A Word From Your Senior Editor

Dear authors and readers,

At the beginning of the 5th year of life of EurJIC there is a shared feeling of satisfaction for the high ISI ranking obtained by the Journal (2.222 is the first Impact Factor). It represents the success of the whole community of Inorganic Chemistry. Also the opinion that the chemistry of metal ions is growing in relative importance together with the growth of metal-based catalysis, material sciences, life sciences and environmental chemistry can be heard in Inorganic Chemistry circles. Together with this expansion of inorganic chemistry, the comprehension of the mechanisms of reactions and transformations increases, thanks to the new power of analytical and theoretical tools.

First Impact Factor 2.222

It is with pleasure that we note that the Nobel Committee awarded the Nobel Prize in Chemistry for 2001 to William S. Knowles and Ryoji Noyori for their work on chirally catalysed hydrogenation reactions, and K. Barry Sharpless for his work on chirally catalysed oxidation reactions. They can be defined as organometallic/metallorganic chemists! This must give impetus to this branch of Inorganic Chemistry.

Impetus to Organometallic Chemistry

The number of chemical societies that own the journal has also increased. We welcome the Hungarian Chemical Society and its members, and in particular the Hungarian Academy of Sciences, who merged one of their chemical journals with EurJIC to make this cooperation possible. Once again, one more journal has disappeared through this amalgamation.

Tenth participating society

I would also like to express my gratitude to the Editors and Advisory Board members for their dedication to the Journal. In particular I would like to mention Robert Schoonheydt, Sergio Cenini, and Jacques Livage, who have enthusiastically served until now, and to welcome Guy Bertrand, Pablo Espinet, Anton W. Gal, Tamás Kiss, Maurizio Peruzzini, Rinaldo Poli, Eduardo Ruiz-Hitzky, and Dieter Vogt, the newly appointed members – a dynamic organization thrives on the new ideas that a continuous rotation of the members brings.

New board members

In wishing you a successful new year, I also solicit you to sustain the journal in all the ways that you can: the success of the journal is due to contributors and referees and, of course, to readers.

Finally, the present standard of the journal could not be reached without the excellent performances of the managing editor and of the editorial team.

Thanks to all of them. Our aim for next year is to publish, fast, the best papers in the field.

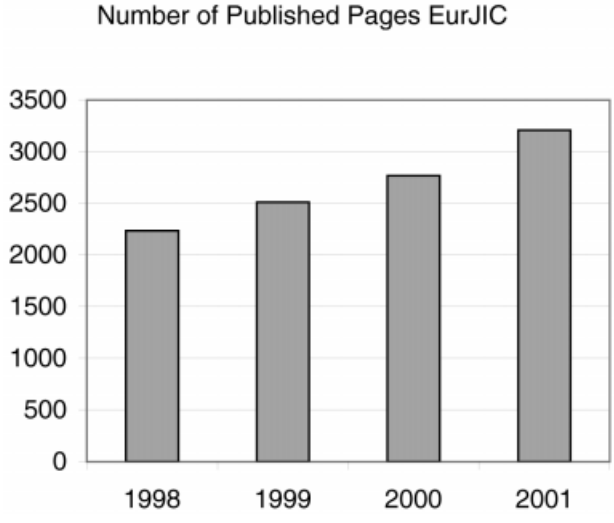
Ivano Bertini
Senior Editor

 Eur. J. Inorg. Chem. **2002**, 4–5 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434–1948/02/0101–0004 $ 17.50+.50/0

A Word From Your Editorial Office:

Many people from authors, referees, and editors to compositors, bookbinders, freelance copy-editors and language-polishers put their best work into producing a high-quality journal. My thanks go to all of them. It has been an exciting year for the European Journal of Inorganic Chemistry, commonly called EurJIC by the ten European Chemical Societies, who own the journals. The nickname, pronounced "Your"JIC, caught on and has now been anchored in the new design of the cover. This innovation was prompted by the long-awaited ISI Impact Factor, which was announced to be 2.222, a good start. A high impact can only come from excellent papers from our authors − now each month authors will have the opportunity to present their chemistry on the front cover. We invite our authors to submit suggestions for this coveted position.

Authors invited to submit cover picture



Last year EurJIC provided you with about 400 more pages of high-quality chemistry than in 2000. Publication times have been reduced (t_{50} now 4.6 months from received date to Web publication for the last quarter of 2001), although we are generous with the time we allow authors to include the improvements suggested by the referees, in order to achieve optimum quality. We do not automatically consider a paper that required over six weeks for revision as a new submission. Precedence is an important aspect for EurJIC, so we request the resubmission of a manuscript only if additional experimental work constitutes a significant part of the revision. We also like to provide referees with enough time to assess a manuscript critically and provide the author with stimulating comments. To reduce postal delays, we send PDF files to request a referee report. Nevertheless, you ALWAYS have the option of asking for a hard copy. I appeal to referees not to click away such e-mails. If your workload does not allow a timely assessment of the manuscript, let the office know promptly. Only if all steps in peer review are efficient, can we give authors the fast response that they expect.

Publication Times shortened

New technologies have also shortened publication times. The EarlyView feature of Wiley Inter Science gives you fully citable papers from EurJIC up to five weeks in advance of print. In particular Short Communications form the focus of this service. Thus the accelerated procedure that starts with the submission of an urgent article ends only with particularly rapid electronic publication.

And finally I would like to thank all Advisory Board Members and all authors who contacted us with suggestions in 2001. Only such open channels of communication can make EurJIC "Your Journal" for top papers in inorganic, bioinorganic, solid-state, physical inorganic and organometallic chemistry.

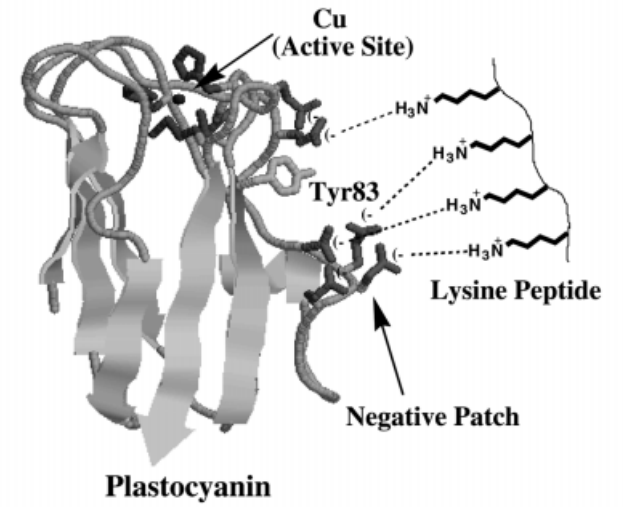
Interactions in Plastocyanin–Lysine Peptide and Related Systems



Keywords: Electron transfer / Proteins / Peptides / Structure–activity relationships

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434–1948/02/0101–0007 $ 17.50+.50/0

Interactions in Plastocyanin−Lysine Peptide and Related Systems

Shun Hirota*[a] and Osamu Yamauchi*[b]

Keywords: Electron transfer / Proteins / Peptides / Structural change / Structure−activity relationships

The structure–function relationship of proteins is one of the major topics of protein studies. In spite of the importance of intermolecular interactions between proteins, which could control their functions, there are only a limited number of detailed studies on the protein structural changes induced by interaction with a protein or a peptide, because the associated changes in properties are small. Charged peptides, however, may be useful for studying the molecular recognition character of proteins and their interaction-induced structural changes, since they do not have any visible absorption. The active site Cu of plastocyanin (PC) exhibited a longer Cu–S(Cys) bond length and a higher redox potential on binding of a lysine peptide, suggesting that lysine peptides induce a structural change in PC to adapt the copper site for facile electron transfer. Structural changes were also observed for cytochrome (cyt) *f*, cyt *c*, and cytochrome *c* peroxidase on interaction with charged peptides.

1. Introduction

Structure−function relationship is one of the major topics in protein studies. In cells, each protein has to recognize its partner effectively, and thus the molecular recognition of proteins has been studied extensively. Intermolecular interactions between proteins and the induced structural changes, which may control their functions, are also important to understand the structure−function relationship of proteins. However, there are only a limited number of detailed studies on the structural changes induced by molecular interactions, because of the lack of a useful method.

Shun Hirota was born in Port Jefferson, New York, in 1965. He obtained his Master's degree from Kyoto University in 1992. He received his Ph.D. degree in 1995 from the Graduate University for Advanced Studies under the supervision of Professor Teizo Kitagawa at the Institute for Molecular Science, Okazaki, Japan. He was a JSPS Research Fellow from 1994 to 1996 and joined Professor Luigi G. Marzilli's research group in the Chemistry Department, Emory University, Atlanta, Georgia, USA in 1995. Since 1996, he has been an assistant professor in the Department of Chemistry, Graduate School of Science, Nagoya University. He has been working in the field of bioinorganic chemistry, and his research interests include structure−function relationship and reaction mechanisms of metalloproteins.

Osamu Yamauchi was born in Nagoya in 1936. He received his Master's degree from Kyoto University in 1961. After spending two years at a pharmaceutical company as research staff member, he resumed his graduate studies at Kyoto University, receiving his Doctor's degree in pharmaceutical sciences in 1967. He was appointed Associate Professor at Osaka University in 1967 and Professor at Kanazawa University in 1980. In 1987 he was appointed Professor at the Department of Chemistry, Nagoya University. He retired from Nagoya University in 2000 and is now Professor at Kansai University and Professor Emeritus of Nagoya University. His research interests include weak interactions involving metal-coordinated amino acids and metalloproteins, self-organization of complex molecules, reactivity of aromatic rings in the vicinity of the metal center, metal-pterin chemistry, and other areas of bioinorganic chemistry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Electron-transfer proteins are indispensable for life. Many of them are charged on their surface and/or have a specific charged site for a specific protein−protein complex formation, and the electrostatic interaction is one of the main forces that guide them to form such a complex for electron transfer. For example, plastocyanin (PC), a mobile electron-transfer protein existing in the thylakoid lumen of photosynthetic organisms, is negatively charged at neutral pH for higher plant and green algae PCs, whereas PCs from cyanobacteria are characterized by high pI values. Higher plant and green algae PCs contain consecutive acidic residues (negative patch) located at the solvent-accessible site near the tyrosine residue remote from the Cu center.[1,2] PC receives an electron from cytochrome *f* (cyt *f*) of the cytochrome b_6f complex, which is an integral oligomeric membrane protein complex existing in the photosynthetic organism. By X-ray structural studies, a lysine (Lys) residue rich positively charged site (positive patch) has been revealed to exist at the solvent-exposed site of cyt *f*,[3] and the electrostatic interaction between the negative patch of PC and the positive patch of cyt *f* has been inferred to be the force for the formation of the cyt *f*·PC complex.

An NMR spectroscopic study on the Cd-substituted PC·cytochrome *c* (cyt *c*) complex indicated that the PC·cyt *c* complex consists of a highly dynamic ensemble of structures.[4] Theoretical docking models demonstrated three docked complexes between PC and cyt *f* and suggested that the negative patch of PC is not important in the active electron transfer complex, although it is important for the initial binding.[5,6] Kostić et al. proposed that PC and cyt *f* or cyt *c* bind and react with each other in different configurations resulting from the protein−protein interaction termed as the gating process for electron transfer,[7−9] showing possible configurations for the diprotein complex by computer simulation.[10,11] A paramagnetic NMR spectroscopy and restrained rigid-body molecular mechanics study also indicated that the electrostatic interactions guide PC and cyt *f* into a position that is optimal for electron transfer,[12] whereas electron transfer has been shown to occur via His87 to Cu in PC by mapping NMR chemical-shift changes.[13] However, kinetic evidence for multiple binary complexes has been obtained for the protein docking and gated electron-transfer reactions between zinc cyt *c* and a new PC from the fern *Dryopteris crassirhizoma*,[14] which has a very large acidic surface extending into the area that is hydrophobic in other PCs.[15]

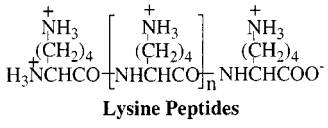
Cyt *c* is a well-known electron-transfer heme protein which is positively charged at neutral pH,[16,17] whereas cytochrome *c* peroxidase (C*c*P), an electron-transfer partner of cyt *c*, is negatively charged at neutral pH.[18] The cyt *c*·C*c*P complex was therefore predicted to be formed by the electrostatic interaction, which has been verified by the X-ray crystal structure analysis of the cyt *c*·C*c*P complex.[19]

Redox-inactive inorganic compounds have been utilized to study the molecular recognition character of electron-transfer proteins. NMR spectroscopic investigations on the complex formation between proteins and Cr^{III} compounds were made,[20,21] and $[Cr(NH_3)_6]^{3+}$ was shown to interact with both the hydrophobic and negative patches of PC,[21] whereas it bound to several sites on the surface of cyt *c*.[20] Sykes et al. showed that small redox-inactive inorganic compounds inhibit electron transfer between PC and cyt *c*,[22] cyt *f*,[23] or inorganic redox partners,[24−26] which has been explained by competitive inhibition due to interaction between the positive charge of the redox-inactive inorganic compound and the negative charge of PC.

2. Plastocyanin−Lysine Peptide Interaction

2.1 Molecular Recognition

Since the electrostatic interaction is essential for complex formation between these electron transfer proteins, we came upon the idea of using charged peptides as models for the protein interacting sites (Figure 1). Positively charged peptides interact with the aspartyl (Asp) and glutamyl (Glu) residues of the negatively charged sites of proteins, whereas negatively charged peptides can interact with the Lys residues of the positively charged sites. Actually, positively charged lysine peptides interacted with the consecutive Asp and Glu residues of the negative patch of PC and competitively inhibited electron transfer from reduced cyt *f* or cyt *c* to oxidized PC (Figure 2).[27] The inhibitory effects of lysine peptides on electron transfer were explained as competitive inhibition due to neutralization of the PC negative patch by formation of PC·lysine peptide complexes (Figure 3). Upon decreasing the net charge of the PC negative patch by mutation, the electron transfer rates from reduced cyt *c* to oxidized PC and the inhibiting effect of lysine peptide decreased. These results strongly indicate that the negative patch of PC is the dominant cyt *c*/*f* recognition site.



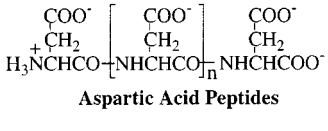


Figure 1. Chemical structures of lysine and aspartic acid peptides

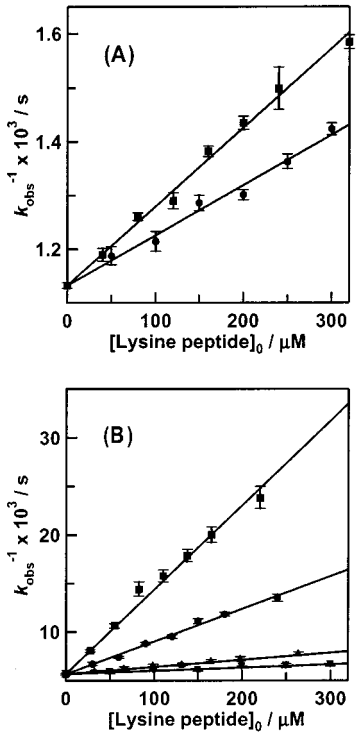

Figure 2. Plots of the reciprocal electron transfer rate constants ($1/k_{obs}$) from reduced cyt *f* or cyt *c* to oxidized PC vs. the initial concentrations of lysine peptides: *di*- (▼), *tri*- (▲), *tetra*- (•), and *penta*-Lys (■); (A) reduced cyt *f*-oxidized PC and (B) reduced cyt *c*-oxidized PC electron-transfer systems; protein concentrations: PC, 5 μM; cyt *f* and cyt *c*, 0.5 μM; Tris-HCl buffers (10 mM), pH = 7.3, containing 10 mM (A) and 60 mM NaCl (B), respectively, were used; modified from refs.[27,54]

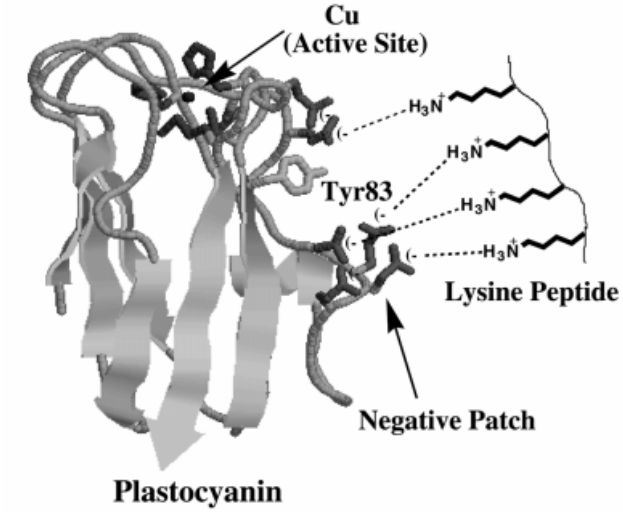

Figure 3. A schematic view of silene PC (PDB 1BYO, ref.[2]) interacting with *tetra*-Lys

The observed inhibition may be interpreted by considering formation of two complexes, a PC·cyt *c*/*f* complex where electron transfer subsequently occurs, and a PC·lysine peptide complex that competitively inhibits formation of the PC·cyt *c*/*f* complex and thus inhibits electron transfer. The complex formations are expressed by Equation (1) and Equation (2), where K_{OS} and K_i are the association constants for PC_{ox}·cyt c/f_{red} and PC_{ox}·lysine peptide complexes, respectively, and k_e represents the electron-transfer rate constant.

$$PC_{ox} + \text{cyt } f/c_{red} \underset{}{\overset{K_{OS}}{\rightleftharpoons}} (PC_{ox}\cdot \text{cyt } f/c_{red})_R \xrightarrow{k_e} (PC_{red}\cdot \text{cyt } f/c_{ox})_R \quad (1)$$

$$PC_{ox} + \text{lysine peptide} \overset{K_i}{\rightleftharpoons} (PC_{ox}\cdot\text{lysine peptide})_R \quad (2)$$

The suffixes ox and red refer to the oxidized and reduced states, and R denotes that the complex is formed at the Cu-remote negative patch of PC. If we write the observed rate constant as k_{obs}, $K_{OS} \times k_e$ as k, and the initial concentrations of PC and lysine peptide as $[PC]_0$ and $[\text{lysine peptide}]_0$, we obtain the relationship

$$\frac{1}{k_{obs}} = \frac{K_i}{k[PC]_0}[\text{lysine peptide}]_0 + \frac{1}{k[PC]_0} \quad (3)$$

Plots of $1/k_{obs}$ against $[\text{lysine peptide}]_0$ give straight lines, substantiating the validity of the assumptions leading to Equation (3). K_i values obtained from least-squares fitting of the data for the cyt *c*−PC electron-transfer system (Figure 2, B) with Equation (3) are listed in Table 1. The association constants for the PC·lysine peptide complexes increase as the length and thus the charge of the peptide increase, which shows that PC effectively recognizes the sites with four or more positive charges. The inhibitory effects demonstrate that these lysine peptides, especially *tetra*- and *penta*-Lys, function as models for the PC interacting site of proteins.

Table 1. Association constants (K_i) for PC−lysine peptide complexes obtained by least-squares fitting of the data in Figure 2 (B) with Equation (3)

Length of lysine peptide	K_i/M^{-1} [a]
di	550±130
tri	1400±200
tetra	5900±300
penta	15300±1000

[a] In 10 mM Tris-HCl buffer, pH = 7.3, containing 10 mM NaCl at 15 °C.

Interactions of lysine peptides with PC were also studied by measuring electron transfer between $[Fe(CN)_6]^{4-}$ and oxidized PC in the presence of the peptides.[28] Lysine peptides up to *penta*-Lys promoted electron transfer from $[Fe(CN)_6]^{4-}$ to PC.[28] The electron transfer promoting effects of lysine peptides may be due to formation of PC·lysine peptide or lysine peptide·$[Fe(CN)_6]^{4-}$ complexes, subsequently forming an electron transferring complex, PC·lysine peptide·$[Fe(CN)_6]^{4-}$, without repulsion of the negative charges.

Table 2. Absorption maximum wavelengths, average ν_{Cu-S} frequencies, EPR parameters, and midpoint redox potentials ($E_{midpoint}$) of wild-type and Tyr83 mutant PCs

Species	Wavelength[a] [nm]	ν_{Cu-S} [b] [cm^{-1}]	EPR parameters $g_{\|\|}$	$\|A_{\|\|}\|$	$E_{midpoint}$[c] [mV]
wild-type	597.5	418.4	2.242	6.2	344
Y83F	597.5	417.9	2.256	5.7	340
Y83S	595.5	420.6	2.239	6.5	325
Y83L	595.5	423.3	2.238	6.5	320
Y83H	598.0	417.0	2.246	6.2	382

[a] Error ±0.5 nm. – [b] Error ±1.0 cm^{-1} for the calculated values. – [c] Versus NHE; measured in 10 mM phosphate buffer, pH = 7.4; error ±5 mV.

2.2 Relationship Between the Spectroscopic and Electrochemical Properties of PC

PC is classified as a type 1 copper protein and contains one copper atom, which is coordinated to two histidine nitrogen atoms, one methionine sulfur atom, and one cysteine sulfur atom in a distorted tetrahedral geometry according to the crystal structures of its oxidized and reduced forms.[1,2,29,30] Oxidized type 1 copper proteins exhibit unique spectroscopic properties, such as a low energy ligand-to-metal charge transfer (LMCT) band near 600 nm in the absorption spectrum and a narrow hyperfine coupling constant ($|A_{||}| < 90{\cdot}10^{-4}$ cm^{-1}) in the electron paramagnetic resonance (EPR) spectrum.[31,32]

Studies on the relationship between the structural and spectroscopic properties of type 1 copper proteins have been reported.[32–42] The general relationship will be discussed along with the properties of wild-type and Tyr83 mutant PCs (Table 2, Figure 4).[43] The spectroscopic and electrochemical properties of the wild-type and Tyr83 mutant PCs were similar but slightly different. In the absorption spectra, an intense band around 600 nm has been assigned to the cysteine thiolate [S(Cys)]-to-Cu^{II} LMCT band (Figure 5).[31,32] Y83H mutant PC which has a longer wavelength peak for this 600-nm band, exhibits an increase and decrease in the intensities of the 460- and 700-nm bands, respectively, compared with the corresponding bands of other PCs.[43] The ratio of the intensity of the 460-nm absorption band to that of the 600-nm band has been found to correlate with the rhombicity of the EPR signal for type 1 copper proteins,[35] and the rhombic distortion has been suggested to be associated with a stronger binding of the axial ligand and a concomitant shift from a trigonal planar toward a tetrahedrally distorted Cu site geometry.[35–37] Actually, wild-type PC which showed a stronger 460-nm absorption band than that of the Y83S or Y83 L proteins, exhibited a more rhombic EPR spectrum with larger $g_{||}$ and smaller $|A_{||}|$ values (Table 2), suggesting a more tetrahedral geometry for the Cu^{II} site.

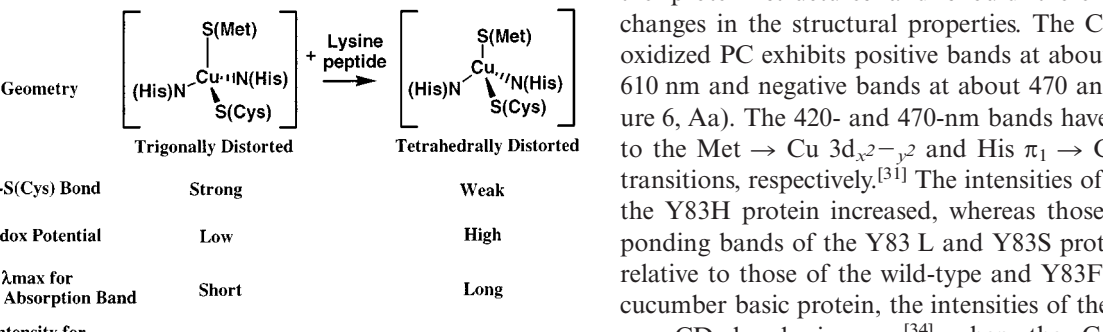

Figure 4. Relationship among the spectroscopic and electrochemical properties and the Cu active site geometry of oxidized PC

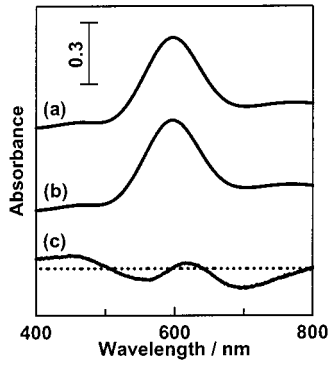

Figure 5. Absorption spectra of oxidized PC with (a) and without *penta*-Lys (b) and their difference spectrum (a – b) multiplied by 20 (c); the baseline of the difference spectrum is shown as a dotted line; concentrations of PC and *penta*-Lys were 100 and 330 μM, respectively; sodium phosphate buffer (10 mM), pH = 7.4, was used; modified from ref.[53]

The circular dichroism (CD) spectra are very sensitive to the protein structures and should therefore reflect the changes in the structural properties. The CD spectrum of oxidized PC exhibits positive bands at about 420, 560, and 610 nm and negative bands at about 470 and 760 nm (Figure 6, Aa). The 420- and 470-nm bands have been assigned to the Met → Cu $3d_{x^2-y^2}$ and His π_1 → Cu $3d_{x^2-y^2}$ CT transitions, respectively.[31] The intensities of these bands of the Y83H protein increased, whereas those of the corresponding bands of the Y83 L and Y83S proteins decreased, relative to those of the wild-type and Y83F proteins.[43] In cucumber basic protein, the intensities of the 420- and 470-nm CD bands increase[34] when the Cu–S(Cys) and Cu–S(Met) bond lengths are extended and shortened by 0.1 and 0.2 Å, respectively,[44] and the Cu–S(Cys) stretching (ν_{Cu-S}) frequency is lower [45] then that in PC.

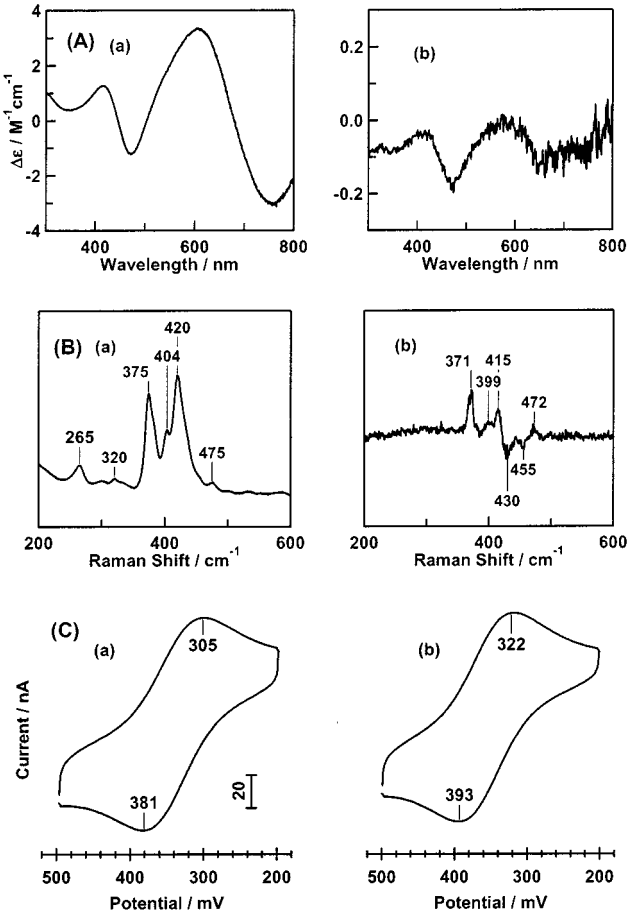

Figure 6. (A) CD spectra of oxidized PC without *tetra*-Lys (a) and the difference CD spectrum obtained by subtracting the CD spectrum from that with *tetra*-Lys (600 μM) (b); (B) RR spectra in the 200−600 cm^{-1} region for oxidized PC without *penta*-Lys (a) and the difference RR spectrum obtained by subtracting the RR spectrum from that with *penta*-Lys (660 μM) (b); (C) cyclic voltammograms of PC without (a) and with *penta*-Lys (260 μM) (b); concentration of PC was 70, 500, and 100 μM for A, B, and C, respectively; sodium phosphate buffer (10 mM), pH = 7.4, was used; modified from refs.[27,43]

Resonance Raman (RR) spectroscopy is a powerful method for investigating the character of the Cu−S(Cys) bond in type 1 copper proteins by exciting the Raman scattering near the S(Cys)-to-Cu^{II} CT band.[40,46−49] The ν_{Cu-S} frequency is shown to be a sensitive probe of the Cu−S(Cys) bond strength and copper coordination geometry for proteins with cysteine thiolate coordination.[39−42] It is closely related to the electron-transfer exothermicity for several type 1 copper proteins.[38] In practice, several bands are observed at 374−475 cm^{-1} for the RR spectrum of oxidized PC excited near its S(Cys)-to-Cu^{II} CT band (Figure 6, Ba), which is mainly due to the mixing of the Cu−S stretch with several angle bendings of the coordinated Cys side chain.[40,46−49] The weighted average frequency based on the S-isotope dependence was shown to correlate with the Cu−S(Cys) distance for azurin, another type 1 copper protein, and its mutants.[39] The average ν_{Cu-S} frequencies of wild-type and Tyr83 mutant PCs were therefore calculated from the intensities and frequencies of three major RR bands, which mainly contain contributions from the ν_{Cu-S} (Table 2).[50] The average ν_{Cu-S} frequency was in the order Y83 L > Y83S > Y83F ≈ wild-type > Y83H, suggesting a stronger Cu−S(Cys) bond in this order. Species exhibiting a more intense 460-nm absorption band exhibits a smaller average ν_{Cu-S}. A similar relationship has also been found by comparison of the properties of type 1 and type 2 cystein-coordinated copper proteins.[40]

As regards the redox potential, Y83F mutant PC exhibited a potential similar to that of wild-type PC, whereas the potentials of Y83S and Y83 L PCs shifted to lower values and the potential of Y83H PC shifted to a higher value relative to that of wild-type PC, where species with a higher ν_{Cu-S} frequency and a stronger Cu−S(Cys) bond exhibited a lower redox potential (Table 2).

The spectroscopic and electrochemical properties of PC may be summarized as follows. Species exhibiting a more intense 460-nm absorption band and a longer wavelength for the 600-nm absorption band show a more tetrahedral geometry for the Cu site, a smaller average ν_{Cu-S} frequency, and a higher redox potential. A weaker Cu−S(Cys) bond would create a weaker ligand field with the Cys ligand, and thus the energy of the S(Cys)-to-Cu^{II} CT band would decrease and the redox potential of Cu would shift to a higher value. In PC, the Cu−S(Met) bond is the longest metal−ligand bond,[1,2] and a stronger Cu−S(Met) axial bond has been suggested to cause a larger displacement of the Cu^{II} from the trigonal plane containing two histidine nitrogen atoms and one cysteine sulfur atom, shifting the active site coordination structure toward a tetrahedral geometry.[35] Comparison between several type 1 copper proteins showed that proteins with a higher energy ligand field associated with rotation of the Cu $d_{x^2-y^2}$ half-filled HOMO exhibit longer Cu−S(Cys) and shorter Cu−S(Met) bonds with a more tetrahedral geometry.[34,35] A weaker Cu−S(Cys) bond would therefore induce a structural change with a shorter Cu−S(Met) bond and a more tetrahedral Cu^{II} geometry, which has been detected by comparison of the Y83H protein with the Y83S and Y83 L proteins (Table 2).

2.3 Active Site Structural Change Induced by Interaction with Lysine Peptide

Redox-induced conformational changes in PC have been studied by infrared spectroscopy, and protonation of (an) Asp or Glu side chain(s) upon PC oxidation, at acidic pH, has been indicated.[51] Recently, Ag- and Cd-substituted PC were used as models for native Cu^{I} and Cu^{II} PCs, respectively, and the metal site structure depending on the charge of the metal ion has been indicated to influence the dissociation between PC and photosystem I.[52] Lysine peptides are very useful for investigating the molecular interaction-induced structural changes of metalloproteins having absorption bands in the visible region, since the peptides do not have any absorptions in the visible region. In this section, we focus on the active site structural changes of oxid-

ized PC by interaction with lysine peptide at its negative patch (Figure 3).

The interaction of PC with lysine peptides was investigated by absorption, CD, and RR spectroscopy, and electrochemical measurements, which revealed changes in the active site Cu coordination geometry upon binding of a lysine peptide at the negative patch.[27,43,53] In the difference absorption spectrum between the spectra with and without *penta*-Lys, peaks and troughs were detected at about 460 and 630 nm and at about 560 and 700 nm, respectively (Figure 5, c). These peaks revealed that the 600-nm absorption band shifts to a longer wavelength and the intensities of the 460- and 700-nm absorption bands increase and decrease, respectively, on interaction with a lysine peptide. As discussed in section 2.2, the intensity increase of the 460-nm absorption band and the shift of the 600-nm absorption band to a longer wavelength can be associated with the lengthening of the Cu−S(Cys) bond and the change from a trigonal planar toward a more tetrahedral Cu site geometry.[35−37] The Cu−S(Cys) bond should therefore be elongated and the Cu site should become more tetrahedral on interaction with the lysine peptide. These structural changes at the Cu site are caused by an electrostatic interaction of the PC negative patch with the lysine peptide, since the intensities of the peaks observed in the difference spectra decreased when NaCl was added to the solution. Moreover, the observed spectral changes decreased when the charges at the negative patch were decreased by site-directed mutagenesis.[27]

The intensities of the peaks and troughs in the difference spectra increased with the concentration of the lysine peptide and became saturated at a certain peptide concentration (Figure 7).[53] The observed intensity changes in the absorption spectra can be interpreted by considering the formation of a 1:1 PC·lysine peptide complex according to Equation (2). If we write the difference between the observed absorption changes at 630 and 560 nm upon lysine peptide binding as ΔΔAbs, the difference between the corresponding absorption coefficient changes as ΔΔε, the concentrations of PC and lysine peptide as [PC] and [lysine peptide], respectively, and the cell length used for the measurements as l, we obtain the relationship of Equation (4).

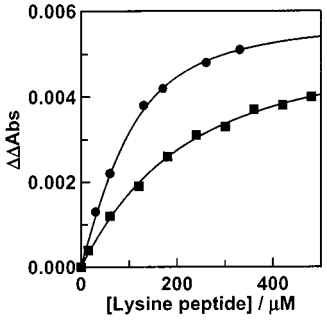

Figure 7. Plots of ΔΔAbs vs. [lysine peptide], together with least-squares fitted lines according to Equation (4); ■ = *tetra*- and • = *penta*-Lys; concentration of PC was 100 μM; modified from ref.[43]

$$\Delta\Delta Abs = \frac{\Delta\Delta\varepsilon \times l}{2}\left\{\left([PC] + [\text{lysine peptide}] + \frac{1}{K_i}\right) - \left[\left([PC] + [\text{lysine peptide}] + \frac{1}{K_i}\right)^2 - 4\,[PC]\,[\text{lysine peptide}]\right]^{1/2}\right\} \quad (4)$$

The K_i values (8000 ± 4000 and 24000 ± 5000 M^{-1} for *tetra*- and *penta*-Lys, respectively) were obtained by least-squares fitting of the experimental data with Equation (4) (Figure 7). Since the fitting was successful, it is reasonable to assume that only one lysine peptide is bound to the negative patch of PC, which is in agreement with the previous conclusion derived from the inhibitory character of lysine peptide on electron transfer from cyt *c* or cyt *f* to PC (see section 2.1).[27,54] The association constants between PC and lysine peptide obtained from the difference absorption spectra were larger than those obtained from electron transfer experiments,[27] which is probably due to NaCl added to the solution to make the electron transfer rate detectable. Absorption spectral studies with various lysine peptides showed that PC interacts effectively only with lysine peptides equal to or longer than *tetra*-Lys, due to the increase in the charges and stronger electrostatic interaction, where a similar conclusion was drawn from the inhibitory effect on electron transfer (see section 2.1). In connection with the absorption change by lysine peptide binding, the association constants between PC and cyt *f* or cyt *c* have been obtained by measuring the increase of the Soret band intensity of cyt *f* or cyt *c* on PC binding.[55−57]

The difference CD spectra of oxidized wild-type and Tyr83 mutant PCs in the presence and absence of *tetra*-Lys are shown in Figure 6, Ab. A positive peak at about 420 nm and a negative peak at about 470 nm were detected in the difference spectra, which demonstrate changes in their CD spectra and thus in the active site structure on interaction with *tetra*-Lys. Since the intensities of the 420- and 470-nm CD bands increase, the Cu−S(Cys) and Cu−S(Met) bond lengths should become longer and shorter, respectively, for PC by interaction with lysine peptides (see section 2.2). When *tetra*-Lys was added to PC, the Raman bands at 375−475 cm^{-1} shifted slightly to lower frequencies with a concomitant slight increase in the intensities of some lower frequency bands in this region, especially the ν_{Cu-S} related 375- and 422-cm^{-1} bands. These results indicate that the Cu−S(Cys) bond was weakened on addition of a lysine peptide. Interestingly, the RR spectral changes of PC were the same for PC−cyt *c* and PC−lysine peptide interactions, indicating that lysine peptides are excellent models for the PC recognition site of proteins. However, ESR spectroscopic measurements on oxidized PC gave no significant change on the Cu^{2+} signal upon addition of lysine peptides.[27,43] The lack of EPR spectroscopic detection of the structural change of PC on addition of lysine peptides could be due to the fact that EPR spectroscopy is more sensitive to the Cu−N bond geometry, while the 375−475-cm^{-1} RR bands are related to the Cu-coordinated Cys residue. In line with this, the 265-cm^{-1} RR band that is as-

signed to the Cu−His stretching mode did not show any change on interaction with lysine peptides.

Electrochemical measurements showed that the redox potential of PC shifted to a higher potential upon lysine peptide binding, which suggests that the structural change induced by binding of lysine peptides to PC adapts the copper site for facile electron transfer (Figure 6, C). This structural change might be related to the report by Kostić et al., who proposed that PC and cyt *c* or cyt *f* bind and react with each other in different configurations resulting from the protein−protein interaction termed as the gating process for electron transfer,[7−9,58] showing possible configurations for the diprotein complex by computer simulation.[10,11]

For the electron transfer from cyt *f* to PC, Tyr83 which is located near the negative patch of PC has been proposed to be involved in the electron transfer pathway, since the reaction rate decreased upon replacement of Tyr with other amino acid residues.[56,57] Ullmann et al. demonstrated by molecular dynamics the possible occurrence of a cation−π interaction at the Tyr83 site, which might be important for electron transfer from cyt *f* to PC.[11] On the other hand, Tyr83 mutants showed minor effects on the interaction between PC and PSI, and electron transfer from PC to $P700^+$ was proposed to occur at the hydrophobic patch.[59−61] Recently, electron transfer from cyt *f* to PC was inferred by NMR spectroscopic measurements to occur via His87 of the hydrophobic patch.[13] Since the structural changes observed for wild-type and Tyr83 mutant PCs by complex formation with lysine peptides were similar,[43] the structural change due to binding of lysine peptides to PC is concluded not to be transmitted through the path of Tyr83−Cys84−copper by a cation−π interaction.

In summary, when wild-type PC interacted with lysine peptide, the intensity of the 460-nm absorption band increased, the maximum wavelength for the 600-nm absorption band became longer, the average ν_{Cu-S} frequency became lower, and the redox potential shifted to a higher value. All these changes may be associated with a slightly more tetrahedral geometry for the Cu site, further supporting the proposal that PC suffers a structural change on interaction with its redox partner, cyt *f*, for facile electron transfer from it.

3. Other Protein−Charged Peptide Interactions

3.1 Interaction of Cyt *f* and Cyt *c* with Aspartic Acid Peptides

Positively charged aspartic acid peptides up to *penta*-Asp (Figure 1) served as competitive inhibitors of electron transfer from cyt *c* or cyt *f* to PC.[54] *Tetra*- and *penta*-Asp also served as competitive inhibitors of electron transfer from $[Fe(CN)_6]^{4-}$ to oxidized cyt *c*.[28] A cyt *c*/*f*·aspartic acid peptide complex is formed by the electrostatic interaction between the aspartic acid peptides and the Lys residues at the surface of cyt *c* or cyt *f*, and the electron-transfer inhibitory effects of aspartic acid peptides are ascribed to formation of the cyt *c*/*f*·aspartic acid peptide complex, similar to that of the PC·lysine peptide complex.

Changes in the absorption spectrum of cyt *c* in the Soret region were detected when aspartic acid peptides, up to *penta*-Asp, were added to the cyt *c* solution (Figure 8, A).[54] These changes were the same as those observed when cyt *c* interacted with PC, indicating that aspartic acid peptides interacted with cyt *c* in the same way as PC. Conformational changes of cyt *c* due to interaction with aspartic acid peptides observed by RR spectroscopy (Figure 8, B) were also similar to those reported for cyt *c* bound to its native partner, cytochrome *c* oxidase,[62] which indicates that aspartic acid peptides interact with cyt *c* in the same way as cytochrome *c* oxidase and serve as good models for the protein interacting sites. Electrochemical measurements showed that the redox potential of cyt *c* and cyt *f* shifts to lower potentials by 7−20 mV upon aspartic acid peptide binding, indicating the enhancement in the electron donor ability of both cyt *c* and cyt *f* upon complex formation with the aspartic acid peptide.[54] The changes in the absorption spectrum and redox potential increased with the length and concentration of the aspartic acid peptides used. The observed structural and redox changes of cyt *c* and cyt *f* are therefore attributed to adduct formations with aspartic acid peptides by electrostatic interactions.

The redox potential of silene PC and *Brassica komatsuna* cyt *f* are 343 and 364 mV, respectively, when no charged

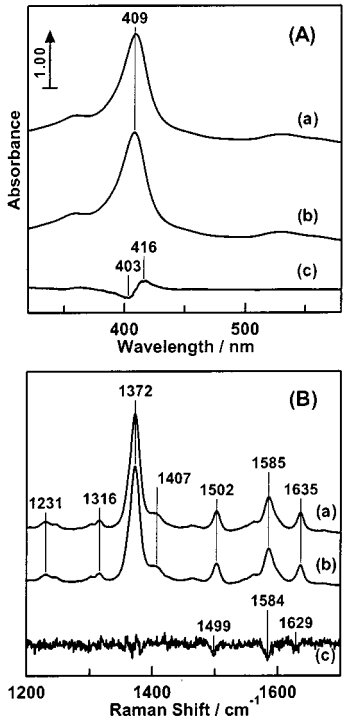

Figure 8. (A) Absorption spectra of oxidized cyt *c* with (a) and without *tetra*-Asp (b) and their difference spectrum (spectrum a − spectrum b) multiplied by 30 (c); (B) resonance Raman spectra in the 1200−1700 cm^{-1} region for cyt *c* with (a) and without *penta*-Asp (b) and their difference spectrum (spectrum a − spectrum b) multiplied by 15 (c); concentration of cyt *c* was 100 and 50 μM for A and B, respectively; Tris-HCl buffer (10 mM), pH = 7.4, was used; modified from ref.[54]

peptides are bound to them,[28,54] and considering their redox potentials, it appears unlikely that efficient electron transfer would occur between these proteins. Our observation that the redox potential of PC shifts to a higher potential and that of cyt *f* to a lower one, upon binding of charged peptides, suggests that redox potential shifts due to complex formation facilitate electron transfer between these proteins of non-physiological interaction and could also facilitate it between their physiological partners.

3.2 Cyt *c*−Cytochrome *c* Peroxidase System

The structural change of oxidized C*c*P due to interaction with lysine peptides was studied by measurements on electron transfer between reduced cyt *c* and C*c*P^{IV}=O (Trp191$^{\cdot+}$) and the absorption spectra in the presence of lysine peptides.[63] Lysine peptides competitively inhibited electron transfer from cyt *c* to C*c*P, which indicated that they interacted with C*c*P at the same site where cyt *c* binds and would be effective models for the C*c*P interacting site of cyt *c*.

Peaks were observed in the difference absorption spectrum of C*c*P between the spectra in the presence and absence of lysine peptides, demonstrating a structural perturbation of C*c*P, at least at its heme site, also occurs on interaction with the lysine peptides (Figure 9). This interaction was also proved to be electrostatic, since no significant peak was detected in the difference absorption spectrum measured in the presence of NaCl.

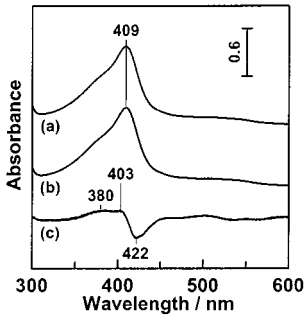

Figure 9. Absorption spectra of oxidized C*c*P with (a) and without *tetra*-Lys (b) and their difference spectrum multiplied by 20 (c); concentrations of C*c*P and *tetra*-Lys were 10 and 100 μM, respectively; Tris-HCl buffer (10 mM), pH = 7.8, was used; modified from ref.[63]

4. Conclusion

We propose that charged peptides are useful for studying the molecular recognition character of proteins and their structural changes induced by the molecular interaction. In particular, charged peptides which are good models of the protein interaction sites could be used for investigating the molecular interaction induced structural changes of metalloproteins which have absorption bands in the visible region, since the peptides have no visible absorption.

Positively charged lysine peptides inhibited electron transfer from reduced cyt *f* or cyt *c* to oxidized PC. Likewise, aspartic acid peptides served as competitive inhibitors of electron transfer from cyt *c* or cyt *f* to PC. They also served as inhibitors of electron transfer from $[Fe(CN)_6]^{4-}$ to oxidized cyt *c*. These inhibitory characters are ascribable to the formation of protein−peptide complexes which inhibit formation of the electron transfer complexes.

Changes in the absorption spectrum which were observed on addition of lysine peptides to the PC solution have been ascribed by RR spectroscopic studies to the change in the active site Cu−Cys geometry upon binding of lysine peptide to the PC negative patch. Similar absorption changes were observed for the PC−cyt *c* interaction, demonstrating that cyt *c* and lysine peptides interact with PC in a similar way. Electrochemical measurements showed that the redox potential of PC shifts to a higher potential upon lysine peptide binding, which suggested that lysine peptides induce a structural change in PC to adapt the copper site for facile electron transfer.

Changes in the absorption spectrum of cyt *c* in the Soret region were also detected when aspartic acid peptides were added to the cyt *c* solution. These changes were similar to those observed when cyt *c* interacted with PC, indicating that PC and aspartic acid peptides interact with cyt *c* in a similar way. Conformational changes of cyt *c* due to interaction with aspartic acid peptides observed in the RR spectra were also similar to those reported for cyt *c* when bound with its native partner, cytochrome *c* oxidase. Electrochemical measurements showed that the redox potential of cyt *c* and cyt *f* shifted to lower potentials upon aspartic acid peptide binding, showing the enhancement in the electron donor ability of both cyt *c* and cyt *f* upon complex formation with the aspartic acid peptide.

Acknowledgments

We are deeply indebted to the co-workers whose names are listed in the papers cited in the references for their contribution and enthusiasm. The support of the research by the Ministry of Education, Culture, Sports, Science and Technology of Japan is gratefully acknowledged.

Protonated Trithiocarbonic Acid − Synthesis, Spectroscopic Characterization and the Crystal Structure of $C(SH)_3^+AsF_6^-$

Rolf Minkwitz,*[a] Frank Neikes,[a] and Ulrike Lohmann[a][†]

Keywords: Carbocations / NMR spectroscopy / Raman spectroscopy / Protonation / Sulfur / Superacidic systems

Protonation of trithiocarbonic acid H_2CS_3 in the superacidic system HF/MF_5 (M = As, Sb) results in the generation and isolation of the extremely water-sensitive salts $C(SX)_3^+MF_6^-$ (M = As, Sb; X = H, D). The slightly yellow salts decompose above 233 K with the formation of $SX_3^+MF_6^-$ and CS_2. These new salts are characterized by vibrational and NMR spectroscopy and $C(SH)_3^+AsF_6^-$ by X-ray diffraction.

Introduction

The NMR spectroscopic evidence that protonated carbonic acid is stable in the superacidic system HSO_3F/SbF_5 below 273 K was found in 1968 by Olah. Based on his extensive ^{13}C NMR investigations he proposed a trihydroxycarbenium ion structure and explained the remarkable thermal stability by comparison with the high resonance stability of protonated guanidine.[1,2] The existence of a symmetrical structure protonated at the carbonyl oxygen atom is supported by theoretical studies.[3−5] The crystal structure of protonated carbonic acid was recently determined by Minkwitz and co-workers [Equation (1)]; the IR spectra of free and sublimable carbonic acid were also reported.[6,7]

$$(Me_3SiO)_2CO + HF/MF_5 \rightarrow 2\ Me_3SiF + C(OH)_3^+MF_6^- \ (M = As, Sb) \quad (1)$$

Formal replacement of the OH groups by SH groups leads to the mono-, di- and trithio-analogues compounds. The evidence for the existence of these species were given by ^1H-NMR studies in the super-acidic system HSO_3F/SbF_5 by Olah.[8] In contrast to the carbonic acid, trithiocarbonic acid can easily be synthesized and isolated from the reaction of barium trithiocarbonate with hydrochloric acid.[9] The physical and spectroscopic data as well as the crystal structures of the reaction products of trithiocarbonic acid with bromine, thiophosgene and chlorosulfane have been reported.[10−14]

In our investigations on protonated carbonic and thiocarbonic acids and their derivatives such as the $(MeO)_2COH^+$, $(MeO)(MeS)CSH^+$ and $(MeS)_2CSH^+$ cations, the determination of the crystal structure of trimercaptocarbenium hexafluoroarsenate was reported.[15−17]

Results and Discussion

Formation of $C(SX)_3^+$ Salts and NMR Spectra

Protonated trithiocarbonic acid is available by the reaction of trithiocarbonic acid with the superacid XF/MF_5 (X = H, D; M = As, Sb) [Equation (2)].

$$H_2CS_3 + HF/MF_5 \rightarrow H_3CS_3^+MF_6^- \quad (2)$$

To avoid the formation of arsenate and antimonate sulfide it is necessary to condense hydrofluoric acid and the Lewis acid alternately in layers. The yellowish, unpleasant smelling and extremely water-sensitive hexafluorometallates decompose, in the case of the arsenate salt, at 208 K and in the case of the antimonate salt at 218 K. The salts are clearly more unstable than the trihydroxycarbenium salts (273 K), and after one day storage under inert conditions at 203 K the decomposition products $SX_3^+MF_6^-$ (X = H, D; M = As, Sb) and CS_2 can be observed spectroscopically [Equation (3)].[1,6]

$$C(SX)_3^+MF_6^- \rightarrow SX_3^+MF_6^- + CS_2 \ (X = H, D; M = As, Sb) \quad (3)$$

This is similar to the decomposition of the trihydroxycarbenium cation as reported by Olah.[1]

The ^1H NMR spectra of freshly prepared $C(SH)_3^+AsF_6^-$ and $C(SH)_3^+SbF_6^-$ dissolved in SO_2 with TMS as external standard at −60 °C show one signal at δ = 8.3 and one at δ = 8.0 for the equivalent mercapto groups. These results are similar to the chemical shifts reported previously by Olah and Minkwitz.[8,15,16] The difference of 0.49 ppm from the reported chemical shift by Olah is explainable by different solvents and temperatures. The ^{13}C NMR signals could not be measured because of poor solubility in SO_2. In solution, the new salts are about 20 K more stable than in the solid state.

Raman Spectra of $C(SX)_3^+MF_6^-$ (M = As, Sb; X = H, D)

The observed Raman frequencies of the $C(SX)_3^+MF_6^-$ (X = H, D; M = As, Sb) are summarized in Table 1. The assignments for the $C(SX)_3^+$ cations were made by comparison with the calculated frequencies of $(CH_3S)_2CS$ and several alkylxanthogenates.[15,16,18−20] The recorded Raman frequencies of protonated, deuterated and free trithiocarbonic acid are also shown in Table 1. The IR spectra could not be measured due to the high reactivity and spontaneous decomposition on the IR window material (Si or CsBr) at 193 K.

Table 1. Raman frequencies and possible assignments of H_2CS_3 and $C(SH)_3^+MF_6^-$ (X = H, D; M = As, Sb)

There are significant differences in the frequency of the SH and CS stretching modes between the spectra of the hexafluroantimonate and hexafluoroarsenate salts. The spectrum of $C(SH)_3^+SbF_6^-$ shows a broad, slightly split line between 2569 and 2396 cm^{-1} similar to the spectra of trithiocarbonic acid, whereas the hexafluoroarsenate spectrum shows a sharp line shifted to higher frequencies by about 70 cm^{-1}. This means that there is a similar association of the molecules due to hydrogen bonds between the antimonate species and the free acid. The sulfur atoms function as both proton and electron donors. The existence of two maximums in the broad SH line can be explained by different SH bonds, similar to the previously reported IR spectra of dialkylphosphinicdithio acids.[21] The annealing of H_2CS_3 and $C(SH)_3^+SbF_6^-$ results in a decreasing width and a shift to higher frequencies of the SH valence mode, as described by Allen and co-workers. The result of these effects is that there are weaker hydrogen bonds in the arsenate species than in the hexafluoroantimonate salts. The observed H/D shift of about 700 cm^{-1} is similar to the expected shift reported by Teller and Redlich.[22]

The second significant difference between the hexafluoroarsenate and -antimonate salts is observed in the C=S valence mode region. The strongest line in the spectra of $X_3CS_3^+SbF_6^-$ (X = H, D) is observed at 1100 cm^{-1} and, analogous to H_2CS_3, is assigned to the C=S stretching mode. However, in the spectra of $X_3CS_3^+AsF_6^-$ (X = H, D) only a very weak line is observed. The measured frequencies and intensities in the region of the C−S stretching mode are similar and independent of the anion. It is doubtful if this difference can be explained by different interactions in the solid state or by different structures in the solid depending on the superacid used. For all substances the characteristic SC=S deformation mode is observed as a very sharp and intense line at 500 cm^{-1}. The vibrational modes of the anions are observed in their typical regions assuming O_h symmetry.

Crystal Structure of $C(SH)_3^+AsF_6^-$

Trimercaptocarbenium hexafluoroarsenate crystallises in the triclinic space group $P\bar{1}$ (no. 2) with six units per cell and the dimensions a = 800.8(2), b = 1154.6(2), c = 1499.7(3) pm, α = 107.74(3)°, β = 99.04(3)° and γ = 104.35(3)° (Table 2).[23] The bond lengths and angles are listed in Table 3. Figure 1 shows the salt with atom labels, and the arrangement of the $C(SH)_3^+AsF_6^-$ in the unit cell is depicted in Figure 2. The antimony and sulfur atoms

were found by the Patterson method. All other atoms were determined by difference Fourier synthesis. A final refinement with anisotropic (except H atoms) thermal parameters gave a value of $R = 0.0328$.

The ideal octahedron structure of the anion is not distorted (O_h symmetry), with almost ideal angles of 90° and lengths of nearly 171 pm, similar to those in known structures.[6,24]

The CS_3 skeleton is surrounded by sulfur atoms in a trigonal planar geometry with angles of about 120° and average bond lengths of 169 pm. The still small differences in the length of the CS bonds imply a non-equal allocation of the positive charge over the sp^2-hybridised CS_3 group. The protons are not located in the CS_3 planes, therefore the symmetry is lowered to C_1 explaining the split SH valence mode in the Raman spectra. This geometry is similar to the structures of the $(CH_3S)_2CSH^+$ and $(CH_3O)(CH_3S)CSH^+$ cations where all cations posses a central sp^2 carbon atom, a delocalised positive charge and terminal groups which are not located in the CX (X = O,S) plane. The three symmetry-independent $C(SH)^+$ cations develop hydrogen bonds with S···F contacts, 10% below the sum of the Van der Waals radii, of about 289.6 pm, 295.4 pm, 305.2 pm and 299 pm.[25]

Experimental Section

All synthetic work and sample handling was performed by employing standard Schlenk techniques and a standard vacuum line (stainless steel or glass). SbF_5 (Merck) was fractionally distilled. Drying of HF and SO_2 were carried out by known literature methods.[26] Reactions in HF/DF were carried out in a KEL-F reactor with a KEL-F valve.[27] Infrared spectra were recorded with a Bruker IFS 113V spectrophotometer. The spectra of dry powders were obtained on a CsI plate in a cooled IR cell.[28] The Raman spectra were recorded with a T64000 (ISA) using a CCD detector (EEV CCD15-11) and an Ar^+ laser tube (514.5 nm) from Spectra Physics. The spectra were recorded in a glass cell cooled with liquid nitrogen. The NMR spectra were recorded with a Bruker DPX 300 spectrometer with TMS as external standard. Single crystals were placed in Lindemann capillaries in a cooled stream of dry nitrogen, and the X-ray diffraction study was carried out at −100 °C using an Enraff Nonius Kappa-CCD Mach3 automated diffractometer with an Oxford Cryosystem cooling unit.

Preparation of $C(SX)_3^+MF_6^-$ (X = H, D; M = As, Sb)

Caution! All contact with these compounds should be avoided as the hydrolysis of AsF_6^- and SbF_6^- salts forms HF, which burns the skin and causes irreparable damage. Safety precautions should be taken when using and handling these materials.

In a typical experiment H_2CS_3 (0.22 g) and anhydrous XF (X = H, D; 4 g) were combined at −196° C in a KEL-F reactor. AsF_5 (0.34 g) or SbF_5 (0.44 g) was then added to this mixture at −196 °C and the contents of the reactor were warmed up to −78 °C. After 10 minutes, the slow removal of all volatile material at −78 °C in vacuum resulted in a slightly yellow solid residue that was identified as $C(SX)_3^+MF_6^-$ (X= H, D; M= As, Sb). The remaining $C(SH)_3^+AsF_6^-$ contained crystals suitable for X-ray diffraction studies. The salts can be stored for one day under inert conditions at −70 °C.

Keywords: Boron / Group 3 metals / Metallocenes / Boratabenzene / Lithium

The syntheses of the new lithium boratabenzenes Li(3,5-$Me_2C_5H_3BNiPr_2$), Li(**3**), and Li_2[(3,5-$Me_2C_5H_3BNMe)_2$-$(CH_2)_2$], Li_2(**5**), via the dicarbanion route are described. Lithium 1-aminoboratabenzenes react with metal trihalides in toluene (110 °C, 3 d) to give the stepped ladder dimers [(3,5-$Me_2C_5H_3BNMe_2)_2Y(\mu$-Cl)$_2$Li]$_2$, (**12**), [(3,5-$Me_2C_5H_3BNMe_2)_2$-$Lu(\mu$-Cl)$_2$Li]$_2$ (**13**), and the mononuclear complexes YCl[3,5-$Me_2C_5H_3BN(SiMe_3)_2]_2$ (**18**), LuCl[3,5-$Me_2C_5H_3BN(SiMe_3)_2]_2$ (**19**), and ScCl(3,5-$Me_2C_5H_3BNiPr_2)_2$ (**20**). When donor solvents such as THF or THP are used, analogous reactions take place at ambient temperature, giving solvates such as (3,5-$Me_2C_5H_3BNMe_2)_2Sm(\mu$-Cl)$_2$Li(THF) (**15**), (3,5-$Me_2C_5H_3BNMe_2)_2Y(\mu$-Cl)$_2$Li(THP) (**16**), (3,5-$Me_2C_5H_3BNi$-$Pr_2)_2Y(\mu$-Cl)$_2$Li(THF)$_2$ (**21**), (3,5-$Me_2C_5H_3BNiPr_2)_2Sm(\mu$-Cl)$_2$Li(THF)$_2$ (**22**), and the ansa complexes [(3,5-$Me_2C_5H_3BNMeCH_2)_2$]Lu(μ-Cl)$_2$Li(THF)$_2$ (**23**) and [(3,5-$Me_2C_5H_3BNMeCH_2)_2$]Lu(μ-Cl)$_2$Li(THP)$_2$ (**24**). The bridge cleavage product Y(acac)(3,5-$Me_2C_5H_3BNMe_2)_2$ (**14**) is obtained from **12** and Na(acac) in toluene at ambient temperature. The complexes **12**, **14**, **16**, **18**·PhMe, **19**·PhMe, **20** (as two polymorphs **α-20** and **β-20**), **21**, and **24** (as the *rac*-stereomer) are characterized by single-crystal structure determinations. In all structures except those of the mononuclear complexes **18** and **19**, the ring-ring rotational positions are close to 180°, cf. e.g. **14**, or to 60°, cf. e.g. **20**; these conformations minimize transannular ligand-ligand repulsions. The internal coordination of a *B*-NMe_2 sidearm, which is unprecedented, is found in the structures of the stepped ladder dimers **12** and **13**, and in the mononuclear complexes **15** and **16**. According to solution NMR spectroscopy, all complexes are dynamic with respect to ring-ring rotation and, in the cases with internal coordination, they are dynamic with respect to the interchange between free and coordinated *B*-NMe_2 sidearms.

Introduction

Boratabenzenes are close relatives of the more familiar cyclopentadienides; this is particularly true of the systematic aspects of their salts and complexes.[2] The boratabenzene chemistry of the scandium group metals is still relatively unexplored, despite an early communication in this field.[2b] We have described the first bis(boratabenzene)scandium chlorides, which were synthesized from $ScCl_3$ and lithium boratabenzenes.[2b,3] Bazan et al. demonstrated that Fu's borabenzene trimethylphosphane adduct $C_5H_5BPMe_3$ [4] reacts with $Sc(THF)_2Ph_3$ to give (1-phenylboratabenzene)scandium complexes.[5] More recently we reported on the synthesis and structural chemistry of the dinuclear (1-methylboratabenzene)yttrium complex [Y(μ-Cl)(3,5-$Me_2C_5H_3BMe)_2]_2$.[6]

Closely related works involve compounds of magnesium in group 2,[7] and a very large variety of complexes of group 4 metals, mainly of zirconium.[4a,5,8] It was decided to study these compounds as they are novel, and because they are thought to mimic catalyst systems of modern Ziegler−Natta olefin polymerization processes that are derived from CpZr and CpTi complexes. Some of the catalyst systems so obtained are rather similar to those derived from $ZrCl_2Cp_2$,[8m] and others display considerably modified properties,[5,8f−8l] thus widening the range of the potential applications of these complexes. A similar parallel between cyclopentadienyl and boratabenzene complexes may be expected for catalysts of the scandium group metals,[9] providing a further incentive to explore the chemistry of boratabenzene complexes of the Sc group metals.

The goal of the present paper is to report on the syntheses and structures of Sc, Y, Sm, and Lu bis(boratabenzene) complexes that bear a *B*-amino group. It will be seen that the presence of a *B*-amino group provides a remarkably rich structural chemistry to this class of complexes.

Results and Discussion

Lithium Boratabenzenes

Lithium boratabenzenes are the most common source of boratabenzene ligands. Their properties are greatly influenced by the *B*-bonded substituents. *B*-(dialkylamino)boratabenzenes differ from boratabenzenes with innocent substituents at boron such as Li(C_5H_5BPh),[10] Li(C_5H_5BMe),[11a] Li(C_5H_5BtBu),[11a] and Li(C_5H_5BH).[4a]

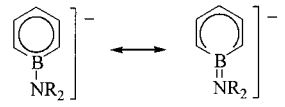
The dialkylamino group strongly perturbs the aromatic π-electron system of the boratabenzene ring. This was first demonstrated for the parent compound $Li(C_5H_5BNMe_2)$, Li(**1**),[11] and was later brought into a wider perspective.[12] Furthermore, and as will be detailed below, the amino functionality may also act as a Lewis base towards the Li^+ ions.



1$^-$

We prefer the more easily accessible 3,5-dimethyl derivatives and use $Li(3,5\text{-}Me_2C_5H_3BNMe_2)$, Li(**2**),[3] the diisopropylamino compound $Li(3,5\text{-}Me_2C_5H_3BN\textit{i}Pr_2)$, Li(**3**), the bis(trimethylsilyl)amino compound $Li[3,5\text{-}Me_2C_5H_3BN(SiMe_3)_2]$,[3] Li(**4**), and the bifunctional boratabenzene $Li_2[(3,5\text{-}Me_2C_5H_3BNMeCH_2)_2]$, Li_2(**5**).

3$^-$: R = *i* Pr

4$^-$: R = $SiMe_3$

5^{2-}

The syntheses of these ligand systems were based on what we call the dicarbanion route.[13] Double potassiation of 2,4-dimethylpenta-1,3-diene (and double bond isomers) gave the dipotassio derivative $K_2[CH_2CMeCHC(CH_2)_2]$ (**6**), which on treatment with BCl_2NMe_2 afforded the 1,2,3,6-tetrahydroborinine (**7a**). After distillation, **7a** is partially isomerized to the dihydroborinine isomers (**8a**) and (**9a**). Treatment with strong bases such as LDA or $LiN(SiMe_3)_2$ resulted in double bond migration and deprotonation to give the boratabenzene as the TMEDA solvate Li(TMEDA)(**2**),[13] or as the donor-free salt Li(**2**).[3] This synthesis is readily reproduced with much better yields than originally published. The new salt Li(**3**) and its TMEDA solvate were obtained analogously. Attempted preparation of Li(**4**) by this method resulted in a low yield (22%) of the ring closure product **7c**, and the subsequent deprotonation by $LiN(SiMe_3)_2$ failed altogether.[14]

As an alternative, the substituent at boron may be modified. This has previously been described for the compounds of the series **a**,[3] and for our pinene-fused boratabenzenes.[15] Three steps are required: i) isomerization of **7a** with HCl to give the less sensitive isomers **8a/9a**; ii) treatment of the mixture **8a/9a** with BCl_3 to produce the chloro compounds **8d/9d**; iii) introduction of the desired new substituent, i.e. in the present case the $N(SiMe_3)_2$ group was introduced by the reaction of the chloro compounds **8d/9d** with a mixture of the secondary amine $NH(SiMe_3)_2$ and NEt_3, to give **8c/9c**, which was then metalated in the usual way.[3]

In a straightforward adaptation of this procedure the chloro compounds **8d/9d** were treated with $(CH_2NHMe)_2$/NEt_3 (1:1) to produce a mixture of ethylene-linked bis(aminodihydroborinines) **10**. Subsequent metalation with $LiN(SiMe_3)_2$ gave the new salt Li_2(**5**) in a high yield. The closely related bis(boratabenzene) $Li_2[(C_5H_5BNMeCH_2)_2]$ has recently been synthesized in a similar manner.[8a]

Complexes: General Comments

The most common cyclopentadienyl complexes of the scandium group metals are the bis(cyclopentadienyl)metal halides.[9] The smaller central metals usually form dinuclear complexes, such as $[Sc(\mu\text{-}Cl)Cp_2]_2$,[16a] and $Yb[(\mu\text{-}Cl)(C_5H_4Me)_2]_2$,[16b] and the larger central metals have a tendency to form higher aggregates. If the Cp ligand is sterically demanding as in the case of the pentamethylcyclopentadienyl ligand Cp*, mononuclear complexes such as $ScClCp^*_2$[17] are favored, despite their coordinative unsaturation. Larger central metals allow the formation of oligomers. For example, $(YClCp^*)_2$ displays a half-bridged dimeric structure $Cp^*_2YCl(\mu\text{-}Cl)YCp^*_2$,[18a] and the corresponding Sm complex is a cyclotrimer $[Sm(\mu\text{-}Cl)Cp^*_2]_3$.[18b] Thus, a subtle interplay of electronic requirements, steric hindrance, and presumably of the (often ignored) lattice energy of the crystal (cf. ref.[6]) determines the structural type observed for a particular compound.

At the outset of this work we decided to study simple metathetical reactions of scandium group metal trihalides with lithium boratabenzenes in a 1:2 ratio. In the related cyclopentadienyl chemistry, refluxing benzene has occasionally been used as the reaction medium[19] to prevent the formation of solvates that is common when the reactions are carried out in THF. In NMR spectroscopic tube experiments we found that higher reaction temperatures were required; heating the suspension of the reactants in toluene at 110 °C for 3 days gave satisfactory results in most cases. In the case of $SmCl_3$/Li(**2**), ill-defined reactions took place above 40 °C; thus THF was used. Other reactions were also carried out in ethereal solvents. Table 1 gives an overview of all products, isolated and characterized; of these, the complexes **11** and **17** have been described in previous work.[3]

Metallocenoids with 1-(Dimethylamino)-3,5-dimethylboratabenzene Ligands

In our earlier work, we obtained the Sc complex **11** from the reaction of $ScCl_3$ with Li(**2**) (ratio 1:2) in toluene. The crystal of complex **11** displays a unique N−B−C η^3-coordination of one boratabenzene ring and a normal, facially bonded second boratabenzene ligand. In solution, the structure is dynamic with effective D_{2h} symmetry.[3] The analogous reactions of the trihalides YCl_3 and $LuCl_3$ with Li(**2**) in toluene produced the dinuclear bis(boratabenzene) complexes **12** and **13** as pale yellow platelets, which, surprisingly, contained two equivalents of loosely bound LiCl. The attempted recrystallization from hot toluene resulted in the very slow separation of solid LiCl. Treatment of complex **12** with sodium acetylacetonate [≡ Na(acac)] gave the bridge cleavage product **14**, which crystallized from toluene as large yellow blocks.

The structure of this mononuclear complex **14** (Figure 1) is discussed in some detail. The overall structure is that of a bent sandwich with a bending angle of 136.1°, and with the acac ligand in the pseudoequatorial plane. The two boratabenzene rings are roughly planar with the boron atom bending away from the metal by 6.3° in the first ring [C11..C15,B1], and by 12.2° in the second ring [C21..C25,B2]. The Y−(C_5B) distance is 2.319 Å for the first ring and 2.355 Å for the second ring. The Y atom is shifted towards the γ ring carbon atoms, the slip distortions[21] are 0.078 Å for the first ring and 0.129 Å for the second ring.

Several details of the structure reflect the importance of intramolecular repulsive ligand-ligand interactions. The two ligands adopt an antiperiplanar conformation. Thus, the rings are eclipsed and the three ring substituents of one ring are staggered with respect to those of the other ring. This motif is found in all structures of this paper, except those of the mononuclear complexes **18** and **19** (see below). The larger folding angle, metal-to-ligand distance, and slip distortion for the second ring relative to the first ring is caused by the transannular repulsion exerted by C13 and the 3,5-methyl groups with C16 and C17. The acac ligand is almost perfectly planar, but bent along the line O1,O2 away from the nearby NMe_2 group of the first ligand; the distance of the Y atom from the acac plane is 0.33 Å. The average B−N distance of 1.403 Å is close to that of typical aminoboranes [1.41 Å].[22] This observation indicates considerable B−N π-interactions which increase with the increasing charge of the central metal and increasing transfer of electron density from the boratabenzene rings to the metal.[7] In benzene, the structure of **14** possesses an effective C_{2v} symmetry, according to NMR spectroscopy, indicating a low barrier to the ring-ring rotation and also to an inversion of the Y(acac) ring in solution.

The nature of the LiCl coordination in **12** and **13** could be clarified by a structure determination of complex **12.** This compound is an approximately centrosymmetric stepped ladder dimer (Figure 2). The new motif of this structure is the internal coordination of a *B*-NMe_2 sidearm of a bent sandwich unit, to a Li^+ of a second bent sandwich, resulting in a central $[YCl_2Li]_2$ unit with a distorted tetrahedral coordination sphere around the Li^+ ions.

Selected bond lengths [Å] and bond angles [°]:Y−O1 2.205(5), Y−C1n 2.667(7) for C13 to 2.731(7) for C11, Y−B1 2.847(8), B1−N1 1.394(10), Y−O2 2.200(5), Y−C2n 2.694(7) for C23 to 2.755(7) for C21, Y−B2 2.941(8), B2−N2 1.411(10), O1−Y−O2 79.25(18).

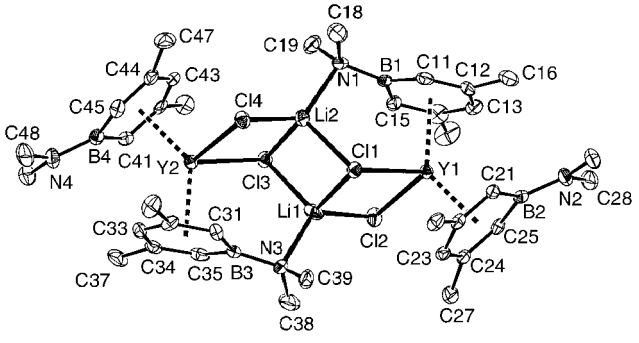

Figure 2. Molecular structure (PLATON plot, see ref.[20], at the 30% probability level) of **12** in the crystal. Selected bond lengths [A]:Y1−Cl1 2.645(2), Y1−Cl2 2.627(2), Y2−Cl3 2.667(2), Y2−Cl4 2.622(2), Li1−Cl1 2.451(13), Li1−Cl2 2.326(12), Li1−Cl3 2.300(15), Li1−N3 2.093(13), Li2−Cl1 2.345(14), Li2−Cl3 2.400(14), Li2−Cl4 2.336(14), Li2−N1 2.081(14), B1−N1 1.472(10), B2−N2 1.449(9), B3−N3 1.475(10), B4−N4 1.447(9).

The coordination of the *B*-dialkylamino group to a metal center has previously been observed in the chiral (*S*)-2-(methoxymethyl)pyrrolidine derivative Li(3,5-$Mo_2C_5H_3B$-SMP),[1b] in the Mg compound $Mg(THF)_2(3,5\text{-}Me_2C_5H_3BNMe_2)_2$,[7] and in the Sc complex **11**.[3] In all these complexes, the relevant B−N bonds are lengthened because of the polarization exerted by the positive metal center. The same is true for **14**, where the distances B1−N1 and B3−N3 [1.474 Å (av.)] with coordinated N centers are longer than the distances B2−N2 and B4−N4 [1.448 Å (av.)] with free N centers. The Li−N bond lengths [2.087 Å (av.)] and may be compared with those in $[LiCH_2CH_2CH_2NMe_2]_4$ [2.068 Å (av.)].[23] It may be speculated that complex **11** has a different structural type because of the smaller ionic radius of Sc^{3+},[24] suggesting that increased ligand-ligand repulsions disfavor structures with two facially bonded boratabenzene ligands.

The attempted preparation of an analogous, solvent-free Sm complex gave an intractable brown material. The alternative use of THF as the solvent readily gave the Sm complex **15** as large purple crystals that still contained coordinated LiCl and one equivalent of THF. Unfortunately, the quality of these crystals was not satisfactory for single crystal structure analysis. In the related cyclopentadienyl chemistry, complexes of the type $Cp''_2Ln(\mu\text{-}Cl)_2Li(OR_2)_2$ with tetrahedrally coordinated lithium, e.g. $(Me_3SiC_5H_4)_2Y(\mu\text{-}Cl)_2Li(THF)_2$ [25a] and $Cp^*_2Yb(\mu\text{-}Cl)_2Li(OEt_2)_2$,[25b] are common. Therefore, we guessed that the structure of **15** was similar, but with an extra solvate molecule due to the compensating internal coordination of the NMe_2 group. We then prepared the analogous Y complex **16** with a coordinated THP, in the same way as complex **15** using THP as the solvent. Complex **16** can also be prepared by simply dissolving the stepped ladder complex **12** in THP and subsequent crystallization. The pale yellow crystals of complex **16** displays the expected mononuclear structure, with an internally coordinated NMe_2 sidearm to yttrium (Figure 3). The coordination of the two ring ligands to the metal shows marked differences. The first ring [C11..C15,B1] with the coordinated sidearm is planar [largest deviation 0.029 Å at C11], with a small slip distortion of 0.066 Å and a long B1−N1 bond length [1.466(8) Å], while the second ring [C21..C25,B2] shows the usual folding along the line C21,C25 with a folding angle of 13(1)°, a large slip distortion of 0.163 Å and a short B2−N2 bond length [1.429(8) Å]. The central YCl_2Li ring is folded by 51.7(3)° bringing the Li^+ center into the vicinity of N1, however, the resulting bond Li−N1 [2.189(11) Å] remains relatively long.

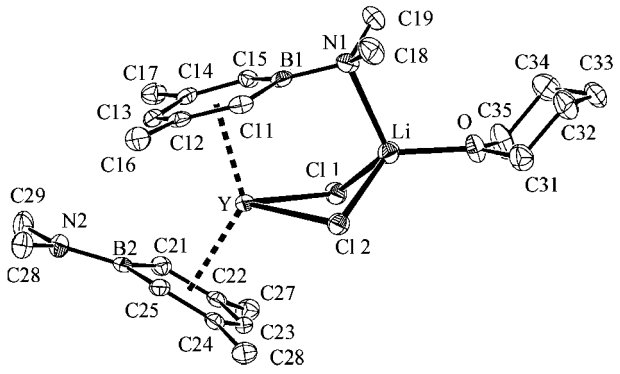

Figure 3. Molecular structure (PLATON plot, see ref.[20], at the 30% probability level) of **16** in the crystal. Selected bond lengths [Å] and bond angles [°]:Y−Cl1 2.6337(17), Y−Cl2 2.6338(17), Y−C1n 2.680(5) for C13 to 2.754(5) for C15, Y−B1 2.832(7), B1−N1 1.466(8), Y−C2n 2.664(5) for C23 to 2.739(5) for C21, Y−B2 2.939(6), B2−N2 1.429(8), Li−Cl1 2.400(10), Li−Cl2 2.371(10), Li−O 1.883(10), Li−N1 2.189(11), Cl1−Y−Cl2 82.00(5), Li−Cl1−Y 80.9(2), Li−Cl2−Y 81.5(2), Cl1−Li−Cl2 92.8(4), angle sum for $BNMe_2$ at N1 344.9° and at N2 360.0°.

Metallocenoids with Bulky *B*-(Amino) Substituents

Sterically demanding *N*-substituents were introduced with the aim to prevent the *B*-NMe_2 sidearm from coordinating to the metal centers. Reactions of the bis(trimethylsilyl)amino derivative Li(**4**) in toluene provided the Sc complex **17**,[3] and the Y and Lu complexes **18** and **19** as mononuclear complexes. The new complexes **18** and **19** crystallize from toluene as yellow rods which contain one equivalent of toluene. The molecular structure of **18** (Figure 4) (in the toluene/containing cocrystal) is essentially the same as that of **17**,[3] a two bladed propeller with crystallographic C_2 symmetry and a relatively short Y−Cl bond coinciding with the two fold symmetry axis. The toluene/containing cocrystal of the Lu complex **19** is isomorphous to that of **18**; for selected data see legend of Figure 4. The bending angles are 138.6° for **18** and 140.5° for **19**, and are close to the value of 140.8° observed for the Sc compound

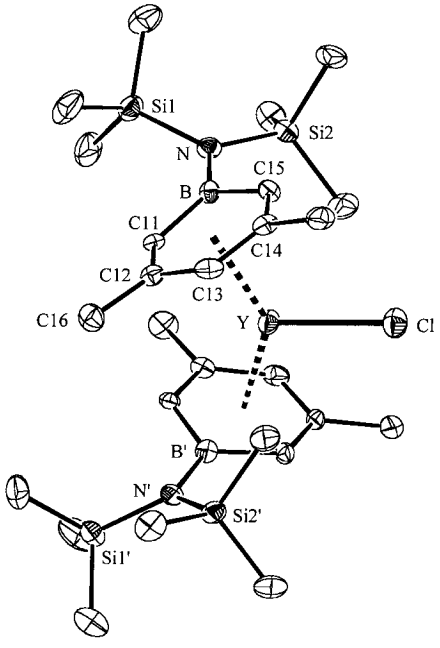

Figure 4. Molecular structure (PLATON plot, see ref.[20], at the 30% probability level) of **18** in the toluene/containing cocrystal and data for **18** and **19**. Selected bond lengths [Å] for **18**: Y−Cl 2.522(2), Y−C1n 2.667(7) for C12 to 2.738(6) for C11, Y−B 2.882(7), B−N 1.493(8), C11−B 1.497(8). C15−B 1.522(9). Selected bond lengths [Å] for **19**: Lu−Cl 2.475(3), Lu−C1n 2.605(9) for C13 to 2.683(8) for C11, Lu−B 2.853(9), B−N 1.464(11), C11−B 1.525(12). C15−B 1.531(11).

17.[3] As discussed recently, the B−N bond length in 1-(dimethylamino)boratabenzene complexes strongly depends on the polarizing influence of the central metal (i.e. primarily on the formal charge of the central metal).[7] The B−N bond lengths in ligand **4** are always relatively long [1.493(8) for **18**, 1.46(1) for **19**, and 1.471(3) Å for **17**]. This indicates weakened B−N π-interactions due to the polarizing influence of the positive Si centers, and presumably also because of the steric repulsion between the borabenzene ring and the close *Si*−Me groups. The large interplanar angles between the C_5B and NSi_2 planes [41.3° for **18**, and 42.2° for **19**] also suggest a rather soft torsional mode around the B−N bond. The fact that even the Y complex **18** is a monomer suggests that ligand **4** provides a more efficient steric protection than the Cp* ligand.

In the following experiments we reduced the size of the substituent at boron and treated $ScCl_3$ with Li(**3**) in a toluene suspension. Thus, we obtained the Sc complex **20** as red crystals. The crystal structure determination of **20** was complicated due to the existence of two modifications. The data of the high-temperature modification **α-20** (Figure 5a and 5b) were collected at −40 °C. The space group of **α-20** was found to be *C*2/*c*; the molecule of **20** possesses crystallographic C_2 symmetry (as in **17**−**19**), but an unusual anisotropic displacement parameter for the Cl atom (perpendicular to the Sc−Cl vector and mainly in the pseudoequatorial plane). This indicates some disorder. This disorder could be due to a large-amplitude vibration for the Sc−Cl bending, or could be a positional disorder of the chlorine atom.

As the temperature is reduced, a reversible phase transition and the formation of twinned crystals of the low-temperature modification **β-20** are observed. The data were collected at −73 °C. The crystal symmetry is now $P\bar{1}$, and the molecular symmetry is reduced to C_1 (Figure 6). The solved structure is less accurate for the low-temperature modification because of the twinning problem. The resulting molecular structure is closely related to those of **18** and **19**.

Attempts to prepare a Y complex analogous to **20** using toluene as the solvent were unsuccessful, only oily materials were obtained. When THF was used as the solvent, complex **21** was readily isolated as yellow crystals, and analogous Sm complex **22** was obtained as purple crystals. The crystals of **21** were of suitable quality to allow a structure determination. The molecular structure of **21** (Figure 7) is related to that of **16**. Since internal coordination of the B−N*i*Pr$_2$ group is now unfavorable because of the larger size of the dialkylamino group, a second donor molecule is added to the coordination sphere of Li instead, and the central Y(μ-Cl)$_2$Li core is planar.

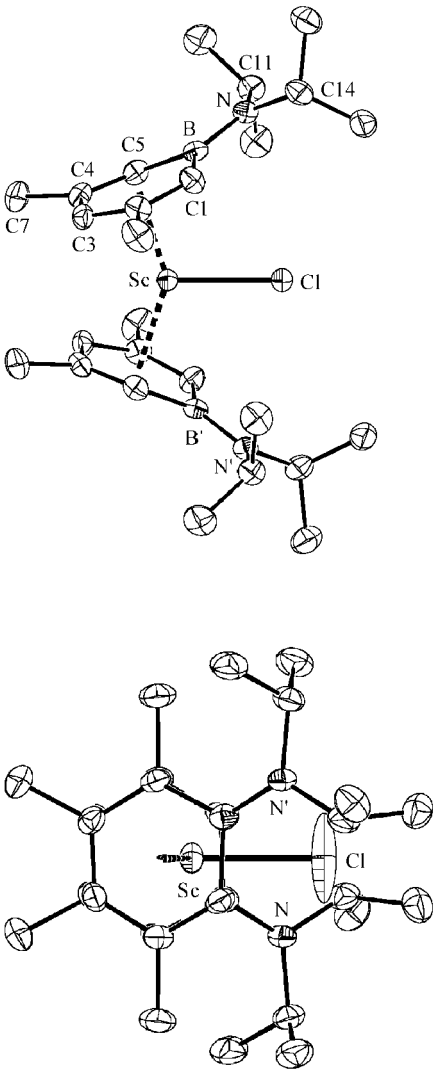

Figure 5. Left: Side-view of the molecular structure (PLATON plot, see ref.[20], at the 30% probability level) of **α-20** in the crystal. Right: Top-view showing the unusual displacement ellipsoid of the Cl atom in the high temperature α-modification. Selected bond lengths [Å] for **α-20**: Sc−Cl 2.377(2), Sc−Cn 2.463(3) for C3 to 2.571(3) for C1, Sc−B 2.756(3), B−N 1.412(4), C1−B 1.542(4). C5−B 1.539(4).

A *B*,*B*′-Bridged ansa Complex

Finally, we treated $LuCl_3$ with the bis(boratabenzene) salt Li_2(**5**) in THF and obtained the complex (**5**)Lu(μ-Cl)$_2$Li(THF)$_2$ (**23**). Crystallization from toluene gave large yellow rods, which according to NMR spectroscopy contained half an equivalent of toluene. The crystals readily lost toluene on standing, thus precluding the characterization by elemental analysis and also the determination of the crystal structure. A completely analogous preparation in THP as the solvent gave the solvate (**5**)Lu(μ-Cl)$_2$Li(THP)$_2$ (**24**), this time without the incorporation of toluene. The crystal structure determination proves the presence of an ansa-bridge that contains two nitrogen stereocenters in an approximate C_2-symmetry (Figure 8). In other words, we find the exclusive formation of the racemic form. We also note that the steric constraints of the ansa-bridge do not permit a perfectly eclipsed arrangement of the two boratabenzene rings. The compounds **23** and **24** are the first examples of group 3 ansa complexes with boratabenzene ligands. In group 4 a number of ansa complexes have been synthesized,[8a,8f,8g] and Ashe III et al. have

shown that the exclusive formation of a related *rac*-stereomer is the result of thermodynamic control.[8a]

Conclusions

In this paper we have extended our earlier work on bis(boratabenzene)scandium complexes and have developed a chapter on the systematic synthetic and structural chemistry of 1-aminoboratabenzene complexes of scandium group metals. The ability of the *B*-dimethylamino group to coordinate to Li^+ centers gives rise to unusual structures such as the stepped ladder structures of **12** and **13**, and to the mononuclear complexes **15** and **16**. With larger substituents at boron this ability is suppressed. Both the 1-di-

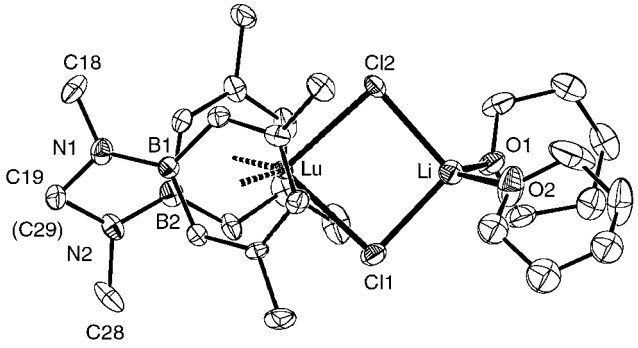

Figure 8. Top-view of the molecular structure (PLATON plot, see ref.[20], at the 30% probability level) of **24** in the crystal. Selected bond lengths [Å] and bond angles [°]:Lu−Cl1 2.579(3), Lu−Cl2 2.583(3), Lu−C1n 2.673(8) for C12 to 2.709(11) for C14, Lu−B1 2.873(12), B1−N1 1.440(15), Lu−C2n 2.671(9) for C23 to 2.702(11) for C21 and C25, Lu−B2 2.857(12), B2−N2 1.424(15), Li−Cl1 2.34(2), Li−Cl2 2.41(2), Li−O1 1.91(2), Li−O2 1.88(3), Cl1−Y−Cl2 85.4(1), Cl1−Li−Cl2 95.0(7), Lu−Cl1−Li 90.6(5), Lu−Cl2−Li 88.7(5), O1−Li−O2 112.5(11), Cl1−Li−O1 111.9(11), Cl1−Li−O2 110.1(9), Cl2−Li−O1 111.9(9), Cl2−Li−O2 114.2(11). The dihedral angle N1−C19−C29−N2 is 73.0(9)°.

isopropylamino ligand **3** and the 1-bis(trimethylsilyl)amino ligand **4** stabilize the coordinatively highly unsaturated mononuclear complexes **17**−**20**, and both these ligands seem to be more effective in this respect than the pentamethylcyclopentadienyl ligand Cp^*. We have also prepared the first group 3 ansa-bridged complexes **23** and **24**.

In most structures a strong preference for the eclipsed ring-ring conformations with 60° and 180° torsional angles is seen, which is enforced by transannular repulsions between the ring substituents in the 1,3,5-positions. In solution, all molecules are dynamic and display the highest possible effective symmetries in their NMR spectra.

Finally, we note that we still do not have boratabenzene complexes of the larger central metals, such as the early lanthanides, the divalent lanthanides, as well as of Th and U. Furthermore, the reaction chemistry of the bonds in the mouth of the bent sandwich molecules remains essentially untouched. We hope that this paper will stimulate other chemists to pursue these open aspects in the future.

Experimental Section

General: All manipulations were carried out under an inert atmosphere of nitrogen by means of standard Schlenk techniques. Hexane was distilled from Na/K alloy and toluene from sodium; Et_2O, THF, and THP were distilled from sodium benzophenone ketyl. Anhydrous lanthanide trichlorides were purchased from commercial sources and used as received. Elemental analyses were performed by Analytische Laboratorien, D-51779 Lindlar, Germany.

NMR spectra were recorded on a Varian Unity 500 (^{1}H, 499.6 MHz. ^{13}C, 125.6 MHz; ^{11}B, 160.3 MHz; ^{7}Li, 194.2 MHz) at ambient temperature. Chemical shifts are given in ppm; they are relative to internal TMS for ^{1}H and ^{13}C, to external $BF{\cdot}OEt_2$ for ^{11}B, and to external $LiBr/D_2O$ for ^{7}Li. Electron-impact mass spectra were recorded on a Finnigan MAT-95 at a nominal electron energy of 70 eV.

1-(Diisopropylamino)-5-methyl-3-methylene-1,2,3,6-tetrahydroborinine (7b): A solution of LiBu in hexane (1.6 M, 281 mL, 0.45 mol) was added to a suspension of KOBu*t* (50.5 g, 0.45 mol) in hexane at 0 °C. After the mixture was stirred at room temperature for 3 h, 2,4-dimethylpenta-1,3-diene[26] (21.6 g, 0.225 mol) in hexane (100 mL) was added and the reaction system was heated under reflux for 20 h. A precipitate of the dipotassio- compound was filtered off and washed thoroughly with hot hexane (3 × 500 mL). The solid was then suspended in hexane (250 mL) and was slowly added to a solution of BCl_2NiPr_2 [27] (40.3 g, 0.222 mol) in hexane/THF (4:1, 560 mL) at 0 °C. The mixture was stirred overnight and a white precipitate of KCl was removed by filtration. After removal of all volatiles, **7b** was collected by condensation (80 °C, 10^{-2} mbar) as a colorless liquid (30.3 g, containing 90% **7b**, 0.133 mol, 60%). On standing at room temperature overnight, **7b** solidified to form large needles, which afforded a spectroscopically pure sample of **7b**.

Data for 7b: ^{1}H NMR (500 MHz, $CDCl_3$): δ = 1.55 (br. s, 2 H, 6-H), 1.81 (s, 5-Me), 2.07 (br. s, 2 H, 2-H), 4.63 (m, 1 H, CH_2=), 4.66 (m, 1 H, CH_2=), 6.01 (m, 4-H), N*i*Pr$_2$: 1.12 (d, *J* = 7.0 Hz, 2 Me), 1.23 (d, *J* = 7.0 Hz, 2 Me), 3.54 (m, NCH), 3.73 (m, NCH). $^{13}C\{^1H\}$ NMR (126 MHz, $CDCl_3$): δ = 24.0 and 27.3 (C-2,6), 26.6 (5-Me), 107.9 (CH_2=), 126.6 (C-4), 139.9 (C-5), 146.8 (C-3), N*i*Pr$_2$: 22.5 (Me), 24.0 (Me), 45.7 (NCH), 48.0 (NCH). ^{11}B NMR (160 MHz, $CDCl_3$): δ = 44.6. MS (70 eV): *m*/*z* (%) = 206 (87) [M^+ + H], 190 (100) [M^+ − Me], 105 (10) [M^+ − N*i*Pr$_2$], 100 (12) [N*i*Pr$_2^+$]. $C_{13}H_{24}BN$ (205.2): calcd. C 76.11, H 11.79, N 6.83; found C 76.28, H 11.99, N 7.56.

1-[Bis(trimethylsilyl)amino]-5-methyl-3-methylene-1,2,3,6-tetrahydroborinine (7c): A crop of the dipotassio- compound, prepared from KOBu*t* (42.1 g, 0.37 mol), LiBu (1.6 M in hexane, 238 mL, 0.38 mol), and 2,4-dimethylpenta-1,3-diene (17.3 g, 0.18 mol), was suspended in hexane (250 mL). The suspension was added to a solution of $BCl_2N(SiMe_3)_2$ [28] (42.1 g, 0.17 mol) in hexane/THF (4:1, 450 mL) at 0 °C. Workup as described for **7b** gave, after condensation (140 °C, 10^{-2} mbar), a colorless liquid of **7c** together with some impurities (12.1 g, containing ca. 82% **7c**, 0.037 mol, 22%).

Data for 7c: ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.25 (s, 2 $SiMe_3$), 1.82 (s, 5-Me), 1.65 (br. s, 2 H, 6-H), 2.06 (br. s, 2 H, 2-H), 4.60 (m, 1 H, CH_2=), 4.70 (m, 1 H, CH_2=), 6.00 (m, 4-H) − $^{13}C\{^1H\}$ NMR (126 MHz, $CDCl_3$): δ = 4.4 ($SiMe_3$), 26.6 (5-Me), 30.7 and 33.8 (C-2,6), 108.7 (CH_2=), 126.9 (C-4), 138.7 (C-5), 146.2 (C-3). ^{11}B NMR (160 MHz, $CDCl_3$): δ = 57.9. MS (70 eV): *m*/*z* (%) = 265 (47) [M^+], 250 (100) [M^+ − Me], 146 (40) [$Si_2Me_6^+$], 73 (79) [$SiMe_3^+$].

Lithium 1-(Diisopropylamino)-3,5-dimethylboratabenzene [Li(3)]: A solution of $LiN(SiMe_3)_2$ in hexane (1.0 M, 20 mL, 20 mmol) was added dropwise to a solution of 1-(diisopropylamino)-5-methyl-3-methylene-1,2,3,6-tetrahydroborinine (**7b**) (4.10 g, 20 mmol) in ether (35 mL) at −78 °C. The mixture was kept at this temperature for 2 h, and was then allowed to warm to ambient temperature. A fine white precipitate gradually formed in the reaction system. After the suspension was stirred for 7 days, the solid was collected by filtration through a frit, washed with hexane (3 ′ 20 mL), and dried overnight under high vacuum to give Li(**3**) as an air- and moisture-sensitive, white powder (3.21 g, 76%).

Data for Li(3): ^{1}H NMR (500 MHz, [D_8]THF): δ = 2.03 (s, 6 H, 3-/5-Me), 5.15 (s, 4-H), 5.30 (s, 2-/6-H), N*i*Pr$_2$: 1.15 (d, *J* = 7.0 Hz, 4 Me), 3.66 (sept, *J* = 7.0 Hz, 2 NCH). $^{13}C\{^1H\}$ NMR (126 MHz, [D_8]THF): δ = 26.0 (3-/5-Me), 100.2 (C-4), 110.9 (br, C-2,6), 142.3 (C-3,5), N*i*Pr$_2$: 23.2 (Me), 46.1 (NCH). ^{11}B NMR (160 MHz, [D_8]THF): δ = 30.5.

TMEDA Solvate Li(TMEDA)(3): The lithium salt Li(**3**) (0.59 g, 2.80 mmol) was added to a solution of TMEDA (0.32 g, 2.80 mmol) in hexane (30 mL). The solution was filtered through a frit to remove some insoluble material and kept at −30 °C overnight to give Li(TMEDA)(**3**) (0.80 g, 87%) as moisture- and air-sensitive colorless rods.

Data for Li(TMEDA)(3): ^{1}H NMR (500 MHz, C_6D_6): δ = 2.34 (s, 3-/5-Me), 5.53 (s, 4-H), 5.81 (s, 2-/6-H), N*i*Pr$_2$: 1.46 (d, *J* = 6.7 Hz, 4 Me), 3.93 (sept, *J* = 6.7 Hz, 2 NCH), TMEDA: 1.45 (s, 2 NCH_2), 1.73 (s, 2 NMe_2). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 26.5 (3-/5-Me), 100.4 (C-4), 110.9 (br, C-2,6), 142.4 (C-3,5), N*i*Pr$_2$: 23.4 (Me), 46.2 (NCH), TMEDA: 45.1 (NMe_2), 55.8 (NCH_2). ^{11}B NMR (160 MHz, C_6D_6): δ = 31.4. $C_{19}H_{39}BLiN_3$ (327.3): calcd. C 69.73, H 12.01, N 12.84; found C 69.73, H 11.86, N 13.03.

1,1′-(*N*,*N*′-Dimethylethylenediamino)bis(3,5-dimethyldihydroborinines) 10: A mixture of *N*,*N*′-dimethylethylenediamine (0.99 g, 11.2 mmol) and triethylamine (2.28 g, 22.5 mmol) was added dropwise to a solution of 1-chloro-3,5-dimethyldihydroborinines[3] (3.15 g, 22.4 mmol) in hexane (25 mL) at 0 °C. The reaction mixture was stirred at ambient temperature for 6 h. A white precipitate, presumed to be $NHEt_3Cl$, was removed by filtration and washed with hexane (3 × 20 mL). The combined filtrate was evaporated to dryness under vacuum to give a pale yellow solid of **10** (2.19 g, 66%) as a mixture of isomers.

Lithium 1,1′-(*N*,*N*′-Dimethylethylenediamino)bis(3,5-dimethylboratabenzene) [Li_2(5)]: A solution of $LiN(SiMe_3)_2$ in hexane (1.0 M, 14.2 mL, 14.2 mmol) was added dropwise to a solution of the dihydroborinines **10** (2.10 g, 7.09 mmol) in ether (10 mL) at −78 °C. The mixture was allowed to warm to ambient temperature and a white precipitate formed. After the suspension was stirred for 1 day, the solid was collected by filtration through a frit, washed with hexane (3 ′ 10 mL), and dried overnight under high vacuum to give Li_2(**5**) as an extremely air- and moisture- sensitive white powder (1.90 g, 87%).

Data for Li_2(5): ^{1}H NMR (500 MHz, [D_6]DMSO): δ = 1.93 (s, 3-/3′-/5-/5′-Me), 2.66 (s, 2 NMe), 2.90 (s, 2 NCH_2), 4.89 (s, 4-/4′-H), 4.94 (s, 2-/2′-/6-/6′-H). $^{13}C\{^1H\}$ NMR (126 MHz, [D_6]DMSO): δ = 26.5 (3-/3′-/5-/5′-Me), 37.9 (NMe), 50.7 (NCH_2), 102.7 (C-4,4′), 108.7 (br, C-2,2′,6,6′), 139.4 (C-3,3′,5,5′). ^{11}B NMR (160 MHz, [D_6]DMSO): δ = 32.4.

Complex [(3,5-$Me_2C_5H_3BNMe_2$)$_2$Y(μ-Cl)$_2$Li]$_2$ (12): A suspension of YCl_3 (2.52 g, 12.9 mmol) and Li(3,5-$Me_2C_5H_3BNMe_2$) [Li(**2**)] (4.13 g, 26.6 mmol) in toluene (60 mL) was stirred at 110 °C for 3 days. An insoluble material, presumed to be LiCl, was filtered off and washed with toluene (20 mL). The combined yellow filtrate was concentrated to ca. 10 mL and kept at room temperature overnight to give **12** as air- and moisture-sensitive, pale yellow platelets. Crystallization of the concentrated mother liquor afforded a second crop of **12** (total: 3.44 g, 64%).

Data for 12: ^{1}H NMR (500 MHz, C_6D_6): δ = 2.24 (s, 3-/5-Me), 2.79 (s, NMe_2), 5.76 (s, 2-/6-H), 5.85 (s, 4-H). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 26.9 (3-/5-Me), 40.1 (NMe_2), 107.9 (C-4), 115.5 (br, C-2,6), 153.7 (C-3,5). ^{11}B NMR (160 MHz, C_6D_6): δ = 37.3. ^{7}Li NMR (194 MHz, C_6D_6): δ = 0.22. $C_{36}H_{60}B_4Cl_4Li_2N_4Y_2$ (925.7): calcd. C 46.71, H 6.53, N 6.05; found C 47.41, H 6.61, N 6.27.

Complex [(3,5-$Me_2C_5H_3BNMe_2$)$_2$Lu(μ-Cl)$_2$Li]$_2$ (13): Treatment of $LuCl_3$ (465 mg, 1.65 mmol) with Li(3,5-$Me_2C_5H_3BNMe_2$) [Li(**2**)] (531 mg, 3.42 mmol), as described for **12,** produced **13**. After crystallization from toluene (ca. 5 mL) at ambient temperature, air- and

moisture-sensitive, pale yellow platelets were obtained (770 mg, 85%).

Data for 13: ^{1}H NMR (500 MHz, C_6D_6): δ = 2.29 (s, 3-/5-Me), 2.77 (s, NMe_2), 5.67 (s, 2-/6-H), 5.85 (s, 4-H). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 27.0 (3-/5-Me), 40.0 (NMe_2), 107.2 (C-4), 113.8 (br, C-2,6), 153.6 (C-3,5). ^{11}B NMR (160 MHz, C_6D_6): δ = 37.0. ^{7}Li NMR (194 MHz, C_6D_6): δ = 0.19. $C_{36}H_{60}B_4Cl_4Li_2Lu_2N_4$ (1097.8): calcd. C 39.39, H 5.51, N 5.10; found C 39.62, H 5.55, N 5.28.

Complex Y(acac)(3,5-$Me_2C_5H_3BNMe_2$)$_2$ (14): Sodium acetylacetonate[29] (114 mg, 0.94 mmol) was added to a yellow solution of [(3,5-$Me_2C_5H_3BNMe_2$)$_2$YCl(LiCl)]$_2$ (**12**) (423 mg, 0.46 mmol) in toluene (15 mL). The reaction mixture was stirred at ambient temperature overnight. An insoluble material, presumed to be a mixture of LiCl and NaCl, was removed by filtration and washed with toluene (5 mL). The combined filtrate was concentrated to ca. 5 mL under vacuum. Large yellow crystals of **14** formed after the liquid was stored at −30 °C for 2 days. Crystallization of the concentrated mother liquor afforded a second crop of **14** (total: 282 mg, 64%), as air- and water-sensitive crystals.

Data for 14: ^{1}H NMR (500 MHz, C_6D_6): δ = 2.05 (s, 2 3-/5-Me), 2.92 (s, 2 NMe_2), 5.52 (t, *J* = 1.8 Hz, 2 4-H), 5.67 (d, *J* = 1.8 Hz, 2 2-/6-H), acac: 1.67 (s, 2 Me), 5.15 (s, CH). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 25.8 (3-/5-Me), 39.1 (NMe_2), 105.1 (C-4), 112.3 (br, C-2,6), 152.0 (C-3,5), acac: 27.2 (C-1,5), 102.2 (C-3), 191.1 (C-2,4). ^{11}B NMR (160 MHz, C_6D_6): δ = 33.4. MS (70 eV): *m*/*z* (%) = 484 (8) [M^+], 385 (<1) [M^+ − acac], 336 (37) [M^+ − $Me_2C_5H_3BNMe_2$], 149 (100) [$Me_2C_5H_3BNMe_2^+$], 134 (28) [149$^+$ − Me]. $C_{23}H_{37}B_2N_2O_2Y$ (485.1): calcd. C 57.07, H 7.70, N 5.79; found C 56.69, H 8.08, N 5.78.

Complex (3,5-$Me_2C_5H_3BNMe_2$)$_2$Sm(μ-Cl)$_2$Li(THF) (15): $SmCl_3$ (277 mg, 1.08 mmol) was added, with stirring, to a solution of Li(3,5-$Me_2C_5H_3BNMe_2$) [Li(**2**)] (343 mg, 2.21 mmol) in THF (20 mL). The reaction mixture was stirred at ambient temperature for 8 h to give a purple solution. The THF was evaporated under reduced pressure, and toluene (10 mL) was then added to the residue. The resulting mixture was stirred vigorously for 1 h. An insoluble material was removed by filtration and washed with toluene (5 mL). The combined filtrate was concentrated to ca. 5 mL and stored at 4 °C to give **15** as moisture-sensitive, purple crystals (397 mg, 62%).

Data for 15: ^{1}H NMR (500 MHz, C_6D_6): δ = 0.61 (br. s, 12 H, 3-/5-Me), 3.68 (br. s, 2 NMe_2), 6.50 (br. s, 2 2-/6-H), 15.84 (br. s, 2 4-H), THF: 1.64 (br, CH_2CH_2), 4.28 (br, 2 OCH_2). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 27.1 (3-/5-Me), 41.0 (NMe_2), 99.3 (br, C-4), 103.8 (br, C-2,6), 159.2 (C-3,5), THF: 25.6 (CH_2CH_2), 69.4 (OCH_2). ^{11}B NMR (160 MHz): δ = 46.2. ^{7}Li NMR (194 MHz, C_6D_6): δ = 6.51. $C_{22}H_{38}B_2Cl_2LiN_2OSm$ (596.4): calcd. C 44.30, H 6.42; found C 44.20, H 6.05.

Complex (3,5-$Me_2C_5H_3BNMe_2$)$_2$Y(μ-Cl)$_2$Li(THP) (16). − Method 1: Treatment of YCl_3 (239 mg, 1.23 mmol) with Li(3,5-$Me_2C_5H_3BNMe_2$) [Li(**2**)] (384 mg, 2.48 mmol) in THP (20 mL), as described for **15**, gave **16**. After crystallization from toluene (ca. 5 mL) at ambient temperature, air- and moisture-sensitive, pale yellow crystals were obtained (371 mg, 55%). **Method 2:** Crystallization of [(3,5-$Me_2C_5H_3BNMe_2$)$_2$YCl(LiCl)]$_2$ (**12**) (565 mg, 0.61 mmol) from THP (8 mL) at ambient temperature gave **16** as pale yellow crystals (556 mg, 83%).

Data for 16: ^{1}H NMR (500 MHz, C_6D_6): δ = 2.31 (s, 2 3-/5-Me), 2.81 (s, 2 NMe_2), 5.86 (s, 2 2-/6-H), 6.06 (s, 2 4-H), THP: 1.08 (br, 2 H, $OCH_2CH_2CH_2$), 1.18 (br, 4 H, OCH_2CH_2), 3.42 (t, 4 H, OCH_2). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 26.7 (3-/5-Me), 39.5 (NMe_2), 108.5 (C-4), 117.1 (br, C-2,6), 151.6 (C-3,5), THP: 22.8 ($OCH_2CH_2CH_2$), 26.0 (OCH_2CH_2), 69.5 (OCH_2). ^{11}B NMR (160 MHz, C_6D_6): δ = 34.9. ^{7}Li NMR (194 MHz, C_6D_6): δ = −0.20. $C_{18}H_{30}B_2Cl_2LiN_2Y(C_5H_{10}O)_{0.8}$ (531.7): calcd. C 49.69, H 7.20, N 5.27; found C 49.73, H 7.15, N 5.31.

Complex YCl[3,5-$Me_2C_5H_3BN(SiMe_3)_2$]$_2$ (18): Treatment of YCl_3 (218 mg, 1.12 mmol) with Li[3,5-$Me_2C_5H_3BN(SiMe_3)_2$] [Li(**4**)] (613 mg, 2.26 mmol) in toluene (15 mL), as described for **12**, gave **18**·(PhMe). After crystallization at −30 °C, air- and moisture-sensitive, yellow crystals were obtained (571 mg, 78%), which seem to easily lose part of the cocrystallized toluene.

Data for 18: ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.19 [s, $N(SiMe_3)_2$], 2.36 (s, 3-/5-Me), 5.82 (br, 4-H), 6.06 (d, *J* = 1.2 Hz, 2-/6-H). $^{13}C\{^1H\}$ NMR (126 MHz, CD_2Cl_2): δ = 4.4 ($SiMe_3$), 27.1 (3-/5-Me), 112.1 (C-4), 129.3 (br, C-2,6), 154.1 (C-3,5). $^{11}B\{^1H\}$ NMR (160 MHz, CD_2Cl_2): δ = 39.2. $C_{26}H_{54}B_2ClN_2Si_4Y(C_7H_8)_{0.5}$ (699.1): calcd. C 50.68, H 8.36, N 4.01; found C 50.30, H 8.11, N 3.81.

Complex LuCl[3,5-$Me_2C_5H_3BN(SiMe_3)_2$]$_2$ (19): Treatment of $LuCl_3$ (364 mg, 1.29 mmol) with Li[3,5-$Me_2C_5H_3BN(SiMe_3)_2$] [Li(**4**)] (729 mg, 2.69 mmol) in toluene (20 mL), as described for **12**, afforded **19**·(PhMe). After crystallization at −30 °C, air- and moisture-sensitive, yellow rods were obtained (686 mg, 72%), which seem to easily lose part of the cocrystallized toluene.

Data for 19: ^{1}H NMR (500 MHz, C_6D_6): δ = 0.37 [s, $N(SiMe_3)_2$], 2.33 (s, 3-/5-Me), 5.52 (br, 4-H), 6.19 (br, 2-/6-H). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 4.6 ($SiMe_3$), 27.1 (3-/5-Me), 108.6 (C-4), 110.4 (br, C-2,6), 157.0 (C-3,5). ^{11}B NMR (160 MHz, C_6D_6): δ = 38.9. $C_{26}H_{54}B_2ClLuN_2Si_4$ $(C_7H_8)_{0.5}$ (785.2): calcd. C 45.13, H 7.45, N 3.57; found C 44.87, H 7.30, N 3.76.

Complex ScCl(3,5-$Me_2C_5H_3BNiPr_2$)$_2$ (20): Treatment of $ScCl_3$ (192 mg, 1.27 mmol) with Li(3,5-$Me_2C_5H_3BNiPr_2$) [Li(**3**)] (543 mg, 2.57 mmol) in toluene (20 mL), as described for **12,** afforded **20**. After crystallization at −30 °C, air- and moisture-sensitive, red crystals were obtained (391 mg, 63%).

Data for 20: ^{1}H NMR (500 MHz, $C_6D_5CD_3$): δ = 1.95 (s, 3-/5-Me), 5.56 (br. s, 2-/6-H), 5.61 (t, *J* = 1.7 Hz, 4-H), N*i*Pr_2: 1.26 (br, 4 Me), 3.78 (br, 2 NCH). $^{13}C\{^1H\}$ NMR (126 MHz, $C_6D_5CD_3$): δ = 26.5 (3-/5-Me), 109.1 (C-4), 117.7 (br, C-2,6), 152.4 (C-3,5), N*i*Pr_2: 23.2 (Me), 46.5 (NCH). ^{11}B NMR (160 MHz, $C_6D_5CD_3$): δ = 34.7. MS (70 eV): *m*/*z* (%) = 488 (3) [M^+], 473 (4) [M^+ − Me], 453 (<1) [M^+ − Cl], 284 (3) [M^+ − $Me_2C_5H_3BNiPr_2$], 205 (25) [$C_{13}H_{24}BN^+$], 190 (100) [$C_{13}H_{24}BN^+$ − Me]. $C_{26}H_{46}B_2ClN_2Sc$ (488.7): calcd. C 63.90, H 9.49, N 5.73; found C 63.65, H 9.66, N 5.66.

Complex (3,5-$Me_2C_5H_3BNiPr_2$)$_2$Y(μ-Cl)$_2$Li(THF)$_2$ (21): Treatment of YCl_3 (206 mg, 1.05 mmol) with Li(3,5-$Me_2C_5H_3BNiPr_2$) [Li(**3**)] (452 mg, 2.14 mmol) in THF (20 mL), as described for **15**, afforded **21**. After crystallization at −30 °C, air- and moisture-sensitive, yellow rods were obtained (399 mg, 64%).

Data for 21: ^{1}H NMR (500 MHz, C_6D_6): δ = 2.40 (s, 2 3-/5-Me), 5.74 (s, 2 4-H), 5.92 (s, 2 2-/6-H), N*i*Pr_2: 1.43 (d, 8 Me), 3.94 (br, 4 NCH), THF: 1.34 (br, 2 CH_2CH_2), 3.58 (br, 4 OCH_2). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 27.4 (3-/5-Me), 104.5 (C-4), 117.5 (br, C-2,6), 151.7 (C-3,5), N*i*Pr_2: 23.4 (*i*Pr-Me), 46.4 (NCH), THF: 25.4 (CH_2CH_2), 68.4 (OCH_2). ^{11}B NMR (160 MHz, C_6D_6): δ = 34.0. ^{7}Li NMR (194 MHz, C_6D_6): δ = −0.33. $C_{34}H_{62}B_2Cl_2Li$-

N_2O_2Y (719.3): calcd. C 56.78, H 8.69, N 3.90; found C 57.14, H 8.91, N 3.95.

Complex $(3,5\text{-}Me_2C_5H_3BNiPr_2)_2Sm(\mu\text{-}Cl)_2Li(THF)_2$ (22): Treatment of $SmCl_3$ (286 mg, 1.11 mmol) with $Li(3,5\text{-}Me_2C_5H_3BNiPr_2)$ [Li(**3**)] (490 mg, 2.32 mmol) in THF (20 mL), as described for **15**, afforded **22**. After crystallization at 4 °C, air- and moisture-sensitive, purple rods were obtained (428 mg, 65%).

Data for 22: ^{1}H NMR (500 MHz, C_6D_6): δ = 2.35 (br. s, 2 3-/5-Me), 7.06 (br. s, 2 2-/6-H), 12.09 (br. s, 2 4-H), N*i*Pr$_2$: 1.0(br, 8 Me), 3.71 (br. s, 4 NCH), THF: 1.57 (br, 2 CH_2CH_2), 3.89 (br, 4 OCH_2). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 29.1 (3-/5-Me), 96.0 (C-4), 106.6 (br, C-2,6), 159.1 (C-3,5), N*i*Pr$_2$: 22.8 (Me), 46.5 (NCH), THF: 25.6 (CH_2CH_2), 68.72 (OCH_2). ^{11}B NMR (160 MHz, C_6D_6): δ = 37.8. ^{7}Li NMR (194 MHz, C_6D_6): δ = 1.59. $C_{26}H_{46}B_2Cl_2LiN_2Sm(C_4H_8O)_{1.5}$ (744.7): calcd. C 51.61, H 7.85, N 3.76; found C 51.70, H 7.66, N 4.60.

Complex $[(3,5\text{-}Me_2C_5H_3BNMeCH_2)_2]Lu(\mu\text{-}Cl)_2Li(THF)_2$ (23): Treatment of $LuCl_3$ (437 mg, 1.54 mmol) with $Li_2[(3,5\text{-}Me_2C_5H_3BNMeCH_2)_2]$ [Li_2(**5**)] (510 mg, 1.66 mmol) in THF (20 mL), as described for **15**, afforded **23**. After crystallization at ambient temperature, air- and moisture-sensitive, large yellow rods were obtained (689 mg, 65%).

Data for 23: ^{1}H NMR (500 MHz, C_6D_6): δ = 2.45 and 2.48 (s, 2 3-/5-Me), 5.19, 5.78, 6.02 (s, 2H each, 2-/4-/6-H), ansa-bridge: 2.76 and 4.18 (m, 2H each, NCH_2CH_2N), 3.08 (s, 2 NMe), THF: 1.32 (br, 2 CH_2CH_2), 3.52 (br, 4 OCH_2). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 27.3 and 27.8 (3-/5-Me), 107.9 (C-4), 104.8 and 112.6 (br, C-2,6), 150.8 and 155.7 (C-3,5), ansa-bridge: 37.7 (NMe), 50.7 (NCH_2), THF: 25.4 (CH_2CH_2), 68.4 (OCH_2). ^{11}B NMR (160 MHz, C_6D_6): δ = 34.8. ^{7}Li NMR (194 MHz, C_6D_6): δ = −0.43.

Complex $[(3,5\text{-}Me_2C_5H_3BNMeCH_2)_2]Lu(\mu\text{-}Cl)_2Li(THP)_2$ (24): Treatment of $LuCl_3$ (266 mg, 0.95 mmol) with $Li_2[(3,5\text{-}Me_2C_5H_3BNMeCH_2)_2]$ [Li_2(**5**)] (307 mg, 1.00 mmol) in THP (15 mL) afforded large yellow rods of **24** (478 mg, 70%).

Data for 24: ^{1}H NMR (500 MHz, C_6D_6): δ = 2.45 and 2.52 (s, 2 3-/5-Me), 5.20, 5.84, 6.02 (s, 2H each, 2-/4-/6-H), ansa-bridge: 2.75 and 4.18 (m, 2 H each, NCH_2CH_2N), 3.09 (s, 2 NMe), THP: 1.23 (br, 2 $OCH_2CH_2CH_2$), 1.24 (br, 4 OCH_2CH_2), 3.47 (br, 4 OCH_2). $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6): δ = 27.3 and 27.9 (3-/5-Me), 107.9 (C-4), 104.8 and 112.5 (br, C-2,6), 150.8 and 155.9 (C-3,5), ansa-bridge: 37.7 (NMe), 50.7 (NCH_2), THP: 23.1 ($OCH_2CH_2CH_2$), 26.3 (OCH_2CH_2), 69.0 (OCH_2). ^{11}B NMR (160 MHz, C_6D_6): δ = 34.8. ^{7}Li NMR (194 MHz, C_6D_6): δ = −0.62. $C_{28}H_{48}B_2Cl_2LiLuN_2O_2$ (719.1): calcd. C 46.77, H 6.73, N 3.90; found C 46.73, H 6.84, N 4.05.

tion parameters, and convergence results are listed in Tables 2 and 3. Before averaging over symmetry-related reflections, numerical[30] or empirical absorption[31] corrections were applied to the data sets with absorption coefficients (μ) larger than 10 cm^{-1}. Structures were solved by direct methods with the help of the SHELXS-97 program[32] and refined on reflection intensities (F^2) using the SHELXL-97 program.[33] In the final least-squares refinements, all non-hydrogen atoms were assigned anisotropic displacement parameters. In the case of **α-20**, the hydrogen atoms were refined isotropically. For all other structures, hydrogen atoms were included as riding with fixed displacement parameters [C−H = 0.98 Å, $U_{iso}(H) = 1.3\ U_{eq}(C)$].

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-166215 (**12**), CCDC-166216 (**14**), CCDC-166217 (**16**), CCDC-166218 (**18**·PhMe), CCDC-166219 (**19**·PhMe), CCDC-166220 (**α-20**), CCDC-166221 (**β-20**), CCDC-166222 (**21**), and CCDC-166223 (**24**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44 (0)1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank Dr. A. Fischer and Dr. J. Ni for helpful advice regarding the synthesis of Li_2(**5**) and Dr. U. Englert concerning the X-ray structure determinations. This work was generously supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Complexes of the (Tetramethylcyclobutadiene)cobalt Fragment with Boratabenzene Ligands and an Unprecedented Formation of a Borabenzene Complex − Structures of $(C_4Me_4)Co(3,5\text{-}Me_2C_5H_3BSnMe_3)$ with an Sn−B Bond and of the Dinuclear Complex $[(C_4Me_4)Co(3,5\text{-}Me_2C_5H_3B)]_2O$[‡]

Gerhard E. Herberich,*[a] Tushar S. Basu Baul,[a,b] and Ulli Englert[a]

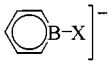
Keywords: Boron / Cobalt / Tin / Borabenzene / Boratabenzene / Cyclobutadiene

The yellow-orange boratabenzene complex Cb*Co(3,5-$Me_2C_5H_3BNMe_2$) (**1**) (Cb* = C_4Me_4) was readily obtained from $[Cb^*Co(NCMe)_3]PF_6$ and Li(TMEDA)(3,5-$Me_2C_5H_3BNMe_2$). Methanolysis of **1** afforded Cb*Co(3,5-$Me_2C_5H_3BOMe$) (**2**). Complex **2** reacted with MeLi and with BCl_3 to give the *B*-methyl analogue **3** and the *B*-chloro compound **4**, respectively. The chloro compound **4** reacted with *i*Bu_2AlH, TlF, and $LiSnMe_3$ to afford the *B*-hydrido derivative **5**, the *B*-fluoro complex **6**, and the *B*-(trimethylstannyl) compound **7**, respectively. A single-crystal structure determination of **7** gave an Sn–B bond length of 2.236(5) Å. The B–O–B-linked dinuclear complex $[(C_4Me_4)Co(3,5\text{-}Me_2C_5H_3B)]_2O$ (**8**) was also characterized structurally. The amino compound **1** underwent an unprecedented quaternization with iodomethane to produce [Cb*Co(3,5-$Me_2C_5H_3BNMe_3$)]I (**10**) which possesses a borabenzene–trimethylamine ligand. Compound **10** is the first borabenzene complex of a metal outside the chromium group. When treated with Bu_4NCN in CH_2Cl_2 nucleophilic substitution of the NMe_3 group took place to give the *B*–CN derivative **11** which is the first *B*-cyanoboratabenzene complex.

Introduction

In the chemistry of borabenzene derivatives[2] it has become customary to distinguish between boratabenzene ions **A** and neutral borabenzene adducts **B**. The area of boratabenzene salts and complexes, especially those of the low-valent d-metals, is well developed. In the most recent years, the first compounds of Mg,[3] of group-3 metals,[1,4] and complexes of the group-4 metals[4b,5] were described. There are also a few studies of p-element compounds.[6] On the other hand, the scope and number of borabenzene adducts is still rather limited,[7] and very few complexes of these have been prepared. Those that have been synthesised are in all cases tricarbonyl compounds of group-6 metals,[7c,8] such as e.g. $Cr(CO)_3(C_5H_5BNC_5H_5)$ and its homologues of Mo and W.[8c]

This paper deals with (boratabenzene)(tetramethylcyclobutadiene)cobalt complexes Cb*Co(C_5H_5BX) (Cb = C_4H_4, cyclobutadiene; Cb* = C_4Me_4). In two previous papers,



A

X = e.g. Me, Ph, NMe_2

B

X = e.g. py, PMe_3, CN*t*Bu

neutral sandwich complexes CbCo(C_5H_5BR) (R = Me,Ph)[9] and Cb*Co(C_5H_5BR) (R = Me, Ph) together with derivatives[10] have been described. In this paper we show that the new metallo-electrophile $[Cb^*Co(NCMe)_3]^+$[11] provides an efficient entry into this class of complexes (with the compounds **1**−**8**) and we present an unprecedented formation of a novel borabenzene complex $\mathbf{9}^+$ in the form of its iodide **10** [≡ (**9**)I] and its transformation into a *B*-cyano compound **11**.

Results and Discussion

Synthesis of Cb*Co(3,5-$Me_2C_5H_3BNMe_2$) (1)

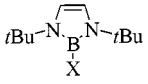
Reaction of the metallo-electrophile [Cb*Co(NCMe)$_3$]PF_6 [11] with the lithium boratabenzene Li(TMEDA)(3,5-$Me_2C_5H_3BNMe_2$)[12] in acetonitrile at ambient temperature resulted in the smooth formation of the sandwich complex **1**, which could be isolated as a yellow-orange crystalline solid in high yield (78%). The complex is highly soluble in most common organic solvents and is markedly sensitive to air and humidity. Because of its ready availability complex **1** has become the starting point for the syntheses described below; Table 1 gives an overview of the reactions involved.

Nucleophilic Substitution at the Boron Atom

Complex **1** can readily be modified by nucleophilic substitution at the boron atom. This is a well-known type of reaction that was observed for the first time in 1971[13] and was later established as a versatile and general synthetic method, e.g. in work with boratabenzene ligands,[14] with 2,5-dihydro-1,2,5-thiadiboroles,[15] with 1,4-diboracyclohexadienes,[16] and with 1*H*-borole ligands.[17]

Methanolysis of **1** takes place in refluxing methanol to give the methoxy compound **2** which is more reactive than **1** and a useful synthetic intermediate. Complex **2** readily reacts with MeLi in ether to afford the 1,3,5-trimethyl compound **3**, and with BCl_3 in dichloromethane solution to produce the *B*-chloro derivative **4**, which, to the best of our knowledge, is the first *B*-chloroboratabenzene complex. Complex **4** can be treated with diisobutylaluminium hydride to give a *B*-hydrido complex **5**. We note in this context, that the first *B*-hydrido complex Fe($C_5H_5BH)_2$ to be described was prepared by a similar nucleophilic substitution reaction.[14] Reaction of **4** with TlF produced the *B*-fluoro complex **6**; the B−F bond in this molecule is seen as a doublet in the $^{11}B\{^1H\}$ NMR spectrum with $^1J(^{19}F-^{11}B) = 55$ Hz. The only previous example of a *B*-fluoroboratabenzene complex is [Ir($PEt_3)_3$(3,5-$Me_2C_5H_3BF$)]($BF_4)_2$ which was obtained from an iridabenzene precursor and BF_3.[18] The nucleophiles used up to this point are of largely different character and the yields obtained are generally quite satisfactory (70−86%).

Treatment of the *B*-chloro complex **4** with $LiSnMe_3$ [19] afforded the anticipated *B*-(trimethylstannyl) derivative **7**, again as yellow-orange crystals. The presence of an Sn−B bond is readily seen in the $^{11}B\{^1H\}$ NMR spectrum of **7**, in the form of tin satellites, and in the $^{119}Sn\{^1H\}$ NMR spectrum, which displays a quadruplet with $^1J(^{119}Sn-^{11}B) = 869$ Hz. This may be compared with the 2,3-dihydro-1*H*-1,3,2-azadiborole **12a** that has an Me_3Sn−B single bond with a trigonal boron atom, and displays $^1J(^{119}Sn-^{11}B) = 1031$ Hz.[20] Alternatively, this may be compared to Li[H_3BSnMe_3] with a tetrahedral boron atom showing $^1J(^{119}Sn-^{11}B) = 554$ Hz.[21] Direct coupling constants qualitatively reflect the amounts of s-orbital contribution to the bonding between the two atoms involved. Thus, the data show that the s-orbital contribution of the boron atom in the Sn−B bond of **7** is only moderately reduced as compared to situations with truly trigonal boron atoms and, on the other hand, confirm that the boron orbital involved in the Co−B bonding largely retains its p-orbital character.



12a: X = $SnMe_3$, **b:** X = CN

Compound **7** is sensitive to air, but not more so than the more sensitive examples **1**, **4**, and **5**. When compound **7** was recrystallized, crystals appeared in the mother liquor that were identified by single-crystal structure determination as the *B*,*B*′-oxo linked dinuclear complex **8**.

Quaternization at the *B*-Amino Group

The *B*-amino group of **1** constitutes a Lewis basic reaction center. Treatment of **1** in THF with iodomethane at ambient temperature resulted in a slow quaternization and formation of the iodide (**9**)I ≡ **10**. This unusual reaction transforms a boratabenzene ligand into a borabenzene−trimethylamine ligand, or in more general terms, a ligand of type **A** into a ligand of type **B**. It also provides access to the first borabenzene complex outside the chromium triad. It is likely that other 1-aminoboratabenzene complexes will display an analogous reactivity, pro-

vided the nucleophilicity of the *B*-amino group is not reduced by strong π-interactions with the boron center or by the presence of sterically hindering *N*-alkyl groups.

A broad range of nucleophilic substitution reactions has been reported for the borabenzene adduct $C_5H_5BPMe_3$;[8b] the corresponding tricarbonylchromium complex $Cr(CO)_3(C_5H_5BPMe_3)$ is much more reactive, at least when treated with $LiC{\equiv}CSiMe_3$.[8b] We found that the NMe_3 group of **10** could readily be substituted on treatment with tetrabutylammonium cyanide in dichloromethane at ambient temperature. The reaction afforded the *B*-cyanoboratabenzene complex **11**, which is the first *B*-cyanoboratabenzene complex to be described.

We are not aware of other sandwich or half-sandwich complexes with a *B*-cyano group as part of a boron ring ligand. The ^{11}B chemical shift of **11** is at remarkably high field, as often observed for compounds with triple-bond systems (CO, CN, and CCR) attached to a boron atom.[22] A comparison of compounds **12a** and **12b** provides a pertinent example with $\delta(^{11}B) = 25.8$ for **12a** and $\delta(^{11}B) = 11.9$ for **12b**.[20] Note that the value for **12a** is in the typical range for this class of compounds,[22] while the value for **12b** is again at unusually high field.

Structure of Cb*Co(3,5-$Me_2C_5H_3BSnMe_3$) (7)

Crystals of **7** that were suitable for single-crystal X-ray work were obtained by slow crystallization from hexane (Figure 1, Table 2). The main aim of this study was the determination of the Sn−B bond length. The structure is described in some detail because of the high quality of the data obtained.

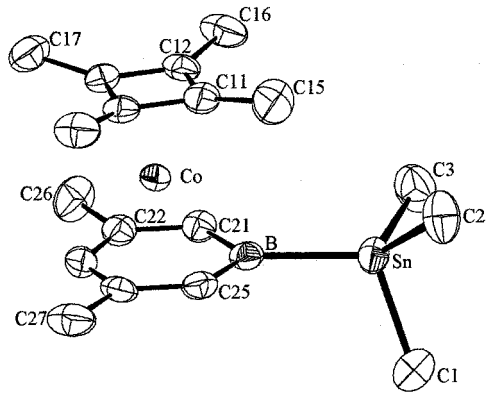


Figure 1. Molecular structure (PLATON plot, see ref.[23] at the 50% probability level) of **7** in the crystal

The molecular structure of **7** is that of a typical sandwich complex, and in its details it is typical of an electron-rich 18e complex. The cyclobutadiene ring is planar and the boratabenzene ring is nearly so [maximum deviation from the best plane 0.023(5) Å at B]. The metal atom is shifted away from the boron atom toward the opposite carbon atom [slip distortion: 0.043 Å] and the boron atom is bent away from the metal atom [folding angle of the boratabenzene ring: 3.5(7)°]. On the other hand, the bonding around the boron atom is strictly trigonal planar (angle sum at boron: 360.0°). Both the slip distortion and the folding angle are comparatively small. The two rings are almost perfectly coplanar [interplanar angle: 1.4(3)°], and the distances of the metal atom to the ring planes amount to 1.7026(6) Å for the Cb* ring and to 1.5622(6) Å for the borabenzene ring.

Table 2. Selected bond lengths [Å] and bond angles [°] of **7**

Co−C11	1.984(5)	Sn−C1	2.158(6)
Co−C12	1.985(4)	Sn−C2	2.150(6)
Co−C13	1.990(4)	Sn−C3	2.148(6)
Co−C14	1.983(4)	Sn−B	2.236(5)
Co−C21	2.122(4)	C21−C22	1.407(6)
Co−C22	2.100(5)	C22−C23	1.415(7)
Co−C23	2.078(5)	C23−C24	1.400(7)
Co−C24	2.122(4)	C24−C25	1.417(7)
Co−C25	2.126(4)	C21−B	1.506(7)
Co−B	2.214(5)	C25−B	1.519(7)
C1−Sn−C2	102.6(3)	C1−Sn−B	109.5(2)
C1−Sn−C3	106.9(3)	C2−Sn−B	121.5(2)
C2−Sn−C3	103.2(3)	C3−Sn−B	111.9(2)
Sn−B−C21	121.4(4)	Sn−B−C25	124.9(3)
C21−B−C25	113.7(4)		

A particularly interesting aspect of the structure is the presence of a $B{-}SnMe_3$ group. The Sn−B distance amounts to 2.236(5) Å and the torsional position of the $SnMe_3$ group is such that one *Sn*−Me substituent adopts a *transoid* position relative to the metal atom. This reduces the transannular repulsion between the remaining two *Sn*−Me substituents and the Cb* counter-ligand. Structurally documented and comparable Sn−B bonds are still rare. The closely related complex Cp*Fe($C_5H_5BSnMe_3$) shows the same Sn−B distance of 2.237(5) Å[24] and the observed Sn−B distance is, for instance, 2.274(5) Å for **12a**,[20] and 2.286 and 2.277(17) Å for (*E*)-$Me_3Sn(iPr_2N)$-BCHCHB($NiPr_2$)$SnMe_3$.[25]

Molecular structure (PLATON plot, see ref.[23] at the 30% probability level) of **8** in the crystal; selected bond lengths [Å] and bond angles [°]: Co−C(Cb*) 1.969 (av.), Co−$C_{1,5}$(C_5B) 2.119 (av.), Co−$C_{2,4}$(C_5B) 2.082 (av.), Co−C_3(C_5B) 2.055 (av.), Co1−B1 2.283(9), Co2−B2 2.267(10), O−B1 1.367(10), O−B2 1.404(11); B1−O−B2 131.1(7), O−B1−C21 118.7(8), O−B1−C25 128.8(8), O−B2−C31 120.5(8), O−B2−C35 126.2(8), C21−B−C25 112.0(8), C31−B−C35 112.5(8)

Structure of [Cb*Co(3,5-$Me_2C_5H_3B$)]$_2$O (8)

Crystals of **8** deposited from the mother liquor of the crystallization of **7** after prolonged standing. Compound **8** had presumably formed from **7** and traces of oxygen. The molecules of **8** (Figure 2) consist of two sandwich units with structural features close to those of **7** and a B−O−B bridge linking the two. The B−O bond lengths and the B−O−B angle are in the expected ranges.[26] The bridging ligand is not planar; the observed twisting of the chain C25,B1,O,B2,C35 reduces the repulsive 1,5-interaction between the carbon atoms C25 and C35.

Conclusion

The recently discovered metallo-electrophile [Cb*Co(NCMe)$_3$]PF_6 could readily be combined with boratabenzene salts such as Li(TMEDA)(3,5-$Me_2C_5H_3BNMe_2$) to produce the *B*−NMe_2 complex **1**. This complex may be used as a starting point for the development of bora- and boratabenzene derivatives with the Cb*Co complex fragment. It readily underwent a quaternization with iodomethane to afford complex **11**, which is the first representative of a new type of borabenzene complexes. Nucleophilic substitution at the boron atom has not often been used previously with complex borabenzene derivatives. In this paper we have made use of this type of reaction to synthesize several compounds with uncommon substituents at the boron atom.

Experimental Section

General: Reactions were carried out under dinitrogen by employing conventional Schlenk techniques. Hexane was distilled from potassium, toluene from sodium, THF and Et_2O from sodium benzophenone ketyl, and CH_2Cl_2 from CaH_2. Alumina was heated under high vacuum at 300 °C prior to use and was deactivated (5% H_2O, deoxygenated) after cooling. Melting points were determined in sealed capillaries with a Büchi 510 melting point apparatus and are uncorrected. Elemental analyses were performed by the Analytische Laboratorien, Prof. Dr. H. Malissa and G. Reuter GmbH, 51789 Lindlar. NMR spectra were recorded with a Varian Unity 500 (^{1}H: 499.6 MHz. ^{13}C{^{1}H}: 125.6 MHz; ^{11}B{^{1}H}: 160.3 MHz. ^{19}F: 470.1 MHz; ^{119}Sn: 186.3 MHz) and a Varian VXR 300 (^{1}H: 300 MHz. ^{13}C{^{1}H}: 75.4 MHz). Chemical shifts are given in ppm; they were measured at ambient temperature and are quoted relative to internal TMS for ^{1}H and ^{13}C, relative to external BF_3·OEt_2 for ^{11}B, to external $CFCl_3$ for ^{19}F, and relative to external $SnMe_4$ for ^{119}Sn. Deuterated solvents for NMR spectroscopy were degassed, dried and stored over molecular sieves (4 Å; Merck). Assignments are based on APT and DEPT spectra. IR spectra were measured with a Nicolet Avatar 360 FT IR instrument.

Cb*Co(3,5-$Me_2C_5H_3BNMe_2$) (1): A freshly prepared solution of [Cb*Co(NCMe)$_3$]PF_6 [11] (1.66 g, 4.25 mmol) in acetonitrile (40 mL) was added with stirring to Li(TMEDA)(3,5-$Me_2C_5H_3BNMe_2$)[12] (1.22 g, 4.49 mmol), and stirring was continued at ambient temperature for 5 h. The volatiles were then removed under vacuum and the resulting residue was triturated with hexane. The extract was filtered through a frit covered with alumina (deactivated with 5% H_2O, 5-cm layer) at −80 °C, and the elution was completed with 60 mL of hexane. The volatiles were removed from the hexane solution. The product was crystallized from pentane at −30 °C as yellow-orange crystalline solid. Concentrating the mother liquor and cooling afforded a second crop of **1** (combined yield: 1.05 g, 78%); m.p. 66−67 °C, soluble in all common organic solvents. $C_{17}H_{27}BCoN$ (315.2): calcd. C 64.79, H 8.64, N 4.44; found C 64.71, H 8.77, N 4.90. ^{1}H NMR (CD_2Cl_2): δ = 1.36 (s, Cb*), 2.18 (s, 3-/5-Me), 3.76 (d, 2-/6-H), 4.77 (t, 4-H, $^4J_{24}$ = 1.2 Hz), 2.76 (s, NMe_2). ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 9.7 (C_4*Me*$_4$), 22.6 (3-/5-Me), 39.2 (NMe_2), 77.5 (br, C-2,6), 77.8 (*C*$_4$Me$_4$), 85.2 (C-4), 112.4 (C-3,5); reliable spectra could be obtained more easily from toluene solutions of **1** because of the higher solubility of **1** in this solvent. ^{11}B{^{1}H} NMR (CD_2Cl_2): δ = 22.0.

Cb*Co(3,5-$Me_2C_5H_3BOMe$) (2): A solution of **1** (0.53 g, 1.68 mmol) in methanol (15 mL, 0.37 mol) was heated under reflux at 65 °C for 24 h. After careful removal of the volatiles, the resulting residue was crystallized from hexane to give **2** (0.43 g, 86%) as an orange crystalline solid; m.p. 46−47 °C. $C_{16}H_{24}BCoO$ (302.1): calcd. C 63.61, H 8.01; found C 63.59, H 8.18. ^{1}H NMR (CD_2Cl_2): δ = 1.38 (s, Cb*), 2.04 (s, 3-/5-Me), 3.59 (s, OMe), 3.96 (d, 2-/6-H), 4.86 (t, 4-H, $^4J_{24}$ = 1.0 Hz). ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 9.5 (C_4*Me*$_4$), 22.8 (3-/5-Me), 53.4 (OMe), 78.2 (*C*$_4$Me$_4$), 80.6 (br, C-2,6), 87.0 (C-4), 113.4 (C-3,5). ^{11}B{^{1}H} NMR (CD_2Cl_2): δ = 25.4.

Cb*Co(3,5-$Me_2C_5H_3BMe$) (3): A solution of MeLi (1.52 mL, 1.6 M in diethyl ether, 2.43 mmol) was added dropwise to a stirred solution of **2** (0.38 g, 1.25 mmol) in diethyl ether (20 mL) at −80 °C. The reaction mixture was stirred for additional 30 min under cold conditions, then allowed to warm to room temperature and stirring was continued for 24 h. After removal of the volatiles in a vacuum, the resulting residue was dissolved in hexane. Filtration and concentration gave **3** (0.31 g, 86%) as an orange-yellow crystalline solid; m.p. 127−128 °C. $C_{16}H_{24}BCo$ (286.1): calcd. C 67.17, H 8.45; found C 66.77, H 8.66. ^{1}H NMR (CD_2Cl_2): δ = 0.49 (s, BMe), 1.38 (s, Cb*), 2.04 (s, 3-/5-Me), 4.34 (d, 2-/6-H), 5.01 (t, 4-H), $^4J_{24}$ = 1.0 Hz. ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 0.6 (br, BMe), 9.5 (C_4*Me*$_4$), 22.6 (3-/5-Me), 77.9 (*C*$_4$Me$_4$), 88.9 (C-4), 95.0 (br, C-2,6), 112.7 (C-3,5). ^{11}B{^{1}H} NMR (CD_2Cl_2): δ = 22.4.

Cb*Co(3,5-$Me_2C_5H_3BCl$) (4): A solution of BCl_3 in dichloromethane (2.97 mL, 1.56 M, 4.63 mmol) was added dropwise to a stirred solution of **2** (0.47 g, 1.55 mmol) in hexane (20 mL) at 0 °C. Rapid formation of a precipitate was seen. Stirring was continued for 1 h; then the reaction mixture was allowed slowly to warm to room temperature (12 h). After removal of the volatiles, the resulting residue was dissolved in dichloromethane and filtered through alumina (deactivated with 5% H_2O, 3 cm layer) using the same solvent as eluent. Removal of the solvent left **4** (0.33 g, 70%) as a fine microcrystalline, deep yellow solid; m.p. 159−160 °C. $C_{15}H_{21}BClCo$ (306.5): calcd. C 58.78, H 6.91; found C 58.81, H 6.97. ^{1}H NMR (CD_2Cl_2): δ = 1.39 (s, Cb*), 2.08 (s, 3-/5-Me), 4.50 (d, 2-/6-H), 5.09 (t, 4-H), $^4J_{24}$ = 1.0 Hz. ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 9.4 (C_4*Me*$_4$), 22.3 (3-/5-Me), 80.3 (*C*$_4$Me$_4$), 89.8 (C-4), 91.8 (br, C-2,6), 113.1 (C-3,5). ^{11}B{^{1}H} NMR (CD_2Cl_2): δ = 23.7.

Cb*Co(3,5-$Me_2C_5H_3BH$) (5): To a stirred solution of **4** (0.24 g, 0.78 mmol) in hexane (40 mL) was added diisobutylaluminium hydride in toluene (2.24 mL, 1 M, 2.24 mmol) at −80 °C. The reaction mixture was stirred for 30 min, then it was allowed slowly to warm to room temperature (12 h). The solvents were evaporated under vacuum, and the residue was dissolved in hexane (10 mL) and cooled to −80 °C. Anhydrous methanol (ca. 6 drops) and pyridine (ca. 4 drops) were added. The mixture was stirred for 30 min and

then was allowed to warm to room temperature. Filtration through a cold frit (−80 °C) containing alumina (deactivated with 5% H_2O, 5 cm layer) with diethyl ether as eluent and subsequent concentration of the filtrate gave **5** (0.18 g, 86%) as an orange colored solid; m.p. 138−139 °C. $C_{15}H_{22}BCo$ (272.1): calcd. C 66.22, H 8.15; found C 66.97, H 8.36. ^1H NMR (CD_2Cl_2): δ = 1.39 (s, Cb*), 2.08 (s, 3-/5-Me), 4.65 (dd, $^3J_{12}$ = 4.1, $^4J_{24}$ = 1.1 Hz, 2-/6-H), 5.11 (t, $^4J_{24}$ = 1.1 Hz, 4-H). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 9.9 (C_4Me_4), 22.7 (3-/5-Me), 79.3 (C_4Me_4), 90.1 (C-4), 96.6 (br, C-2,6), 112.5 (C-3,5). ^{11}B NMR (CD_2Cl_2): δ = 16.8 [d, $^1J(^{11}B-^1H)$ = 110.0 Hz].

Cb*Co(3,5-Me$_2$C$_5$H$_3$BF) (6): A solution of **4** (0.18 g, 0.58 mmol) in dichloromethane (20 mL) was treated with excess TlF (0.26 g, 1.16 mmol) and stirred at room temperature for 3 d. The reaction mixture was filtered and normal workup gave **6** (0.13 g, 76%) as a yellow crystalline solid; m.p. 151−152 °C. $C_{15}H_{21}BCoF$ (290.1): calcd. C 62.11, H 7.30; found C 62.20, H 7.40. ^1H NMR (CD_2Cl_2): δ = 1.40 (s, Cb*), 2.06 (s, 3-/5-Me), 4.12 (d, 2-/6-H), 4.95 (t, 4-H, $^4J_{24}$ = 1.0 Hz). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 9.5 (C_4Me_4), 22.5 (3-/5-Me), 79.4 (C_4Me_4), 83.3 (br, C-2,6), 88.1 (C-4), 114.1 (C-3,5). $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 27.0 [d, $^1J(^{19}F-^{11}B)$ = 55 Hz]. ^{19}F NMR (CD_2Cl_2): δ = −174 (br, with 90 Hz splitting).

Cb*Co(3,5-Me$_2$C$_5$H$_3$BSnMe$_3$) (7): A solution of **4** (0.22 g, 0.71 mmol) in THF (10 mL) was added dropwise to an ice-cooled solution of $LiSnMe_3$ [prepared from Sn_2Me_6 (0.23 g, 0.70 mmol) in THF (5 mL) and MeLi in diethyl ether (0.43 mL, 1.65 M, 0.70 mmol) at −80 °C].[19] Stirring was continued for 1 h; then the reaction mixture was allowed to warm to room temperature (12 h). After removal of the volatiles under vacuum, the resulting residue was dissolved in hexane and filtered through a cold frit (−80 °C) containing alumina (deactivated with 5% H_2O, 1-cm layer) with hexane as eluent. Concentration of the eluate yielded **7** (0.25 g, 81%) as yellow-orange crystals; m.p. 110−111 °C. $C_{18}H_{30}BCoSn$ (434.9): calcd. C 49.72, H 6.95; found C 49.57, H 7.35. ^1H NMR (CD_2Cl_2): δ = 0.02 [s, $^2J(^{119}Sn-^1H)$ = 41.4 Hz, $SnMe_3$], 1.37 (s, Cb*), 2.08 (s, 3-/5-Me), 4.83 (d, 2-/6-H), 5.17 (t, 4-H), $^4J_{24}$ = 1.5 Hz. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = −10.4 [s, $^1J(^{119}Sn-^{13}C)$ = 201.6 Hz, $SnMe_3$], 10.1 (C_4Me_4), 22.5 (3-/5-Me), 80.0 (C_4Me_4), 90.8 (C-4), 101.1 (br, C-2,6), 112.1 (C-3,5). $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 20.9 [s, $^1J(^{119}Sn-^{11}B)$ = 0.86 kHz]. $^{119}Sn\{^1H\}$ NMR (CD_2Cl_2): δ = −105.3 [q, $^1J(^{119}Sn-^{11}B)$ = 869 Hz].

Byproduct 8: On standing, the mother liquor of the above preparation of **7** deposited orange-colored crystals of **8**; m.p. 189−190 °C. The compound was identified and characterized by an X-ray structure determination.

[Cb*Co(3,5-Me$_2$C$_5$H$_3$BNMe$_3$)]I (10): MeI (0.16 g, 1.12 mmol) in THF (10 mL) was added dropwise to a solution of **1** (0.35 g, 1.11 mmol) in the same solvent (20 mL) with stirring. A yellow precipitate appeared after ca. 40 min and stirring was continued at ambient temperature for 10 h. The crude product was collected on a frit, washed with THF (2 × 5 mL), then with diethyl ether (2 × 10 mL), and dried under vacuum. The product was dissolved in hot chloroform; subsequent slow cooling to −30 °C yielded **10** (0.43 g, 86%) as yellow microcrystals; m.p. 198−199 °C, soluble in chloroform, dichloromethane, acetone, and methanol. $C_{18}H_{30}BCoIN$ (457.1): calcd. C 47.03, H 6.62; found C 46.78, H 6.62. ^1H NMR (CD_2Cl_2): δ = 1.42 (s, Cb*), 2.18 (s, 3-/5-Me), 3.29 (s, NMe_3), 4.71 (d, 2-/6-H), 5.30 (t, 4-H, $^4J_{24}$ = 1.0 Hz). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 10.3 (C_4Me_4), 22.4 (3-/5-Me), 54.0 (NMe_3), 82.5 (C_4Me_4), 83.4 (br, C-2,6), 93.2 (C-4), 114.4 (C-3,5). $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 25.3.

Cb*Co(3,5-Me$_2$C$_5$H$_3$BCN) (11): A solution of tetrabutylammonium cyanide (0.20 g, 0.74 mmol) in dichloromethane (10 mL) was added dropwise to a solution of **10** (0.30 g, 0.66 mmol) in the same solvent (10 mL). The reaction mixture was stirred for 24 h. After removal of the volatiles, the residue was extracted in toluene (40 mL). Filtration through alumina (deactivated with 5% H_2O, 3-cm layer) using toluene/diethyl ether (95:5, v/v) as eluent, subsequent removal of the volatiles under vacuum, and recrystallisation from dichloromethane/diethyl ether (1:1) yielded **11** (0.15 g, 79%) as a yellow-orange solid; m.p. 155−156 °C. $C_{16}H_{21}BCoN$ (297.1): calcd. C 64.69, H 7.12, N 4.71; found C 65.12, H 7.24, N 5.08. ^1H NMR (CD_2Cl_2): δ = 1.42 (s, Cb*), 2.11 (s, 3-/5-Me), 4.87 (d, 2-/6-H), 5.27 (t, 4-H, $^4J_{24}$ = 1.5 Hz). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, −50 °C): δ = 9.4 (C_4Me_4), 22.0 (3-/5-Me), 81.4 (C_4Me_4), 91.4 (C-4), 96.7 (br, C-2,6), 112.2 (C-3,5), 131.4 (br, CN). $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 7.4. IR (CD_2Cl_2): ν(CN) = 2198 cm^{-1}.

X-ray Crystal Structure Determinations: Diffraction intensity data were collected with ENRAF-Nonius CAD4 diffractometers equipped with graphite monochromators. Crystal data, data collection parameters, and convergence results are listed in Table 3. Before averaging over symmetry-related reflections, numerical[27] or empirical absorption[28] corrections were applied to the data sets. Structures were solved by direct methods with the help of the SHELXS-97 program[29] and refined on reflection intensities (F^2) using the SHELXL-97 program.[30] In the final least-squares refinements, all non-hydrogen atoms were assigned anisotropic displacement parameters. Hydrogen atoms were included as riding with

DNA as a Catalyst and Catalytic Template for the Racemisation of Metal Tris-Phenanthroline Complexes

Alison Rodger,*[a] Bengt Nordén,[b] P. Mark Rodger,[a] and Paula J. Bates[c]

Keywords: Circular dichroism / Bioinorganic chemistry / Coordination chemistry / Racemisation

[Fe(1,10-phenanthroline)$_3$]$^{2+}$ is known to racemise in solution and DNA is known to shift the equilibrium point of the Δ/Λ-[Fe(1,10-phenanthroline)$_3$]$^{2+}$ mixture from 50:50 to a position favouring a slight excess of the Δ enantiomer. In this paper it is shown that DNA catalyses the racemisation reaction, presumably by providing vibrational energy to species that bind in a less favoured mode for that enantiomer. The racemisation of [Co(1,10-phenanthroline)$_3$]$^{3+}$, however, is not enhanced by DNA unless [Co(1,10-phenanthroline)$_3$]$^{2+}$ is also added to the solution. In this case, the DNA acts as a template to facilitate the $Co^{II} \rightleftarrows Co^{III}$ electron transfer. Racemisation occurs while the [Co(1,10-phenanthroline)$_3$]$^{n+}$ is in the labile Co^{II} form.

Introduction

The presence of DNA has long been known to shift the position of the Δ/Λ equilibrium of [Fe(1,10-phenanthroline)$_3$]$^{2+}$ in favour of the Δ enantiomer on a timescale of minutes to hours.[1,2] There is also a suggestion in the literature that [Co(1,10-phenanthroline)$_3$]$^{3+}$ rapidly racemises over a period of minutes,[3] despite the well accepted stability of Co^{III} d^6 amine systems, and there is some suggestion that DNA affects this rate. We therefore chose to investigate both these racemisation reactions in the presence and absence of DNA in order to determine what if any role DNA plays in the kinetics.

Results and Discussion

[Fe(1,10-phenanthroline)$_3$]$^{2+}$: DNA Catalyses a Reaction

The results of the kinetic experiments with a range of DNA:Δ and DNA:Λ ratios for [Fe(1,10-phenanthroline)$_3$]$^{2+}$ are given in Table 1. All CD traces (not shown) fitted to a single exponential decay; the rate of change in the CD signal that is given in the final column is the constant in the exponent. For the simple case of free solution racemisation, the rate constant for the, for example, Δ→ Λ reaction is half the exponent constant, as shown below. The error range quoted shows the scatter between repeat runs. The rate of racemisation in the DNA-free systems at 20 °C and 25 °C, assuming a simple Arrhenius behaviour, gives an activation energy of about 40 kJ mol^{-1}. Mudasir et al. recently reported a rate constant for the racemisation of the Λ enantiomer at room temperature (stated to be approximately 25 °C) to be (0.72 ± 0.05)×10^{-3} s^{-1}.[4] Their value was estimated from two runs where points were measured at intervals (rather than the

Table 1. Rate of change of CD signals for both enantiomers of [Fe(1,10-phenanthroline)$_3$]$^{2+}$ in aqueous solution with and without calf thymus DNA; the columns give the following data: (1) DNA concentration (in base), (2) Δ- or (3) Λ-[Fe(1,10-phenanthroline)$_3$]$^{2+}$ concentrations, (4) DNA:ligand ratio, (5) final CD reading in millidegrees, and (6) the single exponential decay constant for the CD signal as a function of time; all data were collected at 20 °C except for the final row; the value in brackets indicates the variation between identical runs

trace monitored continuously as in our experiments). Assuming their data has been correctly analyzed, in order to be consistent with our data, the room temperature in their experiments must have been above 25 °C (≈28 °C) or their error has been underestimated.

The first observations to be made from our data are that the end point of the kinetics is the same for given concentrations of metal complex and DNA independent of which enantiomer is added initially; however, the value of the end point CD signal varies as a function of the DNA concentration. This variation is due to the DNA shifting the position of the Δ/Λ equilibrium (the end point is when the equilibrium is established) as previously observed by Härd and Nordén[1,2] and also the perturbation of the CD of the cations on binding to DNA. The final observed CD signal at 545 nm is always positive. As the unbound metal complex will be a 50:50 mixture of the two enantiomers at the conclusion of the kinetics, and so have no net CD, this means that the bound metal complexes must always have a net positive CD. Two factors might contribute to this: a Pfeiffer-effect shift in the equilibrium between the two enantiomers to give an excess of one enantiomer[1,2] and/or a positive CD signal being induced into the transition metal complex transitions due to their interaction with the DNA.[5]

To try to understand this behaviour at a molecular level it is helpful to consider the binding modes that have been established[5−7] for $[Ru(1,10\text{-phenanthroline})_3]^{2+}$ (which does not racemise in solution) since previous experience suggests that any information on binding modes determined for ruthenium complexes can be transferred to the iron(II) complex with the same ligands since the charge and steric effects are almost identical. At low ligand loadings, the Δ enantiomer is predominantly a minor groove binder with either one or two chelates pointing into the groove, whereas the Λ enantiomer is 90% in a major groove mode with a chelate partially inserted between two base pairs and with a lower equilibrium binding constant than the Δ enantiomer. When its preferred DNA binding modes have been fully occupied, each enantiomer then occupies less favoured modes and the Λ enantiomer on average binds more strongly.[5,7] Whether the site preference is perturbed by the presence of the other enantiomer is not clear, although the racemate-induced CD spectra[5] suggest the binding modes are not changed when the other enantiomer is present. However, the two enantiomers must reduce each other's binding constants since the racemate binds more weakly to DNA than either enantiomer.[5] For $[Ru(1,10\text{-phenanthroline})_3]^{2+}$ above ≈5:1 DNA:Δ or DNA:Λ ratios the most favoured sites are occupied. Thus in our experiments with $[Fe(1,10\text{-phenanthroline})_3]^{2+}$, except at the beginning of the 2.5:1 runs, it is reasonable to conclude that each enantiomer occupies its preferred site at all times. This means that we therefore have conditions where the Δ enantiomer binds more strongly than the Λ enantiomer, so the positive final CD could simply be due to the Pfeiffer effect causing an excess of Δ.

The other observation to be taken from Table 1 is that the racemisation rates of both enantiomers speed up when DNA is present, although to differing extents. At high DNA concentrations, where the Δ enantiomer has a stronger DNA binding constant,[5] the rate of racemisation of this enantiomer is the faster, whereas at lower DNA concentrations, where the Λ enantiomer binds more strongly to DNA this enantiomer's rate is more enhanced.

The rate enhancements observed in the presence of DNA might be due to the shift of the equilibrium position of the reaction or might be due to the DNA facilitating the reaction and providing a slightly lower energy pathway for racemisation. In order to determine which of these is occurring, let us assume that the latter is not the case, in other words, the DNA-bound molecules do not rearrange (or do so at the free solution rate), and deduce the consequences. We are therefore assuming that the presence of the DNA affects only the concentration of free molecules in solution that can rearrange and plays no direct role in the racemisation reaction, acting only to change the end point of the reaction due to the differing percentages of the two bound enantiomers.

Racemisation reactions probed using CD spectroscopy measure the rate of change of the CD signal (rather than the actual disappearance of one reactant or appearance of one product). To determine the rate of change of the metal complex concentration in the presence of DNA we need to determine the concentrations of each species present as a function of time and multiply by the appropriate Δε values and path lengths (Beer−Lambert analogue). In addition to assuming that the DNA-bound metal complexes cannot racemise, let us also assume that the bound and free forms are in fast equilibrium relative to the rate of racemisation (a reasonable assumption even if the on-rate is diffusion controlled, as the off-rate will be at worst in the microsecond domain given the binding constants of refs.[5,7]). This is schematically illustrated as in Equation (1)

$$\begin{array}{ccc} x + S_f & \xleftrightarrow{K_x} & X \\ k_1 \downarrow\uparrow k_1 & & \\ y + S_f & \xleftrightarrow{K_y} & Y \end{array} \quad (1)$$

where S_f is the concentration of free sites on DNA, x is the free concentration of the enantiomer that begins in excess, X is its bound concentration, k_1 is the rate constant for the conversion of one enantiomer to the other in free solution, K_x is the equilibrium binding association constant for species x with DNA, and the y symbols relate to the other enantiomer.

Because the DNA binding is in fast equilibrium, the rate of change of x and y may be written as in Equation (2):

$$\begin{aligned} \frac{dx}{dt} &= k_1(-x + y) \\ \frac{dy}{dt} &= k_1(x - y) \end{aligned} \quad (2)$$

or in matrix notation as Equation (3):

$$\frac{d\mathbf{c}}{dt} = \Lambda\,\mathbf{c}$$
$$\text{where } \mathbf{c} = \begin{pmatrix} x \\ y \end{pmatrix} \text{ and } \Lambda = k_1 \begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix} \quad (3)$$

Solving Equation (3) gives Equation (4):

$$x(t) = \frac{x_o}{2}(1 + e^{-2k_1 t})$$
$$y(t) = \frac{x_o}{2}(1 - e^{-2k_1 t}) \quad (4)$$

where x_o is the starting concentration of x.

The CD signal as a function of time may be written according to Equation (5):

$$CD(t) = \Delta\varepsilon_x(x(t) - y(t)) + \Delta\varepsilon_X X(t) + \Delta\varepsilon_Y Y(t) K_y \quad (5)$$

where $\Delta\varepsilon_x$ is the CD extinction coefficient for the unbound enantiomer that is in excess at the beginning of the reaction, $\Delta\varepsilon_X$ is the CD extinction coefficient for X when it is bound to DNA etc. Since

$$K_x = \frac{X(t)}{x(t) S_f(t)} \quad (6)$$

from Equations (4) and (5) we may deduce Equation (7):

$$CD(t) = \Delta\varepsilon_x(x_o e^{-2k_1 t}) + \Delta\varepsilon_X K_x\left(\frac{x_o}{2} + \frac{x_o}{2} e^{-2k_1 t}\right) S_f(t) \ldots$$
$$\ldots + \Delta\varepsilon_Y K_y\left(\frac{x_o}{2} - \frac{x_o}{2} e^{-2k_1 t}\right) S_f(t) \quad (7)$$

which is the CD signal as a function of time *if the enantiomers may only racemise in free solution*.

The two sources of time dependence in Equation (7) are the single exponential decay terms with constant $-2k_1$ and $S_f(t)$. The latter can be deemed approximately time independent since the binding constants of the two enantiomers are similar. (At high DNA:metal complex ratios, by analogy with [Ru(1,10-phenanthroline)$_3$]$^{2+}$, 99% of the metal complex will be bound and 1% free for both enantiomers so the amount of free DNA is large and does not vary much during the reaction. At low DNA:metal complex ratios very little of the DNA is unoccupied throughout the reaction. So in both cases, $S_f(t)$ is approximately constant in any one run.) Thus, if racemisation occurs only for free metal complexes [as required for Equation (7)], then the rate of decay of the CD signal is $-2k_1$ for all DNA concentrations. Table 1 summarizes how the rate of decay of the CD signal *changes* with DNA concentration; we therefore must conclude that both enantiomers also rearrange when bound to the DNA and Equation (7) is not valid. In other words *the DNA acts as a catalyst for this reaction, slightly lowering the activation energy relative to the free solution value.*

One can speculate as to how the DNA achieves its catalytic effect. The most likely possibility is that the metal complexes will be moving on and off the DNA and if one enantiomer hits the DNA in one of its less favoured binding positions (e.g. the wrong groove) then during its time on the DNA it is encouraged to bind more strongly by changing its handedness. The natural breathing motions of the DNA would help provide the energy required to break the metal−ligand bond (as required for metal tris-chelate racemisation reactions, with a few exceptions such as dithiocarbamate complexes[8,9]) and the DNA will encourage the formation and net accumulation of the desired product for that DNA binding mode.

[Co(1,10-phenanthroline)$_3$]$^{3+}$: DNA as a Catalytic Template

Following literature claims of racemisation of [Co(1,10-phenanthroline)$_3$]$^{3+}$ [3] in the presence of DNA on a timescale too fast for NMR experiments, we attempted to characterize the kinetics of this process. However, we found no evidence of racemisation for the Co^{III} complex prepared as described in the Exp. Sect. either with or without DNA in the solution. We concluded that the previously observed effect must have been due to trace amounts of the labile Co^{II} complex remaining in solution — our oxidation conditions involved chlorine gas. Electron transfer occurs readily between the Co^{II} and Co^{III} tris-phenanthroline complexes and the Co^{II} form is labile and racemises readily. The net effect of this is the racemisation of the Co^{III} complex. We therefore probed the kinetics of the racemisation of [Co(1,10-phenanthroline)$_3$]$^{3+}$ in the presence of [Co(1,10-phenanthroline)$_3$]$^{2+}$ and DNA.

The racemisation of the Co^{III} complex proceeds slowly in the presence of the Co^{II} complex with a half life of the order of hours (depending on reagent concentrations) rather than minutes or seconds. In a series of experiments at widely varying concentrations of the two metal complexes and DNA, we observed that the DNA causes a significant increase in the rate of racemisation of the Co^{III} complex in the presence of the Co^{II} complex. In other words the DNA enhances the catalytic activity of the Co^{II} complex taking it to half lives of a few seconds (at high enough concentrations, see Table 2). As with [Fe(1,10-phenanthroline)$_3$]$^{3+}$, the rate of change of CD as a function of time in an individual run follows a simple exponential decay; however, the dependence of the rate on the concentration of each reagent is not straightforward as illustrated by a data set for the Λ-enantiomer in Table 2. These observations can be understood when it is realised that the DNA is forming a template to facilitate the electron transfer reaction between two cobalt tris-phenanthroline complexes of different oxidation states. The DNA may also be playing a more active role in the electron transfer. Increased concentrations of the cobalt complexes make such encounters on the DNA more likely. If, for example, Co^{III} is in excess, however, it will inhibit Co^{II} binding and decrease the effect. Similarly, decreasing

Table 2. Rate of change of CD signals for Λ-[Co(1,10-phenanthroline)$_3$]$^{3+}$ in aqueous solution in the presence of (±)-[Co(1,10-phenanthroline)$_3$]$^{2+}$ and calf thymus DNA; the columns give the following data: (1) DNA concentration, (2) Λ-[Co(1,10-phenanthroline)$_3$]$^{2+}$ concentration, (3) (±)-[Co(1,10-phenanthroline)$_3$]$^{2+}$ concentration, (4) DNA:Co^{III} ligand ratio, (5) the single exponential decay constant for the CD signal as a function of time; all data were collected at 20 °C. The +3 charged Co^{III} complex binds much more strongly to DNA than does the Co^{II} complex, hence its smaller concentrations

the DNA concentration increases the likelihood of an encounter between the reacting species until the same saturation occurs.

In conclusion, we have shown that DNA catalyses the racemisation reaction of both Δ- and Λ-[Fe(1,10-phenanthroline)$_3$]$^{2+}$ but has no effect on the stability of Δ- and Λ-[Co(1,10-phenanthroline)$_3$]$^{3+}$. However, in the presence of (±)-[Co(1,10-phenanthroline)$_3$]$^{2+}$ DNA increases the effectiveness of the Co^{II} complex catalysis of the racemisation of both Δ- and Λ-[Co(1,10-phenanthroline)$_3$]$^{3+}$ by acting as a template to enhance the rate of electron transfer between the labile Co^{II} and stable Co^{III} species. The concentration dependence of this process is complicated and maximized for DNA concentrations that encourage Co^{II} and Co^{III} to be bound together on the DNA. Too high a concentration of DNA reduces the nearest-neighbour interaction of the cobalt complexes and too high a concentration of one complex relative to the other means that complexes of different oxidation state are less likely to meet. The Co^{II}, with its intrinsically weaker binding constant, is particularly likely to be displaced. Thus we have an example of a DNA-catalyzed reaction where the DNA does not chemically take part but does provide some energy (about 40 kJ mol^{-1}) to help the rearrangement, and another reaction where DNA is a catalytic template.

Experimental Section

The Δ- and Λ-enantiomers of [Fe(1,10-phenanthroline)$_3$]$^{2+}$ were produced from cold (just above 0 °C) 0.025 M ferroin solution (Aldrich) by adding potassium antimonyl tartrate (also at 0 °C) in a 2:1 molar ratio. $NaClO_4$ (Aldrich) was added to the filtrate and the resulting crystals were collected. The L-enantiomer of antimonyl tartrate (Aldrich) was used to produce the Λ-enantiomer of [Fe(1,10-phenanthroline)$_3$]$^{2+}$. The D-enantiomer of antimonyl tartrate, used to produce the Δ-enantiomer of [Fe(1,10-phenanthroline)$_3$]$^{2+}$, was made by mixing D-tartaric acid and KOH and then adding Sb_2O_3, all in equimolar ratios. The solution was either boiled until all the Sb_2O_3 appeared to have dissolved or, for better yield, heated under reflux for 2 days. The solution was filtered and the filtrate left to evaporate to dryness producing D-potassium antimonyl tartrate. [Fe(1,10-phenanthroline)$_3$]$^{2+}$ enantiomeric purity was determined using the literature values of $\varepsilon_{510\ nm}$ = 11200 mol^{-1} dm^3 cm^{-1} and $\Delta\varepsilon_{545\ nm}$ = 20.0 mol^{-1} dm^3 cm^{-1} for the Δ enantiomer.[10] The Δ enantiomer proved to be 90% enantiomerically pure and the Λ enantiomer 103% (suggesting the literature value for Δε is an underestimate).

The racemisation kinetics of [Fe(1,10-phenanthroline)$_3$]$^{2+}$ were monitored at 20 °C at 545 nm in the presence and absence of calf thymus DNA (Sigma, highly lyophilised sodium salt) using a Jasco J-720 spectropolarimeter. Concentrations in DNA base were determined using $\varepsilon_{258\ nm}$ = 6600 mol^{-1} dm^3 cm^{-1}.[11] All runs could be fitted with a simple single exponential decay (using Kaleidagraph) and the results are reported in Table 1 in terms of the decay constants of the CD signal. All runs were repeated at least once. To ensure that the solutions did not racemise during preparation the [Fe(1,10-phenanthroline)$_3$]$^{2+}$ was kept cold until mixed with the DNA solutions. In fact, the apparent first-order nature of the kinetics [even under stopped flow conditions where data collection started after tens of ms (data not shown)] meant this precaution proved to be unnecessary.

Λ-[Co(1,10-phenanthroline)$_3$]$^{2+}$ was synthesized according to ref.[12] analogously to the [Fe(1,10-phenanthroline)$_3$]$^{2+}$ case. To produce the Co^{III} complexes, the least soluble antimonyl tartrate salt was isolated and then oxidized with chlorine gas to give yellow crystals of resolved [Co(1,10-phenanthroline)$_3$]$^{3+}$. As discussed above it proved crucial to fully oxidize the Co^{II} at this stage. The Δ-enantiomer was prepared analogously to the Λ-enantiomer using the potassium antimonyl D-tartrate as for the Fe complexes. This method gave a >90% yield and higher enantiomeric purity than the Lee method (17% yield).[12] Alternative literature methods for producing enantiomerically pure Co^{III} tris-chelates are more complicated and require expensive reagents.[13] [Co(1,10-phenanthroline)$_3$]$^{3+}$ enantiomeric purity was determined using the literature values of $\varepsilon_{273\ nm}$ = 68000 mol^{-1} dm^3 cm^{-1} and $\Delta\varepsilon_{281\ nm}$ = 222.0 mol^{-1} dm^3 cm^{-1} for the Δ enantiomer.[14] The Δ-enantiomer was 90% enantiomerically pure and the Λ-enantiomer 94%.

The racemisation kinetics of [Co(1,10-phenanthroline)$_3$]$^{3+}$ was monitored using a Jasco J-720 at 379 nm in a 1 cm cuvette or at 307 nm in a 0.8 mm cuvette with a Biologique SFM-3 stopped-flow system attached between the sample compartment and the photomultiplier tube. In the stopped flow system: the light beam was focused with a single lens;[15] data were collected with a band width of 2 nm, response time of 1 s; and the samples were loaded as follows: syringe 1: Co^{III} sample; syringe 2: premixed Co^{II} sample and DNA; syringe 3: water.

The First Assembly of a Nest-Shaped Heterothiometallic Cluster and a Polyoxometalate Anion − Synthesis, Characterization, and Strong Third-Order Nonlinear Optical Response

Chi Zhang,*[a,b,c] Yinglin Song,[a] Fritz E. Kühn,*[b] Yan Xu,[d] Xinquan Xin,[d] Hoongkun Fun,[a,b,c] and Wolfgang A. Herrmann*[b]

Keywords: Polyoxometalates / Transition metals / Cluster compounds / Nonlinear optics

Two heterothiometallic cluster compounds $[MOS_3Cu_3(4\text{-pic})_6]\cdot 0.5[M_2O_7]$ (M = Mo **1**, W **2**) having a cationic cluster skeleton and a polyoxometalate cluster anion, as well as two other clusters $[MOS_3Cu_3(4\text{-pic})_6]\cdot[BF_4]$ (M = Mo **3**, W **4**) have been synthesized for nonlinear optics studies. Single-crystal X-ray diffraction data show that cluster **1** adopts a very interesting arrangement with a cationic nest-shaped cluster skeleton and a polyoxomolybdenum cluster anion. This is the first time that such a skeleton has been found for an Mo/S/Cu heterothiometallic cluster compound and it represents a distinct structural type as compared to the analogous nest-shaped clusters seen with a neutral or an anionic skeleton. The nonlinear optical properties of these four clusters have been investigated with an 8 ns pulsed laser at 532 nm, and optical self-focusing effects have been observed. Clusters **1** and **2** with the polyoxometalate cluster anion exhibit stronger third-order nonlinear optical absorption than clusters **3** and **4** having only a pseudo-halogen group as the anion, which can be attributed to skeletal differences. Clusters **1** and **2** also exhibit very large optical limiting effects toward the ns incident pulsed laser as compared with clusters **3** and **4** and other shaped clusters with the same skeleton factors studied previously. This demonstrates the influence of the cluster skeleton on the nonlinear optical performance.

Introduction

The chemistry of transition metal sulfur clusters has attracted considerable attention[1] and represents an important and active area of research concerning advanced materials, biological processes, and catalytic reactions.[2−4] This is because these clusters possess interesting electronic, biological, optical, structural, and catalytic properties and show promising potential as biological models of some nitrogenases or various other metalloenzymes,[4a,5] as active centers relevant to some industrial catalytic processes,[1a] and as precursor molecules of optically functional materials for optical limiting applications and optical signal detection techniques.[2] Currently, the tremendous interest in these clusters is mainly focused on the search for better materials with third-order nonlinear optical (NLO) properties and superior optical limiting (OL) effects, not only for applications in protecting optical sensors and human eyes from high-intensity laser hazards, but also for their utilization in optical communication, optical signal processing and transmission, optical data acquisition and storage, optical computing, and optic-electronic modulation.

The ongoing research and development in this promising field shows that, in contrast to the other most frequently mentioned NLO materials, such as phthalocyanine or fullerene C_{60} and derivatives thereof,[6,7] these clusters possess the combined advantages of both organic molecules and inorganic compounds: large modifiable structures and structures containing many heavy metal atoms. One of the most important and promising features of these heterothiometallic clusters is the possibility of modifying and eventually optimizing the building blocks through subtle modifications at the molecular level. Thus, all of the structural units, terminal ligands, skeletal elements, and constituent components can be altered just like organic molecules so that the NLO properties can be adjusted through structural manipulation. On the other hand, the incorporation of heavy metal atoms may introduce more sublevels into the energy hierarchy as compared to organic molecules with the

same number of skeleton atoms. This permits more allowed electron transitions, thereby leading to larger NLO effects, especially those beneficial to NLO applications. Our studies on these clusters have demonstrated that, unlike some traditional NLO materials, their skeletons and constituent elements have a considerable influence on their NLO performances, which results in the Mo(W)/S/Cu(Ag) clusters exhibiting rather diverse combinations of NLO effects. Clusters having a cubane-like shape,[2a,8] a half-open cubane-like shape,[2b,9] and a hexagonal prism-shape[10] show strong nonlinear absorption. Strong nonlinear refraction effects are exhibited by some nest-shaped,[11] twin-nest-shaped,[12] and butterfly-shaped clusters.[13] The previously described twenty-nuclear supra-cage-shaped cluster[2d] possesses very large nonlinear susceptibility, while hexagonal prism-shaped clusters,[10] pentanuclear planar "open" clusters,[14] and cluster polymers[15] exhibit large optical limiting properties. Nevertheless, there remains a challenge to develop optically functional materials with strong third-order NLO properties and superior OL effects, and to establish the general relationships between the cluster molecular structures and their NLO performances.

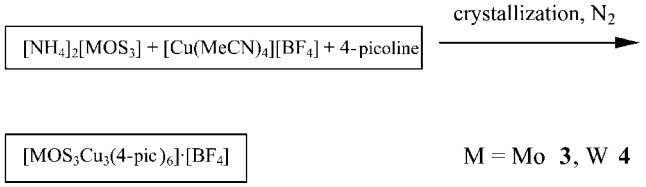
In our systematic efforts to investigate the possibilities of controlling the size and composition of the cluster skeletons and their third-order NLO properties, including the OL effects, as well as the coordination chemistry of thiometalates with Lewis-base adducts through modification of their backbone, we describe herein the synthesis of a series of nest-shaped clusters **1**−**4** by ligand-redistribution reactions, and report the characterization of their structures by X-ray crystallography. To our surprise, the unexpected products, clusters **1** and **2**, adopt a very interesting arrangement with a cationic nest-shaped cluster skeleton and a polyoxometalate cluster anion. This is the first time that such a skeleton has been found for an Mo/S/Cu(Ag) heterothiometallic cluster compound. The results of *Z*-scan experiments show that these clusters possess strong NLO absorptive abilities and effective optical self-focusing behavior, which are simulated by excited-state absorption theory. Large optical limiting effects of this series of clusters are observed in the OL measurements. The third-order nonlinear optical susceptibilities $\chi^{(3)}$ and the third-order nonlinear hyperpolarizabilities γ of these clusters are also reported.

Results and Discussion

Synthetic Reactions

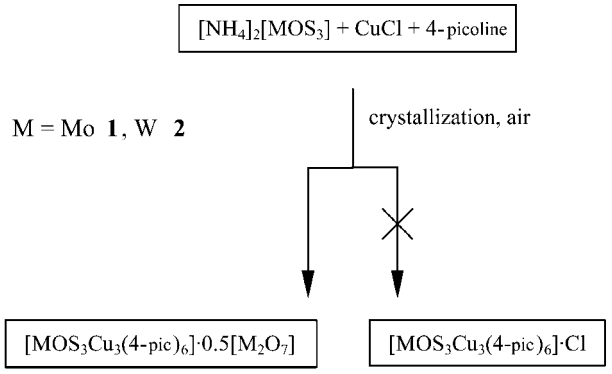
The cationic cluster skeleton $[MOS_3Cu_3(4\text{-pic})_6]^+$ (M = Mo, W; 4-pic = 4-picoline) present in clusters **1**−**4** was straightforwardly prepared in two steps by a ligand-redistribution reaction. In the first step, the copper complex bearing mixed ligands was pre-synthesized as an intermediate, which did not have to be isolated from the reaction system. In the present case, the starting material CuX [X = Cl^-, $(CH_3CN)_4BF_4^-$] was treated with 4-picoline, which served as both the reaction solvent and the σ-donor ligand. Since 4-pic exhibits a strong super-conjugation effect from the methyl group to the pyridine ring, it can be expected to show a high tendency to coordinate to Cu atoms. The gradual dissolution of CuX with the formation of a light-yellow solution were consistent with the formation of the intermediate product, i.e. the Lewis-base adduct $CuX(4\text{-pic})_3$.[16] Then the synthon thiometalate $[MOS_3]^{2-}$ was added to the reaction system as a bidentate ligand. The solution immediately turned from light-yellow to black-red (or orange-red) in color, which suggested that the target cluster compounds had been formed. Since the sequence of some Cu^I-philic ligands of Mo(W)/S/Cu(Ag) compounds can be regarded as $S^{2-} >$ (py, PPh_3) $> X^-$ (X = Cl, Br, I, CN), the former ligands can substitute part or all of the latter ligands, while the required coordination number of copper is not more than four. Two bonds of $CuX(4\text{-pic})_3$ were broken by the attack of the S^{2-} of the $[MOS_3]^{2-}$ moiety and in forming the final cationic cluster skeleton.

At the stage of forming the final cluster molecules, the BF_4^- anion in the reaction systems of clusters **3** and **4** can help to achieve a charge balance with the cationic cluster skeleton $[MOS_3Cu_3(4\text{-pic})_6]^+$ leading to formation and precipitation of the clusters $[MOS_3Cu_3(4\text{-pic})_6]\cdot[BF_4]$ (M = Mo **3**, W **4**) as expected (Scheme 1). To our surprise, the same does not take place in the reactions leading to the formation of clusters **1** and **2**. This is due to the fact that the expected target clusters $[MOS_3Cu_3(4\text{-pic})_6]\cdot Cl$ were not formed in the same way. These target clusters were to have been prepared to explore the relationship between the constituent components of the clusters and their NLO properties through comparing the isomorphous clusters with the same cationic cluster skeleton and different anions. Previous work has shown that large cations of appropriate size may combine with the anionic cluster skeletons through either charge-transfer or other non-bonding interactions.[17] In such a reaction system, the oxophilic Ca^{2+}, La^{3+}, and Nd^{3+} cations may be coordinated by the oxygen atoms of DMSO or DMF to form the larger bivalent and trivalent complex cations $[M(DMSO)_x]^{n+}$ or $[M(DMF)_x]^{n+}$ (M = Ca, La, Nd; x = 6, 8; n = 2, 3). These complex cations can induce the cluster anions in the solution to assemble into some special structural types of heterothiometallic clusters. In the present reaction systems involving clusters **1** and **2**, we assume that the crystallizing procedure, not being performed in an oxygen- and moisture-free environment, results in the transformation of excess $[MOS_3]^{2-}$ into $[M_2O_7]^{2-}$ (M = Mo, W) due to exposure to oxygen and atmospheric moisture. The polyoxometalate anion $[M_2O_7]^{2-}$, being larger than the Cl^- anion, is much more effective in precipitating the cationic cluster skeletons. Even



Scheme 1

if the clusters $[MOS_3Cu_3(4\text{-pic})_6]\cdot Cl$ have already formed, the small Cl^- anion can still be easily displaced by $[M_2O_7]^{2-}$. Since the polyoxometalate anion $[M_2O_7]^{2-}$ with the larger, more suitable size can stabilize an appropriately sized cation, the original cluster cations $[MOS_3Cu_3(4\text{-pic})_6]^+$ tend to combine with this large polyoxometalate anion $[M_2O_7]^{2-}$ by the assembly reaction in solution, finally crystallizing from the solution in the form of the interesting cluster skeleton with a cationic nest-shaped cluster skeleton and a polyoxometalate cluster anion (Scheme 2).



Scheme 2

Structural Description

The crystal structures of these clusters $[MOS_3Cu_3(4\text{-pic})_6]\cdot L$ (M = Mo, W; L = 0.5 M_2O_7, BF_4) reveal a nest-shaped cluster cation and a polyoxometalate cluster anion in the case of **1**, or a pseudo halogen group BF_4^- anion in the case of **4**. To the best of our knowledge, the nest-shaped clusters always adopt the configuration of a neutral skeleton, e.g. $[MOS_3Cu_3I(py)_5]$,[11b] or an anionic skeleton, e.g. $[Bu_4N]_2[MOS_3Cu_3BrCl_2]$[11a] or $[PPh_4]_2[MOS_3(CuCl)_3]$[18] (M = Mo, W). This is the first time that clusters such as **1**, with a cationic nest-shaped cluster skeleton and a polyoxometalate cluster anion, have been found for Mo/S/Cu(Ag) systems and they show a surprising difference in comparison with their nest-shaped cluster analogues. ORTEP plots of clusters **1** and **4** are shown in Figures 1 and 2. Selected

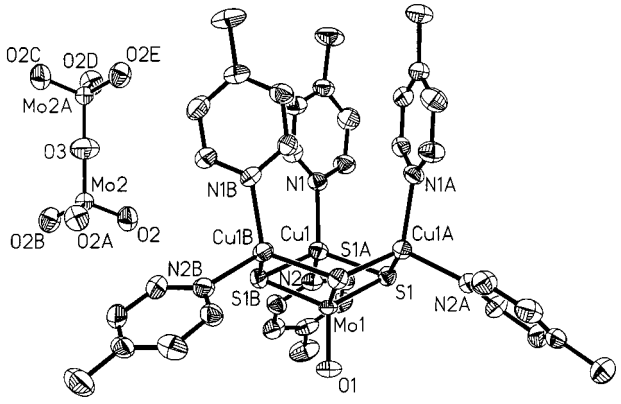


Figure 1. A perspective view of the structure of cluster $[MoOS_3Cu_3(4\text{-pic})_6]\cdot 0.5[Mo_2O_7]$ (**1**)

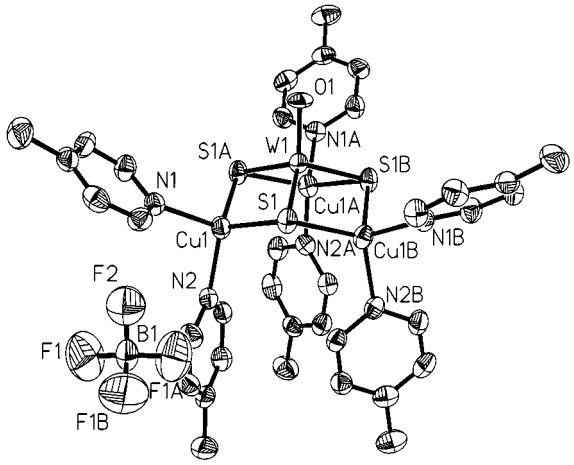

Figure 2. A perspective view of the structure of cluster $[WOS_3Cu_3(4\text{-pic})_6]\cdot[BF_4]$ (**4**)

bond lengths and angles are listed in Tables 1 and 2. Since the structures of the $[MOS_3Cu_3(4\text{-pic})_6]^+$ cation in clusters **1** and **4** are isomorphous, only the structure of cluster **1** is described in detail.

The cationic skeleton of **1**, with an $MoOS_3Cu_3$ aggregate, displays a nest-shaped structure. The central Mo atom is tetrahedrally coordinated by three S atoms and one O atom. The Mo(1)−O(1) bond length of 1.699(8) Å is characteristic of a double bond, while the three equivalent Mo−S bond lengths of 2.2692(17) Å are in the typical range for single bonds. Compared to the free $[MoOS_3]^{2-}$ ion, the $MoOS_3$ fragment adopts an ideal crystallographic C_3 symmetry at 0.3333, 0.3333, z axis through the Mo(1) atom and the O(1) atom, with three equal S−Mo−S bond angles [107.78(5)°]. In addition, weak interactions exist between the Mo atom and the three Cu atoms, while the Mo−Cu distances [2.6879(9) Å] in cluster **1** are slightly shorter than those in $[MoCu_3OS_3(PPh_3)_3\{S_2P(OBu)_2\}]$ [2.739(3) Å][19] and $[MoCu_3OS_3(PPh_3)_3(CH_3COO)]$ [2.710(1) Å].[20] The three Cu atoms exhibit the same coordination mode. Each adopts a distorted tetrahedral geometry and is coordinated by two μ_3-S atoms and two 4-pic ligands, forming three almost equivalent $CuS_2(4\text{-pic})_2$ units. These three $CuS_2(4\text{-pic})_2$ units are joined by a central Mo atom through three pairs of S−S edges, thereby forming the skeleton of the cation $[MOS_3Cu_3(4\text{-pic})_6]^+$. Since they have similar coordination environments, there is no obvious difference between Cu(1), Cu(1A), and Cu(1B). The Cu(1)−S(1) bond length [2.2777(19) Å] is almost identical to the Cu(1)−S(1)($-x + y + 1, -x + 3, z$) [2.2789(18) Å] and S(1)−Cu(1)($-y + 3, x - y + 2, z$) bond lengths [2.2789(18) Å], but the Cu(1)−N(1) distance [2.059(6) Å] is a little shorter than the Cu(1)−N(2) distance [2.107(6) Å]. On the other hand, the average Cu−S bond length [2.2785(18) Å] in cluster **1** is greater than that in its anionic analogue $[Bu_4N]_2[MoOS_3Cu_3BrCl_2]$ [2.238(3) Å] and is akin to that in its neutral analogue $[MoOS_3Cu_3I(py)_5]$ [2.288(5) Å]. This may be attributed to the fact that in cluster **1** and $[MoOS_3Cu_3I(py)_5]$ there is a strong super-conjugation effect in the pyridine

ring that may result in 4-pic or py showing a high tendency to coordinate to a Cu atom, while the coordination between the Cu atom and the S atoms is weakened accordingly.

The unexpected polyoxometalate dianion $[Mo_2O_7]^{2-}$ formed in the present case originated from the adventitious introduction of air during the crystallization period. The dianion possesses a strict crystallographic C_2 symmetry, in which two MoO_4 tetrahedra share a vertex. The two equivalent MoO_3 moieties in the $[Mo_2O_7]^{2-}$ anion are oriented essentially perpendicularly to their respective Mo(2)−O(3) bonds in an almost eclipsed arrangement. All three independent Mo(2)−O(2) bond lengths are equal [1.705(7) Å] and are slightly longer than the Mo(1)−O(1) bond lengths, this being characteristic of a double bond, while the Mo(2)−O(3) bond lengths [1.8557(13) Å] are in the typical range for single bonds. All six independent O(2)−Mo(2)−O(2)($-x + y - 1, -x + 1, z$) bond angles are the same [108.1(3)°] and are clearly smaller than the O(1)−Mo(1)−S(1) and O(2)−Mo(2)−O(3) bond angles. It is interesting and noteworthy that the O(1)−Mo(1)−S(1) [111.12(5)°] and O(2)−Mo(2)−O(3) [110.8(3)°] bond angles are in the same range, which may be attributed to the Mo(2)−O(3) bond length being typical of a single bond, like the Mo(1)−S single bond. It is also noteworthy that the $[Mo_2O_7]^{2-}$ anion shows a perfectly straight Mo−O−Mo axis in the present case with the Mo(2)−O(3)−Mo(2)($-x, -y + 2, -z$) bond angle being equal to 180.0°, which is clearly different from that described previously [Mo−O−Mo angle 153.6(5)°].[21]

Spectral Characterization

The IR spectra of the $[MOS_3Cu_3(4\text{-pic})_6]\cdot L$ clusters (M = Mo, W; L = 0.5 M_2O_7, BF_4) exhibit strong characteristic bands at 436 cm^{-1} (**1**), 428 cm^{-1} (**2**), 437 cm^{-1} (**3**), and 428 cm^{-1} (**4**) attributable to the μ_3-S stretching vibration, while very strong absorptions at 908 cm^{-1} (**1**), 925 cm^{-1} (**2**), 910 cm^{-1} (**3**), and 924 cm^{-1} (**4**) can be attributed to the characteristic $\nu(M-O_t)$ vibration of the bridging MOS_3 group. In addition, due to the presence of $[M_2O_7]^{2-}$ anions, the absorption at 885 cm^{-1} (**1**) and 865 cm^{-1} (**2**) in the IR region may correspond to the stretching vibration of M−O double bonds in $[M_2O_7]^{2-}$ anions (M = Mo, W).

The similarity in the structures of these clusters leads to similar electronic spectra, as shown in Figure 3. The red shifts in the spectra of clusters **1** and **3** are expected, since these species contain one Mo atom instead of one W atom. The first absorption peaks of these four clusters located at 424 nm ($3.8\cdot10^3$ $cm^{-1}\cdot mol^{-1}\cdot dm^3$) (**1**), 392 nm ($6.1\cdot10^3$ $cm^{-1}\cdot mol^{-1}\cdot dm^3$) (**2**) and 407 nm ($3.1\cdot10^3$ $cm^{-1}\cdot mol^{-1}\cdot dm^3$) (**3**), 376 nm ($3.9\cdot10^3$ $cm^{-1}\cdot mol^{-1}\cdot dm^3$) (**4**) can be assigned to charge-transfer bands of the type $(\pi)S\rightarrow(d)M$ (M = Mo, W) arising from the MOS_3 moiety. The charge-transfer bands of **1** and **3** are blue-shifted, while those of **2** and **4** are red-shifted compared to those of the free $[MOS_3]^{2-}$ anion (459 nm for Mo and 375 nm for W,

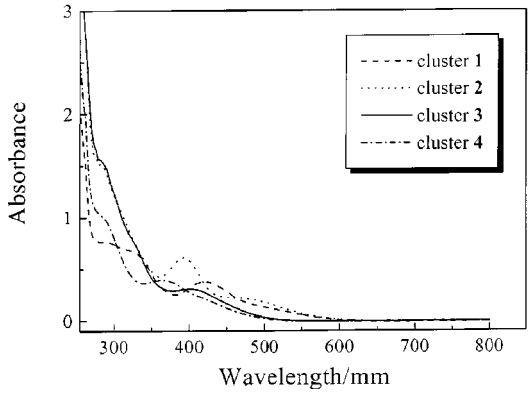

Figure 3. Electronic spectra of $1.0\cdot10^{-4}$ mol·dm^{-3} MeCN solutions of clusters **1**−**4** with an optical pathlength of 1 cm

respectively).[22] The electronic spectra of these four clusters show relatively low linear absorption in the visible and near-infrared regions, promising low intensity loss, and little temperature change caused by photon absorption when pulsed light propagates in the materials, showing that the clusters have potential as optical limiters.

Nonlinear Optical Properties

The third-order nonlinear optical (NLO) properties and the optical limiting (OL) performances of clusters **1**−**4** in MeCN solution were investigated with an 8-ns duration incident pulsed laser at 532 nm. The nonlinear absorption components of clusters **1**−**4** were evaluated by *Z*-scan experiments with an open-aperture configuration (Figure 4). The NLO absorption data obtained under the conditions used in this study can be adequately described by Equations (1) and (2),[23] which describe a third-order NLO absorptive process:

$$T(Z)=\frac{1}{\sqrt{\pi}\,q(Z)}\int_{-\infty}^{+\infty}\ln[1+q(Z)e^{-\tau^2}]\,d\tau \qquad (1)$$

$$q(Z)=\int_{0}^{+\infty}\int_{0}^{+\infty}\alpha_2\frac{I_0}{1+(Z/Z_0)^2}e^{[-2(r/\varpi_0)^2-(t/t_0)^2]}\;\frac{1-e^{-\alpha_0 L}}{\alpha_0}r\,dr\,dt \qquad (2)$$

Here, α_0 and α_2 are linear and effective third-order NLO absorptive coefficients, light transmittance T is a function of the sample's Z-position (with respect to focal point Z = 0), Z is the distance of the sample from the focal point, L is the sample thickness, I_0 is the peak irradiation intensity at focus, $Z_0 = \pi\omega_0^2/\lambda$, where ω_0 is the spot radius of the laser pulse at focus and λ is the laser wavelength, r is the radial coordinate, t is the time, and t_0 is the pulse width.

The nonlinear refractive properties of clusters **1**−**4** were assessed by dividing the normalized Z-scan data obtained under the closed-aperture configuration by the normalized Z-scan data obtained under the open-aperture configuration (Figure 5). An effective third-order nonlinear refractive index n_2 can be derived from the difference between normalized transmittance values at valley and peak positions ($\Delta T_{v\text{-}p}$) using Equation (3), where I is the incident pulsed light intensity.[24]

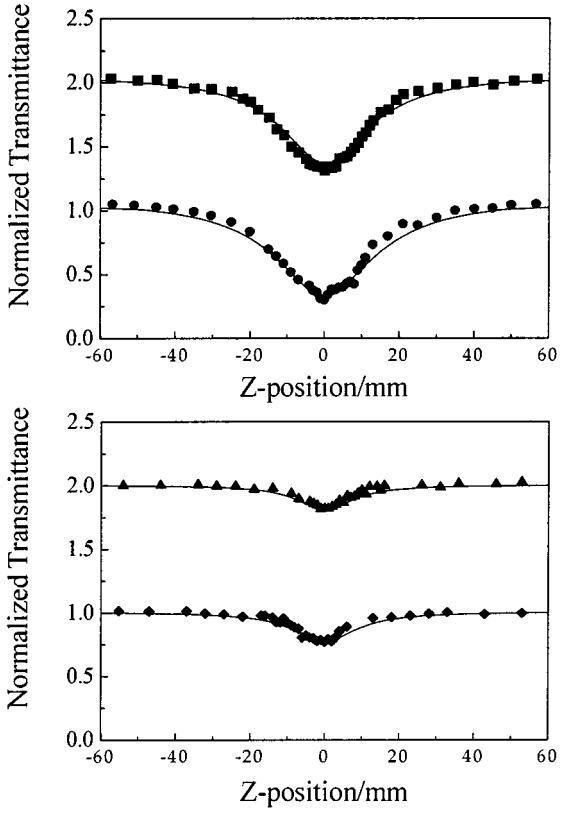

Figure 4. Open-aperture *Z*-scan data of clusters **1** (filled squares), **2** (filled circles), **3** (filled triangles), and **4** (filled diamonds) in MeCN solution at 532 nm with 8 ns wide laser pulses; the solid curves are the theoretical fits based on *Z*-scan theoretical calculations; the *Z*-scan data of both **1** and **3** have been shifted vertically by 1 unit for presentation purposes

$$n_2=\frac{\lambda\alpha_0}{0.812\,\pi I(1-e^{-\alpha_0 L})}\Delta T_{V-P} \qquad (3)$$

Based on our previous time-resolved nonlinear transmission studies[14a] and the NLO experimental results reported here, we can reasonably conclude that the physical origin of the observed reverse saturable absorption (RSA) in clusters **1**−**4** can be attributed to excited-state absorptive nonlinearities. Figures 4 and 5 show the typical NLO absorptive and refractive effects, respectively, of clusters **1**−**4**, in which the filled squares **1**, circles **2**, triangles **3**, and diamonds **4** represent the experimental data from the *Z*-scan measurements, while the solid lines represent the theoretical fitting on the basis of Equations (1)−(3) to the experimental data. A reasonably good fit between the experimental data and theoretical curves was obtained, which suggests that the experimentally obtained NLO effects are effectively third-order in nature. The effective α_2 values of $1.1\cdot10^{-9}$ m·W^{-1} (**1**), $1.2\cdot10^{-9}$ m·W^{-1} (**2**), $5.8\cdot10^{-10}$ m·W^{-1} (**3**), $6.3\cdot10^{-10}$ m·W^{-1} (**4**), and n_2 values of $1.22\cdot10^{-8}$ esu (esu = $7.162\cdot10^{13}$ m^5·v^{-2}) (**1**), $7.18\cdot10^{-9}$ esu (**2**), $6.52\cdot10^{-9}$ esu (**3**), and $5.93\cdot10^{-10}$ esu (**4**), were derived for the samples from

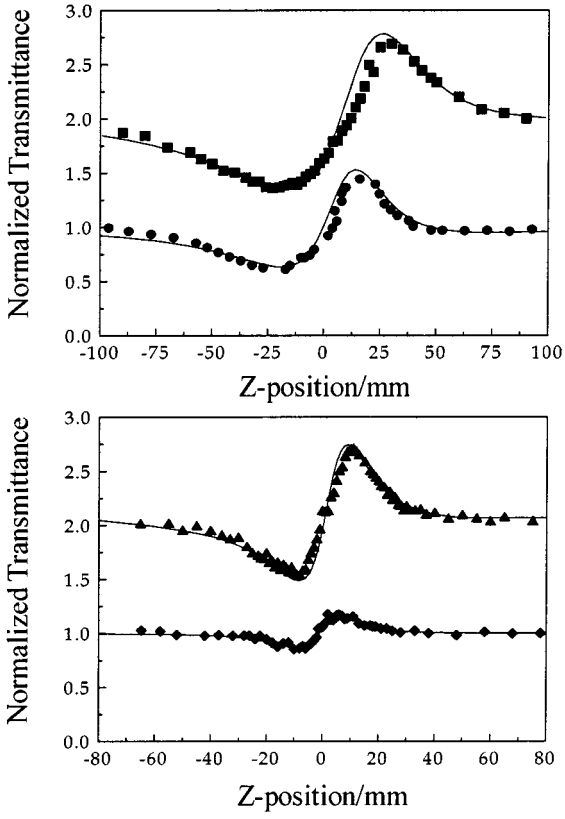

Figure 5. Closed-aperture *Z*-scan data of clusters **1** (filled squares), **2** (filled circles), **3** (filled triangles), and **4** (filled diamonds) in MeCN solution at 532 nm with 8 ns wide laser pulses; the solid curves are the theoretical fits based on *Z*-scan theoretical calculations; the *Z*-scan data of both **1** and **3** have been shifted vertically by 1 unit for presentation purposes

their respective theoretical curves. In accordance with the observed α_2 and n_2 values, the modulus of the effective third-order susceptibility $\chi^{(3)}$ can be calculated by Equation (4).[23a]

$$|\chi^{(3)}| = \sqrt{\left(\left|\frac{9\times10^{8}\varepsilon_0 n_0^2 c^2}{2\nu}\alpha_2\right|^2 + \left|\frac{cn_0^2}{80\pi}n_2\right|^2\right)} \quad (4)$$

Here, ν is frequency of the laser light, n_0 is the linear refractive index of the sample, and ε_0 and c are the permittivity and the speed of light in a vacuum, respectively. For $3.52\cdot10^{-4}$ (**1**), $2.67\cdot10^{-4}$ (**2**), $4.82\cdot10^{-4}$ (**3**), and $3.75\cdot10^{-4}$ mol·dm^{-3} (**4**) MeCN solutions, the $\chi^{(3)}$ values were calculated to be $8.7\cdot10^{-10}$ (**1**), $9.3\cdot10^{-10}$ (**2**), $2.6\cdot10^{-10}$ (**3**), and $3.1\cdot10^{-10}$ esu (**4**). The corresponding moduli of the hyperpolarizabilities γ of $1.32\cdot10^{-30}$ esu (**1**) and $1.87\cdot10^{-30}$ esu (**2**), $2.89\cdot10^{-31}$ esu (**3**) and $4.43\cdot10^{-31}$ esu (**4**), were separately obtained from $\chi^{(3)} = \gamma\cdot NF^4$, where N is the number density (concentration) of the clusters in the samples and $F^4 = 3.1$ is the local field correction factor.

From the above discussions, we can reasonably state that clusters **1**−**4** exhibit similar NLO properties. All exhibit strong RSA and effective self-focusing performances, as depicted in Figures 4 and 5. In the light of the aforementioned nonlinear absorptive and refractive experimental data, an obvious skeleton atom effect on the nonlinear optical properties was observed. For clusters **1**, **2** and **3**, **4**, a significant improvement in the NLO absorptive effects was observed on going from Mo-containing cluster **1** to W-containing cluster **2**, and from cluster **3** to cluster **4**, respectively, i.e. with increasing size of metal atom; this is indicative of a heavy atom effect. On the other hand, although the clusters **1**−**4** possess the same cationic cluster skeleton, their different anions, especially the polyoxometalate anions in clusters **1** and **2**, result in stronger nonlinear absorptive performances and larger $\chi^{(3)}$ values being observed for clusters **1** and **2** as compared to those of clusters **3** and **4**, which demonstrates the evident skeleton influence on the NLO properties of clusters **1**−**4**.

The presence of the combined effects of strong RSA and self-focusing in clusters **1**−**4** may significantly enhance the overall optical limiting (OL) performance of these four clusters. The optical limiting effects of clusters **1**−**4** are depicted in Figure 6. The linear and nonlinear transmission data (open triangles for **1**, filled squares for **2**, open circles for **3**, and filled diamonds for **4**) were measured with 532 nm laser pulses of 8-ns duration at cluster concentrations of $3.52\cdot10^{-4}$ (**1**), $2.67\cdot10^{-4}$ (**2**), $4.82\cdot10^{-4}$ (**3**), and $3.75\cdot10^{-4}$ mol·dm^{-3} (**4**) in MeCN solution. Figure 6 shows how the transmittances of the cluster sample solutions decrease as the laser fluence increases, and how the solution becomes increasingly less transparent as the incident fluence rises, characterizing the typical optical limiting effects. Experiments using neat MeCN solvent gave no detectable OL effect. This indicates that solvent contributions are negligible. The values of the limiting threshold, which is defined as the incident fluence at which the actual transmittance falls to 50% of the corresponding linear transmittance, were measured as 0.26 J·cm^{-2} (**1**), 0.20 J·cm^{-2} (**2**), 0.45 J·cm^{-2} (**3**), and 0.34 J·cm^{-2} (**4**), with the same linear transmittance of 72% in each case.

Table 3 lists the heterothiometallic clusters presented here and investigated previously, together with their limiting thresholds, along with data for some other frequently mentioned OL materials. From the perspective of the OL application, the present four clusters having a nest-shaped skeleton are clearly better than the known good optical limiting materials fullerene C_{60}[6b] and cubane-like shaped clusters,[2a,8] while their limiting thresholds are greater than those of phthalocyanine derivatives,[7b] the hexagonal prism-shaped cluster $[Mo_2Ag_4S_8(PPh_3)_4]$,[10b] and some pentanuclear planar "open" shaped clusters $[MS_4Cu_4L_2(py)_6]$,[14] which are among the best optical limiting materials reported to date. Comparison of clusters **1**, **2** and clusters **3**, **4** allows a comparison of Mo- and W-containing systems. The W-containing clusters always seem able to outperform their corresponding Mo-containing counterparts in OL performance at a given wavelength and with similar linear transmittance, just as in this report where the OL effect of **2** is superior to that of **1**, while **4** is better than **3**. This is consistent with the fact that the OL effects of Ag-containing clusters are better than those of their Cu-containing homologues, which may be due to the

Table 3. The limiting thresholds of some OL materials measured at 532 nm with ns laser pulses

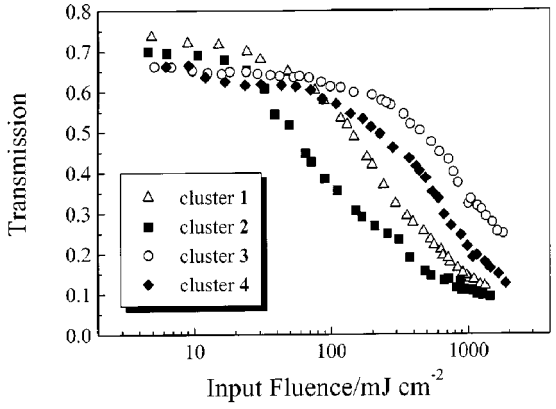

Figure 6. The 8 ns optical limiting effects of clusters **1**–**4** in MeCN solution; the energy transmission is plotted *vs.* the input fluence

heavy-atom effect. The importance of the heavy atom effect with regard to the efficiency of nonlinear absorption and the OL capabilities has already been noted in the case of the metallophthalocyanine system.[7b,25] Moreover, the OL behavior of cluster **1** is greater than that of cluster **3** and the limiting threshold of **2** is superior to that of **4**, which suggests a cluster skeleton effect on their NLO and OL properties. It has been proven that both the cluster skeletons and the heavy atoms are responsible for the NLO effects of the heterothiometallic clusters,[14a] although which one plays a more active and important role in their NLO performances is still not very clear. It currently represents a great challenge and considerable efforts still need to be made to further explore this promising field of research.

Experimental Section

General: All reactions and manipulations were conducted using standard Schlenk techniques under an atmosphere of nitrogen unless specifically mentioned. The compounds $(NH_4)_2[MOS_3]$ (M = Mo, W) were prepared according to the literature.[22] Likewise, the complex $[Cu(MeCN)_4]\cdot[BF_4]$ was synthesized based on a literature procedure.[26] The solvents were carefully dried and distilled prior to use; other chemicals were generally used as received from commercial sources. – Elemental analyses for carbon, hydrogen, and nitrogen were performed on a Perkin–Elmer 240C elemental analyzer. – Infrared spectra were recorded with a Nicolet FT-170SX Fourier transform spectrometer (KBr pellets). – Electronic spectra were measured on a Shimadzu UV-3100 spectrophotometer.

$[MoOS_3Cu_3(4\text{-pic})_6]\cdot 0.5[Mo_2O_7]$ (1): CuCl (0.297 g, 3 mmol) was added to 4-picoline (20 mL) and the solution was stirred for ca. 5 min at room temperature. Then, $(NH_4)_2MoOS_3$ (0.293 g, 1.2 mmol) was added. The reaction mixture immediately turned black-red. After stirring for a further 10 min, the solution was filtered to afford a black-red filtrate. Black-red crystals (0.132 g, 19.8%) were obtained after several days by layering the filtrate with *i*PrOH in air. – $C_{36}H_{42}Cu_3Mo_2N_6O_{4.5}S_3$ (1109.5): calcd. C 39.0, H 3.8, N 7.6; found C 38.7, H 3.9, N 7.8. – UV/vis (MeCN, λ_{max}/nm, 10^3 ε/cm$^{-1}\cdot$mol$^{-1}\cdot$dm^3): 424 (3.8), 326 (6.8), 290 (7.7). – IR (KBr pellets): $\tilde{\nu}$ = 1615 (vs), 1421 (s), 908 (vs), 885 (s), 813 (vs), 492 (vs), 436 (vs).

$[WOS_3Cu_3(4\text{-pic})_6]\cdot 0.5[W_2O_7]$ (2): Cluster **2** was synthesized following the same procedure as used in the preparation of cluster **1**, except that $(NH_4)_2WOS_3$ (0.398 g, 1.2 mmol) was used instead of $(NH_4)_2MoOS_3$ (1.2 mmol). Orange-red crystals (0.143 g, 18.5%) were obtained. − $C_{36}H_{42}Cu_3N_6O_{4.5}S_3W_2$ (1285.3): calcd. C 33.6, H 3.3, N 6.5; found C 34.0, H 3.5, N 6.8. − UV/vis (MeCN, λ_{max}/nm, 10^3 ε/cm^{-1}·mol^{-1}·dm^3): 392 (6.1), 283 (15.2). − IR (KBr pellets): $\tilde{\nu}$ = 1615 (vs), 1423 (s), 925 (vs), 865 (s), 813 (vs), 492 (vs), 428 (vs).

$[MoOS_3Cu_3(4\text{-pic})_6]\cdot[BF_4]$ (3): $Cu(MeCN)_4BF_4$ (0.944 g, 3 mmol) was added to 4-picoline (20 mL) and the solution was stirred for ca. 5 min at room temperature. Then, $(NH_4)_2MoOS_3$ (0.244 g, 1 mmol) was added. The reaction mixture immediately turned deep-red. After stirring for a further 10 min, the solution was filtered to afford a deep-red filtrate. Deep-red crystals (0.818 g, 78.3%) were obtained after several days by layering the filtrate with *i*PrOH. − $C_{36}H_{42}BCu_3F_4MoN_6OS_3$ (1044.3): calcd. C 41.4, H 4.1, N 8.1; found C 41.6, H 4.3, N 8.2. − UV/vis (MeCN, λ_{max}/nm, 10^3 ε/cm^{-1}·mol^{-1}·dm^3): 407 (3.1), 281 (15.8). − IR (KBr pellets): $\tilde{\nu}$ = 1614 (vs), 1420 (s), 910 (vs), 813 (vs), 492 (vs), 437 (vs).

$[WOS_3Cu_3(4\text{-pic})_6]\cdot[BF_4]$ (4): Cluster **4** was synthesized following the same procedure as used in the preparation of cluster **3**, except that $(NH_4)_2WOS_3$ (0.332 g, 1 mmol) was used instead of $(NH_4)_2MoOS_3$ (1 mmol). Orange-red crystals (0.965 g, 85.2%) were obtained. − $C_{36}H_{42}BCu_3F_4N_6OS_3W$ (1132.2): calcd. C 38.2, H 3.8, N 7.4; found C 38.3, H 3.9, N 7.5. − UV/vis (MeCN, λ_{max}/nm, 10^3 ε/cm^{-1}·mol^{-1}·dm^3): 376 (3.9), 284 (10.7). − IR (KBr pellets): $\tilde{\nu}$ = 1614 (vs), 1420 (s), 924 (vs), 813 (vs), 492 (vs), 428 (vs).

Crystal Structure Determinations: Well-shaped single crystals of clusters **1** and **4** of suitable dimensions were selected and mounted on glass fibers. The diffraction data for **1** were collected on a Siemens Smart CCD area-detector diffractometer using the ω-scan technique. The data reductions for **1** were performed on a Silicon Graphics Indy workstation using Smart-CCD software. The diffraction data for **4** were collected on an Enraf−Nonius CAD4 four-circle diffractometer with unit-cell parameters determined from the automatic centering of 25 reflections by the least-squares method. Intensities were corrected for Lorentz polarization effects and an absorption correction was applied using the ψ-scan technique. The structures of both **1** and **4** were solved by direct methods and refined by full-matrix least-squares against F^2 using the SHELXL-97 programs.[27] All non-hydrogen atoms were refined anisotropically by the full-matrix least-squares method. The hydrogen atoms were placed in their calculated positions, assigned fixed isotropic thermal parameters, and allowed to ride on their respective parent atoms. The data processing and structure refinement parameters are listed in Table 4.

Crystallographic data (excluding structure factors) for the cluster structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-164299 (cluster **1**) and CCDC-164300 (cluster **4**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Optical Measurements: A solution of the respective cluster **1**−**4** in MeCN was placed in a 5-mm quartz cuvette for optical limiting

property measurements, which were performed with linearly polarized 8-ns pulses at $\lambda = 532$ nm generated from a Q-switched frequency-doubled Nd:YAG laser. The clusters **1**−**4** proved to be stable towards air and laser light under the experimental conditions. The spatial profiles of the optical pulses were of near-Gaussian transverse mode. The pulsed laser was focused onto the sample cell using a mirror of focal length 30 cm. The spot radius of the laser beam was measured as 55 μm (half-width at $1/e^2$ maximum). The energy of the input and output pulses was measured simultaneously by precision laser detectors (Rjp-735 energy probes), which were linked to a computer through an IEEE interface,[28] while the incident pulse energy was varied by a Newport Com. attenuator. The interval between the laser pulses was chosen as 1 s to avoid the influence of thermal and long-term effects.

The third-order NLO absorptive and refractive properties of clusters **1**−**4** were determined by performing *Z*-scan measurements.[23a] The samples were mounted on a translation stage that was controlled by computer to move along the axis of the incident laser beam (*Z*-direction) with respect to the focal point rather than being positioned at its focal point. To determine both the sign and magnitude of the nonlinear refraction, a 0.2 mm diameter aperture was placed in front of the transmission detector and the transmittance was recorded as a function of the sample position on the *Z* axis (closed-aperture *Z*-scan). To determine the nonlinear absorption, the *Z*-dependent sample transmittance was measured without the aperture (open-aperture *Z*-scan).

Reactions of Secondary Dithioxamides with $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-}Cl)]_2$: The Role of Steric Hindrance on Amidic Nitrogen in Determining the Reaction Products

Santo Lanza,*[a] Giuseppe Bruno,[a] Francesco Nicolò,[a] Archimede Rotondo,[a] and Giuseppe Tresoldi[a]

Keywords: N ligands / Bimetallic complexes / Ruthenium / Ion pairs / Chiral auxiliaries

The reactions of secondary dithioxamides H_2R_2DTO **1**–**11** [R = methyl **1**, ethyl **2**, *n*-propyl **3**, *n*-butyl **4**, isoamyl **5**, benzyl **6**, *p*-tolyl **7**, (*R*)-1-phenylethyl **8**, (*R*,*S*)-1-phenylethyl **9**, isopropyl **10**, cyclohexyl **11**] with the chloride-bridge dimer $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-}Cl)]_2$ complex readily afforded either bimetallic ruthenium complexes of formula $[(\eta^6\text{-}p\text{-cymene})RuCl_2](\mu\text{-}R_2DTO)$ (R = methyl **12a**, R = ethyl, **12b**, R = *n*-propyl **12c**; R = *n*-butyl **12d**; R = isoamyl **12e**; R = benzyl **12f**; R = *p*-tolyl **12g**) or mononuclear "piano stool" geometry ion pairs $\{(\eta^6\text{-}p\text{-cymene})RuCl(H_2R_2DTO)^+,(Cl^-)$ κ-*S*,*S*′ Ru} [R = (*R*)-1-phenylethyl, **13a**; R = (*R*,*S*)-1-phenylethyl, **13b**; R = isopropyl, **13c**; R = cyclohexyl, **13d**]. The driving force of the reactions was the bulkiness of the R groups attached to dithioxamides, leading respectively from primary and aromatic *N*-bonded carbons to neutral bimetallic species **12a**–**g**, or from secondary *N*-bonded carbons to monometallic **13a**–**d** species. These latter compounds could be easily dehydrohalogenated to give neutral "piano stool" complexes $[(\eta^6\text{-}p\text{-cymene})RuCl(HR_2DTO)$ κ-*S*,*S*′ Ru] [R = (*R*)-1-phenylethyl **14a**; R = (*R*,*S*)-1-phenylethyl **14b**; R = isopropyl **14c**; R = cyclohexyl **14d**]. All complexes were characterised in solution by ^1H and $^{13}C\{^1H\}$ NMR spectroscopy. Complex **12f** was also characterised by mass spectrometry, and **12g** by solid state X-ray crystallography.

Introduction

Dimeric $[(\eta^6\text{-arene})RuCl(\mu\text{-}Cl)]_2$ species provide an ideal way of entering the synthesis of η^6-monoarene "three legged piano stool" ruthenium complexes, where the η^6-coordinated arene are the "bench", and the other ligands "the legs" of the stool.[1] However, when the $[(\eta^6\text{-arene})RuCl(\mu\text{-}Cl)]_2$ chloride-bridge dimers are reacted under particular experimental conditions with binucleating chelate ligands, binuclear complexes of the type $[(\mu\text{-L-L})\{RuCl_2(\eta^6\text{-arene})\}_2]$ can be also obtained.[2] Mononuclear η^6-arene ruthenium complexes revealed themselves as effective enantioselective catalysts in a number of asymmetric organic transformations when ruthenium is itself presented as a stereogenic centre or ligands are chiral species such as BINAP[3] or aminophosphanyl-phosphinite.[4]

We have previously reported that the platinum complexes [Pt(PN)Cl(HR_2DTO) κ-*S*,*S*′ Pt] (PN = 2-diphenylphosphanyl-pyridine. HR_2DTO^- = alkyl-substituted dithioxamidato) react with the ruthenium dimer $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-}Cl)]_2$ giving rise to heterobimetallic "piano stool" ruthenium complexes:[5]

In complex **I** (Figure 1), the ruthenium is a stereogenic centre since the three legs of the stool are different. The stereochemistry of **I** remains ambiguous if one considers only the configuration of the ruthenium centre; thus, we have proposed that the best way to describe the asymmetry of **I** is to consider the Ru−Pt axis as an unprecedented element of chirality. As a matter of fact, the reactivity of [Pt(PN)Cl(HR_2DTO) κ-*S*,*S*′ Pt] type compounds opens the way to a new class of organometallic complexes. When these square planar complexes containing *S*,*S*′-coordinated

dithioxamides are forced to chelate by the unusual *N,N′*-coordination mode with a second prochiral metal fragment such as $[Ru(\eta^6\text{-}p\text{-cymene})Cl]^+$, new binuclear species exhibiting very interesting stereochemical features are formed. Starting from this point, we found it interesting to see how un-coordinated secondary dithioxamides react with the ruthenium dimer $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-}Cl)]_2$. The coordination chemistry of secondary dithioxamides ligands is very rich; the multi-site donor nature of the two nitrogen and two sulfur atoms, their respective hard and soft character, the possibility of modulating electronic and geometrical properties by loss of one or two protons, and finally, the dicompartmental rigid structure of the dianionic rubeanate ligand have been largely exploited to form complexes of different coordination type, geometries, and nuclearity.[6] The organometallic chemistry of these ligands, on the contrary, has hitherto been rather unexplored: only one report has appeared in the last few years,[7] even though the alkyl groups of secondary dithioxamides could be usefully exploited as molecular probes or as electronic, steric, and enantioselective tools for modelling peculiar properties of the molecules.

The present paper stems from a systematic study devoted to the synthesis of η^6-arene-ruthenium(II) complexes containing dithioxamides: the aim of the research is to investigate the stereochemical effect of R groups in [RHNSC−CSNHR] or [RHNSC−CSNHR′] molecules in determining the possible stereoselective synthesis of half-sandwich molecules like **I**. In the following we report results concerning the reactions $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-}Cl)]_2$ with a series of disubstituted dithioxamides bearing alkyl substituents of varying molecular complexity.

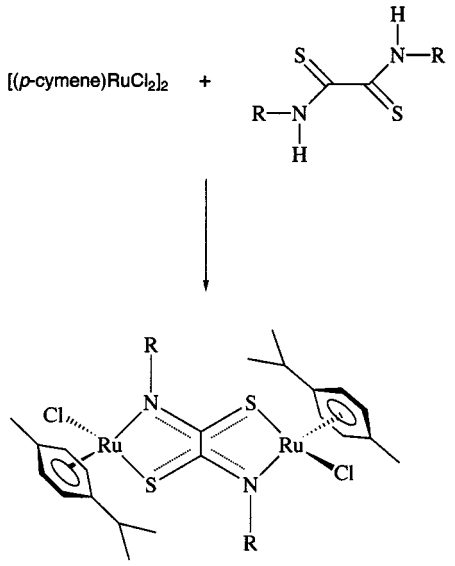
Results and Discussion

Structurally, the ligands [RHNSC−CSNHR] used in the present study can be divided into three families, according to the nature of the carbon bonded to the amidic nitrogens: i) primary [R = methyl (**1**), ethyl (**2**), *n*-propyl (**3**), *n*-butyl (**4**), isoamyl (**5**), and benzyl (**6**); ii) aromatic [*p*-tolyl (**7**)]; and iii) secondary [(*R*)-1-phenylethyl (**8**), (*R*,*S*)-1-phenylethyl (**9**), isopropyl (**10**), and cyclohexyl (**11**)].

The reactions of ligands **1**−**7** with $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-}Cl)]_2$ in chloroform lead to the bimetallic complexes **12a**−**g** in high yields (Scheme 1).

In these compounds the two ruthenium atoms are connected by a dianionic rubeanate frame in an NS−NS binucleating mode, which is the usual coordination mode observed in many other inorganic bi- and polymetallic complexes.[8]

^{1}H NMR spectra of compounds **12a**−**g** show cymene ring protons as four doublets and methyl groups of the isopropyl moiety of cymene as two doublets. $^{13}C\{^1H\}$ NMR spectra, in turn, show four resonances corresponding to CH carbons of cymene ring, and two featuring cymene isopropyl CH_3 carbons (see Exp. Sect.). These spectral patterns are observed since ruthenium atoms are stereogenic, hence



Scheme 1. Reactions of $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-}Cl)]_2$ with the ligands **1**−**7**

the plane perpendicular to the *p*-cymene and passing through the quaternary phenyl carbons C^1 and C^4 is not a symmetry plane. Consequently, the methyl protons of the isopropyl group and the aromatic protons (H^2 and H^6) in the *ortho* position with respect to the same group, as well as H^3 and H^5, are diastereotopic. At the same time NCH_2−R protons in **12a**−**g** are diastereotopic, and appear in the ^{1}H NMR spectra as an ABC_n (n = 0, 1, 2, 3) spin systems. As explained previously, pseudo-octahedral ruthenium atoms are both stereogenic since they are surrounded by four different ligands, hence two diastereomers could have been formed in which the two ruthenium atoms could have equal or opposite configurations. However, we have observed that the reaction is totally diastereoselective and an X ray analysis of **12f** (Figure 2 and Table 1) revealed that only the compound with ruthenium atoms in the opposite configuration is formed.

Compounds **12a**−**g** are highly symmetric *meso* molecules, due to the presence of a centre of inversion in the middle of the central C−C bond of the rubeanate frame. We attempted to destroy this centre of inversion by three distinct strategies: i) metathesis of one of the two chlorides on ruthenium atoms; ii) use of a dithioxamide bearing an optically pure substituent on nitrogens; iii) use of an unsymmetrically disubstituted dithioxamide. This latter procedure is under investigation, since some additional problems concerning stereoselectivity arose that are not yet fully understood. As far as the metathesis of the chloride ligand, our attempt to change only one chloride with iodide failed. Consequently, we have used the enantiopure homochiral dithioxamide **8** to get into asymmetric ruthenium dimers of the type **12a**−**g** by depletion of the inversion centre. This ligand however, as well as **9**−**11**, undergoes a different reaction leading to the monomeric "piano stool" type complexes **13a**−**d** (Scheme 2).

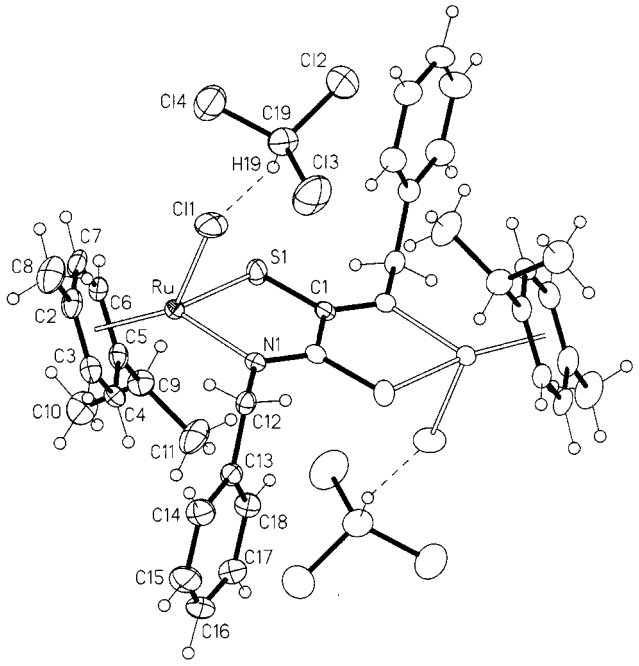


Figure 2. View of the whole molecule of **12f·2CHCl₃** at a crystallographic inversion centre, showing the labelling scheme of its half independent moiety. Thermal ellipsoids are drown at 30% probability, while hydrogen size is arbitrary

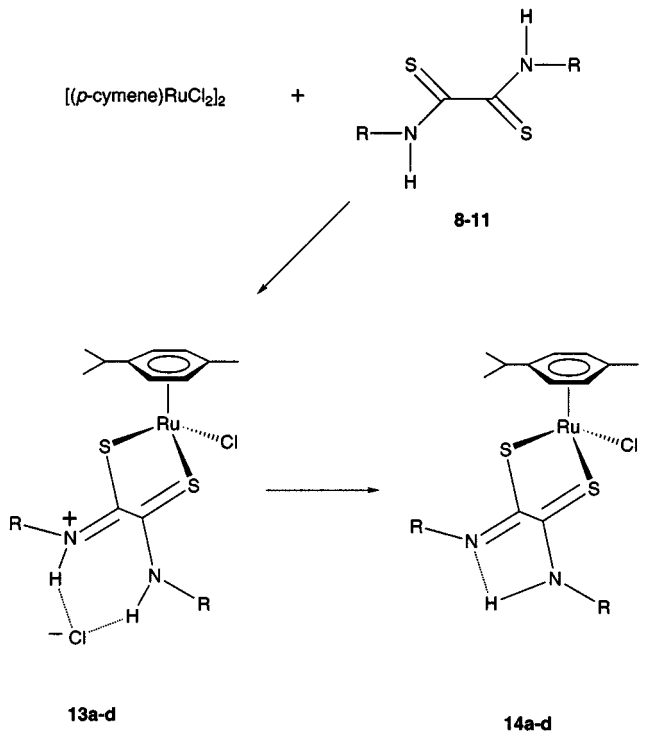

Scheme 2. Reactions of [(η⁶-*p*-cymene)RuCl(μ-Cl)]₂ with the ligands **8−11**

The N−H proton resonances at δ ≈ 13 in **13a−d** suggest that amidic nitrogens are engaged in an =N−H···Cl⁻···H−N= interaction.[6] This proves that the dithioxamide molecules are linked to ruthenium through sulfur atoms. Considering this and the absence of structural data, the geometry of **13a−d** compounds seems to be defined. Mass spectrum of **13a** shows a low intensity but significant peak at M^+ = 634, characterised by the usual ruthenium isotopomers pattern. More intense peaks observed in the spectrum are attributable to HCl, *p*-cymene, and 1-phenylethyldithioxamide. Compounds **13a−d** are tight contact ion pairs, extensively associated (Beer's law holds in the range 5 × 10^{-5} to 6 × 10^{-6} M), in which the steric repulsion between amidic hydrogens requires a torsion angle between the two NCS moieties in the neutral dithioxamide ligand. In fact, the co-planarity of the thioamide groups in an *S*,*S*′-coordinated neutral disubstituted dithioxamide would require a nonbonded H···H distance of ca. 1.4 Å between the amide protons. It may be emphasised that extremely short nonbonded H···H distances have been reported in the range 1.71−1.74 Å.[9]

A series of crystal structures performed on different metal complexes (copper, zinc, bismuth, and tin) containing neutral dithioxamides coordinated in the *S*,*S*′-mode, and having different geometrical environments (square-planar, tetrahedral, octahedral, bipyramidal) have appeared in the literature.[10] In all of them, in the solid state, a torsion angle between the two NCS fragments of about 40° was measured, which, being independent from both the metal and its geometrical environment, can be taken as a characteristic of any neutral *S*,*S*′-coordinated dithioxamides. In spite of

their chemical unequivalence, only one set of NMR signals for the dithioxamide alkyl groups of **13a−d** has been observed; as previously suggested, in the NMR time scale, fast HCl-mediated exchange should be responsible for the alkyl averaging.[11] Compounds **13a−d** can be easily dehydrohalogenated to give neutral rubeanate complexes **14a−d** in a pure form, by means of double phase reaction on a chromatographic column (see Exp. Sect.). HCl can also be removed from **13a−d** ion pairs by means of classical Brønsted bases such as alkylamines, and can be easily added to **14a−d** neutral complexes to restore the ion pairs **13a−d**. This easy and reversible protonation further supports *S*,*S*′ coordination in **14a−d**, as well as in **13a−d**. Complexes **13a** and **14a** are optically pure chiral molecules of C_1 symmetry; therefore in these species, RNCS fragments are diastereotopic, and accordingly two sets of signals appear in the NMR spectra. These complexes present optically pure chiral chelate ligands bonded to the metal by sulfur atoms. It is worth mentioning that in recent years new chiral auxiliaries appearing in the literature have attracted increasing interest and have found applications in synthetic organic chemistry.[12] Several different chiral chelates including diphosphane,[13] diamine,[14] diimine,[15] dithiol ligands,[16] and "mixed" chelates, e.g., S−N[17,18] and P−N[18] combinations, have been incorporated into the catalyst precursors and successfully employed in enantioselective synthesis (up to 90% enantiomeric excess often reported).

Compounds **13b** and **14b** were obtained from a dithioxamide, prepared by racemic phenylethylamine; the diastereoisomeric mixture was not separated, but characterised in solution by NMR spectra subtraction procedure. The reaction of $[(\eta^6\text{-arene})RuCl(\mu\text{-}Cl)]_2$ with **9** produces a mixture containing 50% of the racemate (*R*,*R*) and (*S*,*S*) and 50% of the two (*R*,*S*) and (*S*,*R*) *meso* forms. The NMR spectra of the (*R*,*R*) and (*S*,*S*) racemate is of course equal to that of the optical pure (*R*,*R*) enantiomer **13a**; thus by subtraction of the **13a** spectrum from that of the mixture, the spectrum of the two **13b** *meso* forms of C_s symmetry can be obtained. The diastereoisomers **13b** give rise to perfectly superimposable ^1H and ^{13}C NMR spectra which, owing to the internal reflection plane, show a single set of NMR signals; the two *meso* forms depict an interesting example of stereogenic achirotopic ruthenium centre.[19]

The different reactivity towards ruthenium(*p*-cymene)dichloro dimer of benzyl dithioxamide with respect to 1-phenylethyldithioxamide is rather surprising: a striking change in the reaction products and in the coordination mode of the ligands follows a small change in the molecular complexity of R substituents on nitrogen. This probably means that the *N*,S binucleation is a more favourable coordination mode of dithioxamide ligands towards the organoruthenium fragment $[(arene)RuCl]^+$: a better 'hard/soft' interaction and less steric hindrance should be achieved when only one alkyl substituent interacts with *p*-cymene ring. Vice versa is true when the ligands have sterically hindered amidic nitrogens, the *S*,*S*′ *cis*-chelation should be easier and mononuclear "piano stool" complexes formed preferentially. Actually, dithioxamide ligands other than **6**, **8**, and **9** were designed to verify if the steric hindrance on nitrogen could be responsible for the different reaction paths. Thus, we prepared **1**, **2**, **3**, **4**, and **5** where R = $-CH_2-R'$ (R′ = H, methyl, ethyl, propyl, isobutyl) at the scope of varying the molecular complexity of R′ while leaving the structure of the carbon attached to nitrogen unchanged. Alternatively, **10** and **11** were prepared to increase steric hindrance on the carbon directly attached to nitrogen, and **7** was prepared because the aromatic carbon on nitrogen is part of a flat structure, which does not have three-dimensional hindrance. The analysis of the reaction products confirms that the bulk on the nitrogen-bonded carbon is the structural property of secondary dithioxamides that leads to the synthesis of piano stool complexes **13a−d** rather than to the binuclear compounds **12a−g**.

Conclusions

Secondary dithioxamides *N*-substituted with substituents of various complexity were reacted with ruthenium(*p*-cymene)dichloro dimer. Binuclear $[(p\text{-cymene})ClRu]_2$ (μ-$R_2N_2S_2H_2$ κ-*N*,*S* Ru κ-*N*′,*S*′ Ru′) were synthesized when R = methyl, ethyl, *n*-propyl, *n*-butyl, isoamyl, *p*-tolyl. Mononuclear "piano stool" complexes $\{Ru(p\text{-cymene})Cl(H_2R_2N_2S_2C_2)^+, Cl^-\}$ and $[Ru(p\text{-cymene})Cl(H_2R_2N_2S_2C_2)]$ were obtained when R = cyclohexyl, isopropyl, 1-phenylethyl.

These results suggest that the bulk on the nitrogen-bonded carbon is the structural property of secondary dithioxamides that leads to the synthesis of piano stool complexes rather than to the binuclear compounds. This observation opens interesting perspectives; in fact, unsymmetrically disubstituted dithioxamides [RHNSC−CSNHR′] properly designed could provide binuclear as well as "piano stool" mononuclear chiral diastereomers. Furthermore, the tuning of steric effects, both on nitrogen substituents and on η^6-arene "stools", could promote stereoselective synthesis of "piano stool" type $[(\eta^6\text{-arene})Ru(HDTO)Cl]$ complexes.

Molecular Structure of $[(\eta^6\text{-}p\text{-Cymene})RuCl]_2$(μ-*N*,*N*′-dibenzyl-dithioxamidato κ-*N*,*S* Ru κ-*N*′,*S*′ Ru′)·2$CHCl_3$ (12f·2$CHCl_3$)

The complex consists of two $[(\eta^6\text{-}p\text{-cymene})RuCl]^+$ units *N*,*S*-bis-chelated by a planar bridge [(*N*,*N*′-dibenzyl-dithioxamidato)]$^{2-}$. The compound co-crystallises with solvent molecules (ratio 1:2) interacting with the chloride of the ruthenium moieties: H(19)···Cl(1) 2.407(9) Å, C(19)···Cl(1) 3.327(9) Å, C(19)−H(19)···Cl(1) 160.5(9)°. The observed decay of the diffraction data is due to the crystal packing deterioration due to loss of co-crystallised $CHCl_3$. In the solid state the middle point of the NSC−CSN is both a crystallographic and molecular inversion centre; thus the asymmetric unit contains only half complex moiety H-bonded to a chloroform molecule, as shown in Figure 2.

By considering the (η⁶-*p*-cymene) ligand as a unique coordination site represented by the centre of the benzene ring (Xcym in Table 2), the ruthenium geometry might be described as a significantly distorted tetrahedron. This deformation as evidenced by the space-filling model is mainly due to the metal d orbitals orientation (that is octahedral); these develop bonds toward ligands: the "three legs of the stool" are nearly 90° mutually oriented. The Ru−Ccym bond lengths shift from 2.170(7) for C(4) to 2.256(6) Å for C(2) with the average value 2.198(8) Å; the metal distance from the benzene centre is 1.685(6) Å. The ruthenium coordination geometry is the same as that of [(η⁶-*p*-cymene)RuCl(μ-bis(2-hydroxypropyl)-DTO)Pt(2-diphenylphosphanyl-pyridine)Cl] reported in our previous work[5] on DTO chirality, where ruthenium and platinum are *N*,*N*′- and *S*,*S*′-chelated, respectively. The difference arises from the *N*,*N*′-ditolyl-dithioxamidato, which undergoes *S*,*N*-chelation in order to better distribute the steric hindrance between tolyl substituents and *p*-cymene on two ruthenium centres. This arrangement, similar to an already reported *SN* coordination,[20] causes the C_i symmetry of the binuclear complex (if the tetrahedral ruthenium atom is a chiral centre, then the whole molecule is a *meso* form) and the formation of the observed centrosymmetric crystal packing in the solid state. The coordination through the bigger sulfur atom causes a slight elongation of the Ru−N bond with respect to the mean 2.06(1) Å value reported for the *N*,*N*-chelation.[21]

The DTO bridge exhibits a flat arrangement, observed in all the known complexes of the bis-chelating dithioxamide derivatives. The Ru atom is 0.116(1) Å out of the mean plane of the perfectly planar NSC−CSN fragment, in whose respect the tolyl substituent is disposed orthogonally [dihedral angle 81.5(2)°, torsion angle C(1′)−NCH₂−C_{phen} −92.7(8)°] to minimise the hindrance with the ruthenium bonded *p*-cymene. The C(1)−C(1′) distance of 1.46(1) Å is evidence of the large conjugation on the whole NSC−CSN system, as compared with the tilted conformation of the mono-chelate neutral *S*,*S*′-coordinated complexes with the C−C distance over 1.5 Å.[21]

Experimental Section

General Remarks: ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded, at 298 K, on a Bruker ARX-300 spectrometer equipped with a broad-band probe operating at 300.13 and 75.46 MHz, respectively [δ (ppm) relative to Me_4Si, *J*(Hz)]. Electronic impact (EI) mass spectra were recorded with a Finnigan MAT 90 reverse-geometry double-focusing mass spectrometer. Sample was introduced into the EI source by a heated direct inlet probe. Ion source conditions: ionisation energy 70 eV; acceleration voltage 5 kV; temperature 220 °C.

The reagents are commercially available products used as purchased. Solvents were freshly distilled from sodium wire under a nitrogen atmosphere.

The dithioxamides **1**, **5**, **6**, **8**, **9**, **10**, **11**,[26] **7**,[27] and the starting complex [(η⁶-*p*-cymene)$RuCl_2$]$_2$ [28] were prepared according to known procedures. Compounds **2**, **3**, and **4**, already known,[26] were prepared with the following improved procedure: $H_4N_2C_2S_2$ (1 g, 8.32 mmol) was suspended in 50 mL of water and six fold excess (49.9 mmol) of the corresponding amine was added to the mixture. On stirring, yellow micro crystals of the product separated in a highly pure form.

[Ru(*p*-Cy)Cl]₂(μ-Me₂DTO) (12a): To a solution of [(η⁶-*p*-cymene)$RuCl_2$]$_2$ (612.4 mg, 1 mmol) in chloroform (100 mL), was added ligand **1** (148.2 mg, 1 mmol) and the mixture allowed to stand for 0.5 h at room temperature. After this time, the solution was concentrated to 10 mL and petroleum ether 40−60 (about 100 mL) added. A red brown solid precipitated, which was dissolved in the minimum amount of chloroform and purified by chromatography on silica with chloroform as eluent. The pure product was finally obtained by precipitation adding petroleum ether 40−60 (about 100 mL) to concentrated portions (about 10 mL) of eluates. Yield: 516 mg, 75%. ^{1}H NMR ($CDCl_3$): δ = 1.16, 1.23 [2 d, $^3J_{H,H}$ = 6.7 Hz, 6 H each, $CH(CH_3)_2$, cymene], 2.18 (s, 6 H, CH_3, cymene), 2.81 [seven lines, 2 H, $^3J_{H,H}$ = 6.7 Hz, $CH(CH_3)_2$, cymene], 3.88 (s, 6 H, NCH_3), 5.06, 5.18, 5.26, 5.42, (4 d, 2 H each, $^3J_{H,H}$ = 5.9 Hz, $H^{2,3,5,6}$, cymene). ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 18.8 (s, CH_3, cymene), 22.0, 22.7 [2 s, $CH(CH_3)_2$, cymene], 30.9 [s, $CH(CH_3)_2$, cymene], 50.6 (s, NCH_3), 81.3, 81.8, 85.6, 85.8, (4 s, $C^{2,3,5,6}$, cymene), 99.9, 104.2, (2 s, $C^{1,4}$, cymene), 188.7 (s, CS). $C_{24}H_{34}Cl_2N_2Ru_2S_2$ (687.72): calcd. [Ru(*p*-Cy)Cl]$_2$(μ-*p*-Tolyl$_2$DTO) (12g): This reddish compound was prepared as described for **12a** by using **7** (324.5 mg, 1 mmol) in place of **1**. Yield: 588 mg, 70%. ^1H NMR ($CDCl_3$): δ = 1.07, 1.10 [2 d, 6 H each, $^3J_{H,H}$ = 6.9 Hz, $CH(CH_3)_2$, cymene], 2.05 (s, 6 H, CH_3, cymene), 2.42 (s, 6 H, $NC_6H_5CH_3$), 2.61 [seven lines, 2 H, $^3J_{H,H}$ = 6.9 Hz, $CH(CH_3)_2$, cymene], 4.60, 4.76, 4.79, 5.01 (4 d, 2 H each, $^3J_{H,H}$ = 5.7 Hz, $H^{2,3,5,6}$, cymene), 7.25 (2 d, 4 H, $^3J_{H,H}$ = 8.4 Hz, H_m of $NC_6H_4CH_3$), 7.44 (m, 4 H, H_o of $NC_6H_4CH_3$). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 18.7 (s, CH_3, cymene), 21.3 (s, $NC_6H_5CH_3$), 21.6, 22.9 (2 s, $CH(CH_3)_2$, cymene), 30.7 [s, $CH(CH_3)_2$, cymene], 81.4, 81.5, 84.4, 87.5 (4 s, $C^{2,3,5,6}$, cymene), 100.9, 103.7 (2 s, $C^{1,4}$, cymene), 123.4, 129.5 (2 s, CH_{Ph} of $NC_6H_5CH_3$), 135.7, 152.9 (2 s, C_{quat} of $NC_6H_5CH_3$), 192.4 (s, CS). $C_{36}H_{42}Cl_2N_2Ru_2S_2$ (839.91): calcd. C 51.48, H 5.04, N 3.34, S 7.63, Cl 8.44; found C 51.35, H 5.09, N 3.28, S 7.65, Cl 8.32.

Complex {[Ru(*p*-Cy)Cl(H$_2$-(R)-1-phenylethyl$_2$DTO)]$^+$, (Cl^-)} (13a): To a solution of $[(\eta^6$-*p*-cymene)$RuCl_2]_2$ (612.4 mg, 1 mmol) dissolved in chloroform (100 mL), was added **8** (657.0 mg, 2 mmol), and the mixture allowed to stand for 0.5 h at room temperature. After this time the solution was concentrated to a small volume (about 10 mL), and petroleum ether 40−60 (100 mL) was added. Complex **13a** precipitated as a brown powder. Yield: 622 mg, 98% − ^1H NMR ($CDCl_3$): δ = 1.13, 1.16 [2 d, 3 H each, $^3J_{H,H}$ = 7.0 Hz, $CH(CH_3)_2$, cymene], 1.89, 1.93 [2 d, 3 H each, $^3J_{H,H}$ = 7.0 Hz, $NHCH(CH_3)Ph$], 2.19 (s, 3 H, CH_3, cymene), 2.62 [seven lines, 1 H, $^3J_{H,H}$ = 7.0 Hz, $CH(CH_3)_2$, cymene], 5.26, 5.41 [2 q, 1 H each, $^3J_{H,H}$ = 7.0 Hz, $NHCH(CH_3)Ph$], 5.39, 5.45, 5.51, 5.56, (4 d, 1 H each, $^3J_{H,H}$ = 5.9 Hz, $H^{2,3,5,6}$, cymene), 7.34 [m, 6 H, $H_{m,p}$ of $NHCH(CH_3)Ph$], 7.56, 7.61 [2 d, 4 H, $^3J_{H,H}$ = 7.0 Hz, H_o of $NHCH(CH_3)Ph$], 13.3 [br. s, 2 H, $NHCH(CH_3)Ph$]. $^{13}C\{^1H\}$ NMR (298 K, $CDCl_3$): δ = 18.7 (s, CH_3, cymene), 21.5, 22.4 [2 s, $NHCH(CH_3)Ph$], 22.2, 22.5 [2 s, $CH(CH_3)_2$, cymene], 31.2 [s, $CH(CH_3)_2$, cymene], 60.5, 61.0 [2 s, $NHCH(CH_3)Ph$], 86.5, 86.7, 87.4, 87.8 (4 s, $C^{2,3,5,6}$, cymene), 104.3, 107.7 (2 s, $C^{1,4}$, cymene), 127.4−128.8 [CH_{Ph} of $NHCH(CH_3)Ph$], 139.8, 140.4 [2 s, C_{quat} $NHCH(CH_3)Ph$], 186.9, 187.1 (2 s, CS). $C_{28}H_{34}Cl_2N_2RuS_2$ (634.69): calcd. C 52.99, H 5.40, N 4.41, S 10.10, Cl 11.17; found C 52.88, H 5.52, N 4.45, S 10.05, Cl 11.12.

{Ru(*p*-Cy)Cl(H$_2$-(*R*,S)-1-phenylethyl$_2$DTO)$^+$, (Cl^-)} (13b): This brown compound was prepared as described for **13a** by using **9** (657.0 mg, 2 mmol) in place of **8**. Yield: 609 mg, 96%. ^1H NMR ($CDCl_3$): δ = 1.08 [d, 6 H, $^3J_{H,H}$ = 7.0 Hz, $CH(CH_3)_2$, cymene], 1.93 [d, 6 H, $^3J_{H,H}$ = 7.0 Hz, $NHCH(CH_3)Ph$], 2.13 (s, 3 H, CH_3, cymene), 2.52 [seven lines, 1 H, $^3J_{H,H}$ = 7.0 Hz, $CH(CH_3)_2$, cymene], 5.37, 5.49 (2 d, 2 H each, $^3J_{H,H}$ = 5.9 Hz, $H^{2,3,5,6}$, cymene), $NHCH(CH_3)Ph$ obscured by *p*-cymene ring signals, 7.33 [m, 6 H, $H_{m,p}$ of $NHCH(CH_3)Ph$], 7.58 [d, 4 H, $^3J_{H,H}$ = 7.0 Hz, H_o $NHCH(CH_3)Ph$], 13.4 [br. s, 2 H, $NHCH(CH_3)Ph$]. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 18.4 (s, CH_3, cymene), 21.6 and 22.3 [2 s, $CH(CH_3)_2$, cymene], 22.4 (s, $NHCH(CH_3)Ph$], 30.7 [s, $CH(CH_3)_2$, cymene], 60.6 [s, $NHCH(CH_3)Ph$], 79.7, 83.3 (2s, $C^{2,3,5,6}$, cymene), 99.4, 105.0 (2 s, $C^{1,4}$, cymene), 128.58 −140.19 (aromatic carbons of $NHCH(CH_3)Ph$), 185.8 (s, CS). − $RuC_{28}H_{34}N_2S_2Cl_2$ (634.69):

calcd. C 52.99, H 5.40, N 4.41, S 10.10, Cl 11.17; found C 52.87, H 5.53, N 4.44, S 10.07, Cl 11.15.

{Ru(*p*-Cy)Cl(H_2-*i*Pr_2DTO)$^+$, (Cl^-)} (13c): This brown compound was prepared as described for **13a** by using **10** (408.6 mg, 2 mmol) in place of **8**. The reaction product was a diastereoisomer mixture analysed without purification. Yield: 490 mg, 96%. ^{1}H NMR ($CDCl_3$): δ = 1.24 [d, 6 H, $^3J_{H,H}$ = 6.9 Hz, CH(CH_3)$_2$, cymene], 1.24 [d, 12 H, $^3J_{H,H}$ = 6.9 Hz, NHCH(CH_3)$_2$], 5.64, 5.49 (2 d, 2 H each, $^3J_{H,H}$ = 6.0 Hz, $H^{2,3,5,6}$, cymene), 2.26 (s, 3 H, CH_3, cymene), 2.81 [seven lines, 1 H, $^3J_{H,H}$ = 6.9 Hz, C*H*(CH$_3$)$_2$, cymene], 12.6 [br. s, 2 H, N*H*CH(CH$_3$)$_2$], 4.17 [seven lines, $^3J_{H,H}$ = 6.9 Hz, 2 H, NHC*H*(CH$_3$)$_2$], − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 18.6 (s, CH_3, cymene), 22.2 [s, CH(*C*H$_3$)$_2$, cymene], 24.6, 24.8 [2 s, NHCH(*C*H$_3$)$_2$], 31.0 [s, *C*H(CH$_3$)$_2$, cymene], 59.9 [s, NH*C*H(CH$_3$)$_2$], 86.1, 87.0 (2 s, $C^{2,3,5,6}$, cymene), 103.9, 107.1 (2 s, $C^{1,4}$, cymene), 184.4 (s, *C*S). − $RuC_{18}H_{30}N_2S_2Cl_2$ (510.55): calcd. C 42.35, H 5.92, N 5.49, S 12.56, Cl 13.89; found C 42.27, H 5.98, N 5.45, S 12.55, Cl 13.90.

{Ru(*p*-Cy)Cl[H_2-(cyclohexyl)$_2$DTO]$^+$ (Cl^-)} (13d): This brown compound was prepared as described for **13a** by using **11** (569.0 mg, 2 mmol) in place of **8**. Yield: 567 mg, 95%. ^{1}H NMR ($CDCl_3$): δ = 1.28 [d, 6 H, $^3J_{H,H}$ = 6.7 Hz, CH(CH_3)$_2$, cymene], 1.86 (m, 20 H, CH_2 of NHC_6H_{11}), 2.29 (s, 3 H, CH_3, cymene), 2.84 [seven lines, 1 H, $^3J_{H,H}$ = 6.7 Hz, C*H*(CH$_3$)$_2$, cymene], 4.21 (m, 2 H, CH of NHC_6H_{11}), 5.50, 5.66 (2d, 2 H each, $^3J_{H,H}$ = 5.9 Hz, $H^{2,3,5,6}$, cymene), 12.6 (br. s, 2 H, N*H*C_6H_{11}). ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 18.9 (s, CH_3, cymene), 22.5 [s, CH(*C*H$_3$)$_2$, cymene], 24.8, 25.0, 25.1, 30.0, 30.1 (5 s, CH_2 of NHC_6H_{11}), 31.3 [s, *C*H(CH$_3$)$_2$, cymene], 60.3 (s, CH of NHC_6H_{11}), 86.3, 87.3 (2 s, $C^{2,3,5,6}$, cymene), 104.1, 107.5, (2 s, $C^{1,4}$, cymene), 184.8 (s, *C*S). − $RuC_{24}H_{38}N_2S_2Cl_2$ (590.68): calcd. C 48.80, H 6.48, N 4.74, S 10.86, Cl 12.00; found C 48.84, H 6.55, N 4.71, S 10.80, Cl 12.04.

Ru(*p*-Cy)Cl[H-(*R*)-1-(phenylethyl)$_2$DTO] (14a): A solution of **13a** (634.7 mg, 1 mmol) dissolved in about 15 mL of chloroform was purified by column chromatography. During chromatography, owing to HCl loss, the brown solution turned yellow. The yellow eluate was concentrated to a small volume (about 10 mL), and then petroleum ether/diethyl ether (boiling range 40−60 °C) was added (about 100 mL). The complex precipitated as yellow powder. Yields: 425 mg, 71%. ^{1}H NMR ($CDCl_3$): δ = 1.21, 1.22 [2 d, 3 H each, $^3J_{H,H}$ = 7.0 Hz, CH(CH_3)$_2$, cymene], 1.56 and 1.58 [2 d, 3 H each, $^3J_{H,H}$ = 7.0 Hz, NHCH(CH_3)Ph], 2.25 (s, 3 H, CH_3, cymene), 2.79 [seven lines, 1 H, $^3J_{H,H}$ = 7.0 Hz, C*H*(CH$_3$)$_2$, cymene], 5.2 [NHC*H*(CH$_3$)Ph partially obscured by *p*-cymene ring signals], 5.36 (m, 4 H, $H^{2,3,5,6}$, cymene), 7.35 [m, 10 H, $H_{o,m,p}$ of NHCH(CH$_3$)Ph], − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 18.6 (s, CH_3, cymene), 21.0, 22.4 [2s, NHCH(*C*H$_3$)Ph], 22.4 and 22.5 [2 s, (CH*C*H$_3$)$_2$, cymene], 30.9 [s, *C*H(CH$_3$)$_2$, cymene], 55.8, 58.0 [2 s, NH*C*H(CH$_3$)Ph], 84.5, 84.6, 85.7, 85.8 (4 s, $C^{2,3,5,6}$, cymene), 101.6, 104.7 (2 s, $C^{1,4}$, cymene), 126.61−143.08 [C_{Ph} of NHCH(CH$_3$)Ph], 177.9, 181.0 (2 s, *C*S). − $RuC_{28}H_{33}N_2S_2Cl$ (598.23): calcd. C 56.22, H 5.56, N 4.68, S 10.72, Cl 5.93; found C 56.25, H 5.55, N 4.72, S 10.80, Cl 5.85.

Ru(*p*-Cy)Cl[H-(*R*,S)-1-(phenylethyl)$_2$DTO] (14b): This compound was obtained by following the procedure reported for **14a**, starting from complex **13b** (634.7 mg, 1 mmol). Yields: 425 mg, 71%. ^{1}H NMR ($CDCl_3$): δ = 1.12 [d, 6 H, $^3J_{H,H}$ = 7.0 Hz, CH(CH_3)$_2$, cymene], 1.59 [d, 6 H, $^3J_{H,H}$ = 7.0 Hz, NHCH(CH_3)Ph], 2.21 (s, 3 H, CH_3, cymene), 2.66 [seven lines, 1 H, $^3J_{H,H}$ = 7.0 Hz, C*H*(CH$_3$)$_2$, cymene], ≈ 5.3 [m, NHC*H*(CH$_3$)Ph partially obscured by *p*-cymene ring signals], 5.36 (m, 4 H, $H^{2,3,5,6}$, cymene), 7.3 [m, 10 H, $H_{o,m,p}$ of NHCH(CH$_3$)Ph]. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 18.5 (s, CH_3, cymene), 20.9, 22.4 [2 s, NHCH(*C*H$_3$)Ph], 22.4 [s, CH(*C*H$_3$)$_2$], 30.8 [s, *C*H(CH$_3$)$_2$, cymene], 57.9 [s, NH*C*H(CH$_3$)Ph], 84.6, 85.5, (2 s, $C^{2,3,5,6}$, cymene), 101.6, 104.7 (2 s, $C^{1,4}$, cymene), 128.4−143.3 [aromatic carbons of NHCH(CH$_3$)Ph], 179.6 (1s, *C*S). − $RuC_{28}H_{33}N_2S_2Cl$ (598.23): calcd. C 56.22, H 5.56, N 4.68, S 10.72, Cl 5.93; found C 56.23, H 5.57, N 4.70, S 10.82, Cl 5.83.

[Ru(*p*-Cy)Cl(H−*i*Pr_2DTO)] (14c): This compound was obtained following the procedure reported for **14a**, starting from **13c** (510.5 mg, 1 mmol). Yields: 379 mg, 80%. ^{1}H NMR ($CDCl_3$): δ = 1.24 [d, 6 H, $^3J_{H,H}$ = 6.8 Hz, CH(CH_3)$_2$, cymene], 1.25 [d, 12 H, $^3J_{H,H}$ = 5.8 Hz, NCH(CH_3)$_2$], 2.24 (s, 3 H, CH_3, cymene), 2.85 [seven lines, 1 H, $^3J_{H,H}$ = 6.8 Hz, C*H*(CH$_3$)$_2$, cymene], 4.36 [seven lines, 2 H, $^3J_{H,H}$ = 5.8 Hz, NC*H*(CH$_3$)$_2$], 5.30, 5.47 (2 d, 2 H each, $^3J_{H,H}$ = 5.8 Hz, $H^{2,3,5,6}$, cymene). − $RuC_{18}H_{29}N_2S_2Cl$ (474.09): calcd. C 45.60, H 6.17, N 5.91, S 13.52, Cl 7.48; found C 45.52, H 6.27, N 5.90, S 13.48, Cl 7.55.

{Ru(*p*-Cy)Cl[H−(cyclohexyl)$_2$DTO]} (14d): This compound was obtained following the procedure reported for **14a**, starting from complex **13d** (590.7 mg, 1 mmol). Yields: 432 mg, 78%. ^{1}H NMR ($CDCl_3$): δ = 1.25 [d, 6 H, $^3J_{H,H}$ = 6.9 Hz, CH(CH_3)$_2$, cymene], 1.25−2.02 (m, 20 H, CH_2 of $NHCC_6H_{11}$), 2.23 (s, 3 H, CH_3, cymene), 2.84 [seven lines, 1 H, $^3J_{H,H}$ = 6.90 Hz, C*H*(CH$_3$)$_2$, cymene], 4.04 (m, 2 H, CH of $NHCC_6H_{11}$), 5.30, 5.45 (2 d, 2 H each, $^3J_{H,H}$ = 6.3 Hz, $H^{2,3,5,6}$, cymene). ^{13}C {^{1}H} NMR ($CDCl_3$): δ = 18.4 (s, CH_3, cymene), 22.2 [s, CH(*C*H$_3$)$_2$, cymene], 24.2, 24.4, 25.3, 31.2, 31.5, (5 s, CH_2 of $NHCC_6H_{11}$), 30.6 [s, *C*H(CH$_3$)$_2$, cymene], 57.2 (s, CH of $NHCC_6H_{11}$), 85.2, 84.0 (2 s, $C^{2,3,5,6}$, cymene), 104.1, 101.1 (2 s, $C^{1,4}$, cymene), 177.4 (s, *C*S). − $RuC_{24}H_{37}N_2S_2Cl$ (554.22): calcd. C 52.01, H 6.73, N 5.05, S 11.57, Cl 6.40; found C 52.07, H 6.75, N 5.01, S 11.51, Cl 6.47.

Single-Crystal X-ray Diffraction Studies of 12f: Suitable crystals of the complex **12f** (with R = R′ = benzyl) were obtained by slow evaporation of solvent from a chloroform/MeOH (1:1) solution. Diffraction data were collected on a Siemens R3m/V automatic four-circle diffractometer. Lattice parameters were obtained from least-squares refinement of the setting angles of 30 reflections within 15 ≤ 2θ ≤ 30° range. A summary of the crystallographic data and the structure refinement is reported in Table 1. A significant crystal deterioration was evidenced by the measurement of three standard reflections, monitored every 97 measurements. When the standard intensities decreased below 40% of the starting values, a new crystal was mounted to complete data collection (one third of the whole data). The reflection intensities were evaluated by a learnt-profile procedure[22] among 2θ shells, and then corrected for Lorentz-polarization effects. The data of each set were scaled on the standard intensities separately, while an inter-scaling factor was included and refined in the last least-square model recycling. No account was taken for absorption and extinction effects.

The structure was resolved by standard methods with the SHELXTL-PLUS system[23] and subsequently completed by a combination of least-squares technique and Fourier Syntheses. All non-hydrogen atoms were refined anisotropically. Whilst the final difference Fourier maps showed several hydrogen positions, the H atoms were placed in calculated positions (d_{X-H} = 0.960 Å) and included in the refinement among the "riding model" method with a unique common refined thermal isotropic displacement parameter [U_{iso} = 0.064(6) Å^2]. The refinement was carried out by the full-matrix least-squares technique, minimising the function $\Sigma w(|F_o| - |F_c|)^2$. In the last difference Fourier map, obtained with

the final weighting scheme $w^{-1} = [\sigma^2(F) + 0.0023*(F)^2]$, the minimum and maximum density residuals were −0.48 and 0.49 eÅ^{-3}, respectively. Neutral-atom scattering factors and anomalous dispersion corrections come from ref.[24]

All calculations were performed using the SHELXTL-PLUS system. The final geometrical calculations and drawings were carried out with the PARST program[25] and the XP utility of the Siemens package, respectively. Selected bond lengths and bond angles are reported in Table 2. By considering that the complex **12f** is placed at a crystallographic inversion centre, Figure 2 shows the atom-labelling scheme of the asymmetric moiety, which represents half a molecule.

Crystallographic data for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 164512. Copies of the data can be obtained free of charge on applicaton to The Director, CCDC, 12 Union Road,m Cambridge CB2 1EZ, UK [Fax: (internat.) + 44 (1223) 336-033; E-mail: deposit@ccdc.cam.ac.uk

Tetra(pyrrolidino)diborane(4), $[(C_4H_8N)_2B]_2$, as a New Improved Alternative Synthetic Route to Bis(pinacolato)diborane(4) − Crystal Structures of the Intermediates

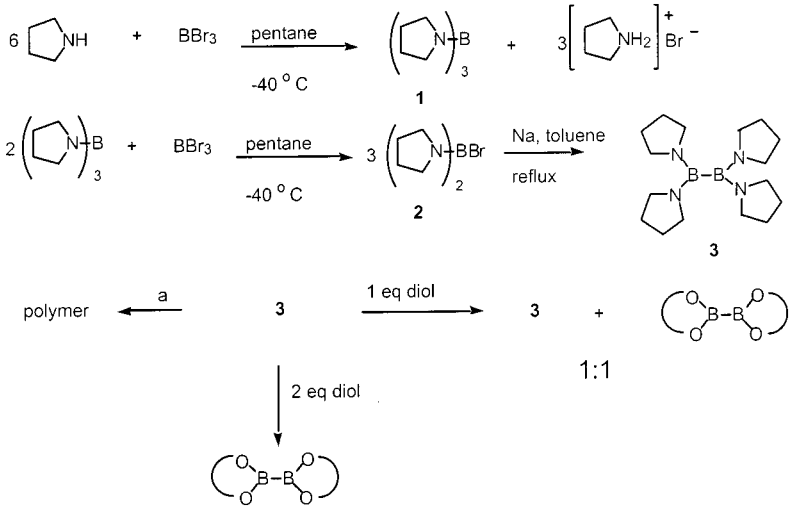
Hijazi Abu Ali,[a] Israel Goldberg,[b] and Morris Srebnik*[a]

Keywords: Boranes / Tris(pyrrolidino)borane / Tetra(pyrrolidino)diborane(4) / Solvolysis / Bis(pinacolato)diborane(4)

The compound tetra(pyrrolidino)diborane(4) (**3**) is an important new and alternative precursor for the preparation and synthesis of bis(pinacolato)diborane(4). The latter is the major intermediate among the diborane derivatives used for many addition and insertion reactions into multiple bonds. The crystal structure of **3** and its precursor, tris(pyrrolidino)-borane, **1**, were determined. In addition the solvolysis reactions and solution behavior of **3** with alcohols were examined.

Introduction

Derivatives of diboranes,[1] in particular tetraalkoxydiboranes, have become increasingly important as a result of the accelerating use of the Suzuki coupling reaction in the synthesis of complex molecular species.[2] The preparation of arylboronates from tetraalkoxydiboranes,[3] and the addition of tetraalkoxydiboranes across alkenes,[4] alkynes,[5] diynes,[4e,5c] enynes,[4e] allenes,[4e,10a,10b] 1,3-butadienes,[4e,6] methylenecyclopropanes,[7] allylic acetates,[8] α,β-unsaturated compounds[4d,9] and various other substrates[10] have contributed to the development of the chemistry of diboranes.[11] Tetraalkoxydiboranes are generally prepared from tetradialkylaminodiboranes, by Wurtz coupling of the corresponding bis(dialkylamino)haloboranes,[12] or by reaction of bis(dialkylamino)dichlorodiboranes with lithium amides.[13] The tetraalkoxydiboranes are then obtained by solvolysis of the tetradialkylaminodiboranes with alcohols.[14]



a. $CDCl_3$ or acetone, 1 day; or CO/toluene 4h. Diol=pinacol or 2-ethoxy-1,3-propoanediol

Scheme 1. Synthesis and reactions of **3**

While many tetradialkylaminodiboranes have been prepared by the above methods, few structures have been reported. In this paper we describe an improved synthesis of

3,[12b] its crystal structure, solution structure and solvolysis reactions, which have not been reported on previously. Compound **3**, we believe, is an important new and alternative precursor for the preparation of bis(pinacolato)diborane(4) which is the major intermediate among the diborane derivatives used for many addition and insertion reactions (see the extended reference list in the manuscript). This crucial compound can be obtained from tetra(dimethylamino)diborane(4), as described by Nöth.[15] This is the only synthetic route for this compound reported in the literature. There are several distinct disadvantages with this route. The preparation of bis(pinacolato)diborane(4) by the published route requires the use of dimethylamine, a dangerous gas above 7° C that is not easy to handle. In addition, dimethylamine is on the list of restricted chemicals, and thus is not available in many parts of the world. Alternatively, pyrrolidine is a stable liquid (87−88° C), easy to handle and is not on any restricted list of chemicals. Further, we have determined that **3**, which is a solid, is more stable to air and hydrolysis than tetra(dimethylamino)diborane(4), which is a very sensitive liquid [Various $(R_2N)_2BX$ compounds, where R = Et, *i*Pr, etc and X = Cl, Br, failed to give B−B compounds in the dehalogenation step]. However, dipyrrolidino behaved like dimethylamine, in that bis(pyrrolidino)bromoborane, **2**, was debrominated by sodium to give **3**. The precursor, tris(pyrrolidino)borane,**1**, is readily prepared from one equiv. of BBr_3 in pentane at − 40° C and six equiv. of pyrrolidine. After filtering the bromide salt, distillation afforded **1**. Bis(pyrrolidino)bromoborane was prepared from one equiv. of BBr_3 in pentane at − 40° C and two equiv. of **1** (Scheme 1). We have determined the stability of **3** in various solvents and found that the compound, while readily converted into tetraalkoxydiboranes by alcohols, polymerizes in the presence of acetone, chloroform, THF and CO/toluene. It is very stable to inert solvents like benzene, toluene and hydrocarbons.

Results and Discussion

Compound **1** crystallizes with four molecules in the asymmetric unit cell, two of which are shown in (Figure 1). The molecular entities have a planar BN_3 core, but they differ slightly in the conformation of the peripheral ring fragments. The latter are bent above and below the BN_3 plane, and are affected by severe disorder problems (in two of the four species). This is consistent with the low crystal density and loose intermolecular organization which facilitate the assumedly dynamic conformational behavior of the saturated rings at 110 K (Even at this low temperature the observed disorder of these rings could not be accounted for by a suitable combination of several static structures with partial occupancies and acceptable geometries. However, this order may still be static with several closely related positions, as this might also give rise to overlapped atoms that are not easy to resolve into separate positions). The bond lengths and angles involving B and N are similar to those previously observed in related triazaborane structures.[16]

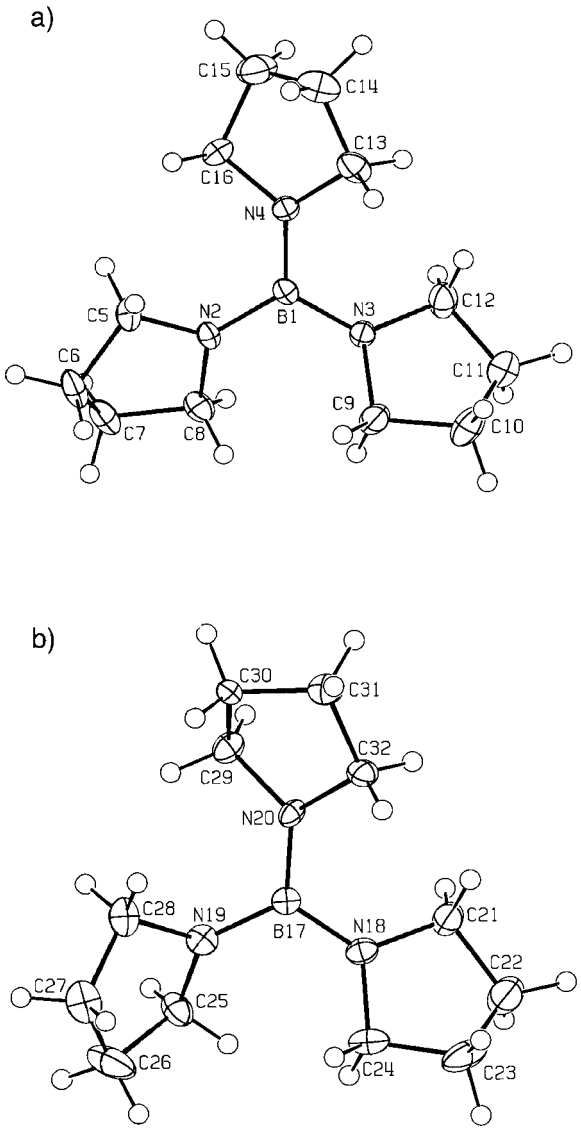

Figure 1. View of the molecular structure of **1** showing the atom numbering scheme (only the two ordered species of the asymmetric unit are shown). Ellipsoids represent thermal displacement parameters at the 50% probability level. The conformational lability of these species is reflected in the larger volume and higher anisotropy of the peripheral C-atoms. Selected bond lengths (Å) and angles (°) include: B1−N2 1.457(5), B1−N3 1.434(5), B1−N4 1.429(5), B17−N18 1.430(5), B17−N19 1.449(5), B17−N20 1.430(5), mean C−N 1.465, mean C−C 1.529; sum of angles at B1 360.0; sum of angles at B17 359.9.

The crystal structure is illustrated in (Figure 2). It shows a layered arrangement of the roughly flat molecules parallel to the *ab* plane of the unit-cell, that is stabilized by weak van der Waals forces between the lipophilic surfaces of adjacent species.

The molecular structure of **3** is shown in (Figure 3). It has a crystallographic twofold rotational axis which coincides with the B−B bond. As in related compounds, it maintains the trigonal planar geometry around the boron atoms. However, the observed B−B distance of 1.739(4) Å is slightly longer than in previously reported analogues. [12b,13,17] This may be due to the bulky pyrrolidino

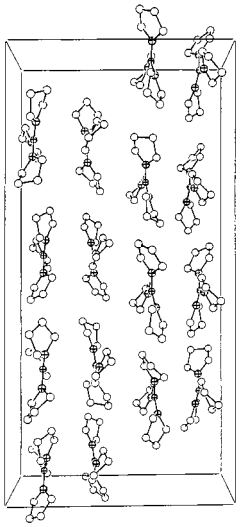

Figure 2. Crystal structure of **1** viewed approximately down the *a* axis (*b* is vertical) which shows the contents of a single unit-cell and the hypercentric layered molecular organization.

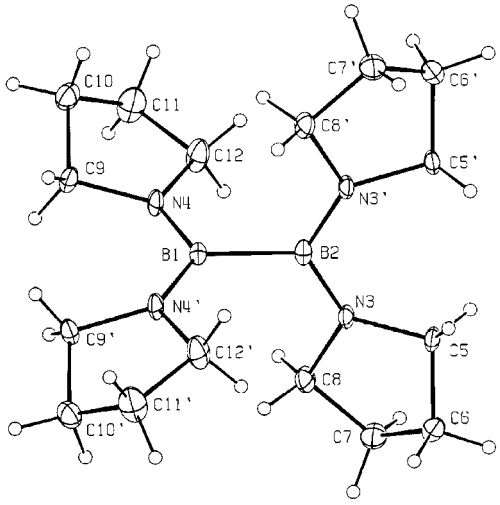

Figure 3. View of the molecular structure of **3**, showing the atom numbering scheme. Ellipsoids represent thermal displacement parameters at the 50% probability level. The molecules are located in the crystal on twofold symmetry axes; primed atoms are related to nonprimed atoms by symmetry transformation: $1 - x, y, 11/2 - z$. Selected bond lengths (Å) and angles (°) include: B1−B2 1.739(4), B1−N3 1.424(2), B1−N4 1.427(2), mean C−N 1.472, mean C−C 1.523, N4−B1−N4′ 121.7(2), N3−B2−N3′ 120.8(2), N4−B1−B2 119.1(1), N3−B2−B1 119.6(1), N4−B1−B2−N3 −103.6(1), N4−B1−B2−N3′ 76.4(1).

groups around the boron atoms. The molecule adopts a staggered conformation around the B−B bond (Figure 4) in order to avoid collision between the inner hydrogen atoms. The N−B−B−N torsion angles are 76.4 and 103.6°.[12b] The crystal structure is stabilized by weak van der Waals forces between the lipophilic surfaces of adjacent molecules, and readily cleaves along the interfaces between the molecular layers (Figure 4).

Compound **3** is monomeric in solvents like benzene or in hydrocarbons. It is more stable in air than tetra(dimethylamino)diborane(4). In terms of chemical reactivity

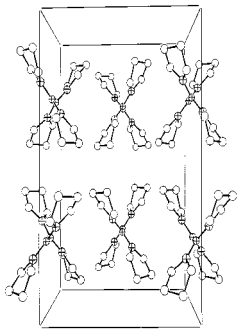

Figure 4. View of the crystal structure of **3** down the *b* axis of the unit cell (contents of 11/2 unit cells are shown). Note the staggered disposition of the five-membered rings with respect to the B−B bond, and the layered organization of the molecular entities in the crystals of this material.

and solvolysis, the pyrrolidino compound behaves in a similar manner to the tetradimethylamino analogue, but is more reactive than other tetradialkylamine derivatives. It reacts with one equiv. of pinacol to give a 1:1 mixture of bis(pinacolato)diborane(4),[15] and starting material. However, with two equiv. of pinacol, pure bis(pinacolato)diborane(4) is obtained in an 83% yield (Scheme 1). With two equiv. of 2-ethoxy-1,3-propanediol, the corresponding 2,2′-bis(5-ethoxy-1,3-dioxa-2-boracyclohexane), $[(C_5H_{10}O_3)B]_2$, is produced. Allowing a solution of freshly prepared **3** in $CDCl_3$, acetone or in CO in toluene, for 4 h results in the disappearance of starting material and the precipitation of a new compound, as indicated by ^1H, ^{13}C, ^{11}B NMR, GCMS and GPC analysis (Scheme 1). GPC analysis of the new compound indicates that it is a polymer (M_w = 19,458; M_n = 19,139; M_w/M_n = 1.02).[18] The small signals in the variable-temperature NMR spectra (Figure 5) at around δ = 1.75 and 2.95 are not impurities, but rather arise from the formation of a polymer, the structure of which has not yet been determined. However, a variable-temperature

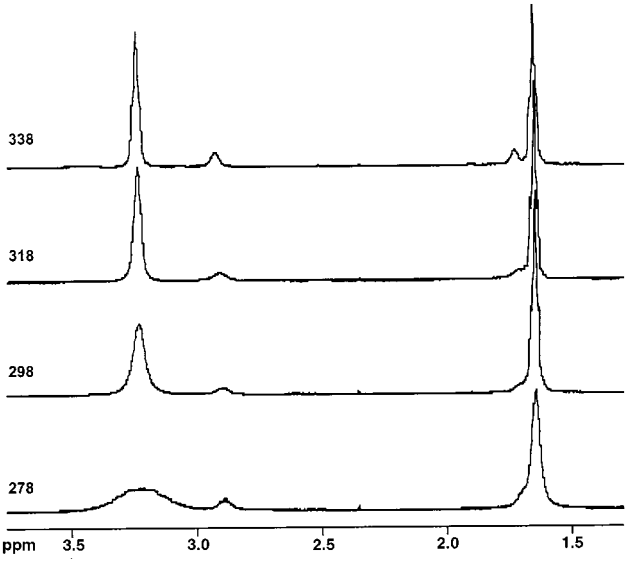

Figure 5. Variable-temperature (K) ^1H NMR spectra of **3** in $CDCl_3$.

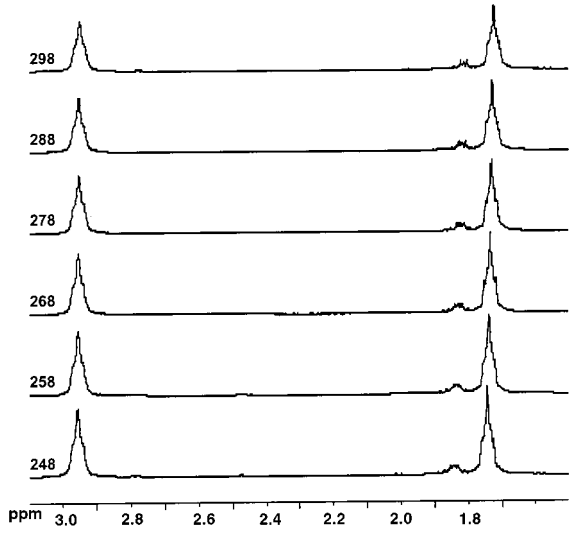

Figure 6. Variable-temperature (K) ^{1}H NMR spectra of the polymer in $CDCl_3$.

NMR spectroscopic study of the polymer in $CDCl_3$ has been performed (Figure 6). The signal of the monomer at $\delta = 1.64$ is shifted downfield in the polymer, while the signal at $\delta = 3.23$ is shifted upfield.

The ^{1}H NMR spectrum of **3** at 25 °C initially shows two broad singlets at $\delta = 1.64$ and 3.23. In the ^{13}C NMR spectrum, the C1 carbon atom of the pyrrolidino ring cannot be seen at room temperature. These phenomena may be due to the proximity of C1 to the boron atom, as well as the tumbling effect that takes place for large molecules in solution. Such spectra could also result from the restricted rotation around the B−B or B−N bond, or from both. However, when a $CDCl_3$ solution of **3** is heated from 278 to 338 K, the broad signals in the ^{1}H NMR spectrum are resolved into triplets ($^3J = 6.5$ Hz) (Figure 5), whereas C1 in the ^{13}C NMR spectrum is resolved into a singlet at $\delta = 49.43$. For the monomer, temperatures lower than 278 K result in the broadening of both signals in the ^{1}H NMR spectrum, and all splitting is lost, while for the polymer, lower temperatures give enhanced signals.

Conclusion

We have discovered that tetra(pyrrolidino)diborane(4) (**3**) is an excellent new precursor for the preparation of bis(pinacolato)diborane(4). Its crystal structure has been determined, as well as that of tris(pyrrolidino)borane. We have shown that **3** is stable in benzene, toluene and hydrocarbons, but tends to polymerize in acetone, chloroform, THF, and CO/toluene. We found that most bis(dialkylamino)-haloboranes are not suitable for the coupling reaction and give primarily the tris(dialkylamino)boranes and very low yields of the B−B product. Thus, tetra(pyrrolidino)diborane(4) is a valuable precursor for the preparation of bis(pinacolato)diborane(4) (obtained in an 83% yield), and is an alternative to $B_2(NMe_2)_4$.

Experimental Section

General Remarks: All reactions were carried under a nitrogen atmosphere using vacuum line and glove box techniques. Solvents were purified by distillation from appropriate drying agents under a nitrogen atmosphere. Starting materials were purchased from commercial suppliers and used without further purification. − ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ solution using a Varian Unity (300 or 75 MHz) spectrometer with Me_4Si as an internal standard. ^{11}B NMR spectra were recorded with a Bruker MSL-400 (128 MHz) spectrometer using $BF_3{\cdot}OEt_2$ as an external standard. − GC/MS spectra were obtained on a HP GCD PLUS instrument in EI mode on a 30 m methylsilicone column.

$(C_4H_8N)_3B$ (1): Pyrrolidine (86 g, 1.21 mol) and pentane (150 mL) was put into a dry 500 mL flask, closed with a rubber septum, under a nitrogen atmosphere. The flask was placed in a dry ice bath (− 78° C). Tribromoborane (51.25 g, 0.20 mol) was added slowly under nitrogen into a flask containing pentane (50 mL) which had been cooled to about − 40° C. This solution was added dropwise, with stirring, to the cooled amine-pentane solution. After an additional 3 h, the solution was allowed to warm to room temperature. The mixture was filtered under a nitrogen atmosphere, and pentane was added to transfer the solid to the filter funnel. The pentane was removed from the clear solution under vacuum, and the residue was distilled under vacuum to give colorless crystals (35.80 g, 81%). M.p. 40° C, b.p. 105° C/1.5Torr. − ^{1}H NMR ($CDCl_3$): $\delta = 1.66$ (t, 12 H, CH_2, $^3J_{H\text{-}H} = 6.6$ Hz), 3.04 (t, 12 H, CH_2N, $^3J_{H\text{-}H} = 6.6$ Hz). − ^{13}C{^{1}H} NMR ($CDCl_3$): $\delta = 24.61$ (CH_2), 46.84 (CH_2N). − ^{11}B NMR ($CDCl_3$): $\delta = 23.75$. − MS (EI), *m/z* (%) = 221 (20.4) [M^+], 192 (10.14), 178 (12.19), 151 (100), 123 (12.00), 109 (10.36), 82 (32.06), 70 (15.39), 40 (21.65). − $C_{12}H_{24}N_3B$: calcd. C 65.17, H 10.94, N 19.00; found C 64.96, H 10.81, N 18.81.

$(C_4H_8N)_2BBr$ (2): A solution of tribromoborane (16.29 g, 0.065 mol) in pentane (50 mL) was added to a vigorously-stirred solution of tris(pyrrolidino)borane (30 g, 0.13 mol) in pentane (150 mL) at − 50 to − 40° C, over a period of 20 min.. After an additional 3 h, the solution was allowed to warm to room temperature. The pentane was removed by rapid distillation at 1.5 Torr and the residue was distilled at 0.5 Torr giving the product as a pure liquid (39.51 g, 84%). B.p. 90° C \0.5Torr. − ^{1}H NMR ($CDCl_3$): $\delta = 1.71$ (t, 8 H, CH_2, $^3J_{H\text{-}H} = 6.75$ Hz), 3.31 (t, 8 H, CH_2N, $^3J_{H\text{-}H} = 6.75$ Hz). − ^{13}C{^{1}H} NMR ($CDCl_3$): $\delta = 26.56$ (CH_2), 50.01 (CH_2N). ^{11}B NMR ($CDCl_3$): $\delta = 24.51$ − $C_8H_{16}N_2BBr$: calcd. C 41.60, H 6.98, N 12.13; Br, 34.60; found C 41.31, H 7.21, N 11.46; Br, 34.93.

$[(C_4H_8N)_2B]_2$ (3): A solution of bis(pyrrolidino)bromoborane (21.8 g, 0.094 mol) in dry toluene (6 mL) was added slowly to highly-dispersed molten sodium (2.6 g, 0.11 mol) in dry toluene (20 mL) at 110 ° C. After 4 h, the resulting solids were filtered under a nitrogen atmosphere. The toluene was removed from the filtrate by vacuum distillation and the residue distilled at 160 ° C\0.5 Torr to give the product as a clear liquid, which on cooling gave colorless crystals (7.1 g, 50%). M.p. 75 °C, b.p. 160 °C\0.5 Torr. − ^{1}H NMR ($CDCl_3$) at 338 K: $\delta = 1.64$ (broad t, 16 H, CH_2, $^3J = 6.5$ Hz), 3.23 (broad t, 16 H, CH_2N). − ^{13}C{^{1}H} NMR ($CDCl_3$) at 338 K: $\delta = 26.53$ (CH_2), 49.43 (CH_2N). ^{11}B NMR ($CDCl_3$): $\delta = 33.96$. − MS (EI): *m/z* (%) = 302 (23.4) [M^+], 230 (100), 203 (46.6), 202 (39.2), 163 (64), 151(100), 133 (24.5), 107 (29.7), 82 (100), 70 (93.4). − $C_{16}H_{32}N_4B_2$: calcd. C 63.61, H 10.67, N 18.54; found C 63.53, H 10.69, N 18.27.

$[(C_5H_{10}O_3)B]_2$: A solution of tetra(pyrrolidino)diborane(4) (3.0 g, 0.01 mol) in benzene (20 mL) was added to a vigorously stirred

X-ray Crystallographic Study: Single crystals of **1** and **3** suitable for X-ray diffraction analysis were obtained from a saturated pentane solution at ≈ −20 °C. The crystal data and structure refinement for both are summarized in Table 1. **$(C_4H_8N)_3B$ (1)**. Crystals of this low-melting compound are extremely sensitive to air and moisture, and were coated with a layer of hydrocarbon oil in order to minimize deterioration. The X-ray diffraction measurements were carried out at ca. 110 K on a Nonius−Kappa CCD diffractometer, using Mo-K_α (λ = 0.7107 Å) radiation and 0.9° φ and Ω scans. The structure was solved by direct methods (SIR-92)[19] and refined by full-matrix least-squares based on F^2 for all reflections (SHELXL-97).[20] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were located in calculated positions to correspond to standard bond lengths and angles, and were included in the refinement with isotropic displacement parameters using a riding model. Even at 110 K, the molecular structure of this compound is affected by severe conformational disorder of the five-membered rings. The asymmetric unit of the observed structure consists of four molecular entities that exhibit somewhat different conformations and varied degrees of disorder. The latter is reflected in the large-amplitude thermal displacement parameters of the C atoms, and could not be modeled; it is particularly evident in two out of the four crystallographically independent species. The dynamic nature of the structure gives rise to a large percentage of weak reflections in the diffraction pattern (revealing the appearance of several superlattice peaks as well), and affects the precision of this determination.

$[(C_4H_8N)_2B]_2$ (3): The analyzed crystal of **3** was coated with a layer of hydrocarbon oil in order to minimize deterioration and mounted on a glass fiber. The X-ray diffraction measurements were carried out as for **1**, using 1.0° Phi and Omega scans; solution and refinement were as for **1**.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-165578 (**1**) and CCDC-165579 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization of Dirhodium(II,II)−Porphyrin-Based Multiredox Systems

Sandra Lo Schiavo,*[a] Scolastica Serroni,[a] Fausto Puntoriero,[a] Giuseppe Tresoldi,[a] and Pasquale Piraino[a]

Keywords: Rhodium / Porphyrins / Electrochemistry / Luminescence

Dirhodium(II,II)–porphyrin-based multiredox systems were easily prepared by combining the versatile reactivity, both axial and equatorial, of the $[Rh_2(form)_2(O_2CCF_3)_2(H_2O)_2]$ (form = *N*,*N*′-di-*p*-tolylformamidinate) complex and the well-known coordination capability of *meso*-substituted phenylporphyrins. In this way, redox systems featured by porphyrins axially or equatorially coordinated to the dirhodium subunits were obtained. Electrochemical and luminescence properties of the new assemblies were also investigated. Porphyrin–dirhodium(II,II) multiredox assemblies were synthesized by exploiting both the classical axial and the peculiar equatorial reactivity of the complex $[Rh_2(form)_2(O_2CCF_3)_2(H_2O)_2]$ (**1**) (form = *N*,*N*′-di-*p*-tolylformamidinate). The species $[Rh_2(form)_2(PCOO)_2]$ (**2**), featuring two bridged (carboxyphenyl)porphyrins in the equatorial positions, was prepared by metathetical reaction of **1** with the sodium salt of *meso*-5-(4-carboxyphenyl)-5,10,15-triphenylporphyrin (PCOO). Conversely, redox systems in which porphyrins are axially ligated to dirhodium were obtained by treating **1** with a variety of functionalized *meso*-pyridylporphyrins. Depending on the number and position of the peripheral pyridyl substituents, assemblies with different nuclearity, both in terms of metal and porphyrin subunits, were isolated. The 1:2 dirhodium/porphyrin adduct, $[Rh_2(form)_2(O_2CCF_3)_2(PyP)_2]$ (**3**) was obtained by treatment of **1** with triphenyl(pyridyl)porphyrin (PyP). By combination of **1** with the *cis*-5,10-diphenyl-15,20-dipyridylporphyrin (*cis*-DPyP) the molecular square box, $[Rh_2(form)_2(CF_3CO_2)_2(cis\text{-DPyP})]_4$ (**4**) was isolated in good yield. The reaction of **1** with 5,10,15,20-tetrakis(4-pyridyl)porphyrin (TPyP) is dependent on the experimental conditions and led to two different products: the grid polymer $[\{Rh_2(form)_2(CF_3CO_2)_2\}_2(TPyP)]_n$ (**5**) and the symmetric tetramer $[\{Rh_2(form)_2(CF_3CO_2)_2\}_4(TPyP)]$ (**6**), respectively. All the products were characterized by conventional spectroscopic methods. Proton NMR spectroscopy resulted particularly useful for the characterization of dirhodium–phenyl(pyridyl)porphyrin aggregates. The 2,6-pyridyl proton resonances are highly affected by coordination and experience significantly upfield shifts with respect to the corresponding unbound porphyrin. Systems **2**, **3**, **4**, and **6** underwent many redox processes in the potential window under investigation (+2; −1.4 V), each one of them can be assigned to the specific subunits of the molecular arrays. The emission studies performed on the same aggregates revealed that the porphyrin-based emission was significantly quenched by, most likely, reductive electron transfer from dirhodium subunits to the excited porphyrin chromophores. Such a process appears to be larger in the pyridylporphyrin–dirhodium systems with respect to the (carboxyphenyl)porphyrin ones.

Introduction

Redox multicomponent systems continue to be a topic of current interest owing to their diverse potential of application in the field of the molecular materials. Apart from their molecular properties (magnetism, electrical conductivity) these systems, depending on their structural features, may also display interesting specific functions (catalytic, host−guest interactions, electron reservoir, etc.) or act as models for electron or energy transport.[1] The choice of the redox components represents a crucial point in the synthetic approach to redox systems. The inclusion of transition metals constitutes one of the most promising means of introducing redox activity in a multicomponent system. These, besides acting as redox-active moieties, may play an important role from a synthetic point of view.[2] In fact, the self-assembly by metal complexation has provided a widely used route to supramolecular arrays.

Our experience in the chemistry of redox-active dirhodium(II,II) complexes, with lantern structures, led us to explore the possibility to build dirhodium multiredox based systems. By exploiting the metal-mediated self-assembly process, we recently succeeded in preparing a series of multiredox molecular square boxes incorporating two or four dirhodium(II,II) units, as redox metal centres, and dicarboxylate dianions as connectors.[3] The electrochemical

investigations performed on these square boxes $[Rh_2(form)_2(dicarboxylate)]_4$ [form = *N*,*N*′-di-*p*-tolylformamidinate, dicarboxylate = oxalate (ox) or terephthalate (tp)] featuring the *cis*-$Rh_2(form)_2$ moieties as angular components and *trans*-dicarboxylates as ligand connectors, provided evidence that no significant electronic interaction was operating among the dirhodium centres. The same electrochemical behaviour was also observed by introducing the redox active connector, *meso*-carboxyphenyl-functionalized porphyrin, 5,10-bis(4-carboxyphenyl)-15,20-diphenylporphyrin [$P(COO)_2$] into the cyclic structure. In fact, the porphyrin−dirhodium(II,II) macrocycle $[Rh_2(form)_2\{P(COO)_2\}]_2$ exhibits a CV pattern consistent with four independent redox centres releasing electrons at potential values that are mostly unchanged with respect to those of the parent species.[3]

Porphyrins are particularly attractive as building blocks for molecular materials as they couple a rich photochemistry to some interesting redox properties. They are among the most popular emitters, and indeed porphyrin-based molecules play the role of photo-active subunits in most natural photosynthetic systems,[4a] as well as in many artificial systems for solar energy conversion processes.[4b] The emission studies performed on the $[Rh_2(form)_2\{P(COO)_2\}]_2$ metallacycle revealed a luminescence decrease with respect to the free porphyrin, attributed to a reductive electron-transfer quenching of the porphyrin excited state by the dirhodium subunits.[3]

As a continuation of this study we planned the synthesis of new redox- and photo-active porphyrin−dirhodium(II,II) assemblies. The construction of such new assemblies was achieved by combining the versatile reactivity of the $[Rh_2(form)_2(O_2CCF_3)_2(H2O)_2]$ (**1**) complex[5,6] with the coordination capability of *meso*-substituted phenylporphyrins.[7]

Complex **1**, besides the well-known axial reactivity of dirhodium(II,II), allows the introduction at the equatorial position of bridging, neutral or charged, ligands.[6] Such a synthetic approach, successfully applied to the building of the above-mentioned square molecular boxes,[3] allows us to bridge carboxyphenylporphyrins at the equatorial positions of the dirhodium(II,II) species.

On the other hand, the classical axial reactivity of dirhodium(II,II) may be exploited to synthesise dirhodium(II,II)−pyridylporphyrin arrays with different shape or topology, depending on the number and geometry of the peripheral pyridyl substituents. Furthermore, dirhodium(II,II) may be used as *exo*-bidentate connectors, providing the right linear component to form square molecular boxes or grid polymers when combined with the appropriate angular component.1

In the present paper we report on the synthesis and characterization of a number of redox dirhodium(II,II)−porphyrin assemblies, with *meso*-substituted phenylporphyrins axially or equatorially ligated to dirhodium moieties. The electrochemical as well as the luminescence properties of the new multiredox systems have been also investigated.

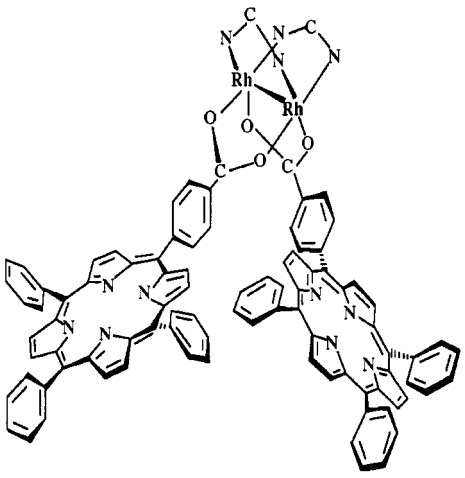

Figure 1. Structure proposed for $[Rh_2(form)_2(PCOO)_2]$ (**2**)

Results and Discussion

Synthesis and Characterization

$[Rh_2(form)_2(PCOO)_2]$ (2)

Dirhodium(II,II) systems bearing porphyrins in their equatorial positions have been synthesized by metathetical reaction of **1** with the sodium salt of *meso*-5-(4-carboxyphenyl)-10,15,20-triphenylporphyrin (PCOO). The addition of $[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$ (**1**) to a methanol/water solution of PCOONa (prepared in situ by treatment of the (carboxyphenyl)porphyrin with NaOH, see Exp. Sect.) affords $[Rh_2(form)_2(PCOO)_2]$ (**2**) in good yield. Compound **2** is a dark red-violet solid dissolving well in benzene and chlorinated solvents, sparingly in coordinating solvents such as acetone, acetonitrile, and alcohols. Elemental analysis, IR and NMR spectroscopic data are in agreement with the proposed structure (Figure 1), which retains the lantern structure of the parent complex **1**, i.e. with the two formamidinate and porphyrincarboxylate groups symmetrically bridged in a *cisoid* arrangement around the Rh_2^{4+} core.

The proton NMR spectrum of **2** does not differ significantly from those of the precursor subunits, with the exception of the pyrrole proton pattern, which consists of a rather broad singlet at $\delta = 8.88$, while in uncoordinated carboxyphenylporphyrin it appears as two doublets and one singlet. As already observed for the dirhodium−porphyrin molecular square box $[Rh_2(form)_2\{P(COO)_2\}]_2$ also bearing carboxyphenylporphyrins in the equatorial position, the electronic absorption spectrum of **2** appears as the sum of those of their constituents, suggesting that no significant electronic interaction is operating among the redox centres.

Reations of $Rh_2(form)_2(CF_3COO)_2(H_2O)_2$ (1) with Mixed meso-(4-Pyridyl)phenylporphyrins

Dirhodium(II,II)−porphyrin-based systems were also obtained by exploitation the classical axial reactivity of the

dirhodium(II,II) complexes towards Lewis bases. To this aim, the reactions of **1** with a series of functionalized *meso*-pyridylporphyrins were investigated.

$[Rh_2(form)_2(CF_3CO_2)_2(PyP)_2]$ (3)

The reaction of **1** with 5,10,15-triphenyl-20-(4-pyridyl)-porphyrin (PyP) led to the $[Rh_2(C_{15}H_{15}N_2)_2(CF_3CO_2)_2(PyP)_2]$ (**3**) adduct containing, as expected, two PyP axially coordinated to the dirhodium system via the peripheral pyridyl groups (Figure 2). The NMR spectra and the presence in the IR spectra of $\nu_{asym}(CO_2)$ and $\nu(N-C-N)$ bands at 1626 and 1594 (s) cm^{-1}, respectively, very similar to those of the parent complex **1**, confirm that the Rh_2^{4+} core remains unchanged upon the reaction.

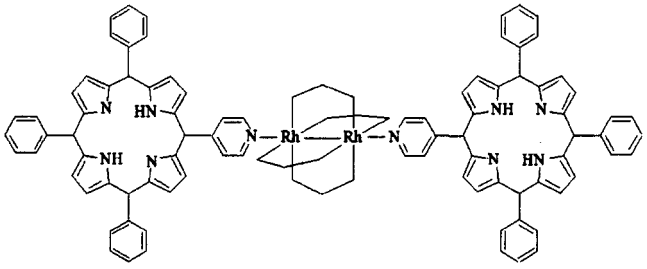

Figure 2. Structure proposed for $[Rh_2(form)_2(O_2CCF_3)_2(PyP)_2]$ (**3**)

Table 1. 300 MHz ^1H NMR chemical ($CDCl_3$, room temp.) shift for the (2,6- and 3,5-pyridyl)porphyrin protons; 2D ^1H NOESY spectra were performed to determine the correct assignment

Free porphyrins	2,6	3,5	Complexes	2,6	3,5
PyP	9.01	8.16	**3**	8.31	7.90
cis-DPyP	9.02	8.15	**4**	8.42	7.93
TPyP	9.06	8.16	**6**	7.78	7.97

Proton NMR spectroscopy is very diagnostic of the pyridylporphyrin coordination.[7] In the NMR spectra of pyridylporphyrins axially ligated to dirhodium(II,II) (present work), we found an upfield shift of the 2,6-pyridyl proton resonances (Table 1), which may be attributed to the π-back-donation from dp orbitals of the metal centre to π-anti-bonding orbitals of the porphyrin system. Consistently, the proton spectrum of **3** displays, for the 2,6-pyridyl protons, a doublet centred at δ = 8.31, with a $J_{H,H}$ coupling constant of 5.4 Hz, significantly upfield shifted as compared to free porphyrin (δ = 9.01), while the 3,5-pyridyl proton resonances are translated only by 0.26 upfield from the free one (δ = 7.90 vs. 8.16, respectively) (2D ^1H NOESY spectra were performed to determine the correct assignment). On the contrary, no shift is observed for the phenyl as well as for pyrrole proton resonances upon coordination.

$[Rh_2(form)_2(CF_3CO_2)_2(cis\text{-}DPyP)]_4$ (4)

Dirhodium(II,II) species, besides providing angular building blocks for the construction of molecular boxes, as we and others recently demonstrated,[3,8] exhibit the right properties (rigidity, geometry, and axial coordination capability) to act as *exo*-bidentate connectors of angular species leading to square molecular boxes. With this aim we explored the reactions of **1** with the 5,10-diphenyl-15,20-dipyridylporphyrin (*cis*-DPyP), which has in the past was been used successfully as an angular connector of transition metal complexes leading to square molecular boxes.[7a,7b,7f−7h]

Reaction of **1** with 1 mol-equiv. of *cis*-DPyP, in $CHCl_3$, at room temperature led to the formation of a 1:1 stoichiometry adduct, as indicated by elemental analysis and proton NMR integration data. Such a stoichiometry, in principle, may be indicative of the desired square box as well as of a polymeric species. The proper mass spectroscopic studies (MALDI, FAB- and ESI-MS), which in the lack of X-ray diffractometry data constitute the most powerful tool for establishing the nuclearity of such macrocycles, did not give unambiguous results, but, in any case showed no peaks due to long chain order oligomers.[9] No evidence of polymeric materials both as a precipitate and soluble by-products was observed, even by monitoring the reaction by NMR spectroscopy. These observations, along with the chemical and redox properties and the NMR investigations, suggest for **4** the cyclic structure showed in Figure 3.

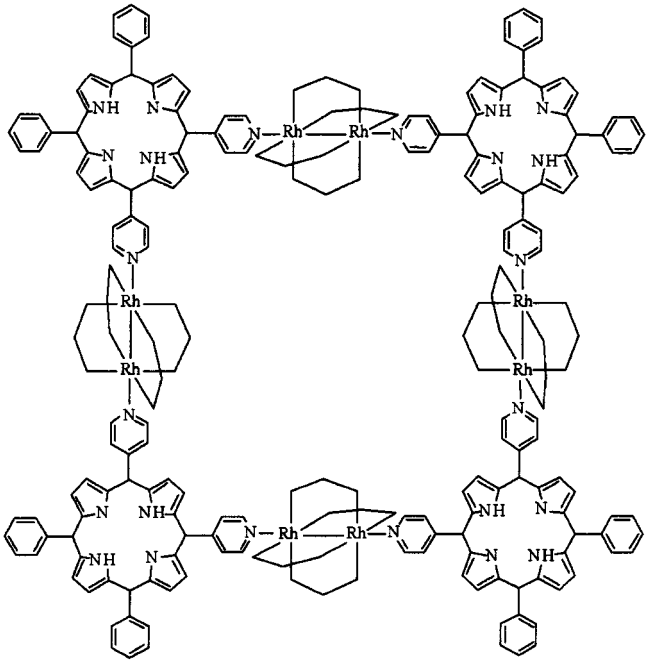

Figure 3. Structure proposed for $[Rh_2(form)_2(O_2CCF_3)_2(cis\text{-}DPyP)_2]_4$ (**4**)

This compound is, in fact, soluble in benzene and chlorinated solvents (interestingly, it is more soluble than the precursor *cis*-DPyP), but not in alcohols or acetonitrile or other coordinating solvents. Secondly, the proton spectra appear very simple and with well-resolved signals in agreement with a species at high symmetry, and finally, the redox properties are consistent with the proposed molecular structure (see below).

The inspection of the proton spectra reveals that the proton pattern resonances related to the dirhodium unit differ slightly from those of the starting building-block, while some differences are observed for the porphyrin proton resonances with respect to the free one. Consistent with the proposed structure, two equally intense doublets are observed for the (2,6- and 3,5-pyridine)porphyrin protons at $\delta = 8.42$ and 7.93, respectively, significantly shifted from free *cis*-DPyP ($\delta = 9.02$ and 8.15, respectively). Also, the phenyl as well as the pyrrole proton patterns are in agreement with a *cis* coordination for the bound *cis*-diphenyldipyridylporphyrin.[7a,7b,7f−7h] The two magnetically equivalent phenyl rings afford, in fact, two distinct proton sets for the two pairs of *ortho*- and (*meta* + *para*)-H, not shifted from free *cis*-DPyP. A slight overlapping is observed in the pyrrole proton patterns, which consist of two doublets and one singlet, accounting for four and eight protons each, respectively [three doublets are observed for free *cis*-DPyP, with a 2:4:2 proton ratio]. This is very likely caused by the pyrrole protons located inside the macrocycle that experience a downfield shift of $\delta = 0.03$ as compared to the unbound porphyrin.

$[\{Rh_2(form)_2(CF_3CO_2)_2\}_2(TPyP)]_n$ (5) and $[\{Rh_2(form)_2(CF_3CO_2)_2\}_4(TPyP)]$ (6)

The reaction of **1** with 5,10,15,20-tetrakis(4-pyridyl)porphyrin (TPyP) yielded different products depending on the molar ratio, as well as on the order of addition, of the reactants. The addition of **1** to a chloroform solution of TPyP led to a rust-coloured precipitate having a 1:2 stoichiometry between the dirhodium species and the TPyP porphyrin. Its insolubility in the most common solvents prevented its spectroscopic characterization and argues for the formation of a grid polymeric material of formula $[\{Rh_2(C_{15}H_{15}N_2)_2(CF_3CO_2)_2\}_2(TPyP)]_n$ (**5**).

When the reaction was performed in the presence of an excess of **1** (see Exp. Sect.), the species $[\{Rh_2(C_{15}H_{15}N_2)_2(CF_3CO_2)_2\}_4(TPyP)]$ (**6**), bearing four dirhodium subunits symmetrically coordinated to TpyP, was obtained in high yield. Elemental analyses and proton NMR integration agree with the requirements of the tetramer formulation as shown in Figure 4.

Consistently the aromatic region of ^1H NMR spectrum (Figure 5) shows only two doublets for the 2,6- and 3,5-pyridine protons at $\delta = 7.78$ and 7.97 ($J = 6.4$ Hz), respectively, significantly shifted with respect to those of free TPyP ($\delta = 9.06$ and 8.16, respectively), while, as expected for such a highly symmetric species, only one singlet at $\delta = 8.97$ is observed for the eight pyrrole protons, upfield shifted by 0.13 with respect to those of the free TPyP.[6d,6g] No changes are observed in the proton patterns related to the dirhodium subunits with respect to the parent complex **1**.

Complex **6** was very soluble in noncoordinating solvents (Et_2O, chlorinated solvents, etc.), remarkably more soluble than TPyP, and was stable as solid for a long time. In solution it slowly decomposed (3−4 d) releasing the parent complex **1** and an insoluble rust-coloured precipitate that was identified as **5** by IR and elemental analyses.

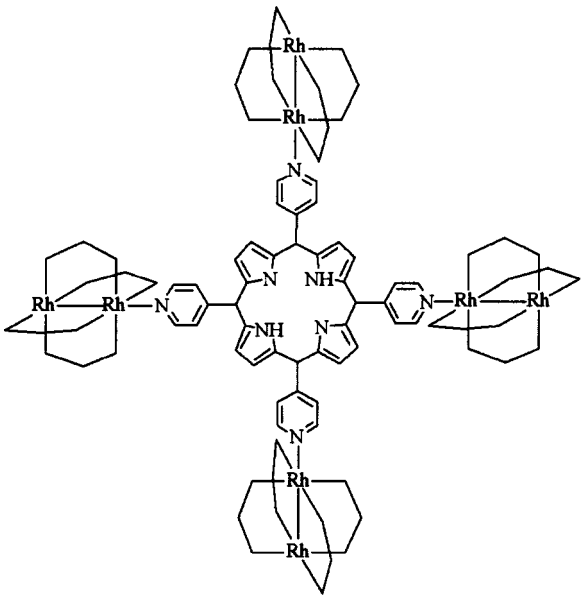

Figure 4. Structure proposed for $[\{Rh_2(form)_2(O_2CCF_3)_2\}_4(TPyP)]$ (**6**)

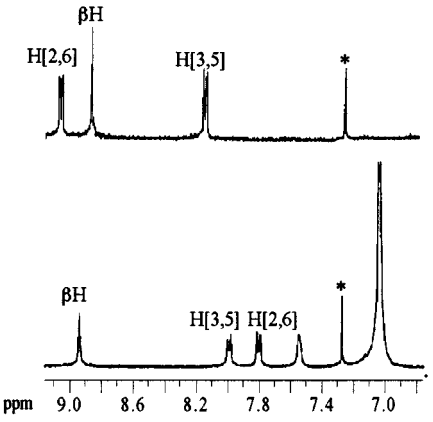

Figure 5. Aromatic region of the ^1H NMR spectra [$CDCl_3$ (*) room temp.] of TPyP (top) and (**6**) (bottom)

Electronic Spectra of 3, 4, and 6

The electronic absorption spectra of **3**, **4**, and **6** do not reveal significant modifications in the Soret and Q bands as compared to those of the unbound pyridylporphyrins, suggesting, once again, the absence of significant electronic interactions among porphyrin and the dirhodium subunits, as already observed for $[Rh_2(form)_2\{P(COO)_2\}]$ (**2**) and the square box $[Rh_2(form)_2\{P(COO)_2\}]_2$.

Electrochemistry

The new multicomponent redox systems exhibit several oxidation processes and one reduction process in the poten-

Table 2. Redox data of the new compounds; experiments were performed in argon-purged 1,2-dichloroethane solutions; all the processes are reversible except where otherwise noted; <#>: numbers of exchanged electrons

tial window examined (+ 2, −1.4 V vs. SCE), as evidenced by the redox data gathered in Table 2.

The first oxidation (+0.37 V vs. SCE) of complex **2** (Figure 6a) is attributed to the oxidation of the Rh_2^{4+} subunit, on the basis of: i) the reversibility of the process, ii) the number of electrons exchanged, iii) comparison with the potential of the oxidation process of the same subunit in the square species $[Rh_2(form)_2\{P(COO)_2\}]_2$ (+0.38 V vs. SCE).[3] Comparison with the molecular square $[Rh_2(form)_2\{P(COO)_2\}]_2$ also allowed us to attribute the second oxidation of **3** to the simultaneous one-electron oxidation of the two porphyrin subunits and the third one to the Rh_2^{5+}/Rh_2^{6+} process.

As far as compound **3** is concerned, it is interesting to note that its structure is similar to that of **2**, in particular, one "central" Rh_2^{4+} subunit is connected to two "peripheral" porphyrin fragments. However, significant differences in the properties of **2** and **3** may arise from the different nature of the linkages between subunits and from the presence, in compound **3**, of strong electron-withdrawing CF_3COO^- groups on the Rh_2^{4+} subunit (see Figures 1 and 2, respectively). Compound **3** indeed shows a redox pattern (Figure 6b) similar to that of **2**, and the attribution of the various processes to specific subunits is the same (see above). The relevant differences are the potentials of the oxidation processes centred in the Rh_2^{4+} subunit, that are substantially shifted to more positive values (ca. 200 mV; see Table 2). This is also in agreement with the oxidation reported for $[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$.[5,10]

Compound **4** exhibits three oxidation processes, each one involving four electrons. Comparison with the data of the parent compounds allows us to assign the observed processes as follows: the first process is due to four simultaneous one-electron Rh_2^{4+}/Rh_2^{5+} processes, the second one to the porphyrin subunits, and the third one to four simultaneous one-electron Rh_2^{5+}/Rh_2^{6+} processes. According to redox data shown in Table 2, the oxidation of the porphyrin fragments in **4** is more difficult than the analogous processes in **2** and **3**. This can be rationalised by considering

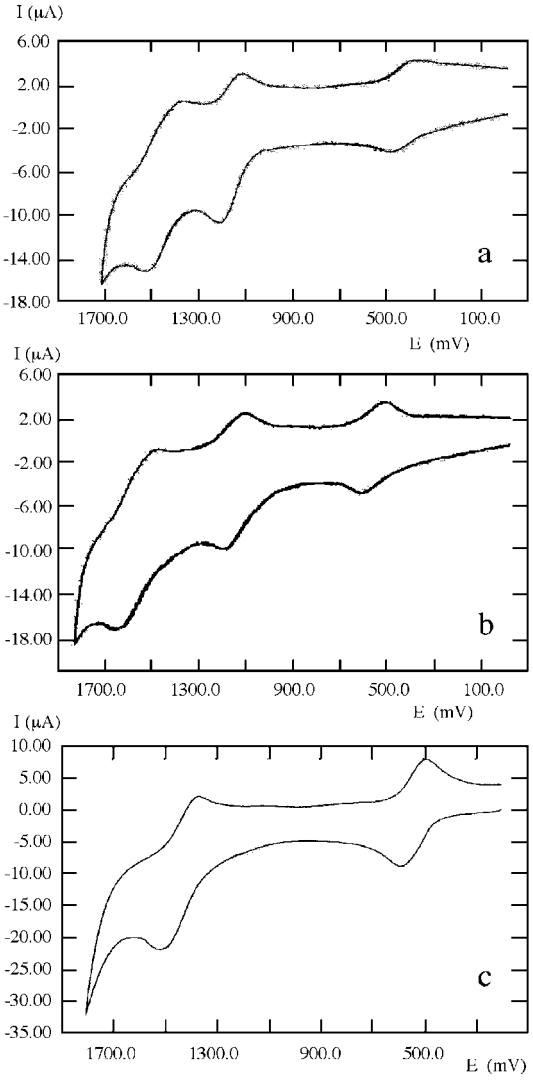

Figure 6. Cyclic voltammograms of compounds of **2** (a), **3** (b), and **6** (c); only the oxidation portion is shown

that: i) in **4** each porphyrin is connected to *two* already oxidized Rh_2^{5+} subunits when their oxidation occurs, ii) the presence of two pyridine groups most likely stabilises porphyrin orbitals.

The oxidation pattern of compound **6** is slightly different from those of the other new species reported here, in that it consists of only two processes in the potential window investigated (Figure 6c). Based on the number of exchanged electrons and of the potential values, it is possible to assign the observed processes to the successive one-electron oxidations of the four dirhodium subunits, i.e. Rh_2^{4+}/Rh_2^{5+} and Rh_2^{5+}/Rh_2^{6+} processes. The lack of the porphyrin-centred oxidation between the two dirhodium-based processes, opposed to the behaviour of the other new compounds, is probably due to the presence of the four already oxidized Rh_2^{5+} subunits, which displaces porphyrin oxidation to more positive potentials (after the second dirhodium-based oxidation). Moreover, the presence of four pyridine groups on the porphyrin fragment may also concur with this displacement.

On reduction, all the new species show a single process that is easily assigned to a porphyrin-centred reduction.[3] The number of exchanged electrons in each process is equal to the number of identical porphyrin subunits present in the examined compound. It is interesting to note that on increasing the number of pyridines the reduction process moves to less negative potentials (Table 2).

Luminescence

On the basis of the redox properties of the multicomponent systems **2**, **3**, **4**, and **6**, it was expected that the dirhodium(II,II) subunits could play the role of efficient quenchers of porphyrin-based luminescence by electron transfer. This was confirmed by the observed emission data, which are reported in Table 3 along with those related to the unbound chromophores PCOO, PyP, *cis*-DPyP, and TPyP.

Table 3. Luminescence data for the multicomponent systems **2**, **3**, **4**, and **6**, together with the related free porphyrins in air-equilibrated dichloromethane at room temperature

Compounds	Emission maxima [nm][a]	τ [ns]	ΔG [eV][b]
P(COO)	648	8.6	
2	648	1.5	−0.35
PyP	650	8.5	
3	no emission	−	−0.21
cis-DPyP	655	8.5	
4	no emission	−	−0.20
TPyP	655	8.5	
6	no emission	−	−0.27

[a] Only the highest-energy feature of the emission spectrum, taken as the E_{00} energy, is reported. [b] Driving force for the reductive electron transfer quenching, calculated as in Equation (1) (see text).

As expected, the uncoordinated porphyrins are strong emitters under the experimental conditions used. However, such an emission is significantly reduced in **2**, whereas **3**, **4**, and **6** do not exhibit any emission at all. This finding clearly indicates that a quenching of the porphyrin-based emission occurs in the studied multicomponent complexes due to the presence of the dirhodium subunits. A possible mechanism for the quenching is reductive electron transfer. Actually, the driving force ΔG for reductive electron transfer quenching of the porphyrin-based excited state by the dirhodium(II,II) subunits can be approximated by Equations (1) and (2), where entropy contributions and work terms are neglected.[11]

$$\Delta G = e[E_{ox} - {}^*E_{red}] \quad (1)$$

$${}^*E_{red} = E_{red} + E_{00} \quad (2)$$

In these Equations, E_{ox} is the oxidation potential of the dirhodium(II,II) subunit(s), E_{red} is the reduction potential of the porphyrin subunit(s), and E_{00} is the energy of the luminescent excited state of the corresponding model compounds, approximate to the highest-energy feature of the emission spectra. The ΔG values obtained are also shown in Table 2 and indicate that electron transfer from the dirhodium subunits to the excited porphyrin chromophores is moderately exergonic in all the cases. Electron transfer rate constants for moderately exergonic processes depend on the electronic interactions between the partners, in turn governed by several factors such as donor−acceptor distance, nature of spacers, and reorganization energy.[11] Compound **2** is luminescent, although with a reduced lifetime compared to PCOO. So the rate of the process k_{et} for this system can be easily obtained by Equation (3), in which τ_0 is the luminescence lifetime of the free porphyrin, PCOO, and τ is the luminescence lifetime of the species in the presence of the quencher, **2**.

$$k_{et} = 1/\tau - 1/\tau_0 \quad (1)$$

From the data in Table 3, k_{et} is 5.2×10^8 s^{-1} in **2**. It could be noted that this value is smaller than that estimated by a different method (luminescence quantum yield comparison between the free chromophore and chromophore-quencher systems) for a molecular square basically containing the same components.[3] However, in complex **2** each chromophore is connected to a single dirhodium(II,II) quencher, while in the molecular square compound reported in literature the chromophore was connected to two potentially quencher subunits, which both could contribute to the quenching process.

Complexes **3**, **4**, and **6** do not exhibit any emission, so the electron transfer rate constants cannot be evaluated by Equation (3). However, the complete quenching of the porphyrin emission in these complexes suggests that the electron transfer rate constants in **3**, **4**, and **6** are probably at least one order of magnitude larger than the value obtained for **3**. Differences in the driving force cannot be responsible for the difference in the electron-transfer rate, in that they are in the opposite direction (Table 3). The reason probably lies in the nature of the linkage between the chromophore(s) and the quencher subunits. Apparently, the pyridine linkage which is present in **3**, **4**, and **6** allows a better electronic coupling between donor and acceptor partners than the bridged carboxylate one, operating in **2** and in the molecular square $[Rh_2(form)_2\{P(COO)_2\}]_2$.

It should be noted that the occurrence of electron transfer between porphyrin and dirhodium subunits, which indicates that electronic coupling between the subunits takes place, is not in contradiction with the negligible interactions inferred by absorption spectra and redox properties. It is well known that electronic coupling as small as tens of cm^{-1}, which hardly cause changes in absorption spectra and redox properties of the individual subunits of the multicomponent arrays, are sufficient to promote fast intercomponent energy and/or electron-transfer processes.[12]

Conclusions

In the present paper, we have reported the results of our studies aimed at the synthesis and characterization of dirhodium−porphyrin assemblies as models of photoactive multiredox systems. The synthesis of such new assemblies

was achieved by combining the versatile reactivity, both axial and equatorial, of the $[Rh_2(form)_2(O_2CCF_3)_4(H_2O)_2]$ (**1**) complex with the coordination capability of *meso*-substituted phenylporphyrins. In this way, systems, featuring pyridylporphyrins axially coordinated or (carboxyphenyl)porphyrins equatorially bridged to the dirhodium subunits, were readily obtained. We have also explored the possibility of building dirhodium−porphyrin-based molecular square boxes. The capability of **1** to act as a precursor for new mixed dirhodium complexes, via the *cis*-$Rh_2(form)_2$ moieties, has already been exploited to synthesize the molecular square box $[Rh_2(form)_2\{P(COO)_2\}]_2$.[3] The square molecular box $[Rh_2(form)_2(CF_3CO_2)_2(cis\text{-DPyP})]_4$ (**4**), in which the dirhodium subunit acts as an *exo*-bidentate ligand, was obtained by assembling **1** with the *cis*-5,10-diphenyl-15,20-dipyridylporphyrin (*cis*-DPyP), which in turn constitutes the angular building block. It should also be remarked that the synthesis of the tetramer species $[\{Rh_2(form)_2(CF_3CO_2)_2\}_4(TPyP)]$ was achieved by reaction of **1** with 5,10,15,20-tetrakis(4-pyridyl)porphyrin (TPyP).

All the new systems undergo many redox processes in the potential window under investigation. It is important to stress that the redox patterns, especially in the oxidation part, are strictly related to the structure of the compounds.

In the multicomponent porphyrin−dirhodium assemblies studied here, the porphyrin-based emission is significantly quenched, most likely by reductive electron transfer from the dirhodium subunits to the excited porphyrin chromophores, a process which is moderately exergonic in all the cases. The rate constants of the processes appear to be larger in the compounds in which a pyridine linkage between dirhodium and porphyrin subunits is present compared with the compound in which the linkage is realized through bridging carboxylates, suggesting that the donor−acceptor electronic coupling is larger in the former cases.

Experimental Section

Materials: The starting complex $[Rh_2(form)_2(CF_3COO)_2(H_2O)_2]$ was prepared according to literature data.[5] The *meso*-5-(4-carboxyphenyl)-10,15,20-triphenylporphyrin was purchased from Mid-Century Company, Illinois. All other chemicals are commercially available and used as supplied. None of the compounds here reported were air-sensitive, but all reactions were carried out under dry nitrogen. Elemental analyses were performed by REDOX snc Laboratorio di Microanalisi, Monza, Italy.

Apparatus: Infrared spectra were recorded on KBr pellets with a Perkin−Elmer FT 1720X spectrometer. Electronic absorption spectra were recorded with a Perkin−Elmer Lambda 5 UV/Visible spectrophotometer. The NMR measurements were performed with a Bruker AMX 300 spectrometer using standard pulse sequences. Electrochemical measurements were carried out in argon-purged 1,2-dichloroethane at room temperature with a PAR 273 multipurpose equipment interfaced to a PC. The working electrode was a glassy carbon (8 mm^2, Amel) electrode. The counter electrode was a Pt wire, and the quasi-reference electrode was an Ag wire (ferrocene was used as internal standard). The concentration of the complexes was about 5×10^{-4} M. Tetrabutylammonium hexafluorophosphate was used as supporting electrolyte and its concentration was 0.05 M. Cyclic voltammograms were obtained at scan rates of 20, 50, 200, and 500 mV/s. For reversible processes, half-wave potentials (vs. SCE) were calculated as the average of the cathodic and anodic peaks. The criteria for reversibility were the separation between cathodic and anodic peaks, the close to unity ratio of the intensities of the cathodic and anodic currents, and the constancy of the peak potential on changing the scan rate. For irreversible processes, the values reported in Table 2 are the peaks estimated by differential pulse voltammetry (DPV). The number of exchanged electrons was measured with differential-pulse voltammetry (DPV) experiments performed with a scan rate of 20 mV/s, a pulse height of 75 mV, and a duration of 40 ms. Experimental error on the redox potentials was ± 10 mV. For the irreversible or quasi-reversible processes, an estimation of the number of the electrons involved can be inferred by current intensity of the anodic (for oxidation processes) or cathodic (for reduction processes) peaks. The luminescence experiments were performed in air-equilibrated dichloromethane solution at 298 K. Luminescence spectra were obtained with a Jobin Yvon-Spex Fluoromax 2 fluorimeter (experimental error on luminescence maxima was ± 4 nm). The spectra were corrected for detector response. The luminescence lifetimes were measured by an Edinburgh FL 900 Single-Photon-Counting Spectrometer (experimental error on lifetimes was ± 10%).

Preparations

$Rh_2(form)_2(PCOO)_2$ (2): To a mixture of methanol (50 mL) and 5-(4-carboxyphenyl)-10,15,20-triphenylporphyrin (0.150 g, 0.228 mmol) was added an aqueous solution (5 mL) of NaOH (0.010 g, 0.250 mmol). The resulting solution was stirred for ca. 1 h and then filtered. A chloroform solution (10 mL) of **1** (0.139 g, 0.152 mmol) was added dropwise to the filtrate, and the resulting mixture stirred for 36 h. After this time, the resulting brown red solid was collected by filtration, dissolved in 30 mL of benzene and the resulting mixture filtered. By addition of *n*-heptane (30 mL) to the filtrate, **2** was obtained as a red-brown microcrystalline precipitate. Yield: 0.185 g (62%). $C_{120}H_{88}N_{12}O_4Rh_2$ (1967.92): calcd. C 73.24, H 4.51, N 8.54; found C 73.34, H 4.58, N 8.60. IR (KBr pellet, nujol mulls): $\tilde{\nu}$ = 1619 [m, $\nu_{asym}(CO_2)$], 1593 cm^{-1} [s, ν(N−C−N)]. UV/Vis (C_6H_6): λ_{max} = 423.8, 514.4, 549.0, 591.2, 649.2 nm. ^{1}H NMR (CD_2Cl_2): δ = −2.66 (s, 4 H), 2.32 (s, 12 H), 7.16 (m, 16 H), 7.75 (m, 22 H), 8.20 (m, 14 H), 8.50 (d, 4 H, J = 8 Hz), 8.83 (br. s, 16 H).

$[Rh_2(form)_2(CF_3CO_2)_2(PyP)_2]$ (3): A chloroform solution (20 mL) of **1** (0.100 g, 0.110 mmol) was added to a solution of PyP (0.135 g, 0.220 mmol) in the same solvent (50 mL), and the resulting red-violet solution stirred for ca. 24 h. After this time, the solution was filtered and the solvents were evaporated to dryness using a rotary evaporator. The residue was washed with *n*-hexane and recrystallized from chloroform/*n*-heptane. Compound **3** was obtained as a dark-violet precipitate. Yield: 0.208 g (90%). $C_{120}H_{88}F_6N_{14}O_4Rh_2$ (2109.93): calcd. C 68.31, H 4.20, F 5.40, N 9.29; found C 68.12, H 4.30, F 5.35, N 9.22. IR (KBr pellet, nujol mulls): $\tilde{\nu}$ = 1626 [m, $\nu_{asym}(CO_2)$], 1594 cm^{-1}[s, ν(N−C−N)]. UV/Vis ($CHCl_3$): λ_{max} = 419, 515, 549, 589, 644 nm. ^{1}H NMR ($CDCl_3$): δ = −2.79 (s, 2 H), 2.22 (s, 12 H), 7.02 (m, 16 H), 7.54 (t, br, 2 H), 7.77 (m, 20 H), 7.90 (d, J = 5.4 Hz, 4 H), 8.24 (m, 10 H), 8.31 (d, J = 5.4 Hz, 4 H), 8.82 (d, 4 H, J = 4.83 Hz), 8.86 (s, 8 H), 8.95 (d, 4 H, J = 4.83 Hz).

$[Rh_2(form)_2(CF_3CO_2)_2(cis\text{-DPyP})]_4$ (4): A chloroform solution (75 mL) of *cis* -DPyP (0.087 g, 0.142 mmol) was added to a solution of **1** (0.130 g, 0.142 mmol) in the same solvent (30 mL). The resulting red-violet solution was stirred for 24 h, then filtered and

dried using a rotary evaporator. The residue was washed with *n*-hexane, and then dissolved in benzene (50 mL) and the resulting solution filtered. The addition of *n*-heptane to the filtrate afforded **5** as a dark-violet solid. Yield: 0.138 g (65%). $C_{76}H_{58}F_6N_{10}O_4Rh_2$ (5980.70): calcd. C 61.05, H 3.91, F 7.62, N 9.37; found C 60.95, H 3.96, F 7.49, N 9.29. IR (KBr pellet, nujol mulls): $\tilde{\nu}$ = 1622 [m, $\nu_{asym}(CO_2)$], 1592 cm^{-1} [s, ν(N−C−N)]. UV/Vis ($CHCl_3$): λ_{max} = 419, 515, 549, 589, 644 nm. ^1H NMR ($CDCl_3$): δ = −2.76 (s, 2 H), 2.13 (s, 12 H), 7.00 (m, 16 H), 7.51 (t, br, 2 H), 7.77 (m, 6 H, *m*-,*p*-H Ph), 7.93 (d, br, 4 H), 8.2 (m, 4 H, *o*-H Ph), 8.42 (d, br, 4 H), 8.78 (d, 2 H, J = 4.62 Hz), 8.87 (s, 4 H), 8.93 (d, 2 H, J = 4.62 Hz).

$[\{Rh_2(form)_2(CF_3CO_2)_2\}_2(TPyP)]_n$ (5): A chloroform solution (70 mL) of TPyP (0.040 g, 0.066 mmol) was added to a solution of **1** (0.120 g, 0.132 mmol) in the same solvent (30 mL). Immediately, **6** was formed as a red-brown precipitate. The resulting mixture was stirred overnight, and then the precipitate was collected by filtration, washed several times with $CHCl_3$, and dried in vacuo. Yield: 0.141 g (90%). $C_{108}H_{86}F_{12}N_{16}O_8Rh_4$ (2375.59): calcd. C 54.61, H 3.65, F 9.60, N 9.43; found C 54.43, H 3.64, F 9.43, N 9.44. IR (KBr pellet, nujol mulls): $\tilde{\nu}$ = 1626 [m, $\nu_{asym}(CO_2)$], 1594 cm^{-1} [s, ν(N−C−N)]. The low solubility of **5** prevented a full spectroscopic characterization.

$[\{Rh_2(form)_2(CF_3CO_2)_2\}_4(TPyP)]$ (6): A chloroform solution (70 mL) of TpyP (0.033 g,053 mmol) was added to a solution of **1** (0.120 g, 0.218 mmol) in the same solvent (30 mL). The resulting solution was stirred for 24 h and then left to stand for ca. 2 d. Then the solution was dried using a rotary evaporator, and the residue washed with *n*-hexane. Crystallization of the residue by diethyl ether/*n*-hexane (0 °C) afforded **6** as a dark-red microcrystalline solid. Yield: 0.135 g (60%). $C_{176}H_{146}F_{24}N_{24}O_{16}Rh_8$ (4132.48): calcd. C 51.15, H 3.56, F 11.03, N 8.13; found C 51.30, H 3.62, F 11.00, N 8.21. IR (KBr pellet, nujol mulls): $\tilde{\nu}$ = 1626 [m, $\nu_{asym}(CO_2)$], 1594 cm^{-1} [s, ν(N−C−N)]. UV/Vis ($CHCl_3$): λ_{max} = 419, 515, 549, 589, 644 nm. ^1H NMR ($CDCl_3$): δ = −2.90 (s, 2 H), 2.26 (s, 48 H), 7.0 (m, 64 H), 7.52 (t, br, 8 H), 7.78 (d, J = 6.4 Hz, 8 H), 7.97 (d, J = 6.4 Hz, 8 H), 8.97 (s, 8 H).

Kinetics and Reaction Mechanisms of Complexes with Cobalt−Carbon σ Bonds of the Type $\{(NH_3)_5Co-R\}^{n+}$ in Aqueous Solutions, a Pulse Radiolysis Study

Nurit Shaham,[a] Alexandra Masarwa,[a] Yoseph Matana,[b] Haim Cohen,[a,b] and Dan Meyerstein*[a,c]

Keywords: Cobalt / Kinetics / N ligands / Reaction mechanisms / Radiolysis

The kinetics of formation of complexes with cobalt–carbon σ bonds in the reaction between $\{Co^{II}(NH_3)_5H_2O\}^{2+}$ or $\{Co^{II}(NH_3)_6\}^{2+}$ with different aliphatic radicals was studied in aqueous solutions using the pulse radiolysis technique. The formation of the complexes $\{(NH_3)_5Co^{III}–R\}^{n+}$ obey pseudo first order rate laws and the rate constants for R = CH_3 and $CH_2CO_2^-$ are $(3.0\pm0.3)\times10^7$ and $(2.1\pm0.3)\times10^7$ $M^{-1}s^{-1}$, respectively. The UV/Vis spectra of the complexes are reported and found to be in agreement with previous results for analogous complexes. The results point out that the reactions $(NH_3)_5Co^{III}–R + R^{\cdot} + NH_3 \rightarrow Co(NH_3)_6^{2+} + R_2$ are fast thus limiting the radical route as a synthetic tool for the $(NH_3)_5Co^{III}–R$ complexes.

Introduction

The properties of complexes with cobalt−carbon σ bonds were widely studied for two main reasons:

1. The importance of the coenzyme vitamin B_{12}.

2. The kinetic stability of the cobalt−carbon σ bond, which provides the ability to synthesize a variety of complexes of this type.

The discovery that coenzyme B_{12} is a cobalt(III) complex containing a cobalt−carbon σ bond initiated many studies concerning the mechanisms of formation and decomposition of these bonds. It was argued that a prerequisite for the formation of a stable alkylcobalt(III) compound is an unsaturated equatorial ligand system. Thus, the complexes studied so far mainly contained ligands, which are considered coenzyme vitamin B_{12} analogues, i.e. unsaturated ligands bound to the cobalt ion in a planar configuration as analogous to the corrins,[1] e.g. unsaturated tetraazamacrocylic ligands.[2−4] These ligands stabilize the cobalt ion in three oxidation states; +1, +2 and +3. Alkylcobalt(III) compounds containing solely saturated ligands have been reported for relatively few cases,[4−6] the ligands were mainly saturated tetraazamacrocyclic ones, these complexes have been prepared employing various synthetic methods. Meyerstein et al.[7] studied the formation and decomposition of $(nta)Co^{III}-R$ complexes formed in the reactions of (nta)cobalt(II) complexes with various aliphatic radicals $^{\cdot}R$ [where nta is nitriloacetate, $N(CH_2CO_2^-)_3$], to elucidate the factors affecting the rates of cobalt−carbon bond formation. It was found that the stability of the cobalt−carbon bond towards homolytic cleavage is in the order $CH_3 > CH_2OH > CH(CH_3)OH > C(CH_3)_2OH$. The results also pointed out, that nta indeed stabilizes transient complexes of the type $\{(nta)Co^{III}-R(H_2O)\}^-$. The formation and decomposition mechanisms were further studied using the high-pressure technique.[8] It was concluded that metal−carbon bond formation is very similar to ligand-exchange processes in terms of volume changes, and follows an I_d mechanism in the case of cobalt(II). Homolysis of the cobalt−carbon bond is presumably accompanied by an additional contribution due to the volume difference between the low spin $LCo^{III}-R$ complexes and the high-spin $LCo^{II}(H_2O)$ complexes.[9] Recently, Kofod et al.[10,11] prepared several alkylcobalt(III) complexes with ammonia ligands such as $\{(NH_3)_5Co^{III}-CH_3\}^{2+}$, *trans*-$\{Co(en)_2(NH_3)(CH_3)\}^{2+}$ and $\{Co(NH_3)_6\}$-*mer*,*trans*-$\{Co(NO_2)_3(NH_3)_2(CH_3)\}_2$-*trans*-$\{Co(NO_2)_4(NH_3)_2\}$. Kofod[10] synthesized and spectroscopically characterized the complex $\{(NH_3)_5Co^{III}-CH_3\}^{2+}$ by alkylation of $Co(NH_3)_6^{2+}$ using methylhydrazine with dioxygen as the oxidizing agent, a route that had originally been developed for the preparation of organocobalt(III) compounds with unsaturated ligands.

Basically the strength of the cobalt−carbon σ bond depends on several factors:

1. The equatorial ligands, which influence the redox potential of the central cobalt ion. Changes in the structure and identity of the ligands cause changes in the properties of the complexes. The redox potential of the central cobalt ion is affected by the σ donor character of the ligands.

2. The character of the ligand in the *trans* position to the R group. It was shown that for a series of cobalt−methyl compounds ligands in the *trans* position [e.g.: CN^-, NO_2^-, H_2O, NH_3 and en (1,2-ethanediamine)], considerably affect the cobalt−carbon bond length and the UV/Vis absorption spectra (in agreement with the spectroscopic series $H_2O < NH_3 < CN^- \approx NO_2^-$).[12]

3. The character of the substituents on the aliphatic residue, R.

4. Steric hindrance which stems from the equatorial ligand structure and from the substituents on R.

It was decided to check whether the complexes $\{(NH_3)_5Co^{III}-R\}^{n+}$ can be synthesized according to Equation (1). This would open up the possibility of synthesizing a large variety of these complexes using radiation chemistry techniques. The results indicate that this technique might indeed be used, though it has its limitations. The new complexes were characterized spectrophotometrically, and their kinetics of formation and decomposition were studied.

$$\{(NH_3)_5Co(H_2O)\}^{2+} + {}^{\cdot}R \longrightarrow \{(NH_3)_5Co^{III}\text{-}R\}^{n+} \quad (1)$$

Results

N_2O-saturated aqueous solutions containing $(0.2-4.0)\times10^{-3}$ M $CoSO_4$, 20% NH_3 and in addition 1 M of one of the following substances, CH_3OH, CH_3COONa or $(CH_3)_2SO$, were irradiated by a short electron pulse from the linear accelerator. The experimental results, see below, point out, that under these conditions the primary radicals are transformed into the desired aliphatic radicals during the pulse. As the reaction of the $^{\cdot}OH$ radicals with NH_3 under our experimental conditions (ca. 11 M NH_3), competes with the reaction of $^{\cdot}OH$ radicals with $CH_3CO_2^-$ and CH_3OH,[13] see Table 1, the results (vide infra) indicate that the produced $^{\cdot}NH_2$ radicals react with the organic substrates to produce the desired aliphatic radicals by analogous reactions to those of the $^{\cdot}OH$ radical. This result is not surprising as the dissociation energy of the H_2N-H bond is considerably larger than that of the C−H bonds in $CH_3CO_2^-$ and CH_3OH.[14]

Table 1. Rate constants relevant to this study

Reaction	k [$M^{-1}s^{-1}$]
$(CH_3)_2SO + {}^{\cdot}OH \rightarrow (CH_3)_2S^{\cdot}(O)OH$	6.6×10^9 [21]
followed by:	
$(CH_3)_2S^{\cdot}(O)OH \rightarrow {}^{\cdot}CH_3 + (CH_3)S(O)OH$	1.5×10^7 [s^{-1}] [21]
$(CH_3)_2SO + {}^{\cdot}H \rightarrow (CH_3)_2S(OH)^{\cdot}$	2.7×10^6 [22]
$(CH_3)_2SO + e^-_{aq} \rightarrow$ products	1.6×10^6 [23]
$CH_3COO^- + {}^{\cdot}OH \rightarrow {}^{\cdot}CH_2COO^- + H_2O$	8.5×10^7 [24]
$CH_3COO^- + {}^{\cdot}H \rightarrow {}^{\cdot}CH_2COO^- + H_2$	3.5×10^5 [25]
$CH_3COO^- + e^-_{aq} \rightarrow$ products	$< 1.0\times10^6$ [26]
$CH_3OH + {}^{\cdot}OH \rightarrow {}^{\cdot}CH_2OH + H_2O$	9.7×10^8 [13]
$CH_3OH + {}^{\cdot}H \rightarrow {}^{\cdot}CH_2OH + H_2$	2.6×10^6 [13]
$CH_3OH + e^-_{aq} \rightarrow$ products	$< 1.0\times10^4$ [13]
$NH_3 + {}^{\cdot}OH \rightarrow {}^{\cdot}NH_2 + H_2O$	1.0×10^8 [13]

In all the systems studied a formation reaction was observed after the formation of the aliphatic radicals (Figure 1). The formation of the intermediates (for methyl and acetate) obey pseudo-first-order rate laws (Figure 1). The observed rates are proportional to the initial concentration of $[(NH_3)_5Co(H_2O)]^{2+}$ or $[Co(NH_3)_6]^{2+}$ (Figure 2). The rates are independent of the concentration of all other components of the solution, pulse intensity and the wavelength at which the reaction is observed. The products are unstable, vide infra, i.e. they are not $(NH_3)_5Co(H_2O)^{2+}$ or $Co(NH_3)_6^{3+}$. Therefore it is reasonable to propose that the intermediates formed in this process are of the type $\{(NH_3)_5Co^{III}-R\}^{2+}$, i.e. complexes with cobalt−carbon σ bonds, and that the reactions observed are as described in Equation (1). The results are summed up in Table 2. Though the straight lines in Figure 2 have no positive intercept, i.e. the reactions $R^{\cdot} + R^{\cdot} \rightarrow R_2$ do not compete with Equation (1) under the experimental conditions, the yield of the intermediates $(NH_3)_5Co^{III}-R$, as measured by its absorption, increases with an increase in $[(NH_3)_5Co(H_2O)^{2+}]$ (Figure 3). The spectra of the intermediates formed, Table 3, are similar to those of other complexes of this type,[10] a typical spectrum is shown in Figure 4.

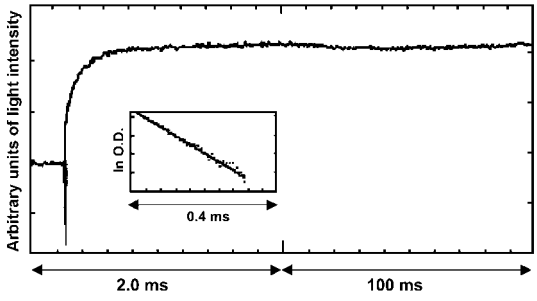

Figure 1. Formation kinetics of $[(NH_3)_5Co^{III}-CH_2CO_2^-]^+$; computer output of light intensity vs. time; N_2O-saturated solution with 1 M CH_3CO_2Na, 1×10^{-3} M $CoSO_4$, ca. 20% NH_3, the solution was irradiated with a maximum pulse and the kinetics were followed at 300 nm

Table 2. Measured rates of reaction of aliphatic radicals with $\{(NH_3)_5Co(H_2O)\}^{2+}$

Reaction	k_{1meas} [$M^{-1}s^{-1}$][a]
$\{(NH_3)_5Co(H_2O)\}^{2+} + {}^{\cdot}CH_3 \rightarrow \{(NH_3)_5Co-CH_3\}^{2+}$	3.4×10^7
$\{(NH_3)_5Co(H_2O)\}^{2+} + {}^{\cdot}CH_2COO^- \rightarrow \{(NH_3)_5Co-CH_2COO^-\}^+$	2.1×10^7
$\{(NH_3)_5Co(H_2O)\}^{2+} + {}^{\cdot}CH_2OH \rightarrow \{(NH_3)_5Co-CH_2OH\}^{2+}$	[b]

[a] The measured values are somewhat higher than k_1, see discussion. [b] The results imply that this process is an equilibrium process with a very small equilibrium constant, therefore it is difficult to establish this rate constant.

Mechanism of Decomposition of the Complexes $\{(NH_3)_5Co^{III}-R\}^{n+}$

The decomposition processes for all the intermediates in this study obey first-order rate laws. The measured decom-

[a] The pulses were given before the decomposition reaction occurs.

Discussion

Formation and Decomposition of the Complex $\{(NH_3)_5Co-CH_3\}^{2+}$

The experimental results indicate:

1) The reaction of the $^{\cdot}CH_3$ radical with the cobalt complex is relatively fast and the kinetics follows a pseudo-first-order rate law. The intercept of the line in Figure 2 is close to zero, i.e. K_1 is large and k_{-1} is small.

$$\{(NH_3)_5Co(H_2O)\}^{2+} + {}^{\cdot}CH_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \{(NH_3)_5Co^{III}\text{-}CH_3\}^{2+} \quad (2)$$

2) However, surprisingly the yield of the intermediate formed also depends on the initial cobalt complex concentration, Figure 3.

3) The decomposition reaction of the complex $\{(NH_3)_5Co^{III}-CH_3\}^{2+}$ obeys a first-order rate law, with a rate that does not depend on the concentrations of the solution components, i.e. the decomposition reaction does not proceed by homolysis.

4) The major final product is ethane, which is surprising for a first-order decomposition of the intermediate. The ratio of [ethane]/[methane] formed depends on the initial $[Co(NH_3)_6^{2+}]$ and the total number of pulses delivered to the sample, Table 5.

These results seemed to suggest that the ethane is not a product of the decomposition of the intermediate complex, $\{(NH_3)_5Co^{III}-CH_3\}^{2+}$, which decomposes heterolytically according to Equation (3). The ethane might alternatively be formed by Equation (4), however the small intercept in Figure 2 rules out that this is the major source of ethane, and suggests that Equation (5) also occurs. Reactions analogous to Equation (5) were observed for a variety of complexes, Table 6. If the rate constant of Equation (5) is high enough it will compete with Equation (2), thus explaining qualitatively the dependence of the $[C_2H_6]/[CH_4]$ ratio on the $[Co(NH_3)_6^{2+}]_0$ concentration and on the number of pulses delivered to the solution, Table 5.

Table 6. Rates of reaction of methyl radicals with $\{LM-CH_3\}^{n+}$

Reaction	$2k$ [$M^{-1}s^{-1}$]	Ref.
$\{(NH_3)_5Co-CH_3\}^{2+} + {}^{\cdot}CH_3$	$(6\pm3)\times10^8$	this work

$\{(nta)(H_2O)Fe-CH_3\}^{-} + {}^{\cdot}CH_3$	$(1.1\pm0.3)\times10^9$	[28]
$\{(nta)(H_2O)Mn-CH_3\}^{-} + {}^{\cdot}CH_3$	$(3.2\pm0.6)\times10^9$	[28]
$\{(cyclam)(H_2O)Ni-CH_3\}^{2+} + {}^{\cdot}CH_3$	8×10^7	[27]
$\{(hedta)Fe-CH_3\}^{2+} + {}^{\cdot}CH_3$	$(2.7\pm0.2)\times10^7$	[9]

$$\{(NH_3)_5Co^{III}-CH_3\}^{2+} \xrightarrow{H_2O} \{(NH_3)_5Co(H_2O)\}^{3+} + CH_4 \quad (3)$$

$k = 2.2\times10^{-4}\ s^{-1}$

$$2\,{}^{\cdot}CH_3 \longrightarrow C_2H_6 \quad (4)$$

$k = 1.6\times10^9\ M^{-1}s^{-1}$ [16]

$$\{(NH_3)_5Co^{III}-CH_3\}^{2+} + {}^{\cdot}CH_3 \longrightarrow \{(NH_3)_5Co(H_2O)\}^{2+} + C_2H_6 \quad (5)$$

To check whether the addition of Equation (5) to the reaction scheme indeed explains the experimental results and in order to estimate the rate constant of this reaction, the dependence of the ratio $[C_2H_6]/[CH_4]$ was simulated. The simulation experiment was done using the pro-K global analysis/simulation software (Applied Photophysics). The simulation was run assuming that only Equations (2), (4) and (5) have to be included, since Equation (3) is relatively very slow, and assuming that the concentration of methane formed equals the final concentration of the intermediate complex $\{(NH_3)_5Co-CH_3\}^{2+}$. The simulation had to account for the dependence of the $[C_2H_6]/[CH_4]$ ratio in the products on the $[Co(NH_3)_6^{2+}]_0$ concentration and on the number of consecutive pulses delivered to the sample, Table 5. The results clearly indicate that methane is mainly formed during the first pulses, while Equation (5) dominates during later pulses and ethane is primarily formed, Table 5. Initially the measured $k_1 = 3.4\times10^7\ M^{-1}s^{-1}$ was used to obtain a first estimate for k_5. Subsequently, the effect of the thus calculated k_5 on k_1 was examined, by simulating the rates of intermediate formation and both rates were iteratively adjusted. The following values best fit the experimental data: $k_1 = (3.0\pm0.3)\times10^7\ M^{-1}s^{-1}$ and $k_5 = (6\pm3)\times10^8\ M^{-1}s^{-1}$. Using these rate constants the concentrations of $\{(NH_3)_5Co-CH_3\}^{2+}$ by one pulse were calculated and the thus simulated data compared with those experimentally obtained from the optical density (O.D.) due to the transient complex, Figure 3. Obviously these rate constants simulate well with this data. The simulation points out that the yield of ethane according to Equation (4)[16] is negligible under most experimental conditions; k_5 can be compared to other reported values for analogous reactions, see Table 6. The rate constant for Equation (5) is at the higher end of the published data for these types of reactions.

It is of interest to compare the properties of $\{(nta)(H_2O)Co^{III}-CH_3\}^{-}$ [7] and $\{(NH_3)_5Co\text{-}CH_3\}^{2+}$. The former decomposes homolytically considerably faster than the heterolytic decomposition of the latter one. This is probably due to the fact that $\{Co(NH_3)_6\}^{2+}$ is a considerably stronger reducing agent than $\{Co(nta)(H_2O)_2\}^{-}$ [17] and therefore the electrons of the metal−carbon σ bond are nearer to the cobalt center in the $\{(nta)(H_2O)Co^{III}-CH_3\}^{-}$ complex. In other words the cobalt−carbon bond in $\{(NH_3)_5Co\text{-}CH_3\}^{2+}$ has a more ionic nature than that in $\{(nta)(H_2O)Co^{III}-CH_3\}^{-}$ which is more covalent and therefore tends more towards homolysis.

Formation and Decomposition of the Complex $\{(NH_3)_5Co-CH_2CO_2^{-}\}^{+}$

The acetate system behaves analogously to the methyl system. Formation and decomposition rates were measured (Tables 2 and 4) and corresponding dependencies of the formation rate constant and the intermediate concentration on initial cobalt(II) concentration were found (Figures 2 and 3). Therefore it is reasonable to conclude that the same reaction mechanism [analogous to Equations (2)−(5)] applies. The final products in this system were not measured as one of the possible products − acetate − is identical to the starting material. The rate for the reaction of the acetate radical with the intermediate (k_5 analogue) for this system was derived from a simulation of the dependency of the intermediate concentration versus the initial Co^{II} concentration (Figure 3) using the measured formation constant and a radical reaction constant (k_4 analogue) of $5.0\times10^8\ M^{-1}s^{-1}$.[15] The derived rate constant for the reaction of the intermediate with the acetate radical, $k_{5'} = (1\pm0.5)\times10^7$

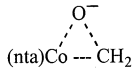
$M^{-1}s^{-1}$, is considerably lower than that for the methyl system. This observation is tentatively attributed to higher steric hindrance in this system.

Formation and Decomposition of the Complex $\{(NH_3)_5Co-CH_2OH\}^{2+}$

The formation constant of the intermediate $\{(NH_3)_5Co-CH_2OH\}^{2+}$ could not be measured as in this case the back reaction of Equation (6), the homolysis, is apparently fast.

$$\{(NH_3)_5Co(H_2O)\}^{2+} + {}^{\cdot}CH_2OH \rightleftharpoons \{(NH_3)_5Co^{III}-CH_2OH\}^{2+} \quad (6)$$

The experimental results point out that the equilibrium constant of Equation (6) is much smaller than that measured for the analogous intermediate with nta as ligand. In the nta analog it was suggested[7] that the intermediate formed is $\{(nta)(Co^{III}-CH_2O^-\}$, this intermediate does not decompose readily according to the homolytic reaction since it is stabilized by partial bonding of the oxygen atom to the cobalt center due to electrostatic interactions;[7] i.e. the intermediate formed is:



As in the NH_3 system the intermediate formed is $\{(NH_3)_5Co\text{-}CH_2OH\}^{2+}$ and no *cis* ammonia release is expected[18] as no such stabilization is possible and it decomposes very fast according to the homolytic pathway.

Spectra of the Complexes $\{(NH_3)_5Co^{III}-R\}^{n+}$

The general spectra of the $\{(NH_3)_5Co^{III}-R\}^{n+}$ complexes resemble the spectrum of the complex $\{(NH_3)_5Co^{III}-CH_3\}^{2+}$,[10] and the spectra of the complexes $\{(H_2O)(nta)Co^{III}-R\}^{2+}$.[7] This confirms the identity of the nature of the transient complexes formed, as complexes of cobalt(III) with cobalt−carbon σ bonds, $\{(NH_3)_5Co^{III}-R\}^{n+}$.

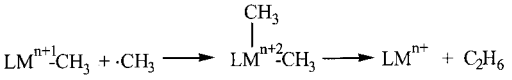
Concluding Remarks

The rate constants measured in this study, for the formation of the cobalt complexes with the cobalt−carbon σ bonds, with the different radicals, are similar to the known rate constants for ligand exchange of the complex $\{Co(H_2O)_6\}^{2+}$ in aqueous solutions, $k = 5\times10^6\ s^{-1}$. Reactions leading to the formation of the metal−carbon bonds clearly proceed according to the inner-sphere mechanism. The results are thus in agreement with a mechanism where the rate-determining step is the ligand-exchange step. Similar conclusions were reported previously for a variety of reactions in which metal−carbon σ bonds are formed by radical reactions.[2,7,19]

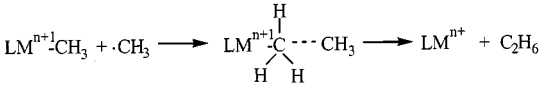
A comparison of the rates of reaction of ${}^{\cdot}CH_3$ radicals with a variety of complexes of the type $L_mM^{n+1}-CH_3$, Table 6, is of interest. Though all the other reactions measured are for $L_mM^{n+1}-CH_3$ complexes which decompose homolytically, the rate constant for $\{(NH_3)_5Co^{III}-CH_3\}^{2+}$, which decomposes heterolytically, falls well into the observed range for the other reactions, i.e. the rate constants of these reactions do not depend strongly on the "ionicity" or "covalency" of the metal−carbon σ bond. Contrary to the previously published systems, which decompose homolytically (with the exception of the copper systems, which decompose in a bimolecular reaction), $\{(NH_3)_5Co-CH_3\}^{2+}$ decomposes heterolytically, implying that the $Co-CH_3$ bond is considerably more ionic.

In principle two possible mechanisms might be envisioned for the radical complex reaction:

a) a second CH_3 radical coordinates at the *cis* position to the first one, followed by reductive elimination of ethane:



b) the second CH_3 radical attacks, and binds to, the carbon atom bound to the central metal cation:



Reaction a) can be disqualified, based on the velocity of the reaction, as the derived reaction rate for the process is significantly faster than typical ligand exchange reactions for such a system. Recently, van Eldik et. al.[18] measured the ligand exchange rate for the *trans*-labilized NH_3 ligand of the $\{(NH_3)_5Co-CH_3\}^{2+}$ system as $k_{sat} = 1.8\ s^{-1}$ (a *cis* ligand should be more difficult to exchange). This mechanism is also in agreement with the observation that $k_{(NH_3)_5Co^{III}-CH_3 + {}^{\cdot}CH_3} >> k_{(NH_3)_5Co^{III}-CH_2CO_2^- + {}^{\cdot}CH_2CO_2^-}$ as the latter reaction is sterically hindered.

Complexes with cobalt−carbon σ bonds can be synthesized by a radical process. Nevertheless, this technique has a disadvantage, the results imply that the reaction according to Equation (5) is very fast, especially for systems without steric hindrance, in comparison to Equation (2). Therefore, the attainable yields of the desired intermediates are expected to be relatively low.

Experimental Section

Materials: All solutions were prepared from AR grade chemicals and from distilled water which was further purified by passing through a Milli Q Millipore setup, final resistivity > 10 MΩ/cm.

pH: The pH was measured with a Corning 22 pH meter and adjusted by addition of $HClO_4$ and/or NaOH.

Radiolytic Technique: Pulse radiolysis experiments were carried out using the Varian 7715 linear electron accelerator at the Hebrew

University of Jerusalem. The pulse duration was 0.1−1.5 μs with a 200-mA current of 5-MeV electrons. The dose per pulse was 3−30 Gray. Irradiations were carried out in a 4-cm spectrosil optical cell, the analyzing light was passed three times through the cell. A 150-W xenon arc produced the analyzing light. The experimental setup was identical with that described earlier in detail.[20] For dosimetry, an N_2O-saturated solution containing 1×10^{-3} M $Fe(CN)_6^{4-}$ was used. The yield was measured by using $\varepsilon_{420} = 1000\ M^{-1}cm^{-1}$. The values of the molar extinction coefficient calculated from the dosimetry measurements have an error limit of ±15% due to the scatter in the pulse intensity and due to uncertainties in G values. A ^{60}Co source, Noratom, with a dose rate of ca. 6 Gray/min was used for low-dose rate experiments and product analysis.

Product Analysis: GC analysis: 30-mL samples in closed glass vials under N_2O were irradiated by the linear accelerator and/or by the ^{60}Co source. The gaseous products were analyzed using a Varian Model 3700 gas chromatograph.

Production of Radicals: The radiolysis of water in dilute aqueous solutions can be summarized as follows:

$$H_2O \xrightarrow{e^-,\gamma} {}^{\cdot}OH\,(2.65);\ {}^{\cdot}H\,(0.60);\ e^-_{aq}\,(2.65);\ H_2\,(0.45);\ H_2O_2\,(0.75) \qquad (7)$$

(G values in parentheses, are defined as the number of molecules of each product/100 eV radiation absorbed by the solution).[20] In concentrated solutions the yields of the radicals are somewhat higher and those of H_2O_2 and H_2 are somewhat lower. In N_2O-saturated solutions the hydrated electron is converted into the hydroxyl radical via:[13]

$$e^-_{aq} + N_2O \longrightarrow N_2 + {}^{\cdot}OH + OH^- \qquad (8)$$
$$k = 9.1\times10^9\ M^{-1}s^{-1}$$

at pH > 3 the contribution of ·H atoms to the total free radical yield is less than 10%. Methyl radicals were produced by reactions summarized in Table 1. The other alkyl radicals used in this study were prepared by hydrogen abstraction reactions of the primary radicals with the appropriate aliphatic solutes, these reactions are also summarized in Table 1.

Acknowledgments

This study was supported in part by a grant from the Budgeting and Planning Committee of The Council of Higher Education and the Israel Atomic Energy Commission. D. M. wishes to thank the Alexander von Humboldt Foundation for support and Mrs. Irene Evens for her ongoing interest and support.

Electronic Properties of the Axial Co−C and Co−S Bonds in B_{12} Systems − A Density Functional Study

Lucio Randaccio,*[a] Silvano Geremia,[a] Mauro Stener,[a] Daniele Toffoli,[a] and Ennio Zangrando*[a]

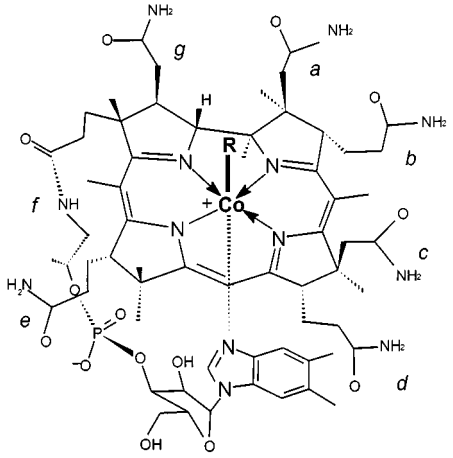
Keywords: Cobalamines / Coenzymes / Density functional calculations / X-ray diffraction

The numerous accurate structural data of cobalamins now available allows us to optimize the geometry of these systems, based on a simplified model by using density functional theory (DFT) calculations. This approach, which reproduces the trend of the experimental distances derived from EXAFS and X-ray crystal structures in the corrin macrocycle, permit us to interpret the electronic properties in the NB3–Co–X axial system. In particular, the results are analyzed for cobalamins containing a sulfur ligand which exhibits a "regular" *trans* influence, i.e., when the Co–S bond shortens, the *trans* Co–NB3 bond lengthens. This feature appears in contrast with an anomalous effect ("inverse" *trans* influence) postulated a few years ago by analyzing the structural data of several alkylcobaloximes, $LCo(DH)_2R$, a simple B_{12} model, and attributed principally to the electronic properties of the alkyl group R. The present study on the NB3–Co–S fragment does not indicate that the "inverse" *trans* influence is a general rule in cobalamins. The accurate crystal structures of the $[(SO_3)Cbl](NH_4)$ and [(thiourea)Cbl](PF_6) cobalamins based on synchrotron diffraction data at 100 K are also reported for comparison with the theoretical study. The former crystal structure, including one co-crystallized glycerol molecule, presents "for the first time" an ordered hydrogen-bonding pattern for the solvent molecules.

Introduction

Methionine synthase, whose cofactor is methylcobalamin (MeCbl; R = Me; Scheme 1) catalyzes the conversion of homocysteine to methionine.[1] The MeCbl-based enzymes (methyltransferases) catalyze the transfer of methyl groups from a nitrogen atom of methyltetrahydrofolate to cob(I)alamin (to form MeCbl) for onward transmission to an S atom of homocysteine. The enzymatic scheme proposed for the methionine synthase requires a reversible heterolytic cleavage of the Co−Me bond in the methyl carbocation and the strongly nucleophilic cob(I)alamin species.[2] In order to interpret the MeCbl function, several reactions of thiolates with organocobalt B_{12} model complexes have been carried out. However, the reports of these reactions were controversial.[3] Alkylthiolate cobalamin complexes, RS−Cbl, are also of interest as analogues of the RS and Co^{II}Cbl radical pair involved[4] in the mechanism of the coenzyme B_{12} (AdoCbl) dependent ribonucleotide reductase.[5]

Hence, knowledge of the properties and the behavior of thiolate−cobalamins is of significant interest. However, few thiolates have been isolated and characterized so far, and these have been principally by EXAFS[6] and NMR spectroscopy,[7,8] the former study also including (HSO_3)Cbl.



Scheme 1. Cobalamin

Only recently has the structural characterization of the NB3−Co−S fragment in $[(SO_3)Cbl](NH_4)$ (**1**) and $[(NH_2)_2CSCbl]Cl$ (**2**) been reported.[9]

Combining EXAFS and crystallographic results, it was concluded[6] that the S-containing ligands, such as thiolates and HSO_3^- have a weak *trans*-influencing ability, similar to that of H_2O[10] or CN.[11] Inversely, SO_3^{2-} exerts a strong *trans* influence similar to that of the methyl group.[9]

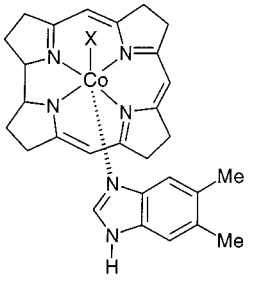
In order to verify the *trans* influence of HSO_3^-, we tried to prepare (HSO_3)Cbl according to a previous report.[6] The successive crystallographic analysis, described here, revealed that the compound is better formulated as $[(SO_3)Cbl](NH_4)$·glycerol solvate (**3**). Furthermore, in order to provide a more widespread comparison, the structural determination of $[(NH_2)_2CSCbl](PF_6)$ (**4**), more accurate than that of **3**, is also reported.

It is clear that the understanding of the chemical behavior of cobalamins requires an in-depth study of their electronic properties. However, despite the numerous experimental results, only a few attempts to understand their behavior on theoretical grounds have been carried out so far, principally on simple models[12] and in a few instances on R(Co−corrin)base (Scheme 2).[13] These studies, sometimes reaching conflicting conclusions, have been based on semiempirical approaches.[14] More recently, density functional theory (DFT) has been applied to calculate the geometry of some alkyl(Co−corrin)bases [15,16] and Co−corrin.[17] Furthermore, up to a few years ago, structural data on cobalamins were too low in accuracy for meaningful comparisons to be made.[18] Here, we report a theoretical approach, based on application of the density functional theory to the simplified model X(R)(Co−corrin)Bzm (Bzm = 5,6-dimethylbenzimidazole, X = R if alkyl group; Scheme 2), since the accurate structural data of several cobalamins is now available.[9−11,19,20] To complement this theoretical approach, which compares, for the first time, the electronic properties of the Co−S and Co−C bonds in the corrin model of cobalamins, some relationships with accurate structural data are reported.



Scheme 2. Model corrin system used for calculations

Crystallographic Results

Crystal Packing

The cobalamin molecules are packed in their crystals in such a way as to form large cavities, in which solvent molecules are located (or ionic species when present, as in ClCbl·2LiCl[20]). These cavities may be described as being made by a central channel, running along a crystallographic 2_1 axis, and connected to side pockets at intervals defined by this axis.[19] The channel content is characterized by a disordered pattern of water molecules, while an ordered scheme of full-occupancy water molecules characterizes the pockets.[19]

Moreover, the crystal packing of isomorphous cobalamins can be divided into four clusters (I−IV),[9,18] according to the *c*/*a* and *b*/*a* ratios of the unit cell parameters. Isostructural cobalamins, which belong to the same cluster, display very similar amide side chain conformations,[9] and hence a closely related arrangement of solvent molecules within the pocket. Cobalamin **3** has unit cell parameters very similar to those of **1**, in spite of the presence of one glycerol molecule per Co atom and, hence, it still belongs to cluster I, which is characterized by an intramolecular H bond between the amide chain *c* and the axial sulfite ligand. Analogously, cobalamin **4** belongs to cluster II, as does $[(NH_2)_2CSCbl]Cl$ (**2**), and it does not exhibit any intramolecular H bond, the chain *c* points away from the axial thio-

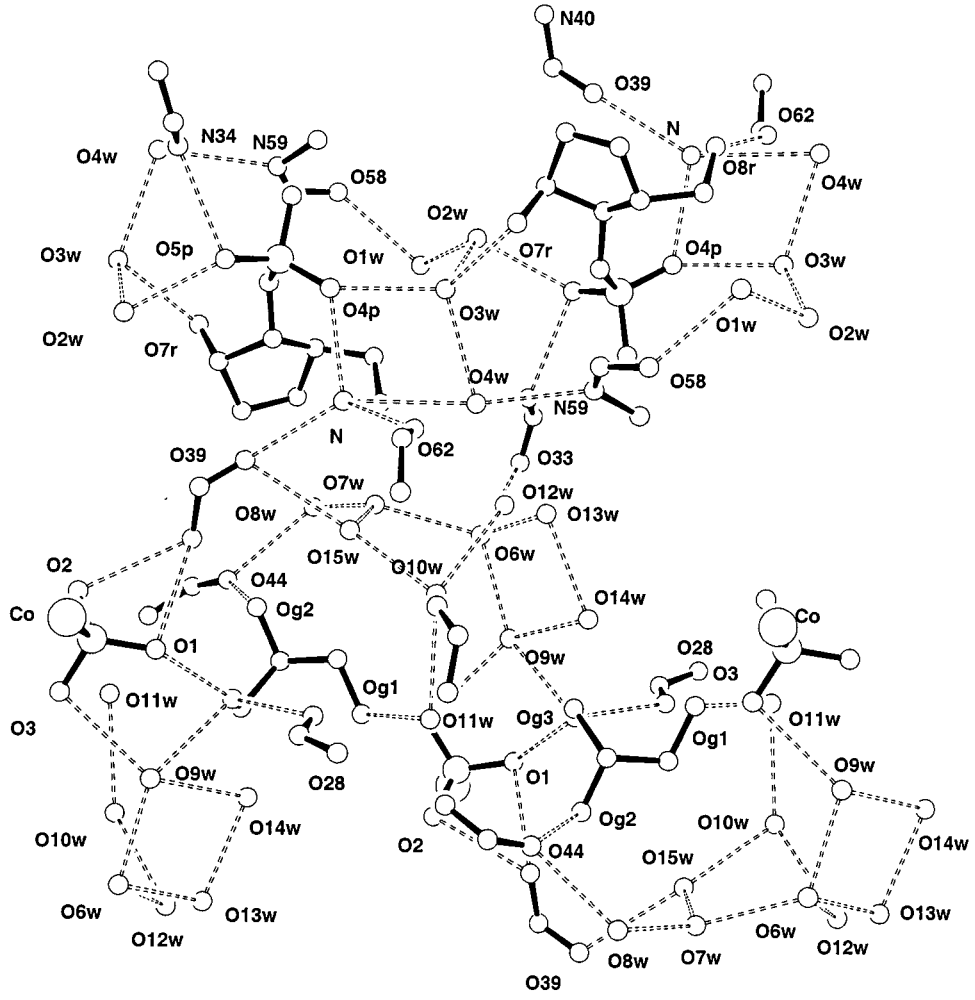

Figure 1. Hydrogen-bonding scheme (dashed lines) within the pocket for **3**; the content of a portion of the channel, running approximately along the horizontal direction of the figure, is also shown

urea ligand. The proposed H-bond scheme for **3** is given in Table 1 and the scheme within the cavity is shown in Figure 1. The structure within the pocket essentially corresponds to that found in **1** (see Figure 2 of ref.[9]), with only slight modifications (involving Ow3, Ow4, and OR7), as might be expected from the H-bond donor/acceptor scheme found in the crystal structure of vitamin B_{12r}, determined by neutron diffraction.[21] The glycerol molecules and the SO_3^{2-} groups are located within the channel, *where for the first time in a cobalamin crystal structure, the solvent molecules exhibit an ordered H-bond pattern*.

The H-bonding scheme within the cavity of **4** is significantly more detailed than that found in **2**, showing an ordered arrangement of the water molecules with full occupancy in the pocket and a disordered one in the channel, as has usually been the case in cobalamin crystal structures reported thus far. Of the disordered PF_6^- anion, the species with the highest occupancy (0.65) is located in the interface region, whereas the lower one (0.35) is in the channel.

Molecular Structure

The ORTEP drawings of **3** and **4** are shown in Figure 2 and Figure 3, respectively, and coordination distances are given in Table 2, where they are compared with those detected in the crystal structures of **1** and **2**. The folding angles, φ, defined as the dihedral angle between the two best-fit planes through N21/C4/C5/C6/N22/C9/C10 and C10/C11/N23/C14/C15/C16/N24, are also given in Table 2.

The axial distances in **1** and **3** are similar, whereas the Co−NB3 and Co−S distances are longer in **4** with respect to those of **2**. While the low accuracy of the latter structure[9] justifies the difference in the Co−NB3 distances, the discrepancy is more evident in the Co−S bond lengths. Actually, a re-examination of the difference Fourier map of **2** revealed a peak, along the Co−S bond, which could be assigned to a partially occupied (0.27) oxygen atom of a water ligand. This affected the previous refinement, which resulted in an artificial shortening of the Co−S distance.

Co−N22	1.913(2)	1.911(5)	1.894(9)	1.916(4)
Co−N23	1.890(3)	1.904(5)	1.91(1)	1.926(5)
Co−N24	1.886(4)	1.901(5)	1.881(9)	1.895(4)
φ	16.3(1)	16.5(2)	14.9(3)	14.5(1)

Comparison of data confirms the previous finding that the Co−NB3 distance in the sulfite derivative is significantly longer than that in the thiourea analogue. On the other hand, the Co−S distance in the latter is about 0.06 Å longer than the corresponding values in **1** and **3**. Therefore, our previous conclusion,[9] that the Co−SO_3 and Co−$SC(NH_2)_2$ bond lengths were very similar, must be revised.

The sulfite geometry in **3** is characterized by S−O distances in the range 1.459(5)−1.490(5) Å and by approximately tetrahedral angles around S, which do not differ significantly from those found in **1** (Table 3). The orientation of SO_3 with respect to the equatorial plane appears to be determined by the intramolecular H bond [3.001(8) Å] between O2S and the NH_2 group of the amide chain *c*. In **4**, the Co−S−C angle is 118.9(3)° and the approximately planar S−$C(NH_2)_2$ group is oriented with respect to the equatorial moiety in such a way that the N21−Co−S−C and Co−S−C−N2 torsion angles are 107.1(4) and −143.7(8)°, respectively. The thiourea N1 atom is involved in a H bond with a water molecule [N1···Ow9 [2.99(1) Å].

The value of 10^7 of the equilibrium constant for the substitution of water by sulfite in aquocobalamin,[22] and the close similarities of the Co−SO_3 fragment geometry in **1** and **3**, strongly suggest the [(SO_3)Cbl](NH_4) formulation for **3**. Furthermore, the site assigned to the NH_4^+ ion corresponds to that occupied by K^+ in the isostructural CNCbl·KCl,[11] which belongs to the same cluster I. In addition, it has been claimed that (HSO_3)Cbl may be prepared from aquocobalamin,[6] by dissolving it in sodium acetate buffer (pH = 5) and adding sodium sulfite.[23] Thus, these results appear to favor the (HSO_3)Cbl formulation for **3**, assuming that the ammonium cation position is occupied by a water molecule (as found in **4**). However, this appears unlikely because of the four H-bond short contacts around this site (2.886, 2.734, 2.800, and 2.796 Å with O39, OP4, O62, and OR8, respectively, Table 1) should require a water molecule to be involved in bifurcate (probably long) H bonds. An early report[24] indicated that in acetate buffer at pH = 5.0, the complex exists as sulfitocobalamin, as evidenced by both IR spectroscopy (which showed no significant change over a pH range of 4−14) and electrophoresis (which indicates an overall charge of −1). Finally, the calculated geometry for the HSO_3^- group does not reproduce the experimental data as it does for the thiourea derivative (see below).

Discussion

Comparison of X-ray (XRD) and EXAFS Results

Several accurate X-ray structural determinations of the axial distances in cobalamins are now available.[9−11,19,20] Comparison with those previously determined by EXAFS may be useful in order to establish the reliability of bond lengths determined solely by using the first-shell Fourier filter analysis of EXAFS data.[6,25] In particular, such a comparison is important in view of the recent controversial EX-

Table 3. Calculated and experimental bond lengths [Å] and angles [°] of the Co−SO_3 fragment in **1** and **3** and of the Co−$SC(NH_2)_2$ in **4**; the calculated geometry for the HSO_3^- derivative is also reported

AFS results concerning the considerable lengthening of the Co−N axial bond (by about 0.3 Å) in the protein-bound B_{12} coenzyme with respect to the free coenzyme.[26,27] In molecular biology, EXAFS is an ideal complement to biocrystallography in establishing the coordination distances in metalloenzyme and, under favorable circumstances, it can give coordination distances with an accuracy of 0.01 Å.[28] However, the analysis generally furnishes several solutions,[26] often difficult to interpret without comparison with accurate X-ray structural data, which often cannot be obtained for metalloproteins. Thus, such a dramatic impasse may be overcome if a model with precisely determined structure is available. Comparison of data for cobalamins, reported in Table 4, shows that the equatorial Co−Neq distances obtained by EXAFS and XRD are very similar. In fact, those determined by EXAFS range from 1.88(1) to 1.91(1) Å,[6] very close to the mean value of 1.895 Å based on 14 accurate X-ray structural determinations of R(X)−Cbl.[11] On the other hand, differences between axial distances, determined by means of EXAFS and XRD, range from −0.14 to +0.22 Å (Table 4). Thus, for example, the trend of the *trans* influence of the R(X) group, derived from EXAFS spectroscopy, is completely different. Such a large discrepancy has been ascribed to the presence of the four equatorial nitrogen atoms, which limits the accuracy of the axial distances because their contribution to the EXAFS spectrum interferes with that of the axial ligands.[27,29] The treatment of EXAFS data with the global mapping technique[26] has solved such a discrepancy in the case of $(H_2O)Cbl^+$, although it has been pointed out that multiple solutions are generally possible.[27,29] Thus, for $(H_2O)Cbl^+$, an alternative solution gave Co−N and Co−O distances in agreement with the crystallographic results (Table 4). More recently, an improvement of the global mapping technique, which reduces the parameters/observables ratio, has been proposed for the interpretation of EXAFS spectra of simple cobaloximes, a B_{12} model.[29] However, the lack of any structural information may sometimes render the choice among different solutions difficult.

Table 4. Cobalamins Co−X and Co−NB3 axial distances [Å] determined by X-ray diffraction (XRD) and EXAFS with relative differences Δ; the references in the footnotes correspond to XRD and EXAFS data, respectively

DFT-Optimized Geometry

Calculated and experimental coordination distances for several cobalamins are reported in Table 5. As expected,[30] calculated distances are shorter than the experimental ones, with the exception of the axial distances of the sulfite derivative and, to a lesser extent, of the Co−OH_2 and Co−CF_3 distances. The relatively enormous lengthening of the calculated axial distances in the SO_3^{2-} derivative corresponds to large deviations from the tetrahedral value for the angles about the sulfur atom (Table 3). In fact, calculated Co−S−O (in the range 101.9−104.5°) and O−S−O angles (in the range 113.8−115.4°) are larger and smaller, respectively, than the experimental ones. This inconsistency in the geometry can be attributed to the repulsion of the negatively charged oxygen atoms of SO_3^{2-}. Analogous comparison for the thiourea derivative does not show any discrepancy (Table 3). Calculations carried out for the HSO_3^- derivative also indicate that "addition" of a proton to SO_3^{2-} decreases the O···O repulsion, reducing the angular distortion in the $CoSO_3$ fragment. If the calculated values for the latter are considered, instead of those of sulfite, the experimental trend of the axial distances, when X is varied, is very

well reproduced. Thus it seems likely that the longer values of the calculated axial distances in $(SO_3)Cbl^-$ are due to a calculation artifact, ascribable to the high negative charge localized on the sulfite O atoms. This excess of charge should be caused by the lack, in the model molecule employed in calculations, of the interactions with the solvent (via H bonds), which delocalize the partial negative charge in the real system. This artifact gives rise to a strong apparent repulsion between the O atoms, indicated in the calculated structure by the flattening of the S tetrahedron towards the equatorial moiety (Table 3), which, in turn, enhances the steric repulsion with the macrocycle and provokes a lengthening of the Co−S bond, as well as a flattening of the corrin ligand (steric *cis* influence). In fact, the calculated folding angle φ of 10.26° [14.12° for $(HSO_3)Cbl$], is significantly smaller than the experimental one of 16.4° in the sulfite derivative. Consequently, the benzimidazole group is repelled away from the corrin with a concurrent lengthening of the Co−NB3 distance (steric *trans* influence).

The plots of calculated Co−NB3 and Co−X distances against the corresponding experimental values show fairly linear trends, excluding the calculated values for SO_3^{2-} (Figure 4). It should be stressed that in the simplified model of the corrin ligand used in the present calculations, H atoms have replaced the side groups. This does not allow consideration of the intramolecular interactions of the axial ligands with the corrin side chains. These interactions, such as the intramolecular H bonds between X and the corrin side chain *c* (when present), could affect the axial distances to some extent. It is of interest to compare the calculated axial distances for CN and Me derivatives of Table 5 with those obtained by Jensen et al.[16] by DFT calculations using the B3LYP method. These authors have found Co−C distances only marginally longer (ca. 0.03 Å), but Co−NB3 distances about 0.2 Å longer, than those calculated by our method.

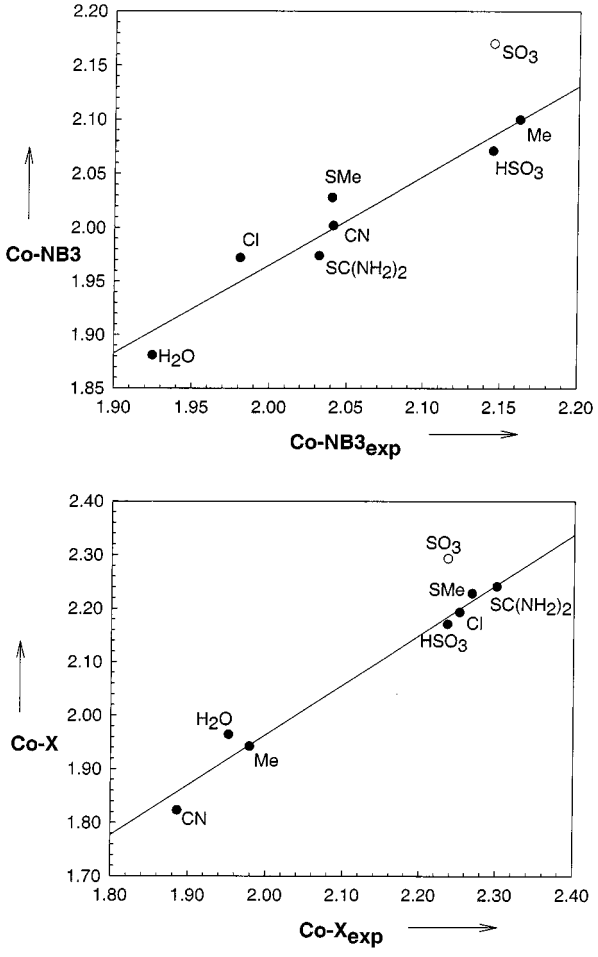

Figure 4. Plot of calculated Co−NB3 and Co−X distances [Å] in cobalamins vs. the corresponding experimental values; only experimental distances with e.s.d. values < 0.005 Å have been included (the experimental value of SO_3 is used also for HSO_3, see text)

[a] Present work. − [b] Ref.[17]; a C_2 symmetry has been assumed in these calculations. − [c] Ref.[11] − [d] Missing data in ref.[17]

The experimental trend of the equatorial distances is well reproduced, with the Co−N21 and Co−N24 distances shorter than the Co−N22 and Co−N23 (Table 5). The calculated distances within the equatorial Co−corrin moiety are essentially unaffected by the axial ligands. In Table 6 a comparison for X = CMe_3 (the strongest σ-donating and bulkiest group) and for X = H_2O (the weakest σ-donating and the less bulky one) is reported. The C_2 symmetry of the corrin unit is quite well preserved, with differences in the symmetry equivalent to distances not exceeding 0.008 Å for X = H_2O, and 0.004 Å for X = CMe_3. The comparison of corrin distances shows no significant influence of the X axial ligand, since the differences between analogous distances also do not exceed 0.008 Å. However, the deviation from planarity, signified by φ values of 16.91 and 6.82° for the H_2O and CMe_3 derivatives, respectively, reflects the bulk of the axial ligand.

The trend of the experimental distances in the delocalized moiety of the corrin (Scheme 2) is fairly well reproduced (Table 6). The calculated values of the C−C single bonds of the pyrrole rings are shorter, by 0.02−0.06 Å, than those determined experimentally, the larger differences involve the more "crowded" bonds, such as C_q-C_q, where C_q represents a quaternary C atom. These discrepancies should be ascribed to the simplified equatorial ligand used in the calculations. This cannot reproduce the *steric pressure exerted by the side chains which lengthen in cobalamins the corrin C−C single bonds.*[10] On the contrary, the expected trend (short−long−short distances) in the pyrrole fragment $C(sp^2)-C(sp^3)-C(sp^3)-C(sp^2)$ is well reproduced.

It is interesting to compare the present results with those of Rovira et al.[17] derived by means of density functional molecular dynamics within the Car−Parrinello scheme for the square-planar Co(corrin), assumed to have C_2 symmetry. It was found that the corrin distances were not influenced at all by the oxidation state +1 ($S = 0$), or +2 ($S = 1$) of the metal center. The calculated distances reproduced the experimental trend in the delocalized moiety of the corrin (Table 6). As expected, the pyrrole C−C single bonds were shorter, to a greater or lesser extent, than the experimental ones, but longer than our calculated values, by about 0.02 Å. On the contrary, the calculated Co−N equatorial distances of the present work compare well with those of Rovira. Therefore, the axial ligands do not appear to influence the equatorial distances, as suggested by those authors.[17]

Electronic Properties of the Co−C and Co−S Bonds

Mullikan populations (MP) on the NB3−Co−X fragment are given in Table 7. As it is well known, Mulliken population analysis allows a partial charge to be attributed to a particular atom in a molecule. This procedure is not rigorous, since there is not a physical definition of the atomic charge within a molecule; however, it can be very helpful for interpretative purposes.[31]

Table 7. Mullikan population on the NB3−Co−X fragment for several cobalamins X-Cbl

X	NB3	Co	X
H_2O	−.4673	.7290	.2842
Cl	−.4757	.4524	−.2269
CN	−.4874	.5280	−.3270
CF_3	−.4924	.4311	−.0416
Me	−.5000	.5449	.0726
CMe_3	−.4966	.6481	.1029
$SC(NH_2)_2$	−.4781	.3813	.7247
SMe	−.4844	.3745	.0792
HSO_3	−.4862	.3205	.1737
SO_3	−.4952	.3308	−.4111

The only linear relationship is found between MP of NB3 and the calculated Co−NB3 distances, as shown in Figure 5 for several X groups. The trend of the Mulliken charge on the NB3 group, reported in Table 7 is surprising to some

extent, especially if the observed random fluctuation of the charge on Co and X group is considered. This behavior may be rationalized if we consider the nature of the chemical bonds in which the metal atom is involved. In fact, while the NB3 group is always connected to the Co atom, preserving the nature of the atom pair, the nature of the atom of the X group connected to Co varies and it is therefore more difficult to compare the Mulliken charges on Co and X groups along the series. Apart from the stability of the Mulliken charge on NB3, it is interesting to observe that the negative charge increases when the *trans* influence of the X group becomes higher. This finding is consistent with a model of the NB3−Co chemical bond in terms of electronic charge donation from the nitrogen atom to the metal ion. In fact, the NB3−Co distance increases with the increase of the *trans* influence of X, and consequently the weakening of the latter bond leaves an excess of negative charge on the NB3 atom.

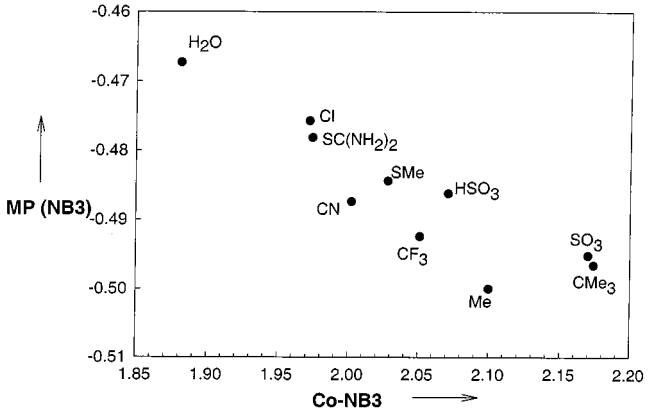

Figure 5. Plot of Mullikan population (MP) on NB3 vs. the calculated Co−NB3 distances [Å] for several X groups

Some peculiarities of the Mulliken charges on Co and X are worth noting. First, the positive charge of the metal ion is lower (< 0.4 au) when the Co is bound to a sulfur atom of the X group, irrespective of the position of the system along the series of increasing *trans* influence. This behavior can be explained by the "soft" character of the sulfur atom, which may be seen as an "electron reservoir" and is therefore able to screen more effectively the positive metal charge than the other ligands. The second interesting point is the very high positive charge of the thiourea. This finding clearly indicates that a strong conjugation is present in this ligand between the lone pairs of N and the C−S double bond. The latter is further polarized by the presence of the positive metal ion, which should enhance the conjugation via a Co−S π donation to the metal ion. Finally, the third observation regards the very high negative charge (−0.41 au) present on the SO_3 group. It has already been pointed out that the theory does not compare favorably with experimental data for this system, as previously described.

The NB3−Co−SR Fragment

Recently, we have found a good linear relationships between the Co−N and Co−X axial distances in cobalamins in comparison with the corresponding variables in cobaloximes, $LCo(DH)_2R$ (where DH = monoanion of dimethylglyoxime, L = neutral Lewis base, R = alkyl group).[11] This allowed an evaluation of the Co−NB3 and Co−SMe distances in cobalamins.[9] On the basis of these linear equations, slightly modified by including the recent data of the more accurate structures of MeCbl, CNCbl,[11] and AdoCbl,[32] ($r^2 = 0.980$, $n = 6$ for the Co−S bond and $r^2 = 0.966$, $n = 7$ for the Co−NB3 bond) the Co−SMe and Co−NB3 distances are found to be 2.26 and 2.04 Å, respectively. During the preparation of the present manuscript, we became aware of an accurate structural determination of (γ-glutamylcysteinyl)cobalamin (GCS-Cbl),[33] where the Co−S and Co−NB3 bond lengths were found to be 2.267(2) and 2.049(6) Å, respectively. These values are very close to those predicted above.

When X = HSO_3^-, SMe, and $SC(NH_2)_2$, the trend for the calculated Co−NB3 distances (Table 5) is as follows:
$SC(NH_2)_2$ (1.974) < SMe (2.028) < HSO_3^- (2.071 Å)
Inversely, the Co−S distances increase in the opposite order:
$SC(NH_2)_2$ (2.241) > SMe (2.228) > HSO_3^- (2.171 Å)

The above trends give an example of a "regular" *trans* influence, which is when the Co−S bond shortens and the Co−NB3 bond lengthens. A plot of the Co−NB3 vs. Co−S distances is reported in Figure 6. Correspondingly, the positive charge on Co (MP) decreases with the lengthening of the Co−NB3 distance, but it increases with the Co−S bond, shortening from $SC(NH_2)_2$ to HSO_3^- (Figure 7, bottom).

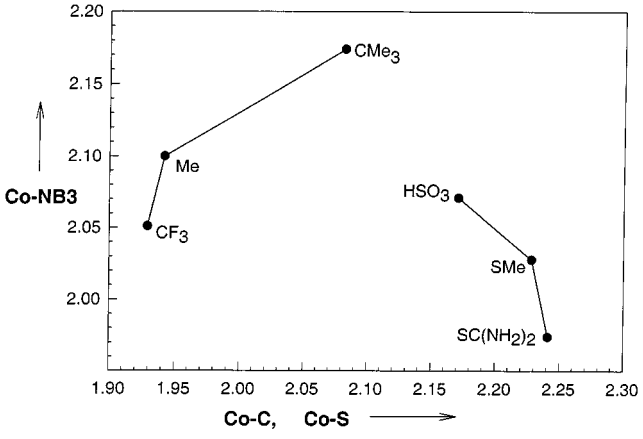

Figure 6. Plot of calculated Co−NB3 distances vs. the corresponding Co−X distances [Å] in cobalamins with alkyl and sulfur ligands

On the other hand, an "inverse" *trans* influence (i.e. both the Co−NB3 and Co−R distances increase) has been found[15] when the σ-donating ability of the R group increases from CN to Et. This finding was obtained by DFT calculations applied to the same simplified model corrin we have used in the present calculation.

Although the present Co−NB3 distances are approximately 0.15 Å shorter (and even more) than those calculated

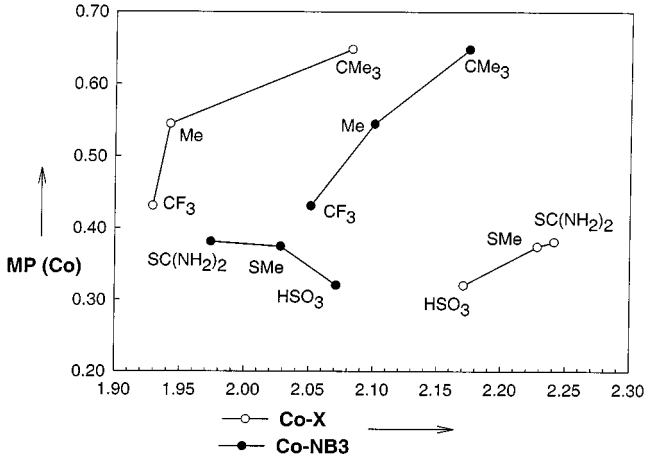

Figure 7. Plot of the Mullikan population (MP) on cobalt vs. the calculated axial bond lengths in cobalamins with alkyl (upper) and sulfur ligands (bottom)

by Andruniow et al.,[15] we have found this "inverse" *trans* influence for R = CF_3, Me and CMe_3 (Figure 6 and Table 5). Consistently, the positive charge on Co significantly increases with the lengthening of both the Co−NB3 and Co−C bonds (Figure 7, top). These findings appear to suggest that the different trend of the charge on Co with axial distances, in the two series containing S and C ligands, may be related to the "regular" or "inverse" *trans* influence of Figure 6. In fact, in the "regular" *trans* influence, the increase of the σ donation of the L group is reflected by the decrease of the Co positive charge. Therefore, the effect appears to be electronic in nature. On the other hand, in the "inverse" *trans* influence the positive metal charge increases with the σ-donating power of the R group. Thus, it cannot be an electronic, but rather a steric effect, due to the larger dimension of the σ-donor group (CMe_3). The steric repulsion, caused by the bulk of R, lengthens both the Co−R (steric *cis* influence) and Co−Nax (steric *trans* influence) distances and consequently the σ donation from ligands to the metal decreases, leading to a more positively charged metal.

The "inverse" *trans* influence, derived through an analysis of structural data in several alkylcobaloximes, $LCo(DH)_2R$, a simple B_{12} model,[34] was attributed principally to the electronic properties of R. However, it has been shown that in these complexes the bulk of R (independently of its electronic properties) also contributes significantly in determining the Co−R distance, because of its interaction with the equatorial ligand.[35] In fact, compared to the Me analogue, alkylcobaloximes with strong electronic withdrawing and bulky R groups, such as $CH(CN)CH_2CN$,[36] and $CF(CF_3)_2$,[37] show a significant lengthening of the Co−C bond (up to 0.08 Å) and a shortening of the Co−L bond (up to 0.03 Å). The present analysis of the NB3−Co−S fragment geometry does not support the idea that the "inverse" *trans* influence is a general rule also in cobalamins.

Experimental Section

Materials: Commercial samples of $(H_2OCbl)Cl$, stated purity by manufacturer about 96%, were purchased from Fluka. The other reactants were reagent grade and used without further purification. The complexes $[C_{62}H_{88}CoN_{13}O_{17}PS](NH_4)\cdot 12(H_2O)$ $(C_3H_8O_3)$ (**3**) and $[C_{63}H_{92}CoN_{15}O_{14}PS](PF_6)\cdot 13.3(H_2O)$ (**4**) were prepared in situ, growing the single crystals by the hanging drop method of vapor diffusion.

Preparation of 3: 2 μL of an aqueous $(H_2OCbl)Cl$ solution at 25 mg/mL was mixed with 2 μL of the precipitant solution containing $(NH_4)_2SO_4$, 20% glycerol, and 0.06 M $NaHSO_3$. Typical concentration range for precipitants were 20−45% in $(NH_4)_2SO_4$. Suitable single crystals were obtained only with 45% $(NH_4)_2SO_4$. Addition of LiCl did not result in formation of crystals. Attempts with PEG (with or without LiCl) were unsuccessful. The formation of the sulfite derivative, starting from $NaHSO_3$, is due to the high formation constant ($pK = -7$, with respect to the aquocobalamin) of $(SO_3)Cbl^-$, which allows its formation even in acid conditions (pH close to 4), where the concentration ratio $[HSO_3^-]/[SO_3^{2-}]$ is about 1000.

Preparation of 4: Several attempts to grow high quality single crystals were carried out, exploiting the procedure previously described,[10] slightly modified by addition of $(NH_4)PF_6$ in the ranges 0.10−0.50 M (by 0.05 M steps) and 0.05−0.16 M (by 0.01 M steps) and by substituting $(NH_4)_2SO_4$ with 20% glycerol as precipitant agent. Single crystals were obtained when 2 μL of an aqueous $(H_2OCbl)Cl$ solution at 25 mg/mL was mixed with 2 μL of the precipitant solution $(NH_4)PF_6$ (0.13 M), 20% glycerol and 0.30 M thiourea.

X-ray Structural Determinations: Diffraction experiments were carried out at the X-ray diffraction beamline of the Elettra Synchrotron, Trieste (Italy), using the rotating crystal method. Data were collected on a 345 mm MAR image plate with crystals mounted in loops and frozen to 100 K using a nitrogen-stream cryo-cooler. Crystallographic data for **3** and **4** are given in Table 8. The diffraction data were integrated using the DENZO program [38] and reflections subsequently were scaled and merged using the SCALEPACK program.[38] Friedel equivalent reflections were not merged and no absorption correction was applied. The phase problem was solved using the coordinates of an isomorphous structure as a starting model. The structural parameters were refined by full-matrix least squares on F^2 for all data using SHELXL-97.[39] The Fourier and Fourier difference maps clearly indicated that in **3** the PF_6^- anion is disordered over two different sites with occupancy factors of 0.65 and 0.35. Final *R* factors and details of refinements are reported in Table 8. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication, CCDC-161809 (**3**) and -161810 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Method: The electronic structures of the systems under study were determined by solving the Kohn−Sham equations,[40] in the framework of Density Functional Theory (DFT), employing the ADF suite of quantum chemistry packages.[41,42] The simplified model for the corrin ligand, shown in Scheme 2, was used as in previous calculations.[13,15] During the SCF procedure, the Local Density Approximation (LDA) to the exchange correlation energy functional was applied, accordingly to the Vosko, Wilk

and Nusair VWN parameterization.[43] The basis set consisted of Slater Type Orbitals (STO) taken from the database of ADF: For all the atoms a Double Zeta plus Polarization (DZP) frozen core set was chosen, with the exception of the cobalt atom where, as suggested by a previous study,[30] the more extended Triple Zeta (TZ) frozen core was utilized. The geometry of the systems was optimized employing a quasi-Newton procedure with analytical energy gradients and default convergence criteria. Since we are mainly interested in the geometry of the systems, the VWN exchange-correlation potential was employed, which performs better and is more accurate for structural analysis than the more demanding GGA potentials, as has been already pointed out in a previous computational study on transition metal compounds.[30] A larger basis set (TZP) has been tested for the SO_3 group with the aim of improving the capability of the method in order to describe negative fragments with a diffuse electron density. However, we did not observe any improvement. It can therefore be concluded that the method employed gives reliable results, and that the cause of the disagreement with the experiment must be found elsewhere.

Ion Conducting Behavior in $(Lu_{1-x}M_x)_2(WO_4)_3$ Solid Solutions (M = Sm, Ho, Er) with the $Sc_2(WO_4)_3$ Type Structure

Nobuhito Imanaka,*[a] Joachim Köhler,[b] Shinji Tamura,[a] and Gin-ya Adachi[a]

Keywords: Conducting materials / Ceramics / Electrochemistry / Tungsten / Solid-phase synthesis

Solid solutions in the trivalent cationic conducting system $(Lu_{1-x}M_x)_2(WO_4)_3$ (M = Er, Ho, Sm) that crystallize in the $Sc_2(WO_4)_3$ type structure were prepared and their conducting behaviors were characterized electrochemically. The partial replacement of the Lu^{3+} cation site in $(Lu_{1-x}M_x)_2(WO_4)_3$ by larger M^{3+} cations caused a crystal lattice expansion. Due to the opened ion-migration pathways, the solid solutions generally exhibited an increased cationic conductivity relative to pure $Lu_2(WO_4)_3$. The ion conductivity can be optimized by substituting the appropriate amount of M^{3+} into $(Lu_{1-x}M_x)_2(WO_4)_3$ in order to adjust the expansion of the migration pathways for the Lu^{3+} cations. Furthermore, a relationship between the average ionic radius of the trivalent cations involved and the ionic conductivity was characterized which makes it possible to predict the composition of the optimum ion-conducting compound in each solid solution system with the $Sc_2(WO_4)_3$ type structure.

Introduction

Compounds that crystallize in the scandium tungstate $Sc_2(WO_4)_3$ type structure and behave as trivalent cationic solid electrolytes have been intensively studied in recent years.[1−9] This research has focused mainly on the synthesis of various isostructural compounds with $Sc_2(WO_4)_3$-type structures and their characterization with respect to the trivalent cationic conduction properties. The $Sc_2(WO_4)_3$-type structure, in general $M_2(XO_4)_3$, is adopted by a huge number of tungstates (X = W) and molybdates (X = Mo). Considering $M_2(WO_4)_3$, M can be represented by trivalent cations of the heavier rare earth metals Er−Lu, Sc or by trivalent cations of the main group elements In and Al;[10] the corresponding molybdates, $M_2(MoO_4)_3$, are formed by Ho−Lu, Sc, In and Al.[10] In addition, it is possible to synthesize solid solutions by the partial replacement of a given M^{3+} cation with another trivalent cation B^{3+} $[(M_{1-x}B_x)_2(XO_4)_3]$[11] or by replacing the anionic part of the structure to give $M_2(W_{1-y}Mo_yO_4)_3$.[12] Furthermore, simultaneous substitutions in both the cationic as well as anionic part can be performed resulting in solid solutions such as $[M_2(WO_4)_3]_{1-x}[B_2(MoO_4)_3]_x$.[13] The number of possible compounds further increases when trivalent cations that are not usually able to form tungstates with the $Sc_2(WO_4)_3$ structure type are substituted into the host lattice. For example, $Gd_2(WO_4)_3$ crystallizes with the insulating $Eu_2(WO_4)_3$-type structure. However, a certain amount of Gd^{3+} (up to 60% of the trivalent cations) can be incorporated into $Sc_2(WO_4)_3$ maintaining the $Sc_2(WO_4)_3$-type structure and exhibiting ionic conduction characteristics.[14]

The ion conducting properties of a remarkable number of compounds with the $Sc_2(WO_4)_3$ type structure have been determined. It has been shown that the ion-conducting behaviors are strongly dependent on the nature of the trivalent cations. However, ordering principles are needed to manage and to oversee the huge amount of different conduction data.

Recently, the existence of such a principle was indicated during systematic investigations in the solid solution systems $(Sc_{1-x}M_x)_2(WO_4)_3$ (M = Lu, Dy, Gd) and $[Sc_2(WO_4)_3]_{1-x}[M_2(MoO_4)_3]_x$ (M = Lu, Gd, Sm, Nd). In these compounds, the Sc^{3+} conductivity was shown to be dependent on the crystal lattice expansion.[13,15]

It is the aim of this paper to determine whether this relationship can be generalized and extended to other solid solution systems with another trivalent-cation conducting tungstate series, such as trivalent ion species with ionic radii appreciably larger than that of Sc^{3+}. For this purpose, solid solutions in the system $(Lu_{1-x}M_x)_2(WO_4)_3$ (M = Er, Ho, Sm), which behave as Lu^{3+} ion conductors, have been prepared and characterized for the first time. The Lu^{3+} ion conducting system has been chosen for two reasons: i) the cationic radius of Lu^{3+} ($r_{Lu}{}^{3+}$ = 0.1001 nm)[16] is considerably larger than that of Sc^{3+} ($r_{Sc}{}^{3+}$ = 0.0885 nm),[16] and ii) because of the fast ion-conduction properties of $Lu_2(WO_4)_3$ {among compounds with the $Sc_2(WO_4)_3$-type structure,

$Lu_2(WO_4)_3$ exhibits the second highest conductivity [the optimum conducting compound is $Sc_2(WO_4)_3$ itself][1,5].

Results and Discussion

The ionic radii of several trivalent cations are summarized in Table 1 according to the coordination number of six in an octahedral environment.[16] Solid solutions between $Lu_2(WO_4)_3$ and $M_2(WO_4)_3$, with the $Sc_2(WO_4)_3$-type structure, are formed. Changing the size of the trivalent cation M^{3+} leads to drastically altered conditions for the formation of solid solutions. This relationship is displayed in Figure 1, where the solubility of $M_2(WO_4)_3$ in $Lu_2(WO_4)_3$ is given as a function of the ionic radius of M. For better illustration, the corresponding data of the previously described solid solutions in the systems $(Sc_{1-x}M_x)_2(WO_4)_3$ (M = Lu, Dy, Gd)[15] and $[Sc_2(WO_4)_3]_{1-x}[M_2(MoO_4)_3]_x$ (M = Lu, Gd, Sm, Nd)[13] are also shown. The ionic radii of W^{6+} (0.056 nm)[16] and Mo^{6+} (0.055 nm)[16] are almost identical and a corresponding influence on the mutual solubility can be neglected. For example, both $Gd_2(WO_4)_3$ and $Gd_2(MoO_4)_3$ can be dissolved into $Sc_2(WO_4)_3$ to about 60 mol %.[13,15] Thus, a direct comparison of the tungstate and molybdate systems, as shown in Figure 1, is possible. It can be seen that solid solutions between different tungstates/molybdates can be formed over the entire composition range ($0 < x < 1$) only for dopant cations M^{3+} with an ionic radius smaller than 0.105 nm. This value seems to be a stability limit for the $Sc_2(WO_4)_3$-type structure. The incorporation of larger cations causes a gradual decrease of the solid solution limit with increasing ionic radius of M^{3+}; for example, $x = 0.6$ for M = Gd ($r_{Gd}^{3+} = 0.1078$ nm[16]) and $x = 0.4$ for M = Sm ($r_{Sm}^{3+} = 0.1098$ nm[16]). Cations larger than Nd^{3+} cannot be dissolved into the $Sc_2(WO_4)_3$-type structure. The large cations cause strong local distortions in the crystal lattice which in turn collapses at a certain dopant level in order to release the strain and to form a new type of crystal structure. For example, pure $Gd_2(WO_4)_3$ and $Sm_2(WO_4)_3$ do not form the $Sc_2(WO_4)_3$-type structure but rather crystallize in the $Eu_2(WO_4)_3$-type structure.[10] Higher concentrations of M ($x > 0.6$ for M = Gd or $x > 0.4$ for M = Sm) in $(Lu_{1-x}M_x)_2(WO_4)_3$ destabilize the $Sc_2(WO_4)_3$ structure and favor the formation of either solid solutions in the corresponding $Eu_2(WO_4)_3$-type structure or mixtures of $Lu_2(WO_4)_3$ and $M_2(WO_4)_3$. On the other hand, $Er_2(WO_4)_3$ and $Ho_2(WO_4)_3$ crystallize in the $Sc_2(WO_4)_3$ type, and complete solid solution formation with $Lu_2(WO_4)_3$ becomes possible.

$Sc_2(WO_4)_3$, $Lu_2(WO_4)_3$ as well as the corresponding solid solutions $(Lu_{1-x}M_x)_2(WO_4)_3$ (M = Er, Ho, Sm) behave as trivalent cation conductors[13] and the ion-conduction properties vary with changing size and concentration of the different M^{3+} cations. The main effect of the incorporated larger M^{3+} cations in the $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions is to increase the lattice parameters *a*, *b*, and *c*, as indicated by the corresponding shifted d-spacings of individual peaks in the X-ray diffraction pattern.[13] The size of the unit cell increases isotropically and linearly with increasing substitution ratio, as shown in Figure 2 for solid solutions in the $(Lu_{1-x}Er_x)_2(WO_4)_3$ system. The substitution ratio is directly related to the average radius of the trivalent cations r_m [$r_m = (1-x)\cdot r_{Lu}^{3+} + x\cdot r_M^{3+}$]. The linear dependence between the average cationic radius and the cell volume, as shown in Figure 2, will be of importance for the subsequent discussion.

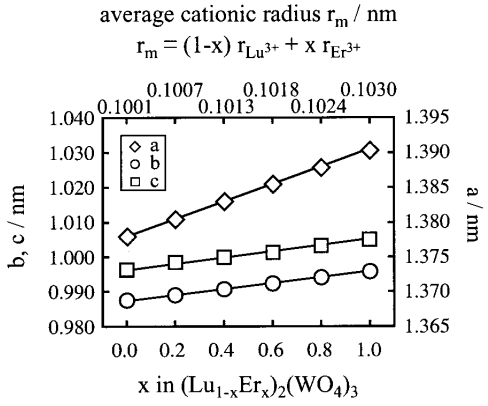

Figure 2. A plot of the lattice cell parameter of $(Lu_{1-x}Er_x)_2(WO_4)_3$ solid solutions versus the composition and the average trivalent cationic radius, r_m

Table 2. Figure 3. A plot of the trivalent cation conductivity at 600 °C (log $\sigma_{600\,°C}$) versus the compositional parameter, x, for the $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions with M = Sm (○), Ho (□), Er (▼)

The conductivities of several $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions differing in the compositional parameter x have been determined. The corresponding conductivity data at 600 °C (log $\sigma_{600\,°C}$) are tabulated in Table 2 in addition to the corresponding activation energies (E_a) as well as the average ionic radii of the involved trivalent cations. The activation energies are calculated from the log σT vs. 1/T relationship in the temperature range of 400−700 °C by using the common Arrhenius equation. A plot of the trivalent ion conductivities (log σ) of $(Lu_{1-x}M_x)_2(WO_4)_3$ at 600 °C versus the $M_2(WO_4)_3$ content (x) in $(Lu_{1-x}M_x)_2(WO_4)_3$ (M = Er, Ho, Sm) is shown in Figure 3. As a result, by expanding the crystal lattice due to the incorporation of larger cations M^{3+} into $(Lu_{1-x}M_x)_2(WO_4)_3$, the migration pathways within the crystal structure become more opened, which leads to a reduction in the electrostatic interaction between the mobile trivalent cations and the anionic host lattice. Thus, the migration of the trivalent Lu^{3+} cations is improved and increased conductivities are obtained in comparison to pure lutetium tungstate.

However, although the unit cell expands continuously over the whole composition region ($0 < x < 1$) and a corresponding continuous enhancement of the conductivity would be expected, a more complex behavior of log σ is found depending on the concentration and the size of the substituting cation, M^{3+}. Starting from the viewpoint of pure $Lu_2(WO_4)_3$, the conductivity increases continuously with increasing x because of the opening of the migration pathways due to the incorporation of the larger cation M^{3+}. However, at a certain composition, log σ reaches a maximum and the addition of further $M_2(WO_4)_3$ only reduces the ion-conduction properties. In our previous studies, trivalent cations with an ionic radius larger than Lu^{3+} are shown to be less mobile due to steric reasons.[5] Thus, although the crystal lattice is continuously expanding with increasing substitution ratio, the ionic conductivity decreases after reaching a maximum due to the exchange of mobile Lu^{3+} cations by M^{3+} cations that show a less-mobile behavior in $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions. The corresponding activation energies seem to confirm the aforementioned assumption by exhibiting the same dependency on the composition in each single system as the conductivity. The lowest and highest activation energies were observed (see Table 2) in solid solutions with the best and worst conductivities, respectively. This behavior is fully consistent with the corresponding results in the solid solution systems $(Sc_{1-x}M_x)_2(WO_4)_3$ (M = Lu, Dy, Gd) and $[Sc_2(WO_4)_3]_{1-x}[M_2(MoO_4)_3]_x$ (M = Lu, Gd, Sm, Nd), where the Sc^{3+} cations have been unambiguously identified as the main charge-carrying species in the high ion-conducting compounds.[13,15]

Although the optimum conductivity in each single system (different systems refer to different M^{3+} cations) is observed for different compositions [different x in $(Lu_{1-x}M_x)_2(WO_4)_3$] in Table 2, the maximum appears at almost the same average ionic radius, r_m, of the concerned trivalent cations. A similar behavior was also observed during systematic investigations in the solid solution systems $(Sc_{1-x}M_x)_2(WO_4)_3$ (M = Lu, Dy, Gd) and $[Sc_2(WO_4)_3]_{1-x}[M_2(MoO_4)_3]_x$ (M = Lu, Gd, Sm, Nd).[13,15] The corresponding relationship between the conductivity

(log σ) and the average ionic radius, r_m, is shown in Figure 4, with the Sc^{3+}-conducting systems included for comparison (Figures 4b and 4c). The maximum ion conductivity in each solid solution system, corresponding to the main conducting species (Sc^{3+} or Lu^{3+} cations), appears at a similar average trivalent cationic radius within the Sc^{3+}- and Lu^{3+}-conducting compounds, respectively. It amounts to approximately 0.0938−0.0943 nm in $(Sc_{1-x}M_x)_2(WO_4)_3$ and $[Sc_2(WO_4)_3]_{1-x}[M_2(MoO_4)_3]_x$ and to about 0.1011−0.1017 nm in the $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions. The size of the trivalent cations is directly related to the expansion of the crystal lattice (cf Figure 2), i.e. to the extension of the migration pathways. According to the different ionic size of Sc^{3+} and Lu^{3+}, the optimum conductivities in $(Lu_{1-x}M_x)_2(WO_4)_3$ appear for compounds with a larger lattice cell volume ($V_{opt-cell}$ = 1.41−1.42 nm^3) than the $(Sc_{1-x}M_x)_2(WO_4)_3$ and $[Sc_2(WO_4)_3]_{1-x}[M_2(MoO_4)_3]_x$ solid solutions ($V_{opt-cell}$ = 1.29−1.31 nm^3). Comparing these optimum cell volume to the ionic size of the charge-carrying Lu^{3+} ($Vr_{Lu}{}^{3+}$ = 0.0042 nm^3) and Sc^{3+} ($Vr_{Sc}{}^{3+}$ = 0.0029 nm^3) cations by forming the corresponding quotients $V_{opt-cell}/Vr_M{}^{3+}$ leads to values of 0.00297 (Lu^{3+}) and 0.00223 (Sc^{3+}). The similarity of these values might indicate the existence of a certain cell volume/cation size relation of approximately 0.002−0.003, which is most appropriate for the transport of trivalent cations within the $Sc_2(WO_4)_3$-type structure series. While this simple model is based only on steric considerations and neglects a more complex situation including polarizabilities, electrostatic interactions, and local ordering of the different cation types, which might also influence the migration behavior of the cations within the conduction layers to some extent, it provides information which makes it possible to roughly predict the composition of the optimum conducting compound of mixed solid solutions crystallizing with $Sc_2(WO_4)_3$-type structures, despite its simplicity.

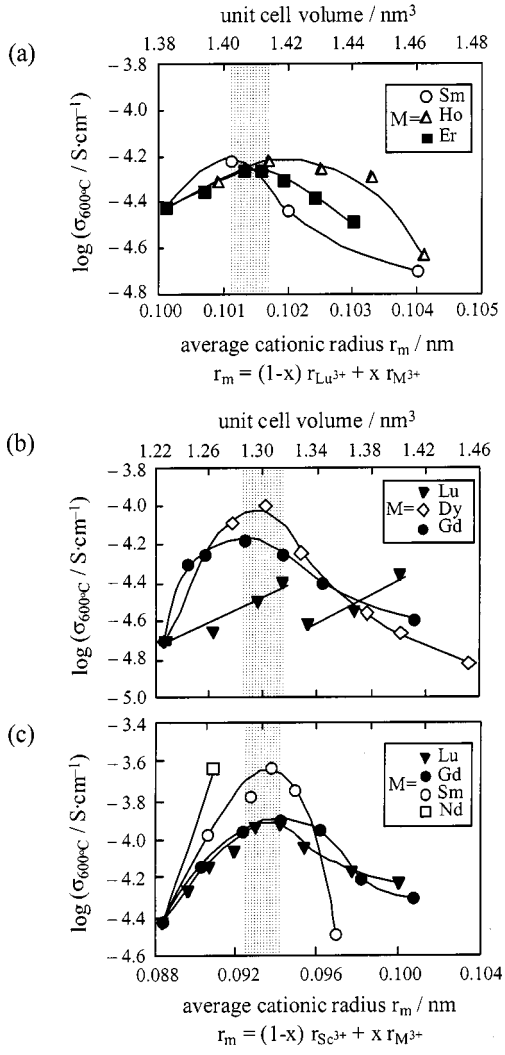

Figure 4. A plot of the trivalent cation conductivity at 600 °C (log $\sigma_{600\ °C}$) versus the average trivalent cationic radius, r_m, for: (a) $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions [M = Sm (○), Ho (□), Er (■)]; (b) $(Sc_{1-x}M_x)_2(WO_4)_3$ solid solutions[12] [M = Lu (▼), Dy (◇), Gd (•)]; (c) $[Sc_2(WO_4)_3]_{1-x}[M_2(MoO_4)_3]_x$ solid solutions[13] [M = Lu (▼), Gd (•), Sm (○), Nd (□)]; the shaded region corresponds to the optimal cationic radius where the highest conductivity data can be observed

Conclusions

The trivalent-cation conducting solid solution system of $(Lu_{1-x}M_x)_2(WO_4)_3$ (M = Er, Ho, Sm) shows a monotonous expansion of crystal lattice by substituting Lu^{3+} cation site for larger M^{3+} cations. Due to the linear relationship between the average cationic radius and the unit cell volume of the solid solutions, the optimum ion-conducting compound in a certain solid solution system with a given M^{3+} cation can be easily elucidated only by calculating the $V_{opt-cell}/Vr_M{}^{3+}$ quotient (0.002−0.003) to adjust the expansion of the crystal lattice in an optimum surroundings for the mobile cations. Ideally, only the compound with the composition which corresponds to that optimum unit cell volume need be prepared. This provides a helpful tool for the understanding of the trivalent cationic conduction characteristics in the various tungstate and molybdate compounds with the $Sc_2(WO_4)_3$-type crystal structure.

Experimental Section

Polycrystalline $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions (M = Er, Ho, Sm) were prepared in conventional solid-state reactions by heating a thoroughly ground mixture of reagent grade Lu_2O_3, WO_3, and the lanthanide oxides M_2O_3 (purity of all reagents 99.9% or higher) in the corresponding stoichiometric ratio at a temperature of 1200 °C for 24 h in an oxygen atmosphere. After regrinding, the procedure was repeated with the same experimental conditions. The colors of the obtained powders are white (Lu/Gd compounds), pink (Lu/Er), slight yellow (Lu/Ho), and salmon-pink (Lu/Sm). The resulting materials were characterized by X-ray powder diffraction analysis (XRD) using Cu-K_α radiation (Mac Science M18XHF diffractometer).

For the electrical conductivity measurements, pelletized samples of $(Lu_{1-x}M_x)_2(WO_4)_3$ were sintered in an oxygen atmosphere for 12 h at 1200 °C, and sputtered on opposite faces with ionically blocking platinum. Electrical conductivity measurements such as impedance analysis and time-dependent dc-polarization measurements of all

samples were performed following the usual procedures as reported elsewhere.[1−9] In dc electrolysis experiments, the $(Lu_{1-x}M_x)_2(WO_4)_3$ samples were exposed to a direct voltage of 6V for about 4−6 weeks at 800−850 °C in air, using ion-blocking Pt electrodes. After the electrolysis procedure, the cathodic and anodic surfaces as well as the bulk of the samples were characterized by electron-probe microanalysis(EPMA).

[17] As in previous reports on trivalent cation compounds with the $Sc_2(WO_4)_3$-type structure,[1−9] the conducting properties of the $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions (M = Er, Ho, Sm) have been characterized by several electrochemical methods, including time-dependent polarization measurements (under various atmospheres) and dc electrolysis experiments. As a main result, the electrical conductivity in the $(Lu_{1-x}M_x)_2(WO_4)_3$ solid solutions is found to be purely cationic with an ion-transference number higher than $t_i^+ = 0.99$. No electronic or anionic O^{2-} conduction has been observed. The migrating cations have been directly identified by EPMA for the samples after the dc electrolysis using the same experimental setup as reported elsewhere.[1−9] Thus, the data presented are discussed in terms of trivalent cationic conduction.

Syntheses and Characterization of Copper(II) Complexes of the New Ligands *N*-[(2-Pyridyl)methyl]-2,2′-dipyridylamine and *N*-[Bis(2-pyridyl)methyl]-2-pyridylamine

Simon P. Foxon,[a] Olaf Walter,[b] and Siegfried Schindler*[a]

Keywords: Copper / Oxygen / Coordination chemistry / Ligand effects / Tripodal ligands

The two new ligands *N*-[(2-pyridyl)methyl]-2,2′-dipyridylamine (**L1**) and *N*-[bis(2-pyridyl)methyl]-2-pyridylamine (**L2**) have been synthesized and the copper(II) complexes $[Cu(\mathbf{L1})_2(CH_3OH)_2](ClO_4)_2$, $[Cu(\mathbf{L1})_2(H_2O)_2](ClO_4)_2$, $[Cu_3(\mathbf{L1})_2(DMF)_2Cl_6]$, $[Cu(\mathbf{L1})Cl_2]_n$, $[Cu(\mathbf{L2})(Cl)(ClO_4)]$, and $[Cu(\mathbf{L2})Cl_2]$ have been structurally characterised. The reactions of dioxygen with the copper(I) complexes with ligands **L1** and **L2** were investigated, but no copper–dioxygen intermediates could be detected spectrophotometrically.

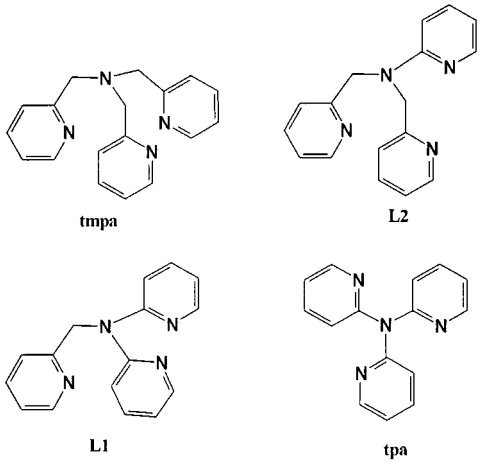
Introduction

A large number of biologically important metalloproteins utilise copper ions in their active sites for the redox-processing of molecular dioxygen.[1−6] Examples include hemocyanin (O_2 carrier in the blood of arthropods and molluscs), tyrosinase (*o*-phenol monooxygenase), and other oxidases, which couple oxidation of the substrate with copper-mediated reduction of dioxygen to hydrogen peroxide or water.[7−11]

The function of the metalloprotein is closely related to the structure of its active site, i.e. the geometrical arrangement of amino acid residues around the copper ions. There has been considerable interest in the design of ligands and the characterisation of copper complexes that may constitute models of the active site structure in such metalloproteins.[1,4−6,12−16] In particular, copper complexes of tris(2-pyridylmethyl)amine (tmpa) and closely related ligands have been widely employed in order to explore and understand the thermodynamic and kinetic aspects of the reaction of copper(I) compounds with dioxygen.[1,17−22]

We recently carried out a detailed study on a family of three ligands closely related to tmpa, in which each "arm" of the tripodal parent ligand tmpa was systematically lengthened by the insertion of a methylene spacer group.[23] This systematic approach allowed an evaluation of the effect of the chelate ring size on the following properties: copper(I)-oxygen reactivity, the coordination geometry around the copper ion, the Cu^{II}/Cu^{I} redox couple, and spectroscopic features (UV/Vis, EPR).

The properties of these complexes were found to be strongly affected by changing the chelate ring size and, therefore, we also became interested in performing a similar investigation in which the tripodal ligand, tmpa, had each "arm" systematically shortened (Scheme 1). The tripodal amine, tris(2-pyridyl)amine (tpa; unfortunately tmpa has also been abbreviated as tpa in the literature) has been known for a long time,[24] but the two ligands *N*-[(2-pyridyl)-methyl]-2,2′-dipyridylamine (**L1**) and *N*-[bis(2-pyridyl)methyl]-2-pyridylamine (**L2**), intermediate between tmpa and tpa, are as yet unknown in the literature.



Scheme 1. The ligands tpa, **L1**, **L2**, and tmpa

Herein, we report the synthesis of these two new ligands and the characterisation of their copper(II) complexes, as

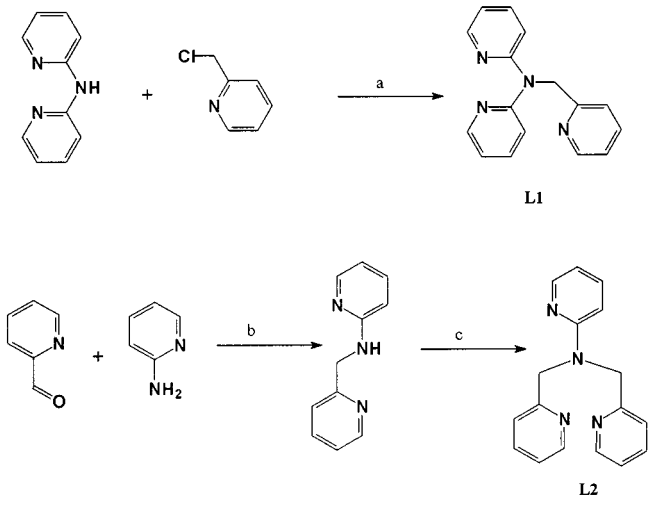
well as some preliminary studies of the reactivity of the copper(I) complexes with dioxygen.

Results and Discussion

The ligands *N*-[(2-pyridyl)methyl]-2,2′-dipyridylamine (**L1**) and *N*-[bis(2-pyridyl)methyl]-2-pyridylamine (**L2**) were synthesized by nucleophilic substitution reactions of the precursor amines with 2-picolyl chloride (Scheme 2). The resulting ligands were isolated in multigram quantities in modest yields. The two ligands are crystalline solids and were obtained in a highly pure state by recrystallisation from an appropriate solvent (see Exp. Sect.).



Scheme 2. Synthesis of the ligands **L1** and **L2**; reagents and conditions: **a**: KOH/DMSO, room temp., 2 h. **b**: i. benzene, reflux, 18 h, ii. $NaBH_4$, 18 h. **c**: i. NaH, DMF, room temp., 1 h, ii. picolyl chloride, DMF, room temp., 18 h

The copper(II) complexes used in this study were prepared by adding a copper(II) salt to the appropriate ligand. Crystals suitable for single-crystal X-ray diffraction studies were obtained either by slow evaporation of the solvent(s) from solutions in methanol, water, acetonitrile, or mixtures thereof, or by slow diffusion of diethyl ether into solutions of the complexes in DMF or acetonitrile.

L1 is a versatile ligand. It incorporates rigidity in the form of the dipyridyl moiety, while "flexibility" is provided by the pendant pyridyl "arm". The dipyridyl moiety of **L1** acts as a rigid bidentate donor to the copper(II) centres and it is observed that in the structures presented herein, the third pyridyl nitrogen atom does not coordinate to the same copper(II) centre. We demonstrate in this work that by changing the solvent and counteranions a variety of unique and different structures incorporating the common motif of ligand **L1** can readily be prepared.

Ligand **L2** is closely related to bis(2-pyridylmethyl)amine (dipica), but has been derivatised by the incorporation of an extra pyridine moiety. This introduces the possibility of additional coordination and hence the formation of new coordination compounds.

It should be noted that the proposed formulae obtained on the basis of elemental analyses of the copper(II) complexes differ from the structures obtained by single-crystal X-ray diffraction studies. This is due to the removal of solvent molecules from the crystal lattices in preparing samples for elemental analysis.

X-ray Structures

A summary of the crystallographic data and refinement parameters for the structures reported in this study can be found in Table 1. Selected bond lengths and angles for the copper(II) complexes are reported in Table 2.

Ligand L1

Crystals of **L1** were obtained by slow evaporation of the solvent from a solution of the ligand in acetonitrile at room temperature. An ORTEP representation of the crystal structure of ligand **L1** is shown in Figure 1. The crystal structure of **L1** shows no extraordinary features and is comparable to the reported structures of tpa and its derivatives.[25,26]

$[Cu(L1)_2(CH_3OH)_2](ClO_4)_2$ (1a)

Blue block-shaped crystals of **1a** were grown by slow diffusion of diethyl ether into a solution of the complex in DMF/methanol. The structure of the cation of **1a** is shown in Figure 2, while the coordination parameters around the copper(II) centre are listed in Table 2.

The structure of **1a** (Figure 2) reveals that two molecules of **L1** coordinate to the central copper(II) ion. Each **L1** molecule coordinates to the copper(II) centre through the two pyridine nitrogen atoms, N(2) and N(3), of the dipyridyl moiety. Due to the copper ion occupying a crystallographic inversion centre, the coordinated pyridyl nitrogen atoms and the copper(II) ion are rigorously coplanar. The equatorial ligands form a rectangular rather than a square basal plane around the copper(II) ion, as is evident from the N−N distances [$N(2)-N(3)^i$ = 2.9627(13) Å, N(2)−N(3) = 2.7365(13) Å]. Two methanol molecules are coordinated to the copper(II) ion in the axial positions. The resulting geometry around the copper(II) coordination sphere in **1a** can be described as elongated tetragonal [Cu(1)−N(2) = 2.0181(13) Å, Cu(1)−N(3) = 2.0150(13) Å, Cu(1)−O(1) = 2.4187(13) Å], which is characteristic of d^9 hexacoordinate copper(II) complexes. Furthermore, the methanol molecules are not perpendicular to the equatorial plane, which is evident from the angles [N(3)−Cu(1)−O(1) = 94.41(5)°, $N(3)^i$−Cu(1)−O(1) = 85.59(5)°], with each methanol molecule being *slightly* tilted towards the uncoordinated pyridyl moiety. This is perhaps unsurprising, considering the interesting and unexpected observation of a strong *intramolecular* hydrogen bonding interaction between the "pendant" pyridyl nitrogen N(4) and O(1) of the methanol molecule in the structure of **1a** [O(1)···N(4) = 2.7472(13) Å].

Although methanol is not a particularly good ligand, especially when bound at the axial coordination positions of the Jahn−Teller sensitive copper(II) ion, metal-bound methanol molecules have been observed in transition metal

[c] $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$; $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, $P = [\max(F_o^2 \text{ or } 0) + 2(F_c^2)]/3$. [d] Denotes the value of the residual considering all the reflections. [e] $S = [\Sigma w(F_o^2 - F_c^2)^2]/[(n - p)^{1/2}]$, n: number of data, p: parameters used.

complexes, particularly when stabilized by hydrogen bonding within solvated "cavities".[27] A similar observation of an *intramolecular* hydrogen bond between copper(II)-bound solvent molecules and pendant pyridyl moieties has been demonstrated by Mascharak et al. in the case of a ligand system incorporating an amide functionality.[28]

$[Cu(L1)_2(H_2O)_2](ClO_4)_2 \cdot 2DMF$ (1b)

The crystal structure of **1b** (Figure 3) displays similarities to that of **1a**. The geometry around the copper(II) coordination sphere in **1b** can also be described as elongated tetragonal [Cu(1)−(N2) = 2.0156(11) Å, Cu(1)−N(3) = 2.0175(11) Å, Cu(1)−O(1) = 2.3847(11) Å]. In this structure, there is a dihedral angle of 55.22° between the coordinated pyridyl rings of the two **L1** ligands. Furthermore, two water molecules occupy the axial sites of the copper(II) centre. They each form two strong hydrogen bonds; one *intramolecular* hydrogen bond to the pendant pyridyl "arm" [O(1)−N(4) = 2.8396(11) Å] and an *intermolecular* hydrogen bond to a DMF solvent molecule [O(1)−O(2)DMF = 2.7969(11) Å]. The copper(II) centre does not lie on an inversion centre and therefore the basal plane of the four equatorial nitrogen atoms does not form a perfect square basal plane.

In contrast to the well-known ligand tmpa (Scheme 1), there have been surprisingly few structurally characterised copper(II) complexes of tris(2-pyridyl)amine (tpa) reported in the literature; a search of the Cambridge Structural Data Base[29] reveals there to be only four.[30−33] In three of these four examples, two tpa ligands are found to be ligated to the copper(II) centre, while the other example is a larger tetrameric array.[33] In all the characterised structures, only two of the three pyridine nitrogen atoms are found to coordinate to the copper(II) centre. The single-crystal X-ray structures of the cations of **1a** and **1b** display similar features to those reported for the copper(II) complex $[Cu(tpa)_2(MeCN)_2](SO_3CF_3)_2$.[32] In this structure, the copper(II) ion is also found to occupy a crystallographic inversion centre. The tpa moiety coordinates to the copper(II) centre in an identical manner as observed for **L1**, and the two axial sites are occupied by acetonitrile solvent molecules. The third pyridine moiety of tpa remains uncoordinated. However, the crystal structures of **1a** and **1b** show one notable and interesting difference from that of $[Cu(tpa)_2(MeCN)_2](SO_3CF_3)_2$. The coordination of methanol molecules to the copper(II) centre of **1a** and of water molecules to the copper(II) centre in **1b** is stabilised by *intramolecular* hydrogen bonds formed between the coordinated solvent

molecules and each pendant pyridyl "arm" as discussed above.

$[Cu_3(L1)_2(DMF)_2Cl_6]\cdot 2DMF$ (1c)

Crystals of **1c** suitable for single-crystal X-ray diffraction analysis were grown over a period of a few days by slow diffusion of diethyl ether into a solution of the complex in DMF at room temperature. Single-crystal X-ray diffraction analysis revealed that **1c** crystallises in the triclinic space group $P\bar{1}$. The structure is shown in Figure 4, while the coordination parameters around the copper(II) centres are listed in Table 2.

The first striking observation is that the coordination complex contains more than one copper ion. The crystal structure reveals a ratio of three copper(II) ions to two **L1** molecules (Figure 4). The coordination geometry around

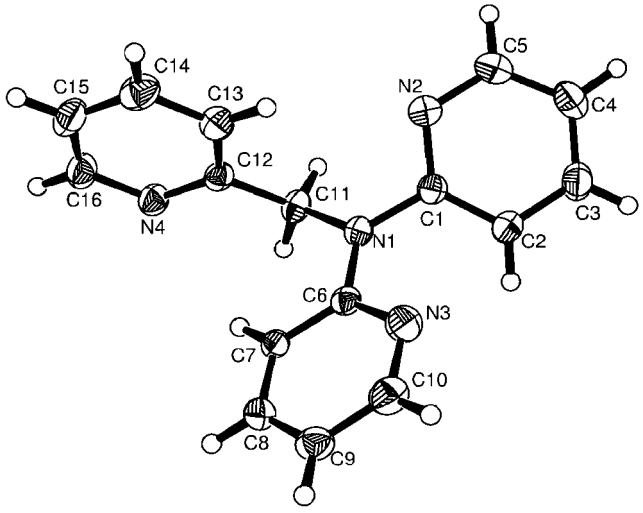

Figure 1. ORTEP representation (50% thermal probability ellipsoids) of the crystal structure of **L1**

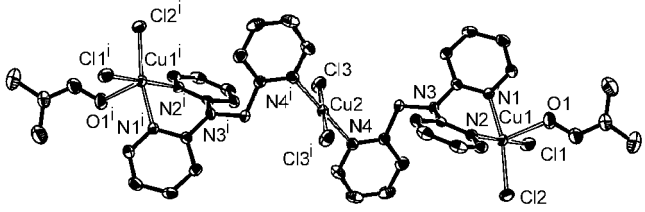

Figure 4. ORTEP representation (50% thermal probability ellipsoids) of the crystal structure of **1c**; two DMF solvent molecules have been omitted for clarity

Cu(1) can be described as being close to square pyramidal, with N(1) and N(2) of the dipyridyl moiety of **L1** and two chloride anions, Cl(1) and Cl(2), forming the square basal plane [Cu(1)−N(2) = 2.0161(19) Å, Cu(1)−N(1) = 2.0307(19) Å, Cu(1)−Cl(2) = 2.2687(9) Å, Cu(1)−Cl(1) = 2.2769(8) Å]. The oxygen atom O(1) of a DMF solvent molecule occupies the axial position [Cu(1)−O(1) = 2.2870(18) Å]. The Cu(1) ion is found to be displaced from the basal plane by 0.179 Å. In common with the two previously described structures incorporating **L1**, N(4) of the third pyridyl arm is found not to coordinate to the Cu(1) centre. In contrast to the two previous structures, however, N(4) is unable to take part in *intramolecular* hydrogen bonding interactions with the coordinated anions and solvent molecule. Instead, N(4) coordinates to a second copper(II) ion in the structure, Cu(2) [Cu(2)−N(4) = 1.988(2) Å]. Cu(2) is found to occupy the crystallographic inversion centre of the unit cell. Another ligand of **L1** is coordinated through $N(4)^i$ [related to N(4) by the operation of inversion at Cu(2)] to Cu(2). A chloride ion Cl(3) and its symmetry-equivalent $Cl(3)^i$ complete the coordination sphere around Cu(2) [Cu(2)−Cl(3) = 2.2396(9) Å]. No other anions or DMF solvent molecules are found to occupy the vacant axial coordination sites of the Cu(2) centre. Due to the crystallographic restraint imposed on Cu(2), the coordination geometry around the Cu(2) ion can be rigor-

ously defined as square planar. Two DMF solvent molecules (not shown) complete the structure.

$[Cu(L1)Cl_2]_n$ (1d)

Thin plate-like crystals of **1d** were grown by slow evaporation of the solvents from a solution of the complex in aqueous acetonitrile. The crystal structure is shown in Figure 5, while the coordination parameters around the copper(II) centre are listed in Table 2. During the refinement procedure, high residual electron densities were observed in the Fourier difference map. This is a direct result of the low crystal quality (possibly due to extremely thin plates being stuck together) resulting in high residual electron densities along the crystallographic twofold screw axis.

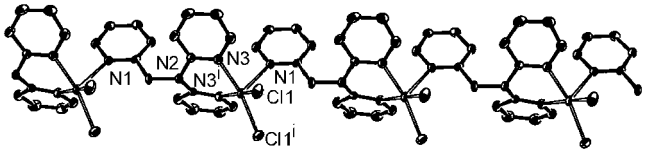

Figure 5. ORTEP representation (50% thermal probability ellipsoids) of the crystal structure of **1d**

The most striking feature is that **1d** has an infinite polymeric structure in the solid state. The ORTEP plot in Figure 5 shows three of the repeating units. The asymmetric unit cell consists of one half of a molecule of the formula "[Cu(**L1**)Cl_2]". The other symmetry-equivalent "half" of the structure is generated by reflecting the asymmetric unit contents through a mirror-plane consisting of the atoms Cu(1), N(1), N(2), and C(1)−C(6). The basal plane around each copper(II) centre in this structure is identical and is comprised of two pyridine nitrogen atoms of the dipyridyl moiety, N(1) and N(2), and two chloride anions, Cl(1) and Cl(2) [Cu(1)−N(1) = 2.033(14) Å, Cu(1)−N(2) = 2.014(14) Å, Cu(1)−Cl(2) = 2.275(5) Å, Cu(1)−Cl(1) = 2.276(5) Å]. The third pyridyl "arm" of **L1**, containing N(4), is not found to coordinate to the same copper(II) centre, as was seen in the structure of **1c**, but rather to a neighbouring copper(II) centre occupying the vacant axial position [N(4)−Cu(2) = 2.427(6) Å] and thus completing the distorted square-pyramidal coordination geometry around the copper(II) centre. No solvent molecules were found within the crystal lattice.

The two copper(II) chloride complexes of **L1** included in our study, **1c** and **1d**, show the effect of solvent coordination upon the nature of the final copper(II) complex obtained. Crystals of **1c**, the structure presented in Figure 4, were grown from a DMF-containing solution. In the crystal structure, DMF was found to occupy the axial site of the distorted square-pyramidal coordination environment of Cu(1) and consequently of its symmetry-equivalent $Cu(1)^i$ as well.

On moving to a medium containing predominantly acetonitrile, crystals of **1d** were obtained, the structure of which is shown in Figure 5. Here, the crystal structure revealed that no solvent molecules are coordinated to the copper(II) centres. The structure of **1d** shows similarities to that of **1c** in that N(4) of the pendant pyridyl "arm" coordinates to a neighbouring copper(II) centre. However, in contrast to the structure of **1c**, the N(4) atom in **1d** is found to occupy the axial coordination position around the square-pyramidal copper(II) centres, previously occupied by a DMF molecule in **1c**. It is interesting to note that no bridging by the chloride ion takes place, a common occurrence in copper halide polymeric structures.

$[Cu(L2)(Cl)(ClO_4)]$ (2a)

Blue block-shaped crystals of **2a** suitable for single-crystal X-ray analysis were grown by slow diffusion of diethyl ether into a solution in acetonitrile. An ORTEP plot of the crystal structure is presented in Figure 6. Selected crystallographic data and bond angles and distances are listed in Table 1 and 2, respectively.

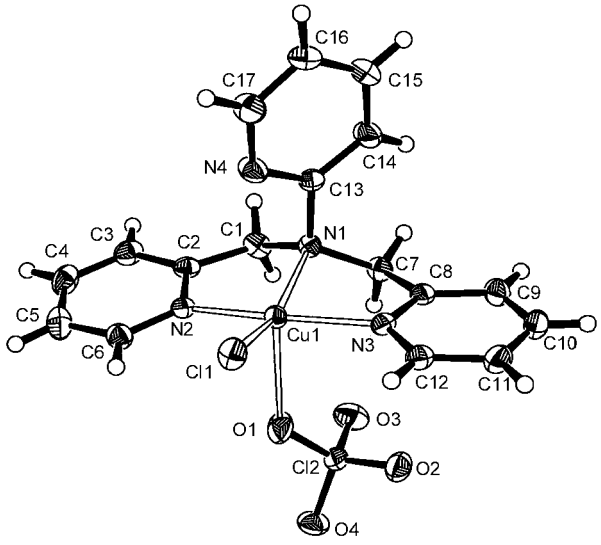

Figure 6. ORTEP representation (50% thermal probability ellipsoids) of the crystal structure of **2a**

As shown in Figure 6, two of the pyridyl rings of **L2** coordinate to the copper(II) centre in **2a**. The copper(II) centre is pentacoordinate, being coordinated by the pyridyl nitrogen atoms N(2) and N(3), the tertiary amine nitrogen N(1), chloride ion Cl(1), and O(1) of the perchlorate anion. The coordination environment around the copper(II) centre is best described as distorted square-pyramidal, with N(1), N(2), N(3), and Cl(1) forming the basal plane [Cu(1)−N(2) = 1.982(2) Å, Cu(1)−N(3) = 1.991(2) Å, Cu(1)−N(1) = 2.073(2) Å, Cu(1)−Cl(1) = 2.2265(7) Å] and O(1) of the perchlorate anion occupying the axial position [Cu(1)−O(1) = 2.4837(7) Å]. The coordination of the perchlorate anion in **2a** is also evident from the IR spectrum recorded from a Nujol mull. The strong band at

1089 cm^{-1} can be assigned as the coordinated perchlorate anion.

$[Cu(L2)Cl_2]\cdot H_2O$ (2b)

Green crystals suitable for single-crystal X-ray analysis were grown by slow evaporation of the solvents from a solution in aqueous methanol. An ORTEP plot of the crystal structure is displayed in Figure 7. Selected crystallographic data and bond lengths and angles are listed in Table 1 and 2, respectively.

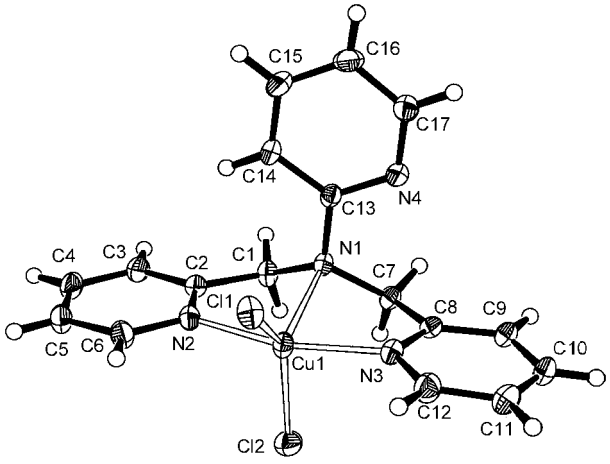

Figure 7. ORTEP representation (50% thermal probability ellipsoids) of the crystal structure of **2b**; a solvating water molecule has been omitted for clarity

As shown in Figure 7, and as was observed for **2a**, only two of the pyridyl rings of **L2** coordinate to the copper(II) centre in **2b**. The copper(II) centre is five-coordinate, being ligated by the pyridyl nitrogen atoms N(2) and N(3), the tertiary amine nitrogen N(1), and two chloride ions [Cu(1)−N(2) = 1.9798(17) Å, Cu(1)−N(3) = 1.9836(17) Å, Cu(1)−Cl(1) = 2.2619(6) Å, Cu(1)−Cl(2) = 2.3271(6) Å, Cu(1)−N(1) = 2.3399(17) Å]. At first sight, the geometry around the copper(II) centre might appear to be distorted trigonal bipyramidal, with the pyridyl nitrogen atoms N(2) and N(3) occupying the axial positions and the two chloride ions and N(1) occupying the equatorial plane. However, closer inspection reveals that the coordination environment around the Cu(1) centre is nearer to that found in square-pyramidal coordination complexes, with N(2), N(3), Cl(1), and Cl(2) forming the basal plane and the apical position being occupied by N(1). This is substantiated by examining the bond angles around the Cu(1) centre involving the atoms Cl(1), Cl(2), and N(1) [122°, 99°, 139° (sum = 360°)], which deviate from the value of 120° expected for a regular trigonal-bipyramidal geometry. Furthermore, the bond angle N(2)−Cu(1)−N(3) = 160.70(7)° is clearly less than 180°. This bond angle is a result of the small bite angles in each of the two five-membered chelate rings involving Cu(1), N(1), N(2), or N(3). These distortions and the value of the trigonality index τ of 0.36 (the index τ is zero for a square pyramid and unity for a trigonal bipyramid)[34] suggest that the coordination environment around Cu(1) is best described as trigonal-bipyramidal distorted square-based pyramidal (TBDSBP).

Ligand **L2** is a derivative of the parent amine (dipica) [dipica = bis(2-pyridylmethyl)amine] and shows a similar mode of coordination to copper(II) ions.[35−37] **L2** differs in that it possesses an additional pyridyl ring on the secondary aliphatic amine nitrogen atom, increasing the potential for additional coordination. There are numerous examples of derivatives of dipica, and the resulting ligands and metal complexes show interesting and novel properties.[38,39]

The structure of **2b** is similar to that reported for a copper complex of a derivatised dipica ligand.[38] This ligand was prepared by converting the secondary amine functional group of the precursor amine dipica into a tertiary amide group. The coordination parameters around the copper(II) centre are close to those seen in **2b**. In the structure, the tertiary amido nitrogen atom occupies the apical position at the copper(II) centre, with the other four ligating atoms (two pyridyl nitrogen atoms and two chloride ions) forming a distorted square plane in a similar manner to that shown in Figure 7. The coordination environment around the copper(II) centre is best described as trigonal-bipyramidal distorted square-based pyramidal (TBDSBP), having a trigonality index τ of 0.30.

UV/Vis Spectroscopy

The copper(II) complexes of **L2** are characterised by a rather broad d−d absorption band (ca. 650−1000 nm) in their solution (acetonitrile) electronic spectra; a low- or high-energy shoulder is often present as well, or occasionally two distinct absorption maxima are observed. In many cases, it has been demonstrated that the presence of a single d−d band with a low-energy shoulder is typical of a trigonal-bipyramidal geometry at copper, whereas an absorption with a high-energy shoulder indicates a square-pyramidal geometry. Examination of the electronic spectroscopic data of the copper(II) complexes of **L2** (see Exp. Sect.) indicates that, on the basis of this criterion, **2a** adopts a square-pyramidal geometry, whereas **2b** can best be described as having a geometry around the copper(II) centre close to trigonal bipyramidal. Complexes of **L1** are characterised by a rather broad absorption band at around 650 nm, indicating a square-pyramidal geometry in solution.

Electrochemistry

The half-wave potentials of complexes **1a**, **1d**, **2a**, and **2b** were determined by cyclic voltammetry in acetonitrile; the results are summarised in Table 3. All compounds displayed a reversible cyclic voltammogram, demonstrating that stable copper(I) complexes of the two ligands can be formed. Figure 8 shows the cyclic voltammogram of **2b**. Complexes with **L1** as a ligand are more easily reduced than those with **L2** as a ligand.

Table 3. Cyclic voltammetry of **1a**, **1d**, **2a**, and **2b** in acetonitrile

Compound[a]	E_p^{red} (V)	E_p^{ox} (V)	$E_{1/2}$ (V)	ΔE (mV)

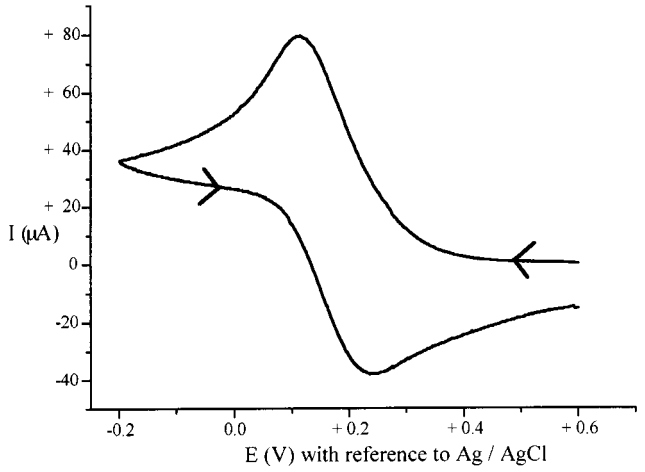

Figure 8. Cyclic voltammogram of **2b** in acetonitrile at 298 K; scan rate = 100 mV s^{-1}; concentration of complex = 1 mM; concentration of the supporting electrolyte $[NBu_4]PF_6$ = 0.1 M

Reactions of Dioxygen with Copper(I) Complexes of L1 and L2

As yet, we have been unable to isolate solid copper(I) complexes of **L1** or **L2**; only yellow-orange oils have been obtained. Therefore, to gain information on the reactions of dioxygen with the copper(I) complexes of **L1** or **L2**, these compounds were prepared in situ by mixing stoichiometric amounts of copper(I) salts with the ligands in acetone or propionitrile. Reactions of these solutions with dioxygen were investigated under the same conditions as employed for $[Cu(tmpa)(CH_3CN)]^+$ and its derivatives, using low-temperature stopped-flow techniques.[23] We observed that the copper complexes of both ligands were slowly oxidised, but in contrast to $[Cu(tmpa)(CH_3CN)]^+$ no "dioxygen adducts" were observed as intermediates.

Our earlier findings clearly demonstrated the influence of chelate ring size on the stability (or inertness) of copper "dioxygen" complexes.[23] $[Cu(tmpa)(CH_3CN)]^+$ reacts very rapidly with dioxygen to first form a superoxo complex, which reacts further to form a peroxo complex that is stable at low temperatures. Only one chelate ring is enlarged in $[Cu(pmea)]^+$, but we found that no superoxo complex could be detected in the course of its reaction with dioxygen; the initially formed peroxo complex rapidly underwent further reactions. In contrast to the findings for $[Cu(pmea)]^+$, a stopped-flow kinetic investigation showed that neither a superoxo nor a peroxo intermediate was observable during the reaction of $[Cu(pmap)]^+$ with dioxygen. $[Cu(tepa)]^+$ was found not to react with dioxygen. It was thus concluded that increasing the chelate ring size suppresses the formation of stable dioxygen adduct complexes in this series.

Unfortunately, reducing the chelate ring size by using **L1** or **L2** as described herein did not lead to a more stable copper superoxo or peroxo complex because intramolecular coordination of one of the pyridine donors was suppressed. The reaction of the copper(I) complex of tpa with dioxygen has been investigated previously and a cubane-like cluster was obtained as a product.[33] The authors did not report any dioxygen adduct complex as an intermediate during the course of this reaction.

Conclusions

We have reported the synthesis and characterisation of two new ligands, **L1** and **L2**, together with a series of copper(II) complexes derived from these ligands. The crystal structures of the complexes of **L1** demonstrate that in each case one of the three pyridyl donors remains uncoordinated, as observed in the copper complexes of tpa. However, the crystal structures of **1a** and **1b** show an important difference to copper tpa complexes: the coordination of methanol molecules to the copper(II) centre of **1a** and of water molecules in **1b** is stabilised by *intramolecular* hydrogen bonding between the coordinated solvent molecules and each pendant pyridyl "arm". Furthermore, using chloride as an anion in the syntheses of the copper(II) complexes of **L1** demonstrated an interesting solvent effect. In DMF, the trinuclear complex **1c**, incorporating coordinated DMF molecules is obtained, thus preventing the formation of a polymeric material. In contrast, in acetonitrile, no solvent molecules are coordinated and a polymeric complex **1d** is formed instead.

Ligand **L2** can be regarded as a derivative of bis(2-pyridylmethyl)amine (dipica) and the two complexes **2a** and **2b** are related to the complexes with dipica as ligand. **L2** differs from dipica in that it possesses a third pyridyl ring (not coordinated in **2a** and **2b**), increasing the potential for additional coordination.

As yet, it has not been possible to obtain copper(I) complexes of ligands **L1** or **L2** in a solid form, but reactions of dioxygen with these compounds formed in situ from a copper(I) salt and the ligand have been investigated. In contrast to the reaction of dioxygen with the copper(I) complex of tmpa, no dioxygen adducts could be observed as intermediates. Instead, complexes of both ligands were slowly oxidized to the copper(II) complexes, in line with their rather positive redox potentials.

Experimental Section

General Remarks: Reagents and solvents used were of commercially available reagent quality. Acetonitrile, propionitrile, diethyl ether,

and acetone were dried by standard methods. $[Cu(CH_3CN)_4]ClO_4$ and $[Cu(CH_3CN)_4]PF_6$ were synthesized according to literature procedures.[40] The purities of the ligands were assessed by TLC, elemental analysis, and ^1H and ^{13}C NMR. UV/Vis spectra were measured on a Hewlett−Packard 8452 A spectrophotometer using standard 1 cm quartz cuvettes. ^1H and ^{13}C NMR spectra were recorded on a Bruker DXP 300 AVANCE spectrometer. Infrared spectra were recorded from samples in either Nujol mulls or KBr pellets on an ATJ Mattson Infinity 60 AR FT-IR instrument. Cyclic voltammetry was performed using an EG&G Model 263 potentiostat at 25 °C at a scan rate of 100 mV s^{-1}. The solutions under investigation contained 1 mM copper complex and 0.1 M $[NBu_4]PF_6$ in acetonitrile that had been deoxygenated by bubbling nitrogen through it. A conventional H-type cell was used, with glassy carbon, Pt, and Ag/AgCl as working, counter, and reference electrodes, respectively.

Variable-Temperature Stopped-Flow Measurements: Solutions of the complexes for the collection of time-resolved UV/Vis spectra were prepared in a glovebox and transferred to the low-temperature stopped-flow instrument by means of syringes. Dioxygen-saturated solutions were prepared by bubbling dioxygen through propionitrile or acetone in syringes (solubility of dioxygen in propionitrile at 25 °C is 0.0088 M,[20] while in acetone it is 0.0102 M[41]). The reactions were studied under pseudo-first-order conditions ([complex] $<$ $[O_2]$), and time-resolved UV/Vis spectra of the reactions of dioxygen with copper(I) complexes were recorded with a modified Hi-Tech SF-3 L low-temperature stopped-flow unit (Salisbury, U.K.) equipped with a J&M TIDAS 16−500 photodiode-array spectrophotometer (J&M, Aalen, Germany).

Syntheses of Ligands and Complexes

Caution! Perchlorate salts are potentially explosive and should be handled with great care.

***N*-[(2-Pyridyl)methyl]-2,2′-dipyridylamine (L1):** Powdered potassium hydroxide (5.2 g, 93 mmol) was added to DMSO (40 mL). 2,2′-Dipyridylamine (3.42 g, 20 mmol) was added to this mixture. The resulting deep-orange coloured solution was stirred at room temperature for 45 min. 2-Picolyl chloride hydrochloride (3.28 g, 20 mmol) was then added and the orange solution was stirred at room temperature for 1 h. It was then diluted with water (50 mL), which led to the immediate deposition of a fine yellow precipitate. This precipitate was collected by filtration, washed with water (3 × 30 mL), and the yellow solid was recrystallised from hexane (75 mL) containing the minimum volume of dichloromethane. On cooling to 0 °C, fine yellow crystals formed. These were collected by filtration, washed with a little cold hexane, and dried to yield **L1** as a pale-yellow solid (2.9 g, 55%, 11 mmol). $C_{16}H_{14}N_4$: calcd. C 73.26, H 5.38, N 21.36; found C 73.31, H 5.50, N 21.23. M.p. 106−108 °C. FDI-MS: m/z = 262 [M^+]. ^1H NMR ($CDCl_3$, 300 MHz): δ = 5.60 (s, 2 H, $-CH_2-$), 6.82−6.86 (m, 2 H, ArH), 7.05−7.09 (m, 1 H, ArH), 7.24−7.32 (m, 3 H, ArH), 7.48−7.55 (m, 3 H, ArH), 8.28−8.30 (m, 2 H, ArH), 8.52 (d, 1 H, ArH). ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 53.6, 114.4, 117.3, 121.2, 121.6, 136.5, 137.3, 148.2, 149.0, 156.8, 159.5. IR (KBr): $\tilde{\nu}$ = 3059 (w), 3004 (w), 2961 (w), 2925 (w), 2362 (w), 2337 (w), 1967 (w), 1943 (w), 1915 (w), 1893 (w), 1874 (w), 1845 (w), 1829 (w), 1796 (w), 1778 (w), 1737 (w), 1717 (w), 1701 (w), 1651 (w), 1585 (s), 1564 (m), 1470 (s), 1427 (s), 1379 (m), 1349 (m), 1325 (m), 1281 (m), 1260 (m), 1245 (m), 1225 (m), 1209 (m), 1173 (w), 1149 (m), 1130 (w), 1088 (m), 1044 (w), 983 (w), 901 (w), 873 (w), 772 (m), 753 (m), 737 (m), 661 (w), 612 (w), 585 cm^{-1} (w).

***N,N*-(2-Pyridyl)(2-pyridylmethyl)amine:** A solution of 2-pyridinecarboxaldehyde (9.2 mL, 96 mmol) and 2-aminopyridine (7.5 g, 80 mmol) in benzene (150 mL) was refluxed for 18 h with the continuous removal of water by means of a Dean−Stark trap. The solvent was subsequently removed in vacuo and the residue was taken up in absolute ethanol (200 mL). To this yellow solution, $NaBH_4$ (4.0 g, 105.8 mmol) was added and the solution was stirred at room temperature for 18 h. The excess $NaBH_4$ was then cautiously quenched by adding first water (100 mL) and then saturated aqueous NH_4Cl solution (100 mL) at 70 °C. Thereafter, the volatiles were removed in vacuo and the residue was redissolved in water (200 mL). The resulting aqueous solution was extracted with ethyl acetate (3 × 150 mL) and the combined organic fractions were dried over anhydrous magnesium sulfate. Upon removal of the solvent, a viscous yellow oil was obtained. The product was purified by vacuum distillation to yield a pale-yellow viscous liquid (6.0 g, 41%, 32.4 mmol). FDI-MS: m/z = 185 [M^+]. ^1H NMR ($CDCl_3$, 300 MHz): δ = 4.65 (d, 2 H, $-CH_2-$, $^3J_{H,H}$ = 5.3 Hz), 5.86 (br, 1 H, NH), 6.43−6.45 (m, 1 H, ArH), 6.53−6.58 (m, 1 H, ArH), 7.13−7.17 (m, 1 H, ArH), 7.30−7.40 (m, 2 H, ArH), 7.58−7.63 (m, 1 H, ArH), 8.09−8.11 (m, 1 H, ArH), 8.54−8.55 (m, 1 H, ArH). ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 47.2, 107.7, 112.9, 121.6, 122.0, 136.6, 137.3, 147.9, 149.0, 158.3, 158.5. IR (KBr): $\tilde{\nu}$ = 3278 (br, m), 3084 (m), 3056 (m), 3018 (m), 2927 (w), 2865 (w), 1603 (s), 1571 (s), 1506 (s), 1490 (s), 1438 (m), 1332 (m), 1293 (m), 1254 (w), 1151 (m), 1120 (w), 1084 (w), 1049 (w), 983 (m), 771 (m), 686 (m), 611 (m), 527 cm^{-1} (m).

***N*-[Bis(2-pyridyl)methyl]-2-pyridylamine (L2):** Sodium hydride (60% dispersion in mineral oil; 1.3 g, 32.5 mmol) was added to anhydrous DMF (100 mL) under nitrogen. The resulting grey slurry was stirred at room temperature until hydrogen evolution had ceased (ca. 0.5 h). A solution of *N,N*-(2-pyridyl)(2-pyridylmethyl)amine (5.0 g, 27 mmol) in anhydrous DMF (60 mL) was then added dropwise to the sodium hydride slurry. The resulting orange solution was stirred until hydrogen evolution had ceased (ca. 1 h). To the amine carbanion, a solution of 2-picolyl chloride (free base) (3.79 g, 30 mmol) in anhydrous DMF (50 mL) was added dropwise and the brown solution was stirred overnight at room temperature. The light-orange solution obtained was then cautiously quenched by the addition of water (200 mL), and brine (50 mL) was also added. The aqueous solution was exhaustively extracted with dichloromethane (4 × 150 mL). The combined organic phases were washed with brine (200 mL) and dried over anhydrous magnesium sulfate. Removal of the solvent in vacuo yielded the crude product as a light-tan coloured solid. It was taken up in warm diethyl ether (100 mL), which led to the separation of a brown oil. The ethereal solution was decanted and the solvent was removed in vacuo. The crude cream-coloured product was recrystallised once from diethyl ether. On cooling to 0 °C, a fine white precipitate appeared, which was collected by filtration and dried in vacuo (5.3 g, 70%, 19.2 mmol). $C_{17}H_{16}N_4$: calcd. C 73.89, H 5.84, N 20.27; found C 73.94, H 5.97, N 20.03. M.p. 92−94 °C. FDI-MS: m/z = 276 [M^+]. ^1H NMR ($CDCl_3$, 300 MHz): δ = 4.99 (s, 4 H, $-CH_2-$), 6.47−6.61 (m, 2 H, ArH), 7.11−7.15 (m, 2 H, ArH), 7.22−7.25 (m, 2 H, ArH), 7.34−7.40 (m, 1 H, ArH), 7.55−7.60 (m, 2 H, ArH), 8.18 (d, 1 H, ArH), 8.54 (d, 2 H, ArH). ^{13}C NMR ($CDCl_3$, 75 MHz): δ = 54.1, 106.1, 112.7, 121.1, 122.0, 136.6, 137.5, 148.0, 149.4, 158.1, 158.7. IR (KBr): $\tilde{\nu}$ = 3046 (w), 3006 (w), 2964 (w), 2924 (w), 2924 (w), 2362 (w), 2338 (w), 1965 (w), 1916 (w), 1867 (w), 1843 (w), 1831 (w), 1768 (w), 1736 (w), 1719 (w), 1701 (w), 1596 (m), 1564 (m), 1492 (m), 1434 (m), 1391 (w), 1351 (m), 1283 (w), 1241 (w), 1180 (w), 1152 (w), 1094 (w), 1069 (w), 1047 (w),

976 (w), 938 (w), 884 (w), 848 (w), 779 (w), 753 (m), 664 (w), 635 (w), 615 (w), 589 (w), 568 (w), 545 cm^{-1} (w).

$[Cu(L1)_2(CH_3OH)_2](ClO_4)_2$ (1a): To a solution of **L1** (0.1 g, 0.38 mmol) in methanol (3 mL) was added a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.071 g, 0.19 mmol) in methanol (3 mL). Diethyl ether (100 mL) was then added, which led to the deposition of a fine blue precipitate. The mixture was stirred for a few minutes and then filtered. Dark-blue block-shaped crystals suitable for X-ray analysis were grown by slow evaporation of the solvents from a solution in aqueous methanol.

$[Cu(L1)_2(H_2O)_2](ClO_4)_2 \cdot 2DMF$ (1b): To a solution of **L1** (0.1 g, 0.38 mmol) in methanol (3 mL) was added a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.071 g, 0.19 mmol) in methanol (3 mL). Diethyl ether (100 mL) was then added, which led to the deposition of a fine blue precipitate. The mixture was stirred for a few minutes and then filtered. The precipitate was collected by filtration to give the crude product as a light-blue solid (0.135 g, 86%). Dark-blue block-shaped crystals suitable for X-ray analysis were grown by vapour diffusion of diethyl ether into a solution in DMF. $C_{32}H_{32}N_8Cu Cl_2O_{10}$: calcd. C 46.70, H 3.92, N 13.61; found C 46.49, H 3.83, N 13.36. UV/Vis [CH_3CN; λ_{max}, nm (ε, M^{-1} cm^{-1})]: 210 (8970), 250 (8847), 294 (8048), 410 (109), 656 (79).

$[Cu_3(L1)_2(DMF)_2Cl_6]$ (1c): Ligand **L1** (0.10 g, 0.38 mmol) in DMF and $CuCl_2 \cdot 2H_2O$ (0.065 g, 0.38 mmol) in DMF (2 mL) were combined. Diethyl ether was then slowly allowed to diffuse into the resulting solution of **1c**. After a few days, blue/green block-shaped crystals of **1c** were formed.

$[Cu(L1)Cl_2]_n$ (1d): To a solution of **L1** (0.1 g, 0.38 mmol) in acetonitrile (3 mL) was added a solution of $CuCl_2 \cdot 2H_2O$ (0.066 g, 0.38 mmol) in methanol (5 mL). The mixture was stirred for a few minutes and then filtered. Crystals suitable for X-ray analysis formed soon thereafter (0.65 g, 50%).

$[Cu(L2)Cl]ClO_4$ (2a): To a solution of **L2** (0.1 g, 0.36 mmol) in methanol (10 mL) was added a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.067 g, 0.18 mmol) and $CuCl_2 \cdot 2H_2O$ (0.036 g, 0.18 mmol) in methanol (5 mL). The mixture was stirred for a few minutes and then filtered. Diethyl ether (100 mL) was quickly added to the filtrate, which led to the deposition of a sky-blue precipitate. This precipitate was collected by filtration and dried in vacuo to yield a light-green solid (0.16 g, 90%, 0.33 mmol). Crystals suitable for X-ray analysis were grown by vapour diffusion of diethyl ether into a solution in DMF. $C_{17}H_{16}N_4CuCl_2O_4$: calcd. C 43.01, H 3.82, N 11.80; found C 43.04, H 3.43, N 11.64. UV/Vis [CH_3CN, (ε, M^{-1} cm^{-1})]: λ_{max} = 214 (14372), 260 (20809), 366 (417), 708 nm (125).

$[Cu(L2)Cl_2]$ (2b): To a solution of **L2** (0.1 g, 0.36 mmol) in methanol (10 mL) was added a solution of $CuCl_2 \cdot 2H_2O$ (0.062 g, 0.36 mmol) in methanol (5 mL). The mixture was stirred for a few minutes and then filtered. Diethyl ether (100 mL) was quickly added to the filtrate, which led to the deposition of a green precipitate. This precipitate was collected by filtration and dried in vacuo to yield a light-green solid (0.13 g, 86%, 0.31 mmol). Crystals suitable for X-ray analysis were grown from methanol/water (2:1; 10 mL). $C_{17}H_{16}N_4CuCl_2$: calcd. C 49.71, H 4.42, N 13.64; found C 49.87, H 4.15, N 13.50. UV/Vis [CH_3CN (ε, M^{-1} cm^{-1})]: λ_{max} = 212 (12735), 228 (11593), 260 (12801), 800 nm (320).

X-ray Crystallographic Study: Crystal data and experimental conditions are listed in Table 1. Selected bond lengths and bond angles with standard deviations in parentheses are presented in Table 2. Intensity data were collected on a Siemens SMART 1000 CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Exposure times were 10 s per frame for **L1**, **1a**, **1b**, and **1c** and 20 s per frame for **1d**, **2a**, and **2b**, collected using the ω-scan technique (Δω = 0.45° for **L1**, **1a**, **1b**, and **1c** and 0.4° for **1d**, **2a**, and **2b**). The collected reflections were corrected for Lorentz, polarization, and absorption effects. The structures were solved by direct methods and refined by full-matrix least-squares methods on F^2.[42–44]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-167124–167130. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223 336033; E-mail: deposit@ccdc.cam.ac.uk].

Novel Chiral Metallocenophanes Derived from [2.2]Paracyclophane and Their Use in Olefin Polymerization[‡]

Henning Hopf,*[a] Sethuraman Sankararaman,[b] Ina Dix,[a] Peter G. Jones,[c] Helmut G. Alt,*[d] and Andrea Licht[d]

Keywords: Metallocenophanes / Planar chirality / Fulvenes / Metallacycles / Olefin polymerization

The 4-fulvenyl[2.2]paracyclophane (**1**) was transformed, by treatment with lithium aluminium hydride and methyllithium in tetrahydrofuran, to the corresponding cyclopentadienyl anions **6** and **8**, respectively. The iron complex **7** was prepared from **6**, while **8** was converted into the metal complexes **9** (Fe complex), **10** (Ti), **11** (Zr), **12** (Ti), and **13** (Zr). All new metallocene complexes were characterized by their spectroscopic data. In addition, a single crystal X-ray crystallographic analysis was performed for complex **11**. The metallacyclic zirconocene complex **15** was synthesized by the reaction of the dichloride derivative **13** with two equivalents of *n*-butyllithium. After activation of complexes **10**–**13** and **15** with methylalumoxane (MAO) they were used for the catalytic polymerization of ethene and propene.

Introduction

Chiral metallocene complexes are important reagents and catalysts in stereoselective synthesis of organic fine chemicals and polymers.[2] In principle, chirality may be generated in a metallocene moiety by the introduction of both achiral and chiral substituents. Whereas in the latter case the resulting metallocene unit necessarily has to be chiral, the former case is more complex. Chirality, and especially the resolution of the enantiomers of the substituted metallocene complexes, now depends on various factors, including the height of the rotational barrier and the substitution pattern. For example, a metallocene complex carrying two achiral, non-identical substituents in one cyclopentadienyl ring will always be chiral and in principle resolvable, regardless of the barrier of rotation of the five-membered rings. Placing one substituent in either ring, however, does not necessarily induce chirality. Provided the rotational barrier of this derivative is sufficiently low, one conformation having a plane of symmetry is always accessible and the metallocene complex is hence unresolvable. One of the most widely used ways of reducing conformational mobility in metallocene complexes consists of the introduction of a molecular bridge between the two "decks" of the metal organic compound.[3,4] As far as chiral substituents are concerned, we are interested in combining molecules with a chiral plane, in particular monosubstituted [2.2]paracyclophanes, with a metallocene. Because of the rigidity of the molecular framework, these cyclophanes are always chiral, regardless of the type of the substituent and its position in these bridged aromatic compounds. By condensing 1,3-cyclopentadiene and indene with 4-formyl-[2.2]paracyclophane, i.e. applying the Thiele fulvene synthesis to this aldehyde, we have recently been able to prepare a number of fulvenyl paracyclophanes.[5] In the present paper we describe the preparation of ferrocene, zirconocene, and titanocene complexes of these new chiral ligands, and we report on first polymerization experiments in which these metal complexes (in racemic form) were used as catalysts for the polymerization of olefins (ethene, propene).

Results and Discussion

Stereochemistry of Addition of Methyllithium to 4-(6-Fulvenyl)[2.2]paracyclophane (1)

The formation of cyclopentadienyl anions by addition of organolithium reagents to the 6-position of fulvenes is a

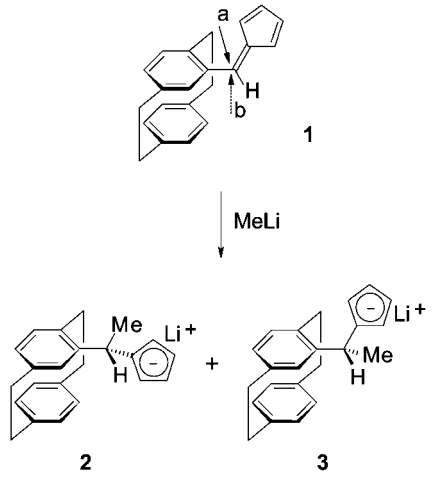
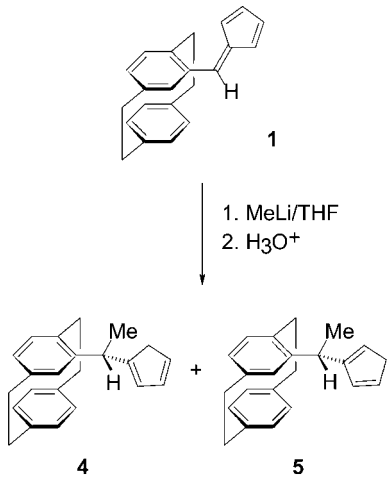


Scheme 1. Stereochemistry of addition of methyllithium to the fulvene **1**



Scheme 2. Addition of methyllithium to the fulvene **1**

well-known process for generating these species, which are necessary for subsequent metallocene formation.[6,7] To investigate the stereochemistry of this process we selected the fulvene derivative **1** (Scheme 1), which is easily available in gram quantities.[5]

Unlike in the 4-formyl and 4-acetyl derivatives of [2.2]paracyclophane,[8] the conformation of the substituent in 4-fulvenyl[2.2]paracyclophane (**1**) is rigid. In our earlier studies we had shown by NMR spectroscopy and X-ray crystal structure analysis[5] that the most stable conformation of **1** in solution and in the solid state is the one in which the proton at C-6 of the fulvene ring is located in the intraannular space of the cyclophane part of the hydrocarbon, the bulky cyclopentadienyl unit pointing towards the exterior. The barrier for rotation around the C−C bond connecting the cyclophane residue and the fulvene unit is high (26 kcal·mol^{-1}). Addition of methyllithium to **1** at C-6 to provide the corresponding cyclopentadienyl anion led to the generation of a new chiral centre, and in principle a pair of diastereomeric cyclopentadienides (**2** and **3**) could be obtained, depending on the approach of the nucleophile as shown by pathways **a** and **b** in Scheme 1. However, in the former pathway the methyllithium approaches from the exterior of the cyclophane unit and it is sterically less hindered compared to pathway **b**. In this latter trajectory the approach of the metal organic reagent is sterically demanding because of hindrance by the bridge hydrogen atoms and also the unsubstituted aromatic ring of the phane unit. Both these effects essentially block one face of the C-6 position of the fulvene substituent. The approach of methyllithium via pathway **a** should hence be preferred, leading to the formation of a single diastereomer of the cyclopentadienide.

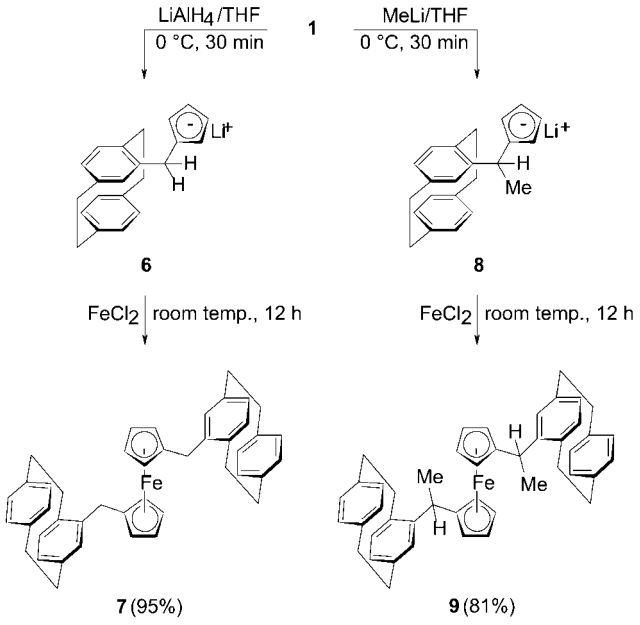
In order to verify this hypothesis, we added methyllithium to the racemic mixture of **1** and subsequently quenched the reaction mixture with acid. Careful analysis of the high-resolution ^{1}H and ^{13}C NMR spectra clearly indicated the formation of two isomeric products **4** and **5** in a nearly 2:1 ratio (Scheme 2), each one as a single diastereomer. In the ^{1}H NMR spectrum of the mixture of **4** and **5** the methine proton (C*H*−CH_3) appeared as overlapping quadruplets at δ_H = 3.90 and 3.87 (J = 7.1 Hz) and the methyl protons as a single doublet at δ = 1.23 (J = 7.1 Hz). In the corresponding ^{13}C NMR spectrum the methine carbon atom was registered at δ_C = 38.0 and 37.43 and the methyl carbon atom at δ_C = 23.59 and 22.92. The methylene carbon atom of the cyclopentadiene ring appeared at δ_C = 42.77 and 41.12.

Thus, we conclude that the addition of methyllithium to fulvene **1** is highly stereoselective in that the methyl group approaches from the less hindered face of the fulvene (pathway **a** in Scheme 1), leading to the formation of a single diastereomer of the cyclopentadienyl anion. This diastereomer is a crucial intermediate en route to the metallocenes. This argument is further substantiated by the X-ray crystal structure of the zirconocene dichloride **11** (to be discussed below) that clearly reveals the stereochemistry of the newly generated chiral center upon addition of methyllithium. It should be mentioned that the diastereoselectivity of the addition of organometallic reagents to the 4-formyl- and 4-acetyl derivatives of [2.2]paracyclophane is poor because of the high conformational mobility of these functional groups in comparison to the fulvenyl substituent.[7]

Synthesis of Metallocenes

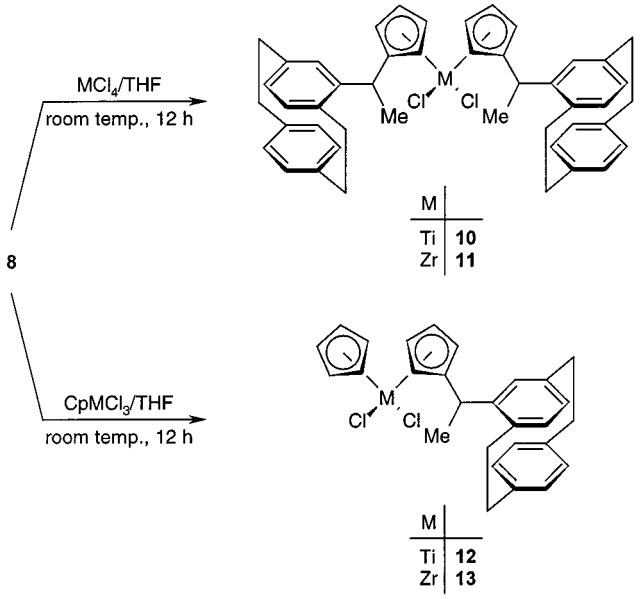
The ferrocene derivatives **7** and **9** were prepared by reaction of the corresponding lithium cyclopentadienides **6** and **8**, respectively, with $FeCl_2$ in anhydrous tetrahydrofuran (Scheme 3). In both complexes the proton resonance signals corresponding to the cyclopentadienyl ring appeared between δ = 4.0−4.5 in the ^{1}H NMR spectra (Cp_2Fe: δ_H = 4.0−4.2). In the ^{13}C NMR spectra the corresponding carbon atoms were registered in the range δ_C = 65−70 (Cp_2Fe: δ_C = 65−67). Further, it is also evident from the NMR spectra that both **7** and **9** were produced as a 1:1 mixture of diastereomers. In the ^{1}H NMR spectrum of **9** the methyl

groups produced two overlapping doublets (δ_H = 1.52 and 1.50). In the ^{13}C NMR spectrum of both compounds two sets of signals for each carbon atom were present indicating the formation of two isomers. Finally, in the mass spectra of these ferrocene derivatives the molecular ion peak appeared as the base peak, corresponding to the generation of the respective ferrocenium ions of **7** and **9**.



Scheme 3. Synthesis of the ferrocenes **7** and **9** from the fulvene **1**

The metallocene dichloride derivatives **10** and **11** were synthesized by reaction of the lithium cyclopentadienide **8** with $TiCl_4$ and $ZrCl_4$, respectively, as shown in Scheme 4. Both **10** and **11** were obtained as a 1:1 mixture of two diastereomers, as evident from the ^1H and ^{13}C NMR spectra. In the case of **10** the methine proton (C*H*−CH_3) appeared as overlapping quadruplets for the two diastereoisomers at δ = 4.52 and 4.56, and the methyl protons at δ_H = 1.35 and 1.31, each as a well-resolved doublet (J = 6.9 Hz).



Scheme 4. Synthesis of metallocene dichlorides from the fulvene **1**

The cyclopentadienyl protons were registered in the same region as the aromatic protons of the cyclophane unit between δ = 6.0 and 7.0. (Cp_2TiCl_2, δ_H = 6.59). However, in the ^{13}C NMR spectrum of **10** the carbon signals corresponding to the cyclopentadienyl unit appeared at lower δ_C values in the region of 110 to 120, in contrast to the aromatic carbon atoms, which absorbed above δ = 130. Similarly, in the case of **11** the methine proton (C*H*−CH_3) appeared as overlapping quadruplets at δ_H = 4.48 and 4.46 and the methyl protons at δ_H = 1.44 and 1.42 as two overlapping doublets (J = 6.8 Hz). In the mass spectra of **10** and **11** the molecular ions generate a cluster of peaks due to the isotopes of chlorine and the metal atom. The intensities of these peaks matched with the calculated values based on the natural isotopic abundances of chlorine and the metal atom. Finally, the structure of the zirconocene dichloride **11** was confirmed by single crystal X-ray crystallographic analysis as shown in Figure 1.

Compound **11** crystallizes with two independent half molecules and two molecules of deuteriochloroform in the asymmetric unit. The two half molecules are completed by the operation of a twofold axis. The centrosymmetric space group *Pbcn* only allows the determination of the relative configuration of the two diastereomeric molecules; both showing the same relative configuration (4*R*,17*S*). The angles between the cyclopentadiene units in the molecules amount to 54.42(11)° (C19 to C23) and 56.69(10)° (C19′ to C23′). To minimize the electronic repulsion of the π-systems, the angles between the four coplanar carbon atoms in the [2.2]paracyclophane units and the cyclopentadiene units are 78.29(10)° (C4/C5/C7/C8 to C19−C23) and 70.75(10)° (C4′/C5′/C7′/C8′ to C19′−C23′), corresponding to an approximately perpendicular arrangement. The zirconium atoms show a distorted tetrahedral coordination involving the two chlorine atoms and the centroids of the π-cyclopentadienyl units. The Zr−C bonding to the cyclopentadienyl moieties can be described as pentahapto coordinated, since the distances between the metal atoms and the coordinated carbons atoms deviate from each other negligibly: 2.483(3) to 2.561(3) Å (C19 to C23) and 2.477(3) to 2.578(3) Å (C19′ to C23′). The average Zr−C distance amounts to 2.515 Å for Zr and 2.518 Å for Zr′ and is in good agreement with the vapor-phase electron-diffraction study of the (π-$C_5H_5)_2ZrCl_2$ molecule:[9] 2.522(5) Å. The centroids of the cyclopentadienyl rings are separated from the heavy atoms by 2.209 Å (Zr) and 2.214 Å (Zr′). The Zr−Cl bond lengths of 2.442(1) (Zr−Cl) and 2.444(8) Å (Zr′−Cl′) are very close to the sum of Pauling radii (2.44 Å)[10] and correspond to the values found in other zirconium complexes with coordinated cyclopentadienyl groups.[11,12] The Cl−Zr−Cl angles of 95.9(4) (Zr) and 95.8(4)° (Zr′) are somewhat less than the 97.1° for (π-$C_5H_5)_2ZrCl_2$.[11]

The ordered deuteriochloroform molecule C99−Cl99 is stabilized by Cl···Cl interactions in the range of the double

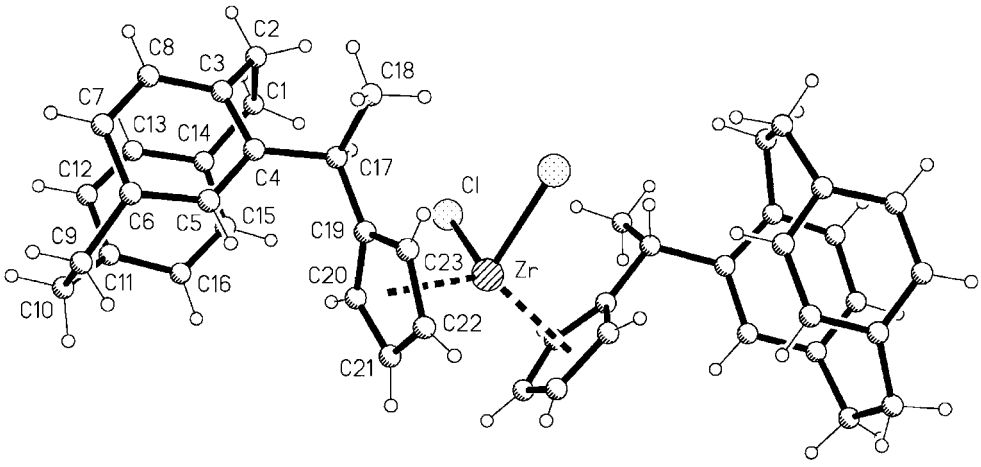


Figure 1. The structure of one independent molecule of **11** in the crystal; radii are arbitrary

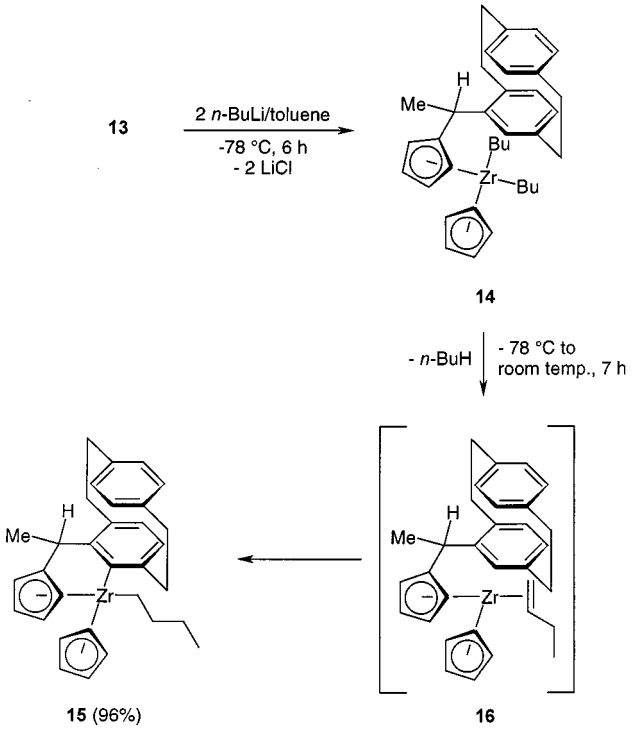
van-der-Waals radius. This molecule connects the two independent zirconocenes to another via two chlorine atoms and interacts via the third chlorine atom with the other solvent molecule: Cl′···Cl99 3.633(1) Å, Cl···Cl98 3.518(1) Å, Cl97···Cl94 3.654(7) Å.

The mixed ligand metallocene dichloride derivatives **12** and **13** were prepared by metathetic reaction of **8** with $CpTiCl_3$ and $CpZrCl_3$, respectively, in anhydrous tetrahydrofuran (Scheme 4). Both **12** and **13** formed as single diastereomers, as evident from the ^1H and ^{13}C NMR spectroscopic data. For example, the methine proton of **12** appeared as a quadruplet at $\delta_H = 4.54$ and the methyl protons absorbed as a doublet at $\delta_H = 1.30$ ($J = 7.0$ Hz). Analogously, in the case of **13** the methine proton was registered as a quadruplet $\delta_H = 4.40$ and the methyl protons appeared as a doublet at $\delta_H = 1.35$ ($J = 7.0$ Hz). In both complexes **12** and **13** the unsubstituted cyclopentadienyl ligand protons are represented by a sharp singlet at $\delta = 6.61$ and 6.52, respectively (for five proton integration) in the ^1H NMR spectra. In the ^{13}C NMR spectra the corresponding carbon atoms appear as a single resonance line at $\delta = 119.9$ and 115.8, respectively, indicating free rotation of the cyclopentadienyl ligand in these complexes.

Synthesis of a Metallacyclic Zirconocene Complex by Using a CH Bond Activation Reaction

The metallocene dichloride complex **13** is well suited as a starting material for the synthesis of metallacyclic complexes. Only a single reaction product was obtained when **13** was treated with two equivalents of *n*-butyllithium in toluene. The key reaction step in this transformation is a CH bond activation that led to cyclometallation as shown in Scheme 5.

During this reaction a zirconocene dibutyl complex **14**,[13] which was stable in solution at low temperatures (−40 °C) for several minutes, was formed as an intermediate. The unsubstituted parent compound of this complex was characterized using NMR spectroscopy.[14]



Scheme 5. Synthesis of the metallacyclic complex **15** from the metallocene dichloride complex **13**

Subsequently, **14** is proposed to lose *n*-butane[15,16] in a β-H transfer reaction, resulting in the formation of a reactive (η^2-butene) complex, **16**. "$Cp_2Zr(\eta^2$-butene)", generated as an intermediate during the reaction of Cp_2ZrCl_2 with two equivalents of *n*-butyllithium, has been stabilized with trimethylphosphane and characterized.[17−19] One phenyl moiety of the [2.2]paracyclophane group of **16** shown in Scheme 5 then reacted further to yield the corresponding metallacycle **15** by a CH bond activation and hydrogen transfer reaction.[20] The proposed structure of metallacycle **15** is based on comparison with similar

phenylalkyl-substituted zirconocene complexes[21] and the steric situation at the cyclophane moiety. Within the reaction pathway only one isomer is formed (see NMR spectroscopic data) that can have either (*R*) or (*S*) configuration at the 1,1-ethylidene bridge.

Polymerization Experiments

The resultant metallocene complexes are precursors for homogeneous ethylene and propylene polymerization. The complexes are activated by adding a 3000-fold molar excess of MAO. The formation of an active catalyst system is indicated by a colour change.

a) Ethylene Polymerization

The polymerization activities of the activated metallocene complexes, the number average of the molecular weight M_n, the weight average M_w, the centrifuge average M_z, the viscosity average M_η, and the polydispersity D of the resulting polyethylenes are listed in Table 1.

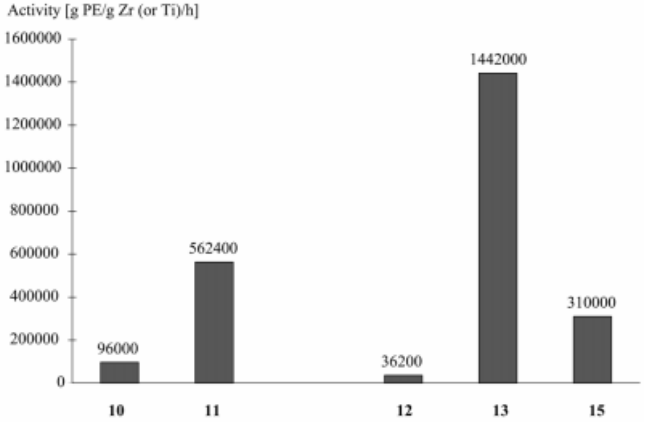
Table 1. Overview of the ethylene polymerization experiments and polymer analytical results. High temperature gel permeation chromatography (HT-GPC): M_n = number average of the molecular weight (kg/mol), M_w = weight average of the molecular weight (kg/mol), M_z = centrifuge average of the molecular weight (kg/mol), M_η = viscosity average of the molecular weight (kg/mol), D = polydispersity ($D = M_w/M_n$)

Metallocene complex	Activity [g PE / g M / h] M = Ti, Zr	Fouling	HT-GPC M_n M_w M_z M_η D
10 	96000	middle	1350 17590 395510 9770 13.0
11 	562400	middle	370 4580 230360 2480 12.2
12 	36200	low	280 2570 39530 1630 9.1
13 	1442000	low	290 1490 8590 1220 5.2
15 	310000	low	370 3240 292010 3240 8.8

The central metal has a strong influence on the polymerization behaviour of the metallocene complexes;[21] in both bis[(paracyclophanyl)ethylcyclopentadienyl]metallocene and [(paracyclophanyl)ethylcyclopentadienyl]-(cyclopentadienyl)metallocene complexes, the zirconium complexes $(Cp')_2ZrCl_2$ (**11**) and $Cp'CpZrCl_2$ (**13**) are much more active than the corresponding titanium complexes $(Cp')_2TiCl_2$ (**10**) and $Cp'CpTiCl_2$ (**12**). The reason for this effect is the lower thermal stability of the titanium analogues.[22]

The bulky paracyclophanyl moiety exerts two different influences on the active metal centre. On the one hand, steric crowding can have a stabilizing effect on sensitive metal centres, as in the case of the titanium complexes.[23] Therefore, the productivity of $(Cp')_2TiCl_2$ (**10**) containing two bulky moieties is higher than that of $Cp'CpTiCl_2$ (**12**) containing only one bulky group, despite the stronger blockage of the active metal centre.

On the other hand, steric crowding lowers the productivity, as in the case of the zirconium complexes. The productivity of $(Cp')_2ZrCl_2$ (**11**) is much lower than that of $Cp'CpZrCl_2$ (**13**). Similarly, steric overloading is responsible for the lower productivity of the metallacyclic zirconium complex **15** compared to the corresponding precursor **13**. After activation of the metallacycle with MAO, the ring could be expanded during the polymerization process by repeated ethylene insertion into the metal−carbon σ bond of the metallacycle.[24,25] Finally, an insoluble polymer was formed that was directly attached to one π-ligand of the active catalyst cation. The polyethylene fixed to the paracyclophanyl moiety increased the steric overloading and lowered the productivity of complex **15** significantly (Scheme 6).



Scheme 6. Comparison of the catalytic activities of the metallocene complexes **10**−**13** and **15** for the polymerization of ethylene

This incorporation of the zirconium complex into the polymer backbone is an elegant and inexpensive way to inherently increase heterogeneity and form a supported and self-immobilizing catalyst for ethylene polymerization. As a result of the conversion, the polyolefins formed with the

heterogeneous catalysts precipitate onto the catalyst's surface and not onto internal wall surfaces, causing reactor fouling. The conversion of a homogeneous metallocene/MAO catalyst into a heterogeneous catalyst is absolutely necessary for the "slurry loop" process.

b) Propylene Polymerization

The polymerization activities of the activated metallocene complexes, the molecular weights, and the isotacticities of the resulting polypropylenes are listed in Table 2.

Table 2. Overview of the propylene polymerization experiments and polymer analytical results.

Metallocene complex	Activity [g PP / g Zr / h]	Molecular mass[a] M^+ [*m*/*z*]	Tacticity (only isotactic contribution mmmm)[b] [%]
13 	49370	Low-molecular weighted oil 952[c]	4.6
15 	39350	Low-molecular weighted oil 953[c]	4.8

[a] Determined by mass spectrometry due to the low molecular weight. – [b] Determined by ^{13}C NMR spectroscopy (solvent 1,2,4-trichlorobenzene/1,1,2,2-tetrachlorodeuterioethane; 60° C). – [c] Highest peak in mass spectrum.

The synthesized metallocene complexes were activated with MAO; only the monosubstituted Cp′CpZrCl_2 (**13**) and the corresponding metallacycle **15** were active in the propylene polymerization with a productivity of 49370 g PP/g Zr/h (**13**) and 39350 g PP/g Zr/h (**15**). The produced polypropylenes were atactic, low-molecular weight oils with an isotactic share of only 4.6% (**13**) and 4.8% (**15**).

The comparatively low activity in propylene polymerization can be explained by the steric crowding of the active centre. The bulky paracyclophanyl group not only blocks the access of the monomer to the metal but also the growth and orientation of the polymer chain. The atactic character of the polymer is the result of random coordination of the prochiral monomer to the metal. This random coordination is probably due to the lack of a favoured configuration of the catalyst. The low-molecular weight is an indication of early termination reactions.

Experimental Section

The instrumentation used in this study has been described in the previous publications of this series.[1]

Addition of Methyllithium to Fulvene 1: Formation of 4-[1-(1-Cyclopenta-1,3-dienyl)ethyl][2.2]paracyclophane (4) and 4-[1-(2-Cyclopenta-1,3-dienyl)ethyl][2.2]paracyclophane (5): To an ice-cold solution of fulvene **1** (0.28 g, 1 mmol) in 5 mL of anhydrous THF, was added dropwise an ethereal solution of MeLi (0.65 mL of 1.6 M solution, 1.1 mmol) under N_2. The initially dark-red solution turned yellow. After 30 min of stirring, 10 mL of 1 N HCl was added and the mixture was extracted with dichloromethane. The organic layer was separated and washed with saturated brine solution and dried with anhydrous magnesium sulfate. Evaporation of the solvent yielded a yellow viscous oil (0.3 g, 100%) consisting of a mixture of compounds **4** and **5** in a 2:1 ratio (NMR analysis). – ^1H NMR ($CDCl_3$, 400 MHz): δ = 1.23 (d, *J* = 7.1 Hz, 3 H), 2.65–3.10 (m, 9 H), 3.40 (m, 1 H), 3.87 and 3.90 (overlapping quadruplets, *J* = 7.1 Hz, 1 H), 5.85 and 6.00 (broad s, 2 × 1 H), 6.10–6.30 (m, 4 H), 6.35–6.55 (m, 4 H), 6.65 (m, 1 H). – ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 22.8 (q), 23.5 (q), 33.2 (t), 33.3 (t), 34.7 (t), 35.1 (t), 35.2 (t), 35.3 (t), 35.3 (t), 37.3 (d), 37.9 (d), 41.0 (t), 42.7 (t), 127.4 (d), 128.5 (d), 130.1 (d), 130.3 (d), 130.5 (d), 130.9 (d), 130.9 (d), 131.3 (d), 132.1 (s), 132.3 (d), 132.5 (d), 132.6 (d), 132.6 (d), 132.9 (d), 133.0 (d), 133.7 (d), 134.4 (d), 135.4 (d), 135.4 (d), 136.9 (s), 137.0 (s), 139.3 (s), 139.4 (s), 139.4 (s), 139.5 (s), 139.7 (s), 139.7 (s), 144.5 (s), 145.3 (s), 149.6 (s), 151.8 (s). – MS (EI, 70 eV): *m*/*z* (%) = 301 (10), 300 [M^+] (44), 196 (30), 195 (76), 181 (42), 165 (34), 155 (12), 153 (12), 142 (11), 141 (12), 128 (16), 119 (18), 104 (14), 91 (14), 86 (18), 84 (28).

Bis[(4-[2.2]paracyclophanyl)methylcyclopentadienyl]iron(II) (7): To an ice-cold, stirred solution of fulvene **1** (0.57 g, 2 mmol) in 20 mL of anhydrous THF, was added $LiAlH_4$ (76 mg, 2 mmol) under N_2. The initially dark-red solution turned yellow. After stirring for 30 min at 0 °C the solution was added dropwise with a syringe to a stirred, ice-cold slurry of $FeCl_2$ (130 mg, 1 mmol) in 20 mL of anhydrous THF. After the addition was complete the solution was warmed to room temp. and stirred overnight. The reaction was quenched by dropwise addition of 20 mL of 1 N HCl. The organic layer was separated and the aqueous layer was extracted with dichloromethane (2 × 20 mL). The combined organic layers were washed with water (20 mL) and dried ($MgSO_4$). Removal of the solvent yielded a brownish yellow solid (0.6 g, 95%) that was purified for analytical purposes by column chromatography on silica gel with pentane and dichloromethane (1:1, v/v) to yield ferrocene **7** as a bright yellow solid, m.p. 196–200 °C- IR (KBr): $\tilde{\nu}$ = 2924 cm^{-1}, 2851, 1593, 1412, 716, 502. – UV/Vis ($CHCl_3$): λ_{max} (log ε) = 266 nm (3.87), 300 (3.27), 314 (3.12). – ^1H NMR ($CDCl_3$, 400 MHz): δ = 2.80 (m, 2 H), 2.93 (m, 2 H), 2.98–3.25 (m, 12 H), 3.34 (m, 2 H), 3.51 (m, 2 H), 3.89 (broad s, 4 H), 3.95 (broad s, 4 H), 6.00 (s, 2 H), 6.36 (m, 2 H), 6.40 (m, 4 H), 6.46 (m, 2 H), 6.52 (m, 2 H), 6.68 (m, 2 H). – ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 33.5 (t), 33.9 (t), 34.0 (t), 34.2 (t), 35.0 (t), 35.3 (t), 67.9 (d), 68.1 (d), 69.1 (d), 69.6 (d), 69.8 (d), 87.5 (s), 128.5 (d), 128.6 (d), 130.5 (d), 132.2 (d), 132.2 (d), 133.1 (d), 133.2 (d), 134.5 (d), 134.7 (d), 134.7 (d), 137.3 (s), 137.3 (s), 139.3 (s), 139.5 (s), 139.6 (s), 140.4 (s), 140.5 (s). – MS (EI, 70 eV): *m*/*z* (%) = 627 (50), 626 [M^+] (100), 522 (16), 521 (10), 405 (12), 342 (16), 341 (16), 340 (26), 300 (14), 237 (12), 181 (20), 180 (22), 179 (56), 164 (20), 104 (18). – HMRS: *m*/*z* calcd. for $C_{44}H_{42}Fe$: 626.2636; found 626.2627. – $C_{44}H_{42}Fe$ (626.3): calcd. C 84.31, H 6.76; found C 84.34, H 6.69.

Bis[1-(4-[2.2]paracyclophanyl)ethylcyclopentadienyl]iron (II) (9): To an ice-cold, stirred solution of fulvene **1** (0.57 g, 2 mmol) in 20 mL of anhydrous THF, was added dropwise an ethereal solution of MeLi (1.25 mL of 1.6 M solution, 2 mmol) under N_2. The initially dark-red solution turned yellow. After 30 min the solution was ad-

ded dropwise with a syringe to a stirred, ice-cold slurry of $FeCl_2$ (130 mg, 1 mmol) in 20 mL of anhydrous THF. After the addition the solution was stirred at room temp. overnight and worked up as described for **7** to yield a dark-red solid (0.52 g, 81%). The crude product was purified by column chromatography on silica gel with pentane and dichloromethane (1:1, v/v) to yield ferrocene **9** as a bright yellow solid, m.p. 200−202 °C; 1:1 mixture of diastereomers as inferred from the NMR spectra. − IR (KBr): $\tilde{\nu}$ = 2926 cm^{-1}, 2851, 1591, 1411, 901, 716. − UV/Vis ($CHCl_3$): λ_{max} (log ε) = 262 nm (4.05), 296 (3.42), 310 (3.36). − ^1H NMR ($CDCl_3$, 400 MHz): δ = 1.50 and 1.52 (overlapping doublets, *J* = 7.4 Hz, 6 H), 2.75 (m, 2 H), 2.90−3.30 (m, 12 H), 3.50 (m, 2 H), 3.90 (m, 2 H), 4.18 (s, 2 H), 4.32 (d, *J* = 10.8 Hz, 2 H), 4.41 (s, 2 H), 4.50 (d, *J* = 11.4 Hz, 2 H), 5.74 (s, 1 H), 5.76 (s, 1 H), 6.25 (m, 4 H), 6.35 (m, 2 H), 6.55 (m, 4 H), 6.64 (d, *J* = 7.5 Hz, 1 H), 6.68 (d, *J* = 7.4 Hz, 1 H). − ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 23.4 (q), 23.5 (q), 33.0 (t), 33.0 (t), 34.8 (t), 34.9 (t), 35.1 (t), 35.2 (t), 36.4 (d), 36.6 (d), 67.9 (d), 68.3 (d), 68.5 (d), 68.6 (d), 69.0 (d), 69.5 (d), 69.8 (d), 92.9 (s), 93.2 (s), 130.2 (d), 130.2 (d), 130.3 (d), 130.8 (d), 130.9 (d), 132.4 (d), 132.4 (d), 132.6 (d), 132.7 (d), 132.9 (d), 132.9 (d), 135.1 (d), 135.1 (d), 136.3 (s), 136.3 (s), 139.2 (s), 139.3 (s), 139.5 (s), 139.5 (s), 139.6 (s), 139.6 (s), 146.2 (s), 146.2 (s). − MS (EI, 70 eV): *m*/*z* (%) = 655 (50), 654 [M^+] (100), 640 (8), 639 (10), 535 (10), 420 (12), 419 (38), 355 (20), 354 (26), 315 (20), 251 (20), 193 (52), 179 (32), 165 (22), 104 (45). − $C_{46}H_{46}Fe$ (654.7): calcd. C 84.37, H 7.09; found C 84.32, H 7.09.

Bis{[1-(4-[2.2]paracyclophanyl)]ethylcyclopentadienyl}titanium Dichloride (10): A solution of the lithium cyclopentadienide (**8**) (2 mmol in 20 mL of anhydrous THF, prepared by the method described above for the synthesis of **9**) was added dropwise with a syringe to a stirred, ice-cold solution of $TiCl_4$ (190 mg, 1 mmol) in 20 mL of anhydrous THF. During the addition the yellowish solution turned dark red. The reaction mixture was stirred at room temp. for 12 h and worked up as described for **7** to yield a red solid (0.57 g, 83%). This solid was further purified by recrystallization by dissolving it in a minimum amount of dichloromethane and adding pentane until a slight turbidity appeared. Upon cooling the solution in the freezer (−25 °C), the titanocene dichloride **10** was obtained as a bright red solid, m.p. > 250 °C (dec.). − IR(KBr): $\tilde{\nu}$ = 2925 cm^{-1}, 2852, 1592, 1486, 824, 717. − UV/Vis ($CHCl_3$): λ_{max} (log ε) = 260 nm (4.49), 396 (3.44). − ^1H NMR ($CDCl_3$, 400 MHz): δ = 1.31 (d, *J* = 6.9 Hz, 3 H), 1.35 (d, *J* = 7.0 Hz, 3 H), 2.65 (m, 2 H), 2.85−3.15 (m, 10 H), 3.20 (m, 2 H), 3.45 (m, 2 H), 4.52 and 4.56 (two overlapping quadruplets, 2 H, *J* = 6.9 and 7.0 Hz), 5.49 (m, 1 H), 5.53 (m, 1 H), 6.20 (m, 2 H), 6.25−6.40 (m, 6 H), 6.45−6.60 (m, 8 H), 6.58 (m, 1 H), 6.69 (m, 1 H), 6.71 (m, 1 H), 6.75 (m, 1 H), 6.86 (m, 1 H). − ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 22.2 (q), 22.3 (q), 33.3 (t), 33.3 (t), 34.9 (t), 35.0 (t), 35.2 (t), 35.3 (t), 38.5 (d), 38.6 (d), 109.8 (d), 110.8 (d), 119.9 (d), 119.9 (d), 120.8 (d), 121.0 (d), 122.2 (d), 122.2 (d), 129.6 (d), 129.7 (d), 130.6 (d), 130.7 (d). 131.5 (d), 131.5 (d), 132.1 (d), 132.6 (d), 132.6 (d), 133.1 (d), 135.9 (d), 136.0 (d), 137.0 (s), 137.1 (s), 139.3 (s), 139.3 (s), 139.7 (s), 139.8 (s), 139.8 (s), 142.3 (s), 143.0 (s), 144.9 (s), 145.0 (s). − MS (EI, 70 eV): *m*/*z* (%) = 716 [M^+] (3), 598 (12), 419 (8), 384 (34), 383 (22), 382 (30), 300 (16), 299 (10), 298 (22), 278 (12), 196 (20), 195 (78), 194 (18), 193 (100), 192 (12), 181 (20), 180 (18), 179 (32), 178 (34), 165 (50), 119 (42), 105 (54), 104 (30), 78 (230), 77 (12).

Bis{[1-(4-[2.2]paracyclophanyl)]ethylcyclopentadienyl}zirconium Dichloride (11): Compound **11** was prepared by the procedure described for the synthesis of **10**, using $ZrCl_4$ (230 mg, 1 mmol). The crude product was obtained as a grey solid (0.70 g, 92%). The solid was triturated with diethyl ether (20 mL) and filtered to obtain pure zirconocene dichloride **11** as a tan-coloured solid (0.37 g). Further recrystallization from dichloromethane in the freezer (−25 °C) yielded colourless crystals of **11**, m.p. 280−285 °C (dec.). The ether soluble portion was evaporated to dryness and the ^1H NMR spectrum of this solid (0.31 g) indicated mainly **11**, along with small amounts of **4** and **5**. − IR (KBr): $\tilde{\nu}$ = 2926 cm^{-1}, 1592, 833, 821. − UV/Vis ($CHCl_3$): λ_{max} (log ε) = 296 nm (3.52), 340 (3.27), 372 (2.85). − ^1H NMR ($CDCl_3$, 400 MHz): δ = 1.42 and 1.44 (two overlapping doublets, 3 H each, *J* = 6.8 Hz), 2.72 (m, 2 H), 2.90−3.10 (m, 8 H), 3.15 (m, 2 H), 3.25 (m, 2 H), 3.53 (m, 2 H), 4.46 and 4.48 (two overlapping quadruplets, 1 H each, *J* = 6.8 Hz), 5.52 (d, *J* = 1.1 Hz, 1 H), 5.54 (d, *J* = 1.2 Hz, 1 H), 6.25−6.45 (m, 8 H), 6.45−6.65 (m, 8 H), 6.75 (m, 2 H), 6.82 (m, 2 H). − ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 22.6 (q), 33.3 (t), 33.3 (t), 34.9 (t), 34.9 (t), 35.2 (t), 35.3 (t), 37.6 (d), 37.7 (d), 106.5 (d), 107.1 (d), 115.1 (d), 115.2 (d), 116.9 (d), 117.4 (d), 118.0 (d), 118.4 (d), 129.5 (d), 129.6 (d), 130.3 (d), 130.4 (d), 131.4 (d), 131.4 (d), 132.1 (d), 132.6 (d), 133.1 (d), 135.8 (d), 136.9 (s), 136.9 (s), 137.9 (s), 138.3 (s), 139.3 (s), 139.3 (s), 139.7 (s), 139.8 (s), 145.2 (s), 145.2 (s). − MS (EI, 70 eV): *m*/*z* (%) = 763 (0.8), 761 (0.8), 760 (1.8), 759 (1.4), 758 (1.4) [molecular ions], 668 (46), 465 (10), 463 (16), 462 (10), 459 (22), 359 (28), 357 (38), 355 (44), 300 (62), 196 (30), 195 (100), 194 (36), 181 (56), 164 (52), 155 (16), 119 (30), 104 (28). − $C_{46}H_{46}ZrCl_2$ (761.0): calcd. C 72.4, H 6.04, Cl 9.33; found C 71.57, H 6.04, Cl 9.59.

Cyclopentadienyl[1-(4-[2.2]paracyclophanyl)ethylcyclopentadienyl]-titanium Dichloride (12): A solution of the lithium cyclopentadienide (**8**) (2.0 mmol in 20 mL of anhydrous THF) was added dropwise to a stirred, ice-cold solution of $CpTiCl_3$ (0.44 g, 2.0 mmol) in 20 mL of anhydrous THF. During the addition, the colour of the solution turned from yellow to dark red. After stirring at room temp. for 12 h, the reaction was worked up as described above to yield a dark red solid (0.9 g, 94%). Recrystallization from a mixture of dichloromethane and ether in the freezer (−25 °C) yielded the product as dark red needles (0.52 g), m.p. 208 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 3106 cm^{-1}, 2926, 2852, 1590, 856, 822. − UV/Vis ($CHCl_3$): λ_{max} (log ε) = 258 nm (4.42), 392 (3.32). − ^1H NMR ($CDCl_3$, 400 MHz): δ = 1.30 (d, *J* = 7.0 Hz, 3 H), 2.71 (m, 1 H), 2.90−3.05 (m, 4 H), 3.14 (m, 1 H), 3.26 (m, 1 H), 3.48 (m, 1 H), 4.54 (q, *J* = 7.0 Hz, 1 H), 5.50 (d, *J* = 1.1 Hz, 1 H), 6.22 (m, 1 H), 6.30−6.45 (m, 3 H), 6.54 (m, 4 H), 6.61 (s, 5 H), 6.73 (m, 1 H), 6.90 (m, 1 H). − ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 22.3 (q), 33.2 (t), 34.9 (t), 35.1 (t), 35.3 (t), 38.4 (d), 110.2 (d), 119.9 (d), 120.3 (d), 120.4 (d), 123.7 (d), 129.6 (d), 130.5 (d), 131.5 (d), 132.1 (d), 132.6 (d), 133.1 (d), 135.9 (d), 137.0 (s), 139.3 (s), 139.7 (s), 139.7 (s), 143.3 (s), 144.8 (s). − MS (EI, 70 eV): *m*/*z* (%) = 486 (5), 485 (7), 484 (22), 483 (14), 482 (30) [molecular ions], 450 (12), 448 (16), 447 (30), 446 (18), 411 (26), 410 (60), 409 (18), 408 (22), 345 (32), 344 (26), 343 (74), 315 (28), 313 (42), 305 (32), 300 (32), 299 (100), 278 (22), 277 (26), 275 (33), 262 (28), 207 (30), 195 (90), 180 (36), 179 (50), 165 (50), 119 (100), 104 (28), 78 (10).

Cyclopentadienyl[1-(4-[2.2]paracyclophanyl)ethylcyclopentadienyl]-zirconium Dichloride (13): The complex was prepared by employing the procedure described for **12** using $CpZrCl_3$ (0.52 g, 2 mmol). The crude product was obtained as a tan-coloured solid (0.66 g, 64%) that was purified by recrystallization from a mixture of dichloromethane and diethyl ether in the freezer (−25 °C) to yield pure **13** as a colourless solid, m.p. 142−145 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 2927 cm^{-1}, 1591, 835, 821, 813. − UV/Vis ($CHCl_3$): λ_{max} (log ε) = 296 nm (3.51), 330 (sh, 3.25), 378 (2.60). − ^1H NMR ($CDCl_3$, 400 MHz): δ = 1.35 (d, *J* = 7.0 Hz, 3 H), 2.72 (m, 1 H), 2.90−3.30

(m, 6 H), 3.49 (m, 1 H), 4.40 (q, J = 7.0 Hz, 1 H), 5.46 (s, 1 H), 6.20 (m, 1 H), 6.28−6.35 (m, 2 H), 6.38 (m, 1 H), 6.45 (m, 2 H), 6.52 (s, 5 H), 6.55 (m, 2 H), 6.69 (m, 1 H), 6.80 (m, 1 H). − ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 22.6 (q), 33.2 (t), 34.9 (t), 35.1 (t), 35.3 (t), 37.6 (d), 103.4 (s), 106.7 (d), 115.5 (d), 115.8 (d), 117.0 (d), 119.0 (d), 129.6 (d), 130.3 (d), 131.4 (d), 132.1 (d), 132.6 (d), 133.1 (d), 135.8 (d), 136.8 (s), 138.4 (d), 139.3 (s), 139.7 (s), 139.8 (s), 145.1 (s). − MS (EI, 70 eV): *m/z* (%) = 530 (5), 529 (5), 528 (10), 527 (6), 526 (16), 525 (10), 524 (12) [molecular ions], 494 (20), 493 (18), 492 (54), 491 (30), 490 (76), 489 (50), 488 (100), 475 (12), 473 (12), 459 (12), 452 (16), 388 (20), 387 (20), 386 (36), 385 (36), 384 (52), 369 (14), 359 (14), 357 (28), 355 (26), 300 (24), 299 (26), 231 (40), 229 (26), 227 (38), 225 (36), 195 (72), 193 (38), 179 (76), 165 (76), 152 (12), 128 (12), 119 (40), 104 (42), 91 (12), 78 (14). − $C_{28}H_{28}ZrCl_2$ (526.7): calcd. C 63.87, H 5.38, Cl 13.35; found C 63.15, H 5.38, Cl 12.13.

X-ray Crystallography: A summary of the crystal data, data collection, and refinement parameters for the crystal structure of **11** is given in Table 3.

Table 3. X-ray structure refinement of **11**

Compound	**11**
Empirical formula	$C_{48}H_{46}Cl_8D_2Zr$
M_r	1001.69
Crystal habit	colourless tablet
Crystal size [mm]	0.35×0.31×0.13
Crystal system	Orthorhombic
Space group	*Pbcn*
Cell constants:	
a [Å]	30.6365(10)
b [Å]	14.0545(5)
c [Å]	20.9986(7)

Structure Determination of 11: A cut tablet was mounted on a glass fibre in inert oil and transferred to the cold gas stream of a Bruker SMART 1000 CCD diffractometer fitted with a Siemens LT-2 low-temperature attachment. Data were collected with ω- and φ-scans using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). An absorption correction was performed using the multi-scan method (program SADABS). All unique data were used for calculations (program SHELXL-97, G. M. Sheldrick, University of Göttingen). The structure was solved by direct methods and refined anisotropically by full-matrix least-squares on F^2. The deuteriochloroform molecule containing C96 is severely disordered. Two alternative positions were refined with occupancies of 0.600(3) for C96/Cl94/Cl95/Cl96 and 0.400(3) for C96′/Cl91/Cl92/Cl93, but the high residual electron density in the solvent region indicates further disorder. The hydrogen atoms were refined with a riding model or as rigid methyl groups.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-171642. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Butyl(η^5-cyclopentadienyl)[η^5:η^1-1-(4-[2.2]paracyclophanyl)ethylcyclopentadienyl]zirconium (15): *n*-Butyllithium (1.1 mL, 1.75 mmol) was added to a suspension of metallocene dichloride complex **13** (0.46 g, 0.88 mmol) in 50 mL of toluene at −78 °C under argon. After warming the reaction mixture to room temp. and stirring it for 11 h, the initially light brown suspension had turned into an orange solution. The reaction mixture was filtered through sodium sulfate. Removal of the solvent yielded a red oil (0.43 g, 96%). − ^{1}H NMR (C_6D_6, 250 MHz): δ = 0.59 (m, 1 H), 0.82 (m, 1 H), 1.05 (t, J = 14.3 Hz, 3 H), 1.12 (d, J = 7.0 Hz, 3 H), 1.39 (m, 2 H), 1.57 (m, 4 H), 2.64 (m, 2 H), 2.92 (m, 4 H), 2.97 (d, J = 7.0 Hz, 1 H), 4.97 (m, 1 H), 5.19 (m, 1 H), 5.68 (s, 5 H), 5.96 (s, 2 H), 6.35 (m, 1 H), 6.36 (m, 1 H), 6.40 (m, 1 H), 6.48 (m, 1 H), 6.83 (m, 2 H). − ^{13}C NMR (C_6D_6, 62.9 MHz): δ = 14.2 (CH_3), 21.7 (CH_3), 30.1 (CH_2), 34.3 (CH_2), 35.3 (CH_2), 35.9 (CH_2), 39.0 (CH_2), 39.6 (CH), 58.5 (CH_2), 101.3 (CH), 105.5 (CH), 110.2 (CH), 113.7 (CH), 117.8 (CH), 128.7 (CH), 130.3 (CH), 132.3 (CH), 133.3 (CH), 133.3 (CH), 133.6 (C_q), 135.5 (CH), 139.6 (C_q), 139.8 (C_q), 143.2 (C_q), 147.3 (C_q), 181.8 (C_q). − MS (EI, 70 eV): *m/z* (%) = 512 (10), 511 [M$^+$] (8), 457 (58), 455 (75), 453 (100), 451 (10), 352 (5), 348 (10), 347 (50), 345 (10), 321 (7), 181 (2), 165 (2), 92 (5), 91 (4).

Activation of the Metallocene Complexes with MAO: The respective metallocene complex, 10−15 mg, was activated with MAO (30% in toluene) (Zr/Al = 1:3000). A portion of the catalyst solution containing 0.5−1.5 mg metallocene complex was used within 1 h for the homo-polymerization of the olefin.

Homo-Polymerization of Ethylene: *n*-Pentane (500 mL) and the catalyst solution were placed in a 1-L Büchi laboratory autoclave. The autoclave was thermostated at 60 °C. An ethylene pressure of 10 bar (99.98% ethylene) was applied after an internal temperature of 50 °C had been reached. The mixture was stirred for 1 h at 60 (±2) °C. The reaction was terminated by releasing the pressure from the reactor. The obtained polymer was dried in vacuo.

Homo-Polymerization of Propylene in Bulk: The catalyst solution was placed in a 1-L Büchi laboratory autoclave followed by the condensation of 500 mL of propylene (polymerization grade). The autoclave was thermostated at 60 °C and the mixture was stirred for 1 h at 60 (±2) °C. The reaction was terminated by releasing the pressure from the reactor.

Keywords: NMR spectroscopy / Solid-state structures / Tin / Chromium / Molecular modeling / X-ray diffraction

The title compound was studied by dynamic NMR spectroscopy in solution and in the solid state, and by MM3 molecular mechanics calculations of model compounds. Barriers to rotation of the trimethyltin group, the tricarbonylchromium group, the triisopropylsilyl group, and the isopropyl groups were all too small to measure by NMR in solution i.e. less than about 5 kcal/mol. All of these barriers could be measured, however, in the solid state, are of different sizes, and are surprisingly large, up to 12.9 kcal/mol. A crystal structure determination shows close intermolecular interactions of these triple rotors that explain these high rotation barriers.

Introduction

Dynamic NMR studies of intramolecular motions in the solid state promise to provide particularly interesting insights when energy barriers found are markedly different from those in solution. Rotational barriers in the solid state are expected to be higher than in solution, since the lattice will usually further hinder any intramolecular process.[1,2] A crystal structure provides direct information on intermolecular interactions that may explain these differences. We now report an investigation of the title compound **1** with a variety of triple rotors.[3] Rotations involve the trimethylstannyl group, the tricarbonylchromium group, and all four bonds to the silicon atom in the *N*-(triisopropylsilyl) (*N*-TIPS) group, so six different bonds in all were investigated. Each rotation has a substantial barrier in the solid state, yet all the corresponding processes in solution were fast on the NMR timescale at all accessible temperatures.

An X-ray diffraction study shows that these groups are strongly hindered by groups in neighbouring molecules, but since barrier sizes are different, the rotations do not appear to be correlated. The parent *N*-(triisopropylsilyl)indole (**2**) was also studied by dynamic NMR in order to assist in elucidating the conformational process in the *N*-TIPS group. Furthermore, MM3 molecular mechanics calculations[4] were carried out on **2** and on 4-(trimethylstannyl)indole (**3**).

Results

Structure

The NMR results are best interpreted in terms of the molecular structure found in the crystal, with some assistance from MM3 calculations for an isolated molecule of the parent *N*-(triisopropylsilyl)indole (**2**), so these structural studies will be reported first. It should be noted that the solution or gas-phase conformations might be different from that of the crystal, particularly for the *N*-TIPS group. The structure of **1** in the crystal is shown in Figure 1 along with two different representations of parts of the unit cell to indicate intermolecular interactions.

The compound is chiral and there are four molecules of each enantiomer in the unit cell. Figure 1 (a and b), show a molecule in the crystal with the (*S*) configuration, based on C(11) as the chiral centre in that diagram, with Sn, Cr, C(6), and C(10) as substituents.[5] Equally, diagrams **1**, and **4**−**7** show the (*S*) configuration, and the discussion below refers to this. As many molecules exist in the (*R*) configuration in the crystal and in solution, with torsion angles of opposite sign,[6] so the discussion could be extended mutatis mutandis to cover them. Greater detail of the crystal structure is given in the Exp. Sect.

The tricarbonylchromium conformation is as in formula **4**. Both the trimethyltin and TIPS groups are in *peri* positions on the indole ring, and have a conformation with two substituents R towards the other *peri* position on either side of the plane and the third substituent close to the plane away from the *peri* interaction, as shown diagrammatically[6] in **5** and **6**. Within the *N*-TIPS group, the isopropyl group conformations can be defined by the N−Si−C−H^n torsion angles, and in the crystal these are (g, $-g$, g) for the groups a−c in the order shown in **6**. Thus reasonably, the two out-of-plane isopropyl groups that flank the *peri* position have their methine proton nearest to that position (see **7**). Molecular mechanics calculations for *N*-(triisopropylsilyl)indole (**2**) located a range of minima, each of which, like **6**, has one Si−*i*Pr bond near to the plane close to the C-2 position of the indole ring. These con-

formational minima, listed in Table 1 along with the experimentally determined conformation for **1**, differ in the rotational arrangement of the three isopropyl groups as defined by the three N−Si−C−H torsion angles.[7−11] The most stable conformation, as shown in diagram **8**, is (*g*, −*g*, *a*) rather than (*g*, −*g*, *g*) (diagram **7**), which is calculated to be 1.19 kcal/mol less stable, but is the conformation found in the crystal. The structural difference between **7** and **8** is quite small, involving little more than 120° of rotation of the isopropyl group nearest to the tricarbonylchromium group. The calculated and measured torsion angles for the conformation **7**, found in the crystal, agree well.

Table 1. MM3 calculations of steric energies of conformations of *N*-(triisopropylsilyl)indole (**2**); conformations are described by the angle α, the torsion angle φ_a made with the indole plane by the isopropyl group, and the H−C−Si−N torsion angles φ_n, quoted in the alphabetical order shown; the experimental values for the (*g*, −*g*, *g*) conformation are included beneath the calculated values for that conformation

[a] Crystal values for compound **1**.

NMR Spectra

In the ^{13}C NMR spectrum of compound **1** in solution at room temperature, a set of signals corresponding to rapid rotation of all groups is seen, and at 133 K the singlets from the trimethyltin and isopropylsilyl groups are essentially unchanged with no sign of incipient dynamic broadening. While the carbonyl carbon signal is so broad as to be undetectable at this low temperature, this appears to be an effect of relaxation rather than a dynamic process. We conclude that all rotations are still fast on the NMR timescale for compound **1** *in solution* at that low temperature, so the associated barriers would be less than about 5 kcal/mol.

Several regions of ^{13}C CPMAS NMR spectra of crystalline compound **1** under various conditions are shown in Figures 2, 3, and 4, and described fully in the Exp. Sect. While the signals of the isopropyl methyl carbon atoms and aromatic carbon atoms are quite sharp at room temperature (line width at half-height $\Delta\nu_{1/2} \approx 50-60$ Hz), the isopropyl methine ($\Delta\nu_{1/2} \approx 90$ Hz), the trimethyltin ($\Delta\nu_{1/2} \approx 120$ Hz), and carbonyl ($\Delta\nu_{1/2} \approx 250$ Hz) signals are very broad. In contrast to the solution behaviour, all of the signals, except those for aromatic carbon atoms, show dynamic behaviour as the temperature is lowered, eventually showing decoalescence over different temperature ranges, suggesting three different conformational processes. We will discuss these in turn.

As the temperature was lowered from ambient, the broad trimethyltin carbon signal in the CPMAS spectrum sharpened and became more intense initially, then broadened in a conventional dynamic sense, and eventually split below about 233 K to give three singlets, see Figure 4 (spectra at 213 K and 173 K). A complete line-shape treatment yields rate constants at a series of temperatures (see Table 2), and a barrier to rotation in the solid state of 11.1 kcal/mol.

The room-temperature singlet due to the isopropyl methine carbon atoms in the CPMAS spectrum of **1** broadened rather more noticeably than the methyl singlet and split below about 273 K into what eventually became three equal signals. That methyl carbon singlet split below about 253 K into six signals, two of which overlapped. The variable-temperature spectra are shown in Figure 4, and chemical shifts are listed in Table 4 in the Exp. Sect. A complete line-shape fit of spectra at several temperatures led to rate constants shown in Table 2 and a barrier to rotation of about 12.9 kcal/mol for conformational interconversion of the TIPS group in the solid state. As the temperature was raised from room temperature, both signals of the isopropyl carbon atoms broadened compared with others in the spectrum.

The broad signal for the carbonyl carbon atoms in the CPMAS spectrum at room temperature disappeared completely at about 253 K as the temperature was lowered, and reappeared as a very broad singlet at about 213 K. This signal increased in intensity and split at about 193 K to appear at 173 K as a 1:1:1 triplet, see Figure 3. A complete line-shape fit of spectra towards the low-temperature limit could not be achieved, suggesting that the broadening e.g. at 193 K was not due to conformational exchange. Thus, with such an exchange, the peak at $\delta \approx 233$ should have been broader than the two peaks at $\delta \approx 240$ at 193 K, but it was not. The appearance as a singlet above room temperature but as a triplet at 173 K nonetheless indicates that rotation of the tricarbonylchromium group had become slow. This together with a consideration of the temperature range suggests the barrier is between 8 and 12 kcal/mol.

Each of these signals we have discussed showed additional changes at temperatures above the conventional dynamic-NMR range involving broadening and more or less disappearance of singlet signals as the temperature was further raised. In two cases and putatively in the third this was followed by a resharpening of the singlet signals at even higher temperatures. These not unprecedented

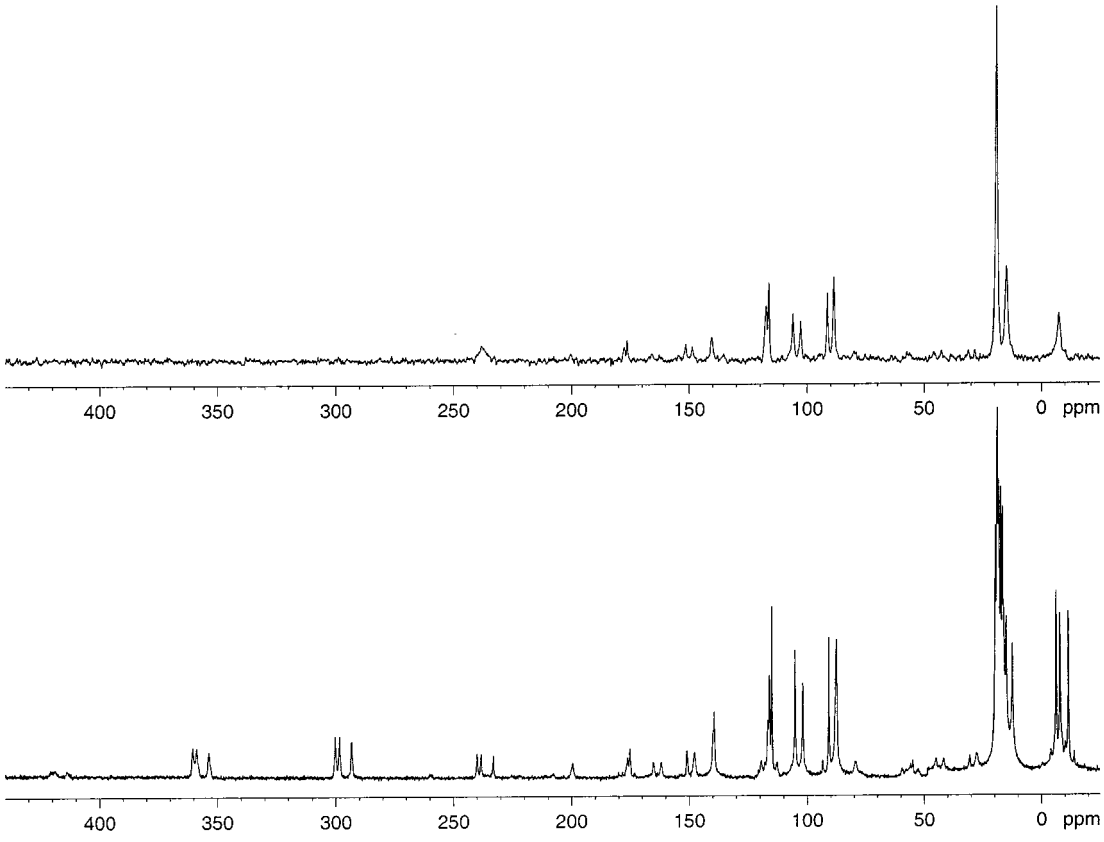

Figure 2. CPMAS ^{13}C NMR spectra of compound **1** at 173 K (bottom) and 297 K (top) − the more intense peaks are between $\delta = -12$ and +22, between $\delta = +85$ and +120, and between $\delta = +232$ and +242; other peaks are side-bands

245 K		600
238 K		400
230 K		120

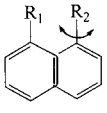
observations[12−14] are a feature of dynamic NMR spectroscopy in the solid state and will be discussed below.

The striking result, therefore, for compound **1** is the NMR observation of three different dynamic processes with barriers up to 12.9 kcal/mol in the solid state. These processes are taking place at a much greater rate in solution, meaning that all barriers must be less than 5 kcal/mol.

Discussion

The barrier of 11.1 kcal/mol for rotation of the trimethyltin group in the solid state is remarkable. Such a symmetrical threefold rotation process of an MR_3 group attached to an aromatic ring should have a low barrier. Thus, the barrier to rotation of a *tert*-butyl group on a benzene-type ring is less (perhaps much less) than 5 kcal/mol, since such barriers have been determined by dynamic NMR in solution only when there was an adjacent *ortho* or *peri* substituent.

Trimethyltin group rotation barriers should certainly be markedly smaller than this, since the four longer Sn−C bonds (211−215 pm) reduce steric hindrance compared with C−C bonds (153−155 pm) in a *tert*-butyl group. There is both experimental and computational evidence confirming that the trimethyltin rotation barriers are very small in the fluid state. Thus, in 1,8-bis(trimethylstannyl)naphthalene (**9**), the barrier is 4.7 kcal/mol,[15] whereas in 1,8-di-*tert*-butylnaphthalene (**10**), the *tert*-butyl group rotational barrier is about 6.5 kcal/mol.[16] The presence of two rotors may of course mean that these are not simple rotation processes.



9 $R_1 = R_2 = SnMe_3$
10 $R_1 = R_2 = CMe_3$
11 $R_1 = H$, $R_2 = CH_2CMe_3$
12 $R_1 = H$, $R_2 = N(i\text{Pr})_2$
13 $R_1 = H$, $R_2 = Si(i\text{Pr})_3$

Table 3 shows molecular mechanics calculations (MM3) of rotational barriers in an isolated molecule in a series of trimethylstannyl- and *tert*-butyl-substituted aromatic compounds. The calculated values for trimethylstannyl group rotation barriers are very much smaller than those for *tert*-butyl groups, and clearly fall well below the range that might be measured by dynamic NMR studies even under the most favourable circumstances.

Table 3. MM3 calculated rotational barriers [kcal/mol] for *tert*-butyl and trimethyltin aromatic compounds

	Rotational barrier X = C	Rotational barrier X = Sn
Me_3X−benzene	0.46	0.03
1-Me_3X−naphthalene	3.67	1.97
4-Me_3X−indole	2.18	1.05

The fact that barriers are threefold, involving 120° of rotation, is one reason for their small size. Interestingly, higher, NMR-accessible rotational barriers have been found for less symmetrical $MR^1R^2R^3$ substituents when the rotation is twofold or even more so, onefold. Thus for 1-substituted naphthalenes, a barrier of 5.3 kcal/mol has been measured for 1-neopentylnaphthalene (**11**) (twofold)[17] and of 15.3 kcal/mol for 1-(diisopropylamino)naphthalene (**12**) (onefold).[18] These various points combine to suggest that the trimethylstannyl group rotation barriers should be very low for **1** in solution. The 11.1 kcal/mol barrier observed for the trimethylstannyl group rotation in **1** in the solid state is thus surprisingly high and is presumably due almost completely to interactions beyond the molecule itself.

There has already been some exploration,[7−11] of the conformational possibilities for three isopropyl or similar groups attached to a tetrahedral atom, including triisopropylsilyl groups.[10,11] The most recent report[11] includes results both in solution and the solid state for compound **13** with a TIPS group attached to the 1-position in naphthalene. All the more stable conformations calculated have the same arrangement about the C(ring)−Si bond analogous to **6**, with one isopropyl group close to the plane of the ring towards the 2-position. This, unsurprisingly, is the same conformation we now report for the N−Si bond of compound **1** both in the crystal and by calculation.

The conformation about the three Si−diisopropyl bonds has to be considered next, since each C−Si−C−H torsion angle in **13** and each N−Si−C−H torsion angle in **1** can be either +*gauche* or −*gauche* or *anti*, see **7** and **8**. The crystal structure of **1** shows the (*g*, −*g*, *g*) conformation, but information beyond this depends on NMR observations and calculations.

The solution NMR of compound **13** is much more interesting than that of compound **1**, since processes become slow on the NMR time scale at low temperatures and two different more or less equally populated conformations interconvert slowly at about 128 K. At even lower temperatures interconversion of isopropyl groups within these conformations became slow, the barriers to these processes being between 5.7 and 6.25 kcal/mol. In contrast, the solution spectra of compound **1** and of *N*-(triisopropyl)indole (**2**) are temperature-independent, so barriers are significantly lower.

In the solid state, NMR shows that compound **13** persists in adopting two conformations that show distinct spectra below about 223 K. Distinct barriers to rotation about the

different C−Si bonds could not be determined from the spectra, but rotation in the lattice has a barrier about 5 kcal/mol greater than in solution.

The ^{13}C NMR results for the TIPS group of compound **1** in the solid state can readily be interpreted in terms of the bond conformations found in the crystal structure. The changes in the isopropyl group signals lead to a barrier of 12.9 kcal/mol, compared with less than 5 kcal/mol in solution, but they cannot be used to distinguish the N−Si and the three C−Si bond rotations.

MM3 calculations suggest (see Table 1), that the (*g*, −*g*, *g*) conformation for **1** has torsion angles gratifyingly similar to those found in the crystal, but that this conformation is about 1.19 kcal/mol less stable than the (*g*, −*g*, *a*) conformation and 0.04 kcal/mol less stable than the (*a*, −*g*, *g*) conformation. This last conformation is too symmetrical to explain the low-temperature NMR spectra, except by invoking an unsymmetrical lattice. The fact that the most stable calculated conformation (*g*, −*g*, *a*) is not the one found in the crystal (*g*, −*g*, *g*), need not reflect shortcomings of the calculations, for it may be evidence of a conformational change induced by crystal lattice forces.

In view of the results in Table 3 for calculated barriers to trimethylstannyl group rotation, it is of interest to know the difference in *N*-TIPS rotation barriers to be expected when the 1-naphthyl group of **13** is replaced by the *N*-indolyl group of **1**. Calculation of TiPSi rotational barriers is complicated, however, as one torsion usually entrains another.[10] We therefore calculated the barrier to a simplified 120° rotation about the *peri* bond for **13** and for *N*-TIPS-indole (**2**) in the conformation with isopropyl groups (*g*, *g*, *g*). This is not a very stable conformation, but the calculation is straightforward since the three *gauche* isopropyl group conformations need not rearrange dramatically during the overall rotation. The barrier to rotation about the *peri* bond in these circumstances is calculated to be 5.6 kcal/mol for **13**, and only 3.2 kcal/mol for the indole **2**. Since the experimental solution barrier in **13** is about 6 kcal/mol this suggests that the barrier for reorientation in the TIPS group of **1** in solution be very much less than 5 kcal/mol. In this light, the 11.9 kcal/mol barrier found for **1** in the solid state is uncommonly high.

There have already been extensive NMR[14,19−22] and other studies[14] of the tricarbonylchromium η^6 complexes of aromatic compounds in the solid state. In crystals of the simple highly symmetrical benzene complex,[19] two distinct processes are taking place: Firstly there is an in-plane rotation of the benzene ligand in 60° jumps, with a barrier of 3.7−4.7 kcal/mol. This was studied using solid-state wideline ^2H wideline NMR techniques.[21] Additionally, there is a dynamic process in which tricarbonylchromium fragments rotate by 120° steps with respect to the crystal lattice (a crystallographic mirror plane bisects the molecule) with a barrier of about 17 kcal/mol.

Even more relevant to our work is what is known from NMR studies of tricarbonylchromium complexes of a set of polymethylbenzenes in the solid state.[14] A range of behaviour has been observed, but there are some general features. At low temperatures the carbonyl carbon signal appears either as a 1:1:1 triplet or a 2:1 doublet indicating that reorientation involving the carbonyl group is slow. On raising the temperature, signals broaden and coalesce, then continue to broaden until they disappear. At temperatures between 20 and 40°C and higher, the broad signal reappears and becomes sharper as the temperature rises.

The carbonyl spectrum of compound **1** in the solid state fits with this pattern, but it is interesting to note that for nine of the ten compounds studied,[14] the changes took place over a higher temperature range than for **1**, implying a higher reorientation barrier. The main difference between **1** and the polymethylbenzenes is that close π-stacking of the aromatic rings is absent in the crystal due to the presence of the bulky trimethylstannyl and TiPSi groups. Lattice effects on rotation in **1** are thus less critical.

Only the pentamethylbenzene complex shows the tricarbonylchromium group rotating with a lower barrier, about 7.5 kcal/mol, but in this case the aromatic ring is not reorienting even at room temperature. The barrier is 17 kcal/mol in benzenetricarbonylchromium,[18] and is even higher in the more symmetrical mesitylene and hexamethylbenzene complexes. Since the barriers reflect intermolecular interactions in different crystal environments, too much time should not be spent on comparisons.

The apparent disappearance of the carbonyl signal over a temperature range above coalescence is most likely associated with the very high chemical shift anisotropy of the CO carbon atoms ($\Delta\sigma \approx 430$ ppm). In the intermediate exchange region (relative to the chemical shift anisotropy), the CO line width $\Delta\nu_{1/2}$ will be of the order of $\Delta\sigma$ (ca. 33 kHz), which means that the spin-spin relaxation time (T_2) will be of the order of 10 μs. This is comparable to the dead-time delay used (15 μs in our experiments), hence complete loss of signal intensity for the CO carbon atoms is observed as a result of T_2 relaxation during the dead-time. For aliphatic carbon atoms, on the other hand, $\Delta\sigma$ is near 0 ppm and corresponding T_2 effects can be safely ignored.

The broadening of the $SnMe_3$ signals in the solid-state NMR spectrum as the temperature is raised from 273 K to room temperature, reaches a maximum breadth at about room temperature (Figure 4). This indicates that the bond rotation frequency at this temperature is comparable to the proton decoupling frequency used, and line broadening results.[12−14] Since the decoupling power used corresponds to a frequency of ca. 50 kHz, we can conclude that the frequency of rotation for the ring−Sn bond is of the same order at 297 K, the temperature of maximum signal broadening, whence the rotational barrier is calculated to be 10.9 kcal/mol at this temperature. This barrier value agrees well with that derived independently from the classical dynamic NMR changes at much lower temperatures shown in Figure 4.

In the same way, the two isopropyl carbon peaks at room temperature begin to broaden as the temperature is raised beyond about 353 K, this being more marked with the methine carbon signal. This is attributed to the onset of the same decoupling frequency effect.

A feature that emerges from the crystal structure of **1** is the interaction of adjacent molecules, and this is of course related to the high rotational barriers reported. The crystal is racemic with eight molecules in the unit cell, four of each enantiomer. Figure 1 (c) shows how three molecules of the same configuration are grouped round a central area with each one of the three molecules turning a different feature towards this centre, either a trimethyltin group, a tricarbonylchromium group, or a triisopropylsilyl group. Figure 1 (d) shows other interactions of adjacent molecules. At the top are two molecules whose contact is through the TIPS groups of each; at the bottom, contact is through a TIPS and a trimethyltin group. These and other views of groups of molecules all indicate that the principal interaction of neighbouring molecules is between TIPS and trimethyltin groups, and it is not surprising that these groups have particularly high rotation barriers in the solid state.

We failed to observe any of these exchange processes for **1** by solution NMR even at 133 K. All six rotation barriers clearly become much lower when derivative **1** passes from the solid to fluid solution state, as reported in a number of other cases.

Experimental Section

The synthesis of complex **1** has been described previously.[3]

High-resolution solid-state ^{13}C NMR spectra were recorded at 75.5 MHz with a Bruker MSL300 spectrometer (7.05 T) using a standard Bruker double-resonance magic angle sample spinning (MAS) probe. The samples were fitted into the cylindrical zirconia rotor (7 mm external diameter) and then spun at MAS frequency in the range 3−7 kHz (with stability better than ca. ±5 Hz). High-resolution solid-state ^{13}C NMR spectra were recorded using cross-polarisation (CP), MAS, and high-power ^{1}H decoupling applied during acquisition. Typical operating conditions for ^{13}C CPMAS experiments were: ^{1}H 90° pulse duration = 5 μs; contact time = 1 ms; recycle delay = 2 s. The stability and accuracy of the temperature controller used (Bruker B-VT1000) were ca. ±1 K. The ^{13}C chemical shifts are given relative to tetramethylsilane (Table 4). Fitting of the dynamic NMR changes in the trimethyltin and isopropylmethine signals with temperature was on the basis of a three-site mutual exchange. Fitting of the isopropylmethyl signal was on the basis of a six-site mutual exchange, which may not be strictly appropriate, but in view of the small chemical shift range of the six signals is likely to yield a reasonable approximation for that signal. Details of the crystal structure determination are shown in Table 5. Crystals were mounted on a thin glass fibre using silicon grease and cooled on the diffractometer to 100 K using an Oxford Cryostream low-temperature attachment. Approximate unit cell dimensions were determined by the Nonius Collect program[23] from 5 index frames of width 2° in using a Nonius Kappa CCD diffractometer, with a detector-to-crystal distance of 30 mm. The Collect program was then used to calculate a data collection strategy to 99.5% completeness for 2θ = 27.5° using a combination of 2° and ω scans of 10 s·deg^{-1} exposure time. Crystals were indexed using the DENZO-SMN package[24] and positional data were refined along with diffractometer constants to give the final unit cell parameters. Integration and scaling (DENZO-SMN, Scalepack[24]) resulted in unique data sets corrected for Lorentz and polarisation effects and for the effects of crystal decay and absorption by a combination of averaging of equivalent reflections and an overall volume and scaling correction. Structures were solved using SHELXS-97[25] and developed by alternating least-squares cycles

Semi-Rigid Bis-Phosphane Ligands for Metallamacrocycle Formation

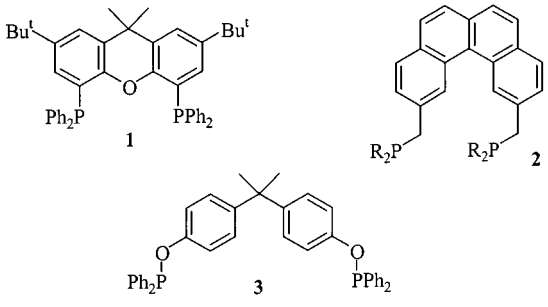
Susan K. Armstrong,*[a] Ronald J. Cross,[b] Louis J. Farrugia,[b] David A. Nichols,[b] and Alexis Perry[b]

Keywords: Phosphanes / Metallacycles / Platinum / Ditopic ligands / X-ray structures

Efficient syntheses are described for the new bridging bis-phosphanes DPPN (**4**) and DPEN (**5**) built around the restricted rigidity of a 2,7-dialkoxynaphthalene backbone. These show marked preference for bridging pairs of metal atoms (Pt^{II}, Mo^0) to form metallamacrocycles or oligomers. Single-crystal X-ray structure determinations of four dimeric complexes with Pt^{II} and Mo^0 are reported. The dimeric platinum complexes can be obtained as the kinetically favoured *trans*,*trans* products, which isomerise to the *cis*,*cis* forms in the presence of free ligand. *cis*,*cis*-$[Pt_2Cl_4(DPEN)_2]$ (**12**) shows marked hydroformylation catalytic activity.

Introduction

Wide bite-angle and bridging phosphane ligands and their metal complexes have recently undergone a marked resurgence of interest. Some bis-phosphanes, like van Leeuwen's "xantphos" **1** (Scheme 1) and related ligands with calculated bite angles around 110−115°, are well suited to *cis* chelation in a trigonal bipyramidal complex.[1,2] The xanthene skeleton imposes a well-defined bite angle on such ligands, which has been linked to the high activity of hydroformylation catalysts derived from them, particularly rhodium and platinum derivatives.[3,4] *trans*-Spanning bis-phosphane ligands and their metal complexes have recently been reviewed.[5] *trans*-Spanning has been reliably achieved by, among others, Venanzi and co-workers, who used the rigid benzo[c]phenanthrene skeleton in ligands **2** (Scheme 1).[6] More flexible long-chain bis-phosphanes occasionally coordinate *trans*, though these are often in equilibria with other geometries[7] unless constrained by other ligands. An alternative strategy has been to synthesise some *trans*-spanning ligands in situ.[8,9] Ditopic bis-phosphanes are designed for coordination to two metal centres, with[10] or without (e.g. Faraone's ligand **3**[11]) metal−metal bonding. A further class of ligands involves monophosphanes on solid supports, whose coordination geometry is subject to different controls.[12,13]



Scheme 1

We were interested to study the complexation behaviour of novel phosphanes, designed to be wide-angle chelators or bridging, and the catalytic activity of their transition metal complexes. For a ligand to be widely used, it must be readily available, with a short and high-yielding synthesis. We report here the efficient syntheses and complexing properties of two new semi-rigid, ditopic bis-phosphane ligands which further explore the relationship between ligand geometry and the structures of their transition metal complexes. The work extends recent reports on the formation of metallamacrocycles using related ligand types.[11]

Results and Discussion

Two new bis-phosphane ligands, 2,7-bis(3-diphenylphosphanylpropoxy)naphthalene (DPPN) **4** and 2,7-bis(2-diphenylphosphanylethoxy)naphthalene (DPEN) **5** (Scheme 2), were designed to allow similar separation be-

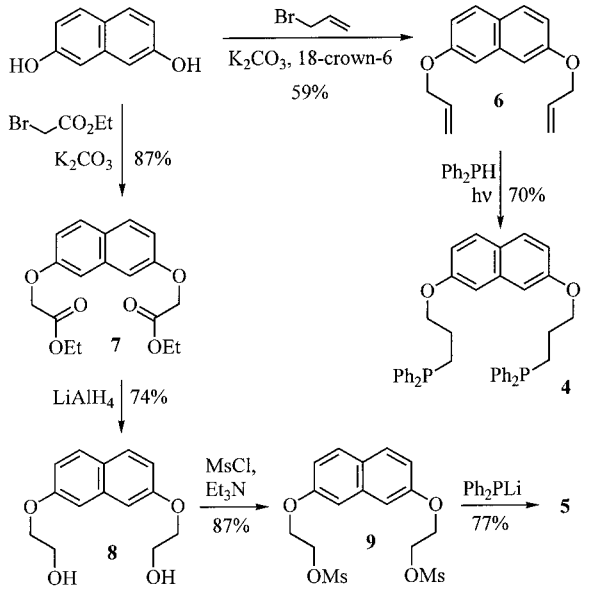
tween the P atoms to that found in the Venanzi ligands of type **2**, but with a more flexible ligand backbone. Bisphosphanes **2** suffer from lengthy and low-yielding synthetic approaches. By contrast, we sought ligands which could be synthesised by short, straightforward routes.

Ligand Synthesis

For the synthesis of DPPN **4** (Scheme 3), 2,7-dihydroxynaphthalene was alkylated with allyl bromide to give bisallyl ether **6** by a modification of the literature procedure. Addition of 18-crown-6 to the reaction mixture, and improved purification methods, enabled us to improve the published yield of 45% crude[14] or 27% pure[15] to a relatively good 59% of recrystallised product. Ultraviolet irradiation of bis-ether **6** and diphenylphosphane in the absence of solvent gave the bis-phosphane DPPN (**4**) in an overall yield for this two-step synthesis of 41%. DPPN is a very viscous colourless oil which oxidises slowly in air (more rapidly in solution). In the synthesis of DPEN (**5**), the same starting material was alkylated with ethyl bromoacetate to give bis-ester **7**, which was reduced to the corresponding diol **8**[16] and then converted into bis-mesylate **9**. Treatment of **9** with lithium diphenylphosphide gave the bis-phosphane DPEN (**5**) in an overall yield of 49%. DPEN is a white, crystalline air-stable solid which oxidises slowly in solution.

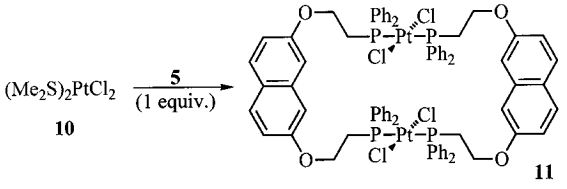


Scheme 3

Platinum(II) Complexes

The formation of square-planar platinum(II) complexes is known to be dependent on a number of factors, both kinetic and thermodynamic, including solvent polarity,[17] the *trans* effect of resident ligands, and the order of adding the reagents.[18,19] In addition, when polydentate ligands are involved, solution concentration exerts an effect, with high dilution favouring monomers whilst higher concentrations can promote dimer or oligomer formation. With suitable magnetic nuclei, the geometry of the products can often be determined from the magnitude of the coupling constants to ^{195}Pt. These are greatly dependent on the *trans* influence of the ligands opposite. For example, a phosphane *trans* to chloride has $^{1}J_{P\text{-}Pt}$ about 3500 Hz whereas a phosphane *trans* to another phosphane has $^{1}J_{P\text{-}Pt}$ near 2500 Hz.[20]

The geometry of the platinum complexes formed from DPEN (**5**) was dependent on the reaction conditions. Addition of up to one equivalent of **5** in dichloromethane to a solution of $[PtCl_2(SMe_2)_2]$ (**10**; *cis*/*trans* mixture) in the same solvent produced a complex mixture of products (Scheme 4). The $^{31}P\{^{1}H\}$ NMR spectrum of this mixture consisted of about ten signals, of varying intensities, with their associated ^{195}Pt satellites. Analysis of the ^{31}P-^{195}Pt coupling constants showed that it contained signals due to both *cis*- and *trans*-coordinated phosphanes. Only one compound, significantly less polar than the rest, could be isolated from the mixture by column chromatography. The $^{31}P\{^{1}H\}$ NMR spectrum of this complex gave $J_{Pt\text{-}P}$ = 2562 Hz indicating *trans* coordination of the ligand. A FAB mass spectrum indicated that the complex was dimeric. Slow diffusion of diethyl ether into a concentrated dichloromethane solution of the complex produced yellow prisms, and a single crystal X-ray analysis (Figure 1) showed the complex to be the metallamacrocycle *trans*,*trans*-$[Pt_2Cl_4(DPEN)_2]$ (**11**). The yield of **11** was only 10%, however, and the remainder of the products in the mixture could not be separated; their behaviour on chromatography and on attempted crystallisation suggested facile interconversion.



Scheme 4

Figure 1 shows that complex **11** forms a centrosymmetric dimer with the DPEN ligand bridging between Pt centres in a mutually *trans*,*trans* arrangement, as expected from the colour and the NMR evidence. The four ligating P and Cl atoms form a slightly distorted square planar arrangement (these four atoms deviate from their least-squares plane by ±0.03 Å). The nearly linear $PtCl_2$ unit is displaced towards the centre of the metallamacrocyclic ring and towards the other centrosymmetrically related Pt atom [Pt(1)···Pt(1)^{ii} = 10.691(1) Å]. The space-filling diagram of **11** (Figure 2) shows the hetero-ring system to have a central hydrophobic cavity of radius ≈5 Å.

When this experiment was repeated using **4**, an intractable mixture of complexes was again produced. The $^{31}P\{^{1}H\}$ NMR spectrum of the crude product again showed a mixture of signals, of varying intensities, with their associated ^{195}Pt satellites. Analysis of the ^{31}P-^{195}Pt coupling constants showed that it contained signals due to both *cis*- and

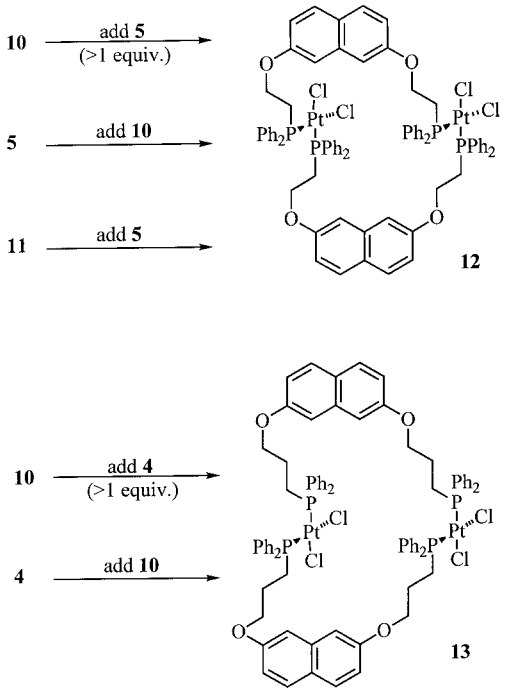
Figure 1. Figure 2. Space-filling plot of compound **11** showing the central cavity of the metallamacrocycle

trans-coordinated phosphanes, but in this case no single complex could be isolated by either chromatography or crystallisation.

Other methods of treating either **4** or **5** with Pt^{II} complex **10** produced a quite different outcome. The major products in almost all cases were the *cis,cis* complexes **12** (of DPEN) and **13** (of DPPN) (Scheme 5). These complexes show $J_{Pt\text{-}P}$ of 3627 Hz and 3646 Hz respectively, indicating exclusively *cis* coordination of the phosphanes. They were shown to be dimeric by FAB-MS, and to be *cis,cis*-dimers by single crystal X-ray analysis (Figures 3 and 4). Complex geometry was independent of precursor concentration over a range of 1.5−39 mmol l^{-1}, and apparently independent of solvent polarity (20% CH_2Cl_2 in toluene gave identical results to chloroform). Use of an excess of the bis-phosphane invariably resulted in formation of *cis,cis* complexes **12** or **13** as the sole or overwhelmingly major product. Similarly on inverse addition, i.e. addition of **10** to the bis-phosphane, the *cis,cis* complexes were the only products visible by ^{31}P NMR spectroscopy. These results led us to conclude that *cis,cis* complexes **12** and **13** were the thermodynamic products, and equilibration to them was catalysed by an excess of the phosphane, either by adding an excess of the ligand, or by having the excess present during the (inverse) addition of the platinum precursor. The mixture formed on "normal" addition of one equivalent of phosphane appeared to be a mixture of kinetic and thermodynamic products, of which the *trans,trans*-dimer **11** was the only one isolated. We tested this hypothesis by treating such mixtures with an excess of the bis-phosphane ligand **4** or **5** and in both cases the *cis,cis* complexes **12** and **13** became the only products observed by ^{31}P NMR spectroscopy.

Figure 3 shows that complex **12** forms a centrosymmetric dimer, this time with the DPEN ligand bridging between Pt centres in a mutually *cis,cis* arrangement. The geometry about the Pt centre shows a slight tetrahedral distortion away from a regular square planar environment. The "twist" angle between the $PtCl_2$ plane and the PtP_2 plane is 12.7°. The Pt−P bonds are shorter and Pt−Cl bonds longer than observed for **11**, consistent with the differing *trans* influences. The $PtCl_2$ groups lie exterior to the metallamacrocycle and the 2,7-dialkoxynaphthalene rings of the DPEN ligands are approximately parallel to each other and nearly in van der Waals contact, as shown in Figure 5. Figure 4 shows that complex **13** forms another centrosymmetric dimer, with the DPPN ligand bridging between Pt centres again in a mutually *cis,cis* arrangement. The geometry about the Pt centre is a more regular square-planar



Scheme 5

environment than found in **12** – the "twist" angle between the $PtCl_2$ plane and the PtP_2 plane is only 3.3°. The Pt−P and Pt−Cl bond lengths are very similar to those observed for **12**. The longer "reach" of the DPPN ligands allows the two $PtCl_2$ groups to lie interior to the metallamacrocycle so that the Cl(1)···Cl(1)^{ii} non-bonded distance is 3.942 Å, about 0.4 Å longer than the sum of van der Waals radii. This is shown in Figure 6.

It was observed by $^{31}P\{^1H\}$ NMR spectroscopy that treatment of a solution of pure *trans,trans*-dimer **11** with a small amount of **5** at room temperature rapidly converted it to the *cis,cis*-dimer **12** in the few minutes taken to obtain a spectrum. At lower temperatures, however, it was possible to observe the isomerisation process (Figure 7). A $^{31}P\{^1H\}$ NMR spectrum (Figure 7, trace a) was obtained from a solution of *trans,trans*-dimer **11** before cooling to 203 K. A few crystals of **5** were then added to the sample tube which was briefly shaken before being immediately frozen in liquid nitrogen and returned to the NMR probe. Over two hours at 203 K (traces b and c), little change was observed to the signal with J = 2530 Hz (δ = 6.4) representing *trans,trans*-dimer **11**, although a few signals for intermediates did appear at δ = 10.7 and δ = 5.7. On warming to 223 K, the signal with J = 2530 Hz rapidly broadened and eventually vanished (trace d). On warming to 243 K, it was replaced by a signal with J = 3624 Hz (δ = 6.1) representing the *cis,cis*-dimer **12**. After 40 minutes at this temperature, the broad signals representing intermediates had disappeared, and the only significant species present were the *cis,cis*-dimer **12** and free phosphane at δ = −24 (trace e). No further change was observed after 19 h at room temperature (trace f). The broadness of the signals (traces b−d) did not allow identification of the intermediate fluxional five-coordinate platinum complexes.

Other Metal Complexes

In view of the interesting metallamacrocycles **11**−**13** formed by DPEN (**5**) and DPPN (**4**) with Pt^{II}, and their isomerisation behaviour, a brief investigation was made of the complexation of these new ligands with a wider range of transition metals. The results were, however, harder to obtain and interpret than with platinum.

Stirring an equimolar mixture of **5** and $[PdCl_2(MeCN)_2]$ overnight in dichloromethane produced a yellow solid, the $^{31}P\{^1H\}$ NMR spectrum of which consisted of several singlets. All attempts to isolate a pure complex from the mixture were unsuccessful, although a FAB mass spectrum suggested that the main species present was again dimeric and corresponded to $[Pd_2Cl_4(DPEN)_2]$. Attempts to prepare rhodium complexes of DPEN were unsuccessful. Reactions with (acetylacetonato)Rh(norbornadiene), (1,5-cyclooctadiene)$_2Rh_2Cl_2$, $[RhCl(CO)(PPh_3)_2]$ and $[RhCl(PPh_3)_3]$ all produced intractable mixtures from which no complexes could be isolated.

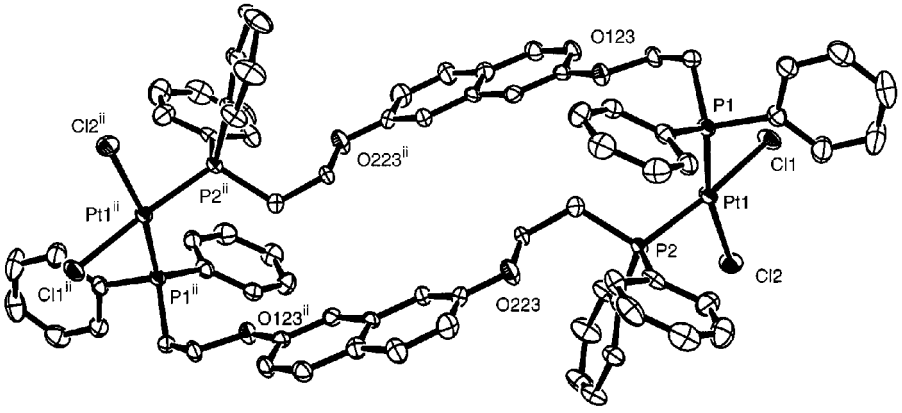


Figure 3. Ortep plot of compound **12** with thermal ellipsoids shown at the 50% probability level; atoms with primed labels are related to unprimed atoms by the symmetry operation (1 − x, 1 − y, −z); selected bond lengths (Å) and angles (°): Pt−Cl(1) 2.3495(19), Pt−Cl(2) 2.3566(18), Pt−P(1) 2.2567(18), Pt−P(2) 2.2479(19), Pt···Pt^{ii} 14.174(1); Cl(1)−Pt−Cl(2) 87.56(7), P(1)−Pt−P(2) 97.54(7)

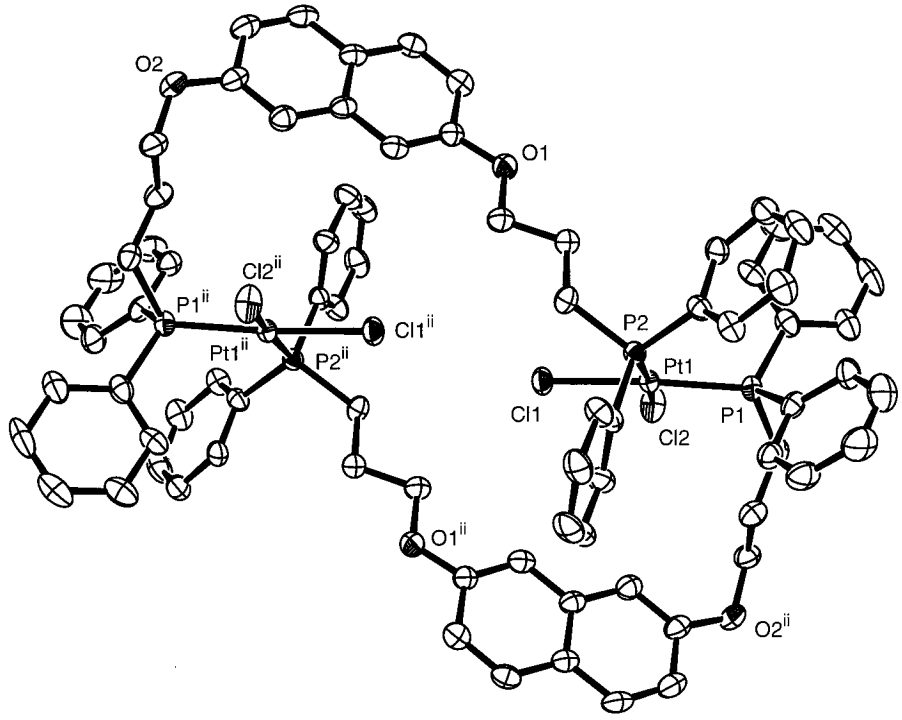

Figure 4. Ortep plot of compound **13** with thermal ellipsoids shown at the 50% probability level; atoms with primed labels are related to unprimed atoms by the symmetry operation ($-x$, $-y$, $1-z$); selected bond lengths (Å) and angles (°): Pt−Cl(1) 2.3500(9), Pt−Cl(2) 2.3467(10), Pt−P(1) 2.2544(9), Pt−P(2) 2.2510(9), Pt···Pt^{ii} 8.369(1); Cl(1)−Pt−Cl(2) 86.20(7), P(1)−Pt−P(2) 98.41(7)

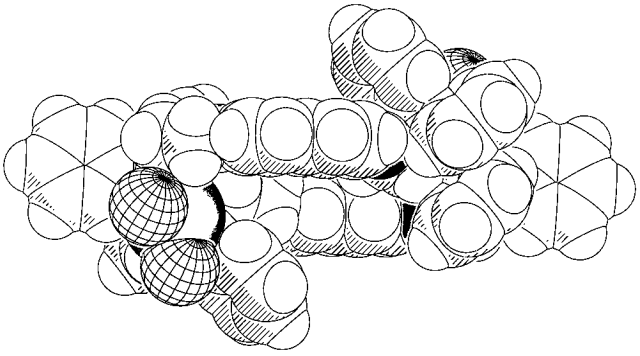

Figure 5. Space-filling plot of compound **12** showing the parallel close packing of the 2,7-dialkoxynaphthalene rings

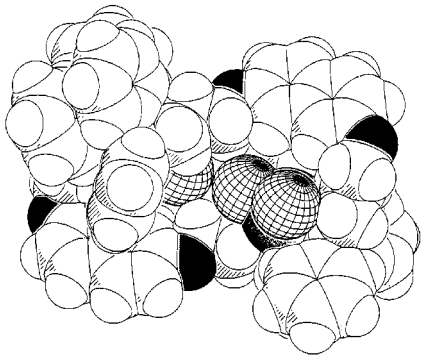

Figure 6. Space-filling plot of compound **13** showing the close Cl···Cl contact

Refluxing a suspension of **5**, molybdenum hexacarbonyl and sodium borohydride in ethanol[21] produced a pale-yellow solid, shown by single crystal X-ray analysis to be the *cis,cis*-dimer $[Mo_2(CO)_8(DPEN)_2]$ (**14**) (Scheme 6 and Figure 8). The DPEN ligand adopts a similar conformation to that observed in **12**. The phosphane ligands coordinate in a *cis* fashion to the Mo centres and the two $Mo(CO)_4$ moieties lie exterior to the metallacyclic ring. The 2,7-dialkoxynaphthalene rings of the DPEN are approximately parallel to each other, as seen in **12**.

Catalytic Application

Recent work by van Leeuwen and co-workers on the catalytic hydroformylation of alkenes has highlighted an important application of phosphanes with wide bite angles.[1] They have reported excellent linear/branched product selectivity in the hydroformylation of terminal alkenes when the wide-angle bis-phosphane "xantphos" (**1**) or the corresponding bis-arsane is used in a Pt/Sn catalyst system. With this in mind, we set out to investigate whether our bridging bis-phosphanes would give similar catalytic activity. We note that the dimeric complex *cis,cis*-$[Pt_2Cl_4(DPEN)_2]$ (**12**) has a P−Pt−P angle (97.5°) in the normal range for a complex having two *cis*-coordinated monophosphane ligands.[22−24] The ditopic ligands in a dimeric complex cannot, however, be expected to behave exactly as independent monodentate phosphanes, nor yet as the two phosphanes of a chelating ligand such as **1**. We applied van Leeuwen's procedure to the hydroformylation of 1-octene with *cis,cis*-$[Pt_2Cl_4(DPEN)_2]$ (**12**) as the catalyst.

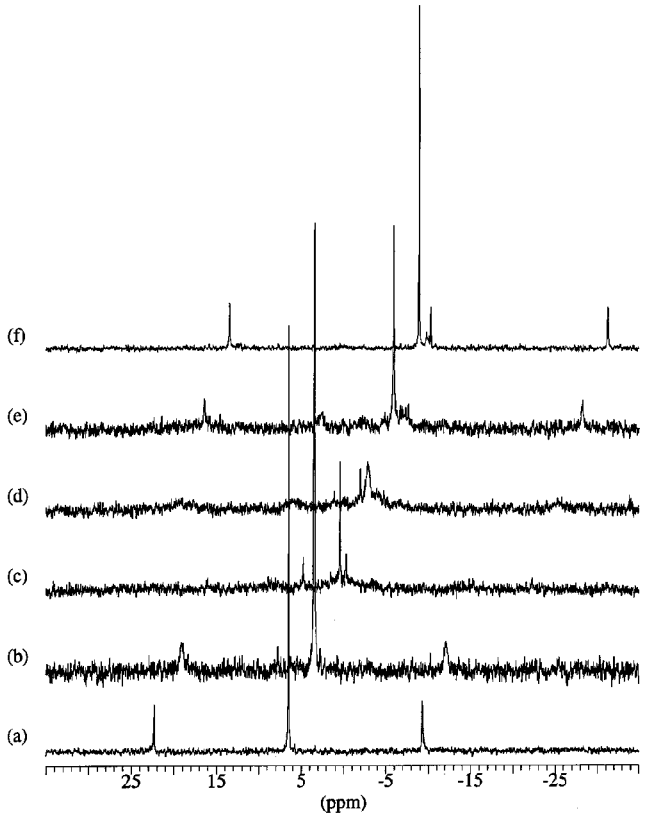

Figure 7. Stacked ^{31}P NMR spectra showing the changing Pt−P coupling constant on warming the mixture of complex **11** and DPEN **5** from 203 K; the spectra have been normalised to take account of the number of scans, but were run unlocked. They are plotted with an increment of 3 ppm between traces, and with traces (a) and (f) plotted at half the vertical intensity of the intervening spectra. Traces: (a) 298 K before commencing experiment; (b) 203 K after 35 min; (c) 203 K after 160 min; (d) 223 K after 210 min; (e) 243 K after 290 min; (f) 298 K after 24 h

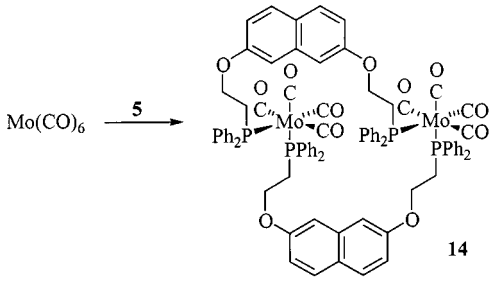
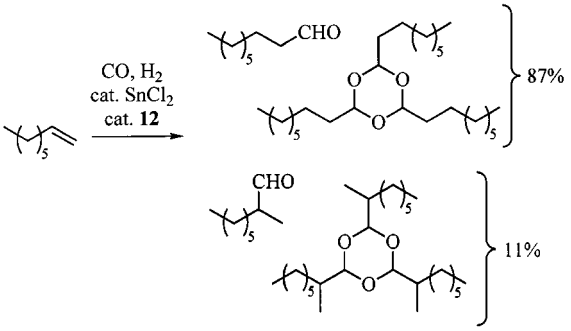
The substrate was heated to 60 °C under an atmosphere of CO (20 bar) and H_2 (20 bar) in the presence of **12** (0.4 mol %) and $SnCl_2$ (0.8 mol %). After 18 hours, GCMS and ^1H NMR analysis of the mixture showed complete conversion of 1-octene to nonanal (87%) and 2-methyloctanal (11%) (both of which tended to trimerise in solution) with 2% of an unidentified by-product (Scheme 7). This activity and selectivity compares reasonably well with previously reported, monomeric, hydroformylation catalysts.



Scheme 6



Scheme 7

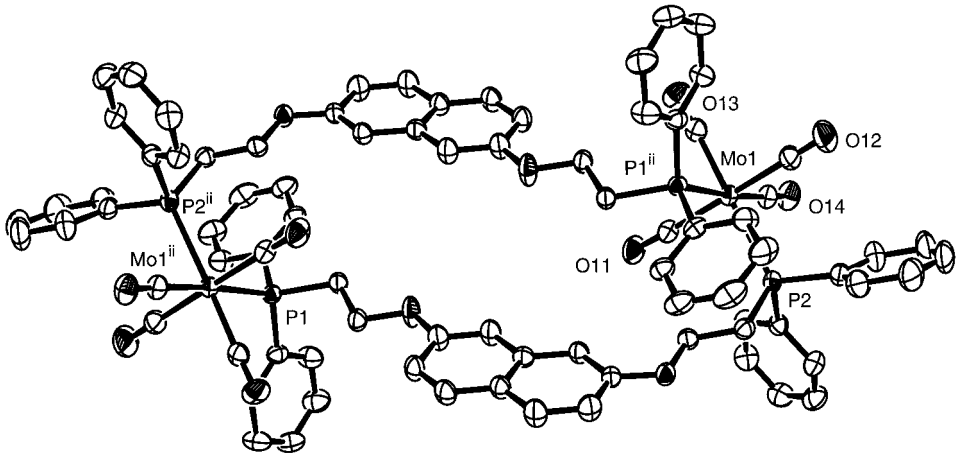


Figure 8. Ortep plot of compound **14** with thermal ellipsoids shown at the 50% probability level; atoms with primed labels are related to unprimed atoms by the symmetry operation (−*x*, −*y*, 1 − *z*); selected bond lengths (Å) and angles (°): Mo−P(1) 2.5434(9), Mo−P(2) 2.5536(9), Mo···Mo^{ii} 13.720(1); P(1)−Mo−P(2) 98.75(3)

Conclusion

Short, straightforward and efficient syntheses of two new bis-phosphane ligands, DPPN (**4**) and DPEN (**5**), have been developed. Both ligands are ditopic: in transition metal complexation, dimeric or oligomeric complexes are greatly favoured. No monomeric complexes have been observed using Pt^{II}, Pd^{II} or Mo^0.

In the case of platinum, although kinetic conditions lead to a mixture of products, employing an excess of ligand to catalyse isomerisation allows clean formation of the 28-membered metallamacrocycle **12** from DPEN (**5**) and the 32-membered metallamacrocycle **13** from DPPN (**4**). These complexes feature *cis* coordination at both square-planar metal centres. The synthesis of a 28-membered molybdenum macrocycle **14** also revealed a preference for *cis* coordination, in this case as part of an octahedral geometry. The very strong preferences of these ligands for forming metallamacrocyclic complexes is interesting, particularly when contrasted with the strong preference for *trans*-chelation shown by Venanzi's related ligands **2**: clearly, formation of monomers with *trans*-coordinated phosphanes is not favoured by ligands of this general shape and size unless rigid steric constraints prevent bridging.

The potential importance of ditopic bis-phosphanes and their macrocyclic transition metal complexes is demonstrated by the activity and linear selectivity of platinum complex **12** as a hydroformylation catalyst.

Experimental Section

General Remarks: All reactions were carried out using oven-dried glassware under a nitrogen atmosphere using standard Schlenk techniques unless stated otherwise. THF and CH_2Cl_2 were freshly distilled from sodium/benzophenone and calcium hydride respectively. Pet. ether refers to petroleum ether boiling between 40 and 60 °C. $PtCl_2(SMe_2)_2$ was prepared by the literature method.[18] Other reagents and starting materials were used as supplied without further purification. Column chromatography was carried out using silica gel (finer than 230 mesh ASTM) and reagent grade solvents which were not purified further before use.

All NMR spectra were obtained from $CDCl_3$ solutions unless stated otherwise. ^1H and ^{13}C NMR spectra were recorded using a Bruker DPX 400 spectrometer operating at 400 and 100 MHz, respectively. ^{31}P NMR spectra were recorded using a Bruker WP 200 SY spectrometer operating at 81 MHz. Chemical shifts (δ) are given in ppm relative to residual $CHCl_3$ (δ = 7.27) for ^1H, $CDCl_3$ (δ = 77.0) for ^{13}C, and 85% H_3PO_4 (δ = 0.0, external) for ^{31}P. Coupling constants (*J*) are given in Hz. Infra-red spectral analysis was performed on a Jasco 410 spectrometer, using KBr discs; absorbances are quoted in wavenumbers (cm^{-1}). Mass spectra were obtained using a JMS 700 spectrometer operating, unless stated otherwise, in FAB mode for coordination complexes, whose isotope patterns matched calculated patterns in all cases,[25] and in EI mode for their organic precursors. GC-MS was carried out using a Hewlett Packard 5890 Series II model GC, with a mass selective detector type 5971.

2,7-Bisallyloxynaphthalene (6): Potassium carbonate (3.80 g, 27.5 mmol) and 18-crown-6 (496 mg, 1.88 mmol) were added to a solution of 2,7-dihydroxynaphthalene (2.00 g, 12.5 mmol) in acetone (30 mL) under air. The mixture was refluxed for 1 h and then allyl bromide (2.7 mL, 31 mmol) was added and the mixture refluxed for a further 15 h. The reaction mixture was allowed to cool, filtered and then concentrated. The crude product was purified by column chromatography (silica, 5% EtOAc/hexane) and recrystallised from hexane to give bis-ether **6** as colourless plates (1.76 g, 59%): m.p. 60−62 °C [ref.[15] 62.5−63 °C (MeOH)]. ^1H NMR: δ = 4.65 (dt, *J* = 5.3, 1.4 Hz, 4 H, CH_2O), 5.33 (dq, *J* = 10.5, 1.4 Hz, 2 H, CH_AH_B=CH), 5.48 (dq, *J* = 17.3, 1.5 Hz, 2 H, CH_AH_B=CH), 6.13 (ddt, *J* = 17.2, 10.5, 5.3 Hz, 2 H, CH_2=C*H*), 7.02−7.05 (m, 4 H, $C_{3,6}$ H, $C_{1,8}$ H), 7.66 (d, *J* = 8.6 Hz, 2 H, $C_{4,5}$ H). ^{13}C NMR: δ = 68.8 (CH_2O), 106.5 (C_3, C_6), 116.4 (C_1, C_8), 117.7 (CH_2=CH), 124.4 (C_{4a}), 129.1 (C_4, C_5), 133.2 (CH_2=*C*H), 135.8 (C_{8a}), 157.1 (C_2, C_7). IR: $\tilde{\nu}$ = 3084 w, 2921 w, 2866 w, 1631 m, 1514 m, 1425 m, 1387 m, 1250 m, 1209 s, 1017 m, 936 m, 823 m. MS: *m*/*z* (%) = 240 (100) [M^+], 212 (13) [M^+ − CO], 199 (24) [M^+ − allyl], 185 (39), 171 (94) [M^+ − allyl − CO], 143 (25), 128 (35), 102 (26).

DPPN (4): Bisallyloxynaphthalene **6** (500 mg, 2.08 mmol) was dissolved in diphenylphosphane (0.90 mL, 5.2 mmol) and the resulting solution was irradiated with ultraviolet light from a medium-pressure mercury lamp for 18 h. The gelatinous mass was then washed with pentane, dissolved in ethyl acetate and concentrated. The crude product was purified by column chromatography (silica, 5% EtOAc/pet. ether) to give DPPN **4** as a very viscous colourless oil (891 mg, 70%). ^1H NMR: δ = 1.99−2.05 (m, 4 H, CH_2CH_2P), 2.27−2.31 (m, 4 H, CH_2P), 4.13 (t, *J* = 6.3 Hz, 4 H, CH_2O), 6.97−7.00 (m, 4 H, $C_{1,8}$ H, $C_{3,6}$ H), 7.32−7.38 (m, 12 H, Ph), 7.44−7.50 (m, 8 H, Ph), 7.64 (d, *J* = 9.6 Hz, 2 H, $C_{4,5}$ H). ^{13}C NMR: δ = 24.5 (d, *J* = 12 Hz, CH_2CH_2P), 25.8 (d, *J* = 17 Hz, CH_2P), 68.2 (d, *J* = 14 Hz, CH_2O), 106.1 (s, C_3, C_6), 116.2 (s, C_1, C_8), 124.2 (s, C_{4a}), 128.4−128.6 (m, Ph *p*-C and Ph *m*-C), 129.0 (s, C_4, C_5), 132.7 (d, *J* = 18 Hz, Ph *o*-C), 135.9 (s, C_{8a}), 138.4 (d, *J* = 13 Hz, Ph *i*-C), 157.4 (s, C_2, C_7). $^{31}P\{^1H\}$ NMR: δ = −16.4 (s, PPh_2). IR (neat): $\tilde{\nu}$ = 3069 m, 2944 m, 1627 s, 1514 s, 1434 s, 1387 s, 1253 m, 1210 s, 1159 m, 1026 m, 832 m, 751 s, 699 s. MS: *m*/*z* (%) = 612 (11) [M^+], 582 (13) [M^+ − CH_2O], 496 (64) [M^+ − $C_6H_{12}O_2$], 227 (29) [$Ph_2P(CH_2)_3^+$], 199 (100) [$CH_2PPh_2^+$], 183 (50). HRMS: calculated for $C_{40}H_{38}O_2P_2$: 612.2347; found 612.2347.

2,7-Bis(ethoxycarbonylmethoxy)naphthalene (7): Potassium carbonate (34.5 g, 250 mmol) and ethyl bromoacetate (6.1 mL, 55 mmol) were added to a solution of 2,7-dihydroxynaphthalene (4.00 g, 25.0 mmol) in acetone (100 mL) under air and the mixture was refluxed for 21 h. The reaction mixture was allowed to cool, filtered and then concentrated to give diester **7** (7.19 g, 87%). A portion was recrystallised from ethanol to give diester **7** as a white microcrystalline solid: m.p. 124−125 °C [ref.[26] 126 °C (EtOH)]. ^1H NMR: δ = 1.31 (t, *J* = 7.1 Hz, 6 H, CH_3CH_2O), 4.30 (q, *J* = 7.1 Hz, 4 H, CH_3CH_2O), 4.72 (s, 4 H, CH_2C=O), 6.98 (d, *J* = 2.5 Hz, 2 H, $C_{1,8}$ H), 7.10 (dd, *J* = 8.9, 2.5 Hz, 2 H, $C_{3,6}$ H), 7.69 (d, *J* = 8.9 Hz, 2 H, $C_{4,5}$ H). ^{13}C NMR: δ = 14.1 (CH_3CH_2O), 61.4 (CH_3CH_2O), 65.4 (CH_2C=O), 106.7 (C_3, C_6), 116.4 (C_1, C_8), 125.2 (C_{4a}), 129.4 (C_4, C_5), 135.3 (C_{8a}), 156.5 (C_2, C_7), 168.8 (C=O). IR: $\tilde{\nu}$ = 2993 w, 2916 w, 1760 s, 1629 m, 1203 s, 1076 m, 847 w, 834 w. MS: *m*/*z* (%) = 332 (100) [M^+].

2,7-Bis(2′-hydroxyethoxy)naphthalene (8): A solution of lithium aluminium hydride (0.85 g, 22 mmol) in THF (50 mL) was cooled to 0 °C and a solution of diester **7** (6.84 g, 20.6 mmol) in THF (85 mL) was added. The resulting mixture was stirred for 60 min and then allowed to warm to room temperature and stirred overnight. Further portions of $LiAlH_4$ (1.3 g in total) were added until

the reaction had gone to completion as indicated by TLC. The reaction mixture was quenched with EtOAc and then satd. aq. potassium sodium tartrate solution was added. The mixture was filtered, extracted with EtOAc, dried (Na_2SO_4) and concentrated to give diol **8** (3.79 g, 74%). A portion was recrystallised from methanol to give diol **8** as a white microcrystalline solid: m.p. 151−152 °C [ref.[16] 152−153 °C]. ^{1}H NMR: δ = 2.04 (t, *J* = 6.1 Hz, 2 H, OH), 4.03 (td, *J* = 4.2, 5.3 Hz, 4 H, C*H*$_2$OH), 4.20 (t, *J* = 4.5 Hz, 4 H, C*H*$_2$CH$_2$OH), 7.03 (dd, *J* = 8.8, 2.5 Hz, 2 H, $C_{3,6}$ H), 7.07 (d, *J* = 2.4 Hz, 2 H, $C_{1,8}$ H), 7.68 (d, *J* = 8.9 Hz, 2 H, $C_{4,5}$ H). ^{13}C NMR: δ = 61.5 (CH_2OH), 69.2 (*C*H$_2$CH$_2$OH), 106.3 (C_3, C_6), 116.3 (C_1, C_8), 125.2 (C_{4a}), 129.3 (C_4, C_5), 135.4 (C_{8a}), 157.2 (C_2, C_7). IR: ṽ = 3334 br, 2931 w, 2882 w, 1631 s, 1387 m, 1213 s, 1081 m, 838 m. MS: *m*/*z* (%) = 248 (77) [M$^+$], 204 (35), 160 (100).

2,7-Bis(2′-hydroxyethoxy)naphthalene bis(methanesulfonate)ester (9): Methanesulfonyl chloride (1.6 mL, 21 mmol) and triethylamine (2.9 mL, 21 mmol) were added to a solution of diol **8** (2.17 g, 8.75 mmol) in THF (100 mL) and the mixture was stirred for 30 min at room temperature. The reaction mixture was then filtered and the solvent removed. The residue was dissolved in EtOAc, washed with water, dried (Na_2SO_4) and concentrated. The crude product was recrystallised from dichloromethane and methanol to give dimesylate **9** as colourless plates (3.09 g, 87%): m.p. 134−135 °C. ^{1}H NMR: δ = 3.12 (s, 6 H, CH_3S), 4.36−4.38 (m, 4 H, C*H*$_2$CH$_2$OS), 4.64−4.66 (m, 4 H, CH_2OS), 7.01−7.05 (m, 4 H, $C_{3,6}$ H, $C_{1,8}$ H), 7.70 (d, *J* = 8.7 Hz, 2 H, $C_{4,5}$ H). ^{13}C NMR: δ = 37.8 (CH_3SO_2), 65.8 (CH_2), 67.9 (CH_2), 106.5 (C_3, C_6), 116.3 (C_1, C_8), 125.0 (C_{4a}), 129.5 (C_4, C_5), 135.5 (C_{8a}), 156.7 (C_2, C_7). IR: ṽ = 3025 w, 2941 w, 1629 s, 1517 m, 1353 s, 1256 m, 1216 s, 1171 s, 1069 m, 1024 m, 981 s, 930 s, 822 s. MS: *m*/*z* (%) = 404 (57) [M$^+$], 123 (100) [$C_2H_4OMs^+$], 79 (28) [$SO_2CH_3^+$]. $C_{16}H_{20}O_8S_2$ (404.45): calcd. C 47.51, H 4.98; found C 47.49, H 4.88.

DPEN (5): *n*-Butyllithium (2.5 M solution in hexanes, 2.3 mL, 5.75 mmol) was added to a solution of diphenylphosphane (1.0 mL, 5.75 mmol) in THF (6 mL). After stirring at room temperature for 15 minutes, a solution of dimesylate **9** (1.04 g, 2.57 mmol) in THF (60 mL) was added and the mixture stirred overnight. The solvent was removed and the residue dissolved in dichloromethane, washed with water, dried ($MgSO_4$) and concentrated. The crude product was recrystallised from ethyl acetate and pet. ether and washed with pentane to give DPEN (**5**) as white needles (1.15 g, 77%): m.p. 137−138 °C. ^{1}H NMR: δ = 2.65 (t, *J* = 7.7 Hz, 4 H, CH_2P), 4.22 (q, *J* = 7.5 Hz, 4 H, CH_2O), 6.80 (d, *J* = 2.2 Hz, 2 H, $C_{1,8}$ H), 6.90 (dd, *J* = 8.9, 2.3 Hz, 2 H, $C_{3,6}$ H), 7.35−7.42 (m, 12 H, Ph), 7.51−7.55 (m, 8 H, Ph), 7.60 (d, *J* = 8.9 Hz, 2 H, $C_{4,5}$ H). ^{13}C NMR: δ = 28.3 (d, *J* = 13 Hz, CH_2P), 65.2 (d, *J* = 27 Hz, CH_2O), 106.0 (s, C_3, C_6), 116.3 (s, C_1, C_8), 124.3 (s, C_{4a}), 128.6 (d, *J* = 7 Hz, Ph *m*-C), 128.8 (s, Ph *p*-C), 129.0 (s, C_4, C_5), 132.7 (d, *J* = 19 Hz, Ph *o*-C), 135.7 (s, C_{8a}), 137.9 (d, *J* = 12 Hz, Ph *i*-C), 156.9 (s, C_2, C_7). ^{31}P{^{1}H} NMR: δ = −22.8 (s, PPh_2). IR: ṽ = 3066 w, 2914 w, 1630 s, 1514 m, 1433 s, 1211 s, 1168 m, 1018 m, 834 m, 741 s, 697 s. MS: *m*/*z* (%) = 584 (4) [M$^+$], 553 (5) [M$^+$ − CH_3O], 371 (23) [M$^+$ − $C_2H_4PPh_2$], 341 (42) [M$^+$ − $C_2H_4PPh_2$], 328 (21), 212 (83) [$C_2H_3PPh_2^+$], 183 (100) [$C_{13}H_{11}O^+$]. HRMS: calculated for $C_{38}H_{34}O_2P_2$: 584.2034; found 584.2037.

***trans,trans*-[Pt$_2$Cl$_4$(DPEN)$_2$] (11):** A solution of DPEN (**5**; 250 mg, 0.43 mmol) in dichloromethane (8 mL) was added dropwise over 5 minutes to a solution of [$PtCl_2(SMe_2)_2$] (**10**; 167 mg, 0.43 mmol) in dichloromethane (5 mL). The mixture was stirred at room temperature for 5 min and then the solvent was removed. Column chromatography (silica, CH_2Cl_2) of the crude product mixture gave **11** as a yellow solid (37 mg, 10%). Slow diffusion of Et_2O into a CH_2Cl_2 solution of **11** produced yellow prisms suitable for X-ray analysis. ^{1}H NMR: δ = 3.08−3.15 (m, 8 H, CH_2P), 4.00−4.05 (m, 8 H, CH_2O), 6.70 (d, *J* = 2.3 Hz, 4 H, $C_{1,8}$ H), 6.85 (dd, *J* = 8.8, 2.4 Hz, 4 H, $C_{3,6}$ H), 7.42 (t, *J* = 7.6 Hz, 16 H, Ph *o*-H), 7.50 (t, *J* = 7.4 Hz, 8 H, Ph *p*-H), 7.54 (d, *J* = 8.9 Hz, 4 H, $C_{4,5}$ H), 7.81 (dt, *J* = 7.0, 5.6 Hz, 16 H, Ph *m*-H). ^{13}C NMR: δ = 28.9 (CH_2P), 62.4 (t, *J* = 4 Hz, CH_2O), 105.0 ($C_{3,6}$), 115.8 ($C_{1,8}$), 123.6 (C_{4a}), 127.6 (t, *J* = 5 Hz, Ph *m*-C), 128.3 ($C_{4,5}$) 128.8 (Ph *ipso*-C), 130.1 (Ph *p*-C), 133.0 (t, *J* = 6 Hz, Ph *o*-C), 134.9 (C_{8a}), 156.1 ($C_{2,7}$). ^{31}P{^{1}H} NMR: δ = 9.00 (*J* = 2563 Hz). IR: ṽ = 3053 w, 2919 w, 1631 s, 1513 m, 1435 s, 1253 m, 1209 s, 1158 m, 1101 m, 740 m, 691 s. MS: *m*/*z* (%) = 1701 (1.8) [$Pt_2Cl_4(DPEN)_2^+$], 1665 (1.3) [M$^+$ − Cl], 1628 (0.8) [M$^+$ − 2Cl]. HRMS: calculated for $C_{76}H_{69}Cl_4O_4P_4Pt_2$: 1701.2200; found 1701.2217.

***cis,cis*-[Pt$_2$Cl$_4$(DPEN)$_2$] (12). By Addition of an Excess of Phosphane:** A solution of DPEN (**5**; 150 mg, 0.26 mmol) in dichloromethane (8 mL) was added dropwise to a solution of [$PtCl_2(SMe_2)_2$] (**10**; 67 mg, 0.17 mmol) in toluene (90 mL) and dichloromethane (15 mL) and the mixture was stirred for 18 h at room temperature. The white precipitate formed was collected by filtration to obtain *cis,cis*-[$Pt_2Cl_4(DPEN)_2$] (**12**; 104 mg, 72%). Recrystallisation from a concentrated chloroform solution of **12** gave colourless prisms. ^{1}H NMR: δ = 2.88−2.94 (m, 8 H, CH_2P), 4.56 (quintet, *J* = 6.4 Hz, 8 H, CH_2O), 6.76 (d, *J* = 2.2 Hz, 4 H, $C_{1,8}$ H), 6.83 (dd, *J* = 8.8, 2.3 Hz, 4 H, $C_{3,6}$ H), 7.22 (br t, *J* = 6.9 Hz, 16 H, Ph *o*-H), 7.37 (t, *J* = 7.3 Hz, 8 H, Ph *p*-H), 7.48 (d, *J* = 8.9 Hz, 4 H, $C_{4,5}$ H), 7.57, (dd, *J* = 8.1, 10.7 Hz, 16 H, Ph *m*-H). ^{13}C NMR: δ = 30.3 (5-line m,[27] J_{P-C} = 22 Hz, CH_2P), 64.8 (CH_2O), 107.2 ($C_{3,6}$), 116.3 ($C_{1,8}$), 124.9 (C_{4a}), 128.8 (t, *J* = 5 Hz, Ph *m*-C), 129.4 ($C_{4,5}$), 130.1 (4 line m,[27] J_{P-C} = 32 Hz, Ph *i*-C), 131.5 (br. s, *p*-C), 133.7 (t, *J* = 5 Hz, *o*-C), 135.9 (C_{8a}), 156.6 (C_2). ^{31}P{^{1}H} NMR: δ = 6.49 (PPh_2, J_{Pt-P} = 3627 Hz). IR: ṽ = 1631 s, 1436 m, 1209 m, 694 m. MS: *m*/*z* (%) = 1701 (2.5) [$Pt_2Cl_4(DPEN)_2^+$], 1665 (13) [M$^+$ − Cl], 1629 (2) [M$^+$ − 2Cl]. HRMS: calculated for $C_{76}H_{68}Cl_3O_4P_4Pt_2$: 1665.2433; found 1665.2432. $C_{76}H_{68}Cl_4O_4P_4Pt_2$ (1701.3): calcd. C 53.7, H 4.03; found C 52.9, H 3.97.

***cis,cis*-[Pt$_2$Cl$_4$(DPEN)$_2$] (12). By Inverse Addition:** A solution of [$PtCl_2(SMe_2)_2$] (**10**; 167 mg, 0.43 mmol) in dichloromethane (5 mL) was added dropwise over 5 minutes to a stirred solution of DPEN (**5**; 250 mg, 0.43 mmol) in dichloromethane (8 mL). After 7 minutes, the solvent was removed to give a white solid (414 mg) consisting largely of *cis,cis*-[$Pt_2Cl_4(DPEN)_2$] (**12**; identified by ^{1}H and ^{31}P NMR spectroscopy and by MS) together with small quantities of higher oligomers.

***cis,cis*-[Pt$_2$Cl$_4$(DPPN)$_2$] (13):** A solution of [$PtCl_2(SMe_2)_2$] (**10**; 128 mg, 0.33 mmol) in dichloromethane (4 mL) was added dropwise over 5 minutes to a solution of DPPN (**4**; 200 mg, 0.33 mmol) in dichloromethane (4.5 mL). After 7 minutes the solvent was removed to give *cis,cis*-[$Pt_2Cl_4(DPPN)_2$] (**13**) as a white solid (281 mg, 97%) which contained small quantities of a closely similar compound, presumed from NMR and MS evidence to be a *cis,cis,cis*-trimer. Recrystallisation from dichloromethane produced **13** as colourless prisms suitable for X-ray analysis. ^{1}H NMR (CD_2Cl_2): δ = 2.20−2.30 (m, 8 H, C*H*$_2$CH$_2$P), 2.45−2.55 (m, 8 H, CH_2P), 4.15 (t, *J* = 6.1 Hz, 8 H, CH_2O), 6.91 (dd, *J* = 2.4, 8.8 Hz, 4 H, $C_{3,6}$ H), 7.10−7.14 (m, 16 H, Hs *meta* to P), 7.21 (s, 4 H, $C_{1,8}$-H), 7.29 (t, *J* = 7.0 Hz, 8 H, Hs *para* to P), 7.41 (dd, *J* = 8.2, 10.0 Hz, 16 H, Hs *ortho* to P), 7.62 (d, *J* = 8.9 Hz, 4 H, $C_{4,5}$ H). ^{31}P{^{1}H} NMR: δ = 7.18 (*J* = 3646 Hz). MS: *m*/*z* (%) = 1757 (1.3) [$Pt_2Cl_4(DPPN)_2^+$], 1721 (9.5) [$Pt_2Cl_3(DPPN)_2^+$], 1685 (2.5) [$Pt_2Cl_2(DPPN)_2^+$].

NMR Study of the Isomerisation of *trans,trans*-[$Pt_2Cl_4(DPEN)_2$] (11) to *cis,cis*-[$Pt_2Cl_4(DPEN)_2$] (12): A solution of *trans,trans*-[$Pt_2Cl_4(DPEN)_2$] (**11**; approx. 10 mg) in $CDCl_3/CH_2Cl_2$ was placed in an NMR tube and cooled to 203 K within the NMR machine. A ^{31}P NMR spectrum was taken. A microspatula was then used to add the minimum quantity of DPEN (**5**; approx. 0.5 mg) to the sample, which was briefly shaken then immediately frozen in liquid nitrogen and returned to the NMR machine. The sample was warmed to 298 K over 27 hours, during which time the sample was converted into *cis,cis*-[$Pt_2Cl_4(DPEN)_2$] (**12**). $^{31}P\{^1H\}$ NMR: initial: $\delta = 6.94$ ($J = 2530$ Hz); final: $\delta = 6.12$ ($J = 3624$ Hz). See Figure 7 for details.

[$Mo_2(CO)_8(DPEN)_2$] (14): $Mo(CO)_6$ (50 mg, 0.19 mmol) and $NaBH_4$ (13 mg, 0.35 mmol) were added to a suspension of DPEN (**5**; 100 mg, 0.17 mmol) in ethanol (5 mL). The mixture was refluxed for 15 h then allowed to cool to room temperature, by which time the initial white precipitate had become yellow. Water (10 mL) was added, the mixture filtered and the product washed from the resulting solid with dichloromethane. The solvent was then removed to give a pale-yellow solid (71 mg). Colourless prisms of complex **14** grown from a CH_2Cl_2 solution were suitable for X-ray analysis. ^1H NMR: $\delta = 2.50-2.55$ (m, 8 H, CH_2P), 4.08−4.13 (m, 8 H, CH_2O), 6.85−6.95 (m, 8 H, $C_{3,6}$ H and $C_{1,8}$ H) 7.27−7.45 (m, 40 H, PPh_2), 7.62 (d, $J = 9$ Hz, 4 H, $C_{4,5}$ H). $^{31}P\{^1H\}$ NMR: $\delta = 19.39$. MS: *m/z* (%) = 1586 (0.28) [$Mo_2(CO)_8(DPEN)_2^+$], 1530 (0.18) [$Mo_2(CO)_6(DPEN)_2^+$], 1474 (0.21) [$Mo_2(CO)_4(DPEN)_2^+$], 1446 (0.23) [$Mo_2(CO)_3(DPEN)_2^+$], 1411 (0.57).

Hydroformylation of 1-Octene using *cis,cis*-[$Pt_2Cl_4(DPEN)_2$] (12): A solution of *cis,cis*-[$Pt_2Cl_4(DPEN)_2$] (**12**; 54 mg, 0.03 mmol), $SnCl_2$ (12 mg, 0.06 mmol) and 1-octene (1.38 mL, 8.1 mmol) in dichloromethane (25 mL) in a reaction vessel was placed in a stainless steel autoclave. The reaction mixture was placed under 20 bar of CO and 20 bar of H_2 at 60 °C for 18 h. GCMS showed 100% conversion of 1-octene; this was confirmed by ^1H NMR spectoscopy. GC: t_R = 7.07 minutes (11.1%, 2-methyloctanal), 8.73 minutes (87.3%, nonanal), 50.11 minutes (1.6%, unidentified). Due to aldehyde trimerisation the ^1H NMR spectrum showed two sets of signals associated with nonanal, and two associated with 2-methyloctanal. Nonanal monomeric form: ^1H NMR: $\delta = 0.89$ (m, 3 H, CH_3), 1.29 [m, 12 H, $CH_3(CH_2)_6$], 2.43 (td, $J = 1.8$, 7.3 Hz, 2 H, CH_2CHO), 9.67 (s, 1 H, CHO). Nonanal cyclic trimer form: ^1H NMR: $\delta = 0.89$ (m, 9 H, 3 × CH_3), 1.29 [m, 36 H, $CH_3(CH_2)_6$], 1.57 (m, 6 H, 3 × $OCHCH_2$), 4.84 (t, $J = 5.3$ Hz, 3 H, 3 × OCH). 2-Methyloctanal monomeric form: ^1H NMR: $\delta = 0.89$ (m, 3 H, CH_3CH_2), 1.01 (d, $J = 7.0$ Hz, 3 H, CH_3CH), 1.29 [m, 10 H, $CH_3(CH_2)_5$], 2.25 (m, 1 H, $CHCH_3$), 9.51 (d, 1 H, CHO). 2-Methyloctanal cyclic trimer form: ^1H NMR: $\delta = 0.86$ (m, 9 H, 3 × CH_3CH_2), 0.89 (d, J =

Crystallographic Structure Determinations: Details of data collection procedures and structure refinements are given in Table 1. Single crystals of suitable size were attached to glass fibres using acrylic resin, and mounted on a goniometer head in a general position. All samples suffered solvent loss, this being particularly severe for compounds **12** and **13**, which required that these crystals were glued to the glass fibre under solvent and transferred as rapidly as possible to the cold stream of the Oxford Instruments Cryostream. For compounds **12**, **13** and **14**, low temperature data were collected on a Bruker-Nonius KappaCCD diffractometer, running under the Collect software, while data for compound **11** were collected on a Enraf−Nonius Turbo-CAD4 diffractometer at ambient temperature. Graphite monochromated X-radiation (λ = 0.71073 Å) was used for all studies. Precise unit cell dimensions for the CAD4 dataset were determined from 25 high-angle reflections which were flagged during data collection. Precise unit cell dimensions for the KappaCCD data-sets were determined by post-refinement using the Scalepack[28] program. Frame images were integrated using Denzo-SMN[28] and the resultant raw intensity files processed using a locally modified version of DENZOX[29] and then sorted and merged using SORTAV.[30] Empirical absorption corrections by the method of Blessing[31] for compounds **12**, **13** and **14** and Stuart and Walker[32] for **11** were applied to the data. No significant crystal decay was noted for any sample. The structures were solved by DIRDIF-99,[33] SIR-92[34] or SHELXS-97.[35] All non-H atoms were allowed anisotropic thermal motion. Aliphatic and aromatic C−H hydrogen atoms were included at calculated positions, with C−H = 0.96 Å, and were refined with a riding model and with U_{iso} set to 1.2 times that of the attached C atom. Refinement was with SHELXL97−2[35] using full-matrix least-squares on F^2 and all the unique data. All samples showed the presence of disordered solvent molecules, and the SQUEEZE procedure of Spek and van der Sluis[36] was used to model this extra electron density where appropriate. For compound **11** an extra 47 e/cell were indicated, this being potentially due to CH_2Cl_2, H_2O or Et_2O. For compound **12** three independent ordered molecules of $CHCl_3$ per asymmetric unit were found, and only a small residual solvent accessible void totalling ≈40 Å^3 was left. The SQUEEZE was not considered necessary in this case. For compound **13**, two ordered and one disordered CH_2Cl_2 molecules per asymmetric unit were found, along with indications of a further 1/2 molecule. An extra 83 e/cell were recovered by the SQUEEZE procedure, consistent with a 1/2 molecule of CH_2Cl_2. This was thus included in the cell contents. For compound **14** two ordered molecules of CH_2Cl_2 were observed as well as large voids containing further disordered solvent. The SQUEEZE procedure recovered 38 e/cell, consistent with a further 1/2 molecule of CH_2Cl_2. Neutral atom scattering factors, coefficients of anomalous dispersion and absorption coefficients were obtained from reference.[37] Thermal ellipsoid plots were obtained using the program ORTEP-3 for Windows.[38] All calculations were carried out using the WinGX package[39] of crystallographic programs.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-165290 (**11**), CCDC-165291 (**12**), CCDC-165292 (**13**) and CCDC-165293 (**14**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to Mr James Gall for assistance with NMR spectroscopy, to Dr David Rycroft for assistance with Figure 7, and to Glasgow University Chemistry Department for financial support of this work. We thank EPSRC for a grant (GR/M91433) towards the purchase of a Kappa CCD diffractometer.

The Insertion of Heterocumulenes into Zn−H and Zn−OH Bonds of Pyrazolylborate−Zinc Complexes

Michael Rombach,[a] Horst Brombacher,[a] and Heinrich Vahrenkamp*[a]

Dedicated to Professor Ernst Anders on the occasion of his 60th birthday

Keywords: Zinc / Pyrazolylborate ligands / Heterocumulenes / Insertion / Hydroxide ligands / Enzyme models

The pyrazolylborate–zinc complexes $Tp^{Ph,Me}$Zn–H and $Tp^{Ph,Me}$Zn–OH undergo insertion reactions with heterocumulenes. CO_2, CS_2 and RNCS insert into the Zn–H function to yield the corresponding Zn–OCH(O), Zn–SCH(S) and Zn–SCH(NR) complexes. The primary products resulting from the insertion of CS_2, COS and RNCS into the Zn–OH function undergo rearrangements and subsequent reactions. $Tp^{Ph,Me}$Zn–OH and CS_2 or COS yield $Tp^{Ph,Me}$Zn–SH and COS or CO_2, whereas with RNCS the complexes $Tp^{Ph,Me}$Zn–SC(O)NHR are formed. In the presence of alcohols these are incorporated in the Zn–OH insertion products: CS_2/methanol yields $Tp^{Ph,Me}$Zn–SC(S)OMe and RNCS/ethanol yields $Tp^{Ph,Me}$Zn–SC(NR)OEt. All product types were characterized by X-ray crystallography. The reactions and structures support the four-centre reaction mechanism proposed for hydrolytic zinc enzymes.

Introduction

Hydrolytic zinc enzymes normally contain a zinc-aqua unit L_nZn-OH_2 in the resting state which becomes active by conversion into the powerful nucleophile L_nZn-OH.[1,2] In one of the simplest zinc-enzyme-catalyzed processes, the hydration of CO_2 by carbonic anhydrase,[3] the primary step consists formally of the insertion of CO_2 into this Zn−OH function producing an intermediate zinc-bicarbonate complex. Numerous research groups,[4,5] including ourselves,[6−9] have tried to model the function of carbonic anhydrase using $Zn-OH_2$ or Zn−OH complexes. Until now, however, zinc-bicarbonate complexes, which seem to be the most labile intermediates, have been elusive. Their existence as intermediates and the mechanistic details of the $Zn-OH/CO_2$ reaction have been elucidated in great detail by mechanistic and theoretical investigations.[3,10]

Our activities in this field are centred on the easily accessible pyrazolylborate-zinc hydroxide complexes Tp*Zn−OH, which we have called the Freiburg enzyme model.[11] We have described some reactions of these complexes with CO_2,[6−8] and related heterocumulenes such as CS_2 and RNCS,[7,12] and we have developed mechanistic proposals for the hydrolytic function of the Zn−OH unit based on preparative and kinetic work[13] as well as on theoretical considerations[12] and a structure correlation analysis.[13]

A characteristic feature of the Tp*Zn−OH/heterocumulene reactions is that their primary reaction products undergo subsequent reactions, either by proton migration or solvent incorporation.[6−8,12] In order to learn more about the possible primary products we therefore looked for a Tp*Zn complex as a starting material which bears a nucleophilic yet nonprotic ligand X capable of allowing insertion of the heterocumulene into the Zn−X function. We found that Zn−SH or Zn−SR complexes are not suitable for this purpose due to reluctance of the sulfur ligands to undergo Zn−S bond cleavage.[14,15] It turned out, however, that the Zn−H function in Tp*Zn−H complexes has all of the desired characteristics. This paper describes the heterocumulene reactions of $Tp^{Ph,Me}$Zn−H (**1**). The related reactions of $Tp^{Ph,Me}$Zn−OH (**2**), which have also yielded new insights, are included. The independent chemistry of $Tp^{Ph,Me}$Zn−OR complexes which bear the highly nucleophilic and extremely labile alkoxide ligands will be described in a separate paper.[16]

Results and Discussion

Reactions of $Tp^{Ph,Me}Zn-H$

$Tp^{tBu}Zn-H$ was prepared previously by Parkin from ZnH_2 and the ligand,[17] and $Tp^{p\text{-}Tol,Me}Zn-H$ by Kläui from the corresponding fluoride and triethylsilane.[18] The reactivity of the former towards protic reagents and alkyl halides had already been studied, as had its reaction with CO_2 to form $Tp^{tBu}Zn$-formate, which was characterized spectroscopically.[17]

We chose the Kläui method to prepare **1**. Both the formation of $Tp^{Ph,Me}Zn-F$ from $KTp^{Ph,Me}$, $Zn(ClO_4)_2$ and KF and its conversion into **1** with triethylsilane are high yield processes. The hydride complex **1** is remarkably stable. It melts without decomposition above 200 °C, and can be handled for short periods in the open atmosphere. Its ^1H NMR spectrum in $CDCl_3$ shows the hydride resonance at $\delta = 4.06$, which is in the range observed for the other two Tp*Zn−H complexes.

The structure of the hydride complex **1** is displayed in Figure 1. Although an electron density which roughly corresponds to that of a hydrogen atom could be localized at the position given in the figure, it is unrealistic to assign it to the zinc-bound hydride due to the observed distance of 1.9 Å, which is well above the accepted Zn−H distance of ca. 1.60 Å.[19] Compound **1** shares this feature with $Tp^{tBu}Zn-H$,[17] for which the hydride position was also not located but whose ZnN_3H arrangement is practically identical to that in **1**. Thus the main purpose of Figure 1 is to show the encapsulation of the Zn−H function by the phenyl groups on the pyrazole rings and to give one representative drawing of the complete pyrazolylborate ligand $Tp^{Ph,Me}$ which is omitted for clarity in all subsequent figures.

$Tp^{Ph,Me}Zn-H$ reacts readily with CO_2 or CS_2 in excess at ambient temperature to yield the corresponding formate or dithioformate complexes **3** and **4**. The transfer of the hydridic H atom from zinc to carbon, i.e. the insertion of the heterocumulene into the Zn−H function, is obvious from the NMR spectroscopic data and was confirmed by the structure determinations (see below). Likewise the isothiocyanates RNCS (R = methyl, phenyl and *p*-nitrophenyl) are inserted with formation of the corresponding iminothioformates **5a−c**. All three are crystalline solids with high thermal stabilities, whose formate nature is again evident from the formate proton resonances in the ^1H NMR spectrum.

The structure determinations of **3**, **4** and **5c** revealed the common features and characteristic differences of the species. In all drawings the attachment of the pyrazolylborate ligand to zinc is reduced to the attachment of its nitrogen donors for the purpose of an unobscured view of the heterocumulene-derived ligand. The latter is displayed such that its bond to zinc is vertical and the least-squares plane including its bond to zinc is in the plane of the drawing.

The formate complex **3** (Figure 2) is the first structurally authenticated formate complex in the group of TpZn-carboxylate complexes. The attachment of the formate ligand to zinc with a somewhat elongated Zn−O1 bond and a rather weak, but non-negligible, Zn···O2 interaction must be classified as semibidentate. In comparison, the acetate in $Tp^{tBu}Zn-OC(O)Me$ is clearly monodentate with Zn−O1 = 1.86 Å and Zn−O2 = 2.95 Å.[17] The extensive discussion of bidentate bonding of ligands to TpZn units[5,13] has identified another indicator for the strength of the interaction of the zinc ion with the second donor of the bidentate ligand. This is the position of the pyrazolylborate nitrogen *trans* to this second donor. In the case of **3** this is N2. N2 is not precisely *trans* to O2 (N2−Zn−O2 = 169.0°), it is not part of the planar ZnOOCH array (displacement 0.20 Å), and its bond to zinc is not longer than the other two Zn−N bonds. Thus the formate attachment is actually weakly semibidentate, resembling the nitrate attachment in $Tp^{tBu}Zn-ONO_2$.[20]

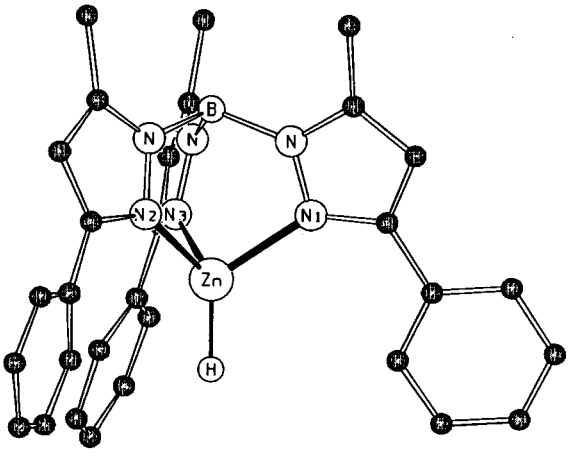

Figure 1. Molecular structure of $Tp^{Ph,Me}Zn-H$ (**1**); bond lengths: Zn−N1 2.079(5), Zn−N2 2.081(4), Zn−N3 2.054(5) Å

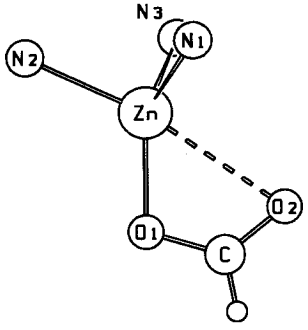

Figure 2. Zinc coordination in $Tp^{Ph,Me}Zn-OCHO$ (**3**); bond lengths: Zn−O1 1.918(3), Zn···O2 2.642(3), Zn−N1 2.034(5), Zn−N2 2.058(4), Zn−N3 2.068(4), O1−C 1.277(7), O2−C 1.208(7) Å; bond angles: Zn−O1−C 106.6(4), O1−C−O2 124.2(5)°

The dithioformate complex **4** (Figure 3) is, to the best of our knowledge, the first structurally authenticated classical coordination compound with a dithioformate ligand. In contrast, dithioformate complexes are not uncommon in organometallic chemistry where, as a rule, the dithioformate ligand bridges two metal atoms.[21] In **4** the attachment and orientation of the HCS_2 unit is quite similar to that of the HCO_2 unit in **3**. Again, the Zn−S2 interaction is not only obvious from the Zn−S2 distance of 3.02 Å but also from the strict planarity of the Zn−SCHS array and the *trans* arrangement of N3 and S2 with a bond angle of 176.3°. The N3 nitrogen is 0.13 Å above the Zn−SCHS plane, and its Zn−N bond is 0.07 Å longer than the average of the other two Zn−N bonds. The dithioformate ligand itself shows no unusual features, displaying an sp^2 carbon, a short C−S1 single bond and a long C−S2 double bond, in agreement with the semibidentate attachment. Thus the protection in the ligand pocket around zinc allows the labile dithioformate to exist as a stable dithiocarboxylic acid derivative with completely normal bonding parameters.

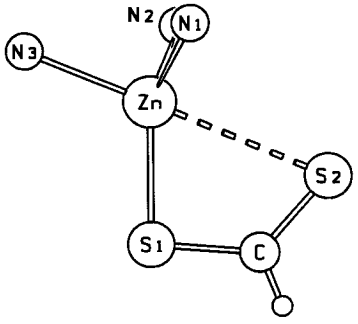

Figure 3. Zinc coordination in $Tp^{Ph,Me}Zn-SCHS$ (**4**); bond lengths: Zn−S1 2.291(1), Zn···S2 3.019(1), Zn−N1 2.019(2), Zn−N2 2.065(2), Zn−N3 2.111(2), S1−C 1.694(3), S2−C 1.623(3) Å; bond angles: Zn−S1−C 96.64(12), S1−C−S2 126.8(2)°

The iminothioformate ligand in **5c** (Figure 4) shows the closest approximation to a bidentate attachment. The Zn−S bond is longer than that in **4** and the Zn−N7 distance is close to that of a single bond. The array of Zn, S, N1, N7 and C is planar within ± 0.03 Å, and the N1−Zn−N7 angle is 177.1°. We see no obvious reason why the weakly bound N7 nitrogen in **5c** should be a better donor for zinc than the weakly bound O2 oxygen in **3** or the S2 sulfur in **4**. But while the whole range of attachments between monodentate and symmetrically bidentate is observed for zinc carboxylates[5,13] or zinc dithiocarboxylates and related species,[22,23] the unsymmetrical four-membered Zn−S−C−N chelate ring as in **5c** seems to be typical for zinc complexes of such ligands, specifically those derived from 2-mercaptopyridine-like heterocycles.[24−26] The basic form of the ligand in **5c**, iminothioformic acid HC(SH)(NH), exists only as thioformamide $HC(S)NH_2$. Its *N*-substituted derivatives, HC(SH)(NR), represented by the iminothioformate ligand in **5c**, can, however, exist as such under very favourable conditions.[27] We are not aware, however, that an anionic ligand of the type HC(S)(NR) has been used in a coordination compound before.

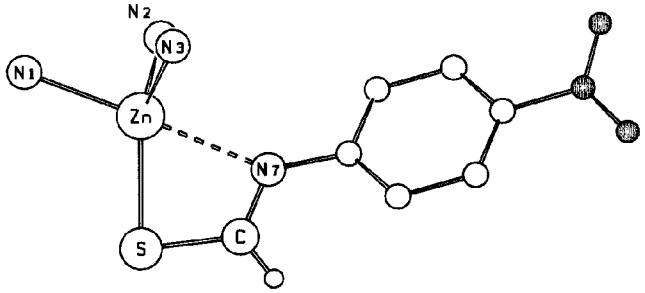

Figure 4. Zinc coordination in $Tp^{Ph,Me}Zn-SCH(NC_6H_4$-*p*-$NO_2)$ (**5c**); bond lengths: Zn−S 2.341(1), Zn···N7 2.373(3), Zn−N1 2.127(3), Zn−N2 2.048(3), Zn−N3 2.074(3), S−C 1.704(4), N7−C 1.277(5) Å; bond angles: Zn−S−C 83.24(14), Zn−N7−C 91.8(3), S−C−N7 118.7(3)°

Reactions of $Tp^{Ph,Me}Zn-OH$

We have previously described reactions of Tp*Zn−OH complexes with CO_2 in alcohols,[7,8] with CS_2 in alcohols[7] and in nonprotic solvents,[12] and with phenylisothiocyanate.[7] We had two reasons to repeat such reactions with $Tp^{Ph,Me}Zn-OH$ (**2**). Firstly, it was hoped that they would proceed like the reaction of $Tp^{Ph,Me}Zn-H$ (**1**) without subsequent reactions, thereby giving access to carbonic acid derivatives analogous to the formic acid derivatives **3**−**5**. Secondly, the favourable crystallization tendency of all $Tp^{Ph,Me}Zn-X$ complexes should allow for structural comparisons between the formic acid and carbonic acid derived complexes. The first expectation was not fulfilled: all heterocumulene insertions were accompanied by subsequent reactions. The structural comparisons, however, proved to be valuable.

The investigation of the reaction of **2** with CS_2 under nonprotic conditions was initiated by the theoretical prediction that it would lead to $Tp^{Ph,Me}Zn-SH$ and COS.[12] To our surprise this was actually the case and has resulted in a fruitful collaboration with the theoretical group of Anders.[12] In water-free dichloromethane, **2** and a stoichiometric amount of CS_2 were converted quantitatively to $Tp^{Ph,Me}Zn-SH$[14] and COS within 12 hours at room temperature. The COS resulting from this reaction in toluene was identified by mass spectrometry. Thereby it was found that under these conditions it was contaminated with CO_2, leading to the assumption that COS itself undergoes the same reaction. This was verified subsequently by the isolation of $Tp^{Ph,Me}Zn-SH$, again in a high yield, from the reaction of **2** with COS. The theoretical analysis of these interconversions,[12] whose insertion mechanism and proton migrations are of relevance for the functionality of the zinc enzyme carbonic anhydrase, will be published separately.[28] In the context of the present work these findings confirm the observation that insertions into the Zn−OH function of Tp*Zn−OH complexes will be accompanied by molecular rearrangements.

The simplest of these rearrangements, an OH/NH tautomerization, was now observed when reacting **2** with isothiocyanates in water-free dichloromethane. Methyl and

phenyl isothiocyanate yielded the thiocarbamate complexes **6a** and **6b**, respectively. Insertion alone would result in the iminothiocarbonate complexes $Tp^{Ph,Me}Zn-SC(NR)OH$. The migration of the OH proton to the more basic nitrogen should be a facile process.

$Tp^{Ph,Me}Zn\text{-}S\text{-}CO\text{-}NHR$

6a: R = CH_3, **6b**: R = C_6H_5

Esterification rather than proton migration was the subsequent reaction when performing such insertions in the presence of alcohols. As observed before for a related system,[7] CS_2 was inserted in the presence of one equivalent of methanol to yield the xanthogenate complex **7**. The insertion of *p*-nitrophenyl isothiocyanate in ethanol-stabilized chloroform produced the iminothiocarbonate complex **8**. Both results can be interpreted as an esterification of the primary insertion products $Tp^{Ph,Me}Zn-S-CS-OH$ and $Tp^{Ph,Me}Zn-S-C(NR)-OH$. However, initial replacement of OH by OR to form $Tp^{Ph,Me}Zn-OR$ as the species which is then subjected to insertion, cannot be ruled out with complete certainty. Although the alkoxides Tp*Zn−OR exist only in extremely low concentrations as equilibrium species of Tp*Zn−OH in alcohol solvents,[29] they might be the precursors of the product complexes **7** and **8**.

$Tp^{Ph,Me}Zn\text{-}S\text{-}CS\text{-}OMe$ **7** $\qquad$ $Tp^{Ph,Me}Zn\text{-}S\text{-}C(NC_6H_4NO_2)\text{-}OEt$ **8**

The molecular structure of the thiocarbamate complex **6a** (Figure 5) corresponds to that of the related thiocarboxylate complexes Tp*Zn−S−CO−R,[30] and the ligand attachment, orientation and bond lengths are quite similar to the only other structurally characterized zinc complex of this type, a bis(thiocarbamato)-bis(amine) zinc complex.[31] The long C···O distance indicates a very weak C···O interaction, as does the uniformity of the Zn−N distances. The fact that the carbamate oxygen rather than the carbamate nitrogen is in the vicinity of the zinc ion points to steric rather than electronic reasons for the arrangement of the thiocarbamate ligand. The Zn−S−C−O array is only roughly planar (± 0.08 Å) and N2 is displaced 0.4 Å from this plane. The bond lengths and angles within the thiocarbamate ligand are normal, therefore the attachment of the thiocarbamate ligand to zinc causes no unusual bonding features for the metal ion or for the ligand.

The structure of the xanthogenate complex **7** (Figure 6) complements that of $Tp^{Cum,Me}Zn-S-CS-OEt$.[7] Unlike in **6a** the sterically more demanding OR unit of the xanthogenate ligand is oriented towards zinc rather than the second sulfur atom. This points to a Zn···O interaction, as does the Zn···O distance which corresponds to that in the formate complex **3**. Likewise, the strict planarity of all five atoms of the Zn−S−CS−O unit and the displacement of N1 by 0.25 Å from this plane correspond to the situation in **3**, grouping the xanthogenate ligand in the weakly semibidentate class. The bonding details of the $MeOCS_2$ ligand

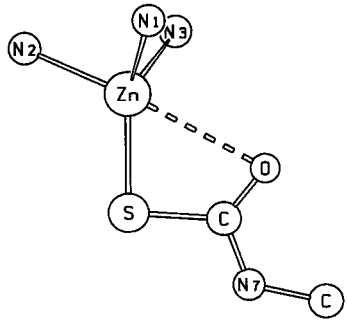

Figure 5. Zinc coordination in $Tp^{Ph,Me}Zn-S-CO-NHMe$ (**6a**); bond lengths: Zn−S 2.244(1), Zn···O 2.869(4), Zn−N1 2.085(3), Zn−N2 2.091(3), Zn−N3 2.044(3), S−C 1.734(5), C−O 1.223(5), C−N7 1.348(6) Å; bond angles: Zn−S−C 94.15(17), S−C−O 124.1(4)°

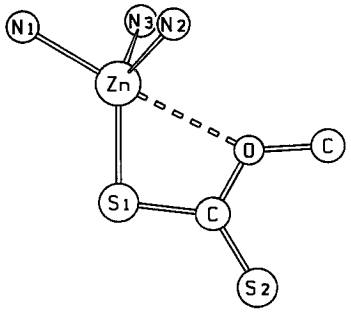

Figure 6. Zinc coordination in $Tp^{Ph,Me}Zn-S-CS-OMe$ (**7**); bond lengths: Zn−S1 2.244(3), Zn···O 2.685(3), Zn−N1 2.051(7), Zn−N2 2.036(8), Zn−N3 2.031(7), S1−C 1.72(1), C−S2 1.62(1), C−O 1.37(1) Å; bond angles: Zn−S1−C 97.5(4), S1−C−O 111.2(7)°

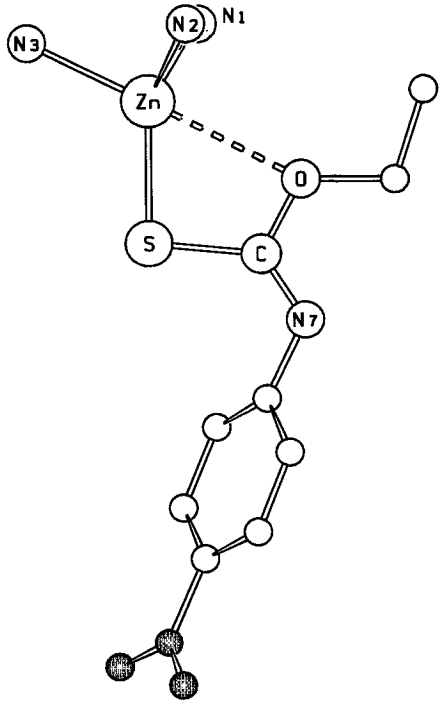

Figure 7. Zinc coordination in $Tp^{Ph,Me}Zn-S-C(NR)-OEt$ (**8**); bond lengths: Zn−S 2.254(2), Zn···O 2.680(5),Zn−N1 2.038(7), Zn−N2 2.034(6), Zn−N3 2.087(7), S−C 1.75(1), C−N7 1.27(1), C−O 1.35(1) Å; bond angles: Zn−S−C 95.8(3), S−C−O 112.1(6)°

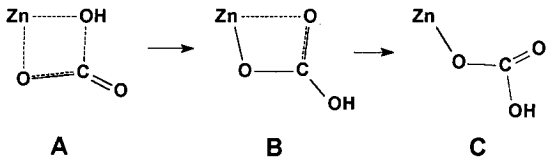
in **7** are in full agreement with those of the $EtOCS_2$ ligand, as discussed in comparison with reference compounds for $Tp^{Cum,Me}Zn-S-CS-OEt$.[7]

The iminothiocarbonate ligand in **8** (Figure 7) seems to represent a type of ligand that has been unknown in coordination chemistry so far. Its attachment to zinc is quite similar to that of the xanthogenate ligand in **7**, however. This extends to the molecular details of the ligand as well as to its zinc−ligand interactions. Although the Zn···O contact shows the same interatomic distance as that in **7**, it seems to be somewhat stronger, as evidenced by the extension of the Zn−N3 bond *trans* to the Zn···O interaction, the O−Zn−N3 angle of 178.3° and the position of N3 in the plane defined by the Zn−S−C−O unit. It is noteworthy to compare the orientations of the *p*-nitrophenyl groups in **5c** (Figure 4) and **8**, which again point to the fact that electronic rather than steric influences determine the preferred donor for the weak interaction with the zinc ion.

Mechanistic Implications

The theoretical and mechanistic analysis of the key reaction of hydrolytic zinc enzymes − the nucleophilic attack of the Zn−OH function at the electrophilic centre of the substrate, specifically CO_2 − has led to the proposal that a four-centre mechanism prevails.[3,11,12] In this process, as displayed below for the hydration of CO_2, the zinc-bound OH is a leaving group, and the transformation of CO_2 to bicarbonate proceeds via the bidentate to the monodentate attachment of the latter.

The insertions of the heterocumulenes described here result in bonding situations which model transient bonding situations along the reaction coordinate of the enzymatic process. Three stages can be identified: Situation **A** is represented by the structures of **7** and **8** which contain the weakly bound oxygen donor as an alkoxide function which models the OH function of the enzyme. The substrate (CO_2 being modelled by CS_2 or RNCS) is attached in a four-centre fashion, and the Zn−OR bond is noticeably weakened. Situation **B** results from **A** either by proton transfer (Lipscomb mechanism[3]) or by internal rotation (Lindskog mechanism[3]). It is best represented by the structure of **5c** with a rather strong Zn−N interaction. The transition from situation **B** to **C** with a progressive weakening of the Zn···O interaction is represented by the structures of **3**, **6a** and **4**, in that order. While the formate ligand in **3** is an example of semibidentate coordination, the thiocarbamate ligand in **6a** is close to being monodentate. The six structures described here do not represent situation **C** (strictly monodentate). The latter is, however, approximated in our complexes $Tp^{Ph}Zn-SC(O)CH_3$ [30] and $Tp^{tBu,Me}Zn-OC(O)OCH_3$.[6]



We have discussed in detail the changes in the coordination sphere of zinc upon the transition from **A** to **B**, as modelled by Tp*Zn(X)(Y) complexes.[11] The six structures in this paper provide further examples for this discussion which describes the path from the substrate attachment to the OH elimination as a transition along the Berry coordinate of the Berry pseudorotation of AB_5 molecules. They represent various stages of the interconversion between square-pyramidal and trigonal-bipyramidal coordination of zinc, as can be seen from their trans N−Zn−X angles (see Figure 2−7) ranging from 169−178°. Likewise their "percentage of trigonal-bipyramidal" values, as calculated by the dihedral angle method[13] range from 62% (**6a**) to 72% (**4**). A detailed discussion of these features, however, is not appropriate, as the distortions in the coordination sphere of zinc are spread over a range which is too narrow.

In summary, the chemical interconversions described in this paper have shown that the strong Zn−X nucleophiles Zn−H and Zn−OH can attack and incorporate all classical heterocumulenes and thereby model the biological Zn−OH/CO_2 chemistry. The structures of the resulting complexes have provided valuable insights into the molecular transformations occurring during the hydration of CO_2 as catalyzed by the zinc enzyme carbonic anhydrase.

Experimental Section

General: For general working and measuring procedures, see ref.[32] All reactions were performed in air- and water-free solvents under an inert atmosphere. $Tp^{Ph,Me}Zn-OH$[33] and COS[34] were prepared by the published procedures.

$Tp^{Ph,Me}Zn-F$: A solution of $Zn(ClO_4)_2 \cdot 6H_2O$ (1.43 g, 3.83 mmol) in 20 mL of methanol was added with stirring to a solution of $KTp^{Ph,Me}$ [33] (2.00 g, 3.83 mmol) in 100 mL of dichloromethane. A colourless precipitate was formed. After 2 h of stirring a solution of KF (222 mg, 3.83 mmol) in 10 mL of methanol was added. After stirring for 20 h and filtration the solution was reduced to 50 mL in vacuo and kept at −20 °C. $Tp^{Ph,Me}Zn-F$ (1.83 g, 84%) precipitated as colourless crystals, m.p. 244 °C. $C_{30}H_{28}BFN_6Zn$ (567.8): calcd: C 63.46, H 4.97, N 14.80, Zn 11.50; found C 62.44, H 4.92, N 14.51, Zn 11.69. ^1H NMR ($CDCl_3$): δ = 2.53 [s, 9 H, Me(pz)], 6.22 [s, 3 H, H(pz)], 7.33−7.49 (m, 9 H, Ph), 7.91 (d, *J* = 7.4 Hz, 6 H, Ph). ^{19}F NMR ($CDCl_3$): δ = 219.6.

1: A solution of $Tp^{Ph,Me}Zn-F$ (1.50 g, 2.64 mmol) and Et_3SiH (4.2 mL, 3.07 g, 26.0 mmol) in 25 mL of toluene was heated to reflux for 2 days. Upon cooling to room temp. the product was precipitated. All volatiles were removed in vacuo, and the residue was recrystallized from hot toluene, yielding 1.31 g (90%) of **1** as colourless crystals, m.p. 239 °C. $C_{30}H_{29}BN_6Zn$ (549.8): calcd: C 65.54, H 5.38, N 15.29, Zn 11.89; found C 64.72, H 5.37, N 14.75, Zn 11.79. ^1H NMR ($CDCl_3$): δ = 2.47 [s, 9 H, Me(pz)], 4.06 (s, 1 H, ZnH), 6.17 [s, 3 H, H(pz)], 7.19−7.36 (m, 9 H, Ph), 7.72 (d, *J* = 8.0 Hz, 6 H, Ph).

3: CO_2 gas, which was dried by passing through a suspension of P_2O_5 in toluene, was bubbled through a solution of **1** (200 mg, 0.36 mmol) in 30 mL of toluene for 1 h. Evaporation to dryness and recrystallization from hot acetonitrile yielded 164 mg (76%) of **3** as colourless crystals, m.p. 252 °C. $C_{31}H_{29}BN_6O_2Zn$ (593.8):

calcd: C 62.70, H 4.92, N 14.15; found C 62.44, H 4.92, Zn 14.18. ^{1}H NMR ($CDCl_3$): δ = 2.53 [s, 9 H, Me(pz)], 6.21 [s, 3 H, H(pz)], 7.34 (m, 9 H, Ph), 7.58 (m, 7 H, Ph and HCO_2).

4: A solution of **1** (100 mg, 0.18 mmol) and CS_2 (138 mg, 1.82 mmol) in 15 mL of toluene was stirred at 40 °C for 16 h. Evaporation to dryness and recrystallization from hot acetonitrile yielded 97 mg (85%) of **4** as pale yellow crystals, m.p. 204 °C. $C_{31}H_{29}BN_6S_2Zn$ (625.9): calcd: C 59.48, H 4.67, N 13.43, S 10.25; found C 59.67, H 4.71, N 13.70, S 9.98. ^{1}H NMR ($CDCl_3$): δ = 2.56 [s, 9 H, Me(pz)], 6.17 [s, 3 H, H(pz)], 7.32 (m, 9 H, Ph), 7.53 (m, 6 H, Ph), 10.24 (s, 1 H, HCS_2).

5a: Like **4**, from **1** (200 mg, 0.36 mmol) and CH_3NCS (27 mg, 0.36 mmol). Yield 118 mg (52%) of **5a** as colourless crystals, m.p. 214 °C. $C_{32}H_{32}BN_7SZn$ (622.9): calcd: C 61.70, H 5.18, N 15.74, S 5.15; found C 62.10, H 5.26, N 16.09, S 4.76. ^{1}H NMR ($CDCl_3$): δ = 1.60 (s, 3 H, NMe), 2.55 [s, 9 H, Me(pz)], 6.17 [s, 3 H, H(pz)], 7.30 (m, 9 H, Ph), 7.63 (m, 7 H, Ph and HC).

5b: A solution of **1** (200 mg, 0.36 mmol) and C_6H_5NCS (49 mg, 0.36 mmol) in 30 mL of toluene was heated to reflux for 15 h. Evaporation to dryness and recrystallization from hot acetonitrile yielded 164 mg (66%) of **5b** as colourless crystals, m.p. 181 °C. $C_{37}H_{34}BN_7SZn$ (685.0): calcd: C 64.88, H 5.00, N 14.31, S 4.68; found C 64.34, H 4.99, N 14.23, S 4.33. ^{1}H NMR ($CDCl_3$): δ = 2.56 [s, 9 H, Me(pz)], 5.59 (m, 3 H, Ph-NCS), 6.14 [s, 3 H, H(pz)], 6.72 (m, 2 H, Ph-NCS), 7.24 (m, 9 H, Ph), 7.54 (m, 6 H, Ph), 7.72 (s, 1 H, HC).

5c: A solution of **1** (200 mg, 0.36 mmol) and *p*-NO_2-C_6H_4NCS (66 mg, 0.36 mmol) in 30 mL of acetonitrile was stirred for 15 h. Evaporation to 15 mL in vacuo and cooling to −20 °C resulted in the crystallization of 173 mg (65%) of yellow **5c**, m.p. 239 °C. $C_{37}H_{33}BN_8O_2SZn$ (730.0): calcd: C 60.88, H 4.56, N 15.35, S 4.39; found C 60.92, H 4.59, N 15.57, S 4.21. ^{1}H NMR ($CDCl_3$): 2.57 [s, 9 H, Me(pz)], 5.64 (d, *J* = 8.2 Hz, 2 H, C_6H_4), 6.15 [s, 3 H, H(pz)], 7.24 (m, 9 H, Ph), 7.50 (m, 6 H, Ph), 7.64 (d, *J* = 8.2 Hz, 2 H, C_6H_4), 7.81 (s, 1 H, HC).

Reaction of 2 with CS_2: A mixture of **2** (25.0 mg, 44 μmol) and CS_2 (336 mg, 4.42 mmol) in 5 mL of toluene under an atmosphere of argon in a sealed 10 mL flask was stirred for 40 h. GC-MS analysis of samples taken from the gas phase with a syringe showed them to contain CO_2 and COS in about a 1:2 ratio.

$Tp^{Ph,Me}Zn-SH$ from 2 and CS_2: A solution of **2** (250 mg, 0.44 mmol) and CS_2 (37.0 mg, 0.49 mmol) in 20 mL of dichloromethane was stirred for 16 h. Evaporation to dryness and recrystallization from acetonitrile yielded 157 mg (61%) of $Tp^{Ph,Me}Zn-SH$.[14]

$Tp^{Ph,Me}Zn-SH$ from 2 and COS: COS gas was passed for 15 min through a solution of **2** (250 mg, 0.44 mmol) in 20 mL of dichloromethane/toluene (4:1). After stirring for 15 h, evaporation to dryness and recrystallization from acetonitrile yielded 183 mg (71%) of $Tp^{Ph,Me}Zn-SH$.[14]

6a: A solution of **2** (250 mg, 0.44 mmol) and CH_3NCS (32.3 mg, 0.44 mmol) in 20 mL of dichloromethane was heated to reflux for 40 h. Evaporation to dryness and recrystallization from benzene yielded 266 mg (84%) of **6a** as colourless crystals, m.p. 184 °C. $C_{32}H_{32}BN_7OSZn{\cdot}C_6H_6$ (638.9 + 78.1): calcd: C 63.65, H 5.34, N 13.67, S 4.47; found C 63.43, H 5.33, N 13.77, S 4.62. ^{1}H NMR ($CDCl_3$): δ = 1.91 (s, 3 H, NCH_3), 2.52 [s, 9 H, Me(pz)], 4.90 (s, 1 H, NH), 6.13 [s, 3 H, H(pz)], 7.30 (m, 15 H, Ph + C_6H_6), 7.67 (m, 6 H, Ph).

6b: Like **6a** from **2** (250 mg, 0.44 mmol) and C_6H_5NCS (59.7 mg, 0.44 mmol). Yield 290 mg (77%) of **6b** as colourless crystals, m.p.

188 °C. $C_{37}H_{34}BN_7OSZn·2C_6H_6$ (701.0 + 156.2): calcd: C 68.66, H 5.41, N 11.44, S 3.74; found C 68.60, H 5.53, N 11.15, S 3.93. ^{1}H NMR ($CDCl_3$): δ = 2.53 [s, 9 H, Me(pz)], 6.17 [s, 3 H, H(pz)], 6.66 (d, *J* = 8.1 Hz, 2 H, NPh), 6.86 (m, 1 H, NPh), 7.04 (m, 2 H, NPh), 7.22 (m, 9 H, Ph), 7.35 (s, 12 H, C_6H_6), 7.61 (m, 6 H, Ph).

7: A solution of **2** (250 mg, 0.44 mmol), CS_2 (37.0 mg, 0.49 mmol) and CH_3OH (15.6 mg, 0.49 mmol) in 20 mL of dichloromethane was stirred for 16 h. Evaporation to dryness and recrystallization from acetonitrile yielded 228 mg (79%) of **7** as colourless crystals, m.p. 222 °C. $C_{32}H_{31}BN_6OS_2Zn$ (656.0): calcd: C 58.59, H 4.76, N 12.81, S 9.78; found C 58.67, H 4.84, N 12.81, S 9.98. ^{1}H NMR ($CDCl_3$): δ = 2.55 [s, 9 H, Me(pz)], 2.64 (s, 3 H, OMe), 6.16 [s, 3 H, H(pz)], 7.31 (m, 9 H, Ph), 7.53 (m, 6 H, Ph).

8: A solution of **2** (250 mg, 0.44 mmol) and *p*-NO_2-C_6H_4NCS (79.6 mg, 0.44 mmol) in 40 mL of chloroform containing ca. 1% of ethanol as a stabilizer was heated to reflux for 40 h. All volatiles were removed in vacuo, and the residue was dissolved in 10 mL of *n*-heptane/dichloromethane (4:1). Slow evaporation of the dichloromethane resulted in the precipitation of 145 mg (42%) of **8** as yellow crystals which lost the solvent of crystallization upon drying in vacuo, m.p. 234 °C. $C_{39}H_{37}BN_8O_3SZn$ (774.0): calcd: C 60.52, H 4.82, N 14.48, S 4.14; found C 60.39, H 4.66, N 14.70, S 4.38. ^{1}H NMR ($CDCl_3$): δ = 0.17 [t, *J* = 6.9 Hz, 3 H, CH_3(Et)], 2.57 [s, 9 H, Me(pz)]; 2.72 [q, *J* = 6.9 Hz, 2 H, CH_2(Et)], 6.19 [s, 3 H, H(pz)], 6.78 (m, 2 H, C_6H_4), 7.37 (m, 9 H, Ph), 7.65 (m, 6 H, Ph), 8.12 (m, 2 H, C_6H_4).

Structure Determinations:[35] All crystals were obtained as described above from the reaction solutions. Diffraction data were recorded at 180 K (**1** at room temp.) on a Bruker Smart CCD diffractometer and subjected to an empirical absorption correction (program SADABS). The structures were solved with direct methods and refined anisotropically with the SHELX program suite.[36] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. Parameters were refined against F^2. The *R* values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[37] Table 1 lists the crystallographic data.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We are indebted to Mrs. Petra Klose for technical assistance and to Drs. Werner Deck and Alexander Trösch for help with the crystallography.

The First Structurally Characterized 4-Halo-2,5-Cyclohexadienone Transition Metal Complex

Udo Radius*[a] and Juri Attner[a]

Keywords: Coordination chemistry / Macrocyclic ligands / Calixarenes / Molybdenum / Tungsten

The calix[4]arene molybdenum imido complex [CaxO_4Mo(N*t*Bu)] (**1**) reacts with HCl to give, in a reversible reaction, the 1,2-addition product [Cax(OH)O_3Mo(N*t*Bu)Cl] (**4**). Reaction with $PhICl_2$ does not lead to scission of the imido group either, but results in an unprecedented 1,6-addition of chlorine to the metallocalixarene to give a molybdenum 4-chloro-2,5-cyclohexadienone complex [Cax$^{Cl}O_4$Mo(N*t*Bu)Cl] (**5**), which has been structurally characterized. This compound is the first example of a structurally characterized 4-halo-2,5-cyclohexadienone transition metal complex.

Introduction

Macrocyclic ligands have played an important role in the development of modern coordination chemistry and continue to do so.[1] Macrocyclic complexes are usually associated with high thermodynamic and kinetic stability and are therefore used as templates in supramolecular chemistry, in multi-component assembly processes, and as molecular receptors for guest molecules. Such ligands can act as spectator ligands for organometallic transformations at the metal atom.[2] However, in many cases, the ligands are also involved in the reaction processes. In metalloporphyrin chemistry, for example, reactions at the porphyrin periphery are quite common and these ligands are susceptible to redox processes and electrophilic as well as nucleophilic attack.[3]

Calix[4]arenes or calix[4]arene ethers,[4] with a pre-organized set of oxygen donor atoms in a quasi-planar arrangement, may be regarded as oxygen analogues of porphyrins and related nitrogen-containing macrocyclic ligands. These molecules have received considerable attention because of their host−guest chemistry and their ability to bind metals.[4,5] In the last few years, the potential of these types of ligands in organometallic and coordination chemistry has been clearly demonstrated. The simplest of the calixarenes, the calix[4]arene system, usually binds in a tetradentate fashion and retains its *cone*-like appearance.[5] In contrast to transition metal chemistry involving porphyrins, tetraazaannulenes, calixpyrroles, and related nitrogen donor ligands,[6] the calix[4]arene backbone is usually not involved in organometallic transformations.[7] Calix[4]arenes are therefore ideal co-ligands in transition metal chemistry, they tolerate acidic, basic, reductive, and oxidative conditions.

We report herein on a selective halogenation of the macrocyclic ligand in a metallocalix[4]arene through an unprecedented 1,6-chlorination. The resulting product represents the first isolated and structurally characterized 4-halo-2,5-cyclohexadienone complex.

Results and Discussion

As part of our program on molybdenum calix[4]arene complexes,[8] we have synthesized molybdenum imido complexes previously.[8b] The ultimate aim of this work was the synthesis of compounds of the general type [CaxO_4MoX_2] or [CaxO_4MoXX′] (Cax = hydrocarbon backbone of the *p-tert*-butylcalix[4]arene, $C_{44}H_{52}$; X = monoanionic ligand), which represent important starting materials for molybdenocalix[4]arene chemistry. Since the direct reaction of [$MoCl_5$] with *p-tert*-butylcalix[4]arene does not afford calix[4]arene molybdenum halides,[8a] we were led to investigate the reaction of [CaxO_4Mo(N*t*Bu)] (**1**) with HCl and Cl_2. Preliminary experiments revealed that a solution of [CaxO_4W(N*t*Bu)] (**2**) in dichloromethane reacts spontaneously with gaseous HCl at −20 °C to give the known calix[4]arene tungsten dichloro complex [CaxO_4WCl_2] (**3**).[7d]

Whereas the imido ligand $[NR]^{2-}$ in **2** can be selectively replaced by two chloride ligands $[Cl]^-$, the reactivity of the analogous molybdenum compound **1** with respect to hydrochlorination is totally different (see Scheme 1). The reaction of **1** with one equivalent of HCl affords a dark-violet solution, which contains, according to NMR spectroscopy, a compound with local C_s symmetry of the calix[4]arene ligand, presumably [Cax(OH)O_3Mo(N*t*Bu)Cl] (**4**). The ^{1}H NMR spectrum of **4** features three signals due to the *t*Bu protons and three signals due to the protons of the methylene bridges, with relative integrals of 1:1:2. The signal of the OH proton can be detected at δ = 15.5. This low field

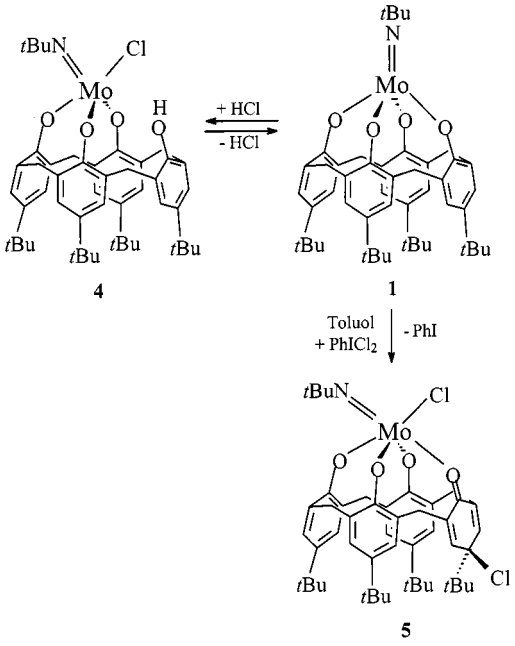
resonance is indicative of protonation at the basic oxygen atoms of the calix[4]arene ligand. Similarly downfield shifted signals have been detected previously, for example in [{Cax(OH)$_2$O$_2$Mo$_2$(OAc)$_2$}(THF)], as reported by Lippard and co-workers.[9] However, the exact stereochemistry at the molybdenum center in **4** has not been established and protonation at the imido nitrogen atom cannot be totally excluded at present. We were not able to substitute the imido group, even by using a slight excess of HCl. The use of a larger amount of HCl in the reaction does not lead to scission of the imido group through proton transfer, but rather to decomposition of **4**. The protonated ligand Cax(OH)$_4$ was unequivocally detected in these reaction mixtures.



Scheme 1

Complex **4** decomposes to starting material **1** when solutions of this compound are concentrated in vacuo. The addition of HCl to **1** is totally reversible over several cycles. Reducing the pressure leads to elimination of HCl from **4**, and all attempts to remove **4** from equilibrium or to crystallize the complex have so far proved unsuccessful. Complex **4** could only be detected in solution and, as shown in Scheme 1, is the net result of a reversible 1,2-addition of HCl to the metal−oxygen bond of **1**.

The molybdenum imido function of **1** is similarly unreactive with respect to chlorine-transfer reagents. The addition of an equimolar amount of PhICl$_2$ to a solution of **1** in toluene causes a spontaneous color change of the reaction mixture to dark violet. After workup, the molybdenum complex [Cax^{Cl}O$_4$Mo(N*t*Bu)Cl] (**5**) could be isolated in good yield (see Scheme 1). Calix[4]arene Cax(OH)$_4$ does not react with PhICl$_2$ under comparable reaction conditions.

Spectroscopic data of the reaction product are in good agreement with an addition of Cl$_2$ to the imido compound **1**. The FD mass spectrum features a molecular peak at *m*/*z* = 885 (78%), which is the sum of the molar masses of **1** and Cl$_2$. The ^{1}H NMR spectrum of **5** shows a typical pattern for a pseudo-C_s-symmetric structure of the calix[4]arene ligand in solution. The resonance of the imido *t*Bu protons is detectable at δ = 1.44, ca. 0.4 ppm further upfield than in the case of the starting compound **1**. The ^{13}C NMR spectrum features signals for quaternary carbon atoms with unusual shifts for calix[4]arene complexes, a resonance at δ = 42.5, and a signal at δ = 191.2. These signals can be attributed to a carbon atom of a *C*(*t*Bu)Cl group and to a carbonyl carbon atom, respectively. Furthermore, the infrared spectrum of **5** shows a strong band at 1668 cm^{-1} in the typical absorption region of carbonyl groups of α,β-unsaturated ketones.[10] These ^{13}C NMR and IR spectroscopic results suggest a 1,6-addition of chlorine to the molybdenum imido complex **1**, one chlorine atom being located at the metal atom and the other at the *para* position of one of the phenoxide units of the calix[4]arene ligand (see Scheme 1).

The result of an X-ray crystallographic study of crystals of **5** is shown in Figure 1 and confirms the structure proposed above. Complex **5** crystallizes in the monoclinic space group $P2_1/c$ with four formula units and four additional hexane molecules in the unit cell. The molybdenum atom is sixfold coordinated by four oxygen atoms O(1) to O(4), a nitrogen atom, and the chlorine atom Cl(1). Whereas the N−Mo−O(1) arrangement is almost linear with an angle of 176.2(15)°, the O(2)−Mo−O(4) and O(3)−Mo−Cl(1) angles of 159.6(12)° and 164.1(9)° demonstrate the distortion from an idealized octahedron. The molybdenum−oxygen distances to the oxygen atoms of the phenolate groups O(2), O(3), and O(4) are within the typ-

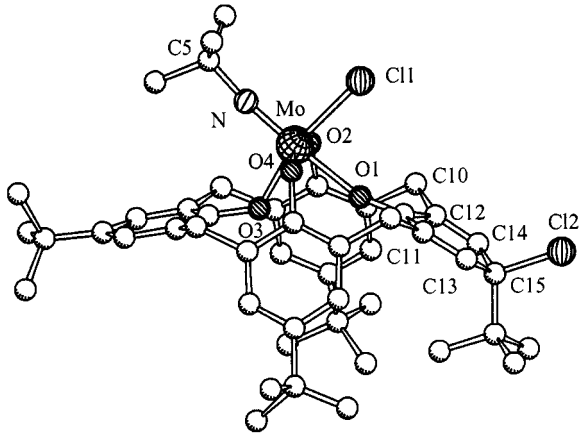


Figure 1. SCHAKAL plot of the molecular structure of [Cax^{Cl}O$_4$-Mo(N*t*Bu)Cl] **5**; hydrogen atoms are omitted for clarity and disorders of the *t*Bu groups are not resolved in the drawing; selected bond lengths [pm] and angles [°]: Mo−Cl(1): 241.0(1), Mo−N: 170.3(4), Mo−O(1): 216.0(3), Mo−O(2): 193.7(3), Mo−O(3): 191.9(3), Mo−O(4): 194.2(3), O(1)−C(10): 122.1(5), C(10)−C(11): 144.7(5), C(10)−C(12): 145.7(5), C(11)−C(13): 133.1(6), C(12)−C(14): 132.5(6), C(13)−C(15): 150.9(6), C(14)−C(15): 149.9(6), C(15)−Cl(2): 183.3(5), O(2)−C(20): 136.6(5), O(3)−C(30): 135.1(5), O(4)−C(40): 136.8(5); Mo−N−C(5): 173.0(4), Mo−O(1)−C(10): 163.1(3), Mo−O(2)−C(20): 125.3(2), Mo−O(3)−C(30): 119.6(3), Mo−O(4)−C(40): 124.6(2), N−Mo−O(1): 176.2(2), Cl(1)−Mo−O(3): 164.1(9), O(1)−Mo−O(3): 81.6(1), O(2)−Mo−O(4): 159.6(2)

ical range for molybdenum(VI) calix[4]arene complexes,[8] being between 191.9(3) pm and 194.2(3) pm; the Mo−Cl(1) distance of 241.0(1) pm is also unexceptional.[11] Interestingly, the molybdenum−nitrogen bond length to the imido ligand N atom of 170.3(4) pm is approximately 1.5 pm shorter than the Mo−N distance in the starting compound **1**, and the Mo−N−C(5) group is close to linear. These structural parameters are, as was likewise shown for **1**, in accordance with the triple bond character of the molybdenum−nitrogen bond.[12]

Significantly elongated with respect to the other molybdenum−oxygen bond lengths is the Mo−O(1) distance of 216.0(3) pm. This correlates with a short O(1)−C(10) contact of 122.1(5) pm, which is in the range for C=O double bonds.[13] The carbon atoms C(10) to C(15) of the carbon ring system connected to O(1) show alternating C−C bond lengths of 145.2(5) pm on average for $C_{ipso}-C_{ortho,}$ 132.8(6) pm for $C_{ortho}-C_{meta}$, and 150.4(6) pm for $C_{meta}-C_{para}$. This is in accordance with a description of the previously aromatic unit of the calix[4]arene as an α,β-unsaturated ring system. The C(15)−Cl(2) distance of 183.3(5) pm corresponds to a carbon−chlorine bond length involving an sp^3-hybridized carbon atom. As a net result, the structure of complex **5** in solution and in the solid state is best described as the 1,6-addition product of chlorine to **1**. To the best of our knowledge, no such selective 1,6-addition of chlorine to an organic or inorganic substrate has ever been observed previously.

Conclusion

The occurrence of electrophilic halogen attack in electrophilic aromatic substitution reactions,[14] especially on phenols,[15] is well-known. Such attack occurs in reactions in which a halogen atom replaces a substituent on the aromatic ring and the resulting kinetically unstable 4-halo-2,5-cyclohexadienone usually decomposes after the initial attack. If the starting phenol has a hydrogen atom in the *para* position, the dienone enolizes to the 4-halo product. With *p*-alkylphenols, the initial halogen attack leads to an "*ipso*-dienone". This can be used for further reactions, e.g. Diels−Alder reactions, or it can revert to the starting material through dehalogenation. 4-Alkyl-4-chloro-2,5-cyclohexadienones have previously been isolated by Fischer and Henderson.[16] Steroidal derivatives have been structurally characterized, as have related polyhalogenated compounds.[17] Calix[4]arene $Cax(OH)_4$ itself does not react with $PhICl_2$ under the reaction conditions that lead to **5**, giving an indication of the importance of the metal complex fragment coordinated at the calix[4]arene ligand in determining the outcome of the reaction.

The cyclohexadienone part of the macrocyclic ligand in **5** is the first example of a structurally characterized 4-halo-4-alkyl-2,5-cyclohexadienone in the coordination sphere of a transition metal complex. This moiety is stabilized by the highly Lewis acidic molybdenum(VI) complex fragment. After initial chlorine attack at the negatively charged and therefore activated ring system of the calix[4]arene ligand, the molecule does not regain its aromaticity but remains with an intact cyclohexadienone system, this being stabilized by attack of chlorine at the (positively charged) metal atom.

Experimental Section

General details were as given in our earlier reports.[8] Compounds **1** and **2** were prepared as described previously;[8b] $PhICl_2$ was prepared according to a published procedure.[18]

[$CaxO_4WCl_2$] (3) from [$CaxO_4W(N$*t*Bu)] (2): Gaseous HCl was for a short time passed into a solution of [$CaxO_4W(N$*t*Bu)] (**2**; 200 mg) in CH_2Cl_2 (20 mL), during which the color of the solution changed from yellow to dark red. After stirring for 5 min, all volatile materials were removed in vacuo. The main component of the remaining solid was identified as the known calix[4]arene tungsten complex [$CaxO_4WCl_2$] (**3**).[7d]

[Cax(OH)O_3Mo(N*t*Bu)Cl] (4): [$CaxO_4Mo(N$*t*Bu)] (**1**; 100 mg, 0.123 mmol) and pyHCl (14.0 mg, 0.123 mmol) were taken up in C_6D_6 (1.00 mL) in an NMR tube. The main species present in the resulting violet reaction mixture was identified by ^{1}H NMR spectroscopy as the addition product [Cax(OH)O_3Mo(N*t*Bu)Cl] (**4**). ^{1}H NMR (C_6D_6): δ = 0.69 [s, 18 H, $C(CH_3)_3$], 1.33 [s, 9 H, $C(CH_3)_3$], 1.35 [s, 9 H, $C(CH_3)_3$], 1.40 [s, 9 H, $NC(CH_3)_3$], 3.28 (d, $^2J_{H,H}$ = 13.9 Hz, 2 H, CH_2), 3.52 (d, $^2J_{H,H}$ = 14.7 Hz, 2 H, CH_2), 5.05 (d, $^2J_{H,H}$ = 14.5 Hz, 4 H, CH_2), 6.71 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H, Aryl-H_m), 6.91 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H, Aryl-H_m), 7.24 (s, 2 H, Aryl-H_m), 7.28 (s, 2 H, Aryl-H_m), 15.47 (br. s, 1 H, OH).

Evaporation of the volatiles from the solution led only to the starting material **1**. Compound **4** could also be obtained by the reaction of **1** with a stoichiometric amount of HCl in toluene or benzene.

[$Cax^{Cl}O_4$Mo(N*t*Bu)Cl] (5): A solution of [$CaxO_4Mo(N$*t*Bu)] (**1**; 800 mg, 0.99 mmol) in toluene (40 mL) was treated with $PhICl_2$ (271 mg, 0.99 mmol) and the resulting dark-violet solution was stirred for 8 h at room temperature. All volatile material was then removed in vacuo and the solid residue was extracted into hexane (60 mL). Removal of the solvent and drying in vacuo afforded **5** as a dark-violet solid; yield: 594 mg (68%). Crystals of **5** suitable for X-ray crystallography were obtained from saturated solutions of the compound in hexane. ^{1}H NMR ($CDCl_3$): δ = 1.02 [s, 9 H, $C(CH_3)_3$], 1.12 [s, 18 H, $C(CH_3)_3$], 1.33 [s, 9 H, $C(CH_3)_3$], 1.44 [s, 9 H, $NC(CH_3)_3$], 3.09 (d, $^2J_{H,H}$ = 13.2 Hz, 2 H, CH_2), 3.35 (d, $^2J_{H,H}$ = 14.6 Hz, 2 H, CH_2), 4.04 (d, $^2J_{H,H}$ = 13.2 Hz, 2 H, CH_2), 4.57 (d, $^2J_{H,H}$ = 14.6 Hz, 2 H, CH_2), 6.80 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H, Aryl-H_m), 7.02 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H, Aryl-H_m), 7.04 (s, 2 H, Aryl-H_m), 7.07 (s, 2 H, Aryl-H_m). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 25.87 [$C(CH_3)_3$], 26.24, 28.62, 31.63 [$C(CH_3)_3$], 31.73 [$C(CH_3)_3$], 31.95 [$C(CH_3)_3$], 33.06 (CH_2), 34.06, 34.36 [$C(CH_3)_3$], 35.73 (CH_2), 42.52 [C(*t*Bu)Cl], 73.25 [$NC(CH_3)_3$], 124.42, 125.16, 126.46 (Aryl-C_m), 127.46, 127.56, 127.84, 139.89 (Aryl-C_o), 144.53, 144.88, 145.34 (Aryl-C_p), 148.08 (Aryl-C_m), 167.62, 168.33 (Aryl-C_i), 191.17 (Aryl-C=O). IR (KBr): $\tilde{\nu}$ = 1668 cm^{-1} [vs br, ν(C=O)]. FD-MS (10 kV): *m*/*z* (%) = 885 (78) $[M + 2H]^+$, 815 (31) $[M + H - NC_4H_9]^+$, 792 (100) $[M - C_4H_9 - Cl]^+$. EI-MS: *m*/*z* (%) = 847 (1) $[M - Cl - H]^+$, 813 (4) $[M - 2Cl]^+$, 791 (62) $[M - Cl - C_4H_9]^+$, 735 (27) $[M - Cl - 2(C_4H_9)]^+$. $C_{48}H_{61}Cl_2NO_4Mo$ (882.9): calcd. C 65.30, H 6.96, N 1.59; found C 64.93, H 7.05, N 1.84.

X-ray Crystallographic Study: Data were collected on a Stoe-IPDS diffractometer (Ag-K_α radiation, λ = 0.56087 Å), *T* = 205(2) K;

data collection and refinement: SHELXS-97[19] and SHELXL-97,[20] monoclinic, space group $P2_1/c$; lattice constants a = 17.453(4), b = 13.199(3), c = 23.524(5) Å, β = 96.02(2)°; V = 5389.0(19) Å^3, Z = 4, μ(Ag-K_α) = 0.944 mm^{-1}, $2\Theta_{max}$ = 39°; 9292 independent reflections measured, of which 6564 were considered observed with $I > 2\sigma(I)$; max./min. residual electron density 0.70 and −0.65 e/Å^3. 561 parameters (Mo, O, and N anisotropic; C anisotropic except disordered *t*Bu groups and solvent molecule; the positions of the H atoms were calculated for idealized positions); R_1 = 0.056; wR_2 = 0.1378.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-163977. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge, CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Electron Transfer in Mn-Tripod Complexes

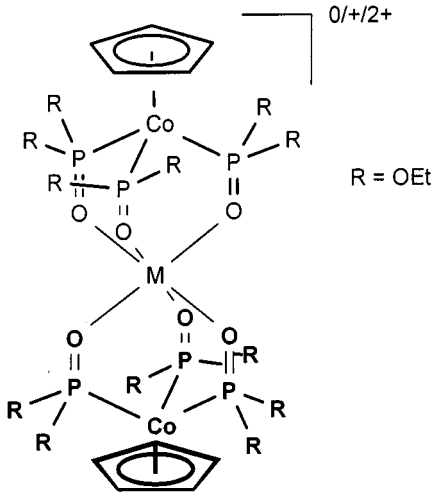
Ulrich Kölle*[a] and Ulli Englert[a]

Keywords: Electrochemistry / Electron transfer / Tripodal ligands / Manganese

A heterogeneous electron-transfer rate constant $k_0 \approx 7–8 \times 10^{-7}$ cm s^{-1} for the reduction/oxidation of the bis-tripod complex $[CpCo^{III}\{P(OEt)_2O\}_3]_2Mn^{III/II}$ redox couple was measured by cyclic voltammetry. The homogeneous self-exchange rate was calculated as $k_2 = 4.25 \cdot 10^{-3}$ M^{-1}s^{-1} from the cross reaction of the Mn^{II} tripod complex with ferrocenium salt. X-ray structure determinations for both complexes showed a near regular octahedral oxygen coordination for the Mn^{II} complex and a sizeable Jahn–Teller distortion for the Mn^{III} complex. Applying current ET theory for the comparison of heterogeneous and homogeneous rates and estimates of reorganization energies leads to the conclusion that the major part of the latter is due to inner reorganization of the Mn tripod.

Introduction

The Kläui Tripod ligand $[CpCo^{III}\{P(OR)_2O\}_3]^-$ (see bold face part in Scheme 1) is unique as a tripodal oxygen ligand as it combines high complex stability constants with a relatively weak ligand field.[1] Thus, nearly all of the main group metals as well as the major part of the d- and f-block elements have been complexed by this ligand in the form of either (Trpd)ML or $(Trpd)_2M$ complexes, where M is fixed in a regular octahedral six oxygen environment. The 3d transition metal complexes are generally high spin with the exception of Co^{III}, which gives rise to a temperature-dependent spin equilibrium,[2–4] which is low spin at low temperatures and partly high spin at higher temperatures.



Scheme 1

These complexes are particularly well suited for redox studies,[5,6] since the ligand $[CpCo^{III}\{P(OR)_2O\}_3]^-$ itself offers a relatively broad potential window where the carrier metal Co^{III} is redox inert. This feature is explored by recording decomposition potentials for $(Trpd)_2M$ complexes featuring a redox-inert central metal. Reduction and oxidation limits depend somewhat on the charge of this central metal and have been determined as −1 and +0.76 V for the reduction and oxidation of the ligand anion $[CpCo\{P(OEt)_2O\}_3]^-$ (as the Na^+ salt), −1 V for $[CpCo\{P(OEt)_2O\}_3]_2Mg$ (reduction only) and −1.75 and +1.75 V for $[(CpCo\{P(OEt)_2O\}_3)_2Al]^+$. Reversible redox transitions for the central metal have been found to occur about 1 V more negative than those of the respective aqua ions $M(H_2O)_6^{3+/2+}$ for a variety of complexes of 3d metals.[5] Since for the latter the $M^{3+/2+}$ potentials become increasingly positive along the d block, tripod complexes allow us to determine redox transitions such as $Mn^{II/III/IV}$ and $Ni^{II/III}$ which are inaccessible for the aqua ions by direct electrochemical measurement. Table 1 lists observed redox transitions in $[CpCo\{P(OEt)_2O\}_3]_2M$ for 3d metals M. As can be clearly seen, a wide potential range is covered

Table 1. Redox transitions in $(Trpd)M^{n+}$ complexes

Electronic configuration	Transition $M^{n+}(L_{OEt})_2/M^{(n\pm1)+}(L_{OEt})_2$	$E_{1/2}$ [a]
d^0/d^1	Ti^{IV}/Ti^{III}	−0.30
d^1/d^2	V^{IV}/V^{III}	0.933
d^2/d^3	V^{III}/V^{II}	−1.54
d^3/d^4	Cr^{III}/Cr^{II}	−1.57
	Mn^{IV}/Mn^{III}	1.53
d^4/d^5	Mn^{III}/Mn^{II}	0.12
d^5/d^6	Fe^{III}/Fe^{II}	−0.72
d^6/d^7	Co^{III}/Co^{II}	0.745
d^7/d^8	Ni^{III}/Ni^{II}	1.255

[a] V vs. SCE in acetonitrile.

[a] Institute for Inorganic Chemistry, Aachen Technical University, 52056 Aachen, Germany

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434–1948/02/0101–0165 $ 17.50+.50/0

by the accessible redox transitions and each electron configuration change d^{n+1}/d^n from $n = 0$ to 8 is represented by at least one redox pair. A second remarkable feature of the tripod complexes is their ready solubility in relatively nonpolar solvents. Thus neutral $(Trpd)_2M$ complexes (with a central metal M^{II}) are soluble in ether, dichloromethane and slightly soluble even in hydrocarbon solvents. Cationic $[(Trpd)_2M]PF_6$ (with a central metal M^{III}) complexes are readily dissolved in acetonitrile.

Due to the fixed geometry of the ligand sphere and the strictly outer-sphere character of the electron transfer, geometrical factors are identical for each of the above listed redox changes. Moreover, since the molecular dimensions of the complexes [about 27 × 23 Å for $P(OEt)_2$ tripod ligands] are rather large and the periphery of the molecule is strongly hydrophobic, solvation terms in the electron transfer process should play a minor role and are strictly identical in all cases. Therefore the differences in rate constants for transitions between different electron configurations reflect the geometrical change as well as an intrinsic barrier for an electron entering or leaving either a dσ or a dπ orbital, as well as electron repulsion and exchange terms.

The work presented here concentrates on the Mn^{II}/Mn^{III} couple as the most noteworthy and unusual redox couple within the bis tripod series.

Results

Heterogeneous Electron Transfer

Among all the redox couples studied the high spin $Mn^{III/II}$ pair is a highly remarkable case. Figure 1 depicts cyclic voltammograms at different scan rates starting either from the Mn^{II} or the Mn^{III} complex as the species in solution. As can be seen there is an extraordinarily large separation between the anodic and cathodic peak: $\Delta E_p = 1.03$ V at v = 50 mV/s to $\Delta E_p = 1.36$ V at v = 1000 mV/s. The much smaller peak height in the return sweep is not due to a chemical follow up reaction but rather to the diffusional broadening of the concentration gradient at the electrode

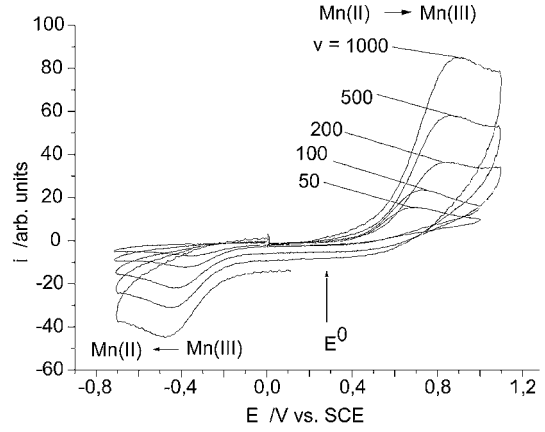


Figure 1. Cyclic voltammogram of $[CpCo\{P(OEt)_2O\}_3]_2Mn^{II}$ in CH_2Cl_2 at different sweep rates, 0.05 to 1.0 V/s

due to the prolonged time elapsed between the forward and the return sweep. The picture is symmetrical in that Mn^{II} oxidation or Mn^{III} reduction is the higher peak depending on the starting complex. This couple is an extreme case of chemically fully reversible non-Nernstian behavior with a very small heterogeneous electron-transfer constant.

The parameters were evaluated by digital simulation using the Gosser program adapted for Windows.[8] The heterogeneous transfer constant k_0 was adjusted mainly so as to match the experimental peak separation, whereas the transfer coefficient α was adjusted to the ratio of the cathodic to the anodic peak current as well as to the width of the peaks. Diffusion coefficients for the tripod couples had been determined previously as $\approx 3 \cdot 10^{-6}$ cm^2 s^{-1}.[8] The cyclic voltammograms recorded at sweep rates above 0.5 V/s require increasingly smaller k_0 values for simulation. This effect is traced back to the influence of uncompensated solution resistance at higher scan rates. Therefore values at $v = 0.05-0.5$ V s^{-1} giving $k_0 = 7-8 \cdot 10^{-7}$ cm s^{-1} are considered most reliable for this Mn^{II}/Mn^{III} couple.

In such cases the mean of the oxidation and reduction peak of the couple cannot simply be taken as the formal redox potential since this assumption is valid only under Nernstian or near Nernstian behavior. This problem was addressed by scrutinizing the oxidation of Mn^{II} with different ferrocenium salts of known reversible redox potential. Thus Mn^{II} is readily oxidized by the ferrocenium ion ($E_{1/2} = 0.400$ V vs. SCE) but not by the decamethylferrocenium ion ($E_{1/2} = -0.168$ V), whereas Mn^{III} does not oxidize ferrocene but does oxidize decamethylferrocene. The redox potential must thus be located between decamethylferrocene and ferrocene. The value for $E_{1/2}$ determined from simulation of the experimental cyclic voltammogram was 0.280 ± 0.008 V vs. SCE referred to $Fc^{+/0}$ vs. SCE as 0.4000 V.

Homogeneous Cross Reaction with Ferrocenium Ion

Direct determination of the self-exchange rate for the Mn tripod couple was not possible due to the lack of suitable signals in the NMR spectrum. Moreover, it was observed with a variety of other tripod couples that self exchange between tripod complexes is rather slow on the NMR time scale and exchange line broadening is small compared to the paramagnetic linewidth. A cross reaction with a transfer agent of known self-exchange rate was therefore sought in order to arrive at an estimate for the Mn self exchange reaction. The ferrocenium ion was found to be best suited for this purpose since its reversible potential is close to the $(Trpd)_2Mn^{III/II}$ potential. Self-exchange rates for the ferrocene/ferrocenium couple are known in a variety of solvents[9] and have been shown to be not very solvent dependent. Moreover, given the redox potential evaluated above, the driving force of the cross reactions is only about $\Delta E^0 = 0.12$ V. This low driving force places the reaction of Mn^{II}-tripod with the ferrocenium ion in a time domain suitable for stopped flow kinetics despite the rather high self-exchange rate of the latter of $\approx 10^7$ M^{-1} s^{-1}. A dichlorome-

thane solution of $(Trpd)_2Mn^{II}$ ($1.0 \cdot 10^{-2}$ M) and ferrocenium chloride ($1.3 \cdot 10^{-2}$ M) was mixed in a stopped flow cell at ambient temperature (22 °C) and the decay of the ferrocenium absorption [Equation (1)] was followed at 618 nm. Evaluation of the kinetic trace according to 2nd order kinetics gave a rate constant k_2 = 1400 s^{-1} M^{-1}.

$$(Trpd)_2Mn^{II} + Fc^+ \rightarrow (Trpd)_2Mn^{III\,+} + Fc \quad (1)$$

Structural Rearrangement Concomitant with Electron Transfer

A high spin d^4 electronic configuration is usually subject to substantial Jahn−Teller distortion. Since this distortion was originally anticipated as one of the principal factors for the exceptionally slow electron transfer in the $(Trpd)_2Mn$ case a quantization of the effect seemed highly desirable. We have thus undertaken single crystal X-ray structure determinations of both Mn complexes. Though bis-tripod complexes have been prepared throughout the transition series,[1] apart from the structure of a tripod-Na salt,[5] structural details of bis-tripod complexes have not been evaluated. The structures determined in this work are therefore the first X-ray structure determinations on bis-tripod complexes. $[CpCo\{P(OEt)_2O\}_3]_2Mn$ readily crystallizes from ether, whereas $[(CpCo^{III}\{P(OEt)_2O\}_3)_2Mn][PF_6] \cdot CH_2Cl_2$ crystallized by diffusion of ether into a dichloromethane solution. The structures were solved by direct methods[10] and refined on F^2.[11] Empirical absorption corrections[12] were applied to both data sets. Parameters for the structure determinations of the Mn^{II} and the Mn^{III} complex are given in Table 2.

$(Trpd)_2Mn^{II}$ crystallizes in the triclinic space group $P\bar{1}$ with two independent molecules in the unit cell. Since the most relevant structural features are expected to occur in the Mn−O bond lengths and angles we concentrate on these. Mn−O bond lengths in the two independent molecules are (three unrelated by symmetry in each molecule) 2.137(7), 2.146(7), 2.160(6) and 2.160(6), 2.155(7), 2.161(7) Å for Mn^{II}. They are nearly equal within the limits of error. The coordination environment of the Mn^{II} ion is a slightly distorted octahedron, with bond angles of 87.6(3) and 92.4(3)°.

The Mn^{III} complex crystallizes in the monoclinic space group *C*2/*c* with the complex molecule on a crystallographic inversion center. As far as Mn−O bond lengths are concerned, three distinctly different distances [1.981(5),

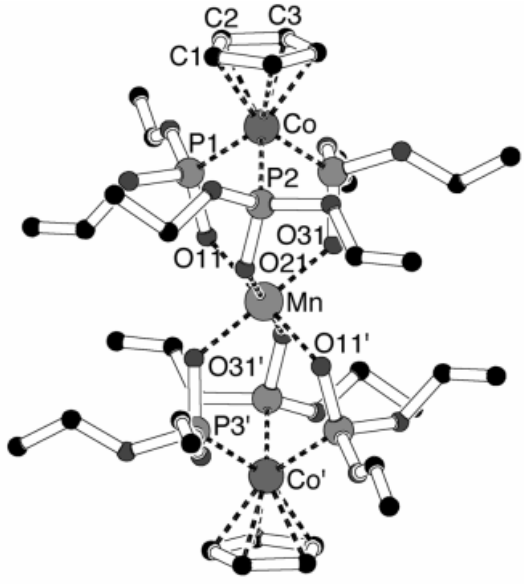

Figure 2. Perspective view of the $[(CpCo\{P(OEt)_2O\}_3)_2Mn]^+$ cation; see text for bond lengths and angles

2.053(4) and 1.923(4) Å] are found. The O−Mn−O bond angles differ only by about 2 °, ranging from 89 to 91°. There is thus a distinct deviation from the octahedral geometry, with each ligand giving rise to three different O−Mn bond lengths. The molecular symmetry of the MO_6 core in $[(Trpd)_2Mn^{III}]^+$ is thus C_i. Figure 2 shows a view of the molecule showing the overall atom connectivity.

Discussion

Comparison of Heterogeneous and Homogeneous Rate Constants

In view of the similarity of homogeneous electron transfer with electron transfer through an interface the rate constants k_{ex} and k_0 for either process of a given redox couple are related, as shown in Equation (2):

$$\frac{k_0}{A_{electrode}} = \left(\frac{k_{ex}}{A_{solution}}\right)^{1/2} \tag{2}$$

The applicability of Equation (2) to practical cases is, however, hampered by the inaccessibility of the frequency factors A.

Weaver[13] has suggested an expression [Equation (3)] that allows a direct comparison of the heterogeneous transfer rate of a redox couple with the rate of a cross reaction between this couple and a second oxidant/reductant:

$Red_1 + Ox_2 \rightarrow Ox_1 + Red_2$

where in our case index 1 refers to the Mn tripod and index 2 to ferrocene. The basic idea is to convert the heterogeneous constant to a pseudo-homogeneous one by treating the electrode as a surface with the dimensions of the coreactant in the bimolecular reaction [first term of the l.h.s. of Equation (3)].

$$\log\left(4\pi N_A r_h^2 k_{0,cor}\right) - \log(k_{ex}) = \log\left(\frac{\kappa_e \delta r_e}{\kappa_h \delta r_h}\right) + \ldots$$
$$\ldots \left[\Delta G^{\#}_{i,2} + \frac{N_A e^2}{4\pi\varepsilon_0}\left(\frac{1}{2r_2} - \frac{1}{(r_1 + r_2)} + \frac{1}{4r_{1-e}}\right)\left(\frac{1}{\varepsilon_{opt}} - \frac{1}{\varepsilon_s}\right)\right] / 2RT \tag{3}$$

In this equation $k_{0,cor}$ is the heterogeneous rate constant corrected for the driving force in the homogeneous reaction (0.12 V), κ a transmission coefficient, δr a reaction zone thickness and r_1, r_2, r_{1-e} are reactant radii and reactant electrode distances, respectively. The second term of the r.h.s. is the inner-shell reorganization of the coreactant (ferrocene) and the difference in outer-shell reorganization of self exchange and cross reaction. In general, κ and δr will be similar for both reactions, and for a fast reacting coreactant $\Delta G^{\#}_{i,2}$ will be small as well as $\Delta G^{\#}_{out}$ ($2r_2 \approx r_1 + r_2 < 4r_{1-e}$), which means that the first term of the r.h.s. vanishes and also that the bracketed term will be small, leading to Equation (4):

$$4\pi N_A r_h^2 k_{0,cor} = k_{ex} \tag{4}$$

Correcting k_0 for the driving force (0.12 V) gives $k_{0,cor} = 7.5 \cdot 10^{-6}$ cm s^{-1} and taking r_h as 27 Å, the radius of the tripod ligand, gives a value of $4.5 \cdot 10^3$ M^{-1} s^{-1} for the r.h.s. of Equation (4) compared to $1.4 \cdot 10^3$ M^{-1} s^{-1} for the measured rate of the cross reaction. Application of Equation (3) gives 3.5 for the r.h.s. as compared to 2.2 for the l.h.s., i.e. one order of magnitude difference. In view of the inherent assumptions, the similarity of the two values demonstrates that the same physical factors are responsible for homogeneous and heterogeneous electron transfer. Thus the very slow heterogeneous rate for the Mn couple is not an "electrochemical" effect

Estimate of the Self-Exchange Rate for the $(Trpd)_2Mn^{+/0}$ Couple

Self-exchange rates from cross reactions can be obtained using Marcus' cross relation [Equation (5)]:[14]

$$k_{12} = (\sqrt{k_{11}} k_{22} K_{12} f_{12}) W_{12} \tag{5}$$

which in the case of a small driving force and largely canceling work terms w_{ij} simplifies to Equation (6):

$$k_{12} \cong (\sqrt{k_{11}} k_{22} K_{12}) \tag{6}$$

Inserting the stopped flow determined value of k_{12} (1400 s^{-1} M^{-1} see above), the value 4.3 10^6 $M^{-1}s^{-1}$ as given for k_{ii}(ferrocene) in dichloromethane,[15] and the driving force of 0.12 V into Equation (6) gives a self exchange rate of $4.25 \cdot 10^{-3}$ $M^{-1}s^{-1}$ for the $(Trpd)_2Mn^{+/0}$ couple. This value signifies a rather slow exchange, surpassed among simple transition metal complexes only by a number of $Co^{II/III}$ couples with amine and pyridine ligands.[16]

Activation and Reorganization Energies

Using transition state theory[17] we may calculate activation and reorganization energies from Equation (7):

$$\frac{k_{obs}}{K_{os}} = k_{ex} = \nu_n \kappa \exp\left(-\frac{\Delta G^{\#}}{RT}\right) \tag{7}$$

Equation (7) is appropriate for homogeneous self exchange where k_{obs} in the domain far from the diffusion limit is directly related to k_{ex} only through the outer sphere complex formation constant K_{os}. In the case of one neutral reactant there will be no coulombic barrier to outer sphere complex formation, so K_{os} reduces to Equation (8):

$$K_{os} = \frac{4\pi N_A r^2 \delta r}{1000} \quad (8)$$

For the Mn tripod couple we set $\kappa = 1$ (adiabatic limit) and the frequency factor $\nu_n = 17.4 \cdot 10^{12}$ s^{-1} from a tentative assignment of a band at 580 cm^{-1} in the IR spectrum of M(tripod)$_2$ complexes to the M−O stretching vibration (a deviation from this value will have little influence on the final result).[18] Taking r = 27 Å and δr = 0.6 Å[19] gives K_{os} = 3.2 M^{-1} and, from Equation (7), $\Delta G^{\#}_{MnMn}$ = 92 kJ/mol.

Alternatively we may set $r^2 = r_{Fc} \cdot r_{Mn} = 3.8 \cdot 27$ Å^2 in Equation (8) for the cross reaction Equation (1) and 0.6 Å for δr, giving K_{os} = 0.46 M^{-1}. Similarly, the introduction of a frequency factor of 10^{13} s^{-1}, as a mean of the values derived for the Mn tripod and ferrocene,[9] and $k_{obs} = 1.4 \cdot 10^3$ M^{-1} s^{-1} in Equation (7) leads to $\Delta G^{\#}_{FcMn}$ = 54 kJ/mol.

For the cross reaction $\Delta G^{\#}$ can be divided into the driving force and reorganization free energy λ according to Equation (9):

$$\Delta G^{\#} = \frac{\lambda}{4}\left(1 + \frac{\Delta G^0}{\lambda}\right)^2 \quad (9)$$

leading to λ = 238 kJ/mol. (for $\Delta G° < \Delta G^{\#}$ and $\lambda \approx \Delta G^{\#}$) which must be compared to the value of approx. 370 kJ/mol for the self exchange reaction. To obtain the inner reorganization energy for the cross reaction from Equation (10):

$$\lambda = \lambda_{in} + \lambda_{out} \quad (10)$$

we estimate the outer (solvent) reorganization part through the familiar expression of Equation (11):

$$\lambda_{out} = \frac{e^2 N_A}{4\pi\varepsilon_0}\left(\frac{1}{2r_{Fc}} + \frac{1}{2r_{Mn}} - \frac{1}{R}\right)\left(\frac{1}{\varepsilon_{opt}} - \frac{1}{\varepsilon_s}\right) \quad (11)$$

where r_{Fe}, r_{Mn} and R are the radii of ferrocene, Mn tripod and intercomplex distance in the transition state, and ε_{opt} and ε_s are the optical (n^2) and static dielectric constants of the solvent (dichloromethane). Inserting the radii as above and taking R as the sum of the reactant radii one obtains λ_{out} = 62.4 kJ/mol (i.e. $\Delta G^{\#}_{out}$ = 15.6 kJ/mol) which is about one quarter of the total reorganization energy of the cross reaction. Since the inner reorganization energy for ferrocene as extracted from ferrocene/ferrocenium self exchange is small ($\Delta G^{\#}_{in}$ = 3.8 kJ/mol[20]) the major part, i.e. about 40 kJ/mol is left as the internal reorganization for the Mn part in the cross reaction. Doubling this value and adding the solvent reorganization energy evaluated through the appropriate version of Equation (11), ($\Delta G^{\#}_{out}$ = 6.4 kJ/mol) one arrives at 86.5 kJ/mol for the self exchange, in fair agreement with the value obtained from the rate calculated for Mn self exchange (92 kJ/mol, see above).

The most relevant species to compare with the tripod complexes are the aqua ions $M(H_2O)_6^{n+}$. In the case of the $Mn(H_2O)_6^{3+/2+}$ couple no direct measurement of the self-exchange rate constant exists. Whereas Diebler and Sutin[21] in earlier work proposed $k_{11} \approx 10^{-4}$ M^{-1}s^{-1} from cross reactions in different acid media, Macartney and Sutin in later work[22] extracted a range of self-exchange constants ranging from 10^{-9} to about 10^{-3} M^{-1}s^{-1} dependent on the partner in the cross reaction. These electron transfer reactions involving the strongly acidic $Mn(H_2O)_6^{3+}$ ion show branched kinetics in the rate law comprising acid dependent and acid independent paths. The nature of the actual transition state therefore cannot be deduced with certainty from the experiments, and neither is the outer sphere character of the redox transitions granted in each case. In spite of these uncertainties $Mn(H_2O)_6^{III/II}$ electron transfer appears to be among the slowest observed for first row transition metal aqua ions.

In view of a value of k_{ex} of $4 \cdot 10^{-3}$ M^{-1} s^{-1} found for the outer sphere tripod-$Mn^{III/II}$ self-exchange rate constant, the greater value of Macartney and Sutin appears as the more probable one since an outer-sphere reaction of the aqua ions should not be slower than that of the much larger tripod complexes.

It may be tempting to trace the rather slow $Mn^{III/II}$ self exchange back to the Jahn−Teller distortion of Mn^{III} and the mean value (0.167 Å) geometric rearrangement accompanying the redox change. However, the X-ray structure determination of a Mn^{III} alum did not reveal such an effect, not even an indication for a dynamic Jahn−Teller distortion.[23] Thus, $Mn^{III/II}$ electron exchange seems to be slow with and without Jahn−Teller distortion. Moreover, ET in other M^{II}/M^{III} tripod couples which can be expected to show similar differences in M−O distances in the two oxidation states is found to be orders of magnitude faster [$\log(k_{het}) \approx 10^{-2}$ cm s^{-1}]. There appears thus to be no simple relationship between the geometry difference of the two oxidation states and the electron transfer rate.

The particular kinetic inertness of the $Mn^{III/II}$ couple in electron transfer is obviously related to the high thermodynamic stability of the Mn^{II} state towards oxidation as well as reduction. This feature dominates the coordination chemistry of Mn^{II} and is even evident in organometallic complexes such as high spin manganocenes.[24] The origin of slow electron transfer kinetics is thus traced back to the destruction of the half-filled d shell, i.e. the loss of exchange energy, when going from Mn^{II} to Mn^{III}, a fact that hitherto has not been considered as a parameter in electron transfer theory.

Experimental Section

Tripod complexes were prepared from $[CpCo\{P(OEt)_2O\}_3]Na$ and the respective metal salt in water or dichloromethane according to ref.[5] Samples of neutral tripod complexes were recrystallized from toluene or diethyl ether and for cationic complexes from dichloromethane/ether. Crystals of $[(CpCo\{P(OEt)_2O\}_3)_2Mn][PF_6]\cdot CH_2Cl_2$ were grown by diffusion of ether into a dichloromethane solution.

Electrochemical measurements were performed using EG&G equipment as previously described.[7] The kinetics of the homogeneous cross reaction was performed with a home-made stopped flow apparatus built around a High-Tech Scientific optical mixing cell and recorded with a J&M Tidas Diode array spectrophotometer taking spectra at 12 ms intervals. At 22 °C a 10^{-2} M solution of $[CpCo\{P(OEt)_2O\}_3]_2Mn$ in CH_2Cl_2 was mixed with an equal volume of a 1.3 10^{-2} M solution of ferrocenium chloride in CH_2Cl_2 giving a final concentration of $5{\cdot}10^{-3}$ and $6.5{\cdot}10^{-3}$ M, respectively. The decay of the ferrocenium absorption at 618 nm was monitored. Under these conditions the reaction had a half-life of 0.84 s. The absorption decay was fitted to second order kinetics leaving k and the initial absorption as adjustable parameters.

Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-162976 for $[CpCo^{III}\{P(OEt)_2O\}_3]_2Mn$ and -162977 for $[(CpCo^{III}\{P(OEt)_2O\}_3)_2Mn][PF_6]{\cdot}CH_2Cl_2$. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[24] We have found high spin Cp_2Mn to be neither reducible nor oxidizable electrochemically in THF between the limits −2.6 and 1.2 V vs. SCE (U. Koelle, unpublished results). In contrast, the low-spin complex Cp^*_2Mn is reported to lead to a stable anion in cyclic voltammetry in spite of the fact that Cp* (η^5-C_5Me_5) ligands shift reduction potentials to more negative values.

Mercury(II) Complexes with Heterocyclic Thiones − Preparation and Characterization of the 1:1 and 1:2 Mercury(II) Complexes with Benzo-1,3-imidazole-2-thione

Zora Popović,*[a] Željka Soldin,[a] Dubravka Matković-Čalogović,[a] Gordana Pavlović,[b] Maša Rajić,[c] and Gerald Giester[d]

Keywords: Mercury / Sulphur heterocycles / Crystal structure / TGA-DTA analysis

A series of complexes $HgX_2(bzimtH_2)$ and $HgX_2(bzimtH_2)_2$ (X = Cl^-, Br^-, I^-, SCN^-; $bzimtH_2$ = benzo-1,3-imidazole-2-thione) was obtained by reaction of the mercury(II) salts with benzo-1,3-imidazole-2-thione in the appropriate molar ratio (1:1 or 1:2). $Hg(bzimtH)_2$ was obtained by the deprotonation of $bzimtH_2$ with mercury(II) acetate (irrespective of the molar ratio of the reactants). The complexes were characterised by chemical and thermal analysis, IR, ^1H, and ^{13}C NMR spectroscopy, and some [$HgX_2(bzimtH_2)$, X = I^- and $HgX_2(bzimtH_2)_2$, X = I^- and SCN^-] by X-ray single crystal diffractometry. ^1H and ^{13}C NMR spectroscopic measurements in dimethyl sulphoxide revealed that the sulphur atom is coordinated to the mercury centre. The greatest complexation effects on the chemical shifts were observed for the thione carbon atom and thioamide proton. The crystal structures of $HgI_2(bzimtH_2)_2$ and $Hg(SCN)_2(bzimtH_2)_2{\cdot}C_2H_5OH$ consist of discrete monomeric molecules with halide or pseudohalide donor atoms and thione sulphur atoms tetrahedrally coordinated to the mercury atom. The structure of $HgI_2(bzimtH_2)$ is polymeric with a trigonal bipyramidal 3 + 2 coordination geometry around the mercury atom. Polymerisation occurs through Hg···I interactions with neighbouring molecules. The distribution of the π-electron density in $bzimtH_2$ corresponds to the thioketo tautomeric form in the solid state, and also in the DMSO solution of the complexes. Intermolecular hydrogen bonds of the type N–H···N, N–H···S and N–H···I are observed.

Introduction

The coordination chemistry of mercury(II) with sulphur-donor ligands is a topic of current research, largely because of the importance of such complexes as structural models in biological systems,[1] and also as solid-state materials.[2] The ability of mercury(II) halides and pseudohalides to form 1:1 and 1:2 complexes with neutral ligands has been known for years.[3,4] The most common neutral donors are phosphane and amine derivatives, and recently heterocyclic thiones.[5−7] Beside such complexes, heterocyclic thiones also give sulphide-like compounds of the type HgL_2 (L = deprotonated thione ligand), by deprotonation.[8,9]

The crystal structures of mercury(II) complexes with heterocyclic thiones revealed the monodentate thione sulphur-donating character of the ligand, although chelation was observed in a few cases.[8,10] The great structural variety of the aforementioned complexes reflects the flexibility of the coordination geometry of mercury. All structures can be regarded as being composed of an inner HgX_2 or HgX_3 unit. In these units the mercury behaves as a Lewis acid and becomes less strongly coordinated to an outer group. This leads to more highly coordinated species, HgX_2L_n or HgX_3L_m, where n is 2, 3 or 4, but m is most commonly 2. It is not fully clear what factors determine the coordination of mercury in such an environment. It is well known that mercury(II) halides form 1:1 or 1:2 complexes with neutral ligands, depending on the molar ratio of the reactants. The crystal structures of the 1:2 complexes usually consist of discrete monomeric molecules with a tetrahedrally coordinated mercury atom (more or less distorted). In contrast, the crystal structures of the 1:1 complexes often involve discrete dimeric molecules, with the mercury atom in a distorted tetrahedral environment.[8,12−16] We have examined a series of such complexes so as to gain an insight into the steric and electronic effects of halide or pseudohalide and heterocyclic thione ligands on the mercury coordination sphere, and into the donor potential towards the mercury atom.[8,11−16]

Continuing with our previous work, we now examine the structural characteristics of the 1:1 and 1:2 mercury(II) halide and mercury(II) thiocyanate complexes with benzo-1,3-

imidazole-2-thione in the solid state and in dimethyl sulphoxide.

Results and Discussion

Mercury(II) complexes $HgX_2(bzimtH_2)$ (**1**−**4**) and $HgX_2(bzimtH_2)_2$ (**5**−**8**) were prepared according to the following general procedure (Scheme 1). A methanol solution of $bzimtH_2$ was added dropwise to a methanol solution of the mercury(II) halide in the appropriate molar ratio. In the preparation of the thiocyanato complexes an ethanol solution was used instead of a methanol solution. Furthermore, due to the photosensitivity of the complexes, the reaction was performed in the dark. The reaction mixtures were left for a few days (with the exception of the thiocyanato complexes which were left for a few weeks), after which crystalline products formed and were filtered off, washed with cold methanol and dried. Complexes **1**−**8** are generally insoluble in common organic solvents, but fairly soluble in solvents with pronounced donor properties such as dimethyl sulphoxide (DMSO), dimethylformamide (DMF), pyridine etc. $Hg(bzimtH)_2$ (**9**) was obtained by treating mercury(II) acetate with $bzimtH_2$ in a 1:2 molar ratio in ethanol. Complex **9** is insoluble in common organic solvents and also insoluble in DMSO, DMF, pyridine, or similar solvents.

Infrared and NMR Spectra

The absence of the ν(S−H) absorption band at 2500 cm^{-1} in the spectrum of free $bzimtH_2$, as well as the presence of the ν(N−H) band confirm that the thione tautomer is the dominant form of the ligand in the solid state (Scheme 2, a). The spectra of **1**−**8** (Table 1) show strong absorption bands in the range 3180−3100 cm^{-1}, corresponding to the ν(N−H) stretching band. A small shift from the bands seen in the spectrum of free $bzimtH_2$ is observed, indicating that the nitrogen atom does not take part in the coordination to the mercury centre. This shift probably results from the variation in the hydrogen-bonding interactions and electronic changes within the ligand on coordination to the mercury ion. Absorption bands which are associated with the C−N vibration mode also show insignificant shifts, suggesting that $bzimtH_2$ is not bonded through the nitrogen atom. Coordination of the metal ion by the nitrogen atom in the thioamide ligands is accompanied by a negative shift of these bands. Such a shift, as well as the negative shift of the ν(N−H) absorption bands, is observed only in the spectrum of **9**, suggesting the existence of mercury and nitrogen interactions. Substitution of sulphur with selenium in $bzimtH_2$ was used to determine the vibrations related to the C−S modes.[17] In the IR spectrum of $bzimtH_2$, the region below 700 cm^{-1} undergoes substantial modification on selenation. Thus, the authors suggested the contribution of the C−S modes to these bands. In the spectra of **1**−**8**, a significant change in intensities and frequencies of these bands was observed, supporting the fact that $bzimtH_2$ is coordinated through the sulphur atom.

Scheme 2. (a) thione tautomer; (b) thiol tautomer; (c) zwitterionic resonance form of the thione tautomer

^1H and ^{13}C NMR spectroscopic data for **1**−**8** in their DMSO solutions are consistent with the finding that the sulphur atom is coordinated to the mercury atom, as previously found for similar mercury(II) complexes with imidazole-2-thione and some of its derivatives.[8,18−20] In the ^1H NMR spectra of $bzimtH_2$ and of complexes **1**−**8** (Table 2), the signals for the thioamide N−H protons (1-,3-H) are observed in the range δ = 12.50−13.90 (numbering of the carbon atoms is displayed in Scheme 2). The absence of the signal for the thiol proton (−SH, δ ≈ 3.5) in the ^1H NMR

spectrum of free $bzimtH_2$ confirms that the thione tautomer is the dominant form in the DMSO solution and also in the solid state.[17,21] The ^1H NMR spectra also show that the 1- and 3-H protons are more deshielded in the complexes by δ = 1.40−1.81, than in the free thione molecule. The deshielding occurs as a result of the positive charge in the imidazole ring and the stronger hydrogen bonding in the complexes than in the free $bzimtH_2$. Broadening of the N−H signal in the complexes also supports hydrogen bonding. For all other protons, small complexation effects are detected, due to their greater distance from the binding site. For the thiocyanato complexes, the N−H resonance is not discernible due to strong hydrogen bonding. Additional evidence with regard to the coordination site in complexes **1−8** is provided by the ^{13}C NMR spectra (Table 3). The greatest change in the chemical shift was found for the thione carbon (C-2) signal, which shifts from δ = 7.10 to δ = 12.70. These upfield shifts are consistent with the reduction of the π-electron density in the exocyclic carbon−sulphur bond, which occurs as a result of the *S*-bonded $bzimtH_2$.

[a] Complexation shift is defined as the ^{13}C chemical shift difference of corresponding nuclei in the complex and in the free thione molecule.

Crystal Structures of 3, 7, and 8

Crystal Structure of $HgI_2(bzimtH_2)$ (3)

In the structure of **3**, the mercury atom is coordinated by two iodine atoms [Hg−I1 2.676(1) and Hg−I2 2.816(1) Å] and one sulphur atom from $bzimtH_2$ [Hg−S1 2.467(2) Å]. It has a distorted trigonal geometry (Figure 1, Table 4). The Hg−I1 bond is shorter than the sum of the covalent radii for the trigonal mercury and iodine atoms (1.39 + 1.33 Å),[22,23] while Hg−I2 is longer, since I2 acts as the bridging atom. Further, in the structure of $HgI_2(imtH_2)$[8] ($imtH_2$ = 1,3-imidazole-2-thione), the Hg−I(terminal) distance is shorter [2.6518(7) Å] and closer to the value for linear mercury coordination (2.63 Å), while the Hg−I(bridging) distance is very similar [2.8187(7) Å] (Table 5). A similar trigonal coordination pattern is found in the structure of $HgI_2(H_4pymtH)$[16] (H_4pymtH = 3,4,5,6-tetrahydropyrimidine-2-thione), where the thione ligand contains a saturated heterocyclic ring. The analogous Hg−I bond lengths are 2.6872(7) and 2.7044(6) Å, respectively. The Hg−S bond in

3 is slightly longer than the sum of the covalent radii for trigonal Hg and S atoms (2.43 Å).[22,23] It is longer, but not significantly, than the corresponding bond in $HgI_2(imtH_2)$ [2.460(2) Å].

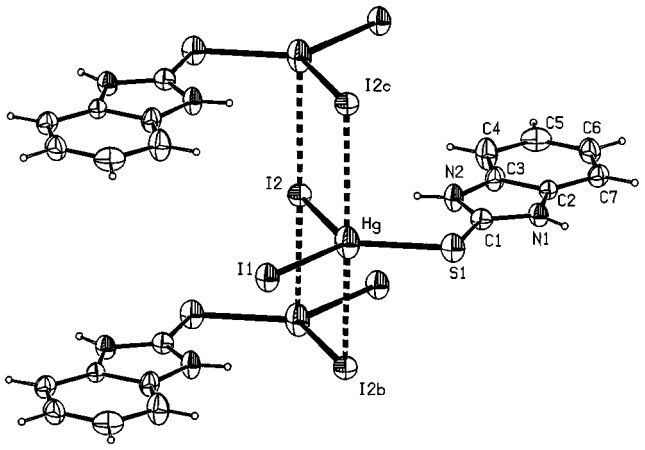

Figure 1. ORTEP drawing of di-μ-iodobis[iodo(benzo-1,3-imidazolium-2-thiolato-*S*)mercury(II)] (**3**), with the atom numbering scheme; the Hg···I contacts are drawn by dashed lines indicating trigonal pyramidal coordination around the mercury centre; symmetry transformation used to generate equivalent atoms: (b) = 1/2 − *x*, *y* − 1/2, 1 − *z* and (c) = 1/2 − *x*, *y* + 1/2, 1 − *z*; the thermal ellipsoids are at the 50% probability level at 200 K

Distortion of the trigonal geometry is determined by the bond angles, which are in the range from 112.94(4) to 127.34(6)°. The largest angle is that of S1−Hg−I1, and is accompanied by the short Hg−I1 bond length. In HgI_2(-$imtH_2$), where the Hg−I bond is shorter than that in **3**, the S−Hg−I angle is greater [134.63(5)°].

The number of atoms coordinated to mercury increases to five through Hg···I interactions with two neighbouring molecules which are related by mirror plane symmetry, thus effectively forming a trigonal-bipyramidal coordination sphere around the mercury centre, elongated in the axial direction [Hg···$I2^i$ 3.3774(6) Å; *i* = 1/2 − *x*, −1/2 + *y*, 1 − *z*]. By these interactions polymeric chains parallel to the *b* axis are formed. In $HgI_2(imtH_2)$ and $HgI_2(H_4pymtH)$, the mercury atom is disordered and is forced out of the mirror plane in order to form Hg···I contacts with distances of 3.486(1) and 3.517(3) Å, respectively. The distance to the other neighbouring I is very long (> 3.9 Å). While describing these two structures, we commented that if the mercury atom was in the mirror plane the distance to the neighbouring iodine atoms would be close to 3.7 Å which, in our opinion, would not be shorter than the sum of the van der Waals radii for Hg (1.55 to 1.65 Å)[24,25] and I (1.98 Å).[25] Therefore, only the 3 + 1 coordination was possible. The short Hg···I contacts and the 3 + 2 coordination in **3** are in support of our values.

In complex **3**, the larger $bzimtH_2$ allows shorter Hg···I contacts as a result of the hydrogen-bonding pattern. In the structure of $HgI_2(imtH_2)$,[8] only N−H···S intermolecular hydrogen bonds are formed (Table 5), while in **3** hydrogen bonds of the type N−H···I are observed, with values of 3.586(7) Å for the intramolecular, and 3.807(9) Å for the intermolecular hydrogen bonds (Table 6). We believe that the strength of Hg···I contacts in **3** is also influenced by the

extended π-delocalized ring system in $bzimtH_2$, which in comparison with the five-membered aromatic ring in $imtH_2$ and also with the saturated ring in H_4pymtH, enables a better π-stacking assembly of the ligand molecules. The stacking occurs along the *b* axis. Centrosymmetrical dimers parallel to the *ac* plane are formed through intermolecular hydrogen bonds. The intermolecular hydrogen bonds and Hg···I contacts interconnect molecules of **3** into a 2D network parallel to the *ab* plane (Figure 2).

Crystal Structure of $HgI_2(bzimtH_2)_2$ (7)

The molecular structure of **7** reveals a tetrahedrally coordinated mercury atom, with two thione sulphur atoms [Hg−S1 2.612(2) and Hg−S2 2.640(3) Å] and two covalently linked iodine atoms [Hg−I1 2.7204(8) and Hg−I2 2.6970(9) Å] (Figure 3). The Hg−S bond lengths are longer than the sum of covalent radii for tetrahedral Hg and S atoms (2.52 Å), but the Hg−I bond lengths are significantly shorter than 2.81 Å (1.48 + 1.33 Å).[22,24]

The tetrahedral environment is distorted since the bond angles are in the range from 88.36(8) to 124.43(3)° for S1−Hg−S2 and I1−Hg−I2, respectively. The largest bond angle is seen for the strong bonds formed with the iodine atoms.[14,16,20] In the structure of an analogous iodo derivative, $HgI_2(meimtH_2)_2$, the Hg−S distances are shorter and the Hg−I distances are longer than in **7** (Table 5).[14,20] This

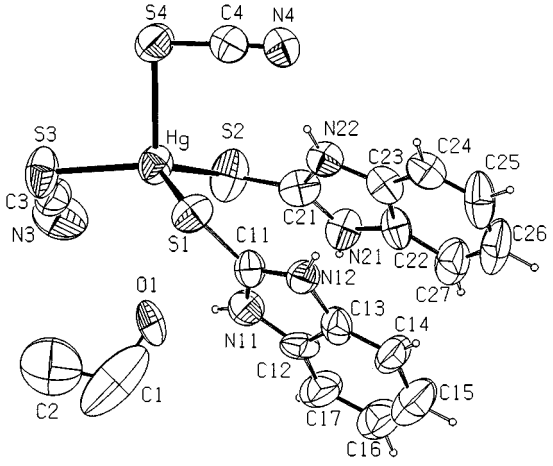

Figure 5. ORTEP drawing of the 1:1 ethanol solvate of bis[thiocyanato(benzo-1,3-imidazolium-2-thiolato-*S*)]mercury(II) (**8**), with the atom numbering scheme; the thermal ellipsoids are at the 50% probability level at 293 K

is caused by different intermolecular interactions. In both structures (obtained at 293[14] and at 160 K[20]), the NH groups of the imidazole ring take part in the intra- and intermolecular hydrogen bonds of the type N−H···I, and are in the range 3.586−3.611(9) Å. In **7**, the N−H···I hydrogen bonds are slightly longer (Table 6). Furthermore, in **7** there is an intermolecular bond of the type N−H···S with a length of 3.339(8) Å, and a longer intramolecular bond with a length of 3.553(8) Å (Table 6, Figure 4), while in $HgI_2(meimtH_2)_2$ such hydrogen bonds do not exist at all.

Crystal Structure of $Hg(SCN)_2(bzimtH_2)_2$·EtOH (8)

The less accurate geometrical parameters of **8** are associated with the significant intensity decay due to crystal decomposition under X-rays (see Exp. Sect.). The mercury atom is coordinated by two sulphur atoms of $bzimtH_2$ [Hg−S1 2.499(6) and Hg−S2 2.508(6) Å] and two sulphur atoms of SCN^- [Hg−S3 2.500(5) and Hg−S4 2.680(6) Å], thereby having a deformed tetrahedral geometry (Figure 5). The bond angles around the mercury centre range from 97.1(2)° for S3−Hg−S4, to 119.3(2)° for S1−Hg−S3. The Hg−S(thione) bond lengths are comparable with those observed in the structures of $Hg(SCN)_2(H_4pymtH)_2$[13] and the two polymorphs of $Hg(SCN)_2(pySH)_2$ (pySH = pyridine-2-thione)[11] [the bond ranges are 2.458(1)−2.526(2) Å for Hg−S(thione) bonds, and 2.556(2)−2.685(2) Å for Hg−S(SCN) bonds in these three structures].

The Hg−S1, Hg−S2, as well as the Hg−S3 bond in **8** are shorter than the sum of covalent radii for tetrahedral Hg and S atoms. This is an unexpected result for the Hg−S3 bond. In contrast, the Hg−S4 bond is among the longest ones found so far, but still in the range of the Hg−S(SCN) bonds. This could be due to the involvement of the N4 atom as a proton acceptor in both intra- and intermolecular N−H···N hydrogen bonds with the NH groups from $bzimtH_2$, while N3 participates only in one intermolecular hydrogen bond (Table 6).

Besides intra- and intermolecular N−H···N hydrogen bonds, an intermolecular N−H···O hydrogen bond, with a length of 2.82(3) Å (Table 6), forms between the complex and the ethanol molecules (Figure 6).

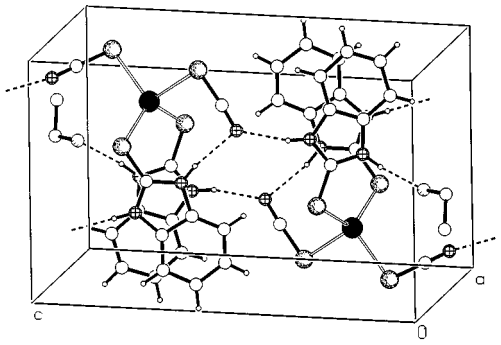

Figure 6. The crystal packing of **8**; dashed lines indicate intermolecular N−H···N and N−H···O hydrogen bonds between complex molecules and complex molecule and ethanol, respectively

Geometry of bzimtH$_2$ in 3, 7, and 8

The crystal structure of bzimtH$_2$ reveals a thioketo C=S bond length of 1.684(3) Å.[21] Such a bond possesses approx. 58% of the π-bond character. On complexation, the C=S bond exhibits a decrease in the π-bond character, to approx. 40%.[26]

The C−N bond lengths in all three complexes are similar to those in the free ligand,[21] with shorter C−N bonds involving the thioketo C atom and longer C−N bonds involving the C atoms common to the five- and six-membered ring. All C−N bonds are shorter than the theoretical C−N single bond length of 1.47 Å, and longer than the C=N double bond length of 1.27 Å (Table 4).[27]

The internal bond lengths, as well as the planarity of the bzimtH$_2$ molecule, strongly confirm that the aromatic character of the imidazole ring is preserved in the mercury(II) complexes, and suggest that the zwitterionic resonance form participates in the structure of the ligand (Scheme 2, c).

Thermal Analysis (TGA-DTA)

The samples of bzimtH$_2$ and **1**−**9** were heated from room temperature to 700 °C. Thermal data are summarised in Table 7. The DTA curve of free bzimtH$_2$ shows a single and broad endothermic peak at 300 °C that corresponds to its degradation.

The DTA and TGA curves for **1**−**8** essentially show two degradation processes. The TGA profile for these compounds suggests that bzimtH$_2$ is lost first (two endothermic overlapping peaks), and degradation of the mercury(II) halide or pseudohalide follows (determined by the third endothermic peak). Some of the complexes undergo melting as presented in Table 7. The relatively high melting points of these compounds suggest the presence of strong intermolecular bonding. The observed mass losses for the aforementioned processes are in good agreement with the calculated ones. The DTA curve for **9** shows three processes. Both endothermic minima at 240 °C and 290 °C, with a corresponding mass loss of 46.58%, represent degradation of the ligand due to the breaking of the C−S bond. Decomposition of the residue starts at 390 °C.

Experimental Section

Materials and Physical Measurements: Mercury(II) halides and benzo-1,3-imidazole-2-thione were used as received from Aldrich

Table 7. Thermoanalytical data for benzo-1,3-imidazole-2-thione and its mercury(II) complexes

without further purification. Mercury(II) thiocyanate was prepared by the reaction of mercury(II) nitrate monohydrate and ammonium thiocyanate. The mercury content in the complexes was determined by complexometric titration, with sodium diethyl dithiocarbamate, of the solution obtained after decomposition of the specimen in aqua regia.[28] CHNS analyses were performed in the Analytical Services Laboratories of the Institute Ruder Boškovic. The IR spectra were obtained from KBr pellets in the range 4000−450 cm^{-1} with a Perkin−Elmer FTIR 1600 spectrometer. The ^1H and ^{13}C NMR spectra were measured with a Varian Gemini 300 spectrometer, operating at 75.46 MHz for the ^{13}C nucleus. The samples were dissolved in [D_6]DMSO in 5-mm NMR tubes. The concentration was 0.05 M for ^1H NMR measurements and 0.25 M for the ^{13}C NMR measurements. Spectra were recorded at 20 °C. Chemical shifts (ppm) were referred to TMS. Digital resolution was 0.32 Hz per point in ^1H and 0.70 Hz per point in the ^{13}C one-dimensional spectra. The thermal measurements were performed using a simultaneous TGA-DTA analyser (TA Instruments, SDT Model 2960 coupled with MS). The samples were placed in small alumina sample pans. The TGA and DTA curves were obtained by placing the samples (approximately 2 mg in mass) in open sample pans, with a heating rate of 10 °C/min and nitrogen (purity > 99.996%) flowing at a rate of 50 mL/min. The SDT was calibrated with indium.

$HgCl_2(bzimtH_2)$ (1): A solution of benzo-1,3-imidazole-2-thione (0.25 g, 1.66 mmol) in 20 mL of methanol was added dropwise to a solution of mercuric chloride (0.4 g, 1.47 mmol) in 10 mL of methanol. A pale pink crystalline product was obtained the following day, which was filtered off, washed with cold methanol and dried in air. Yield: 0.50 g (81%). $C_7H_6Cl_2HgN_2S$ (421.7): calcd. C 19.92, H 1.42, Hg 47.57, N 6.64, S 7.59; found C 20.25, H 1.61, Hg 47.82, N 6.64, S 7.50.

$HgBr_2(bzimtH_2)$ (2): A solution of benzo-1,3-imidazole-2-thione (0.19 g, 1.26 mmol) in 20 mL of methanol was added dropwise to a solution of mercuric bromide (0.4 g, 1.11 mmol) in 10 mL of methanol. A pale yellow crystalline product was obtained the following day, which was filtered off, washed with cold methanol and dried in air. Yield: 0.45 g (79%). $C_7H_6Br_2HgN_2S$ (510.6): calcd. C 16.45, H 1.18, Hg 39.29, N 5.48, S 6.27; found C 17.07, H 1.06, Hg 39.58, N 5.41, S 6.35.

$HgI_2(bzimtH_2)$ (3): A solution of benzo-1,3-imidazole-2-thione (0.15 g, 0.99 mmol) in 10 mL of methanol was added dropwise to a solution of mercuric iodide (0.4 g, 0.88 mmol) in 20 mL of methanol. After a few days, the yellow crystals were filtered off, washed with cold methanol and dried in air. Yield: 0.50 (94%). $C_7H_6I_2HgN_2S$ (604.6): calcd. C 13.89, H 0.99, Hg 33.18, N 4.63; found C 14.38, H 1.54, Hg 33.32, N 5.22.

$Hg(SCN)_2(bzimtH_2)$ (4): A solution of benzo-1,3-imidazole-2-thione (0.21 g, 1.40 mmol) in 20 mL of 96% ethanol was added dropwise to a solution of mercuric thiocyanate (0.4 g, 1.26 mmol) in 120 mL of 96% ethanol. The reaction mixture was left in the dark due to the photosensitivity of the complex. After a few weeks, the yellow crystalline product was filtered off, washed with cold ethanol and dried in air. Yield: 0.36 g (61%). $C_9H_6HgN_4S_3$ (466.9): calcd. C 23.13, H 1.28, Hg 42.96, N 11.99, S 20.56; found C 23.08, H 1.49, Hg 43.27, N 11.88, S 20.58.

$HgCl_2(bzimtH_2)_2$ (5): A solution of benzo-1,3-imidazole-2-thione (0.49 g, 3.26 mmol) in 40 mL of methanol was added dropwise to a solution of mercuric chloride (0.4 g, 1.47 mmol) in 10 mL of methanol. A pale pink crystalline product was obtained the following day, which was filtered off, washed with cold methanol and dried in air. Yield: 0.62 g (74%). $C_{14}H_{12}Cl_2HgN_4S_2$ (571.9): calcd. C 29.38, H 2.10, Hg 35.08, N 9.79, S 11.19; found C 29.72, H 2.48, Hg 35.27, N 9.65, S 11.24.

$HgBr_2(bzimtH_2)_2$ (6): A solution of benzo-1,3-imidazole-2-thione (0.37 g, 2.46 mmol) in 30 mL of methanol was added dropwise to a solution of mercuric bromide (0.4 g, 1.11 mmol) in 10 mL of methanol. After a few days, the pale pink crystalline product was filtered off, washed with cold methanol and dried in air. Yield: 0.61 g (84%). $C_{14}H_{12}Br_2HgN_4S_2$ (660.8): calcd. C 25.42, H 1.82, Hg 30.36, N 8.47, S 9.69; found C 25.57, H 2.23, Hg 30.81, N 8.25, S 9.56.

$HgI_2(bzimtH_2)_2$ (7): A solution of benzo-1,3-imidazole-2-thione (0.29 g, 1.93 mmol) in 20 mL of methanol was added dropwise to a solution of mercuric iodide (0.4 g, 0.88 mmol) in 20 mL of methanol. After a few days, the yellow crystals were filtered off, washed with cold methanol and dried in air. Yield: 0.28 g (42%). $C_{14}H_{12}I_2HgN_4S_2$ (754.8): calcd. C 22.26, H 1.59, Hg 33.20, N 7.45; found C 22.00, H 1.79, N 8.60, Hg 33.70.

$Hg(SCN)_2(bzimtH_2)_2$·EtOH (8): A solution of benzo-1,3-imidazole-2-thione (0.42 g, 2.80 mmol) in 20 mL of 96% ethanol was added dropwise to a solution of mercuric thiocyanate (0.4 g, 1.26 mmol) in 120 mL of 96% ethanol. The reaction mixture was left in the dark due to the photosensitivity of the complex. After a few weeks, the pale yellow crystals were filtered off, washed with cold ethanol and dried in air. Yield: 0.55 g (71%). Since the crystals lose ethanol on standing, especially on grinding, analysis of the non-solvated sample has been carried out. $C_{16}H_{12}HgN_6S_4$ (617.1): calcd. C 31.11, H 1.94, Hg 32.50, N 13.61, S 20.74; found C 31.25, H 2.57, Hg 32.75, N 13.51, S 20.80.

$Hg(bzimtH)_2$ (9): A solution of benzo-1,3-imidazole-2-thione (0.41 g, 2.73 mmol) in 30 mL of methanol was added dropwise to a solution of mercuric acetate (0.4 g, 1.26 mmol) in 30 mL of methanol. The colourless crystalline product was filtered off, washed with cold methanol and dried in air. Yield: 0.51 g (81%). $C_{14}H_{10}HgN_4S_2$ (499.0): calcd. C 33.67, H 2.00, Hg 40.20, N 11.27, S 12.88; found C 33.02, H 2.52, Hg 40.25, N 11.00, S 12.80.

X-ray Crystallographic Structure Determination of 3, 7, and 8: Single-crystal X-ray diffraction data were collected for **3**, **7**, and **8** using Mo-K_α radiation (graphite monochromator). Data for the small crystals of **3** were collected with a Nonius Kappa CCD diffractometer (capillary optics) at 200 K, while those of **7** and **8** were collected at room temperature with the Philips PW1100 diffractometer. Crystal data and details of the data collection and refinement procedure are given in Table 8. The unit-cell parameters were obtained by the least-squares refinement procedure of the setting angles of well-centred reflections: 35 in the range $10.0° \leq \theta \leq 15.1°$ for **7**, 42 reflections in the range $10.0° \leq \theta \leq 16.5°$ for **8**, and of all reliable data in the structure of **3**. Data reduction was done by the Denzo-SMN program[29] for **3** and by the STADI4 program[30] for **7** and **8**. Due to the significant crystal decay of **8** under X-ray exposure (approx. 30% in 2 d), a reliable data set for the structure refinement was obtained from 3 crystals. Data were corrected for the Lorentz polarisation and absorption effects and then scaled. The numerical Gaussian method for absorption correction based on crystal dimensions was applied for **7** and **8** by the X-RED program,[31] while for **3**, a semi-empirical method was applied by XEMP.[32] The non-H atoms of the ethanol molecule in **8** exhibit large thermal displacement parameters due to crystal decay. The freshly prepared crystals could be described as a 1:1 ethanol solvate, but after the data collection procedure only half of the ethanol molecule is found within the asymmetric unit. The geometry of the

Table 8. EtOH molecule (C−C and C−O bonds and C−C−O angle) has been modelled with restraints. All structures were solved by direct methods in SHELXS,[33] and refined by the least-squares procedure with anisotropic thermal parameters for non-H atoms by the SHELXL97 program.[34] The hydrogen atoms were placed at calculated positions and refined by the riding model [Csp^2−H 0.93 Å; Nsp^2−H 0.86 Å; with U_{iso}(H) = 1.2 U_{eq}]. The molecular geometry calculations and drawings were performed by PLATON.[35] Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-162383−162385 for complexes **3**, **7**, and **8**, respectively. A Congested $Ru(dps)_2$ or $Ru(dprs)_2$ Core (dps = di-2-pyridyl sulfide; dprs = di-2-pyrimidinyl sulfide) Promotes Sulfur Inversion of *N*,*S*-Chelate Thioethers Containing CH_2R and 2-Pyridyl or 2-Pyrimidinyl Groups

Giuseppe Tresoldi,*[a] Sandra Lo Schiavo,[a] Santo Lanza,[a] and Paola Cardiano[a]

Keywords: Ruthenium / N ligands / S ligands / Sulfur inversion / Activation barriers

The thioethers L [L = 4-methylbenzyl 2-pyridyl sulfide (**L_1**), 4-chlorobenzyl 2-pyridyl sulfide (**L_2**), 3-chlorobenzyl 2-pyridyl sulfide (**L_3**), 1,4-bis(2-pyridylthiomethyl)benzene (**L_4**), 4-methylbenzyl 2-pyrimidinyl sulfide (**L_5**), and 4-chlorobenzyl 2-pyrimidinyl sulfide (**L_6**)], containing a CH_2R group bonded to the sulfur atom, were prepared and characterized. Compounds **L_1**, **L_2**, **L_3**, and **L_4** reacted with *cis*-Ru(*N*,*N*-dprs)$_2$Cl$_2$ or *cis*-Ru(*N*,*N*-dps)$_2$Cl$_2$ (dprs = di-2-pyrimidinyl sulfide, dps = di-2-pyridyl sulfide) leading to the complexes [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-L)][PF$_6$]$_2$ and [Ru(*N*,*N*-dps)$_2$(*N*,*S*-L)][PF$_6$]$_2$. Similar products were obtained from [Ru(*N*,*N*-dps)$_2$(NO$_2$)(NO)][PF$_6$]$_2$ and **L_5** or **L_6**. As a consequence of the L ligand *N*,*S*-chelation, all the complexes contain the four-membered ring RuSCN(*Ru*–*N*). Since the ruthenium and sulfur atoms are stereogenic centres, with Δ and Λ, and *R* and *S* configurations, respectively, they led to four isomers, including the enantiomers. NMR investigations show that the sulfur inversion produces an exchange between the diastereoisomers Δ*R* and Δ*S*, as well as Λ*S* and Λ*R*. The one-dimensional band-shape analysis of the exchanging methylene proton signals showed that the inversion barriers ($\Delta G^{\ddagger}_{298\,K}$) for the dprs complexes are in the 54.9–53.8 kJ mol^{-1} range, with the two invertomers exhibiting similar abundance. Substitution of dprs with dps affects the relative invertomer population leaving the magnitude of $\Delta G^{\ddagger}_{298\,K}$ (52.0–50.6 kJ mol^{-1}) practically unchanged. Conversely, the substitution of the pyridine thioethers (**L_1**, **L_2**) with pyrimidine thioethers (**L_5**, **L_6**) influences the inversion barriers, and $\Delta G^{\ddagger}_{298\,K}$ values of 47.5 and 47.0 kJ mol^{-1} were found for [Ru(*N*,*N*-dps)$_2$(*N*,*S*-**L_5**)][PF$_6$]$_2$ and [Ru(*N*,*N*-dps)$_2$(*N*,*S*-**L_6**)][PF$_6$]$_2$, respectively. An intramolecular mechanism without any bond rupture is suggested on the basis of the $\Delta S^{\ddagger}$ values (negative or close to zero) and the NMR spectra, temperature-reversible and concentration-independent. The contemporary presence of the congested Ru(*N*,*N*-dps)$_2$ or Ru(*N*,*N*-dprs)$_2$ core and sterically demanding *N*,*S*-coordinated thioether ligands is invoked to explain the low energy barrier of the process. This hypothesis is also corroborated by the different behaviour observed for the complex [Ru(bipy)$_2$(*N*,*S*-**L_1**)][PF$_6$]$_2$.

Introduction

The chemistry of the ruthenium compounds containing 2,2′-bipyridine (bipy), polypyridine and similar ligands has been thoroughly explored over many years. This interest has stemmed mainly for the relevance of this chemistry to photophysical, photochemical, and redox phenomena.

Recently we have focused our attention on the bipy or bipy-like ruthenium(II) complexes in which one or more ligands are replaced by di-2-pyridyl sulfide (dps) or other bipy-like nonplanar ligands,[1−3] with the aim of modifying the chemical and physical properties of the complexes.

The dps ligand can in principle exhibit a variety of bonding modes to metal ions: *N*- or *S*-monodentate, *N*,*N*- or *N*,*S*-chelate and *N*,*N*- or *N*,*S*-bridging. However, normally it functions as an *N*,*N*-chelate ligand, adopting a twisted *N*,*N*-inside conformation.[1−11] The control of the coordination mode of this and similar ligands may be achieved by opportune choice of the starting complex. The complexes Ru(diimmine)$_2$Cl$_2$ (diimmine = bipy or 1,10-phenanthroline or similar ligands) are expected to favour the *N*,*N*-chelation,[12−14] whereas Ru(dps)$_2$Cl$_2$ or other sterically hindering diimmines are expected to give species in which dps exhibits a different bonding mode.[15,16]

As proof of this, the *cis*-Ru(bipy)$_2$ fragment favours the *N*,*N*-chelation of dps,[1] whereas the congested *cis*-Ru(*N*,*N*-dps)$_2$ fragment prevents the *N*,*N*-chelation and leads to *N*,*S*-coordinated dps complexes.[17] The crystal structure of [Ru(*N*,*N*-dps)$_2$(*N*,*S*-dps)][PF$_6$]$_2$·H$_2$O[17] clearly shows the distortion of the RuSCN(*Ru*−*N*) ring as well as the steric hindrance effect on the *N*,*S*-coordinate ligand. [The four-membered ring and the coordinated pyridine ring are almost coplanar whereas the pendant pyridine is rotated by 113.9(2)°.] The above complex and the similar species [Ru(*N*,*N*-dps)$_2$(*N*,*S*-phpys)][PF$_6$]$_2$ and [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-phpys)][PF$_6$]$_2$ (phpys = phenyl pyridyl sulfide; dprs = di-2-pyrimidinyl sulfide), as a consequence of the *N*,*S*-coordination, exhibit a sulfur stereogenic centre (*R* and *S* configura-

tions) and a pendant ring. The ^1H and ^{13}C NMR spectra were temperature-dependent and the fluxionality of the complexes was interpreted in terms of restricted rotation of the pendant rings and inversion at the sulfur atom. However, only an estimation of the activation energy data for the restricted rotation was possible due to the complex splitting patterns of the proton signals of the coordinated and pendant rings and the numerous partial overlaps of these signals.

In order to elucidate the mechanism of the sulfur inversion, in this paper we report on the synthesis of a series of the novel thioethers [4-methylbenzyl 2-pyridyl sulfide (**L$_1$**), 4-chlorobenzyl 2-pyridyl sulfide (**L$_2$**), 3-chlorobenzyl 2-pyridyl sulfide (**L$_3$**), 1,4-bis(2-pyridylthiomethyl)benzene (**L$_4$**), 4-methylbenzyl 2-pyrimidinyl sulfide (**L$_5$**), and 4-chlorobenzyl 2-pyrimidinyl sulfide (**L$_6$**)] containing sulfur-bonded CH_2R groups. We also report on their coordination chemistry that leads to the formation of the complexes [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-L)][PF_6]$_2$, and [Ru(*N*,*N*-dps)$_2$(*N*,*S*-L)][PF_6]$_2$.

These tris(chelated) ruthenium complexes containing the *N*,*S*-coordinated thioethers exist as the enantiomers Δ and Λ, and in presence of the stereogenic sulfur atom (configuration *S* and *R*) four isomers can exist (Δ*S*, Δ*R*, Λ*S* and Λ*R*). When the thioether is *N*,*S*-chelated, the two methylene protons of the CH_2R group bonded to the sulfur atom are anisochronous. Their ^1H NMR signals are well separated by other signals and very sensitive to the inversion and racemisation processes.

By NMR studies in acetone two exchanging diastereoisomers were identified and the inversion at the sulfur atom examined. The complex [Ru(bipy)$_2$(*N*,*S*-**L$_1$**)][PF_6]$_2$ was also prepared and, in contrast to the other complexes, its NMR spectra, in the range 200−330 K are temperature-independent and show the presence of two non-exchanging isomers.

Results

Synthesis and Characterization of the 4-Methylbenzyl 2-Pyridyl Sulfide (L$_1$), 4-Chlorobenzyl 2-Pyridyl Sulfide (L$_2$), 3-Chlorobenzyl 2-Pyridyl Sulfide (L$_3$), 1,6-Bis(2-pyridylthiomethyl)benzene (L$_4$), 4-Methylbenzyl 2-Pyrimidinyl Sulfide (L$_5$), and 4-Chlorobenzyl 2-Pyrimidinyl Sulfide (L$_6$)

The novel thioether ligands were prepared by heating equimolar amounts of the appropriate mercapto and bromide derivative [2-sulfanylpyridine and 4-methylbenzyl bromide (**L$_1$**) or 4-chlorobenzyl bromide (**L$_2$**) or 3-chlorobenzyl bromide (**L$_3$**), 2-sulfanylpyrimidine and 4-methylbenzyl bromide (**L$_5$**), or 4-chlorobenzyl bromide (**L$_6$**)] in the presence of K_2CO_3 under reflux in DMF under N_2. Compound **L$_4$** was prepared from 2-sulfanylpyridine and α,α′-dichloro-*p*-xylene (or 2-bromopyridine and α,α′-disulfanyl-*p*-xylene) in a molar ratio of 2:1. The DMF was removed by distillation at 100 Torr. The thioethers were obtained as oils by extraction in CH_2Cl_2. Crystallization from CH_2Cl_2/heptane at room temperature (**L$_1$** and **L$_4$**) or at −18 °C (**L$_2$**, **L$_3$**, **L$_5$**, and **L$_6$**) gave white solids. The structures of these compounds were determined by a combination of elemental analysis and usual spectroscopic techniques. The ^1H and ^{13}C NMR spectroscopic data of the ligands in $(CD_3)_2CO$ are collected in Table 1 with the numbering scheme for proton and carbon assignments.

The pyridine proton signals of **L$_1$**, **L$_2$**, **L$_3$**, and **L$_4$** appear as four multiplets in the δ = 7.04−8.46 range, whereas the pyrimidine signals of **L$_5$** and **L$_6$** appear as a triplet and a doublet at δ = 7.15 and 8.59, respectively. The signals of methylene protons were found as singlets in the range δ = 4.37−4.46.

The ^{13}C signals were easily assigned. The pyridine quaternary carbon signals of **L$_1$**, **L$_2$**, **L$_3$**, and **L$_4$** are observed at δ ≈ 159.0, and other pyridine signals in the range δ = 120.2−150.1. The pyrimidine quaternary carbon signals of **L$_5$** and **L$_6$** are observed at δ ≈ 172.0, and other pyrimidine signals at δ ≈ 117.7 (C^5) and 158.1 (C^6 and C^4).

Synthesis of the Compounds

The air-stable compounds [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-L)][PF_6]$_2$ (L = **L$_1$**, **L$_2$** and **L$_4$**), [Ru(*N*,*N*-dps)$_2$(*N*,*S*-L)][PF_6]$_2$ (L = **L$_1$**, **L$_2$** and **L$_3$**) and [Ru(*N*,*N*-bipy)$_2$(*N*,*S*-**L$_1$**)][PF_6]$_2$ were obtained by the reaction of the appropriate dichlorobis(diimmine) complex with an excess of L in boiling ethanol/water (1:1), followed by addition of aqueous NH_4PF_6. The complexes [Ru(*N*,*N*-dps)$_2$(*N*,*S*-**L$_5$**)][PF_6]$_2$ and [Ru(*N*,*N*-dps)$_2$(*N*,*S*-**L$_6$**)][PF_6]$_2$ were prepared from the nitrosyl compound [Ru(*N*,*N*-dps)$_2$(NO_2)(NO)][PF_6]$_2$.[1] All the complexes were soluble in acetone or acetonitrile and slightly soluble in methanol, ethanol, and water.

Conductivity measurements in acetonitrile solution indicate that these compounds are 1−2 electrolytes. Analytical and selected IR data are given in the Exp. Sect.

Dynamic NMR Studies

Variable-temperature ^1H NMR spectra of the compounds were obtained in $(CD_3)_2CO$ in the range 190−330 K. Selected data are listed in Table 2.

Solution Behaviour of the Complexes [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-L$_1$)][PF_6]$_2$, [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-L$_2$)][PF_6]$_2$ and [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-L$_4$)][PF_6]$_2$

At 205 K the NMR spectra of these complexes show the presence of two slow-exchanging isomers in similar abundance. The spectrum of [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-**L$_1$**)][PF_6]$_2$ is shown in Figure 1 and selected data are listed in Table 2. According to the presence of two isomers (population ratio 53:47) two signals are observed in the methyl region (Figure 1a) at δ = 2.28 and 2.27 (the first signal due to the major isomer). Furthermore, four doublets are observed in the methylene region: two doublets of minor intensity at δ = 5.20 and 4.13 (labelled A and B, respectively) and two doublets of major intensity at δ = 4.64 and 4.00 (labelled C and D, respectively). The H^3 pyridine signals appear (Figure 1b) at an abnormally low frequency (δ = 6.23 and 6.13, the first signal of major intensity) due to the strong shielding effect of the phenyl ring. Some signals partially over-

[a] ^1HNMR spectra recorded at 300.13 MHz and ^{13}C NMR data at 75.56 MHz, T = 298 K in $(CD_3)_2CO$; δ values with respect to internal $SiMe_4$, J_{HH} in Hz. – [b] Unresolved AA'BB' system. – [c] Assigned to $C^{9'}$.

lapped are present in the range δ = 7.20−9.00 whereas in the range δ = 9.00−9.54 the H^6 pyridine and some pyrimidine signals are easily identified.

The almost complete assignment of the signals was based on low-temperature 2D COSY and phase-sensitive 2D NOESY (Figure 2a) experiments. In this way, 24 signals as doublet doublets were assigned to the protons of eight pyrimidine rings with coupling constant J_{45} = 4.60 Hz, J_{46} = 2.15 Hz, and J_{56} = 5.95. In particular, the H^6 pyrimidine protons of the major isomer are observed at δ = 8.79, 8.85, 8.88, and 9.36, while those of the minor isomer at δ = 8.88, 8.81, 9.22, and 9.54.

The 2D NOESY (Figure 2a) was performed at 230 K. At this temperature the significant signals are split and the interchange process is slow. The cross-peaks, due to chemical exchange of magnetization (Figure 2b), are detected between the methylene protons A−D as well as the B−C protons and, in the aromatic region, between the H^3 pyridine protons, between the $H^{6'}$ pyrimidine protons at δ = 9.54 and 9.36 as well as those at δ = 9.22 and 8.88. Figure 2a also shows the negative cross-peaks. The strong NOEs include intra-ring *ortho* interactions (e.g. 6−5, 5−4, and 4−3 in the *N,S*-coordinated pyridine ring and 6−5 in the pyrimidine rings), adjacent-group interactions (e.g. methyl/phenyl protons, not shown in figure, methylene/phenyl protons), and most significantly the following interactions: protons of phenyl ring/H^3 pyridine protons, H^6 pyridine protons and $H^{6'}$ pyrimidine protons at δ = 9.22 and 8.88, methylene proton of the major isomer at δ = 4.64/$H^{6'}$ pyrimidine protons at δ = 9.36. If we assume that there is no restricted rotation, e.g. methylene and phenyl groups freely rotate, since the ruthenium and sulfur atoms are stereogenic

[a] Recorded in $(CD_3)_2CO$ at 300.13 MHz, δ in ppm with respect to internal $SiMe_4$. Coupling constants (Hz) in the pyridine rings: J_{43} = 7.7−8.1, J_{45} = 7.4−7.8, J_{65} = 4.8−5.5, J_{64} = 1.1−1.9, J_{53} = 0.7−1.3, and J_{63} = 0.7−0.8; in the pyrimidine rings: J_{65} = 5.5−6.0, J_{45} = 4.6−5.0, and J_{64} = 2.0−2.1. − [b] The phenyl signals are observed as unresolved AA′BB′ systems in the range δ = 7.2−7.8. − [c] Assigned to the major isomer. − [d] Overlapped signals of the two isomers. − [e] Uncoordinated side. − [f] Not assigned.

centres (configurations Δ and Λ, *R* and *S*, respectively), the complex has a total of four isomers including the enantiomers. Thus, the above-mentioned positive and negative cross-peaks found in the 2D NOESY imply that in the two isomers (Figure 3) the phenyl protons, in *ortho* positions with respect to the methylene group, are in close proximity to the H^3 pyridine protons (in Figure 3 only a phenyl *ortho*-proton is shown). Furthermore, the H^6 pyridine proton is in close proximity to the H^6 pyrimidine proton at δ = 8.88 (major isomer) or that at δ = 9.22 (minor isomer). Moreover, in the major isomer the methylene protons are in close proximity to the $H^{6'}$ pyrimidine proton at δ = 9.36. These results are indicative of a sulfur inversion, which exchanges the two diasteroisomers $\Delta R \rightleftarrows \Delta S$ (or $\Lambda S \rightleftarrows \Lambda R$), as depicted in Figure 3.

On warming the NMR solutions, all the spectral lines broaden. In particular the coalescence for the exchange $A \rightleftarrows D$ and $B \rightleftarrows C$ occurred around 280 K.

At 330 K, the highest temperature reached, two averaged methylene doublets and a single methyl signal were observed (Table 2). It is pertinent to note at this point that the splitting patterns of methylene protons, at high temperature, definitely eliminate the possibility of racemisation ($\Delta \rightleftarrows \Lambda$). In fact, in presence of a fast inversion and racemisation the averaged environments of the methylene protons should become equivalents. Furthermore, EXSY experiments in the range 300−330 K exclude a slow racemisation process. The complete assignment of the signals was performed with the help of the COSY spectrum. In the aromatic region, at this temperature, twelve pyrimidine proton signals due to four rings of the *N,N*-coordinated ligands are observed. In particular, the signals at δ = 9.33, 8.89 and 8.70 (two overlapped signals) were assigned to the H^6 pyrimidine protons, while four pyridine proton signals of the *N,S*-coordinated ligand are detected (Table 2).

The rates of the processes were deduced by band-shape analysis of the methylene signals, which are well separated by other signals and very sensitive to the process by virtue of the methylene closeness to the site of inversion. Some experimental and computer-simulated spectra are shown in Figure 4. As evident from the figure, the shifts are found to be strongly temperature-dependent. In order to correct for this temperature dependence a linear interpolation was used.[18] The resulting rate data were checked on the H^3 pyridine signals. Activation energy data were calculated from 16 independent fittings in the temperature range 205−330 K. Activation energy data for the other dprs com-

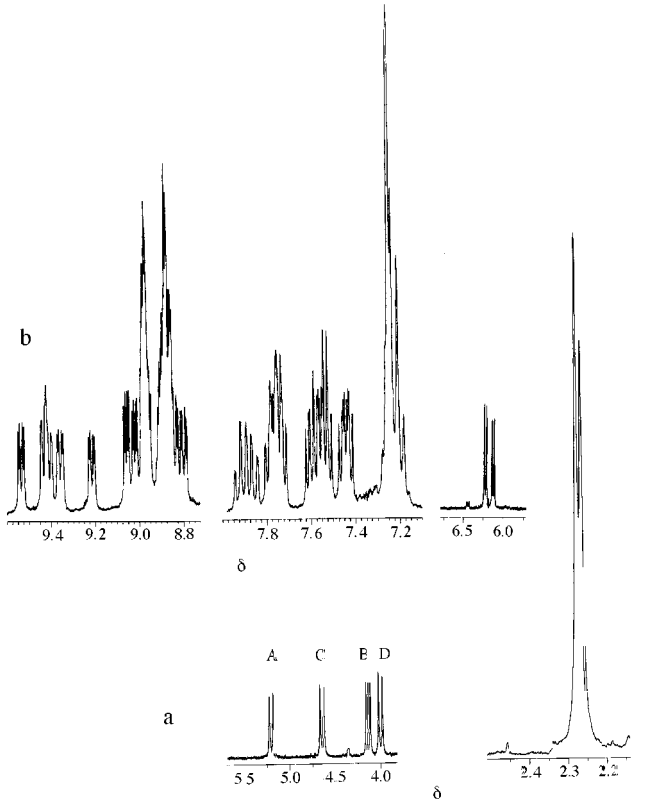

Figure 1. ^{1}H NMR spectrum of [Ru(*N,N*-dprs)$_2$(*N,S*-L$_1$)][PF$_6$]$_2$ at 205 K in (CD$_3$)$_2$CO; a) methylene and methyl region, b) aromatic region

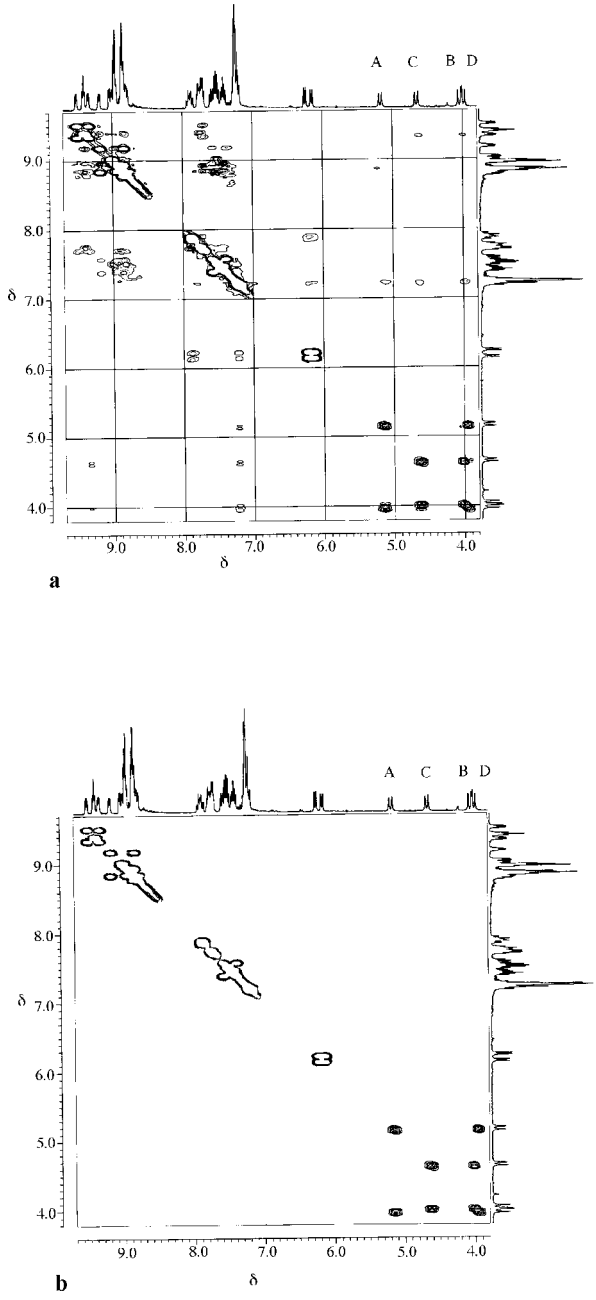

Figure 2. Phase-sensitive 2D NOESY of [Ru(*N,N*-dprs)$_2$(*N,S*-**L$_1$**)][PF$_6$]$_2$ at 230 K in (CD$_3$)$_2$CO; a) positive and negative cross-peaks, b) only positive cross-peaks

plexes were obtained by similar method and collected in Table 3.

The ^{13}C NMR spectra were easily interpreted, at least for the carbon signals of the *N,S*-ligand, by comparison of the spectra of the present complexes with those of the free ligands and other complexes containing *N,S*-chelated ligands,[17] with the help of CH-correlation experiments and jmod pulse sequences. ^{13}C NMR spectra of all three dprs complexes were similar (Table 4) and the results for [Ru(dprs)$_2$(*N,S*-**L$_1$**)][PF$_6$]$_2$ will serve to illustrate the analysis of the problem.

The ^{13}C NMR spectrum at 228 K comprised three regions of interest for the *N,S*-chelate ligand: (i) the methyl region that displayed the methyl resonances of the two isomers as overlapped signals at δ = 19.95; (ii) the methylene region with two signals at δ = 38.70 and 40.20 (the latter of the major isomer); (iii) the phenyl and pyridyl region (δ = 165−126) in which the C^7 quaternary carbon atoms of the two isomers are observed as overlapped signals. The C^3 pyridine carbon atom of the minor isomer and C^5 pyridine carbon atom of the major isomer led to superimposed signals whereas other resonances are well separated.

On warming the NMR solutions above 245 K some signals broaden, and in the range 265−285 K some signals vanish (in particular the methylene signals). In the fast exchange regime (328 K) averaged signals of the two isomers were observed (Table 4).

In the ^{13}C NMR spectrum of [Ru(dprs)$_2$(*N,S*-**L$_4$**)][PF$_6$]$_2$ the **L$_4$** carbon signals of the uncoordinated pyridyl ring and of the methylene group in the uncoordinated side are also observed. These signals and the corresponding signals of the free ligand show, at the same temperature, nearly the same chemical shift.

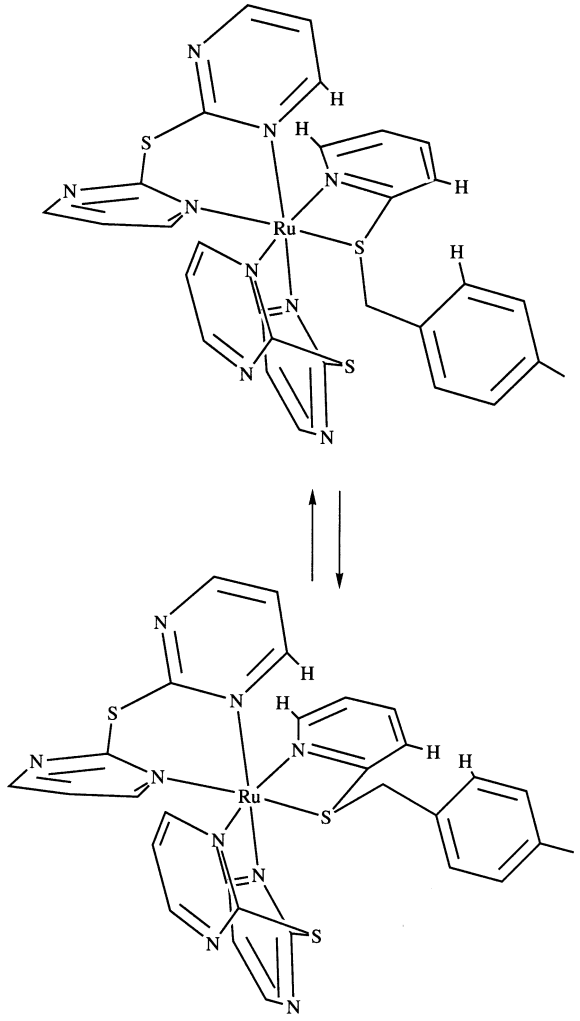

Figure 3. Schematic representation of the proposed structure for the diastereoisomers of $[Ru(N,N\text{-dprs})_2(N,S\text{-}\mathbf{L_1})][PF_6]_2$ and of the close proximity between the phenyl *ortho*-protons (only one is shown) and H^3 pyridine protons and that between the H^6 pyridine protons and H^6 pyrimidine proton at $\delta = 8.88$ (major isomer) or at $\delta = 9.22$ (minor isomer)

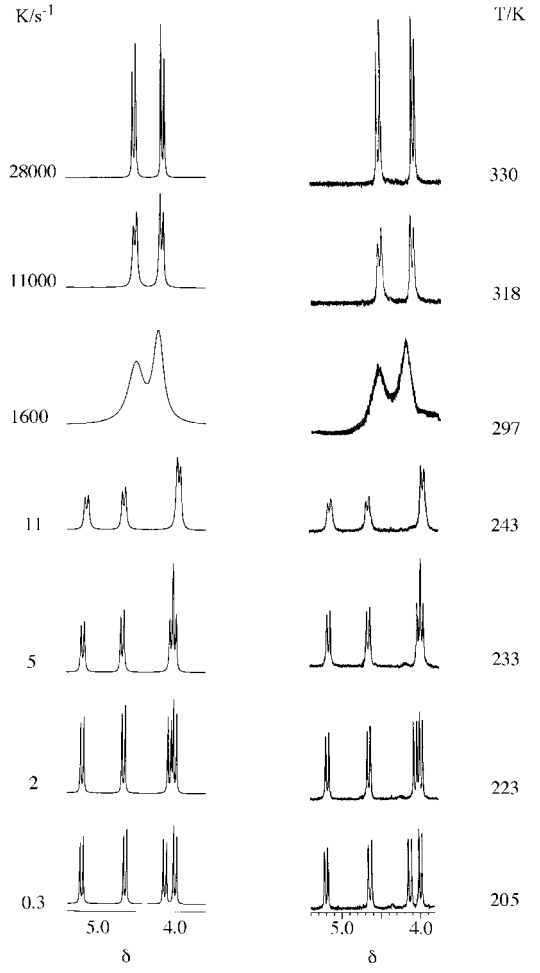

Figure 4. Selected variable-temperature ^1H NMR spectra of $[Ru(N,N\text{-dprs})_2(N,S\text{-}\mathbf{L_1})][PF_6]_2$ at 205 K in $(CD_3)_2CO$ (methylene region); computer-synthesised spectra of the same region are shown on the left

Solution Behaviour of the Complexes $[Ru(dps)_2(N,S\text{-}\mathbf{L_1})][PF_6]_2$, $[Ru(dps)_2(N,S\text{-}\mathbf{L_2})][PF_6]_2$ and $[Ru(dps)_2(N,S\text{-}\mathbf{L_3})][PF_6]_2$

Also for these complexes, two slow-exchanging isomers are present at 205 K, but the population ratio between the isomers is ca. 2:1 (Table 3). Furthermore, the methylene proton signals appear different with respect to those of the $[Ru(dprs)_2(N,S\text{-L})][PF_6]_2$ complexes in that now the methylene signals (Figure 5) of the minor isomer (C and D) are framed by those of the major isomer (A and B).

The 2D ^1H NOESY experiment on $[Ru(dps)_2(N,S\text{-}\mathbf{L_2})][PF_6]_2$ is shown in Figure 5. The positive cross-peaks show the chemical exchange between the methylene protons (A−D and B−C), between the H^6 pyrimidine protons at $\delta = 9.00$ and 8.57 (the first signal of major intensity), and between the H^6 pyrimidine protons at $\delta = 9.22$ and 9.02 (the first signal of major intensity). The most significant negative cross-peaks show strong NOEs due to the close proximity of phenyl protons and H^3 pyridine protons of *N*,*S*-chelated ligand and between the H^6 pyridine protons of *N*,*S*-chelated ligand and the H^6 pyridine protons of *N*,*N*-chelated ligands at $\delta = 9.00$ and 8.57, respectively. Thus, also in this case there are two exchanging diastereoisomers. In the major isomer the phenyl protons are in close proximity to the H^3 proton at $\delta = 6.23$ and in the minor isomer of the H^3 proton at $\delta = 6.31$. Rates of the process were deduced by band-shape analysis of the methylene signals. Also in this case a linear interpolation was necessary due to the strong temperature dependence of the signals. Activation energy data were collected in Table 3.

Solution Behaviour of the Complexes Containing Pyrimidine Thioethers as N,S-Ligands: $[Ru(dps)_2(N,S\text{-}\mathbf{L_5})][PF_6]_2$ and $[Ru(dps)_2(N,S\text{-}\mathbf{L_6})][PF_6]_2$

In contrast to the complexes containing pyridine thioethers as *N*,*S*-ligands, which showed some broad signals at room temperature (in particular broad methylene signals, see Figure 4), the ^1H NMR spectra of these complexes showed well-resolved signals in agreement with the presence

[a] Recorded in $(CD_3)_2CO$ at 75.56 MHz. – [b] Assignments of the quaternary phenyl carbon atoms C^7 and C^{10} possibly reversed. – [c] Assigned to the major isomer. – [d] Overlapped signals of the two isomers. – [e] Uncoordinated side.

of two fast-exchanging isomers (Figure 6). Unluckily, experimental difficulties ruled out the possibility of performing one- and two-dimensional experiments below 190 K. At this temperature the signal broadening, due to the inversion process, was not negligible and prevented the assignment of most signals. However, the band-shape analysis of the methylene signals above 190 K allows the evaluation of the activation energies. According to the fast inversion observed at room temperature, the mean values of the activation barriers, $\Delta G^{\ddagger}$ and $\Delta H^{\ddagger}$, for these complexes were 47.2 and 39.7 kJ mol^{-1}, respectively, whereas for the corresponding complexes containing thioarylpyridine as *N,S*-ligands (e.g. $[Ru(dps)_2(N,S\text{-}\mathbf{L_1})][PF_6]_2$ and $[Ru(dps)_2(N,S\text{-}\mathbf{L_2})][PF_6]_2$) the mean values were 52.9 and 49.6 kJ mol^{-1}, respectively.

Although some carbon signals (in particular of the minor isomer) were not observed in the slow exchange regime, the ^{13}C NMR spectra (Table 4) of $[Ru(dps)_2\,L][PF_6]_2$ complexes (L = $\mathbf{L_1}$, $\mathbf{L_2}$, $\mathbf{L_3}$, $\mathbf{L_5}$, and $\mathbf{L_6}$) confirm the presence of the two exchanging isomers.

Discussion

Our previous studies[17] on the dynamic behaviour of $[Ru(N,N\text{-dprs})_2(N,S\text{-phpys})][PF_6]_2$ and $[Ru(N,N\text{-dps})_2(N,S$-

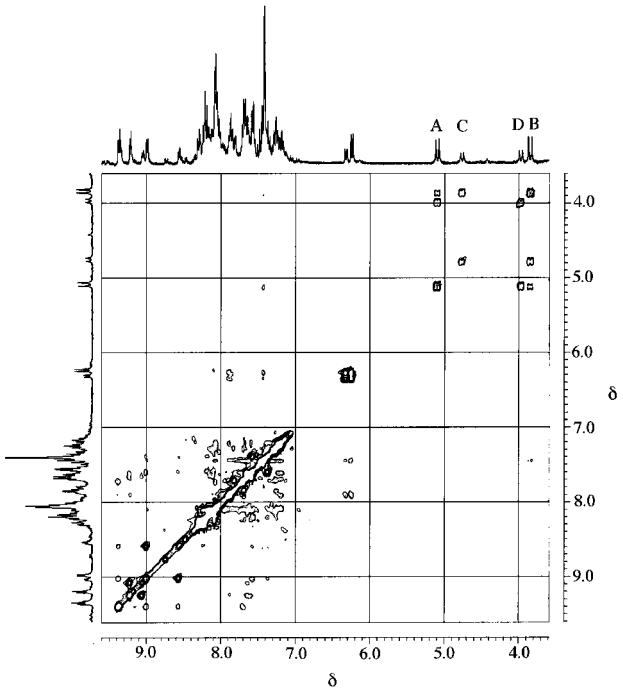

Figure 5. Phase-sensitive 2D NOESY of [Ru(*N*,*N*-dps)$_2$(*N*,*S*-**L$_2$**)][PF$_6$]$_2$ at 218 K in (CD$_3$)$_2$CO; positive and negative cross-peaks are shown

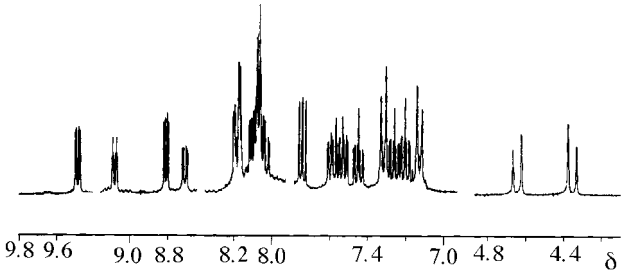

Figure 6. ^{1}H NMR spectrum of [Ru(*N*,*N*-dps)$_2$(*N*,*S*-L$_5$)][PF$_6$]$_2$ at 298 K in (CD$_3$)$_2$CO

phpys)][PF$_6$]$_2$ (phpys = phenyl pyridyl sulfide) show, in the range 180−240 K, that a restricted rotation of the pendant phenyl ring was operative, affecting only the phenyl proton signals. Above 240 K extensive internal arrangements, involving sulfur inversion were invoked to explain the higher temperature changes in the aromatic region of ^{1}H NMR spectra.

In contrast, the NMR spectra of the present complexes, at the lower temperatures reached (190 K), clearly show the presence of two slow-exchanging invertomers and the absence of any restricted rotation. Very likely, restricted rotation of the methylene or phenyl group occurs below the above temperature, but experimental difficulties ruled out the possibility of supporting this suggestion. Thus, the present tris(chelated) ruthenium complexes containing the ruthenium chiral atom (configurations Δ and Λ) and the sulfur chiral atom (configurations *S* and *R*) can exist only as four isomers. The process consistent with the NMR behaviour is the inversion at the sulfur atom ($R \rightleftarrows S$), whereas the possibility of racemisation ($\Delta \rightleftarrows \Lambda$) can be discarded.

The inversion at the sulfur atom may occur through one of three processes: a) a dissociative mechanism; b) a mechanism involving association of solvent or anion or free ligand; or c) intramolecular mechanism without any bond rupture. A dissociative mechanism with sulfur or nitrogen decoordination is unlikely on the basis of the $\Delta S^{\ddagger}$ values and ^{1}H NMR spectra, which are temperature-reversible and concentration-independent.

In particular, for the complexes containing pyrimidine thioether ligands, the dissociative mechanism may involve exchange of the coordinated and uncoordinated N-atoms through dissociation of the ruthenium−N bond, rotation around the pyrimidine−S bond, inversion at the sulfur atom and reformation of the pyrimidine−ruthenium bond. This mechanism can be definitively rejected in that it should make the H^6 and H^4 pyrimidine protons equivalent, whereas the latter protons are nonequivalent even when the process becomes fast at the NMR time scale. A dissociative mechanism involving nitrogen decoordination in the pyridine thioethers complexes can also be discarded on the basis of the pyridine basicity (pK_a = 5.25) being much larger than that of the pyrimidine (pK_a = 1.23), which suggests better σ-donor capability of the pyridine.

Even though the determination of $\Delta S^{\ddagger}$ values is based on extrapolation to $1/T = 0$ in the Eyring diagrams and, owing to the long distance over which this extrapolation has to be taken, is subject to considerable uncertainty, the data collected show that the activation entropies for [Ru(*N*,*N*-dprs)$_2$(*N*,*S*-L)][PF$_6$]$_2$ (L = **L$_1$**, **L$_2$**, and **L$_4$**) and [Ru(*N*,*N*-dps)$_2$(*N*,*S*-L)][PF$_6$]$_2$ (L = **L$_5$** and **L$_6$**) are, without doubt, negative (Table 3). Thus, the transition state conformations should be sterically even more congested than the ground state conformations, suggesting that a dissociative mechanism can be discarded. For [Ru(*N*,*N*-dps)$_2$(*N*,*S*-L)][PF$_6$]$_2$ (L = **L$_1$**, **L$_2$**, and **L$_3$**), the activation entropies are -8.2 ± 5.9 J K^{-1} mol^{-1}, $+3.4 \pm 4.0$ J K^{-1} mol^{-1}, and $+5.3 \pm 7.0$ J K^{-1} mol^{-1}, respectively. Although these values, different to those of other complexes, are close to zero, it is pertinent to note that the $\Delta G^{\ddagger}_{298\,K}$ values for the process in the corresponding dprs and dps complexes (Table 3) are of comparable magnitude, strongly suggesting that a similar mechanism is operative.

On the other hand, a mechanism involving association of solvent or anion or free ligand can be discarded on the basis of the following NMR findings: (i) the ^{1}H NMR spectra are temperature-reversible and concentration-independent; (ii) when free ligand is added separate signals are observed and the exchange rates are not affected; (iii) for the complex [Ru(dprs)$_2$(*N*,*S*-**L$_4$**)][PF$_6$]$_2$ the presence of the uncoordinated side in the thioether ligand does not affect the process; and (iv) addition of chloride or hexafluorophosphate anion does not affect the exchange rate.

The only mechanism, therefore, consistent with all the experimental results appears to be the pyramidal inversion without any bond rupture. However, the inversion barriers for the present complexes are low with respect to those

found in iron or ruthenium complexes containing bridging[19] or chelating[20] ligands, and other complexes containing *N,S*-coordinated ligands that form five-membered chelate rings.[21,22] Furthermore, decreasing the size of the ring containing the sulfur atom ought to make the access to the planar transition state more difficult, with a consequent increase in the pyramidal inversion energy barrier.[20]

The low $\Delta G^{\ddagger}$ values of the present complexes, which reflect differences between the ground- and transition-state energy, are mainly due to relatively high-energy ground states rather than low-energy transition states. This may be explained in terms of the contemporary presence of the congested Ru(*N,N*-dps)$_2$ or Ru(*N,N*-dprs)$_2$ fragments and steric demanding thioether ligands *N,S*-coordinated. This hypothesis is supported by the NMR spectra of the [Ru(bipy)$_2$(*N,S*-**L$_1$**)][PF$_6$]$_2$ that show the presence of two non-exchanging isomers, even at the highest temperatures achievable in acetone. The planar disposition of the bipy ligands in the last complex very likely reduces the steric hindrance of the [Ru(*N,N*-diimmine)$_2$ fragment and the ground-state energy with consequent increase of the $\Delta G^{\ddagger}$ value.

Conclusion

The synthesis of a series of novel thioethers bearing CH_2R groups allowed us to extend the chemistry of polypyridine ruthenium(II) compounds containing *N,S*-coordinated ligands with a four-membered chelate ring, and to elucidate the sulfur inversion mechanism. The pyramidal inversion, without bond rupture, is likely to be the only mechanism consistent with the dynamic behaviour of the present complexes. The steric hindrance of the ruthenium substrates and the steric demand of the thioether ligand *N,S*-coordinated appear to play a determinant role for the inversion process.

The process occurs at distinctly lower rates in the complexes containing pyridine thioethers (**L$_1$**, **L$_2$**, **L$_3$**, **L$_4$**) than in those containing pyrimidine derivatives (**L$_5$**, **L$_6$**), the differences in the averaged $\Delta G^{\ddagger}$ values being 8 kJ mol^{-1}. Steric and electronic effects may be invoked to explain this difference. In fact, the pyridine H^3 proton, in close proximity to the phenyl ring in the *N,S*-coordinated ligand, should increase the energy barrier of the dynamic process. On the other hand, the substitution in the thioether ligand of the pyridine with pyrimidine should weaken the ruthenium−sulfur bond (pyrimidine is a better electron-withdrawing group than pyridine) and decrease the energy barrier. Further attempts are in progress with the aim to study the effect of more or less congested Ru(*N,N*-diimine)$_2$ cores on the structure of the isomers and the exchange process.

Experimental Section

Di-2-pyridyl sulfide,[24] [Ru(dps)$_2$Cl$_2$]·2H$_2$O,[1] [Ru(dprs)$_2$Cl$_2$]·2H$_2$O,[17] and [Ru(dps)$_2$(NO)(NO$_2$)][PF$_6$]$_2$·H$_2$O[1] were prepared by published methods. Other reagents and solvents were used as received. − Elemental analyses were carried by Redox Microanalytical Laboratory of Cologno Monzese (Milano). − Conductivity measurements were done with a Radiometer CDM 3 conductivity meter. − Infrared spectra were recorded with an FT-IR 1720X spectrophotometer with samples as Nujol mulls placed between KBr plates. − The ^{1}H and ^{13}C NMR spectra were recorded with a Bruker AMX 300 spectrometer. The following Bruker programs were used: zg, homodecnew, zgpg, jmod, cosy, noesy.pt, hxco, invb. Simulations of static and dynamic spectra were performed using the G NMR program.

4-Methylbenzyl 2-Pyridyl Sulfide (L$_1$): The compounds 2-sulfanylpyridine (11.1 g, 0.1 mol), 4-methylbenzyl bromide (18.5 g, 0.1 mol), and potassium carbonate (11.0 g, 0.08 mol) were vigorously stirred in dimethylformamide (40 cm^3), and heated under reflux for 5 h, under N_2. The dimethylformamide was then distilled under reduced pressure (100 Torr) and the residue extracted with CH_2Cl_2 (ca. 250 cm^3). To the solution was added aluminium oxide (activated neutral, STD grade, 10 g). The mixture was allowed to stand until the solution was almost colourless (ca. 1 d). By evaporation of the filtered solution, a pale yellow oil was obtained that was dissolved in 150 cm^3 of CH_2Cl_2/heptane (1:2). A white solid was formed by slow concentration. Yield 11.0 g (51%). − Selected IR data (KBr): $\tilde{\nu}$ = 1578 vs, 1557 s, 1515 s, 1454 vs, 1415 vs, 1124 vs, 841 br, 758 vs, 740 ms, 726 s cm^{-1}. − $C_{13}H_{13}NS$ (215.31): calcd. C 72.50, H 6.10, N 6.50, S 14.90; found C 72.60, H 6.15, N 6.55, S 14.90.

4-Chlorobenzyl 2-Pyridyl Sulfide (L$_2$): This compound was obtained starting from 2-sulfanylpyridine (11.1 g, 0.1 mol), 4-chlorobenzyl chloride (16.1 g, 0.1 mol), and potassium carbonate (11.0 g, 0.08 mol) in dimethylformamide (40 cm^3) under reflux for 7 h, under N_2. After removal of the DMF, extraction with CH_2Cl_2 (ca 250 cm^3), and addition of aluminium oxide (10 g), the mixture was allowed to stand until the solution was colourless. The filtered solution was concentrated to give an oil that was kept at −24 °C. Colourless needles were formed. Yield 10.0 g (42%). − Selected IR data (KBr): $\tilde{\nu}$ = 1578 vs, 1556 vs, 1490 vs, 1453 vs, 1414 vs, 1122 vs, 1091 vs, 1015 vs, 853 br, 756 vs, 730 s, 725 s cm^{-1}. − $C_{12}H_{10}ClNS$ (235.73) calcd: C 61.15, H 4.30, N 5.95, S 13.60; found C 61.10, H 4.35, N 6.00, S 13.60.

3-Chlorobenzyl 2-Pyridyl Sulfide (L$_3$): This white compound was obtained in the same manner as above, starting from 2-sulfanylpyridine (11.1 g, 0.1 mol), 3-chlorobenzyl bromide (20.5 g, 0.1 mol), and potassium carbonate (11.0 g, 0.08 mol). Reaction time: 3 h. Yield 8.0 g (34%). − Selected IR data (KBr): $\tilde{\nu}$ = 1597s, 1579 vs, 1556 vs, 1453 vs, 1414 vs, 1123 vs, 876 br, 787 br, 757 vs, 725 vs cm^{-1}. − $C_{12}H_{10}ClNS$ (235.73): calcd. C 61.15, H 4.30, N 5.95, S 13.60; found C 61.20, H 4.35, N 6.00, S 13.70.

1,4-Bis[(phenylsulfanyl)methyl]benzene (L$_4$): The compounds 2-bromopyridine (15.8 g, 0.1 mol), 1,4-benzenedimethanethiol (8.52 g, 0.05 mol), and potassium carbonate (11 g, 0.08 mol) were vigorously stirred in dimethylformamide (40 cm^3) and heated under reflux for 5 h. The solvent was then removed ant the resulting brown solid extracted with a mixture (210 cm^3) of CH_2Cl_2 and heptane (1:2). The first crop of solid separated by slow evaporation (ca. 2 h) as a white pure product. To the solution was added the residue, CH_2Cl_2 (100 cm^3), and aluminium oxide (activated neutral, STD grade, 10 g). The mixture was allowed to stand until the solution was almost colourless (ca. 1 d). By slow concentration of the filtered solution the second crop of product was obtained. Total yield 19.5 g (60%). − Selected IR data (KBr): $\tilde{\nu}$ = 1576 vs, 1550 s, 1514 s, 1121 vs, 894 s, 823 s, 757 vs, 732 s, 724 vs, 504s cm^{-1}. −

$C_{18}H_{16}N_2S_2$ (324.46): calcd. C 66.65, H 4.95, N 8.65, S 19.75; found C 66.60, H 5.00, N 8.55, S 19.70. − Compound **L_4** was also obtained in the same way starting from 2-sulfanylpyridine (11.3 g, 0.1 mol) and α,α′-dichloro-*p*-xylene (8.75 g, 0.05 mol). Yield ca. 50%.

4-Methylbenzyl 2-Pyrimidinyl Sulfide (L_5): This white compound was obtained as like **L_2** from 2-sulfanylpyrimidine (11.2 g, 0.1 mol), 4-methylbenzyl bromide (18.5 g, 0.1 mol), and potassium carbonate (11.0 g, 0.08 mol). Yield 10.6 g (49%). − Selected IR data (KBr): $\tilde{\nu}$ = 1565 vs, 1546 vs, 1516 s, 1205 s, 1181 s, 1170 s, 803 s, 771 vs, 757 ms, 744 s. 727s cm^{-1}. − $C_{12}H_{12}N_2S$ (216.30): calcd: C 66.65, H 5.60, N 12.95, S 14.80; found C 66.60, H 5.65, N 12.85, S 14.90.

4-Chlorobenzyl 2-Pyrimidinyl Sulfide (L_6): This white compound was obtained like **L_2** from 2-sulfanylpyrimidine (11.2 g, 0.1 mol), 4-chlorobenzyl chloride (16.1 g, 0.1 mol), and potassium carbonate (11.0 g, 0.08 mol). Yield 10.6 g (45%). − (KBr): $\tilde{\nu}$ = 1566 vs, 1548 vs, 1490 s, 1206 s, 1184 s, 1159 s, 1093 vs, 1015 s, 812 s, 769 s, 750 vs, 722 s cm^{-1}. − $C_{11}H_9ClN_2S$ (236.72): calcd. C 55.80, H 3.85, N 11.85, S 13.55; found C 55.80, H 3.95, N 11.80, S 13.60.

$[Ru(dprs)_2(L_1)][PF_6]_2$: $[Ru(dprs)_2Cl_2]\cdot 2H_2O$ (0.196 g, 0.33 mmol) and **L_1** (0.190 g, 0.882 mmol) were heated under reflux in 60 cm^3 of ethanol/water (1:1). After 1 h, the red complex was dissolved and the yellow solution was filtered hot. By addition of 30 cm^3 of water containing 0.49 g (3 mmol) of NH_4PF_6 a yellow precipitate was obtained. It was filtered, washed with 50 cm^3 of cold water, and dried overnight. The solid was washed copiously with diethyl ether and dried again. It was then dissolved in acetone (20 cm^3), and diethyl ether (ca. 40 cm^3) was added slowly until a yellow solid was obtained. The compound was washed with diethyl ether and dried over P_4O_{10} under vacuum. Yield 0.165 g (50%). − Selected IR data (KBr): $\tilde{\nu}$ = 1619 br, 1577 s, 1549 s, 1167 s, 1127 s, 847 br, 768 s, 754 vs, 723 s, 558 vs cm^{-1}. − $C_{29}H_2F_{12}N_9P_2RuS_3$ (986.76): calcd. C 35.30, H 2.55, N 12.80, S, 9.75; found C 35.30, H 2.60, N 12.75, S 9.80. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 270 S cm^2 mol^{-1}.

$[Ru(dprs)_2(L_2)][PF_6]_2$: The compound was obtained in the same way as the previous complex, starting from $[Ru(dprs)_2Cl_2]\cdot 2H_2O$ (0.196 g, 0.33 mmol) and **L_2** (0.208 g, 0.882 mmol). Yield 0.160 g (48%). − Selected IR data (KBr): $\tilde{\nu}$ = 1579 vs 1549 vs, 1492 s, 1396 vs, 1167 vs, 847 br, 768s, 754 vs, 558 vs cm^{-1}. − $C_{28}H_{22}ClF_{12}N_9P_2RuS_3$ (1007.18): calcd. C 33.40, H 2.20, N 12.50, S 9.55; found C 33.40, H 2.25, N 12.40, S 9.60. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 290 S cm^2 mol^{-1}.

$[Ru(dprs)_2(L_4)][PF_6]_2$: The crude product was prepared in the same way as above, starting from $[Ru(dprs)_2Cl_2]\cdot 2H_2O$ (0.196 g, 0.333 mmol) and **L_4** (0.216 g, 0.666 mmol). The solid was dissolved in acetone (10 cm^3) and added to the top of a chromatography column (diameter 2 cm) packed with aluminium oxide [60 g; Aldrich, neutral, STD grade, 150 mesh, deactivated with water (2.4 g)]. The first orange band was eluted with acetone/CH_2Cl_2 (3:2) (60 cm^3) and acetone (ca 300 cm^3). The orange solid obtained by removal of the solvent was collected and washed with diethyl ether. Further elution with acetone (ca. 400 cm^3) gave a yellow band, which was concentrated (10 cm^3) and precipitated with diethyl ether (90 cm^3). The yellow solid obtained was washed copiously with diethyl ether and dried over P_4O_{10} under vacuum. Yield 0.140 g (30%). − Selected IR data (KBr): $\tilde{\nu}$ = 1617 br, 1577 vs, 1549 vs, 1511 ms, 1167 vs, 846 vs, 766 s, 754 vs, 723 ms, 558 vs cm^{-1}. − $C_{34}H_{28}F_{12}N_{10}P_2RuS_4$ (1095.91): calcd. C 37.25, H 2.60, N 12.80, S 11.70; found C 37.20, H 2.65, N 12.65, S 11.65. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 295 S cm^2 mol^{-1}.

$[Ru(dps)_2(L_1)][PF_6]_2$: The compound was obtained in the same way as above, starting from $[Ru(dps)_2Cl_2]\cdot 2H_2O$ (0.195 g, 0.33 mmol) and **L_1** (0.190 g, 0.882 mmol). Yield 0.163 g (50%). − Selected IR data (KBr): $\tilde{\nu}$ = 1641 br, 1586 s, 1556 s, 1284 s, 1162 s, 1127 s, 845 br, 766 vs, 741 ms, 725 s, 558 vs cm^{-1}. − $C_{33}H_{29}F_{12}N_5P_2RuS_3$ (982.81): calcd. C 40.35, H 2.95, N 7.15, S 9.80; found C 40.40, H 3.00, N 7.05, S 9.85. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 304 S cm^2 mol^{-1}.

$[Ru(dps)_2(L_2)][PF_6]_2$: The compound was obtained in the same way as above, starting from $[Ru(dps)_2Cl_2]\cdot 2H_2O$ (0.195 g, 0.33 mmol) and **L_2** (0.208 g, 0.882 mmol). Yield 0.134 g (40%). − Selected IR data (KBr): $\tilde{\nu}$ = 1588 vs, 1555 s, 1421 vs, 1284 s, 1163 s, 1129 s, 1087 s, 1063 s, 843 br, 768 vs, 740 ms, 727 s, 558 vs cm^{-1}. − $C_{32}H_{26}ClF_{12}N_5P_2RuS_3$ (1003.23): calcd. C 38.30, H 2.60, N 7.00, S 9.60; found C 38.40, H 2.70, N 7.00, S 9.65. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 295 S cm^2 mol^{-1}.

$[Ru(dps)_2(L_3)][PF_6]_2$: The compound was obtained in the same way as above, starting from $[Ru(dps)_2Cl_2]\cdot 2H_2O$ (0.195 g, 0.33 mmol) and **L_3** (0.208 g, 0.882 mmol). Yield 0.167 g (50%). − Selected IR data (KBr): $\tilde{\nu}$ = 1588 vs, 1555 ms, 1422 vs, 1284 s, 1164 s, 1129 s, 1087 s, 1064 s, 845 br, 768 vs, 740 ms, 727 s, 558 vs cm^{-1}. − $C_{32}H_{26}ClF_{12}N_5P_2RuS_3$ (1003.23): calcd. C 38.30, H 2.60, N 7.00, S 9.60; found C 38.40, H 2.70, N 6.95, S 9.55. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 290 S cm^2 mol^{-1}.

$[Ru(dps)_2(L_5)][PF_6]_2$: NaN_3 (0.0325 g, 0.5 mmol) was dissolved in warm methanol (8 cm^3) and added dropwise to a stirred solution of $[Ru(dps)_2(NO)(NO_2)][PF_6]_2\cdot H_2O$ (0.431 g, 0.5 mmol) in acetone (30 cm^3). The solution colour changed from yellow to dark-red. To the solution, protected from light, was added, after 3 min **L_5** (0.324 g, 1.5 mmol), after 2 min a 70% aqueous solution of HPF_6 (3 cm^3), and again a methanol (8 cm^3) solution of NaN_3 (0.0325 g, 0.5 mmol), dropwise. The mixture was stirred for 2 h, filtered, concentrated (20 cm^3), and the product precipitated with diethyl ether (100 cm^3). The yellow solid obtained was dried over P_4O_{10}, under vacuum, crystallised from acetone (10 cm^3) and diethyl ether (90 cm^3), washed with diethyl ether, and dried again. Yield 0.16 g (33%). − Selected IR data (KBr): $\tilde{\nu}$ = 1590 s, 1455 vs, 1423 s, 1286 s, 1165 s, 1064 s, 846 br, 770 s, 726 ms, 558 vs cm^{-1}. − $C_{32}H_{28}F_{12}N_6P_2RuS_3$ (983.80): calcd. C 39.05, H 2.85, N 8.55, S 9.80; found C 39.00, H 2.90, N 8.55, S 9.70. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 305 S cm^2 mol^{-1}.

$[Ru(dps)_2(L_6)][PF_6]_2$: The complex was obtained in the same way as $[Ru(dps)_2(L_5)][PF6]_2$ using **L_6** (0.355 g, 1.5 mmol) instead of **L_5**. Yield 0.15 g (30%). − Selected IR data (KBr): $\tilde{\nu}$ = 1590 s, 1455 vs, 1422 s, 1286 s, 1164 s, 1064 s, 845 br, 770 s, 726 ms, 558 vs cm^{-1}. − $C_{31}H_{25}ClF_{12}N_6P_2RuS_3$ (1004.22): calcd. C 37.10, H 2.50, N 8.35, S 9.60; found C 37.10, H 2.60, N 8.25, S 9.70. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 305 S cm^2 mol^{-1}.

$[Ru(bipy)_2(L_1)][PF_6]_2$: The compound was obtained in the same way as $[Ru(dps)_2(\mathbf{L_1})][PF_6]_2$, starting from $[Ru(bipy)_2Cl_2]\cdot 2H_2O$ (0.174 g, 0.33 mmol) and **L_1** (0.190 g, 0.882 mmol). Yield 0.153 g (50%). − Selected IR data (KBr): $\tilde{\nu}$ = 1605 vs, 1585 s, 1515 s, 1243 s, 1162 s, 1125 s, 1070 ms, 1046 ms, 850 br, 764 vs, 740 ms, 730 s, 558 vs cm^{-1}. − $C_{33}H_{29}ClF_{12}N_5P_2RuS$ (918.69): calcd. C 43.15, H 3.20, N 7.60, S 3.50; found C 43.10, H 3.30, N 7.50, S 3.55. − Conductivity: Λ_M(MeCN, 2 × 10^{-4} mol dm^{-3}, 20 °C) = 296 S cm^2 mol^{-1}.

A Simple Example of the Fluxional Behaviour of Ruthenium-Coordinated C_2-Symmetric Monodentate Ligands − Synthesis, ^{1}H NMR Spectroscopic Study, and Crystal Structure of *cis*-[Ru(bpy)$_2$(4Pic)$_2$](PF$_6$)$_2$

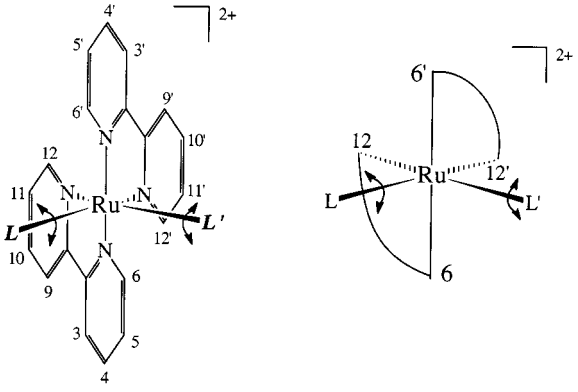
Keywords: Ruthenium / NMR spectroscopy / Nitrogen heterocycles / Fluxionality

In complexes of the type *cis*-[Ru(bpy)$_2$(L)$_2$](PF$_6$)$_2$ the fluxional behaviour (dynamics of rotation) of the monodentate heterocyclic ligands (L) in solution can be well investigated with ^{1}H NMR spectroscopy. As both the *cis*-[Ru(bpy)$_2$] moiety and the coordinated 4-picoline have a C_2 symmetry, no atropisomers of *cis*-[Ru(bpy)$_2$(4Pic)$_2$](PF$_6$)$_2$ are possible, and as a result a relatively easily understandable ^{1}H NMR spectrum is observed. The fast and slow rotation of the 4-picoline ligands have been monitored using variable-temperature 1D and 2D ^{1}H NMR spectroscopy. In addition the room temperature, solid state, X-ray structure is presented.

Introduction

The investigation of the coordinative and fluxional behaviour (dynamics of rotation) of metal-coordinated heterocyclic ligands is important for the understanding of the biological functions and activity of transition metal ions in living systems.[1,2] The solid-state and solution studies on platinum compounds with *cis* bifunctionally coordinated DNA (model) bases, have provided an enormous insight into the activity of these kinds of antitumour complexes on a molecular level.[3,4] Ruthenium complexes which are currently under investigation for their potential use as antitumour agents [2,5] are mostly octahedral six-coordinated complexes; the *cis* bifunctional coordination of heterocyclic ligands is therefore different from square-planar platinum complexes and is as yet not well understood. The ruthenium(II) antitumour complex *cis*-[Ru(dmso)$_4$Cl$_2$] was the first suitable system to study the coordinative and fluxional behaviour of *cis bis*-adducts of the type *cis*-[Ru(dmso)$_2$Cl$_2$(L)(L′)] with L and L′ being heterocyclic N-donor ligands.[6−12] The recent finding that structurally similar *cis*-dichlororuthenium(II) complexes of the type *cis*-[Ru(LL′)$_2$Cl$_2$] {in which LL′ is a chelating N-donor ligand like 2,2′-bipyridine[13] or 2-(phenyl)azopyridine[14]} show very different biological activity, inspired us to investigate in detail the coordination and the fluxional behaviour of monodentate heterocycles in the complexes of the type *cis*-[Ru(LL′)$_2$(L)$_2$](PF$_6$)$_2$.



Scheme 1. Structural (left) and schematic (right) representation of the A enantiomer of the *cis*-[Ru(bpy)$_2$(L)$_2$]$^{2+}$ system and proton numbering scheme of the bpy

In the complexes *cis*-[Ru(bpy)$_2$(L)$_2$](PF$_6$)$_2$ (Scheme 1), in which the L's are imidazole-type ligands, the ligands can flip around their Ru−N axis, either fast or slowly on the NMR timescale, depending on the size of the substituents on the imidazole ring and on the temperature.[15,16] With the relatively small 1-methylimidazole (MeIm), the ^{1}H NMR spectrum of the complex shows fast rotation of the monodentate ligands at all the measured temperatures. The sterically more demanding 1,2-dimethylimidazole (Me2Im) and 1-methylbenzimidazole (MeBim) are fast rotating on the ^{1}H NMR timescale, at temperatures above room temp.,

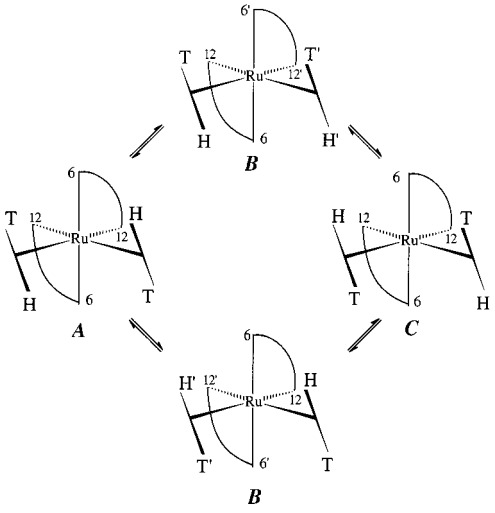
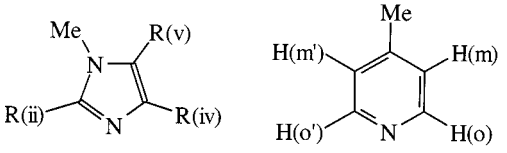
but are relatively slow rotating at temperatures below 0 °C.[15,16]

1-Methylimidazole, 1,2-dimethylimidazole, and 1-methylbenzimidazole are so-called lopsided ligands of which one site can be defined as the head (H) and the other as the tail (T). In octahedral sites, lopsided ligands can theoretically orient in 4 staggered positions, but in practice usually only one orientation is preferential. In *cis*-$[Ru(bpy)_2(L)_2](PF_6)_2$ (L = imidazole ligand) two staggered orientations are not accessible because of the steric bulk of the bidentate bpy; however, the imidazole ligands do occur in the other two orientations on the ruthenium. All the resulting four possible atropisomers have been observed and identified for the Me_2Im and MeBim complexes: two head-to-head (HH) isomers (which have the corresponding atoms of the imidazole at the same site of the N−Ru−N plane) and two head-to-tail (HT) isomers (in which the corresponding atoms of the imidazole ligands are at opposite sites of the N−Ru−N plane) (Scheme 2).[15,16] The two HT isomers, A and C, both have a twofold symmetry axis which causes the two bpy ligands and the two imidazole ligands to be identical and indistinguishable with ^{1}H NMR spectroscopy. Due to the twofold symmetry in the *cis*-$[Ru(bpy)_2]$ moiety, the hypothetical HH atropisomers, B and B′, are identical to each other; the HH orientation of the lopsided monodentate ligands causes the two bpy ligands in these atropisomers to be inequivalent, as can be observed with ^{1}H NMR spectroscopy. In general, the presence of atropisomers causes complex, but interesting spectra; therefore the use of a relatively simple system with high symmetry is important for a detailed understanding of the data.



Scheme 2. Schematic representation of the 4 possible atropisomers of the A enantiomer of the *cis*-$[Ru(bpy)_2(L)_2]_2$, system. For L = 4-picoline these atropisomers all become identical

In the present study the synthesis and room temperature, solid state, X-ray structure of the high-symmetry molecule *cis*-$[Ru(bpy)_2(4Pic)_2](PF_6)_2$ (**1**) is described and the fluxional behaviour of the 4-picoline (4Pic) ligands in solution



Scheme 3. Structural representation and proton numbering scheme of 1-Methylimidazoles (left) and 4-picoline (right)

is discussed. The rod-like 4Pic ligand coordinates via the N-atom, and therefore is not a lopsided ligand like the methylimidazole ligands (Scheme 3). The CH_3 groups of the 4Pic ligand rotate rapidly making the ligand rod like. Due to the three twofold symmetry axes present in complex **1** {one for the *cis*-$[Ru(bpy)_2]$ moiety and one for each Ru-picoline moiety}, no atropisomers of *cis*-$[Ru(bpy)_2(4Pic)_2](PF_6)_2$ are possible, resulting in fully interpretable ^{1}H NMR spectroscopic data.

Results and Discussion

Solid-State Structure

The *cis*-$[Ru(bpy)_2]$ moiety is chiral, and in the crystal structure of I both the A and A enantiomers have been found in the unit cell (complex A and B). In Figure 1 the molecular structure of one of the two symmetry-independent enantiomers is reported together with the atom numbering. The most significant geometrical parameters are summarized in Table 1. The structure of each enantiomer shows a six-coordinated pseudo-octahedral ruthenium ion with all ligands in a *cis* configuration. The Ru−N bond lengths for the bpy ligands in the two *cis*-$[Ru(bpy)_2(4Pic)_2]^{2+}$ moieties range from 2.042(4) to 2.084(4) Å and are significantly shorter than those involving the 4Pic ligands [2.103(4) to 2.122(4) Å]. These values are quite similar to those in *cis*$[Ru(bpy)_2(L)_2](BF_4)_2$, where

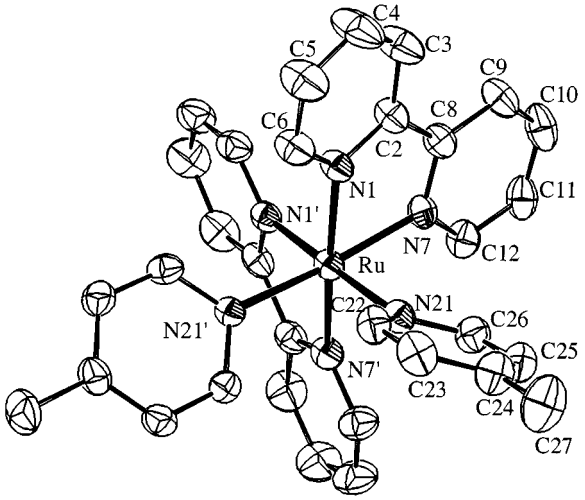


Figure 1. Thermal ellipsoid plot of one of the A enantiomers of 1. The PF_6^- anions, co-crystallised solvent molecules and protons are omitted for clarity. The view is approximately the same as in Schemes 1 and 2. Relevant data are given in Tables 1 and 2

Table 1. Selected bond lengths [Å] and bond angles [°] for the two independent complex units A and B of *cis*-$[Ru(bpy)_2(4Pic)_2](PF_6)_2$

	Complex A	Complex B
Rul−N7	2.060(4)	2.042(4)

Rul−Nl′	2.070(4)	2.073(4)
Rul−N7′	2.056(5)	2.053(5)
Rul−N21	2.103(4)	2.122(4)
Rul−N21′	2.104(5)	2.108(4)
N7−Rul−N1	78.7(2)	78.9(2)
Nl−Rul−N21	97.6(2)	99.1(2)
Nl′−Rul−N21	87.6(2)	85.6(2)
N7−Rul−Nl′	96.0(2)	96.2(2)
N7−Rul−N21′	90.4(2)	90.1(2)
Nl−Rul−N21′	84.9(2)	88.0(2)
Nl′−Rul−N21′	99.0(2)	98.3(2)
N21−Rul−N21′	90.6(2)	91.7(2)
N7−Ru I−N7′86.4(2)	87.1(2)	
N1−Rul−N7′	96.7(2)	94.3(2)
Nl′−Rul−N7′	79.1(2)	79.1(2)
N21−Rul−N7′	92.8(2)	91.2(2)
N7−Rul−N21	176.2(2)	177.2(2)
N1−Rul−Nl′	173.5(2)	172.1(2)
N7′−Rul−N21′	176.0(2)	175.9(2)

the Ru−N bond lengths range from 2.04 to 2.05 Å for the bpy ligands and from 2.09 to 2.10 Å for the Im ligands.[17] Labelling the bpy involving the N1 and N7 as bpy#1, that involving the Nl′ and N7′ as bpy#2, the 4-picoline involving N21 as 4Pic#1 and the 4-picoline involving the N21′ as 4Pic#2, the mean values of the dihedral angles between the least-squares plane through the ligands in the two *cis*-$[Ru(bpy)_2(4Pic)_2]^{2+}$ complexes are: 58.9(2)° (bpy#1−4Pic#1), 85.6(1)° (bpy#1−4Pic#2), 84.3(2)° (bpy#2−4Pic#1), 46.8(1)° (bpy#2−4Pic#2), 79.3(1)° (bpy#l-bpy#2) and 59.5(1)° (4Pic#1−4Pic#2).

In conclusion, in both *cis*-$[Ru(bpy)_2(4Pic)_2]^{2+}$ cations the 4Pic ligands, gauche to each other, are orthogonal only to one bpy, whereas they are tilted with respect to the other bpy on angles which range from 47 to 59°. The bond lengths and angles in the PF_6^- anions and in the acetone solvate molecule are as expected. The *cis*-$[Ru(bpy)_2(4Pic)_2]^{2+}$ cations interact with the PF_6^- anions through an array of CH···F hydrogen interactions.

Solution Structure

The ^{1}H NMR spectrum of **1** in [D_6]acetone at room temp. (Figure 2) shows a total of ten multiplet signals in the aromatic region, four doublets and four triplets of equal intensity and two doublets with an integral value twice as high as that of the other eight multiplets. All resonances could be assigned as shown in Figure 2 on the basis of COSY and NOESY spectra (see Supplementary Material), in a similar way as has been described for the analogous imidazole complexes.[15,16] The fact that the two H(*ortho*) protons [and the two H(*meta*) protons] resonate at the same frequency, indicates that the picolines rotate fast on the NMR timescale around their Ru−N axes. Upon lowering the temperature, the eight bpy signals show a small down-field shift, but remain sharp multiplets over the whole temperature range measured. In contrast, the two 4Pic doublets H(*ortho*) and H(*meta*), at δ = 8.4 and 7.3, respectively, first start broadening on lowering the temperature and finally, both, split up in two doublets at −90 °C separated by 56 and 27 Hz, respectively (Figure 2).

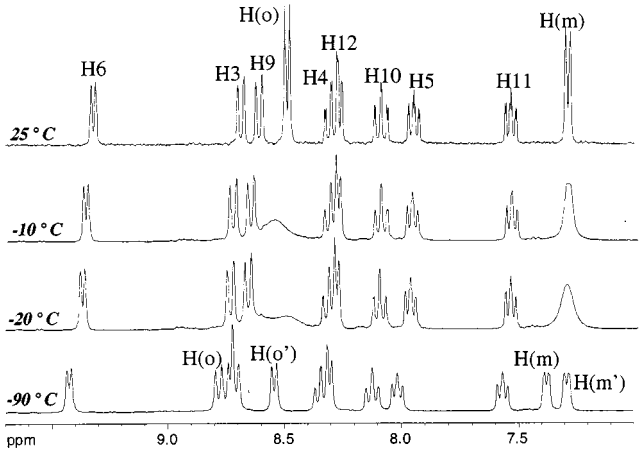

Figure 2. Aromatic region of the ^{1}H NMR spectra of I in [D_6]acetone at room temp., −10, −20, and −90 °C

The fact that the four aromatic 4-picoline protons have become inequivalent at low temperatures, whilst the two bpy ligands and the two picoline ligands remain indistinguishable, indicates that the 4Pic ligands slowly flip by 180° between two orientations, on the NMR timescale, and all four atropisomers depicted in Scheme 2 are present. Due to the symmetries present in the system (which makes the four atropisomers identical and thus indistinguishable) only a total of 12 resonances are found in the aromatic region of the spectrum.

2D NMR techniques like NOESY and **ROESY** are powerful methods for accurately determining the orientation of monodentate ligands in atropisomers and their rotational behaviour (via interligand NOE cross-peaks and exchange cross-peaks). In Figure 3 the aromatic region of a **ROESY** spectrum of I is shown and the most characteristic interligand cross-peaks are indicated. The most down-field shifted H(*ortho*) doublet shows a NOE cross-peak with the bpy H6, as well as the H12 (of the other bpy!) indicating this resonance belonging to the H(o) proton, which is wedged in between the two bpy ligands. The NOE cross-peak of the other H(*ortho*) doublet, H(o′), with only the H6 resonance confirms the assignment of this peak to the 4Pic H(o′) proton which is oriented in between a bpy and the other picoline. The relative down-field shift of the H(o) with respect to the H(o′) signal is nicely explained by the stronger deshielding the former protons experience with respect to the latter. In Figure 4, a space-filling model of I clearly shows the H(o) proton to be wedged in between the two bpy ligands, but not above the (shielding) aromatic pyridine rings. The H(o′) proton is situated close to one bpy on the opposite site with respect to where the H(o) of the other 4Pic is positioned, but in addition, this proton is oriented just above the aromatic ring of the neighbouring pico-

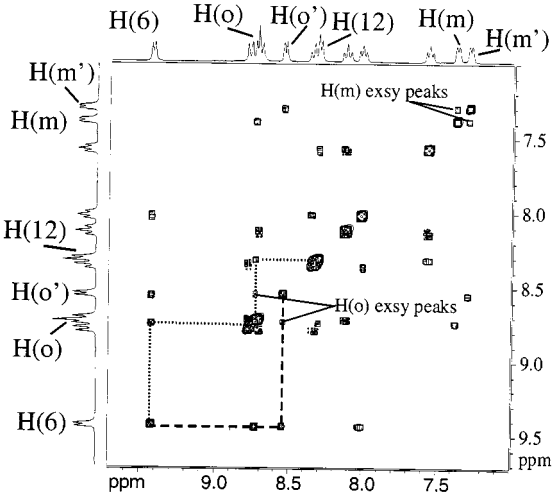

Figure 3. Positive (EXSY) and negative (NOE) level of the aromatic region of the **ROESY** spectrum of I in [D_6]acetone at −100 °C, recorded with a mix time of 500 ms. The H(o)−H6 and H(o)−H12, and the H(o′)−H12 NOE cross-peaks are indicated with a dotted and dashed line, respectively. The observed exchange peaks are between the H(o) and H(o′), and the H(m) and H(m)′ resonances

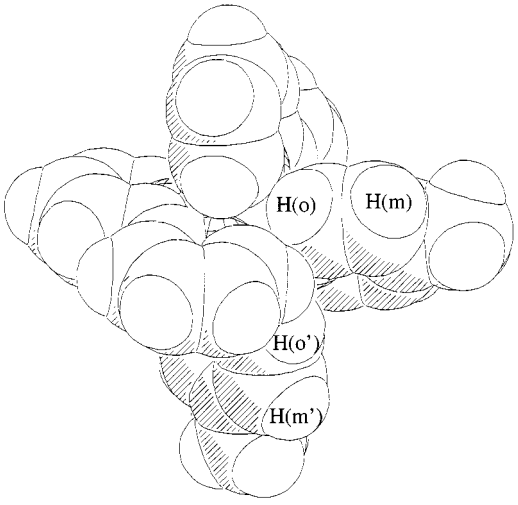

Figure 4. Space-filling representation of the solid state molecular structure of the A enantiomer of the cation of 1. The H(o) proton is clearly wedged in between the H6 site of one bpy and the H12 site of the other bpy, whilst the H(o′) proton is close to the pyridine rings of a bpy as well as the neighbouring 4-picoline

line ligand, which nicely supports the explanation of the relative upfield shift of 0.2 ppm of this proton. However, the solution and solid state orientations of the ligands should, by no means, be considered to be the same by default.

Although the VT ^{1}H NMR spectroscopic data indicate the slowing down of the rotation of the picolines around their Ru−N axes at lower temperatures, the ligands do not stand still on the NMR timescale at the lowest temperature investigated (−100 °C). In Figure 3 the exchange level of the ROESY spectrum is shown in which clear cross peaks are present between the two H(*ortho*) proton signals, H(o) and H(o′), of the picoline and also between the two H(*meta*) proton resonances, H(m) and H(m′). The picoline thus exhibits a greater fluxionality than the bulky MeBim and Me2Im ligands in the analogous complexes, that only show exchange cross-peaks at higher temperatures.[15,16] In practice this means that the four atropisomers of I can interchange even at temperatures as low as −90 to −100 °C, albeit slow on the NMR timescale. Picoline is obviously less hindered in its rotation around its Ru−N axis than are the bicyclic MeBim or the Me2Im in the $[Ru(bpy)_2(L)_2]^{2+}$ complexes. On the other hand, the VT NMR spectroscopic data of the 4Pic complex clearly show a slow rotation of the monodentate ligands at lower temperatures, whereas the MeIm complex does not reach the stage of slow rotation under the same conditions. Assuming the ruthenium(II)−nitrogen bonds to be similar in picoline and imidazole complexes, the six-membered ring ligand has its protons *ortho* to the coordinating nitrogen lying closer to the coordination plane than the analogous protons, H(ii) and H(iv), in the heterocyclic five-membered ring. As there are no electrostatic effects expected to influence the orientational and fluxional behaviour of the monodentate ligands in the complex *cis*-$[Ru(bpy)_2(L)_2](PF_6)_2$, the differences observed for complexes with different ligands can be attributed mainly to steric differences. For the above mentioned monodentate ligands the order of steric hindrance in these complexes is found to be:

$$\text{MeIm} < \text{4Pic} < \text{Me2Im} = \text{MeBim}$$

From the atropisomerisation study on the imidazole complexes,[15,16] it is reasonable to assume that the interconversion of the 4 rotamers of I occurs by the flipping of one picoline at a time, by 180°. As all the 4 rotamers are identical, the rate of the back and forward flipping of one picoline between two rotamers is the same. This facilitates the determination of the thermodynamic parameters, because the atropisomerisation process of **1** can now be regarded as a simple dynamic system with 2-site mutual exchange, i.e. two identical compounds interconverting into each other by the flipping of one picoline ligand. Using the temperatures (T_c and the rate constants (k_c) determined at the coalescence points of the H(*ortho*) signals (235 K, 124 s^{-1}) and the H(*meta*) signals (225 K, 60 s^{-1}), from the Eyring equation,[18] the consecutively determined free energy of activation $\Delta G^{\#}$ for the picoline rotation in I is 48 kJ·mol^{-1}, the free enthalpy of activation, $\Delta H^{\#}$, is 30 kJ·mol^{-1}, and the free entropy of activation, $\Delta S^{\#}$, is −75 J·K^{-1}·mol^{-1}. The Arrhenius activation energy E_A is found to be 32 kJ mol^{-1}.

Conclusion

The *cis*-$[Ru(bpy)_2Cl_2]$ complex has been investigated for its binding properties to DNA[13,19] and DNA model bases[20] and appears to be a borderline complex with respect to monofunctional or bifunctional coordination to DNA purines. The restricted rotational behaviour of lopsided methylimidazole ligands in *cis*-$[Ru(bpy)_2(L)_2](PF_6)_2$ has confirmed the steric hindrance of the bidentate ligands with

incoming N-heterocycles.[15,16] In the present study the *cis*-$[Ru(bpy)_2(4Pic)_2](PF_6)_2$ complex is shown to be a relatively simple, but very interesting system in the investigation of the fluxional behaviour of heterocyclic monodentate ligands on octahedral complexes. The differences in fluxional behaviour between the heterocyclic six-membered ring 4Pic and the five-membered ring MeIm ligands as observed with VT NMR spectroscopy in the complexes *cis*-$[Ru(bpy)_2(L)_2](PF_6)_2$ emphasise that the coordinative behaviour of heterocyclic ligands, on six-coordinated complexes like ruthenium is influenced by small differences in steric properties. In addition, the high symmetry complex **1** has allowed for relatively easy determination of the thermodynamic parameters of the fluxional behaviour of such complexes.

Experimental Section

General Remarks: NMR: Bruker DPX 300 MHz spectrometer. For [D_6]acetone as solvent, δH = 2.06, between −90 °C and +50 °C. NOESY[21] and ROESY[22,23] spectra with mixing times of 1.0 s and 0.5 s, respectively, were obtained using the Bruker pulse programs. Hydrated $RuCl_3$ was used as received from Johnson Matthey Inc. 2,2-Bipyridine (Fluka), 4-picoline (Merck) were used without further purification. *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ was prepared according to a literature procedure.[24]

***cis*-$[Ru(bpy)_2(4Pic)_2](PF_6)_2$ (1):** Preparation was performed by a method slightly different from that reported by Henderson et al.[25] *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (0.26 g, 0.5 mmol) and 4-picoline (0.5 g, ca 5 mmol) in 50 mL of water were refluxed for 3 hours. At room temperature the reaction mixture was filtered and to the clear red solution a concentrated aqueous solution of NH_4PF_6 (1.6 g, 10 mmol) was added. The formed precipitate was isolated by filtration and washed with water. After recrystallisation from acetone/water, complex I was obtained as an orange red microcrystalline powder that was isolated by filtration and washed with diethyl ether. Yield: 0.30 g (75%), characterisation by NMR spectroscopy and elemental analyses. Recrystallisation from acetone/water yielded red crystals suitable for X-ray diffraction study. Because of the photolability of complex I the NMR samples were stored in the dark.

X-ray Crystallographic Study: Data were collected on a Bruker SMART diffractometer equipped with graphite monochromated Mo-K_α radiation source (λ = 0.71073 Å) and a CCD detector. The frames data were processed to give structure factors using the program SAINT.[26] The crystal data and the most relevant experimental parameters used in the X-ray measurements and in the crystal structure analyses are reported in Table 2. The phase problem was solved by Direct Methods by using SIR92[27] that revealed two independent complex molecules of formula $C_{32}H_{30}F_{12}N_6P_2Ru$ and one acetone solvent molecule in the asymmetric unit. Atomic coordinates and anisotropic thermal parameters were refined by blocked full-matrix least-squares methods on F^2 using the SHELXL-97 program.[28] The hydrogen atoms were placed at their calculated positions with the geometrical constraint C−H 0.96 A and refined "riding" on their corresponding carbon atoms. The final molecular geometry was analysed with the program PARST97.[29] All calculations were carried out on the DEC Alpha 250 workstation at the Centro di Studio per la Strutturistica Diffrattometrica of C.N.R., Parma. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-143552. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Novel Monodentate Phosphoramidites By Chiral Pool Synthesis Starting from D-Mannitol, and Their Pd^{II} and Rh^{I} Complexes

Alexander Bayer,[a] Ulf Thewalt,[b] and Bernhard Rieger*[a]

Keywords: Asymmetric synthesis / Chiral pool / Rhodium / P ligands / Palladium

The new monodentate phosphoramidites **6a**–**e** were prepared in an ex-chiral-pool synthesis from readily available D-mannitol in high yields. A ring opening of 1,2;5,6-dianhydro-3,4-*O*-isopropylidene-D-mannitol (**4**) with nucleophiles provides the chiral diols **5a**–**e** with different steric demand as key intermediates. The ligands **6a**–**e** are synthesized by refluxing **5a**–**e** with hexamethyltriaminophosphane (HMTAP) and lead, after treatment with $[PdCl_2(COD)]$ or $[Rh(COD)_2][SO_3CF_3]$, to the corresponding Pd complex **8a** and rhodium(I) complexes **7a**–**e**, respectively. The *cis*-arrangement of the ligands and the C_2-symmetry of the complexes in the solid state is demonstrated by an X-ray structure investigation performed on **8a**. In addition, variable temperature NMR experiments show that **8a** keeps its C_2-symmetric coordination geometry even at temperatures up to 90 °C (decomposition).

Introduction

Worldwide activity in the development of C_2-symmetric, bridged bisphosphane complexes for asymmetric catalyzed reactions began in the late 1970's and continued strongly until the end of the 1980's. Then, major emphasis was spent on the development of biocatalysts for catalytic organic transformations. It is well known that both enzymes and organometallic complexes occupy their own specific catalytic field. In organometallic chemistry bidentate ligands were supposed to be superior to the monodentate ones as the resulting rigidity of the catalysts favors effective chiral induction.[1] Consequently, monodentate ligands were neglected in asymmetric hydrogenations until Pringle et al. questioned the superiority of bidentate structures. These authors found higher enantioselectivities (92% *ee*) using an asymmetric monophosphonite rather then the corresponding C_2-symmetric diphosphonite in the hydrogenation of methyl-2-acetamido acrylate.[2] Excellent enantioselectivities (>99% *ee*) have also been reported with monodentate phosphites[3] and phosphoramidites,[4,5] inducing a renaissance in the investigation of monodentate ligands of the above type. However, a disadvantage of these species is their limitation to the binaphthol backbone, which does not allow a rational catalyst design.

We report here on a straightforward and highly variable synthetic protocol based on an ex-chiral-pool synthesis starting from D-mannitol[6] to generate monodentate phosphoramidites bearing four stereogenic centers. This approach allows us to introduce a variety of substituents with different steric demand at key positions at the stereogenic centers by using selected nucleophiles in epoxide ring-opening reactions. The structure and dynamic behavior of the corresponding Pd^{II} and Rh^{I} complexes was investigated by a combination of X-ray diffraction in the solid state and variable temperature NMR spectroscopy in solution.

Results and Discussion

The starting material for our synthetic strategy is the commercially available and cheap D-mannitol (**1**), which was converted into the 1,2;3,4;5,6-tri-*O*-isopropylidene derivative (**2**). Subsequent acidic cleavage of two protecting groups yielded the 3,4-*O*-isopropylidene-D-mannitol (**3**) selectively.[7,8] 1,2;5,6-Dianhydro-3,4-*O*-isopropylidene-D-mannitol (**4**) was prepared from **3** in a simple one pot synthesis according to a literature procedure.[9] The stereoisomer 1,2;5,6-dianhydro-3,4-*O*-isopropylidene-L-iditol,[7] with a different configuration at carbon atoms C2 and C5, is also available and provides access to additional chiral diols. Ring-opening reactions using organolithium or Grignard compounds afford the chiral key-diols **5a**−**e**. Nucleophilic attack of $LiAlH_4$ opens the epoxide ring to form (2*R*,3*R*,4*R*,5*R*)-3,4-*O*-isopropylidene-2,3,4,5-hexanetetraol (**5a**).[10] Compounds **5b**−**e** were prepared by treatment with organocuprates − generated from the copper(I) bromide−dimethyl sulfide complex − and the correspond-

ing alkyl- or phenylmagnesium bromides in diethyl ether.[11] The monodentate phosphoramidites (**6a**−**e**) were formed in high yields by refluxing **5a**−**e** and HMTAP in toluene (Figure 1).

The corresponding yellow-orange Rh^I complexes **7a**−**e** and the pale yellow Pd^{II} complex **8a** were prepared by stirring two equivalents of monodentate ligand **6a**−**e** with $[Rh(COD)_2][SO_3CF_3]$ or $[PdCl_2(COD)]$ in dichloromethane.

We were not able to obtain suitable crystals of one of the rhodium(I) complexes for X-ray diffraction, but we succeeded in crystallizing the isoelectronic Pd^{II} species **8a** from methanol. Its X-ray structure clearly shows the *cis*-coordination of the two monodentate phosphoramidite ligands **6a** and the expected square-planar coordination environment of Pd^{II} (Figure 2a, Table 1) with a chiral, C_2-symmetric arrangement of both P ligands (Figure 2b).

No sign of other diastereomers (rotamers) could be found, indicating a stable chiral conformation, at least in the solid state. The side-view (Figure 2b) furthermore shows that the tunable substituents (Figure 1, CH_2−R) of the monodentate phosphoramidites (Figure 2, R = H; C1, C10) occupy the top-left and bottom-right quadrants, thus defining a chiral cage around the metal center, the size of which is determined by the nucleophile used for the epoxide ring-opening. Quadrant diagrams have often been used to explain the achieved enantioselectivity with several known asymmetric diphosphane-rhodium catalysts in hydrogenations. Knowles suggested to use X-ray structures to predict the absolute configuration of hydrogenation products from the chiral cage of the catalyst.[12] We are looking forward to check these predictions in applying **7a**−**e** in the asymmetric hydrogenation of prochiral olefins. The rigidity of the C_2-symmetric ligand arrangement in solution is further supported by variable temperature ^{31}P NMR spectroscopy. The spectra of **8a** show a sharp singlet at δ = 102.49, which remains unaltered between −30 °C and +90 °C (decomposition). The Rh^I complexes **7a**−**e** have ^{31}P NMR spectra with a single sharp doublet. Variable temperature NMR experiments performed on **7a** show an unaltered signal at δ = 118.92 between −30 °C and +60 °C, which again indicates the presence of a single isomer. At higher temperatures a second doublet grows at δ = 86.67, which could be due to a further complex species. This second species undergoes decomposition, as we noticed from a NMR measurement the next day, while the initial Rh^I complex is still present.

Conclusion

We have introduced an efficient, ex-chiral-pool synthetic route to a new family of chiral, monodentate phosphorus ligands with different steric demand. Their corresponding C_2-symmetric Rh^I and Pd^{II} complexes bear two *cis*-arranged ligands both in the solid state and in solution. In addition, the complexes are thermally stable up to 60 and 90 °C, respectively. Due to the variability of the ligand synthesis, changes of the configuration of the stereogenic cen-

ters (Figure 2, C2, C5 and C11, C14) and modifications of their substitution can easily be introduced. This is a prerequisite for adopting the catalysts to new substrates in asymmetric transformations. Investigations on this topic are underway.

Experimental Section

General Remarks: All reactions and manipulations were performed using standard Schlenk techniques. The reagents were obtained from Aldrich, Fluka, Merck and Strem and used without purification. Diethyl ether, tetrahydrofuran, toluene and pentane were distilled from $LiAlH_4$, dichloromethane was distilled from CaH_2 under nitrogen.

Melting points were determined on a Büchi Melting Point B-540 and are uncorrected. Optical rotation was obtained on a POLARmonitor from IBZ Messtechnik. Elemental analyses were carried out on a Elementar Vario EL. Mass spectrometry was performed on a Finnigan MAT, TSQ 7000 (FAB, matrix: 2-nitrophenyloctyl ether) and a Finnigan MAT, SSQ 7000 (CI: CH_4. EI: 70 eV). ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on Bruker DRX 400 spectrometer. Chemical shifts are reported in ppm downfield from tetramethylsilane with the solvent as the internal standard or 85% H_3PO_4 as the external standard.

Synthesis of Chiral Diols 5a−e: The diols **5a** and **5b** were prepared according to known procedures.[10,11]

General Procedure for the Synthesis of 5c−e: $CuBr{\cdot}SMe_2$ (3 mmol) was added to a stirred suspension of the appropriate alkyl- or phenylmagnesium bromide (120 mmol) in diethyl ether (100 mL) at −40 °C. After stirring at −40 °C for 2 h, **4** (30 mmol) in 30 mL tetrahydrofuran was added. After 1 h stirring at room temperature the mixture was poured into a saturated aqueous NH_4Cl solution. The organic layer was extracted, washed with water, dried over Na_2SO_4 and the solvents evaporated to dryness to give the pure products **(5c−e)** after flash chromatography (eluting with hexane/EtOAc; 7:3).

(4*R*,5*R*,6*R*,7*R*)-5,6-*O*-isopropylidene-4,5,6,7-decanetetraol (5c): Oil. Yield: 6.78 g, 91.8%. $[\alpha]_D^{23} = +25.8$ ($c = 1.0$, $CHCl_3$). ^1H NMR (400 MHz, $CDCl_3$): δ = 3.61−3.59 (m, 2 H, CH), 3.55−3.49 (m, 2 H, CH), 1.74−1.66 (m, 2 H, CH_2), 1.58−1.45 (m, 2 H, CH_2), 1.45−1.33 (m, 4 H, CH_2), 1.32 (s, 6 H, CH_3), 0.91 (t, 6 H, CH_3). ^{13}C NMR: δ = 108.67, 83.24, 72.88, 36.34, 26.85, 18.26, 14.00. Synthesis of Rhodium(I) Complexes. General Procedure for the Synthesis of 7a−e: A solution of 2 equivalents of the corresponding monodentate phosphoramidite **6a−e** in 20 mL dichloromethane was added to a stirred solution of $[Rh(COD)_2][SO_3CF_3]$ (300 mg, 0.64 mmol) in 30 mL of dichloromethane at 0 °C. After stirring for 2 h at room temperature, the solvent was removed under reduced pressure. The resulting orange solid was washed twice with 50 mL pentane and dried in vacuo.

{Bis[(4*R*,5*S*,6*S*,7*R*)-5,6-*O*-isopropylidene-2-dimethylamino-4,7-dimethyl-1,3,2-dioxaphosphepane]Rh(COD)} Trifluoromethanesulfonate (7a): Yield: 557 mg, 98.2%. ^1H NMR (400 MHz, $CDCl_3$): δ = 5.53−5.45 (m, 2 H, CH_{COD}), 5.19−5.11 (m, 2 H, CH_{COD}), 4.33−4.23 (m, 2 H, CH), 4.09−3.99 (m, 2 H, CH), 3.42−3.36 (m, 2 H, CH), 3.30−3.24 (m, 2 H, CH), 3.03−2.98 (m, 12 H, N−CH_3), 2.77−2.31 (m, 8 H, CH_2 $_{COD}$), 1.39 (s, 6 H, CH_3), 1.36 (s, 6 H, CH_3), 1.33 (d, 6 H, CH_3), 1.29 (d, 6 H, CH_3). ^{31}P NMR: δ = 118.92 (d). X-ray Crystallography of 8a: The crystal used in this study was mounted onto the end of an glass fiber. X-ray data were collected at −100 °C on a STOE IPDS unit (Imaging Plate Diffraction System). Graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. Crystal data are listed in Table 2 together with refinement details. Absorption corrections were not applied. The structure was solved by the Patterson method with the SHELXS-86 program.[13] The atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined using the SHELXL-97 program;[14] full-matrix method, F^2 data. Hydrogen atoms were included in the final refinement cycles in a riding mode.
Crystallographic data (excluding structure factors) for the structure(s) included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-165693. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Pyrazolylborate Nickel(II) Complexes as Catalysts for the Formation of Polyketones from Ethene and Carbon Monoxide − Partial Hydrolysis of the Bis(pyrazolyl)borate Yields a Pyrazolyl(hydroxo)borate Ligand

Wolfgang Kläui,*[a] Barbara Turkowski,[a] Gerd Rheinwald,[b] and Heinrich Lang[b]

Keywords: Nickel / N ligands / Homogeneous catalysis / Copolymerization / Polyketones / Solvolysis

The new nickel(II) complex [Ni{BBN(pz)$_2$}(*o*-tol)(PPh$_3$)] (**1**) of the bis(pyrazolyl)borate ligand [BBN(pz)$_2$]$^-$ (BBN = 1,5 borabicyclo[3.3.1]nonane) has been prepared by reaction of [NiBr(*o*-tol)(PPh$_3$)$_2$] with K[BBN(pz)$_2$]. In the presence of moisture this reaction yields the nickel(II) complex [Ni{BBN(pz)(OH)}(*o*-tol)(PPh$_3$)] (**2**). The hydroxoborate ligand [BBN(pz)(OH)]$^-$ acts as an *N*,*O*-chelate ligand in **2**. Compound **1** and the analogous nickel complex [Ni{HB(3-Phpz)$_3$}(*o*-tol)(PPh$_3$] show very similar activity in the catalytic copolymerization of carbon monoxide and ethene. This suggests that the borane hydrogen and the noncoordinated pyrazolyl ring in the latter are not essential for the catalysis. Compound **2** is inactive. Both **1** and **2** were characterised by X-ray crystallography.

Introduction

Recently we have found that the nickel(II) complex [Ni{HB(3-Phpz)$_3$}(*o*-tol)(PPh$_3$)] catalyses the copolymerization of carbon monoxide and ethene under mild reaction conditions.[1] The coordination around nickel is planar with the tripodal tris(pyrazolyl)borate moiety acting as a bidentate ligand. In the solid state the third, noncoordinated pyrazolyl ring faces away from the coordination plane. This has the effect that borane hydrogen lies in the vicinity of nickel (Figure 1).

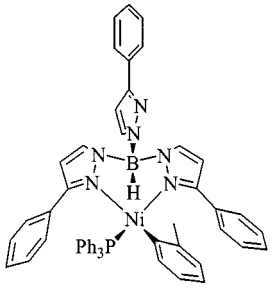

Figure 1. The structure of [Ni{HB(3-Phpz)$_3$}(*o*-tol)(PPh$_3$)]

It was not clear at all why this nickel(II) complex is catalytically active. Does the tridenticity of the ligand play a role? Is the borane hydrogen important for the catalysis?

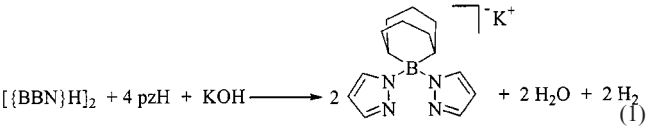
Straße der Nationen 62, 09107 Chemnitz, Germany

To answer these questions, we have now synthesised an analogous nickel(II) complex with the dipodal bis(pyrazolyl)borate ligand [BBN(pz)$_2$]$^-$. The potassium salt of this ligand is accessible from BBN, potassium pyrazolide and pyrazole [Equation (1)].[2,3]



Herein we report the synthesis, crystal structure, and catalytic activity of the novel organonickel(II) complex [Ni{BBN(pz)$_2$}(*o*-tol)(PPh$_3$)] (**1**) (Figure 2).

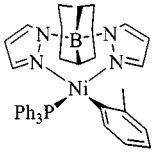


Figure 2. The structure of [Ni{BBN(pz)$_2$}(*o*-tol)(PPh$_3$)] (**1**)

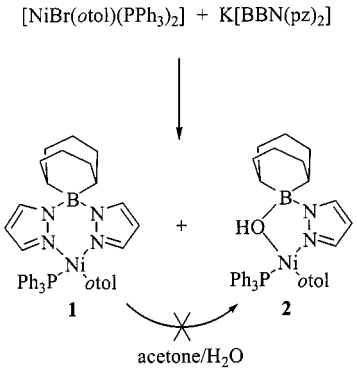
Results and Discussion

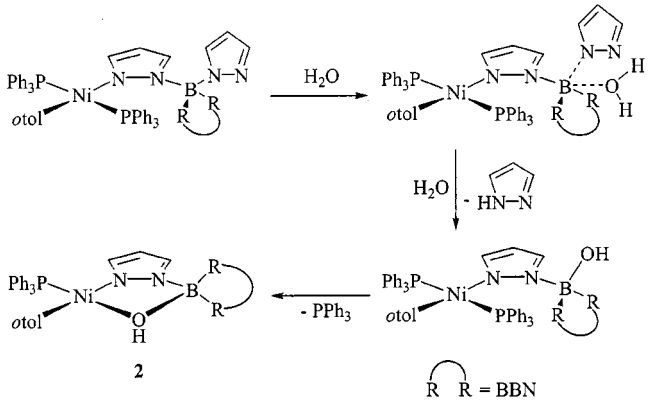
Synthesis of the Nickel(II) Complexes

[Ni{BBN(pz)$_2$}(*o*-tol)(PPh$_3$)] (**1**) was prepared by reacting [NiBr(*o*-tol)(PPh$_3$)$_2$] with K[BBN(pz)$_2$] in THF (Scheme 1). In the presence of moisture the ligand [BBN(pz)$_2$]$^-$ partly hydrolyses to form a hydroxoborate. This in turn acts as an *N*,*O*-chelate ligand to give the unusual complex [Ni{BBN(pz)(OH)}(*o*-tol)(PPh$_3$)] (**2**).

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434−1948/02/0101−0205 $ 17.50+.50/0



Scheme 1. Synthesis of the nickel complexes [Ni{BBN(pz)$_2$}-(*o*-tol)(PPh$_3$)] (**1**) and [Ni{BBN(pz)(OH)}(*o*-tol)(PPh$_3$)] (**2**)



Scheme 2. Hydrolysis of the [BBN(pz)$_2$]$^-$ ligand during the synthesis of **2**

The ^{1}H NMR spectra of **1** and **2** are similar and show the expected signals. The signals of the pyrazolyl ring and of the methyl group of the *o*-tolyl ligand in **2** experience a low-field shift in comparison with the ones of **1**. The BBN signals of both nickel complexes in the range $\delta = 0.5-2.3$ are broad and unresolved. The signal shifted downfield to $\delta = 4.4$ is assigned to the C7 proton, which is oriented towards the nickel atom (see Figure 3). A similar effect has been observed in the nickel complex [Ni{Et$_2$B(pz)$_2$}$_2$].[4] The signal of the hydroxyl proton in **2** appears as a doublet at $\delta = -0.5$. A ^{1}H{^{31}P} NMR decoupling experiment shows that the doublet structure is due to a $^3J_{PH}$ coupling.

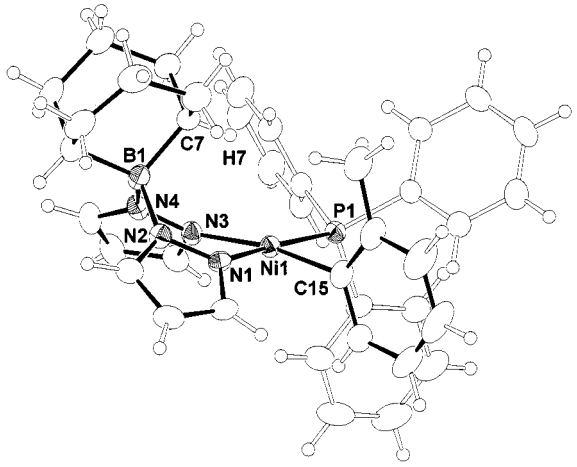


Figure 3. ZORTEP plot of [Ni{BBN(pz)$_2$}(*o*-tol)(PPh$_3$)] (**1**)

We have tried to pin down the conditions under which the hydroxoborate complex **2** is formed. From separate experiments we know that: (i) complex **1** does not hydrolyse to yield complex **2**, and (ii) the hydrolysis of the ligand [BBN(pz)]$^-$ in the absence of the nickel complex [NiBr(*o*-tol)(PPh$_3$)$_2$] is much slower than the formation of **2**. In Scheme 2 we have postulated how the formation of **2** could occur.[5]

Crystal Structures of the Nickel(II) Complexes

[Ni{BBN(pz)$_2$}(*o*-tol)(PPh$_3$)] (1)

The nickel complex **1** crystallises from acetone as dark yellow plates [monoclinic space group *Pn* with $a = 12.1313(8)$, $b = 13.0085(8)$, $c = 12.6192(8)$ Å, and $\beta = 107.492(2)°$]. The compound co-crystallizes with one molecule of acetone per formula unit. Figure 3 shows the structure of **1** in the crystal.

The four-coordinate nickel atom is in a planar arrangement. The bis(pyrazolyl)borate ligand coordinates in a bidentate fashion with a bite angle N1−Ni1−N3 of 89.80(13)°, and forms a six-membered chelate ring in a boat conformation. The *o*-tolyl ring is orientated nearly perpendicular to the coordination plane [torsion angle P1−Ni1−C15−C16: 99.2(4)°] in order to minimise the interaction with the neighbouring ligands.

The incorporated acetone molecule shows a weak non-classical hydrogen bond between H25 and the symmetry generated O1a (values are given in Table 1). The bond lengths and bond angles are in the expected[1] range (see Table 1).

[Ni{BBN(pz)(OH)}(*o*-tol)(PPh$_3$)] (2)

The nickel complex **2** crystallises from acetone as dark-yellow triclinic blocks [triclinic space group $P\bar{1}$ with $a = 12.1983(10)$, $b = 12.3689(10)$, $c = 13.7388(11)$ Å, $\alpha = 112.086(2)$, $\beta = 112.360(2)$ and $\gamma = 90.462(2)°$]. The compound co-crystallizes with one molecule of acetone per formula unit. Figure 4 shows the structure of **2** in the crystal.

The nickel atom is in a planar environment. The hydroxoborate ligand coordinates in a bidentate fashion with the nitrogen of the pyrazolyl ring and the oxygen of the hydroxyl group. The five-membered chelate ring shows an envelope conformation with a bite angle N1−Ni1−O1 of 81.5°.

The deviations from the least-squares plane including the atoms N1, N2, B1, O1, and Ni1 are: 0.0472(0.0008), 0.0488(0.0010), −0.1612(0.0010), 0.1836(0.0009) and −0.1184(0.0007) Å, respectively.

[a] Symmetry operation: $a = -1/2 + x, 1 - y, -1/2 + z$.

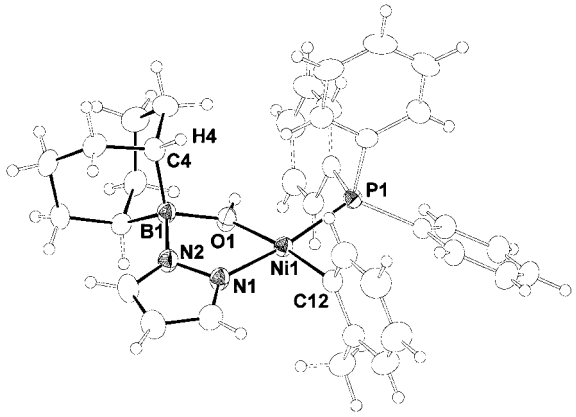

Figure 4. ZORTEP plot of [Ni{BBN(pz)(OH)}(*o*-tol)(PPh_3)] (**2**)

As in **1**, the incorporated acetone shows a weak nonclassical hydrogen bond between H1 and O2a as well as between H22 and O2b.

The bond lengths and bond angles are in the expected range.[1,6,7] Selected distances and angles of **2** are presented in Table 2.

Copolymerization Reactions with [Ni{$BBN(pz)_2$}(*o*-tol)(PPh_3)] (1)

The copolymerization of carbon monoxide and ethene was performed according to the reaction conditions reported for [Ni{$HB(3\text{-}Phpz)_3$}(*o*-tol)(PPh_3)] as catalyst.[1]

Table 2. Selected distances (Å) and angles (°) of **2**

Ni1−C12	1.8839(16)	C12−Ni1−O1	172.72(6)
Ni1−N1	1.8986(13)	N1−Ni1−O1	81.54(6)

C1−O2a[a]	3.3089		
C22−H22	0.98(2)	C22−H22−O2b[b]	162.98
H22−O2b[b]	2.4144		
C22−O2b[b]	3.3655		

[a] Symmetry operation: $a = 2 - x, 1 - y, 1 - z$. − [b] Symmetry operation: $b = 1 - x, 1 - y, 1 - z$.

The formation of polyketone is dependent on the carbon monoxide pressure (see Table 3)

The highest efficiency for the copolymerization of ethene and carbon monoxide with [Ni{$HB(3\text{-}Phpz)_3$}(*o*-tol)(PPh_3)] is observed with 3.5 bar of carbon monoxide.[1] Under the same reaction conditions complex **1** appears somewhat less efficient although the catalytic activity of [Ni{$HB(3\text{-}Phpz)_3$}(*o*-tol)(PPh_3)] and **1** is essentially the same.

The reaction of [$NiBr$(*o*-tol)(PPh_3)$_2$] with K[$BBN(pz)_2$] in the presence of moisture leads to the formation of [Ni{BBN(pz)(OH)}(*o*-tol)(PPh_3)] (**2**). However, **2** displays no activity in the formation of polyketone under the same reaction conditions as used with **1**. This is an interesting result as our group has recently found nickel complexes with *N*,*O*-chelate ligands that show a very high efficiency in the copolymerization of carbon monoxide and ethene.[6] It is still not clear which factors are essential for the catalytic activity of the nickel complexes. However, from the results described here we can conclude: (i) that the noncoordinated pyrazolyl ring of the tripodal nitrogen ligand in [Ni{$HB(3\text{-}Phpz)_3$}(*o*-tol)(PPh_3)] plays no important role in the copolymerization reaction, and (ii) that the borane hydrogen atom is not important for the catalytic activity via, for example, the formation of a nickel hydride species.

Table 3. Copolymerization of carbon monoxide and ethene at 60 °C in toluene; comparison of the nickel catalysts **1** and [Ni{$HB(3\text{-}Phpz)_3$}(*o*-tol)(PPh_3)][1]

Catalyst	Ethene pressure (bar)	CO pressure (bar)	Polyketone (g)	Efficiency (gPK/gNi)
1	40	20	0.47	60
1	40	10	0.70	90
1	40	3.5	0.38	50
[Ni{$HB(3\text{-}Phpz)_3$}(*o*-tol)(PPh_3)]	40	2.0	0.23	34
[Ni{$HB(3\text{-}Phpz)_3$}(*o*-tol)(PPh_3)]	40	3.5	1.15	167
[Ni{$HB(3\text{-}Phpz)_3$}(*o*-tol)(PPh_3)]	40	5.0	0.31	45

Experimental Section

General Remarks: All reactions were carried out under nitrogen using standard Schlenk techniques unless stated otherwise. All solvents were purified and degassed by standard procedures. THF for the synthesis of **2** was not dried. The compounds $K[BBN(pz)_2]$[3] and $[NiBr(o\text{-tol})(PPh_3)_2]$[8] were synthesized according to literature procedures. Filtration was done with 1 μm membrane filters (regenerated cellulose, Schleicher & Schuell). One dimensional ^1H and ^{31}P NMR spectra were recorded on a Bruker DRX 200 spectrometer at 296 K. The proton chemical shifts (δ) are given in ppm and referenced to the signal of partially deuterated $CDCl_3$ at δ = 7.3. The phosphorus chemical shifts are referenced to the signal of external H_3PO_4. Infrared spectra were recorded on a FT-IR Bruker IFS 66 spectrometer. EIMS data were recorded on a Varian MAT 311 A instrument, ionisation energy 70 eV. FAB mass spectra were recorded on a Finnigan MAT 8200 spectrometer using an NBA matrix. Elemental analyses were performed on a Perkin−Elmer CHN-2400/II elemental analyser.

Preparation of the Nickel(II) Complexes 1 and 2: A solution of $[NiBr(o\text{-tol})(PPh_3)_2]$ (1.0 g, 1.3 mmol) and $K[BBN(pz)_2]$ (0.39 g, 1.3 mmol) in 25 mL of dry THF for **1** or in 25 mL of wet THF for **2** was stirred overnight. The solvent was evaporated, the residue was taken up in dichloromethane and filtered through a membrane filter. After evaporation of the solvent the residue was washed with about 10 mL of hexane. Crystallisation from diethyl ether (**1**) or acetone (**1** and **2**) yielded **1** and **2** as yellow crystals suitable for X-ray analysis.

$[Ni\{BBN(pz)_2\}(o\text{-tol})(PPh_3)]$ (1): Yield: 0.51 g (57%). ^1H NMR ($CDCl_3$): δ = 1.3−2.3 (broad, 13 H, BBN), 2.3 (s, 3 H, *o*-tol C*H*$_3$), 4.4 (s, 1 H, BBN), 5.7 (t, 1 H, pyrazolyl C^4 *H*), 5.9 (dt, $^3J_{H,H}$ = 2, $^5J_{P,H}$ = 1 Hz, 1 H, pyrazolyl C^4 *H*), 6.4 (dd, $^3J_{H,H}$ = 7, *J* = 2 Hz, 1 H, *o*-tol), 6.6−6.7 (m, 2 H, *o*-tol), 6.8 (dd, $^3J_{H,H}$ = 2, $^5J_{P,H}$ = 1 Hz, 1 H, pyrazolyl C$^{3/5}$ *H*), 6.9 (d, $^3J_{H,H}$ = 2 Hz, 1 H, pyrazolyl C$^{3/5}$ *H*), 7.2−7.7 (m, 19 H, PPh_3, *o*-tol, pyrazolyl C$^{3/5}$ *H*). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 29.5. IR (KBr): $\tilde{\nu}$ = 3630 cm^{-1} (s, sharp, O−H), 3043, 2978, 2936 (m, C−H), 2914 (s, C−H), 2863 (vs, C−H), 1497 (w, C=C), 1434 (s, P−C), 1404 (m, P−C). MS (EI, 220 °C): *m/z* (%) = 616 (3) [M$^+$], 550 (<1) [M$^+$ − pz], 524 (3) [M$^+$ − *o*-tol], 354 (20) [PPh$_3$(*o*-tol)]$^+$, 262 (100) [PPh$_3$]$^+$. $C_{36}H_{40}BN_2NiOP{\cdot}C_3H_6O$ (675.28): calcd. C 69.37, H 6.87, N 4.15; found C 69.31, H 6.85, N 4.27.

General Preparation for the Synthesis of Polyketone: Compound **1** (0.12 mmol, 0.086 g) in 10 mL of toluene was transferred into a 100 mL autoclave. The solution was pressurised with carbon monoxide and then with ethene and stirred with a magnetic stirrer at 60 °C for 16 h. The white solid was filtered off, washed with hexane, and dried (see Table 3).

Crystal Structure Analysis: For compounds **1** and **2** data collection was carried out using a CCD area detector SMART 1 K by Bruker AXS GmbH with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). Data collection was done at 173 K. For protection against oxygen or moisture, the preparation of single crystals was done in a perfluoroalkyl ether from ABCR GmbH & Co KG (viscosity 1600 cSt). The unit cell was determined with the program SMART.[9] For data integration and refinement of the unit cell the program SAINT[9] was used. The space group was determined using the programs XPREP[9] (**1**) and ABSEN[10] (**2**) and the empirical absorption correction was done with SADABS.[9] The structures were solved by direct methods using the programs SHELX-97[11] for (**1**) and SIR97[12] for (**2**), the structure refinement was based on least-squares methods based on F^2 with SHELX-97.[11] The plots of the molecular structures were visualised using the program ZORTEP.[13]

All non-hydrogen atoms were fully refined in the calculated positions. For **2** the hydrogen atoms were taken from the electron density difference map and refined freely. For **1** the hydrogen atoms were positioned as riding on their neighbouring atoms and refined depending on its position. The figure in parenthesis after each calculated value represents the standard deviation in units of the last significant digit. Crystal data and refinement parameters are summarized in Table 4.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-165852 (**1**) and 165853 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(1223)336−033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structure, and Catalytic Activity of Some New Chiral 2-Menthylindenyl and 2-Menthyl-4,7-dimethylindenyl Rhodium Complexes

Herbert Schumann,*[a] Oleg Stenzel,[a] Sebastian Dechert,[a] Frank Girgsdies,[a] Jochanan Blum,[b] Dmitri Gelman,[b] and Ronald L. Halterman[c]

Dedicated to Prof. Dr. Rudolf Taube on the occasion of his 70th birthday

Keywords: Homogeneous catalysis / Hydroformylation / Hydrogenation / Indenyl ligands / Rhodium

Optically active rhodium complexes containing the chiral, menthyl-substituted indenyl ligands (–)-2-menthyl-4,7-dimethylindene and (–)-2-menthylindene are described. Metathesis reactions of the chiral lithium salts of these indenyl systems with the appropriate starting materials yielded the complexes (–)-(2-menthyl-4,7-dimethylindenyl)$Rh(CO)_2$ (**2**), (–)-(2-menthyl-4,7-dimethylindenyl)Rh(dppe) (**3**), (+)-(2-menthylindenyl)Rh(dppe) (**5**), (–)-(2-menthylindenyl)$Rh(PMe_3)_2$ (**6**), and (–)-(2-menthylindenyl)Rh(nbd) (**8**). All compounds obtained were diastereomerically pure. The structures of **2**, **3**, and **6** were determined by single crystal X-ray diffractometry. Complexes **3** as well as (–)-bis(η^2-ethylene)(η^5-2-menthyl-4,7-dimethylindenyl)rhodium(I) (**9**), (–)-(cycloocta-1,5-diene)(η^5-1-menthyl-4,7-dimethylindenyl)rhodium(I) (**10**), (–)-(cycloocta-1,5-diene)(η^5-2-menthyl-4,7-dimethylindenyl)rhodium(I) (**11**), and (–)-(cycloocta-1,5-diene)(η^5-2-menthylindenyl)rhodium(I) (**12**) were found to be active as double bond hydrogenation catalysts. Two of them proved to induce asymmetry up to 18% *ee*. These complexes also promote the hydroformylation of olefins yielding both linear and branched aldehydes in varying ratios but hardly transfer chirality.

Introduction

Rhodium catalysts are widely used in organic synthesis and some are currently used in large-scale industrial processes.[1] Combining the high reactivity of rhodium with chiral phosphane, sulfide, or cyclopentadienyl ligands containing chiral substituents led to their wide application as asymmetric catalysts.[2,3] Over the last few years we have exploited the use of the inexpensive commercially available chiral compound menthol in combination with dinuclear rhodium complexes to prepare chiral catalysts. Using a menthyl-substituted phosphane as a chiral ligand in the complex $[(R^*Ph_2P)(CO)Rh(\mu\text{-}Cl)(\mu\text{-}SR)Rh(CO)(PPh_2R^*)]$ [R* = (+)-neomenthyl; R = *t*Bu, $CH_2CH_2Si(OEt)_3$] asymmetric hydrogenation of methyl (*Z*)-α-acetamidocinnamate could be performed. An optical purity of up to 97% *ee* at low conversions was achieved, but it dropped gradually when the reduction advanced.[4] Using a menthyl-substituted thiolato group as a chiral bridging ligand in (+)-*cis*-$[tBu_3P(CO)Rh(\mu\text{-}Cl)(\mu\text{-}SR^*)Rh(CO)PtBu_3]$ [R* = (+)-neomenthyl], an optical purity of up to 50% *ee* was obtained in moderate yields.[5] Our newly developed synthesis of conformationally well-defined, enantiomerically pure 3-menthylindenyl[6] and 2-menthylindenyl ligands[7] and their transition metal complexes,[8,9] enable us to describe in this paper a third example for exploiting the menthyl-derived chirality in catalysis.

Results and Discussion

Rhodium Complexes

The metathesis reaction of two equivalents of the lithium salt **1** with the binuclear rhodium complex $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$, in diethyl ether at 0 °C, followed by warming to room temperature, gave the corresponding indenyl complex **2** in 74% yield (Scheme 1). Although the indenyl ligand is chiral, owing to the menthyl substituent, it possesses homotopic π-faces and can form only one chiral indenyl metal complex after metalation. The crude product was obtained by removing the solvent, and purified by chromatography under an inert atmosphere on dried alumina with *n*-

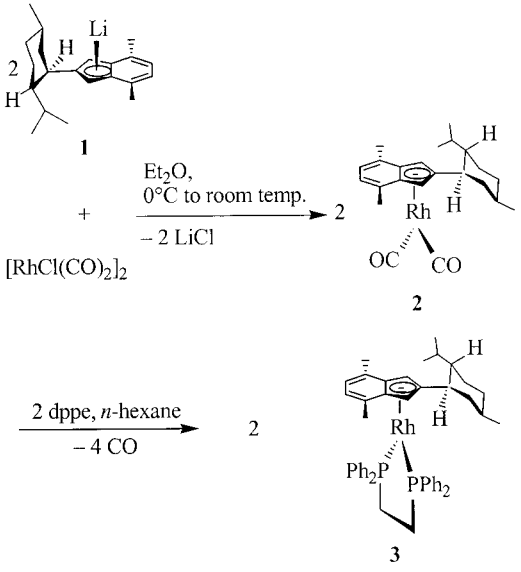
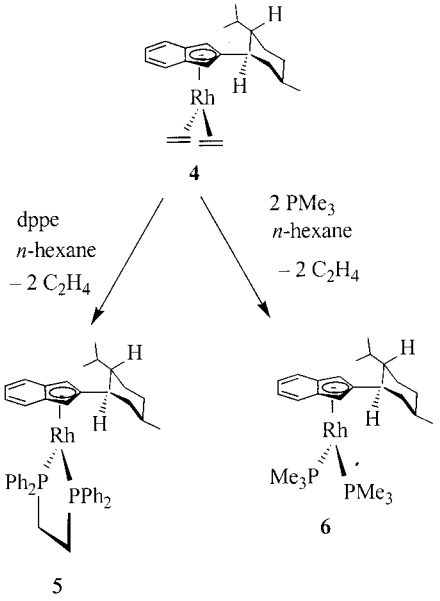
hexane as eluent, followed by crystallization from *n*-pentane. Contact with even traces of oxygen during chromatography led to the immediate decomposition of the complex and dimerization of the indenyl ligand to give 1,1′-bis(2-menthyl-4,7-dimethylindene) and 1,1′-bis(2-menthylindene), respectively.[10] Upon addition of bis(diphenylphosphanyl)ethane to **2**, followed by prolonged heating, **3** was obtained in 73% yield (Scheme 1).



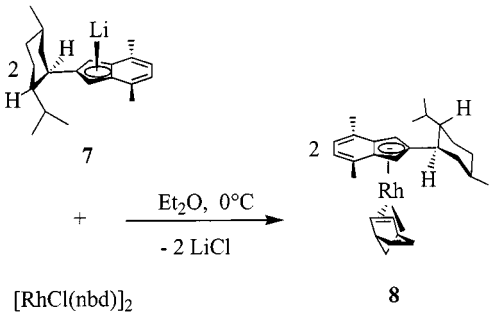
Scheme 1

The same substitution procedure could be used to obtain **5** and **6** by adding bis(diphenylphosphanyl)ethane or trimethylphosphane, respectively, to (−)-bis(η²-ethylene)(η⁵-2-menthylindenyl)rhodium(I) (**4**) (Scheme 2).



Scheme 2

The rhodium complex **8** was synthesized and isolated in 87% yield by the metathesis reaction of two equivalents of the lithium salt **7** with the binuclear rhodium complex [(nbd)Rh(μ-Cl)$_2$Rh(nbd)] (Scheme 3).



Scheme 3

In contrast to their solutions, pure crystalline **2**, **3**, **5**, and **8** are stable to air and moisture, while **6** readily decomposes. The complexes are soluble in polar solvents such as THF, pyridine, and diethyl ether as well as in aromatic solvents such as toluene, and in nonpolar solvents such as *n*-hexane.

Compounds **2**, **3**, and **6** gave suitable single crystals for X-ray diffraction analysis upon recrystallization from *n*-pentane. They crystallized in the same orthorhombic space group $P2_12_12_1$ with one or three crystallographically independent molecules in the asymmetric unit. The solid state structures of these molecules are shown in Figure 1, Figure 2, and Figure 3, respectively. The trimethylphosphane groups in **6** are disordered about two positions, with occupancy factors of 0.504(4) and 0.496(4), as shown in Figure 4.

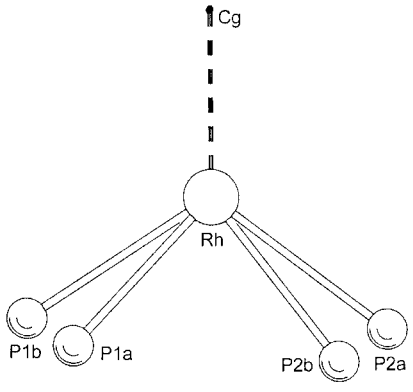

Figure 4. Disorder of **6** in the crystal[14]

All four complexes are monomeric, free of solvent, diastereomerically pure and clearly show the characteristic three stereocenters of the menthyl moiety. In all cases the transition metals of the formal oxidation state +1 are coordinated in a trigonal planar arrangement by the centroids of the cyclopentadienyl systems and the neutral ligands. It is particularly noteworthy that the terpene moiety adopts similar conformations, with the menthyl moiety being nearly perpendicular to the indenyl plane and the bulky isopropyl group pointing away from the metal. The corresponding dihedral angles[15] are: **2**: −8°; **3**: 24°, 29°, 17°; **6**: 14°. The average bonding distances of rhodium to the five-membered indenyl rings are 2.30 Å (**2**, **6**) and 2.32 Å (**3**); the average bond lengths for rhodium to the neutral ligands are 1.86 Å for complex **2**, 2.20 Å for complex **3**, and 2.22 Å for complex **6**. These distances are in close agreement with the bond lengths given for dicarbonyl(η^5-indenyl)rhodium (2.29 Å and 1.86 Å),[16] dicarbonyl(η^5-4,5,6,7-tetramethylindenyl)rhodium (2.29 Å and 1.86 Å),[17] (η^5-indenyl)bis(trimethylphosphane)rhodium(I) (2.32 Å and 2.21 Å),[18] and (η^5-indenyl)(methyl)[1,2-bis(diphenylphosphanyl)propane]-rhodium(III) (2.28 Å and 2.27 Å).[19] The CO−Rh−CO angle of 90.2° in **2** (91.7°[16] and 92.5°[17]) and the P(1)−Rh−P(2) angles of 84.2°, 85.2°, and 84.8° for **3** as well as 96.2° and 94.6° for **6** (96.7°[18] and 85.2°[19]) correlate with the corresponding angles in related complexes. The carbonyl ligands are almost linearly coordinated (177.9°). The average methyl−P−methyl angle of 99.9° is smaller

than the expected tetrahedral angle of 109.5°. It correlates with 101.5° in the compound $[Al_2Cl_2Me_4][(\eta^5$-cyclopentadienyl)bis(trimethylphosphane)rhodium(I)].[20]

The five-membered rings of the indenyl systems are not equally bound to Rh but resemble a distorted η^5-coordination. The bond lengths of the carbon atoms C(X01), C(X02), and C(X03) to the metal are 0.08−0.27 Å shorter than the bond lengths of the bridging atoms C(X04) and C(X09). In general, slip distortions Δ[21] and ring slippages RS[21] toward the C(X02) atoms are found. The values for Δ and RS are 0.186 Å and 0.189 Å in **2**, 0.157 Å, 0.152 Å, 0.177 Å and 0.175 Å, 0.180 Å, 0.243 Å in **3**, and 0.178 Å and 0.205 Å in **6**. The tendency towards a slight η^3-coordination accounts for the non-planar cyclopentadienyl ring and thus for the hinge angles HA[22] and fold angles FA.[22] The values for HA and FA are 10.6° and 10.5° in **2**, 7.7°, 6.8°, 8.0° and 8.3°, 5.4°, 8.1° in **3**, and 8.1° and 8.0° in **6**. The values are in the range expected for distorted η^5-coordination, as found in (COD)(η^5-indenyl)rhodium[23] (Δ = 0.152 Å, HA = 8.9°, FA = 7.4°), $(C_2H_4)_2$(η^5-indenyl)rhodium(I)[24] (Δ = 0.161 Å, HA = 8.1°, FA = 7.4°), bis(trimethylphosphane)(η^5-indenyl)rhodium(I)[25] (Δ = 0.201 Å, HA = 8.4°, FA = 7.9°) and fail to show the characteristics of η^3-coordination found in tris(dimethylphenylphosphane)(η^3-indenyl)rhodium(I)[26] (Δ = 0.79 Å, HA = 25°, FA = 28°). Such distortions are also detectable by the differences in the C−C bond lengths in the five-membered indenyl rings. The maximum variations of 0.06 Å (**2**), 0.05 Å (**3**), and 0.03 Å (**6**) are higher than can be accounted for by the influence of the condensed six-membered ring alone. In general the trend towards η^3-coordination is not strong; although the distortions are much higher than they are for the asymmetrical substituted (1-menthylindenyl)metal complexes, where the substitution patterns favor not only a distortion toward C(X02) but toward C(X03) as well.[8]

As the HOMO of the indenyl unit in rhodium complexes can best be stabilized at a rotation angle RA of 0°[16,18,24] the neutral ligands are aligned parallel to the longitudinal axis of indene. In these cases, values for RA of 0.1° (**2**), 1.8°, 11.4°, and 11.9° (**3**) as well as 6.3° and 3.5° (**6**) are observed.

NMR Spectra

The assignment of the ^{1}H and ^{13}C signals was based on ^{1}H,^{1}H COSY and ^{1}H,^{13}C correlated spectra as well as on two-dimensional NOE experiments. All described transition metal complexes exhibit C_1 symmetry in their solution NMR spectra. The neutral ligands dppe in **5** and PMe_3 in **6** exhibit two ^{31}P NMR signals and thus do not seem to rotate around the indenyl−rhodium axis on the NMR time scale as has been found for similar complexes.[27] For the two CO ligands in **2**, for example, only one signal occurs and for the four coordinating carbon atoms of the nbd ligand only two signals occur. This gives rise to an empirical low induction of the chiral indenyl ligand on the remote neutral ligands or to rotating ligands on the ^{13}C NMR time scale.

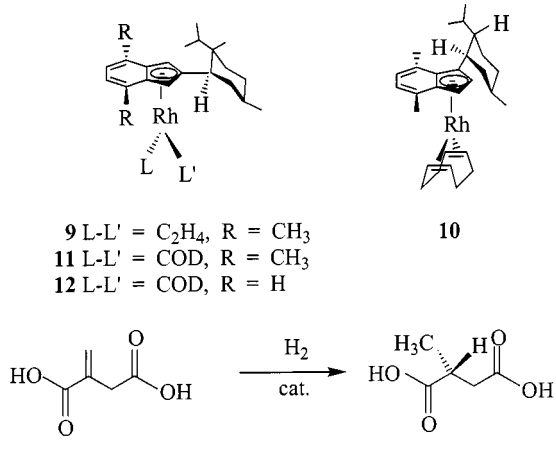
Characteristic $^1J_{CRh}$ coupling constants varying between 1.0 and 7.9 Hz for the five-membered indenyl rings and from 10.3 to 85.4 Hz for the neutral ligands could be determined. Higher coupling constants correlate to higher electron density, therefore the bridging atoms C^8 and C^9 are more weakly bonded in comparison to the atoms C^1 to C^3, which show higher values. This is consistent with the $\eta^2+\eta^3$-coordination found in the solid state structures. The higher $^1J_{XRh}$ values of the neutral ligands are due to the shorter bond lengths in comparison to the indenyl−rhodium bond.

Decoupled ^{103}Rh NMR spectra of **3** and **8** in Et_2O/D_2O (3:1) were recorded and chemical shifts between δ = −143.4 and −834.1 relative to hexachlororhodate in D_2O were observed. The intensity of the high-field shift increases along with the stronger σ-donor bonded to the metal[28] and higher alkylation of the indenyl ligand.[8]

Catalysis

Catalytical Hydrogenation

The applicability of the rhodium complex **3** and of the related compounds (−)-bis(η^2-ethylene)(η^5-2-menthyl-4,7-dimethylindenyl)rhodium(I) (**9**),[29] (−)-(cycloocta-1,5-diene)(η^5-1-menthyl-4,7-dimethylindenyl)rhodium(I) (**10**),[8] (−)-(cycloocta-1,5-diene)(η^5-2-menthyl-4,7-dimethylindenyl)rhodium(I) (**11**),[29] and (−)-(cycloocta-1,5-diene)(η^5-2-menthylindenyl)rhodium(I) (**12**)[29] (Scheme 4), described by us earlier, as hydrogenation catalysts was studied. The prochiral itaconic acid was chosen as the substrate.



Scheme 4

All tested catalysts proved highly active. Usually a quantitative yield of the methylsuccinic acid was obtained within 4 h at 60−70 °C. However, only the two COD-containing rhodium-menthylindenyl complexes **10** and **11** were found to induce chirality, and lead to the formation of (*S*)-(−)-methylsuccinic acid in 18 and 16% *ee*, respectively. Complex **11** only has the chiral influence of the menthyl substituent, and the observed low stereoselectivity is similar to that seen with menthylcyclopentadienyl metal complexes.[30] Complex **10**, however, contains an additional facial chirality element, and gave an unexpectedly lower selectivity than other bis(1-menthylindenyl)metal catalyzed reactions.[31] It is rather

surprising that catalyst **12**, which has also a COD moiety but differs from **11** by having no indenyl-bound methyl groups, does not promote enantioselective hydrogenation of the itaconic acid.

Catalytic Hydroformylation

The observation that cyclohexene is hydroformylated in the presence of catalyst **2** at 120 °C and 40 bar CO/H_2, giving a quantitative yield of cyclohexanecarboxaldehyde within 3 h, led us to investigate the transformation of an olefin which can yield isomeric products. Using styrene as a prochiral substrate our rhodium complexes afforded 2- and 3-phenylpropanal (branched and linear products) in 23−100% yield. The results of some representative experiments are summarized in Table 1.

Table 1. Hydroformylation of styrene in the presence of some rhodium catalysts

Entry	Catalyst[a]	Total yield after 22 h	Linear/branched ratio
1	**2**	25	1:7.8[b]
2	**2**[c]	26	1:9.0
3	**3**	30	1:14.0
4	**4**	61	1:3.4
5	**10**	89[d]	1:6.2[e]
6	**11**	23	1:3.9
7	**12**	83	1:1.6

[a] Reaction conditions: 0.1 mol of styrene, 1 mmol of catalyst, 10 mL of toluene, 20 bar H_2, 20 bar CO, 60 °C, 22 h. [b] At 100−120 °C (2−4 h) the ratio became 1:0.8. [c] The complex was entrapped in a silica sol-gel matrix according to ref.[32]. [d] After 36.5 h. [e] At 100 °C the ratio became 1:1.1.

Due to the stereogenic centers in the catalyst precursors one would expect the chirality to be transferred to the branched aldehyde. However, styrene was found to undergo quantitative hydroformylation at 100 °C in the presence of **10** to give nearly identical amounts of the linear and the racemic branched aldehyde. As no chirality could be detected in the branched product, we lowered the temperature to 60 °C. At this temperature catalysts **2**, **3**, **4**, **11**, and **12** led to 23−83% aldehydes after 22 h, and even under these conditions no appreciable chirality transfer was observed: the highest *ee* value of 3% was obtained with catalyst **3** (entry 3).

Although we did not visually detect the separation of any metallic rhodium during the hydroformylation that could have been responsible for the achiral processes, we performed an experiment with sol-gel entrapped complex **2** to prevent any possible decomposition of the original chiral catalyst (entry 2). We found, however, that the homogeneous and the immobilized catalysts gave almost identical results and no significant enantioselectivity could be detected. Another reason for the atactic activity might have been the formation of achiral complexes of the type $RhH(CO)_2(L)(L')$ by substitution of the indenyl moiety. However, these complexes could still not explain the different linear/branched ratios, as they vary with changes of the indenyl (entry 6 vs. 7) and the neutral ligands. Values between 1:0.78 (catalyst **2** at 120 °C) and 1:14 (catalyst **3** at 60 °C) were found. The highest selectivity is obtained using the bulky dppe ligand, and the selectivity decreases with increasing temperature. Typically, linear/branched ratios of 1:1 and 1:3 are mentioned in the literature.[33]

In addition to styrene, *n*-dodecene was also reacted in the presence of catalyst **2** at different temperatures and pressures. Samples of the reaction mixture were withdrawn every hour and analyzed by GC and ^1H NMR spectroscopy. After 6 h (80 bar total pressure) conversions of 97% were obtained at 80 °C. If the temperature was lowered to 60 °C only 38% yield was obtained.

When using 1-dodecene as a substrate partial isomerization of the double bond occurred prior to the hydroformylation. In addition to 1-tridecanal and 2-methyldodecanal in the ratio 1:0.7, 3-ethylundecanal and 4-propyldecanal were formed in 8 and 7% yield (80 °C and 80 bar). This isomerization of 1-dodecene to 2- and 3-dodecene does not occur at 60 °C.[34]

Conclusions

Metathesis reactions of $[RhCl(L)(L')]_2$, with chiral, menthyl-functionalized indenyl salts and ligand substitution reactions provide a convenient entry into chiral rhodium complexes. X-ray diffraction analyses of the monomeric, stereomerically pure complexes **2**, **3**, and **6** confirm the enantiomeric purity of the stereogenic centers in the ligands and that the indenyl moiety is $\eta^2+\eta^3$-coordinated. Complex **3** and the analogeous rhodium complexes **9**, **10**, **11**, and **12** show a high activity in the catalytic hydrogenation of itaconic acid. Both catalysts **10** and **11** induced chirality in the product. Complexes **2**−**4** and **10**−**12** show considerable activity in the hydroformylation of olefins with highly varying linear/branched ratios between 1:0.78 and 1:14 but promote very little chirality transfer.

Experimental Section

All operations involving organometallic compounds were carried out under an inert atmosphere of nitrogen or argon using standard Schlenk techniques in dry, oxygen-free solvents. Melting points were measured in sealed capillaries with a Büchi 510 melting point apparatus and are uncorrected. Optical rotations were determined on a Schmidt+Haensch Polartronic-D and a Perkin−Elmer model 141 polarimeter. The NMR spectra were recorded on a Bruker ARX 200 (^1H: 200 MHz; ^{13}C: 50.32 MHz; ^{31}P: 80.94 MHz) or ARX 400 (^1H: 400 MHz; ^{13}C: 100.64 MHz; ^{103}Rh: 12.60 MHz) spectrometer at ambient temperature. Chemical shifts are reported in ppm relative to the ^1H or the ^{13}C signal of the deuterated solvents. Chemical shifts of ^{31}P and ^{103}Rh are given relative to 85% phosphoric acid in D_2O and hexachlororhodate in D_2O. The IR spectra were recorded on a Nicolet Magna System 750 spectrometer. Mass spectra (EI, 70 eV) were obtained using a Varian MAT 311 A/AMD instrument. Only significant fragments containing the isotopes of the highest abundance are listed. Relative intensities in % are given in parentheses. Elemental analyses were performed on a Perkin−Elmer Series II CHNS/O Analyzer 2400. (−)-(2-Men-

thyl-4,7-dimethylindenyl)lithium (**1**),[7] (−)-(2-menthylindenyl)lithium (**7**),[7] tetracarbonyldi-μ-chlorodirhodium(I),[35] (−)-bis(η²-ethylene)(η⁵-2-menthyl-4,7-dimethylindenyl)rhodium(I) (**9**),[29] (−)-bis(η²-ethylene)(η⁵-2-menthylindenyl)rhodium(I) (**4**),[29] (−)-(cycloocta-1,5-diene)(η⁵-1-menthyl-4,7-dimethylindenyl)rhodium(I) (**10**),[8] (−)-(cycloocta-1,5-diene)(η⁵-2-menthyl-4,7-dimethylindenyl)rhodium(I) (**11**),[29] and (−)-(cycloocta-1,5-diene)(η⁵-2-menthylindenyl)rhodium(I) (**12**)[29] were prepared according to published procedures. 1,2-Bis(diphenylphosphanyl)ethane and di-μ-chlorobis(η⁴-norbornadiene)dirhodium(I) were used as purchased without further purification.

(−)-Dicarbonyl(η⁵-2-menthyl-4,7-dimethylindenyl)rhodium(I) (2): (−)-(η⁵-2-menthyl-4,7-dimethylindenyl)lithium (**1**) (0.62 g, 2.15 mmol) was added to a solution of tetracarbonyldi-μ-chlorodirhodium(I) (0.42 g, 1.08 mmol) in diethyl ether (15 mL) at 0 °C. The suspension was stirred for 3 h, heated to 25 °C and stirred for further 10 h. The solvent was removed under vacuum (10^{-2} mbar), leaving a solid which was subsequently suspended in *n*-hexane (2 mL) and fractionally chromatographed under nitrogen on alumina. Elution with *n*-hexane initially gave colorless and finally yellow solutions. The solvents of the yellow fractions were removed under vacuum (10^{-2} mbar) yielding an orange solid. Recrystallization from warm *n*-pentane (5 mL) gave 0.70 g (74%) of **2** as orange crystals, m.p. 125 °C dec. $[\alpha]_D^{25} = -31.8$ (*c* = 7.6, *n*-hexane). ^{1}H NMR ([D$_6$]benzene, 400 MHz): δ = 0.67 (d, ^3J = 7.0 Hz, 3 H, H$^{7'/9'/10'}$), 0.68 (d, ^3J = 6.9 Hz, 3 H, H$^{7'/9'/10'}$), 0.93 (d, ^3J = 6.5 Hz, 3 H, H$^{7'/9'/10'}$), 0.80−2.05 (m, 10 H, H$^{1',2',3',4',5',6',8'}$), 2.14 (s, 3 H, H$^{10/11}$), 2.15 (s, 3 H, H$^{10/11}$), 4.48 (d, ^4J = 2.0 Hz, 1 H, H$^{1/3}$), 5.50 (d, ^4J = 2.0 Hz, 1 H, H$^{1/3}$), 6.67 (m, 2 H, H^{5,6}). ^{13}C{^{1}H} NMR ([D]chloroform, 50.32 MHz): δ = 15.6, 18.07, 18.11, 21.6, 22.8 (C$^{7',9',10,10',11}$), 25.0, 35.4, 47.8 (C$^{2',5',6'}$), 28.2, 33.6, 40.2, 50.5 (C$^{1',3',4',8'}$), 72.1 (d, $^1J_{CRh}$ = 3.2 Hz, C$^{1/3}$), 75.9 (d, $^1J_{CRh}$ = 3.1 Hz, C$^{1/3}$), 114.3 (d, $^1J_{CRh}$ = 2.1 Hz, C$^{8/9}$), 115.8 (d, $^1J_{CRh}$ = 2.0 Hz, C$^{8/9}$), 128.1 (d, $^1J_{CRh}$ = 1.6 Hz, C^2), 125.07, 125.08 (C^{4,7}), 125.5, 125.6 (C^{5,6}), 191.3 (d, $^1J_{CRh}$ = 85.4 Hz, CO). Hydrogenation of Itaconic Acid: Typically, a mini-autoclave was charged under nitrogen in a glove box with the chiral rhodium catalyst (1 mmol) and a solution of itaconic acid (2.6 g, 20 mmol) in methanol (7 mL). The autoclave was sealed, purged three times with H_2 and pressurized to 14 bar. The reaction vessel was placed in a preheated oil bath thermostated at the desired temperature (accuracy ±0.5 °C). After 4 h the autoclave was cooled, opened and its contents were treated with 10% aqueous NaOH (5 mL). The rhodium catalyst was extracted with diethyl ether (3 × 5 mL). Addition of excess 3 M HCl to the aqueous solution, threefold extraction with diethyl ether (20 mL), drying with Na_2SO_4 and removal of the solvent under vacuum (10^{-2} mbar) afforded methylsuccinic acid as a colorless powder in quantitative yield. When catalyst **10** was employed at 60 °C or catalyst **11** at 70 °C, the *ee* values of the resulting (−)-methylsuccinic acid were 18 and 16%, respec-

tively. Complexes **3**, **9** and **12** proved equally active as hydrogenating catalysts but did not induce asymmetry in the product.

Hydroformylation Reactions: In a typical experiment a mini-autoclave was charged under nitrogen in a glove box with a mixture of styrene (10.4 g, 0.1 mol), the appropriate rhodium complex (1 mmol) and toluene (10 mL). The reaction vessel was purged three times with nitrogen and loaded with 20 bar each of H_2 and CO. The autoclave was placed in a thermostated oil bath and heated at 60 °C for 22 h. After cooling, the autoclave was opened, the toluene was distilled off, and the catalyst was removed by filtration through a silica 60 column, using hexane as eluent. The hexane also eluted the linear aldehyde, $C_6H_5CH_2CH_2CHO$. The branched product $C_6H_5CH(CHO)CH_3$, was eluted with a 8:2 ratio of hexane/diethyl ether. The ratio of the two products was determined by NMR spectroscopy. Polarimetric measurements indicated that the enantiomeric excess of (−)-$C_6H_5CH(CHO)CH_3$ was low in all experiments and did not exceed 3%. The hydroformylation experiments with the various catalysts are summarized in Table 1.

Crystal Structure Determination: Data were collected on a Siemens SMART CCD diffractometer (graphite monochromated Mo-K_α radiation, $\lambda = 0.71073$ Å) with an area detector by use of ω scans at room temperature for **2** and at 173 K for **3** and **6**. The structures were solved by direct methods using SHELXS-97[36] and refined on F^2 using all reflections with SHELXL-97.[37] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in calculated positions and assigned to an isotropic displacement parameter of 0.08 Å^2. The idealized methyl groups were allowed to rotate about their X−C bond. Absolute structure parameters were determined according to Flack[38] with SHELX-97. SADABS[39] was used to perform area-detector scaling and absorption corrections. The maximum and minimum transmission factors and the resulting crystallographic data are given in Table 2. The geometrical aspects of the structures were analyzed by using the PLATON program.[40]

Crystallographic Data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-165792 (**2**), CCDC-165793 (**3**), and CCDC-165794 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Metal-Ion Extraction by Immobilised Aza Crown Ethers

Leon G. A. van de Water,[a] Willem L. Driessen,*[a] Jan Reedijk,[a] and David C. Sherrington[b]

Keywords: Aza crown ethers / Functional polymers / Cadmium / Silver

The immobilisation of [15]aneNO$_4$, [15]aneN$_2$O$_3$, and [18]aneN$_2$O$_4$ onto the oxirane and thiirane containing copolymers *p*(GMA-O) and *p*(GMA-S) resulted in six aza crown ether containing polymers with interesting metal-ion affinities. The pendent hydroxy or thiol groups, originating from the polymeric backbones, appeared to play an important role in the observed metal-ion affinities. The metal-ion affinity of *p*(GMA-O)-[15]aneN$_2$O$_3$ for a range of cations was found to decrease with decreasing ionic radius: $Ag^+ > Pb^{2+} > Cd^{2+} > Cu^{2+}$. The thiol-containing analogue of this polymer, *p*(GMA-S)-[15]aneN$_2$O$_3$, showed a reversed Cd^{2+}/Cu^{2+} selectivity. This illustrates the capability of pendent hydroxy groups to seriously reduce the stability of complexes of small cations compared to those of large cations. All the modified oxirane resins tested were found to be Ag^+-selective in the presence of a range of divalent (heavy) transition-metal ions. The difference in ring size between [15]aneN$_2$O$_3$ and [18]aneN$_2$O$_4$ was found to have a significant effect on the uptake values of Cu^{2+} and Zn^{2+}, as these ions are too small to fit into the ligand cavity of [18]aneN$_2$O$_4$. The uptake values for the larger Ag^+ and Pb^{2+} were found to be similar for both resins. Loaded resins were successfully regenerated (with an efficiency of 99%) by treatment with 2.0 m acid solutions (Pb^{2+} and Cd^{2+}) or with a 3.35 m NH_3 + 2.0 m NH_4NO_3 solution (Ag^+).

Introduction

Heavy-metal ions, like Cd^{2+}, Pb^{2+}, Hg^{2+}, and Cr^{3+}, exhibit toxic effects in biological systems, even at low concentration levels, as organic tissues exhibit affinity for many heavy-metal ions. Accumulation often occurs in particular organs and this results in undesired health effects.[1] Although the removal of these toxic metal ions from the environment has attracted much attention over the past decades, the pollution of surface and ground water remains a serious problem.[2] Purification systems for the removal of these toxic metal ions from aqueous solutions should possess a high degree of selectivity for heavy- and transition-metal ions due to the presence of relatively large amounts of alkali and alkaline earth metal ions in surface and ground water. Apart from toxic metal ions, those with a high commercial value also need to be recovered. Examples of these are Rh, Ir, Pd (applied in catalysis), Pt (catalysis, medicine), Ag (^{111}Ag-based immunotherapy, photographic technology), and Au (jewellery, medicine).[3]

Crown ethers are a class of ligands with metal-ion affinities that are a function of the nature, number, and spatial arrangement of the donor atoms, substitutions of the ligand backbone, the flexibility, and the hole size of the macrocycle. For instance, all-oxygen crown ethers have been found to be selective for alkali and alkaline earth metal ions, and there appears to be a correlation between ionic radius and macrocyclic cavity size.[4] The affinity of crown ethers that contain nitrogen and/or sulfur donor atoms is directed more towards (heavy) transition metal ions, and the size selectivity of this type of crown ether is much lower.[5]

Selective extraction of heavy-metal ions from aqueous solutions may be accomplished by functionalising non-hydrophobic[6] supporting materials with (multidentate) ligands, which contain donor atoms with affinity for the target metal ion(s).[7,8] In the present study, copolymers of ethylene glycol dimethacrylate (EDMA) (as the crosslinker) and glycidyl methacrylate [*p*(GMA-O)[9]], or its sulfur analogue [*p*(GMA-S)[10]] have been used as supporting materials (see Scheme 1). These polar copolymers can be functionalised easily by a ring-opening of the oxirane and thiirane moieties with nucleophiles, thereby generating additional hydroxy or thiol groups on the polymer.

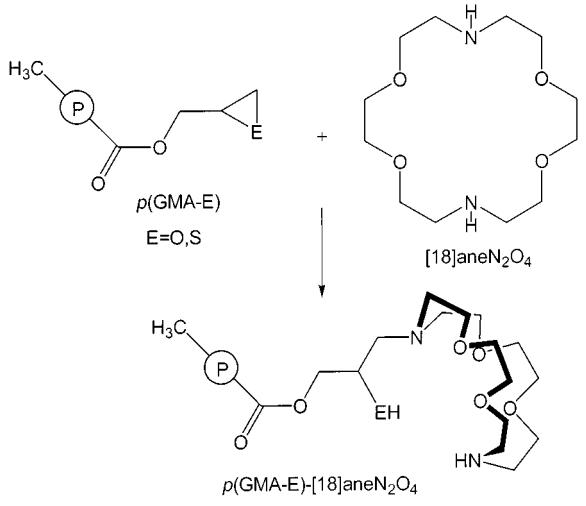
When a crown ether is used as the nucleophile, a so-called lariat ether is formed on the polymer, whereby both the crown ether and the pendent hydroxy or thiol groups may be involved in metal-ion binding. Lariat ethers are known to be very suitable for selectively binding metal ions.[11] The results of the immobilisation of the tetrathia-monoaza crown ligand [16]aneNS$_4$ onto both *p*(GMA-O) and *p*(GMA-S), and the metal-ion binding studies of the resulting functionalised polymers, have been reported previously.[12] Both functionalised polymers were found to have a high capacity and selectivity towards Ag^+ ions, due to the high affinity of soft sulfur atoms for soft Ag^+ ions. The affinity for Pb^{2+} and Cd^{2+}, however, was found to be much lower, as the thioether ligands on the polymers form only moderately stable complexes with these latter metal ions. To improve the extraction of these metal-ion species, the immobilisation of three macrocyclic ligands without sulfur-donor atoms, 1,4,7,10-tetraoxa-13-azacyclopentadecane ([15]aneNO$_4$), 1,4,10-trioxa-7,13-diazacyclopentadecane ([15]aneN$_2$O$_3$), and 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane ([18]aneN$_2$O$_4$) is reported here. In Scheme 2, the immobilisation reactions onto *p*(GMA-O) and *p*(GMA-S) are illustrated for [18]aneN$_2$O$_4$. The metal-ion uptake results, both under competitive and non-competitive conditions, the regeneration characteristics of the metal-loaded polymers, and distribution-coefficient determinations of these six functionalised polymers (**1**−**6**) are presented here.



Scheme 2. Immobilisation of [18]aneN$_2$O$_4$ onto *p*(GMA-O) and *p*(GMA-S)

Results and Discussion

Crown Ether Modified Polymers

The microanalytical data of the functionalised resins **1**−**6** are presented in Table 1. Three different batches have been synthesised for each of the resins **3** and **5**. Oxirane and thiirane conversions are relative values with respect to the oxirane and thiirane concentrations on the starting polymers. Conversions and ligand concentrations are based on the nitrogen contents of the functionalised resins. The ligand concentrations of modified thiirane resins are less accurate than those of modified oxirane resins, due to the presence of a small amount of nitrogen in the starting polymer *p*(GMA-S).

The reactivity of [15]aneNO$_4$ is considerably higher than that of the other two macrocyclic ligands, the ligand concentration on **1** being 1.58 mmol/g and the ligand concentrations on **3** and **5** being approximately 0.80 mmol/g and 0.60 mmol/g, respectively. The presence of unchanged oxirane and thiirane groups on the modified resins is unlikely as either methanol, that was used in the immobilisation reactions, or traces of water may have reacted with these groups. This is confirmed by the IR spectra of the resins: characteristic peaks originating from both the epoxy group {850, 910 cm^{-1} (epoxy-ring vibration) and 1340, 1480 cm^{-1} [δ(CH)epoxy]}, or the thiirane group {615, 910 cm^{-1} (thiirane-ring vibration) and 1330, 1440 cm^{-1} [δ(CH)thiirane]}, have disappeared, indicating complete conversion of the epoxy and thiirane groups.

The solid-state CP MAS ^{13}C NMR spectra of the starting polymers *p*(GMA-O) and *p*(GMA-S) and of the modified resins indicate that peaks originating from the ligands, occurring at δ = 70.1 (*C*H$_2$-O), have appeared in the spectra of the modified polymers. This is in accordance with the ^{13}C NMR spectroscopic data of the free macrocycles in solution. The *C*H$_2$-N peak, found at δ ≈ 49 in solution, is obscured by the intense backbone peak at δ = 45.2. The CH$_2$ (epoxy) peak at δ = 48.0 and the CH$_2$ (thiirane) peaks

Table 1. Microanalytical data, oxirane/thiirane-group conversions, and ligand concentrations of the resins, based on the weight-% nitrogen; conversions and ligand concentrations of the modified thiirane resins are less accurate and are given in parentheses

	Resin	% C	% H	% N	% S	Conversion [%]	Ligand conc. [mmol/g]
1	*p*(GMA-O)-[15]aneNO$_4$	55.58	7.72	2.22		62	1.58

at δ = 30.5 and 38.3 are no longer present in the spectra of the modified oxirane and thiirane resins.

Metal-Uptake Experiments

All metal-uptake experiments were performed as a function of the pH. Buffered metal chloride solutions were used for the experiments involving Cu^{2+}, Cd^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}, and Ca^{2+}, whilst for the experiments involving Ag^{+} and Pb^{2+} (competitive as well as non-competitive) nitrate salts were used. In these latter experiments, the pH was adjusted with dilute HNO_3 or with dilute NH_3. No Ag^{+}-uptake experiments were performed with modified thiirane resins, as the thiol groups on these resins are known to irreversibly bind large amounts of Ag^{+} ions.[12]

Because resins **1**−**6** have different ligand concentrations, it would not be correct to compare the capacity values (*C* in mmol/g resin) of the different resins. Therefore, the ligand occupation (*L* in %) was calculated in order to have a more appropriate basis for comparison of the resins, where *L* (in %) = [uptake capacity (*C*) for M^{n+} (in mmol/g resin)]/[ligand concentration (in mmol/g resin)].

[15]aneNO_4

The metal-ion uptake results with **1** {*p*(GMA-O)-[15]aneNO_4} under non-competitive conditions are presented in Figure 1 (a). The maximum uptake of Ag^{+} is 0.74 mmol/g at pH = 6.6 (47% ligand occupation), and is clearly a function of the pH. Cd^{2+} is the only other metal ion that is extracted significantly, although the maximum uptake is only 0.22 mmol/g at pH = 1.2. The Cd^{2+} uptake is probably due to the binding of polychlorocadmates to the resin.[12−14] The Ca^{2+} and Na^{+} uptakes have also been determined, since oxa crown ethers are known to form stable complexes with alkali and alkaline earth metal ions, but no uptake was observed.

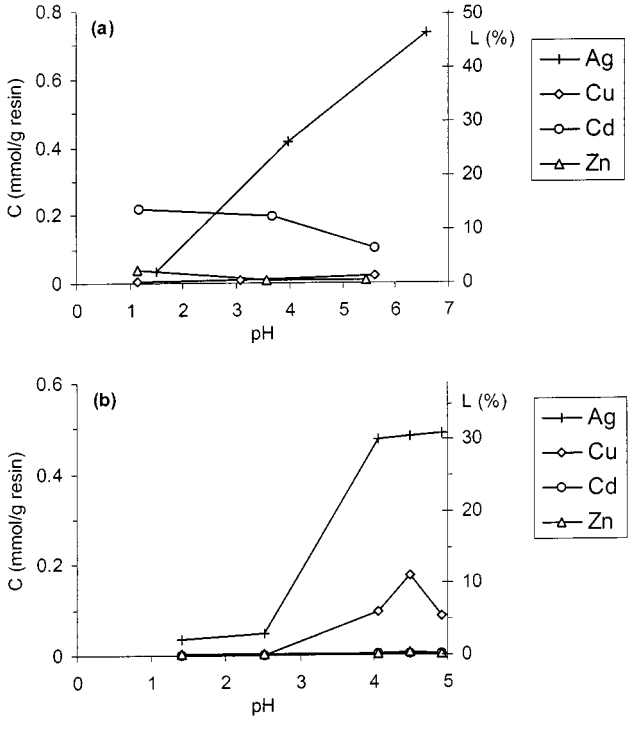

Figure 1. Metal-ion uptake behaviour of **1** {*p*(GMA-O)-[15]aneNO_4}: a) under non-competitive conditions; b) under competitive conditions, using metal nitrates

The experiment under competitive conditions (using metal nitrates) shows that Ag^{+} is the predominantly adsorbed species, although some Cu^{2+} is also extracted, see Figure 1 (b). This Cu^{2+} uptake is not in agreement with the non-competitive experiment, where no Cu^{2+} uptake was observed. The most likely explanation for this phenomenon is that the high acetate concentration in the non-competitive experiment (originating from the buffer) prevents the binding of Cu^{2+} to the ligands on the resin, as these acetate ions themselves are relatively strong ligands for Cu^{2+}. The absence of an acetate buffer in the competitive experiment thus allows Cu^{2+} ions to bind to the resin. The competitive experiment also shows that, at low pH, no Cd^{2+} is taken up. This behaviour is in agreement with the hypothesis that the Cd^{2+} uptake in the non-competitive experiment is due to the formation of polychloro species, as chloride ions were present in the non-competitive experiment and absent in the competitive experiment.

The capacity of modified thiirane resin **2** was determined for Cu^{2+}, Cd^{2+}, Zn^{2+}, and Ca^{2+}. The maximum uptake values of these metal ions were found to be 0.19 mmol/g, 0.18 mmol/g, 0.12 mmol/g, and 0.03 mmol/g, respectively. A significant part of this uptake, however, can be ascribed to the thiol groups on the resin. This is suggested by blank experiments with a resin containing only thiol and hydroxy groups, which showed an uptake of 0.14 mmol/g Cu^{2+} and 0.09 mmol/g Cd^{2+}. The competitive experiment with **2** shows that the resin is moderately Cu^{2+} selective, the maximum uptake being 0.15 mmol/g at pH 6.0.

[15]aneN_2O_3

The uptake results with **3b** {*p*(GMA-O)-[15]aneN_2O_3} under non-competitive conditions are presented in Figure 2 (a). The highest uptake is observed for Ag^{+}, 0.52 mmol/g at pH = 6.4 (ligand occupation of 59%). The metal uptake of all tested species shows a pronounced pH dependence, which is probably due to protonation of the nitrogen atom(s) of [15]aneN_2O_3 at low pH. In fact, Cd^{2+} is the only species that is adsorbed at low pH. The Cd^{2+} uptake at high pH is slightly lower than the Pb^{2+} uptake, but it clearly exceeds the uptake of Cu^{2+}. The observed order in the metal-uptake values, $Ag^{+} > Pb^{2+} > Cd^{2+} > Cu^{2+} > Co^{2+} > Zn^{2+} \approx Ni^{2+}$, is different from the order found for the formation constants of complexes of the free macrocycle [15]aneN_2O_3 with these metal ions in aqueous solution: $Cu^{2+} > Cd^{2+} > Pb^{2+} \approx Ag^{+} > Zn^{2+} > Co^{2+} > Ni^{2+}$.[15] In contrast, the order of stability constants of these cations with two structurally related cryptands (see Figure 3) in aqueous solution was found to be $Ag^{+} > Pb^{2+} > Cu^{2+} > Cd^{2+}$, Zn^{2+}, Co^{2+}, Ni^{2+} for cryptand-211, and $Pb^{2+} > Ag^{+} > Cd^{2+} > Cu^{2+} > Zn^{2+} > Co^{2+} > Ni^{2+}$ for cryptand-221.[15] The difference between the order of the stability constants of crown ether [15]aneN_2O_3 on one hand, and resin **3b** and cryptands-211 and -221 on the other hand, must be due to the presence of additional oxygen-

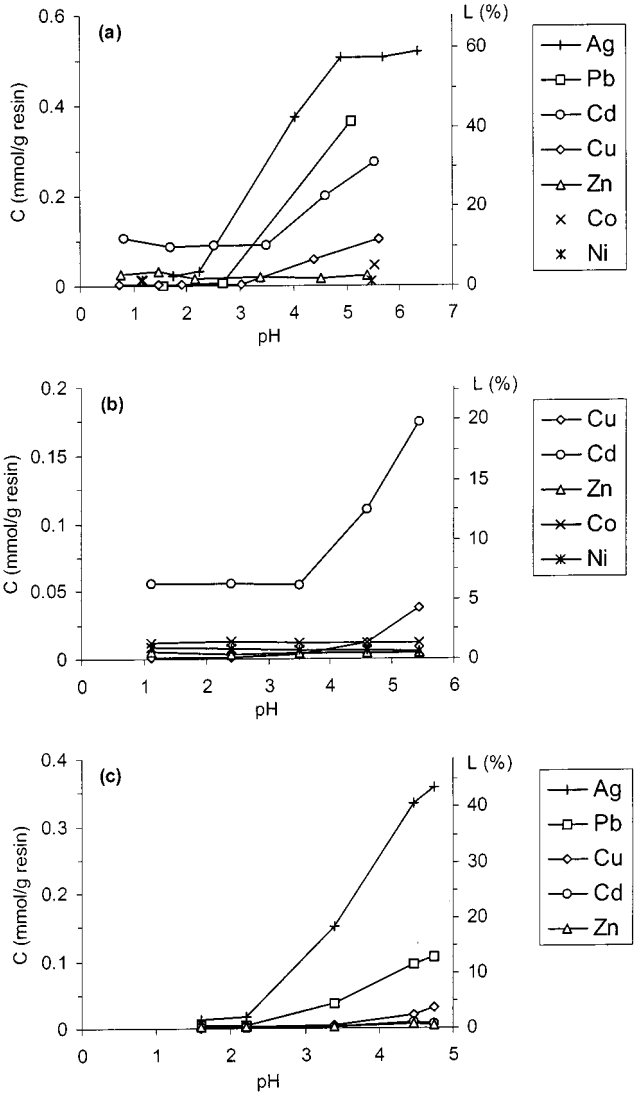

Figure 2. Metal-ion uptake behaviour of **3b** {*p*(GMA-O)-[15]aneN$_2$O$_3$}: a) under non-competitive conditions; b) under competitive conditions using metal chlorides; c) under competitive conditions using metal nitrates

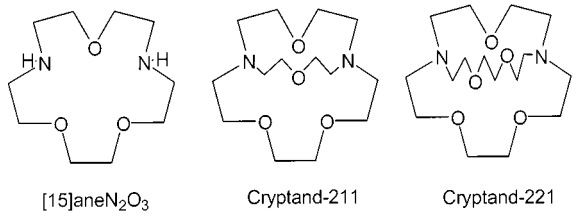

Figure 3. Structural formulae of [15]aneN$_2$O$_3$, cryptand-211 and cryptand-221

donor atoms on resin **3b** (the hydroxy groups originating from the backbone) and on the cryptands. These additional oxygen donors may change the stability of the different metal complexes.

The metal uptake by **3b** seems to be related to the ionic radii of the metal-ion species, as the metal uptake decreases with decreasing ionic radius, see Table 2. Exceptions to this trend are Ag^+ and Cu^{2+}. The relatively high value for Ag^+ can be explained by the different valencies of the tested metal ions. Ag^+ is the only monovalent species, and a higher uptake may be explained by the fact that only one negative charge has to be compensated for upon coordination, either by deprotonation of the immobilised ligand, or by the coordination of an accompanying anion. The somewhat high uptake of Cu^{2+}, compared to Co^{2+}, Zn^{2+}, and Ni^{2+}, can be ascribed to the high affinity of Cu^{2+} for nitrogen ligands.

Table 2. Ionic radii and uptake values for **3b** {*p*(GMA-O)-[15]aneN$_2$O$_3$}; ionic radii are all appropriate for coordination number 6

	Ionic radius [Å]	Uptake by **3b** [mmol/gram]
Pb^{2+}	1.19	0.36
Ag^+	1.15	0.52
Cd^{2+}	0.95	0.27
Co^{2+}	0.75	0.05
Zn^{2+}	0.74	0.02
Cu^{2+}	0.73	0.10
Ni^{2+}	0.69	0.01

The size-selective uptake by **3b** {*p*(GMA-O)-[15]aneN$_2$O$_3$} may be explained by the presence of the pendent hydroxyethyl groups, originating from the backbone. This additional coordinating oxygen donor imposes extra steric crowding on a metal ion that is already coordinated by the crown ether, and this steric crowding is best accommodated by the largest metal ions, whereas the stability of the complexes of small ions, such as Cu^{2+} and Zn^{2+}, is seriously reduced.[16,17] This results in the observed selectivity for Cd^{2+} over Cu^{2+}, Cd^{2+} over Zn^{2+}, and Pb^{2+} over Zn^{2+}. This effect is similar to the observed higher stability of large cations with the cryptands-211 and -221 in comparison with the parent macrocycle [15]aneN$_2$O$_3$.[15] The effect of the addition of hydroxyalkyl groups to oxa-aza ethers on the stability of the corresponding metal-ion complexes has been described in several papers.[16–18]

The selectivity for Cd^{2+} over Cu^{2+} is illustrated by the results of the competitive experiment, using metal chlorides [see Figure 2 (b)]. Hardly any Cu^{2+} is adsorbed between pH = 1 and 4.6, and only at pH = 5.4 some Cu^{2+} was found to be co-extracted with Cd^{2+}. The selectivity for Cd^{2+} over Cu^{2+} at pH = 4.6 is 10:1.

The selectivity for Cd^{2+} over Cu^{2+} and for Cd^{2+} over Zn^{2+} has been further investigated. In the presence of a tenfold excess of Cu^{2+}, the Cd^{2+} selectivity at pH = 4.9 is reduced to only 1.8:1, and at pH = 5.9 this is only 0.8:1, which suggests that an excess of Cu^{2+} causes a severe decrease in the Cd^{2+} selectivity. The selectivity for Cd^{2+} over Zn^{2+} is of interest as these species belong to the same group of the periodic table and hence often occur together in nature. The Cd^{2+}/Zn^{2+} selectivity in the competitive experiment, with equal amounts of Cd^{2+} and Zn^{2+} ions, is as high as 37:1 at pH = 5.4 [see Figure 2 (b)]. In an experiment at pH = 5.8, with Zn^{2+} present in a tenfold excess, the

Cd^{2+}/Zn^{2+} selectivity appears to still be 8.8:1. *p*(GMA-O)-[15]aneN_2O_3 thus exhibits a very reasonable selectivity for Cd^{2+} over Zn^{2+}, which can be ascribed to the difference in octahedral ionic radii (0.95 Å versus 0.74 Å). Similarly, cryptand-221 was reported to form complexes with Cd^{2+} and Zn^{2+} which significantly differ in stability, log*K* being 10.04 in the case of Cd^{2+} and 5.41 in the case of Zn^{2+}.[15] For [15]aneN_2O_3, the difference in log*K* values was found to be much smaller: 6.46 for Cd^{2+} versus 5.19 for Zn^{2+}.

The result of the competitive experiment, using metal nitrates, is depicted in Figure 2 (c). The same trend as under non-competitive conditions is observed: **3b** {*p*(GMA-O)-[15]aneN_2O_3} predominantly adsorbs Ag^+, although some Pb^{2+} is co-extracted at higher pH. The Ag^+ uptake at pH = 4.7 is 0.36 mmol/g.

The results of the non-competitive experiment with **4** {*p*(GMA-S)-[15]aneN_2O_3} are presented in Figure 4 (a), and show that the Cu^{2+} uptake exceeds the Cd^{2+} uptake. No correlation between the uptake and the ionic radii of the metal ions is observed, indicating that the role of the pendent thiol groups is entirely different from the role that pendent hydroxy groups play. The coordination of these thiol groups enhances the stability of the Cu^{2+} complex on the resin more than that of the Cd^{2+} complex. The maximum uptake of Cu^{2+} is 0.24 mmol/g (at pH = 5.7), for Cd^{2+} this is 0.18 mmol/g (at pH = 5.6). The experiment, under competitive conditions [Figure 4 (b)], shows that *p*(GMA-S)-[15]aneN_2O_3 is Cu^{2+}-selective in the presence of other divalent metal chlorides. Upon changing the polymeric backbone from *p*(GMA-O) to *p*(GMA-S), a reversed Cu^{2+}/Cd^{2+} selectivity is obtained, which can only be ascribed to the different effect that the pendent hydroxy and thiol groups have on the stability of the complexes formed on the resins. The donor strength of thiol groups towards (heavy) transition metal ions is higher than that of hydroxy groups, and this bond strength effect predominates any destabilising steric effect of the additional donor groups. In other words, the Cu^{2+} complex on *p*(GMA-S)-[15]aneN_2O_3 is stabilised by the pendent thiol group, where, in the case of *p*(GMA-O)-[15]aneN_2O_3, the steric effect of the pendent hydroxyethyl group predominates the bond strength effect of this group.

[18]aneN_2O_4

A range of metal ions has been tested under non-competitive conditions with **5a** {*p*(GMA-O)-[18]aneN_2O_4}, see Figure 5. The metal-ion uptake values are in the order $Ag^+ > Pb^{2+} > Cd^{2+} > Cu^{2+}, Zn^{2+}$. The solution data[15] are somewhat different as in this case the Cu^{2+} complex was found to be more stable than the Cd^{2+} complex, which again may be due to the presence of the additional hydroxyethyl groups on the polymer, which destabilises the Cu^{2+} complex. The uptake of Ag^+ and Pb^{2+} is very similar to that of **3b**. The uptake curves again show a pH dependence, and the maximum uptake of Ag^+ is again higher than that of Pb^{2+}, 0.61 mmol/g for Ag^+ at pH = 6.4 (ligand occupation of 92%) vs. 0.37 mmol/g for Pb^{2+} at pH = 5.1 (ligand occupation of 56%). The ligand occupations of Ag^+ and Pb^{2+} are (slightly) higher than those found with **3b**, suggesting that the larger macrocyclic cavity slightly enhances the stability of the Ag^+ and Pb^{2+} complexes. This effect was also observed for [18]aneN_2O_4 in solution.[15] The Cd^{2+} capacity of **5a** is lower than that of **3b** and is not a function of the pH. The uptake at low pH (pH = 1 and 2), which may be due to polychlorocadmate complexes (such as $[CdCl_4]^{2-}$), is higher than for resin **3b**, suggesting that this complex anion fits better into the larger binding cavity of **5a**. At increasing pH, no increased Cd^{2+} uptake is observed, which suggests that the Cd^{2+} ion cannot effectively be accommodated in the ligand cavity of *p*(GMA-O)-[18]aneN_2O_4. Cu^{2+} and Zn^{2+} are not extracted at all by **5a**, which is an illustration of the fact that they are too small for the macrocyclic cavity of [18]aneN_2O_4.

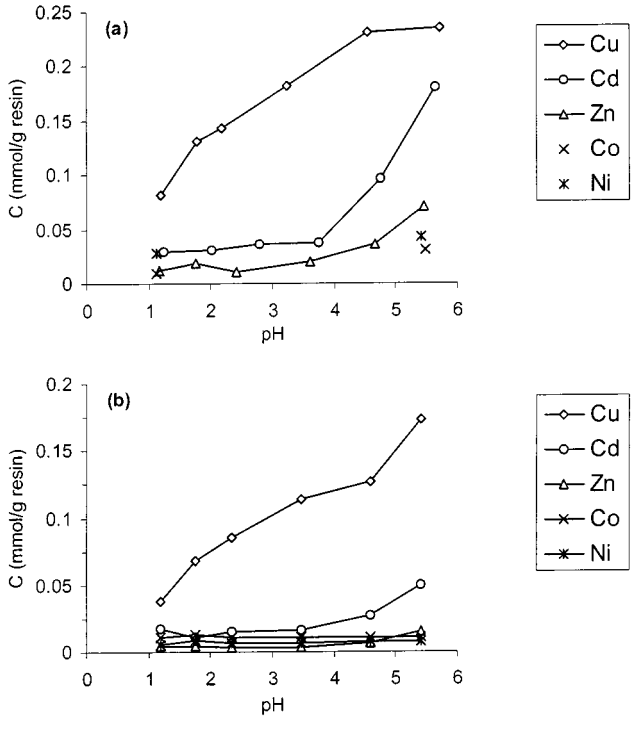

Figure 4. Metal-ion uptake behaviour of **4** {*p*(GMA-S)-[15]aneN_2O_3}: a) under non-competitive conditions; b) under competitive conditions using metal chlorides

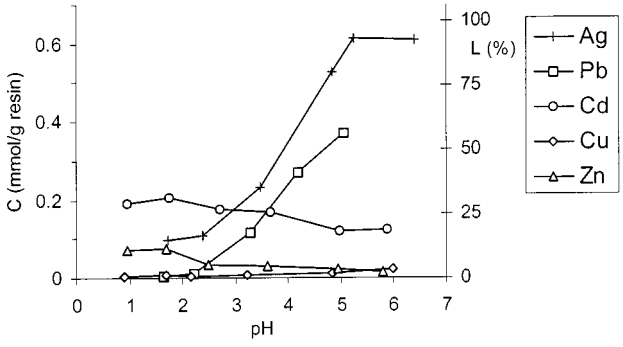

Figure 5. Metal-ion uptake behaviour of **5a** {*p*(GMA-O)-[18]aneN_2O_4} under non-competitive conditions

[18]aneO$_6$ is known to have a high affinity for K^+ and, to a lesser extent, for Na^+. The uptake of these two species by *p*(GMA-O)-[18]aneN$_2$O$_4$ was therefore investigated and appeared to be remarkably low, the maximum value for K^+ being 0.03 mmol/g at pH = 6.2.

The competitive experiment with **5a**, using the chlorides of Cu^{2+}, Cd^{2+}, Zn^{2+}, Co^{2+}, and Ni^{2+}, shows hardly any metal uptake at all. Only some Cd^{2+} is extracted over the whole pH range, the maximum uptake being only 0.09 mmol/g at pH = 1.7. This illustrates that these metal-ion species are too small to be accommodated in the macrocyclic cavity of [18]aneN$_2$O$_4$, and thus form very weak complexes with the resin. The competitive experiment using metal nitrates shows that both Ag^+ and Pb^{2+} are extracted, albeit to a small extent. The maximum values for these ions at pH = 4.8 are 0.17 mmol/g and 0.15 mmol/g, respectively.

The capacity of the modified thiirane resin **6** has been determined under non-competitive conditions, using buffered metal chloride solutions of Cu^{2+}, Cd^{2+}, Zn^{2+}, Co^{2+}, and Ni^{2+}. The maximum uptake values for all these metal-ion species has been observed at pH = 5.5, the values being 0.29 mmol/g, 0.23 mmol/g, 0.10 mmol/g, 0.04 mmol/g and 0.04 mmol/g, respectively. A solution of Pb(NO$_3$)$_2$, of which the pH was adjusted to 4.9, has been used to determine the Pb^{2+} uptake, which appeared to be 0.45 mmol/g.

The competitive experiment, using metal chlorides, reveals that **6** extracts both Cu^{2+} and Cd^{2+}, the maximum uptake of these metals being 0.21 mmol/g and 0.10 mmol/g, respectively.

Regeneration Experiments

The small quantity of **1** {*p*(GMA-O)-[15]aneNO$_4$} available, allowed only one regeneration experiment. The Ag^+-loaded resin was successfully regenerated with a 1.0 M HNO_3 solution, which left only 3.0% of the initial amount of Ag^+ on the resin.

Modified oxirane resin **3c** {*p*(GMA-O)-[15]aneN$_2$O$_3$} was loaded with Ag^+, Pb^{2+}, and Cd^{2+} at pH values where maximum uptake was observed in the non-competitive experiments. Aqueous solutions of acid (2.0 M HNO_3 in the case of Ag^+ and Pb^{2+}, and 2.0 M H_2SO_4 for Cd^{2+}), 3.35 M NH_3 in combination with 2.0 M NH_4NO_3, and 1.0 M $(NH_2)_2CS$ were used as potential stripping agents. The results are presented in Table 3.

Table 3. Relative amounts of residual Ag^+, Pb^{2+}, and Cd^{2+} on **3c** {*p*(GMA-O)-[15]aneN$_2$O$_3$} (in %) after stripping with 2.0 M HNO_3/H_2SO_4, 3.35 M NH_3 + 2.0 M NH_4NO_3 and 1.0 M $(NH_2)_2CS$

Stripping agent	Ag^+	Pb^{2+}	Cd^{2+}
HNO_3/H_2SO_4	5.74	0.55	1.12
NH_3 + NH_4NO_3	1.47	50.6	1.52
$(NH_2)_2CS$	16.4	37.5	14.5

The binding of metal ions by **3c** is due to the coordination of amines, oxygen ethers and hydroxyethyl moieties. Dilute acid is therefore likely to be an effective stripping agent, as the metal-binding sites can easily be protonated, and may subsequently release metal ions. This appears to be the case, as the residual amounts of Ag^+, Pb^{2+}, and Cd^{2+} on the resin after treatment with acid are only 5.7%, 0.6% and 1.1%, respectively. The stripping of Ag^+, however, appears to be more successful with NH_3 + NH_4NO_3, leaving only 1.5% of the initial amount of Ag^+ on the resin. Apparently, NH_3 is able to compete with the amines of the ligands on the resin in the case of Ag^+. This is probably due to the high stability of the formed $[Ag(NH_3)_2]^+$ complexes in solution. Cd^{2+} is also successfully stripped in this way, but when stripping with NH_3 + NH_4NO_3 is attempted for the Pb^{2+}-loaded resin, 51% of the initial amount of Pb^{2+} remains on the resin.

$(NH_2)_2CS$, which appeared to be the most successful stripping agent for the removal of metal ions from resins containing [16]aneNS$_4$,[12] appears to be the least effective agent for the removal of Ag^+, Pb^{2+}, or Cd^{2+} from *p*(GMA-O)-[15]aneN$_2$O$_3$. Unlike *p*(GMA-O)-[15]aneN$_2$O$_3$, however, *p*(GMA-O)-[16]aneNS$_4$ binds metal ions through its sulfur atoms, and $(NH_2)_2CS$ appears to be particularly useful for the disruption of these metal ion−sulfur bonds. On the other hand, *p*(GMA-O)-[15]aneN$_2$O$_3$ only contains oxygen- and nitrogen-donor atoms, and therefore other stripping agents are required, such as acid or NH_3 + NH_4NO_3.

Distribution-Coefficient Measurements

Distribution coefficients were determined for Ag^+, Pb^{2+}, Cu^{2+}, and Cd^{2+} with resins **3c** {*p*(GMA-O)-[15]aneN$_2$O$_3$} and **5c** {*p*(GMA-O)-[18]aneN$_2$O$_4$}. The results are presented in Table 4 and Figure 6. The experiments were performed at pH values where maximum uptake in the non-

Table 4. log*D* values for modified oxirane resins **3c** {*p*(GMA-O)-[15]aneN$_2$O$_3$} and **5c** {*p*(GMA-O)-[18]aneN$_2$O$_4$} with Ag^+, Pb^{2+}, Cu^{2+}, and Cd^{2+}; the pH of the experiment is indicated in parentheses

Resin	Ag^+	Pb^{2+}	Cu^{2+}	Cd^{2+}
p(GMA-O)-[15]aneN$_2$O$_3$	4.65 (6.8)	3.01 (5.1)	1.57 (5.9)	2.1 (5.9)
p(GMA-O)-[18]aneN$_2$O$_4$	3.69 (5.7)	2.66 (5.4)	0.42 (5.9)	1.60 (2.1)

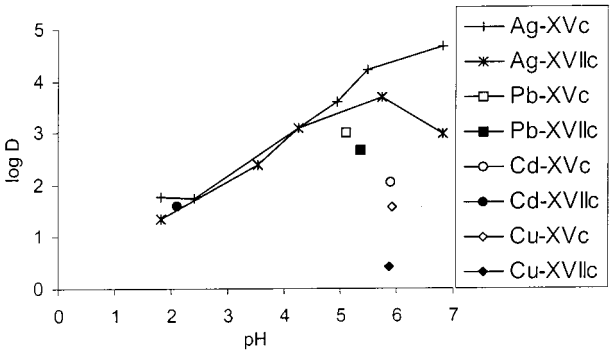

Figure 6. Distribution coefficients (log*D*) for Ag^+, Pb^{2+}, Cu^{2+}, and Cd^{2+} with **3c** {*p*(GMA-O)-[15]aneN$_2$O$_3$} and **5c** {*p*(GMA-O)-[18]aneN$_2$O$_4$}

competitive experiments was observed. In the case of Ag^+, log*D* values were determined as a function of the pH.

The results show the same trend as has been observed in the batch metal-uptake experiments: Both resins form their most stable complexes with Ag^+, and the stability is clearly a function of the pH. The stability of the Ag^+-p(GMA-O)-[18]aneN_2O_4 complex at pH = 6.8 is lower than at pH = 5.7, in contrast to the non-competitive uptake experiment and also in contrast to the log*D* curve of the Ag^+-p(GMA-O)-[15]aneN_2O_3 complex. A possible explanation for this may be that only a very small amount of Ag^+ was present in the log*D* experiments. At pH = 6.8, the small amount of NH_3 that was used to adjust the pH may have been enough to keep a significant part of the Ag^+ in solution. In the capacity measurements under non-competitive conditions, a larger excess of Ag^+ ions with respect to NH_3 was used, and the effect of the NH_3 is therefore likely to be smaller in that case.

The influence of the ring size on the log*D* values is not the same for each metal-ion species. Although the log*D* values of all metal ions are higher with *p*(GMA-O)-[15]aneN_2O_3, the difference is rather small in the case of Ag^+ and Pb^{2+}. This indicates that both the 18-membered and the 15-membered macrocycle form stable complexes with these metal-ion species. In the case of Cu^{2+}, however, the difference in the log*D* values is significant: 1.57 with *p*(GMA-O)-[15]aneN_2O_3 and only 0.42 with *p*(GMA-O)-[18]aneN_2O_4 at pH = 5.9. This illustrates once more that the cavity size of [18]aneN_2O_4 is too large for Cu^{2+}, whereas the [15]aneN_2O_3-containing resin yields somewhat more stable Cu^{2+} complexes. The log*D* value found for Cu^{2+} with *p*(GMA-O)-[16]aneNS_4 was found to be somewhat higher[12] (2.1), suggesting that the absence of thioethers in the immobilised macrocyclic ligands decreases the stability of the corresponding Cu^{2+} complexes. The log*D* values obtained for Cd^{2+} are similar to those found for *p*(GMA-O)-[16]aneNS_4.[12] These results are in accordance with chromatography experiments involving mixed-donor crown ethers, immobilised onto thin layer plates.[19] A range of macrocycles were impregnated on silica plates and mixtures of metal ions were separated on the basis of their different R_f values. The observed stability trends were $Cu^{2+} > Cd^{2+} > Ba^{2+}$ for macrocycles containing N and S donor atoms and $Ba^{2+} > Cd^{2+} > Cu^{2+}$ for those containing N and O donors.[19]

Conclusion

The immobilisation of [15]aneN_2O_3 onto *p*(GMA-O) resulted in a resin with a high capacity for Ag^+, and a somewhat lower capacity for Pb^{2+} and Cd^{2+}. A correlation between the ionic radii and the uptake values was observed for a range of metal ions. With decreasing ionic radius, a decrease in metal-ion uptake was observed. This effect was not observed for *p*(GMA-S)-[15]aneN_2O_3. The size selectivity is most probably due to the presence of pendent hydroxy groups on the modified oxirane resin. These additional neutral oxygen-donor atoms are known to destabilise complexes of small metal ions more than those of larger metal ions do. This effect only becomes apparent when crown ethers without sulfur atoms are applied, since no size selectivity due to the pendent hydroxy groups was observed for *p*(GMA-O)-[16]aneNS_4 and other thia crown ether containing modified oxirane resins.[12,20] With *p*(GMA-O)-[15]aneN_2O_3, Cd^{2+} over Cu^{2+} and Zn^{2+}, and Pb^{2+} over Cu^{2+} and Zn^{2+} selectivities have been obtained.

p(GMA-S)-[15]aneN_2O_3 shows a reversed Cd^{2+}/Cu^{2+} selectivity, which is due to the presence of pendent thiol rather than pendent hydroxy groups on the resin. Thiol groups have a higher donor strength, and their stabilising effect is larger on Cu^{2+} complexes than on Cd^{2+} complexes, and loss of the Cd^{2+} over Cu^{2+} selectivity, observed for *p*(GMA-O)-[15]aneN_2O_3, is the result.

The distribution-coefficient measurements show that Cu^{2+} forms less stable complexes with *p*(GMA-O)-[15]aneN_2O_3 than with resins containing thia crown ethers.[12] This suggests that the presence of thioethers, in the macrocyclic ligands, increases the stability of the Cu^{2+}. *p*(GMA-O)-[18]aneN_2O_4 extracts amounts of Ag^+ and Pb^{2+} that are similar to *p*(GMA-O)-[15]aneN_2O_3, but the uptake of Cd^{2+}, Cu^{2+}, and Zn^{2+} appeared to be drastically reduced. The cavity size of [18]aneN_2O_4 is apparently too large to accommodate these latter metal ions. As with *p*(GMA-O)-[15]aneN_2O_3, the ionic radius of the metal ions is an important factor in the interpretation of the uptake results obtained. The increase in the cavity size of the macrocycle has its largest effect on the smallest metal ions, as the difference in the log*D* value of the small Cu^{2+} ion with *p*(GMA-O)-[15]aneN_2O_3 and *p*(GMA-O)-[18]aneN_2O_4 illustrates. For large metal-ion species, such as Ag^+ and Pb^{2+}, comparable log*D* values have been obtained for the two resins.

Regeneration experiments, performed with Ag^+-, Pb^{2+}-, and Cd^{2+}-loaded *p*(GMA-O)-[15]aneN_2O_3, showed that stripping with 2.0 M acid is successful for Pb^{2+} and Cd^{2+}. The combination of NH_3 + NH_4NO_3 appeared to be the most successful method for Ag^+. It was not possible to remove the metal ions with $(NH_2)_2CS$ from the loaded resins, in contrast to the loaded resins that contain thia crown ethers. Apparently, the type of donor atoms that bind a metal ion determines the type of stripping agent that is best applicable.

The absence of sulfur atoms in the crown ethers that have been described in the present study has resulted in selectivity patterns that are governed by several factors. The ring size of the macrocycle, the effect of the pendent hydroxy groups and the relative positions of the metal ions and the donor atoms on the HSAB scale all become important when oxygen donor atoms, which are relatively weak donor atoms for (heavy) transition-metal ions, are used in crown ether containing metal-ion extractants. This has resulted in functionalised polymers with an enhanced affinity for large heavy-metal ions such as Cd^{2+} and Pb^{2+}, compared to resins containing thia-aza crown ethers.

Experimental Section

Starting Materials: [15]aneNO$_4$ and [15]aneN$_2$O$_3$ were purchased from Aldrich, and [18]aneN$_2$O$_4$ was obtained from Fluka. All other reagents and solvents were purchased from commercial sources and were used as received, unless stated otherwise. DMF was stored under dinitrogen over molecular sieves (4 Å). Toluene was distilled from sodium metal and stored under dinitrogen over molecular sieves (4 Å). Methanol was distilled from magnesium and stored under dinitrogen over molecular sieves (4 Å).

Physical and Chemical Measurements: The metal contents of the digested samples (vide infra) of loaded resins were measured by atomic absorption spectroscopy (AAS) with a Perkin−Elmer 3100 AAS and flame emission spectrometer, using a linear calibration method. − Elemental analyses (C,H,N,S) were carried out by the Microanalytical Department of the University College of Dublin (Republic of Ireland). − Solid-state CP MAS ^{13}C NMR spectra (cross polarisation and magic-angle spinning) were recorded with a Bruker MSL-400 spectrometer, operating at 100.6 MHz for ^{13}C. The sample spinning rate was 7000 Hz. The cross-polarisation contact time was 1.0 ms, with 3−5 s recycle delays between successive scans. − ^{1}H NMR and ^{13}C NMR spectra were recorded with a 200 MHz JEOL JNM FT NMR spectrometer. Chemical shifts are quoted with respect to TMS as an internal reference.

Synthesis of the Ion Exchangers: Oxa-aza crown ethers were immobilised onto *p*(GMA-O) and *p*(GMA-S), according to the same general procedure.[12,21] The synthetic details for resins **1**−**6** are presented in Table 5. The epoxide concentration on *p*(GMA-O) was 4.21 mmol/g in all cases. The *p*(GMA-S) batch that was used for the synthesis of *p*(GMA-S)-[15]aneNO$_4$ contained 2.76 mmol thiirane groups per g, the thiirane contents of the batches used for *p*(GMA-S)-[15]aneN$_2$O$_3$ and *p*(GMA-S)-[18]aneN$_2$O$_4$ were 2.35 mmol/g and 3.00 mmol/g, respectively. The reaction temperature was 80 °C in all cases. After each immobilisation, unchanged ligand was collected, analysed by NMR spectroscopy, and re-used in some cases.

To a solution of the ligand in toluene or in a mixture of toluene and methanol (1:1, v/v), *p*(GMA-O) or *p*(GMA-S) was added (molar ratio ligand/epoxide/thiirane groups, 1.5:1) and the mixture was heated at 75−100 °C under dinitrogen for 5 d. The resulting resins were filtered off and purified by Soxhlet extraction with toluene (6 h) and ethanol (6 h), respectively. The resins were dried in vacuo at 50 °C for 16 h. Finally, the resins were conditioned with 0.5 M H_2SO_4 (30 min) and 0.5 M NaOH (30 min), washed with water and dried in vacuo at 50 °C for 48 h. The ligand concentrations of the functionalised polymers were calculated on the basis of the weight-% of nitrogen (microanalysis), whereby allowances were made for the nitrogen content of the thiirane-containing *p*(GMA-S) backbone, as traces of (thio)urea were left after the conversion of oxirane to thiirane.[10,12]

Metal-Uptake Experiments: The metal-uptake experiments, with the exception of those involving Ag^+ and Pb^{2+}, were performed using standard metal chloride solutions of 0.16 M and 0.6 M buffer solutions of NaCl/HCl (pH = 0.9−2.3) and NaOAc/HOAc (pH = 2.5−6.0). All experiments were performed in polyethylene bottles mounted on a shaker at room temperature. The capacities for Cu^{2+}, Cd^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, and Ca^{2+} under non-competitive conditions were determined as a function of the pH. Batches of 70−100 mg of resin were used, together with a mixture of 25 mL of metal-ion solution and 25 mL of buffer. For the determination of the Cu^{2+} capacities at pH > 5, a lower Cu^{2+} concentration (10 mL of the standard Cu^{2+} solution and 40 mL of buffer) was used to prevent precipitation of Cu^{II} hydroxides. After a shaking time of 48 h, the samples were filtered, washed with water, ethanol and diethyl ether, and dried in vacuo at 50 °C.

Batch metal-uptake experiments under competitive conditions were performed with standard metal chloride solutions of Cu^{2+}, Cd^{2+}, Zn^{2+}, Ni^{2+}, and Co^{2+} in a pH range of 0.9 to 6. Batches of 70−100 mg of resin were used, together with a mixture of 5 mL of each metal ion solution and 25 mL of buffer. After a shaking time of 48 h, the samples were further handled as described for the non-competitive experiments.

Table 5. Synthetic details of immobilisation reactions of N,O-mixed donor crown ethers (Tol = toluene; IPA = 2-propanol; reaction time = 5 d)

Ligand	Support epoxide/thiirane	Solvent	Product (yield)
[15]aneNO$_4$	*p*(GMA-O)	Tol (20 mL)	*p*(GMA-O)-[15]NO$_4$

Batch metal-uptake experiments involving Ag^+ and Pb^{2+} were performed using standard metal nitrate solutions of 0.10 M. The capacities for Ag^+ and Pb^{2+} were determined with batches of 70−100 mg of resin over a pH range of 1 to 6. The pH of the metal solutions was adjusted with dilute HNO_3 and dilute NH_3, respectively. In the case of Pb^{2+}, pH values higher than 5.3 were not attainable due to precipitation of $Pb(OH)_2$. The experiments involving Ag^+ were performed under exclusion of light.

Batch metal-uptake experiments involving Ag^+ and Pb^{2+} under competitive conditions were performed using standard metal nitrate solutions (0.10 M) of Ag^+, Pb^{2+}, Cu^{2+}, Cd^{2+}, and Zn^{2+}. Batches of 70−100 mg of resin were used, together with a mixture of 10 mL of each of the metal solutions, and the pH was adjusted in the same way as in the non-competitive experiments with Ag^+ and Pb^{2+}. The samples were shaken for 48 h and further handled as described for the metal chloride experiments.

In the regeneration experiments, a range of potential stripping agents were tested for their ability to remove metal ions from loaded resins. A sufficient amount of ion exchanger was loaded with the appropriate metal ion solution and subsequently contacted with aqueous solutions of a range of acids or competing ligands, using parts of the same batch of loaded resin.

Distribution coefficients [D = (mg M^{n+}/g of dry resin)/(mg M^{n+}/mL of solution)] were determined as a function of pH according to Roozemond et al.[22] In each case, 0.2 g of resin, 25 mL of buffer solution and 25 mL of an appropriate metal ion solution, containing such an amount of metal ions that the polymer-bound ligands were present in about eightfold excess, were shaken for 48 h. In the case of Ag^+ and Pb^{2+}, no buffer solutions were used, instead the pH was adjusted with dilute HNO_3 or NH_3.

Samples for metal analysis were prepared by heating the loaded samples overnight with concentrated H_2SO_4 (reflux) and subsequently with concentrated HNO_3 until clear solutions were obtained.

Acknowledgments

Mr. J. G. Hollander is gratefully acknowledged for the collection of the solid-state CP MAS ^{13}C NMR spectra presented in this paper. Dr. W. Buijs (DSM Research) is thanked for his suggestions and fruitful discussions and Ing. F. ten Hoonte is acknowledged for technical assistance.

Keywords: Ruthenium / N,P ligands / Catalysis / Oxidations

The interaction of $[RuCl_2(PPh_3)_3]$ with one equivalent of *N*,*N*′-bis[2-(diphenylphosphanyl)benzyl]-1*R*,2*R*-cyclohexanediamine [1*R*,2*R*-P(NH)(NH)P] in dichloromethane at room temperature gave *trans*-[$RuCl_2\{\kappa^3$-1*R*,2*R*-P(NH)(NH)P$\}(PPh_3)$] (**1**). When heated under reflux in toluene under a nitrogen atmosphere, **1** was converted into *trans*-[$RuCl_2\{\kappa^4$-1*R*,2*R*-P(NH)(NH)P$\}$] (**2**). However, when **1** was stirred at room temperature in air, it was oxidized to *trans*-[$RuCl_2\{\kappa^3$-1*R*,2*R*-PN(NH)P$\}(PPh_3)$] (**3**). Depending on the reaction conditions, **3** was converted into *trans*-[$RuCl_2\{\kappa^3$-1*R*,2*R*-P(NH)(NH)P=O$\}(PPh_3)$] (**4**) when heated to 80 °C in toluene in air, to *cis*-[$RuCl_2\{\kappa^4$-1*R*,2*R*-PN(NH)P$\}$] (**5**) when stirred at room temperature in acetone in air, or to *trans*-[$RuCl_2\{\kappa^4$-1*R*,2*R*-PN(NH)P$\}$] (**6**) when heated under reflux in acetone under a nitrogen atmosphere. When heated under reflux in toluene under a nitrogen atmosphere, **5** isomerized to **6** quantitatively. When heated under reflux in mesitylene under a nitrogen atmosphere, **6** was slowly reduced to **2**. The solid state structures of **3** and **5** were ascertained by X-ray crystallography. Catalytic studies showed that **1** could catalyze the oxidation of alkanes and alkenes with molecular oxygen.

Introduction

Transition-metal complexes with chiral diamino-, diimino-, and diamidodiphosphane ligands have been shown to be effective catalysts for asymmetric hydrogen-transfer reactions,[1] epoxidations,[2] and allylic alkylations,[3−4] respectively. Thus, the synthesis of chiral diamino-, diimino-, and diamidodiphosphane ligands and their application as auxiliaries for the preparation of chiral catalysts have aroused considerable recent interest. We have investigated the preparation and chemistry of diamino-, diimino-, and diamidodiphosphane ligands,[5−10] and reported the synthesis of *N*,*N*′-bis[2-(diphenylphosphanyl)benzyl]-1*R*,2*R*-cyclohexanediamine [1*R*,2*R*-P(NH)(NH)P] and its Ru^{II},[7] Cu^{I}, and Ag^{I} complexes.[8] In this report, we describe the synthesis, reactivity, and catalytic activity of *trans*-[$RuCl_2\{\kappa^3$-1*R*,2*R*-P(NH)(NH)P$\}(PPh_3)$] (**1**).

Results and Discussion

Unlike the reaction with $[RuCl_2(DMSO)_4]$ in refluxing toluene, which gave the complex *trans*-[$RuCl_2\{\kappa^4$-1*R*,2*R*-P(NH)(NH)P$\}$] (**2**),[7] 1*R*,2*R*-P(NH)(NH)P reacted with $[RuCl_2(PPh_3)_3]$ in dichloromethane at room temperature to give *trans*-[$RuCl_2\{\kappa^3$-1*R*,2*R*-P(NH)(NH)P$\}(PPh_3)$] (**1**), which was fully characterized by elemental analysis, NMR spectroscopy, and mass spectrometry. The ^{31}P NMR spectrum of **1** exhibited two doublets at δ = 48.6 (d, $^2J_{PP}$ = 28.9 Hz) and 38.9 (d, $^2J_{PP}$ = 28.9 Hz) for the coordinated P atom of the P(NH)(NH)P ligand and PPh_3, respectively, and a singlet at δ = −13.3 (s) for the dangling P atom of the P(NH)(NH)P ligand. The positive FAB mass spectrum of **1** showed a peak corresponding to its molecular ion $[M]^+$ at *m*/*z* = 1096 for ^{102}Ru and ^{35}Cl. The tridentate nature of the P(NH)(NH)P ligand was also confirmed by X-ray crystallography. While this work was in progress, the synthesis and structure of **1** appeared in the literature.[11] Our structural and spectroscopic data of **1** agree with the literature data.

When heated to reflux in toluene under a nitrogen atmosphere, **1** was converted quantitatively to *trans*-[$RuCl_2\{\kappa^4$-1*R*,2*R*-P(NH)(NH)P$\}$] (**2**), which was confirmed by comparing the spectroscopic data with the literature values.[1,7] However, when stirred in dichloromethane in air at room temperature, **1** was converted into *trans*-[$RuCl_2\{\kappa^3$-1*R*,2*R*-PN(NH)P$\}(PPh_3)$] (**3**) (Scheme 1). The structure of **3** was established by X-ray crystallography (Figure 1). Selected bond lengths and bond angles are given in Table 1.

Structural analysis revealed that the κ^3-1*R*,2*R*-P(NH)(NH)P ligand had been oxidized to a κ^3-1*R*,2*R*-

PN(NH)P ligand with the amino group *trans* to the PPh_3 group oxidized to an imino group. The N(1)−C(19) and N(2)−C(26) distances of 1.505(8) and 1.28(1) Å are consistent with a carbon−nitrogen single and double bond, respectively. The Ru atom adopts a slightly distorted octahedral geometry with a *trans*-$RuCl_2$ arrangement. The [1*R*,2*R*-PN(NH)P] ligand acts as a tridentate ligand with one of the two phosphanyl groups being uncoordinated. The sixth site is occupied by a PPh_3 ligand. The Ru−P, Ru−Cl, and Ru−N distances are in the range expected for similar com-

plexes of general formula [$RuCl_2${P(NH)(NH)P}].[1,7,11] The Ru−N distances [Ru−N(1) 2.192(6), Ru−N(2) 2.059(7) Å] reflect that the imino nitrogen, N(2), is more tightly bound to the Ru centre than the amino nitrogen, N(1). The Ru−P distance of the PPh_2 group [Ru−P(2) 2.261(2) Å] is shorter than that of the PPh_3 group [Ru−P(3) 2.355(2) Å]. This may be a reflection of the chelate effect as well as the *trans* influence. The closing of the Cl(1)−Ru−Cl(2) angle [168.0°(1)] reflects the steric crowding and chelate ring strain in the complex, as the chloro ligands are pushed away from the bulky PPh_3 toward the imino moiety *trans* to it. The solid-state structure is supported by ^1H, ^{13}C and ^{31}P NMR, IR, and MS data. The $^{31}P\{^1H\}$ NMR spectrum of **3** exhibits two doublets and a singlet at δ = 55.5 (d, $^2J_{PP}$ = 27.2 Hz), 31.1 (d, $^2J_{PP}$ = 27.2 Hz), and −14.9 (s), which can be assigned to P(2), P(3), and P(1) (see Figure 1 for atom numbering), respectively. The presence of the imino group is further supported by the ^1H NMR spectrum and ^{13}C NMR spectrum, which shows a doublet at δ = 8.55 (d, $^4J_{P-CH}$ = 8.8 Hz, 1 H) for the proton and a singlet at δ = 164.9 for the carbon of the -CH=N- group. Furthermore, the IR spectrum shows the $\nu_{C=N}$ absorption at 1621 cm^{-1}. The positive FAB mass spectrum exhibits the molecular ion peak $[M]^+$ at *m*/*z* = 1094.

When heated to 80 °C in air in toluene, **3** was converted quantitatively to a purple red species, **4**, within 4 h. The $^{31}P\{^1H\}$ NMR spectrum of **4** exhibited two doublets and a singlet at δ = 47.1 (d, $^2J_{PP}$ = 28.8 Hz), 39.1 (d, $^2J_{PP}$ = 28.8 Hz), and 30.6 (s). The chemical shifts of the two doublets are very similar to those of **1**. Thus, the doublets at δ = 47.1 and 39.1 can be assigned to the phosphorus atoms of the tridentate ligand and PPh_3, respectively. The $^{31}P\{^1H\}$ NMR spectroscopic data suggest that the imino group in **3** has been reduced to an amino group. This is supported by the absence of the imino proton, imino carbon, and the $\nu_{C=N}$ band in the ^1H NMR, ^{13}C NMR, and IR spectra, respectively. The chemical shift of the singlet corresponds to that of a phosphane oxide, suggesting that the pendant phosphane had been oxidised to a phosphane oxide. This is further supported by the IR data, which shows the $\nu_{P=O}$ absorption at 1191 cm^{-1}, and the mass spectroscopic data (FAB, positive), which displays the molecular ion peak $[M]^+$ at *m*/*z* = 1112. Based on the spectroscopic data, compound **4** was formulated as *trans*-[$RuCl_2${κ^3-1*R*,2*R*-P(NH)(NH)P=O}(PPh_3)] with the structure shown in Scheme 1.

When stirred at room temperature in acetone in air, however, **3** was converted into a mixture of compounds. The ^{31}P NMR spectrum of the reaction mixture showed that in addition to **4** (approximately 5%), a new species **5** was also observed, which exhibited a pair of doublets at δ = 51.5 (d, $^2J_{PP}$ = 30.3 Hz) and 46.3 (d, $^2J_{PP}$ = 30.3 Hz). Compounds **4** and **5** could be easily separated by column chromatography. The structure of **5** was ascertained by X-ray crystallography (Figure 2). Crystals of **5**·H_2O suitable for X-ray diffraction study were grown by slow evaporation of **5** in an acetone/hexane mixture. The water molecule probably came from acetone, which had not been dried prior to use. Selected bond lengths and bond angles are given in Table 1. Structural analysis revealed that the tridentate κ^3-1*R*,2*R*-PN(NH)P ligand had become a tetradentate κ^4-1*R*,2*R*-PN(NH)P ligand with the imino nitrogen N(1) and the phosphorus atom P(1) of the aminophosphanyl group *trans* to the Cl atoms. The Ru atom had adopted a slightly distorted octahedral geometry with a *cis*-$RuCl_2$ arrangement. The Cl(1)−Ru−Cl(2) bond angle is 87.2(1)°. The Ru−P, Ru−Cl, and Ru−N distances are similar to those of **3**. The differences in Ru−P [Ru−P(1) 2.299(2), Ru−P(2) 2.270(2) Å], Ru−Cl [Ru−Cl(1) 2.453(1), Ru−Cl(2) 2.442(1) Å], and Ru−N [Ru−N(1) 2.026(5), Ru−N(2) 2.142(4) Å] distances are a reflection of the *trans* influence. The N(2)−C(8) and N(1)−C(1) distances of 1.497(5) and 1.295(6) Å are consistent with a carbon−nitrogen single and double bond, respectively.

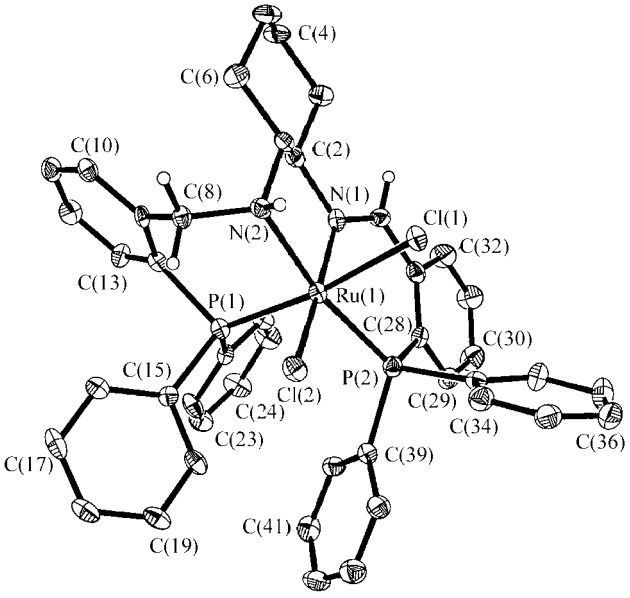

Figure 2. A perspective drawing of compound **5**; all the phenyl and cyclohexyl protons are omitted for clarity

When heated under reflux in toluene under a nitrogen atmosphere for 12 h, **5** was converted quantitatively (by ^{31}P NMR) to a red species **6**. In its ^{31}P NMR spectrum, **6** exhibited two doublets at δ = 54.3 (d, $^2J_{PP}$ = 26.7 Hz) and 36.1 (d, $^2J_{PP}$ = 26.7 Hz), which could be assigned to the PPh_2 groups attached to the imino and amino group, respectively. In its mass spectrum (FAB, positive), **6** exhibited the $[M]^+$ peak at *m*/*z* = 832 for ^{102}Ru and ^{35}Cl. Thus, compound **6** can be formulated as *trans*-[$RuCl_2${κ^4-1*R*,2*R*-PN(NH)P}]. Compound **6** could also be obtained quantitatively (by ^{31}P NMR) when an acetone solution of **3** was heated to reflux under a nitrogen atmosphere for 12 h. A ^{31}P NMR study showed that the imino group of **6** could be slowly reduced to an amino group upon prolong heating in a high boiling hydrocarbon solvent under a nitrogen atmosphere. When **6** was heated under reflux in mesitylene under a nitrogen atmosphere, the $^{31}P\{^1H\}$ NMR spectrum of the

solution showed that as well as the resonances of **6**, a singlet at δ = 46.5 corresponding to a resonance of **2** emerged. After heating for 48 h under reflux the reaction proceeded cleanly with about 50% of **6** being converted into **2**, based on ^{31}P NMR spectroscopic data. No other phosphorus-containing species could be observed. The mechanism of this reduction is not clear, but it is very likely that the hydrogen source for the reduction is the solvent.

Catalytic Oxidation

Preliminary results showed that under oxygen, **1** catalysed the oxidation of octane primarily to 2-, 3-, and 4-octanone, hexene to 1,2-hexanediol, and styrene to benzoic acid (Table 2). For the octane oxidation, the effect of temperature was more critical than pressure. For example, when the catalytic reaction was carried out at 130 °C and an oxygen pressure of 5 MPa, the turnover frequency (TOF) was 67. A drop in oxygen pressure to 2.4 MPa did not affect the TOF significantly. The TOF was about 62. However, when the temperature was decreased to 110 °C, the TOF dropped to about 0.4. The activity of $[RuCl_2(PPh_3)_3]$ as a catalyst for the oxidation of styrene and octane with oxygen were also examined. The results (the last two entries of Table 2) showed that under the same conditions $[RuCl_2(PPh_3)_3]$ catalysed the oxidation of styrene with oxygen to benzaldehyde and styrene oxide with a very low conversion (0.4%), and was inactive toward the oxidation of octane with oxygen. Thus, **1** is a better catalyst than $[RuCl_2(PPh_3)_3]$ for the oxidation of styrene and octane with oxygen.

Ruthenium-catalysed oxidation of alkane with peroxo species has drawn considerable interest recently. However, most of the studies were concentrated on the use of peroxo species as oxidants in the catalytic reaction;[12−14] there were very few studies using molecular oxygen as oxidant.[15] The present study provides an additional example of a catalytic system where molecular oxygen can be used to oxidise a saturated hydrocarbon. The mechanism of the catalytic oxidation is not clear. However, based on the reactivity of **1** with air, compounds **3** and **4** may be involved as intermediates in the catalytic cycle. The transformation of **3** to **4** is rather unusual. Rather than just oxidising the pendant phosphane to a phosphane oxide, the oxidation was accompanied by the reduction of an imino group to an amino group.

Experimental Section

General Procedures: Unless otherwise stated, all reactions were carried out under an atmosphere of dry nitrogen using standard Schlenk and vacuum-line techniques. Solvents were dried by standard procedures, distilled, and deaerated prior to use. All chemicals

Table 2. Catalytic oxidation of 1-hexene, styrene and octane with O_2 using **1** as catalyst

[a] Determined by GLC analysis based on the starting substrate using acetophenone as an internal standard. [b] Identified by GC-MS. [c] Determined by GLC analysis based on the converted substrate using acetophenone as an internal standard. [d] Substrate (2.0 g): catalyst (1 mg) = 26100 (mole ratio), reaction time = 2 h. [e] Substrate (2.7 g): catalyst (2 mg) = 14200 (mole ratio), reaction time = 4 h. [f] Substrate (1.4 g): catalyst (2 mg) = 6700 (mole ratio), reaction time = 64 h. [g] Catalyst: $RuCl_2(PPh_3)_3$, substrate (2.7 g): catalyst (2 mg) = 12500 (mole ratio), reaction time = 4 h. [h] Catalyst: $RuCl_2(PPh_3)_3$, substrate (1.4 g): catalyst (2 mg) = 5900 (mole ratio), reaction time = 17 h.

used were of reagent grade, obtained from the Aldrich Chemical Company, and, where appropriate, were degassed before use. The compounds 1*R*,2*R*-P(NH)(NH)P[8] and $[RuCl_2(PPh_3)_3]$[16] were prepared according to literature methods. Microanalyses were performed at the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences. The IR spectra (KBr pellets) were recorded on a Nicolet Nagna-IR 550 spectrometer, and NMR spectra on a JEOL EX270 spectrometer. Chemical shifts of ^1H NMR spectra were referenced to internal deuterated solvents and then recalculated to TMS (δ = 0.00), those of $^{31}P\{^1H\}$ NMR spectra were referenced to external 85% H_3PO_4. Low-resolution mass spectra were obtained on a Finnigan MAT SSQ-710 or MAT 95 spectrometer in positive FAB mode and reported as *m*/*z*. Gas chromatograms were obtained on a HP 5890 GC system or a HP 6890−5972 GC-MSD system. The progress of all the reactions was monitored by $^{31}P\{^1H\}$ NMR spectroscopy.

Preparation of *trans*-[RuCl$_2${κ^3-1*R*,2*R*-P(NH)(NH)P}(PPh$_3$)] (1): A solution of 1*R*,2*R*-P(NH)(NH)P (0.212 g, 0.320 mmol) and $[RuCl_2(PPh_3)_3]$ (0.305 g, 0.318 mmol) in CH_2Cl_2 (20 cm^3) was stirred under a nitrogen atmosphere at room temperature for 4 h. The solution was filtered and the solvent of the filtrate was removed in vacuo to give a dark red residue. The residue was dissolved in a minimum amount of chloroform and purified by chromatography on a silica gel column using chloroform as eluent to give an orange band. Removal of the solvent from the orange band gave an orange solid, which was recrystallized from dichloromethane/hexane to give orange crystals. Yield: 0.264 g, 64%; m.p. 186−187 °C (decomp). IR (KBr): $\tilde{\nu}$ = 3257 cm^{-1} w, 3186 w, 3047 m, 2930 w, 1490 m, 1434 s, 1189 w, 1086 m, 1035 w, 994 m, 958 w, 753 s, 702 vs, 574 w, 552 s and 467 w. ^1H NMR: ($CDCl_3$): δ = 6.41−7.82 (m, 43 H), 3.98 (m, 2 H), 3.79 (m, 2 H), 3.53 (m, 2 H), 3.04 (m, 1 H), 2.57 (m, 1 H), 0.98−1.48 (m, 8 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 47.0 (d, $^2J_{PP}$ = 28.2 Hz), 39.3 (d, $^2J_{PP}$ = 28.2 Hz), −13.1 (s). $C_{62}H_{59}Cl_2N_2P_3Ru{\cdot}CH_2Cl_2{\cdot}CHCl_3$ (1301.37): calcd. C 59.07, H 4.80, N 2.15; found C 59.09, H 4.81 , N 2.14. LRMS (FAB+): *m*/*z* = 1096 [M]$^+$ for ^{102}Ru and ^{35}Cl. $[\alpha]_D^{20}$ = 55.83 (*c* = 0.5, CH_2Cl_2).

Preparation of *trans*-[RuCl$_2${κ^4-1*R*,2*R*-P(NH)(NH)P}] (2): A solution of **1** (0.081 g, 0.074 mmol) in toluene (10 cm^3) was heated to reflux under a nitrogen atmosphere for 12 h. After cooling to room temperature, the solution was filtered, and the solvents evaporated to dryness in vacuo to give an orange residue. The residue was washed with diethyl ether (2 × 5 cm^3) and recrystallized from a CH_2Cl_2/hexane mixture to give orange crystals of **2**. Yield: 0.060 g, 97% (0.072 mmol). The identity of **2** was confirmed by comparing the IR, NMR [^1H and $^{31}P\{^1H\}$], and MS (FAB+) data of **2** with those of an authentic sample of *trans*-[RuCl$_2${κ^4-1*R*,2*R*-P(NH)(NH)P}].

Preparation of *trans*-[RuCl$_2${κ^3-1*R*,2*R*-PN(NH)P}(PPh$_3$)] (3): A solution of **1** (0.020 g, 0.018 mmol) in dichloromethane (5 cm^3) was allowed to stir at room temperature in air. The progress of the reaction was monitored by $^{31}P\{^1H\}$ NMR spectroscopy. After 2 days, the ^{31}P NMR spectrum showed that **1** had completely reacted. The solution was then filtered and the filtrate was evaporated to dryness. The residue was dissolved in a minimum amount of chloroform and purified by chromatography on a silica gel column using chloroform as eluent to give a red band, which upon work-up and crystallisation from a $CHCl_3$/THF/hexane mixture gave red crystals of **3**. Yield: 0.018 g, 91%; m.p. 148−149 °C (decomp). IR (cm^{-1}, in KBr): $\tilde{\nu}$ = 3258 w, 3058 m, 2929 m, 2865 w, 1621 m, 1584 w, 1481 m, 1430 s, 1093 m, 751 s, 705 vs and 524 s. ^1H NMR ($CDCl_3$): δ = 8.55 (d, $^4J_{P-H}$ = 8.8 Hz, 1 H), 5.94−8.02 (m, 43 H), 4.55 (m, 1 H), 3.86−4.21 (m, 4 H), 3.03 (m, 1 H), 2.26 (m, 1 H), 0.96−1.35 (m, 6 H). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 164.9 (s), 126.8−136.1 (m), 64.5 (s), 53.7 (s), 43.6 (s), 40.4 (s), 29.2(s). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 55.5 (d, $^2J_{PP}$ = 27.2 Hz), 31.1 (d, $^2J_{PP}$ = 27.2 Hz), −14.9 (s). $C_{62}H_{57}Cl_2N_2P_3Ru{\cdot}CH_2Cl_2{\cdot}C_6H_{14}$ (1266.15): calcd. C 65.46, H 5.81, N 2.21; found C 65.09, H 5.86, N 2.19. LRMS (FAB+): *m*/*z* = 1094 [M]$^+$ for ^{102}Ru and ^{35}Cl. $[\alpha]_D^{20}$ = 60.90 (*c* = 0.5, CH_2Cl_2).

Preparation of *trans*-[RuCl$_2${κ^3-1*R*,2*R*-P(NH)(NH)P=O}(PPh$_3$)] (4): A solution of **3** (0.050 g, 0.046 mmol) in toluene (10 cm^3) was heated to 80 °C in air. After heating at 80 °C in air for 4 h, the solution turned purple red and the ^{31}P NMR signals due to **3** had completely disappeared. The solvent was subsequently removed in vacuo to give a purple red residue, which upon crystallization from a $CHCl_3$/THF/hexane mixture gave purple red crystals. Yield: (quantitative by $^{31}P\{^1H\}$ NMR), 0.050 g, 98%; m.p. 198−199 °C (decomp). IR (KBr): $\tilde{\nu}$ = 3263 cm^{-1} w, 3048 m, 2929 w, 2852 w, 1584 w, 1486 m, 1429 s, 1305 w, 1264 m, 1191 s, 1124 s, 1088 s, 1026 m, 995 m, 803 m, 747 s, 721 s, 695 vs, 550 vs and 534 s. ^1H NMR ($CDCl_3$): δ = 6.20−8.10 (m, 43 H), 3.91 (m, 4 H), 3.57 (m, 2 H), 3.05 (m, 1 H), 2.65 (m, 1 H), 0.80−1.60 (m, 8 H). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 126.8−136.6 (m), 60.8 (s), 49.0 (s), 48.7 (s), 31.1 (s), 24.8 (s). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 47.1 (d, $^2J_{PP}$ = 28.8 Hz), 39.1 (d, $^2J_{PP}$ = 28.8 Hz), 30.6 (s). $C_{62}H_{59}Cl_2N_2OP_3Ru{\cdot}C_4H_{10}O{\cdot}CHCl_3$ (1304.54): calcd. C 61.69, H 5.25, N 2.15; found C 61.51, H 5.75, N 2.01. LRMS (FAB+): *m*/*z* = 1112 [M]$^+$ for ^{102}Ru and ^{35}Cl. $[\alpha]_D^{20}$ = 34.95 (*c* = 0.5, CH_2Cl_2).

Preparation of *cis*-[RuCl$_2${κ^4-1*R*,2*R*-PN(NH)P}] (5): A solution of **3** (0.050 g, 0.046 mmol) in acetone (10 cm^3) was stirred in air at room temperature for 4 days. The solution was filtered and the solvent from the filtrate was removed in vacuo to give a dark red residue. The residue was dissolved in a minimum amount of chloroform and purified by chromatography on a silica gel column using chloroform as eluent to give a red band. This was followed by eluting with acetone to afford another red band. The red band from chloroform, after work up, was identified as the starting material **3** (0.028 g, 56% recovery).

Removal of the solvent from the second red band led to a red solid, which upon crystallisation from a $CHCl_3$/THF/hexane mixture gave red crystals of **5**. Yield: 0.016 g, 42%; m.p. 102−104 °C (decomp). IR (KBr): $\tilde{\nu}$ = 3253 cm^{-1} w, 3058 m, 2924 m, 1623 m, 1486 m, 1439 s, 1113 m, 761 s, 710 vs and 539 s. ^1H NMR ($CDCl_3$): δ = 8.69 (s, 1 H), 6.00−7.89 (m, 28 H), 4.85 (m, 1 H), 4.10−4.28 (m, 2 H), 3.61 (m, 1 H), 2.99 (m, 1 H), 1.93−2.38 (m, 3 H), 0.88−1.40 (m, 5 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 51.5 (d, $^2J_{PP}$ = 30.3 Hz), 46.3 (d, $^2J_{PP}$ = 30.3 Hz). $C_{44}H_{42}Cl_2N_2P_2Ru{\cdot}3H_2O$ (886.80): calcd. C 59.59, H 5.46, N 3.16; found C 59.05, H 5.75, N 3.25. LRMS (FAB+): *m*/*z* = 832 [M]$^+$ for ^{102}Ru and ^{35}Cl. $[\alpha]_D^{20}$ = 60.18 (*c* = 0.5, CH_2Cl_2).

Preparation of *trans*-[RuCl$_2${κ^4-1*R*,2*R*-PN(NH)P}] (6). Method (a): A solution of **5** (0.030 g, 0.036 mmol) in toluene (10 cm^3) was heated under reflux overnight under a nitrogen atmosphere. The solution was filtered and the solvent from the filtrate was removed in vacuo to give a dark red residue. The dark residue was washed with Et_2O (2 × 5 cm^3) and recrystallized from a dichloromethane/hexane mixture to give red crystals of **6**. Yield: 0.029 g, 97%; m.p. 198−200 °C. IR (KBr): $\tilde{\nu}$ = 3258 cm^{-1} w, 3054 m, 2924 m, 1629 m, 1481 m, 1430 s, 1114 m, 747 s, 700 vs and 524 s. ^1H NMR ($CDCl_3$): δ = 9.41 (s, 1 H), 6.21−7.83 (m, 28 H), 4.55 (m, 2 H), 3.68 (m, 1 H), 2.21−2.80 (m, 4 H), 1.01−1.56 (m, 6 H). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 54.3 (d, J_{PP} = 26.7 Hz), 36.1 (d, J_{PP} =

26.7 Hz). $C_{44}H_{42}Cl_2N_2P_2Ru{\cdot}CH_2Cl_2{\cdot}C_6H_{14}$ (1003.86): calcd. C 61.02, H 5.82, N 2.79; found C 60.33, H 5.31, N 2.36. LRMS (FAB+): *m*/*z* = 832 $[M]^+$ for ^{102}Ru and ^{35}Cl. $[\alpha]_D^{20}$ = 56.07 (*c* = 0.5, CH_2Cl_2).

Method (b): A solution of **3** (0.050 g, 0.046 mmol) in acetone (10 cm^3) was heated to reflux under a nitrogen atmosphere for 12 h. The solution was filtered and the solvent was removed in vacuo from the filtrate to give a dark red residue. The dark residue was washed with Et_2O (2 × 5 cm^3) and recrystallized from a chloroform/hexane mixture to give red crystals of **6**. Yield: 0.037 g, 97%.

Thermolysis of 6: A solution of **6** (0.020 g, 0.024 mmol) in mesitylene (10 cm^3) was heated under reflux under a nitrogen atmosphere for 48 h. The $^{31}P\{^1H\}$ NMR spectrum of the solution showed that as well as the resonances due to **6**, a new singlet at δ = 46.5 had appeared. The solution was filtered and the solvent removed from the filtrate in vacuo, to give a dark red residue. The residue was dissolved in a minimum amount of chloroform and purified by chromatography on a silica gel column using chloroform as eluent to give two red bands. Work up of the first band gave orange crystals of **2** (0.010 g, 50% yield) and second band red crystals of **6** (0.009 g, 45% recovery). Their identities were confirmed by comparing their IR, NMR (^{1}H and ^{31}P), and MS (FAB+) data with those of authentic samples of **2** and **6**.

Catalytic Studies: Catalytic experiments were carried out in a 50-cm^3 stainless steel autoclave (model FW-005) equipped with a temperature control unit. ***Caution:*** *The catalytic reactions must be carried out with safety protection as the reactions may become very violent and explode.* All the catalytic reactions, unless otherwise stated, were carried out in the absence of any solvent. Upon transferring the catalyst, the substrate and a magnetic stirring bar to the autoclave, the autoclave was flushed with oxygen three times by pressurising the autoclave to the desired pressure for 30 s before releasing the pressure. After the autoclave had been thoroughly flushed with oxygen, it was pressurised to the desired oxygen pressure, stirred and quickly raised to the desired temperature. The reaction mixture was allowed to react at the desired temperature for the desired period before it was cooled to room temperature. Then the pressure of the autoclave was released slowly and the reaction mixture was analysed by GC. The identities of the products were verified by GC-MS. Control experiments without the catalysts were performed under identical conditions. The results of the catalytic studies are listed in Table 2.

X-ray Crystallography: Pertinent crystallographic data and other experimental details are summarized in Table 3. Crystals of **3**·C_4H_8O and **5**·H_2O suitable for X-ray diffraction study were grown by slow evaporation of **3** in a THF/hexane mixture and **5** in an acetone/hexane mixture, respectively. The crystals were wrapped in epoxy glue to prevent them from losing solvent, and mounted on a thin glass fibre. No decay in intensity was encountered during the data collection. Intensity data were collected at 293 K on a Bruker Axs SMART 1000 CCD area-detector diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The collected frames were processed with the software SAINT[17] and an absorption correction was applied (SADABS)[18] to the collected reflections. The space groups of each crystal were determined from the systematic absences and Laue symmetry check and confirmed by successful refinement of the structure. The structures of all compounds were solved by direct methods (SHELXTL)[19] and refined against F^2 by full-matrix least-squares analysis. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated in their idealized positions and allowed to ride on their respective parent carbon atoms. The Flack parameter for compounds **3** and **5** is 0.07(4) and −0.04(3), respectively.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-161383 (**3**) and CCDC-164794 (**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

In order to gain a deeper insight into structure-property relationships of the donor (D)–acceptor (A) interactions in cationic sesquifulvalene complexes the mono- and dicationic complexes $[(\eta^5\text{-}C_5H_5)Fe\{\mu\text{-}(\eta^5\text{-}C_5H_4)(\eta^7\text{-}C_7H_6)\}M'L']^+$ were synthesized as BF_4 and PF_6 salts: M′L′ = $Cr(CO)_3$ (**3**PF_6); M′L′ = none (**4**BF_4); M′L′ = $Ru(\eta^5\text{-}C_5H_5)^+$ [**5**$(PF_6)_2$]; M′L′ = $Ru(\eta^5\text{-}C_5Me_5)^+$ [**6**$(PF_6)_2$]. The ferrocenyl substituent works as the electron donor and the tropylium moiety as the electron acceptor. For the electronic ground state the NMR spectroscopic results demonstrate an increasing charge delocalization in the order M′L′ = $Cr(CO)_3$ < $Ru(\eta^5\text{-}C_5Me_5)^+$ < $Ru(\eta^5\text{-}C_5H_5)$ < none. The same order of the acceptor moieties is observed for the difference between the oxidation and reduction potentials, which are related to an electrochemically reversible and a complete irreversible one-electron transfer, respectively. A comparison of the structural data of **3**–**6** reveals a small but distinct contribution of the cross-conjugated mesomeric form to the bis(aromatic) mesomeric form in the ground state of the sesquifulvalene complexes, which increases, when the electron-withdrawing ability of the acceptor becomes stronger. The UV/Vis spectra are dominated by two intense absorption bands in the visible and near-UV region, which are assigned to a low-energy donor-(metal)–acceptor charge-transfer (D–A CT) transition and to a high-energy donor(ligand)–acceptor charge-transfer (L–A CT) transition. For these archetype sesquifulvalene complexes the first hyperpolarizability β was determined by means of hyper-Rayleigh scattering (HRS). Whereas for **3** no second harmonic signal could be detected and **4** shows fluorescence due to two-photon absorptions, **5** and **6** possess appreciable β values.

Introduction

Structure-property relationships in nonlinear optical (NLO) chromophores have proven to be very useful, in particular for organic polyene-bridged donor−acceptor (D−A) molecules, as it has been demonstrated for the bond-length alternation (BLA) in relation to second harmonic generation (SHG).[1,2] As in D−A substituted polyenes, a description of the bonding situation in mono- and dinuclear sesquifulvalene complexes which demonstrates weak to strong NLO effects, is achieved by different mesomeric forms. The ground state is mainly represented by the polar bisaromatic form **A** as deduced by means of several structure determinations, whereas the excited CT state is supposed to have more contributions from the cross-conjugated form **B** (Figure 1).[3,4]

It would be worthwhile to know, whether a contribution of the cross-conjugated form **B** to the ground state would affect the SHG according to the BLA in acyclic α,ω-donor−acceptor substituted conjugated polyenes.

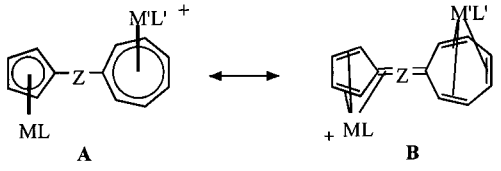

Figure 1. The bis(aromatic) (**A**) and cross-conjugated (**B**) form of mono- and dinuclear sesquifulvalene complexes [e.g. ML = $Fe(\eta^5\text{-}C_5H_5)$; M′L′ = none, $Cr(CO)_3$; Z denotes a conjugated π-bridge]

The crystal structure determinations of the hitherto structurally characterized mono- and dinuclear sesquifulvalene-type complexes do not indicate any significant contribution of the cross-conjugated form **B** to the ground state. This is partly due to the poor quality of the crystals, resulting in a low accuracy of the crystal structure analyses, and partly due to the fact that there are no structural changes, which point to the lack of any remarkable delocalization of charge.[3−7] However, we were now able to determine the structures of some sesquifulvalene complexes, wherein the five- and seven-membered rings are directly connected, in sufficiently high quality to discuss some structure−property relationships. In this paper we additionally present syntheses, spectroscopic and redox properties of the mono- and dinuclear archetype

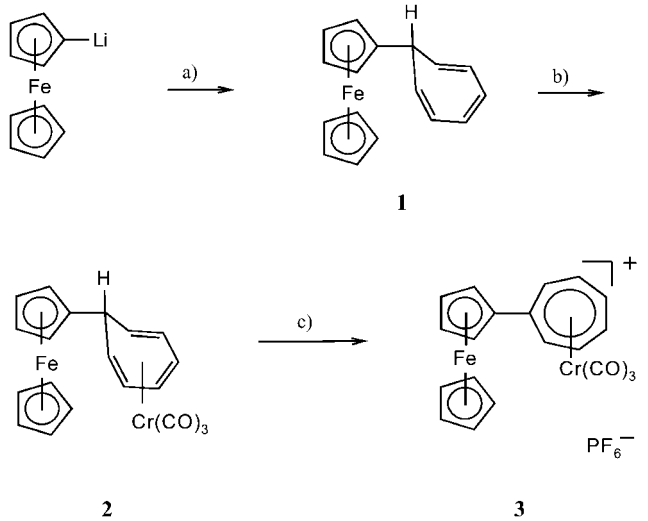
Archetype sesquifulvalene complexes of the general composition $[MLFe\{\mu\text{-}(\eta^5\text{-}C_5H_4)(\eta^7\text{-}C_7H_6)\}M'L']^+$ [ML = $(\eta^5\text{-}C_5H_5)Fe$; M′L′ = $Cr(CO)_3$ (**3**), none (**4**), $Ru(\eta^5\text{-}C_5H_5)^+$ (**5**), $Ru(\eta^5\text{-}C_5Me_5)^+$ (**6**)], and the tropylium cation **7** and its M′L′ complexes [M′L′ = none (**7**), $Cr(CO)_3$ (**8**), $Ru(\eta^5\text{-}C_5H_5)^+$ (**9**), $Ru(\eta^5\text{-}C_5Me_5)^+$ (**10**)]

Results and Discussion

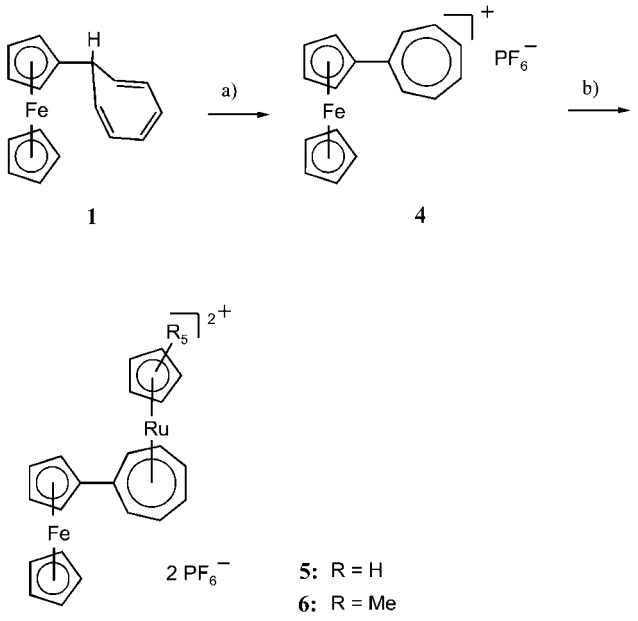
Synthesis

For the cationic target complexes the starting compound is the monohydro-sesquifulvalene complex **1**, which is readily prepared by the nucleophilic addition of monolithiated ferrocene[8] to the tropylium cation (Scheme 1a).[3,4] The subsequent preparation of the cationic dipolar sesquifulvalene complexes is determined by the nature of the electron-accepting function. The reaction of the cycloheptatriene complex **1** with $Cr(CO)_3(EtCN)_3$ [9] yields the dimetallic monohydro-sesquifulvalene complex **2** (Scheme 1b) which is converted into the dipolar monocationic, dinuclear product **3** after the hydride elimination by the trityl cation (Scheme 1c).



Scheme 1. Synthesis of the dimetallic monohydro-sesquifulvalene complexes **2** and the formation of the monocationic dinuclear sesquifulvalene complex **3:** a) $[C_7H_7]PF_6$, Et_2O; b) $Cr(CO)_3(EtCN)_3$, THF; c) $[Ph_3C]PF_6$, CH_2Cl_2

The preparation of the dicationic congeners **5** and **6** occurs by a hydride abstraction from **1**, revealing the cationic ferrocenyl-substituted tropylium compound **4**,[10] and is accomplished by the coordination of the proper metal−ligand fragment $Ru(\eta^5\text{-}C_5R_5)^+$ [11a,11b] to the tropylium moiety (Scheme 2).



Scheme 2. Synthesis of the monometallic monocationic and dinuclear dicationic sesquifulvalene complexes **4**, **5**, and **6**, respectively: a) $[Ph_3C]PF_6$, CH_2Cl_2; b) $[(\eta^5\text{-}C_5R_5)Ru(MeCN)_3]PF_6$ (R = H, Me), CH_2Cl_2

Most remarkable in the course of the synthesis of the cationic sesquifulvalene complexes is a dramatic color change upon hydride abstraction. The dichloromethane solutions of the ferrocenyl derivatives change color from orange or brick-red to deep green-blue on going from the neutral monohydro-sesquifulvalene complexes to the cationic sesquifulvalene species.

NMR Spectroscopy

The assignment of the ^1H and ^{13}C NMR signals was performed using the splitting pattern in the ^1H NMR spectra, and by means of $^1H^1H$ and $^1H^{13}C$ correlation spectroscopy. From the NMR spectroscopic data in Table 1, which also includes the data of the unsubstituted tropylium cation and its M′L′ complexes [M′L′ = $Cr(CO)_3$ (**8**), $Ru(\eta^5\text{-}C_5H_5)^+$ (**9**), $Ru(\eta^5\text{-}C_5Me_5)^+$ (**10**)], it becomes evident that the shift ranges of the acceptor of the sesquifulvalene complexes correspond to the shifts of the signals of the unsubstituted tropylium cation **7** and its complexes **8**−**10**. In general a high-field shift of the signals of the tropylium moiety is also observed when the ferrocenyl donor is bound to the seven-membered ring. This effect of the donor substituent is also recognized for the distal ligands L′ whose signals are slightly high-field shifted when **5** and **6** are compared with **9** and **10**. Additionally, the small low-field shift of the resonance signal of the carbonyl ligands in **3** compared to **8** is in agreement with a slight increase in electron density on the metal center Cr, upon donor substitution on the tropylium ring. The high-field shift of the resonance signals of

[a] Solvent: CD_3NO_2 rel. TMS, numbering scheme see Figure 4.

the tropylium moiety goes along with a general low-field shift of the ferrocene signals, which increases in the order M′L′ = $Cr(CO)_3$ < $Ru(\eta^5\text{-}C_5Me_5)^+$ < $Ru(\eta^5\text{-}C_5H_5)^+$ < none. This behavior of the dipolar sesquifulvalene complexes **3**−**6** clearly elucidates a strong donor (metallocene)−acceptor (tropylium moiety) interaction in the ground state and, moreover, points to a growing charge delocalization in the same order.

Redox Properties

Cyclic voltammetry studies were conducted on all of the sesquifulvalene complexes as well as for the unsubstituted tropylium cation (**7**) and the corresponding mononuclear complexes $[(\eta^7\text{-}C_7H_7)M'L']^+$ [M′L′ = $Cr(CO)_3$ (**8**), $Ru(\eta^5\text{-}C_5H_5)^+$ (**9**), $Ru(\eta^5\text{-}C_5Me_5)^+$ (**10**)]. Electrochemical studies on **7**,[12] **8**,[13] and **9**[11a] have already been described. However, since the published data were obtained under different conditions, the reduction potentials of **7**−**9** were revised under conditions comparable to those applied for the sesquifulvalene complexes. As is known from the literature, the tropylium cation **7** and its complex congeners **8** and **9** undergo irreversible one-electron reduction steps, which is in agreement with the results obtained for the sesquifulvalene complexes (vide infra). The reduction potentials (Table 2) obtained for the tropylium derivatives **7**−**10** change in the order of M′L′ = $Cr(CO)_3$ < $Ru(\eta^5\text{-}C_5Me_5)^+$ < none < $Ru(\eta^5\text{-}C_5H_5)^+$, and illustrate an increase in the electron-withdrawing ability roughly in accordance with the NMR spectroscopic data.

Table 2. Cyclic voltammetry data of the cationic sesquifulvalene complexes $[(\eta^5\text{-}C_5H_5)Fe\{\mu\text{-}(\eta^5\text{-}C_5H_4)(\eta^7\text{-}C_7H_6)\}M'L']^+$ (**3**−**6**) and the mononuclear tropylium species $[(\eta^7\text{-}C_7H_7)M'L']^+$ (**7**−**10**)

[a] Obtained from $MeNO_2$ solutions, 0.4 M $[nBu_4N]PF_6$, room temperature, reference electrode Ag/AgCl. − [b] In V vs. $Fe(C_5H_5)_2/[Fe(C_5H_5)_2]^+$. − [c] $\Delta E_p = |E_{pa} - E_{pc}|$ in mV, ΔE_p(ferrocene) = 73 mV, scan rate: 100 mV/s. − [d] Peak potential of the irreversible one-electron reduction, scan rate: 100 mV/s. − [e] $\Delta E = E_{1/2} - E_{pc}$ in mV. − [f] See also ref.[12] − [g] See also ref.[11a] − [g] See also ref.[13]

The cyclic voltammograms of the corresponding cationic sesquifulvalene complexes **3**−**6** also reveal an irreversible one-electron reduction process in the potential domain of the unsubstituted tropylium species (Figure 3) in addition to an oxidation step in the range of free ferrocene. The potentials of the electrochemically irreversible reduction of the sesquifulvalene complexes are slightly cathodically shifted with respect to the unsubstituted tropylium cations **7**−**10** (Table 2) as expected, due to the electron-donating property of the ferrocenyl substituent.

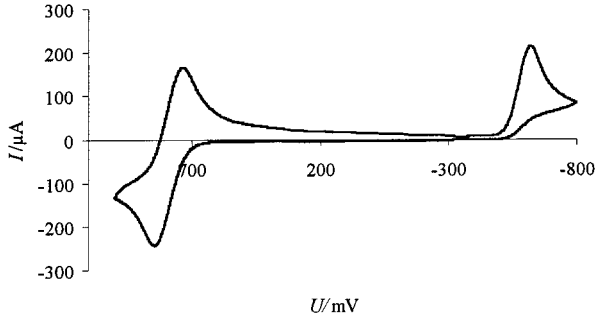

Figure 3. Representative cyclic voltammogram of the cationic sesquifulvalene complexes $[(\eta^5\text{-}C_5H_5)Fe\{\mu\text{-}(\eta^5\text{-}C_5H_4)(\eta^7\text{-}C_7H_6)\}M'L']^+$ [here M′L′ = none (**4**); for more details see Table 2]

The oxidation step involves an electrochemically reversible one-electron transfer, which is 320−440 mV anodically shifted with respect to free ferrocene (Table 2) caused by the electron-withdrawing ability of the tropylium moiety. The anodic shift of the oxidation potentials changes in the order M′L′ = $Cr(CO)_3$ < none < $Ru(\eta^5\text{-}C_5Me_5)^+$ = $Ru(\eta^5\text{-}C_5H_5)^+$. This order differs somewhat from the outcome of

the NMR spectroscopic study. This may be due to the fact, that in the NMR spectroscopic studies only the donor−acceptor interaction of the ground state is measured, whereas in cyclic voltammetry experiments the donor−acceptor interactions of the starting complex as well as of the oxidized (or reduced) product, including reorganization energies, will contribute to the oxidation (or reduction) potential.

Assuming that the oxidation potentials roughly correlate with the energy of the HOMO and the reduction potentials to the energy of the LUMO, the differences of the redox potentials E (Table 2) allow the tentative conclusion that the HOMO−LUMO gap for the sesquifulvalene complexes **3**−**6** should roughly decrease in the order M′L′ = $Cr(CO)_3$ > $Ru(\eta^5\text{-}C_5Me_5)^+$ > $Ru(\eta^5\text{-}C_5H_5)^+$ > none.

Crystal Structure Analyses

Crystal structure analyses were obtained for all of the sesquifulvalene complexes studied, and selected structural data are listed in Table 3. The crystal structure of complex **3** [M′L′ = $Cr(CO)_3$] has already been published,[3] as well as the molecular structure of **4** as a hexafluorophosphate salt.[14] However, **4** was synthesized as a tetrafluoroborate salt and the molecular structure data were obtained with higher accuracy.[4]

Solving the molecular structure of complex **6** [M′L′ = $Ru(\eta^5\text{-}C_5Me_5)^+$] proved to be more difficult because of the presence of three different independent molecules, and the intercalation of four independent solvent molecules of $MeNO_2$ as evidenced by means of NMR spectroscopy and elemental analysis. The structural data of all three independent molecules of **6** are in agreement within the margin of error. In Table 3 the selected structural data of only one independent molecule of the unit cell of **6** are presented. The molecular structures of the sesquifulvalene complexes **5** and **6** are depicted in Figure 4.

The molecular structures of the sesquifulvalene complexes **3**−**6** have an almost coplanar alignment of the sesquifulvalene rings. The twisting angle between the best planes of the five- and seven-membered rings varies between 0 and 17° for **4** and **6**, respectively. The dinuclear complexes exhibit a *transoid* conformation of the complex moieties due to the nonbonding repulsions between the metal fragments in a *cisoid* conformation. A *cisoid* conformation is observed only for complexes with increased length of the π-bridge between the five- and seven-membered ring.[3−7]

Since mutual electronic influence of the donor and acceptor group is expected to affect the molecular structure, the discussion concerning the structural details is focussed on geometric parameters directly related to the sesquifulvalene entity (Figure 5). As for sesquifulvalenes themselves the bonding situation in their complexes can in principle be described in terms of two mesomeric forms, the bis(aromatic) form **A** and the cross-conjugated form **B** (Figure 1), which is composed of an η^6-fulvene complex and a free or coordinated cycloheptatriene moiety. For both types of complexes characteristic structural features are expected

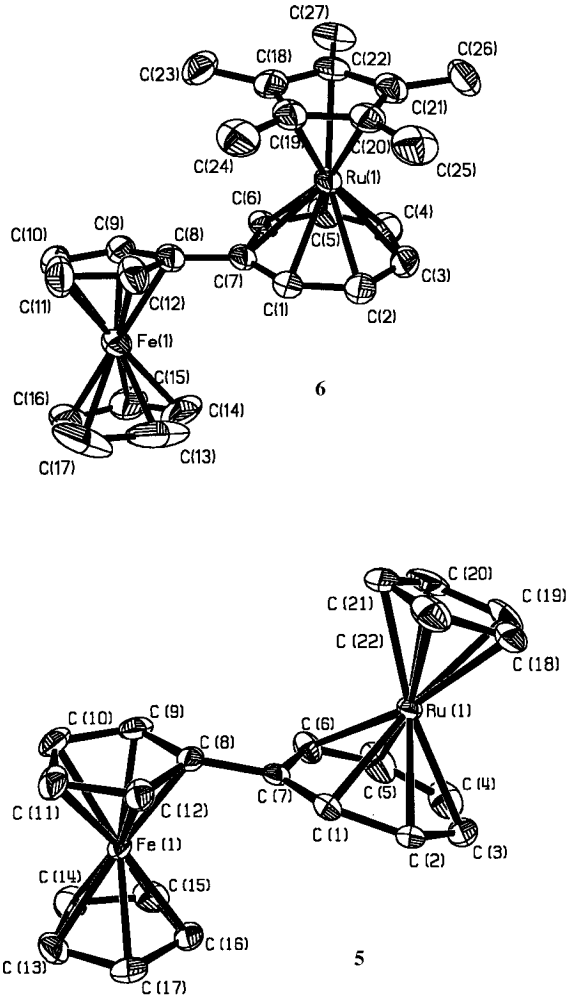

Figure 4. Molecular structures of the cationic sesquifulvalene complexes $[(\eta^5\text{-}C_5H_5)Fe\{\mu\text{-}(\eta^5\text{-}C_5H_4)(\eta^7\text{-}C_7H_6)\}M'L']^+$ [M′L′ = $Ru(\eta^5\text{-}C_5H_5)^+$ (**5**), $Ru(\eta^5\text{-}C_5Me_5)^+$ (**6**); 50% ellipsoids, the hydrogen atoms, solvent molecules and counter ions are omitted for clarity, for **6** only one independent molecule is shown]

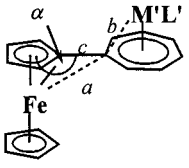

Figure 5. Schematic presentation of the molecular structure of the sesquifulvalene complexes including the notations of special geometric parameters found in Table 3

which are known from corresponding mononuclear complexes and their uncoordinated monocyclic organic species.[15−17]

In fact, a comparison of the structural data listed in Table 3, on average, reveals a characteristic long-short pattern of the endocyclic C−C bonds for the coordinated or free tropylium moiety, which is less significant in the dinuclear species. In accordance to it, the C−C distances between the bridge-head carbon atom C8 and the proximal carbon atoms C9 and C12 of the five-membered ring are distinctly longer than the C−C distances within the endocyclic buta-

diene unit C9...C12. A similar bond length variation is found in η^6-fulvene complexes, although to a larger extent.[17] This characteristic bond length pattern goes along with a decrease of the bending angle α and the distance *a* between the Fe atom of the ferrocenyl unit and the bridge-head carbon atom C7 of the seven-membered ring, which are the most important structural features indicating the contribution of the cross-conjugated mesomeric form **B** to the electronic ground state (see Figure 1). The bending angle α and the distance Fe···C7 decrease in the order M′L′ = $Cr(CO)_3$ > $Ru(\eta^5\text{-}C_5Me_5)^+$ > none > $Ru(\eta^5\text{-}C_5H_5)^+$. Similarly, a considerable increase of the bond length *b* between M′ (Cr or Ru) and C7 is observed with respect to the remaining metal−carbon bond lengths of the tropylium complexes (M′−Cn, see Table 3), which amounts to about 10 pm for **3** and **6**, but about 20 pm for **5**. Apparently, the gradual change from an aromatic to a fulvene-like coordination mode is a result of an increased D−A interaction due to the growing electron-withdrawing ability of the acceptor.[18]

Electronic Excitation

UV/Vis spectroscopic studies were performed with solutions of different solvent polarity such as dichloromethane and nitromethane, to elucidate solvatochromism which gives an indication of the dipole change Δμ between the ground and the excited state,[19] and is thus relevant for the first hyperpolarizability β according to the two-level approximation.[20,21] The UV/Vis spectra of the complexes under study contain two strong absorption bands in the visible and near-UV region (Figure 6, Table 4), which undergo considerable negative solvatochromism, i.e. hypsochromic shift with increasing solvent polarity. These two bands are characteristic for dipolar ferrocene bearing NLO chromophores. Recently, it was shown by means of DF calculations that for (*E*)-1-ferrocenyl-2-(*p*-nitrophenyl)ethene the high-energy absorption band must be assigned to a cyclo-

pentadienyl ligand−acceptor charge-transfer (L−A CT) transition whereas the low-energy absorption band is caused by a donor (metal)−acceptor charge-transfer (D−A CT) transition.[22] The CT transitions both provide a delocalization or even transfer of the positive charge from the tropylium moiety to the donor upon excitation, which is experimentally proven by the negative solvatochromism.[23]

This assignment is also supported by the fact that both of the CT transitions are strongly influenced by the nature of the acceptor, which is in accordance with recently published results about sesquifulvalene complexes with more extended π-bridges between the metallocene donor and the tropylium moiety acceptor.[3−5] However, the electronic influence of the acceptor on the L−A and D−A CT transitions is different. The D−A CT transitions decrease in energy in the order $M'L' = Cr(CO)_3 > Ru(\eta^5\text{-}C_5Me_5)^+ > Ru(\eta^5\text{-}C_5H_5)^+ >$ none. This order correlates with that of the HOMO−LUMO splitting assumed from the cyclic voltammetry results. The order varies for the L−A CT transition: $M'L' = Ru(\eta^5\text{-}C_5Me_5) > Ru(\eta^5\text{-}C_5H_5)^+ >$ none $> Cr(CO)_3$. The extraordinary low-energy shift of the D−A CT band of the mononuclear complex **4** compared to the dinuclear species may be explained by the formation of additional molecular orbitals (MO) upon coordination of a metal−ligand fragment, thus forming occupied bonding MOs which would be lower in energy, and empty antibonding MOs which would be higher in energy compared to the orbitals of the initial uncoordinated tropylium moiety.

As mentioned before the electronic excitations are governed by a distinct blue-shift on increasing the solvent polarity. The extent of the solvatochromism for both of the absorption bands can only be determined for **3** and **4**, since the maximum of the high-energy L−A CT absorption band of **5** and **6** in CH_3NO_2 is too far blue-shifted into the absorption region of the solvent to be determined. Nevertheless, from the obtained data it turns out that the change in polarity is similar for both of the CT transitions, and hence both should contribute to the first hyperpolarizability.[20,21]

NLO Measurements

The low-lying excited states of the sesquifulvalene complexes under study along with their facile polarizability, indicated by their pronounced solvatochromism, makes these types of complexes very promising for the second harmonic generation. Due to the cationic nature of the sesquifulvalene complexes the hyper-Rayleigh scattering (HRS)[24] is the only method for determining the first hyperpolarizability β which represents the molecular capability of transforming incoming light with frequency ω to frequency 2ω. However, a draw-back of the HRS method may be fluorescence due to two-photon absorption.[25−27] After realizing the problem of multiphoton absorption induced fluorescence concerning the determination of the first hyperpolarizability, several techniques have been investigated to overcome this problem. These include long-wavelength measurements,[28,29] time-resolved HRS[28] measurements of the two-photon fluorescence spectrum to abstract the fluorescence contribution to the HRS signal,[30] and a high-frequency demodulating technique to suppress the multiphoton fluorescence contribution to the HRS signal.[25]

A ''low-cost'' check for the two-photon fluorescence was recently described,[4,5] and uses bandpass filters with peak transmittance at different wavelengths introduced in front of the photomultiplier of the HRS set-up. The broad fluorescence signal, which yields the emission maximum at λ/2 of the fundamental wavelength, is easily discerned from the narrow second harmonic signal at λ/2.

In the course of this study the mononuclear complex **4** indicates two-photon fluorescence (Figure 7) whereas for **3** no intensity for the second harmonic signal was detected (Table 4). For the remaining complexes **5** and **6** the first hyperpolarizability β has been determined. The static first hyperpolarizability β_0 has been calculated by means of the two-level model,[21] taking into account the low-energy D−A CT transition. Nevertheless, it has to be emphasized that the high-energy L−A CT transition will also contrib-

ute to the first hyperpolarizability as indicated by the solvatochromism. The experimentally obtained first hyperpolarizability β and the calculated static hyperpolarizability β_0 for **5** and **6** (Table 4) are comparable although slightly larger for **5** with M′L′ = Ru(η^5-C_5H_5)$^+$ which has been shown to be the stronger electron-accepting moiety by means of NMR spectroscopy and cyclic voltammetry studies. However, the β and β_o values are not large and are comparable with the ferrocenyl-substituted (borabenzene)cobalt complex cation [CpFe{μ-(η^5-C_5H_4)(η^6-B(C_5H_5)}CoCp]$^+$.[18] Their values are difficult to discuss with respect to increasing D−A interaction due to (i) the margin of error in the determination of the first hyperpolarizability by HRS, (ii) the fact that the SHG signal occurs in the region of considerable D−A CT absorption, and (iii) the contribution of both the L−A CT and D−A CT transition to the SHG.

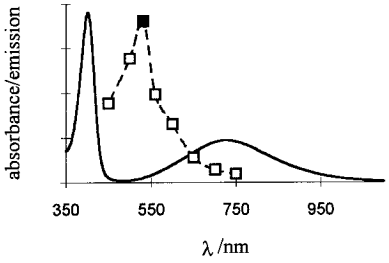

Figure 7. Absorption and emission spectrum of **4**

Conclusions

A series of cationic ferrocenyl-containing mono- and dimetallic dipolar sesquifulvalene complexes [CpFe{μ-(η^5-C_5H_4)(η^7-C_7H_6)M′L′]$^+$ [M′L′ = $Cr(CO)_3$, none, Ru(η^5-C_5H_5)$^+$, Ru(η^5-C_5Me_5)$^+$] were synthesized and both spectroscopically and structurally characterized. In these complexes the metallocenyl unit acts as an electron donor and the positively charged tropylium moiety as an electron acceptor. From the NMR spectroscopic data an increased delocalization of the positive charge is concluded for the ground state in the series M′L′ = $Cr(CO)_3$ < Ru(η^5-C_5Me_5)$^+$ < Ru(η^5-C_5H_5)$^+$ < none. The increased delocalization of the positive charge goes along with a growing contribution of the cross conjugated mesomeric form **B** to the bis(aromatic) mesomeric form **A** in the electronic ground state (Figure 1) as confirmed by gradual structural changes: i) the increasing bond length alternation in the five-membered ring, ii) the decreasing bending angle α between the C_5H_4 plane and the bonding vector of the bond C7−C8 linking the five- and seven-membered ring, and iii) the decreasing distance between the Fe atom of the ferrocene and the bridge-head carbon atom C7 of the seven-membered ring. The electronic excitation reveals two absorption bands in the visible and near-UV region that are assigned to an energetically low-lying D−A CT transition and an energetically higher lying L−A CT transition. Both CT transitions will contribute to the efficiency of the second harmonic generation. However, the first hyperpolarizability β, which is determined by HRS, is only obtained for the dinuclear species **5** [M′L′ = Ru(η^5-C_5H_5)$^+$] and **6** [M′L′ = Ru(η^5-C_5Me_5)$^+$]. For complex **4** fluorescence was observed whereas for **3** no SHG could be observed.

Experimental Section

Manipulations were carried out under dry nitrogen using standard Schlenk techniques. Solvents were saturated with nitrogen. Diethyl ether (Et_2O), tetrahydrofuran (THF), *n*-hexane and toluene were freshly distilled from the appropriate alkali metal or metal alloy. Dichloromethane (CH_2Cl_2) and nitromethane ($MeNO_2$) were dried with calcium hydride. NMR: Varian Gemini 200 BB; Bruker AM 360; measured at 295 K rel. TMS. UV/Vis: Perkin−Elmer Model 554. IR: nujol mull, KBr cells, FT-IR, Perkin−Elmer Model 325. MS: Finnigan MAT 311 A (EI-MS). Elemental analyses: CHN-O-Rapid, Fa. Heraeus. Tropylium hexafluorophosphate (**7**),[31] monolithioferrocene,[8] triphenylcarbenium hexafluorophosphate/tetrafluoroborate,[32] tricarbonyltris(propionitrile)chromium(0),[9,33] tris(acetonitrile)(η^5-cyclopentadienyl)ruthenium(II) hexafluorophosphate,[34] tris(acetonitrile)(η^5-pentamethylcyclopentadienyl)ruthenium(II) hexafluorophosphate,[11b] tricarbonyl(η^7-cycloheptatrienylium)chromium(0) hexafluorophosphate (**8**),[35] (2,4,6-cycloheptatrien-1-yl)ferrocene (**1**), tricarbonyl[η^6-1-(ferrocenyl)cycloheptatriene]chromium(0) (**2**)[3,4] and tricarbonyl[(η^7-1-(ferrocenyl)cycloheptatrienylium]chromium(0) hexafluorophosphate (**3**)[3] were synthesized according to literature procedures.

1-(Ferrocenyl)cycloheptatrienylium Tetrafluoroborate ($4BF_4$): A solution of $[Ph_3C]BF_4$ (610 mg, 1.85 mmol) in CH_2Cl_2 (20 mL) was added to a solution of **1** (510 mg, 1.85 mmol) in CH_2Cl_2 (20 mL) and stirred for 30 min at room temperature. The color of the solution turned from brick-red to deep green-blue. The product precipitates on addition of Et_2O. The crystalline material was filtered off and recrystallized by gas-phase diffusion of Et_2O into a concentrated solution of $\mathbf{4}BF_4$ in CH_2Cl_2. Yield: 410 mg (61%) of black-blue cubes. ^{1}H NMR (CD_3NO_2): δ = 8.49−8.26 (m, 6 H, C_7H_6), 5.51 (pt, *J* = 2.0 Hz, 2 H, C_5H_4), 5.45 (pt, *J* = 2.0 Hz, 2 H, C_5H_4), 4.41 (s, 5 H, C_5H_5). ^{13}C NMR (CD_3NO_2): δ = 175.8 (C-7), 148.8 (C-3,-4), 148.1 (C-2,-5), 147.9 (C-1,-6), 84.5 [$C_q(C_5H_4)$], 81.8 (C_5H_4), 75.7 (C_5H_5), 73.4 (C_5H_4). IR (KBr): $\tilde{\nu}$ = 3100, 3060, 1498, 1443, 1383, 1272, 1084 (ν_{B-F}), 1059, 1035 cm^{-1}. $C_{17}H_{15}BF_4Fe$ (362.0): calcd. C 56.41, H 4.18; found C 56.14, H 4.16.

{(Tricarbonyl)(η^7-cycloheptatrienylium-1-yl)chromium(0)}ferrocene Hexafluorophosphate ($3PF_6$): The synthesis performed was slightly modified according to the literature procedure.[3] Instead of $[Ph_3C]BF_4$ the PF_6 salt was used. The reaction was conducted at 0 °C. Quantities used: [η^5-C_5H_5)Fe{μ-(η^5-C_5H_4)(η^6-C_7H_7)}Cr(CO)$_3$] (**2**) (150 mg, 0.36 mmol) in CH_2Cl_2 (20 mL), $[Ph_3C]PF_6$ (140 mg, 0.36 mmol) in CH_2Cl_2 (10 mL). Yield: 120 mg (61%) of blue-black needles. ^{1}H NMR (CD_3NO_2): δ = 6.75 (m, 2 H, 2-,5-H), 6.55 (dd, *J* = 6.1, 2.9 Hz, 2 H, 3-,4-H), 6.45 (d, *J* = 9.5 Hz, 2 H, 1-,6-H), 5.12 (pt, *J* = 2.0 Hz, 2 H, C_5H_4), 4.97 (pt, *J* = 2.0 Hz, 2 H, C_5H_4), 4.28 (s, 5 H, C_5H_5). ^{13}C NMR (CD_3NO_2): δ = 223.87 (CO), 133.13 (C-7), 105.59 (C-2,5), 104.71 (C-3,-4), 99.76 (C-1,-6), 81.32 [$C_q(C_5H_4)$], 75.97 (C_5H_4), 72.88 (C_5H_5), 70.82 (C_5H_4). IR (KBr): $\tilde{\nu}$ = 3100, 2038 (ν_{CO}), 1996 (ν_{CO}), 1549, 1487, 1384, 1291, 838 (ν_{P-F}) cm^{-1}; (CH_3NO_2): $\tilde{\nu}$ = 2054 (ν_{CO}), 2014 (ν_{CO}) cm^{-1}. UV/Vis (CH_3NO_2): λ_{max} (ε) = 395 (5280), 574 (4880) nm (M^{-1}·cm^{-1}). $C_{20}H_{15}CrF_6FeO_3P$ (556.2): calcd.: C 43.19, H 2.72; found C 42.68, H 2.97.

Generel Procedure for the Preparation of the Dicationic Dinuclear Sesquifulvalene Complexes: A solution of the monocationic tropylium compound **4** in CH_2Cl_2 was treated with an equimolar amount of the appropriate (cyclopentadienyl)ruthenium salt and stirred overnight. The precipitated product was filtered off, washed with CH_2Cl_2, and recrystallized from $MeNO_2/Et_2O$.

(η^5-Cyclopentadienyl)[η^7-1-(ferrocenyl)cycloheptatrienylium]-ruthenium(II) Bis(hexafluorophosphate) [5(PF_6)$_2$]: Quantities used: [(η^5-C_5H_5)Fe(η^5-C_5H_4−C_7H_6)]PF_6 (**4**PF_6) (280 mg, 0.67 mmol), [(η^5-C_5H_5)Ru(CH_3CN)$_3$]PF_6 (290 mg, 0.67 mmol), CH_2Cl_2 (30 mL). Yield: 402 mg (82%) of deep blue, rhombic plates. ^{1}H NMR (CD_3NO_2): δ = 7.60 (dd, *J* = 5.4, 2.0 Hz, 2 H, 3-,4-H), 7.34 (m, 2 H, 2-,5-H), 7.27 (d, *J* = 9.8 Hz, 2 H, 1-,6-H), 6.11 (s, 5 H, C_5H_5'), 5.47 (pt, 2 H, C_5H_4), 5.33 (pt, 2 H, C_5H_4), 4.37 (s, 5 H, C_5H_5). ^{13}C NMR (CD_3NO_2): δ = 138.7 (C-7), 104.1 (C-3,-4), 102.0 (C-2,-5), 92.9 (C-1,-6), 91.3 (C_5H_5'), 81.5 (C_5H_4), 81.4 [$C_q(C_5H_4)$], 75.4 (C_5H_5), 72.2 (C_5H_4). IR (KBr): $\tilde{\nu}$ = 3126, 1548, 1498, 1474, 1420, 1301, 1266, 834 (ν_{P-F}) cm^{-1}. UV/Vis (CH_3NO_2): λ_{max} (ε) = 614 (5270) nm ($M^{-1}\cdot cm^{-1}$). $C_{22}H_{20}F_{12}FeP_2Ru$ (731.3): calcd. C 36.14, H 2.76; found C 35.80, H 2.76.

[η^7-1-(Ferrocenyl)cycloheptatrienylium](η^5-pentamethylcyclopentadienyl)ruthenium(II) Bis(hexafluorophosphate) [6(PF_6)$_2$]: Quantities used: [(η^5-C_5H_5)Fe(η^5-C_5H_4−C_7H_6)]PF_6 (**4**PF_6) (160 mg, 0.38 mmol), [(η^5-C_5Me_5)Ru(CH_3CN)$_3$]PF_6 (192 mg, 0.38 mmol), CH_2Cl_2 (20 mL). Yield: 213 mg (70%) of violet-blue rhombic plates. ^{1}H NMR (CD_3NO_2): δ = 7.35 (m, 2 H, 3-,4-H), 7.10 (m, 2 H, 2-,5-H), 7.09 (d, *J* = 7.3 Hz, 2 H, 1-,6-H), 5.34 (pt, 2 H, C_5H_4), 5.27 (pt, 2 H, C_5H_4), 4.36 (s, 5 H, C_5H_5), 1.98 (s, 15 H, C_5Me_5). ^{13}C NMR (CD_3NO_2): δ = 133.8 (C-7), 109.9 (C_5Me_5), 105.3 (C-3,-4), 104.2 (C-2,-5), 97.8 (C-1,-6), 79.6 (C_5H_4), 77.6 [$C_q(C_5H_4)$], 74.1 (C_5H_5), 71.6 (C_5H_4), 10.4 (C_5Me_5). IR (KBr): $\tilde{\nu}$= 3086, 2978, 1628, 1546, 1474, 1383, 1292, 1027, 837 (ν_{P-F}) cm^{-1}. UV/Vis (CH_3NO_2): λ_{max} (ε) = 605 (4510) nm ($M^{-1}\cdot cm^{-1}$). $C_{27}H_{30}F_{12}FeP_2Ru \times 4/3(CH_3NO_2) \times 1/3\ H_2O$ (888.77): calcd. C 38.24, H 3.93, N 2.10; found C 37.01, H 3.89, N 2.13.

Tricarbonyl(η^7-cycloheptatrienylium)chromium(0) Hexafluorophosphate (8PF_6): The synthesis was performed with a slight modification from the literature procedure.[35] To a solution of [(η^6-C_7H_8)Cr(CO)$_3$] (190 mg, 0.8 mmol) in CH_2Cl_2 (10 mL), a solution of [Ph_3C]PF_6 (320 mg, 0.8 mmol) in CH_2Cl_2 (10 mL), was added. The reaction mixture was stirred for 30 min at room temperature. The product was precipitated upon addition of Et_2O. The crystalline material was filtered off and recrystallized by gas-phase diffusion of Et_2O into a concentrated solution of **8**PF_6 in $MeNO_2$. Yield: 210 mg (70%) of red cubes. ^{1}H NMR (CD_3NO_2): δ = 6.67 (s, C_7H_7). ^{13}C NMR (CD_3NO_2): δ = 221.69 (CO), 106.51 (C_7H_7). IR (KBr): $\tilde{\nu}$ = 3092, 2067 (ν_{CO}), 2026 (ν_{CO}), 1455, 839 (ν_{P-F}) cm^{-1}; ($MeNO_2$): $\tilde{\nu}$ = 2069 (ν_{CO}), 2029 (ν_{CO}) cm^{-1}. UV/Vis (CH_3NO_2): λ_{max} (ε) = 400 (sh) (160) nm ($M^{-1}\cdot cm^{-1}$). $C_{10}H_7CrF_6O_3P$ (372.1): calcd. C 32.28, H 1.90; found C 32.06, H 2.12.

[a] GoF (goodness of fit) = $[\Sigma w(F_o^2 - F_c^2)^2/(n-p)]^{1/2}$ (*n* = numbers of reflections, *p* = numbers of parameters). − [b] $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\{\Sigma w(F_o^2)^2\}]^{1/2}$.

(η^7-Cycloheptatrienylium)(η^5-cyclopentadienyl)ruthenium(II) Bis-(hexafluorophosphate) [9(PF_6)$_2$]: The synthesis was performed with a slight modification from the literature[11a] (see also the preparations of **5**PF_6 and **6**PF_6). Quantities used: [C_7H_7]PF_6 (**7**) (120 mg, 0.5 mmol), CH_2Cl_2 (20 mL), [(η^5-C_5H_5)Ru(CH_3CN)$_3$]PF_6 (220 mg, 0.5 mmol). Yield: 160 mg (80%) of a pale yellow solid. ^{1}H NMR (CD_3NO_2): δ = 7.80 (s, 7 H, C_7H_7), 6.37 (s, 5 H, C_5H_5). ^{13}C NMR (CD_3NO_2): δ = 107.51 (C_7H_7), 93.07 (C_5H_5). IR (KBr): $\tilde{\nu}$ = 3127, 3085, 2971, 1458, 1421, 832 (ν_{P-F}) cm^{-1}. $C_{12}H_{12}F_{12}P_2Ru$ (547.2): calcd. C 26.34, H 2.21; found C 26.30, H 2.55.

(η^7-Cycloheptatrienylium)(η^5-pentamethylcyclopentadienyl)-ruthenium(II) Bis(hexafluorophosphate) [10(PF_6)$_2$]: The synthesis was performed under identical conditions as for **9**(PF_6)$_2$. Quantities used: [C_7H_7]PF_6 (**7**) (100 mg, 0.4 mmol), CH_2Cl_2 (20 mL), [(η^5-C_5Me_5)Ru(CH_3CN)$_3$]PF_6 (200 mg, 0.4 mmol). Yield: 150 mg (80%) of pale yellow prisms. ^{1}H NMR (CD_3NO_2): δ = 7.48 (s, 7 H, C_7H_7), 2.23 (s, 15 H, C_5Me_5). ^{13}C NMR (CD_3NO_2): δ = 112.58 (C_5Me$_5$), 107.60 (C_7H_7), 10.91 (C_5Me_5). IR (KBr): $\tilde{\nu}$ = 3084, 2972, 1475, 1456, 1420, 1391, 1082, 1028, 832 (ν_{P-F}) cm^{-1}. $C_{17}H_{22}F_{12}P_2Ru$ (617.4): calcd. C 33.07, H 3.49; found C 32.82, H 3.55.

X-ray Structure Determination: Crystals of **4**BF_4, **5**(PF_6)$_2$, and **6**(PF_6)$_2$ suitable for an X-ray structure determination, were obtained by gas-phase diffusion of Et_2O into an $MeNO_2$ solution of the complex. The data were collected with four-circle diffractometers [**4**BF_4, and **6**(PF_6)$_2$: Hilger and Watts, Mo-K_α, λ = 0.71073 Å; **5**(PF_6)$_2$: Siemens aix, Mo-K_α, λ = 0.71073 Å]. The structures were solved by direct methods (SHELXS-86) and the refinements on F^2 were carried out by full-matrix least-squares techniques (SHELXL-93).[36] All non hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined with a fixed isotropic thermal parameter related by a factor of 1.2 to the value of the equivalent isotropic parameter of their carrier atom. Weights were optimized in the final refinement cycles. In the structure of **6**, four independent molecules of CH_3NO_2 are present within the asymmetric unit. The position of an additional water molecule could be detected and was refined. An extinction coefficient correction of 0.0011 was applied. For more information see Table 5. Crystallographic data for the structures reported in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-142001 [**5**(PF_6)$_2$], and -42000 [**6**(PF_6)$_2$]. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Cyclic Voltammetry: Measurements were performed in $MeNO_2$ with 0.4 M [N(nBu)$_4$]PF_6 as supporting electrolyte. An Amel 5000 system was used with a Pt wire as the working electrode and a Pt plate (0.6 cm^2) as the auxiliary electrode. The potentials were measured against Ag/Ag$^+$ and are referenced against $E_{1/2}$([Fe(C_5H_5)$_2$]/[Fe(C_5H_5)$_2$]$^+$) = 0 V.

Hyper-Rayleigh Scattering: Hyper-Rayleigh scattering measurements were performed with a pulsed Nd:YAG laser at a wavelength of λ = 1064 nm. For the experimental setup see ref.[24] Solutions of the complexes in $MeNO_2$ with concentrations in the range of 10^{-4} to 10^{-6} M were used with *p*-nitroaniline as a reference [β($MeNO_2$) = 34.6·10^{-30} esu].[37] Fluorescence checks were made by replacing the interference filter in front of the photomultiplier tube with filters that have transmittances at 400, 450, 500, 532, 560, 600, 650, and 700 nm.[4]

Bis(keto-phosphane) and Bis(enolato-phosphane) Ruthenium Complexes − Synthesis and X-ray Structure Determination of RuCl(NO)[η^2-*(P,O)*-$Ph_2PCH{=}C(tBu)O]_2$

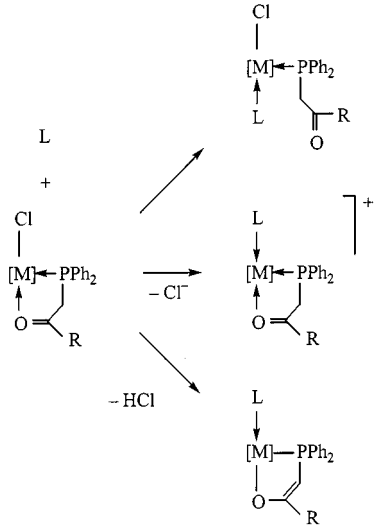
Bernard Demerseman*[a] and Loïc Toupet[b]

Keywords: Ruthenium / O,P ligands / Carbonyl ligands / Nitrosyl ligands / Isomerizations

A slow reaction consisting of a cleavage of one Ru–Cl bond occurred when a mixture of $RuCl_2[Ph_2PCH_2C(tBu){=}O]_2$ (**1**) and $[NH_4][PF_6]$ was dissolved in methanol as shown by a subsequent reaction with carbon monoxide affording the stable cationic derivative $\{RuCl(CO)[Ph_2PCH_2C(tBu){=}O]_2\}[PF_6]$ (**2**). By contrast, the straightforward reaction of **1** with carbon monoxide yielded $RuCl_2(CO)[Ph_2PCH_2C(tBu){=}O][Ph_2PCH_2C(=O)tBu]$ (**3**) which contains unreactive Ru–Cl bonds. The isomerization of **2,** which is induced under sun light exposure, is the preliminary step to the selective formation of the *all-cis* bis(enolato-phosphane) derivative *(ccc)*-$Ru(CO)_2[\eta^2$-*(P,O)*-$Ph_2PCH{=}C(tBu)O]_2$ (**9**). The isomeric bis(enolato-phosphane) derivative *(cct)*-$Ru(CO)_2[\eta^2$-*(P,O)*-$Ph_2PCH{=}C(tBu)O]_2$ (**10**), with *trans* phosphorus and *cis* carbonyl ligands, respectively, was selectively obtained under mild basic conditions, starting from *(cct)*-$RuCl_2(CO)_2[Ph_2PCH_2C(=O)tBu]_2$ (**4**), which results from the reaction of **3** with carbon monoxide under thermal activation. Through an oxidative addition process, the reaction of **1** with $[NO][BF_4]$ yielded $\{RuCl_2(NO)[Ph_2PCH_2C(tBu){=}O][Ph_2PCH_2C(=O)tBu]\}[BF_4]$ (**13**) with *trans* phosphorus and *trans* chloride ligands, respectively. Simple deprotonation of **13** generated the enolato-phosphane Ru^{IV} complex $RuCl_2(NO)[Ph_2PCH{=}C(tBu)O][Ph_2PCH_2C(=O)tBu]$ (**14**) which retains the same geometry. Under basic conditions, the bis(enolato-phosphane) derivative $RuCl(NO)[\eta^2$-*(P,O)*-$Ph_2PCH{=}C(tBu)O]_2$ (**15**) was obtained. The formation of **15** surprisingly showed a *trans* to *cis* rearrangement of the two phosphorus coordinating atoms, as further confirmed by an X-ray structure determination.

Introduction

Several pathways are available to the coordinatively saturated keto-phosphane complex $RuCl_2[\eta^2$-*(P,O)*-keto-phosphane$]_2$ for the incorporation of a donor ligand L (Scheme 1). These include: (i) a transformation of the coordination mode of the functional phosphane involving opening of the Ru-oxygen bond, (ii) the abstraction of one chloride generating a cationic derivative, or (iii) the formal (and nonreductive) elimination of HCl under basic conditions, facilitated by concomitant enolisation of the keto-phosphane ligand. To date, the first of these mechanistic possibilities, namely the change in coordination mode from η^2-*(P,O)* to η^1-*(P)* is well documented.[1−13] In order to emphasise the interest of an alternative preliminary cleavage of one Ru−Cl bond, the synthesis of a coordinatively unsaturated and highly reactive $\{RuCl[\eta^2$-*(P,N)*-functional phosphane$]_2\}^+$ species has been achieved starting from $RuCl_2[\eta^2$-*(P,N)*-functional phosphane$]_2$ complexes.[14] We report herein further comparison between these distinct reactivities, starting from a $RuCl_2[\eta^2$-*(P,O)*-keto-phosphane$]_2$ complex, namely $RuCl_2[Ph_2PCH_2C(tBu){=}O]_2$ (**1**)[11] and using carbon monoxide as an entering substrate L. The generation, under mild basic conditions, of rigid and strongly bound η^2-*(P,O)*-enolato-phosphane ligands leading to



Scheme 1

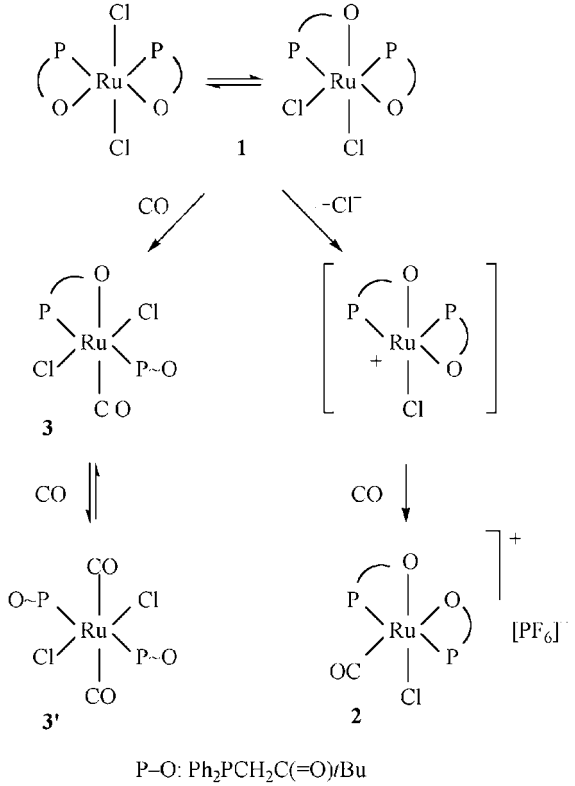
stability in stereoisomeric $Ru(CO)_2[\eta^2$-*(P,O)*-$Ph_2PCH{=}C(t\mathrm{Bu})O]_2$ derivatives is of interest. The reaction of $[NO][BF_4]$ with **1** afforded a new family of ruthenium(IV) derivatives. The bis(enolato-phosphane) complex $RuCl(NO)[\eta^2$-*(P,O)*-$Ph_2PCH{=}C(t\mathrm{Bu})O]_2$ has been characterised by an X-ray structure determination.

Results and Discussion

1. Cationic (Keto-phosphane) Complexes Involving Carbon Monoxide

A cleavage of one Ru−Cl bond is likely to have occurred when $RuCl_2[Ph_2PCH_2C(t\mathrm{Bu}){=}O]_2$ (**1**) (which behaves in solution as a mixture of two isomers with *cis* phosphorus and *trans* or alternatively *cis* chlorine coordinating atoms)[11] was reacted with a solution of $[NH_4][PF_6]$ in methanol. The examination of the resulting orange solution by $^{31}P\{^1H\}$ NMR spectroscopy showed a new set of resonances consisting of an AB spin system as expected for two inequivalent phosphorus *nuclei* and the observation of a low coupling constant value (^2J = 40.0 Hz) which indicated a retention of their mutual *cis* arrangement.[15] A subsequent admittance of a carbon monoxide atmosphere resulted in the formation of the cationic complex $\{RuCl(CO)[\eta^2$-*(P,O)*-$Ph_2PCH_2C(t\mathrm{Bu}){=}O]_2\}[PF_6]$, **2**, which was isolated as orange-yellow crystals in 65% yield (Scheme 2). The structure of **2** was determined from a combination of elemental analysis, IR spectroscopy and ^1H, $^{31}P\{^1H\}$, $^{13}C\{^1H\}$, and ^{13}C NMR spectroscopy. Elemental analysis indicated a retention of one chlorine atom *per* Ru. The $^{31}P\{^1H\}$ NMR spectrum consisted of an AB spin system and a high coupling constant value (^2J = 328 Hz) indicated a relative *trans* arrangement of the two phosphorus *nuclei*. The IR spectrum of **2** indicated that the two keto-phosphane ligands [ν(C=O): 1621 and 1596 cm^{-1}] are η^2-*(P,O)*-coordinated,[11] and produced a very strong absorption attributed to the carbon monoxide ligand [ν(C≡O): 1991, 1977 cm^{-1} (the absorption is slightly split at its summit, most likely due to a solid state effect)]. The examination of **2** by ^1H and $^{13}C\{^1H\}$ NMR spectroscopy provided further evidence for one carbon monoxide ligand and two inequivalent keto-phosphane ligands, thus again indicating that the two coordinated oxygen atoms are located in a relative *cis* arrangement. The neutral complex $RuCl_2(CO)[\eta^2$-*(P,O)*-$Ph_2PCH_2C(t\mathrm{Bu}){=}O][\eta^1$-*(P)*-$Ph_2PCH_2C(=O)t\mathrm{Bu}]$ (**3**)[11] was obtained when a solution of **1** and $[NH_4][PF_6]$ in methanol was stirred under a carbon monoxide atmosphere. Attempts to obtain **2** by reacting **3** with $[NH_4][PF_6]$ or $Ag[BF_4]$ failed.

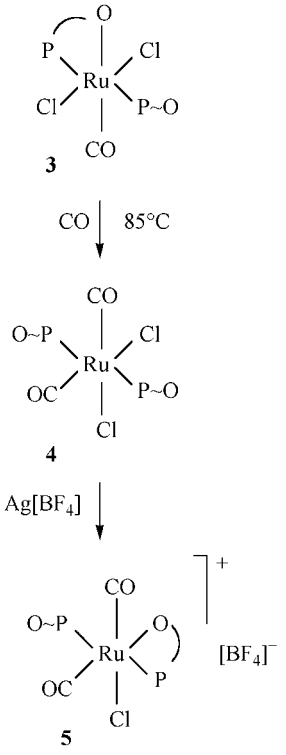
A preliminary cleavage of one Ru−Cl bond from **1** may account for the formation of **2** and not surprisingly, the reaction of $Ag[BF_4]$ with a solution of **1** in dichloromethane similarly generated a new species as shown by $^{31}P\{^1H\}$ NMR spectroscopy (see Exp. Sect.). Removal of the solvent resulted in the fast decomposition and further characterisation of the likely unsaturated species was not attempted. The distinct chemical pathways leading to **2** and **3** involve a *cis* to *trans* rearrangement of the phosphorus coordinating atoms. Requirement of an entrance of carbon monoxide *trans* relative to a coordinated oxygen atom may be responsible for the rearrangement achieving *trans* O−Ru−CO arrangements in **2** and **3**. Since complex **3** reversibly adds carbon monoxide to generate the fragile derivative *all-trans* $RuCl_2(CO)_2[\eta^1$-*(P)*-$Ph_2PCH_2C(=O)t\mathrm{Bu}]_2$ (**3′**)[11] (Scheme 2), we looked for a comparison between the hemilabile properties of the keto-phosphane ligands in complexes **2** and **3**.



Scheme 2

Under a moderate thermal activation, as previously reported, when starting from $RuCl_2$[ether-phosphane]$_2$ complexes,[10] complex **3** irreversibly added carbon monoxide to yield $RuCl_2(CO)_2[Ph_2PCH_2C(=O)t\mathrm{Bu}]_2$ the *cis,cis,trans* stereoisomer, **4** (Scheme 3) as it is thermodynamically favoured and stable. Thus, complex **4** was isolated as colourless crystals in 92% yield after a solution of **3** in hot toluene (85 °C) was stirred under a carbon monoxide atmosphere. The IR spectrum of **4** showed the two carbonyl ligands [ν(C≡O): 2056, 1992 cm^{-1}] to be in a relative *cis* arrangement besides a single absorption [ν(C=O): 1705 cm^{-1}] as expected for two equivalent η^1-*(P)*-coordinated keto-phosphanes. The $^{31}P\{^1H\}$ NMR spectrum consisted of a single resonance and the ^1H NMR spectrum showed the resonance attributed to the four equivalent PCH_2 protons as a virtual triplet. A clean reaction occurred when a stoichiometric amount of $Ag[BF_4]$ was added to a solution of **4** in dichloromethane and afforded the expected cationic derivative **5** which was also isolated as colourless crystals in 80% yield (Scheme 3). The formation of **5** merely consists of the removal of one chloride ligand from **4** allowing an η^2-*(P,O)*-coordination of one keto-phosphane ligand. As ex-

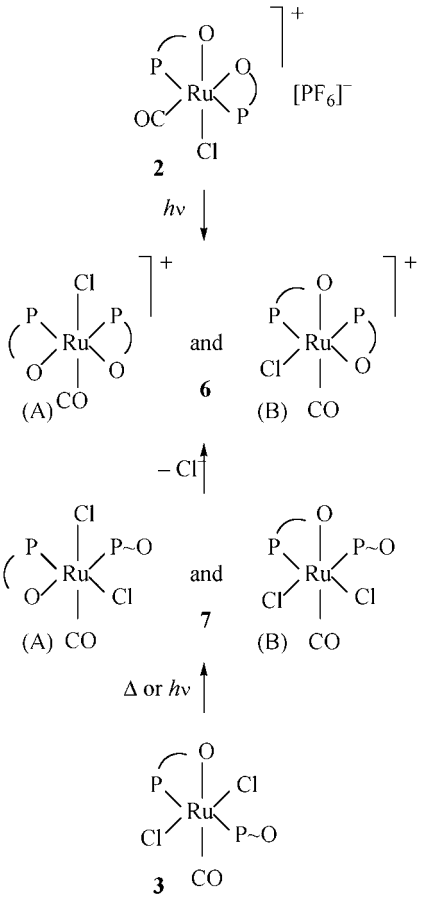
pected, the two keto-phosphane ligands in **5** were found inequivalent by $^{31}P\{^1H\}$ NMR spectroscopy and the observation of a high coupling constant value (^2J = 305 Hz) indicated a relative *trans* arrangement of the phosphorus *nuclei*. The IR spectrum of **5** showed that the two carbonyl ligands [ν(C≡O): 2072, 2015 cm^{-1}] are in a relative *cis* arrangement but that the distinct absorptions [ν(C=O): 1707, 1614 cm^{-1}] are attributable to the two keto-phosphane ligands, which are η^1-*(P)*- and η^2-*(P,O)*-coordinated, respectively.



Scheme 3

Complexes **2** and **5** are both stable and inert under a carbon monoxide atmosphere. Thus, a straightforward comparison of their structures is enough to emphasise an unusual strength of the O→Ru bonds in cationic complex **2**: an easy cleavage would allow carbon monoxide fixation by **2** resulting in formation of **5**.

Emphasising the easiness of photochemical activation, sun light exposure of a dichloromethane solution of **2** cleanly produced a pale precipitate of **6** which was collected in 82% yield (Scheme 4). In contrast, complex **2** decomposed under thermal activation (ethanol at reflux). The $^{31}P\{^1H\}$ NMR spectrum of **6** disclosed besides a single resonance, an AB spin system with a low coupling constant value (^2J = 24.0 Hz), thus suggesting a mixture of two species. At least one of them involves two phosphorus coordinating atoms in a relative *cis* arrangement. The ^1H NMR spectrum only allowed the determination of the relative abundance of the major unsymmetrical species in solution, and owing to a very low solubility, we failed to obtain a tractable $^{13}C\{^1H\}$ NMR analysis. Therefore, we sought for chemical evidence providing further information concerning the structure of **6**.

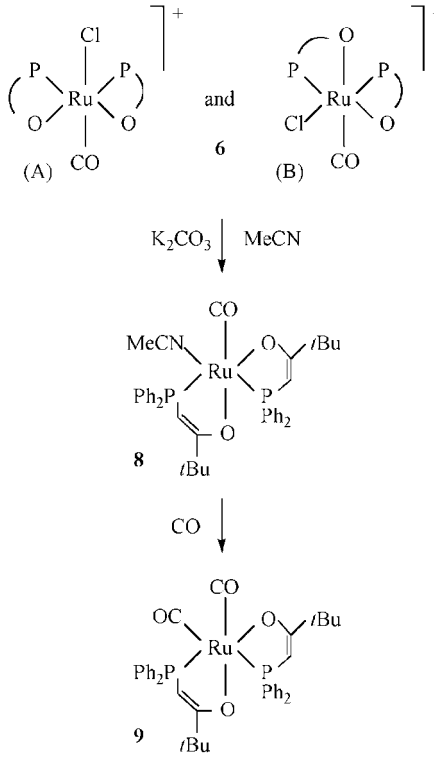


Scheme 4

A rearrangement of complex **3** similarly occurred under sun light exposure but also under thermal activation, to afford **7** as a mixture of two isomers both disclosing a relative *cis* arrangement of the phosphorus atoms by $^{31}P\{^1H\}$ NMR spectroscopy (Scheme 4). As expected for a mixture of two isomers, the $^{13}C\{^1H\}$ NMR spectrum disclosed two C≡O resonances and the observation of low $^2J_{PC}$ coupling constant values (^2J = 23 and 27 Hz, respectively) indicated that carbon monoxide was located in a *cis* position relative to the two phosphorus atoms. Only two structures, namely (A) and (B) in Scheme 4, remained conceivable on the basis of a *facial* arrangement of a carbon monoxide ligand and two phosphorus coordinating atoms. When compared to ether-phosphane complexes,[11] the relative abundance of the two isomers was also found to be solvent dependent by ^1H NMR spectroscopy (see Exp. Sect.), but no fluxional process between the coordinating modes of the two keto-phosphane ligands was observed at ambient temperature. Of further interest with respect to this study is the addition of $[NH_4][PF_6]$ to a solution of **7** in methanol which immediately resulted in the formation of a precipitate of **6.** Abstraction of one chloride ligand located *trans* relative to a phosphorus atom in **7**, affords the mixture of isomers which is assumed for **6** (Scheme 4).

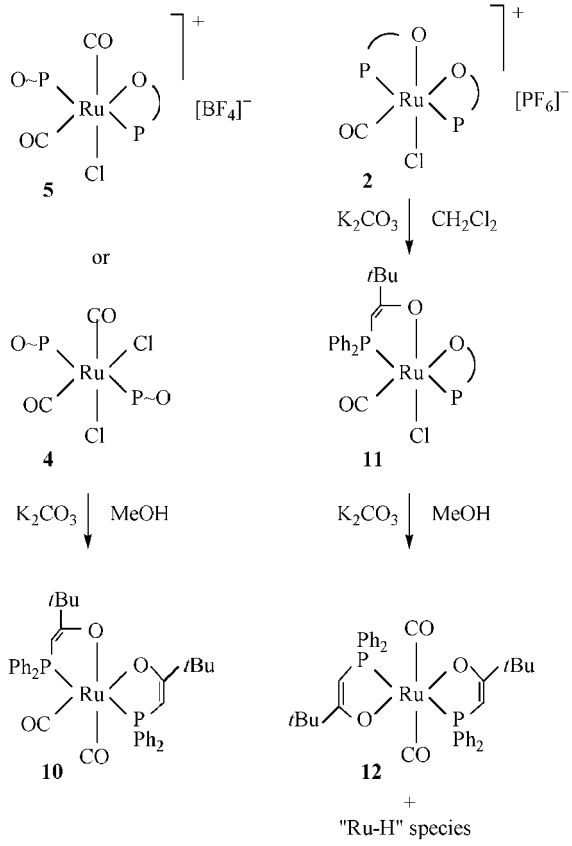
2. Neutral Bis(enolato-phosphane) Complexes Involving Carbon Monoxide

Owing to the very low solubility of **6** and the presence of two isomers for both **6** and **7**, some doubt remained concerning their structures. Complex **6** reacted with acetonitrile and K_2CO_3 resulting in a nearly quantitative formation of the neutral bis(enolato-phosphane) complex Ru(CO)(MeCN)[η^2-*(P,O)*-$Ph_2PCH{=}C(t\text{Bu})O]_2$ (**8**) and further reaction of **8** with carbon monoxide selectively led to the bis(enolato-phosphane) derivative *all-cis* $Ru(CO)_2[\eta^2$-*(P,O)*-$Ph_2PCH{=}C(t\text{Bu})O]_2$ (**9**) the structure of which was unambiguously determined (Scheme 5). $^{31}P\{^1H\}$ NMR spectroscopic studies were enough to specify the structure of **9** and indicated two inequivalent enolato-phosphane ligands and also showed that the phosphorus atoms are in a relative *cis* arrangement (^2J = 24.0 Hz). The ^1H NMR spectrum of **9** showed two distinct PCH= protons whereas a relative *cis* arrangement of the two carbonyl ligands was inferred from both IR and $^{13}C\{^1H\}$ NMR spectroscopy.



Scheme 5

The reaction of **4** or **5** with carbon monoxide under basic conditions (K_2CO_3 in methanol) was found to be very selective and afforded the bis(enolato-phosphane) derivative $Ru(CO)_2[\eta^2$-*(P,O)*-$Ph_2PCH{=}C(t\text{Bu})O]_2$ (**10**) with *cis* carbonyl ligands, *cis* oxygen and *trans* phosphorus coordinating atoms (Scheme 6). Complex **10** is a stereoisomer of **9**. Its IR spectrum indicated the relative *cis* arrangement of the two C≡O ligands and the conversion of both keto-phosphanes from **4** (or **5**), into enolato-phosphane ligands that were found to be equivalent by $^{31}P\{^1H\}$ NMR spectroscopy. The ^1H NMR spectrum of **10** showed the resonance, attributed to the two equivalent PCH= protons, as a virtual triplet, as expected from a mutual *trans* arrangement of the two phosphorus coordinating atoms.



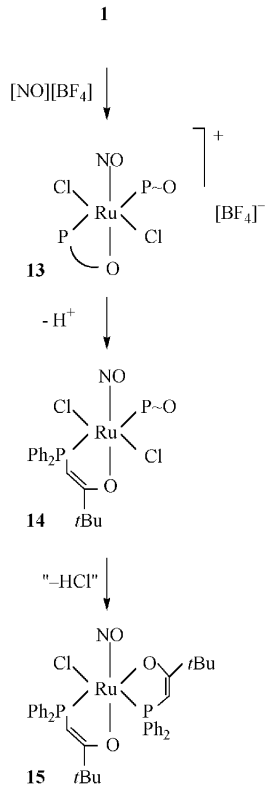
Scheme 6

Owing to its structure with *trans* phosphorus and *cis* oxygen coordinating atoms, the cationic complex **2** may appear as a precursor for the access to **10**. However, the reaction of **2** and K_2CO_3 in dichloromethane selectively afforded the *all-trans* derivative **11** (Scheme 6). We had previously reported the synthesis of **11** starting from **3** and allowing the access of a third stereoisomer of **9** and **10**, namely *all-trans* $Ru(CO)_2[\eta^2$-*(P,O)*-$Ph_2PCH{=}C(t\text{Bu})O]_2$ (**12**).[11] When compared to the nearly quantitative synthesis of **9** and **10**, complex **12** was previously obtained in a markedly lower yield (24%). Therefore, the formation of **12** was re-investigated. Complex **11** was reacted with K_2CO_3 in methanol under a carbon monoxide atmosphere and the resulting crude material was examined by $^{31}P\{^1H\}$NMR spectroscopy that disclosed a mixture of **12** and of a second unidentified species but neither **9** nor **10** were detected. Fractional crystallization allows pure **12** to be obtained but we failed to isolate the second species which is likely a Ru−H complex as suggested by ^1H NMR spectroscopy (see Exp. Sect.).

3. Neutral Bis(enolato-phosphane) Complexes Involving Nitrogen Monoxide

The nitrosonium cation $[NO]^+$ is isoelectronic with carbon monoxide but also a strong oxidising reagent and the reaction of $[NO][BF_4]$ with a $RuCl_2$(ether-phosphane)$_2$ complex had proved to result in a Ru^{II} to Ru^{III} oxidation.[1] By contrast, the reaction of **1** with $[NO][BF_4]$ in dichloromethane afforded an orange solid that may be assumed to mainly contain *all-trans* (on the basis of two *trans* phosphorus and two *trans* chlorine coordinating atoms) $\{RuCl_2(NO)[Ph_2PCH_2C(t\text{Bu})=O][Ph_2PCH_2C(=O)t\text{Bu}]\}$-$[BF_4]$ (**13**). The structure of **13** was suggested by spectroscopic studies. The IR spectrum of **13** showed besides the characteristic absorption attributed to the $[BF_4]^-$ counter anion, a very strong absorption attributed to a nitrosyl ligand [ν(NO): 1884 cm^{-1}] and two absorptions [ν(C=O): 1701 cm^{-1} and 1595 cm^{-1}] emphasising two distinct keto-phosphane ligands, that are η^1-*(P)*- and η^2-*(P,O)*-coordinated, respectively. $^{31}P\{^1H\}$ NMR spectroscopy indicated a relative *trans* arrangement of the two inequivalent phosphorus *nuclei*, but ^1H NMR spectroscopy indicated two equivalent PCH_2 protons for each keto-phosphane, as may be expected when two chloride ligands are in a relative *trans* arrangement. Unfortunately, attempts of purification of **13** failed, instead affording the stable enolato-phosphane derivative *all-trans* $RuCl_2(NO)[Ph_2PCH=C(t\text{Bu})O]$-$[Ph_2PCH_2C(=O)t\text{Bu}]$ (**14**) (Scheme 7). The structure of **14** was similarly determined by spectroscopic studies but also elemental analysis and a peculiarly easy deprotonation of the η^2-*(P,O)*-coordinated keto-phosphane ligand in **13** straightforwardly accounts for the formation of **14**. A formal removal of HCl from **14** was achieved under basic conditions (KOH or K_2CO_3 in methanol) and afforded the bis(enolato-phosphane) complex $RuCl(NO)[Ph_2PCH=C(t\text{Bu})O]_2$ (**15**) which surprisingly showed a relative *cis* arrangement of the phosphorus coordinating atoms (Scheme 7). The spectroscopic data collected for **15** only allowed us to further specify a structure involving two distinct enolato-phosphane ligands but did not provide any information on the symmetry.

A complete determination of the structure of **15** was achieved by an X-ray analysis that revealed a distorted octahedron (Figure 1). Examination of bond angles clearly indicated that the nitrosyl ligand behaves as a 3e-donor [O(1)−N(1)−Ru: 172.88(16)°] and is located *trans* relative to an oxygen atom [N(1)−Ru−O(3): 174.40(7)°].[16] The two phosphorus atoms are in a relative *cis* arrangement [P(1)−Ru−P(2): 101.685(18)°] and located *trans* relative to the oxygen [O(2)−Ru−P(1): 167.43(4)°] and chlorine [Cl(1)−Ru−P(2): 166.697(19)°] atoms. The two Ru−O bond lengths [Ru−O(3): 1.9930(13), Ru−O(2): 2.0820(13) Å] account for distinct *trans* influences from nitrosyl and phosphorus, whereas the two Ru−P bonds lengths [Ru−P(1): 2.3409(5), Ru−P(2): 2.3646(5) Å] remain close. The lengths of the C=C bonds involved in the two cycles [C(1)−C(2): 1.350(3), C(19)−C(20): 1.365(3) Å] are normal as expected for enolato-phosphane ligands.



Scheme 7

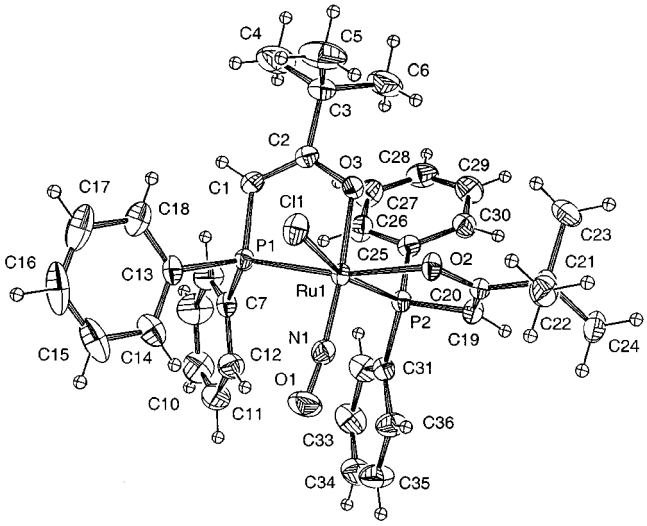


Figure 1. ORTEP drawing of $RuCl(NO)[Ph_2PCH=C(t\text{Bu})O]_2$ **(15)** showing 50% thermal ellipsoids; selected bond lengths (Å) and angles (°): Ru(1)−N(1) 1.7355(17), Ru(1)−O(3) 1.9930(13), Ru(1)−O(2) 2.0820(13), Ru(1)−P(1) 2.3409(5), Ru(1)−P(2) 2.3646(5), Ru(1)−Cl(1) 2.4193(5), O(1)−N(1) 1.162(2), C(1)−C(2) 1.350(3), C(19)−C(20) 1.365(3), N(1)−Ru(1)−O(3) 174.40(7), N(1)−Ru(1)−O(2) 99.30(7), O(3)−Ru(1)−O(2) 86.30(6), N(1)−Ru(1)−P(1) 92.74(5), O(3)−Ru(1)−P(1) 81.67(4), O(2)−Ru(1)−P(1) 167.43(4), N(1)−Ru(1)−P(2) 94.15(6), O(3)−Ru(1)−P(2) 86.65(4), O(2)−Ru(1)−P(2) 81.16(4), P(1)−Ru(1)−P(2) 101.685(18), N(1)−Ru(1)−Cl(1) 94.42(6), O(3)−Ru(1)−Cl(1) 85.82(4), O(2)−Ru(1)−Cl(1) 87.42(4), P(1)−Ru(1)−Cl(1) 88.051(18), P(2)−Ru(1)−Cl(1) 166.697(19), O(1)−N(1)−Ru(1) 172.88(16)

The *trans* to *cis* rearrangement of the two phosphorus coordinating atoms which is involved in the **14** to **15** transformation is intriguing because no pentacoordinated intermediate that still contains a strongly bonded enolato-phosphane ligand is expected from **14**. A possible pathway leading to **15** will consist of a preliminary deprotonation of the η^1-*(P)*-coordinated keto-phosphane in **14**. The coordination of the anionic oxygen atom may occur as a result of the ability of nitrosyl ligands to behave as either a 3e or 1e donor and this will generate an heptacoordinated intermediate transiently scrambling the octahedral structure.[17] Subsequent elimination of one chloride anion achieves the formation of **15**. From a steric point of view, complex **15** seems very close when compared to the bis(enolato-phosphane) complexes **9**, **10** and **12**, which seem equally stable, providing evidence for a lack of steric constraints.

Conclusion

The coordination of the oxygen atoms from the two keto-phosphane ligands leads to an unusually strong stabilization in the cationic complex $\{RuCl(CO)[Ph_2PCH_2C(tBu)=O]_2\}[PF_6]$ (**2**). The stereoisomeric *all-cis*, *cct,* and *all-trans* $Ru(CO)_2[\eta^2$-*(P,O)*-$Ph_2PCH=C(tBu)O]_2$ complexes, were selectively obtained under mild conditions and such a result indicates high energetic barriers between the three corresponding families of compounds. Thus, the behaviour of complex **2** under mild basic conditions clearly shows **2** to be an *all-trans* derivative. However, the families are strongly related to the number x of carbon monoxide ligands: the observation of the *cct* family requires $x = 2$ whereas only *all-trans* and *all-cis* derivatives are observed when $x = 1$, and a distinct geometry was observed when $x = 0$. As new evidence for synthetic usefulness, the precursor $RuCl_2[Ph_2PCH_2C(tBu)=O]_2$ (**1**) is able to coordinate not only carbon monoxide but also the isolelectronic nitrosonium cation. The coordination of $[NO]^+$ thus provides an entry to a family of octahedral ruthenium (IV) complexes such as $RuCl(NO)[\eta^2$-*(P,O)*-$Ph_2PCH=C(tBu)O]_2$, (**15**), the reactivity of which is under investigation.

Experimental Section

General: The reactions were performed according to Schlenk type techniques. Solvents were distilled under an inert atmosphere after drying according to conventional methods. Elemental analyses were performed by the "Service de Microanalyse du CNRS" Vernaison, France. Infrared spectra were recorded on a Nicolet 205 FT-infrared spectrometer as Nujol mulls. NMR spectra were recorded at 297 K on AC 300 FT Bruker instrument (^{1}H: 300.13, ^{13}C: 75.47, ^{31}P: 121.50 MHz; absolute values of coupling constants in Hz) and referenced internally to the solvent peak. The following abbreviations are used: s, singlet; d, doublet; t, triplet; vt, virtual triplet; m, unresolved multiplet. The precursor complex $RuCl_2[Ph_2PCH_2C(tBu)=O]_2$ (**1**) was synthesised as reported previously.[11]

Generation of the $\{RuCl[Ph_2PCH_2C(tBu)=O]_2\}^+$ Species: An aliquot of the solution resulting from the reaction of **1** with NH_4PF_6 in methanol (see synthesis of **2**) was examined by $^{31}P\{^1H\}$ NMR spectroscopy (MeOH/$CDCl_3$): δ = 62.8 (d), 70.7 (d), ^2J = 38 Hz. However, a second and minority species was detected: δ = 67.1 (d), 68.4 (d), ^2J = 37 Hz. In another experiment, an equivalent amount of $Ag[BF_4]$ was added to a solution of **1** in CH_2Cl_2. The mixture was stirred for 1 h and decanted. The supernatant solution was examined by $^{31}P\{^1H\}$ NMR spectroscopy (CH_2Cl_2/CD_2Cl_2): δ = 63.7 (d), 73.2 (d), ^2J = 39 Hz. Only one species was observed in CH_2Cl_2 suggesting that the observation of a second set of resonances in methanol indicated a solvated species.

***trans-(P,P)*-$\{RuCl(CO)[Ph_2PCH_2C(tBu)=O]_2\}[PF_6]$ (2):** A mixture consisting of sample **1** (5.20 g, 7.02 mmol) and NH_4PF_6 (1.20 g, 7.36 mmol) in methanol (80 mL), under an inert atmosphere, was stirred overnight to obtain an orange solution that was then stirred for 2 h under a carbon monoxide atmosphere. The resulting yellow precipitate was collected by filtration and then extracted with dichloromethane (40 mL). The solution was filtered and the filtrate was covered with methanol (20 mL) and diethyl ether (130 mL) to afford orange-yellow crystals. Yield: 4.00 g, 65%. IR: ν(C≡O) = 1991, 1977 cm^{-1}; ν(C=O) = 1621, 1596 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 35.0 (d), 48.4 (d, ^2J = 328 Hz). ^{1}H NMR (CD_2Cl_2): δ = 0.93 (s, 9 H, *t*Bu), 1.06 (s, 9 H, *t*Bu), 3.72 (dd, 1 H, $^2J_{H,H}$ = 18.7, $^2J_{PH}$ = 11.2 Hz, PCH_2, H_a), 3.97 (dd, 1 H, $^2J_{H,H}$ = 17.9, $^2J_{PH}$ = 11.1 Hz, P′CH_2, H_a), 4.74 (ddd, 1 H, $^2J_{H,H}$ = 17.9, $^2J_{PH}$ = 11.4, $^4J_{PH}$ = 3.1 Hz, P′CH_2, H_b), 4.83 (ddd, 1 H, $^2J_{H,H}$ = 18.7, $^2J_{PH}$ = 10.4 Hz, $^4J_{PH}$ = 1.5 Hz, PCH_2, H_b), 7.45−7.99 (m, 20 H, Ph). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 26.7 (s, C*Me*$_3$), 26.8 (s, C*Me*$_3$), 42.9 (d, $^1J_{PC}$ = 26.2 Hz, PCH_2), 43.4 (d, $^1J_{PC}$ = 26.9 Hz, PCH_2), 47.1 (d, $^3J_{PC}$ = 2.9 Hz, *C*Me$_3$), 47.7 (d, $^3J_{PC}$ = 3.4 Hz, *C*Me$_3$), 127.4−134.3 (m, 2 Ph_2P groups), 202.3 (dd, $^2J_{PC}$ = 13.6 and 11.4 Hz, C≡O), 235.9 (dd, $^2J_{PC}$ = 6.2, $^3J_{PC}$ = 4.9 Hz, C=O), 239.6 (dd, $^2J_{PC}$ = 5.5, $^3J_{PC}$ = 3.8 Hz, C=O). $C_{37}H_{42}ClF_6O_3P_3Ru$ (878.2): calcd. C 50.61, H 4.82, Cl 4.04, P 10.58; found C 50.82, H 4.89, Cl 4.03, P 10.23.

***ttt*-$RuCl_2(CO)[Ph_2PCH_2C(=O)tBu][Ph_2PCH_2C(tBu)=O]\cdot 2/3CH_2Cl_2$ (3):** The synthesis of **3** starting from **1** was reported previously.[11] A more straightforward synthesis starting from $[RuCl_2(p\text{-cymene})]_2$ is described herein. A mixture consisting of a sample of $[RuCl_2(p\text{-cymene})]_2$ (3.91 g, 6.38 mmol) and keto-phosphane $Ph_2PCH_2C(tBu)=O$ (7.26 g, 25.5 mmol) was dissolved in dichloromethane (60 mL) and methanol (140 mL) was then added. This mixture was stirred for 3 days under a carbon monoxide atmosphere and the resulting orange-yellow slurry was concentrated under vacuum. Diethyl ether was first added to collect the yellow precipitate. The solid was washed with diethyl ether then dried under vacuum and identified as *all-trans* $RuCl_2(CO)_2[Ph_2PCH_2C(=O)tBu]$, **3′**, by IR spectroscopy.[11] (Yield: 8.30 g, 82%). The crude product was dissolved in dichloromethane (50 mL) and the orange solution was stirred overnight in an open Erlenmeyer flask allowing the evolution of one mol of carbon monoxide. The solution was then covered with ethanol (250 mL) and the natural preferential evaporation of dichloromethane resulted in the formation of yellow crystals of **3**. Yield: 7.75 g, 74%. IR and NMR spectroscopic data as reported previously.[11]

***cct*-$RuCl_2(CO)_2[Ph_2PCH_2C(=O)tBu]_2$ (4):** A mixture consisting of a sample of **1** (4.06 g, 4.92 mmol) (or corresponding amounts of **3** or **3′**) and hot toluene (50 mL, 85 °C) was stirred for 2 days under a carbon monoxide atmosphere. The resulting colourless solution was evaporated under vacuum to leave a solid that was dissolved in dichloromethane (20 mL). Methanol (35 mL) was added and slow

evaporation of the solution afforded colourless crystals of **4**. Yield: 3.59 g, 92%. IR: ν(C≡O) = 2056, 1992 cm^{-1}; ν(C=O) = 1705 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 19.2 (s). ^1H NMR (CD_2Cl_2): δ = 0.82 (s, 18 H, 2 *t*Bu), 4.43 (vt, 4 H, $|^2J_{PH} + {}^4J_{PH}|$ = 7.7 Hz, 2 PCH_2), 7.38−7.84 (m, 20 H, Ph). $C_{38}H_{42}Cl_2O_4P_2Ru$ (796.7): calcd. C 57.29, H 5.31, Cl 8.90, P 7.78; found C 57.40, H 5.29, Cl 8.85, P 7.76.

{RuCl(CO)$_2$[Ph$_2$PCH$_2$C(=O)*t*Bu][Ph$_2$PCH$_2$C(*t*Bu)=O]}[BF$_4$] (5): A mixture consisting of a sample of **4** (1.00 g, 1.26 mmol) and $Ag[BF_4]$ (0.25 g, 1.28 mmol) in dichloromethane (30 mL) was stirred overnight. The resulting solution was decanted, then filtered and covered with diethyl ether (80 mL) to afford colourless crystals of **5**. Yield: 0.86 g, 80%. IR: ν(C≡O) = 2072, 2015 cm^{-1}; ν(C=O) = 1707, 1614 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 19.3 (d), 44.8 (d, ^2J = 305 Hz). ^1H NMR (CD_2Cl_2): δ = 1.02 (s, 9 H, *t*Bu), 1.05 (s, 9 H, *t*Bu), 4.04 (dd, 1 H, $^2J_{H,H}$ = 17.0, $^2J_{PH}$ = 10.2 Hz, P′CH_2, H_a), 4.15 (dd, 1 H, $^2J_{H,H}$ = 18.5, $^2J_{PH}$ = 11.8 Hz, PCH_2, H_a), 4.51 (dd, 1 H, $^2J_{H,H}$ = 16.8, $^2J_{PH}$ = 9.1 Hz, P′CH_2, H_b), 4.79 (dd, broad, 1 H, $^2J_{H,H}$ ≈ 18.5 Hz, $^2J_{PH}$ ≈ 12.0 Hz, PCH_2, H_b), 7.35−7.90 (m, 20 H, Ph). $C_{38}H_{42}BClF_4O_4P_2Ru$ (848.0): calcd. C 53.82, H 4.99, Cl 4.18, P 7.30; found C 53.66, H 5.11, Cl 5.02, P 7.06, retention of some dichloromethane is likely to be responsible for the high chlorine value.

***cis*-*(P,P)*-{RuCl(CO)[Ph$_2$PCH$_2$C(*t*Bu)=O]$_2$}[PF$_6$] (6):** A Schlenk flask was filled with a solution consisting of a sample of **2** (4.11 g, 4.68 mmol) in dichloromethane (60 mL). The flask was then exposed to sunlight. After three weeks (corresponding to ≈ 70 h of exposure according to our feasibility) the resulting cream-coloured precipitate was collected by filtration, then washed with diethyl ether (50 mL). Yield: 3.39 g, 82%. IR: ν(C≡O) = 1995 cm^{-1}; ν(C=O) = 1613 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2), asterisk marked values for the unsymmetrical isomer: δ = 55.3* (d), 56.2 (s), 62.5* (d), ^2J = 24 Hz*. ^1H NMR (CD_2Cl_2), asterisk marked values for the unsymmetrical and major (3:1) isomer: δ = 1.15* (s, *t*Bu), 1.41 (s, *t*Bu), 1.45* (s, *t*Bu), 3.63* (dd, $^2J_{H,H}$ = 18.6 Hz, $^2J_{PH}$ = 9.9 Hz, 1 H from a PCH_2 group), 4.21−4.30 (m, 2 H from PCH_2* groups, and 4 H from the two equivalent PCH_2 that showed close chemical shifts of the inequivalent protons), 4.56* (dd, $^2J_{H,H}$ = 18.7 Hz, $^2J_{PH}$ = 10.2 Hz, 1 H from a PCH_2 group), 6.56−7.87 (m, 20 H, Ph, both isomers). $C_{37}H_{42}ClF_6O_3P_3Ru$ (878.2): calcd. C 50.61, H 4.82, Cl 4.04, P 10.58; found C 50.71, H 4.92, Cl 4.18, P 10.69.

***ccc*-RuCl$_2$(CO)[Ph$_2$PCH$_2$C(=O)*t*Bu][Ph$_2$PCH$_2$C(*t*Bu)=O] (7):** A mixture consisting of a sample of **3** (7.53 g, 9.12 mmol) and toluene (80 mL), was heated to reflux for 20 h to afford a pale-yellow precipitate that was collected by filtration then washed with hexane and dried under vacuum. Yield: 5.63 g, 80%. Exposure of a solution of **3** in dichloromethane (as detailed for synthesis of **6**) to sunlight afforded a mixture of **6** and remaining **3**. Despite the fact that pale-yellow crystals were obtained upon addition of diethyl ether to a concentrated solution of the crude solid in dichloromethane, we failed to obtain **7** in a high state of purity as shown by elemental analyses. IR: ν(C≡O) = 1968 cm^{-1}; ν(C=O) = 1703, 1629 cm^{-1}. $^{31}P\{^1H\}$ NMR ($CDCl_3$), asterisk marked values for the major isomer: δ = 41.7 (broad), 47.4* (d), 47.8* (d), 59.7 (d, ^2J = 23 and 27 Hz*). $C_{37}H_{42}Cl_2O_3P_2Ru$ (768.7): calcd. C 57.82, H 5.51, Cl 9.22, P 8.06; found C 56.96, H 5.56, Cl 10.62, P 7.90. Attempts at recrystallization from hot acetonitrile yielded yellow crystals that retain acetonitrile (≈ 1.3 MeCN/Ru) but no significant change was observed from $^{31}P\{^1H\}$ NMR and IR spectroscopy. A concomitant crystallization of the two isomeric forms with only one retaining some solvent may account for the failure in obtaining a satisfactory elemental analysis. $^{31}P\{^1H\}$ NMR (CD_2Cl_2), asterisk marked values for the major isomer: δ = 39.9 (broad), 45.8* (d), 47.8* (d), 58.8 (d, ^2J = 23 and 27 Hz*). ^1H NMR (CD_2Cl_2), asterisk marked values for the major isomer: δ = 0.59 (s, *t*Bu), 0.70* (s, *t*Bu), 1.05 (s, *t*Bu), 1.28* (s, *t*Bu), 1.94 (s, MeCN), 2.62 (m, broad, 1 H from a PCH_2 group), 3.14 (m, broad, 1 H from a PCH_2 group), 4.02−4.30 (m, 5 H from PCH_2 groups), 4.67* (dd, $^2J_{H,H}$ = 17.2 Hz, $^2J_{PH}$ = 7.4 Hz, 1 H from a PCH_2 group), 6.75−7.86 (m, Ph). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 2.2 (s, *Me*CN), 25.8 (s, C*Me*$_3$), 25.8 (s, C*Me*$_3$), 27.0 (s, C*Me*$_3$), 27.0 (s, C*Me*$_3$), 36.9 (d, $^1J_{PC}$ = 28.0 Hz, PCH_2), 37.4 (d, $^1J_{PC}$ = 33.4 Hz, PCH_2), 45.4 (d, $^3J_{PC}$ = 1.5 Hz, *C*Me$_3$), 45.9 (m, 2 *C*Me$_3$), 46.0 (d, $^3J_{PC}$ = 3.9 Hz, *C*Me$_3$), 47.2 (d, broad, $^1J_{PC}$ = 35.3 Hz, PCH_2), 49.0 (d, $^1J_{PC}$ = 31.5 Hz, PCH_2), 117.1 (s, Me*C*N), 127.7−137.5 (phenyl-groups resonances), 197.9 (dd, $^2J_{PC}$ = 17.7 and 13.0 Hz, C≡O), 204.3 (dd, $^2J_{PC}$ = 17.5 and 14.3 Hz, C≡O), 209.6 (d, $^2J_{PC}$ = 6.4 Hz, C=O), 209.7 (d, $^2J_{PC}$ = 10.7 Hz, C=O), 227.9 (d, $^2J_{PC}$ = 3.3 Hz, C=O), 228.4 (broad, C=O). Isomeric ratio as determined by ^1H NMR spectroscopy: 3:1 in $CDCl_3$, < 5:4 in CD_2Cl_2.

***ccc*-Ru(CO)(MeCN)[Ph$_2$PCH=C(*t*Bu)O]$_2$ (8):** A mixture consisting of a sample of **6** (3.39 g, 3.86 mmol), K_2CO_3 (1.20 g, 8.68 mmol) and acetonitrile (50 mL), was stirred overnight and then evaporated to dryness. The remaining solid was extracted with dichloromethane (50 mL). The solution was filtered and the clear filtrate was evaporated under vacuum to leave a cream-coloured powder that was found by NMR spectroscopy and elemental analysis to be pure. Yield: 2.62 g, 92%. IR: ν(C≡N) = 2325 cm^{-1}; ν(C≡O) = 1924 cm^{-1}; ν(C=CO) = 1506, 1493 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 45.3 (d), 48.8 (d), ^2J = 27. ^1H NMR (CD_2Cl_2): δ = 0.92 (s, 9 H, *t*Bu), 1.22 (s, 9 H, *t*Bu), 1.54 (s, 3 H, MeCN), 4.09 (d, 1 H, $^2J_{PH}$ = 3.5 Hz, PCH=), 4.46 (d, 1 H, $^2J_{PH}$ = 2.0 Hz, P′CH=), 6.83−7.66 (m, 20 H, Ph). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 3.1 (s, *Me*CN), 29.6 (s, C*Me*$_3$), 30.1 (s, C*Me*$_3$), 39.1 (dd, $^3J_{PC}$ = 12.6 Hz, $^4J_{PC}$ = 3.6 Hz, *C*Me$_3$), 39.2 (d, $^3J_{PC}$ = 12.6 Hz, *C*Me$_3$), 69.7 (d, $^1J_{PC}$ = 61.1 Hz, PCH=), 73.5 (d, $^1J_{PC}$ = 62.9 Hz, PCH=), 120.0 (d, $^3J_{PC}$ = 14.3 Hz, Me*C*N), 127.4−133.6 (m, phenyl-groups resonances), 134.2 (d, $^1J_{PC}$ = 51.5 Hz, PhP, *ipso*), 137.4 (d, $^1J_{PC}$ = 56.5 Hz, PhP, *ipso*), 138.9 (d, $^1J_{PC}$ = 53.1 Hz, PhP, *ipso*), 140.0 (d, $^1J_{PC}$ = 49.7 Hz, PhP, *ipso*), 198.9 (d, $^2J_{PC}$ = 17.1 Hz, =CO), 198.9 (d, $^2J_{PC}$ = 10.8 Hz, =CO), 202.7 (dd, $^2J_{PC}$ = 17.5 and 13.0 Hz, C≡O). $C_{39}H_{43}NO_3P_2Ru$ (736.8): calcd. C 63.58, H 5.88, N 1.90, P 8.41; found C 63.28, H 6.12, N 1.96, P 8.72.

***ccc*-Ru(CO)$_2$[Ph$_2$PCH=C(*t*Bu)O]$_2$·1/6CH$_2$Cl$_2$ (9):** A solution consisting of a sample of **8** (2.50 g, 3.39 mmol) and dichloromethane (35 mL), was stirred under carbon monoxide for 20 h, and then evaporated under vacuum to dryness to leave a white solid. Yield: 2.38 g, 95%. IR: ν(C≡O) = 2051, 1972 cm^{-1}; ν(C=CO) = 1507, 1500 cm^{-1}. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 34.3 (d), 44.0 (d, ^2J = 24 Hz). ^1H NMR (C_6D_6): δ = 1.22 (s, 9 H, *t*Bu), 1.52 (s, 9 H, *t*Bu), 4.41 (dd, 1 H, $^2J_{PH}$ = 3.1 Hz, $^4J_{PH}$ = 0.7 Hz, PCH=), 4.65 (d, 1 H, $^2J_{PH}$ = 4.0 Hz, P′CH=), 6.84−7.63 (m, 20 H, Ph). $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 30.0 (s, C*Me*$_3$), 30.5 (s, C*Me*$_3$), 39.8 (dd, $^3J_{PC}$ = 12.6, $^4J_{PC}$ = 2.7, *C*Me$_3$), 39.8 (d, $^3J_{PC}$ = 12.6 Hz, *C*Me$_3$), 70.8 (dd, $^1J_{PC}$ = 60.6 Hz, $^3J_{PC}$ = 3.1 Hz, PCH=), 71.8 (d, $^1J_{PC}$ = 64.6 Hz, PCH=), 128.1−140.8 (m, phenyl-groups resonances), 191.2 (dd, $^2J_{PC}$ = 102.3 and 11.7 Hz, C≡O), 199.7 (dd, $^2J_{PC}$ = 15.3 and 10.8 Hz, C≡O), 200.4 (dd, $^2J_{PC}$ = 15.3, $^3J_{PC}$ = 1.8 Hz, =CO), 200.8 (d, $^2J_{PC}$ = 14.4 Hz, =CO). $C_{38}H_{40}O_4P_2Ru$·1/6CH_2Cl_2 (737.9): calcd. C 62.12, H 5.51, Cl 1.60, P 8.40; found C 62.14, H 5.66, Cl 1.27, P 8.03.

***cct*-Ru(CO)$_2$[Ph$_2$PCH=C(*t*Bu)O]$_2$ (10):** A sample of **1** (4.60 g, 5.57 mmol) was converted into crude **4** (as detailed above) before

adding K_2CO_3 (1.00 g, 7.24 mmol) and methanol (50 mL). This mixture was stirred for 7 days at room temperature. The solvent was then removed under vacuum to leave a white solid that was extracted with dichloromethane (30 mL). The solution was filtered and methanol (40 mL) was added to the colourless filtrate. Through slow evaporation, the mixture afforded colourless crystals of **10**. Yield: 3.04 g, 75%. IR: ν(C≡O) = 2029, 1963 cm^{-1}; ν(C=CO) = 1494 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 44.4 (s). ^1H NMR (CD_2Cl_2): δ = 0.97 (s, 18 H, 2 *t*Bu), 4.48 (vt, 2 H, $|^2J_{PH} + {}^4J_{PH}|$ = 5.8 Hz, 2 PCH=), 7.36−7.80 (m, 20 H, Ph). $C_{38}H_{40}O_4P_2Ru$ (723.8): calcd. C 63.06, H 5.57, P 8.56; found C 63.22, H 5.77, P 8.47.

Formation of *ttt*-RuCl(CO)[$Ph_2PCH{=}C(tBu)O$][$Ph_2PCH_2C(tBu){=}O$] (11): The synthesis of **11** by reacting **3** with K_2CO_3 in dichloromethane has been reported previously.[11] Starting from **2**, complex **11** was selectively obtained also.

Formation of *ttt*-Ru(CO)$_2$[$Ph_2PCH{=}C(tBu)O$]$_2$ (12): A mixture consisting of a sample of **1** (0.77 g, 1.04 mmol) and K_2CO_3 (0.31 g, 2.24 mmol) in methanol (30 mL), was stirred for 4 days under a carbon monoxide atmosphere. The solvent was then removed under vacuum and the residue was extracted with dichloromethane (30 mL). A white powder was obtained after filtration of the solution and subsequent evaporation. The examination of the solid by NMR spectroscopy disclosed a mixture of two complexes when very weak additional resonances are omitted. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 27.1 (s, complex **12**)[11] and 29.9 (d), 51.5 (d) ^2J = 242 Hz (unidentified compound). ^1H NMR ($CDCl_3$), selected values attributed to the unidentified compound: δ = − 5.07 (dd, 1 H, $^2J_{PH}$ = 20.4 and 19.5 Hz, RuH), 3.92 (dd, 1 H, $^2J_{H,H}$ = 17.0 Hz, $^2J_{PH}$ = 6.8 Hz, PCH_2, H_a), 4.13 (dd, $^2J_{H,H}$ = 17.0 Hz, 1 H, $^2J_{PH}$ = 7.6 Hz, PCH_2, H_b), 4.62 (dd, 1 H, $^2J_{PH}$ = 3.5 Hz, $^4J_{PH}$ = 3.0 Hz, PCH=).

***ttt*-RuCl$_2$(NO)[$Ph_2PCH_2C(=O)tBu$][$Ph_2PCH_2C(tBu){=}O$][BF_4] (13):** A sample of **1** (5.00 g, 6.75 mmol) and [NO][BF_4] (0.85 g, 7.28 mmol) were successively added to cold dichloromethane (60 mL, −80 °C). The mixture was allowed to reach ambient temperature and stirred overnight. The resulting solution was evaporated under vacuum to obtain an orange solid (5.52 g). The NMR spectroscopic analysis of this crude material indicated a mixture of several products and we failed to isolate a pure compound after recrystallization from a dichloromethane/diethyl ether mixture. When additional weak IR absorptions and NMR resonances are omitted, the collected spectroscopic data suggested the assumed structure. IR: ν(NO) = 1884 cm^{-1}; ν(C=O) = 1701 cm^{-1}, 1595 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 20.3 (d), 49.8 (d, ^2J = 371 Hz). ^1H NMR (CD_2Cl_2): δ = 0.84 (s, 9 H, *t*Bu), 1.05 (s, 9 H, *t*Bu), 4.39 (dd, 2 H, $^2J_{PH}$ = 9.1 Hz, $^4J_{PH}$ = 2.4 Hz, PCH_2), 4.70 (d, broad, 2 H, $^2J_{PH}$ = 10.0 Hz, P′CH_2), 7.00−7.70 (m, 20 H, Ph). Attempts at recrystallization of the compound from slow evaporation of its solution in a dichloromethane/ethanol mixture afforded orange crystals of the enolato-phosphane derivative **14** instead of **13**.

***ttt*-RuCl$_2$(NO)[$Ph_2PCH{=}C(tBu)O$][$Ph_2PCH_2C(=O)tBu$] (14):** Complex **14** was obtained in 65% yield relative to **1** after recrystallization of **13** in a dichloromethane/ethanol mixture (see synthesis of **13**) or alternatively by reacting **13** with K_2CO_3 in dichloromethane. Further recrystallization from a dichloromethane/methanol mixture afforded orange needles. IR: ν(NO) = 1858 cm^{-1}; ν(C=O) = 1702 cm^{-1}; ν(C=CO): 1520 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 14.9 (d, PCH_2), 53.1 (d, PCH=, ^2J = 385 Hz). ^1H NMR (CD_2Cl_2): δ = 0.87 (s, 9 H, *t*Bu), 0.98 (s, 9 H, *t*Bu), 4.29 (dd, 2 H, $^2J_{PH}$ = 9.9 Hz, $^4J_{PH}$ = 1.8 Hz, PCH_2), 4.63 (dd, 1 H, $^2J_{PH} \approx {}^4J_{PH} \approx$ 4.1 Hz, PCH=), 7.37−7.78 (m, 20 H, Ph). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 26.4 (s, C*Me*$_3$), 28.9 (s, C*Me*$_3$), 33.4 (d, $^1J_{PC}$ = 30.4 Hz, PCH_2), 38.6 (d, $^3J_{PC}$ = 12.3 Hz, *C*Me$_3$), 45.6 (d, $^3J_{PC}$ = 1.8 Hz, *C*Me$_3$), 72.1 (dd, $^1J_{PC}$ = 63.8 Hz, $^3J_{PC}$ = 1.8 Hz, PCH=), 128.5 (d, $^2J_{PC}$ = 10.9 Hz, Ph_2P, *ortho*), 128.6 (d, $^2J_{PC}$ = 10.0 Hz, Ph_2P, *ortho*), 129.8 (dd, $^1J_{PC}$ = 43.8 Hz, $^3J_{PC}$ = 2.4 Hz, Ph_2P, *ipso*), 130.9 (d, $^4J_{PC}$ = 2.7 Hz, Ph_2P, *para*), 131.1 (d, $^4J_{PC}$ = 2.3 Hz, Ph_2P, *para*), 132.0 (dd, $^1J_{PC}$ = 57.2 Hz, $^3J_{PC}$ = 2.3 Hz, Ph_2P, *ipso*), 133.1 (dd, $^3J_{PC}$ = 9.1 Hz, $^5J_{PC}$ = 1.7 Hz, Ph_2P, *meta*), 134.3 (d, $^3J_{PC}$ = 8.8 Hz, Ph_2P, *meta*), 198.6 (dd, $^2J_{PC}$ = 16.9 Hz, $^3J_{PC}$ = 8.9 Hz, =CO), 209.8 (d, $^2J_{PC}$ = 5.4 Hz, C=O). ^{13}C NMR (CD_2Cl_2), selected values: δ = 33.4 (td, $^1J_{HC}$ = 130 Hz, PCH_2), 72.1 (ddd, $^1J_{HC}$ = 169 Hz, PCH=). $C_{36}H_{41}Cl_2NO_3P_2Ru$ (769.7): calcd. C 56.18, H 5.37, Cl 9.21, N 1.82, P 8.05; found C 55.84, H 5.43, Cl 9.85, N 1.84, P 7.79.

***ccc*-RuCl(NO)[$Ph_2PCH{=}C(tBu)O$]$_2$ (15):** **1** (5.30 g, 7.16 mmol) and [NO][BF_4] (0.93 g, 7.96 mmol) produced crude complex **13** and this was added to ethanol (80 mL) and then KOH (0.80 g, 14.3 mmol) and the mixture was stirred at ambient temperature for 2 days. The resulting orange slurry was evaporated under vacuum to leave a solid that was extracted with dichloromethane (60 mL). The solution was filtered and the filtrate was covered with methanol (150 mL) to afford well-formed orange-red crystals. Yield: 3.02 g, 58%. Complex **15** may be similarly obtained starting from **14**. IR: ν(NO) = 1805 cm^{-1}; ν(C=CO) = 1507, 1497 cm^{-1}. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 40.7 (d), 46.5 (d), ^2J = 20. ^1H NMR (CD_2Cl_2): δ = 0.95 (s, 9 H, *t*Bu), 1.35 (s, 9 H, *t*Bu), 4.22 (dd, $^2J_{PH}$ = 6.3 Hz, 1 H, $^4J_{PH}$ = 1.4 Hz, PCH=), 4.63 (d, 1 H, $^2J_{PH}$ = 5.6 Hz, P′CH=), 7.00−7.64 (m, 20 H, Ph). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 29.0 (s, C*Me*$_3$), 29.7 (s, C*Me*$_3$), 39.1 (d, $^3J_{PC}$ = 12.6 Hz, *C*Me$_3$), 39.7 (dd, $^3J_{PC}$ = 12.6 Hz, $^4J_{PC}$ = 4.5 Hz, *C*Me$_3$), 71.1 (dd, $^1J_{PC}$ = 65.5 Hz, $^3J_{PC}$ = 1.8 Hz, PCH=), 73.5 (d, $^1J_{PC}$ = 66.4 Hz, PCH=), 128.2−137.0 (m, phenyl-groups resonances), 198.0 (d, $^2J_{PC}$ = 13.5 Hz, =CO), 201.3 (dd, $^2J_{PC}$ = 10.3 Hz, $^3J_{PC}$ = 3.1 Hz, =CO). $C_{36}H_{40}ClNO_3P_2Ru$ (733.2): calcd. C 58.97, H 5.50, Cl 4.84, N 1.91, P 8.45; found C 58.80, H 5.54, Cl 4.79, N 1.95, P 8.66.

Crystal Data for 15: $C_{36}H_{40}ClNO_3P_2Ru$, M = 733.15, crystal size 0.40 × 0.38 × 0.32, monoclinic, space group $P2_1/c$, Z = 4, a = 18.2203(2) Å, b = 10.9932(1) Å, c = 18.3698(3) Å, β = 109.1277(6)°, U = 3476.42(8) Å^3, $\delta_{calcd.}$ = 1.401 g cm^{-3}, T = 293(2) K, $F(000)$ = 1512, Mo-K_α radiation (λ = 0.71069 Å), μ = 0.655 mm^{-1}, 7952 reflections measured in the range 2.28° ≤ θ ≤ 27.50°, 7952 unique (R_{int} = 0.03%) which were used in all calculations. The structure was refined using full-matrix least-squares on F^2 to R_1 = 0.0296, wR_2 = 0.0745, S = 1.071, for 6891 reflections (>2σ) and 398 refined parameters, R_1(all data) = 0.0371, wR_2(all data) = 0.0805, goodness-of-fit on F^2 = 1.071. The sample was studied with a NONIUS Kappa CCD diffractometer with graphite monochromator. The cell parameters were obtained with Denzo and Scalepack.[18] The data collection ($2\theta_{max}$ = 60°, 148 frames via 1.9° ω rotation and 13 s per frame, index ranges 0 ≤ h ≤ 23, 0≤ k ≤ 14, −23 ≤ l ≤ 22) gave 19547 reflections.[19] The data reduction led to 7952 independent reflections from which 6891 had $I > 2\sigma(I)$. The structure was solved with SIR-97 which revealed the non hydrogen atoms.[20] After anisotropic refinement, many hydrogen atoms may be found with Fourier difference calculations. The whole structure was refined with SHELXL97 by full-matrix least-squares methods on F^2 [x, y, z, β_{ij} for Ru, P, Cl, O, C and N atoms; x, y, z in riding mode for H atoms; $w = 1/[\sigma^2(F_0^2) + (0.038P)^2 + 1.72P]$ where $P = (F_0^2 + 2F_c^2)/3$ with the resulting R = 0.029, wR = 0.075 and S = 1.071 (residual around solvent molecules); minimum and maximum final electron density: −0.619 and 0.695 eÅ^{-3}].[21] ORTEP views were prepared with PLATON98.[22]

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-165881. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation and Properties of Rh^I and Ir^I Ethylene Complexes Containing the Chiral *P,N*-Chelate Ligand (4*S*)-2-[2-(Diphenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline

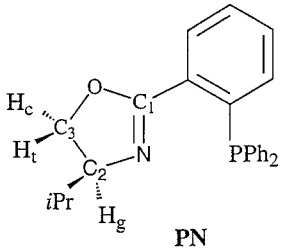
Daniel Carmona,*[a] Joaquina Ferrer,[a] Elena Lalaguna,[a] Mónica Lorenzo,[a] Fernando J. Lahoz,[a] Sergio Elipe,[a] and Luis A. Oro[a]

Keywords: N,P ligands / Chirality / NMR spectroscopy / Alkene ligands / Iridium / Rhodium

The synthesis and characterization of the chiral complexes [MCl(η^2-C_2H_4)(PN)] [M = Rh (**1**), Ir (**2**)] and [IrCl(η^2-C_2H_4)$_2$(PN)] (**3**) {PN = (4*S*)-2-[2-(diphenylphosphanyl)-phenyl]-4-isopropyl-1,3-oxazoline}, including the X-ray crystal structure of **2**, are reported. The solution behavior has been studied by NMR spectroscopy. For the rhodium complex **1** it is shown that a rotation of the olefin about the Rh-midpoint of the ethylene axis must be operating in solution at ambient temperature. The iridium analogue **2** is, however, stereochemically rigid and interconverts in solution, in the presence of ethylene, with the bis-ethylene derivative **3**.

Introduction

Many important enantioselective catalytic reactions employ transition metal complexes with chiral ligands as catalysts.[1] In this context, chiral chelate phosphino−oxazoline ligands have recently proven to be useful in the control of the enantioselectivity of various metal-catalyzed asymmetric reactions.[2] The pronounced difference in electronic as well as steric properties between the two chelating atoms (hard N and soft P) has been shown to be the key to these reactions. Most of the published work in this field focuses on the catalytic aspects of the reactions and, in some instances, the involved metallic species have not been fully characterized. For example, although mixtures of chiral phosphino−oxazoline ligands and different diolefin rhodium(I) complexes have been successfully applied as catalysts in the hydrosilylation of ketones, the potentially active complexes formed have not been characterized.[2a−2c] Analogously, asymmetric allylic alkylations have been carried out using catalysts prepared in situ from [Ir(μ-Cl)(cod)]$_2$ and phosphino−oxazoline ligands.[2d] However, the crystal structure of a cationic iridium complex [Ir(cod)(PN)]$^+$ {PN = (4*S*)-2-[2-(diphenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline, Figure 1} − an efficient catalyst for the enantioselective hydrogenation of prochiral imines − has been determined by X-ray diffraction.[2e] In the present paper, we report the preparation, characterization, and NMR spectroscopic properties of the new rhodium(I) and iridium(I) ethylene complexes [RhCl(η^2-C_2H_4)(PN)] (**1**) and [IrCl(η^2-C_2H_4)$_n$(PN)] [*n* = 1 (**2**), 2 (**3**)] containing the chelating enantiopure ligand PN. In the rhodium complex **1** the ethylene is fluxional. Three motions can be envisaged for coordinated ethylene: i) rotation about the metal−alkene bond, ii) rotation about the carbon−carbon bond, and iii) alkene dissociation.[3] The spectroscopic data indicated that, whereas the olefin rotation takes place at an intermediate rate at room temperature, the intermolecular exchange of ethylene is very slow.



PN

Figure 1. (4*S*)-2-[2-(diphenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline (PN)

Results and Discussion

The reaction of the dimers [M(μ-Cl)(η^2-C_2H_4)$_2$]$_2$ (M = Rh,[4] Ir[5]) with PN, in a 1:2 molar ratio, led to an orange precipitate which was analyzed as [MCl(η^2-C_2H_4)(PN)] [M = Rh (**1**), Ir (**2**)]. However, when the mononuclear tetrakis(ethylene)iridium(I) complex [IrCl(η^2-C_2H_4)$_4$][5] was reacted in diethyl ether with PN (1:1 molar ratio, 20 °C), a

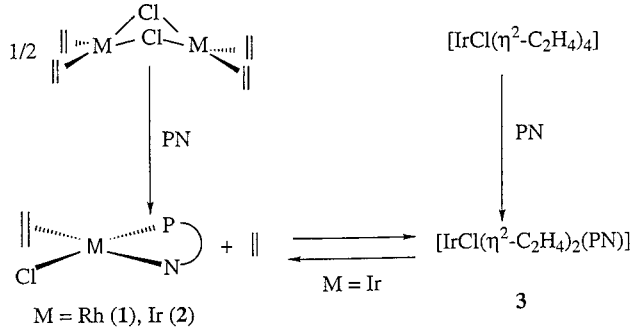
mixture of the mono- (**2**) and the bis(ethylene) complex [IrCl(η^2-C_2H_4)$_2$(PN)] (**3**) was obtained instead (Scheme 1). Complexes **1** and **2** decomposed slowly as solids, even under an atmosphere of ethylene, over a period of a few days and did so more rapidly in solution (several hours). In solution, at temperatures higher than −10 °C, the pentacoordinate adduct **3** is also unstable to the loss of ethylene.



Scheme 1

Only one set of signals was observed in the NMR spectra of compounds **1** and **2**, indicating that, in both cases, one single geometrical isomer exists in solution. The $^{13}C\{^1H\}$ NMR spectrum of the rhodium complex **1**, measured in $CDCl_3$ at −40 °C, showed two doublets at δ = 58.81 and 53.48 for the ethylene carbons, with $^1J_{RhC}$ coupling constants of 14.7 and 11.5 Hz, respectively.[6] Because no $^{13}C-^{31}P$ coupling was observed, we assume that the olefin and the phosphorus atom of the phosphino−oxazoline ligand occupy positions mutually *cis*. NOE measurements at −80 °C in CD_2Cl_2 showed interactions between the ethylene protons at ca. δ = 3.32 and some of the phenyls protons of the phosphino−oxazoline ligand. However, no NOE enhancement of the ethylene protons was observed when the CH_3 protons of the isopropyl oxazoline group were irradiated. These NOE data support the above-mentioned *cis* disposition. In the case of the iridium complex **2**, two sharp singlets at δ = 44.90 and 38.11 were observed, at ambient temperature, for the C_2H_4 carbons. Furthermore, the ^{13}C and ^1H NMR spectra of complex **1** showed a temperature dependence for the signals of the ethylene ligand, clearly indicating fluxionality: in the ^{13}C NMR spectrum, at room temperature, only one broad signal centered at ca. δ = 55.9 (line-width at half-height of 150 Hz) appeared for the C_2H_4 carbons, while the other peaks remained sharp. Upon heating to 45 °C (the rate of ethylene loss precluded measurements at higher temperatures) this signal becomes sharper indicating the equivalence of the two carbons.

The ^1H NMR spectra provided additional information about the behavior of the molecules in solution. Thus, at room temperature, the four ethylene protons of the rhodium complex **1** gave rise, in deuterated chloroform, to a broad resonance centered at ca. δ = 3.0 (line-width at half-height of 150 Hz), which progressively sharpened upon heating (line-width at half-height of 75 Hz at 45 °C). Unfortunately, a sharp time-averaged spectrum was not obtained. On cooling to −40 °C, the broad signal resolved into three broad humps centered at ca. δ = 3.32, 2.25 and 2.08, with respective integrals of 2, 1, and 1 protons. On the other hand, at room temperature, the signal of added ethylene,[7] at ca. δ = 5.4, showed only a slight broadening (line-width at half-height of 24 Hz), indicating that the exchange equilibrium between **1** and free ethylene is slow. An estimate of the barrier for the fluxional process in **1** gives a value of about 54 kJ·mol^{-1}, obtained as the resonances begin to broaden above the limiting low-temperature spectrum.[8] This value is similar to those found for other 16-electron square-planar rhodium(I) or platinum(II) ethylene derivatives such as [Rh(acac)(η^2-C_2H_4)$_2$] (51.3 kJ·mol^{-1})[9] or [Pt(acac)X(η^2-C_2H_4)] [X = Cl (52.3 kJ·mol^{-1}),[10] Br (53.1 kJ·mol^{-1}),[11] in which the fluxional mechanism has been proposed to be the rotation of the olefin about the metal-centroid of the olefin axis. The encountered value for the activation energy definitively ruled out the possibility of intermolecular exchange of the ethene molecule as the main fluxional process because the rhodium−ethylene bond dissociation energy has been measured as ca. 130 kJ·mol^{-1}.[12] On the other hand, a rotation about the carbon−carbon double bond axis would disrupt the coordination bond and the expected energy requirements would be therefore greater than the 54 kJ·mol^{-1} observed.[13] Consequently, to account for the equilibration of the protons and the carbons of the olefin in the rhodium complex, an intramolecular restricted rotation about the rhodium−alkene bond must be operating. The unequivocal detection of this mode of rotation (through the ^{13}C NMR measurements) was facilitated by the chirality of the PN ligand. It should be noted that in symmetrical, nonrigid, square-planar ethylene complexes it is not possible to distinguish between the two intramolecular motions because it is invisible to conventional spectroscopic probes, whereas experiments using complexes with chiral centers allow the distinction between rotation about the metal−alkene or the carbon−carbon axes.

For the iridium complex [IrCl(η^2-C_2H_4)(PN)] (**2**), ^1H NMR measurements revealed that the fluxional movement of the ethylene ligand was slowed down since its proton resonances appeared invariantly as three broad peaks at δ = 2.80, 2.02 and 1.67 (2,1,1 protons, respectively) from ambient temperature to 45 °C. At room temperature, its ^{31}P NMR spectrum consisted of a narrow singlet at δ = 9.42. Ethylene rotation barriers are usually higher in Ir^I compounds than in their Rh^I analogues. Thus, for example, the reported ethylene rotation barrier for [(η^5-C_5H_5)Rh(η^2-C_2H_4)$_2$][14] is 65.6 kcal mol^{-1}, while it is 80.7 kJ·mol^{-1} for the analogous iridium complex;[15] as in our case, no rotation has been observed for related penta- or tetracoordinated complexes of Ir^I.[16] Although it is not clear how the metal and alkene characteristics may affect the relative importance of the σ and the π back-donation,[17] the more basic iridium atom will most probably give rise to a stronger metal−ligand π-interaction. The stronger back-donation to the empty π* orbitals of the ethylene will additionally weaken the C=C bond, and this may be a plausible explanation for the higher barrier for the rotation of the olefin observed in the iridium complexes.

As stated above, the bis(ethylene)iridium complex **3** loses ethylene above −10 °C to form complex **2**. The ^{31}P NMR spectrum of CD_2Cl_2 solutions of **3**, at ambient temperature, displayed a broad signal centered at δ = 8.9 (linewidth at half-height of 73 Hz). This signal sharpened progressively as the temperature increased and became sharp at 45 °C. Below −20 °C, the singlet splits into two broad signals of approximately the same intensity centered at δ = 9.4 and 0.4. The relative intensity of these signals changes with temperature, the amount of the resonance at higher field increasing as the temperature decreases. Thus, at −40 °C the ratio (signal at ca. δ = 9.4 to signal at ca. δ = 0.4) was 2:8 and at −90 °C, 1:9. When ethylene was bubbled through the mixture at −40 °C (2 min) the resonance centered at ca. δ = 9.4 disappeared, whereas the signal at ca. δ = 0.4 remained. Removal of the ethylene atmosphere, by passing a stream of argon, regenerated the signal at δ = 9.4. A reversible equilibrium [Equation (1)] between species **2** (δ = 9.43, −40 °C) and **3** (δ = 0.35, −40 °C) can explain all these observations. As expected, bubbling ethylene or lowering the temperature displaces equilibrium 1 to the right and vice versa.

$$\underset{\mathbf{2}}{[IrCl(\eta^2\text{-}C_2H_4)(PN)]} + C_2H_4 \rightleftharpoons \underset{\mathbf{3}}{[IrCl(\eta^2\text{-}C_2H_4)_2(PN)]} \quad (1)$$

Recently, Milstein et al.[16b] reported that in the related $[IrCl(\eta^2\text{-}C_2H_4)_2L_2]/[IrCl(\eta^2\text{-}C_2H_4)L_2]$ (L = PEt_3) system, the bis(ethylene) adduct is more stable than the mono(ethylene) one. As the authors stated, the strong electron-donating character of the PEt_3 ligands could stabilize the pentacoordinated species. In good agreement with this proposal is the fact that, in the analogous PPh_3 system, the bis(ethylene) adduct is unstable to the loss of ethylene at temperatures higher than −50 °C.[18] Therefore, our results are in agreement with the expected intermediate electron-donating properties of the PN ligand.

We have carried out a crystal X-ray diffraction study of complex **2** in order to establish unambiguously the proposed structure. A molecular representation of the molecule is shown in Figure 2. Selected bond lengths and angles are given in Table 1.

The principal structural feature of **2** is the square-planar geometry about the iridium atom with the coordinated ethylene molecule nearly perpendicular to the best PN−Ir−Cl plane and *cis* to the phosphorus atom of the phosphino−oxazoline, as indicated by the spectroscopic data. As is usually observed in square-planar olefin complexes, the structure shows some deviation from ideal symmetry[19] [max. dev. 0.125(1) Å out of coordination plane for Cl atom]. The ethylene C−C bond is inclined at 84.7(3)° to the coordination plane and its center is 0.044(6) Å out of this plane. The C=C bond length is 1.392(8) Å, quite similar to the bond length found in the closely related square-planar Ir^I−ethylene complex *trans*-$[IrCl(\eta^2\text{-}C_2H_4)(PPh_3)_2]$ [1.376(10) Å][19] and compares well with the range of other reported Ir^I−ethylene complexes [1.35−1.47 Å, mean value 1.411(3) Å].[20] The PN ligand and the iridium atom form a six-membered chelate ring, puckered towards a screw-boat conformation[21] [Q = 0.604(3), F = 19.0(5)°, q = 61.8(5)°], with all three carbon atoms situated above the plane of the complex.

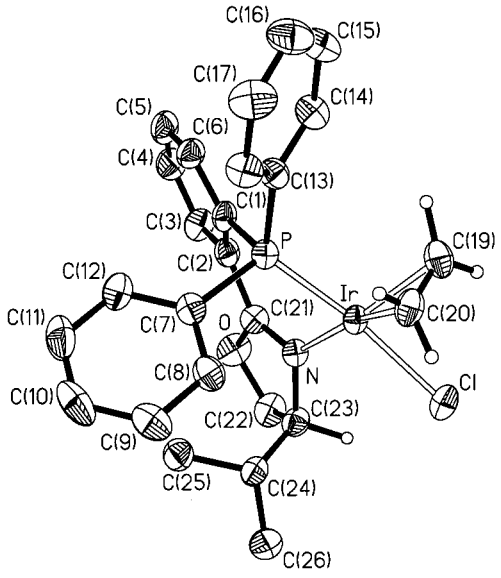


Figure 2. A molecular representation of complex **2** showing the atomic labelling scheme used; hydrogens are shown for the ethylene ligand and the asymmetric carbon of the oxazoline ligand

Table 1. Selected bond lengths (Å) and angles (°) for complex **2**

Experimental Section

General Comments: The compounds described herein were handled with exclusion of air by using standard Schlenk techniques. All solvents were dried by known procedures and distilled under argon prior to use. NMR spectra were recorded on a Varian UNITY, a Varian Gemini 2000, or a Bruker ARX 300 MHz spectrometers. Chemical shifts (δ values) are given relative to TMS (^1H and ^{13}C) or to 85% H_3PO_4 aqueous solution (^{31}P). Coupling constants (J) are given in Hertz. For proton and carbon labelling, see Figure 1. Infrared spectra were recorded as Nujol mulls on polyethylene sheets using a Nicolet 550 spectrometer. The C, H and N analyses were performed on a Perkin−Elmer 2400 CHNS/O analyzer. The precursors $[Ir(\mu\text{-}Cl)(\eta^2\text{-}C_8H_{14})_2]_2$,[22] $[M(\mu\text{-}Cl)(\eta^2\text{-}C_2H_4)_2]_2$ (M = Rh, Ir)[4,5] and $[IrCl(\eta^2\text{-}C_2H_4)_4]$[5] and the ligand (4*S*)-2-[2-(di-

phenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline (PN)[23] were prepared according to published procedures.

Synthesis of [RhCl(η²-C_2H_4)(PN)] (1): A solution of PN (237 mg, 0.634 mmol) in dichloromethane (2 mL) was added to a suspension of [Rh(μ-Cl)(η²-C_2H_4)$_2$]$_2$ (124 mg, 0.319 mmol) in diethyl ether (10 mL) at ambient temperature under argon. After 1 h, the resulting solution was concentrated to ca. 5 mL and a solid precipitated. The solvent was removed with a syringe and the solid residue washed with cold Et_2O and dried in vacuo to give **1** as an orange powder. Yield 285 mg (83%). Solid **1** must be stored under ethylene at 4 °C. $C_{26}H_{28}ClNOPRh$ (539.57): calcd. C 57.87, H 5.23, N 2.59; found C 57.85, H 5.37, N 2.44. ^{1}H NMR ($CDCl_3$, room temp.): δ = 8.00−6.98 (m, 14 H, Ph's of PN), 5.46 (ddd, *J* = 2.7, 5.5, 8.7, 1 H, H_g of PN), 4.26 (m, 2 H, H_c and H_t of PN), 2.45 (dsept, *J* = 2.7, 7.0, 1 H, C*H*Me$_2$ of PN), 3.01 (br. s, 4 H, C_2H_4), 0.79 (d, *J* = 7.0, 3 H, Me of PN), 0.05 (d, *J* = 7.0, 3 H, Me of PN). ^{13}C NMR ($CDCl_3$, −40 °C): δ = 161.79 (d, J_{PC} = 7.8, C_1 of PN), 135.2−126.9 (m, Ph's of PN), 70.43 (s, C_2/C_3 of PN), 67.79 (s, C_3/C_2 of PN), 58.81 (d, $^1J_{RhC}$ = 14.71, C_2H_4), 53.48 (d, $^1J_{RhC}$ = 11.54, C_2H_4), 30.83 (s, *C*HMe$_2$ of PN), 18.86 (s, Me of PN), 12.83 (s, Me of PN). ^{31}P NMR ($CDCl_3$, room temp.): δ = 52.5 (d, $^1J_{RhP}$ = 177). IR: ν(CN) 1616 cm^{-1}; ν(CO) 1242 cm^{-1}.

Synthesis of [IrCl(η²-C_2H_4)(PN)] (2): Under argon, a red suspension of the bis(ethylene)iridium(I) dimer [Ir(μ-Cl)(η²-C_2H_4)$_2$]$_2$ [5b] (75 mg, 0.132 mmol) in diethyl ether (15 mL) was cooled to −20 °C and PN was added (98 mg, 0.262 mmol). A deep red solution was immediately formed and after a short time a red powder precipitated. After stirring the solution for one hour, solid **2** was filtered off, washed with diethyl ether and dried in vacuo. Yield 116 mg (70%). Complex **2** must be stored under ethylene at 4 °C. $C_{26}H_{28}ClIrNOP$ (629.11): calcd. C 49.64, H 4.48, N 2.23; found C 50.24, H 4.74, N 2.02. ^{1}H NMR ($CDCl_3$, room temp.): δ = 8.07−7.01 (m, 14 H, Ph's of PN), 5.72 (m, *J* = 2.7, 1 H, H_g of PN), 4.32 (m, 2 H, H_c and H_t of PN), 2.49 (dsept, *J* = 2.7, 7.0, 1 H, C*H*CMe$_2$ of PN), 2.80 (br. s, 2 H, C_2H_4), 2.02 (br. s, 1 H, C_2H_4), 1.67 (br. s, 1 H, C_2H_4), 0.81 (d, *J* = 7.0, 3 H, Me of PN), 0.16 (d, *J* = 7.0, 3 H, Me of PN). ^{13}C NMR ($CDCl_3$, room temp.): δ = 162.10 (d, J_{PC} = 5.96, C_1 of PN), 137.0−127.0 (m, Ph′s of PN), 70.58 (s, C_2/C_3 of PN), 68.35 (s, C_3/C_2 of PN), 44. 90 (s, C_2H_4), 38.11 (s, C_2H_4), 31.09 (s, *C*HMe$_2$ of PN), 18.66 (s, Me of PN), 13.32 (s, Me of PN). ^{31}P NMR ($CDCl_3$, room temp.): δ = 9.42 (s). IR (Nujol): ν(CN) 1616 cm^{-1}; ν(CO) 1245 cm^{-1}.

Preparation of a Mixture of [IrCl(η²-C_2H_4)(PN)] (2) and [IrCl(η²-C_2H_4)$_2$(PN)] (3): Ethylene was bubbled through a pale orange suspension of [Ir(μ-Cl)(η²-C_8H_{14})$_2$]$_2$ (100 mg, 0.112 mmol) in diethyl ether (5 mL) at −20 °C. After stirring for 15 min, PN (83 mg, 0.222 mmol) was added to the resulting colorless solution containing the tetrakis(ethylene)iridium(I) [IrCl(η²-C_2H_4)$_4$]. After 20 min stirring, an orange solid precipitated which was filtered off under an argon atmosphere and dried in vacuo. The solid obtained was characterized as a mixture of **2** and **3**.

3: ^{1}H NMR (CD_2Cl_2, −90 °C): δ = 8.40−6.90 (m, 14 H, Ph's of PN), 5.56 (m, 1 H, H_g of PN), 4.55 (m, 2 H, H_c and H_t of PN), 2.72 (br. s, 1 H, C_2H_4), 2.63 (br. s, 1 H, C_2H_4), 2.44 (m, 2 H, C*H*CMe$_2$ of PN and 1 H of C_2H_4), 2.22 (br. s, 1 H, C_2H_4), 2.04 (br. s, 2 H, C_2H_4), 1.74 (br. s, 2 H, C_2H_4), 0.90 (br. s, 3 H, Me of PN), 0.83 (br. s, 3 H, Me of PN). ^{31}P NMR (CD_2Cl_2, −90 °C): δ = 0.40 (s).

Crystallographic Data Collection and Refinement of the Structure: Crystals suitable for X-ray diffraction were grown by slow diffusion of pentane into a solution of **2** in dichloromethane under an ethylene atmosphere; a red irregular block (0.36 × 0.38 × 0.42 mm) was glued to the end of a glass fiber and mounted on a four-circle diffractometer (Siemens P4) working with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and operating at 173 K. A summary of crystal data, intensity collection procedure, and refinement parameters for the structural analysis is reported in Table 2. Precise lattice parameters were determined by a least-squares fit from 64 centered reflections in the region 25 ≤ 2θ ≤ 38°. Three standard reflections were monitored every 97 measured reflections to check crystal and instrument stability throughout data collection; no significant variations of the intensities were observed. All data were corrected for Lorentz and polarization effects, and a semiempirical (ψ-scan method) absorption correction was also applied.[24] The structure was solved by Patterson and conventional Fourier techniques, and refined by full-matrix least-squares methods on F^2 (SHELXL-97)[25] with initial isotropic thermal parameters. Anisotropic thermal parameters were used in the last cycles of refinement for all non-hydrogen atoms. The hydrogen atoms of the methyl groups were included in calculated positions (C−H = 0.98 Å), and the remaining hydrogens were located in difference Fourier maps; all were included in the refinement riding on their respective carbon atom with four different common isotropic thermal parameters for the distinct types of H atoms. The absolute structure was estimated by the refinement of the Flack parameter, *x* = −0.006(7).[26] Atomic scattering factors, corrected for anomalous dispersion for heavy atoms, were taken from ref.[27] Crystallographic data for the structure reported in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-167640. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44−1223/336−033; Email: deposit@ccdc.cam.ac.uk].

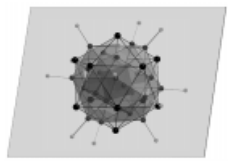
COVER PICTURE



The cover picture shows the penetrating polyhedra of copper and tellurium atoms that are found in the molecular structure of the mixed-valence copper telluride cluster $[Cu_{26}Te_{12}(PEt_2Ph)_{12}]$ (copper atoms: blue; tellurium atoms: black; phosphorus atoms: green; organic groups omitted). Polyhedral substructures are very often found in the cluster frameworks of small or middle-sized, phosphane-ligated copper chalcogenide clusters, since highly symmetric atomic arrangements play a key role in the formation of the most stable isomers. Another approach tomeet the symmetry requirements is realized by large $[Cu_{2n}E_n(PR_3)_m]$ clusters (E = S, Se, Te) that adopt layer-type molecular structures when $2n$ is 70 or more. Hence, they denote the transition to the structural features of binary copper chalcogenide phases. The structural properties of copper sulfide, copper selenide and copper telluride clusters that were developed from single-crystal X-ray analyses, as well as the results of further physico-chemical or quantum-chemical investigations on these substances, are comprehensively discussed in the microreview by D. Fenske et al.

Chalcogen-Bridged Copper Clusters

Stefanie Dehnen,[a] Andreas Eichhöfer,[b] and Dieter Fenske*[a]

Dedicated to Professor Günter Schmid on the occasion of his 65th birthday

Keywords: Copper / Sulfur / Selenium / Tellurium / Clusters

The investigation of coinage metal molecular clusters bridged by chalcogen atoms represents an area of ever increasing activity in recent chemical and material science research. This is largely due to the relatively high ionic and even higher electric conductivity of binary coinage metal chalcogenides, which leads to properties intermediate between those of semiconducting and metallic phases. In addition, the size-dependency of the chemical, physical, and structural properties of substances on going from small molecules to bulk materials is of general interest. Approaches towards the synthesis and investigation of such clusters have included the study of colloidal nanoparticles with a narrow size distribution, as well as the formation and isolation of crystalline cluster compounds amenable to structural determination by single-crystal X-ray diffraction analysis. Irrespective of the chosen synthesis route, the molecules have to be kinetically protected from decomposition to the thermodynamically favored binary phases by a suitable ligand sphere, often consisting of tertiary phosphane molecules, or a combination of phosphanes and organic groups. In this report, we concentrate on the syntheses and structural as well as physical properties of ligand-stabilized, chalcogen-bridged copper clusters, which have been comprehensively studied by means of experimental and quantum chemical investigations.

1. Introduction

The synthesis of chalcogen-bridged molecular clusters of the coinage metal elements represents an area of ever increasing activity in recent chemical and material science research. This can be mainly ascribed to two aspects. Firstly, binary coinage metal chalcogenides exhibit relatively high

Andreas Eichhöfer (left) was born in Hünfeld, Germany, in 1964. He received his diploma in 1991, and subsequently graduated in 1993 in the group of Prof. D. Fenske at the university of Karlsruhe with a doctoral degree on metal-phosphorous cluster complexes. He then moved to the group of Prof. G. Fritz at the same institute to work on carbosilanes as precursor compounds for the fabrication of SiC fibers. After that he returned to his previous group and became a research scientist at the Institute of Nanotechnology at the Forschungszentrum Karlsruhe in 1999, where he is currently investigating the syntheses and properties of semiconductor cluster compounds.

Stefanie Dehnen (center) was born in Gelnhausen, Germany, in 1969. She obtained her diploma from the University of Karlsruhe in 1993 and her doctoral degree in 1996 under the supervision of Prof. D. Fenske on experimental and theoretical investigations of copper sulfide and copper selenide clusters. After a postdoctoral stay with Prof. R. Ahlrichs (1997) she returned to the inorganic chemistry department at the University of Karlsruhe where she is presently preparing her Habilitation. In 1997, she was awarded a Feodor-Lynen-Stipendium of the Alexander-von-Humboldt-Stiftung, and in 1998, she received a Margarete-von-Wrangell-Habilitations-Stipendium of the state of Baden-Württemberg. Her current research interests comprise the synthesis, structural elucidation and chemical reactivity of binary or ternary polyanions of main group elements.

Dieter Fenske (right) was born in Dortmund, Germany, in 1942. He studied chemistry at the University of Münster where he also received his doctoral degree in 1973 with Prof. H. J. Becher. After the completion of his Habilitation at the University of Münster in 1978, he became Professor of Inorganic Chemistry at the University of Karlsruhe in 1981. Five years later, he was offered a Chair of Inorganic Chemistry at the University of Frankfurt, from where he returned to the University of Karlsruhe in 1988 to become Chair of Inorganic Chemistry. He received offers for the same position from the Universities of Marburg and Münster and is a laureate of the Leibniz Award and the Wilhelm Klemm Award. In 1998 he became Director of the Institute of Nanotechnology at the Forschungszentrum Karlsruhe. His research field concerns the synthesis, structures, and properties of main group element-bridged clusters of transition metals, especially group 8–10 elements.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ionic[1] and even higher electric[2] conductivity in the solid state, leading to properties intermediate between those of semiconducting and metallic phases. Secondly, the size-dependence of the chemical, physical, and structural properties of substances on going from small molecules to bulk materials is of general interest.[3] Several research groups have concentrated on the synthesis and properties of colloid nanoparticles with narrow cluster size distributions.[4] Another approach is the formation and isolation of crystalline cluster compounds suitable for single-crystal X-ray diffraction analysis. In both cases, the molecules have to be kinetically protected from further reaction to the thermodynamically favored binary phases. Therefore, a ligand sphere coordinating to the outer metal or chalcogen atoms is necessary; in most cases this consists of tertiary phosphane molecules or a combination of phosphanes and organic groups.

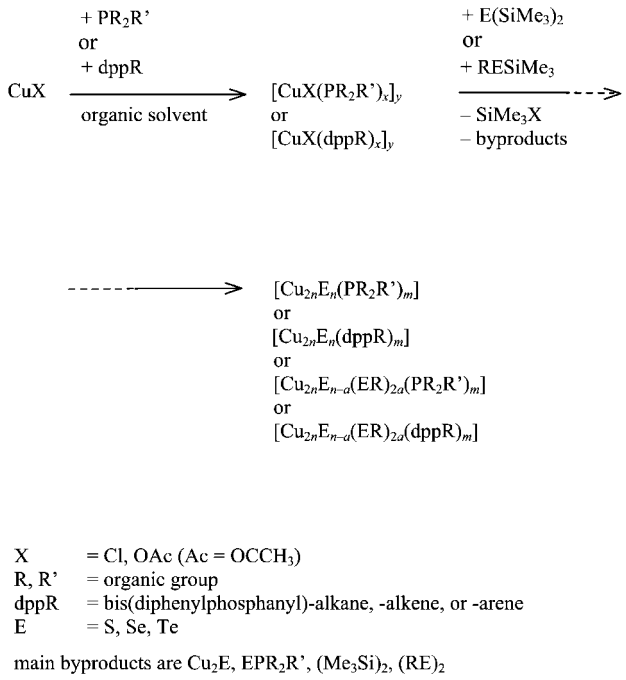
In this paper, we focus on ligand-stabilized, chalcogen-bridged copper clusters, which have hitherto been the most frequently studied. Experimental[5−33] and quantum chemical[34−37] investigations have been undertaken during the last decade in order to study the transition from the definitely non-metallic Cu_2E monomer (E = S, Se, Te) to the bulk Cu_2E.[38−40] From a synthetic point of view, the most important result was the elucidation of the close relationship between the chosen reaction conditions and the formation of the desired products, together with the use of this knowledge in the synthesis of different cluster types.[9−31] Furthermore, the great number of isolated and structurally characterized cluster compounds and the comprehensive computational work[34−37] in this area has allowed the delineation and rationalization of size-dependent structure principles for these molecules. Last but not least, various calculations and measurements have been carried out to obtain insights into the physical properties of the cluster materials.[32,33]

2. General Synthetic Routes

The compounds are − with some exceptions − highly air- and moisture-sensitive. Therefore, all reaction steps have to be carried out under strict exclusion of air and moisture in a high purity dried nitrogen atmosphere by employing standard Schlenk-line techniques on a double-manifold vacuum line. All solvents must be dried and freshly distilled prior to use.

Most chalcogen-bridged copper compounds have been synthesized according to the following general reaction pathway and possess one of the given formulae (Scheme 1).

The CuX-to-phosphane ratio, the counterion X of the copper salt, and especially the nature of the phosphane used, are very important. In the first step, the phosphane complexes the copper salt to generate a reactive species, the reactivity of which can be subtly regulated by the choice of X and PR_2R'. Furthermore, the driving force of the reactions is the formation of thermodynamically stable $SiMe_3X$ and can thus be controlled by the choice of X according to



Scheme 1. General synthetic route for the formation of phosphane-ligated chalcogen-bridged copper clusters

the bond strength of the Si−X bond.[41] Finally, the steric demand of the PR_2R' molecules on the cluster surface − as measured by Tolman's cone angle θ[42] (see Table 1) − is related, although not linearly, to the final size and shape of the copper chalcogenide core.

Table 1. Values of Tolman's cone angle θ for phosphanes PR_2R' used in the syntheses of copper chalcogenide clusters (ref.[42])

PR_2R'	θ [°]
PMe_2Ph	127
PEt_3	132
$PnPr_3$	132
PEt_2Ph	136
$PPhnPr_2$	136
$PEtPh_2$	141
PPh_2nPr	141
PPh_3	145
$PMeiPr_2$	146
$PCyPh_2$	153
$PiPr_3$	160
$PtBu_2Me$	161
$PnButBu_2$	165
PCy_3	170
$PtBu_3$	182

In addition, other reaction conditions such as the chosen solvent, the reaction temperature, or the temperature program strongly influence the course of the synthesis. It has been shown that, under similar reaction conditions, the use of derivatives $RE(SiMe_3)$ (R = organic group) leads to the formation of completely different structures to those reactions employing $Se(SiMe_3)_2$. The reason for this is the different reactivity of the reactants as well as partly incomplete Se−C bond cleavage. Thus, some RE^- fragments are bound

at the periphery of the cluster framework, acting as terminal ligands in addition to the phosphane groups.

Regarding the given general formula of the products, the copper atoms can be assigned a formal charge of 1+ while the chalcogen ligands are formally viewed as E^{2-} or RE^{-} groups. However, some of the selenium-bridged species and many copper telluride clusters form non-stoichiometric compounds that display mixed-valence metal centers, leading either to an overall electron deficiency or an electron excess. This corresponds to observations made for the binary phases Cu_2S, $Cu_{2-x}Se$, and $Cu_{2-x}Te$.[38−40]

Even though most ligated copper chalcogenide clusters have been prepared as described herein, it should be mentioned that other synthetic routes to ligated or "naked" $[Cu_{2n}E_n]$ cluster compounds have been studied. Besides syntheses in solvent environments[5−31] that led to the formation of, for example, $[PhMe_3As]_4[Cu_8\{S_2C_2(CN)_2\}_6]$,[5] $(Me_4N)_2[Cu_5(SPh)_7]$,[6] $(Ph_4P)_4[Cu_{12}S_8]$,[7] or $[Cu_6\{Se(2,4,6\text{-}iPr_3C_6H_2)\}_6]$,[8] ligand-free particles have been obtained and characterized by means of laser ablation techniques in combination with mass spectrometry.[32]

3. Synthesis Details, Molecular Structures, and Stabilities

3.1. Sulfur-Bridged Copper Clusters

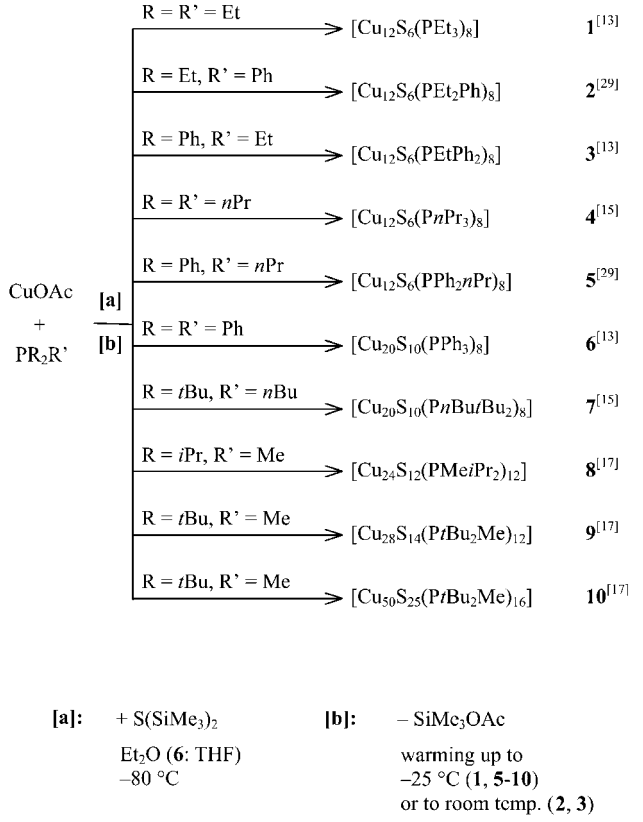
3.1.1. Syntheses

The reactions yielding the phosphane-ligated, sulfur-bridged copper clusters that have been isolated and structurally characterized to date are summarized in Scheme 2, in order of increasing cluster size.

Sulfur-bridged clusters could not be obtained by reactions starting from copper halides. The reason for this is the lower reactivity of primary copper acetate-phosphane complexes compared to the analogous halide complexes, as a result of the chelating acetate ligands that can be displaced in a double-step substitution of selenium ligands for oxygen.[43] Reactants of higher reactivity lead directly to the formation and precipitation of Cu_2S, even at low temperatures. The kinetic restrictions at the beginning of the synthesis are in addition to those at the end of the cluster growth. The phosphane molecules have to provide a certain minimum steric demand and it has not yet proved possible to generate sulfur-bridged copper clusters with PMe_3 ligands.

3.1.2. Structures and Stabilities

Half of the total number of known copper sulfide clusters have the general formula $[Cu_{12}S_6(PR_2R')_8]$, which represents the smallest known copper chalcogenide $[Cu_{2n}E_n]$ cluster core (**1**−**5**).[13,15,18] The respective molecular structures correspond to one of two possible isomers that can both be derived from a highly symmetric polyhedron of metal and chalcogen atoms. The highly symmetrical conformation is the reason for the strong preference for "Cu_{12}" species. An



Scheme 2. Survey of the synthesis of sulfur-bridged copper clusters protected by terminal phosphane ligands

S_6 octahedron is penetrated by a Cu_{12} cubooctahedron. However, the latter is distorted as a result of the coordination of the phosphane ligands, as there is only enough space for eight rather than twelve phosphane molecules at the cluster surface within a reasonable Cu−P bond length. Different distributions of the terminal ligands with respect to the cubooctahedron atoms lead to the formation of isomers I or II, respectively. Both cluster structures, as well as a computed hypothetical "naked", undistorted $[Cu_{12}S_6]$ core,[35] are shown in Figure 1.

In the "Cu_{12}" clusters, two coordination modes of the copper atoms can be observed. The four copper atoms that are not bound by phosphane ligands are almost linearly coordinated by sulfur atoms and are positioned either in the equatorial Cu_4 ring of the cubooctahedron (I) or two each reside in the top and bottom Cu_4 planes (II). The eight remaining copper atoms bound by the PR_2R' groups are surrounded in an almost trigonal-planar manner by two sulfur neighbors and one phosphorus atom. The phosphane molecules can be thought of as "pulling" their respective metal atoms out of the basic Cu_{12} polyhedron, whereas the "naked" copper atoms are slightly displaced towards the cluster center. All the sulfur ligands act as μ_4-bridges between copper atoms. In molecules of type I, the eight phosphorus atoms are arranged around the cluster surface so as to form an approximate cube, whereas in the other isomer, if the phosphorus atoms are formally linked, a P_8 Δ-dodecahedron is obtained. Both arrangements are among the most stable polyhedra of eight points on the surface of a sphere.

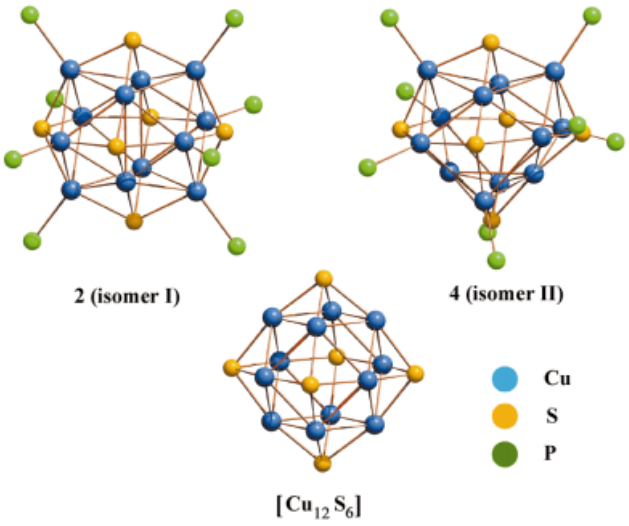


Figure 1. Molecular structures of $[Cu_{12}S_6(PEt_2Ph)_8]$ (**2**) and $[Cu_{12}S_6(PnPr_3)_8]$ (**4**) (without organic groups) and of a calculated "naked" $[Cu_{12}S_6]$ core

Quantum chemical investigations with the program system TURBOMOLE,[44,45] employing MP2[46] and DFT[47] methods, were carried out assigning the highest possible symmetry in order to explain the obvious experimental preference for type I clusters over those of type II.[36] For model ligands PH_3 (MP2 and DFT; highest possible symmetry: D_{4h} for type I or S_4 for type II), both structures representing local minima on the energy hypersurface were found to be isoenergetic within the limits of the methods used. On calculating clusters $[Cu_{12}S_6(PR_3)_8]$ with R = Et or R = Pr according to both structural isomers (DFT; highest possible symmetry: C_{4h} or S_4), i.e. one real (**1**, **4**) and one hypothetical species each, one does not find a direct correlation between the substituents on the phosphorus atoms and the thermodynamic stabilization. Thus, further kinetic effects such as solubility and mobility of the organic groups at the experimental temperatures (>> 0 K) probably play key roles in the choice of isomers. The fact that the same cone angle values are found for PEt_3 and $PnPr_3$ underlines this conclusion (see Table 1).

Another pair of isomers is formed in the presence of the sterically more demanding phosphanes PPh_3 or $PnButBu_2$, where there are 20 copper atoms in the cluster framework.[13,15] The respective molecular structures of **6** (type I) and **7** (type II) are shown in Figure 2.

Again, the positions of the eight Cu−P groups determine the shapes of the clusters, the cores of which can be regarded as distortions of the formal condensation product of two of the $Cu_{12}S_6$ units shown in Figure 1. This relationship is particularly clear when "Cu_{12}" and "Cu_{20}" clusters of type I are compared. After the loss of one apical sulfur ligand and four phosphane molecules from each, as well as one Cu_4 ring, a $[Cu_8S_5(PR_3)_4]$ and a $[Cu_{12}S_5(PR_3)_4]$ fragment are fused in such a way that two face-sharing fragments of the "Cu_{12}" cubooctahedra of cluster type I (idealized symmetry of the Cu−S−P core: D_{4h}) are obtained in

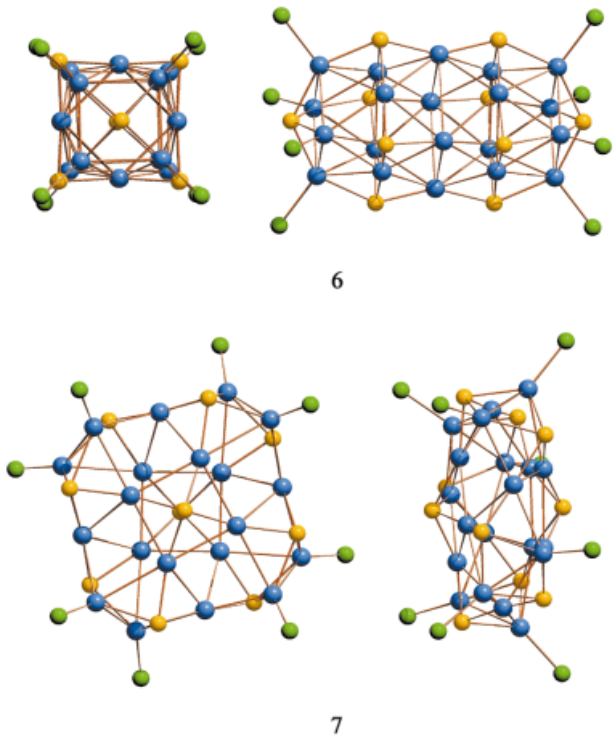

Figure 2. Molecular structures of $[Cu_{20}S_{10}(PPh_3)_8]$ (**6**) (top) and $[Cu_{20}S_{10}(PnButBu_2)_8]$ (**7**) (bottom) (without organic groups), each shown both along and perpendicular to the $S_{apical}-S_{apical}$ axis

the case of **6**. In **7** (type II, idealized symmetry of the Cu−S−P core: D_4), the ligands do not occupy coordination sites at the two outer Cu_4 rings but bind to the second and fourth rings resulting in the oblate and slightly twisted isomer. The respective S_{10} polyhedra are a bicapped tetragonal prism (**6**) and a highly compressed, bicapped tetragonal anti-prism (**7**). A tetragonal prismatic P_8 arrangement is found in **6**, while a P_8 tetragonal anti-prism is found in **7**. Coordination numbers and geometries are similar to the situation in the "Cu_{12}" species.

The structural differences between pairs of isomeric copper sulfide clusters can clearly be ascribed to the coordination sites of the phosphane groups, which are directed towards the respective copper atoms by their own steric demand to give the best protecting ligand shell around the Cu−S core. If different phosphanes display the same cone angle, isoenergetic structural isomers result, so that further kinetic aspects will dominate, as shown for the "Cu_{12}" species. If the PR_2R' groups are so small that even variation of the ligand positions does not result in a complete ligand sphere, or if the phosphane molecules are so bulky that one would have to have one fewer ligand, resulting in a non-ideal P_n polyhedron and an incomplete ligand sphere, the cluster growth continues until the optimum ratio of $[Cu_{2n}S_n]$ core and PR_2R' number and arrangement is achieved.

A continuation of the cluster growth also takes place in the presence of $PMeiPr_2$. Being too bulky for an arrangement of eight molecules around a $[Cu_{12}S_6]$ core and not generating a suitable ligand sphere with six terminal li-

gands, the phosphane groups enforce a formal dimerization of "Cu_{12}" clusters to the $[Cu_{24}S_{12}]$ core in **8**.[17] Figure 3 shows the formal dimerization of two "$[Cu_{12}S_6(PR_2R')_8]$" clusters of type II, which results in the molecular structure of **8** after the loss of four phosphane groups.

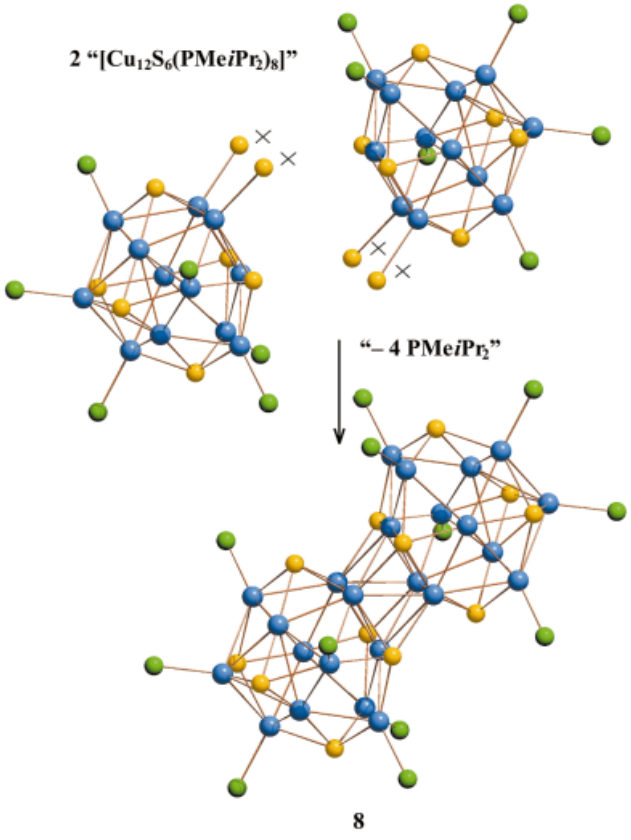

Figure 3. Formal dimerization/condensation reaction of two hypothetical clusters "$[Cu_{12}S_6(MeiPr_2)_8]$", resulting in the molecular structure of $[Cu_{24}S_{12}(PMeiPr_2)_{12}]$ (**8**) (without organic groups); phosphane ligands that are formally lost during the dimerization/condensation are drawn yellow and are marked by a cross

In contrast to the formal condensation (2 × "Cu_{12}") − 4 Cu → "Cu_{20}", which leads to the sharing of a Cu_4 rectangular face in **6**, in this case one observes a fusion of two Cu_3 triangular faces of the two basic cubooctahedra, forming a Cu_6 octahedron around the inversion center of the cluster. These six copper atoms show a novel coordination pattern. They are surrounded exclusively by sulfur neighbors in a trigonal-planar geometry. Conversely, the four sulfur atoms in the cluster center are found to act as μ_5-bridges, whereas all sulfur ligands in the clusters discussed so far and all the other ones in **8** are μ_4-bridging. The μ_5-bridges exhibit longer average Cu−S bond lengths than the μ_4-bridging sulfur ligands, as they bind to four copper neighbors with normal distances [2.159(3)−2.378(3) Å] and form one significantly longer Cu−S bond to a copper atom of the opposite asymmetric unit [2.485(3), 2.509(3) Å].

In the molecular structure of **8**, one observes the beginning of a transition from the so-called "small" copper sulfide clusters to the "middle-sized" species. Both cluster sizes possess spherical Cu−S−P frameworks with copper centers near the S_n polyhedron edges, but the "middle-sized" examples show some new structural features besides those already found for the "small" clusters: coordination numbers other than four for sulfur atoms, and copper centers that bind to more than two sulfur neighbors.

This same observation can be made for clusters **9** and **10**, particularly for the latter.[17] Unlike the species already discussed, these two clusters are topologically unrelated to the smaller examples. However, they are structurally related between themselves, and are actually formed in the same reaction. The molecular structures of **9** and **10** are shown in Figure 4, emphasizing their structural relationship by respective orientation. The basic S_{14} and S_{25} polyhedra are compared in Figure 5.

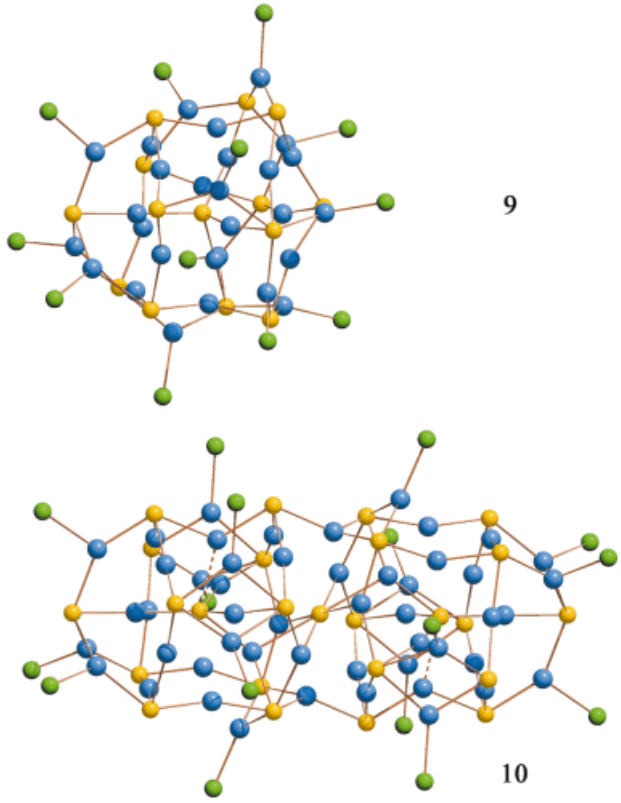

Figure 4. Molecular structures of $[Cu_{28}S_{14}(PtBu_2Me)_{12}]$ (**9**) and $[Cu_{50}S_{25}(PtBu_2Me)_{16}]$ (**10**) (without organic groups)

Besides various bridging modes of the sulfur atoms (μ_3 to μ_5 in **9**; μ_4 to μ_6 in **10**) and the greater numbers of three sulfur ligands around several of the copper atoms in **10**, both systems show another new structural feature characterizing "middle-sized" Cu−S clusters: Only for these two largest examples of copper sulfide cluster compounds does one find sulfur atoms inside an outer Cu−S shell, generating inner Cu−S units. In **9**, one sulfur ligand lies at the center of a distorted S_{13} deltahedron. Four copper atoms then bond around the central sulfur atom to yield an inner $[SCu_4]$ unit. The remaining copper centers are positioned either slightly below the surface of the S_{13} polyhedron if they show no Cu−P bonds, or slightly above if they are

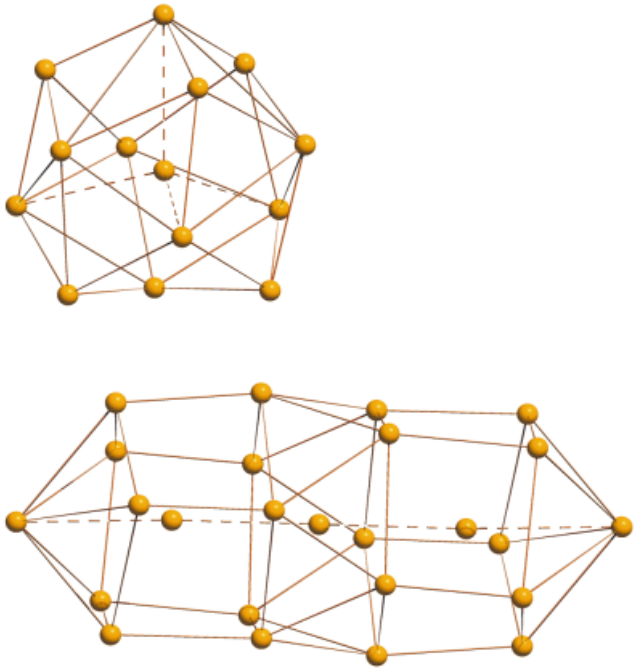

Figure 5. S_{14} (top) and S_{25} (bottom) polyhedra in **9** and **10**, respectively; the straight lines between the S atoms do not represent bonding interactions, but merely help to visualize the geometries of the polyhedra

bound by phosphane groups. A near C_3 symmetry of the Cu−S core is lost because of the "irregular" position of a single copper atom, which is also responsible for the μ_3- or μ_5-bridging mode of two sulfur ligands. The spherical cluster core is enclosed by a distorted icosahedron made up of the twelve phosphorus atoms. The sulfur substructure of **10** constitutes a cylinder-shaped polyhedron of near D_{5d} symmetry with a length of 17.14 Å. Underlining the supposition that **10** is formed through a form of dimerization−condensation from **9**, three inner sulfur atoms are present. Two of them − formally equivalent to the central sulfur atom in **9** − are also μ_4-bridging, resulting in an [SCu_4] fragment. However, one of the respective copper centers belongs to the cluster surface rather than being an inner metal atom, as a result of the structural differences between **9** and **10** when considering the center in **10**. Here, one observes the most unusual aspect of any of the copper sulfide clusters yet reported. The central sulfur ligand binds to six nearest copper atoms in a slightly corrugated chair-type manner. This arrangement, which is not found in any of the known copper sulfide compounds, displays very long Cu−S distances in the range of 2.633(4)−2.673(5) Å, which are about 0.3−0.5 Å longer than standard Cu−S bonds. Considering the ten next nearest copper atoms, 2.896(5)−3.814(5) Å out from the sulfur center, a near-spherical [SCu_{16}] arrangement is found for the cluster center. These structural observations are evidence for an interstitial S^{2-} anion rather than a covalently-bonded sulfur ligand. A summary of interatomic distances found in known copper sulfide systems for the different coordination numbers around copper is given in Table 2.

Considering the Cu−S distances listed in Table 2, one can recognize a first step in the direction of solid-state Cu−S phases in the structure of **10**.

By a comprehensive ab initio study of clusters [$Cu_{2n}S_n(PH_3)_m$] (n = 1−4, 6, 10; m = 0, 2, 4, 6, 8) at the MP2 level (program system TURBOMOLE), stabilization energies for the attachment of successive Cu_2S units to a given "naked" cluster (n = 1−4, 6, 10; m = 0; Figure 6), as well as the variation in the phosphane binding energies for clusters containing up to twelve copper atoms (n = 1−4, 6; m > 0; Figure 7), were calculated.[35]

For "naked" clusters, the stabilization energies increase continuously with the cluster size, which shows that the investigated molecules are thermodynamically unstable species in vacuo and that they have to be stabilized by ligands. Moreover, the increment in the stabilization energy per monomer unit decreases with increasing cluster size in the expected way, since it should theoretically converge at infinite cluster size, i.e. solid Cu_2S. Finally, the calculated Cu−P binding energy per Cu−P bond decreases rapidly from a value of ca. 140 kJ·mol^{-1} for [$Cu_2S(PH_3)_2$] − with a short relaxation when the Cu/P ratio is decreased (1 for n = 1−3, >1 for n = 4, 6) − to a value of ca. 56 kJ·mol^{-1} for the "Cu_{12}" species. Even if one assigns a higher Cu−P binding energy to the "real" tertiary phosphanes that bind to organic groups, it is evident that the phosphane ligands are bonded only very weakly to the copper sulfide core. Therefore, an additional stabilization by solvents or a crystal lattice is required.

3.2. Selenium-Bridged Copper Clusters

3.2.1. Syntheses

Scheme 3 summarizes the reactions yielding all PR_2R'-ligated, selenium-bridged copper clusters that have been isolated and structurally characterized to date, in order of increasing cluster size.

Unlike the sulfur-bridged compounds, the synthesis of selenium-bridged clusters can start from either copper acetate or copper chloride. This can be attributed to the lower standard formation enthalpy of Cu_2Se ($\Delta H_f° = -65.2$ kJ·mol^{-1})[49] when compared to its sulfur analogue Cu_2S ($\Delta H_f° = -81.2$ kJ·mol^{-1}).[50] Thus, the formation of Cu_2Se does not occur as rapidly as that of Cu_2S, although $Se(SiMe_3)_2$ is, in principle, more reactive than $S(SiMe_3)$. The cluster growth and protection of selenium-bridged clusters can therefore often be observed even at room temperature. However, with copper acetate as the starting material and by choosing low temperatures, one can obtain smaller clusters that could be considered as intermediates in the formation of the larger molecules. In addition to a great number of "stoichiometric" compounds that formally contain Cu^+ and Se^{2-}, some clusters have been characterized as having a Cu:Se ratio of less than two, indicating mixed-valence metal centers. All selenium ligands have a formal charge of −2 as one does not find any Se−Se binding inter-

Table 2. Interatomic distances of selected $Cu^{I}-S$ systems and metallic copper

System	Cu−Cu [Å]	Cu−S distances for the different coordination numbers (*CN*) [Å]			ref.
		CN = 2	*CN* = 3	*CN* = 4

copper metal	2.56	–	–	–	[38a]

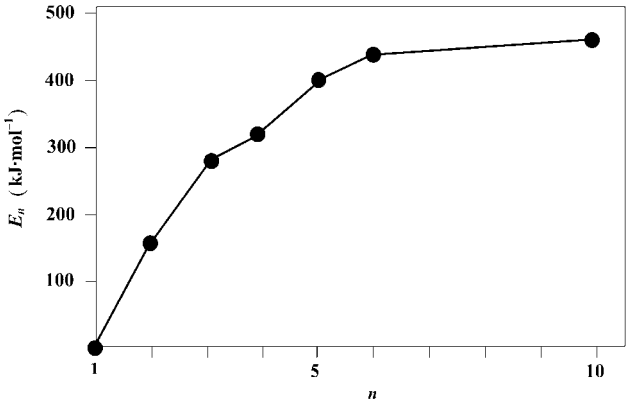

Figure 6. Variation in the stabilization energies per monomer unit in "naked" clusters $[Cu_{2n}S_n]$ (n = 1−4, 6, 10) with the given values taking into account the total energies of the most stable structural isomers computed at the MP2 level

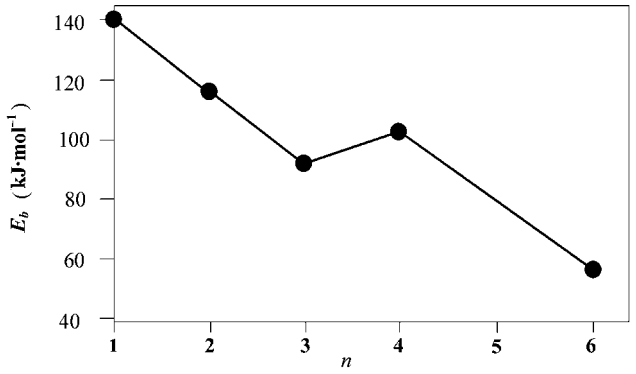

Figure 7. Variation in the Cu−P binding energies per Cu−P bond in phosphane-ligated clusters $[Cu_{2n}S_n(PH_3)_m]$ (n = 1−4, 6; m = 2, 4, 6, 8) with the given values taking into account the total energies of the most stable structural isomers computed at the MP2 level with respect to the total energy of PH_3 calculated by the same method

actions; therefore, one can assign Cu^{I} and Cu^{II} centers within the same cluster core in **14**, **17**, **27**, and **33**. The phosphane ligands again play a key role in determining the observed cluster sizes and shapes. The number of observed compositions is approximately four times that of the number of copper sulfide species, and the cluster growth proceeds to much higher nuclearity. Again, the lower tendency for precipitation of the binary phase can be invoked to account for this observation.

Another route to selenium-bridged copper clusters is by synthesis using $RSeSiMe_3$ (R = organic group) in the presence of either tertiary phosphanes or chelating ligands such as 1,2-bipyridyl, diphenylphosphanyl acid, or bidentate phosphanes dppR (R = organic spacer). The compounds prepared in this way are listed in Scheme 4 in order of increasing size.

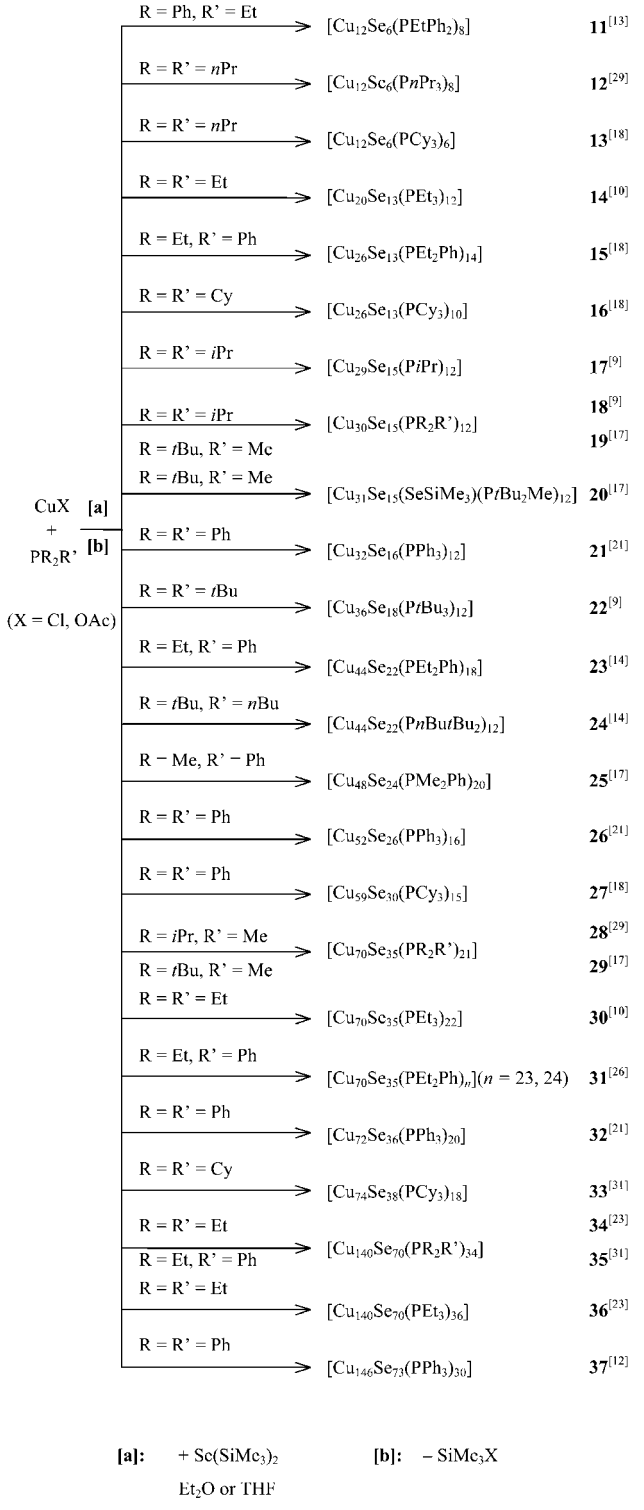
Again, one finds clusters containing exclusively Cu^{I} centers, as well as compounds with mixed-valence metal centers. In contrast to the compounds presented in Schemes 2 and 3, one of the selenido/selenolato-bridged clusters (**52**; see below) apparently contains Cu^{0} as well as Cu^{I}. Apart from this peculiarity, the cluster size and conformation of the Se^{2-}/SeR^{-}-bridged compounds is not only influenced by the nature and steric demand of the phosphane used, but is also dependent on the spatial properties of the organic substituent on the selenium reactant. This determines both the Se^{2-}/SeR^{-} ratio as well as the arrangements of the Se^{2-} ligands positioned inside the cluster core and of the SeR^{-} ligands on the periphery of the molecules.

3.2.2. Structures and Stabilities

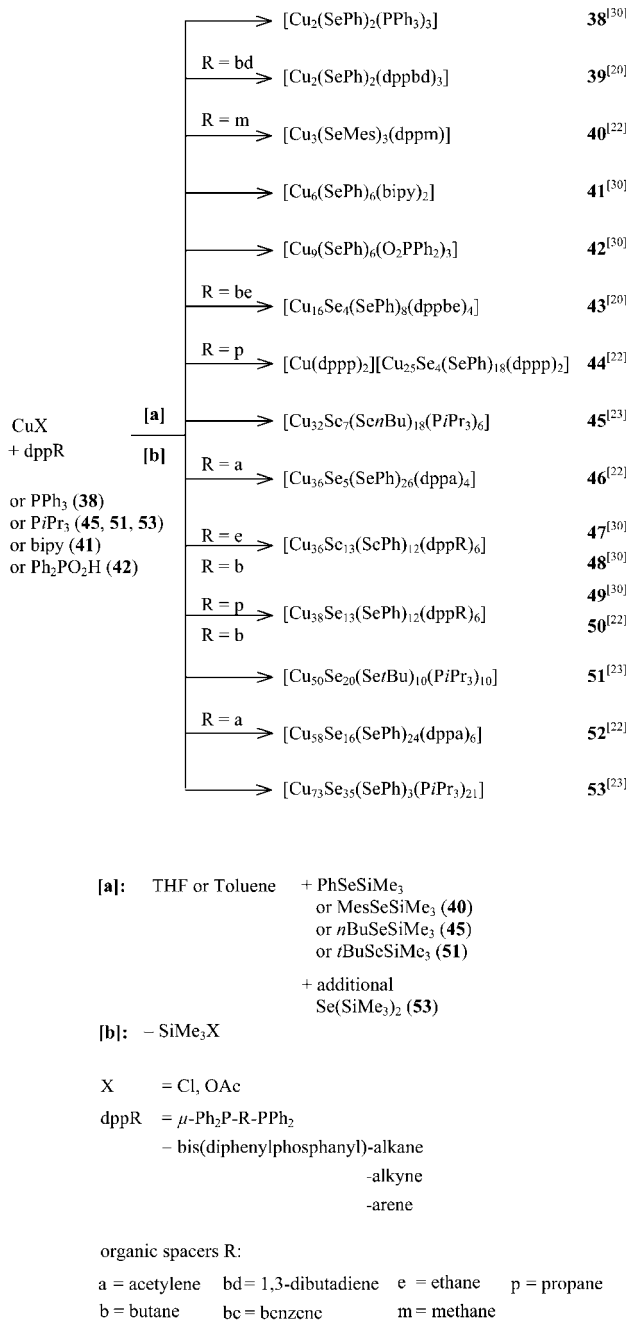
3.2.2.1. Se^{2-}-Bridged Copper Clusters

The subtle, nonlinear structural influence of the phosphane ligands allows the formation of different clusters of sometimes significantly different size and shape in the presence of the same phosphane. The isolation of a particular cluster compound is then determined by the choice of reaction conditions. Conversely, the use of different PR_2R' ligands can lead to clusters of the same $[Cu_{2n}Se_n]$ cores that may display differing numbers of terminal ligands and/or structural isomerism. These observations have already been illustrated and explained for the sulfur-bridged copper clusters, but they are more important for the Cu−Se species and a much greater structural variety is found. As with the copper sulfide compounds, one can distinguish between "small" and "middle-sized" clusters with regard to their shape and the coordination properties of the atoms involved. However, a third group, the "large" clusters, exists for the Cu−Se system. Whereas the transition from the first to the second type of molecular size is rather smooth, a clear break occurs when the number of copper atoms exceeds 59.

The only composition and structure that is equivalent for both copper sulfide and selenide clusters is $[Cu_{12}E_6(PR_2R')_8]$ (E = S, Se; PR_2R' = $PEtPh_2$, $PnPr_3$; respective cone angles: 141°, 132°). Compounds **11**[13] and **12**[29] are topologically identical to their sulfur analogues **3**



Scheme 3. Survey of the synthesis of selenium-bridged copper clusters protected by terminal phosphane ligands



Scheme 4. Survey of the synthesis of selenido/selenolato-bridged copper clusters protected by monodentate or chelating bidentate ligands

and **4**. The use of a much bulkier phosphane ligand, PCy_3, does not lead to a condensation or dimerization of cluster cores as observed for **6**−**8**, which contain PR_2R' groups of medium or large steric bulk. In contrast to the copper sulfide clusters in the presence of PPh_3, $PnButBu_2$, or $PMeiPr_2$, a reduction to six terminal ligands is acceptable in the case of **13**[18] (Figure 8) and the resulting ligand shell can encapsulate the $Cu_{12}Se_6$ cluster core. The clearly larger cone angle of PCy_3 compared to PPh_3, $PnButBu_2$, or $PMeiPr_2$ (170° *vs.* 145°, 146°, or 165°) is sufficient to allow a distorted P_6 octahedron to protect the copper selenide framework. However, as might be expected, a third version of the distortion of the $[Cu_{12}E_6]$ core is observed in this case.

Considering the clusters presented thus far, there seems to be a strong preference for highly symmetrical substructures of all the components involved in the heavy atom framework. Capped or uncapped, sometimes condensed,

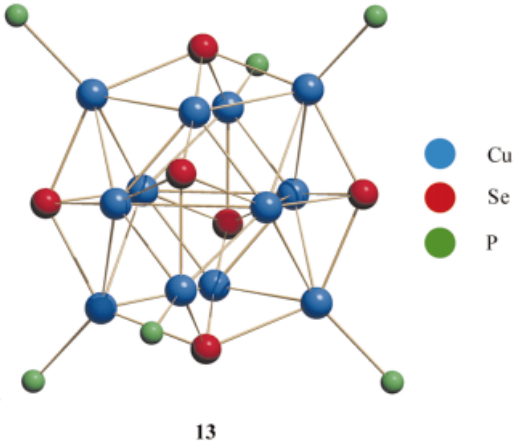


Figure 8. Molecular structure of $[Cu_{12}Se_6(PCy_3)_6]$ (**13**) (without organic groups)

octahedral, prismatic, cubic, dodecahedral, cubooctahedral, or icosahedral arrangements of either metal, chalcogen, or phosphorus atoms penetrate or enclose each other in all the structures. Among the compounds discussed, the "Cu_{12}" molecules possess the most symmetrical substructures. However, selenium ligands evidently prefer higher bridging modes. Therefore, the formation of "small" clusters with mostly μ_4-bridging selenium ligands is disfavored and these are consequently less common than larger ones. For the Cu−Se clusters, three further "middle-sized" compounds can be considered with regard to their symmetry properties as well as for a further illustration of the structural influence of the phosphanes. The cluster frameworks of **14**[10] and the $[Cu_{26}Se_{13}]$ isomers **15**[18] and **16**[18] can again be described as alternate packings of copper, selenium, and phosphorus polyhedra, respectively. However, regular polyhedra are only observed in the structures of **14** and **15**, whereas the $[Cu_{26}Se_{13}]$ core of **16**, being surrounded by only ten PCy_3 ligands instead of 14 PEt_2Ph groups, does not conform to a known polyhedral pattern. The molecular structures of **14**−**16** are shown in Figure 9.

To some extent, **14** and **15** are topologically related as both contain a centered icosahedron of selenium atoms. However, the penetrating polyhedra of copper atoms have different shapes according to the differing numbers of copper atoms and Cu−PR_2R' fragments (**14**: R = R′ = Et, **15**: R = Et, R′ = Ph) in the two clusters (Figure 10).

In **14**, a Cu_8 cube surrounds the inner selenium atom below Se_3 faces of the Se_{12} icosahedron. An outer Cu_{12} icosahedron follows, which is positioned above and rotated by 90° with respect to the Se_{12} shell. The eight copper centers inside the cluster thus form tetrahedral $[CuSe_4]$ groups and the twelve outer ones display an $[Se_3CuP]$ environment by binding to the similarly orientated P_{12} icosahedron formed by the PEt_3 ligands. In **15**, the inner selenium atom has twelve nearest copper neighbors that form an icosahedron, each edge being positioned below an Se−Se edge of the enclosing Se_{12} polyhedron and lying perpendicular to it, resulting in a coordinative occupation of one copper atom per Se_3 face. Slightly above the Se_{12} icosahedral surface, an

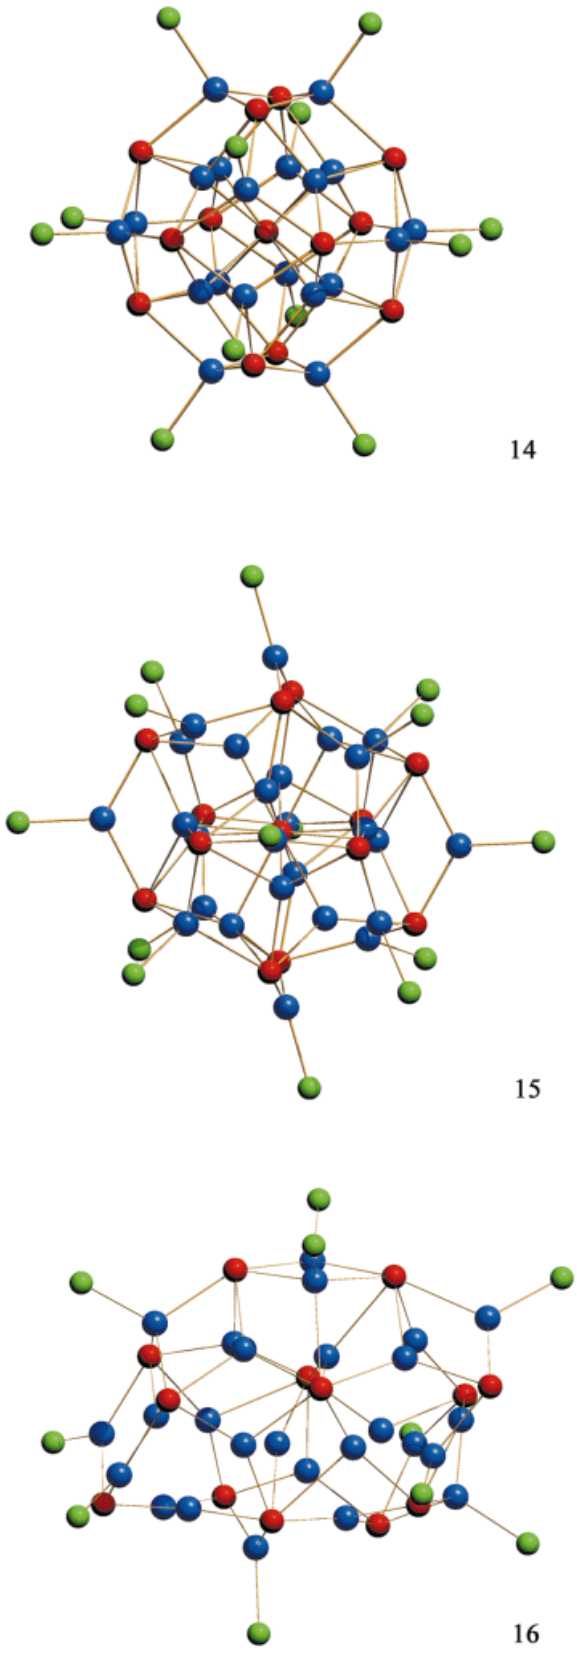

Figure 9. Molecular structures of $[Cu_{20}Se_{13}(PEt_3)_{12}]$ (**14**), $[Cu_{26}Se_{13}(PEt_2Ph)_{14}]$ (**15**), and $[Cu_{26}Se_{13}(PCy_3)_{10}]$ (**16**) (without organic groups)

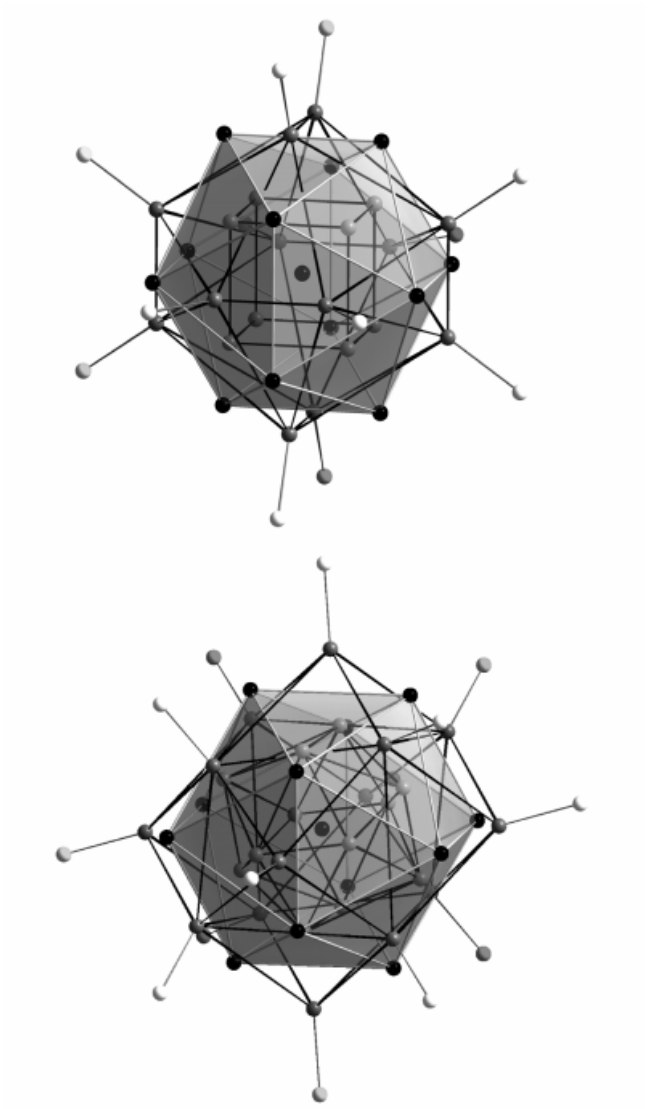

Figure 10. A comparison of the interpenetrating polyhedra in **14** (top) and **15** (bottom) that form the heavy atom cluster cores; the lines merely represent polyhedral edges and do not imply bonding interactions

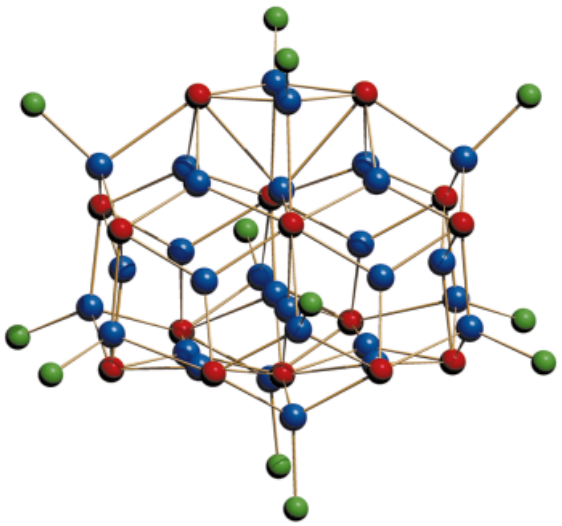
arrangement of 14 $Cu-PEt_2Ph$ units can be described as a sixfold capped cube. The twelve inner copper atoms and the eight metal centers of the capped cube, which all reside near Se_3 faces, are approximately tetrahedrally coordinated by either four selenium ligands or three selenium ligands and one phosphorus ligand. This is characteristic of those clusters larger than those classified as "small". The six remaining $Cu-PEt_2Ph$ fragments are situated above six Se−Se edges and therefore represent tricoordinated $[Se_2CuP]$ units, as found in both "small" and "middle-sized" clusters. On comparing the Cu/Se ratios for **14** and **15**, the fundamental difference that can be invoked to account for the structural differences becomes apparent. Cluster **14** represents a mixed-valence compound formally incorporating six Cu^{II} and 14 Cu^{I} centers to neutralize the 26− charge of the Se_{13} substructure. However, the intermetallic distances in **14** [Cu(1)−Cu(1): 2.821(4), Cu(1)−Cu(2): 2.678(4) Å] do not indicate significant interatomic interactions despite the partial depletion of electrons. The only structural indication of different valence situations in **14** or **15** is that, apart from equal average Cu−P bond lengths (2.247 Å in **14** and **15**) and similar average intermetallic distances Cu−Cu (2.707 Å in **14**, 2.682 Å in **15**), one finds significantly shorter average Cu−Se bonds in the mixed-valence compound **14** (2.365 Å) than in **15** (2.457 Å). The molecular structure of **16** differs from those of **14** and **15** in that the selenium substructure consists of a very irregular Se_{13} deltahedron. Twelve of the copper centers and ten $Cu-PCy_3$ fragments bind to the Se_{13} polyhedron in such a way that they are again three- or four-coordinated. Unlike the situation in **14** or **15**, one additionally observes four copper atoms that are almost linearly coordinated by two selenium neighbors. This pattern is typical for "small" Cu−E clusters and again underlines the partial maintenance of these properties in the "middle-sized" compounds. The structure of **16** acutally resembles more the molecular structures of the next larger clusters **17**−**19** (Figure 11), being reduced by three or four copper atoms, two selenium, and two phosphane ligands.

Like the "Cu_{12}"−"Cu_{20}", the "Cu_{12}"−"Cu_{24}", or the "Cu_{28}"−"Cu_{50}" relationship discussed for copper sulfide clusters, the molecular structures of **14** and **15** can be seen to be closely related, at least in principle, even though the numbers and ratios of heavy atoms are very different. In contrast, a similar number of copper and selenium atoms *can* but does not always lead to a topological relationship (cf. **15/16**). Compounds **17**−**21**[9,17,21] contain 29, 30, 31, or 32 copper atoms and either 15 or 16 selenium ligands. Nevertheless, three completely different molecular frameworks are observed. The first structure type is adopted by **17**,[9] **18**,[9] and **19**.[17] As an example, the molecular structure of **17** is shown in Figure 11.



17

Figure 11. Molecular structure of $[Cu_{29}Se_{15}(PiPr)_{12}]$ (**17**) (without organic groups)

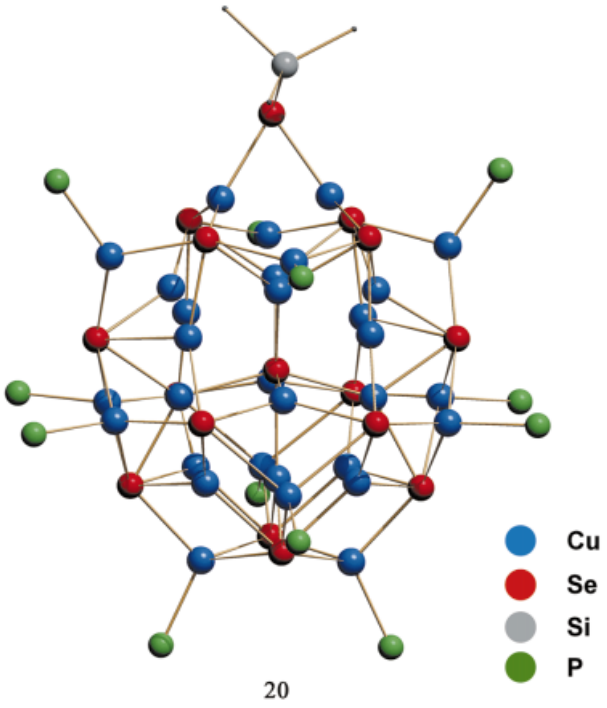


Figure 12. Molecular structure of $[Cu_{31}Se_{15}(SeSiMe_3)(PtBu_2Me)_{12}]$ (**20**) (without organic groups)

Although the number of copper atoms in **17** is one less than in **18** or **19**, indicating a mixed-valence situation in this system, all the clusters show equivalent Cu−Se−P cores. The additional copper atom in **18** or **19** is positioned in the cluster center. A reaction employing the same reactants and temperatures as for the synthesis of **19**, but using a 40% higher $PtBu_2Me$:CuOAc ratio, yields compound **20**[17] (see also Scheme 8). Although the cluster core of **20** (Figure 12) can also be described in terms of five parallel planes of copper and selenium atoms that are then surrounded by twelve phosphane ligands, analogous atomic arrangements or corresponding polyhedra in **19** or **20** are not found.

The $SeSiMe_3$ group, which is unique in the copper chalcogenide clusters, not only influences the molecular structure of **20**, but also indicates the obvious reason for the structural differences. Compound **20** can be viewed as a "frozen" intermediate en route to the formation of a larger cluster such as the "Cu_{70}" cluster **29**[17] (see below), since it still bears a leaving group. The latter uniquely acts as a protecting unit in addition to the phosphane ligands and consequently further cluster growth is slowed down to such an extent that compound **20** crystallizes instead. Thus, its formation is naturally independent of the cluster growth yielding **19**. A third structure type for this size of cluster is found for **21**,[21] as shown in Figure 13. The selenium atoms form a flattened polyhedron consisting of non-bonded Se_3 triangles. One observes four distinct copper environments: 24 of the copper atoms cap the selenium triangles, and of these 16 are bonded only to selenium ligands producing a distorted trigonal-planar coordination geometry slightly below the Se_3 faces. The other eight of these copper centers

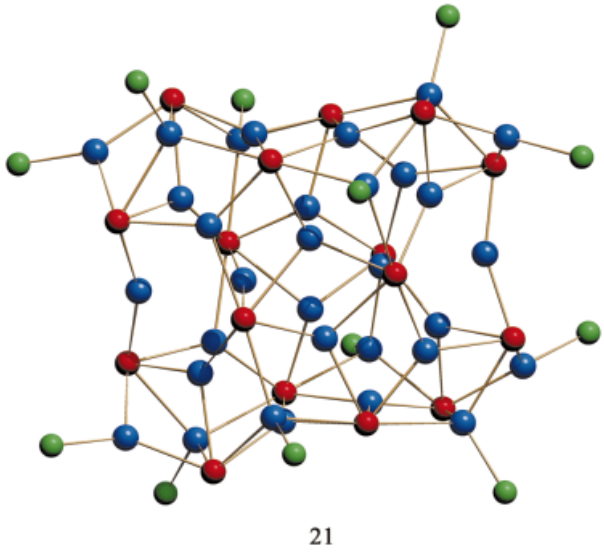

Figure 13. Molecular structure of $[Cu_{32}Se_{16}(PPh_3)_{12}]$ (**21**) (without organic groups)

are also coordinated by a phosphane ligand, giving a tetrahedral environment with the copper atoms situated on the exterior of the selenium substructure. Of the remaining copper atoms, four are coordinated in a quasi-linear fashion to two selenium ligands, and four are bonded in a distorted trigonal-planar manner to two selenium neighbors and one phosphorus atom from PPh_3. These coordination patterns, as well as bridging modes of μ_5 and μ_6 for the selenium ligands, are common for "middle-sized" Cu−E clusters. Compounds **16**, **17**, and **21** also represent exceptions for their cluster size in that they do not contain copper or selenium atoms inside an approximately spherical Cu−Se shell. All other "middle-sized" clusters containing 20 or more copper atoms (beginning with compound **14**) feature central copper atoms (**18**, **19**) or central selenium ligands (**14**, **15**, **20**).

The larger molecules **22**−**27**[9,14,17,18,21] all feature selenium atoms enclosed within an Se_n polyhedron (n = 18, 22, 24, 26, or 30). The number of inner selenium ligands increases with increasing cluster size from one central atom (**22**),[9] through two inner atoms (**23**−**25**),[14,17] to three selenium centers inside the cluster core (**26**, **27**).[18,21] The respective underlying selenium substructures are summarized and compared in Figure 14.

Even though these six compounds can be considered as spherical, "middle-sized" clusters, and all possess central units within a Cu−Se surface, two distinct basic shapes can be discerned. Compounds **22** and **26** (Figure 15) are based on a triangular structure, whereas **23**−**25** and **27** form ellipsoid-type cluster surfaces (Figures 16 and 17).

The molecular structure of **22** displays idealized D_3 symmetry, while the Cu−Se core of **26** shows near C_3 symmetry, although in neither case is this realized in the crystal (**22**: C_2 symmetry; **26**: C_1 symmetry). Along the idealized threefold axes, one finds one selenium ligand at the top and one at the bottom of the approximate flattened trigonal prism

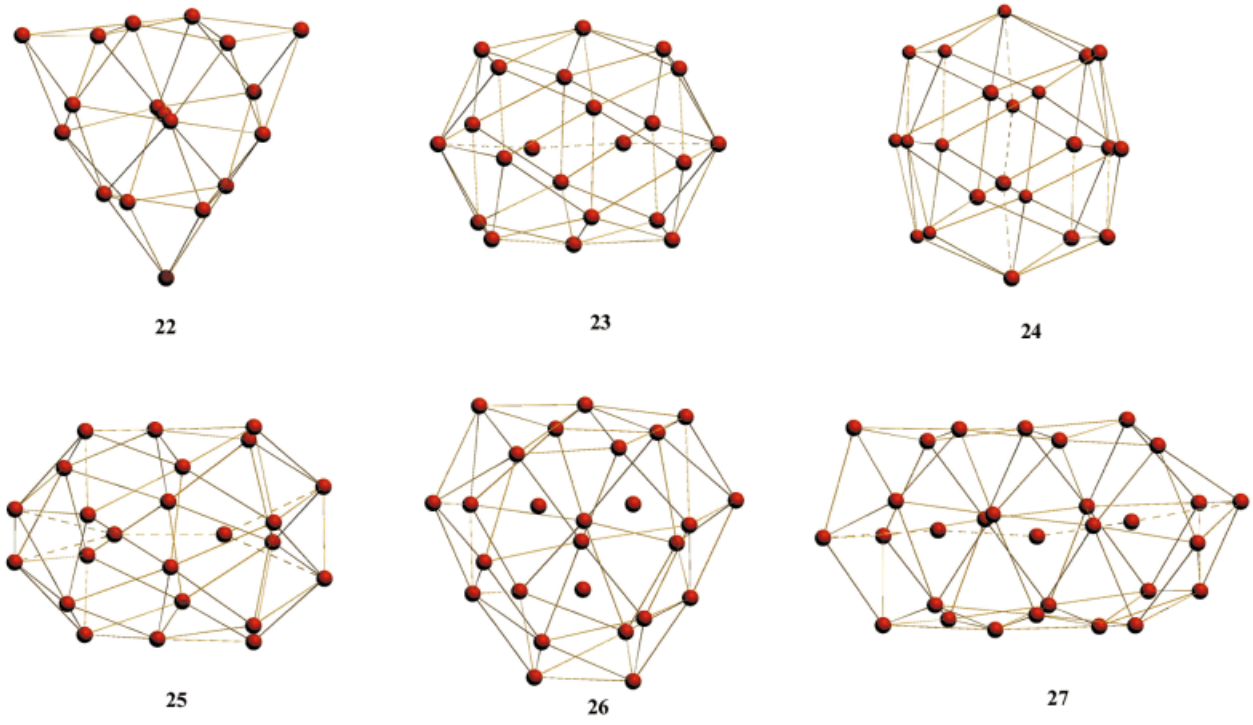

Figure 14. Selenium substructures in **22**−**27** (from top left to bottom right); the Se−Se lines do not represent bonding interactions, but merely help to visualize the geometries of the polyhedra

formed by the cluster atoms. In **22**, a third selenium ligand is positioned between these two at the cluster center. Conversely, in **26** a triangle of three inner selenium atoms lies at the center of the Cu−Se core, and two copper atoms are arranged along the near C_3 axis, between this Se_3 triangle and the two aforementioned selenium ligands. Considering first the central cores, the clusters are formed in the usual way by alternating bonds from copper to selenium atoms. For **22**, this leads to [Se_2Cu], [Se_3Cu], or [Se_2CuP] coordination environments around the copper centers and μ_3- to μ_6-bridging selenium ligands with Cu−Se distances of 2.347(4)−2.875(5) Å. The larger cluster core of **26** consequently features higher coordination numbers, including almost tetrahedral [Se_3CuP] arrangements besides di- or tricoordinated copper atoms as found in **22**, and the selenium atoms act as μ_4- to μ_8-bridges with a wide Cu−Se distance range of 2.19−2.91 Å. Twelve P*t*Bu_3 ligands enclose the copper selenide core of **22** in the following way. Six are bonded over rectangular faces when the cluster is viewed in a simplified manner as a trigonal prism. Six further P*t*Bu_3 units are situated over the respective triangular faces. In addition to nine PPh_3 ligands that are bonded over the rectangular faces of the "prismatic" Cu−Se core in **26**, seven phosphane groups surround the cluster core in a different manner on the two triangular faces in such a way that three are positioned on one side and four on the other.

By using different phosphane ligands and changing the CuOAc/PR_2R' molar ratios and final reaction temperatures, the structural isomers **23** and **24** can be obtained. The spatial demands of the phosphane ligands enabled ligand shells composed of either 18 PEt_2Ph or 12 P*n*Bu*t*Bu_2 groups to adequately protect a [$Cu_{44}Se_{22}$] core. In **23**, the phosphorus atoms form a quite regular polyhedron of alternating, eclipsed P_3, P_6, P_6, and P_3 rings perpendicular to the long axis of the cluster. The twelve phosphorus atoms at the periphery of the cluster core in **24** constitute a highly distorted icosahedron. As a result of the different numbers and arrangements of PR_2R' ligands, which modify the core geometry in the usual way by "pulling" the ligated copper atoms out of the Cu−Se core to some extent, some differences are observed when the copper selenide frameworks are considered in detail. This is clearly apparent when the respective Se_{22} substructures are compared (Figure 14). Both can be described as a staggered arrangement of three Se_6 rings, the middle one being larger than the outer rings. One additional selenium ligand caps each of the two terminal Se_6 faces of the face-sharing hexagonal anti-prisms. Apart from different distortions of these peripheral Se_{20} polyhedra (total lengths or widths of the Se_{22} substructures according to the orientations in Figure 14: 11.43 or 8.64 Å in **23**; 8.34 or 10.60 Å in **24**), the relative positions of the inner Se_2 units are perpendicular to each other. One can therefore consider units of twelve copper and two selenium atoms in each cluster core that have completely different orientations, a consequence of the significantly different situations on the cluster surface mentioned above. The isomerism observed with the "Cu_{44}" clusters again shows that certain [$Cu_{2n}E_n$] compositions represent "islands of stability" − within given limits of structural isomers − that are obtained experimentally whenever a suitable ligand shell

can be realized by means of the available phosphane molecules.

Two further ellipsoid-like arrangements are found for clusters **25** and **27**, respectively. Apparently, it is not possible for a phosphane shell composed of PMe_2Ph ligands (cone angle: 127°) to surround a $[Cu_{44}Se_{22}]$ cluster. Instead, the smallest compound to be sufficiently stable and insoluble to allow its isolation is the slightly larger cluster **25**, although this is structurally related to the smaller species **23**. The ellipsoid-like Se_{24} substructure of **25** (Figure 14) can be derived from the Se_{22} arrangement in **23** by simple substitution of each of the single Se caps in the smaller

polyhedron by two selenium ligands capping the outer Se_6 rings. Again, one finds all the coordination features typical for "middle-sized" Cu−Se clusters, even four copper atoms showing an almost tetrahedral environment of four selenium ligands. However, unlike all the smaller clusters that contain selenium atoms inside the cluster core, **25** features two tetrahedral $[SeCu_4]$ units − these being linked by a *trans*-edge junction through a compressed Cu_4 tetrahedron − with a uniquely low bridging mode (μ_4) for the two inner selenium ligands (cf. the bridging modes of the inner selenium ligands in **14**, **15**, **20**, **22**−**24**: μ_5 to μ_8, μ_{12}). Besides **14** and **17**, **27** is the third copper selenide cluster that has too few metal centers for an overall +1 oxidation state for the copper atoms. However, no single Cu^{2+} center can be assigned and the lack of one electron is likely to be delocalized over the whole cluster framework. As with **23**−**25**, the molecule is oblong in shape. It represents the largest spherical copper selenide cluster yet known, and thus it concludes the series of "middle-sized" Cu−Se clusters. The selenium atoms form a highly irregular Se_{27} polyhedron around three inner chalcogen centers (Figure 14), which can alternatively be viewed as an approximate arrangement of the selenium ligands into three layers. The molecular structure of **27** includes all possible coordination environments around copper atoms, i.e. $[Se_2Cu]$, $[Se_3Cu]$, $[Se_4Cu]$, $[Se_2CuP]$, and $[Se_3CuP]$. Selenium ligands are observed to act as μ_4-, μ_5-, μ_6-, or μ_7-bridges.

Summarizing the structural properties of the "small" Cu−Se clusters **11**−**13**, and the "middle-sized" ones **14**−**27**, the spherical shape and the absence of any topological relationship with the bulk material Cu_2Se are a central feature. Only the tendency towards higher coordination numbers at the copper centers, i.e. three and four, with increasing cluster size approaches the situation in the binary phase. However, the main difference between "small" and "middle-sized" clusters is the occurrence of inner atoms that first appear within a copper selenide core of 33 atoms (**14**). The coordination patterns in the "middle-sized" molecules typically show a mixture of higher and lower coordination numbers or bridging modes, whereas only lower coordination numbers are observed in "small" clusters.

Although only eleven more copper atoms are observed in compounds **28**−**31**[10,17,26,29] than in **27**, these represent the smallest examples of a new type of copper selenide clusters. The so-called "large" Cu−Se clusters are characterized by significantly different cluster shapes, structural principles, and relationships to the bulk material than the smaller species. Clusters **28**−**37** display *A*-*B*-*A*-type packed layers of selenium atoms that form large triangles. At first sight, this might appear to be reminiscent of the "triangular" structures of **22** or **26**. However, a closer look clearly reveals the differences between these two clusters and the layer-type structures of the "large" clusters. Compounds **28**−**37** are all based on three *hcp* selenium layers, of which the middle one is the largest. Figure 18 shows the selenium networks of the "large" clusters **28**[29] (as an example of a $Cu_{70}Se_{35}$ core), **32**[21] ($Cu_{72}Se_{36}$ core), **33**[31] ($Cu_{74}Se_{38}$ core), **34**[23] ($Cu_{140}Se_{70}$ core), and **37**[12] ($Cu_{146}Se_{73}$ core). It is worth

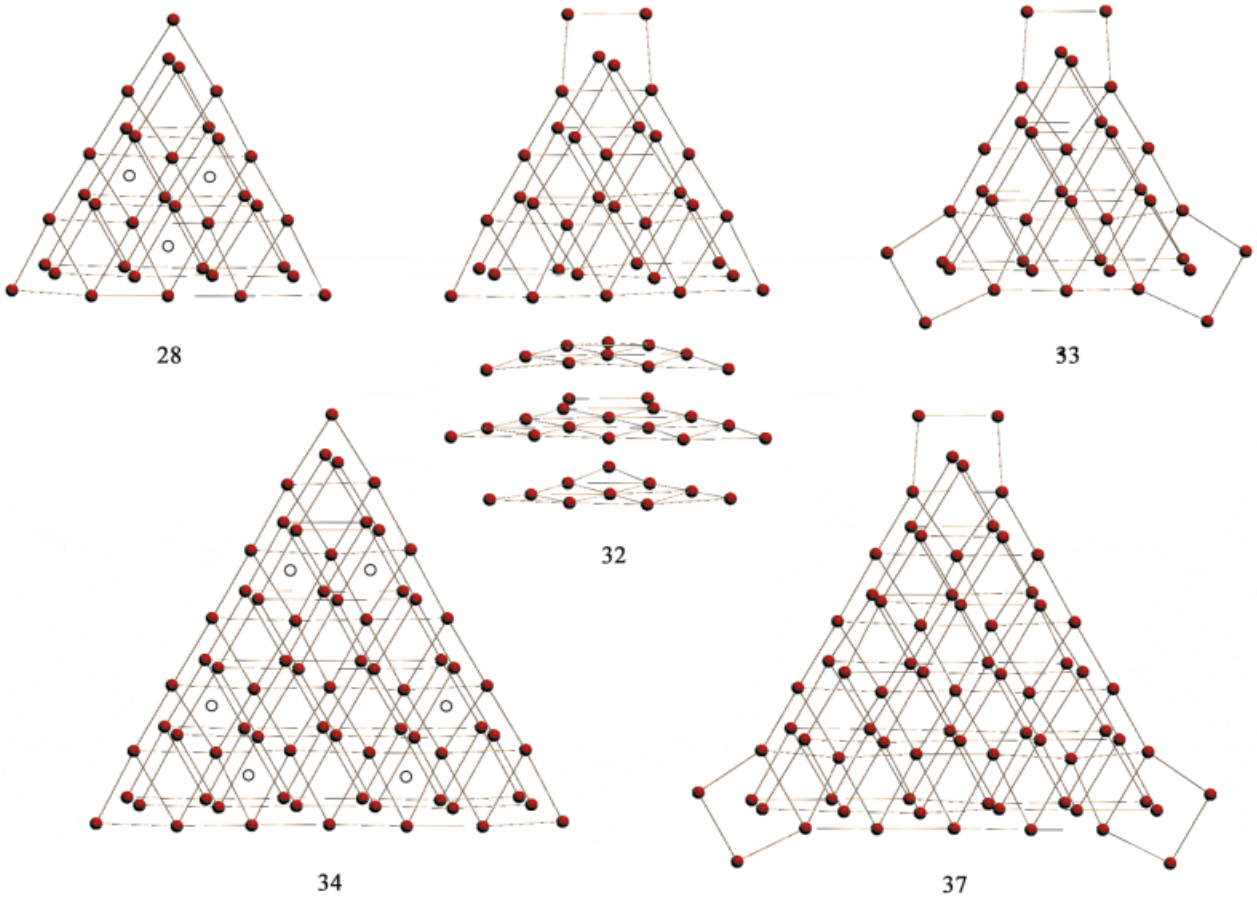

Figure 18. Selenium substructures in **28**, **32**, **33**, **34**, and **37** (from top left to bottom right) that contain 35, 36, 38, 70, or 73 selenium atoms; the drawn Se−Se contacts do not represent binding interactions, but merely serve to visualize the *A-B-A* packing of selenium atoms in three layers; this is additionally demonstrated by the supplementary view of the Se_{36} substructure of **32** (top middle); open circles mark disorder positions of copper atoms (see text)

mentioning that this structural pattern seems to be exceptionally favored for huge copper selenide clusters since it is observed over a size range from "Cu_{70}" to "Cu_{146}", i.e. over a more than twofold increase in the nuclearity.

Clusters **28**−**31** contain Se_{10}, Se_{15}, and Se_{10} layers that form perfect triangles. Thus, the next largest selenium substructure should be formed by an arrangement of triangular Se_{15}, Se_{21}, and Se_{15} layers incorporating one more row of selenium atoms each. However, the corresponding "[$Cu_{102}Se_{51}$]" cluster core is not yet known. Instead, one observes the formation of intermediate clusters incorporating selenium layers similar to those in **28**−**31**, but with the middle one deviating from a perfectly triangular shape. In **32**, one corner of the middle layer is modified with respect to the corresponding layer of the "Cu_{70}" clusters in that two selenium atoms replace one former corner atom. Similarly, all three corners are modified in this way to result in the $Se_{10}-Se_{18}-Se_{10}$ selenium framework of **33**; this compound is another "Cu-deficient" cluster featuring fewer copper centers than Cu_{2n} with respect to Se_n. The third "ideal" cluster composition has been observed in compounds **34**−**36**. The underlying selenium layers contain 21, 28, and 21 atoms, respectively. By replacing all corner selenium centers of the middle triangle by two chalcogen atoms, one obtains the Se_{73} substructure that is observed in **37**. For this third possible size, successive modification of one or two triangle corners of the middle layer has not yet been observed, whereas for the first size (35 selenium atoms), a modification of one or three corners has been found.

The reason for the missing "Cu_{102}" cluster might be related to the primary steps of the cluster growing mechanism. Selenium networks consisting of three triangular *hcp* layers based on $0.5\cdot[n\cdot(n+1)]$ selenium atoms (n = number of straight rows in the triangular network) in *A-B-A* order permit three possible orientations of the central threefold axis of the network {layers with a central Se atom are those containing $0.5\cdot[n\cdot(n+1)]$ atoms, where $n = (3m+1)$, i.e. Se_1, Se_{10}, Se_{28}, etc.; layers where $n = 3m$ or $n = (3m+2)$ have a central hole: Se_3, Se_6, Se_{15}, Se_{21}, Se_{36}, Se_{45}, etc.}: one either finds a hole (representing the unoccupied *C* position), one selenium atom in the middle layer (located in a *B* position), or two selenium atoms belonging to the two outer layers (located in *A* positions). Since all the "large" Cu−Se clusters characterized to date have only been consistent with the last two possibilities, the presence of a central Cu_xSe_y axis ($Se_A-Cu-Cu-Se_A$ in **28**−**33**; $Cu-Se_B-Cu$ in **34**−**37**) would seem to be necessary for the formation of a stable cluster core. Assuming that the cluster growth starts

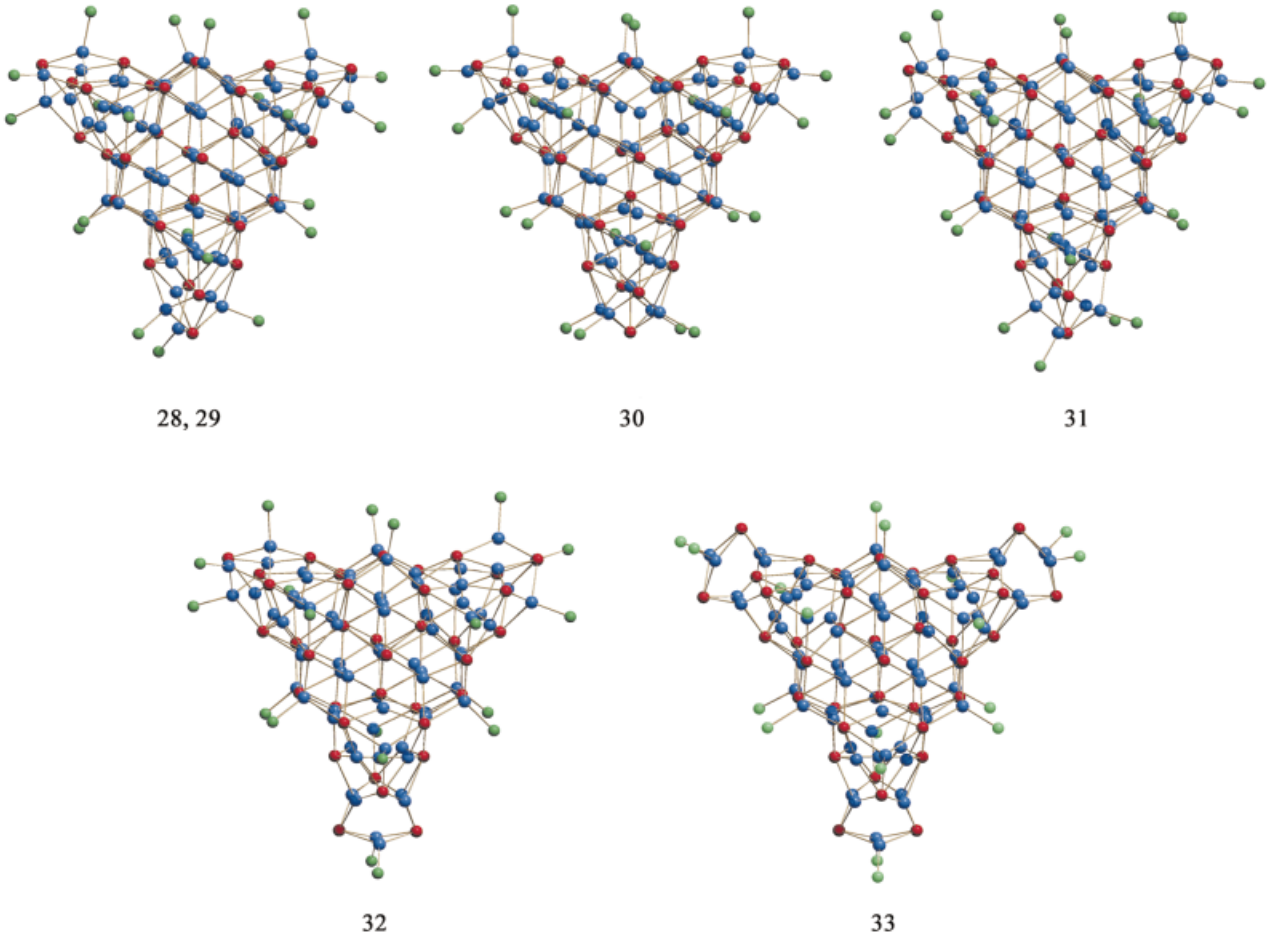

Figure 19. Molecular structures of $[Cu_{70}Se_{35}(PR_2R'_{21}]$ (R = *i*Pr, *t*Bu; R′ = Me) (**28**, **29**), $[Cu_{70}Se_{35}(PEt_3)_{22}]$ (**30**), $[Cu_{70}Se_{35}(PEt_2Ph)_n]$ (n = 23, 24) (**31**), $[Cu_{72}Se_{36}(PPh_3)_{20}]$ (**32**), and $[Cu_{74}Se_{38}(PCy_3)_{18}]$ (**33**) (without organic groups); two copper atoms that are positioned around the central Se−Cu−Cu−Se axis are statistically distributed with occupancies of 0.67 over three positions in **28**, **29**, and **31**

from the center of the molecule, the need for such a $[Cu_2Se]$ or a $[Cu_2Se_2]$ fragment situated along the C_3 axis appears understandable for a non-spherical cluster. Therefore, only those molecules that contain either one (middle; cf. **34**−**37**) or two (outer; cf. **28**−**33**) selenium layers with a central selenium atom instead of a central triangular hole are formed and observed experimentally. Both the Se_{15} and the Se_{21} layers that would conceivably form a "Cu_{102}" molecule do not contain central selenium atoms, thus suggesting why the $[Cu_{102}Se_{51}]$ core has not been observed.

In Figure 19, the cluster cores of the clusters containing 70 (**28**−**31**), 72 (**32**), and 74 (**33**) copper atoms are compared.

The "Cu_{70}" core is quite tolerant with regard to its ligand shell. An increase in the spatial demand of the PR_2R' molecules is not strictly coupled with a decreasing number of terminal ligands. However, one still finds a rough correlation, since 21 of the bulkier phosphane ligands PMe*i*Pr$_2$ (cone angle: 146°) and P*t*Bu$_2$Me (cone angle: 161°) are arranged around the Cu−Se core in **28** and **29**, whereas 22, and 23 or 24, terminal ligands are observed for the smaller phosphanes PEt_3 (cone angle: 132°; **30**) or PEt_2Ph (cone angle: 136°; **31**), respectively. Clusters **28**, **29**,[17] and **31**[26] differ marginally in their molecular structures. The only observable difference between **28** and **29** is a slightly less complete ligand shell achieved by the less sterically demanding PMe*i*Pr$_2$ groups. Cluster **31** displays a disorder problem with the PEt_2Ph groups, such that it cannot be determined with complete certainty whether the total number of phosphane ligands amounts to 23 or 24. Accordingly, for the formation of the cluster, another two (or three) additional phosphane molecules − compared to **28** or **29** − are situated at the triangle corners in such a way that two (or three) corners possess four instead of three Cu−PEt_2Ph groups, while one (or no) corner still bears three groups. The intermediate number of phosphane ligands, 22, is accompanied by a more distinct structural modification in **30**. Again, this affects the corner region. In contrast to all the corner arrangements of copper and selenium atoms in the other "Cu_{70}" clusters, none of which can be described in terms of regular patterns, in **30**[10] only two corners have an irregular structure. The third one shows a highly symmetrical $[Cu_9Se_3(PEt_3)_4]$ configuration featuring a centered cube of copper atoms that is capped on three faces by μ_4-selenium ligands and bears a square of four phosphane groups on the four outer atoms. This peculiarity of one cluster corner in

30 is one of two reasons for the absence of pseudo-threefold molecular symmetry. A C_3 symmetry of the $[Cu_{70}Se_{35}]$ core of **28**, **29**, or **31** is additionally approached − apart from one "wrong" Cu−PR_2R' position in **28** and **29** − by the statistical disorder of two copper atoms. The latter are distributed over three positions − each with site occupancies of 0.67 − forming a triangle around and perpendicular to the Se−Cu−Cu−Se pseudo-threefold axis running through the center of the molecule. In Figure 18, the three disorder sites are marked with open circles. The disorder of the PEt_2Ph ligands in **31** also leads to a pseudo-C_3 axis if 24 phosphane groups are assigned to the ligand shell. In contrast, close inspection of the cluster center in **30** reveals an unoccupied copper atom position. The two other metal atom sites are fully occupied, leading to a lower − yet crystallographically realized − C_2 symmetry.

The molecular structure of **32** can be derived from that of **28** or **29** in a simple manner if one first fully occupies all the copper atom positions around the Se−Cu−Cu−Se axis as mentioned above, and then formally substitutes one corner selenium atom by an $[Se_2(CuPPh_3)_2]$ unit after removal of three PPh_3 ligands at that corner. This leads to a modification of the middle selenium layer, as discussed earlier. Additionally, the number of phosphane groups that enclose the respective corner is reduced to two, since two of the three copper atoms that are coordinated by PR_2R' ligands in the analogous corner in **28** or **29** remain "naked" in **32**. Modification of all three cluster corners in this way, again together with full occupation of the Cu_3 group around the cluster center, generates the structure of the mixed-valence cluster framework in **33**. With idealized C_{3h} symmetry for the cluster framework, the symmetry of the molecule does not exceed C_2 in the crystal due to slight distortions and the positions of the organic groups bonded to the phosphorus atoms.

The largest copper selenide clusters yet known contain 140 or 146 copper atoms and 70 or 73 selenium ligands, respectively. The molecular structures of **34**, **36**,[23] and **37** are shown in Figure 20.

The different number of PR_2R' groups observed in **34** or **35**,[31] on the one hand, and in **36** on the other, affects the molecular structures in a different manner as seen for the "Cu_{70}" species **30** and **31**. Considering the corners again, **34**, with 34 terminal PEt_3 ligands, resembles an enlarged analogue of **30**. As in the smaller compound, two corners are arranged irregularly, whereas the third shows the regular, centered-cubic pattern. On increasing the number of PEt_3 groups to 36, as in **36**, all three corners now show this ordered arrangement of copper, selenium, and phosphorus atoms. This corner unit, which is only found for the PEt_3-ligated "large" Cu−Se clusters, underlines the structural relationship between **30**, **34**, and **36**, and again highlights the steric influence of a particular PR_2R' ligand. All other phosphane ligands that surround "large" copper selenide clusters feature larger cone angles, which could be the reason for the adoption of a more staggered arrangement if four Cu−PR_2R' units are present at a corner. Consequently, in **35**, all three corners show arrangements like that in the smaller analogue **31**. Disorder of copper atoms that increases the apparent idealized molecular symmetry is again present in the "Cu_{140}" clusters. A twofold disorder of one copper atom, between positions on the pseudo-C_3 axis (above and below the central selenium atom), results in an apparent "$Cu_{0.5}$"−Se−"$Cu_{0.5}$" central axis. In addition, four copper atoms are disordered over six equivalent sites, each with occupancies of 0.67. As for the "Cu_{70}" clusters, these sites lie within the plane of the middle selenium layer. However, in contrast to the smaller clusters **28**, **29**, and **31**, where the disorder sites form part of the $[Cu_3Se_3]$ hexagon at the center of the clusters, the six disorder sites in **34**−**36** are more distant from the cluster centers, as marked with open circles in Figure 18.

The formal replacement of each of the three corner selenium atoms and twelve PR_2R' molecules in **36** by three $[Se_2Cu(PR_2R')_2]$ units, as well as full occupation of all the copper sites present in the "Cu_{140}" clusters, exactly yields the composition and D_{3d} symmetric molecular structure of **37**. Thus, the structural relationship between **36** and **37** is analogous to that between the "Cu_{70}" and the "Cu_{72}" and "Cu_{74}" clusters.

All the "large" Cu−Se clusters show an *A-B-A* packing of hexagonal layers of selenium atoms. The metal centers occupy either trigonal or tetrahedral holes, or are situated outside the selenium layers in trigonal or tetrahedral coordination environments. Thus, the layer-type clusters clearly show a closer relationship to solid-state structures than do the spherical ones. However, for the $Cu_{2-x}Se$ phases, hexagonal structures are unknown and only cubic modifications are found. Interestingly, for the Cu_2S (chalcosine) high-temperature phase,[38] a hexagonal lattice with mainly trigonally-surrounded copper atoms, with some tetrahedrally and linearly coordinated ones, does exist. In contrast, the cubic $Cu_{2-x}Se$ crystal structures[39] can be derived from an antifluorite lattice[51] by positioning the selenium atoms at defined lattice sites, and positioning six to eight copper atoms per unit cell − according to the phase composition − in trigonal, tetrahedral, or octahedral holes. In α-Cu_2Se, the metal centers are positioned in an ordered manner within the selenium lattice, whereas in β-Cu_2Se they are statistically disordered over the observed sites. Even though the reported structural properties of copper selenide binary phases are not uniform, there is a clear agreement regarding the dominant coordination number of four for the copper atoms and the absence of any linearly-coordinated metal centers. Due to the hexagonal modification and the preferred coordination number of three for the copper atoms, the layer-type Cu−Se clusters approach the bulk material situation only in principle. Table 3 summarizes the interatomic distances in several copper(I) selenide compounds with respect to different coordination numbers around the metal atoms (cf. Table 2 for Cu−S systems).

Regarding the copper selenide clusters reviewed here, it is clear that a given phosphane ligand does not just generate clusters within a given size range, with another PR_2R' ligand resulting in the next largest clusters, and so on. Instead, it is evident that even very different types of phos-

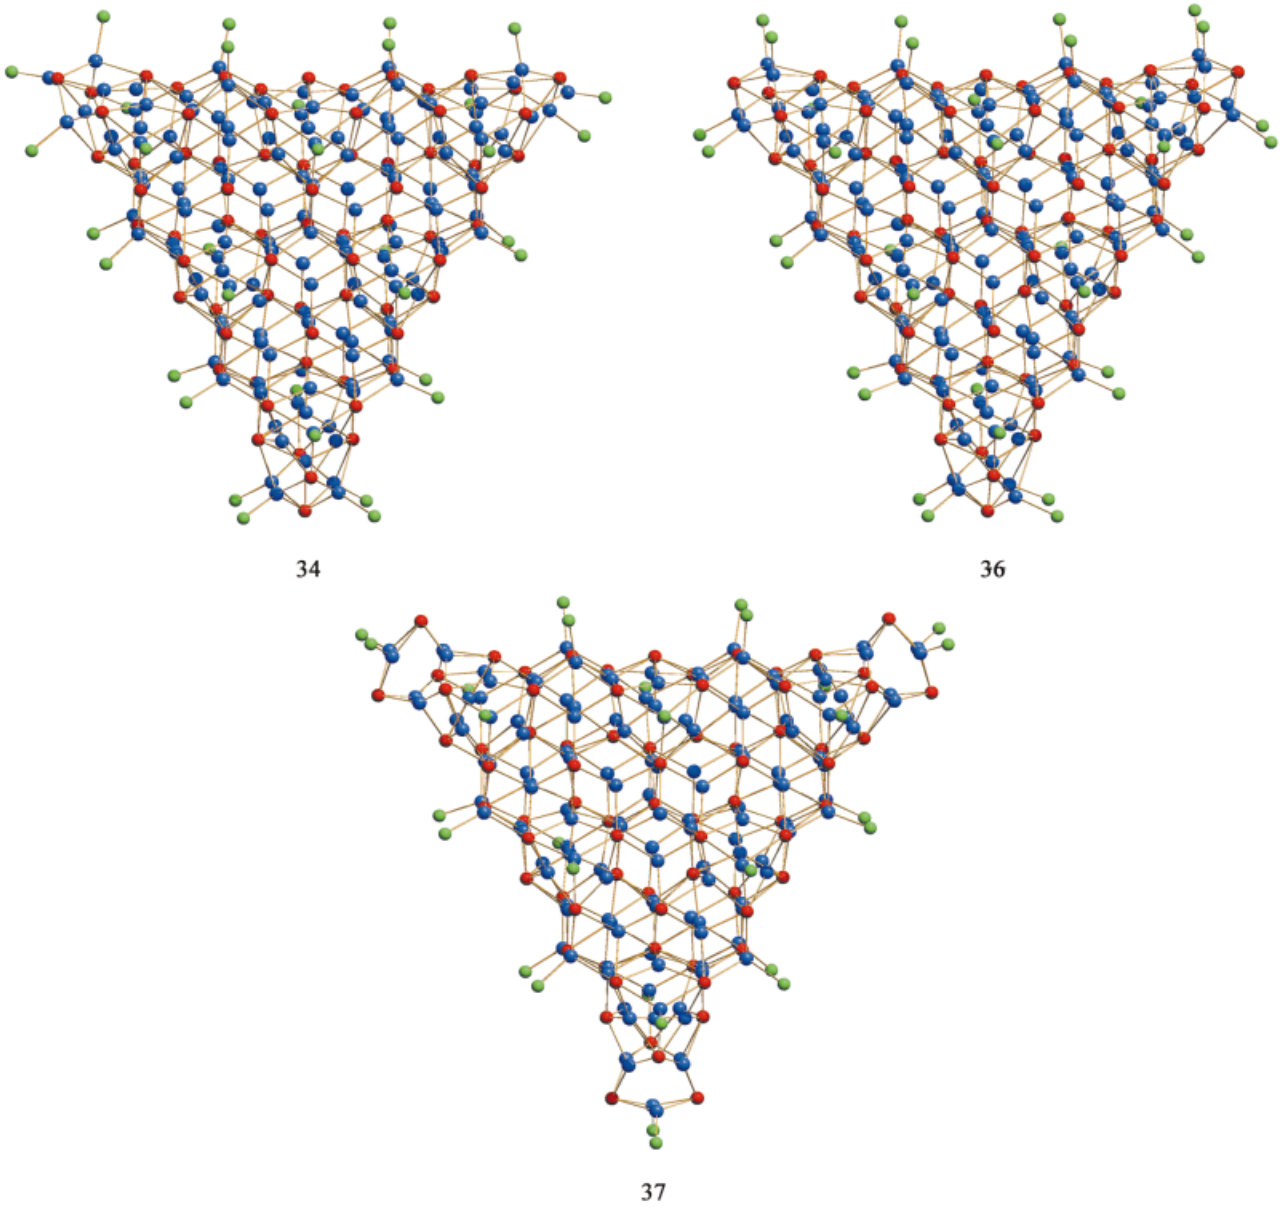

Figure 20. Molecular structures of $[Cu_{140}Se_{70}(PEt_3)_{34}]$ (**34**), $[Cu_{140}Se_{70}(PEt_3)_{36}]$ (**36**), and $[Cu_{146}Se_{73}(PPh_3)_{30}]$ (**37**) (without organic groups); in **34** and **36**, the two central copper atoms each have occupancies of 0.5, to result in one atom overall, which is statistically distributed over two sites; six further copper atoms are assigned occupancies of 0.67, resulting in four instead of six metal atoms in the overall formula

Table 3. Interatomic distances of selected Cu^I−Se systems

System	Cu−Cu [Å]	Cu−S distances for the different coordination numbers (*CN*) [Å]			Ref.

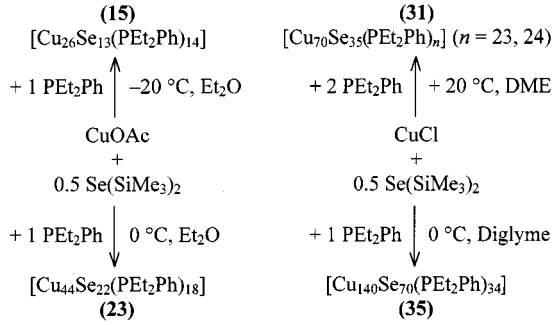
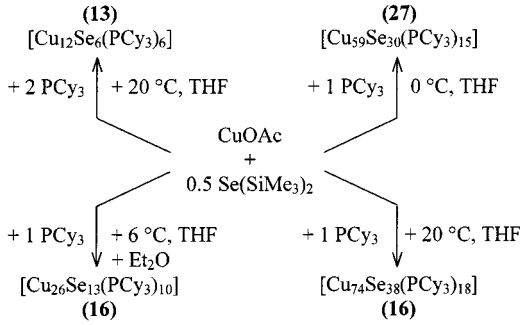
phanes, of different steric bulk, can lead to the formation and crystallization of similar, isomeric, or even identical Cu−Se cores if the ligand shells comply with certain requirements of regular geometry and thus protective properties. Inspection of Scheme 3 reveals that several clusters, varying significantly in size, may be formed in the presence of the same phosphane, although under different reaction conditions, so long as various suitable ligand shells can be

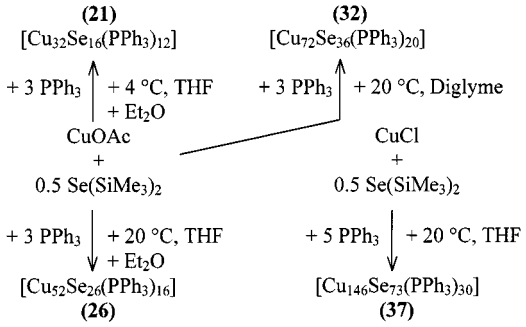
realized. In order to illustrate the size dependence of the cluster core on the use of different copper salts, reaction stoichiometries, solvents, and reaction temperatures, selected cluster formation reactions are shown in Schemes 5, 6, 7, and 8 with precise specifications of the respective conditions. Each scheme deals with one phosphane type.



Scheme 5. Synthesis of various copper selenide clusters in the presence of PEt_2Ph under different reaction conditions

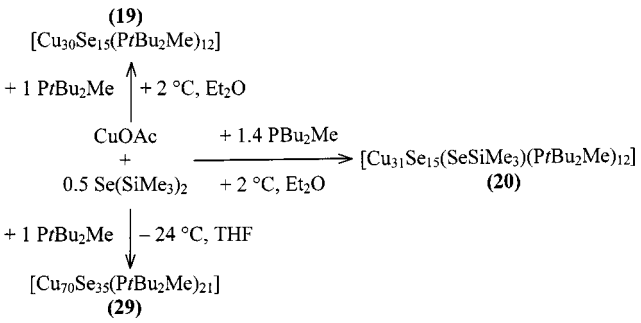


Scheme 6. Synthesis of various copper selenide clusters in the presence of PCy_3 under different reaction conditions



Scheme 7. Synthesis of various copper selenide clusters in the presence of PPh_3 under different reaction conditions

As for the copper sulfide clusters, comprehensive theoretical investigations within the MP2 approximation (program system TURBOMOLE) were carried out for the $[Cu_{2n}Se_n]$ clusters.[34] Again, stabilization energies per monomeric unit for a "naked" cluster growth from $n = 1$ through $n = 2-4$, 6 to $n = 10$ were calculated, along with phosphane binding energies for mono-, di-, tri-, tetra-, and hexameric species. The results are presented in Figures 21 and 22, respectively. The corresponding graphs for the Cu−S clusters, shown in Figures 6 and 7, respectively, are given once more for comparison purposes.



Scheme 8. Synthesis of various copper selenide clusters in the presence of $PtBu_2Me$ under different reaction conditions

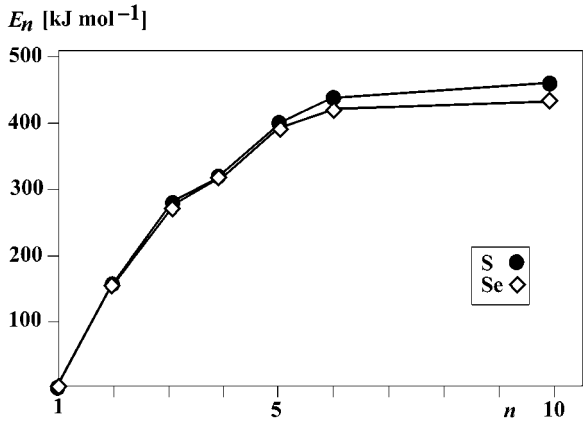


Figure 21. Variation of the stabilization energies per monomer unit in "naked" clusters $[Cu_{2n}E_n]$ (E = S, Se; $n = 1-4$, 6, 10) with the given values taking into account the total energies of the most stable structural isomers computed at the MP2 level

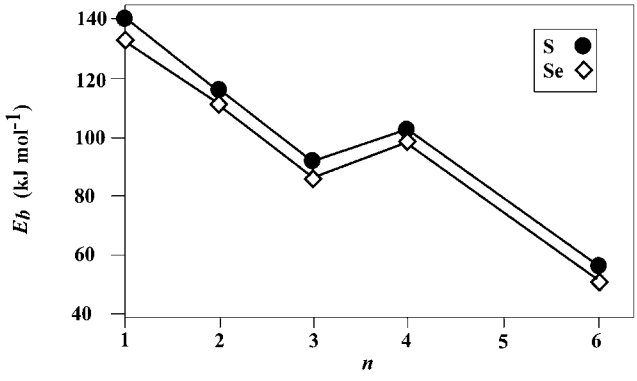

Figure 22. Variation of the Cu−P binding energies per Cu−P bond in phosphane-ligated clusters $[Cu_{2n}E_n(PH_3)_m]$ (E = S, Se; $n = 1-4$, 6; $m = 2$, 4, 6, 8); the given values taking into account the total energies of the most stable structural isomers computed at the MP2 level with respect to the total energy of PH_3 calculated by the same method

The variations in both energies are similar for the quantum chemically investigated sulfur- and selenium-bridged copper clusters. Thus, the kinetic rather than the thermodynamic stabilities of the species, and the very low

Cu−P binding energy, are the same as for the Cu−S compounds. Additionally, a comparison of the energetic properties of sulfur- vs. selenium-bridged copper clusters leads to two results. First, after nearly identical stabilization energies (maximum differences: ±5 kJ·mol^{-1}, < 2%) up to $n = 4$, a slightly higher stabilization for the Cu−S species is seen from $n = 6$ onwards. This correlates with a larger absolute value for the formation enthalpy of solid Cu_2S ($\Delta H_f° = -81.2$ kJ·mol^{-1}) than for solid Cu_2Se ($\Delta H_f° = -65.2$ kJ·mol^{-1}). However, the differences between the stabilization energies per monomeric unit for the calculated, rather small clusters do not exceed 5%. Thus, it is understandable why laser ablation spectra of copper chalcogenides do not vary much for the different chalcogens. Secondly, the Cu−P bond energies are generally 4−7 kJ·mol^{-1} (4−9%) higher for the sulfur-bridged compounds. This correlates with the discrepancy between the experiments reported by Dance et al.,[32] which show similar behavior for different chalcogens − in agreement with the calculations on "naked" species − and the experimental observations of significant differences in the syntheses and structures of phosphane-coordinated sulfur- and selenium-bridged copper clusters. The larger Cu−P binding energies computed for Cu−S clusters, relative to those computed for their Cu−Se analogues, help to explain the different ranges of observed products in the following way. Assuming that on going from the Cu−Se to the Cu−S systems the activation energy E_a for the Cu−P bond cleavage increases by a similar value as the Cu−P binding energy itself, a decrease in the respective reaction rate constant k can be calculated by means of the Arrhenius equation[54] [Equation (1)].

$$k = A \cdot e^{-E_a/RT} \quad (1)$$

At a typical cluster formation temperature of $T = 250$ K, an increase in the activation energy E_a of about 5 kJ·mol^{-1} causes a reduction in the rate constant k by one order of magnitude. Thus, the cluster growth that is initiated by the loss of a primary terminal phosphane ligand shell will occur at a lower rate for sulfur-bridged clusters. Consequently, unlike the selenium-bridged copper clusters, the Cu−S species show a much lower tendency to aggregate beyond "Cu_{12}".

3.2.2.2. Se^{2-}/SeR^--Bridged Copper Clusters

The use of alkylated or arylated derivatives $RSeSiMe_3$ (R = organic group) results in aggregation according to another mechanism, and leads to the formation of selenido/selenolato-bridged copper clusters. The given synthetic route using $RSeSiMe_3$ (Schemes 1 and 4) has not produced any selenolato-free species. This observation is at variance with those made for similar reactions with tellurolato reactants $RTeSiMe_3$ (see below). The experimentally isolated and characterized compounds listed in Scheme 4 display significantly different structures with respect to the purely E^{2-}-bridged molecules (E = S, Se). This applies even for reactions in the presence of tertiary phosphanes PPh_3 or P*i*Pr$_3$ used for the syntheses of the copper selenide clusters. The expanded ligand properties of SeR^-, which can act as both a bridging and a terminal ligand, lead to the crystallization of low nuclearity complexes with two, three, six, or nine metal centers (**38**−**42**),[20,22,30] if Se−C bond cleavage is suppressed. Larger cluster compounds can be isolated whenever Se^{2-} particles are produced during the reaction to facilitate the formation of inner selenium bridges. However, those molecules containing both selenide and selenolato ligands show structural patterns that are also common for Cu−Se clusters as far as the inner core is concerned. Figure 23 depicts compounds **38**−**42**, which only contain selenolato ligands and not selenide.

The binuclear complexes **38**[30] and **39**[20] formally show analogous molecular formulae but differ structurally according to the requirements of the different ligating components that are present. These requirements are of structural relevance for all Se^{2-}/SeR^--bridged copper clusters, as outlined in the following. Firstly, bidentate phosphanes dppR (R = organic spacer) bridge two copper centers at the periphery of the polynuclear complex or cluster molecule and therefore act simultaneously as both protecting groups and linking molecules. Secondly, selenolato ligands SeR^- have the capability to bridge between two *or* three metal centers. Additionally, they *can* be terminally bonded, as in **39**, when the Cu−Cu distance (9.01 Å) is too large for a monoatomic μ_2-bridge. Thirdly, tertiary phosphanes PR_2R' act exclusively as terminal ligands. Therefore, the copper atoms in **38** are bridged by $SePh^-$ fragments at a Cu−Cu distance of 2.846(1) Å. The molecular structure of **40**[22] also conforms to these constraints, again with the ubiquitous key factor of optimal protection of the heavy atom framework by organic groups. Compounds **41**[30] and **42**[30] are the only examples that could be isolated employing the bidentate amine ligand bipyridyl (**41**) or diphenylphosphanyl acid Ph_2PO_2H (**42**). Compound **41** seems to represent a "snapshot" molecule during cluster growth, since two $[Cu(bipy)]^+$ fragments are unsymmetrically attached to a regular cluster center. The latter is formed by a distorted Cu_4 tetrahedron [Cu−Cu: 2.650(4)−2.824(4) Å], the six edges of which are each μ_2-bridged by $SePh^-$ ligands. However, four of the phenyl selenolato groups act as μ_3-bridges in the molecule, since two bind to each of the additional $Cu(bipy)^+$ units. Having achieved charge neutrality, the sufficiently protected compound precipitated in this low nuclearity state. Much higher molecular symmetry − even crystallographic symmetry − is found for **42**. Two six-membered $Cu_3(SePh)_3$ rings are linked by three "naked" copper centers leading to a μ_3-bridging function of the $SePh^-$ groups. Additionally, the rings are clamped by three $Ph_2PO_2^-$ ligands, which bind to the six copper atoms in the two six-membered rings. Twelve phenyl groups perfectly wrap the uncharged cluster and therefore allow the termination of atomic aggregation and crystallization in THF.

As was found for the copper chalcogenide clusters **1**−**37**, the nature of the phosphane ligands plays a key role in determining the size and structures of the observed product molecules, even though they are no longer the sole protective groups at the cluster peripheries. Great success in the synthesis of copper selenide/selenolate clusters was achieved by the use of bidentate phosphanes. The variation of or-

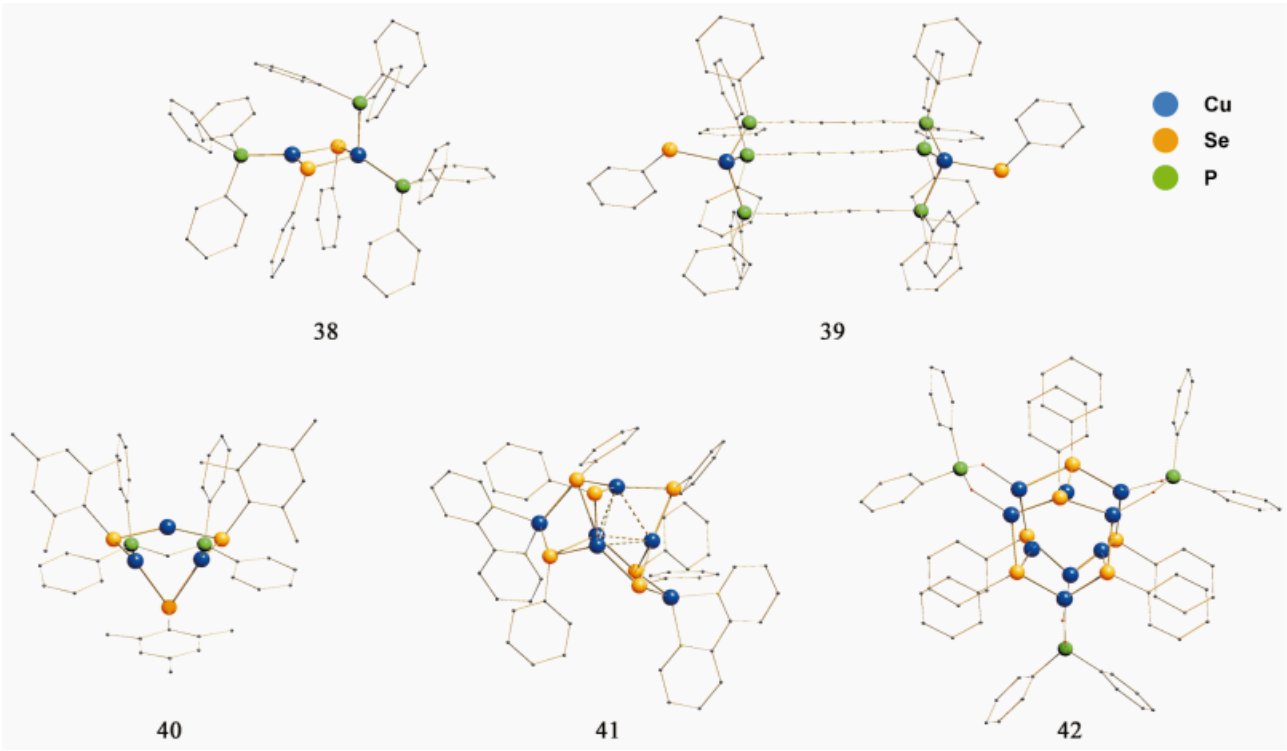

Figure 23. Molecular structures of $[Cu_2(SePh)_2(PPh_3)_3]$ (**38**), $[Cu_2(SePh)_2(dppbd)_3]$ (**39**), $[Cu_3(SeMes)_3(dppm)]$ (**40**), $[Cu_6(SePh)_6(bipy)_2]$ (**41**), and $[Cu_9(SePh)_6(O_2PPh_2)_3]$ (**42**) (without hydrogen atoms)

ganic spacers between the two ligating $[Ph_2P]$ fragments replaces the former variation of organic substituents R of PR_2R' in the selenolate-free clusters. Again, a given dppR ligand does not inflexibly restrict the synthesis to the formation of one single cluster product. Other reaction conditions discriminate between several potential compounds that can all be conveniently protected by the phosphane employed. Thus, with ethane, propane, butane, acetylene, or benzene spacers, one obtains clusters with 16, 25, 36, 38, or 58 copper centers (**43**,[20] **44**,[22] **46**−**50**,[22,30] **52**[22]), respectively. The only tertiary phosphane PR_3 to have been successfully used for the formation of higher nuclearity $Se^{2-}/SePh^-$-bridged copper clusters is P*i*Pr$_3$. With this ligand, the synthesis of molecules featuring 32, 50, or even 73 metal centers (**45**, **51**, and **53**)[23] was observed, depending on the reaction conditions. Figure 24 shows the molecular structures of **43** and the anion in **44**, which represents the only ionic copper selenide cluster compound isolated to date.

Both clusters are oblong in shape. The selenium substructure of **43** can, however, be viewed as an incipient hexagonal packing of selenium atoms. The middle "layer" consists of six atoms arranged in a zigzag fashion, while the two enclosing "layers" each contain three selenium centers occupying the quasi *A* position with respect to the quasi *B* position of the atoms in between. Four of the chalcogen bridges do not bind to phenyl groups and act as μ_4- or μ_6-bridging ligands. The $SePh^-$ ligands bind to two or three copper neighbors each, and at the same time contribute to the protection of the Cu−Se core by means of their organic substituents. Six copper atoms are linearly coordinated by two

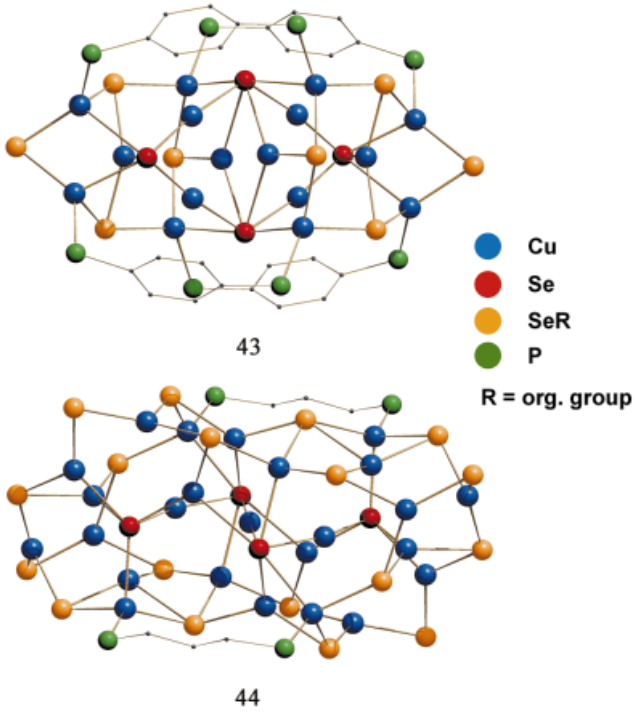

Figure 24. Molecular structures of $[Cu_{16}Se_4(SePh)_8(dppbe)_4]$ (**43**) and the anion in $[Cu(dppp)_2][Cu_{25}Se_4(SePh)_{18}(dppp)_2]$ (**44**) (without terminal phenyl groups)

selenium ligands, two show an almost trigonal-planar $[Se_3Cu]$ coordination, whereas the remaining eight metal centers occupy the centers of slightly distorted $[Se_3P]$ tetra-

hedra. Unlike in **43**, the chalcogen framework of **44** is composed of an ellipsoid-type deltahedron of four Se^{2-} ligands and 18 selenium atoms of the $SePh^-$ groups. Again, the bridging mode of the chalcogen centers is higher for the "naked" ligands (μ_5 or μ_7) than for the $SePh^-$ fragments (μ_2 to μ_4 with regard to the Cu−Se bonds). Eighteen copper atoms are positioned at the cluster periphery and belong to almost planar [Se_3Cu] or distorted tetrahedral [Se_3CuP] units. The observation that less linear [Se_2Cu] arrangements are present (four in **43**, three in **44**) underlines the trend to higher coordination numbers at the metal center with increasing molecular size, as reported for the copper selenide clusters without selenolato ligands. The cluster core is large enough to accommodate seven inner copper atoms that are either two-, three-, or four-coordinated by selenium neighbors. Comparing the compositions of **43** and the anion in **44**, one perceives an increasing preference for ligation by $SePh^-$ ligands rather than by phosphane donors. This may be explained by the dual character of the $SePh^-$ groups, which primarily form fairly stable Cu−Se cluster bonds, but also bear protective organic substituents. Thus, the ratio of selenolato selenium atoms to phosphorus atoms increases from 1:1 in **43** to 4.5:1 in **44**.

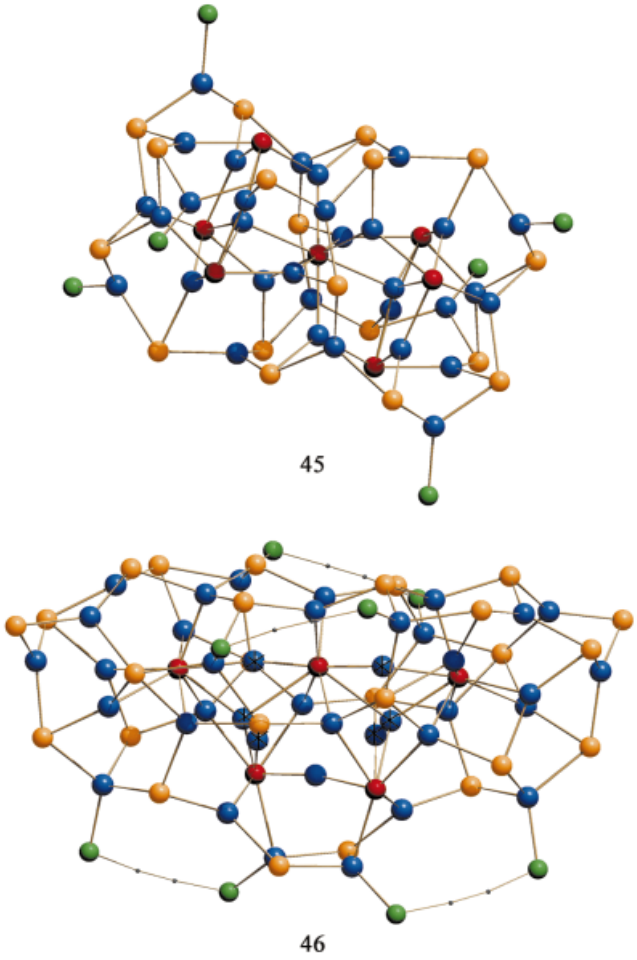

Figure 25. Molecular structures of $[Cu_{32}Se_7(SenBu)_{18}(PiPr_3)_6]$ (**45**) and $[Cu_{36}Se_5(SePh)_{26}(dppa)_4]$ (**46**) (without *n*-butyl, isopropyl, or phenyl groups); three copper atoms (marked with an asterisk) in the cluster center of **46** are distributed over six sites with occupancies of 0.5

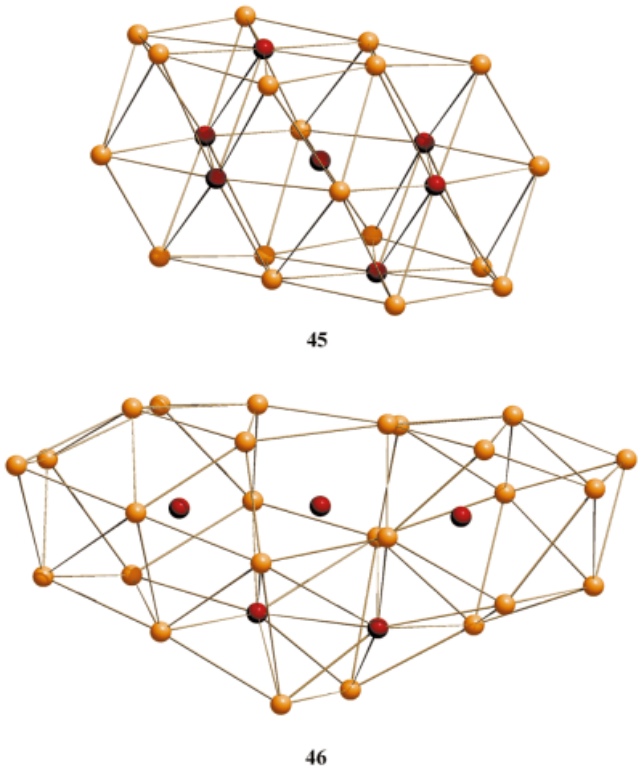

Figure 26. Selenium substructures in **45** (top) and **46** (bottom); the Se−Se lines do not represent bonding interactions, but merely help to visualize the *A-B-C* packing of selenium atoms in three layers in **45** or explain the geometry of the polyhedron in **46**

The molecular structures of the cluster compounds **45** and **46** are shown in Figure 25, while Figure 26 compares the selenium substructures in these two clusters.

As in the comparison between **43** and **44**, we again have a smaller cluster for which the structure is based on a regular packing of selenium atoms in hexagonal layers (**45**) and a larger, rather spherically shaped compound that features a polyhedral selenium framework (**46**). However, the selenium layers in the $SenBu^-$-bridged species **45** are packed in an *A-B-C* fashion similar to the Cu_2Se solid-state structure, which is unparalleled for all copper chalcogenide clusters characterized to date. This similarity between the atomic arrangement of a cluster molecule and the non-molecular Cu_2Se suggests that a nanosized fragment of a bulk structure may indeed be stabilized by coating the surface with suitable groups. This tendency has also been observed in three silver selenide/selenolate clusters, $[Ag_{112}Se_{32}(SenBu)_{48}(PtBu_3)_{12}]$, $[Ag_{114}Se_{34}(SenBu)_{46}(PtBu_3)_{14}]$, and $[Ag_{172}Se_{40}(SenBu)_{92}(dppp)_4]$.[55] Compound **45** is the only copper selenide/selenolate compound that contains $SenBu^-$ groups like those found in these silver clusters. It is not yet proven, but is nevertheless conceivable, that the packing of the selenium atoms is influenced by the nature of the organic group attached to the selenolato ligand. The chalcogen layers in **45** are centered by a large planar rhombus of nine selenium atoms. Five of them are "naked" Se^{2-} ligands in

the cluster network, while the four vertex atoms belong to Se*n*Bu$^-$ groups. Above and below this middle layer, one finds two similar but truncated rhombuses consisting of only eight selenium atoms, the "central" ones not being bonded to organic substituents. However, the size dependency of the structural properties seems to be different from that of the selenolato-free copper clusters. Thus, layer-type structures are observed even for smaller molecules like **43** or **45**, as well as for larger spherical ones. Additionally, a return to lower average coordination numbers in larger clusters may arise, as observed in **45**. The location of the copper atoms in **45** can be described with reference to the selenium grid. The six phosphane-bound copper centers bind to two selenium atoms of Se*n*Bu$^-$ ligands and are situated on the cluster periphery. Six copper atoms are located approximately within the selenium layers and have trigonal-planar coordination geometries with normal Cu−Se bond lengths of 2.406(2)−2.483(2) Å. The other 20 metal centers are positioned between the layers of selenium atoms. Two of these show ideal tetrahedral environments, while the others are shifted away from the centers of tetrahedral holes. As a result, each of these displays only three normal Cu−Se bonds, with the fourth Cu−Se distance being relatively long (3.18−3.35 Å). The tendency to occupy tetrahedral holes − even unsymmetrically − is again consistent with the structural properties of bulk Cu_2Se. In **46**, five inner Se^{2-} ligands are enclosed by a shell of 26 $SePh^-$ fragments. The bridging modes of the Se^{2-} ligands amount to μ_7 or μ_8, whereas the selenium atoms of the $SePh^-$ groups act only as μ_2- to μ_4-bridges between adjacent copper atoms. The copper centers show coordination numbers of two, three, or four, within $[Se_2Cu]$, $[Se_3Cu]$, and $[Se_4Cu]$ or $[Se_3CuP]$ units, respectively. Depending on their position inside the cluster or at the surface, the selenium neighbors of the metal atoms are exclusively Se^{2-}, or both Se^{2-} and $SePh^-$ ligands. As for compounds **43** or **44**, the number of terminal selenolato groups is greater than the number of ligating phosphorus atoms (SeR/P ratios: 3:1 in **45**, 3.25:1 in **46**).

Four very similar Cu/Se/SePh clusters are formed in the presence of either dppe, dppp, or dppb (**47**−**50**). The syntheses of the isomeric, mixed-valence compounds **47** and **48**, containing 36 copper centers, were carried out in THF. The isomeric "Cu_{38}" clusters **49** and **50**, which formally contain exclusively Cu^+, were crystallized from toluene. Besides the different solvents, the reactions producing the dppb-ligated compounds **48** and **50** differed in the CuCl:dppb ratios (3.1:1 for **48**, 5:1 for **50**). In Figure 27, the molecular structures of **47** and **49** are given as examples.

Cluster **47** crystallizes in the trigonal space group $R\bar{3}$, whereas **48**−**50** crystallize in triclinic $P\bar{1}$. Despite the different crystallographic symmetries, all four compounds display very similar structural properties. A closer look at the atomic arrangements may explain the preference for this prototypical cluster framework in terms of the highly symmetrical substructures. A central selenium atom positioned at the inversion centers of the clusters is surrounded by a distorted icosahedron of twelve copper atoms. The latter is itself enclosed by another distorted Se_{12} icosahedron. An

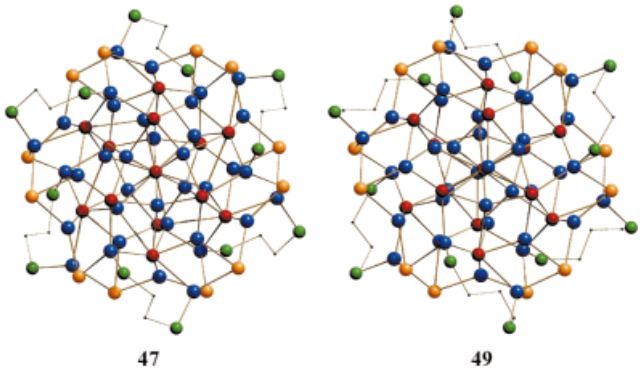

Figure 27. Molecular structures of $[Cu_{36}Se_{13}(SePh)_{12}(dppe)_6]$ (**47**) and $[Cu_{38}Se_{13}(SePh)_{12}(dppp)_6]$ (**49**) (without phenyl groups)

alternate packing of Cu_{12} and Se_{12} icosahedra has already been discussed for the Cu−Se clusters **14** and **15** (Figures 9 and 10). In these compounds, one polyhedron is positioned with its edges perpendicular to the edges of the polyhedron beneath. Unlike that pattern, the Se_{12} and Cu_{12} icosahedra in **47**−**50** are arranged such that one of the idealized fivefold axes of one polyhedron is parallel to one of the idealized threefold axes of the other and vice versa. The central $[Se_{13}Cu_{12}]$ unit of **47** is shown as an example in Figure 28.

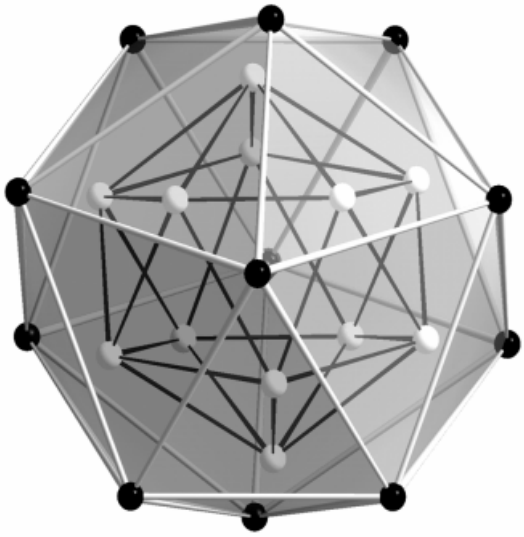

Figure 28. The central $[Se_{13}Cu_{12}]$ unit in **47**; the drawn lines only represent polyhedral edges and do not imply bonding interactions

In this way, six edges and six faces of the Cu_{12} icosahedron are bridged by the selenide ligands that form the Se_{12} polyhedron. The cluster core is then extended to the periphery by coordination of the Se_{12} substructure by another 24 copper atoms, twelve of which are ligated by the six dppR ligands. All 24 of these copper atoms are also bridged by twelve μ_3-$SePh^-$ groups, which are positioned at the cluster surface between the phosphane molecules. Except for the μ_{12}-bridging central selenium atom, the selenide ligands act as μ_6-bridges (six in both **47** and **48**, all twelve in **49** and **50**) or μ_5-bridges (six in both **47** and **48**) between copper centers. The different numbers of copper neighbors

per selenium atom in **47** or **48** on the one hand, and in **49** or **50** on the other, is caused by two copper atoms being formally absent in the molecular structures of **47** or **48**, resulting in the mixed-valence situation, but present in **49** and **50**. The respective copper atoms each coordinate to one of the Se_{12} icosahedral faces and form a straight Cu−Se−Cu axis, with the central selenium atom in the middle. At the same time, this $[Cu_2Se]$ arrangement represents an idealized threefold axis that is not realized crystallographically in **49** or **50**. The metal centers are surrounded in a distorted trigonal-planar or tetrahedral fashion. All Cu−Se distances in the mixed-valence clusters lie within the range of the Cu−Se bond lengths in all four clusters [2.301(4)−2.888(3) Å] and thus give no evidence for any localization of the Cu^{2+} centers. However, the range of the Cu−Cu contacts in **47** or **48** [2.511(3)−2.943(4) Å] is rather narrower than that found for **49** or **50** [2.305(4)−3.040(3) Å]. The spherical, somewhat oblate molecules show a maximum total diameter of 23.9−25.7 Å.

The use of different selenolato sources and different optimized reaction conditions leads to three different copper selenide/selenolate clusters with terminal $PiPr_3$ ligands, i.e. **45** (Figures 25 and 26), **51**, and **53**. The latter is synthesized in an unusual manner by the use of both $PhSeSiMe_3$ and $Se(SiMe_3)_2$ in the same reaction and is discussed below. Scheme 9 summarizes the syntheses of the $PiPr_3$-ligated clusters, specifying the reaction conditions in detail. Figure 29 shows the molecular structure of compound **51**.

Looking at Figure 29, one gets the impression that "normal" cluster growth occurred in the presence of a tertiary phosphane, and with Se−C bond cleavage, to result in the formation of a copper selenide cluster represented by the $[Cu_{40}Se_{20}]$ central unit of **51**. Only the lateral attachment of two symmetry-equivalent $[Cu_5(SetBu)_5(PiPr_3)_2]$ fragments reminds us of the presence of the selenolato reactant. This is in contrast to the equally $PiPr_3$-ligated structure of **45**, which shows only seven Se^{2-} ligands along with 18 $SetBu^-$ groups. No definite correlation between the clearly different courses of cluster formation and the respective reaction conditions can be delineated based on such a limited sample size, but it is very likely that the Cu:P ratio of the reactants and the temperature play important roles. The copper atoms in **51** bind to Se^{2-}, $SePh^-$, and $PiPr_3$ ligands in different ratios to achieve coordination numbers of two (albeit with a bent coordination geometry indicating a weak third interaction), three, or four. The selenium atoms bearing *tert*-butyl groups act as μ_3-bridges between copper atoms, whereas the Se^{2-} ligands bridge between five, six, or seven copper neighbors. The molecules are protected in the usual way by the $PiPr_3$ ligands and the organic substituents of the $SetBu^-$ groups.

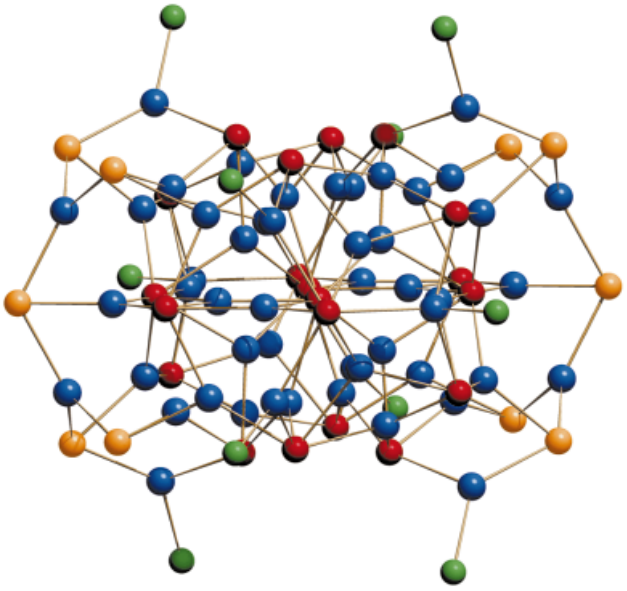

Figure 29. Molecular structure of $[Cu_{50}Se_{20}(SetBu)_{10}(PiPr_3)_{10}]$ (**51**) (without organic groups)

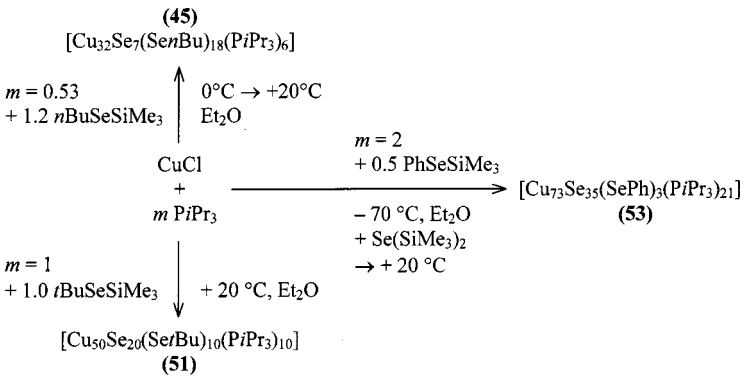
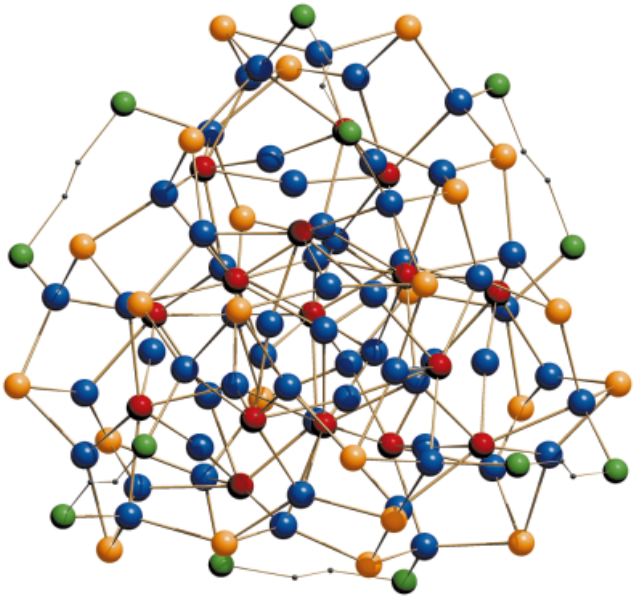
The molecular structure of another dppR-ligated copper cluster (R = a = acetylene) with both selenido and selenolato ligands, **52**, again possesses a high symmetry. This time, the molecular symmetry is underlined by a very high crystallographic symmetry. The compound crystallizes in the cubic space group $F\bar{4}3c$ and thus represents the second known copper chalcogenide cluster besides **14** (space group $Fm\bar{3}$) with a cubic crystal lattice. The molecular structure of **52** is illustrated in Figure 30.



Scheme 9. Synthesis of various selenido/selenolato-bridged copper clusters in the presence of $PiPr_3$ under different reaction conditions



52

Figure 30. Molecular structure of $[Cu_{58}Se_{16}(SePh)_{24}(dppa)_6]$ (**52**) (without phenyl groups)

As observed for compounds **47**−**50**, the cluster core is oblate in shape, but in contrast to **47**−**50** it is not based on icosahedral fragments. Instead, a central Cu_4 tetrahedron shares its corners with four further Cu_4 units, which, in turn, share their *trans* faces with a Cu_6 octahedron. The remaining 30 copper atoms are situated between these polyhedra or are connected at the exterior of the polyhedral arrangement. The copper substructure of **52** is shown in Figure 31.

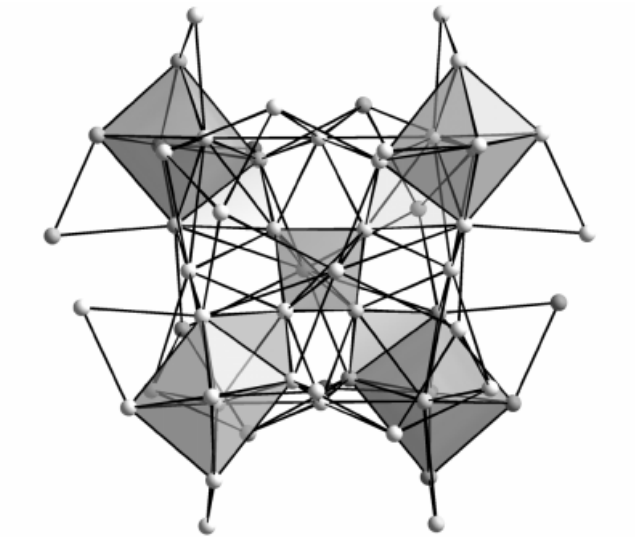


Figure 31. The copper substructure in **52**; the connected Cu_4 tetrahedra and Cu_6 octahedra are highlighted by gray shading; Cu−Cu distances are drawn up to 3.012(4) Å

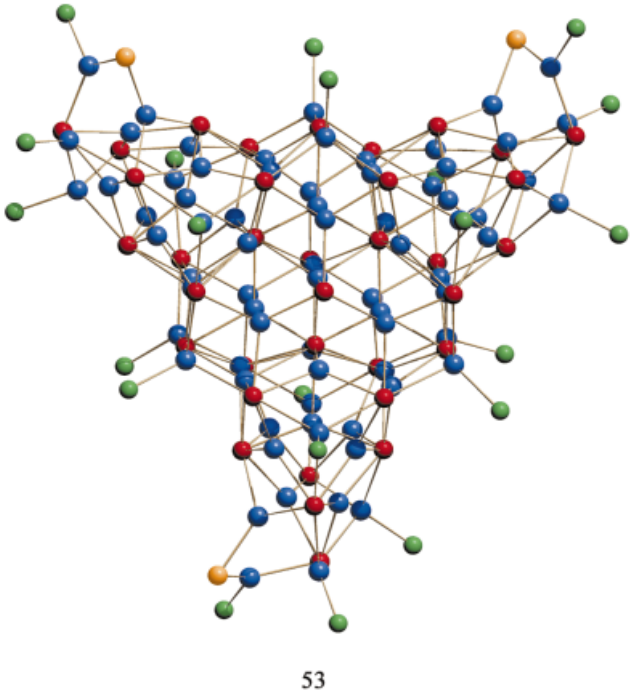
Even though the Cu_{58} substructure has to be assigned a formal charge 56+ (assuming Se^{2-} and $SePh^-$ ligands as well as electroneutrality in the sum), which implies an extraordinary mixed-valence Cu^+/Cu^0 compound, one does not find any indication of exceptional Cu−Cu binding interactions. The Cu−Cu distances lie within the usual range of 2.540(3)−3.012(4) Å. Thus, the cluster core is held together by bridging selenido or selenolato ligands in the usual way. The former act as μ_5- or μ_6-bridges, while the latter form μ_3-bridges between adjacent copper atoms. Despite the large cluster size, metal centers with near-linear, trigonal-planar, and tetrahedral coordination are observed. Therefore, it is again apparent that the size-dependencies of the structural principles discussed for chalcogenolato-free copper sulfide or copper selenide clusters are generally invalid in the Cu/Se/SeR cluster systems. Six dppa ligands and 24 phenyl groups of the $SePh^-$ fragments protect the cluster molecule. Hence, **52** continues the series of compounds that show a significant preference for protection by the SeR^- groups rather than by the phosphane ligands. The clusters **43** and **47**−**51** represent exceptions from this series as their SeR/P ratios all amount to 1:1.

The largest cluster that displays both Se^{2-} as well as SeR^- ligands in the cluster framework is **53**. Its molecular structure is shown in Figure 32.



53

Figure 32. Molecular structure of $[Cu_{73}Se_{35}(SePh)_3(PiPr_3)_{21}]$ (**53**) (without organic groups)

This cluster displays a $[Cu_{70}Se_{35}]$ core, which is identical to that observed in **28** and **29** (Figures 18 and 19). Only three additional Cu−SePh fragments positioned at the corners of the triangular molecule distinguish **53** from the slightly smaller "Cu_{70}" clusters. The fact that one observes a typical copper selenide cluster structure with only a few

selenolato groups present is surprising, since $PhSeSiMe_3$ was the first selenium source to be added during the synthesis. This again illustrates the distinct preference for the "Cu_{70}" molecular structure, which is formed whenever the reaction conditions (Scheme 9) and the solubility situation enable the cluster growth to proceed until this large cluster compound crystallizes.

3.2.3. Optical Spectra and Thermal Behavior

The discrete molecular cluster species reviewed thus far are ideal subjects for studying the molecular quantum size effect,[3] which is one of the most absorbing questions connected with research in the field of cluster chemistry. In this regard, one must investigate the electronic properties of the cluster species, and first of all the relationship between cluster size and the HOMO−LUMO gap. Theoretical investigations have provided preliminary answers to this question.[34,37] The first dipole- and spin-allowed singlet or triplet excitations of selected "naked" copper selenide clusters $[Cu_{2n}Se_n]$ (up to $n = 15$) were calculated at the CIS level[56] (CIS = configuration interaction considering single excitations) for structures previously optimized for the same symmetry employing the CCSD(T) method[57] [CCSD(T) = coupled cluster approximation up to single and double excitation with additional consideration of third excitations by means of perturbation theory] ($n = 1, 2$) or the MP2 method ($n > 2$). Triplet excitations were investigated in order to take into account the fact that relativistic effects (spin-orbit coupling)[58] are significant in Cu−Se compounds. The results are presented in Figure 33.

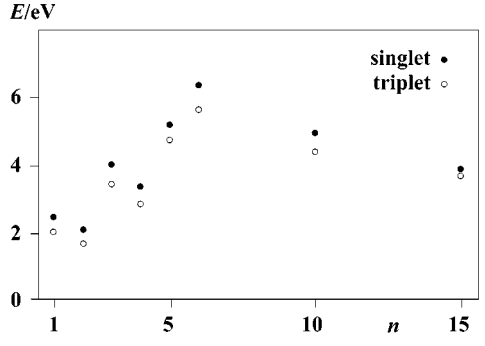


Figure 33. First dipole- and spin-allowed singlet or triplet excitations of selected "naked" copper selenide clusters $[Cu_{2n}Se_n]$ (up to $n = 15$), calculated at the CIS level (CIS = configuration interaction with single excitations) for structures previously optimized for the same symmetry employing the CCSD(T) method [CCSD(T) = coupled cluster up to single and double excitation with additional consideration of third excitations by means of perturbation theory] ($n = 1, 2$) or the MP2 method ($n > 2$)

The changes in the energy values for singlet or triplet excitations with increasing cluster size show similar trends, with the triplet excitation energies being 0.2−0.7 eV lower than the singlet ones. The excitation energies increase with a slight oscillation to a value of around 6 eV for the hexamer ($n = 3$), decreasing thereafter down to a value of ca. 3.8 eV for the $[Cu_{30}Se_{15}]$ species. The initial increase in the excitation energy values can be explained firstly by a stabilization of selenium *p*-orbitals by admixture of *s*-, *p*-, or *d*-contributions from the copper atoms, and secondly by an increasing degree of completion of the selenium shell around the copper substructure. The latter reduces the space for electrons in excited states with *s*-character. Thus, for $[Cu_{12}Se_6]$, significant *p*-type contributions are observed for the calculated transitions. The two exceptions ($n = 2, 4$) to this trend feature less compact molecular structures, which lead to lower excitation energies. Once the covering of selenium atoms on the copper framework has been completed, the overall size of the cluster molecules becomes more important. This confirms the assumption of separating the Se-*p* and Cu-*s* states to form valence and conducting bands. For clusters of ever increasing size, and ultimately bulk Cu_2Se, the first excitation energy should approach a value of ca. 1 eV.[59,60] According to the quantum chemical investigations, "naked" "middle-sized" copper selenide clusters should be colorless insulators that gradually adopt semiconductor properties with increasing cluster size. Calculations on small PH_3- or PMe_3-ligated copper selenide clusters indicate an increase in the first excitation energies compared to the corresponding "naked" clusters. Estimating a degree of error of about 1.5 eV, the respective transitions could indeed lead to the absorption of violet light, in agreement with the observed red color of the small copper selenide clusters.

The crystals obtained in the cluster formation reactions are colored. The intensity of the color increases on going from sulfur- to selenium- to tellurium-bridged compounds (see below), as expected for an increase in covalent or (semi)metallic binding properties. Small copper sulfide or selenide clusters form light-red, orange, or purple crystals. With increasing cluster size, the color becomes dark-red, reddish-black, and finally black with a metallic sheen. The optical spectra of some copper selenide cluster compounds were studied by means of solid-state UV/Vis spectroscopy. The single-crystalline samples were powdered and sus-

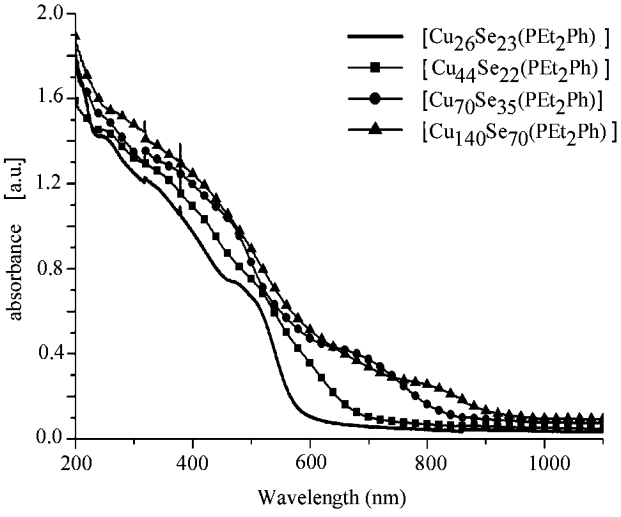

Figure 34. Solid-state UV/Vis absorption spectra of PEt_2Ph-ligated compounds **15**, **23**, **31**, and **35** that contain 26, 44, 70, and 140 copper atoms; for the measurements, powdered single-crystalline samples in mineral oil were placed between two quartz plates

pended in mineral oil between two quartz plates. Figure 34 shows the absorption spectra of the PEt_2Ph-ligated compounds **15**, **23**, **31**, and **35**, which contain 26, 44, 70, and 140 copper atoms, respectively. The influence of the phosphane ligands should be broadly the same for all four clusters, hence the increments in the position of the absorption band can be attributed solely to the increasing size and structural changes of the Cu−Se framework.

A shift of the absorption band to higher wavelengths with increasing cluster size is observed. In principle, this is consistent with a decrease in the HOMO−LUMO gap in the same direction. Although the experimental value for the band gap in Cu_2Se (1.1 eV, i.e. 1127 nm, from optical measurements;[59] 0.37 eV, i.e. 3350 nm, from electrochemical measurements[61]) is not reached, the trend can be explained in terms of the quantum size effect. An approximation of the HOMOs and LUMOs with increasing nuclearity is clearly observed. The broadness of the bands in the cluster spectra may be a result of the measurements being made at room temperature and/or a charge-transfer contribution to the observed transitions.

It has been known for several years that Cu−P bond cleavage occurs upon heating the copper selenide clusters, forming Cu_2Se as a black powder. In addition, XPS experiments (XPS = X-ray photoelectron spectroscopy) have shown that partial removal of the terminal ligands under the experimental conditions (room temperature, high vacuum) leads to an aggregation of the remaining clusters to larger, still ligated particles with a very narrow size distribution.[33] This agrees with the results of the quantum chemical investigations, which indicated the clusters to be metastable species with respect to the binary chalcogenide Cu_2E, and pointed to very low calculated Cu−P binding energies (see above). Thermogravimetric analysis of **31** (Figure 35) showed that all the phosphane ligands are removed in a single-step process within 20 minutes. The temperature required for this process is dependent on the experimental pressure.

Carrying out the experiment at normal pressure in a nitrogen flow, the ligands are all lost at 226 °C. On reducing the pressure down to $2\cdot10^{-6}$ mbar, this temperature decreases to 145 °C. However, on calculating the mass difference, one observes a loss of 33.6% rather than the 35.6% that should have been lost theoretically. This observation, as well as a residue of 1.2% carbon in the resulting copper selenide powders, indicates a slight amount of decomposition of the PR_2R' ligands. Following the process by means of powder diffraction, the intense reflections of the crystalline cluster in the range $2\Theta = 2-10°$ disappear during the thermogravimetric experiments, and are replaced by lower intensity reflections in the 2Θ range 10−55°. Sharp reflections from crystalline α-Cu_2Se are finally observed after annealing the powder at 600 °C. The Scherrer equation[62] [Equation (2)] gives a relationship between the medial peak width β and the particle size *D*.

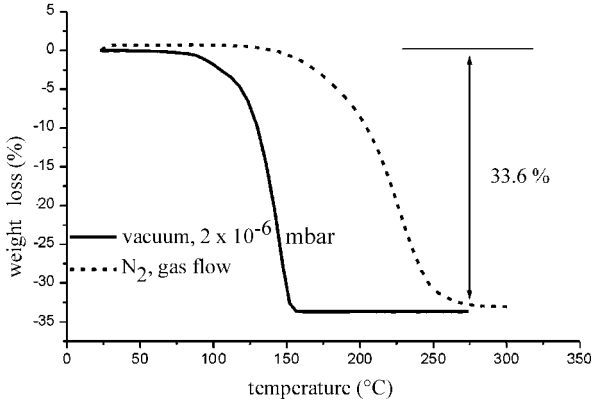

Figure 35. Results of a thermogravimetric analysis of **31** under different pressures

$$D = (K\cdot\lambda\cdot57.3)/(\beta\cdot\cos\theta) \quad (2)$$

where *D* is the average particle size perpendicular to the reflecting plane, *K* is the atomic form factor (here 1.0), λ is the wavelength of the X-ray radiation (here Cu-K_α: λ = 1.5418 Å), β is the peak width measured at half maximum intensity, and θ is the diffraction angle.

After calibration of the peak width at half maximum intensity for the diffractometer using LaB_6, an average particle size of $D = 117$ Å could be calculated for Cu_2Se powders generated by heating **31** to 150 °C at $2\cdot10^{-6}$ mbar for 20 min. This value for *D* is 7.8 times the size of the $[Cu_{70}Se_{31}]$ core of **31** (15 Å). The results give a further indication of a partial, controlled collapse of the cluster particle lattice.

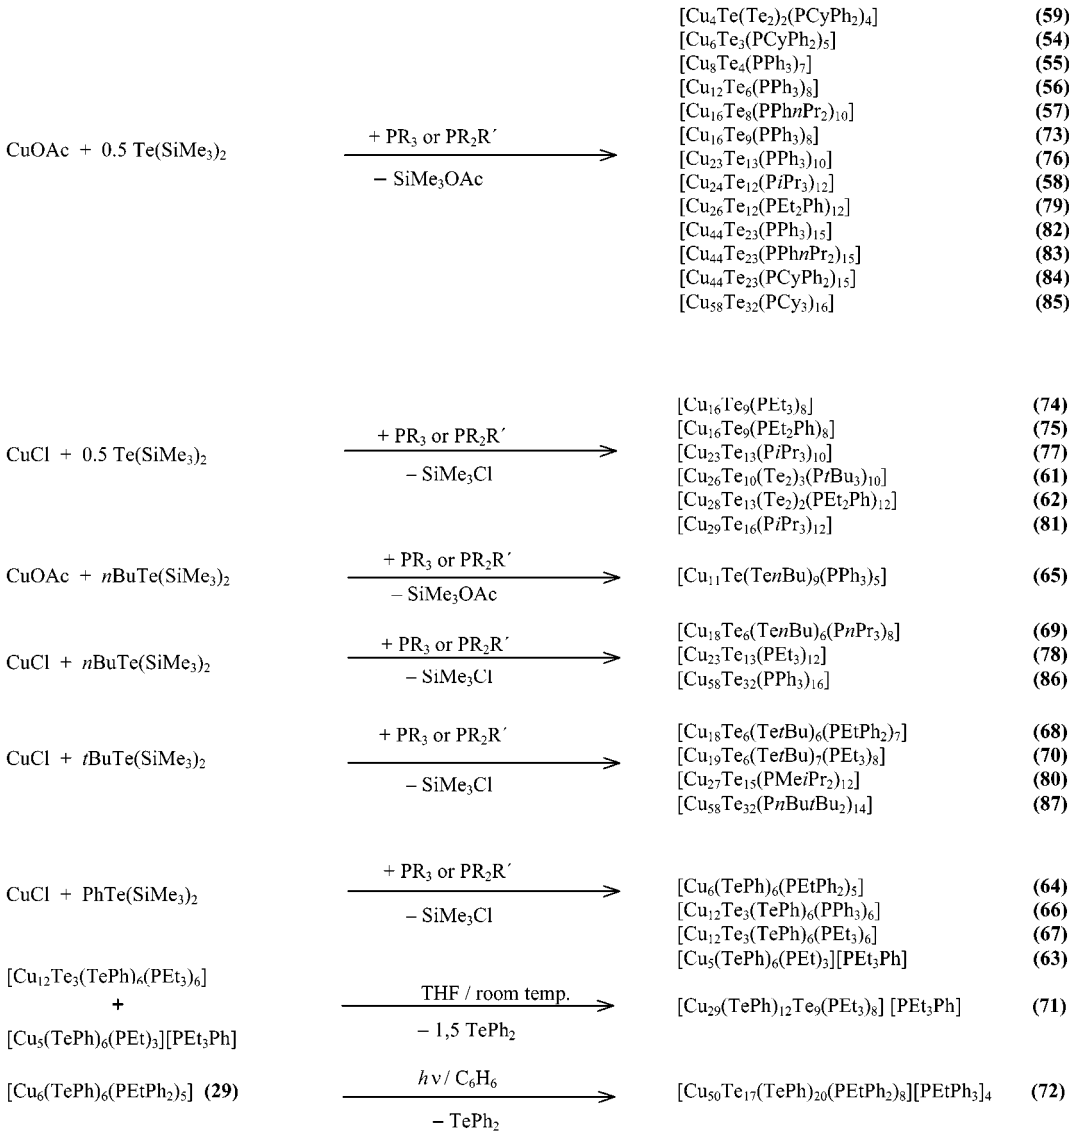
3.3. Tellurium-Bridged Copper Clusters

In this section we focus on the description of the syntheses and structures of ligand-stabilized copper telluride cluster molecules. Solid-state copper tellurides as well as ternary alkali metal copper telluride compounds, which consist of *n*-dimensionally linked copper telluride clusters, are beyond the scope of this review. Their syntheses have become more frequent, although there are still only a limited number of examples, e.g. KCuTe,[63] NaCuTe,[48a] KCu_3Te_2,[64] $NaCu_3Te_2$,[65] $K_2Cu_5Te_5$,[66] and $K_4Cu_8Te_{11}$,[67] all of which have been prepared by means of melt reactions. The recently synthesized compound $K_3Cu_{11}Te_{16}$ [68] is the first example of a ternary alkali metal copper telluride crystallized from supercritical 1,2-diaminoethane.

3.3.1. Synthesis

According to the reaction pathways shown in Scheme 10, the syntheses of ligand-stabilized copper telluride clusters have mainly been achieved in one of three different ways.[11,16,19,20,24,25,31,69]

The reaction of copper(I) acetate with $Te(SiMe_3)_2$ at low temperatures (−50 to −20 °C) yields small cluster compounds with stoichiometric compositions. At higher reaction temperatures, up to 25 °C, larger clusters can be isolated that are mostly of the mixed-valence type. Similar mixed-valence compounds have also been isolated from reactions of copper(I) chloride with $Te(SiMe_3)_2$ at lower tem-



Scheme 10. Survey of the reaction pathways for the synthesis of ligand-stabilized tellurido or tellurido/tellurolato-bridged copper clusters

peratures (down to −70 °C). By treating copper(I) chloride or copper(I) acetate with tellurolate compounds $RTeSiMe_3$ (R = *t*Bu, *n*Bu, Ph), one obtains clusters containing both RTe^- and Te^{2-} ligands as a result of the facile cleavage of the Te−C bond. In some cases, we isolated clusters featuring Te−Te bridges. Examples of syntheses of larger copper telluride clusters starting from cluster precursors are the light-induced formation of $[Cu_{50}Te_{17}(TePh)_{20}(PEtPh_2)_8][PEtPh_3]_4$ (**72**) from $[Cu_6(TePh)_6(PEtPh_2)_5]$ (**64**) in benzene,[19] and the co-condensation of $[Cu_{12}Te_3(TePh)_6(PEt_3)_6]$ (**67**) with $[Cu_5(TePh)_6(PEt)_3][PEt_3Ph]$ (**63**) to form $[Cu_{29}(TePh)_{12}Te_9(PEt_3)_8]$ $[PEt_3Ph]$ (**71**).[69]

Table 4 summarizes all the Cu−Te cluster compounds that have been synthesized and structurally characterized by single-crystal X-ray diffraction analysis to date. The species can be subdivided into four main groups, three of which consist of compounds of stoichiometric compositions $[Cu_{2n}Te_{n-x}(TeR)_{2x}(PR_2R')_m]$ that differ in the nature of their tellurium ligands, while the fourth represents the group of mixed-valence clusters.

3.3.2. Structures

The structures of the tellurium-bridged copper clusters (Figures 39−42; see below) differ from those of the copper sulfide or selenide clusters, with the exception of some smaller ones. This can be understood against the background of the larger atomic and ionic radii of the tellurium atoms compared to the lighter chalcogen atoms, allowing higher coordination numbers and therefore new binding geometries, which lead to different structures. In addition, one finds a greater tendency to form mixed-valence clusters. This is in line with the existence of many stable binary compounds with compositions $Cu_{2-x}Te$[40] and with the situ-

Table 4. Classification of copper telluride clusters into stoichiometric or mixed-valence systems according to the types of tellurium ligands

ation found in the ternary alkali copper telluride compound $K_2Cu_5Te_5$.[66]

In the case of copper telluride clusters, we have not yet reached the turning point in size where the whole core structures display bulk structure characteristics, as seen for the copper selenide species. Nevertheless, the tellurium frameworks in the largest cluster compounds, **85**−**87**, display hexagonal structure properties. Powder diffraction patterns of Cu_2Te could also be indexed on the basis of a hexagonal cell of tellurium atoms, although the structural details for bulk Cu_2Te have not yet been completely established.[40b]

In all the copper tellurium cluster molecules, the tellurium atoms form polyhedra with triangular faces. In the larger ones, some of the tellurium atoms are located inside the polyhedra. For smaller cluster molecules, the tellurium polyhedra can usually be derived from classical polyhedra (Figure 36). Those of the larger ones often show unusual cage structures. The distances between the tellurium atoms are usually nonbonding, except for the Te−Te units in **59**−**62** (Table 5).

The copper atoms reside in the holes and on the surface of the polyhedra and are coordinated by either two, three, or four tellurium atoms, with some being additionally coordinated by one further phosphane ligand (Figure 37).

The Cu−Te distance ranges that are regarded as bonding contacts are listed in Table 6 for all the clusters under discussion. Even though coordination numbers (*CN*) for Te^{2-} ligands range from 4 to 12 and those for TeR^- are usually smaller (*CN* = 2, 3, 4), there is no significant difference in the average Cu−Te distances for the Te^{2-} and TeR^- ligands.

Those tellurium atoms that are located in the center of the cluster molecules tend to bond to a large number of copper atoms. In some compounds, the copper atoms themselves form polyhedra, which can be described as Frank−Kasper polyhedra.[70] In these cases, the clusters consist of interpenetrating Frank−Kasper polyhedra, which are well-known from a number of intermetallic phases (e.g. Laves phases) (Figure 38).

However, the observed Cu−Cu distances (Table 7) give no indication of strong metal−metal, i.e. d^{10}−d^{10} interactions. Theoretical investigations pointed to the same conclusion.[34b,71] The shortest Cu−Cu contacts were observed in the molecular structures of **62** (2.383 Å) and **78** (2.382 Å), but these involve copper atoms exhibiting elongated thermal ellipsoids.

In the following section, all cluster structures will be briefly described and discussed according to the division into four groups indicated in Table 4.

3.3.2.1. Stoichiometric Clusters Containing Only Te^{2-} Ligands

The molecular structures of the stoichiometric copper telluride clusters **54**−**58** are shown in Figure 39.

In **54**, three tellurium atoms form a triangle, in the center of which a copper atom is coordinated in a slightly distorted triangular fashion. Four $[CuPPh_2Cy]$ units are doubly-bridging two of the edges. The third edge is bridged by a copper atom, which is coordinated by two phosphane ligands.

The tellurium atoms in **55** form a tetrahedron, the six edges of which are bridged by $[CuPPh_3]$ groups. An additional μ_3-$[CuPPh_3]$ fragment is bonded to a Te_3 face, and one naked copper atom is located in the center of the Te_4 tetrahedron.

Cluster **56** features a Te_6 octahedron. Six $[CuPPh_3]$ groups act as μ_2-bridges above six of the octahedral edges. Two further $[CuPPh_3]$ groups are coordinated by three tellurium atoms, giving a tetrahedral environment about the

copper atoms. The other four copper atoms are each coordinated by three tellurium atoms. Thus, **56** represents a novel isomer of the $[Cu_{12}E_6(PR_3)_8]$ clusters (see above), which was not observed for E = S, Se.

An octahedron of tellurium atoms is also found in **57**. However, two further tellurium atoms additionally cap two opposite triangular faces. Eight [CuPPh*n*Pr$_2$] groups are bonded along the edges of this polyhedron. Of the other eight copper centers, two are tetrahedrally coordinated by one phosphane and a Te_3 face. The six remaining metal atoms are bonded in a distorted trigonal-planar mode by three tellurium atoms, and are located inside the cluster cavity.

The Te_{12} substructure of **58** cannot be described as a classical deltahedron, but rather shows an arrangement of two highly distorted face-sharing tetragonal antiprisms. Four [CuP*i*Pr$_3$] groups bridge one Te−Te non-bonding edge

each, and eight [CuP*i*Pr$_3$] units act as μ_3-bridges above Te_3 faces. The other twelve copper atoms are each surrounded by three tellurium atoms and are slightly shifted away from the Te_3 planes towards the center of the molecule.

3.3.2.2. Stoichiometric Clusters Containing Te−Te Bridges

Some reactions of copper(I) chloride or copper(I) acetate lead to the formation of copper telluride clusters that contain Te−Te bridges (**59**−**62**; Figure 40).

In **59**, three tellurium atoms form an approximate isosceles triangle with a Te−Te bond along the short edge (Te−Te: 2.791 Å). The two longer edges of the triangle are bridged by one [CuPPh$_2$Cy] unit each. The two other copper atoms are located above and below the triangular face and are additionally coordinated by phosphane ligands.

The four copper atoms in **60** form a "butterfly" structure bridged by two ditelluride ligands (Te−Te: 2.800−2.812 Å). Each copper atom is additionally coordinated by a phosphane ligand.

Clusters **61** and **62** are spherical molecules based on tellurium polyhedra, parts of which are strongly distorted due to the presence of Te−Te bonds. Both compounds display Frank−Kasper polyhedra containing 15 (**61**) or 16 (**62**) tellurium atoms centered by one additional tellurium ligand. The tellurium polyhedron of **61** is similar to that observed in **20**, although it differs in the presence of three Te−Te bonds (2.936−3.011 Å). The copper atoms are bonded to the tellurium atoms in a different arrangement to that in **20**. Eight [CuP*t*Bu$_3$] units are situated above Te_3 faces of the polyhedron, while two such units are edge-bridging. Eleven further copper atoms are coordinated by three tellurium atoms, eight of which are localized below Te_3 faces, while the other three bind between the central tellurium atom and the tellurium atoms of the polyhedron. The remaining copper atoms are localized in the center of the molecule and are each tetrahedrally surrounded by four tellurium atoms.

In **62**, two of the copper centers display relatively high thermal parameters, from which it can be concluded that their positions are only partly occupied. A deficiency of electrons at the tellurium atoms resulting from the partial occupation of copper sites could either be formally delocalized in the valence band or localized as a ditelluride group following a structural deformation similar to a Peierls deformation.[72] Considering the tellurium polyhedra, the molecular structure of **62** shows two short Te−Te bonds (2.848 and 2.876 Å) and four Te−Te distances in the range 3.150−3.351 Å. The latter tellurium atoms have thermal ellipsoids that are elongated in the direction of the formal Te−Te bond. As the Te−Te bonds and copper centers seem to be disordered to a certain extent in **62**, the given formula represents the idealized composition of a stoichiometric cluster compound with three Te−Te bonds. The situation in **62** can therefore be viewed as being somewhat similar to that in CuS, a well-known mixed-valence compound that can be described as $(Cu^+)_2Cu^{2+}(S_2)^{2-}S^{2-}$ or as $(Cu^+)_3(S_2)^{2-}S^-$.[73]

3.3.2.3. Stoichiometric Clusters Containing Tellurido and Tellurolato Ligands

In a different approach towards the synthesis of copper telluride cluster compounds, we used alkyl- and aryl(trimethylsilyl)tellurium compounds RTeSiMe$_3$ (R = organic group). Due to the facile cleavage of the carbon−tellurium bond, one obtains clusters featuring either exclusively TeR^- ligands, a mixture of TeR^- and Te^{2-} ligands, or solely Te^{2-} ligands. The tellurium atoms of the tellurolato ligands bridge at most two or three copper atoms, whereas "naked" Te^{2-} ligands can coordinate to up to seven copper atoms. The polyhedra of tellurium atoms usually possess unusual structures, even in the smaller clusters. In the larger clusters, one already observes the characteristics of layer-type ar-

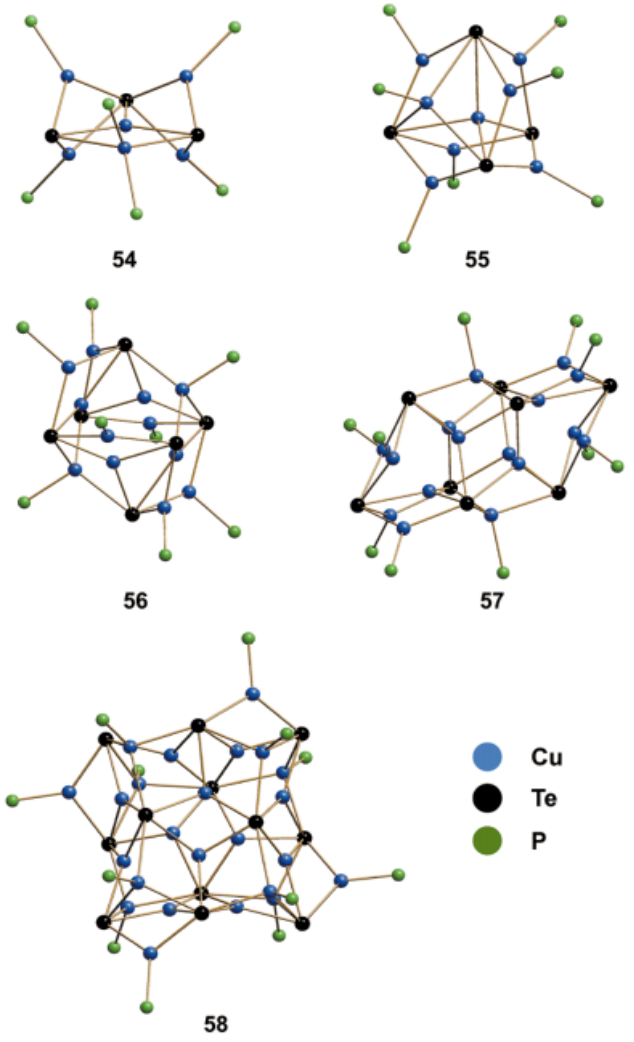

Figure 39. Molecular structures of stoichiometric copper telluride clusters $[Cu_6Te_3(PCyPh_2)_5]$ (**54**), $[Cu_8Te_4(PPh_3)_7]$ (**55**), $[Cu_{12}Te_6(PPh_3)_8]$ (**56**), $[Cu_{16}Te_8(PPhnPr_2)_{10}]$ (**57**), and $[Cu_{24}Te_{12}(PiPr_3)_{12}]$ (**58**); C and H atoms are omitted for clarity

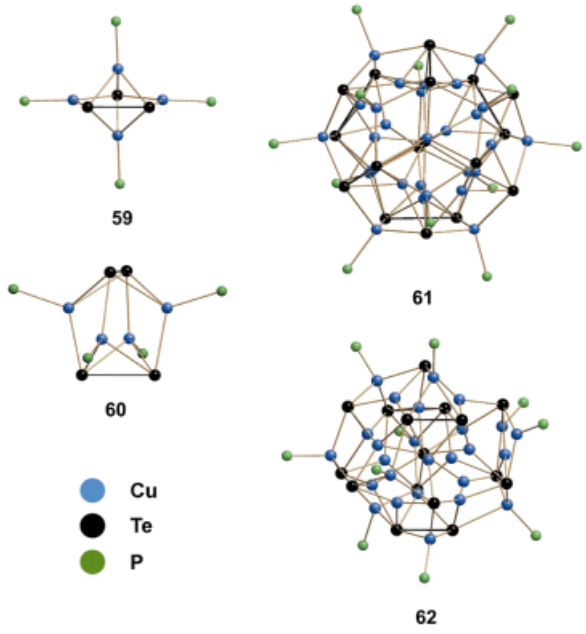

Figure 40. Molecular structures of stoichiometric copper telluride clusters $[Cu_4Te(Te_2)_2(PCyPh_2)_4]$ (**59**), $[Cu_4(Te_2)_2(PiPr)_4]$ (**60**), $[Cu_{26}Te_{10}(Te_2)_3(PtBu_3)_{10}]$ (**61**), and $[Cu_{28}Te_{13}(Te_2)_2(PEt_2Ph)_{12}]$ (**62**) containing Te−Te bridges; C and H atoms are omitted for clarity

rangements of tellurium atoms. As in the cluster compounds discussed earlier, the copper atoms are coordinated in linear, trigonal, or tetrahedral geometries by tellurium atoms. Metal centers coordinated by two or three chalcogens may also be ligated by a phosphane ligand. The molecular structures of the copper telluride/tellurolate clusters **63**−**66** and **68**−**72** are shown in Figure 41.

The ionic cluster compound **63** contains six $TePh^-$ ligands, the tellurium atoms of which define an octahedron. In contrast to **64** (see below), all the tellurolato ligands act as μ_2-bridges. There are two distinct coordination geometries around the copper centers. Two of the metal centers are located inside the cluster below Te_3 faces. The others are coordinated by three tellurium atoms above Te_3 faces, and are also ligated by one phosphane ligand each.

The structure of **64** is also based on a non-bonded octahedral array of tellurolato ligands. With the exception of one tellurium atom, which forms two Cu−Te bonds, all of these are bridging three copper sites. Four of the copper atoms adopt tetrahedral geometries, either with three tellurium atoms and one phosphorus ligand or through two Cu−Te and two Cu−P bonds. The other two copper atoms lie in opposite deltahedral Te_3 faces of the Te_6 octahedron. Compound **64** is therefore related to the recently published homoleptic hexanuclear copper selenolate complex $[Cu_6\{Se(2,4,6\text{-}iPr_3C_6H_2)\}_6]$.[8]

In **65**, the nine tellurium atoms of the tellurolato ligands form three-quarters of a cubooctahedron, which is capped on the hexagonal face by the Te^{2-} ligand. Seven $TenBu^-$ groups act as μ_3-bridges between copper atoms, while the other two bind to four copper atoms. The "naked" tellurium atom at the base of the cluster coordinates to seven copper atoms. Five of the eleven metal atoms are ligated by triphenylphosphane ligands, four of which are tetrahedrally coordinated due to three additional Cu−Te bonds. One $[CuPPh_3]$ unit bridges only two tellurium atoms, resulting in an almost trigonal-planar coordination environment. Three of the six interstitial copper atoms exhibit tetrahedral coordination geometries, while the other three show three bonding contacts to tellurium atoms and have nearly trigonal-planar coordination geometries.

Clusters **66** and **67** are identical except for the organic groups R of the PR_3 ligands. Both contain two tellurolato layers of three $TePh^-$ groups each and one central tellurido layer of three Te^{2-} ligands. The resulting Te_9 polyhedron can alternatively be viewed as two face-sharing Te_6 octahedra. Six of the twelve copper atoms are coordinated in a distorted trigonal fashion by three tellurium atoms, resulting in shorter contacts to the Te^{2-} ligands than to the $TePh^-$. The other six copper atoms are tetrahedrally surrounded by three tellurium atoms and one phosphane li-

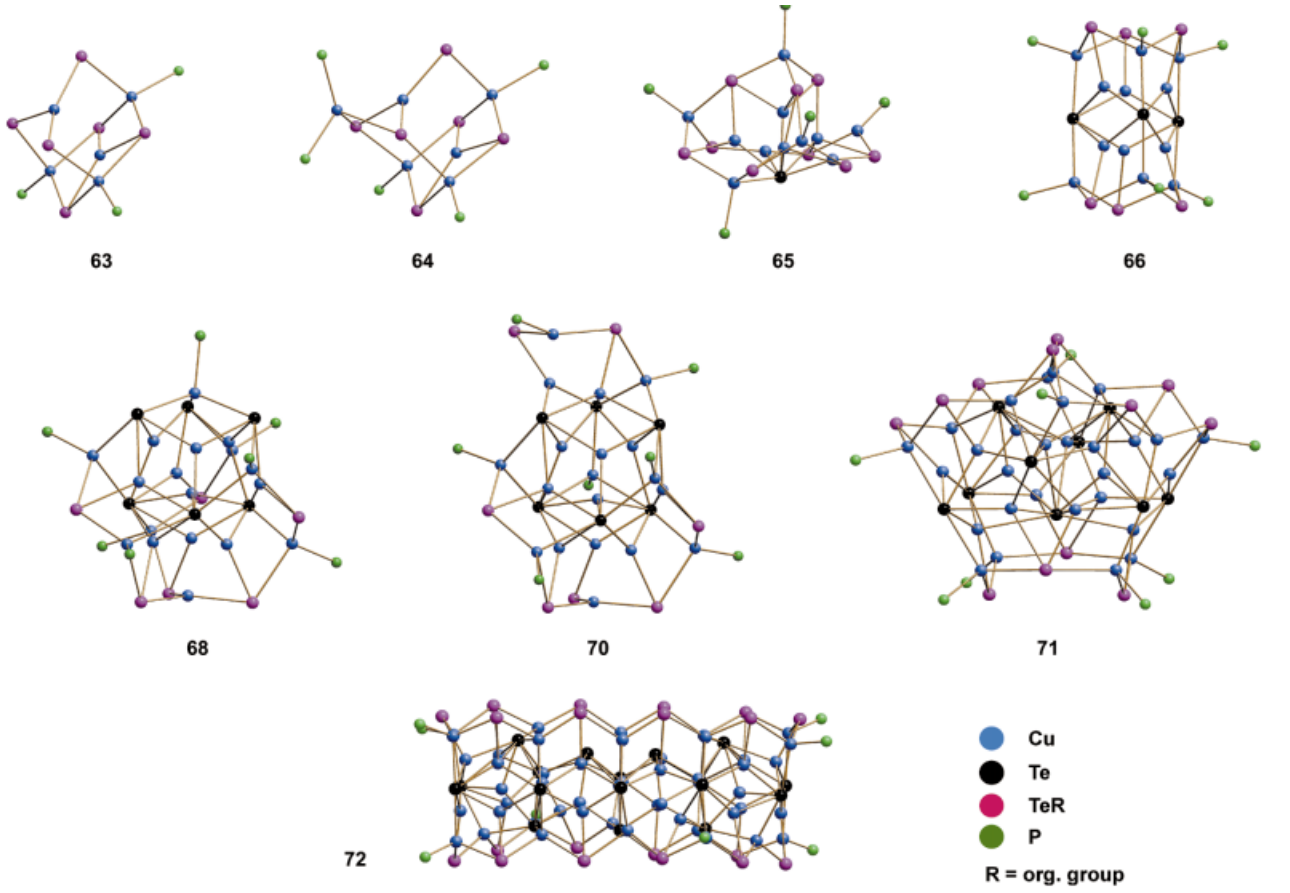

Figure 41. Molecular structures of stoichiometric copper telluride/tellurolate clusters $[Cu_5(TePh)_6(PEt)_3][PEt_3Ph]$ (**63**), $[Cu_6(TePh)_6(PEtPh_2)_5]$ (**64**), $[Cu_{11}Te(Te\mathit{n}Bu)_9(PPh_3)_5]$ (**65**), $[Cu_{12}Te_3(TePh)_6(PPh_3)_6]$ (**66**), $[Cu_{18}Te_6(Te\mathit{t}Bu)_6(PEtPh_2)_7]$ (**68**), $[Cu_{19}Te_6(Te\mathit{t}Bu)_7(PEt_3)_8]$ (**70**), $[Cu_{29}(TePh)_{12}Te_9(PEt_3)_8][PEt_3Ph]$ (**71**), and $[Cu_{50}Te_{17}(TePh)_{20}(PEtPh_2)_8][PEtPh_3]_4$ (**72**) containing TeR^- ligands; C and H atoms are omitted for clarity

gand. Compounds **66** and **67** might be viewed as condensation products of two $(TePh)_6$ frameworks like those found in **64**.

The molecular structures of **68** and **69** differ only by an extra phosphane ligand bonded to the former, in line with the smaller cone angle of $P\mathit{n}Pr_3$ relative to that of $PEtPh_2$. The layering of the tellurium atoms is clearly evident, and the twelve atoms adopt a distorted hexagonal packing. The three layers consist of a "top" layer of three "naked" Te^{2-} ligands, a second layer of three $Te\mathit{n}Bu^-$ and three Te^{2-} ligands, with the former lying at the corners of the triangular array, and a third basal triangle consisting of another three $Te\mathit{n}Bu^-$ groups. Eight of the copper atoms cap open Te_3 triangular faces, with a fourth bonding interaction to a phosphane ligand. Of the interstitial copper atoms, seven display only three bonding contacts to the neighboring tellurium atoms, while three metal atoms are tetrahedrally surrounded by tellurium atoms.

Compared to **68** and **69**, **70** contains one additional [Cu-Te*t*Bu] group. However, the structures are partly comparable. Again, a layering of the tellurium atoms can be observed, which is related to that in **68** and **69** as follows. There are now four formal layers of tellurium atoms, with one $Te\mathit{t}Bu^-$ group less in the former middle layer, and two additional $Te\mathit{t}Bu^-$ groups at the "top" of the molecule forming the fourth layer. One of the seven $Te\mathit{t}Bu^-$ ligands acts only as a doubly-bridging ligand, whereas the other six form μ_3-bridges between copper atoms. The six Te^{2-} ligands and 16 of the copper centers are situated in similar positions as in **68** or **69**. Three further copper atoms are located between the "top" Te−Te unit and the adjacent "naked" Te_3 layer. The similarities and differences between the structures of **68**, **69**, and **70** demonstrate the complicated influence of the phosphane ligands, which have different cone angles, and of the tellurolate ligands, which have different degrees of flexibility in their organic substituents. These systems may stem from a common intermediate, but due to the different steric demands of the ligands they develop in different ways.

The synthesis of the ionic cluster compound, **71**, is the only example to date of a co-condensation reaction of two smaller clusters to form a larger one. However, the structure of **71** cannot be considered as being built-up from recognizable structural fragments of the precursor compound. The tellurium atoms form an unusual polyhedron consisting of twelve $TePh^-$ ligands and nine Te^{2-} ligands. Two of the tellurolato ligands act as μ_4-bridges, while the other ten act as μ_3-bridging atoms between the copper centers. The tel-

luride ligands each coordinate six, seven, eight, or ten copper atoms with Cu−Te distances between 2.58 and 3.14 Å. Eight of the copper atoms coordinated by phosphane ligands cap Te_3 faces at the cluster surface, while four further copper atoms without phosphane ligands coordinate to Te_3 faces from the inside of the cluster core. The remaining 17 copper atoms are surrounded in a tetrahedral manner in the center of the molecule. Interestingly, a structurally related silver tellurium compound, $[Ag_{30}(TePh)_{12}Te_9(PEt_3)_{12}]$,[69] can be prepared by the direct reaction of AgCl with $Te(SiMe_3)_2$/$PhTeSiMe_3$, which is in contrast to the synthesis of **71**. This cluster represents the only known example of a copper-telluride-tellurolate cluster that shows a distinct structural relationship with its silver analogue.

Upon standing in daylight, solutions of **64** in benzene gradually darken to a brown color. Over the course of several days, brown platelets of the ionic, mixed tellurido/tellurolato cluster **72** crystallize from these solutions. In contrast, when solutions of **64** in benzene are protected from light, they show no sign of darkening, even after several weeks at room temperature. The detection of a $^{125}Te\{^1H\}$ NMR signal at $\delta = 688$ reveals the formation of $TePh_2$ in the solution, giving good evidence for the mechanism of formation of the "naked" tellurido ligands. The most striking feature of the cluster core is the manner in which the tellurium ligands are arranged: the molecule consists of "top" and "bottom" layers of μ_3-$TePh^-$ ligands with a central tellurido (Te^{2-}) layer. Sandwiched between these are the 50 copper atoms along with the remaining seven tellurido ligands. The 20 phenyltellurolato ligands are each bonded to three copper atoms and, in conjunction with the eight coordinated PEt_2Ph ligands, serve to effectively stabilize the inner copper telluride core. The telluride ligands of the middle Te_{10} layer act as μ_6- and μ_7-bridges between the copper sites. The seven remaining Te^{2-} centers function as μ_6-, μ_7-, or μ_8-ligands. Eight of the copper atoms are bonded to Te_3 faces at the surface of the cluster molecule and to one phosphane ligand. The 42 copper atoms in the center of the molecule are either trigonally (18) or tetrahedrally (24) coordinated by their tellurium neighbors.

3.3.2.4. Mixed-Valence Clusters

Counting the electrons for **73**−**85** on the assumption of Te^{2-} and Cu^+ leads to an overall electron excess for **79** and to electron deficiencies for the other compounds. These compounds can therefore be thought of as being of mixed-valence type. The molecular structures of **73**, **76**, **79**−**82**, and **85** are depicted in Figure 42.

The smallest mixed-valence cluster molecules, **73**−**75**, feature 16 copper atoms arranged around a Te_9 polyhedron. However, the tellurium substructure cannot be derived from the skeleton of **57** by simply adding one tellurium atom, as one might have assumed. Two of the copper atoms that are coordinated by a phosphane ligand bridge Te−Te nonbonding edges. The other six $[CuPR_2R']$ units bridge three tellurium atoms, the copper atoms thus being tetrahedrally coordinated. The remaining eight copper atoms are coordinated by three tellurium atoms in a distorted trigonal-planar manner. Assuming that the tellurium atoms have a formal charge of 2−, one can formally assign 14 Cu^+ centers and two Cu^{2+} centers. However, the co-existence of Cu^{2+} and Te^{2-} is unlikely for thermodynamic reasons because of an electron-transfer process from the reducing Te^{2-} ligand to the oxidizing Cu^{2+} center. An assignment of

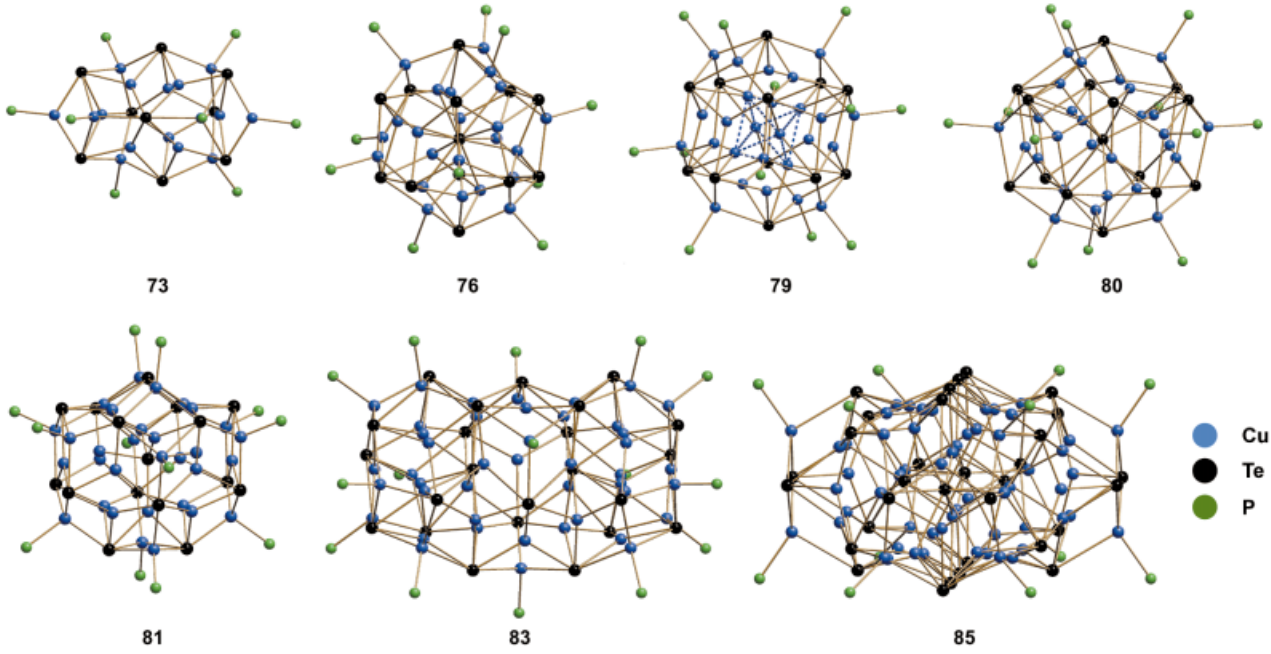

Figure 42. Molecular structures of mixed-valence copper telluride clusters $[Cu_{16}Te_9(PPh_3)_8]$ (**73**), $[Cu_{23}Te_{13}(PPh_3)_{10}]$ (**76**), $[Cu_{26}Te_{12}(PEt_2Ph)_{12}]$ (**79**), $[Cu_{27}Te_{15}(PMe\textit{i}Pr_2)_{12}]$ (**80**), $[Cu_{29}Te_{16}(P\textit{i}Pr_3)_{12}]$ (**81**), $[Cu_{44}Te_{23}(PPh_3)_{15}]$ (**82**), and $[Cu_{58}Te_{32}(PCy_3)_{16}]$ (**85**); C and H atoms are omitted for clarity

16 Cu^+, seven Te^{2-}, and two Te^- is not supported by structural means. The compounds should therefore rather be described in terms of a "pure" Cu^+ substructure ligated by tellurium centers with an average charge of −1.78. This electron deficiency can be delocalized in the valence band of the compound, as has recently been shown by calculations on the electron-rich compound **79** (see below).[74]

Thirteen tellurium atoms form a distorted, centered icosahedron in the closely-related compounds **76**−**78**. In **76** and **77**, ten of the 20 Te_3 faces are bridged by copper-phosphane units, whereas ten more copper atoms are situated below the remaining faces, either trigonally coordinated or tetrahedrally surrounded due to an additional Cu−Te bond to the central tellurium atom. Compound **78** needs twelve phosphane ligands for a sufficient shielding of the cluster core. This can be ascribed to the smaller steric demand of the phosphane PEt_3 (Table 1) compared to PPh_3. As a result, in **78**, twelve of the copper atoms are coordinated above Te_3 faces and eight below. The three remaining copper atoms in all three compounds are positioned inside the respective icosahedra. They each have three tellurium neighbors, two of which belong to the Te_{12} shell, while the third is the central tellurium ligand. Formal counting of charges leads to an electron excess of three and, assigning a charge of 1+ to every copper atom as discussed above, an average charge of −1.77 is obtained for the 13 tellurium ligands.

An icosahedron of tellurium atoms is also found in **79** but, in contrast to those observed in **76**−**78**, it does not contain a central atom. The arrangement of the copper atoms above the Te_3 faces is similar to that found in **78**. This might have been anticipated, given the Tolman angle for both phosphanes. Twelve $[CuPEt_2Ph]$ units are bonded above Te_3 faces and eight copper atoms cap the other Te_3 faces from the interior. In contrast to the situation in **76**−**78**, in **79** six rather than three copper atoms are located in the center of the cluster molecule, forming an octahedron with intermetallic distances between 2.592 and 2.607 Å. These distances lie within the range of Cu−Cu distances measured in the other copper telluride clusters under investigation. Therefore, it cannot be concluded from these distances whether d^{10}−d^{10} interactions are present within the Cu_6 octahedron. However, it is remarkable that two of the copper atoms must be formally uncharged Cu^0 atoms, alongside 24 Cu^+ centers, if one assigns a formal charge of 2− to all the tellurium ligands. Calculations of the electronic band structure reveal that a localization of the oxidation states does not occur and that the excess electron density cannot be assigned to d^{10}−d^{10} interactions.[74] The "additional" electron pair, which arises if one assigns exclusively Cu^+ and Te^{2-} centers, is better described as an MO embedded in the valence band of tellurium 5p orbitals and copper 4s orbitals.

The cluster molecules **80** and **81** are constructed in an analogous way. Both compounds consist of tellurium polyhedra which, however, form Frank−Kasper polyhedra: **80** contains a Te_{14} polyhedron, while **81** is based on a Te_{15} polyhedron. Both chalcogen substructures enclose an additional tellurium ligand at the center. Similar to the situations in **76**−**79**, all Te_3 faces are μ_3-capped by copper atoms. The Te_{14} polyhedron displays 24 such faces and the Te_{15} substructure forms 26 Te_3 triangles. Copper atoms that are additionally coordinated by a phosphane ligand are situated above the Te_3 faces, while the other copper atoms lie below, as observed previously. In both **80** and **81**, twelve copper atoms that are coordinated by a phosphane ligand are tetrahedrally coordinated above the cluster surface. One then finds 17 (**81**) or 15 (**80**) copper atoms below the Te_3 faces in the two cluster structures. Similarly to the situation in **76**−**78**, three metal centers are situated inside the polyhedral cages. Assuming that only Cu^+ centers and Te^{2-} ligands are present, three electrons are formally missing in each compound. Therefore, **80** and **81** are also compounds of mixed-valence type, each featuring three formal Cu^{2+} centers. However, from the structural data it is again impossible to divide the atomic positions into those that are occupied by Cu^{2+} and those that are Cu^+ sites.

The largest copper telluride cluster molecules synthesized to date are also mixed-valence compounds. Compounds **82**−**87** display ellipsoidal tellurium deltahedra with an increasing number of inner tellurium atoms, ranging from two inner tellurium atoms in **82**−**84**, to four such tellurium atoms in the centers of the molecular structures of **85**−**87**. As usual, the copper atoms that are coordinated by phosphane ligands are coordinated above the Te_3 triangles on the cluster surface. The other copper atoms are either coordinated by three or, especially in the cluster center, by four tellurium ligands. The structures of **85**−**87** already suggest the formation of distorted layers of tellurium atoms showing incipient characteristics of bulk Cu_2Te.[40] However, the turning point has not yet been reached for copper telluride cluster compounds. If one continues the reported tendency for ever bigger molecules being required for the observation of bulk structure properties on going from Cu−S to Cu−Se clusters, the cluster size that might begin to show Cu_2Te structural characteristics should in fact be considerably larger than a "Cu_{58}" species, and probably even larger than a "Cu_{70}" analogue of the turning point to "large" clusters found for the copper selenide system.

3.3.3. Optical Spectra in the Solid State

The colors of the microcrystalline powders of the various copper telluride clusters already reveal differences in the electronic properties of the compounds. Larger clusters are significantly darker in color than the smaller ones. For a more detailed investigation, UV/Vis spectra of the stoichiometric clusters **55** and **57**, as well as of the mixed-valence compounds **73**, **76**, **79**, and **83** were measured in the solid state.[24] Absorption spectra of the crystalline samples were measured in transmission mode from suspensions in Nujol between two quartz plates. As representative examples, the spectra of **57**, **73**, and **83** are shown in Figure 43.

In line with its red color, **57** exhibits charge-transfer bands between 600 and 200 nm, together with bands that can be assigned to transitions related to the ligands. The UV/Vis spectrum of **73** also shows similar bands between

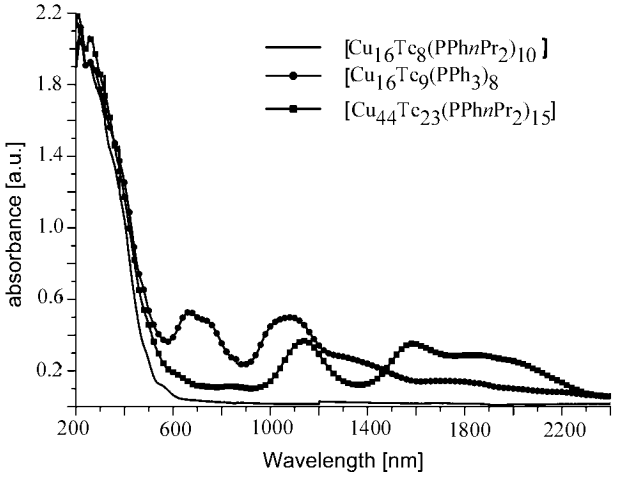

Figure 43. The UV/Vis solid-state absorption spectra (Nujol mulls) of copper telluride clusters $[Cu_{16}Te_8(PPh_nPr_2)_{10}]$ (**57**), $[Cu_{16}Te_9(PPh_3)_8]$ (**73**), and $[Cu_{44}Te_{23}(PPh_nPr_2)_{15}]$ (**83**)

600 and 200 nm, but additionally displays broad and weaker peaks at higher wavelengths, specifically at 670, 750, 1050, and 1350 nm. As outlined above, **73** can be described as a mixed-valence compound with an overall electron deficiency that is delocalized in the valence band. In general, compounds containing metal atoms in formally different oxidation states exhibit interesting spectroscopic behavior. Depending on the degree of delocalization of the charges over the molecular framework, one may detect additional bands in the near-infrared region. According to the classification of Robin and Day,[75] which describes the different degrees of electron delocalization between the metal atoms, the copper telluride clusters under investigation should belong to class IIIa (metal clusters). In this class, metal centers with different valencies cannot be distinguished and total delocalization of the charge is achieved. The larger cluster **83** also formally contains an electron deficiency of two and thus shows broad peaks that are shifted even further to longer wavelengths than in the case of **73**. Since the energy of the mixed-valence transition is strongly correlated with the degree of delocalization, an even better charge delocalization − i.e. a smaller transition energy − is observed for **83**, as might have been expected for such a large cluster. In **79**, the assignment of formal charges results in two Cu^0 atoms and 24 Cu^+ centers, which implies a formal electron excess of two. In principle, this should also cause mixed-valence bands. However, the absorption spectrum of **79** only shows a red shift of the onset of the charge-transfer bands with respect to **57** from 600 to 800 nm. It cannot yet be established whether this is a general behavior of the two different types of mixed-valence copper telluride clusters possessing either an electron deficiency or an electron excess.

4. Conclusion and Outlook

Reactions of copper salts such as copper(I) acetate and copper(I) chloride with silylated chalcogen compounds $E(SiMe_3)_2$ or $RE(SiMe_3)$ (E = S, Se, Te; R = organic group) in the presence of tertiary phosphane ligands lead to the formation of ligand-stabilized copper chalcogenide or copper chalcogenide/chalcogenolate cluster molecules of different sizes. The synthesis of the cluster molecules is influenced in a complex manner by the reactants, ligands, and solvents used, and by the reaction temperature.

All copper sulfide clusters characterized to date show spherical molecular structures that give an insight into the structural principles of $[Cu_2E]_n$ aggregates. Rules that lead to maximum stability have been delineated by comparing the observed structures, and by quantum-chemically investigating a series with up to 20 copper atoms. They are strictly adhered to by small clusters, and remain widely valid for the larger Cu−S cluster compounds.

In the case of the copper selenide clusters, the molecular structures of smaller or middle-sized clusters of up to 59 copper atoms exhibit spherical cluster shapes and also follow the structural principles elucidated for the copper sulfide species. These cluster structures differ significantly from those of the larger molecules that possess hexagonal lattices of selenium atoms. Hence, the cluster formation of the smaller copper chalcogenide clusters seems to follow spontaneous aggregation processes leading to molecular species, whereas the crystallization of the larger ones represents instead the incipient formation of ordered solid-state structures. Although the final structure determination of the low-temperature α-Cu_2Se phase is still a point of discussion, the best refinement of the data is achieved by assuming a cubic lattice of selenium atoms with copper atoms occupying the tetrahedral and trigonal holes.[76] Therefore, it is possible that the cluster molecules display fragments of a new structure type of an as yet unknown Cu_2Se polymorph.

In contrast to the clusters containing sulfur or selenium ligands, copper telluride systems show a significant tendency to form non-stoichiometric clusters, with either an electron deficiency or an electron excess. This is not only evident from the overall charge, but is also shown by the occurrence of intervalence bands in the optical spectra of these compounds. Structural considerations as well as calculations on the electronic band structure reveal that a localization of the different formal oxidation states is not possible. Even though compound **79** contains a central Cu_6 octahedron with sufficiently short Cu−Cu distances, the charge excess cannot be assigned to $d^{10}-d^{10}$ interactions. The "additional" electron pair that arises from the formal assignment of charges Cu^+ and Te^{2-} is instead delocalized in an MO embedded in the tellurium(5*d*)−copper(4*s*) valence band. The distinct differences from the Cu_2S or Cu_2Se mixed-valence cluster systems can generally be attributed to the small differences between the ionization potentials (IP), electron affinities (EA), and electronegativities (EN) of copper and tellurium, which do not allow a discrete separation into Cu^+ and Te^{2-} centers [IP(Cu): 745.4, IP(Te): 869.2; EA(Cu): 118.5, EA(Te):190.2; EN(Cu, Pauling): 1.9, EN(Te): 2.1].

In the future, we aim to further investigate the thermal properties of these materials and to use them as precursor

compounds for the synthesis of nanostructured Cu_2E (E = S, Se, Te) phases. This will include the preparation of thin films of these materials, which may have applications in solar cell technology, as well as the synthesis of $Cu_{2-x}E$ compounds of precise, known compositions that may show interesting magnetic and electrical properties.

Meltable Stannaborate Salts

Benno Ronig,[a] Ingo Pantenburg,[a] and Lars Wesemann*[a]

Keywords: Boranes / Ionic liquids / Tin / Cations

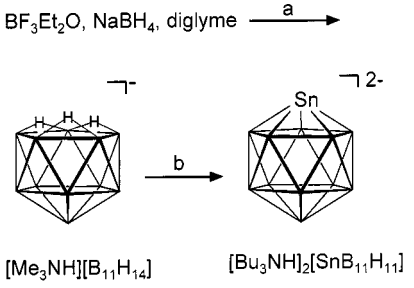
In a one-pot procedure, four imidazolium salts of alkylated stanna-*closo*-dodecaborate anions were synthesized. Alkyl substituents at the stannaborate anion and imidazolium cation were varied between ethyl and butyl, resulting in a range of melting points from 55 to 105 °C. The structures in the solids were determined in the case of [EMIM][Et–$SnB_{11}H_{11}$] (**1**) and [EMIM][Bu–$SnB_{11}H_{11}$] (**2**).

Introduction

Salts with a melting point under 100 °C are named ionic liquids, and are currently of growing interest.[1,2] This might be due to the expected high potential of these salts as an alternative reaction media in processes of technical relevance. The almost undetectable volatility of these compounds is one reason they might substitute conventional solvents. Obviously, the cation in these salts plays an important role for the low melting point and so far work is concentrated on *N*,*N*′-dialkylimidazolium and *N*-alkylpyridinium ions. A variety of classical, weak coordinating anions ($AlCl_4^-$, BF_4^-, PF_6^-, $CF_3SO_3^-$, NO_3^-, etc.) with these imidazolium or pyridinium cations exhibit the interesting properties of ionic liquids. Recently, C. A. Reed has presented the first studies on ionic liquids based on carborate salts of imidazolium and pyridinium cations.[3] Melting points down to 45 °C were determined for [*N*-ethyl-*N*′-methylimidazolium][propylcarba-*closo*-dodecaborate(12)]. Since the heteroborate anions are prominent for their very weak coordinating abilities, and they show resistance towards moisture and air, it is worthwhile to study these salts. We are currently investigating the chemistry of the easily accessible *closo*-heteroborate $[SnB_{11}H_{11}]^{2-}$. In this publication, we present imidazolium salts of the alkylated stanna-*closo*-dodecaborate with low melting points.

Results and Discussion

The synthesis of the nearly icosahedral stannaborate cluster was discovered by Todd in 1992,[4] and recently we have shown that this dianion can be used as a ligand in transition metal chemistry.[5] The air-stable stanna-*closo*-dodecaborate salt can be synthesized with a variety of counter-cations, offering the possibility of further modifying the solubility of the cluster salt. A key compound in this context is the tributylammonium salt $[Bu_3NH]_2[SnB_{11}H_{11}]$, since it drops out of water and the cations can be easily replaced by interaction with a base like KH. The ionic liquids of the alkylstannaborate anion are straightforwardly synthesized in to a two-step procedure. Starting from $[Me_3NH][B_{11}H_{14}]$ the stannaborate $[Bu_3NH]_2[SnB_{11}H_{11}]$ was synthesized in amounts of five grams and a yield of ca. 85% (Scheme 1).



Scheme 1. a) 1. 106 °C, 2. H_2O, $[Me_3NH]Cl$; b) 1. 4 equiv. BuLi, 2. $SnCl_2$, 3. H_2O, $[Bu_3NH]Cl$

The air-stable stannaborate was treated with 1 equiv. of the respective alkyl iodide. After this quantitative alkylation, 2 equiv. of super-hydride $KHBEt_3$ were added in order to substitute the ammonium against the potassium cation. The solvent was changed to water and the ionic liquid was precipitated in high yield after addition of the respective imidazolium iodide (Scheme 2).

The new salts **1**–**4** were characterized by elemental analysis, DSC, NMR, and IR spectroscopy, and in the case of **1** and **2** also by single-crystal X-ray structure analysis. In contrast to the ionic liquids based on the classical anions like $[AlCl_4]^-$ or $[BF_4]^-$, the synthesized stannaborate salts were not hygroscopic, and showed no tendency to react with water and air even at higher temperatures. After melt-

Scheme 2

ing the borates **1**−**4** at 200 °C for several hours, repeated elemental analyses confirmed the correct composition. In the series of the imidazolium salts **1**−**4**, the lowest melting point of 55 °C was achieved for the derivative with the butyl substituents at the imidazolium cation and the tin atom in the cluster. According to this concept, we tried to synthesize the octyl-substituted salt, but were not able to purify this waxy solid for satisfactory elemental analysis.

The imidazolium salts **1** and **2** crystallized in the monoclinic space group $P2_1/c$ and showed no disorder in the solid state. For both compounds, we did not find any indications for cation−anion contacts. In Figures 1 and 2, an ORTEP plot of the salts is shown. The interatomic distances in **1** and **2** are not unusual, and selected values and angles are listed in the captions of Figures 1 and 2.

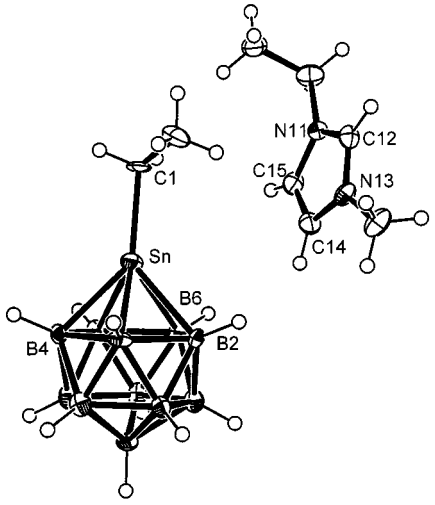

Figure 1. ORTEP drawing of the salt **1**; thermal ellipsoids are drawn at the 50% probability level; selected interatomic distances [Å]: Sn−C1 2.148(4), Sn−B2 2.308(5), Sn−B3 2.323(5), Sn−B4 2.311(6), Sn−B5 2.299(5), Sn−B6 2.298(6), N11−C12 1.332(7), C12−N13 1.332(7), N13−C14 1.380(7), C14−C15 1.353(8), C15−N11 1.380(8)

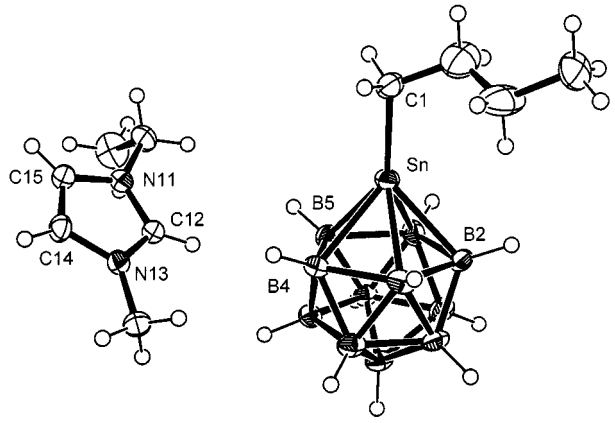

Figure 2. ORTEP drawing of the salt **2**; thermal ellipsoids are drawn at the 50% probability level; selected interatomic distances [Å]: Sn−C1 2.122(5), Sn−B2 2.307(6), Sn−B3 2.314(5), Sn−B4 2.312(5), Sn−B5 2.303(6), Sn−B6 2.312(5), N11−C12 1.335(6), C12−N13 1.329(6), N13−C14 1.386(6), C14−C15 1.355(7), C15−N11 1.376(6)

Conclusion

The quantitative alkylation of the stannaborate dianion offers the possibility of introducing this heteroborate into imidazolium salts exhibiting a low melting point. Positional disorder in the solid state is not an indicator for the relative low melting point of **1** and **2**.

Experimental Section

General: All experiments were carried out under dry nitrogen using standard Schlenk techniques. Solvents were freshly distilled under an inert gas from appropriate drying agents. All imidazolium iodides were prepared according to procedures known from the literature.[6] NMR spectroscopy was performed with a Bruker AC 200 spectrometer (^{1}H: 200 MHz, int. TMS; ^{13}C{^{1}H}: 50 MHz, int. TMS; ^{11}B and ^{11}B{^{1}H}: 64 MHz, ext. $BF_3{\cdot}OEt_2$). IR spectrometer: IFS66v/s Bruker. Elemental analyses were carried out in the Institut für Anorganische Chemie der Universität zu Köln with a Heraeus C,H,N,O-Rapid analyser. DSC measurements were performed with a Netzsch STA 409-Skimmer thermal analyser.

[EMIM][1-Et−SnB$_{11}$H$_{11}$] (1): 1-Iodoethane (0.08 mL, 0.99 mmol) was added to a solution of $[Bu_3NH]_2[SnB_{11}H_{11}]$ (510 mg, 0.82 mmol) in 40 mL of THF at room temperature. The mixture was heated under reflux for 3 h. Afterwards, the solvent was evaporated in vacuum and the residue dried for another 24 h. This was then dissolved in 20 mL of THF and treated with $LiHBEt_3$ (1.95 mL, 1 M solution in THF, 1.95 mmol). The solution was stirred for another 2 h and volatiles were removed in vacuum. The remaining white solid was dissolved in 50 mL of H_2O and [EMIM]I (0.40 g, 1.68 mmol) was added. The white precipitate was filtered off and dried in vacuum. Single crystals were obtained by slow evaporation of methanol from the product. Yield: 234 mg, 0.60 mmol, 73.3%. ^{1}H NMR (CD_2Cl_2): δ = 1.58 (t, ^3J = 7.3 Hz, 3 H, $SnCH_2CH_3$), 1.69 (t, ^3J = 7.8 Hz, 3 H, NCH_2CH_3), 2.62 (q, ^3J = 7.8 Hz, 2

H, SnCH_2CH$_3$), 3.97 (s, 3 H, NCH_3), 4.27 (q, ^3J = 7.3 Hz, 2 H, NCH_2CH$_3$), 0.99 (t, ^3J = 7.1 Hz, 3 H, CH$_2$CH$_2$CH_3), 7.30 (s, 2 H, NC*H*C*H*N), 8.69 (s, 1 H, NC*H*N). ^{11}B{^{1}H} NMR (CD$_2$Cl$_2$): δ = −12.5 (s, B12), −17.0 (s, B2−6 and B7−11). ^{13}C{^{1}H} NMR (CD$_2$Cl$_2$): δ = 9.0 (SnCH$_2$*C*H$_3$), 13.7 (Sn*C*H$_2$CH$_3$), 15.5 (NCH$_2$*C*H$_3$), 37.1 (N*C*H$_3$), 46.0 (N*C*H$_2$CH$_3$), 122.3 (N*C*H$_2$CH$_2$N), 124.1 (NCH$_2$*C*H$_2$N), 135.8 (N*C*H$_2$N). $C_8H_{27}B_{11}N_2Sn$ (388.9): calcd. C 24.71, H 7.00, N 7.20; found C 25.41, H 7.02, N 7.43. DSC: M.p. 105.7 °C. IR (KBr): ṽ = 2490 (vs), 2866 (vw), 2926 (w), 2958 (w), 3095 (s), 3097 (s), 3109 (s), 3140 (s), 3159 cm^{-1} (w).

X-ray Crystallographic Analysis of 1: $C_8H_{27}B_{11}N_2Sn$, formula mass 388.92 g/mol; monoclinic, space group $P2_1/c$ (no.14); a = 7.451(1), b = 17.564(2), c = 14.081(2) Å, β = 99.09(2)°, V = 1819.7(4) Å^3, Z = 4, $d_{calcd.}$ = 1.420 g·cm^{-3}, μ(Mo-K_α) = 1.392 mm^{-1}. Image Plate STOE (IPDS) diffractometer; Mo-K_α radiation (λ = 0.71073 Å); graphite monochromator. Data collection at 170 K on a crystal of dimensions 0.2 × 0.2 × 0.1 mm, using ω scans in the range 2.3° ≤ θ ≤ 27.0°, yielded 15956 reflections. The data were corrected for Lorentz and polarization effects. Numerical absorption corrections with programs X-RED (Stoe, Darmstadt, **2001**) and X-SHAPE (Stoe, Darmstadt, **1999**): T_{min}/T_{max} = 0.7474/0.8849. 3925 unique reflections with $I > 2\,\sigma(I)$ remained for structure solution by direct methods.[7] The structure model was completed by Fourier difference synthesis, F^2 refinement;[8−10] anisotropic parameters for non-hydrogen atoms and hydrogen atoms placed in calculated positions (C−H = 0.98 Å; B−H = 1.1 Å). Convergence obtained for 200 variables, 3925 data, and R_1(all) = 0.094, wR_2(all) = 0.087, GooF = 0.826. A final difference Fourier map showed the highest peak with 0.56 e·Å^{-3} 1.22 Å from B2 and the deepest hole with −1.40 e·Å^{-3} 0.02 Å from the Sn.

[EMIM][1-Bu−SnB$_{11}$H$_{11}$] (2): 1-Iodobutane (0.05 mL, 0.44 mmol) was added to a solution of [Bu$_3$NH]$_2$[SnB$_{11}$H$_{11}$] (235 mg, 0.38 mmol) in 40 mL of THF at room temperature. The mixture was heated under reflux for 3 h. Afterwards, the solvent was evaporated in vacuum and the residue dried for another 24 h. This was then dissolved in 20 mL of THF and treated with LiHBEt$_3$ (0.83 mL, 1 M solution in THF, 0.83 mmol). The solution was stirred for another 2 h and volatiles were removed in vacuum. The remaining white solid was dissolved in 50 mL of H$_2$O and [EMIM]I (0.18 g, 0.76 mmol) was added. The white precipitate was filtered off and dried in vacuum. Single crystals were obtained by slow evaporation of methanol from the product. Yield: 113 mg, 0.27 mmol, 62%. ^{1}H NMR (CD$_2$Cl$_2$): δ = 0.99 (t, ^3J = 7.1 Hz, 3 H, CH$_2$CH$_2$CH_3), 1.57 (m, 5 H, CH$_2$CH_2CH$_3$ and NCH$_2$CH_3), 1.99 (m, 2 H, SnCH$_2$CH_2CH$_2$), 2.70 (t, ^3J = 7.1 Hz, 2 H, SnCH_2), 3.97 (s, 3 H, NCH_3), 4.27 (q, ^3J = 7.3 Hz, 2 H, NCH_2CH$_3$), 7.30 (s, 2 H, NC*H*C*H*N), 8.69 (s, 1 H, NC*H*N). ^{11}B{^{1}H} NMR (CD$_2$Cl$_2$): δ = −12.3 (s, B12), −16.9 (s, B2−6 and B7−11). ^{13}C{^{1}H} NMR (CD$_2$Cl$_2$): δ = 13.5 (CH$_2$CH$_2$*C*H$_3$), 15.5 (NCH$_2$*C*H$_3$), 16.9 (SnCH$_2$*C*H$_2$), 26.8 (SnCH$_2$*C*H$_2$), 30.3 (Sn*C*H$_2$), 37.1 (N*C*H$_3$), 46.1 (N*C*H$_2$CH$_3$), 122.3 (N*C*H$_2$CH$_2$N), 124.1 (NCH$_2$*C*H$_2$N), 136.0 (N*C*H$_2$N). $C_{10}H_{31}B_{11}N_2Sn$ (417.0): calcd. C 28.80, H 7.42, N 6.72; found C 29.02, H 7.21, N 6.76. DSC: M.p. 80.3 °C. IR (KBr): ṽ = 2496 (vs), 2849 (vw), 2866 (vw), 2922 (w), 2957 (w), 3093 (s), 3113 (s), 3146 cm^{-1} (s)

X-ray Crystallographic Analysis of 2: $C_{10}H_{31}B_{11}N_2Sn$: formula mass 416.97 g/mol; monoclinic, space group $P2_1/c$ (no.14); a = 11.378 (1), b = 11.030 (1), c = 16.911 (2) Å, β = 100.81(2)°, V = 2084.6 (4) Å^3, Z = 4, $d_{calcd.}$ = 1.329 g·cm^{-3}, μ(Mo-K_α) = 1.220 mm^{-1}. Image Plate STOE (IPDS) diffractometer; Mo-K_α radiation (λ = 0.71073 Å); graphite monochromator. Data collection at 170 K on a crystal of dimensions 0.3 × 0.25 × 0.1 mm using ω scans in the range 1.8° ≤ θ ≤ 24.1° yielded 12909 reflections. The data were corrected for Lorentz and polarization effects. Numerical absorption corrections with programs X-RED (Stoe, Darmstadt, **2001**) and X-SHAPE (Stoe, Darmstadt, **1999**): $T_{min.}/T_{max}$ = 0.7218/0.8928. 3287 unique reflections with $I > 2\,\sigma(I)$ remained for structure solution by direct methods.[7] The structure model was completed by Fourier difference synthesis, F^2 refinement;[8−10] anisotropic parameters for non-hydrogen atoms, and hydrogen atoms placed in calculated positions (C−H = 0.98 Å; B−H = 1.1 Å). Convergence obtained for 219 variables, 3287 data, and R_1(all) = 0.072, wR_2(all) = 0.069, GooF = 0.878. A final difference Fourier map showed the highest peak with 0.92 e·Å^{-3} 1.03 Å from C3 and the deepest hole with −0.50 e·Å^{-3} 0.38 Å from H2a.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-169179 (**1**) and -169180 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[BMIM][1-Et−SnB$_{11}$H$_{11}$] (3): Salt **3** was synthesised according to the procedure outlined for the synthesis of **1**, starting from [Bu$_3$NH]$_2$[SnB$_{11}$H$_{11}$] (413 mg, 0.67 mmol) with 1-iodoethane (0.06 mL, 0.74 mmol) and LiHBEt$_3$ (1.44 mL, 1 M solution in THF, 1.44 mmol). The salt was precipitated by adding [BMIM]I (0.36 g, 1.35 mmol). The white solid was dried in vacuum. Yield: 170 mg, 0.41 mmol, 61.2%. ^{1}H NMR (CD$_2$Cl$_2$): δ = 0.97 (t, ^3J = 7.3 Hz, 3 H, CH$_2$CH$_2$CH_3), 1.39 (m, 2 H, CH$_2$CH_2CH$_3$), 1.69 (t, ^3J = 7.8 Hz, 3 H, SnCH$_2$CH_3),), 1.89 (m, 2 H, NCH$_2$CH_2CH$_2$),), 2.62 (q, ^3J = 7.8 Hz, 2 H, SnCH_2), 3.98 (s, 3 H, NCH_3), 4.21 (q, ^3J = 7.3 Hz, 2 H, NCH_2CH$_3$), 7.30 (s, 2 H, NC*H*C*H*N), 8.70 (s, 1 H, NC*H*N). ^{11}B{^{1}H} NMR (CD$_2$Cl$_2$): δ = −11.9 (s, B12), −17.1 (s, B2−6 and B7−11). ^{13}C{^{1}H} NMR (CD$_2$Cl$_2$): δ = 9.0 (CH$_2$CH$_2$*C*H$_3$), 13.6 (SnCH$_2$*C*H$_3$), 13.7 (CH$_2$*C*H$_2$CH$_3$), 19.7 (NCH$_2$CH$_2$*C*H$_2$), 32.3 (Sn*C*H$_2$), 37.2 (N*C*H$_3$), 50.7 (N*C*H$_2$CH$_3$), 122.6 (N*C*H$_2$CH$_2$N), 124.0 (NCH$_2$*C*H$_2$N), 136.2 (N*C*H$_2$N). $C_{10}H_{31}B_{11}N_2Sn$ (417.0): calcd. C 28.80, H 7.42, N 6.72; found C 29.25, H 7.48, N 6.87. DSC: M.p. 64.0 °C. IR (KBr): ṽ = 2501 (vs), 2868 (w), 2930 (w), 2958 (s), 3093 (s), 3115 (s), 3109 (s), 3142 (w), 3157 cm^{-1} (w).

[BMIM][1-Bu−SnB$_{11}$H$_{11}$] (4): Salt **4** was synthesised according to the procedure outlined for the synthesis of **1**, starting from [Bu$_3$NH]$_2$[SnB$_{11}$H$_{11}$] (302 mg, 0.49 mmol) with 1-iodobutane (0.07 mL, 0.61 mmol) and LiHBEt$_3$ (1.00 mL, 1 M solution in THF, 1.00 mmol). The salt was precipitated by adding [BMIM]I (0.275 g, 1.16 mmol). The light yellow-brown solid was dried in vacuum. The residue was dissolved in 5 mL of acetone, and precipitated by adding 20 mL of water. The light brown salt was filtered and dried in vacuum. Yield: 130 mg, 0.29 mmol, 60%. ^{1}H NMR (CD$_2$Cl$_2$): δ = 0.97 (m, 6 H, CH$_2$CH_3 and CH$_2$CH_3), 1.37 (m, 4 H, SnCH$_2$CH$_2$CH_2 and NCH$_2$CH$_2$CH_2), 1.63 (m, 4 H, SnCH$_2$CH_2CH$_2$ and NCH$_2$CH$_2$CH_2), 1.88 (m, 2 H, NCH$_2$CH_2), 2.66 (m, 2 H, SnCH_2CH$_2$), 3.98 (s, 3 H, NCH_3), 4.20 (t, ^3J = 7.3 Hz, 2 H, NCH_2CH$_3$), 7.28 (s, 2 H, NC*H*C*H*N), 8.70 (s, 1 H, NC*H*N). ^{11}B{^{1}H} NMR (CD$_2$Cl$_2$): δ = −12.1 (s, B12), −16.9 (s, B2−6 and B7−11). ^{13}C{^{1}H} NMR (CD$_2$Cl$_2$): δ = 13.5 (CH$_2$CH$_2$*C*H$_3$), 15.5 (NCH$_2$*C*H$_3$) 16.9 (SnCH$_2$*C*H$_2$), 26.8 (SnCH$_2$*C*H$_2$), 30.3 (Sn*C*H$_2$), 37.1 (N*C*H$_3$), 46.1 (N*C*H$_2$CH$_3$), 122.3 (N*C*H$_2$CH$_2$N), 124.1 (NCH$_2$*C*H$_2$N), 136.0 (N*C*H$_2$N).

A Unique Heterotopic Ligand for Sequential Synthesis of Polymetallic Complexes

Katja E. Berg,[a][‡] Yann Pellegrin,[a] Geneviève Blondin,[a] Xavier Ottenwaelder,[a] Yves Journaux,[a] María Moragues Canovas,[a] Talal Mallah,[a] Simon Parsons,[b] and Ally Aukauloo*[a]

Keywords: Copper / Heterotopic ligands / Iron / Metalations / Oxamate

A new organic ligand bearing four coordination sites that may be metallated in a stepwise manner is described, together with its Cu^{II} and Fe^{II} derivatives. This may be considered as the first ligand precursor for trimetallic systems.

Introduction

The design of new coordination complexes that play the role of ligands in the elaboration of polymetallic complexes is one of the challenging issues in the domain of modern inorganic chemistry.[1] The preparation of such complexes using a "step-by-step" approach is a prerequisite to building molecular extended systems with new architectures or even discrete molecules containing an increasing number of metallic centres with predetermined physical properties.[2−13]

Oxamato ligands have been extensively used to generate families of polymetallic compounds according to a sequential strategy.[2−7] However, the pitfall of this generation of oxamato complexes was the isolation of only heterobimetallic complexes. In order to overcome this drawback, it seems evident that the ligand must embody predetermined instructions that will, under the supervision of the chemist, lead toward the desired edifice. Recently, Chaudhuri et al. described a well-founded route leading to the formation of discrete heterotrimetallic complexes in a stepwise fashion.[14] Thus, in comparison to the chemistry described for instance with $[Cu(opba)]^{2-}$ [opba = *o*-phenylenebis(oxamato)],[2,3] an additional chelating anchor in the initial building block should consequently allow us to synthesize molecules of higher nuclearity and dimensional arrays.

In this communication, we describe the synthesis of an organic ligand that contains three different types of coordination sites. The chemical difference in the binding nature of the three coordination sites of the ligand renders the metalation process selective, allowing stepwise reactions that may lead to novel higher nuclearity trimetallic systems, be it discrete or extended in nature. Herein we report the preparation and the crystal structure of the first coordination complex $[\mathbf{L}Cu]^{2-}$ where $H_4\mathbf{L}$ stands for *N*,*N*′-(dipyrido[3,2-*a*:2′,3′-*c*]phenazine-11,12-diyl)bis(oxamic acid). The versatility of this ligand **L** towards selective metalation is also shown with the characterisation of the $[Fe(\mathbf{L_1})_3]^{2+}$ complex together with the tetranuclear $[Fe(\mathbf{L}Cu)_3]^{4-}$ adduct.

The synthesis of the heterotopic ligand follows the condensation of *o*-diones with aromatic *o*-diamines as shown in Scheme 1.[15] The ethyl ester derivative, noted $\mathbf{L_1}$, was isolated quantitatively as a yellow powder by condensation of equimolar amounts of **1**[16] and 1,10-phenanthroline-5,6-dione[17] in refluxing methanol.

Selective metalation of the bis(oxamato) cavity with a copper(II) ion was carried out in basic medium by slow addition of a copper(II) salt in solution, and the corresponding phosphonium salt was obtained by metathesis. Insertion of a copper ion in the bis(oxamato) cavity was evidenced by a red shift of about 50 cm^{-1} for the C=O stretching. Crystallisation in a mixture of acetonitrile and water gave red tablets that were analysed by X-ray diffraction. The structure of $[\mathbf{L}Cu](PPh_4)_2{\cdot}0.5CH_3CN$ consists of the dianionic copper(II) complex, tetraphenylphosphonium cations, and acetonitrile molecules of crystallisation. As shown in Figure 1, a perspective side view of the dianion complex $\mathbf{L}Cu^{2-}$ indicates an almost planar structure of the ligand skeleton with maximum deviation from the mean molecular plane of 0.317(3) Å for atom O(17).

The copper atom sits in a planar-trapezoidal N_2O_2 coordination environment. The average bond lengths between

the copper and the two deprotonated nitrogen atoms of the amide functions and the two oxygen atoms from the carboxylate groups are 1.898 and 1.936 Å, respectively. Comparatively, these bond lengths are in agreement with those found for similar environments of copper(II).[18] To the best of our knowledge, this is the first X-ray structure whereby a phenanthroline-carrying ligand is not involved in the coordination sphere of the metal ion. The solid-state EPR spectrum (100 K) of this copper complex, shown in Figure 2, is characteristic of a copper(II) ion in a square-planar geometry. The best agreement between the experimental solid-state spectrum and the simulated one was obtained for the following parameters: $A_{\perp} = 33.275$ G, $A_{\parallel} = 214.587$ G, $g_{\perp} = 2.040$, and $g_{\parallel} = 2.191$.

Benefiting from the high affinity constant of the iron(II) ion for phenanthroline to form the tris(phenanthroline) complex ($K_c = 10^{21}$),[19] we set out to metallate the phen-

anthroline end of the $\mathbf{L_1}$ ligand. The ^{1}H NMR spectrum of the $[Fe(\mathbf{L}_1)_3]^{2+}$ clearly indicates that the compound is diamagnetic and all signals of the ligand are present. The less resolved signals and the chemical shifts for the protons carried by the phenanthroline skeleton are attributable to the presence of the iron(II) ion. No apparent shift was observed for the proton signals of the ethyl groups indicating that no metal ion was coordinated to this cavity. This was also confirmed by infrared spectroscopy where no shift in the vibration frequencies of the carbonyl groups was observed.

Finally, treatment of $[Fe(\mathbf{L}_1)_3]^{2+}$ with an adequate amount of tetramethylammonium hydroxide in an aqueous solution, followed by addition of a copper(II) salt, gave, after conventional work up, a deep red solid. The infrared spectrum of $(NMe_4)_4[Fe(\mathbf{L}Cu)_3] \cdot 10H_2O$ indicates the presence of a tetramethylammonium cation and metalation of the oxamato cavity. The pattern of the signals is similar to that of the mononuclear counterpart, bringing thus a solid evidence that all the oxamate groups are coordinated in the same fashion. The more convincing piece of evidence of the content of copper ions for complex $(NMe_4)_4$-$[Fe(\mathbf{L}Cu)_3] \cdot 10H_2O$ comes from the magnetic susceptibility measurement where the χT value for a wide range of temperatures equals to the sum of three spins $S = 1/2$ for each corresponding copper(II) ion.

We have shown in this report the versatility of this new heterotopic ligand in the design of multinuclear compounds in a rationale way. We are currently using the tetranuclear complex as ligand to bind a third generation of metal ions through the external oxygen atoms of the oxamato groups to give discrete molecules or an extended network of heteropolymetallic compounds.

Experimental Section

Diethyl *N*,*N*′-(Dipyrido[3,2-*a*:2′,3′*c*]phenazine-11,12-diyl)bis(oxamate) ($\mathbf{L_1}$): To a stirred solution of 1,10-phenanthroline-5,6-dione[17] (0.42 g, 2 mmol) in methanol (100 mL) under reflux was added dropwise a slurry of the diamine **1**[16] (0.68 g, 2 mmol) in methanol (50 mL). After the addition was completed, the mixture was kept under constant stirring for 30 min. The deep yellow precipitate was filtered off, washed with ether and dried under vacuum (0.92 g, 90%). ^{1}H NMR ([D$_6$]DMSO): δ = 1.38 (t, 3 H), 4.40 (q, 4 H), 7.95 (dd, 2 H), 8.64 (s, 2 H), 9.26 (dd, 2 H), 9.55 (dd, 2 H), 10.9 (s, 2

H). IR (KBr): $\tilde{\nu}$ = 3285 cm^{-1} (NH), 1755 and 1695 cm^{-1} (C=O).

$(PPh_4)_2$[CuL]: To a suspension of **L_1** (513 mg, 1 mmol) in water (25 mL) was added a methanolic solution of Me_4NOH (25%) (1.7 mL, 4 mmol). After complete dissolution, an aqueous solution of $Cu(NO_3)_2 \cdot 3H_2O$ (246 mg, 1 mmol) was added dropwise with stirring. The dark brown solution was filtered to remove any insoluble material and concentrated under reduced pressure. To the solution was added an excess of Ph_4PCl and the complex extracted twice with dichloromethane. The organic phase was dried with $MgSO_4$, filtered and the solvents were evaporated to dryness yielding a red solid. Crystallisation in a mixture of acetonitrile and water (90:10) afforded well-shaped crystals of the copper complex suitable for X-ray analysis. IR (KBr): $\tilde{\nu}$ = 1675 and 1645 cm^{-1} (C=O).

$[Fe(L_1)_3](BF_4)_2 \cdot 2H_2O$: In methanol (30 mL), **L_1** (154 mg, 0.3 mmol) was suspended and a methanolic solution (10 mL) of $Fe(BF_4)_2 \cdot 6H_2O$ (33 mg, 0.1 mmol) was added dropwise, giving a deep red solution. A red solid was isolated after concentration of the reaction mixture and precipitation with diethyl ether (90%). ^1H NMR ([D_6]DMSO): δ = 1.38 (t, 3 H), 4.46 (q, 4 H), 7.82 (dd, 2 H), 7.95 (dd, 2 H), 8.74 (s, 2 H), 9.62 (dd, 2 H), 11.2 (s, 2 H). IR (KBr): $\tilde{\nu}$ = 3415 cm^{-1} (NH), 1745 and 1710 cm^{-1} (C=O). $C_{78}H_{64}N_{18}O_{20}B_2F_8Fe$ (1802.9): calcd. C 51.96, H 3.58, N 13.98; found C 50.99, H 3.49, N 14.14.

$(NMe_4)_4[Fe(CuL)_3] \cdot 10H_2O$: The synthesis of $[Fe(LCu)_3]^{6-}$ was similar to that of $[LCu]^{2-}$, starting with $[Fe(L_1)_3]^{2+}$ in methanol and adding 12 equiv. of base and 3 equiv. of the copper(II) salt. It was isolated as a red solid by concentration of the filtered solution and precipitation with diethyl ether. IR (KBr): $\tilde{\nu}$ = 1670 and 1635 cm^{-1} (C=O). $C_{72}H_{60}Cu_3FeN_{22}O_{28}$ (2080.3): calcd. C 47.35, H 4.46, Cu 9.16, Fe 2.68, N 14.81; found C 47.18, H 4.86, Cu 9.22, Fe 2.56, N 14.86.

Crystal Data for $(PPh_4)_2$[CuL]·0.5CH_3CN: $C_{71}H_{49.5}CuN_{6.5}O_6P_2$, M = 1433.11, $P\bar{1}$, a = 11.141(3), b = 14.724(5), c = 19. 586(6) Å, α = 75.617(2), β = 75.43(2), γ = 84.592(2) °, V = 3010.3(16) $Å^3$, T = 220 K, Z = 2, 14106 reflections measured, of which 10676 were unique (R_{int} = 0.0190). Data collection, solution, and refinement: ω-θ, standard Patterson methods with subsequent full-matrix least-squares refinement. Shelxl-97.[20] The final $wR(F^2)$ was 0.1893 (all data). The crystal drawings were carried out with the Crystal Maker program.[21] Crystallographic data (excluding structure factors) reported in this paper have been deposited at the Cambridge Crystallographic Data Centre and allocated the deposition number CCDC-164965. New Organometalated Phosphinato-*O*,*O*′ Ligands in the Planar Eight-Membered Ring [{Cp(CO)$_2$Fe}*t*BuPO$_2$FeCl$_2$]$_2$

Ingo-Peter Lorenz,*[a] Markus Maier,[a] and Kurt Polborn[a]

Keywords: Iron / Heterocycles / O ligands / Oxidations / Self-assembly

By simple oxidation of the diferriophosphonium salt [Fp$_2$P(H)*t*Bu]$_2$FeCl$_4$ (**1′d**) with air the planar eight-membered heterocycle {Fp*t*BuPO$_2$FeCl$_2$}$_2$ (**2**) was generated. Compound **2** contains two organometalated phosphinato-*O*,*O*′ ligands bridging two tetrahedrally configured iron(III) centres [Fp = CpFe(CO)$_2$ = ferrio]. The new ferrio phosphinato ligand Fp*t*BuPO$_2^-$ was synthesized in a controlled manner for the first time. Compound **1′d** was obtained by the so-called insertion reaction of Fp$_2$ and *t*BuPCl$_2$, or by the silyl method using CpFe(CO)$_2$Cl and *t*BuP(SiMe$_3$)$_2$, both in toluene with traces of water present.

Introduction

The phosphinato ligand R$_2$PO$_2^-$ has a significant position among the classical ligands. Their syntheses, stability, and complex chemical behaviour towards the main group and transition elements (mono-, bidentate and bridging ligands), as well as their applications, especially as coordination polymers, has been the subject of numerous publications.[1] Within the scope of our investigations on organometalated phosphorus compounds,[2] which follow the isolobal theory, we succeeded in the synthesis and structural characterisation of the cage-like molecule [{CpFe(CO)$_2$(Mes)PO$_2$}$_4${MesPO$_3$Fe$_2$(OH)Cl}$_2$].[3] Besides the phosphonato ligand RPO$_3^{2-}$, it contains for the first time the organometalated phosphinato ligand FpRPO$_2^-$ (Fp = CpFe(CO)$_2$; R = Mes). The very complex framework of 4 iron(III) and 6 phosphorus centres connected by oxygen atoms, was formed unexpectedly by simple oxidation of the ferriophosphonium salt [Fp$_2$P(H)Mes]Cl with air.[3] Our attempts to separate the novel ferriophosphinato ligand from this cage compound have not been hitherto successful.

Mono-, di- and triferriophosphanes Fp$_n$PR$_{3-n}$ (n = 1−3) can be easily oxidised to the corresponding organometallated (chalcogeno)phosphoranes Fp$_n$PR$_{3-n}$(E) (E = O, S, Se), as well as the organic derivatives PR$_3$.[4] While the organic phosphonium salts [PR$_4$]X are normally air-stable, the diferriophosphonium salts [Fp$_2$P(H)R]X (X = any anion) turned out to be very reactive towards oxidising reagents, especially air oxygen.[3]

In the following, we report on the simple and selective transformation of a dimetalated phosphonium salt into an eight-membered planar ring molecule containing two Fe^{III} centres as well as two bidentate bridging ferriophosphinato-*O*,*O*′ ligands.

Results and Discussion

Our aim was to prove the surprising result of the oxidation of the PH-functionalized diferrio(mesityl)phosphonium salt [Fp$_2$P(H)Mes]Cl with air, leading to the cage molecule.[3] Therefore, we first synthesized a series of PH- and PCl-functionalized diferrio(organyl)phosphonium salts of the type [Fp$_2$P(X)R]$_2$FeCl$_4$ (X = H, Cl; R = Me, Et, *i*Pr, *t*Bu, Ph, *p*Tol, Xyl, Mes), which could then be oxidized. We used the so-called insertion method, which is the reaction of RPCl$_2$ with the dimer {CpFe(CO)$_2$}$_2$ (Scheme 1).

Depending on the substituent R and the solvent, we were able to obtain both the corresponding PCl- and PH-functionalized diferriophosphonium salts. In toluene at 80 °C both derivatives were obtained concurrently, whereby traces of H$_2$O played a role. Whereas in the case of R = Me, Et, Ph, and Tol, only the PCl phosphonium salts [Fp$_2$P(Cl)R]$_2$FeCl$_4$ (**1a**, **b**, **e**, and **f**) were formed, for R = *i*Pr, *t*Bu, Xyl, and Mes; however, the PH derivatives [Fp$_2$P(H)R]$_2$FeCl$_4$ (**1′c**, **d**, **g**, and **h**) were also obtained in considerable amounts, besides the PCl compounds. The best yields for **1a**−**h** and **1′a**−**h** were achieved when the starting materials Fp$_2$ and RPCl$_2$ were used in a 3:2 ratio. When dichloromethane was used as the solvent, only the PCl derivatives **1b**−**d** were formed at room temp. As NMR experiments with the combinations H$_2$O/toluene, D$_2$O/toluene, and H$_2$O/C$_6$D$_6$ and absolutely dry toluene as the solvent have shown, the hydrogen atom is derived from traces of water in the toluene. It is surprising that the P−Cl moiety, once formed could not be transformed into the PH entity. Further experiments showed that P−Cl could be changed into P−OH or P−OR by reaction with H$_2$O or ROH, respectively.[5]

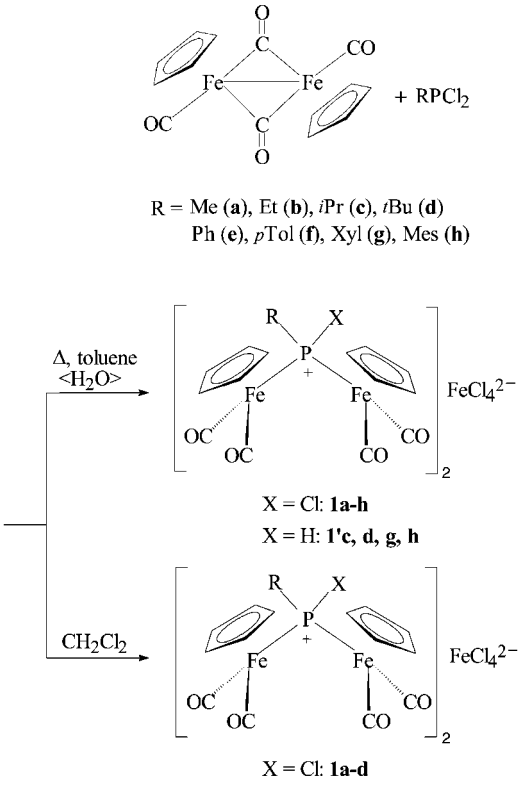
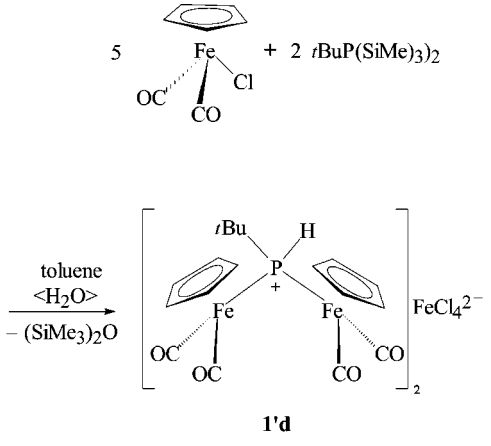


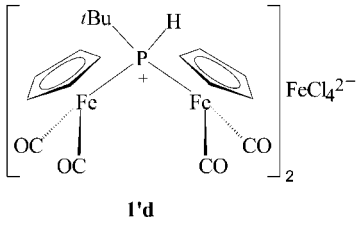
Scheme 1

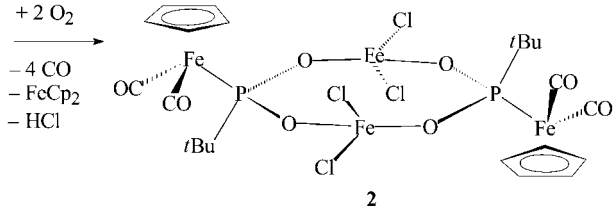
We were not able to successfully obtain single crystals of any PH derivative, $[Fp_2P(H)R]_2FeCl_4$, but we succeeded in obtaining single crystals of the PCl compounds, $[Fp_2P(Cl)R]_2FeCl_4$ (R = Me, Et, *i*Pr, *t*Bu) **1a**−**d**. In this context, however, we only report on the molecular structure of the *tert*-butyl derivative **1d**, instead of the analogous **1′d**, which is the starting material for the formation of the novel ring molecule **2**. Compound **1′d** was obtained by using the silyl method, where $CpFe(CO)_2Cl$ was treated with *t*BuP-$(SiMe_3)_2$ in toluene at room temperature in the presence of traces of water (Scheme 2).



Scheme 2

The phosphonium salts **1a**−**h** and **1′c**, **d**, **e**, **g**, and **h** were treated with air oxygen for periods ranging from a few days to weeks. Only the mixed PH/Cl-functionalized salt with R = *t*Bu (**1d/1′d**) yielded a homogeneous product with **2**, besides the by-product ferrocene. Related experiments showed that the pure, rather stable PCl derivative **1d** could not be oxidized to give **2**. On the other hand, the oxidation of the pure PH compound **1′d** gave a greater yield of **2** than using the mixed salt **1d/1′d**. A plausible reaction mechanism is shown in Scheme 3, in which the balance of electrons and stoichiometry is correct. In the first step, the phosphonium cation is oxidised by oxygen under elimination of one ferrio group. In the next step, the resulting unstable monoferriophosphinic acid reacts with the $FeCl_4^-$ counter anion, which is derived by oxidation from the $FeCl_4^{2-}$ present in the starting material **1′d**. The resulting eight-membered ring of **2** seems to be the consequence of self assembling under thermodynamic control.





Scheme 3

The IR spectra (solid, KBr) of the mixed compound **1d/1′d** and the pure **1d** and **1′d** show the characteristic vibrations $\nu(CO_t)$ at 2055, 2031, and 1989 cm^{-1}. The ^{31}P NMR spectrum of **1d** shows a singlet at $\delta = 289$ and that of **1′d** shows a doublet at $\delta = 31$ ($^1J_{PH} = 303$ Hz), which are in the expected regions. The ^1H NMR spectra of both compounds **1d** and **1′d** show two signals at $\delta = 5.36$ (s, Cp) and 1.29 (s, Me), **1′d** additionally a doublet at $\delta = 3.40$ ($^1J_{PH} = 303$ Hz). In the FAB$^+$ (*m*NBA) mass spectra the parent signals are found at *m*/*z* = 477 [M(*PCl*)]$^+$ (**1d**) and 443 [M(*PH*)]$^+$ (**1′d**), respectively. In the case of the mixed salt **1d/1′d**, both signals appear in a 1:1 ratio. The elemental analysis does not indicate any exact product distribution in the mixed salt, the Cl value, however, points to an excess of the PCl-functionalised derivative **1d** in the mixed salt.

All attempts to obtain single crystals of **1′d** failed. The PCl-functionalised derivative **1d**, however, could be obtained as single crystals suitable for an X-ray structure analysis. In **1d**[6] both the Fe atoms and the central P atom are

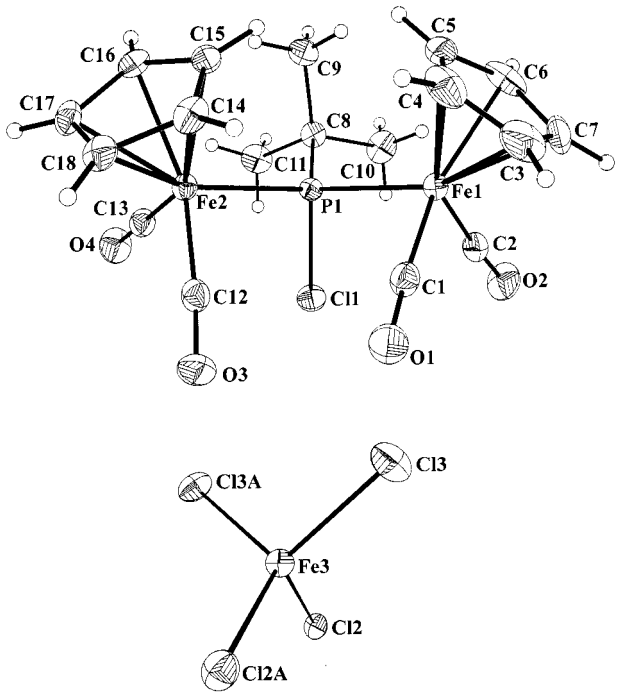


Figure 1. Molecular structure of **1d** (only 1 cation and the anion) in the crystal; selected bond lengths [Å] and angles [°]: Fe1−P1 2.3070(9), Fe2−P1 2.2930(10), P1−Cl1 2.0989(11), P1−C8 1.900(3), Fe3−Cl*n* 2.3159(11), 2.3231(10); Fe1−P1−Fe2 119.78(4), Fe1−P1−Cl1 102.46(4), Fe1−P1−C8 114.47(11), Fe2−P1−Cl1 102.46(4), Fe2−P1−C8 114.66(11), Cl1−P1−C8 98.57(11), Cl*x*−Fe3−Cl*y* 103.67(6), 115.52(4), 107.96(4), 106.52(6)

pseudo-tetrahedrally coordinated (Figure 1). The two Fe−P distances have the same size and fit very well within the range of symmetric diferriophosphonium salts.[2] There is no bonding interaction between the two Fe centres (Fe−Fe 3.979 Å). Because of the steric effect of the two ferrio groups, the tetrahedron of the P atom is strongly distorted [Fe1−P1−Fe2 119.78(4)°; Cl1−P−C8 98.57(11)°].

Compound **2** is slightly soluble and paramagnetic (μ_B = 6.04 B.M.).[7] Therefore, NMR measurements were not possible, and the spectroscopic characterization was restricted. The IR spectrum of **2** shows, besides the absorptions of the Cp and *t*Bu groups, those of the corresponding ν(CO) at 2044 and 1999 cm^{-1} and ν(PO_2) at 1070 and 971 cm^{-1}. In the EI (*m*NBA) mass spectrum the signal of highest mass appears at *m*/*z* = 791 as the fragment $[M - 2\ CO]^+$; the further fragmentation includes Cl and CO eliminations with signals at *m*/*z* = 719, 692, and 664 $[M - 2\ CO - 2Cl - nCO]^+$ (*n* = 0−2).

The solution of the composition and the structure of **2** could only be achieved by a single-crystal X-ray diffraction analysis[6] (Figure 2). Accordingly, **2** consists of a nearly planar centrosymmetric eight-membered ring with alternating O−P−O−Fe positions and C_i symmetry. The four tetrahedra at both P and Fe centres are linked by four common O atoms. The maximum deviation of the least-squares plane over all atoms is 0.067 Å. The heterocycle of **2** has a diameter of about 4.7 Å (Fe2−Fe2A 4.576 Å, P1−P1A 4.792 Å). The tetrahedra are completed at the Fe atoms by

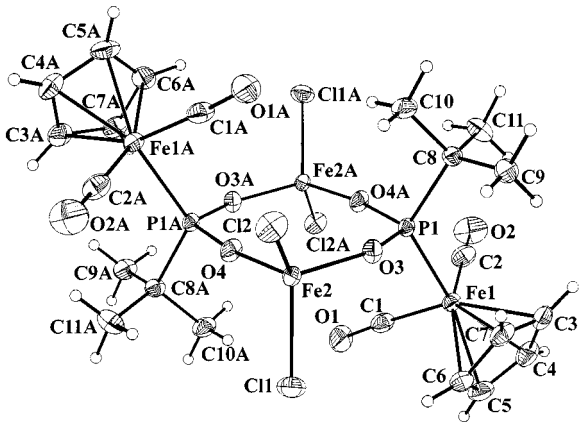

Figure 2. Molecular structure of **2** (only 1 cation and the anion) in the crystal; selected bond lengths [Å] and angles [°]: P1−Fe1 2.2190(11), P1−C8 1.860(4), P1−O3 1.552(3), P1−O4A 1.555(2), Fe2−O3 1.845(3), Fe2−O4 1.825(3), Fe2−Cl1 2.2029(12), Fe2−Cl2 2.1910(12); O3−P1−O4A 108.6(2), Fe2−O3−P1 146.5(2), P1−O4A−Fe2A 171.5(2), O3−P1−C8 103.7(2), O3−P1−Fe1 109.82(11), O3−Fe2−O4 110.80(12), O3−Fe2−Cl1 107.04(9), O3−Fe2−Cl2 109.43(9), Cl1−Fe2−Cl2 110.60(5)

two Cl atoms, and at the P atoms by a ferrio and a *t*Bu group. The P−O and Fe−O distances are in pairs nearly in the same range [P1−O3 1.552(3), P1−O4A 1.555(2) Å, Fe2−O3 1.845(3), Fe2−O4 1.825(2) Å]. The exocyclic distances P1−Fe1, P1−C8 and Fe2−Cl1 are 2.219(0), 1.860(4) and 2.203(0) Å. The corresponding ring angles of the Fe and P atoms are quite similar [O3−Fe2−O4A 110.80(12), O3−P1−O4A 108.6(2)°], the angles including the substituents, however, differ more noticeably [Cl1−Fe2−Cl2 110.60(5), Fe1−P1−C8 120.44(13)°]. The angles at the ring O atoms are surprisingly different [P1−O3−Fe2 146.5(2)° and P1A−O4−Fe2 171.5(2)°].

The structural constitution of **2** is very similar to that of cyclic tetrametaphosphates[7] and dimeric diorganophosphinato complexes of transition metals,[1] which in contrast are not planar. Formally, **2** can be regarded as the dimeric compound of a (*tert*-butyl)(ferrio)phosphinato-*O*,*O*′ complex of tetrahedrally configured Fe^{III}, where the phosphinato ligand is not behaving as a chelating ligand towards *one* Fe^{III} atom, but as a bridging ligand between *two* Fe^{III} centres. Theoretical calculations (B3LYP, hybrid density functional theory) indicate a planar ring skeleton with island-like π-electron delocalisation.[9]

Our experimental results are a first step towards the synthesis of novel organometalated phosphinato ligands, for which a similar manifold coordination chemistry and field of application is expected as for the organic phosphinato ligands. Because of the simultaneous coupling to two metal centres − perhaps two different ones − they seem to be more interesting.

Experimental Section

1d/1′d: A solution of $\{CpFe(CO)_2\}_2$ (2.0 g, 5.64 mmol) and *t*$BuPCl_2$ (0.3 mL, 3.7 mmol) in 80 mL of toluene was stirred at 80 °C for 12 h. A yellow solid precipitated that was filtered off, washed

with 50 mL of dry toluene, and dried in vacuo. Yield: 1.4 g (75%) of **1d/′d** as a bright yellow powder, no correct elemental analysis was obtained because of the existence of a mixture of PCl- and PH-functionalised product.

1d: A solution of $\{CpFe(CO)_2\}_2$ (2 g, 5.64 mmol) and tBuPCl$_2$ (0.3 mL, 3.7 mmol) in 20 mL of dichloromethane was kept at room temperature for up to 1 week. The product **1d** separated as very thin plates at the surface of the glass. Yield: 0.2 g (10%). FAB$^+$ MS (*m*NBA): *m*/*z* = 477 [M]$^+$. IR (KBr): ν(CO) = 1987, 2003, 2030, 2050 cm^{-1}. ^{31}P NMR (CD_3CN, 109.4 MHz): δ = 289. ^{13}C NMR (CD_3CN, 67.9 MHz): δ = 211 (CO), 90 (Cp), 50 [$C(CH_3)_3$], 30 (CH_3). ^{1}H NMR (CD_3CN, 270.2 MHz): δ = 5.55 (Cp), 1.45 (CH_3). $C_{36}H_{38}Cl_6Fe_5O_8P_2$ (1152.6): calcd. C 37.5, H 3.3, Cl 18.4; found C 36.7, H 3.1, Cl 18.4.

1′d: A solution of $CpFe(CO)_2Cl$ (5.0 g, 23.54 mmol) and 1 mL (4.70 mmol) of tBuP(SiMe$_3$)$_2$ in 100 mL of toluene was stirred at 25 °C for 12 h. A yellow solid precipitated, which was filtered off, washed with 80 mL of dry toluene, and dried in vacuo. Yield: 4.2 g (82%). FAB$^+$ MS (*m*-NBA): *m*/*z* = 443 [M]$^+$. IR (KBr): ν(CO) = 1987, 2024, 2034 cm^{-1}. ^{31}P NMR (CD_3CN, 109.4 MHz): δ = 27 (d, $^1J_{PH}$ = 303 Hz). ^{13}C NMR (CD_3CN, 67.9 MHz): δ = 91 (Cp), 50 [$C(CH_3)_3$], 30 (CH_3). ^{1}H NMR (CD_3CN, 270.2 MHz): δ = 5.41 (Cp), 3.4 (d, $^1J_{PH}$ = 303 Hz, PH), 1.27 (d, $^3J_{PH}$ = 18 Hz, CH_3). $C_{36}H_{40}Cl_4Fe_5O_8P_2$ (1083.7): calcd. C 39.9, H 3.7, Cl 13.1; found C 38.7, H 3.5, Cl 16.2.

2: A solution of **1′d** (140 mg, 0.12 mmol) in 12 mL of acetonitrile was kept for about 2 weeks in an air atmosphere. After this time, small prismatic, deep purple-red single crystals of **2** separated at the bottom of the vessel. They were isolated by decantation of the solution. In the mother liquor some of product **2** still remained, which could not, however, be separated as a pure product. Yield: 33 mg (33%). EI MS (*m*NBA): *m*/*z* = 791 [M − 2 CO]$^+$, 692, 664 [M − 2 CO − 2 Cl − *n*CO (*n* = 0, 2)]$^+$. IR (KBr): ν(PO_2) = 971, 1070 cm^{-1}, ν(CO) = 1999, 2044 cm^{-1}. $C_{22}H_{28}Cl_4Fe_4O_8P_2{\cdot}2CH_3CN$ (929.7): calcd. C 33.6, H 3.7, Cl 15.1; found C 33.1, H 3.9, Cl 14.3.

Syntheses and Structures of New Tellurium−Mercury Clusters with Twelve- and Six-Membered Rings

Ernesto Schulz Lang,*[a] Renato A. Zan,[a] Claudia C. Gatto,[a] Robert A. Burrow,[a] and Ezequiel M. Vázquez-López[b]

Keywords: Tellurium / Mercury / Cluster compounds / Metallacycles

Clusters with polycyclic twelve-membered rings were formed exclusively from the reaction of $[Hg(TePh)_2]$ with HgX_2 in pyridine. Clusters with just six members were formed from the same reaction in DMSO. In both cases, the solvent was coordinated to the clusters. The clusters, $[Hg_6(\mu\text{-}Br)_2Br_2(\mu\text{-}TePh)_8(py)_2]$ and $[Hg_3X_3(\mu\text{-}TePh)_3]\cdot 2DMSO$ (X = Cl, Br, I), were characterized by single-crystal X-ray crystallography.

Mercury chalcogenide compounds have found considerable use in industry, especially as low band gap semiconductors, in photovoltaic applications, and IR detection devices.[1] The synthesis and structural characterization of metal chalcogenide molecules with a defined size and structure provide an interesting approach to this class of materials.[2] Coordination compounds can be adequate precursors because the structure and properties of the resulting material can be modified by the synthesis conditions or the nature and properties of the ligands. Diorganochalcogenide compounds, RE−ER (E = S, Se, Te), could be optimal ligands, because they react with mercury under mild conditions to yield $[Hg(ER)_2]$ complexes. Although they eventually form polymeric structures by weak intermolecular Hg···E interactions,[3,4] the sulfide and selenide derivatives react with equimolar amounts of $HgCl_2$ in pyridine to yield metallacyclic compounds $[Hg_4Cl_4(\mu\text{-}ER)_4(py)_n]$ (E = S, R = *t*Bu, *n* = 2;[5] E = Se, R = Et, *n* = 4; E = Se, R = *t*Bu, *n* = 4.[3]) The different stoichiometry of the compounds appears to depend on the steric hindrance between pyridine and organic substituent R. Surprisingly, analogous tellurium derivatives have not been reported until now. As part of our interest in organotelluride chemistry,[6] we have investigated the reaction of $[Hg(TePh)_2]$[7] with $HgBr_2$ in coordinating solvents, in which only the first is soluble.

The solid isolated from the reaction mixture could be fully characterized as the cluster $[Hg_6(\mu\text{-}Br_2)Br_2(\mu\text{-}TePh)_8(py)_2]$ (**1**) by single-crystal X-ray diffraction[8] (Figure 1). The structure of **1** exemplifies a rare multinuclear compound. The molecule can be considered as being formed from two six-membered $Hg_3(\mu\text{−}TePh)_3$ rings that are bridged by two (μ-TePh) ligands. Additionally, a bromine atom asymmetrically bridges the two mercury atoms in each ring [Hg(1)−Br(8) 2.941(2), Hg(3)−Br(8) 2.845(2) Å]. A terminal bromine atom coordinates to the third mercury atom at a shorter distance [Hg(2)−Br(9) 2.641(2) Å].

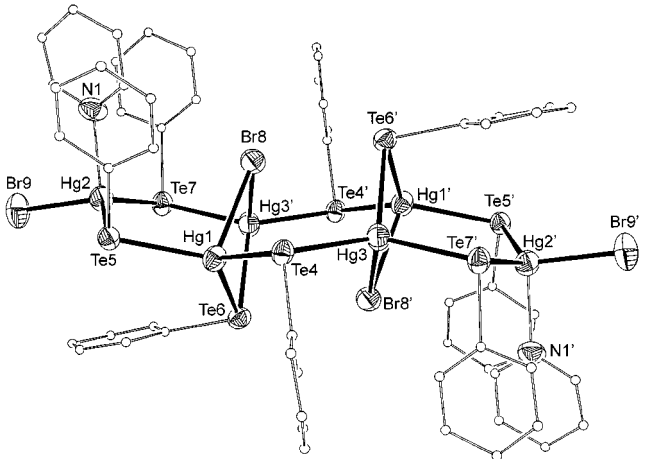

Figure 1. Structure of **1** (with H atoms omitted and each carbon atom represented by a conventional radius for clarity); selected bond lengths [Å]: Hg(1)−Te(4) 2.7489(13), Hg(1)−Te(6) 2.7552(15), Hg(1)−Te(5) 2.7796(13), Hg(1)−Br(8) 2.941(2), Hg(2)−N(1) 2.421(19), Hg(2)−Br(9) 2.641(2), Hg(2)−Te(5) 2.7432(13), Hg(2)−Te(7) 2.7568(15), Hg(3)−Te(7)′ 2.7511(13), Hg(3)−Te(4) 2.7564(13), Hg(3)−Br(8)′ 2.845(2), Hg(3)−Te(6)′ 2.8500(15), Te(6)−Hg(3)′ 2.8501(15), Te(7)−Hg(3)′ 2.7511(13); ′ = $-x+1, -y, -z+1$

The structure of **1** resembles those found of $[Et_4N]_4[Hg_7(\mu\text{-}Se)_6(\mu\text{-}Se_2)(\mu_3\text{-}Se)_2]$[9a] (Figure 2A) and $[nBu_4N]_4[Hg_4(\mu\text{-}Te)_2(\mu\text{-}Te_2)_2(\mu\text{-}Te_3)_2]$[9b] (Figure 2B), both of which contain only two coordinated chalcogen atoms. In these anionic clusters, two Hg_3Se_3 or $Hg_2(Te_3)Te$ rings are

bridged by Se^{2-}, Se_2^{2-}, and $HgSe_2^{2-}$, or Te_2^{2-} and Te^{2-} units. The Hg−Hg distances in **1** [Hg(1)−Hg(3) = 3.6249(11) Å is the shortest] preclude a metal−metal interaction.

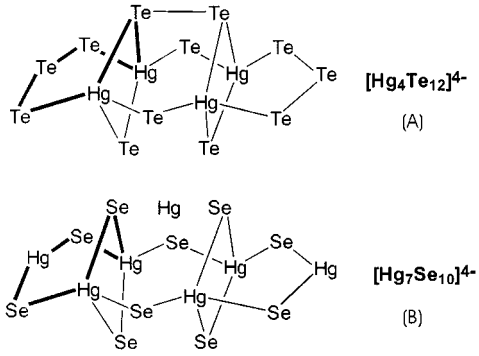

Figure 2. Structures of the clusters $[Hg_7(\mu\text{-}Se)_6(\mu\text{-}Se_2)(\mu_3\text{-}Se)_2]^{4-}$ [9a] (A) and $[Hg_4(\mu\text{-}Te)_2(\mu\text{-}Te_2)_2(\mu\text{-}Te_3)_2]^{4-}$ [9b] (B)

Although the coordination geometry around all the mercury atoms in **1** is a distorted tetrahedron, two different environments coexist about the atoms: $HgBrTe_3$ [for Hg(1) and Hg(3)] and $HgBrTe_2N$ [for Hg(2)]. No compounds with the same environment around the three-coordinate Te atom (two Hg atoms and an alkyl or aryl group) have been reported in the Cambridge Crystallographic Database.[10] However, the Hg−Te bond lengths [2.7423(13)−2.8500(15) Å] are similar to those found in other mercury(II) tellurides containing two-coordinate Te atoms (two Hg atoms)[9b,13] or three-coordinate with two Hg atoms and one P atom.[12] The only other reported Hg−Te distances for three-coordinate Te (two Hg atoms and a Te atom) are much longer.[9a,9b] The Hg−Br and Hg−N distances are normal.[13] All the Te atoms are trigonal-pyramidal with each bonding to two Hg atoms and a carbon atom of the phenyl group [bond angles ranging between Hg(1)−Te(6)−Hg(3) 80.57(4)° and C(71)−Te(7)−Hg(3)′ 104.6(5)°; ′ = $-x + 1$, $-y$, $-z + 1$].

Compound **1** is sparingly soluble in most organic solvents except pyridine, DMSO, and DMF. Furthermore, **1** is a very stable compound and was the main product formed when mixtures of $[Hg(TePh)_2]$ and $HgBr_2$ and an excess of other ligand (for instance PPh_3) in pyridine were allowed to crystallize. On the other hand, all attempts to substitute pyridine for another ligand were unsuccessful.

The reaction of $[Hg(TePh)_2]$ and $HgBr_2$ in DMSO yielded a crystalline light yellow solid (**2a**), whose composition was determined by single-crystal X-ray diffraction as $[Hg_3Br_3(TePh)_3]\cdot 2DMSO$.[13] The molecular structure of **2a** (Figure 3) consists of a six-membered ring with alternating Hg and Te atoms in a chair conformation. Although a similar conformation is observed as for **1**, in this case the orientation of all phenyl groups of the TePh ligands are on the same side of the ring (in **1**, two groups occupy one side and one group occupies the other). A terminal bromine atom coordinates to each mercury atom. The Hg−Te and Hg−Br distances are similar to the corresponding distances observed in **1**. If we consider only the interactions noted above, the coordination geometry around the mercury atom would be trigonal-planar. However, two DMSO molecules (one of them crystallographically disordered about two positions) occupy positions on either side of the Hg_3Te_3 ring with the oxygen atoms directed to the center of the ring. The distance of O(21) to the mercury atoms is shorter than that of O(11) [Hg(1)−O(21) 3.176(11), Hg(2)−O(21) 2.832(9), Hg(3)−O(21) 2.908(9), Hg(1)−O(11) 3.2380(15), Hg(2)−O(11) 3.344(9) and Hg(3)−O(11) 3.346(8) Å]. Atom O(21) seems to establish a weak interaction with the tellurium atoms; the Te···O(21) distances range between 3.161(8) and 3.252(9) Å. Each mercury atom also interacts weakly with the bromine atoms of the neighboring molecules [Hg(1)···Br(1)′ = 3.2380(15), Hg(2)···Br(2)′′ = 3.4881(15) and Hg(3)···Br(3)′′′ = 3.4640(16) Å; ′ = $x + 1$, $-y + 1$, $-z$; ′′ = $-x + 1$, $-y + 1$, $-z + 1$; ′′′ = $-x + 1$, $-y$, $-z + 1$]. If all weak interactions are considered, the resulting coordination polyhedron around the mercury atom can be described as a strongly distorted octahedron, while the co-

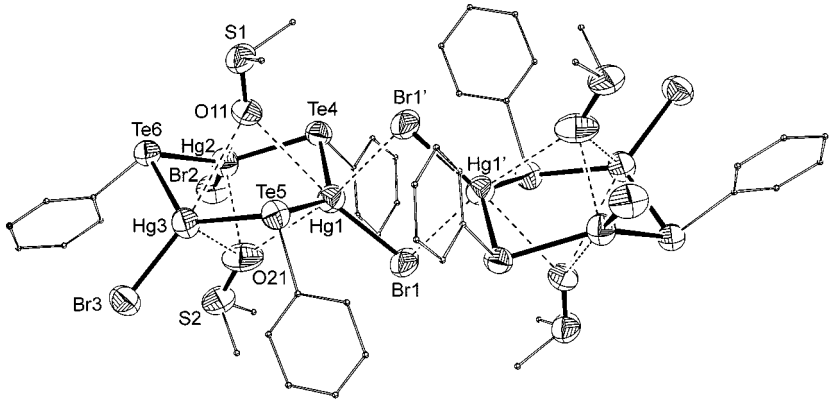

Figure 3. Two molecules of **2a**, showing intermolecular interactions (H atoms are omitted and each carbon atom represented by a conventional radius for clarity); selected bond lengths [Å]: Hg(1)−Br(1) 2.6134(13), Hg(1)−Te(4) 2.6884(9), Hg(1)−Te(5) 2.6974(9), Hg(2)−Br(2) 2.5859(15), Hg(2)−Te(6) 2.6855(9), Hg(2)−Te(4) 2.7139(9), Hg(3)−Br(3) 2.5824(13), Hg(3)−Te(5) 2.6929(9), Hg(3)−Te(6) 2.7062(9), Hg(1)−Br(1)′ 3.2380(15); ′ = $-x + 1, -y + 1, -z$

ordination geometry about the tellurium atoms is trigonal-pyramidal with the Hg−Te−Hg angles approximately 90°.

As compound **1** comprises $Hg_3(\mu\text{-}TePh)_3$ units, **2a** therefore could be considered to be its structural precursor. An interesting aspect is that changing the reaction solvent affects the stoichiometry as well as the structure of the resulting compound. Furthermore, the DMSO molecules in **2a** seem to shield the mercury atoms, but they are not strongly bonded to them. The compounds $[Hg_3Cl_3(\mu\text{-}TePh)_3]\cdot 2DMSO$ (**2b**) and $[Hg_3I_3(\mu\text{-}TePh)_3]\cdot 2DMSO$ (**2c**), which are isostructural with analogs **2a**, were also characterized. Studies to evaluate the stoichiometry and structure of the products from the reaction of **2** with other ligands in different solvents are underway in our laboratory.

Experimental Section

$(PhTe)_2Hg$ (0.61 g, 1.0 mmol) was dissolved in 10 mL of dry pyridine for **1** or DMSO for **2a**, and subsequently $HgBr_2$ (0.36 g, 1 mmol) was added under dry N_2. After stirring for 4 h at room temperature, the yellow solution was filtered. The addition of ethanol (2 mL) produced yellow crystals after a week (**1**: 0.497 g, 60% yield based on $HgBr_2$, m.p. 104 °C; **2a**: 0.172 g, 32% yield based on $HgBr_2$, m.p. 118 °C; **2b**: 0.223 g, 45% yield based on $HgCl_2$, m.p. 106−107 °C; **2c**: 0.263 g, 45% yield based on HgI_2, m.p. 125−126 °C).

Redox Control of Conformation and Luminescence of a Dinuclear Ruthenium(II) Complex with a Bis-dipyridophenazine Bridging Ligand

Mara Staffilani,[a] Peter Belser,*[b] Luisa De Cola,[a] and František Hartl*[a]

Keywords: Ruthenium / Spectroelectrochemistry / Redox control / Cyclic voltammetry / Electron transfer / Bridging ligands

This spectroelectrochemical study deals with an interesting luminescent dinuclear complex $[\{Ru(bpy)_2\}_2(\mu\text{-bdppz})]^{4+}$ ($\mathbf{1}^{4+}$), where bpy stands for 2,2′-bipyridine and bdppz for 1,1′-dipyrido[3,2-*a*:2′,3′-*c*]phenazin-1,1′-yldipyrido[3,2-*a*:2′,3′-*c*]phenazine. The electronic coupling between the phenazine moieties through the central C–C bond can be easily modified as a function of the ligand oxidation state. Upon stepwise one-electron reduction in acetonitrile, complex $\mathbf{1}^{4+}$ is reversibly transformed into $\mathbf{1}^{3+}$ and $\mathbf{1}^{2+}$, with consequent major structural and electronic changes of the bridging ligand and with quenched MLCT emission of the excited $Ru(bpy)_2$ moieties.

Introduction

The control of the electronic interaction between different molecular components opens new strategies for the construction of nanometre-sized molecular devices, for example in the field of information and data storage.[1] The possibility to modulate the physical response of chromophoric units by an external stimulus such as redox- or light-driven reaction is a fascinating and booming research topic.[2] An important issue for experimental and theoretical investigations in coordination chemistry in this area is tuneable electronic communication between remote redox-active metal centres with attached chromophoric units or other functionalities (e.g. sensors). The key position of the connecting wire in such an assembly of molecular components can be occupied by a well-defined di- or oligonucleating ligand with tuneable energies of its frontier orbitals and molecular structure as a function of its oxidation state.[3] In this work we focus on an interesting dinucleating α-diimine ligand 1,1′-dipyrido[3,2-*a*:2′,3′-*c*]phenazin-1,1′-yldipyrido[3,2-*a*:2′,3′-*c*]-phenazine (bdppz) and its homodinuclear complex $[\{Ru(bpy)_2\}_2(\mu\text{-bdppz})]^{4+}$ ($\mathbf{1}^{4+}$; bpy = 2,2′-bipyridine).[4,5] The bridging ligand consists of two well-known 1,1′-dipyrido[3,2-*a*:2′,3′-*c*]phenazine (dppz)[4c,6] moieties linked by a C−C bond (see Scheme 1). It is noteworthy that the central part of the bdppz ligand, reaching up to the phenazine nitrogens, formally corresponds to the bridging 3,3′,4,4′-tetraimino-3,3′,4,4′-tetrahydrobiphenyl (tib) ligand with interesting conformation, electronic and redox properties studied in its homodinuclear complex $[\{Ru(bpy)_2\}_2(\mu\text{-tib})]^{4+}$.[7] Comparison between the bdppz and tib ligands will follow.

Results and Discussion

The cyclic and differential pulse voltammograms of $\mathbf{1}^{4+}$ in butyronitrile (Figure 1) reveal a two-electron anodic process (Table 1) that corresponds to unresolved one-electron oxidations of both Ru^{II} centres to Ru^{III} in $\mathbf{1}^{6+}$. The inefficient electronic communication between the two remote Ru centres through the bridging ligand in $\mathbf{1}^{4+}$ is caused to some extent by a large twist at the central C−C bond, in analogy with the related but less extended tib quinonediimine system, that better conjugates the chromophores;[7] the poor overlap between the $d_\pi(Ru)$ orbitals and the central phenazine π-system is also important in this regard.[8,9] The initial reduction of $\mathbf{1}^{4+}$ is indeed largely localised on the phenazine nitrogens of the C−C-linked dppz moieties and occurs as two separate reversible one-electron steps (Table 1). The 2,2′-bipyridine ligands remain insensitive to the reduction of the bridge and reduce reversibly pair-wise in unresolved two-electron processes (Table 1). These assignments have received unambiguous support from the redox properties of the reference[8b] mononuclear complex $[Ru(bpy)_2(dppz)]^{2+}$ ($\mathbf{2}^{2+}$) (Scheme 1 and Table 1) and related diruthenium systems.[9] The pairwise response of the 2,2′-bipyridine ligands to the reduction indicates the persistent inefficient electronic interaction between the ruthenium centres across the presumably planar two-electron reduced bdppz bridge, in contrast to the tib ligand.[7]

The absorption properties of the dinuclear complex $\mathbf{1}^{4+}$ undergo major changes upon stepwise reduction to $\mathbf{1}^{2+}$ in

a UV/Vis spectroelectrochemical cell[10] (Figure 2). The absorption band of $\mathbf{1}^{4+}$ at 407 nm belongs to an intraligand (IL) π-π* transition localised on the phenazine moieties of the bdppz ligand. This band is indeed present in the absorption spectrum of the bdppz ligand, at 413 nm in dichloromethane (insert to Figure 2); it disappears from the absorption spectrum of $\mathbf{1}^{4+}$ upon reduction to $\mathbf{1}^{3+}$ (Figure 2). The pronounced shoulder at 454 nm in the absorption spectrum

of $\mathbf{1}^{4+}$ is assigned to a set of metal-to-ligand [d_π(Ru)-to-π* (bpy)] charge transfer (MLCT) transitions, consistent with the assignments reported for $\mathbf{2}^{2+}$ [4c] and related diruthenium complexes.[9] The shoulder indeed disappears upon the 2e-oxidation of the ruthenium ions to Ru^{III} in $\mathbf{1}^{6+}$ (Scheme 1)[11] but remains almost unchanged upon reduc-

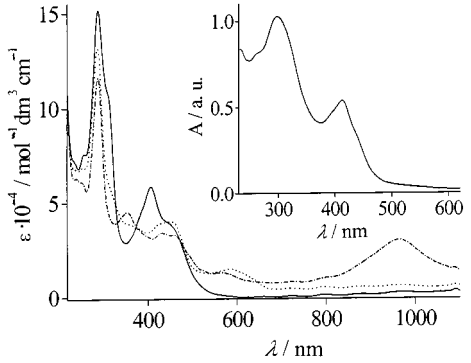

Figure 2. UV/Vis spectra of $5 \cdot 10^{-4}$ M $\mathbf{1}^{4+}$ (——), $\mathbf{1}^{3+}$ (− − −) and $\mathbf{1}^{2+}$ (−·−·−) in butyronitrile/$3 \cdot 10^{-1}$ M Bu_4NPF_6, recorded in an OTTLE cell;[10] inset: UV/Vis spectrum of the noncoordinated bdppz ligand (saturated solution in dichloromethane)

tion of $\mathbf{1}^{4+}$ to $\mathbf{1}^{3+}$ (Figure 2). A new structured absorption band of 1e-reduced $\mathbf{1}^{3+}$ at ca 580 nm belongs to IL transitions due to the radical $[bdppz]^{\cdot-}$ ligand (Figure 2), similarly to that reported for $\mathbf{2}^{2+}$.[8b] Importantly, when proceeding further with the reduction to $\mathbf{1}^{2+}$, a new broad and intense low-lying absorption band arises at 965 nm (Figure 2). It corresponds to an IL π-π* transition within the new π-system of the planar C=C-linked phenazine moieties of $[bdppz]^{2-}$. This absorption band shifts to 650 nm in the UV/Vis spectrum of the complex $H_2\mathbf{1}^{4+}$ (Figure 3 and Scheme 1) formed by protonation of the negatively charged phenazine nitrogens in $\mathbf{1}^{2+}$ (see Exp. Sect.). It is noteworthy that $H_2\mathbf{1}^{4+}$ deprotonates smoothly back to orange $\mathbf{1}^{4+}$ upon addition of H_2O_2.

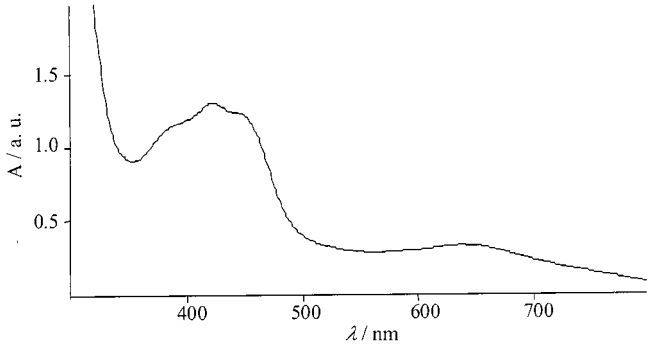

Figure 3. UV/Vis spectrum of $H_2\mathbf{1}^{4+}$ produced by chemical reduction of $\mathbf{1}^{4+}$ with Zn in deaerated acidified acetonitrile

The chemical reversibility of the coupled reduction/protonation processes and their localisation on the phenazine moieties was also revealed by cyclic voltammetry. For reference $\mathbf{2}^{2+}$, the phenazine-centred reduction at the dppz ligand in acetonitrile becomes electrochemically irreversible in the presence of exactly one equivalent of trifluoromethanesulfonic acid. The cyclic voltammogram indeed exhibits a large separation between the reduction of $\mathbf{2}^{2+}$, at $E_{p,c} = -1.23$ V, and the reverse anodic process, at $E_{p,a} = -0.29$ V, assigned to the oxidation of $H\mathbf{2}^{2+}$. In contrast, the bpy-centred cathodic steps are much less affected by the protonation, only being shifted by ca. 100 mV to more positive potentials, while the ruthenium-centred oxidation remains unchanged (Table 1). The product $H\mathbf{2}^{2+}$ does not decompose during the complete cyclic voltammetric scan (v = 100 mV/s), as testified by identical $i_{p,c}$ (reduction of $\mathbf{2}^{2+}$) and $i_{p,a}$ (oxidation of $H\mathbf{2}^{2+}$) peak current values. An analogous voltammetric response was also observed for dinuclear $\mathbf{1}^{4+}$ in acidified acetonitrile; however, the voltammetric peaks associated with the electrochemical reduction and coupled protonation of the phenazine nitrogen sites become very broad and determination of the cathodic and anodic peak potentials lacks precision.

The emission of complex $\mathbf{1}^{4+}$ at 650 nm with lifetime τ = 130 ns in acetonitrile (Figure 4) becomes completely quenched upon the stepwise electrochemical reduction to $\mathbf{1}^{3+}$ and $\mathbf{1}^{2+}$. The same result was obtained for reference $\mathbf{2}^{2+}$ and 1e-reduced $\mathbf{2}^{+}$. The corresponding experiments were conveniently run in situ within the thin-layer spectroelectrochemical cell, as described in the Exp. Sect. The luminescence can be switched OFF and ON repeatedly between $\mathbf{1}^{3+}$ and $\mathbf{1}^{4+}$, respectively. For $\mathbf{1}^{3+}$ (and $\mathbf{2}^{+}$) the quenching is attributed to efficient electron transfer from the electrochemically reduced phenazine moiety of bdppz (or dppz, in the case of $\mathbf{2}^{+}$) to the excited $*\{Ru^{III}(bpy^{\cdot-})\}$ unit. The value of the Gibbs energy change associated with the electron transfer process can be estimated through the zero-zero excitation energy E_{00} and the electrochemical potentials of the ground-state redox couples [Equation (1), for $\mathbf{1}^{3+}$], where $E°(bpy^{-1/0})$ denotes the 1e-reduction of the $Ru(bpy)_2$ moiety.

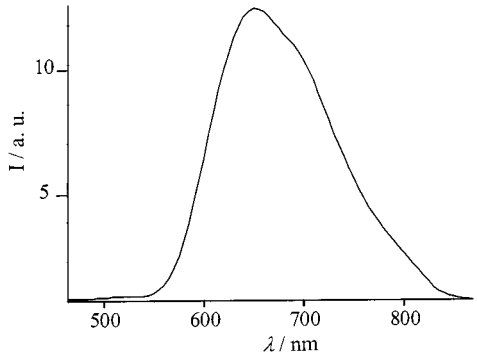

Figure 4. Emission of $\mathbf{1}^{4+}$ in acetonitrile, recorded upon excitation with 450 nm light

$$\Delta G° = E°(bdppz^{-1/0}) - E°(bpy^{-1/0}) - E_{00} = -1.23 - (-1.80) - 2.14\ eV < 0 \quad (1)$$

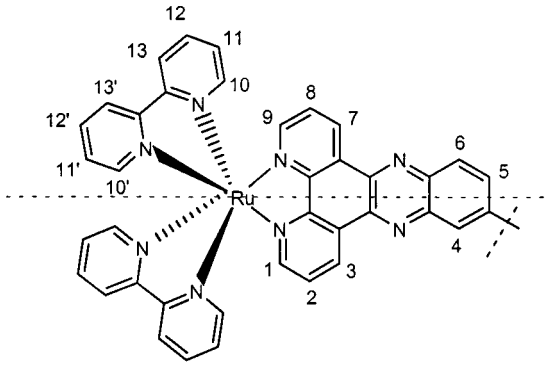
No luminescence was observed for 2e-reduced $\mathbf{1}^{2+}$ or its protonated form $H_2\mathbf{1}^{4+}$ (see Exp. Sect.), probably due to its low-lying non-luminescent bdppz-centred π-π* excited state (see above).

In conclusion, we present the redox behaviour of a diruthenium complex where the phenazine portion of the bridging bdppz ligand can be reversibly reduced in two separate one-electron steps. Interestingly, in the two-electron reduced state the bdppz ligand becomes planar. Its central C−C-linked bis(phenazine) portion responds to the reductions similarly to the less extended bis(*o*-quinonediimine) tib ligand.[7] In the planar conformation the bridging $[bdppz]^{2-}$ ligand is characterized by a new low-lying excited state, localised on the planar C=C-linked bis(phenazine) portion, that acts as an energy trap for the higher-lying (MLCT) excited states. Importantly, the energy of the lowest excited state can be increased upon reversible protonation. These properties of the binucleating bdppz ligand classify it as a redox- and pH-controllable molecular switch of long-distance electron/energy transfer in appropriately selected donor-acceptor dyads. In this regard, detailed photophysical and spectroelectrochemical investigations of bdppz-bridged homo- and heterodinuclear complexes are in progress.

Experimental Section

General: All solvents and reagents used in the preparations were reagent grade, purchased from Fluka or Aldrich, and used as supplied. Silica gel preparative plates and aluminium oxide chromatographic columns were used for purification of the metal complexes. The preparative SiO_2 plates were made of silica gel purchased from Merck (60, particle size 0.040−0.063 mm) and prepared according to the procedure indicated by Merck. Aluminium oxide for chromatography was purchased from Fluka (type 507 C neutral, Brockmann grade I, particle size 0.05−0.15 mm, pH 7.0 ± 0.5). For electrochemistry, butyronitrile (Acros) was dried over CaH_2 and freshly distilled under nitrogen prior to use; acetonitrile (Fluka, spectroscopic grade) was used as received. The supporting electrolyte Bu_4NPF_6 (Aldrich) was recrystallized twice from ethanol and dried overnight under reduced pressure at 60 °C.

^{1}H NMR spectra were recorded on a Varian Gemini 300 (300.075 MHz) spectrometer; chemical shifts are given in ppm, using the solvent itself as internal standard. Assignment of the signals was performed using the COSY technique. The numbering of the protons is shown in Scheme 2. ESI (Electron Spray Ionisation) mass spectra were obtained with a Bruker FTMS 4.7 T Bio APEXII spectrometer. UV/Vis absorption spectra were recorded on a Hewlett Packard 8453 diode-array spectrophotometer, and the reported emission spectrum (corrected for the photomultiplier response) on a Spex 1681 spectrophotometer (λ_{exc} = 450 nm).



Scheme 2

Cyclic voltammetric and differential pulse voltammetric scans were performed with a gas-tight single-compartment cell under an atmosphere of dry nitrogen or argon. The cell was equipped with a Pt disk working (apparent surface area of 0.42 mm^2), Pt wire auxiliary, and Ag wire pseudoreference electrodes. The working electrode was carefully polished with a 0.25 μm-grain diamond paste between scans. All redox potentials are reported against the ferrocene-ferrocenium (Fc/Fc^+) redox couple used as an internal standard[12] ($E_{1/2}$ = 0.42 V vs. SCE in acetonitrile). The potential control was achieved with a PAR Model 283 potentiostat. UV/Vis spectroelectrochemical experiments were performed with an optically transparent thin-layer electrochemical (OTTLE) cell,[10] equipped with a Pt minigrid working electrode and quartz optical windows. The controlled-potential electrolyses were carried out with a PA4 potentiostat (EKOM, Czech Republic). All electrochemical samples were $5\cdot10^{-4}$ M in the studied complex and contained $3\cdot10^{-1}$ M Bu_4NPF_6. The spectroelectrochemical cell was also conveniently employed for recording emission spectra during the electrochemical quenching experiments and determination of emission lifetime. In this case the emission spectra were recorded using an optical fibre connected to a nitrogen laser and a streak camera (Hamamatsu C5680−21), equipped with a M 5677 sweep unit. Excitation at 337 nm was achieved by a pulsed (fwhm 600 ps) nitrogen laser (LTB, MGS 405 TD) operating at a repetition rate of 20 Hz.

1,1′-Dipyrido[3,2-*a*:2′,3′-*c*]phenazin-1,1′-yldipyrido[3,2-*a*:2′,3′-*c*]-phenazine (bdppz): 1,10-phenanthroline-5,6-dione[4] (0.420 g, 2.0 mmol) and 3,3′,4.4′-biphenyltetramine (0.214 g, 1.0 mmol) were suspended in 10 mL acetic acid (100%) and heated at 120 °C for 1 h. After cooling to room temperature, 100 mL of water was added to the reaction mixture. The olive-green precipitate was filtered off, washed with water, aqueous sodium hydrogen carbonate (10%) and again with water. The solid was dried under vacuum at 50 °C (0.484 g, yield 86%). The bdppz ligand is practically insoluble in all common solvents, therefore a direct analytical proof has not been possible.

[{Ru(bpy)$_2$}$_2$(μ-bdppz)](PF$_6$)$_4$ (1^{4+}): [$Ru(bpy)_2Cl_2$]·$2H_2O$ (0.104 g, 0.2 mmol),[5] bdppz (0.056 g, 0.1 mmol) and 2 drops of HPF_6 (60% solution in water) were suspended in ethylene glycol (6 mL) and heated in a microwave oven (3 times for 2 min). The solvent was removed under reduced pressure. Water (20 mL) and NH_4PF_6 (1 g) were then added to produce a red precipitate that was separated by suction filtration. The crude product was purified on a column of neutral aluminium oxide (10 × 2 cm) with acetone/water (98:2) as eluent. The orange-red band (TLC: R_f = 0.22, support SiO_2, eluent $MeCN/H_2O/MeOH/KNO_3$ 4:1:1:0.1) was collected, the solvents were removed under reduced pressure and the residual solid was further purified on SiO_2 plates ($MeCN/H_2O$/*tert*-butyl alcohol/KNO_3 4:1:1:0.1). Isolation (with acetone/NH_4PF_6 as eluent) of the orange-red band gave the pure product (0.055 g, 28% yield). ^{1}H NMR (CD_3CN): bdppz signals δ = 7.92 (dd, 4 H, H2 and H8), 8.20 (d, 4 H, H1 and H9), 8.69 (d, 2 H, H6), 8.76 (d, 2 H, H5), 9.04 (s, 2 H, H4), 9.71 (d, 4 H, H3 and H7); bpy signals δ = 7.28 (dd, 2 H, H11), 7.47 (dd, 4 H, H11′), 7.75 (d, 4 H, H10), 7.86 (d, 4 H, H10′), 8.03 (dd, 4 H, H12), 8.12 (dd, 4 H, H12′), 8.53 (d, 4 H, H13), 8.56 (d, 4 H, H13′). See Scheme 2 for proton numbering. ESI-MS: *m*/*z* = 839.59 [$M^+ - 2PF_6^-$], 551.74 [$M^+ - 3PF_6^-$], 347.56 [$M^+ - 4PF_6^-$]. HRMS for $C_{76}H_{50}N_{16}Ru_2$ (1389.5): calcd. 347.5617; found 347.5618.

Reversible Protonation of 2e-Reduced 1^{2+}: The doubly protonated complex H_2**1**$^{4+}$ was prepared in situ by reducing **1**$^{4+}$ with metallic zinc in acidified acetonitrile or acetone. The parent complex (4.6 mg, $2.3\cdot10^{-3}$ mmol) was dissolved in 50 mL of the solvent. This solution (8 mL) was acidified with HCl (2 mL) and stirred with added Zn granules (1 g, about 1 mm size) for 15 min. The UV/Vis spectrum of the product (see Figure 3) was identical with that of H_2**1**$^{4+}$ generated in situ by reducing **1**$^{4+}$ in acetonitrile in the UV/Vis spectroelectrochemical cell in the presence of exactly two equivalents of trifluoromethanesulfonic acid. Addition of hydrogen peroxide to the green solution of H_2**1**$^{4+}$ resulted in a rapid and complete recovery of orange **1**$^{4+}$, as confirmed by UV/Vis spectroscopy.

Ditrielanes $(R_3Si)_2E-E(SiR_3)_2$ and Heterocubanes $(R_3Si)_4E_4Y_4$ (R_3Si = tBu_3Si, tBu_2PhSi; E = Al, Ga, In, Tl; Y = O, Se)[‡]

Nils Wiberg,*[a] Thomas Blank,[a] Kerstin Amelunxen,[a] Heinrich Nöth,[a][‡‡] Hansgeorg Schnöckel,[b][‡‡] Elke Baum,[b][‡‡] Andreas Purath,[b][‡‡] and Dieter Fenske[b][‡‡]

Keywords: Aluminium / Ditrielanes / Gallium / Heterocubanes / Indium / Silicon / Thallium

Ditrielanes $R^*_2E-ER^*_2$ (R^* = Si*t*Bu$_3$; E = Al, In, Tl), $R'_2E-ER'_2$ (R' = Si*t*Bu$_2$Ph; E = In, Tl) and $R^*_2Ga-GaR^*(SiMe_3)$ are prepared in alkanes (i) from ECl_3 (E = Al, In, Tl) and NaR^* via isolable R^*_2ECl (reaction of $GaCl_3$ and NaR^* leads to $R^*_2Ga{\cdot}GaR^*$ instead of $R^*_2Ga-GaR^*_2$), (ii) from EBr (E = In, Tl) and NaR^* or NaR' (reaction of AlBr or GaBr and NaR^* leads to $R^*_4Al_4$ or $R^*_8Ga_{18}$ and $R^*_8Ga_{22}$), (iii) from $NaGa_2R^*_3$ and Me_3SiCl. According to X-ray structure analyses, the ditrielanes contain two planar groups R_2EE which are orthogonal to each other (R = R^*; angle REER ca. 90°) or nearly orthogonal (R = R'; angle REER ca. 80°). All compounds are deeply colored. The λ_{max} value of the visible absorption shifts with increasing atomic number of E and with the increasing angle between the R_2EE planes to longer wavelengths (ruby $R^*_4Al_2$, deep-violet $R^*_4In_2$, dark-green $R^*_4Tl_2$; red-violet R'_4In_2, dark-blue R'_4Tl_2). Thermolysis of $R^*_4E_2$ in alkanes at about 100 °C leads to $R^*_3Al_2^{\cdot}$/$R^*_4Al_3^{\cdot}$/$R^*_4Al_4$, to $R^*_3Ga_2^{\cdot}$/$R^*_4Ga_4$, to $(R^*_4In_6)$/$R^*_8In_{12}$ and to Tl, respectively. R'_4E_2 thermolizes under formation of an In or Tl mirror. The ditrielanes $R^*_4E_2$ are stable against MeOH at normal conditions, but react with HBr under Si–E and E–E bond cleavage with the formation of R^*EBr_2 (e.g. R^*InBr_2) besides R^*H and H_2. Air transforms the ditrielanes into R^*OH or $R'OH$. On the other hand, halogens oxidize $R^*_4E_2$ under formation of R^*_2EHal (e.g. R^*_2AlI), R^*EHal_2 (e.g. R^*InBr_2) or thermolysis products of the dihalides (e.g. R^*Br/TlBr). Selenium gives with $R^*_4E_2$ heterocubanes $R^*_4E_4Se_4$ (E = Al, In, Tl). Analogous heterocubanes $R^*_4E_4O_4$ (E = Al, Ga) are synthesized from tetrahedranes $R^*_4E_4$ and oxygen. X-ray structure analyses for $R^*_4In_4Se_4$, $R^*_4Al_4O_4$ – besides the mentioned ditrielanes – are presented.

Introduction

Silyltrielanes $REHal_2$ and R_2EHal with R = R*= Si*t*Bu$_3$ (supersilyl) or R = R' = Si*t*Bu$_2$Ph and E = triel = B, Al, Ga, In, Tl, introduced in preceding publications,[1−3] are synthesized with the purpose of dehalogenation to form silylated triel cluster compounds. Indeed, silylditrielanes R_2E-ER_2 (R = R*, R'; E = Al, Ga, In, Tl) represent examples with the smallest triel clusters. Its syntheses, characterization, reactions and X-ray structure analyses are presented afterwards together with some heterocubanes $R^*_4E_4Y_4$, which represent reaction products of $R^*_4E_2$ and selenium as well as $R^*_4E_4$ and oxygen (for preliminary communications, relevant to this subject, see refs.[4,5]; for syntheses of some larger silylated triel clusters from R^*EHal_2 and R^*_2EHal see refs.[6−8]).

In fact, except for the compounds dealt with in this publication, only three other examples of *silyl-ditrielanes*, namely $[(Me_3Si)_3Si]_4E_2$ with E = Ga,[9] In,[10] Tl[11] have been published to date. On the other hand, some *organyl-* and *aminyl-ditrielanes* R_4E_2 are known with R = $CH(SiMe_3)_2$/E = Al,[12] Ga,[13] In;[14] R = 2,4,6-*i*Pr$_3$C$_6$H$_2$/E = Al,[15] Ga,[16] In;[17] R = 2,4,6-$(CF_3)_3C_6H_2$/E = Ga,[18] In;[18] R = 2,2,6,6-$Me_4NC_5H_6$/E = Ga;[19] and R_2 = −*t*BuN−MeSi(N*t*Bu)$_2$SiMe−N*t*Bu−/E = Ga,[20] In[20] amongst others (for aminylditrielanes cf. in addition ref.[21]).

Results and Discussion

Syntheses of $R^*_4E_2$ and R'_4E_2 (R* = Si*t*Bu$_3$, R' = Si*t*Bu$_2$Ph)

According to Scheme 1, the reactions of NaR* with *triel(III) compounds* $\mathbf{EX_3}$ (E = Al, Ga, In, Tl; X = Cl, Br) in alkanes at room temperature lead to tetrasupersilylditrielanes $R^*_2E-ER^*_2$ [**1**−**4**; due steric and/or electronic reasons, instead of $R^*_4Ga_2$ (**2**) only the radical $R^*_3Ga_2^{\cdot}$ (**2a**) is isolated[5]]. Isolable intermediates are R^*EHal_2 [1,2] and R^*_2EHal.[1,2] As already discussed elsewhere,[5] NaR* reacts with R^*_2EHal under NaHal elimination to radicals $R^{*\cdot}$ and

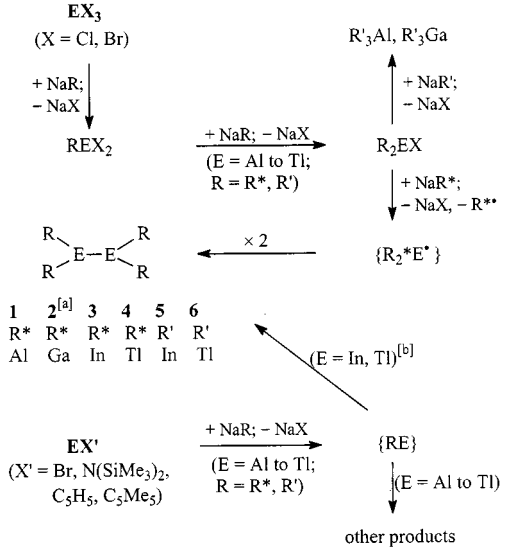
$R^*_2E^{\cdot}$. For steric reasons only the dimerization of the radicals under formation of R^*_2 and $(R^*_2E)_2$ is possible and no recombination of both radicals to form R^*_3E occurs (the cone angle for R* amounts to 130°;[15] even $R^*_2Tl^+$ and NaR* give $R^*_4Tl_2$ and not R^*_3Tl[7]). Obviously, the same is valid for the reaction of the triel(III) compound BX_3 (X = Cl, Br) and NaR*, with the difference that dimerization of the radicals $R^*_2B^{\cdot}$ obtained from R^*BHal_2 [2] and R^*_2BHal[2] is also not possible for steric reasons. Therefore, in the place of $R^*_4B_2$ other products are formed possibly from the anion $R^*_2B^-$, obtained according to the reaction $R^*_2B^{\cdot} + NaR^* \rightarrow NaBR^*_2 + R^{*\cdot}$.[2]



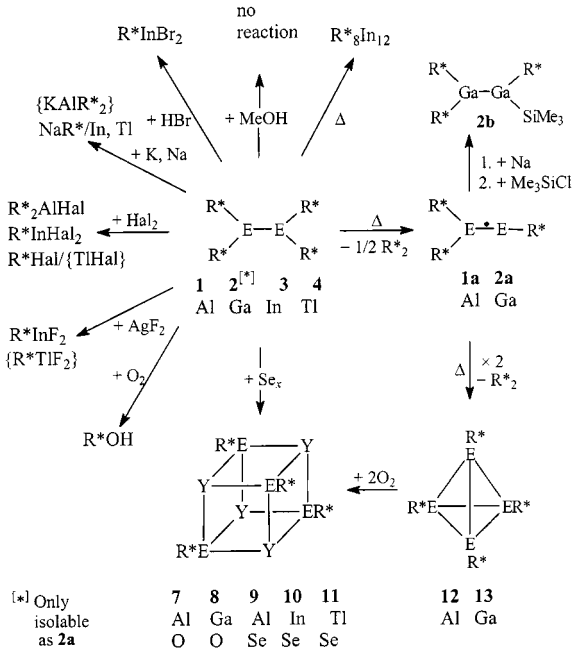
Scheme 1. Syntheses of ditrielanes R_4E_2 with E = Al, Ga, In, Tl and R = R* = Si*t*Bu$_3$ and R = R′ = Si*t*Bu$_2$Ph: [a] instead of $R^*_4Ga_2$ the radical $R^*_3Ga_2^{\cdot}$ (**2a**) is formed (cf. Scheme 2); [b] in the presence of NaR

The reactions of NaR′ instead of NaR* with $\mathbf{EX_3}$ (E = Al, Ga, In; X = Cl, Br) in alkanes (Scheme 1) lead to isolable monotrielanes R'_3E and not to ditrielanes $R'_2E{-}ER'_2$, via $R'EHal_2$ (isolated)[3] and R'_2EHal (not isolated).[3] Certainly, this time the exchange of halogen in R'_2EHal for R′ is possible for steric reasons {the reaction of $GaCl_3$ with $LiSi(SiMe_3)_2$ leads analogously to $[(Me_3Si)_3Si]_3Ga$,[22] whereas $InCl_3$ and $LiSi(SiMe_3)_3$ gives $[(Me_3Si)_3Si]_4In_2$ [10]}.

For the reactions of NaR* or NaR′ with *triel(I) compounds* **EX**, those of InBr or TlBr produce the ditrielanes $R^*_4In_2$, R'_4In_2, or $R^*_4Tl_2$, R'_4Tl_2 (**3**−**6**) besides disilanes R^*_2 and R'_2 as well as indium or thallium, respectively (Scheme 1). In fact, the ditrielane formation is fully unclear to date. Nevertheless, silyltrielylenes RE may probably be the first products of the **EX**/NaR reactions. On the other hand, the action of NaR* on GaBr gives the gallium cluster compounds $R^*_8Ga_{18}$ and $R^*_8Ga_{22}$,[23] the formation of which indicates another possible way of stabilization of gallylene R*Ga. The reaction of AlBr with NaR* leads to $R^*_4Al_4$ (**12**).[24]

The diindanes **3** and **5** are also produced in alkanes from InX [X = $N(SiMe_3)_2$, C_5H_5, C_5Me_5] and NaR* as well as NaR′, and the dithallane **6** forms from $TlN(SiMe_3)_2$ and NaR*. By analogy $[(Me_3Si)_3Si]_4Tl_2$ is prepared from $TlN(SiMe_3)_2$ and $RbSi(SiMe_3)_3$.[11] On the other hand, the reaction of C_5Me_5In with NaR* gives − besides **3** − the octaindane $R^*_6In_8$,[6] whereas the reaction of $TlN(SiMe_3)_2$ with NaR′ leads to an insoluble black substance, not identified to date. Obviously, the indylene R*In or thallylene R′Tl, possibly formed as intermediates in the latter cases, may polymerize with or without elimination of R. In accordance with this, the action of $LiC(SiMe_3)_3$ on InBr leads − possibly by way of $(Me_3Si)_3CIn$ − to $[(Me_3Si)_3C]_4In_4$.[25] In addition, it is worth mentioning that the diindane **3** also forms by reaction of $R^*_6In_8$ (see above) with NaR* in heptane at 25 °C or with Na in benzene at 95 °C.

In concluding this part, we again point to the difficulty of preparing $R^*_4Ga_2$ (**2**), due to its instability against decomposition into $R^*_3Ga_2^{\cdot}$ (**2a**) and $R^{*\cdot}$ (cf. Scheme 2). To date, only one supersilyldigallane, namely $R^*_3Ga_2(SiMe_3)$ (**2b**), has been prepared by reaction of Me_3SiCl with the THF adduct of $NaGa_2R^*_3$, obtained by reduction of **2a** with Na in THF:[5] **2a** + Na and then $Me_3SiCl \rightarrow$ **2b** + NaCl (cf. Scheme 2). Preparation methods for R'_4Al_2 and R'_4Ga_2 are still lacking. Here amongst others, the reactions of *triel(II) compounds* $\mathbf{EX_2}$ like $Ga_2X_4{\cdot}2D$ (D = donor) with NaR′ must be studied, as it is known that the reactions of $Ga_2Br_4{\cdot}2$dioxane or $In_2Br_4{\cdot}2$TMEDA with $LiCH(SiMe_3)_2$ lead to $[(Me_3Si)_2CH]_4Ga_2$ or $[(Me_3Si)_2CH]_4In_2$,[13,14] and the reaction of $Ga_2Cl_4 \equiv Ga^+[GaCl_4]^-$ with $LiSi(SiMe_3)_3{\cdot}$THF to $[(Me_3Si)_3Si]_4Ga_2$.[9]



Scheme 2. Reactions and thermolyses of ditrielanes $R^*_4E_2$ (E = Al, Ga*), In, Tl; R* = Si*t*Bu$_3$) as well as formation of heterocubanes $R^*_4E_4Y_4$ (E = Al, Ga, In, Tl; Y = O, Se); compounds in brackets are unstable and/or not fully characterized

Table 1. Characterization of ditrielanes R_4E_2 and heterocubanes $R^*_4E_4Y_4$ with R = Si*t*Bu$_3$ (R*), Si*t*Bu$_2$Ph (R′), SiMe$_3$, E = triel and Y = chalcogen

Characterization of $R^*_4E_2$ and R'_4E_2 (R* = Si*t*Bu$_3$, R′ = Si*t*Bu$_2$Ph)

Table 1 summarizes the ditrielanes **1**−**6** prepared by us, together with some characteristic properties. The compounds are remarkable colored and more or less soluble in organic media. They melt with decomposition (see below) and are air-sensitive. In addition, the ditrielanes **1**, **4** and **6** are highly unstable in the presence of light [$R^*_4Al_2$/daylight → *tetrahedro*-$R^*_4Al_4$/R^*_2 (in weeks); $R^*_4Tl_2$/R'_4Tl_2/daylight → Tl/R^*_2/R'_2 (in hours)].

The ^{1}*H NMR* and ^{13}*C NMR* shifts of the *t*Bu groups of $R^*_4E_2$ and R'_4E_2 appear − according to its peripheral position − in small regions [δ(^{1}H) = 1.24−1.36; δ(^{13}C) = 31.9−35.6/23.6−28.8]. On the other hand, the ^{29}*Si NMR* shifts show E-specific areas at δ ≈ 45−50 for E = Al, Ga, δ ≈ 55−75 for E = In, and δ ≈ 95−105 for E = Tl.

The color of ditrielanes R_4E_2, that is λ_{max} of its *UV/Vis spectra*, depends on the nature of the triel E and on the geometry of the central framework (planar, gauche, orthogonal) which itself is essentially determined by the steric behavior of R. (Certainly, the electronic behavior of R is essential too.) Figure 1 shows the UV/Vis spectra of the ditrielanes R_4E_2 with fixed substituent R = R* and fixed REER torsion angles τ (90°). Evidently, with increasing atomic number of the triel, λ_{max} of $R^*_4E_2$, shifts to longer wavelengths (525/560/628 nm for **1**/**3**/**4**), corresponding to a bathochromic colorshift from ruby (**1**) to deep-violet (**3**) to dark-green (**4**; accordingly, λ_{max} of **2**, not isolated to date, should have an absorption maximum of about 540 nm). Obviously, according to Table 1, the same is valid for **5** and **6** (τ about 80°; red-violet and dark-blue).

On the other hand, the color of ditrielanes R_4E_2 with fixed triel E shows a bathochromic shift with increasing REER torsion angle τ. Accordingly, the dialanes

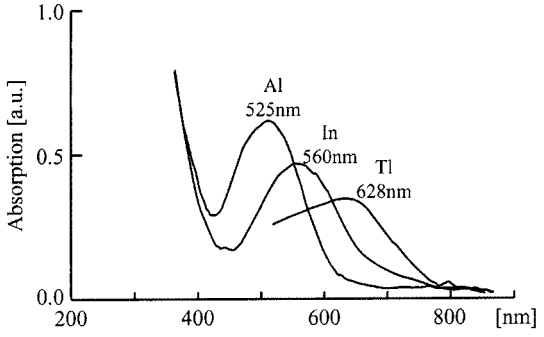

Figure 1. UV/Vis spectra of ditrielanes $R^*_2E-ER^*_2$ (E = Al, In, Tl; ε ≈ 50000 for λ_{max})

[(Me$_3$Si)$_2$CH]$_4$Al$_2$ [12]/[2,4,6-*i*Pr$_3$C$_6$H$_2$]$_4$Al$_2$ [15]/$R^*_4Al_2$ with τ = 8/45/90° are colorless/yellow-green/ruby (λ_{max} = 370/420/525 nm), the diindanes [(Me$_3$Si)$_2$CH]$_4$In$_2$ [14]/R'_4In_2/$R^*_4In_2$ with τ = 6/80/90° are orange-red/red-violet/deep-violet (λ_{max} = 380/530/560 nm), or the dithallanes R'_4Tl_2/$R^*_4Tl_2$ with τ = 82/90° are dark-blue/dark-green (λ_{max} = 591/628 nm). [For electronic effects of R cf. yellow [(Me$_3$Si)$_2$CH]$_4$Ga$_2$ (planar)[13] and more electronegatively substituted colorless R′′$_4$Ga$_2$ (evidently planar as R′′$_4$In$_2$) with R′′ = 1/2 −*t*BuN−MeSi(N*t*Bu)$_2$SiMe−N*t*Bu−.[20]]

Reactions of $R^*_4E_2$ and R'_4E_2 (R* = Si*t*Bu$_3$, R′ = Si*t*Bu$_2$Ph)

In the following, the behavior of R_4E_2 (R = R*, R′) against acids/bases, redox agents and heat is discussed. The first step of the mentioned reactions may involve addition of a donor or cleavage of the E−E bond as well as cleavage of the Si−E bonds leading to compounds which themselves

may give secondary products. Selected reactions that we studied are shown in Scheme 2.

We have never observed − probably for steric reasons − a formation of adducts $R_4E_2{\cdot}D$ of the mentioned ditrielanes **1** and **3**−**6** with Donors D (e.g. halogenides, ethers). This is unlike other − less overcrowded − ditrielanes which may work as *Lewis acids* [cf. for example the adducts $Dis_4Al_2{\cdot}D$ with Dis = $CH(SiMe_3)_2$ and D = Br^-, H^-, Me^- [26]]. In addition, the ditrielanes **1** and **3** are methanol-stable (certainly, MeOH would act first as a donor against $R^*_4E_2$ in the course of methanolyses). Also, our ditrielanes do not work as *Brönsted acids* (e.g. against NaR*, NaR′) unlike Dis_4Al_2 with Dis = $CH(SiMe_3)_2$.[26]

On the other hand, $R^*_4In_2$ (**3**) transforms, with excess hydrogen bromide, in benzene at 25 °C into R^*InBr_2 and R*H (molar ratio 1:1) and also H_2 (Scheme 2). Obviously, **3** behaves here as a *Lewis base* against HBr. The reaction may proceed either by $R^*_4In_2 + 4\ HBr \rightarrow R^*_2In_2Br_2 + 2\ R^*H + 2\ HBr \rightarrow 2\ R^*InBr_2 + 2\ R^*H + H_2$ (cf. reaction of Dis_4Ga_2 with RCOOH[26]) or − less likely − by $R^*_4In_2 + 4\ HBr \rightarrow 2\ R^*_2InBr + H_2 + 2\ HBr \rightarrow 2\ R^*InBr_2 + 2\ R^*H + H_2$ (cf. reaction of Dis_4Al_2 with LiOR;[26] certainly, an In−In bond cleavage with HBr would require the ditrielane to be a Lewis base, which is not true for **3** but might be observed for $R^*_2In_2Br_2$). In this connection, it is worth mentioning that $R^*_4Tl_2$ (**4**) reacts with HBr in a molar ratio of 1:2 (THF, −30 °C) with the formation of R*H and a red substance. The latter compound may be the dithallane $R^*_2Tl_2Br_2$ according to NMR spectroscopy. It slowly decomposes already at −30 °C into R*Br and a black residue which has not yet been characterized (for some reactions of halosupersilylthallanes cf. ref.[7]). We could synthesize the orange digallane $R^*_2Ga_2Cl_2$ by reaction of $R^*GaCl_2{\cdot}THF$ and potassium in heptane, which − according to X-ray structure analysis − exists as a dimer with the As_4S_4 structure (exchange of As/S against Ga/Cl).[27]

Other examples for acid/base reactions of R_4E_2 may be that of $R^*_4Tl_2$ (**4**) and R'_4Tl_2 (**6**) with Ph_3CCl in benzene or cyclohexane at 0 °C which lead exclusively to R^*_2/R'_2 and a colorless residue (TlCl?). Certainly, the course of the mechanism is completely unclear at this time. The acid/base reactions of ditrielanes R_4E_2 (R = R*, R′) with $EHal_3$, which may lead to haloditrielanes $R_nE_2Hal_{4-n}$ (cf. R_nEHal_{3-n} [1,2]), have to be studied.

According to Scheme 2, the ditrielanes $R^*_4E_2$ can be both *oxidized* (e.g. with halogens, chalcogenes) and *reduced* (e.g. with alkali metals). The dialane $R^*_4Al_2$ (**1**) reacts cleanly in alkanes at 50 °C with iodine or hydrogen − according to Scheme 2 − under formation of the monotrielanes R^*_2AlX (X = I, H), as published elsewhere.[5] Obviously, the products are probably formed from the sterically overcrowded dialane as follows: $\mathbf{1} \leftrightarrows 2\ R^*_2Al^{\cdot}$; $2\ R^*_2Al^{\cdot} + X_2 \rightarrow 2\ R^*_2AlX$. Bromine transforms $R^*_4In_2$ (**3**) into R^*InBr_2 and R*Br (Scheme 2). The reaction may proceed either by In−In or by In−Si bond cleavage via R^*_2InBr or $R^*_2In_2Br_2$. Bromination of $R^*_4Tl_2$ (**4**) results − possibly by way of R^*TlBr_2 finally to TlBr ($R^*TlBr_2 \rightarrow R^*Br + TlBr$). Fluorination of $R^*_4In_2$ (**3**) with AgF_2 produces − according to Scheme 2 − the dihalide R^*InF_2 ($\mathbf{3} + 4\ AgF_2 \rightarrow 2\ R^*InF_2 + 2\ R^*F + 4\ AgF$). R^*TlF_2 possibly plays the role of an intermediate in the reaction of $R^*_4Tl_2$ (**4**) with AgF_2, finally leading to TlF ($R^*TlF_2 \rightarrow R^*F + TlF$).

The main products of the reactions of ditrielanes **1**, **3**−**6** with air are the silanols $t\mathrm{Bu}_3\mathrm{SiOH}$ (Scheme 2) and $\mathrm{Ph}t\mathrm{Bu}_2\mathrm{SiOH}$. Selenium transforms $R^*_4E_2$ (**1**, **3** and **4**) − according to Scheme 2 − into the heterocubanes $R^*_4E_4Se_4$ (**9**, **10**, **11**) and also R^*_2 (no R^*_2Se is formed). This is unlike the reactions of Dis_4E_2 [Dis = $CH(SiMe_3)_2$; E = Al, Ga, In] with transfer agents for chalcogens Y like Me_3NO, Me_2SO, and Et_3PY among others, which lead to compounds $Dis_2E-Y-EDis_2$.[26] The mechanism for the formation of **9**−**11** is still unclear. Perhaps, the ditrielanes $R^*_4E_2$ react with Se_x − for steric reasons − not to selanes $R^*_2E-Se-ER^*_2$ but to diselanes $R^*_2E-SeSe-ER^*_2$ which − via R^*_2 and $R^*E(Se)_2ER^*$ (central four-membered ESeESe ring) − transform into the heterocubanes.

On the other hand, heterocubanes $R^*_4E_4O_4$ (**7** and **8**) are produced − according to Scheme 2 − by reaction of the tetrahedranes $R^*_4Al_4$ (**12**)[24] and $R^*_4Ga_4$ (**13**)[28] with oxygen instead of selenium (cf. Scheme 2). In fact, **12** and **13** are − like other known silyl-substituted tetrahedranes (e.g. $[(Me_3Si)_3Si]_4Ga_4$ [29]) and unlike organyl-substituted tetrahedranes (e.g. $[(Me_3C)_3Si]_4Ga_4$ [30] and $[(Me_3Si)_3C]_4In_4$ [31]) − extremely oxygen-sensitive ($[(Me_3Si)_3C]_4In_4$ may be oxidized with *o*-nitrosotoluene[31]). Certainly, **12** and **13** also react with the oxygen homologues that − as is known − even attack organyl-substituted tetrahedranes like $[(Me_3Si)_3C]_4Ga_4$ [30] and $[(Me_3Si)_3C]_4In_4$ [21]. In this connection the question arises whether the latter reactions can be reversed. In fact, deselenation of **10** should give the tetrahedrane $R^*_4In_4$ which has not be prepared to date.[6] For characteristic properties of the mentioned heterocubanes cf. Table 1.

The reactions of ditrielanes with alkali metals have not been studied in detail, thus far. Obviously, potassium transforms the dialane $R^*_4Al_2$ (**1**) in pentane at room temperature into an insoluble compound which is also obtained from R^*_2AlHal (Hal = Cl, Br) and K and reacts with Ph_3CH under formation of R^*_2AlH (for details cf. ref.[2]). On the other hand, $R^*_4In_2$ (**3**) or $R^*_4Tl_2$ (**4**) give with sodium in benzene or cyclohexane at 40 °C − according to Scheme 2 − supersilylsodium NaR* and In or Tl along with R^*_2/R*H. Radical anions $R_4E_2^{\cdot -}$, which form by reaction of alkali metals with organylditrielanes,[26] are not observed in the case of the ditrielanes **1**, **3** and **4** (certainly, electron intake leads to a planarisation of the ditrielanes,[24] which is sterically impossible for $R^*_4E_2$).

Regarding the redox reactions of R_4E_2 (R = R*, R′) so far discussed, there is some reason from mass spectrometric studies (see below) to believe that they start with the formation of radicals $R_2E^{\cdot}$. As stated elsewhere,[5] *thermolysis in solution* leads in the case of $R^*_4Al_2$ (**1**), probably by a fast and reversible Al−Al bond dissociation, to radicals $R^*_2Al^{\cdot}$ in low equilibrium concentration, but at the same time by a slow and irreversible Si−Al bond dissociation to radicals $R^{*\cdot}$ and $R^*_3Al_2^{\cdot}$ (**1a**). The latter are stable at room

temperature and transform at 80−100 °C − according to Scheme 2 − possibly via $R^*_2Al_2$ into isolable trialanyl radicals $R^*_4Al_3^{\cdot}$ and *tetrahedro*-tetraalane $R^*_4Al_4$ (**12**),[5] whereas the radicals $R^{*\cdot}$ dimerize under formation of the disilane R^*_2 (the radical $R^*_4Al_3^{\cdot}$ may be formed by addition of $R^*_2Al_2$ and $R^*_2Al^{\cdot}$, and the tetrahedrane **12** by dimerization of $R^*_2Al_2$).[5] On the other hand, $R^*_4Ga_2$ (**2**) very easily thermolizes in solution into $R^{*\cdot}$ and the isolable digallanyl radical $R^*_3Ga_2^{\cdot}$ (**2a**) making the isolation of the digallane **2** unsuccessful to date[5] (the formation of $R^*_2Ga^{\cdot}$, the precursor of **2**, from R^*_2GaHal and NaR*, only occurs at temperatures where **2** already decomposes into **2a**). The radicals **2a** themselves decompose in alkanes at 100 °C − according to Scheme 2 − possibly via $R^*_2Ga_2$ into the *tetrahedro*-tetragallane $R^*_4Ga_4$ (**13**) along with R^*_2 and R*H.[28]

According to ESR spectroscopic studies, alkane solutions of $R^*_4In_2$ (**3**) and $R^*_4Tl_2$ (**4**) always contain radicals, the nature of which, however, is unclear. Interestingly, heating of equimolar amounts of **1** and **3** in alkanes at 90 °C do not lead to any cross-over product $R^*_2Al-InR^*_2$, but only to the thermolysis products of **1** (see above), leaving **3** intact. At 100 °C the diindane **3** thermolizes very slowly in alkanes with the formation of the dodecaindane $R^*_8In_{12}$ along with R^*_2 and R*H (cf. Scheme 2).[6] Thus, an intermediate is formed which may be $R^*_4In_6$ (in fact, it reacts like $R^*_6In_8$ with NaR* under formation of **3**, see preparation of the diindane). By the way, $R^*_8In_{12}$ also forms by thermolysis of $R^*_6In_8$ in benzene at 100 °C. The dithallane **4** slowly (in hours) decomposes in alkanes at 40 °C into R^*_2 and a dark brown residue (Tl?). The ditrielanes R'_4E_2 (**5**, **6**) are more stable than $R^*_4E_2$ (**3**, **4**) and thermolize in C_6D_6 at 140 °C (**5**) or 106 °C (**6**) under formation of R′D and In or Tl mirrors, respectively.

In high vacuum, the mentioned ditrielanes R_4E_2 (R = R*, R′) are comparably volatile. From the mass spectrum (chemical ionization with NH_3^+) of $R^*_4Al_2$ (**1**), $R^*_4In_2$ (**3**), R'_4In_2 (**5**) and R'_4Tl_2 (**6**) the $M/2^+$ peak is seen instead of an M^+ peak, which is an indication that the ditrielanes vaporize under cleavage of the E−E bonds. Accordingly its *thermolysis* in the *gas phase* takes place under formation of radicals $R_2E^{\cdot}$. In addition, the mass spectra (CI) of **1** (but not of **3**, **5** and **6**) shows peaks for fragments with an intact E−E framework, namely $R^*_2Al_2^+ + H$ and $R^*_2Al_2^+ - t$Bu. Obviously, the steric overcrowding of **1** facilitates not only Al−Al, but also Si−Al bond cleavage (in fact, the digallane **2** exists as radical **2a**; see above).

Structures of $R^*_4E_2$, R'_4E_2 and $R^*_4E_4Y_4$ (R* = Si*t*Bu$_3$, R′ = Si*t*Bu$_2$Ph; Y = O, Se)

The structures of $R^*_4In_2$ (**3**; revisited),[4] $R^*_4Tl_2$ (**4**), R'_4In_2 (**5**), R'_4Tl_2 (**6**), $R^*_4Al_4O_4$ (**7**) and $R^*_4In_4Se_4$ (**10**) are shown in Figures 2−4, together with selected bond lengths and angles. For comparison, bond lengths and angles of $R^*_4Al_2$ (**1**)[5] and $R^*_4Ga_4O_4$ (**8**) [28] are also quoted. In addition, Table 1 presents bond lengths and angles of the ditrielanes and heterocubanes under discussion as well as E−E bond lengths and R−E−E−R torsion angles of other ditrielanes R_4E_2.

According to X-ray structure analyses and Figure 2, in **1**, **3** and **4** the Al, In and Tl atoms are planar coordinated with two Si atoms and one triel atom E, whereby the $EESi_2$ planes are orthogonal or nearly orthogonal to each other (cf. Table 1). Interestingly, in ditrielanes R_4E_2 with sterically less overcrowded silyl substituents the angles between the EER_2 planes decrease with decreasing bulkiness of R and are 79.9° for **5** and 82.2° for **6**, according to Figure 3 and Table 1 {for comparison $[(Me_3Si)_3Si]_4E_2$: 80° (Ga)[9]/78.6° (In)[10]/78.1° (Tl)}.[11] Significant smaller angles between the EER_2 planes show the organylditrielanes Tip_4E_2 and − above all − Dsi_4E_2 [for E = Al/Ga/In in Tip_4E_2 with Tip = 2,4,6-*i*Pr$_3$C$_6$H$_2$ 45/44/48° and in Dsi_4E_2 with Dsi = $(Me_3Si)_2CH$ 8/5/7°; cf. Table 1].

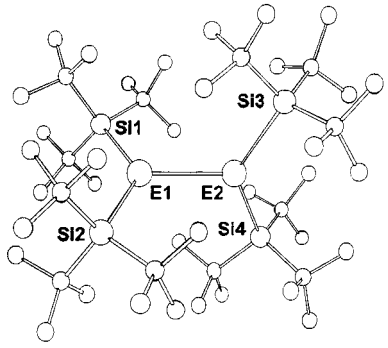

Figure 2. Crystal structures of **1**, **3** and **4** with atom numbering (SCHAKAL; H atoms omitted for clarity); selected distances [Å] and angles [°] with standard deviations: **$R^*_4Al_2$** (local symmetry D_{2d}; E1/E2 = Al1/Al1A; Si1/Si2/Si3/Si4 = Si1/Si1A/Si1B/Si1C; see ref.[5]): Al1−Al1A 2.751(2), Al1−Si1 2.717(5), Si−C (mean value) 1.97; Si1−Al1−Si1A 128.26(5), Si1−Al1−Al1A 115.87(2), C−Si−C (mean value) 109.1; Si−Al−Al−Si 90.0; **$R^*_4In_2$** (local symmetry ca. D_{2d}; E1/E2 = In1/In1A; Si1/Si2/Si3/Si4 = Si1/Si2/Si1A/Si2A): In1−In1A 2.928(3), In1−Si1 2.7835(6), In1−Si2 2.7886(6), Si−C (mean value) 1.96; Si1−In1−Si2 130.13(2), Si1−In1−In1A 115.4(1), Si2−In1−In1A 114.42(1), C−Si−C (mean value) 109.6; Si−In−In−Si 87.0; **$R^*_4Tl_2$** (local symmetry ca. D_{2d}; E1/E2 = Tl1/Tl2): Tl1−Tl2 2.961(1), Tl1−Si1 2.768(3), Tl1−Si2 2.779(4), Tl2−Si3 2.788(3), Tl2−Si4 2.781, Si−C (mean value) 1.95; Si1−Tl1−Si2 130.4(1), Si3−Tl2−Si4 130.5(1), Si1−Tl1−Tl2 114.7(2), Si2−Tl1−Tl2 114.9(2), Si3−Tl2−Tl1 114.4(1), Si4−Tl2−Tl1 115.1(1), C−Si−C (mean value) 110.1; Si−Tl−Tl−Si 89.6

The space-filling properties of the groups R* and R′ lead to unusually long E−E distances in **1** (2.75 Å), **3** (2.93 Å), **5** (2.94 Å), **4** (2.96 Å) and **6** (2.88 Å). Those in $R^*_4E_2$ are longer than those found in any dialane, diindane or dithallane with a covalent E−E bond (cf. Table 1, footnote[d]). As expected, the E−E distances in R_4E_2 increase with increasing bulkiness of R [CH(SiMe$_3$) (Dsi) < 2,4,6-*i*Pr$_3$C$_6$H$_2$ (Tip) < Si(SiMe$_3$)$_3$ (Hsi) < Si*t*Bu$_3$ (R*)], but naturally are also dependent on τ; they amount to 2.65/2.66/2.75 Å for $Dsi_4Al_2/Ti_4Al_2/R^*_4Al_2$; 2.54/2.52/2.60 Å for $Dsi_4Ga_2/Tip_4Ga_2/Hsi_4Ga_2$; 2.83/2.78/2.87/2.93 Å for $Dsi_4In_2/Tip_4In_2/Hsi_4In_2/R^*_4In_2$; and 2.91/2.96 Å for $Hsi_4Tl_2/R^*_4Tl_2$ (cf. Table 1). Interestingly, the E−E distance decreases on going from R_4Al_2 to analogously substituted R_4Ga_2 by ca. 0.1 Å. This may be due to a decrease of the triel atomic

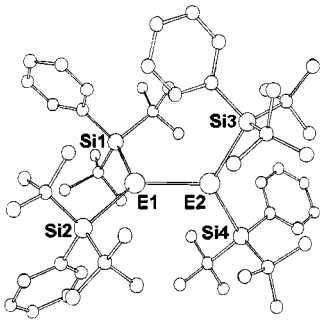

Figure 3. Crystal structures of **5**, **6** with atom numbering (SCHAKAL; H atoms omitted for clarity); selected distances [A] and angles [°] with standard deviations: **R′$_4$In$_2$** (E1/E2 = In1/In2): In1−In2 2.938(1), In1−Si1 2.655(2), In1−Si2 2.795(1), In2−Si3 2.826(2), In2−Si4 2.671(1), Si−C (mean value) 1.96; Si1−In1−Si2 122.74(5), Si3−In2−Si4 120.10(5), Si1−In1−In2 117.73(4), Si2−In1−In2 119.43(4), Si3−In2−In1 113.50(4), Si4−In2−In1 126.39(3), C−Si−C (mean value) 110.4; Si−In−In−Si 79.9; **R′$_4$Tl$_2$** (E1/E2 = Tl1/Tl2): Tl1−Tl2 2.881(2), Tl1−Si1 2.674(2), Tl1−Si2 2.685(2), Tl2−Si3 2.685(2), Tl2−Si4 2.687(2), C−Si (mean value) 1.93; Si1−Tl1−Si2 120.69(6), Si3−Tl2−Si4 124.96(6), Si1−Tl1−Tl2 123.37(5), Si2−Tl1−Tl2 115.93(5), Si3−Tl2−Tl1 119.20(5), Si4−Tl2−Tl1 115.76(5), C−Si−C (mean value) 110.5; Si−Tl−Tl−Si 82.19

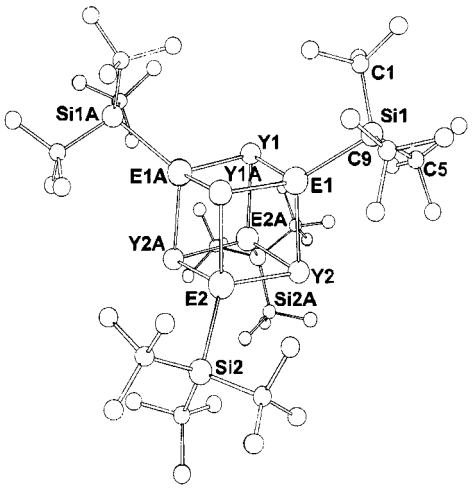

Figure 4. Crystal structures of **7**, **8**, **9** with atom numbering (SCHAKAL; H atoms omitted for clarity); selected distances [A] and angles [°] with standard deviations [R*$_4$Al$_4$O$_4$ together with R*$_4$Al$_4$ (molar ratio 1:2) in the crystal]: **R*$_4$Al$_4$O$_4$** (local symmetry C_2; E =Al, Y = O): Al1−O2 1.826(7), Al1−O1A 1.831(6), Al1−O1 1.838(6), Al1A−O1 1.831(6), Al2−O2A 1.836(6), Al2−O2 1.837(6), Al2−O1A 1.840(6), Al2A−O1 1.840(6), Al2A−O2 1.836(6), Al−Al (mean value) 2.612, Si1−Al1 2.486(1), Si2−Al2 2.486(1), Si−C (mean value) 1.94; Al1A−O1−Al1 90.7(3), Al1A−O1−Al2A 90.7(3), Al1−O1−Al2A 90.4(3), Al1−O2−Al2A 90.9(3), Al1−O2−Al2 91.0(3), Al2A−O2−Al2 90.8(3), O2−Al1−O1A 89.4(3), O2−Al1−O1 89.5(3), O1A−Al1−O1 89.3(3), O2A−Al2−O2 89.2(3), O2A−Al2−O1A 89.1(3), O2−Al2−O1A 88.8(3), Al−Al−Al (mean value) 60.0, Si−Al−Al (mean value) 144.7, Si−Al−O (mean value) 126.0, C−Si−C (mean value) 111.8; **R*$_4$Ga$_4$O$_4$** (local symmetry C_2; E = Ga, Y = O; see ref.[23]): Ga1−O1A 1.923(4), Ga1−O1 1.912(4), Ga1−O2 1.909(4), Ga2−O1A 1.915(3), Ga2−O2 1.902(4), Ga2−O2A 1.928(4), Ga−Ga (mean value) 2.712, Ga1−Si1 2.425(1), Ga2−Si2 2.423(1), Si−C (mean value) 1.93; O2−Ga1−O1 90.2(2), O1−Ga1−O1A 89.7(2), O2−Ga1−O1A 89.96(2), O2−Ga2−O2A 90.1(2), O2−Ga2−O1A 90.2(2), O1A−Ga2−O2A 89.5(1), Ga1A−O1A−Ga2 90.3(2), Ga2−O1A−Ga1 89.7(2), Ga1A−O1A−Ga1 90.3(2), Ga2−O2−Ga1 90.5(2), Ga2−O2−Ga2A 89.9 (2), Ga1−O2−Ga2A 90.0(2), Si−Ga−Ga (mean value) 144.5, Si−Ga−O (mean value) 123.7, C−Si−C (mean value) 112.3; **R*$_4$In$_4$Se$_4$** (local symmetry C_2; E = In, Y = Se): In1−Se1A 2.681(1), In1−Se1 2.682(1), In1−Se2 2.681(1), In2−Se1A 2.680(2), In2−Se2 2.675(1), In2−Se2A 2.677, In−In (mean value) 3.553, In1−Si1 2.577(2) In2−Si2 2.565(3), Si−C (mean value) 1.95; Se2−In1−Se1 96.27(2), Se1−In1−Se1A 95.93(2), Se2−In1−Se1A 97.01(3), Se2−In2−Se2A 97.16(2), Se2−In2−Se1A 97.19(3), Se1A−In2−Se2A 96.97(2), In1A−Se1A−In2 82.76(2), In2−Se1A−In1 82.44(2), In1A−Se1A−In1 83.57(2), In2−Se2−In1 82.54(2), In2−Se2−In2A 82.45(2), In1−Se2−In2A 83.39, In−In−In (mean value) 60.0, Si−In−In (mean value) 144.9, Se−In−Se (mean value) 96.5, In−Se−In (mean value) 82.9, Si−In−Se (mean value) 120.3, C−Si−C (mean value) 112.2

radius in the direction Al → Ga because of a d-orbital contraction which only effects r_{Ga}, but not r_{Al}. Cf. remarks in ref.[41] It is possible that the atomic radii r_{Al}/r_{Ga} = 1.25/1.26 Å normally used[32] are incorrect and may be exchanged by calculated mean values 1.30/1.24 Å (accordingly r_{In}/r_{Tl} amounts to 1.43/1.53 Å).[10] This means that the steric hindrance increases on going from **1** to **2** with the consequence that **2** is much more unstable with respect to elimination of R* than the dialane. Indeed, **2a** is isolated instead of **2**.

Another consequence of the steric hindrance of the R* or R′ groups to each other in the R_2E and REER parts of the ditrielanes R_4E_2 are unusually long Si−E distances {found in R*$_4$Al$_2$/R*$_4$In$_2$/R*$_4$Tl$_2$/R′$_4$In$_2$/R′$_4$Tl$_2$ 2.72/2.79/2.78/2.74/2.68 Å and in [(Me$_3$Si)$_3$Si]$_4$E$_2$ 2.41 (Ga)[9]/2.66 (In)[10]/2.67 Å (Tl)[11]}. For the same reason the Si−E−Si bond angles are certainly somewhat larger than 120° but much smaller than occurs in the less crowded halogenides R*$_2$EHal (R*$_4$Al$_2$/R*$_4$In$_2$/R*$_4$Tl$_2$/R′$_4$In$_2$/R′$_4$Tl$_2$: 128/130/130/121/123°; R*$_2$EHal about 150°, see ref.[2]).

The central frameworks of the heterocubanes R*$_4$E$_4$O$_4$ (**7**, **8**[28]), shown in Figure 4, form nearly nondistorted cubes, the corners of which are alternatively occupied by E and O atoms (mean angles AlOAl/OAlO = 90.8/89.2°; GaOGa/OGaO = 90.1/89.9°; cf. also Table 1). Obviously, the oxidation of the tetrahedranes R*$_4$Al$_4$ (**12**) or R*$_4$Ga$_4$ (**13**) to **7** or **8** which are also described as E_4 tetrahedranes each with a face capped by a chalcogen atom (cf. Scheme 2), leads to an expansion of the Al$_4$/Ga$_4$ cores as seen by the E−E distances in **13** (2.57 Å) and **8** (2.71 Å). Indeed, the X-ray structure analysis of **7** refers to crystals that contain **7** and **12** in a molar ratio of 1:2. As is known from crystals containing **8** and **13**, bond lengths and angles lie between those of **8** and **13**. Therefore, the E−E distances in pure **7** are certainly somewhat longer than the 2.61 Å obtained (found for **12** 2.60 Å).

According to Figure 4, the heterocubane R*$_4$In$_4$Se$_4$ (**10**) is analogously structured to **7** or **8**. Certainly, the In$_4$Se$_4$ cube deviates somewhat from being regular (mean angles InSeIn/SeInSe = 82.9/96.8°; cf. also Table 1), and the expansion of the In$_4$ tetrahedrane by going from R*$_4$In$_4$ [not synthesized to date; In−In distance must be even shorter than in **3** (2.93 Å)] to **10** (In−In distance 3.55 Å) is very pronounced. Altogether, the heterocubane **10** is analogously structured to the many other heterocubanes $R_4E_4Y_4$ (E = Al, Ga, In; Y = S, Se, Te) which have been prepared to date (e.g. cf. refs.[30,31]).

Experimental Section

General Remarks: All experiments were carried out in flame-dried glass apparatus with standard Schlenk techniques under dry argon or nitrogen. During all manipulations, air and moisture were strictly excluded. The solvents (pentane, heptane, benzene, cyclohexane, toluene, tetrahydrofuran) were distilled from sodium/lead or sodium/benzophenone. Available for use were: H_2, HBr, Cl_2, Br_2, I_2, Se, Ph_3CH, Ph_3CCl, Bu_3SnH, $AlBr_3$, $GaCl_3$, $InBr_3$, InBr, $TlCl_3$, TlBr and AgF_2. The following compounds were synthesized according to literature procedures: NaR*,[33] NaR*·2THF,[33] NaR′,[3] R*$_2$AlHal,[2] C_5H_5In,[34] C_5Me_5In,[35] $TlN(SiMe_3)_2$,[36] C_5H_5Tl,[37] R*$_4$Al$_4$,[24] and R*$_4$Ga$_4$.[28] Synthesis of $InN(SiMe_3)_2$ resulted from the addition of $LiN(SiMe_3)_2$ (0.897 g, 5.36 mmol)[40] in 10 mL of THF to InCl (0.806 g, 5.36 mmol) in 20 mL of THF (−78 °C). After warming to 25 °C, the light-yellow solution contained $InN(SiMe_3)_2$ exclusively according to the NMR spectra. Filtration of the insoluble residue (LiCl) and removal of all volatile compounds with an oil-pump vacuum led to colorless $InN(SiMe_3)_2$ in quantitative yield. ^{1}H NMR (C_6D_6, int. TMS): δ = 0.324. ^{13}C{^{1}H} NMR (C_6D_6, int. TMS): δ = 5.96. ^{29}Si{^{1}H} NMR (C_6D_6, ext. TMS): δ = 2.69. The products R*$_2$,[33] R*H,[33] R*Hal,[33] R*OH,[38] R*C_6H_5,[33] NaR′,[3] R′$_2$,[39] R′H,[39] R′OH[39] were identified by comparison with authentic samples [tBu$_3$Si in R*OH: δ(^{1}H) = 1.090; δ(^{13}C) = 22.67/29.69; δ(^{29}Si) = 10.30; tBu$_2$Si in R′$_2$: δ(^{1}H) = 1.244, δ(^{13}C) = 28.00/33.05, δ(^{29}Si) = 139.5; tBu$_2$Si in R′H: δ(^{1}H) = 1.063, δ(^{13}C) = 19.1/29.2, δ(^{29}Si) = 13.4; tBu$_2$Si in R′OH: δ(^{1}H) = 1.073; δ(^{13}C) = 21.5/28.5; δ(^{29}Si) = 1.01]. For NMR spectra a Jeol GX-270 (^{1}H/^{13}C/^{29}Si: 270.17/67.94/53.67 MHz) and Jeol EX-400 (^{1}H/^{13}C/^{29}Si: 399.78/100.54/79.43 MHz) were used. The ^{29}Si NMR spectra were recorded with the INEPT or DEPT pulse sequence using empirically optimized parameters for the mentioned groups. For mass spectra a Varian CH7 and a MStation JMS 700 of Jeol were used, for UV/Vis spectra a 555-UV/Vis spectrometer from Perkin−Elmer.

Syntheses, Thermolysis and Reactions of R*$_4$Al$_2$ (1). − (i): $AlBr_3$ (0.537 g, 2.01 mmol) and NaR* (1.35 g, 6.07 mmol) in 60 mL of heptane (−78 °C) gave, after heating at room temperature for 24 h, **1** and R*$_2$ in a molar ratio of 1:1 (according to NMR spectra) along with NaBr. After filtration of the insoluble residue (NaBr) and concentration of the filtrate to 20 mL, tetrasupersilyldialane **1** (0.762 g, 0.896 mmol; 89%) was obtained in 1 week at −23 °C as air-sensitive, methanol-stable, benzene-labile, photo- and thermolabile, ruby crystals which decomposed at 63 °C (the oxidation with *air* leads to R*OH as the only R*-containing compound). **1** also forms from equimolar amounts of R*$_2$AlHal (Hal = Cl, Br) and NaR* in pentane (see ref.[5]). $C_{48}H_{108}Al_2Si_4$ (851.7): calcd. C 67.34, H 12.73; found C 67.69, H 12.78. NMR: see Table 1. UV/Vis (heptane): λ_{max} = 525 nm (ε ≈ 50000). MS (EI; 70 eV): m/z = 452 (1) [R*$_2$Al$_2^+$], 395 (11) [R*$_2$Al$_2^+$ − tBu], 425 (4) [R*$_2$Al$^+$], 368 (8) [R*$_2$Al$^+$ − C_4H_8], 226 (13) [R*Al$^+$]. CI (NH_3; 25−50 °C): m/z = 453 (95) [R*$_2$Al$_2^+$ + H], 395 (15) [R*$_2$Al$_2^+$ − tBu], 442 (20) [R*$_2$Al$^+$ + NH_3], 425 (40) [R*$_2$Al$^+$], 216 (100) [SitBu$_3^+$ + NH_3], 199 (5) [SitBu$_3^+$]. X-ray structure analysis: see Figure 2 and ref.[5] − **(ii):** For thermolysis of **1** see ref.[5] − **(iii):** Irradiation of **1** (0.016 mmol) in C_6D_{12} (0.6 mL) slowly leds (in weeks) to **12**,[24] R*$_2$ and R*H in a molar ratio of ca. 1:1:3. − **(iv):** For reaction of hydrogen and iodine with **1** see ref.[5]; for reaction with oxygen see above; for reaction with selenium see below. − **(v):** In the presence of 0.8 mmol of potassium (K), a red solution of R*$_4$Al$_2$ (0.042 g, 0.05 mmol) in 10 mL of pentane transforms over 24 h to a gray residue (intermediate colors: violet, green, colorless). The solution then contains R*$_2$ and R*H according to NMR specroscopy. The residue reacts with Ph_3CH to form R*$_2$AlH.[5]

Synthesis, Thermolysis and Reactions of R*$_3$Ga$_2$˙ (2a); Formation of R*$_3$Ga$_2$(SiMe$_3$) (2b). − (i): $GaCl_3$ (0.184 g, 1.045 mmol) and NaR*·2THF (1.35 mmol) in 20 mL of pentane (−30 °C) gave, after warming to room temperature over 24 h, black-blue **2a** (detected by ESR spectroscopy) and R*$_2$ (detected by NMR spectroscopy) along with NaCl. After filtration of the insoluble residue (NaCl), concentration of the filtrate to 7 mL and cooling to −23 °C, superdisilane R*$_2$ formed as colorless crystals and then trisupersilyldigallanyl (**2a**) (0.110 g, 0.15 mmol, 14.4%) over 5 d as oxygen- and moisture-sensitive black-blue crystals, which decomposed at ca. 55 °C. **2a** was also formed from equimolar amounts of R*$_2$GaHal (Hal = Cl, Br) and NaR* in heptane.[5] For characterization and for thermolysis (formation of **13**) and reduction of **2a** (formation of $NaGa_2R^*_3$·3THF) see ref.[5] − **(ii):** Reaction of 0.1 mL of tributylstannane with **2a** in 10 mL of pentane immediately leds to a deep-red solution with − according to NMR spectroscopy (C_6D_6) − an unidentified substance with R* groups [δ(^{1}H) = 1.107, 1.214, 1.322] along with R*H and R*$_2$. The latter decomposed under decolorization of the C_6D_6 solution. − **(iii):** Reaction of chlorine (0.038 mmol) in 0.1 mL of CCl_4 with **2a** (0.04 mmol) in 10 mL of pentane (−78 °C) immediately led to a deep-red solution which contained − according to NMR spectroscopy (C_6D_6) − unidentified substances with R* groups [δ(^{1}H) = 1.092, 1.205, 1.238, 1.260; δ(^{29}Si) = 6.27, 17.56, 39.91, 51.22] along with R*H, R*$_2$, R*Cl and R*$_2$GaCl. One compound was identical to the substance found from R*$_4$Tl$_2$ with Na in C_6D_6 [δ(^{1}H/^{29}Si) = 1.092/6.27] and obviously contains no Ga and Tl, respectively. The other compounds may be the digallane R*$_3$Ga$_2$Cl or products formed from it. − **(iv):** For synthesis of trisupersilyltrimethylsilyldigallane R*$_3$Ga$_2$(SiMe$_3$) (**2b**) from $NaGa_2R^*_3$·3THF and Me_3SiCl and for characterization of this digallane see ref.[8]

Syntheses, Thermolysis and Reactions of R*$_4$In$_2$ (3). − (i): $InCl_3$ (0.778 g, 3.50 mmol) and NaR*·2THF (10.5 mmol) in 40 mL of THF (−78 °C) gave **3** and R*$_2$ in a molar ratio of 1:1 (according to NMR spectra) along with NaCl after warming to room temperature over 5 h. After exchange of THF with 80 mL of toluene, filtration of the insoluble residue (NaCl) and concentration of the filtrate to 20 mL, 0.112 g (1.09 mmol; 63%) of tetrasupersilyldiindane **3** was obtained over some days at −23 °C as air-sensitive, methanol-stable, deep-violet crystals which decomposed at 125 °C (the oxidation with air led to R*OH as the only R*-containing compound). **3** and In (or Na_xIn_y) is also formed from InBr (2.91 mmol) and NaR* (2.91 mmol) in 25 mL of THF (warming from −78 °C to 25 °C[4]) or from C_5H_5In (3.24 mmol) and NaR* (2.50 mmol) in 40 mL of pentane (warming from −78 °C to 25 °C, 12 h), or from $InN(SiMe_3)_2$ (0.49 mmol) and NaR* (0.49 mmol) in 15 mL of pentane (warming from −78 °C to 25 °C, 14 d). $C_{48}H_{108}In_2Si_4$ (1027.4): calcd. C 56.12, H 10.60; found C 55.75, H. 10.53. NMR: see Table 1. UV/Vis (heptane): λ_{max} = 560 nm (ε ≈ 50000). MS (EI; 70 eV): m/z = 513 (19) [R*$_2$In$^+$], 457 (3) [R*$_2$In$^+$ − C_4H_8], 314 (100) [R*In$^+$]. CI (NH_3; 25−50 °C): m/z = 513 [R*$_2$In$^+$]. X-ray structure analysis: see Figure 2 and ref.[4] Remarks: Reaction of equimolar amounts of C_5Me_5In and NaR* in pentane (warming from −120 °C to −78 °C/48 h, then to 25 °C) led to **3** and R*$_6$In$_8$ in a molar ratio of 1:1.[6] R*$_6$In$_8$ itself thermolized in C_6D_6 at 100 °C/20 d into R*$_8$In$_{12}$ besides R*D/In and reacted with NaR* in heptane (warming from −78 °C to 25 °C) or with Na in C_6D_6 at 95 °C with the formation of **3** and R*$_2$/In (or Na_xIn_y). − **(ii):** Thermolysis of **3** in alkanes at 100 °C took place via an unidentified intermediate (R*$_4$In$_6$?) with the formation of R*$_8$In$_{12}$;[6] the

intermediate transformed, in the presence of NaR*·2THF in heptane, into **3** and an unidentified residue (In or Na_xIn_y). Thermolysis of **3** (0.191 mmol) in the presence of **1** (0.101 mmol) in 20 mL of heptane (5 h, 90 °C) led to the thermolysis products of **1**[5]; **3** remained unchanged. − **(iii):** Irradiation of **3** has not been studied thus far. − **(iv):** The reaction of silver difluoride (AgF_2) with **3** led to R^*InF_2, see ref.[1]; for the reaction with oxygen see above; for the reaction with selenium see below. − **(v):** Reaction of sodium (0.9 mmol) and **3** (0.01 mmol) in 0.7 mL of C_6D_6 led at 40 °C and 3 d to R^*_2, R*D, $R^*C_6D_5$ and NaR* in a molar ratio of ca. 1:2:2:7 with a color change from deep-violet to red and formation of a residue (In or Na_xIn_y), according to NMR spectra. − **(vi):** After warming hydrogen bromide (HBr) (0.41 mmol) and **3** (0.071 mmol) in 0.6 mL of C_6D_6 from −78 °C to room temperature (decolorization, formation of H_2), the solution contained R^*InBr_2 [2] and R*H in a molar ratio of ca. 1:1, according to NMR spectroscopy. − **(vii):** After warming bromine (Br_2) (0.07 mmol) and **3** (0.061 mmol) in 4 mL of pentane from −78 °C to room temperature (decolorization), the solution contained R^*InBr_2 [2] and R*Br in a molar ratio of ca. 1:1 along with a grayish residue, according to NMR spectroscopy.

Syntheses, Thermolysis and Reactions of $R^*_4Tl_2$ (4). − (i): A solution of $TlCl_3$ (0.584 g, 1.88 mmol) and NaR*·2THF (5.64 mmol) in 30 mL of THF was kept at −78 °C for 20 h and then warmed to room temperature. The dark green solution − over a black residue − then contained an unidentified compound [multiplet at $\delta(^{29}Si)$ = 166.2 which points at a substance with two or more Tl atoms]. After filtration of the insoluble residue (NaCl) and concentration of the filtrate to 10 mL, tetrasupersilyldithallane **4** (0.035 g, 0.030 mmol; 24%) was obtained over 14 d at −23 °C as air-sensitive, methanol-stable, deep green crystals which decomposed at 56 °C (the oxidation with air led to R*OH as the only R*-containing compound). The reaction of $TlN(SiMe_3)_2$ (0.272 g, 0.746 mmol) and NaR* (0.166 g, 0.746 mmol) in 30 mL of pentane led to $NaN(SiMe_3)_2$ [40] and R^*_2 after 72 h at −90 °C and warming to −30 °C, according to NMR spectroscopy [$\delta(^{29}Si)$ = 166.2]. Then, after concentration of the solution to 10 mL, crystals of deep-green **4** were obtained at −23 °C in 14 d. Crystalline **4** and Tl (or Na_xTl_y) also formed from TlBr and NaR* in THF (warming from −78 °C to 25 °C)[4] or from C_5H_5Tl (1.785 mmol) and NaR* (1.785 mmol) in 40 mL of pentane at −80 °C. ^1H NMR (C_6D_6, int. TMS): δ = 1.318 (d, $^4J_{HTl}$ = 8.4 Hz, 108 H, Si*t*Bu$_3$). $^{13}C\{^1H\}$ NMR (C_6D_6, int. TMS): δ = 28.6/33.1 (d/d, $^2J_{CTl}/^3J_{CTl}$ = 155.8/49.9 Hz, (12 C/36 C, *C*Me$_3$/C*Me*$_3$). $^{29}Si\{^1H\}$ NMR (C_6D_6, ext. TMS): δ = 99.5 (two doublets with $^1J_{Si}{}^{205/203}{}_{Tl}$ = 1628/1610 Hz; the absence of $^2J_{Si}{}^{205/203}{}_{Tl}$ is unclear, 4 Si, Si*t*Bu$_3$). UV/Vis (heptane): λ_{max} = 628 nm (ε ≈ 50000). X-ray structure analysis: see Figure 2. − **(ii):** Thermolysis of **4** in alkanes at 40 °C led to R^*_2 and a dark-brown residue (Tl?). − **(iii):** Irradiation of **4** in C_6D_{12} with daylight led to R^*_2 and Tl over a few hours. − **(iv):** Reaction of silver difluoride (AgF_2) with **4** led to R*F and R^*_2, see ref.[2]; for the reaction with oxygen see above; for the reaction with selenium see below. − **(v):** By dropwise addition of bromine (Br_2) in 10 mL of pentane to **4** (0.1 mmol) in 15 mL of pentane (−78 °C), the solution decolorized with the formation of a residue (TlBr?) and contained only R*Br according to NMR spectroscopy − **(vi):** After warming hydrogen bromide (HBr) (0.358 mmol) and **4** (0.166 mmol) in 0.6 mL of [D_8]THF at temperature of liquid nitrogen to −30 °C, the solution changed its color from deep green to red. It then contained a thallium compound which − according to NMR spectroscopy at −30 °C in C_6D_8O − may have the composition R*BrTl−TlBrR* [$\delta(^1H)$ = 1.322 (d, $^4J_{HTl}$ = 8.4 Hz, Si*t*Bu$_3$); $\delta(^{29}Si)$ = 98.9 (two d, $^1J_{Si}{}^{205/203}{}_{Tl}$ = 1451/1438 Hz, Si*t*Bu$_3$]. The solution decolorized after warming to room temperature and then contained R*Br. At the same time a residue [colorless TlBr, black $(R^*Tl)_n$?][7] was formed. The decomposition partly took place at −30 °C. − **(vii):** After warming a mixture of triphenylmethyl chloride (Ph_3CCl) (0.083 mmol) and **4** (0.082 mmol) in 0.6 mL of pentane from −196 °C to 25 °C (decolorization; formation of TlCl?), the solution then contained R^*_2 according to NMR spectroscopy. − **(viii):** Reaction of sodium (Na) (0.9 mmol) and **4** (0.01 mmol) in 0.7 mL of C_6D_6 led at 40 °C in 1 d, under change of color from deep-green to brown and formation of a residue (Tl or Na_xTl_y) to R^*_2, R*D and NaR* (molar ratio ca. 1:1:1), according to NMR spectroscopy, along with an unidentified substance [$\delta(^1H)$ = 1.104; $\delta(^{29}Si)$ = 6.3].

Syntheses and Thermolysis of R'_4In_2 (5). − (i): A mixture of InBr (0.207 g, 1.06 mmol) and NaR′ (0.254 g, 1.05 mmol) in 30 mL of pentane/18 mL of THF was kept for 12 h at −78 °C. After warming to 25 °C, the color of the solution changed from yellow to green to deep-violet and it then contained − according to NMR spectroscopy − **5** and R'_2 in a molar ratio of 1:1. After filtration of the insoluble residue (NaBr, In) and concentration of the filtrate to 10 mL, tetrakis(di-*tert*-butylphenylsilyl)diindane (**5**) (0.168 g, 0.152 mmol; 85%) was obtained as red-violet, air-sensitive crystals. **5** was also formed from C_5Me_5In (0.155 g, 0.620 mmol) and NaR′ (0.151 g, 0.622 mmol) in 20 mL of pentane (12 h at −78 °C or 6 h at −120 °C). After warming to 25 °C, the solution exclusively contained − according to NMR spectroscopy − **5** and R'_2 in a molar ratio of 1:1. The concentrated filtrate led to crystalline R'_4In_2 (0.090 g, 0.080 mmol; 75%) at −23 °C. ^1H NMR (C_6D_6, int. TMS): δ = 1.242 (s, 72 H, Si*t*Bu$_2$), 7.840/7.179 (m/m, 8 H/12 H, *m*-/*o*-,*p*-CH of Ph). $^{13}C\{^1H\}$ NMR (C_6D_6, int. TMS): δ = 23.6/31.9 (s/s, 8 C/24 C, *C*Me$_3$/C*Me*$_3$), 127.8/128.1/128.3/136.9 (s/s/s/s, 8 C/4 C/8 C/4 C, *m*-/*p*-/*o*-/*i*-CH of Ph). $^{29}Si\{^1H\}$ NMR (C_6D_6, ext. TMS): δ = 54.4 (s, 4 Si, Si*t*Bu$_2$). UV/Vis (heptane): λ_{max} = 530 nm (ε ≈ 50000). MS (CI: NH_3; 25−50 °C): *m*/*z* = 553 [R'_2In^+]. X-ray structure analysis: see Figure 3. − **(ii):** Thermolysis of 0.127 mmol of **5** in 0.6 mL of C_6D_{12} at 140 °C/12 h led to R′D and an In mirror; some **5** remained unchanged. − **(iii):** The oxidation of **5** with air led to R′OH as the only R′-containing compound.

Syntheses, Thermolysis and Reactions of R'_4Tl_2 (6). − (i): A mixture of TlBr (0.225 g, 0.790 mmol) and NaR′ (0.192 g, 0.790 mmol) in 20 mL of THF was kept for 12 h at −90 °C. After warming to 25 °C, the color of the solution changed from yellow to dark-blue, and it then contained − according to NMR spectroscopy − **6** and R'_2 in a molar ratio of 1:1. After filtration of the insoluble residue (NaBr, Tl) and concentration of the filtrate to 5 mL, tetrakis(di-*tert*-butylphenylsilyl)dithallane (**6**) (0.151 g, 0.117 mmol; 94%) was obtained as air-sensitive, photo-labile, black-blue crystals which decomposed at 125 °C. ^1H NMR (C_6D_6, int. TMS): δ = 1.290 (broad, 72 H, Si*t*Bu$_2$), 7.814/7.528 (m/m, 8 H/12 H, *m*-/*o*-/*p*-CH of Ph). $^{13}C\{^1H\}$ NMR (C_6D_6, int. TMS): δ = 27.0/32.5 (broad/broad, 8 C/24 C, *C*Me$_3$/C*Me*$_3$), 128.6/135.9/137.0/137.7 (s/s/s/s, 8 C/4 C/8 C/4 C, *m*-/*p*-/*o*-/*i*-CH of Ph). $^{29}Si\{^1H\}$ NMR (C_6D_6, ext. TMS): δ = 103.7 (2 doublets with $^1J_{Si}{}^{205/203}{}_{Tl}$ = 982/973 Hz; the absence of $^1J_{Si}{}^{205/203}{}_{Tl}$ is unclear; 4 Si, Si*t*Bu$_2$). UV/Vis (heptane): λ_{max} = 591 nm (ε ≈ 50000). MS (CI; NH_3; 25−50 °C): *m*/*z* = 643 (R'_2Tl^+). X-ray structure analysis: see Figure 3. Remarks: Reaction of equimolar amounts of $TlN(SiMe_3)_2$ and NaR′ in alkanes did not lead to **6**, but to a black residue [$(R'Tl)_x$?].[5] − **(ii):** Thermolysis of 0.113 mmol of **6** in 0.6 mL of C_6D_{12} at 106 °C/48 h completely led to R′D and a Tl mirror. − **(iii):** Irradiation of **6** in C_6D_{12} with daylight led to R'_2 and Tl over a few hours. − **(iv):** After warming a mixture of 0.036 mmol of triphenylmethyl chloride (Ph_3CCl) and **6** (0.020 mmol) in 0.6 mL of C_6D_{12} from −78 °C to 25 °C, it turned

from black-blue to colorless within 10 min (formation of TlCl?), and then contained only R′$_2$, according to NMR spectroscopy. − **(v):** The oxidation of **6** with air led to R′OH as the only R′-containing compound.

Syntheses of R*$_4$E$_4$Y$_4$ (E = triel, Y = O, Se). − (i): Reaction of gray selenium (Se$_x$) (0.022 g, 0.273 mmol) in 0.8 mL of C_6D_{12} with **1** (0.122 g, 0.144 mmol) led to R*$_4$Al$_4$Se$_4$ (**9**) and R*$_2$ and R*H at 60 °C over 12 h. From the reaction mixture at 5 °C **9** was obtained as air- and moisture-sensitive light-red crystals which were not suitable for X-ray analysis but certainly contained molecules structured like **10** (see below). $C_{48}H_{108}Al_4Se_4Si_4$ (1221.5): calcd. C 29.53, H 5.57; found C 29.85, H 5.64. ^{1}H NMR (C_6D_6, int. TMS): δ = 1.337 (s, 108 H, Si*t*Bu$_3$). ^{13}C{^{1}H} NMR (C_6D_6, int. TMS): δ = 25.2/32.9 (s/s, 12 C/36 C, *C*Me$_3$/*C*Me$_3$). ^{29}Si NMR: Not observed. ^{79}Se NMR (C_6D_6, ext. SeMe$_2$ in C_6D_6): δ = −178.4 (s, 4 Se). − **(ii):** Reaction of gray selenium (Se$_x$) (0.054 g, 0.681 mmol) in 30 mL of heptane with R*$_4$In$_2$ (0.350 g, 0.341 mmol) led at 90 °C in 7 h to R*$_4$In$_4$Se$_4$ (**10**), R*$_2$ and R*H. All the volatile compounds were removed in an oil-pump vacuum, the residue was taken up in heptane (30 mL), the precipitate (Se) was then filtered off from the solution and the latter concentrated to 10 mL. From the solution at −23 °C **10** (0.123 g, 0.089 mmol; 46%) was obtained as air- and moisture-sensitive yellow crystals. $C_{48}H_{108}In_4Se_4Si_4$ (1572.9): calcd. C 36.66, H 6.92; found C 36.32, H 6.87. ^{1}H NMR (C_6D_6, int. TMS): δ = 1.328 (s, 108 H, Si*t*Bu$_3$). ^{13}C{^{1}H} NMR (C_6D_6, int. TMS): δ = 25.5/32.2 (s/s, 12 C/36 C, *C*Me$_3$/C*Me*$_3$). ^{29}Si{^{1}H} NMR (C_6D_6, ext. TMS): δ = 44.6 (s, 4 Si, Si*t*Bu$_3$). ^{79}Se NMR (C_6D_6, ext SeMe$_2$ in C_6D_6): δ = −322.4 (s, 4 Se). X-ray structure analysis: see Figure 4. − **(iii):** Reaction of gray selenium (Se$_x$) (0.014 g, 0.178 mmol) in 5 mL of pentane with **4** (0.107 g, 0.090 mmol) led to R*$_2$, R*H and a new substance at −30 °C in 8 h [δ(^{29}Si) = 88.56; δ(^{79}Se) = −498.3] which then decomposed at −25 °C in hours. It possibly contained molecules R*$_4$Tl$_4$Se$_4$ (**11**) structured like **9** [δ(^{79}Se) = −178.4] or **10** [δ(^{79}Se) = −322.4]. − **(iv):** From a solution of **12** (0.05 mmol) in 2 mL of heptane in the presence of traces of dry oxygen (O_2) a mixture of **7**/**12** was formed in 2 weeks as air- and moisture-sensitive violet crystals (for **12** see ref.[25]). Further oxidation of **7**/**12** leads to colorless **7**. ^{1}H NMR (C_6D_6, int. TMS): δ = 1.31 (s, 108 H, Si*t*Bu$_3$ of **7**), 1.36 (s, 108 H, Si*t*Bu$_3$ of **12**). ^{13}C{^{1}H} NMR (C_6D_6, int. TMS): δ = 24.1/32.2 (s/s, 12 C/36 C, *C*Me$_3$/C*Me*$_3$ of **7**), 25.5/32.8 (s/s, 12 C/36 C, *C*Me$_3$/C*Me*$_3$ of **12**). ^{29}Si{^{1}H} NMR (C_6D_6, ext. TMS): δ = 16.2 (s, 4 Si, Si*t*Bu$_3$ of **12**), not observed (Si*t*Bu$_3$ of **7**). X-ray structure analysis: see Figure 4. − **(v):** For synthesis of colorless R*$_4$Ga$_4$O$_4$ (**8**), see ref.[28]; X-ray analysis: see Figure 4.

X-ray Structure Determinations: Siemens P4 with an area detector for R*$_4$Al$_2$, R*$_4$Al$_4$O$_4$, R*$_4$Ga$_4$O$_4$, STOE IPDS with an area detector for R*$_4$In$_2$, R*$_4$Tl$_2$, R*$_4$In$_4$Se$_4$, R′$_4$In$_2$, R′$_4$Tl$_2$. Crystals were mounted in perfluorpolyether oil. The structures were solved by direct methods [SHELXS-97/SHELXL-97: R*$_4$Al$_2$; XS (SHELXS, version 5)/SHELXL-93: R*$_4$Al$_4$O$_4$, R*$_4$Ga$_4$O$_4$; SHELXS/SHELXL-93: R*$_4$In$_2$, R*$_4$Tl$_2$, R*$_4$In$_4$Se$_4$, R′$_4$In$_2$, R′$_4$Tl$_2$] and full matrix against F^2. All non-hydrogen atoms were refined anisotropically and H atoms were included in the refinement at calculated positions with a riding model and fixed isotropic U_i values. All *t*Bu groups of **4** were rotationally disordered; this could explain the high *R* values of the dithallane structure. The structures of the compounds that are shown in Figures 2−4, crystallographic details are summarized in Table 2. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-163234 (R*$_4$In$_2$), -163352 (R*$_4$Tl$_2$), -163236 (R′$_4$In$_2$), -163353 (R′$_4$Tl$_2$), -163233 (R*$_4$Al$_4$O$_4$/2R*$_4$Al$_4$), -163235 (R*$_4$In$_4$Se$_4$) (for R*$_4$Al$_2$ see ref.[5], for R*$_4$Ga$_4$O$_4$ see ref.[28]). Copies can be obtained free of charge on application

[41] Electrostatic repulsions of the E atoms in organyl- and silyldi-trielanes R_2E-ER_2 which are stronger for dialanes than for digallanes due to higher similar charges on E in the first case may result in a bond length shortening in direction Al−Al → Ga−Ga (electronegativities: C/Si/Al/Ga = 2.50/1.74/1.47/1.82[32]). On the other hand, the Si−Al/Si−Ga distances in $(tBu_2PhSi)_3E$ (2.59/2.58 Å)[3] or in R^*_2ECl (2.53/2.49 Å)[2] shorten in direction Si−Al → Si−Ga, though the electrostatic attractions of Si−E are stronger in the first case. The latter facts confirm the stated decrease of the atomic radius by going from Al (1.30 Å) to Ga (1.24 Å). The bond lengths shortening in direction X−Al → X−Ga (the same non-metal X) may be decreased, or even reversed as a consequence of decreasing electrostatic attractions of X and Al/Ga atoms in direction X−Al → X−Ga (for more electronegative partners X like halogens X−Al bonds are always shorter than X−Ga bonds; e.g. 2.16/2.25 Å in R^*_2Al-Cl R^*_2Ga-Cl[2]).

Disodium Tetrasupersilyltetragallanediide $Na_2Ga_4R^*_4$·2THF ($R^* = Si\mathit{t}Bu_3$) – Preparation of a Novel Gallium Cluster Compound via Dichlorodisupersilyldigallane $R^*_2Ga_2Cl_2$[‡]

Keywords: Clusters / Gallium / Oligogallanes / Silicon / Sodium

Red tetragallanediide $Na_2Ga_4R^*_4$·2THF was prepared by reduction of the monogallane R^*GaCl_2·THF in heptane or the *tetrahedro*-tetragallane $R^*_4Ga_4$ in benzene/tetrahydrofuran (THF) with sodium at 100 °C. Potassium worked analogously as a reduction agent. As an intermediate of the dehalogenation of R^*GaCl_2·THF, the orange digallane $R^*_2Ga_2Cl_2$ and the dark violet tetrahedrane $R^*_4Ga_4$ were formed. The extreme air- and moisture-sensitive $Na_2Ga_4R^*_4$·2THF was stable against Me_3SiCl, but reacted with oxygen under formation of $R^*_4Ga_4$, and with GaBr under formation of several products (isolation and X-ray structure analysis of R^*GaBr_2·THF). According to X-ray structure analyses, (i) the tetragallanediide contains a nonplanar Ga_4 ring with short Ga–Ga bonds, whereby three Ga atoms on opposite sides of the ring are each connected with one of the two Na(THF) groups, (ii) the digallane is dimeric, whereby it takes the structure of As_4S_4 (exchange of As/S against Ga/Cl). The possible ways of R^*GaCl_2·THF reduction are discussed, an explanation of the structure of $Na_2Ga_4R^*_4$·2THF is given, and halides $R_nE_nHal_2$ (E = Al–Tl) are presented.

Introduction

Uncharged or negatively charged cluster compounds R_mE_n of the heavier main group III elements Al, Ga, In, Tl have – unlike such compounds with clusters of boron B[1] – only been known quite recently. In fact, the former clusters tend to disproportionate into R_3E and E (or R_2 and E). However, this process can be hindered by employing bulky substituents R.

A particularly great number of sterically overloaded, non- or negatively charged clusters R_mGa_n of gallium, the element that forms the focus of this publication, have been synthesized to date (cf. ref.[2] and references for over 30 gallium cluster compounds cited therein). For example, with supersilyl ($Si\mathit{t}Bu_3$ = R*) which we use as a bulky substituent R, the following gallium cluster compounds have hitherto been prepared: $R^*_3Ga_2^{\cdot}$,[3] $R^*_3Ga_2^-$,[3] $R^*_4Ga_3^{\cdot}$,[3] $R^*_4Ga_3^-$,[3] $R^*_4Ga_4$,[4] $R^*_6Ga_8$,[5] $R^*_6Ga_8^{2-}$,[5] $R^*_6Ga_{10}^-$,[6] $R^*_6Ga_{13}^-$,[6] $R^*_8Ga_{18}$,[2] and $R^*_8Ga_{22}$.[2] Herein, we report on the reduction of R^*GaCl_2·THF with alkali metals M. This led, via the dimeric digallane $R^*_2Ga_2Cl_2$ (**1**) and the already known[4] tetrahedrane $R^*_4Ga_4$ (**3**), to the cluster compound $Na_2Ga_4R^*_4$·2THF (**2**). This cluster **2** contains the dianion $R^*_4Ga_4^{2-}$, which, after dark-red $Tip_6Ga_4^{2-}$ (Tip = 2,4,6-*i*$Pr_3C_6H_2$)[7] and dark-red $Dis_2Ga_4^{2-}$ [Dis = 2,6-(Tip)$_2C_6H_3$],[8] represents a third tetragallanediide thus far prepared with a novel butterfly-shaped Ga_4 framework [$Tip_6Ga_4^{2-}$ contains a star-shaped Ga_4 framework, similar to the neutral, light orange Tip_6Ga_4,[7] and $Dis_2Ga_4^{2-}$ (neutral species unknown) contains a square-shaped Ga_4 framework[8]]. Dimeric $R^*_2Ga_2Cl_2$, on the other hand, is analogously structured as the already published dimeric $R_2E_2X_2$ with E/R = Ga/Si(SiMe$_3$)$_3$ [9] and In/C(SiMe$_3$)$_3$ [10] (X in each case is Cl or Br). Indeed, there have also been indications of the existence of $R^*_2E_2Hal_2$ with other main group III elements E ($R^*_2B_2Cl_2$, $R^*_2In_2Br_2$, $R^*_2Tl_2Br_2$ among others),[11] but to date no X-ray structure analyses exist from the latter compounds.

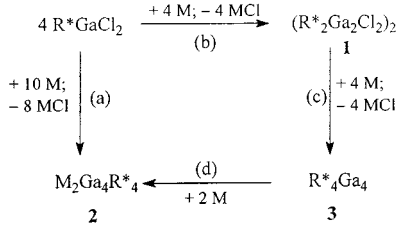
Results and Discussion

Syntheses and Reactions of 1 and 2

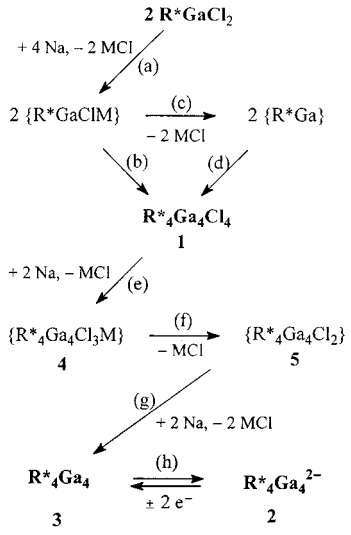
As was stated in a preceding publication,[12] the reduction of R*$GaCl_2$·THF (THF = tetrahydrofuran) with sodium in heptane at 100 °C gave, according to equation (a) in Scheme 1, the violet tetrasupersilyl-*tetrahedro*-tetragallane R*$_4Ga_4$ (**3**) and an unidentified water- and oxygen-sensitive red gallium cluster compound. We have since been able to identify the red compound as $Na_2Ga_4R^*_4$·2THF (**2**) (see Scheme 1; interestingly, the reaction of homologous R*$AlCl_2$·THF with Na does not proceed in this way; see ref.[12]). As with sodium, potassium reduced R*$GaCl_2$·THF under formation of a THF adduct of $K_2Ga_4R^*_4$. After filtration of the insoluble material and exchange of heptane for benzene, the tetragallanediide slowly crystallized (in weeks) at 5 °C as red prisms that were extremely water- and oxygen-sensitive. Indeed, in the presence of traces of air the tetragallanediide was oxidized to **3** according to $R^*_4Ga_2^{2-} \leftrightarrows R^*_4Ga_4 + 2e^-$ [reverse of equation (d) in Scheme 1]. Thereby, the tetrahedrane was formed as an intermediate that itself rapidly reacted with oxygen under formation of the heterocubane $R^*_4Ga_4O_4$ [the latter hydrolyzed to R*Ga(OH)$_2$].[4] Certainly, oxidation of **2** with R*Br should quantitatively lead to **3** (ref.[3]).



Scheme 1. Reaction of R*$GaCl_2$·THF with alkali metals M = Na, K (THF excluded for clarity; R* = Si*t*Bu_3)

Besides **3**, as a further intermediate of the reduction of R*$GaCl_2$·THF with alkali metals, the water- and oxygen-sensitive digallane $(R^*_2Ga_2Cl_2)_2$ (**1**) could be isolated as orange crystals [equation (b) in Scheme 1]. The reduction of **1** then led, by way of the tetrahedrane **3**, to the tetragallanediide **2** [equation (c) and (d) in Scheme 1]. In fact, **3** could be reduced according to equation (d) in Scheme 1 with Na in a mixture of benzene and THF at 100 °C. In this respect, the latter reaction offered another possibility for producing **2**.

Certainly, the first reaction of R*$GaCl_2$·THF with M = Na or K – leading via **1** and **3** to **2** – consists of an exchange of chlorine by M [equation (a) in Scheme 2]. Possibly, R*GaClM forms from R*$GaCl_2$·THF/Na via the radical R*GaCl$^{\cdot}$, which would then be rapidly reduced by Na. Therefore, the radical concentration would remain low, forestalling a radical dimerization. In fact, the formed gallanide R*GaClM could obviously then react with the starting material R*$GaCl_2$ under formation of **1** [equation (b) in Scheme 2] or might – more probably for steric reasons – eliminate MCl with formation of the gallylene R*Ga, which after insertion into a Ga–Cl bond of R*$GaCl_2$ would give the isolated product **1** [equations (c), (d) in Scheme 2; cf. dehalogenation of R*$SiHal_3$ (ref.[13])].



Scheme 2. Possible ways from R*$GaCl_2$·THF/Na in heptane at 100 °C, via **1** (and perhaps **4** and **5**) to **3** and its reduction product **2** (M = Na or K; R* = Si*t*Bu_3; THF excluded for clarity); bold-face formulae refer to isolated products

Further intermediates on the way from R*$GaCl_2$·THF to **3** were definitively not seen. Obviously, all these formed much more slowly from reactants than they transformed into following products. Certainly, many ways are imaginable that lead to the tetragallanediide. To our mind, the reaction of **1** with M transforms via $R^*_4Ga_4Cl_3M$ (**4**) and $R^*_4Ga_4Cl_2$ (**5**) into **3** [equations (e), (f), and (g) in Scheme 2]. A fast reduction of **3** finally gives **2** [equation (h) in Scheme 2]. In fact, compounds related to **4** and **5**, namely $R_4Ga_4I_3^-$ [R = $Si(SiMe_3)_3$][6] and $R_4In_4Br_2$ [R = $C(SiMe_3)_3$][10] could be isolated (cf. Figure 4; compound **5** might be prepared by mild chlorination of **3**).

Structures of 1, 2, and R*$GaBr_2$·THF

Figure 1 shows the structure of the molecule $Na_2Ga_4R^*_4$·2THF (**2**) in the crystal (red prisms, monoclinic, *C*2/*c*) together with selected bond lengths and angles. The central structural element of **2** is a nonplanar, butterfly-shaped Ga_4 ring with nearly equal Ga–Ga bond lengths (2.43 Å; distances of opposite Ga atoms 3.21 Å), and nearly equal Ga–Ga–Ga bond angles (82.6°) as well as Ga–Ga–Ga–Ga torsion angles (39.4°; the angle between the Ga–Ga–Ga planes amounts to 122.9°). In the course of the two-electron reduction of the tetrahedrane $R^*_4Ga_4$ (Ga–Ga distances 2.57 Å[4]) the Ga–Ga bonds shorten (by 0.14 Å on average) and the Ga_4 cluster opens. In fact, the Ga–Ga distances in **2** are comparable to the Ga–Ga bond length in R^*_2Ga–GaR* (2.43 Å), which itself relates to a bond order of 1.5 (see ref.[3]; the mean Ga–Ga distances in

Tip_6Ga_4,[7] $Tip_6Ga_4^{2-}$,[7] and $Dis_2Ga_4^{2-}$ [8] amount to 2.47, 2.39 and 2.46 Å).

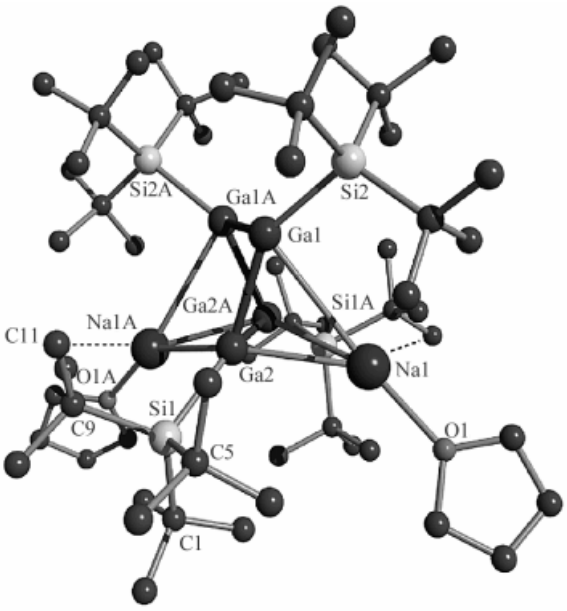


Figure 1. A view of molecule **2** (local symmetry C_2) in the crystal (H atoms excluded for clarity); the dotted line represents the (electrostatic) contacts of Na^+ with a CH_3 group of Si*t*Bu$_3$; selected bond lengths [Å] and angles [°]: Ga1−Ga1A 2.416(1), Ga1−Ga2 2.4238(6), Ga1−Si2 2.4488(9), Ga1−Na1 3.470(1), Ga1−Ga2A 3.206(1) Ga2−Si1 2.4401(8), Ga2−Ga2A 2.4530(8), Ga2−Na1 2.934(1), Ga2−Na1A 3.303, Si−C (mean value) 1.96, C11−Na1A 2.988(4), Na1−O1 2.252(3); Ga1A−Ga1−Ga2 82.98(1), Ga1A−Ga1−Si2 132.11(3), Ga2−Ga1−Si2 140.49(2), Ga1A−Ga1−Na1 106.74(3), Ga2−Ga1−Na1 56.41(3), Si2−Ga1−Na1 91.32(3), Ga1−Ga2−Si1 133.30(2), Ga1−Ga2−Ga2A 82.20(2), Si1−Ga2−Ga2A 142.99(2), Ga1−Ga2−Na1 80.11(3), Si1−Ga2−Na1 115.52(4), Ga2A−Ga2−Na1 75.03(4), Ga1−Ga2−Na1A 111.70(3), Si1−Ga2−Na1A 92.33(4), Ga2A−Ga2−Na1A 59.12(4), Na1−Ga2−Na1A 129.14(3), C−Si−C (mean value) 110.1; Ga1−Ga2−Ga2A−Ga1A 39.32, Ga2−Ga2A−Ga1A−Ga1 39.39

To explain the structure of **2**, one can assume that each Na atom transfers its s electron *entirely* to the Ga_4 cluster, which then works as a 2π-aromatic system with shortened and nearly equal Ga−Ga bonds (see Figure 2a). Obviously, the nonplanarity of the Ga_4 ring in **2** is, in this case, a consequence of steric hindrance of the four supersilyl groups with respect to each other (as a consequence of the overcrowding, **2** does not react with Me_3SiCl). Incidentally, 1,2-dihydro-1,3-diborets $R_4B_2C_2$ (R = organyl, silyl) also show a nonplanar 2π-aromatic B_2C_2 ring.[14]

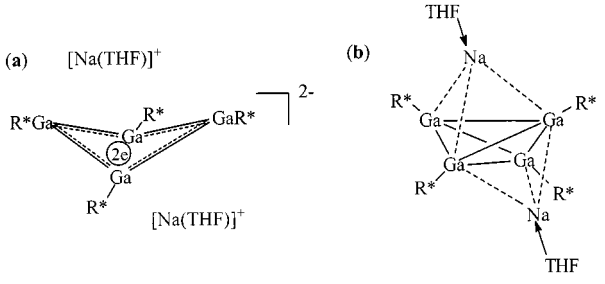

Figure 2. Illustration of the central framework of **2** (a) as a 2π-aromatic system, (b) as a twofold-capped tetrahedron

If on the other hand, each Na atom transfers its s electron only *partly* to Ga_4 in **2**, the Na_2Ga_4 framework of the molecule must be viewed as a whole. The Wade-Mingos rules (cf. ref.[1]) − which associate the number of cluster electrons with the cluster structure − predict a bicapped tetrahedron (see Figure 2b) for the Na_2Ga_4 part of **2**, according to the present $10 = 2n - 2$ cluster electrons [n = number of cluster atoms that deliver 1 electron (Na·THF) or 2 electrons (GaR*) each]. An argument for the latter description is the stability of the tetragallanediide even in pure THF [no indication of formation of independent cations $Na(THF)_n^+$]. Therefore, it might be imaginable that the reaction of **2** with GaBr results in an exchange of $Na(THF)^+$ against the "isoelectronic" Ga^+ under production of the novel gallium cluster compound $R^*_4Ga_6$ which is in great demand. In fact, **2** and GaBr transform in pentane/toluene/THF into the gallane R^*GaBr_2·THF (see below) and other products (not identified to date).

According to Figure 1, the Na atoms in **2** are each coordinated with three Ga atoms (Na−Ga distances 2.93/3.30/3.45 Å) on opposite sides of the Ga_4 ring, and in addition with the O atom of one THF molecule (Na−O distance 2.52 Å), as well as one CH_3 group of the substituents Si*t*Bu$_3$ (Na−C distance 2.99 Å). The mean values of the Si−Ga bond lengths (2.44 Å), C−Si bond lengths (1.96 Å), and C−Si−C bond angles (110.1°) are normal for supersilylated gallium cluster compounds.[2−6]

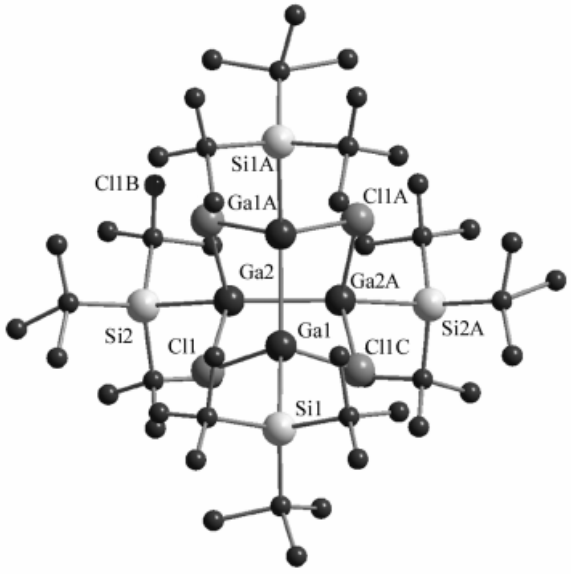

Figure 3. A view of the molecule **1** (local symmetry approx. S_4) in the crystal (H atoms excluded for clarity); selected bond lengths [Å] and angles [°]: Ga1−Ga1A/Ga2−Ga2A 2.546(3)/2.548(3), Ga1−Cl1/Ga2−Cl1 2.415(3)/2.403(3), Ga1−Si1/Ga2−Si2 2.473(4)/2.469(4), Si−C (mean value) 1.95; Cl1−Ga1−Cl1C/Cl1−Ga2−Cl1B 90.6(2)/90.6(2), Cl1−Ga1−Ga1A/Cl1−Ga2−Ga2A 100.38(9)/100.58(9), Ga1−Cl1−Ga2 101.72(10), Cl1−Ga1−Si1/Cl1−Ga2−Si2 104.96(9)/104.46(9), Si1−Ga1−Ga1A/Si2−Ga2−Ga2A 143.64(9)/144.07(9), C−Si−C (mean value) 112.0, C−Si−Ga (mean value) 106.8

Figure 3 shows the structure of the molecule $R^*_4Ga_4Cl_4$ (**1**) together with selected bond lengths and angles. Hereafter, dichlorodisupersilyldigallane $R^*_2Ga_2Cl_2$ represents a dimer, whereby the central Ga_4Cl_4 framework is structured analogously to As_4S_4 [1] [exchange of As/S by Ga/Cl; $(HGa)_4Cl_4$ is isoelectronic with As_4S_4]. The Ga atoms are distorted-tetrahedrally coordinated by Si, Ga, and 2Cl (angles Si−Ga−Cl/Si−Ga−Ga/Cl−Ga−Ga/Cl−Ga−Cl ca. 105/144/100/90°). The Cl atoms are two-coordinated by 2Ga (angle Ga−Cl−Ga ca. 102°). The two $R^*Cl_2Ga-GaCl_2R^*$ moieties show eclipsed conformations.

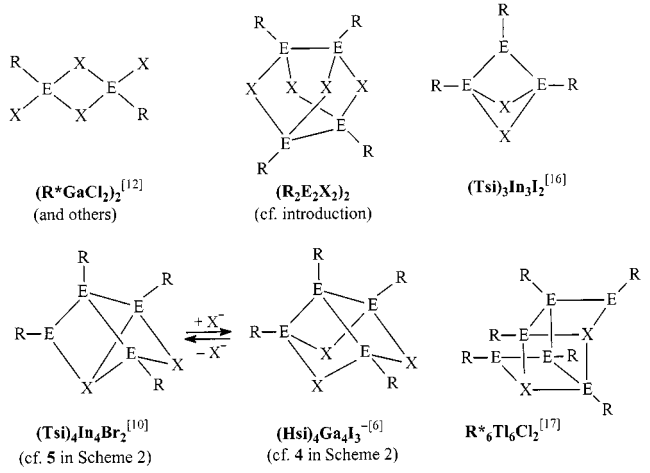

Figure 4. Examples of dihalides with the formulae $R_nE_nX_2$ [R = Si*t*Bu$_3$ (R*), Si(SiMe$_3$)$_3$ (Hsi), C(SiMe$_3$)$_3$ (Tsi); E = Al−Tl; X = halogen] and their adducts with halides [e.g. REX_3^-,[8] $R_2E_2X_4^{2-}$,[8] and $R_4E_4X_3^-$ (see above)[8]]; for monohalides $R_{n-1}E_nX$ with n = 1, 2, 3 see refs.[11,12,17]

The Ga−Ga distances in **1** (2.55 Å) are longer than those in the hitherto studied digallanes R_4Ga_2, $R_2Ga_2Hal_2$ (monomer or dimer), $R_2Ga_2Hal_4^{2-}$, $R_2Ga_2Hal_2$·2D (D = ethers, amines, phosphanes), and $Ga_2Hal_6^{2-}$ (2.39 to 2.54 Å).[3] Thereby, the Ga−Ga bond lengths shorten by going from $R^*_4Ga_4Cl_4$ [2.55 Å; R* = supersilyl Si(CMe$_3$)$_3$] to the analogously structured $R_4Ga_4Cl_4$ [2.50 Å; R = hypersilyl Si(SiMe$_3$)$_3$][9] due to steric effects. Certainly, the size of the supersilyl groups is not sufficient to prevent a dimerization of $R^*_2Ga_2Cl_2$, as is true for $Mes^*_2Ga_2Cl_2$ (Mes* = supermesityl = 2,4,6-*t*Bu$_3$C$_6$H$_2$),[15] but obviously it hinders the transformation of **1** into an adduct $R^*_2Ga_2Cl_2$·2THF in the presence of THF. The Ga−Cl distances in **1** (2.42 Å) are significantly longer than those in dimeric R^*GaCl_2 (2.18 to 2.39 Å) or monomeric R^*_2GaCl (2.25 Å).[12]

Indeed, dimeric **1** represents one member of compounds of formulae $R^*_nGa_2Cl_{4-n}$ or more generally, $R_nGa_2Hal_{4-n}$ with n = 2. Among the other members, $R^*_3Ga_2Cl$ (n = 3) is possibly obtained as the product of chlorination of the radical $R^*_3Ga_2^{\cdot}$,[3] whereas $R^*_4Ga_2$ (n = 4) loses R* and exists only as radical $R^*_3Ga_2^{\cdot}$.[11] The digallanes $R^*Ga_2Cl_3$ (n = 1) and Ga_2Cl_4 (n = 0) are unknown to date. Certainly, Ga_2Cl_4, with a structure like **1** (exchange of R* with Cl, e.g. by reaction of **1** with HCl in alkanes at low temperatures) is isomeric to the long-known $Ga^+GaCl_4^-$.[1]

On the other hand, $R^*_2Ga_2Cl_2$ represents one homologue of compounds of formulae $R^*_nGa_nCl_2$, or more generally, $R_nE_nHal_2$ (E = triel = element of the third main group), that are themselves halogen derivatives, $R^*_{n+2-m}E_nHal_m$, of compounds with the general formulae $R^*_{n+2}E_n$ (m = 0). Figure 4 shows some examples of $R_nE_nHal_2$ and their ad-

ducts with halogenides, the structures of which are known (obviously, the Ga atoms in $R_nE_nHal_2$ try to obtain the coordination number 4 by forming inter- or intramolecular halogen bridges).

The molecule R*$GaBr_2$·THF, which was obtained as one of the products of the reaction of **2** with GaBr (see above), but has already been synthesized by reaction of $GaBr_3$ with NaR* in THF[12] is analogously structured as the other donor adducts R*$EHal_2$·D (E = B to Tl),[12] and shows a distorted tetrahedral coordination of Ga with one Si atom (from R*), two Cl atoms, and one O atom (from THF). For bond lengths and angles of dibromosupersilylgallane−tetrahydrofuran(1:1), the structure of which is not discussed in detail, see ref.[18]. Further data can be found in Table 1.

Experimental Section

General: All experiments were performed under purified nitrogen or in vacuo, using Schlenk techniques. Available for use were: Na, K, C_6D_6, C_4D_8O, Me_3SiCl, and the solvents heptane, benzene, and tetrahydrofuran. The following compounds were synthesized according to literature procedures: R*$GaCl_2$·THF,[12] and R*$_4Ga_4$ (**3**).[4] For NMR spectra a Jeol GSX-270 and Jeol EX-400 were available. The ^{29}Si NMR spectra were recorded with the INEPT or DEPT pulse sequence using empirically optimized parameters for the mentioned groups.

Synthesis of the THF Adducts of $M_2Ga_4R^*_4$ (M = Na, K). − (i): 0.402 g (0.975 mmol) of R*$GaCl_2$·THF and 1.00 g (43.5 mmol) of Na were heated for 7 h in 20 mL of heptane at 100 °C. According to NMR (C_6D_6), the reaction mixture (now red) then contained compound **2**. After filtration of the heptane-insoluble materials, evaporation of volatile products under an oil-pump vacuum, and dissolution of the residue in 5 mL of benzene, 0.080 g (0.06 mmol; 26%) of disodium tetrasupersilyltetragallanediide−tetrahydrofuran(1:2) (**2**) was obtained in 8 weeks at 5 °C as water- and oxygen-sensitive, red prisms. ^{1}H NMR (C_6D_6, int. TMS): δ = 1.47 (broad, 4 Si, Si*t*Bu_3), 1.32/3.40 (m/m, 8 H/8 H, CH_2/CH_2O). ^{13}C{^{1}H} NMR (C_6D_6, int. TMS): δ = 23.1/25.2 (s/s, 6 C/6 C, *C*Me_3/*C*Me_3), 30.2/34.4 (s/s, 18 C/18 C, C*Me*$_3$/C*Me*$_3$), 25.5/67.9 (s/s, 8 H/8 H, CH_2/CH_2O). ^{29}Si{^{1}H} NMR (C_6D_6, ext. TMS): δ = 40.7/48.6 (s/s, 2 Si/2 Si, Si*t*Bu_3/Si*t*Bu_3). X-ray structure analysis: see Figure 1. Remarks: a) The insoluble material of the reaction mixture consists of **3**, among others; identification by comparison with an authentic sample[4]. It was separable from insoluble Na and NaCl by dissolving it in 10 mL of THF (see ref.[12]). b) After dissolving 0.015 g (0.01 mmol) of **2** in 0.5 mL of [D_8]THF, no changes in color or NMR spectra were observed. − **(ii):** Heating of **3** (0.095 g, 0.88 mmol) and 0.005 g (0.218 mmol) of Na in 0.4 mL of C_6D_6/0.1 mL of THF for 2 h at 100 °C led − according to NMR − exclusively to the formation of **2**. For characterization see above. − **(iii):** The reaction of R*$GaCl_2$·THF with K in heptane at 100 °C (cf. reaction with Na, above) led to a solution, in 7 h, containing a substance that was probably a THF adduct of dipotassium tetrasupersilyltetragallanediide $K_2Ga_4R^*_4$. The ^{1}H, ^{13}C, and ^{29}Si NMR shifts of this substance were identical with those for **2** (see above).

Reactions of the THF Adducts of $M_2Ga_4R^*_4$ (M = Na, K). − (i): Red **2** (0.015 g, 0.01 mmol) in 0.5 mL of C_6D_6 reacted with traces of oxygen, in the first instance under formation of the violet tetrahedrane **3**, which then transformed into the colorless heterocubane R*$_4Ga_4O_4$ (identification of the products by comparison with authentic samples[4]). Obviously, the same is valid for the THF adduct of $K_2Ga_4R^*_4$. − **(ii):** Chlorotrimethylsilane (Me_3SiCl) did not react with **2** in benzene even at 100 °C. − **(iii):** Gallium monobromide (GaBr)[19] (0.9 mmol) in 3 mL of toluene/1 mL of THF was added to 0.4 mmol of **2** in 20 mL of heptane at −78 °C. After warming the solution to room temperature, and evaporation of volatile products under an oil-pump vacuum, a dark brown residue was obtained. Extraction of the latter with pentane gave a metallic residue (Ga) and a violet solution that contained several compounds, according to NMR. Colorless crystals of dibromosupersilylgallane−tetrahydrofuran(1:1) R*$GaBr_2$·THF (identified by comparison with an authentic sample[12] and by X-ray structure analysis) were obtained from the pentane extract. Obviously, the solution contains in addition, violet tetrasupersilyl-*tetrahedro*-tetragallane (**3**) among others.

Synthesis of Dimeric $R^*_2Ga_2Cl_2$ (1): R*$GaCl_2$·THF (0.514 g, 1.247 mmol) and 1.50 g (38.4 mmol) of K were heated for 2 h in 40 mL of heptane at 100 °C. According to NMR, the solution then contained **1** (besides small amounts of R*$GaCl_2$·THF and the THF adduct of $K_2Ga_4R^*_4$). After filtration of the insoluble materials (K and KCl), evaporation of the volatile products under an oil-pump vacuum, and dissolution of the residue in 8 mL of heptane, 0.09 g (0.07 mol; 28%) of the dimeric dichlorotetrasupersilyldigallane $R^*_2Ga_2Cl_2$ (**1**) was obtained in 6 weeks at −25 °C as water- and oxygen-sensitive orange crystals. ^{1}H NMR (C_6D_6, int. TMS): δ = 1.346 (s, 108 H, Si*t*Bu_3). ^{13}C{^{1}H} NMR (C_6D_6, int. TMS): δ = 25.2/32.6 (s/s, 12 C/36 C, *C*Me_3/C*Me*$_3$). ^{29}Si{^{1}H} NMR (C_6D_6, ext. TMS): δ = 30.9 (s, 4 Si, Si*t*Bu_3). X-ray structure analysis: see Figure 3. Remarks: The ^{29}Si NMR signal at δ = 30.9 was also observed, besides signals for R*$GaCl_2$·THF and for **2** by way of the reaction of R*$GaCl_2$·THF with Na in heptane at 100 °C after 30 min. Consequently, **1** was also intermediately formed during the reduction of R^*_2GaCl·THF with Na.

X-ray Structure Determinations: Data collections were performed using Mo-K_α radiation with a STOE IPDS diffractometer at T = 200 K (**2**, R*$GaBr_2$·THF) or with a Siemens SMART diffractometer at 193 K (**1**). Structures were solved with direct methods. Refinement was with full matrix on F^2. All non-hydrogen atoms were included as riding models with fixed isotropic U values in the final refinement. Due to high thermal motion and disordering within the Si*t*Bu_3 substituents only a rather poor-quality X-ray structure determination of **1** was achieved. For further data, see Table 1. Crystallographic data (excluding structure factors) for the structures reported have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-165315 (**2**), -167434 (**1**), and -167745 (R*$GaBr_2$·THF). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Construction of (Salophen)ruthenium(II) Assemblies Using Axial Coordination

Kelly Chichak,[a] Ulrich Jacquemard,[a] and Neil R. Branda*[a,b]

Keywords: Axial coordination / N,O ligands / Ruthenium / Schiff bases / Supramolecular chemistry

Mononuclear and binuclear carbonylruthenium(II) complexes with N_2O_2 Schiff base ligands based on 3,5-di-*tert*-butylsalicylaldehyde and three different *ortho*-diamines have been prepared. The mononuclear Ru(BSP)(CO) [BSP = *N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-phenylenediamine] complex **4** acts as a versatile supramolecular synthon, as illustrated by the fact that it spontaneously forms linear and three-dimensional assemblies through axial coordination with pyridyl Lewis bases. Using this motif, neutral and charged assemblies **6**, **9**, and **12** were prepared. The versatility of the salophen ligand was highlighted by the preparation of bimetallic carbonylruthenium(II) compounds **14**–**17** from 1,2,4,5-tetraaminobenzene and 2,3,7,8-tetraaminodibenzo-[1,4]dioxin. The bimetallic complexes were isolated as a mixture of *cis* and *trans* diastereomers with respect to the spatial relationship between the two axially bound carbon monoxide ligands. The electronic spectral and electrochemical properties of the pyridyl adducts **5**, **15**, and **17** were compared. The properties of **17** closely resembled **5** due to the insulating effect of the extended central tetraamino fragment, while **15** behaved as a single, novel chromophore. The electrochemical studies revealed that the central tetraamino linker regulates the communication between the two metal centers of **15** and **17**. It was found that the two metal atoms of **15** sense each other to a larger extent than those of **17**.

Introduction

The use of vacant axial coordination sites on metalloporphyrins in conjunction with substituted pyridines in order to create supramolecular assemblies with well-defined architectures and novel properties has been well exploited and extensively documented.[1] The construction of more elaborate porphyrin-based assemblies would provide access to new materials with tunable optical and electrochemical properties, suitable for modeling photosynthetic functions such as energy capture and transfer reactions, as well as new photonic devices such as solar cells and gated molecular circuitry.[2] However, there are significant shortcomings when substituted porphyrins are used. The syntheses tend to give low yields and it is tedious to isolate and purify the macrocycles, making the "design-to-realization" period for the highly functionalized porphyrin building blocks lengthy. Alternative molecular platforms that provide free binding sites suitable for axial coordination, which are more conducive to convenient synthesis, modification and isolation need to be explored.

Metallosalens **1** [salen = *N*,*N*′-bis(salicylidene)ethylenediamine] and metallosalophens **2** [salenophen = *N*,*N*′-bis(salicylidene)-1,2-phenylenediamine] have received little attention as sources of planar supramolecular building blocks. These tetravalent ligands are particularly attractive for several reasons: 1) they are conveniently prepared in a single synthetic step by condensing substituted *ortho*-diamines with salicylaldehyde, and as a result, can be readily tailored by modifying the substituents on the diamine synthon; 2) they form stable coordination compounds with a wide variety of metal ions, which can be easily isolated; 3) if the appropriate metal ion is inserted into the ligands, the resulting complexes display accessible axial Lewis-acidic sites. Despite this appeal, we are aware of only one report describing the use of metallosalens or metallosalophens in the construction of multicomponent supramolecular assemblies through axial coordination. In this report, the authors describe how 4,4′-bipyridine axially coordinates to two methyl(salen)cobalt(III) complexes to produce a linear three-component assembly.[3]

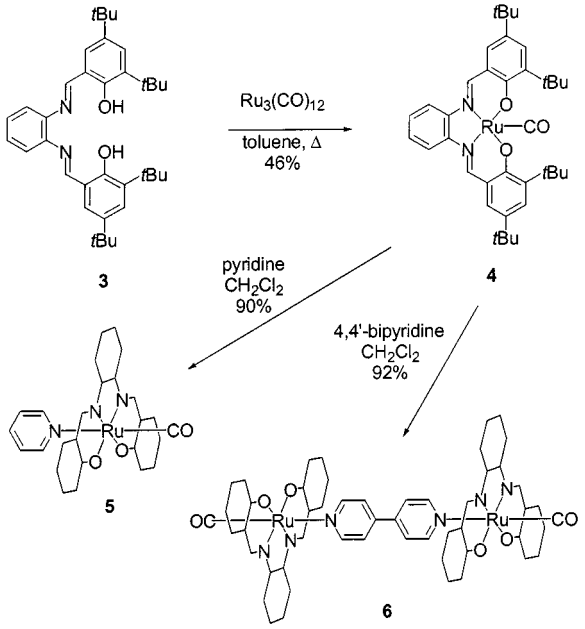
(II) synthons[4] prompted us to evaluate the versatility of the (salophen)ruthenium(II) analogues in supramolecular chemistry. The reported examples of axial coordination to carbonyl(salen)ruthenium(II) and carbonyl(salophen)ruthenium(II) complexes are limited in their scope and have certainly not been given the same degree of attention as their porphyrin counterparts. Here, we describe the application of the Ru(BSP)(CO) building block **4** [BSP = *N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-phenylenediamine] in the generation of supramolecular linear and three-dimensional assemblies **6**, **9**, and **12**. The syntheses and characterization of bis(metallosalophen) complexes **14**−**17** are also reported.

Results and Discussion

Synthesis of the (Salophen)ruthenium(II) Building Block

In an early report involving metal−carbonyl insertion into salens, Calderazzo and co-workers describe the reaction of the unsubstituted ligand **1** (M = 2 H) with $Ru_3(CO)_{12}$ to produce a metallosalen dimer in high yield.[5] Owing to the insolubility of this dimeric product, it was characterized primarily using elemental analysis techniques, which gave the correct 1:1 metal-to-ligand stoichiometry for the coordination compound but not its three-dimensional structure. The authors postulated that the dimer is held together through axial coordination to the ruthenium center of each monomer by one of the Lewis basic oxygen atoms of the other. This claim was based on the fact that analogous iron(III) coordination compounds have been characterized in the solid state. In a later report, Farrell and co-workers described how the [Ru(**1**)(CO)]$_2$ dimer can be broken into its monomeric fragments only when heated in pyridine, where it dissociates to yield the pyridine-coordinated metallosalen monomer Ru(CO)(py)(salen).[6] Khan and co-workers described an alternative, milder approach to metal−carbonyl insertion, whereby a variety of chloro- and methoxy-substituted salens and salophens were treated with $Cs_2[RuCl_4(CO)(H_2O)]$.[7] To the best of our knowledge, the axial coordinating behavior of these chloro- and methoxy-substituted ruthenium(II) Schiff base complexes has not been reported.

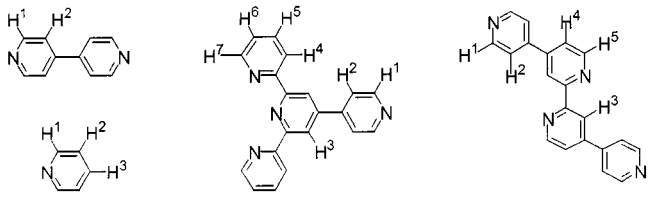
In light of the dimerization product described by Calderazzo and Farrell, and the less than satisfactory structural and binding information on the reported metallo-Schiff base complexes, we sought a more soluble salophen ligand that is amenable to facile characterization in self-assembly processes. We chose *N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-phenylenediamine (**3**) which precipitates as a yellow solid when 3,5-di-*tert*-butylsalicylaldehyde and 1,2-diaminobenzene are condensed in hot ethanol.[8] Metal insertion was accomplished by heating ligand **3** with an excess of $Ru_3(CO)_{12}$ in toluene (Scheme 1). Ru(BSP)(CO) (**4**) was isolated as a burgundy air-stable solid by a combination of column chromatography through activated alumina and recrystallization from aqueous ethanol. The isolation of **4** as a monomer was first suggested by the absence of signals in the positive ion ES mass spectrum, corresponding to higher aggregates or multiply charged species, and then by the ease of forming axially coordinated supramolecular assemblies (see later). In addition to peaks corresponding to the parent ion (*m*/*z* = 668) and the loss of carbon monoxide (*m*/*z* = 640), the ES mass spectrum of a nitromethane solution of **4** contains peaks corresponding to the hydrated (*m*/*z* = 686) and solvated (*m*/*z* = 729 for $[M + CH_3NO_2]^+$) coordination compounds. We are assuming that the molecule of the solvent (CH_3NO_2 or H_2O) most likely occupies the axial site on the metal center. Clearly, the presence of the bulky *tert*-butyl substituents on the salophen ligand inhibits the dimerization of Ru(BSP)(CO) (**4**). Similar results have been reported for the zinc analogues of these types of coordination compounds.[9] Computer-assisted molecular modeling of **4** reveals that the sterically demanding *tert*-butyl substituents prevent the metallosalophens from approaching each other, thus inhibiting the formation of an analogous dimer to that originally reported by Calderazzo.



Scheme 1

The pyridine adduct Ru(BSP)(CO)(py) (**5**) was constructed when **4** was treated with an excess of pyridine in dichloromethane at room temperature. Compound **5** was isolated as a purple solid, by filtering the solution through silica gel which effectively removed any unchanged **4** as the pyridyl adduct is the only compound that elutes with CH_2Cl_2. The formation of **5** is confirmed by the upfield shifts ($\Delta\delta$ = −0.6 to −0.1) of the signals for the protons on the coordinated pyridine because these protons lie within the shielding regions of the aromatic rings of the salophen (Table 1). The generation of **5** using such mild conditions clearly indicates that, although the bulkiness of the *tert*-butyl substituents inhibits the dimerization of **4**, they do not impede the approach of Lewis bases such as pyridine towards the metal center. The ES mass spectrum

Table 1. Selected ^{1}H NMR spectroscopic data of the pyridyl-coordinated metallosalophen assemblies prepared in this study



Compound	δ (Δδ)[a]						
	H^1	H^2	H^3	H^4	H^5	H^6	H^7
5[b]	8.12 (−0.46)	7.09 (−0.18)	7.59 (−0.10)				
6[b]	8.19 (−0.52)	7.16 (−0.40)					
9a[c]	8.48 (−0.48)	8.16 (−0.13)	9.39 (−0.17)	7.63 (−0.20)	8.00 (−0.13)	7.21 (−0.15)	8.91 (−0.17)
9b[c]	8.53 (−0.47)	8.27 (−0.12)	9.55 (−0.20)	7.38 (−0.21)	7.95 (−0.13)	7.11 (−0.15)	8.27 (−0.12)
12a[c]	8.23 (−0.79)	7.58 (−0.66)	9.04 (−0.49)	7.45 (−0.62)	7.88 (−0.58)		
12b[c]	8.24 (−0.56)	7.59 (−0.33)	9.03 (−0.52)	7.56 (−0.47)	7.54 (−0.58)		
15[b] [d]	8.20 (−0.38)	7.16 (−0.11)	7.64 (−0.05)				
17[b] [d]	8.16 (−0.42)	7.14 (−0.13)	7.63 (−0.06)				

[a] Upfield shifts of the signals for the protons in the assemblies relative to those in free pyridine for assemblies **5**, **15 (*cis*)** and **15 (*trans*)**, and **17 (*cis*)** and **17 (*trans*)**, 4,4′-bipyridine for assembly **6**, complex **7** for assembly **9a**, tetrapyridine **8** for assembly **9b**, complex **10** for assembly **12a**, and tetrapyridine **11** for assembly **12b**. [b] In CH_2Cl_2. [c] In [D_6]acetone. [d] As a mixture of both *cis*- and *trans*-isomers.

of **5** shows a peak for the parent ion (m/z = 747), as well as peaks corresponding to the exchange of pyridine with a nitromethane solvent molecule (m/z = 729), to the loss of pyridine (m/z = 668) and to the loss of both axial ligands (m/z = 640). The intense band for $\tilde{\nu}$(CO) in the IR spectrum of **5** is shifted to a higher frequency (1944 cm^{-1}) than that for **4** (1931 cm^{-1}), as is expected for the strengthening of the CO bond on addition of a π-acid.[10] The magnitude of this shift is comparable with that reported for the $\tilde{\nu}$(CO) of the metallosalen **1** [M = Ru(CO)], as the [Ru(**1**)(CO)]$_2$ dimer is converted into its pyridine adduct.[6]

Construction of Neutral Assemblies

The use of the novel metallosalophen **4** as a supramolecular synthon was studied using ^{1}H NMR spectroscopy and then by the isolation of several air-stable multicomponent assemblies. A linear trimeric assembly [Ru(BSP)(CO)]$_2$(4,4′-bpy) (**6**) was prepared by treating a dichloromethane solution of 4,4′-bipyridine with 2.2 equiv. of Ru(BSP)(CO) (**4**) in the same solvent (Scheme 1). The ^{1}H NMR spectrum of **6**, whether generated in situ or isolated as described for **5**, shows the expected upfield shifts for the signals assigned to the protons of the coordinated 4,4′-bipyridine fragment (Figure 1 and Table 1). Our studies reveal that ligand exchange is slow on the NMR timescale and sharp peaks, that do not change, of the statistical mixture of mono- and di-addition products are visible when 1.0 mol-equiv. of **4** is added (Figure 1). The ES mass spectrum of **6** exhibits a parent ion peak (m/z = 1492), as well as a peak (m/z = 824) corresponding to the loss of one metallosalophen. The spectrum also contains peaks that correspond to the fragmentation of the metallosalophen as previously seen for **4** and **5**. The IR spectrum of toluene solutions of **6** exhibits an intense band for $\tilde{\nu}$(CO) at 1947 cm^{-1}.

Construction of Charged Assemblies

Metallosalophen assemblies incorporating coordination compounds as the central fragments were also prepared (Scheme 2). Addition of 2.0 mol-equiv. of Ru(BSP)(CO) (**4**) to the bis[4′-(4′′′-pyridyl)-2,2′:6′,2′′-terpyridine]ruthenium complex **7**[11] in acetone afforded the triad **9a**, which was isolated as a purple solid by precipitation with pentane. The iron analogue **9b** was readily synthesized from its simplest building blocks in a single self-assembly process, when equal parts of 4′-(4′′′-pyridyl)-2,2′:6′,2′′-terpyridine (**8**)[12] and Ru(BSP)(CO) (**4**) were added to an acetone solution containing 0.5 mol-equiv. of Fe(BF$_4$)$_2$(H$_2$O)$_6$. The ES mass spectra of both **9a** and **9b** each show parent ion peaks (m/z = 1028 for [M − 2 PF$_6$]$^{2+}$ and 1006 for [M − 2 BF$_4$]$^{2+}$), as well as peaks corresponding to the loss of one metallosalophen (m/z = 695 for [M − **4** − 2 PF$_6$]$^{2+}$ and 672 for [M − **4** − 2 BF$_4$]$^{2+}$). The IR spectrum for **9a** and

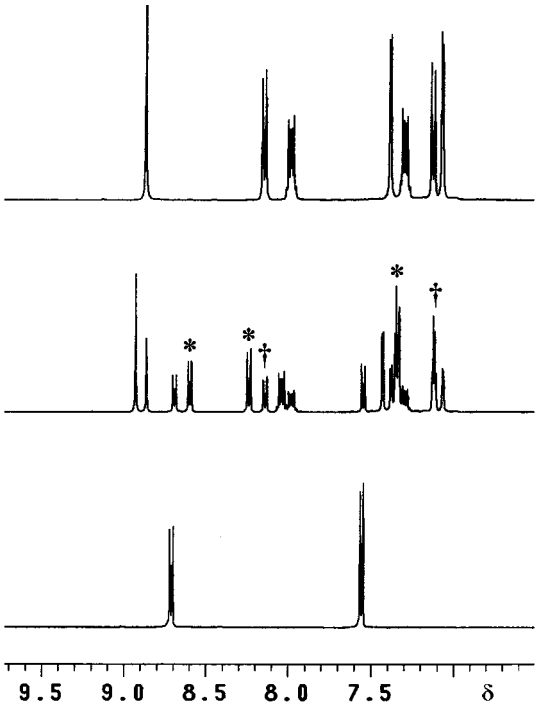


Figure 1. ^{1}H NMR (300 MHz) spectra of 4,4′-bipyridine (bottom trace), **4** + 1.0 equiv. of 4,4′-bipyridine (center trace), and **4** + 0.5 equiv. of 4,4′-bipyridine (top trace); signals corresponding to the protons of 4,4′-bipyridine for both the mono- (*) and the di-coordination (†) assemblies are highlighted; all spectra were run in CD_2Cl_2

9b obtained in the solid state exhibits intense bands for $\tilde{\nu}$(CO) at 1933 and 1934 cm^{-1}, respectively.

The syntheses of the octahedral ruthenium(II) and iron(II) assemblies **12a** and **12b** were accomplished according to our recently reported metal-directed synthesis employed to prepare the corresponding metalloporphyrin analogues (Scheme 2).[4a] The addition of [D_6]acetone to a 3:6:1 molar mixture of solid 4,4′-di(4′′-pyridyl)-2,2′-bipyridine (**11**),[13] Ru(BSP)(CO) (**4**), and $Fe(BF_4)_2(H_2O)_6$, followed by 5 min of heating, cleanly afforded assembly **12b**. The octahedral assembly **12a** was prepared by treating the pre-assembled ruthenium(II) core fragment **10** with a slight excess of **4**. The ES mass spectra of both **12a** and **12b** each show a peak corresponding to the dications (*m*/*z* = 2519 for [M − 2 PF_6]$^{2+}$ and 2496 for [M − 2 BF_4]$^{2+}$, respectively), as well as peaks for the loss of subsequent metallosalophens. The IR spectra for **12a** and **12b** obtained in the solid state exhibit intense bands for $\tilde{\nu}$(CO) at 1947 and 1946 cm^{-1}, respectively.

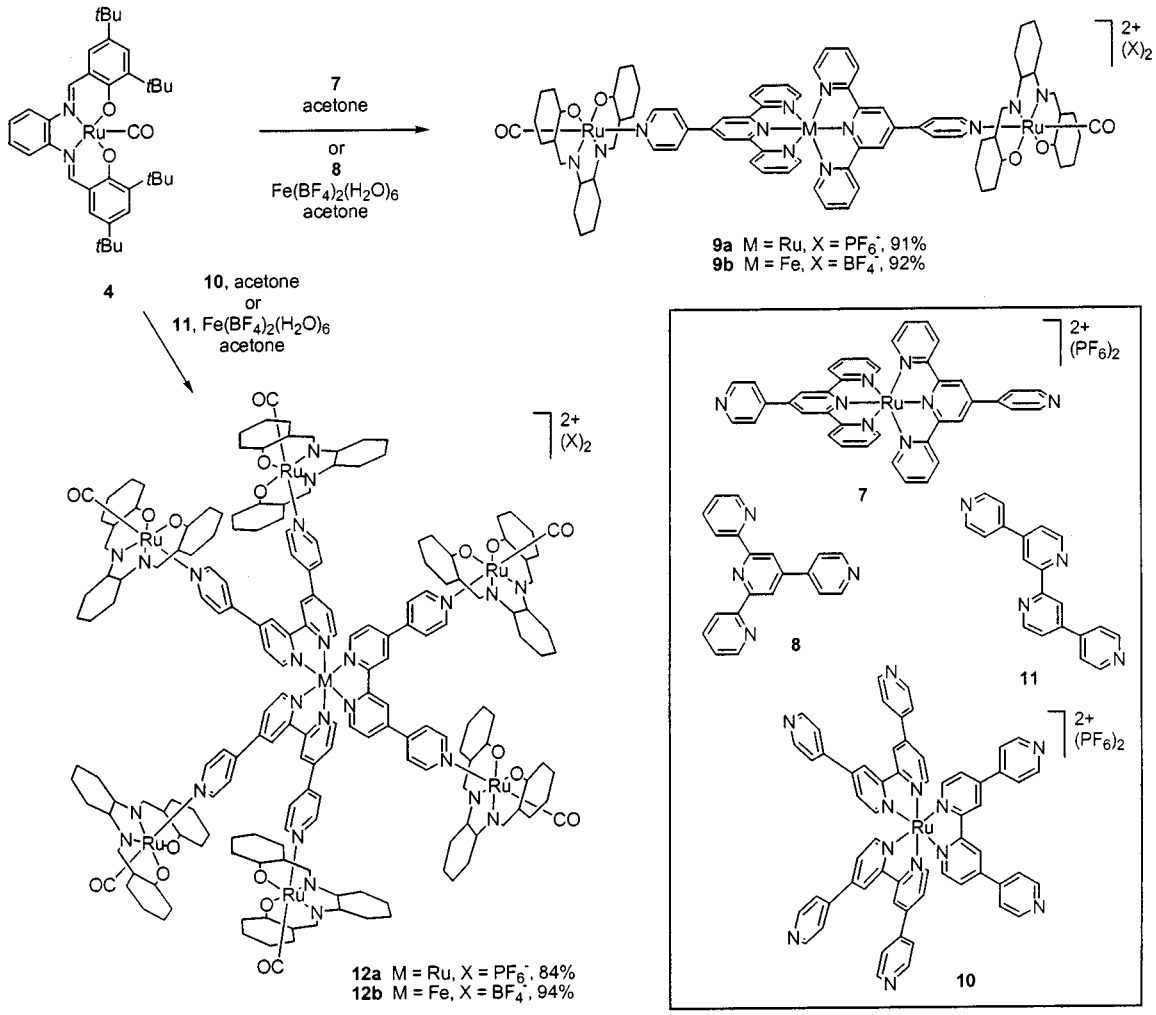
Synthesis of Bis(salophens)

Illustrative examples that highlight the versatility of the salophen ligand are bis(metallosalophen) complexes **14**−**17**. These metallosalophens offer two accessible axial metal binding sites, separated by different intermetal distances based on the size of the tetraamine synthon (7.62 Å for **14** and **15**, and 12.32 Å for **16** and **17**). The corresponding salophen ligands used to prepare these complexes were synthesized by condensing the 1,2,4,5-tetraaminobenzene hydrochloride salt for **14**, and the 2,3,7,8-tetraaminodibenzo-[1,4]dioxin hydrochloride salt **13**[14] for **16**, with 3,5-di-*tert*-butylsalicylaldehyde in ethanol under reflux (Scheme 3). Metal insertion was accomplished by heating the resulting salophens with $Ru_3(CO)_{12}$ in either toluene or diglyme, followed by purification using column chromatography through alumina. Complexes **14** and **16** were isolated as deep-red air-stable solids.

The ES mass spectrum of **14** shows the parent ion peak (*m*/*z* = 1258), as well as peaks corresponding to the solvated complex (*m*/*z* = 1336 for [M + H_2O + CH_3NO_2]$^+$, 1318 for [M + CH_3NO_2]$^+$ and 1370 for [M − CO + H_2O + 2 CH_3NO_2]$^+$). The ES mass spectrum of **16** shows a similar trend. The IR spectra for these bis(metallosalophens) obtained in the solid state exhibit intense bands for $\tilde{\nu}$(CO) at 1950 cm^{-1} for **14**, and at 1943 cm^{-1} for **16**.

The ^{1}H NMR spectrum of **14** in acetone reveals that the isolated product is a mixture of *cis* and *trans* diastereomers based on how the two carbonyl ligands project in space with respect to each other.[15] This is manifested as the appearance of two singlets of equal intensity assigned to the C−H protons on the central tetraaminobenzene ring fragment of **14**. The production of these stereoisomers is not unexpected, since the chelation sites are far away from each other so that they can act independently during the metal-insertion reactions. The diastereomeric mixture is even more apparent in the case of the pyridine adduct **15**, which was formed by treating complex **14** with pyridine, followed by the filtering of the solution through a plug of silica gel to remove trace amounts of unchanged **14**. The ^{1}H NMR spectrum of **15** shows an analogous pair of singlets assigned to the C−H hydrogen atoms on the central tetraaminobenzene fragment. The signals corresponding to the protons of the imine and flanking *tert*-butyl substituents on the bis(salophen) ligand, as well as C−H protons on the coordinated pyridine also appear as duplicate signals. These environmental effects are not limited to ^{1}H NMR spectroscopy, but are also apparent in the ^{13}C NMR spectrum for **15**, which contains duplicate signals for the coordinated pyridine ligand. On the other hand, the symmetrical nickel(II) analogue of **13** (Figure 2), prepared as a burgundy precipitate by treating the metal-free salophen ligand with 5 equiv. of $Ni(OAc)_2(H_2O)_4$, shows an absence of signal splitting in both the ^{1}H and ^{13}C NMR spectra (see Exp. Sect.).

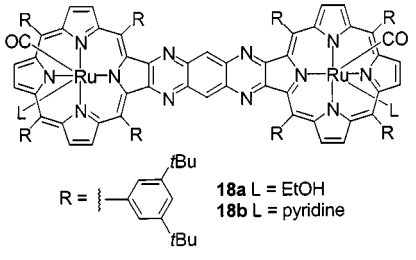
The ^{1}H NMR spectra of the coordination compounds using the larger bis(metallosalophens) **16** and **17** show an absence of signal splitting for all protons, due to the greater separation between the two coordination sites. The ^{13}C NMR spectrum of **16** also lacks any signal splitting, however, the ^{13}C NMR spectrum of **17** exhibits two sets of signals corresponding to the coordinated pyridine ligands. All of the carbon atoms on the salophen ligand remain unaffected and appear as one set of signals. Again, the symmetrical nickel(II) analogue of **16** (Figure 2) does not show any multiple peaks in its NMR spectra.

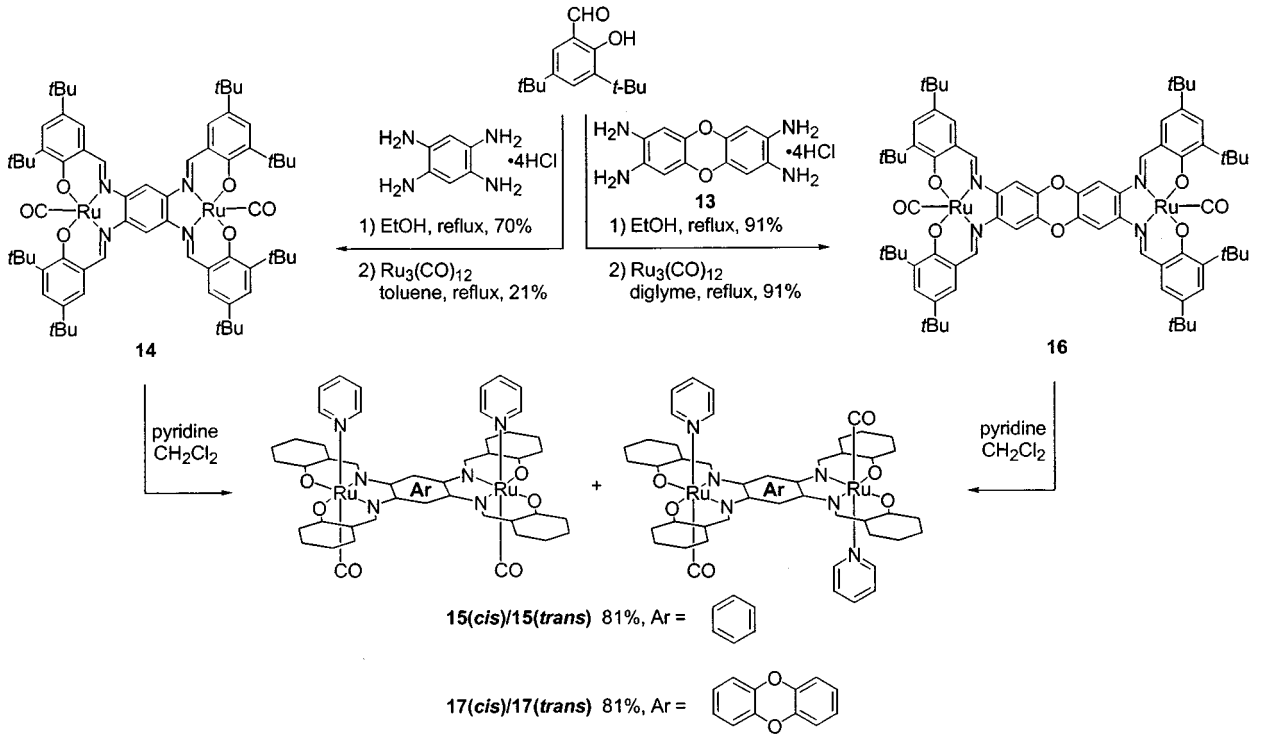


Scheme 2

The ES mass spectrum of **15** shows the parent ion peak (m/z = 1416) and peaks corresponding to the loss of pyridine (m/z = 1338 for $[M - py]^+$ and 1258 for $[M - 2\,py]^+$). The ES mass spectrum of **17** shows a similar pattern. The IR spectra of the pyridine complexes **15** and **17** in the solid state show two intense overlapping bands for the stretching vibrations of the axial carbon monoxide (1955 cm^{-1} and 1924 cm^{-1} for **15**, 1951 cm^{-1} and 1934 cm^{-1} for **17**). The IR spectra measured in toluene exhibit two completely resolved $\tilde{\nu}$(CO) at 1944 cm^{-1} and 1924 cm^{-1} for **15**, and at 1947 cm^{-1} and 1934 cm^{-1} for **17**. A solvent dependency was also observed for the $\tilde{\nu}$(CO) of both pyridine complexes, and the IR spectra of dichloromethane solutions show a single band at 1940 cm^{-1} and 1931 cm^{-1} for **15** and **17**, respectively.

The convenience of incorporating the bis(metallosalophens) into supramolecular chemistry becomes clear when their syntheses are compared with that of the analogous bis(metalloporphyrin) **18a**. Although the metal insertion into Crossley's bis(porphyrin)[16] proceeded uneventfully by heating the bis(porphyrin) with an excess of $Ru_3(CO)_{12}$ in phenol, the preparation of the free-based porphyrin was accomplished in 5 steps giving a 50% yield as reported by Burn and co-workers.[17] This is a significant drawback when compared with our single-step preparation of the bis(salophen) precursor to **14**, and the two-step procedure for the precursor of **16**. The bis(metalloporphyrin) **18a** was purified as a brown air-stable solid by a combination of column chromatography through water-activated alumina and recrystallization from aqueous ethanol. When an excess of pyridine was added to **18a** in dichloromethane, the more Lewis-basic amine immediately displaced the labile ethanol affording the pyridine adduct.





Scheme 3

UV/Vis Spectroscopic Analysis

Initial photophysical studies reveal that UV/Vis absorption spectra of metallosalophen assemblies **6**, **9**, and **12** are essentially the sum of the absorption spectra of the corresponding components, and electronic absorptions are limited to minor shifts ($\Delta\lambda = \pm 2$ nm) (Table 2), although the steady-state emission spectra vary significantly (not shown). A more detailed description of the supramolecular absorption and emission properties of the metallosalophen assemblies will be the subject of a separate report.

The absorption spectra of dichloromethane solutions of **5**, **15** (as the mixture of *cis* and *trans* isomers), and **17** (as the mixture of *cis* and *trans* isomers) are characterized by intense ligand-centered (LC) bands with maxima in the 250−400 nm region (Figure 3).[7,18] These bands have been designated as π−π* and n−π* transitions for the electrons localized on the azomethine group of the Schiff base ligand. The bands at longer wavelengths are most likely due to ligand(π)−metal(d*) charge transfer, as has been reported for similar complexes.[7,18a,18c] The similarity of the electronic spectra of complexes **5** and **17** suggests that the central dibenzodioxin fragment effectively separates the metal centers from each other, allowing them to act independently. However, this effect does not apply to complex **15**, which exhibits a unique pattern of red-shifted charge-transfer bands. This observation is indicative of the fact that **15** is behaving as one extended chromophore and not as two independent metallosalophens.

Electrochemistry of Bis(salophens)

The cyclic voltammograms of dichloromethane solutions of complexes **5**, **15** (as the mixture of *cis* and *trans* isomers), and **17** (as the mixture of *cis* and *trans* isomers) do not show any reduction waves at negative potentials, but do show two quasi-reversible ($\Delta E = 70-90$ mV) oxidation waves centered at 0.58 V (assigned as a Ru^{II}/Ru^{III} process) and 1.29 V (assigned as a Ru^{III}/Ru^{IV} process) vs. saturated Ag/AgCl (Figure 4).[18a] For the scan rates used, the cathodic-to-anodic peak current ratio (i_{pc}/i_{pa}) is constantly equal to unity for the first oxidation and slightly less than unity for the second oxidation; the quotient of the anodic peak current and the square root of the scan rate ($i_{pa}/v^{1/2}$) remains constant. Complex **5** is well behaved, showing two one-electron oxidations at 0.56(7) and 1.29(4) V. For the bimetallic species **15** and **17**, the first oxidation waves are two-electron processes [actually, two one-electron oxidations at each ruthenium(II) center] and are shifted to slightly more positive potentials [0.60(0) and 0.58(2) V for **15** and **17**, respectively]. This indicates that the metal centers do not communicate with each other for the Ru^{II}/Ru^{III} couple. The second oxidation wave of the bimetallic species are split into two one-electron oxidation waves at 1.27(7)/1.36(8) V for **15** and 1.28(4)/1.33(0) for **17**, indicative of weak interactions between the covalently linked metallosalophens. This metal-to-metal communication is amplified in the case of the smaller complex **15** ($\Delta V = 91$ mV), as compared with the larger complex **17** ($\Delta V = 50$ mV).

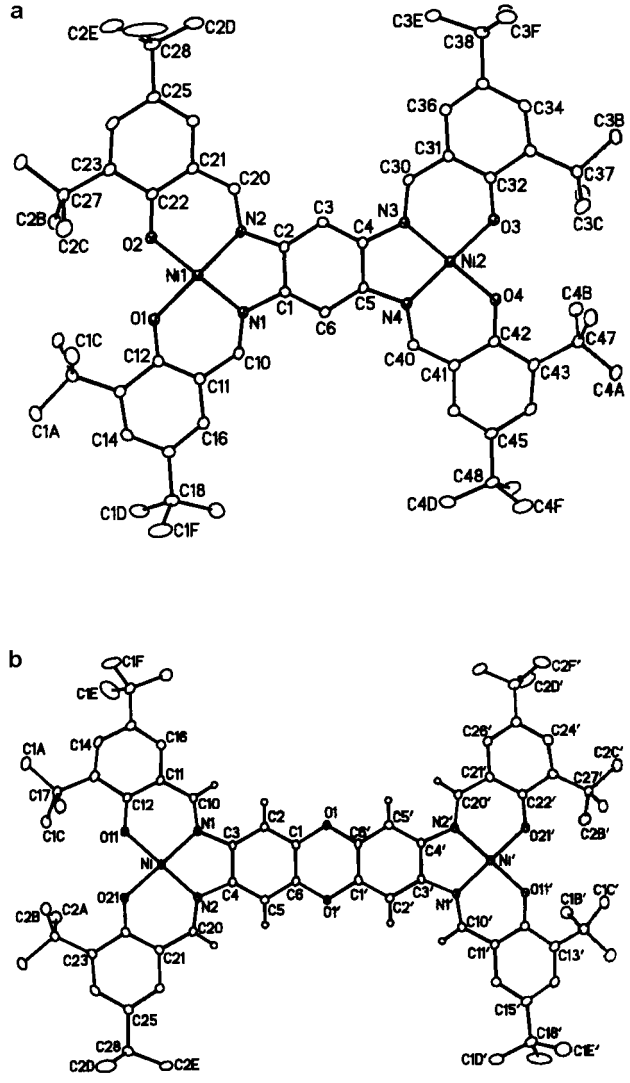


Figure 2. Molecular structures of the nickel(II) analogues of (a) **14** and (b) **16** in the crystal; solvent molecules (acetone/CH_2Cl_2 for **14** and THF for **16**) have been removed for clarity; the thermal ellipsoids are drawn at the 20% probability level

Table 2. Selected UV/Vis absorption data of the pyridyl-coordinated metallosalophen assemblies prepared in this study

Compound	λ_{max} [nm] (log ε [$M^{-1}cm^{-1}$])[a]

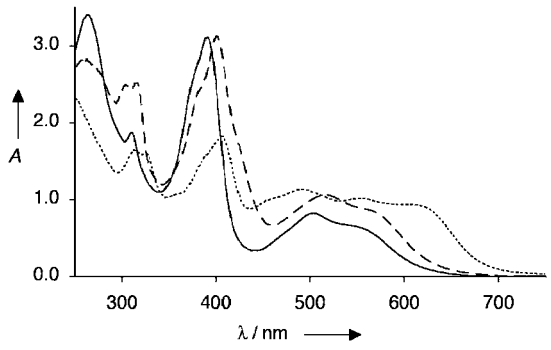

Figure 3. UV/Vis absorption spectra of Ru(BSP)(CO)(py) (**5**) (solid line), $Ru_2[(BS2P)(CO)_2(py)_2]$ (**15**, both isomers) (dotted line), and $Ru_2[(BS2DP)(CO)_2(py)_2]$ (**17**, both isomers) (dashed line) in CH_2Cl_2 at room temperature

Conclusion

In summary, this work highlights the fact that mononuclear and binuclear ruthenium(II) carbonyl Schiff base complexes can be prepared in a facile manner from *ortho*-diamines and 3,5-di-*tert*-butylsalicylaldehyde. We have also established that Ru(BSP)(CO) (**4**) has the same axial coordination properties as our previously reported Ru(CO)(TTP) supramolecular synthons. The ease with which salophens can be modified represents a significant synthetic advantage over its metalloporphyrin analogue, as was demonstrated by the formation of the carbonylbis(metallosalophens)ruthenium(II). The ease of synthetically tailoring the *ortho*-diamine synthon of the salophen ligands should spark efforts to further develop this class of supramolecular building blocks.

Experimental Section

General Remarks: All solvents (Caledon) were distilled prior to use. Solvents used for UV/Vis spectroscopy were deoxygenated by bubbling argon through the solvent. Solvents for NMR analysis (Cambridge Isotope Laboratories) were used as received. All reagents and starting materials were purchased from Aldrich. *N*,*N*′-Bis(3,5-di-*tert*-butylsalicylidene)-1,2-phenylenediamine (**3**),[8] $[Ru(pytpy)_2][PF_6]_2$ (**7**)[11] [pytpy = 4′-(4′′′-pyridyl)-2,2′:6′,2′′-terpyridine], 4′-(4′′′-pyridyl)-2,2′:6′,2′′-terpyridine (**8**),[12] $[Ru(dpybpy)_3][PF_6]_2$ (**10**)[4a] [dpybpy = 4,4′-di(4′′-pyridyl)-2,2′-bipyridine], and 4,4′-di(4′′-pyridyl)-2,2′-bipyridine (**11**)[13] were prepared as described in the literature. ^1H NMR characterizations were performed with a Varian Inova-500 instrument, working at 499.92 or with a Varian Inova-300 instrument, working at 299.96 MHz. Chemical shifts (δ) are reported in ppm relative to tetramethylsilane using the residual solvent peak as a reference standard. FT-IR measurements were performed using a Nicolet Magna-IR 750

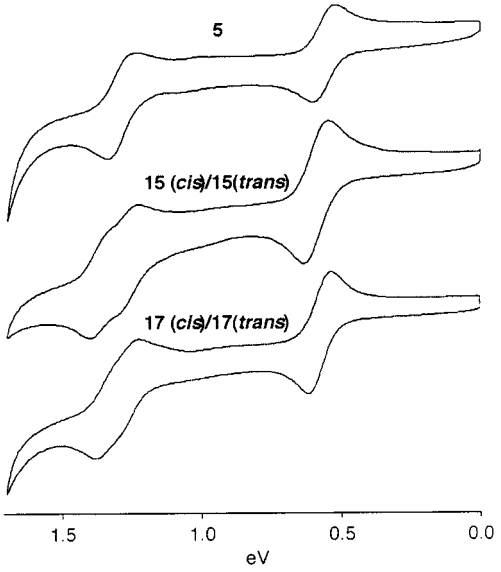

Figure 4. Cyclic voltammograms of (a) Ru(BSP)(CO)(py) (**5**), (b) $Ru_2[(BS2P)(CO)_2(py)_2]$ (**15**, both isomers), and (c) $Ru_2[(BS2DP)(CO)_2(py)_2]$ (**17**, both isomers) at identical scan rates of 50 mV/s in CH_2Cl_2 with 0.1 M TBAP at room temperature

microscope. UV/Vis measurements were performed using a Varian Cary 400 Scan spectrophotometer. Cyclic voltammetry measurements were performed in CH_2Cl_2 using a PINE bipotentiostat, a platinum working electrode, a platinum counter electrode and an Ag/AgCl reference electrode, and tetrabutylammonium hexafluorophosphate as the electrolyte. MALDI mass spectra were recorded with an Applied Biosystems Voyager Elite equipped with delayed extraction and an ion mirror (reflectron). Electrospray ionization mass spectra were recorded with a Micromass ZabSpec Hybrid Sector-TOF with positive mode electrospray ionization. All isotopic abundances match the calculated values.

Ru(BSP)(CO) (4): A solution of *N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-phenylenediamine (**3**) (130 mg, 0.242 mmol) and $Ru_3(CO)_{12}$ (65.0 mg, 0.102 mmol) in toluene (5 mL) was heated under reflux for 15 h under argon. The reaction mixture was cooled to room temperature, filtered through Celite, and concentrated under reduced pressure. The resulting dark red residue was chromatographed on alumina (II−III) eluting first with toluene to remove an orange band, followed by CH_2Cl_2 to remove a yellow band, and then with a mixture of EtOH/CH_2Cl_2 (5:95) to remove a red-pink band. The red-pink band was concentrated to dryness under vacuum affording **4** as a glassy red solid that was recrystallized from aqueous EtOH. Yield: 73 mg (46%). ^{1}H NMR (300 MHz, [D$_6$]acetone, 22 °C): δ = 9.34 (s, 2 H), 8.29 (dd, *J* = 3.3, 9.6 Hz, 2 H), 7.48 (d, *J* = 2.7 Hz, 2 H), 7.40 (d, *J* = 2.7 Hz, 2 H), 7.33 (dd, *J* = 3.3, 9.6 Hz, 2 H), 1.55 (s, 18 H), 1.33 (s, 18 H). ^{13}C NMR APT (125.7 MHz, [D$_6$]acetone, 22 °C): δ = 170.6 (C), 157.2 (CH), 146.9 (C), 142.7 (C), 135.2 (C), 131.0 (CH), 130.1 (CH), 126.7 (CH), 121.7 (C), 116.1 (CH), 36.6 (C), 34.5 (C), 31.7 (CH_3), 30.4 (CH_3). HRMS (ES+): *m*/*z* = 668.2552 [M$^+$]. Selected IR: $\tilde{\nu}$ = 1931 (CO) cm^{-1}.

Ru(BSP)(CO)(py) (5): A solution of pyridine (0.25 mL) in CH_2Cl_2 (5 mL) was treated with Ru(BSP)(CO) (**4**) (38.0 mg, 0.055 mmol) and stirred at room temperature for 30 min. Silica gel (1 g) was added and the solvents were evaporated. The solid residue was applied to a small column of silica gel (1 × 2 cm) and eluted with CH_2Cl_2. The first band was collected and concentrated to dryness affording **5** as a purple solid. Yield: 37 mg (90%).^{1}H NMR (300 MHz, CD_2Cl_2, 22 °C): δ = 8.90 (s, 2 H), 8.12 (m, 2 H), 8.01 (dd, *J* = 3.3, 9.9 Hz, 2 H), 7.59 (m, 1 H), 7.42 (d, *J* = 2.7 Hz, 2 H), 7.32 (dd, *J* = 3.3, 9.6 Hz, 2 H), 7.09 (m, 4 H), 1.56 (s, 18 H), 1.28 (s, 18 H). ^{13}C NMR APT (125.7 MHz, CD_2Cl_2, 22 °C): δ = 170.0 (C), 155.0 (CH), 149.5 (CH), 145.9 (C), 143.0 (C), 138.0 (CH), 135.1 (C), 130.1 (CH), 130.0 (CH), 126.2 (CH), 124.6 (CH), 120.5 (C), 115.1 (CH), 36.3 (C), 34.1 (C), 31.4 (CH_3), 29.9 (CH_3). HRMS (ES+): *m*/*z* = 747.2974 [M$^+$]. Selected IR: $\tilde{\nu}$ = 1942 (CO) cm^{-1}.

[Ru(BSP)(CO)]$_2$[4,4′-bipy] (6): A solution of 4,4′-bipyridine (3.9 mg, 0.025 mmol) in CH_2Cl_2 (5 mL) was treated with Ru(BSP)(CO) (**4**) (35.0 mg, 0.051 mmol) and stirred at room temperature for 30 min. Silca gel (1 g) was added and the solvents were evaporated. The solid residue was applied to a small column of silica gel (1 × 2 cm) and eluted with CH_2Cl_2. The first band was collected and concentrated to dryness affording **6** as a purple solid. Yield: 34.0 mg (92%).^{1}H NMR (300 MHz, CD_2Cl_2, 22 °C): δ = 8.91 (s, 4 H), 8.19 (dd, *J* = 1.5, 6.6 Hz, 4 H), 8.02 (dd, *J* = 3.6, 9.9 Hz, 4 H), 7.43 (d, *J* = 2.4 Hz, 4 H), 7.34 (dd, *J* = 3.3, 9.6 Hz, 4 H), 7.16 (dd, *J* = 1.5, 6.6 Hz, 4 H), 7.11 (d, *J* = 2.4 Hz, 4 H), 1.50 (s, 36 H), 1.27 (s, 36 H). ^{13}C NMR APT (125.7 MHz, CD_2Cl_2, 22 °C): δ = 169.9 (C), 155.1 (CH), 150.3 (CH), 146.4 (C), 145.8 (C), 143.0 (C), 135.2 (C), 130.0 (CH), 126.1 (CH), 122.4 (CH), 120.5 (C), 115.1 (CH), 36.2 (C), 34.1 (C), 31.3 (CH_3), 29.9 (CH_3). MS (ES+): *m*/*z* = 1492 [M$^+$]. Selected IR: $\tilde{\nu}$ = 1938 (CO) cm^{-1}.

[Ru(BSP)(CO)]$_2$[Ru(pytpy)$_2$][PF$_6$]$_2$ (9a): A solution of [Ru(pytpy)$_2$][PF$_6$]$_2$ (**7**)[11] (2.2 mg, 2.2 μmol) in acetone (5 mL) was treated with Ru(BSP)(CO) (**4**) (3.4 mg, 5.0 μmol) and stirred at room temperature for 30 min. The solvents were evaporated and the resulting solid was triturated in a mixture of Et_2O/pentane (20:80) and dried under vacuum. Yield: 4.7 mg (91%). ^{1}H NMR (300 MHz, [D$_6$]acetone, 22 °C): δ = 9.40 (s, 4 H), 9.39 (s, 4 H), 8.91 (d, *J* = 8.1 Hz, 4 H), 8.48 (d, *J* = 6.6 Hz, 4 H), 8.39 (dd, *J* = 3.6, 9.9 Hz, 4 H), 8.17 (d, *J* = 6.6 Hz, 4 H), 8.00 (t, *J* = 7.8 Hz, 4 H), 7.63 (d, *J* = 4.8 Hz, 4 H), 7.50 (d, *J* = 2.4 Hz, 4 H), 7.40 (m, 8 H), 7.21 (t, *J* = 6.0 Hz, 4 H), 1.61 (s, 36 H), 1.32 (s, 36 H). MS (ES+): *m*/*z* = 1028 [M − 2 PF$_6$]$^{2+}$. Selected IR: $\tilde{\nu}$ = 1933 (CO) cm^{-1}.

[Ru(BSP)(CO)]$_2$[Fe(pytpy)$_2$][BF$_4$]$_2$ (9b): A solid mixture of 4′-(4′′′-pyridyl)-2,2′:6′,2′′-terpyridine (**8**)[12] (3.1 mg, 0.01 mmol), $Fe(BF_4)_2(H_2O)_6$ (1.7 mg, 5.0 μmol), and Ru(BSP)(CO) (**4**) (15.0 mg, 0.022 mmol) was dissolved in acetone (5 mL) and stirred at room temperature for 30 min. The solvents were evaporated and the resulting solid product was triturated in a mixture of Et_2O/pentane (20:80) and dried under vacuum. Yield: 20.1 mg (92%).^{1}H NMR (300 MHz, [D$_6$]acetone, 22 °C): δ = 9.56 (s, 4 H), 9.42 (s, 4 H), 8.86 (d, *J* = 7.8 Hz, 4 H), 8.53 (d, *J* = 6.6 Hz, 4 H), 8.40 (dd, *J* = 3.3, 9.6 Hz, 4 H), 8.27 (d, *J* = 6.6 Hz, 4 H), 7.95 (t, *J* = 7.8 Hz, 4 H), 7.50 (d, *J* = 2.4 Hz, 4 H), 7.40 (m, 12 H), 7.11 (t, *J* = 6.0 Hz, 4 H), 1.63 (s, 36 H), 1.32 (s, 36 H). MS (ES+): *m*/*z* = 1006 [M − 2 BF$_4$]$^{2+}$. Selected IR: $\tilde{\nu}$ = 1934 (CO) cm^{-1}.

[Ru(BSP)(CO)]$_6$[Ru(dpybpy)$_3$][PF$_6$]$_2$ (12a): A solution of [Ru(dpybpy)$_3$][PF$_6$]$_2$ (**10**)[4a] (2.0 mg, 1.5 mmol) in acetone (5 mL) was treated with Ru(BSP)(CO) (**4**) (6.4 mg, 9.6 mmol) and stirred under reflux for 30 min. The solvents were evaporated and the resulting solid product was triturated in a mixture of Et_2O/pentane (20:80) and dried under vacuum. Yield: 6.8 mg (84%).^{1}H NMR (500 MHz, [D$_6$]acetone, 22 °C): δ = 9.27 (s, 12 H), 9.04 (s, 6 H), 8.31 (m, 12

H), 8.23 (d, J = 6.5 Hz, 12 H), 7.88 (d, J = 6.0 Hz, 6 H), 7.58 (d, J = 6.5 Hz, 12 H), 7.45 (m, 18 H), 7.38 (dd, J = 3.5, 9.5 Hz, 12 H), 7.30 (s, 12 H), 1.55 (s, 108 H), 1.30 (s, 108 H). MS (ES+): m/z = 2519.5 $[M - 2\,PF_6]^{2+}$. Selected IR: $\tilde{\nu}$ = 1946 (CO) cm^{-1}.

$[Ru(BSP)(CO)]_2[Fe(dpybpy)_2][BF_4]_2$ (12b): A solid mixture of 4,4′-di(4′′-pyridyl)-2,2′-bipyridine (**11**)[13] (1.2 mg, 3.9 μmol), $Fe(BF_4)_2(H_2O)_6$ (0.5 mg, 1.5 μmol), and Ru(BSP)(CO) (**4**) (6.5 mg, 9.5 μmol) was dissolved in acetone (5 mL) and stirred under reflux for 30 min. The solvents were evaporated and the resulting solid product was triturated in a mixture of Et_2O/pentane (20:80) and dried under vacuum. Yield: 7.1 mg (94%). ^1H NMR (500 MHz, [D$_6$]acetone, 22 °C): δ = 9.28 (s, 12 H), 9.03 (s, 6 H), 8.32 (m, 12 H), 8.24 (d, J = 7.0 Hz, 12 H), 7.59 (d, J = 7.0 Hz, 12 H), 7.56 (dd, J = 1.5, 6.0 Hz, 6 H), 7.54 (d, J = 6.0 Hz, 6 H) 7.45 (m, 12 H), 7.38 (dd, J = 3.5, 10.0 Hz, 12 H), 7.31 (d, J = 2.5 Hz, 12 H), 1.57 (s, 108 H), 1.31 (s, 108 H). MS (ES+): m/z = 2496.5 $[M - 2\,BF_4]^{2+}$. Selected IR: $\tilde{\nu}$ = 1946 (CO) cm^{-1}.

***N*,*N*′′,*N*′′′,*N*′′′′-Tetra-(3,5-di-*tert*-butylsalicylidene)-1,2,4,5-phenylenetetraamine [Bis(salophen) Precursor to 14] (BS2P):** 3,5-Di-*tert*-butylsalicylaldehyde (1.00 g, 4.27 mmol) and 1,2,4,5-benzenetetramine tetrahydrochloride (250 mg, 0.880 mmol) were heated in EtOH (5 mL) under reflux for 15 h. The solution was cooled to −10 °C and stirred for 3 h. The yellow-orange precipitate was collected by filtration, washed with EtOH and dried under vacuum. Yield: 610 mg (70%). M.p. 285−286 °C. ^1H NMR (360 MHz, CD_2Cl_2, 27 °C): δ = 13.53 (s, 4 H), 8.83 (s, 4 H), 7.49 (d, J = 2.2 Hz, 4 H), 7.32 (d, J = 2.3 Hz, 4 H), 7.25 (s, 4 H), 1.52 (s, 36 H), 1.33 (s, 36 H). ^{13}C NMR APT (125.7 MHz, $CDCl_3$, 27 °C): δ = 164.7 (CH), 158.7 (C), 141.6 (C), 140.6 (C), 137.3 (C), 128.6 (CH), 127.0 (CH), 118.4 (C), 111.2 (CH), 35.2 (C), 34.1 (C), 31.5 (CH_3), 29.5 (CH_3). Porphyrin(pyridine) Complex 18b: A solution of pyridine (0.25 mL) in dichloromethane (5 mL) was treated with porphyrin complex **18a** (30.0 mg, 0.012 mmol) and stirred at room temperature for 30 min. The solvents were evaporated and the residue applied to a small column of silica gel (1 × 2 cm) and eluted with CH_2Cl_2. The first band was collected and concentrated to dryness affording a dark brown solid. Yield: 20.0 mg (63%). ^{1}H NMR (300 MHz, CD_2Cl_2, 22 °C): δ = 8.69 (s, 4 H), 8.65 (d, J = 4.8, Hz 4 H), 8.57 (d, J = 4.8 Hz 4 H), 8.45 (s, 2 H), 8.05 (m, 4 H), 8.03 (m, 4 H), 7.96 (m, 8 H), 7.90 (m, 4 H), 7.81 (m, 4 H), 6.29 (t, J = 7.5 Hz, 2 H), 5.46 (t, J = 7.5 Hz, 4 H), 2.13 (d, J = 5.1 Hz, 4 H), 1.55 (s, 72 H), 1.53 (s, 36 H), 1.52 (s, 36 H). ^{13}C NMR (125.7 MHz, CD_2Cl_2, 22 °C): δ = 153.4, 149.4, 149.3, 149.3, 149.2, 149.0, 146.4, 144.8. 143.9, 142.6, 141.7, 141.7, 139.8, 136.5, 135.4, 135.4, 132.8, 132.1, 131.4, 130.0, 129.8, 129.5, 129.4, 129.0, 128.7, 128.6, 125.5, 122.6, 121.4, 120.2, 120.1, 35.4, 35.3, 32.3, 31.8. MS (ES+): m/z = 2508 [M − 2 py]$^+$. Selected IR: $\tilde{\nu}$ = 1966 (CO) cm^{-1}.

X-ray Crystallographic Study: The crystallographic data for the complexes Ni_2(BS2P), and Ni_2(BS2DP) are shown in Table 3. Crystals of Ni_2(BS2P) were grown from a mixture acetone/CH_2Cl_2 and crystals of Ni_2(BS2DP) were grown from THF. X-ray data were collected with a Bruker PLATFORM/SMART 1000 CCD at 193 K using a graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) by taking ω scans at 0.2° intervals. The structures were solved by direct methods/fragment search using the computer program DIRDIF-96 and refined by full-matrix least squares, with anisotropic displacement parameters for the non-hydrogen atoms, using the computer program SHELXL-93. Hydrogen atoms were introduced in their idealized positions as indicated by the sp^2 or sp^3 geometries of their attached carbon atoms. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-162995 (**14**) and -162996 (**16**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Unusual Coordination of the Rare Neutral Imine Tautomer of 9-Methyladenine Chelating in the *N*6,*N*7-Mode to Ruthenium(II) Complexes

Keywords: Ruthenium / Cytotoxicity / NMR spectroscopy / DNA model bases

The coordination of the DNA model base 9-methyladenine (9-MeAde) to both complexes *cis*-[Ru(bpy)$_2$Cl$_2$] and α-[Ru(azpy)$_2$(NO$_3$)$_2$] is reported. Structural characterisation using 2D NMR techniques and variable-temperature NMR studies between 25 and –55 °C show that in the compounds α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$ (**1**) and *cis*-[Ru(bpy)$_2$(9-MeAde)](PF$_6$)$_2$ (**2**), 9-MeAde is coordinated to the ruthenium ion in a chelating mode via its N7 and exocyclic N6 atoms. The NMR spectroscopic data unambiguously prove the occurrence of the rare imine tautomer of 9-MeAde in these complexes, which is clearly stabilised by the bidentate coordination of 9-MeAde in both complexes. Variable-temperature NMR spectra and 2D COSY data show that the H2 resonance of 9-MeAde in **1** and **2** appears as a doublet at low temperatures and shows a COSY cross peak to the NH1 resonance of 9-MeAde, which confirms the protonation at the N1 site. This protonated N1 site, together with an observed pK_a of ca. 6.5 of compound **1** is in agreement with the presence of the imine tautomeric form of 9-MeAde. As the binding mode of 9-MeAde to both *cis*-[Ru(bpy)$_2$] and α-[Ru(azpy)$_2$] moieties is the same, this binding mode does not explain the earlier observed difference in cytotoxicity between *cis*-[Ru(bpy)$_2$Cl$_2$] and α-[Ru(azpy)$_2$Cl$_2$].

Introduction

Currently, several ruthenium complexes are under investigation for their antitumour properties, and amongst them are polypyridyl−ruthenium complexes.[1−3] The in vitro cytotoxicity of three isomeric bis(2-phenylazopyridine)ruthenium(II) complexes, [Ru(azpy)$_2$Cl$_2$], has recently been reported.[4] The so-called α isomer, α-[Ru(azpy)$_2$Cl$_2$] (α corresponding with the isomer in which the coordinating pairs Cl, N(py), and N(azo) are *cis*, *trans*, and *cis*, respectively), shows remarkably high cytotoxicity against a series of tumour-cell lines.[4] This high cytotoxicity is in contrast to the low cytotoxicity of its isomeric complexes[4] β-[Ru(azpy)$_2$Cl$_2$] and γ-[Ru(azpy)$_2$Cl$_2$] and the structurally related complex[5] *cis*-[Ru(bpy)$_2$Cl$_2$] (where bpy is 2,2′-bipyridine). Therefore, in the search for a structure-activity relationship of antitumour-active ruthenium complexes, the investigation of complexes of the type *cis*-[Ru(LL)$_2$Cl$_2$] (with LL being a heterocyclic bidentate ligand like azpy or bpy) is very useful. Since it is generally accepted that DNA might be the target for antitumour-active ruthenium complexes,[1−3] as in the case for antitumour-active platinum complexes,[6−8] the interaction of the [Ru(azpy)$_2$Cl$_2$] complexes with DNA model bases has been studied.[3,9] The α-[Ru(azpy)$_2$Cl$_2$] compound is poorly soluble in aqueous solutions, and therefore the analogous water-soluble nitrate complex, α-[Ru(azpy)$_2$(NO$_3$)$_2$], has been synthesized and used for DNA model base binding studies.[9]

The reaction of the DNA model base 9-ethylguanine (9-EtGua) to α-[Ru(azpy)$_2$(NO$_3$)$_2$] and the structurally similar, but noncytotoxic *cis*-[Ru(bpy)$_2$Cl$_2$], results in monofunctional binding of 9-EtGua in both cases.[9,10] The 9-EtGua binding studies and rotational aspects of smaller model bases, like 1-methylbenzimidazole, show that the α-[Ru(azpy)$_2$] moiety[3] is more versatile in its coordination to heterocycles than the *cis*-[Ru(bpy)$_2$] moiety.[11,12] To obtain a better understanding of all factors influencing the biological properties of α-[Ru(azpy)$_2$Cl$_2$] and *cis*-[Ru(bpy)$_2$Cl$_2$] (Figure 1), the binding of other DNA model bases and oligonucleotides is under investigation. The interaction with the DNA model base 9-methyladenine is presented in this paper. Of all DNA nucleobases, the adenine base exhibits the most flexible binding-site behaviour with metal ions.[13] In 9-substituted adenine derivatives the ring nitrogen atoms N1 and N7 are the predominant binding sites.[13] In certain cases metal ions may also bind to the exocyclic amino group after deprotonation of the exocyclic N6 nitrogen atom.[14−18]

Bidentate coordination of adenine derivatives is shown in dinuclear complexes in which the adenine derivative acts as

a bridging ligand between the two metal sites. This bridging coordination occurs via the N6 and N7 atoms of the 9-ethyladenine (9-EtAde), like in the dinuclear Mo structure[19] [Mo$_2$(O$_2$CCHF$_2$)$_2$(9-EtAde)$_2$(MeCN)$_2$](BF$_4$)$_2$·2MeCN and a related dinuclear Rh structure.[20,21] In the tetrameric carbonylrhodium(I) complex [(CO)$_2$Rh(μ-3-MeAde$_{-H}$)]$_4$ the bridging *N*6,*N*7 coordination of deprotonated 3-methyladenine (3-MeAde) is also shown.[22] In a dirhenium carboxylate complex the bridging coordination of adenine occurs via its N1 and N6 atoms.[23] Bidentate coordination in which the N6 and N7 atoms of adenine (Ade) derivatives are coordinated to the same metal site have been reported for the tetrameric (cymene)Ru^{II} complex[24] [{Ru(Ade$_{-H}$)-(η^6-*p*-cymene)}$_4$](CF$_3$SO$_3$)$_4$, the trinuclear complex [{Ru(9-EtAde$_{-H}$)(η^6-*p*-cymene)}$_3$](CF$_3$SO$_3$)$_3$, and in related complexes[25] with adenosine bases. Also, in the case of other metal complexes like Mo, Ir, and Rh, an *N*6,*N*7 coordination of adenine derivatives to one metal site has been observed.[26−28]

In DNA, adenine is mainly present in its amine tautomeric form (Figure 2) in which form it can take part in Watson−Crick base pairing with thymine. It is estimated[29]

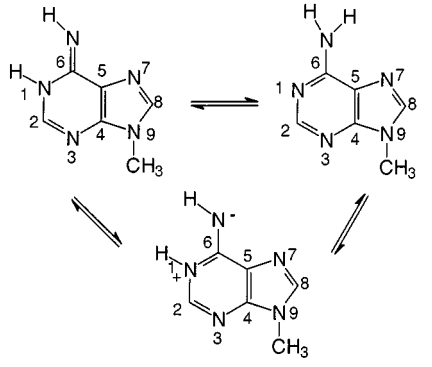

Figure 2. Tautomeric structures of 9-MeAde: the imine form (left) the amine form (right) and the zwitterionic form (bottom)

that the ratio of the amine to the imine tautomer (Figure2) in neutral adenine is approximately 10^4 to 10^5. This tautomeric equilibrium might be influenced by metal coordination.[29−31] To the best of our knowledge, only a few examples of metallated adenine derivatives are known in which it is explicitly proven by NMR spectroscopy and/or a crystal structure that the adenine derivative is in the neutral imine form.[14,17−21] The imine form of adenine in DNA might result in nucleobase mispairing, which eventually results in mutations if not repaired.[29,30] Regarding the potential antitumour activity of ruthenium complexes, it is of biological relevance to obtain a better insight in their binding to adenine derivatives. In this paper the binding of 9-methyladenine (9-MeAde) to α-[Ru(azpy)$_2$(NO$_3$)$_2$] and *cis*-[Ru(bpy)$_2$Cl$_2$] is presented. NMR spectroscopic data show that in these adducts, 9-MeAde is coordinated in its rare imine form, likely stabilised by the *N*6,*N*7 coordination.

Results and Discussion

Synthesis and Characterisation

On dissolving α-[Ru(azpy)$_2$(NO$_3$)$_2$] in H$_2$O, hydrolysis of the nitrate ions occurs, resulting in α-[Ru(azpy)$_2$(H$_2$O)$_2$]$^{2+}$,[3,9] which consecutively coordinates to 9-MeAde. Also upon reaction of *cis*-[Ru(bpy)$_2$Cl$_2$] and 9-MeAde it is the aqua complex, *cis*-[Ru(bpy)$_2$(H$_2$O)$_2$]$^{2+}$, that coordinates to 9-MeAde. The reaction of α-[Ru-(azpy)$_2$(NO$_3$)$_2$] with 9-methyladenine (9-MeAde) was carried out at 40 °C because we have observed[9] that isomerisation from the α to the β isomer in aqueous solution does not occur at or below 40 °C. Both in α-[Ru(azpy)$_2$(NO$_3$)$_2$] and in *cis*-[Ru(bpy)$_2$Cl$_2$], two coordination sites, which are identical due to the presence of a C_2 axis in the complexes, are in theory available for coordination to DNA model bases after hydrolysis of the anions. However, NMR spectroscopy clearly proves the coordination of only one 9-MeAde ligand to the α-[Ru(azpy)$_2$] and *cis*-[Ru(bpy)$_2$] moieties. Also, when the reaction of α-[Ru(azpy)$_2$(NO$_3$)$_2$] or *cis*-[Ru(bpy)$_2$Cl$_2$] with 9-MeAde was repeated in a ratio 1:2, no bifunctional adducts of the type α-[Ru(azpy)$_2$(9-MeAde)$_2$](PF$_6$)$_2$ or *cis*-[Ru(bpy)$_2$(9-MeAde)$_2$](PF$_6$)$_2$ were obtained. The starting materials α-[Ru(azpy)$_2$(NO$_3$)$_2$] and *cis*-[Ru(bpy)$_2$Cl$_2$] were racemic mixtures containing equal amounts of Λ and Δ isomers, but as 9-MeAde is not chiral, no diastereoisomers were formed and consequently only one set of signals was observed. Nucleosides do have a chiral centre and on reaction of α-[Ru(azpy)$_2$(NO$_3$)$_2$] with guanosine[9] and adenosine[32] two different sets of signals were observed for the diastereoisomeric complexes. The binding pattern of adenine derivatives to metal complexes

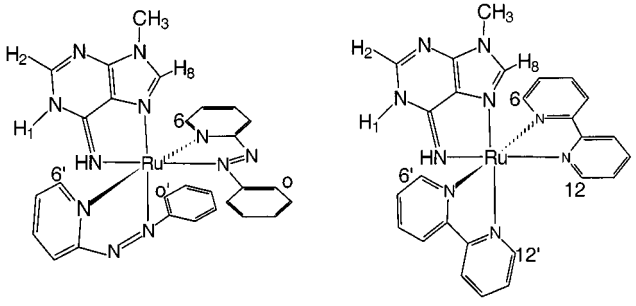

Figure 3. *N*6,*N*7-Bidentate coordination of 9-MeAde in the Λ enantiomers of α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$ (left) and *cis*-[Ru(bpy)$_2$(9-MeAde)](PF$_6$)$_2$ (right) (with proton numbering used for the NMR assignments)

is known to be very complex (vide supra), and the bidentate coordination of 9-MeAde to the α-[Ru(azpy)$_2$] and *cis*-[Ru(bpy)$_2$] moieties was not for certain beforehand. Moreover, NMR characterisation of bidentate coordination and confirmation of the imine tautomer of adenine derivatives in metal complexes is not very clear from literature, and especially the assignment of adenine resonances is sometimes confusing.[20,21] Therefore, in the presented work, a detailed NMR study was performed in order to investigate the binding mode of 9-MeAde in the bifunctional ruthenium(II) complexes.

Mass spectrometry data of α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$ show two molecule-ion peaks; apparently a part of the sample is protonated and a part of the sample is deprotonated, i.e. *m*/*z* = 616 {α-[Ru(azpy)$_2$(9-MeAde)]$^{2+}$ − H$^+$}$^+$ and *m*/*z* = 308 {α-[Ru(azpy)$_2$(9-MeAde)]$^{2+}$}. The same observation was made in *cis*-[Ru(bpy)$_2$(9-MeAde)](PF$_6$)$_2$, i.e. two signals appear in the mass spectra, belonging to *cis*-[Ru(bpy)$_2$(9-MeAde)]$^{2+}$ and {*cis*-[Ru(bpy)$_2$(9-MeAde)]$^{2+}$ − H$^+$}$^+$. The elemental analysis of *cis*-[Ru(bpy)$_2$(9-MeAde)](PF$_6$)$_2$ shows the presence of co-crystallised water and acetone. The pseudo-crystalline material did not allow single-crystal X-ray analysis.

NMR Structural Characterisation of α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$

The ^{1}H NMR spectrum of the reaction product of α-[Ru(azpy)$_2$(NO$_3$)$_2$] with 9-methyladenine (9-MeAde), i.e. α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$ (**1**), in [D$_6$]acetone at 25 °C (see Figure 4, Table 1) shows two sets of azpy signals, which are the first indication of the formation of a 1:1 adduct. The α-[Ru(azpy)$_2$] backbone is C_2-symmetric, so both coordination sites are equivalent. The coordination of a DNA model base to one of the two coordination sites results in a compound that no longer has a C_2 axis, resulting in non-equivalent azpy ligands. The integration of the signals of 9-MeAde relative to the azpy signals confirms the monofunctional coordination of 9-MeAde. The assignment of all signals was made from 2D NOESY and COSY NMR spectroscopic data at 25 °C and variable-temperature ^{1}H NMR measurements (vide infra). Characteristic signals of coordinated 9-MeAde are H8 at δ = 8.51, H2 at δ = 8.18, NH1 as a broad signal at δ = 12, and the NH6 signal overlapping with the *meta* signals at δ ≈ 7.4. These NMR spectroscopic data do not answer the question whether 9-MeAde is present in its neutral imine form or protonated amine form, since four resonances of 9-MeAde would be expected in both cases. This question will be addressed in the next section.

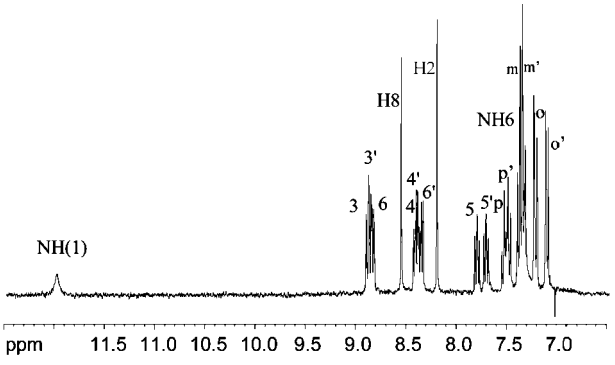

Figure 4. Low-field region of the ^{1}H NMR spectrum of α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$ in [D$_6$]acetone at 25 °C

No isomerisation of the α-[Ru(azpy)$_2$] moiety had taken place, since the interligand NOE cross-peak between the pyridine H6 protons and the phenyl ring *ortho* signals, H6-*o*′ and H6′-*o*, indicate presence of the α isomer.[3,9] The H8 resonance of the coordinated 9-MeAde was determined by its intraligand NOE cross peak with the CH$_3$ signal. The H8 signal of the coordinated 9-MeAde has an NOE cross peak to the *ortho* signal of one of the azpy ligands. This confirmed the *N*7 coordination of 9-MeAde and indicated the orientation of 9-MeAde in the complex with the H8 situated above the aza bond of the azpy ligand. In comparison to the resonance of H6, the signal of H6′ is shifted upfield by almost 0.5 ppm. This is easily explained by the orientation of 9-MeAde, which causes the H6′ of the azpy ligand to be shielded by the five-membered ring of 9-MeAde.

The experimental conditions used for the reaction of α-[Ru(azpy)$_2$(NO$_3$)$_2$] and 9-MeAde were the same as for the analogous reaction with 9-EtGua previously reported,[9] resulting in α-[Ru(azpy)$_2$(9-EtGua)(H$_2$O)](PF$_6$)$_2$ with a coordinated water molecule in the final adduct. Therefore, a coordinated water molecule was to be expected in the complex with 9-MeAde; however, the ^{1}H NMR spectrum shows no resonance to be assigned to this coordinated water ligand. This observation, in fact, is the first indication of a bidentate coordination of 9-MeAde to the α-[Ru(azpy)$_2$] moiety. Even though in theory, the absence of the proton

Table 1. Proton chemical shift values [ppm] for 9-methyladenine (9-MeAde) and α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$ (**1**) in D$_2$O (a) and [D$_6$]acetone (b) at 25 °C

	6/6′	3/3′	4/4′	5/5′	*p*/*p*′	*m*/*m*′	*o*/*o*′	H8	H2	NH(1)	NH(6)

1 (a)	8.51	8.75	8.26/	7.59	7.51	7.33	7.06	8.07	8.02		
pH < 5	7.95	8.75	8.26	7.59	7.51	7.33	7.22				
1 (b)	8.83	8.91	8.38	7.80	7.50	7.39	7.24	8.53	8.20	11.9	7.4
	8.35	8.91	8.41	7.71	7.48	7.38	7.12				

resonance of coordinated water could also be caused by rapid exchange with residual water present in [D_6]acetone. To exclude the possibility of water exchange by traces of H_2O in [D_6]acetone (98%), [D_6]acetone (100%) was used, and again no proton resonance of a coordinated water molecule could be assigned.

The ^{1}H NMR spectrum of **1** in D_2O at 25 °C and pH ≈ 5, shows that the H8 resonance (δ = 8.10) is shifted downfield in comparison to the free ligand (δ = 7.93), whereas the H2 resonance is shifted upfield (from δ = 8.20 for the free ligand to δ = 8.03 in the complex). In [D_6]acetone the H8 (δ = 8.52) resonance of 9-MeAde in the complex is shifted significantly downfield corresponding to the free base (δ = 7.81) (Table 1). This downfield shift is most probably due to the deshielding effect of the phenyl ring of the azpy ligand. The phenyl ring rotates fast on the NMR time scale around the CN axis, but is likely to spend most of the time in an orientation with the phenyl ring not in-plane with the chelate, but more perpendicular to it. This would imply the H(*o*) atoms to be on average close to the H8, which is confirmed by the NOE cross peak between these two signals.

Variable-Temperature NMR Experiments of α-[Ru(azpy)$_2$-(9-MeAde)](PF$_6$)$_2$

The above-mentioned NMR spectroscopic data of **1** at room temperature show four aromatic 9-MeAde signals that suggest the 9-MeAde to be present in the imine tautomer. Therefore, the possible imine tautomer and coordination mode of 9-MeAde in the complex was further investigated by using variable-temperature NMR, as it is known that low-temperature measurements can shift signals apart and slow down rotational or exchange properties. In fact, upon lowering the temperature of **1** in [D_6]acetone from

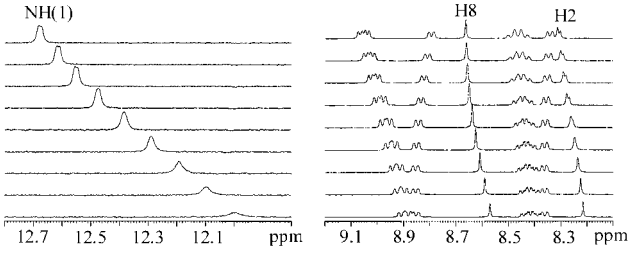

Figure 5. Variable-temperature ^{1}H NMR spectra of parts of the aromatic region of α-[Ru(azpy)$_2$(9MeAde)](PF$_6$)$_2$ in [D_6]acetone from 25 °C (bottom spectrum) to −55 °C (top spectrum); the shifting and sharpening of the NH1 signal (left) and the doubling of the H2 signal (right), prove the protonated N1 site

room temperature (25 °C) to −55 °C (Figure 5), the low-field broad signal (δ = 11.9) sharpened and shifted downfield (δ = 12.7). More importantly, the H2 signal of 9-MeAde also shifted downfield and became a doublet at −25 °C (see Figure 5). At temperatures below −55 °C, the H2 signal overlaps with the H6′ signal (not shown in Figure 5). 2D COSY experiments at −50 °C provide a cross peak between the singlet at δ = 12.8 and the doublet at δ = 8.3 (see Figure 6). This cross peak unambiguously confirms the signal at δ = 12.8 to be the NH1 (which means that this site is protonated) and the signal at δ = 8.3 to be the H2 proton. Although the NH1 resonance is not as clearly split into a doublet as the H2 resonance, probably due to line-broadening as the result of exchange with bulk water present in [D_6]acetone, the ^3J coupling of NH1 (which is hardly seen) is the same as the H2 resonance, i.e. 2.9 Hz. The exchange of the NH1 with bulk water is confirmed by the EXSY cross peak between residual water present in [D_6]acetone and the NH1 signal. In the 2D ROESY spectrum a weaker cross peak between the bulk water resonance and H2 was also observed, which is attributed to an exchange-COSY signal. The fact that the ^3J splitting of the H2 resonance is only observed at low temperatures is due to slower exchange of the NH1 proton with bulk water.

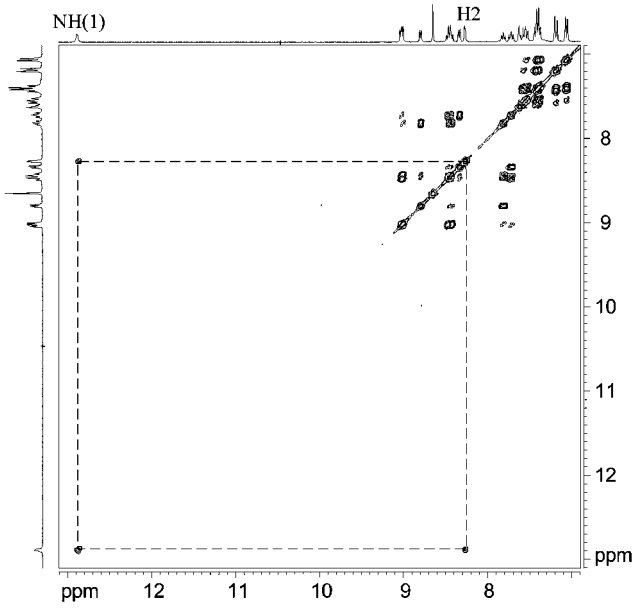

Figure 6. Low-field region of the COSY spectrum of α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$ in [D_6]acetone at −50 °C; the cross peak between the 9-MeAde NH(1) and H2 resonances is indicated with a dashed line

As the adduct **1** was isolated at pH ≈ 5, the protonation of N1 is not likely when 9-MeAde is in its amine form as the pK_a of an *N*7-metallated 9-MeAde is thought to be < 4, as in the case of Pt complexes.[33,34] Thus, in compound **1** the N1 protonation would only be possible if the 9-MeAde was present in its imine form. However, 9-MeAde being present in the zwitterionic form (Figure 2) could not a priori be excluded, as in that case the N1 and N6 atoms were also both protonated. For example, in the case of a (cymene)Ru^{II} complex [{Ru(Ade$_{-H}$)(η^6-*p*-cymene)}$_4$]-(CF$_3$SO$_3$)$_4$, Ade is probably present in the zwitterionic form, as shown by the relatively long N6−C6 distance in the crystal structure.[24] The combination of NMR spectroscopic and crystal structural data of the complex[19] [Mo$_2$(O$_2$CCHF$_2$)$_2$(9-EtAde)$_2$(MeCN)$_2$](BF$_4$)$_2$·2MeCN is in agreement with the results presented here. This crystal structure shows that the 9-EtAde molecules are bridging

ligands coordinated via the N7 and N6 nitrogen atoms and, importantly, are present in the neutral imine tautomer. The ^{1}H NMR spectrum of this Mo structure at −40 °C shows the NH1 signal at low field and the H2 resonance of 9-EtAde as a doublet, and so these resonances have a similar appearance as the 9-MeAde resonances of the present sample **1** at −55 °C. This confirms the presence of the imine form of 9-MeAde in sample **1**. In DNA, adenine in the imine form is very exceptional, but metal coordination might influence the equilibrium.[29−31] The imine form of 9-MeAde in **1** must apparently be stabilised by the bidentate coordination via the N7 and exocyclic N6 atoms. The presence of 9-MeAde coordinated in a bidentate fashion in **1** was also confirmed by the absence of an NMR signal of a coordinated water (vide supra), and by the pH experiments showing only one protonation step (vide infra).

As at low temperatures, 9-MeAde resonances no longer overlap with azpy resonances. 2D NOESY experiments were also performed at −50 °C. For example, at −50 °C the NH6 singlet was clearly seen at δ = 7.6, whereas at room temperature this signal showed overlap with the *meta* signals at δ ≈ 7.4. 2D NOESY and ROESY NMR spectroscopic data (600 MHz, Figure 7) at −50 °C show NOE signals between the H8 and H_o resonances, and between the NH6 and H6 resonances, confirming the orientation of 9-MeAde caused by the chelating mode of 9-MeAde via its N7 and N6 nitrogen atoms, i.e. the H8 positioned above the aza bond and the NH6 close to the H6 of the azpy ligand. In the NOE level of the 2D ROESY spectrum NH1 shows an NOE cross peak to NH6, which confirms the imine form. The NH1−NH6 distance (2.25 Å) of 9-EtAde, which is also present in the neutral imine form in the structure $[Rh_2(DTolF)_2(9\text{-}EtAde)_2(CH_3CN)][BF_4]_2$ (DTolF = *N*,*N*′-*para*-ditolylformamidinate), shows that an NOE cross-peak between NH1 and NH6 in compound **1** is likely.[20,21] However, the assignment[20] of the NH1 and NH6 signals of $[Rh_2(DTolF)_2(9\text{-}EtAde)_2(CH_3CN)][BF_4]_2$ is confusing as it was done by selective decoupling. By this method it is impossible to discriminate between both signals. On the other hand, it is also stated[21] that the NH1 and H2 resonances of $[Rh_2(DTolF)_2(9\text{-}EtAde)_2(CH_3CN)][BF_4]_2$ were determined by selective decoupling. In this presented work we have shown that 2D COSY NMR is a powerful technique for assigning the NH1 and H2 resonances of 9-MeAde in the imine form, and by using 2D NOESY NMR, the coupling between the NH1 and NH6 resonances proves the assignment of the NH6 resonance of 9-MeAde.

Protonation and Deprotonation of α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$

A pH titration of **1** in the pH range from 1 to 14, followed by ^{1}H NMR spectroscopy, shows only one protonation step, indicating a pK_a of 6.5 for NH1 (see Supporting Information, S1). The fact that only one protonation step was observed confirms the bidentate coordination of 9-MeAde. In the case of α-[Ru(azpy)$_2$(9-EtGua)(H$_2$O)](PF$_6$)$_2$, two protonation steps were observed;[9] one for N1 of 9-EtGua and one for coordinated

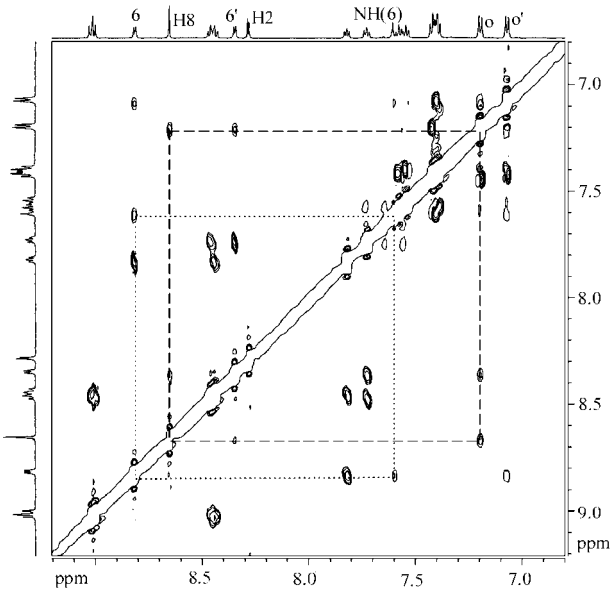

Figure 7. Aromatic region of the NOESY spectrum of α-[Ru(azpy)$_2$(9-MeAde)](PF$_6$)$_2$ in [D$_6$]acetone at −50 °C; the cross peaks between the 9-MeAde H8 and H_o resonances and the H6 and NH(6) signals are indicated with dashed and dotted lines, respectively

H_2O. The acidity of the free imine tautomer of 9-MeAde is estimated to have a pK_a for N1 of about 12.[15] In the case of adenine in the Hg complex [Hg(9-MeAde-*N*6)(1,3-dimeU-*C*5]NO_3·H_2O, in which 9-MeAde is present in its imine form and coordinated only via its exocyclic N6 nitrogen atom, the pK_a for deprotonation of NH1 is 4.5.[15] Therefore, in **1** the effect of ruthenium(II) is an increase in the acidity by about 5.5 log units in comparison to the acidity of the free imine tautomer of 9-MeAde; this shift seems to be reasonable in comparison to the Hg compound.[15]

The deprotonation behaviour of 9-MeAde of **1** in [D$_6$]-acetone was more complicated than in water. Depending on the pH at which the product of the reaction between α-[Ru(azpy)$_2$(NO$_3$)$_2$] and 9-MeAde was isolated, a mixture of **1** and the deprotonated form, α-[Ru(azpy)$_2$(9-MeAde$_{-H}$)](PF$_6$) (**1$_{-H}$**) could be obtained. In the ^{1}H NMR spectrum of either pure **1** or a mixture of **1** and **1$_{-H}$**, one set of signals was observed at room temperature. In the fully protonated sample, lowering the temperature of the sample only resulted in a shift of the signals and appearance of the NH1 and H2 resonances as doublets, as mentioned above and shown in Figure 5. However, in the case of a sample in which both **1** and **1$_{-H}$** were present, lowering the temperature resulted in ^{1}H NMR spectra showing signal broadening (from ca. 5 °C to −45 °C) and on further cooling, re-sharpening in two sets of signals at −75 °C (in a **1**/**1$_{-H}$** ratio of 1.5:1). This signal broadening and re-sharpening is likely due to **1** and **1$_{-H}$** being in fast exchange at the NMR time-scale at room temperature, intermediate exchange at temperatures from ca. 5 °C to −45 °C, and at slow exchange at −75 °C, resulting in the appearance of signals of both **1** and **1$_{-H}$**. After addition of some HNO_3

(1 M) to this sample of **1** and $\mathbf{1_{-H}}$, ^{1}H NMR spectroscopic data at −75 °C showed that the signals of $\mathbf{1_{-H}}$ were converted into one set of resonances (those of **1** only). Similarly, the addition of an excess of triethylamine in situ to **1** in [D_6]acetone at −75 °C resulted in one set of signals of α-[Ru(azpy)$_2$(9-MeAde$_{-H}$)](PF_6). In particular, the disappearance of the NH1 signal and the appearance of H2 as a singlet resonance instead of a doublet after addition of excess triethylamine in situ, indicated deprotonation of the NH1 site of 9-MeAde in the imine form. The significant upfield shift of the NH6 signal to δ = 5.7 can be seen as a characteristic after deprotonation of the NH1 site.

NMR Structural Characterisation of *cis*-[Ru(bpy)$_2$(9-MeAde)](PF_6)$_2$

The downfield region of the ^{1}H NMR spectrum of *cis*-[Ru(bpy)$_2$(9-MeAde)](PF_6)$_2$ (**2**) at 25 °C in [D_6]acetone (Table 2) shows two sets of bpy multiplet signals and the characteristic four singlet signals (H8, H2, NH1, and NH6) of the coordinated 9-MeAde ligand. The fact that the two bpy ligands were non-equivalent upon coordination of 9-MeAde, and the integration of the signals of 9-MeAde relative to the bpy signals, confirmed the presence of just one molecule of 9-MeAde. With the use of 2D NOESY and COSY experiments the bpy and 9-MeAde signals were assigned. The H8 resonance of 9-MeAde was assigned using the intraligand NOE coupling between the CH_3 and H8 signals. Interestingly, the H8 signal appears at higher field than the H2 resonance in contrast to the signals observed in the analogous ^{1}H NMR spectrum of **1** in which the H8 and H2 resonances appear in opposite order. The H8 signal at δ = 8.00 is shifted downfield with respect to the H8 of free 9-MeAde. The H2 resonance at δ = 8.11 is shifted upfield (δ = 0.3) relative to free 9-MeAde. Similar to the previously discussed NMR spectroscopic data of **1**, the absence of a coordinated water signal in the ^{1}H NMR spectrum of **2** suggests the bidentate coordination of 9-MeAde to the *cis*-[Ru(bpy)$_2$] moiety.

Variable-temperature ^{1}H NMR spectra show, similar to **1**, downfield shifting and sharpening of the NH1 signal of 9-MeAde and downfield shifting of the H2, H8, and NH6 signals of 9-MeAde upon decreasing the temperature. Remarkable again, is the splitting of the H2 signal into a doublet, most clearly seen at −50 °C (Figure 8). The NH1 and H2 signals were confirmed by a COSY cross peak between these two signals (see Supporting Information, Figure S2). A 2D ROESY NMR spectrum (600 MHz) (see Supporting Information, Figure S3) at −50 °C shows an NOE cross peak between NH1 and NH6 and together with the COSY cross peak NH1−H2, this confirms the imine tautomer of 9-MeAde. The H6 signal of bpy shows an NOE cross peak to NH6 and the H8 resonance shows an NOE cross peak to the H6′ signal. These NOE data are in agreement with the orientation of 9-MeAde caused by the bidentate coordination via its N7 and N6 nitrogen atoms. In summary, the 2D NMR spectroscopic data and variable-temperature ^{1}H NMR measurements indicate that in **2** 9-MeAde is in the neutral imine form and this tautomeric form is most likely stabilised by the chelating coordination via its N7 and N6 atoms. In this coordination mode the large difference in chemical shift of the H6 and H6′ resonances is explained because the H6′ atom is in the shielding cone of 9-MeAde.

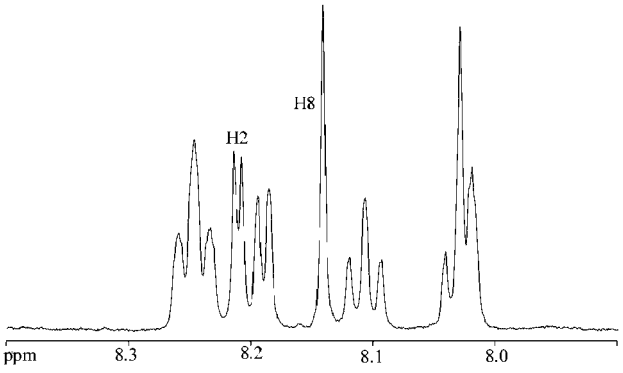

Figure 8. Enlargement of the aromatic region of the ^{1}H NMR spectrum in [D_6]acetone at −50 °C of *cis*-[Ru(bpy)$_2$(9-MeAde)](PF_6)$_2$ showing the 9-MeAde H2 signal as a doublet

Analogous to the results of **1**, after addition of triethylamine in situ at −50 °C, the ^{1}H NMR spectra of **2** show the disappearance of the NH1 signal, the appearance of the H2 signal, no longer as a doublet, and the NH6 resonance dramatically shifted upfield to δ = 5.3. These results are consistent with the formation of *cis*-[Ru(bpy)$_2$(9-MeAde$_{-H}$)](PF_6), in which 9-MeAde is still present in the imine form, now deprotonated at N1. Unfortunately, due to the poor solubility of **2** in water, the pK_a of this compound could not be determined.

Conclusions

The strong differences in biological activity between the structurally similar complexes *cis*-[Ru(bpy)$_2$Cl$_2$] and α-[Ru(azpy)$_2$Cl$_2$] encouraged us to investigate the binding of DNA model bases to the hydrolysis products of both com-

plexes. In this paper the coordination of 9-MeAde to both *cis*-$[Ru(bpy)_2(H_2O)_2]^{2+}$ and α-$[Ru(azpy)_2(H_2O)_2]^{2+}$ is presented. NMR spectroscopic data prove that, although the ruthenium ions in these two complexes have two available coordination sites, only one 9-MeAde coordinates to the metal ion. NMR structural characterisation using 2D NMR techniques and variable-temperature ^1H NMR spectra show that in both compounds α-$[Ru(azpy)_2$(9-MeAde)$](PF_6)_2$ (**1**) and in *cis*-$[Ru(bpy)_2$(9-MeAde)$](PF_6)_2$ (**2**), 9-MeAde is present in its rare neutral imine tautomeric form, apparently stabilised by the chelating coordination via its N7 and exocyclic N6 atoms. As the coordination mode of 9-MeAde is the same in both the azpy complex **1**, as in the bpy complex **2**, the difference in cytotoxicity of the parent chloride complexes cannot be explained by differences in the coordination of 9-MeAde around the ruthenium centre. At present, further investigation is focussed on the steric properties of the *cis*-$[Ru(LL)_2Cl_2]$ complexes (with LL being a heterocyclic bidentate ligand), to investigate the influence of steric hindrance of the LL ligand toward the free coordination sites in order to obtain a structure-activity relationship of antitumour-active ruthenium complexes. Nevertheless, the interesting imine tautomer of 9-MeAde, stabilised by the bidentate coordination to the ruthenium ion reported here, represents a structural model for any metal ion of interest with a nucleobase where coordination influences the tautomeric equilibrium. There might be biological consequences of the occurrence of the imine form of 9-MeAde upon coordination of 9-MeAde to ruthenium(II). It has already been questioned whether Pt coordination does shift the tautomer equilibrium towards the imine form, but Lippert et al. reported[35] that for the compound $[Cl_3Pt(9MeA)]^-$ the shift in favour for the imine tautomer is too small to explain the observed preferential Ademine−Thymine (AT) transversion. It is generally accepted that the mutation pathway of the AT transversion involves a pairing between one of the two adenines in the rare imine tautomer and the other adenine in the normal amine tautomer in a *syn* conformation.[35] Speculatively, the obvious shift towards the imine tautomer of 9-MeAde presented in this study might result in AT transversions when these ruthenium compounds coordinate to DNA.

In conclusion, a very interesting bidentate coordination of 9-MeAde in the complexes α-$[Ru(azpy)_2$(9-MeAde)$](PF_6)_2$ and *cis*-$[Ru(bpy)_2$(9-MeAde)$](PF_6)_2$ is observed in which 9-MeAde is present in its neutral imine tautomer.

Experimental Section

General Remarks: NMR experiments were performed at 300.13 MHz with a Bruker 300 DPX spectrometer and at 600.13 MHz with a Bruker 600 DPX spectrometer. Spectra were recorded in $[D_6]$acetone, calibrated on the residual solvent peak (δ_H = 2.06) using standard Bruker pulse programs. NOESY and ROESY spectra were recorded with mixing times of 1.0 and 0.5 s, respectively. The pH-dependent experiments were performed in D_2O and the pH was adjusted by HNO_3 (0.1 M) and NaOH (0.1 M). The direct pH-meter readings were used to estimate the pK_a values (no correction for the pD value was performed). Elemental analyses were carried out by the Chemical Services Unit of the University College, Dublin. Mass spectra were obtained by the chemical services of the Gorlaeus Laboratories with a Finnigan MAT 900 instrument equipped with an electrospray interface (ESI). Hydrated $RuCl_3$ was used as received from Johnson and Matthey, Inc. 2-(Phenylazopyridine) and α-$[Ru(azpy)_2Cl_2]$ were synthesised according to published methods.[36−38] α-$[Ru(azpy)_2(NO_3)_2]$ was prepared as described previously.[9] 9-Methyladenine was prepared by methylation of adenine with methyl iodide.[39] *cis*-$[Ru(bpy)_2Cl_2]$ $2H_2O$ was prepared according to a literature procedure.[40]

α-$[Ru(azpy)_2$(9-MeAde)$](PF_6)_2$ (1): 9-Methyladenine (0.027 g, 0.18 mmol) was added to solution of α-$[Ru(azpy)_2(NO_3)_2]$ (0.10 g, 0.17 mmol) in 32 mL of water. The purple reaction mixture was stirred at 40 °C for 7 d. After filtration, a concentrated aqueous solution of NH_4PF_6 was added and the precipitate was collected by filtration. The purple solid was purified by dissolution in acetone and addition of diethyl ether, and this purification step was repeated several times. Yield 0.12 g (77%). ESI MS: *m*/*z* = 616 (92) $\{\alpha\text{-}[Ru(azpy)_2(9\text{-}MeAde)]^{2+} - H^+\}^+$, 308 (100) $\{\alpha\text{-}[Ru(azpy)_2(9\text{-}MeAde)]^{2+}\}$. $C_{28}H_{25}F_{12}N_{11}P_2Ru$ (906.58): calcd. C 37.1, H 2.78, N 17.0; found C 37.1, H 2.76, N 16.1.

***cis*-$[Ru(bpy)_2$(9-MeAde)$](PF_6)_2$ (2):** A mixture of *cis*-$[Ru(bpy)_2Cl_2]$ (0.100 g, 0.19 mmol) and 9-MeAde (0.035 g, 0.23 mmol) in 70 mL of water and 30 mL of ethanol was heated under reflux for 16 h. The reaction mixture was concentrated by rotary evaporation and filtered at room temperature before a concentrated aqueous solution of NH_4PF_6 was added. The resulting orange precipitate was isolated by filtration and recrystallised from acetone/water. The orange crystalline material was washed with diethyl ether. Yield: 0.08 g (68%). ESI MS: *m*/*z* = 562 (68) $\{cis\text{-}[Ru(bpy)_2(9\text{-}MeAde)]^{2+} - H^+\}^+$,281 (100) $\{cis\text{-}[Ru(bpy)_2(9\text{-}MeAde)]^{2+}\}$. $C_{26}H_{23}F_{12}N_9P_2Ru{\cdot}C_3H_6O{\cdot}2.5H_2O$ (852.53 + 58 + 45): calcd. C 36.8, H 2.77, N 13.3; found C 36.8, H 3.05, N 13.3.

Note added in proof (November 9, 2001): The proposed structural details of **1** and **2** as discussed in this paper are confirmed by the recently elucidated crystal structure of α-$[Ru(azpy)_2$(3-MeAde)$](PF_6)$, which will be reported soon.

Acknowledgments

We thank C. Erkelens and A. W. M. Lefeber for assistance with the NMR pulse techniques and Johnson Matthey Chemicals for a generous loan of $RuCl_3{\cdot}3H_2O$. This research was sponsored by the Council for Chemical Sciences of The Netherlands Organisation for Scientific Research. Additional support from COST Action D8 (1997−2001) (Chemistry of Metals in Medicine) is gratefully acknowledged.

Keywords: Manganese / Spectroelectrochemistry / Cyclic voltammetry / Homogeneous catalysis / Oxidations

A series of manganese complexes of the type MnL_3 were synthesised and characterised, with HL being (substituted) 2-(2′-hydroxyphenyl)oxazoline ligands. The molecular structures of [Mn(5′-Mephox)$_3$] and [Mn(5′-Clphox)$_3$] reveal their meridional configuration with a significant Jahn–Teller distortion. The ligand substituents exert a significant influence on the redox and catalytic properties of the manganese complexes. Cyclic voltammetry experiments show that the electrochemically quasi-reversible Mn^{II}/Mn^{III} and reversible Mn^{III}/Mn^{IV} redox couples shift towards higher potentials with more electron-withdrawing substituents. The same trend applies for the oxidation of the manganese(IV) complexes. Electrolysis experiments monitored with UV/Vis and EPR spectroscopy revealed that the reduction of the manganese(III) complexes to manganese(II), and their oxidation to manganese(IV) are both chemically reversible, while subsequent oxidation of the manganese(IV) species was found to be irreversible. All complexes are active oxidation catalysts with dihydrogen peroxide as the oxidant. In the oxidation of styrene, up to 220 turnover numbers were obtained towards styrene oxide. The turnover numbers in the oxidation reactions as well as the selectivity in the oxidation of styrene and *cis*-stilbene are affected significantly by the substituents, but no clear correlation with the electrochemical properties was observed. The most striking substituent effect is the higher stability of [Mn(5′-NO_2phox)$_3$] compared to the other complexes during styrene oxidation with dihydrogen peroxide in methanol.

Introduction

The presence of manganese at the active site of a wide variety of enzymes involved in oxidation catalysis has inspired the synthesis and study of manganese complexes as structural or functional models for these enzymes.[1,2] Several of these complexes have successfully been used in bleaching reactions[2] or in (asymmetric) oxidation reactions of organic substrates.[3] In most oxidation reactions, oxidants such as *tert*-butyl hydroperoxide, sodium hypochlorite, or iodosylbenzene are used. These reagents are relatively expensive and environmentally unacceptable. There is a wide interest in the use of cleaner and cheaper oxidants like molecular oxygen or hydrogen peroxide. Coordination compounds known to use hydrogen peroxide as oxidant in oxidation are manganese complexes with 1,4,7-trimethyl-1,4,7-triazacyclononane (Me_3tacn) and derived ligands and Mn−porphyrin catalysts.[4]

The introduction of substituents on the ligands has been shown to affect various properties of the catalysts. For instance, in the Mn−Me_3tacn complexes, the presence of substituents at the nitrogen atoms at the 1-, 4-, and 7-positions in the triazacyclononane ring is essential for the catalytic activity.[2] Another example is the introduction of halogen or nitro groups on porphyrin catalysts, which resulted in a higher resistance towards oxidative degradation.[5] The higher stability probably arises from a combination of electronic effects, replacement of C−H bonds by less oxidisable carbon−halogen bonds and steric crowding to reduce intermolecular catalyst degradation. As for porphyrin complexes, the catalytic efficiency of Mn−salen complexes has been reported to improve by introduction of electron-withdrawing nitro substituents.[6] However, in Mn(salen)-catalysed asymmetric epoxidation reactions, the enantiomeric excess (*ee*) of the product was significantly lower if catalysts containing ligands with electron-withdrawing substituents were used.[3,7] In fact, the most commonly used Mn−salen catalysts contain only alkyl, or alkyl and aryl groups as substituents. The use of these complexes results in high enanti-

omeric excesses of the product, but the catalyst stability is rather low, usually resulting in turnover numbers below 40 for reactions with dihydrogen peroxide as the oxidant.[3]

The didentate ligand 2-(2′-hydroxyphenyl)oxazoline (Hphox) has, like the salen ligands, a mixed N,O donor set. It is readily accessible and more stable against hydrolysis than the salen ligands.[8] Complexes with Hphox ligands and various transition metal complexes,[9,10] including manganese(III),[1,11−13] have been shown to catalyse oxidation reactions. We now wish to report novel manganese complexes MnL_3 [with HL being substituted 2-(2′-hydroxyphenyl)oxazoline ligands, see Scheme 1], their electrochemical properties, and their use as catalysts for oxidation reactions with dihydrogen peroxide as the oxidant.

Results and Discussion

Syntheses and Characterization of the [MnL_3] Complexes

Complexes of the type [MnL_3] were obtained by two different methods. The syntheses of [Mn(5′-Clphox)$_3$], [Mn(3′-Mephox)$_3$], [Mn(5′-Mephox)$_3$], and [Mn(5′-MeOphox)$_3$] from $Mn(OAc)_2$ and the appropriate ligand in methanol, are similar to the synthesis of [Mn(phox)$_3$].[12] The synthesis of [Mn(5′-NO_2phox)$_3$] and [Mn(3′,5′-dClphox)$_3$] was accomplished by applying the procedure used for the synthesis of [tris(8-oxyquinoline)−manganese(III)].[14] This latter method involves the addition of an ethanolic solution of the ligand to $Mn(OAc)_3$ in ethanol. In this manner, a dark brown precipitate could be isolated within a number of hours, which − after recrystallisation − afforded the desired compounds in good purity.

For all complexes, the parent peak observed in the electrospray mass spectra was the $[MnL_2]^+$ fragment. Further characterisation of the complexes was performed with IR and UV/Vis spectroscopy. The UV/Vis spectra of the complexes, except [Mn(5′-NO_2phox)$_3$], exhibit a ligand-to-metal charge transfer (LMCT) band around 370 nm and π→π* transitions of the ligand at around 310, 260, and 210 nm. No d-d transitions are observed due to the poor solubility of the complexes. The π→π* transitions are also present in the spectra of the free ligands. For [Mn(5′-NO_2phox)$_3$], two intense absorption bands at 340 and 222 nm are observed. These bands are also observed in the free ligand and can be ascribed to π→π* transitions (see the spectroelectrochemical section below). For all complexes, the manganese(III) oxidation state is confirmed by the absence of an EPR signal (at 77 K and 298 K) and by the magnetic moments at room temperature ranging from 4.10 μ_B ([Mn(3′,5′-dClphox)$_3$]) to 4.96 μ_B ([Mn(5′-MeOphox)$_3$]). These data are close to the spin-only value of 4.92 μ_B for high-spin manganese(III), the deviation being caused by orbital effects. ^{1}H NMR spectroscopy of the complexes have been used,[1,13] however, the paramagnetic ^{1}H NMR signals of these complexes could not be assigned; in order to assign the signals, systematic substitution of the hydrogen atoms is required.

Molecular Structure of [Mn(5′-Mephox)$_3$]

In the unit cell of [Mn(5′-Mephox)$_3$], with $Z = 4$, two similar, independent molecules are present. The crystallographic data are presented in Table 1.

A Platon[15] plot of one of the independent molecules of [Mn(5′-Mephox)$_3$] is shown in Figure 1. The molecular structure largely resembles that of [Mn(phox)$_3$],[12] having the MnN_3O_3 chromophore in a meridional configuration with a significant tetragonal distortion. The absence of

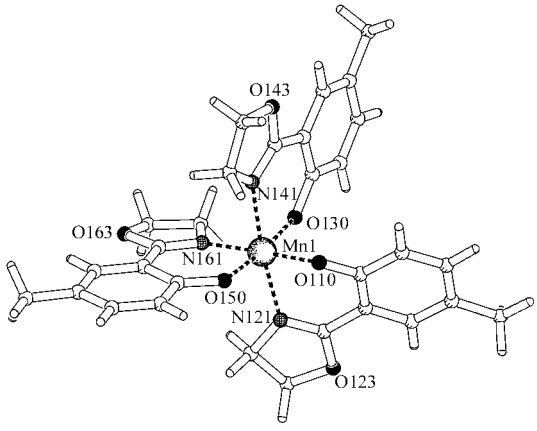

Figure 1. Platon[15] projection of one of the independent molecules of *mer*-[Mn(5′-Mephox)$_3$]

counter ions and the differences in the Mn−L bond lengths due the Jahn−Teller effect, characteristic for a d^4 configuration, confirm the manganese(III) oxidation state.

Selected bond lengths and bond angles for one [Mn(5′-Mephox)$_3$] molecule are given in Table 2. The differences in the ligand−metal bond lengths between the two independent molecules fall within 0.01 Å, while the bond angles deviate within a few degrees. The largest difference is found for the angle contained by the *trans*-O−Mn−O bonds, that expands from 173.15(18)° in one independent molecule to 177.7(2)° in the other. The structure of [Mn(5′-Mephox)$_3$] (Figure 1) has the elongated Jahn−Teller axis along the N(121)−Mn−N(141) bonds, as revealed by the long bond lengths Mn−N(121) and Mn−N(141) of 2.232(5) and 2.246(5) Å, respectively, compared to 2.033(6) Å for the Mn−N(161) bond. The Mn−O bond lengths are around 1.90 Å.

[a] Due to the presence of two independent molecules in the asymmetric unit, the donor atoms for [Mn(5′-Mephox)$_3$] listed in this Table should be read as O1xx and N1xx.

Molecular Structure of [Mn(5′-Clphox)$_3$]

The crystallographic data are presented in Table 1. The unit cell, with $Z = 2$, contains the two meridional stereoisomers of the complex. Selected bond lengths and bond angles are given in Table 2. The structure of [Mn(5′-Clphox)$_3$] (Figure 2) has the elongated Jahn−Teller axis along the N21−Mn−N41 axis as shown by the long bond lengths Mn−N21 and Mn−N41 of 2.238(6) and 2.244(5) Å, respectively, compared to 2.033(5) Å for the Mn−N61 bond. The Mn−O bond lengths are around 1.90 Å. The ligand bite angle varies between 84.0(2)° and 87.58(19)° for the O30−Mn1−N41 and O10−Mn1−N21 angles, respectively.

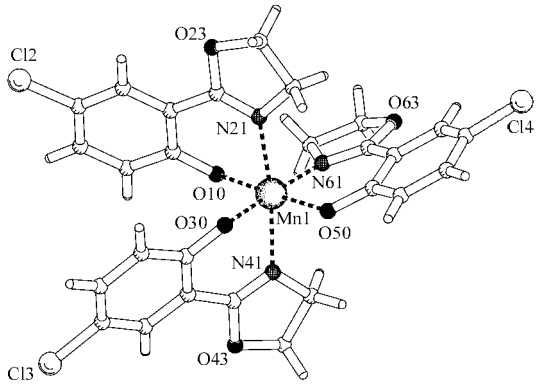

Figure 2. Platon[15] projection of *mer*-[Mn(5′-Clphox)$_3$]

As a matter of fact, all bond angles and distances for [Mn(5′-Mephox)$_3$] and [Mn(5′-Clphox)$_3$] are uneventful and very similar to those of [Mn(phox)$_3$].[12] The Mn−N bond lengths of these complexes of the type [MnL$_3$] vary from 2.033(5) to 2.060(2) Å for the equatorial Mn−N bonds and from 2.192(2) to 2.246(2) Å for the axial Mn−N bonds, while the Mn−O bond lengths are between 1.8823(17) and 1.958(2) Å.

Redox Properties of the [MnL$_3$] Complexes

Cyclic Voltammetry

The redox properties of the [MnL$_3$] complexes were investigated in acetonitrile. The potentials are given against Ag/AgCl. The investigated phox-type ligands were not redox-active between +2.00 and −2.00 V, except for H-5′-NO_2phox, which is reducible at −1.22 V (see below).

The [MnL$_3$] complexes show a (quasi)reversible one-electron cathodic wave ascribed to the reduction of manganese(III) to manganese(II), and a fully reversible one-electron anodic wave corresponding to the oxidation of manganese(III) to manganese(IV). The $E_{1/2}$ and ΔE_p values for these redox couples (Table 3) are strongly influenced by the ligand substituents.

The Mn^{III}/Mn^{IV} redox couples are fully reversible, as indicated by the peak-to-peak separations ranging from 65 to 90 mV and the i_{pc}/i_{pa} ratio of 1.[16] The linear relationship

Table 3. Electrochemical data for the oxidation and reduction of the manganese(III) centre of the [MnL$_3$] complexes

Complex[a]	Mn^{III}/Mn^{II} $E_{1/2}$	ΔE_p	Mn^{III}/Mn^{IV} $E_{1/2}$	ΔE_p

[Mn(3′-Mephox)$_3$]	−0.52	230	+0.40	90
[Mn(5′-MeOphox)$_3$]	−0.49	220	+0.41	90

[a] In acetonitrile solutions containing 0.05 M Bu_4NPF_6 at a scan rate of 0.10 V/s; $E_{1/2}$ in V (vs. Ag/AgCl), ΔE_p in mV.

between the peak current i_{pa} and the square root of the scan rate (v) in the range of 0.2 to 2 V/s is indicative of a diffusion-controlled process.[16] The marked positive shift of both the reduction and oxidation potentials of the $[MnL_3]$ complexes with the electron-withdrawing substituents on the phox ligands closely resembles the redox properties of related mononuclear manganese(IV)[17] and manganese(III)[18,19] complexes with substituted phenolate ligands showing the same trend. For the Mn^{III}/Mn^{II} redox couples, large differences between the complexes are observed in the ΔE_p value. For the Mn−phox complexes with the electron-withdrawing substituents, the peak-to-peak separation lies between 80 and 120 mV, just slightly above the value expected for a electrochemically reversible process.[16] However, the complexes with more electron-donating ligands show much larger peak-to-peak separation, indicating quasi-reversible redox processes.

At higher potentials, yet another anodic process is observed for the formally manganese(IV) centre. The ligand substituents again exert a significant effect on the oxidation potentials (Table 4). No clear correlation exists in this case between the substituent's nature and the ΔE_p values.

Table 4. Electrochemical data for the Mn−phox complexes: electrochemically irreversible oxidations of the manganese(IV) species at higher potentials

Complex[a]	E_{pa}	E_{pc}	ΔE_p

$[Mn(5'\text{-}Clphox)_3]^+$	+1.31	+1.16	150
$[Mn(phox)_3]^+$	+1.30	+1.06	240
$[Mn(5'\text{-}Mephox)_3]^+$	+1.13	+0.95	180
$[Mn(3'\text{-}Mephox)_3]^+$	+1.17	+0.90	270
$[Mn(5'\text{-}MeOphox)_3]^+$	+0.98	−	−

[a] In acetonitrile solutions containing 0.05 M Bu_4NPF_6 at a scan rate of 0.10 V/s; E_{pa} and E_{pc} in V (vs. Ag/AgCl), ΔE_p in mV.

The oxidation of the manganese(IV) complexes is chemically irreversible, as evidenced by the peak-current ratios i_{pc}/i_{pa}, significantly smaller than 1 at moderate scan rates. The cyclic voltammogram of $[Mn(5'\text{-}MeOphox)_3]$ does not show any cathodic counter-peak on the reverse scan beyond the oxidation of the manganese(IV) compound.

Reduction of the formally manganese(II) species was observed, in the available potential window, only for the complexes with the most electron-withdrawing phox ligands, $[Mn(3',5'\text{-}dClphox)_3]$ and $[Mn(5'\text{-}NO_2phox)_3]$ (Figure 3). In both cases, the reduction of the manganese(II) species consumed more than one electron, as deduced from the comparison of the corresponding cathodic peak currents with those for the reversible Mn^{III}/Mn^{II} and Mn^{III}/Mn^{IV} couples. The reduction of $[Mn(5'\text{-}NO_2phox)_3]^-$ at $E_{pc} = -1.56$ V produced a species that could be further reduced at $E_{pc} = -1.81$ V. The latter cathodic step is chemically reversible, pointing to the reduction of the nitro groups on the phox ligands. The cyclic voltammogram of the uncoordinated H-5′-NO_2phox ligand shows an irreversible reduction step at $E_{pc} = -1.22$ V, followed by a quasi-reversible

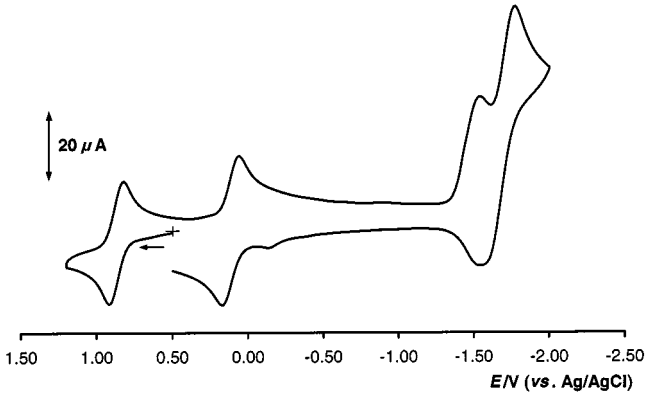

Figure 3. Cyclic voltammogram of $[Mn(5'\text{-}NO_2phox)_3]$ at a scan rate of 0.10 V/s in an acetonitrile solution containing 0.05 M Bu_4NPF_6

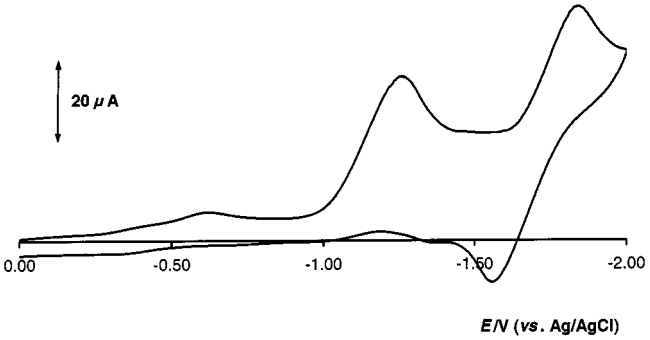

Figure 4. Cyclic voltammogram of H-5′-NO_2phox at a scan rate of 0.10 V/s in an acetonitrile solution containing 0.05 M Bu_4NPF_6

step at $E_{1/2} = -1.68$ V (Figure 4). The potential of this quasi-reversible step is nearly identical with that of the reversible cathodic process ($E_{1/2} = -1.66$ V), following the irreversible reduction of $[Mn(5'\text{-}NO_2phox)_3]^-$, suggesting that the irreversible process in the complex results in dissociation of at least one $[5'\text{-}NO_2phox]^-$ ligand. This anionic compound is obviously also produced during the irreversible reduction of H-5′-NO_2phox at $E_{pc} = -1.22$ V. Further evidence for this explanation was obtained from corresponding UV/Vis spectroelectrochemical experiments (vide infra). This behaviour is in agreement with that reported for the 4-nitro-thiophenolate anion ($[4\text{-}O_2NC_6H_4S]^-$), which can be reduced, reversibly, at the nitro group.[20] The latter cathodic process also occurred upon the reduction of the complex $[Pt^{II}(bpy^{\cdot-})(4\text{-}O_2NC_6H_4S)_2]^-$.[20] In view of these arguments, it is not surprising that the irreversible reduction of $[Mn(3',5'\text{-}dClphox)_3]^-$ at $E_{pc} = -1.86$ V is not followed by such a reversible cathodic step because further reduction of the liberated $[3',5'\text{-}dClphox]^-$ ligand is not facile. The reduction of the latter Mn^{II} complex was followed instead by a minor, irreversible wave at $E_{pc} = -2.10$ V, belonging to a secondary product that remains unassigned.

The strong dependence of the electrode potentials on the electron-withdrawing (NO_2, Cl) or electron-donating (Me, MeO) character of the phox substituents implies that the frontier molecular (redox) orbitals of the high-spin man-

ganese(III) complexes possess a significant contribution from the phox ligands. This qualitative presumption has been indeed confirmed by Extended Hückel calculations with the programme CACAO,[21] using the X-ray structure data of $[Mn(phox)_3]$. The calculated data show that the closely spaced HOMO and HOMO-1 ($\Delta E = 0.064$ eV) frontier orbitals of the complex are delocalised over the manganese(III) ion and the phox ligands. The one-electron containing HOMO possesses 69% Mn and 22% phenolate character. The singly occupied HOMO-1 has a similar character, with a slightly larger phenolate contribution (27%) and smaller Mn contribution (65%). The oxidation and reduction processes of the studied $[ML_3]$ complexes to the manganese(IV) and manganese (II) complexes, respectively, may therefore be assigned as predominantly metal-localized, although with a significant ligand influence.

UV/Vis Spectroelectrochemistry with $[Mn(phox)_3]$ and $[Mn(5'\text{-}NO_2phox)_3]$

A valuable approach in investigating the redox behaviour of the Mn−phox complexes of the type $[MnL_3]$ is to monitor the spectroscopic changes during electrolysis with methods such as UV/Vis and EPR spectroscopy. With these spectroelectrochemical methods, the chemical reversibility of the redox processes can be studied on the time scale of minutes. UV/Vis spectroelectrochemistry has been employed for mononuclear manganese complexes with nitrogen ligands[22] and mixed oxygen/nitrogen ligands.[23] To obtain more insight into the redox behaviour of $[Mn(phox)_3]$ and $[Mn(5'\text{-}NO_2phox)_3]$, the changes in their UV/Vis spectra were studied during electrolysis in acetonitrile at room temperature. The results are summarized in Table 5.

Table 5. UV/Vis absorption bands of the formally manganese(II), manganese(III), and manganese(IV) compounds, recorded in the course of the spectroelectrochemical experiments

Complex	λ_{max} (ε)[a]
$[Mn(phox)_3]^+$	216, 293 (1.2×10^4), 380 (sh), 430 (sh), 575 (4.0×10^3)
$[Mn(phox)_3]$	216, 319 (9.7×10^3), 360 (sh)
$[Mn(phox)_3]^-$	222, 349 (1.5×10^4)
$[Mn(5'\text{-}NO_2phox)_3]^+$	211, 230, 320 (4.0×10^4), 390 (sh), 582 (7.6×10^3)
$[Mn(5'\text{-}NO_2phox)_3]$	222, 358 (4.4×10^4)
$[Mn(5'\text{-}NO_2phox)_3]^-$	222, 340 (sh), 397 (6.2×10^4)

[a] In acetonitrile; λ_{max} in nm, ε in $M^{-1}\cdot cm^{-1}$; the ε values for the bands around 210−220 nm vary depending on the concentration of the complexes; sh = shoulder.

The reduction of $[Mn(phox)_3]$ at −0.55 V resulted in a colour change from green to light-brown. The most remarkable feature in the UV/Vis spectra of the manganese(II) product is the appearance of a peak at 349 nm, attributed to an LMCT transition. The π→π* transition of the ligand shifted slightly from 216 to 222 nm. Isosbestic points are observed at 381, 329, 242, and 214 nm. Reoxidation of the stable manganese(II) species at −0.29 V resulted in complete reappearance of the initial UV/Vis spectrum of $[Mn(phox)_3]$.

The reduction of $[Mn(5'\text{-}NO_2phox)_3]$ at +0.08 V resulted in a yellow solution. In the UV/Vis spectra, the shift of the absorption peak at 358 nm to 397 nm is attributed to changes in the intense π→π* transition of the nitro group (Figure 5).

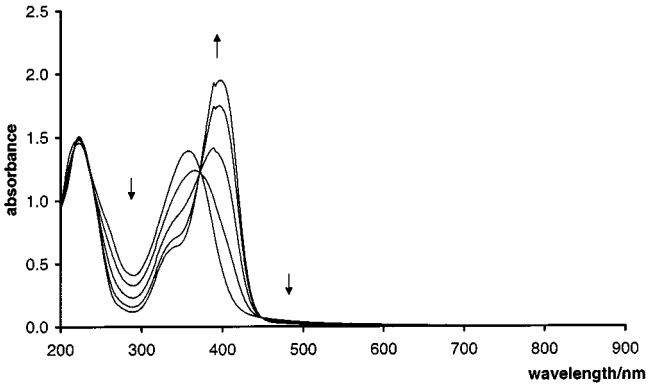

Figure 5. UV/Vis spectroscopic changes recorded during the electrochemical reduction of $[Mn(5'\text{-}NO_2phox)_3]$ from manganese(III) to manganese(II)

The peak at 222 nm, ascribed to the aromatic π→π* transition, hardly changes. Two isosbestic points occur at 372 and 449 nm. The presence of the π→π*(NO_2) absorption band makes it difficult to compare the spectra of the manganese(II) complexes $[Mn(5'\text{-}NO_2phox)_3]^-$ and $[Mn(phox)_3]^-$. However, the shoulder in the spectrum of the manganese(II) species at 340 nm has presumably the same origin as the peak at 349 nm in the UV/Vis spectrum of $[Mn(phox)_3]^-$. This observation is important, because it indicates that one-electron-reduced $[Mn(phox)_3]^-$ and $[Mn(5'\text{-}NO_2phox)_3]^-$ are electronically similar. Both anionic complexes are also inherently stable.

Cyclic voltammetry revealed that the anionic complexes $[Mn(3',5'\text{-}dClphox)_3]^-$ and $[Mn(5'\text{-}NO_2phox)_3]^-$ undergo irreversible reduction that may result in dissociation of one or more anionic phox ligands (see previous section). This assumption could be confirmed by UV/Vis spectroelectrochemistry. The UV/Vis spectra recorded during the reduction of $[Mn(5'\text{-}NO_2phox)_3]^-$ at −1.56 V exhibit isosbestic points at 483, 408, and 207 nm and a shift of the intense absorption band due to the π→π*(NO_2) transition from 397 nm to 426 nm (Figure 6).

Importantly, the UV/Vis spectrum of the product (absorption maxima at 426, 330 and 228 nm) is identical with that of $[5'\text{-}NO_2phox]^-$ recorded after the one-electron reduction of H-5′-NO_2phox (Figure 6, inset). This result implies that the irreversible reduction of $[Mn(5'\text{-}NO_2phox)_3]^-$ indeed affords the uncoordinated $[5'\text{-}NO_2phox]^-$ ligand, which dissociates due to the decreased positive charge on the manganese centre in the primarily $Mn^{II}\rightarrow Mn^{I}$ electron-transfer step. The liberated anion $[5'\text{-}NO_2phox]^-$ is further reversibly reduced at the NO_2 group at $E_{1/2} = -1.66$ V, resulting in the formation of $[5'\text{-}NO_2phox]^{2-}$. As expected, the latter reduction process increases the energy of the

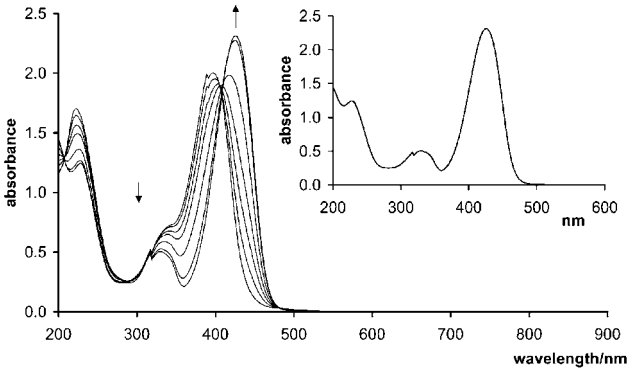

Figure 6. UV/Vis spectroscopic changes recorded during the in situ irreversible reduction of $[Mn(5'\text{-}NO_2phox)_3]^-$; inset: UV/Vis spectrum of $[5'\text{-}NO_2phox]^-$ formed during the irreversible reduction of $[H\text{-}5'\text{-}NO_2phox]^-$

$\pi\rightarrow\pi^*(NO_2)$ electronic transition[20] and the corresponding absorption band shifts from 426 nm for $[5'\text{-}NO_2phox]^-$ to 291 nm for $[5'\text{-}NO_2phox]^{2-}$.

The oxidation of the Mn−phox complexes to the manganese(IV) species is fully reversible according to cyclic voltammetry. The spectroelectrochemical experiments show that this also applies for the time scale of minutes. In the UV/Vis spectra recorded during the stepwise electrolytic oxidation of $[Mn(5'\text{-}NO_2phox)_3]$ at 0.90 V, two isosbestic points are observed at 331 and 408 nm (Figure 7).

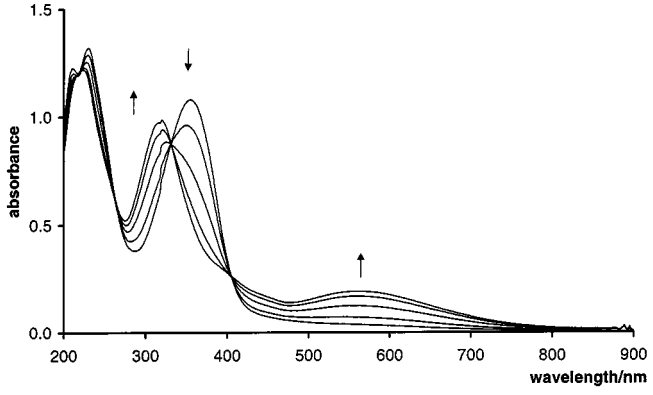

Figure 7. UV/Vis spectroscopic changes recorded during the electrochemical oxidation of $[Mn(5'\text{-}NO_2phox)_3]$ from manganese(III) to manganese(IV)

The most important feature in the UV/Vis spectrum of the manganese(IV) complex is the new broad absorption band at 582 nm; based on its intensity, it can be assigned to an LMCT transition. This visible absorption results in the dark blue colour of the complex, also known for some other manganese(IV) complexes.[24,25] The $\pi\rightarrow\pi^*(NO_2)$ transition shifts from 358 to 320 nm. Further oxidation of $[Mn(5'\text{-}NO_2phox)_3]^+$ at +1.59 V led to irreversible disappearance of the LMCT band and degradation of the complex.

UV/Vis spectra collected during the stepwise oxidation of $[Mn(phox)_3]$ at +0.52 V, show new absorption maxima at 575 and 293 nm. Isosbestic points are present at 371, 332 and 277 nm. The new broad peak at 575 nm corresponds to that at 582 nm in the UV/Vis spectrum of the dark blue $[Mn(5'\text{-}NO_2phox)_3]^+$ complex, indicating that similar complexes are formed. The $[Mn(phox)_3]^+$ compound shows a small oxidation wave at +1.30 V. The UV/Vis spectra taken during this anodic step reveal a new absorption band at 424 nm and isosbestic points at 470 and 371 nm, while all other UV/Vis bands are diminished. Continued anodic scan shows a large wave at +1.72 V, with a peak current of approximately three times the intensity compared to the reversible one-electron oxidation of manganese(III) to manganese(IV). Similar to the oxidation of $[Mn(5'\text{-}NO_2phox)_3]^+$, irreversible disappearance of all UV/Vis absorption bands indicate oxidative degradation of the phox derivative.

EPR Spectroelectrochemistry with $[Mn(phox)_3]$ and $[Mn(5'\text{-}NO_2phox)_3]$

The UV/Vis spectroelectrochemical experiments prove that the manganese(II) and manganese(IV) complexes were stable on a time scale of several minutes. For EPR spectroelectrochemistry butyronitrile was used due to fairly good solubility of the complexes in this solvent, particularly at low temperatures. As no EPR signals of the starting complexes or their reduced or oxidized forms were observed at 223 K, EPR spectroelectrochemical experiments were performed at 77 K in a solid matrix of the frozen solutions that had first been subjected to bulk electrolysis at the E_{pa} or E_{pc} values of the precursor manganese(III) compounds upon the UV/Vis spectroscopic control (see Figures 5 and 7). The EPR spectra of the stable manganese(II) complexes show a typical six-line hyperfine signal due to coupling of the electron spin with the nuclear spin of ^{55}Mn ($I = 5/2$).[26] The EPR signals of both $[Mn(5'\text{-}NO_2phox)_3]^-$ and $[Mn(phox)_3]^-$ occur at $g = 2.00$ with $a_{Mn} = 9.0$ mT.

At 77 K, no EPR signals were observed for the oxidized manganese(IV) products $[Mn(phox)_3]^+$ and $[Mn(5'\text{-}NO_2phox)_3]^+$, even though spectra are commonly observed for other manganese(IV) complexes.[26] Their absence in this case cannot be readily explained. The cyclovoltammetric and UV/Vis spectroelectrochemical data nevertheless reveal that oxidation of $[Mn(phox)_3]$ and $Mn(5'\text{-}NO_2phox)_3]$ results in the formation of stable isostructural manganese(IV) complexes, so relaxation phenomena are likely responsible for this observation.

Catalytic Studies with the $[ML_3]$ Complexes

Oxidation of Styrene

The effect of the ligand substituents on the catalytic activity of the studied complexes $[MnL_3]$ was investigated for the oxidation of styrene in methanol at room temperature, as well as in acetone at 0 °C. The successful use of acetone as a solvent at 0 °C has been reported for oxidations with dihydrogen peroxide catalysed by Mn−Me_3tacn complexes.[27] Such reaction conditions also proved to be very suitable for the Mn−phox-catalysed oxidations. The catalytic efficiency for the different $[MnL_3]$ complexes, ex-

Table 6. Turnover numbers in the oxidation of styrene with dihydrogen peroxide in methanol or acetone catalysed by Mn−phox complexes

Catalyst	Methanol[a] Styrene oxide	Benzaldehyde	Acetone[b] Styrene oxide	Benzaldehyde	Diol[c]
[Mn(5′-NO_2phox)$_3$]	34[d]	2	207	5	18
[Mn(3′,5′-dClphox)$_3$]	23	2	108	4	5
[Mn(5′-Clphox)$_3$]	27	2	192	4	12
[Mn(phox)$_3$]	34	2	220	5	11
[Mn(5′-Mephox)$_3$]	24	2	181	4	9
[Mn(3′-Mephox)$_3$]	27	2	80	3	3
[Mn(5′-MeOphox)$_3$]	5	2	76	2	5

[a] Reactions were carried out under standard conditions: 14 μmol of the indicated Mn−phox complex was dissolved, with stirring, in 20 mL of methanol at room temperature. Subsequently, 14 mmol of substrate, 2.0 mmol of 1-MeIm, and 21 mmol of dihydrogen peroxide were added (t = 0); turnover numbers are the total turnover numbers obtained at t = 15 min. [b] Reactions were carried out under standard conditions: 10 mL of acetone and 21 mmol of dihydrogen peroxide were stirred at 0 °C for 30 min. Subsequently, 14 mmol of substrate, 2.0 mmol of 1-MeIm, and 14 μmol of the indicated Mn−phox complex were added (t = 0); turnover numbers are the total turnover numbers obtained at t = 15 min. [c] 1-Phenyl-1,2-ethanediol. [d] 72, 3, and 2 turnover numbers towards styrene oxide, benzaldehyde, and 1-phenyl-1,2-ethanediol, respectively, as determined at t = 120 min (end of the reaction).

Table 7. Turnover numbers and *cis*/*trans* ratios of the products in the oxidation of *cis*-stilbene by Mn−phox complexes with dihydrogen peroxide

Complex[a]	*cis*-Oxide	*trans*-Oxide	Benzaldehyde	Ratio *cis*/*trans*
[Mn(5′-NO_2phox)$_3$]	32	64	2	1:2.0
[Mn(3′,5′-dClphox)$_3$]	22	37	2	1:1.7
[Mn(5′-Clphox)$_3$]	18	50	2	1:2.8
[Mn(phox)$_3$]	17	50	2	1:2.9
[Mn(5′-Mephox)$_3$]	13	46	1	1:3.5
[Mn(3′-Mephox)$_3$]	9	31	2	1:3.4
[Mn(5′-MeOphox)$_3$]	4	19	1	1:4.8

[a] Reactions were carried out by stirring 10 mL of acetone and 21 mmol of H_2O_2 at 0 °C: after 30 min, subsequently 5.0 mmol of the substrate, 2.0 mmol of 1-methylimidazole, and 14 μmol of the complex were added (t = 0); turnover numbers are the total turnover numbers obtained at t = 15 min.

pressed in turnover numbers, is listed in Table 6. All reactions were performed in the presence of 2.0 mmol of 1-methylimidazole (1-Meim). An alkaline additive is required for reactions with manganese catalysts and H_2O_2; it is thought that the additive might act as a base and as an axial ligand.[12]

Small amounts of the side product benzaldehyde were obtained in all reactions. For the reactions in acetone, 1-phenyl-1,2-ethanediol was also detected as a side product. The turnover numbers towards the main product, styrene oxide, are significantly influenced by the substituents on the ligands in the [MnL_3] complexes. For the reactions in methanol, all Mn−phox complexes gave turnover numbers towards styrene oxide between 23 and 34 after 15 min, which represents an efficiency of approximately 2% relative to dihydrogen peroxide. The results in acetone show a dramatic increase in turnover numbers compared to the reactions in methanol. The efficiency relative to the oxidant increased simultaneously, varying from 5 to 15%.

In both solvents, [Mn(phox)$_3$] and [Mn(5′-NO_2phox)$_3$] show the highest efficiency. The use of Mn−phox complexes with more electron-donating ligands resulted in a significant decrease in efficiency compared to [Mn(phox)$_3$], while the use of complexes with electron-withdrawing ligands only resulted in a slightly lower efficiency. The turnover numbers obtained with the least efficient Mn−phox catalyst, [Mn(5′-MeOphox)$_3$], are relatively more enhanced in acetone compared to methanol. For the reactions in acetone, the influence of the presence of a substituent at the 3′-position is more pronounced compared to the reactions in methanol. The complexes with such ligands, [Mn(3′,5′-dClphox)$_3$] and [Mn(3′-Mephox)$_3$], exhibited much lower efficiency compared to complexes with a substituent at the 5′-position only.

Oxidation of Stilbene

In oxidation reactions of *cis*-alkenes catalysed by manganese complexes, such as Mn−salen,[7] isomerisation can occur, resulting in both *cis*- and *trans*-epoxides. For the Mn−salen complexes, this effect has been studied in detail. It has been found that the *cis*/*trans* ratio is mainly influenced by the reaction conditions,[28] the oxidant,[28,29] and the substituents on the ligand.[6,30] The oxidation of *cis*-stilbene with Mn−phox complexes results in both *cis*- and *trans*-stilbene oxide. Oxidation of *cis*-stilbene was performed with all studied [MnL_3] complexes (Table 7).

In all described reactions more *trans*- than *cis*-stilbene oxide was formed, together with small amounts of the cleavage product benzaldehyde. The ligand substituents clearly

affected the *cis*/*trans* ratio of the stilbene oxides, the complexes with electron-withdrawing ligands produced a larger amount of *cis*-stilbene oxide, while the reaction with [Mn(5′-MeOphox)$_3$] resulted in the largest relative fraction of *trans*-stilbene oxide.

The catalytic activity of the unsubstituted precursor catalyst [Mn(phox)$_3$] under similar reaction conditions for the oxidation of *trans*-stilbene and cyclohexene was also studied. Oxidation of *trans*-stilbene resulted in a TON of 49 towards the *trans*-stilbene epoxide and a TON of 3 towards the by-product benzaldehyde. Oxidation of cyclohexene with [Mn(phox)$_3$] gave a TON of 98 towards the epoxide, and additionally the allylic oxidation products were formed with a TON of 28.

Catalyst Stability

In both methanol and acetone, the catalytic reactions with most of the Mn−phox complexes were very fast during the first few minutes, and no clear differences in the reaction rates were found. After 15 min, no catalytic activity could be observed. The only exception is the [Mn(5′-NO$_2$phox)$_3$] catalyst, which remained active for up to 1 h. For [Mn(phox)$_3$] and [Mn(5′-NO$_2$phox)$_3$], the total turnover numbers to styrene oxide in time is depicted in Figure 8.

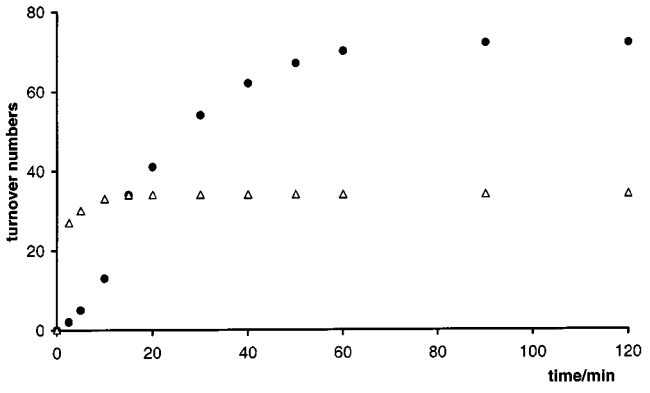

Figure 8. Oxidation of styrene with dihydrogen peroxide in methanol: cumulative turnover number in time towards styrene oxide; • = [Mn(5′-NO$_2$phox)$_3$] as catalyst; Δ = [Mn(phox)$_3$] as catalyst

The oxidation reaction with [Mn(phox)$_3$] was initially very fast, but the activity quickly diminished, with a concomitant loss of colour. In contrast, a significantly slower colour change was observed for the [Mn(5′-NO$_2$phox)$_3$]-catalysed reaction. The oxidation with this catalyst had a short induction period. Catalytic activity persisted for 1 h, resulting in a total turnover number of 72 towards styrene oxide. With both catalysts, benzaldehyde was formed in the first minutes of the reaction, while 1-phenyl-1,2-ethanediol was formed in a gradually increasing amount.

Concluding Remarks

A series of novel, readily available manganese complexes of the type [MnL$_3$] with phenol-substituted 2-(2′-hydroxyphenyl)oxazoline ligands have been synthesized. The complexes are nearly isostructural, as evidenced by the results from X-ray crystallographic studies of [Mn(phox)$_3$],[12] [Mn(5′-Mephox)$_3$] and [Mn(5′-Clphox)$_3$].

The substituents on the phenolate ring of the ligands influence the redox properties of the complexes. The electrochemically quasi-reversible Mn^{II}/Mn^{III} and reversible Mn^{III}/Mn^{IV} redox couples sensitively shifted towards higher potentials with more electron-withdrawing substituents. The same trend applies for the irreversible oxidation of the manganese(IV) complexes. (Spectro)electrochemical studies show that the manganese centre could coordinate all three anionic phox ligands in the formal oxidation states Mn^{II}, Mn^{III}, and Mn^{IV} without any pronounced change of the complex structure. The UV/Vis spectra document that reoxidation of the manganese(II) product and the back-reduction of the manganese(IV) species led to the recovery of the parent [MnL$_3$] species, proving that these redox processes are chemically reversible. In contrast to this stability, oxidation of manganese(IV) or reduction of manganese(II) resulted in decomposition, in the latter case involving the dissociation of at least one anionic [5′-NO$_2$phox]$^-$ ligand. The dissociation of the anionic phox ligand(s) probably also takes place during the reduction of [Mn(3′,5′-dClphox)$_3$]$^-$. The other formally manganese(II) anionic complexes were reduced at significantly more negative potentials and the corresponding cathodic waves were not observed within the available potential window. Ligand dissociation during the reduction of the manganese(II) complexes is not surprising, as the manganese(I) ion is hardly capable of coordinating exclusively strong σ- and π-donors, such as the anionic phox ligands.

The Mn−phox complexes are all active catalysts for the oxidation of styrene and *cis*- and *trans*-stilbene with dihydrogen peroxide as the oxidant. The substituents on the phenolate ring of the ligands significantly influenced the turnover numbers and selectivities in the oxidation reactions. The effect of the ligand substituents on the turnover numbers is roughly similar in acetone and methanol. However, considerably higher turnover numbers were obtained for styrene oxidation in acetone than in methanol, resulting in a turnover number of up to 220 towards styrene oxide with [Mn(phox)$_3$] as the catalyst, which also corresponds to increased efficiency towards dihydrogen peroxide from 2 to 15%. Although a clear general pattern can be noticed, exact correlation between the redox properties of the complexes and the turnover numbers and selectivities obtained in oxidation catalysis could not be found. This variation was probably caused by the effects that the ligands have on various reactions in solution, such as equilibria between different complexes in solution, dihydrogen peroxide decomposition and oxidation of the substrate.

The most remarkable substituent effect, the higher stability against oxidative degradation of the Mn−phox complex with the most electron-withdrawing substituents, [Mn(5′-NO$_2$phox)$_3$], was observed both in the electrochemical experiments and in oxidation catalysis. Further studies

on stability and decomposition will be published elsewhere.[31]

Experimental Section

General Remarks: The ligands were synthesised according to the synthesis for Hphox.[8] The synthesis of $[Mn(phox)_3]$ has been published before.[12] Solvents of technical grade, p.a. grade, or, for acetonitrile (Rathburn), HPLC grade quality were used as received. All p.a. grade solvents were purchased from Baker, except for acetone (Acros). Deuterated solvents for NMR measurements were obtained from Euriso-top ($CDCl_3$ and $[D_6]$DMSO) or Cambridge Isotope Laboratories, Inc. (CD_3OD). The following materials were supplied by Merck: Na_2SO_4, ferrocene, $Mn(OAc)_2{\cdot}4H_2O$, 2-aminoethanol, dihydrogen peroxide (35% in water), styrene, benzyl alcohol, and benzaldehyde. All other chemicals used were purchased from Acros.

Ligands

H-5′-NO_2phox: Starting from 15.35 g (78 mmol) of methyl 5-nitrosalicylate: Yield 7.21 g (35 mmol, 45%) of a yellow powder. ^{1}H NMR ($[D_6]$DMSO): δ = 4.17 (t, 2 H, NCH_2), 4.53 (t, 2 H, OCH_2), 7.07 (d, 1 H, H3′), 8.25 (dd, 1 H, H4′), 8.58 (d, 1 H, H6′), 13.1 (br, 1 H, OH). ^{13}C NMR ($[D_6]$DMSO): δ =52.0 (C4), 68.2 (C5), 109.4 (C1′), 118.5 (C3′), 124.3 (C5′), 128.9 (C6′), 138.1 (C4′), 164.9 (C2′), 165.9 (C2).

H-3′,5′-dClphox: Starting from 18.23 g (82 mmol) of methyl 3,5-dichlorosalicylate: Yield 16.35 g (70 mmol, 85%) of a pale yellow solid. ^{1}H NMR ($CDCl_3$): δ = 4.13 (t, 2 H, NCH_2), 4.47 (t, 2 H, OCH_2), 7.43 (d, 1 H, H6′), 7.52 (d, 1 H, H4′), 12.6 (br, 1 H, OH). ^{13}C NMR ($CDCl_3$): δ =53.3 (C4), 67.4 (C5), 112.3 (C1′), 122.4 (C3′), 122.9 (C5′), 126.0 (C6′), 132.9 (C4′), 154.6 (C2′), 165.1 (C2).

H-5′-Clphox: Starting from 10.69 g (58 mmol) of methyl 5-chlorosalicylate: Yield 7.40 (38 mmol, 66%) of a pale pink solid. ^{1}H NMR ($[D_6]$DMSO): δ = 4.07 (t, 2 H, NCH_2), 4.48 (t, 2 H, OCH_2), 7.02 (d, 1 H, H3′), 7.49 (m, 2 H, CH4′, H6′), 12.28 (s, 1 H, OH). ^{13}C NMR (D_6[DMSO]): δ =53.0 (C4), 67.3 (C5), 111.3 (C1′), 118.3 (C4′), 122.2 (C5′), 126.6 (C6′), 133.1 (C4′), 157.8 (C2′), 164.3 (C2).

H-5′-Mephox: Starting from 7.83 g (47 mmol) of methyl 5-methylsalicylate: Yield 6.18 g (35 mmol, 74%) of a pale pink solid. ^{1}H NMR ($CDCl_3$): δ = 2.23 (s, 3 H, CH_3), 4.02 (t, 2 H, NCH_2), 4.37 (t, 2 H, OCH_2), 6.79 (d, 1 H, H4′), 7.14 (d, 1 H, H3′), 7.39 (s, 1 H, H6′). ^{13}C NMR ($CDCl_3$): δ =20.3 (CH_3), 53.4 (C4), 66.6 (C5), 110.2 (C1′), 116.4 (C3′), 127.6 (C5′), 127.8 (C6′), 134.0 (C4′), 157.6 (C2′), 166.1 (C2).

H-3′-Mephox: Starting from 7.18 g (55 mmol) of ethyl 3-methylsalicylate: Yield 6.23 g (35 mmol, 88%) of a pale pink solid. ^{1}H NMR ($CDCl_3$): δ = 2.27 (s, 3 H, CH_3), 4.02 (t, 2 H, NCH_2), 4.35 (t, 2 H, OCH_2), 6.75 (t, 1 H, H5′), 7.20 (d, 1 H, H4′), 7.47 (d, 1 H, H6′). ^{13}C NMR ($CDCl_3$): δ =15.9 (CH_3), 53.4 (C4), 66.7 (C5), 110.0 (C1′), 118.0 (C5′), 125.5 (C6′), 125.7 (C3′), 134.1 (C4′), 158.1 (C2′), 166.5 (C2).

H-5′-MeOphox: Starting from 8.92 g (49 mmol) of methyl 5-methoxysalicylate: Yield 3.50 g (18 mmol, 37%) of a pale pink solid. ^{1}H NMR (CD_3OD): δ = 3.72 (s, 3 H, $ArOCH_3$), 4.05 (t, 2 H, NCH_2), 4.41 (t, 2 H, OCH_2), 6.84 (d, 1 H, H3′), 6.96 (dd, 1 H, H4′), 7.12 (d, 1 H, H6′). ^{13}C NMR (CD_3OD): δ =54.5 (C4), 56.4 ($ArOCH_3$), 68.2 (C5), 111.6 (C1′), 112.3 (C6′), 118.4 (C3′), 121.7 (C4′), 153.2 (C2′), 154.8 (C5′), 166.9 (C2).

General Synthetic Procedure for the Complexes $[Mn(5'\text{-}NO_2phox)_3]$ and $[Mn(3',5'\text{-}dClphox)_3]$: The appropriate ligand (3.0 mmol), dissolved in 10 mL of ethanol, was added to a solution of $Mn(OAc)_3{\cdot}2H_2O$ (0.27 g, 1.0 mmol) in 10 mL of ethanol. The product slowly precipitated as a black solid. Recrystallisation from ethanol afforded a black crystalline product.

$[Mn(5'\text{-}NO_2phox)_3]$: Yield 0.51 g (0.75 mmol, 75%). IR: $\tilde{\nu}$ = 1622 (s), 1312 (s), 1121 (m), 1058 (m), 871 (m), 838 (m), 714 cm^{-1} (m). $C_{27}H_{21}MnN_6O_{12}$: calcd. C 47.94, H 3.13, N 12.42; found C 47.68, H 3.37, N 12.12. ES-MS: *m*/*z*: 468 $[Mn(5'\text{-}NO_2phox)_2]^+$, 209 [H-5′-$NO_2$phox + H^+]. μ_{eff} = 4.87 μ_B (at 22.5 °C).

$[Mn(3',5'\text{-}dClphox)_3]$: Yield 0.51 g (0.68 mmol, 68%). IR: $\tilde{\nu}$ = 1617 (s), 1582 (m), 1437 (s), 1418 (s), 1370 (m), 1308 (m), 1234 (s), 1194 (m), 954 (m), 872 (m), 784 (s), 751 (m), 738 cm^{-1} (m). $C_{27}H_{18}Cl_6MnN_3O_6$: calcd. C 43.35, H 2.43, N 5.62; found C 43.08, H 2.45, N 5.31. ES-MS: *m*/*z*: 519, 517, 515 $[Mn(3',5'\text{-}dClphox)_2]^+$, 234, 232 [H-3′,5′-dClphox + H^+]. μ_{eff} = 4.10 μ_B (at 22.5 °C).

$[Mn(5'\text{-}Clphox)_3]$: To a solution of $Mn(OAc)_2{\cdot}4H_2O$ (0.25 g, 1.0 mmol) in 20 mL of MeOH was added 0.59 g (3.0 mmol) of H-5′-Clphox. After the addition of 10 mL of diethyl ether, the ligand dissolved and within several minutes the solution turned dark green. The dark green complex precipitated within 1 d. Recrystallisation from ethanol afforded X-ray quality crystals. Yield 0.52 g (0.81 mmol, 81%). IR: $\tilde{\nu}$ = 1622 (s), 1458 (s), 1405 (m), 1314 (s), 1237 (s), 1224 (s), 1100 (m), 1055 (m), 941 (m), 827 (m), 820 (m), 728 cm^{-1} (m). $C_{27}H_{21}Cl_3MnN_3O_6$: calcd. C 50.30, H 3.28, N 6.52; found C 50.41, H 3.30, N 6.33. ES-MS: *m*/*z*: 449, 447 $[Mn(5'\text{-}Clphox)_2]^+$, 200, 198, [H-5′-Clphox + H^+]. μ_{eff} = 4.74 μ_B (at 22.5 °C).

General Synthetic Procedure for $[Mn(3'\text{-}Mephox)_3]$, $[Mn(5'\text{-}Mephox)_3]$ and $[Mn(5'\text{-}MeOphox)_3]$: A solution of the ligand (3.0 mmol) and 0.30 g (3.0 mmol) of triethylamine in 10 mL of methanol was added to a solution of $Mn(OAc)_2{\cdot}4H_2O$ (0.25 g, 1.0 mmol) in 10 mL of methanol. The solution turned dark green immediately and within a number of days the complex precipitated. The complexes were recrystallised from methanol/water (2:1) ($[Mn(3'\text{-}Mephox)_3]$ and $[Mn(5'\text{-}MeOphox)_3]$) or ethanol ($[Mn(5'\text{-}Mephox)_3]$).

$[Mn(5'\text{-}Mephox)_3]$: Yield 0.43 g (0.72 mmol, 72%). X-ray quality crystals were obtained after recrystallisation from methanol. IR: $\tilde{\nu}$ = 1626 (s), 1601 (m), 1552 (m), 1485 (m), 1472 (s), 1323 (s), 1257 (m), 1242 (s), 1233 (s), 1201 (m), 1074 (m), 1057 (s), 866 (m), 826 (m), 792 cm^{-1} (m). $C_{30}H_{30}MnN_3O_6$: calcd. C 61.75, H 5.18, N 7.20; found C 61.53, H 5.32, N 7.30. ES-MS: *m*/*z*: 583 $[Mn(5'\text{-}Mephox)_3]^+$, 407 $[Mn(5'\text{-}Mephox)_2]^+$, 178 [H-5′-Mephox + H^+]. μ_{eff} = 4.47 μ_B (at 22.5 °C).

$[Mn(3'\text{-}Mephox)_3]$: Yield 0.45 g (0.77 mmol, 77%). X-ray Crystallographic Study: The data were collected with an Enraf−Nonius CAD-4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and ω-2θ scan. The cell dimensions were determined by 24 independent reflections. The data were corrected for linear decay, but not for absorption effects. Atomic scattering factors and anomalous dispersion constants were taken from the International Tables for X-ray Crystallography.[32] For both compounds the positions of the heavy atoms were determined from Patterson maps (DIRDIF).[33] The remainder of the non-hydrogen atoms were found in subsequent ΔF syntheses (XTAL).[34] Hydrogen atoms were placed at calculated positions and were not included in refinement. Full-matrix least-squares refinement (XTAL)[34] on F of the positional and the anisotropic thermal parameters of the non-hydrogen atoms. The hydrogen atoms, with fixed isotropic thermal parameters, were included, riding on a fixed distance of their parent atoms. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-144587 [Mn(5′-Mephox)$_3$] and -144588 [Mn(5′-Clphox)$_3$]. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Equipment: IR spectra were recorded with a Perkin−Elmer FT-IR Paragon 1000 spectrometer. Samples were measured as KBr pellets. ^{1}H and ^{13}C NMR (^{1}H decoupled) spectra of the ligands were recorded with Jeol JNM-FX 200 or Bruker 300 DPX MHz spectrometers. ^{1}H NMR spectra of the complexes (up to 0.2 mM) were recorded with a Bruker 300 DPX MHz spectrometer. These spectra were collected using an inversion recovery pulse sequence π-τ-π/2. The value of τ (12 or 13 ms) was chosen such that the paramagnetic signals were relaxed, while the signals from the diamagnetic compounds in solution remained inverted. Other operating parameters were as follows: spectrometer frequency 300.13 Hz; data block size (SI) 32 K; acquisition time 200 ms; line broadening 5 Hz; window 30 kHz. Elemental analyses were carried out by the Microanalytical Laboratory, University College Dublin or at Leiden University with a Perkin−Elmer series II CHNS/O analyser 2400. A Johnson Matthey Alfa Products Mk1 magnetic susceptibility balance was used to determine the magnetic moments of the powdered complexes at room temperature. Standard electrospray mass spectra of the complexes were recorded with a Finnigan MAT TSQ-70 mass spectrometer, equipped with an electrospray interface (ESI). The spectra were collected by constant infusion of the analyte, dissolved in a methanol/water (80:20) mixture containing 1% acetic acid. A Varian Star 3400CX gas chromatograph with a J&W Scientific/Fisons DB-1701 (14% cyanopropylphenyl-methylpolysiloxane) column was used for analysis of the oxidation experiments. The turnover numbers given are the total turnover numbers per manganese ion after the indicated period of time. All reactions were performed at least in duplicate.

Cyclic Voltammetry: The cyclic voltammetry measurements were performed with an Autolab PGstat10 potentiostat controlled by the GPES4 software. A three-electrode system was used, consisting of a glassy carbon (GC) working electrode, a platinum (Pt) auxiliary electrode, and an Ag/AgCl reference electrode. All potentials are given versus Ag/AgCl. The experiments were carried out in acetonitrile at room temperature under argon with tetrabutylammonium hexafluorophosphate (Aldrich) as the supporting electrolyte. Under these conditions, the ferrocene/ferrocenium (Fc/Fc$^+$) couple was located at +0.44 V with a peak separation of 80 mV. Except for H-5′-NO_2phox that shows a reduction wave at −1.22 V (see above), the other ligands are not redox-active between +2.00 and −2.00 V.

Spectroelectrochemistry and Bulk Electrolysis: Butyronitrile (Acros Chimica, analytical grade) was dried with CaH_2 and freshly distilled under nitrogen. The samples were prepared under nitrogen using standard Schlenk techniques. The spectroelectrochemical experiments were conducted with saturated solutions of the complexes containing 0.3 M Bu_4NPF_6, recrystallised twice from absolute ethanol and dried in vacuo at 80 °C for 10 h. A PA4 potentiostat (EKOM, Czech Republic) was used to carry out the controlled-potential electrolyses. Bulk electrolyses were carried out in a gas-tight cell that consisted of three chambers separated at the bottom by S4 frits, with a Pt working electrode (120 mm^2 surface) in the middle, and Ag wire pseudo-reference and Pt gauze auxiliary electrodes in the lateral chambers. Chemical reduction was achieved with cobaltocene ($CoCp_2$; Aldrich), $E_{1/2}$ = −1.34 V vs. Fc/Fc$^+$. The UV/Vis spectroelectrochemical experiments at room temperature were performed with a previously described[35] Optically Transparent Thin-Layer Electrochemical (OTTLE) cell equipped with a Pt mini-grid working electrode (32 wires/cm) and quartz optical windows. The UV/Vis spectra were recorded with a software-updated Perkin−Elmer Lambda 5 spectrophotometer. X-band EPR spectra were obtained in an airtight tube cell at 77 K with a Varian Century E-104A spectrometer. EPR g values were determined relative to the 2,2′-diphenyl-1-picrylhydrazyl radical (DPPH; Aldrich) as an external "g mark" (g = 2.0037).

MO Calculations: Extended Hückel calculations were performed with the computer program CACAO (Computer Aided Composition of Molecular Orbitals).[36] The calculations were based on the X-ray diffraction data for [Mn(phox)$_3$].[12]

Catalytic Oxidation Reactions: Blank experiments were carried out in the absence of the catalyst or using manganese salts or ligands only. These experiments did not result in any epoxidation activity. Hydrogen peroxide decomposition (catalase activity) was observed with some of the reaction conditions, but systematic studies to this reaction have not been performed. − **In Methanol:** Upon stirring, 14 μmol of the catalyst was dissolved in 20 mL of MeOH at room temperature. To the resulting green solution, 14 mmol of styrene, 5.0 mmol of chlorobenzene, and 2.0 mmol of 1-methylimidazole (1-Meim) were added, followed (at t = 0 min) by 21 mmol of dihydrogen peroxide (35% in water). Except for the solution of [Mn(5′-NO_2phox)], which slowly started to turn pale yellow after t = 10 min, the colour of the solutions of the other complexes became yellowish to colourless within the first few minutes of the reactions. At t = 15 min, a sample was taken for analysis using gas chromatography with chlorobenzene as the internal standard. − **In Acetone:** Dihydrogen peroxide (21 mmol of a 35% solution in water) and 10 mL of acetone were stirred for 30 min at 0 °C. Thereafter, 14 mmol of styrene, 5.0 mmol of chlorobenzene, and 2.0 mmol of 1-Meim were added, followed by 14 μmol of the powdered catalyst (t = 0). The green solution changed to a slightly red-brown colour within the first few minutes of the reaction. After 10 min, the solution slowly turned to pale green-yellow. At t = 15 min, a sample was taken for analysis using gas chromatography with chlorobenzene as the internal standard. ***Caution!*** The mixture of acetone and dihydrogen peroxide is potentially explosive, especially under acidic conditions.[37,38] However, it can be handled safely by performing reactions on a small scale at 0 °C, using slightly alkaline conditions, as described above.

Zinc- and Tin-Mediated C−C Coupling Reactions of Metalated (2-Pyridylmethyl)(trialkylsilyl)amines − Mechanistic, NMR Spectroscopic, and Structural Studies

Matthias Westerhausen,*[a] Tobias Bollwein,[a] Nikolaos Makropoulos,[a] Stefan Schneiderbauer,[a][‡] Max Suter,[a][‡] Heinrich Nöth,[a][‡] Peter Mayer,[a][‡] Holger Piotrowski,[a][‡] Kurt Polborn,[b][‡] and Arno Pfitzner[c][‡]

Keywords: Amides / C−C coupling / Magnesium / Metalations / Metallacycles / Pyridyl ligands / Tin / Zinc

The zincation of (2-pyridylmethyl)(triisopropylsilyl)amine (**1**) gives dimeric methylzinc (2-pyridylmethyl)(triisopropylsilyl)-amide (**2**). Further addition of dimethylzinc to a toluene solution of **2** at raised temperatures yields the C–C coupling product [1,2-dipyridyl-1,2-bis(triisopropylsilylamido)ethane]-bis(methylzinc) (**3**). Heating of molten **2**, or UV irradiation of **2**, results in the formation of **3** and zinc bis[(2-pyridylmethyl)-(triisopropylsilyl)amide] (**4**). The reaction between the zinc dihalide complexes of **1** [**5a** (X = Cl) and **5b** (X = Br)] and methyllithium yields the C–C coupling product **3** and the heteroleptic complex **2**, observed by NMR spectroscopy. During this reaction, zinc metal precipitates. The magnesiation of **1** with dibutylmagnesium gives magnesium bis[(2-pyridylmethyl)(triisopropylsilyl)amide] (**6**) in a quantitative yield. Subsequent addition of dimethylmagnesium results in a dismutation reaction and the formation of heteroleptic methylmagnesium (2-pyridylmethyl)(triisopropylsilyl)amide (**7**). Treatment of **1** with dimethylmagnesium also gives **7**. This complex slowly undergoes an intramolecular metalation during which dark red single crystals of (tetrahydrofuran)-magnesium 2-(triisopropylsilylamidomethylidene)-1-azacyclohexa-3,5-dien-1-ide (**8**) precipitate. In this compound the aromaticity of the pyridyl fragment is abolished. The magnesiation of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**I**) proceeds quantitatively to give methylmagnesium (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amide (**9**). This compound also undergoes an intramolecular metalation reaction, which results in the loss of the aromaticity of the pyridyl substituent and the formation of (tetrahydrofuran)magnesium 2-(*tert*-butyldimethylsilylamidomethylidene)-1-azacyclohexa-3,5-dien-1-ide (**10**). The metalation of **1** with tin(II) bis[bis(trimethylsilyl)amide] yields [bis(trimethylsilyl)amido]tin(II) (2-pyridylmethyl)(triisopropylsilyl)amide (**11**). The elimination of tin metal occurs even at room temperature, and the C–C coupling product [1,2-dipyridyl-1,2-bis(triisopropylsilylamido)ethane]tin(II) (**12**) is formed. The metalation of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine with $Sn[N(SiMe_3)_2]_2$ gives [bis(trimethylsilyl)amido]tin(II) (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amide (**13**). Within a few minutes, precipitation of tin metal takes place and the C–C coupled product [1,2-bis(*tert*-butyldimethylsilylamido)-1,2-dipyridylethane]tin(II) (**14**) is produced. In order to examine the importance of the pyridyl ligand for the C–C coupling reactions, zinc bis[*N*-(*tert*-butyldimethylsilyl)benzylamide] (**15**) was prepared by means of the metathesis reaction between lithium *N*-(*tert*-butyldimethylsilyl)benzylamide and zinc(II) halide. Treatment of **15** with dimethylzinc yields heteroleptic methylzinc *N*-(*tert*-butyldimethylsilyl)benzylamide (**16**). Refluxing of **16** with an excess of dimethylzinc in toluene does not give any C–C coupling reactions.

Introduction

A novel oxidative C−C coupling reaction subsequent to zincation of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**I**) has been found.[1] The metalation of amine **I** with dimethylzinc yielded dimeric methylzinc (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amide (**II**), according to Scheme 1. Either thermal decomposition or the addition of another equivalent of dimethylzinc at elevated temperatures then resulted in the oxidative C−C coupling reaction and hence in the formation of [1,2-bis(*tert*-butyldimethylsilylamido)-1,2-dipyridylethane]bis(methylzinc) (**III**) and the precipitation of zinc metal. The thermal decomposition of **II** also resulted in the formation of amine **I**, which was zincated by **II** still present to give zinc bis[(*tert*-butyldimethylsilyl)(2-pyridylmethyl)amide] (**IV**), according to Scheme 2.[1]

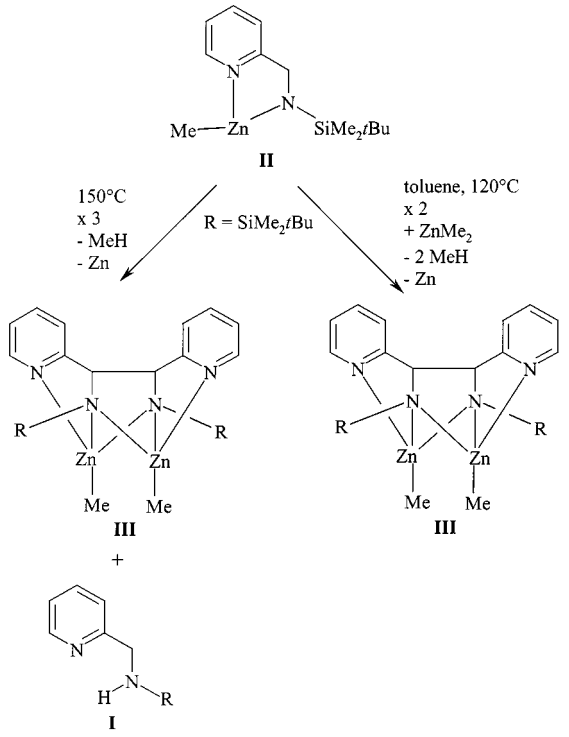
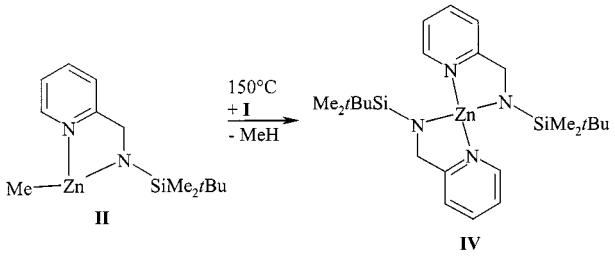


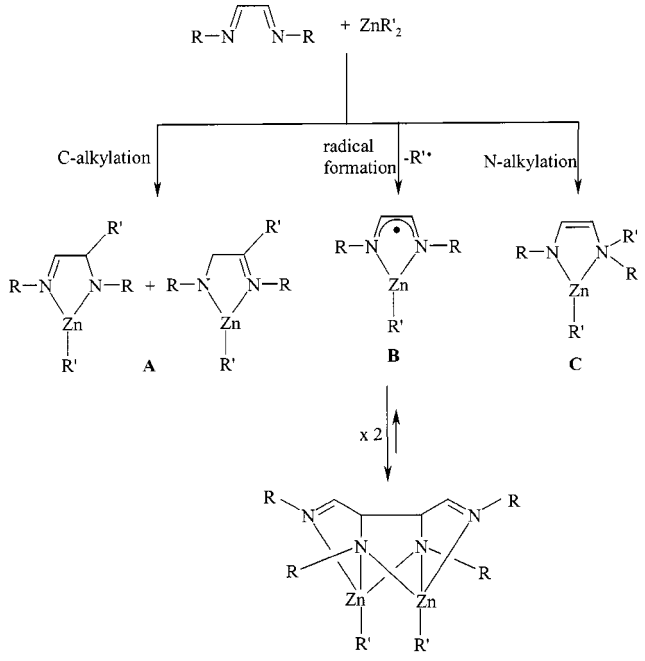
Scheme 1



Scheme 2

The reaction between *N*,*N*′-di(*tert*-butyl)-1,4-diazabutadiene and dialkylzinc offered three different possible reaction pathways:[2,3] *C*-alkylation (**A**),[4,5] radical formation (**B**),[6,7] and *N*-alkylation (**C**)[4,5] after a homolytic Zn−C bond cleavage. An overview of these reactions is given in Scheme 3. The radicals **B** were in equilibrium with the dimeric species, as shown in this reaction diagram.[2,8,9] Mechanistically the formation of the C−C-coupled dimer can be explained by recombination of radicals.

This mechanism is not transferable to the oxidative C−C coupling reaction described here, for several reasons. During the zincation and subsequent C−C coupling, no radicals were detected by ESR spectroscopy and neither was a monomer−dimer equilibrium observed. In order to investigate the mechanism of the oxidative C−C coupling reaction shown in Scheme 1, it was necessary to address several questions: the influence of the steric hindrance of the *N*-bonded trialkylsilyl group, the standard potential E^0(M/M^{2+}) of the metalation reagent, and the role of the pyridyl substituent.



Scheme 3

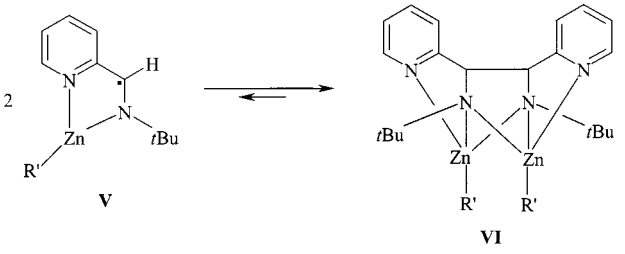
Results and Discussion

Synthesis and Mechanistic Studies

It has already been shown that methylzinc (*tert*-butyl)(2-pyridylmethyl)amide undergoes a monomer/dimer equilibrium favoring the dimeric molecule **VI** (Scheme 4),[2,8] which has also been structurally characterized.[9] The substitution of the *tert*-butyl group for a trialkylsilyl substituent results in drastic changes in the chemical and physical behavior of these molecules. On one hand, the *N*-trialkylsilyl substitution prevents the monomerization process, while on the other a novel synthetic route to these tetradentate ligands in a quantitative yield is possible, by means of the C−C coupling reaction.

Influence of the Size of the Trialkylsilyl Substituents

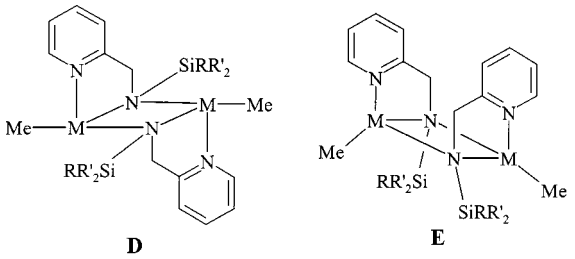
The lithiation of 2-(aminomethyl)pyridine and the subsequent metathesis reaction with chlorotriisopropylsilane yields (2-pyridylmethyl)(triisopropylsilyl)amine (**1**). The zincation of **1** gives dimeric methylzinc (2-pyridylmethyl)-



Scheme 4

(triisopropylsilyl)amide (**2**), with a central Zn_2N_2 ring. The addition of dialkylzinc to a solution of **2** in toluene at raised temperatures results in a C−C coupling reaction and the formation of [1,2-bis(triisopropylsilylamido)-1,2-dipyridylethane]bis(methylzinc) (**3**). Heating of molten **2**, or UV irradiation of **2**, yields **3** and zinc bis[(2-pyridylmethyl)(triisopropylsilyl)amide] (**4**) in an equimolar ratio, together with zinc and methane. Compound **4** represents a structure similar to **IV**, the only difference being the substituents at the silicon atom.

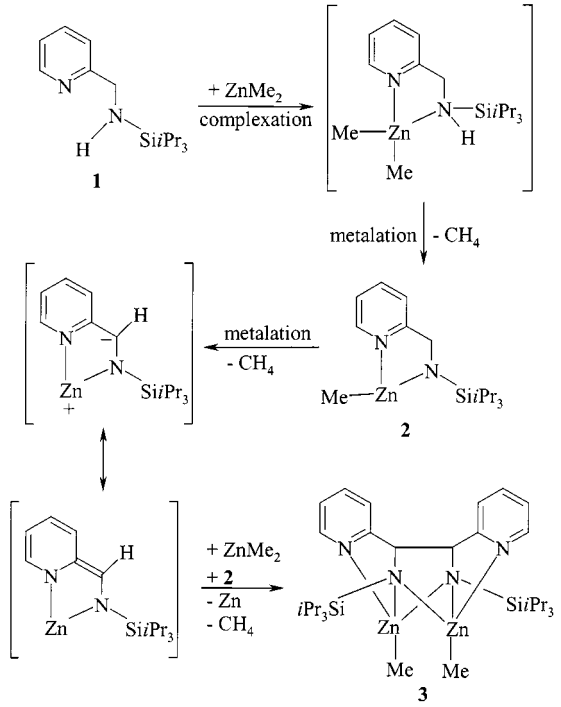
The quantitative synthesis of **3** is achieved by means of a reaction between **1** and at least 1.5 equiv. of dimethylzinc. The mechanistic picture is presented in Scheme 5. The first step is the complexation of dimethylzinc by **1**, as described below for the zinc dihalide complexes and similar to already published adducts.[6,10] Subsequently, the amine moiety is zincated. The methylene groups are then metalated by a methylzinc moiety. Whether this zincation step happens intramolecularly (monomolecular) or intermolecularly (bimolecular or even higher order) is uncertain, especially in view of the fact that the compounds described above are dimeric both in the solid state and in solution. The relaxation of the anionic charge produces a bis(amide). However, this intermediate forms only at higher temperatures and was not observable in the zinc-mediated C−C coupling reaction. At these temperatures, the zinc atom could be eliminated as Zn^0, with (pyridylmethylidene)(trialkylsilyl)amine being formed. In the presence of additional dimethylzinc and another equivalent of **2**, the C−C coupling occurs immediately with evolution of methane (mass spectrometric identification) and precipitation of zinc metal (proof by X-ray powder diffraction[1]). Because of the dimeric nature of **2**, only the (*R*,*R*) and the (*S*,*S*) isomers of **3** are formed, and no *meso* isomer is observed. The steric demand of the trialkylsilyl groups influences the conformation of the dimeric methylzinc (2-pyridylmethyl)(trialkylsilyl)amide as shown in Scheme 6 (structure types **D** and **E**), but not the reactivity towards dimethylzinc.



Scheme 6. Schematic drawing of the two possible conformations **D** and **E** for the dimeric derivatives of the type $[R-M-N(SiRR'_2)CH_2-py]_2$ with M as Zn (**2** and **II**) and Mg (**7** and **9**)

Mixing of compounds **III** and **3** in toluene does not afford the mixed compound with a triisopropylsilyl group at one nitrogen atom and a *tert*-butyldimethylsilyl substituent at the other, which we also interpret as support for the ionic mechanism. However, irradiation of this mixture does produce this mixed derivative, most probably through a C−C bond cleavage, as shown for the equilibrium in Scheme 4 for the *N*-*tert*-butyl derivative.

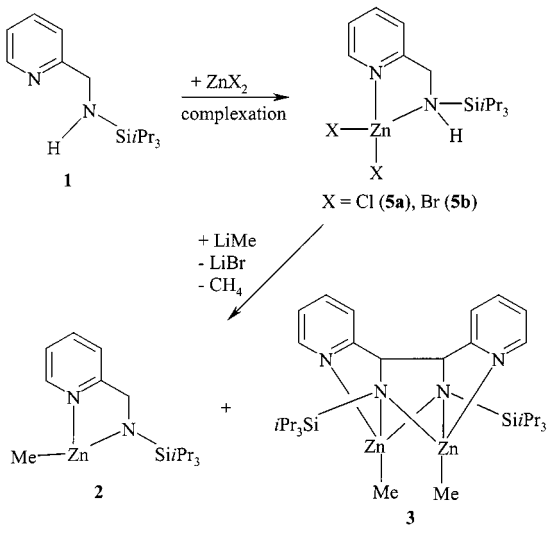
Another possibility for the synthesis of **3** is shown in Scheme 7. Treatment of **1** with zinc dihalides yields the corresponding adducts **5a** (X = Cl) and **5b** (X = Br), which are only partly soluble in common organic solvents. The addition of methyllithium to **5b** results in the formation of the C−C coupling product **3** and the heteroleptic complex **2**, as observed by NMR spectroscopy. During this reaction, zinc metal precipitates in accordance with the proposed mechanism.



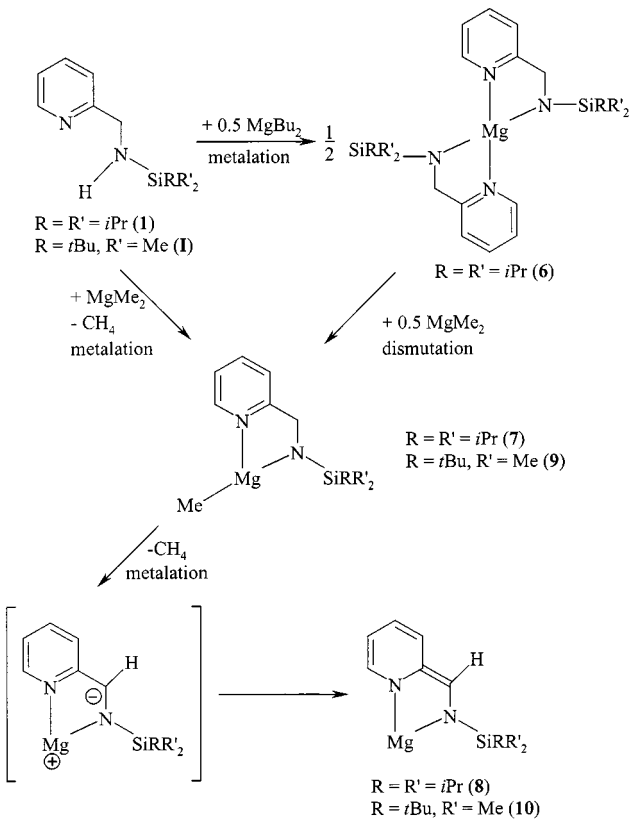
Scheme 5

Influence of the Standard Potential $E^0(M/M^{2+})$

If the reaction were to be performed with other metals, other pathways should be followed, depending on the potential $E^0(M/M^{2+})$, which for zinc is −0.7626 V.[11] In order to investigate the reaction mechanism, the less noble magnesium [$E^0(Mg/Mg^{2+}) = -2.356$ V[11]] and the nobler tin [$E^0(Sn/Sn^{2+}) = -0.137$ V[11]] were applied. The magnesiation of **1** with dibutylmagnesium gives magnesium bis[(2-pyridylmethyl)(triisopropylsilyl)amide] (**6**) in a quantitative yield. Subsequent addition of dimethylmagnesium results in a dismutation reaction and the formation of heteroleptic methylmagnesium (2-pyridylmethyl)(triisopropylsilyl)amide (**7**). Treatment of **1** with dimethylmagnesium in an equimolar ratio gives mainly **7**; the reaction solution turns dark, however. Reduction of the volume and cooling to approximately 5 °C results in the precipitation of dark red, single crystals of (tetrahydrofuran)magnesium 2-[(triisopropylsilyl)amidomethylidene]-1-azacyclohexa-3,5-dien-1-ide (**8**) in a rather low yield, embedded in a dark oil. The first reaction step is clearly the metalation of the amine **1**, followed



Scheme 7



Scheme 8

by a further metalation of the methylene group. The anionic charge is then transferred to the pyridyl nitrogen atom, thus forming a bis(amide) as shown in Scheme 8. The stronger metalation power[12] of a magnesium-bonded methyl group allows intramolecular H abstraction and the breakdown of the aromaticity of the pyridyl moiety at lower temperatures. The reduced aromatic character of *C*-bonded pyridyl moieties is already well known in the case of [bis(2-pyridyl)methyl]lithium.[13–15] No precipitation of magnesium metal is observed in the course of this reaction. During the zincation of **1**, no similar zinc bis(amide) was detected, because on the one hand elevated temperatures are necessary for the metalation of the methylene fragment and on the other hand the reduction of the zinc dication is more easily accessible than that of the magnesium dication. Complex **8**, if dissolved in common organic solvents, decomposes into a variety of as yet unidentified products, which prevents spectroscopic characterization.

The magnesiation of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (**I**) proceeds quantitatively, to give methylmagnesium (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amide (**9**). Even though this metalation is performed in THF, **9** crystallizes from a toluene solution isotypically to the corresponding zinc derivative,[1] as a dimer without coordination of further neutral coligands. This compound undergoes an intramolecular metalation reaction, which results in the loss of the aromaticity of the pyridyl substituent and the formation of (tetrahydrofuran)magnesium 2-[(*tert*-butyldimethylsilyl)amidomethylidene]-1-azacyclohexa-3,5-dien-1-ide (**10**). In a concentrated THF solution, dark red crystals, containing both the compounds **9** and **10** in an equimolar ratio, precipitate at 5 °C within 3 d. This magnesiation step occurs even in the dark and at low temperatures. Attempts to crystallize pure **10** were not successful. Thanks to this cocrystallization during the intramolecular magnesiation process, **9** and **10** were removed from the reaction solution environment, which allowed their molecular structures to be crystallographically determined, since the crystalline material constituting **10** decomposes very slowly in the solid state. In solution, however, as yet unknown decomposition reactions occur.

The metalation of **1** with tin(II) bis[bis(trimethylsilyl)amide][16–20] yields a green solution of [bis(trimethylsilyl)amido]tin(II) (2-pyridylmethyl)(triisopropylsilyl)amide (**11**). The elimination of tin metal occurs even at room temperature, as proven by X-ray powder diffraction analysis (Figure 1). In an equimolar quantity, the C–C coupling product tin(II) 1,2-dipyridyl-1,2-bis(triisopropylsilylamido)ethane (**12**) forms according to Scheme 9. Because of the size of the Sn^{2+} cation and the stereochemical activity of the lone pair, only one metal center is coordinated to this tetradentate ligand, through three nitrogen atoms. The magnetic equivalence of both pyridyl groups can be explained by a fast (on the NMR timescale) exchange reaction. NMR spectroscopic investigation of the crystals shows the presence of a small amount of the *meso* isomer **12′**, because the fixation of the geometry is less restrictive in regard to the reaction pathway due to the mononuclearity of these tin(II) complexes.

The smaller *tert*-butyldimethylsilyl group at the amide moiety gives products similar to those described above. The metalation of (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine **I** with $Sn[N(SiMe_3)_2]_2$ gives [bis(trimethylsilyl)amido]tin(II) (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amide (**13**). Within a few minutes, the precipitation of tin

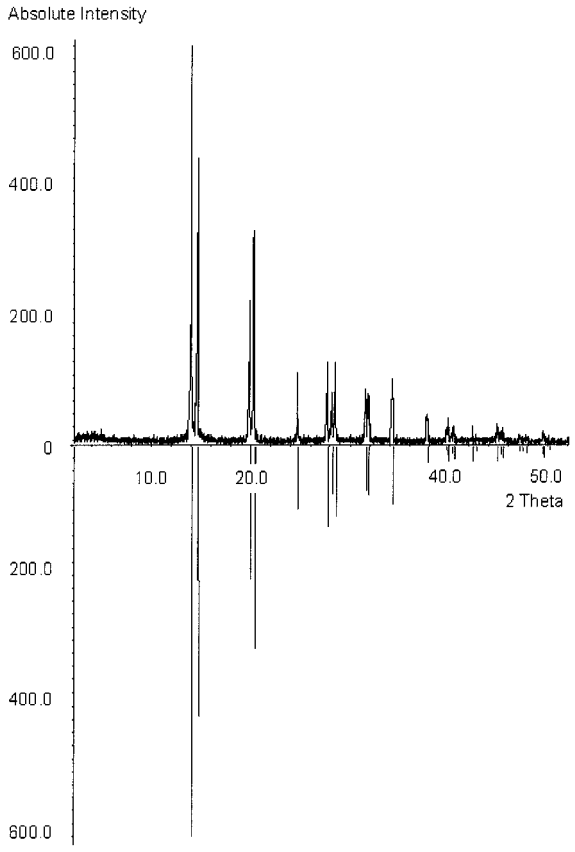


Figure 1. X-ray powder diffractogram of tin that precipitated during the C−C coupling reactions (top) and the reference line spectrum (bottom)

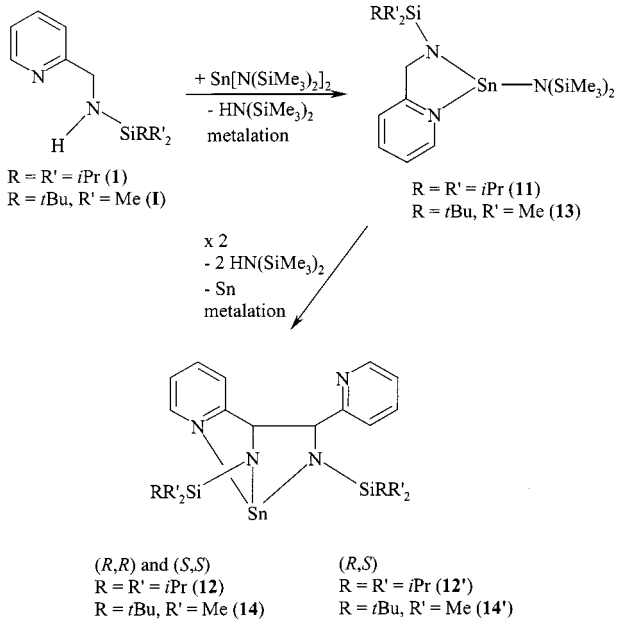


Scheme 9

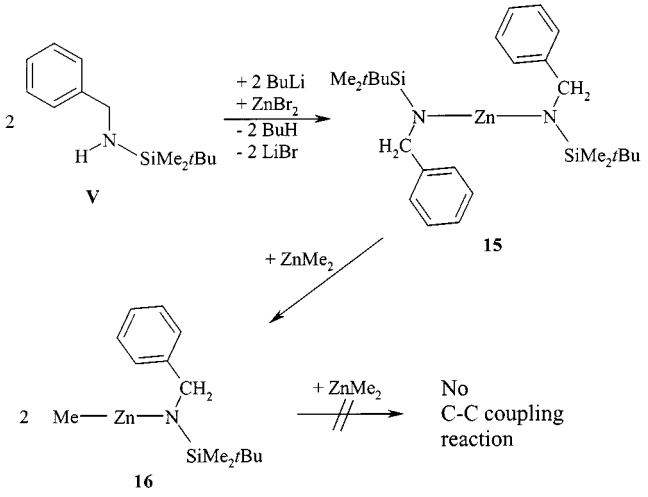
metal and the C−C coupling reaction begin. Thanks to the less crowded trialkylsilyl substituent, the (*R*,*R*) and (*S*,*S*) isomers **14** are formed together with a small quantity of the *meso* form **14′**.

All these C−C coupling products are colorless and no equilibrium similar to the reaction described in Scheme 4 was observed. Solutions of these derivatives in toluene and heptane showed no EPR signal, and so there was no indication of a radical mechanism. We interpret all these findings in terms of the involvement of a polar reaction mechanism.

Importance of the Pyridyl Fragment

The pyridyl substituent could be important for this reaction in two ways. On the one hand, it might function as an anchor group to bind dimethylzinc and thus to enforce a close contact between the metalating reagent and the amine. On the other, the reaction mechanism involves a step in which the aromaticity of the pyridyl substituent is disturbed and a bis(amide) is formed. Therefore, the use of an *N*-silylated benzylamine (formal replacement of the pyridyl nitrogen atom by a CH fragment) was investigated. This change strongly decreased the reactivity of (benzyl)(*tert*-butyldimethylsilyl)amine towards dimethylzinc. The zincation did not offer access to the corresponding zinc amides.

In order to examine the importance of the pyridyl ligand for the C−C coupling reactions, zinc bis[(benzyl)(*tert*-butyldimethylsilyl)amide] (**15**) was prepared by lithiation of (benzyl)(*tert*-butyldimethylsilyl)amine (**V**)[21] and the subsequent metathesis reaction with zinc(II) halide according to Scheme 10. Treatment of **15** with dimethylzinc yielded heteroleptic methylzinc (benzyl)(*tert*-butyldimethylsilyl)amide (**16**).[22]



Scheme 10

Compound **16** behaves as a characteristic heteroleptic alkylzinc amide, as is well known for a wide variety of compounds of the general type R−Zn−NR′R′′ (see examples in the literature[23−26]). No C−C coupling reaction between **16** and excess dimethylzinc was observed, even in refluxing toluene.

From these observations, we conclude that a derivative with a disturbed aromatic character in the pyridyl fragment seems to play the key role in this mechanism. For the C−C coupling reaction, the presence of the methylpyridyl moiety

is essential, whereas the steric demand of the *N*-bonded trialkylsilyl substituent is only of secondary importance. The standard potential determines the reaction conditions for the C−C coupling. Whereas mild conditions are sufficient for the use of tin(II), the reaction solutions had to be heated to perform the coupling with zinc(II). Magnesium was not able to initiate the C−C bond formation but we were therefore able in this case to determine the crystal structures of molecules that most probably serve as intermediates in the metalation reactions with zinc(II) and tin(II) reagents.

Structural Investigations

Figure 2 shows the molecular structure and numbering scheme of **2**. The crystallographic C_2 axis generates the second half of the molecule; the symmetry-related atoms are marked with primes. Scheme 7 shows the possible conformations for dimeric methylzinc (2-pyridylmethyl)(trialkylsilyl)amides. Whereas type **D** is already known for the *N*-(*tert*-butyldimethylsilyl)-substituted derivative **II**,[1] compound **2** crystallizes in structure type **E**. However, the conformation of the dimer is without importance for the reactivity in the C−C coupling reaction. The central feature is the slightly folded Zn_2N_2 ring (folding angle 167.1°) with Zn−N bond lengths of approximately 211 pm (Table 1). The transannular Zn1···Zn1′ contact lies at 284.7 pm.

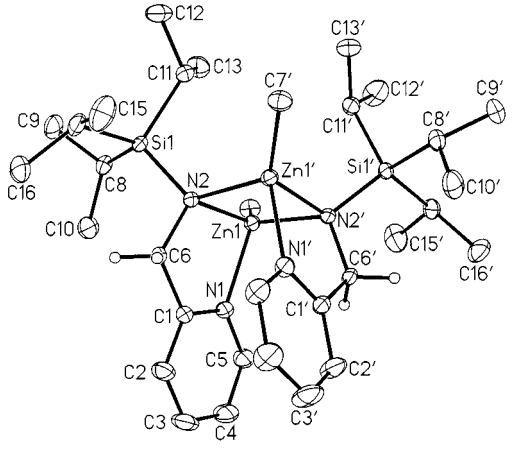


Figure 2. Molecular structure of **2**; the ellipsoids represent 40% probability; atoms generated by the crystallographic C_2 symmetry ($-x$, y, $-z + 1.5$) are marked with apostrophes; the hydrogen atoms are omitted for clarity, with the exception of those at C6/C6′

Figure 3 represents the molecular structure of **3**. The numbering scheme coincides with that of **2** and thus offers the possibility of direct comparison of the structural parameters (Table 1). The C−C coupling of the bidentate anions results in the formation of both the (*R*,*R*)- and the (*S*,*S*)-1,2-bis(pyridyl)-1,2-bis(triisopropylsilylamido)ethane dianions. Thanks to the crystallographically enforced inversion center, both of these isomers are included in the investigated single crystals, whereas no (*R*,*S*) isomer was observed either in the crystalline state or in solution.

The Zn−N bonds of the pyridine moiety are elongated in comparison to those in the sterically unhindered (bipyridine-*N*,*N*′)zinc dichloride, with values of 206 pm.[27] In the pyridine complex bis(1,4-dihydropyridyl)bis(pyridine-*N*)zinc,[28] on the other hand, Zn−N values of 198 and 213 pm have been observed for the anionic and the neutral ligands, respectively. Enhanced steric demand results in a further elongation of this bond, as shown for (bipyridine-*N*,*N*′)bis[bis(trimethylsilyl)methyl]zinc.[29]

The C6−C6′ bond formation increases the intramolecular steric strain, as is also demonstrated by the C6−C6′ bond length of 160 pm, a value in the same range as, for example, strongly strained [1.1.1]propellanes.[30] A slightly smaller value was previously found by van Koten and coworkers for compound **VI** [R = Et, 157.0(8) pm[2,9]]; the Zn−N bond lengths to the amido ligands show a mean value of 208.5 pm,[2,9] whereas values of 212.3 pm are observed in **3**. Furthermore, a strong folding of the Zn_2N_2 ring is imposed. Whereas the folding angle in **2** is 167.1°, the corresponding value after C−C bond formation lies at 109.9°. Because of this folding, the triisopropylsilyl substituents are pushed apart from each other and the *Zn*-bonded methyl groups move toward each other and consequently between the *i*Pr_3Si substituents. The Zn1−N2−Si1 angle is therefore enhanced. Furthermore, the short transannular Zn1···Zn1′ contact of 272.8 pm increases the electrostatic repulsion between the metal cations. In **VI**, a comparable metal−metal contact of 274.9(1) pm was found.[2] The rearrangement of the aliphatic substituents gives rise to a slight contraction of most of the bond lengths. The Zn1−C7 distance is approximately 3 pm smaller, whereas this trend is less dramatic for the Si1−N2 and Si1−C bonds.

Figure 4 shows the molecular structure and numbering scheme of **8**. The disordered THF molecule between these dimeric magnesium bis(amides) is neglected, due to the lack of short contacts between this solvent molecule and **8**. Derivative **8** represents the key compound in explaining the mechanism discussed above. The numbering scheme is similar to that shown for **2** and **3**; atoms generated by crystallographic inversion symmetry are marked with apostrophes. The central feature is the Mg_2N_2 ring with distorted tetrahedrally coordinated magnesium atoms. The N2−Mg1−N2′ angle in this centrosymmetric ring has a value of 95.2°. The Mg−O distances of 202.7 pm lie in the expected region.[31,32] Selected structural parameters are summarized in Table 1.

Special attention should be drawn to the amidomethylpyridyl fragment. The aromaticity of the pyridyl moiety is broken, and alternating long and short C−C bonds are observed. The negative charge is located on both the nitrogen atoms, thus giving a cyclic magnesium bis(amide). The N1−C5 distance of 135.9 pm represents a characteristic value for an N−C single bond to an sp^2-hybridized carbon atom, whereas the N1−C1 bond (140.7 pm) seems to be elongated. The N2−C6 distance of 145.6 pm is larger, due to the tetrahedral environment of N2 and the steric strain induced by the trialkylsilyl substituent. The C−C bonds of the pyridyl fragment show a slight degree of conjugation, as the C−C single bonds are shorter (mean value 142.6)

[a] Data from the solid state structure of **9**. [b] Parameters from the crystal structure of **9·10**. [c] Mg1−O01.

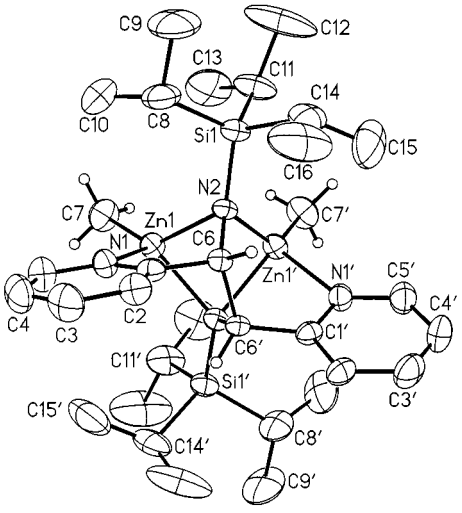

Figure 3. Molecular structure of **3**; the ellipsoids represent 40% probability; atoms generated by the crystallographic C_2 symmetry ($-x + 2$, y, $-z + 0.5$) are marked with apostrophes;the hydrogen atoms are omitted for clarity, with the exception of those at C6/C6′

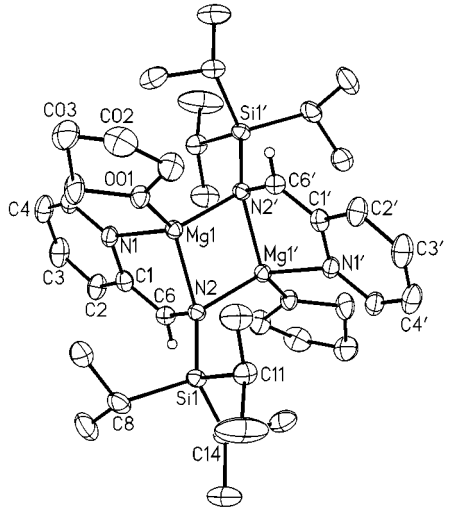

Figure 4. Molecular structure of **8**; the ellipsoids represent 40% probability; atoms generated by the crystallographic inversion symmetry ($-x$, $-y + 1$, $-z + 2$) are marked with apostrophes; the hydrogen atoms are omitted for clarity, with the exception of those at C6/C6′

than expected (reference value 1.48 pm[33]) whereas the C=C double bonds (mean value 136.0 pm) are widened (reference value 1.34 pm[33]).

The Mg1−N1 bond length of 203.5 pm is rather short, due to the low coordination number of N1 and the electrostatic attraction between the nitrogen atom and the metal center. The distorted tetrahedral surrounding and the steric shielding of N2 produce a longer N2−Mg1 bond length. The transannular Mg1···Mg1′ contact of 281.9 pm is rather short, however, this is a consequence of the small endocyclic Mg−N bonds lengths.

Figure 5 represents the molecular structure and numbering scheme of dimeric **9**. This molecule shows point symmetry and so structure type **D** is achieved. Atoms generated by the inversion symmetry are marked with apostrophes. In comparison with the isotypic zinc complex **II** and with **2**, the metal−carbon bonds of **9** are elongated by approxim-

ately 15 pm in accordance to the van der Waals radii difference (r_{Mg} = 170 pm; r_{Zn} = 140 pm[34]); however, the difference between the Mg−N and Zn−N bond lengths is far less distinct. Because of the slightly larger metal centers, the transannular M1···M1 contacts of **9** are larger than those in the similar zinc derivatives **II** and **2**. This is achieved by widening of the Mg1−N2−Mg1′ bond angle compared with the corresponding values in the zinc complexes.

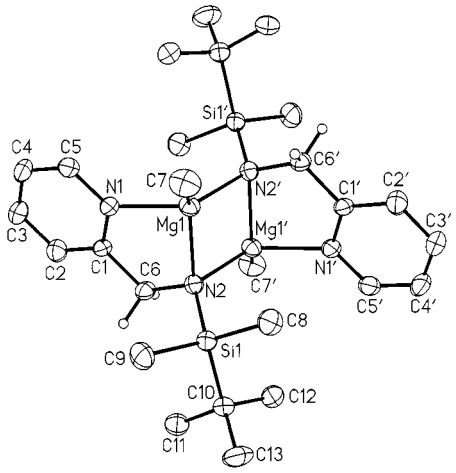

Figure 5. Molecular structure of **9**; the ellipsoids represent 40% probability; atoms generated by the crystallographic inversion symmetry ($-x + 1, -y + 1, -z$) are marked with apostrophes; the hydrogen atoms are omitted for clarity, with the exception of those at C6/C6′

Figure 6 represents the molecular structure and numbering scheme of **10**. This molecule cocrystallizes in an equimolar ratio with **9** as shown in Figure 7. The solid-state structure can be regarded as a layer structure, with the molecules of **9** in (*h*,*k*,0) and those of **10** in (*h*,*k*,0.5). Both these molecules show inversion symmetry and a nearly similar arrangement of their substituents. The magnesium atoms are in a distorted tetrahedral environment. The molecular structure of **9** is similar to the structure described above and no detailed discussion is necessary. However, **10** shows some remarkable structural features. The center of interest concerns the disturbed aromaticity of the pyridyl fragment, which is similar to that in **8**. Detailed discussion therefore seems unnecessary.

Mononuclear 1,2-dipyridyl-1,2-bis(trialkylsilylamido)-ethane complexes of tin(II) preferentially form as (*R*,*R*) and (*S*,*S*) isomers; however, a minor quantity of the *meso* form is also produced from this reaction. This situation allows these isomers to be compared in the crystalline state, and so the numbering schemes are alike for all these derivatives. Figures 8 to 10 show the molecular structures and numbering schemes of **12**, **12′**, and **14**, respectively; Table 2 contains selected structural data. The backbone consists of the stereogenic centers C1 and C2. The *Sn*-bonded pyridyl fragment is located at C1, whereas the uncoordinated pyridyl substituent is bonded to C2. The tin atoms are in a trigonal-pyramidal environment formed by the three nitrogen atoms N1, N2, and N21, whereas N22 shows no short contacts to any tin(II) centers. The Sn−N21 bond lengths are nearly 20

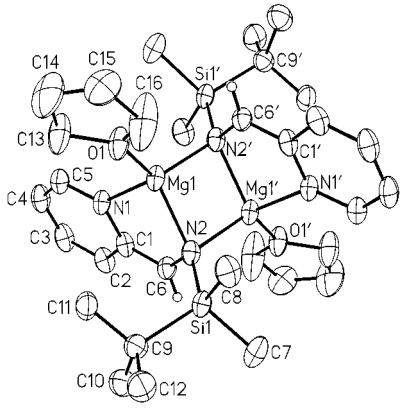

Figure 6. Molecular structure of **10**; the ellipsoids represent 30% probability; atoms generated by the crystallographic inversion symmetry ($-x + 2, -y + 2, -z + 1$) are marked with apostrophes; the hydrogen atoms are omitted for clarity, with the exception of those at C6/C6′

pm larger than the tin−nitrogen distances to the negatively charged atoms N1 and N2. The sterically less demanding *tert*-butyldimethylsilyl substituent allows shorter Sn−N bonds than the *N*-bonded triisopropylsilyl group. A remarkable difference concerns the newly formed C1−C2 bond. Whereas this bond is extremely long in compounds **12** and **12′**, a characteristic value of 153.5(6) is found in **14**. However, the ring strain in **14** gives rise to an elongated C1−C11 bond. A comparison of the structural parameters of **12** [(*R*,*R*) and (*S*,*S*) isomers] and **12′** (*meso* isomer) show two main differences, namely the smaller Sn−N21 bond length and the smaller Sn−N2−Si2 bond angle in **12′**. Both these observations can be attributed to reduced intramolecular steric strain in this isomer.

The stereochemically active lone pair at tin(II) gives rise to the pyramidal coordination sphere at the metal center. Similar observations are already well known for other tin(II) amides. The Sn−N1 and Sn−N2 bond lengths are comparable to those published for $Sn[N(SiMe_3)_2]_2$.[35−37] A higher coordination number of three[38] or four[39] at the tin(II) center results in longer Sn−N bonds.

In **14**, the nitrogen atoms N1 and N2 are in a planar environment (angle sums of N1 and N2: 359.3 and 359.7°). The larger trialkylsilyl substituents produce distortions and smaller angle sums at the amide moieties (**12**: N1 354.4°, N2 358.1°; **12′**: N1 357.8°, N2 350.2°).

NMR Spectroscopy

NMR spectroscopic data for the zinc- and magnesium-containing molecules are summarized in Table 3; the numbering scheme is given in Scheme 11. The influence of the trialkylsilyl substituents on the chemical shifts of the pyridylmethyl fragments is very small. The compound classes are therefore distinguishable by the δ values of the methylene moieties in the proton NMR experiments: the (2-pyridylmethyl)(trialkylsilyl)amines **1** (R = Si*i*Pr$_3$) and **I** (R = SiMe$_2$*t*Bu) show their resonances at δ = 4.1. Substitution of the H atom by a methylmetal fragment (**2** and **II**: Zn; **7** and **9**: Mg) produces a low-field shift of approximately 0.6 ppm,

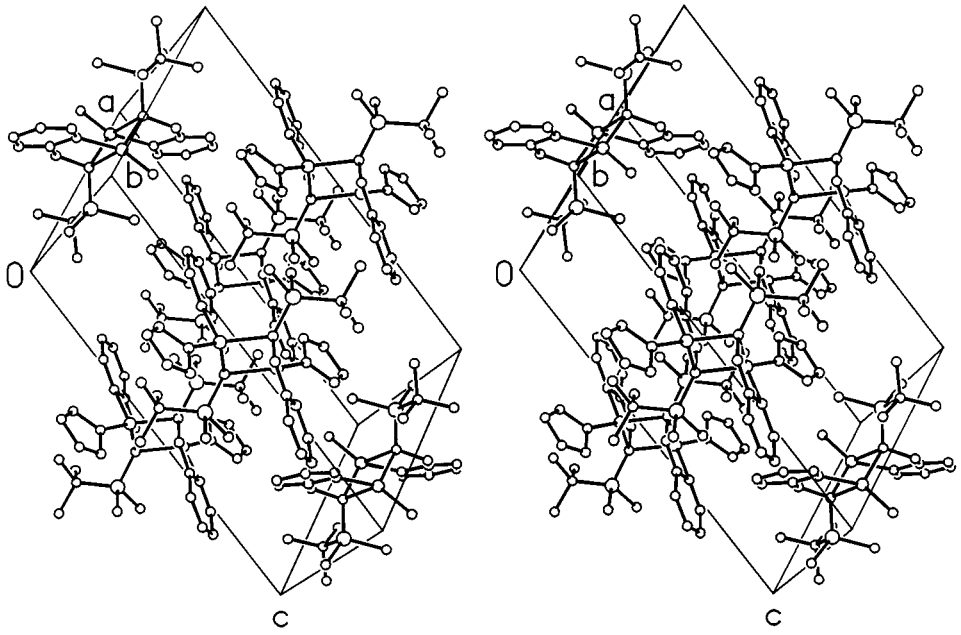

Figure 7. Representation of the arrangement of the molecules of **9·10** in the unit cell; the atoms are shown with arbitrary radii (see text)

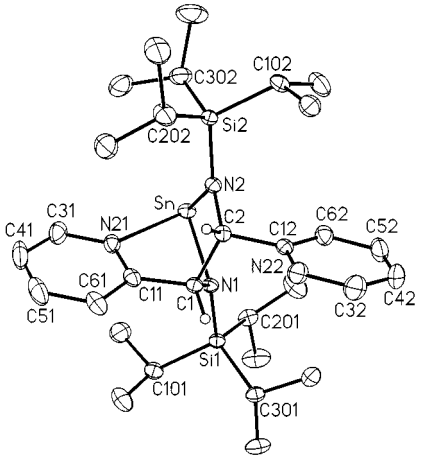

Figure 8. Molecular structure of **12**; the ellipsoids represent 40% probability; the hydrogen atoms are omitted for clarity, with the exception of those at C1 and C2

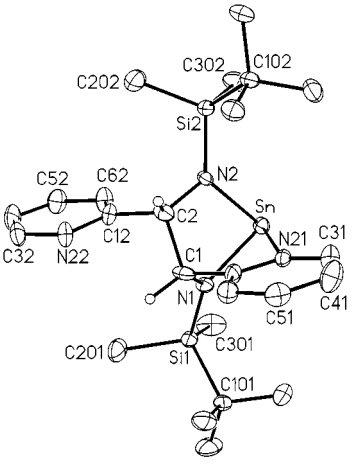

Figure 10. Molecular structure of **14**; the ellipsoids represent 40% probability; the hydrogen atoms are omitted for clarity, with the exception of those at C1 and C2

whereas the C−C-coupled derivatives **3** and **III** give chemical shifts of $\delta = 4.0$. The resonances of these methylene moieties in metal bis[(2-pyridylmethyl)(trialkylsilyl)amide] (Zn: **4** and **IV**; Mg: **6**) appear at a rather low field at $\delta = 4.9$. Similar tendencies are deducible from the $^{13}C\{^1H\}$ NMR experiments; the amines **1** and **I** have values of $\delta = 48$, whereas the metalated amines show low-field shifts of approximately 6 ppm regardless of the metal (Zn or Mg). The C−C coupling gives chemical shifts of approximately $\delta = 67$ for these carbon atoms. In the NMR spectroscopic experiments, the influences both of the steric demand of the trialkylsilyl substituents and of the nature of the metal center (Zn or Mg) seem to play a minor role regarding the NMR spectroscopic data of the pyridylmethyl groups. The dependence on the solvent was elucidated for compound **9**; the influence of the solvent on the NMR spectroscopic data

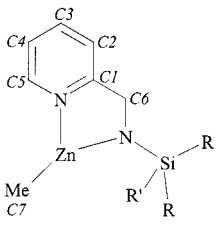
is of the same magnitude as that of the substitution pattern.

The NMR parameters of the tin(II) complexes are summarized in Table 4. All these complexes are mononuclear, and variations in the NMR spectroscopic data are therefore to be expected. The solid-state structures of **12** and **14** show that only one pyridyl group bonds to the tin center, whereas the other one shows no short contacts to a metal atom. In solution, both pyridyl fragments are chemically and magnetically equivalent; the exchange process is fast on the NMR timescale even at low temperatures. In general, the δ values of the methylene fragments are shifted towards lower field, relative to the zinc and magnesium derivatives, in the proton and $^{13}C\{^1H\}$ NMR experiments. The $^{119}Sn\{^1H\}$ chemical shifts were found in the characteristic region for triply coordinated tin(II) compounds.[40−42]



Scheme 11. Numbering scheme of the (2-pyridylmethyl)(trialkylsilyl)amide ligand for the assignment of the NMR spectroscopic data

The ^1H NMR spectroscopic data for **15** and **16**[22] are summarized in Table 5; the corresponding values for (benzyl)(trialkylsilyl)amine (**V**)[21] are also included for comparison. The low-field shift of the methylene moiety of **16** compared to **15** is contrary to the observations concerning the pyridyl compounds **2** and **4** as well as **II** and **IV**, respectively, where the ^1H NMR spectra show the CH_2 signals of the heteroleptic derivatives **2** and **II** at a higher field.

Conclusion

The zinc-mediated C−C coupling reaction is not dependent on the intramolecular steric strain introduced by the trialkylsilyl substituents. However, the use of the triisopropylsilyl ligand permitted the crystallographic characterization of the cyclic magnesium bis(amide) **8**, which is thought to be the intermediate in this reaction. The intermediate with the smaller *tert*-butyldimethylsilyl substituent cocrystallized with **9**, and its fast decomposition was prevented due to its removal from the reaction mixture. Furthermore, the solid-state structures of **2** and **II** vary with the steric demand of the trialkylsilyl group but the reactivity is all but retained. As one would expect, this coupling reaction is strongly dependent on the redox potential of the metal employed in this reaction. The pyridyl substituent is necessary to support the C−C coupling reaction. The key step of the mechanism is the metalation of the methylene group and a charge migration to the pyridyl nitrogen atom, thus forming a cyclic bis(amide). Because of the C−C coupling, the aromaticity of the pyridyl group is regained; this may be the driving force for this step. This also provides an explanation of why no similar molecule is observed in the zinc-mediated reaction: the elevated reaction temperature prevents the reaction from stopping at this step, since the reduction of the metal is too easy.

The zinc-mediated C−C coupling reaction results in the formation of the (*R*,*R*)- and (*S*,*S*)-isomeric 1,2-dipyridyl-1,2-bis(trialkylsilylamido)ethane ligand. The *meso* form is not observed in the course of this reaction. However, the tin-mediated C−C coupling yields a mixture of all possible isomers, although the demanding trialkylsilyl groups favor the (*R*,*R*) and (*S*,*S*) forms. Whereas the zinc- and magnesium-containing complexes crystallize as dimers, the mononuclear tin compounds are monomeric in the solid state and in solution.

This zinc-mediated C−C coupling reaction is novel in zinc chemistry. However, it allows the quantitative synthesis of a dinuclear zinc complex with the metal atoms in close contact with one another, due to the folding of the Zn_2N_2 ring. Further investigations will now concentrate on the influence of the trialkylsilyl substituents on the properties of these compounds and comparison with the *tert*-butyl-substituted derivatives described earlier by van Koten and coworkers.[2,9]

Experimental Section

General Remarks: All experiments and manipulations were carried out under argon. Reactions were performed with standard Schlenk techniques and dried, thoroughly deoxygenated solvents. (*tert*-Butyldimethylsilyl)(2-pyridylmethyl)amine (**I**),[1] tin(II) bis[bis(trimethylsilyl)amide],[16−20] (Benzyl)(*tert*-butyldimethylsilyl)amine,[21] and dimethylmagnesium[43] were prepared according to literature procedures. NMR spectra were recorded with Jeol GSX270 and EX400 spectrometers. A Nicolet 520 FT-IR spectrophotometer was used to record the IR spectra; solid substances were measured in nujol between KBr plates (vs very strong, s strong, m medium strong, w weak, vw very weak, sh shoulder). The low carbon and nitrogen values of the elemental analyses are the result of carbide, carbonate, and nitride formation during combustion of the compounds. The NMR parameters are listed in Tables 3−5.

2-(Triisopropylsilylaminomethyl)pyridine [(2-Pyridylmethyl)(triisopropylsilyl)amine] (1): 2-(Aminomethyl)pyridine (3.24 g, 30.0 mmol) was dissolved in THF (20 mL). At −78 °C, a hexane solution of *n*-butyllithium (2.5 M, 12.0 mL, 30.0 mmol) was added dropwise. After complete addition, chlorotriisopropylsilane (6.42 mL, 30.0 mmol), dissolved in THF (5 mL), was added to the still cooled solution. The solution was then slowly warmed to room temperature and all volatile materials were removed under vacuum. Pentane (15 mL) was added to the remaining pink suspension and all insoluble solids were removed by filtration. After that, all volatile materials were distilled again in vacuo at 120 °C. The remaining oily liquid consisted of analytically pure **1**, which turned brown immediately upon exposure to air; yield: 7.25 g (27.4 mmol, 91%). IR: $\tilde{\nu}$ = 3373 m, 3091 w, 3011 sh, 2942 vs, 2892 vs, 2863 vs, 2758 vw, 2722 w, 1700 vw, 1646 vw, 1592 s, 1571 s, 1464 vs, 1434 s, 1407 s, 1387 m, 1382 m, 1366 w, 1342 w, 1319 vw, 1294 vw, 1255 w, 1249 w, 1213 w, 1145 sh, 1125 s, 1094 m, 1084 m, 1070 m, 1047 m, 1013 m, 994 m, 952 vw, 918 w, 883 vs, 841 w, 799 m, 752 s, 728 w, 680 s, 639 m, 830 m, 602 w, 553 w, 502 w, 462 w, 404 vw cm^{-1}. MS (EI): *m*/*z* (%) = 265 (11), 264 (46) [M^+], 263 (100) [$M^+ - H$], 223 (5), 222 (19), 221 (70) [$M^+ - C_3H_7$], 220 (11), 219 (10), 136 (5), 135 (29), 134 (9), 87 (5), 73 (6), 59 (10). $C_{15}H_{28}N_2Si$ (264.48): calcd. C 68.11, H 10.67, N 10.59; found C 67.19, H 10.29, N 10.72.

Methylzinc (2-Pyridylmethyl)(triisopropylsilyl)amide (2): A toluene solution of dimethylzinc (2.0 M, 11.5 mL, 23.0 mmol) was added to **1** (6.03 g, 22.8 mmol) in 10 mL of toluene. After 10 h, the volume of the dark solution was reduced to a few milliliters. At 5 °C, colorless **2** (5.10 g, 7.41 mmol, 65% of the dimer) precipitated. M.p. 72−74 °C. IR: $\tilde{\nu}$ = 3393 vw, 3138 vw, 3081 vw, 2764 vw, 2726 vw, 2269 vw, 1987 vw, 1922 vw, 1868 vw, 1842 vw, 1635 vw, 1603 s, 1571 m, 1541 vw, 1507 vw, 1486 m, 1471 sh, 1463 m, 1431 s, 1406 w, 1389 w, 1383 w, 1357 w, 1320 vw, 1284 m, 1245 w, 1207 vw, 1151 m, 1123 w, 1100 w, 1054 m, 1063 vs, 1016 m, 1011 m, 1003 m, 995 m, 987 m, 972 sh, 917 m, 883 vs, 846 sh, 836 s, 823 m, 803 vs, 794 vs, 754 vs, 723 m, 647 vs, 625 s, 562 w, 508 s, 487 m, 471 m, 460 m, 445 m, 412 m cm^{-1}. MS (EI): *m*/*z* (%) = 341 (3) [M$^+$/2], 263 (7) [M$^+$/2 − ZnMe], 222 (21), 221 (100) [263 − C_3H_6], 219 (94), 135 (24), 134 (14). $[C_{16}H_{30}N_2SiZn]_2$ (687.78): calcd. C 55.88, H 8.79, N 8.15; found C 55.19, H 8.64, N 8.13.

[1,2-Dipyridyl-1,2-bis(triisopropylsilylamido)ethane]bis(methylzinc) (3): A toluene solution of dimethylzinc (2.0 M, 7.5 mL, 15.0 mmol) was added dropwise to a solution of **1** (1.63 g, 6.16 mmol) in toluene (5 mL). After 1 h, the green solution was heated under reflux for an additional 20 h. The volume of the solution was then reduced to half of its original amount. At 5 °C colorless crystals of **3** (1.18 g, 1.72 mmol, 56%) precipitated. M.p. 250 °C (dec.). IR: $\tilde{\nu}$ = 3099 m, 3077m, 2711 w, 1993 vw, 1956 vw, 1920 vw, 1601 vs, 1571 s, 1474 vs, 1439 vs, 1410 sh, 1388 s, 1382 sh, 1365 w, 1345 m, 1331 w, 1288 s, 1254 s, 1241 sh, 1233 sh, 1210 w, 1158 sh, 1148 vs, 1105 s, 1070 sh, 1050 sh, 1041 vs, 1019 vs, 994 s, 970 w, 918 vs, 884 vs, 847 m, 780 vs, 753 s, 721 vw, 686 sh, 671 vs, 654 vs, 644 vs, 631 sh, 607 s, 565 m, 529 vs, 512 vs, 477 s, 417 m, 392 vw, 331 w, 283 cm^{-1} w. MS (EI): *m*/*z* (%) = 265 (23), 264 (81) [$C_{15}H_{28}N_2Si$], 263 (100) [$C_{15}H_{27}N_2Si$], 221 (16) [263-C_3H_6], 220 (13), 219 (19), 135 (15). $C_{32}H_{58}N_4Si_2Zn_2$ (685.76): calcd. C 56.04, H 8.53, N 8.17; found C 55.52, H 8.40, N 7.63.

Zinc Bis[(2-pyridylmethyl)(triisopropylsilyl)amide] (4): An *n*-hexane solution of *n*-butyllithium (2.5 M, 2.8 mL, 7.0 mmol) was added dropwise to **1** (1.85 g, 7.0 mmol) in THF (10 mL) at −78 °C. The solution was then warmed to 0 °C and zinc(II) bromide (0.79 g, 3.5 mmol) was added. After this had been stirred for 10 h, all volatile materials were removed in vacuo at room temperature. From the remaining oil, 0.89 g of colorless waxy crystals of **4** (1.51 mmol, 43%) were isolated.

[(2-Pyridylmethyl)(triisopropylsilyl)amine-*N*,*N*′]zinc(II) Chloride (5a): A suspension of zinc(II) chloride (1.14 g, 8.37 mmol) in THF (7 mL) was added to a solution of **1** (2.22 g, 8.39 mmol) in THF. After 10 min of stirring, the solution was cooled to −20 °C and a colorless precipitate of **5a** (2.15 g, 5.38 g, 64%) formed. M.p. 203 °C. MS (EI): *m*/*z* (%) = 363 (77) [M$^+$ − Cl], 307 (16), 263 (13) [M$^+$ − $ZnCl_2$], 221 (64) [263 − C_3H_6], 207 (30), 155 (27) [Si*i*Pr$_3$ − H_2], 154 (100), 136 (72), 105 (33) [263 − HSi*i*Pr$_3$], 91 (43) [263 − HNSi*i*Pr$_3$], 43 (48) [C_3H_7]. $C_{15}H_{28}N_2SiZnCl_2$ (400.764): calcd. C 44.95, H 7.04, N 6.99; found C 41.84, H 6.45, N 7.32.

[(2-Pyridylmethyl)(triisopropylsilyl)amine-*N*,*N*′]zinc(II) Bromide (5b): Zinc(II) bromide (1.61 g, 7.15 mmol) was added at 0 °C to a solution of **1** (1.77 g, 7.15 mmol) in THF (10 mL). The brown suspension was stirred for 12 h. The precipitate was collected and washed with several portions of pentane. After drying in vacuo, colorless **5b** (3.12 g, 6.36 mmol, 89%) was isolated. M.p. 236 °C (dec.). IR: $\tilde{\nu}$ = 3216 m, 1608 s, 1572 m, 1473 m, 1444 m, 1433 m, 1397 w, 1383 m, 1366 vw, 1353 vw, 1284 w, 1253 w, 1227 vw, 1213 w, 1157 vw, 1105 w, 1069 w, 1054 w, 1029 s, 1007 m, 983 m, 964 w, 914 m, 883 s, 842 w, 826 vw, 802 vw, 768 s, 753 s, 723 s, 673 s, 653 w, 605 w, 552 vw, 488 w, 473 vw, 445 w, 414 w, 398 vw, 368 vw, 339 cm^{-1} vw. MS (EI): *m*/*z* (%) = 409 (2) [M$^+$ − Br], 263 (1) [M$^+$ − $ZnBr_2$], 222 (68), 221 (100) [263 − C_3H_6], 136 (49). $C_{15}H_{28}N_2SiZnBr_2$ (489.664): calcd. C 36.79, H 5.76, N 5.72, Br 32.63; found C 34.98, H 5.48, N 5.51, Br 33.5.

Magnesium Bis[(2-pyridylmethyl)(triisopropylsilyl)amide] (6): A solution of **1** (2.57 g, 9.7 mmol) in pentane (50 mL) was cooled to 0 °C. A hexane solution of dibutylmagnesium (1.0 M, 4.85 mL, 4.85 mmol) was added dropwise. After 24 h of stirring at room temperature, the volume of the solution was reduced to a few milliliters and toluene (30 mL) was added. Colorless needles of **6** (2.53 g, 4.61 mmol, 95%) precipitated within hours. Dec. 100 °C. IR: $\tilde{\nu}$ = 1661 w, 1630 w, 1592 s, 1570 m, 1464 vs, 1435 s, 1407 s, 1382 m, 1366 w, 1343 w, 1319 vw, 1292 vw, 1214 w, 1150 sh, 1124 s, 1094 s, 1072 s, 1047 s, 1013 s, 995 m, 918 w, 882 s, 841 w, 798 s, 753 m, 728 w, 673 s, 653 m, 639 m, 602 m, 553 m, 501 m, 404 cm^{-1} w. MS (70 eV, EI): *m*/*z* (%) = 503 (10), 429 (20), 355 (31), 281 (46), 221 (100) [py−CH_2−Si*i*Pr$_2$]. $C_{30}H_{54}MgN_4Si_2$ (551.26): calcd. C 65.36, H 9.87, N 10.16; found C 59.55, H 9.79, N 8.00.

Methylmagnesium (2-Pyridylmethyl)(triisopropylsilyl)amide (7). − Method A: Compound **1** (1.85 g, 7 mmol) was added dropwise at 0 °C to a THF/dioxane solution of dimethylmagnesium (7 mL, 1.0 M), dissolved in 25 mL of additional THF. After 3 d of stirring at room temperature, the volume of the solution was reduced and needles of **7** precipitated at 5 °C in a quantitative yield. − **Method B:** Compound **6** (2.7 mmol) was dissolved in THF (20 mL), and a THF/dioxane solution of dimethylmagnesium (2.7 mL, 1.0 M) was added at 0 °C. After stirring for 3 d, the same workup procedure as described for Method A was applied. This compound was characterized by NMR spectroscopy, due to its slow decomposition even at room temperature.

Methylmagnesium (*tert*-Butyldimethylsilyl)(2-pyridylmethyl)amide (9): Toluene (10 mL) was added to a THF/dioxane solution of dimethylmagnesium (1 M, 2.42 mL, 2.42 mmol) at 0 °C. (*tert*-Butyldimethylsilyl)(2-pyridylmethyl)amine (0.54 g, 2.42 mmol) was now added dropwise to this solution. After 72 h of stirring at room temperature, the volume was reduced to a few milliliters. Colorless crystals of **9** (0.53 g, 1.03 mmol, 85%) precipitated at 5 °C. Slow dec. at room temperature. IR: $\tilde{\nu}$ = 1654 w, 1601 s, 1592 sh, 1569 s, 1472 s, 1435 s, 1408 m, 1388 m, 1360 w, 1294 vw, 1284 vw, 1251 s, 1210 vw, 1150 sh, 1116 s, 1100 s, 1048 s, 1018 m, 1007 m, 941 m, 908 w, 830 vs, 806 sh, 775 s, 758 sh, 661 m, 643 sh, 629 w, 566 w, 534 m, 523 m, 497 m, 416 w, 405 w, 370 w, 334 cm^{-1} vw. MS (70 eV, EI): *m*/*z* (%) = 221 (100) [py−CH_2NSiMe$_2$*t*Bu], 207 (11) [py−CH_2NSiMe$_2$*t*Bu − Me], 191 (4) [py−CH_2NSiMe$_2$*t*Bu − 2 Me], 165 (83) [py−CH_2NSiMe$_2$], 134 (37) [py−CH_2NSi], 57 (21) [*t*Bu]. $C_{26}H_{48}Mg_2N_4Si_2$ (521.48): calcd. C 59.88, H 9.28, N 10.75; found C 58.31, H 9.26, N 10.01.6

Bis[(trimethylsilyl)amido]tin(II) (2-Pyridylmethyl)(triisopropylsilyl)-amide (11): Compound **1** (1.1 g, 4.1 mmol) was added at room temperature to a solution of of tin(II) bis[bis(trimethylsilyl)amide] (1.62 mL, 4.1 mmol) in 20 mL of toluene. After stirring for 6 d, the volume was reduced to a few milliliters and 5 mL of THF was added. Cooling to −20 °C afforded colorless crystals of **11**. This compound slowly underwent the C−C coupling reaction and so only the NMR spectroscopic data are presented in Table 4.

[1,2-Dipyridyl-1,2-bis(triisopropylsilylamido)ethane]tin(II) (12): Tin(II) bis[bis(trimethylsilyl)amide] (4.5 mL, 11.7 mmol) was added at room temperature to a solution of **1** (3.1 g, 11.7 mmol) in toluene (40 mL). During heating of this solution, the precipitation of tin metal was observed. After decantation, the volume of the solution

[Bis(trimethylsilyl)amido]tin(II) (*tert*-Butyldimethylsilyl)(2-pyridylmethyl)amide (13): Amine **I** (0.77 g, 3.46 mmol) was dissolved in toluene (20 mL). At room temperature, tin(II) bis[bis(trimethylsilyl-)amide] (1.35 mL 3.46 mmol) was added. After 6 d of stirring, the volume of the solution was reduced and **13** precipitated quantitatively at 5 °C as a polycrystalline material, which decomposed slowly even at room temperature. IR: $\tilde{\nu}$ = 2953 vs, 2894 vs, 2850 vs, 2799 w, 1993 vw, 1905 vw, 1854 vw, 1608 s, 1570 m, 1505 sh, 1485 m, 1470 s, 1440 s, 1420 m, 1387 m, 1358 w, 1281 s, 1251 vs, 1180 w, 1155 m, 1099 s, 1050 s, 1005 m, 993 m, 946 vs, 901 vs, 863 vs, 832 vs, 777 s, 757 s, 716 m, 700 m, 668 vs, 582 vw, 490 w, 463 vw, 416 vw, 361 w.

[1,2-Bis(*tert*-butyldimethylsilylamido)-1,2-dipyridylethane]tin(II) (14): Tin(II) bis[bis(trimethylsilyl)amide] (2 mL, 5.12 mmol) was added at room temperature to a solution of **I** (1.14 g, 5.12 mmol) in toluene (20 mL). Heating for 3 d at 80 °C resulted in the precipitation of tin metal. After removal of the metal, the volume of the solution was reduced. At −20 °C, 1.40 g of colorless crystals of **14** (2.55 mmol, 98%) precipitated. M.p. 143 °C. IR: $\tilde{\nu}$ = 1684 sh, 1656 w, 1601 s, 1587 s, 1567 s, 1470 vs, 1462 vs, 1440 s, 1432 s, 1416 m, 1410 m, 1356 m, 1338 w, 1319 m, 1285 m, 1252 vs, 1208 sh, 1154 m, 1141 m, 1102 s, 1090 vs, 1071 vs, 1046 s, 1014 s, 1005 s, 994 s, 969 vs, 958 s, 937 m, 922 s, 903 s, 886 vs, 829 vs, 807 vs, 776 vs, 767 vs, 748 vs, 673 m, 660 s, 641 s, 622 m, 606 s, 573 w, 545 m, 522 s, 490 m, 456 w, 415 m, 393 m, 371 w, 357 w, 335 vw, 323 vw, 300 vw, 283 cm^{-1} w. Zinc Bis[(benzyl)(*tert*-butyldimethylsilyl)amide] (15): A hexane solution of butyllithium (2.5 M, 3.95 mL, 9.88 mmol) was added dropwise at −78 °C to (*tert*-butyldimethylsilyl)(2-pyridylmethyl)amine (1.93 g, 8.99 mmol) in pentane (10 mL). During the warm-up, a colorless solid precipitated. This suspension was stirred at room temperature for an additional 8 h. At −18 °C the lithium salt crystallized and was isolated by decanting the mother liquor. This crystalline material was redissolved in pentane (25 mL) at 0 °C. Zinc(II) bromide (1.00 g, 4.44 mmol) was then added and the solution was stirred at room temperature for several days. A colorless precipitate formed and was separated. The volume of the solution was reduced to afford an oily residue. At −18 °C, 1.25 g of colorless crystals of **15** (2.47 mmol, 55%) grew in the oil. M.p. 65 °C. ^{1}H NMR ([D$_6$]benzene): δ = 7.17 (m, 5 H, Ph), 3.86 (s, 2 H, CH_2), 0.96 (s, 9 H, tBu), 0.02 (s, 6 H, $SiCH_3$). ^{13}C{^{1}H} NMR ([D$_6$]benzene): δ = 148.21 (C_q, Ph), 129.36 (Ph), 127.29 (Ph), 126.79 (Ph), 51.92 (CH_2), 27.31 (CCH_3), 19.76 (CCH_3), −3.63 ($SiCH_3$). ^{29}Si{^{1}H} NMR ([D$_6$]benzene): δ = 7.05. IR: $\tilde{\nu}$ = 3409 vw, 3087 vw, 3067 w, 3028 w, 2954 vs, 2926 vs, 2899 vs, 2883 vs, 2855 vs, 2806 sh, 2799 w, 2718 vw, 1680 sh, 1650 vs, 1619 sh, 1605 m, 1583 m, 1568 sh, 1537 vw, 1509 sh, 1494 m, 1471 vs, 1463 s, 1453 s, 1389 s, 1361 m, 1306 w, 1292 vw, 1252 vs, 1209 w, 1199 w, 1166 vw, 1115 s, 1102 s, 1070 m, 1028 m, 1007 m, 973 vw, 938 w, 912 vw, 898 w, 845 vs, 831 s, 814 s, 774 vs, 749 s, 728 m, 696 s, 663 m, 586 w, 561 w, 482 m, 420 w, 369 w, 334 cm^{-1} vw. MS (EI): *m*/*z* (%) = 504 (1) [M^+], 489 (1) [M^+ − Me], 447 (47) [M^+ − tBu], 367 (14), 353 (29), 165 (17) [$C_{13}H_{22}NSi$-C_4H_8], 164 (100) [$C_{13}H_{22}NSi$ − tBu], 162 (32), 148 (13), 135 (58), 91 (29) [Bzl], 73 (25) [$SiMe_2t$Bu − C_3H_6], 59 (41) [$SiMe_2t$Bu − C_4H_8], 57 (13) [tBu]. $C_{26}H_{44}N_2Si_2Zn$ (506.225): calcd. C 61.69, H 8.76, N 5.54, found C 61.95, H 9.17, N 5.42.

Crystal Structure Determinations: Data were collected with a STOE-IPDS diffractometer (compounds **2**, **12**, **12′**, and **14**) and a Siemens P4 diffractometer with a Siemens SMART-CCD area detector (compounds **8**·0.5THF, **9**, and **9·10**) using oil-coated, rapidly cooled single crystals.[44,45] The data for **3** were collected with a Nonius CAD4 diffractometer using a single crystal sealed in a glass capillary. In all cases, graphite-monochromated Mo-K_α radiation (λ = 71.073 pm) was used. Crystallographic parameters, details of data collection, and refinement procedures are summarized in Table 6.

The structures were solved by direct methods and refined with the software packages SHELXL-93 and SHELXL-97.[48] Neutral scattering factors were taken from Cromer and Mann[49] and those for the hydrogen atoms from Stewart et al.[50] The non-hydrogen atoms were refined anisotropically. The H atoms were considered with a riding model under restriction of ideal symmetry at the corresponding carbon atoms or refined isotropically. Crystallographic details can be obtained from the Cambridge Data Centre quoting the CCDC numbers given in Table 6.[47]

Acknowledgments

This work was financially supported by the Deutsche Forschungsgemeinschaft, Bonn, and the Fonds der Chemischen Industrie, Frankfurt/Main. We thank Mr. S. Correll for performing the X-ray powder diffraction experiments of precipitated zinc and tin metals and Dr. A. Lötz for the ESR experiments. Prof. G. van Koten (Utrecht University) provided helpful suggestions and contributions to the discussion of the mechanism. T. B. wishes to express his gratitude to the Fonds der Chemischen Industrie for a Ph.D. scholarship.

Zirconocenes as Photoinitiators for Free-Radical Polymerisation of Acrylates

Eleonora Polo,*[a] Andrea Barbieri,[a] Silvana Sostero,[a] and Malcolm L. H. Green[b]

Keywords: Metallocenes / Zirconium / Photolysis / Homogeneous catalysis / Polymerizations

This paper reports the photochemical behaviour of unbridged (**1**–**6**) and bridged zirconocenes (**7r**, **7m**), whose substituents differ in both electron-donor and steric properties. The study of the electronic spectra and EPR spin-trapping experiments showed the photogeneration of ligand- and zirconium-centred radicals at wavelengths higher than 350 nm. This feature makes these complexes suitable as photoinitiators for radical polymerisation processes. *tert*-Butyl acrylate polymerisation has been studied in detail and the results are particularly encouraging as far as the reaction yields and the stereochemistry are concerned. In particular, the complexes **4**–**6**, due to the tuneability of their structure and their stability in solution, look the most promising reagents.

Introduction

Photochemical or photoinitiated polymerisations play a central role in several commercial technologies[1−3] and they are largely employed today in the areas of surface coatings, photoresists, adhesives, and holography. In particular, a growing area of interest is the design of new photoinitiators for use in pigmented coatings. Among those, initiators showing absorption peaks at wavelengths higher than 350 nm[4] are of particular interest since they can be used with the visible light produced by continuous wave lasers.

Photoinitiated reactions offer several potential advantages over conventional thermally activated processes since the absorption of a photon generates an electronic excited state whose chemical reactivity can differ substantially from that of the ground state. As a consequence, the involvement of an excited state can induce a reaction pathway that does not occur thermally or occurs only at very high temperatures.

Light is a clean, tuneable and versatile "reagent", since it allows the selective activation of a photoinitiator also in the presence of organic solvents and chemical contaminants. Regulation of light intensity affords a convenient means of controlling reaction kinetics and photoinitiation can also be spatially directed and turned on or off simply by switching the light source. Other potential advantages of the photochemical reactions include reduced energy requirements, increased shelf life of substrate formulations, and greater compatibility with heat-sensitive materials. Other commendable features are low toxicity and friendly environmental impact.

The desire to expand the application of photoinitiated chemistry beyond organic systems has led recently to the discovery of several classes of inorganic and organometallic photoinitiators.[5−9] Among them, metallocenes have attracted increasing interest because it is possible to tailor the polymer microstructure by systematic, rational variation of the cyclopentadienyl ligand substituents, whether they are connected by an interannular bridge or not. Moreover, they leave low-toxic residues and they photobleach with high efficiency, thus leaving clear or colourless coatings after exposure to argon lasers.[5]

Despite their importance in organometallic chemistry and catalysis, to now few studies have been performed on the photochemistry of metallocene complexes of Ti, Zr, and Hf.[10−17] Moreover, while the relationship between the catalytic activity of Group IV metallocenes and their structure has been thoroughly studied, very little is known about its correlation with their electronic properties.

In this paper we report the photochemical behaviour of zirconocenes, whose substituents differ in both electron-donor and steric properties. Several unbridged zirconium complexes have been studied: bis(η^5-cyclopentadienyl)zirconium dichloride (Cp_2ZrCl_2, **1**), bis(η^5-pentamethylcyclopentadienyl)zirconium dichloride ($Cp^*_2ZrCl_2$, **2**), bis(η^5-indenyl)zirconium dichloride (Ind_2ZrCl_2, **3**), bis(η^5-tetrahydroindenyl)zirconium dichloride (THI_2ZrCl_2, **4**), bis(η^5-hexahydroazulenyl)zirconium dichloride [$(C7)_2ZrCl_2$, **5**], and bis[η^5-(4,5,6,7,8,9-hexahydro-1*H*-cyclopentacyclooctenyl)]zirconium dichloride [$(C8)_2ZrCl_2$**6**].

They have been also compared with two bridged complexes, *rac*-[ethylenebis(4,7-dimethyl-η^5-1-indenyl)]zirconium dichloride (*rac*-$EBDMIZrCl_2$, **7r**), and its *meso* isomer *meso*-$EBDMIZrCl_2$ (**7m**), in order to check if some of the

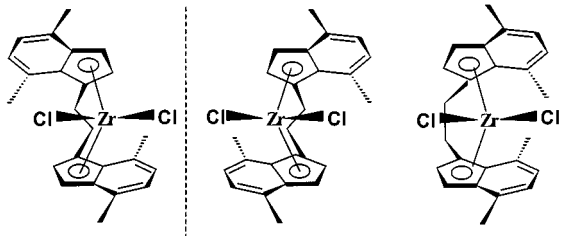
original stereocontrol properties were retained after irradiation and could be applied in catalysis.



7r **7m**

Preliminary olefin photopolymerisation tests have also been carried out to verify their activity as photoinitiators for α-olefins.

Results and Discussion

Photochemistry

UV/Vis spectra of the zirconocenes under study were recorded in benzene, THF and CH_2Cl_2. No solvent effect was observed, neither on the λ_{max}, or on the ε_{max} values. The results are reported in Table 1. All complexes exhibit at least one electronic transition in the visible range of the spectrum (at $\lambda > 320$ nm) with ε values of the order of 10^3 $mol^{-1}\cdot L\cdot cm^{-1}$. The progressive red-shift of the bands as the electron-donor activity of the cyclopentadienyl substituents increases supports the hypothesis of LMCT character for the low-energy electronic transition.

Selective photolysis was carried out on the complexes at the wavelength corresponding to their LMCT transition, in order to ascertain if they can be employed as initiators in radical photopolymerisation and to optimise the reaction conditions. The primary quantum yield corresponding to the metal-ring cleavage is of the order of 0.28 for all the unbridged compounds, and of 0.11 for $EBDMIZrCl_2$ (**7r** and **7m**). Long-time photolysis led to the bleaching of the solutions due to evolution of the complexes, as determined by NMR analysis.

Table 1. Spectral band maxima of zirconocene complexes in solution (benzene, THF or CH_2Cl_2)

Zirconocene	λ_{max} [nm]	ε_{max} ($mol^{-1}\cdot L\cdot cm^{-1}$)
Cp_2ZrCl_2	290	2400
	340	620
$Cp^*_2ZrCl_2$	350	1580
	370	1990
Ind_2ZrCl_2	310	1475
	380	720
THI_2ZrCl_2	310	1600
	350	1100
$(C7)_2ZrCl_2$	310	2380
	345	1540
$(C8)_2ZrCl_2$	305	2920
	345	1720
meso-$EBDMIZrCl_2$	380	1130
rac-$EBDMIZrCl_2$	425	1350

The solvent nature strongly affects the stability of the complexes in solution, and it emphasises the differences among the metallocenes; in particular, in benzene and in toluene, (Figure 1) after 1 h of irradiation, only the 5−10% (by UV/Vis spectroscopy) of the complexes **4**−**6** were decomposed and the degradation rates were $Ind_2ZrCl_2 > Cp^*_2ZrCl_2 > Cp_2ZrCl_2 >> (THI)_2ZrCl_2 > (C7)_2ZrCl_2/(C8)_2ZrCl_2$.

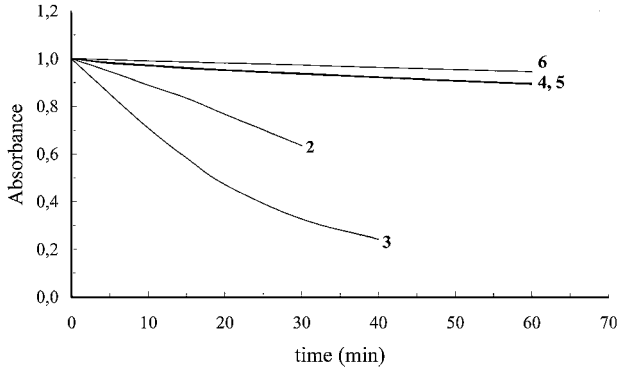


Figure 1. Absorption maxima decay of the zirconocenes **2**−**6** in benzene as a function of time

Pure solutions of **4**−**6** in benzene or in toluene were more stable and the photodecomposition was reversed after 24 h of storage in the dark. The initial spectral pattern and absorbance values were almost completely recovered.

Figure 2 shows that in THF the photodecomposition of the compounds **1**−**6** was faster (30−70%) and followed the same trend as in benzene solution. The increased rate of decomposition may be due to stronger coordinating properties of THF. We note that the UV/Vis spectra in THF have a different shape from those in toluene or benzene.

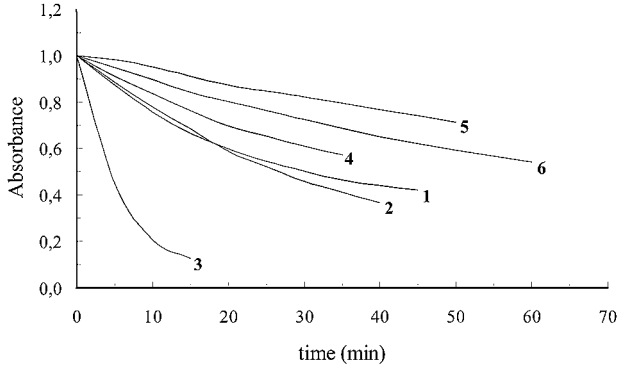

Figure 2. Absorption maxima decay of the zirconocenes **1**−**6** in THF as a function of time

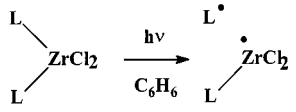
EPR Spin Trapping Investigation

In order to assess the nature of the primary photochemical act, EPR/spin trapping experiments have been carried out by direct irradiation of benzene solutions of the zirconocenes inside the spectrometer cavity. Different spin traps, i.e. *N*-*tert*-butyl-α-phenylnitrone (PBN), nitrosodurene (ND), and 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO), were used in order to identify unambiguously the nature of the radical species.[18−19] By comparison with NIEHS Spin Trap Database data,[20] the hyperfine coupling constants (*hfcc*) of the spin adducts detected and reported in Table 2, could be assigned to cyclopentadienyl-type radicals. Therefore, the primary photochemical act can be described by Scheme 1.

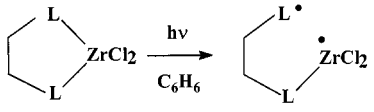
Table 2. Hyperfine coupling constants of cyclopentadienyl-type spin adducts (all values are expressed in Gauss)

Zirconocene	ND	PBN	DMPO
Cp_2ZrCl_2	a_N = 13.7	a_N = 14.6	a_N = 14.0
	a_H = 15.3	a_H = 2.9	a_H = 20.2
$Cp^*_2ZrCl_2$	a_N = 13.5	a_N = 14.6	a_N = 14.8
		a_H = 4.0	a_H = 20.3
Ind_2ZrCl_2	a_N = 13.8	a_N = 14.6	a_N = 14.0
	a_H = 15.4	a_H = 2.5	a_H = 20.0
THI_2ZrCl_2	a_N = 13.8	a_N = 14.6	a_N = 14.2
	a_H = 13.8	a_H = 3.2	a_H = 20.8
$(C7)_2ZrCl_2$	a_N = 13.8	a_N = 14.5	a_N = 14.2
	a_H = 15.9	a_H = 2.9	a_H = 20.4
$(C8)_2ZrCl_2$	a_N = 13.8	a_N = 14.7	a_N = 14.0
	a_H = 21.3	a_H = 3.0	a_H = 20.3
$EBDMIZrCl_2$	a_N = 14.0	a_N = 14.6	a_N = 14.3
	a_H = 9.8	a_H = 2.3	a_H = 20.4



Scheme 1

The case of the bridged *rac*- and *meso*-metallocenes is rather complicated since the photodissociation of one of the two L−Zr bonds gives a biradical species as a consequence of the bridge and because the light causes also a partial interconversion between the two isomeric forms.[17] In this case, the primary photochemical act can be described by Scheme 2.



Scheme 2

The presence of radical intermediates in the zirconocenes' photochemical reactions suggests a possible use as photoinitiators for radical polymerisation processes. In order to test the effectiveness of these organometallic photoinitiators, similar EPR/spin trapping experiments were performed in the presence of different alkenes, i.e. 1-pentene, methyl methacrylate (MMA) and *tert*-butyl acrylate (*t*BA), and in different solvents, benzene and dichloromethane. During irradiation of the zirconocene/alkene mixtures the growth of a new EPR signal characteristic of a carbon-centred radical has been detected (a_N = 14.7−14.9 G; a_H = 3.0−3.6 G). The results are reported in Table 3.

Removal of the solvent left a polymeric film, while no polymer formation was observed even after prolonged irradiation in the absence of metallocenes. This observation supports the proposal that the radical species produced upon irradiation can add to the double bond of the monomers, thus initiating the radical polymerisation process. When the same experiments were carried in CH_2Cl_2, the $^{\cdot}CH_2Cl$ radical was also detected (a_N = 14.2 G; a_H = 3.1 G) (see Table 3, last column). This species can act as a second photoinitiator and this accounts for the higher monomer conversions obtained when the polymerisations were carried in halogenated solvents.[21−23]

The stability of the complexes in the presence of the monomers has been also determined. We found that in benzene and in toluene only 10% of the complexes was decomposed after 1 h of irradiation, whilst in THF the decomposition was more rapid and ca. 60% of the complexes **4−6** was decomposed, while the other metallocenes were completely decomposed in the same period.

Polymerisation Studies

On the basis of these findings, polymerisation tests were performed on *tert*-butyl acrylate, since the polymerisation of acrylates is of industrial interest and has been the subject of intensive experimental investigations and practical application. Recently, zirconocene complexes were introduced as catalysts or catalyst precursors for methyl methacrylate polymerisation.[24−27] We tested the most promising metallocenes in benzene and in CH_2Cl_2, and we can compare our data with what reported[28−34] for similar systems. We have also determined whether there is evidence for stereochemical control by the *ansa*-zirconocenes **7r** and **7m** (Table 4). The tacticity of the poly(*t*BA) formed has been estimated by deconvolution of the methine peaks which occurs at δ ≈ 42 in the ^{13}C NMR spectra (Figure 3).

The EPR data (vide supra) for the polymerisations in CH_2Cl_2 with the complexes **4−6** gave higher product yields than in benzene solutions due to the synergistic effect of the $^{\cdot}CH_2Cl$ radical. This effect was quite negligible with the *ansa*-bridged metallocenes **7r** and **7m**. The stereochemical outcome of the reaction was independent of the solvent and of stereochemistry of the compounds **7r** and **7m.**

The polymer yields shown in Table 4 compare favourably with the yields reported for polymerisations using chiral metallocenes with alumoxanes.[28] For example, after only 1 h, we have 22−36% polymer yield, when the literature values were only 13% after 17 h. The stereochemical properties of the polymers (Table 4) are comparable to those reported for other catalysts,[30−34] even though the latter had more complex and rigid stereochemical features.

Conclusion

Known and new zirconocene complexes are described here to be photoinitiators for radical polymerisation processes. *tert*-Butyl acrylate polymerisation has been studied in detail with both bridged (**7r** and **7m**) and unbridged complexes (**4**−**6**) and the results are particularly encouraging as far as the reaction yields and the stereochemistry are concerned. Also the use of non-halogenated solvents is environmentally desirable.

We propose to take advantage of the ability to modify the structure of the complexes **4**−**6**,[35] in order to tune the optical properties and radical stability.

Experimental Section

General Remarks: All manipulations of air- and/or moisture-sensitive materials were carried out under an inert gas using a dual vacuum/argon line and standard Schlenk techniques. All solvents were thoroughly dehydrated and deoxygenated under argon before use. They were dried and purified by refluxing under argon over a suitable drying agent (benzene, toluene and THF over Na/benzophenone ketyl; CH_2Cl_2 over CaH_2) followed by distillation, and stored under argon in Young's ampoules. Solvents and solutions were transferred, using a positive pressure of argon, through stainless-steel cannulae (diameter 0.5−2.0 mm) and mixtures were filtered in a similar way using modified cannulae which could be fitted with glass-fibre filter disks (Whatman GFC).

Preparation of the Complexes: Metallocenenes THI_2ZrCl_2 (**4**),[35] $(C7)_2ZrCl_2$ (**5**),[35] $(C8)_2ZrCl_2$ (**6**),[35] Ind_2ZrCl_2 (**3**),[36] and EBDMIZrCl$_2$ [37] were prepared as described previously; Cp_2ZrCl_2 (**1**), and $Cp^*_2ZrCl_2$ (**2**) were purchased from Sigma-Aldrich Chem. Co. and used without further purification.

NMR Spectra: ^1H (200.13 MHz) and ^{13}C (50.32 MHz) nuclear magnetic resonance spectra were recorded at room temperature

with a Bruker AC200 spectrometer. Spectra were referenced internally using the residual protio solvent resonance relative to tetramethylsilane ($\delta = 0$). Deuterated solvents were dried and distilled under argon over a suitable drying agent (CaH_2 for $CDCl_3$ and K for C_6D_6) and stored under argon in Young's ampoules.

EPR Studies: The spin traps PBN, ND and DMPO were purchased from Sigma-Aldrich Chem. Co. and used without further purification, except from DMPO, which was distilled under vacuum below 40 °C to remove paramagnetic impurities. The EPR/spin trapping experiments were performed with a Bruker EMX spectrometer, operating in the X-band (microwave frequency: 9.6 GHz; microwave power: 2 mW; modulation frequency: 100 kHz; modulation amplitude: 1 G; sweep rate: 50 G/min; time constant: 20 ms). Sample solutions were irradiated with a 350-W medium-pressure Hg lamp directly into the EPR spectrometer (Bruker ER-4104OR, TE102) cavity. Solid α,α′-diphenyl-β-picrylhydrazyl was used as external reference for *g* values. The *hfcc* values were calculated by best-fit simulation of experimental spectra using the NIEHS WinSim software.[38]

Photochemical Experiments: Irradiation was performed using an Oriel 500-W high-pressure Hg lamp using either a grating monochromator (Jasco CT-25A) or cut-off filters for wavelength selection. UV/Vis spectra were recorded with a Jasco UVIDEC-610 double-beam spectrophotometer.

Polymerisation Tests: 1-Pentene, methyl methacrylate and *tert*-butyl acrylate were dehydrated over molecular sieves (4Å) and freed from the stabilisers by filtration before use. In a typical experiment a 20% monomer solution in a 4-mL cuvette was irradiated for 1 h in the presence either of 7 mg of an unbridged metallocene at $\lambda = 350$ nm, or of 3 mg of an *ansa*-bridged metallocene at $\lambda = 410$ nm. After 1 h, the polymerisation was quenched with methanol and HCl, and the polymer was recovered after removal of the solvents under reduced pressure.

Dynamic Behaviour of Tris(2-methylallyl)chromium − NMR and DFT Results

Richard Blom*[a] and Ole Swang[a]

Keywords: Chromium / Allyl complexes / Paramagnetism / NMR spectroscopy / Density-functional calculations

The variable-temperature ^{1}H NMR spectra of paramagnetic (2-Me-allyl)$_3$Cr in [D$_8$]toluene were recorded in the temperature range from 243 to 323 K. The changes observed in the spectra are interpreted in terms of intramolecular dynamic behaviour. Line-shape analyses gave an entropy of activation $\Delta H^{\ddagger}$ of 40(5) kJ/mol, and an entropy of activation $\Delta S^{\ddagger}$ of –31(4) J/mol·K for the observed transformation. This corresponds to a free energy of activation $\Delta G^{\ddagger}$ of 49(6) kJ/mol at 300 K. Different possible mechanisms were investigated by DFT. The presence of two different conformers, which were converted into each other by rotation of one allyl ligand around the allyl–chromium axis, may explain the observations.

Introduction

Homoleptic allyl complexes of the early transition elements (Groups 4−6) were prepared for the first time in the 1960s.[1] The complexes can act as one-component catalysts for polymerisation of 1-olefins and α,ω-dienes, both in homogeneous solutions and as deposits on oxide supports.[2] Despite their practical potential, the molecular structures of these complexes have not been determined experimentally, which is mostly due to their thermal instability. One property that has been widely studied for the Group 4 allyl complexes is the "rotation" of the allyl ligand that interchanges the *syn* and *anti* protons.[3] The activation energy for this transformation is typically found to be in the range 40 to 60 kJ/mol using variable-temperature NMR.

The Cr^{III} complex Cr(C$_3$H$_5$)$_3$ is paramagnetic, and has therefore not been analysed properly by NMR methods. An early crystal structure has been reported;[4] unfortunately, the quality of the data did not allow detailed structural information to be deduced, but the gross picture is a molecule with close to C_3 symmetry and close to trihapto-bonded allyl ligands. We recently reported the molecular structures of both Cr(allyl)$_3$ and Cr(2-Me-allyl)$_3$ from DFT calculations.[5] Both these molecules have C_{3h} symmetry. The dimeric Cr^{II} complex Cr$_2$(C$_3$H$_5$)$_4$, prepared by thermal decomposition of Cr(C$_3$H$_5$)$_3$, has been fully characterised by single-crystal X-ray diffraction;[6] it is diamagnetic and has thus also been characterised by ^{13}C NMR.[7]

In the present paper we report the observed high-power ^{1}H NMR spectra of (2-Me-allyl)$_3$Cr, dissolved in deuterated toluene, in the temperature range from −60 to +40 °C. From line-shape analysis, we have deduced the kinetic parameters for the transformation observed and we have used DFT calculations to test possible mechanisms that can explain the observed dynamics.

Results and Discussion

^{1}H NMR spectra recorded at different temperatures are shown in Figure 1. Except for a strong signal at $\delta \approx 0$ (not shown), no other signals, other than those shown in Figure 1, were observed in the range from $\delta = -5000$ to +5000. The signal at $\delta \approx 0$ results from the diamagnetic species present: the protons of the imperfectly deuterated solvent, residual pentane, and 2,5-dimethylhexa-1,5-diene, formed as a by-product during the synthesis. At low temperatures, there are three broad signals at $\delta \approx 70$, 85, and 160, with relative peak areas of roughly 1:2:3.

Normally, one would assign these three peaks to the three symmetrically independent protons present: the protons of the methyl groups, the *syn* protons and the *anti* protons. As the temperature increased, there seemed to be a coalescence of all peaks at approximately 295 K. The fact that all observed protons ended up being magnetically equivalent, indicates that either a facile proton exchange was taking place in the complex, or that our first interpretation is wrong. NMR signals from paramagnetic species are notoriously difficult to assign, and some peaks might not be observable due to extreme broadening by the paramagnetic centre present. If the latter were the case, the protons closest to the chromium atom would be most heavily influenced by the paramagnetic effect; hence, their resonances could be expected to be undetectable. An alternative assignment of the three peaks could then be that the three peaks stem from three individual methyl groups or from three different individual protons of the methyl groups. In either case, all protons of the methyl groups become equivalent at elevated

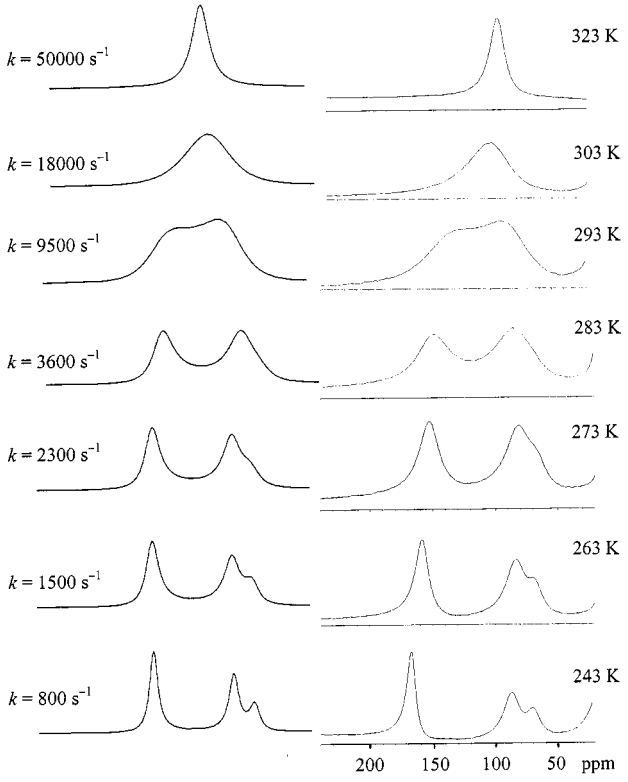

Figure 1. Experimental (right column) ^{1}H NMR spectra of (2-Me-allyl)$_3$Cr recorded in [D$_8$]toluene at the temperatures indicated; on the left are the modelled spectra shown with the corresponding rates

temperatures. Non-equivalent methyl groups can indicate that more than one conformation is present.

As noted above, NMR spectroscopy often gives little information on the structure of organometallic Cr^{III} complexes due to extreme line broadening.[8] The half-width of the peaks observed at low temperatures are large, the narrowest peak at $\delta = 160$ having a half-width of about 2400 Hz at 243 K, which is at the lower end of the estimated range suggested for Cr^{III} species (3000−25000 Hz at 500 MHz).[9] The enhancement of the nuclear longitudinal relaxation rate due to dipolar coupling to unpaired electrons is proportional to r^{-6}. The distance between the paramagnetic centre and the allylic protons is about 73% of the average distance to the methyl protons, meaning that the expected half-width of the allylic protons will be around 16000 Hz (80 ppm). Possible fluxional behaviour might increase the half-width further, and consequently the peaks would easily go into the background and thus remain unobserved. In addition, Cr(allyl)$_3$ does not give any peaks in the range from $\delta = -300$ to 300, which is a further indication that the allylic protons were not observed within this range for (2-Me-allyl)$_3$Cr.

The calculated structure of the tris(2-methylallyl)chromium molecule, structure **1** on the left in Figure 2, has been reported earlier.[5] It has C_{3h} symmetry and a ^{4}A′ electronic ground state, and in the following, its energy will be taken as the zero reference.

One might envisage three different interpretations of the observed NMR spectra:

A. Proton transfer from a methyl group to a terminal CH_2 group. The transfer may be either intra-allylic, or it may be a concerted mechanism involving all three allyl ligands.

B. Rotation of the allyl groups around the allyl−chromium axis. Actually, if we only observe the methyl groups, rotation around the allyl−metal axis cannot be separated, mechanistically, from the *syn*/*anti* exchange described in the introduction. Both routes were examined.

C. Rotation of the methyl groups.

Reaction path A may include an intermediate in which a hydrogen atom is removed from the methyl group of a 2-methylallyl ligand, giving an intermediate having both a hydrido and a trimethylenemethane ligand. For simplicity, the latter will be called corvyl[10] in the following discussion. This reaction path is shown as (i) in Figure 2. The intermediate, (corvyl)(hydrido)bis(2-methylallyl)chromium (**2**) was calculated to be as much as 105 kJ/mol higher in energy than its homoleptic allyl analogue. The distance between the hydrido ligand and one carbon atom of the corvyl ligand was chosen as a reaction coordinate for the reconstruction from (corvyl)(hydrido) to homoleptic triallyl. A transition state was found to be only 11 kJ/mol higher in energy than the (corvyl)(hydrido) intermediate, with a C−H distance of 1.66 Å. The complete exchange of a hydrogen atom requires the formation of (corvyl)(hydrido), then a 120° rotation of the corvyl ligand, followed by the reconnection of the corvyl and the hydrido ligands to a 2-methylallyl ligand. The exchange transforms a methyl group into a CH_2 group and at the same time transforms a CH_2 group into a methyl group. The activation energy of 116 kcal/mol is too high for reaction (i) to take place within the NMR timescale at the temperature in question, and hence other reaction paths must be investigated.

One could envisage a concerted transfer of hydrogen atoms between all three methylallyl groups. Structural optimisations were attempted in which all C−H distances for the transferring hydrogen atoms were constrained to be equal; the starting geometry is shown in Scheme 1. These attempts were fruitless, as they invariably converged to unphysical geometries of very high energies (> 250 kJ/mol). We therefore concluded that a proton transfer between the methyl group and the CH_2 group of the allyl ligand has too high a barrier, and thus cannot be used to explain the dynamics in the observed ^{1}H NMR spectra.

Our suggested mechanisms B and C are both based on the assumption that the allylic protons of the ligands are unobserved. Mechanism B concerns a rotation of one of the allyl ligands as shown as route (ii) in Figure 2. In the ground-state geometry all the methyl groups are connected by symmetry, and are thus expected to give only one peak in the ^{1}H NMR spectrum. However, by rotating one allyl group around the allyl−chromium axis by approximately 180°, a conformer is obtained in which all three methyl groups are, in principle, non-equivalent. This conformer **3** is expected to give three signals in the NMR spectrum, and

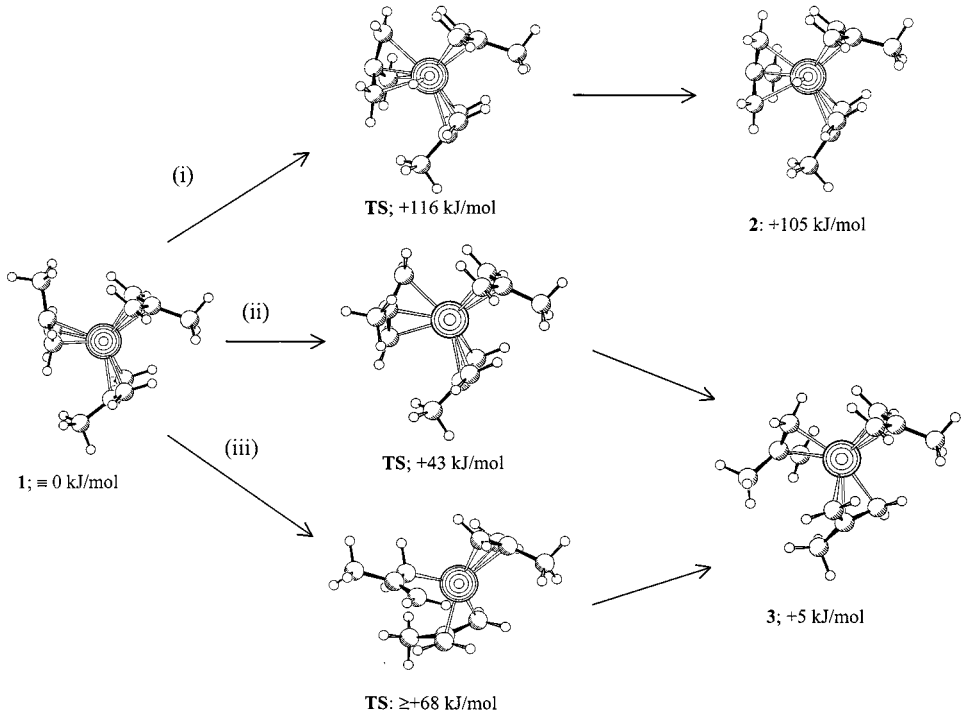

Figure 2. The structures and energies of central species and transition states (TS) obtained from DFT calculations: (i) transformation of one allyl ligand into a hydrido(trimethylenemethyl) complex; (ii) pure rotation of one allyl ligand around the allyl−chromium axis; (iii) $\eta^3 \rightarrow \eta^1 \rightarrow \eta^3$ transformation leading to the same conformer as route (ii); see text for more details

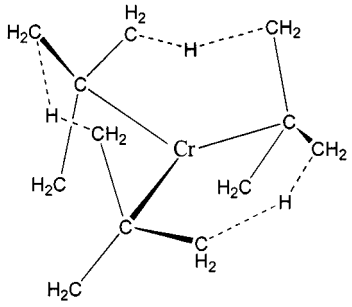

Scheme 1

the energy is only 5 kJ/mol higher than the ground-state geometry. The rotation goes through a transition state, the structure of which is shown in the centre of Figure 2, with a relative energy of 43 kJ/mol. Considering the accuracy of the DFT energies, it is reasonable to suggest that both conformers are present at low temperatures. A possible interpretation of the observed ^{1}H NMR spectra is then that the high-symmetry conformer **1** gives rise to the single peak at $\delta = 160$, while the two broad peaks at $\delta = 70$ and 87, of different intensities, are due to the three methyl peaks of conformer **3**. For the latter conformer there is an additional fluxionality due to the flipping of two methyl groups having van der Waals contacts from side to side. The barrier for this flipping was estimated from DFT modelling to be 8 kJ/mol. This is below the detection limit in the NMR experiment. At elevated temperatures, the rotation of the allyl groups becomes rapid, interchanging the two conformers rapidly at the NMR time scale, leaving only one single methyl peak at temperatures above 300 K. A rough lineshape analysis was carried out in order to estimate the activation energy for the rotation process assuming two different species, one species with nine magnetically equivalent protons, and a second species containing three magnetically inequivalent sets of protons. The modelled spectra are given on the left-hand side in Figure 1. From the analyses we obtained an enthalpy of activation $\Delta H^{\ddagger}$ of 40(5) kJ/mol and an entropy of activation $\Delta S^{\ddagger}$ of −31(4) J/mol·K, corresponding to a free energy of activation $\Delta G^{\ddagger}$ of 49(6) kJ/mol at 300 K. The equilibrium constant for the transformation **1** $\rightleftarrows$ **3** was estimated to be 1.2(1). The DFT activation barrier obtained is within the error of the experimental value.

Actually, another mechanism leading to **3** could include a pseudo-rotation that interchanges the (assumed unobserved) *syn* and *anti* protons of the allyl ligand. Such a "rotation" is believed to proceed first by transferring the η^3-allyl ligand into an η^1-bonding mode, followed by a rotation around the $C_\alpha-C_\beta$ bond, and finishing by re-transferring the allyl ligand into an η^3-bonded mode. Setting the $Cr-C_\alpha-C_\beta-C_{(methyl)}$ dihedral angle equal to 180°, and minimising all other degrees of freedom, we found a DFT energy of 69 kJ/mol. This energy, which may be regarded as

a lower limit for the reaction barrier, is significantly higher than the pure rotation around the allyl−metal axis. We infer that the latter mechanism will dominate over the former.

The last possibility that should be considered is mechanism C, rotation of the methyl groups. Methyl rotations are, in most cases, unobserved by dynamic NMR due to the low energy barrier. However, one might speculate if steric requirements and/or the paramagnetism and consequently large shift differences could lead to observable methyl rotations. DFT calculations give a barrier of 7 kJ/mol for the methyl rotation in the high-symmetry ground-state conformer, which is too low when compared to the experimental value.

Conclusions

The observed line widths in the ^{1}H NMR spectra of tris(2-methylallyl)chromium are in accordance with what one would expect from Cr^{III} complexes. The estimated free energy of activation deduced from line-shape analysis of the NMR spectra, 49(6) kJ/mol, is in accordance with a mechanism where two conformers are present, and the conformers can be transformed into one another by rotation of one allyl ligand around the allyl−chromium axis. The other mechanisms investigated by using DFT calculations all have energies that are discrepant with the experimental results. However, we can only explain our observations by assuming that the terminal allylic protons are not observed in the spectra. This assumption is reasonable in light of the close distances between these protons and the paramagnetic metal centre.

Experimental Section

Experimental Details: Tris-(2-methylallyl)chromium [(2-$CH_3C_3H_4)_3Cr$] was prepared according to known procedures.[11] The complex could be stored as a 0.050 M pentane solution (determined by ICP) at −40 °C for at least two weeks. All handling of the complex was carried out at temperatures below −20 °C under argon. NMR samples were prepared by transferring 0.5−1.0 mL of the pentane solution to an NMR tube connected to an argon/vacuum line. The pentane was removed at approximately −30 °C under reduced pressure. Then, 0.5 mL of [D_8]toluene was distilled into the NMR tube, which was kept in liquid nitrogen until it could be sealed. Before the tube was introduced into the NMR magnet, the solution was allowed to thaw at −78 °C in a dry-ice/ethanol bath. The NMR measurements were performed with a Bruker DMX 200 Avance spectrometer operating at 200 MHz. A high-power ^{1}H NMR probe was utilised to achieve a spectrum over a wide frequency range. The probe was capable of producing 90° radio frequency (rf) pulses as short as 1.5 ms. In the present experiments, a more moderate pulse power of approx. 3 ms 90° pulse was utilised. A pulse length of 1.2 ms was used, corresponding to approximately 40°. The sweep width was set to 1.3 MHz, the repetition time was 3.02 s, and 96 scans were acquired in every experiment. A 0.6 ms dead time was allowed between pulse and acquisition, and the acquisition time was 19.4 ms. Line-shape analysis was carried out using the program WINDNMR.[12] Due to a software limitation in the maximum possible natural half-width of the peaks, only spectra in the temperature range 263 to 303 K were used in the analysis.

Computational Details: The DFT calculations were carried out using the program system ADF, developed by Baerends et al.[13] The frozen-core approximation was used for all atoms except hydrogen, keeping the orbitals up to and including 2p for chromium and 1s for carbon frozen in their atomic shapes. The orbitals were described by Slater-type orbital (STO) basis sets. The number of unfrozen basis functions, in order of increasing angular momentum, was (5,3,3) for chromium, (2,2,1) for carbon, and (2,1) for hydrogen, yielding TZVP quality for Cr and DZVP for C and H (note that for Cr, the number of unfrozen orbitals is larger than the number of valence orbitals). Slater exchange and the VWN parameterisation of the LDA correlation energy,[14] with the gradient corrections of Becke[15] for exchange and of Perdew[16] for correlation, were used for the exchange-correlation energies; the gradient corrections were added self-consistently. The accuracy of the numerical integration was set to $10^{-6.0}$, which may be assumed to give a numerical noise level of less than 0.1 kcal/mol in the final energies.[17] The calculations were carried out while making no initial assumptions of molecular symmetry. The calculations were run without restrictions, with separate sets of Kohn−Sham orbitals for each spin. No vibrational spectra have been computed.

Acknowledgments

We would like to thank Per Olav Kvernberg at the University of Oslo for recording the NMR spectra. The work has been carried out with financial support from the Norwegian Research Council (Grant 110675/420), and a grant of computer time from the NOTUR program (http://www.notur.org).

Carboxylation of 2-Hydroxyethyl-Substituted Tetrachloro(ethane-1,2-diamine)-platinum(IV) Complexes — A New Synthetic Approach to Anticancer Platinum Compounds

Markus Galanski,*[a] Wolfgang Zimmermann,[a] Michael Berger,[a] Christian Baumgartner,[a] Gerald Giester,[b] and Bernhard Klaus Keppler*[a]

Keywords: Platinum / Structure elucidation / Carboxylation / Antitumor agents

The present study has focused on a general reaction procedure for the derivatization of hydroxyethyl-substituted tetrachloro(ethane-1,2-diamine)platinum(IV) compounds at peripheral hydroxyl groups using acyl chlorides. A new class of platinum(IV) complexes could be synthesized which now opens the possibility for the first time to couple the cytotoxic platinum(IV) moiety to carrier molecules like proteins and antibodies in a very selective way. Moreover, it is now possible to synthesize platinum(IV) complexes with ligands in the equatorial plane which are not very stable in the presence of oxidizing agents.

Introduction

Since its discovery as a very effective antitumour compound, cisplatin,[1,2] *cis*-diamminedichloroplatinum(II), has become the dominant anticancer drug in clinics worldwide. Numerous platinum complexes have been synthesized and tested with respect to their cancerostatic activity so far, but only the second and third generation complexes carboplatin, *cis*-diammine(1,1-cyclobutanedicarboxylato)-platinum(II), and oxaliplatin, (*trans*-*R,R*-cyclohexane-1,2-diamine)oxalatoplatinum(II), are in clinical use today.[3] Because of severe side-effects and limitations of the platinum based drugs in use, research has focused on four major goals: (i) reduction of toxicity; (ii) expansion of platinum chemotherapy to a broader range of cancers; (iii) circumvention of resistance to Pt drugs; and (iv) synthesis of platinum compounds for oral administration. At the moment, only a few Pt complexes are in clinical trials.[4,5] Besides ZD0473[6] a sterically hindered compound and BBR3464[7] a trinuclear complex, satraplatin[8] (JM216) an orally available platinum(IV) compound is under development in the clinic.

The synthesis of JM216 is not only an approach to a new class of Pt^{IV} antitumour agents, but it also constitutes a new synthetic pathway in platinum chemistry, which was previously limited to ligand substitution or oxidation of platinum(II) species with hydrogen peroxide or chlorine gas to the corresponding Pt^{IV} complexes. Kinetically inert hydroxoplatinum(IV) complexes were used and carboxylated with anhydrides, acyl chlorides, pyrocarbonates and isocyanates to form carboxylates, carbonates and carbamates.[9–13] Unfortunately, the reactions are limited to a few carboxylating agents. Moreover, carboxylates will be lost again after reduction of the platinum(IV) species in the body. This would be a problem when linking of antitumour platinum fragments to carrier molecules is planned using the method described before. Therefore, we have focused on derivatization of kinetically inert tetrachloroplatinum(IV) complexes not directly at the metal centre but at peripheral functional groups. For this purpose, hydroxyethyl-substituted tetrachloro(ethane-1,2-diamine)platinum(IV) complexes and acyl chlorides have been used to set up a general reaction procedure.

Results and Discussion

The synthesis of the hydroxyethyl-substituted tetrachloro(ethane-1,2-diamine)platinum(IV) complexes *N*-(2-hydroxyethyl)ethane-1,2-diamine and *N,N′*-bis(2-hydroxyethyl)ethane-1,2-diamine which were selected for the carboxylation reactions starts from K_2PtCl_4 (Scheme 1). In the free diamine ligands there is no chiral atom. After coordination of *N,N′*-bis(2-hydroxyethyl)ethane-1,2-diamine to the platinum(II) centre, two chiral nitrogen atoms are produced resulting in the *trans*-*R,R*-, *trans*-*S,S*-, and *cis*-*R,S*-isomers.[14,15] The coordination of *N*-(2-hydroxyethyl)-ethane-1,2-diamine to platinum generates two isomers (*R* and *S*). The oxidation to the corresponding Pt^{IV} species

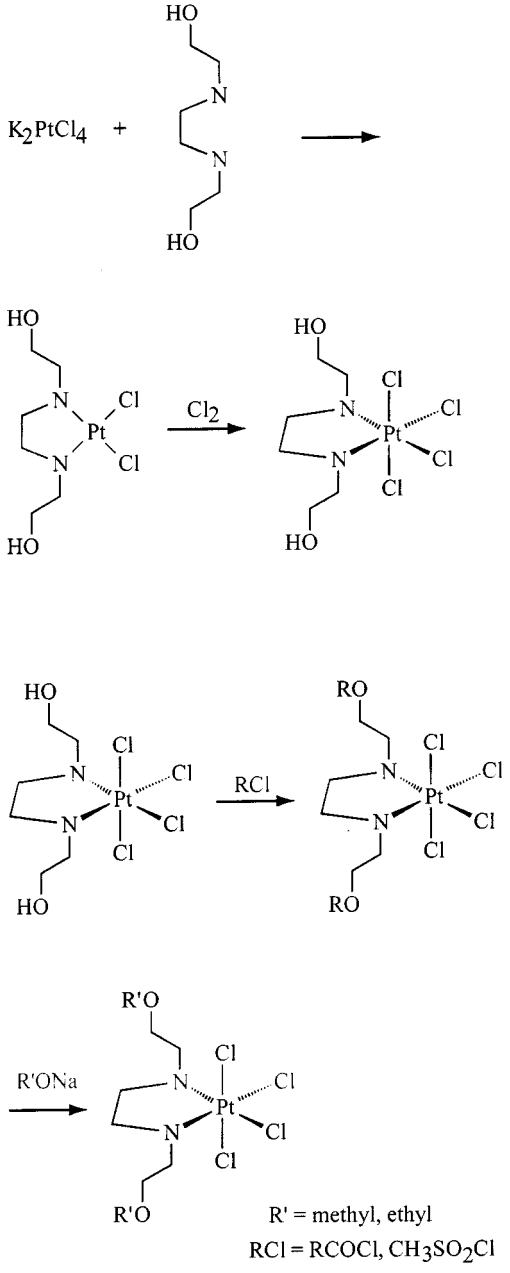

Scheme 1. Synthesis of the tetrachloro[*N,N'*-bis(2-hydroxyethyl)-ethane-1,2-diamine]platinum(IV) starting compound **2** and subsequent derivatization

was done in aqueous suspension with chlorine gas at room temperature.

For carboxylation of the peripheral OH groups, the tetrachloroplatinum(IV) compounds were suspended in dry acetone. After the addition of an excess of dry pyridine and acyl chloride, the mixture was stirred at room temperature and then under reflux. Water was added after cooling to room temperature. The precipitates were filtered off, dried, dissolved and precipitated with an appropriate organic solvent. The ether synthesis was carried out via sulfonation of the OH groups with mesyl chloride and subsequent reaction with sodium ethanolate or sodium methanolate without isolation of the intermediate ester.

The compounds were characterized by elemental analysis and, if soluble enough, by NMR spectroscopy. The theoretical values of the elemental analyses are in good agreement with those found experimentally. During the synthesis of the *N,N'*-bis(2-hydroxyethyl)-substituted (ethane-1,2-diamine)platinum(IV) complexes it was possible to isolate (*OC*-6-32)-*R,S*-tetrachloro[*N,N'*-bis(2-hydroxyethyl)ethane-1,2-diamine]platinum(IV) (**2**) and to resolve its structure by single crystal structure analysis (Figure 1).

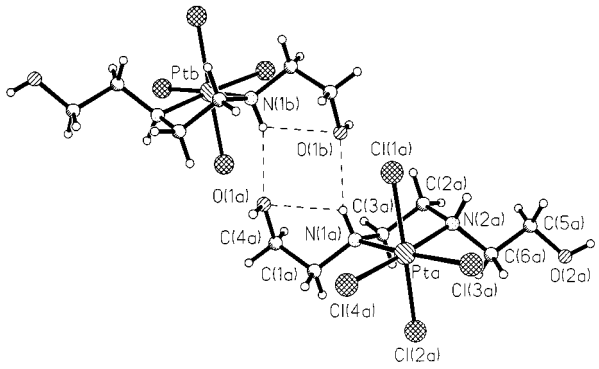

Figure 1. Structure of **2** in the crystal; selected distances (Å) and angles (°): Pt−N(1) 2.093(4), Pt−N(2) 2.086(4), Pt−Cl(1) 2.3094(13), Pt−Cl(2) 2.3202(13), Pt−Cl(3) 2.3227(13), Pt−Cl(4) 2.3259(12), C(2)−C(3) 1.499(7); N(1)−Pt−N(2) 84.57(17), N(1)−Pt−Cl(1) 87.68(12), N(2)−Pt−Cl(1) 86.47(13), N(1)−Pt−Cl(2) 90.54(12), N(2)−Pt−Cl(2) 93.56(13), Cl(1)−Pt−Cl(2) 178.20(5), N(1)−Pt−Cl(3) 174.31(12), N(2)−Pt−Cl(3) 89.87(12), Cl(1)−Pt−Cl(3) 90.81(5), Cl(2)−Pt−Cl(3) 90.99(5), N(1)−Pt−Cl(4) 94.75(12), N(2)−Pt−Cl(4) 176.98(13), Cl(1)−Pt−Cl(4) 90.56(5), Cl(2)−Pt−Cl(4) 89.38(5), Cl(3)−Pt−Cl(4) 90.75(5), C(3)−N(1)−Pt 105.5(3), C(2)−N(2)−Pt 106.9(3), N(2)−C(2)−C(3) 109.6(4), N(1)−C(3)−C(2) 109.2(4)

The O and N atoms are arranged in an octahedral manner around the platinum(IV) centre. The angular sum in the square planar plane (N1, N2, Cl3, Cl4) is 359.94°, with angles of 84.57(17)° (N2−Pt−N1), 90.75(5)° (Cl3−Pt−Cl4), 89.87(12)° (Cl3−Pt−N2) and 94.75(12)° (Cl4−Pt−N1). The Cl1−Pt−Cl2 axis is nearly linear with an angle of 178.20(5)°. The Pt−N and Pt−Cl distances [Pt−N1 2.093(4) Å, Pt−N2 2.086(4) Å, Pt−Cl1 2.3094(13) Å, Pt−Cl2 2.3202(13) Å, Pt−Cl3 2.3227(13), Å Pt−Cl4 2.3259(13) Å] are in the normal range for aminetetrachloroplatinum(IV) complexes. The bond lengths between the axial chloro ligands (Cl1 and Cl2) and Pt are significantly smaller than the corresponding Pt−Cl distances in the equatorial plane. The angular sum in the ethane-1,2-diamineplatinum(IV) chelate (five-membered ring) is 515.77°; the Pt−N1−C3−C2−N2 ring adopts a half-chair conformation with dihedral angles of 19.3, 44.7, 55.7, 35.9 and 8.9° at Pt−N1, N1−C3, C3−C2, C2−N2, and N2−Pt, respectively. The values found are in good agreement with those expected for cyclopentane in a half-chair conformation (13, 34, 42, 34 and 13°, respectively).

Furthermore, the structure of **2** is stabilized by intramolecular and intermolecular hydrogen bonds in the crystal. An intramolecular hydrogen bond is formed between N1 and O1, with a donor acceptor contact distance of 2.812 Å. O1

is also involved in the intermolecular hydrogen bond network with a very weak interaction to the proton at N1 (N1−H1···O1, N1−O1 3.186 Å). Moreover, intermolecular donor−acceptor contacts of 2.745 Å (O1−O2) and 3.254 Å (O2−Cl4), were found. A short intermolecular C−O contact of 3.195 Å (C2−O1, C2−H···O1) could be detected between O1 and C2 of the neighbouring ethane-1,2-diamine unit; this is in the typical range for C−H···O hydrogen bonds. It may indicate attractive interactions further stabilizing the structure of **2** in the crystal.

Besides the well-known procedures for the synthesis of platinum(IV) compounds, for example oxidation with H_2O_2 or Cl_2, or carboxylation of di- and tetrahydroxoplatinum(IV) complexes, a pathway to a new class of Pt^{IV} compounds is demonstrated.

In the present study simple acyl chlorides have been chosen for the carboxylation reaction, while hydroxyethyl-substituted tetrachloro(ethane-1,2-diamine)platinum(IV) complexes were used as the cytotoxic moiety. Tetrachloroplatinum(IV) compounds are kinetically inert so side products can be limited during the carboxylation. However, although it is known that tetrachloroplatinum(IV) complexes are easily reduced to their corresponding platinum(II) counterparts in vivo,[16] it occurs now without loss of the ester residue. Contrary to the limited possibilities of a carrier-mediated transport in platinum(IV) chemistry, a new synthetic approach to anticancer platinum(IV) compounds for drug targeting has been found. This new procedure is not only a completion of the synthesis of tumour inhibiting platinum-based drugs, but it also opens up the possibility for the first time of coupling the cytotoxic moiety to carrier molecules like proteins or antibodies in a very selective way. A platinum(IV) conjugate with albumine has recently been synthesized by us and will be published elsewhere. Moreover, it is now possible to synthesize platinum(IV) complexes with ligands (e.g. ethers, crown ethers) in the equatorial plane which are not very stable in the presence of oxidizing agents.

Conclusion

In conclusion it has been demonstrated that a new class of platinum(IV) complexes could be synthesized starting from tetrachloro[*N*-(2-hydroxyethyl)ethane-1,2-diamine]-platinum(IV) and tetrachloro[*N*,*N*′-bis(2-hydroxyethyl)-ethane-1,2-diamine]platinum(IV) by carboxylation of the peripheral hydroxyl groups with acyl chlorides.

Besides the synthesis of platinum(IV) compounds with ligands in the equatorial plane that are not very stable under oxidizing conditions, it is now possible for the first time to generate platinum(IV) conjugates with proteins or antibodies in a very selective way.

Experimental Section

General Remarks: All chemicals obtained from commercial suppliers were used as received and were of analytical grade. Water was doubly distilled. All synthetic procedures were carried out in the dark.

^1H and ^{13}C NMR experiments were performed at 200.13 MHz (^1H) and 50.32 MHz (^{13}C) on a Bruker Ac 200 MHz spectrometer at 24 °C with standard Bruker pulse programs.

Elemental analyses were performed by the microanalytical laboratory at the Universities of Heidelberg and Vienna.

Synthesis of Hydroxyethyl-Substituted (Ethane-1,2-diamine)platinum(II) and -(IV) Complexes. Dichloro[*N*,*N*′-bis(2-hydroxyethyl)-ethane-1,2-diamine]platinum(II) (1): A solution of *N*,*N*′-bis(2-hydroxyethyl)ethane-1,2-diamine (1.7916 g, 12.09 mmol) in 60 mL of ethanol was treated with K_2PtCl_4 (5.0176 g, 12.09 mmol). After addition of 115 mL of doubly distilled water the pH of the solution was adjusted to 7 using diluted hydrochloric acid and stirred at room temperature. The precipitate was collected over a period of 20 hours. During this time the pH was kept constant at 7 by addition of dilute NaOH. The yellow precipitate was washed with water and dried over P_4O_{10}. $C_6H_{16}Cl_2N_2O_2Pt$ (414.2): calcd. C 17.40, H 3.89, N 6.76, Cl 17.12, Pt 47.10; found C 17.45, H 3.63, N 6.62, Cl 17.45, Pt 47.23. Yield: 3.928 g, 78.5%.

Tetrachloro[*N*,*N*′-bis(2-hydroxyethyl)ethane-1,2-diamine]-platinum(IV) (2): Chlorine gas was bubbled through a suspension of dichloro[*N*,*N*′-bis(2-hydroxyethyl)ethane-1,2-diamine]platinum-(II) (2.000 g, 4.82 mmol) in 45 mL of water at room temperature. After 100 min the yellow precipitate was collected and washed with water (3 × 2 mL). The red filtrate thus obtained was then left to stand at room temperature for several days, after which time more product had precipitated. This precipitate was filtered off and washed with water. The precipitates were dried over P_4O_{10}. $C_6H_{16}Cl_4N_2O_2Pt$ (485.1): calcd. C 14.86, H 3.32, N 5.77, Cl 29.23, Pt 40.22; found C 14.74, H 3.35, N 5.75, Cl 28.94, Pt 40.16. Yield: 1.582 g, 68.0%.

Dichloro[*N*-(2-hydroxyethyl)ethane-1,2-diamine]platinum(II) (1a): A solution of *N*-(2-hydroxyethyl)ethane-1,2-diamine (2.514 g, 24.14 mmol) in 20 mL of water was treated with 150 mL of an aqueous solution of K_2PtCl_4 (10.006 g, 24.11 mmol). The pH was adjusted to 7 using diluted hydrochloric acid and stirred at room temperature. The precipitate was collected over a period of 20 hours. During this time the pH was kept constant at 7 by addition of dilute NaOH. The yellow precipitate was collected, washed with water and dried over P_4O_{10}. $C_4H_{12}Cl_2N_2O_2Pt$ (386.1): calcd. C 12.98, H 3.27, N 7.57, Cl 19.16, Pt 52.71; found C 12.94, H 3.24, N 7.54, Cl 19.28, Pt 52.75. Yield: 5.608 g, 63.0%.

Tetrachloro(*N*-(2-hydroxyethyl)ethane-1,2-diamine)platinum(IV) (2a): Synthesis and workup was performed as described for **2**. $C_4H_{12}Cl_4N_2O_2Pt$ (457.1): calcd. C 10.89, H 2.74, N 6.35, Cl 32.15, Pt 44.23; found C 10.87, H 2.77, N 6.31, Cl 32.09, Pt 44.15. Yield: 1.067 g, 45.0%.

Carboxylation Reactions and Ether Synthesis

Tetrachloro[*N*,*N*′-bis(2-octadecanoyloxyethyl)ethane-1,2-diamine]-platinum(IV) (3): Compound **2** (294.0 mg, 0.606 mmol) was suspended in dry acetone and mixed with dry pyridine (1.078 g, 13.63 mmol) and octadecanoic acid chloride (1.474 g, 4.87 mmol). The mixture was stirred at room temperature overnight and for 5 hours under reflux. After cooling to room temperature, 70 mL of water was added and the resulting mixture was stored overnight in the refrigerator. The precipitate was filtered off and washed thoroughly with water. After drying over P_4O_{10} the crude product was dissolved in 20 mL of chloroform and precipitated with diethyl

ether. The solid was washed several times with diethyl ether. After filtration the precipitate (light brownish) was dried over P_4O_{10}. $C_{42}H_{84}Cl_4N_2O_4Pt$ (1018.0): calcd. C 49.55, H 8.32, N 2.75, Pt 19.16; found C 49.18, H 8.06, N 2.83, Pt 19.52. Yield: 213 mg, 35%.

Tetrachloro[*N*,*N*′-*bis*(2-hexadecanoyloxyethyl)ethane-1,2-diamine]-platinum(IV) (4): The synthesis was carried out as described for **3**. $C_{38}H_{76}Cl_4N_2O_4Pt$ (961.9): calcd. C 47.45, H 7.96, N 2.91, Pt 20.28; found C 47.28, H 7.75, N 2.95, Pt 20.65. Yield: 181 mg, 47%.

{*N*,*N*′-Bis[2-(1-adamantanoyloxy)ethyl]ethane-1,2-diamine}-tetrachloroplatinum(IV) (5): The synthesis was carried out as described for **3**. ^{1}H NMR ($CDCl_3$): δ = 1.3−2.2 ($H_{adamantane}$), 2.7−4.6 (NC*H*$_2$, OC*H*$_2$), 6.3−8.9 (N*H*). ^{13}C NMR ($CDCl_3$): δ = 27.7 (C_{ad}), 36.3 (C_{ad}), 38.8 (C_{ad}), 40.9 (C_{ad}), 53.7 (N*C*H$_2$), 55.1 N*C*H$_2$), 60.7 (O*C*H$_2$), resonance for C=O was not found. $C_{28}H_{44}Cl_4N_2O_4Pt$ (809.6): calcd. C 41.54, H 5.48, N 3.46, Pt 24.10; found C 41.67, H 5.47, N 3.71, Pt 24.33. Yield: 302 mg, 60%.

{*N*,*N*′-Bis[2-(6,7,9,10,12,13,15,16-octahydrobenzo[*b*][1,4,7,10,13]-pentaoxacyclopentadecin-2-carbonyloxy)ethyl]ethane-1,2-diamine}-tetrachloroplatinum(IV) (6): The synthesis was carried out as described for **3**. The excess of free carboxylic acid is soluble in the water/acetone mixture; further workup is not necessary. $C_{36}H_{52}Cl_4N_2O_{14}Pt$ (1073.7): calcd. C 40.27, H 4.88, N 2.61, Pt 18.17; found C 39.96, H 4.84, N 2.71, Pt 18.37. Yield: 284 mg, 76%.

{*N*-[2-(1-Adamantanoyloxy)ethyl]ethane-1,2-diamine}tetrachloro-platinum(IV) (7): The synthesis was carried out as described for **3** with **2a** as starting compound. The precipitate was dried over P_4O_{10}. $C_{15}H_{26}Cl_4N_2O_2Pt$ (603.3): calcd. C 29.86, H 4.34, N 4.64, Pt 32.34; found C 30.28, H 4.39, N 4.39, Pt 32.23. Yield, 212 mg, 56%.

Tetrachloro[*N*,*N*′-*bis*(2-methoxyethyl)ethane-1,2-diamine]-platinum(IV) (8): Mesyl chloride (661 mg, 5.772 mmol) and dry pyridine (913 mg, 11.54 mmol) were added to a suspension of **2** (700 mg, 1.322 mmol) in dry chloroform. The mixture was stirred for 12 hours at room temperature and for 3 hours under reflux. After that, the suspension was evaporated to dryness and the resulting solid washed with ethanol and diethyl ether. The solid (yellow-brownish, 531 mg) was dried over P_4O_{10}. Some of the product (200 mg) was then reacted with an excess of $NaOCH_3$ (168 mg) in 10 mL of dry methanol. After stirring for eight hours at room temperature, the solution was reduced to 3 mL. Water (20 mL) was then added, and the precipitate was filtered off, washed with water and methanol and dried under reduced pressure. $C_8H_{20}Cl_4N_2O_2Pt$ (513.2): calcd. C 18.73, H 3.93, N 5.46, Pt 38.02; found C 18.26, H 4.02, N 5.53, Pt 37.96. Yield: 132 mg, 51%.

Tetrachloro[*N*-(2-ethoxyethyl)ethane-1,2-diamine]platinum(IV) (9): Mesyl chloride (727 mg, 6.348 mmol) and dry pyridine (1.004 g, 12.70 mmol) were added to a suspension of **2a** (700 mg, 1.587 mmol) in dry acetone. The mixture was stirred for 12 hours at room temperature and for 3 hours under reflux. After that, the suspension was filtered and reduced to 10 mL. Dry acetone (40 mL) and $NaOCH_2CH_3$ (2.159 g, 31.74 mmol) were then added. After stirring for eight hours at room temperature, the solution was reduced to 3 mL. Water (20 mL) was then added, and the precipitate was filtered off, washed with water and methanol and dried under reduced pressure. $C_6H_{16}Cl_4N_2O_1Pt$ (469.1): calcd. C 15.36, H 3.44, N 5.97, Pt 41.59; found C 14.79, H 3.40, N 5.72, Pt 41.67. Yield: 362 mg, 49%.

X-ray Crystallographic Study: X-ray diffraction measurements were performed on a Nonius Kappa instrument with a CCD detector at 293 K, using graphite-monochromated Mo-K_α radiation. Crystal data, data collection parameters and structure refinement details are given in Table 1. The structure was solved by direct methods and refined by full-matrix least-squares techniques. The non-H atoms were refined with anisotropic displacement parameters, while H atoms were calculated and allowed to ride. Details of the computer programs used are as follows: data reduction: DATAP;[17] structure solution: SHELXS-97;[18] structure refinement: SHELXL-97;[19] molecular diagram: ORTEP.[20] The scattering factors were obtained from a literature source.[21] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-162129. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Ligand Effects on the Reactivity of $Cu^{I}L$ Complexes Towards $Cl_3CCO_2^-$

Nadav Navon,*[a] Ariela Burg,[a] Haim Cohen,[a,b] Rudi van Eldik,[c] and Dan Meyerstein[a,d]

Keywords: Copper / Ligands / Redox chemistry / Kinetics / Reaction mechanisms

The effect of the nature of the ligand L on the mechanism and kinetics of the reaction of $Cu^{I}L$ with $Cl_3CCO_2^-$ in aqueous solution is reported. The results demonstrate that the rate of the chlorine abstraction reaction, which is usually the rate-determining step in the process, is affected by: a) the redox potential of the $Cu^{II/I}L$ couple, b) the hybridization on Cu^{I} in the $Cu^{I}L$ complex, c) steric hindrance, d) electron density on the central Cu^{I} cation, at the binding site of the chlorine atom to be abstracted. Measurement of $\Delta V^{\neq}$ for the chlorine abstraction step indicates that this reaction proceeds by the inner-sphere mechanism, as expected. When the redox potential of the $Cu^{II/I}L$ couple is considerably cathodically shifted the transient complex $LCu^{II}–CCl_2CO_2^-$ is relatively long-lived.

Introduction

Copper(I) complexes catalyze a variety of organic reactions, which are of synthetic and of industrial importance.[1–3] Many of these processes are initiated by halide abstraction from aryl or alkyl halides. The halide abstraction reaction by the Cu^{I} catalyst is believed to be the rate-determining step of these processes. The addition of organic polyhalides to alkenes is a good example of such reactions.[3] The detailed mechanisms of these reactions have not been fully elucidated. Due to the low solubility of Cu^{I} halides and to the disproportionation of Cu^{+}_{aq} the concentration of Cu^{I} species in these systems is usually very low. In principle the addition of appropriate ligands for Cu^{I}, e.g. CH_3CN,[4] alkenes[5] and NH_3 [5] increases the concentration of the Cu^{I} species in the system and is therefore expected to increase the rate of the catalytic process. Tri- and tetradentate ligands, which stabilize Cu^{I}, were indeed shown to accelerate catalytic processes.[6–8] However, these ligands might also affect the reactivity of the Cu^{I} complexes due to one, or more, of the following reasons:

1. If the stability constant of the Cu^{I} complex with the ligand is larger than that of the corresponding Cu^{II} complex then the redox potential of the $Cu^{II/I}$ couple is shifted anodically, i.e. the Cu^{I} complex is a weaker reducing agent than Cu^{+}_{aq}, and vice versa.

2. Ligands can slow down the rate of Cu^{I} reactions due to steric effects.

3. Ligands might impose a coordination geometry, which affects the energy of the transition state thus affecting the rate of the reaction.

The effect of ligands that stabilize copper(I) on the rates and mechanisms of the catalytic processes was not studied in detail. The effect of fumarate on the reaction of Cu^{+}_{aq} with Cl_3CCOO^- (TCA) was recently[6] studied. The results demonstrate that the rate of reaction between Cu^{I}-($HOOCCH=CHCOO^-$) and Cl_3CCOO^- is very slow. Cl^- is a product of the reaction, its yield equals half the concentration of $Cu^{I}L$. The general reaction mechanism is:

$$Cu^{+}_{aq} + L \rightleftarrows Cu^{I}L \quad (1)$$

$$Cu^{I}L/Cu^{+}_{aq} + Cl_3CCOO^- \rightarrow (LCu^{II}Cl)/(CuCl)^+ + {}^{\cdot}CCl_2COO^- \quad (2)$$

$k_2 = 6.0 \pm 1.0\ M^{-1}s^{-1}$ for Cu^{+}_{aq} and $k_2 < 0.015\ M^{-1}s^{-1}$ for $Cu^{I}(HOOCCH=CHCOO^-)$

$$Cu^{I}L/Cu^{+}_{aq} + {}^{\cdot}CCl_2COO^- \rightarrow (LCu^{II}-CCl_2CO_2^-)^-/(Cu^{II}-CCl_2CO_2^-) \quad (3)$$

$$(LCu^{II}-CCl_2CO_2^-)^-/(Cu^{II}-CCl_2CO_2^-) + H_3O^+ \rightarrow Cu^{2+}_{aq} + HCCl_2COO^- + L \quad (4)$$

$$(Cu^{II}L)^+/Cu^{2+}_{aq} + {}^{\cdot}CCl_2COO^- \rightarrow (LCu^{III}-CCl_2CO_2^-)/(Cu^{III}-CCl_2CO_2^-)^+ \quad (5)$$

$$(LCu^{III}-CCl_2CO_2^-)/(Cu^{III}-CCl_2CO_2^-)^+ + Cu^{I}L/Cu^{+}_{aq} \rightarrow (LCu^{II}-CCl_2CO_2^-)^-/(Cu^{II}-CCl_2CO_2^-) + Cu^{II}L^+/Cu^{2+}_{aq} \quad (6)$$

These results indicate that carrying out catalytic processes in the absence of a large excess of alkenes is desired. It seemed of interest to extend this study to the effect of other ligands on this reaction. For this purpose the following ligands were chosen:

1. CH_3CN, which is often used as a solvent for the catalytic processes.

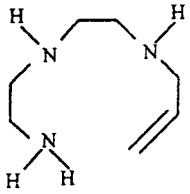
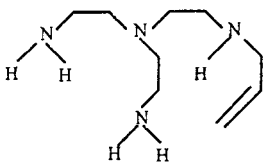
2. NH_3, a σ-donor ligand that shifts the redox potential of the Cu^{II}/Cu^{I} couple somewhat cathodically.

3. L^1 [7] and L^2,[8] ligands that were recently designed with the aim to stabilize Cu^{I} while cathodically shifting the redox potential of the Cu^{II}/Cu^{I} couple. It was therefore hoped that they will accelerate catalytic processes in which the Cu^{I} acts as a reducing agent in the rate determining step.



L^1



L^2

It was hoped that the choice of different types of ligands for this study might shed light on the factors affecting the rates of halide abstraction reactions by Cu^{I} complexes and thus enable the design of improved catalytic processes. In order to gain more insight on the detailed mechanism of the reaction of Cu^{+}_{aq} with $Cl_3CCO_2^-$ the volume of activation of this reaction was determined. The experimental conditions were identical to those used for the determination of the volume of activation for the reaction of Cu^{+}_{aq} with O_2,[9] i.e. He-saturated solutions containing 0.05 M $CuSO_4$, 1.0 M CH_3OH, 0.01 M Cl_3CCO_2Na, $1.0\cdot10^{-4}$ M HOOCCH=CHCOO$^-$ at pH = 3.0 were irradiated at different pressures.

Results and Discussion

In the following sections the effects of each ligand on the mechanism and kinetics of the reaction of Cu^{I} with CCl_3COO^- is described and discussed separately. Then the effects of the ligands are compared and general conclusions are derived.

CH_3CN

Acetonitrile forms the complexes $Cu(CH_3CN)_n^+$, n = 1−4, with Cu^{I} in aqueous solutions. In the concentration range of $(0.05-1.5)\cdot10^{-1}$ M CH_3CN the main complexes present in the solutions are $Cu^{I}(CH_3CN)^+$ and $Cu^{I}(CH_3CN)_2^+$.

$$Cu^{+}_{aq} + CH_3CN \rightleftarrows Cu(CH_3CN)^+ \quad \log\beta_1 = 3.27^{[4a]} \tag{7a}$$

$$Cu^{+}_{aq} + 2\,CH_3CN \rightleftarrows Cu(CH_3CN)_2^+ \quad \log\beta_2 = 4.32^{[4b]} \tag{7b}$$

Since these complexes have no absorption bands in the near UV/Vis region, the effect of acetonitrile on the rate of the reaction of $Cu^{I}L$ with $CCl_3CO_2^-$ was studied in the presence of low concentrations of fumaric acid. The Cu^{I}(fumaric acid) complex has a strong absorption band in the near UV region[10] and the ligand exchange reaction Cu^{+}_{aq} + HOOCCH=CHCOO$^-$ ⇄ $Cu^{I}(HO_2CCH=CHCO_2^-)$ is very fast.[11a] The addition of fumarate thus simplifies the use of spectrophotometry in order to follow the rate of reaction of Cu^{I}. The technique used was pulse radiolysis. When N_2O-saturated aqueous solutions at pH = 3.0 containing $5.0\cdot10^{-2}$ M $CuSO_4$, 1.0 M CH_3OH, $2.0\cdot10^{-4}$ M fumaric acid and $(0.05-1.5)\cdot10^{-1}$ M CH_3CN are irradiated, all the primary radicals are transformed according reactions (7)−(11) to a mixture of Cu^{+}_{aq}, Cu^{I}(fumaric acid) and $Cu^{I}(CH_3CN)_n^+$.[6,12]

$$^{\cdot}OH/^{\cdot}H + CH_3OH \rightarrow {}^{\cdot}CH_2OH + H_2O/H_2 \quad k_{OH} = 4.6\cdot10^8\ M^{-1}s^{-1},^{[13]}\ k_H = 1.6\cdot10^6\ M^{-1}s^{-1}\ ^{[13]} \tag{8}$$

$$^{\cdot}CH_2OH + Cu^{2+}_{aq} \rightarrow Cu^{+}_{aq} + CH_2O + H_3O^+ \quad k = 1.6\cdot10^8\ M^{-1}s^{-1}\ ^{[10]} \tag{9}$$

$$e^-_{aq} + Cu^{2+}_{aq} \rightarrow Cu^{+}_{aq} \quad k = 3.3\cdot10^{10}\ M^{-1}s^{-1}\ ^{[13]} \tag{10}$$

$$Cu^{+}_{aq} + HOOCCH=CHCOO^- \rightleftarrows Cu^{I}(HOOCCH=CHCOO^-) \tag{11}$$

at pH = 3.65, $k_{11} = 1.7\cdot10^9\ M^{-1}s^{-1}$;[11] at pH =3.65, $k_{-11} = 2.4\cdot10^5\ M^{-1}s^{-1}$ [11]

This mixture reacts with the H_2O_2 formed by the pulse and the excess Cu^{I} is long-lived.[6,11] The mixture of Cu^{+}_{aq}, Cu^{I}(HOOCCH=CHCOO$^-$) ($K = 8.7\cdot10^3\ M^{-1}$ at pH = 3.0 [11] and $Cu^{I}(CH_3CN)_n^+$ thus reaches equilibrium within less than 50 μs after the pulse.

The complex Cu^{I}(HOOCCH=CHCOO$^-$) has an absorption band at λ_{max} = 346 nm.[11] When $(0.5-4.0)\cdot10^{-2}$ M trichloroacetic acid is added to the solutions the disappearance of Cu^{I}(HOOCCH=CHCOO$^-$) is observed within several hundreds of seconds.

The kinetics of this process were followed spectrophotometrically, using the M→L charge transfer band of the complex Cu^{I}(HOOCCH=CHCOO$^-$). The kinetics obey a first-order rate law, i.e. the reaction exhibits a first-order dependence on the concentration of Cu^{I}. The observed rate of this process is proportional to the concentration of the trichloroacetate, Figure 1, and decreases with the increase in the acetonitrile concentration, Figure 2. In order to obtain an upper limit for the rate constant of the reaction between $Cu^{I}(CH_3CN)_2^+$ and Cl_3CCOO^-, the rate was measured in solutions containing high concentrations of acetonitrile [$(0.05-1.5)\cdot10^{-1}$ M] in the presence of three different concentrations of fumarate ($2.0\cdot10^{-4}$, $6\cdot10^{-4}$ and $2\cdot10^{-3}$ M) at a constant concentration of Cl_3CCOO^- ($2.0\cdot10^{-2}$ M). The results are presented in Figure 2. The results demonstrate that the rate decreases as the concentration of acetonitrile is increased and seems to approach a limiting value, at [CH_3CN] = 0.15 M the same k_{obs} ($3.0\cdot10^{-3}$ s^{-1}) is measured for the three systems. In these systems at [CH_3CN] = 0.15 M, between 96.5% (for [fumarate] = $2.0\cdot10^{-3}$ M) and 99.5% (for [fumarate] = $2.0\cdot10^{-4}$ M) of the Cu^{I} is present in the form of the $Cu^{I}(CH_3CN)_2^+$,

$Cu^{I}(CH_3CN)_3^+$ and less than 0.2% Cu^+_{aq} in the latter system. The calculated rate of the reaction between $Cu^{I}(CH_3CN)_2^+$ and Cl_3CCOO^- is $k_{11} = 0.15$ $M^{-1}s^{-1}$, which is considerably higher than that which can be attributed to Cu^+_{aq} present in these solutions.

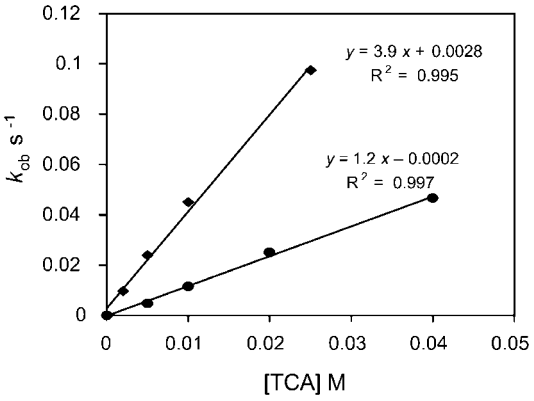


Figure 1. Dependence of the rate of the disappearance of Cu^{I}-(HOOCCH=CHCOO$^-$) on $[Cl_3CCO_2^-]$; ■ N_2O saturated solutions, containing $5\cdot10^{-2}$ M $CuSO_4$, $2\cdot10^{-4}$ M fumaric acid, 1 M CH_3OH and $0.1-2.5\cdot10^{-2}$ Cl_3CCO_2H at pH = 3.0; • same solution but with 0.02 M CH_3CN

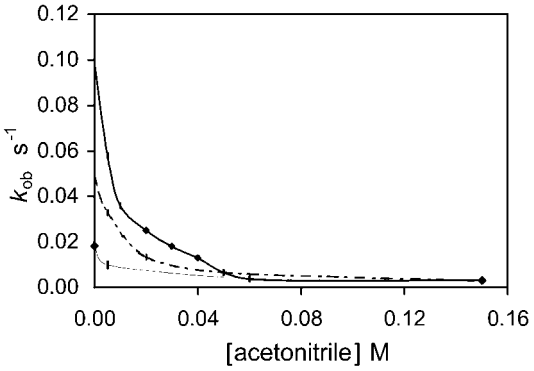

Figure 2. Dependence of the observed rate constant on $[CH_3CN]$; solution composition: N_2O saturated, containing $5\cdot10^{-2}$ M $CuSO_4$, $(0.2-2.0)\cdot10^{-4}$ M fumaric acid: ····· $2.0\cdot10^{-3}$ M, –·–·– $6.0\cdot10^{-4}$ M, —— $2.0\cdot10^{-4}$ M, 0–0.15 M CH_3CN, 1 M CH_3OH and $2.0\cdot10^{-2}$ Cl_3CCO_2H at pH = 3.0

$$Cu(CH_3CN)_n^+ + Cl_3CCOO^- \rightarrow {}^{\cdot}CCl_2CO_2^- + Cu(CH_3CN)_nCl^+ \quad (12)$$

As reaction (2) and/or (12) are the rate-determining steps the observed rate equals $2k_{12}$, therefore $k_{12} = 0.075 \pm 0.011$ $M^{-1}s^{-1}$ for $Cu(CH_3CN)_2^+$. The reaction mechanism is analogous to reactions (1)–(6). Reaction (2) occurs via Cu^+_{aq} and/or via the $Cu^{I}(CH_3CN)_n^+$ reaction (12). The rate of reaction is independent of the concentration of all other components of the solution (i.e. of $[CuSO_4]$, $[CH_3OH]$) and the pulse intensity. Analysis of the results presented in Figure 1, remembering that k [Cu^{I}(HOOCCH=CHCO$_2^-$) + $Cl_3CCO_2^-$] < 0.015 $M^{-1}s^{-1}$ and k[$Cu^{I}(CH_3CN)^+_2$ + $Cl_3CCO_2^-$] = 0.075 $M^{-1}s^{-1}$, indicates that the contribution of Cu^+_{aq} to the observed rate is 0.24 s^{-1}, therefore a rate of 0.96 s^{-1} has to the attributed to the reaction of $Cu^{I}(CH_3CN)^+$ with $Cl_3CCO_2^-$.

The kinetics are then described by the following equations:

$Cu^+_{aq} + L \rightleftarrows Cu^{I}L$
(L = fumarate)
$Cu^+_{aq} + n\ CH_3CN \rightleftarrows Cu^{I}(CH_3CN)^{n+}$

$$Cu^{I}(CH_3CN)^+ + TCA \xrightarrow{k_2} P$$

(TCA = trichloroacetate; P = products)
$d[P]/dt = k_2[Cu^{I}]_T[TCA]$
$K_1 = [Cu^{I}L]/[Cu^+_{aq}][L]$, $\beta_1 = [Cu^{I}(CH_3CN)^+]/[Cu^+_{aq}][CH_3CN]$, $\beta_2 = [Cu^{I}(CH_3CN)_2^+]/[Cu^+_{aq}][CH_3CN]^2$
$[Cu^{I}]_T = [Cu^+_{aq}] + [CuL] + [Cu^{I}(CH_3CN)^+] + [Cu^{I}(CH_3CN)_2^+]$

Inserting the known values of K_1, β_1, β_2, [L] and $[CH_3CN]$, one obtains $k_2 = 0.62 \pm 0.012$ $M^{-1}s^{-1}$ for $Cu^{I}(CH_3CN)^+$.

NH_3

In order to measure the rate of reaction between $Cu^{I}(NH_3)_2^+$ and Cl_3CCOO^-, Ar-saturated solutions containing $5.0\cdot10^{-4}$ M or $1.0\cdot10^{-3}$ M Cu^{I} and 1.0 M NH_3 were prepared. Under these conditions the Cu^{I} complex present in the solution is $Cu^{I}(NH_3)_2^+$ due to equilibrium (13).

$$Cu^+_{aq} + 2\ NH_3 \rightleftarrows Cu^{I}(NH_3)_2^+ \quad (13)$$
$$\log \beta_2 = 10.4^{[14]}$$

These solutions were mixed in a fast-mixing cell with Ar-saturated solutions containing $(0.1-1.0)\cdot10^{-2}$ M Cl_3CCOO^-. Soon after the mixing, the formation of an absorption band at $\lambda = 620$ nm, typical for $Cu^{II}(NH_3)_4^{2+}$,[5] was observed. The kinetics of this process obey a first-order rate law, i.e. the reaction exhibits a first-order dependence on the concentration of Cu^{I}. The observed rate is propor-

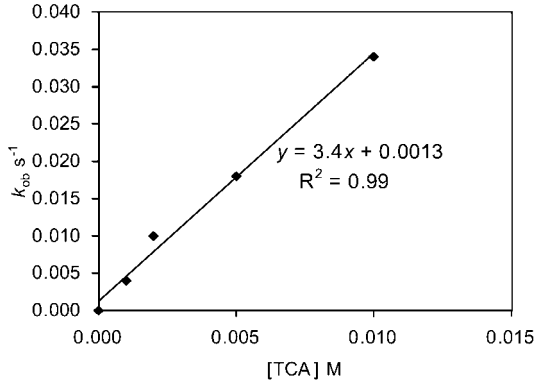

Figure 3. Dependence of the observed rate constant on $[Cl_3CCO_2^-]$; solution composition: Ar-saturated, containing $1.0\cdot10^{-3}$ M Cu^{I}, 1 M NH_3 and $(0.1-1.0)\cdot10^{-2}$ M $Cl_3CCO_2^-$ at pH = 11.0

tional to the concentration of the trichloroacetate, Figure 3. The kinetic equations that describe this system are as follows:

$$\begin{aligned} &Cu(NH_3)_2^+ + TCA \rightarrow P \\ &(P = \text{products}) \\ &d[P]/dt = k_{14}[Cu(NH_3)_2^+][TCA], [TCA] >> \\ &[Cu(NH_3)_2^+], k_{obs} = k_{14}[TCA] \end{aligned} \quad (14)$$

The rate constant is calculated from the slope of the line in Figure 3 as $k = 3.4 \pm 0.5$ M^{-1}s^{-1}. The yield of $Cu^{II}(NH_3)_4^{2+}$, measured in solutions containing an excess of Cu^I in comparison to Cl_3CCOO^-, is in agreement with the expected ratio $Cu^{II}(NH_3)_4^{2+}$/TCA = 2. These results are in agreement with the mechanism described in reactions (2)−(6). Equation (14a) is analogous to reaction (2).

$$Cu(NH_3)_2^+ + ClCCOO_2^- \rightarrow {}^{\cdot}CCl_2CO_2^- + Cu(NH_3)_2Cl^+ \quad (14a)$$

As reaction (14a) is the rate-determining step the observed rate equals $2k_{14}$, therefore $k_{14a} = 1.7 \pm 0.25$ M^{-1}s^{-1}.

L^1

L^1 forms a complex with Cu^I according to Equation (15).

$$\begin{aligned} &Cu^+_{aq} + L^1 \rightleftarrows (CuL^1)^+ \\ &\log K = 11.94^{[7]} \end{aligned} \quad (15)$$

In order to measure the rate of the reaction between $(CuL^1)^+$ and Cl_3CCOO^-, Ar-saturated solutions containing $1.0 \cdot 10^{-3}$ M $(CuL^1)^+$ at pH = 7.0 were prepared. These solutions were mixed in a fast-mixing cell with Ar-saturated solutions containing $(0.16-2.0) \cdot 10^{-1}$ M Cl_3CCOO^-. After mixing, the disappearance of the absorption band at $\lambda = 236$ nm, due to $[CuL^1]^+$,[7] is observed. The kinetics of this process obey a first-order rate law for the concentration of Cu^I. The observed rate is proportional to the concentration of trichloroacetate, Figure 4. The rate constant calculated from the slope of the line in Figure 4, $k = 0.27 \pm 0.04$ M^{-1}s^{-1}. The yield of $[CuL^1]^{2+}$, measured in solutions containing an excess of Cu^I, is in agreement with the expected ratio $[CuL^1]^{2+}$/TCA = 2. Thus, for each mol TCA two mol of $[CuL^1]^+$ are transformed into $[CuL^1]^{2+}$.

These results are in agreement with the mechanism described in reactions (2)−(6). Equation (16) is analogous to Equation (2).

$$(CuL^1)^+ + Cl_3CCOO^- \rightleftarrows {}^{\cdot}CCl_2CO_2^- + L^1Cu^{II}Cl^+ \quad (16)$$

As reaction (16) is the rate-determining step the observed rate equals $2k_{16}$, therefore $k_{16} = 0.14 \pm 0.02$ M^{-1}s^{-1}.

L^2

L^2 forms a complex with Cu^I according to Equation (17).[8]

$$\begin{aligned} &Cu^+_{aq} + L^2 \rightleftarrows [CuL^2]^+ \\ &\log K = 13.40 \end{aligned} \quad (17)$$

In order to measure the rate of the reaction between $(CuL^2)^+$ and Cl_3CCOO^-, the stopped-flow technique was used. Ar-saturated solutions containing $8.0 \cdot 10^{-4}$ M $(CuL^2)^+$ at pH = 6.5 were mixed with Ar-saturated solutions containing $(0.5-2.0) \cdot 10^{-1}$ M Cl_3CCOO^- and 0.5 M $NaClO_4$ at the same pH. After the mixing, two processes were observed (Figure 5). The first process, the formation of an absorption band at $\lambda = 350$ nm, occurs within a few seconds. The second process, the disappearance of the absorption band formed in the first process, occurs within several tens of seconds. The kinetics of the first process obey a first-order rate law in the concentration of Cu^I. The observed rate is proportional to the concentration of trichloroacetate (Table 1). The kinetics of the second process obey a first-order rate law and do not depend on the composition of the solutions, within the experimental error.

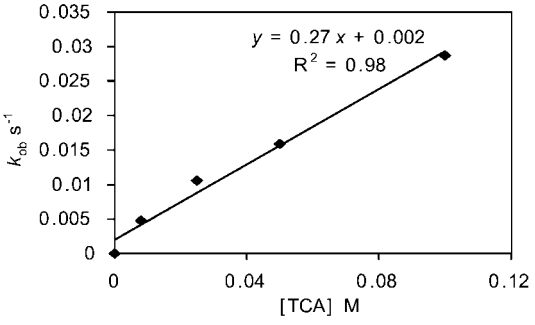

Figure 4. Dependence of the observed rate constant on $[Cl_3CCO_2^-]$; solution composition: Ar-saturated, containing $5.0 \cdot 10^{-4}$ M $(Cu^IL^1)^+$ and $(0.08-1.0) \cdot 10^{-1}$ M $Cl_3CCO_2^-$ at pH = 7.0

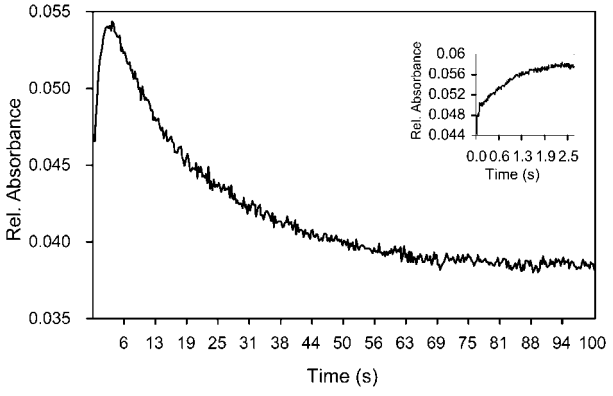

Figure 5. Computer output of the absorbance vs. time; experimental conditions: Ar-saturated solutions containing $8.0 \cdot 10^{-4}$ M $(CuL^2)^+$ at pH = 6.5 were mixed with Ar-saturated solutions containing 0.02 M $Cl_3CCO_2^-$ and 0.5 M $NaClO_4$ at the same pH measured at $\lambda = 350$ nm

Table 1. Observed rate constants in the L^2 system under different conditions; k_1: the observed rate constants of the first process (error limits ± 0.10); k_2: the observed rate constants of the second process (error limits ± 0.01)

	$[Cu^{I}L^2]^+$ $4.0\cdot10^{-4}$ M		$[Cu^{I}L^2]^+$ $4.0\cdot10^{-4}$ M $[Cu^{II}L^2]^{2+}$ $2.5\cdot10^{-4}$ M		$[Cu^{I}L^2]^+$ $4.0\cdot10^{-4}$ M $[Cu^{II}L^2]^{2+}$ $2.0\cdot10^{-3}$ M	
[TCA]	k_1 [s^{-1}]	k_2 [s^{-1}]	k_1 [s^{-1}]	k_2 [s^{-1}]	k_1 [s^{-1}]	k_2 [s^{-1}]
0.025	0.37	0.02	1.4	0.03	0.44	0.03
0.050	0.70	0.03	1.9	0.05	0.74	0.04
0.10	1.4	0.05	3.4	0.07	1.5	0.06

The effect of $[CuL^2]^{2+}$ on the rate of the processes was measured. Ar-saturated solutions containing $8.0\cdot10^{-4}$ M $[CuL^2]^+$ and $(0.5-4.0)\cdot10^{-3}$ M $[CuL^2]^{2+}$ at pH = 6.5 were mixed with Ar-saturated solutions containing $(0.5-2.0)\cdot10^{-1}$ M Cl_3CCOO^- and 0.5 M $NaClO_4$ at the same pH. The results are summed up in Table 1. The results show that the presence of $[CuL^2]^{2+}$ in similar concentrations as to those of $[CuL^2]^+$ accelerates the rate of the first process. However, in the presence of an excess of $[CuL^2]^{2+}$, in comparison to $[CuL^2]^+$, the rate of the first process is similar to that obtained in the absence of $[CuL^2]^{2+}$. The rate constant of the second process is independent of $[CuL^2]^{2+}$ within the experimental accuracy. The yield of Cl^- was determined and equals half the concentration of Cu^{I}. The yield of Cl^- is independent of the concentration of $[CuL^2]^{2+}$.

Based on these results and on the assumption that the absorption band at $\lambda = 350$ nm is due to the formation of the transient complex $L^2Cu^{II}-CCl_2CO_2^-$ (complexes with $Cu^{II}-C$ σ-bonds are known to absorb in this wavelength region[15]) it is reasonable to propose that the following reactions and kinetic equations describe the system:

$$Cu(I)L + RX \xrightarrow{k_I} Cu(II)L + {}^{\cdot}R + X^- \quad (I)$$

$(L - L^2, X - Cl^-, RX - ClC(Cl)_2CO_2^-)$

$$^{\cdot}R + Cu(I)L \xrightarrow{k_{II}} LCu(II)\text{-}R \quad (II)$$

$$^{\cdot}R + LCu(II)\text{-}R \xrightarrow{k_{III}} Cu(I)L + R_2 \quad (III)$$

$$^{\cdot}R + Cu(II)L \xrightarrow{k_{IV}} LCu(III)\text{-}R \quad (IV)$$

$$Cu(I)L + LCu(III)\text{-}R \xrightarrow{fast} LCu(II)\text{-}R + Cu(II)L \quad (V)$$

$$LCu(II)\text{-}R + H_3O^+ \xrightarrow[very\ slow]{k_{VI}} Cu(II)L + RH \quad (VI)$$

$k_{VI} = 0.04 \pm 0.02\ s^{-1}$

$$d[LCu(II)\text{-}R]/dt = k_{II}[^{\cdot}R][Cu(I)L] - k_{III}[^{\cdot}R][LCu(II)\text{-}R] + k_{IV}[^{\cdot}R][Cu(II)L]$$

Applying the steady-state assumption for $[^{\cdot}R]$:

$$d[^{\cdot}R]/dt = k_I[Cu^{I}L][RX] + (k_{II}[Cu^{I}L] + k_{III}[LCu^{II}-R] + k_{IV}[Cu^{II}L])[^{\cdot}R] = 0$$

$$[^{\cdot}R] = k_I[Cu^{I}L][RX]/(k_{II}[Cu^{I}L] + k_{III}[LCu^{II}-R] + k_{IV}[Cu^{II}L])$$

$$d[Cu^{II}-R]/dt = (k_{II}[Cu^{I}L] - k_{III}[Cu^{II}-R] + k_{IV}[Cu^{II}L])k_I[Cu^{I}L][RX]/(k_{II}[Cu^{I}L] + k_{III}[LCu^{II}-R] + k_{IV}[Cu^{II}L])$$

The latter rate law is in agreement with the experimental observations:

a) At low $[Cu^{II}L]$ the contribution of k_{IV} $[Cu^{II}L]$ to the nominator is larger than to the denominator as $(k_{II}[Cu^{I}L] + k_{III}[LCu^{II}-R]) > (k_{II}[Cu^{I}L] - k_{III}[LCu^{III}-R])$. It should be noted that $[Cu^{II}L]$ is always > 0 as it is formed in reaction (I).

b) At high $[Cu^{II}L]$, i.e. when $k_{IV}[Cu^{II}L] >> (k_{II}[Cu^{I}L] + k_{III}[LCu^{II}-R])$ the rate law is reduced to $d[Cu^{II}-R]/dt = k_I[Cu^{I}L][RX]$ and therefore it is concluded that the large error limit is due to the observation that $k_{IV}[Cu^{II}L]$ is still not large enough and that $[Cu^{II}L] > 0$ even when no $Cu^{II}L$ was added to the solutions.

$$(CuL^2)^+ + Cl_3CCOO^- \rightarrow {}^{\cdot}CCl_2CO_2^- + Cu(L^2)Cl^+ \quad (18)$$

$k_{18} = 7.0 \pm 2.0\ M^{-1}s^{-1}$

Volume of Activation

The volume of activation of reaction (2) for $Cu^+{}_{aq}$ was derived by measuring the pressure effect on the rate of this reaction in the presence of fumarate as the rate constant for the reaction of Cu^{I}(fumarate) with Cl_3CCOO^- is too slow to be measured.[6] The volume of activation was derived analogously to the method used for the reaction of $Cu^+{}_{aq}$ with O_2.[9] The observed volume of activation $\Delta V_2^{\neq}(Cu^+{}_{aq})_{obs} = -9.9 \pm 1.0$ mL/mol. However, as $\Delta V_1^0 = -4.5 \pm 1.0$ mL/mol one calculates $\Delta V_2^{\neq}(Cu^+{}_{aq}) = -14.4 \pm 2.0$ mL/mol. This result clearly demonstrates that reaction (2) proceeds via an associative transition state in agreement with expectations.

Ligand Effects on the Reactivity of $Cu^{I}L$

Before analyzing the ligand effect on the reaction mechanism and kinetics, the thermodynamics of the chlorine ab-

straction, the rate-determining step in most of the systems studied, should be considered.

The ΔH of the reactions between Cu^{I} and Cl_3CCOO^- in aqueous solution can be roughly estimated using the equation $\Delta H = \Delta H(Cl{-}CCl_2) - \Delta H^0_f(Cl_g) - \Delta H^0_f(Cl^-_{aq}) + [\Delta H^0_f(Cu^{2+}_{aq}) - \Delta H^0_f(Cu^+_{aq})]$. Thus $\Delta H = 3.5$ kcal mol^{-1} and $\Delta H = -2.7$ kcal mol^{-1} is obtained for Cu^+_{aq} and $[Cu^{I}L^2]^+$, respectively. [The calculation is based on data from ref.[16] assuming that the solvation energy of the radical $^{\cdot}CCl_2CO_2^-$ does not differ considerably from that of Cl_3CCOO^-. The ΔH calculation for $(Cu^{I}L^2)^+$ is based on the redox potential of the complex assuming a small ΔS value for this redox process.]

The small free energy gain, if any, in these reactions in combination with the low rates for the self exchange rate of Cu^{I} [$k(Cu^+_{aq}/Cu^{2+}_{aq}) = 5{\cdot}10^{-7}$ M^{-1}s^{-1}][17] and the probably low self exchange rate for the couple $Cl_3CCOO^-/{}^-Cl_3CCOO^-$ suggests that reaction (2) proceeds by the inner sphere mechanism and not by the outer sphere mechanism. The large negative volume of activation measured for reaction (2) verified this expectation.

Since the Cu^{I} complexes act as reducing agents in these reactions with Cl_3CCOO^- it seemed reasonable to expect that the rate constants of these reactions will be correlated to the redox potential of the $Cu^{II/I}L$ couples. The measured rate constants of these reactions for the different complexes and their redox potentials are summed up in Table 2. The results point out that there is no simple correlation between the redox potentials of the Cu^{I} complexes and the observed rate constants. The results thus demonstrate that the rate of this reaction also depends on other factors; in the following paragraphs these effects are discussed.

Table 2. A comparison between the rate constants of the reaction of the Cu^{I} complexes with that of $Cl_3CCO_2^-$ along with their redox potentials

Complex	k [M^{-1}s^{-1}][a]	$E^0_{Cu(II)L/Cu(I)L}$ [V]
Cu^+_{aq}	6.0	0.15
$(Cu^{I}L^2)^+$	7.0	−0.12[b]
$Cu^{I}(NH_3)_2^+$	1.2	0.032[c]
$Cu^{I}(CH_3CN)^+$	0.62	0.34[c]
$(Cu^{I}L^1)^+$	0.14	−0.035[d]
$Cu^{I}(CH_3CN)_2^+$	0.075	0.41[c]
Cu^{I}(fumarate)$^+$ [e]	< 0.015	0.38[c]

[a] The error limits for the rate constants are ± 15%. [b] Data taken from ref.[8] [c] The redox potentials were calculated using the stability constants of the complexes (error limits ± 10%). [d] Data taken from ref.[7] [e] Data taken from ref.[4]

$Cu^{I}(CH_3CN)^+$ and $Cu^{I}(CH_3CN)_2^+$ are weaker reducing agents than Cu^+_{aq} and indeed their rates of reaction with Cl_3CCOO^- are considerably smaller than that of Cu^+_{aq}, as expected. (However, other factors might contribute to the low reactivity of $Cu^{I}(CH_3CN)_2^+$, see below.)

Though $(Cu^{I}L^1)^+$ is a better reducing agent than $Cu^{I}(NH_3)_2^+$ its reactivity is lower. This observation is probably due to the steric hindrance imposed by the ligand. The reaction of $(Cu^{I}L^2)^+$ with Cl_3CCOO^- probably first requires a ligand exchange step, most likely a release of the alkene bonding. Still the rate of this reaction is similar to that of Cu^+_{aq} and 45 times faster than that of $(Cu^{I}L^1)^+$ despite the steric hindrance that the L^2 ligand imposes on the central copper cation. This is attributed to the redox potential of $(Cu^{I}L^2)^+$.

$Cu^{I}(NH_3)_2^+$ is a considerably stronger reducing agent than Cu^+_{aq}; however, $Cu^{I}(NH_3)_2^+$ is considerably less reactive towards Cl_3CCOO^- than Cu^+_{aq}. This observation is attributed to the fact that when the linear $Cu^{I}(NH_3)_2^+$ complex, which has an sp hybridization, reacts with Cl_3CCOO^- in an inner sphere process the hybridization has to be changed, probably to an sp^3 one, a process which costs energy and therefore slows down the reaction. A similar argument probably contributes to the low reactivity of $Cu^{I}(CH_3CN)_2^+$. On the other hand Cu^+_{aq} is $Cu(H_2O)_4^+$,[18] i.e. it has an sp^3 hybridization and the reaction probably proceeds by a ligand exchange step followed by the chlorine abstraction.

The complex $Cu^{I}(HOOCCH{=}CHCOO^-)$ is the least reactive complex towards Cl_3CCOO^- though it is a better reducing agent than $Cu^{I}(CH_3CN)_2^+$. The low reactivity of $Cu^{I}(HOOCCH{=}CHCOO^-)$ is attributed to the fact that the Cu^{I} forms a d-π* complex with the fumarate. This type of binding reduces the electron density in the position *trans* to the ligand and therefore decreases the complex reactivity. A similar phenomenon was found for the reaction between $Cu^{I}(HOOCCH{=}CHCOO^-)$ and dioxygen.[9]

Finally it should be pointed out that if $[Cu^{I}L^2]^+$ would be used under catalytic conditions the rate-determining step would not be the chlorine abstraction reaction but the decomposition of $L^2Cu^{II}{-}R$ which might complicate the reaction mechanism as reactions of $^{\cdot}R$ with $L^2Cu^{II}{-}R$ are plausible.[8] The stabilization of $L^2Cu^{II}{-}R$ is attributed to the redox potential of the $(CuL^2)^{2+/+}$ couple. Thus, the results point out that the cathodic shift of the redox potential of the $Cu^{II/I}$ couple might in some cases complicate catalytic processes. The transient $L^2Cu^{II}{-}CCl_2CO_2^-$ is the most stable LCu^{II}-alkyl complex in aqueous solution, observed to date.[15,19]

Conclusion

The implications of the results, presented in this study, on catalytic processes catalyzed by Cu^{I} complexes, in which the redox step is the rate-determining step, are:

1. Solvents such as acetonitrile, that form complexes with Cu^{I} and anodically shift its redox potential, decrease the reactivity. Therefore, in catalytic systems, the use of solvents that do not form Cu^{I} complexes will considerably improve the rate of the processes.

2. The observation that the $Cu^{I}(HOOCCH{=}CHCOO^-)$ complex reacts considerably slower than Cu^+_{aq} with Cl_3CCOO^- suggests that it would be advantageous to work in catalytic systems, which are all carried out in organic solvents, in the absence of a large excess of alkenes.

3. Ligands such as L^1 and L^2, which have substituents that bind to the central cation only in its uncommon oxida-

tion state, might be used to improve the properties of processes that are redox-catalyzed.

4. Even ligands that accelerate the rate of the redox step might slow down the catalytic processes if they stabilize one of the intermediates in the catalytic process.

Experimental Section

Materials: All solutions were prepared from A. R. grade chemicals and from distilled water further purified by passing through a Milli Q Millipore setup, final resistivity > 10 MΩ/cm. L^1 and L^2 were synthesized and analyzed by procedures described in refs.[7,8] Cl^- was analyzed by using a Dionex ion chromatograph. Solutions of $[Cu^{I}L^1]^+$ and $[Cu^{I}L^2]^+$ were prepared by the comproportionation process, reaction (19). Solid copper was added to deaerated solutions containing $CuSO_4$ and excess of L^1 or L^2 at pH = 6.5.

$$Cu^0_{(s)} + (Cu^{II}L)^{2+}_{aq} + L \rightleftarrows 2\,(Cu^{I}L)^+ \quad (19)$$

(L = L^1 or L^2)

Solutions of $Cu^{I}(NH_3)_2^+$ were prepared by comproportionation of $Cu(NH_3)_4^{2+}$ in 1 M NH_3.

Kinetic Measurements: Reactions with half lives longer than 2 s were carried out using a fast mixing cell (SFA-11 Rapid Kinetics Accessory Hi-Tech Scientific Ltd.), which was connected to a Hewlett Packard 8452A diode array spectrophotometer. Stopped flow experiments were carried out using an SX.18 Applied PhotoPhysics stopped flow that enables kinetic measurements of reactions with lifetimes of 2 ms. The detector was a 05−109 Spectra Kinetics Monochromator that enabled measurements in the range of 200−700 nm. The optical path was 10 nm.

Pulse-Radiolysis Experiments: These were carried out using the Varian 7715 linear electron accelerator of the Hebrew University of Jerusalem. The pulse duration was 0.1−1.5μs with a 200-mA current of 5-MeV electrons. The dose per pulse was 3−30 Gray. Irradiations were carried out in a 4-cm spectrosil optical cell, the analyzing light passed through the cell three times. A 150-W Xenon lamp produced the analyzing light. The experimental setup was identical to that described earlier in detail.[11] For dosimetry, an N_2O-saturated solution containing $1.0\cdot10^{-3}$ M KSCN was used. The yield of $(SCN)_2^{\cdot-}$ was measured by taking ε_{475} = 7600 $M^{-1}cm^{-1}$ and the dose per pulse was calculated assuming $G(SCN)_2^{\cdot-}$ = 6.0[20] and an optical path of 12.3 cm. High-pressure pulse-radiolysis experiments for the determination of volumes of activation were carried out using the technique recently described in detail.[21]

Reactivity of $Ph_2P(O)py$-2 with Platinum(II) Alkyl Derivatives − Building-up of a Chiral Phosphorus Atom through C,N-Cyclometallation

Giovanni Minghetti,*[a] Angelino Doppiu,[a] Sergio Stoccoro,[a] Antonio Zucca,[a] Maria Agostina Cinellu,[a] Mario Manassero,*[b] and Mirella Sansoni[b]

Keywords: Platinum / N ligands / Cyclometallation / Alkyl derivatives / Crystal structure

The reaction of $Ph_2P(O)py$-2 (HL) with methyl- and dimethylplatinum(II) derivatives afforded a series of six-membered *C,N*-cyclometallated species, [PtX(L′)(L)] (X=halide or Me; L′ = neutral ligand, e.g. SMe_2, $SOMe_2$, CO, PAr_3) arising from activation of one $C(sp^2)$–H bond of a phenyl substituent. The metallation entailed elimination of methane and caused the phosphorus atom to become chiral. The series includes the complex [Pt(Me)(CO)(L)] where the platinum atom is bonded to three different carbon atoms (C_{sp}^3, C_{sp}^2, C_{sp}). From the neutral species cationic derivatives $[Pt(L')(L'')(L)]^+$ (L′ = SMe_2, L′′ = CH_3CN; L′–L′′ = dppe; L′ = SMe_2 or $SOMe_2$, L′′ = H_2O) could be obtained. The new complexes were isolated and fully characterised by elemental analyses and spectroscopic techniques (IR, NMR, FAB-MS). The solid-state structures of [PtCl(SMe_2)(L)], [PtCl(CO)(L)], [Pt(Me)($SOMe_2$)(L)], and [Pt(SMe_2)(H_2O)(L)][BF_4] were determined by single-crystal X-ray diffraction.

Introduction

In recent years, coordination of pyridylphosphanes to typical soft acceptors such as Rh^I, Pd^{II}, or Pt^{II} has been extensively studied,[1] whereas much less investigated is the behaviour of the pyridylphosphane oxides.[2] In a previous paper we described the reactivity of palladium(II) and platinum(II) halides with the ligands $Ph_2P(O)CH(Me)py$-2 and $Ph_2P(O)CH_2py$-2.[3] We observed that they can act either as N-monodentate or N,O-*endo*-bidentate ligands to afford $[(HL)_2MX_2]$ or $[(HL)MX_2]$ adducts, respectively. In the case of $Ph_2P(O)py$-2, only a 1:1 species $[(HL)PdCl_2]$ was obtained; spectroscopic data are in agreement with a chelating behaviour to give a five-membered ring. In no case were the phenyl substituents involved; no C−H activation was observed to give cyclometallated species.

Now, following our interest in the reactivity of alkyl derivatives of platinum(II),[4] we report a study on the interaction of $Ph_2P(O)py$-2 with the methyl- and dimethylplatinum species *trans*-[PtCl(Me)(SMe_2)$_2$], $[Pt(Me)_2(\mu\text{-}SMe_2)]_2$, *trans*-[PtCl(Me)($SOMe_2$)$_2$], and *cis*-[Pt(Me)$_2$($SOMe_2$)$_2$] to afford a series of six-membered *N,C*-cyclometallated derivatives.

Results and Discussion

The N,O-ligand diphenyl(2-pyridyl)phosphane oxide (HL)[3] and the starting methyl- and dimethylplatinum complexes *trans*-[PtCl(Me)(SMe_2)$_2$],[5] *trans*-[PtCl(Me)-($SOMe_2$)$_2$],[6] $[Pt(Me)_2(\mu\text{-}SMe_2)]_2$,[5] and *cis*-[Pt(Me)$_2$-($SOMe_2$)$_2$][6] were obtained as previously described. The reaction of the chloro(methyl) complexes with the ligand affords compounds [PtCl(SMe_2)(L)] (**1**) and [PtCl(SO-Me_2)(L)] (**2**), respectively (see Scheme 1). Compounds **1** and **2** have been characterised by elemental analyses, conductivity measurements, FAB MS, IR, and ^1H-, and $^{31}P\{^1H\}$-NMR spectra. In the FAB MS spectra the molecular ions were observed at m/z = 570 and 586, respectively; in the IR spectra the absorption assigned to ν(P=O) is not significantly shifted with respect to the free ligand (1190 cm^{-1}), suggesting that the oxygen atom is not involved in the coordination to the platinum atom. In agreement, in the $^{31}P\{^1H\}$ NMR spectra, the resonances at δ = 31.15 (compound **1**) and 31.65 (compound **2**) are only slightly deshielded compared to that of the ligand (δ = 22.0). We have previously reported that in the adduct $[Pd(Cl)_2(HL)]$ (*N,O*-coordination) the ^{31}P resonance is strongly deshielded (δ = 60.5).

The ^1H NMR spectra allow a choice to be made between the two possible isomers having a Cl−Pt−C or a Cl−Pt−N *trans* arrangement; the H(6) proton of the pyridine ring is remarkably deshielded, as often observed for six-membered species with the chloride ligand *cis* to the nitrogen atom.[7] In addition, the very large value of $^3J_{Pt,H}$ relative to the methyl protons of SMe_2 in compound **1** supports the pres-

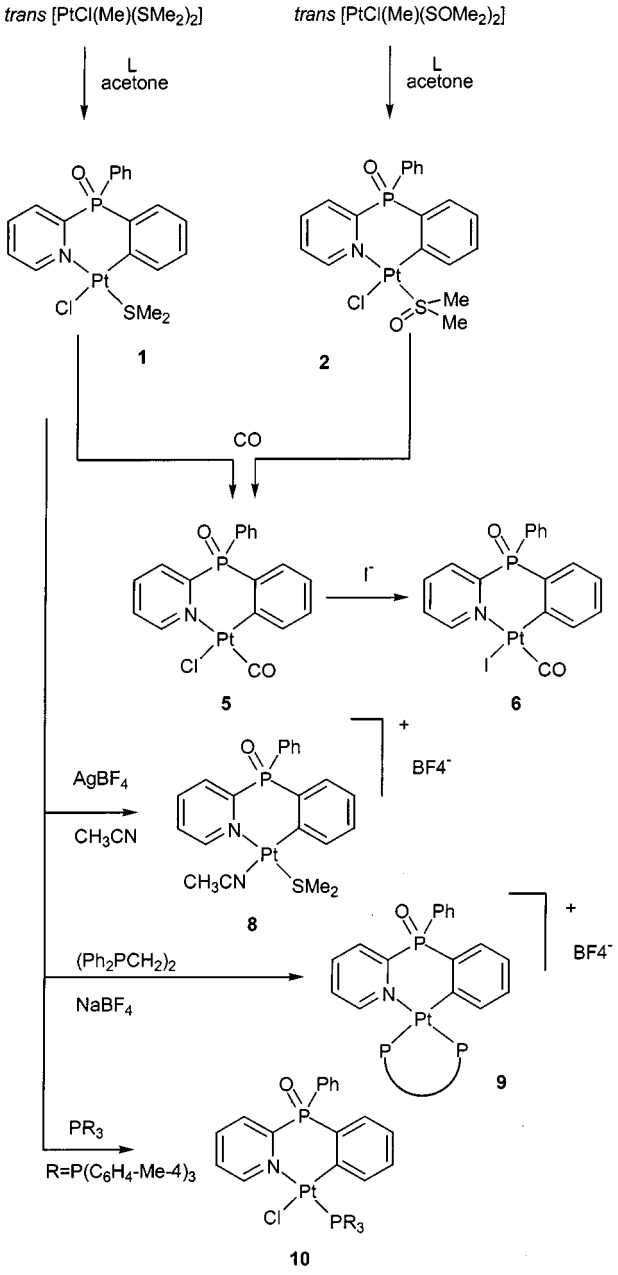

Scheme 1

ence of a ligand (in a *trans* configuration) with low *trans* influence.[8]

The methyl groups of the coordinated SMe_2 ligand are diastereotopic; one of them resonates at rather high field ($\delta = 1.63$) with respect to the other one ($\delta = 2.49$) ($\Delta\delta = 0.86$). The shift at higher field of one of the resonances is likely related to the shielding effect of the phenyl ring. In an attempt to obtain more information on the structure of compound **1** in solution, an NOE difference experiment was carried out, but failed owing to interconversion of the methyl groups, due to either dissociation/association or partially hindered rotation of the Pt−S bond.

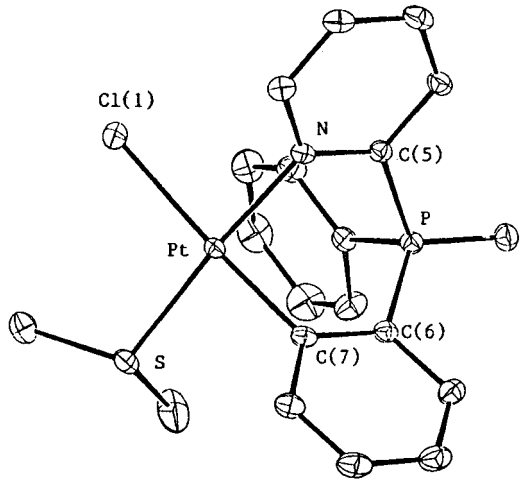

Figure 1. ORTEP view of compound **1**; thermal ellipsoids are drawn at the 30% probability level

Table 1. Selected bond lengths [Å] and angles [°] with e.s.d.s in parentheses

a) Compound **1**

Pt−Cl(1)	2.400(1)	Pt−S	2.268(1)
Pt−N	2.046(2)	Pt−C(7)	2.003(2)
Cl(1)−Pt−S	97.01(2)	Cl(1)−Pt−N	87.78(5)
Cl(1)−Pt−C(7)	176.81(7)	S−Pt−N	175.20(5)
S−Pt−C(7)	85.92(6)	N−Pt−C(7)	89.29(8)

b) Compound **5**

Pt−Cl	2.403(1)	Pt−N	2.069(3)
Pt−C(7)	2.028(3)	Pt−C(18)	1.897(4)
C(18)−O(2)	1.061(5)		
Cl−Pt−N	88.3(1)	Cl−Pt−C(7)	177.3(1)
Cl−Pt−C(18)	93.5(1)	N−Pt−C(7)	89.5(1)
N−Pt−C(18)	177.4(2)	C(7)−Pt−C(18)	88.8(2)

In the solid state, the nature of complex **1** was confirmed by X-ray diffraction. Suitable crystals were obtained by slow concentration of a $CHCl_3$ solution. The structure consists of the packing of $[PtCl(SMe_2)(L)]$ and $CHCl_3$ molecules in the molar ratio 1:1 with no unusual van der Waals contacts. An ORTEP view or the complex molecule is shown in Figure 1 and selected bond parameters are reported in Table 1.

The metal atom displays a square-planar coordination with a very slight square-pyramidal distortion, maximum distances from the best plane being −0.012(1) and +0.013(2) Å for Pt and C(7), respectively. The inner coordination sphere of the metal atom in the present compound is identical with that found in $[PtCl(SMe_2)(L^2)]$ (**13**) (HL^2= 6-*tert*-butyl-2,2′-bipyridine)[8] where the L^2 ligand is coordinated through a nitrogen atom and the C(3) atom of the substituted pyridine ring. Corresponding bond lengths involving the metal atom are all very similar in the two com-

pounds, thus, Pt−Cl = 2.400(1) (here) and 2.395(2) Å (**13**); similarly, Pt−S = 2.268(1) and 2.263(2) Å, Pt−N = 2.046(2) and 2.042(4) Å, and Pt−C = 2.003(2) and 1.990(5) Å, respectively, here and in **13**.

The Pt−N−C(5)−P−C(6)−C(7) six-membered ring is in a boat conformation, with atoms N, C(5), C(6), and C(7) strictly coplanar, and atoms Pt and P lying 1.008(1) and 0.752(2) Å above that plane, respectively. The best plane of atoms N, C(5), C(6), and C(7) forms dihedral angles of 44.4(1)° with the Pt−N−C(7) plane and of 41.2(1)° with the C(5)−P−C(6) plane.

Compound **2** is similar to **1**, having the $SOMe_2$ ligand in place of SMe_2; the ^1H NMR spectra provide evidence for the same isomer as **1** and an *S*-bonded dimethyl sulfoxide.

Both compounds **1** and **2** reacted under mild conditions with carbon monoxide to give **5**; the stretching vibration of the terminal CO is observed at a rather high value, 2122 cm^{-1} (Nujol) typical of platinum(II) species. The chloride ligand in complex **5** could be easily replaced by iodide through exchange with LiI. A lowering of ν(CO) in complex **6** [PtI(CO)L] ($\Delta\nu$ = 28 cm^{-1}) is consistent with substitution of iodide in exchange for the more electronegative chloride.

An ORTEP view of the molecular structure of **5** is shown in Figure 2, and selected bond parameters are listed in Table 1. Crystals of this compound contain molecules of **5** and water molecules in the molar ratio 1:0.667. In **5**, the Pt^{II} atom is in the usual square-planar coordination. Bond lengths and angles involving the Pt−Cl−(N,C) moiety are all very similar to those already discussed for compound **1**. The Pt−CO bond length [1.897(4) Å] is in good agreement with those found in $[Pt_2(Me)_2(CO)_2(N,C^{\wedge}C,N\text{-terpy-2H})]$[9] [1.890 Å (average of two)] and in [Pt(COPh)(Me)-(CO)(PPh_3)][10] [1.897(7) Å]. The C−O distance [1.061(5) Å] is rather short.

From compound **1**, the ligand SMe_2 could be substituted by other neutral ligands such as $P(C_6H_4\text{-Me-}4)_3$. In compound **10** the phosphane group is *trans* to the nitrogen atom as shown by the $^1J_{Pt,P}$ value of 4279 Hz.

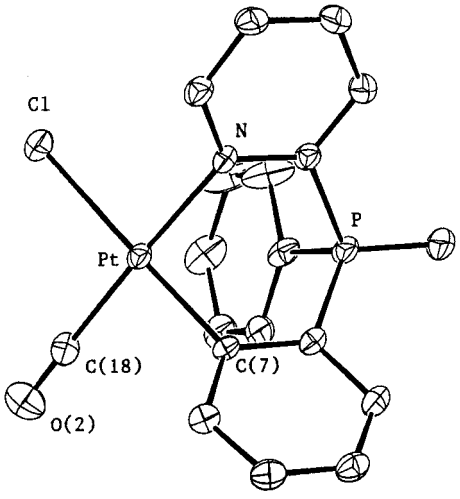

Figure 2. ORTEP view of compound **5**; thermal ellipsoids as in Figure 1

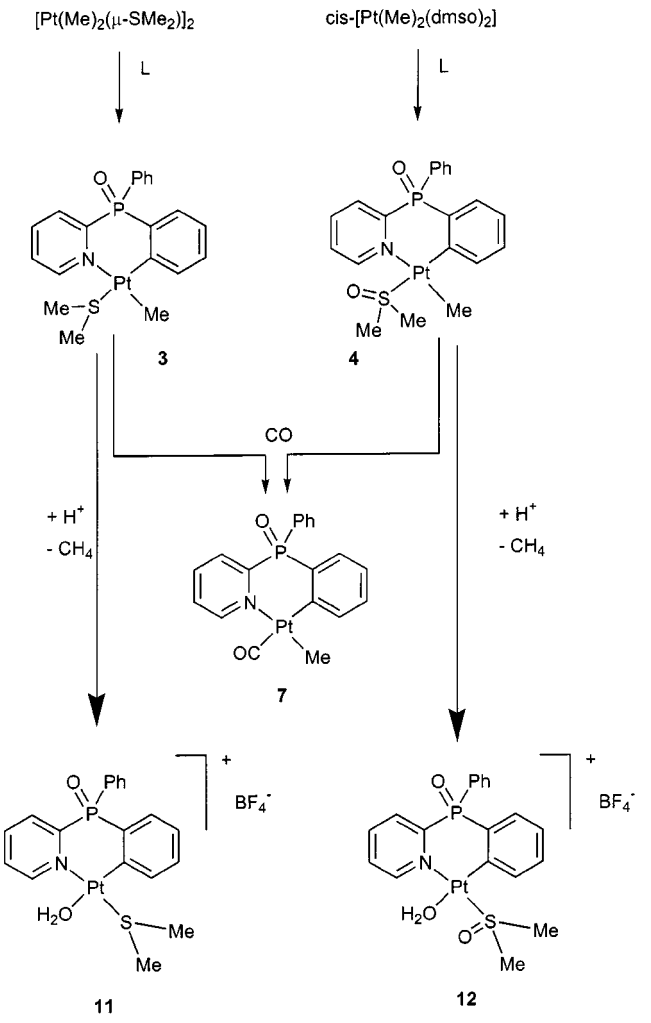
The chloride ion could be displaced by means of silver salts to give cationic species such as **8** {$[Pt(MeCN)(SMe_2)(L)][BF_4]$}, or by chelating ligands in the presence of a non-coordinating anion. Thus compound **9** {$[Pt(dppe)(L)][BF_4]$} could be easily isolated by reaction of **1** with dppe and $Na[BF_4]$ [dppe = 1,2-bis(diphenylphosphanyl)ethane]. In the cationic species **9**, in addition to the six-membered N,C-ring, a second five-membered ring was formed by chelation of dppe. The behaviour of the diphosphane is unambiguously shown by the $^{31}P\{^1H\}$ NMR spectrum. Noteworthy is the long-range coupling ($^4J_{P,P}$ = 9.2 Hz) between the ^{31}P nucleus in the C,N-cycle and the ^{31}P *trans* to the carbon atom. The molecular ion at *m/z* = 871 in the FAB mass spectrum confirms the nature of the cation.

The behaviour of the ligand HL towards the dimethyl derivatives $[Pt(Me)_2(\mu\text{-}SMe_2)]_2$ and *cis*-$[Pt(Me)_2(SOMe_2)_2]$ is similar to that observed in the case of the monoalkyl species. Indeed, metallation of a phenyl group occurs with loss of methane (Scheme 2) to give the six-membered *C*,*N*-metallated compounds **3** and **4**, respectively (Scheme 2).



Scheme 2

One isomer only was formed having the methyl group *trans* to the nitrogen atom (as shown by ^{1}H NMR spectra). The structure in solution for **3** and **4** were ascertained by means of ^{1}H NMR NOE difference spectra, which unambiguously show that in $CDCl_3$ solution the methyl group is coordinated *trans* to the pyridine ring. For example, in the case of **3**, irradiation of the coordinated methyl group at $\delta = 0.59$ enhanced the doublet ($\delta = 7.52$) of the H *ortho* to the C(sp^2)−Pt bond. At variance, irradiation of the singlet at $\delta = 1.80$ (SMe_2) revealed contacts with the coordinated methyl group ($\delta = 0.59$) and the H(6) proton of the substituted pyridine ring ($\delta = 8.76$). Contacts among the C_6H_5 protons (two multiplets at $\delta = 7.30$ and 7.64) and the methyl group of the coordinated dimethyl sulfide suggest that in the boat conformation of the six-membered cyclometallated ring they are spatially close.

The structure consists of the packing of molecules of **4** and water molecules in the molar ratio 1:0.25. The asymmetric unity of **4**·0.25H_2O contains two crystallographically independent molecules of **4**. An ORTEP view of molecule A is shown in Figure 3. Selected bond parameters for both molecules are reported in Table 2. Corresponding bond lengths and angles in the two molecules are all very similar. Pt−N1 and Pt−S1 bond lengths (2.130 and 2.303 Å, respectively, average of two), are both elongated by the influence of the *trans*-carbon atoms. All other bond lengths and angles are normal.

Also, with these methyl species, carbon monoxide easily displaced the ligands SMe_2 or $SOMe_2$ from **3** and **4**, respectively, to afford the not trivial derivative **7** [Pt(Me)(CO)(L)] where three carbon ligands, C(sp^3), C(sp^2), C(sp) are assembled around the platinum center.

The CO ligand is coordinated *cis* to the pyridine ring as shown, inter alia, by ^{1}H NMR NOE difference spectra; irradiation of the singlet at $\delta = 0.76$ (CH_3−Pt) produced enhancement of the doublet at $\delta = 7.56$, assigned to the hydrogen atom *ortho* to the C(sp^2)−metal bond, proving that the coordinated methyl group is close in space to the metallated phenyl ring. In addition, the $^2J_{Pt,H}$ of the methyl protons (88.2 Hz) is consistent with a methyl group *trans* to a nitrogen atom.[4] Under mild conditions, no migration insertion to give an acyl group was observed.

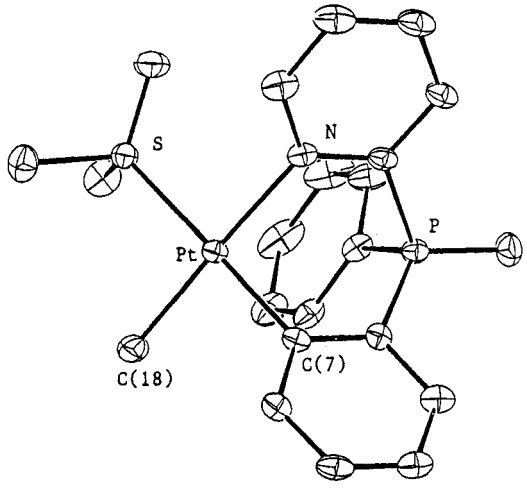


Figure 3. ORTEP view of compound **4**; thermal ellipsoids as in Figure 1

Table 2. Selected bond lengths [Å] and angles [°] with e.s.d.s in parentheses

a) Compound **4**

	Molecule A	Molecule B
Pt−S	2.305(2)	2.300(2)
Pt−N	2.139(5)	2.121(6)
Pt−C(7)	2.040(6)	2.032(6)
Pt−C(18)	2.074(8)	2.088(8)
S−Pt−N	90.8(1)	89.8(2)
S−Pt−C(7)	175.3(2)	176.9(2)
S−Pt−C(18)	91.4(2)	92.9(2)
N−Pt−C(7)	90.8(2)	88.7(2)
N−Pt−C(18)	177.7(2)	177.3(2)
C(7)−Pt−C(18)	87.0(3)	88.7(3)

b) Compound **11**

Pt−S	2.273(1)	Pt−O(2)	2.133(2)
Pt−N	2.036(3)	Pt−C(7)	1.986(3)
S−Pt−O(2)	91.2(1)	S−Pt−N	178.2(1)
S−Pt−C(7)	89.1(1)	O(2)−Pt−N	88.6(1)
O(2)−Pt−C(7)	177.9(1)	N−Pt−C(7)	91.2(1)

A remarkable result was obtained by reaction of compounds **3** and **4** with the complex acid [H_3O]-18-crown-6-[BF_4] (Scheme 2). We have preferred this acid because it is solid, easily obtainable, and can be weighted accurately so that an excess can be avoided. This excess could potentially also attack the Pt−C(sp^2) bond, destroying the cyclometallated ring. Indeed, the Pt−C(sp^3) bond is cleaved selectively with elimination of methane. In the resulting cationic derivatives, **11** and **12**, the fourth position in the coordination sphere of the platinum atom is filled by a molecule of water *trans* to the carbon atom. The isomerization observed is likely due to the remarkable difference of the lability production action (*trans* effect) between the C- and N-ligands.

Crystals of **11** suitable for X-ray diffraction were isolated from a dichloromethane solution. The structure of **11** consists of the packing of [Pt(OH_2)(SMe_2)(L)]$^+$ cations and [BF_4]$^-$ anions in the molar ratio 1:1. An ORTEP view of the cation in **11** is shown in Figure 4. Selected bond lengths and angles are listed in Table 2. The Pt−S, Pt−N, and Pt−C7 distances, 2.273(1), 2.036(3), and 1.986(3) Å, respectively, are very close to the corresponding distances already discussed for compound **1** [2.268(1), 2.046(2), and 2.003(2) Å, respectively]. The Pt−O2 bond length [2.133(2) Å] is significantly shorter than the Pt−OH_2 distance [2.186(2) Å] found in cation [Pt{C_6H_3(CH_2NMe_2)$_2$-2,6}(OH_2)]$^+$,[11] which to the best of our knowledge, is a rare example of a cyclometallated aqua complex of Pt^{II} for which a crystal structure determination has been reported.

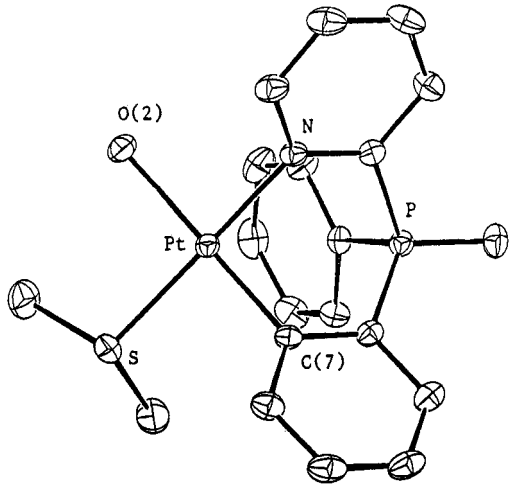

Figure 4. ORTEP view of the cation in compound **11**; thermal ellipsoids as in Figure 1

The hydrogen atoms of the coordinated water molecule are both involved in interionic hydrogen bonds, one towards the O1 phosphane oxide atom of a neighbouring cation [O2····O1 = 2.573(3) Å] and the other towards a fluorine atom of the $[BF_4]^-$ anion [O2····F1 = 2.719(4) Å], as shown in Figure 5.

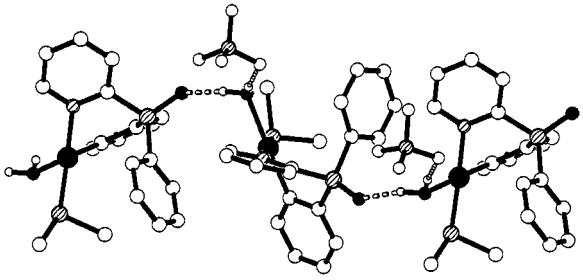

Figure 5. A view of the hydrogen-bonding network in the crystal packing of compound **11**

Conclusion

In a previous paper, we reported on the reactivity of some (2-pyridyl)phosphane oxides with platinum and palladium halides. At variance with the behaviour shown in the reaction with mono- and dimethyl derivatives, no involvement of the phenyl substituents was observed; only 1:1 or 1:2 (Pt/LH) adducts were obtained. It seems, therefore, that metallation is easier, at least in the case of platinum, when methane rather than hydrogen chloride elimination is involved. This points to methyl or methyl halide derivatives as suitable starting materials to achieve activation of $C(sp^2)-H$ bonds. It is worth underlining the fact that in this case, metallation entailed the building-up of a stereogenic centre, the phosphorus atom, inside the *C,N*-metallated ring. The behaviour of analogous intermediates of palladium(II) is currently under investigation.

Experimental Section

General: The ligand HL and the platinum complexes *trans*-$[PtCl(Me)(SMe_2)_2]$, $[Pt(Me)_2(\mu\text{-}SMe_2)]_2$, *trans*-$[PtCl(Me)(SOMe_2)_2]$, and *cis*-$[Pt(Me)_2(SOMe_2)_2]$, were obtained as previously described.[5−6] $[H_3O]$-18-Crown-6-$[BF_4]$ was synthesised as reported elsewhere.[12] All solvents were distilled and dried according to established methods. Elemental analyses were performed with a Perkin−Elmer Elemental Analyzer 240B by Mr. A. Canu (Dipartimento di Chimica, Università di Sassari). Infrared spectra were recorded with a Perkin−Elmer 983 spectrophotometer; the values are given in cm^{-1}. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded with a Varian VXR 300 spectrometer operating at 299.9 and 121.4 MHz, respectively. Chemical shifts are given in ppm relative to internal TMS (^1H) or external H_3PO_4 (^{31}P). Mass spectra were obtained with a VG 7070EQ instrument operating under FAB conditions with 3-nitrobenzyl alcohol as supporting matrix.

General Procedures: The compounds **1**−**4** were synthesised according to the following procedure. The relevant starting complex (ca. 0.1 g) and a stoichiometric amount of the ligand were dissolved in anhydrous acetone (ca. 30 mL). The solution was heated at reflux for 24 h under nitrogen, it was then concentrated to dryness. The solid was dissolved in dichloromethane (20 mL) and the resulting solution was filtered through Celite and concentrated to a small volume. Dropwise addition of *n*-hexane afforded a white crystalline solid, which was filtered off and collected. − Compound **5** was obtained in almost quantitative yield by carbonylation (p_{CO} = 1 bar) of a dichloromethane solution (5 mL) of either **1** or **2** (ca. 0.1 g) for 24 h at room temperature. Compound **7** was obtained from either **3** or **4** in quantitative yield, according to a similar procedure, but with shorter reaction time (6 h). − Compounds **11** and **12** were prepared in ca. 80% yield according to the following procedure. The relevant starting complex **1** or **2** (ca. 0.100 g), was dissolved in dichloromethane (5 mL) and a stoichiometric amount of the complex acid $[H_3O]$-18-crown-6-$[BF_4]$ was added. The solution was kept unstirred for 8 h. The white crystals that formed were washed with dichloromethane and collected.

X-ray Data Collection and Structure Determinations: Crystal data and other experimental details are summarized in Tables 3 and 4. The diffraction experiments were carried out with a Bruker SMART CCD area-detector diffractometer at 223 K using Mo-K_α radiation (λ = 0.71073 Å) with a graphite crystal monochromator in the incident beam. Cell parameters and orientation matrices were obtained from the least-squares refinement of 124 (for **1**·CHCl$_3$), 123 (for **5**·0.67H$_2$O), 59 (for **4**·0.25H$_2$O), and 112 (for **11**) reflections measured in three different sets of 15 frames each, in the range $3° < \theta < 23°$. At the end of data collections the first 50 frames, containing 417, 334, 335, and 267 reflections (for **1**·CHCl$_3$, **5**·0.67H$_2$O, **4**·0.25H$_2$O, and **11**, respectively) were recollected to have a monitoring of crystal decay, which was not observed, so no time-decay correction was needed. The collected frames were processed with the software SAINT,[13] and an empirical absorption correction was applied (SADABS)[14] to the collected reflections. Scattering factors and anomalous dispersion corrections were taken from ref.[15] The calculations were performed with a Pentium III PC using the Personal Structure Determination Package,[16] and the physical constants tabulated therein. The structures were solved by Patterson and Fourier methods and refined by full-matrix least squares, using all reflections and minimizing the function $\Sigma w(F_o^2 - k|F_c|^2)^2$ (refinement on F^2). Anisotropic thermal factors were refined for all the non-hydrogen atoms. The hydrogen atoms of the coordinated water molecule in **11** were detected in the final Fourier maps and not refined. The hydrogen atoms of the clathrate water molecules in **5**·0.67H$_2$O and **4**·0.25H$_2$O were neglected. All the other hydrogen atoms were placed in their ideal positions (C−H = 0.97 Å; *B* = 1.10 times that of the carbon atom to which they are attached) and not refined. The final Fourier maps show maximum residuals of 1.0(2) e/Å^3 at 0.76 Å from Pt for **1**·CHCl$_3$, 1.8(3) e/Å^3 at 0.91 Å from Pt for **5**·0.67H$_2$O, 3.0(7) e/Å^3 at 0.83 Å from Pt(A) for **4**·0.25H$_2$O, and 1.0(2) e/Å^3 at 0.89 Å from Pt for **11**. The atomic coordinates of the structure models have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-164381 (**1**·CHCl$_3$), -164382 (**5**·0.67 H$_2$O), -164383 (**4**·0.25 H$_2$O), -164384 **11**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Methyl- and Acetylpalladium(II) Complexes Containing a P,N,O Tridentate Hydrazone Ligand

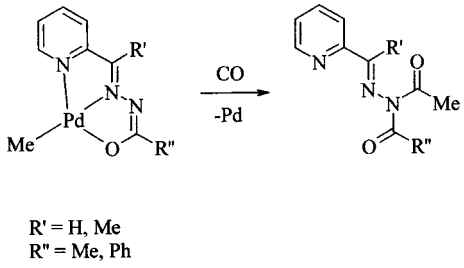
Paolo Pelagatti,*[a] Alessia Bacchi,[a] Mauro Carcelli,[a] Mirco Costa,[b] Hans-Werner Frühauf,[c] Kees Goubitz,[d] Corrado Pelizzi,[a] Michele Triclistri,[b] and Kees Vrieze[c]

Keywords: Hydrazones / Insertions / Palladium / Tridentate ligands

The hydrazone ligand 2-(diphenylphosphanyl)benzaldehyde benzoylhydrazone (HPNO) forms the methyl Pd^{II} complex [Pd(HPN)(Me)Cl] (**1**) in high yield when treated with [(COD)Pd(Me)Cl] in dichloromethane or diethyl ether at room temperature. In complex **1**, the ligand remains neutral and is P,N bidentate. The deprotonation of the ligand by Et_3N affords [Pd(PNO)(Me)] (**2**), in which the anionic ligand is P,N,O tridentate. When **1** is treated with $AgCF_3SO_3$, the cationic complex $[Pd(HPNO)(Me)]^+[CF_3SO_3]^-$ (**3**) is formed; here the neutral ligand coordinates in a tridentate P,N,O fashion. All three methyl complexes were subjected to 30 atm of CO pressure, resulting in the isolation of the corresponding acetyl complexes [Pd(HPN)(MeCO)Cl] (**4**), [Pd(PNO)(MeCO)] (**5**) and $[Pd(HPNO)(MeCO)]^+[CF_3SO_3]^-$ (**6**). Complex **4** is completely stable in solution in the absence of CO, whereas **5** and **6** quickly decarbonylate to regenerate the starting methyl complexes **2** and **3**. Complexes **5** and **6** can also be obtained in high yields by treatment of **4** with Et_3N and $AgCF_3SO_3$, respectively. The X-ray crystal structures of the complexes **2**, **5** and **6** were determined.

Introduction

Recently, we have shown that ionisable tridentate hydrazone ligands of the type HNN′O, derived from the condensation of different hydrazides with 2-formyl- or 2-acetylpyridine, can give rise to two different kinds of methylpalladium(II) complexes: namely [Pd(HNN′)(Me)Cl] and [Pd(NN′O)(Me)], respectively.[1] In the first, the neutral ligands display an N,N′ bidentate behaviour, with the oxygen excluded from the coordination sphere, while in the second the anionic ligands bind palladium through all three donor atoms. Under a CO atmosphere, [Pd(HNN′)(Me)Cl] complexes convert quantitatively into the corresponding acetyl complexes [Pd(HNN′)(MeCO)Cl], and the ligands do not vary their coordination mode. Surprisingly, when the [Pd(NN′O)(Me)] complexes are subjected to a CO atmosphere they quickly decompose to Pd black, with isolation of a new organic molecule corresponding to the ligand acylated at the hydrazone nitrogen (Scheme 1).



Scheme 1

With the aim of isolating acetyl palladium(II) complexes in which the metal is three-coordinated to an anionic ligand, we have introduced a P atom, with a higher affinity towards palladium, into the chelating system. The previously synthesised acylhydrazone ligand 2-(diphenylphosphanyl)benzaldehyde benzoylhydrazone (HPNO in Scheme 2),[2] was used in the synthesis of a series of methylpalladium(II) complexes, which were subsequently carbonylated in order to isolate the corresponding acetyl complexes. The HPNO ligand has already shown its versatility: depending on the experimental conditions it can be either

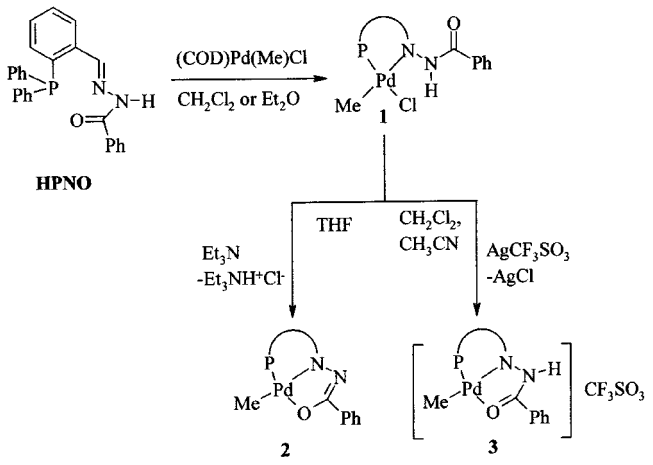
P,N bidentate or P,N,O tridentate when protonated, and P,N,O tridentate when deprotonated.[3]



Scheme 2

We report in this paper on the synthesis and characterisation of a series of methylpalladium(II) complexes possessing HPNO as a ligand, as well as on their reactivity towards CO, with particular regard to the influence that the coordination mode of the ligand exerts on the carbonylation course.

Results and Discussion

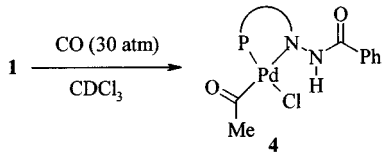
The ligand HPNO reacts at room temperature with [(COD)Pd(Me)Cl], both in dichloromethane and diethyl ether, resulting in the formation of the complex [Pd(HPN)(Me)Cl] (**1**), in which the metal is coordinated by the neutral ligand in a P,N mode (Scheme 2). The large shifts to lower fields both of the signals of the phosphane moiety in the ^{31}P NMR spectrum (from $\delta = -12.5$ to 38.4) and of the HC=N proton in the ^{1}H NMR spectrum (from $\delta = 8.95$ to 9.53), relative to the free ligand, indicate the involvement of both the P and the N atom in the coordination. The exclusion of the oxygen from the coordination sphere is demonstrated by the strong IR stretching band at 1684 cm^{-1}, which is a value typical for an uncoordinated amide C=O group.[1][3a] The neutral character of the ligand is confirmed by a weak IR band at 3206 cm^{-1} and by a singlet at $\delta = 11.19$ in the ^{1}H NMR spectrum recorded in $CDCl_3$. The methyl group bonded to palladium resonates in the ^{1}H NMR spectrum as a doublet at $\delta = 0.73$, with a phosphorous coupling constant of 1.9 Hz; these are typical values for a phosphane and a methyl situated *cis* to one another in a square-planar arrangement around a palladium(II) ion.[4]

The addition of a slight excess of Et_3N to a THF solution of **1** causes the deprotonation of the ligand, affording the complex [Pd(PNO)(Me)] (**2**), in which the ligand is now P,N,O tridentate (Scheme 2). Both ν(N−H) and ν(C=O) are absent in the IR spectrum, while in the ^{31}P NMR spectrum there is a singlet at $\delta = 32.0$; the methyl group bonded to palladium is seen as a doublet centred at $\delta = 0.61$ in the ^{1}H NMR spectrum, with a phosphorous coupling constant equivalent to that found in **1**. The shielding of the signals observed in the NMR spectra of **2**, relative to those in **1**, is attributable to the higher electron density due to the anionic tridentate coordination on the metal. The HC=N proton resonates as a singlet at $\delta = 8.52$, a value very similar to those found for palladium(II) complexes of the type [Pd(PNO)X] (X = OAc, Cl, I, C≡C−R).[2,5] Yellow crystals suitable for X-ray analysis were collected after slow diffusion of *n*-hexane into a dichloromethane solution of **2** at −20 °C; the resulting structure confirmed the proposed nature of **2**.

The addition of a chloride scavenger, such as $AgCF_3SO_3$, to a dichloromethane solution of **1** resulted in the immediate precipitation of AgCl and isolation of the cationic methyl complex $[Pd(HPNO)(Me)]^+[CF_3SO_3]^-$ (**3**), in which the neutral ligand was P,N,O tridentate (Scheme 2). The ^{31}P NMR spectrum shows a singlet at $\delta = 36.2$, while the HC=N proton resonance is found as a singlet at $\delta = 9.36$. The involvement of the C=O in the coordination is proved by the lowering in frequency of the ν(C=O), which is now visible as a strong bifurcated band at 1560−1597 cm^{-1};[3,6] two strong signals always present at 1298 cm^{-1} and 1240 cm^{-1} in the IR spectrum testify to the presence of a triflate anion.[7] The neutral nature of the hydrazone is indicated both in the IR spectrum and in the ^{1}H NMR spectrum, by a weak band at 3189 cm^{-1} and by a broad singlet at $\delta = 13.49$; the strong deshielding of this last signal is due to the three-coordination of the ligand, which makes the hydrazone proton highly acidic. Finally, the methyl ligand gives rise to a doublet at $\delta = 0.87$, with a phosphorous coupling constant of 3 Hz, which is in agreement with the values found for cationic methylpalladium(II) complexes with phosphanyl-imine ligands.[4b]

All the isolated methyl complexes were treated with CO, with the aim of isolating the corresponding acetyl complexes. Complex **1** did not react either at 1 atm or at 10 atm of CO, but when 30 atm of CO were employed it converted completely into the acetyl [Pd(HPN)(MeCO)Cl] (**4**) within 22 h at room temperature (Scheme 3). The reaction was monitored by ^{1}H and ^{31}P NMR spectroscopy, in a single-crystal sapphire high pressure NMR tube. During the carbonylation the disappearance of the singlet of **1** and the simultaneous appearance of a new singlet at $\delta = 20.2$ was observed in the ^{31}P NMR spectrum, while in the ^{1}H NMR spectrum the doublet at $\delta = 0.73$ of **1** progressively disappeared in favour of a singlet at $\delta = 2.06$. These findings agreed with the formation of an acetylpalladium(II) complex,[4] but unfortunately it was not possible to detect any intermediate species. The IR spectrum of **4** in KBr showed a strong ν(C=O) vibration at 1696 cm^{-1}, which indicates the P,N bidentate coordination mode of the ligand; this band was distinguishable from the one due to the ν(MeCO), which was a sharp band at 1665 cm^{-1}. The ν(N−H) vibration was also visible as a weak band at 3204 cm^{-1}. Complex **4** was stable in $CDCl_3$ at room temperature, as demonstrated by the fact that no changes were observed in the ^{1}H

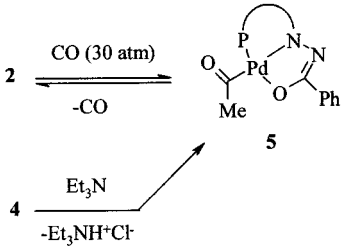
NMR spectrum over 24 h. Slow diffusion of diethyl ether into a $CDCl_3$ solution of **4** refrigerated at −20 °C provided pale yellow crystals suitable for X-ray analysis. Although it was not possible to complete the refinement of the structure, owing to the presence of a disordered solvent molecule, the diffractometric analysis did confirm the proposed structure, with the acetyl group *cis* to the phosphane.



Scheme 3

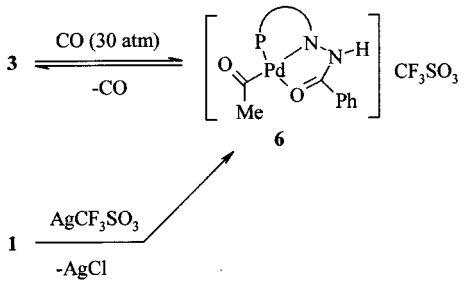
On the basis of these results, all subsequent carbonylations were carried out at a CO pressure of 30 atm.

The carbonylation of **2** was carried out in a steel autoclave at 25 °C for 24 h, with dichloromethane or THF as solvent. After CO release and removal of the solvent, the ^1H NMR spectrum of the residue, recorded in $CDCl_3$, still showed the doublet due to the starting methyl complex **2** at $\delta = 0.61$, together with a new singlet at $\delta = 2.30$, indicative of the formation of the acetyl complex [Pd(PNO)(MeCO)] (**5**) (Scheme 4); the integrals of the two NMR lines were in a 1:2 ratio. However, when the solution was allowed to stand in the absence of CO, the singlet rapidly disappeared in favour of the more shielded doublet, and after a few hours only the signals belonging to **2** were present in the spectrum: in the absence of CO the rapid decarbonylation of **5** took place, without release of palladium black (Scheme 4). The same behaviour was observed in the ^{31}P NMR spectrum recorded in $CDCl_3$, in which there were two different singlets centred at $\delta = 25.0$ (**5**) and $\delta = 32.0$ (**2**). In the IR spectrum of the solid mixture, the ν(MeCO) of **5** was clearly visible at 1675 cm^{-1}; this did not vanish with time, showing that the decarbonylation occurs only in solution.



Scheme 4

The carbonylation of **3** was carried out in a steel autoclave for 24 h at 25 °C, with dichloromethane as solvent. The ^1H NMR spectrum of the residue in $CDCl_3$ again showed the doublet of the starting methyl at $\delta = 0.87$, but in addition there was a singlet centred at $\delta = 2.35$. The two lines were in a 4:1 ratio, indicating that only 20% of **3** had been converted into $[Pd(HPNO)(MeCO)]^+(CF_3SO_3)^-$ (**6** in Scheme 5). As already seen for **5**, but in an even faster process, complex **6** in solution lost CO to regenerate **3**; the decarbonylation process also took place in solution at −18 °C. The rapidity of the decarbonylation prevented the recording of the ^{31}P NMR spectra of **6**. The IR spectrum of the mixture showed a ν(MeCO) band at 1700 cm^{-1} and, as with **5**, decarbonylation in the solid state also did not take place in this case.



Scheme 5

With the aim of obtaining pure **5** and **6**, solutions of **4** in THF and in CH_2Cl_2 were treated with a slight excess of Et_3N and with a stoichiometric amount of $AgCF_3SO_3$, respectively (Schemes 4 and 5). In both cases, in order to prevent decarbonylation, the products were quickly precipitated with a large excess of diethyl ether. In this way **5** and **6** were obtained in good yields and purities. In solution, however, they rapidly lost CO, as already found during the NMR examination, but it was possible in both cases to collect crystals suitable for X-ray analysis from refrigerated THF/*n*-hexane mixtures, thus confirming the proposed structures.

The need to use high CO pressures for the conversion of the methyl complexes into the corresponding acetyl ones is not surprising with phosphane-containing ligands.[4a] Moreover, the decarbonylation undergone by **5** and **6** is a common process for three-coordinate acetylpalladium(II) complexes.[4b,8] However, is worth noting that the carbonylation of the three-coordinate methyl complex **2** did not result in the formation of palladium black and acylation of the ligand, contrary to what was seen with the related [Pd(NN′O)(Me)] complexes (Scheme 1).

The lack of acetyl transfer from palladium to the ligand in this system may be attributable to the presence of the soft phosphorus donor atom in the chelating ligand. The phosphorus coordinates more strongly than nitrogen, thus meaning that breaking of the Pd−P bond is now unlikely, and therefore our previous hypothesis[1] of a unidentate intermediate in the acylation of the N,N′,O ligands is corroborated.

Crystallographic Section

Complexes **2** and **5** are neutral, while complex **6** is cationic and was isolated as a triflate salt. Compound **5** crystallised with two independent, but not significantly different, molecules in the unit cell. The crystal structures and numbering schemes of compounds **2**, **5** (molecule A) and **6** are shown in Figure 1−3 respectively; selections of relevant

bond lengths and angles are given in Table 1, Table 2 and Table 3. The ligand behaves in all cases as a tridentate P,N,O donor, and the square planar geometry around palladium is completed by a methyl group in **2** and by an acetyl group in **5** and **6**. Two chelating rings are formed by coordination of the metal: the five-membered N−N−C−O−Pd ring is always strictly planar, while the six-membered N−C−C−C−P−Pd ring shows an envelope conformation with the phosphorus at the flap, a feature common in similar systems.[2,3,5] The distances between P and the mean plane containing the remaining five atoms varies from 0.38 Å in **2** to 0.52 Å in **6**. As commonly observed for analogous compounds,[1] the acyl groups in **5** and **6** are nearly perpendicular to the coordination planes, as indicated by the torsion angles: O1−Pd1−C27−O2 = 90(1)°, O3−Pd2−C55−O4 = 88(1)° (**5**, molecules A and B respectively) and O1−Pd−C27−O2 = −114.0(5)° (**6**). Minor differences due to subtle electronic effects are observed between some distances in the coordination systems among the three compounds: an apparent slight elongation of the Pd−N bond is observed on passing from the *trans* methyl [**2**, 2.058(1) Å] to the *trans* acyl group [**5**, 2.093(9) and 2.089(9) Å for molecules A and B] for the deprotonated form of the PNO ligand. These distances are longer than those observed in complexes with the same or a strictly related hydrazone ligand and containing as groups *trans* to N a chloride [2.001(2) Å],[3a] a *t*Bu-alkynyl [2.028(7) Å],[3a] an iodide [1.99(1), 2.03(1) Å],[5a] an acetate [1.974(4) Å][5b] or a phenylalkynyl [2.010(3) Å] moiety.[2] The major differences between the anionic (**2** and **5**) and the neutral forms (**6**) of the PNO ligand are confined mainly to the carbonyl bond of the N−C=O system. For the deprotonated ligand we observe a shift towards the enol form, as already shown by semiempirical calculations and crystal structures of the chloride and *t*Bu-alkynyl palladium complexes of the ligand.[3a] The contribution of the enol form causes the C−O bond length to be slightly longer in **2** and **5** [1.294(2) Å, **2**, 1.28(1) Å, **5**, both molecules] than in **6** [C−O = 1.246(6)

Å]; accordingly, the N−C(O) bond is shorter in the anionic form [1.319(2), 1.33(1), 1.33(2) Å for **2** and **5**, molecules A and B] than in the neutral one [1.337(7) Å for **6**]. Previous calculations[3a] have shown that the anionic charge is largely localized on the oxygen. The Pd−O bond is correspondingly stronger when the ligand has anionic character [2.103(1), 2.100(8), 2.070(8) Å in **2** and **5**] than in the neutral form [2.125(3) Å for **6**].

As observed in the similar compounds above, the terminal phenyl ring C9−C14 apparently has a certain degree of rotational freedom [N2−C8−C9−C10 ranging from −17.8(2) to 25.6(2)°] around the C8−C9 bond that, in all cases, does not appear to be involved in any double bond character delocalization with the hydrazone system [C8−C9 ranging from 1.47(2) to 1.492(2) Å].

The most relevant feature of the crystal packing of the three compounds is given by the charge-assisted hydrogen bond between the cationic complex and the triflate in **6**: N2−H···O5 (N2···O5 = 2.826Å; N2−H−O5 = 121.3°).

Conclusion

The tridentate P,N,O hydrazone ligand HPNO can form three different kinds of methylpalladium(II) complexes, in which it adopts different coordination modes: *i*) neutral P,N (**1**), *ii*) anionic P,N,O (**2**), and *iii*) neutral P,N,O (**3**). The isolation of one or the other depends on the experimental conditions. The methyl complexes **1**, **2** and **3** convert into the corresponding acetyl complexes **4**, **5** and **6** when subjected to high CO pressures; the carbonylations do not af-

fect the coordination modes of the ligand. The stability of the acetyl species in solution towards the loss of CO depends on the chelating behaviour of the ligand: only **4** is completely stable, whereas the three-coordinate acetyl derivatives **5** and **6** quickly decarbonylate to regenerate the starting methyl complexes. In contrast to the carbonylations with HNN′O ligands, no acetylation of HPNO was observed during the carbonylation of **2**. Pure **5** and **6** can be obtained by treating **4** with Et_3N and with $AgCF_3SO_3$, respectively.

Experimental Section

General Remarks: All reactions were performed under an atmosphere of nitrogen, by employing standard Schlenk techniques. Solvents were dried prior to use and stored under nitrogen. Elemental analysis (C, H, N and S) were performed with a Carlo Erba Mod. EA 1108 apparatus. Infrared spectra were recorded with a Nicolet 5PCFT-IR spectrophotometer in the 4000−400 cm^{-1} range as KBr disks. ^1H NMR spectra were obtained on a Bruker 300 FT instrument with $SiMe_4$ as internal standard, while $^{31}P\{^1H\}$NMR spectra were recorded on a Bruker CPX 200 FT with H_3PO_4 (85%) as external standard. MS spectra (C.I., methane) were recorded on a Finnigan SSQ 710 spectrometer. 2-(Diphenylphosphanyl)benzaldehyde benzoylhydrazone (HPNO) was synthesised as previously reported.[2] [(COD)Pd(Me)Cl] was prepared according to the literature,[8] while $AgCF_3SO_3$ was purchased from Aldrich.

[Pd(HPN)(Me)Cl] (1). Method a: HPNO (180 mg, 0.441 mmol) was dissolved in CH_2Cl_2 (30 mL), and [(COD)Pd(Me)Cl] (117 mg, 0.453 mmol) was added. The resulting yellow solution was stirred at room temperature for two hours and was then concentrated to a volume of about 5 ml; on addition of 40 mL of diethyl ether a yellow solid precipitated and was filtered off, washed with diethyl ether and dried in vacuum. Yield: 220 mg (88%).

Method b: [(COD)Pd(Me)Cl] (130 mg, 0.490 mmol) was suspended in diethyl ether (20 mL) and HPNO (200 mg, 0.490 mmol) was added; a yellow solid immediately precipitated. The mixture was stirred at room temperature for 2 hours and the solid was then removed by filtration, washed with diethyl ether and dried in vacuum. Yield: 263 mg (95%). $C_{27}H_{24}ClN_2OPPd$ (565.3): calcd. C 57.36, H 4.28, N 4.96; found C 56.98, H 4.22, N 4.84. ^1H NMR ($CDCl_3$): δ = 0.73 (d, $^3J_{P-H}$ = 1.9 Hz, 3 H, Pd-Me), 7.40−7.60 (m, 17 H, Ph), 8.25 [d, ^3J = 8.2 Hz, 2 H, Ph(C=O)], 9.53 (s, 1 H, CH=N), 11.19 (s, 1 H, N−H). ^{31}P NMR ($CDCl_3$): δ = 38.4 (s). IR (KBr): ṽ = 3206 w (N−H), 1684 s cm^{-1}(C=O). MS-CI: *m*/*z* = 527 $[M - HCl]^+$.

[Pd(PNO)(Me)] (2). Method a: HPNO (108 mg, 0.264 mmol) was dissolved in THF (20 mL) and Et_3N (40 mg, 0.395 mmol, 0.06 mL) was added. [(COD)Pd(Me)Cl] (70 mg, 0.264 mmol) was added to the pale yellow solution, whereupon triethylamine hydrochloride precipitated; after 3 hours of stirring at room temperature the mixture was filtered to afford a yellow solution, which was concentrated under vacuum to a volume of about 5 mL. Addition of 30 mL of diethyl ether and refrigeration at −20 °C overnight caused the precipitation of a yellow solid, which was filtered off, washed with diethyl ether and dried in vacuum. Yield: 67 mg (48%).

Method b: Compound **1** (70 mg, 0.124 mmol) was dissolved in THF (20 mL), and Et_3N (19 mg, 0.188 mmol, 0.03 mL) was added; the mixture was stirred at room temperature for 3 hours and then filtered, and the resulting yellow solution was worked up as reported in method *a*. Yield: 53 mg (82%). Crystals suitable for X-ray analysis were collected from a CH_2Cl_2/*n*-hexane mixture refrigerated at −20 °C. $C_{27}H_{23}N_2OPPd$ (528.9): calcd. C 61.32, H 4.38, N 5.30; found C 61.17, H 4.32, N 5.42. ^1H NMR ($CDCl_3$): δ = 0.61 (d, $^3J_{P-H}$ = 1.9 Hz, 3 H, Pd-Me), 7.39−7.60 (m, 17 H, Ph), 8.22 [dd, ^3J = 7.6, ^4J = 1.5 Hz, 2 H, Ph(C=O)], 8.52 (s, 1 H, CH=N). ^{31}P NMR ($CDCl_3$): δ = 32.0 (s). MS-CI: *m*/*z* = 528 $[M]^+$.

[Pd(HPNO)(Me)]$^+$[CF_3SO_3]$^-$ (3): Compound **1** (100 mg, 0.177 mmol) was placed in a Schlenk tube and dissolved in CH_2Cl_2 (15 mL). $AgCF_3SO_3$ (45 mg, 0.177 mmol) dissolved in CH_3CN (2 mL) was added, resulting in the immediate precipitation of AgCl. The resulting mixture was stirred at room temperature for 2 h, filtered and concentrated under vacuum; addition of Et_2O and refrigeration at −18 °C overnight afforded **3** as a microcrystalline yellow solid. Yield: 86 mg (72%). $C_{28}H_{24}F_3N_2O_4PPdS$ (678.9): calcd. C 49.53, H 3.56, N 4.13, S 4.72; found C 49.53, H 3.35, N 4.06, S 4.71. ^1H NMR ($CDCl_3$): δ = 0.87 (d, $^3J_{P-H}$ = 3 Hz, 3 H, Pd-Me), 7.40−8.03 (m, 17 H, Ph), 8.23 [d, ^3J = 7.9 Hz, 2 H, Ph(C=O)], 9.36 (s, 1 H, CH=N), 13.49 (s, 1 H, N−H). ^{31}P NMR ($CDCl_3$): δ = 36.2 (s). IR (KBr): ṽ = 3189 w (N−H), 1597 s − 1560 s (C=N + C=O), 1298 s − 1240 s cm^{-1} (S=O).

Synthesis of the Acetyl Complexes

Carbonylation Reactions: The carbonylation of complex **1** was carried out as described below. **Method a:** A magnetic stirring bar was placed in a 150 mL capacity steel autoclave, together with the complex (30 mg) dissolved in chloroform or dichloromethane (20 mL). The reactor was purged twice with CO and then pressurized to 30 atm. The mixture was stirred overnight at 25 °C, CO was then released, and the solution was filtered through celite in order to remove the traces of palladium black sometimes formed. The resulting yellow solution was treated with diethyl ether until precipitation of [Pd(HPN)(MeCO)Cl] (**4**). This was filtered and washed with diethyl ether. Yield: 37 mg (99%).

The same procedure applied to complexes **2** and **3** did not permit the isolation of pure acetyl complexes because of the decarbonylation that took place when the CO pressure was released.

Method b (Only for Complex 1): Complex **1** (20 mg, 0.035 mmol) was placed in a 5 mm o.d. single-crystal sapphire high-pressure NMR tube and dissolved in about 1 mL of deuterated chloroform. The tube was purged twice with CO and then pressurized at 30 atm. The reaction was followed by ^1H and ^{31}P NMR spectroscopy at 20 °C until the complete disappearance of the starting signals (20 h). The final solution was worked up as reported above.

SAFETY NOTE: Since high gas pressures are involved, safety precautions must be taken at all stages involving HP NMR tubes.[9]

[Pd(HPN)(MeCO)Cl] (4): $C_{28}H_{24}ClN_2O_2PPd{\cdot}CDCl_3$ (713.7): calcd. C 48.80, H 3.53, N 3.93; found C 49.00, H 3.71, N 3.90. ^1H NMR ($CDCl_3$): δ = 2.06 (s, 3 H, MeCO), 7.30−7.59 (m, 17 H, Ph), 8.02 [d, ^3J = 6.9 Hz, 2 H, Ph(C=O)], 9.63 (s, 1 H, CH=N), 11.84 (s, 1 H, N−H). ^{31}P NMR ($CDCl_3$): δ = 20.2 (s). IR (KBr): ṽ = 3204 w (N−H), 1696 s (C=O), 1665 s cm^{-1} (MeCO). Crystals suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into the deuterated chloroform solution of **4** at −20 °C.

[Pd(PNO)(COMe)] (5): Compound **4** (30 mg, 0.051 mmol) was dissolved in THF (20 mL) and treated with Et_3N (8 mg, 0.01 mL, 0.081 mmol). The mixture was stirred at room temperature for 2 h and then filtered; the resulting yellow solution was concentrated in

vacuum and **5** was precipitated with diethyl ether, filtered and dried in vacuum. Crystals suitable for X-ray analysis were obtained from a THF/*n*-hexane mixture, refrigerated to −18 °C. $C_{28}H_{23}N_2O_2PPd$ (556.9): calcd. C 60.39, H 4.16, N 5.03; found C 60.52, H 4.24, N 5.11. ^{1}H NMR ($CDCl_3$): δ = 2.30 (s, 3 H, MeCO), 8.18 [br. d, 2 H, Ph(C=O)], 8.51 (br, 1 H, CH=N). The other data are obscured by the signals of **2**. ^{31}P NMR ($CDCl_3$): δ = 25.0 (s). IR (KBr): $\tilde{\nu}$ = 1675 m cm^{-1} (MeCO).

[Pd(HPNO)(MeCO)]$^+$[CF_3SO_3]$^-$ (6): Compound **4** (30 mg, 0.044 mmol) was dissolved in CH_2Cl_2 (20 mL), and $AgCF_3SO_3$ (11.4 mg, 0.044 mmol) dissolved in acetonitrile (1 mL) was added. The mixture was stirred at room temperature for 2 h and then filtered, giving a yellow solution that was concentrated under reduced pressure. The product was precipitated by addition of diethyl ether, filtered and dried in vacuum. Crystals suitable for X-ray analysis were collected from a THF/*n*-hexane mixture refrigerated at −18 °C. $C_{29}H_{24}F_3N_2O_5PPdS$ (706.9): calcd. C 49.27, H 3.42, N 3.96, S 4.53; found C 49.38, H 3.38, N 4.02, S 4.30. ^{1}H NMR ($CDCl_3$): δ = 2.35 (s, 3 H, MeCO), 8.20 [br. d, 2 H, Ph(C=O)]. The other data were obscured by signals of **3**. IR (KBr): $\tilde{\nu}$ = 3183 w (N−H), 1700 s (MeCO), 1602 s (C=N), 1559 vs (C=O), 1296 vs − 1224 vs cm^{-1} (S=O).

X-ray Data Collection, Structure Determination and Refinement of Compounds 2, 5 and 6

Air-stable crystals suitable for structural determination by single-crystal X-ray diffraction were obtained for compounds **2**, **5** and **6**. Relevant details about X-ray experimental conditions, data collection and refinement are given in Table 4. Data for compounds **5** and **6** were collected on Siemens AED diffractometers, while for compound **2** a Philips PW1100 diffractometer was used and the ψ-scan empirical absorption correction was applied. For compounds **2** and **6**, graphite monochromated Mo-K_α radiation was used (λ = 0.71069Å). For the thick crystals of **5**, graphite monochromated Cu-K_α radiation (λ = 1.54184 Å) was chosen for data collection.

Data were corrected for Lorentz and polarisation effects. Crystal decay was observed for **5** and data were rescaled accordingly. The phase problem for all the compounds was solved by direct methods with SIR97.[10] Data refinement was performed by full-matrix, least-squares on $F2$ with SHELXL-97.[11] For compounds **5** and **6**, the Walker and Stewart[12] absorption correction was applied after the last isotropic refinement cycle. In all cases non-hydrogen atoms were refined anisotropically. While in compound **2** all hydrogen atoms were located in the Fourier maps and refined isotropically; in compound **6** some of them were placed in calculated positions. For compound **5**, all hydrogens were placed in calculated positions and constrained to ride on their carrying atoms. The geometry of the structures was inspected and analysed by PARST-97[13] and ORTEP-3[14] and compared with literature data with the aid of the Cambridge Structural Database software.[15]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-155797 (**2**), -155798 (**5**) and -155799 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]

A Zinc(II) Complex Composed of a Tridentate Ligand Bearing Podand Pyrenyl Moieties

Toshiyuki Moriuchi,[a] Masahito Nishiyama,[a] and Toshikazu Hirao*[a]

Keywords: Coordination modes / N ligands / Crystal engineering / Zinc / Receptors

The structural characterization and function of Zn^{II} complexes composed of a tridentate ligand bearing podand pyrenyl moieties as a fluorophore [2,6-pyridinedicarboxaldehydebis(1-pyrenylmethylimine) (L^1)] are described. The tridentate podand ligand L^1 forms a 2:1 complex, $[Zn(L^1)_2(BF_4)_2]$, with $Zn(BF_4)_2$ although the 1:1 complex $[Zn(L^1)(OAc)_2]$ is obtained with $Zn(OAc)_2$. The X-ray crystal structure determination of $[Zn(L^1)_2(BF_4)_2]$ reveals that two tridentate podand ligands L^1 coordinate meridionally to Zn^{II} ion to give an orthogonally oriented molecular turn around the approximately octahedral Zn^{II} center. One pyridyl moiety of L^1 is sandwiched in between two podand pyrenyl moieties of another L^1 through π-π interactions, together with an extended π-stacking through π-π interactions between the pyrenyl moieties in the crystal packing. $[Zn(L^1)(OAc)_2]$ serves as a fluorophore metalloreceptor possessing a two-guest binding ability. $[Zn(L^1)(OAc)_2]$ affords the 1:2 complex $[Zn(L^1)(G^1)_2]$ (G = guest molecule) with 4-nitrobenzoate ion (G^1). The X-ray crystal structure of $[Zn(L^1)(G^1)_2]$ confirms that $Zn(L^1)^{2+}$ accommodates two 4-nitrobenzoate moieties and that the coordination geometry around Zn^{II} is a distorted square pyramid. Two independent molecules are present in the asymmetric unit to form the π-stacked dimer by face-to-face overlap. Fluorescence quenching of $[Zn(L^1)(G^1)_2]$ is observed by intramolecular electron transfer from the pyrenyl moieties to the Zn^{II}-bound 4-nitrobenzoates.

Introduction

The organization of host molecules by complexation with metal ions has attracted much attention.[1] Metalloreceptors, which possess metal binding sites and additional interaction sites of ligands, have been regarded as useful organized host molecules.[2] Such metalloreceptors can undergo the desired conformational change for binding of guest molecules. The utilization of the allosteric effect is also a convenient approach to organize component molecules.[3]

A change in the fluorescent properties is generally considered to be a signal that a guest binding process has occurred.[4] The pyrene unit is one of the most commonly used fluorophores due to its strong luminescence and chemical stability.[5] Another interesting feature of the pyrene unit is the π-π interaction between pyrene aromatic rings in the crystal packing, which can permit the formation of highly ordered molecular aggregates in the solid state by architecturally controlled self-assembly.[6]

The complexation of a tridentate ligand with a Zn^{II} ion is expected to provide two labile coordination sites. Another advantage in the use of Zn^{II} as a binding site is its photophysical innocuousness and its Lewis acidity towards binding anions.[7] Flexible podand ligands allow metal complexes to possess a varied geometry at the metal center due to their different modes of coordination.[8] On this basis, the introduction of pyrene units, which serve as a fluorophore and provide an additional site for π-π interaction, into the podand moieties of a tridentate ligand should provide an efficient Zn^{II} metalloreceptor possessing a two-guest binding ability through first- and second-sphere coordination. In this context, we describe herein the structural characterization and fluorescence properties of Zn^{II} complexes composed of a tridentate ligand bearing podand pyrenyl moieties.

Results and Discussion

The tridentate podand ligand, 2,6-pyridinedicarboxaldehydebis(1-pyrenemethylimine) (L^1), which was obtained by Schiff base condensation of 2,6-pyridinedicarboxaldehyde with 1-pyrenemethylamine in methanol, was used to serve as a tridentate ligand bearing podand pyrenyl moieties as the fluorophore and additional interaction sites. Treatment of the tridentate podand ligand L^1 with $Zn(BF_4)_2$ led to the formation of the 2:1 complex $[Zn(L^1)_2(BF_4)_2]$ (Scheme 1), although the 1:1 complex $[Zn(L^1)(OAc)_2]$ was produced with $Zn(OAc)_2$.

The structure of the 2:1 complex $[Zn(L^1)_2(BF_4)_2]$ was confirmed by X-ray crystallography (Table 1). The crystal structure of $[Zn(L^1)_2(BF_4)_2]$ revealed that two tridentate podand ligands L^1 coordinate meridionally to Zn^{II} ion to give an orthogonally oriented molecular turn around an approximately octahedral Zn^{II} center (Figure 1). Selected bond lengths and bond angles are listed in Table 2. Six of their

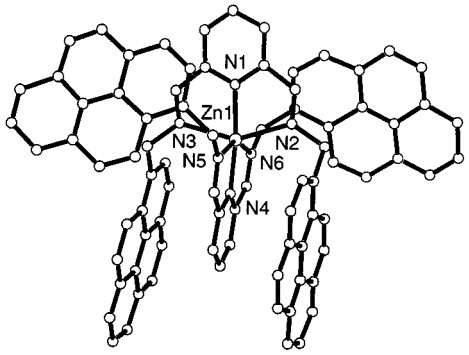

Figure 1. Molecular structure of $[Zn(L^1)_2(BF_4)_2]$ (hydrogen atoms and tetrafluoroborate ligands are omitted for clarity)

coordination sites are occupied by nitrogen donors of two pyridinedicarboxaldehydebisimine chelates. The N−Zn−N angles deviate from 90°, probably due to the formation of the five-membered chelate rings with extended conjugation. The most noteworthy structural feature is that one pyridyl moiety of L^1 is sandwiched between two podand pyrenyl moieties of another L^1 in a π-π interaction within which the distance between the pyridyl and pyrenyl moieties is ca. 3.5 Å. Furthermore, $[Zn(L^1)_2(BF_4)_2]$ shows extended π-stacking along a single axis in the crystal; the pyrenyl moieties are closely associated with the pyrenyl moieties of the neighboring molecules with ca. 3.5 Å separation and the remaining pyrenyl moieties surround the extended π-stacking through edge-to-face interaction with ca. 3.8 Å separation.

The coordinatively labile Zn^{II} center in $[Zn(L^1)(OAc)_2]$ bearing the tridentate podand ligand L^1 is able to provide two binding sites for two anions as guest molecules. The ancillary acetates were displaced by treatment of $[Zn(L^1)(OAc)_2]$ with the 4-nitrobenzoate ion (G^1), giving the 1:2 complex $[Zn(L^1)(G^1)_2]$ quantitatively. The 1:2 complex $[Zn(L^1)(G^2)_2]$ was obtained in a similar manner with the 3,5-dinitrobenzoate ion (G^2). The crystal structure of $[Zn(L^1)(G^1)_2]$ confirmed that $Zn(L^1)^{2+}$ accommodates two 4-nitrobenzoate ions and that two independent molecules are present in the asymmetric unit with almost the same conformation, as depicted in Figure 2. The structural parameter $\tau = (\beta - \alpha)/60$ for the coordination geometry of the five-coordinated complex proposed by Addison and Reedijik shows $\tau = 0.39$ and 0.33 for $[Zn(L^1)(G^1)_2]$, where α and β represent two basal angles ($\beta > \alpha$).[9] The parameters for an ideal square pyramidal and trigonal bipyramidal geometries are $\tau = 0$ ($\alpha = \beta = 180°$) and $\tau = 1$ ($\alpha = 120°$ and $\beta = 180°$), respectively. The τ values of $[Zn(L^1)(G^1)_2]$ indicate that the coordination geometry around Zn^{II} is a distorted square pyramid. Two imine nitrogens and two oxygens of the 4-nitrobenzoate moieties reside in the basal plane while one pyridyl nitrogen occupies the axial position. It is notable that two independent molecules overlap in a face-to-face manner to form a π-stacked dimer in which two 4-nitrobenzoate moieties lie in almost parallel planes and one pyrenyl moiety is sandwiched in-between. Furthermore, these π-stacked dimers are connected through

[a] Two independent molecules exist in the asymmetric unit.

a π-π interaction with ca. 3.4 Å separation between the remaining pyrenyl moieties in the crystal.

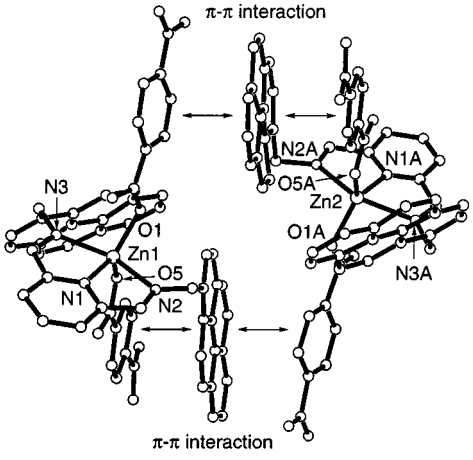

Figure 2. Molecular structure of $[Zn(L^1)(G^1)_2]$ (hydrogen atoms are omitted for clarity)

In the fluorescence spectra, the tridentate podand ligand L^1 shows both monomer and excimer emissions, as shown in Figure 3. $[Zn(L^1)(OAc)_2]$, on the other hand, only exhibits the monomer emission, due to a conformational change induced by complexation. Interestingly, fluorescence quenching was observed with $[Zn(L^1)(G^1)_2]$ by intramolecular electron transfer from the pyrenyl moieties to the Zn^{II}-bound 4-nitrobenzoates (Figure 4).[10] For the intramolecular electron-transfer process, the pyrenyl moieties and 4-nitrobenzoates should be close enough to each other for overlap of the orbitals. Both podand pyrenyl moieties are considered to interact with each Zn^{II}-bound 4-nitrobenzoate through π-π interactions by virtue of the flexibility of the podand pyrenylmethyl moieties in this system. The binding of two 3,5-dinitrobenzoates also resulted in fluorescence quenching in $[Zn(L^1)(G^2)_2]$.

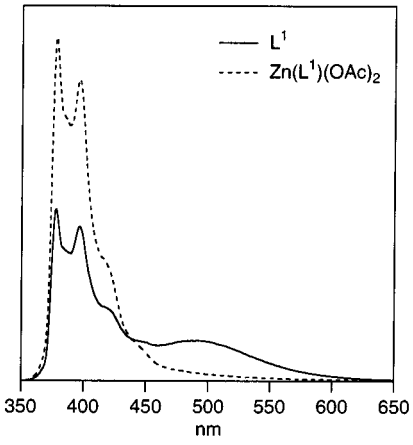

Figure 3. Fluorescence spectra of L^1 and $[Zn(L^1)(OAc)_2]$ in dichloromethane (1.0×10^{-5} M, $\lambda_{ex} = 344$ nm)

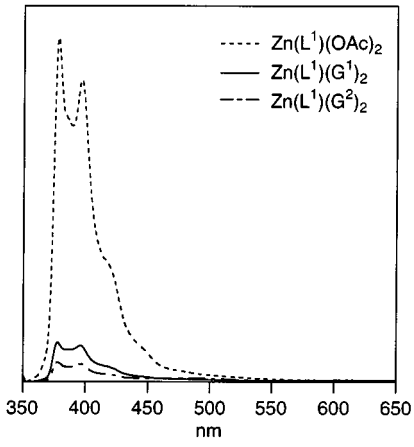

Figure 4. Fluorescence spectra of $[Zn(L^1)(OAc)_2]$, $[Zn(L^1)(G^1)_2]$, and $[Zn(L^1)(G^2)_2]$ in dichloromethane (1.0×10^{-5} M, $\lambda_{ex} = 344$ nm)

Conclusion

The synthesis, structural characterization, and fluorescence properties of Zn^{II} complexes composed of a tridentate ligand bearing podand pyrenyl moieties have been described. The tridentate podand ligand L^1 forms the 2:1 complex $[Zn(L^1)_2(BF_4)_2]$ with $Zn(BF_4)_2$ and the 1:1 complex $[Zn(L^1)(OAc)_2]$ with $Zn(OAc)_2$. The aggregation of py-

renyl moieties through π-π interaction resulted in extended π-stacking, which permits architecturally controlled self-assembly in the solid state.

The coordinatively labile Zn^{II} center in $[Zn(L^1)(OAc)_2]$ provided a metalloreceptor possessing a two-guest binding ability. Fluorescence quenching by intramolecular electron transfer from the pyrenyl moieties to the guest molecules within $[Zn(L^1)(G)_2]$ was attained due to the flexibility of the podand moieties. Investigations on the scope of the allosteric metalloreceptor are currently in progress.

Experimental Section

General Methods: All reagents and solvents were purchased from commercial sources and were further purified by standard methods if necessary. Melting points were determined on a Yanagimoto Micromelting Point Apparatus and are uncorrected. Infrared spectra were obtained with a Perkin−Elmer Model 1605 FT-IR. ^{1}H NMR spectra were recorded on a Varian Mercury 300 (300 MHz) spectrometer with tetramethylsilane as an internal standard. Mass spectra were run on a JEOL JMS-DX303HF mass spectrometer. Electronic spectra were obtained using a Shimazu MultiSpec-1500 photodiode array spectrophotometer. Fluorescence emission spectra were recorded using a Shimazu RF-5300PC spectrofluorophotometer and were not corrected for instrument response. Fluorescence emission measurements were carried out in degassed solvents at 25 °C.

Synthesis of 2,6-Pyridinedicarboxaldehydebis(1-pyrenemethylimine) (L^1): A mixture of 2,6-pyridinedicarboxaldehyde (0.27 g, 2.0 mmol), 1-pyrenemethylamine hydrochloride (1.07 g, 4.0 mmol), and triethylamine (1.4 mL, 10 mmol) in methanol (80 mL) was stirred under argon at room temperature for 3 h. The precipitate was collected by vacuum filtration and rinsed with methanol. The tridentate podand ligand L^1 was isolated in 96% yield by recrystallization from dichloromethane/ether. M.p. 196−198 °C (uncorrected). IR (KBr): $\tilde{\nu}$ = 1635, 1585 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 5.61 (d, J = 1.5 Hz, 4 H), 7.75 (t, J = 7.8 Hz, 1 H), 8.20−7.99 (m, 18 H), 8.37 (d, J = 9.0 Hz, 2 H), 8.51 (t, J = 1.5 Hz, 2 H). $C_{41}H_{27}N_3 \cdot 0.5H_2O$ (570.7): calcd. C 86.29, H 4.95, N 7.36; found C 86.65, H 4.86, N 7.31.

Preparation of $[Zn(L^1)_2(BF_4)_2]$: A mixture of L^1 (112 mg, 0.20 mmol) and $Zn(BF_4)_2$ (24 mg, 0.10 mmol) in acetonitrile (10 mL) was stirred under argon at room temperature for 3 h. After evaporation of the solution, $Zn(L^1)_2(BF_4)_2$ was isolated in 84% yield by recrystallization from acetonitrile/methanol. M.p. 246−247 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 1644, 1587 cm^{-1}. ^{1}H NMR (300 MHz, CD_3CN): δ = 4.88 (d, J = 1.5 Hz, 8 H), 6.09−5.99 (m, 6 H), 7.37 (d, J = 8.1 Hz, 4 H), 7.70 (t, J = 1.5 Hz, 4 H), 8.29−7.75 (m, 32 H). $C_{82}H_{54}B_2F_8N_6Zn \cdot 2CH_3OH$ (1426.5): calcd. C 70.73, H 4.38, N 5.89; found C 70.53, H 4.11, N 6.12.

Preparation of $[Zn(L^1)(OAc)_2]$: A mixture of L^1 (169 mg, 0.30 mmol) and $Zn(OAc)_2$ (55 mg, 0.30 mmol) in dichloromethane (20 mL) was stirred under argon at room temperature for 3 h. Most of the dichloromethane solvent was evaporated, and $[Zn(L^1)(OAc)_2]$ was precipitated with ether. The precipitate was collected by vacuum filtration and dried to give $[Zn(L^1)(OAc)_2]$ in 98% yield. M.p. 173−174 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 1614, 1592 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.17 (s, 6 H), 5.96 (d, J = 1.5 Hz, 4 H), 7.31 (d, J = 7.8 Hz, 2 H), 7.77 (t, J = 1.5 Hz, 2 H), 7.85 (t, J = 7.8 Hz, 1 H), 8.26−8.01 (m, 18 H). $C_{45}H_{33}N_3O_4Zn \cdot H_2O$ (763.2): calcd. C 70.82, H 4.62, N 5.51; found C 70.79, H 4.69, N 5.47.

Preparation of $[Zn(L^1)(G^1)_2]$: A mixture of $[Zn(L^1)(OAc)_2]$ (75 mg, 0.10 mmol) and potassium 4-nitrobenzoate (40 mg, 0.20 mmol) in methanol (15 mL) was stirred under argon at room temperature for 3 h, resulting in a yellow precipitate. The precipitate was collected by vacuum filtration and dried to give a quantitative yield of $[Zn(L^1)(G^1)_2]$. M.p. 237−238 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 1632, 1590 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 5.73 (d, J = 1.5 Hz, 4 H), 8.16−7.66 (m, 29 H), 8.30 (br. t, 2 H). $C_{55}H_{35}N_5O_8Zn$ (959.3): calcd. C 68.86, H 3.68, N 7.30; found C 68.51, H 3.89, N 7.24.

Preparation of $[Zn(L^1)(G^2)_2]$: A mixture of $[Zn(L^1)(OAc)_2]$ (75 mg, 0.10 mmol) and potassium 3,5-dinitrobenzoate (47 mg, 0.20 mmol) in methanol (15 mL) was stirred under argon at room temperature for 3 h, resulting in a yellow precipitate. The precipitate was collected by vacuum filtration and dried to give a quantitative yield of $[Zn(L^1)(G^2)_2]$. M.p. 256−257 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 1626, 1591 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 5.55 (d, J = 1.5 Hz, 4 H), 8.17−7.76 (m, 24 H), 8.36 (t, J = 2.1 Hz, 2 H), 8.38 (t, J = 7.8 Hz, 1 H), 8.75 (br. t, 2 H). $C_{55}H_{33}N_7O_{12}Zn \cdot 2H_2O$ (1085.33): calcd. C 60.87, H 3.44, N 9.03; found C 60.47, H 3.38, N 8.74.

X-ray Crystal Structure Determination: The measurement for $[Zn(L^1)_2(BF_4)_2]$ was made on a Rigaku RAXIS-RAPID Imaging Plate diffractometer with graphite-monochromated Mo-K_α radiation. A total of 56986 independent reflections was obtained of which 15981 were unique. The structure was solved by heavy-atom Patterson methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. $R1$ = 0.119, $wR2$ = 0.371. The measurement for $[Zn(L^1)(G^1)_2]$ was made on a Bruker SMART 1000 diffractometer with graphite-monochromated Mo-K_α radiation. A total of 12923 independent reflections were obtained of which 10897 were unique. The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. $R1$ = 0.053, $wR2$ = 0.084. Crystallographic details are given in Table 1. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-169877 for $[Zn(L^1)_2(BF_4)_2]$ and CCDC-169878 for $[Zn(L^1)(G^1)_2]$. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].
