n*-hexanols.

Results and Discussion

The molecular structure of $[L_4^3Fe^{III}(Cl)(\mu\text{-}O)Fe^{III}Cl_3]$ (**1**) has been resolved by X-ray diffraction (cf. Figure 1).[11] The structure can be described as two different units bridged by an oxo group. The first unit is an iron center in a pseudo-octahedral environment with the L_4^3 ligand wrapping around the metal in a *cis*-β fashion; a chloro ligand and the oxo bridge complete the coordination sphere. The second unit is an Fe^{III} moiety in a tetrahedral environment with three chloro ligands and the oxo bridge. Very few examples of this type of unsymmetrical dinuclear Fe^{III} complexes have been described.[12−15] Moreover the complex described here is the first one which has been obtained with pyridine groups.

Although the possibility that the unsymmetrical diiron units can be considered as models for biological systems has been envisioned,[12−15] no reactivity studies have been carried out with these complexes. The catalytic activity of **1** towards oxidation of *n*-hexane with molecular dioxygen has been evaluated in the presence of acetic acid and trimethylhydroquinone as reductant. At the beginning of the reaction the solution is purple, although this color disappears after about 10 minutes. The results were monitored period-

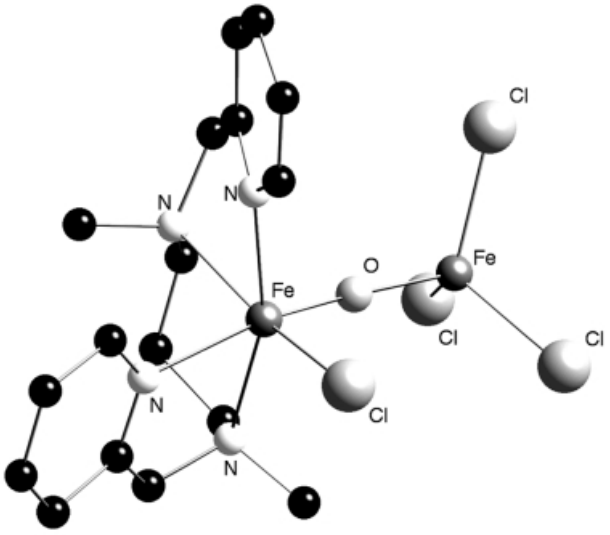

Figure 1. Molecular structure of $[L_4^3Fe^{III}(Cl)(\mu\text{-}O)Fe^{III}Cl_3]$ (**1**)

ically by GC and those recorded after 2 and 16 hours are gathered in Table 1. The total number of turnovers (ca. 10) is reached after 2 hours and further reaction time does not increase the yield nor alter the distribution of the products. Separate experiments confirmed that the presence of **1** in the reaction mixture was necessary for the oxidation of the substrate. Very interestingly, the alcohol-to-ketone ratio is much higher than 1. Such a high ratio is indicative of the absence of radical chain autoxidation, thereby suggesting the involvement of a metal-centered oxidation.[3] The evolution of this ratio from 15.5 to 50 when the reaction time increases seems artificial. Indeed, the yield of ketones decreases slightly while the yield in alcohols increases. As this phenomenon concerns a low number of turnovers, it is probably the consequence of side reactions, for example, reduction of the ketones by the excess reductant. Moreover, these side reactions take place over a period much longer than the time necessary to reach the total number of turnovers; they are therefore too slow to be responsible for the high A/K ratio observed after 2 hours.

Table 1. Oxidation of *n*-hexane by O_2 with by catalyst/trimethylhydroquinone/acetic acid[a]

System (duration)	Products (T.N.)					TTN[b]	A/K[c]
	1-ol	2-ol	3-ol	2-one	3-one		
1 in solution (2 h)	1.0	3.4	4.9	0.3	0.3	9.9	15.5
1 in solution (16 h)	1.1	3.7	5.2	0.1	0.1	10.2	50
1 on silica (2 h)	0.2	1.0	1.3	0.5	0.5	3.5	2.5
1 on silica (16 h)	5.1	17.8	22.2	1.9	2.1	49.1	11.3

[a] Yields are given as turnover numbers (T.N.) based on **1**. Reaction conditions: 1 atm. O_2 at 25 °C in 2.6 mL of dry acetonitrile; final concentration for the catalyst in the reaction mixture 0.33 mmol·L^{-1}. catalyst/*n*-hexane/trimethylhydroquinone/acetic acid 1:3000:350:250. [b] TTN stands for total number of turnovers. [c] Alcohols/ketones ratio.

Concerning the total number of turnovers and the A/K ratio, the results listed in Table 1 are of the same order as those reported for the oxidation of cyclohexane and *n*-pentane catalyzed by $[\{Fe(HBpz_3)(hfacac)\}_2O]$.[16] The same experiments were carried out without any acetic acid: the same product distribution was observed but the total yield was reduced by a factor of three. This suggests that maintaining a dimeric structure for the catalyst by means of an acetate bridge increases the lifetime of the catalyst **1**. We are currently trying to isolate the species that forms in the presence of acetate. Recently, White et al. made similar observations: they used acetate to increase the product yield and robustness of their catalyst.[17]

The same conclusion is suggested by the results obtained in heterogeneous conditions.(cf. Table 1). Upon immobilizing the L_4^3 ligand on a silica support,[18,19] the yield is increased by a factor of five after 16 hours. Contrary to the experiments in solution, these results improve drastically with time. This is not surprising if one considers that the substrate has to reach the metal center and the product has to be removed in solution before analysis. The reactivity has also been explored under slightly different conditions (results not reported in Table 1). This allows us to determine the following: i) as under homogeneous conditions, acetic acid increases the yield; ii) when the silica support was not treated with the C-18 chain (see figure in Supporting Information), the yield decreased. It appears that a hydrophobic matrix facilitates the reactivity. One can propose that, because of the long alkyl chains, the hydrophobic substrate is driven to the reactive site and the polar products are easily eliminated; iii) whatever the conditions, the heterogeneous catalyst was always more efficient than the homogeneous one for a reaction time of 16 hours.

In order to propose a mechanism for the catalytic oxidation of *n*-hexane by O_2 in the presence of trimethylhydroquinone and **1**, we have studied the reaction between **1** and the reductant in the absence of any substrate. The evolution as a function of time of a solution of equimolar amounts of **1** and trimethylhydroquinone (TMH_2Q) in acetonitrile under argon has been followed by UV/Visible spectroscopy (Figure 2). The characteristic LMCT bands of the unsymmetrical dimer **1** at 347 nm and 420 nm[20] decrease in intensity as the reaction evolves. At the same time the characteristic bands of trimethylquinone at 255 and 266 nm appear. No further change is observed after one hour. However, if dioxygen is gently bubbled through the reaction mixture for three days, the electronic spectrum reveals that the dinuclear compound **1** partly reforms (see Figure 2). With a TMH_2Q/**1** ratio of 1:1 the reoxidation by O_2 is slow. However, when using a much larger amount of reductant relative to **1**, we observed that this redox process becomes cyclic — and much faster (ca. 1 minute for each cycle) — by degassing or oxygenating the solution. It is most likely that in the presence of an excess of TMH_2Q, an Fe^{III}-TMHQ complex is formed, as indicated by the purple color (λ_{max} = 568 nm) attributed to a charge transfer between a phenolato group and Fe^{III}.[21,22] The Fe^{II}-trimethylhydroquinone complex then formed is reoxidized by O_2 much

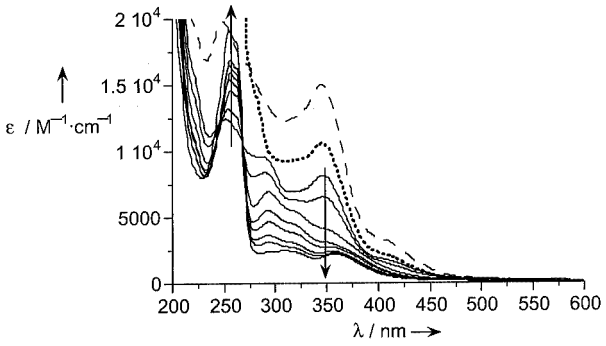

Figure 2. UV/Vis spectra of: (a) **1** + 1 equiv. of trimethylhydroquinone under argon (full line); (b) spectrum obtained after three days under O_2 at the end of evolution (a) (dotted line); spectrum of $L_4^3Fe^{III}(Cl)(\mu\text{-}O)Fe^{III}Cl_3$ **1** (dashed line)

more rapidly than the Fe^{II}-Cl complexes in the above experiment. Thus it appears that TMH_2Q plays a double role in the catalysis: reduction of Fe^{III} and displacement of the chloro ligands to give a Fe^{II}-trimethylhydroquinone complex that is more sensitive to O_2. The importance of ligation of hydroquinones to iron has already been pointed out.[23]

The observations reported above are in agreement with a mechanism implying a high-valent iron species: initial reduction of the dinuclear Fe^{III}-oxo complex **1** by trimethylhydroquinone to the Fe^{II} level allows dioxygen to interact with the metal centers to finally yield a high valent iron-oxo entity. However some questions remain to be elucidated, in particular the chemical nature (mono- or dinuclear) of the active species has to be addressed.

Conclusion

Compared to synthetic models, the pre-eminence of enzymatic systems resides in the separation of the successive steps in the catalytic cycle, whereas for model systems all the reactants are mixed together. The crucial reaction, i.e. oxidation of *n*-hexane by a putative mono- or dinuclear Fe^{IV} species, is in competition with oxidation of the excess reductant. The challenge for chemists in the coming years is therefore to devise catalytic systems in which the different steps can be timely orchestrated.

Experimental Section

The ligand L_4^3 was prepared following the method reported for the ligand bispicen[24] but using *N*,*N*′ dimethyl-1,3-propane diamine as starting material.

Synthesis of 1: A 7 mL methanolic solution of $FeCl_3{\cdot}6H_2O$ (165 mg, 0.61 mmol) was added to a solution of L_4^3 (1 equiv., 173 mg) in 10 mL of MeOH. The solution was stirred for a few minutes and a dark orange powder precipitated. The solid was filtered and washed twice with methanol (174 mg, 50%). Crystals were obtained within a few hours by diffusion of *tert*-butyl methyl ether into a solution of **1** in acetonitrile. $C_{17}H_{24}Cl_4Fe_2N_4O{\cdot}1/2CH_3OH$ (569.92 g·mol^{-1}): calcd. C 36.88, H 4.60, Cl 24.88, Fe 19.60, N 9.83; found C 36.74, H 4.50, Cl 24.77, Fe 19.34, N 9.74.

Syntheses of the grafted ligand and supported catalyst are available as Supporting information(see footnote on the first page of this article).

A Novel Nanostructured Open-Channel Coordination Polymer with an Included Fused-Polyiodide Ring

Jack Y. Lu*[a] and Vaughn Schauss[a]

Keywords: Nanostructures / Hydrothermal synthesis / Copper / Iodine

A novel three-dimensional nanostructured open-channel metal-organic framework polymer with inclusion of a polyiodide cluster has been synthesized via an oxidation reaction mechanism under hydrothermal conditions.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

The synthesis of new metal-organic polymers via self-assembly processes is a topical and important subject.[1] The diversities of the structures and new topologies discovered in metal-organic polymers are due to the wide variety of metal centers and organic building blocks used. Metal centers play a key role in molecular recognition processes in extended materials and biological systems.[2] We and others have recently demonstrated that copper ions and carboxylate ligands form metal-organic frameworks in which the copper(II) atoms display either a mixed octahedral/square pyramidal geometry in a triple-layer two-dimensional (2-D) open-framework,[3a] a square pyramidal coordination 2-D net in an interpenetrating 2-D/3-D structure,[3b] a square planar motif,[3c] or a trigonal bipyramidal geometry in a mixed-bonding 3-D network;[3d] the copper oxidation states are +1,[2a] +2,[4a] mixed-valence,[4b,4c] and/or with Cu−Cu bonds.[2a,4b,4c] The interest in copper arises mainly from its attractive magnetic[4b] and photoluminescence properties,[2a] novel structural features[2b,3,4a,4b] and its biological relevance in the binuclear "Cu_A" site of cytochrome oxidases and related model compounds.[4c,5] The synthetic methods used for preparing metal-organic network structures are conventional solution methodology in organic solvents or hydrothermal/solvothermal reactions under pressure. In most cases, a reduction or oxidation reaction mechanism has not been invoked during the self-assembly of metal-organic polymers. It has been found that Cu^{II} ions can be reduced to Cu^{I} by pyridine[6a] or pyridylcarboxylate[6b] under hydrothermal conditions. Often, fascinating structures and reaction chemistry can be achieved from the reduction of copper valence states.[4b,6] Hydrothermal processes are therefore considered to be necessary conditions for these reductions. It may not be surprising that the synthesis utilizing oxidation reaction route under hydrothermal conditions is hardly explored.[7] Here we report a novel open-channel framework polymer with polyiodide guests synthesized via an oxidation reaction route under hydrothermal conditions: $\{[Cu_2(IN)_3]\cdot I_5^-\cdot 2/3I_2\cdot H_2O\}_\infty$ (IN: isonicotinato) **1**.

X-ray single crystal analysis[8] revealed that compound **1** consists of a 3-D open-channel metal-organic framework with large polyiodide rings formed from fused polyiodide clusters. The metal-organic framework is comprised of two independent Cu atoms and three isonicotinato ligands. The two independent copper atoms are bridged by the oxygen atoms of three bidentate isonicotinato ligands (Figure 1). Cu(1) has a square-pyramidal geometry made up of two pyridyl groups of two IN units and three oxygen atoms from three bridging carboxylate groups of the IN units. Cu(2) has a distorted square-planar geometry consisting of one pyridyl group of an IN ligand and three oxygen atoms from three bridging carboxylate groups of IN units. This mixed square-planar/square-pyramidal binuclear unit, $[Cu_2(IN)_3]$, propagates to form an unusual nanostructured open-channel metal-organic framework polymer (Figure 2). The $[Cu_2(IN)_3]_6$ fragment displays a spiral-galaxy shape open-channel structure along the (1 1 1) direction (Figure 2). The open channel has a diameter of about 1.15 nm, similar to that of carbon nanotubes (1.2 ± 0.1 nm).[9] The association of $[Cu_2(IN)_3]_6$ fragments leads to triangular and rhombohedral units (Figure 3). These open-channel units in the structure extend in three dimensions. This complex is very different from the binuclear copper-carboxylate networks reported previously[2b,4b,10] as it can accommodate large polyiodide clusters in the open channels. The polyiodide consists of an I_5^- unit that is constructed from an I^- and two I_2 units (Figure 4). The I_2 units [I(1)−I(2), 2.774(1) Å; I(4)−I(5), 2.790(1) Å] and I^- anion have distances [I(3)−I(4), 3.115(1) Å; I(3)−I(2), 3.187(1) Å] shorter than those found in known polyiodides {I^-−I: 3.357(2) Å,[11] and 3.3 Å[12]}. It is noteworthy that every six I_5^- units are fused together around an I_2 molecule [I(6)−I(7), 2.723(7)

Å] with I(5)···I(6) interactions of 3.560(10) Å (Figure 4). This distance is similar to those long range I···I interactions reported in $(Hpy)_2I_3I_7$ [3.545(13) Å].[13] The iodine molecule in the center of the fused cluster is disordered about a $\bar{3}$ site with six orientations. The fused polyiodide clusters are then linked by another I_2 molecule [I(8)−I(8), 2.759(1) Å] via long range interactions [I(3)···I(8), 3.478(1) Å]. This type of linkage results in large polyiodide rings within the open channels of the metal-organic framework (Figure 5).

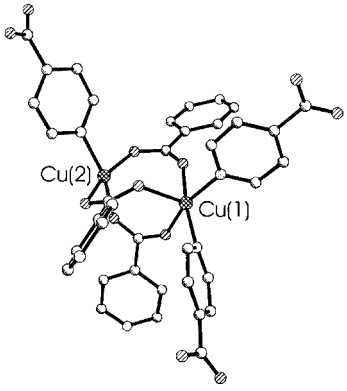

Figure 1. View of the coordination of the copper pair

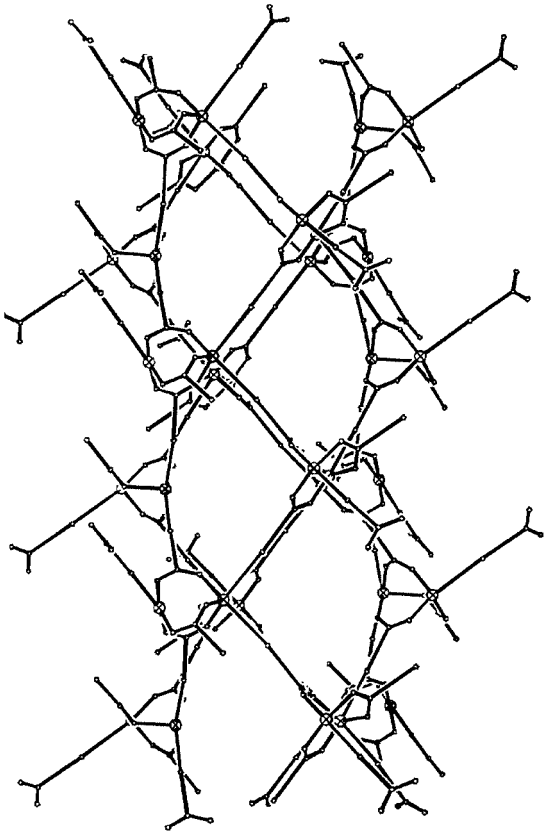

Figure 2. View of the open-channel network in **1**; isonicotinato units are represented by lines for clarity

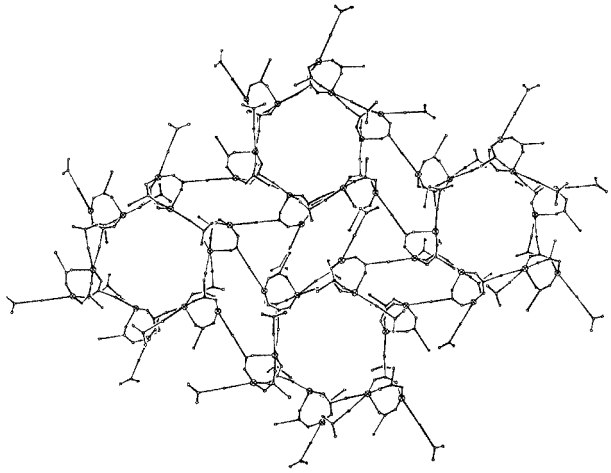

Figure 3. View of the different shape of the channels in the structure

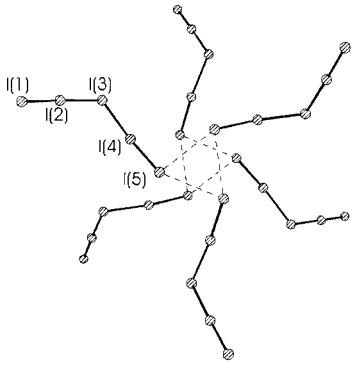

Figure 4. View of the I_5^- units in a fused polyiodide cluster; the iodine molecule with six orientations in the cluster center is not shown

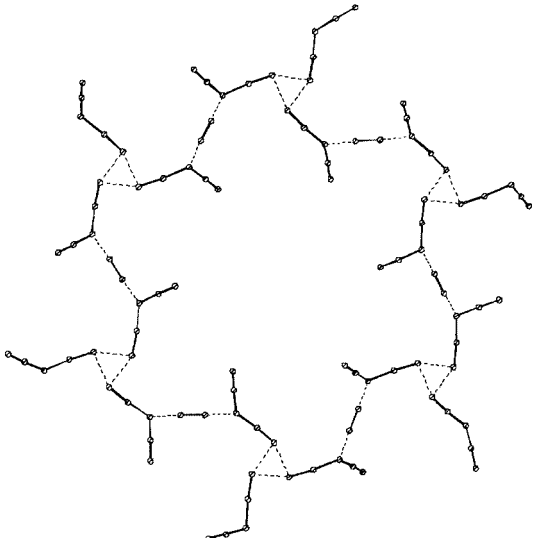

Figure 5. View of a polyiodide ring

The oxidation reaction route under hydrothermal conditions is different from that reported recently, where oxygen was used as an initiator.[7] The I_2 here acts as an oxidizer

as well as an iodine source. The half-cell potential[14] of iodine in acidic aqueous solution is +0.615 V, and that of copper is +0.153 V, based on the following half-cell reactions:

$$I_2(aq) + 2\,e \rightleftarrows 2\,I^-$$

$$Cu^{2+} + e \rightleftarrows Cu^+$$

Cu^I may also undergo disproportionation (auto-oxidation reaction) based on the following potential diagram:

$$Cu^{2+} \overset{0.153\ V}{\rightarrow} Cu^+ \overset{0.521\ V}{\rightarrow} Cu$$

Once the reaction has been initiated, the formation of the $[Cu_2(IN)_3]^+$ unit and the formation of polyiodide shifts the equilibrium of the following reaction to the right-hand side:

$$IN + CuI + I_2 \rightarrow [(Cu_2(IN)_3](I_5^-)$$

Note that the nanostructured open-channel framework in **1** is formed from the inclusion of polyiodide species. This structure is unique and unprecedented. Polyiodide species have been attracting attention recently,[11−13] and metal-organic open-framework structures templated by iodine species should be even more attractive. The synthesis of this novel polyiodide inclusion open-channel framework polymer also demonstrates that novel compounds that may not be accessible using known methods can be synthesized by an oxidation reaction route.[7] The reaction conditions are mild enough to keep the building blocks intact during the oxidation and self-assembly process.

Experimental Section

Black lustrous crystals of **1** were obtained by reacting CuI, isonicotinic acid and iodine (1:2:1) in 6 mL of water under hydrothermal conditions at 140 °C for three days. Yield: 56%.

Zinc(II), Samarium(III) and Tin(II) Complexes Featuring a Tridentate Nitrogen Donor for the Ring-Opening Copolymerization of (D,L)-Lactide and Glycolide

Anca Dumitrescu,[a] Blanca Martin-Vaca,[a] Heinz Gornitzka,[a] Jean-Bernard Cazaux,[a] Didier Bourissou,*[a] and Guy Bertrand*[a,b]

Keywords: N ligands / Zinc / Samarium / Ring-opening polymerization / Copolymerization

The synthesis, structure, and catalytic activity in ring-opening polymerization of zinc(II), samarium(III) and tin(II) complexes featuring a tridentate nitrogen donor are described.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The design of discrete metal complexes that could be highly active and selective catalysts for the polymerization of a variety of monomer classes is of considerable current interest.[1] A significant aim is to construct less expensive catalysts while retaining the benefits of discrete metal complexes. These goals are especially important with respect to the copolymerization of lactide (L) and glycolide (G), to give poly(lactide-*co*-glycolide) (PLGA), biodegradable and biocompatible polyesters that are garnering great interest due to their biomedical, pharmaceutical, and agricultural applications.[2] To this end complexes of various metals (aluminum,[3−5] tin,[6] zinc,[7−9] iron,[10] magnesium,[7d] zirconium[11]) and lanthanides (yttrium,[12,13] lanthanum,[12,13] samarium,[13] ytterbium[13]) have been studied.

Chelating nitrogen ligands are often used for stabilizing low-valent species.[14] We have recently shown that diamidoamino ligands $[(RNCH_2CH_2)_2NR']^{2-}$, initially developed by Cloke,[15] are particularly well adapted for the stabilization of neutral as well as cationic group 13 Lewis acids.[3] Due to the formation of a rather rigid bicyclic core, these tridentate nitrogen donors enforce an approximately trigonal-monopyramidal coordination geometry around the metal, and the ensuing empty axial coordination site has been used for promoting the ring-opening polymerization of heterocycles such as propylene oxide and (D,L)-lactide.[3] We have also shown that stannylenes featuring diamidoamino ligands are monomers both in solution and in the solid state.[16] Here we report the synthesis and structural investigation of related zinc(II) and samarium(III) derivatives which adopt dimeric structures in the solid state. The catalytic activities of the zinc, samarium and previously reported tin complexes for the ring-opening copolymerization of (D,L)-lactide and glycolide are compared.

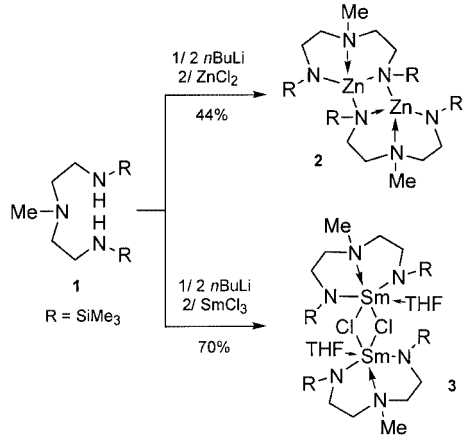
Results and Discussion

Deprotonation of the triamine **1**[3] with two equivalents of *n*BuLi and treatment of the ensuing dilithium salt with anhydrous $ZnCl_2$ and $SmCl_3$ affords the neutral complexes **2** and **3** in 44 and 70% yield, respectively (Scheme 1).



Scheme 1. Synthesis of compounds **2** and **3**

The dimeric structure of **2**, both in solution and in the solid state, was demonstrated by the presence of two sets of signals for the $SiCH_3$ groups in the ^1H and ^{13}C NMR spec-

tra and by an X-ray analysis (single crystals were obtained in pentane at −30 °C) (Figure 1). Derivative **2** contains a central rectangular $(Zn-N)_2$ four-membered ring, which is centered on the crystallographically imposed inversion center of the molecule. The Zn1−N2 [2.238(5) Å] and Zn1−N3 [1.907(0) Å] distances are in the typical range for dative (2.10−2.40 Å) and covalent (1.80−1.90 Å) Zn−N bonds,[17] respectively, while the Zn1−N1 [2.105(4) Å] and Zn1−N1a [2.025(2) Å] distances are, as expected, half-way between covalent and dative bonds. Since Zn−N and Sn−N bond lengths are very similar,[17,18] and since secondary bulky amines normally guarantee monomeric structures for both homoleptic zinc and tin amides, the dimeric structure adopted by **2** is rather surprising. It probably results from the geometry enforced by the diamidoamino ligand, which is certainly more adapted for a bent stannylene[18] than for a linear, allenic-type zinc derivative.[17]

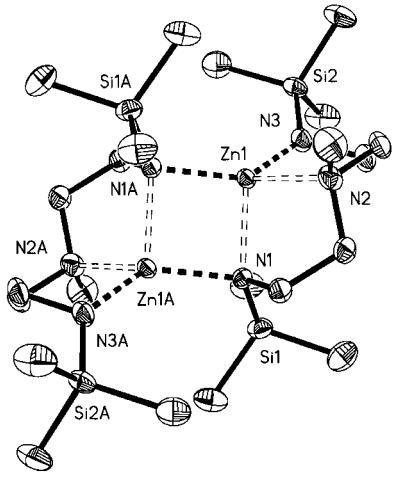


Figure 1. Molecular structure of **2** in the solid state; the hydrogen atoms are omitted for clarity; selected bond lengths (Å) and angles (°): Zn1−N1 2.105(2), Zn1−N1A 2.025(2), Zn1−N2 2.238(2), Zn1−N3 1.907(2), N1−Si1 1.736(2), N3−Si2 1.694(2); N1−Zn1−N2 85.25(6), N1−Zn1−N3 124.48(7), N1−Zn1−N1A 92.49(6), N2−Zn1−N3 86.96(7), N2−Zn1−N1A 127.35(6), N3−Zn1−N1A 133.36(6)

Complex **3** also adopts a dimeric structure but the two $[(Me_3SiNCH_2CH_2)_2NMe]Sm(THF)$ units are bridged by two chlorine atoms (Figure 2). As observed in $[(Cy_2N)_2Sm(\mu\text{-}Cl)(THF)]_2$,[19] the amido nitrogens are in a trigonal planar environment and the $(Sm-Cl)_2$ core is perfectly planar. However, each samarium atom is hexacoordinate and has a strongly distorted octahedral geometry. In other words, the coordination of the amino nitrogen to the lanthanide center does not prevent the coordination of a THF molecule: this is of particular interest for ring-opening polymerization via a coordination-insertion mechanism.[20]

The zinc, samarium and tin derivatives **2**−**4** initiate the bulk copolymerization of (D,L)-lactide and glycolide (Table 1). As estimated from ^{1}H NMR spectroscopy, complete conversion of both monomers requires about 3 h at 180 °C with the zinc complex **2**. Copolymers possessing higher molecular weight could be obtained by increasing

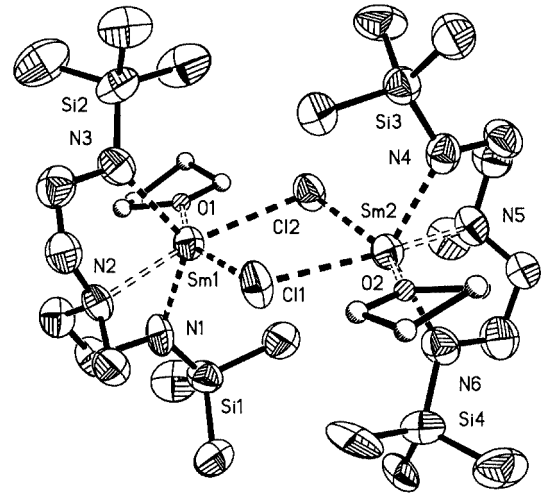

Figure 2. Molecular structure of **3** in the solid state; the hydrogen atoms are omitted for clarity; selected bond lengths (Å) and angles (°): Sm1−Cl1 2.773(3), Sm1−Cl2 2.797(3), Sm1−N1 2.290(12), Sm1−N2 2.574(9), Sm1−N3 2.299(12), Sm1−O1 2.519(8), N1−Si1 1.678(12), N3−Si2 1.695(12); N1−Sm1−N2 68.9(3), N1−Sm1−N3 124.1(4), N1−Sm1−Cl1 104.0(3), N1−Sm1−Cl2 122.1(3), N1−Sm1−O1 83.2(4), Cl1−Sm1−Cl2 75.65(9)

the reaction time but at the expense of the molecular weight distribution (from 2.3 to 3.6) (entries 1−3). However, high-molecular weight copolymers with narrow distribution and various glycolide contents could be prepared by optimizing the reaction conditions (entries 4 and 5). With the samarium derivative **3**, high conversions of both monomers are observed after only 30 minutes at 180 °C and even 160 °C (entries 6 and 7). When carrying out the copolymerization of a stoichiometric mixture of (D,L)-lactide and glycolide at 160 °C, using **3** as the initiator, a copolymer of high molecular weight and narrow molecular distribution (M_n = 26.200, M_w/M_n = 1.8) was obtained after 3.5 h (entry 9). The tin derivative $[MeN(CH_2CH_2NSiMe_3)_2]Sn$ (**4**)[16] is even more active. Conversions higher than 95% are obtained after only 30 minutes at 180 °C. Upon increasing the reaction time, the molecular weight progressively decreases, while the molecular weight distribution increases, probably due to transesterification reactions (entries 10−12).[21] At 140 °C (entries 13−15), these side reactions are significantly reduced, while the tin catalyst remains very active (conversions higher than 90% after 20 minutes); under these conditions, very high molecular weight copolymers are obtained (M_n = 85.150, M_w/M_n = 1.9) (entry 14).

Conclusion

Since the electronic and steric properties of the ligand can be tuned easily, metal complexes of type **2**−**4** are promising candidates for ring-opening polymerization of heterocycles,[22] as well as for the metal-organic vapor phase epitaxy (MOVPE)[23] and metal-organic chemical vapor deposition (MOCVD).[24]

[a] Molar ratio. [b] Obtained from ^{1}H NMR spectroscopy. [c] Obtained from GPC analysis by using polystyrene standards.

Experimental Section

General: All reactions were performed under argon atmosphere using standard Schlenk tube techniques. Solvents were dried by standard procedures and distilled prior to use. Amine **1** was prepared according to a literature procedure.[3b] ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded on a Bruker AC250 spectrometer. ^{1}H and ^{13}C{^{1}H} chemical shifts are reported in ppm relative to Me_4Si as an external standard.

{[MeN(CH$_2$CH$_2$NSiMe$_3$)$_2$]Zn}$_2$ (2): An ether suspension (5 mL) of $ZnCl_2$ (0.58 g, 4.3 mmol) was added at −78 °C to an ether solution (10 mL) of the dilithium salt of *N*-methyl-*N*′,*N*′′-bis(trimethylsilyl)-diethylenetriamine (**1**) (4.3 mmol). The solution became yellow, and was allowed to warm to room temperature. After stirring overnight, removal of the solvent under vacuum and extraction with pentane (25 mL), colorless crystals of **2** were obtained at −20 °C. Yield 0.6 g (44%); m.p. 239 °C (dec.). ^{1}H NMR (250 MHz, C_6D_6): δ = 0.25 (s, 18 H, $SiCH_3$), 0.30 (s, 18 H, $SiCH_3$), 1.68−1.62 (m, 2 H, CH_2), 2.03 (m, 4 H, CH_2), 2.11 (s, 6 H, NCH_3), 2.3−2.1 (m, 2 H, CH_2), 2.98 (m, 4 H, CH_2), 3.05 (m, 4 H, CH_2) ppm. ^{13}C{^{1}H} NMR (62.9 MHz, C_6D_6): δ = 3.2 ($SiCH_3$), 3.3 ($SiCH_3$), 44.5 (NCH_3), 47.6 (CH_2), 47.7 (CH_2), 60.3 (CH_2), 65.9 (CH_2). $C_{11}H_{29}N_3Si_2Zn$ (324.9): calcd. C 40.66, H 9.00, N 12.93; found C 40.28, H 9.35, N 12.71.

{[(Me$_3$SiNCH$_2$CH$_2$)$_2$NMe]Sm(THF)Cl}$_2$ (3): A THF suspension (5 mL) of $SmCl_3$ (1.2 g, 4.7 mmol) was added at −78 °C to a tetrahydrofuran solution (10 mL) of the dilithium salt of **1** (4.7 mmol). The solution was allowed to warm to room temperature and stirred for 4 hours. After removal of the solvent under vacuum and extraction with toluene (5 mL), colorless crystals of **3** were obtained at −20 °C. Yield 1.7 g (70%); m.p. 173 °C (dec.). $C_{15}H_{37}ClN_3OSi_2Sm$ (517.5): calcd. C 34.82, H 7.21, N 8.12; found C 34.65, H 7.53, N 7.91.

X-ray Crystallography: Data for both structures were collected at low-temperatures using an oil-coated shock-cooled crystal on a Bruker-AXS CCD 1000 diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. The structures were solved by direct methods using SHELXS-97[25] and refined with all data on F^2 using SHELXL-97.[26] All non-hydrogen atoms were treated anisotropically. The hydrogen atoms were geometrically idealized and refined using a riding model.

2: Monoclinic, space group $P2_1/n$; T = 173 K; a = 11.668(2), b = 11.300(2), c = 13.894(2) Å; β = 111.67(2)°; V = 1702.4(5) Å^3; Z = 4; R [$I > 2\sigma(I)$] = 0.0241, $wR2$ (all data) = 0.0646 for 2598 unique reflections, 161 parameters, GooF = 1.004.

3: Orthorhombic, space group *Pbca*; T = 173 K; a = 13.184(1), b = 18.567(2), c = 38.049(3) Å; V = 9313.9(14) Å^3; Z = 16; R [$I > 2\sigma(I)$] = 0.0543, $wR2$ (all data) = 0.1453 for 6051 unique reflections, 451 parameters, GooF = 0.820.

CCDC-183554 (**2**) and -183555 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Electron-deficient compounds / Carbenoids / Phosphorus / Fluorine

The presence of a σ-withdrawing group such as the 2,6-bis-(trifluoromethyl)phenyl substituent does not prevent the isolation of a highly electrophilic phosphenium salt.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Bulky hydrocarbon substituents are commonly used for the thermodynamic and kinetic stabilization of highly reactive species such as low-coordinate compounds.[1] Due to their peculiar properties,[2] related fluorinated substituents have recently attracted considerable attention, and have allowed for the isolation of several group 14 carbenoids (Figure 1). The stability of the monomeric bis(aryl)germylene,[3] -stannylene[4] and -plumbylene[5] **I**−**III** is only partly due to steric shielding,[6] the most important factor being the electron-donating ability of the fluorine lone pairs of the *o*-CF_3 groups to the electron-deficient center. Carbenes are even more reactive,[7] but using their reluctance to insert into C−F compared to C−H bonds,[8] the highly persistent triplet bis(aryl)carbene **IV**[9] and the first stable singlet (aryl)carbenes **V**[10] and **VI**[11] have been prepared. The 2,6-bis(trifluoromethyl)phenyl group Ar_F remains electronically a spectator in the (amino)(aryl)carbenes **V**,[10] while its electron-withdrawing properties are involved in the push-pull stabilization of the (aryl)(phosphanyl)carbenes **VI**.[11]

Much less is known about the group 15 carbenoids.[12] Because of their inherent electrophilicity, most of the known phosphenium salts (R_2P^+) feature two π-donor substituents such as amino groups.[13] Notable exceptions are the (amino)(mesityl)-[14] and (phosphanyl)(supermesityl)-phosphenium[15] salts, which both feature an electron-rich

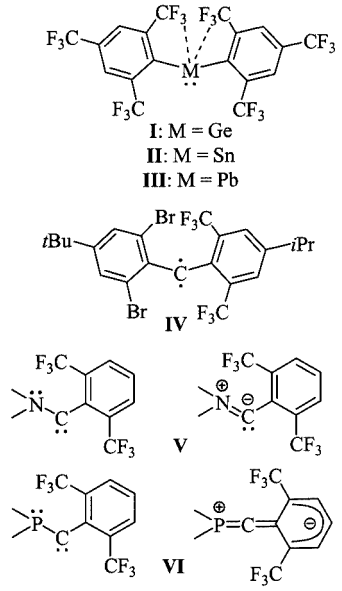

Figure 1. Structure of group 14 carbenoids **I**−**VI**

aryl substituent. Given the potential uses of phosphenium salts as strong π-acceptor ligands,[16] it was of interest to investigate the possibility of preparing a phosphenium salt featuring an electron-withdrawing group. Here we report the synthesis, structural analysis and reactivity of the [2,6-bis(trifluoromethyl)phenyl](diisopropylamino) phosphenium salt **3**.

Results and Discussion

Treatment of the chlorophosphane **1** with silver trifluoromethanesulfonate in dichloromethane, a common method for preparing phosphenium salts, led to derivative **2** (Scheme 1), which was isolated as white crystals in 70% yield. The covalent nature of **2** was suggested by the mod-

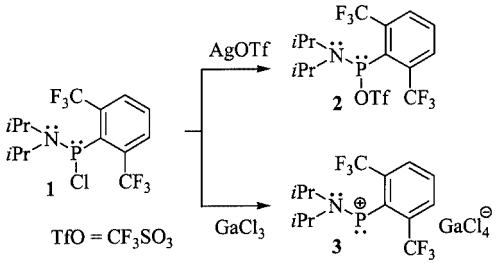
erate deshielding of the ^{31}P NMR signal (**1**: δ = 123.9 ppm; **2**: δ = 186.5 ppm), and confirmed by an X-ray analysis (Figure 2 and Table 1). Compound **2** is the first covalent (trifluoromethanesulfonate)phosphane to be structurally characterized.[17] The P(1)−N(1) bond is very short [1.626(4) Å] and the P(1)−O(1) bond is very long [1.882(2) Å], suggesting that a less coordinating anion should allow for the isolation of the highly electrophilic ionic form. Indeed, the desired phosphenium salt **3** was obtained from **1** by chloride abstraction with gallium trichloride (Scheme 1). The ionic nature of **3** in solution was unambiguously deduced from the dramatic downfield shift observed in the ^{31}P NMR spectrum (**3**: δ = 423 ppm). Single crystals of **3** suitable for an X-ray analysis were obtained from dichloromethane solution at low temperature (Figure 3 and Table 1).



Scheme 1. Synthesis of compounds **2** and **3**

The values of the shortest P···Cl contacts [3.378(9) and 3.848(6) Å] confirm the ionic nature of **3**. The nitrogen atom is in a planar environment and the P(1)−N(1) bond is short

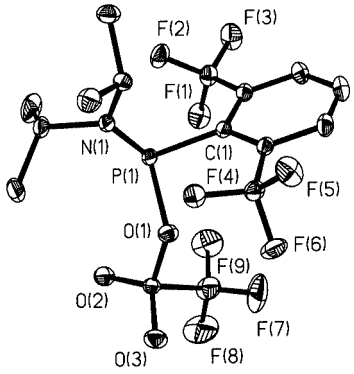


Figure 2. Thermal ellipsoid diagram (30% probability) of **2**; the hydrogen atoms have been omitted for clarity; selected bond lengths (Å) and angles (°): P(1)−N(1) 1.626(4), P(1)−C(1) 1.863(3), P(1)−O(1) 1.882(2), N(1)−P(1)−C(1) 104.15(10), N(1)−P(1)−O(1) 110.03(9), C(1)−P(1)−O(1) 91.38(12), C(9)−N(1)−C(12) 114.96(18), C(9)−N(1)−P(1) 129.06(11), C(12)−N(1)−P(1) 115.81(12)

[1.605(2) Å], as expected from the donation of the nitrogen lone pair to the vacant 3p(P) orbital. The aryl group is almost perpendicular to the plane defined by the C(9), C(12), N(1), P(1) and C(1) atoms [torsion angle N(1)−P(1)−C(1)−C(2) 94.8(2)°], which rules out any conjugation of the π system with the vacant 3p(P) orbital. Of further interest, the absence of an interaction between the phosphorus lone pair and the withdrawing aryl group is confirmed by the small C(1)−P(1)−N(1) angle [105.1(1)°] and the long P(1)−C(1) bond [1.845(2) Å]. All these data suggest that there is no π interaction between the aryl group and the phosphorus center, as observed for the (amino)(aryl)carbene

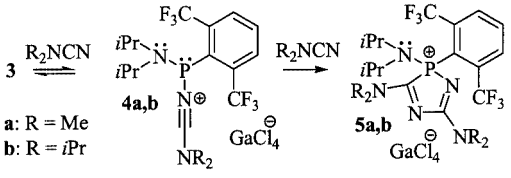
V. However, two close P···F contacts are present in the solid state [2.554(2) and 2.562(11) Å, sum of the van der Waals radii: 3.37 Å], as observed for the heavier group 14 carbenoids. Low-temperature experiments were prevented by the poor solubility of **3**, but the presence of a single ^{19}F NMR signal at room temperature suggests fast rotation of the *o*-CF_3 groups and thus weak P···F interactions.

The high electrophilicity of **3** is apparent from its chemical behavior. Cyanamides do not react with the bis(diisopropylamino)phosphenium salt. In marked contrast, however, dimethylcyanamide reacts smoothly with **3** (Scheme 2) The cationic five-membered heterocycle **5a** was obtained in 60% yield and characterized by multinuclear NMR spectroscopy. The formation of **5a** probably results from a [3+2] dipolar cycloaddition between the acid-base complex **4a** and a second molecule of cyanamide. This hypothesis was confirmed using diisopropylcyanamide. Steric protection allowed the characterization of the acid-base adduct **4b** when only one equivalent of cyanamide was used (Scheme 2). Addition of a second equivalent led to the cationic five-membered heterocycle **5b**, which was isolated in 65% yield as white crystals and structurally characterized (Figure 4 and Table 1).



Scheme 2. Synthesis of compounds **4** and **5**

Concluding Remarks

The presence of an electron-withdrawing group such as a 2,6-bis(trifluoromethyl)-substituted aryl does not prevent the isolation of highly electrophilic phosphenium salts **3**. According to X-ray analysis, its structure is half-way between that of the related carbenes and heavier homologues. The electrophilic character of **3** is illustrated by the unusual formation of acid-base complexes **4** with cyanamides. The availability of phosphenium salts featuring a withdrawing group opens the way for new developments in the coordination chemistry of strong π-acceptor ligands.

Experimental Section

General Procedures: All reactions and manipulations were carried out under dry nitrogen in conventional glassware using standard Schlenk techniques. Solvents were dried according to standard procedures. ^1H, ^{13}C, ^{19}F and ^{31}P NMR spectra were recorded on Bruker AC200, WM250 or AMX400 spectrometers. All downfield chemical shifts are expressed with a positive sign, in ppm, relative to an external standard (Me_4Si for ^1H and ^{13}C, CF_3CO_2H for ^{19}F and 85% H_3PO_4 for ^{31}P).

Synthesis of the Chlorophosphane 1: Diisopropylamine (2 g, 19 mmol) was added to a toluene solution (15 mL) of 2,6-bis(trifluoromethyl)phenyldichlorophosphane (3 g, 9.5 mmol) and the reaction mixture was refluxed for 18 h. The solvent was then removed under vacuum and the residue extracted with pentane (30 mL). The chlorophosphane **1** was crystallized from a pentane solution at −30 °C. Yield 2.7 g (75%); m.p. 94 °C. ^1H NMR (CD_2Cl_2): δ = 1.1 (d, $^3J_{H,H}$ = 6.7 Hz, 6 H, CH_3), 1.3 (d, $^3J_{H,H}$ = 6.7 Hz, 6 H, CH_3), 3.6 (sept, $^3J_{H,H}$ = 6.7 Hz, 2 H, C*H*CH_3), 7.7 (t, $^3J_{H,H}$ = 8.2 Hz, 1 H, H_p), 8.0 (d, $^3J_{H,H}$ = 8.2 Hz, 2 H, H_m) ppm. ^{19}F NMR (CD_2Cl_2): δ = 22.4 (d, $^4J_{P,F}$ = 44 Hz) ppm. ^{31}P NMR (CD_2Cl_2): δ = 123.9 (sept, $^4J_{P,F}$ = 44 Hz) ppm. $C_{14}H_{17}ClF_9NP$ (436.7): calcd. C 38.50, H 3.92, N 3.21; found C 38.78, H 4.23, N 2.99.

Synthesis of the (Trifluoromethylsulfonyl)phosphane (2): Silver trifluoromethanesulfonate (2.1 g, 7.9 mmol) was added to a dichloromethane solution (15 mL) of the chlorophosphane **1** (3 g, 7.9 mmol) at −78 °C. After warming to room temperature and filtration, the phosphane **2** was crystallized from a dichloromethane solution at −30 °C. Yield 2.7 g (70%). ^1H NMR ($CDCl_3$): δ = 0.9 (d, $^3J_{H,H}$ = 5.4 Hz, 6 H, CH_3), 1.3 (d, $^3J_{H,H}$ = 5.4 Hz, 6 H, CH_3), 3.3 (sept, $^3J_{H,H}$ = 5.4 Hz, 1 H, C*H*CH_3), 3.4 (sept, $^3J_{H,H}$ = 5.4 Hz, 1 H, C*H*CH_3), 6.7 (t, $^3J_{H,H}$ = 6.4 Hz, 1 H, H_p), 7.4 (d, $^3J_{H,H}$ = 6.4 Hz, 2 H, H_m) ppm. ^{19}F NMR ($CDCl_3$): δ = 12.7 (s, 3 F, CF_3SO_3), 20.3 (d, $^4J_{P,F}$ = 43 Hz, 6 F, *o*-CF_3) ppm. ^{31}P NMR

($CDCl_3$): δ = 186.5 (sept, $^4J_{P,F}$ = 43 Hz) ppm. $C_{15}H_{17}F_9NO_3PS$ (493.3): calcd. C 36.52, H 3.47, N 2.84; found C 36.15, H 3.26, N 3.14.

Synthesis of the Phosphenium Salt 3: Gallium trichloride (0.46 g, 2.6 mmol) was added to a dichloromethane solution (4 mL) of the chlorophosphane **1** (1 g, 2.6 mmol) at −78 °C. After warming to room temperature, the reaction mixture was stirred for 30 minutes. The phosphenium salt **3** was crystallized from a dichloromethane solution at −30 °C. Yield 0.9 g (62%); m.p. 164 °C. ^{1}H NMR (CD_2Cl_2): δ = 1.6 (br., 12 H, CH_3), 4.4 (br., 2 H, C*H*CH_3), 8.3 (br., 3 H, H_p and H_m) ppm. ^{13}C NMR (CD_2Cl_2): δ = 25.0 (br., CH3), 62.7 (br., CHCH3), 124.3 (q, $^1J_{C,F}$ = 276 Hz, CF_3), 128.5 (d, $^1J_{C,P}$ = 78 Hz, C_{ipso}), 133.4 (s, C_m), 133.3 (q, $^2J_{C,F}$ = 32 Hz, C_o), 136.5 (s, C_p) ppm. ^{19}F NMR (CD_2Cl_2): δ = 22.4 (d, $^4J_{P,F}$ = 40 Hz) ppm. ^{31}P NMR (CD_2Cl_2): δ = 423 (br.) ppm. $C_{14}H_{17}Cl_4F_6GaNP$ (555.8): calcd. C 30.25, H 3.08, N 2.52; found C 29.87, H 2.78, N 2.35.

Synthesis of the Heterocycle 5a: Dimethylcyanamide (0.05 g, 0.68 mmol) was added at room temperature to a dichloromethane solution (4 mL) of the phosphenium salt **3** (0.2 g, 0.34 mmol). The reaction mixture was stirred for 30 minutes and the solvent was evaporated under vacuum. The heterocycle **5a** was crystallized from a 1:2 dichloromethane/diethyl ether solution at −30 °C. Yield 0.18 g (60%). ^{1}H NMR (CD_2Cl_2): δ = 1.4 (d, $^3J_{H,H}$ = 6.4 Hz, 6 H, CHC*H*$_3$), 1.5 (d, $^3J_{H,H}$ = 6.4 Hz, 6 H, CHC*H*$_3$), 3.2 (d, $J_{P,H}$ = 1.2 Hz, 3 H, NCH_3), 3.2 (s, 3 H, NCH_3), 3.3 (d, $J_{P,H}$ = 0.8 Hz, 3 H, NCH_3), 3.6 (b, 3 H, NCH_3), 3.8 (sept.d, $^3J_{H,H}$ = 6.4, $^3J_{P,H}$ = 19.2 Hz, 2 H, C*H*CH_3), 8.1 (pseudo-t, $^3J_{H,H}$ = 7.6 Hz, 1 H, H_p), 8.2 (d, $^3J_{H,H}$ = 7.6 Hz, 1 H, H_m), 8.3 (d, $^3J_{H,H}$ = 7.6 Hz, 1 H, H_m) ppm. ^{13}C NMR (CD_2Cl_2): δ = 22.0 (s, CH*C*H$_3$), 22.9 (s, CH*C*H$_3$), 37.7 (d, $J_{C,P}$ = 3.6 Hz, NCH_3), 38.2 (s, NCH_3), 43.5 (s, NCH_3), 43.6 (s, NCH_3), 52.6 (s, *C*HCH$_3$), 123.5 (q, $^1J_{C,F}$ = 275 Hz, CF_3), 126.2 (d, $^1J_{C,P}$ = 108 Hz, C_{ipso}), 133.0 (q, $^2J_{C,F}$ = 32 Hz, C_o), 133.1 (q, $^2J_{C,F}$ = 33 Hz, C_o), 133.6 (s, C_m), 133.7 (s, C_m), 135.2 (s, C_p), 166.3 (d, $J_{P,C}$ = 24 Hz, CN), 175.2 (d, $J_{P,C}$ = 37 Hz, CN) ppm. ^{31}P NMR (CD_2Cl_2): δ = 64.2 (s) ppm. $C_{26}H_{29}Cl_4F_6GaN_5P$ (768.0): calcd. C 40.66, H 3.81, N 9.12; found C 40.31, H 3.42, N 9.54.

Synthesis of the Acid-Base Adduct 4b: Diisopropylcyanamide (0.04 g, 0.34 mmol) was added at room temperature to a dichloromethane solution (4 mL) of the phosphenium salt **3** (0.2 g, 0.34 mmol). The reaction was stirred for 1 h and the solvent was evaporated under vacuum. The acid-base adduct **4b** was obtained as a colorless oil and characterized without purification. Yield 0.14 g (60%). ^{1}H NMR (CD_2Cl_2): δ = 1.1 (d, $^3J_{H,H}$ = 5.6 Hz, 6 H, CHC*H*$_3$), 1.4 (d, $^3J_{H,H}$ = 6.5 Hz, 12 H, CHC*H*$_3$), 1.5 (d, $^3J_{H,H}$ = 5.6 Hz, 6 H, CHC*H*$_3$), 3.6 (br., 1 H, C*H*CH$_3$), 3.8 (br., 2 H, C*H*CH$_3$), 3.9 (br., 1 H, C*H*CH$_3$), 8.0 (t, $^3J_{H,H}$ = 8.0 Hz, 1 H, H_p), 8.2 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, H_m) ppm. ^{13}C NMR (CD_2Cl_2): δ = 21.4 (s, CH*C*H$_3$), 22.0 (s, CH*C*H$_3$), 26.0 (d, $J_{C,P}$ = 8 Hz, CH*C*H$_3$), 49.0 (d, $J_{C,P}$ = 24 Hz, *C*HCH$_3$), 56.1 (s, *C*HCH$_3$), 56.8 (s, *C*HCH$_3$), 124.0 (q, $^1J_{C,F}$ = 276 Hz, *o*-CF_3), 129.0 (d, $^1J_{C,P}$ = 48 Hz, C_{ipso}), 132.9 (q, $^3J_{C,F}$ = 32 Hz, C_m), 134.0 (s, C_p), 134.5 (dq, $J_{C,P}$ = 17, $^2J_{C,F}$ = 30 Hz, C_o) ppm. ^{31}P NMR (CD_2Cl_2): δ = 110.9 (br.) ppm.

Synthesis of the Heterocycle 5b: Diisopropylcyanamide (0.08 g, 0.68 mmol) was added at room temperature to a dichloromethane solution (4 mL) of the phosphenium salt **3** (0.2 g, 0.34 mmol). The reaction was stirred for 2 h and the solvent was evaporated under vacuum. The heterocycle **5b** was crystallized from a 1:2 dichloromethane/diethyl ether solution at −30 °C. Yield 0.22 g (65%). ^{19}F NMR ($CDCl_3$): δ = 22.7 (s) ppm. ^{31}P NMR ($CDCl_3$): δ = 57.1 (s) ppm. $C_{28}H_{45}Cl_4F_6GaN_5P$ (808.2): calcd. C 41.61, H 5.61, N 8.67; found C 41.99, H 5.87, N 8.44.

X-ray Crystallographic Studies of Compounds 2, 3 and 5b: Crystal data for all structures are presented in Table 1. Data were collected on a Bruker-AXS CCD 1000 diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods by means of SHELXS-97[18] and refined with all data on F^2 by means of SHELXL-97.[19] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the molecules were geometrically idealized and refined using a riding model.
CCDC-179375 (**2**), -179376 (**3**) and -179377 (**5b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Cobalt(II)/(III) Complexes Containing *o*-Iminothiobenzosemiquinonato(1−) and *o*-Iminobenzosemiquinonato(1−) π-Radical Ligands

Diran Herebian,[a] Prasanta Ghosh,[a] Hyungphil Chun,[a] Eberhard Bothe,[a] Thomas Weyhermüller,[a] and Karl Wieghardt*[a]

Keywords: Cobalt / Electrochemistry / EPR spectroscopy / N ligands / Radicals / S ligands

The coordination chemistry of 6-amino-2,4-di-*tert*-butylthiophenol ($H[L_S^{AP}]$) and of 2-anilino-4,6-di-*tert*-butylphenol ($H[L_O^{AP}]$) with cobalt(II) ions was investigated in the presence and absence of dioxygen. It was shown that both compounds were redox-non-innocent ligands, existing in different protonation and oxidation levels as: (i) *o*-aminophenolates(1–) $[(L_X^{AP})^{1-}]$, (ii) *o*-imidophenolates(2–) $[(L_X^{IP})^{2-}]$, and (iii) one-electron oxidized forms *o*-iminobenzosemiquinonates(1–) $[(L_X^{ISQ})^{1-}]$, which are π-radicals (X = S, O for the sulfur or oxygen derivative). The following complexes were synthesized: $[Co^{II}(L_S^{AP})_2]_2$ (**1**), $[Co^{II}(L_S^{ISQ})_2]_2$·0.5*n*-hexane (**2**·0.5*n*-hexane), $[Co^{III}I(L_S^{ISQ})_2]$ (**3**), $[Co^{III}I(L_O^{ISQ})_2]$ (**4**), and $[Co^{III}Cl(L_O^{ISQ})_2]$ (**5**). The compounds **2**·0.5*n*-hexane, **4**, and **5** were structurally characterized by X-ray crystallography. It was shown that the different protonation and oxidation levels of the ligands could readily be identified by X-ray crystallography. Complex **2** could be reversibly oxidized and reduced electrochemically, yielding a monocation and a monoanion, respectively. It was shown that these processes were metal-centered ($[Co^{III}(L_S^{ISQ})_2]^+$, $[Co^{II}(L_S^{ISQ})_2]$, and $[Co^{I}(L_S^{ISQ})_2]^-$). The electronic structures were elucidated by UV/Vis and EPR spectroscopy and magnetochemistry. Complexes **3**, **4**, and **5** were shown to be singlet diradicals.

1. Introduction

Despite a recent assertion to the contrary,[1] *N*,*S*-coordinated *o*-aminothiophenolate ligands are redox-non-innocent in the sense that they can exist at four distinctly different protonation and oxidation levels (Scheme 1).[2] We have recently shown that the monomeric diamagnetic, square-planar complexes $[M^{II}(L_S^{ISQ})_2]$ (M = Ni, Pd, Pt) contain two *N*,*S*-coordinated *o*-iminothiobenzosemiquinonato(1−) π-radical ligands $[(L_S^{ISQ})^{1-}]$, which are strongly antiferromagnetically coupled intramolecularly.[2] The species are thus considered to be diradicals with singlet ground states.

As shown in Scheme 2, the geometrical differences between *N*,*S*-coordinated *o*-aminothiophenolato(1−) $[(L_S^{AP})^{1-}]$, *o*-imidothiophenolato(2−) $[(L_S^{IP})^{2-}]$, and their monoanionic radical form $(L_S^{ISQ})^{1-}$ can readily be identified by X-ray crystallography. The same has been shown to hold for *O*,*N*-coordinated *o*-aminophenolates $[(L_O^{AP})^{1-}]$, *o*-imidophenolate(2−) $[(L_O^{IP})^{2-}]$, and *o*-iminobenzosemiquinonate(1−) radicals $[(L_O^{ISQ})^{1-}]$.[3−7] In these and in the current study, the ligands used were Sellmann's 6-amino-2,4-di-*tert*-butylthiophenol[8] ($H[L_S^{AP}]$) and 2-anilino-4,6-di-*tert*-butylphenol[4] ($H[L_O^{AP}]$). Here we report the coordination chemistry of cobalt(II) and -(III) with these ligands (Scheme 3).

Coordination of the unsubstituted *o*-aminothiophenol with cobalt(II) in the absence of air yielded orange-brown, paramagnetic $[Co^{II}(SC_6H_4NH_2)_2]_2$. Its dimeric nature was inferred from the temperature dependence of its magnetic moment, yielding an $S_t = 0$ ground state from two antiferromagnetically coupled high-spin Co^{II} ions ($S_{Co} = {}^3/_2$). In the presence of oxygen a deep blue material was obtained $[Co^{II}(SC_6H_4NH)_2]$, but its exact nature was not established. Finally, a diamagnetic green $[Co^{III}(SC_6H_4NH_2)_3]$ species was reported. None of these species was structurally characterized, and the problems of differing oxidation and protonation levels were not considered.[9,10] Recently, Artaud et al.[11] reported a structurally characterized dinuclear

complex of cobalt(II) with the ligand 2,3-bis(2-mercaptoanilino)butane, which is very similar to the bis(phenyl) analogue reported by Kawamoto, Kuma, and Kushi.[12] We show here for the first time that both compounds contain *N*,*S*-coordinated *o*-iminothiobenzosemiquinonate(1−) π-radicals.

2. Results and Discussion

2.1. Synthesis and Characterization of Complexes

2.1.1. Complex 1

Treatment of the ligand 6-amino-2,4-di-*tert*-butylthiophenol[8] ($H[L_S^{AP}]$) with $CoCl_2$ (2:1) in dry acetonitrile under strictly anaerobic conditions produced, upon addition of 2 equiv. of the base triethylamine, an orange precipitate of $[Co^{II}(L_S^{AP})_2]_2 \cdot 2CH_3CN$ (**1**·2CH_3CN) in good yields. This material was extremely air-sensitive even in the solid state and had to be stored under argon.

In the infrared spectrum of **1**, an antisymmetric and two symmetric ν(N−H) stretching frequencies were observed: at 3322 and at 3268 and 3246 cm^{-1}, respectively. This clearly indicated the presence of two *N*-coordinated amino groups (R−NH_2) in **1**. The electronic spectrum of **1** measured in CH_2Cl_2 solution displayed no intense absorption maxima > 450 nm (ε > 10^3 M^{-1} cm^{-1}), indicating that the ligand was aromatic and that it was *N*,*S*-coordinated as the monoanion $(L_S^{AP})^{1-}$.

Complex **1** was paramagnetic. Figure 1 displays the temperature dependence of the magnetic moment of **1**. It was possible to fit the data to a dimer model with $S_{Co} = {}^3/_2$ by use of the spin Hamiltonian $H = -2J\, S_1 \cdot S_2$ ($S_1 = S_2 = {}^3/_2$). The following parameters yielded a satisfactory fit: $g_{Co} = 2.2$, $J = -144$ cm^{-1}, $\chi_{TIP} = 0.95 \times 10^{-3}$ e.m.u., and 1% of a paramagnetic impurity ($S = {}^3/_2$). Thus, a strong intramolecular antiferromagnetic coupling between two mononuclear units $Co^{II}(L_S^{AP})_2$ prevailed, yielding an $S = 0$ ground state. In agreement with this, the X-band EPR spectrum of a toluene solution of **1** at 10 K displayed a signal ($g = 4.3$) typical for an $S = {}^3/_2$ ground state of the mononuclear unit. Thus, in solution, dimeric **1** was in equilibrium with its monomer. For the dimer in the solid state we propose one of the two following structures, depending on the

relative configuration of the two $(L_S^{AP})^{1-}$ ligands to each other in a monomer that can be *trans* or *cis*. The spectroscopic and magnetic properties of **1** were quite similar to those reported for $[Co^{II}(abt)_2]$,[9] "abt^{1-}" representing the unsubstituted *o*-aminothiophenolate(1−) anion.

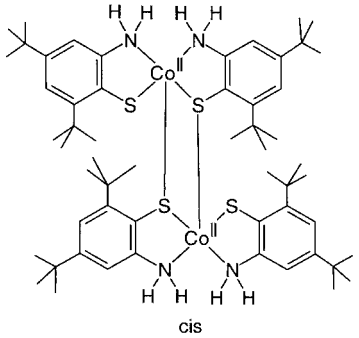
or

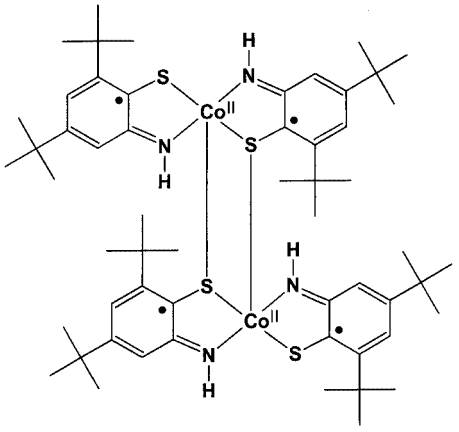


1

2.1.2. Complex 2

When orange-red crystals of **1** were exposed to air at 20 °C, a rapid color change to black was observed. Dissolution of this material in CH_2Cl_2 under argon produced a deep blue solution, from which black crystals of $[Co^{II}(L_S^{ISQ})_2]_2$·0.5*n*-hexane (**2**·0.5*n*-hexane) were obtained upon addition of *n*-hexane.

In the infrared spectrum of **2**, only a single N−H stretching frequency (at 3296 cm^{-1}) was observed, as to be expected for an imino group. The temperature dependence of the magnetic susceptibility of a solid sample of the dimeric species **2** was recorded in the range 4−240 K. The effective magnetic moment varied between 0.65 μ_B at 10 K and 1.6 μ_B at 240 K (per Co). This behavior was consistent with the presence of two Co^{II} ions with $S = {}^1/_2$, weakly antiferromagnetically coupled to yield an $S_t = 0$ ground state. From a fit of the data shown in Figure 1, $J = -7$ cm^{-1} was calculated. The X-band EPR spectrum of a frozen toluene solution of **2** at 10 K displayed an $S = {}^1/_2$ signal at $g \approx 2$, indicating that dimeric **2** existed in solution in equilibrium with its monomer. In agreement with the results of an X-ray structure determination (see below), we assigned the following structure to **2**.

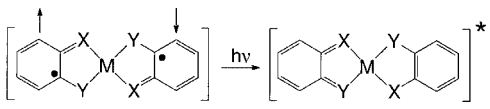


2

It thus appeared that **2** was the four-electron oxidation product of **1**, as in Equation (1).

$$[Co^{II}(L_S^{AP})_2]_2 + O_2 \rightarrow [Co^{II}(L_S^{ISQ})_2]_2 + 2\,H_2 \quad (1)$$

The electronic spectrum of **2** in CH_2Cl_2 solution at 25 °C, shown in Figure 2, displayed a very intense ($\varepsilon > 10^4$ M^{-1} cm^{-1}) absorption at 673 nm, responsible for the deep blue color of **2**, which was absent in the spectrum of **1**. This band corresponded to a spin- and dipole-allowed transition observed for all square-planar complexes containing two *cis* or *trans X*,*Y*-coordinated radicals.[2,4,13]



All the spectroscopic data of **2** thus pointed to the presence of two *N*,*S*-coordinated *o*-iminothiobenzosemiquinonato(1−) π-radicals in a monomeric subunit with an $S = {}^1/_2$ ground state.

Interestingly, we discovered that the electronic spectrum of **2** in CH_2Cl_2 (or in methylcyclohexane) was temperature-dependent. Upon cooling from +25 to −70 °C, the intense band at 673 nm disappeared, but was regenerated upon

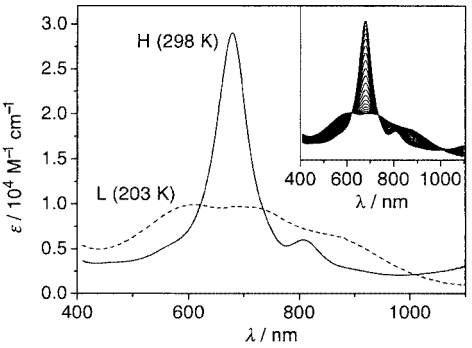


Figure 2. Electronic spectra of the high-temperature form (H) of **2** (at 25 °C) and of its low-temperature form (L) at −70 °C (absorption coefficients are calculated per cobalt ion); the inset shows the temperature dependence of the spectra between 25 and −70 °C (in 5 °C steps)

warming. Figure 2 shows the spectra of the high- and low-temperature forms. We analyzed these spectral changes on the assumption of the equilibrium shown in Equation (2) and calculated the following thermodynamic data: $\Delta G^{300} = -4.3$ kJ mol^{-1}, $\Delta H = 35 \pm 2$ kJ mol^{-1}, $\Delta S = 131 \pm 7$ J mol^{-1} K^{-1} (in methylcyclohexane) and $\Delta G^{300} = -3.6$ kJ mol^{-1}, $\Delta H = 33 \pm 2$ kJ mol^{-1}, $\Delta S = 122 \pm 9$ J mol^{-1} K^{-1} (in dichloromethane).

$$[Co^{III}(L_S{}^{IP})(L_S{}^{ISQ})]_2 \overset{K}{\rightleftharpoons} [Co^{II}(L_S{}^{ISQ})_2]_2 \quad (2)$$

Similar valence tautomeric equilibria have been reported by Pierpont et al.[14−16] for (catecholato)cobalt(III) and (semiquinonato)cobalt(II) complexes, as shown in Equation (3). For this equilibrium, $\Delta G^{300} = -3.3$ kJ mol^{-1}, $\Delta H = 33.9(1)$ kJ mol^{-1}, and $\Delta S = 124(1)$ J mol^{-1} K^{-1} were reported [bpy represents the ligand 2,2′-bipyridine, $(DBSQ)^{1-}$ is either 3,5- or 3,6-di-*tert*-butyl-1,2-benzosemiquinonate(1−), and $(DBCat)^{2-}$ is the corresponding one-electron reduced catecholate(2−)].

$$[Co^{III}(bpy)(DBSQ)(DBCat)] \rightleftarrows [Co^{II}(bpy)(DBSQ)_2] \quad (3)$$

It should be noted that the valence tautomeric equilibrium (2) was only observed in solution. In the solid state, the electronic spectrum of **2** did not change over the temperature range 10−300 K. This was also in qualitative agreement with the observations of Pierpont et al. on the $[Co^{II}(bpy)(DBSQ)_2]$ system. They reported that the transition temperature was about 50 °C higher in the solid state than in solution. They also concluded that "changes in bond energy and vibrational frequency associated with the electron transfer step are the primary contributors to the thermodynamic changes of the equilibrium". The above results for **2** represent the first example of valence tautomers of an *N*,*S*-coordinated *o*-aminothiophenolate complex.

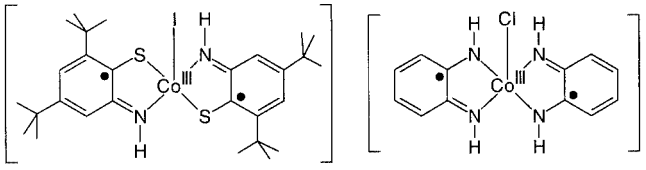
Interestingly, Pierpont's tautomers involved octahedral cobalt(II)/(III) complexes in which the transition from a low-spin cobalt(III) (d^6, $S = 0$) to a high-spin cobalt(II) (d^7, $S = {}^3/_2$) configuration was accompanied with increasing temperature by a net change of the effective magnetic moment from 1.7 μ_B for the cobalt(III) form ($S_t = {}^1/_2$) to ca. 5.5 μ_B for the cobalt(II) form. In contrast, equilibrium (2) was not associated with a similar net change of the effective magnetic moment with increasing temperature. Both monomeric subunits $[Co^{III}(L_S{}^{IP})(L_S{}^{ISQ})]$ and $[Co^{II}(L_S{}^{ISQ})_2]$ possessed an $S = {}^1/_2$ ground state, which may antiferromagnetically couple to an overall diamagnetic ground state in the dimers.

2.1.3. Complex 3

Treatment of **2**, in CH_2Cl_2 under Ar, with I_2 (1:1) dissolved in *n*-hexane changed the blue color to dark green. From this solution a dark green microcrystalline residue of $[Co^{III}I(L_S{}^{ISQ})_2]$ (**3**) was obtained in good yields [Equation (4)].

$$[Co^{II}(L_S{}^{ISQ})_2]_2 + I_2 \rightarrow 2[Co^{III}I(L_S{}^{ISQ})_2] \quad (4)$$

Complex **3** is diamagnetic ($S = 0$), as judged from its "normal" ^{1}H NMR spectrum. In the infrared spectrum, a single N−H stretching frequency was observed at 3231 cm^{-1}, indicating the presence of two equivalent imino groups. Figure 3 shows the electronic spectrum of **3** in CH_2Cl_2 solution. The very intense absorption at 641 nm ($\varepsilon = 1.7 \times 10^4$ M^{-1} cm^{-1}) was again indicative of the presence of two $(L_S{}^{ISQ})^{1-}$ π-radical ligands. We therefore propose the following structure for **3**.



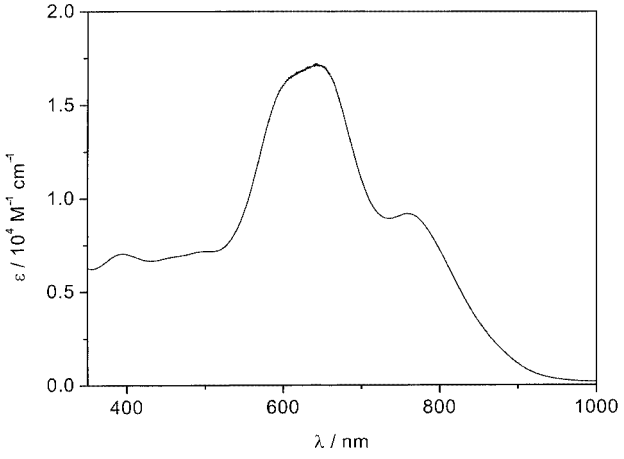


Figure 3. Electronic spectrum of **3** in CH_2Cl_2 solution at 20 °C

This complex is analogous to diamagnetic $[Co^{III}Cl(s\text{-}bqdi)_2]$, which has been structurally characterized.[17] The ligand $(s\text{-}bqdi)^{1-}$ is the *N*,*N*-coordinated *o*-diiminobenzosemiquinonate(1−) π-radical.

2.1.4. Complexes 4 and 5

Treatment of 2-anilino-4,6-di-*tert*-butylphenol ($H[L_O^{AP}]$) in acetonitrile with CoI_2 (ca. 2:1) in the presence of air and triethylamine as base resulted in the precipitation of dark microcrystalline $[Co^{III}I(L_O^{ISQ})_2]$ (**4**). This compound is the exact sulfur-free analogue of **3**. Note that, in contrast to **3**, compound **4** was formed with oxygen as the sole oxidant.

Complex **4** is also diamagnetic ($S = 0$). Figure 4 shows the electronic spectrum of **4** dissolved in CH_2Cl_2. The intense absorption maxima at 695 nm ($\varepsilon = 1.87 \times 10^4$ M^{-1} cm^{-1}) and 884 nm (1.03×10^4 M^{-1} cm^{-1}) were again indicative of the presence of two *O*,*N*-coordinated $(L_O^{ISQ})^{1-}$ π-radical ligands.

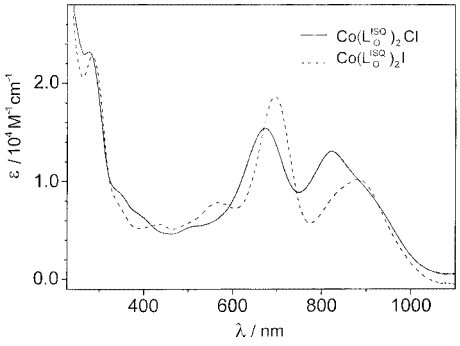

Figure 4. Electronic spectra of **4** and **5** in CH_2Cl_2 solution at 20 °C

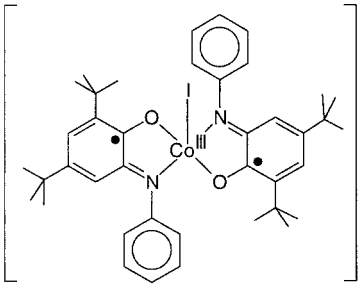
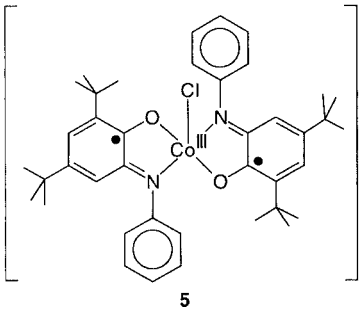


4



5

In an attempt to generate the exact analogue of **2**, the reaction between $[Co(H_2O)_6](BF_4)_2$ and $H[L_O^{AP}]$ (1:1) and NEt_3 in CH_3CN in the presence of air was studied. A dark solid obtained from this reaction mixture was recrystallized from a $CH_3CN/CHCl_3$ (1:1) mixture, yielding single crystals of $[Co^{III}Cl(L_O^{ISQ})_2]$ (**5**). Note that the coordinated chloride ion in **5** had to have been abstracted from chloroform. Complex **5** is also diamagnetic, and isostructural with **4**. Complex **5** could also be synthesized more straightforwardly by employment of the method used to prepare **4** by use of $CoCl_2$ as starting material. The corresponding cobalt halide for the preparation of **4** and **5** was employed only in slight excess over the amount of ligand (ca. 1:1 and not 1:2 as required stoichiometrically) in order to avoid the formation of the known octahedral complex $[Co^{III}(L_O^{ISQ})_3]$.[3]

2.2. Crystal Structures

The crystal structures of complexes **2**·0.5*n*-hexane, **4**, and **5** were determined by single-crystal X-ray crystallography at 100 K, and for **2** also at 295 K. Figure 5 shows the structure of the neutral dimer in crystals of **2**, whereas the structures of the mononuclear, neutral molecules in crystals of **4** and **5** are both displayed in Figure 6. Selected bond lengths are summarized in Table 1.

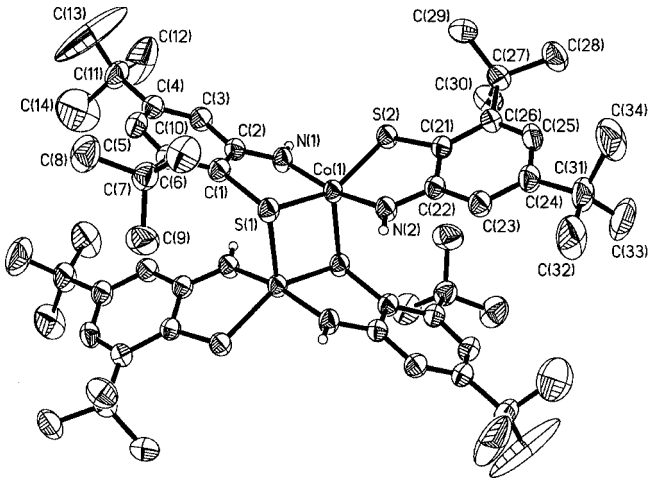


Figure 5. Structure of the neutral dimer in crystals of **2**·0.5*n*-hexane at 293 K; thermal ellipsoids are drawn at the 40% probability level; small open circles are observed hydrogen atoms of the imine groups; all other H atoms are omitted

We describe the structures of **4** and **5** first, because previous structural work on *O*,*N*-coordinated *o*-iminobenzosemiquinonato π-radical complexes such as the octahedral $[M(L_O^{ISQ})_3]$ (M = Co^{III},[3] Cr^{III},[5] Fe^{III} [5]), the square-planar $[M(L_O^{ISQ})_2]$ (M = Cu^{II}, Ni^{II}, Pd^{II}, Pt^{II}),[4] or the square-planar $[M(L_O^{ISQ})(bpy)]PF_6$ (M = Pd^{II}, Pt^{II})[7] has allowed the unequivocal structural characterization of the $(L_O^{ISQ})^{1-}$ radical anion. In all these structures the geometrical features of the ligand are identical within the small experimental error of ±0.01 Å (3σ): (i) the C−O and C−N distances are short at 1.30 Å and 1.35 Å, respectively, and (ii) the C−C distances in the six-membered ring invariably show a quinoid-type distortion, with two short C−C distances at 1.37 Å and four longer ones at ca. 1.42 Å. Furthermore, for the neutral species $[M(L_O^{IP})(bpy)]$ (M = Pd^{II},

Pt^{II}),[7] we have clearly established by X-ray crystallography that the *O*,*N*-coordinated dianion $(L_O^{IP})^{2-}$ has distinctly different geometrical features. The C−O and C−N distances are significantly longer, at 1.35 and 1.39 Å, respectively, and the C−C distances of the now aromatic ring are equal, at 1.39 Å. These parameters are given in Scheme 2.

It is now immediately evident from the data in Table 1 and Scheme 2 that both organic ligands in **4** and **5** are *O*,*N*-coordinated, monoanionic π-radicals $(L_O^{ISQ})^{1-}$. The electronic structures of **4** and **5** may therefore correctly be described as singlet diradical, each containing a low-spin, diamagnetic, trivalent cobalt(III) ion bound to two strongly antiferromagnetically coupled π-radicals. These conclusions agree nicely with Peng's results on the *o*-diiminobenzosemiquinonate (s-bqdi) π-radical complexes $[Co^{III}(s\text{-}bqdi)_2(py)]Cl$,[18] $[Co^{III}(s\text{-}bqdi)_2(PPh_3)](ClO_4)$,[19] and $[Co^{III}Cl(s\text{-}bqdi)_2]$,[17] all of which were singlet diradicals. These authors were also able to perform the structural characterization of the mononuclear, square-planar species $[Co^{II}(s\text{-}bqdi)_2]$ ($S = {}^1/_2$),[17] which also contained two *N*,*N*-coordinated *o*-diiminobenzosemiquinonate radicals.

While the occurrence of three different oxidation levels − namely, fully aromatic, semiquinone radical, and quinone forms − has been firmly established in the literature for *o*-catecholates,[20] *o*-phenylenediamines,[21] and *o*-aminophenols,[3−7] this appears not to be the case for *o*-aminothiophenols, for which the occurrence of *o*-iminothiobenzosemiquinonate π-radicals has until very recently been questioned.[1] We have shown for a series of diamagnetic square-planar complexes $[M(L_S^{ISQ})_2]$ (M = Ni, Pd, Pt)[2] that the semiquinone oxidation level is in fact readily available for *o*-aminothiophenols and we have identified the same structural markers as described above for the *o*-aminophenol derivatives (Scheme 2). *N*,*S*-coordinated *o*-iminothiobenzosemiquinonate radicals possess short C−S bonds, at 1.72−1.74 Å, and short C−N bonds, at 1.35−1.37 Å, and two short C−C and four longer ones (semiquinone sequence). In contrast, in octahedral $[Co^{III}(en)_2(S{-}C_6H_4{-}NH_2)](ClO_4)Cl$[22] containing an *N*,*S*-coordinated *o*-aminothiophenolate(1−), the C−S distance is observed to be 1.764(4) Å and the C−N bond length 1.458(4) Å, both of which represent typical single bonds. The six C−C bonds are of equal length, at av. 1.384 Å.

The structure of **2** reveals a nearly ideal square-based pyramidal environment for both cobalt ions in the dinuclear, *S*-bridged neutral molecule (CoN_2S_3). Two *N*,*S*-coordinated, oxidized *o*-aminothiophenolato ligands are in the equatorial plane, and the two imine and the two sulfur

donors are each *trans* with respect to each other. One of the two thiolates per cobalt ion forms a bridge with an S-donor in the axial position of the other cobalt ion. The axial Co−S distance in the thiolato bridge [2.351(1) Å] is longer than the corresponding Co−S bond in the equatorial position [2.202(1) Å], and the Co−S bond in the non-bridging thiolate is the shortest at 2.152(1) Å. Thus, the dinuclear molecule in **2** possesses two terminal (nonbridging) *N*,*S*-coordinated ligands and two bridging ligands of this type. Comparison of the dimensions of the non-bridging ligand in **2** with those given in Scheme 2 for an *N*,*S*-coordinated *o*-iminothiobenzosemiquinonate radical immediately implies that this oxidation level is present: the C−S and the C−N bonds are short at 1.720(3) Å and 1.338(4) Å, respectively, and the ring clearly displays quinoid character.

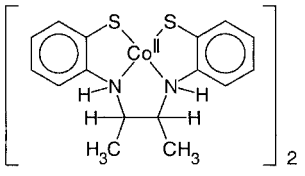
For the bridging ligand, the same oxidation level appears to be appropriate, because the C−N bond is short at 1.348(4) Å and the ring exhibits quinoid character (two shorter C−C bonds and four longer ones). Only the C−S bond at 1.751(3) Å appears to be too long for an *o*-iminothionebenzosemiquinonate radical, but this sulfur atom forms the S-bridge to the second half of the molecule, which may cause the observed lengthening of the C−S bond. We therefore suggest that the molecules in **2** are correctly described as $[Co^{II}(L_S^{ISQ})_2]_2$.

Since we had discovered that **2** displayed valence tautomerism in solution, we also collected an X-ray data set of **2** at 100 K (the above results were obtained from measurements at 295 K). The two structures obtained are identical within experimental error. This is in agreement with the fact that the solid-state electronic spectrum of **2** is temperature-independent in the range 10−300 K.

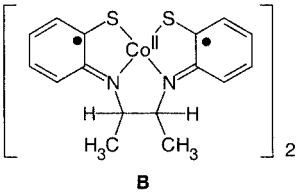
It is interesting that Kawamoto[12] reported the crystal structure of the *monomer* $[Co^{II}(ddbt)]$ ($S = {}^1/_2$), where $(ddbt)^{2-}$ is the diradical-derived from 2,2′-bis(1,2-diphenylenediimine)benzenethiolate. The average C−S bond and C=N bonds here are 1.739(6) and 1.36(1) Å, respectively. The phenyl groups, in a *trans* arrangement relative to one another, effectively prevent dimer formation.

Artaud et al.[11] substituted the two bulky phenyl groups in $[Co^{II}(ddbt)]$ by methyl groups and reported the synthesis of the dinuclear cobalt complexes containing the reduced aromatic *o*-aminothiophenolate ligand (**A**) and its oxidized form (**B**). In contrast to their report, the crystal structure reported is actually that of **B**, since the average C−S and C−N bonds are short at 1.725(6) and 1.35(1) Å, respectively, both rings display quinoid character, and both nitrogen donor atoms are sp^2-hybridized and not sp^3 as required for **A**.

Ref. [11]



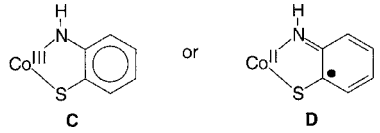
A



B

In our view, these authors had not prepared a pure sample of **A**. All the reported spectroscopic and magnetic properties correspond satisfactorily to those of **B** and **2**. In none of the above papers has the ligand diradical character been addressed.

As we have pointed out previously,[2] there are three interesting structures of organometallic cobalt complexes containing either an *N*,*S*-coordinated, aromatic *o*-iminothiophenolate(2−) anion or its one-electron oxidized form *o*-iminothiobenzosemiquinonate(1−). The question, then, is whether we can distinguish between the two forms **C** and **D**.



C **D**

X-ray structure determinations of $[(tripod)Co(abt)]BF_4$ [23] and $[Co\{P(OCH_3)_3\}_3(abt)]PF_6$ [24] clearly showed that the ligand abt was present as the *o*-iminothiobenzosemiquinonato π-radical, and that both compounds should therefore be viewed as singlet diradicals in which a low-spin Co^{II} ion ($S_{Co} = {}^1/_2$) is antiferromagnetically coupled to an organic π-radical, yielding the observed $S_t = 0$ ground state. The same arguments hold for the neutral complex $Co[\eta^5\text{-}C_5(CH_3)_5][(NH)SC_6H_4]$,[25] in which an *N*,*S*-coordinated *o*-iminothiobenzosemiquinonato radical (and not the reduced aromatic dianion) is also present. It should be noted that *N*,*S*-coordinated dianions $(L_S^{IP})^{2-}$ have the following geometrical features: i) the C−S bond is long at 1.755 Å, as is the C−N bond at 1.40 Å, and ii) the six C−C distances are equal at av. 1.385 Å.

2.3. Electro- and Spectroelectrochemistry

Cyclic voltammograms (CV) of complex **2** were recorded in CH_3CN solutions containing 0.10 M $[nBu_4N]PF_6$ as supporting electrolyte at a glassy carbon working electrode and

an $Ag/AgNO_3$ reference electrode. Ferrocene was used as an internal standard; all potentials are referenced versus the ferrocenium/ferrocene couple (Fc^+/Fc). Table 2 summarizes the results.

Since the original publications by Holm and coworkers[26−27] in the 1970s it has become well established that square-planar complexes of the type $[M(L^{ISQ})_2]$ [M = Ni, Pd, Pt; $(L^{ISQ})^{1-}$ represents *o*-iminothiobenzosemiquinonate(1−), *o*-iminobenzosemiquinonate(1−), or *o*-diiminobenzosemiquinonate(1−)] are the central members of a five-membered electron-transfer series, the component species of which (n = 2−, 1−, 0, 1+, 2+) are interrelated by reversible one-electron transfer reactions. This has also been shown to be the case for the complexes of Table 2. The reduced and oxidized forms of these neutral species have been shown to contain reduced or oxidized forms of the ligands and a divalent metal center [Equation (5)] by spectroelectrochemical methods.

$$[M^{II}(L^{IP})_2]^{2-} \underset{+e}{\overset{-e}{\rightleftharpoons}} [M^{II}(L^{ISQ})(L^{IP})]^{1-} \underset{+e}{\overset{-e}{\rightleftharpoons}} [M^{II}(L^{ISQ})_2] \underset{+e}{\overset{-e}{\rightleftharpoons}} [M^{II}(L^{IBQ})(L^{ISQ})]^{1+} \underset{+e}{\overset{-e}{\rightleftharpoons}} [M^{II}(L^{IBQ})_2]^{2+} \quad (5)$$

$E^1_{1/2}$ $E^2_{1/2}$ $E^3_{1/2}$ $E^4_{1/2}$

Figure 7 shows the CV of **2** in CH_3CN (0.10 M $[n\mathrm{Bu_4N}]PF_6$) at 20 °C over the potential range from +0.6 to −2.1 V vs. Fc^+/Fc. Three reversible electron-transfer waves were observed, at −1.90, −0.72, and −0.17 V, each wave corresponding to a one-electron transfer event per cobalt ion present, as established by coulometry. Since we have established that **2** is a dimer in the solid state, we briefly studied its solution behavior. A frozen CH_2Cl_2 solution of **2** at 10 K displayed a weak X-band EPR spectrum at $g \approx 2.0$ typical for the $S = {}^1/_2$ monomeric species $[Co^{II}(L_S^{ISQ})_2]$. Hence, the equilibrium Equation (6) exists in solution, and both the dissociation and formation rates of this equilibrium are expected to be very fast with respect to the scan rates employed in the cyclic voltammetry experiments. From the results described below we inferred that the monomers were the electroactive species.

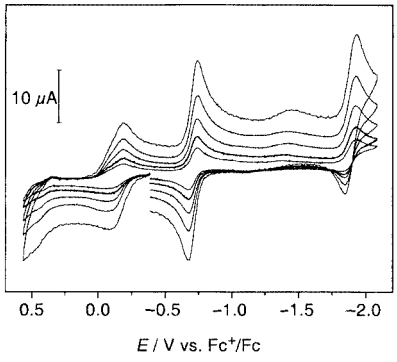

Figure 7. Cyclic voltammogram of **2** in CH_3CN solution (0.10 M $[n\mathrm{Bu_4N}]PF_6$) at 20 °C at a glassy carbon working electrode; scan rates: 50, 100, 200, 400, 500 mV s^{-1}

$$[Co^{II}(L_S^{ISQ})_2]_2 \underset{k_r}{\overset{k_f}{\rightleftharpoons}} 2\,[Co^{II}(L_S^{ISQ})_2] \quad (6)$$

Coulometric measurements established that the monomer of **2** could be reduced in a one-electron fashion at a fixed potential of −1.0 V and by another electron at −2.0 V, and oxidized by 1 e^- at 0.15 V. Thus a monocation, a monoanion, and a dianion can be reversibly generated from **2** electrochemically. The dianion proved to be too sensitive for further investigation. Figure 8 shows the electronic spectra of **2** and of its electrochemically generated monocation and monoanion in CH_3CN; Table 3 summarizes these results.

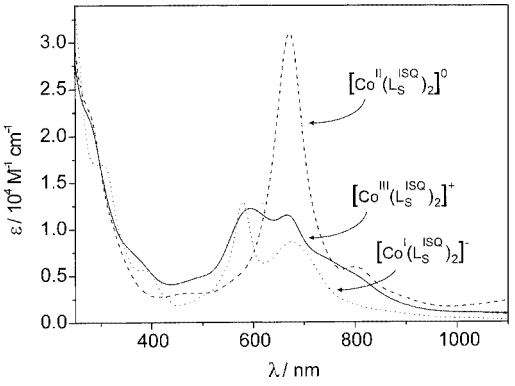

Figure 8. Electronic spectra of **2** and of its electrochemically generated monocation and monoanion in CH_3CN solution (0.10 M $[n\mathrm{Bu_4N}]PF_6$) at 20 °C

[a] Molar absorption coefficients are given *per cobalt ion* (monomer). [b] High-temerature spectrum (20 °C). [c] Low-temperature spectrum (−70 °C). [d] Electrochemically generated in CH_3CN (0.10 M $[n\mathrm{Bu_4N}]PF_6$).

Rather surprisingly, the spectra both of the monocation and of the monoanion of **2** did not resemble those reported[2] for $[M^{II}(L_S^{IBQ})(L_S^{ISQ})]^+$ and $[M^{II}(L_S^{IP})(L_S^{ISQ})]^-$ (M = Ni, Pt), respectively. We therefore concluded that a distribution of ligand and metal oxidation levels as in these cases did not prevail for the oxidized and reduced forms of

2. In fact, it was rather remarkable that the spectra of these two species were fairly similar, both displaying two prominent absorption maxima in the visible region, at ca. 590 and 675 nm ($\varepsilon \approx 10^4$ M^{-1} cm^{-1}). Furthermore, these spectra resembled that of $[Co^{III}(L_S^{ISQ})_2I]$ (**3**), shown in Figure 3. We therefore suggest that neither the oxidation of **2** nor its reduction was ligand-centered. Instead, the spectra imply the presence of two $(L_S^{ISQ})^{1-}$ π-radical ligands and metal-centered redox activity [Equation (7)].

$$\underset{S=0}{[Co^{III}(L_S^{ISQ})_2]^+} \underset{-e}{\overset{+e}{\rightleftharpoons}} \underset{S=1/2}{[Co^{II}(L_S^{ISQ})_2]^0} \underset{-e}{\overset{+e}{\rightleftharpoons}} \underset{S=0}{[Co^{I}(L_S^{ISQ})_2]} \qquad (7)$$

$$E^3_{1/2} \qquad E^2_{1/2}$$

Note that the electronic spectrum of the valence tautomer of **2** (see above), namely $[Co^{III}(L_S^{IP})(L_S^{ISQ})]_2$, was significantly different from those reported here for the monocation and -anion, but that it did closely resemble those reported for $[Ni^{II}(L_S^{IP})(L_S^{ISQ})]^-$ and $[Pt(L_S^{IP})(L_S^{ISQ})]^-$, both of which displayed three absorption maxima, at 650, 840, 971 nm for the Ni complex and at 850, 916, 980 nm for the Pt analogue.[2] In $[Co^{III}(L_S^{IP})(L_S^{ISQ})]_2$ these bands were shifted to higher energies (611, 712, 885 nm). It is also remarkable that the electronic spectra of **4** and **5** (Figure 6) were also very similar to those of $[Co^{III}(L_S^{ISQ})_2]^+$ and $[Co^{I}(L_S^{ISQ})_2]^-$.

We would like to stress that the assignments of oxidation levels of the metal ions and the ligands for the monoanion of **2** and its monocationic form are tentative at present; they are based only on the similarity of their electronic spectra. Further investigations of these species are clearly necessary.

Experimental Section

Syntheses: The ligands 2-anilino-4,6-di-*tert*-butylphenol ($H[L_O^{AP}]$) and 6-amino-2,4-di-*tert*-butylthiophenol ($H[L_S^{AP}]$) were prepared according to published procedures.[4,8]

$[Co^{II}(L_S^{AP})_2]_2\cdot 2CH_3CN$ ($1\cdot 2CH_3CN$): A degassed solution of the ligand $H[L_S^{AP}]$ (0.50 g, 2.0 mmol) and $CoCl_2$ (0.13 g, 1.0 mmol) in dry acetonitrile (40 mL) was stirred under strictly anaerobic conditions (under Ar) for 10 min at ambient temperature. Triethylamine (0.20 g, 2.0 mmol) was added dropwise to the filtered green solution, and stirring was continued for 40 min. A microcrystalline solid precipitated from the light orange solution and was collected by filtration. The material was extremely air-sensitive and had to be stored under argon. Yield: 0.39 g (73% with respect to Co). $C_{56}H_{88}Co_2N_4S_4\cdot 2CH_3CN$ (1143.55): calcd. C 62.93, H 8.28, Co 10.31, N 7.34; found C 62.7, H 8.4, Co 10.5, N 7.2. IR (KBr disk): $\tilde{\nu}$ = 3322, 3268, 3246 [$\nu(NH_2)$] cm^{-1}.

$[Co^{II}(L_S^{ISQ})_2]_2\cdot n$-Hexane ($2\cdot n$-Hexane): When a solid sample of $1\cdot 2CH_3CN$ (0.39 g) was exposed to air, the orange microcrystals immediately turned black. Some of this black material (0.20 g) was dissolved in CH_2Cl_2 (40 mL) under argon. *n*-Hexane (20 mL) was added to the blue solution, and the solvents were allowed to evaporate slowly. Black crystals of $2\cdot n$-hexane (0.17 g, 73%) were obtained. Single crystals of this material were grown from a benzene/*n*-hexane mixture (1:1) under argon by slow evaporation. $C_{56}H_{84}Co_2N_4S_4\cdot C_6H_{14}$ (1145.61): calcd. C 65.00, H 8.62, N 4.89; found C 64.8, H 8.7, N 5.0. MS (ESI$^+$): *m*/*z* = 1059 [M$^+$]. IR (KBr disk): $\tilde{\nu}$ = 3296 [ν(N−H)] cm^{-1}.

$[Co^{III}I(L_S^{ISQ})_2]$ (3): A solution of iodine (0.05 g, 0.20 mmol) in *n*-hexane (25 mL) was added dropwise with stirring under argon to a solution of $2\cdot n$-hexane (0.225 g, 0.20 mmol) in CH_2Cl_2 (40 mL). The blue color of the solution changed to dark green. After the mixture was stirred for 15 min at 20 °C, the solvents were evaporated under reduced pressure. *n*-Hexane (20 mL) was added to the dark residue. A dark green residue was filtered off. This material was recrystallized from a mixture of CH_2Cl_2 (40 mL) and CH_3CN (25 mL) (which were allowed to slowly evaporate) in an argon stream. Yield: 0.17 g (68% based on **2**). $C_{28}H_{42}CoIN_2S_2$ (656.62): calcd. C 51.22, H 6.45, Co 8.98, I 19.33, N 4.27, S 9.77; found C 51.4, H 6.5, Co 9.2, I 18.9, N 4.2, S 10.2. MS (EI): *m*/*z* = 529 [M$^+$ − I]. ^{1}H NMR (250 MHz, $CDCl_3$, 300 K): δ = 1.73 (s, 18 H), 1.33 (s, 18 H), 7.67 (br, 2 H), 7.85 (br, 2 H), 12.85 (br, 2 H, N−H) ppm. IR (KBr disk): $\tilde{\nu}$ = 3231 [ν(N−H)] cm^{-1}.

$[Co^{III}I(L_O^{ISQ})_2]$ (4): Triethylamine (0.3 mL) was added to a solution of the ligand $H[L_O^{AP}]$ (0.30 g, 1.0 mmol) and CoI_2 (0.20 g, 0.64 mmol) in CH_3CN (25 mL). The solution was stirred in the presence of air at 20 °C for 30 min and filtered. A black precipitate formed upon standing for 12 h at ambient temperature, and was collected by filtration. Yield: 0.17 g (43% based on $H[L_O^{AP}]$). Single crystals suitable for X-ray crystallography were grown from a methanol/chloroform solution (1:2) of the above black material. $C_{40}H_{50}CoIN_2O_2$ (776.69): calcd. C 61.80, H 6.49, N 3.61; found C 62.0, H 6.5, N 3.5. MS (EI): *m*/*z* = 776 [M$^+$], 649 [M$^+$ − I]. ^{1}H NMR (400 MHz, $CDCl_3$, 300 K): δ = 8.78 (t, 2 H), 7.90 (s, 2 H), 7.57 (t, 4 H), 7.42 (s, 2 H), 7.31 (d, 4 H), 1.53 (s, 18 H), 1.10 (s, 18 H).

$[Co^{III}Cl(L_O^{ISQ})_2]$ (5): A solution of triethylamine (0.6 mL) in CH_3CN (10 mL) was added to a solution of $[Co(H_2O)_6](BF_4)_2$ (0.68 g, 2.0 mmol) and the ligand $H[L_O^{AP}]$ (0.60 g, 2.0 mmol) in CH_3CN (30 mL). The mixture was stirred in the presence of air at room temperature for 2 h and filtered. The solvent was allowed to evaporate, yielding a dark solid residue that was recrystallized from a $CH_3CN/CHCl_3$ (1:1) mixture to give a small amount (ca. 10%) of crystalline **5**. The Cl^- ligand in **5** is believed to be abstracted from the $CHCl_3$ solvent. $C_{40}H_{50}ClCoN_2O_2$ (685.24): calcd. C 70.11, H 7.35, N 4.09; found C 70.2, H 7.3, N 4.0. MS (ESI$^+$): *m*/*z* = 684 [M$^+$]; 649 [M − Cl$^+$].

X-ray Crystallographic Data Collection and Refinement of the Structures: Dark red-brown single crystals of **2**, and black crystals of **4** and **5**, were coated with perfluoropolyether. Suitable crystals were picked up with a glass fiber and were immediately mounted in the nitrogen cold stream of the diffractometers to prevent loss of solvent. Intensity data were collected at 100 K with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å); a second crystal of **2** was measured at 293(2) K. Final cell constants were obtained from a least-squares fit of a subset of several thousand strong reflections. Data collection was performed by hemisphere runs, taking frames at 0.3° (Siemens SMART) and 1.0° (Nonius Kappa-CCD) in ω. A semiempirical absorption correction was performed on the low-temperature data set of **2** by use of the program SADABS.[28] Intensity data of **2** measured at room temperature, **4**, and **5** were corrected with the Gaussian-type face-indexed absorption correction routine embedded in XPREP.[29] The ShelXTL[29] software package was used for solution, refinement, and depiction of the

structure. The structures were readily solved by Patterson methods and difference Fourier techniques. The hexane solvent molecule in the room-temperature structure of **2** was found to be disordered and not fully occupied. A split-atom model with restrained C−C distances and a reduced occupation factor satisfactorily described the disorder. All non-hydrogen atoms, except C atoms in disordered parts, were refined anisotropically and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. Crystallographic data of the compounds and diffractometer types used are listed in Table 4. CCDC-178090−178093 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Physical Measurements: Electronic spectra of complexes and spectra of the spectroelectrochemical measurements were recorded with an HP 8452A diode array spectrophotometer (range: 190−1100 nm). Cyclic and square-wave voltammograms and coulometric experiments were performed with an EG&G potentiostat/galvanostat. Temperature-dependent (2−298 K) magnetization data were recorded with a SQUID magnetometer (MPMS Quantum design) in an external magnetic field of 1.0 T. The experimental susceptibility data were corrected for underlying diamagnetism by use of tabulated Pascal's constants. X-band EPR spectra were recorded with a Bruker ESP 300 spectrometer.

Intramolecular Lithium Cation Solvation in the "Active Ligand Periphery" of a Tripodal Triaminostannate

Matthias Lutz,[b] Christian Galka,[a] Matti Haukka,[b] Tapani A. Pakkanen,*[b] and Lutz H. Gade*[a]

Keywords: Tin / Lithium / N ligands / Metal-metal interactions / Rhodium

The tris(aminosilyl)methane derivative $HC\{SiMe_2NH(2\text{-}MeOC_6H_4)\}_3$ (**1**) was reacted with three molar equivalents of *n*-butyllithium in pentane to give the solvate-free trilithium triamide $HC\{SiMe_2N(Li)(2\text{-}MeOC_6H_4)\}_3$ (**2**) for which an X-ray diffraction study established the internal solvation of the lithium ions. The trilithium triamide **2** was converted to the triamidostannate $[HC\{SiMe_2N(2\text{-}MeOC_6H_4)\}_3SnLi]$ (**3**) by treatment of **2** with one molar equivalent of $SnCl_2$. Both the NMR spectroscopic data obtained in solution and an X-ray structure analysis confirmed the intramolecular coordination of the lithium cation by the peripheral *ortho*-methoxy groups. Reaction of compound **3** with 0.5 molar equivalents of the dinuclear compound $[Rh(COD)Cl]_2$ in toluene afforded the mixed heterodimetallic complex $[HC\{SiMe_2N(2\text{-}MeOC_6H_4)\}_3Sn(Li)\text{–}Rh(\eta^4\text{-}C_8H_{12})(Cl)]$ (**4**), for which a doublet resonance at high field in the ^{119}Sn NMR spectrum (δ = –196.3; $^1J_{SnRh}$ = 871.6 Hz) confirmed the formation of a Sn–Rh bond. The X-ray structure analysis revealed that the Rh centre in **4** adopts a slightly distorted, square-planar coordination mode, with a tin-rhodium bond length of 2.6048(4) Å, and that the chloro ligand is additionally bonded to the lithium cation.

Introduction

The structural chemistry and reactivity of neutral and anionic tin(II) compounds has attracted much attention in recent years.[1] Group 14 metal-amido and -imido derivatives, in particular, have displayed a great variety of forms of aggregation and reaction patterns.[2,3] The combination of thermodynamic stabilization of the triamidometallates by their integration into a rigid molecular cage structure along with the well-defined orientation and high variability of the peripheral N-substituents has established the tripodal triamidometallates as a versatile new class of ligands in the coordination chemistry of the transition metals.[4] The electronegative N-substituents at the divalent metal atoms render them less oxidizable than would be expected for alkyl- or aryl-substituted derivatives.

An interesting aspect of the structural chemistry of the lithium triamidometallates in solution and in the solid state is the type of interaction between the anionic cage and the countercation (in most cases solvated Li^+). Both solvent-separated salts (**I**) and contact ions have been found (Figure 1).[5] In the latter, the alkali metal ion is either bound directly to the group 14 metal (**II**), in what is thought to be primarily an ionic metal-metal bonding interaction, or attached to the amido-N atoms in a bridging coordination mode (**III**), thus breaking the overall threefold symmetry of the system.

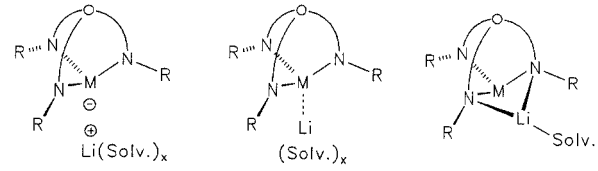

Figure 1. Different modes of cation-anion interactions in triamidostannates and their principal structural types

Which of the structural alternatives discussed above is observed in a given case has been found to be largely unpredictable. It was therefore thought that the design of an amido tripod containing a specific binding site for the metal cation in the ligand periphery would yield "ion pairs" of predefined arrangement.

In an extension of our concept of the "active ligand periphery" in polydentate amides[6,7] containing additional donor functions for cation binding, we synthesised a tripod with peripheral 2-anisyl groups. In this paper we report the

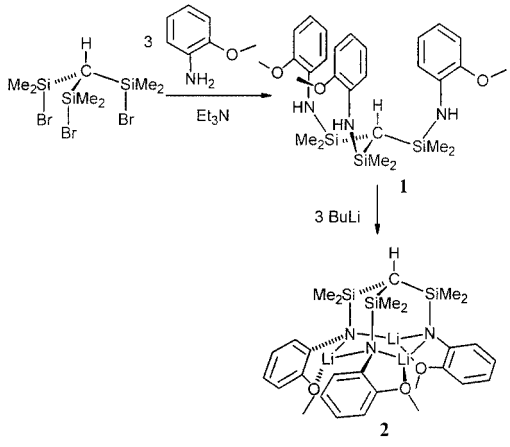
synthesis and crystallographic characterisation of the tripodal triamine, the corresponding trilithium triamide, and its triaminostannate. The "ligand properties" of the latter are demonstrated by the characterisation of a heterobimetallic rhodium complex containing this novel type of stannate fragment.

Results and Discussion

Preparation and Crystallographic Studies of $HC\{SiMe_2NH(2\text{-}MeOC_6H_4)\}_3$ (1) and the Lithium Triamide $HC\{SiMe_2N(Li)(2\text{-}MeOC_6H_4)\}_3$ (2)

Reaction of $HC(SiMe_2Br)_3$ [8] in diethyl ether with three molar equivalents of 2-methoxyaniline in the presence of Et_3N as auxiliary base yielded the triamine $HC\{SiMe_2NH(2\text{-}MeOC_6H_4)\}_3$ (**1**) as a colourless solid (Scheme 1).



Scheme 1

The spectroscopic and analytical data are consistent with an effective threefold symmetry of **1** in solution. The low-field shift of the apical C−H proton resonance (δ = 0.93 ppm in C_6D_6) which we observed previously for aryl-substituted tris(aminosilyl)methane derivatives[9] indicated a preferred conformation of the molecule in solution that is inverted with respect to the adamantane-related arrangement found for the corresponding alkyl-substituted derivatives.[10] The peripheral groups of the ligand precursor are thus effectively turned "inside-out". This type of molecular structure is also prevalent in the solid state as was found in an X-ray diffraction study of the compound. The molecular structure of **1** is depicted in Figure 2 along with the principal bond lengths and interbond angles. The main structural features resemble those of the previously characterised triamine $HC\{SiMe_2NH(4\text{-}CH_3C_6H_4)\}_3$, the three *ortho*-anisyl groups being very regularly arranged with the aromatic rings in the same plane as the quasi-planar amine units and the methoxy groups pointing outwards.

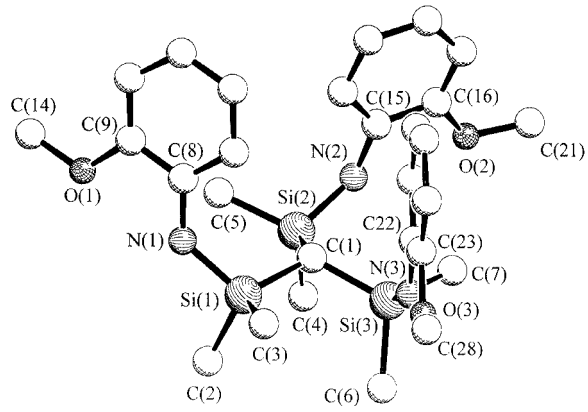


Figure 2. View of the molecular structure of **1**; principal bond lengths (Å) and angles (°): C(1)−Si(1) 1.8829(17), C(1)−Si(2) 1.8825(16), C(1)−Si(3) 1.8867(17), N(1)−Si(1) 1.7358(16), N(2)−Si(2) 1.7439(14), N(3)−Si(3) 1.7395(15), N(1)−C(8) 1.394(2), N(2)−C(15) 1.390(2), N(3)−C(22) 1.394(2); N(1)−Si(1)−C(1) 110.75(7), N(2)−Si(2)−C(1) 109.97(7), N(3)−Si(3)−C(1) 109.73(8), C(8)−N(1)−Si(1) 129.96(14), C(15)−N(2)−Si(2) 129.48(12), C(22)−N(3)−Si(3) 131.19(13)

Upon reaction of **1** with three molar equivalents of *n*-butyllithium in pentane, the solvent-free trilithium triamide $HC\{SiMe_2N(Li)(2\text{-}MeOC_6H_4)\}_3$ (**2**) was obtained as an extremely air- and moisture-sensitive compound (Scheme 1). The signal patterns in the ^1H, ^{13}C, ^{29}Si and ^7Li NMR spectra indicate a threefold symmetrical structure in solution which does not appear to undergo dynamic processes on the NMR time scale. The high molecular symmetry of the trilithium salt **2** was also found in the single crystal X-ray structure. The molecular structure is shown in Figure 3 along with the principal metric parameters.

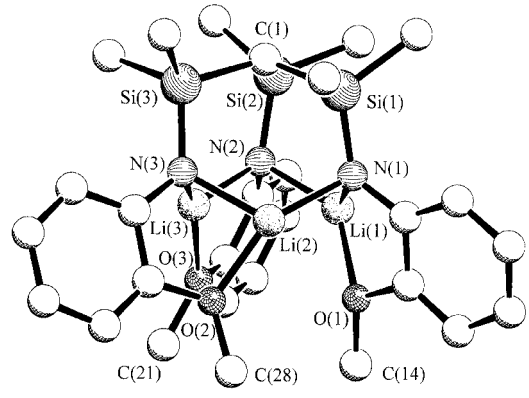

Figure 3. View of the molecular structure of **2**; principal bond lengths (Å) and angles (°): C(1)−Si(1) 1.904(2), C(1)−Si(2) 1.8902(19), C(1)−Si(3) 1.895(2), N(1)−Si(1) 1.7197(16), N(2)−Si(2) 1.7189(16), N(3)−Si(3) 1.7205(17), Li(1)−O(1) 1.963(4), Li(1)−N(1) 1.973(4), Li(1)−N(2) 1.997(4), Li(2)−O(3) 1.938(4), Li(2)−N(3) 2.000(4), Li(2)−N(1) 2.011(4), Li(3)−O(2) 1.915(4), Li(3)−N(2) 1.976(4), Li(3)−N(3) 1.992(4); N(1)−Si(1)−C(1) 107.00(8), N(2)−Si(2)−C(1) 106.40(8), N(1)−Si(1)−C(1) 106.39(8), Li(1)−N(1)−Li(2) 93.98(17), Li(3)−N(2)−Li(1) 92.76(17), Li(3)−N(3)−Li(2) 85.70(18), O(1)−Li(1)−N(1) 83.59(15), O(3)−Li(2)−N(3) 83.54(15), O(2)−Li(3)−N(2) 84.94(16)

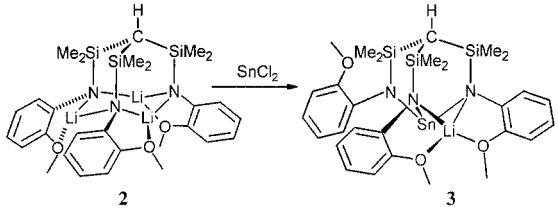
The structural centrepiece is an adamantane-related heteroatom cage comprising three Li, N and Si atoms as well as the carbon atom C(1) at the apex of the trisilylmethane unit. This type of structural motif has been reported previously for a series of achiral[8,10] and C_3-chiral[11] tripodal lithium amides. The most remarkable feature is the internal solvation of the lithium ions which generates a rare tris-solvated lithium amide ring structure. The lithium atoms themselves attain a highly nonsymmetrical coordination geometry that is closer to a T-arrangement than to the conventional trigonal structure. In spite of this unequal distribution of the donor atoms, the lithium atoms are very symmetrically disposed vis-à-vis the negatively charged amido functions, as is evident from the approximately equal Li−N distances [overall variation: Li(1)−N(1)/N(2) 1.963(4)/1.973; Li(2)−N(1)/N(3) 2.000(4)/2.011(4); Li(3)−N(2)/N(3) 1.976(4)/1.992(4) Å]. The lithium atoms are not located within the planes defined by the two amido-N atoms they bridge and the oxygen atom of the solvating ether function but are rather displaced outside the cage structure. Due to the Li coordination, the aryl rings of the anisyl groups adopt a symmetrical propeller arrangement.

Synthesis and Structures of the Lithium Triamidostannate(II) HC{SiMe$_2$N(2-MeOC$_6$H$_4$)}$_3$SnLi (3) and the Rh−Sn Heterodimetallic Complex HC{SiMe$_2$N(2-MeOC$_6$H$_4$)}$_3$Sn(Li)−Rh(η^4-C$_8$H$_{12}$)(Cl) (4)

The trilithium triamide **2** was converted into the triamidostannate [HC{SiMe$_2$N(2-MeOC$_6$H$_4$)}$_3$SnLi] (**3**) by treatment of **2** with one molar equivalent of $SnCl_2$ in toluene at elevated temperature in an ultrasound bath. The reaction product crystallised as a colourless solid and was isolated in 63% yield (Scheme 2).



Scheme 2

The observation of three ^{1}H and ^{13}C NMR resonances for the $SiMe_2$ groups (^{1}H: δ = 0.14, 0.59, 0.62 ppm; ^{13}C: δ = 4.9, 5.6, 6.6 ppm) and two NMR resonances for the MeO groups (^{1}H: δ = 3.04, 3.34 ppm; ^{13}C: δ = 55.0, 55.6 ppm) as well as the detection of two ^{29}Si NMR signals for the $SiMe_2$ groups (δ = −1.9, −1.2 ppm) indicate a reduction of the effective symmetry in solution from C_3 to C_S. These spectral patterns are consistent with the coordination of the lithium cation to two amido N-atoms and its internal "solvation" by two of the *ortho*-anisyl groups. In order to establish the details of the molecular structure of this new type of lithium stannate(II), an X-ray diffraction study was carried out (Figure 4).

Figure 4a

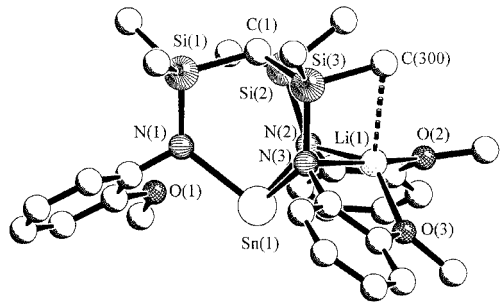


Figure 4b

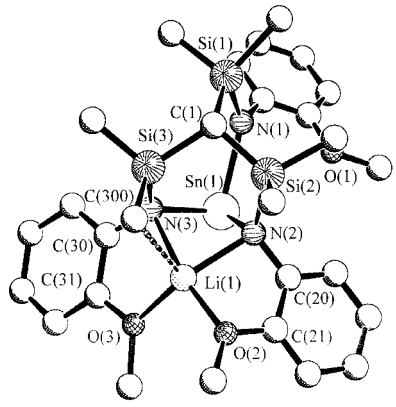

Figure 4. View of the molecular structure of **3**; principal bond lengths (Å) and angles (°): Sn(1)−N(1) 2.255(2), Sn(1)−N(2) 2.2235(19), Sn(1)−N(3) 2.096(2), Sn(1)−Li(1) 2.931(4), Li(1)−N(2) 2.039(5), Li(1)−N(3) 2.139(5), Li(1)−O(2) 1.908(5), Li(1)−O(3) 2.044(5); N(1)−Sn(1)−N(2) 94.20(7), N(1)−Sn(1)−N(3) 96.55(7), N(2)−Sn(1)−N(3) 77.84(7), N(3)−Li(1)−N(2) 81.03(17), N(2)−Li(1)−O(2) 88.2(2), N(3)−Li(1)−O(3) 85.39(18)

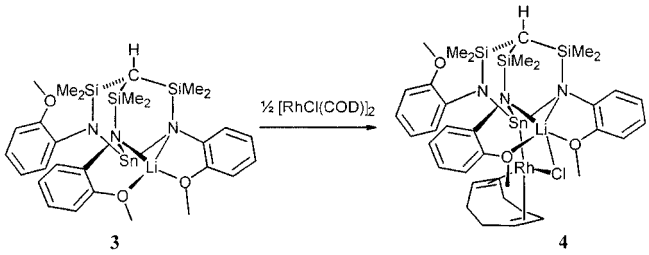
The lithium stannate **3** crystallises in the centrosymmetrical space group $P2_1/n$, and possesses a molecular structure in the solid which, albeit distorted, is consistent with the C_s-symmetry derived from the NMR spectroscopic data recorded in solution. The most characteristic structural feature of **3** is undoubtedly the intramolecular coordination of the lithium cation by the peripheral *ortho*-methoxy groups. The Li−O bond lengths found in **3** [1.908(5) Å and 2.044(5) Å] are similar to those found in structurally related solvated metallates, such as HC{SiMe$_2$N[(*S*)-CH(Me)Ph]}$_3$SnLi(THF) [1.95(1) Å][13b] and MeSi{SiMe$_2$N(*t*Bu)}$_3$Pb-Li(THF) [2.11(7) Å].[5b] Significantly, the lithium cation is placed above the plane, which is spanned by the atoms O2, N2, N3 and O3. This exposed position of the lithium leads to a very close contact with the adjacent methyl group C300 [*d*(Li1−C300) = 2.603(2) Å] which effectively occupies the vacant coordination site of the lithium centre. Such "agostic" interactions with hydrocarbon fragments are quite common in lithium amides provided that the coordination numbers of the lithium centres are low.[12] It is therefore surprising to observe this structural feature for four-coordinate lithium, which is probably due to the unusual coordination geometry (distorted square

planar instead of tetrahedral) imposed by the rigid caged structure of the triamidostannate(II).

It is noteworthy that compound **3** is also formed in an in situ reaction of $[HC\{SiMe_2NH(2\text{-}MeOC_6H_4)\}_3]$ (**1**) with *n*-butyllithium and $SnCl_2$ in diethyl ether, and therefore no indication for a competitive coordination of the anisyl groups vs. diethyl ether has been found. However, the formation of **3** using diethyl ether as a reaction medium is accompanied by a redox process (formation of the free ligand) and is therefore unsuitable for a high yield synthetic protocol.

Due to the efficient intramolecular cation solvation, the lithium stannate **3** can be viewed as a neutral compound. In reactions of **3** with transition metal complexes it was therefore expected to act as a neutral "ligand" and thus display a behaviour that differs from the anionic stannates we studied recently.[5,13] Reaction of compound **3** with 0.5 molar equivalents of the dinuclear compound $[Rh(COD)Cl]_2$ in toluene afforded the mixed heterodimetallic complex $[HC\{SiMe_2N(2\text{-}MeOC_6H_4)\}_3Sn(Li)-Rh(\eta^4\text{-}C_8H_{12})(Cl)]$ (**4**) in high yield (Scheme 3).



Scheme 3

The observation of a doublet resonance at high field in the ^{119}Sn NMR spectrum ($\delta = -196.3$; $^1J_{SnRh} = 871.6$ Hz) confirms the formation of a Sn−Rh bond and the elemental analysis the formulation given above. The resonance patterns attributable to the stannate fragment in the ^1H, ^{13}C, and ^{29}Si NMR spectra are very similar to those of **3** indicating the retention of the local C_S symmetry. This is consistent with the anticipated nature of the tin cage as a formally neutral ligand at the rhodium, which retains its square planar coordination geometry due to the presence of the chloro ligand and the chelating COD ligand. In order to obtain a detailed insight into the relative arrangement of the two metal complex fragments a single crystal X-ray structure analysis of complex **4** was carried out. Its molecular structure is depicted in Figure 5 along with the principal bond lengths and angles.

As can be seen in Figure 5, the overall structure of the stannate fragment in the heterodimetallic complex is the same as in the noncoordinated compound **3**. A structural effect of the transition metal coordination of the tin in **4** is the slight contraction of the Sn−N bonds relative to those in **3** [average Sn−N distance in **4** is 2.136(2) Å compared to 2.192(2) Å in **3**] which we observed in all the structurally characterised transition metal-stannate complexes. The Rh centre in **4** adopts a slightly distorted, square-planar coordination mode and the tin-rhodium bond length of

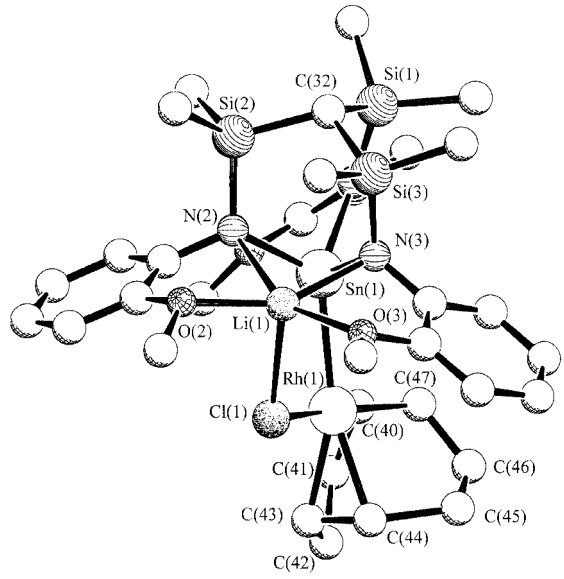


Figure 5. View of the molecular structure of **4**; principal bond lengths (Å) and angles (°): Sn(1)−N(1) 2.108(2), Sn(1)−N(2) 2.137(19), Sn(1)−N(3) 2.164(2), Sn(1)−Li(1) 2.891(5), Sn(1)−Rh(1) 2.6048(3), Rh(1)−C(43) 2.163(4), Rh(1)−C(44) 2.169(4), Rh(1)−C(40) 2.114(3), Rh(1)−C(47) 2.106(3), Li(1)−N(2) 2.371(6), Li(1)−N(3) 2.167(6), Li(1)−O(2) 1.976(5), Li(1)−O(3) 2.115(6), Li(1)−Cl(1) 2.426(5), Rh(1)−Cl(1) 2.3721(7); N(1)−Sn(1)−N(2) 99.80(9), N(1)−Sn(1)−N(3) 98.77(9), N(2)−Sn(1)−N(3) 83.35(8), N(3)−Li(1)−N(2) 77.96(18), N(2)−Li(1)−O(2) 76.76(19), N(3)−Li(1)−O(3) 77.97(19), Cl(1)−Rh(1)−Sn(1) 83.017(19), Cl(1)−Li(1)−Sn(1) 76.26(14), Rh(1)−Sn(1)−Li(1) 89.04(11), Rh(1)−Cl(1)−Li(1) 107.07(12)

2.6048(4) Å is within the range of previously characterised Rh−Sn complexes.[14] The chloro ligand is additionally bonded to the lithium cation of the stannate unit. Although the Li(1)−Cl(1) distance of 2.426(5) Å is ca. 0.2 Å greater than the Li−Cl bond length found in $[HC\{SiMe_2N(Li)[(S)\text{-}3,3\text{-dimethyl-2-butyl}]\}_3\text{-}LiCl(Et_2O)_3]$[11a] it is similar to those previously characterised in a series of Li−Cl complexes.[15]

The lithium stannate ligand has a stronger *trans* influence than the chloro ligand as is evident from the metal-carbon distances to the COD ligand [Rh(1)−C(43) 2.163(4), Rh(1)-2.169(4) Å *trans* to Sn(1) in comparison to Rh(1)−C(40) 2.114(3), Rh(1)−C(47) 2.106(3) *cis* to Sn(1)]. As a neutral ligating unit it therefore resembles the ubiquitous group 15 donor ligands.[16] The *trans* influence of the lithium stannate ligand in **4** is similar to that previously found in square-planar $[Rh(\eta^4\text{-}C_8H_{12})(\kappa^2\text{-}P,Sb\text{-}i\text{Pr}_2\text{PCH}_2\text{Sb}t\text{Bu}_2)]\text{-}PF_6$.[16a]

Conclusion

We have shown in this first study of the tin(II) chemistry of a new tripodal amido ligand containing an "active ligand periphery" that the type of lithium-stannate interaction may be controlled by secondary coordinating functions in the ligand. The stannates thus obtained can be viewed as neutral species that may serve as neutral Sn-donor "ligands" in transition metal chemistry. The scope of this ap-

proach, in particular the application of monodentate ligands with extremely large cone angles in transition metal complexes, is currently being studied in our laboratories.

Experimental Section

All manipulations were performed under nitrogen (desiccant P_4O_{10}, Granusic®, J.T. Baker) on a high vacuum line using standard Schlenk techniques, or in a glovebox. All reaction flasks were heated prior to use during three evacuation-refill cycles. Solvents and solutions were transferred by needle-septa techniques. Solvents were dried according to standard methods and saturated with nitrogen. The deuterated solvents used for the NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and stored over 4 Å molecular sieves. Solids were separated from suspensions by filtration through dried Celite. The ^{1}H, ^{7}Li, ^{13}C, ^{19}F, ^{29}Si and ^{119}Sn NMR spectra were recorded on Bruker AC 200, Bruker Avance 250 and Bruker AMX 400 FT NMR spectrometers. ^{1}H and ^{13}C data are listed in parts per million [ppm] relative to tetramethylsilane and are referenced using the residual protonated solvent peak (^{1}H) or the carbon resonance (^{13}C). ^{7}Li data are listed in ppm relative to LiCl/D_2O (1 M, external). ^{29}Si data are listed in ppm relative to tetramethylsilane as an external standard. ^{119}Sn data are listed in ppm relative to tetramethyltin as an external standard. Infrared spectra were recorded on a Nicolet Magna IRTM 750 spectrometer. Elemental analyses were carried out with a Leco CHNS-932 microanalyzer and a CE-instruments EA 1110 CHNS-O microanalyzer, respectively. $[Rh(COD)Cl]_2$,[17] and $[HC(SiMe_2Br)_3]$[8] were prepared according to published procedures. *o*-Methoxyaniline employed in the ligand synthesis was distilled prior to use. All other chemicals used as starting materials were obtained commercially and used without further purification.

Preparation of Compounds. $[HC\{SiMe_2NH(2\text{-}MeOC_6H_4)\}_3]$ (1): At 0 °C a solution of $[HC(SiMe_2Br)_3]$ (5.22 g, 12.2 mmol) in diethyl ether (20 mL) was added dropwise to a vigorously stirred solution of 2-methoxyaniline (4.51 g, 36.7 mmol) and triethylamine (3.71 g, 36.7 mmol) in diethyl ether (50 mL). After the addition was completed the reaction mixture was stirred for another 12 h at room temperature. The solution was filtered through Celite and the residue was extracted with diethyl ether (3 × 20 mL). The solvent was removed in vacuo and the pale yellow crude product was recrystallized from diethyl ether (10 mL) at −35 °C to yield 5.61 g (83%) of a colourless powder. ^{1}H NMR (200.13 MHz, C_6D_6, 295 K): δ = 0.43 [s, 18 H, $Si(CH_3)_2$], 0.93 [s, 1 H, $HC(SiMe_2)_3$], 3.27 (s, 9 H, OCH_3), 4.60 (s, 3 H, N*H*), 6.54−6.87 (m, 12 H, aryl hydrogens) ppm. ^{13}C{^{1}H} NMR (50.32 MHz, C_6D_6, 295 K): δ = 2.9 [$Si(CH_3)_2$], 4.6 [$HC(SiMe_2)_3$], 55.1 (OCH_3), 110.6, 115.2, 117.7, 121.8, 137.4, 148.6 (aryl carbons) ppm. ^{29}Si{^{1}H} NMR (39.76 MHz, C_6D_6, 295 K): δ = 1.6 [$Si(CH_3)_2$] ppm. IR (KBr): $\tilde{\nu}$ = 3373 cm^{-1} vs, 3060 w, 2958 m, 2894 w, 2843 w, 2830 w, 1602 vs, 1519 vs, 1909 ww, 1858 ww, 1449 m, 1398 s, 1329 m, 1301 m, 1261 w, 1244 w, 1219 w, 1179 m, 1111 s, 1054 w, 1037 m, 1000 s, 900 vs, 846 vs, 767 w, 744 m, 738 m, 687 vw. $C_{28}H_{43}N_3O_3Si_3$ (553.92): calcd. C 60.71, H 7.82, N 7.59; found C 60.55, H 7.93, N 7.56.

$[HC\{SiMe_2N(Li)(2\text{-}MeOC_6H_4)\}_3]$ (2): *n*-Butyllithium (14 mL, 22.4 mmol of a 1.6 mol/L solution in hexane) was added to a slurry of $[HC\{SiMe_2NH(2\text{-}MeOC_6H_4)\}_3]$ **(1)** (4.13 g, 7.45 mmol) in pentane (50 mL) at −20 °C. The reaction mixture was slowly warmed up to ambient temperature and stirring at room temperature was continued for 2 h. The off white slurry was subsequently refluxed for 15 min and stirred for a further 12 h at room temperature. The reaction mixture was filtered through a G3 frit, washed with pentane (3 × 10 mL) and dried under vacuum to yield 4.00 g (94%) of a colourless, microcrystalline powder. ^{1}H NMR (250.13 MHz, C_6D_6, 295 K): δ = −0.59 [s, 1 H, $HC(SiMe_2)_3$], 0.61 [s, 18 H, $Si(CH_3)_2$], 3.00 (s, 9 H, OCH_3), 6.44 (dd, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.3 Hz, 3 H), 6.58 (dt, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.3 Hz, 3 H), 6.94 (dt, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.3 Hz, 3 H), 7.07 (dd, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.3 Hz, 3 H) ppm. ^{7}Li{^{1}H} NMR (97.21 MHz, C_6D_6, 295 K): δ = −0.4 ppm. ^{13}C{^{1}H} NMR (62.89 MHz, C_6D_6, 295 K): δ = 6.2 [$Si(CH_3)_2$], 12.4 [$HC(SiMe_2)_3$], 54.5 (OCH_3), 109.1, 113.7, 123.2, 123.4, 149.6, 152.8 (aryl carbons) ppm. ^{29}Si{^{1}H} NMR (49.69 MHz, C_6D_6, 295 K): δ = −1.9 [$Si(CH_3)_2$] ppm. $C_{28}H_{40}Li_3N_3O_3Si_3$ (571.72): calcd. C 58.82, H 7.05, N 7.35; found C 58.65, H 6.93, N 7.42.

$[HC\{SiMe_2N(2\text{-}MeOC_6H_4)\}_3SnLi]$ (3): Toluene (30 mL) was added to a mixture of $[HC\{SiMe_2N(2\text{-}MeOC_6H_4)\}_3Li_3]$ **(2)** (1.00 g, 1.75 mmol) and $SnCl_2$ (332 mg, 1.75 mmol) at room temperature. The resulting mixture was sonicated for 6 h at 60 °C and subsequently filtered through Celite. The residue was extracted with hot toluene (2 × 10 mL) and the solvent of the filtrate was evaporated under vacuum. The obtained off white residue was washed with diethyl ether (10 mL) and pentane (2 × 10 mL) and dried under vacuum to give 746 mg (63%) of a colourless, microcrystalline powder. ^{1}H NMR (400.13 MHz, C_6D_6, 295 K): δ = −0.49 [s, 1 H, $HC(SiMe_2)_3$], 0.14, 0.59, 0.62 [s, 18 H, $Si(CH_3)_2$], 3.04, 3.34 (s, 9 H, OCH_3), 6.52 (dd, $^3J_{H,H}$ = 7.9, $^4J_{H,H}$ = 1.2 Hz, 2 H), 6.67 (dd, $^3J_{H,H}$ = 9.7, $^4J_{H,H}$ = 1.5 Hz, 1 H), 6.82 (dt, $^3J_{H,H}$ = 7.9, $^4J_{H,H}$ = 1.8 Hz, 2 H), 6.85 (dt, $^3J_{H,H}$ = 7.9, $^4J_{H,H}$ = 1.4 Hz, 1 H), 6.93 (dt, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.5 Hz, 2 H), 7.01 (dt, $^3J_{H,H}$ = 7.3, $^4J_{H,H}$ = 1.5 Hz, 1 H), 7.34 (dd, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.8 Hz, 2 H), 7.42 (dd, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.5 Hz, 1 H) ppm. ^{7}Li{^{1}H} NMR (77.77 MHz, C_6D_6, 295 K): δ = −0.3 ppm. ^{13}C{^{1}H} NMR (100.61 MHz, C_6D_6, 295 K): δ = 4.9, 5.6, 6.6 [$Si(CH_3)_2$], 8.2 [$HC(SiMe_2)_3$], 55.0, 55.6 (OCH_3), 111.0, 111.6, 120.0, 121.2, 121.6, 123.4, 130.3, 142.5, 143.0, 154.7, 155.1 (aryl carbons) ppm. ^{29}Si{^{1}H} NMR (39.76 MHz, C_6D_6, 295 K): δ = −1.9, −1.2 [$Si(CH_3)_2$] ppm. ^{119}Sn{^{1}H} NMR (93.28 MHz, C_6D_6, 291 K): δ = −96.5 ppm. $C_{28}H_{40}LiN_3O_3Si_3Sn$ (676.53): calcd. C 49.71, H 5.96, N 6.21; found C 49.84, H 5.90, N 5.94.

$[HC\{SiMe_2N(2\text{-}MeOC_6H_4)\}_3Sn(Li)-Rh(\eta^4\text{-}C_8H_{12})(Cl)]$ (4): Toluene (10 mL) was added to a solid mixture of $[HC\{SiMe_2N(2\text{-}MeOC_6H_4)\}_3SnLi]$ **(3)** (380 mg, 0.56 mmol) and $[Rh(COD)Cl]_2$ (139 mg, 0.28 mmol) at room temperature. The orange solution was stirred for a further 12 h at room temperature and subsequently filtered through Celite. The residue was extracted with toluene (10 mL) and the filtrate was dried under vacuum. The obtained yellow residue was washed with pentane (10 mL) and diethyl ether (5 mL) and dried under vacuum to yield 410 mg (79%) of a yellow, microcrystalline powder. ^{1}H NMR (250.13 MHz, C_6D_6, 323 K): δ = −0.51 [s, 1 H, $HC(SiMe_2)_3$], 0.30, 0.40, 0.45 [s, 18 H, $Si(CH_3)_2$], 1.09−1.86 (m, 8 H, allylic hydrogens), 3.51 (s, 6 H, OCH_3), 3.78 (s, 3 H, OCH_3), 3.98 (d, $^3J_{H,H}$ = 2.8 Hz, 2 H, olefinic hydrogens), 4.33 (d, $^3J_{H,H}$ = 2.5 Hz, 2 H, olefinic hydrogens), 6.61−7.41 (m, 12 H, aryl hydrogens) ppm. ^{7}Li{^{1}H} NMR (97.21 MHz, C_6D_6, 295 K): δ = 1.5 ppm. ^{13}C{^{1}H} NMR (62.89 MHz, C_6D_6, 323 K): δ = 5.0 [$Si(CH_3)_2$], 5.6 [br, $Si(CH_3)_2$], 8.1 [$HC(SiMe_2)_3$], 28.0, 33.7 (allylic carbons), 55.0, 55.2 (OCH_3), 63.8 (d, $^1J_{RhC}$ = 13.3 Hz, olefinic carbons), 94.5 (d, $^1J_{RhC}$ = 8.3 Hz, olefinic carbons), 110.7, 110.9, 121.3, 121.8, 122.2, 122.8, 128.1, 130.9, 141.6, 141.8, 155.6, 155.9 (aryl carbons) ppm. ^{29}Si{^{1}H} NMR (49.69 MHz, C_6D_6, 295 K): δ = 1.4, 2.0 [$Si(CH_3)_2$] ppm. ^{119}Sn{^{1}H} NMR (149.19 MHz, C_6D_6, 291 K): δ = −196.3 (d, $^1J_{RhSn}$ = 871.6 Hz, N_3Sn−Rh) ppm. IR (KBr): $\tilde{\nu}$ = 3379 cm^{-1} s, 3068 vw, 2961m, 2834 vw, 2289 vw, 2019

X-ray Crystallographic Study of Compounds 1−4

The X-ray diffraction data were collected on a Nonius KappaCCD diffractometer (**1**, **2**, and **4**) or on an IPDS (STOE) diffractometer (**3**) using Mo-K_α radiation (λ = 0.71073 Å). The Denzo-Scalepack[18] program package or IPDS programs were used for cell refinements and data reduction. A multi-scan absorption correction, based on equivalent reflections (XPREP in SHELXTL v5.1),[19] was applied to the data of **4** (T_{max}/T_{min} 0.26648/0.21770). Structures were solved by direct methods using the SHELXS-97[20] (**1**, **3** and **4**) or SIR-97[21] (**2**) program. All structures were refined with the SHELXL-97[22] program. In **3** hydrogens were located from a difference Fourier map and refined isotropically. In **1**, **2** and **4** hydrogens were placed on an idealized position and constrained to ride on their parent atom. The crystallographic data are summarised in Table 1. The molecular structures of the complexes along with principal bond lengths and angles are presented in Figure 2−5.

CCDC-178729 (**1**), -178730 (**2**), -178731 (**3**) and -178732 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Early Transition Metal Complexes of Triphosphorus Macrocycles

Robert J. Baker,[a] Philip C. Davies,[a] Peter G. Edwards,*[a] Robert D. Farley,[a] Sudantha S. Liyanage,[a] Damien M. Murphy,[a] and Ben Yong[a]

Keywords: Macrocyclic ligands / P ligands / Titanium / Vanadium / Chromium

The reactions of 1,5,9-triethyl-1,5,9-triphosphacyclododecane, [12]aneP_3Et_3, with first-row transition metal halides MCl_3 [M = Ti (**1**), V (**2**), and Cr (**3**)] or their THF adducts are reported. The oxidation of **2** gives the complex ([12]aneP_3Et_3)-$V(O)Cl_2$ (**4**). This is the first example of a phosphane ligand that is *trans* to a vanadyl moiety. Also reported are V^{III} (**5**) and Cr^{III} (**6**) complexes of the pendant ether macrocycles [12]ane$P_3(C_2H_4OEt)_3$ and 12[ane]$P_3(C_3H_6OMe)_3$ respectively. The complexes **1**–**6** have been characterised crystallographically and represent a rare class of phosphane complexes of these metals. The paramagnetic d^1 compounds are characterised by EPR and ENDOR spectroscopy, simulation of which gives valuable structural information of these species in frozen solution. With [12]aneP_3Et_3, Nb^{III} and Nb^{IV} chlorides give air-sensitive materials which could not be fully characterised although by comparison with compound **4**, EPR and ENDOR spectroscopy indicate the principal oxidation product to be ([12]aneP_3Et_3)$Nb(O)Cl_2$ (**7**).

Introduction

Phosphane ligands are known to readily form complexes with late transition metals. Phosphane complexes of the early transition metals, however, are still relatively uncommon and less well studied; this being predominantly due to inherent kinetic lability that limits the opportunity to obtain discrete and well-behaved complexes for further studies. The understanding of appropriate reaction conditions has led to a resurgence of interest in this field.[1] The majority of phosphane complexes of group-5 metals are stabilised by metal−metal interactions.[2] In view of the intrinsic lability of phosphane complexes of these electropositive metals, and the observation that the majority of organometallic derivatives of group-4 and -5 metals are stabilised by cyclopentadienyl and related ligands,[3] we have chosen to take advantage of the macrocyclic coordination effect and to study the coordination chemistry of 1,5,9-trialkyl-1,5,9-triphosphacyclododecane ([12]aneP_3R_3) macrocycles with early transition metals. These phosphane macrocycles[4] also bear a resemblance to the cyclopentadienyl family of ligands in that they can be considered to coordinate in a 6-electron, facial tridentate fashion. Thus the reactivity of complexes of these ligands will be of interest. In this paper we will describe the chemistry of group-4 and -5 metals with [12]aneP_3R_3 ligands and some related chemistry of chromium.

Results and Discussion

M^{III} Complexes (M = Ti, V, Cr)

Complexes of [12]aneP_3Et_3 (1,5,9-triethyl-1,5,9-triphosphacyclododecane) are readily formed by the addition of the ligand to a dichloromethane solution of MCl_3·3THF and are obtained as light blue (Ti), green (V) and blue (Cr) paramagnetic solids. The new compounds and their syntheses are outlined in Scheme 1. The chromium complex is also an intermediate in the synthesis of free [12]aneP_3Et_3 and may be formed by halogen oxidation of the $Cr(CO)_3$ adduct.[4]

The reaction of [12]aneP_3Et_3 with solutions of $TiCl_3$·3THF causes an immediate colour change to pale blue, and crystalline **1** can be isolated in good yield. Analytical and mass spectrometric data are consistent with the formula ([12]aneP_3Et_3)$TiCl_3$, and the magnetic susceptibility indicates a d^1 paramagnet. The crystal structure of **1** is shown in Figure 1 and selected bond lengths and angles are given in Table 1. The structure shows the expected octahedral geometry at the metal centre with the macrocycle capping one face. The complex shows a weak Jahn−Teller distortion, as expected for d^1 Ti^{III}. Although the quality of structural data is poor, one titanium−phosphorus bond appears marginally longer than the other two [2.623(4) Å compared to 2.608(4) Å and 2.609(4) Å] and is *trans* to the longest titanium−chlorine bond [2.371(4) Å compared to 2.331(4) Å and 2.358(3) Å]. There is no evidence of any agostic interactions in the solid-state structure or in the infrared spectrum.

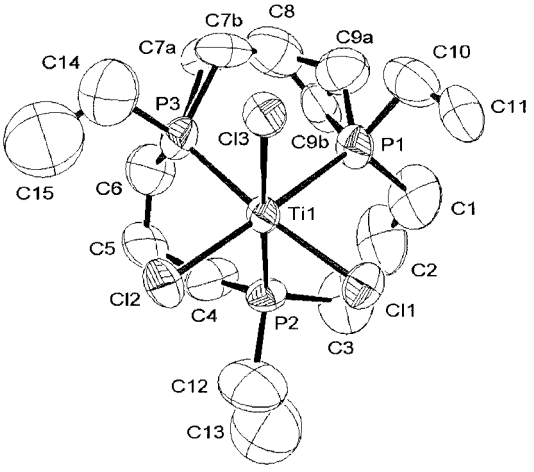

Figure 1. A view of the X-ray crystal structure and atom labelling scheme of ([12]aneP_3Et_3)$TiCl_3$ (**1**); thermal ellipsoids are set at 50% probability

There are a few examples of tris(monophosphane)titanium(III) complexes. $TiCl_3P_3$ (P = PCy_3, P*i*Pr_3, PBu_3) which have been reported to form at low temperatures, but at higher temperatures phosphane dissociation occurs and $TiCl_3P_2$ predominates.[5,6] The tridentate ligand trimpsi {trimpsi = *tert*-butyltris[(dimethylphosphanyl)methyl]silane, *t*BuSi(CH_2PMe_2)$_3$} forms a complex with $TiCl_3$ but the crystal structure has not been reported.[8] All crystallographically characterised (phosphane)Ti^{III} complexes contain cyclopentadienyl ligands except $Ti(BH_4)_3(PMe_3)_2$ which shows M−P distances of 2.571(3) and 2.539(3) Å;[9] All known titanium−phosphane distances fall within the range 2.58±0.07 Å, regardless of oxidation state or coordination number. The P−Ti−P bond angles in **1** are somewhat compressed [average 82.71(13)°] compared to those of **2** and **3** although they are similar to those reported for (trimpsi)$Ti(CO)_4$, and other chelating phosphanes more generally.[8]

The addition of [12]aneP_3Et_3 to VCl_3·3THF gives rise to ([12]aneP_3Et_3)VCl_3 (**2**) which may be isolated as a green crystalline solid in good yield. Analytical and mass spectrometric data confirm the nature of **2** and the magnetic susceptibility is consistent with d^2 V^{III}. Somewhat surprisingly, this complex is almost indefinitely stable to air as a solid, but it is moderately air-sensitive in solution. There are numerous other (phosphane)V^{III} complexes known but these contain mainly monodentate phosphanes and are stabilised by cyclopentadienyl ligands;[10] notable exceptions are [$(Me_2PCH_2CH_2)_2N$]VCl_2 (and organometallic derivatives)[11] and (trimpsi)VCl_3,[7] although neither have been structurally characterised. The crystal structure of **2** is shown in Figure 2, selected bond lengths and angles are given in Table 1. There are no related structurally characterised six-coordinate (phosphane)vanadium(III) complexes with which to make comparisons (five-coordination being more common for simple V^{III} complexes); however, the vanadium−phosphane bond lengths in **2** are similar to

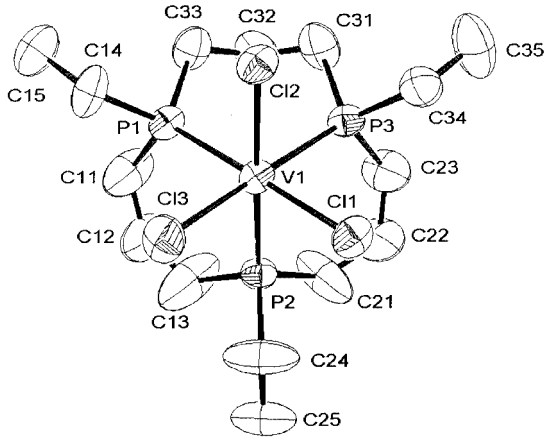

Figure 2. A view of the X-ray crystal structure and atom labelling scheme of ([12]aneP_3Et_3)VCl_3 (**2**); thermal ellipsoids are set at 50% probability

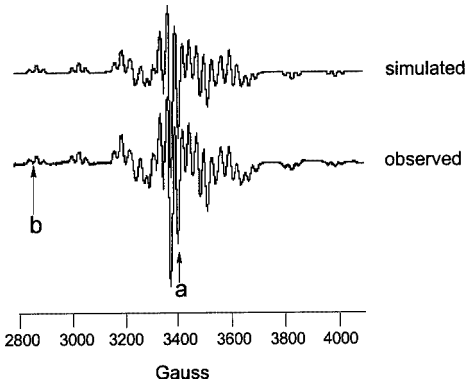

Figure 3. X-band EPR spectrum of **4** recorded in CD_2Cl_2/[D_8]toluene at 10 K

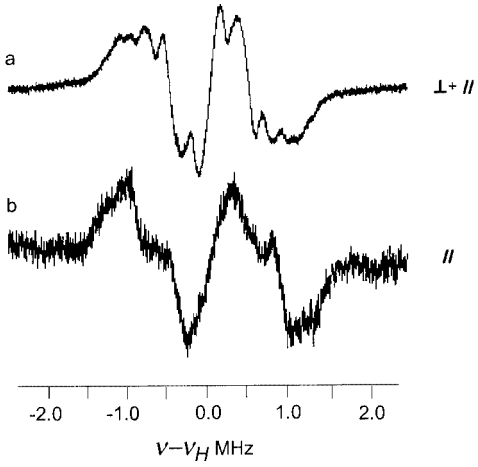

Figure 4. ^{1}H ENDOR spectrum of **4** measured at 10 K; spectrum (a) was recorded at the field position a, and spectrum (b) recorded at field position b, shown in Figure 3

those reported for $VCl_3(PMePh_2)_2$ [av. 2.527(18) Å][12] and $CpVCl_2(PMe_3)_2$ [av. 2.509(1) Å].[13] Although there is no significant difference in the V−P distances between **2** and complexes of monodentate phosphanes, the five-coordinate complexes are coordinatively unsaturated which presumably contributes to their much greater sensitivity to air and moisture. The preferential oxidation of the metal in **2** also suggests that the M−P bond is relatively inert. The majority of monodentate phosphane complexes are labile in solution (as shown by the ease in which they can be replaced with alternative σ-donor ligands), but the macrocyclic coordination effect, coupled with the coordinative saturation appears to make **2** more stable than (phosphane)vanadium complexes previously reported.

The EPR spectrum of **2** does not show a resonance due to the d^2 V^{III} centre. The absence of an observable EPR signal could also be due to relaxation effects which are not quenched even at low temperatures (10 K). Indeed, there are very few examples of EPR-active V^{III} species.[14] Exposure of solutions of **2** to air results in EPR and ENDOR spectra (Figures 3 and 4, respectively, corresponding spin Hamiltonian parameters are listed in Table 2) which can be assigned to the oxidation product of **2**, ([12]aneP_3Et_3)-$V(O)Cl_2$ (**4**). This EPR spectrum displays a characteristic superhyperfine pattern composed of a triplet of doublets, superimposed on the ^{51}V hyperfine lines (most clearly seen in the outer $m_I = \pm 7/2, \pm 5/2$ lines of the $A_{\|}$ component). As discussed in detail below, this superhyperfine pattern demonstrates the presence of two distinct phosphorus environments in **4**. Compound **4** can also be prepared and isolated in high yield by bubbling air through a dichloromethane solution of **2** containing a few drops of water. It is interesting to note that phosphane oxide is not formed by this procedure, again illustrating the relative robustness of these macrocyclic phosphane complexes. In addition to the molecular ion for **4** being observed in the mass spectrum, analytical data is consistent with the formulation and magnetic susceptibility confirms the presence of d^1 V^{IV}.

The deep blue, air-stable **4** has been structurally characterised and its crystal structure is shown in Figure 5, with selected bond lengths and angles shown in Table 1. This is the first reported complex to have an octahedral VO unit with phosphanes as ligands; the only other vanadyl species with ancillary phosphane ligands are $V(O)Cl_2(PPh_3)_2$

(which shows a trigonal-bipyramidal structure with the phosphane ligands in the axial positions[15]) and $V(O)Cl_2[P(SiMe_3)_3]_2$ [16] (which shows the same structural motif). Compound **4** can be described as a distorted octahedral complex with an unusually long V=O bond of 1.836(18) Å, and this is manifested in the infrared spectrum which shows a low-frequency V=O stretch at 936 cm^{-1}. The majority of vanadyl complexes are five-coordinate with a relatively short V=O bond (typically 1.55−1.68 Å) which is often considered to have some triple-bond character. For example $VOCl_2(NMe_3)_2$[17] has a V=O bond length of 1.590(2) Å, whilst in $V(O)Cl_2[P(SiMe_3)_3]_2$ the V=O bond length is 1.602 Å although the $V(O)Cl_2$ unit is disordered. The bond lengths in **4** show that there are two significantly different phosphorus environments (also indicated in the EPR spectrum); the V−P bond *trans* to the oxo group is longer than that to the equatorial phosphane moieties by 0.14(3) Å. Differences in V−P distances are substantially greater than those which may be attributed to Jahn−Teller distortions in **1** and **2**; this is presumably due to the high *trans* influence of the oxygen atom which commonly dictates the predominance of five-coordination in vanadyl chemistry. The relatively weak V=O bond can, in turn also be explained by a *trans* influence of the σ-donor phosphane ligand. This structure is a unique example of a V=O unit with a phosphane ligand in *trans* position and demonstrates the significance of the *trans* influence of a phosphane ligand on a bond that is commonly very strong. Recently, a structure of the first example of an imido ligand *trans* to a phosphane ligand has been reported[18] which also shows an unusually long V−P bond *trans* to the imido functionality [V−P = 2.642(2) Å]. The V−P bond length in $V(O)Cl_2(PPh_3)_2$ is 2.6217(11) Å, but this long bond length was ascribed to steric effects of the ligand. The collective shortening of the M−P bonds (in comparison to **2**) on oxidation to a more electropositive +4 state reflects the expected decrease in ionic radius upon oxidation. This feature may also indicate that the phosphane ligand is predominantly acting as a σ-donor, and back donation to the phosphane π-acceptor orbitals is of less importance.

The deep blue chromium complex ([12]aneP_3Et_3)$CrCl_3$ (**3**) is an intermediate in the liberation of free [12]aneP_3Et_3. The halogen oxidation of the tertiary phosphane macrocycle on a Cr^0 template differs to that of the molybdenum complex reported previously. Addition of chlorine to a solution of ([12]aneP_3Et_3)$Cr(CO)_3$ yields the chromium(III) complex ([12]aneP_3Et_3)$CrCl_3$, whereas under the same conditions, the molybdenum template yields seven-coordinate ([12]aneP_3Et_3)$Mo(CO)_2Cl_2$. In contrast, the secondary phosphane macrocycle complex ([12]aneP_3H_3)$Cr(CO)_3$ forms an octahedral dicarbonyl(halo)Cr^{II} halide complex.[4] Presumably the greater σ-donor ability of the tertiary phosphane macrocycle is more able to stabilise the higher oxidation state in **3**. Similar halogen oxidations of tricarbonylCr^0 complexes of linear triphosphanes have been reported to result in oxidation of the metal atom with loss of all carbonyl ligands but also with concomitant oxidation of the phosphane ligand.[18] Compound **3** can also be synthesised

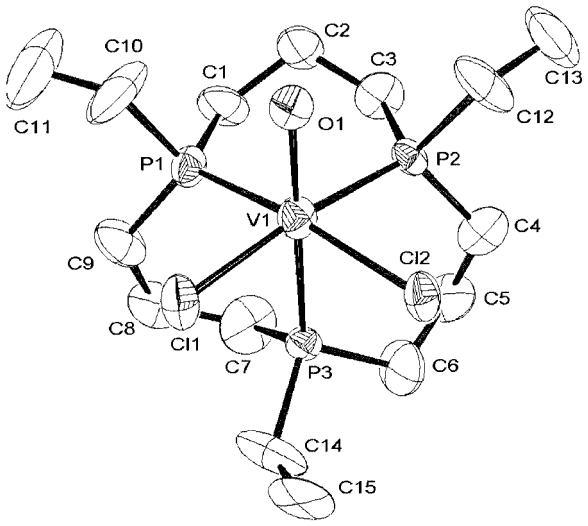

Figure 5. A view of the X-ray crystal structure and atom labelling scheme of ([12]aneP_3Et_3)$V(O)Cl_2$ (**4**); thermal ellipsoids are set at 50% probability

by the addition of [12]aneP_3Et_3 to a suspension of $CrCl_3(THF)_3$; crystals isolated by either method give rise to satisfactory analytical, mass spectrometric and magnetic susceptibility data.

The crystal structure of **3** is shown in Figure 6 and selected bond lengths and angles are shown in Table 1. The structure shows the macrocycle facially capping an octahedral metal atom, as expected. The average Cr−P bond length is 2.447(3) Å, whilst the average Cr−Cl bond length is 2.337(2) Å and variations in these distances are less than for **1** and **2** as might be expected for a d^3 metal centre. They are also similar to those reported for *fac*-[$CrCl_3$(tripod)] [Cr−P 2.456(2) Å (av.); Cr−Cl 2.306(2) Å (av.)] [tripod = $MeC(CH_2PMe_2)_3$][19] and *mer*-[$CrCl_3\{P(CH_2CH_2PPh_2)_3\}$] [av. Cr−P and Cr−Cl are 2.451(5) and 2.306(5) Å, respectively].[20] The average P−Cr−P angles in **3** [91.02(8)°] are close to the ideal values for an octahedron, unlike those in *fac*-[$CrCl_3$(tripod)] [83.47(7)°]. This difference indicates a greater flexibility in the macrocycle compared to the tripodal phosphane; restricted flexibility in tripodal ligands of this type has previously been commented on.[19]

Addition of [12]aneP_3R_3 to solutions of $TiCl_4$, $ZrCl_4$, and $HfCl_4$ resulted in coordination of the macrocycle (verified by ^{31}P NMR spectroscopy) although tractable materials could not be isolated. In the case of Zr and Hf, singlets with relatively small coordination chemical shifts were observed ($\Delta\delta$ = 15, 16 ppm, respectively) which showed only a small and linear temperature dependence and remained unchanged upon addition of excess ligand (indicating the absence of facile ligand exchange processes).

M^{III} Complexes of Pendant Ether Macrocycles

We have previously reported the synthesis of a series of ([12]aneP_3R_3)$M(CO)_3$ complexes (M = Mo, Cr; R = alkyl chain with a pendant donor function).[21] Oxidation of these chromium compounds with chlorine gives rise to ([12]aneP_3R_3)$CrCl_3$ (R = $H_3COC_3H_6$, $C_2H_5OC_2H_4$) in

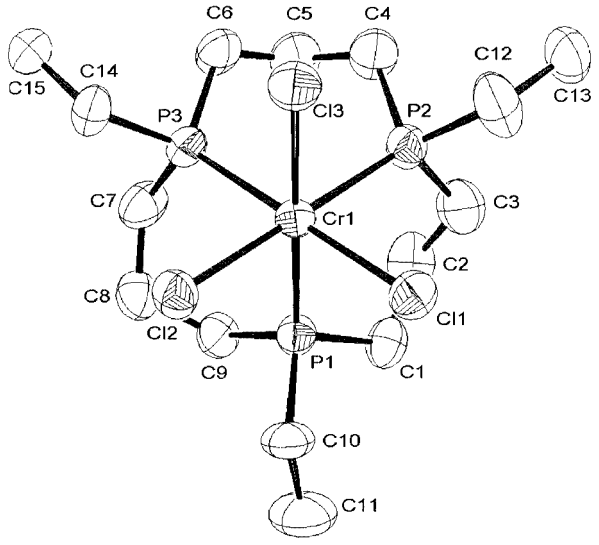

Figure 6. A view of the X-ray crystal structure and atom labelling scheme of one of the two independent molecules of ([12]aneP_3-Et_3)$CrCl_3$ (**3**); thermal ellipsoids are set at 50% probability; pyridine of crystallisation is omitted for clarity

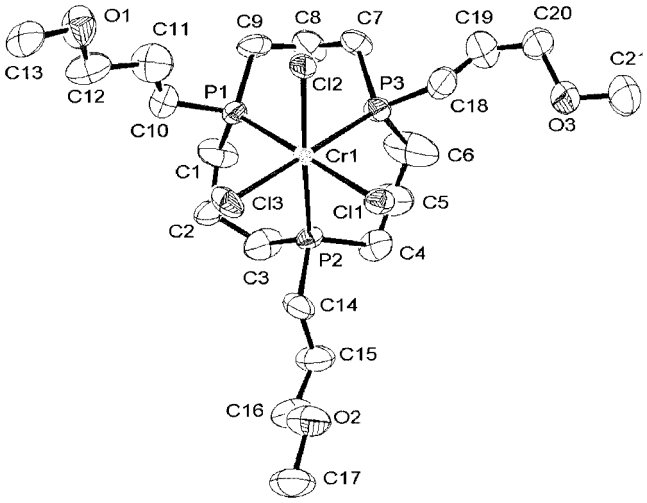

Figure 7. A view of the X-ray crystal structure and atom labelling scheme of {[12]aneP_3($C_3H_6OMe)_3$}$CrCl_3$ (**5**); thermal ellipsoids are set at 50% probability

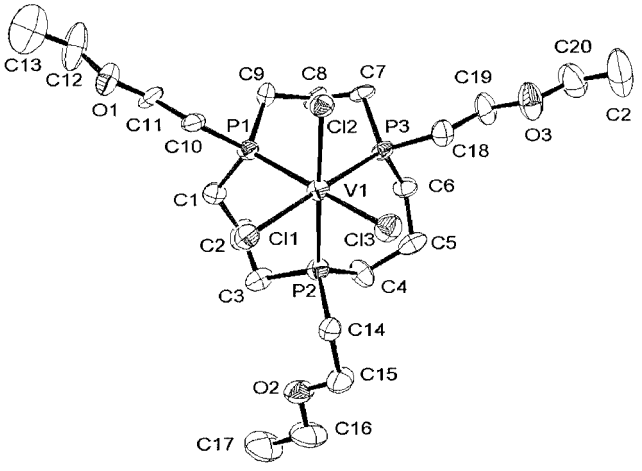

Figure 8. A view of the X-ray crystal structure and atom labelling scheme of {[12]aneP_3($C_2H_4OEt)_3$}VCl_3 (**6**); thermal ellipsoids are set at 50% probability

good yield. The crystal structure of [1,5,9-tris(3-methoxypropyl)-1,5,9-triphosphacyclododecane]chromium trichloride (**5**) is shown in Figure 7 and selected bond lengths and angles are given in Table 1. The structure (bond lengths and angles) is very similar to that of **3** which is not unexpected. Liberation of the macrocycle by digestion in strong base gives rise to the free macrocycle stereospecifically and in good yields. Reaction of the ethoxyethyl pendant donor macrocycle with $VCl_3(THF)_3$ gives rise to the green solid **6** that is similar to **2**. The crystal structure is shown in Figure 8 and selected bond lengths and angles are given in Table 1. The vanadium atom is facially capped by the macrocycle and the pendant donor atoms are well away from the metal centre, indicating that there is no bonding interaction in the solid state. The structural features are very similar to those of **2**. Attempts to force coordination of at least one pendant arm by halide abstraction have so far proved unsuccessful.

Nb^{III} and Nb^{IV} Complexes

The addition of 1 mol-equiv. of [12]aneP_3Et_3 to a frozen solution of $NbCl_3$(DME) or $NbCl_4(THF)_2$ in dichloromethane followed by warming gives rise to paramagnetic, air-sensitive solutions, manipulation of these caused decomposition (to oily materials) precluding the measurement of reliable characterisation data although EPR spectroscopy of these solutions confirmed the presence of d^2 Nb^{III} and d^1 Nb^{IV}, respectively. The Nb^{IV}-containing solution is reversibly thermochromic, being deep blue at ca. −30 °C and green at ambient temperature (20 °C). These colours are precedented for chloro(phosphane)niobium complexes and could be due to a temperature-dependent monomer/dimer equilibrium since $NbCl_4(dmpe)_2$ is blue[22] whilst $Nb_2Cl_8(PMe_3)_4$ is green.[23] The behaviour of the Nb^{III}-containing solutions is similar to those of **4** in that brief exposure to air gives rise to the loss of a resonance attributable to Nb^{III} and the appearance of a new EPR spectrum that can be attributed to the d^1 Nb^{IV} species **7** (vide infra). Attempts to grow crystals of these Nb compounds failed. Addition of [12]aneP_3Et_3 to $Nb(O)Cl_3(MeCN)_2$ gave rise to an intractable white precipitate which was not further characterised.

EPR and ENDOR Spectroscopy

The EPR spectra of **1** and **4** are shown in Figures 9 and 3, respectively. The spin Hamiltonian parameters for the Ti^{3+} and V^{4+} complexes were obtained by computer simulations (Figures 10 and 3, respectively) and the values used are presented in Table 2. Both systems are characterised by an axial g tensor of the form $g_{\|} > g_{\perp}$ which indicates that the metal ion experiences a tetragonally distorted octahedral environment. The high abundance of ^{51}V (I = 7/2) dominates the spectrum of **4**. The Ti^{3+} and V^{4+} ions have sim-

ilar d^1 electronic structures, and based on the similarities with the g values ($g_\perp = 1.915$ for Ti and 1.984 for V; $g_\parallel = 1.9695$ for Ti and 1.978 for V) both spectra are consistent with a similar crystal-field environment. Therefore, although the EPR spectra appear different, they imply very similar structures and confirm the tetragonal distortion in both **1** and **4**.

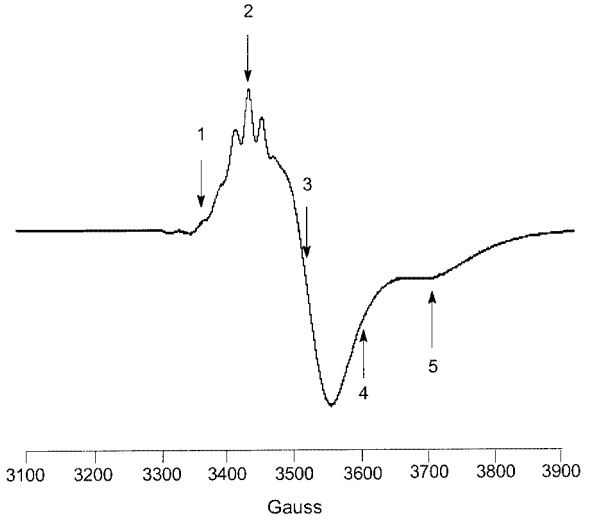

Figure 9. X-band EPR spectrum of **1** recorded in CD_2Cl_2/[D_8]toluene at 10 K

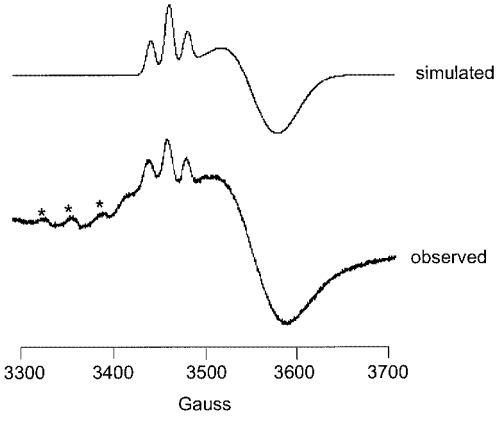

Figure 10. Computer simulation of the X-band EPR spectrum of **1**; the peaks marked * in the experimental spectrum are due to artefacts caused by the inhomogeneous nature of the sample or impurities in the complex

Due to the unpaired d^1 electron not being completely delocalised in the metal d orbitals, a weak superhyperfine interaction with the surrounding ligands can be observed; this is most clearly evident in the vanadyl spectrum (Figure 3). The outer ^{51}V hyperfine lines in Figure 3 clearly reveal a pattern composed of a triplet of doublets and this originates from the weak coupling between the d^1 electron and two equivalent phosphane moieties, and a smaller coupling to a third phosphorus nucleus. The two equivalent phosphane moities produce the triplet pattern while the third remote phosphorus nucleus creates the smaller doublet structure. Thus, the unpaired spin of the V^{4+} ion is delocalised onto the surrounding phosphorus nuclei, two of which are equivalent while the third is slightly more distant, a structural feature also observed in the crystalline state by X-ray crystallography. This EPR spectrum looks remarkably similar to that reported for $VOCl_2(PEt_3)_2$, except for the presence of the weak coupling to the third phosphorus atom, whilst the g and A values are almost identical.[13] The EPR spectrum of **4** was sufficiently resolved, that accurate values of the ^{31}P superhyperfine tensors could be obtained. The values of $^{P}A_\parallel = 24.5$ G, $^{P}A_\perp = 27$ G for the two equivalent phosphane moities and $^{P}A_\parallel = 6$ G, $^{P}A_\perp = 6.1$ G for the third inequivalent P nucleus, were tested by computer simulation (Figure 3). It was necessary to introduce a small contribution from two equivalent Cl nuclei in order to improve the quality of the fit. The satisfactory fit between the experimental and simulated spectra confirm the accuracy of the assignments (Table 2). These superhyperfine couplings were subsequently used to estimate the extent of electron delocalisation onto the P nuclei, and the results of this analysis are given in Table 3.

Based on the spin Hamiltonian parameters used in the simulations, we can suggest that the two chlorine nuclei are virtually equivalent and therefore approximately equidistant from the V centre. The s and p orbital spin density on the Cl nuclei is also found to be appreciably larger compared to the P nuclei (Table 3). This indicates, to a first approximation, that the V−Cl distances are slightly shorter compared to the V−P distances (as demonstrated from the crystal structures) and thereby produce a larger superhyperfine interaction. Although the spin densities are higher on ^{35}Cl, the A_O and B_O values for ^{31}P are larger than ^{35}Cl, so that a larger ^{31}P splitting is observed in the spectrum.

The EPR spectrum for the Ti^{3+} complex **1** was less well resolved and the lines significantly broader, so only the larger superhyperfine interaction with the phosphorus nuclei could be simulated with any degree of accuracy (seen as a triplet in the $g_\parallel$ region i.e. position 2 in Figure 9). The spin Hamiltonian parameters used in the simulations are given in Table 2. As for the vanadium case discussed above, two of the phosphane nuclei appear to be equivalent, while the third one was not resolved, presumably in part due to a relatively small superhyperfine coupling consistent with a tetragonally distorted structure. Again this feature is also confirmed by X-ray crystallography.

Electron nuclear double resonance (ENDOR) measurements were also made on **1** and **4** and the results are shown in Figures 11 and 4, respectively. Although the EPR spectrum of **4** was well resolved, it was not sufficiently intense to allow detailed ENDOR measurements to be made. The ^1H ENDOR spectra, measured at the field positions marked a and b in Figure 3, are shown in Figure 4. However, the titanium EPR spectrum (1), was sufficiently intense that a detailed magnetic angle selected ENDOR analysis could be performed as shown in Figure 11.

The ENDOR spectra of **1** and **4** (Figures 11 and 4, respectively) were recorded at positions corresponding to the z axis of the EPR framework (i.e. in **4** this is the V=O bond direction), while the perpendicular direction refers to the xy

Table 3. Calculated spin densities on surrounding nuclei for **1**, **4**, and **7**

Complex	Nucleus	A_O [G]	B_O [G]	a_{iso} [G]	B [G]	C_S^2	C_P^2	Spin density
1	$^{31}P \times 2$	3631	102	20.3	0.633	0.559%	0.62%	1.18%
4	$^{31}P \times 2$	3631	102	26.1	0.833	0.72%	0.816%	1.53%
	$^{31}P \times 1$	3631	102	6.0	0.05	0.16%	0.05%	0.21%
	$^{35,37}Cl \times 2$	1665	48.6	2.03	0.966	0.12%	1.98	2.1%
7	$^{31}P \times 2$	3631	102	26.6	1.66	0.72%	1.62%	2.024%

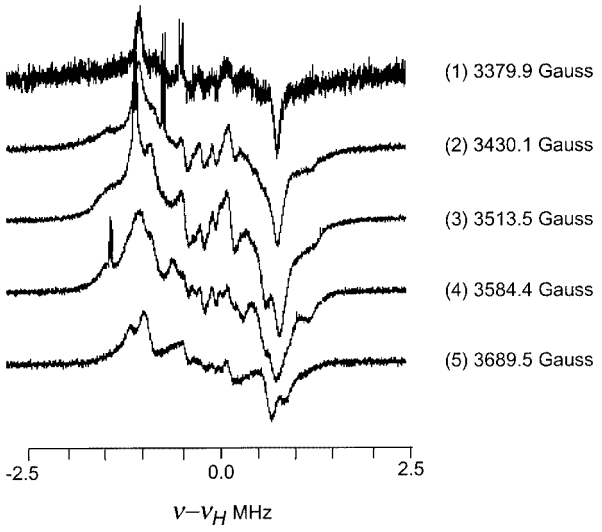

Figure 11. ^1H ENDOR spectra of **1** recorded at 10 K in CD_2Cl_2/[D_8]toluene; the spectra marked (1)−(5) were recorded using the static field positions of 3379.9 G (1), 3430.1 G (2), 3513.5 G (3), 3584.4 G (4), 3689.5 G (5), as shown in Figure 9

plane. In both ENDOR spectra, strong couplings (of approx. 1 MHz) and smaller, more poorly resolved inner couplings of less than 0.5 MHz are observed. It is interesting to note that the ENDOR spectra are slightly different for both samples. In the vanadium case a strong peak is clearly visible with a coupling of about 1 MHz but a distinctive shoulder at about 1.3 MHz, can also be seen (Figure 4, b). Based on the structures of the two complexes, two dominant groups of protons are expected, corresponding to the protons of the cyclododecane ring and those of the ethyl groups. The former set of protons are closer to the V nucleus and would therefore be expected to produce the larger ENDOR coupling compared to the more remote ethyl groups. It may therefore be suggested that the strong coupling of ca. 1 MHz corresponds to the cyclododecane protons while the inner and less well-resolved couplings of ca. 0.5 MHz are due to the ethyl groups. The differences between the titanium and vanadium ^1H ENDOR spectra are very small, however, and the implied inequivalency of the CH_2 protons cannot be confirmed by alternative spectroscopic methods (e.g. by IR spectroscopy). The ENDOR spectrum measured at position 2 in Figure 9 refers to a position in which the magnetic field is pointing "off-axis", between the z direction and the xy plane. In this case, the ENDOR spectrum becomes much more complicated as several molecular orientations are selected simultaneously, and very careful simulation is needed in order to assign each coupling to a specific CH_2 group.

The EPR spectrum of **7** (Figure 12) is strikingly similar to that of ([12]aneP_3Et_3)V(O)Cl_2 (**4**). The shape of the spectrum and the spin Hamiltonian parameters reveal that the symmetry and electronic configuration of the metal atoms must be analogous in both cases, i.e. it indicates that the overall structural features are very similar to those of ([12]aneP_3Et_3)V(O)Cl_2. The presence of two equivalent phosphane moieties is again demonstrated by the characteristic triplet pattern discussed above for **4** (Table 2), but unfortunately the slightly more distant phosphane group cannot be simulated with any degree of accuracy due to the larger EPR linewidths. The g values for the vanadyl and niobyl complexes (Table 2) are both axial in nature, and the average g values for the niobyl complex are slightly lower, which is expected considering the larger spin-orbit coupling constant for Nb compared to V. The similar shifts in g values ($\Delta g = 0.006$ for V and $\Delta g = 0.007$ for Nb), however, indicates similar symmetries for both ions. These values also suggest that the unpaired electron is either in the d_{xy} or $d_{x^2-y^2}$ orbital.

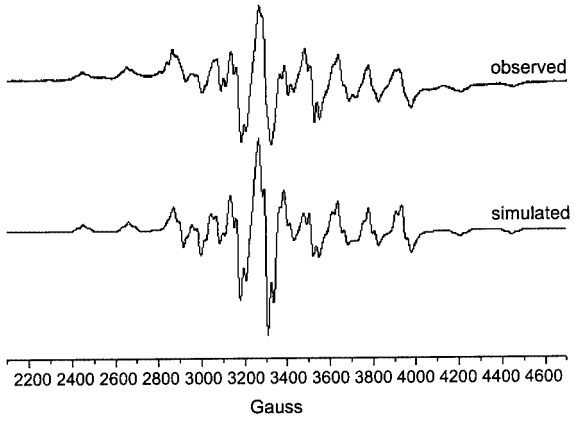

Figure 12. X-band EPR spectrum of **7** recorded in CD_2Cl_2/[D_8]toluene at 10 K

The superhyperfine interaction of the Nb nucleus with the ^{31}P nuclei can be analysed in order to extract some spatial information on the M−P (M = V, Nb) distances. This can be done by breaking the hyperfine tensor into an isotropic (a_{iso}) and anisotropic (B) component. The anisotropy is very small compared to the isotropic coupling and it can be accounted for on the basis of dipolar interactions

through space between the unpaired electron and the phosphorus nuclei. This assumption is reasonable as little backbonding is expected with the d^1 metal ions.

A simple point dipole model can be used to calculate the contribution to the anisotropic coupling from dipolar sources. With this approximation, the distance between the metal centre (V and Nb) and the interacting phosphane nucleus can be determined. Using this model and a calculated anisotropic term of 1.32 G (3.6174 MHz) and 1.66 G (4.5956 MHz) for the vanadyl and niobyl compounds, respectively, the estimated distances are calculated as V−P = 2.388 Å and Nb−P = 2.587 Å. The shortest experimentally determined V−P bond length is 2.408(10) Å (from the crystal structure of **4**), which is in good agreement with the calculated bond length based on the EPR data. The resolution of the third inequivalent P nucleus was not sufficiently good to allow an accurate estimation of the V−P bond length for this more remote phosphane group. On the basis of the EPR spectrum, its satisfactory simulation and the metrical parameters obtained, we tentatively assign the formula ([12]aneP_3Et_3)Nb(O)Cl_2 to **7**. Although incompletely characterised, **7** is only the second example of an oxo(phosphane)niobium(IV) complex, the first being Nb(O)$Cl_2(PEt_3)_2$.[24] Crystals of **7** were not obtained, and there are only three crystallographically characterised examples of phosphane complexes containing Nb=O, these being compounds of d^0 Nb^V. Nevertheless, the M−P bond length is 2.64(3) Å in Nb(O)$Cl_3(PMe_3)_3$,[25] and 2.708 Å in [Et_3PH][Nb(O)$Cl_4(PEt_3)$],[15] which compare well with the calculated bond length in **7** from the EPR data.

Conclusion

We have demonstrated that the ligand [12]aneP_3Et_3 forms relatively robust six-coordinate complexes with early transition metals. We have reported the structural characterisation of a range of complexes and shown that the EPR and ENDOR spectra of these compounds are highly informative and not only confirm the structural features determined by crystallography but also give substantial insight into the nature of paramagnetic niobium species for which other reproducible data could not be obtained. The first complex with a phosphane ligand *trans* to an oxo function in V^{IV} has been reported and the ligand effect on the V=O bond has been investigated. Preliminary results indicate that the complexes described are reactive towards alkylating agents, other metathetical reagents and are active in alkene polymerisation catalysis; details of these studies will be published in due course. The results also imply that the macrocycle coordination effect helps stabilise these phosphane complexes in relatively regular six-coordinate environments, whereas for higher coordination numbers, this effect is not as substantial as expected and tractable seven-coordinate d^0 M^{IV} complexes could not be obtained. This might result from the flexibility of the 12-membered macrocycle as well as stereochemically nonrigid (and intrinsically more reactive) seven-coordination. Consequently, smaller ring macrocycles might be expected to form more stable systems and the study of 9-,[26,27] 10-,[28] and 11-membered triphosphorus macrocycles is in progress.

Experimental Section

All reactions were carried out under nitrogen (purified by passing through a CrO column) using standard Schlenk line techniques or in a Vacuum Atmospheres drybox. Solvents were dried with standard drying agents and distilled immediately before use. Petroleum ether had a boiling range of 40−60 °C. The Zr, Hf, and Nb halides were sublimed before use. All other chemicals were dried over molecular sieves (liquids) or used as received (Aldrich). The compounds $TiCl_4(THF)_2$, $ZrCl_4(THF)_2$, $HfCl_4(THF)_2$, $TiCl_3(THF)_3$, $VCl_3(THF)_3$,[29] $NbCl_4(THF)_2$, $NbCl_3$(DME),[30] Nb(O)Cl_3(MeCN)$_2$,[26] [12]aneP_3Et_3,[4] [12]ane$P_3Et_3Cr(CO)_3$, and ([12]aneP_3R_3)$Cr(CO)_3$ (R = $CH_3OC_3H_6$. $C_2H_5OC_2H_4$)[22] were prepared by literature methods. ^1H and ^{13}C NMR spectra were recorded with a Bruker DPX400 spectrometer operating at 400.13 MHz and 100 MHz, respectively. ^{31}P NMR spectra were acquired using a JEOL FX90Q at 36.2 MHz and referenced to 85% H_3PO_4. Magnetic moments were determined by the Evans method[31] or by the Gouy method with a Johnson Matthey magnetic susceptibility balance; an experimental diamagnetic correction was measured for the free phosphane macrocycles and applied. Mass spectra (EI) were recorded with a VG Platform II Fisons mass spectrometer. Infrared spectra were recorded with a Nicolet 510 FT-IR spectrometer as a nujol mull between CsI plates. The EPR/ENDOR spectra were recorded with a CW X-band Bruker ESP 300E series spectrometer equipped with an ESP360 DICE ENDOR unit, operating at 12.5 kHz field modulation in a Bruker EN 801 cavity. All spectra (EPR and ENDOR) were recorded at 10 K using an Oxford instruments ESR 900 continuous flow He Cryostat; the ENDOR spectra were obtained at 4 mW microwave power, 8 dB RF power from a ENI A-300 RF amplifier again at 12.5 kHz modulation frequency. Computer simulations were carried out using Bruker's Simfonia program.

([12]aneP_3Et_3)$TiCl_3$ (1): To a purple solution of $TiCl_3(THF)_3$ (0.20 g, 0.51 mmol) in dichloromethane (20 mL) was added a solution of [12]aneP_3Et_3 (0.15 g, 0.51 mmol) in dichloromethane (10 mL). The solution immediately turned blue and a fine grey precipitate was observed. This was stirred for 2 h, filtered and the solvent removed in vacuo. The blue residue was washed with petroleum ether (3 × 10 mL) and recrystallised from dichloromethane/petroleum ether at −30 °C to give (0.21 g, 90%) of **1**. Crystals suitable for X-ray analysis were obtained by vapour diffusion of petroleum ether into a dichloromethane solution. $C_{15}H_{33}Cl_3P_3Ti$ (460.6): calcd. C 39.09, H 7.17; found: C 38.7, H 7.0. IR (nujol): $\tilde{\nu}_{max}$ = 1377 (sh), 1072 (br), 802 (br), 376 (br), 257 (w), 210 (w) cm^{-1}. MS: m/z = 460.57 [M^+]. μ_{eff} = 1.82 BM.

([12]aneP_3Et_3)VCl_3 (2): To a red solution of $VCl_3(THF)_3$ (0.20 g, 0.50 mmol) in dichloromethane (20 mL) was added a solution of [12]aneP_3Et_3 (0.15 g, 0.50 mmol) in dichloromethane (10 mL). The solution immediately turned green and a light green precipitate was observed. This was stirred for 2 h, filtered, and the solvent removed in vacuo. The green residue was washed with petroleum ether (3 × 10 mL) and recrystallised from dichloromethane/petroleum ether at −30 °C to give **2** (0.22 g, 94%). Crystals suitable for X-ray analysis were obtained by vapour diffusion of petroleum ether into a dichloromethane solution. $C_{15}H_{33}Cl_3P_3V$ (463.6): calcd. C 38.67, H 7.52; found: C 38.4, H 7.5. IR (nujol): $\tilde{\nu}_{max}$ = 1269 (sh), 1121

([12]aneP_3Et_3)$CrCl_3$·0.5py (3). Method 1: Cl_2 was bubbled through a solution of ([12]aneP_3Et_3)$Cr(CO)_3$ (2.0 g, 4.5 mmol) in dichloromethane (50 mL) for 5 min. This was stirred for 4 h and the solvent removed in vacuo to yield a violet microcrystalline solid that was recrystallised from dichloromethane to give blue **3** (1.88 g, 90%). Crystals suitable for X-ray analysis were obtained by vapour diffusion of toluene into a pyridine solution of **3**. $C_{17.5}H_{35.5}Cl_3CrN_{0.5}P_3$ (504.3): calcd. C 41.67; H,7.04; found: C 41.7, H 7.2. IR (nujol): $\tilde{\nu}_{max}$ = 310 (br), 240 (w) cm^{-1}. μ_{eff} = 3.66 BM. **Method 2:** To a purple suspension of $CrCl_3(THF)_3$ (0.10 g, 0.25 mmol) in dichloromethane (20 mL) was added a solution of [12]aneP_3Et_3 (0.08 g, 0.51 mmol) in dichloromethane (10 mL). The solution immediately turned blue. This was stirred for 4 h, filtered and the solvent removed in vacuo. The blue residue was washed with petroleum ether (3 × 10 mL) and recrystallised from dichloromethane/petroleum ether to give **3** (0.07 g, 65%).

([12]aneP_3Et_3)$V(O)Cl_2$ (4): To a dichloromethane solution of **2** (0.10 g, 0.22 mmol) was added distilled water (5 mL) and this was stirred for 2 h whilst air was slowly bubbled through the solution. The solution was dried with CaH_2, filtered, concentrated to 5 mL and cooled to −30 °C. The resulting blue crystals were isolated and dried in vacuo to yield **7** (0.08 g, 86%). Crystals suitable for X-ray analysis were obtained by slow cooling of a saturated petroleum ether solution. $C_{15}H_{33}Cl_2OP_3V$ (444.2): calcd. C 37.56, H 6.93; found: C 37.0, H 6.2. IR (nujol): $\tilde{\nu}_{max}$ = 936(V=O) cm^{-1}. MS: m/z = 444.15 [M$^+$]. μ_{eff} = 1.65 BM.

([12]aneP_3R_3)$CrCl_3$ (5): Cl_2 was bubbled through a solution of ([12]aneP_3R_3)$Cr(CO)_3$ (R = $CH_2CH_2CH_2OCH_3$) (2.0 g, 3.5 mmol) in dichloromethane (50 mL) for 5 min. This was stirred for 4 h and the solvent removed in vacuo to yield a deep blue microcrystalline solid that was recrystallised from dichloromethane/petroleum ether to give **9** (1.79 g, 86%). $C_{24}H_{52}Cl_3CrO_3P_3$ (639.9): calcd. C 42.25, H 7.28; found: C 42.7, H 7.3. IR (nujol): $\tilde{\nu}_{max}$ = 312 (br), 220 (w) cm^{-1}. μ_{eff} = 3.59 BM.

([12]aneP_3R_3)VCl_3 (6): To a red solution of $VCl_3(THF)_3$ (0.20 g, 0.50 mmol) in dichloromethane (20 mL) was added a solution of [12]aneP_3R_3 (R = $CH_2CH_2OCH_2CH_3$) (0.22 g, 0.50 mmol) in dichloromethane (10 mL). The solution immediately turned green and a light green precipitate was observed. This was stirred for 2 h, filtered and the solvent removed in vacuo. The green powder was recrystallised from dichloromethane/petroleum ether at −30 °C to give **6** (0.25 g, 84%). Crystals suitable for X-ray analysis were obtained by vapour diffusion of petroleum ether into a dichloromethane solution. $C_{24}H_{52}Cl_3O_3P_3V$ (638.9): calcd. C 45.17, H 8.20; found: C 45.0, H 8.3. IR (nujol): $\tilde{\nu}_{max}$ = 277 (w), 242 (w), 214 (w) cm^{-1}. MS: m/z = 638.86 [M$^+$]. μ_{eff} = 2.51 BM.

([12]aneP_3Et_3)$Nb(O)Cl_2$ (7): To $NbCl_3$(DME) (0.10 g, 0.34 mmol), frozen in liquid nitrogen, was added a solution of 12[ane]P_3Et_3 (0.10 g, 0.34 mmol) in dichloromethane (20 mL) and the mixture allowed to warm to room temperature with gentle agitation. The resulting dark green solution was filtered through Celite. The resulting green solution (in a Schlenk flask) was briefly exposed to air (by removing and replacing the stopper) and the inert gas was immediately reinstated. This solution was transferred to an EPR tube and the spectrum run immediately. Attempts to prepare samples of **7** by addition of water and air (as for compound **4**) resulted in complete decomposition and dissociation of the macrocyclic ligand (by NMR).

X-ray Crystallography: The crystal data for compounds **1**−**6** are given in Table 4. For compounds **1**, **2**, **4**−**6**, intensity data were collected with a FAST TV area detector diffractometer at the window of a rotating anode generator, with a molybdenum target [λ(Mo-K_α) = 0.71069 Å] and driven by MADNES[32] software (for **2** and **4**). The structures were solved by heavy atom methods (SHELXS)[33] and refined by full-matrix least squares based on F_o^2 (SHELXL 93).[34] All non-hydrogen atoms are anisotropic with H-atoms included in calculated positions (riding model) and isotropic displacement parameters which were refined. Diagrams were

drawn with SNOOPI[35] or ORTEP for Windows.[36] Sources of scattering factors are given in ref.[33] For compound **1**, the structure was finally refined to $R = 0.1042$. The quality of the crystal was very poor and it was also a very weak diffractor. One of the three $CH_2CH_2CH_2$ chains was disordered and two of its carbon atoms were refined with partial occupancies. All non-hydrogen atoms were refined anisotropically with ISOR = 0.02 restraints being applied to several carbon atoms. The C−C bond lengths were constrained at 1.52(2) Å. The H atoms of the disordered $CH_2CH_2CH_2$ chain were ignored; all others were included in calculated positions (riding model). For compound **4**, the data were collected with a small and weakly diffracting crystal and refined to a final $R = 0.1012$. The pendant ethyl carbon atoms showed high thermal motion (as is not unexpected for compounds of this nature) and correspondingly large ellipsoids although no positional disorder for these atoms could be satisfactorily modelled. Although the R factors for these two compounds are relatively high, the quality of the structures is adequate to allow comparisons of metal−ligand bond lengths and angles. Data for **3** were obtained with an Enraf−Nonius CAD4 diffractometer. The structure was solved by direct methods and refined on F^2 by full-matrix least squares (SHELX97)[37] using all unique data. Empirical absorption corrections were carried out by the DIFABS method.[38] CCDC-171468 (**1**), -143583 (**2**), -171469 (**3**), -143586 (**4**), -171471 (**5**), and -171470 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: N ligands / Hydrogen bonds / Ambidentate ligands / X-ray Crystallography / Cations

The synthesis and structural chemistry of a series of new divalent transition metal complexes of the bis-bidentate ligand 3,3′-diamino-2,2′-bipyridine (**L1**) and its dication $\mathbf{L1H_2}$ are described. Ligand **L1** reacts with salts of divalent transition metals to afford the (1:1) metal-ligand complexes (**2a**–**2d**) as well as the tris complexes (**3a**–**3f**). All complexes were fully characterised by spectroscopic methods and the following compounds $[Cu(\mathbf{L1})Cl_2]_2$ (**2a**), $[Cu(\mathbf{L1})(OAc)_2]$ (**2b**), $[Zn(\mathbf{L1})_3][OTf]_2$ (**3a**), and $[Zn(\mathbf{L1})_3][ZnCl_4]$ (**3e** and **3f**) were structurally characterised. Results from single crystal X-ray diffraction measurements indicate that formation of an intramolecular hydrogen bond between the two amino groups allows the ligand to coordinate divalent metal ions through their diimine binding sites. Furthermore, the structure of compound **2a** reveals that it crystallises as a dimer in which each copper ion is bound to two pyridine nitrogen atoms and two chloride ions in a distorted square planar arrangement, with a long axial contact from a neighbouring amino group completing the approximately square-pyramidal geometry at Cu^{II}. Complexation of this ligand in acidic conditions afforded the compound $[Cu(\mathbf{L1H_2})Cl_4]$ (**4**), as well as the two salts $[\mathbf{L1H_2}][CuCl_4]$ (**5a**) and $[\mathbf{L1H_2}][ZnCl_4]$ (**5b**). All three compounds have been structurally characterised and results indicate that the dication ($\mathbf{L1H_2}$) displays a different coordination preference for the chelation of metal ions. In all three cases, both of the heterocyclic N atoms of the ligand are protonated, thus preventing chelation to the metal ion, although for compound **4** crystallographic studies reveal that the two amino functionalities coordinate the copper(II) ion.

Introduction

The construction of multicomponent molecular systems represents an important first step in the development of novel molecular and supramolecular systems for catalysis, light-to-energy conversion, and molecule-based devices. For systems in which the components are transition metal ions, the emphasis lies in the design of the bridging ligands as well as on the choice of the metal ions. Consequently, the careful choice of bridging ligands, as suitable linkers for transition metal ions in a wide variety of oxidation states, is currently viewed as a critical element in successful design. One of the simplest but most widely used organic linkers is the bidentate ligand 2,2′-bipyridine. In recent years, this ligand has been incorporated into a huge diversity of supramolecular inorganic architectures including helices, ladders, grids and chains.[1] Furthermore, chemical modification of the 2,2′-bipyridine ligand by the introduction of additional functionality at the 4-, 5- and 6-positions is well-known, and the coordination chemistry of these compounds has been actively explored. In contrast, however, much fewer 3,3′-disubstituted bipyridines are available and the coordination chemistry of only a small number of such compounds has been studied. This is primarily due to the expectation that van der Waals repulsions between large substituents in the 3,3′-positions could prevent the pyridine rings from adopting a near *cis*-coplanar conformation, rendering them unfavourable ligands for chelation. Nevertheless, small substituents in the 3 and 3′ positions such as methyl groups,[2] carboxylic acids,[3,4] and methyl esters[5] have all been reported not to inhibit the binding of a metal ion to the diimine binding site, despite the fact that the pyridine rings in these systems are indeed displaced from co-planarity by 30−35°. Furthermore, in the early 1980's Rebek et al. were able to successfully exploit the 3,3′-substitution positions for the preparation of a novel crown ether derivative which bound transition metal ions at the diimine site, or alkali metal ions at the crown ether.[6]

Dinuclear complexes in which the metal fragments are joined by an appropriate bridging organic ligand have been of particular interest with a view to the preparation of vari-

ous types of organometallic frameworks. Indeed, the dual coordinating ability of the oxalate ion (ox = $C_2O_4^{2-}$) has made it a particularly versatile bridging species for the controlled self-assembly of one-, two- and three-dimensional inorganic architectures.[7] Along these lines, with a view to prepare novel coordination polymers, we have recently turned our attention to study the coordination behaviour of the potentially ambidentate ligand 3,3′-diamino-2,2′-bipyridine (**L1**). This ligand has two possible modes for binding namely, symmetric and asymmetric (Figure 1).

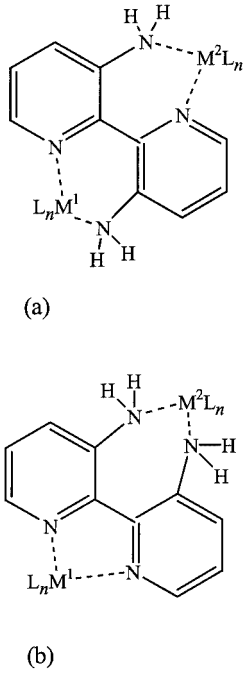

Figure 1. Potential symmetric (a) and asymmetric (b) binding modes of ligand **L1**

Since only one coordination compound incorporating ligand **L1** has been previously characterised by X-ray crystallography,[8] we have primarily set out to investigate the coordination chemistry of this compound and determine: (i) which pair of nitrogen atoms are preferred for coordination, (ii) whether the second pair of nitrogen atoms can contribute to the coordination in any way, and (iii) to what degree the substituents influence the angle between the planes of the pyridine rings.

Results and Discussion

Ligand Synthesis

The synthesis of **L1** has been achieved by two independent routes. The first method involves the preparation of 3,3′-dinitro-2,2′-bipyridine following the Ullman coupling procedure, first described by MacBride et al.[9] This was then followed by a reduction step to afford ligand **L1**. Unfortunately, the reaction conditions described by MacBride proved to be problematic, giving poor yields of a very insoluble material that was difficult to purify. After carefully monitoring the progress of the reaction, we found that it was only necessary to heat the reaction mixture for 2.5 h (cf. 15 h in the original literature).[8] The warm reaction mixture could then be poured directly into water and filtered immediately, washing with concentrated ammonia solution. This process essentially removes any insoluble impurities on the sinter, and the product which precipitates from the filtrate on cooling is easily extracted into hot dioxane, giving 3,3′-dinitro-2,2′-bipyridine in good yield. This compound is then readily reduced with Sn^{II}/HCl to afford ligand **L1**. Since the initial preparation of the dinitro precursor proved to be problematic, a second route to **L1** was also investigated. This involves the Ullman coupling of 3-acetylamino-2-chloropyridine following the route of Kaczmarek et al.,[10] followed by acidic hydrolysis to afford **L1** in substantially improved yields.

Syntheses of Metal Complexes of L1

An overview of the prepared metal complexes is provided in Scheme 1.

The complexation reactions can be divided up into three classes: (i) binding to metal salts through the diimine nitrogens, (ii) tris complexation by binding to the diimine nitrogens, and (iii) binding of the bis-protonated ligand $\mathbf{L1H_2}$ to a metal through the amino groups. The first class involves reaction of an acetonitrile solution of the ligand **L1** with one equivalent of a salt of a divalent metal, M^{II} = Cu, Mn, Zn. This afforded a range of complexes with 1:1 ligand-to-metal ratios, namely compounds **2a**−**2e**. From the microanalysis data of complex **2a**, we could deduce that ligand **L1** forms a 1:1 complex with copper(II) chloride, although the crystal structure later revealed that **2a** actually crystallises as an unusual 2:2 centrosymmetric complex of ligand **L1** and copper(II) chloride (Figure 2a).

The ligand **L1** binds copper through the diimine coordination site, and dimers are formed by a pair of bonds from neighbouring amino groups.

Copper(II) acetate forms a variety of structures with unsubstituted 2,2′-bipyridine. The formation of multinuclear systems containing two or three copper ions,[11,12,13] polymers[14] and a mononuclear cation[15] $[Cu(bipy)_2(acetate)]^+$ are facilitated by the possibility of acetate either acting as a bidentate ligand, or using one oxygen atom to bridge two metal centres. To determine in our case whether or not the amino groups of 3,3′-diamino-2,2′-bipyridine would also contribute to the coordination of the copper ion, complex **2b** was prepared and its structure determined by X-ray crystallography. The molecular structure of **2b** is shown in Figure 3.

The diimine binding site of the bipyridine together with two acetate ligands are bound to the copper ion, thus enabling us to conclude that the amino groups are not involved in coordination to the copper ion when the bidentate acetate ligands can each provide two donor atoms.

Reactions of ligand **L1** with manganese(II) chloride or manganese(II) bromide also gave compounds with 1:1 metal-to-ligand ratios, although crystals suitable for single crystal X-ray diffraction could not be grown to-date. Never-

theless, we would expect the manganese(II) to favour an octahedral coordination, which could be completed by bridging halides in a similar manner to the salt formed between manganese(II) chloride and 2,2′-bipyridine, in which both chlorides bridge two neighbouring Mn^{II} ions.[16] Reactions of ligand **L1** with one equivalent of zinc(II) chloride in acetonitrile yielded complex **2e** whose chemical analysis suggested a 1:1 ratio of ligand to metal salt. These results parallel the reaction of unsubstituted 2,2′-bipyridine with zinc(II) chloride which forms a simple four-coordinate 1:1 complex.[17] In contrast, X-ray diffraction studies showed

that crystals grown from an acetonitrile/ethanol solution of the 1:1 complex **2e** belong to the second class of coordination compounds, i.e. that **3e** is the Zn^{2+} tris complex of **L1** with a tetrachlorozincate counterion. Similarly, crystals grown from **2e** in DMF/methanol were shown by X-ray crystallography to be a DMF solvate **3f** whose asymmetric unit contains three tris complexes each hydrogen bonded to one DMF solvent molecule. The closely related tris complex **3a** was prepared by reaction of zinc(II) triflate with three equivalents of **L1**. From these observations we can conclude that compound **2e** can readily rearrange in solution to afford a tris complex. Reaction of three equivalents of ligand **L1** with copper(II), nickel(II) or cobalt(II) triflates afforded the second series of 3:1 compounds, namely the tris complexes **3b**−**3d**.

Under acidic conditions it is reasonable to expect the coordination chemistry of ligand **L1** to change significantly as the more basic pair of nitrogens is protonated. Judging from the pK_b's of aniline (4.6) and pyridine (5.0) the amino nitrogen atoms would be expected to be slightly more basic; however, the crystalline salts of 3-aminopyridine are protonated on the ring nitrogen atom.[18,19] The pK_b's of the two nitrogen sites are probably quite similar. If the amino groups are protonated, metal ion binding at the diimine site may be disfavoured since there would be repulsions between the two positively charged ammonium groups in the 3- and 3′ positions. Protonation of the ring nitrogen atoms would leave open the possibility of metal ion binding to the amino groups, forming a less favourable seven-membered chelate ring.

Reaction of **L1** with copper(II) chloride in dilute hydrochloric acid yielded a third class of compound, namely complex **4**. In this case, both heterocyclic nitrogen atoms are protonated preventing coordination to the copper and, as a consequence, the two amino groups and four chloride ions are bound to the Cu^{II} completing an octahedral coordination sphere (Figure 4).

On one occasion, isomeric red crystals were also isolated from the preparation of **4**. X-ray crystallography showed that this compound was the tetrachlorocopper(II) salt of the 3,3′-diamino-2,2′-bipyridinediium dication **5a** (Figure 5). The only compound isolated from the reaction of ligand **L1** with zinc(II) chloride in a hydrochloric acid/acetonitrile mixture was shown by X-ray methods to be the corresponding tetrachlorozinc(II) salt **5b** (Figure 5).

Our findings clearly show that the pyridine rings are the favoured binding sites for coordination to divalent transition metal ions. However, by controlling the pH of the reaction mixture, it is possible to coordinate metal ions through the diamino functionality. In theory this ligand can adopt either an asymmetric or symmetric bridging mode for coordination, although the latter mode of binding has not been observed for this ligand to-date. This is in contrast to the closely related ligand 3,3′-dihydroxy-2,2′-bipyridine, which binds Ru^{II} as a mononucleating ligand through its diimine sites as well as in a symmetric "turned-around" mode presenting two N,O-donor sites to two Ru^{II} ions in an ambidentate manner.[20] For both the dihydroxy and the

Figure 5. Compounds **4**, **5a**, and **5b**

diaminobipyridine ligands, the asymmetric mode of binding is unfavourable for dual chelation due to the fact that coordination through the diimine binding site requires an essentially planar arrangement of the two pyridine rings, whereas chelation through the diamino or dihydroxy groups requires it to be substantially twisted. As a consequence, the flexibility of the ligand is limited by the coordination requirements

of the first binding site. In this respect the bipyridine and phenanthroline families of molecules differ quite considerably. The dual chelating ability of the dipyridocatecholate (dpcat) ligand was first reported in 1975 by Balch et al.,[21] and during recent years Ward et al. have prepared dinuclear ruthenium(II) complexes of the ambidentate bridging ligand phenanthroline-5,6-diimine (pdi).[22] In this system coordination through the diamino groups of the bridging ligand is accomplished by their oxidation to the diimine state with the loss of two hydrogen atoms. Complexation by the diaminobipyridine ligand in this manner is highly unlikely since oxidation of the diamino groups would in this case occur at the expense of losing the aromaticity in both of its pyridine rings.

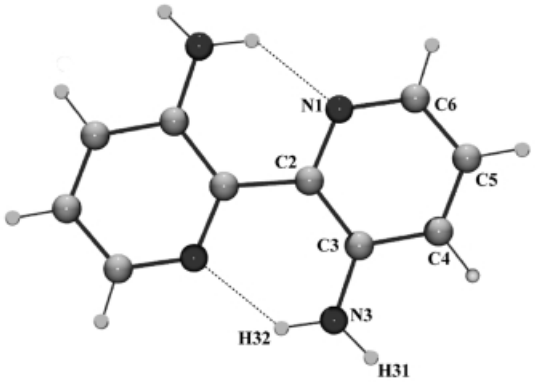

Figure 6. The molecular structure of **L1**; the dotted lines indicate the pair of intramolecular H bonds (N−H···N = 1.948 Å)

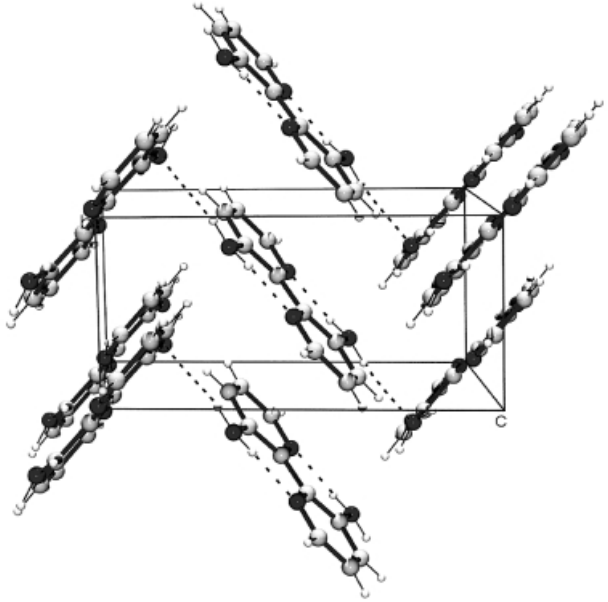

Figure 7. Molecular packing arrangement for **L1**; intra- and intermolecular H-bonding interactions are indicated by dashed lines

X-ray Structural Studies

The X-ray crystal structure of the free ligand **L1** (Figure 6) shows that the free ligand is held in a centrosymmetric *trans* conformation via a pair of intramolecular hydrogen bonds between an amino hydrogen atom and the heterocyclic nitrogen atom of the opposite ring [N−H···N = 1.948(18) Å, N−H···N = 132.7(14)°].

The molecules are packed so that the second amino hydrogen atom can participate in an intermolecular hydrogen bond to the amino N atom of another molecule, with an N···H bond length of 2.40(2) Å, and close to linear bonding at the hydrogen [N−H···N = 168.5(15)°] (Figure 7). This interaction leads to a slight pyramidalisation of the amino nitrogen atom as indicated by the sum of bond angles around nitrogen (352.5°), which enables the lone-pair electron density to participate in the intermolecular hydrogen

bond. Each pyridine ring is planar, but the amino nitrogen atom is displaced to one side of this plane by 0.061(1) Å and its two hydrogen atoms are displaced by −0.12 and −0.15 Å to the other side. The molecular geometry of the pyridine rings is summarised in Table 1. In comparison with the similar *trans* conformation also adopted by 2,2′-bipyridine in the solid state,[23] differences are observed in the geometry of the pyridine rings.

For ligand **L1**, the C(2)−C(3) bond is slightly longer 1.4241(18) Å [cf. 1.394(2) for bipy] and the exocyclic C(3)−C(2)−C(2′) angle is widened from to 121.2(1)° to 123.67(14)°. This is accompanied by a consequent contraction of the endocyclic angle at C(2) by 2.7° to 119.86(11)° and an increase in the endocyclic angle at N(1) by 3.5° to 120.77(11)°. The amino group is displaced away from the opposite pyridine ring by 2.6° in the plane of the molecule. These effects enable the molecule to optimise its hydrogen bonding interactions.

The crystal structures of complexes of **L1** with copper(II) chloride (**2a**) and copper(II) acetate (**2b**), the tris complexes of **L1** with zinc(II) (**3a**, **3e** and **3f**), the complex of the dication of **L1** with copper(II) chloride (**4**) and two salts of the dication of **L1** are described. The molecular geometry of the pyridine rings for selected compounds is summarised in Table 1. Intramolecular hydrogen bonding interactions as well as the conformational geometry for ligand **L1** are listed in Table 2.

[Cu(L1)Cl$_2$]$_2$ (2a)

Remarkably, complex **2a** crystallises as a 2:2 centrosymmetric complex of ligand **L1** and copper(II) chloride (Figure 2a). The Cu^{II} metal ion adopts a near square-pyramidal geometry with two pyridine nitrogen atoms and two chloride ions bound in a distorted square-planar arrangement with angles between neighbouring atoms at copper in the range 80.9(1) to 94.8(1)°. A long axial contact from an amino nitrogen of a neighbouring bipyridine molecule to the copper metal [Cu···NH$_2$ = 2.625(3) Å] completes the five-coordinate geometry. The Cu^{II} is displaced out of the best planes of each pyridine ring by 0.482(1) and 0.468(1) Å, respectively, and the angle between the [Cl(1), Cl(2), Cu] plane and the [N(1A), N(1B), Cu] plane is 25.1(1)°. As shown in Figure 2a, these molecules are arranged in dimers as a consequence of a pair of long axial contacts between a copper ion and an amino nitrogen atom belonging to the opposite half of the dimer. A coordinating amino group approaches one face of the copper ion at angles to the other four ligating atoms in the range of 84−111°, leaving the opposite face of the copper ion exposed. The shortest contact from this face is intermolecular to a pyridine ring and is 3.785(4) and 3.626(4) Å for Cu···C(3A) of ring A and Cu···C(4A) of ring B, respectively. An intramolecular hydrogen bond [N···H = 2.19(4) Å, N···H−N = 136(3)°] leads to the best planes of the two attached pyridine rings lying at only 24.4(1)° to each other (Table 2). There is a slight folding of pyridine ring A about the C(3A)···C(6A) vector, and a slight folding of ring B about the C(2B)···C(5B) vector. This folding serves to displace the amino groups out of the best planes of their respective pyridine rings in opposite directions: N(3A) is displaced towards the copper ion to which it binds by 0.374(3) Å, while N(3B) is displaced by only 0.174(3) Å in the opposite direction. The bonding geometries at C(3A) and C(3B) remain planar. Small in-plane angular displacements of the C−N bonds at C(3A) and C(3B) in the range of 2−3° contribute to increase the distance between the amino groups, as observed in the structure of the free ligand. The molecules are packed such that there is an intermolecular hydrogen bond between H(31B) and a neighbouring chlorine atom [H(31B)···Cl = 2.47 Å] (Figure 2b). Two types of 1:1 complexes with copper(II) chloride have been reported for the unsubstituted 2,2′-bipyridine ligand.[24] The first complex is comprised of long chains in which the octahedrally bound copper(II) ions are linked by bridging chloride ions. The second complex contains a pentacoordinate Cu^{II} ion with only one bridging chloride linking adjacent metal centres. The two Cu−N bond lengths in complex **2a** [1.998(2) and 2.015(3) Å] are slightly shorter than those in the 1:1 complexes of bipyridine with copper(II) [2.026(5)−2.079(3) Å]. In contrast, the 1:1 complex of copper(II) chloride with 5,5′-diamino-2,2′-bipyridine adopts a tetracoordinate structure with even shorter Cu−N bond lengths of 1.981(1) Å.[25] Interestingly, a derivative of 3-amino-2,2′-bipyridine-6-carboxylate is reported to bind copper(II) through both a deprotonated amino group, a pyridine nitrogen and a carboxylate group.[26]

[Cu(L1)(OAc)$_2$]·3H$_2$O (2b)

To determine whether the amino groups of 3,3′-diamino-2,2′-bipyridine would still contribute to the coordination of the copper ion, the structure of the hydrated 1:1 complex **2b** with copper(II) acetate was determined by X-ray crystallography (Figure 3). The bipyridine binds to copper

through its pyridine nitrogen atoms [Cu(1)−N(3A) = 1.969(5), Cu(1)−N(3B) = 1.985(5) Å] and two acetate ligands coordinate in a bidentate manner to complete a distorted octahedral geometry. Both acetates form one short bond to copper [Cu(1)−O(1) = 1.961(4), Cu(1)−O(3) = 1.959(5) Å]. However, in contrast to **2a**, the acetate ligands make a second pair of longer contacts [Cu(1)−O(2) = 2.616(5), Cu(1)−O (4) = 2.571(6) Å] to the copper from above and below the equatorial plane. The bite angles of each acetate at the copper metal are 55.1(2) and 56.0(2)°, respectively. This mode of binding is very similar to that of the single acetate moiety in the perchlorate and tetrafluoroborate salts of the acetato-bis-bipyridinecopper(II) cation, which contain one short Cu−O bond [2.031(5) and 1.980(4) Å] and a longer Cu··O contact [2.648(5) and 2.785(5) Å].[14] The structures of the acetate ligands in **2b** are asymmetric, with longer C−O bonds [1.268(8) and 1.272(7) Å] to the oxygens which bind more tightly to the copper than for the other pair of oxygens [1.238(9) and 1.236(7) Å].

In analogy with complex **2a**, the two pyridine rings are connected by an intramolecular hydrogen bond that links the two amino groups (Table 2). The angle between the planes of the two pyridine rings is 28.9(2)° and each amino nitrogen atom is displaced by similar amounts from the plane of its attached pyridine ring, namely by 0.22(1) Å for N(3A) and 0.26(1) Å for N(3B). This serves to orient the amino groups away from each other and differs from the more asymmetric disposition of amino groups in **2a**, where one amino group coordinates the copper ion. The asymmetric unit contains two well-ordered water molecules, one of which is hydrogen bonded to an acetate oxygen O(1) and an amino hydrogen H(31B) from different molecules in the crystal structure as well as to the second water molecule.

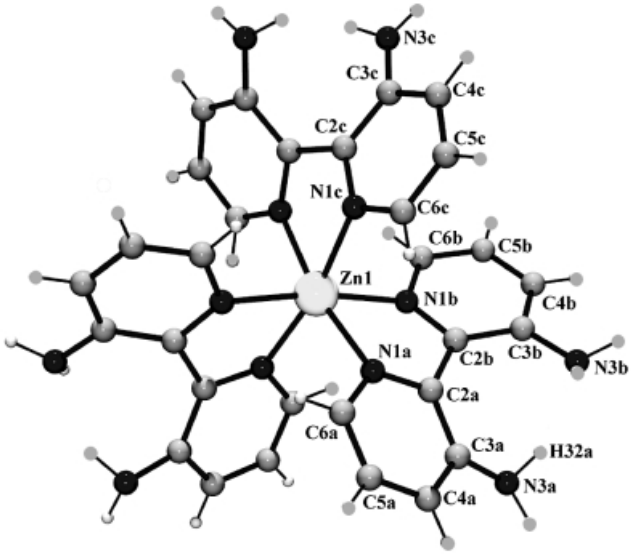

Figure 8. Molecular structure of **3a**; selected distances [Å] and angles [°]: N(1A)−Cu 2.160(3), N(1B)−Cu 2.132(3), N(1C)−Cu 2.164(3); N(1A)−Cu−N(1B) 76.1(1), N(1A)−Cu−N(1C) 169.2(1), N(1A)−Cu−N(1A′), 91.2(2), N(1A)−Cu−N(1B′) 97.9(1), N(1A)−Cu−N(1C′) 96.5(1), N(1B)−Cu−N(1C) 95.3(1), N(1B)−Cu−N(1B′) 171.5(2), N(1B)−Cu−N(1C′) 91.3, N(1C)−Cu−N(1C′) 76.9(2)

The second water molecule lies in a channel that runs through the crystal parallel to the *c* axis that contains an additional, disordered water molecule.

[Zn(L1)$_3$][CF$_3$SO$_3$]$_2$ (3a), [Zn(L1)$_3$][ZnCl$_4$]·CH$_3$CN (3e) and [Zn(L1y)$_3$][ZnCl$_4$]·DMF (3f)

The structures of the cations in all three compounds are very similar. The molecular structure of **3a** is shown in Figure 8. (NB The structures of **3a** and **3e** were solved in space groups which require the cation to lie on twofold axes, thus only one-and-a-half ligand molecules are crystallographically unique. However, the bisected ligand does not exactly conform to this twofold axis due to the asymmetry expected in the arrangement of the amino groups, where one must hydrogen bond to the other).

In all complexes three bipyridine ligands bind the zinc(II) metal through their diimine binding sites, and the cations are all octahedral with Zn−N bond lengths in the range 2.132(3)−2.164(3) Å and bond angles around the Zn^{2+} in the range 76.1(1)−97.9(1)°. The Zn−N bond lengths fall within the range typical for Zn^{2+}tris(bipyridine) complexes (2.133−2.166 Å).[27−29]

[Cu(L1H$_2$)Cl$_4$] (4)

Reaction of **L1** with copper(II) chloride in dilute hydrochloric acid yielded complex **4,** which was characterised by X-ray crystallography. The molecular structure is shown in Figure 4. Both heterocyclic nitrogen atoms are protonated and the two amino groups, which together with four additional chloride ligands complete the charge balance, are bound to the copper ion, giving an octahedral coordination sphere around the Cu^{II} ion. The endocyclic bond angles at both pyridinyl nitrogen atoms show the expected widening by 2−3° relative to the free ligand **L1** due to protonation. The Cu^{II} metal ion shows the expected Jahn−Teller distortion, namely the C−N and C−Cl bonds along one axis are longer than other similar bonds in the complex. The N(3B)−Cu bond [2.467(4) Å] is 0.35 Å longer than the N(3A)−Cu bond [2.120(4) Å], although both are shorter than the pair of bonds from amino nitrogens to coppers in the 2:2 complex **2a**. Both amino groups show a tetrahedral bonding geometry, indicative of the binding interactions between nitrogen and copper. The 1,6-bite angle of the diamino groups at the copper metal is 84.2(1)°. The molecule achieves this mode of coordination by increasing the angle between the best planes of the two pyridinium rings to 68.4(1)° from the *cis* coplanar arrangement. The amino nitrogen atoms are nearly coplanar with their pyridine rings, in contrast to the complexed neutral ligand. The two C−NH_2 bond lengths are different; this bond is longer [1.419(6) vs. 1.384(6) Å] for the amino group which binds the copper more tightly, since the nitrogen lone pair is less available for conjugation with the pyridine ring. Indeed, the shorter bond is similar in length to those in the unbound dication in **5a** and **5b**, suggesting that this amino group only binds weakly to the copper. The molecules are packed in such a way that there are intermolecular hydrogen bonds

between all six nitrogen-bonded hydrogen atoms and neighbouring chloride ions in the range of 2.24−2.67 Å.

Only a few structurally characterised examples of 2,2′-diaminobiaryl systems binding in this way have been reported in the chemical literature. 2,2′-Diaminobiphenyl and 1,2-diaminocyclohexane bind platinum(II) chloride[30] and two molecules of 2,2′-diamino-6,6′-dimethylbiphenyl bind to rhodium(III) chloride[31] with bite angles for the diamino groups at the metal atom in the 87−89° range. Several complexes of the 3-aminopyridinium cation coordinated through the amino groups to copper(II) have been reported and provide a useful comparison.[32,33] For these complexes, the Cu−N distances are in the range 2.043−2.071 Å, similar to the shorter of the Cu−N bonds in **4**, and the C−NH_2 bond lengths are in the range 1.400−1.432 Å, similar to the C(3A)−N(3A) bond length in **4**.

[L1H$_2$][CuCl$_4$] (5a) and [L1H$_2$][ZnCl$_4$] (5b)

The molecular structure of the zinc salt **5b** is presented in Figure 9. The geometry and conformation of the dication in both compounds is very similar, however the geometry of the anion in the former is intermediate between tetrahedral and square planar, whereas in the latter it is tetrahedral.

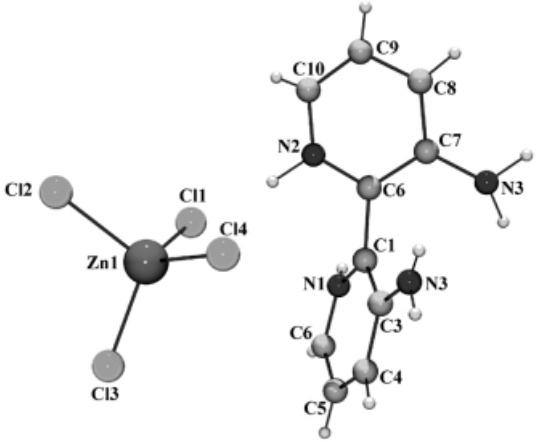

Figure 9. Molecular structure of **5b**

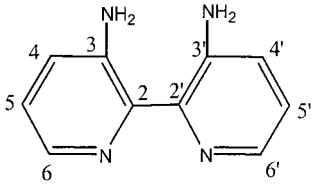
Protonation of the ring diimine nitrogens leads to widening of the endocyclic ring angles at these heteroatoms in the range of 123.6(5)−124.6(4)°. The best planes of the pyridinium rings lie at 54.5(1)° and 53.0(3)° from the *cis* coplanar arrangement, which serves to separate the amino nitrogen atoms at van der Waals distances of 3.063(6) Å and 3.023(9) Å. The shortest N···H separations between the two amino groups are ca. 2.7 Å, although the positions of the hydrogen atoms determined from these room temperature measurements are not very accurate. In contrast to the complexed dication in **4**, the bonding geometries at the amino nitrogen atoms are in most cases nearer to planar (the average sum of bond angles at the amino N are in the range 347−360°). The bonds between the amino nitrogen atoms and the pyridine rings are in the range 1.341(6)−1.369(8) Å (Table 1), and are shorter than in 3-aminopyridine (1.384 Å).[34] This is in accordance with the expected increase in π-overlap between each amino group's lone pair and the positively charged heterocyclic ring. The corresponding bond lengths in the complexed dication **4** are ca. 0.4 Å longer than in **5a** and **5b** since the nitrogen atoms' lone pairs are utilised in forming dative bonds.

NMR Spectroscopy

All NMR spectra were measured in [D_6]DMSO for consistency. The ^{1}H NMR chemical shifts for selected compounds are shown in Table 3.

Table 3. ^{1}H NMR spectroscopic data for selected compounds containing **L1**



Compound	Solvent	H6, H6′	H5, H5′	H4, H4′
Free ligand (**L1**)	[D_6]DMSO	7.76	7.02	7.02
L1·2HCl	[D_6]DMSO	8.09	7.60	7.65
(**L1**H$_2$)[ZnCl$_4$] (**5b**)	[D_6]DMSO	8.07	7.55	7.55
[Dichloro(**L1**)zinc(II)] (**2e**)	[D_6]DMSO	7.80 (br)	7.04 (br)	7.14 (br)
[Zn(**L1**)$_3$][ZnCl$_4$] (**3e**)	[D_6]DMSO	7.84	7.05	7.14
[Zn(**L1**)$_3$][CF_3SO_3]$_2$ (**3a**)	[D_6]DMSO	7.62	7.16	7.40

In comparison with the free ligand **L1**, the positive charge resulting from protonation of both rings causes a downfield shift of the aromatic protons since they are now more deshielded than in **L1**. The protons in the 4- and 5-positions are shifted by approximately 0.6 ppm whereas the H-6 protons are shifted to a lesser degree by 0.3 ppm. These shifts are observed for both the HCl salt as well as compound **5b**. For the tris-zinc compound **3a**, complexation causes a small upfield shift of the protons in the 6-position, since there is a small diamagnetic interaction of the ring current with the metal ion resulting in a shielding effect of the protons α to the metal centre. The protons in the 4- and 5-positions are deshielded slightly (0.1−0.4 ppm) with respect to the free ligand **L1**. Interestingly, the ^{1}H NMR spectrum for the 1:1 complex **2e** is very broad, indicating an exchange process, and has similar chemical shifts to a solution of the tetrachlorozincate salt of the tris-zinc complex **3e**. It is notable that the ^{1}H NMR spectrum of the latter differs from that of **3a**, the triflate salt of the tris-zinc complex, which would not be expected to be involved in any exchange processes. Crystalline **3e** was initially grown from solutions of **2e**, thus it seems that the two chlorides and ligand **L1** bound to zinc in **2e** are exchanging between zinc ions.

Conclusion

Substitution at the 3,3′-positions does not prevent coordination to the pyridine rings. Compound **L1** behaves as a bidentate ligand coordinating metal ions preferentially through the nitrogen atoms of the pyridine rings. Furthermore, this ligand displays an unusual pH-dependent coordination chemistry, enabling the diamino group to participate in the coordination chemistry when both pyridine nitrogens are protonated. The second mode of binding, namely the symmetrical bridging mode, has not been observed for this ligand to-date. Attempts to prepare dinuclear complexes with ligand **L1** acting as an asymmetric bridge have so far been unsuccessful. This is most probably due to the fact that the asymmetric bridging mode is sterically difficult for divalent metal ions since chelation through the diamino functionality requires the ligand to be substantially more twisted. The above findings lead us to conclude that this ligand is not particularly well suited for linking metal ions for the assembly of coordination polymers. Tris-bipyridine complexes of selected paramagnetic ions do, however, display the phenomenon of spin-crossover. As a consequence, the preparation and magnetic studies of further derivatives of **L1** are currently in progress.[35]

Experimental Section

General: 3-Amino-2-chloropyridine, copper bronze (99%) and tin(II) chloride (98%) were purchased from Aldrich. 2-Chloro-3-nitropyridine (97%), DMF (99.8% over molecular sieves) and dioxane (99.5%) were purchased from Fluka. Solvents were dried before use. NMR spectra were measured on a JEOL GX 270 spectrometer (270 MHz for ^{1}H and 67.8 MHz for ^{13}C) using tetramethylsilane (TMS) as standard, and measured in ppm downfield from TMS, or on a Bruker AC-300 spectrometer (300 MHz for ^{1}H and 75 MHz for ^{13}C) and calibrated against the deuterated solvent. Chemical shifts δ are given in ppm and coupling constants (*J*) are given in Hz. IR spectra were recorded on an ATI Mattson Genesis Series FT-IR or a Perkin−Elmer Spectrum One FT-IR spectrophotometer as liquid films, nujol mulls or KBr pellets. Mass spectra were recorded at the EPSRC Mass Spectrometry Centre and at the University of Berne. Microanalyses were performed at the Analytical Centre, University of Kent, UK, and at the University of Fribourg, Switzerland. Flash chromatography was performed on 40−63 silica gel (Merck).

Synthesis of 3,3′-Diamino-2,2′-bipyridine (L1)

Method A: 2-Chloro-3-nitropyridine (2.00 g, 12.62 mmol) was reacted with freshly activated copper bronze (2.00 g) in dry DMF (40 mL) at 150 °C under nitrogen for 2.5 h.[8] After 2 h TLC (SiO_2, CH_2Cl_2) indicated that the starting material had been consumed. The resulting mixture was poured into water (40 mL), the solid filtered immediately and then washed with concentrated ammonia (2 × 20 mL). The remaining solid was then extracted into boiling dioxane (2 × 150 mL), stirring for about 20 min each time. After evaporating the combined extracts to dryness, the solid was recrystallised from ethanol to give 3,3′-dinitro-2,2′-bipyridine as a yellow solid (yield 1.16 g, 73%). M.p. 205−206 °C. ^{1}H NMR ($CDCl_3$): δ = 8.87 (dd, $J_{6,5}$ = 4.7 Hz, $J_{6,4}$ = 1.7 Hz, 2 H, 6-,6′-H), 8.58 (dd, $J_{4,5}$ = 8.4 Hz, $J_{4,6}$ = 1.5 Hz, 2 H, 4-,4′-H), 7.65 (m, 2 H, 5-,5′-H). ^{13}C NMR ($CDCl_3$): δ = 152.9 (6-,6′-C), 150.7 (2-,2′C), 144.0 (3-,3′-C), 133.1 (4-,4′-C), 124.6 (5-,5′-C). IR (KBr pellet): $\tilde{\nu}$ = 3084, 1590, 1561, 1534, 1440, 1417, 1366, 1048, 1038, 865, 855, 821, 790, 751, 621, 529 cm^{-1}. The dinitro product (0.8 g, 3.25 mmol) was added to a solution of tin(II) chloride dihydrate (5.6 g, 29.5 mmol) in conc. HCl (32%, 14 mL).[7] The solution was refluxed for 0.5 h, to give a yellow solution (**Important:** *do not let the solution cool, otherwise a green insoluble solid precipitates out of solution*). After adjustment of the pH to 12−13 with a solution of NaOH, the solution was extracted with chloroform, and the solvents evaporated to give **L1** as a yellow solid. (yield 0.5 g, 86%). Single crystals suitable for X-ray diffraction were grown from ethyl acetate by slow evaporation of the solvent at room temperature. M.p. 133−134 °C. ^{1}H NMR ($CDCl_3$): δ = 7.96 (dd, $J_{6,5}$ = 7.0 Hz, $J_{6,4}$ = 3.0 Hz, 2 H, 6,6′-H), 7.02 (m, 4 H, 5,5′-H and 4,4′-H), 6.27 (br. s, 4 H, 2 × NH_2). ^{13}C NMR ($CDCl_3$): δ = 143.8 (3,3′-C), 140.6 (2,2′-C), 135.7 (6,6′-C), 123.9 (4,4′-C), 122.9 (5,5′-C). IR (KBr): $\tilde{\nu}$ = 3354, 3221, 2925, 2855, 1586, 1548, 1444, 1430, 1316, 1269, 1149, 1060, 1024, 796, 729, 638 cm^{-1}.

Method B: Freshly distilled acetic anhydride (200 mL, 2.02 mol) was added to 2-chloro-3-aminopyridine (20.0 g, 0.156 mol) and the solution left to stir overnight. The excess acetic acid and acetic anhydride were both removed by distillation under reduced pressure. On cooling in ice the remaining oil produced an off-white solid which was recrystallised from toluene to give 3-acetylamino-2-chloropyridine (20.1 g, 74.0%) as white crystals, M.p. 89 °C. Activated copper bronze (18 g, 0.283 mol) was added to a solution of 3-acetylamino-2-chloropyridine (20.0 g, 0.117 mol) in dry DMF (100 mL) under nitrogen.[9] This mixture was then heated at 110 °C until TLC (SiO_2,ethyl acetate) showed the absence of starting material (3−4 h). After cooling, water (20 mL) was added and the solution filtered. The filter cake was washed with more water (20 mL), ammonium hydroxide (40 mL, 0.88 grav) and finally more water (20 mL). The cake was allowed to dry fully in a desiccator. The desired solid was then extracted with dichloromethane (5 × 200 mL) and the solvents evaporated to give crude 3,3′-diacetylamino-2,2′-bipyridine (yield 12.2 g, 76.6%). M.p. 230°C (dec.) (ref.[9] 225−226 °C), ^{1}H NMR ($CDCl_3$): δ = 9.13 (dd, $J_{4,5}$ = 8.5 Hz, $J_{4,6}$ = 1.7 Hz, 2 H, 4,4′-H), 8.35 (dd, $J_{6,5}$ = 5.9 Hz, $J_{6,4}$ = 1.5 Hz, 2 H, 6,6′-H), 7.36 (dd, $J_{5,6}$ = 13.1 Hz, $J_{5,4}$ = 4.5 Hz, 2 H, 5,5′-H), 2.20 (s, 6 H, 2 × -CH_3). ^{13}C NMR ($CDCl_3$): δ = 169.2 (C=O), 141.7 (2,2′-C), 140.3 (6,6′-C), 136.5 (4,4′-C), 129.8 (3,3′-C), 123.9 (5,5′-C), 25.4 (2 × -CH_3). IR (KBr): $\tilde{\nu}$ = 3344 (N−H str), 1691 (C=O str) cm^{-1}. This crude product (12.0 g, 44.4 mmol) was added to concentrated HCl (50 mL) and the mixture refluxed for 30 min. After cooling in ice, concentrated ammonium hydroxide was added (80 mL, 0.88 grav) to give bright yellow crystals of pure **L1** (yield 8.03 g, 95.2%).

3,3′-Diamino-2,2′-bipyridinediium Dichloride: A 2 M solution of HCl (10 mL) was added to ligand **L1** (1.0 g, 4.4 mmol) and the solution stirred for 24 h. The desired salt was precipitated from the solution by the dropwise addition of acetonitrile to give a bright yellow, amorphous solid which was washed with water and dried (yield 0.89 g, 63.9%). M.p. 181 °C (dec.), ^{1}H NMR (D_2O): δ = 8.20 (dd, $J_{6,5}$ = 5.2 Hz, $J_{6,4}$ = 1.2 Hz, 2 H, 6,6′-H), 8.01 (dd, $J_{4,5}$ = 8.9 Hz, $J_{4,6}$ = 5.4 Hz, 2 H, 4,4′-H), 7.90 (dd, $J_{5,4}$ = 8.9 Hz, $J_{5,6}$ = 5.4 Hz, 2 H, 5,5′-H). ^{13}C NMR (D_2O): δ = 146.7 (6,6′-C), 133.1 (4,4′-C), 132.9 (2,2′-C), 129.0 (5,5′-C), 122.1 (3,3′-C) IR (KBr

disc): $\tilde{\nu}$ = 3378−3207 (N−H str), 2958 (C−H, arom. str), 2631 (N^+−H str), 1546 (C=N, arom. str) cm^{-1}.

Tetrachlorobis(3,3′-diamino-2,2′-bipyridine)dicopper(II) (2a): Equimolar amounts of ligand **L1** (0.30 g) and copper(II) chloride dihydrate (0.22 g) were stirred together in acetonitrile overnight. The resulting precipitate was filtered, dried and recrystallised from water to give single crystals of **2a** as green blocks (yield 0.49 g, 97%). M.p 266−267 °C. $C_{10}H_{10}Cl_2CuN_4$ (320.7): calcd. C: 37.5, H 3.1, N 17.5; found C 37.3, H 3.1, N 17.9. IR (Nujol): $\tilde{\nu}$ = 3345, 3305, 3218, 1643, 1633, 1590, 1581, 1330, 1313, 1267, 1230, 1201, 1149, 1076, 1064, 944, 904, 823, 798,723, 713, 686 cm^{-1}.

Diacetato(3,3′-diamino-2,2′-bipyridine)copper(II)·3H_2O (2b): Following the above procedure for **2a**, reaction of ligand **L1** (0.30 g) and copper(II) acetate hydrate (0.32 g) yielded a solid which was collected, dried and recrystallised from aqueous ethanol to afford single crystals of **2b** as dark green prisms (yield 0.55 g, 93%). M.p. 212−214 °C. $C_{14}H_{16}N_4O_4Cu{\cdot}3H_2O$ (421.9): calcd. C 39.8, H 5.2, N 13.3; found C 40.0, H 4.8, N 13.5. IR (Nujol): $\tilde{\nu}$ = 3491, 3415, 3329, 3173, 1639, 1579, 1279, 1245, 1156, 1051, 1012, 922, 815, 799, 667 cm^{-1}.

Catena-dichloro(3,3′-diamino-2,2′-bipyridine)manganese(II) (2c): Reaction of **L1** (0.30 g) with manganese(II) chloride tetrahydrate (0.32 g) as for **2a** gave a dark crystalline solid tentatively assigned as **2c** (yield 0.41 g, 82%). M.p. > 330 °C. $C_{10}H_{10}Cl_2MnN_4$ (312.1): calcd. C 38.5, H 3.3, N 18.0; found C 38.3, H 3.2, N 17.7. IR (Nujol): $\tilde{\nu}$ = 3440, 3392, 3334, 3305, 3205, 1735**,** 1615, 1593, 1295, 1242, 1159, 1025, 952, 918, 817, 786, 770, 734 cm^{-1}.

Catena-dibromo(3,3′-diamino-2,2′-bipyridine)manganese(II) (2d): Reaction of **L1** (0.30 g) with manganese(II) bromide hexahydrate (0.52 g) as for **2a** gave a black solid tentatively assigned as **2d** (yield 0.47 g, 73%). M.p. dec. 280 °C. $C_{10}H_{10}Br_2MnN_4$ (401.0): calcd. C 30.0, H 2.5, N 14.0; found C 29.9, H 2.5, N 13.7. IR (Nujol): $\tilde{\nu}$ = 3330, 3301, 3203, 1712, 1627, 1589, 1314, 1263, 1207, 1156, 1012, 972, 839, 801, 737 cm^{-1}.

Tris(3,3′-diamino-2,2′-bipyridine)zinc(II) Trifluoromethanesulfonate (3a): Reaction of an acetonitrile solution of **L1** (0.56 g, 3.0 mmol) with zinc(II) trifluoromethanesulfonate tetrahydrate (0.41 g, 1.0 mmol) following the procedure as for **2a** afforded yellow single crystals of **3a** after recrystallisation from water (yield 0.84 g, 91%). M.p. 308 °C. $C_{32}H_{30}F_6N_{12}O_6S_2Zn$ (922.2): calcd. C 41.7, H 3.3, N 18.2; found C 41.3, H 3.1, N 18.5. ^{1}H NMR ([D_6]DMSO): δ = 7.84 (br. d, J = 3.4 Hz, 6 H, 3 × 6-,6′-H), 7.26 (dd, $J_{4,5}$ = 7.9 Hz, $J_{4,6}$ = 1.3 Hz, 6 H, 3 × 4-,4′-H), 7.16 (dd, $J_{4,5}$ = 8.1 Hz, $J_{5,6}$ = 4.6 Hz, 6 H, 3 × 5-,5′-H). ^{13}C NMR ([D_6]DMSO): δ = 144.1 (3,3′-C), 138.0 (2,2′-C), 135.2 (6,6′-C), 124.5 (4,4′-C), 123.2 (5,5′-C). IR (Nujol): $\tilde{\nu}$ = 3373, 3331, 3208, 1642, 1630, 1584, 1332, 1258, 1237, 1224, 1165, 1152, 1029, 804, 726, 706, 641 cm^{-1}.

Tris(3,3′-diamino-2,2′-bipyridine)copper(II) Trifluoromethanesulfonate (3b): Copper(II) trifluoromethanesulfonate (0.65 g, 1.79 mmol) was added to solution of **L1** (1.0 g, 5.38 mmol) in acetonitrile (25 mL) and stirred for 10 min. Standing overnight produced ruby red crystals of **3b** as its acetonitrile solvate (yield 0.90 g, 54%). M.p. 249 °C. $C_{32}H_{30}CuF_6N_{12}O_6S_2{\cdot}CH_3CN$ (961.7): calcd. C 42.5, H 3.5, N 18.9, Cu 6.6; found C 42.2, H 3.3, N 19.2, Cu 6.5. IR (Nujol): $\tilde{\nu}$ = 3376, 2960, 1638, 1590, 1264, 1168, 1032, 804, 724, 638 cm^{-1}.

Tris(3,3′-diamino-2,2′-bipyridine)nickel(II) Trifluoromethanesulfonate (3c): Reaction of an acetonitrile solution of **L1** (0.56 g, 3.0 mmol) with nickel(II) trifluoromethanesulfonate pentahydrate (0.41 g, 1.0 mmol) following the procedure as for **2a** gave pale-yellow single crystals of **3c** after recrystallisation from water (yield 0.89 g, 98%). M.p. 336 °C (dec.). $C_{32}H_{30}F_6N_{12}NiO_6S_2$ (915.5): calcd. C 42.0, H 3.3, N 18.4; found C 41.9, H 3.3, N 18.6. IR (Nujol): $\tilde{\nu}$ = 3369, 3331, 3209, 1643, 1632, 1590, 1257, 1234, 1165, 1028, 803, 641 cm^{-1}.

Tris(3,3′-diamino-2,2′-bipyridine)cobalt(II) Trifluoromethanesulfonate (3d): Reaction of an acetonitrile solution of **L1** (0.56 g, 3.0 mmol) with cobalt(II) trifluoromethanesulfonate tetrahydrate (0.41 g,1.0 mmol) gave dark-red single crystals of **3d** after recrystallisation from water (yield 0.82 g, 97%). M.p. 330 °C (dec. starts at 300 °C). $C_{32}H_{30}CoF_6N_{12}O_6S_2$ (915.7): calcd. C 42.0, H 3.3, N 18.4; found C 41.9, H 3.1, N 18.7. IR (Nujol): $\tilde{\nu}$ = 3372, 3330, 3209, 1642, 1602, 1590, 1258, 1235, 1224, 1165, 1029, 803, 724, 641 cm^{-1}.

Dichloro(3,3′-diamino-2,2′-bipyridine)zinc(II) (2e): Ligand **L1** (0.15 g, 0.81 mmol) was stirred with dry zinc(II) chloride (0.11 g, 0.81 mmol) in acetonitrile (10 mL) overnight. A fine, bright-yellow precipitate and was separated from the solution by centrifugation, and dried under vacuum to give **2e** (yield 0.22 g, 86%). M.p. > 310 °C. $C_{10}H_{10}Cl_2N_4Zn$ (322.5): calcd. C 37.24, H 3.13, N 17.37; found C 37.50, H 3.13, N 17.23. ^{1}H NMR ([D_6]DMSO): δ = 7.80 (br., 2 H, 6,6′-H), 7.14 (br., 2 H, 4,4′-H) 7.04 (br., 2 H, 5,5′-H), 7.00 (br., 4 H, 2 × NH_2). ^{13}C NMR ([D_6]DMSO): δ = 144.4 (3,3′-C), 139.0 (2,2′-C), 134.1 (6,6′-C), 123.1 (4,4′-C), 122.9 (5,5′-C). IR (KBr pellet): $\tilde{\nu}$ = 3409, 3327, 3234, 1638, 1626, 1593, 1583, 1467, 1440, 1344, 1331, 1271, 1248, 1203, 1157, 1102, 1075, 806, 773, 726, 710, 650, 594 cm^{-1}.

Tris(3,3′-diamino-2,2′-bipyridine)zinc(II) Tetrachlorozincate(II) (3e) and Its DMF Solvate (3f)

Slow evaporation of a 1:1 ethanol/acetonitrile mixture of the 1:1 complex **2e** yielded single crystals which were characterised by X-ray crystallography to be the tris complex **3e**. M.p > 310 °C. ^{1}H NMR ([D_6]DMSO): δ = 7.84 (dd, $J_{6,5}$ = 4.2 Hz, $J_{6,4}$ = 1.5 Hz, 6 H, 3 × 6,6′-H), 7.14 (dd, $J_{4,5}$ = 8.2 Hz, $J_{4,6}$ = 1.5 Hz, 6 H, 3 × 4,4′-H), 7.05 (dd, $J_{5,4}$ = 8.2 Hz, $J_{5,6}$ = 4.2 Hz, 6 H, 3 × 5,5′-H), 6.97 (br., 12 H, 6 × NH_2). IR (KBr pellet): $\tilde{\nu}$ = 3514, 3327, 3214, 2925, 1945, 1634, 1588, 1465, 1445, 1321, 1270, 1242, 1206, 1152, 1101, 1076, 1022, 875, 883, 806, 732, 707, 639, 589 cm^{-1}. A second set of crystals were grown by diffusion of methanol into a DMF solution of **2e**. The crystals were characterised as being compound **3f**, a DMF solvate of **3e**. M.p. 335−338 °C. ^{1}H NMR ([D_6]DMSO): δ = 7.84 (dd, $J_{6,5}$ = 4.2 Hz, $J_{6,4}$ = 1.5 Hz, 6 H 3 × 6,6′-H), 7.14 (dd, $J_{4,5}$ = 8.2 Hz, $J_{4,6}$ = 1.5 Hz, 6 H, 3 × 4,4′-H), 7.05 (dd, $J_{5,4}$ = 8.2 Hz, $J_{5,6}$ = 4.2 Hz, 6 H, 3 × 5,5′-H), 6.97 (br., 12 H, 6 × NH_2). ^{13}C NMR ([D_6]DMSO): δ = 144.39 (3,3′-C), 138.84 (2,2′-C), 134.43 (6,6′-C), 123.49 (4,4′-C), 123.04 (5,5′-C). IR (Nujol): $\tilde{\nu}$ = 3401, 3331, 3191, 1634, 1588, 1325, 1270, 1242, 1206, 1155, 1102, 1075, 806, 726, 707, 640 cm^{-1}.

3,3′-Diamino-2,2′-bipyridinium Tetrachlorocuprate(II) (4): Copper(II) chloride dihydrate (0.45 g) dissolved in 1 M HCl (5 mL) was added to a solution of **L1** (0.50 g) in acetonitrile (5 mL) and stirred for 30 min. The resulting green precipitate was collected by filtration. A second batch of green solid crystallised out of the filtrate and was collected affording compound **4** in an overall yield of 0.57 g (54%). M.p. 290−291°C. $C_{10}H_{12}Cl_4CuN_4$ (393.6): calcd. C 29.6, H 3.0, N 13.8, Cu 16.1; found C 29.7, H 3.0, N 14.2, Cu 15.7. IR (Nujol): $\tilde{\nu}$ = 3346, 3295, 3215, 1634, 1586, 1582, 1330, 1314, 1266, 1229, 1200, 1150, 904, 819, 799, 714, 684, 648 cm^{-1}.

3,3′-Diamino-2,2′-bipyridinium Tetrachlorocuprate(II) (5a): On one occasion a few red crystals were isolated on evaporation of the

above filtrate. These crystals were carefully separated from the green crystals and characterised by X-ray crystallography as being **5a**, the salt of the diprotonated ligand **L1**. M.p > 300°C. $C_{10}H_{12}Cl_4CuN_4$ (393.6): calcd. C 29.6, H 3.0, N 13.8, Cu 16.1.%; found C 29.6, H 3.0, N 14.2, Cu 15.9.

3,3′-Diamino-2,2′-bipyridinium Tetrachlorozincate(II) (5b): Aqueous HCl (10 mL, 4.77 M) was added to a solution of **L1** (150 mg) in acetonitrile (10 mL). Zinc(II) chloride (110 mg) was then added and the reaction mixture was stirred overnight. The volume of the resulting yellow solution was reduced until a solid started to precipitate. The product was then filtered, washed with ether and dried under vacuum to give **5b** (yield 0.23 g, 72%). M.p. > 310 °C. $C_{10}H_{12}Cl_4N_4Zn$ (395.4): calcd. C 30.4, H 3.1, N 14.2; found C 30.5, H 3.1, N 13.9. ^{1}H NMR ([D$_6$]DMSO): δ = 8.07 (dd, $J_{6,5}$ = 4.3 Hz, $J_{6,4}$ = 1.3 Hz, 2 H, 6,6′-H), 7.55 (m, 4 H, 4,4′-H, 5,5′-H), 3.76 (br., 6 H, 2 × NH_2, 2 × NH). ^{13}C NMR ([D$_6$]DMSO): δ = 145.4 (3,3′-C), 132.6 (6,6′-C), 128.8 (2,2′-C) 128.6 (4, 4′-C), 126.9 (5,5′-C). IR (KBr): $\tilde{\nu}$ = 3436, 3352, 3313, 3199, 3067, 2908, 1640, 1630, 1619, 1561, 1553, 1471, 1384, 1300, 1165, 1154, 945, 806, 785 cm^{-1}.

X-ray Structure Determinations: All crystal data are summarised in Table 4 and 5 unless otherwise stated. Data were collected with Mo-K_α radiation (λ = 0.71073 Å) using a graphite monochromator with the exception of compounds **L1** and **3e**, which were collected with Cu-K_α radiation (λ = 1.54178 Å). Structure solution was performed by Patterson or direct methods using SHELXS-97.[36] Refinement: Full-matrix least-squares on F^2 (SHELXL-97)[36] all non-hydrogen positions found and refined with anisotropic temperature factors. Hydrogen atoms were located from Fourier distance maps and refined isotropically. Graphics are drawn with the WINGX package for windows.[37]

CCDC-173203−173211 (**L1, 2a, 2b, 3a, 4, 5a, 5b, 3e, 3f**, respectively) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was supported in part by the University of Nottingham Trent, University of Berne and the SNF (NRP 47, Supramolecular Functional Materials). We thank BENEFRI and EPSRC services for single crystal X-ray crystallographic measurements and the EPSRC and University of Berne mass spectrometry services for data. We thank Professor Silvio Decurtins (Ph.D Supervisor of M.-C. Senna) for his support and encouragement, and for allowing M.

Accessibility Studies of Sol-Gel Processed Phosphane-Substituted Iridium(I) Complexes in the Interphase[‡]

Ekkehard Lindner,*[a] Thomas Salesch,[a] Stefan Brugger,[a] Stefan Steinbrecher,[b] Erich Plies,[b] Michael Seiler,[c] Helmut Bertagnolli,[c] and Hermann A. Mayer[a]

Dedicated to Professor Gottfried Huttner on the occasion of his 65th birthday

Keywords: Iridium / Immobilization / Sol-gel processes / Accessibility studies / NMR spectroscopy

The synthesis of the T-silyl functionalized, and therefore sol-gel processable, Vaska complex $[IrCl(CO)\{(C_6H_5)_2PC_6H_4(CH_2)_4Si(OMe)_3\}_2]$ **[4(T^0)]** succeeded by reaction of $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (COE = cyclooctene; **1**) with the phosphane $(C_6H_5)_2PC_6H_4(CH_2)_4Si(OMe)_3$ **[3(T^0)]** in the presence of carbon monoxide. Subsequently, **4(T^0)** was co-polycondensed with five equivalents of $(MeO)_3Si(CH_2)_3C_6H_4(CH_2)_3Si(OMe)_3$ **{5[Ph(1,4-C$_3$T^0)$_2$]}** to give the polysiloxane-bound complex **X1**. For accessibility studies of the reactive centers, **X1** was reacted in the interphase systems gas/solid and liquid/solid with HCl, Cl_2, CH_3I ($^{13}CH_3I$), $Cl_2HCCHCl_2$, SO_2, O_2, and NCC≡CCN, in the course of which the xerogels **X2**–**X7** were formed. With the exception of the reversible species **X5** (SO_2) and **X6** (O_2) the reactions proceeded quantitatively. The composition of the polymers and the structures of the reactive centers were elucidated by means of multinuclear solid-state NMR (^{13}C, ^{29}Si, ^{31}P), IR, EDX, and EXAFS spectroscopy.

Introduction

In the last few years polymer-supported catalysts have evolved into an area of intensive research with the goal of combining the advantages of homogeneous and heterogeneous catalysis.[1−10] The catalysts are easily separable from the reaction products and they can be used for several runs, although frequently with some loss of activity due to metal leaching. In addition the reactive centers are very often not well defined, which also causes a decrease of the activity and selectivity. So far these drawbacks have prevented a commercial application of heterogenized catalysts. A versatile approach to reduce or even eliminate these problems is the introduction of the concept of an interphase.[11−14] Interphases are systems in which a stationary phase (comprised of a polymer, space, and reactive centers) and a mobile component (gas, liquid, or dissolved reactants) penetrate each other on a molecular scale without forming a homogeneous phase. Stationary phases are usually generated by simultaneous co-condensation of T-silyl-functionalized transition metal complexes with various bifunctionalized alkoxysilanes.[15−20] This procedure affords the possibility of modifying materials by controlling the mobility of the entire polymer, the density, and the distance of the reactive centers as well as swelling capabilities.

A major problem intrinsic to interphases is that of low diffusion, which adversely influences the activity of the catalysts as not all reactive centers are readily accessible for the substrates. Excellent model systems for accessibility studies are iridium complexes, which are much more stable than their corresponding rhodium congeners.

The objective of this work was to study the performance of organometallic model reactions in interphases. Therefore the reactive behavior of an iridium(I) complex incorporated into a stationary phase towards a series of molecules with different shapes and sizes like oxygen, sulfur dioxide, dicyanoethyne, and different halogenated substrates was examined. The resulting products were characterized by several spectroscopic methods as well as by EXAFS and EDX.

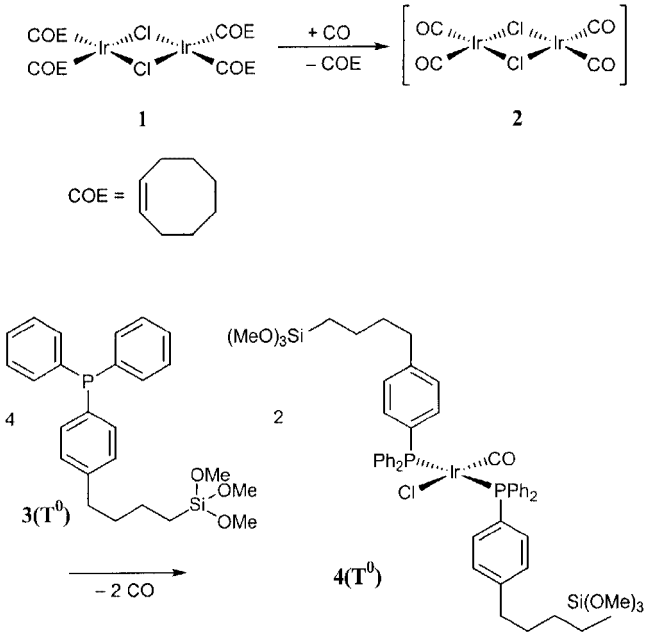
Results and Discussion

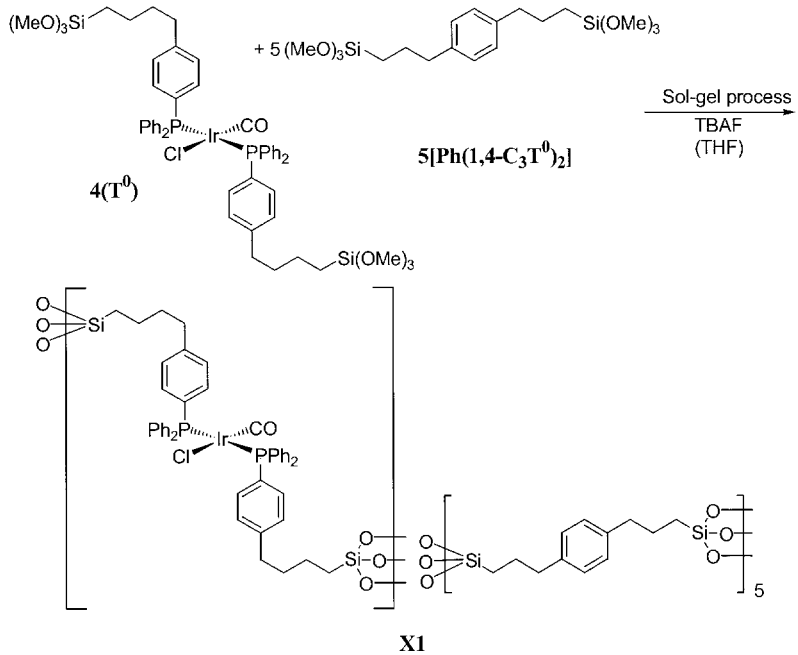
Sol-Gel Processing of the Monomeric Iridium(I) Precursor Complex 4(T^0)

The iridium(I) complex **4(T^0)** was obtained by a modification of the synthetic pathway of Roberto et al. (Scheme 1).[21] A stoichiometric amount of the T-silyl-functionalized phosphane ligand **3(T^0)**[22] was added to an acetonitrile solution of $[Ir(\mu\text{-}Cl)(CO)_2]_2$ (**2**) to give a light brown solution of **4(T^0)** which was subjected to the sol-gel process directly. A single peak in the $^{31}P\{^1H\}$ NMR spectrum of **4(T^0)** at $\delta = 24.7$ ppm and one ν(CO) absorption in the IR spectrum at 1966 cm^{-1} indicated the completeness of the reaction.[23,24]



Scheme 1

A 1:5 mixture of the iridium complex **4(T^0)** and of the co-condensation agent **5[Ph(1,4-C_3T^0)$_2$]**[18] was hydrolyzed and polycondensed in water/THF in the presence of tetrabutylammonium fluoride (TBAF) as catalyst at room temperature (Scheme 2). The resulting xerogel **X1** was isolated as a pale yellow powder which is rather air stable. Only one signal, with a chemical shift of $\delta = 24.4$ ppm, is observed in the ^{31}P CP/MAS NMR spectrum of the polysiloxane-bound iridium(I) complex **X1**, in agreement with the spectrum of the monomeric complex **4(T^0)** measured in solution (Figure 1). To decide whether the phosphanes in **X1** are *cis* or *trans* oriented to each other a *J*-resolved 2D ^{31}P CP/MAS NMR spectrum according to a phase-cycled spin-echo-experiment was recorded (Figure 2).[25] The observed $^2J_{P,P}$ coupling constant of approximately 400 Hz is consistent with a *trans* configuration. In the ^{13}C CP/MAS NMR spectrum of **X1** all main signals stem from the co-condensing moiety. The missing signal for the Si–OMe function indicates a high degree of hydrolysis. All silicon atoms in the polysiloxane matrix are in the direct proximity of protons, therefore silyl species are detectable by cross polarization (CP). The signals in the ^{29}Si CP/MAS NMR spectrum of the copolymer **X1** are located in the typical range for T-silyl functions and their substructures T^2 and T^3 [$\delta = -57.3$



Scheme 2

(T^2), −65.7 ppm (T^3)]. The degree of condensation, which was determined by commonly used methods,[26,27] is 87%. Spin-lattice relaxation times of the protons in the rotating frame ($T_{1\rho H}$) were determined by a direct spin lock-τ-CP experiment[28] via the ^{29}Si and ^{31}P nuclei. In all cases the observed decays of the magnetization were monoexponential. Thus the relaxation mechanism is spin-diffusion controlled and the material can be considered as homogenous. The formation of domains larger than 1−2 nm in diameter is excluded.

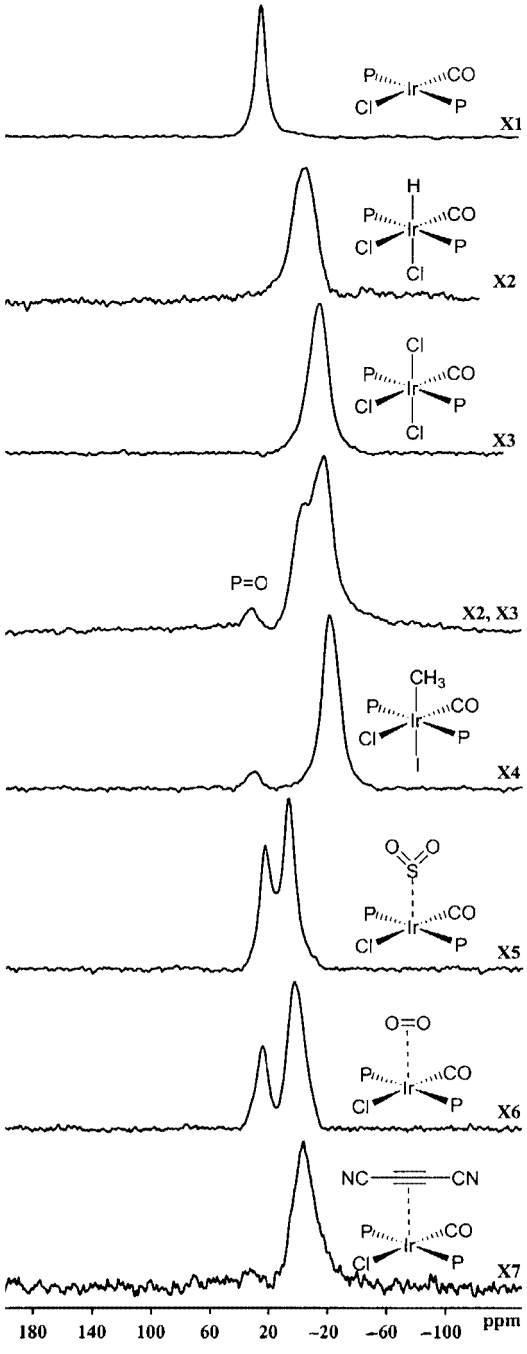


Figure 1. ^{31}P CP/MAS NMR spectra of the stationary phases **X1**−**X7**

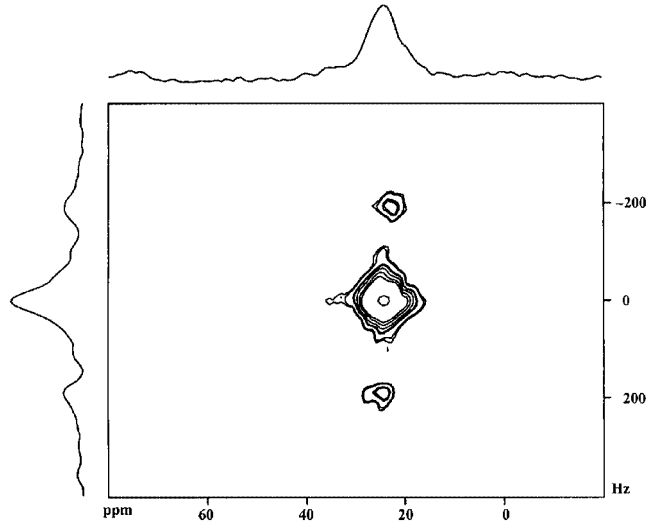

Figure 2. *J*-resolved 2D ^{31}P CP/MAS NMR spectrum of **X1**

The ν(CO) vibration (1965 cm^{-1}) in the IR spectrum of **X1** is similar to that of **4(T^0)** in solution (Figure 3). The elemental composition of the stationary phase **X1** was determined by EDX (Table 1).

Oxidative Addition Reactions on the Stationary Phase X1 with Hydrogen Chloride, Chlorine, Tetrachloroethane, and Methyl iodide (^{13}C-Methyl Iodide)

Treatment of the solid **X1** with hydrogen chloride or chlorine (interphase system: solid/gas) led to a color change from yellow to white and the polymer-anchored iridium complexes **X2** and **X3**, respectively, were formed quantitatively. The ^{31}P CP/MAS NMR and IR spectra are in full agreement with the data recorded for the corresponding monomeric complexes in solution (see Exp. Sect. and Figure 1 and 3).[29]

In the case of the reaction between **X1** and tetrachloroethane in benzene (interphase system: solid/liquid) a mixture of two different products was obtained. One component proved to be the meridional trichloroiridium(III) complex **X3**, the monomeric congener of which was described in earlier work by Al-Najjar.[30] Interestingly the second species turned out to be complex **X2**, already isolated from the reaction between hydrogen chloride and **X1**. Obviously after initial oxidative addition of the C−Cl bond both a β-C−Cl and a β-C−H elimination take place at room temperature in a competitive reaction path. The ^{31}P CP/MAS NMR spectrum reveals two resonances at δ = −3.0 (**X2**) and −18.2 ppm (**X3**) (Figure 1).[31] An unresolved broad absorption in the C≡O region between 2030 and 2080 cm^{-1} was found in the IR spectrum of this mixture (Figure 3). A direct comparison of these results with those of the known monomeric iridium(III) complexes[29] confirms the adopted structures depicted in Scheme 3.

Methyl iodide could also be oxidatively added in benzene to the iridium complex in **X1** in the interphase (solid/liquid) to give the air-stable light brown polymer **X4** (Scheme 3). The carbonyl ligand gives rise to a strong absorption band at 2042 cm^{-1}, which is in accordance with literature values

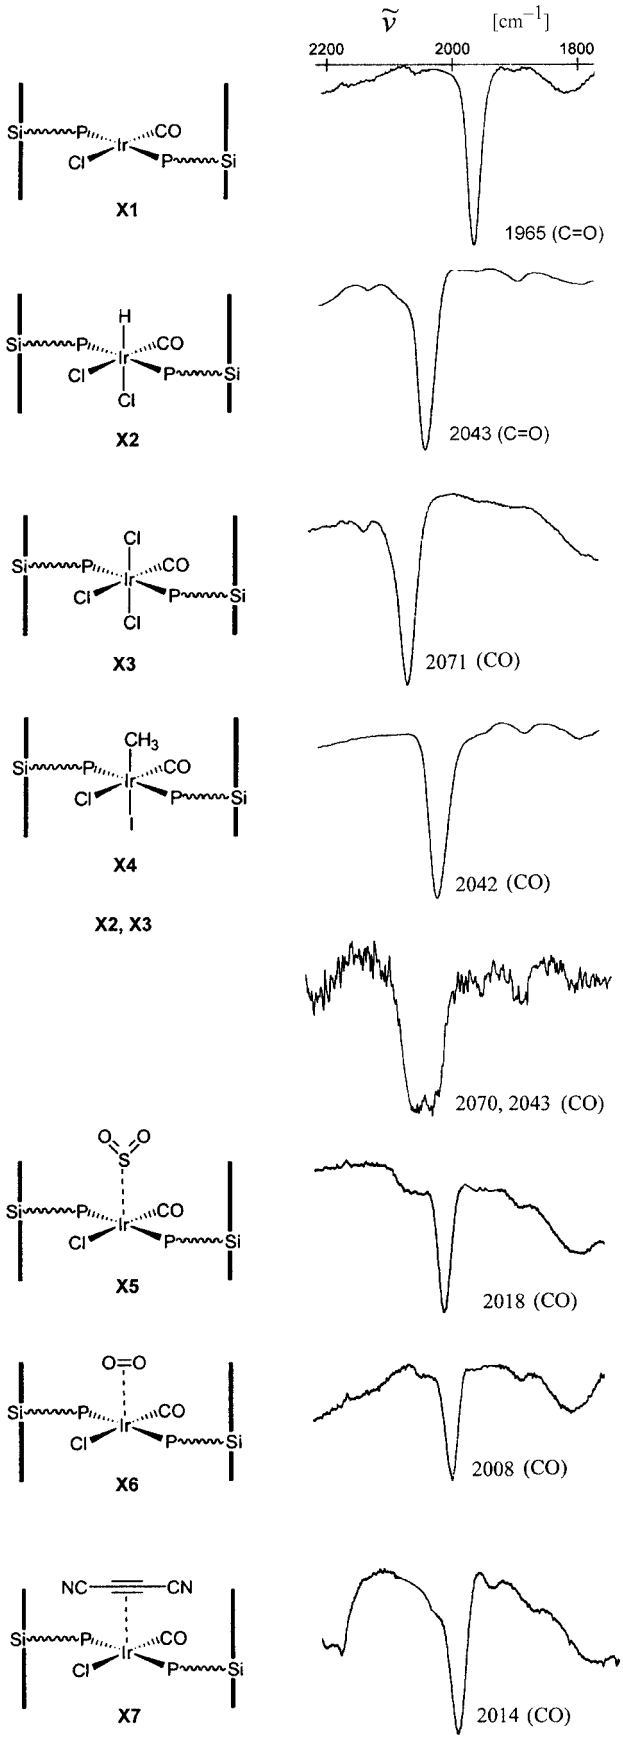

Figure 3. IR spectra of the stationary phases **X1**−**X7**

for the corresponding monomeric complex in solution.[32] Only one resonance is observed in the ^{31}P CP/MAS NMR of **X4** (Figure 1), indicating a complete conversion in the reaction. If ^{13}C-labeled methyl iodide was used an additional intense signal was observed in the ^{13}C CP/MAS NMR spectrum, which is consistent with an iridium-bound methyl group (Figure 4).

Reactions of the Stationary Phase X1 with Sulfur Dioxide, Oxygen, and Dicyanoethyne

In the solid/gas and solid/liquid interphase systems the polysiloxane-bound iridium(I) complex **X1** was reacted with sulfur dioxide, oxygen, and dicyanoethyne to give the polymeric products **X5**, **X6**, and **X7**, respectively (Scheme 3). The C≡O stretching vibration in the IR spectra of these materials confirmed a complete conversion. Absorptions at 2018, 2008, and 2014 cm^{-1} (Figure 3) were observed, which are shifted to higher wave numbers relative to **X1** (1966 cm^{-1}). These spectra were recorded under a sulfur dioxide (**X5**) or oxygen (**X6**) atmosphere. If these gases are removed, the spectrum of the starting compound **X1** appears again. However, the ^{31}P CP/MAS NMR spectra of **X5** and **X6** reveal two ^{31}P resonances (Figure 1). Since the rotors could not be packed under an oxygen or sulfur dioxide atmosphere a reversible reaction took place resulting in partial formation of the starting material **X1**. In contrast to this observation the dicyanoethyneiridium(I) complex **X7** shows only one ^{31}P signal at $\delta = -3.3$ ppm (Figure 1). These findings are in agreement with literature data[33] for the monomeric congeners in which oxygen, dicyanoethyne, and sulfur dioxide are η^2-, η^z-, and η^1-coordinated, respectively.

EXAFS and EDX Measurements of Selected Stationary Phases

One of the most powerful methods to obtain interatomic distances of amorphous materials is extended X-ray absorption fine structure spectroscopy (EXAFS). The xerogel **X4** was chosen as an example to determine the bond lengths between the metal center and the coordinating atoms of the ligand. The k^3-weighted EXAFS function (see a in Figure 5) of **X4** can be described best by six different atom shells. The first intensive peak in the corresponding Fourier transform (see b in Figure 5) is mainly due to the carbon atoms. Chlorine and phosphorus atoms were found in the case of the most intense peak, and the third intense peak belongs to the iodine and oxygen atoms. For the most intense peak of the Fourier transform (see b in Figure 5), two equivalent phosphorus atoms and one chlorine atom, with Ir−P and Ir−Cl bond lengths of 2.40 and 2.46 Å, were found. These results reveal a good agreement between the experimental and the calculated functions. A significant improvement in the fit of the first intense peak was obtained if two carbon atoms with Ir−C1 (Ir−CO bond) and Ir−C2 (Ir−CH$_3$) bond lengths of 1.86 and 2.19 Å, respectively, are considered (see b in Figure 5). Additionally, one iodine and one oxygen atom, with an Ir−I bond length of 2.63 Å and

Table 1. Elemental analysis of compounds **X1**−**X4** by EDX; hydrogen cannot be measured by X-ray emission spectroscopy therefore the reference data have been renormalized to exclude hydrogen

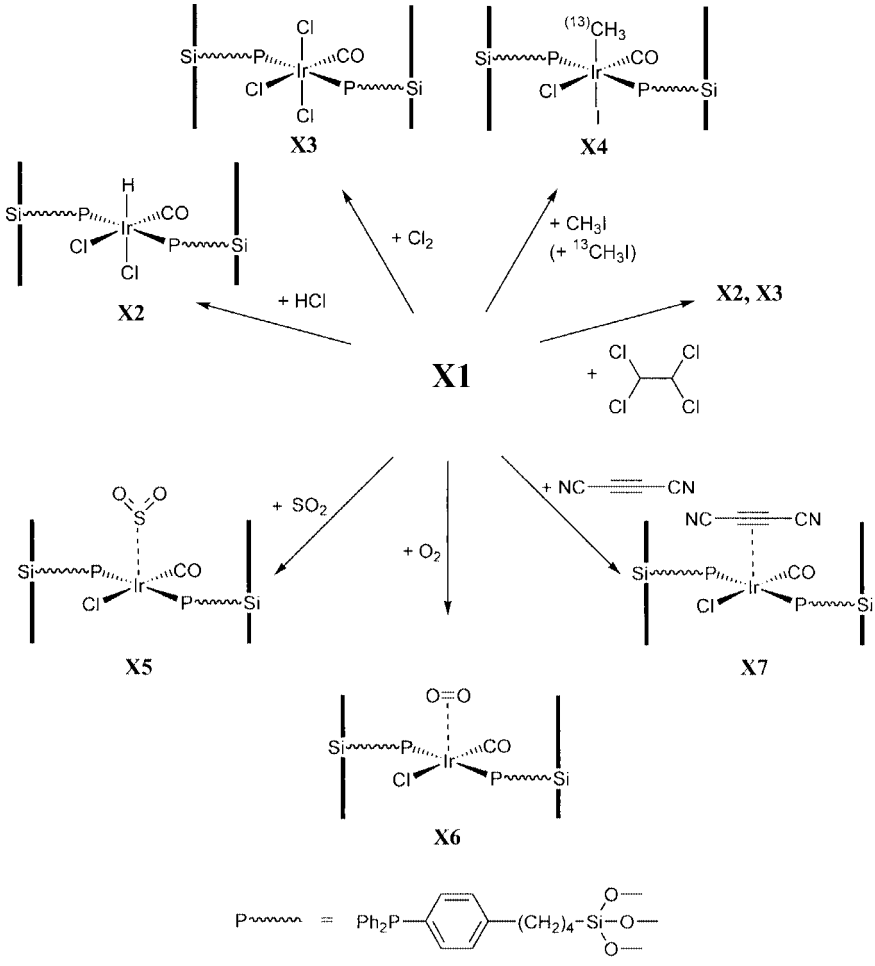

Scheme 3

an Ir−O bond length of 3.08 Å, were detected, leading to an improvement of 7.4 and 18.9% in the fit, respectively. The interatomic distances of **X4** are similar to those in similar iridium(III) complexes such as $[IrCl_3(CO)(PPh_3)_2]$,[34] $[IrCl(H)(SH)CO(PPh_3)_2]$,[35] and $[Ir(OClO_3)(CH_3)(H_2O)(CO)(PPh_3)_2]ClO_4$ [36] (Table 2).

The EDX spectra of compounds **X3** and **X4** are displayed in Figure 6. The K_α lines of carbon, oxygen, silicon, phosphorus, and chlorine and the L_α line of iridium are clearly visible. The M_α and M_β lines of iridium are overlapped by the K_α peak of phosphorus. In the case of **X4**, the L line series of iodine also appears in the spectrum. The increasing

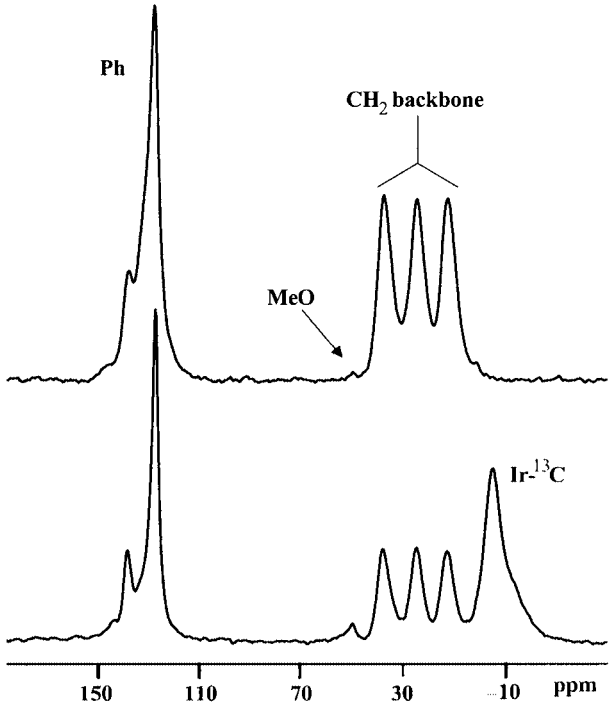

Figure 4. ^{13}C CP/MAS NMR spectra of the stationary phase **X4** (top: without ^{13}C labeling of the methyl iridium group; bottom: with ^{13}C labeling of the methyl iridium group)

content of chlorine in the xerogels **X1**−**X3** is evident as the intensity of the chlorine K line emission increases in the same direction.

Quantification of the EDX spectra was carried out using the ZAF correction procedure. However, as this correction procedure is valid only for flat specimens, and as the xerogels exhibit a pronounced morphology (Figure 7), special care had to be taken to find a locally flat specimen area larger than the expected electron range, which is certainly below 10 μm under the present conditions. Other sources of error, especially in light element analysis, are uncertainties in fundamental parameters and spectrometer calibration at X-ray energies below 1 keV. Spectral interference occurring between iridium and phosphorus can be corrected by peak deconvolution. Due to its high fluorescence yield, the Au-M_α line also appears under the K_β emission of phosphorus. However, the gold coating can be neglected with respect to quantification as, owing to its thickness of only 20 nm, additional absorption effects are not introduced.

Despite the numerous sources of error simultaneous quantification of all the elements present was carried out successfully. The elemental analyses by EDX are summarized in Table 1 and compared to data obtained from theory. These have been renormalized to exclude hydrogen as a

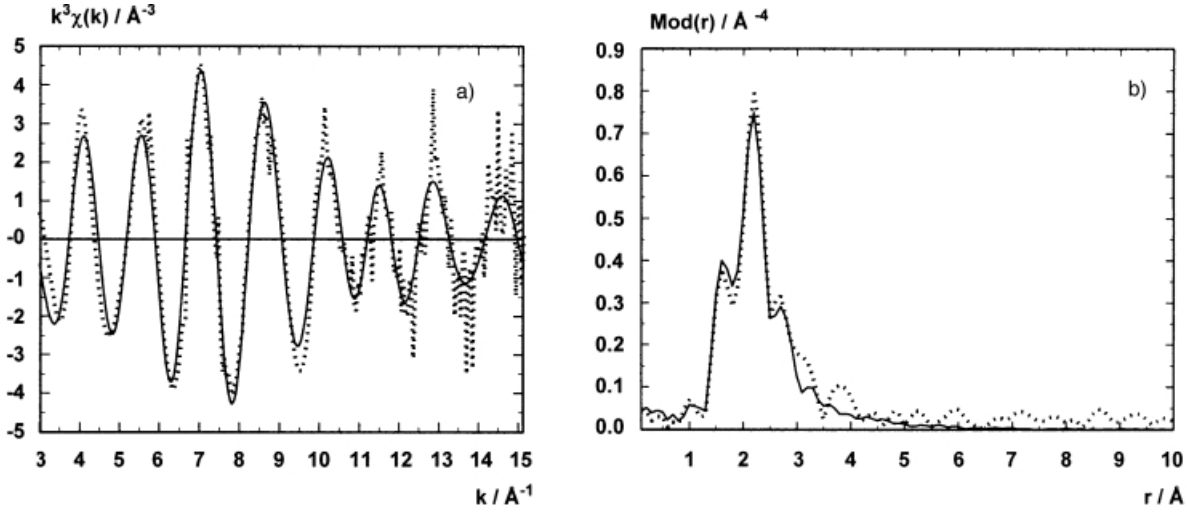

Figure 5. Experimental (dotted line) and calculated (solid line) $k^3\chi$ (k) functions (a) (k range: 2.99−15.14 $Å^{-1}$) and their Fourier transforms (b) for **X4** (Ir- L_3-edge) (see Table 2 for fit parameter)

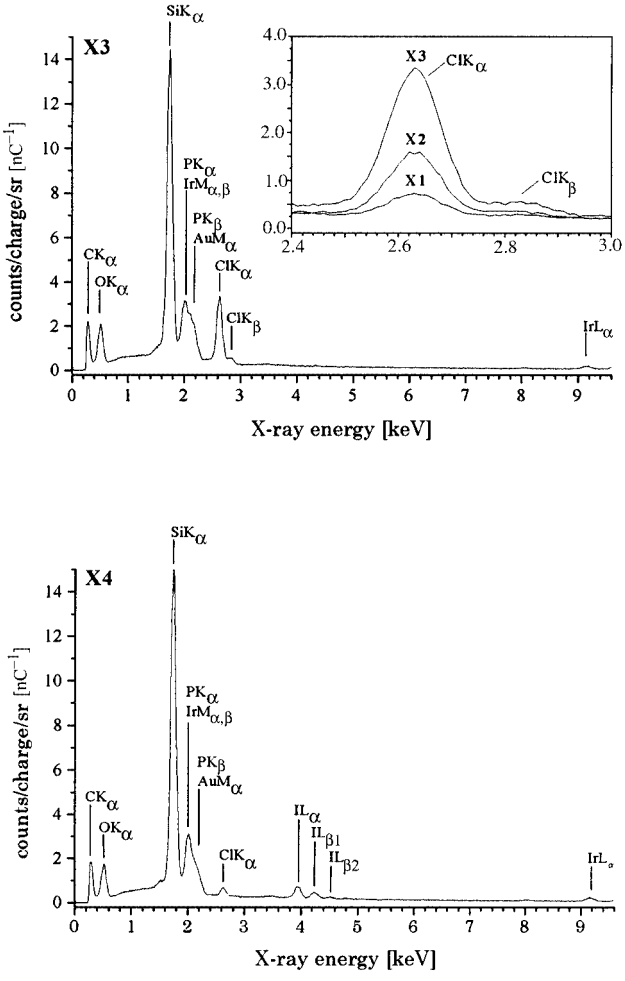

Figure 6. Energy-dispersive X-ray spectra of compounds **X3** (top) and **X4** (bottom); as shown by comparison of the Cl-K_α emission line intensities in the inlay, the chlorine content clearly increases from **X1**−**X3**; quantification results are summarized in Table 1

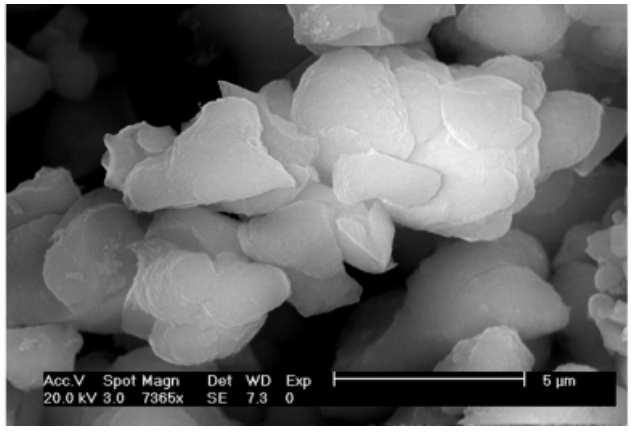

Figure 7. Scanning electron micrograph of **X1**

single-electron atom does not emit characteristic X-rays. Except for the iridium content in xerogel **X3** the elemental analyses support the reference data within the limits of error with the given samples.

Conclusion

For successful catalytic processes in interphases the polysiloxane-bound reactive centers should be completely accessible for substrate molecules. Therefore catalytic model reactions, for example the activation of small and larger molecules, are of great importance for the better understanding of catalytic reactions in interphases. To introduce reactive centers a phosphaneiridium(I) complex has been chosen because such a system is suitable for the envisaged model reactions. For the construction of a mobile stationary phase the T-silyl functionalized iridium complex **4(T^0)** was co-polycondensed with the bifunctionalized co-condensation agent $(MeO)_3Si(CH_2)_3C_6H_4(CH_2)_3Si(OMe)_3$ {**5[Ph(1,4−$C_3T^0)_2$]**} which has already been successfully employed in the rhodium-catalyzed hydroformylation of 1-hexene. The iridium-containing xerogel **X1** was then subjected to various oxidative additions and to the coordination of an alkyne. It could be unequivocally demonstrated that the iridium centers in **X1** were completely accessible for a variety of substrates with different shapes and sizes. The higher cross linkage of the T-silyl bifunctionalized co-condensation agent in the hybrid polymer matrix does not exert a disadvantageous effect on the accessibility of the metal centers. This fact presents a necessary precondition for a successful catalytic process. With the examples of the reactions with sulfur dioxide and dioxygen it could be shown that substrate molecules are also able to leave the polysiloxane matrix reversibly without any interference.

Most of these model reactions were also carried out with the corresponding rhodium(I) interphase system. However, the formed complexes proved to be unstable and partially decomposed.

Experimental Section

General: IR data were obtained on a Bruker IFS 48 FT−IR spectrometer. CP/MAS solid state NMR spectra were recorded on a Bruker DSX 200 multinuclear spectrometer equipped with a wide-bore magnet (field strength 4.7 T). Magic angle spinning was applied up to 10 kHz (4 mm ZrO_2 rotors) and 3−4 kHz (7 mm ZrO_2 rotors). Frequencies and standards: ^{31}P: 81.961 MHz (4.7 T) [85% H_3PO_4, $NH_4H_2PO_4$ (δ = 0.8 ppm) as second standard]; ^{13}C: 50.228 MHz (4.7 T), [TMS, carbonyl resonance of glycine (δ = 176.05 ppm) as second standard]; ^{29}Si: 39.73 MHz (4.7 T), (Q_8M_8 as second standard). All samples were packed with exclusion of molecular oxygen. The *J*-resolved 2D phase-cycled spin-echo-experiment was carried out according to ref.[25] [90° proton pulse length 3.8 µs, 180° proton pulse length 7.6 µs, contact time T_c 1 ms, recycle delay 1.5 s, time domain (F1) 64, time domain (F2) 2048, number of scans 512]. The cross polarization constants T_{XH} were determined by variation of the contact time T_c (14−16 experiments). The proton relaxation times in the rotating frame $T_{1\rho H}$ were measured by direct proton spin lock-τ-CP experiments[28] via ^{31}P. The relaxation parameters were obtained using Bruker software SIMFIT and WINFIT following the procedure described in ref.[15]

The EXAFS measurements were performed at the Ir−L_3-edge at 11215 eV on the beamline X1.1 at the Hamburger Synchrotron-

strahlungslabor (HASYLAB) at DESY, Hamburg at 20 °C, with a Si(111) double crystal monochromator under ambient conditions (5.46 GeV, beam current 120 mA). Data were collected in transmission mode with ion chambers. Energy calibration was monitored with 20 μm thick platinum metal foil at the L_3-edge at 11564 eV. All measurements were performed under an inert gas atmosphere. The samples were prepared from a mixture of **X4** and polyethylene. Data were analyzed with a program package specially developed for the requirements of amorphous samples.[37] The program AUTOBK of the University of Washington[38] was used for background removal, and the program EXCURV92[39] was used for the evaluation of the XAFS function. The resulting EXAFS function was weighted with k^3. Data analysis in k space was performed according to the curved-wave multiple-scattering formalism of the program EXCURV92. The mean free path of the scattered electrons was calculated from the imaginary part of the potential (VPI was set to −4.00), the amplitude reduction factor AFAC was fixed at 0.8, and an overall energy shift ΔE_0 was introduced to fit the data. In the fitting procedure the intermolecular coordination numbers were varied and the intramolecular coordination numbers were fixed according to the known values of the ligands around the iridium atom of **X4**.

Scanning electron microscopy[40] was performed on an XL 30 scanning electron microscope from Philips equipped with an DX-4 energy dispersive X-ray detection system by EDAX. This consists of a liquid-nitrogen-cooled lithium-drifted silicon detector with an active area of 10 mm^2 and the eDXi 2.11 software package. The detector resolution is 149 eV at Mn-K_α (5.984 keV) and the sample-detector distance is 50 mm in the present system. The sample powder was placed on a commercial specimen stub covered with an adhesive tab and subsequently covered with a sputtered 20 nm gold layer to ensure conductivity. The primary beam energy was 20 keV during all investigations. A probe current of 192 pA was applied for recording electron micrographs, whereas X-ray emission spectra were acquired under spot illumination applying a probe current of 569 pA for 400 live seconds (dead time approx. 33%). Measurements were repeated several times at various specimen positions to ensure reproducibility. Quantification of the X-ray spectra was carried out employing the ZAF correction procedure[41−43] after subtraction of the Bremsstrahlung background.

All reactions and manipulations were carried out under argon with usual Schlenk techniques. All solvents were distilled from sodium benzophenone or calcium hydride. H_2O was distilled under inert gas prior to use. All solvents and reagents were stored under argon. $[IrCl(COE)_2]_2$ was purchased from Aldrich, all other chemicals were bought from Fluka. The T-silyl functionalized triphenylphoshine **3(T^0)** and dicyanoethyne were prepared according to literature methods.[22,44]

Carbonylchlorobis[diphenyl{4-[4-(trimethoxysilyl)butyl]-phenyl}phosphane-κP]iridium(I) [4(T^0)]: In a three-necked flask $[IrCl(COE)_2]_2$ (350.0 mg, 0.390 mmol) was suspended in 10 mL of acetonitrile. After 10 min the argon was replaced by carbon monoxide. Undissolved $[IrCl(COE)_2]_2$ disappeared immediately, and a yellow solution was obtained, which indicated the formation of $[IrCl(CO)_2]_2$. After 10 min under an atmosphere of CO the T-silyl functionalized triphenylphosphane **3(T^0)** (684.3 mg, 156 mmol) was added. The color of the solution changed to brown yellow. According to the $^{31}P\{^1H\}$ NMR and IR spectra the reaction was finished after 20 min. The complex **4(T^0)** was sol-gel processed without further purification. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 24.7 (s) ppm. IR (KBr): $\tilde{\nu}$ = 1966 (C≡O) cm^{-1}.

Xerogel X1: In a 100 mL Schlenk-tube 5 mL of the crude solution of **4(T^0)** in acetonitrile (441.7 mg, 0.39 mmol) was added to 4 mL of THF. Subsequently, the co-condensation agent **5[Ph(1,4-C_3T^0)$_2$]** (784.9 mg, 195 mmol) was reacted with the above-mentioned mixture in the presence of 1 mL of water and 0.1 mL of a 0.1 M solution of tetrabutylammonium fluoride (TBAF) in THF as the catalyst. Stirring overnight afforded a light yellow gel. The liquid constituents were separated from the crude gel by filtration (P3) and the product was washed three times each with 10 mL of THF and 10 mL of *n*-hexane. Finally the xerogel was dried under vacuum for 4 h to give a yellow powder. Yield: 895.1 mg. ^{13}C CP/MAS NMR: δ = 139.3, 128.3 (C-phenyl, backbone and ligand), 37.9, 25.2, 12.9 (CH_2, backbone and spacer) ppm. ^{29}Si CP/MAS NMR: δ = −56.6 (T^2), −65.7 (T^3) ppm. ^{31}P CP/MAS NMR: δ = 24.4 ppm. IR (KBr): $\tilde{\nu}$ = 1965 (C≡O) cm^{-1}.

General Procedure for the Synthesis of the Xerogels X2, X3, X5, and X6 (Gas/Solid Interphases): X1 (100.0 mg) was placed in a 100 mL Schlenk tube with a magnetic stirring bar. Subsequently argon was replaced by the respective gaseous reactants at room temperature. After removal of excess reactant by argon the xerogels **X2**, **X3**, **X5**, and **X6** were obtained. In the case of the polymers **X2** and **X3** the yields were quantitative.

X2: X1 was treated with hydrogen chloride. Yield: 101.2 mg. ^{31}P CP/MAS NMR: δ = −3.2 ppm. IR (KBr): $\tilde{\nu}$ = 2043 (C≡O) cm^{-1}.

X3: X1 was treated with chlorine. Yield: 102.1 mg. ^{31}P CP/MAS NMR: δ = −20.4 ppm. IR (KBr): $\tilde{\nu}$ = 2071 (C≡O) cm^{-1}.

X5: X1 was treated with sulfur dioxide. Yield: 101.6 mg. ^{31}P CP/MAS NMR: δ = 23.9 (**X1**), 7.8 (**X5**) ppm. IR (KBr): $\tilde{\nu}$ = 2018 (C≡O) cm^{-1}.

X6: X1 was treated with oxygen. Yield: 101.6 mg. ^{31}P CP/MAS NMR: δ = 24.1 (**X1**), 3.0 (**X6**) ppm. IR (KBr): $\tilde{\nu}$ = 2008 (C≡O) cm^{-1}.

General Procedure for the Synthesis of the Xerogels X4 and X7 and Treatment of X1 with Tetrachloroethane (Liquid/Solid Interphases): A suspension of **X1** (100.0 mg) in 5 mL of benzene was treated with 0.5 mL of methyl iodide, $^{13}CH_3I$, dicyanoethyne, or tetrachloroethane, and the mixture stirred for 24 h at ambient temperature. The liquid constituents were removed by filtration (P3) and, after drying under vacuum, the respective xerogels were obtained.

X4: X1 was reacted with CH_3I or $^{13}CH_3I$. Yield: 96.4 mg (96.3 mg for $^{13}CH_3I$). ^{13}C CP/MAS NMR: δ = 139.1 (139.4*), 128.6 (128.3*) (C-phenyl, backbone and ligand), 50.1 (50.1*) (OCH_3), 37.6 (38.2*), 24.5 (24.9*), 12.5 (12.7*) (CH_2, backbone and spacer), −5.1 ($^{13}CH_3$-Ir) ppm. The asterisk indicates data for the ^{13}C labeled compound. ^{31}P CP/MAS NMR: δ = −20.2 ppm. IR (KBr): $\tilde{\nu}$ = 2042 (C≡O) cm^{-1}.

X6: X1 was reacted with dicyanoethyne. Yield: 95.8 mg. ^{31}P CP/MAS NMR: δ = −3.3 ppm. IR (KBr): $\tilde{\nu}$ = 2192 (C≡N), 2014 (C≡O) cm^{-1}.

Behavior of X1 Toward Tetrachloroethane: X1 was reacted with tetrachloroethane. Yield: 96.7. ^{31}P CP/MAS NMR: δ = −3.5 (**X2**), −18.3 (**X3**) ppm. IR (KBr): $\tilde{\nu}$ = 2070, 2043 (C≡O) cm^{-1}.

Keywords: Copper / N Ligands / Calixarenes / Bioinorganic chemistry / Electrochemistry

The supramolecular biomimetic chemistry based on calix[6]arene N-ligands has been further explored. A tris(imidazole)Cu^{I} complex was treated with 1 mol-equiv. of cuprous ion under dioxygen to produce a tetranuclear cupric species. X-ray structural determination of this novel Cu_4 complex revealed that the self-inclusion of an imidazolyl coordinating arm into the hydrophobic calixarene cavity provides the base of coordination for a $\{ClImCu(OH)_2CuIm_2\}_2$ assembly. The Cu_4 core is maintained in solution and is stable even in a coordinating solvent such as acetonitrile. Magnetic susceptibility measurements evidenced a strong antiferromagnetic coupling in each $Cu(OH)_2Cu$ subunit with $J = -408\ cm^{-1}$. The complex displayed catecholase activity in the presence of 3,5-di-*tert*-butylcatechol behaving as a four-electron hole with, however, a sluggish $Cu^{I}_4 \rightarrow Cu^{II}_4$ regeneration through O_2 autooxidation. Finally, electrochemical studies revealed two oxidative reversible processes that successively gave rise to a $\{Cu^{II}Cu^{III}\}\{Cu^{II}_2\}$ and a $\{Cu^{II}Cu^{III}\}_2$ mixed-valence species that could be characterized by UV/Vis and EPR spectroscopy. The overall structure and behavior of this tetranuclear complex is reminiscent of multicopper enzymes.

Introduction

The synthesis of polynuclear complexes that can be studied in solution is an important topic in view of the potential role of such species in multi-metal-centered catalysis in both biological and industrial reactions. Multi-copper-containing oxygenases and oxidases have been intensively studied in recent years.[1−3] Indeed they have revealed a synergism between the copper sites on the activation of O_2. While dinuclear systems are now fairly well documented,[4] clusters of higher nuclearity appear more difficult to study. Several tetranuclear copper complexes have been described recently, displaying a wide diversity of structures of the metal cluster.[5−7] However, little information concerning their redox properties has been reported,[8] partly because of their lack of stability in solution.

In the recent past, we have been particularly interested in the synthesis, structural characterization and reactivity of copper complexes containing calix[6]arene-based N-ligands. We have shown that these supramolecular systems provide remarkable models for the type 2 active sites of copper enzymes in both Cu^{I} and Cu^{II} states.[9−11] In the process of studying the reactivity of the tris(imidazole)-based mononuclear cuprous complexes,[10] we have found that, in the presence of a second mol-equiv. of Cu^{I}, they can give rise to highly stable tetranuclear species. Here, we report the synthesis and structural characterization of a novel complex presenting a $[Cu_2(OH)_2]_2$ core with some very interesting redox properties.

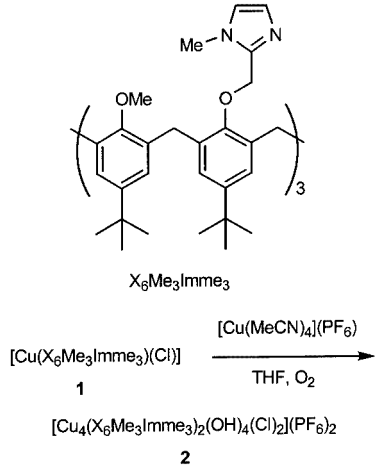
Results

Synthesis and Characterization of $[Cu_4(X_6Me_3Imme_3)_2(OH)_4(Cl)_2](PF_6)_2$ (2)

Equimolar quantities of ligand $X_6Me_3Imme_3$ [12] and CuCl were first allowed to react in THF under argon to produce the cuprous complex $[Cu(X_6Me_3Imme_3)Cl]$ (**1**) that slowly precipitated out of the solution (Scheme 1). Upon

the addition of 1 mol-equiv. of $[Cu(MeCN)_4](PF_6)$ followed by dioxygen bubbling, a green solution was obtained and a blue precipitate slowly formed overnight. The isolated solid **2** was quite soluble in chlorinated solvents. Besides the absorptions characteristic of $X_6Me_3Imme_3$ and PF_6^-, the IR spectrum displayed a strong absorption at 3510 cm^{-1} that can be assigned to OH ligands. The UV/Vis spectrum in CH_2Cl_2 exhibited features at 359 and 633 nm attributed to LMCT (hydroxide or chloride to Cu^{II}) and d-d transitions, respectively. The EPR spectrum (100 K in CH_2Cl_2 or CH_2Cl_2/MeCN) showed only very weak signals at $g = 2$ and 4. The half field lines indicate the presence of exchange-coupled Cu^{II} ions,[13] whereas the signal at $g = 2$ may be attributed to traces of monomeric cupric impurities. The ^1H NMR spectrum presented both well-defined and broad peaks. However, most of the resonances were located in the diamagnetic region, suggesting an antiferromagnetic coupling between the copper ions. Elemental analysis of compound **2** was in good agreement with the formula $[Cu_4(X_6Me_3Imme_3)_2(OH)_4(Cl)_2](PF_6)_2$. Finally, the dicationic nature of complex **2** was confirmed by ES-MS analysis performed either in CH_2Cl_2 or MeCN solution. It is noteworthy that the ES-MS experiment showed that the tetranuclear entity was conserved in solution even in a dissociating and coordinating solvent such as MeCN.



Scheme 1. Synthesis of tetranuclear complex **2**

Crystal Structure of 2

The molecular structure of this tetranuclear complex is depicted in Figure 1 and selected interatomic distances and angles are listed in Table 1. It presents an inversion center in the middle of a "stepped-cubane" Cu_4O_4 core, located between two tris(imidazolyl)calix[6]arene-based ligands that are stacked head to head. The metallic core can be viewed as two Cu_2O_2 units linked together, in which the two copper ions have a different coordination sphere.

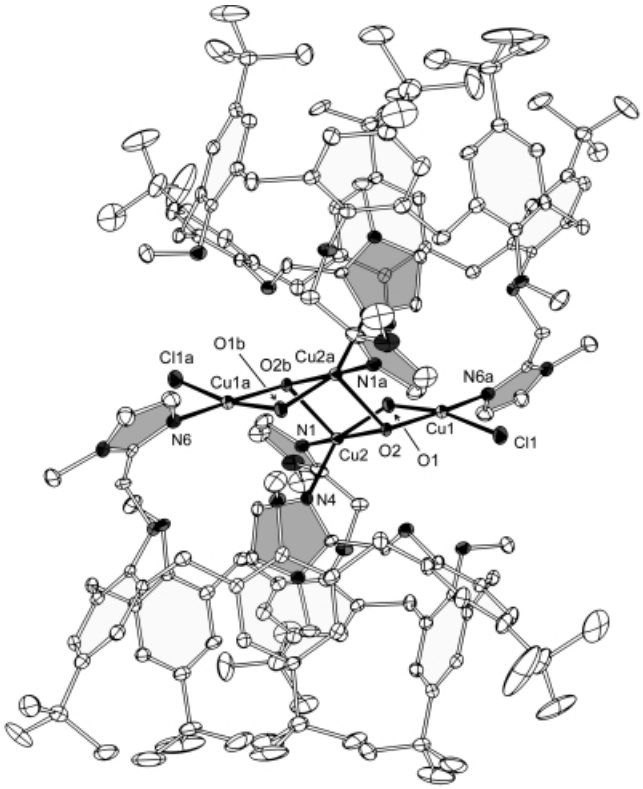


Figure 1. Crystal structure of $[Cu_4(X_6Me_3Imme_3)_2(OH)_4(Cl)_2](PF_6)_2$ (**2**) showing ellipsoids at 20% probability; hydrogen atoms, hexafluorophosphate counterions and solvent of crystallization have been omitted for clarity

[a] Symmetry transformation for equivalent atoms: $1 - x, -y, 1 - z$.

In each discrete subunit, the Cu−O bond lengths (1.91−1.99 Å) as well as the Cu···Cu and O···O distances [d(Cu1···Cu2) = 2.98 Å; d(O1···O2) = 2.46 Å] are similar

to those reported for other bis(μ-hydroxo)dicopper(II) complexes.[14] A global charge of 2+, attested by the presence of two PF_6^- counter anions, indicates that the bridging oxygen atoms belong to hydroxo ligands (their hydrogen atoms could not be determined experimentally). The Cu_2O_2 subunit is asymmetric with bridging angles Cu1−O1−Cu2 and Cu1−O2−Cu2 angles equal to 101.8 and 97.9°, respectively. Cu1 lies in a square-planar geometry provided by one chloride ion, one calixarene-linked imidazole group and the two bridging hydroxide ions. Cu2 is coordinated in a distorted square-based pyramid ($\tau = 0.26$).[15] The base of the pyramid is constituted by the two bridging hydroxide ions and two imidazole moieties attached to the second calixarene ligand. The fifth ligand is a hydroxo group belonging to the other Cu_2O_2 core. The corresponding axial bond Cu2−O2a [2.272(7) Å] is indeed much longer than the equatorial bonds Cu2−O1 and Cu2−O2. The intersubunit distance between the two central copper ions of the tetranuclear core is only slightly longer than the Cu···Cu intrasubunit distance [*d*(Cu2···Cu2a) = 3.05 Å versus *d*(Cu1···Cu2) = 2.98 Å]. Interestingly, the calix[6]arene structures are in a cone conformation with one of the imidazole arms folded into the cavity. One C−N bond of the included imidazole ring faces an aromatic C−C bond of the host at a distance of 3.80 Å. The *N*-methyl group also stands at a relatively short distance from one of the calixarene aromatic rings (3.66 Å from the methyl group to the centroid of the aromatic ring). These observations are indicative of stabilizing π−π and CH−π host−guest interactions.[16]

Magnetism

The magnetic properties of the tetranuclear complex **2** are depicted in Figure 2. The $\chi_M T$ value at 300 K (0.66 $cm^3 \cdot K \cdot mol^{-1}$) is lower than expected for four noninteracting copper(II) ions (1.6 $cm^3 \cdot K \cdot mol^{-1}$) and decreases upon cooling. This behavior is characteristic of a strong antiferromagnetic interaction between the copper ions. The plateau of $\chi_M T$ below 70 K is due to uncoupled copper(II) impurities. As explained above, **2** can be described as two (μ-hydroxo)copper(II) binuclear subunits. As far as the magnetic properties are concerned, a weak interaction is expected between the two subunits. Let us briefly review some magneto-structural correlations concerning the bis(μ-hydroxo)-bridged copper(II) binuclear complexes. Hatfield et al. have shown that the singlet−triplet gap in such compounds varies in a regular way with the Cu−O−Cu bridging angle.[17] For bridging angles larger than 98° antiferromagnetic interactions are observed. With an average bridging angle Cu1−O−Cu2 of 99.8° in the $Cu1Cu2O_2$ subunit of **2**, a strong antiferromagnetic interaction between the copper(II) ions Cu1−Cu2 is expected. Therefore, on the first attempt, we tried to fit magnetic data using a modified Bleaney−Bowers equation taking into account the presence of two subunits. Paramagnetic impurities were accounted for by a Curie law. By least-squares fitting of the magnetic data, the following values were found: $g = 2.06$, $J = -408$ cm^{-1}, $C = 0.065$ $cm^3 \cdot K \cdot mol^{-1}$. The reliability factor $[R(\chi_M) = \Sigma(\chi_M^{obs} - \chi_M^{calc})^2/\Sigma(\chi_M^{obs})^2]$ is then $7 \cdot 10^{-5}$. On the second attempt we tried to fit the data with a tetranuclear model using complete diagonalization of the hamiltonian matrix. Interestingly, there is no improvement in the quality of the fit by using a tetranuclear model. Moreover, the *J* value for the dinuclear subunit does not change and good fits are obtained with positive and negative values for the interaction between the two central copper ions Cu2 and Cu2a. This is not unexpected; the antiferromagnetic interaction between the copper ions in the dinuclear subunits is so strong that it is not possible to measure the weakest interaction at low temperature because the dinuclear subunits are already diamagnetic at this temperature. The *J* value of -408 cm^{-1} found for the dinuclear subunit is in agreement with the theoretical calculation and the data published in the literature for an asymmetric unit.[18]

Catecholase Activity

(μ-Hydroxo)dicopper(II) centers have been found in several active sites of enzymes.[1,2] Among the so-called type 3 copper proteins, catechol oxidase[3] catalyzes the two-electron oxidation of catechols to quinones. As complex **2** may be viewed as a dimeric form of a type 3 center, we thought of testing its activity in oxidation catalysis. Therefore, we studied the ability of compound **2** to dehydrogenate 3,5-di-*tert*-butylcatechol (dtbc) to 3,5-di-*tert*-butyl-*o*-quinone (dtbq). The reaction was conducted in a 0.088 mM dichloromethane solution of **2** with various concentrations of dtbc. Immediately after introduction of dtbc, we observed the bleaching of the initially blue solution, indicative of reduction of the four copper(II) centers to copper(I). The redox process was monitored by UV/Vis spectroscopy (see Figure 3). The absorption at 400 nm, characteristic of the *o*-quinone product ($\varepsilon = 1900$ $M^{-1} \cdot cm^{-1}$), revealed the formation of 2 equiv. of dtbq. After this first very fast process, the absorption at 400 nm only slowly increased at a rate (2.2 h^{-1}) that was independent of the dtbc concentration. This shows that the tetranuclear complex **2** is an excellent oxidant for dtbc. However, its subsequent regeneration through autooxidation of the cuprous species is slow, leading to sluggish catalytic activity.

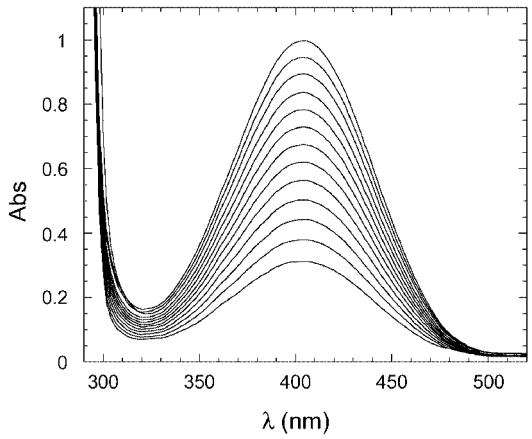

Figure 3. UV/Vis spectra of the formation of the *o*-quinone band recorded every 10 min (CH_2Cl_2 solution, [**2**] = 0.088 mM, $[dtbc]_0$ = 10.3 mM)

Electrochemistry

The electrochemical behavior of this complex has been examined in different solvents. The most interesting results were obtained in MeCN, although compound **2** is only sparingly soluble in this solvent. In pure PhCN or CH_2Cl_2 (in which **2** is highly soluble), the voltammograms displayed an elusive behavior with oxidation peaks of very low intensity. However, addition of MeCN as a co-solvent allowed the recovery of the interesting redox properties that are described as follows. On the one hand, cyclic voltammetry (CV) in the cathodic range only showed a broad peak corresponding to the reduction of some of the copper centers down to Cu^0. This is indeed indicated by the presence of an anodic redissolution peak on the reverse scan (Figure 4). In the anodic range on the other hand, two nearly reversible one-electron processes were observed at $E'°(1)$ = 0.11 V [$\Delta E_p(1)$ = 320 mV] and $E'°(2)$ = 0.66 V [$\Delta E_p(2)$ = 100 mV] with $i_{pa}/i_{pc} \approx 1$. The corresponding waves were better defined when scanning from the more anodic potential, i.e. when the totally oxidized form was generated at the surface of the electrode prior to scanning. It is noteworthy that the intensity of the peaks was much lower than those observed for the monomeric calix[6]arene-based N_3Cu family,[9,19] indicating slower diffusion processes. Rotating disk voltammetry (RDV) displayed two successive oxidation waves with a different height. The first well-defined oxidation wave was followed by a second one that was broader and 1.5 to 2 times less intense. Bulk electrolyses and coulometries gave a number of exchange electrons close to one for each oxidation step.[20] They also result in total dissolution of **2** in MeCN. After the exhaustive electrolysis of the solution (2 electrons), the RDV showed a broad composite reduction wave at a half-wave potential between the two initial oxidation waves. Evolution of the EPR spectrum was monitored after each step of the electrolysis. After a one-electron oxidation, a well-defined EPR spectrum was observed (150 K, frozen MeCN solution). The corresponding parameters ($g_\perp$ = 2.07, $g_{//}$ = 2.30, $A_{//}$ = 140 G) are typical of a magnetically isolated Cu^{II} ion sitting in a distorted square-based pyramidal environment. Interestingly, after the second one-electron exchange, an identical spectrum was recorded with double intensity, however. By UV/Vis spectrophotometry (Figure 5), the two successive oxidations resulted in the disappearance of the LMCT band and a shift of the d−d transition from 633 to 720 nm. Both oxidation steps are chemically reversible, as indicated by the restoration of the initial voltammetric and spectroscopic characteristics of the solution after counter-electrolyses.

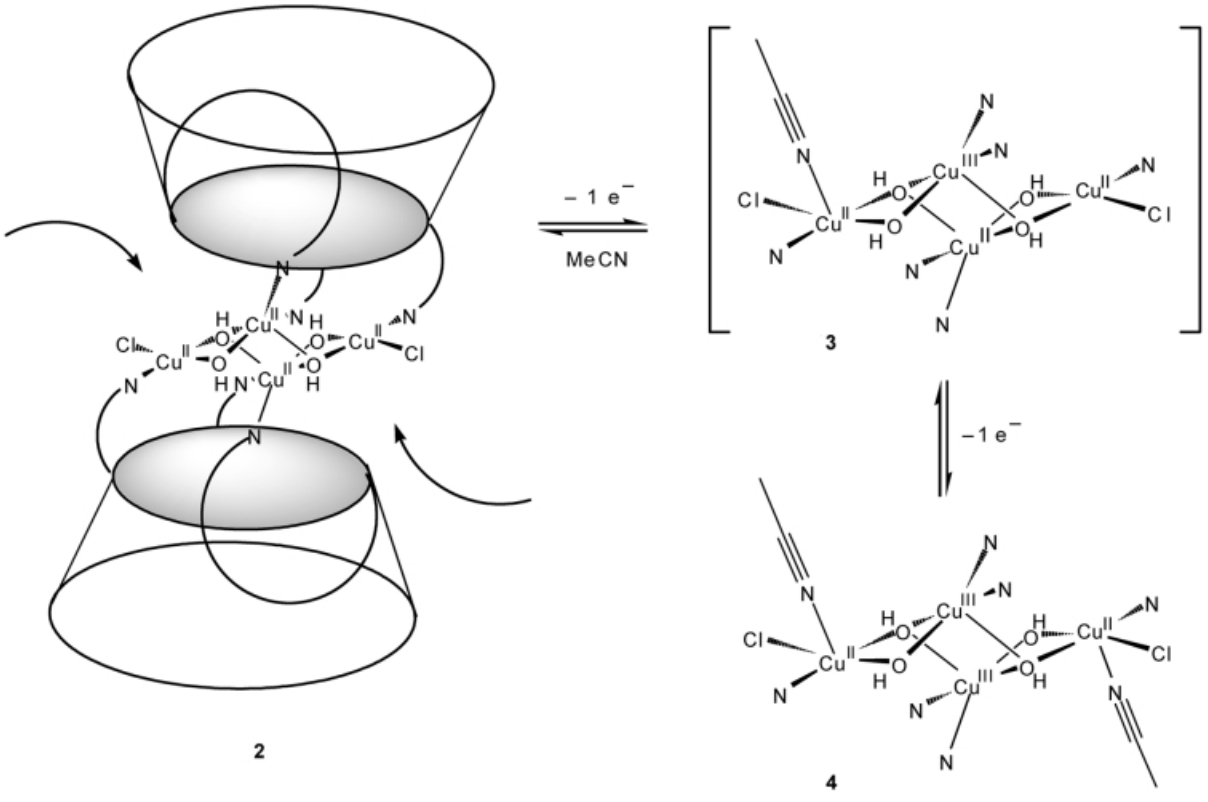
Discussion

The "stepped-cubane" structure of compound **2** is fairly uncommon for tetranuclear copper(II) complexes.[21] To the best of our knowledge, only one complex with similar Cu_4O_4 array has been previously reported.[22] Even more surprising is the exceptional stability of the tetranuclear

core towards coordinating solvent or redox processes. The complex results from the spontaneous assembly of two calixarene-based tridentate N-ligands, four copper atoms, one dioxygen molecule and two chloride ions. The calixarene structures seem to be frozen in a cone conformation due to the self-inclusion of one of their imidazole arms. As a result, the supramolecular assembly[23] displays interesting features: it forms a sandwich that holds and protects the Cu_4 metal core but simultaneously maintains a pathway for an external molecule to interact with it. As shown by the spontaneous dehydrogenation of 2 equiv. of dtbc into dtbq when complex **2** is introduced, the system can behave as a four-electron hole. On the other hand, the electrochemical studies showed that, in the cathodic range, complex **2** tends to decomposition after electrochemical reduction to Cu^I; this is due to the poor ability of OH^- bridges to coordinate Cu^I centers.[24] In the anodic range complex **2** can undergo two sequential one-electron oxidation processes, giving finally rise to a bis(mixed-valence) tetranuclear $[(Cu^{II}Cu^{III})]_2$ compound (**4**) (Scheme 2). Indeed, the central core of **2** is rich in anionic ligands with the two chloride and the bridging hydroxide ions. Together with the tetragonal environment of the copper ions, these features favor the stabilization of the copper(III) state. Formation of Cu^{III} derivatives, with a mixed-valence behavior, has been described in rare examples of Cu_3 and Cu_4 complexes of oxime derivatives.[25–27] The stabilization of Cu^{III} has been shown to be related to the electron-donating ability of the ligand in monomers[28] as well as in dimers.[29] In the present case, the reversibility, both electrochemical and chemical, of the redox process militates the integrity of the tetranuclearity of the system. The EPR study showed that the oxidation process gives rise to gradual apparition of magnetically isolated Cu^{II} ions. Hence, knowing that (i) the presence of MeCN is necessary for the observation of the redox systems, (ii) the spectroscopic data (NMR and UV/Vis) of **2** remained unchanged upon addition of MeCN to a CH_2Cl_2 (or $CHCl_3$) solution, and (iii) the EPR spectrum of the oxidized complex is typical of Cu^{II} sitting in a square-based pyramidal environment, we propose the sequence of reactions depicted in Scheme 2. The central copper atoms are successively oxidized to the diamagnetic Cu^{III} state leading to the formation of intermediate **3** and the final product **4**. At each step of the oxidation process, a peripheral Cu^{II} ion (Cu1) neighboring a central Cu^{III} (Cu2) becomes magnetically isolated and possibly five-coordinate due to the binding of acetonitrile in the axial position.[30] It is noteworthy that, conversely, oxidation of the peripheral Cu1 copper ions would have led to a weakly coupled dinuclear copper(II) central unit for the deoxidized species with a characteristic triplet EPR spectrum, not observed. The splitting into two one-electron redox systems, instead of a two-electron oxidation process, could result from an original cooperative/interactive phenomenon between the two dimeric units of the Cu_4 core, which should thus be considered as a pair of interacting dimers, as has been proposed in other cases.[25] This is in accordance with the dependence on the scan direction for CV and change from a two-to-one RDV wave



Scheme 2. Proposed electrochemical oxidation pathway for **2** in the presence of MeCN; the arrows emphasize the most accessible sites of the Cu_4O_4 core for an external molecule

after electrolysis, which is indicative of a structural rearrangement of the $[(Cu_2)_2]$ core upon oxidation.

Conclusion

Under specific conditions, reaction of the tridentate calix[6]arene-based ligand $X_6Me_3Imme_3$ with 2 mol-equiv. of copper gives rise to a tetranuclear copper(II) complex that is very stable in solution. The molecular structure of this novel compound displays a rare "stepped-cubane" Cu_4O_4 core. It also points out the self-inclusion of one imidazole arm of the calixarene ligand into its cavity. Such a self-inclusion phenomenon should be controllable by the steric hindrance of the coordinating arm. This very interesting supramolecular feature suggests that novel geometries for the coordinated metal center are actually accessible within the calix[6]arene-based tripodal systems. We are currently exploring this structural aspect. The tetranuclear complex also presents remarkable stability and redox properties that are related to its supramolecular architecture. Indeed, it can either behave as a four-electron hole, displaying catecholase activity, or itself be reversibly oxidized into mixed-valence species $Cu_3^{II}Cu^{III}$ and $Cu_2^{II}Cu_2^{III}$. In the field of biomimetic modeling, its behavior evidences an interesting similarity with multicopper enzymes in which some copper centers are specifically devoted to electron transfer and others to interaction with the substrate.[27,31] We are now actively studying the potential electrocatalytic properties of this novel Cu_4 system with promising preliminary experiments.

Experimental Section

Materials and Methods: All solvents and reagents were obtained commercially. THF was distilled from sodium/benzophenone under argon. ^{1}H NMR spectra were recorded either with a Bruker ARX 250 or a Bruker AC200 spectrometer. IR spectra were recorded with a Perkin−Elmer 783 spectrometer. Elemental analyses were performed at the Institut de Chimie des Substances Naturelles, Gif sur Yvette, France. Electrochemical experiments were carried out under dry, dioxygen-free N_2 in a dry-box manufactured by Jacomex. The electrochemical cell was specifically designed to fit the rotating disk electrode (EDI Tacussel) for a minimum volume of solution in the main compartment. The auxiliary and reference (ferrocenium/ferrocene = Fc^+/Fc) electrodes were in separate compartments connected to the main compartment through ground joints terminated by frits (Vycor tips from PAR). For voltammetric measurements, a platinum disk (diameter 2 mm) was employed, and the electrolyses were performed with the same electrode, but rotated, equipped with a disk (diameter 4 mm). A model PAR 173 potentiostat equipped with a PAR 179 digital coulometric unit, was monitored by a PAR 175 programmer. The chart recorder was a T-2Y SEFRAM ENERTEC. EPR spectra were recorded using a Bruker Elexys spectrometer (X-band). The UV/Vis spectra were recorded with a Cary 50 spectrophotometer or a Hitachi U-2010 spectrophotometer. Magnetic measurements were performed with a Quantum Design SQUID MPMS5 magnetometer. The data were collected in the range 1.8−300 K for a powdered microcrystalline sample of **2** at 0.5 T. Diamagnetic corrections were applied based on Pascal's constant.

[Cu($X_6Me_3Imme_3$)(Cl)] (1): Under argon, dry THF (2 mL) was added to a mixture of CuCl (7.0 mg, 0.067 mmol) and $X_6Me_3Imme_3$ [12] (87.0 mg, 0.067 mmol). The mixture was stirred at 40 °C for 1 h. The colorless supernatant was separated from the slightly blue precipitate by centrifugation and concentrated under vacuum. Heptane (5 mL) was added and a white precipitate formed, which was isolated by centrifugation, washed with heptane (2 mL) and dried under vacuum at 30 °C for 12 h to yield a white powder (62.8 mg, 67%). Sometimes, precipitation occurred a few minutes after addition of THF to the starting materials. In this case, the mixture was stirred at room temperature for 2 h and the precipitate was collected by centrifugation and washed with heptane. ^{1}H NMR ($CDCl_3$, 200 MHz, 25 °C): δ = 0.80 (s, 27 H, *t*Bu), 1.34 (s, 27 H, *t*Bu), 2.20 (s, 9 H, OCH_3), 3.22 (d, J = 14.2 Hz, 6 H, Ar-αCH_{eq}), 3.81 (s, 9 H, NCH_3), 4.43 (d, J = 14.7 Hz, 6 H, Ar-αCH_{ax}), 4.99 (s, 6 H, Im-αCH_2), 6.65 (s, 6 H, ArH), 6.94 (br. s, 6 H, ImH), 7.19 (s, 6 H, ArH) ppm. IR (KBr): $\tilde{\nu}$ = 1500, 1482, 1465, 1418, 1396, 1365 cm^{-1}. $C_{84}H_{108}ClCuN_6O_6$ (1396.79): calcd. C 72.23, H 7.79, N 6.02; found C 72.22, H 7.88, N 6.15.

[Cu_4($X_6Me_3Imme_3$)$_2$(OH)$_4$(Cl)$_2$](PF$_6$)$_2$ (2): Under argon, dry THF (4 mL) was added to a mixture of CuCl (12.5 mg, 0.126 mmol) and $X_6Me_3Imme_3$ (164 mg, 0.126 mmol). The mixture was stirred at room temperature for 30 min during which a white precipitate of [Cu($X_6Me_3Imme_3$)(Cl)] slowly appeared. [$Cu(CH_3CN)_4$](PF_6) (47 mg, 0.126 mmol) was added to the reaction mixture. Dry oxygen was then bubbled into the solution, which turned green. A blue precipitate slowly appeared. After 2 h, the oxygen bubbling was stopped and the mixture was stirred overnight. The green supernatant was removed and the blue precipitate was washed with THF (5 × 2 mL), dissolved in CH_2Cl_2, filtered through Celite, precipitated with pentane and dried under vacuum to yield a blue powder (131 mg, 63%). M.p. >260 °C (dec.). ^{1}H NMR ($CDCl_3$, 250 MHz, 300 K): δ = 0.5, 0.77 (s, 18 H, *t*Bu), 0.91 (s, 18 H, *t*Bu), 1.28 (s, 18 H, *t*Bu), 1.38 (s, 18 H, *t*Bu), 1.43 (s, 18 H, *t*Bu), 1.51 (s, 18 H, *t*Bu), 1.89, 2.83, 2.90, 3.75, 4.30, 4.75, 5.98, 6.12 (s, 4 H, ArH), 6.52 (s, 2 H, ArH), 6.72 (s, 2 H, ArH), 6.82 (s, 2 H, ArH), 6.85 (s, 2 H,

Crystal Structure Determination:[32] X-ray quality crystals of $[Cu_4(X_6Me_3Imme_3)_2(OH)_4(Cl)_2](PF_6)_2$ were obtained by slow diffusion of Et_2O into a CH_2Cl_2/MeCN or $CHCl_3$/MeCN solution of complex **2**. Data were collected at 223 K using a Nonius Kappa CCD diffractometer.[33] After a last series of Fourier analysis, two fragments remained partially resolved and were attributed to a disordered MeCN molecule and an incomplete ether solvent molecule. Crystallographic data are listed in Table 2.

[20] It is noteworthy that the number of electrons in the first step can exceed one electron up to 1.3−1.5 if the potential is maintained for a long-lasting electrolysis with a low current level (less than 10% of the initial level). This is accompanied by an increase of the first wave and a decrease of the second.

Keywords: Boranes / Carbenes / Density functional calculations / Lithium / Nucleophilic substitution

N-Methylimidazole added to the strong organometallic Lewis acid $B(C_6F_5)_3$ at the donor nitrogen atom to form the adduct **3** (characterized by X-ray diffraction). Deprotonation at the imidazole carbon atom C-2 was achieved by treatment with methyllithium to generate the reactive "Arduengo carbene anion" intermediate **4**, which underwent a rapid subsequent intramolecular nucleophilic aromatic substitution reaction at one of the adjacent C_6F_5 groups to form the tricyclic betaine-type product **5**. Rearrangement of **4** by 1,2-boron migration was not observed. The respective isomer **7** was prepared independently by deprotonation of *N*-methylimidazole, followed by C-2 addition of $B(C_6F_5)_3$. The corresponding *N*-methylimidazolide-2–$B(C_6H_5)_3$ adduct **8** was characterized by X-ray diffraction and shown to have a cyclodimeric structure made up of intermolecular bis(π-arene)(imidazole)lithium units. A DFT study revealed that the *N*-borated Arduengo carbene anions are in general very effectively kinetically protected from undergoing intramolecular rearrangement to their thermodynamically favored 2-boratoimidazole anion isomers by 1,2-BR_3 migration.

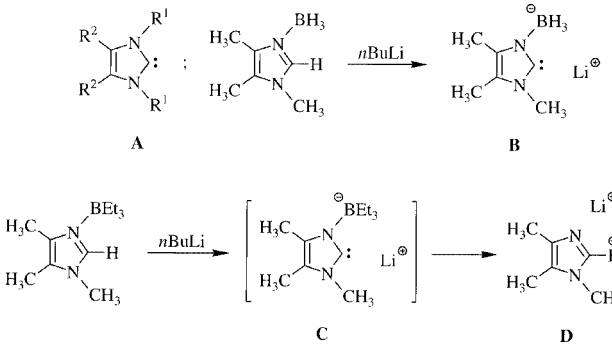
Introduction

The chemistry of the stable nucleophilic carbenes of the imidazol-2-ylidene type (**A**) has been developed considerably in recent years,[1−7] their use as stabilizing ligands in catalysis included.[8−11] Many other heteroatom combinations have successfully been employed for such carbene stabilization,[7d,12−14] but surprisingly little is known about the use of heteroatom-containing substituents at the nitrogen donor substituents themselves.[15−17] This would, however, be very interesting, since suitably constructed heteroatom moieties at one or both nitrogen atoms of the "Arduengo carbenes" would be expected to change the properties of such systems considerably, and would potentially open up routes to new applications of such compounds.

Siebert has recently described such a system:[17] CH deprotonation of the *N*-methylimidazole−BH_3 adduct resulted in the formation of **B** (isolated as a dimer), which may be regarded as an anionic analogue of the neutral imidazol-2-ylidine carbene species **A**. Compound **B** displayed interesting chemistry, largely determined by its nucleophilic character. Surprisingly, the analogous BEt_3 adduct **C** was reported by Siebert et al. to be unstable under the reaction conditions and to rearrange spontaneously to **D**.



We have now developed synthetic routes to systems of types **B** and **D** by the use of triarylborane reagents and have characterized some novel chemical and structural features of such anions.

Results and Discussion

Experimental Studies

For this study, the examples of the two imidazolylborate anion types were prepared by two separate routes, since it turned out that they did not spontaneously interconvert un-

[‡] X-ray crystal structure analyses
[‡‡] Quantum chemical calculations
[a] Organisch-Chemisches Institut der Universität Münster, Corrensstraße 40, 48149 Münster, Germany

der our chosen reaction conditions. The systems described here were all derived from the parent heterocycle, the *N*-methylimidazole precursor **1**.

In the first series of experiments, the neutral starting material **1** was treated with 1 mol-equiv. of the strong organometallic Lewis acid tris(pentafluorophenyl)borane (**2a**).[18−20] The addition reaction was carried out at ambient temperature in pentane (12 h), and furnished the 1:1 addition product **3** as a white solid in > 90% yield. The ^{1}H NMR spectrum of **3** showed a singlet at δ = 7.82 ppm (1 H, 2-H), and the corresponding ^{13}C NMR C-2 resonance was observed at δ = 137.7 ppm. At ambient temperature, the "tetraarylborate" system equilibrates conformationally on the ^{19}F NMR timescale (563 MHz), and so only three ^{19}F NMR resonances were observed (at δ = −133.1, −158.6, and −164.6 ppm), in 2:1:2 ratio. The ^{11}B NMR signal at δ = −8.0 ppm indicated borate formation.

Compound **3** was characterized by X-ray diffraction. The crystal was twinned, but the structure could be solved with a sufficient accuracy. The analysis established that the bulky $B(C_6F_5)_3$ moiety was coordinated to the imidazole N1 nitrogen donor. The resulting N1−B bond length amounts to 1.605(6) Å [1.597(6) Å, the values in brackets correspond to the second independent molecule in the crystal, which is chemically equivalent]. The π-system inside the imidazole ring of the neutral adduct **3** is largely delocalized, as is evident from the respective bond lengths inside the five-membered heterocycle. The N1−C2 bond is the shortest, at 1.317(6) Å [1.303(6) Å], followed by the adjacent C2−N3 linkage at 1.336(6) Å [1.333(6) Å]. The N1−C5 [1.380(6) Å [1.389(6) Å]) and the N3−C4 bonds [1.380(6) Å [1.376(7) Å]) are almost identical in length. The C4−C5 bond is shorter [1.342(7) Å [1.350(8) Å]), whereas the exocyclic N3−C6 bond is much longer, at 1.469(6) Å [1.458(7) Å].

The conformational arrangement of **3** in the crystal is such that two of the C_6F_5 rings at the boron atom, together with the imidazole ring, form a three-bladed propeller arrangement[21] {with the dihedral angle N1−B−C11−C12 being −57.5(6)° [128.4(5)°] and N1−B−C21−C22 amounting to −65.0(5)° [106.5(5)°]}. The remaining C_6F_5 ring serves as the pivot. Its plane is rotated towards a perpendicular orientation relative to the *N*-methylimidazole ring {dihedral angles N1−B−C31−C32 179.2(4)° [+3.5(7)°], C2−N1−B−C31 −120.3(5)° [−118.3(5)°], Figure 1).

Treatment of **3** with methyllithium resulted in methane liberation, with formation of the product **5** (see Scheme 1). The ^{1}H NMR spectrum of **5** showed that the 2-H proton had been removed as expected, but the probably initially generated "anionic Arduengo carbene" product **4** proved unstable under the reaction conditions. It underwent a rapid intramolecular nucleophilic aromatic substitution with formation of a C−C bond to one of the three adjacent C_6F_5 rings at the boron atom.[22] The ^{13}C NMR resonance of the C-2 carbon atom was consequently observed at δ = 147.3 ppm (shifted ca. 50 ppm to high field from a typical value for a boron-substituted carbene **B**[23]). The remaining ^{1}H/^{13}C NMR resonances of the imidazole nucleus appeared

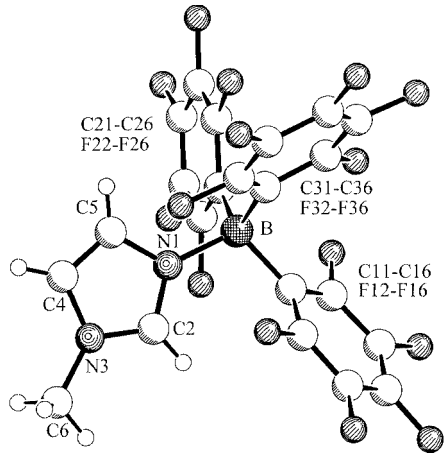


Figure 1. Projection of the molecular structure of **3**, showing the propeller-like arrangement of two C_6F_5 rings and the imidazole ring at the B−C31 pivot (only one of the two independent molecules is depicted); selected bond lengths [Å] and angles [°]: N1−C2 1.317(6)/1.303(6), N1−C5 1.380(6)/1.389(6), N1−B 1.605(6)/1.597(6), C2−N3 1.336(6)/1.333(6), N3−C4 1.380(6)/1.376(7), N3−C6 1.469(6)/1.458(7), C4−C5 1.342(7)/1.350(8), B−C11 1.640(7)/1.643(7), B−C21 1.654(7)/1.643(7), B−C31 1.632(7)/1.640(7); C2−N1−C5 106.8(4)/106.6(4), C2−N1−B 127.7(4)/129.0(4), C5−N1−B 125.5(4)/124.3(4), N1−C2−N3 110.3(4)/111.3(4), C2−N3−C4 107.7(4)/107.2(4), C2−N3−C6 125.6(4)/126.5(5), C4−N3−C6 126.7(4)/126.3(5), N3−C4−C5 106.4(4)/106.7(5), C4−C5−N1 108.8(4)/108.1(5), N1−B1−C11 108.5(4)/108.9(4), N1−B1−C21 101.8(4)/103.1(4), N1−B1−C31 112.6(4)/112.5(4), C11−B−C21 115.0(4)/116.5(4), C11−B−C31 105.2(4)/104.0(4), C21−B−C31 113.8(4)/112.0(4)

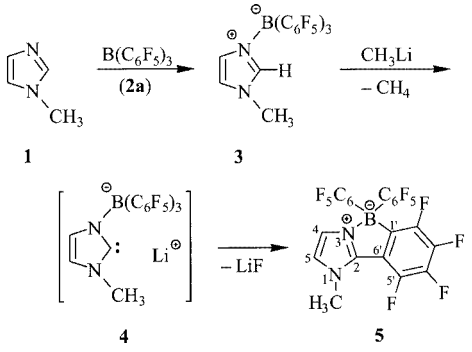
at δ = 6.99/122.2 (4-H/C-4) and δ = 6.29/126.7 (5-H/C-5). The N−CH_3 ^{1}H NMR resonance was observed as a doublet at δ = 3.08 ppm. Detailed NMR analysis, including selective ^{1}H/^{19}F decoupling, revealed that this was due to ^{1}H/^{19}F long-range coupling between the N−CH_3 protons and the 5′-F atom at the annelated C_6F_4 ring ($^6J_{H,F}$ = 4.0 Hz).[24−26] The corresponding N-CH_3/5′-F coupling was determined at $^5J_{C,F}$ = 16.7 Hz.[27−30]



Scheme 1

The ^{11}B NMR resonance of product **5** occurred at δ = −7.6 ppm. The product exhibited the signals of a pair of symmetrically equivalent C_6F_5 substituents at the boron atom [^{19}F NMR: δ = −133.7, −157.1, −163.1 (*o*-, *p*-, *m*-F) ppm; ^{13}C NMR: δ = 148.4, 140.3, 137.6 (C-*o*, -*p*, -*m*)]

and, in addition, a typical set of four C−F signals corresponding to the annelated C_6F_4 moiety [$^{19}F/^{13}C$ NMR: δ = −131.0/148.2 (2′-F/C-2′), −151.1/140.5 (3′-F/C-3′), −156.2/142.1 (4′-F/C-4′), −135.7/141.5 (5′-F/C-5′)]. Figure 2 shows the typical appearance of the ^{19}F NMR spectrum of the product **5**.

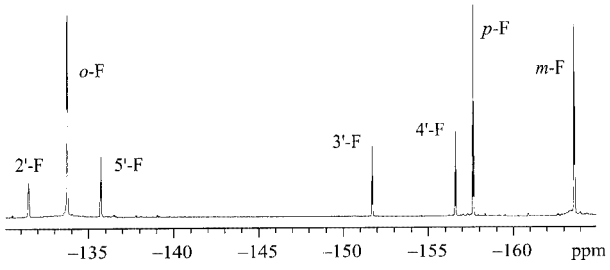


Figure 2. ^{19}F NMR spectrum of the cyclic betaine product **5** (in [D_6]benzene/[D_8]THF, 10:1, 563.6 MHz, at ambient temperature)

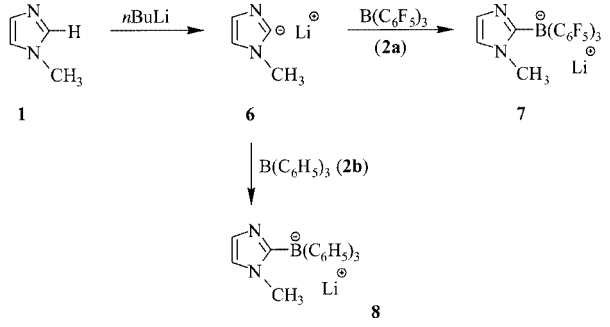
This experiment showed that, in this system, the *C*-borato anion **D**-type products could not be obtained by rearrangement of their Arduengo carbene anion isomers **C**. The respective system **4** was probably generated from **3** on treatment with the base methyllithium, but was shown to be unstable not with regard to rearrangement, but with regard to the much more favored intramolecular S_{NAr} reaction resulting in the observed final product **5**. In this system we therefore had to prepare the *C*-borato **D**-type isomer of the Arduengo carbene anion by a different route.

N-Methylimidazole was deprotonated at C-2 by prolonged treatment (3 d) with *n*-butyllithium at ambient temperature, as described in the literature,[31−38] to yield 2-lithio-1-methylimidazolide (**6**). This was then treated with 1 mol-equiv. of $B(C_6F_5)_3$ to yield the corresponding borate anion product **7** cleanly (see Scheme 2).



Scheme 2

Comparison of characteristic NMR spectroscopic data between compounds **6** and **7** showed that the electrophilic borane had selectively added at carbon atom C-2 of the imidazolide ring system. Most characteristically, the ^{13}C NMR resonance of the carbon atom C-2 had shifted from a very lowfield value of δ = 201.7 ppm in **6** by ca. +40 ppm to δ = 162.2 ppm in **7**. The 4-H and 5-H ^1H NMR resonances were also found at smaller values in **7** (δ = 6.61, 6.58 ppm) relative to the starting material **6** (δ = 7.23, 6.89 ppm). In addition, the ^{11}B NMR resonance of **7** was found at δ = −16.6 ppm, in the range typical for a *C*-bonded borate[39−40] [the *N*-bonded tris(pentafluorophenyl)borate systems typically show ^{11}B NMR resonances between δ = −7 and −9 ppm].

We also treated **6** with $B(C_6H_5)_3$ and obtained the salt **8** [^{13}C NMR: δ = 174.0 (C-2); ^1H NMR: δ = 6.69, 6.66 (4-H, 5-H); ^{11}B NMR: δ = −9.4]. Product **8** was characterized by X-ray crystal structure analysis. This shows the $B(C_6H_5)_3$ group attached at the imidazolide *carbon* atom C2. The C2−B bond length is found at a typical value of 1.634(2) Å. The imidazole π-system in compound **8** is delocalized, similar values as in **3** (see above) being observed: the C4−C5 bond is the shortest in the five-membered ring, at 1.334(2) Å, followed by C2−N3 [1.344(2) Å] and C2−N1 [1.367(2) Å]. The N1−C5 [1.373(2) Å] and N3−C4 bonds [1.374(2) Å] are almost equal in length. The N1−C6 linkage is much longer, at 1.453(2) Å.

The extraordinary structural feature of compound **8** is the coordinative attachment of the lithium cation to the complex anion moiety. It is bonded to N3 [Li−N3 distance: 1.922(3) Å]. One of the phenyl groups at the boron atom is rotated conformationally in such a way [θ(C2−B−C21−C22) = 86.9(2)°] that its π-face is located within bonding distance above Li. An unsymmetrical intramolecular π-arene−lithium interaction results from this orientation, with Li−C(phenyl) distances of 2.467(4) (C26), 2.641(4) (C21), 2.982(4) (C25), 3.192(4) (C22), 3.526(4) (C24), and 3.600(4) Å (C23). The coordination sphere of the lithium cation is completed by a similarly significant intermolecular π-arene−Li interaction with the C11* to C16* phenyl−B ring of an adjacent molecule of **8**. The observed *intermolecular* Li−C(phenyl)* distances are similar [2.393(4) (C15*), 2.515(4) (C16*), 2.629(4) (C14*), 2.895(4)

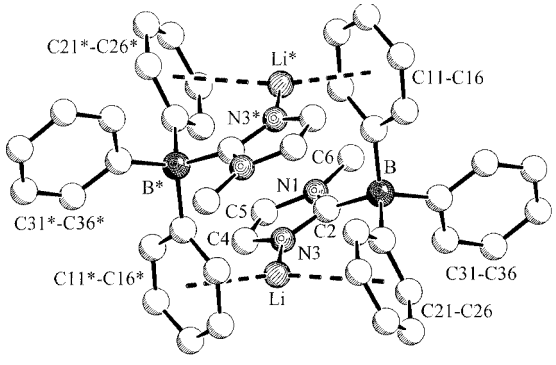


Figure 3. View of the dimeric lithiocene-type structure of **8** in the crystal; selected bond lengths [Å] and angles [°]: Li−N3 1.922(3), N1−C2 1.367(2) N1−C5 1.373(2), N1−C6 1.453(2), C2−N3 1.344(2), N3−C4 1.374(2), C4−C5 1.334(2), B−C2 1.634(2), B−C11 1.640(2), B−C21 1.650(2), B−C31 1.635(2); C2−N1−C5 108.9(1), C2−N1−C6 128.1(1), C5−N1−C6 123.0(1), N1−C2−N3 107.8(1), C2−N3−C4 107.0(1), C2−N3−Li 124.7(1), C4−N3−Li 128.3(1), N3−C4−C5 110.3(1), N1−C4−C5 106.0(1), N1−C2−B 128.1(1), N3−C2−B 124.1(1), C2−B−C11 109.3(1), C2−B−C21 106.6(1), C2−B−C31 110.8(1), C11−B−C21 111.4(1), C11−B−C31 109.9(1), C21−B−C31 108.8(1)

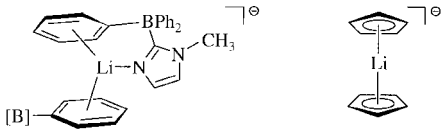
(C11*), 2.958(4) (C13*), and 3.066(4) Å (C12*)] to the *intramolecular* π-arene−lithium bond lengths observed in **8** (Figure 3).[41−43] The lithium−arene interaction is probably largely electrostatic in nature, as is usually observed in organolithium chemistry,[44−48] and the anionic nature of the hetaryltris(aryl)borate unit therefore facilitates the formation of this cyclodimeric structure of **8** in the solid state. Compound **8** thus represents a (dimeric) example of a distorted anionic donor ligand stabilized bis(π-arene)Li−L$^-$ lithiocene-type structure, the π-arene-derived bent lithiocene relative of the often observed Cp-derived lithiocene anions[49−51] **9**. The arene(centroid)−Li−arene(centroid) angle in **8** is 133.1°.

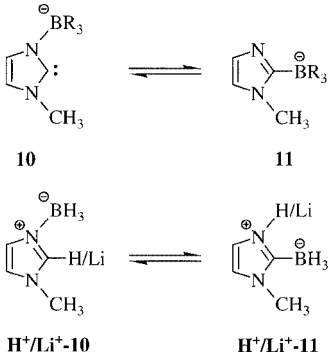


8 **9**

Theoretical Studies

Our experimental investigation had shown that the Arduengo carbene anion **4** generated in situ underwent a favored intramolecular aromatic nucleophilic substitution reaction to yield **5** rather than rearrange to the isomeric anion **7**. We were able to show by independent synthesis that **7** was stable and isolable under the applied reaction conditions. The observed resistance of **4** to rearrangement prompted us to investigate the isomerization hypersurface by theoretical methods with regard to the relative energies of the isomeric anions involved, as well as the energy profiles of their putative thermally induced interconversions with suitable model systems.

For quantum chemical investigation of the equilibrium between *N*-borane-substituted and *C*-borane-substituted imidazol-2-ylidene anions we chose the B3LYP density functional.[52−53] The structures were fully optimized without symmetry restrictions by use of the Turbomole program.[54] A triple zeta Gaussian AO basis set with additional polarization functions (TZVP)[55] was used in the optimization of the geometries and energy calculations. The calculated reaction energies for the rearrangement shown in Scheme 3 are given in Table 1.



10 **11**

H$^+$/Li$^+$-10 **H$^+$/Li$^+$-11**

Scheme 3

Table 1. Reaction energies for the rearrangement of the borane (B3LYP/TZVP)

Starting compound	$\Delta_R E$ [kcal mol^{-1}]
10a (R = H)	−17.4
10b (R = CH_3)	−12.8
10c [R = (C_6H_5)]	−13.7
10d [R = (C_6F_5)]	−15.8
Li$^+$-10a	−16.9
H$^+$-10a	+5.0

Inspection of Table 1 clearly shows that the borate substituent thermodynamically prefers to be bound to C-2 of the anionic heterocyclic moiety. If the N−C fragment is regarded as an imidazolide, the Lewis acidic borane compensates the negative charge much more efficiently when bound to the carbon atom than when bound to the nitrogen atom. The different borane substituents have only a small influence on the reaction energy.

For the lithiated compound (**Li$^+$-10a**, Li at C-2), which may be viewed as a better model for the experimentally investigated situation, no significant change in the reaction energy is observed, although carbon atom C-2 is now no longer divalent. The metal atom does not change the unfavorable situation of two eclipsed vicinal sp^2 lone pairs at the carbenic center and the nitrogen atom, respectively. Only when the corresponding imidazole−borane complex (**H$^+$-10a**) is considered do we find a reversal of the equilibrium. Now the stronger boron−nitrogen interaction determines the preference for the isomer **H$^+$-10a** over the rearranged **H$^+$-11a**.

We have also localized a transition state for the intramolecular rearrangement of **10a** to **11a**.[56] The rearrangement of the borane does not proceed through the ring plane but is tilted, with a dihedral angle of 117.6° to the ring atoms (Figure 4). This is an indication of the symmetry-forbidden character of the reaction, which is also reflected in the high barrier of 40.5 kcal mol^{-1} on going from **10a** to **11a**.[57]

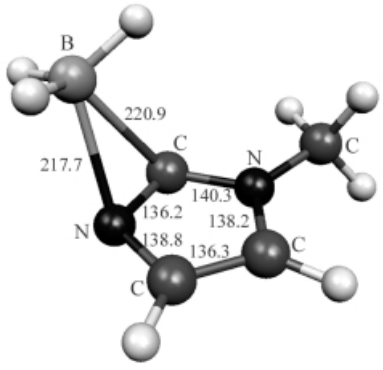


Figure 4. Transition structure of the reaction **10a** → **11a** (B3LYP/TZVP); bond lengths in pm

The nature of the transition structure was confirmed by a frequency calculation, which yielded one imaginary frequency (−119 cm^{-1}). Semiempirical (AM1) calculation of

the intrinsic reaction coordinate showed that this structure indeed linked **10a** and **11a**. By restricting the molecular symmetry to C_s, we obtained a second transition structure, with the borane in the plane, but with a much higher energy relative to **10a** (57.9 kcal mol^{-1}).

Attempts to locate a transition state for the shift of a $B(CH_3)_3$ group failed to give a similar stationary point, but ended with a loose complex of the borane with the anion (B−N 3.5 Å; B−C 3.6 Å), with a relative energy of 31.2 kcal mol^{-1} compared with **10b**. It is very likely that the $B(aryl)_3$ compounds, for which we did not try to calculate a barrier, behave in the same manner.

Our theoretical study revealed that the *C*-borated anions of type **D** (e.g. **7**) were thermodynamically favored over their "Arduengo carbene anion" isomers **B**, **C**, and, for example, **4**, but that their interconversion was practically precluded by a very high barrier of the respective 1,2-BR_3 shift. From our theoretical study it must be assumed that any such rearrangement, when experimentally observed,[17] is likely to have proceeded intermolecularly.[7d,60] Thus, we must conclude that the *N*-borato Arduengo carbene anions should exhibit their characteristic chemistry − as observed for **4** in the Experimental Study − when prepared or generated under conditions precluding *intermolecular* rearrangement pathways to their thermodynamically favored *C*-2-borated imidazole anion isomers. We expect that these findings should stimulate the use of such anionic Arduengo carbenes, especially as ligands in transition metal chemistry and catalysis, beyond the chemistry already reported for the special example of the BH_3-derived system **B**.[61]

Experimental Section

General: Reactions with organometallic compounds were carried out under argon in Schlenk-type glassware or in a glovebox. Solvents, including deuterated solvents used for NMR spectroscopy, were dried and distilled under argon prior to use. The following instruments were used for physical characterization of the compounds: Bruker AC 200 P NMR spectrometer (^{11}B: 64 MHz) at 300 K and Varian Unity plus (^{1}H: 600 MHz. ^{13}C: 150 MHz. ^{19}F: 564 MHz) NMR spectrometer at 298 K, a Nicolet 5 DXC FT-IR spectrometer, and a Micromass Quattro LC-Z mass spectrometer for HRMS determination. Elemental analyses were carried out with a Foss-Heraeus CHN-rapid elemental analyzer or a Vario El III micro elemental analyzer; melting points were determined by differential scanning calorimetry (2010 DSC, Du Pont/STA Instruments). Tris(pentafluorophenyl)borane (**2a**) was prepared according to a literature procedure.[18−20] 1-Methylimidazole (**1**) and triphenylborane (**2b**) were commercially available and were used without further purification. 1-Methylimidazole was stored over molecular sieves.

1-Methylimidazole−Tris(pentafluorophenyl)borane (3): Tris(pentafluorophenyl)borane (**2a**, 1.02 g, 2.00 mmol) was added to a suspension of 1-methylimidazole (**1**, 164 mg, 2.00 mmol) in 20 mL of pentane at 0 °C. The reaction mixture was allowed to warm to room temperature and was stirred for another 12 h. The precipitated product was collected by filtration to yield 1.08 g (91%) of **3** as a white solid, m.p. 249 °C. IR (KBr): $\tilde{\nu}$ = 3001, 1649, 1566, 1530, 1380, 1281, 1259, 1100, 991, 865, 751 cm^{-1}. ^{1}H NMR (600 MHz, [D_6]benzene): δ = 7.82 (s, 1 H, 2-H), 7.06 (s, 1 H, 4-H), 7.01 (d, $^3J_{H,H}$ = 1.2 Hz, 1 H, 5-H), 3.81 (s, 3 H, N−CH_3) ppm. ^{13}C NMR (150 MHz, [D_6]benzene): δ = 148.3 (dm, $^1J_{C,F}$ = 242 Hz, *o*-Ph), 140.2 (dm, $^1J_{C,F}$ = 247 Hz, *p*-Ph), 137.7 (CH, C-2), 137.4 (dm, $^1J_{C,F}$ = 246 Hz, *m*-Ph), 127.1 (CH, C-4), 121.9 (CH, C-5), 36.1 (CH_3, N−CH_3) ppm; *ipso*-carbon signal not detected. ^{19}F NMR (564 MHz, [D_6]benzene): δ = −133.1 (m, 6 F, *o*-Ph), −158.6 (m, 3 F, *p*-Ph), −164.6 (m, 6 F, *m*-Ph) ppm. ^{11}B NMR (64 MHz, [D_6]benzene): δ = −8.0 ($\nu_{1/2}$ = 140 Hz) ppm. $C_{22}H_6BF_{15}N_2$ (594): calcd. C 44.48, H 1.02, N 4.72; found C 43.98, H 1.08, N 5.27.

X-ray Crystal Structure Analysis of 3: Empirical formula $C_{22}H_6BF_{15}N_2$, M = 594.10, colorless crystal 0.25 × 0.20 × 0.10 mm, a = 11.222(2), b = 12.315(2), c = 16.463(3) Å, α = 88.32(1), β = 72.69(2), γ = 86.91(1)°, V = 2168.8(7) $Å^3$, $\rho_{calcd.}$ = 1.820 g cm^{-3}, μ = 18.15 cm^{-1}, empirical absorption correction from ψ scan data ($0.660 \le T \le 0.839$), Z = 4, triclinic, space group $P\bar{1}$ (no. 2), λ = 1.54178 Å, T = 223 K, ω scans, 9282 reflections collected ($-h$, $\pm k$, $\pm l$), [(sin θ)/λ] = 0.62 $Å^{-1}$, 8808 independent (R_{int} = 0.037) and 5107 observed reflections [$I \ge 2\ \sigma(I)$], 723 refined parameters, R = 0.082, wR^2 = 0.246, max. residual electron density 0.68 (−0.49) e $Å^{-3}$, crystals were always twinned (thin plates with a small tilt), by use of ω scans to collect the integrated intensities of all individuals, hydrogen atoms calculated and refined as riding atoms.

Treatment of Compound 3 with Methyllithium, Formation of the Heterocycle 5: Benzene/tetrahydrofuran (10:1, 2 mL) was added to a mixture of 1-methylimidazole−tris(pentafluorophenyl)borane (**3**, 100 mg, 168 μmol) and methyllithium (3.70 mg, 168 μmol). The resultant reaction mixture was stirred for 12 h, the solvent was removed in vacuo, and benzene was added. The LiF precipitate was removed by filtration, and evaporation of the solvent in vacuo yielded **5** as a light brown solid, yield: 83 mg (92%), m.p. 76 °C. IR (KBr): $\tilde{\nu}$ = 2966, 1647, 1616, 1519, 1486, 1467, 1382, 1287, 1266, 1098, 1058, 975, 835, 778 cm^{-1}. ^{1}H NMR (600 MHz, [D_6]benzene/[D_8]tetrahydrofuran 10:1): δ = 6.99 (d, $^3J_{H,H}$ = 1.8 Hz, 1 H, 4-H), 6.29 (d, $^3J_{H,H}$ = 1.8 Hz, 1 H, 5-H), 3.08 (d, $J_{H,F}$ = 4.0 Hz, 3 H, N−CH_3) ppm. ^{13}C NMR (150 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = 148.4 (dm, $^1J_{C,F}$ = 241 Hz, *o*-Ph), 148.2 (dm, $^1J_{C,F}$ = 245 Hz, C-2′), 147.3 (C, C-2), 142.1 (dm, $^1J_{C,F}$ = 257 Hz, C-4′), 141.5 (dm, $^1J_{C,F}$ = 255 Hz, C-5′), 140.5 (dm, $^1J_{C,F}$ = 251 Hz, C-3′), 140.3 (dm, $^1J_{C,F}$ = 251 Hz, *p*-Ph), 137.6 (dm, $^1J_{C,F}$ = 250 Hz, *m*-Ph), 126.7 (CH, C-5), 122.2 (CH, C-4), 116.7 (C, *ipso*-C), 35.6 (CH_3, $J_{C,F}$ = 16.7 Hz, N−CH_3) ppm; signals of C-1′ and C-6′ not detected. ^{19}F NMR (564 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = −131.0 (m, 1 F, 2′-F), −133.7 (m, 4 F, *o*-Ph), −135.7 (m, 1 F, 5′-F), −151.1 (m, 1 F, 3′-F), −156.2 (m, 1 F, 4′-F), −157.1 (m, 2 F, *m*-Ph), −163.2 (m, 4 F, *m*-Ph) ppm. ^{11}B NMR (64 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = −7.6 ($\nu_{1/2}$ = 130 Hz) ppm. $C_{22}H_5F_{14}N_{22}$ (574): calcd. C 46.03, H 0.88, N 4.88; found C 45.59, H 1.54, N 4.58.

2-Lithio-1-methylimidazole (6):[13] A solution of 1-methylimidazole (1.18 g, 14.1 mmol) in 20 mL of toluene was cooled to −78 °C and treated with an equivalent amount of *n*-butyllithium in hexane (9.00 mL, 14.4 mmol). After the mixture had stirred for 2 d at room temperature, the solvent was removed in vacuo. Pentane was added, the solid was separated by filtration, and the product was dried in vacuo to yield 1.24 g (99%) of **6**. ^{1}H NMR (600 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = 7.23 (s, 1 H, 4-H), 6.89 (s, 1 H, 5-H), 3.64 (CH_3, N−CH_3) ppm. ^{13}C NMR (150 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = 201.7 (C, C-2), 128.4 (CH, C-4), 117.8 (CH, C-5); 35.7 (CH_3, N−CH_3).

Lithium (1-Methylimidazol-2-yl)tris(pentafluorophenyl)borate (7): Tris(pentafluorophenyl)borane (**2a**, 512 mg, 1.00 mmol) was added to a suspension of 2-lithio-1-methylimidazole (**6**, 88.0 mg, 1.00 mmol) in 20 mL of pentane at room temperature. The reaction mixture was stirred for 24 h. The precipitated product was collected by filtration to yield **7** as a gray solid (380 mg, 63%), m.p. 255 °C. IR (KBr): $\tilde{\nu}$ = 1646, 1523, 1465, 1366, 1282, 1091, 981, 796, 740, 695 cm^{-1}. ^1H NMR (600 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = 6.61 (d, $^3J_{H,H}$ = 1.2 Hz, 1 H, 4-H), 6.58 (d, $^3J_{H,H}$ = 1.2 Hz, 1 H, 5-H), 3.17 (s, 3 H, N−CH_3) ppm. ^1H NMR (150 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = 162.2 (C, C-2), 148.7 (dm, $^1J_{C,F}$ = 241 Hz, *o*-Ph), 140.3 (dm, $^1J_{C,F}$ = 249 Hz, *p*-Ph), 137.3 (dm, $^1J_{C,F}$ = 250 Hz, *m*-Ph), 125.9 (CH, C-4), 121.2 (CH, C-5), 33.7 (CH_3, N−CH_3) ppm, *ipso*-carbon signal not detected. ^{19}F NMR (564 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = −124.6 (m, 1 F, *o*-Ph), −132.7 (m, 1 F, *o*-Ph), −133.0 (br, 3 F, *o*-Ph), −132.6 (m, 1 F, *o*-Ph), −161.6 (br, 2 F, *p*-Ph), −162.8 (m, 1 F, *p*-Ph), −165.6 (m, 1 F, *m*-Ph), −166.0 (br, 5 F, *m*-Ph) ppm. ^{11}B NMR (64 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = −16.6 ($\nu_{1/2}$ = 50 Hz) ppm. HRMS: calculated for $[C_{22}H_5N_2BF_{15}]^-$ 593.0310; found 593.0384.

Lithium (1-Methylimidazol-2-yl)triphenylborate (8): As described above, 2-lithio-1-methylimidazole (**6**, 264 mg, 3.00 mmol) in 20 mL of toluene was treated with triphenylborane (**2b**, 762 mg, 3.00 mmol) to yield **8** (619 mg, 62%) as a white solid, m.p. 283 °C. IR (KBr): $\tilde{\nu}$ = 3055, 1580, 1481, 1426, 1385, 1278, 1122, 1154, 1032, 943, 854, 758, 710 cm^{-1}. ^1H NMR (600 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = 7.55 (m, 6 H, *o*-Ph), 7.18 (m, 6 H, *m*-Ph), 7.04 (m, 3 H, *p*-Ph), 6.69 (d, $^3J_{H,H}$ = 1.2 Hz, 1 H, 5-H), 6.66 (d, $^3J_{H,H}$ = 1.2 Hz, 1 H, 4-H), 3.06 (s, 6 H, N−CH_3) ppm. ^{13}C NMR (150 MHz, [D_6]benzene/[D_8]tetrahydrofuran, 10:1): δ = 174.0 (q, $^1J_{CB}$ = 50 Hz, C-2), 160.3 (q, $^1J_{CB}$ = 57 Hz, *ipso*-C), 135.6 (CH, *o*-Ph), 127.1 (CH, *m*-Ph), 124.6 (CH, C-4), 123.5 (CH, *p*-Ph), 120.5 (CH, C-5), 35.4 (CH_3, N−CH_3) ppm. ^{11}B NMR (64 MHz, [D_6]benzene): δ = −9.4 ($\nu_{1/2}$ = 44 Hz) ppm. HRMS: calculated for $[C_{22}H_{20}N_2B]^-$ 323.1724; found 323.1781.

X-ray Crystal Structure Analysis of 8: Empirical formula $C_{22}H_{20}BLiN_2$, M = 330.15, light yellow crystal 0.45 × 0.30 × 0.30 mm, a = 10.701(1), b = 14.818(1), c = 11.104(1) Å, β = 91.65(1)°, V = 1760.0(3) $Å^3$, $\rho_{calcd.}$ = 1.246 g cm^{-3}, μ = 0.71 cm^{-1}, empirical absorption correction by SORTAV (0.969 ≤ T ≤ 0.979), Z = 4, monoclinic, space group $P2_1/n$ (no. 14), λ = 0.71073 Å, T = 198 K, ω and ψ scans, 14410 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.66 $Å^{-1}$, 4269 independent (R_{int} = 0.050) and 2820 observed reflections [$I \geq 2\,\sigma(I)$], 236 refined parameters, R = 0.050, wR^2 = 0.102, max. residual electron density 0.25 (−0.17) e $Å^{-3}$, hydrogen atoms calculated and refined as riding atoms.

Data sets were collected with Enraf−Nonius CAD4 and Nonius KappaCCD diffractometers, the latter equipped with a rotating anode generator (Nonius FR591). Programs used: data collection EXPRESS (Nonius B.V., 1994) and COLLECT (Nonius B.V., 1998), data reduction MolEN (K. Fair, Enraf-Nonius B.V., 1990) and Denzo-SMN (Z. Otwinowski, W. Minor, *Methods Enzymol.*, **1997**, *276*, 307−326), absorption correction for CCD data SORTAV (R. H. Blessing, *Acta Crystallogr.* **1995**, *A51*, 33−37; R. H. Blessing, *J. Appl. Crystallogr.* **1997**, *30*, 421−426), structure solution SHELXS-97 (G. M. Sheldrick, *Acta Crystallogr.* **1990**, *A46*, 467−473), structure refinement SHELXL-97 (G. M. Sheldrick, Universität Göttingen, 1997), graphics SCHAKAL (E. Keller, Universität Freiburg, 1997). CCDC-173951 (**3**) and -173952 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Molecular Mercury Zinc Sulfides

Michael Rombach[a] and Heinrich Vahrenkamp*[a]

Dedicated to Professor Dieter Fenske on the occasion of his 60th birthday

Keywords: Mercury / Zinc / S ligands / Tripod ligands

Reactions between $Tp^{Ph,Me}$Zn-SH and mercury bis(trimethylsilyl)amides yield the monomeric complexes $Tp^{Ph,Me}$-Zn–S–$HgCH_2Ph$ (**1**) and $Tp^{Ph,Me}$Zn–S–Hg–S–Zn$Tp^{Ph,Me}$ (**2**). The bent Zn–S–Hg and linear S–Hg–S arrays in these molecular metal sulfides were confirmed by structure determinations.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

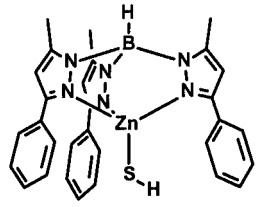
Introduction

The most characteristic feature of sulfur as a ligand in metal complexes is its tendency to be three- or four-coordinate by bridging several metal atoms. This has long been known for classical[1] as well as for organometallic[2] coordination chemistry. In recent years Fenske and co-workers have provided impressive examples of high-nuclearity clusters constructed by the nucleation of metal ions around sulfide ions.[3−5]

In contrast, transition metal complexes containing conventional divalent sulfur in monomeric M−S−M arrays are rare. Outside the field of plain thiometalates[6] there are only scattered examples in the literature.[7] Among the few complexes in which two metals are linked by nothing but a sulfide ligand are $[Cp(CO)_3W]_2S$,[8] $[(Ph_3P)Au]_2S$[9] and $[(triphos)Ni]_2S^{2+}$.[10] As a rule the high inertness of the L_nM units contained in these complexes has rendered their metal centers M inaccessible to aggregation triggered by loss of their ligands L.

Our present work in this field, after past experiences with polynuclear organometallic complexes,[2] results from our attempts to construct monofunctional zinc complexes for biomimetic and catalytic studies. Since sulfur ligation of zinc is a common feature of both industrially applied and biological zinc species, we have also experimented with thiolates and sulfide as ligands for zinc. Like others we experienced aggregation of the complexes[11−13] and nucleation around sulfide in the complex cores.[14,15] However, by using bulky pyrazolylborate ligands we also learnt to protect the zinc ions by encapsulation. This way zinc-hydrosulfide complexes became accessible as the very stable and versatile Tp*Zn−SH species,[16] and we could prepare $Tp^{Cum,Me}$Zn−S−Zn$Tp^{Cum,Me}$ as the first molecular zinc sulfide.[17]

After exploiting the basic chemistry of the Zn−SH function[16] we have started using the Tp*Zn−SH units as building blocks for new complexes. The present paper describes the application of $Tp^{Ph,Me}$Zn−SH for the preparation of two molecular mercury zinc sulfides.



$Tp^{Ph,Me}$Zn–SH

Results and Discussion

Preparations

The most straightforward way of utilizing the Tp*Zn−S moiety for preparative purposes would be the deprotonation of Tp*Zn−SH. It turned out, however, that the "thiolates" Tp*Zn−S^- are not stable enough for this purpose.[16] Therefore we resorted to the implicit deprotonation approach, which consists in the reaction between a thiol and a metal bis(trimethylsilyl)amide. In this approach the metal-bound amide is the base for deprotonation and at the same time the ligand being substituted by the thiolate. We have used this method before for the synthesis of otherwise inaccessible zinc thiolates,[18] and we now applied it to the corresponding mercury amides.

The reaction between $Tp^{Ph,Me}Zn-SH$ and benzylmercury bis(trimethylsilyl)amide yielded the Zn−S−Hg complex **1**. Likewise $Tp^{Ph,Me}Zn-SH$ and mercury bis[bis(trimethylsilyl)amide] produced the Zn−S−Hg−S−Zn complex **2**. Both reactions resulted in air-stable colourless crystalline compounds in reasonable yields. While their IR data are uninformative, their ^1H NMR spectra (see Exp. Sect.) prove the presence of the Tp and Bz ligands. Compounds **1** and **2** are the first fully characterized mixed-metal sulfide complexes of the second subgroup. Mixed-metal sulfide clusters containing zinc and cadmium have been described but not isolated in a pure form.[19,20]

Structures

Complex **1** (see Figure 1) contains a nearly right-angled Zn−S−Hg array. Its two constituents, the Tp*ZnS unit and the BzHgS unit, are quite normal with typical Zn−S, Hg−S and Hg−C bond lengths. Reference compounds are the Tp*Zn−SH complexes themselves[16] and the organomercury thiolates.[21] As expected for two-coordinate mercury, the S−Hg−C array is very close to being linear. The dihedral angle defined by the Zn−S and C−C bonds with respect to the Zn−S−Hg axis is 174°.

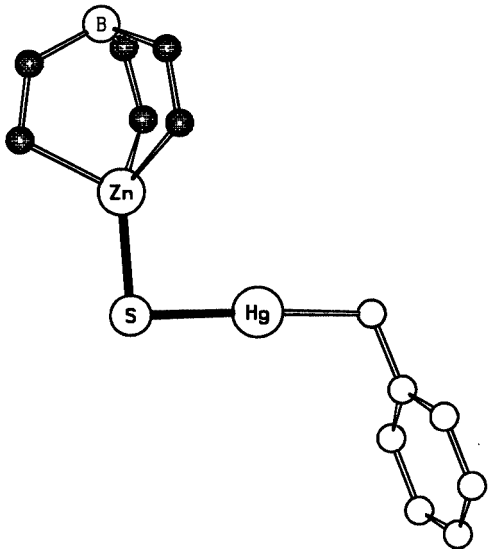

Figure 1. Molecular structure of complex **1** (for reasons of clarity the pyrazolylborate ligand is reduced to its BN_6 skeleton); important bond lengths (Å) and angles (°): Zn−N 2.065−2.092(5), Zn−S 2.221(2), Hg−S 2.316(2), Hg−C 2.115(1); Zn−S−Hg 93.41(7), S−Hg−C 176.3(5)

Complex **2** (see Figure 2) is centered around a nearly linear S−Hg−S array with Hg−S distances very similar to those in **1**. The two Hg−S−Zn angles are larger than the one in **1** and differ by 12°, probably due to steric congestion. The two Tp*Zn−S units are practically superimposable with that in **1**. While in **1** the Hg−S−Zn and Hg−C−C units define a trans array, the corresponding two Hg−S−Zn units in **2** are gauche, their dihedral angle being 95°. Complex **2** can be compared with monomeric mercury bis(thiolates), whose structures in the solid state range from linear two-coordinate to polymers with four- and five-coordinate mercury.[22] Furthermore the Zn−S−Hg−S−Zn sequence in **2** is analogous to the 1D polymeric array of mercury and sulfur in cinnabar, the thermodynamically more stable modification of HgS.[23] In cinnabar the Hg−S bond lengths are 2.37 Å and the dihedral angle is 93°.

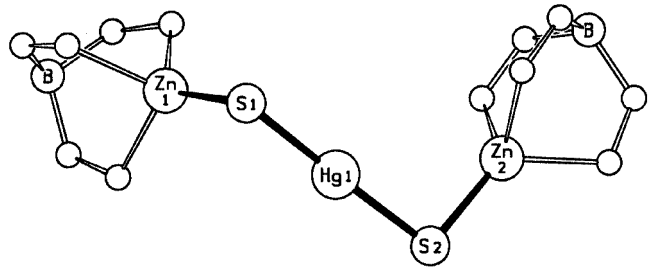

Figure 2. Molecular structure of complex **2** (for reasons of clarity the pyrazolylborate ligands are reduced to their BN_6 skeletons); important bond lengths (Å) and angles (°): Zn−N 2.070−2.086(3), Zn1−S1 2.226(1), Zn2−S2 2.219(1), Hg−S1 2.299(1), Hg−S2 2.303(1); Zn1−S1−Hg 108.70(5), Zn2−S2−Hg 96.75(5)

Conclusions

The facile preparations of **1** and **2** have proved the suitability of the Tp^*ZnS^- unit for the construction of molecular metal sulfides. Except for our Tp*Zn−S−ZnTp* [17] no such sulfides of zinc, cadmium or mercury with simple M−S−M arrays seem to have been reported, even though the standard arrangements of the types $M_3(\mu_3\text{-}S)$ and $M(\mu\text{-}S)_2M'$ are known for heterometallic mercury complexes.[24,25] Furthermore, the chain-like array of three metal and two sulfur atoms in **2** seems to be unprecedented in coordination chemistry, although the relation to cinnabar makes it understandable that it exists in complex **2**. The tendency of mercury to have a linear twofold coordination and the highly covalent nature of the mercury-ligand bonds may be important for the stabilization of these molecular metal sulfides. We believe, however, that the protection by the encapsulating Tp* ligands will stabilize similar complexes with other metals too.

Experimental Section

General: For general working and measuring procedures, see ref.[26] All reactions were performed under an inert atmosphere. $Tp^{Ph,Me}Zn-SH$[16] and the mercury silylamides[27] were prepared according to the published procedures.

Complex 1: $BzHgN(SiMe_3)_2$ (163 mg, 0.36 mmol) and $Tp^{Ph,Me}Zn-SH$ (210 mg, 0.36 mmol) in 20 mL of dichloromethane were stirred for 2 h. After removal of all volatiles in vacuo the residue was recrystallized from acetonitrile, yielding 179 mg (57%) of

1 as colorless crystals which turned to a powder upon drying in vacuo, M.p. 202 °C (dec.). $C_{37}H_{35}BHgN_6SZn$ (872.6): calcd. C 50.33, H 4.04, N 9.63; found C 50.73, H 4.03, N 9.61. ^{1}H NMR ($CDCl_3$): δ = 1.76 (s, 2 H, CH_2), 2.56 [s, 9 H, Me(pz)], 6.17 [s, 3 H, H(pz)], 6.69 (m, 2 H, Bz), 6.89 (m, 1 H, Bz), 7.06 (m, 2 H, Bz), 7.30 (m, 9 H, Ph), 7.61 (m, 6 H, Ph) ppm.

Complex 2: $Tp^{Ph,Me}Zn-SH$ (500 mg, 0.86 mmol) and $Hg[N(SiMe_3)_2]_2$ (224 mg, 0.43 mmol) in 30 mL of dichloromethane were stirred for 15 min, upon which the solution turned black. After removal of all volatiles in vacuo the residue was taken up in a minimum amount of hot acetonitrile, filtered hot and the filtrate kept at room temp. for one day. 210 mg (36%) of **2** were precipitated as colorless crystals, which turned to a powder upon drying in vacuo. M.p. 248 °C (dec.). $C_{60}H_{56}B_2HgN_{12}S_2Zn_2$ (1362.3): calcd. C 52.90, H 4.14, N 12.34; found C 52.72, H 4.20, N 12.42. ^{1}H NMR ($CDCl_3$): δ = 2.55 [s, 18 H, Me(pz)], 6.12 [s, 6 H, H(pz)], 7.04 (m, 18 H, Ph), 7.48 (m, 12 H, Ph).

Structure Determinations:[28] Crystals of **1** and **2** were obtained from the reaction mixtures. Diffraction data were recorded at room temp. with the ω/2θ technique on a Nonius CAD4 diffractometer fitted with a molybdenum tube (Mo-K_α, λ = 0.7107 Å) and a graphite monochromator and subjected to empirical absorption corrections. The structures were solved by direct methods and refined anisotropically with the SHELX program suite.[29] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5-times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = [\Sigma[w(F_0^2 - F_c^2)^2]\Sigma[w(F_0^2)^2]]^{1/2}$. Drawings were produced with SCHAKAL.[30] Table 1 lists the crystallographic data.

Synthesis of μ-$C_2S_4^{4-}$ Cobalt Complexes by Activation of the 1,3,4,6-tetrathiapentalene-2,5-dione, and Electrochemical Study of [$(Cp^*Co)_2(\mu\text{-}C_2S_4)$]

Fabrice Guyon,*[a] Isabelle V. Jourdain,[a] Michael Knorr,[a] Dominique Lucas,[b] Theresa Monzon,[b] Yves Mugnier,[b] Narcis Avarvari,[c] and Marc Fourmigué[c]

Keywords: Cobalt / S ligands / Cyclopentadienyl ligands / Electrochemistry

The bimetallic complex [$Cp^{(*)}Co)_2(\mu\text{-}C_2S_4)$] in which the two metal centres are linked by an ethylenetetrathiolate $C_2S_4^{4-}$ unit, was synthesized in high yield by oxidative addition of 1,3,4,6 tetrathiapentalene-2,5-dione to [$Cp^{(*)}Co(CO)_2$]. The X-ray crystal structure of the intermediate product $Cp^*Co(dmid)$ ($dmid^{2-}$ = 4,5-disulfanyl-1,3-dithiol-2-onate) is presented. The electrochemical behaviour of the [$(Cp^*Co)_2(\mu\text{-}C_2S_4)$] complex was studied in detail in the oxidative range. This study has shown that the nature of the product obtained after oxidation depends on the presence of complexing agent in the solution. The mechanism has been elucidated in a CH_2Cl_2 solution in the presence of $P(OMe)_3$. In addition, chemical oxidation was conducted with several oxidizing agents (Br_2, $TCNQF_4$, and $AgBF_4$). The molecular structure of the tetrathiooxalate bridged complex [$(Cp^*Co\{P(OMe)_3\})_2(\mu\text{-}C_2S_4)$][$BF_4$]$_2$ was established by an X-ray diffraction study.

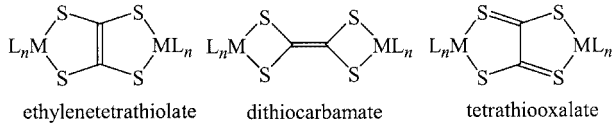
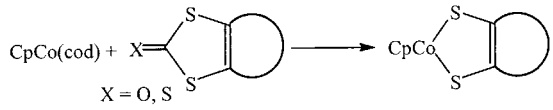
Introduction

Complexes containing the ethylenetetrathiolate $C_2S_4^{4-}$ unit as a bridging ligand between two metal centres are rather rare, despite their potential to form systems with metallic or semiconducting properties.[1] The reason for this is the lack of a general procedure to generate this sulfur-rich ligand. Most of the tetrathiolate transition metal complexes have been synthesised by metal-promoted head-to-head reductive dimerization of CS_2. Representative examples include [$(Cp_2Ti)_2(\mu\text{-}C_2S_4)$],[2] [$(Cp^*Co)_2(\mu\text{-}C_2S_4)$],[3] [$(Cp^*Ni)_2(\mu\text{-}C_2S_4)$],[4] and [{M(triphosp)}$_2(\mu\text{-}C_2S_4)$] (M = Rh or Ir).[5] However, we have found in our laboratories that the reaction of [$Cp^*Co(CO)_2$] with CS_2 leads to the formation of a mixture in which μ-dithiolene and μ-dithiocarbamate [$(Cp^*Co)_2(\mu\text{-}C_2S_4)$] isomers coexist.[6] The same result was observed in the case of the titanium complex [$(Cp_2Ti)_2(\mu\text{-}C_2S_4)$].[7] Recently, Rauchfuss et al. reported the synthesis of [$(Cp^*Rh)_2(\mu\text{-}C_2S_4)$] via an efficient reductive dechlorination of the tetrathiooxalate derivative [$(Cp^*RhCl)_2(\mu\text{-}C_2S_4)$].[8]



The synthesis of metal dimers containing the $C_2S_4^{4-}$ bridging ligand was also explored using the well-known reactivity of dithiocarbonate groups towards strong bases by starting from 1,3,4,6-tetrathiapentalene-2,5-dione (tpd). This method was found unsuccessful, however, or led to the desired product in low yield.[9,10] Another reactivity pattern of dithiocarbonate groups has already been employed for the synthesis of cobaltocene dithiolene complexes, used as model for the molybdenum cofactor.[11] The reaction consists of the oxidative addition of 1,3-dithiol-2-one or 1,3-dithiole-2-thione to [CpCo(cod)] (cod = cyclooctadiene).



With the aim of generating dimetallic complexes, it was tempting to apply this strategy by using bis(1,3-dithiol-2-one) and bis(1,3-dithiole-2-thione) as precursors. In this paper we report on the very efficient formation of [$Cp^{(*)}Co)_2(\mu\text{-}C_2S_4)$] complexes starting from tpd. The electrochemical properties of the [$Cp^{(*)}Co)_2(\mu\text{-}C_2S_4)$] complexes have been studied in detail in CH_2Cl_2 and CH_3CN solutions. The molecular structures of the intermediate product

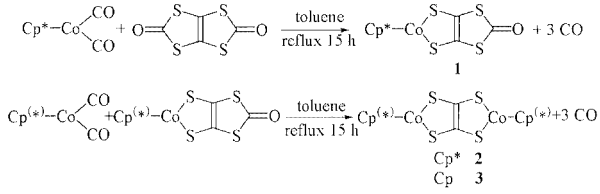
[Cp*Co(dmid)] ($dmid^{2-}$ = 4,5-disulfanyl-1,3-dithiol-2-onate) and of the oxidized species $[(Cp^*CoL)_2(\mu\text{-}C_2S_4)](BF_4)_2$ [L = $P(OMe)_3$] are also described.

Results and Discussions

Synthesis

The reaction of equimolar quantities of 1,3,4,6-tetrathiapentalene-2,5-dione (tpd) and $[Cp^*Co(CO)_2]$ in refluxing toluene afforded the intermediate complex [Cp*Co(dmid)] (**1**), which has already been isolated by the conventional metathesis of Na_2dmid and $[Cp^*Co(CO)I_2]$.[12] Recrystallization from toluene and hexane provided single crystals of **1**. The crystal structure was determined, since it has not been reported previously (see below). This intermediate **1** reacted with a second equiv. of $[Cp^*Co(CO)_2]$ under the same reaction conditions to afford the dimetallic diamagnetic complex $[(Cp^*Co)_2(\mu\text{-}C_2S_4)]$ (**2**). This compound was isolated as a green crystalline powder with a yield close to 90%, based on tpd (Scheme 1).



Scheme 1

Of course, this synthesis could also be achieved in one step by the reaction of 2 equiv. of $[Cp^*Co(CO)_2]$ and 1 equiv. of tpd. The isolation of **1** allowed us to deduce the dithiolene nature of the bridge instead of a dithiocarbamate core. Using an analogous procedure, we were able to synthesise the new $[(CpCo)_2(\mu\text{-}C_2S_4)]$ compound **3** in an appreciable yield (58%). In contrast to **2**, the solubility of the complex **3** was very poor in common organic solvents, which prevented any solution NMR characterization. The synthesis of **3** demonstrates the efficiency of this method, since it has not been obtained previously by the action of CS_2 on $[CpCo(CO)_2]$.[3b]

Structural Analysis of 1

The structure shown in Figure 1 is very similar to those of the structurally characterized heteroleptic cyclopentadienyl(dithiolene)cobalt complexes,[13] and particularly that of the [Cp*Co(dmit)] molecule ($dmit^{2-}$ = 4,5-disulfanyl-1,3-dithiole-2-thionate).[14] In this compound, the $Co(C_3OS_4)$ moiety is nearly planar and perpendicular to the Cp* moiety [89.3(1)°]. Selected bond lengths and angles are listed in Table 1, and have been compared with those of [Cp*Co(dmit)]. The short length of the C(1)−C(2) bond [1.337(5) Å] of the ligand is in agreement with a dithiolene structure and proves that the reaction between the tpd and the $[Cp^*Co^I(CO)_2]$ compound leads to the coordination of $dmid^{2-}$ on the Cp^*Co^{III} fragment.

Electrochemical Experiments

The electrochemical behaviour of several $C_2S_4^{4-}$ bridged complexes has been studied, but the reported results point out different observations in the oxidation range. Indeed, the cyclic voltammograms of $[(Cp^*Ni)_2(\mu\text{-}C_2S_4)]$[4] and $[(Cp^*Rh)_2(\mu\text{-}C_2S_4)]$[8a] complexes in CH_2Cl_2 show a one-electron process, whereas in the case of $[\{Rh(triphosp)\}_2(\mu\text{-}C_2S_4)]$ a two electron oxidation is observed in CH_2Cl_2 or CH_3CN solutions.[5] Therefore, in order to evaluate the influence of the solvent, the redox behaviour of **2** was studied in CH_2Cl_2 and CH_3CN solutions.

The rotating-disk voltammogram in CH_2Cl_2 displays one anodic and two cathodic waves, all with nearly the same height. These were named O_1', R_1, and R_2, respectively, each associated with a one-electron transfer (Figure 2 and Table 2). In cyclic voltammetry, the first reductive step was found to be reversible, but not the second one, presumably because of the reactivity of the electrogenerated dianion $[(Cp^*Co)(\mu\text{-}C_2S_4)]^{2-}$ with the electrophilic dichloromethane (Scheme 2).[15] This is in contrast to what was observed in acetonitrile (see below). Exploring the oxidation, we ob-

served in CH_2Cl_2 solution a peak O_1' at +0.62 V versus SCE (E_p) coupled on the backward scan with a peak at +0.15 V, which is indicative of a chemical reaction following the one-electron oxidation of the neutral complex. An exhaustive controlled-potential oxidation of **2** consumed nearly 1 F/mol of the initial complex, and left the product reducible at +0.15 V; the electrolysed solution was ESR-silent, which traduces the diamagnetism of this product. We propose that the chemical reaction consists in the dimerization of the intermediate $[(Cp^*Co)_2(\mu\text{-}C_2S_4)]^+$ (Scheme 2). Indeed, this oxidation behaviour has already been observed for the analogous rhodium complex $[(Cp^*Rh)_2(\mu\text{-}C_2S_4)]$[8b] and for a dithiolene cobaltocene complex.[16] With this latter complex, it has also been shown that in the presence of a strong two-electron donor ligand the stabilization occurs via the formation of an adduct.[16] Thus, in order to explain the mechanism of the oxidation of **2** in the presence of a strong Lewis base, electrochemical experiments were conducted in CH_2Cl_2, where an excess of $P(OMe)_3$ was initially added to **2**. The resulting RDE voltammogram is depicted (see b in Figure 3). Reduction wave R_1 is still present, but with a considerably reduced height, attesting to the fact that **2** is still in solution, but in a limited amount (nearly 25% based on the relative value of $i_{d,R1}$). New oxidation waves appear at −0.62, −0.23, and +0.06 V, named $O_1{*}'$, $O_1^{\#\prime}$, and $O_2{*}'$, respectively. These can be explained by considering that **2** is able to coordinate one or two $P(OMe)_3$ moieties. As $P(OMe)_3$ is a strong σ-donor, the most negative oxidation wave, namely $O_1{*}'$, must be assigned to the two-ligand containing complex $[(Cp^*Co\{P(OMe)_3\})_2(\mu\text{-}C_2S_4)]$ (**2b**). Oxidation wave $O_1^{\#\prime}$ is attributed to the mono adduct $[(Cp^*Co)_2\{P(OMe)_3\}(\mu\text{-}C_2S_4)]$ (**2a**), which is predominant since $O_1^{\#\prime}$ is noticeably more intense than R_1 or $O_1{*}'$.

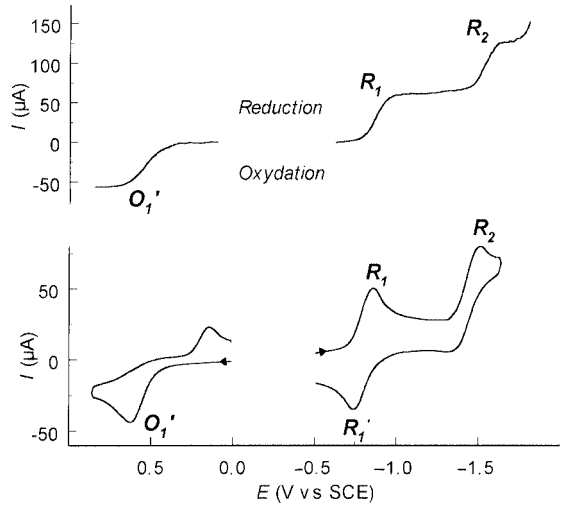

Figure 2. Rotating-disk and cyclic voltammogram of 2.7 mM of **2** in CH_2Cl_2, 0.2 M Bu_4NPF_6; CV: sweep rate = 200 $mV{\cdot}s^{-1}$, initial potential = −0.1 (anodic scan) and −0.65 V (cathodic scan); RDV: rotation speed = 15 rps

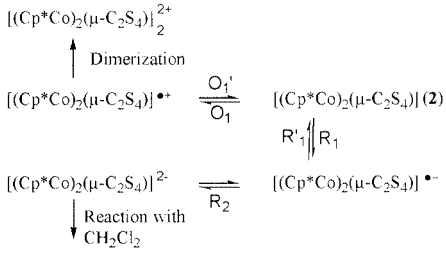

Scheme 2

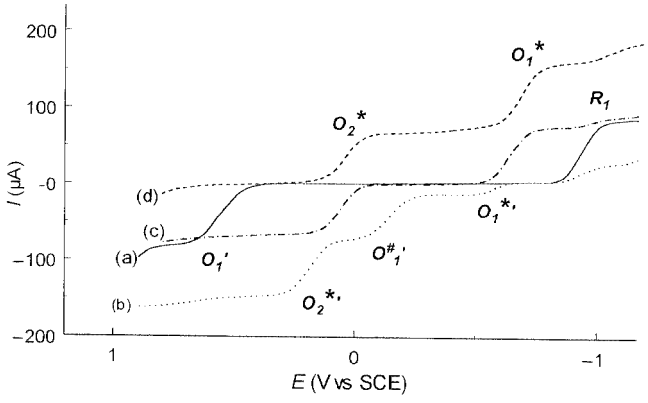

Figure 3. Rotating-disk voltammogram of 4.1 mM of **2** in CH_2Cl_2 0.2 M Bu_4NPF_6, rotation speed = 10 rps; a (——): **2** alone; b (···) after addition of 33 mol-equiv. of $P(OMe)_3$; c (·-·-) after electrolysis at −0.05 V; d (---) after electrolysis at +0.3 V

An exhaustive controlled-potential electrolysis, performed on the plateau of wave $O_1^{\#\prime}$ (E_w = −0.05 V vs. SCE), consumed nearly 1 F/mol of **2**. The resulting RDE voltammogram (see c in Figure 3) displays the anodic wave $O{*}_2'$ together with the cathodic wave $O{*}_1$, which means that at the monooxidized state, the bis(adduct) $[(Cp^*Co\{P(OMe)_3\})_2(\mu\text{-}C_2S_4)]^{+\cdot}$ (**2e**) is the only stable species. This was confirmed by ESR analysis of the electrolysed solution. The apparently complex morphology of the spectrum (Figure 4) arises from the coupling of the unpaired spin with two phosphorus and two cobalt nuclei (g_{iso} = 2.020; a_{Co} = 3.4 G; a_P = 22.6 G). Particularly, the hyperfine coupling constants are close to those found for similar complexes.[17]

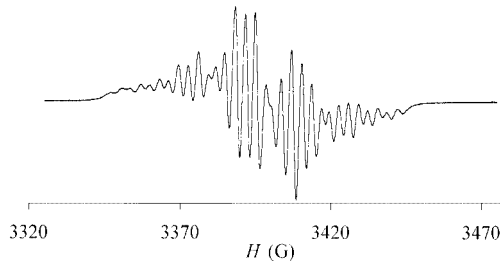

Figure 4. The ESR spectrum (X-band) of **2e**, obtained after the electrolysis (E_w = −0.05 V vs. SCE) of a CH_2Cl_2 solution of **2** in the presence of an excess of $P(OMe)_3$

The second stage of oxidation was also studied. Indeed, starting from **2e**, an electrolysis at 0.3 V (plateau of wave $O^*_2{}'$), consumed nearly 1 equiv. of electrons and quantitatively yielded $[(Cp^*Co\{P(OMe)_3\})_2(\mu\text{-}C_2S_4)]^{2+}$ (**2g**), which is evidenced in RDE voltammetry by the successive cathodic waves O^*_2 and O^*_1 (see d in Figure 3). In contrast with the first oxidation, the electron transfer is not associated herein with any chemical reaction. In summary, the detailed mechanism of the oxidation of **2** in the presence of $P(OMe)_3$ can be formalized according to Scheme 3. The overall process is governed by both electron transfer and $P(OMe)_3$ exchange reaction thermodynamics.

The electrochemical analysis of **2**, performed in acetonitrile, indicates that the dimerization does not occur, like in dichloromethane. Indeed, the rotating-disk voltammogram (Figure 5 and Table 2) exhibits a two-electron charge transfer in the oxidative range, based on the height of the oxidation wave, which is nearly twice compared to that of the reduction ones. In cyclic voltammetry, the oxidation peak O'_1, found at +0.32 V, is associated in the forward scan with a reduction peak located at +0.14V. Moreover, an exhaustive controlled-potential oxidation (E_w = +0.46 V vs. SCE) consumed 2 F/mol of initial complex, ultimately leaving the product reducible at +0.14 V. In addition, the electrolysed solution was found to be ESR-silent. We propose that the final two-electron oxidized complex incorporates two molecules of MeCN, like with $P(OMe)_3$. Within the framework of Scheme 3, the mechanism involves, after the first electron-transfer (**2** → **2c**), the addition of one molecule of solvent (**2c** → **2d**), which prevents the dimerization from occurring. At this stage, there are two possibilities, either the addition of the second molecule of solvent occurs before the second electron step (pathway **2d** → **2e** → **2g**) or after (**2d** → **2f** → **2g**). It must be outlined that this second electrochemical step occurs at the same potential as the oxidation **2** → **2c** due to the basicity of the acetonitrile, which leads to only one wave or peak in the voltammogram of **2**, with a two-electron transfer.

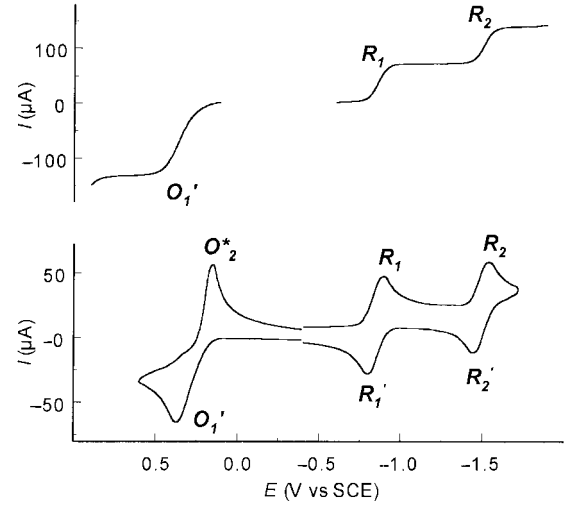

Figure 5. Rotating-disk and cyclic voltammogram of 2.8 mM of **2** in CH_3CN 0.2 M Bu_4NPF_6; CV: sweep rate = 100 $mV{\cdot}s^{-1}$, initial potential = −0.4 V (anodic and cathodic scans); RDV: rotation speed = 10 rps

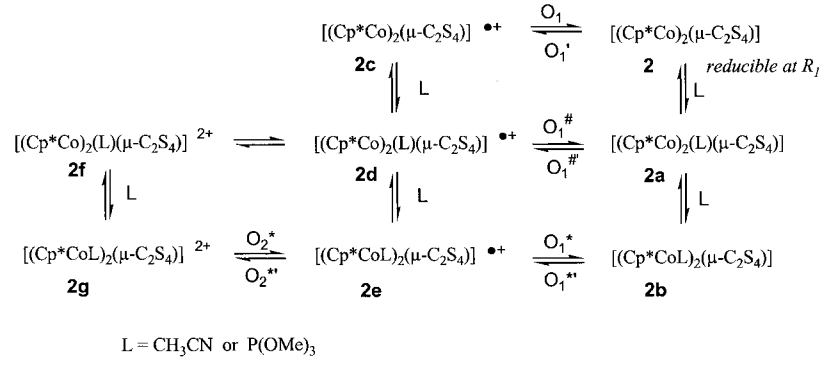
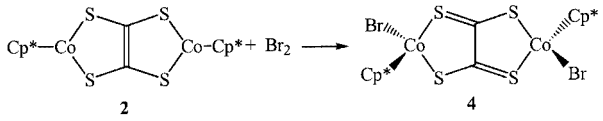
It must be noted from Table 2 that going from CH_2Cl_2 to MeCN causes a strong shift in the oxidation potential (−260 mV against +80 mV in reduction), which may arise from the influence of the kinetics of the chemical reaction following the first electron transfer.[18] In any case, the potential difference between CH_2Cl_2 and MeCN cannot be explained by the complexation of MeCN in the neutral state since we have verified that there is no change at all in the UV/Vis spectra of **2** from one solvent to the other.



Scheme 3

Chemical Oxidation

In agreement with the results of the electrochemical studies, it can be shown that $[(Cp^*Co)_2(\mu\text{-}C_2S_4)]$ can be chemically oxidized without destroying its CoC_2S_4Co core. Oxidation of **2** by 1 equiv. of Br_2 gives the diamagnetic neutral complex $[(Cp^*CoBr)_2(\mu\text{-}C_2S_4)]$ (**4**) (Scheme 4).



Scheme 4

The coordination of halides upon oxidation has already been observed for a (dithiolene)cobalt complex,[19] as well as for $[(Cp^*Rh)_2(\mu\text{-}C_2S_4)]$.[8a] The cyclic voltammogram of **4** (Figure 6) shows that the bromine atoms can be reductively decoordinated [Equation (1)]. Indeed, after a first reduction peak located at −0.26 V, the peak R_1 was observed at the second stage.

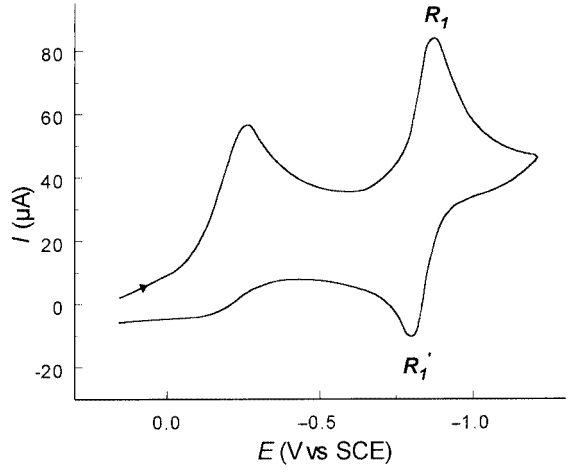


Figure 6. Cyclic voltammogram of 3.2 mM of **4** in CH_2Cl_2 of 0.2 M Bu_4NPF_6 (sweep rate = 100 $mV \cdot s^{-1}$)

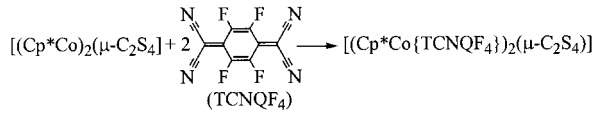
$$[(Cp^*CoBr)_2(\mu\text{-}C_2S_4)] + 2\,e^- \rightarrow [(Cp^*Co)_2(\mu\text{-}C_2S_4)] + 2\,Br^- \quad (1)$$

4 **2**

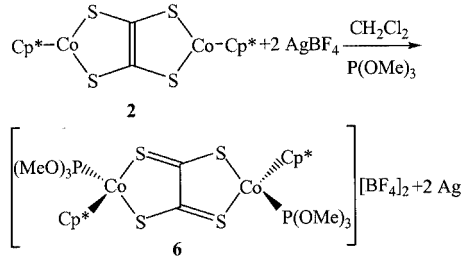
Complex **2** was also oxidized by the strong oxidizer $TCNQF_4$ (perfluoro-7,7,8,8-tetracyano-*p*-quinodimethane). Indeed, treatment of an acetonitrile solution of $TCNQF_4$ with a 0.5 mol-equiv. of **2** was found to afford $[(Cp^*Co\{TCNQF_4\})_2(\mu\text{-}C_2S_4)]$ (**5**) as a blue powder (Scheme 5).



Scheme 5

The stoichiometry of **5** was ascertained from the elemental analysis. Despite the tendency of the $TCNQF_4^{-\cdot}$ to form dimeric dianionic moieties,[20] the elemental analysis suggests that the dication $[(Cp^*Co)_2(\mu\text{-}C_2S_4)]^{2+}$ is stabilized by the coordination of the anionic $TCNQF_4^{-\cdot}$ on both cobalt atoms. Unfortunately, all our attempts to grow crystals of **4** and **5** were unsuccessful.

Information about the structural changes induced by the two-electron oxidation was obtained by chemical oxidation of **2** in the presence of a Lewis base in a CH_2Cl_2 solution. Treatment with 2 equiv. of $AgBF_4$ and an excess of trimethyl phosphite induced a change of colour of the solution from green to brown. After filtration, addition of diethyl ether afforded dark brown needles of compound $[(Cp^*Co\{P(OMe)_3\})_2(\mu\text{-}C_2S_4)](BF_4)_2$ (**6**) (Scheme 6). Note that the cationic part of this salt is equivalent to compound **2g** in Scheme 3.



Scheme 6

The ^1H NMR spectrum of **6** consists of a single sharp signal in the C_5Me_5 region, which is consistent with a symmetric structure and a diamagnetic ground state. Integration of the C_5Me_5 fine peak vs. the $P(OMe)_3$ signal indicates that each centre is coordinated by a molecule of a trimethyl phosphite. The symmetric structure is confirmed by the $^{31}P\{^1H\}$ NMR spectrum since only one signal is observed at $\delta = 126.8$ ppm.

Electrochemical analysis of **6** provided the same RDE voltammogram as that of Figure 3d. In this there is no difference between the chemical and electrochemical approaches to the oxidation of **2**.

Structural Analysis

In addition to the NMR solution study, the solid-state structure of **6** was probed by X-ray crystallography. Crystallographic analysis established the 1:2 stoichiometry, i.e., one organometallic dication for two BF_4^- counterions. Analysis of the bond lengths shows that the C_2S_4 core is better described in **6** as tetrathiooxalate than ethylenetetrathiolate bridge. Especially since the S_2C-CS_2 distance is 0.1 Å longer in **6** than in reported complexes formulated as $C_2S_4^{4-}$ bridged complexes (Table 3). In addition, the Co–S bond is significantly lengthened in **6** in comparison to the neutral complex. Thus, the oxidation essentially affects the C_2S_4 ligand. Accordingly, with its dicationic nature, complex **6** can be described as two Co^{III} centres linked by a $C_2S_4^{2-}$ bridge. This description is similar to that of the $[(Cp^*RhCl)_2(\mu\text{-}C_2S_4)]$ compound reported by Rauchfuss et

Table 3. Selected bonds [Å] and angles [°] of μ-C_2S_4 bridged complexes

al.[8a] The two $P(OMe)_3$ ligands are complexed in a *trans* manner giving rise to a C_{2h} structure (Figure 7). The Co−P distance [2.1693(11) Å] lies in the range of what is generally observed for this bond.[21] Due to this complexation, the C_2S_4 plane does not lie perpendicular to the Cp* plane, which is in opposition to what was observed in the case of **2**.[3b] The CoS_2 unit makes an angle of 52.1(1)° with the C_5Me_5 ring plane. The Co−C distances [2.080(4)−2.120(4) Å] are appreciably long compared with those of the neutral complex **2** [2.026(6)−2.040(6) Å].

Conclusion

In summary, we have found a new efficient method for the preparation of dimetallic cobalt complexes bridged by the $C_2S_4^{4-}$ unit starting from 1,3,4,6-tetrathiapentalene-2,5-dione. Electrochemical and chemical oxidations of $[(Cp^*Co)_2(\mu\text{-}C_2S_4)]$ have shown that the loss of electrons involves mainly the bridging ligand without breaking the link between the two metal centres. The stabilization of the oxidized species results from coordination, complexation, or dimerization according to the nature of the solution in which the oxidation is conducted.

Further studies will concentrate on the formation of the first heterobimetallic complexes bridged by the $C_2S_4^{4-}$ ligand.

Experimental Section

General Comments: All reactions were carried out under dry argon using standard Schlenk techniques. Solvents were purified by standard methods and freshly distilled under nitrogen. The NMR spectra were recorded with a Bruker AC and a Bruker Avance 300 MHz spectrometer. Electron spin resonance spectra were recorded at room temperature with a Bruker ESP 300 spectrophotometer. Field calibrations were made with dpph (g = 2.0034). Elemental analyses were performed at the Université de Bourgogne with an EA 1108 Fisons instrument. The 1,3,4,6-tetrathiapentalene-2,5-dione[22] and $Cp^*Co(CO)_2$ [23] were prepared according to published literature methods and $CpCo(CO)_2$ was purchased from Aldrich. The method described by Wheland and Martin was employed for the synthesis of $TCNQF_4$.[24]

Electrochemical Experiments: Voltammetric analyses were carried out in a standard three-electrode cell with a Tacussel UAP4 unit cell. The electrolyte consisted of 0.2 M n-Bu_4NPF_6 solution in CH_2Cl_2 or in MeCN. The reference electrode was a saturated calomel electrode (SCE) separated from the analysed solution by a sintered glass disk; the auxiliary electrode was a platinum wire. For all voltammetric measurements the working electrode was a carbon disk electrode initially polished with alumina. The controlled potential electrolyses were performed with an Amel 552 potentiostat coupled to an Amel 771 integrator. A carbon gauze was used at the anode, a platinum plate as the cathode, and an SCE as the reference electrode, each electrode being separated from the others by sintered glass disks. After each measurement the reference electrode was checked against the ferrocene-ferricinium couple (+0.46 V in CH_2Cl_2 and +0.4 V in MeCN).

Synthesis of $[Cp^*Co(C_3OS_4)]$ (1): Equimolar quantities (1 mmol) of $[Cp^*Co(CO)_2]$ and 1,3,4,6-tetrathiapentalene-2,5-dione were heated under reflux in toluene (30 mL) overnight under argon. After filtration, the green solution was removed under reduced

pressure. Washing the residue by a small quantity of pentane (5 mL) afforded the complex **1** as a green powder (0.36 g, 96% yield). A single crystal of **1** was obtained by recrystallization from toluene and hexane. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.97 (s, Me_5C_5) ppm. IR (KBr): ν̃ = 1626 and 1670 (C=O), 1340 (C=C) cm^{-1}.

Synthesis of [(Cp*Co)$_2$(μ-C$_2$S$_4$)] (2): Equimolar quantities (1 mmol) of [Cp*Co(CO)$_2$] and **1** were heated under reflux in toluene (30 mL) overnight under argon. Cooling the solution in an ice bath resulted in the precipitation of complex **2** as green needles, which were collected by filtration. Yield: 0.485 g (90%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.86 (s, Me_5C_5) ppm. IR (KBr): ν̃ = 1375 (C=C) cm^{-1}. UV/Vis (CH_2Cl_2): λ_{max} = 322, 809 nm. MS: *m*/*z* = 540 [M$^+$]. $C_{22}H_{30}Co_2S_4$: calcd. C 48.89, H 5.56, S 23.70; found C 48.52, H 5.65, S 23.15.

Synthesis of [(CpCo)$_2$(μ-C$_2$S$_4$)] (3): A mixture of $CpCo(CO)_2$ (0.5 mL, 3.47 mmol) and 1,3,4,6-tetrathiapentalene-2,5-dione (360 mg, 1.73 mmol) were heated under reflux in toluene overnight under argon. After cooling to room temperature, the blue reaction mixture was filtered. The collected solid afforded complex **3** as a dark blue powder. Yield: 0.400 g (58%). MS: *m*/*z* = 400 [M$^+$]. $C_{12}H_{10}Co_2S_4$: calcd. C 36.01, H 2.50, S 32.04; found C 36.25, H 2.39, S 31.67.

Synthesis of [(Cp*CoBr)$_2$(μ-C$_2$S$_4$)] (4): To a solution of MeCN (30 mL), containing 60 mg of **2** (0.111 mmol), was added 6 μL (0.117 mmol) of Br_2.The colour of the solution turned slowly from green to blue. After 12 h of stirring, the precipitate was filtered off and washed with diethyl ether to afford the complex **4** as a blue powder. Yield: 62 mg (80%). ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 1.50 (s, Me_5C_5) ppm. $C_{22}H_{30}Br_2Co_2S_4$ (700): calcd. C 37.71, H 4.29, S 18.32; found C 37.42, H 4.19, S 17.66.

Synthesis of [(Cp*Co{TCNQF$_4$})$_2$(μ-C$_2$S$_4$)] (5): An MeCN solution (10 mL) of $TCNQF_4$ (60 mg, 0.214 mmol) was added to an MeCN solution (20 mL), containing 58 mg of **2** (0.107 mmol). The resulting solution was stirred overnight at ambient temperature. The complex **5** was obtained as a blue powder after filtration and washing with CH_2Cl_2. Yield: 89 mg (76%). IR (KBr): ν̃ = 2216 and 2198 (C≡N) cm^{-1}. $C_{46}H_{30}Co_2F_8S_4N_8$ (1092): calcd. C 50.55, H 2.75, N 10.26; found C 49.90, H 2.79, N 9.65.

Synthesis of [(Cp*Co{P(OMe)$_3$})$_2$(μ-C$_2$S$_4$)](BF$_4$)$_2$ (6): Complex **2** (0.070 g, 0.130 mmol) was dissolved in 20 mL of CH_2Cl_2 in the presence of $P(OMe)_3$ (0.12 mL, 1 mmol). This solution was added to a suspension of $AgBF_4$ (0.051 g, 0.260 mmol) in 5 mL of CH_2Cl_2. After 1 h of stirring, the brown solution was filtered. Addition of 10 mL of ether afforded dark brown crystalline solid of **6**, which was washed with 2 × 10 mL of ether. Yield: 0.095 g (85%). ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 1.66 (s, 15 H), 3.8 (m, 9 H) ppm. ^{13}C NMR (300 MHz, CD_2Cl_2): δ = 11.8 ($C_5\mathit{Me}_5$), 58.59 [$P(OMe)_3$], 105.3 (C_5Me_5), 115 (C=C) ppm. ^{31}P{H} NMR (300 MHz, CD_2Cl_2): δ = 126.8 [$P(OMe)_3$].

Crystallographic Data Collection and Structure Determination for 1 and 6: A single crystal of each compound was mounted in a glass capillary using Araldite glue. Data were collected with a Stoe-IPDS diffractometer, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Details are given in Table 4. Numerical absorption correction was applied (FACEIT, Stoe). The structure was solved by direct methods and refined by full-matrix least-squares on F^2 with anisotropic thermal parameters for all non-H atoms. H atoms were introduced at calculated positions and constrained to ride on the parent C atoms. All calculations were performed with the SHELTX package.[25] CCDC-77465 for [Cp*Co(dmid)] and -177466 for [(Cp*Co{P(OMe)$_3$})$_2$(μ-C$_2$S$_4$)](BF$_4$)$_2$ contain the supplementary crystallographic data for this paper. These data can

Synthesis and Reactivity Towards Cationic Group 11 Metal Centers of an Extended Silacalix-[3]-phosphinine Macrocycle

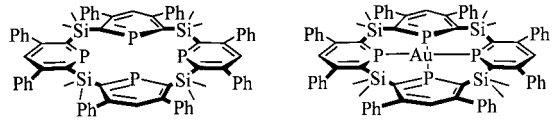
Audrey Moores,[a] Nicolas Mézailles,[a] Nicole Maigrot,[a] Louis Ricard,[a] François Mathey,*[a] and Pascal le Floch*[a]

Keywords: Copper / Gold / Phosphinines / Macrocycles / Silver

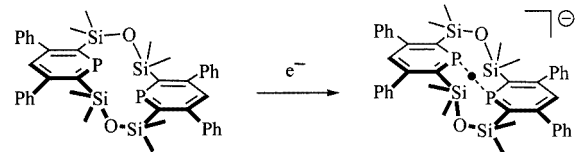
A synthetic route to a new type of phosphinine-based macrocycle has been developed. This approach involves the reaction of a phosphinine bearing two pendant $SiMe_2OSiMe_2CCR$ (R = Ph) (**5**) groups with two equivalents of a diazaphosphinine (**1**). The 2,6-bis(azaphosphininedimethylsilyl)-phosphinine (**6**) formed was then reacted under dilute conditions with a second equivalent of phosphinine **5** to produce the new macrocycle **4**. The X-ray crystal structure of **4** reveals no particular strain, and the macrocycle was fluxional in solution even at low temperature (–60 °C). Reactions of macrocycle **4** with $[Cu(MeCN)_4][BF_4]$, $[Ag][BF_4]$ and $[AuCl(SMe_2)]$ in the presence of $GaCl_3$ as chloride abstractor yielded the corresponding cationic complexes **8**, **9**, and **10**. The X-ray crystal structure of the copper complex **8** was recorded. As expected, the overall geometry around copper is trigonal planar. The macrocycle adopts a distorted arrangement to accommodate this geometry, and the phosphinines do not bind copper in a linear fashion. The examination of metric parameters suggests that the aromaticity of the rings has not been perturbed due to a weak bonding between phosphorus atoms and copper.(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Silacalix-[*n*]-phosphinines are a new class of phosphorus macrocycles that possess unusual electronic properties relative to classical sp^3-hybridized phosphorus species.[1] Recently we showed that the combination of a rigid structure (when $n = 4$) and the presence of strong π-acceptor phosphorus atoms within these macrocycles make them suitable ligands for the stabilization of reduced transition metal centers.[2] Thus, when cationic gold(I) was encapsulated in the cavity, these macrocycles behaved as phosphorus equivalents of CO matrices and the corresponding reduced gold(0) complex proved to be particularly stable.[3]



Another exciting feature of their reactivity was recently shown by studying their reduction. In the case of small macrocycles, the close vicinity of the two phosphorus atoms can be exploited to create new types of bonding. Thus, when two phosphinine units are linked by $-(Me_2Si-O-SiMe_2)-$ linkers in a cyclophane type structure, the mono-electronic reduction affords a mono-radical anion featuring a one-electron phosphorus–phosphorus single bond.[4]



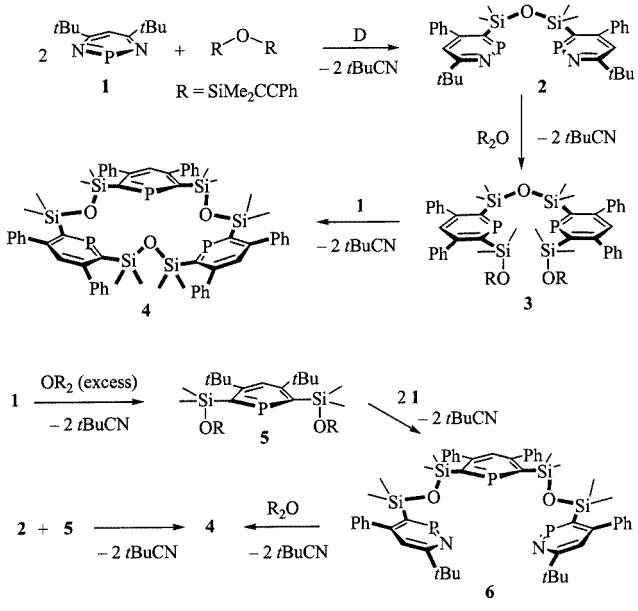
Regarding their coordinative properties, it appears that most species synthesized to date are quite rigid and allow the coordination of metal fragments that adopt a very specific geometry. Thus, silacalix-[*n*]-phosphinines incorporating $SiMe_2$ linkers are well adapted for the stabilization of metals that adopt a square planar or linear geometry ($n = 4$), or that might be coordinated through the face of an octahedron ($n = 3$).[1a] On the other hand, phosphorus analogs of cyclophane cannot incorporate metallic fragments and essentially behave as classical chelates.[5] With the aim of expanding the range of available macrocycles we recently investigated the synthesis of large and flexible species. Herein, we report on the synthesis of an extended silacalix-[3]-phosphinines and on a preliminary investigation of their coordinative properties towards cationic group 11 metals.

Results and Discussion

Among the different synthetic pathways, we deliberately chose one that relies on the reactivity of 1,3,2-diazaphosphinines towards functional alkynes. Indeed, as showed in previous studies, this method proved to be the most convenient way of assembling polyfunctional ligands and soph-

[a] Laboratoire "Hétéroéléments et Coordination" UMR CNRS 7653, Ecole Polytechnique,91128 Palaiseau Cedex, France

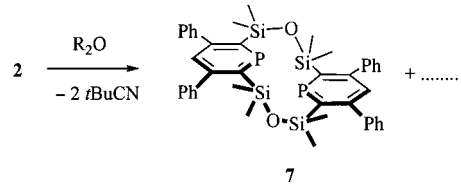
isticated edifices in one or two steps.[1b] In order to synthesize the extended and flexible structure **4** we focused our study on the preparation of a macrocycle incorporating $-(Me_2Si-O-SiMe_2)-$ spacer groups. Three different synthetic strategies were envisaged. The first one involved the condensation of the bidentate ligand **3** (formed from **2**), bearing two pendant $SiMe_2OSiMe_2CCPh$ groups, with one equivalent of a diazaphosphinine **1**. This approach was clearly advantageous since it could be carried out using a "one-pot sequence". The second and the third approach were different, but also utilized the same 2,6-disusbstituted phosphinine **5** as precursor. In the second approach, the macrocycle was built step by step from **5** by reacting two equivalents of **1** before closing the cavity with a third equivalent of diyne.[6] Finally, the third approach hinged on the direct condensation of **5** with the bis(monoazaphoshinine) **2**. All these pathways are summarized in the following scheme (Scheme 1).



Scheme 1

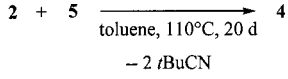
In the first approach, the preparation of the intermediate **2** was easily achieved by heating the diyne with two equivalents of **1** at 80 °C for 18 hours in toluene. Bis(azaphosphinine) **2**, which is highly sensitive towards moisture, was characterized by ^{31}P NMR exclusively (δ = 305.6 ppm). Unfortunately, whatever the amount of diyne used (from 2 to 10 equiv.), the second step did not cleanly afford the expected bis(phosphinine) **3**, but mainly the diphosphacyclophane **7**[1c] and a mixture of unidentified side-compounds (Scheme 2).

As previously noted, the close vicinity of the two reacting sites clearly favors the cyclisation. The two other pathways proved to be much more adapted to the synthesis of **4**. These require as a prerequisite the synthesis of phosphinine **5**. This was readily achieved by reacting diyne in excess with one equivalent of diazaphosphinine **1** in toluene at 110 °C



Scheme 2

for 5 hours. In the second method, reaction of **5** in toluene at 50 °C for 18 hours with two equivalents of **1** yielded compound **6** nearly quantitatively as attested by ^{31}P NMR spectroscopy (δ = 305.3 ppm). As with **2**, the high reactivity of the P=N moiety precluded the isolation and further characterization of **6**. The closing of the cavity was realized by reacting **6** with one equivalent of diyne. The use of dilute conditions turned out to be necessary to avoid the formation of linear oligomers and a series of competitive experiments showed the ideal concentration to be 5×10^{-3} mol/L. Additionally, as previously noted, we found that maintaining a steady concentration of reagents was absolutely necessary to achieve a complete conversion.[1b,1c] Unfortunately, these conditions dramatically increased the duration of experiments and the formation of **4** necessitated 2 weeks of heating. Following this experimental procedure, macrocycle **4** was isolated with an overall yield of 20% after chromatography. Finally, the third approach yielded **4** with a comparable yield. In both experiments, macrocycle **4** was easily purified by chromatography over silica gel and isolated as a very stable white powder.



Scheme 3

As expected, ^{31}P NMR spectroscopic data suggest that the macrocycle is fluxional and its signal appeared as a singlet even at −60 °C. The formulation of **4** was also confirmed by ^{1}H and ^{13}C spectroscopy. Additional evidence was given by an X-ray crystal structure analysis. An ORTEP view of one molecule of **4** is presented in Figure 1 and the most relevant bond lengths and bond angles are listed in the corresponding legend. As can be seen, the size of the cavity is large and the distance between the two closest P atoms (P1 and P3) is 4.620 Å (P2−P3, 5.256 Å; P1−P2, 6.177 Å). No particular strain can be observed in the macrocycle and metric parameters within each ring are quite similar and roughly similar to those recorded for other silylphosphinines. Apart from these data, the structure of **4** does not deserve particular comments.

To test the coordinative ability of **4**, we logically turned our attention to cationic group 11 metal centers, which are known to accommodate a trigonal planar geometry when they are encapsulated in a suitable environment.[7] Ligand **4** was reacted with $[Cu(MeCN)_4][BF_4]$,[8] $[Ag][BF_4]$, and $[Au(Me_2S)Cl]$[9] in the presence of $GaCl_3$ as chloride ab-

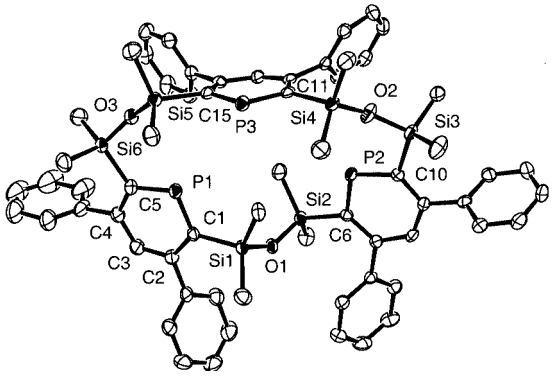


Figure 1. X-ray structure [50% TME (Thermal Motion Ellipsoids)] of one molecule of macrocycle **4**. All the hydrogen atoms and the solvents of crystallization (1 toluene, $^1/_2$ hexane and 1 H_2O) have been omitted. The numbering is arbitrary and different from that used for in the assignment of NMR spectroscopic data; selected bond lengths [Å] and angles [°]: P1−C1, 1.740(3); C1−C2, 1.411(4); C2−C3, 1.383(4); C3−C4, 1.395(4); C4−C5, 1.404(4); C5−P1, 1.742(3); C1−Si1, 1.890(3); Si1−O1, 1.638(2); O1−Si2, 1.638(2). P1−C1−C2, 121.5(2); C1−C2−C3, 122.8(3); C2−C3−C4, 126.0(3); C3−C4−C5, 123.1(3); C4−C5−P1, 121.2(2); C5−P1−C2, 105.3(1); P1−C1−Si1, 114.4(1); P1−C5−Si6, 113.9(2); C1−Si1−O1, 109.6(1); Si1−O1−Si2, 141.9(1)

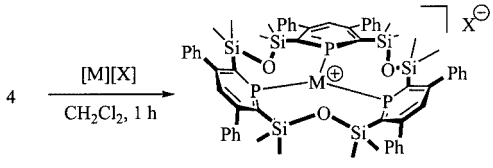
stractor. All reactions cleanly proceeded at room temperature, in CH_2Cl_2 as solvent, to yield complexes **8**, **9**, and **10**, respectively, within 1 hour (Scheme 4). All three complexes were isolated as very stable powders and characterized by NMR spectroscopy and elemental analysis. The magnetic equivalency of the three phosphinine rings in each complex, which is in good agreement with a planar geometry around the metal, is evidenced by a singlet in ^{31}P NMR. Apparently, the coordination of the metal does not significantly affect the aromaticity within the phosphinine rings and, in ^{13}C NMR spectroscopic data, only minor differences can be noted between chemical shifts of the free ligand and those in complexes **8**, **9**, and **10**. A comparison between **4** and its gold derivative **10** is highly illustrative. Thus, for the carbon ring atoms, the $\Delta\delta$ ($\delta_{complex} - \delta_{ligand}$) are small: −8.74 ppm for C2, 3.3 ppm for C3 and 0.5 ppm for C4. This observation tends to show that the coordination of the macrocycle to the metal is relatively weak.



8: M = Cu, X = BF_4
9: M = Ag, X = BF_4
10: M = Au, X = $GaCl_4$

Scheme 4

In order to gain structural information, the X-ray structure of the copper complex **8** was recorded. A view of one molecule of **8** is presented in Figure 2 and the most relevant bond lengths and angles are listed in legend below. The structure consists of discrete monomeric units of the cationic copper complex and a tetrafluoroborate anion. As can be seen, the ligands adopt a highly distorted arrangement to accommodate the trigonal planar geometry around the central Cu atom. Interestingly, the copper atom is not located in the ideal axis of the phosphorus atom lone pair and in each phosphinine subunit, an important deviation is noted. Thus, the P1−Cu bond protrudes from the plane defined by the ring by 42° (34° for P2 and 22° for P3). This phenomenon is not unprecedented and reflects the important 3s character of the phosphorus atom lone pair. Similar deviations have already been observed in a helical edifice incorporating cationic biphosphinine Cu^I subunits and in chelate diphosphaferrocene based structures.[10] In P-sp^2 based ligands this geometric distortion is generally associated with a weak phosphorus−metal bonding. On the other hand, phosphorus−copper bond lengths compare with those recorded in other phosphinine[11] and tertiary phosphane Cu^I complexes.[12]

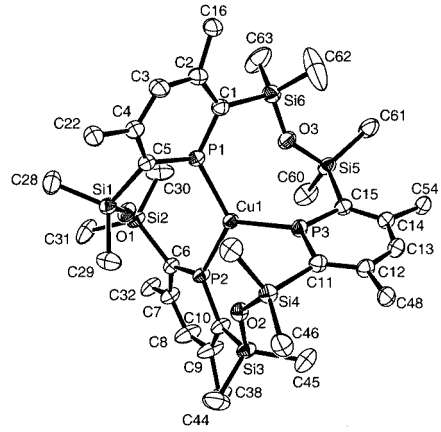


Figure 2. X-ray structure [50% TME (Thermal Motion Ellipsoids)] of one molecule of complex **8**. All the hydrogen atoms and the counter anion have been omitted for clarity. The numbering is arbitrary and different from that used in the assignment of NMR spectroscopic data.Selected bond lengths [Å] and angles [°]: P1−C1, 1.724(3); C1−C2, 1.409(4); C2−C3, 1.395(4); C3−C4, 1.399(4); C4−C5, 1.405(3); C5−P1, 1.727(3); C1−Si6, 1.890(3); Si1−O1, 1.624(2); O1−Si2, 1.628(2); C1−Si6, 1.890(3); P1−Cu1, 2.2419(7); P2−Cu1, 2.2386(7); P3−Cu1, 2.2318(7); P1−C1−C2, 118.4(2); C1−C2−C3, 123.2(2); C2−C3−C4, 126.8(2); C3−C4−C5, 121.9(3); C4−C5−P1, 119.5(2); C1−P1−C5, 108.8(1); P1−C5−Si1, 115.2(1); P1−C1−Si6, 117.1(2); C5−Si1−O1, 103.0(1); Si1−O1−Si2, 169.6(1); P1−Cu1−P2, 124.91(3); P2−Cu1−P3, 118.41(3); P3−Cu1−P1, 116.66(3)

Another interesting feature is provided by the analysis of metric parameters within the phosphinine subunits. Apart from the opening of the internal P−C−P angle, which ranges from 105.3(1) in **4** to 108.8(1) in **8** as a result of the re-hybridization at phosphorus, bond lengths and angles are not dramatically modified. In general, coordination of a phosphinine onto a metal fragment results in a lengthening of the P=C bond as a result of π-back donation in the π* LUMO, which is antibonding between P and C.[13] In **8**, P=C bond lengths compare with those of the free macrocycle **4**.

In conclusion, we have developed a straightforward route to a new type of an extended silacalix-[3]-phosphinine that

is well-tailored for the encapsulation of metal fragments adopting a trigonal planar geometry. Further studies aimed at studying the coordination of metallic centers having a catalytic activity are currently in progress in our laboratories.

Experimental Section

General: All reactions were routinely performed under an inert atmosphere of argon or nitrogen by using Schlenk and glove-box techniques with dry deoxygenated solvents. Dry THF and hexanes were obtained by distillation from Na/benzophenone and dry CH_2Cl_2 and $CDCl_3$ from P_2O_5. Dry CD_2Cl_2 was distilled and stored, like $CDCl_3$, on 4-Å Linde molecular sieves. Nuclear magnetic resonance spectra were recorded on a Bruker Avance 300 spectrometer. Solvent peaks are used as internal reference relative to Me_4Si for ^1H and ^{13}C chemical shifts (ppm). ^{31}P chemical shifts are relative to a 85% H_3PO_4 external reference. The following abbreviations are used: b; broad, singlet; d, doublet; t, triplet; m, multiplet; p, pentuplet; sext, sextuplet; sept, septuplet; v, virtual, q, quaternary. Mass spectra were obtained at 70 eV with a HP 5989B spectrometer coupled to a HP 5980 chromatograph by the direct inlet method. Elemental analyses were performed by the "Service d′analyse du CNRS", at Gif sur Yvette, France.

Synthesis of Phosphinine 5: A solution of diazaphosphinine **1** in toluene (21.7 mL, 0.0858 mmol/mL, 1.85 mmol) and 1,1,3,3-tetramethyl-1,3-bis-phenylethynyl-disiloxane (4.63 g, 13 mmol) was heated at 110 °C for 5 hours. After cooling to room temperature, celite (2 g) was added and toluene was evaporated yielding a brown powder. This solid was then added onto the top of a silica gel packed column for flash chromatography. A first fraction eluted with hexanes to yield excess diyne. A second fraction eluted with a mixture of hexane/toluene (90:10) and yielded mixed products. A third fraction gave the correct product. After evaporation of the solvents, phosphinine **5** was recovered as an orange oil. Yield: 1.13 g (85.8%). ^1H NMR (300 MHz, $CDCl_3$, 278 K): δ = 0.11 [s, 12 H, $Si(CH_3)_2OSi(CH_3)_2C{\equiv}C$], 0.24 [s, 12 H, $C{\equiv}CSi(CH_3)_2$], 7.2−7.5 (m, 21 H, phenyls and phosphinines *H*) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 278 K): δ = 2.8 [s, $C{\equiv}CSi(CH_3)_2$], 3.4 [d, *J* = 8.0 Hz, $Si(CH_3)_2OSi(CH_3)_2C{\equiv}C$], 94.2 (s, $C{\equiv}C{-}Si$), 104.35 (s, C_6H_5-$C{\equiv}C$), 123.3 (s, C^4 of $C{\equiv}C$-C_6H_5), 127.8 (s, C^4 of C_6H_5 on phosphinine), 128.1 (s, C^3 of C_6H_5 on phosphinine), 128.5 (s, C^3 of $C{\equiv}C$-C_6H_5), 128.9 (s, C^2 of $C{\equiv}C$-C_6H_5), 129.5 (s, C^2 of C_6H_5 on phosphinine), 132.2 (s, C^1 of $C{\equiv}C$-C_6H_5), 133.0 (d, *J* = 20.7 Hz, C^4 of phosphinine), 145.7 (d, *J* = 2.9 Hz, C^1 of C_6H_5 on phosphinine), 154.1 (d, *J* = 10.3 Hz, C^3 of phosphinine), 164.3 (d, *J* = 87.9 Hz, C^2 of phosphinine) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 278 K): δ = 275.6 (s) ppm. $C_{41}H_{45}O_2PSi_4$ (713.11): calcd. C 69.06, H 6.36; found C 69.36, H 6.18.

Synthesis of Macrocycle 4: Phosphinine **5** (2.07 g, 2.9 mmol) was added to a solution of diazaphosphinine **1** in toluene (79 mL, 73.5 mmol/L, 5.8 mmol) at room temperature. The volume of the solution was reduced to half and the resulting mixture was then heated at 50 °C for 18 hours. After checking the complete formation of the bis(monoazaphosphinine)phosphinine **6** by ^{31}P NMR spectroscopy, dry toluene (300 mL) was added prior to one equivalent of 1,1,3,3-tetramethyl-1,3-bis-phenylethynyl-disiloxane (0.97 g, 2.9 mmol). The resulting solution was heated at 130 °C for 20 days. After cooling to room temperature, celite (5 g) was added and the solvent was evaporated to yield a brown powder. This coated celite was the added onto the top of a silica gel packed column for flash chromatography. After eluting traces of remaining diyne with hexane, macrocycle **4** was eluted with a mixture of hexane/toluene (80:20). After evaporation of the solvents, **4** was recovered as a colorless powder. Yield: 635 mg (20%). ^1H NMR (300 MHz, $CDCl_3$, 278 K): δ = 0.00 [s, 36 H, $Si(CH_3)_3$], 7.2−7.5 (m, 33 H, C_6H_5 and H_4 of phosphinines) ppm. ^{13}C NMR (75.5 MHz, $CDCL_3$, 278 K): δ = 3.7 [s, $Si(CH_3)_3$], 127.4 (s, C_{ipso} of C_6H_5), 127.8 (s, C^3 of C_6H_5), 129.6 (s, C^2 of C_6H_5), 132.5 (d, *J* = 20.9 Hz, C^4 of phosphinines), 145.8 (s, C^1 of C_6H_5), 153.3 (d, *J* = 9.5 Hz, C^4 of phosphinines), 164.5 (d, *J* = 90.1 Hz, C^2 of phosphinines) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 278 K): δ = 276.9 ppm. MS (*m*/*z*, relative intensity): 1135 (M − 1, 50). $C_{63}H_{69}O_3P_3Si_6$ (1135.65): calcd. C 66.63, H 6.12; found C 66.05, H 5.94.

Synthesis of Complex 8: Macrocycle **4** (57 mg, 0.050 mmol) and $[Cu(MeCN)_4][BF_4]$ (15.8 mg, 0.050 mmol) were allowed to react in CH_2Cl_2 (3 mL) at room temperature. After one hour of stirring, the solvent was evaporated and complex **8** was washed twice with hexanes (2 × 2 mL). After filtration and drying under vacuum, **8** was recovered as a yellow powder. Yield: 62 mg (96%). ^1H NMR (300 MHz, $CDCl_3$, 278 K): δ = 0.00 [s, 36 H, $Si(CH_3)_3$], 7.2−7.5 (m, 33 H, C_6H_5 and H^4 of phosphinines) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 278 K): δ = 3.73 [s, $Si(CH_3)_3$], 3.79 [s, $Si(CH_3)_3$], 128.7 (s, C_{ipso} of C_6H_5), 128.8 (s, C^3 of C_6H_5), 129.1 (s, C^2 of C_6H_5), 132.9 (AXX′X′′, ΣJ = 35.6 Hz, C^4 of phosphinines), 143.5 (s, C^1 of C_6H_5), 156.4 (AXX′X′′, ΣJ = 14.9 Hz, C^3 of phosphinines), 159.2 (AXX′X′′, ΣJ = 40.2 Hz, C^2 of phosphinines) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 278 K): δ = 217.7 ppm. $C_{63}H_{69}BCuF_4O_3P_3Si_6$ (1286.01): calcd. C 58.84, H 5.41; found C 58.72, H 5.54.

Synthesis of Complex 9: Macrocycle 4 (50 mg, 0.044 mmol) and $AgBF_4$ (8.6 mg, 0.044 mmol) were dissolved in CH_2Cl_2 (2 mL) at room temperature. The solution was stirred for one hour. It became light brown. After evaporation of the solvent, the solid obtained was washed twice with hexanes (2 × 2 mL). Complex **9** was collected by filtration. After drying under vacuum, **9** was recovered as a beige powder. Yield: 54 mg (92%).^1H NMR (300 MHz, $CDCl_3$, 278 K): δ = 0.00 [s, 36 H, $Si(CH_3)_3$], 7.2−7.5 (m, 33 H, C_6H_5 and H^4 of phosphinines) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 278 K): δ = 4.11 [s, $Si(CH_3)_3$], 4.18 [s, $Si(CH_3)_3$], 128.6 (s, C_{ipso} of C_6H_5), 128.7 (s, C^3 of C_6H_5), 128.9 (s, C^2 of C_6H_5), 133.9 (AXX′X′′, ΣJ = 28.7 Hz, C^4 of phosphinines), 143.6 (s, C^1 of C_6H_5), 156.0 (AXX′X′′, ΣJ = 11.5 Hz, C^3 of phosphinines), 162.0 (AXX′X′′, ΣJ = 51.7 Hz, C^2 of phosphinines) ppm. ^{31}P NMR (121.5 MHz, $CDCl_3$, 278 K): δ = 222.3 ppm. $C_{63}H_{69}AgBF_4O_3P_3Si_6$ (1330.33): calcd. C 56.88, H 5.23; found C 57.00, H 5.42.

Synthesis of Complex 10: Macrocycle **4** (50 mg, 0.044 mmol) and [AuCl(SMe2)] (13 mg, 0.044 mmol) were dissolved in CH_2Cl_2 (2 mL) at room temperature. The resulting solution was cooled to −80 °C and a solution of $GaCl_3$ (10 mg, 0.057 mmol) in CH_2Cl_2 (prepared in the glovebox) was added into the mixture by cannula. The resulting solution was warmed to room temperature and then stirred for one hour. After evaporation of the solvent, the solid obtained was washed successively with hexanes and ether (2 × 2 mL). Complex **10** was collected by filtration. After drying under vacuum, **10** was recovered as a yellow powder. Yield: 66 mg (97%).^1H NMR (300 MHz, $CDCl_3$, 278 K): δ = 0.00 [s, 36 H, $Si(CH_3)_3$], 7.2−7.5 (m, 33 H, C_6H_5 and H^4 of phosphinines) ppm. ^{13}C NMR (75.5 MHz, $CDCl_3$, 278 K): δ = 3.90 [s, $Si(CH_3)_3$], 3.95 [s, $Si(CH_3)_3$], 128.7 (s, C_{ipso} of C_6H_5), 128.8 (s, C^3 of C_6H_5), 129.1 (s, C^2 of C_6H_5), 133.1 (AXX′X′′, ΣJ = 34.5 Hz, C^4 of phosphinines), 143.8 (s, C^1 of C_6H_5), 156.6 (AXX′X′′, ΣJ = 14.9 Hz, C^3 of phosphinines), 159.2 (AXX′X′′, ΣJ = 46.0 Hz, C^2 of phosphinines) ppm. ^{31}P NMR (121.5 MHz, CH_2Cl_2, 278 K): δ = 249.5 ppm.

$C_{63}H_{69}AuCl_4GaO_3P_3Si_6$ (1544.15): calcd. C 49.00, H 4.50; found C 48.88, H 4.55.

X-ray Structure Determinations: Single crystals of **4** were obtained by diffusing methanol into a toluene solution of the compound. Crystals of **8** were obtained by diffusing hexane into a chloroform solution of the complex. Data were collected on a Nonius Kappa CCD diffractometer using a Mo-$K\alpha$ (λ = 0.71069 Å) X-ray source and a graphite monochromator. Experimental details are described in Table 1. The crystal structures were solved using SIR 97[14] and Shelxl-97.[15] ORTEP drawings were made using ORTEP III for Windows.[16] In the structure of **8** a 1/2 $CHCl_3$ located near a symmetry center was accounted with SQUEEZE. Analysis of the principal mean square displacements in the structure of complex **8** may indicate a slight libration or long range disorder of the BF_4 anion. CCDC-178617 (for **4**) and -178618 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Oligoalkyne-Bridged (η^4-Cyclobutadiene)(η^5-cyclopentadienyl)cobalt Fragments − Syntheses and Properties

Joerg Classen,[a] Rolf Gleiter,*[a] and Frank Rominger[a]

Dedicated to Professor Dwaine O. Cowan

Keywords: Alkynes / Conjugation / Electron transfer / Rod-like molecules / Cobalt

The syntheses of (η^5-cyclopentadienyl)(η^4-tetraphenylcyclobutadiene)cobalt units bridged by buta-1,3-diyne, octa-1,3,5,7-tetrayne, and dodeca-1,3,5,7,9,11-hexayne units (**15**, **18**, **21**) are reported. All three species could be obtained by Hay coupling of the corresponding mono-, di-, and triyne units **14**, **17**, and **20**. In the case of **14**–**17** and **21**, the molecular structures were confirmed on the basis of X-ray studies on single crystals. Cyclic voltammetry revealed a weak interaction between the metal centers of **15** and no interaction between the metal centers of **18** and of **21**.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Transition metal complexes with two redox centers are of current interest in basic and applied research.[1] Since the first investigation of biferrocene,[1,2] biferrocenylene,[3,4] and diferrocenylacetylene[5,6] almost 30 years ago, the interest in dinuclear complexes has increased considerably.[7−20] Of current interest are species with rigid alkyne units between the metal units. The metal centers can be connected through the ligands as in **1**−**3**, or they can be connected directly to the alkyne bridges as in **4** and **5**.[13−20] In both types, voluminous termini are connected with a rigid carbon rod. The most frequent metal species to mark the end of the rod are iron- and rhenium-based fragments. In this paper we report on the synthesis, structural and spectroscopic properties of molecular wires consisting of C_4 to C_{12} chains bridging two (η^5-cyclopentadienyl)(η^4-tetraphenylcyclobutadiene)cobalt units.

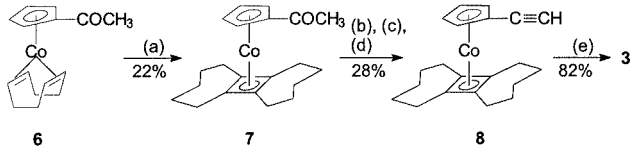
Syntheses of 14−20

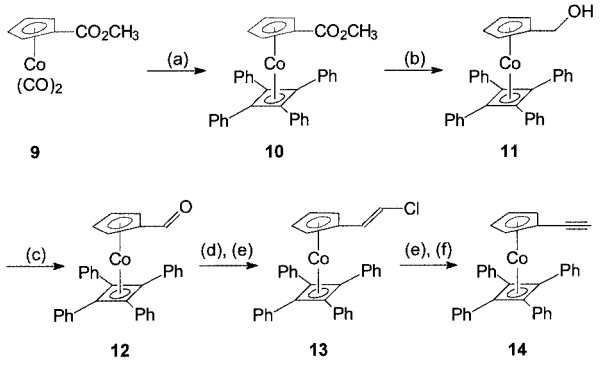
Initiated by electrochemical studies on species with (η^4-cyclobutadiene)(η^5-cyclopentadienyl)cobalt fragments, we synthesized **3** and compared its electrochemical properties with related species. The synthesis of **3** is briefly outlined in Scheme 1 and has been described in the literature.[11] The further extension of the length of the alkyne bridges was hampered by the two low yielding steps for obtaining the starting material **8** (Scheme 1).[11] The replacement of the cyclooctadiene unit in **6** by a tricyclo[7.5.0.0^{1,7}]tetradeca-1,8-diene group could only be achieved in 22% yield.[11] Furthermore, the conversion of the acetyl group in **7**[11] to the alkyne unit according to a protocol described by Negishi, furnished **8** in only 28% yield.[11] In order to obtain higher yields of the starting material we replaced 1,8-cyclotetradecadiyne by the less expensive tolan and chose a different route to generate the alkyne unit. Our synthesis of the monoalkyne complex **14** is summarized in Scheme 2. The dicarbonyl(η^5-methoxycarbonylcyclopentadienyl)cobalt complex **9**[21] was converted into the metallocene **10**,[22,23] and subsequently reduced to the alcohol **11**[24] according to known procedures. The conversion into the aldehyde **12**[25] was accomplished with $BaMnO_4$ oxidation,[26] followed by a Wittig reaction with (chloromethyl)-triphenylphosphonium chloride, giving a 1:1 mixture of (*E*)/(*Z*)-alkenes **13**.[24] Treatment of the mixture with potassium

[a] Organisch-Chemisches Institut der Universität Heidelberg, Im Neuenheimer Feld 270, 69120 Heidelberg, Germany

tert-butoxide yielded a mixture of the (*E*) diastereomer and the alkyne **14**.[24] After separation of **14**, the (*E*) diastereomer was treated with phenyllithium at room temperature, giving **14** again. The overall yield of the five steps shown in Scheme 2 was 10%. The structure of **14** could be confirmed by a diffraction analysis on single crystals.

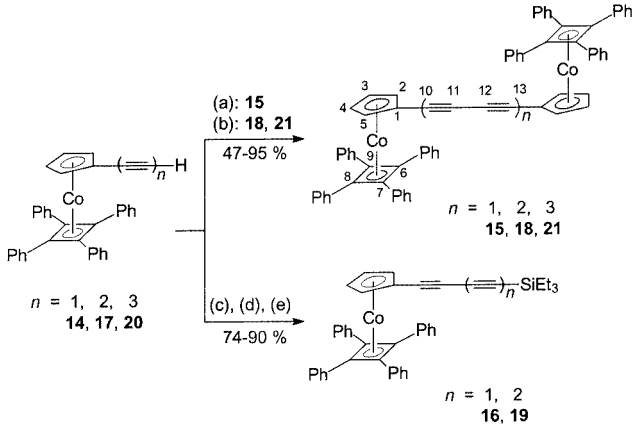


Scheme 1. Preparation of **3**: a) 1,8-cyclododecadiyne; b) LDA/THF; c) $ClPO(OEt)_2$; d) LDA, HCl; e) $Cu(OAc)_2$, pyridine



Scheme 2. Preparation of **14**: a) tolan, xylene, 120 °C; b) $LiAlH_4$/ether; c) $BaMnO_4$; d) $ClCH_2P(C_6H_5)_3{}^+Cl^-$; e) KO*t*Bu; f) C_6H_5Li

To transform **14** into its dimer **15**, we tested the protocols of Eglinton[27,28] and Hay.[29] The reaction of **14** with dry copper(II) acetate and dry pyridine at 90 °C was not successful, only decomposition of the starting material was observed. We were able to isolate 93% of the dimer **15** using the coupling reported by Hay[29] (Scheme 3). The structure of **15** could be confirmed by X-ray investigations on single crystals (see below).



Scheme 3. Synthesis of **15**, **16**, **18**, **19**, **21**: a) CuCl/pyridine + O_2; b) CuCl/TMEDA + O_2 c) *n*BuLi; d) CuCl; e) $Br-C\equiv C-SiMe_3$, $EtNH_2$

In order to obtain longer chains we had to find a reasonable path to elongate **14** by one ethynyl unit. This could be achieved by a modified Cadiot−Chodkiewicz reaction[13,14,30−33] involving **14** and (triethylsilyl)ethynyl bromide,[32,33] as shown in Scheme 3 in 90% yield. The parent compound **17** could be obtained by solvolysis of **19** with 5 M NaOH[10,34] in DMF.

Coupling of **17** to the dimer with four alkyne units could be achieved with Cu^I in the presence of tetramethylethylenediamine (TMEDA) (Scheme 3) and oxygen. The moderate yield of this product **18** can be attributed to the instability of **17** under the coupling conditions. The yield of **18** could be increased to 95% when **17** was produced in situ and not isolated.

Compound **21** was prepared by the elongation of the alkyne chain of **17** by one unit using the homocoupling protocol as shown in Scheme 3. As a side reaction, **18** could be isolated, therefore the yield of **19** was lower (74%) relative to the coupling reaction which led to **16**. In order to obtain **21**, the triethylsilyl group of **19** was removed by NaOH in DMF in situ, followed by a Cadiot−Chodkiewicz reaction (Scheme 3). In this case the product was obtained in 47% yield. The single crystals obtained of **21** were of poor quality. Therefore, the X-ray data can only be used as proof of the constitution and conformation of the end groups.

Structural Investigations

We were able to isolate single crystals for **14**−**17** and **21**. In Figures 1 and 2 we display as examples the molecular structures of **15** and **17**. Selected bond lengths of **14**−**17** are summarized in Table 1. The asymmetric unit of **14** contains two independent molecules, one of them is disordered with respect to the position of the alkyne unit attached to the Cp ring. The alkyne unit can be located at two adjacent Cp carbon atoms with nearly the same occupancies. In the discussion only the results of the non-disordered molecule are considered.

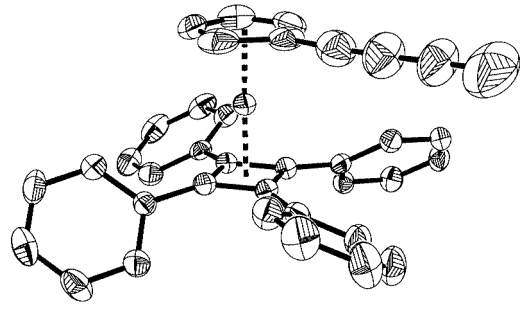


Figure 1. ORTEP plot (50% probability) of the molecular structure of **17**

The mean distances between the cobalt atom and the cyclopentadienyl (Cp) ring (1.68 Å for all structures) are slightly shorter than between the cobalt atom and the cyclobutadiene (Cb) unit (1.69 Å for all structures). These values are close to those reported for (η^4-cyclobutadiene)(η^5-

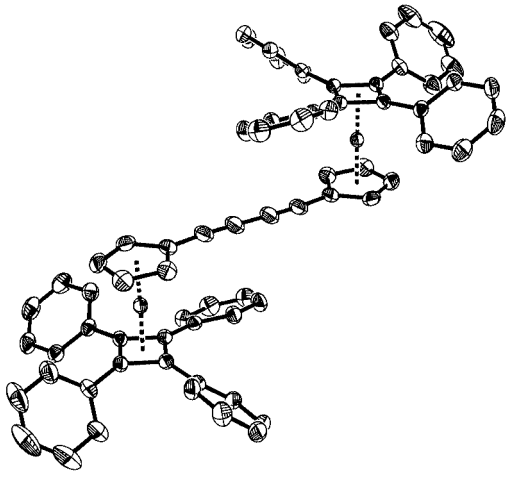

Figure 2. ORTEP plot (50% probability) of the molecular structure of **15**

Table 1. Selected bond lengths [Å] and bond angles [°] of **14**−**17**; for the numbering see Scheme 3

	14	**15**	**16**	**17**
Cp−Co (mean values)	1.675(3)	1.675(2)	1.679(2)	1.682(4)
Cb−Co (mean values)	1.691(3)	1.693(2)	1.692(2)	1.693(3)

cyclopentadienyl)cobalt,[35] where the mean distance between the Cp ring and the cobalt atom is 1.66 Å, and the distance between the cobalt atom and the Cb ring is 1.68 Å.[34] The distances between the Cp ring and the sp carbon centers (C1−C10, Scheme 3) vary between 1.44 Å (**14**) and 1.42 Å (**15**−**17**). The bond length of the terminal triple bond in **14** [1.143(7) Å] is unrealistically short. This can be attributed to the librational shortening caused by the strong anisotropic motion of this molecular tail, which cannot be modeled correctly by an ellipsoid-shaped description. The distances found for the other triple bonds (C10−C11 and C12−C13) vary between 1.20 Å (**15**, **16**) and 1.28 Å (**17**). The angles at the triple bonds deviate slightly from 180°, as reported for other long alkyne chains.[32,33] The C−C bond lengths within the Cb and Cp rings are found to be equal. The phenyl rings are twisted out of the plane of the Cp ring in a propeller-like fashion (see Figure 2).

The molecular structure of **21** in the solid state is shown in Figure 3. In this molecule both tetraphenylcyclobutadiene units are far removed from each other, therefore they can adopt the *syn* conformation (Figure 3). The crystal data of **21** reveal *R* values that are too large to be used for a quantitative evaluation (cf. Table 2). This shortcoming is mainly due to three disordered dichloromethane molecules in the asymmetric unit. Nevertheless, **21** is the first example with a hexayne unit between two Cp ligands. It can be compared with $(CO)_2Cp^*Fe-(C\equiv C)_6-FeCp^*(CO)_2$, in which the C_{12} chain is bound directly to the metal centers.[36]

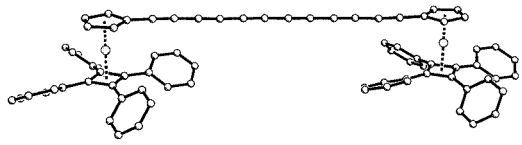

Figure 3. Molecular structure of **21** (ball-and-stick model)

Spectroscopic and Cyclovoltammetric Data

The NMR spectroscopic data of the new alkynes are listed in the Exp. Sect. The assignment of all ^{13}C signals was possible by carrying out a DEPT experiment. In Figure 4 the superimposed UV/Vis spectra of **15**, **18**, and **21** are shown. It demonstrates a shift to longer wavelengths of the absorbance bands with increasing chain length, as reported for related species.[10,13−17,36]

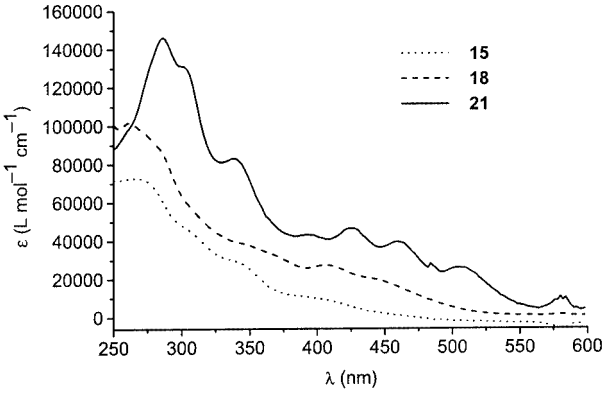

Figure 4. UV/Vis spectra of **15**, **18**, and **21**

In order to investigate the extent of metal−metal interaction in **15**, **18**, and **21**, cyclic voltammetric (CV) measurements were carried out. The uncertainty of the signals is somewhat larger (±25 mV) than usual (±15 mV), because of the low solubility of the samples in dichloromethane. As a reference, compound **14** was used, which is the simplest common building block of all three oligomers. The CV measurement of **14** shows a reversible oxidation at 540 mV (Figure 5). The CV of **15** reveals two oxidations, one at 490 mV, the second at 720 mV. The former is reversible, the latter is irreversible at different scan rates of up to 2 V/s.

The first oxidation of **15** was observed at a lower potential (by 50 mV) than that of the reference compound **14**. This result can be rationalized by assuming a lower HOMO energy due to the interaction of both metal fragments. The positive charge of the resulting radical cation is delocalized over both Co atoms through the alkyne backbone, resulting in a higher second oxidation potential. The potential separation of 230 mV suggests that the electronic interaction is relatively weak,[38] therefore, we assign **15** to class II in

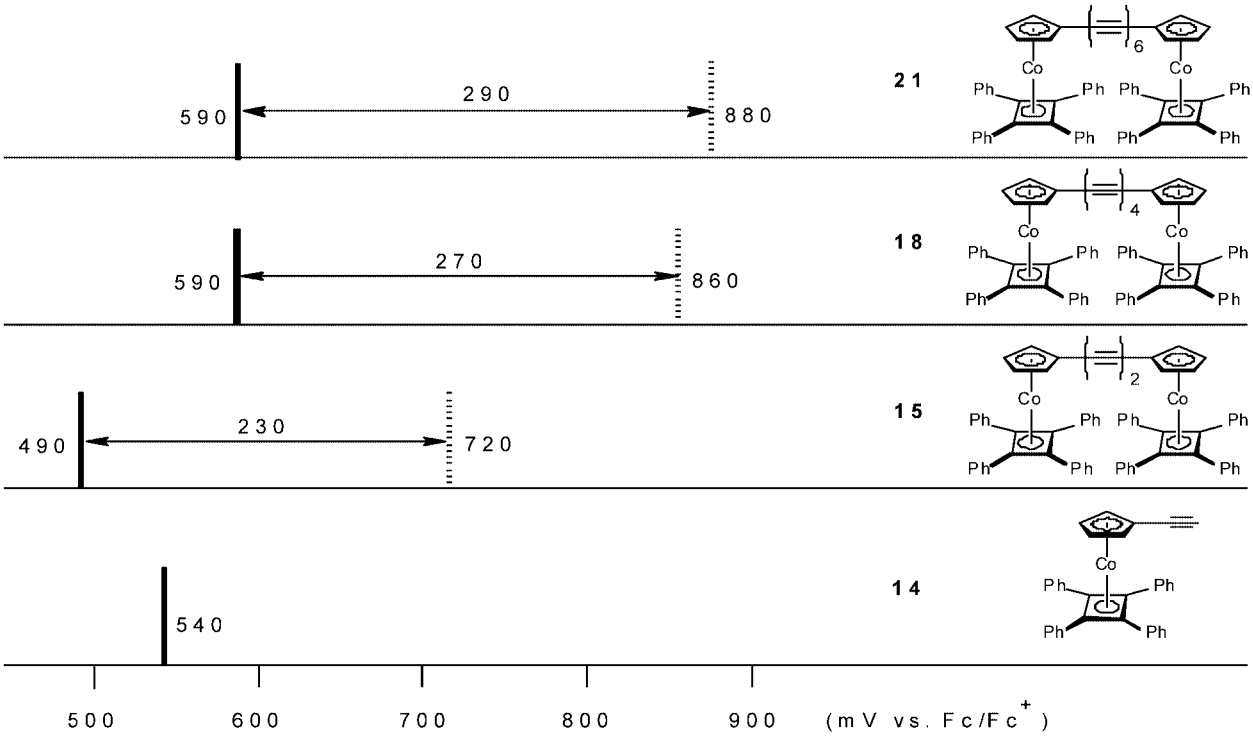

Figure 5. Comparison of the CV data of **14**, **15**, **18**, and **21**

the Robin and Day classification of mixed-valent compounds.[37]

A different situation is observed for **18** and **21**, where the first reversible oxidation potential is shifted towards a higher potential (by 50 mV) with respect to **14**. The second oxidation of **18** and **21** is irreversible at different scan rates of up to 2 V/s. The larger potential separation of 270 (**18**) and 290 mV (**21**) seems to indicate an increase in the electronic interaction with increasing alkyne chain length. However, a larger π-system is expected to result in a decrease in the HOMO energy, which in turn should cause a more facile oxidation. This contradiction can be explained by a reversible two-electron oxidation, where both Co atoms are oxidized to Co^{II} at similar potentials. At the second irreversible potential, an oxidation of one or both Co^{II} atoms to Co^{III} may occur. Another explanation is an ECE mechanism, where the first oxidation is followed by a chemical transformation, which renders the second oxidation irreversible. The latter complexes show no electronic interaction, so they can be assigned to class I in the Robin and Day classification of mixed-valent compounds.[37]

Concluding Remarks

Our goal was to find a reasonable path to prepare polyalkynes with (η^5-cyclopentadienyl)(η^4-tetraphenylcyclobutadienyl)cobalt fragments at both ends of the carbon rod. This could be achieved using **14** as a starting material. This compound was made available in five steps from **10**, with an overall yield of 10%. With **14** as the key intermediate, we were able to synthesize **15**, **18**, and **21**. The key steps were the Hay coupling reaction of the corresponding mono-, di-, and triyne units **14**, **17**, and **20**, respectively. The yields of **18** and **21** could be improved by preparing **17** and **20** in situ by deprotection of the protected diyne **16** and triyne **19**, respectively. By means of X-ray studies of the single crystals of **14**−**17** and **21** we could confirm the structure and conformation of the alkynes. For the polyyne part of all the studied samples, clear short−long C≡C−C bond alternation is observed. Our CV studies do not indicate a metal−metal interaction through the alkyne rod for **18** and **21**, whereas in **15**, where the distance between the metal centers is shorter, a slight shift with respect to **14** is observed.

Experimental Section

General Remarks: All melting points are uncorrected. The NMR spectra were measured with a Bruker Avance 500 spectrometer (^{1}H NMR at 500 MHz and ^{13}C NMR at 125.77 MHz) using the solvent as internal standard (δ). The mass spectra refer to data recorded with a JEOL JMS-700 instrument. IR spectra were recorded with a Bruker Vector 22. All reactions with CpCo(COD) were carried out in dried glassware under argon, using dried and oxygen-free solvents.

(η^5-Formylcyclopentadienyl)(η^4-tetraphenylcyclobutadienyl)cobalt(I) (12):[25] $BaMnO_4$ (2.0 g, 7.8 mmol) was added to a solution of **11** (200 mg, 0.4 mmol) in 100 mL of dichloromethane.[26] The suspen-

sion was stirred for 24 h under argon. After filtration, the solvent was removed to give 198 mg (99%) of **12** as an orange solid. ^{1}H NMR (CD_2Cl_2): δ = 4.91 (pt, 2 H, CpH), 5.23 (pt, 2 H, CpH), 7.21−7.34 (m, 12 H, *o*,*p*-ArH), 7.41−7.47 (m, 8 H, *m*-ArH), 9.31 (s, 1 H, CHO) ppm. ^{13}C NMR (CD_2Cl_2): δ = 77.5, 92.9 (s), 83.4, 88.9 (d, Cp), 127.3 (d, *p*-Ar), 128.5 (d, *o*-Ar), 129.1 (d, *m*-Ar), 135.2 (s, Ar), 190.9 (d, CHO) ppm.

[η^5-(*E*)-1-Chloroethenylcyclopentadienyl](η^4-tetraphenylcyclobutadienyl)cobalt(I) [(*E*)-13] and (η^5-Ethynylcyclopentadienyl)(η^4-tetraphenylcyclobutadienyl)cobalt(I) (14): Potassium *tert*-butoxide (106 mg, 1.0 mmol) was added to a solution of (chloromethyl)triphenylphosphonium chloride (350 mg, 1.0 mmol) in 20 mL of THF. At −70 °C, a cooled (−65 °C) solution of **12** (342 mg, 0.7 mmol) in 20 mL of THF was added to this solution. The resulting mixture was stirred for 30 min at −65 °C and then 30 min at room temperature. Subsequently, a solution of potassium *tert*-butoxide (106 mg, 1.0 mmol) in 20 mL of THF was added and the mixture refluxed for 17 h. After cooling and addition of 20 mL of distilled water, the layers were separated, and the aqueous layer was washed four times with diethyl ether. After drying ($MgSO_4$) of the combined organic layers, the solvent was removed and the crude mixture was purified by column chromatography on alumina (light petroleum ether to light petroleum ether/diethyl ether, 10:1). This procedure yielded 166 mg (46%) of (*E*)-**13** as a yellow solid. Following the isolation of (*E*)-**13**, 134 mg (39%) of the alkyne complex **14** was obtained as a yellow solid. ^{1}H NMR (CD_2Cl_2): δ = 4.63 (pt, 2 H, CpH), 4.67 (pt, 2 H, CpH), 5.84 (d, 1 H, C=CH), 5.93 (d, 1 H, C=CH), 7.19−7.30 (m, 12 H, *o*,*p*-ArH), 7.37−7.45 (m, 8 H, *m*-ArH) ppm. ^{13}C NMR (CD_2Cl_2): δ = 76.2 (s), 81.1 (d, Cp), 84.8 (d, Cp), 93.1 (s), 115.8 (d, C=C), 126.7 (d, *p*-Ar), 127.2 (d, C=C), 128.4 (d, *o*-Ar), 129.1 (d, *m*-Ar), 136.1 (s, Ar).

Transformation of (*E*)-13 to 14: Phenyllithium (0.6 mL, 1.1 mmol, 1.8 M) was added to a solution of (*E*)-**13** (500 mg, 0.9 mmol) in 20 mL of THF. After stirring for 20 h, the mixture was hydrolyzed with 25 mL of brine. The aqueous layer was extracted four times with diethyl ether, the combined organic layers were dried ($MgSO_4$) and the solvent was removed. After purification by column chromatography on alumina (neutral, grade III, light petroleum ether), 275 mg (59%) of the alkyne **14** was obtained as a yellow solid, m.p. 148 °C. ^{1}H NMR (CD_2Cl_2): δ = 2.51 (s, 1 H, CCH), 4.62 (pt, 2 H, CpH), 4.79 (pt, 2 H, CpH), 7.23−7.28 (m, 12 H, ArH), 7.45−7.49 (m, 8 H, ArH) ppm. ^{13}C NMR (CD_2Cl_2): δ = 76.4, 76.7, 78.2, 79.5 (s, cbd-C, Cp, C_{Alkyne}), 84.9 (d, Cp), 86.6 (d, Cp), 126.9 (d, *p*-Ar), 128.4 (d, *o*-Ar), 129.3 (d, *m*-Ar), 135.8 (s, Ar) ppm. IR (KBr): $\tilde{\nu}$ = 3056, 2924, 2109, 1628, 1600, 1498, 1445 cm^{-1}. HRMS (FAB): calcd. 504.1288; found 504.1273.

{μ-[Butadiynediylbis(η^5-cyclopentadienyl)]}bis(η^4-tetraphenylcyclobutadienyl)dicobalt(I) (15): A solution of CuCl (16 mg, 0.16 mmol) in 15 mL of dry pyridine, saturated with oxygen was added to a Schlenk flask. To this mixture **14** (209 mg, 0.4 mmol) was added, and oxygen was passed through the mixture for 46 h. After removal of the pyridine under vacuum, the crude product was purified by column chromatography on alumina (neutral, grade III) with light petroleum ether/diethyl ether (60:1), giving 192 mg (93%) of **15** as a yellow-orange solid, m.p. 240 °C. ^{1}H NMR (CD_2Cl_2): δ = 4.69 (pt, 4 H, CpH), 4.81 (pt, 4 H, CpH), 7.16−7.25 (m, 24 H, ArH), 7.39−7.47 (m, 16 H, ArH) ppm. ^{13}C NMR (CD_2Cl_2): δ = 74.1, 76.4, 77.1, 78.5 (s, C_{Alkyne}, cbd-C, Cp), 84.9 (d, Cp), 87.3 (d, Cp), 126.9 (d, *p*-Ar), 128.5 (d, *o*-Ar), 129.2 (d, *m*-Ar), 135.5 (s, Ar) ppm. IR (KBr): $\tilde{\nu}$ = 3056, 2924, 2148, 1604, 1497, 1446 cm^{-1}. HRMS (EI): calcd. 1006.2420; found 1006.2432.

(η^4-Tetraphenylcyclobutadienyl)[η^5-(triethylsilylbutadiynyl)cyclopentadienyl]cobalt(I) (16): *n*-Butyllithium (645 mg, 1.5 mmol, 1.6 M solution) was slowly added to a solution of **14** (695 mg, 1.4 mmol) in 100 mL of THF, at −35 °C. Subsequently, CuCl (263 mg, 1.4 mmol) was added and the mixture was stirred for 30 min at −15 °C. After stirring at room temperature for 10 min, the suspension was cooled to −25 °C and freshly distilled ethylamine (5 mL) and bromo(triethylsilyl)acetylene (330 mg, 1.5 mmol) were added. After further stirring for 18 h, the hydrolysis was carried out with 50 mL of saturated NH_4Cl solution. The workup was completed by extraction of the aqueous layer with diethyl ether and drying of the combined organic layers with $MgSO_4$. Removal of the solvent gave a crude product. Further purification by column chromatography on silica with light petroleum ether/dichloromethane (7:1) yielded 804 mg (91%) of **16** as a yellow solid, m.p. 146 °C. ^{1}H NMR (C_6D_6): δ = 0.56 (q, CH_2, 6 H), 1.01 (t, CH_3, 9 H), 4.31 (pt, CpH, 2 H), 4.61 (pt, CpH, 2 H), 7.04−7.12 (m, 12 H, ArH), 7.54−7.59 (m, 8 H, ArH) ppm. ^{13}C NMR (C_6D_6): δ = 4.7 (t, CH_2), 7.7 (q, CH_3), 73.5, 74.5, 77.0, 77.7, 86.0, 91.1 (s, Cp, C_{Alkyne}, cbd-C,), 85.1 (d, Cp), 87.4 (d, Cp), 126.9 (d, *p*-Ar), 128.4 (d, *o*-Ar), 129.2 (d, *m*-Ar), 135.6 (s, Ar) ppm. IR (KBr): $\tilde{\nu}$ = 2955, 2874, 2206, 1630, 1499, 1460 cm^{-1}. HRMS (EI): calcd. 642.2153; found 642.2159. $C_{43}H_{39}CoSi$ (642.2): calcd. C 80.35, H 6.12; found C 80.10, H 6.32.

(η^5-Butadiynylcyclopentadienyl)(η^4-tetraphenylcyclobutadienyl)cobalt(I) (17): NaOH (0.3 mL of an aqueous 5 M solution) was added to a solution of **16** (337 mg, 0.5 mmol) in 30 mL of DMF. After 5 min, 2 M HCl was added until pH < 4 (ca. 2 mL). The resulting precipitate was filtered, washed extensively with water, dissolved in diethyl ether, and dried with $MgSO_4$. Removal of the solvent yielded 264 mg (95%) of **17** as a gold-colored, oxygen-sensitive solid. ^{1}H NMR ($CDCl_3$): δ = 2.32 (s, 1 H, CCH), 4.68 (pt, 2 H, CpH), 4.82 (pt, 2 H, CpH), 7.22−7.33 (m, 12 H, ArH), 7.43−7.49 (m, 2 H, ArH) ppm. ^{13}C NMR (C_6D_6): δ = 69.3, 69.7, 72.4, 73.4, 77.1, 77.2 (s, C_{Alkyne}, cbd-C, Cp), 85.2 (d, Cp), 87.3 (d, Cp), 126.9 (d, *p*-Ar), 128.4 (d, *o*-Ar), 129.2 (d, *m*-Ar), 135.6 (s, Ar) ppm. IR (KBr): $\tilde{\nu}$ = 3060, 2209, 1609, 1499 cm^{-1}. HRMS (FAB): calcd. 528.1289; found 528.1312.

{μ-[Octatetraynediylbis(η^5-cyclopentadienyl)]}bis(η^4-tetraphenylcyclobutadienyl)dicobalt(I) (18): NaOH (0.15 mL of 1 M solution) was added to a solution of **16** (145 mg, 0.23 mmol) in 15 mL of DMF. After 5 min, HCl (1.5 mL of 2 M solution) was added. The organic layer was washed three times with water and brine. The aqueous layer was extracted twice with diethyl ether, the combined organic layers were dried with $MgSO_4$ and concentrated to 20 mL. The solution was poured into a mixture of acetone (20 mL), *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (14 mg) and CuCl (12 mg). After 4 h of passing oxygen through the mixture, hydrolysis with 30 mL of saturated NH_4Cl solution was carried out. After extraction of the aqueous layer with dichloromethane, the combined layers were adsorbed on silica. The purification by column chromatography on silica with light petroleum ether/dichloromethane (4:1) yielded 113 mg (95%) of **18** as an orange-red solid, m.p. 218 °C. ^{1}H NMR ($CDCl_3$/CD_2Cl_2, 2:1): δ = 4.74 (pt, 4 H, CpH), 4.89 (pt, 4 H, CpH), 7.23−7.36 (m, 24 H, ArH), 7.42−7.49 (m, 16 H, ArH) ppm. ^{13}C NMR ($CDCl_3$/CD_2Cl_2, 2:1): δ = 63.9, 66.1, 73.6, 74.9, 75.9, 77.2 (s, C_{Alkyne}, cbd-C, Cp), 85.3 (d, Cp), 87.5 (d, Cp), 126.7 (d, *p*-Ar), 128.1 (d, *o*-Ar), 128.7 (d, *m*-Ar), 134.8 (s, Ar) ppm. IR (KBr): $\tilde{\nu}$ = 3061, 2925, 2194, 1630, 1498, 1449 cm^{-1}. HRMS (FAB): calcd. 1055.2498; found 1055.2483.

(η^4-Tetraphenylcyclobutadienyl)[η^5-(triethylsilylhexatriynyl)cyclopentadienyl]cobalt(I) (19): *n*-Butyllithium (73 mg, 0.17 mmol

of a 1.6 M solution) in *n*-hexane was slowly added to a cooled solution (−40 °C) of **17** (81 mg, 0.15 mmol) in 10 mL of THF. Subsequently, CuCl (30 mg, 0.16 mmol) was added. After stirring the mixture for a further 5 min at −30 °C, the stirring was continued at room temperature for 10 min. Subsequently, freshly distilled ethylamine (1 mL) and bromo(triethylsilyl)acetylene (70 mg, 0.25 mmol) were added at −25 °C. Stirring was continued for 50 min at that temperature and the mixture was then hydrolyzed with 15 mL of a saturated NH_4Cl solution. The extraction of the aqueous layer with diethyl ether and the removal of the solvent gave a crude product, which was further purified by column chromatography on silica with light petroleum ether/dichloromethane (5:1) gave 75 mg (74%) of **19** as a yellow-brown solid, m.p. 114 °C. ^{1}H NMR ($CDCl_3$): δ = 0.68 (q, 6 H, CH_2), 1.05 (t, 9 H, CH_3), 4.69 (pt, 2 H, CpH), 4.84 (pt, 2 H, CpH), 7.22−7.34 (m, 12 H, ArH), 7.43−7.48 (m, 8 H, ArH) ppm. ^{13}C NMR ($CDCl_3$): δ = 4.2 (CH_2), 7.4 (CH_3), 62.1, 65.3, 73.2, 74.2, 76.2, 76.9, 86.0, 89.7 (s, C_{Alkyne}, cbd-C, Cp), 85.2 (Cp), 87.3 (Cp), 126.7 (d, *p*-Ar), 128.1 (d, *o*-Ar), 128.8 (d, *m*-Ar), 134.9 (Ar) ppm. IR (KBr): $\tilde{\nu}$ = 2953, 2921, 2879, 2176, 2067, 1605, 1497, 1454 cm^{-1}. HRMS (FAB): calcd. 666.2153; found 666.2148. $C_{45}H_{39}CoSi$ (666.2): calcd. C 81.06, H 5.89; found C 81.19, H 6.15.

{μ-[Dodecahexaynediylbis(η^5-cyclopentadienyl)]}bis(η^4-tetraphenylcyclobutadienyl)dicobalt(I) (21): The removal of the protection group from **19** was achieved by adding NaOH (0.12 mL of a 5 M aqueous solution) to a solution of **19** (115 mg, 0.17 mmol) in 35 mL of DMF at room temp. After 5 min, the solution was acidified by adding HCl (35 mL of a 2 M aqueous solution). The resulting precipitate was filtered, washed extensively with water, and dissolved in diethyl ether. The aqueous layer was extracted twice with diethyl ether, the combined organic layers were dried with $MgSO_4$ and concentrated to 20 mL. The solution was poured into a solution of acetone (36 mL), *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (0.053 mL) and CuCl (18 mg). After 80 min of passing oxygen through the mixture, 60 mL of diethyl ether and 50 mL of saturated NH_4Cl solution were added. The organic layer was washed twice with water. and the combined aqueous layers were washed with dichloromethane. The combined organic layers were dried with $MgSO_4$, absorbed on silica and purified by column chromatography on silica with light petroleum ether/dichloromethane (7:1), yielding 45 mg (47%) of **21** as a red solid, m.p. 210 °C. ^{1}H NMR (CD_2Cl_2: δ = 4.74 (pt, 4 H, CpH), 4.90 (pt, 4 H, CpH), 7.21−7.44 (m, 40 H, ArH) ppm. ^{13}C NMR (CD_2Cl_2): δ = 64.0, 64.2, 64.3, 65.9, 73.4, 75.3, 76.4, 77.8 (s, cbd-C, Cp, C_{Alkyne}), 86.2 (d, Cp), 88.2 (d, Cp), 127.2 (d, *p*-Ar), 128.5 (d, *o*-Ar), 129.1 (d, *m*-Ar), 135.1 (s, Ar) ppm. IR (KBr): $\tilde{\nu}$ = 2148, 2041, 1630, 1498, 1261 cm^{-1}. HRMS (FAB): calcd. 1102.2393; found 1102.2366.

Cyclovoltammetry: The electrochemical measurements were performed with an Ecochem PGStat 20. A glassy carbon disk electrode with a 3 mm diameter was used as the working electrode. The Ag/AgCl reference electrode was separated from the solution by a G4-frit and a Haber−Luggin capillary. As the electrolyte, a 0.1 M solution of nBu$_4$N$^+$PF$_6^-$ in anhydrous, degassed CH_2Cl_2 was used. All reported potentials are referred to the Fc/Fc$^+$ couple, which

was used as an internal calibrant. All measurements were performed at room temperature.

X-ray Crystallography and Structure Solution: The crystallographic data were recorded with a Bruker Smart CCD diffractometer at 200 K for **14**−**17** and **21**. Relevant crystal and data collection parameters are given in Table 2. The structures were solved using direct methods (**14**−**16**, **21**) or the Patterson heavy atom method (**17**), least-squares refinement, and Fourier techniques. Structure solution and refinement were performed with SHELXTL.[39] CCDC-172774 (**14**), -172775 (**15**), -172776 (**16**), -172777 (**17**), and -172778 (**21**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Allylpalladium Complexes of Mixed-Donor Diphosphazane Ligands Bearing a Stereogenic Phosphorus Centre: Structure and Stereodynamics

Swadhin K. Mandal,[a] G. A. Nagana Gowda,[b] Setharampattu S. Krishnamurthy,*[a] Chong Zheng,[c] Shoujian Li,[c] and Narayan S. Hosmane[c]

Keywords: Allyl complexes / P ligands / Palladium / N ligands

(η^3-Allyl)palladium complexes of general formula [Pd(η^3-R′C_3H_4){η^2-$Ph_2PN(R)PPh(N_2C_3HMe_2$-3,5)}](PF_6) (**3**–**6**) and [Pd(η^3-R′C_3H_4){η^2-$Ph_2P(S)N(CHMe_2)PPh(N_2C_3HMe_2$-3,5)}]($PF_6$) (**7**–**8**), containing pyrazolyl-substituted diphosphazane ligands bearing a stereogenic phosphorus centre, have been synthesised. NMR spectroscopic and X-ray diffraction studies showed that the diphosphazane ligand in [Pd(η^3-R′C_3H_4){η^2-$Ph_2PN(R)PPh(N_2C_3HMe_2$-3,5)}](PF_6) [R′ = Me or Ph; R = $CHMe_2$ (**3** and **5**) or (*S*)-*CHMePh (**4** and **6**)] displayed unprecedented *P,N*-coordination instead of the hitherto observed *P,P*-coordination. These complexes existed in solution as mixtures of *endo,syn,trans*, *exo,syn,trans*, and *endo,syn,cis* diastereomers. In the solid state, only the *endo,syn,trans* isomer was observed for complex **5**. Phase-sensitive 2-D NOESY and ROESY spectra showed that the complexes **3**–**5** underwent *syn,anti* isomerisation; the NMR spectroscopic data were consistent with a mechanism involving the opening of the η^3-allyl group at the *trans* position with respect to the phosphorus centre. The isomerisation thus appeared to be electronically controlled. The complexes [Pd(η^3-MeC_3H_4){η^2-$Ph_2P(S)N(CHMe_2)PPh(N_2C_3HMe_2$-3,5)}]($PF_6$) (**7**) and [Pd($\eta^3$-$PhC_3H_4$){$\eta^2$-$Ph_2P(S)N(CHMe_2)$-$PPh(N_2C_3HMe_2$-3,5)}]($PF_6$) (**8**), bearing the diphosphazane monosulfide $Ph_2P(S)N(CHMe_2)PPh(N_2C_3HMe_2$-3,5) (**1c**), displayed *P,S*-coordination and existed in solution as six and four isomers, respectively. Exchange was observed among four of the six isomers of **7** and among all the four isomers of **8** at 298 K, through the opening of the η^3-allyl moiety, which appeared to be subject to both electronic and steric control.

Introduction

Palladium-catalysed allylic substitution reactions have emerged as a powerful methodology in organic synthesis;[1] the use of chiral auxiliary ligands can result in the formation of optically active products. Initially, chiral diphosphane ligands were predominantly used, while in recent years, asymmetric mixed-donor ligands have proven to be advantageous. The use of P,N-,[2] P,S-,[3] and S,N-donor[4] ligands in particular has resulted in high enantiomeric excesses in allylic alkylation reactions, which is attributed to the electronic effects of two different donor centres present in these ligand systems. In contrast to most other transition metal catalysed reactions, palladium-catalysed allylic alkylations do not rely solely on a single mechanism as a source of asymmetry.[5] Differentiation of the enantiotopic faces of a π-system is one possible mechanism, but the source of the enantioselectivity is complicated by the problems associated with the regioselectivity of nucleophilic attack, possibility of various configurational isomers, and the existence of several stereodynamic processes.[6] The reaction proceeds through a (π-allyl)palladium intermediate and the configuration of the organic product strongly depends on the nature of this intermediate. There is growing interest in understanding the solution structures and the dynamic solution behaviour of the chiral (η^3-allyl)palladium intermediates, as these may be related to synthetic methods affording optically active products.[7] The situation becomes even more complicated when both the auxiliary ligands and the allyl moiety are asymmetrical; in this case, various geometrical isomers with different allyl face coordination would result, as well as allylic arrangements. As a part of our ongoing investigations into the organometallic chemistry of diphosphazane ligands,[8–9] we have recently begun a program of NMR studies of (π-allyl)palladium complexes of diphosphazane and related ligand systems based on the P−N−P motif. The diphosphazane ligands display versatile transition metal organometallic chemistry[10] and these ligand systems can be suitably modified, thus providing access to a range of mixed-donor ligands. Despite extensive studies of the reactions of diphosphazane ligands with sev-

eral transition metal precursors, the allylpalladium chemistry of unsymmetrical diphosphazane ligands has not been explored except for a brief report on allylpalladium complexes of $Ph_2PN(H)P(O)Ph_2$.[10d] Here we report the synthesis, solution characterisation and dynamic behaviour of (η^3-allyl)palladium complexes bearing phosphorus-stereogenic diphosphazane ligands − $Ph_2PN(R)PPh(N_2C_3HMe_2$-3,5) [R = $CHMe_2$ (**1a**) or (*S*)-*CHMePh (**1b**)] − and the diphosphazane monosulfide ligand $Ph_2P(S)N(CHMe_2)PPh(N_2C_3HMe_2$-3,5) (**1c**). In the case of **1b**, the (S_CR_P) diastereomer, the absolute configuration of which has been determined by X-ray crystallography,[8d] was used for the preparation of allylpalladium complexes.

Results and Discussion

Synthesis

The cationic allyl complexes **3**−**8** were prepared by treatment of the chloro-bridged allylpalladium dimer **2** with the appropriate ligands in the presence of NH_4PF_6 in acetone (Scheme 1). These complexes have been characterised by elemental analyses and NMR spectroscopic data (see Exp. Sect.). Several isomers are possible for complexes that contain an unsymmetrically substituted allyl group. In the first place, isomers can arise because of different modes of coordination of the ligands (e.g., *P*,*P* or *P*,*N* for **1a** or **1b**, *P*,*S* or *P*,*N* or *N*,*S* for **1c**). Secondly, geometrical isomers can be formed because the substituent on the allyl moiety can be oriented in a *cis* or *trans* position with respect to one of the phosphorus atoms. Thirdly, several allylic arrangements are also possible since the substituent on the allyl moiety can be positioned *syn* or *anti* with respect to the central allyl proton. Additionally, for each of these isomers, diastereomers can arise owing to the different face coordination (*exo* or *endo*) of the allyl group. The isomeric composition in each case was determined by NMR spectroscopy. The salient features of the spectroscopic data and dynamic behaviour are discussed below.

NMR Studies on $[Pd(\eta^3\text{-}R'C_3H_4)\{\eta^2\text{-}Ph_2PN(R)PPh(N_2C_3HMe_2$-3,5)$\}](PF_6)$ (3−6)

The $^{31}P\{^1H\}$ NMR spectra of complexes **3**−**6** in $CDCl_3$ in each case displayed six doublets (see Table 1) in different isomeric ratios, revealing the presence of three isomers. The structures proposed for these isomers are shown in Figure 1. Analysis of the ^{13}C NMR spectra of the allyl carbon nuclei pointed to *P*,*N*-coordination through the nitrogen atom at the 2-position of the pyrazole ring (see Table 2). The resonances of the central allyl carbon atoms of all the isomers appeared as doublets. For *P*,*P*-coordination, one should observe a doublet of doublets pattern in the ^{13}C NMR spectra for each of the palladium-bound allyl carbon nuclei. The signals for terminal allyl carbon nuclei appeared as two doublets and were assigned on the basis of the two-bond phosphorus-carbon coupling and a 2-D ^{13}C-^1H HSQC experiment. The doublets in the ^{13}C NMR spectra in the δ = 94−105 and 78−80 ppm ranges, with $^2J_{P,C}$ values of 28−31 Hz, were assigned to the substituted terminal allyl and unsubstituted terminal allyl carbon atom, respectively, *trans* to the coordinated phosphorus centre. On the other hand, the resonances for the substituted and unsubstituted terminal allyl carbon nuclei *trans* to the nitrogen atom appeared in more shielded regions (δ = 64−77 and

[a] The ^{13}C NMR spectra were recorded in $CDCl_3$ at 298 K except for **3** and **8**, in which cases a 1:1 mixture of $CDCl_3$ and CH_2Cl_2 was used. The ^{13}C-^{31}P coupling constants are given in parentheses. C_t is the terminal allyl carbon atom *trans* to the coordinated phosphorus centre. C_t' is the terminal allyl carbon atom *cis* to the coordinated phosphorus centre. C_c is the central allyl carbon atom. [b] $^2J_{P,C\ trans}$. [c] $^2J_{P,C\ cis}$. [d] Overlapped with central allyl carbon resonance of **4a**. [e] Overlapped with C_t' resonance of **7a**. [f] Overlapped with central allyl carbon resonance of **7c**.

51−56 ppm, respectively) with $^2J_{P,C}$ coupling constants in the 3−6 Hz range, typical for two-bond coupling of phosphorus and carbon nuclei in a *cis* orientation. It is well documented that in cationic allyl complexes with phosphorus ligands the ^{31}P nucleus shows a larger coupling constant with the terminal allyl carbon atom in the *trans* position than with that in the *cis* position.[11] In all the major isomers (**3a**, **4a**, **5a**, and **6a**) and in the second most abundant isomers (**3b**, **4b**, **5b**, and **6b**), the coordinated phosphorus atom and the substituent on the allyl moiety had a *trans* disposition. The remaining isomers (**3c**, **4c**, **5c**, and **6c**) were assigned structures in which the coordinated phosphorus atom and the substituent on the allyl moiety had a *cis* disposition. The *P*,*N*-coordination was also supported by the ^{31}P chemical shifts (see Table 1).

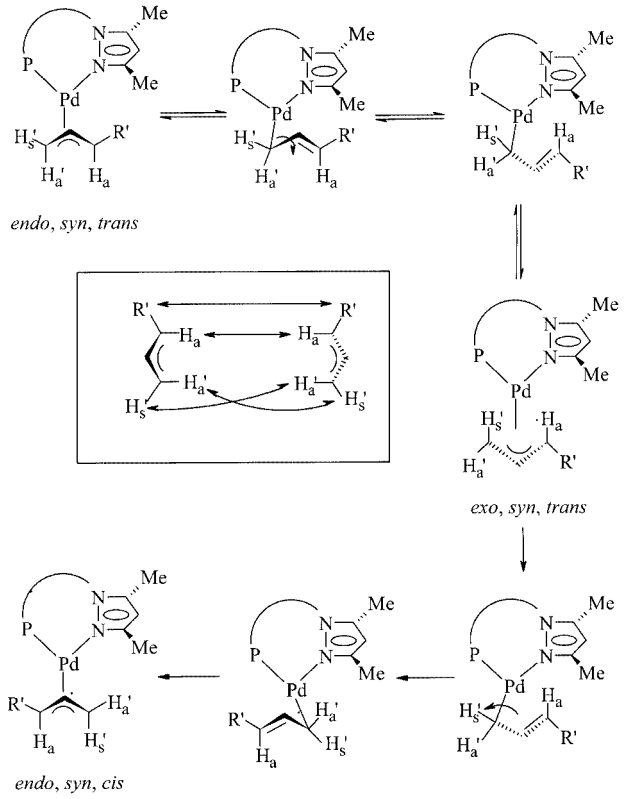
Transition metal complexes of the ligands **1a** and **1b** usually feature *P*,*P*-coordination.[9] The driving force for *P*,*N*-coordination in the (η^3-allyl)palladium complexes **3**−**6** might be the formation of a stable six-membered chelate ring around the palladium centre rather than the four-membered ring that would result from *P*,*P*-coordination. Moreover, coordination of a stronger σ-donor nitrogen atom would electronically stabilise the allyl−palladium bonding much more than coordination with a stronger π-acceptor phosphorus centre, by enhancing the metal-to-allyl back-bonding.[12] Such a pronounced electronic effect is well known[13] and is reflected in the ^{13}C NMR parameters (see Table 2).

The ^1H NMR spectra of the complexes **3**−**6** showed three sets of four nonequivalent resonances for the allylic protons at 298 K. The magnetic nonequivalence of the allylic protons arises because of the asymmetry in the ligands **1a** and **1b**. The presence of two *anti*-allyl protons in each set of signals indicated a *syn* arrangement of the allyl substituent with respect to the central allyl proton in each isomer. The major isomers of these complexes showed NOE contacts between the 3-Me protons of the pyrazole ring and the central allyl proton H_c. This result indicated that the central allyl hydrogen atom H_c pointed towards the 3-Me group of the pyrazole. Hence, the major isomers (**3a**−**6a**) have the *endo*,*syn*,*trans* arrangement.[7b,14] For the second set of isomers (**3b**−**6b**), the pyrazole 3-Me protons did not show NOE contacts to the central allyl proton H_c but there was an NOE contact to the *anti*-allyl proton H_a. The central allyl proton H_c thus pointed away from the 3-Me group of the pyrazole, and so these isomers (**3b**−**6b**) could be assigned the *exo*,*syn*,*trans* configuration. The central allyl proton resonances for the *endo* isomers **3a**−**6a** appeared at a more deshielded region (δ ≈ 5.7 ppm) than those (δ ≈ 4.5 ppm) for the *exo* isomers **3b**−**6b**. This trend has also been observed for other allylpalladium complexes $[Pd(\eta^3\text{-}1,3\text{-}R'_2C_3H_3)\{\eta^2\text{-}Ph_2PN(R)PPh(N_2C_3HMe_2\text{-}3,5)\}](PF_6)$ [R′ = H, Me or Ph; R = $CHMe_2$ or (*S*)-*CHMePh] bearing **1a** and **1b** ligands.[15] On this basis, we assigned the *endo*,*syn*,*cis* configuration (see Figure 1) to the third set of minor isomers (**4c**−**6c**) as the chemical shifts of the H_c protons in each of these isomers were close to those observed for **4a**−**6a**. The *cis* geometries and the *syn*-allylic arrangements for the minor isomers were confirmed by ^{13}C NMR (see Table 2) and 2-D NMR spectroscopy, respectively. The ^{13}C and ^1H NMR signals for isomer **3c** could not be ob-

served because of its low abundance and poor solubility in $CDCl_3$. However, the ^{31}P chemical shift and P-P coupling constant values for **3c** were similar to those of **4c**, and so an *endo*,*syn*,*cis* configuration may tentatively be assigned to **3c**. An important difference was observed between the relative abundances of the isomers of 1-methylallyl and 1-phenylallyl derivatives. For the 1-methylallyl derivatives (**3** and **4**), the *exo*,*syn*,*trans* isomers were present to an extent of 40%, whereas for the 1-phenylallyl derivatives (**5** and **6**), the *exo*,*syn*,*trans* isomers were present to an extent of less than 10%. The low relative abundances of the *exo*,*syn*,*trans* isomers in the case of 1-phenylallyl derivatives is probably related to the steric demand of the larger phenyl group on the allyl moiety.

Dynamic Behaviour of the Complexes 3−6

The dynamic behaviour of the complexes **3**−**6** was examined by ^1H-^1H NOESY and ROESY spectra. No exchange among the isomers of complexes **4**−**6** was observed in $CDCl_3$ at 298 K. For complex **3**, on the other hand, exchange between the isomers **3a** and **3b** was observed at 298 K in [D_6]acetone. The high-temperature (323 K) ^1H-^1H NOESY and ROESY spectra for the complexes **4** and **5** revealed that the major isomers **4a** and **5a** exchanged with the minor isomers **4b** and **5b**, respectively, in a way similar to that observed for the isomers **3a** and **3b** at 298 K. The phase-sensitive ^1H-^1H NOESY spectrum of complex **4** recorded at 323 K is shown in Figure 2 and the exchange results are summarised in Scheme 2. Pregosin and coworkers[16] have shown that this type of exchange can be explained in terms of a selective opening of the η^3-allyl moiety at the *trans* position with respect to the phosphorus centre to generate an η^1-bonded intermediate, followed by a rotation around the sp^3-sp^2 C−C bond and reversion to the η^3-mode of coordination by the other face of the allyl group. This type of electronic control over the interconversion process is especially well known in cases of mixed-donor P,N-, P,S-, and P,O- bidentate ligand systems.[17−19] The minor isomers (**4c** and **5c**) did not show any observable exchange even at 323 K, but their formation can be interpreted, starting from isomers **4b** and **5b**, respectively, in terms of *cis*,*trans* isomerisation by rotation around the Pd−C bond in the corresponding η^1-bonded intermediate.



Scheme 2

Solid-State Structure of Complex 5a

The details of the crystal data are presented in Table 3. The molecular structure is shown in Figure 3. The solid-state structure reveals the presence of only one isomer with *P*,*N*-coordination and a *trans* disposition of the *syn*-allylphenyl group with respect to the coordinated phosphorus centre. The central allyl carbon atom C(2) and the 3-methyl carbon atom C(10) of the pyrazole ring in **5a** lie on the same side of the coordination plane defined by P(2)−Pd(1)−N(3), thus revealing an *endo* arrangement in the solid state (*endo* refers to the relative orientation of the central C−H vector pointing towards the 3-methyl group on the pyrazole ring[7b,14]). The bonding parameters fall in the expected ranges observed for cationic allylpalladium

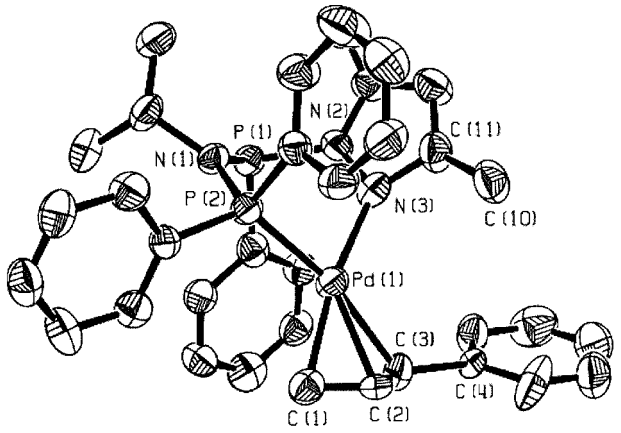

Figure 3. Molecular structure of **5a** in the solid state (the hydrogen atoms and the hexafluorophosphate anion are not shown); selected bond lengths [Å] and angles [°]: Pd(1)−C(1) = 2.075(2), Pd(1)−C(2) = 2.137(2), Pd(1)−C(3) = 2.263(2), Pd(1)−P(2) = 2.293(3), Pd(1)−N(3) = 2.075(1); N(3)−Pd(1)−P(2) = 85.4(3), C(1)−Pd(1)−C(3) = 64.0(8), N(3)−Pd(1)−C(1) = 169.8(5), C(3)−Pd(1)−P(2) = 167.8(6), P(2)−N(1)−P(1) = 122.5(6)

complexes bearing P,N-ligands.[17b,20] The coordination geometry around the metal centre is distorted square-planar, with the N(3)−Pd(1)−P(2) and C(1)−Pd(1)−C(3) bond angles 85.4(3)° and 64.0(8)°, respectively. The two terminal allyl carbon atoms are not exactly coplanar with the coordination plane formed by P(2)−Pd(1)−N(3). The distances of the terminal allyl carbon atoms C(1) and C(3) are 0.120 Å and 0.089 Å, respectively, whereas the central allyl carbon atom C(2) lies at a distance of 0.703 Å from the plane. The terminal Pd−C(allyl) bond lengths are significantly different from one another. The carbon atom *trans* to the phosphorus atom displays the expected longer bond length [Pd(1)−C(3) = 2.263(2) Å], as compared to its partner *trans* to the nitrogen atom [Pd(1)−C(1) = 2.075(2) Å]. This is consonant with the larger *trans* influence of the phosphorus donor.[13] This elongation of the Pd−C(terminal allyl) bond length *trans* to the phosphorus atom relative to that *trans* to the nitrogen atom is consistent with the proposed mechanism (Scheme 2) involving selective opening of one of the allyl termini. The six-membered chelate ring adopts a distorted boat conformation; P(2) is almost coplanar (deviation 0.168 Å) with the plane formed by N(1)−N(2)−N(3), while Pd(1) and P(1) lie on the same side of this plane at 1.063 and 0.778 Å, respectively. The P(1)−N(1)−P(2) bond angle is increased to 122.5(6)°, compared to a value of ca. 100° observed for *P,P*-coordinated complexes.[9]

NMR Studies on Complexes 7 and 8

The $^{31}P\{^{1}H\}$ NMR spectrum of an analytically pure sample of [Pd(η³-1-MeC_3H_4){η²-$Ph_2P(S)N(CHMe_2)PPh$-($N_2C_3HMe_2$-3,5)}](PF_6) (**7**) in $CDCl_3$ showed ten doublets arising from six AX spin systems. The two missing doublets (from the fifth and sixth isomers) overlapped with those arising from the major isomers, as revealed by a ^{31}P-^{31}P COSY spectrum. A 24-line spectrum was consistent with the formation of six isomers. The relative integrated intensities of the doublets indicated that the six isomers were present in the ratio 21:10:9:6:2:1. The allyl ^{13}C resonances for these isomers were assigned by recourse to a ^{13}C-^{1}H HSQC experiment. Analysis of the ^{13}C NMR spectrum showed a doublet pattern with a $^{2}J_{P,C}$ value of ca. 30 Hz for one of the two terminal allyl carbon resonances in the cases of isomers **7a**−**7d**, indicating bonding of one phosphorus atom with the palladium centre. From the ^{31}P chemical shifts (Table 1 and see also below), we were able to conclude that the pyrazolyl-bearing phosphorus atom and the sulfur atom were coordinated to the palladium centre. This conclusion was supported by the ^{13}C chemical shifts of the allyl carbon nuclei, when compared with the chemical shifts of allyl carbon nuclei of *P,N*-coordinated complexes **3**−**6** (see Table 2). It may be noted that the chemical shifts of allyl carbon nuclei *trans* to the nitrogen atom indicated that they were more shielded (by about 10−20 ppm) than the allyl carbon nuclei *trans* to the sulfur atom, if we consider the similar allyl isomers in both cases. Ligand **1c**, in contrast to **1a** and **1b**, thus did not coordinate through the nitrogen atom of the pyrazole ring, *P,S*-coordination presumably being favoured because of the formation of a stable five-membered ring around the palladium centre. The competitive *N,S*-coordination would give rise to the formation of a seven-membered chelate ring around the palladium atom. The fifth and sixth isomers (**7e** and **7f**) could not be detected by ^{13}C NMR, owing to their low relative concentrations (present at less than 5%). However, the similarity of their ^{31}P chemical shifts with those of other isomers (**7a**−**7d**) and the multiplicities of the allyl resonances in the ^{1}H NMR spectrum suggested that these isomers must be structurally closely related to **7a**−**7d**.

The ^{1}H NMR spectrum of complex **7** showed several broad signals; in addition, the chemical shifts of several allylic proton resonances were very close. However, a careful analysis of various 2-D NMR spectra (^{1}H-^{1}H DQF COSY, NOESY, and ROESY) resulted in a correct assignment of the allyl protons. The intra-allyl NOESY spectrum revealed that in the four isomers **7a**−**7d** there was a *syn* arrangement of the allylmethyl group with respect to the central allyl proton (H_c), while in the isomers **7e** and **7f** there was an *anti* arrangement of the allylmethyl group and the central allyl proton. The interligand NOE cross-peaks confirmed the configurations of these isomers. One of the methyl groups of the pyrazole ring came close to the central allyl proton H_c and to the *syn*-proton H_s' in the *endo* isomer, whereas for the *exo* isomer the *anti*-allyl proton H_a' showed NOE contact with this methyl group. The structures assigned to the six isomers on the basis of NMR measurements are shown in Figure 4. The structural assignments for **7a** and **7b** are unequivocal, while there is some uncertainty with regard to the structural assignments for the other isomers (**7c**−**7f**) because of the overlap of the pyrazole methyl proton signals arising from these minor isomers. However, studies on the exchange behaviour of the isomers (see below) lent support to the assignments.

The ^{1}H-^{1}H phase-sensitive NOESY and ROESY spectra at 298 K in $CDCl_3$ showed that isomers **7a**−**7d** were in

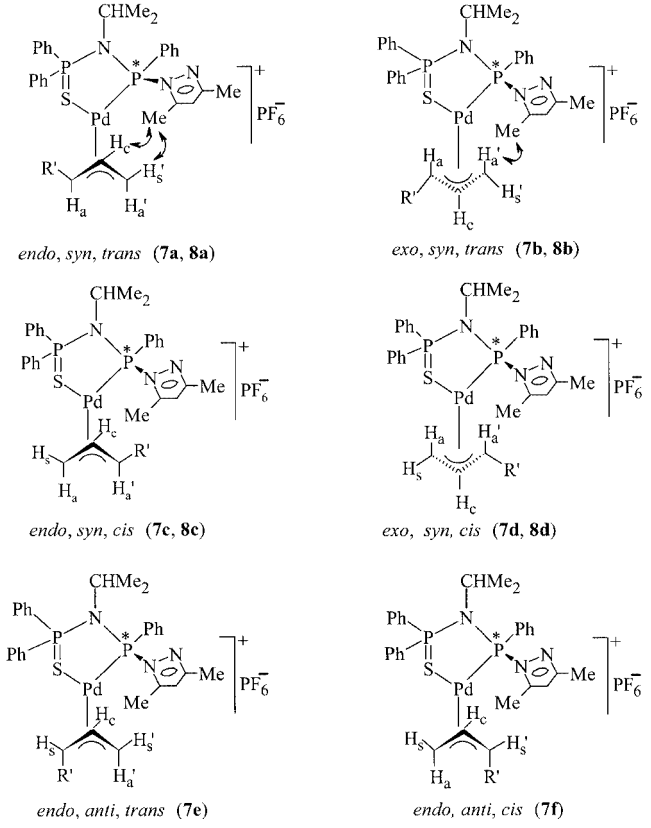

Figure 4. The six isomers for the (methylallyl)palladium complex $[Pd(\eta^3\text{-}MeC_3H_4)\{\eta^2\text{-}Ph_2P(S)N(CHMe_2)PPh(N_2C_3HMe_2\text{-}3,5)\}](PF_6)$ (**7**) and the four isomers observed in solution for the (phenylallyl)palladium complex $[Pd(\eta^3\text{-}PhC_3H_4)\{\eta^2\text{-}Ph_2P(S)N(CHMe_2)PPh(N_2C_3HMe_2\text{-}3,5)\}](PF_6)$ (**8**)

equilibrium with one another. The exchange followed an η^3-η^1-η^3 pathway, with the opening of the allyl terminus at the position *trans* with respect to the phosphorus centre. The isomer **7a** showed dynamic behaviour with isomer **7b** through a s*yn*,*anti* isomerisation process. Hence, **7b** could be assigned the *exo*,*syn*,*trans* structure, as the starting isomer **7a** had the *endo*,*syn*,*trans* structure. On the other hand, the isomer **7a** transformed into **7d** by a *cis*,*trans* isomerisation process, indicating that **7d** should be the *exo*,*syn*,*cis* isomer. The isomer **7b** showed *cis*,*trans* exchange with the isomer **7c**, and so the isomer **7c** should be *endo*,*syn*,*cis*. Exchange cross-peaks were also observed between isomers **7a** and **7c**, as well as between isomers **7b** and **7d**. The exchange equilibria may be represented schematically as in Scheme 3.

The $^{31}P\{^1H\}$ NMR spectrum of complex **8** (see Figure 5) revealed eight doublets arising from four isomers. A detailed NMR investigation (^1H NMR, ^{13}C NMR, ^1H-^1H DQF COSY, NOESY, and ROESY) indicated that all four isomers involved *P*,*S*-coordination with *syn*-allylphenyl arrangement, and that the major isomer had the *endo*,*syn*,-*trans* configuration (**8a**) as shown in Figure 4. In contrast to complex **7**, no *anti* isomer was formed in this case, owing to the presence of a relatively more bulky phenyl group on the allyl moiety. The exchange behaviour for **8a**−**8d** was similar to that observed for **7a**−**7d**; the exchanges are depicted in Scheme 4. The results can be explained in terms of the pathways shown in Scheme 5, the isomers **8a** and **8d** being related by *cis*,*trans* isomerisation and **8a** and **8b** by *syn*,*anti* isomerisation, with both processes occurring by means of a selective opening of the terminal allyl Pd−C bond located *trans* to the better π-acceptor phosphorus centre. Hence, the conversion of **8a** into **8b** or **8d** was electronically controlled.

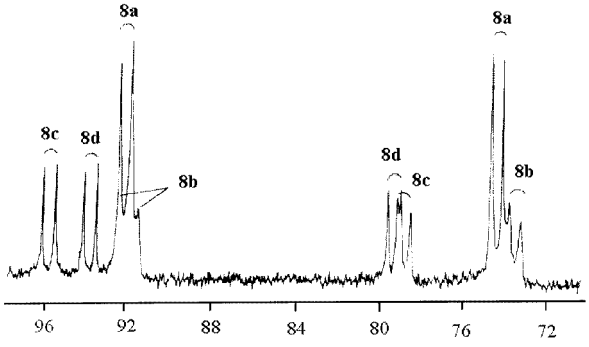

Figure 5. The $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$, 161.9 MHz) of complex **8** at 298 K, showing the presence of four isomers

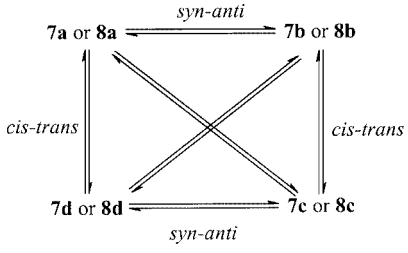
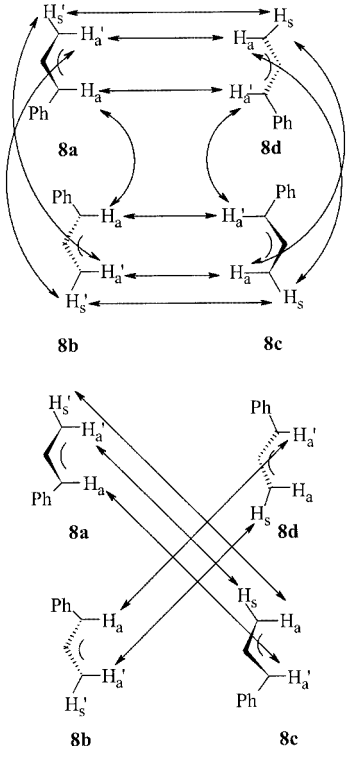
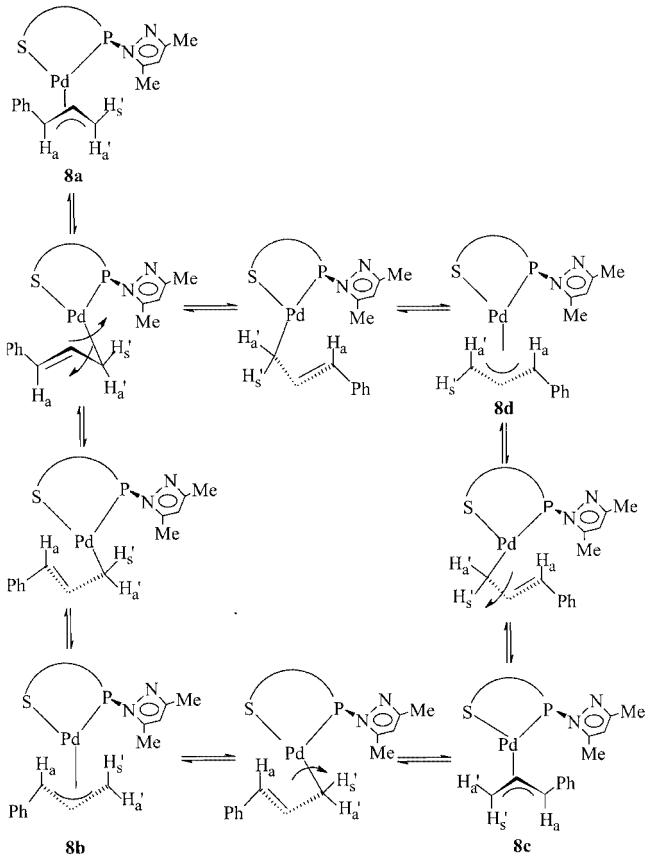


Scheme 3



Scheme 4



Scheme 5

In contrast, the isomerisation between **8d** and **8c** took place by a selective opening of the η^3-allyl group at the *cis* position with respect to the phosphorus centre, and hence was subject to steric control over the opening of the η^3-allyl moiety. The presence of a bulky allylphenyl group at the position *cis* to the $-PPh(N_2C_3HMe_2$-3,5) group in isomer **8d** exerted a more pronounced steric repulsion than in isomer **8a**, in which the allylphenyl group resided at the position *cis* to the sterically less demanding $-P(S)Ph_2$ group. Hence, the opening of the η^3-allyl moiety to a three-coordinated η^1-bonded intermediate in isomer **8d** relieved the steric strain. This type of steric control over *syn*,*anti* isomerisation has been observed in the case of a cationic allylpalladium complex bearing a P,S-ligand with a bulky allyl moiety.[18] Moreover, the isomer **8a** exchanged with **8c**, and **8b** exchanged with **8d**. Direct exchange between isomers **8a** and **8c** or between **8b** and **8d** should not be permitted, in view of their structural differences. However, NMR measurements clearly indicated exchange between **8a** and **8c** as well as **8b** and **8d**. The exchange information was transmitted via the intermediates **8b** or **8d**, resulting in an equilibrium among all four isomers **8a**−**8d**. The rapid dynamic processes for **7** and **8** were most probably related to the fact that the free nitrogen atom on the pyrazole ring can coordinatively interact with the palladium centre in the η^1-bonded intermediate. Such an interaction would stabilize the η^1-bonded intermediate and could accelerate the dynamic process. It is well known that catalytic amounts of anions such as chloride or fluoride or polar solvents such as DMSO and acetonitrile, which can coordinate to the palladium centre, accelerate the dynamic processes in allylpalladium complexes.[21]

Trends in ^{31}P Chemical Shifts

The ^{31}P resonances were assigned on the basis of the $\Delta\delta$ [$\Delta\delta = \delta$(complex) − δ(free ligand)] and sensitivity of the chemical shifts upon variation of the allyl moiety (see Table 1). The chemical shifts of one of the phosphorus nuclei in each of complexes **3**−**6** lay in the $\delta = 71-73$ ppm range, with $\Delta\delta$ being only 4.2−0.5 ppm. The constancy in the magnitude of chemical shifts on changing the allyl component and the low $\Delta\delta$ value suggested that this chemical shift could be assigned to the noncoordinated phosphorus atom bearing the pyrazole moiety. On the other hand, the chemical shifts of the other phosphorus nuclei showed a greater range of variation ($\delta = 75-80$ ppm). These phosphorus chemical shifts lay very much further downfield from that of the free ligand, and the magnitude of $\Delta\delta$ was in the 30.7−35.0 ppm range. Hence, this chemical shift was assigned to the coordinated $-PPh_2$ phosphorus atom. For the *P*,*S*-coordinated complexes **7** and **8**, the $-P(S)Ph_2$ and the −PPh(pyrazole) chemical shifts were assigned the values $\delta = 73.6-79.5$ and 91.7−95.7 ppm, respectively, based on the magnitude of $\Delta\delta$ and chemical shifts observed for allylpalladium complexes of the ligands $Ph_2P(S)N(CHMe_2)PPh_2$ and $Ph_2P(S)N(CHMe_2)P(S)Ph_2$, and also the chemical shifts of *P*,*P*-coordinated complexes of **1a**.[15]

With regard to P−P couplings, two observations were worthy of note:

(1) The $^2J_{P,P}$ values for *P*,*N*-coordinated complexes of **1a** and **1b** lay in the 29−31 Hz range, whereas $^2J_{P,P}$ values for *P*,*P*-coordinated allyl complexes are observed in the range of ca. 100 Hz.[15]

(2) The $^2J_{P,P}$ values for the *P*,*S*-coordinated complexes of **1c** were in the 80−100 Hz range.

Conclusions

Diphosphazane ligands of the type $Ph_2P(E)N(R)PPh(N_2C_3HMe_2$-3,5) (**1**), bearing a stereogenic phosphorus centre, exhibited diverse allylpalladium chemistry including various fluxional processes in solution. The preferred mode of coordination with the ligands $Ph_2PN(R)PPh(N_2C_3HMe_2$-3,5) [R = $CHMe_2$ (**1a**) or (*S*)-*CHMePh (**1b**)] was through the phosphorus and nitrogen atoms rather than the usually observed *P*,*P*-coordination. The former mode of coordination should electronically stabilise the allyl−palladium bonding, besides giving rise to the formation of a six-membered chelate ring. On the other hand, the monosulfide ligand $Ph_2P(S)N(R)PPh(N_2C_3HMe_2$-3,5) (**1c**) displayed *P*,*S*-coordination and also gave rise to a larger number of diastereomers with different allylic arrangements than observed in the *P*,*N*-coordinated ligands (**1a** and **1b**), which were more selective towards stabilisation of particu-

lar allyl diastereomers. In addition, in the case of *P,N*-coordinated complexes, there was a drastic decrease in the relative abundances of the *exo*,*syn*,*trans* isomers of 1-phenylallyl derivatives (below 10%) compared to those (40%) of the *exo*,*syn*,*trans* isomers of 1-methylallyl derivatives. Such a trend was not observed for the *P,S*-coordinated complexes. As far as the dynamic behaviour is concerned, the activation barriers for exchange processes among various allyl isomers bearing the P,S-ligand were less than those observed for the allyl isomers formed by P,N-ligands. The exchange pathway involved an η^1-allyl species generated by the opening of the η^3-allyl moiety at the position *trans* with respect to phosphorus atom in the case of *P,N*-coordinated complexes, and so was subject to electronic control. In the case of *P,S*-coordinated complexes, on the other hand, exchange among the allyl diastereomers occurred through the opening of the η^3-allyl moiety at either end (both *trans* with respect to the phosphorus atom as well as the sulfur atom). One possible reason for this difference is that the *trans* influences exerted by the two donor atoms − namely, phosphorus and sulfur − of the P,S-ligand (**1c**) would be reasonably similar to each other, whereas the *trans* influence of the phosphorus atom of the P,N-ligand (**1a** or **1b**) would be much larger than that of the nitrogen atom, as evident from the ^{13}C chemical shift values of the allyl termini.

Experimental Section

General Remarks: Reactions and manipulations were carried out under purified nitrogen by standard Schlenk and vacuum-line techniques. The solvents were purified by standard procedures[22] and distilled under nitrogen. The chloro-bridged allyl dimers $[Pd(\eta^3\text{-}1\text{-}MeC_3H_4)(\mu\text{-}Cl)]_2$ and $[Pd(\eta^3\text{-}1\text{-}PhC_3H_4)(\mu\text{-}Cl)]_2$ were prepared as previously described.[23] Diphosphazane ligands **1a**, the (S_CR_P) diastereomer of **1b** and diphosphazane monosulfide **1c** were prepared according to literature procedures.[8d,9c] The NMR spectra were recorded with Bruker DRX 500 MHz and Bruker AMX 400 MHz spectrometers. Chemical shifts downfield from the reference standard were assigned positive values. Elemental analyses were carried out with a Perkin−Elmer 2400 CHN analyser. The $^{31}P\{^1H\}$ and ^{13}C NMR spectroscopic data are given in Tables 1 and 2, respectively. The remaining NMR spectroscopic data are given below.

Synthesis of Palladium Complexes

$[Pd(\eta^3\text{-}1\text{-}MeC_3H_4)\{\eta^2\text{-}Ph_2PN(CHMe_2)PPh(N_2C_3HMe_2\text{-}3,5)\}](PF_6)$ (3): A mixture of $[Pd(\eta^3\text{-}1\text{-}MeC_3H_4)(\mu\text{-}Cl)]_2$ (0.039 g, $0.99\cdot10^{-4}$ mol), NH_4PF_6 (0.033 g, $2.02\cdot10^{-4}$ mol), and **1a** (0.095 g, $2.13\cdot10^{-4}$ mol) was dissolved in 20 mL of acetone. The solution was stirred for 2 h at 298 K and the white precipitate formed during the reaction was filtered off. The resulting colourless filtrate was concentrated to 10 mL under reduced pressure, and the solution was layered by addition of 5 mL of hexane (b.p. 40−60 °C) to yield colourless microcrystals. Yield: 0.140 g (93%). $C_{30}H_{36}F_6N_3P_3Pd$ (751.9): calcd. C 47.93, H 4.79, N 5.59; found C 47.56, H 4.88, N 5.53. m.p.191−194 °C (dec.). [Pd(η^3-1-PhC_3H_4){η^2-Ph_2P(S)N($CHMe_2$)PPh($N_2C_3HMe_2$-3,5)}]-(PF_6) (8): Starting materials: [Pd(η^3-1-PhC_3H_4)(μ-Cl)]$_2$ (0.052 g, 1.00·10^{-4} mol), NH_4PF_6 (0.033 g, 2.02·10^{-4} mol), and **1c** (0.100 g, 2.09·10^{-4} mol). Yellow crystals were obtained by layering with hexane (b.p. 40−60 °C). Yield: 0.142 g (84%); m.p. 171−174 °C (dec.). $C_{35}H_{38}F_6N_3P_3PdS$ (846.1): calcd. C 49.70, H 4.49, N 4.97; found C 49.62, H 4.55, N 4.65. *endo*,*syn*,*trans* isomer (**8a**): ^{1}H NMR (400 MHz, $CDCl_3$): δ = 0.39 (br. s, CH_3 $CHMe_2$), 1.19 (br. s, CH_3 $CHMe_2$), 2.05 (s, 5-CH_3 $N_2C_3HMe_2$-3,5), 2.37 (s, 3-CH_3 $N_2C_3HMe_2$-3,5), 2.79 (br. s, H_a'), 4.23 (br. s, H_s'), 4.61 (br., CH $CHMe_2$), 5.63 (br., H_a), 6.04 (br., H_c), 6.28 (br. s, CH $N_2C_3HMe_2$-3,5), 6.52−7.98 (m, aryl protons) ppm. ^{13}C NMR [100.6 MHz, $CDCl_3$ and CH_2Cl_2 (1:1)]: δ = 13.5 (s, CH_3 $N_2C_3HMe_2$-3,5), 13.9 (br., CH_3 $N_2C_3HMe_2$-3,5), 23.0 (s, CH_3 $CHMe_2$), 58.0 (br., CH $CHMe_2$), 110.8 (s, CH $N_2C_3HMe_2$-3,5), 126.0−155.7 (aryl carbon atoms). *exo*,*syn*,*trans* isomer (**8b**): ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.23 (br. s, H_a'), 3.77 (br., H_s'), 5.49 (br. H_a), 6.11 (br., H_c). *endo*,*syn*,*cis* isomer (**8c**): ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.70 (br., H_a), 4.68 (br. t, H_s), 4.73 (br. d, H_a'), 6.18 (br., H_c). *exo*,*syn*,*cis* isomer (**8d**): ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.69 (br., H_a), 4.79 (br., H_s), 5.00 (br. d, H_a'), 6.00 (m, H_c) ppm.

X-ray Crystallography: Crystal data for complex **5a** were collected by using a Siemens SMART CCD diffractometer. The crystallographic data and details on data collection are summarised in Table 3. The structure was solved by direct methods, using the program SIR-97[24] and refined on F^2 values for all unique data by full-matrix, least squares by using SHELXTL.[25] The non-hydrogen atoms were refined anisotropically. The hydrogen atoms were fixed at their calculated geometrical positions and refined isotropically. CCDC-172846 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 3. Crystal data and structure refinement for complex **5a**

Empirical formula	$C_{35}H_{38}F_6P_3N_3Pd$
Formula mass	813.99
Temperature	293(2) K
Wavelength	0.71073 Å
Crystal system	monoclinic
Space group	$P2_1$
Unit cell dimensions	a = 9.8783(8) Å b = 18.1125(14) Å; c = 10.2360(8) Å β = 97.223(2)°
Volume	1816.9(2) Å^3
Z	2
Density (calculated)	1.488 Mg/m^3
Absorption coefficient	0.703 mm^{-1}
F(000)	828
Crystal size	0.12 × 0.06 × 0.06 mm
θ range for data collection	2.01−23.28°.
Index ranges	$-10 \le h \le 10$, $-20 \le k \le 20$, $-11 \le l \le 9$
Reflections collected	8238
Independent reflections	4817 [R(int) = 0.0275]
Completeness to θ = 23.28°	99.7%
Refinement method	full-matrix, least squares on F^2
Data/restraints/parameters	4817/1/435
Goodness-of-fit on F^2	1.140
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0740, $wR2$ = 0.1785
R indices (all data)	$R1$ = 0.1058, $wR2$ = 0.2102
Absolute structure parameter	0.00(7)
Extinction coefficient	0.0055(13)
Largest diff. peak and hole	2.298 and −0.676 e·Å^{-3}

μ-Imido, μ-(η²,η²-N,N-Hydrazido) and μ-(η¹-C:η²-C,N-Isocyanido) Dinuclear (Fulvalene)zirconium Derivatives

Marta González-Maupoey,[a] Gema M. Rodríguez,[a] and Tomás Cuenca*[a]

Keywords: Zirconium / Fulvalene ligands / Imido ligands / Hydrazido ligands / Isocyanido ligands

Treatment of the chloro(fulvalene)zirconium(III) compound $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}Cl)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ with an equimolar amount of azobenzene in toluene, under extremely anhydrous conditions, gives the μ-[bis(imido)] derivative $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}NPh)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**1**). However, when this reaction is carried out under insufficiently dry conditions a mixture of the previously reported μ-oxo complex $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}O)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ and 1,2-diphenylhydrazine is obtained. When the chloro(fulvalene)zirconium(III) compound reacts with benzo[*c*]cinnoline the μ-(η²,η²-N,N-hydrazido) complex $[Zr(\eta^5\text{-}C_5H_5)Cl]_2[\mu\text{-}(NC_6H_4C_6H_4N)][\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**2a**) is obtained, which rearranges to the thermodynamically more stable **2b**. Addition of an equimolar amount of RNC (R = *n*Bu, C_6H_{11}) to a toluene solution of $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}Cl)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ gives $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNR)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ [R = *n*Bu (**3**), C_6H_{11} (**4**)]. Reaction of $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CN\textit{t}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ with 1 equiv. of $PhCH_2MgCl$ or $(PhCH_2)_2Mg(THF)_2$ afforded the monobenzyl derivatives $[Zr(\eta^5\text{-}C_5H_5)]_2(CH_2Ph)(Cl)(\mu\text{-}CN\textit{t}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**5** and **6**). When this reaction was carried out with 2 equiv. or an excess of $PhCH_2MgCl$, a mixture of the monobenzyl and dibenzyl compounds $[Zr(\eta^5\text{-}C_5H_5)]_2(CH_2Ph)(Cl)(\mu\text{-}CN\textit{t}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**5**) and $[Zr(\eta^5\text{-}C_5H_5)(CH_2Ph)]_2(\mu\text{-}CN\textit{t}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**7**) is obtained. Similar reactions with 1 or 2 equiv. of $(CH_3)_3SiCH_2Li$ afford a mixture of the monoalkyl and dialkyl compounds $[Zr(\eta^5\text{-}C_5H_5)]_2[CH_2Si(CH_3)_3](Cl)(\mu\text{-}CN\textit{t}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**8**) and $\{Zr(\eta^5\text{-}C_5H_5)[CH_2Si(CH_3)_3]\}_2(\mu\text{-}CN\textit{t}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**9**) compounds. Moreover, methylation of $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CN\textit{n}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ gives the analytically pure tetramethyl derivative $[Zr(\eta^5\text{-}C_5H_5)(CH_3)]_2(\mu\text{-}CN\textit{n}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**10**), whereas $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNC_6H_{11})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ reacts with MeLi to give a mixture of the monomethyl derivatives $[Zr(\eta^5\text{-}C_5H_5)]_2(CH_3)(Cl)(\mu\text{-}CNC_6H_{11})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**11** and **12**), as well as the dimethyl compound $[Zr(\eta^5\text{-}C_5H_5)(CH_3)]_2(\mu\text{-}CNC_6H_{11})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**13**).

Introduction

Complexes with cyclopentadienyl ancillary ligands have dominated the study of early transition metal chemistry. Mono- and dicyclopentadienyltitanium, -zirconium and -hafnium derivatives are considered the most widely studied organometallic transition compounds. The stability, solubility and reactivity of these complexes are dramatically influenced by modifying their cyclopentadienyl ligands.[1]

The presence of two metal centres in homo- and heterodimetallic complexes has generated considerable effort in recent years, with a myriad of studies on their properties as well as cooperative investigations into their reactivity, which were then compared with analogous mononuclear cyclopentadienyl compounds.[2] For such organometallic complexes, particular attention has been devoted to compounds in which two metal centres are coordinated by a fulvalene bridging ligand.[3] The fulvalene group is especially interesting as it tends to form dinuclear complexes with short distances between the two metal centres, which may even have slight metal−metal interactions, as in compound **I**. With this disposition the metal centres are in close proximity, making the possible cooperative effects capable of enhancing or modifying the chemical reactivity. Free rotation of the rings around the C−C bond in the fulvalene plane makes two *cis*,*trans* conformations (**I**, **II**) of the metal fragments possible. The preferred conformation depends mainly on electronic and steric factors. In this type of ligand each cyclopentadienyl group is substituted through one bond to a second identical group. It makes the metal centre more electron-deficient, reducing secondary reactions such as ring C−H bond activation because of the rigid system that generates the fulvalene.

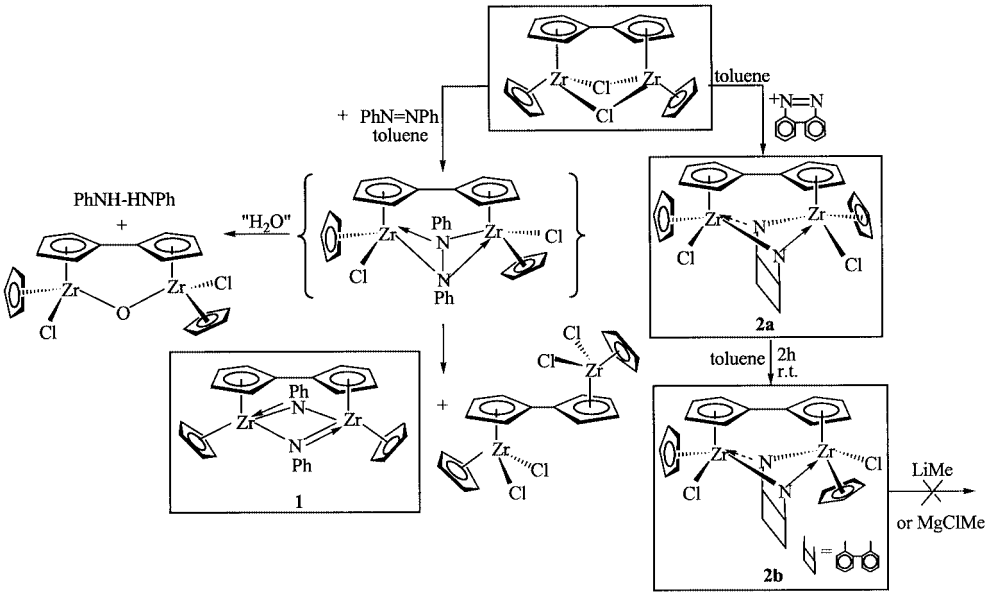


Scheme 1

To enable systematic studies of such compounds we have developed a high-yield route to titanium and zirconium compounds.[4] In recent years, the synthesis and reactivity of dinuclear organotitanium and -zirconium compounds containing the fulvalene ligand have been the focus of our research[5,6] and the study of fundamental chemical reactions with a variety of new fulvalene derivatives has been published.[7] In this paper we report the formation of dinuclear (fulvalene)zirconium complexes where both metal atoms are bridged by an additional μ-imido, μ-(η^2,η^2-N,N-hydrazido) or μ-(η^1-C:η^2-C,N-isocyanido) ligand.

Results and Discussion

μ-Imido, μ-(η^2,η^2-N,N-Hydrazido) Derivatives

Imido complexes of group-4 elements have been synthesized by different routes.[8] According to the described method using the N=N bond cleavage of an azobenzene,[9] the known chloro(fulvalene)zirconium(III) compound [Zr(η^5-C_5H_5)(μ-Cl)]$_2$[μ-(η^5,η^5-$C_{10}H_8$)][4a] reacts with an equimolar amount of PhN=NPh in toluene, under extremely anhydrous conditions, as shown in Scheme 1. The initially deep violet solution first turns dark yellow and then orange with gradual precipitation of a yellow solid. The solid was identified by elemental analysis and IR spectroscopy as the known chloro(fulvalene)zirconium(IV) complex [Zr(η^5-C_5H_5)Cl$_2$]$_2$[μ-(η^5,η^5-$C_{10}H_8$)].[5c] This compound is rather insoluble in the usual organic solvents and can be separated by simple filtration. By removing the solvent in vacuo from the resulting solution, an orange product was obtained in 46% yield, characterized as the μ-[bis(phenylimido)] derivative [Zr(η^5-C_5H_5)(μ-NPh)]$_2$[μ-(η^5,η^5-$C_{10}H_8$)] (**1**).

Complex **1** can be considered as arising from an initial interaction of the zirconium(III) compound with the organic reagent to give a hydrazido intermediate species, which evolves through N−N bond breaking and a subsequent intermolecular ligand exchange to yield the final mixture containing **1** and the chloro(fulvalene)zirconium(IV) complex. This latter step may be favoured by the low solubility of [Zr(η^5-C_5H_5)Cl$_2$]$_2$[μ-(η^5,η^5-$C_{10}H_8$)]. Attempts to isolate and characterise the hydrazido intermediate species by carrying out the reaction under milder conditions have not been successful. When this reaction is carried out under insufficiently dry conditions, the final product always contained a mixture of the previously reported μ-oxo complex [Zr(η^5-C_5H_5)Cl]$_2$(μ-O)[μ-(η^5,η^5-$C_{10}H_8$)][4a] and 1,2-diphenylhydrazine, identified by analytical and NMR spectroscopic characterisation. This is consistent with the reaction pathway shown in Scheme 1, indicating that the proposed hydrazido intermediate species reacts with water, resulting in the immediate hydrolysis of the Zr−N bonds to give a mixture of the oxo zirconium compound and hydrazine. Several studies reveal that III is an unstable oxidation state for zirconium. It rapidly reacts with oxygen through a peroxo intermediate species, which immediately transforms into the final products, probably containing oxozirconium(IV) species.[1,10] Peroxo and hydrazido are isoelectronic and their zirconium-type derivatives are rare. In order to determine whether a stable hydrazido complex could be isolated, we treated the starting chlorozirconium(III) compound with benzo[*c*]cinnoline, an organic molecule similar to azobenzene in which the biphenyl system connecting the nitrogen atoms prevents the N−N bond from breaking due to the additional C−C bond. Equimolar amounts of the two compounds reacted overnight in toluene solution to give the complex [Zr(η^5-C_5H_5)Cl]$_2$[μ-(η^2,η^2NC$_6$H$_4$C$_6$H$_4$N)][μ-(η^5,η^5-$C_{10}H_8$)] (**2a**), which converted in toluene solution into **2b** within 2 h (see Scheme 1). Compound **2b** remains unaltered under reflux in toluene

solution after 5 h. The N−N bond cleavage and intermolecular ligand exchange processes were not observed and the compound was isolated as a yellow microcrystalline solid in 60% yield.

Both compounds are air- and moisture-sensitive and must be manipulated under dry conditions. They are soluble in aromatic and chlorinated solvents and insoluble in alkanes. Formulation of **1** as an imido-bridged dinuclear compound is based on analytical and spectroscopic data and comparisons with similar structurally characterized titanium and zirconium species.[11] We propose that compound **2** is an unusual μ-(η^2,η^2-hydrazido) bridge derivative. Mass spectra confirm the dinuclear nature of these compounds. The presence of the fulvalene ligand must contribute to the formation and stabilization of the μ-(phenylimido) and μ-(η^2,η^2-hydrazido) disposition.

A medium-intensity absorption at 568 cm^{-1} in the IR spectrum of **2** can be assigned to the ν(N−N) stretching mode and implies that on coordination an important reduction in the N−N multiple-bond character has taken place which supports the bonding description given in Scheme 1. The ^1H NMR spectrum for complex **1** (C_6D_6 or $CDCl_3$, room temperature) shows one singlet and three resonances assigned to the cyclopentadienyl and the phenyl group protons, respectively. The fulvalene ligand gives two pseudotriplets corresponding to an AA′BB′ spin system. These spectroscopic features agree with the C_{2v} symmetrical arrangement depicted in Scheme 1 for a dimetallic species with the zirconium centres linked by a fulvalene ligand and two bridging phenylimido groups giving a central Ti_2N_2 heterocyclic ring. The ^1H NMR spectrum of **2a** (C_6D_6 or $CDCl_3$, room temperature) shows one singlet and four multiplets corresponding to an ABCD spin system assigned to the cyclopentadienyl and fulvalene groups, respectively. The phenyl protons appear as eight signals and are readily assignable (see Exp. Sect.). These spectroscopic data indicate the formation of a dinuclear zirconium species with a chiral ligand arrangement around each equivalent zirconium centre, with the bridging hydrazido ligand centrally disposed and located perpendicular to the C_{ipso}−C_{ipso} bond of the fulvalene unit and the cyclopentadienyl and chloro ligands in a *cis* disposition. This arrangement makes the two phenylhydrazido rings nonequivalent, generating eight resonances for the corresponding protons. When **2a** is maintained in toluene solution at room temperature, a new compound **2b** is formed within 2 h (Scheme 1). Its ^1H NMR spectrum shows the same set of resonances for the cyclopentadienyl and the fulvalene protons observed for **2a**, but they are slightly shifted (see Exp. Sect.). However, the phenyl protons appear as four signals (two doublets of doublets and two doublets of triplets with coupling constant values of $^3J_{H\text{-}H}$ = 8 Hz and $^4J_{H\text{-}H}$ = 0.97 Hz). Compounds **2a** and **2b** offer identical elemental analyses, IR and mass spectroscopic data. These observations may be explained by an enantiomeric isomerization process, if the ligands bonded to one of the zirconium centres re-coordinate in **2a** to give the thermodynamically more stable **2b**, in which the cyclopentadienyl and chloro ligands adopt a *trans* disposition. While the nature of the structure of **1** and **2** is of interest, all attempts to obtain crystals of crystallographic quality were unsuccessful.

Terminal η^1-hydrazido(2−) coordination M=N−NR_2 has been well established for transition metal complexes.[12] There has been some concern about the nature of these species and it has been noted that these compounds appear closer to isodiazene (M−N=NR_2) than hydrazido(2−) derivatives.[13] Hydrazido as a bridging dianion ligand is much less common and has been observed in a few transition metal derivatives such as the dinuclear compounds $[W(NPh)Me_3]_2[\mu\text{-}(\eta^1,\eta^1\text{-}NH_2NH_2)][\mu\text{-}(\eta^2,\eta^2\text{-}NHNH)]$[14] and $[Sm(C_5Me_5)]_2[\mu\text{-}(\eta^2,\eta^2\text{-}NRNR)]$ (R = Ph, H).[15]

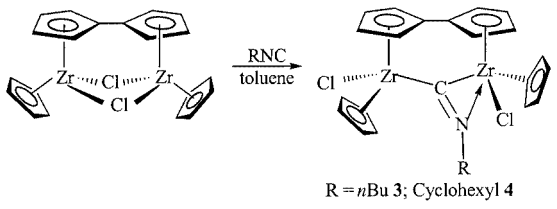
No reaction was observed when **2b** was treated with MeLi or MeMgCl in THF or toluene under varying conditions; the starting substances were always recovered. The lack of reactivity reflects the stability of this type of compound, with its coordinatively saturated metal centres decreasing its electrophilicity. Compound **1** must be consistent with a formal 18 valence electron species with 4 electrons donated from each μ-imido ligand to the "Zr_2" unit. The hydrazido group in **2** is considered as a 6-electron ligand, thereby also making this compound formally an 18 valence electron species.

μ-(η^1-C:η^2-C,N-Isocyanido) Derivatives

The (fulvalene)bis[chloro(cyclopentadienyl)zirconium] fragment "$(ZrCpCl)_2(C_{10}H_8)$" can provide an excellent support to promote uncommon ligand dispositions. Particularly interesting is the μ-isocyanido bonding mode found in the compounds $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNR)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (R = *t*Bu;[5c,5i] 2,6-$Me_2C_6H_3$ [6a]), which have an unsymmetrical bridging ligand, a μ-(η^1-C:η^2-C,N) 4-electron ligand (σ,π), between their zirconium atoms. We have reported the synthesis of complexes of this type by RNC addition to the dinuclear zirconium(III) derivative $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}Cl)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$. Analogous dicyclopentadienyl compounds have also been described.[16]

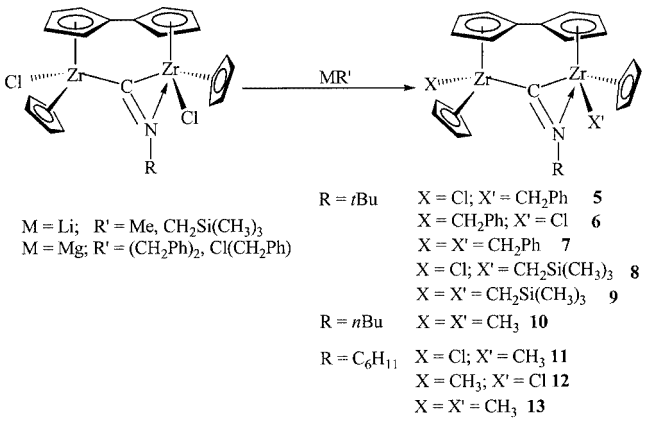
Addition of RNC (R = *n*Bu, C_6H_{11}) to a toluene solution of $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}Cl)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (molar ratio 1:1) results in an immediate colour change from violet to bright red. After work up, compounds $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNR)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ [R = *n*Bu (**3**), C_6H_{11} (**4**)] were isolated in high yield (ca. 80%) (Scheme 2) as red solids, characterized by analytical and spectroscopic methods. Compound **4** was obtained as a partial toluene solvate, indicated by elemental analysis and ^1H NMR spectroscopy. These compounds are air- and moisture-sensitive and must be manipulated under dry conditions. They are soluble in benzene, toluene and chloroform but insoluble in alkanes. Characteristic absorptions at $\tilde{\nu}$ = 1656 [1650(sh)] and 1637 cm^{-1} due to ν(C=N) vibrations are observed in the IR spectra of **3** and **4**, similar to those found for other compounds of this type.[5i,6a,7c] The ^1H NMR spectra in $CDCl_3$ at room temperature show the expected two ABCD spin systems for the fulvalene protons and two signals for the cyclopentadienyl rings, consistent with a dinuclear species

with two zirconium atoms each in a different coordination environment. Characteristic resonances for the cyclohexyl and *n*-butyl groups are also observed. The spectrum of **3** also shows an AB spin system for the diastereotopic "N−CH_2" protons. Similar spectroscopic features were observed in the ^{13}C NMR spectra. The resonance for the isocyanide carbon atom (CN−) is observed at δ = 295.0 ppm in compound **3** but not observed for **4**.



Scheme 2

Alkylation of $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNR)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (R = *t*Bu,[5i] *n*Bu, C_6H_{11}) with R′M [R′ = Me, $CH_2Si(CH_3)_3$, M = Li; R′ = $(PhCH_2)_2$, $(PhCH_2)Cl$, M = Mg] was also studied (Scheme 3). $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNtBu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ reacts with 1 equiv. of $PhCH_2MgCl$ or $(PhCH_2)_2Mg(THF)_2$ to afford an orange yellow oil. Its ^1H NMR spectrum in C_6D_6 indicated a mixture containing the two isomers of the monobenzyl derivatives $[Zr(\eta^5\text{-}C_5H_5)]_2(CH_2Ph)(Cl)(\mu\text{-}CNtBu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**5** and **6**) in a 1:3 molar ratio. When the reaction was carried out with 2 equiv. or an excess of $PhCH_2MgCl$, a mixture of the monobenzyl compound **5** and the dibenzyl complex $[Zr(\eta^5\text{-}C_5H_5)(CH_2Ph)]_2(\mu\text{-}CNtBu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**7**) (30%:70%) was obtained. In an attempt to isolate a pure monoalkyl complex, the bulkier $(CH_3)_3SiCH_2Li$ was used as an alkylating reagent, but the final results were similar to those found with the benzyl and the previously reported methyl reagents.[7c] The starting dichloro compound reacted with 1 or 2 equiv. of $(CH_3)_3SiCH_2Li$ in toluene at room temperature for 16 h to give a mixture of the monoalkyl complex $[Zr(\eta^5\text{-}C_5H_5)]_2[CH_2Si(CH_3)_3](Cl)(\mu\text{-}CNtBu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**8**) and the dialkyl compound $[Zr(\eta^5\text{-}C_5H_5)]_2[CH_2Si(CH_3)_3]_2(\mu\text{-}CNtBu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**9**). Moreover, when $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNnBu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ was treated in toluene with 2 equiv. of MeLi, the dimethyl complex $[Zr(\eta^5\text{-}C_5H_5)(CH_3)]_2(\mu\text{-}CNnBu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**10**) was isolated as an analytically pure substance, unlike the mixture of the monomethyl and dimethyl compounds obtained in the methylation of $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNtBu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$.[7c] Reaction of $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNC_6H_{11})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ with MeLi in a molar ratio of 1:2 gave the dimethyl compound $[Zr(\eta^5\text{-}C_5H_5)(CH_3)]_2(\mu\text{-}CNC_6H_{11})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**13**), which was always obtained with small amounts of the monomethyl derivatives $[Zr(\eta^5\text{-}C_5H_5)]_2(CH_3)(Cl)(\mu\text{-}CNC_6H_{11})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (**11** and **12**). Attempts to separate this mixture by repeated recrystallization were unsuccessful.



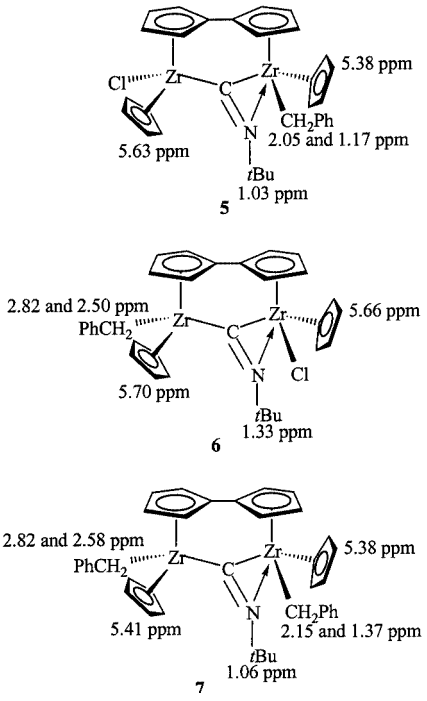
Scheme 3

Compounds **5**−**13** are moisture-sensitive but thermally stable in the solid state, allowing them to be stored under inert conditions for weeks. They are soluble in aromatic hydrocarbons, THF, dichloromethane and chloroform, but insoluble in diethyl ether and alkanes. The pairs of compounds obtained, **5/6**, **5/7** and **8/9**, and the compounds **11**−**13**, show the same solubility in all common solvents and therefore could not be separated. Consequently, they have been characterized by NMR spectroscopy but satisfactory elemental analyses were not obtained; **10** can be obtained as a pure compound and has been analytically and spectroscopically identified.

The ^1H NMR spectra of complexes **5**−**13** in C_6D_6 at room temperature show two ABCD spin systems (eight signals) for the fulvalene ligand and two signals for the cyclopentadienyl ring protons. The expected resonances for the protons of the isocyanide alkyl substituents are observed. The spectra of **5**−**9** show one singlet for the *tert*-butyl protons. Four signals are assigned to the *n*-butyl protons in **10** with the "NCH_2−" methylene groups as diastereotopic protons and four signals are assigned to the cyclohexyl protons in **13**. These spectroscopic data indicate the formation of dinuclear zirconium compounds with the metal atoms in nonequivalent coordination environments.

The "CH_2Ph" methylene group protons appear as AB spin systems with two doublets for **5** and **6** (δ = 2.05, 1.17 ppm and δ = 2.82, 2.50 ppm, respectively) and four doublets for **7** (δ = 2.82, 2.58, 2.15, 1.37 ppm) suggesting the presence of CH_2 diastereotopic groups. Two of the chemical shifts of the methylene groups in **7** (δ = 2.15 and 1.37 ppm) compare well with the signals for the same protons in **5** (δ = 2.05 and 1.17 ppm), while the other two methylene groups in **7** (δ = 2.82 and 2.58 ppm) compare with the corresponding signals in **6** (δ = 2.82 and 2.50 ppm). These spectroscopic features suggest that the CH_2 groups in each pair of compounds occupy very similar chemical environments and must be bonded to the same type of zirconium atom. The presence of the bridging isocyanido group can exert an important influence in the reactivity of these fulvalene derivatives. The η^2-side-on coordination of the isocyanido bridge[5i] to one of the zirconium atoms involves donation of the nitrogen atom's free electron pair to the metal centre to give an 18-electron valence shell. The increase of

the electronic density at this zirconium centre must cause shielding of the NMR signals for all of the directly bonded ligands.[7c] These observations allow the structures of **5** and **6** to be distinguished (Scheme 4).



Scheme 4

Similar spectroscopic behaviour has been observed in the ^{1}H NMR spectrum (C_6D_6, room temperature) for the diastereotopic "CH_2SiMe_3" methylene group protons for compounds **8** and **9** (one and two AB spin systems respectively; see Exp. Sect.). Two markedly different chemical shifts are found for the methyl protons in the dimethyl derivatives **10** (δ = 0.29 and −0.37 ppm) and **13** (δ = 0.29 and −0.32 ppm).

These experimental results highlighted differences in the reactivity of the two Zr−Cl bonds present in the starting $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNR)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ compounds and allow us to conclude that the ease of alkylation of the chloride ion bonded to the tetracoordinated zirconium atom is greater than the alkylation of the chloride ion bonded to the pentacoordinated zirconium atom. This proposal is consistent with the results obtained in the methylation reactions of the dichloro compound $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CN\textit{t}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$.[7c]

Conclusion

This report shows that dinuclear zirconium(IV) complexes, containing one fulvalene and one additional group (imido, η^2,η^2-N,N-hydrazido or η^1-C:η^2-C,N-isocyanido) as bridging ligands, can be synthesized by adding neutral organic reagents (azobenzene, benzo[*c*]cinnoline, isocyanide) to the easily accessible zirconium(III) derivative $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}Cl)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$. Alkylation reactions of the chloro(fulvalene)isocyanido complexes show important differences in the reactivity of both chloride ions present in the $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNR)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ compounds.

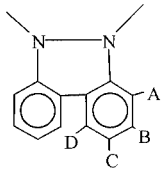
Experimental Section

General Remarks: All manipulations were performed under argon using Schlenk and high-vacuum line techniques or a glovebox model HE-63. The solvents were purified by distillation under argon before use, by employing the appropriate drying/deoxygenating agent. Deuterated solvents were stored over activated 4 Å molecular sieves and degassed by several freeze-thaw cycles. Azobenzene, benzo[*c*]cinnoline, *n*-butyl isocyanide, cyclohexyl isocyanide, BzMgCl and MeLi (Aldrich) were purchased from commercial sources and used without further purification. $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}Cl)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$,[4a] $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CN\textit{t}Bu)[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$,[5i] $(CH_3)_3SiCH_2Li$[17] and $Bz_2Mg(THF)_2$ [18] were prepared by known procedures. C,H, N microanalyses were performed with a Perkin−Elmer 240B and/or a Heraeus CHN-O-Rapid microanalyzer. IR spectra were recorded with a Perkin−Elmer Spectrum 2000 spectrophotometer by using KBr pellets; only selected IR data are reported. NMR spectra, measured at 25 °C, were recorded with a Varian Unity 300 (^{1}H at 300 MHz and ^{13}C at 75 MHz) and a 500 Plus (^{1}H at 300 MHz and ^{13}C at 125 MHz) spectrometer and chemical shifts are referenced to residual proton and carbon signals of the solvent.

$[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}NPh)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (1): 1.7 g (9.7 mmol) of PhN=NPh was added at room temperature to a solution of 5 g (9.7 mmol) of $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}Cl)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ in toluene (100 mL). The reaction mixture was heated under reflux (80 °C) and stirred for 12 h. The deep violet solution first turned dark yellow and then changed into a suspension of a yellow solid in an orange solution. After cooling, the yellow solid was separated by filtration and identified as $[Zr(\eta^5\text{-}C_5H_5)Cl_2]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ by IR spectroscopy and elemental analysis (1.8 g, 63% yield). The resulting solution was concentrated to 10 mL and cooled to −30 °C overnight to give compound **1** as a yellow-orange microcrystalline solid. The compound was recrystallised from toluene/hexane (1.4 g, 46% yield). ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 6.04, 5.65 (AA′BB′ spin system, 4 + 4 H, J = 2.7 Hz, $C_{10}H_8$), 5.97 (s, 10 H, C_5H_5), 7.18 (t, 4 H, Ph), 6.77 (t, 2 H, Ph), 6.04 (d, 4 H, Ph) ppm. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ = 6.21 (s, 10 H, C_5H_5), 6.19, 6.05 (AA′BB′ spin system, 4 + 4 H, J = 2.7 Hz, $C_{10}H_8$), 7.07 (t, 4 H, Ph), 6.59 (t, 2 H, Ph), 5.95 (d, 4 H, Ph) ppm. $C_{32}H_{28}N_2Zr_2$ (623.06): calcd. C 61.69, H 4.50, N 4.50; found C 61.34, H 4.55, N 3.75.

$[Zr(\eta^5\text{-}C_5H_5)Cl]_2[\mu\text{-}(\eta^2,\eta^2\text{-}NC_6H_4C_6H_4N)][\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (2): 1.2 g (6.8 mmol) of benzo[*c*]cinnoline was added at room temperature to a solution of 3.5 g (6.8 mmol) of $[Zr(\eta^5\text{-}C_5H_5)(\mu\text{-}Cl)]_2[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ in toluene (100 mL). The reaction mixture was heated under reflux and stirred for 12 h. The deep violet solution slowly turned orange-yellow. After cooling and filtration, the resulting solution was concentrated to 10 mL and cooled to −30 °C overnight to give compound **2** as a yellow microcrystalline solid. The compound was recrystallised from toluene/hexane (2.8 g, 60% yield). **2a:** IR (KBr): $\tilde{\nu}$ = 568 cm^{-1} [ν(N−N)]. ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 6.93, 5.92, 5.82, 5.54 (ABCD spin system, 4 × 2 H, $C_{10}H_8$), 5.58 (s, 10 H, C_5H_5), 8.18 (dd, 1 H, Ph), 7.25 (dd, 1 H, Ph), 7.17 (dd, 1 H, Ph), 7.13 (t, 1 H, Ph), 7.04 (t, 1 H, Ph), 6.70

(dd, 1 H, Ph), 6.69 (t, 1 H, Ph), 6.67 (t, 1 H, Ph) ppm. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): δ = 6.83, 6.65, 6.33, 5.83 (ABCD spin system, 4 × 2 H, $C_{10}H_8$), 5.71 (s, 10 H, C_5H_5), 7.68 (dd, 1 H, Ph), 7.59 (dd, 1 H, Ph), 7.46 (dd, 1 H, Ph), 7.27 (t, 1 H, Ph), 7.17 (t, 1 H, Ph), 7.08 (dd, 1 H, Ph), 6.91 (t, 1 H, Ph), 6.82 (t, 1 H, Ph) ppm. **2b:** IR (KBr): $\tilde{\nu}$ = 568 cm^{-1} [ν(N−N)]. ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 7.43, 6.97, 5.54, 5.17 (ABCD spin system, 4 × 2 H, $C_{10}H_8$), 5.51 (s, 10 H, C_5H_5), 7.61 [dd, $^3J_{H\text{-}H}$ = 8, $^4J_{H\text{-}H}$ = 0.97 Hz, 2 H, Ph(A)], 7.19 [dd, $^3J_{H\text{-}H}$ = 8, $^4J_{H\text{-}H}$ = 0.97 Hz, 2 H, Ph(D)], 7.11 [dt, $^3J_{H\text{-}H}$ = 8, $^4J_{H\text{-}H}$ = 0.97 Hz, 2 H, Ph(B)], 6.68 (dt, $^3J_{H\text{-}H}$ = 8, $^4J_{H\text{-}H}$ = 0.97 Hz, 2 H, Ph(C) ppm; the numbering assignment is shown in Scheme 5. ^{13}C NMR (125 MHz, C_6D_6, 25 °C). δ = 122.9, 121.0, 113.3, 110.4 ($C_{10}H_8$), 115.3 (C_5H_5), 101.2 (C_{ipso}, $C_{10}H_8$), 135.7, 131.6, 129.1 ppm, and signals collapsed by the C_6D_6 resonances. $C_{32}H_{26}Cl_2N_2Zr_2$ (691.95): calcd. C 55.54, H 3.79, N 4.05; found C 56.06, H 3.96, N 3.63.



Scheme 5

[Zr(η^5-C_5H_5)Cl]$_2$(μ-CN*n*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (3): A solution of [Zr(η^5-C_5H_5)(μ-Cl)]$_2$[μ-(η^5,η^5-$C_{10}H_8$)] (1.00 g, 1.94 mmol) in 75 mL of toluene was treated at room temperature with *n*-butyl isocyanide (0.20 mL, 2.00 mmol). The violet solution turned red within an hour. After filtration, the solvent was completely removed in vacuo and the resulting red solid washed with *n*-hexane. After recrystallization from toluene/hexane, a sample of **3** suitable for analysis was obtained (1.04 g, 90%). IR (KBr): $\tilde{\nu}$ = 1656 [1650 (sh)] cm^{-1} [ν(C=N)]. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 6.18, 5.82 (s, 2 × 5 H, C_5H_5), 6.41, 6.40, 6.28, 6.00, 5.63, 5.40, 4.83, 4.78 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 3.88, 3.35 (AB spin system, 2 × 1 H, N−CH_2−[CH$_2$]$_2$−CH$_3$), 1.85 (m, 2 H, N−CH$_2$−CH_2−CH$_2$−CH$_3$), 1.46 (m, 2 H, N−CH$_2$−CH$_2$−CH_2−CH$_3$), 1.03 (t, 3 H, N−CH$_2$−CH$_2$−CH$_2$−CH_3) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 295.0 (*C*N*n*Bu), 133.2, 120.4 [C_{ipso}, $C_{10}H_8$], 122.3, 117.1, 105.4, 102.7, 101.8, 101.4, 100.1, 95.6 ($C_{10}H_8$), 109.76, 108.62 (C_5H_5), 57.7, 31.7, 20.8, 14.0 (CN*nBu*) ppm. $C_{25}H_{27}Cl_2NZr_2$ (594.87): calcd. C 50.48, H 4.57, N 2.35; found C 50.01, H 4.67, N 2.15.

[Zr(η^5-C_5H_5)Cl]$_2$(μ-CNC_6H_{11})[μ-(η^5,η^5-$C_{10}H_8$)] (4): According to the procedure described for **3**, 1.93 g (3.75 mmol) of [Zr(η^5-C_5H_5)(μ-Cl)]$_2$[μ-(η^5,η^5-$C_{10}H_8$)] and 0.48 mL (3.77 mmol) of cyclohexyl isocyanide were allowed to react in 150 mL of toluene to give **4** (2.25 g, 97%) as a partial toluene solvate, indicated by elemental analysis and ^{1}H NMR spectroscopy. IR (KBr): $\tilde{\nu}$ = 1637 cm^{-1} [ν(C=N)]. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 6.18, 5.81 (s, 2 × 5 H, C_5H_5), 6.41, 6.37, 6.28, 5.98, 5.64, 5.42, 4.96, 4.82 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 3.85, 1.86, 1.29 (C_6H_{11}) ppm. ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 119.9, 113.5 (C_{ipso}, $C_{10}H_8$), 123.4, 117.5, 104.8, 102.5, 101.8, 101.1, 100.8, 95.7 ($C_{10}H_8$), 109.8, 109.0 (C_5H_5), 67.5, 32.8, 32.3, 25.2 [CN(C_6H_{11})] ppm. $C_{27}H_{29}Cl_2NZr_2$·1/2toluene (666.98): calcd. C 54.88, H 4.95, N 2.10; found C 54.74, H 5.01, N 2.06.

[Zr(η^5-C_5H_5)]$_2$(CH_2Ph)(Cl)(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (5 and 6): 1.23 mL of a 2 M solution of BzMgCl in THF (2.45 mmol) was added to a solution of [Zr(η^5-C_5H_5)Cl]$_2$(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (1.46 g, 2.45 mmol) in toluene (50 mL) at −78 °C. The reaction mixture was warmed to room temperature and stirred for 18 h with formation of an $MgCl_2$ precipitate. After filtration, the solvent was removed and an orange yellow solid was obtained which was washed with diethyl ether and hexane. Recrystallization from toluene/hexane gave an orange yellow microcrystalline solid. **5** and **6** have the same composition and therefore they must have an identical elemental analysis. However, the isolated final solid consisted mainly of **5** and **6**, but it contained a small amount of unidentified impurities that could not be removed, and satisfactory elemental analysis was not obtained. Spectroscopic data showed the presence of **5** (25%) and **6** (75%). **6:** ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 7.40−6.98 (m, 5 H, CH_2*Ph*), 5.70, 5.66 (s, 2 × 5 H, C_5H_5), 6.50, 6.36, 5.76, 5.65, 5.05, 4.46, 4.41, 4.40 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 2.82, 2.50 (AB spin system, 2 × 1 H, CH_2Ph), 1.03 (s, 9 H, *t*BuNC) ppm. **5:** ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 7.40−6.98 (m, 5 H, CH_2*Ph*), 5.63, 5.38 (s, 2 × 5 H, C_5H_5), 5.57, 5.55, 5.45, 5.27, 5.06, 4.86, 4.60, 4.48 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 2.05, 1.17 (AB spin system, 2 × 1 H, CH_2Ph), 1.33 (s, 9 H, *t*BuNC) ppm.

[Zr(η^5-C_5H_5)]$_2$(CH_2Ph)(Cl)(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (5) and [Zr(η^5-C_5H_5)(CH_2Ph)]$_2$(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (7): According to the same procedure described for the preparation of **5** + **6**, using 2.46 mL of a 2 M solution of BzMgCl in THF (4.90 mmol) and 1.46 g (2.45 mmol) of [Zr(η^5-C_5H_5)Cl]$_2$(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] a mixture of **5** (30%) + **7** (70%) was obtained and spectroscopically characterized. **5** and **7** have the same solubility in all common solvents. They could not be separated and satisfactory elemental analyses were not obtained. **7:** ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 7.40−6.98 (m, 5 H, CH_2*Ph*), 5.41, 5.38 (s, 2 × 5 H, C_5H_5), 6.60, 6.50, 5.29, 5.14, 4.99, 4.48, 4.46, 4.40 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 2.82, 2.58, 2.15, 1.37 (two AB spin systems, 4 × 1 H, CH_2Ph), 1.06 (s, 9 H, *t*BuNC) ppm.

[Zr(η^5-C_5H_5)]$_2$[CH_2Si(CH_3)$_3$](Cl)(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (8) and [Zr(η^5-C_5H_5)]$_2$[CH_2Si(CH_3)$_3$]$_2$(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (9): 0.09 g (1.0 mmol) of (CH_3)$_3$SiCH_2Li was added to a solution of [Zr(η^5-C_5H_5)Cl]$_2$(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (0.6 g, 1.0 mmol) in toluene (50 mL) at −78 °C. The reaction mixture was warmed to room temperature and stirred for 16 h with the formation of an LiCl precipitate. After filtration, the solvent was removed and a red solid was obtained which was washed with diethyl ether and hexane. Recrystallization from toluene/hexane gave an orange microcrystalline solid identified as a mixture of **8** + **9** (molar ratio 2:1) with the presence of a small amount of the starting zirconium compound. When 0.19 g (2.0 mmol) of (CH_3)$_3$SiCH_2Li was used to react with 0.6 g (1.0 mmol) of [Zr(η^5-C_5H_5)Cl]$_2$(μ-CN*t*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] a mixture of **8** + **9** (molar ratio 1:3) with no traces of the starting zirconium compound was obtained. **8** and **9** have the same solubility in all common solvents. They could not be separated and satisfactory elemental analyses were not obtained. Spectroscopic data showed the presence of **8** (25%) + **9** (75%). **8:** ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 5.64, 5.62 (s, 2 × 5 H, C_5H_5), 6.58, 6.26, 5.72, 5.50, 5.40, 5.39, 4.86, 4.70 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 1.37 (s, 9 H, CN*t*Bu), 0.20 (s, 9 H, SiMe_3), −0.19, −0.40 (AB spin system, CH_2SiMe$_3$) ppm. **9:** ^{1}H NMR (500 MHz, C_6D_6, 25 °C): δ = 5.65, 5.47 (s, 2 × 5 H, C_5H_5), 6.38, 6.32, 5.60, 5.44, 5.20, 4.58, 4.55, 4.40 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 1.08 (s, 9 H, CN*t*Bu), 0.42, 0.29 (s, 9 × 2 H, SiMe_3), 0.33, 0.11, −0.05, −0.37 (two AB spin systems, CH_2SiMe$_3$) ppm.

[Zr(η^5-C_5H_5)(CH_3)]$_2$(μ-CN*n*Bu)[μ-(η^5,η^5-$C_{10}H_8$)] (10): 1.12 mL of a 1.50 M solution of LiMe in diethyl ether (1.70 mmol) was added at −78 °C to a solution of [Zr(η^5-C_5H_5)Cl]$_2$(μ-CN*n*Bu)[μ-(η^5,η^5-

$C_{10}H_8$)] (0.50 g, 0.84 mmol) in toluene (50 mL). The reaction mixture was stirred for 30 min and warmed to room temperature. After filtration, the solvent was removed and an orange-yellow solid was obtained. Recrystallization from toluene/hexane gave **10** as a microcrystalline solid (0.21 g, 46%). IR (KBr): $\tilde{\nu}$ = 1660 [1620 (sh)] cm^{-1} [ν(C=N)]. ^1H NMR (500 MHz, C_6D_6, 25 °C): δ = 5.58, 5.44 (s, 2 × 5 H, C_5H_5), 5.97, 5.94, 5.36, 5.33, 5.13, 4.57, 4.42, 4.12 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 3.41, 2.89 (AB spin system, $N-CH_2-[CH_2]_2-CH_3$), 1.57 (m, $N-CH_2-CH_2-CH_2-CH_3$), 1.23 (m, $N-CH_2-CH_2-CH_2-CH_3$), 0.89 (t, $N-CH_2-CH_2-CH_2-CH_3$), 0.29, −0.37 (s, $Zr-CH_3$) ppm. ^{13}C NMR (125 MHz, C_6D_6, 25 °C): δ = 116.2, 111.9 (C_{ipso}, $C_{10}H_8$), 116.6, 110.0, 101.8, 101.0, 99.9, 97.6, 96.7, 92.8 ($C_{10}H_8$), 105.7, 105.6 (C_5H_5), 57.9, 32.3, 21.0, 14.2 (CN*nBu*), 13.4, 9.5 ($Zr-CH_3$) ppm. $C_{27}H_{33}NZr_2$ (554.04): calcd. C 58.54, H 5.96, N 2.53; found C 58.11, H 6.12, N 2.29.

$[Zr(\eta^5\text{-}C_5H_5)]_2(CH_3)(Cl)(\mu\text{-}CNC_6H_{11})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (11 + 12) and $[Zr(\eta^5\text{-}C_5H_5)(CH_3)]_2(\mu\text{-}CNC_6H_{11})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (13): 1.0 mL of a 1.50 M solution of MeLi in diethyl ether (1.5 mmol) was added to a solution of $[Zr(\eta^5\text{-}C_5H_5)Cl]_2(\mu\text{-}CNC_6H_{10})[\mu\text{-}(\eta^5,\eta^5\text{-}C_{10}H_8)]$ (0.5 g, 0.75 mmol) in toluene (50 mL) at −78 °C. The reaction mixture was warmed to room temperature and stirred for 16 h with formation of an LiCl precipitate. After filtration, the solvent was removed and a red solid was obtained which was washed with hexane. Recrystallization from toluene/hexane gave a red solid identified by NMR spectroscopy as a mixture of **11** + **12** + **13** (molar ratio 1:1:4). They could not be separated and satisfactory elemental analyses were not obtained. **13:** ^1H NMR (500 MHz, C_6D_6, 25 °C): δ = 5.60, 5.43 (s, 2 × 5 H, C_5H_5), 5.96, 5.94, 5.36, 5.32, 5.15, 4.60, 4.58, 4.19 (two ABCD spin systems, 8 × 1 H, $C_{10}H_8$), 3.60 (m, 1 H, *ipso*-C_6H_{11}), 2.00−1.00 (C_6H_{11}), 0.29, −0.32 (s, $Zr-CH_3$) ppm.^{13}C NMR (125 MHz, C_6D_6, 25 °C): δ = 115.9, 111.7 (C_{ipso}, $C_{10}H_8$), 117.4, 110.4, 101.7, 100.8, 99.2, 98.0, 97.7, 92.9 ($C_{10}H_8$), 106.0, 105.6 (C_5H_5), 65.8, 33.8, 33.1, 25.8 (C_6H_{11}), 14.4, 9.8 ($Zr-CH_3$) ppm.

Synthesis and Structure of Diboraporphyrinogenes

Anke Eckert,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

Dedicated to Prof. Dr. Robert Corriu

Keywords: Boranes / Boraporphyrinogens / Porphyrins / Macrocycles

Reactions of 5,5′-dilithiated 1,1-bis(2-thienyl)ethane (**3**) with different substituted dichloroboranes led to the novel 5,15-diboraporphyrinogenes **5**–**8**, in good yields. Amino groups at the boron atoms stabilize the macrocycles **5**–**7**, whereas the first organyl-stabilized diboraporphyrinogene **8** contains the 2,3,5,6-tetramethylphenyl substituent at the boron atoms. A [3+1] approach yields the 5,10-diboraporphyrinogene **13** by treating 2,5-bis[1-(5-lithio-2-thienyl)ethyl]thiophene (**4**) with the 2,5-diborylthiophene derivative **9**. Analogously, the mixed 5,10-diboraporphyrinogenes **15** and **16** are formed from **4** and 2,5-diborylfuran **11** and 2,5-diboryl-*N*-methylpyrrole **12**, respectively. The constituents of the new compounds follow from spectroscopic and structural data.

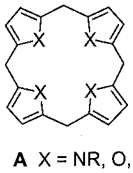
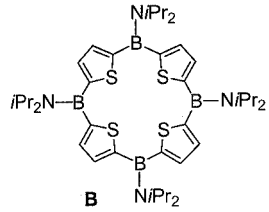
Introduction

Different syntheses for porphyrins are known: 5,10,15,20-Tetraphenylporphyrin is formed in a one-pot reaction of pyrrole with benzaldehyde in the presence of a catalyst.[1] The [2+2] approach uses dipyrromethanes[2] or dipyrromethenes.[3] In a [3+1] formation of porphyrin a 2,5-difunctionalized pyrrole reacts with a tripyrrolic species to produce the macrocycle.[4] The latter two types of porphyrin formation are used for the synthesis of diboraporphyrinogenes.

The chemistry of porphyrinogenes containing thiophene, furan and *N*-protected pyrrole instead of pyrrole has been studied intensely since the isolation of the first chalcogen porphyrinogene by Johnson et al. in 1971.[5] The heteroatom analogs **A** of the porphyrin may be regarded as bridged [20]annulenes having a paratropic ring current.[6] They are oxidized to yield dicationic aromatic compounds having diatropic ring currents.[7]



A X = NR, O, S



B

Different boron-containing porphyrins and porphyrinogenes have been synthesized. Recently, Corriu, Douglas, Siebert et al.[8] reported the first tetraboratetrathiaporphyrinogene **B**, and porphyrins with boron atoms in side chains have been used for BNCT (boron neutron capture therapy) studies.[9] Boryl and diborane(4)-diyl groups bridging the nitrogen atoms[10] have been incorporated into porphyrins.

The tetraboratetrathiaporphyrinogene **B** is nonplanar in the solid and has no delocalized electrons in the macrocycle. In solution a magnetic ring current or an electronic interaction of the thiophene units through the boron atoms can be ruled out. Compound **B** exhibits an ^{11}B NMR signal at δ = 40 ppm, which is expected for diaryl(dialkylamino)boranes. Attempts to reduce **B** to the dianion $\mathbf{B}^{2-}$ and to form metal complexes of the macrocycle have not been successful.

We are interested in the synthesis and characterization of diboraporphyrins, in their electronic structures and in the ligand properties of the diboraporphyrinogenes **C** and **D**, which formally derive from **A** by exchange of two *meso*-carbon atoms for two boron atoms. The empty p_z orbitals of the boron atoms may allow macrocyclic conjugation when **C** and **D** are deprotonated to give dianions. The formation of silyl- and stannyl-bridged macrocycles has been reported.[11]

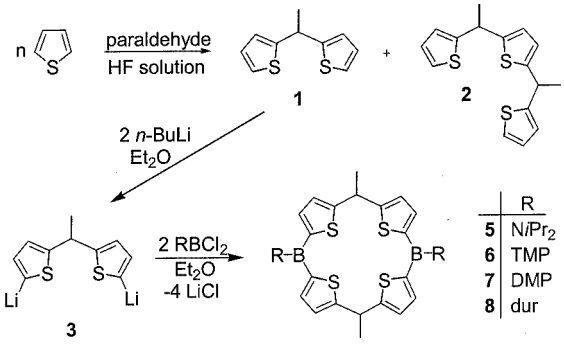
Results and Discussion

Synthesis of Diboraporphyrinogenes

Liquid 1,1-bis(2-thienyl)ethane (**1**) is formed[12] in 39% yield by treating thiophene and paraldehyde with a solution of 40% HF. After distillation of **1**, a dark residue is obtained, probably a mixture of thiophene and the aldehyde condensation products (Scheme 1). Under the same conditions we obtained a mixture of **1** and **2** in a ratio of 5:7; 28.3% of thiophene reacted to give **1** and **2** in 42 and 58% yield, respectively. Deprotonation of **1** with butyllithium in diethyl ether at room temperature leads to 1,1-bis(5-lithio-2-thienyl)ethane (**3**). Under these conditions it is not necessary to use a solvent mixture of hexane and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmeda) as proposed.[8,13] Due to its high reactivity **3** is prepared in situ for the synthesis of the macrocycles **5**−**8**.



Scheme 1

Reaction of **3** with iPr_2N-BCl_2 leads to the yellow, air- and moisture-sensitive tetrathiadiboraporphyrinogene **5** in 95% yield. Its composition follows from spectroscopic data and its structure is confirmed by an X-ray diffraction analysis. In the solid **5** has a center of inversion and is nonplanar, which may prevent possible electron delocalization. The observed B−C distances of 1.58(2) Å are in the range expected for B−C single bonds (1.56−1.60 Å). The short B−N distance of 1.40(1) Å results from the donor effect of the nitrogen atom. In the thienyl ring the bond lengths C1−C2, C3−C4, C5−C6 and C7−C8 are smaller than C2−C3 and C6−C7, which may indicate a localized π system[14] and no electronic interaction between the thiophene units across the boron atoms (Figure 1).

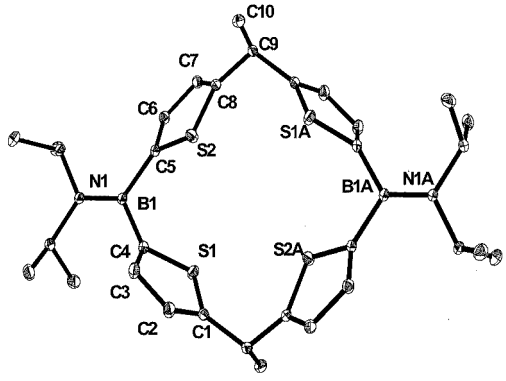


Figure 1. Molecular structure of **5** in the crystal, selected bond lengths [Å] and angles [°]: C1−C2 1.358(2), C2−C3 1.426(2), C4−B1 1.584(2), B1−N1 1.401(1), B1−C5 1.575(2); C4−B1−N1 124.56(10), C5−B1−N1 122.23(10), C5−B1−C4 113.20(9)

The ^1H NMR spectrum of **5** exhibits the expected doublet and septuplet of the isopropyl substituent, the doublet and quadruplet of the bridging $HCCH_3$ group and the two doublets of the thiophene protons at δ = 6.78 and 6.84 ppm, shifted high-field by 0.4 ppm relative to those of **1**. Similar shifts have been explained by a π interaction of the heterocycle with the boryl substituent.[15] In the ^{11}B NMR spectrum a broad signal appears at δ = 35 ppm, indicating a B−N π interaction. The ^{13}C NMR spectrum shows signals for the $HCCH_3$ groups at δ = 14.5 and 50.3 ppm, the signals of the isopropylamino substituents appear at δ = 25.3 and 37.1 ppm. For the thienyl rings three sharp and one broad signal for the *ipso*-carbon atoms are observed.

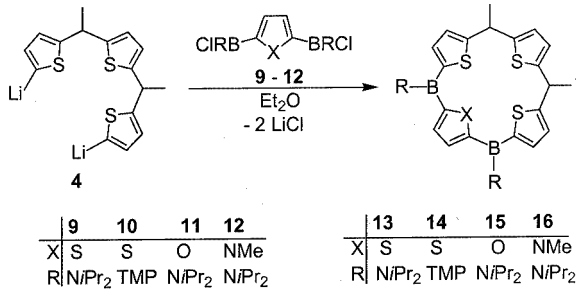
Attempts to replace the diisopropylamino substituents in **5** with $AlMe_3$ and MeOH were not successful; instead cleavage of the macrocycle occurred. We could not obtain any metal complexes of **5** with rhodium, ruthenium and silver reagents.

Treatment of **3** with dichloro(2,2′,6,6′-tetramethylpiperidyl)borane and dichloro(2,6-dimethylpiperidyl)borane yielded the yellow 5,15-diboraporphyrinogenes **6** and **7** in 51 and 60% yield, respectively. As for **5** and **8** (see below), the macrocycles **6** and **7** are air- and moisture-sensitive. Their ^{11}B NMR spectra exhibit broad signals at δ = 43 ppm (**6**) and δ = 42 ppm (**7**), which appear in the same region as that of the tetrathiatetraboraporphyrinogene **B**.[8] Because of the amino substituents at the boron atoms, the tetrathia-5,15-diboraporphyrinogenes **5**−**7** are electronically saturated due to the π interactions with the nitrogen atoms.

In order to obtain a sterically rather than an electronically stabilized macrocycle we prepared the first aryl-stabilized tetrathia-5,15-diboraporphyrinogene **8**, in 45% yield by treating **3** with dichloro(2,3,5,6-tetramethylphenyl)borane. In yellow **8** the boron atoms are sterically protected by the duryl substituents (dur), because the ring planes are perpendicular to the plane of the trigonal-planar arranged boryl groups [^{11}B NMR: δ = 70 (br)]. Compound **8** is an interesting molecule for deprotonation of the 10,20-positions. If we could deprotonate **8** to obtain the dianion $[\mathbf{8} - 2\ H^+]^{2-}$, we may create a conjugated π system in the macrocycle.

Deprotonation of **2**, analogously to **1**, forms the dilithio compound **4** as a red solution which reacts with the 2,5-bis(boryl)thiophenes **9**[16] and **10** at low temperature to give the tetrathia-5,10-diboraporphyrinogenes **13** and **14** as yellow solids in 61 and 62% yield, respectively (Scheme 2). Applying the [3+1] method for the synthesis of porphyrins it is possible to prepare mixed porphyrinogenes. The reaction of **4** with the 2,5-bis(boryl)furan **11** and 2,5-bis(boryl)-*N*-methylpyrrole **12** in diethyl ether leads to the formation of **15** and **16** in 40 and 47% yield, respectively. Their ^{11}B NMR

signals appear in the expected region (δ = 39, 43 ppm) as (amino)dithienylboranes (δ = 38 ppm).[17]



Scheme 2

The 5,10-diboraporphyrinogenes **13**−**16** are yellow solids, sensitive to air and moisture. They show similar properties to those of the 5,15-diboraporphyrinogenes **5**−**8**. It was not possible to replace the boron substituent with $AlMe_3$ or MeOH without destruction of the macrocycles. Furthermore, attempts to obtain metal complexes with ruthenium, rhodium or silver reagents were unsuccessful. Treatment of **13**−**16** with tricarbonyltris(acetonitrile)-chromium did not lead to a macrocyclic tricarbonyl(thiophene)chromium complex.

Conclusion

The synthesis of 5,15- (**5**−**7**) and 5,10-diboraporphyrinogenes **13**−**16** is possible when electron-donating amino substituents like diisopropylamino, dimethylpiperidyl and tetramethylpiperidyl reduce the Lewis acidity of the boron atoms. Despite this electronic stabilization, the yellow macrocycles are sensitive to moisture and air. The sterically active 2,3,5,6-tetramethylphenyl substituents protect the boron atoms in yellow **8**, which after deprotonation to the dianion may have better ligand properties towards transition metals than that of **5**.

Experimental Section

General: Reactions were carried out under dry nitrogen using standard Schlenk techniques. Solvents and chemicals were dried, distilled, and saturated with nitrogen. Glassware was dried with a heat-gun under high vacuum. ^1H, ^{11}B, ^{13}C NMR: Bruker DRX 200 spectrometer, NMR references are $(CH_3)_4Si$ and $BF_3{\cdot}Et_2O$. Mass spectra were obtained with a Joel JMS-700 spectrometer, using EI, CI and FAB techniques. Melting points (uncorrected) were measured with a Büchi apparatus, using a capillary, which was filled under nitrogen and sealed. Cl_2BNiPr_2,[14] Cl_2BTMP,[18] Cl_2BDMP,[19] Cl_2Bdur,[20] 2,5-bis[chlorobis(diisopropylamino)boryl]thiophene,[16] 1,1-bis(2-thienyl)ethane[12] were prepared according to literature procedures.

1 and 2: A solution of paraldehyde (52.8 g, 0.4 mol) in thiophene (101 g, 1.2 mol) was placed in a 1-L plastic flask. The flask was immersed in an ice-bath and 50 g of 40% hydrofluoric acid was added with stirring as follows: 5 g at the beginning, 10 g after 1.5 h and the rest after 3 h. Stirring was continued for 4 h at 0 °C and 3 d at room temperature. Distilled water (300 mL) and diethyl ether (200 mL) were added to the reaction mixture. After separating the organic layer, it was washed twice with a solution of NaOH (0.1 N) and dried with Na_2SO_4. Distillation gave **1** (10.3 g, 0.055 mol, 42%), b.p. 90 °C/1.0 mbar and **2** (23.5 g, 0.077 mol, 58%) as a brown, oily residue. **1:** ^1H NMR (CD_2Cl_2, 200.1 MHz): δ = 1.87 (d, $^3J_{H,H}$ = 7 Hz, 1 H, $CHCH_3$), 4.74 (q, $^3J_{H,H}$ = 7 Hz, 3 H, $CHCH_3$), 7.03 (m, 4 H, CH), 7.24 (d, 2 H, CH) ppm. ^{13}C NMR (CD_2Cl_2, 50.3 MHz): δ = 24.9 ($CHCH_3$), 36.6 ($CHCH_3$), 124.1, 127.0, 150.6 (CH) ppm. EI-MS: *m*/*z* (%) = 194 (75) $[M]^+$, 179 (100) $[M - CH_3]^+$. **2:** ^1H NMR (CD_2Cl_2, 200.1 MHz): δ = 1.75 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 4.60 (q, $^3J_{H,H}$ = 7 Hz, 2 H, $CHCH_3$), 6.80 (m, 3 H, CH), 6.90 (m, 3 H, CH), 7.15 (d, 2 H, CH) ppm. ^{13}C NMR (CD_2Cl_2, 50.3 MHz): δ = 24.4 ($CHCH_3$), 36.7 ($CHCH_3$), 124.2, 125.4, 127.3, 148.5, 150.5 (CH) ppm. EI-MS: *m*/*z* (%) = 304 (70) $[M]^+$; 289 (100) $[M - CH_3]^+$.

5: To a stirred solution of 1,1-bis(2-thienyl)ethane (**1**) (1.0 g, 5.2 mmol) in diethyl ether (20 mL), a 2.5 M solution of butyllithium in hexane (4.2 mL) was added dropwise at room temp. The colorless solution turned red within 30 min. After cooling to −30 °C, Cl_2BNiPr_2 (1.0 g, 5.5 mmol) was added dropwise and stirred for 14 h at 20 °C. The solid was then filtered and washed with diethyl ether and the solvent was removed under vacuum to give a yellow solid which was washed twice with pentane. Yield: 1.50 g (2.5 mmol, 95%) of yellow **5**, m.p. 175 °C (decomp.). ^1H NMR ($CDCl_3$, 200.1 MHz): δ = 1.20 [d, $^3J_{H,H}$ = 7 Hz, 24 H, $CH(CH_3)_2$], 1.71 (d, $^3J_{H,H}$ = 7 Hz, 3 H, $CHCH_3$), 4.03 [s, $^3J_{H,H}$ = 7 Hz, 4 H, $CH(CH_3)_2$], 4.57 (q, $^3J_{H,H}$ = 7 Hz, 2 H, $CHCH_3$), 6.76 (d, $^3J_{H,H}$ = 4.0 Hz, 4 H, H_{ar}), 6.84 (d, $^3J_{H,H}$ = 4.0 Hz, 4 H, H_{ar}) ppm. ^{11}B NMR ($CDCl_3$, 64.1 MHz): δ = 35.0 ppm. ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 14.5 ($CHCH_3$), 25.3 [$CH(CH_3)_2$], 37.1 [$CH(CH_3)_2$], 50.3 ($CHCH_3$), 125.0, 134.0, 154.8 (C_{ar}), 143 (br, CB) ppm. FAB-MS: *m*/*z* (%) = 606 (90) $[M]^+$, 591 (43) $[M - CH_3]^+$, 507 (49) $[M - NiPr_2]^+$. HR-FAB-MS: *m*/*z* (%) = $C_{32}H_{44}N_2S_4{}^{11}B_2$ $[M]^+$ calcd. 606.2575; found 606.2615; Δ*m* = 4.0 mmu.

6: The compound was prepared, analogously to **5**, from **1** (0.95 g, 4.9 mmol), *n*-butyllithium (4.2 mL) and dichloro(2,2′,6,6′-tetramethylpiperidyl)borane (1.1 g, 4.98 mmol). Yield: 0.86 g (1.3 mmol, 51%) of yellow **6**, m.p. 185 °C (decomp.). ^1H NMR (200 MHz, $CDCl_3$): δ = 1.43 [s, 24 H, $C(CH_3)_2$], 1.68 (m, 12 H, CH_2), 1.77 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 4.63 (q, $^3J_{H,H}$ = 7 Hz, 2 H, $CHCH_3$), 6.87 (m, 8 H, H_{ar}) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 43.3 ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 14.0 ($CHCH_3$), 24.5 [$C(CH_3)_2$], 32.1 (CH_2), 36.1 (CH_2), 55.4 [$CH(CH_3)$], 123.6; 126.5; 150.0 (C_{ar}) ppm, CB signal not detected. CI-MS: *m*/*z* (%) = 743 (10) [M + C_4H_8 gas], 687 (15) $[M]^+$, 672 (13) $[M - CH_3]^+$. HR-FAB-MS: $C_{38}H_{52}N_2S_4{}^{11}B_2$ $[M]^+$ calcd. 686.3200; found 686.3220; Δ*m* = 2.0 mmu.

7: The compound was prepared analogously to **5**, from 1,1-bis(2-thienyl)ethane (1.82 g, 9.4 mmol), *n*-butyllithium (8.3 mL) and dichloro(2,6-dimethylpiperidyl)borane (1.83 g, 9.6 mmol). Yield: 1.78 g (2.8 mmol, 60%) of yellow **7**, m.p. 185 °C (decomp.). ^1H NMR (200 MHz, $CDCl_3$): δ = 1.36−1.87 (m, 28 H, H_{dmp} and $CHCH_3$), 4.35 (q, $^3J_{H,H}$ = 7 Hz, 2 H, CH_3HC_{dmp}), 4.47 (q, $^3J_{H,H}$ = 7 Hz, 2 H, CH_3HC_{dmp}), 4.67 (q, $^3J_{H,H}$ = 7 Hz, 2 H, $CHCH_3$), 6.93−7.06 (m, H_{ar}) ppm. ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 42.3 ppm. ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 14.1 (H_3CHC_{dmp}

and $CHCH_3$), 23.1, 24.3, 26.2, 28.5, 31.6, 34.1 (CH_2), 36.2 ($CHCH_3$), 48.0, 49.1, 49.9, 52.5 (CH_3HC_{dmp}), 124.4, 134.5, 152.6 (C_{ar}), 142 (br, C−B) ppm. EI-MS: *m*/*z* (%) = 630 (15) $[M]^+$, 615 (7) $[M - CH_3]^+$. HR-EI-MS: $C_{40}H_{44}N_2S_4{}^{11}B_2$ $[M]^+$ calcd. 630.2574; found 630.2609; Δm = 3.5 mmu.

8: The compound was prepared analogously to **5**, from **1** (1.2 g, 6.2 mmol), *n*-butyllithium (5.4 mL) and dichloro(2,3,5,6-tetramethylphenyl)borane (1.3 g, 6.2 mmol). Yield: 0.92 g (1.4 mmol, 45%) of yellow **8**, m.p. 180 °C (decomp.). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.79 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 1.95 (s, 9 H, CH_{3dur}), 2.19 (s, 15 H, H_3C_{dur}), 4.68 (q, $^3J_{H,H}$ = 7 Hz, 2 H, $CHCH_3$), 6.95 (m, 8 H, H_{ar}), 7.57 (s, 2 H, HC_{dur}) ppm. ^{11}B NMR ($CDCl_3$, 64.2 MHz): δ = 70 (br) (special parameters have been used: *SW* = 1000 ppm, *TD* = 8 k, *NS* = 1 k) ppm. ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 19.8, 20.1 (H_3C_{dur}), 24.3 ($CHCH_3$), 37.2 ($CHCH_3$), 124.2, 127.0 (C_{ar}), 131.2, 133.0, 134.0, 134.5 (C_{dur}), 142.6 (C_{dur}), 163 (br, B−C_{ar}) ppm. FAB-MS: *m*/*z* (%) = 673 (5) $[M + H]^+$; 540 (6) $[M - dur]^+$. HR-FAB-MS: $C_{40}H_{42}B_2S_4$ $[M]^+$ calcd. 672.2355; found 672.2377; Δm = 2.2 mmu.

13: To a solution of 2,5-bis[1(2-thienyl)ethyl]thiophene (**2**) (1.0 g, 3.3 mmol) in diethyl ether (20 mL), a 2.5 M solution of butyllithium (3 mL) was added slowly. After stirring for 30 min at room temp., the red solution was cooled to −30 °C and 2,5-bis[chlorobis(diisopropylamino)boryl]thiophene (**9**) (1.23 g, 3.3 mmol) was added slowly. The solution was warmed to 20 °C over 14 h, LiCl was filtered off, and the solvent was evaporated under vacuum to give a residue, which was extracted with pentane. Evaporation of the solvent gave yellow **13**, m.p. 178 °C (decomp.), yield: 1.22 g (2.0 mmol, 61%). ^{1}H NMR ($CDCl_3$, 200.1 MHz): δ = 1.26 [d, $^3J_{H,H}$ = 7 Hz, 24 H, $CH(CH_3)_2$], 1.70 (d, $^3J_{H,H}$ = 7 Hz, 6 H, $CHCH_3$), 4.09 [sept, $^3J_{H,H}$ = 7 Hz, 4 H, $CH(CH_3)_2$], 4.53 (q, $^3J_{H,H}$ = 7 Hz, 2 H, $CHCH_3$), 6.64−6.90 (m, 6 H, H_{ar}), 7.08 (m, 2 H, H_{ar}) ppm. ^{11}B NMR ($CDCl_3$, 64.2 MHz): δ = 36.5 ppm. ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 14.3 ($CHCH_3$), 23.3, 23.7 [$CH(CH_3)_2$], 36.6 [$CH(CH_3)_2$], 47.2 ($CHCH_3$), 123.2, 124.0, 124.3, 124.5, 129.1, 131.2 (C_{ar}), 149 (br, CB) ppm. EI-MS: *m*/*z* (%) = 606 (15) $[M]^+$, 591 (10) $[M - CH_3]^+$, 507 (20) $[M - NiPr_2]^+$.

14: The compound was prepared analogously to **13**, from **2** (0.17 g, 0.4 mmol), *n*-butyllithium (0.4 mL) and 2,5-bis[chloro(2,2′,6,6′-tetramethylpiperidyl)boryl]thiophene (**10**) (0.19 g, 0.42 mmol). Yield: 0.19 g (0.3 mmol, 62%) yellow **14**, m.p. 185 °C (decomp.). ^{1}H NMR ($CDCl_3$, 200.1 MHz): δ = 1.29 [s, 24 H, $C(CH_3)_2$], 1.62 (d, 6 H, $CHCH_3$), 1.72−1.91 (m, 12 H, CH_2), 4.54 (q, 2 H, $CHCH_3$), 6.67 (s, 2 H, CH_{thio}), 6.89−7.01 (m, 4 H, CH_{thio}), 7.16−7.27 (m, 2 H, CH_{thio}) ppm. ^{11}B NMR ($CDCl_3$, 64.2 MHz): δ = 40 (br) ppm. ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 14.4 [$CH(CH_3)$], 30.0 [$C(CH_3)_2$], 32.2 (CH_2), 36.6 (CH_2), 46.6 [$CH(CH_3)$], 122.9; 123.8; 126.7 (C_{ar}), 148.4 (br, CB) ppm. EI-MS: *m*/*z* (%) = 684 (20) $[M - H_2]^+$, 604 (10) $[M -$ thiophene$]^+$.

15: The compound was prepared analogously to **13**, from **2** (0.30 g, 0.1 mmol), *n*-butyllithium (0.9 mL) and 2,5-bis[chlorobis(diisopropylamino)boryl]furan (**11**) (0.33 g, 1.0 mmol). Yield: 0.24 g (0.4 mmol, 40%) of yellow **15**, m.p. 187 °C (decomp.). ^{1}H NMR ($CDCl_3$, 200.1 MHz): δ = 1.27 [d, 24 H, $^3J_{H,H}$ = 5.0 Hz, $CH(CH_3)_2$], 1.49 [d, 6 H, $^3J_{H,H}$ = 4.8 Hz, $CH(CH_3)_2$], 4.01 [sept, 4 H, $^3J_{H,H}$ = 5.0 Hz, $CH(CH_3)_2$], 4.56 [q, 2 H, $^3J_{H,H}$ = 4.8 Hz, $CH(CH_3)_2$], 6.68(m, 2 H, H_{ar}), 6.87−6.93 (m, 3 H, H_{ar}), 7.14−7.23 (m, 3 H, H_{ar}) ppm. ^{11}B NMR ($CDCl_3$, 64.2 MHz): δ = 39.0 ppm. ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 14.4 ($CHCH_3$), 23.6, 24.2 [$CH(CH_3)_2$], 36.5 [$CH(CH_3)_2$], 47.0 ($CHCH_3$), 123.3; 123.8; 123.9; 124.3; 125.4(C_{ar}), 150 (br, CB) ppm. EI-MS: *m*/*z* (%) = 590 (5) $[M]^+$, 490 (12) $[M - NiPr_2]^+$.

16: The compound was prepared analogously to **13**, from **2** (0.55 g, 1.8 mmol), *n*-butyllithium (1.6 mL) and 2,5-bis[chlorobis(diisopropylamino)boryl]-*N*-methylpyrrole (**12**) (0.67 g, 1.8 mmol). Yield: 0.51 g (0.85 mmol, 47%) of yellow **16**, m.p. 190 °C (decomp.). ^{1}H NMR ($CDCl_3$, 200.1 MHz): δ = 1.35 [d, 24 H, $^3J_{H,H}$ = 5.0 Hz, $CH(CH_3)_2$], 1.73 [d, 6 H, $^3J_{H,H}$ = 4.8 Hz, $CH(CH_3)_2$], 3.27 (s, 3 H, NCH_3), 3.75 [sept, 4 H, $^3J_{H,H}$ = 5.0 Hz, $CH(CH_3)_2$], 4.54 [q, 2 H, $^3J_{H,H}$ = 4.8 Hz, $CH(CH_3)_2$], 6.21 (m, 2 H, H_{py}), 6.63−6.68 (m, 3 H, H_{thio}), 6.83−7.11 (m, 3 H, H_{thio}) ppm. ^{11}B NMR ($CDCl_3$, 64.2 MHz): δ = 43.9 ppm. ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 14.1 ($CHCH_3$), 23.0; 25.3 [$CH(CH_3)_2$], 36.2 [$CH(CH_3)_2$], 47.2 ($CHCH_3$), 50.7 (NCH_3), 107.1; 114.1 ($C_{ar,py}$), 122.9; 124.1; 124.8 ($C_{ar,thio}$), 148 (br, CB) ppm. CI-MS: *m*/*z* (%) = 661 (20) $[M + H + C_4H_8]^+$, 604 (45) $[M + H]^+$, 581 (8) $[M + H - Me]^+$, 524 (15) [M + H − *N*-methylpyrrole].

Crystal Structure Determination of 5: Intensity data were collected with a Bruker AXS SMART 1000 area detector (Mo-K_α radiation, λ = 0.71073, ω-scans, *T* = −83 °C). All calculations were performed using SHELXLT 5.1.[21] Non-hydrogen atoms were refined with anisotropic displacement factors. Hydrogen atoms were located in a difference Fourier synthesis and refined with isotropic displacement factors. Crystal data and details of the structure determination are given in Table 1. CCDC-175313 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structures, and Donor−Acceptor Adducts of Tris(3,3-dimethyl-1-butynyl)borane

Michael J. Bayer,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

Dedicated to Prof. Günter Schmid on the occasion of his 65th birthday

Keywords: Alkynes / Tris(alkynyl)boranes / Donors / Boron

The synthesis and properties of tris(3,3-dimethyl-1-butynyl)-borane (**1**), the first donor-free tris(alkynyl)borane, and of its adducts **2** [donor = pyridine (**2a**), triphenylphosphane (**2b**), tetrahydrofuran (**2c**)] are reported. X-ray structure analyses reveal that the B–C bond lengths in **1** are shorter than in **2**; however, the C≡C triple bond lengths are similar to those of the donor-stabilized compounds **2a**, **2b**, and **2c**.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

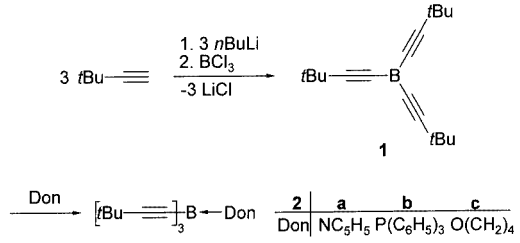
Tris(alkynyl)boranes were first obtained by Krüerke[1] as donor-stabilized compounds by the reaction of tetraphenylalkynylborates with HCl in the presence of tetrahydrofuran and trialkylamines, respectively. Another approach was described by Ashby et al.[2] who treated sodium acetylide or sodium organylacetylides with boron trifluoride−amine to yield the corresponding amine−B-$(C{\equiv}CH_3)_3$ adducts [amine = C_5H_5N, $(CH_3)_3N$, $(CH_3)_2NH$], and $H_5C_5N{-}B(C{\equiv}CC_6H_5)_3$. Köster et al.[3] prepared tris(alkynyl)borane−trimethylamine adducts by oxidizing alkynylborane adducts of trimethylamine with trimethylamine oxide, the resulting alkynylbis(alkoxy)boranes rearrange to form tris(alkynyl)borane−trimethylamine and tris(alkoxy)borane. Wheatley et al.[4] treated phenylacetylene with *n*-butyllithium and boron trifluoride−diethyl ether in tetrahydrofuran/toluene and obtained the tris-(phenylethynyl)borane−tetrahydrofuran adduct as a hydrogen-bonded dimer. Siebert, Cederbaum et al.[5] published the X-ray structure analysis of the adduct $H_5C_5N{-}B(C{\equiv}CH)_3$ and ab initio calculations on the electronic structure of the donor-free tris(ethynyl)borane. Attempts to synthesize donor-free tris(alkynyl)boranes led to polymeric products.[2]

We report here on the synthesis of tris(3,3-dimethyl-1-butynyl)borane (**1**), the first donor-free tris(alkynyl)borane. Furthermore, the NMR spectroscopic and structural data of **1** and of its pyridine, triphenylphosphane, and tetrahydrofuran adducts **2a**−**c** are described.

Results and Discussion

Synthesis

Tris(3,3-dimethyl-1-butynyl)borane (**1**) is obtained quantitatively by the reaction of deprotonated 3,3-dimethyl-1-butyne with boron trichloride at −78 °C in pentane. Treatment of **1** with pyridine, triphenylphosphane, and tetrahydrofuran leads to the donor-stabilized tris(alkynyl)boranes **2a**−**c** (Scheme 1).



Scheme 1

The composition of the new compounds is derived from NMR and mass spectra and confirmed by X-ray structure analyses. The ^{11}B NMR signal of **1** shows a remarkable shift at δ = 38 ppm upfield from shifts for alkyl- and alkenylboranes.[6] The ^1H NMR spectrum of **1** exhibits a resonance at δ = 1.26 ppm for the methyl protons and in the ^{13}C NMR spectrum the broadened signal for the boron-bound α-carbon atoms is detected at δ = 91 ppm. In comparison

[a] Anorganisch-Chemisches Institut der Universität Heidelberg, Im Neuenheimer Feld 270, 69120 Heidelberg, Germany
Fax: (internat.) + 49-(0)6221/545609
E-mail: ci5@ix.urz.uni-heidelberg.de

to 3,3-dimethyl-1-butyne[7] [$\delta(^{13}C) = 67.3$] the signal for the α-carbon atom of **1** is shifted by 24 ppm to lower field, while the resonance of the β-carbon atoms ($\delta = 126.3$ ppm) is shifted by 32 ppm to higher field. The signals for the *tert*-butyl substituent are observed at $\delta = 30.5$ ppm for methyl groups and $\delta = 28.7$ ppm for the quaternary carbon atom. An EI mass spectrum of **1** shows the molecular ion peak [M^+] at $m/z = 254$ with an intensity of 72%, and the IR spectrum features for the C≡C triple bond a strong stretching vibration at $\tilde{\nu} = 2171.5\ cm^{-1}$ indicating that this bond is not elongated (confirmed by X-ray structure data, see below).

The ^{11}B NMR shift of **2a** at $\delta = -15$ ppm indicates a fourfold coordination of the boron atom. In the ^1H NMR spectrum the signal for *tert*-butyl group is observed at $\delta = 1.22$ ppm, and the ^{13}C NMR spectrum exhibits the resonances of the *tert*-butyl substituent at $\delta = 31.4$ ppm for the methyl groups and at $\delta = 29.7$ ppm for the quaternary carbon atom. The boron-bound α-carbon signals appear at $\delta = 106$ ppm, which is shifted to lower field than that of **1**. At $\delta = 128.2$ ppm the resonance for the β-carbon atoms is found.

The ^{11}B NMR signal of **2b** at $\delta = -26$ ppm is upfield relative to that of **2a**. In the ^1H NMR spectrum a singlet is observed for the *tert*-butyl groups at $\delta = 0.88$ ppm. The ^{13}C NMR spectrum exhibits four resonances at $\delta = 29.7$ (CMe_3), 30.9 (CH_3), 107 (broad, CB) and 125.2 ppm (β-carbon atoms). Four signals in the aromatic region are assigned to the triphenylphosphane donor. The ^{31}P NMR signal of **2b** is found at $\delta = 4.0$ ppm. The ^{11}B NMR shift of **2c** at $\delta = -9$ ppm is downfield compared with the values of **2a** and **2b**. The ^1H and ^{13}C NMR signals of complexed **1** in **2c** do not deviate significantly from the data of **2a** and **2b**. In the EI mass spectrum no peak for the molecular ion [M^+] of **2a**–**c** but that of **1** and peaks for pyridine, triphenylphosphane, and tetrahydrofuran, respectively, are detected.

Attempts to synthesize tris(alkynyl)boranes with a number of terminal alkynes (propyne, 1-butyne, trimethylsilylacetylene, phenylacetylene, mesitylacetylene) were not successful. Instead mixtures of polymeric products of unknown compositions were formed.

Crystal Structures

The molecular structure of **1** was obtained by performing a single-crystal X-ray diffraction analysis. Colorless crystals of **1** were grown from pentane at 4 °C, its molecular structure is shown in Figure 1. In **1** the C≡C triple bond lengths [1.203(2) Å] are similar, but the B–C distances [1.519(2) Å] are shorter than those of the adducts $H_8C_4O{-}B(C{\equiv}C{-}C_6H_5)_3$ [1.209(3), 1.580(4) Å][4] and $H_5C_5N{-}B(C{\equiv}CH)_3$ [1.188(2), 1.586(2) Å].[5] The catecholborylacetylene $H_4C_6O_2B{-}C{\equiv}CH$ [1.195(3), 1.520(4) Å][8] has C≡C and B–C bond lengths similar to those of **1**.

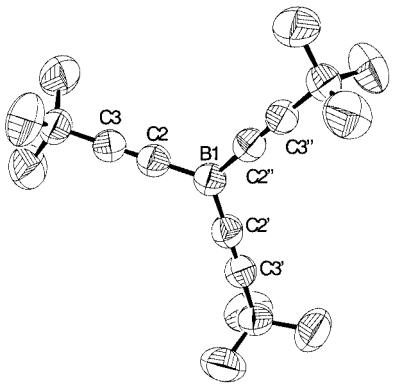


Figure 1. Molecular structure of **1** in the crystal; selected bond lengths [Å] and angles [°]: B1–C2 1.519(2), C2–C3 1.203(2), C3–C4 1.467(2), C2–B1–C2′ 120.00(1), C2–B1–C2′′ 120.00(1), C2′–B1–C2′′ 120.00(1)

Single crystals of **2a** and **2b** were grown from a solution of toluene at −30 °C, while **2c** crystallizes in tetrahydrofuran at −30 °C. Their molecular structures with distorted tetrahedral coordination at the boron atoms are shown in Figures 2–4. The lengths of the C≡C triple bonds [1.196(6)–1.212(1) Å] lie in the range of the donor-free tris(alkynyl)borane **1** [1.203(2) Å], while the B–C bond lengths [1.575(6)–1.593(2) Å] are similar to those in similar adducts of tris(alkynyl)boranes.[4,5] The B–C bonds are elongated compared with those of **1**.

Because the C≡C triple bonds in **1** are not elongated and the B–C distances are shorter in comparison to those of the donor-stabilized compounds **2a**–**c** it may be concluded that a small pπ–pπ interaction between the sp-hybridized carbon atoms and the sp^2-boron atom is present. This is supported by ab initio calculations on the unknown tris(ethynyl)borane,[5] which indicate weak π interactions between the boron atom and the C≡C triple bond. Furthermore, ab initio calculations on the model compound ethynylborane ($H_2B{-}C{\equiv}CH$) showed that a (polar) heteroallene structure with a B=C double bond is only of minor import-

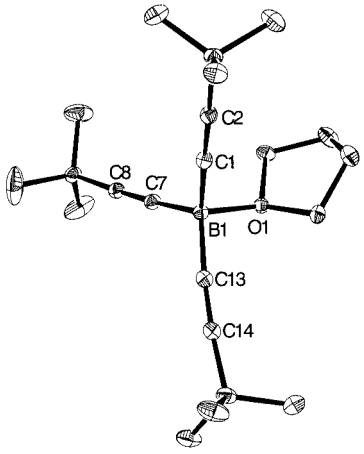

Figure 4. Molecular structure of **2c** in the crystal; selected bond lengths [Å] and angles [°]: B1−C1 1.580(1), B1−C7 1.578(1), B1−C13 1.575(1), C1−C2 1.210(1), C7−C8 1.212(1), C13−C14 1.209(1), B1−O1 1.605(1), C1−B1−O1 104.5(1), C7−B1−O1 104.2(1), C13−B1−O1 103.0(1), C1−B1−C7 112.6(1), C1−B1−C13 115.6(1), C7−B1−C13 115.2(1)

ance.[9] The observed shortening of the B−C bond length may be explained by the different boron hybridizations present in **1** (sp^2) and in the adducts **2** (sp^3).

Conclusion

In this paper we report on the synthesis of the first donor-free tris(alkynyl)borane. By treating of 3,3-dimethyl-1-butynyllithium with boron trichloride in a ratio of 3:1 tris(3,3-dimethyl-1-butynyl)borane (**1**) is formed. Reactions with several other terminal alkynes did not yield the corresponding tris(alkynyl)boranes, but mixtures of polymeric products with unknown compositions were obtained. Addition of pyridine, triphenylphosphane or tetrahydrofuran to **1** yields the donor-stabilized derivatives **2a**, **2b**, and **2c**, respectively. X-ray structure analyses of **1**, **2a**, **2b**, and **2c** show that the lengths of the C≡C triple bonds of **1** are similar to the C≡C triple bonds of **2a**−**c**, while the B−C bonds in **1** are shorter compared with the B−C bonds in **2a**−**c**. This result seems to be in agreement with the presence of a (C−B)π interaction as indicated by ab initio calculations on the nonexistent tris(ethynyl)borane[5] and by NMR studies of several alkenyl- and alkynylboranes.[6] However, the elongation of the B−C bonds more likely is a consequence of the decrease of the 2s character in the boron−carbon bonds of **2a**−**c**, rather than a (C−B)π bond in **1**.

Experimental Section

General: Reactions were carried out under dry argon or nitrogen, using standard Schlenk techniques. Solvents were dried, distilled, and saturated with nitrogen. Glassware was dried with a heat-gun under high vacuum. ^1H, ^{13}C, ^{31}P and ^{11}B NMR: Bruker DRX 200 spectrometer, $Et_2O{\cdot}BF_3$ was used as external standard for ^{11}B NMR, 30% H_3PO_4 for ^{31}P NMR. As internal references for ^1H and ^{13}C NMR spectra the signals of the deuterated solvents were used and calculated for TMS. The mass spectra were measured with a ZAB-2F VH Micromass CTD spectrometer and with a Jeol MS station JMS 700 using EI and HR-EI techniques. IR spectra were recorded with a Perkin−Elmer 983G spectrometer. Melting points (uncorrected) were measured with a Büchi apparatus using capillaries, which were filled under argon or nitrogen, and sealed.

Tris(3,3-dimethyl-1-butynyl)borane (1): To a solution of 5 g (61 mmol) of 3,3-dimethyl-1-butyne in 140 mL of pentane 61 mmol of *n*BuLi was added at −20 °C. The mixture was allowed to warm to room temp. and stirred for 1 h. Then the suspension was cooled to −78 °C and transferred to a solution of 3.3 g (28 mmol) of BCl_3 in 40 mL of pentane at −78 °C. The reaction mixture was allowed to warm slowly to room temp. and was stirred for 12 h. After filtration, the solvent was evaporated to give **1** as colorless solid (5.04 g, 97.5%, m.p. 48 °C). ^1H NMR (200 MHz, $CDCl_3$): δ = 1.26 [s, 27 H, $C(CH_3)_3$] ppm. ^{11}B NMR (64 MHz, $CDCl_3$): δ = 38 ppm ($\Delta_{1/2}$ = 580 Hz). $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$): δ = 28.7 [$C(CH_3)_3$], 30.5 [$C(CH_3)_3$], 91 (br., B*C*≡C), 126.3 ppm (BC≡*C*). EI-MS: *m/z* (%) = 254 (72) [M^+], 239 (38) [$M^+ - CH_3$], 197 (78) [$M^+ - C_4H_9$], 173 (20) [$M^+ - C_6H_9$], 67 (100) [$C_5H_7^+$], 57 (43) [$C_4H_9^+$], 41 (74) [$C_3H_5^+$]. HR-MS (EI): *m/z* = 254.2208 [M^+]; calcd. for $^{12}C_{18}{}^1H_{27}{}^{11}B_1$: 254.2206 (Δ = 0.2 mmu). IR: $\tilde{\nu}$ = 2171.5 cm^{-1} (C≡C).

Tris(3,3-dimethyl-1-butynyl)borane−Pyridine Adduct (2a): 133 mg (0.52 mmol) of **1** was dissolved in 15 mL of pentane and treated with 45 mg (0.57 mmol) of pyridine at −10 °C. The mixture was allowed to warm to room temp. and was stirred for 4 h. Then the solvent was removed under vacuum to yield **2a** as colorless solid (168 mg, 96.3%, m.p. 74 °C). ^1H NMR (200 MHz, $CDCl_3$): δ = 1.22 [s, 27 H, $C(CH_3)_3$], 7.62 (m, 2 H, H_{py}), 8.03 (m, 1 H, H_{py}), 9.28 ppm (m, 2 H, H_{py}). ^{11}B NMR (64 MHz, $CDCl_3$): δ = −15 ppm ($\Delta_{1/2}$ = 139 Hz). $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$): δ = 29.7 [$C(CH_3)_3$], 31.4 [$C(CH_3)_3$], 106 (br., B*C*≡C), 128.2 (BC≡*C*), 125.1, 140.6, 146.1 ppm (C_{py}). EI-MS: *m/z* (%) = 254 (81) [M^+ −py], 239 (49) [$M^+ - py - CH_3$], 197 (100) [$M^+ - py - C_4H_9$], 173 (22) [$M^+ - py - C_6H_9$], 79 (96) [py^+], 67 (60) [$C_5H_7^+$], 57 (36) [$C_4H_9^+$], 52 (87) [$C_4H_4^+$], 41 (86) [$C_3H_5^+$].

Tris(3,3-dimethyl-1-butynyl)borane−Triphenylphosphane Adduct (2b): 90 mg (0.35 mmol) of **1** was dissolved in 20 mL of toluene, and a solution of 93 mg (0.35 mmol) of PPh_3 in 10 mL of toluene was added at room temp. After 4 h of stirring, the solvent was

removed under vacuum to give **2b** as colorless solid (143 mg, 78.3%, m.p. 96 °C). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.88 [s, 27 H, $C(CH_3)_3$], 7.10−7.20 ppm (m, 15 H, Ar-H). ^{11}B NMR (64 MHz, $CDCl_3$): δ = −26 ppm (Δ1/2 = 174 Hz). $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$): δ = 29.7 [$C(CH_3)_3$], 30.9 [$C(CH_3)_3$], 107 (br., B*C*≡C), 125.3 (BC≡*C*), 128.2, 129.0, 134.0, 137.8 ppm (Ar-C). ^{31}P NMR (81 MHz, $CDCl_3$): δ = 4.0 ppm. EI-MS: *m*/*z* (%) = 262 100) [PPh_3^+], 254 (14) [$M^+ - PPh_3$], 239 (12) [$M^+ - PPh_3 - CH_3$], 197 (36) [$M^+ - PPh_3 - C_4H_9$], 108 (33) [PPh^+].

Tris(3,3-dimethyl-1-butynyl)borane−Tetrahydrofuran Adduct (2c): 169 mg (0.67 mmol) of **1** was dissolved in 15 mL of pentane and treated with 5 mL of tetrahydrofuran at −10 °C. The mixture was allowed to warm up to room temp. and was stirred for 4 h. Then the solvents were removed under vacuum to yield **2c** as colorless solid (202 mg, 92.4%, m.p. 63 °C). ^{1}H NMR (200 MHz, [D_8]THF): δ = 1.15 [s, 27 H, $C(CH_3)_3$], 1.78 (m, 4 H, β-H_{thf}), 3.63 ppm (m, 4 H, α-H_{thf}). ^{11}B NMR (64 MHz, [D_8]THF): δ = −8 ppm ($\Delta_{1/2}$ = 412 Hz). $^{13}C\{^1H\}$ NMR (50 MHz, [D_8]THF): δ = 26.5 (β-C_{thf}), 31.5 [$C(CH_3)_3$], 32.0 [$C(CH_3)_3$], 68.5 (α-C_{thf}), 89 (br., B*C*≡C), 104.6 ppm (BC≡*C*). EI-MS: *m*/*z* (%) = 254 (64) [M^+ − THF], 239 (43) [M^+ − THF − CH_3], 197 (100) [M^+ − THF − C_4H_9], 72 (84) [THF^+], 57 (14) [$C_4H_9^+$].

X-ray Crystal Structure Analyses of 1, 2a, 2b, and 2c: Crystal data and details of the structure determinations are compiled in Table 1. Intensity data were collected with a Bruker AXS Smart 1000 CCD area detector (Mo-K_α radiation, λ = 0.71073 Å, ω-scan). An empirical absorption correction was applied (SADABS). The structures were solved by direct methods and refined by full-matrix least squares based on F^2 with all measured reflections.[10] Non-hydrogen atoms were refined anisotropically. Hydrogen atoms for **2a** were located in a difference Fourier map and refined isotropically, for **1** and **2b** they were inserted in calculated positions. CCDC-179205−179209 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Tellurium(IV) Tetraalkoxides and Chlorotellurium(IV) Alkoxides Derived from β-Donor Alcohols

Holger Fleischer,*[a] Yvonne Dienes,[a] and Dieter Schollmeyer[b]

Keywords: Tellurium / Donor-acceptor systems / Ab initio calculations / X-ray diffraction / NMR spectroscopy

$Te(OiPr)_3OCH_2CH_2XMe_n$ (**1a**–**1c**) and $Te(OCH_2CH_2NMe_2)_4$ (**2**) were synthesised by the reaction of $Te(OiPr)_4$ with $HOCH_2CH_2XMe_n$, while $TeCl_2(OCH_2CH_2OMe)_2$ (**3**) and $TeCl_3OCH_2CH_2XMe_n$ (**4a**–**4c**) resulted from the reaction of $TeCl_4$ with the corresponding silylated alcohols $Me_3SiOCH_2CH_2XMe_n$ (X = N, n = 2; X = O or S, n = 1). These compounds are the first known representatives of the hitherto unknown classes of tellurium(IV) tetraalkoxides and chlorotellurium(IV) alkoxides derived from β-donor-substituted alcohols. The donor atom X in the alkoxy ligand enables an intramolecular donor-acceptor Te···X interaction, which stabilises the di- and trichlorotellurium alkoxides, but reduces the reactivity of the tellurium atom towards nucleophiles, a result from which an associative-dissociative mechanism was inferred for the nucleophilic substitution in $TeCl_4$. In contrast to this, all O*i*Pr ligands of $Te(OiPr)_4$ can be exchanged by reaction with $HOCH_2CH_2XMe_n$. As was shown by multinuclear NMR studies, the kinetics and equilibrium of the reaction of $Te(OiPr)_4$ with $HOCH_2CH_2XMe_n$ depend substantially on X and thus demonstrate the presence of Te···X interactions in solution. The molecular and crystal structure of **3** was investigated by single-crystal X-ray diffraction. In the solid state of **3**, two kinds of molecules are present, differing in the coordination modes of the Te atoms. In each molecule, two intramolecular dative Te···O bonds [264.3(2)–267.7(2) pm] exist, approximately *trans* to the covalent Te–O bonds. Two C_1-symmetric molecules are linked by intermolecular Te···Cl contacts to a third, namely the C_2-symmetric molecule, giving coordination numbers of six and seven for the Te atoms of the C_2- and C_1-symmetric moieties, respectively. Ab initio (MP2/LANL2DZP) geometry optimizations and thermochemical calculations of the model compounds $TeCl_3OCH_2CH_2XH_n$ (**4α**–**4γ**) and $Te(OH)_3OCH_2CH_2XH_n$ (**1α**–**1γ**) as well as an analysis of the bonds in terms of natural bond orbitals were performed in order to study the nature of the Te···X bond and its dependence on conformational restraints. The donor power of the N atom was found to be greater than those of the O and S atoms and the Te···X interactions are stronger for $TeCl_3OCH_2CH_2XH_2$ than for $Te(OH)_3OCH_2CH_2XH_2$; σ-type n(X)–σ*(Te–E) interactions are important for the Te···X bond and compete with π-type n(O)–σ*(Te–E) interactions, which in turn are of importance for the E–Te–O–C conformation (E = O, Cl).

Introduction

In contrast to $SiCl_4$, $GeCl_4$ or $SnCl_4$, $TeCl_4$ does not react with alcohols themselves by means of partial or full exchange of the chloride ligands by alkoxy groups, but dissolves in many alcohols without decomposition.[1] In order to obtain tellurium(IV) tetraalkoxides, $Te(OR)_4$, from $TeCl_4$ and the appropriate alcohol, HOR, the latter has to be activated. This activation can either be achieved by *O*-silylation or *O*-metallation of the alcohol prior to the synthesis or by addition of tertiary amines which drive the reaction by formation of the corresponding ammonium chloride.[2−4] Alternatively, $Te(OR)_4$ can be derived from $Te(OR')_4$ and HOR by ligand exchange according to Equation (1).

$$Te(OR')_4 + 4\ HOR \rightleftarrows Te(OR)_4 + 4\ HOR' \quad (1)$$

Gottlieb and co-workers showed that the equilibrium in Equation (1) is quickly reached for R, R′ = Me, Et in chloroform or benzene as solvents. They also found out that Equation (1) showed a statistical product distribution characteristic of thermally neutral reactions.[5] The equilibrium according to Equation (1) can be shifted towards the right if HOR′ can be removed by distillation or $Te(OR)_4$ is precipitated from the reaction mixture.[6,7]

Reaction of $TeCl_4$ with silylated alcohols according to Equation (2) represents a good approach to the synthesis of chlorotellurium(IV) alkoxides, $TeCl_{4-n}(OR)_n$.[3]

$$TeCl_4 + n\ Me_3SiOR \rightarrow TeCl_{4-n}(OR)_n + n\ Me_3SiCl \quad (2)$$

The chlorotrimethylsilane which is formed as a by-product, can easily be distilled off together with the solvent. Trichlorotellurium(IV) alkoxides like trichlorotellurium(IV)

[a] Institut für Anorganische Chemie und Analytische Chemie, Johannes Gutenberg Universität Mainz, Duesbergweg 10−14, 55099 Mainz, Germany
[b] Institut für Organische Chemie, Johannes Gutenberg Universität Mainz, Duesbergweg 10−14, 55099 Mainz, Germany

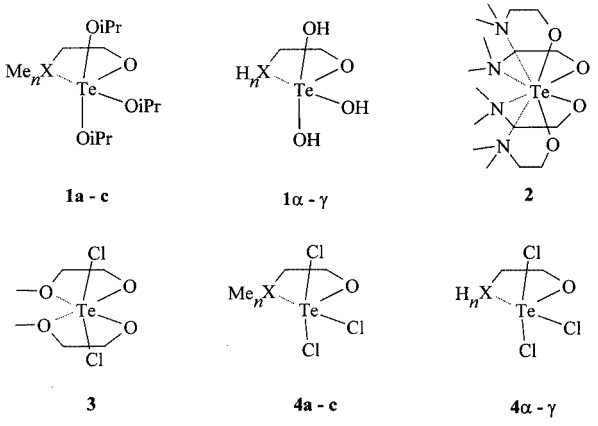
2-propoxide or ethoxide, which are reported to be unstable, could be stabilised as 1:1 adducts with THF or ethyl acetate.[7]

A number of tellurium compounds exhibit intramolecular donor-acceptor interactions, i.e. a Lewis acidic Te centre.[8,9] Concerning organotellurenyl halides, for example, these interactions enable the isolation of these otherwise unstable compounds. We were thus interested to see whether tellurium(IV) alkoxides and especially chlorotellurium(IV) alkoxides could be stabilised by such intramolecular donor-acceptor interactions and how these interactions would influence structure and reactivity.

Results and Discussion

Synthesis and ^{125}Te NMR Spectra

$Te(OiPr)_3OCH_2CH_2NMe_2$ (**1a**), $Te(OiPr)_3OCH_2CH_2OMe$ (**1b**) and $Te(OiPr)_3OCH_2CH_2SMe$ (**1c**) (Scheme 1) were prepared from equimolar amounts of $Te(OiPr)_4$ and the β-donor alcohols $HOCH_2CH_2NMe_2$, $HOCH_2CH_2OMe$ and $HOCH_2CH_2SMe$, respectively, by means of stirring the reactants in benzene and distilling off all volatile products under reduced pressure. $Te(OCH_2CH_2NMe_2)_4$ (**2**) could be prepared in this way as well by treating $Te(OiPr)_4$ with 4 equiv. of $HOCH_2CH_2NMe_2$. Reactions of equimolar amounts of $TeCl_4$ and the silylated β-donor alcohols $Me_3SiOCH_2CH_2XMe_n$ (X = N, n = 2; X = O or S, n = 1) resulted in good yields of the trichlorotellurium(IV) alkoxides $TeCl_3OCH_2CH_2NMe_2$ (**4a**), $TeCl_3OCH_2CH_2OMe$ (**4b**) and $TeCl_3OCH_2CH_2SMe$ (**4c**) (Scheme 1).

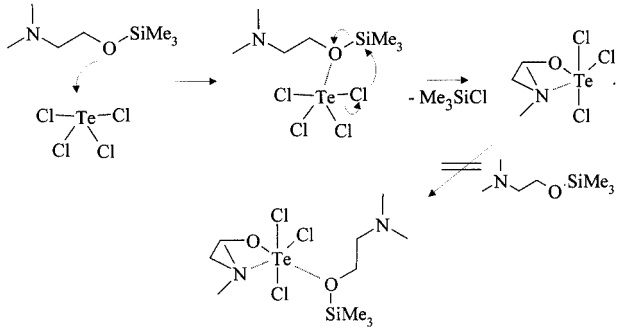


Scheme 1. Structural formulae of compounds and model compounds presented in this paper

Reaction of $TeCl_4$ with 2 or more equiv. of $Me_3SiOCH_2CH_2OMe$ resulted in the formation of $TeCl_2(OCH_2CH_2OMe)_2$ (**3**), whose crystal structure was solved and refined (see below).

At room temperature, **1a**−**c** and **2** are viscous colourless liquids that are quickly hydrolysed when exposed to air, whereas **3** and **4a**−**c** are colourless or slightly grey solids which are less sensitive to air, but decompose on melting. The positions of the ν(Te−Cl) bands in the Raman spectrum of **4a** indicate an aggregation in the solid state via Te−Cl···Te bridges. Whereas **4b** easily dissolves in chloroform, **4c** is soluble only in more polar solvents like THF. Compound **4a** is not soluble without decomposition, hence no high-resolution NMR spectra could be obtained for it.

When treating $TeCl_4$ with $Me_3SiOCH_2CH_2NMe_2$ and $Me_3SiOCH_2CH_2SMe$, no more than one Cl atom could be exchanged for an $OCH_2CH_2XMe_n$ group, even if an excess of the silylated alcohol was used and longer reaction times were applied. This is in contrast to the reaction of $Te(OiPr)_4$ with $HOCH_2CH_2NMe_2$, where all O*i*Pr groups could be substituted by $OCH_2CH_2NMe_2$ groups, leading to compound **2**. Thus, the conclusion could be drawn that the nucleophilic substitution reactions with the Te atoms in $TeCl_4$ and $Te(OiPr)_4$ proceed with different mechanisms and that the intramolecular Te···N interactions in **1a** and **4a** exhibit different strengths (see also the ab initio studies below). For $TeCl_4$, an associative-dissociative mechanism (Scheme 2) is assumed, whereas for $Te(OiPr)_4$ a dissociative-associative mechanism (Scheme 3) is more likely.

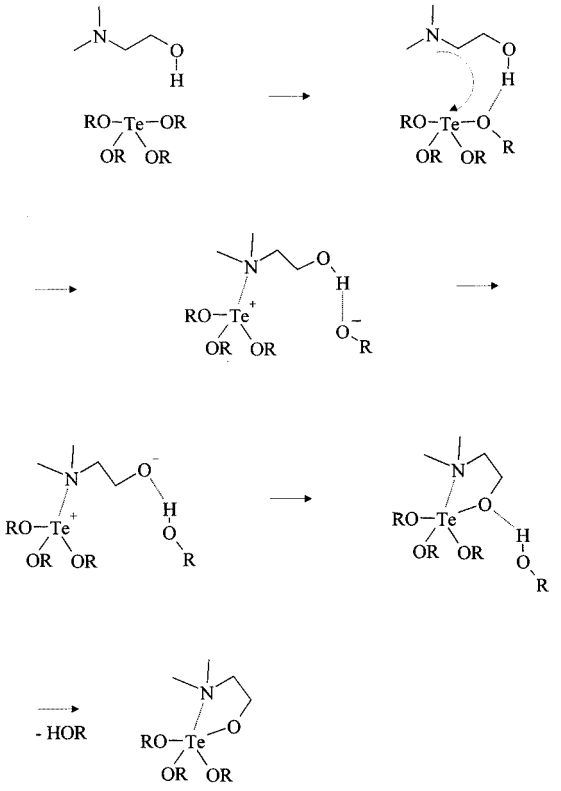


Scheme 2. Proposed associative-dissociative mechanism for the nucleophilic substitution at $TeCl_4$

In the associative-dissociative mechanism, the intramolecular Te···N bond shields the Te atom and reduces its Lewis acidity, so that interaction with the O atom of the silyl ether is not strong enough to cleave the O−Si bond.

For $Te(OiPr)_4$, a hydrogen bond assisted cleavage of a Te−O bond is supposed to precede the transfer of a proton from HOR^1 to OR^- and the addition of the thus formed OR^{1-} to $[Te(OR)_3]^+$. The different mechanisms of the nucleophilic substitution for $TeCl_4$ and $Te(OiPr)_4$ are due to a smaller Lewis acidity of $Te(OiPr)_4$ than $TeCl_4$ and a greater basicity of OR than the Cl ligand.

Whereas the ^{125}Te NMR shift of **1b** (δ = 1540 ppm) is very similar to that of $Te(OiPr)_4$ (δ = 1538 ppm), signals of **1c** (δ = 1519 ppm), **1a** (δ = 1454 ppm) and **2** (δ = 1410 ppm) exhibit a significant high-field shift. This effect is attributed to an increased coordination number of the tellurium atom due to intramolecular Te···X interactions. This interpretation is supported by the observation that on addition of an equimolar amount of H_2SO_4 to a solution of **1a** in $CDCl_3$, the ^{125}Te NMR signal undergoes a low-field shift to δ = 1558 ppm, an effect which is attributed to protonation of the nitrogen atom with subsequent cleavage of the Te···N bond, according to Equation (3).



Scheme 3. Proposed dissociative-associative mechanism for the nucleophilic substitution with $Te(OiPr)_4$ (R = O*i*Pr)

$$\mathbf{1a} + H_2SO_4 \rightarrow [Te(OiPr)_3OCH_2CH_2NHMe_2][HSO_4] \quad (3)$$

The chemical shifts of **1a**, **1b** and **1c**, and their comparison with that of $Te(OiPr)_4$ indicate an increase in Te···X bond strength in the order X = N > S > O. The difference between the ^{125}Te NMR shifts of **1a** and **2** is attributed to a further increase in the coordination number of the Te atom and to the different inductive effects of the O*i*Pr and the $OCH_2CH_2NMe_2$ groups. Each of the intramolecular Te···N interactions in **2** must be weaker than the one in **1a**, since the difference in the ^{125}Te NMR shifts of **1a** and **2** is only half as much as that between **1a** and $Te(OiPr)_4$.

In order to investigate the molecular dynamics of the Te···X interactions, ^{125}Te NMR spectra of **1a**, **1b** and **1c** were recorded at different temperatures (Table 1). The data shows δ(^{125}Te) of **1a** to have a large, δ(^{125}Te) of **1c** a small, and δ(^{125}Te) of **1b** to have hardly any positive temperature gradient. As the temperature increases, the differences in δ(^{125}Te) of **1a**, **1b** and **1c** decrease, a fact attributed to a substantial weakening of the Te···X interactions at higher temperatures.

Table 1. ^{125}Te NMR shifts of **1a**−**c** at different temperatures

Ligand Exchange of $Te(OiPr)_4$ with $HOCH_2CH_2XMe_n$

The equilibria and kinetics of the ligand-exchange reactions according to Equations (4a)−(4d) were investigated by means of NMR titration of solutions of $Te(OiPr)_4$ in $CDCl_3$ with $HOCH_2CH_2XMe_n$ [X = N, *n* = 2; X = O or S, *n* = 1; in Equations (4a)−(4d), R′ = $CH_2CH_2XMe_n$].

$$Te(OiPr)_4 + HOR' \rightleftarrows Te(OiPr)_3OR' + HOiPr \quad (4a)$$

$$Te(OiPr)_3OR' + HOR' \rightleftarrows Te(OiPr)_2(OR')_2 + HOiPr \quad (4b)$$

$$Te(OiPr)_2(OR')_2 + HOR' \rightleftarrows Te(OiPr)(OR')_3 + HOiPr \quad (4c)$$

$$Te(OiPr)(OR')_3 + HOR' \rightleftarrows Te(OR')_4 + HOiPr \quad (4d)$$

With X = N, six solutions were investigated, containing a given amount of $Te(OiPr)_4$ in $CDCl_3$ but different amounts of $HOCH_2CH_2NMe_2$. Figure 1 shows the ^{125}Te NMR spectra of these solutions, marked A−F. Five different signals can be observed, attributed to the five species of $Te(OiPr)_{4-n}(OCH_2CH_2NMe_2)_n$ (*n* = 0−4), with the signals of $Te(OiPr)_4$ (*n* = 0), **1a** (*n* = 1) and **2** (*n* = 4) known from the spectra of the pure compounds. The single species of $Te(OiPr)_{4-n}(OCH_2CH_2NMe_2)_n$ are sufficiently stable on the NMR time scale towards ligand exchange among each other or with free alcohol, so that no coalescence of their ^{125}Te NMR signals occurs. Unlike these results, the ligand exchange between $Te(OiPr)_4$ and HOMe, HOEt or HO*i*Pr, respectively,[5] and that between $Te(OiPr)_4$ and $Te(OMe)_4$,[10] proceed at such a rate at room temperature that only averaged ^{125}Te NMR signals could be observed.

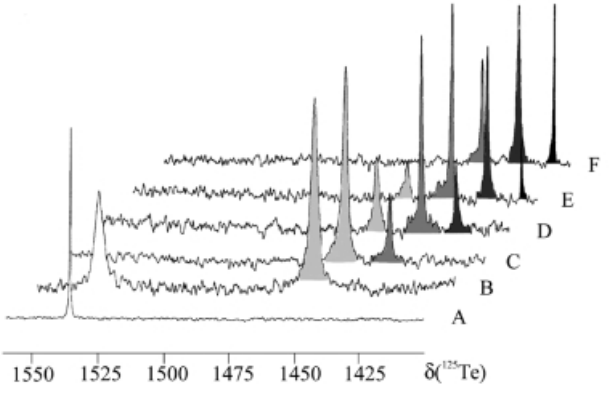

Figure 1. ^{125}Te NMR spectra of a solution of $Te(OiPr)_4$ in $CDCl_3$ with 0.00 (A), 0.65 (B), 1.26 (C), 1.97 (D), 2.77 (E) and 3.89 (F) equiv. of $HOCH_2CH_2NMe_2$; the different signals correspond to the entire species of $Te(OiPr)_{4-n}(OCH_2CH_2NMe_2)_n$ (*n* = 0−4); the darkening of the peaks' grey shadings corresponds to an increase in *n*

The ^{1}H NMR spectrum of solution B lacks any signal attributable to $HOCH_2CH_2NMe_2$, showing that the equilib-

rium according to Equation (4a) with X = N is shifted far towards the right side. Thus, formation of **1a** from Te(O-*i*Pr)$_4$ and $HOCH_2CH_2NMe_2$ is favoured thermodynamically. Since the signal of $HOCH_2CH_2NMe_2$ is missing, no equilibrium constant could be obtained from the spectral intensities.

The equilibrium constants for Equations (4b)−(4d) were estimated considering the relative abundance of Te(*i*PrO)$_{4-n}$(OCH$_2$CH$_2$NMe$_2$)$_n$, HO*i*Pr and $HOCH_2CH_2NMe_2$ in solutions C−F, derived from the intensities of their signals. Due to experimental errors, the values obtained for K_{4b}, K_{4c} and K_{4d} vary between the different solutions as described in the following: $35 < K_{4b} < 44$, $5.4 < K_{4c} < 8.1$, and $1.1 < K_{4d} < 1.4$. Hence, substitution of O*i*Pr for $OCH_2CH_2NMe_2$ is favoured for all compounds Te(O*i*Pr)$_{4-n}$(OCH$_2$CH$_2$NMe$_2$)$_n$ (n = 0−3). The more $OCH_2CH_2NMe_2$ groups, however, are bound to the Te atom, the less favourably substitution takes place.

Information about the kinetics of reactions according to Equations (4a) and (4b) was obtained from ^{1}H NMR spectra. Sample B contains the following three moieties with isopropoxy groups: Te(O*i*Pr)$_4$, **1a** and HO*i*Pr. Nevertheless, only a single set of isopropoxy signals was observed, leading to the assumption of a rapid exchange of O*i*Pr groups between the different species. As the concentration of $HOCH_2CH_2NMe_2$ increases, two sets of signals were observed for each of the O*i*Pr and the $OCH_2CH_2NMe_2$ groups. One set of each could be attributed to the free alcohols, HO*i*Pr and $HOCH_2CH_2NMe_2$, the other one was due to an O*i*Pr and $OCH_2CH_2NMe_2$ group, respectively, both being bound to the Te atom.

Hence it follows that the exchange rate of O*i*Pr between HO*i*Pr and Te(O*i*Pr)$_{4-n}$(OCH$_2$CH$_2$NMe$_2$)$_n$ decreases with increasing n, a fact attributed to the shielding of the tellurium atom by the $OCH_2CH_2NMe_2$ ligands. This is also reflected in the widths of the ^{125}Te signals, which become sharper with increasing n. It is noteworthy that each of the NMe_2, NCH_2 and OCH_2 groups of **2** gives rise to more than a single signal in the ^{1}H NMR spectrum, with the NMe_2 and OCH_2 groups also giving two signals each in the ^{13}C NMR spectrum. This is seen to be due to differences between equatorial and apical ligands and due to differences between coordinating and noncoordinating $OCH_2CH_2NMe_2$ groups.

In contrast to the NMR titration of Te(O*i*Pr)$_4$ with $HOCH_2CH_2NMe_2$, neither titration of Te(O*i*Pr)$_4$ with $HOCH_2CH_2OMe$ nor with $HOCH_2CH_2SMe$ leads to separated signals for Te(O*i*Pr)$_{4-n}$(OCH$_2$CH$_2$XMe)$_n$ (X = O or S, n = 0−4) in the ^{125}Te NMR spectra of the respective solutions (not depicted). The addition of $HOCH_2CH_2OMe$ to a solution of Te(O*i*Pr)$_4$ in $CDCl_3$ led to an enormous line broadening with hardly any change of the chemical shift. This result is presumably due to a fast exchange between the O*i*Pr and the OCH_2CH_2OMe ligands, assuming that all species Te(O*i*Pr)$_{4-n}$(OCH$_2$CH$_2$OMe)$_n$ (n = 0−4) have a similar chemical shift, which could at least be shown for n = 0 [Te(O*i*Pr)$_4$, δ = 1538 ppm] and n = 1 (**1b**, δ = 1540 ppm). Titration of a solution of Te(O*i*Pr)$_4$ in $CDCl_3$ with $HOCH_2CH_2SMe$ led to a significant broadening and a high-field shift of the ^{125}Te NMR signal. At room temperature, no signal could be observed with 5.5 equiv. of the alcohol added, while at −20 °C a single broad signal appeared at δ = 1480 ppm. These results are explained as well through a rapid exchange between the O*i*Pr and the OCH_2CH_2SMe ligands, the high-field shift being due to the different chemical shifts of Te(O*i*Pr)$_4$ and **1c** (δ = 1519 ppm). Similar to the ^{125}Te NMR spectra, the ^{1}H NMR spectra of the solutions of Te(O*i*Pr)$_4$ with either $HOCH_2CH_2OMe$ or $HOCH_2CH_2SMe$ give only averaged signals for chemically different O*i*Pr or OCH_2CH_2XMe groups.

Crystal and Molecular Structures of 3

In Figure 2, a section of the crystal structure of **3** is shown, illustrating the coordination of the Te atoms and the intermolecular association of the molecules. In the solid state, there are two nonequivalent molecules of **3**, differing in the coordination modes of the Te atoms as well as in their conformations.

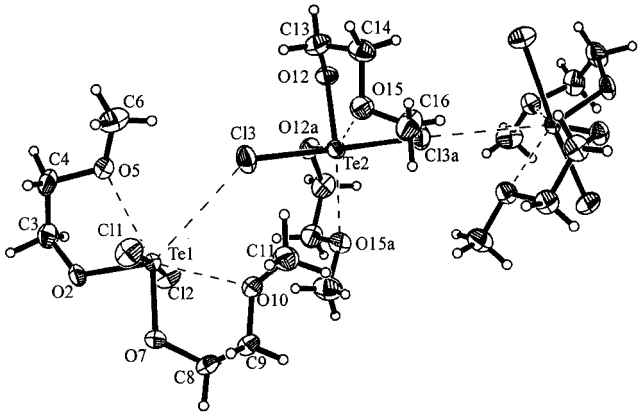

Figure 2. Molecular structure of **3** in the solid state; displacement ellipsoids are at the 50% probability level

Te1 exhibits heptacoordination with a distorted pentagonal-bipyramidal configuration (see bond angles in Table 2); Te1, O2, O5, O7 and O10 are nearly in a plane. Due to the effect of the lone pair of Te1, Cl3 lies slightly outside the plane. The two methyl groups bound to O5 and O10, respectively, are *cis* with respect to the O5−Te1−O10 plane. In contrast to Te1, Te2 is hexacoordinate with a stereochemically active lone pair, leading to a distorted pseudo-pentagonal-bipyramidal configuration; Te2 lies on a twofold axis and the entire molecule exhibits C_2 symmetry. Hence, the methyl groups bound to O15 and O15a, respectively, are *trans* with respect to the O15−Te2−O15a plane. Considering the covalent bonds of the Te atoms only, Te1 and Te2 exhibit pseudo-trigonal-bipyramidal configurations, in accordance with the VSEPR rules; the Cl atoms are in the apical positions, the O atoms and the lone pair are situated in the equatorial positions.

Table 2. Selected XRD and ab initio (MP2/LANL2DZP) atomic distances (in pm) and bonding angles (in °) of **3**

	XRD		XRD	Ab initio

The molecular structure of **3**, restrained to C_2 symmetry, was optimised by ab initio methods (MP2/LANL2DZP). The optimised molecular structure agrees quite well with that of the C_2-symmetric unit in the solid state, despite the different phases (isolated vs. solid state) and the different structural types (r_e vs. r_α). An analysis of the Te···O bonds in terms of natural bond orbital interactions shows that these bonds are mainly due to n(O)−σ*(Te−O) interactions between one nonbonding orbital of the donor O atom and the antibonding orbital of the Te−O bond in *trans* position to it. The energy for both of these interactions was estimated to be 72 kJ·mol^{-1}.

Ab initio Studies

With the model compounds $Te(OH)_3OCH_2CH_2NH_2$ (**1α**), $Te(OH)_3OCH_2CH_2OH$ (**1β**), $Te(OH)_3OCH_2CH_2SH$ (**1γ**), $TeCl_3OCH_2CH_2NH_2$ (**4α**), $TeCl_3OCH_2CH_2OH$ (**4β**), and $TeCl_3OCH_2CH_2SH$ (**4γ**), the intramolecular Te···X (X = N, O, S) interactions were investigated in detail. The following two conformations were taken into consideration for each of the model compounds: one exhibiting a Te···X bond, and the second without such an interaction. The optimised molecular structures are depicted in Figures 3 and 4, and structural and energy data are given in Tables 3 and 4.

If only the covalently bound ligands are considered, the Te atoms exhibit pseudo-trigonal-bipyramidal configurations, in accordance with the VSEPR rules. The lone pair of the Te atom occupies an equatorial position, and for **4α**, **4β** and **4γ**, the apical positions are occupied by two Cl atoms which exhibit a greater distance to the Te atom than the equatorial Cl atom. An exothermal process for all model compounds is the conversion of the conformation without the Te···X bond into the conformation with the Te···X bond. From the ΔH^{298} values given in Tables 3 and 4 it follows that Te···X bonds are stronger for the trichlorotellurium(IV) alkoxides **4α**−**4γ** than for the tellurium(IV) tetraalkoxides **1α**−**1γ**, i.e. the Te atom is a better electron-pair acceptor in the former than in the latter. Furthermore, the N atom is a much better donor than the O or the S atom.

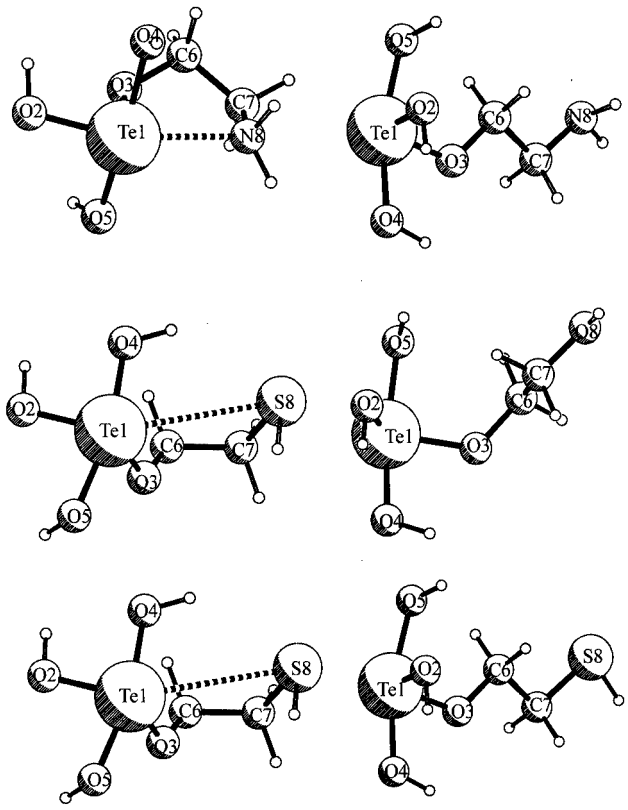

Figure 3. Ab initio molecular structures of model compounds $Te(OH)_3OCH_2CH_2NH_2$ (**1α**), $Te(OH)_3OCH_2CH_2OH$ (**1β**) and $Te(OH)_3OCH_2CH_2SH$ (**1γ**) with Te···X bond (on the left) and without Te···X bond (on the right; X = N8, O8, S8)

The results derived from thermochemical data are confirmed by an NBO analysis of the Te···X bond and by the structural parameters. The interaction of an occupied, nonbonding orbital of the donor atom, n(X), with the unoccupied, anti-bonding orbital of the Te−O or Te−Cl bond in the *trans* position, σ*(Te−O_{trans}) or σ*(Te−Cl_{trans}), is important for the Te···X bonds in $Te(OH)_3OCH_2CH_2XH_n$ and $TeCl_3OCH_2CH_2XH_n$, respectively. The energies of the n(X)−σ*(Te−Cl_{trans}) interactions in **4α**−**γ** are higher than those of the n(X)−σ*(Te−O_{trans}) interactions in **1α**−**γ**, and also higher when X is N than when X is O or S. According to second-order perturbation theory, the smaller the energy difference and the greater the overlap integral between two orbitals, the greater is the energy of their interaction. Both factors favour the interaction of n(N) compared to n(O) or n(S) with σ*(Te−Cl_{trans}) or σ*(Te−O_{trans}).

The structural parameters and their differences between the two conformations of the same model compound also serve as a measure of the strength of the Te···X bond. In the conformations of **1α**, **1β** and **4α**−**γ** with a Te···X

[a] Lorentz and polarisation corrections were performed on the data. Absorption correction was performed with the MULABS program.[17] Hydrogen atoms were localised and isotropically refined by using a riding model. All non-hydrogen atoms were refined anisotropically. [b] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [c] $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o)^2]^2\}^{1/2}$.

"bond", all Te···X distances are smaller than the sum of the van der Waals radii (155, 152, 180 and 206 pm for N, O, S and Te, respectively[12]). The Te···N distance in **4α** corresponds quite well to that in *o*-$TeCl_3[C_6H_4CH(Me)NMe_2]$ [241.1(7) pm].[13] The Te···S bond in **1γ** nearly equals the sum of the van der Waals radii and the term "bond" has to be dealt with carefully. To compare the Te···X distance for different donor atoms with different covalent radii, the relative length, *l*, is used (for definition see Tables 3 and 4).[14] Since the bond with the smaller *l* is the stronger one, the Te···X bonds are again found to be stronger with X = N than with X = O or S and stronger in **4α**−**γ** than in **1α**−**γ**. Accordingly, the Te1−Cl2 bond in the *trans* position to the Te1···X8 bond is significantly longer in **4α** than in **4β** or **4γ**, demonstrating the stronger *trans* effect of the N atom compared to the O or S atom.

Optimal π-type n_p(O3)−σ*(Te1−E2) (**1α**−**γ**: E = O; **4α**−**γ**: E = Cl) interactions are not compatible with optimal σ-type n(X8)−σ*(Te1−E2) interactions (see Figure 5). In the conformation without a Te···X "bond", the absolute values of the C6−O3−Te1−E2 torsion angles are between 60 and 80° and permit a good overlap between n_p(O3) and σ*(Te1−E2). In the conformations with a Te···X "bond" the five-membered ring formed requires enlarged C6−O3−Te1−E2 torsion angles in order to obtain X in *trans* position to the Te1−E2 bond for a good σ-type n(X8)−σ*(Te1−E2) interaction. The π-type n_p(O3)−σ*(Te1−E2) interaction is significantly reduced in such a conformation (see Tables 3 and 4, b), but at least for **1α** and **4α**−**γ** it is more than compensated by the n(X8)−σ*(Te1−E2) interaction.

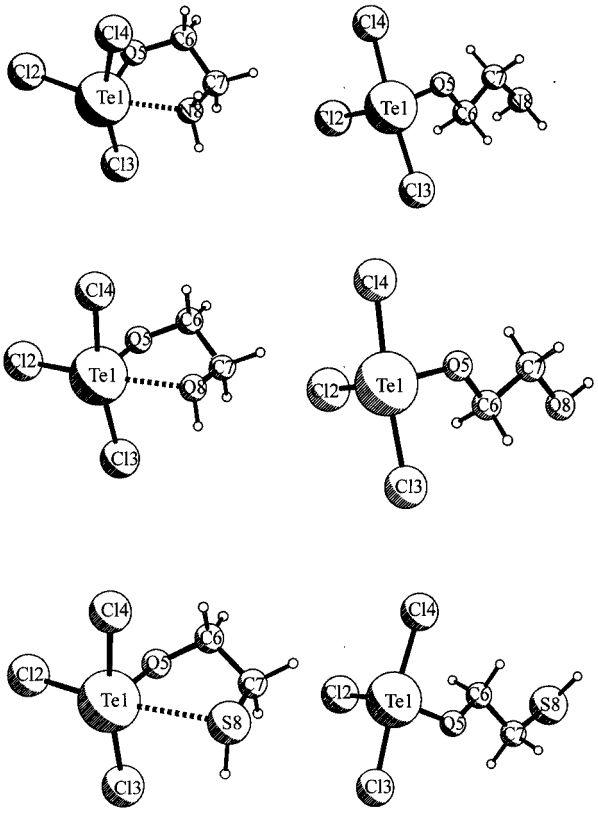

Figure 4. Ab initio molecular structures of model compounds $TeCl_3OCH_2CH_2NH_2$ (**4α**) $TeCl_3OCH_2CH_2OH$ (**4β**) and $TeCl_3OCH_2CH_2SH$ (**4γ**) with Te···X bond (on the left) and without Te···X bond (on the right; X = N8, O8, S8)

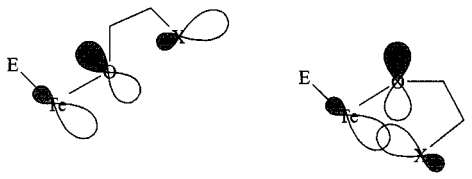

Figure 5. Conformations of the $ETeOCH_2CH_2X$ fragment for optimum π-type n_p(O)−σ*(Te−E) (on the left) and σ-type n(X)−σ*(Te−E) interactions (on the right), respectively

Conclusion

Tellurium(IV) tetraalkoxides, dichlorotellurium(IV) dialkoxides and trichlorotellurium(IV) alkoxides derived from β-donor-substituted alcohols are stabilised kinetically and thermodynamically by intramolecular Te···X interactions. In the trichlorotellurium(IV) alkoxides, this interaction re-

duces the reactivity of the Te atom towards nucleophiles and only with X = O substitution of a second Cl atom was feasible, leading to $TeCl_2(OCH_2CH_2OMe)_2$. Of all donor atoms investigated, nitrogen forms the strongest Te···X interaction. Substitution of Cl for alkoxide ligands substantially reduces the acceptor power of the Te atom; π-type $n_p(O)-\sigma^*(Te-E)$ interactions and σ-type $n(X)-\sigma^*(Te-E)$ interactions compete with each other in $TeCl_3(OCH_2CH_2XH_n)$ (E = Cl) and $Te(OH)_3(OCH_2CH_2XH_n)$ (E = O), and the stronger one determines the conformation.

Experimental Section

General Procedures: All procedures were carried out under an inert gas or under vacuum, using carefully dried glassware and solvents purified according to standard methods. $Te(OiPr)_4$ was prepared according to Mehrotra et al.[6] NMR: Bruker DRX 400, $B_1(^1H)$ = 400.000, $B_1(^{13}C)$ = 100.577, $B_1(^{125}Te)$ = 126.387 MHz; standards: TMS (^1H, ^{13}C) and $Te(CH_3)_2$ (^{125}Te). Raman: SPEX 1402, excitation with a Kr Laser (647 nm). CHNS analyses were performed with an Elemental Vario EL2.

Syntheses

Tellurium 2-(Dimethylamino)ethoxide Tris(2-propoxide), $Te(OiPr)_3OCH_2CH_2NMe_2$ (1a): A solution of 2-(dimethylamino)ethanol, $HOCH_2CH_2NMe_2$ (0.48 g, 5.3 mmol), in 30 mL of benzene was slowly added to a stirred solution of $Te(OiPr)_4$ (1.94 g, 5.3 mmol) in 50 mL of benzene. Subsequently, the benzene and 2-propanol formed during the reaction were distilled off in a slight vacuum; **1a** was isolated from the crude product by a fractionated distillation under high vacuum (113 °C/1.5 10^{-2} mbar, partial decomp.). Yield: 1.54 g (73.9%). ^1H NMR ($CDCl_3$): δ = 1.16 [d, $^3J_{H,H}$ = 6.12 Hz, 18 H, $OCH(CH_3)_2$], 2.41 [s, 6 H, $N(CH_3)_2$], 2.66 (t, $^3J_{H,H}$ = 5.2 Hz, 2 H, NCH_2), 4.17 (t, $^3J_{H,H}$ = 5.2 Hz, 2 H, OCH_2), 4.40 [m, 3 H, $OCH(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 26.2 [$OCH(CH_3)_2$], 44.0 [$N(CH_3)_2$], 59.2 (NCH_2), 61.5 (OCH_2), 64.9 [$OCH(CH_3)_2$] ppm. $^{125}Te\{^1H\}$ NMR ($CDCl_3$): δ = 1454 ppm. $C_{13}H_{31}NO_4Te$ (393.00): calcd. C 39.73, H 7.95, N 3.56 ; found C 40.47, H 7.74 N 3.24.

Tellurium 2-(Methoxy)ethoxide Tris(2-propoxide), $Te(OiPr)_3OCH_2CH_2OMe$ (1b): The preparation was carried out by analogy to that of **1a**, using 2-(methoxy)ethanol, $HOCH_2CH_2OMe$ (0.28 g, 3.7 mmol), and $Te(OiPr)_4$ (1.35 g, 3.7 mmol). The colourless and viscous crude product was washed with a small amount of dietyl ether and dried in vacuo. Yield: 1.25 g (88.9%). ^1H NMR (C_6D_6): δ = 1.33 [d, $^3J_{H,H}$ = 6.1 Hz, 18 H, $OCH(CH_3)_2$], 3.13 (s, 3 H, OCH_3), 3.30 (t, $^3J_{H,H}$ = 4.7 Hz, 2 H, H_3COCH_2), 4.21 (t, $^3J_{H,H}$ = 4.7 Hz, 2 H, $TeOCH_2$), 4.76 [sept, $^3J_{H,H}$ = 6.1 Hz, 3 H, $OCH(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 26.1 [$OCH(CH_3)_2$], 57.9 (H_3CO), 62.6 ($TeOCH_2$), 65.4 [$OCH(CH_3)_2$], 74.2 (H_3COCH_2) ppm. $^{125}Te\{^1H\}$ NMR (C_6D_6): δ = 1540 ppm. $C_{12}H_{28}O_5Te$ (379.94): C 37.94, H 7.43; found C 33.68, H 6.34%. The deviation between calculated and found data for the C,H analysis of compound **1b** is due to the thermal instability of the compound and its sensitivity to air.

Tellurium 2-(Methylsulfenyl)ethoxide Tris(2-propoxide), $Te(OiPr)_3OCH_2CH_2SMe$ (1c): The preparation was carried out by analogy to that of **1a**, using (2-methylsulfenyl)ethanol, $HOCH_2CH_2SMe$ (0.37 g, 4.0 mmol), and $Te(OiPr)_4$ (1.48 g, 4.1 mmol). The colourless and viscous crude product was washed with a small amount of diethyl ether and dried in vacuo. Yield: 1.62 g (98.2%). ^1H NMR (C_6D_6): δ = 1.30 [d, $^3J_{H,H}$ = 6.1 Hz, 18 H, $OCH(CH_3)_2$], 1.85 (s, 3 H, SCH_3), 2.54 (t, $^3J_{H,H}$ = 6.2 Hz, 2 H, SCH_2), 4.17 (t, $^3J_{H,H}$ = 6.2 Hz, 2 H, OCH_2), 4.71 [sept, $^3J_{H,H}$ = 6.1 Hz, 3 H, $OCH(CH_3)_2$] ppm. $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 26.1 [$OCH(CH_3)_2$], 37.9 (SCH_2), 61.4 (OCH_2), 65.7 [$OCH(CH_3)_2$] ppm; the signal of (H_3CS) was not observed. $^{125}Te\{^1H\}$ NMR (C_6D_6): δ = 1519 ppm. $C_{12}H_{28}O_4STe$ (396.02): C 36.40, H 7.13, S 8.10; found C 35.36, H 6.70, S 8.32.

Tellurium Tetrakis[2-(dimethylamino)ethoxide], $Te(OCH_2CH_2NMe_2)_4$ (2): The preparation was carried out by analogy to that of **1a**, using $Te(OiPr)_4$ (1.15 g, 3.2 mmol), 2-(dimetylamino)ethanol, $HOCH_2CH_2NMe_2$ (1.16 g, 13.0 mmol), and 50 mL of benzene. The colourless and viscous crude product was washed with a small amount of diethyl ether and dried in vacuo. Yield: 1.21 g (80.0%). ^1H NMR ($CDCl_3$): δ = 2.36 + 2.25 + 2.21 [3 s, 24 H, $N(CH_3)_2$], 2.83 + 2.68 + 2.45 + 2.41 (4 m, 8 H, NCH_2), 4.36 + 4.09 + 4.01 + 3.54 (4 m, 8 H, OCH_2) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 43.5 + 44.9 [$N(CH_3)_2$], 58.4 (NCH_2), 60.3 + 62.4 (OCH_2) ppm. $^{125}Te\{^1H\}$ NMR ($CDCl_3$): δ = 1410 ppm. Raman: $\tilde{\nu}$ = 2941 [vs, ν(C−H)], 2863 [s, ν(C−H)], 2827 [s, ν(C−H)], 2784 [s, ν(C−H)], 2766 [s, ν(C−H)], 781 [m, ν(Te−O)], 711 [w, ν(Te−O)], 571 [m, ν(Te−O)], 533 [vs, ν(Te−O)] cm^{-1}. $C_{16}H_{40}N_4O_4Te$ (480.10): C 40.02, H 8.40, N 11.67; found C 41.02, H 8.48, N 11.79.

Tellurium Dichloride Bis[2-(methoxy)ethoxide], $TeCl_2(OCH_2CH_2OMe)_2$ (3): $TeCl_4$ (1.05 g, 3.9 mmol) and $Me_3SiOCH_2CH_2OMe$ (2.35 g, 15.9 mmol) were dissolved in 20 mL of benzene. The major part of the solvent together with the chlorotrimethylsilane formed during the reaction was then distilled off under normal pressure. The brown viscous residue was dissolved in 10 mL of toluene. From this solution **3** precipitated at −45 °C as colourless crystals. Yield: 1.27 g (93.3%). M.p. 102 °C. ^1H NMR ([D$_8$]THF): δ = 3.50 (s, 3 H, H_3CO), 3.65 (t, $^3J_{H,H}$ = 4.4 Hz, 2 H, H_3COCH_2), 4.58 (t, $^3J_{H,H}$ = 4.5 Hz, 2 H, $TeOCH_2$) ppm. $^{13}C\{^1H\}$ NMR ([D$_8$]THF): δ = 55.8 (OCH_3), 70.2 ($MeOCH_2$), 72.5 ($TeOCH_2$) ppm. $^{125}Te\{^1H\}$ NMR ([D$_8$]THF): δ = 1759 ppm. $C_6H_{14}Cl_2O_4Te$ (348.68): C 20.67, H 4.05; found C 18.93, H 3.72.

Tellurium Trichloride 2-(Dimethylamino)ethoxide, $TeCl_3OCH_2CH_2NMe_2$ (4a): $Me_3SiOCH_2CH_2NMe_2$ (3.20 g, 19.8 mmol) and $TeCl_4$ (5.32 g, 19.7 mmol) were dissolved in 80 mL of THF. The major part of the solvent together with the chlorotrimethylsilane formed during the reaction was then distilled off under normal pressure. A brownish solid precipitated which was isolated, washed several times with petroleum ether and dried in vacuo. Yield: 5.56 g (87.6%). M.p. 130 °C (decomp.). Raman: $\tilde{\nu}$ = 2975 [m, ν(C−H)], 2935 [w, ν(C−H)], 2919 [w, ν(C−H)], 1259 [w, δ(CH_2)], 1172 [w, δ(CH_3)], 764 [w, ρ(CH_2)], 590 (w), 560 [s, ν(Te−O)], 473 (m), 399 (m), 289 [s, ν(Te−Cl)], 270 [s, ν(Te−Cl)], 232 [m, ν(Te−Cl)] cm^{-1}. $C_4H_{10}Cl_3NOTe$ (322.08): C 14.92, H 3.13, N 4.35; found C 14.87, H 3.12, N 4.37.

Tellurium Trichloride 2-(Methoxy)ethoxide, $TeCl_3OCH_2CH_2OMe$ (4b): The preparation was carried out by analogy to that of **4a**, using $TeCl_4$ (2.51 g, 9.3 mmol), $Me_3SiOCH_2CH_2OMe$ (1.38 g, 9.3 mmol) and 30 mL of THF. The brown viscous residue was dissolved in 10 mL of toluene. From this solution **4b** precipitated at −45 °C as a colourless solid. Yield: 2.31 g (80.4%). M.p. 148−150 °C (decomp.). MS (field ionisation): *m*/*z* (%) = 309.8 (12) [M^+], 274.9 (100) [M − Cl]$^+$. ^1H NMR ($CDCl_3$): δ = 3.76 (s, 3 H, OCH_3), 4.03 (m, 2 H, $MeOCH_2$), 4.82 (m, 2 H, $TeOCH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 46.2 (OCH_3), 65.4 ($MeOCH_2$), 72.7

($TeOCH_2$) ppm. $^{125}Te\{^1H\}$ NMR ($CDCl_3$): δ = 1747 ppm. $C_3H_7Cl_3O_2Te$ (309.04): C 11.66, H 2.28; found C 11.98, H 2.05.

Tellurium Trichloride 2-(Methylsulfenyl)ethoxide, $TeCl_3OCH_2CH_2SMe$ (4c): The preparation was carried out by analogy to that of **4a**, using $TeCl_4$ (2.30 g, 8.5 mmol), $Me_3SiOCH_2CH_2SMe$ (1.42 g, 8.6 mmol) and 30 mL of THF. From the yellow solution, which remained after distillation of the main part of the solvent and the chlorotrimethylsilane, a colourless solid precipitated which was washed with petroleum ether and dried in vacuo. Yield: 1.71 g (61.6%). M.p. 170−173 °C (decomp.). MS (field ionisation): *m*/*z* (%) = 325.8 (100) [M^+], 288.8 (22) [M − Cl]$^+$. ^1H NMR ([D$_8$]THF): δ = 2.52 (s, 3 H, SCH_3), 3.18 (t, $^3J_{H,H}$ = 5.2 Hz, 2 H, SCH_2), 5.04 (t, $^3J_{H,H}$ = 5.2 Hz, 2 H, OCH_2) ppm. $^{13}C\{^1H\}$ NMR ([D$_8$]THF): δ = 16.4 (SCH_3), 39.2 (SCH_2), 64.7 (OCH_2) ppm. $^{125}Te\{^1H\}$ NMR ([D$_8$]THF): δ = 1693 ppm. $C_3H_7Cl_3OSTe$ (325.10): C 11.08, H 2.17, S 9.86; found C 11.36, H 2.36, S 10.04.

Single-Crystal X-ray Diffraction: The single-crystal X-ray diffraction experiment was performed with a SMART CCD (Bruker AXS) diffractometer with low-temperature unit, employing Mo-K_α radiation (λ = 71.073 pm). The crystal structure was solved with direct methods and difference Fourier analysis (SIR-92)[15] and refined against F^2 (SHELXL-97).[16] For further details, see Table 5. CCDC-173865 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Methods: The ab initio calculations were performed by using the GAUSSIAN-94 and GAUSSIAN-98 software packages.[18,19] For these the following procedure was applied: Starting from a molecular structure with reasonable atomic distances, bond and torsion angles, the energy was calculated at the Hartree Fock level, using an effective core double-zeta pseudopotential basis set,[20,21] augmented by d-type polarisation functions for all non-hydrogen atoms, with exponents for Te, S and Cl according to Höllwarth et al,[22] and 0.75, 0.80 and 0.85 for C, N and O, respectively (HF/LANL2DZP). The geometry was optimised by using energy gradients obtained according to the algorithm of Schlegel,[23] and the HF/LANL2DZP energy of the stationary point reached at the end of the optimisation was calculated. The HF/LANL2DZP-optimised geometry was re-optimised by using energy gradients from second-order perturbation calculation according to Møller and Plesset using the above-mentioned basis set (MP2/LANL2DZP). Again, the energy of the stationary point at the end of the optimisation was calculated. The chemical bonds of the optimised molecule were analysed in terms of natural bond orbitals (NBO).[24,25] The normal modes of vibration were then calculated from numerical (GAUSSIAN94) or analytical (GAUSSIAN98) force constants. By means of statistical thermodynamics, the enthalpy at 298 K, H^{298}, was calculated. Only MP2/LANL2DZP molecular structures, energies, and enthalpies are given in this paper.

Synthesis and Crystal Structures of the First Two Novel Dicarboxylate Organotin Polymers Constructed from Dimeric Tetraorganodistannoxane Units

Rui-Hu Wang,[a] Mao-Chun Hong,*[a] Jun-Hua Luo,[a] Rong Cao,*[a] and Jia-Bao Weng[a]

Keywords: Carboxylate ligands / Tin / X-ray diffraction / Polymers

Assembly of nitroterephthalic acid (H_2NTPA) or diphenic acid (H_2DPA) with trimethyltin chloride under hydrothermal conditions produces a one-dimensional chain polymer $[(Me_2Sn)_2(\mu_3\text{-NTPA})(\mu_3\text{-O})]_n$ (**1**) or a two-dimensional corrugated sheet polymer $[(Me_2Sn)_4(\mu_3\text{-DPA})(\mu_4\text{-DPA})(\mu_3\text{-O})_2]_n$ (**2**), respectively. Both consist of different types of dimeric dicarboxylatotetraorganodistannoxane secondary building units.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

The design and synthesis of novel coordination polymers with unusual and tailorable structures are fundamental steps to discover and fabricate various technologically useful materials.[1−4] The majority of such species have been constructed from organic ligands and metal ions by spontaneous self-assembly. Recently, much effort has been devoted to the design and construction of new supramolecular frameworks by using metal clusters[5,6] or metal-organic secondary building units (SBUs)[7−13] as building blocks, and multifunctional organic ligands as linkers. Such assembly has resulted in a host of intriguing structural topologies and an extensive application in material science. For instance, the use of carboxylate-bridged zinc clusters as metal-organic SBUs and 1,4-benzenedicarboxylate or 1,3,5-benzenetricarboxylate as linkers by Yaghi et al. has provided several novel porous metal-organic frameworks which can absorb and desorb small gas molecules.[9−13]

It is well-known that the discrete dimeric dicarboxylatotetraorganodistannoxane complexes $\{[R_2Sn(O_2CR')_2O]_2\}$ have been extensively studied due to their wide application in biology and catalysis; most of them were obtained by the assembly of monofunctional carboxylate ligands and organotin reagents.[14−20] To the best of our knowledge, the crystal structures of only two organotin polymers containing dimeric tetraorganodistannoxane units have been reported.[21,22] It is predictable that extended structures may be obtained by using bifunctional dicarboxylate ligands instead of monofunctional carboxylate ligands as linkers and the dimeric tetraorganodistannoxane as nodes. However, the reported dicarboxylate organotin complexes exist as dinuclear[23−25] and one-dimensional zigzag chain structures.[26−29] With the aim of extending the chemistry of dimeric dicarboxylatotetraorganodistannoxane, we have recently begun to study the reactions of organotin and di- or polycarboxylic acid ligands under hydrothermal conditions. Here we report the syntheses and crystal structures of two novel organotin complexes consisting of dimeric dicarboxylatotetraorganodistannoxane SBUs, $[(Me_2Sn)_2(\mu_3\text{-NTPA})(\mu_3\text{-O})]_n$ (**1**) and $\{(Me_2Sn)_4(\mu_3\text{-DPA})(\mu_4\text{-DPA})(\mu_3\text{-O})_2\}_n$ (**2**), assembled from nitroterephthalic acid (H_2NTPA) or diphenic acid (H_2DPA) with trimethyltin chloride under hydrothermal conditions.

The hydrothermal reaction of H_2NTPA or H_2DPA, 4,4′-bipyridne and trimethyltin chloride in a molar ratio 1:1:2 at 140 °C for three days produced colorless crystals of **1** or **2**, respectively (Scheme 1). These compounds are insoluble in common solvents, such as water, methanol, acetone, acetonitrile, dichloromethane, tetrahydrofuran, *N*,*N*′-dimethylformamide and dimethyl sulfoxide. The presence of the carboxylate group was confirmed by very strong IR absorption peaks in the solid-state spectrum at 1647 and 1365 cm^{-1} for **1** and 1699 and 1680 cm^{-1} for **2**. Signals for the nitro group in **1** were identified at 1549, 1531 and 1340 cm^{-1}; these values are unchanged with respect to those of the starting acid.

A single crystal X-ray diffraction analysis reveals that complex **1** has a one-dimensional chain motif constructed from novel approximately rectangular rings. As shown in Figure 1, each ring is composed of two NTPAs and two dimeric tetraorganodistannoxane units. The dihedral angle of the two phenyl rings in the ring is 91.9° i.e. they are almost perpendicular. NTPA in a μ_3-bridging mode links two dimeric tetraorganodistannoxane units and the dimeric tetraorganodistannoxane units are shared by the approximate rectangular rings to form a one-dimensional chain coordination polymer. This structural feature of **1** is quite different from that of $\{([Me_2Sn(OAc)]_2O)_2\}_n$, the only known one-dimensional organotin polymer, in which the acetate

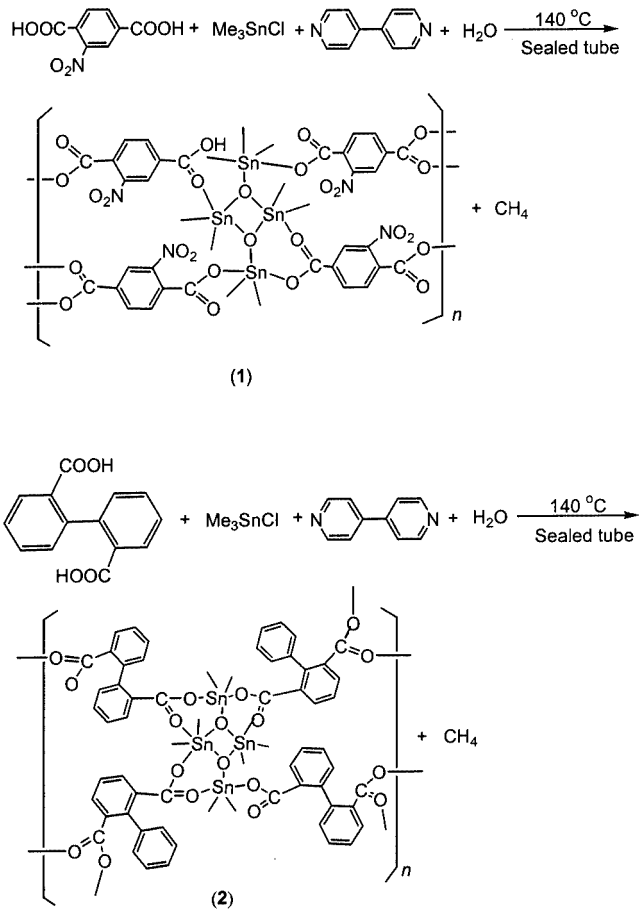

Scheme 1. Synthesis of complexes **1** and **2**

links the dimeric tetraorganodistannoxane units in a tetradentate mode.[21]

The SBU in **1** is the predominant structural form in five types of dimeric dicarboxylatotetraorganodistannoxane in which each Sn atom is in a five-coordinate geometry.[14] It consists of a central planar $(Me_2Sn)_2O_2$ four-membered ring and two peripheral Me_2Sn units attached to two μ_3-oxygen atoms. NTPA acts as a tridentate ligand which coordinates to an outer Sn atom through an oxygen atom of the carboxylate adjacent to NO_2 and chelates between exocyclic and endocyclic Sn atoms forming a stable six-membered ring through the other carboxylate oxygen atoms. The NO_2 in NTPA is not involved in coordination to Sn atoms. Thus, the Sn atoms in the SBU adopt a distorted trigonal bipyramidal geometry. The exocyclic and endocyclic Sn atoms lie 0.1442 and 0.1492 Å out of the plane defined by the three coordinated oxygen atoms, respectively.

Complex **2** is a two-dimensional corrugated sheet polymer made up of the dimeric tetraorganodistannoxane units and bridging DPA ligands. As shown in Figure 2, the SBU in **2** is different from that in complex **1**. The central four-membered ring $(Me_2Sn)_2O_2$ is connected to two independently exocyclic Sn atoms through μ_3-oxygen atoms. The distance between the two Sn atoms in the four-membered ring is 3.325 Å, which is longer than 3.264 Å in complex **1**, but smaller than the sum of the van der Waals radii of Sn^{II} (3.40 Å), suggesting the possible presence of a weak metal-metal interaction. There are two types of DPA ligands which are distinguished by their bridging fashions. One acts as a tetradentate ligand and bridges a pair of exocyclic and endocyclic Sn atoms to form two stable six-membered rings; the other adopts a μ_3-bridging mode through bonding to an exocyclic Sn atom and chelating between exocyclic and endocyclic Sn atoms. Thus, an endocyclic Sn(1) atom adopts a six-coordinate geometry with a deviation of 0.0088 Å from the plane defined by the four coordinated oxygen atoms [O(1) O(2) O(11) and O(41)], two methyl groups occupy the apical positions, with a Me−Sn(1)−Me bond angle of 157.4°, and the other endocyclic Sn(3) atom and two exocyclic Sn atoms (Sn2 and Sn4) are a five-coordinate with deviations of 0.0191, 0.1161 and 0.0110 Å from the plane defined by the coordinated oxygen atoms, respectively.

In complex **2**, DPA is a chiral ligand and the dihedral angles of two phenyl rings are 99.4° for the tridentate mode and 87.1° for the tetradentate mode. It is noteworthy that a μ_4-bridging DPA moiety links the dimeric tetraorganodist-

annoxane units, forming a helical chain, and a μ_3-bridging DPA moiety links the helical chains by ligating the remaining coordination sites of the dimeric tetraorganodistannoxane units, forming a curved two-dimensional sheet structure (Figure 3). The main structural feature of **2** is quite different from that of a two-dimensional rhombohedral grid polymer composed of ladder-type dimeric tetraorganodistannoxane units and 4-hydroxyl-3-methoxybenzoic acid dianion.[22] As shown in Figure 4, the two-dimensional sheet is folded in a highly corrugated way with DPA as the turning points when viewed along *c* axis. The distance between adjacent sheets is 9.54 Å.

In summary, this work demonstrates that the assembly of dicarboxylate ligands — such as nitroterephthalic acid and diphenic acid — and trimethyltin chloride allows for the formation of organotin polymers consisting of dimeric dicarboxylatotetraorganodistannoxane units, which act as metal-organic SBUs in the extended structures. To the best of our knowledge, they are the first dicarboxylate polymers consisting of dimeric dicarboxylatotetraorganodistannoxane SBUs of which the crystal structures have been determined. Thus, our report may open a new approach for the assembly of different types of discrete dimeric dicarboxylatotetraorganodistannoxane complexes into extended polymers through using di- or polycarboxylates as linker ligands instead of monofunctional carboxylates. Extension of this work, including more di- or polycarboxylate ligands and other organotin compounds, is in progress.

Experimental Section

Synthesis of $[(Me_2Sn)_4(\mu_3\text{-}O)_2(\mu_3\text{-}NTPA)_2]_n$ (1): A mixture of H_2NTPA (0.11 g, 0.5 mmol), 4,4′-bipyridne (0.08 g, 0.5 mmol) and

trimethyltin chloride (0.20 g, 1 mmol) in 16 mL of H_2O was placed in a Parr Teflon-lined stainless steel vessel and heated to 140 °C for 72 h, then cooled to room temperature during 5 hours. Colorless crystals were obtained and collected by filtration and washed with water. Yield: 56%. $C_{12}H_{15}NO_7Sn_2$ (522.6): calcd. C 27.58, H 2.87, N 2.68; found C 27.23, H 2.67, N 2.54. IR (KBr pellet): $\tilde{\nu}$ = 3456 (w), 3084 (vw), 2918 (vw), 1647 (s), 1591 (s), 1549 (m), 1531 (s), 1491 (m), 1412 (s), 1365 (s), 1340 (s), 1304 (m), 1254 (w), 1147 (vw), 1066 (vw), 928 (vw), 825 (w), 796 (m), 783 (m), 633 (m), 577 (m), 499 (m) cm^{-1}.

Synthesis of $\{(Me_2Sn)_4(\mu_3\text{-}O)_2(\mu_3\text{-}DPA)(\mu_4\text{-}DPA)\}_n$ (2): The procedure is similar to the synthesis of complex **1** except that H_2DPA (0.12 g, 0.5 mmol) was used instead of H_2NTPA. Yield: 70%. $C_{36}H_{40}O_{10}Sn_4$ (1107.5): calcd. C 39.04, H 3.61; found C 39.32, H 3.43%. IR (KBr pellet): $\tilde{\nu}$ = 3061 (w), 2864 (m), 2825 (m), 1699 (s), 1680 (s), 1599 (s), 1572 (m), 1539 (w), 1475 (w), 1452 (w), 1412 (w), 1360 (s), 1250 (s), 1213 (s), 1140 (m), 1099 (w), 1063 (m), 1003 (m), 939 (w), 822 (vw), 808 (m), 796 (m), 758 (m), 708 (w), 625 (m), 584 (vw) cm^{-1}.

X-ray crystallography: The crystal data and structure determination summary for **1** and **2** are listed in the Table 1. Intensity data for **1** and **2** were measured on a Siemens Smart CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 298 K. Empirical absorption corrections were applied with the SADABS program. The structures were solved by direct methods and all calculations were performed using the SHELXL PC program. The positions of the H-atoms were generated geometrically (C−H bond fixed at 0.96 Å), assigned isotropic thermal parameters, and allowed to ride on their parent carbon atoms before the final cycle of refinement. The structures were refined by full-matrix least-squares minimization of $\Sigma(F_o - F_c)^2$ with anisotropic thermal parameters for all atoms except the H-atoms.
CCDC-181351 (**1**) and -181352 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A Single-Strand Helical Motif Induced by Self-Assembly of $[Ag(TFP)]^+$ Moieties with Nitrate Anions − ^{31}P NMR Spectroscopic and X-ray Crystal Structure Characterization of the Complexes Involved in Equilibrium Reactions of Silver Salts and TFP Ligand

Fiorella Bachechi,[a] Alfredo Burini,*[b] Rossana Galassi,[b] Bianca Rosa Pietroni,[b] and Dania Tesei[b]

Keywords: P ligands / Silver / Helical structures / NMR spectroscopy / Equilibrium reactions

The ability of the ligand tris(2-furyl)phosphane (TFP) to coordinate Ag^I ions has been investigated. The molar ratio and the nature of the counterions used (NO_3^-; BF_4^-) affected the reaction. Moreover, equilibrium reactions were observed and the $[Ag(TFP)_n]^+$ (n = 1–4) species involved were identified by variable-temperature ^{31}P NMR spectroscopy. The $[Ag(TFP)_3]BF_4$ complex turned out to be the more labile species in solution and it disproportionates by means of an S_N2 mechanism to yield the complexes $[Ag(TFP)_2(H_2O)]BF_4$ (**3**) and $[Ag(TFP)_4]BF_4$ (**4**). Most of the compounds detected in solution were isolated and characterized in the solid state. The molecular structures of the complexes $[Ag(TFP)NO_3]$ (**1**), $[Ag(TFP)_3NO_3]$ (**2**), and $[Ag(TFP)_2(H_2O)]BF_4$ (**3**) were determined by X-ray crystal structure diffraction confirming the solution characterization data. In these structures the TFP ligand was always only bonded to the metal centre by the phosphorous atom. It is noteworthy to underline that the molecular structure of complex **1** consists of an infinite single-strand helix arising from the ability of the bridging nitrate anions to connect the $[Ag(TFP)]^+$ units. In the structure the nitrate anions are coordinated to the metal centres in unusual modes acting simultaneously as chelating and bridging ligands.

Introduction

There is a growing interest in investigating the role of tris(2-furyl)phosphane (TFP) in catalytic systems[1] and a comparative study between the function of Ph_3P or TFP in palladium(0)-catalysed reactions has been reported.[2] The coordinative ability of TFP with transition metal ions is not well known and few examples of TFP complexes have been structurally characterized, i.e. $[Fe_2(CO)_5(TFP)\mu\text{-}P(2\text{-furyl})_2]$[3] and $[Rh(CO)Cl_2(TFP)_2HgCl]$.[4]

As a part of an investigation on the chemistry of late transition metal ions coordinated to tertiary phosphane ligands containing heterocycles[5,6] we have studied the ability of TFP to coordinate Ag^I.

Silver(I) is one of the metal ions involved in the formation of helical compounds obtained by the self-assembly of silver salts and appropriate ligands.[7,8] Helical motifs are of great current interest in supramolecular chemistry,[9] organic synthesis,[10] material science[11] and metal complex drugs.[12] In general, the organization in helical structures derives from coded self-assembly of metal ions and simple ligands. Here we report the formation of a single-strand helical polymer governed by the nitrate counterion instead of the ancillary ligand coordinated to the metal centre. It is well known that even weakly coordinating anions have an effect on the coordination number and on the molecular structure of the transition metal complexes.[13] Thus, as far as silver(I) derivatives are concerned, different arrangements occur depending on the anion used. Tetranuclear cubane-like compounds $[AgPR_3X]_4$ (R = Et or Ph) were isolated when strongly coordinating anions (X^-) such as Cl^- or Br^- were used,[14,15] while mononuclear derivatives (i.e. $[Ag(PCy_3)_2NO_3]$, $[Ag(PCy_3)_2ClO_4]$) have been obtained by using weakly coordinating anions. In these last examples the silver ions are tetracoordinated and tricoordinated, respectively.[16] However, bicoordinated $[Ag(PR_3)_2]X$ compounds have also been structurally characterized {e.g.$[Ag\{P(CH_2CH_2CN)_3\}_2]NO_3$,[17] $[Ag\{P(mes)_3\}_2]PF_6$ (mes = $C_6H_2Me_3$-2,4,6)}.[18] Moreover, the NO_3^- counterion influences the ring conformations and the nuclearity of cyclic silver derivatives.[5,19]

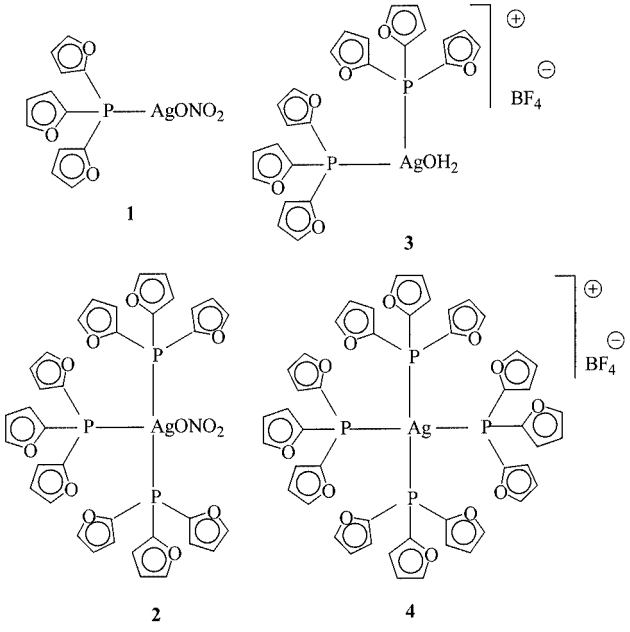
Results and Discussion

The reactions of TFP phosphane ligand with silver(I) ions were affected by the molar ratio and by the nature of

the counterion used and equilibrium reactions were observed. With $AgNO_3$ as the silver salt and a 1:1 or 1:3 Ag/TFP molar ratio, the complexes $[Ag(TFP)NO_3]$ (**1**) and $[Ag(TFP)_3NO_3]$ (**2**) were isolated. Two other species: $[Ag(TFP)_2(H_2O)]BF_4$ (**3**) and $[Ag(TFP)_4]BF_4$ (**4**) were obtained treating TFP with $AgBF_4$ in THF solution and with either a 1:1 or 1:2 Ag/TFP molar ratio. Compound **4** is insoluble in THF and for this reason it was easily separated from the reaction mixture containing the more soluble compound **3**. However, compound **4** can be obtained in good yields when the right stoichiometry is used. The silver complexes synthesized and studied are represented in Scheme 1.



Scheme 1

The molecular structures of compounds **1**−**3** were obtained by X-ray crystal structure determinations while the species present in solution were identified by variable-temperature ^{31}P NMR investigations.

Molecular and Crystal Structure of $[Ag(TFP)NO_3]$ (1)

The molecular structure of complex **1** with the atom numbering scheme is shown in Figure 1 and selected bond lengths and angles are listed in Table 1. In the solid-state structure of **1**, the silver ion is tetracoordinated. It is only linked to the potentially bidentate TFP ligand by the phosphorus atom; with a P(1)−Ag(1) distance of 2.366(3) Å. This length is short but still in the range of the P−Ag bond lengths (2.50−2.37 Å) found in other tertiary (phosphane)-silver derivatives.[16,17,20,21] The coordination sphere around the silver ion is completed by three oxygen atoms of the nitrate anion which is coordinated to the metal centre in quite a complex and unusual mode. In fact the nitrate group is bonded to the silver ion by O(4) [Ag(1)−O(4) = 2.38(1) Å] and O(6) [Ag(1)−O(6) = 2.63(1) Å] as an asymmetric

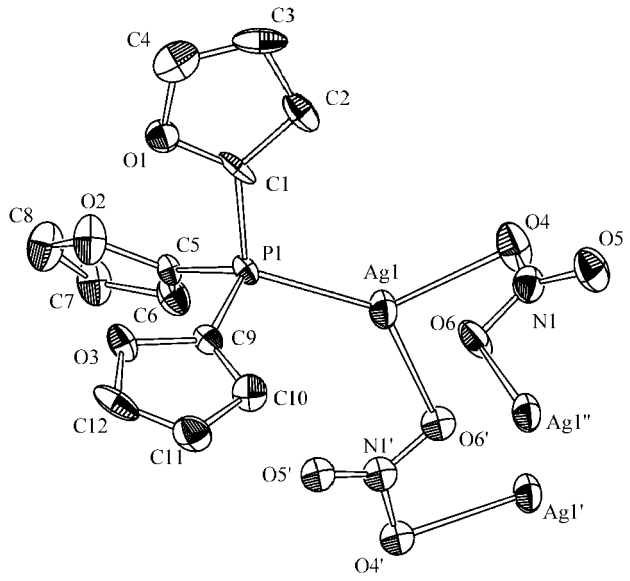


Figure 1. ORTEP plot of complex **1**, with the numbering schemes of the atoms; primed atoms are related by $P2_1$ symmetry with operators $-x$, $1/2 + y$, $1/2 - z$ for Ag(1) and $-x$, $-1/2 + y$, $1/2 - z$ for Ag(1′); thermal ellipsoids are shown at 40% probability levels

chelating ligand. In addition, O(6′) [symmetry-related by a 2_1 screw axis to O(6)] is coordinated to the same silver ion Ag(1) [Ag(1)−O(6′) = 2.35(1) Å] and O(6) is coordinated to a silver ion Ag(1′′) {symmetry-related by a 2_1 screw axis to Ag(1)} [Ag(1′′)−O(6) = 2.35(1) Å]. In this way the nitrate anion acts as both a chelating and a bridging ligand. On the whole the Ag−O distances observed in compound **1** are similar to those found in $[Ag(PPh_3)NO_3]$ showing a zigzag chain of $AgNO_3$,[20] but they are shorter than those found in the related polymeric helical complex $[Ag(pydz)NO_3]$ (pydz = pyridazine).[7] However, the most relevant feature of the structure arises from the ability of the bridging nitrate anions to connect each $[Ag(TFP)]^+$ unit, forming an infinite single-strand helix, Figure 2. The silver ion also weakly interacts with O(5) of the 2_1-symmetry-related nitrate anion through the long 2.95(1) Å distance. Neglecting this last interaction, the coordination geometry around the metal centre can be described as a distorted tetrahedron with coordination angles P(1)−Ag(1)−O(4) = 128.1(3)°, P(1)−Ag(1)−O(6′) = 132.0(2)°, O(4)−Ag(1)−O(6′) = 99.9(3)°, and a bite angle of the nitrate group O(4)−Ag(1)−O(6) = 45.9(2)°. The crystal structure consists of the packing of single helices of both chiralities, coupled by centres of symmetry running along the *b* axis, Figure 3. The period of the helix is 7.37(1) Å and along the helix the Ag atoms lie at distances of 4.890(1) Å. The distance between Ag atoms, which belong to close centrosymmetric helices, is 5.642(2) Å. It is interesting to note that, from the particular arrangement of the helices, channels are formed in the centrosymmetric unit cell where small molecules could be trapped even though this has not yet been attempted.

Molecular Structure of $[Ag(TFP)_3NO_3]$ (2)

The molecular structure of complex **2**, with the atom numbering scheme, is shown in Figure 4 and selected bond lengths and angles are listed in Table 1. As far as we know, only one other example of $[Ag(PR_3)_3X]$ complexes has been reported in the literature, namely $[Ag(PPh_3)_3Cl]$,[22] showing a distorted tetrahedral geometry. Complex **2** contains mononuclear units in which the silver ion is five-coordinated by three phosphorus atoms of three TFP ligands and by two oxygen atoms belonging to the chelate nitrate ion. The geometry around the metal centre is a distorted square-base pyramid, where the silver ion lies 0.8098 Å out of the base formed by P(1), P(3), and two O atoms. The Ag−P bond lengths are longer [2.508(7), 2.512(7), 2.493(7) Å] than those found in complex **1** but slightly shorter than the Ag−P bond lengths found in $[Ag(PPh_3)_3Cl]$ (2.52−2.56 Å). The nitrate ion is symmetrically bonded to the silver ion with a bite angle of 42(1)° and the Ag(1)−O(11) and Ag(1)−O(12) bond lengths are 2.71(3) Å and 2.72(4) Å, respectively.

Molecular Structure of $[Ag(TFP)_2(OH_2)]BF_4$ (3)

The molecular structure of complex **3**, with the atom numbering scheme, is shown in Figure 5 and selected bond lengths and angles are listed in Table 1.

The silver atom of the sixteen-electron complex **3** is tricoordinated with a distorted trigonal geometry. The metal ion is bonded to two TFP ligands by the P atoms and to one oxygen atom of a water molecule. The two Ag−P bond lengths are equivalent [2.425(3) Å and 2.426(2) Å]. They are very close to those found in $[Ag\{P(C_6H_4Me\text{-}m)_3\}_2NO_3]$[17] (2.4128 Å), shorter than those found in $[Ag(PPh_3)_2NO_3]$[23] and $[Ag(PCy_3)_2NO_3]$ (ca. 2.44 Å),[16] but longer than those found in $[Ag(PCy_3)_2ClO_4]$[16] [2.394(2), 2.393(3) Å] and in $[Ag\{P(CH_2CH_2CN)_3\}_2]NO_3$ [2.3832(9) Å].[17] The P(1)−Ag(1)−P(2) angle is 131.2(1)°. In the molecular structure of complex **3** an oxygen atom of a water molecule is coordinated to the metal ion [Ag(1)−O(7) 2.36(1) Å], revealing the poor coordinative ability of the oxygen atoms present in the furyl rings of the TFP ligand. Only one structure was recently reported,[4]

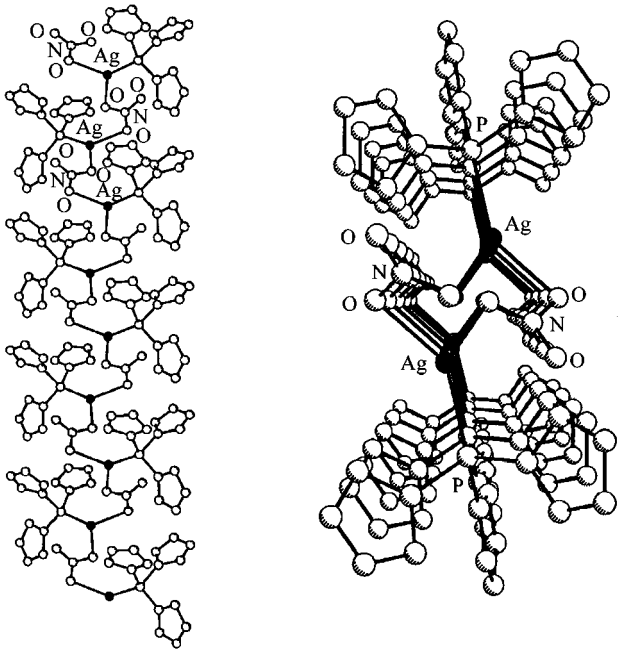

Figure 2. Complex **1**: (left) side view of the helical polymer chain extended along the crystallographic *b* axis with a helical period of 7.370(1) Å; the distance between Ag atoms is 4.891(1) Å; (right) top view along the axis of the polymer chain showing the twofold helical symmetry of the structure

where the furyl rings interact through the oxygen atoms to the metal centre {i.e. $[Rh(CO)Cl_2(TFP)_2HgCl]$; Hg−O distances 2.855(3) and 3.025(3) Å}. The BF_4^- anion is present in the structure of **3** as a counterion and weakly interacts with the water molecule [O(7)···F(1) 3.09 Å and O(7)···F(2) 2.93 Å].

^{31}P NMR Spectroscopic Investigation

The isolation in the solid state of several $[Ag(TFP)_nX]$ (n = 1−4; X = NO_3; BF_4) species highlights that equilibrium reactions could occur in solution. On the other hand silver(I) complexes are known to behave in this way when coordinated to labile monodentate ligands.[24,25] Thus to in-

[a] The spectrum was recorded at 193 K in $CDCl_3$ + CF_2Br_2 solution.

vestigate this aspect, variable-temperature ^{31}P NMR spectra were recorded on compounds **1**−**4**, Table 2.

Compound **1**, that has a polymeric nature in the solid state, probably exists as a monomeric unit in solution. This hypothesis is reasonable because the silver ions forming the helical structure are held together only by bridging nitrate groups that, in solution, can easily break the bridging bonds. On the other hand the loss of the polymeric nature of compound **1** is underlined by the presence of the equilibrium reaction to be discussed.

Owing to rapid intermolecular ligand exchange in $CDCl_3$ solution, the ^{31}P NMR spectrum of compound **1**, recorded at 296 K, shows a broad signal at δ = −56.30 that is shifted to lower fields with respect to the free TFP ligand (δ = −77.37). By cooling the solution at 218 K the signal sharpened into two doublets of doublets, Figure 6. Each doublet of doublets is due to the spin-spin coupling of the phosphorus atom of the ligand with the two magnetically active isotopes of the silver ion (^{107}Ag spin 1/2, natural abundance 51.82%; ^{109}Ag spin 1/2, natural abundance 48.18%). Taking into consideration that the coupling constants decrease when the number of the phosphane ligands coordinated to the silver ion increase, the two AB systems of the ^{31}P NMR spectrum were assigned to $[Ag(TFP)NO_3]$ (**1**) and $[Ag(TFP)_2NO_3]$ complexes. Thus the signal centred at δ = −63.30, $^{1}J(^{31}P,^{107}Ag)$ = 699 Hz and $^{1}J(^{31}P,^{109}Ag)$ = 803 Hz was assigned to compound **1**; while the doublet of doublets centred at δ = −62.40, $^{1}J(^{31}P,^{107}Ag)$ = 467 Hz and $^{1}J(^{31}P,^{109}Ag)$ = 537 Hz was attributed to the compound $[Ag(TFP)_2NO_3]$. The values of the coupling constants observed for both complexes are in perfect agreement with the expected magnetogyric ratios. This interpretation of the spectrum was confirmed by the isolation in the solid state of complex $[Ag(TFP)_2(OH_2)]BF_4$ (**3**) showing the chemical shift of the ^{31}P nucleus and the Ag,P coupling constants similar to that observed for the species $[Ag(TFP)_2NO_3]$ identified only in solution (see discussion reported below). From the data the following equilibrium reaction seems to occur in solution:

$2\ [Ag(TFP)NO_3] \rightleftarrows [Ag(TFP)_2NO_3] + AgNO_3$.

The ^{31}P NMR spectrum of the analytically pure sample of $[Ag(TFP)_3NO_3]$ (**2**) recorded in $CDCl_3$ solution at 296 K shows two signals, a sharp one at δ = −11.14 and a broad one at δ = −57.00. By cooling the solution to 218 K the phosphorus, silver spin-spin coupling is solved, Figure 7. The spectrum shows a singlet at δ = −10.00 assigned to tris(2-furyl)phosphane oxide and a doublet of doublets at δ = −62.40 [$^{1}J(^{31}P,^{107}Ag)$ = 467 Hz and $^{1}J(^{31}P,^{109}Ag)$ = 537 Hz] that, as reported above, belongs to the $[Ag(TFP)_2NO_3]$ complex. Thus, we can conclude that when the complex $[Ag(TFP)_3NO_3]$ is dissolved in the presence of atmospheric oxygen, it gives rise to a dissociative process, and a fast oxidation of the free TFP ligand occurs. The lability of complex **2** in solution results in low yields of this compound.

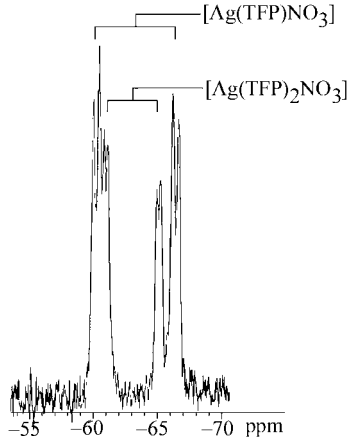

Figure 6. ^{31}P NMR spectrum recorded at 218 K; the signal centred at δ = −63.30 belongs to the complex $[Ag(TFP)NO_3]$ (**1**) while the doublet of doublets centred at δ = −62.40, was attributed to the compound $[Ag(TFP)_2NO_3]$

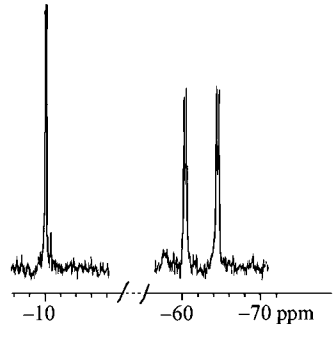

Figure 7. ^{31}P NMR spectrum recorded at 218 K; the species $[Ag(TFP)_3NO_3]$ decomposed in $CDCl_3$ solution to give tris-(2-furyl)phosphane oxide and $[Ag(TFP)_2NO_3]$ signals at δ = −10.00 and −62.40, respectively

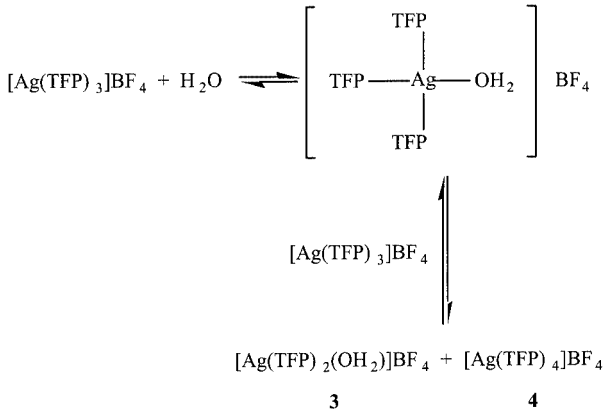
Differing from the compounds discussed above, complexes **3** and **4** were simultaneously obtained by the same reaction mixture (see Exp. Sect.). This could be explained taking into consideration, the hypothesis, that in the first step the labile complex $[Ag(TFP)_3]BF_4$ is formed, which disproportionates to give the bis and tetrakis complexes **3** and **4**, respectively. The plausible S_N2 mechanism is reported in Scheme 2. The presence of water molecules in the reaction mixture could be due to the highly hygroscopic $AgBF_4$ salt used in the reaction.



Scheme 2

The proposed mechanism and the equilibrium reactions involved were confirmed by the ^{31}P NMR spectrum obtained after dissolving an analytical sample of **3** in $CDCl_3$. The spectrum recorded at 193 K is shown in Figure 8. It consists of three systems centred at $\delta = -60.08$, -58.42, and -56.74. On the basis of the coupling constants the doublet of doublets at $\delta = -60.08$ [$^1J(^{31}P,^{107}Ag) = 519$ Hz and $^1J(^{31}P,^{109}Ag) = 573$ Hz] was assigned to complex **3**, while the doublet of doublets at $\delta = -56.74$ [$^1J(^{31}P,^{107}Ag) = 246$ Hz and $^1J(^{31}P,^{109}Ag) = 285$ Hz] was attributed to the tetrakis complex **4**. The different chemical shift (ca. 2 ppm) of **3** compared to that observed in the analogous $[Ag(TFP)_2NO_3]$ complex, could be due to the influence of the different anions of these two complexes or to the water molecule presents in the coordination sphere of **3**. The last signal of the spectrum centred at $\delta = -58.42$ consists of an unresolved doublet of doublets belonging to the species $[Ag(TFP)_3]BF_4$, that being labile, gives quite a broad signal at low temperatures. The complex was not isolated in the solid state; thus, it seems to be only a transient species in solution.

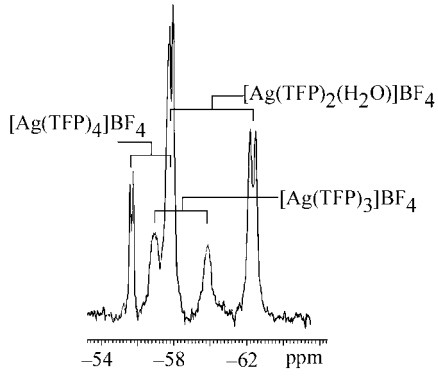


Figure 8. ^{31}P NMR spectrum recorded at 193 K; the three systems centred at $\delta = -60.08$, -58.42, and -56.74 were assigned to the complexes $[Ag(TFP)_2(H_2O)]BF_4$ (**3**) $[Ag(TFP)_3]BF_4$ and $[Ag(TFP)_4]BF_4$ (**4**), respectively

A successful attempt to obtain complex **4** in good yield was done treating the TFP ligand and $AgBF_4$ in a 4:1 molar ratio; from this reaction mixture only a small amount of complex **3** was obtained. The ^{31}P NMR spectrum of an analytical sample of **4** recorded at 296 K shows a sharpened signal at $\delta = -57.48$ that is solved in a doublet of doublets at 218 K, the chemical shifts and the coupling constants observed were the same as those reported above. The ligand lability of complex **4** is confirmed by the loss of the Ag,P coupling at temperatures above ca. 218 K.

Experimental Section

General: Elemental analyses were carried out with a Carlo Erba 1106 elemental microanalyser. ^1H and ^{31}P NMR spectra were performed in $CDCl_3$ solution with Varian VXR-300 spectrometers. Referencing is relative to TMS (^1H) and 85% H_3PO_4 (^{31}P). Variable-temperature ^{31}P NMR spectroscopic experiments were recorded over the temperature range 193−296 K. The reactions were carried out in the darkness at room temperature under nitrogen and with purified solvents.

Reaction of TFP with $AgNO_3$ (1:1 Molar Ratio); Compound 1: To a solution of TFP (0.10 g; 0.43 mmol) in THF (6 mL), crystalline $AgNO_3$ (0.074 g; 0.43 mmol) was added. Methanol (4 mL) was added to the reaction mixture to solubilize the silver salt. After 2 h, the solution was concentrated to dryness. The crude product was crystallized by slow diffusion of hexane into a dichloromethane solution. Colourless needles of **1** suitable for an X-ray crystal structure determination were formed after a few days (yield 0.104 g, 60%). $C_{12}H_9AgNO_6P$ (**1**) (402.0): calcd. C 35.85, H 2.26, N 3.48; found C 36.25, H 2.35, N 3.26. ^1H NMR ($CDCl_3$; 296 K): $\delta = 6.51$ (m, 3 H), 7.11 (m, 3 H), 7.74 (m, 3 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$; 296 K): $\delta = -56.30$ (m, br.)

Reaction of TFP with $AgNO_3$ (3:1 Molar Ratio); Compound 2: To a solution of TFP (0.10 g; 0.43 mmol) in THF (6 mL), crystalline $AgNO_3$ (0.024 g; 0.14 mmol) and methanol (4 mL) were added. After 2 h, the solution was concentrated to dryness. The solid obtained was dissolved in the minimum amount of dichloromethane and, after filtration, the solution was cooled to 4 °C. Colourless crystals of **2** suitable for an X-ray crystal structure determination grew overnight (yield 0.030 g; 30%). $C_{36}H_{27}AgNO_{12}P_3$ (**2**) (866.4): calcd. C 49.91, H 3.14, N 1.62; found C 49.74, H 3.24, N 1.65. ^1H NMR ($CDCl_3$; 296 K): $\delta = 6.47$ (m, 9 H), 7.13 (m, 9 H), 7.70 (s, 9 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$; 296 K): $\delta = -11.14$ (s), -57.00 (m, br.)

Reaction of TFP with $AgBF_4$ (2:1 Molar Ratio); Compounds 3 and 4: To a solution of TFP (0.15 g; 0.65 mmol) in THF (6 mL), $AgBF_4$ (0.068 g; 0.32 mmol) was added. A cloudy solution was immediately obtained. After 1 h, the white precipitate was separated from the supernatant by centrifugation, to give the analytical sample of **4** (yield 0.085 g; 47%, calculated respect to the amount of the TFP ligand used). The solution was concentrated to dryness and the crude product obtained was dissolved in hot chloroform. Crystals

of **3** suitable for an X-ray crystal structure determination (yield 0.089 g; 40%, calculated with respect to the amount of the TFP ligand used) were obtained by cooling the chloroform solution to 4 °C. With TFP and $AgBF_4$ in a 1:1 molar ratio, compounds **3** and **4** were both obtained. $C_{24}H_{20}AgBF_4O_7P_2$ (**3**) (677.0): calcd. C 42.58, H 2.98; found C 42.89, H 2.75. ^1H NMR ($CDCl_3$; 296 K): δ = 1.85 (s, 2 H), 6.48 (m, 6 H), 7.19 (m, 6 H), 7.68 (s, 6 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$; 296 K): δ = −55.77 (s, br.). $C_{48}H_{36}AgBF_4O_{12}P_4$ (**4**) (1123.4): calcd. C 51.32, H 3.23; found C 51.40, H 3.11. ^1H NMR ($CDCl_3$; 296 K): δ = 6.36 (m, 12 H), 6.74 (m, 12 H), 7.38 (s, br 12 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$; 296 K): δ = −57.48 (s, br.)

Reaction of TFP with $AgBF_4$ (4:1 Molar Ratio); Compound 4: To a solution of TFP (0.15 g; 0.65 mmol) in THF (6 mL), $AgBF_4$ (0.031 g; 0.16 mmol) was added. The cloudy solution was stirred for 0.5 h and a white precipitated of **4** formed (0.15 g; yield 84%). The supernatant, separated by centrifugation from the precipitate, was concentrated to dryness. The oily crude product was washed with hexane and then crystallized from $CHCl_3$; a small amount of **3** was recovered. $C_{48}H_{36}AgBF_4O_{12}P_4$ (**4**) (1123.4): calcd. C 51.32, H 3.23; found C 51.18, H 3.07. ^1H NMR ($CDCl_3$; 296 K): δ = 6.36 (m, 12 H), 6.74 (m, 12 H), 7.38 (s, br., 12 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$; 296 K): δ = −57.48 (s, br.)

X-ray Crystal Structure Analyses of 1, 2, and 3: X-ray diffraction data of single crystals of the three complexes were collected with a Rigaku AFC5R diffractometer with graphite-monochromated Cu-K_α radiation and a 12-kV rotating anode generator. Intensity data were collected by the ω-2θ technique to a maximum 2θ value of about 124°. Corrections for Lorentz polarisation and absorption were applied to the data of the three compounds. A linear correction factor was applied to the data of **2** to account for the intensity decay of −61% detected in the intensities of the standard reflections. The structures were solved by Patterson methods and subsequent Fourier analyses and refined by the full-matrix least-squares method with anisotropic thermal parameters for all non-hydrogen atoms of **1** and **3** and for the heavier atoms of **2**, while the carbon and oxygen atoms of the furyl groups were refined isotropically. The hydrogen atoms were included at calculated positions and not refined for the three compounds. Crystal parameters and structure determination data are given in Table 3. Atomic scattering factors and anomalous dispersion terms were taken from the International Tables.[26] All calculations were performed by using the TEXAN crystallographic software package.[27] CCDC-164610 (**1**), -164611 (**2**) and -164612 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the

Strong Ferromagnetic Coupling in Linear Mixed μ-Acetato, μ-Hydroxo Trinuclear Copper(II) Complexes with *N*-sulfonamide derivatives − Synthesis, Structure, EPR and Magnetic Properties

Laura Gutierrez,[a] Gloria Alzuet,[a] Jose A. Real,[a] Joan Cano,[b] Joaquin Borrás,*[a] and Alfonso Castiñeiras[c]

Keywords: Copper / Sulfonamide ligands / Magnetic properties / EPR spectroscopy / Density functional calculations

Two new trinuclear copper(II) complexes have been synthesised and structurally characterised: $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**) [HL1 = *N*-(pyrid-2-ylmethyl)benzenesulfonylamide] and $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (**2**) [HL2 = *N*-(pyrid-2-ylmethyl)naphthalenesulfonylamide]. In both complexes the central copper ion has a regular square planar geometry. The coordination spheres of the terminal copper atoms are square pyramidal, the apical positions being occupied by a DMF oxygen atom in **1** and by a sulfonamido oxygen of the contiguous trimer in **2**, as a consequence the latter can be considered a chain of trinuclear species. For the two compounds the three copper atoms are in a strict linear arrangement and adjacent coppers are connected by a hydroxo bridge and a bidentate *syn-syn* carboxylato group. The mixed bridging by a hydroxide oxygen atom and a bidentate carboxylato group leads to a noncoplanarity of the adjacent basal coordination planes with a dihedral angle of 54.4(1)° for compound **1** and 58.34(3)° for compound **2**. Susceptibility measurements (2–300 K) reveal a strong ferromagnetic coupling, J = 94.0 and 59.1 cm^{-1}, respectively, in the mixed-bridged moiety leading to a quadruplet ground state that is confirmed by the EPR spectra. The ferromagnetic coupling arising from the countercomplementarity of the hydroxo and acetato bridges has been discussed on the basis of DFT calculations on model compounds.

Introduction

There is a great deal of interest in multimetallic complexes due to the special chemical and physical properties resulting from the mutual interaction of two or more metal centres.[1] Investigations of trinuclear transition metal complexes have been of increasing interest in recent years. One reason for this was the lack of metallobiomolecules for which the trinuclear core can act as a synthetic analogue. The MCD spectroscopic proof of a trinuclear active site in laccase,[2] the recent discovery of a ferromagnetically coupled Cu^{II} triad in a subunit of methane mono-oxygenase[3] and an X-ray structure analysis of ascorbate oxidase from zucchini,[4] which revealed an angled trimeric Cu^{II} unit as well as a mononuclear type 1 copper(II) centre, have all stimulated an increasing interest in the study of trinuclear copper systems.

Very recently we have reported a ferromagnetically coupled copper(II) triad that has been synthesised and structurally as well as magnetically characterised.[5] This compound presents a linear arrangement of the three copper(II) atoms linked by μ-hydroxo and μ-carboxylato bridges. Until now this complex and that previously reported by Haase et al.[6] are the only ferromagnetic linear trinuclear copper(II) complexes fully characterised.

The importance of these systems does not arise only from the occurrence of this bridging unit in several metalloproteins.[7] These studies are also related to the properties of quadruplet ground states, to magnetostructural correlations in mixed bridged systems, to ferromagnetic exchange coupling, and to long-range coupling effects between terminal copper centres.

Within this framework and following our current study on multiatom-bridged exchange-coupled systems we report here the synthesis, X-ray structure and magnetic properties of two trinuclear copper(II) complexes, $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**) and $[Cu_3(L2)_2(CH_3COO)_2$-

$(OH)_2]_\infty$ (**2**) {HL1 = [*N*-(pyrid-2-ylmethyl)benzenesulfonylamide)] and HL2 = [*N*-pyrid-2-ylmethylnaphthalenesulfonylamide]}. In both compounds the copper atoms are bridged by hydroxo and acetate groups. In compound **2** the trinuclear units are linked by a sulfonamide oxygen atom from the HL2 ligand leading to a three dimensional network. The complexes display a linear arrangement of the copper centres and a strong ferromagnetically coupled pair of copper atoms.

Results and Discussion

Crystal Structure of $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (1)

The trinuclear entity of compound **1** with the atomic labelling scheme used is shown in Figure 1. Selected bond lengths and angles are collected in Table 1. The complex molecule consists of a neutral symmetrical trinuclear unit and two disordered dimethylformamide molecules along with the Cu(2) at the symmetry centre. The terminal copper atoms Cu(1) and Cu(1a) have a distorted square pyramidal geometry (τ parameter 0.30) coordinated by two nitrogen atoms N(1) and N(2) of the pyridyl ring and of the sulfonamidato group of the deprotonated ligand ($L1^-$), the O(1) of the hydroxo bridge, the O(21) of the acetate bridge and the O(30) from a dimethylformamide solvent. The central Cu(2) presents a regular square plane geometry formed from the O(1), O(1a), O(22) and O(22a) atoms of the hydroxo and acetate bridging groups, respectively [deviation of the O(1), O(22), O(1a), O(22a), and Cu(2) atoms from the plane, 0.000].

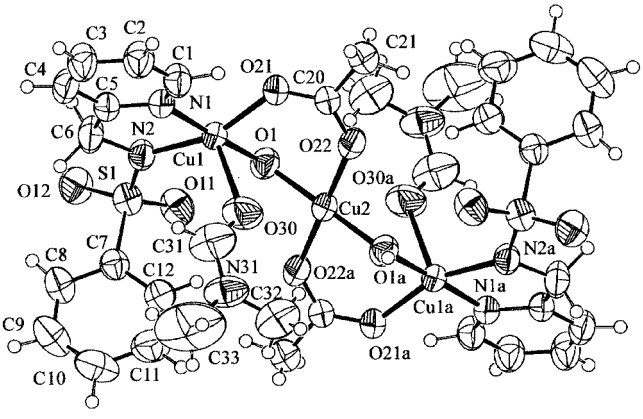

Figure 1. Molecular structure of $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**)

Adjacent copper centres are bridged by the oxygen atom of the hydroxo ligand [Cu(1)−O(1)−Cu(2) = 113.33(15)°] and two oxygen atoms of a bidentate *syn-syn* carboxylato group leading to a mixed-bridged coplanar coordination geometry with Cu(1)···Cu(2) = 3.1656(6) Å. The Cu(2)−O(1) and Cu(2)−O(22) bond lengths are 1.899(3) Å and 1.959(3) Å, respectively. The Cu(1)−N(1) and Cu(1)−N(2) lengths are 2.004(3) Å and 2005(3) Å, respectively, and the Cu(1)−O(1) and Cu(1)−O(21) bond lengths are 1.890(3) Å and 1.981(3) Å. The apical bond length Cu(1)−O(30) is 2.398(4) Å. The two O(30) and O(30a) atoms from the DMF molecules linked to the Cu(1) and Cu(1a) centres are at 2.776(5) Å from the Cu(2). The Cu(1)−O(11) and Cu(1)−O(12) distances are 3.420(2) and 4.422(3) Å indicating that the Cu^{II} ions do not interact with the oxygen atoms of the sulfonamido group. Bond lengths are similar to those of the previously reported $[Cu_3(L)_2(CH_3COO)_2(OH)_2(DMF)_2]$ [HL = *N*-(pyrid-2-ylmethyl)toluensulfonylamide] compound[5] except for the Cu−O(30) bond length, which is significantly shorter (ca. 0.12 Å) in the present compound.

The Cu(1) atom is 0.1706 Å from the square plane formed by the N(1), N(2), O(1) and O(21) atoms. The skeleton Cu(1a)−O(1)−Cu(2)−O(1a)−Cu(1) is in a zigzag with the three copper ions forming a straight line with an angle of 180°. The mixed bridging leads to a noncoplanarity of the basal N(1)N(2)O(1)O(2) and O(1)O(22)O(22A)O(21A) planes characterised by a folding angle of 54.4(1)°.

Crystal Structure of $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (2)

The trinuclear entity with the atomic labelling scheme used is shown in Figure 2. Selected bond lengths and angles are listed in Table 1. The polymer compound consists of trinuclear copper fragments $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]$. The sites of the central and terminal copper ions are nonequivalent. The geometry around the terminal copper atoms Cu(1) and Cu(1A) is distorted square pyramidal (τ parameter 0.22) with a $CuN_2O_2\cdots O$ chromophore. The basal plane is described by the two nitrogen atoms N(1) and N(2) of the pyridyl ring and of the sulfonamidato group of the deprotonated ligand ($L2^-$), the O(1) of the hydroxo bridge and O(21) of the acetate bridge. The apical position is occupied by a sulfonamide O atom [O(11B)] of another $L2^-$ ligand pertaining to a contiguous asymmetric unit. For the central Cu(2) a regular square plane geometry is realised with the O(1), O(1A), O(22) and O(22A) atoms from the hydroxo and acetate bridging groups, respectively.

The Cu−O and Cu−N distances are similar to those found in complex **1**. The Cu(2)−O(1) and Cu(2)−O(22) bond lengths are 1.883(8) Å and 2.005(7) respectively. The Cu(1)−N(1) and Cu(1)−N(2) lengths are 2.022(10) Å and 1.991(9) Å, respectively, and the Cu(1)−O(1) and Cu(1)−O(21) bond lengths are 1.914(7) Å and 1.981(8) Å. The apical bond length Cu(1)−O(11A) is 2.460(8) Å. The Cu(1) atom lies 0.0985 Å above the square plane formed by the N(1), N(2), O(1) and O(21) atoms.

In the same way as in complex **1**, adjacent copper centres are bridged by the oxygen atom O(1) of the hydroxo ligand [Cu(1)−O(1)−Cu(2) = 112.6(4)°] and two oxygen atoms O(21) and O(22) of a bidentate *syn-syn* carboxylato group leading to a mixed-bridged non coplanar coordination geometry [dihedral angle between the mean equatorial planes N(1)N(2)O(1)O(2) and O(1)O(22)O(22A)O(21A), 58.3(3)°]. In the trinuclear entity, the three copper ions are arranged in a strict linear fashion [Cu(1)−Cu(2)−Cu(1A) = 180°]

Table 1. Selected bond lengths [Å] and angles [°] for $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**) and $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (**2**); symmetry transformations used to generate equivalent atoms: #1 $-x, -y + 1, -z + 1$ (compound **1**); #1 $x, -y + 1, z - 1/2$ #2 $-x + 1/2, -y + 3/2, -z$ (compound **2**)

with Cu(2) on the inversion centre and a Cu(1)···Cu(2) distance of 3.1589(15).

As for the coordination mode of the ligand, it is noteworthy that HL2 coordinates to one copper ion in a bidentate fashion through the pyridyl and sulfonamidato N atoms and to another copper(II) of another asymmetric unit through the sulfonamide O atom giving an infinite tridimensional network of trinuclear units. As a consequence of the coordination of the $O_{sulfonamidate}$ atom to the copper ion, there is a small difference between the S−O bond lengths [S−O(11): 1.452 Å, S−O(12): 1.434 Å] the former being larger due to the O(11) that is linked to the copper ion. However, the S−O bond lengths in compound **1** and in the compound previously reported[5] are the same, 1.443 Å, because in these complexes there is no interaction between the copper ion and the $O_{sulfanomidate}$ atom of the SO_2 group.

IR and Electronic Spectra

The IR spectra of both complexes present a similar pattern to that of the previously reported trinuclear compounds with the related *N*-(pyrid-2-ylmethyl)toluensulfonylamide ligand.[5] The IR spectrum of complex **2** shows a band at 3530 cm^{-1} characteristic of the O−H bridging group.[7] The characteristic vibrations of the acetato group in the spectra of both complexes confirm that it acts as a bridging bidentate ligand [$\Delta\nu = \nu_{asymm.}(COO) - \nu_{symm.}(COO) = 144$ and 142 cm^{-1} for compounds **1** and **2**, respectively].[8] The spectrum of complex **1** exhibits a new band at 1653 cm^{-1}, which is assigned to the ν(C=O) vibration of the dimethylformamide. As a consequence of the deprotonation and coordination of the sulfonamido N atom the characteristic bands of the SO_2 group are shifted to lower frequencies. The $\nu(SO_2)_{asymm.}$ vibrations present the

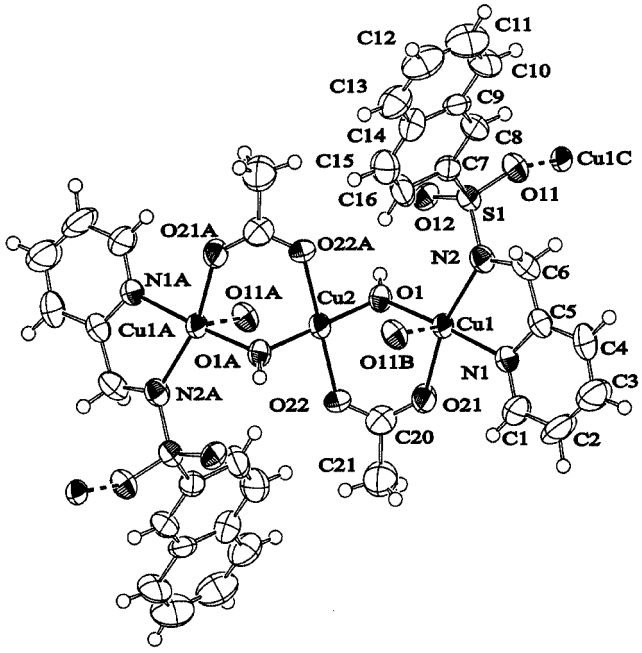

Figure 2. Molecular structure of $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (**2**)

same band at 1256 cm^{-1} for both complexes, however the $\nu(SO_2)_{symm.}$ vibrations are different, 1130 cm^{-1} in compound **1** and 1120 cm^{-1} in compound **2**, probably due to the interaction of one of the oxygen atoms of the sulfonamido group with the metal ion in complex **2**.

The solid-state spectra of both trinuclear complexes exhibit a broad band at about 15314 cm^{-1} (**1**) and 15873 cm^{-1} (**2**) that corresponds to the two chromophores, CuN_2O_2 and CuO_4, present in the compounds.[9] In dichloromethane solution, the d-d band of the complexes is slightly shifted. The small shift of ca. 500 cm^{-1} to lower frequencies in complex **1** and ca. 700 cm^{-1} to higher frequencies in complex **2** can be attributed to solvent effects.

Magnetic Properties

The temperature dependence of the $\chi_M T$ product for $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**) and $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (**2**) (χ_M being the magnetic susceptibility per trimer unit and T the absolute temperature) in the temperature range 2−300 K is shown in Figure 3. As expected, the magnetic behaviour of both complexes is similar and resembles that of the related trinuclear compound $[Cu_3(L)_2(CH_3COO)_2(OH)_2(DMF)_2]$ [HL = *N*-(pyrid-2-ylmethyl)toluensulfonylamide].[5] At room temperature $\chi_M \cdot T$ is 1.51 and 1.32 $cm^3 \cdot mol^{-1} \cdot K$, respectively, a value which is somewhat larger than that expected for a magnetically uncoupled trinuclear Cu^{II} compound (1.23 $cm^3 \cdot mol^{-1} \cdot K$, $g = 2.1$). Upon cooling of the sample, $\chi_M \cdot T$ increases and reaches a value of 2.18 $cm^3 \cdot mol^{-1} \cdot K$ (compound **1**) and of 2.00 $cm^3 \cdot mol^{-1} \cdot K$ (compound **2**) in the 6−15 K temperature range. This behaviour is indicative of strong ferromagnetic coupling between the adjacent Cu^{II} atoms in the trinuclear species. Below 5 K, $\chi_M T$ decreases rapidly down to 1.9 $cm^3 \cdot mol^{-1} \cdot K$ (compound **1**) and to 1.8 $cm^3 \cdot mol^{-1} \cdot K$ (compound **2**), which is most likely due to zero-field splitting (ZFS) within the quadruplet ground state. The occurrence of intermolecular antiferromagnetic interactions may also be operative at very low temperatures.

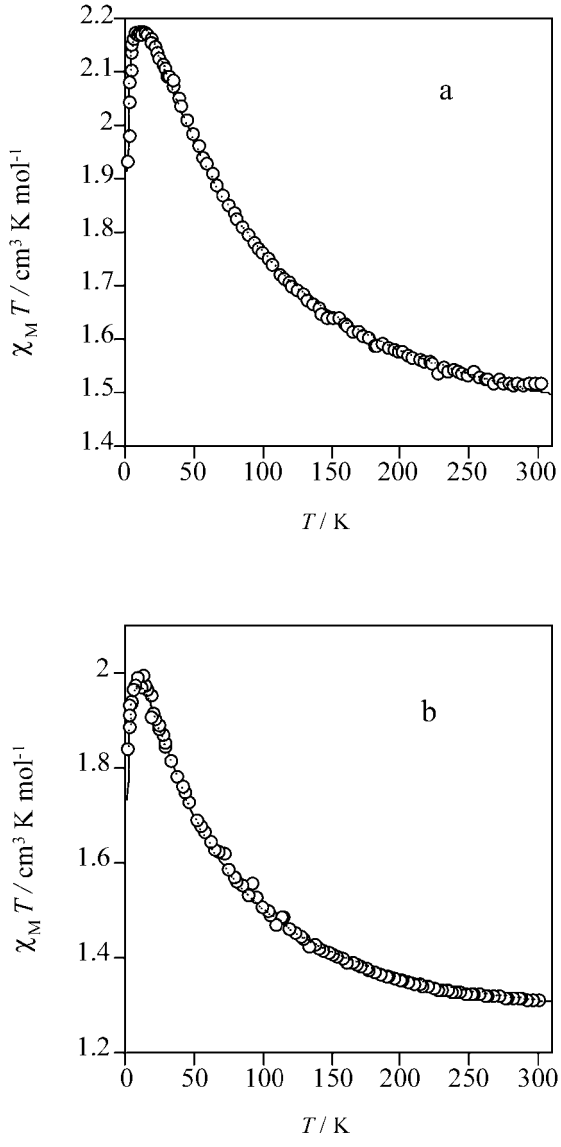

Figure 3. a) Temperature dependence of $\chi_M T$ for $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**); b) temperature dependence of $\chi_M T$ for $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (**2**)

The spin Hamiltonian that is appropriate for describing the exchange interaction in a linear symmetric trimer has the form:

$$H = -J(S_1S_2 + S_2S_3) - J' S_1S_3 + D[S_z^2 - S(S+1)/3] + g\beta HS \quad (1)$$

where the occurrence of axial ZFS between the ±3/2 and ±1/2 Kramer's doublets arising from the $S = 3/2$ ground state have been included. The exchange parameters J and

J' refer to the interaction between two adjacent centres and the interaction between the terminal centres, respectively. The resulting spin multiplets are two doublets ($S = 1/2$) and one quadruplet ($S = 3/2$).[10] D denotes the half energy gap between the above mentioned Kramer's doublets.

In a first step we have set $D = 0$ in expression (1). In this case, the fitting of the experimental data for $T > 10$ K to this Hamiltonian confirms that the values of J and J' are strongly correlated in determining the temperature dependence of the magnetic susceptibility, as has already been observed for other similar systems.[5,11] The fitting to the experimental data, including the low temperature region where D is operative, shows a similar correlation between J and J'. The solid and broken lines in Figure 3 represent typical fits with $J = 94$ cm^{-1}, $J' = -3.6$ cm^{-1}, $|D| = 1.76$ cm^{-1}, $g = 2.17$ and $R = 3.10-5$ (Figure 3a) and $J = 59.1$ cm^{-1}, $J' = -4.6$ cm^{-1}, $|D| = 1.76$ cm^{-1}, $g = 2.06$ and $R = 3.10-4$ (Figure 3b), respectively [R values obtained from the expression $R = \{\Sigma_i[(\chi_M T)_{obs,i} - (\chi_M T)_{calcd,i}]^2/\Sigma_i[(\chi_M T)_{obs,i}]^2\}$. These J and J' values are indicative of a strong ferromagnetic and a weak antiferromagnetic coupling, respectively.

It is well-known that in dinuclear copper(II) complexes with *syn-syn* carboxylato bridges and hydroxo bridges, with an angle at the hydroxo bridge larger than 97.5°, antiferromagnetic coupling occurs;[12] the magnetic coupling in **1** and **2** should therefore be antiferromagnetic. However, when the bridging ligands are different, the two bridges may either increase or cancel out these effects. This phenomenon is known as orbital complementarity and countercomplementarity,[13–20] respectively, and was observed by us for the previously reported $[Cu_3(L)_2(CH_3COO)_2(OH)_2(DMF)_2]$[5] [HL = *N*-(pyrid-2-ylmethyl)toluensulfonylamide]. In this case, the antiferromagnetic contributions of each bridge almost cancelled each other out (these bridges show an orbital countercomplementarity) and the ferromagnetic term dominates ($J_T = J_{AF} + J_F$ with $|J_{AF}|$ being smaller than $|J_F|$). Here, both complexes **1** and **2** are good examples of the countercomplementarity effect imposed by the carboxylato bridge, which attenuates the effect of the antiferromagnetic hydroxo bridge to the point where strong ferromagnetic behaviour is observed.

EPR Spectra

The X-band EPR spectra of complexes **1** and **2** at room temperature are dominated by a transition at 2000 and 2100 G, respectively, which identifies an $S = 3/2$ ground state. The Q-band EPR spectrum at room temperature of compound **1** is shown in Figure 4, where the strong transition at 8000 G confirms the ferromagnetic behaviour of the compound.

For the complex $[Cu_3(L)_2(CH_3COO)_2(OH)_2(DMF)_2]$[5] [HL = *N*-(pyrid-2-ylmethyl)toluensulfonylamide] we have reported variable temperature studies in detail that revealed a strong shift of this resonance towards higher fields upon raising the temperature. This effect was explained from the

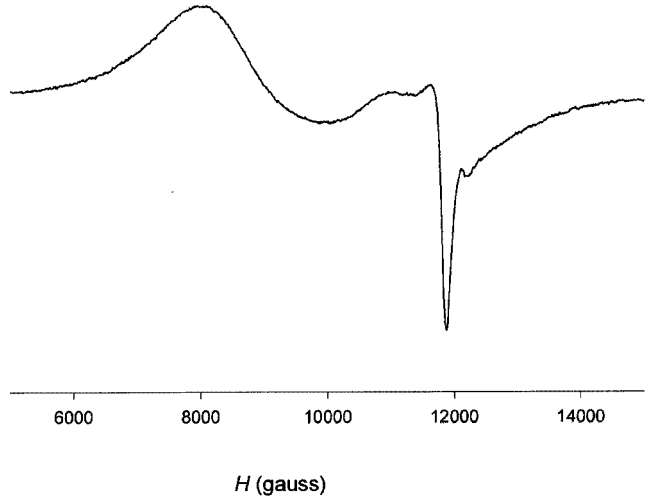

Figure 4. Q-band EPR spectrum at room temperature for $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**)

temperature-dependent contribution of the resonance fields of the three spin states to a composite EPR signal. In the present work, due to the similarity between the structures, magnetic properties and EPR spectra of the compounds $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**) and $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (**2**) and the complex $[Cu_3(L)_2(CH_3COO)_2(OH)_2(DMF)_2]$, we assumed a similar g-temperature dependence for **1** and **2**.

DFT Calculations

In previous work[5] we stated that the nature of the magnetic interaction in this kind of compound is governed by orbital countercomplementarity phenomena, in particular the SOMOs (Singly Occupied Molecular Orbital). In other words, two different bridging ligands can interact with the magnetic orbitals in the metal ions in a different way, destabilising the in-phase combination in one case (Φ_{AS}), and the out-of-phase (Φ_S) in the other. So, in the systems with two bridging ligands, there is a counterbalance and a compensation of their effects in the formation of the SOMOs. This leads to an increase in the energy gap, $\Delta = E_{AS} - E_S$, between the SOMOs, and therefore a reduction in the antiferromagnetic contribution to the magnetic coupling.[5] The antiferromagnetic contributions of each bridge almost cancel each other out and the ferromagnetic term dominates.

When we compare the J values of compounds **1** (94 cm^{-1}), **2** (59.1 cm^{-1}) and that of the related trinuclear complex of ref.[5] (96 cm^{-1}) and try to correlate them with the CuOCu angle φ (113.3°, 112.6° and 114.9° respectively) (Figure 5), we find that the J value of **2** is significantly smaller than the values of the other two compounds, when into account the φ angle is taken.

Several structural parameters can modify the exchange coupling constant value, J, in the family of the compounds studied. The CuOCu angle, φ, can have a dominant influence. As is well-known, there is a strong dependence be-

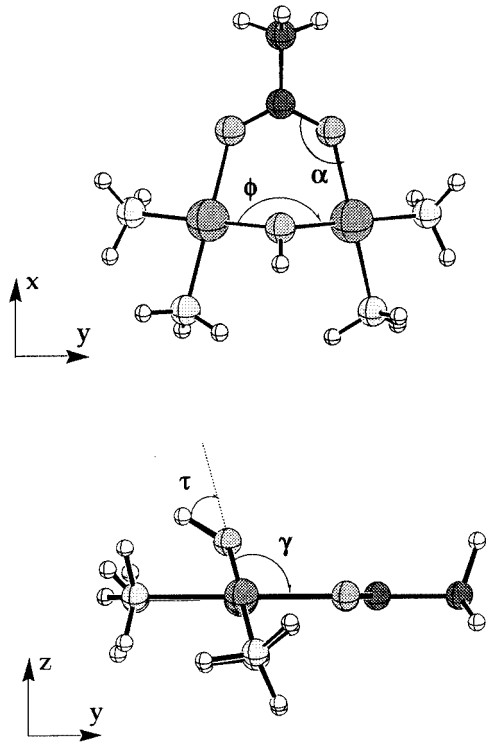

Figure 5. The structural parameters studied in the model **III**

tween the *J* constant and the φ angle in the binuclear bis(μ-hydroxo)Cu^{II} complexes[12,21] $[Cu_2(\mu\text{-}OH)_2]^{2+}$. So, in the last complexes small changes in the φ values produce important variations in the magnitude and the nature of the magnetic interaction. Wieghardt and co-workers[18] have proposed a magneto-structural correlation between the coupling constant *J* and the CuOCu angle φ for μ-hydroxo-μ-carboxylatodicopper(II) complexes. Using this correlation the values of *J* obtained for the trinuclear complexes **1** and **2** are approximately -20 cm^{-1}, which are not in agreement with the experimental results. Later, Chakravarty et al.[22] proposed a linear magneto-structural correlation [$-2J = 11.48\varphi(\text{deg}) - 1373$] for μ-alkoxo/hydroxo-μ-carboxylato dicopper(II) systems. Using this empirical relationship the value of *J* for the three compounds (**1**, **2** and that of ref.[5]) are 36.1, 40.1 and 26.9 cm^{-1}, respectively, which, as in the previous correlation, are not in agreement with the experimental measurements.

In order to understand the different *J* values found in these trinuclear compounds we have performed DFT calculations on three model compounds derived from the structure of the complexes: model **I** [two copper(II) atoms bridged by an acetato group], model **II** [two copper(II) atoms bridged by a hydroxo group] and model **III** [two copper(II) atoms bridged by an acetato and a hydroxo group]. To avoid the extra influences in the *J* constant, we have frozen most of the structural parameters in the variation of φ. Only the α angle (see Figure 5) has been varied in the φ change process. This angle (α), which governs the carboxylate-copper ion conformation (*syn-syn* or *anti-anti*), varies between 123.8 (φ = 90°) and 135.0° (φ = 130°) in the calculated models. The calculations with model **I** have shown that this small change in α causes a slight shift to weaker magnetic interactions for the smaller α values (-12.3 to -50.7 cm^{-1}) because of a loss of overlap between the magnetic orbitals in the metal ions and the HOMO's of the carboxylate ligand.

For a certain value of φ, a zero value for Δ is expected for model **II**, as in the $[Cu_2(\mu\text{-}OH)_2]^{2+}$ complexes. When this angle increases, a splitting of the SOMOs is observed. This energy gap has the opposite sign to the one found for model **I** (see Figure 6). This phenomenon is more pronounced as the φ value increases, and a stronger ferromagnetic character is expected for the magnetic interaction. So, a total counterbalance is found and a maximum ferromagnetic interaction must be observed. From here, the energy gap in the SOMOs of the hydroxo ligand will be bigger than that caused by the carboxylate ligand, and, consequently, a decrease in the ferromagnetic interaction is expected. Similar results have been found for the calculation on model **III**. All these comments are summarised in Figure 6. For model **III** a maximum of *J* is obtained for a φ value of 102.8° (see Figure 7). The more stable structure appears for a φ value of 118.7°, which is slightly bigger than that in the $[Cu_2(\mu\text{-carboxylate})(\mu\text{-}OH)]^{2+}$ complexes.

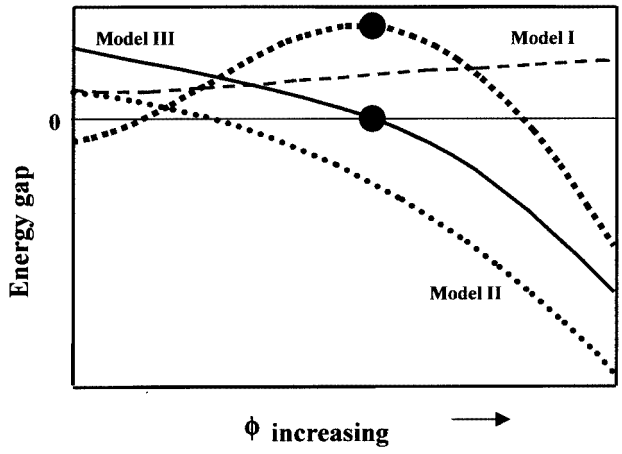

Figure 6. Theoretical dependence of Δ (energy gap) with the φ angle for the models **I** (- - -), **II** (···) and **III** (——); the variation of *J* as a function of φ is shown as a (···) line; the maximum *J* value for the model **III** coincides with the zero value in the energy gap (Δ) (black circles)

Figure 7 shows the theoretical *J* values for model **III**, the experimental ones of dinuclear copper(II) complexes reported in the literature (shown as circles), those found for the trinuclear compounds described here and that described in ref.[5] (shown as crosses). In the range from 103 to 135° the magnetic coupling becomes more antiferromagnetic when φ increases. It should be emphasised that the compounds with an aliphatic peripheral ligand [18–19,23] show φ angles bigger than those with an aromatic peripheral one.[7,24–25] However, our compounds show an intermediate φ value. This is probably due to the trinuclear topology adopted in our series of compounds. We have therefore found

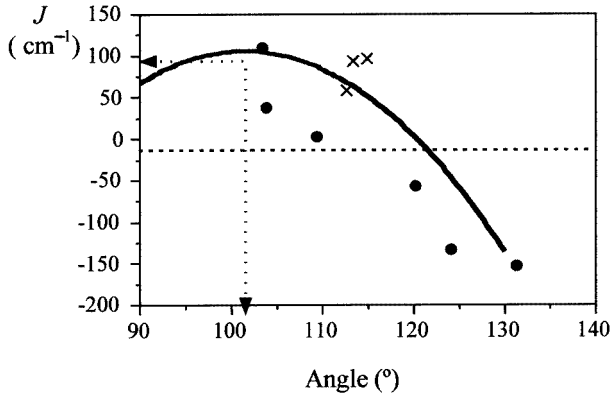

Figure 7. Calculated dependence of J with the φ angle for the model **III**; the arrows point to the maximum J value; experimental J values of dinuclear copper(II) complexes reported in the literature (·) and those of compounds **1**, **2** and that described in ref.[5] (x)

a way to tune the magnitude and the nature of the magnetic interaction through the peripheral ligand and the molecular nuclearity. On the other hand, Figure 7 shows that the experimental J values of trinuclear compounds (**1**, **2** and the compound from ref.[5]) are higher than that found experimentally in dinuclear complexes for similar φ angles. The formation of trinuclear entities implies a change in the coordination sphere. Thus, the compounds in the literature (dinuclear complexes) present a N_2O_2 environment, while the trinuclear complexes show both N_2O_2 and O_4 ones. The higher J value shown by the title compounds could be explained by taking into account the effect of the nature of the donor atoms of the peripheral ligands on the magnetic interaction magnitude.[26] Nevertheless, it is not uncommon that a relatively large range of values for the J constant is observed for a family of complexes with similar φ angles.

To explain this phenomenon, we have studied several structural distortions found in the real systems: changes in the $Cu-N_{peripheral\ ligand}$, $Cu-O_{bridging\ ligands}$ distances, the dihedral angle γ (Figure 5) between the $CuO_{hydroxo}Cu$ and $CuOO_{carboxylate}Cu$ planes, distortions in the carboxylate group, etc. No important effects on the J constant values have been found. Only the relative position of the hydrogen atom in the hydroxo group, defined by the τ angle (see Figure 5), as in the $[Cu_2(\mu\text{-}OH)_2]^{2+}$ complexes, is able to cause meaningful changes in the J constant. Although, as in the $[Cu_2(\mu\text{-}OH)_2]^{2+}$ complexes, a structural correlation can exist between the φ and τ angles[12,21] (the same electronic reasons), there are other factors, such as hydrogen bonds, that can govern the hydrogen-atom position or the τ value. Unfortunately, in many cases, the exact positions of these hydrogen atoms have not been determined by X-ray diffraction; however, it is possible to estimate this position when a solvent molecule or anion forms a hydrogen bond with the hydroxo groups. The hydrogen atom can then be placed in the direction of this bond. In this way the τ angle for these compounds lies between 0 and 51°, with a maximum value for the compound with the anomalous stronger ferromagnetic interaction. In any case, for model **III**, based on compound **2** (τ = 58.5°) and **1** (τ = 0°) we have found J values (36.4 and 85.4 cm^{-1}, respectively) that are in good agreement with the tendency found experimentally.

Although two parameters mostly govern the nature and magnitude of the magnetic interaction in this family of compounds, a lot of other structural parameters exist that have negligible influences.

Experimental Section

General Remarks: The infrared spectra ($\tilde{\nu}$ = 400−4000 cm^{-1}) were obtained on a Mattson Satellite FTIR spectrophotometer. Elemental Analyses were performed on a Carlo Erba AAS instrument. The variable temperature magnetic susceptibility measurements were carried out on a microcrystalline sample using a Quantum Design MPMS2 SQUID susceptometer equipped with a 55 kG magnet and operating at 10 kG in the range of 1.8−400 K. The susceptometer was calibrated with $(NH_4)_2Mn(SO_4)_2{\cdot}12H_2O$. The corrections for the diamagnetism were estimated from Pascal's constants. Diffuse Reflectance and UV/Vis spectra were recorded on a Shimadzu 2101 PC spectrophotometer. The EPR spectra of ground crystals were carried out at the X-band with a Bruker ELEXSYS and at the Q-band frequencies with a Bruker ESP300 spectrometer.

***N*-(pyrid-2-ylmethyl)benzenesulfonylamide (HL1) and *N*-(pyrid-2-ylmethyl)naphthalenesulfonylamide (HL2):** The ligands were obtained by condensation of 2-picolylamine and the corresponding sulfonyl chloride (benzenesulfonyl chloride or 2-naphthalenesulfonyl chloride) following the synthesis procedure previously described.[5] **HL1** (yield 1.38 g, 56%). $C_{12}H_{12}N_2O_2S$ (248): calcd. C 58.1, H 4.8, N 11.3, S 12.9; found C 57.3, H 4.7, N 11.1, S 12.7. IR (KBr): $\tilde{\nu}$ = 1330, 1160 $\nu(SO_2)$, 850 cm^{-1} ν(S−N). **HL2** (yield 2.11 g, 71%). $C_{16}H_{14}N_2O_2S$ (298): calcd. C 64.4, H 4.7, N 9.4, S 10.7; found C 61.5, H 4.8, N 8.9, S 10.4. IR (KBr): $\tilde{\nu}$ = 1329, 1162 $\nu(SO_2)$, 954 cm^{-1} ν(S−N).

Bis(μ-acetato)-bis(μ-hydroxo)-bis[*N*-(pyrid-2-ylmethyl)benzenesulfonylamidate(DMF)$_2$]tricopper(II) (1) and Bis(μ-acetato)-bis(μ-hydroxo)-bis[*N*-(pyrid-2-ylmethyl)naphthalenesulfonylamidate]-tricopper(II) (2): Both copper complexes were prepared by the reaction of the metal acetate (1 mmol in 25 mL DMF) with the ligand (1 mmol in 25 mL DMF). Slow evaporation of the resulting solution at room temperature provided well-developed blue crystals of both compounds suitable for X-ray diffraction. Microanalysis of the dried crystals was satisfactory. **1** (yield 354 mg, 24%). $C_{17}H_{22}Cu_{1.5}N_3O_6S$ (**1**) (491.75): calcd. C 41.48, H 4.47, N 8.54, S 6.50; found C 40.94, H 4.40, N 8.30, S 6.53. IR (KBr): $\tilde{\nu}$ = 3530 ν(O−H), 1567 ν_{as}(COO), 1423 ν_s(COO), 1256, 1130 $\nu(SO_2)$, 970 cm^{-1} ν(S−N). Diffuse Reflectance: (λ_{max}) = 15314 cm^{-1} (653 nm). UV/Vis (dichloromethane/THF/acetic acid): λ_{max} = 14837 cm^{-1} (674 nm), 26882 cm^{-1} (sh) (372 nm). **2** (yield 281 mg, 20%). $C_{36}H_{34}Cu_3N_4O_{10}S_2$ (**2**) (937): C 46.10, H 3.62, N 5.97, S 6.63; found C 45.91, H 3.69, N 6.02, S 6.47. IR (KBr): $\tilde{\nu}$ = 3530 ν(O−H), 1569 ν_{as}(COO), 1427 ν_s(COO), 1256, 1120 $\nu(SO_2)$, 975 cm^{-1} ν(S−N). Diffuse Reflectance: λ_{max} = 15150 cm^{-1} (660 nm). UV/Vis (dichloromethane): λ_{max} = 15873 cm^{-1} (630 nm), 27030 cm^{-1} (sh) (370 nm).

X-ray Crystallographic Study: A blue prismatic crystal of $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**) and a blue plate crystal of $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (**2**) were mounted on a glass fibre. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range of 15.884 < θ < 45.488° (compound **1**)

Table 2. Crystal data and structure refinement for $[Cu_3(L1)_2(CH_3COO)_2(OH)_2(DMF)_2]$ (**1**) and $[Cu_3(L2)_2(CH_3COO)_2(OH)_2]_\infty$ (**2**)

and 16.039° < θ < 45.208° (compound **2**) on an Enraf Nonius CAD4 automatic diffractometer.[27] Data were collected at 293 K using Cu-K_α radiation (λ = 1.54184 Å) and the ω-scan technique, and corrected for Lorentz and polarisation effects.[28] A semi-empirical absorption correction (Ψ-scans) (DIFABS) was made.[29] The structure was solved by direct methods[30] and subsequent difference Fourier maps, and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters.[31] For compound **1** all hydrogen atoms were located from difference Fourier maps except those of two of the phenyl group and of DMF which were located in their calculated positions (C−H 0.93−0.97 Å). The located H atoms were refined isotropically, whereas the calculated H atoms were refined using a riding model. For compound **2** all hydrogen atoms were located in their calculated positions (C−H: 0.93−0.97 Å) and were refined using a riding model. Atomic scattering factors were obtained from the International Tables for X-ray Crystallography.[32] Molecular graphics were obtained from PLATON-98[33] (compound **2**) and from PLATON-99[34] (compound **1**). A summary of the crystal data, experimental details and refinement results are listed in Table 2.

CCDC-168013 (**1**) and -168014 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: A detailed description of the computational strategy adopted in this work has been described elsewhere[12] and is only briefly reviewed here. For the evaluation of the coupling constants of dinuclear models, two separate calculations were carried out by means of density functional theory,[35] one for the triplet state and another for the singlet state. The hybrid B3LYP method,[36] as implemented in Gaussian98,[37] was used in all calculations, mixing the exact Hartree−Fock exchange[38] with Becke's expression for the exchange and with the Lee−Yang−Parr correlation functional.[39] Double-ζ quality and triple-ζ quality basis sets proposed by Ahlrichs[40] were employed for nonmetallic and metallic atoms, respectively. Also, for the metallic atoms, we added two extra polarisation p functions. The presence of a low-energy singlet made it difficult to evaluate, accurately, the energy of the lowest singlet by a single-determinant method. To solve this problem, broken-symmetry wave functions, as proposed by Noodleman et al., were used.[41−44] Previously, it has been found among the most common functionals, that the B3LYP method combined with the broken-symmetry treatment is the strategy that provides the best results for calculating coupling constants.[5,12,45−49] It is clear that for broken-symmetry, Hartree−Fock calculations are necessary to make a correction due to the multideterminant character of the wave function of the low-multiplicity state.[48] On the other hand, for DFT calculations we adopted single-determinant wave functions for which DFT is well defined.[50−52] Then, we used the broken-symmetry energy calculated by DFT methods as the real energy of the state.

Reactivity of $[Ru_2(CO)_6(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)]$ (Fu = 2-furyl) towards Diphosphanes − Substitution, Polymerisation, Cyclometallation and Elimination Reactions

Wai-Yeung Wong,*[a] Fai-Lung Ting,[a] and Wai-Lim Lam[a]

Keywords: Ruthenium / Phosphane ligands / Phosphido complexes

Thermal reaction of $[Ru_2(CO)_6(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)]$ (Fu = 2-furyl) (**1**) with bis(diphenylphosphanyl)methane (dppm), bis(diphenylphosphanyl)amine (dppam), or bis(diphenylphosphanyl)methylamine (dppma), produces the substitution products $[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(\mu\text{-}L)]$ [**2** (L = dppm), **3** (L = dppam), **4** (L = dppma)] in good yields. The Ru–Ru edge is bridged by the diphosphane in each case, while the $\mu\text{-}\eta^1,\eta^2$-bound furyl fragment remains intact. When the reactions were carried out using bis(diphenylphosphanyl)ethane (dppe) or bis(diphenylphosphanyl)propane (dppp), the compounds $[Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1\text{-}C_6H_4PPh(CH_2)_nPPh_2)]$ [**5** (n = 2), **6** (n = 3)] were isolated as the thermodynamic products in which both P atoms chelate to one Ru centre to afford five- (for **5**) and six-membered (for **6**) ruthenacycles, accompanied by orthometallation of one of the phenyl rings of the phosphane ligand. Interestingly, elimination of the coordinated furyl moiety occurs during the formation of **5** and **6**. Upon reaction with bis(diphenylphosphanyl)butane (dppb), bis(diphenylphosphanyl)pentane (dpppe), or bis(diphenylphosphanyl)ferrocene (dppf), cyclometallation is not favoured in each case. Instead, $[\{Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)\}_2(L)]$ [**7a** (L = dppb), **8a** (L = dpppe), **9a** (L = dppf)] and polymeric $[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(L)]_n$ [**7b** (L = dppb), **8b** (L = dpppe), **9b** (L = dppf)] were obtained with the product yield depending on the stoichiometry of the reactants. All these new diruthenium complexes are electron-precise with 34 cluster valence electrons.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

There is a continuing interest in the synthesis and chemistry of phosphido-bridged di- and polynuclear complexes.[1−7] Several recent developments provide a wealth of unexpected and intriguing reactivity of some dinuclear allenyl complexes of the type $[M_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^1_{\alpha,\beta}\text{-}C_\alpha(R)=C_\beta=CR_2)]$ (M = Fe, Ru; R = H, Ph) towards mono- and bidentate phosphanes.[8−12] In these studies, the nature of the phosphane plays a significant role in governing the reaction pathways involved and the final products isolated.[8−12]

We are interested in the use of tris(2-furyl)phosphane (PFu_3) as a ligand in organometallic syntheses.[13,14] The recent preparation of $[Ru_2(CO)_6(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)]$ (**1**) and its reactivity with 1-alkynes sparked our interest in the synthesis of a new class of complexes with different ligand environments.[13] In order to explore the synthetic potential of this system, we have now initiated a comprehensive study of the reactions of **1** with some diphosphane ligands. Herein, we describe results on reactions of **1** with various diphosphanes PPh_2EPPh_2 [E = $(CH_2)_n$, n = 1−5; N(H); N(Me); or $Fe(\eta^5\text{-}C_5H_4)_2$], which lead to the formation and characterisation of a range of novel carbonyl(μ-phosphido)-diruthenium complexes. These products are formed by different reaction pathways embracing (i) simple phosphane substitution with displacement of carbonyl ligands, (ii) polymerization, and (iii) phosphane coordination accompanied by cyclometallation. Another noteworthy feature of these phosphane-containing compounds is the various modes of coordination towards metal atoms which the ligands exhibit[15−18]. Three binding modes have been observed for the diphosphanes used in our studies, namely chelating, intrabridging, and interbridging (Scheme 1).

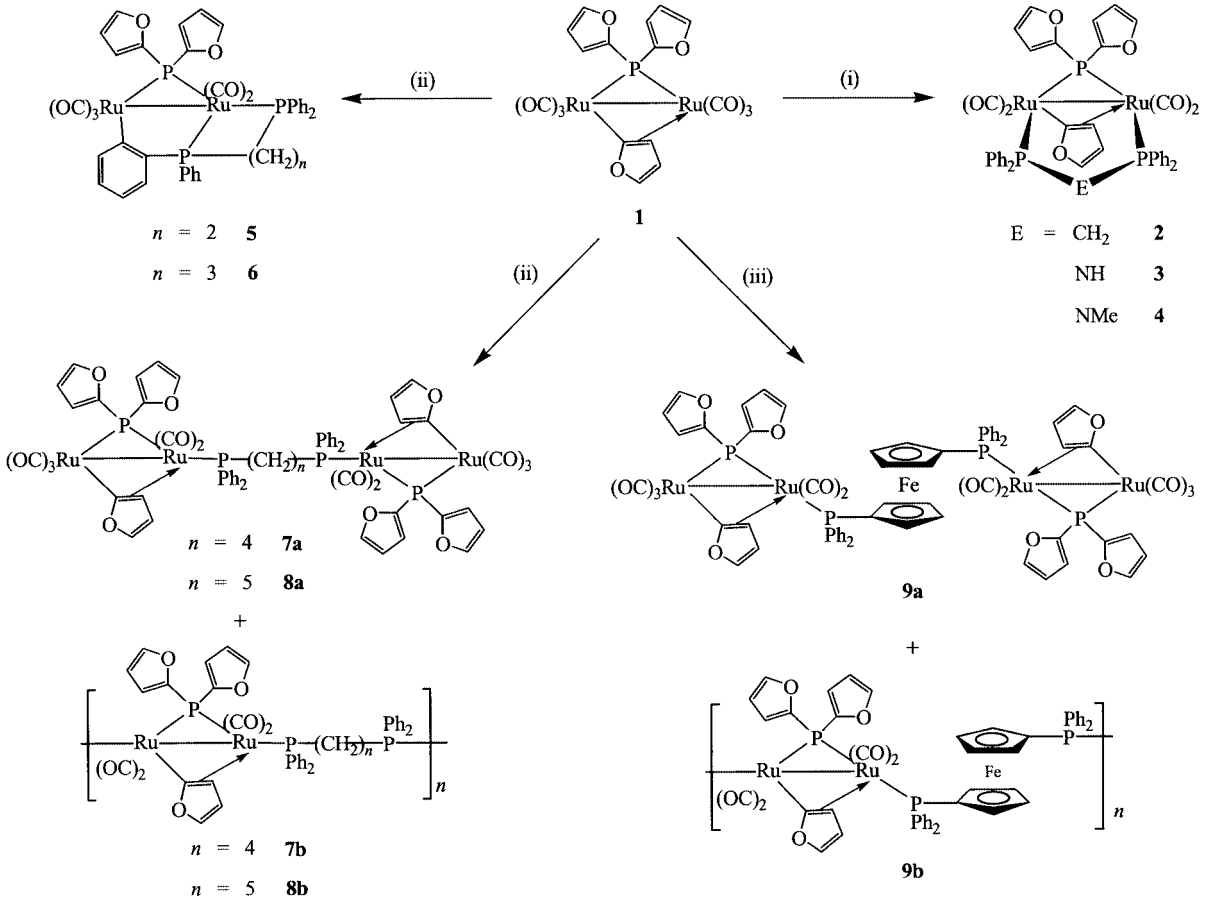
Results and Discussion

Synthesis and Spectroscopic Characterisation

Complex **1** reacts with an equimolar amount of the bidentate phosphane, namely bis(diphenylphosphanyl)methane (dppm), bis(diphenylphosphanyl)amine (dppam), or bis(diphenylphosphanyl)methylamine (dppma), in refluxing toluene to afford three new diruthenium compounds $[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(\mu\text{-dppm})]$ (**2**), $[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(\mu\text{-dppam})]$ (**3**), and $[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(\mu\text{-dppma})]$ (**4**) as the sole products after TLC purification on silica, all in reasonable yield (Scheme 2). They were isolated as bright yellow crystalline solids and are soluble in common organic solvents. These compounds display almost identical IR ν(CO) absorption patterns, suggesting a great resemblance of their structures. Each of the $^{31}P\{^1H\}$ NMR spectra of **2** and **4** consists of two separated sets of resonance signals. The resonance due to the phosphido-P atom shows equal coupling to the two coincidentally equivalent P atoms of the chelating diphosphanes, thus appearing as a pseudo-triplet ($^2J_{P-P}$ = 172 for **2** and 169 Hz for **4**). For **3**, a doublet of doublets appears around δ = 94.0 ppm, attributable to the $\mu\text{-}PFu_2$ entity and two interpenetrating sets of doublets in close proximity centred at δ = 87.16 and 87.18 ppm were also observed for the coordinated dppam ligand.

In order to further investigate, how the separation between the P donor atoms in $PPh_2(CH_2)_nPPh_2$ (i.e. the value of *n*) might affect the chemistry of such classes of complexes, we have examined the reactions that take place with the related bidentate phosphanes containing more methylene groups, namely bis(diphenylphosphanyl)ethane (dppe), bis(diphenylphosphanyl)propane (dppp), bis(diphenylphosphanyl)butane (dppb), or bis(diphenylphosphanyl)pentane (dpppe). To our surprise, two novel 34-electron phosphido-stabilised diruthenium complexes $[Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1\text{-}C_6H_4PPhCH_2CH_2PPh_2)]$ (**5**) and $[Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1\text{-}C_6H_4PPhCH_2CH_2CH_2PPh_2)]$ (**6**) were obtained as the thermodynamically stable products, upon reaction of **1** with dppe or dppp at elevated temperatures. In both structures, the two P atoms chelate to one Ru atom to result in five- (for **5**) and six-membered (for **6**) ruthenacycles, followed by orthometallation of one of the phenyl rings of $PPh_2(CH_2)_nPPh_2$ (*n* = 2, 3).[18] No sign of the formation of polymeric species in these reactions was observed under our experimental conditions. The transformation of these two products is illustrated in Scheme 2. Most interestingly, in marked contrast with **2**−**4**, the $\mu\text{-}\eta^1,\eta^2$-bonded furyl group was found to be detached during the formation of **5** and **6** so as to stabilize the products to retain 34 cluster valence electrons (CVE). However, the mechanism for this reaction is not yet ascertained. The IR spectral features of **5** and **6**



Scheme 2. (i) PPh_2EPPh_2; (ii) $PPh_2(CH_2)_nPPh_2$; (iii) dppf

are almost identical, indicative that they have similar structures. They exhibit different patterns from the dppm analogue. Their ν(CO) bands absorb at lower energies than those of **1**, in agreement with chelation of the strongly electron-donating phosphane ligands. They display three distinct sets of resonances in the $^{31}P\{^1H\}$ NMR spectra and afford a typical AMX spectrum in each case. Compound **5** gives a characteristic doublet of doublets at δ = 99.08 ppm ($^2J_{P-P}$ = 25 and 146 Hz) due to the μ-PFu_2 group and another doublet of doublets at δ = 68.36 ppm ($^2J_{P-P}$ = 25 and 146 Hz) for the orthometallated PPh moiety. We note that the resonance peak at δ = 65.67 ppm due to the PPh_2 group shows equal coupling to the other two *cis*-phosphorus atoms ($^2J_{P-P}$ = 25 Hz), thereby appearing as a virtual triplet. A similar coupling phenomenon has been observed in $[CpW_2(CO)_5(\mu\text{-}PPh_2)(\eta^2\text{-}dppe)]$.[19] The $^{31}P\{^1H\}$ NMR spectrum of **6** reveals three sets of doublets of doublets at δ = 84.27, 21.82, and 20.60 ppm with the most downfield signal corresponding to the phosphido group.

As a continuation of our effort in the study of the effect of the methylene chain length on the identity of products formed, similar reactions with dppb or dpppe were also carried out and in none of the cases was the product analogous to other $PPh_2(CH)_nPPh_2$-bridged species (n = 1−3) obtained. Complex **1** undergoes a rapid ligand substitution reaction with a 0.5 equiv. of dppb or dpppe in refluxing toluene for 1 h to give $[\{Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)\}_2(dppb)]$ (**7a**) (70%) and $[\{Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)\}_2(dpppe)]$ (**8a**) (65%) as yellow solids (Scheme 2). Their structures were firmly supported by spectroscopic data. There is also no indication of the formation of dppb- or dpppe-bridged analogues of **2**−**4**. Apparently, the long methylene bridge separating two bulky PPh_2 groups would favour the isolation of **7a** and **8a**. Although it is commonly found that the dppe and dppp can form stable five- and six-membered chelating rings with the metal centre without imposing strong steric interactions between the two PPh_2 groups,[12,19−22] chelation at the Ru atom by the dppb or dpppe is inhibited since the formation of 7- or 8-membered rings is generally not feasible. Moreover, the formation of a sterically unfavourable four-membered metallacycle for dppm would disfavour coordination via a chelating mode.

When the experiment was conducted with an equimolar amount of **1** and dppb or dpppe for 1 h, polymerisation occurred producing yellow polymers $[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(L)]_n$ [**7b** (L = dppb) or **8b** (L = dpppe)] in high yields and purity, which could not be isolated by TLC or column chromatography. Purification of the polymers was accomplished by extraction of the yellow residues with several portions of hot hexane, followed by repeated precipitation from their toluene solutions with methanol. Both polymers were characterized by Gel Permeation Chromatography (GPC) as low-molecular-weight substances. A prolonged heating of the reaction mixture was found to increase the extent of polymerisation, and we observed that polymer **7b** shows 23 repeating units (M_w = 24500, M_n = 22700) in the main chain when the reaction is carried out for 10 h. They are both air-stable and soluble in common organic solvents. By virtue of symmetry, they both present almost equivalent $^{31}P\{^1H\}$ NMR spectra and each shows two ^{31}P resonances at δ ≈ 34.0 and 39.0 ppm. However, no attempts have been made to fully assign these signals. The rather upfield resonances observed for the μ-phosphido atom in **7** and **8** were found to be in line with that for the disubstituted product $[Ru_2(CO)_4(PFu_3)_2(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)]$ which gave a pseudo AX_2 $^{31}P\{^1H\}$ spectrum with a triplet at δ = 48.00 ppm and a doublet at δ = −12.28 ppm ($^2J_{P-P}$ = 23 Hz) for the μ-PFu_2 and PFu_3 groups, respectively, in an intensity ratio of 1:2.[23]

Attempts have also been made to study the interaction between **1** and the organometallic diphosphane ligand $[Fe(\eta^5\text{-}C_5H_4PPh_2)_2]$ (dppf) in view of the considerable research attention on the use of the latter in the syntheses of di- or polymetallic complexes.[24] Instead of producing a chelating complex as in **2**−**4**, thermal reaction of **1** with dppf in a 2:1 molar ratio for a short period of time (ca. 1 h) afforded the complex $[\{Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)\}_2(dppf)]$ (**9a**) in fairly good yield in which two phosphido-bridged diruthenium fragments are linked by a bridging bis(diphenylphosphanyl)ferrocene moiety (Scheme 2). The two PPh_2 groups in dppf are separated by a large ferrocenyl moiety and are free to form bidentate complex **9a**. On the contrary, the relatively short bridging length between both PPh_2 groups in PPh_2EPPh_2 [E = CH_2, N(H), N(Me)] appears to hinder the adoption of such an interbridging mode. Spectroscopic and MS data of **9a** are consistent with the formula of the product having a 2:1 stoichiometry (Ru_2/dppf) with the loss of two CO ligands. The IR spectrum of **9a** shows a rather different ν(CO) pattern from those of **2**−**4**, indicating that an intrabridging interaction probably did not happen in this case. Like the spectrum of $[\{CpW_2(CO)_6(\mu\text{-}PPh_2)\}_2(dppf)]$,[19] two phosphorus doublets were clearly shown in its $^{31}P\{^1H\}$ NMR spectrum, in agreement with the structure shown. An attempt to generate a polymeric complex was also carried out via the reaction of **1** with dppf in a 1:1 stoichiometric ratio. Only a

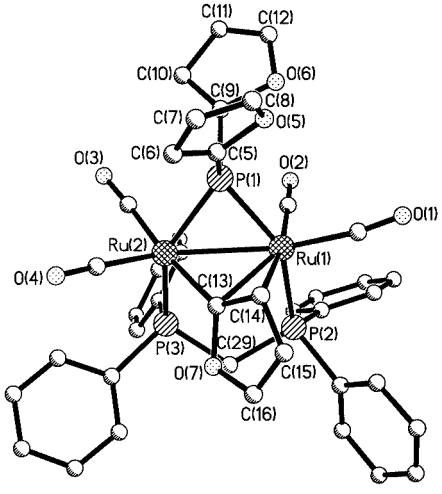


Figure 1. A perspective drawing of compound **2**; for clarity, all H atoms and the labels on the phenyl rings are omitted; the labels on the carbonyl C atoms have the same labels as the O atoms

trace quantity of **9a** was detected in this reaction and its yield was reduced as the time of reflux was increased. An air-stable polymeric substance $[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(dppf)]_n$ (**9b**) was obtained as the major product following similar purification procedures as for **7b** and **8b**. An analytically pure sample of **9b** was collected as an orange solid in 64% yield which is soluble in chlorinated solvents such as CH_2Cl_2 and $CHCl_3$. Analysis of **9b** by GPC revealed a low-molecular-weight polymer (M_w = 11400, M_n = 8550, average degree of polymerization = 8). Compound **9b** displays NMR spectroscopic data that is very similar to that of the model complex **9a,** except that its resonance peaks are rather broad in appearance.

Crystal Structure Analyses

Perspective drawings of the structures of **2** (Figure 1, Table 1), **3** (Figure 2, Table 1), **4** (Figure 3, Table 1), **5** (Figure 4, Table 2), **6** (Figure 5, Table 3), **8a** (Figure 6, Table 4), and **9a** (Figure 7, Table 5) are shown together with the atomic numbering schemes used and selected bond lengths and angles are given. The general structural features of **2**−**4** are very similar. Each of them possesses a difurylphosphido-bridged diruthenium skeleton and the Ru−Ru edge is spanned by a bridging PPh_2EPPh_2 {**2** (E = CH_2), **3** [E = N(H)], **4** [E = N(Me)]} ligand. In each case, the C- or N(R)-bridged (R = H, Me) diphosphane forms a nonplanar, five-membered metallacyclic ring. While the Ru−Ru distances in **2**−**4** are relatively insensitive to the nature of the bridging unit between both of the PPh_2 end groups, they are shorter than those in **1** and other related dialkyne-bridged Ru_2 complexes reported recently [ca. 2.7735(3)−2.8006(6) Å].[13] For **2**−**4**, the P(1) atom is asymmetrically bonded to Ru(1) and Ru(2). The furyl unit is σ-bonded to Ru(2) and π-bonded to Ru(1). These compounds display only slight chelate ring twisting about the Ru−Ru axis for the diphosphane ligands and the torsion angles defined by P(2)−Ru(1)−Ru(2)−P(3) are 7.3, 8.9, and 4.5° for **2**−**4**, respectively. Within the five-membered ruthenacycle in **2**, the structural parameters of the coordinated dppm are very similar to those found in other Ru_2 complexes bridged by dppm, such as in $[Ru_2(CO)_4(\mu\text{-}PPh_2)\{\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C(Ph)=C=CPPh_2\}(\mu\text{-dppm})]$ [2.367(1) Å and 113.6(2)°],[12] $[Ru_2(CO)_3(MeCN)(\mu\text{-}O_2CMe)(\mu\text{-dppm})_2]^+$ [2.37(1) Å and 113(2)°],[25] and $[Ru_2(CO)_2(PPh_3)(\mu\text{-}PPh_2)(\mu_1\text{-}\eta^2\text{-}CH_2PPh_2)(\mu\text{-dppm})]^+$ [2.405(3) Å and 110.0(4)°].[25] The P−N−P angle for **3** is 126.0(4)°, in common with other dinuclear compounds with bridging dppam in the literature.[26–31] The corresponding angle is 121.59(15)° for **4**. These angles are slightly larger than 118.9(2) and 114.6(1)° in free dppam and dppma,[32] respectively. To date, relatively few structural data are available for metal complexes containing dppma as a bridging ligand.[32,33]

The structural characterisations of **5** and **6** provide unequivocal proof of the identity of both molecules in the solid state. Basically, both structures contain a difurylphosphido-substituted diruthenium framework with the $(CH_2)_n$-bridged diphosphane ligands (n = 2, 3) interacting with both metal atoms in an η^1-bonding mode. The furyl moiety that is originally present in **1** has been eliminated. The two P atoms chelate to Ru(1) to afford a sterically favourable five- and six-membered ruthenacycle for **5** and **6**, respectively, accompanied by orthometallation of one of the phenyl rings on the P(3) atom. The coordination around the Ru(1) and Ru(2) atoms is completed by two and three

terminal carbonyl ligands, respectively. For **5**, the dppe ligand was shown to coordinate to the Ru centres, being bonded to Ru(1) through both P(2) and P(3) atoms, and to Ru(2) through the C(33) atom of the orthometallated ring. The torsion angle defined by P(2)−C(26)−C(27)−P(3) is 45.5°. A salient structural feature observed in the structure of **6** is the formation of a six-membered ring, which adopts a stable chair conformation. The P(2) and P(3) atoms are bonded to Ru(1) within the metallacycle. The Ru(2)−C(40) distance [2.174(2) Å] is typical of a Ru−C bond.[12,13,34−36] Both compounds have 34 CVE and the EAN rule supports the metal−metal bond formation based on the three- and five-electron contribution from the phosphido and $C_6H_4PPh(CH_2)_nPPh_2$ (n = 2, 3) units, respectively.

For **8a**, the dpppe ligand links two identical $[Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)]$ units such that the two halves of the molecule are symmetrically related by an inversion centre at C(32). The C−C bonds in the aliphatic pentamethylene chain of the molecule are staggered with C−C bond lengths between 1.509(6) and 1.511(6) Å and C−C−C angles between 111.4(5) and 115.4(6)°. Complex **9a** reveals a symmetrical dppf-bridged structure in which a dppf unit is

sandwiched by two μ-phosphido Ru_2 moieties to afford a heterometallic complex aggregate. The average Ru−Ru bond length is 2.7982(6) Å. The retention of the dissociated furyl fragment in the structure is highlighted by the formation of a σ and a π bonds between the furyl fragment and the Ru_2 core at both ends, similar to those mentioned before in **2**−**4**. The two PPh_2 groups are oriented in an *anti* configuration and the two P atoms are displaced from each cyclopentadienyl ring (away from the Fe atom) by 0.2461 Å for P(2) and −0.2649 Å for P(3). The two phosphanylcyclopentadienyl rings are nearly parallel (dihedral angles 4.4°), planar and deviate by 8.1° from the idealised eclipsed conformation.

Concluding Remarks

The work presented here concerns the reaction chemistry of $[Ru_2(CO)_6(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)]$ (Fu = 2-furyl) (**1**) with various bidentate phosphane ligands. The general reactivity patterns comprise chemical transformations involving (i) substitution of CO ligands by phosphanes via intrabridging or interbridging coordination modes to afford discrete or polymeric molecules, or (ii) cyclometallation reactions accompanied by reductive elimination of the dissociated furyl moiety. In our studies, three bonding types have been encountered for the diphosphanes used: chelating, intrabridging, and interbridging. We have also investigated in detail the factors dictating the preference for a particular coordination geometry and we observe that the mode of coordination is dependent on the nature and the length of the linking chains between the terminal PPh_2 groups. Although the dominant reaction pathway involves replacement of CO li-

gands by phosphido groups to give substitution products in the majority of cases, thermolysis of **1** with dppe or dppp results in orthometallation of the phenyl ring to yield thermodynamically stable 34-electron complexes containing a $\mu\text{-}\eta^1\text{-}C_6H_4PPh(CH_2)_nPPh_2$ (n = 2, 3) moiety along with the unprecedented detachment of the original furyl fragment from precursor **1**. Work is in progress to study the reactivity of **1** with other organic and organometallic nucleophilic reagents.

Experimental Section

General Procedures: All reactions were conducted under dry nitrogen with the use of standard Schlenk techniques. Solvents for preparative work were dried and distilled before use. Unless otherwise stated all reagents were obtained from commercial suppliers and used without further purification. The syntheses of complex **1**[13] and the ligands dppam[28,29] and dppma[32] were carried out as reported previously. IR spectra were recorded as CH_2Cl_2 solutions with a Perkin−Elmer Paragon 1000 PC or Nicolet Magna 550 Series II FTIR spectrometer. NMR spectra were measured in $CDCl_3$ with a JEOL EX270 or a Varian Inova 400 MHz FT NMR spectrometer, with ^1H NMR chemical shifts quoted relative to $SiMe_4$ and ^{31}P chemical shifts relative to an 85% H_3PO_4 external standard. Fast atom bombardment (FAB) mass spectra were recorded in *m*-nitrobenzyl alcohol matrices with a Finnigan-SSQ 710 spectrometer. Separation of products was accomplished by preparative TLC plates coated with silica (Merck, Kieselgel 60). The molecular weight of each polymer sample was estimated by GPC (HP 1050 series HPLC with visible wavelength and fluorescent detectors) against polystyrene standards.

$[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(\mu\text{-}dppm)]$ (2): A solution of complex **1** (50 mg, 0.083 mmol) in toluene (20 mL) was refluxed with dppm (32 mg, 0.083 mmol) for 4 h. The solution gradually changed from pale yellow to dark orange-yellow. The solvent was then removed in vacuo and the residue taken up in CH_2Cl_2 for TLC separation eluting with hexane/CH_2Cl_2 (2:1, v/v). The bright yellow band (R_f = 0.34) consisting of **2** was obtained and the product was isolated in 84% yield (65 mg). Recrystallisation of the product was achieved by concentration of a hexane/CH_2Cl_2 solution at room temperature, affording bright yellow block crystals. IR (CH_2Cl_2): $\tilde{\nu}$ = 2007 s, 1985 vs, 1942 vs [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 3.74 (t, $^2J_{H-P}$ = 10.8 Hz, 2 H, CH_2), 4.87 (m, 1 H, Fu), 5.63 (m, 1 H, Fu), 6.33−6.46 (m, 4 H, Fu), 6.75 (s, 1 H, Fu), 7.27 (m, 16 H, Ph), 7.54 (s, 1 H, Fu), 7.67 (m, 4 H, Ph), 7.74 (s, 1 H, Fu) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 41.61 (d, $^2J_{P-P}$ = 172 Hz, PPh_2), 100.46 (t, $^2J_{P-P}$ = 172 Hz, PFu_2) ppm. FAB MS: m/z = 931 [M^+]. $C_{41}H_{31}O_7P_3Ru_2$ (930.75): calcd. C 52.91, H 3.36; found C 53.14, H 3.30.

$[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(\mu\text{-}dppam)]$ (3): White powdered dppam (32 mg, 0.083 mmol) was added to a toluene solution of **1** (50 mg, 0.083 mmol) and the mixture was stirred under reflux for 3 h to afford a bright yellow solution. The volatile materials were removed in vacuo and subsequent workup by TLC purification with hexane/CH_2Cl_2 (1:1, v/v) as eluent gave a yellow band (R_f = 0.60) which furnished compound **3** as a yellow crystalline solid in 44% (34 mg). IR (CH_2Cl_2): $\tilde{\nu}$ = 2011 s, 1989 vs, 1946 vs [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 4.42 (m, 1 H, NH), 4.75 (m, 1 H, Fu), 5.92 (m, 1 H, Fu), 6.31−6.40 (m, 3 H, Fu), 6.73 (s, 1 H, Fu), 7.17 (m, 1 H, Fu), 7.34 (m, 12 H, Ph), 7.48 (m, 5 H, Fu + Ph), 7.62 (m, 4 H, Ph), 7.71 (s, 1 H, Fu) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 87.16 (d, $^2J_{P-P}$ = 191 Hz, PPh_2), 87.18 (d, $^2J_{P-P}$ = 162 Hz, PPh_2), 93.97 (dd, $^2J_{P-P}$ = 162, 191 Hz, PFu_2) ppm. FAB MS: m/z = 876 [(M − 2 CO)$^+$]. $C_{40}H_{30}NO_7P_3Ru_2$ (931.74): calcd. C 51.56, H 3.25, N 1.50; found C 51.30, H 3.16, N 1.32.

$[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(\mu\text{-}dppma)]$ (4): This compound was prepared similarly as described above for **2** and **3** from **1** (50 mg, 0.083 mmol) and dppma (33 mg, 0.083 mmol). The resulting reddish-orange mixture was subjected to preparative TLC eluting with hexane/CH_2Cl_2 (3:1, v/v). From the bright yellow band (R_f = 0.21), the title compound was obtained in 42% yield (33 mg) as bright yellow block-shaped crystals upon recrystallisation from hexane/CH_2Cl_2 under ambient conditions. IR (CH_2Cl_2): $\tilde{\nu}$ = 2007 s, 1988 vs, 1944 vs [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.47 (t, $^3J_{H-P}$ = 6.4 Hz, 3 H, NMe), 5.02 (m, 1 H, Fu), 5.28 (m, 1 H, Fu), 6.34−6.38 (m, 3 H, Fu), 6.49 (m, 1 H, Fu), 6.68 (m, 1 H, Fu), 7.44 (m, 16 H, Ph), 7.66 (s, 1 H, Fu), 7.72 (m, 4 H, Ph), 7.75 (s, 1 H, Fu) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 91.80 (t, $^2J_{P-P}$ = 169 Hz, PFu_2), 106.92 (d, $^2J_{P-P}$ = 169 Hz, PPh_2) ppm. FAB MS: m/z = 946 [M^+]. $C_{41}H_{32}NO_7P_3Ru_2$ (945.77): calcd. C 52.07, H 3.41, N 1.48; found C 51.73, H 3.25, N 1.70.

$[Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1\text{-}C_6H_4PPh(CH_2)_2PPh_2)]$ (5): A mixture of compound **1** (50 mg, 0.083 mmol) and dppe (33 mg, 0.083 mmol) in toluene was stirred under reflux for 5 h resulting in a reddish-brown mixture. Removal of the solvent followed by TLC separation on silica eluting with hexane/CH_2Cl_2 (2:1, v/v) gave a yellow solid of complex **5** (35 mg, 46%) after recrystallisation from a hexane/$CHCl_3$ mixture at room temperature. IR (CH_2Cl_2): $\tilde{\nu}$ = 2046 vs, 2002 vs, 1980 m, 1961 s [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.98−2.06 (m, 2 H, CH_2), 2.81−2.91 (m, 2 H, CH_2), 5.45 (m, 1 H, Fu), 5.91 (m, 1 H, Fu), 6.01 (m, 1 H, Fu), 6.19 (m, 1 H, Fu), 6.42 (t, $^3J_{H-H}$ = 7.6 Hz, 1 H, Fu), 6.70−7.63 (m, 19 H, aromatic), 8.06 (d, $^3J_{H-H}$ = 7.6 Hz, 1 H, Fu) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 65.67 (t, $^2J_{P-P}$ = 25 Hz, PPh), 68.36 (dd, $^2J_{P-P}$ = 25 and 146 Hz, PPh), 99.08 (dd, $^2J_{P-P}$ = 25 and 146 Hz, PFu_2) ppm. FAB MS: m/z = 850 [(M − 2 CO)$^+$]. $C_{39}H_{29}O_7P_3Ru_2$ (904.72): calcd. C 51.78, H 3.23; found C 51.42, H 3.16.

$[Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1\text{-}C_6H_4PPh(CH_2)_3PPh_2)]$ (6): In a manner similar to compound **5**, refluxing a toluene solution (20 mL) of **1** (50 mg, 0.083 mmol) and dppp (34 mg, 0.083 mmol) in a 1:1 molar ratio for 5 h produced a dark yellowish-brown solution. The usual workup procedures afforded a colourless TLC band (hexane/CH_2Cl_2, 4:1, v/v; R_f = 0.31), which became apparent under UV light. The title complex was subsequently isolated as a pale yellow solid in 40% yield (31 mg). IR (CH_2Cl_2): $\tilde{\nu}$ = 2049 vs, 2004 s, 1985 s, 1959 s [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.03−2.42 (m, 4 H, CH_2), 2.85−3.06 (m, 2 H, CH_2), 5.57 (m, 1 H, Fu), 5.96 (m, 1 H, Fu), 6.10 (m, 1 H, Fu), 6.22 (m, 1 H, Fu), 6.56 (t, $^3J_{H-H}$ = 7.6 Hz, 1 H, Fu), 6.74−7.91 (m, 19 H, aromatic), 8.22 (d, $^3J_{H-H}$ = 7.6 Hz, 1 H, Fu) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 20.60 (dd, $^2J_{P-P}$ = 31 and 38 Hz, PPh), 21.82 (dd, $^2J_{P-P}$ = 4 and 38 Hz, PPh), 84.27 (dd, $^2J_{P-P}$ = 4 and 31 Hz, PFu_2) ppm. FAB MS: m/z = 919 [M^+]. $C_{40}H_{31}O_7P_3Ru_2$ (918.74): calcd. C 52.29, H 3.40; found C 52.01, H 3.19.

$[\{Ru_2(CO)_5(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)\}_2(dppb)]$ (7a) and $[Ru_2(CO)_4(\mu\text{-}PFu_2)(\mu\text{-}\eta^1,\eta^2\text{-}Fu)(dppb)]_n$ (7b): A toluene solution (20 mL) of **1** (50 mg, 0.083 mmol) was heated at reflux in the presence of a 0.5 equiv. of dppb (18 mg, 0.042 mmol). After 1 h, the solvent was removed and the residue chromatographed. A yellow band, eluted with hexane/CH_2Cl_2 (1:1, v/v), yielded the linking cluster **7a** (46 mg, 70%) after recrystallisation from the same solvent mixture.

Mixing compound **1** with 1 mol-equiv. of dppb (0.083 mmol) in toluene (20 mL), followed by heating to reflux for 1 h, generated a deep yellow solution. TLC screening essentially revealed the absence of **7a**. The solvent was removed and the crude solid obtained after washing with hot hexane was redissolved in the minimum volume of toluene. Analytically pure sample of **7b** was isolated as a yellow solid (56 mg, 69%) by repeated precipitation from methanol, washing with hexane and drying in vacuo. **7a**: IR (CH_2Cl_2): $\tilde{\nu}$ = 2060 vs, 2006 vs, 1974 m, 1958 sh [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.09−2.57 (m, 6 H, CH_2), 3.50 (m, 2 H, CH_2), 4.83 (m, 2 H, Fu), 6.04−6.44 (m, 10 H, Fu), 7.08−7.57 (m, 26 H, Fu + Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 34.58 (m, PFu_2 or PPh_2), 48.80 (m, PFu_2 or PPh_2) ppm. FAB MS: *m*/*z* = 1491 [(M − 3 CO)$^+$]. $C_{62}H_{46}O_{16}P_4Ru_4$ (1575.21): calcd. C 47.28, H 2.94; found C 46.95, H 2.80. **7b**: IR (CH_2Cl_2): $\tilde{\nu}$ = 2014 vs, 1982 m, 1951 s [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.00−2.50 (m, 6 H, CH_2), 3.49 (m, 2 H, CH_2), 4.52 (m, 1 H, Fu), 5.36 (m, 1 H, Fu), 5.85−6.32 (m, 4 H, Fu), 7.05−7.56 (m, 23 H, Fu + Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 34.33 (m, PFu_2 or PPh_2), 38.60 (m, PFu_2 or PPh_2) ppm. GPC (THF as eluent): M_w = 5030, M_n = 4810 (*n* = 1.05). When the polymerization was performed for 10 h, M_w = 24500, M_n = 22700 (*n* = 1.08). $C_{44}H_{37}O_7P_3Ru_2{\cdot}0.5C_6H_{14}$ (1015.92): calcd. C 55.57, H 4.37; found C 55.79, H 4.34.

[{$Ru_2(CO)_5$(μ-PFu_2)(μ-η^1,η^2-Fu)}$_2$(dpppe)] (8a) and [$Ru_2(CO)_4$(μ-PFu_2)(μ-η^1,η^2-Fu)(dpppe)]$_n$ (8b): A mixture of **1** (50 mg, 0.083 mmol) and dpppe (19 mg, 0.042 mmol) in toluene (20 mL) was heated to reflux for 1 h. Concentration of the resulting yellow solution followed by TLC separation gave a bright yellow band (R_f = 0.55) from which compound **8a** was isolated in 65% yield (43 mg). When a similar reaction was performed using a 1:1 molar ratio of **1** and dpppe (0.083 mmol), the desired polymer **8b** formed after 1 h of reflux, which was worked up in a fashion identical to that for **7b**, to afford a yellow-orange solid (60 mg, 73%). **8a**: IR (CH_2Cl_2): $\tilde{\nu}$ = 2060 vs, 2006 vs, 1973 m, 1957 sh [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.25−2.62 (m, 8 H, CH_2), 3.48 (m, 2 H, CH_2), 4.83 (s, 1 H, Fu), 4.90 (s, 1 H, Fu), 6.21−6.33 (m, 10 H, Fu), 7.20−7.46 (m, 26 H, Fu + Ph), 7.54 (s, 2 H, Fu) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 34.75 (m, PFu_2 or PPh_2), 49.15 (m, PFu_2 or PPh_2) ppm. FAB MS: *m*/*z* = 1561 [(M − CO)$^+$]. $C_{63}H_{48}O_{16}P_4Ru_4$ (1589.24): calcd. C 47.61, H 3.04; found C 47.32, H 2.85. **8b**: IR (CH_2Cl_2): $\tilde{\nu}$ = 2014 vs, 1981 m, 1951 s [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.08−2.67 (m, 8 H, CH_2), 3.49 (m, 2 H, CH_2), 4.88 (m, 1 H, Fu), 5.39 (m, 1 H, Fu), 6.12−6.34 (m, 4 H, Fu), 7.10−7.89 (m, 23 H, Fu + Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 34.22 (m, PFu_2 or PPh_2), 38.99 (m, PFu_2 or PPh_2) ppm. GPC (THF as eluent): M_w = 8550, M_n = 7270 (*n* = 1.18). $C_{45}H_{39}O_7P_3Ru_2{\cdot}0.5C_6H_{14}$ (1029.95): calcd. C 55.98, H 4.50; found C 55.97, H 4.27.

[{$Ru_2(CO)_5$(μ-PFu_2)(μ-η^1,η^2-Fu)}$_2$(dppf)] (9a) and [$Ru_2(CO)_4$(μ-PFu_2)(μ-η^1,η^2-Fu)(dppf)]$_n$ (9b): Compound **1** (50 mg, 0.083 mmol) and dppf (23 mg, 0.042 mmol) in a 2:1 molar ratio were dissolved and mixed in toluene (20 mL). After heating to reflux and stirring for about 1 h, the resulting mixture was purified by chromatography on silica plates using hexane/CH_2Cl_2 (3:1, v/v) as eluent, leading to the isolation of an orange product **9a** (R_f = 0.38, 38 mg, 53%). When an equimolar amount of **1** and dppf (0.083 mmol) was employed in the reaction whilst stirring for 1 h, an orange solution resulted and the solvent was evaporated. The crude product was then washed with several portions of hot hexane (3 × 10 mL) and the resulting solid was reprecipitated thrice from toluene/methanol to produce an orange powder of **9b** in 64% yield (59 mg) after drying in vacuo. **9a**: IR (CH_2Cl_2): $\tilde{\nu}$ = 2061 vs, 2005 vs, 1978 s, 1957 sh [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 3.78 (m, 4 H, C_5H_4), 4.05 (m, 2 H, C_5H_4), 4.32 (m, 2 H, C_5H_4), 4.52 (s, 2 H, Fu), 5.16 (s, 2 H, Fu), 5.96 (s, 2 H, Fu), 6.18 (m, 4 H, Fu), 6.39 (m, 2 H, Fu), 6.97−7.51 (m, 24 H, Fu + Ph), 7.66 (s, 2 H, Fu) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 36.13 (d, $^2J_{P-P}$ = 20 Hz, PFu_2 or PPh_2), 47.86 (d, $^2J_{P-P}$ = 20 Hz, PFu_2 or PPh_2) ppm. X-ray Crystallography: Except for compounds **6** and **8a**, good-quality crystals of our compounds suitable for X-ray diffraction studies were grown by slow concentration of their respective solutions in hexane/CH_2Cl_2 at room temperature. Crystals of **6**·MeOH and **8a**·CH_2Cl_2 were obtained from an MeOH/$CHCl_3$ and C_6H_{12}/CH_2Cl_2 mixture, respectively. Geometric and intensity data were collected using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) with a Bruker AXS SMART 1000 CCD area-detector diffractometer. The collected frames were processed with proprietary software SAINT[37] and an absorption correction was applied (SADABS[38]) to the collected reflections. The space group of each crystal was determined from the systematic absences and confirmed by successful refinement of the structure. The possible alternative *Pbca* for compound **3** was tried but did not give any reasonable solution. The structures of these molecules were solved by direct methods and expanded by standard difference Fourier syntheses using the software SHELXTL.[39] Structure refinements were made on F^2 by the full-matrix least-squares technique. All non-hydrogen atoms were refined with anisotropic displacement parameters. For **2** and **3**, one of the furyl rings was refined isotropically with constrained geometry and the resulting model yielded reasonable bond lengths and angles. Hydrogen atoms were either generated from Fourier maps or placed in their idealised positions and allowed to ride on the respective carbon atoms. Pertinent crystallographic information is provided in Table 6. CCDC-168743 to -168749 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Syntheses, Structures and Photophysical Properties of Metal Carbonyl Clusters with Dansyl and Acridone Luminophores

Wai-Yeung Wong,*[a] Ka-Ho Choi,[a] and Zhenyang Lin[b]

Keywords: Transition metal / Dansyl group / Acridone / Luminophores

A series of fluorescent transition metal complexes bearing the 5-(dimethylamino)naphthalene-1-sulfonyl (R^1) and acridone (R^2) frameworks have been prepared. Reactions of the fluorescent-labeled alkyne ligands $R^1CH_2C{\equiv}CH$ and $R^2CH_2C{\equiv}CH$ with various metal carbonyl compounds $[Co_2(CO)_8]$, $[Et_3NH][Fe_2(CO)_6(\mu\text{-}CO)(\mu\text{-}S\textit{t}Bu)]$ and $[M_3(CO)_{10}(NCMe)_2]$ (M = Ru, Os) readily afforded new cluster complexes of the stoichiometry $[Co_2(CO)_6(\mu\text{-}\eta^2\text{-}RCH_2CCH)]$ (**1**: R = R^1, **2**: R^2), $[Fe_2(CO)_6(\mu\text{-}S\textit{t}Bu)(\mu\text{-}\eta^2\text{-}RCH_2C{=}CH_2)]$ (**3**: R = R^1, **4**: R^2), $[Ru_3(CO)_9(\mu\text{-}CO)(\mu_3\text{-}\eta^2\text{-}RCH_2CCH)]$ (**5**: R = R^1, **6**: R^2) and $[Os_3(CO)_9(\mu\text{-}CO)(\mu_3\text{-}\eta^2\text{-}RCH_2CCH)]$ (**7**: R = R^1, **8**: R^2) in moderate to good yields. All of these new complexes have been fully characterized by FTIR, ^1H NMR spectroscopy, UV/Vis spectroscopy and fast atom bombardment mass spectrometry (FABMS). The single-crystal X-ray structural analyses and molecular orbital calculations on **1**, **2**, **4** and **8** have been performed. It was found that all of these compounds are fluorescent in solutions at room temperature and a luminescence band characteristic of the inherent fluorophore is observed in these metal structures. However, a strong quenching of the fluorescence intensity of the chromophoric groups was observed upon coordination of metal cluster moieties.

Introduction

Photoluminescence spectroscopy has continued to attract increasing current attention in the scientific community due to its wide applications in environmental and biological sciences and molecular electronics.[1−6] The preparation and photophysical properties of several fluorescent methylmercury acetylides carrying the anthracene, 5-(dimethylamino)naphthalene-1-sulfonyl (dansyl) and 9-acridone frameworks have recently been reported and these compounds could be exploited in the development of new analytical methods for methylmercury in environmental and biological samples.[7] Prodi and co-workers also described the use of a tripodal ligand containing the dansyl chromophore as a luminescent chemosensor for metal ions.[8]

We have a long-term interest in the design and synthesis of luminescent transition metal-containing materials[9,10] and major efforts have been devoted to the studies of organometallic acetylide complexes and polymers incorporating a vast range of aromatic and heteroaromatic spacers.[11−16] In view of the high luminescence quantum yields of the auxiliary dansyl and acridone units,[17] we expect that a properly derivatized molecule such as 5-(dimethylamino)-*N*-(2-propynyl)-1-naphthalenesulfonamide (**I**) and 10-(2-propynyl)-9-acridone (**II**) (Scheme 1) could be employed to attach a fluorescent label to the metal center through an acetylide linkage,[7,10] which is likely to exhibit rich optical and photo-electronic properties. Indeed, two novel blue luminescent platinum(II) acetylide compounds bearing these functionalities have been reported recently by us in preliminary form.[10] We therefore sought to design new molecular systems featuring these luminophores. In this context, we aim at preparing some fluorescent-labeled metal carbonyl complexes of Groups 8 and 9 transition metal elements by using properly tailored acetylenes since the interactions between alkynes and binary low-nuclearity carbonyl complexes of iron, ruthenium, osmium and cobalt have been well documented.[18−28] To the best of our knowledge, studies of luminescent transition metal carbonyl clusters bearing fluorescent labels are scarce. In this article, we describe the synthesis, as well as the spectroscopic, structural and photophysical properties of a new series of fluorescent dinuclear and trinuclear metal complexes incorporating the dansyl and acridone entities.

Results and Discussion

Synthesis

An adaptation of the literature methods was employed to obtain the fluorescent-labeled ligands **I** and **II**.[7,10] The synthetic routes to all the new compounds are shown in Scheme 2. The dinuclear cobalt carbonyl complexes **1** and

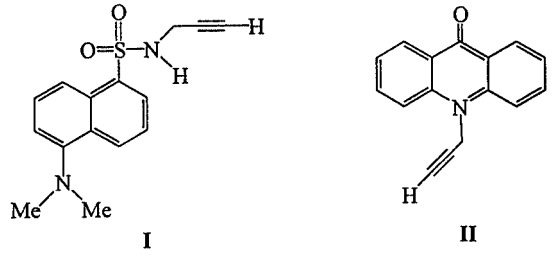
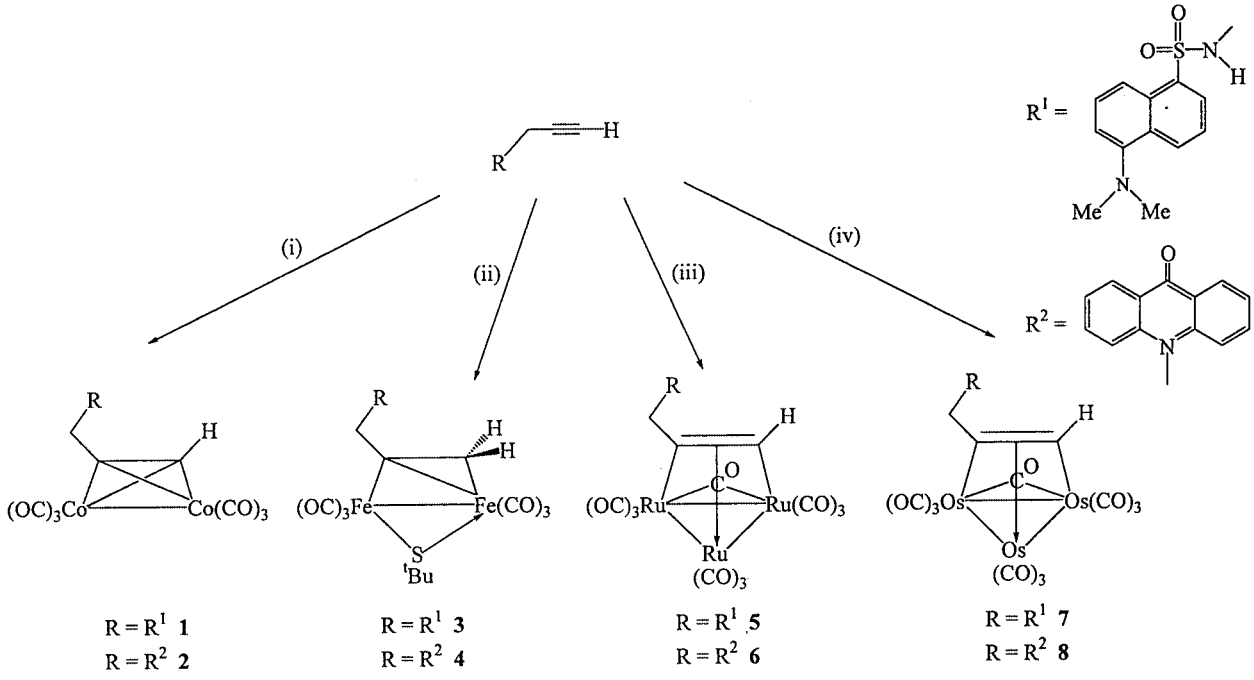


Scheme 1. Structures of **I** and **II**

2 were prepared in moderate yields by reacting $[Co_2(CO)_8]$ with one equivalent of **I** and **II**, respectively, at 0 °C.[25−28] Thermal treatment of **I** and **II** with the iron carbonyl salt $[Et_3NH][Fe_2(CO)_6(\mu\text{-}CO)(\mu\text{-}S\textit{t}Bu)]$ prepared in situ from a $[Fe_3(CO)_{12}]/NEt_3/\textit{t}BuSH$ mixture[18] in a 1:1 molar ratio in refluxing THF afforded the σ,π-vinyl complexes **3** and **4** in yields of 31 and 35%, respectively. This reaction sequence was accompanied by the formation of $[Fe_2(CO)_6(\mu\text{-}S\textit{t}Bu)_2]$ as a by-product.[18] The reactions of the freshly prepared $[Ru_3(CO)_{10}(NCMe)_2]$ with the appropriate alkynes **I** and **II** are straightforward at room temperature with the loss of MeCN to give complexes **5** and **6** as the final products. The facile displacement of two MeCN groups of $[Os_3(CO)_{10}(NCMe)_2]$ by the terminal acetylenes to afford $[Os_3(CO)_9(\mu\text{-}CO)(\mu_3\text{-}\eta^2\text{-}RCCH)]$ was successfully applied to the preparation of alkyne-substituted complexes **7** and **8** as major products.[21−23] All of these compounds were purified by preparative TLC on silica and compounds **1**−**4** were isolated as orange to red solids and products **5**−**8** as yellow solids. Complexes **1**−**8** are highly soluble in common organic solvents such as CH_2Cl_2 and $CHCl_3$ and their solutions slowly decompose when exposed to air. As solid materials they are stable at room temperature for prolonged periods even when precautions to exclude air or moisture are not taken.

Spectroscopic Properties

Collated spectroscopic data (IR, ^1H NMR and FABMS) of these new fluorophore-anchored metal complexes are in agreement with their formulation and full details are given in the Exp. Sect. The disappearance of the IR ν(C≡C) and ν(≡C−H) bands in **1**−**8** indicates that metal carbonyl fragments are coordinated to the acetylenic unit. A broad peak at 1880 cm^{-1} for the Ru complexes **5** and **6**, and 1848 cm^{-1} for the osmium derivatives **7** and **8**, was consistent with the presence of a bridging carbonyl group in each case. In the IR spectra, the band patterns between the uncomplexed and complexed chromophores are similar. Coordination of the alkyne moiety to the metal core was confirmed by the close resemblance of the IR spectral pattern in the ν(CO) region of our complexes with those observed for the reported cobalt−alkyne complexes,[25−28] $[Fe_2(CO)_6(\mu\text{-}SR)(\mu\text{-}\eta^2\text{-}R'C{=}CH_2)]$[18,29] and $'M_3(CO)_{10}'$ cores (M = Ru, Os) which coordinate an alkyne in a $\mu_3\text{-}(\eta^2\text{-}\|)$ fashion.[21−24] The ^1H NMR spectra of the new complexes display resonances stemming from the coordinated dansyl or acridone group but the signals due to −C≡CH for **I** (ca. 1.92 ppm) and **II** (ca. 2.43 ppm) were absent.[7] Except for **3** and **4**, the presence of a singlet peak in the range of δ = 5.74−9.10 is clearly resolved for the −CCH protons in these compounds. Assignments for the signals arising from the protons attached to C_β in the vinyl-bridged diiron compounds **3** and **4** could be made in their corresponding ^1H NMR spectra



Scheme 2. (i) $[Co_2(CO)_8]$, hexane, 1 h, 0 °C; (ii) $[Et_3NH][Fe_2(CO)_6(\mu\text{-}CO)(\mu\text{-}S\textit{t}Bu)]$, THF, reflux, 5 h; (iii) $[Ru_3(CO)_{10}(NCMe)_2]$, CH_2Cl_2/MeCN, room temp., 2 h; (iv) $[Os_3(CO)_{10}(NCMe)_2]$, CH_2Cl_2, room temp., 2 h.

consistent for both structures. For **3**, the two vinyl proton resonances appear as two doublets at δ = 2.63 and 3.48 ppm with a geminal coupling constant of 2.6 Hz, whereas two doublets are apparent at δ = 2.77 and 3.13 ppm (J_{H-H} = 4.6 Hz) for **4**. These data agree with those reported for other [$Fe_2(CO)_6$(μ-SR)(μ-R′$C_α$=$C_βH_2$)] complexes and they are consistent with NMR spectroscopic data for other μ-vinyl systems as well.[18,29] The thiolate moieties in **3** and **4** display the expected singlet peak due to the *tert*-butyl group. These new compounds also gave satisfactory mass spectroscopic data and, in most cases, they showed the molecular ion peaks followed by the consecutive loss of carbonyl fragments. The parent ion peaks indicate a 1:1 (metal/ligand) stoichiometry for the complexes.

Electronic Absorption and Luminescence Spectra

The photophysical properties of complexes **1**−**8** have been studied in CH_2Cl_2 at room temperature and the results are summarized in Table 1. Both of the free alkynes **I** and **II** typically exhibit three intense absorption peaks in the near-UV region that can be ascribed to π−π* transitions within the ligand framework.[10] For the metal cluster complexes, they all show similar structured low-energy bands in the near-UV and the visible regions due to the metal-perturbed intraligand π−π* transitions of the organic units. At the lowest energy regime, absorptions probably arise from the ligand-to-cluster core charge transfer transitions for each appropriate metal cluster fragment (vide infra). Excitation of **1**−**8** in CH_2Cl_2 solutions results in a blue to greenish-blue luminescence band peaking in the range of 506−509 nm for the dansyl derivatives and of 425−431 nm for the acridone counterparts (Figure 1 and Figure 2). The emission wavelengths of the dansyl complexes remain relatively unshifted with respect to that of **I** but we observe a slight bathochromic shift in the peak maxima for the acridone congeners as compared to that of **II**. These featureless luminescence spectra are independent of the excitation wavelength used. Due to their similar structured peak pattern, we consider that the emission features between the uncomplexed and complexed fluorophores should have the same origin for each case and are most likely caused by the metal-perturbed dansyl or acridone emission. Of particular relevance here is the observation of a strong quenching of the fluorescence intensity of the luminophores upon metal coordination in all the cases studied. The fluorescence quantum yields of the metal complexes are less than those of **I** and **II** by one to two orders of magnitude. With reference to previous work on other organometallic systems, we can attribute the quenching in the luminescence intensity to the so-called heavy-atom effect, an energy-transfer or an electron-transfer mechanism.[7,8]

Crystal Structure Analyses

The single-crystal X-ray structures of **1**, **2**, **4** and **8** were established unambiguously and the perspective views are depicted in Figures 3−6, respectively. Pertinent bond

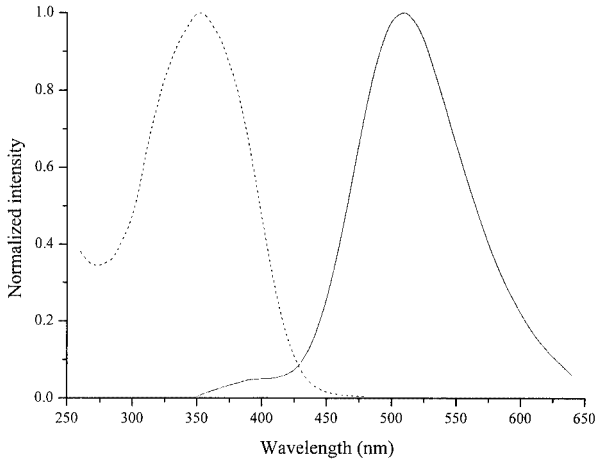


Figure 1. Excitation (---) and photoluminescence (—) spectra of **1** in CH_2Cl_2 at room temperature

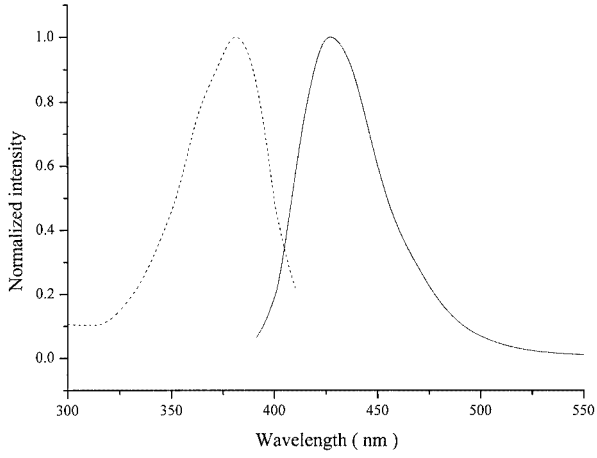

Figure 2. Excitation (---) and photoluminescence (—) spectra of **2** in CH_2Cl_2 at room temperature

lengths and angles are collected in Tables 2−5. Structurally, the essential features of both **1** and **2** are very similar in which the Co(1)−Co(2) axis forms a pseudo-tetrahedron with the C≡C bond of the alkynyl ligands **I** and **II** with the C≡C vector lying perpendicular to the Co−Co vector. In each case, the Co−Co separation [2.492(1) **1**, 2.4791(4) Å **2**] is in the region expected for other Co_2-alkyne systems.[25−28] The C(7)−C(8) bond lengths for **1** and **2** are 1.341(7) and 1.333(3) Å, respectively, suggestive of the loss of the triple bond character of the alkyne ligands upon complexation. There are no unusual structural parameters in the chromophoric groups of both molecules.

The basic structure of **4** consists of a diiron hexacarbonyl core in which the Fe−Fe edge [2.534(2) Å] is bridged by the thiolate and μ-σ-vinyl groups. The thiolate bridge itself spans the Fe−Fe bond asymmetrically with the Fe(1)−S(1) and Fe(2)−S(1) distances being 2.239(2) and 2.279(3) Å, respectively. While the iron−sulfur distances are typical of thiolate-bridged diiron compounds,[29−31] the C(7)−S(1) bond of 1.848(9) Å is slightly longer than the normal carbon−sulfur single bonds of 1.815(1) Å,[32] and this indic-

ates some delocalization of electron density from the thiolate bridge into the metal core. The C(11)−C(12) bond is bound to Fe(2) via a π-interaction [Fe(2)−C(11) 2.131(7), Fe(2)−C(12) 2.14(1) Å] and to Fe(1) via a σ bond [Fe(1)−C(11) 1.983(8) Å]. The C(11)−C(12) bond length of 1.37(1) Å is characteristic of this type of vinylic coordination. The six carbonyl ligands are all terminally bound and essentially linear. By regarding both the vinyl and μ-SR groups as three-electron donors, complex **4** has 34 cluster valence electrons and is electron precise.

For **8**, the triosmium unit is coordinated to an alkyne moiety in a classical μ_3-(η^2-||) manner via two σ bonds through Os(1) and Os(3) and a typical π bond to Os(2). This creates the nido-octahedral M_3C_2 core geometry expected for this type of coordination. The alkyne-metal σ bonds are 2.135(7) and 2.085(6) Å long, while the relevant π-interactions are characteristically longer at 2.181(6) and 2.315(6) Å. The C(11)−C(12) edge bridges the Os(1)−Os(3) bond to afford a four-membered metallacyclic ring, which makes a dihedral angle of 58.1° with the Os_3 triangle. The observation that the C(3)−Os(1)−Os(3) and Os(1)−C(3)−O(3) bond angles of 64.7(2) and 163.3(7)°, respectively, suggests that this carbonyl ligand is tending towards a semi-bridging interaction. In **2**, **4** and **8**, the acridone ring is almost planar (mean deviation is ca. 0.016−0.047 Å) and no evidence of intermolecular stacking interaction between individual acridone units in the crystal lattice was observed in each case.

Molecular Orbital Calculations

In order to study the electronic structures for the new clusters, we have performed molecular orbital calculations on **1**, **2**, **4** and **8** at the B3LYP level of density functional theory (DFT) based on their experimental geometries from X-ray data (see Computational Details section). The characteristics of the molecular orbitals in the frontier region are comparable for these four complexes. The contour plots[33] of the highest occupied (HOMO) and lowest unoccupied (LUMO) molecular orbitals for **1** and **2** are shown in Figure 7. The DFT calculations show that the HOMO−LUMO gaps for the four clusters are close to each other (ca. 23,356 **1**, 23,354 **2**, 25,119 **4** and 23,920 cm^{-1} **8**).

suggesting a dominant ligand-to-metal charge transfer character of their lowest HOMO−LUMO electronic transition. In the related work, the HOMO for **I** was found to possess a significant contribution from the pπ orbital of the NMe_2 group in addition to the π bonding feature within the aromatic unit, whereas the LUMO corresponds to the π* orbital of the aromatic moiety. The energy gap was calculated to be 33,792 cm^{-1}, which is much greater than that of **1**. Contrary to what we have observed here, previous calculations on other $[Os_3(CO)_{10}(\alpha\text{-diimine})]$ clusters[34,35] showed that the HOMOs are mainly metal orbital-based (Os−Os bonding) while the LUMOs are more localized on the α-diimine ligand. Clearly, the bridging acetylene ligands in the currently studied clusters, significantly affect the orbital structures in the HOMO−LUMO region. Examining the orbital energies in the HOMO−LUMO region for our compounds, we found that the molecular orbitals derived from metal d-orbitals (both bonding and antibonding) are shifted down to a lower energy region and the π and π* orbitals of the aromatic units in the ligands go up in energy in comparison to the corresponding MOs calculated for the $[Os_3(CO)_{10}(diimine)]$-type clusters mentioned above. It is because of these changes in the orbital energies that we observe the totally different patterns between the alkyne- and

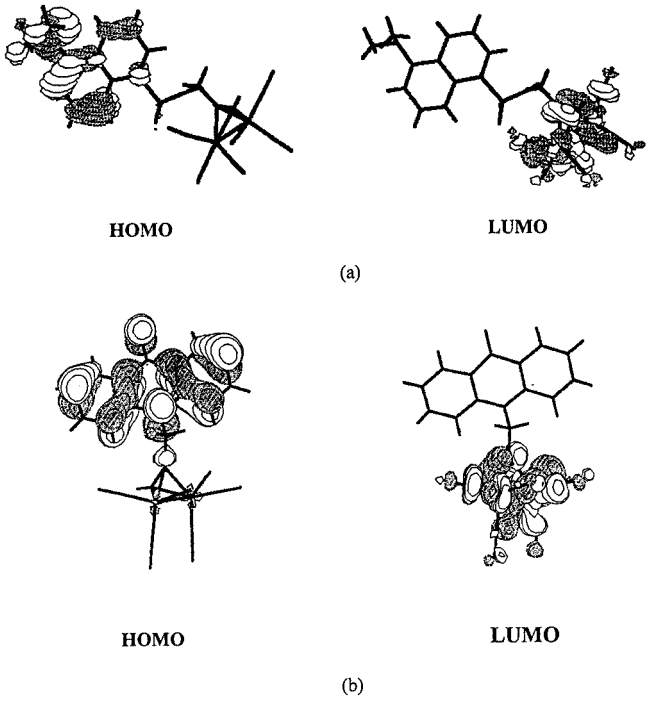

Figure 7. Spatial plots of the highest occupied (HOMO) and the lowest unoccupied molecular orbitals (LUMO) for complexes (a) **1** and (b) **2**

diimine-bridged compounds. The stabilization of the metal d-orbital-based MOs can be related to the π*-accepting properties and strong binding abilities of the bridging acetylene ligands. Since the LUMOs for these clusters involve metal−metal antibonding, and by considering the possible fragmentation, we expect that the life-time of an excited state of such clusters is much shorter when compared to other types of clusters in which there is a significant contribution of the ligands to the LUMOs. This probably results in a poor fluorescence quantum efficiency of the clusters in the present study.

Concluding Remarks

Our present work provides a simple access to a new family of alkyne-derived fluorescent-labeled metal clusters. A series of metal complexes of Groups 8 and 9 elements containing dansyl and acridone chromophores have been synthesized in moderate yields and spectroscopically and photophysically characterized. These new compounds are shown to be emissive in the blue to green-blue region in solutions at room temperature and quenched luminescence bands typical of the fluorophores are observed. In this work, we have also demonstrated how one can modulate the luminescence properties of the fluorophore in the presence of a variety of metal cluster cores and such a quenching process is particularly crucial to our understanding in the development of new molecular luminescent sensing systems. The effect of other transition metals on the luminescent behavior and a more in-depth investigation on analytical applications of these systems will be the subject of a future study.

Experimental Section

General Procedures: All reactions were conducted under an atmosphere of dry nitrogen with the use of standard Schlenk techniques. Solvents for preparative work were dried and distilled before use. Unless otherwise stated all reagents were obtained from commercial suppliers and used without further purification. The syntheses of ligand precursors **I** and **II**[7] and the complexes $[Et_3NH][Fe_2(CO)_6(\mu\text{-}CO)(\mu\text{-}S\textit{t}Bu)]$[18] and $[M_3(CO)_{10}(NCMe)_2]$ (M = Ru, Os)[36,37] were carried out as reported previously. IR spectra were recorded as CH_2Cl_2 solutions on a Perkin−Elmer Paragon 1000 PC or Nicolet Magna 550 Series II FTIR spectrometer. Proton NMR spectra were measured in $CDCl_3$ on a JEOL EX270 or a Varian Inova 400 MHz FT NMR spectrometer, with chemical shifts quoted relative to $SiMe_4$. Fast atom bombardment (FAB) mass spectra were recorded in *m*-nitrobenzyl alcohol matrices on a Finnigan-SSQ 710 spectrometer. Electronic absorption spectra were obtained with an HP 8453 or Cary 100 UV/Vis spectrometer. Corrected emission and excitation spectra were obtained in CH_2Cl_2 with a Perkin−Elmer LS50B or PTI QM1 spectrofluorimeter. The fluorescence quantum yields were determined in CH_2Cl_2 solutions at 290 K against the anthracene standard in the same solvent (Φ = 0.27).[38] Separation of products was accomplished by preparative TLC plates coated with silica (Merck, Kieselgel 60).

Computational Details: Density functional theory calculations at the B3LYP level[39−41] were performed on **1**, **2**, **4** and **8** based on their experimental geometries from X-ray crystallographic data. The basis set used for C, H N and O atoms was 6−31G[42] while effective core potentials with a LanL2DZ basis set[43] were employed for Co, Fe and Os atoms. All calculations were performed with the use of Gaussian 98.[44] In view of the large systems studied here and computing resources available to us, we did not use basis sets with higher quality. Addition of polarization functions to C, N and O would increase the number of basis functions by more than a hundred. Previous molecular orbital calculations on other related systems[45,46] showed that the medium-size basis set provides reasonable results. In addition, we are interested in obtaining the qualitative picture of orbital patterns for the clusters and in comparing the relative HOMO−LUMO gaps. We believe that the addition of polarization functions in our calculations will not alter the conclusions we have made.

$[Co_2(CO)_6(\mu\text{-}\eta^2\text{-}R^1CH_2CCH)]$ (1): $[Co_2(CO)_8]$ (32.1 mg, 0.09 mmol) was dissolved in degassed hexane (10 mL) and the solution was stirred at 0 °C under N_2. The alkyne ligand **I** (22.9 mg, 0.10 mmol) in CH_2Cl_2 (3 mL) was subsequently added. After the mixture was stirred for 1 h, the solvent was removed under reduced pressure. The residue was purified by preparative TLC on silica using hexane/CH_2Cl_2 (1:1, v/v) as eluent to furnish a major brown-red band. The title product was recrystallized from hexane−CH_2Cl_2 to give deep red crystals of **1** in 32% yield (17.3 mg). IR (CH_2Cl_2): ν(N−H) = 3384 w, ν(CO) = 2097s, 2058 vs and 2031 vs cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.88 (s, 6 H, NMe_2), 4.20 (s, 2 H, NCH_2), 4.91 (s, 1 H, NH), 5.74 (s, 1 H, CCH), 7.21 (m, 1 H, aromatic), 7.55 (t, J_{H-H} = 7.6 Hz, 2 H, aromatic), 8.30 (m, 2 H, aromatic) and 8.55 (d, J_{H-H} = 8.6 Hz, 1 H, aromatic). FAB MS: *m*/*z* = 490 [(M − 3CO)$^+$]. $C_{21}H_{16}N_2Co_2O_8S$ (574.29): calcd. C 43.92, H 2.81, N 4.88; found C 43.69, H 2.60, N 4.50.

[$Co_2(CO)_6$(μ-η²-R^2CH_2CCH)] (2): Compound **2** was prepared using the same conditions described above for **1**, but ligand **II** was used instead to produce a deep red solid of **2** (35%) after TLC separation eluting with hexane/CH_2Cl_2 (1:4, v/v). IR (CH_2Cl_2): ν(CO) = 2098s, 2059 vs and 2033 vs cm^{-1}. ^1H NMR ($CDCl_3$): δ = 5.28 (s, 2 H, NCH_2), 5.75 (s, 1 H, CCH), 7.34 (t, J_{H-H} = 7.3 Hz, 2 H, aromatic), 7.62 (d, J_{H-H} = 7.3 Hz, 2 H, aromatic), 7.76 (t, J_{H-H} = 7.3 Hz, 2 H, aromatic) and 8.59 (d, J_{H-H} = 7.3 Hz, 2 H, aromatic). FAB MS: *m*/*z* = 520 [M^+]. $C_{22}H_{11}NCo_2O_7$ (519.20): calcd. C 50.89, H 2.14, N 2.70; found C 50.75, H 2.02, N 2.32.

[$Fe_2(CO)_6$(μ-S*t*Bu)(μ-η²-$R^1CH_2C{=}CH_2$)] (3): The complex [Et_3NH][$Fe_2(CO)_6$(μ-CO)(μ-S*t*Bu)] was freshly prepared by reacting [$Fe_3(CO)_{12}$] (101 mg, 0.20 mmol), *t*BuSH (22.5 μL, 0.20 mmol) and NEt_3 (27.9 μL, 0.20 mmol) in THF (15 mL) at 25−30 °C under N_2. This reaction mixture was then treated with **I** (57.7 mg, 0.20 mmol) and the red solution was heated to reflux for 5 h. The volatile components were removed and the residue was subjected to TLC on silica using hexane/CH_2Cl_2 (2:1, v/v) as eluent to afford a major deep orange product **3** in 31% yield (40.8 mg). IR (CH_2Cl_2): ν(N−H) = 3379 w, ν(CO) = 2070 m, 2038 vs and 1996 vs cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.35 (s, 9 H, *t*Bu), 2.63 (d, J_{H-H} = 2.6 Hz, 1 H, CCH_2), 2.90 (s, 6 H, NMe_2), 3.48 (d, J_{H-H} = 2.6 Hz, 1 H, CCH_2), 4.07 (m, 2 H, NCH_2), 4.83 (t, J_{H-H} = 6.2 Hz, 1 H, NH), 7.21 (d, J_{H-H} = 7.6 Hz, 1 H, aromatic), 7.49−7.61 (m, 2 H, aromatic), 8.25−8.33 (m, 2 H, aromatic) and 8.55 (d, J_{H-H} = 8.4 Hz, 1 H, aromatic). FAB MS: *m*/*z* = 658 [M^+]. $C_{25}H_{26}N_2Fe_2O_8S_2$ (658.30): calcd. C 45.61, H 3.98, N 4.26; found C 45.29, H 3.67, N 4.01.

[$Fe_2(CO)_6$(μ-S*t*Bu)(μ-η²-$R^2CH_2C{=}CH_2$)] (4): A procedure similar to that for **3** was employed using **II** (46.7 mg, 0.20 mmol) to produce orange **4** in 35% yield (42.2 mg) following TLC purification on silica with hexane/CH_2Cl_2 (1:1, v/v) as eluent. IR (CH_2Cl_2): ν(CO) = 2068 m, 2037 vs and 1995 vs cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.41 (s, 9 H, *t*Bu), 2.77 (d, J_{H-H} = 4.6 Hz, 1 H, CCH_2), 3.13 (d, J_{H-H} = 4.6 Hz, 1 H, CCH_2), 5.01 (s, 2 H, NCH_2), 7.31 (t, J_{H-H} = 7.6 Hz, 2 H, aromatic), 7.58 (d, J_{H-H} = 7.6 Hz, 2 H, aromatic), 7.76 (t, J_{H-H} = 7.6 Hz, 2 H, aromatic) and 8.55 (d, J_{H-H} = 7.6 Hz, 2 H, aromatic). FAB MS: *m*/*z* = 603 [M^+]. $C_{26}H_{21}NFe_2O_7S$ (603.21): calcd. C 51.77, H 3.51, N 2.32; found C 51.49, H 3.36, N 2.18.

[$Ru_3(CO)_9$(μ-CO)(μ₃-η²-R^1CH_2CCH)] (5): To an orange solution of [$Ru_3(CO)_{10}(NCMe)_2$] prepared in situ from a mixture of [$Ru_3(CO)_{12}$] (51.1 mg, 0.08 mmol) and NMe_3O (12.0 mg, 0.16 mmol) in CH_2Cl_2/MeCN, **I** (23.1 mg, 0.08 mmol) was added. The resulting mixture was allowed to stir at room temperature for 2 h, after which the solution was concentrated and subjected to TLC separation with pure CH_2Cl_2 as eluent. The title complex was isolated as a deep yellow product in 23% yield (16.0 mg). IR (CH_2Cl_2): ν(N−H) = 3379 w, ν(CO) = 2100 w, 2063 sh, 2055 vs, 2031s, 2012 sh and 1880 w cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.89 (s, 6 H, NMe_2), 3.71 (d, J_{H-H} = 6.4 Hz, 2 H, NCH_2), 4.74 (t, J_{H-H} = 6.4 Hz, 1 H, NH), 7.20 (d, J_{H-H} = 7.2 Hz, 1 H, aromatic), 7.51−7.59 (m, 2 H, aromatic), 8.02 (s, 1 H, CCH), 8.20−8.23 (m, 2 H, aromatic) and 8.56 (d, J_{H-H} = 8.8 Hz, 1 H, aromatic). FAB MS: *m*/*z* = 871 [M^+]. $C_{25}H_{16}N_2O_{12}Ru_3S$ (871.68): calcd. C 34.45, H 1.85, N 3.21; found C 34.59, H 1.90, N 3.20.

[$Ru_3(CO)_9$(μ-CO)(μ₃-η²-R^2CH_2CCH)] (6): Similar to **5**, complex **6** was synthesized from **II** (18.7 mg, 0.08 mmol) and isolated as a deep yellow solid in 27% yield (17.6 mg). IR (CH_2Cl_2): ν(CO) = 2101 w, 2066 vs, 2055 vs, 2034s, 2012 sh and 1881 w cm^{-1}. ^1H NMR ($CDCl_3$): δ = 5.32 (s, 2 H, NCH_2), 7.29−7.39 (m, 4 H, aromatic), 7.67 (s, 1 H, CCH), 7.74 (t, J_{H-H} = 7.4 Hz, 2 H, aromatic) and 8.60 (dd, J_{H-H} = 7.4, 1.2 Hz, 2 H, aromatic). FAB MS: *m*/*z* = 816 [M^+]. $C_{26}H_{11}NO_{11}Ru_3$ (816.58): calcd. C 38.24, H 1.36, N 1.72; found C 38.05, H 1.13, N 1.50.

[$Os_3(CO)_9$(μ-CO)(μ₃-η²-R^1CH_2CCH)] (7): Ligand **I** (11.5 mg, 0.04 mmol) was added to a yellow solution of [$Os_3(CO)_{10}(NCMe)_2$] (37.3 mg, 0.04 mmol) in CH_2Cl_2 (15 mL). The reaction mixture turned orange and stirring was continued at room temperature for 2 h. Upon removal of solvent, the residue was purified by TLC on silica using pure CH_2Cl_2 as eluent to give a yellow-orange product

[$Os_3(CO)_9(\mu$-CO)(μ_3-η^2-R^2CH_2CCH)] (8): Instead of using **I**, the reaction between [$Os_3(CO)_{10}(NCMe)_2$] (37.3 mg, 0.04 mmol) and **II** (9.30 mg, 0.04 mmol) in CH_2Cl_2 resulted in the formation of the desired compound as a yellow solid. Purification was accomplished by TLC on silica using hexane/CH_2Cl_2 (1:1, v/v) as eluent to afford an analytically pure sample of **8** in 39% yield (16.9 mg). IR (CH_2Cl_2): ν(CO) = 2104 w, 2067 vs, 2054 vs, 2029 s, 2005 s and 1848 w cm^{-1}. ^1H NMR ($CDCl_3$): δ = 5.00 (m, 1 H, NCH_2), 5.19 (m, 1 H, NCH_2), 7.26−7.36 (m, 4 H, aromatic), 7.74 (t, J_{H-H} = 7.8 Hz, 2 H, aromatic), 8.59 (dd, J_{H-H} = 7.8, 1.7 Hz, 2 H, aromatic) and 8.99 (s, 1 H, CCH). FAB MS: *m/z* = 1084 [M^+]. $C_{26}H_{11}NO_{11}Os_3$ (1083.97): calcd. C 28.81, H 1.02, N 1.29; found C 28.90, H 1.15, N 1.43.

X-ray Crystallography: Good-quality crystals of our compounds suitable for X-ray diffraction studies were grown by slow evaporation of their respective solutions in hexane−CH_2Cl_2 at room temperature. Geometric and intensity data were collected using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) on a Bruker AXS SMART 1000 CCD area-detector diffractometer. The collected frames were processed with proprietary software SAINT[47] and an absorption correction was applied (SADABS[48]) to the collected reflections. The structures of these molecules were solved by direct methods and expanded by standard difference Fourier syntheses using the software SHELXTL.[49] Structure refinements were made on F^2 by the full-matrix least-squares technique. All other non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were either generated from Fourier maps or placed in their idealized positions and allowed to ride on the respective carbon atoms. Pertinent crystallographic information is provided in Table 6.

CCDC-174709 to -174712 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Detecting Small Structural Changes in Metalloproteins by the Use of NMR Pseudocontact Shifts

Marco Allegrozzi,[a] Ivano Bertini,*[a,b] Sung-Nak Choi,[c] Yong-Min Lee,[a] and Claudio Luchinat[a,d]

Keywords: Metalloproteins / Pseudocontact shifts / Lanthanides / Protein structures / Temperature-dependence / Magnetic susceptibility

The potential use of pseudocontact shifts (PCS) for detecting small structural changes that may occur in a protein in aqueous solution as a function of temperature is demonstrated on lanthanide-substituted calbindin D_{9k}. The protein is a dicalcium protein in which one of the calcium ions can be selectively substituted by lanthanides. The solution structure of the protein had been previously solved at 300 K. New sets of PCS that could readily be obtained at 280 and 310 K from ^{1}H-^{15}N HSQC experiments, together with the other constraints used for the 300 K structure, were used to recalculate the solution structure at the new temperatures, since the new solution structures are consistent with different sets of PCS constraints *and* a single NOE/dihedral angle set of constraints. Temperature-dependent PCS data were collected and analyzed for as many as eleven different paramagnetic lanthanides, but the relevant structural information could already be obtained by using data from only one [erbium(III)] derivative. It is found that small structural changes occur preferentially in nonhelical regions of the protein, i.e. the N- and C-terminal ends, in the linker region between the two helix-loop-helix motifs, as well as at the metal binding loops. This research shows that PCS are most sensitive to small structural rearrangements that may be within the tolerance of the NOE constraints, and can be safely used to monitor changes that would not be detectable by NOE and dihedral angle measurements. From the newly obtained structures, the parameters describing the metal magnetic susceptibility tensors at the different temperatures can be obtained, which represent a further source of information.

Introduction

Solution structures of proteins by NMR spectroscopy are often more cumbersome to obtain than solid state X-ray structures, and are often less resolved. However, the availability of structural information in solution is precious because the protein is closer to its native state and because dynamic information can be extracted from NMR spectroscopic parameters. Another advantage of NMR spectroscopy as a structural tool that is not often appreciated is that small structural changes, for instance those induced by denaturants at sub-denaturing conditions, by interactions with small chemical compounds or with other biomolecules, by pH changes or temperature changes, may be observed in favorable cases, while these changes may not be accessible under the conditions of crystallization. However, the most important class of NMR structural constraints, i.e. NOEs, can be safely used in a semi-quantitative way only, and small structural changes may escape detection. Paramagnetism-based constraints, such as the pseudocontact shifts (PCS)[1−3] that originate from the presence of a paramagnetic metal ion possessing magnetic susceptibility anisotropy, are more promising in this respect. This is due to the favorable functional form of the constraint, which involves both the metal-nucleus distance and the angular coordinates of the nucleus with respect to the principal axes of the magnetic susceptibility tensor, χ [Equation (1)][1,2,4]

$$\delta_i^{pc} = \frac{1}{12\pi r_i^3}\left[\Delta\chi_{ax}\left(3\cos^2\theta - 1\right) + \frac{3}{2}\Delta\chi_{rh}\left(\sin^2\theta\cos 2\Omega\right)\right] \quad (1)$$

where $\Delta\chi_{ax}$ and $\Delta\chi_{rh}$ are the axial and the rhombic anisotropies of the magnetic susceptibility tensor, and r_i, θ and Ω are the polar coordinates of the nucleus *i*. Metalloproteins are ideal systems to measure PCS on nuclei around the metal ion (by taking care to avoid nuclei with contact shifts).

In this work we investigate the possibility of detecting small structural changes that may occur as a function of temperature in a suitable metalloprotein, for example the calcium-binding protein calbindin D_{9k}. The protein has two helix-loop-helix motifs, called EF-hands, joined by a linker region made more flexible by a Pro-Met (P43M) mutation. Each of the two loops hosts a calcium ion. The first EF-hand, the so called ''pseudo EF-hand'', consists of 14 residues and binds calcium by using four backbone carbonyl oxygen atoms and one side-chain carboxylic group, whereas the second EF-hand, the common EF-hand, consists of 12 residues and binds calcium by using one backbone carbonyl oxygen and four side-chain carboxylic groups. Both solution[5−7] and X-ray[8] structures of the protein are available, as well as mobility studies in solution.[9] We exploit the fact that lanthanide ions can be selectively substituted for calcium in the second calcium binding site, and in so doing generate pseudocontact shifts.[7,10,11] Indeed, the solution structure has been solved using the PCS constraints of the peptide NH nuclei, induced by as many as 11 different lanthanides.[7] Therefore, this seemed to us an ideal system to test the sensitivity of PCS towards minor temperature-dependent structural changes. Of course it is assumed (and verified a posteriori) that the structure of all of the lanthanide derivatives is the same.

In this approach two distinct types of phenomena are to be looked for: i) structural changes, occurring anywhere in the protein, causing a change in the polar coordinates of some nuclei with respect to the metal-centered tensor frame, and consequently changing their PCS values; ii) intrinsic (structure-independent) temperature-dependence of the magnetic susceptibility tensor parameters which alter the PCS values of all protein atoms.

Results and Discussion

Structure Calculations at the Three Temperatures

Thirteen sets of ^{15}N-^{1}H HSQC shifts at 280 and 310 K for the peptide ^{15}N-^{1}H nuclei of lanthanide-substituted calbindin D_{9k} have been collected, and added to the existing 300 K data.[7] The two sets of data for the diamagnetic derivatives CaLaCb and CaLuCb were used as a blank for the other 11 paramagnetic sets of data as previously reported.[7] The resulting PCS values are 966 PCS at 280 K and 1028 PCS at 310 K. These data, together with the previously determined 1097 PCS at 300 K,[7] are reported as supplementary material (Table S1). The number of observed ^{1}H-^{15}N HSQC cross-peaks at 310 K are almost the same as those at 300 K, however, there are fewer ^{1}H-^{15}N HSQC cross-peaks at 280 K than at 300 or 310 K, probably due to the increased paramagnetism at lower temperatures.

From the 11 sets of data at each temperature and from the existing solution structure at 300 K,[7] initial estimates of the magnetic susceptibility tensor anisotropies and orientations were obtained using the program FANTASIA.[12] Separate structure calculations were then performed using the program PSEUDYANA,[13] the PCS constraints at either 280 or 310 K, and all the NOEs and other diamagnetic constraints previously collected at 300 K.[14] The rationale behind this procedure is that as long as structure alterations with respect to the 300 K structure are modest, the expected violations of the NOE constraints are within the tolerance level, and this can be verified a posteriori.

After an initial family of structures was obtained at each temperature, the values of the tensors were recalculated using FANTASIA,[12] and PSEUDYANA[13] runs were repeated until convergence was obtained. Calculations were also repeated for the 300 K data, which obviously gave the same family and the same tensors as obtained previously, within the uncertainty margin. The structures at 280 and 310 K showed modest differences (which were outside the uncertainty margin) from the one at 300 K, as well as from one another. A quality factor[7,15] was determined which showed that the agreement between calculated and experimental PCS is good at all three temperatures. The global RMSD values are reported in Table 1, together with the quality factors and target functions at the three temperatures. The latter were somewhat higher than those of the structure at 300 K. This finding is important because it provides an a posteriori validation of the use of NOE constraints at one temperature as structural constraints for a different temperature. This was not completely unexpected, however, as NOE constraints are applied in the form of upper distance limits, and the structural variations are probably within their tolerance level. The final values of the five parameters for the 11 paramagnetic derivatives, together with their errors evaluated through a Monte Carlo analysis,[7] at the three temperatures are presented in Table 2. They will be discussed further, in the context of the analysis of possible structural alterations at the binding site.

Analysis of the Structural Differences

As suggested by the RMSD values in Table 1, structural differences outside the uncertainty seem to arise from changes in temperature for calbindin D_{9k}. A more detailed analysis of the nature and significance of these differences can be attempted by examining the RMSD per residue between the structures at the three temperatures. Figure 1 illustrates the pairwise RMSD per residue between each pair of structures, both referred to the backbone and to all the heavy atoms. It is clear that in several places of the sequence the agreement is significantly poorer than that within each family. This is particularly apparent in the N- and C- terminal parts, in the metal binding loops, as well as in the region of the linker between the two helix-loop-helix motifs, i.e. in all nonhelical parts of the structure. Although the nonhelical regions are those with intrinsically larger RMSD within each family, the RMSD between the families are well above the sum of the RMSD within each family in these

[a] The uncertainties reported correspond to the sum of the standard deviation of the tensor parameters resulting from either the fit of the individual conformers of the family, or fitting partial data sets in which 30% of the input data were randomly deleted according to a MonteCarlo analysis.

regions (Figure 1). In particular, noticeable temperature changes are shown by the φ and ψ angles of the residues in the first loop (residues 17, 18, 21, 22 and 23), in the linker and beginning of the third helix (residues 36−48) and in the second loop (residues 56−62). Furthermore, the orientations of the side-chain of residues Glu 17, Gln 22, Lys 41 and Asn 56 are somewhat different. However, the overall quality of the three structures based on Ramachandran plots[16] is very similar (about 89% of residues in most favored regions and 11% in additionally allowed regions at all temperatures). Interestingly, residues 17, 41 and 56 all precede a glycine in the sequence. The lower conformational barrier of glycine could be responsible for the temperature sensitivity of the preceding residues. The fact that significant differences among the three families are observed, despite the use of a single set of NOEs, suggests that the actual differences may be even larger. Figure 2 summarizes the regions of the protein where temperature-dependent structural changes are observed.

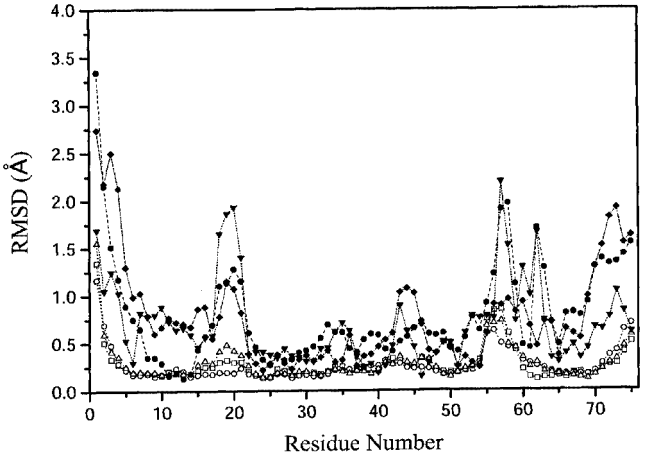

Figure 1. RMSD per residue within each family of structures at 280 K (□), 300 K (○) and 310 K (△), and between mean structures at the two temperatures, 280 K-300 K (▼), 280 K−310 K (◆) and 300 K−310 K (●)

In order to test whether the present results could still be obtained in systems where only one paramagnetic derivative is available, the solution structures at three temperatures were also calculated using the PCS of only the Er^{3+} derivative (chosen among the eleven lanthanides because it provides a sufficiently high number of ^{15}N-^{1}H HSQC cross-peaks with nonnegligible PCS values). The pairwise RMSD values of each family at each of the three temperatures for the backbone are in the range 0.71−0.77 Å, while the RMSD between the different families of structures at the three temperatures are in the range 0.80−1.07 Å. Based on Ramachandran plots,[16] the overall quality of the structures from the Er^{3+} derivative is the same as that from 11 lanthanide derivatives. In all nonhelical parts of the three

Figure 2. Schematic representation of the solution structure of calbindin D_{9k}, highlighting the residues that undergo slight temperature-dependent structural changes (shaded in dark gray)

structures of the Er^{3+} derivative at different temperatures, the agreement is sizably poorer than that within each family. In particular, the φ and ψ angles of the residues in the first loop (residues 19−22), linker (residues 41−44) and second loop (residues 54−62) were affected by variations in temperature. These results are very similar to those obtained by making use of the PCS data for all eleven lanthanide derivatives, and therefore show: i) that the assumption that the structure is lanthanide-independent is verified, and ii) that the present approach may be of general applicability for any paramagnetic metalloprotein.

The significance of the observed temperature-related changes, at least in regions far from the paramagnetic center, should be further checked by going back to the original PCS data. This practice is common in the analysis of differences between solution structures, and originates from the fact that, due to the global nature of the simulated annealing procedure and the local nature of the structural changes, the best check to ascertain the significance of the latter is to relate them to local variations of the constraints. In the present case, the simple comparison of the PCS data at different temperatures for a particular residue or group of residues is not feasible, as: i) a temperature-dependent variation of the magnitude of the tensor parameters (and therefore of the PCS values) is theoretically expected, independent of structural variations, and ii) structural changes at the metal ion site would also alter the tensors, and therefore all the PCS, simultaneously. Therefore, a way of comparing the PCS values should be found that is independent of the tensor variations. A possibility is that of examining the *ratios* between the ^{15}N and ^{1}H PCS for a given NH group for each lanthanide. This ratio should be much less sensitive to tensor variations than to changes in orientation of the N−H vector with respect to either the M−N or M−H vectors.

Therefore, again assuming the same behavior for all lanthanides, a plot of ^{15}N chemical shifts versus ^{1}H chemical shifts of a given NH group for all lanthanides at the same temperature should be a straight line. The slope, which depends on the third power of the ratio between the M−N and M−H distances, is expected not to exceed the range 0.77−1.3 for all NH groups that are farther than 12 Å from the metal.

In the absence of temperature-dependent structural variations, such straight lines for each temperature should be identical, whereas variations in the slopes should indicate a structural change. Examples of such plots are reported in Figure 3. The slopes for Ser 2, Phe 36 and Gly 42 indicate some temperature-dependent changes, whereas Leu 32 and Leu 69 are examples that exhibit structural invariance. From this qualitative analysis evidence is provided for temperature-dependent structural changes for residues Ser 2, Gly 18, Phe 36, Gly 42, Leu 46, Asp 47, Glu 48 and Gly 57, all in nonhelical regions. Despite the fact that the number of residues does not fully correspond to those which show variations in the structure, they still support the hypothesis that indeed the loops and linker undergo temperature-dependent changes. In any case, the structures at the three temperatures reliably show differences in about 25 residues, seven of which are confirmed spectroscopically.

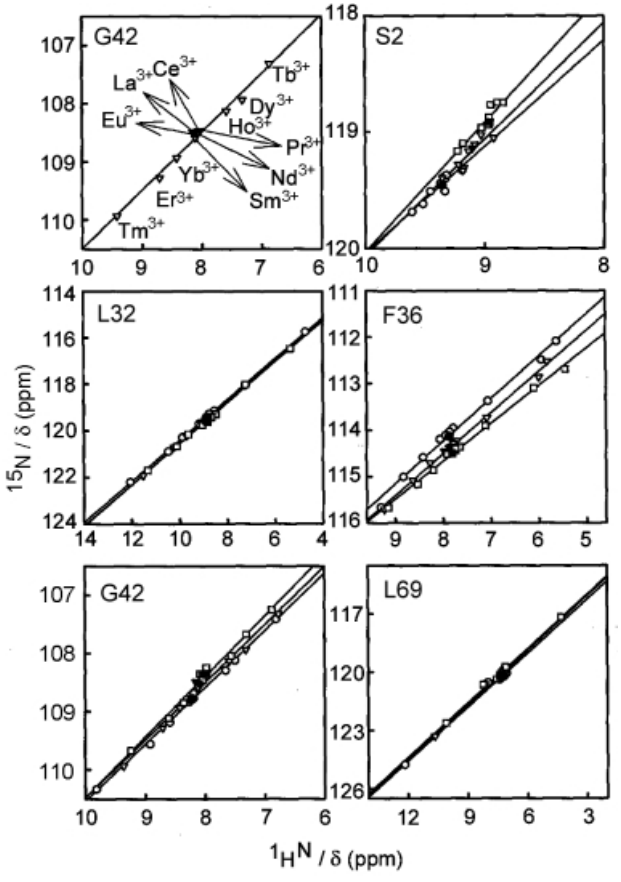

Figure 3. Observed ^{15}N versus ^{1}H chemical shifts of the G42 NH moiety (upper left) with all lanthanide ions at 300 K (▽) (diamagnetic CaLaCb values as filled symbols); analogous plots for selected residues at 280 K (○), 300 K (▽), and 310 K (□) are also shown

Temperature-Dependence of the Tensor Parameters

It is worth examining the temperature-dependence of the $\Delta\chi_{ax}$ and $\Delta\chi_{rh}$ parameters. Theory predicts that these parameters should experience a temperature dependence that is proportional to the temperature dependence of the overall magnetic susceptibility. The latter is expected to have a T^{-2} dependence, with modest positive or negative corrections from a T^{-3} term arising from the thermal population of the excited electronic states.[17–19] The $\Delta\chi_{ax}$ values for the 11 lanthanides as a function of T^{-2} are reported in Figure 4. Most lanthanides show a monotonous change with temperature, with the exception of samarium(III) and europium(III). The behavior of the latter two ions is unexpected. However, the collection of a number of experimental data at different temperatures to address this point is beyond the scope of this paper. Although a quantitative assessment of the slopes is difficult to make, some lanthanides clearly show a more marked temperature dependence [e.g. terbium(III)] and some a less marked one [e.g. dysprosium(III)]. Inspection of Table 2 reveals that some modest, but consistent, changes in the angular parameters are also observed for all lanthanides. Figure 5 illustrates such changes in the form of plots of θ vs. φ, where θ and φ are the angles defining the orientation of the principal axes of the χ tensor with respect to a fixed reference frame. The changes are on average between 5 and 10 degrees, with the largest (almost 20 degrees) being observed for the holmium(III) derivative. These changes are of the same order as the uncertainties; however they are in all cases monotonous with temperature i.e. they have a systematic character that cannot be explained by random errors. In summary, changes both in the magnitude of the susceptibility anisotropy parameters and in the principal axes orientations are detected over the temperature range investigated. The changes in axes orientation, in particular, suggest that population of excited states involving different *f*-orbitals may occur. Overall, the present analysis shows that possible structural or electronic changes at the metal site can be recognized as such and do not prevent detection of small temperature-dependent structural changes in the protein part of paramagnetic metalloproteins when using PCS.

The possibility that the present analysis may be hampered by some kind of circular argument could be considered. However, it is easy to show that the ratios of the PCS values for the ^{15}N and ^{1}H nuclei of a peptide NH moiety are much less sensitive to the orientation of the tensor axes than they are to changes in the orientations of the NH vectors. Furthermore, the tensor parameters are barely sensitive to structural variations that occur far from the metal center and that essentially compensate each other. Sample calculations show that random variations (up to ±40°) of ten different NH vector orientations (i.e. larger structural changes than those observed here) change the magnetic anisotropy parameters of the various lanthanide ions by much less (typically less than 1%) than the changes due to temperature. In another set of sample calculations, variations of ±5° in the tensor orientation for the lanthanide ions with the largest magnetic susceptibility anisotropy change the δ_N/δ_H ratios of the NH groups with the largest pseudocontact shift by less than 4%, i.e., much less than the observed changes in the slopes that have been considered meaningful indications of true structural changes.

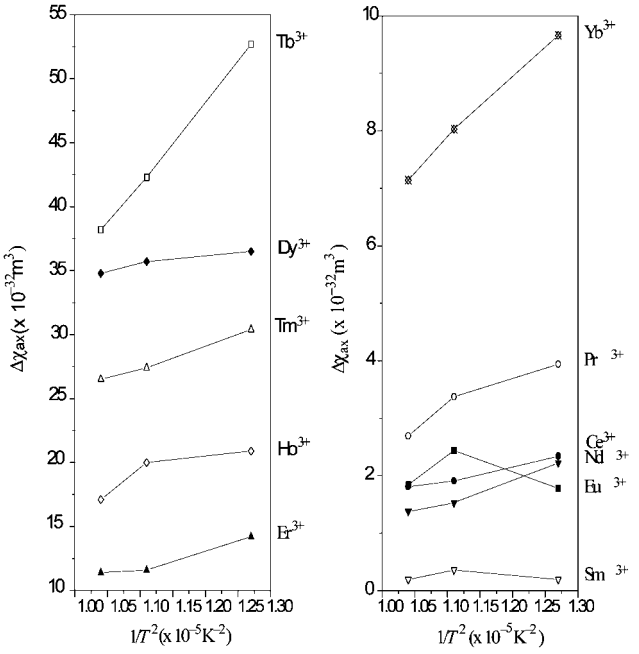

Figure 4. Plot of experimental $\Delta\chi_{ax}$ values vs. $1/T^2$ for all lanthanide ions

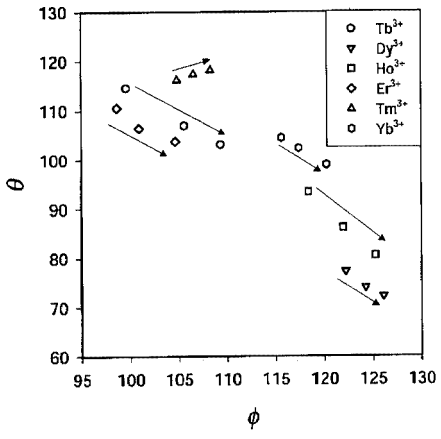

Figure 5. Temperature dependence of the θ and φ values of the principal axis of the χ tensor for the second half of the lanthanide series; the reference system is arbitrary and fixed to the molecular frame; the arrows indicate increasing temperature

Concluding Remarks

The power of PCS in determining the solution structure is proved by the finding that minor changes of PCS, for example with temperature, can be used to relate them to small structural changes, by solving the solution structure with a common set of NOEs and appropriate PCS. This is

shown through lanthanide substitution of a calcium binding protein, calbindin D_{9k}. This finding is qualitative, but is definitively confirmed by the analysis of the $^{15}N/^{1}H$ PCS ratios for NH moieties. If no temperature-dependent change occurs in the NH orientation, the above ratio is constant, even if modest temperature-dependent changes in the metal magnetic susceptibility occur. From the different solution structures, the magnetic susceptibility anisotropies at different temperatures are obtained which are additional and precious pieces of information that may be further analyzed.

Experimental Section

Materials and Methods

Sample Preparation: Protein expression and purification of the ^{15}N-enriched dicalcium form of bovine calbindin D_{9k} (P43M mutant) was performed as reported previously.[20−23] NMR samples were prepared by dissolving the lyophilized protein in 500 μL of 90% H_2O/10% D_2O to give final 2.0 mM protein solutions. The pH was adjusted to 6.0 by means of 0.1 M NaOH or 0.1 M HCl. Lanthanide-containing calbindin D_{9k} (hereafter CaLnCb) samples were obtained by titrating the dicalcium form with 0.02 M solutions of analytical grade $LnCl_3$ (Sigma, Aldrich), up to one equivalent.[7,24] Titrations were followed by 2D ^{1}H-^{15}N HSQC spectroscopy. The samples were kept at 4 °C between measurements.

NMR Spectroscopy: NMR spectra were acquired on Bruker AVANCE 800 and 400 spectrometers operating at 800.13 and 400.13 MHz, respectively. The residual water signal was suppressed by either presaturation during both the relaxation delay and mixing time, or by gradient-tailored excitation (WATERGATE).[25] The spectra were calibrated in the proton dimension at different temperatures according to the empirical relationship[26] $\delta_{HOD} = (-0.012 \times T + 5.11)$ ppm, where T is the temperature in °C. ^{1}H-^{15}N HSQC[27] spectra were recorded for all lanthanide derivatives at 280, 300 and 310 K using a spectral width of 16 ppm and 36 ppm in the ^{1}H and ^{15}N dimension, respectively. 512 increments, each with 1024 complex data points and 32 transients, were collected. The recycle delays were in the range between 0.5 s (CaTbCb) and 1.0 s (CaLaCb). All NMR spectroscopic data were processed with the Bruker XWINNMR software packages. The program XEASY was used for analysis of the 2D spectra.[28]

Computer Programs: The programs FANTASIA, PSEUDYANA are available at http://www.postgenomicNMR.net

Determination of PCS and Simultaneous Refinement of Magnetic Tensor Anisotropies and Solution Structure: Pseudocontact shifts for each paramagnetic lanthanide derivative at 280, 300 and 310 K were calculated by subtracting the shifts of either the CaLaCb or the CaLuCb diamagnetic protein. The pseudocontact shifts at 300 K have been taken from previous work without modification.[7] The variations in pseudocontact shifts for each lanthanide derivative at 280 and 310 K were directly calculated as the differences from the chemical shifts of each lanthanide derivative at 300 K.
The magnetic susceptibility tensor anisotropies for each lanthanide, $\Delta\chi_{ax}$ and $\Delta\chi_{rh}$, were obtained by simultaneously fitting all the PCS values to a family of 30 conformers obtained from solution structure calculations through Equation (1), and the error estimated through a MonteCarlo analysis.[7] These calculations were accomplished with the program FANTASIA.[12] Solution structure calculations at each temperature were performed using all diamagnetic constraints (NOEs, van der Waals) at 300 K and PCS constraints at each temperature. These diamagnetic constraints have been taken from previous work.[14] These amounted to 1793 meaningful NOEs, 191 dihedral angles, 15 hydrogen bonds and 26 T_1.
The quality factor for PCS was defined as:[7,15]

$$Q^{ax} = \frac{\sqrt{\sum_i \left(\delta_i^{obs} - \delta_i^{calc}\right)^2}}{\sqrt{\sum_i \left(\delta_i^{obs}\right)^2}} \qquad (2)$$

where δ_i^{obs} is the i-th experimental PCS value measured, δ_i^{calcd} is the corresponding calculated PCS value, and the summations span all experimental PCS.

Supporting Information Available: A table reporting the PCS values used in the solution structure calculations at three temperatures for all lanthanide derivatives (PDF); see also footnote on the first page of this article.

New Dinuclear Molybdenum(V) Complexes With β′-Hydroxy-β-enaminones Containing a 4-Hydroxy-2-pyrone Ring[‡]

Marina Cindrić,*[a] Višnja Vrdoljak,[a] Neven Strukan,[a] Predrag Tepeš,[b] Predrag Novak,[b] Ana Brbot-Šaranović,[c] Gerald Giester,[d] and Boris Kamenar[a]

Keywords: Amine ligands / Molybdenum / Nitrogen heterocycles

New dinuclear molybdenum(V) complexes of the general formula $[Mo_2O_4L_2D_2]$, were prepared by the reaction of $[Mo_2O_3(acac)_4]$ (acac = acetylacetonate ion) with β′-hydroxy-β-enaminones (L). All prepared complexes consist of $Mo_2O_4^{2+}$ cores coordinated by two ligands L via two donor oxygen atoms as in the analogous β-diketonates. The usual octahedral coordination around the molybdenum atoms is completed by the monodentate solvent molecules D (methanol, ethanol, or 2-propanol). All compounds were characterized by elemental analyses, IR, one- and two-dimensional NMR spectra, and thermal analysis, and some of them by X-ray crystallography (**1a**, **4a**, **8b**, and **9a**).

Introduction

Metal complexes with 2-pyrone derivatives are of interest in coordination and bioinorganic chemistry because of their application in immunoassay procedures and in cytological investigations, as well as for their use as potential HIV protease inhibitors.[1−6] Dehydroacetic acid (dha = 3-acetyl-4-hydroxy-6-methyl-2-pyrone) containing a 4-hydroxy-2-pyrone ring is a frequently investigated compound due to its good complexing properties. However, only two crystal structures of complexes $[Re(dha)Cl_2(OPPh_3)(PPh_3)]\cdot EtOH$[7] and $[Co(dha)_2(dmf)_2]$[8] have been known so far. Furthermore, little is known about complexes with dehydroacetic derivatives such as the β′-hydroxy-β-enaminone, and to the best of our knowledge only the copper(II) complex $[Cu(acrp)_2(py)]\cdot H_2O$ [Hacrp = 4-hydroxy-6-methyl-3-(3-dimethylaminoacryloyl)-2*H*-pyran-2-one] has been structurally characterized.[9] Such complexes have been studied not only as models for the elucidation of interactions between flavonoides and metal ions, but they are also of interest when studying the correlation between their steric, electronic, and hydrogen bonding effects, as well as for their possible relevance to biological processes.[10,11] In addition, the enaminone derivatives are good analytical reagents for spectrofluorometric determination of beryllium.[12]

We have recently published syntheses and structures of several isomeric enaminones obtained by the reaction of ethyl 2-hydroxy-4-(4-hydroxy-6-methyl-2*H*-pyran-2-on-3-yl)-4-oxo-2-butenoate and corresponding amines (*n*-butylamine, aniline, *p*-anisidine, and α-naphthylamine).[13−16] Continuing this research, we describe here nine new dinuclear molybdenum(V) complexes obtained by the reaction of isomeric β′-hydroxy-β-enaminones and $[Mo_2O_3(acac)_4]$ (Scheme 1). All complexes have the general formula $[Mo_2O_4L_2D_2]$, where ligand L is coordinated to molybdenum in a bidentate manner through the deprotonated hydroxyl groups and ketone moieties. The typical octahedral coordination around the Mo atom is completed by the monodentate solvent molecules D.

All compounds were characterized by means of chemical analysis, high-resolution NMR and IR spectroscopy, and thermogravimetric analysis. Four of them were also characterized by X-ray crystallography (**1a**, **4a**, **8b**, and **9a**).

Results and Discussion

Synthesis and Characterization of Complexes

The reaction of ethyl 2-hydroxy-4-(4-hydroxy-6-methyl-2*H*-pyran-2-on-3-yl)-4-oxo-2-butenoate (**ehmpb**) with a suitable amine (*n*-butylamine, aniline, or α-naphthylamine)

[‡] This paper is part of our studies on molybdenum complexes with enaminones.[16]

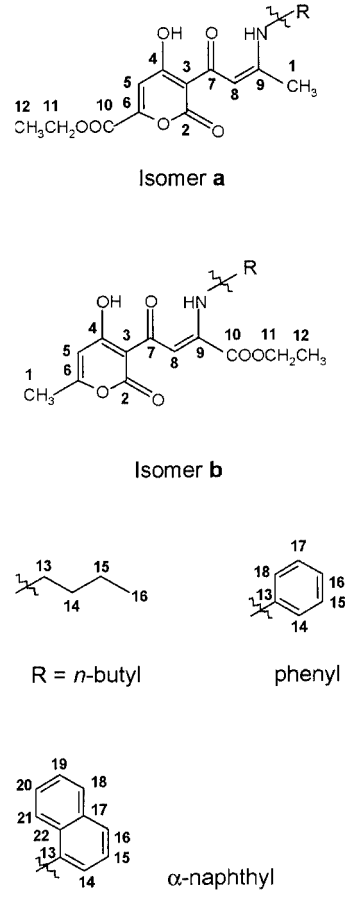
Scheme 1



Scheme 2

resulted in the formation of two isomeric enaminones (Scheme 2), one with the 2-pyrone ring substituted at position 6 by ethoxycarbonyl group (isomer **a**) and the other one substituted by a methyl group (isomer **b**).[14,15] The reaction of **ehmpb** with *n*-butylamine gave both isomers **a** and **b**, but the obtained amount of isomer **b** was insufficient for further synthesis of molybdenum complexes.

New molybdenum(V) complexes of general formula $[Mo_2O_4L_2D_2]$ were prepared by reaction of $[Mo_2O_3(acac)_4]$ with enaminones (Scheme 1) variously substituted at the nitrogen atom (R = *n*-butyl, phenyl, or α-naphthyl). Both isomers **a** and **b** of the phenyl and α-naphthyl derivatives were used as starting reagents for the preparation of the corresponding molybdenum(V) complexes, whereas in the case of the *n*-butyl derivative only isomer **a** was used. Dichloromethane was chosen as the most suitable solvent for all preparations, followed by the addition of the corresponding alcohol D (methanol for the preparation of complexes **1**, **4**, and **7**, ethanol for **2**, **5**, and **8**, and 2-propanol for **3**, **6**, and **9**).

In all complexes, ligand L was coordinated in a bidentate fashion to molybdenum through two oxygen atoms (as in the case of β-diketonates) and not through the nitrogen atom. One neutral solvent molecule D, acting as a monodentate ligand, completed the octahedral coordination of each Mo atom. Such behaviour was expected from the previous studies of molybdenum complexes with analogous ligands.[14,17,18]

Infrared Spectra and Thermal Analyses

All complexes were characterized by IR spectroscopy (selected spectroscopic data are given in Table 1). Two bands at 1735−1720 cm^{-1} and 1650−1700 cm^{-1} can be attributed to the stretching vibrations of the carbonyl group belonging to the ester $COOC_2H_5$ and 2-pyrone, respectively. The stretching frequencies at about 1570 and 1520 cm^{-1} attributed to the coordinated C···O groups and to C···C were observed at lower values compared to those found in the free ligands.[14,15] The single strong absorption maximum at about 950 cm^{-1} belongs to Mo−O (terminal), while the band at 730 cm^{-1} to the Mo−O (bridging) stretching frequencies. The remaining frequencies in the IR spectra are due to the vibrations within the ligands.

Thermal analyses of all prepared specimens revealed two main processes: (1) loss of solvent molecules, and (2) complex decomposition (Table 2). When heated, a weight loss

[a] According to the X-ray structure analysis, complex (**4a**) is solvated with two methanol molecules, while (**8b**) is solvated with two dichloromethane molecules. The crystals were readily loosing solvent at room temperature, so that they were left in a desiccator until constant weight, and analyzed as unsolvated species.

corresponding to the loss of solvated alcohol molecules was only observed in the case of **9a**, while all other complexes were loosing solvated molecules already at room temperature. The presence of solvated molecules in $[Mo_2O_4(C_{18}H_{16}O_6N)_2(CH_3OH)_2]\cdot 2CH_3OH$ (**4a**) and dichloromethane molecules in $[Mo_2O_4(C_{22}H_{18}O_6N)_2(CH_3CH_2OH)_2]\cdot 2CH_2Cl_2$ (**8b**) is established by the crystal structure determination. In general, the first weight loss could be attributed to the loss of coordinated alcohol and the complex conversion into a stable species of the formula $[Mo_2O_4L_2]$. On further heating, significant weight losses are indicative of complex decomposition resulting in the solid residues identified as MoO_3.

NMR Spectroscopy

^1H and ^{13}C resonances were assigned by using one-dimensional proton and carbon experiments as well as two-dimensional COSY sequence combined with $^1H-^{13}C$ correlation techniques through one bond- (HSQC) and multiple bond- (HMBC) procedures. Chemical shifts of the complexes are given in Table 3. A complete and unambiguous atom assignment for complex **4b** was not possible in

Table 2. Thermoanalytical data for $[Mo_2O_4L_2D_2]$ complexes

$[D_6]$acetone owing to its very low solubility in this solvent. In order to increase the solubility we added small amounts of DMSO, but the complex underwent rapid decomposition.

The chemical shift values listed in Table 3 are similar to those reported recently for related systems including molybdenum complexes.[13−16] Both proton and carbon chemical shifts are in the range expected for molybdenum complexes with ligands **a** and **b** [14,15] (Scheme 2). In that respect, the coordination-induced chemical shifts are the most pronounced for C-7 (up to 6 ppm), i.e. for one interacting site rather than for the other one, C-4.[14,15] The effects at C-7 atom are all upfield, as previously reported for related complexes.[16] The changes in chemical shifts for other car-

bon atoms are smaller and exhibit sign alternation as a consequence of the electron redistribution upon complexation with molybdenum.

All NMR spectroscopic data indicate that the ligand is in its enaminonic rather than iminoenolic form, which is in perfect agreement with the crystal structure determinations. The absence of hydroxyl proton resonances in the ^1H spectra confirms the complex formation. The marked downfield shifts of the NH protons ranging from 9.98 ppm up to 12.21 ppm (Table 3) are characteristic of strong hydrogen bonding in solution, as was found in the solid state.[11] The largest shift was observed for **4a**, indicating the strongest N−H···O bond in solution.

X-ray Analysis

Crystal structure determination was carried out for the nonsolvated compound $[Mo_2O_4(C_{16}H_{20}O_6N)_2(CH_3OH)_2]$, (**1a**), and for three solvated complexes $[Mo_2O_4(C_{18}H_{16}O_6N)_2(CH_3OH)_2]\cdot 2CH_3OH$ (**4a**), $[Mo_2O_4(C_{22}H_{18}O_6N)_2(CH_3CH_2OH)_2]\cdot 2CH_2Cl_2$ (**8b**), and $[Mo_2O_4(C_{22}H_{18}NO_6)_2\{(CH_3)_2CHOH)\}_2]\cdot 2(CH_3)_2CHOH$ (**9a**).

Selected interatomic distances and angles for complexes **1a**, **4a**, **8b**, and **9a** are given in Table 4−7, respectively. All four complex molecules contain the $[Mo_2O_4]^{2+}$ core, which displays a crystallographic twofold symmetry in **1a** and **9a** (Figure 1 and 4) but not in **4a** and **8b** (Figure 2 and 3). The Mo−Mo distances, ranging from 2.5319(6) Å in **9a** to 2.5561(5) Å in **4a**, correspond to a single bond between two molybdenum atoms, a result in agreement with the NMR spectroscopic data.[19,20] The molybdenum−to−molybdenum bonds established by structure analyses were confirmed by magnetic measurements.

Each molybdenum atom is in a distorted octahedral coordination, being bonded to one terminal and two bridging oxygen atoms, two oxygens from the bidentate ligand and one from the coordinated alcohol molecule. The shortest bond lengths with the terminal oxo−O, ranging from 1.679(2) Å in **4a** to 1.688(1) Å in **1a**, agree well with the value considered as Mo=O_t double bond.[21] Mo−O_b distances range from 1.914(2) Å in **8b** to 1.946(2) Å in **4a**. Two oxygen atoms from the bidentate ligand molecules are bonded at distances ranging from 2.073(3) to 2.105(2) Å (Mo−O3), and at 2.1380(10) to 2.1893(12) Å (Mo−O4). The Mo−$O_{alcohol}$ bond lengths range from 2.182(3) to 2.242(3) Å (both values observed in **8b**). In all four complexes, the characteristic bond lengths C8=C9, ranging from 1.365(5) to 1.413(2) Å, and C9−N1, from 1.317(2) to 1.344(5) Å, are indicative of the enamine C=C−N−H form of the ligand.

According to the values of the C−N−C13−C14 torsion angle: −165.3(1)° (**1a**), 50.1(4) and 55.0(4)° (**4a**), 41.8(5) and 45.7(6)° (**8b**), and 47.8(3)° (**9a**), the N-substituents have significant flexibility around the single N−C bonds. More-

over, in **4a** the ethyl groups adopt different conformations, with the torsion angles C110−O15−C111−C112 of −82.3(4)° and C210−O25−C211−C212 of 156.3(4)°.

Table 6. Selected interatomic distances (Å) and angles (°) for **8b**. Symmetry transformations used to generate equivalent atoms: *i* = −*x* + 2,−*y* + 1,−*z*; *ii* = −*x* + 2,−*y* + 1,−*z* + 1.

O10−H27···O6^{ii}	0.82	2.00	2.765(2)	155

Owing to the strong N−H···O intramolecular hydrogen bonds, reinforced with π-delocalization along the heterodienic O=C−C=C−NH moiety [*d*(N···O) from 2.611(1) to 2.680(2) Å, *d*(H···O) from 1.95 to 2.05 Å], in all four structures, the enaminonic fragments adopt the form of a six-membered ring.[10,11] As seen from Table 4−7, all complex molecules in the crystal structures are interconnected as chains (along the *c*-axis in **1a**, **8b**, and **9a**, and along the *a*-axis in **4a**) realized through hydrogen bonds. These hydrogen bonds are formed between the coordinated methanol molecule and the carboxylato-oxygen [O9−H1···O6^{ii} of 2.784(2) Å] in **1a**, between ethanol and the keto-oxygens of 2-pyrone [O19−H11···O12^{i} of 2.596(3)

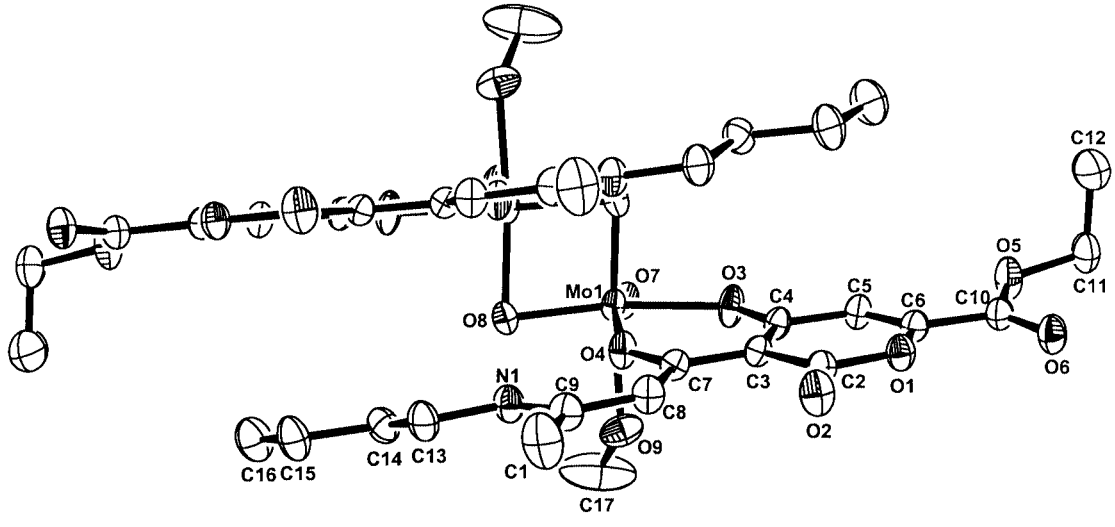

Figure 1. An ORTEP view of the dinuclear complex $[Mo_2O_4(C_{16}H_{20}NO_6)_2(CH_3OH)_2]$ in **1a** (hydrogen atoms are omitted for clarity). Ellipsoids are shown at the 50% probability level.

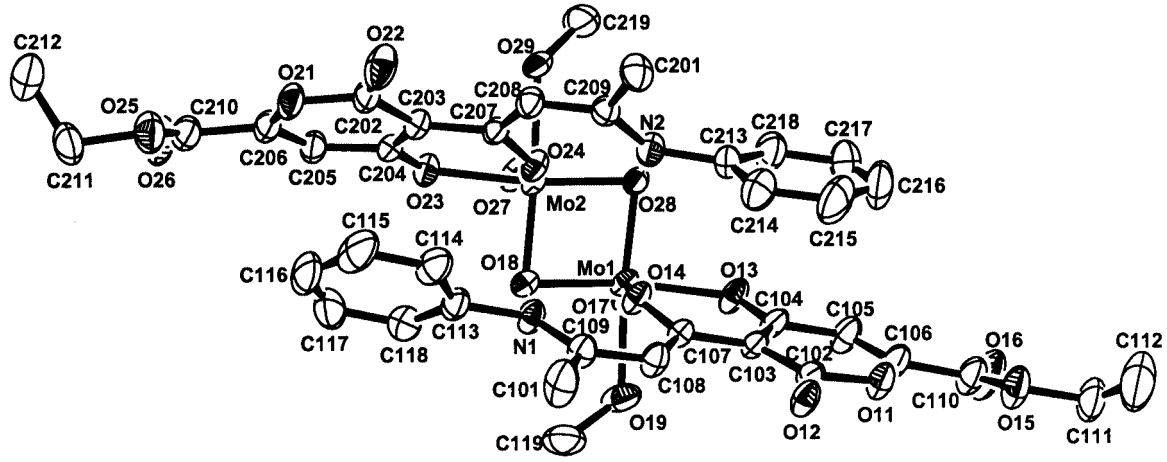

Figure 2. An ORTEP view of the dinuclear complex $[Mo_2O_4(C_{18}H_{16}NO_6)_2(CH_3OH)_2]$ in **4a** (hydrogen atoms are omitted for clarity). Ellipsoids are shown at the 50% probability level.

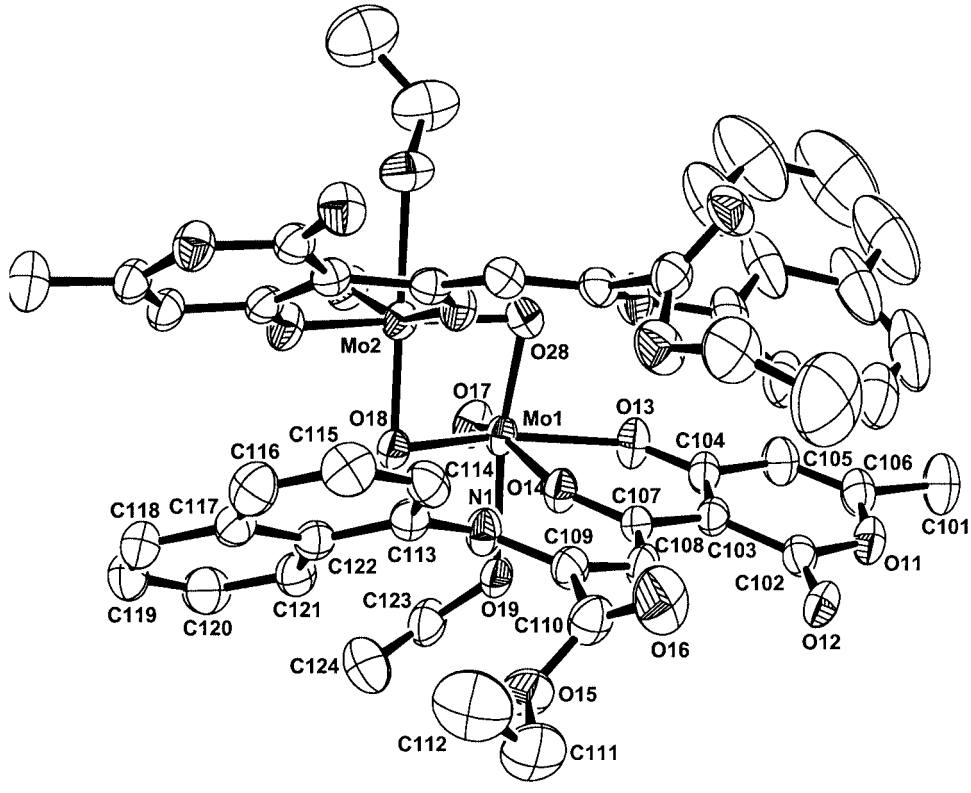

Figure 3. An ORTEP view of the dinuclear complex $[Mo_2O_4(C_{22}H_{18}NO_6)_2(CH_3CH_2OH)_2]$ in **8b**. Hydrogen atoms as well as the analogous labelling of upper part of the molecule are omitted for clarity. Ellipsoids are shown at the 50% probability level.

and O29−H21···O22^{ii} of 2.673(4) Å] in **8b**, and between methanol and the keto-oxygens [O19−H11···O22^{i} of 2.673(3) Å] in **4a**. The molecules in **4a** are further connected through solvent methanol molecule, acting as a proton donor when bonded to the keto group of the pyrone ring [O1−H4···O12^{iii} of 2.675(3) Å], and as a proton acceptor in a bond with coordinated methanol molecule [O29−H21···O1^{ii} of 2.537(3) Å]. In **9a** the complex molecules are interconnected through solvated 2-propanol molecules. Hydrogen bridges are formed between coordinated and solvated 2-propanol molecules [O9−H1···O10 of 2.640(2) Å], and between solvated 2-propanol molecule and ligand carboxylato-oxygen [O10−H27···O6^{ii} of 2.765(2) Å]. Observed values of O−H···O angles and H···O distances, ranging from 1.69 to 2.00 Å, are in the accordance with a proposed hydrogen bonding scheme. The crystal structures

of all compounds are additionally stabilized by C−H···O weak hydrogen bonds in the range from 2.745(2) to 3.358(5) Å.

Experimental Section

General: All chemicals and solvents were of reagent grade and used as purchased. The starting acetylacetonato complex $[Mo_2O_3(acac)_4]$ was prepared as described in the literature.[22,23] Ethyl 2-hydroxy-4-(4-hydroxy-6-methyl-2*H*-pyran-2-on-3-yl)-4-oxo-2-butenoate and isomeric enaminones (Scheme 2) were prepared according to previously described procedures.[13−16] Elemental analyses for C, H and N were provided by the Analytical Services Laboratory of Rudjer Bošković Institute, Zagreb. Molybdenum was determined using the usual procedure.[24] Infrared spectra were recorded in KBr with an FTIR 1600 Fourier transform spectrophotometer in the 4500−450 cm^{-1} region. Thermogravimetric (TG) analyses were measured on a Mettler TG 50 thermobalance using aluminum crucibles under oxygen atmosphere with a heating rate of 5 °C min^{-1}. For all experiments the temperature ranged from 30 to 600 °C. The results were developed by applying the GrafVare 2.1. program.

General Procedures for the Synthesis of Complexes

$[Mo_2O_3(acac)_4]$ (0.25 g, 0.4 mmol) was suspended in dry dichloromethane (25 mL) and appropriate ligand (0.4 mmol) was added. The mixture was gently warmed up for 0.5 h, the solution was filtered off, and corresponding alcohol (30 mL) added to the filtrate. Upon standing at room temperature for 5−10 days the obtained crystalline product was filtered off, washed with cold alcohol and dried. All complexes were orange-red crystalline solids very soluble in coordinating solvents such as DMF, DMSO, picoline, and pyridine, slightly soluble in dichloromethane, acetone, methanol, and ethanol. Elemental analyses, yields (based on $[Mo_2O_3(acac)_4]$) and selected IR data are given in Table 1. Thermal analysis data are given in Table 2. Since the crystals were easily loosing alcohol solvent, all analyses (elemental analyses, thermal analyses, IR, and NMR spectroscopy) were carried out with the samples left in a desiccator until constant weight.

NMR Spectra

NMR experiments were carried out on a Bruker Avance DRX500 spectrometer operating at 500.13 MHz for ^1H, with a 5 mm diameter inverse detection probe and a z-axis gradient coil. The solvent was $[D_6]$acetone and all experiments were performed at ambient temperature. TMS was used as the internal standard.

^1H NMR experiments were executed with a spectral width of 12500 Hz, 65 K data points and 8−32 scans. The sample concentration was 10−15 $mg.ml^{-1}$. The digital resolution was 0.2 Hz per point. In ^{13}C NMR spectra the spectral width was 31400 Hz, the number of data points 65 K, and the number of scans 2500−3000 per spectrum. The digital resolution was 0.5 Hz per point.

Two-dimensional absolute-value COSY spectra were recorded under the following conditions. Spectral width was 6600 Hz in both domains, 2 K data points were applied in time domain and 512 increments were collected for each data set with linear prediction and zero filling to 2 K. The relaxation delay was 1.5 s. Spectra were rocessed with sine or sine squared window functions. The digital resolution was 3.3 Hz per point in both f1 and f2 domains. The number of scans was 8.

Phase sensitive HSQC and absolute value HMBC spectra were recorded with a relaxation delay of 1.5 s and 32 scans per increment. The spectral width was 6600 Hz in acquisition domain f2 and 31000 Hz in time domain f1. Data were collected into 2048 × 256 acquisition matrix and processed by using a 2 K × 1 K transformed matrix with zero filling in f1 domain. Sine multiplication was performed prior to Fourier transformations. In HMBC spectra the delay for long range couplings was set to 60 ms.

[a] According to the X-ray structure analysis, complex **4a** is solvated with two methanol molecules, while **8b** is solvated with two dichloromethane molecules. The crystals were readily loosing solvent at room temperature, so that they were left in a desiccator until constant weight, and analyzed as unsolvated species. [b] $w = 1/[\sigma^2(F_o^2) + (g_1P)^2 + g_2P]$ where $P = (F_o^2 + 2F_c^2)/3$. [c] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [d] $wR = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2}$. [e] $S = [\Sigma[w(F_o^2 - F_c^2)^2]/(N_{obs} - N_{param})]^{1/2}$.

X-ray Crystallography

Single crystals of the complexes **1a**, **4a**, **8b**, and **9a** were grown by slow evaporation of solutions obtained from the above described preparations. The crystals so obtained were, however, unstable as they rapidly lost solvent and decomposed. Intensity data for all four structures were collected at 200 K on a Nonius−Kappa CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.7107 Å), at crystal to detector distance of 28 mm and 50 s exposure time per frame. Data were reduced using DENZO program.[25]

Crystal data, experimental conditions, details of structure determination and final refinement parameters are summarized in Table 8.

Molybdenum atoms in all structures were located by the Patterson method. The remaining non-hydrogen atoms were found in subsequent difference Fourier maps. Refinements in which all non-hydrogen atoms were treated anisotropically were performed by the full-matrix least-squares method based on the F^2 values against all reflections. The last Fourier maps revealed positions of all H atoms but some with poor geometry. Therefore all hydrogen atoms attached to carbon and nitrogen atoms were generated on geometrical grounds. The hydrogen atoms bound to the oxygen atoms of coordinated alcohol molecules were kept fixed during the refinement.

Structure **4a** was refined in noncentrosymmetric space group $Pna2_1$. However, the value of the refined Flack parameter of 0.50(2) is indicative of a racemic twinning.

All calculations were performed on an IBM THINKPAD microcomputer (Pentium II processor, 300 MHz) using SHELXS-97[26] and SHELXL-97[27] programs, and ORTEP[28] to draw the structural diagrams.

CCDC-174217 (**1a**), -174218 (**4a**), -174219 (**8b**) and -174220 (**9a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Highly Soluble Sulfur-Rich [Ni(L)($^{si}S_3$)] Complexes Containing the New Ligand Bis(2-mercapto-3-trimethylsilylphenyl) Sulfide(2−) ($^{si}S_3{}^{2-}$)[‡]

Dieter Sellmann*,*[a] Raju Prakash,[a] Franz Geipel,[a] and Frank W. Heinemann[a]

Dedicated to Professor Joachim Strähle on the occasion of his 65th birthday

Keywords: Nickel / S ligands / Silicon / Hydrazine / Nicotinamide

The new organosulfur ligands $^{si}S_3$-H_2 [$^{si}S_3{}^{2-}$ = bis(2-mercapto-3-trimethylsilylphenyl) sulfide(2–)] and $^{ca}S_3$-H_2 [$^{ca}S_3{}^{2-}$ = bis(2-mercapto-3-carboxyphenyl) sulfide(2–)] were synthesized from $^{H}S_3$-H_2 [$^{H}S_3{}^{2-}$ = bis(2-mercaptophenyl) sulfide(2–)], *n*-butyllithium, and Me_3SiCl or CO_2/H^+. Reaction of $^{si}S_3$-H_2 with $Ni(ac)_2{\cdot}4H_2O$ gave the air-stable and well-soluble trinuclear complex [Ni($^{si}S_3$)]$_3$ (**1**) whose structure was determined by X-ray crystallography. Reactions of complex **1** with nucleophiles L [L = PR_3 (R = *n*Pr, Ph, Cy), N_2H_4, S*t*Bu$^-$, and Cl$^-$] yielded the corresponding neutral or anionic complexes, which were isolated as [Ni(PR_3)($^{si}S_3$)] [R = *n*Pr (**2**), Ph (**3**), Cy (**4**)], Bu_4N[Ni(Cl)($^{si}S_3$)] (**5**), Bu_4N-[Ni(S*t*Bu)($^{si}S_3$)] (**6**), and [Ni(N_2H_4)($^{si}S_3$)] (**8**). The azido complex Et_4N[Ni(N_3)($^{si}S_3$)] (**7**) was prepared from Me_3SiN_3 and the precursor chloro complex Et_4N[Ni(Cl)($^{si}S_3$)]. Reaction of **1** with NH_3 yielded labile [Ni(NH_3)($^{si}S_3$)] (**9**), which was characterized in solution by ^1H and ^{13}C NMR spectroscopy. Analogously, **1** reacts with nicotinamide (NA) or diethylnicotinamide ($NAEt_2$) to give, from equilibrium reactions, the corresponding mononuclear [Ni(L)($^{si}S_3$)] complexes with L = NA, $NAEt_2$. X-ray structure determinations showed that **1**, **3**, **4**, **5**, and **7** all exhibit tetrahedrally distorted planar [Ni(L)($^{si}S_3$)] fragments. Complex **7** is the first structurally characterized azidonickel complex with a coligand having exclusively sulfur donors.

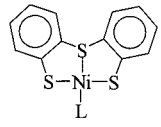
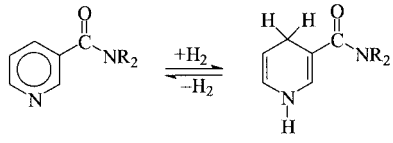
Introduction

The discovery of nickel cysteinate units in the active centers of [NiFe] hydrogenases[1−3] and CO dehydrogenases[4] accounts for much of the current interest in nickel thiolate complexes. Numerous efforts have been made in order to find low molecular weight complexes that model the nickel cysteinate site and the reactivity of these enzymes.[5−10] In this context, we have recently found that [Ni(L)($^{H}S_3$)] complexes containing the [Ni($^{H}S_3$)] complex fragment[11−13] $^{H}S_3{}^{2-}$ = bis(2-mercaptophenyl) sulfide(2−) and L = $NHPnPr_3$ or $N(SiMe_3)_2{}^-$ as coligands exhibit reactions relevant to [NiFe] hydrogenases and CO dehydrogenases, e.g., catalysis of H_2/D_2O exchange[14] and deoxygenation of CO, CO_2, and SO_2.[15]



[Ni(L)($^{H}S_3$)]

The unique reactivity of these complexes could be traced back to the formation of [Ni(L′)(L)($^{H}S_3$)] intermediates (L′ = H_2, CO, CO_2, SO_2) exhibiting five-coordinate nickel centers. The heterolysis of H_2 catalyzed by [Ni($NHPnPr_3$)($^{H}S_3$)][14] prompted us to investigate the activation of H_2 by other [Ni(L)($^{H}S_3$)] complexes, and a particularly intriguing goal was to use H_2 for intramolecularly hydrogenating ligands which can exist in the hydro and dehydro form such as the nicotinamide/dihydronicotinamide couple (NA/NAH_2) [Equation (1)].



(1)

The prerequisite for corresponding experiments were [Ni(NA)($^{H}S_3$)] complexes. Although NA complexes are known

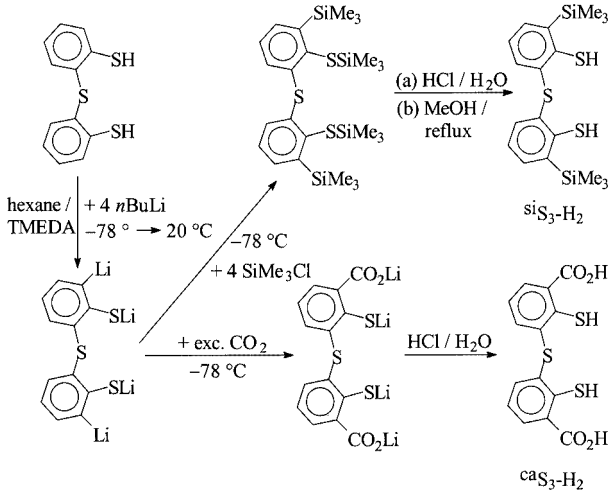
to exist,[16] they could not be obtained with [Ni($^{H}S_3$)] fragments. A major obstacle was the fact that [Ni(L)($^{H}S_3$)] complexes frequently are only very sparingly soluble in common organic solvents. A prime example is the trinuclear parent complex [Ni($^{H}S_3$)]$_3$ which is practically insoluble in all solvents. Due to this we have now tried to obtain better soluble derivatives by introducing $SiMe_3$ or CO_2H substituents into the $^{H}S_3$-H_2 ligand. This paper reports on the synthesis of two new ligands, and a series of nickel complexes with the $SiMe_3$ derivative $^{si}S_3^{2-}$ = bis(2-mercapto-3-trimethylsilylphenyl) sulfide(2−).

Results and Discussion

Synthesis of $SiMe_3$ and CO_2H Derivatives of $^{H}S_3$-H_2

The new ligands $^{si}S_3$-H_2 and $^{ca}S_3$-H_2, where "si" and "ca" denote $SiMe_3$ and CO_2H substituents in the *ortho* position to the SH functions, were obtained in one-pot reactions according to Scheme 1.



Scheme 1. Synthesis of $^{si}S_3$-H_2 and $^{ca}S_3$-H_2

The synthesis route made use of previous results obtained by other authors and us showing that aromatic sulfur compounds such as S(C_6H_5) can be lithiated with excess butyllithium.[17,11]

Treatment of $^{H}S_3$-H_2 with 4 equiv. of *n*BuLi in a hexane/TMEDA mixture (TMEDA = *N*,*N*′-tetramethylethylenediamine) yielded a white to yellow precipitate. This precipitate was not characterized in detail, and its structure, indicated in Scheme 1, was concluded only from subsequent reactions. Treatment of the heterogeneous mixture with 4 equiv. of $SiMe_3Cl$, acidification with hydrochloric acid, and extraction with Et_2O yielded a product in which the thiol functions of $^{si}S_3$-H_2 were still partially silylated by the $SiMe_3$ groups. These $SiMe_3$ groups were removed in boiling MeOH (yielding Me_3SiOMe_3) and the resultant $^{si}S_3$-H_2 was obtained as a brown viscous oil. It was identified by elemental analysis and spectroscopic methods, and could be used for synthesis of complexes without further purification.

In an analogous reaction, treatment of the heterogeneous mixture obtained from $^{H}S_3$-H_2 and butyllithium with gaseous CO_2 and subsequent acidification yielded $^{ca}S_3$-H_2. Upon recrystallization from acetone, it was obtained in green-yellow needles.

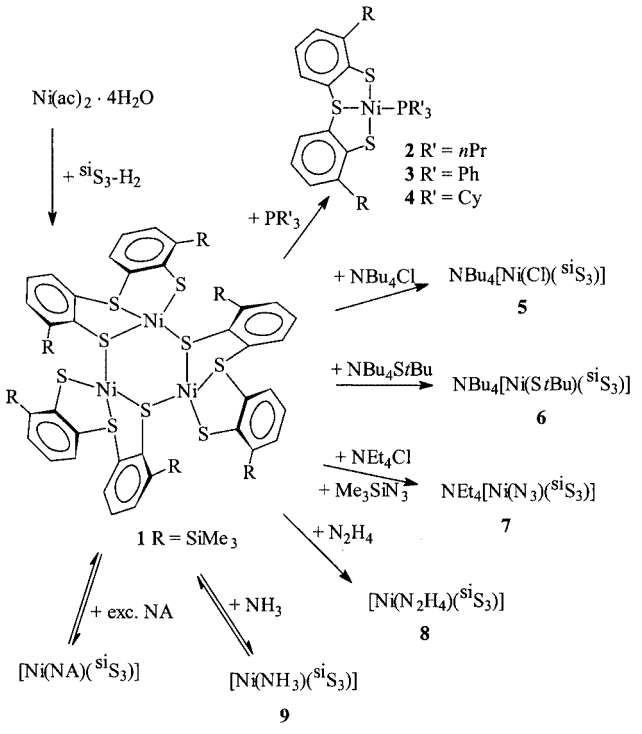
The ^{1}H NMR spectrum of $^{si}S_3$-H_2 exhibits three multiplets for the six aromatic protons, a broad singlet for the two thiols and a sharp singlet for the $SiMe_3$ protons. The ^{1}H NMR spectrum of $^{ca}S_3$-H_2 shows a similar pattern for the aromatic protons and broad peaks at δ = 7.28 and 11.85 ppm for the SH and CO_2H protons. It is worth noting that the SH proton shift is influenced by the benzene ring substituents and appears δ ≈ 4.5 ppm at lower field in $^{ca}S_3$-H_2 than in $^{si}S_3$-H_2. The number and shift of the ^{13}C resonances in the $^{13}C\{^1H\}$ NMR spectra of $^{si}S_3$-H_2 and $^{ca}S_3$-H_2 established that both of the ligands possess C_2 symmetry in solution.

Synthesis, Reaction, and Characterization of Complexes with [Ni($^{si}S_3$)] Fragments

The starting complex [Ni($^{si}S_3$)]$_3$ (**1**) was formed in a straightforward reaction from Ni(ac)$_2$·4H_2O and $^{si}S_3$-H_2 in THF/MeOH mixtures. A dark brown solution resulted from which **1** was obtained analytically pure and in high yield (87%). Complex **1** is stable towards air and moisture for extended periods of time and soluble in many common organic solvents, e.g., THF, CH_2Cl_2, acetone, Et_2O, toluene, hexane, MeCN, DMF, DMSO. In MeOH or pentane, **1** is sparingly soluble. Complex **1** fulfilled one of the expectations connected with the synthesis of $^{si}S_3$-H_2, showing good solubility in organic solvents in which the parent complex [Ni($^{H}S_3$)]$_3$ proved insoluble. The ^{1}H and $^{13}C\{^1H\}$ NMR spectra of **1** were compatible with the trinuclear structure indicated in Scheme 2. This structure was confirmed by a single-crystal X-ray structure determination.

Subsequent experiments were aimed at cleaving trinuclear [Ni($^{si}S_3$)]$_3$ and probing the coordination of σ and σ-π ligands to the [Ni($^{si}S_3$)] fragment. Scheme 2 summarizes the reactions of **1** yielding mononuclear [Ni(L)($^{si}S_3$)] complexes. Treatment of **1** with phosphanes gave [Ni(PR_3)($^{si}S_3$)] with R = *n*-Pr (**2**), Ph (**3**), and Cy (**4**). The reactions could be monitored by the practically instantaneous color change of the THF solution from red-brown to yellow-red or orange, and they took place much faster than the analogous reactions of the parent [Ni($^{H}S_3$)]$_3$ complex with the phosphanes. The phosphane derivatives **2**, **3**, and **4** proved inert with regard to substitution of the phosphane ligands.

Substitution-labile [Ni(L)($^{si}S_3$)] complexes were obtained with L = Cl^- and S*t*Bu$^-$. Treatment of **1** with an equimolar amount of Bu_4NCl yielded dark purple needles of Bu_4N[Ni(Cl)($^{si}S_3$)] (**5**). With Bu_4NS*t*Bu, brown microcrystals of Bu_4N[Ni(S*t*Bu)($^{si}S_3$)] (**6**) were obtained. The chloro derivative [Ni(Cl)($^{si}S_3$)]$^-$ enabled the synthesis of the azido complex, which was not accessible directly from **1**. For this purpose **1** was first treated with Et_4NCl to give Et_4N[Ni(Cl)($^{si}S_3$)] in situ. Subsequent addition of Me_3SiN_3 yielded Et_4N[Ni(N_3)($^{si}S_3$)] (**7**) which was isolated as violet needles. Complexes **5** and **7** demonstrated that typical σ-



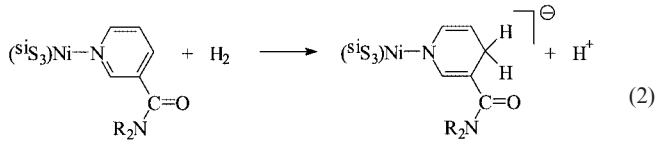
Scheme 2. Synthesis and reactions of $[Ni(^{si}S_3)]_3$ complexes

donor ligands can form stable adducts with $[Ni(^{si}S_3)]$ fragments. With hydrazine, **1** could directly be cleaved to give dark-red $[Ni(N_2H_4)(^{si}S_3)]$ (**8**). The analogous reaction with NH_3 yielded a very labile species that could be generated and characterized only in situ in an NMR tube. All attempts to isolate $[Ni(NH_3)(^{si}S_3)]$ in the solid state remained unsuccessful.

Hydride or CO derivatives of $[Ni(^{si}S_3)]$ could not be obtained. At high pressures of CO (100 bar), minor amounts of **1** were converted into $Ni(CO)_4$ in the course of 10 d. The resulting $Ni(CO)_4$ could be isolated by fractional condensation and was identified by its ν(CO) IR band at 2040 cm^{-1}.[10e]

All of the complexes **1**−**9** proved to be very soluble in THF, CH_2Cl_2, acetone, toluene, MeCN, DMF, and DMSO. As judged by their NMR spectra, they are diamagnetic. The ^1H NMR spectra of all mononuclear complexes **2**−**9** show a typical splitting pattern for the aromatic protons, consisting of three multiplets, and an $SiMe_3$ singlet. The intense $SiMe_3$ singlet is also well suited for probing the purity of the complexes. In addition, the $SiMe_3$ singlet in the ^1H NMR spectrum indicates C_s symmetry of the $[Ni(^{si}S_3)]$ fragments in **2**−**9**. This is corroborated by ^{13}C and ^{31}P NMR spectra as well as by the X-ray structure determination of **3**, **4**, **5**, and **7**. The azido complex **7** shows a characteristic $\nu(N_3)$ band at 2037 cm^{-1}in the IR spectrum, in the solid state as well as in CH_2Cl_2 solution. It is noted that **7** is the first structurally characterized azidonickel complex with a coligand exclusively having sulfur donors.

The formation and characterization of the complexes **7**, **8**, and also **9** proved the capability of the $[Ni(^{si}S_3)]$ fragment to bind σ-donor amine ligands, though the ammonia derivative **9** showed that the resulting mononuclear complexes may be labile. Nevertheless, much effort was spent on the synthesis of $[Ni(^{si}S_3)]$ complexes with nicotinamide (NA) or nicotinamide derivatives (NAR_2) as coligands. The aim of these efforts was to form species that could be hydrogenated by molecular hydrogen according to Equation (2).



(2)

In this reaction we wanted to make use of the heterolytic cleavage of H_2 observed to be catalyzed by $[Ni(NHPnPr_3)(^{H}S_3)]$ in order to achieve the chemical "storage" of H_2 characteristic for the NAD/NADH couple. Taking the pK_a values of different nicotinamide derivatives into account,[18] we have focused on the coordination of either NA or diethylnicotinamide ($NAEt_2$), and treated **1** or the substitution-labile complexes **5** and **6** with varying amounts of NA or $NAEt_2$, ranging from 1:1 ratios to a large excess of NA or $NAEt_2$. In these experiments, mixtures of **1**, the nicotinamide $[Ni(L)(^{si}S_3)]$ complexes and uncoordinated nicotinamide derivatives were obtained that could not be separated. The color change of the THF reaction solutions from dark-brown to red indicated that a reaction took place. Using the $SiMe_3$ signals as a spectroscopic probe enabled us to monitor the reaction course by ^1H NMR spectroscopy. Figure 1 illustrates the reaction between **1** and NA. Figure 1 (a) shows the two $SiMe_3$ singlets of the starting complex **1** at δ = 0.57 and 0.09 ppm. Addition of 1 equiv. of NA gives rise to a new $SiMe_3$ singlet at δ = 0.33 ppm indicating the formation of $[Ni(NA)(^{si}S_3)]$, while the intensity of the two signals of **1** decreases. The intensity of the signal at δ = 0.33 ppm increases when more NA is added. Figure 1 (c) demonstrates that at a 1:10 ratio of **1**/NA, which equals an approximately threefold excess of NA, complex **1** has been converted almost entirely into the derivative $[Ni(NA)(^{si}S_3)]$. Analogous spectra were observed for the reaction between **1** and $NAEt_2$. However, attempts to

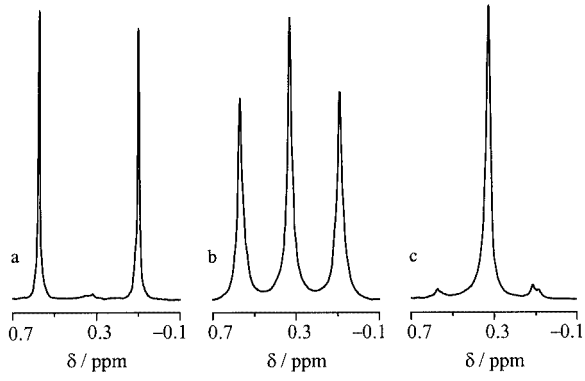


Figure 1. $SiMe_3$ region of ^1H NMR spectra of $[Ni(^{si}S_3)]_3$ in $[D_8]$THF (a) before and (b) after addition of 1 equiv. and (c) after addition of 10 equiv. of nicotinamide

crystallize the [Ni(NA)($^{si}S_3$)] or [Ni(NAEt$_2$)($^{si}S_3$)] complexes from such solutions or to remove the excess of NA or NAEt$_2$ by extraction were unsuccessful. In the latter case, the starting complex **1** was regenerated. This clearly demonstrates that the reaction between **1** and NA or NAEt$_2$ is an equilibrium reaction [Equation (3)].

$$[Ni(^{si}S_3)]_3 + 3\,NA \rightleftharpoons 3\,[Ni(NA)(^{si}S_3)] \quad (3)$$

In this regard, the reactions between **1** and NA or NAEt$_2$ compare with the reversible formation of [Ni(NH$_3$)($^{si}S_3$)] from **1** and NH$_3$. Because it proved impossible to isolate [Ni(NA)($^{si}S_3$)] or [Ni(NAEt$_2$)($^{si}S_3$)] in a pure state, mixtures of the complexes and the respective free NA or NAEt$_2$ were treated with molecular hydrogen in an autoclave at pressures ranging from 10 to 100 bar. However, in no case could the formation of dihydronicotinamide derivatives be observed. The most plausible explanation is that [Ni(NA)($^{si}S_3$)] and [Ni(NAEt$_2$)($^{si}S_3$)] complexes, unlike the phosphorane imine complex [Ni(NHP*n*Pr$_3$)($^{H}S_3$)], do not catalytically heterolyze H_2 or if they do, do not enable the necessary subsequent hydride transfer from the nickel atom to the NA ligand.

X-ray Structure Determinations

Crystal structures of [Ni($^{si}S_3$)]$_3$·0.5CD$_2$Cl$_2$ (**1**·0.5CD$_2$Cl$_2$), [Ni($^{si}S_3$)]$_3$·2THF·3MeOH (**1**·2THF·3MeOH), [Ni(PPh$_3$)($^{si}S_3$)] (**3**), [Ni(PCy$_3$)($^{si}S_3$)]·2CDCl$_3$ (**4**·2CDCl$_3$), Bu$_4$N[Ni(Cl)($^{si}S_3$)]·0.625THF·0.375Et$_2$O (**5**·0.625THF·0.375Et$_2$O), Et$_4$N[Ni(N$_3$)($^{si}S_3$)]·THF (**7**·THF) were determined by X-ray structure analysis. Figures 2 and 3 depict ORTEP diagrams of the structures, Tables 1 and 2 list selected distances and angles.

The unit cells of all compounds contain discrete molecules or ions. The unit cells of **3** and **5** each contain two

can be traced back to the sp^3-hybridized thioether S donors of the $^{si}S_3$ ligand, leading to a butterfly-like shape of the resulting [Ni($^{si}S_3$)] fragments. The characteristic topology of the $^{si}S_3$ ligand also causes the Ni−S(thioether) distances to always be shorter than the Ni−S(thiolate) distances. In this respect, [Ni($^{si}S_3$)] complexes are analogous to [Ni($^{H}S_3$)] complexes that contain the $^{H}S_3$ parent ligand and have been described previously.[11−13]

Trimerization of [Ni($^{si}S_3$)] fragments by thiolate bridges leads to **1**. Complex **1** contains a cyclohexane-like six-membered $[NiS]_3$ ring with a chair conformation, and the structure of **1** parallels that of the parent complex $[Ni(^{H}S_3)]_3$.[12] All bridging Ni−S(thiolate) distances in the six-membered $[NiS]_3$ ring, ranging from 219.4(1) to 222.2(1) pm, are distinctly longer than the terminal Ni−S(thiolate) distances [214.3(1) to 215.6(1) pm]. This elongation of bridging Ni−S distances rationalizes the ready dissociation of **1** in solution when treated with suitable monodentate ligands.

In the complexes **3**, **4**, **5**, and **7**, the fourth coordination site of the [Ni($^{si}S_3$)] fragments is occupied by PPh_3, PCy_3, Cl^-, or N_3^-. The distances and angles in **3**, **4**, **5**, and **7** lie in the range observed for analogous [Ni(L)($^{H}S_3$)] complexes, and thus far, show no anomalies.[10−15] For example, the Ni−S(thioether) distance is always shorter than the Ni−S(thiolate) distances and the [Ni($^{si}S_3$)] fragments exhibit their typical butterfly shape. The N−N distances [118.5(6) and 115.8(6) pm] and Ni−N1−N2 angle [121.2(3)°] in **7** are characteristic for azide complexes in which the azide ligand binds end-on as a σ-donor to the metal atom.[19,20]

Conclusion

This work describes the synthesis of the new ligands $^{si}S_3$-H_2 and $^{ca}S_3$-H_2 and a series of [Ni(L)($^{si}S_3$)] complexes. The major aim of the investigations was to find complexes with [Ni($^{si}S_3$)] fragments that are well soluble in common solvents and more reactive than the [Ni($^{H}S_3$)] parent complexes. These objectives have been reached and, unlike the [Ni($^{H}S_3$)] parent fragment, the [Ni($^{si}S_3$)] complex fragment has been proved to bind even nicotinamide or diethylnicotinamide, though only in equilibrium reactions. Attempts to hydrogenate the nicotinamide complexes in solution to give dihydronicotinamide derivatives, however, remains unsuccessful.

Experimental Section

General Methods: Unless stated otherwise, all reactions and manipulations were carried out under nitrogen at room temperature using standard Schlenk techniques. All solvents were dried and distilled before use. As far as possible, reactions were monitored by IR or NMR spectroscopy. Physical measurements were carried out with the following instruments: IR (KBr discs or CaF_2 cuvettes, solvent bands were compensated), Perkin−Elmer 983, 1620 FT-IR and 16PC FT-IR; NMR: Jeol JMM-GX 270, Jeol JMM-EX 270, and Lambda LA 400 with the residual protio-solvent signal used as an internal reference. Chemical shifts are quoted in the δ scale (down field shifts are positive) relative to tetramethylsilane (^1H, $^{13}C\{^1H\}$ NMR) or 85% H_3PO_4 ($^{31}P\{^1H\}$ NMR). Mass spectra: Jeol MSTATION 700 spectrometer. Elemental analyses: Carlo Erba EA 1106 or 1108 analyzer. Me_3SiCl, Me_3SiN_3, HS*t*Bu, Bu_4NCl, Et_4NCl, N_2H_4 (1 M solution in THF), nicotinamide, *N*,*N*-diethylnicotinamide were purchased from either Aldrich or Fluka. $^{H}S_3$-H_2 was prepared as described in the literature.[11]

$^{si}S_3$-H_2: With continuous vigorous stirring under argon, *n*BuLi in hexane (2.5 M, 45 mL, 112.51 mmol) was slowly added to a suspension of $^{H}S_3$-H_2 (6.49 g, 25.92 mmol) in hexane (200 mL) at −78 °C. After addition of TMEDA (31 mL, 206.01 mmol), the temperature was raised gradually to 25 °C. Stirring was continued for another 72 h, in the course of which the color of the suspension turned from white to yellow. This suspension was cooled to −78 °C, SiMe_3Cl (15 mL, 118.03 mmol) was added slowly, and stirring was continued for 1 h at −78 °C and 24 h at 25 °C, in the course of which the color of the suspension changed back to white. H_2O (50 mL) was added, and all volatile components were removed in vacuo. A red-brown highly viscous residue remained which was dissolved in Et_2O (500 mL). The resulting Et_2O solution was washed by extraction with hydrochloric acid (5%, 3 × 200 mL) and a saturated NaCl/H_2O solution (2 × 100 mL), and dried with solid Na_2SO_4. Removal of all volatile components in vacuo yielded a yellow-red viscous residue, which was dissolved in MeOH (150 mL) and heated to reflux for 12 h. Removal of volatile components in vacuo gave a red-brown viscous oil of $^{si}S_3$-H_2, which could be used for the synthesis of complexes without further purification. Yield: 9.55 g (93%). $C_{18}H_{26}S_3Si_2$ (394.78): calcd. C 54.76, H 6.65, S 24.39; found C 55.01, H 6.58, S 24.28. MS (FD, THF): *m*/*z* = 394 [M^+]. ^1H NMR (269.7 MHz, C_6D_6): δ = 7.23 (d, 2 H, C_6H_3), 7.10 (d, 2 H, C_6H_3), 6.78 (t, 2 H, C_6H_3), 4.61 (br, 2 H, SH), 0.35 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (67.8 MHz, C_6D_6): δ = 141.3, 140.9, 134.6, 134.4, 133.0, 126.3 (C_6H_3), −0.2 ($SiMe_3$) ppm.

$^{ca}S_3$-H_2: To a suspension of $^{H}S_3$-H_2 (7.05 g, 28.17 mmol) in hexane (150 mL), *n*BuLi in hexanes (2.5 M, 45 mL, 112.51 mmol) was added slowly at −78 °C. Under vigorous stirring, TMEDA (31 mL, 206.01 mmol) was added and the temperature gradually raised to 25 °C. The mixture was stirred for another 72 h, in the course of

which the color of the suspension turned from white to yellow. This suspension was cooled down again to −78 °C, CO_2 was bubbled through for 30 min under vigorous stirring and the mixture was gradually warmed to 0 °C in the course of 1 h. All volatile components were removed in vacuo. The resulting mixture was treated with cold water (50 mL) and concentrated hydrochloric acid (70 mL). The resulting mixture was extracted with a mixture of Et_2O (100 mL) and THF (30 mL). The extract was dried with Na_2SO_4 and the solvents were evaporated to give a dry pale yellow residue. This was recrystallized from acetone (60 mL) at −20 °C. Green yellow needles precipitated, which were separated after 2 d, washed with cold acetone (10 mL, 0 °C) and dried in vacuo. Yield: 4.83 g (51%). $C_{14}H_{10}O_4S_3$ (338.43): calcd. C 49.69, H 2.98, S 28.42; found C 49.99, H 3.36, S 27.78. MS (FD, THF): *m*/*z* = 338 [M^+]. IR (KBr): $\tilde{\nu}$ = 2980 [ν(OH)], 2484 [ν(SH)], 1652 [ν(COOH)] cm^{-1}. ^1H NMR (399.7 MHz, [D_8]THF): δ = 11.85 (br, 2 H, COOH), 8.06 (d, 2 H, C_6H_3), 7.30 (d, 2 H, C_6H_3), 7.28 (s, 2 H, SH), 7.08 (t, 2 H, C_6H_3) ppm. $^{13}C\{^1H\}$ NMR (100.4 MHz, [D_8]THF): δ = 167.7 (COOH), 141.5, 135.3, 133.2, 131.2, 126.6, 123.6 (C_6H_3) ppm.

[Ni($^{si}S_3$)]$_3$ (1): $^{si}S_3$-H_2 (3.00 g, 7.60 mmol) in THF (40 mL) was added dropwise to a solution of $Ni(ac)_2{\cdot}4H_2O$ (1.90 g, 7.65 mmol) in MeOH (25 mL). A dark brown solution formed which was stirred for 24 h and then concentrated to dryness. The resulting dark brown residue was redissolved in hexane (20 mL), traces of insoluble particles were removed by filtration after 30 min, and the filtrate was layered with MeOH (50 mL). A dark brown powder precipitated, which was separated, washed with MeOH (30 mL) and pentane (25 mL), and dried in vacuo. Yield: 3.02 g (87%). $C_{54}H_{72}Ni_3S_9Si_6$ (1354.36): calcd. C 47.89, H 5.36, S 21.31; found C 47.58, H 5.53, S 20.98. MS (FD, THF): *m*/*z* = 1354 [M^+], 902 [Ni($^{si}S_3$)]$_2^+$. ^1H NMR (399.7 MHz, [D_8]THF): δ = 7.82 (d, 1 H, C_6H_3), 7.68 (d, 1 H, C_6H_3), 7.40 (d, 1 H, C_6H_3), 7.28 (t, 1 H, C_6H_3), 7.24 (d, 1 H, C_6H_3), 6.96 (t, 1 H, C_6H_3), 0.55 (s, 9 H, $SiMe_3$), 0.08 (s, 9 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (100.4 MHz, [D_8]THF): δ = 158.8, 146.7, 145.1, 139.3, 138.5, 135.4, 134.8, 132.2, 130.9, 127.8, 127.6, 122.1 (C_6H_3), 0.6, −0.6 ($SiMe_3$) ppm.

[Ni(P*n*Pr$_3$)($^{si}S_3$)] (2): P*n*Pr_3 (0.16 mL, 0.99 mmol) was added to a solution of **1** (400 mg, 0.30 mmol) in THF (15 mL). The solution instantaneously changed its color from dark brown to dark yellow, was filtered after 1 h, reduced in volume to 2 mL, and layered with pentane (20 mL). Orange microcrystals precipitated which were separated after 5 d, washed with pentane (10 mL), and dried in vacuo. Yield: 435 mg (80%). $C_{27}H_{45}NiPS_3Si_2$ (611.694): calcd. C 53.02, H 7.42, S 15.73; found C 53.28, H 7.24, S 15.47. MS (FD, THF): *m*/*z* = 611 [M^+]. ^1H NMR (269.7 MHz, $CDCl_3$): δ = 7.64 (d, 2 H, C_6H_3), 7.24 (d, 2 H, C_6H_3), 6.94 (t, 2 H, C_6H_3), 1.74 (m, 6 H, PCH_2), 1.06 (m, 6 H, PCH_2CH_2), 0.37 (s, 18 H, $SiMe_3$), 0.05 (t, 9 H, $PCH_2CH_2CH_3$) ppm. $^{13}C\{^1H\}$ NMR (100.4 MHz, $CDCl_3$): δ = 159.0 (d, $^3J_{P,C}$ = 13.2 Hz), 141.1, 135.1, 133.6, 129.1, 122.3 (C_6H_3), 26.7 (d, $^1J_{P,C}$ = 26.40 Hz), 18.7, 16.7 (d, $^3J_{P,C}$ = 14.1 Hz) ($PCH_2CH_2CH_3$), 0.0 ($SiMe_3$) ppm. $^{31}P\{^1H\}$ NMR (161.8 MHz, $CDCl_3$): δ = 14.6 [P*n*(C_3H_7)$_3$] ppm.

[Ni(PPh$_3$)($^{si}S_3$)] (3): Whilst stirring, a solution of PPh_3 (200 mg, 0.76 mmol) and **1** (280 mg, 0.21 mmol) in THF (10 mL) was heated to reflux for 5 min, in the course of which the color changed from dark brown to red. The red solution was stirred for another 30 min at room temperature, then combined with MeOH (30 mL), filtered, and reduced in volume to ca. 5 mL. Red microcrystals precipitated which were separated after 3 d, washed with MeOH (10 mL), and dried in vacuo. Yield: 268 mg (76%). $C_{36}H_{39}NiPS_3Si_2$ (713.72): calcd. C 60.58, H 5.51, S 13.48; found C 60.48, H 5.80, S 13.51. MS (FD, THF): *m*/*z* = 712 [M^+]. ^1H NMR (269.7 MHz, [D_6]acetone): δ = 7.94 (d, 2 H, C_6H_3), 7.83−7.52 (m, 15 H, C_6H_5), 7.28 (d, 2 H, C_6H_3), 7.04 (t, 2 H, C_6H_3), 0.12 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (67.8 MHz, [D_6]acetone): δ = 159.5 (d, $^3J_{PC}$ = 14 Hz), 143.0, 135.4, 135.3 (d, J_{PC} = 10.8 Hz), 133.3, 131.7, 130.4 (d, $^1J_{PC}$ = 47.4 Hz) 129.6, 129.1 (d, J_{PC} = 10.2 Hz), 122.7 [C_6H_3, $P(C_6H_5)_3$], −0.8 ($SiMe_3$) ppm. $^{31}P\{^1H\}$ NMR (161.8 MHz, [D_6]acetone): δ = 29.4 [$P(C_6H_5)_3$] ppm.

[Ni(PCy$_3$)($^{si}S_3$)] (4): A solution of PCy_3 (200 mg, 0.71 mmol) in THF (2 mL) was added dropwise to a solution of **1** (300 mg, 0.22 mmol) in THF (10 mL). Over the course of ca. 5 min, the color of the solution changed from dark brown to dark yellow. The solution was stirred for 3 h, filtered, reduced in volume to ca. 2 mL, and layered with MeOH (20 mL). Yellow-red microcrystals precipitated, which were separated after 3 d, washed with MeOH (10 mL), and dried in vacuo. Yield: 452 mg (93%). $C_{36}H_{57}NiPS_3Si_2$ (731.889): calcd. C 59.08, H 7.85, S 13.14; found C 59.32, H 7.96, S 12.69. MS (FD, THF): *m*/*z* = 731 [M^+]. ^1H NMR (399.7 MHz, $CDCl_3$): δ = 7.74 (d, 2 H, C_6H_3), 7.28 (d, 2 H, C_6H_3), 6.98 (t, 2 H, C_6H_3), 2.10−1.28 (m, 33 H, PCy_3), 0.37 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (100.4 MHz, $CDCl_3$): δ = 159.0 (d, $^3J_{PC}$ = 10 Hz), 141.2, 135.0, 133.1 (d, $^4J_{PC}$ = 1.6 Hz), 128.7, 122.0 (C_6H_3), 34.5 (d, $^1J_{PC}$ = 20.1 Hz), 30.7, 28.5 (d, $^3J_{PC}$ = 11 Hz), 27.1 [$P(C_6H_{11})_3$], 0.0 ($SiMe_3$) ppm. $^{31}P\{^1H\}$ NMR (161.8 MHz, $CDCl_3$): δ = 31.9 [$P(C_6H_{11})_3$] ppm.

Bu$_4$N[Ni(Cl)($^{si}S_3$)] (5): Bu_4NCl (210 mg, 0.76 mmol) was added to a dark brown solution of **1** (312 mg, 0.23 mmol) in THF (10 mL). The solution was stirred for 12 h, over the course of which its color changed to violet. The solution was filtered, reduced in volume to 2 mL, and layered with Et_2O (20 mL). Pink crystals precipitated which were separated after 7 d, washed with Et_2O (15 mL), and dried in vacuo. Yield: 410 mg (81%). $C_{34}H_{60}ClNNiS_3Si_2$ (729.377): calcd. C 55.99, H 8.29, N 1.92, S 13.19; found C 56.01, H 8.32, N 2.07, S 12.72. ^1H NMR (269.7 MHz, [D_8]THF): δ = 7.60 (d, 2 H, C_6H_3), 7.18 (d, 2 H, C_6H_3), 6.79 (t, 2 H, C_6H_3), 3.57 (m, 8 H, NCH_2), 1.76 (m, 8 H, NCH_2CH_2), 1.39 [m, 8 H, $N(CH_2)_2CH_2$], 0.87 [m, 12 H, $N(CH_2)_3CH_3$], 0.36 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (67.8 MHz, [D_8]THF): δ = 161.6, 139.6, 134.7, 134.6, 128.9, 120.7 (C_6H_3), 59.7, 35.1, 20.7, 14.2 [$N(CH_2)_3CH_3$], −0.2 ($SiMe_3$) ppm.

Bu$_4$N[Ni(S*t*Bu)($^{si}S_3$)] (6): Whilst stirring, NaS*t*Bu (1 mL of 1 M MeOH solution, 1.00 mmol) was added to a solution of **1** (300 mg, 0.22 mmol) in THF (10 mL). After 1 h, Bu_4NOH (0.68 mL, 1 M MeOH solution, 0.68 mmol) was added and the stirring continued for another 2 h. A dark brown solution resulted, which was filtered, concentrated in volume to 2 mL, and layered with pentane (15 mL). Dark brown microcrystals precipitated which were separated after 5 d, washed with pentane (5 mL) and dried in vacuo. Yield: 340 mg (65%). $C_{38}H_{69}NNiS_4Si_2$ (783.106): calcd. C 58.28, H 8.88, N 1.79, S 16.37; found C 58.43, H 8.97, N 1.91, S 15.89. ^1H NMR (269.7 MHz, $CDCl_3$): δ = 7.52 (d, 2 H, C_6H_3), 7.14 (d, 2 H, C_6H_3), 6.78 (t, 2 H, C_6H_3), 3.32 (m, 8 H, NCH_2), 1.59 (m, 8 H, NCH_2CH_2), 1.53 (s, 9 H, S*t*Bu), 1.31 [m, 8 H, $N(CH_2)_2CH_2$], 0.88 [m, 12 H, $N(CH_2)_3CH_3$], 0.34 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (67.8 MHz, $CDCl_3$): δ = 161.6, 139.5, 133.7, 133.0, 127.9, 119.7 (C_6H_3), 58.9 (NCH_2), 40.4, 36.8 (S*t*Bu), 24.2, 19.7 13.9 [$N(CH_2)_3CH_3$], −0.5 ($SiMe_3$) ppm.

Et$_4$N[Ni(N$_3$)($^{si}S_3$)] (7): A solution of Et_4NCl (95 mg, 0.57 mmol) and **1** (250 mg, 0.19 mmol) in THF (10 mL) was stirred for 3 h, over the course of which the color changed from dark brown to purple. Me_3SiN_3 (0.1 mL, 0.76 mmol) was added, whereupon the color became slightly lighter. After 1 h, all volatile materials were

removed in vacuo, the residue was redissolved in THF (10 mL). The THF solution was filtered, reduced in volume to 2 mL and layered with pentane (15 mL). Violet needles precipitated, which were separated after 4 d, washed with pentane (10 mL), and dried in vacuo. Yield: 285 mg (82%). $C_{26}H_{44}N_4NiS_3Si_2$ (623.729): calcd. C 50.07, H 7.11, N 8.98, S 15.42; found C 50.61, H 7.40, N 8.70, S 15.19 − IR (KBr): $\tilde{\nu}$ = 2037 [$\nu(N_3)$] cm^{-1}. ^1H NMR (269.7 MHz, $CDCl_3$): δ = 7.48 (d, 2 H, C_6H_3), 7.26 (d, 2 H, C_6H_3), 6.90 (t, 2 H, C_6H_3), 3.40 (m, 8 H, NCH_2), 1.20 (t, 12 H, NCH_2CH_3), 0.37 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (67.8 MHz, $CDCl_3$): δ = 157.9, 140.0, 134.5, 132.9, 127.8, 120.9 (C_6H_3), 52.6, 7.8 [$N(CH_2CH_3)_4$], −0.9 ($SiMe_3$) ppm.

[Ni(N_2H_4)($^{si}S_3$)] (8): Addition of N_2H_4 (2 mL of 1 M THF solution, 2.00 mmol) to a solution of **1** (250 mg, 0.19 mmol) in THF (10 mL) led to a rapid color change from dark brown to orange. The solution was stirred for 2 h and stored at −30 °C for 12 h. At this temperature, the excess free hydrazine that crystallized from the solution could be removed by filtration at −30 °C. The filtrate was reduced in volume to 2 mL and layered with pentane (20 mL). Dark red crystals precipitated which were separated, washed with pentane (10 mL) and dried in vacuo. Yield: 242 mg (90%). $C_{18}H_{28}N_2NiS_3Si_2$ (489.499): calcd. C 44.71, H 5.84, N 5.79, S 19.90; found C 45.01, H 5.88, N 5.51, S 19.43. IR (KBr): $\tilde{\nu}$ = 3350 [ν(NH)] cm^{-1}. ^1H NMR (269.7 MHz, [D_8]THF): δ = 7.62 (d, 2 H, C_6H_3), 7.25 (d, 2 H, C_6H_3), 6.90 (t, 2 H, C_6H_3), 4.83 (b, 2 H, NH_2NH_2), 3.32 (b, 2 H, NH_2), 0.39 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (67.8 MHz, [D_8]THF): δ = 157.6, 140.9, 135.5, 134.5, 129.9, 122.4 (C_6H_3), −0.4 ($SiMe_3$) ppm.

[Ni(NH_3)($^{si}S_3$)] (9): This compound was synthesized in an NMR tube and characterized only by ^1H and ^{13}C NMR spectra: NH_3 gas (2.5 mL, 0.15 mmol) was injected into the dark brown solution of **1** (25 mg, 0.02 mmol) in [D_8]THF contained in an NMR tube. The color of the solution immediately changed to red. The ^1H and ^{13}C NMR spectra of the solutions indicated the complete conversion of **1** into **9**. ^1H NMR (269.7 MHz, [D_8]THF): δ = 7.63 (d, 2 H, C_6H_3), 7.23 (d, 2 H, C_6H_3), 6.89 (t, 2 H, C_6H_3), 2.27 (b, 3 H, NH_3), 0.37 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (67.8 MHz, [D_8]THF): δ = 158.4, 140.6, 135.3, 134.5, 129.6, 122.0 (C_6H_3), −0.5 ($SiMe_3$) ppm.

[Ni(L)($^{si}S_3$)] Complexes (L = NA or $NAEt_2$): In a typical experiment, NA (0.5 g, 4.09 mmol) or $NAEt_2$ (1.0 mL, 5.95 mmol) was added to a dark brown solution of **1** (500 mg, 0.37 mmol) in THF (10 mL). The solution was stirred for 48 h, over the course of which its color changed to yellow red. The solution was filtered, reduced in volume to 2 mL, and layered with Et_2O (20 mL). Yellow red powders precipitated which were separated after 5 d, washed with Et_2O (15 mL), and dried in vacuo. Elemental analyses and IR and NMR spectra indicated that these powders were mixtures of [Ni(L)($^{si}S_3$)] and **1,** which could not be separated.

^1H NMR Spectroscopic Monitoring of the Reactions between 1 and NA or $NAEt_2$: To a dark brown solution of **1** (25 mg, 0.02 mmol) in [D_8]THF, NA, or $NAEt_2$ (1−10 equiv.) was added stepwise, and the ^1H NMR spectra were recorded after every addition. The $SiMe_3$ signals were used as a spectroscopic probe to monitor the formation of the corresponding [Ni(L)($^{si}S_3$)] complex.

X-ray Structure Determination of [Ni($^{si}S_3$)]$_3$·0.5CD_2Cl_2 (1·0.5CD_2Cl_2), [Ni($^{si}S_3$)]$_3$·2THF·3MeOH (1·2THF·3MeOH), [Ni(PPh_3)($^{si}S_3$)] (3), [Ni(PCy_3)($^{si}S_3$)]·2$CDCl_3$ (4·2$CDCl_3$), Bu_4N[Ni(Cl)($^{si}S_3$)]·0.625THF·0.375Et_2O (5·0.625THF·0.375Et_2O), Et_4N[Ni(N_3)($^{si}S_3$)]·THF (7·THF): In an NMR tube at −30 °C, black blocks of [Ni($^{si}S_3$)]$_3$·0.5CD_2Cl_2 (**1**·0.5CD_2Cl_2) crystallized in the course of 10 d from a CD_2Cl_2 solution of **1** which had been layered with MeOH. From THF/MeOH mixtures, **1** crystallized as **1**·2THF·3MeOH. The crystallographic data of this solvate have been deposited. Red cubes of **3** and orange-prisms of **4**·2$CDCl_3$

Table 3. Selected crystallographic data for [Ni($^{si}S_3$)]$_3$·0.5CD_2Cl_2 (**1**·0.5CD_2Cl_2), [Ni(PPh_3)($^{si}S_3$)] (**3**), [Ni(PCy_3)($^{si}S_3$)]·2$CDCl_3$ (**4**·2$CDCl_3$), Bu_4N[Ni(Cl)($^{si}S_3$)]·0.625THF·0.375Et_2O (**5**·0.625THF·0.375Et_2O), and Et_4N[Ni(N_3)($^{si}S_3$)]·THF (**7**·THF)

were grown at −20 °C over the course of 3−5 d from a concentrated THF solution which was layered with MeOH. Red-violet plates of **5**·0.625THF·0.375Et_2O formed over the course of 7 d when a saturated THF solution of **5** was layered with Et_2O at −30 °C. Red-black crystals of **7**·THF were obtained from a dilute THF/acetone mixture of **7** which was layered with pentane and stored for 8 d at −30 °C. Suitable single crystals were embedded in protective perfluoro polyether or were sealed in glass capillaries under N_2. Data were collected at 200 K (**1**·0.5CD_2Cl_2, **5**·0.625THF·0.375Et_2O, **7**·THF), 220 K (**4**·2$CDCl_3$) or 293 K (**3**) with a Siemens P4 diffractometer or a Nicolet R 3m/V diffractometer (**3**) using Mo-K_α radiation (λ = 71.073 pm), a graphite monochromator, and the ω-scan technique. For all compounds a semi-empirical absorption correction using ψ-scans has been performed. The structures were solved by direct methods, full-matrix least-squares refinement was carried out on F^2 (SHELXTL NT 5.1).[21] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of **1**·0.5CD_2Cl_2 were located from a difference Fourier map, while in all other compounds the H atoms were geometrically positioned with isotropic displacement parameters being 1.5 times U(eq) of the preceding carbon atom. One *n*-butyl group in the cation of **5**·0.625THF·0.375Et_2O was found to be disordered. Two alternative sites could be refined with occupancy factors of 57(2) and 43(2)%, respectively. One THF and one Et_2O molecule of the included solvent share a single site. These disordered molecules have been refined using several restraints. Selected crystallographic data are summarized in Table 3.[22]

Ruthenium-Catalyzed Isomerization of Allylic Alcohols: Oxidation State Determines Resistance Against Diene Inhibition

Robert C. van der Drift,[a] Jeroen W. Sprengers,[a] Elisabeth Bouwman,*[a] Wilhelmus P. Mul,[b] Huub Kooijman,[c] Anthony L. Spek,[c] and Eite Drent[a]

Keywords: Isomerization / Allylic alcohols / Homogeneous catalysis / Ruthenium / Diene inhibition

The novel complex *mer*-[$RuCl_3$(dmso)(phen)] (**1**) has been prepared and characterized by X-ray diffraction. The ruthenium center is in a distorted octahedral environment with the three chloride ions coordinated in a *mer*-fashion and an *S*-bonded dmso ligand *trans* to one of the phen nitrogen atoms. Electrochemical experiments show two reversible waves in acetonitrile solution, corresponding to the couples $Ru^{III/II}$ (0.11 V) and $Ru^{IV/III}$ (1.73 V). The analogous Ru^{II} complex *cis*,*cis*-[$RuCl_2$(dmso)$_2$(phen)] (**2**) shows one reversible wave at 1.08 V, corresponding to the $Ru^{III/II}$ couple. Both complexes exhibit high catalytic activity in the isomerization of 3-buten-2-ol to butanone. The initial turnover frequency (TOF) for **1** in diglyme/water at 130 °C is 295 h^{-1} with a first-order k_{ini} of 0.6 h^{-1}, while **2** reaches an initial TOF of 260 h^{-1} and a k_{ini} of 0.5 h^{-1}. A cumulative turnover number (TON) of 1025 has been obtained with **1** as a catalyst precursor. The activity of **1** and **2** has been compared to that of in situ mixtures with both Ru^{III} and Ru^{II} precursors. All Ru^{II} complexes are deactivated before 100% conversion has been attained. $RuCl_3$ is a good catalyst precursor with an initial TOF of 500 h^{-1}. If $RuCl_3$ is mixed in situ with one equivalent of phen, an induction period of 40 min results and the activity thereafter is much lower than without the addition of phen. With 2 equiv. of phen, no reaction is observed in the first 6 h and only a very low activity is obtained after that. An important difference between **1** and **2** becomes apparent when a conjugated diene is added to the reaction mixture; only **1** remains active. The results demonstrate that only Ru^{III} complexes with one phen ligand are active catalyst precursors for the isomerization of allylic alcohols in the presence of conjugated dienes. The consequence of this observation is further demonstrated by applying both catalyst precursors in the direct one-pot conversion of 1,3-butadiene to butanone. In this reaction, complex **1** (TON = 2050, t = 6 h) forms a much more active precursor than complex **2** (TON = 1300, t = 7 h).

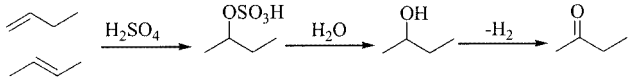
Introduction

Homogeneous catalysis opens new pathways to environmentally benign industrial processes. Many processes in use today produce stoichiometric amounts of inorganic salts. Transition metal catalyzed reactions on the other hand, may offer complete atom-economical routes to important industrial products. For example, butanone (methyl ethyl ketone, MEK) is a megaton-per-year scale solvent traditionally produced from butenes.[1] This process requires the use of stoichiometric amounts of concentrated sulfuric acid as shown in Scheme 1.



Scheme 1. Present-day synthesis of MEK from a mixture of butenes

1,3-Butadiene is an attractive alternative starting material for the preparation of MEK. A viable route would require water as the only other stoichiometric reagent. After acid-catalyzed hydration of butadiene [see (a) in Scheme 2], the 1,2-addition product 3-buten-2-ol can be isomerized to MEK [see (b) in Scheme 2].[2] The equilibrium of Scheme 2 (a) is 97% on the left-hand side, making a one-pot synthesis preferable in order to circumvent an extensive butadiene recycle. For the selective formation of MEK, this calls for catalysts that catalyze the isomerization of the secondary allylic alcohol 3-buten-2-ol but not the primary allylic alcohol 2-buten-1-ol, in the presence of dienes. Despite consid-

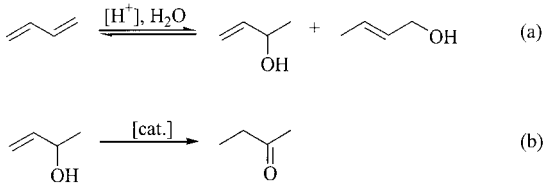
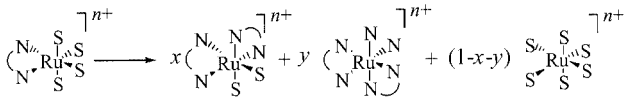
erable efforts this type of catalysts remain scarce.[3] Alternatively, other reagents such as alcohols and amines could be used instead of water to obtain higher conversions, and after isomerization and hydrolysis of the vinyl ether or enamine the carbonyl compound can be obtained.[4,5] In this case an extra, costly purification step will be required to separate MEK from butanal (or to separate the intermediates).



Scheme 2. (a) Acid-catalyzed hydration of 1,3-butadiene (b) followed by isomerization yields MEK in a complete atom-economical process

The feasibility of the one-pot synthesis of MEK from 1,3-butadiene was shown by Drent and co-workers.[6,7] A catalytically active species obtained by in situ mixing of [Ru(acac)$_3$] (Hacac = 2,4-pentanedione) and between 1 and 2 equiv. of 2,2′-bipyridine (bpy) or 1,10-phenanthroline (phen) catalyzes the direct conversion of 1,3-butadiene to MEK (in over 95% selectivity) with a maximum of 1200 turnovers in 32 h. Yet, this turnover number (TON) is not sufficiently high to make this route economically successful. An important catalyst deactivation route proved to be ligand redistribution that results in inactive ruthenium complexes with two and three didentate nitrogen-donor ligands (Scheme 3).[7] Indeed, it has been demonstrated recently that reducing the extent of ligand redistribution may increase the initial activity by a factor of almost ten.[8]



Scheme 3. Ligand redistribution of mono(phen)Ru complexes; S = vacant site or labile ligand; N$_\cup$N = phen; $2x + 3y = 1$, $n = 2, 3$

Although the catalyst precursor consists of an Ru^{III} complex, both Ru^{III} and Ru^{II} complexes can be identified with mass spectrometry (MS) in a used catalyst. This observation raises the question as to what the oxidation state of the ruthenium atom in the catalytically active species is. In this paper the synthesis and characterization of the Ru^{III} compound *mer*-[RuCl$_3$(dmso)(phen)] (**1**) and the analogous Ru^{II} complex *cis,cis*-[RuCl$_2$(dmso)$_2$(phen)] (**2**) are described. The activities of both complexes in the key step of the catalytic process, the isomerization of 3-buten-2-ol to MEK, are compared in the absence and the presence of isoprene (2-methyl-1,3-butadiene) to reveal the role of the ruthenium oxidation state in the isomerization of allylic alcohols.

Results and Discussion

Synthesis and Structure of *mer*-[RuCl$_3$(dmso)(phen)] (1) and *cis,cis*-[RuCl$_2$(dmso)$_2$(phen)] (2)

Synthesis of 1 and 2

To obtain a clear view of the influence of the ruthenium oxidation state in the catalytic process, two complexes are required with ligand environments as identical as possible. It was deduced from earlier studies[7,8] that the catalytically active species should contain only one phen ligand. Furthermore, the complexes should contain innocent ligands that are easily replaced during the catalytic cycle. Numerous ruthenium complexes with two or three phen ligands are known,[9,10] but examples of mono(phen) complexes remain scarce.[9–13] It is especially difficult to prevent ligand redistribution during synthesis.[12] The synthesis of mono(phen) complexes was attempted in our laboratory starting from [Ru(H$_2$O)$_6$](OTs)$_2$, [Ru(MeCN)$_6$](OTf)$_2$ [14] and RuCl$_3$. In all cases, it proved impractical to obtain the ruthenium atom in both the 2+ and 3+ oxidation states. The syntheses of [Ru(acac)$_2$(phen)] and [Ru(acac)$_2$(phen)]PF$_6$ were successful,[15] but the acac ligand could not be replaced under the reaction conditions.
