Lipophilic Ligands Derived from 1,3,5-Triamino-1,3,5-trideoxy-*cis*-inositol (Taci) for Trivalent Lanthanide Complexation in Aqueous and Organic Solutions

Samuel Delagrange,[a] Christelle Gateau,[a] David Chapon,[a] Colette Lebrun,[a] Pascale Delangle,*[a] and Philippe Vottéro[a]

Keywords: Lanthanides / Complexes / N,O ligands / Substituent effects / Stability constants

New lipophilic ligands derived from 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (taci), namely 1,3,5-trideoxy-1,3,5-tris-(ethylamino)-*cis*-inositol (L^1), 1,3,5-tris(butylamino)-1,3,5-trideoxy-*cis*-inositol (L^2), 1,3,5-trideoxy-1,3,5-tris(hexylamino)-*cis*-inositol (L^3) have been synthesized by reductive amination of taci. Their complexing properties towards trivalent lanthanide cations, together with those of 1,3,5-tris(benzylamino)-1,3,5-trideoxy-*cis*-inositol (L^4), have been investigated in solution using mass spectrometry, NMR spectroscopy and potentiometry. It has been shown that each ligand forms trinuclear complexes with the composition $[Ln_3(LH_{-3})_2]^{3+}$. The stability constants (log β_{32-6}) of these complexes have been calculated for Nd^{3+}, Eu^{3+}, and in some cases for Lu^{3+}. The affinity for the lanthanide cations follows the sequence $Lu^{3+} > Eu^{3+} > Nd^{3+}$, for all the ligands. This sequence follows the well-known electrostatic trend. The stability of the complex depends on the conjugate effects of the steric hindrance of the substituents and the basicity of the ligands: $L^1 \approx L^2 <$ taci, in water, and $L^3 < L^2 << L^4$, in water/methanol. Among the ligands studied in this work, L^4 appears to be the most effective complexing agent for the lanthanide cations in water/methanol under slightly acidic conditions.

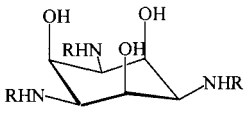
Introduction

The design of selective chelating agents represents one of the basic challenges in the field of coordination chemistry.[1,2] Important medicinal and technological areas such as the treatment of metal intoxication,[3] ligands for magnetic resonance, radiochemical imaging[4,5] or luminescent probes,[6] and selective extractants in industrial processes[7,8] may greatly benefit from such studies.

Separation of trivalent lanthanide and actinide cations, both present in nuclear fuel, is required for nuclear waste management.[9,10] Due to the chemical similarity of these two cation families, their selective extraction by tailored ligands still remains a challenge. For several years, we have been engaged in the studies of polyfunctional ligands based on cyclohexanic platforms for group *f* element selective complexation.[11,12] Among the ligands studied in our laboratory, 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (taci) was found to be a model compound of great interest for this purpose. It is a rigid receptor with preorganized N- and O-donor atoms (Scheme 1), which offer different chelating modes for metal binding. Its coordination properties have been widely investigated and described in the literature.[13,14] In particular, it has been shown that taci forms trinuclear species of the type $[M_3(taciH_{-3})_2]^{3+}$, with trivalent lanthanide cations with an original "sandwich-type" structure (Scheme 2).[15,16] In these complexes, each of the three metal cations binds to an amino group and to two alkoxo groups of each of the two deprotonated ligands. The coordination sphere is completed by peripheral ligands such as H_2O or counterions. For the purposes of our research, taci is especially attractive because, although the 4f complexes are isostructural across the lanthanide series, it shows an uncommon selectivity for the elements at the end of the series.[17]



taci : R=H
L^1 : R = -CH_2-CH_3
L^2 : R = -$(CH_2)_3$-CH_3
L^3 : R = -$(CH_2)_5$-CH_3
L^4 : R = -CH_2-C_6H_5

Scheme 1

Despite the rich coordination chemistry of taci,[14] only a few derivatives have been described in the literature. Several *O*-[18] or *N*-substituted derivatives have been elaborated by Hegetschweiler et al. to modulate metal binding properties.

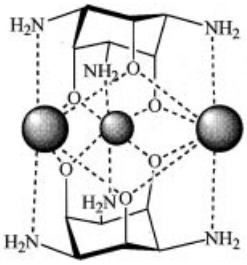


Scheme 2

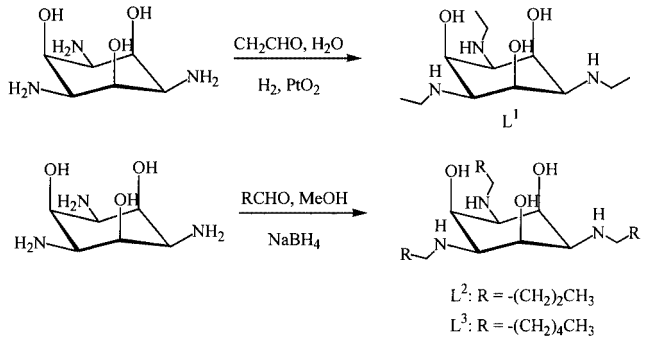
Two types of substituents, with or without additional donor groups, have been introduced at the nitrogen atoms. 1,3,5-trideoxy-1,3,5-tris[(2-hydroxybenzyl)amino]-*cis*-inositol (H_3thci),[19] 1,3,5-trideoxy-1,3-bis[(2-hydroxybenzyl)amino]-*cis*-inositol (H_3bhci) and its bifunctionalized analog, 1,3,5-trideoxy-5-glutaramido-1,3-bis[(2-hydroxybenzyl)amino]-*cis*-inositol (H_3bhci-glu-H)[20] have been prepared as new types of potential hexa- and pentadentate chelators, by hydrogenation of a mixture of taci and salicylaldehyde using Pt as a catalyst. Furthermore, several methylated derivatives have been synthesized to favor one of the binding modes, for steric reasons. For this purpose, 1,3,5-trideoxy-1,3,5-tris-(dimethylamino)-*cis*-inositol (tdci)[21] was obtained by catalytic hydrogenation of taci in the presence of formaldehyde with Pt as the catalyst, and 1,3,5-trideoxy-1,3,5-tris(trimethylamino)-*cis*-inositol (ttci)[21] was obtained by complete methylation of the amino groups using an excess of methyliodide. Even if the direct treatment of taci with methylating agents resulted in *N*- rather than *O*-alkylation, the introduction of only one methyl group at each primary amine proved to be difficult. Hence, starting from taci, 1,3,5-trideoxy-1,3,5-tris(methylamino)-*cis*-inositol (tmaci) was obtained by an indirect route using the corresponding Co^{III} complex $[Co(taci)_2]^{3+}$ as an intermediate.[22] Recently, 1,3,5-tris(benzylamino)-1,3,5-trideoxy-*cis*-inositol (tbci or L^4), obtained by reductive alkylation of taci using $NaBH_4$ as the reducing agent, and 1,3,5-tris(benzylmethylamino)-1,3,5-trideoxy-*cis*-inositol (tbmci) have been reported for the preparation, in nonaqueous medium, of a new type of Ba^{2+} complex having a chiral structure.[23]

In order to develop new lipophilic ligands based on the taci framework, we decided to prepare a series of *N*-alkylated derivatives. To retain the specific coordination properties of taci towards lanthanide(III) ions, the alcohol functions, which are deprotonated during complexation in this particular case, had to remain untouched. Various lipophilic substituents were thus attached to the three nitrogen atoms of taci (Scheme 1). Here, we present the syntheses of a series of new *N*-alkylated derivatives of taci, namely 1,3,5-trideoxy-1,3,5-tris(ethylamino)-*cis*-inositol (L^1), 1,3,5-tris-(butylamino)-1,3,5-trideoxy-*cis*-inositol (L^2), and 1,3,5-trideoxy-1,3,5-tris(hexylamino)-*cis*-inositol (L^3), and the characterization of their lanthanide complexes and those of tbci (L^4) in aqueous and methanolic solutions. The affinity towards Ln^{III} ions will be discussed as a function of ligand substituents, cation size and pH.

Results and Discussion

Ligand Syntheses

The syntheses of the three ligands L^1-L^3 are summarized in Scheme 3. As previously discussed with regard to the ligand tmaci,[22] the introduction of alkyl groups is not a routine task, mainly due to the multifunctionality of taci and the possibility of forming many amines having numerous degrees of substitution. Many procedures for the specific conversion of primary to secondary amines have been reported in the literature, but there is no universal efficient method available. However, the reductive alkylation of primary amines is one of the most useful routes to secondary amines. According to the Hegetschweiler reports,[19–21] catalytic hydrogenation using Pt as the catalyst[24] is probably the best way to prepare *N*-alkylated derivatives starting from taci. This method was then chosen for the reduction of the Schiff bases formed in situ by the treatment of taci with the appropriate carbonyl compound. Indeed, catalytic hydrogenation of the taci sulfate salt in the presence of a large excess of acetaldehyde with Pt as the catalyst, and subsequent elution by ion-exchange chromatography led to L^1 in a 62% yield. Unfortunately, the introduction of butyl substituents at the three nitrogen atoms by the same method was not successful and resulted in the formation of a crude mixture of various compounds, presumably due to the steric hindrance of the imine formed in situ. This reaction was readily driven towards the formation of the desired L^2 in a 65% yield by using sodium borohydride as the reducing agent. L^3 was obtained under the same conditions using 3.3 equivalents of the appropriate carbonyl compound in a 56% yield. As expected, the replacement of the H–N hydrogen atoms by alkyl substituents generates rather lipophilic chelates. The coordination properties of this new ligand set towards trivalent lanthanide cations can be evaluated in different media, depending on the chain length: in water for L^1 and L^2 and in water/methanol for L^2, L^3, and L^4.



Scheme 3

Characterization of Ln^{III} Complexes in Solution by ES-MS

Electrospray ionization mass spectrometry (ES-MS) has been shown to be a suitable technique to qualitatively characterize preformed ions in solution,[25] and has moreover been used for identification of supramolecular coordination

complexes.[26−28] Aqueous and methanolic samples containing the ligand and europium(III) of different molar ratios were analyzed. Due to their characteristic isotopic patterns, the signals for the europium-containing species can easily be recognized, and indicate the number of Eu^{III} cations present in the detected complexes. Figure 1 shows a typical spectrum obtained from a water/methanol solution (1:1, v/v) of L^4 and $Eu(NO_3)_3$ at a molar ratio (M/L) of 1.5 in the absence of added base.

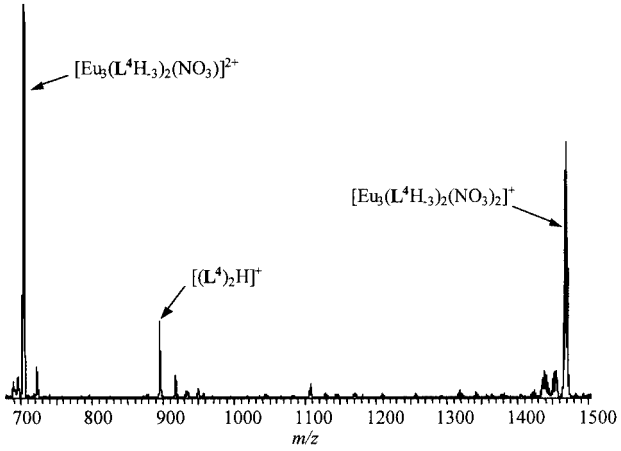


Figure 1. ES-MS spectrum of a water/methanol solution (1:1, v/v) of L^4 and $Eu(NO_3)_3$. c_L/c_M = 1:1.5; $c_L = 1{\cdot}10^{-3}$ M

The only Eu-containing species detected under our experimental conditions are $[Eu_3(LH_{-3})_2(NO_3)_2]^+$ and $[Eu_3(LH_{-3})_2(NO_3)]^{2+}$. The experimental and calculated isotopic patterns are identical. As an example, the peak envelope of $[Eu_3(L^4H_{-3})_2(NO_3)_2]^+$ is depicted in Figure 2.

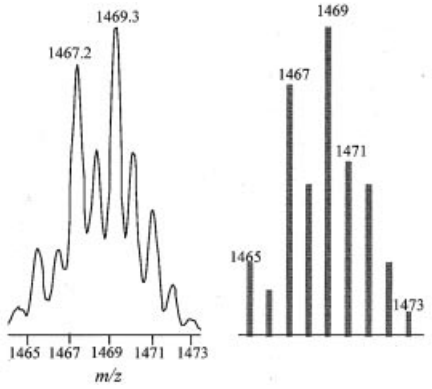

Figure 2. Experimental and calculated isotopic patterns of $[Eu_3(L^4H_{-3})_2(NO_3)_2]^+$. c_L/c_M = 1:1.5; $c_L = 1{\cdot}10^{-3}$ M

In the presence of triethylamine, the hydroxo complexes $[Eu_3(LH_{-3})_2(NO_3)(OH)]^+$ and $[Eu_3(LH_{-3})_2(OH)_2]^+$ are also detected. Fragmentation of the complex resulted in the complete destruction of this species. It is worth noting that whatever the Eu/L ratio, ranging from 1:2 to 2:1, the trinuclear complex is the only species observed. Finally, we have also checked that similar complexes were formed with a series of lanthanide cations including Pr^{3+}, Nd^{3+}, Sm^{3+}, Ho^{3+}, and Lu^{3+}. In all cases, only the ions of the type $[Ln_3(LH_{-3})_2]^{3+}$ have been evidenced in the ES-MS spectra, as was previously observed for the Ln^{III} ion complexation by taci.[17]

Protonation Equilibria

In order to analyze the stability of the metal complexes formed in solution, we first studied the protonation properties of each ligand using potentiometric methods. The protonation constants of ligands L^1, L^2, L^3, and L^4 obtained in water or in water/methanol (1:3, v/v) solutions are listed in Tables 1 and 2, respectively. For comparison, protonation constants of related compounds (taci and tdci) are also reported.

Table 1. Protonation constants ($\log K^H_i$) for taci, L^1, L^2, and tdci determined in water (25 °C; 0.10 M KCl, pK_w = 13.78) using the program HYPERQUAD

Equilibrium quotient	taci	L^1	L^2	tdci
[HL]/[L][H]	8.87(2); 8.90[a]	9.362(6)	9.40(1)	9.68[a]
$[H_2L]/[HL][H]$	7.38(3); 7.40[a]	7.777(6)	7.74(1)	7.62[a]
$[H_3L]/[H_2L][H]$	5.96(3); 5.95[a]	6.257(6)	6.20(1)	5.89[a]
$[H_3L]/[L][H]^3$	22.21	23.40	23.34	23.19

[a] From ref.[15]

Table 2. Protonation constants ($\log K^H_i$) for L^2, L^3, and L^4 determined in water/methanol (1:3, v/v) (25 °C; 0.10 M KCl, pK_w = 13.89) using the program HYPERQUAD

Equilibrium quotient	L^2	L^3	L^4
[HL]/[L][H]	8.44(3)	8.56(2)	7.65(3)
$[H_2L]/[HL][H]$	7.14(3)	7.25(3)	6.16(3)
$[H_3L]/[H_2L][H]$	5.80(6)	5.74(3)	4.48(6)
$[H_3L]/[L][H]^3$	21.38	21.55	18.29

In each case, three constants corresponding to the protonation of the amino groups have been calculated. The values obtained for L^1 and L^2 in water are roughly similar, and as expected the overall basicity of these two ligands (bearing secondary amines) is higher than that of taci (primary amine) and lower than that of tdci (tertiary amine). Due to their poor solubility in water, the protonation properties of ligands L^3 and L^4 have been investigated in water/methanol (1:3, v/v). For comparison, L^2 has also been studied under the same conditions. The protonation constants determined for L^3 are close to those determined for L^2, i.e. the chain length does not significantly affect the basicity of the amino groups. On the other hand, the overall basicity of L^4 is three orders of magnitude lower than that of the alkyl derivatives. Note that benzylamine, with a pK^H value of 9.62, is also known to be a weaker base than butylamine and hexylamine whose pK^H values are 10.78 and 10.64, respectively.[29]

The separation of the pK^H values is in the range 1.3−1.7 and is higher than the statistical separation (log3 = 0.48). This means that the protonation of an amino group is influ-

enced by other amino groups that are already protonated. This is expected since the basic sites are only separated by 3 carbon atoms.[30] Besides, the ΔpK^H values of ca. 1.5 observed between two consecutive protonation constants are similar to those calculated for 1,3,5-triaminocyclohexane (pK^H: 10.16, 8.66, 7.17),[31] and are thus consistent with the expected ligand conformation in solution, i.e. the conformation in which the hydroxy groups are in the axial positions and the amino groups are in the equatorial positions due to the steric hindrance of the bulky substituents.

Stability of the Complexes in Aqueous and H_2O/MeOH Media

The affinity of these ligands for lanthanide(III) cations was also studied by potentiometry in water or in water/methanol (1:3, v/v). The titration curves obtained for the $Ln-L^1$ and $Ln-L^4$ systems are representative of this study and are presented in Figure 3.

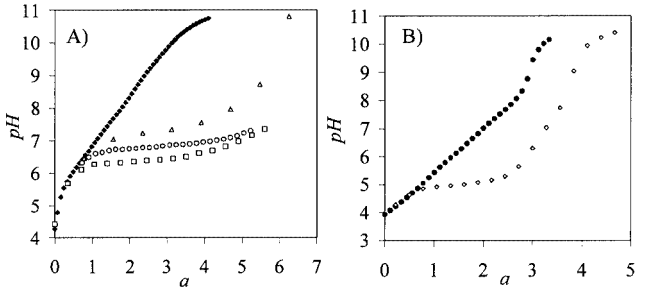

Figure 3. Potentiometric titration curves (experimental points, 25 °C, I = 0.10 M KCl) for: **A)** L^1 (♦) and different systems in water: $Nd^{3+}-L^1$ (Δ), $Eu^{3+}-L^1$ (○), $Lu^{3+}-L^1$ (□); c_L/c_M = 1:1.5; c_L = $1\cdot10^{-3}$ M; **B)** L^4 (●) and $Eu^{3+}-L^4$ (◇) system in water/methanol (1:3, v/v); c_L/c_M = 1:0.5; c_L = $0.5\cdot10^{-3}$ M. a is the number of base added per mol of ligand

The following conclusions can be drawn from the titration curves. The curves obtained for the $Ln^{III}-$ligand L^1, L^2, L^3, and L^4 systems share many features with the titration curves described for $Ln^{III}-$taci systems.[17] Each curve shows distinct regions corresponding to (i) the removal of the first proton from $[H_3L]^{3+}$, (ii) the formation of the complex characterized by the low slope of the pH curve in this range, (iii) the titration of the possible excess ligand (occurring for instance in the case of the $Ln-L^4$ system as shown in Figure 3, B), (iv) a further deprotonation of the complex at high pH values. These experiments unambiguously established the formation of the species $[M_3(LH_{-3})_2]^{3+}$ according to Equation (1):

$$H_3L^{3+} + 1.5\,M^{3+} + 6\,OH^- \rightleftarrows 0.5\,[M_3(LH_{-3})_2]^{3+} + 6\,H_2O \quad (1)$$

In all cases presented here, the HYPERQUAD 2000 program gave convergence for models containing the $[M_3(LH_{-3})_2]^{3+}$ species, and in certain cases, $[M_3(LH_{-3})_2(OH)]^{2+}$ has been suggested if sufficient experimental points in the basic region were available. All other species considered, including mono- and dinuclear complexes, were systematically rejected by the program. The values of the stability constants, β_{32-6} according to Equation (2), calculated from the experimental points using the program HYPERQUAD are compiled in Tables 3 and 4. Figure 4 gives an insight into the species distribution as a function of pH for the $Eu^{3+}-L^1$ and $Eu^{3+}-L^4$ systems.

Table 3. Formation constants ($\log\beta_{32-6} = [Ln_3(LH_{-3})_2]/[Ln]^3[L]^2[H]^{-6}$) of taci, L^1, L^2, and tdci in water (25 °C; 0.10 M KCl, pK_w = 13.78)

Ion	taci	L^1	L^2	tdci
Nd^{3+}	−24.1[a]	−26.4(2)	−27.0(2)[b]	
Eu^{3+}	−17.9[a]; −18.5[c]	−21.4(1)[b]	−21.2(2)[b]	−16.8[c]
Lu^{3+}	−12.5[a]; −11.3[c]	−16.9(2)[b]	−17.6(2)[b]

Table 4. Formation constants ($\log\beta_{32-6} = [Ln_3(LH_{-3})_2]/[Ln]^3[L]^2[H]^{-6}$) of L^2, L^3, and L^4 determined in water/methanol (1:3, v/v) (25 °C; 0.10 M KCl, pK_w = 13.89) using the program HYPERQUAD

Ion	L^2	L^3	L^4
Nd^{3+}	−	−15.9(2)	−13.9(2)
Eu^{3+}	−10.3(2)	−11.8(1)	− 8.3(1)

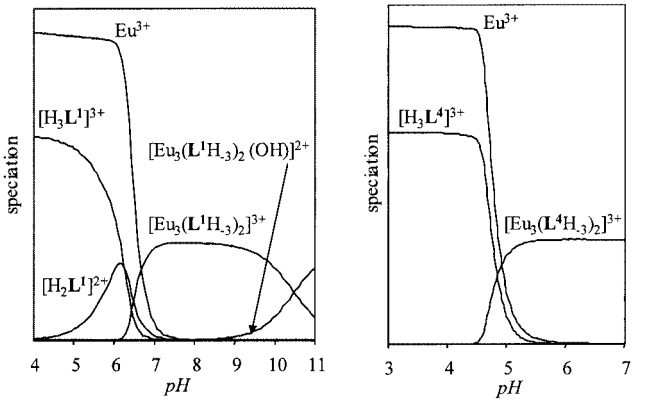

Figure 4. Species distribution as a function of pH for the $Eu^{3+}-L^1$ and $Eu^{3+}-L^4$ systems. c_L/c_M = 1:1.5; c_L = $1\cdot10^{-3}$ M. The formation constants listed in Tables 1 to 4 were used for the calculations

$$3\,Ln^{3+} + 2\,L \rightleftarrows [Ln_3L_2H_{-6}]^{3+} + 6\,H^+ \quad (2)$$

Ligands L^1 and L^2 form stable complexes with Nd^{3+}, Eu^{3+}, and Lu^{3+} in water, with stability constants lower than those previously calculated for taci and the related cations. In water/methanol solution, Nd^{3+} and Eu^{3+} complexes formed with L^4 show a higher stability than those formed with L^2 and L^3. The plots in Figure 5, giving the calculated fraction of free Eu^{3+} versus pH for the different ligands, provide another way of comparing their complexing power. The binding ability follows the sequence $L^1 \approx L^2 <$ taci, in water, and $L^3 < L^2 << L^4$, in water/

methanol. Hence, ligand L^4 is the most effective in complexing europium in water/methanol (1:3, v/v) in the pH range 4.5−5.5, due to its relatively low basicity and high stability constant.

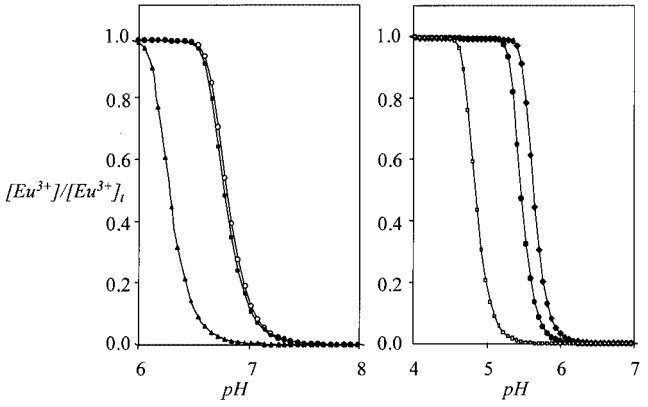

Figure 5. Fraction of calculated free europium concentration as a function of pH for taci (▲), L^1 (■), and L^2 (○) in water (left plot) and for L^2 (●), L^3 (◆), and L^4 (□) in water/methanol (1:3, v/v) (right plot). c_L/c_M = 1:1.5; $c_L = 1{\cdot}10^{-3}$ M

The differences in the Ln^{III} complex stabilities observed between taci and its *N*-functionalized derivatives may be explained by considering the effects of the basicity of the amino groups and the steric hindrance provided by the nitrogen substituent. As the Ln^{III} are very hard cations, the affinity of a family of ligands for these ions is usually correlated to their overall basicity; for a given lanthanide cation, as ΣpK^H increases, the complex stability constant also increases.[32] In this study, ligands based on the taci framework show an exceptional behavior since the more basic the amino groups are, the less effective lanthanide(III) complexation is. For taci and its derivatives, it is difficult to correlate the complexation constants with the overall ligand basicity, as has been done for several aminocarboxylic acids,[33] because the dissociation constants of the alcohol functions are not known. Under the experimental conditions used, these groups are not deprotonated in the absence of the metal, and the influence of nitrogen substitution on the alcohol dissociation constants is thus unknown. Moreover, it can obviously be assumed that the presence of the bulky groups renders the formation of the hindered sandwich-type complexes less favorable, and as a consequence the corresponding stability constant values decrease. Hence, the ligands L^1 and L^2 form less stable complexes than the unsubstituted taci in water. The same conclusion can be reached to explain the lower stability of the complexes formed with L^3 than those formed with L^2 in water/methanol solution.

The trend in the stability constants across the lanthanide series follows the well-known electrostatic trend,[34] i.e. $\log\beta_{32-6}$ increases from Nd^{III} to Lu^{III} and/or Eu^{III}, as seen in Figure 6. Lanthanide(III) complexation in water can be decomposed in two steps: the first step corresponds to dehydration, and the second step, to the reaction between the desolvated species. The compensation effect assumes that the free energy of the first step is negligible,[35] and thus the free energy of the global process reflects the second step, i.e. the interaction between the ligand and the metal ion, leading to an increase in the stability constants from La^{III} to Lu^{III}.

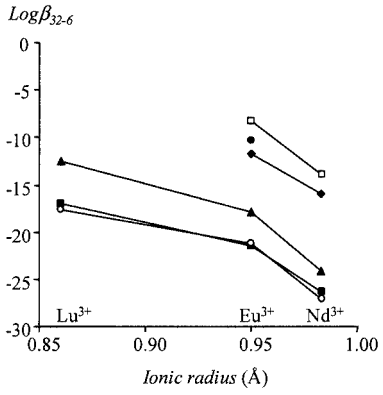

Figure 6. Variation of the $\log\beta_{32-6}$ values as a function of ionic radius for taci (▲), L^1 (■), and L^2 (○) in water and for L^2 (●), L^3 (◆), and L^4 (□) in water/methanol (1:3, v/v)

The great increase in the affinity from La^{III} to Lu^{III}, already observed with the ligand taci,[17] is also seen for the derivatives L^1-L^4. The difference in $\log\beta_{32-6}$ from Eu^{III} to Nd^{III} is 6.2 for taci, and ranges from 4.1 to 5.8 for L^1 to L^4. The simulation of the fraction of free Ln^{3+} in solution in the presence of L^4 as a function of pH clearly shows that the europium cations are totally complexed at pH 5.1, while at the same pH, the neodymium cations remain free in solution. Note that it does not mean that ligand L^4 would be able to selectively complex Eu^{3+} in the pH range 4.6 to 5.1. It would then be necessary to consider the formation of heterotrinuclear complexes, namely $[Eu_2Nd(LH_{-3})_2]^{3+}$ and $[EuNd_2(LH_{-3})_2]^{3+}$. We have already demonstrated the existence of such compounds with taci.[36]

NMR Analysis

In order to gain an insight into the solution structure of these complexes, a ^1H NMR study was undertaken. Solutions containing the water-soluble ligand L^1 and $Eu(OTf)_3$ at a molar ratio (M/L) of 1.5 were analyzed at pD values ranging from 4.70 to 8.21 at 278 K. Addition of small amounts of base (NaOD) clearly show the disappearance of the signals assigned to the ligand, and the appearance of numerous resonances within the 0 to −23 ppm region. As in the complex, each nitrogen atom becomes an asymmetric center, a mixture of diastereoisomers exists in solution and a further analysis of this region is not obvious. At pD 8.21, the spectrum of the sample only shows the resonances assigned to the complex, indicating that the ligand has totally been converted to the Eu^{III} complex. NMR spectra were also recorded at variable temperatures as seen in Figure 7, which represents the spectra of $[Eu_3(L^1)_2H_{-6}]^{3+}$ at 348 K and 278 K. A better resolution of the series of multiplets is obtained at 278 K, but it does not provide suitable informa-

tion to confirm the solution structure of the complex. At 348 K, the signals scattered within 0 and −26 ppm merge into two broad signals centered at δ = −14.2 ppm and −6.3 ppm. Considering the fact that the spectrum of the europium complex with taci only exhibits two signals at δ = −21.72 ppm and −14.49 ppm, assigned to the protons H^N and H^O,[17] the two broad signals may represent the average of all the "H^N" and "H^O" protons. This last result is consistent with the pseudo D_{3h} symmetry of the complex when interconversion around the nitrogen atom is fast. Similar observations were made for europium complexes formed with L^2, L^3, and L^4 in methanol.

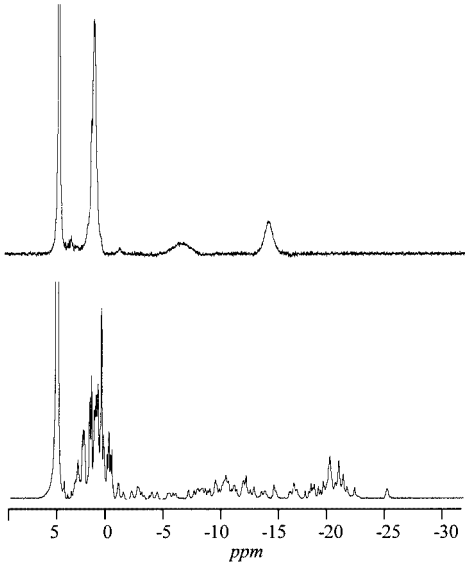

Figure 7. 400 MHz ^{1}H NMR spectra of the $Eu^{3+}-L^1$ system in D_2O (pD = 8.21) at 348 K (top) and 278 K (bottom). c_L/c_M = 1:1.5; $c_L = 1\cdot10^{-2}$ M

Conclusion

The new ligands L^1, L^2, and L^3, synthesized via alkylation of taci with various carbonated chains, as well as the trisbenzyl derivative L^4 show similar complexation properties towards lanthanide(III) cations as the ligand taci. The only species evidenced by electrospray ionization spectrometry and potentiometry is the trinuclear complex $[Ln_3L_2H_{-6}]^{3+}$. In the complex, the coordination of the nitrogen atoms to the lanthanide cations leads to several chiral centers, and thus a more detailed NMR analysis is prevented by the observation of numerous diastereoisomers in solution.

The stability constants of the lanthanide complexes of the four ligands show the well-known electrostatic trend, i.e. an increase from lanthanum to lutetium. Moreover, although ligands L^1-L^4 are more basic than taci, they give less stable complexes with Ln^{III}, indicating that the steric hindrance is the determining factor in the formation of the sandwich complex $[Ln_3L_2H_{-6}]^{3+}$. The ligands may be classified according to their Ln^{III} affinity: $L^1 \approx L^2 <$ taci, in water, and $L^3 < L^2 << L^4$, in water/methanol, and thus among this set of ligands, L^4 appears to be the most effective in binding 4f cations. The striking increase in affinity across the series, previously seen with the ligand taci, is maintained for the lipophilic derivatives L^1-L^4.

Experimental Section

General Information: All solvents and reagents were obtained from commercial suppliers and used without further purification. The precursor taci, used as the sulfate salt, and the ligand tbci (L^4) were prepared according to literature procedures.[21,23] Catalytic hydrogenation was performed within a TOP 80 reactor with controlled hydrogen pressure, temperature and rotation speed. Melting points were measured with an Electrothermal IA93000 and are uncorrected. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Mercury 400 spectrometer. Chemical shifts are reported in ppm with solvent as the internal reference. When necessary, pD was adjusted with a sodium deuteroxide solution ($pD = pH_{read} + 0.41$).[37] Mass spectra were acquired on a LCQ-ion trap (Finnigan-Thermoquest, San Jose, USA) equipped with an electrospray source. Electrospray full scan spectra in the range m/z = 100−1500 were obtained by infusion through a fused silica tubing at 2−10 μL/min. The solutions were analyzed in the positive mode. The LCQ calibration (m/z = 50−2000) was achieved according to the standard calibration procedure from the manufacturer (mixture of caffeine, MRFA and Ultramark 1621). The temperature of the heated capillary for the LCQ was set to 85 °C, the ion-spray voltage was in the range 1−6 kV and the injection time was 5−200 ms. Samples for ES-MS were prepared by dissolving the ligand (10^{-3} M) and the lanthanide salt in water or in water/methanol solution, the pH was then adjusted to the desired value if necessary by adding triethylamine. Elemental analyses were performed by the Service Central d'Analyses (Vernaison-69)

Ligands Synthesis

1,3,5-Trideoxy-1,3,5-tris(ethylamino)-*cis*-inositol (L^1): A solution of the sulfate salt of taci (1.00 g, 3.08 mmol) in H_2O (160 mL) was hydrogenated under hydrogen pressure (12 bars) in the presence of PtO_2 (0.070 g, 0.31 mmol) and acetaldehyde (4.0 mL; 70.9 mmol) at room temperature for 7 days. Two additional portions of acetaldehyde (2 × 4.0 mL; 2 × 70.9 mmol) were added after 2 and 3 days. After filtration through a pad of Celite and concentration in vacuo, the crude product was purified by crystallization from H_2O/EtOH, yielding the sulfate salt of compound L^1 (0.924 g, 65%) as a white solid. ^{1}H NMR (400 MHz, D_2O, 298 K): δ (ppm) = 1.36 (t, J = 7.2 Hz, 9 H, CH_3), 3.25 (q, J = 7.3 Hz, 6 H, NCH_2),. 3.57 (t, J = 3.0 Hz, 3 H, HC_{cycle}-NH,), 4.61 (t, J = 2.9 Hz, 3 H, HC_{cycle}-OH) ppm. $C_{12}H_{30}N_3O_3\cdot SO_4\cdot HSO_4$ (457.51): calcd. C 31.5, H 6.8, N 9.1; found C 31.5, H 7.1, N.8.7.

The sulfate salt of ligand L^1 (0.924 g, 2.02 mmol) was dissolved in H_2O (50 mL) and subjected to ion-exchange chromatography (Amberlite IR 45, OH^- form). H_2O was removed under reduced pressure to afford the free base ligand L^1 (0.573 g, 96%) as a white solid. M.p. 160−161 °C (decomposition). ^{1}H NMR (400 MHz, D_2O, 298 K): δ (ppm) = 1.16 (t, J = 7.2 Hz, 9 H, CH_3), 2.83 (q, J = 7.3 Hz, 6 H, NCH_2), 2.85 (s broad, 3 H, HC_{cycle}-NH), 4.27 (t, J = 2.9 Hz, 3 H, HC_{cycle}-OH) ppm. ^{13}C NMR (100 MHz, D_2O, 298 K): δ (ppm) = 15.1 (CH_3). 41.7 (NCH_2), 59.2 (HC_{cycle}-NH), 70.0 (HC_{cycle}-OH). ES-MS: 262.2 $[M + H]^+$.

1,3,5-Tris(butylamino)-1,3,5-trideoxy-*cis*-inositol (L^2): The sulfate salt of taci (1.00 g, 3.08 mmol) in MeOH (75 mL) was refluxed with

KOH (0.675 g, 12.02 mmol) for 30 min. Butanal (1.8 mL, 20.3 mmol) was added dropwise and the solution was stirred for 3 h. The solution was then cooled to 0 °C and sodium borohydride (1.516 g, 40.08 mmol) was added in small portions. After stirring overnight at room temperature, the reaction was quenched by adding concentrated HCl. The solution was concentrated to dryness and the residue was taken up in H_2O (300 mL). The mixture was extracted with CH_2Cl_2 (150 mL) to remove excess butanal. The aqueous layer was made alkaline (pH ca. 10) by adding KOH pellets and extracted with Et_2O (8 × 200 mL). The solvent was removed in vacuo and the residue was purified by crystallization from CH_3CN, yielding compound L^2 (0.693 g, 65%) as a white solid with m.p. 117 °C. ^{1}H NMR (400 MHz, D_2O, 298 K): δ = 0.89 (t, J = 7.3 Hz, 9 H, CH_3,), 1.33 (sext, J = 7.3 Hz, 6 H, CH_2-CH_3), 1.48 (quint, J = 7.6 Hz, 6 H, -CH_2-), 2.61 (s broad, 3 H, HC$_{cycle}$-NH), 2.66 (t, J = 7.4 Hz, 6 H, NCH_2), 4.21 (s broad, 3 H, HC$_{cycle}$-OH) ppm. ^{13}C NMR (100 MHz, D_2O, 298 K): δ = 15.6 (CH_3). 22.3 (CH_2-CH_3), 33.2 (NCH_2-CH_2), 46.9 (NCH_2), 59.8 (HC_{cycle}-NH), 71.4 (HC_{cycle}-OH). ES/MS: 346.5 $[M + H]^+$, 368.3 $[M + Na]^+$. $C_{18}H_{39}N_3O_3$ (345.53): calcd. C 62.6, H 11.4, N 12.2; found C 62.3, H 11.4, N 12.2.

1,3,5-Trideoxy-1,3,5-tris(hexylamino)-*cis*-inositol (L^3): Following the same procedure as above, treatment of the sulfate salt of taci (0.300 g, 0.925 mmol) with KOH (0.202 g, 3.608 mmol), hexanal (0.37 mL, 3.053 mmol) and sodium borohydride (0.455 g, 12.02 mmol) and crystallization from ethyl acetate yielded compound L^3 (0.222 g, 56%) as a white solid with m.p. 104 °C. ^{1}H NMR (400 MHz, $CDCl_3$, 298 K): δ = 0.89 (t, J = 6.7 Hz, 9 H, CH_3), 1.32 (m, 18 H, (CH_2)$_3$$CH_3$), 1.58 (m, 6 H, C$H_2$), 2.54 (s broad, 3 H, HC$_{cycle}$-NH), 2.76 (t, J = 7.2 Hz, 6 H, NCH_2,), 4.17 (s broad, 3 H, HC$_{cycle}$-OH) ppm. ^{13}C NMR (100 MHz, $CDCl_3$, 298 K): δ = 14.2 (CH_3), 22.8 (CH_2), 27.2 (CH_2), 30.2 (CH_2), 31.9 (CH_2), 47.3 (NCH_2), 59.5 (HC_{cycle}-NH), 69.7 (HC_{cycle}-OH). ES/MS: 430.5 $[M + H]^+$. $C_{24}H_{51}N_3O_3$ (429.69): calcd. C 67.1, H 12.0, N 9.8; found C 67.3, H 12.0, N 9.9.

Potentiometric Measurements

Reagents and Solutions: Solutions of titrants, support electrolyte (KCl), metal ions and ligands were prepared in water (obtained by Millipore/Milli-Q system) or in water/methanol (1:3, v/v); methanol was of analytical grade. Carbonate-free solutions of KOH were prepared from standardized solutions and were discarded when the amount of carbonate was about 1% of the total amount of base. HCl solutions were prepared from standardized solutions. Metal ions solutions were prepared with a concentration of about $1\cdot10^{-2}$ M, from the chloride salts of the metals and standardized by titration with H_2Na_2edta. Ligand solutions were prepared at a concentration of ca. 10^{-3} M.

Equipment and Working Conditions: All potentiometric titrations were carried out at 25.0±0.1 °C. Potential values were measured with a Metrohm combined glass electrode. Atmospheric CO_2 was excluded from the cell during the titration by passing Ar across the top of the experimental solution in the reaction cell. The titrant solutions were dispensed from a Metrohm 751 piston burette. For the titrations carried out in water/methanol (1:3, v/v), the glass electrode was previously treated by soaking it in the solution for one week to prevent erratic responses.

Measurements: The $[H^+]$ of the solutions was determined by measurement of the electromotive force of the cell, $E = E'° + Q \log [H^+] + Ej$; $E'°$, and Q was obtained from previous calibrations.[38] The liquid-junction potential, Ej, was negligible under the experimental conditions used. The value of $K_w = [H^+][OH^-]$ was $10^{-13.78}$ in water. In water/methanol (1:3, v/v), K_w was determined from the alkaline region of the titration curve and was found to be equal to $10^{-13.85}$ under our experimental conditions. The potentiometric equilibrium measurements were made on 30 mL solutions containing 25−50 μmol of the ligand and at an ionic strength of 0.10 M.

For the study of Ln^{III} complexes in water, a batch ("out-of-cell") method was used: solutions of metal ion and ligand with a final concentration of about 10^{-3} M were prepared in separate vials of 2 mL, in which small volumes of standard KOH solution (0.10 M) were added. The [M]/[L] ratios used were 1.5:1 for the Ln^{III}/**L^1** systems, 0.5:1 and 1.5:1 for the Ln^{III}/**L^2** systems. The ionic strength of the solutions was kept at 0.10 M with KCl. Measurements were carried out after stabilization of the pH, which occurred within 12 h.

For the study of the Ln^{III} complexes in water/methanol (1:3, v/v) solution, [M]/[L] ratios were 0.5:1 and under such conditions, stabilization occurred within 4500 s, allowing automatic titrations to be performed. To check if complete equilibration had been achieved during titration, a back titration with HCl (0.10 M) was performed. In all the cases presented here, no hysteresis was observed.

Calculation of Equilibrium Constants: Protonation constants $K^H_i = [H_iL]/[H_{i-1}L][H]$ were calculated by fitting the potentiometric data obtained for the ligand using the program HYPERQUAD.[39,40] Stability constants of the various species formed in solution were obtained from the experimental data using the same program. The initial results were obtained in the form of overall stability constants.

$$\beta_{M_mH_hL_l} = \frac{[M_mH_hL_l]}{[M]^m[H]^h[L]^l}$$

The errors quoted correspond to the standard deviations estimated by Hyperquad 2000, multiplied by a factor of 3.

Synthesis of a New Potentially Hemilabile Ligand: 1-[2-(Diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole, and Comparison of Its Bonding Properties with the Related 1-[2-(Ethylamino)ethyl]-3,5-dimethylpyrazole Ligand toward Rh^{I}

Glòria Esquius,[a] Josefina Pons,[a] Ramón Yáñez,[a] Josep Ros,*[a] René Mathieu,*[b] Bruno Donnadieu,[b] and Noël Lugan[b]

Keywords: Rhodium / P ligands / N ligands / Hemilabile ligands / Hydroformylations

The new ligand 1-[2-(diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole (**2**) has been prepared by the reaction of 1-(chloroethyl)-3,5-dimethylpyrazole and PPh_2Li. The bidentate N,N ligand 1-[2-(ethylamino)ethyl]-3,5-dimethylpyrazole (**1**) and **2** react with $[Rh(COD)(THF)_2][BF_4]$ to give $[Rh(COD)(\mathbf{1})][BF_4]$ (**3**) and $[Rh(COD)(\mathbf{2})][BF_4]$ (**4**), respectively. Substitution of 1,5-cyclooctadiene with carbon monoxide in the latter complexes generates $[Rh(CO)_2(\mathbf{1})][BF_4]$ (**5**) and $[Rh(CO)_2(\mathbf{2})][BF_4]$ (**6**), respectively. Treatment of $[Rh(COD)(THF)_2][BF_4]$ with two equivalent amounts of **2** results in the complex $[Rh(\mathbf{2})_2][BF_4]$ (**7**), which converts to $[Rh(CO)(\mathbf{2})_2][BF_4]$ (**8**) on reaction with carbon monoxide. Ligand **2** in complex **8** exhibits a hemilabile character. The single-crystal X-ray structures of **3**, **4**, and **7** are reported.

Introduction

In recent years the use of hemilabile ligands in coordination and organometallic chemistry has increased because of their potential applications in catalysis. Many bidentate ligands containing two donor centres of different strengths, such as mixed phosphorus-heteroatom ligands, have been reviewed in recent reports and articles.[1,2,3] Their interest in catalysis arises from the easy decoordination of the weak donor centre without the displacement of the ligand, which should confer a better stability to the reaction intermediates. Mixed ligands containing phosphorus along with oxygen, nitrogen or sulphur donor atoms have specifically been designed for use in catalytic reactions such as hydrogenation,[4,5,6] oligomerisation,[7] and hydroformylation of olefins.[8]

Pyrazole-derived molecules are good candidates for the preparation of interesting N,N′ or N,P mixed ligands, owing to their ease of synthesis and the possibility of electronic and steric modulation of their properties. Pyrazole-amines have been extensively studied as ligands for hard transition metal cations.[9] These studies have led to remarkable structures for the resulting complexes, some of which can be regarded as bioinorganic models.[10,11] Some reviews about pyrazole chelating ligands in biological model systems have recently appeared.[12,13]

In pursuing investigations on pyrazole-based polydentate ligands, we have directed our efforts toward the study of their reactivity with soft transition metal ions, in order to compare their behaviour with that of the well-known tris(pyrazolyl)borate anion.[14] Very recently, we have described the coordinating properties of bis[(3,5-dimethylpyrazolyl)methyl]ethylamine toward Rh^{I}. This ligand, which contains two different N donor centres, leads to a $\kappa^2 \rightleftarrows \kappa^3$ equilibrium in solution, revealing its hemilabile character through the reversible decoordination of the amino group. The κ^3 coordination mode has been found in the solid state structure determinations.[15]

In the present paper, we extend this work to a new family of N,P ligands of the phosphanylalkylpyrazole type. Prior to our investigations, only the diphenylphosphanylmethylpyrazole has been described in this class of ligands.[16] We report the synthesis of 1-[2-(diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole and the study of its bonding properties toward Rh^{I}. For comparative purposes, the reactivity of the related N,N′ bidentate ligand 1-[2-(ethylamino)ethyl]-3,5-dimethylpyrazole toward Rh^{I} has also been investigated.

Results and Discussion

The ligand 1-[2-(ethylamino)ethyl]-3,5-dimethylpyrazole (**1**) was synthesised according to a procedure previously described by Driessen.[17]

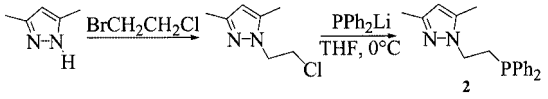
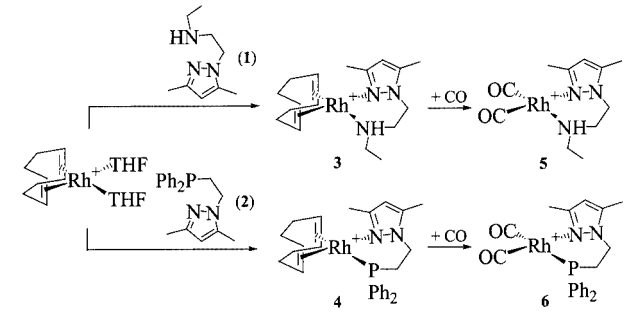
The new ligand 1-[2-(diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole (**2**) was prepared by reaction of 1-(chloroethyl)-3,5-dimethylpyrazole[18] with PPh_2Li, which is generated in situ by deprotonation of PPh_2H by *n*BuLi in tetrahydrofuran, at 0 °C (Scheme 1). The new ligand, isolated in an 83% yield as a colourless oil, was characterised by C, H, and N elemental analyses, IR, ^1H-, ^{13}C, and ^{31}P NMR spectroscopy, and by electron impact mass spectrometry. In the ^{31}P NMR spectrum, the diphenylphosphanyl moiety gives a singlet at $\delta = -20.9$ ppm.



Scheme 1

1-[2-(ethylamino)ethyl]-3,5-dimethylpyrazole (**1**) or 1-[2-(diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole (**2**) react with one equivalent of $[Rh(COD)(THF)_2][BF_4]$, which is generated in situ from the reaction of $[Rh(COD)Cl]_2$ and $AgBF_4$ in tetrahydrofuran, to give the complexes $[Rh(COD)(\mathbf{1})][BF_4]$ (**3**) (89% yield) and $[Rh(COD)(\mathbf{2})][BF_4]$ (**4**) (94% yield), respectively (Scheme 2). Elemental analyses of both complexes are consistent with their formulation.



Scheme 2

We were able to prepare X-ray quality crystals of complexes **3** and **4**, and we performed a crystal structure determination for both complexes. The molecular structures of the complexes consist of discrete $[Rh(COD)(\mathbf{1})]^+$ and $[Rh(COD)(\mathbf{2})]^+$ cations, respectively, and BF_4^- anions. Perspective views of the cation complexes are given in Figures 1, and 2, respectively. Selected bond lengths and angles are provided in Table 1, and the details of the data collection and crystal data are summarised in Table 2. A slightly distorted square-planar geometry is observed around Rh in both structures. Thus, in **3**, the Rh atom deviates by 0.025 Å from the mean coordination plane formed by two N donor atoms of the ligand and the centroid of the olefinic C=C bonds of the COD ligand. In **4**, the Rh atom deviates by 0.139 Å from the mean plane formed by the donor N and P atoms of the ligand and the centroid of the olefinic C=C bonds of the COD ligand. The Rh−N distances of 2.116(3) and 2.148(3) Å for **3**, and of 2.141(2) Å for **4** fall between the experimental values reported for related complexes.[15,19,21] The Rh−P bond length of 2.274(1) Å for **4** is also similar to those found in the literature.[19,22] Due to

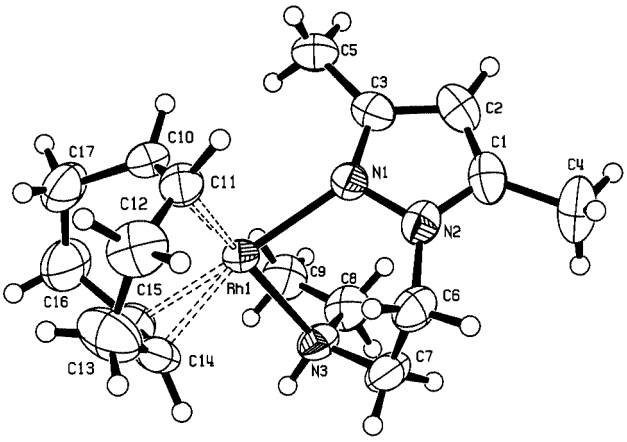


Figure 1. A perspective view of the cation $[Rh(COD)(\mathbf{1})]^+$ showing the numbering scheme

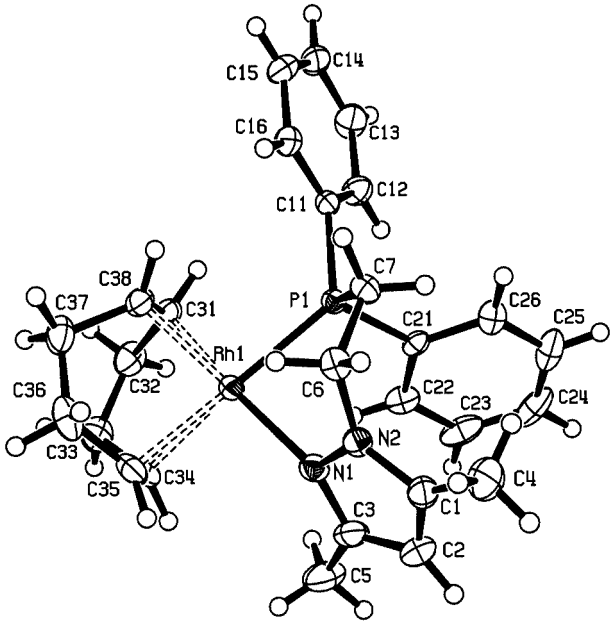

Figure 2. A perspective view of the cation $[Rh(COD)(\mathbf{2})]^+$ showing the numbering scheme

the different *trans* effect of the donor atoms in **4**, the Rh−C bonds *trans* to phosphorus [2.236(2) and 2.216(2) Å] are longer than the Rh−C bonds *trans* to nitrogen [2.132(2) and 2.129(2) Å].[19] The N1−Rh1−N3 angle [82.90(14)°] for **3** and the N1−Rh1−P1 angle [82.68(5)°] for **4** are smaller than 90°, but are consistent with the reported angles for similar complexes.[15,19] It is worth noting that in both structures the six-membered rings formed by the bidentate ligands coordinated to rhodium adopts a boat-type conformation, the Rh1 and C6 (both structures) atoms are at the apex of the boat.

The ^1H NMR spectrum for **3** recorded at 293 K (250 MHz) shows three signals with the relative intensity 2:1:1 at $\delta = 4.37$, 4.29, and 4.21 ppm for the non-equivalent olefinic protons of the 1,5-COD ligand *trans* to the pyrazole ring and *trans* to the amino group. This is fully consistent with the solid state structure, which shows that the nitrogen

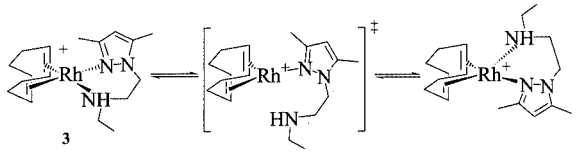
atom of the amino group coordinated to rhodium constitutes a stereogenic centre. Lowering the temperature to 243 K induces the splitting of the signals at δ = 4.37 ppm. On the other hand, increasing the temperature to 323 K results in the broadening of all the signals, and the coalescence of the signals for the olefinic protons of 1,5-COD to a single signal centred at δ = 4.35 ppm is observed at 310 K. This clearly demonstrates that complex **3** undergoes a dynamic process in solution. The coalescence temperature corresponds to a $\Delta G^{\ddagger}$ value of 15(±1) kcal·mol^{-1}.[20] The averaging of the resonances for the olefinic protons of 1,5-COD can reasonably be interpreted in terms of decoordination of one end of the ligand **1**, rotation, and recoordination, thus revealing the hemilabile character of ligand **1** in complex **3**. However, the experimental data do not allow for the unambiguous determination of the end of the ligand which eventually decoordinates. Indeed, except a general broadening of the signals, there are no significant changes in the chemical shifts for the protons of the methyl and ethyl groups of the ligand. Scheme 3 shows the proposed mechanism for this process.



Scheme 3

In the case of complex **4**, the ^{1}H NMR spectrum at room temperature shows three signals characteristic of the CH (δ = 5.59 ppm) and the methyl substituents (δ = 2.34, 2.22 ppm) of the pyrazolyl group. The other resonances are broad signals centred at δ = 5.29 (4 H), 3.71 ppm (2 H) and a large signal between δ = 3.2 and 1.8 ppm (10 H). The signals at δ = 5.29 and 3.71 ppm are in the area characteristic of the olefinic protons of 1,5-COD *trans* to a phosphorus atom and *trans* to a nitrogen atom.[19] Thus, we can deduce that the signal at δ = 5.29 ppm is due to the two olefinic protons of 1,5-COD and the two protons of the methylene group bonded to the nitrogen of the pyrazolyl ring. The large signal is due to both the protons of the methylene group bonded to phosphorus and the alkyl protons of 1,5-COD. These observations suggest that complex **4** undergoes a fluxional process, and variable-temperature experiments were performed at 500 MHz. By lowering the temperature to 230 K, each resonance splits into two more signals at δ = 5.43 and 5.25 ppm for the olefinic protons *trans* to the phosphorus atom, and δ = 3.85 and 3.46 ppm for the olefinic protons *trans* to the nitrogen atom, leading to four signals for the non equivalent olefinic protons of 1,5-COD. The coalescence temperature of the δ = 5.43 and 5.25 ppm resonances occurs at 280 K, while the resonances at δ = 3.85 and 3.46 ppm coalescent 290 K. This corre-

sponds to a $\Delta G^{\ddagger}$ value of 13(±1) kcal·mol^{-1} [20]. No significant differences other than the narrowing of the two signals at δ = 5.33 and 3.68 ppm are observed when the temperature was raised to 333 K. The ^{31}P NMR spectra, recorded in the same temperature range, show a doublet at δ = 28.4 ppm ($^{1}J_{Rh,P}$ = 146.3 Hz), with no other changes, other than a slight displacement with temperature. From these observations it is clear that the fluxional process implies an exchange between the two protons of 1,5-COD which are *trans* to the phosphorus atom, and between the two protons which are *trans* to the nitrogen only. No exchange between the two groups of protons could be evidenced. All this has been corroborated by ^{1}H NMR spin transfer experiments on the olefinic proton resonances. The dynamic behaviour of complex **4** can thus be rationalised in terms of boat-boat configuration inversion of the six-membered ring Rh1−P1−C7−C6−N2−N1 (see Figure 2) in solution. No evidence for a hemilabile behaviour of ligand **2** in complex **4** − that would have led to an averaging of *all* the olefinic proton resonances − could be obtained in the temperature range allowed by the thermal stability of the complex.

In complexes **3** and **4**, the ligand 1,5-COD was displaced by carbon monoxide when the gas was bubbled though the solutions of the complexes in dichloromethane at room temperature, giving [Rh(CO)$_2$(**1**)][BF$_4$] (**5**) and [Rh(CO)$_2$(**2**)][BF$_4$] (**6**), respectively (Scheme 2). Complex **6** reverted back to some extent to complex **4** on evaporation of the solvent. Thus, several cycles of bubbling with carbon monoxide and vacuum drying were necessary to eliminate free 1,5-COD in order to get complex **6** in a reasonable yield.

The IR spectrum of **5** shows two strong absorption bands at 2098 and 2033 cm^{-1} due to νCO vibrations. The ^{1}H NMR spectrum proves the absence of the ligand 1,5-COD, and the appearance of two doublets at δ = 182.5 ppm ($J_{Rh,C}$ = 69.8 Hz) and δ = 181.5 ppm ($J_{Rh,C}$ = 67.3 Hz) in the ^{13}C NMR spectrum confirms the presence of two CO ligands coordinated to the rhodium atom.

The IR spectrum of **6** shows two strong absorption bands at 2103 and 2042 cm^{-1} in the νCO region. Its ^{1}H NMR spectrum confirms the decoordination of the 1,5-COD ligand. The ^{13}C NMR spectrum displays resonances assigned to the two CO ligands as doublet of doublets at δ = 184.8 ppm ($J_{Rh,C}$ = 67 Hz, $J_{P,C}$ = 16 Hz) for the CO *trans* to the nitrogen atom, and at δ = 179.9 ppm ($J_{Rh,C}$ = 60 Hz, $J_{P,C}$ = 104 Hz) for the CO *trans* to the phosphorus atom. The ^{31}P NMR spectrum of **6** displays a doublet at δ = 30.2 ppm with $J_{Rh,P}$ = 120.9 Hz.

The reaction of [Rh(COD)(THF)$_2$][BF$_4$], generated in situ from the reaction of [Rh(COD)Cl]$_2$ and AgBF$_4$ in tetrahydrofuran, and two equivalent amounts of the ligand **1** led to **3** only. This is not surprising since it is known that NN ligands cannot displace 1,5-COD in [Rh(COD)(NN)]BF$_4$ complexes.[23] The same reaction starting with **2** resulted in the formation of a yellow-orange complex **7** in a 92% yield. Elemental analyses and spectroscopic data supported the formation of the [Rh(**2**)$_2$][BF$_4$] complex. The ^{1}H and ^{13}C NMR spectra display the expected signals of the ligand, whereas the ^{31}P NMR spectrum shows a doublet at δ = 44.9 ppm with $^{1}J_{Rh,P}$ = 171 Hz. This complex was also characterised by X-ray crystallography. The molecular structure of **7** consists of discrete [Rh(**2**)$_2$]$^{+}$ cations and BF$_4^{-}$ anions. The cation complex is shown in Figure 3, selected bond lengths and angles are provided in Table 1, and the details of the data collection and crystal data are summarised in Table 2. The structure shows a planar geometry around the rhodium atom, the phosphorus atoms of the two **2** ligands are in a *cis* position. The metal slightly deviates from the mean coordination plane formed by the two N and the two P donor atoms by 0.031 Å. The Rh−N [2.119(2) and 2.113(2) Å] and the Rh−P bond lengths [2.207(1) and 2.223(1) Å] are consistent with those found in the literature.[19,21,22] Phenyl rings are oriented face to face at a distance of 3.287 Å, suggesting a π-π stacking interaction[24]. The P1−Rh1−P2 angle [99.03(3)°] is larger than 90°, and as a consequence the N3−Rh1−P2 angle [83.43(6)°] is more acute than the others [N3−Rh1−N1 = 88.37(9)°; N1−Rh1−P1 = 89.13(7)°].

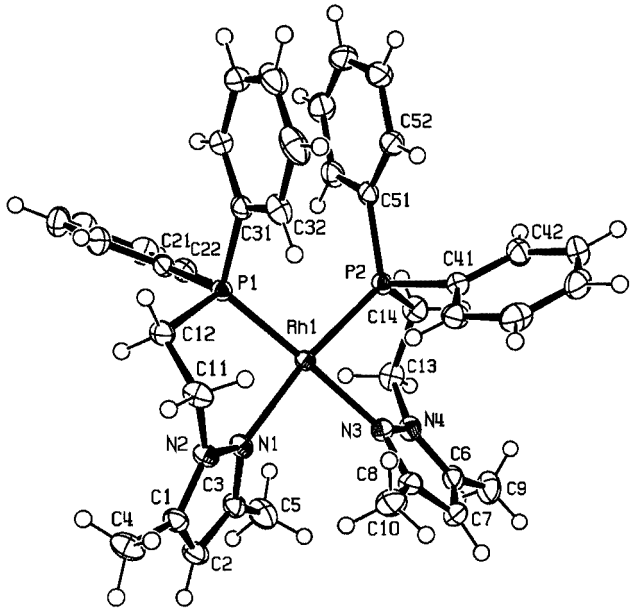


Figure 3. A perspective view of the cation [Rh(**2**)$_2$]$^{+}$ showing the numbering scheme

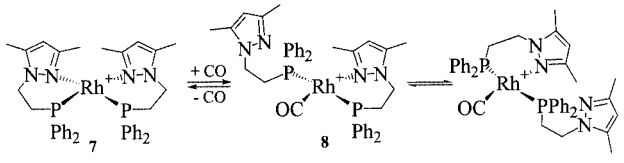
To prove the hemilabile behaviour of the ligand **2** in **7**, carbon monoxide was bubbled into a solution of the complex in dichloromethane. This led to the formation of a new compound that was characterised by IR and NMR spectroscopy as [Rh(CO)(**2**)$_2$][BF$_4$] (**8**). Evaporation of the solvent under vacuum or the bubbling of nitrogen into the solution of **8** slowly regenerated **7**. In solution, **8** shows a νCO absorption band at 2014 cm^{-1}. At room temperature the ^{1}H, ^{13}C, and ^{31}P NMR spectra indicate that the two **2** ligands are equivalent, thus suggesting a fluxional process in solution. Variable temperature ^{31}P{^{1}H} and ^{1}H NMR experiments were performed. The most informative results were obtained from the ^{31}P{^{1}H} experiments in CD_2Cl_2 solution. Indeed, the room temperature spectrum shows a doublet at

δ = 25.8 ppm ($J_{Rh,P}$ = 122 Hz). Lowering the temperature first induces a progressive broadening of the signal to give a broad resonance centred at δ = 23.9 ppm at 193 K. At 173 K, the lowest temperature we could attain, a slightly broad ABX spin system appears. The parameters of the system (δ_A = 28.1 ppm, δ_B = 19.5 ppm; $J_{A,B}$ = 291 Hz, $J_{A,X}$ = 120 Hz, $J_{B,X}$ = 125 Hz) are consistent with a square planar structure in which the two phosphorus atoms are in a *trans* position, and only one of the two **2** ligands is κ^2-coordinated, the second one is κ^1-coordinated by the phosphorus atom to rhodium. At the same temperature the ^{1}H NMR spectrum shows broad resonances only. The coalescence temperature, in the $^{31}P\{^1H\}$ NMR spectra lead to a $\Delta G^{\ddagger}$ value of 8($\pm$1) kcal·mol^{-1}.[20] The fluxionality observed for **8** most likely results from an exchange between the κ^2 and κ^1 modes of bonding for the two **2** ligands, by the opening of one of the rhodium-pyrazolyl bonds. The same type of dynamic process was previously observed for the [Ir(PN)$_2$(CO)][PF$_6$] complex [PN = 1-(2-pyridyl)-2-(diphenylphosphanyl)ethane],[23] and this is frequently observed in complexes containing two hemilabile bidentate ligands.[2,3] Scheme 4 summarises our observations.



Scheme 4

The catalytic activity of complexes **4** and **7** has been evaluated for the hydroformylation of styrene. Under our experimental conditions (dichloromethane as the solvent, 20 bar of a 1:1 mixture of CO and H_2, 50 °C) a low conversion was observed (1% for **4** and 10% for **7**), and only the branched aldehyde was detected.

Conclusions

In this work we have described the synthesis of the new potentially hemilabile N,P bidentate ligand, 1-[2-(diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole (**2**). The reaction of **2** and the related N,N′ bidentate ligand 1-[2-(ethylamino)ethyl]-3,5-dimethylpyrazole (**1**) with the rhodium(I) complex [Rh(COD)(THF)$_2$]BF$_4$ has led to the complexes [Rh(COD)(**1**)]BF$_4$ (**3**) and [Rh(COD)(**2**)]BF$_4$ (**4**), which have been fully characterised. Both these compounds exhibit a fluxional process in solution that can be interpreted in terms of a hemilabile behaviour of the ligand **1** in complex **3**, and a boat-boat ring inversion of the six-membered ring formed on coordination of the ligand **2** in complex **4**. The 1,5-COD ligand in complexes **3** and **4** can easily be displaced by carbon monoxide, leading to the complexes [Rh(CO)$_2$(**1**)]BF$_4$ (**5**) and [Rh(CO)$_2$(**2**)]BF$_4$ (**6**), respectively. The reaction of two equivalents of **2** with [Rh(COD)(THF)$_2$]BF$_4$ leads to [Rh(**2**)$_2$][BF$_4$] (**7**), in which the phosphorus atoms are in a *cis* position. The latter complex reversibly absorbs one molecule of CO to afford complex [Rh(**2**)$_2$(CO)][BF$_4$] (**8**). NMR studies of complex **8** show a dynamic exchange between the κ^2 and κ^1 modes of bonding for the two **2** ligands, by the opening of one of the rhodium-pyrazolyl bonds. In spite of this hemilabile property of ligand **2**, complex **7** shows a low activity for the catalytic hydroformylation of styrene.

Experimental Section

General Procedures: All chemicals were used as received from commercial suppliers, unless otherwise indicated. Reactions were carried out under a dinitrogen atmosphere using vacuum line and Schlenk techniques. Solvents were dried and distilled according to standard procedures and stored under nitrogen. NMR spectra were acquired on a Bruker AC200, AC250, Avance DPX250, or Avance DRX500 spectrometer in $CDCl_3$ solutions, unless otherwise indicated. All the chemical shifts are given in ppm and are referenced with respect to residual protons in the solvent for ^{1}H spectra, to solvent signals for ^{13}C spectra and to external H_3PO_4 for ^{31}P spectra. IR spectra were recorded on a Perkin−Elmer 2000 spectrophotometer with KBr pellets or in dichloromethane solutions with CaF_2 cells. Elemental analyses were performed at the Laboratoire de Chimie de Coordination on a Perkin−Elmer 2400 CHN analyser or at the Universitat Autònoma de Barcelona on a Carlo Erba CHNS EA-1108 apparatus. Electronic impact mass spectra were measured by the staff of the Mass Spectrometry Service at the Université Paul Sabatier (Toulouse). [Rh(COD)Cl$_2$] was prepared according to a literature procedure.[25]

Synthesis of 1-(Chloroethyl)-3,5-dimethylpyrazole:[18] 3,5-Dimethylpyrazole (1.00 g, 10.4 mmol), 40% aq. NaOH (12 mL), tetrabutylammonium bromide (TBAB, 0.483 g, 1.5 mmol), toluene (20 mL), and 1-bromo-2-chloroethane (10 mL, 17.23 g, 120 mmol) were mixed and heated to reflux for 48 h. The mixture was allowed to cool to room temperature, the phases were separated and the aqueous phase was extracted with 3 × 20 mL of dichloromethane. The extracts were combined with the organic phase and the solvents were then removed under vacuum. Addition of diethyl ether (15 mL), filtration and evaporation of the solvent yielded 1-(chloroethyl)-3,5-dimethylpyrazole as a colourless oil. Yield: 88%. M.p. 20−22 °C. $C_7H_{11}ClN_2$ (158.6) (%): calcd. C 53.00, H 6.99, N 17.66; found C 52.69, H 6.63, N 17.83. IR (neat between KBr cells): $\tilde{\nu}$ [cm^{-1}] = 3046 (νC−H$_{ar}$), 2967−2871 (νC−H$_{al}$), 1555 (νC=C$_{ar}$, νC=N$_{ar}$), 1463 (δCH$_{3as}$), 1426 (δC=C$_{ar}$, δC=N$_{ar}$), 1388−1188 (νC−N), 860 (νC−Cl). ^{1}H NMR (250 MHz, $CDCl_3$, 20 °C): δ [ppm] = 5.74 (s, 1 H, CH pyrazole), 4.19 (t, $^3J_{H,H}$ = 6.3 Hz, 2 H, CH_2CH$_2$Cl), 3.79 (t, $^3J_{H,H}$ = 6.3 Hz, 2 H, CH$_2$CH_2Cl), 2.21 (s, 3 H, CCH$_3$), 2.15 (s, 3 H, CCH$_3$). $^{13}C\{^1H\}$ NMR (63 MHz, $CDCl_3$, 20 °C): δ [ppm] = 148.2 (*C*CH$_3$), 139.7 (*C*CH$_3$), 105.1 (CH pyrazole), 49.6 (*C*H$_2$CH$_2$Cl), 43.0 (CH$_2$*C*H$_2$Cl), 13.4 (C*C*H$_3$), 11.0 (C*C*H$_3$). Mass spectroscopic data (EI, *m*/*z*): 158[M$^{+\cdot}$], 122 [M$^+$ − Cl], 109 [M$^+$ − CH$_2$Cl], 96 [M$^{+\cdot}$− C$_2$H$_3$Cl].

Synthesis of 1-[2-(Diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole (2): A solution of *n*BuLi (100 μL, 1.6 mmol, 1.6 M in hexane) was added dropwise to a stirred solution of PPh$_2$H (300 μL, 1.724 mmol) in tetrahydrofuran (10 mL) at 0 °C. After 30 min, the solution of PPh$_2$Li was added dropwise to a stirred solution of 1-(chloroethyl)-3,5-dimethylpyrazole (0.325 g, 2.0 mmol) in tetrahydrofuran (20 mL) at 0 °C. The mixture was maintained at 0 °C for 1 h. The temperature was then raised to room temperature and

after 15 h of stirring the solvent was evaporated under vacuum. 40 mL of dichloromethane were added to the residue and the salts were extracted with 2 × 10 mL of distilled water. Evaporation of the solvent from the organic phase gives 1-[2-(diphenylphosphanyl)-ethyl]-3,5-dimethylpyrazole (**2**) as a colourless oil. Yield: 83%. M.p. 20−22 °C. $C_{19}H_{21}N_2P$ (308.4) (%): calcd. C 74.01, H 6.86, N 9.08; found C 73.72, H 6.68, N 9.28. IR (neat between KBr cells): ṽ [cm^{-1}]: 3074−3046 (νC−H_{ar}), 2923 (νC−H_{al}), 1553 (νC=C_{ar}, νC=N_{ar}), 1482 (δCH_{3as}), 1435 (δC=C_{ar}, δC=N_{ar}), 1387−1184 (νC−N), 764−704 (νP−C, δC−H_{oop}). ^{1}H NMR (200 MHz, $CDCl_3$, 20 °C): δ [ppm] = 7.48−7.29 (m, 10 H, PPh_2), 5.71 (s, 1 H, CH pyrazole), 4.10−3.99 (m, 2 H, CH_2CH$_2$PPh$_2$), 2.61−2.53 (m, 2 H, CH$_2$CH_2PPh$_2$), 2.19 (s, 3 H, CCH_3), 2.06 (s, 3 H, CCH_3). ^{13}C{^{1}H} NMR (63 MHz, $CDCl_3$, 20 °C): δ [ppm] = 147.3 (*C*CH_3), 138.2 (*C*CH_3), 132.7−128.3 (PPh_2), 104.8 (CH pyrazole), 45.4 (d, $^2J_{P,C}$ = 25.0 Hz, *C*H$_2$CH$_2$PPh$_2$), 29.4 (d, $^1J_{P,C}$ = 14.4 Hz, CH$_2$*C*H$_2$PPh$_2$), 13.4 (C*C*H$_3$), 10.8 (C*C*H$_3$). ^{31}P{^{1}H} NMR (81 MHz, $CDCl_3$, 20 °C): δ [ppm] = −20.9 (PPh_2). Mass spectroscopic data (EI, *m/z*): 308 [M$^{+\cdot}$], 231 [M$^+$ − Ph], 123 [M$^+$ − PPh_2], 109 [M$^+$ − CH_2PPh_2], 96 [M$^{+\cdot}$ − $C_2H_3PPh_2$].

Synthesis of [Rh(COD)(1)][BF$_4$] (3): $AgBF_4$ (0.062 g, 0.320 mmol) was added to a solution of [Rh(COD)Cl_2] (0.079 g, 0.160 mmol) in tetrahydrofuran (20 mL). A white solid precipitated (AgCl). After 30 min of stirring the solid was filtered off and 1-[2-(ethylamino)-ethyl]-3,5-dimethylpyrazole ligand (**1**) (0.054 g, 0.320 mmol) was added to the filtrate, leading to the precipitation of complex **3** as a yellow solid. The complex was crystallised in a dichloromethane/ether mixture. Yield: 89%. M.p. 135−137 °C (dec.). $C_{17}H_{29}BF_4N_3Rh$ (465.1) (%): calcd. C 43.90, H 6.28, N 9.03; found C 43.82, H 6.16, N 8.90. IR (KBr): ṽ [cm^{-1}]: 3275 (νN−H), 2960−2835 (νC−H_{al} ligand+COD), 1553 (νC=C_{ar}, νC=N_{ar}), 1469 (δCH_{3as} ligand/δCH_2 COD), 1432 (δC=C_{ar} ligand+COD, δC=N_{ar}), 1386−1188 (νC−N), 1069−964 (νB−F), 801 (δ =CH_{oop} COD), 771 (δC−H_{oop} ligand+COD). ^{1}H NMR (500 MHz, $CDCl_3$, 20 °C): δ [ppm] = 5.87 (s, 1 H, CH pyrazole), 5.51, 4.56 (AB, 2 H, CH_2CH$_2$NHEt), 4.49, 4.40, 4.30, 4.21 (m, 4 H, =CH COD), 4.15 (b, 1 H, NH), 3.54, 2.41 (AB, 2 H, CH$_2$CH_2NHEt), 2.64 (m, 2 H, CH_2 COD), 2.41 (m, 1 H, CH_2CH$_3$), 2.31 (s, 3 H, CCH_3), 2.28 (s, 3 H, CCH_3), 2.19−2.11, 1.67 (m, 6 H, CH_2 COD), 1.71−1.65 (m, 4 H, CHH_{endo} COD), 1.44 (t, $^3J_{H,H}$ = 7.0 Hz, 3 H, CH$_2$CH_3), 1.30 (m, 1 H, CH_2CH$_3$). ^{13}C{^{1}H} NMR (63 MHz, $CDCl_3$, 20 °C): δ [ppm] = 149.4 (*C*CH_3), 142.4 (*C*CH_3), 108.0 (CH pyrazole), 83.6−81.4 (m, =CH COD), 49.8, 49.3 (*C*H$_2$*C*H$_2$NHCH$_2$CH$_3$), 32.2 (*C*H$_2$CH$_3$), 29.0,28.6 (CH_2 COD), 15.6 (CH$_2$*C*H$_3$), 14.0 (C*C*H$_3$), 11.3 (C*C*H$_3$).

Synthesis of [Rh(COD)(2)][BF$_4$] (4): $AgBF_4$ (0.062 g, 0.320 mmol) was added to a solution of [Rh(COD)Cl_2] (0.079 g, 0.160 mmol) in tetrahydrofuran (20mL). A white solid precipitated (AgCl). The solid was then filtered of and 1-[2-(diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole (**2**) (0.099 g, 0.320 mmol) was added to the filtrate solution. After 1 h of stirring, the solvent was evaporated under vacuum and the residue was crystallised in a dichloromethane/ether mixture to give yellow crystals of complex **4**. Yield: 94%. M.p. 208−210 °C (dec.). $C_{27}H_{33}BF_4N_2PRh$ (606.3) (%): calcd. C 53.48, H 5.50, N 4.62; found C 53.06, H 5.17, N 4.41. IR (KBr): ṽ [cm^{-1}]: 3074 (νC−H_{ar}), 2994−2828 (νC−H_{al} ligand+COD), 1555 (νC=C_{ar}, νC=N_{ar}), 1483−1467 (δCH_{3as} ligand/δCH_2 COD), 1436−1428 (δC=C_{ar} ligand+COD, δC=N_{ar}), 1389−1162 (νC−N), 1102−948 (νB−F), 862 (δ =CH_{oop} COD), 777−700 (νP−C, δC−H_{oop} ligand+COD). ^{1}H NMR (250 MHz, $CDCl_3$, 20 °C): δ [ppm] = 7.37 (b, 10 H, PPh_2), 5.59 (s, 1 H, CH pyrazole), 5.29 (b, 2 H, = CH COD *trans* P), 5.33, 5.15 (AB, 2 H, CH_2CH$_2$PPh$_2$), 3.71 (b, 2 H, =CH COD *trans* N), 2.67 (b, 2 H, CH$_2$CH_2PPh$_2$), 2.48 (b, 4 H, CHH_{exo} COD), 2.34 (s, 3 H, CCH_3), 2.22 (s, 3 H, CCH_3), 2.16 (b, 4 H, CHH_{endo} COD). ^{13}C{^{1}H} NMR (50 MHz, $CDCl_3$, 20 °C): δ [ppm] = 149.4 (*C*CH_3), 143.1 (*C*CH_3), 132.7−128.6 (PPh_2), 108.0 (CH pyrazole), 104.8−103.4 (m, =CH COD *trans* P), 78.6−77.5 (m, =CH COD *trans* N), 48.5 (d, $^2J_{P,C}$ = 5.8 Hz, *C*H$_2$CH$_2$PPh$_2$), 27.9−27.4 (*C*H_2 COD), 27.6 (d, $^1J_{P,C}$ = 27.7 Hz, CH$_2$*C*H$_2$PPh$_2$), 15.2 (C*C*H$_3$), 11.3 (C*C*H$_3$). ^{31}P{^{1}H} NMR (81 MHz, $CDCl_3$, 20 °C): δ [ppm] = 28.4 (d, $^1J_{Rh,P}$ = 146.3 Hz, PPh_2).

Synthesis of [Rh(CO)$_2$(1)][BF$_4$] (5): Carbon monoxide was bubbled for 1 h into a solution of [Rh(COD)(**1**)][BF_4] (0.098 g, 0.211 mmol) in dichloromethane (20 mL). **5** was obtained in a 98% yield after evaporation of the solvent, and 1,5-COD was liberated under vacuum. $C_{11}H_{17}BF_4N_3O_2Rh$ (413.0) (%): calcd. C 31.99, H 4.15, N 10.17; found C 32.34, H 4.12, N 9.87. IR (CH_2Cl_2 solution, CaF_2 cells): ṽ [cm^{-1}]: 2099 and 2033 (νCO). ^{1}H NMR (250 MHz, $CDCl_3$, 20 °C): δ [ppm] = 6.08 (s, 1 H,CH pyrazole), 5.60, 4.45 (AB, 2 H, CH_2CH$_2$NHEt), 4.48 (b, 1 H, NH), 3.61, 2.65 (AB, 2 H, CH$_2$CH_2NHEt), 2.88 (m, 2 H, CH_2CH$_3$), 2.43 (s, 3 H, CCH_3), 2.38 (s, 3 H, CCH_3), 1.34 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H, CH$_2$CH_3). ^{13}C{^{1}H} NMR (63 MHz, $CDCl_3$, 20 °C): δ [ppm] = 182.5 (d, $J_{Rh,C}$ = 69.8 Hz, CO), 181.1 (d, $J_{Rh,C}$ = 67.3 Hz, CO), 151.3 (*C*CH_3), 144.1 (*C*CH_3), 107.6 (CH pyrazole), 50.4, 49.6, 47.8 (*C*H$_2$*C*H$_2$NHCH$_2$CH$_3$, *C*H$_2$CH$_3$), 14.5 (C*C*H$_3$), 14.6 (CH$_2$*C*H$_3$), 11.1 (C*C*H$_3$).

Synthesis of [Rh(CO)$_2$(2)][BF$_4$] (6): Carbon monoxide was bubbled for 1 h into a solution of [Rh(COD)(**2**)][BF_4] (0.170 g, 0.280 mmol) in dichloromethane (20 mL), and **6** was obtained. The complex partially reverted back to the reactants when the solvent was evaporated under vacuum, therefore, six cycles of bubbling carbon monoxide and evaporation under vacuum were carried out in order to isolate **6** in a pure form. $C_{21}H_{21}BF_4N_2O_2PRh$ (554.1) (%): calcd. C 45.52, H 3.82, N 5.06; found C 45.02, H 3.49, N 5.21. IR (CH_2Cl_2 solution, CaF_2 cells): ṽ [cm^{-1}]: 2103 and 2042 (νCO). ^{1}H NMR (200 MHz, CD_3COCD_3, 20 °C): δ [ppm] = 7.82−7.56 (m, 10 H, PPh_2), 6.01 (s, 1 H, CH pyrazole), 5.08−4.91 (m, 2 H, CH_2CH$_2$PPh$_2$), 3.30−3.19 (m, 2 H, CH$_2$CH_2PPh$_2$), 2.38 (s, 3 H, CCH_3), 2.32 (s, 3 H, CCH_3). ^{13}C{^{1}H} NMR (63 MHz, CD_2Cl_2, 20 °C): δ [ppm] = 184.8 (dd, $J_{Rh,C}$ = 67 Hz, $J_{P,C}$ = 15.8 Hz CO), 179.9 (dd, $J_{Rh,C}$ = 60 Hz, $J_{P,C}$ = 103.5 Hz CO), 151.3 (*C*CH_3), 145.0 (*C*CH_3), 133.7−128.6 (PPh_2), 108.3 (CH pyrazole), 47.2 (*C*H$_2$CH$_2$PPh$_2$), 27.2 (d, $^1J_{P,C}$ = 30.3 Hz, CH$_2$*C*H$_2$PPh$_2$), 15.3 (C*C*H$_3$), 11.5 (C*C*H$_3$). ^{31}P{^{1}H} NMR (81 MHz, CD_3COCD_3, 20 °C): δ [ppm] = 30.2 (d, $^1J_{Rh,P}$ = 120.9 Hz, PPh_2).

Synthesis of [Rh(2)$_2$][BF$_4$] (7): $AgBF_4$ (0.062 g, 0.32 mmol) was added to a solution of [Rh(COD)Cl_2] (0.079 g, 0.160 mmol) in tetrahydrofuran (20 mL). After filtration of AgCl, 1-[2-(diphenylphosphanyl)ethyl]-3,5-dimethylpyrazole (**2**) (0.221 g, 0.717 mmol) was added to the filtrate solution. The solvent was then removed under vacuum and the yellow-orange residue of complex **7** was washed with pentane and crystallised in a dichloromethane/ether mixture. Yield: 92%. M.p. 147−150 °C (dec.). $C_{39}H_{44}BCl_2F_4N_4P_2Rh$ (891.4) (%): calcd. C 52.55, H 4.98, N 6.29; found C 52.57, H 4.93, N 6.19. IR (KBr): ṽ [cm^{-1}]: 3054 (νC−H_{ar}), 2960−2919 (νC-H_{al}), 1551 (νC=C_{ar}, νC=N_{ar}), 1480−1466 (δCH_{3as}), 1435−1429 (δC=C_{ar}, δC=N_{ar}), 1392−1177 (νC−N), 1098−999 (νB−F), 744−696 (νP−C, δC−H_{oop}). ^{1}H NMR (250 MHz, $CDCl_3$, 20 °C): δ [ppm] = 7.65 (b, 20 H, PPh_2), 5.57 (s, 2 H, CH pyrazole), 4.75 (m, 4 H, CH_2CH$_2$PPh$_2$), 2.70 (m, 4 H, CH$_2$CH_2PPh$_2$), 2.29 (s, 6 H, CCH_3), 1.79 (s, 6 H, CCH_3). ^{13}C{^{1}H} NMR (63 MHz, $CDCl_3$, 20 °C): δ [ppm] = 150.6 (*C*CH_3), 140.6 (*C*CH_3), 135.2−127.8 (PPh_2), 106.7 (CH pyrazole), 47.2 (*C*H$_2$CH$_2$PPh$_2$), 33.5 (d, $^1J_{P,C}$ = 28.0 Hz,

Synthesis of [Rh(CO)(2)$_2$][BF_4] (8): [Rh(**2**)$_2$][BF_4] (0.070 g, 0.087 mmol) in dichloromethane (20 mL) was bubbled with carbon monoxide for 1 h and [Rh(CO)(**2**)$_2$][BF_4] was obtained. The complex was characterised in solution after bubbling nitrogen to eliminate dissolved carbon monoxide, as it reverted back to **7** when the solvent was evaporated under vacuum. IR (CH_2Cl_2 solution, CaF_2 cells): ν̃ [cm^{-1}]: 2088 and 2014 (νCO). ^1H NMR (250 MHz, $CDCl_3$, 20 °C): δ [ppm] = 7.96−6.70 (m, 20 H, PPh_2), 5.50 (s, 2 H, CH pyrazole), 4.53 (m, 4 H, $CH_2CH_2PPh_2$), 2.94 (broad, 4 H, $CH_2CH_2PPh_2$), 2.09 (s, 6 H, CCH_3), 1.85 (s, 6 H, CCH_3). $^{13}C\{^1H\}$ NMR (63 MHz, $CDCl_3$, 20 °C): δ [ppm] = 190.1 (broad d, CO, $J_{Rh,C}$ = 72 Hz), 148.8 (CCH_3), 141.5 (CCH_3), 135.4−127.9 (PPh_2), 106.5 (CH pyrazole), 45.9 ($CH_2CH_2PPh_2$), 29.7 (t, $J_{P,C}$ = 12.5 Hz, $CH_2CH_2PPh_2$), 14.0 (CCH_3), 10.97 (CCH_3). $^{31}P\{^1H\}$ NMR (101 MHz, $CDCl_3$, 20 °C): δ [ppm] = 25.8 (d, $^1J_{Rh,P}$ = 122.5 Hz, PPh_2).

X-ray Crystallographic Study: Crystals of **3**, **4**, and **7** suitable for X-ray diffraction were obtained through recrystallisation from dichloromethane/diethylether mixtures. Data were collected at 293 K for **3** and 160 K for **4** and **7** on a STOE IPDS diffractometer. Full crystallographic data for the three complexes are gathered in Table 2. All calculations were performed on a PC-compatible computer using the WinGX system.[26] The structures were solved by using the SIR92 program,[27] which revealed in each instance the position of most of the non-hydrogen atoms. All remaining non-hydrogen atoms were located by the usual combination of full-matrix least-squares refinement and difference electron density syntheses by using the SHELXS-97 program.[28] Atomic scattering factors were taken from the usual tabulations.[29] Anomalous dispersion terms for Rh, and P (for complexes **4** and **7**) were included in F_c.[30] All non-hydrogen atoms were allowed to vibrate anisotropically. All the hydrogen atoms were set in idealised positions [R_3CH, C−H = 0.96 Å; R_2CH_2 = 0.97 Å; $C(sp^2)$−H = 0.93 Å; U_{iso} 1.2 time greater than the U_{eq} of the carbon atom to which the hydrogen atom is attached] and held fixed during refinements.

CCDC-184360 for **3**, 184358 for **4**, and CCDC-184359 for **7** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and X-ray Molecular Structure of $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ Completing the Structural Characterization of the Series $[W(C_6H_4S_2\text{-}1,2)_3]^{n-}$ (n = 0, 1, 2): Trigonal-Prismatic versus Octahedral Coordination in Tris(benzene-1,2-dithiolato) Complexes

HanVinh Huynh,[a] Thomas Lügger,[a] and F. Ekkehardt Hahn*[a]

Dedicated to Prof. Karl Wieghardt on the occasion of his 60th birthday

Keywords: Tungsten / S ligands / Structure elucidation / Coordination modes

The tris(benzene-1,2-dithiolato) complex $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ **1** was synthesized from $[W(CH_3)_6]$ and $C_6H_4(SH)_2$-1,2 in diethyl ether. Crystals of $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ were obtained from a saturated dichloromethane solution at room temperature. The X-ray crystal structure analysis revealed that the tungsten atom in **1** is coordinated in an almost perfect trigonal-prismatic fashion with W–S distances between 2.3724(14) Å and 2.3840(14) Å.

Introduction

The first molecular trigonal-prismatic tris(dithiolene) metal complex was reported in 1965.[1] Ever since, the reasons for the formation of complexes with a trigonal-prismatic coordination geometry over octahedral complexes have been discussed extensively.[2] In addition, the "non-innocent" nature of benzenedithiolato ligands and their derivatives has more recently become a field of considerable interest.[3] Nevertheless, the trigonal-prismatic coordination geometry is not limited to tris(dithiolene) complexes, but can also be observed for some hexaarylthiolato[4] and hexaorgano complexes with six monodentate ligands. The latter complexes have received a great deal of attention since the molecular structure of the complex $[Li(tmed)]_2[Zr(CH_3)_6]$ containing a distorted trigonal-prismatic coordinated zirconium atom was reported.[5] Recently, $[M(CH_3)_6]^{z-}$ complexes of Ta (z = 1), Nb (z = 1), Re (z = 0) and W (z = 0) have been characterized by X-ray diffraction revealing a regular to slightly distorted trigonal-prismatic coordination geometry.[6] Theoretical studies indicate that d^0 ions in particular tend to form complexes with a trigonal-prismatic geometry.[2c,2d,7] However, the pseudo-octahedral d^0 complex dianion $[Zr^{IV}(C_6H_4S_2\text{-}1,2)_3]^{2-}$ is one of the few exceptions to this postulate.[8] The coordination geometry in $[Mo^{VI}(C_6H_4S_2\text{-}1,2)_3]$ is, as expected, trigonal-prismatic (average twist angle 0°)[9] while the geometry of $[Mo^{V}(C_6H_4S_2\text{-}1,2)_3]^-$ was found to be closer to octahedral (average twist angle 33.5°)[10] than to trigonal-prismatic. Based on this observation a geometry with an even larger twist angle and therefore even closer to octahedral geometry would be expected for the structurally as-yet-uncharacterized d^2 complex $[Mo^{IV}(C_6H_4S_2\text{-}1,2)_3]^{2-}$. However, in the homologous series of tungsten complexes the derivative $[W^{V}(C_6H_4S_2\text{-}1,2)_3]^-$ exhibits a geometry analogous to the Mo^V complex in-between octahedral and trigonal-prismatic (average twist angle 33°),[11] while the complex $[W^{IV}(C_6H_4S_2\text{-}1,2)_3]^{2-}$ is clearly trigonal-prismatic (average twist angle 3.5°).[12] It appears that the stepwise reduction of the d^0 M^{VI} center does not always enhance the tendency for the formation of octahedral complexes. However, the molecular structure of $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ has not been described. To compare the molecular structures of the complete series of complexes $[W(C_6H_4S_2\text{-}1,2)_3]^{n-}$ (n = 0, 1, 2) we prepared the missing derivative $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ and determined its molecular structure by X-ray diffraction.

Results and Discussion

In connection with our research on helicates with benzene-1,2-dithiolato ligands[13] we investigated methods for the preparation of $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$. Published syntheses of tris(benzene-1,2-dithiolato) transition metal complexes[2d] involve the reaction of metal halides with an excess of benzene-1,2-dithiol in CCl_4 with liberation of gaseous HCl. The moderate yields as well as the solvent tox-

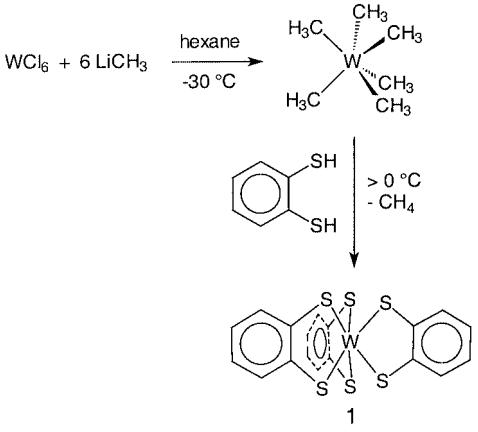
icity and the highly reactive by-product in these syntheses proved disadvantageous in our opinion. A rather exotic way to prepare hexakis(arylthiolato) zirconate complexes with six monodentate thiolato ligands using $[Zr(CH_3)_6]^{2-}$ as a precursor was reported by Giolando et al.[4] Using this approach, we have improved the synthesis for $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ (**1**) by reacting $[W(CH_3)_6]$ with three equivalents of benzene-1,2-dithiol in diethyl ether with formation of unreactive methane gas (Scheme 1). The product can be isolated in pure form and in yields of about 70%. The perorgano precursor was prepared in situ from WCl_6 and CH_3Li in diethyl ether similar to a literature method.[14] Bright purple, air-stable crystals of **1** can be obtained from a saturated turquoise dichloromethane solution at ambient temperature.



Scheme 1. Preparation of $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ from $[W(CH_3)_6]$

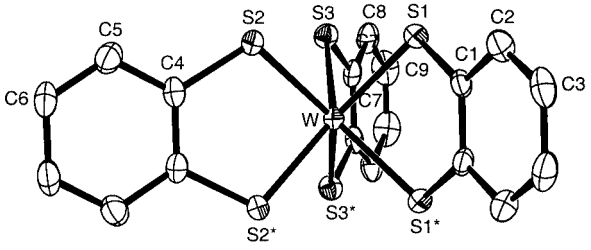


Figure 1. Molecular structure of $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ (**1**) with the crystallographic numbering scheme; hydrogen atoms have been omitted; starred atoms are related to their corresponding atoms by a crystallographic mirror plane; selected bond lengths [Å] and angles [°]: W−S1 2.3840(14), W−S2 2.3836(13), W−S3 2.3724(14), S1−C1 1.743(5), S2−C4 1.747(5), S3−C7 1.742(6); S1−W−S1* 81.97(7), S1−W−S2 80.89(5), S1−W−S2* 134.42(5), S1−W−S3 81.96(5), S1−W−S3* 136.33(5), S2−W−S2* 81.73(6), S2−W−S3 82.02(5), S2−W−S3* 136.24(5), S3−W−S3* 82.30(7), C1−S1−W 103.21(17), C4−S2−W 107.92(18), C7−S3−W 106.17(19)

Figure 1 shows the molecular structure of the neutral complex **1** along with the crystallographic numbering scheme. The molecular geometry of complex **1** is remarkably similar to its lower homologue $[Mo^{VI}(C_6H_4S_2\text{-}1,2)_3]$.[9] The tungsten(VI) ion is coordinated by six sulfur atoms of three benzene-1,2-dithiolato ligands in an almost perfect trigonal-prismatic fashion with a crystallographically imposed twist angle of 0°. A value of 60° would be typical for an octahedron.[8,15] In addition, the WS_6 core deviates less from D_{3h} symmetry than the WC_6 core found in the organometallic precursor.[6] The mean W−S bond length of 2.380 Å, interligand S···S distance of 3.111 Å and intraligand S···S distance of 3.123 Å are slightly longer than those reported for the isostructural Mo^{VI} complex [mean values: *d*(Mo-S) 2.367 Å, *d*(S···S, interligand) 3.091 Å, *d*(S···S, intraligand) 3.110 Å]. This observation can be explained by taking into account the slightly greater ionic radius of W^{VI} compared to that of Mo^{VI}. As expected, the average C−S bond length of 1.727 Å in **1** falls in the range observed for the isostructural molybdenum(VI) complex. As observed for the Mo^{VI} complex the $S_2C_6H_4$ planes in **1** deviate from the WS_2 planes (13.5°, 22.6°, 32.7°) thereby enforcing a deviation from ideal D_{3h} symmetry for the complex (Figure 2).

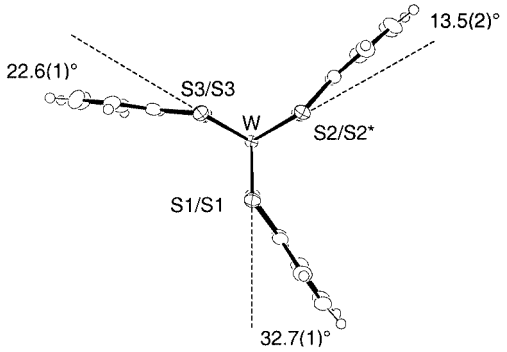

Figure 2. View of $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ projected down the approximate molecular threefold axis, showing the bend of the ligands

A comparison of the molecular structures of the members of the series $[W(C_6H_4S_2\text{-}1,2)_3]^{n-}$ (n = 0, 1, 2) shows no clear correlation of electronic configuration or overall charge of the complexes and the molecular geometry. The one-electron reduction of trigonal-prismatic $[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ results in pseudooctahedral $[W^{V}(S_2C_6H_4)_3]$,[11] with an average twist angle of 33°. The pseudooctahedral coordination was also observed for the analogous Mo^{V} complex.[10] Here it was explained by the occupation of the π-antibonding $4a_1'$ molecular orbital causing destabilization of both S···S interactions and M−S bonds and leading to an octahedral distortion.[10] Following this argument for the tungsten complexes, dianionic $[W^{IV}(C_6H_4S_2\text{-}1,2)_3]^{2-}$ should adopt a symmetry even closer to octahedral than the W^{V} complex due to the fully occupied $4a_1'$ orbital. Surprisingly, this assumption was disproved by the close trigonal-prismatic structure found for $[W^{IV}(C_6H_4S_2\text{-}1,2)_3]^{2-}$,[12] with an average twist angle of only 3.5°. Table 1 summarizes structural parameters for the series $[W(C_6H_4S_2\text{-}1,2)_3]^{n-}$ (n = 0, 1, 2).

From the variation of the twist angles Φ in the series $[M(C_6H_4S_2\text{-}1,2)_3]^{n-}$ (M = Mo, W; n = 0, 1, 2) it appears that the d-electron configuration is not the only governing principle for the formation of a certain coordination geometry. The M^{VI} complexes exhibit a trigonal-prismatic WS_6 core and the one-electron reduction leads to a distorted octahedral geometry. Further reduction leads, at least in the case of W^{IV}, again to an almost trigonal-prismatic geometry. The recently reported structural characterization of two other tris(dithiolene) series[16] $[M\{S_2C_2(CH_3)_2\}_3]^{n-}$

Table 1. Selected mean bond lengths and twist angles for the series $[W(C_6H_4S_2\text{-}1,2)_3]^{n-}$ (n = 0, 1, 2)

(M = Mo, n = 0, −1, −2; M = W, n = −1, −2) revealed distorted trigonal-prismatic structures for all members. These results indicate, once again, that the stabilization of the trigonal-prismatic structure is not only governed by electronic factors but must be considered a complicated process involving various factors.

Experimental Section

General Remarks: Unless stated otherwise, all manipulations were carried out in an atmosphere of dry argon by means of standard Schlenk techniques. Diethyl ether and hexane were freshly distilled from Na-benzophenone prior to use.

$[W^{VI}(C_6H_4S_2\text{-}1,2)_3]$ (1): WCl_6 (198 mg, 0.5 mmol) was suspended in dry diethyl ether (30 mL) and cooled to −78 °C. With vigorous stirring MeLi (2 mL of a 1.6 M solution in diethyl ether, 3.2 mmol) was added dropwise and the mixture was allowed to warm to −35 °C. After stirring for 3 h the red-brown reaction mixture was filtered through celite into a cold solution (−30 °C) of benzene-1,2-dithiol (214 mg, 1.5 mmol) in diethyl ether (10 mL). The reaction mixture was allowed to warm to ambient temperature while methane gas evolved. The product was filtered, washed with diethyl ether (5 mL) and *n*-hexane (20 mL) and dried in vacuo. Yield 236 mg (77%). $C_{18}H_{12}S_6W$ (604.50): calcd. C 35.76, H 2.00, S 31.82; found C 35.60, H 2.13, S 31.66. Additional spectroscopic parameters were identical to those reported in 1966.[2d] Crystals of **1** were obtained from a saturated dichloromethane solution.

X-ray Crystallographic Study: A suitable crystal (0.2 × 0.2 × 0.2 mm^3) was mounted on a Bruker AXS APEX diffractometer equipped with a Mo rotating anode (λ = 0.71073 Å), a cooling device and graphite monochromator. 14512 Raw structure factors ($-19 \le h \le 19$, $-13 \le k \le 14$, $-12 \le l \le 12$, $2\Theta = 4-45°$) were collected at −120 °C using omega- and phi-scans. An empirical absorption correction was applied with SADABS[17] ($T_{min}/T_{max.}$ = 0.3379) before merging. Complex **1** crystallized in the orthorhombic space group *Pnma*, a = 16.034(5), b = 11.793(4), c = 10.276(3) Å, V = 1942.9(10) $Å^3$. Structure solution with SHELXS[18] and subsequent refinement of 139 parameters against 1516 observed [$I > 2\sigma(I)$, 1794 unique collected intensities] structure factors using SHELXL[19] with anisotropic thermal parameters for all non-hydrogen atoms revealed that the unit cell contains Z = 4 molecules $C_{18}H_{12}S_6W$ (604.49 g/mol, $d_{calcd.}$ = 2.067 g/cm^3). The tungsten atom resides at a special position on a mirror plane. Hydrogen positions were determined by difference Fourier techniques and refined with isotropic thermal parameters. Final obtained residues R_{all} = 3.81, $R_{obsd.}$ = 2.94, $R_{w,obsd.}$ = 6.98%, GOF = 1.036. ORTEP[20] was used for all drawings. CCDC-185593 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Extended Electronic Interactions in a Triangular μ-Oxotriruthenium Acetate Cluster Containing Nitric Oxide

Henrique E. Toma,*[a] Anamaria D. P. Alexiou,[a] and Sergio Dovidauskas[a]

Keywords: Ruthenium / Nitrogen oxides / Carboxylate ligands / Cluster compounds / Pi interactions

The binding of NO to the trinuclear cluster $[Ru_3O(CH_3CO_2)_6(py)_2]^+$ (py = pyridine) leads to a stable, diamagnetic $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]^+$ complex, displaying extended electronic interactions which arise from the coupling of the unpaired π^* electron of NO and the unpaired electron in the π-orbitals of the Ru_3O unit. This complex has been isolated and its spectroscopic characterization (EPR, ^1H and ^{13}C NMR, IR, UV/Vis) and electrochemical/spectroelectrochemical properties are reported in this paper. The NO^0 character in the complex is supported by spectroscopic and electrochemical results, as well as by semi-empirical theoretical calculations carried out for the complex. A remarkable point in this system is the dramatic changes in the Ru–NO electronic interactions accompanying the several successive redox states of the triangular Ru_3O center.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Triangular μ-oxoruthenium acetate clusters of general formula $[Ru_3O(CH_3CO_2)_6L_3]^n$ (L = H_2O, N-heterocycles, etc.) are particularly interesting because of their rich mixed-valence chemistry, displaying catalytic properties and versatility as building blocks in supramolecular chemistry.[1] This type of complex exhibits a series of successive oxidation states and the corresponding redox potentials are dependent of the pK_a [2] and E_L parameters[3] of the terminal ligands. In general, clusters containing all ruthenium ions in the formal oxidation state +3 and above are preferentially stabilized by σ-donor ligands (L). Mixed-valence clusters with the formal oxidation state $Ru^{III}Ru^{III}Ru^{II}$, and below, are stabilized by π-acceptor molecules such as CO[4–6] or isocyanide ligands.[7,8]

Nitric oxide is a typical non-innocent ligand. It can bind to a metal center (M) yielding a metal-nitrosyl complex, where the ligand can be classified as NO^+, $NO^{\cdot}$ or NO^-.[9–12] In recent years a great number of reports dealing with NO activity in biological systems have been published,[13–20] and ruthenium nitrosyl complexes have been exploited as potential scavengers or delivery drugs for NO into biological targets.[21–27]

Because of the several available oxidation states, the interaction between NO and the triangular μ-oxoruthenium acetate clusters can be viewed as a puzzling question, especially concerning the electronic delocalization and the nature of the redox orbitals involved. Such important aspects have been focused on in this work, starting from the synthesis and characterization of the novel clusters species $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$ (Figure 1), and carrying out a detailed investigation of its spectroscopic and electrochemical properties, and a theoretical simulation of its electronic structure based on semi-empirical methods. To the best of our knowledge, except for a brief comment by Spencer and Wilkinson on the interaction of nitric oxide with $[Ru_3O(CH_3CO_2)_6L_3]^+$ [L = CH_3OH and $P(C_6H_5)_3$] complexes,[4] the chemistry of this type of nitrosyl-triruthenium acetate cluster has never been reported before.

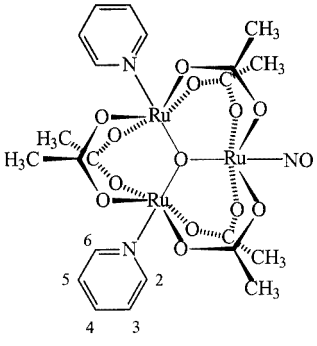

Figure 1. Structural representation of $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$; the labels of pyridine hydrogen atoms are required for the analysis of the NMR spectra

Results and Discussion

The general route for the synthesis of Ru–NO complexes based on the procedures involving $NaNO_2$ and acids[28] was initially attempted in this work, but resulted in low yields

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

and an impure product. Surprisingly, the direct reaction of $[Ru_3O(CH_3CO_2)_6(py)_2(CH_3OH)]^+$ and NO was successful, yielding a rather stable complex, isolated as $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6 \cdot CH_2Cl_2$. Its thermal stability was assayed by thermogravimetry, showing solvent loss in the range 100−253 °C and decomposition of the cluster above this temperature, indicating that the Ru−NO bonding is quite strong.

The first question concerning the nature of the $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]^+$ complex refers to its valence description, for example, as $Ru^{III}Ru^{III}Ru^{III}NO^0$ or $Ru^{III}Ru^{III}Ru^{II}NO^+$, in a formal representation. For discussion purposes, the starting $[Ru_3O(CH_3CO_2)_6(py)_2(CH_3OH)]^+$ was taken as a reference compound exhibiting a formal $Ru^{III}Ru^{III}Ru^{III}$ oxidation state. In the other extreme, the $[Ru_3O(CH_3CO_2)_6(py)_2(CO)]$ complex provides a suitable model illustrating the effects of the strong π-acceptor CO ligand in preferentially stabilizing the formal $Ru^{III}Ru^{III}Ru^{II}(CO)$ oxidation state. NO^+ is a stronger π-acceptor ligand than CO, therefore if the $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]^+$ complex involves NO^+, its acceptor properties would exceed those of the CO analog in terms of π-backbonding effects. In contrast, in the NO^0 form the available π*-electron can preferentially stabilize the $Ru^{III}Ru^{III}Ru^{III}$ cluster by coupling with the ruthenium d_π-electrons. In fact, such an electronic balance is supposed to be very delicate, and the NO^+ or NO^0 character will actually depend upon the relative energies of the metal cluster and NO frontier orbitals.

The complex $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6 \cdot CH_2Cl_2$ exhibits a small room temperature molar paramagnetic susceptibility (6.7×10^{-4} cgs unit) very similar to that determined under the same conditions for the complex $[Ru_3O(CH_3CO_2)_6(py)_2(CO)] \cdot C_6H_6$ (6.8×10^{-4} cgs unit). Presumably, the small paramagnetism in both complexes reflects the temperature-independent paramagnetic susceptibility arising from the mixing with the excited states, which has previously been estimated to fall within the range $2.3-27 \times 10^{-4}$ cgs unit.[29,30] No EPR signal was seen at either room or liquid nitrogen temperatures for the complex $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$, thus suggesting a strong coupling between the available π*-electron in NO^0 and the ruthenium d_π-electrons in the $Ru^{III}Ru^{III}Ru^{III}$ cluster.

Infrared Spectra

The FTIR spectrum of the cluster $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$ (Figure 2) was assigned by comparison with the data for $[Ru_3O(CH_3CO_2)_6(py)_2(CH_3OH)]PF_6$ and similar compounds described in the literature[5,31−33] (FTIR data and assignments are available as Supporting Information). The characteristic peak for the nitrosyl group is found at 1865 cm^{-1} (Figure 2), corresponding to the ν(NO) vibration. This peak is very strong and symmetric, and is not observed in the spectrum of the complex $[Ru_3O(CH_3CO_2)_6(py)_2(CH_3OH)]PF_6$. Another important observation supporting the strong binding of NO is that practically all vibrational modes of the coordinated ligands are changed in the NO complex as a consequence of the electronic perturbation. For instance, the $\nu_{as}(COO^-)$ vibrational peak observed at 1550 cm^{-1} for the methanol complex, is shifted to 1585 cm^{-1} in the NO compound.

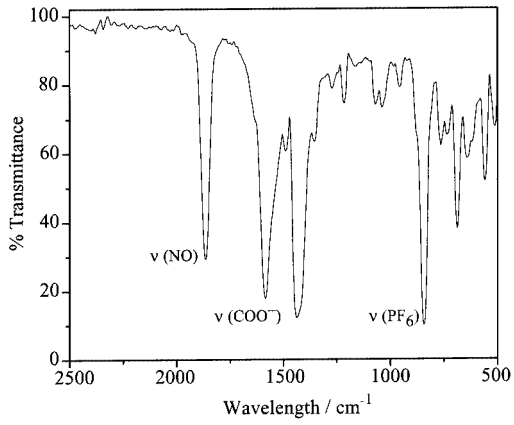

Figure 2. FT-IR spectrum of the $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$ cluster

It should be noted that the ν(NO) peak of free NO is located at 1876 cm^{-1}, but in the metal complexes it is very sensitive to the binding properties and oxidation states of the metal ion. For instance, ν(NO) frequencies for *cis*-$[Ru^{II}(bipy)_2(NO)L]$ complexes (L = N^{3-}, Cl^-, NO_2^-, NH_3, py, CH_3CN) have been observed in the range 1923−1970 cm^{-1}.[34] For $[Ru^{II}(NH_3)_5(NO)]^{3+}$ [35] and *trans*-$[Ru^{II}(NH_3)_4(NO)L]$[36] complexes [L = imidazole, L-histidine, py, isonicotinamide, pyrazine, $P(OEt)_3$], ν(NO) values span the range 1909−1941 cm^{-1}, whereas for L = SO_3^{2-}, ν(NO) = 1871 cm^{-1}. In the case of *trans*-$[Ru^{II}(py)_4(NO)L]$[37] complexes, for L = Cl^-, and Br^-, ν(NO) = 1910 and 1901 cm^{-1}, respectively, but for L = OH^-, ν(NO) = 1860 cm^{-1}. In all such examples, the ruthenium center has been considered as mainly Ru^{II}, thus imputing a predominantly NO^+ character to the nitrosyl ligand. In the case of the reduced complexes $[Ru(bipy)_2(NO)(CH_3CN)]^{2+}$ and $[Ru(bipy)_2(NO)Cl]^+$ ν(NO) is shifted to 1665 and 1640 cm^{-1}, and the spectroscopic and electrochemical data support the hypothesis of NO^+ reduction, yielding NO^0 species.[34]

In the case of *trans*-[Ru(dimethylglyoximato)(NO)Cl],[38] ν(NO) = 1878 cm^{-1} and is very close to the frequency of the free nitric oxide molecule, although a significant NO^+ character has been suggested from its observed reactivity in the presence of nucleophiles.[39] Perhaps because of its partial NO^0 character, only a small shift of ν(NO) to 1855 cm^{-1} is observed in this system upon reduction.

In the complex $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]^+$, the observed ν(NO) frequency (1865 cm^{-1}) falls in the range characteristic of linear nitrosyl complexes M−NO,[12] and is closer to the vibrational frequency of free NO (1876 cm^{-1}) than of NO^+ (2273 cm^{-1}) or NO^- (1358−1374 cm^{-1}). However, it should be noted that in the NO^+ complexes the ν(NO) frequencies can also decrease significantly as a consequence of π-backbonding interactions, and typical values have been observed in the range of 1900−1970 cm^{-1} as shown by the preceding examples. In special cases (as in

the nitrosyl cluster system herein reported) where ν(NO) is close to that of the free NO molecule, the differentiation between a typical NO^0 complex and the case involving a rather strong π-backbonding to NO^+ is not obvious and cannot be carried out exclusively on the basis of the infrared vibrational data.

^{1}H and ^{13}C NMR Spectra

The ^{1}H and ^{13}C NMR spectra of the cluster were assigned by comparison with related clusters[1,5−7,40−52], using peak integration and COSY (^{1}H,^{1}H) and HMQC (^{1}H, ^{13}C) bidimensional techniques (see also Supporting Information). In the ^{1}H and ^{13}C NMR spectra one can observe two signals for the CH_3 groups, in accordance with the C_{2v} cluster symmetry. Selected NMR spectroscopic data are collected in Table 1 in order to illustrate how the signals of the ligands coordinated to the Ru_3O core depend upon the oxidation states of the ruthenium ions. Reduced clusters in the $Ru^{III}Ru^{III}Ru^{II}$ formal oxidation state, including CO species, are diamagnetic and show coordinated ligand signals close to the free ones and slightly downfield shifted. On the other hand, the oxidized clusters ($Ru^{III}Ru^{III}Ru^{III}$) are paramagnetic and their signals are not only sensitive to the inductive effects from the metal center, but also to the paramagnetic anisotropy of the Ru_3O unit.[47] Interestingly, the CH_3 and H_2 proton signals of acetate and pyridine are found at chemical shifts between the signals of the diamagnetic $[Ru_3O(CH_3CO_2)_6(py)_2CO]^0$, $[Ru_3O(CH_3CO_2)_6(py)_3]^0$ and the paramagnetic $[Ru_3O(CH_3CO_2)_6(py)_3]^+$ clusters. This rules out a description in terms of a formal $Ru^{III}Ru^{III}Ru^{II}NO^+$ oxidation state, since its corresponding NMR spectra would be similar to the CO analog.

The NMR spectroscopic data suggest a significant NO^0 character in the cluster system. The formal representation $Ru^{III}Ru^{III}Ru^{III}NO^0$ should be interpreted rather carefully, since there is a strong coupling between the NO^0 π*-electron and the ruthenium d_π-electrons, which results in a large diamagnetism according to magnetic susceptibility measurements. In fact, the increase in the π-electron density is reflected in the *J* values observed for the pyridine ligand signals [$^3J_{H,H}$ = 6.5 Hz, C(2)−H; $^4J_{H,H}$ = 1.5 Hz, C(2)−H; $^3J_{H,H}$ = 7.6 Hz, C(3)−H]. In the oxidized clusters these constants are too small to be observed because the scalar coupling decreases as the oxidation state of the coupled nucleus increases.[53] The CH_2Cl_2 molecule was detected in the ^{1}H and ^{13}C NMR spectra at δ = 5.32 and 55 ppm, respectively, corroborating the elemental analysis and thermogravimetry results.

Electronic Structure

The electronic spectrum of $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$ exhibits a series of superimposed bands in the 300−800 nm range, which can be deconvoluted as shown in Figure 3. The absorption profile is rather unusual, displaying apparently little similarity with those reported in the literature for related complexes.[2,6,7]

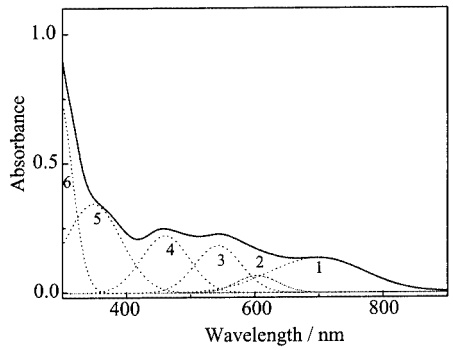

Figure 3. Electronic spectrum of a 10^{-3} M $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$ solution in acetonitrile

The electronic structure of $[Ru_3O(CH_3CO_2)_6L_3]$ clusters has been discussed in terms of a qualitative molecular orbital scheme proposed by Cotton and Norman, centered on the Ru_3O π-system in D_{3h} symmetry.[54] In this scheme, the central oxygen atom is considered to be sp^2 hybridized, leaving a single p_z orbital of π symmetry to interact with the ruthenium d_π orbitals ($d_{zy'}$, $d_{x'z}$, and $d_{x'^2-y'^2}$). The Ru $d_{zy'}$ orbitals are perpendicular to the horizontal symmetry plane of the molecule, and can combine with the O p_z orbital,

giving rise to two a_2'' molecular orbitals, while the $d_{zy'} - d_{zy'}$ combination leads to an e'' molecular orbital. The Ru $d_{x'z}$ orbitals are localized in the Ru_3O plane and their direct combination gives rise to e'(1) and a_2' molecular orbitals. The remaining Ru $d_{x'^2-y'^2}$ orbitals can interact weakly since a considerable distance separates them. However, these orbitals can interact with the p orbitals localized on the oxygen atoms of the bridging acetates, providing a further mechanism for Ru−Ru interactions. This would remove the degeneracy of the three $d_{x'^2-y'^2}$ orbitals, giving rise to e'(2) and a_1' levels.

Under C_{2v} symmetry, the a_2'', a_2', and a_1' levels transform according to b_1, b_2, and a_1, while the e'' and e' levels split into b_1, a_2, and a_1, b_2, respectively. In principle, the qualitative molecular orbital diagram proposed by Cotton and Norman could be employed for extrapolating to C_{2v} symmetry based on a simple correlation procedure. In our case, however, this is not feasible, since the π-interactions with the NO ligand make the qualitative ordering of the molecular orbitals rather complicated.

In order to shed some light on the electronic structure of the nitrosyl cluster, a preliminary molecular orbital calculation was carried out for the model complex $[Ru_3O(CH_3CO_2)_6(NH_3)_2(NO)]^+$ using the ZINDO/S semi-empirical method after a suitable geometry optimization based on the MM^+ force field, as described in the Exp. Sect. The pyridine ligands were replaced by NH_3 in order to simplify the calculations and, specially, to facilitate the interpretation of the electronic properties of the Ru_3O-NO chromophore. It should be noticed that pyridine and NH_3 are very close in the spectrochemical series of ligands, and their influence in the $Ru^{III}Ru^{III}Ru^{III}$ cluster is expected to be rather similar.

The atomic charge distribution for the model complex can be seen in Figure 4. In this complex, the NO ligand bears a very small negative charge (δ = −0.068) while the attached ruthenium ion has a positive charge (δ = 0.593) that is significantly higher than the other two ruthenium ions (δ = 0.353). Therefore, the charge distribution within the Ru_3O-NO moiety indicates a predominant NO^0 character, and also the occurrence of substantial π-backbonding effects involving the Ru−NO bond.

According to the ZINDO/S molecular orbital calculations (Table 2) the NO ligand has a strong influence on several energy levels, particularly those involving the Ru $d_{zy'}$ (MO 99, 96, 90) and Ru $d_{x'z}$ (MO 100, 98, 91) orbitals. For instance, in the case of MO 100 (LUMO 2) the NO character is 83%, while for MO 99 (LUMO 1) there is a nearly equivalent mixture with the Ru d_π orbitals. Among the HOMO levels, MO 96 and 91 exhibit a high contribution of NO (16%), although the highest contribution is observed for MO 90 (42%).

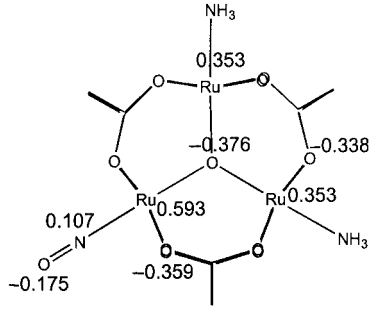

Figure 4. Atomic charge distribution for the model cluster $[Ru_3O(CH_3CO_2)_6(NH_3)_2(NO)]^+$

Table 2. Molecular orbital composition for the cluster $[Ru_3O(CH_3CO_2)_6(NH_3)_2NO]^+$

MO	% Ru	% NO	% CH_3CO_2	% O
		HOMO		
90	42	42	14	
91	63	15	13	6
92	77		22	
93	78		18	2
94	75		18	5
95	82		13	2
96	56	16	10	16
97	65		34	
		LUMO		
98	66	6	27	
99	49	34	6	9
100	14	83	2	

The ZINDO/S method successfully reproduces the observed electronic transitions in the nitrosyl cluster, as shown in Figure 3. Such transitions are also indicated in the molecular orbital scheme (Figure 5) corresponding to symmetry- and spin-allowed transitions. Transition 1, at 691 nm (ε = 1740 $M^{-1}cm^{-1}$), corresponds to the HOMO 0 → LUMO 0 excitation, involving essentially the occupied trinuclear ruthenium-acetate level of a_1 symmetry (MO 97) and the next empty b_2 level (MO 98) displaying some NO character (6%). Transition 2, at 602 nm, is relatively weak, and involves the excitation from MO 97 to MO 99 (b_1), displaying strong NO character. Transition 3, at 538 nm (ε = 2840 $M^{-1}cm^{-1}$), is more intense and involves the excitation from MO 96 (b_1) to MO 99 (b_1); both exhibiting significant NO character. Transition 4, at 451 nm (ε = 3130 $M^{-1}cm^{-1}$), corresponds to excitation from the $Ru_3O(CH_3CO_2)_6$ level [MO 93 (b_2) to MO 98], while transition 5 at 338 nm (ε = 4700 $M^{-1}cm^{-1}$) corresponds, similarly, to the excitation from MO 92 (a_1) to MO 99. The strongest band should correspond to the transition from MO 91 (b_2) to MO 100 (b_2). Unfortunately, in the pyridine complex this band is masked by the strong cluster-to-pyridine charge-transfer bands and also by the internal transitions in the aromatic ligand.

Electrochemical Behavior

The cyclic voltammogram of $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]^+$ is shown in Figure 6 along with those for the reference complexes $[Ru_3O(CH_3CO_2)_6(py)_2(CH_3OH)]^+$ and $[Ru_3O(CH_3CO_2)_6(py)_2(CO)]^0$. The nitrosyl cluster exhibits four successive redox waves at −1.15, −0.44, 1.00 and 1.77 V (vs. Ag/Ag^+), which, in principle, can be ascribed to the

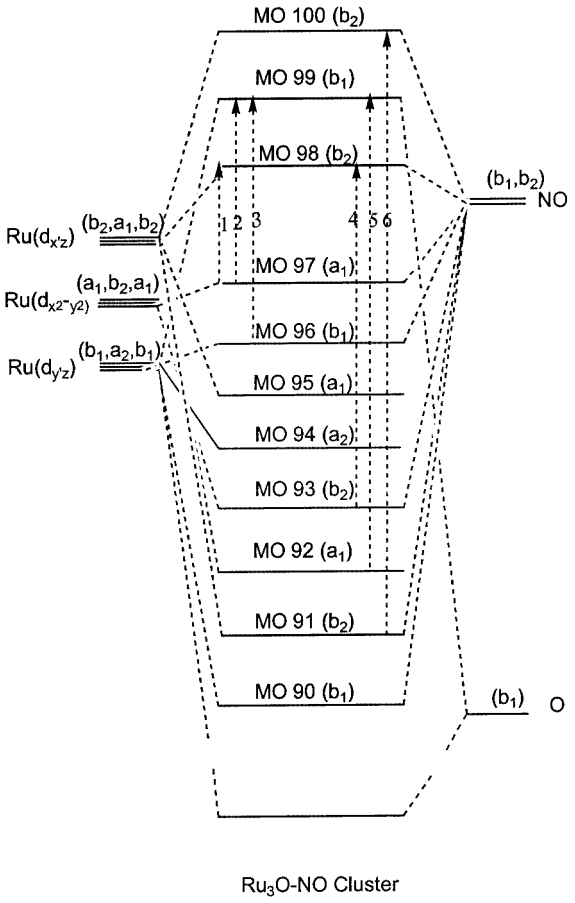

Figure 5. Molecular orbital scheme for the cluster $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]^+$

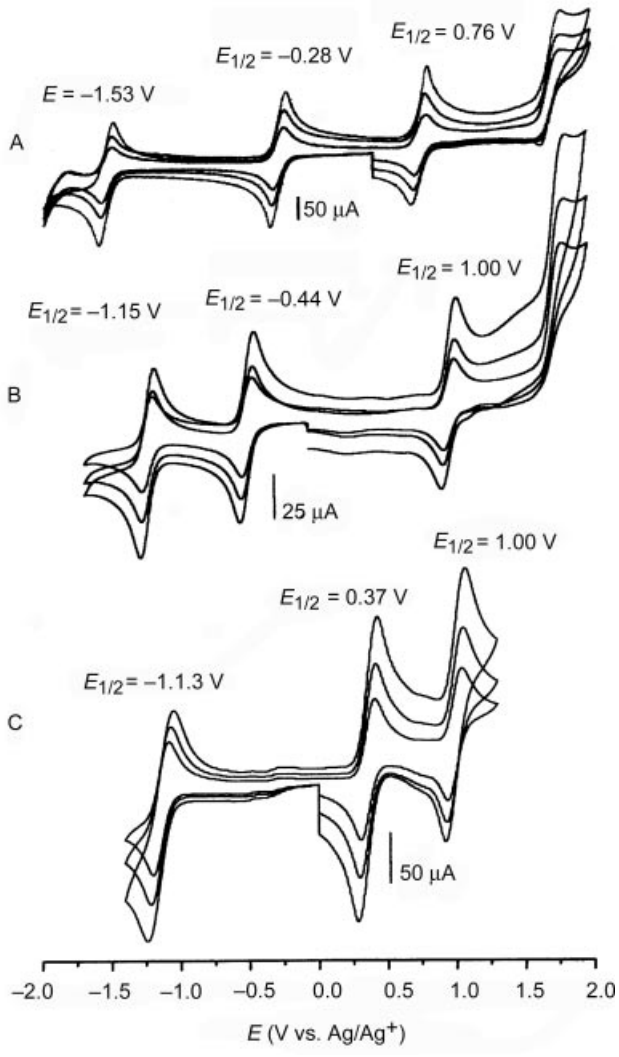

Figure 6. Cyclic voltammogram of the cluster (10^{-3} M), in acetonitrile solution containing 0.1 M $TEAClO_4$: (a) $[Ru_3O(CH_3CO_2)_6(py)_2(CH_3OH)]PF_6$; (b) $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$; (c) $[Ru_3O(CH_3CO_2)_6(py)_2(CO)]$

redox couples $Ru^{III}Ru^{II}Ru^{II}/Ru^{III}Ru^{III}Ru^{II}/Ru^{III}Ru^{III}Ru^{III}/Ru^{IV}Ru^{III}Ru^{III}/Ru^{IV}Ru^{IV}Ru^{III}$ by comparison with the reference compounds.

In our previous work we have shown that the redox potentials of $[Ru_3O(CH_3CO_2)_6L_3]$ clusters are correlated with the donor-acceptor properties of L, forming a well-behaved sequence, when the voltammograms are superimposed according to this trend. This type of behavior, however, is not apparent in Figure 6. On the other hand, the assignment of the wave at −0.44V to the NO^+/NO^0 couple cannot be totally discarded, since this process is usually observed in the range −0.6 to +0.3V vs. Ag/Ag^+ [55,56] for typical NO^+ complexes. This kind of ambiguity probably arises from the fact that the interactions of the NO ligand with the Ru d_π orbitals make the canonical structures $Ru^{III}-NO^0 \rightleftarrows Ru^{II}-NO^+$ practically equivalent, since the strong back-bonding interactions involving $Ru^{II}-NO^+$ would also lead to an electronic configuration rather close to $Ru^{III}-NO^0$. As a consequence, the NO ligand can stabilize both the $Ru^{III}Ru^{III}Ru^{III}$ (by acting as NO^0) and the $Ru^{III}Ru^{III}Ru^{II}$ (by acting as NO^+) formal oxidation states, increasing the separation between the corresponding redox waves at −0.44 and 1.00 V (ΔE = 1.44 V) in comparison with the CH_3OH (ΔE = 1.04 V) and CO (ΔE = 0.63 V) reference compounds. This exceptional ability to stabilize both oxidation states is actually responsible for the non-innocent character of the NO ligand in many transition metal complexes.

Visible-UV and IR Spectroelectrochemistry

In contrast to the electrochemical measurements, the spectroelectrochemical results were severely limited by decomposition reactions taking place over the time scale of the experiments (about ten minutes). The only completely reversible spectroelectrochemical behavior was observed at E^0 = −0.44V, corresponding to the $(Ru^{III}Ru^{III}Ru^{III}-NO^0 \rightleftarrows Ru^{III}Ru^{III}Ru^{II}-NO^+)/Ru^{III}Ru^{III}Ru^{II-}NO^0$ redox process. As shown in Figure 7a, the reduction of the $Ru^{III}Ru^{III}Ru^{III}-NO^0$ complex gives rise to a broad band in the visible-near infrared region (λ_{max} = 710 nm) consistent with intermetallic transitions within the $Ru^{III}Ru^{III}Ru^{II}-NO^0$ chromophore,[7,42,57] and to a strong band at 400 nm, characteristic of ruthenium-to-pyridine

charge-transfer transitions involving the $Ru^{III}Ru^{III}Ru^{III}$-pyridine moiety.

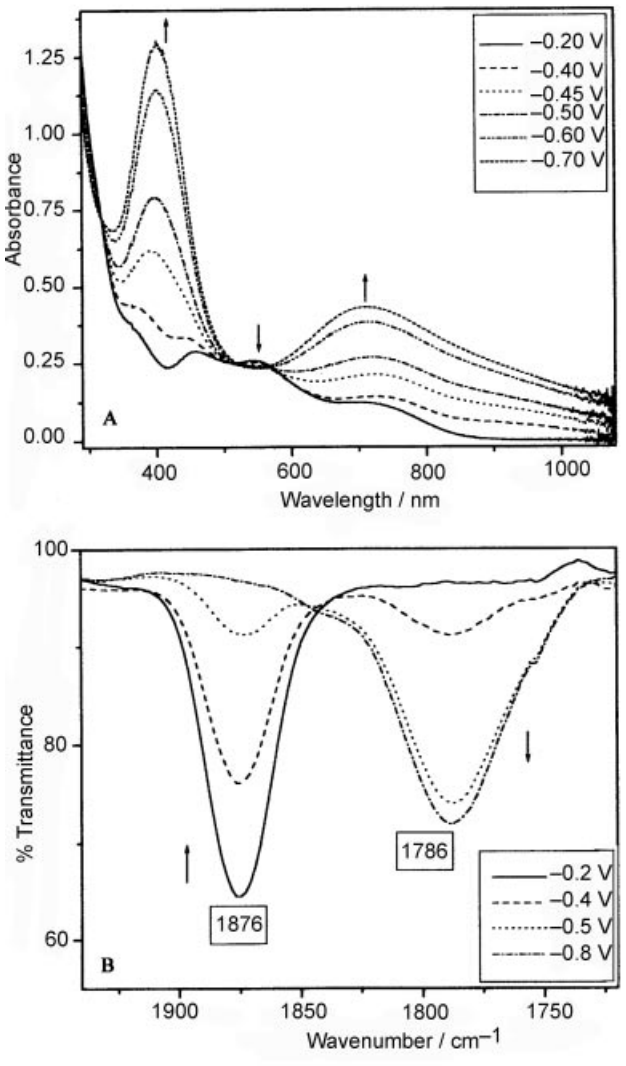

Figure 7. UV/Vis (a) and IR (b) spectroelectrochemistry of $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$ (10^{-3} M), in acetonitrile solution containing 0.10 M $TEAClO_4$

The corresponding FTIR spectroelectrochemistry (Figure 7b) exhibits a systematic conversion of the ν(NO) band at 1876 cm^{-1} into a new band at 1786 cm^{-1} indicating some NO^- character, arising from the ($Ru^{II}-NO^0$) back-bonding interactions within the $Ru^{III}Ru^{III}Ru^{II}-NO^0$ chromophore. Above 1.2V and below −1.2V the irreversible decomposition of the nitrosyl-cluster is observed, with the disappearance of the characteristic ν(NO) bands in the FTIR spectrum.

Conclusion

The interaction of NO with the complex $[Ru_3O(CH_3CO_2)_6(py)_2(CH_3OH)]^+$ leads to a stable nitrosyl-cluster system which can be formally described in terms of the delocalized electronic configuration, $Ru^{III}Ru^{III}Ru^{III}-NO^0 \rightleftarrows Ru^{III}Ru^{III}Ru^{II}-NO^+$. The strong involvement of the NO π*-orbitals is supported by theoretical calculations, as well as by the electronic, spectroscopic and magnetic properties of the complex. The remarkable contribution of NO to the LUMO levels accounts for the unusual absorption profiles observed in the electronic spectra of the cluster, as well as a significant photochemical sensitivity: the cluster releases nitric oxide upon irradiation with visible light. This interesting property is currently being investigated in our laboratory, as well as the related biological effects, including the valuation of $[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$ toxicity.

Experimental Section

General: Tetraethylammonium perchlorate ($TEAClO_4$)[58] and the starting complex $[Ru_3(CH_3CO_2)_6(py)_2(CH_3OH)]PF_6$ were prepared as previously described in the literature.[5] Acetonitrile (HPLC grade, Aldrich) was kept in the presence of 3 Å dry molecular sieves. Other reagents and solvents of analytical grade were used without further purification. Thermogravimetric measurements were performed using a Shimadzu model TGA-50 instrument under the following experimental conditions: 2−4 mg of sample, platinum crucible, N_2 flow of 50 mL·min^{-1}, heating rate of 10 °C·min^{-1}. Infrared spectra were recorded in the region 4000−350 cm^{-1} on a Shimadzu FTIR model 8300 spectrophotometer. The magnetic susceptibilities of powdered samples were measured at room temperature using a Cahn model 7500 electrobalance. The studies in solution were carried out using a 10^{-3} M cluster solution in acetonitrile. X-band EPR spectrum, at 77 K, were conducted with a Bruker EMX spectrometer, operating at 9.53 GHz, 20 MW power and 4−12 G modulation amplitude. ^1H and ^{13}C NMR spectra and two-dimensional COSY (^1H, ^1H) and HMQC (^1H, ^{13}C) spectra were recorded on a Varian INOVA 1 300 MHz and Bruker DRX 500 spectrometers, using a 10^{-2} M cluster solution in CD_3CN. The electronic spectra were recorded on a Hewlett−Packard model 8453 diode-array spectrophotometer, using a 295 nm UV cut-off filter. Cyclic voltammetry and spectroelectrochemistry were carried out with an EG&G model 283 galvanostat/potentiostat. A conventional three-electrode electrochemical cell was used, with a platinum disk as working electrode, a Luggin capillary arrangement with an $Ag/AgNO_3$ (0.01 M) reference electrode in 0.10 M $TEAClO_4$ in acetonitrile, and a platinum wire as auxiliary electrode. UV/Vis spectrochemistry was conducted using a rectangular quartz cell of 0.025 cm internal optical path length, containing an optically transparent gold minigrid electrode, a platinum wire and a small $Ag/AgNO_3$ electrode as working, auxiliary and reference electrodes, respectively. IR spectroelectrochemical measurements were carried out using an acetonitrile solution containing 0.10 M $LiClO_4$ and a homemade IRTRAN thin layer cell, as previously described.[38]

Molecular mechanics geometry optimizations for the model complex $[Ru_3O(CH_3CO_2)_6(NH_3)_2(NO)]^+$ were carried out using the MM^+ module of Hyperchem 6.1 from Hypercube, starting with bond-dipole calculations and stopping at a refinement level of 10^{-3} kcal·$Å^{-1}$·mol^{-1}. In all the attempts, even when using a restricted geometry, the optimization procedure led to a pyramidal Ru_3O structure, rather than to the planar geometry characteristic of this type of system. In order to preserve the planar geometry, the cent-

ral oxygen atom was initially replaced by fluorine, thus allowing a preliminary structural refinement. In the next step, fluorine was replaced by oxygen, and the geometry refinement was carried out again, but stopping just at the point preceding the pyramidal distortion (about 30 cycles). Using this procedure, the central Ru−Ru and Ru−O distances can be adjusted, keeping the oxygen atom inside the triangular ring, without perturbing the remaining, optimized parts of the system. For this frozen undistorted geometry, single-point semi-empirical molecular orbital calculations were carried out, using the spectroscopic implementation of the ZINDO/1 method within the Hyperchem 6.1 package. The semi-empirical method provided the approximate atomic charges, which were used for a new cycle of geometry optimization (MM^+), now replacing the starting bond dipoles. This alternating semi-empirical/molecular mechanics procedure was repeated at least three times, practically ensuring convergence. In this way, the final geometry was planar, exhibiting Ru−Ru(NO) and Ru−Ru distances of 3.257 and 3.266 Å, and three similar Ru−O distances of 1.883 Å; all of them quite similar to the typical crystallographic distances reported in the literature for similar ruthenium acetate clusters.[6,59−61] The theoretical Ru−NO and NO bond lengths were 1.914 and 1.086 Å, respectively. After geometry optimization, the electronic spectra were generated by single CI excitations in an active space involving at least 12 frontier molecular orbitals (seven highest occupied and five lowest unoccupied MOs).

$[Ru_3O(CH_3CO_2)_6(py)_2(NO)]PF_6$: A solution of $[Ru_3(CH_3CO_2)_6(py)_2(CH_3OH)]PF_6$ (0.21 g; 0.21 mmol) in dichloromethane (20 mL) were saturated with Ar for 20 min, then with NO for 15 min (after which the blue solution became violet), and finally with Ar for 20 min. The product was precipitated by adding petroleum ether. The solid was collected on a filter, washed with petroleum ether and dried under vacuum. Yield: 42%. $C_{23}H_{30}Cl_2F_6N_3O_{14}PRu_3$ (1091.6): calcd. C 25.3, H 2.77, N 3.85; found C 25.2, H 2.75, N 3.80. The purity of the final product was confirmed by means of NMR spectroscopy.

Acknowledgments

We are grateful to FAPESP and CNPq for financial support, and to Prof. Ana Maria da Costa Ferreira for conducting the EPR measurements.

Keywords: Electrochemistry / Iron / Phosphorus / Ruthenium / Sandwich compounds / Triple-decker complexes

Triple-decker cationic complexes with a central pentaphospholyl (pentaphosphacyclopentadienyl) ligand $[Cp^*M(\mu\text{-}\eta{:}\eta\text{-}P_5)M'(\eta\text{-}C_5R_5)]^+$ (**3b**: M = M′ = Fe, R = Me; **4a**: M = Ru, M′ = Fe, R = H; **4b**: M = Fe, M′ = Ru, R = H; **4c**: M = Fe, M′ = Ru, R = Me; **5a**: M = M′ = Ru, R = H; **5b**: M = M′ = Ru, R = Me) were synthesized by exploitation of the stacking reactions of pentaphosphametallocenes $Cp^*M(\eta\text{-}P_5)$ (**1**: M = Fe; **2**: M = Ru) with half-sandwich fragments $[(\eta\text{-}C_5R_5)M']^+$. They were isolated as salts with BF_4^- or PF_6^- anions, and the structures of **4a**PF_6 and **5b**PF_6 were determined by X-ray diffraction. Triple-decker complexes with a central pentaphospholyl ligand are less reactive in nucleophilic degradation reactions than analogous complexes with C_4Me_4P and Cp^* ligands in the bridging position. Only **4a** and the previously known analogue **3a** (M = M′ = Fe, R = H), containing the CpFe fragment, are nucleophilically destroyed by MeCN and NaI. The electrochemical properties of **2**, **3a**, **3b**, **4a–c**, **5a** and **5b** and the related cobalt-containing complexes $[(\eta\text{-}C_4Me_4)Co(\mu\text{-}\eta{:}\eta\text{-}P_5)MCp^*]^+$ (**6**: M = Fe; **7**: M = Ru) were investigated.

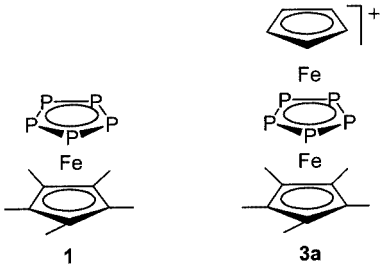
Introduction

Several examples of triple-decker complexes with a central pentaphospholyl (pentaphosphacyclopentadienyl) ligand (*cyclo*-P_5) are known.[1] The first complexes of this type, $(\eta\text{-}C_5R_5)Cr(\mu\text{-}\eta{:}\eta\text{-}P_5)Cr(\eta\text{-}C_5R_5)$ (R = H, Me), were synthesized by Scherer[2] and other authors[3] by treatment of $[(\eta\text{-}C_5R_5)Cr(CO)_x]_2$ (x = 2, 3) with P_4. Scheer has prepared the similar complex $(\eta\text{-}C_5H_4t\text{Bu})Cr(\mu\text{-}\eta{:}\eta\text{-}P_5)Cr(\eta\text{-}C_5H_4t\text{Bu})$ by treatment of $K[(\eta\text{-}C_5H_4t\text{Bu})Cr(CO)_3]$ with $Cr(CO)_5PCl_3$.[4]

A straightforward approach to the synthesis of triple-decker complexes is based on the use of stacking reactions of coordinatively unsaturated metal complex fragments with sandwich compounds.[5] In particular, this approach has proved to be very useful for the preparation of triple-decker complexes with a central *cyclo*-P_5 ligand. By using stacking reactions of pentaphosphaferrocene $Cp^*Fe(\eta\text{-}P_5)$ (**1**) with the fragments $[CpFe]^+$ and $(CO)_3M$ (M = Cr, Mo) Scherer has prepared the triple-decker complexes $[CpFe(\mu\text{-}\eta{:}\eta\text{-}P_5)FeCp^*]^+$ (**3a**) and $(CO)_3M(\mu\text{-}\eta{:}\eta\text{-}P_5)FeCp^*$.[6] We have described the synthesis of complex $[(\eta\text{-}C_7H_7)Mo(\mu\text{-}\eta{:}\eta\text{-}P_5)FeCp^*]^+$ by treatment of **1** with the fragment $[(\eta\text{-}C_7H_7)Mo]^+$.[7]



We report here the results obtained in an extension of this approach to the preparation of new iron- and ruthenium-containing triple-decker complexes with a central pentaphospholyl ligand $[Cp^*M(\mu\text{-}\eta{:}\eta\text{-}P_5)M'(\eta\text{-}C_5R_5)]^+$ (M, M′ = Fe, Ru; R = H, Me),[8] together with their electrochemical and structural properties.

Results and Discussion

Synthesis of Triple-Decker Complexes

In 1987 we described the synthesis of the first 30 VE (valence electron) triple-decker complexes with a central cyclopentadienyl ligand $[Cp^*M(\mu\text{-}\eta{:}\eta\text{-}Cp^*)M'(\eta\text{-}C_5R_5)]^+$ (M = Fe, Ru, Os; M′ = Fe, Ru).[9] These compounds were synthe-

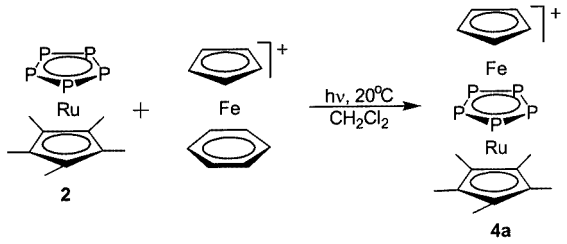
[b] Dipartimento di Chimica, University of Siena, Via Aldo Moro, 53100 Siena, Italy

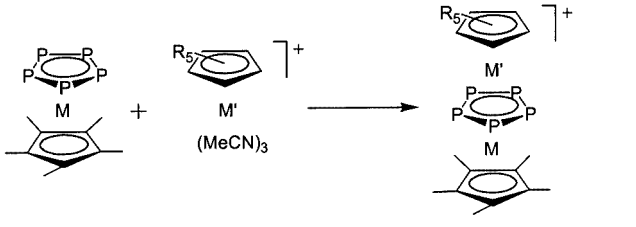
sized by exploitation of the stacking reactions of decamethylmetallocenes MCp^*_2 with the coordinatively unsaturated 12 VE half-sandwich fragments $[(\eta\text{-}C_5R_5)M']^+$. In particular, the iron-containing triple-decker complexes $[CpFe(\mu\text{-}\eta\text{:}\eta\text{-}Cp^*)MCp^*]^+$ were prepared by use of the $[CpFe]^+$ fragment, generated in situ by visible light irradiation of the benzene complex $[CpFe(\eta\text{-}C_6H_6)]^+$. The same method was used later by Scherer for the preparation of complex **3a**.[6a]

Analogously, the iron-ruthenium triple-decker complex **4a** was prepared by us through the use of the stacking reaction of the fragment $[CpFe]^+$ with pentaphospharuthenocene $Cp^*Ru(\eta\text{-}P_5)$ (**2**) (Scheme 1).[10]



Scheme 1. Formation of complex **4a**

Since the methylated fragment $[Cp^*Fe]^+$ cannot be generated from the corresponding benzene complex $[Cp^*Fe(\eta\text{-}C_6H_6)]^+$, due to its rather high stability,[11] we used the labile acetonitrile complex $[Cp^*Fe(MeCN)_3]^+$ as the source of this fragment. The complex $[Cp^*Fe(MeCN)_3]^+$ was successfully used earlier by Herberich for the synthesis of the μ-boratabenzene triple-decker complex $[Cp^*Fe(\mu\text{-}\eta\text{:}\eta\text{-}C_5H_5BMe)FeCp^*]^+$.[12] Treatment of $[Cp^*Fe(MeCN)_3]^+$ with **1** at 20 °C affords the permethylated diiron triple-decker complex **3b** (Scheme 2). However, treatment of $[Cp^*Fe(MeCN)_3]^+$ with **2** under the same conditions failed to give the iron-ruthenium triple-decker complex $[Cp^*Fe(\mu\text{-}\eta\text{:}\eta\text{-}P_5)RuCp^*]^+$. Nevertheless, we were able to synthesize it through the stacking reaction of the fragment $[Cp^*Ru]^+$ with **1** (see below).



3b: M = M' = Fe, R = Me
4b: M = Fe, M' = Ru, R = H
4c: M = Fe, M' = Ru, R = Me
5a: M = M' = Ru, R = H
5b: M = M' = Ru, R = Me

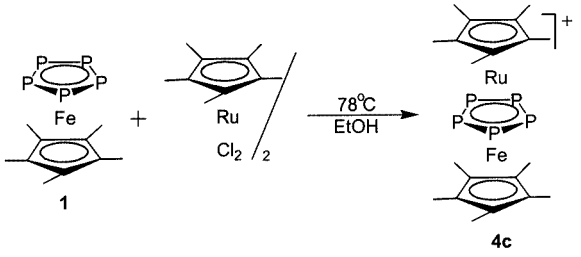
Scheme 2. Formation of complexes **3b**, **4b**, **4c**, **5a** and **5b**

The ruthenium-containing triple-decker complexes $[(\eta\text{-}C_5R_5)Ru(\mu\text{-}\eta\text{:}\eta\text{-}Cp^*)MCp^*]^+$ (M = Ru, Os) had been prepared by us earlier, by use of stacking reactions of decamethylmetallocenes MCp^*_2 with the fragments $[(\eta\text{-}C_5R_5)Ru]^+$ generated by heating the acetonitrile complexes $[(\eta\text{-}C_5R_5)Ru(MeCN)_3]^+$ in $MeNO_2$.[9] We used the same method for the preparation of μ-pentaphospholyl triple-decker complexes containing the unsubstituted Cp ring at the ruthenium atom. It was shown that stacking reactions of the $[CpRu]^+$ fragment, generated from $[CpRu(MeCN)_3]^+$, with compounds **1** and **2** yield the iron-ruthenium and diruthenium triple-decker complexes **4b** and **5a**, respectively (Scheme 2). Heating was essential for successful preparation of these complexes. Under mild conditions (20 °C, CH_2Cl_2) a mixture of products was formed. In the ^{31}P NMR spectra of these mixtures, the signals of the triple-decker complex **4b** or **5a** ($\delta = -37.2$ and -54.9 ppm, respectively) were accompanied by complicated multiplets in the range between $\delta = 250$ and 20 ppm. Such multiplets are characteristic of an AA′MM′X spin system. Probably, the formation of **4b** and **5a** is complicated by side-formation of phosphane-type complexes, due to coordination of ruthenium atoms of the species $[CpRu(MeCN)_x]^+$ ($x \leq 2$) with lone pairs of phosphorus atoms of pentaphosphametallocenes.[13] It was shown by ^{31}P NMR spectroscopy that phosphane-type complexes are unstable and very slowly turn into triple-decker complexes at room temperature. This process becomes faster with increasing temperature, and complexes **4b** and **5a** were isolated in high yields when the reactions were carried out in $MeNO_2$ at 100 °C. It is noteworthy that the formation of the triple-decker complex **4a** mentioned above is also complicated by side-formation of phosphane-type complexes. In order to obtain pure complex **4a**, the crude product was heated under reflux in $MeNO_2$.

μ-Pentaphospholyl triple-decker complexes **4c** and **5b**, containing the Cp* ring at the ruthenium atom, were prepared through stacking reactions of the $[Cp^*Ru]^+$ fragment with **1** and **2** (Scheme 2). It was shown in this case that the methylated fragment $[Cp^*Ru]^+$ can also be generated from the corresponding acetonitrile complex $[Cp^*Ru(MeCN)_3]^+$ in $MeNO_2$ at 100 °C. However, it is more convenient to use labile solvent complexes $[Cp^*Ru(S)_3]^+$ (S = Me_2CO, THF) as the source of the $[Cp^*Ru]^+$ fragment. These solvates were generated in solution by treatment of $[Cp^*RuCl_2]_2$ with Zn dust and $TlBF_4$ in Me_2CO or THF at room temperature.[14] Alternatively, they could also be generated by treatment of $[Cp^*Ru(OMe)]_2$ with CF_3SO_3H.[15] The further stacking reaction of $[Cp^*Ru(S)_3]^+$ with **1** is selective at room temperature, and the iron-ruthenium triple-decker complex **4c** was isolated in 84% yield. However, similar treatment of **2** primarily yields phosphane-type complexes, which turn into the diruthenium triple-decker complex **5b** (82%) in refluxing THF or Me_2CO. Some differences in the conditions of the stacking reactions for **1** and **2** may be connected with the greater stability of phosphane-type complexes formed by **2**.

Complex **4c** was also obtained (80%) by direct treatment of **1** with $[Cp^*RuCl_2]_2$ in refluxing alcohol (Scheme 3). This method had previously been developed by us for the preparation of the arene complexes $[Cp^*Ru(arene)]^+$.[16] Unfortunately, it proved to be useless for the preparation of

5b, probably due to the rather high stability of phosphane-type complexes (formed by reaction between **2** and $[Cp^*RuCl_2]_2$), which do not turn into **5b** even after prolonged heating under reflux in alcohol.



Scheme 3. Formation of complex **4c** by treatment of complex **1** with $[Cp^*RuCl_2]_2$

NMR Spectroscopy

The ^1H, ^{13}C and ^{31}P NMR spectroscopic data for triple-decker complexes **3b**, **4a**−**c**, **5a** and **5b** are given in Table 1. In the ^{31}P NMR spectra, the signals of the phosphorus atoms of the pentaphospholyl ligand are observed as singlets in the $\delta = -58.0$ to -23.0 ppm range. These signals are strongly shifted upfield from the corresponding signals for sandwich compounds **1** and **2** ($\delta = 153.0$ and 83.8 ppm, respectively); this makes ^{31}P NMR spectroscopy very informative for the establishment of the triple-decker structure. Substitution of the ruthenium atoms for iron and introduction of methyl groups also cause upfield shifts of the signal.

In the ^1H NMR spectra, the signals of Cp ring protons and of Cp* methyl groups are observed in the ranges $\delta = 4.0-4.6$ and $1.2-1.5$ ppm, respectively. In the ^{13}C NMR spectra, the signals of the C_5R_5 ring carbon atoms and of the Cp* methyl groups are observed in the ranges $\delta = 74.9-97.1$ and $7.8-9.2$ ppm, respectively. These spectroscopic data are also in accordance with the triple-decker structure.

X-ray Diffraction Study

The structures of complexes **4a**PF_6 and **5b**PF_6 were investigated by single-crystal X-ray diffraction. They contain separated **4a** or **5b** cations and PF_6^- anions. The cations have triple-decker structures formed by three cyclic frames, between which two metal atoms are located (Figures 1 and 2). Selected bond lengths and angles are given in Tables 2 and 3. In both cases the planes of the cyclic ligands are coplanar [for **4a** the dihedral angles Cp/P_5 and Cp^*/P_5 are equal to 1.3 and 3.5°; for **5b** the dihedral angles $Cp^*(1)/P_5$ and $Cp^*(2)/P_5$ are equal to 0.2 and 1.7°, respectively]. The carbon atoms of the Cp* methyl groups in **4a** and **5b** deviate somewhat from the ring planes in direction from the ruthenium atoms, these deviations amounting to 0.06−0.11 Å. The cross-orientation of all five-membered rings is perfectly eclipsed in **4a** and close to eclipsed in **5b**, the corresponding torsion angles for the latter being: P(1−5)CtCt′C(1−5) 12.4−12.8° (average 12.6°) and P(1−5)CtCt′′C(11−15) 5.1−5.2° (average 5.2°).[17] The metal atoms are located over the centres of all the rings; the metal-to-ring distances (Δ) are as follows: Fe···Cp 1.687(3), Ru···Cp* 1.837(1), Fe···P_5 1.527(1), and Ru···P_5 1.669(1) Å for **4a**; Ru(1)···Cp*(1) 1.831(1), Ru(2)···Cp*(2) 1.830(1), Ru(1)···P_5 1.675(1), and Ru(2)···P_5 1.678(1) Å for **5b**. The Fe···Ru [3.196(1) Å] and Ru(1)···Ru(2) [3.352(1) Å] distances are longer than the corresponding sums of the covalent radii for Fe−Ru (average 2.83 Å) and Ru−Ru (average 2.98 Å),[18] suggesting the absence of direct metal−metal bonds in both cases. It is noteworthy that Δ(Ru···P_5) for **4a** and **5b** are longer than the corresponding value in the sandwich compound (η-C_5Me_4Et)Ru(η-P_5) (1.652 Å).[19] The P−P bonds in **4a** (2.155−2.159 Å, average 2.157 Å) and **5b** (2.152−2.161 Å, average 2.156 Å) are longer than the corresponding bonds in (η-C_5Me_4Et)Ru(η-P_5)

Table 1. ^1H, ^{13}C and ^{31}P NMR spectroscopic data for compounds **3b**, **4a**−**c**, **5a** and **5b**

(2.082−2.118 Å, average 2.101 Å). The elongation of the Ru−P and P−P bonds is apparently connected with loosening of bonds upon bifacial coordination of the P_5 ring with two metal atoms as compared with its monofacial coordination with only one metal atom. The values of Δ(Ru···Cp*) for **4a** and **5b**, however, are shorter than the corresponding value in the sandwich compound (η-C_5Me_4Et)Ru(η-P_5) (1.850 Å). Probably, loosening of the Ru−P_5 bond in the triple-decker complexes causes increased occupancy of the Ru−Cp* bond. The values of Δ(Fe···P_5) and Δ(Fe···Cp) in **4a** are close to the corresponding values in the related triple-decker cation [CpFe(μ-η:η-P_5)Fe(η-C_5Me_4Et)]$^+$ [Δ(Fe···P_5) 1.534 Å and Δ(Fe···Cp) 1.679 Å].[6a] However, the P−P bonds in **4a** (average 2.157 Å) are somewhat longer than the corresponding bonds in [CpFe(μ-η:η-P_5)Fe(η-C_5Me_4Et)]$^+$ (average 2.125 Å), which suggests a greater π bond-loosening effect by the Cp*Ru fragment than by (C_5Me_4Et)Fe.

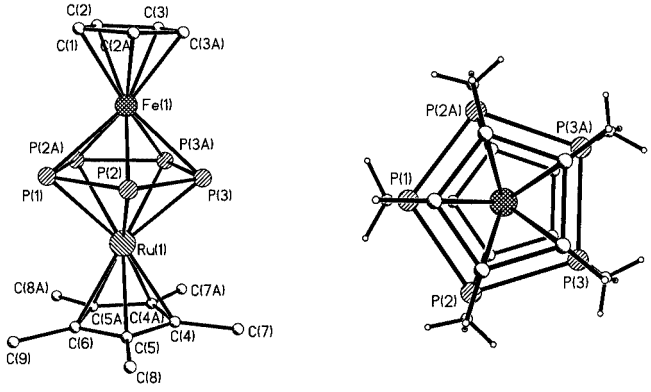

Figure 1. Structure of cation **4a**

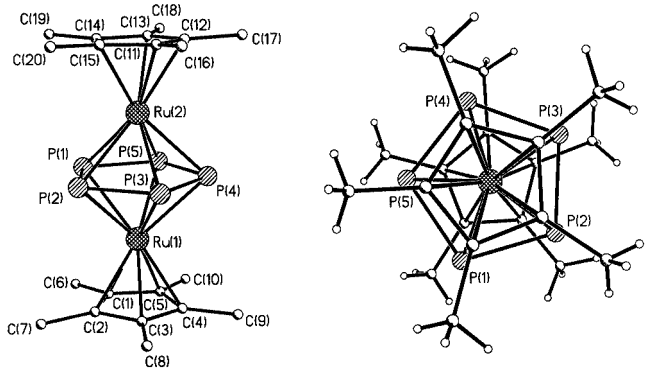

Figure 2. Structure of cation **5b**

Nucleophilic Degradation

The μ-pentaphospholyl triple-decker complexes described here have 30 VEs, which explains their stability in accordance with Hoffmann's rule for triple-decker complexes.[20] They are indefinitely stable under inert gas. However, they are stable in air only for short periods of time and lose solubility after prolonged storage. This is apparently connected with the interaction between lone electron pairs of the phosphorus atoms and oxygen.

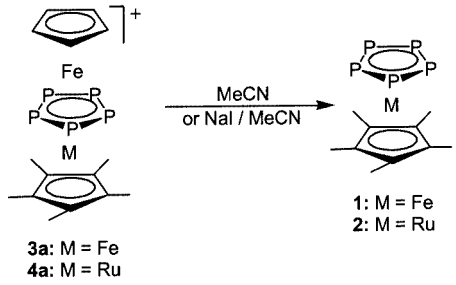
The properties of triple-decker complexes are insufficiently studied. The most studied reaction is nucleophilic degradation. Examples of such reactions have been described for the complexes with bifacially bonded cyclopentadienyl,[9,15d,21] borole,[22] thiadiborolene,[23] boratabenzene,[12,24] and phospholyl[25] ligands.

We studied the reactions of triple-decker complexes **3a**, **3b**, **4a**−**c**, **5a** and **5b** with MeCN and NaI. Only the CpFe-containing complexes **3a** and **4a** proved to be reactive. The reactions proceed with elimination of the [CpFe]$^+$ fragment and formation of the corresponding pentaphosphametallocenes **1** and **2** (Scheme 4). The selectivity of elimination of this fragment in the case of **3a** is apparently connected with hindrance of nucleophilic attack at the metal atom coordinated with the Cp* ring as a consequence of electronic and steric effects.

It is noteworthy that the iron-ruthenium complex **4a** is more reactive than the diiron analogue **3a** towards MeCN. From the ^{31}P NMR spectroscopic data, the degree of conversion in the case of **4a** was ca. 70% after 10 h at 80 °C, while in the case of **3a** at the same temperature it was only ca. 10% after 38 h. Addition of NaI accelerates degradation of **3a**, the degree of conversion being ca. 80% after 10 h. Unlike **3a** and **4a**, the diruthenium complex **5a**, with the same number of methyl groups, proved to be inert to nucleophilic degradation even by NaI in MeCN. This is obvi-



Scheme 4. Nucleophilic degradation of complexes **3a** and **4a**

ously connected with stronger bonding of *cyclo*-P_5 with the ruthenium atom than with iron. The obtained results suggest that the reactivity of μ-pentaphospholyl triple-decker complexes in nucleophilic degradation reactions decreases in the order FeRu > Fe_2 > Ru_2. It should be emphasized that the heterometallic compounds are more reactive than homometallic analogues.

The permethylated complexes **3b** and **4c** proved to be much less reactive than the pentamethylated analogues **3a** and **4a**; in fact, they are not destroyed by NaI in MeCN at 80 °C. Unfortunately, attempts to use other nucleophilic reagents (Me_2SO, $EtNH_2$, KOH, KCN, *t*BuOK and CpTl) resulted only in the formation of unidentified product mixtures.

The reactivity of the diiron triple-decker complex **3a** was compared with that of the related complexes [CpFe(μ-η:η-Cp*)FeCp*]$^+$ and [CpFe(μ-η:η-C_4Me_4P)FeCp*]$^+$, with Cp* and C_4Me_4P ligands in their bridging positions. Unlike diiron complex **3a**, which is destroyed by MeCN or NaI at 80 °C, complexes [CpFe(μ-η:η-Cp*)FeCp*]$^+$ and [CpFe(μ-η:η-C_4Me_4P)FeCp*]$^+$ are destroyed even by Me_2CO at room temperature,[9,25b] the complex with a central Cp* ring being destroyed most rapidly. Thus, the reactivity of the triple-decker complexes of the type [CpFe(ring)-FeCp*]$^+$ in nucleophilic degradation reactions greatly depends upon the central ligand and decreases in the order Cp* > C_4Me_4P > P_5.

Electrochemistry

In agreement with a previous report,[26] the iron building block **1** undergoes either a one-electron reduction or a one-electron oxidation, both showing features of chemical irreversibility. In the case of ruthenium analogue **2** we found clear evidence only of the presence of an irreversible oxidation. A possible reduction is probably localized very close to the solvent discharge. The relevant electrode potentials are compiled in Table 4, together with those for the complexes studied here.

Let us start the examination of the redox behaviour of the current triple-decker complexes with the diiron complexes **3a** and **3b**. Figure 3 shows the cyclic voltammetric response given by the permethylated complex **3b** in dichloromethane solution. It exhibits one oxidation and two separate reduction processes. Both the anodic and the first cathodic steps possess features of chemical reversibility on the cyclic voltammetric timescale [$i_{p(reverse)}/i_{p(forward)} \approx 1$], whereas the second reduction appears partially chemically reversible [$i_{p(reverse)}/i_{p(forward)} = 0.7$ at 0.2 Vs^{-1}]. A further irreversible oxidation, not shown in Figure 3, almost completely overlaps the solvent discharge.

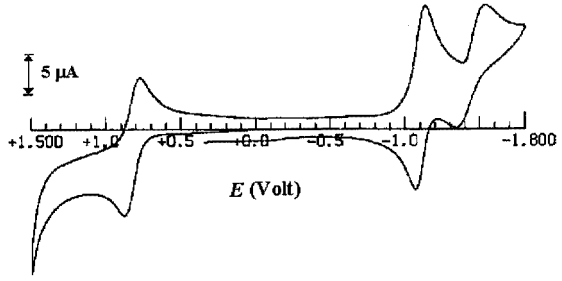


Figure 3. Cyclic voltammogram recorded at a platinum electrode on a CH_2Cl_2 solution containing **3b** (1.2×10^{-3} mol dm^{-3}); supporting electrolyte [Bu_4N][PF_6] (0.2 mol dm^{-3}); scan rate 0.2 Vs^{-1}

Consistent with the behaviour of the related complexes [(triphos)MP_3M(triphos)]$^{n+}$ (M = Ni, Co),[27] Cp* MP_6MCp^* (M = V, Mo, W),[28] Cp*Fe(As_2Se_2)FeCp*,[29]

[a] Measured at 0.2 Vs^{-1}. [b] Peak-potential value. [c] Ill-defined. [d] Measured at 2.0 Vs^{-1}. [e] Difficult to evaluate. [f] Multielectron process. [g] Measured at 5.1 Vs^{-1}.

and in particular $Cp^*CrP_5CrCp^*$,[2] controlled potential coulometry performed in correspondence to the first cathodic step ($E_w = -1.2$ V) consumed one electron per molecule, thus supporting the involvement of one-electron transfers in all the redox processes. This means that the oxidation processes should correspond to the $Fe^{II}Fe^{II}/Fe^{II}Fe^{III}/Fe^{III}Fe^{III}$ sequence, whereas the reduction steps should correspond to the $Fe^{II}Fe^{II}/Fe^{II}Fe^{I}/Fe^{I}Fe^{I}$ sequence. In this context, it should be noted that the Fe^{I} oxidation state is not completely unusual in organometallic chemistry,[30] and the present unexpected processes could be due to cooperative electronic effects inside the triple-decker assembly.

It is interesting to note that, if allowance is made to evaluate the separation between the sequential redox changes $Fe^{II}Fe^{II}/Fe^{II}Fe^{III}/Fe^{III}Fe^{III}$ as roughly about 0.7 V, a K_{com} value of about 7×10^{11} is obtained.[31] This may well indicate that the mixed-valent $Fe^{II}Fe^{III}$ dication electrogenerated in the first oxidation process belongs to the delocalized (in the electrochemical timescale) Robin-Day class III. Analogously, the separation of 0.31 V evaluated for the $Fe^{II}Fe^{II}/Fe^{II}Fe^{I}/Fe^{I}Fe^{I}$ sequence should afford a K_{com} value of 2×10^5, which suggests that the neutral, mixed-valent $Fe^{II}Fe^{I}$ species electrogenerated in the first reduction process should be at the border of the slightly and the completely delocalized classes II and III. In this connection, a $K_{com} = 4 \times 10^{17}$ has been calculated for $Cp^*CrP_5CrCp^*$, which, also supported by EPR spectroscopic measurements, was classified as a delocalized $Cr^{II}Cr^{I}$ system.[2] It should be noted finally that, in spite of the chemical reversibility of the $Fe^{II}Fe^{II}/Fe^{II}Fe^{III}$ and $Fe^{II}Fe^{II}/Fe^{II}Fe^{I}$ redox changes on the cyclic voltammetric timescale, cyclic voltammetric tests performed after the exhaustive $Fe^{II}Fe^{II}/Fe^{II}Fe^{I}$ reduction show that the mixed-valent neutral species undergoes slow decomposition over the long timescales of macroelectrolysis.

The cyclic voltammetric profile of the pentamethylated analogue **3a** is quite similar to that of **3b**, exept for a general shift of all the redox processes towards more positive, or less negative, potential values. Indeed, as far as the anodic region is concerned, no further anodic step (which should correspond to the $Fe^{II}Fe^{III}/Fe^{III}Fe^{III}$ redox change) could be detected within the potential window of the solvent (about +1.7 V), probably because of this general anodic shift. As expected, the decrease in the number of methyl groups makes the $Fe^{II}Fe^{II}/Fe^{II}Fe^{III}$ oxidation somewhat more difficult (by 0.15 V), while favouring the $Fe^{II}Fe^{II}/Fe^{II}Fe^{I}$ reduction step (by 0.2 V) with respect to **3b**. Controlled potential coulometry at the first reduction process consumes one electron per molecule. The resulting solution no longer displays the original peak system, thus indicating that, as happens for **3b**, the neutral species is not indefinitely stable.

Let us now continue to the mixed-metal iron-ruthenium complexes **4a**–**c**. The cyclic voltammetric pattern of permethylated **4c** is very similar to that of the diiron analogue **3b**. An irreversible oxidation is also present at very positive potential values in this case, which in addition is complicated by electrode adsorption phenomena.

As illustrated in Figure 4, complex **4a**, which contains the Cp* ring at the ruthenium atom, undergoes either two discrete reductions, the first of which possesses features of partial chemical reversibility (the current ratio i_{pa}/i_{pc} is equal to 0.8 at 0.2 Vs^{-1}) whereas the second is substantially irreversible, or an irreversible oxidation, probably involving two electrons. From the redox potential of the related complex **3a**, it might be speculated that the first reduction process is centred on the iron fragment.

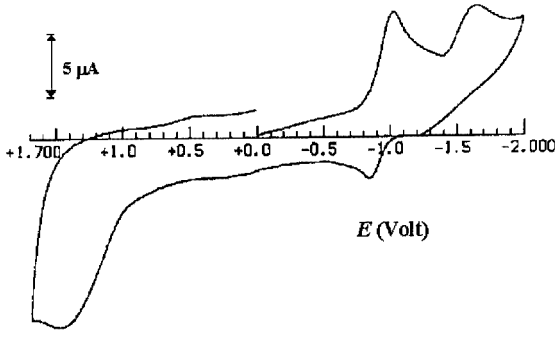

Figure 4. Cyclic voltammogram recorded at a platinum electrode of a CH_2Cl_2 solution containing **4a** (1.1×10^{-3} mol dm^{-3}) and $[Bu_4N][PF_6]$ (0.2 mol dm^{-3}); scan rate 0.2 Vs^{-1}

As illustrated in Figure 5, complex **4b**, which contains the Cp* ring at the iron atom, undergoes two separate oxidations and two apparently closely spaced reductions. In spite of the apparent irreversibility of both oxidation processes, cyclic voltammetry limited to the first oxidation step shows that a directly associated return peak can be detected at a high scan rate (see bottom inset). As far as the appearance of two slightly separated reduction processes is concerned, it must be taken into account that, as illustrated in the top inset, the second process is almost absent at low scan rates, indicating that the first step primarily involves a single two-electron reduction complicated by following chemical reactions.

Let us now examine the diruthenium complexes **5a** and **5b**. As illustrated in Figure 6, permethylated **5b** exhibits a single, partially chemically reversible, reduction process (the current ratio i_{pa}/i_{pc} is equal to 0.4 at 0.2 Vs^{-1} and 0.6 at 2.0 Vs^{-1}). Ill-defined oxidation processes are also present. Comparison with the one-electron oxidation of an equimolar amount of *N*,*N*-dimethyl-1-[1′,2-bis(diphenylphosphanyl)ferrocenyl]ethylamine ($M = 625.5$; $E_p = +0.53$ V) indicates that the cathodic process involves a two-electron addition. On the naive assumption that this process might correspond to the $Ru^{II}Ru^{II}/Ru^{I}Ru^{I}$ transition, its proceeding through a single step should suggest the absence of communication between the two ruthenium centres.

The partially methylated complex **5a** also undergoes a single two-electron reduction, as well as an ill-defined and unsplit multielectron oxidation. Analysis of the cathodic process with scan rate indicates that only at scan rates higher than 1.0 Vs^{-1} does a directly associated reoxidation peak clearly appear in the backscan. This means that the decomposition rate of the electrogenerated monoanion is

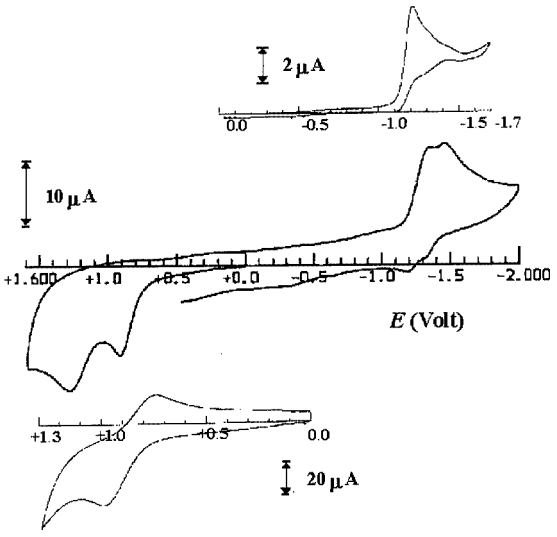

Figure 5. Cyclic voltammograms recorded at a platinum electrode of a CH_2Cl_2 solution containing **4b** (1.3×10^{-3} mol dm^{-3}) and $[Bu_4N][PF_6]$ (0.2 mol dm^{-3}); scan rate 0.2 Vs^{-1}; top inset: scan rate 0.05 Vs^{-1}; bottom inset: 2.0 Vs^{-1}

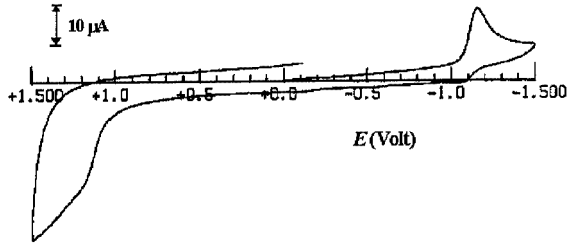

Figure 6. Cyclic voltammogram recorded at a platinum electrode of a CH_2Cl_2 solution containing **5b** (1.3×10^{-3} mol dm^{-3}) and $[Bu_4N][PF_6]$ (0.2 mol dm^{-3}); scan rate 0.2 Vs^{-1}

notably faster than that of **5b**. For **5b**, for instance, a current ratio i_{pa}/i_{pc} of 0.4 is reached at a scan rate of 0.2 Vs^{-1}, whereas for **5a** the same current ratio value is reached at 10.2 Vs^{-1}. Finally, and consistently with the partial demethylation, the reduction process occurs earlier (by 0.17 V) than that of **5b**.

Lastly, let us discuss the related cobalt-containing complexes $[(\eta\text{-}C_4Me_4)Co(\mu\text{-}\eta\text{:}\eta\text{-}P_5)MCp^*]^+$ (**6**: M = Fe; **7**: M = Ru).[32] Figure 7 immediately shows the different role played by a sandwiched iron against a ruthenium centre.

Similarly to the permethylated diiron complex **3b**, the iron-cobalt complex **6** undergoes either an oxidation or two reductions, all showing features of chemical reversibility [Figure 7, (a)]. Controlled potential coulometric experiments performed in correspondence to the first reduction process consume one electron per molecule. The exhaustively reduced solution maintains the red colour of the original species, but displays a cyclic voltammetric profile quite complementary to that shown in Figure 7. At variance with **3b**, this result testifies to the chemical reversibility of the one-electron reduction also on the long timescales of macroelectrolysis. On this basis we assign a one-electron na-

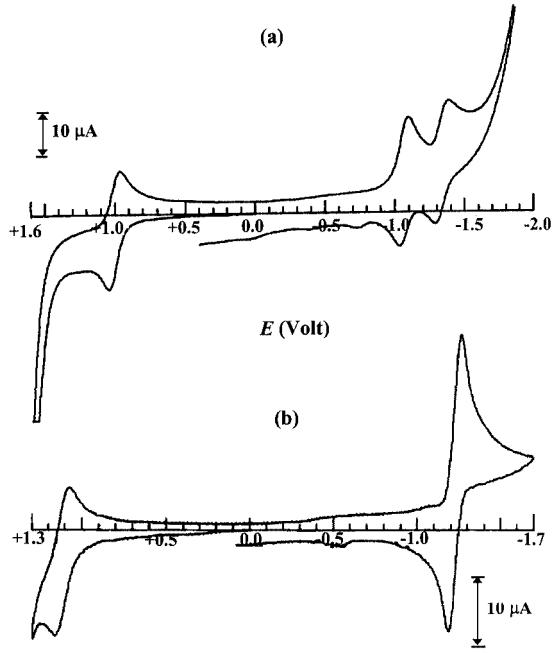

Figure 7. Cyclic voltammograms recorded at a platinum electrode of a CH_2Cl_2 solution containing $[Bu_4N][PF_6]$ (0.2 mol dm^{-3}) and: (a) **6** (1.6×10^{-3} mol dm^{-3}); (b) **7** (1.5×10^{-3} mol dm^{-3}); scan rate 0.2 Vs^{-1}

ture to all the redox processes. As far as the assignment of such redox steps is concerned, it is at the moment difficult to assign the oxidation process to the $Fe^{II}Co^{I}/Fe^{III}Co^{I}$ or to $Fe^{II}Co^{I}/Fe^{II}Co^{II}$ electron transfers, or the Co^{I} or Fe^{II} nature of the reduction processes.

The cyclic voltammetric profile exhibited by the cobalt-ruthenium complex **7** [Figure 7, (b)] is reminiscent of that of the iron-ruthenium complex **4b** and the diruthenium complex **5b**. It is evident that both the oxidation and the reduction have features of chemical reversibility. As can be seen, the height of the reduction step is about twice that of the oxidation step. Comparison of the peak heights with that of an equimolar amount of *N*,*N*-dimethyl-1-[1′,2-bis(diphenylphosphanyl)ferrocenyl]ethylamine reliably allows the cited redox changes to be assigned as two-electron and one-electron processes, respectively. It must be noted that the two-electron reduction in cyclic voltammetry at low scan rates displays a current ratio slightly lower than 1 (i_{pa}/i_{pc} is equal to 0.8 at 0.02 Vs^{-1}), thus suggesting that the electrogenerable monoanion undergoes slow decomposition. As in the case of **6**, it is difficult at the moment to assign the oxidation process as Ru^{II}- or Co^{I}-centred, whereas in this case, probably because of the reduction of the Cp*Ru system being generally more difficult than that of the Cp*Fe system (see **3b** and **5b**), the reduction process seems to involve the simultaneous reduction of both the Ru^{II} and Co^{I} centres.

In conclusion, it has been demonstrated that the presence of a ruthenium atom inside these triple-decker complexes tends to make the corresponding redox changes unstable.

Only if the ruthenium atom is bonded to the Cp* ring do the redox congeners partially increase their stability.

Conclusion

The stacking reactions of pentaphosphametallocenes **1** and **2** with half-sandwich fragments $[(\eta\text{-}C_5R_5)M']^+$ (M′ = Fe, Ru) were used to prepare triple-decker complexes **3b**, **4a**−**c**, **5a** and **5b**, in which the pentaphospholyl ligand is bifacially bonded with two metal atoms. These reactions are often complicated by side-formation of phosphane-type complexes, due to coordination of metal atoms with lone pairs of phosphorus atoms. Such complexes usually turn into triple-decker complexes on heating; the greater stability of phosphane-type complexes formed by **2** results in considerable differences in the conditions for the stacking reactions for **1** and **2**. The main structural feature of μ-pentaphospholyl triple-decker complexes is the elongation of bonds in the triple-decker fragment $M(\mu\text{-}\eta\text{:}\eta\text{-}P_5)M'$ as compared with the corresponding bonds in mononuclear sandwich compounds. Study of nucleophilic degradation reactions has shown that heterometallic (FeRu) triple-decker complexes are more reactive than their homometallic (Fe_2, Ru_2) analogues. Electrochemical data allow assignment of the diiron dication $\mathbf{3b}^{2+}$ as a class III (delocalized) mixed-valent species.

Experimental Section

General: All reactions were carried out under argon in anhydrous solvents. The isolation of products was conducted in air. Starting materials $[Cp^*Fe(CO)_2]_2$,[11] **2**,[33] $[CpFe(\eta\text{-}C_6H_6)]PF_6$,[34] $[Cp^*Fe(MeCN)_3]BF_4$,[11] $[CpRu(MeCN)_3]X$ (X = BF_4, PF_6),[35] $[Cp^*Ru(MeCN)_3]PF_6$ [36] and $[Cp^*RuCl_2]_2$ [37] were prepared as described in the literature. Complex **1** was prepared by Scherer's method,[38] with the use of the simplified isolation procedure given below. ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded with a Bruker AMX 400 spectrometer operating at 400.13, 100.61 and 161.98 MHz, respectively. Materials and the apparatus for electrochemistry have been described elsewhere.[39] *N*,*N*-Dimethyl-1-[1′,2-bis(diphenylphosphanyl)ferrocenyl]ethylamine was an Aldrich product. Potential values are referenced to the saturated calomel electrode (SCE).

$(\eta\text{-}P_5)FeCp^*$ (1): A mixture of $[Cp^*Fe(CO)_2]_2$ (4.5 g, 9.1 mmol) and P_4 (5 g, 40.3 mmol) in decalin (300 mL) was stirred under reflux for 3 h. The reaction solvents were evaporated to a small volume (ca. 30 mL) under atmospheric pressure and the remaining solvent was then removed at 100 °C under water-pump vacuum. Admixed P_4 was sublimed at 100 °C at ca. 0.1 Torr. The solid residue was recrystallized from petroleum ether to give dark green crystals. Yield 3.4 g (59%). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 152.7 ppm.

$[CpFe(\mu\text{-}\eta\text{:}\eta\text{-}P_5)RuCp^*]PF_6$ ($\mathbf{4aPF_6}$): Dichloromethane (10 mL) was added to a mixture of **2** (60 mg, 0.15 mmol) and $[CpFe(\eta\text{-}C_6H_6)]PF_6$ (52 mg, 0.15 mmol) in a Schlenk tube (d = 15 mm). The reaction mixture was irradiated for 10 h with a 400-W high-pressure discharge lamp (sodium lamp or mercury luminescent lamp). Both the Schlenk tube and the lamp were contained in a suitable vessel covered inside with aluminium foil; cooling was accomplished with running water. The solvent was removed in vacuo. The residue was dissolved in $MeNO_2$ (ca. 4 mL) and the solution was heated under reflux for ca. 2 h in order to destroy phosphane-type by-products. After removal of the solvent, unchanged **2** (15 mg) was extracted with ether. The residue was reprecipitated twice from CH_2Cl_2 with ether to give a red-brown solid. Yield 70 mg (71%). $C_{15}H_{20}F_6FeP_6Ru$ (657.06): calcd. C 27.42, H 3.07; found C 27.76, H 3.08.

$[Cp^*Fe(\mu\text{-}\eta\text{:}\eta\text{-}P_5)FeCp^*]BF_4$ ($\mathbf{3bBF_4}$): A mixture of **1** (115 mg, 0.33 mmol) and $[Cp^*Fe(MeCN)_3]BF_4$ (129 mg, 0.32 mmol) in CH_2Cl_2 or Me_2CO (10 mL) was stirred for 2.5 h at room temperature. The solvent was removed in vacuo and the residue was reprecipitated twice from CH_2Cl_2 with ether to give a green solid. Yield 120 mg (60%). $C_{21}H_{32}BCl_2F_4Fe_2P_5$ (**3b**BF_4·CH_2Cl_2; 708.75): calcd. C 35.59, H 4.55; found C 36.22, H 4.70.

$[Cp^*M(\mu\text{-}\eta\text{:}\eta\text{-}P_5)RuCp]X$ ($\mathbf{4bBF_4}$: M = Fe; $\mathbf{5aPF_6}$: M = Ru): A mixture of **1** (or **2**) (0.2 mmol) and $[CpRu(MeCN)_3]X$ (0.21 mmol) in $MeNO_2$ (5 mL) was heated under reflux for 5 h. The solvent was removed in vacuo and the residue was reprecipitated twice from CH_2Cl_2 with ether to give a red-brown solid. Compound **4b**BF_4: Yield 75 mg (63%). $C_{15}H_{20}BF_4FeP_5Ru$ (598.91): calcd. C 30.08, H 3.37; found C 29.46, H 3.36. Compound **5a**PF_6: Yield 58 mg (41%). $C_{15}H_{20}F_6P_6Ru_2$ (702.28): calcd. C 25.65, H 2.87; found C 26.45, H 2.89.

$[Cp^*Fe(\mu\text{-}\eta\text{:}\eta\text{-}P_5)RuCp^*]BF_4$ ($\mathbf{4cBF_4}$). A: A mixture of **1** (80 mg, 0.23 mmol), $[Cp^*RuCl_2]_2$ (57 mg, 0.09 mmol), $TlBF_4$ (125 mg, 0.43 mmol) and Zn dust (100 mg, excess) in Me_2CO (5 mL) was stirred for 2 h at room temperature. The solvent was removed in vacuo and the residue was reprecipitated twice from CH_2Cl_2 with ether to give a red-brown solid. Yield 104 mg (84%). $C_{20}H_{30}BF_4FeP_5Ru$ (669.04): calcd. C 35.90, H 4.52; found C 35.23, H 4.39. **B:** A solution of **1** (87 mg, 0.25 mmol) and $[Cp^*RuCl_2]_2$ (77 mg, 0.125 mmol) in ethanol (5 mL) was heated under reflux for 1 h. The solvent was removed in vacuo and the residue was dissolved in water (5−10 mL). The solution was filtered, and the filtrate was treated with 0.2 mL (excess) of aqueous HBF_4 (48%). The precipitate formed was filtered off, washed with water, dried in vacuo and reprecipitated from CH_2Cl_2 with ether to give a red-brown solid. Yield 134 mg (80%).

$[Cp^*Ru(\mu\text{-}\eta\text{:}\eta\text{-}P_5)RuCp^*]X$ ($\mathbf{5bBF_4}$, $\mathbf{5bPF_6}$). A: A mixture of $[Cp^*RuCl_2]_2$ (32 mg, 0.05 mmol), $TlBF_4$ (70 mg, 0.24 mmol) and Zn dust (100 mg, excess) in THF (5 mL) was stirred for 0.5 h at 0 °C. The solution of the thus formed solvate $[Cp^*Ru(THF)_3]BF_4$ was treated with **2** (41 mg, 0.11 mmol) and the mixture was heated under reflux for 8 h. The solvent was removed in vacuo and the residue was reprecipitated twice from CH_2Cl_2 with ether to give complex **5b**BF_4 as a red-brown solid. Yield 61 mg (82%). $C_{20}H_{30}BF_4P_5Ru_2$ (714.26): calcd. C 33.63, H 4.23; found C 33.45, H 4.18. **B:** A mixture of **2** (30 mg, 0.08 mmol) and $[Cp^*Ru(MeCN)_3]PF_6$ (42 mg, 0.08 mmol) in $MeNO_2$ (5 mL) was heated under reflux for 7 h. The solvent was removed in vacuo and the residue was reprecipitated twice from CH_2Cl_2 with ether to give complex **5b**PF_6 as a red-brown solid. Yield 34 mg (57%). $C_{20}H_{30}F_6P_6Ru_2$ (772.41): calcd. C 31.10, H 3.92; found C 31.28, H 3.72.

Nucleophilic Degradation of 4a by MeCN: A solution of **4a** (26 mg, 0.04 mmol) in MeCN (4 mL) was heated under reflux for 10 h. The solvent was removed in vacuo and the solid residue was extracted with ether. After removal of ether in vacuo, complex **2** was obtained as an orange solid. Yield 8 mg (ca. 50%). The residue, after extrac-

tion with ether, was extracted with CH_2Cl_2. Addition of ether to the solution regenerated starting material **4a** (8 mg, 30%).

Nucleophilic Degradation of 3a by NaI in MeCN: A solution of **3a** (31 mg, 0.05 mmol) and NaI·$2H_2O$ (100 mg, 0.54 mmol) in MeCN (4 mL) was heated under reflux for 10 h. The solvent was removed in vacuo and the solid residue was extracted with ether. After removal of ether in vacuo, complex **1** was obtained as a green solid. Yield 12 mg (ca. 70%).

X-ray Crystal Structure Determinations: Crystals of **4a**PF_6 and **5b**PF_6 were obtained by slow diffusion of petroleum ether into CH_2Cl_2 solutions of the complexes. Data collection was carried out with a Bruker SMART 1000 diffractometer with a CCD detector by a combination of four sets of ω scans (each scan 0.3° in 20 s), each set at different φ (2θ = −28°). Low crystal temperatures were maintained with a Cryostream (Oxford Cryosystems) open-flow N_2 gas cryostat. Unit cell parameters were determined with SMART software[40] and refined with SAINT[41] on all observed reflections. Data reduction was performed with SAINT, absorption corrections were applied with the SADABS program.[42] The detailed crystal data and structure refinement parameters are listed in Table 5. The structures were solved by direct methods and refined by full-matrix, least-squares against F^2 of all data, with SHELXTL software.[43] All non-hydrogen and hydrogen atomic positions were located in difference Fourier maps and refined in anisotropic and isotropic approximations, respectively. CCDC-177284 (**4a**PF_6) and -177285 (**5b**PF_6) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

In Situ Preparation of Palladium Diphosphane Catalysts

Angelica Marson,[a] A. Bart van Oort,[a] and Wilhelmus P. Mul*[a]

Keywords: Palladium / Phosphanes / Homogeneous catalysis / Copolymerization

The efficiency of a superficially simple preparation procedure for palladium-diphosphane catalysts has been examined. Preparation of $Pd(dppe)X_2$ in situ by mixing equimolar amounts of $Pd(OAc)_2$ and 1,2-bis(diphenylphosphanyl)-ethane (dppe) in methanol in the first step unexpectedly affords the bischelate $[Pd(dppe)_2](OAc)_2$ as the (main) kinetic product. Subsequently, the slow reaction of $[Pd(dppe)_2](OAc)_2$ and unreacted $Pd(OAc)_2$ forms the thermodynamically favored monochelate $[Pd(dppe)(OAc)_2]$ (following first-order kinetics). Conversion of the bischelate into the monochelate stops after addition of strong acid (HX) in the second step, thus affording a mixture of active — $Pd(dppe)X_2$ — virtually inactive — $[Pd(dppe)_2]X_2$ — and unstable — PdX_2 — species. This procedure was also evaluated for some other diphosphane ligands and methods are given to overcome the encountered problem.

The potential of homogeneous catalysis in the selective preparation of chemicals has been widely recognized, and the number of applications, both on a laboratory scale and on an industrial scale, is growing steadily.[1] In situ preparation of homogeneous catalysts from readily available precursors is a useful method, in particular when testing larger numbers of catalysts as in parallel screening. A convenient and frequently explored method to prepare cationic palladium diphosphane catalysts in situ involves two steps.[2] First, a suitable palladium source, such as $Pd(OAc)_2$, and the ligand of choice are mixed in a selected solvent [Equation (1)]. Next, a strong acid is added to exchange the anions [Equation (2)].

$$Pd(OAc)_2 + P\text{-}P \rightarrow [Pd(P\text{-}P)(OAc)_2] \quad (1)$$

$$[Pd(P\text{-}P)(OAc)_2] + 2\,HX \rightarrow [Pd(P\text{-}P)X_2] + 2\,HOAc \quad (2)$$

Although this method is often used, little attention has been given to the efficiency of catalyst preparation when using this procedure.

In the mid-eighties it was discovered that palladium(II)-based catalysts modified with the combination of a chelating diphosphane ligand and weakly or non-coordinating anions are highly active for the synthesis of perfectly alternating CO/ethene-based copolymer (PK-E). The most efficient system was based on 1,3-bis(diphenylphosphanyl)propane, which produces snow white PK-E with high rates (of 6 kg PK-E/g Pd·h and higher).[2,3] The activity of the catalyst based on its C_2-bridged counterpart, 1,2-bis(diphenylphosphanyl)ethane (dppe), was considerably lower.[2a] Moreover, the grey color of the PK-E product obtained during CO/ethene copolymerization employing the Pd(dppe)-based catalyst prepared in situ in methanol [Equations (1) and (2)] indicated significant catalyst decomposition to solid palladium(0) ("plating"). This prompted us to examine the in situ catalyst preparation procedure in methanol.

To this end, an equimolar mixture of $Pd(OAc)_2$ and dppe (32 μmol) was prepared in [D_4]methanol (0.8 mL). It was found that instead of the expected monochelate $[Pd(dppe)(OAc)_2]$ (**1**), the bischelate derivative $[Pd(dppe)_2](OAc)_2$ (**2**), characterized by a single ^{31}P NMR resonance at $\delta = 58.7$ ppm, was formed initially. Upon standing, slow conversion of **2** into **1** ($\delta = 63.4$ ppm) was observed (Scheme 1), which was virtually completed only after about 24 h, and accompanied by plating.

Mimicking the full in situ catalyst preparation procedure, six equivalents of a strong acid (CF_3CO_2H) were added well before the conversion of **2** into **1** was completed. Besides the expected exchange of the anions of the various palladium species [**1**, **2**, and unreacted $Pd(OAc)_2$], conversion of the catalytically inactive bischelate $[Pd(dppe)_2](CF_3CO_2)_2$ (**4**, $\delta = 58.6$ ppm) into the active monochelate species $[Pd(dppe)(CF_3CO_2)_2]$ (**3**, $\delta = 69.2$ ppm) also stopped (Scheme 1). This indicates that conversion of **2** into **1** is acetate-assisted. Moreover, a significant amount of palladium black was formed within a few hours due to decomposition of the co-formed palladium trifluoroacetate, a labile species in alcoholic media.

The conversion of **2** into **1** in [D_4]methanol at 20 °C was monitored by ^{31}P NMR spectroscopy and found to nicely follow first-order kinetics ($k = 0.145\ h^{-1}$; see Figure 1). At a higher degree of conversion (>80%), however, this conversion proceeded somewhat slower, which might be due to partial decomposition (plating) of $Pd(OAc)_2$ and **1**. Extrapolation of the kinetic curve to $t = 0$ h showed that, ini-

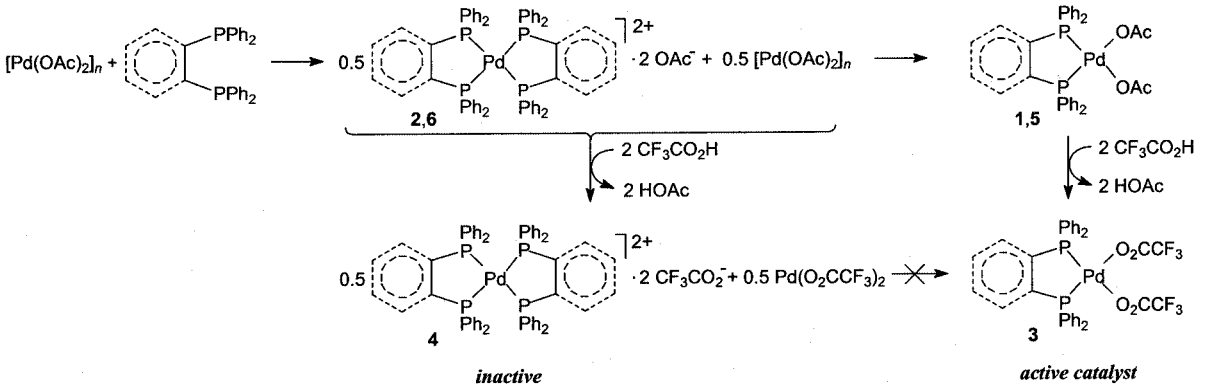

Scheme 1. Reactions observed during preparation of some palladium diphosphane catalysts in situ; P-P = dppe (**1**–**4**) or dppbz (**5**,**6**)

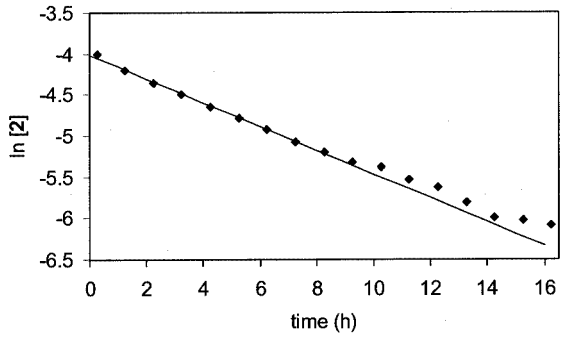

Figure 1. Conversion of **2** + $Pd(OAc)_2$ into **1** in [D_4]methanol at 20 °C

tially, **2** had formed almost quantitatively (approx. 90%). In a separate experiment equimolar amounts of isolated, pure **2** and $Pd(OAc)_2$ were dissolved in [D_4]methanol and the conversion into **1** was found to exhibit identical kinetics.

These observations clearly indicate that **2** is the kinetic product of the reaction of $Pd(OAc)_2$ and dppe, but **1** is thermodynamically favored. Further, it indicates that **1** and **2**, in contrast to Bianchini's recent conclusion,[4] are not involved in an autoionization equilibrium (2 [Pd(dppe)$(OAc)_2$] (**1**) ⇌ [Pd(dppe)$_2$]$(OAc)_2$ (**2**) + $Pd(OAc)_2$ in methanol, otherwise conversion of **2** into **1** would not have proceeded to completeness.[5] This was confirmed in a separate experiment using isolated, pure **1**: upon dissolution in [D_4]methanol, no conversion of **1** into **2** was observed (over 24 h).

It was considered that the initial formation of [Pd(dppe)$_2$]$(OAc)_2$ might be due to a relatively slow dissolution of $Pd(OAc)_2$ in methanol in comparison with dppe, causing an initial deficiency of accessible (dissolved) $Pd(OAc)_2$. To check this hypothesis, an experiment was done in which $Pd(OAc)_2$ was first dissolved in a mixture of methanol/dichloromethane (9:1) before dppe was added. Immediate formation of **2** and some **1** was observed by ^{31}P NMR spectroscopy, followed by slow conversion of **2** into **1**. Extrapolation of the kinetic curve for the conversion of **2** into **1** back to t = 0 h indicated initial formation of **2** and **1** in a ratio of about 80:20. The hypothesis of slow dissolution of $Pd(OAc)_2$ being the prime cause for the initial formation of **2** instead of **1** could therefore be discarded.

The origin of the anomalous course of the reaction is possibly related to the nature of $Pd(OAc)_2$ dissolved in methanol. It is well-known that in solution $Pd(OAc)_2$ may occur in various forms. For example, in benzene and toluene $Pd(OAc)_2$ exists as a linear trimer at 39 °C, and as a monomer at 80 °C, while an acetate-bridged cyclic trimer with D_{3h} symmetry is obtained when $Pd(OAc)_2$ is crystallized from benzene.[6] The ^1H NMR spectrum of $Pd(OAc)_2$ in methanol shows a large number of signals around δ = 2 ppm for the acetate anion, the relative intensities of the signals being dependent on the concentration and on the water content of the methanol, amongst other factors. This is indicative of the presence of $Pd(OAc)_2$ in a variety of aggregates, $[Pd(OAc)_2]_n$, with n = 1, 2, 3, etc., while even the occurrence of ionic species like $[Pd_n(OAc)_{2n-1}]^+(OAc)^-$ cannot be excluded. Apparently, the kinetically preferred pathways along which these clusters break up give rise to the preferential formation of **2**.

Subsequent conversion of **2** into **1** occurs with first-order kinetics and is acetate-assisted, suggesting the involvement of a single species in the rate-determining step. Taking the involvement of acetate into account, a possible option for this species is the adduct of **2** and acetate, five-coordinated, mono-cationic $[Pd(dppe)_2(OAc)]^+$. However, the difference in the ^{31}P chemical shift between **2** (δ = 58.7 ppm) and [Pd(dppe)$_2$]$(CF_3CO_2)_2$ (**4**, δ = 58.6 ppm) is negligible and does not point to association of an acetate anion in the former. Hence, step-wise dissociation of one of the dppe ligands starting from $[Pd(dppe)_2]^{2+}$ (**2**) seems a more likely pathway. The first, rate-determining step could well be the generation of $[Pd(\sigma,\sigma\text{-dppe})(\sigma\text{-dppe})(S)]^{2+}$, which is rapidly transferred into the more stable $[Pd(\sigma,\sigma\text{-dppe})(\sigma\text{-dppe})(OAc)]^+$, from which the dppe ligand can fully dissociate, possibly via a dppe-bridged dimer of type $[(OAc)Pd(\sigma,\sigma\text{-dppe})(\mu\text{-dppe})Pd(OAc)_2]^+$.

Next, the influence of the preparation procedure on the performance of [Pd(dppe)$(CF_3CO_2)_2$] (**3**) as a catalyst for CO/ethene copolymerization was investigated. The catalyst was either prepared in situ in methanol, by mixing dppe and $Pd(OAc)_2$, followed by addition of six equivalents of trifluoroacetic acid after about 10 min (run A) or by anion exchange starting from isolated, pure **1** (run B). The CO/ethene copolymerizations were performed under standard

catalyst screening conditions (90 °C, 5 MPa) for 2.5 h, in a solvent mixture consisting of methanol and water (98:2). In run A a grey copolymer product was obtained at a productivity of 390 g/g Pd·h, while in run B an almost white product was obtained at much higher productivity (910 g/g Pd·h). This clearly shows that preparation of catalyst **3** in methanol in situ from $Pd(OAc)_2$, ligand and acid is inferior to preparation from pure **1**, which is fully in line with the NMR studies. Interestingly, the ester to ketone end-group ratio in the copolymer products (ca. 45:55) deviated from the theoretical value of 1.[7,8] Formation of an excess of ketone end-groups is probably caused by increased partial initiation via a Pd-H species instead of via Pd-OCH_3. This can occur if initiation via the reactions given in Equations (7) to (10) efficiently competes with those given in Equation (5) and (6).

$$[Pd(P\text{-}P)]^{2+} + MeOH \rightleftharpoons [Pd(P\text{-}P)(OMe)]^{+} + H^{+} \quad (5)$$

$$[Pd(P\text{-}P)(OMe)]^{+} + CO + CH_2{=}CH_2 \rightarrow\rightarrow [Pd(P\text{-}P)\{CH_2CH_2C(O)OMe\}]^{+} \quad (6)$$

$$[Pd(P\text{-}P)(OMe)]^{+} \rightarrow [Pd(P\text{-}P)H]^{+} + CH_2O \quad (7)$$

$$[Pd(P\text{-}P)]^{2+} + H_2O \rightleftharpoons [Pd(P\text{-}P)(OH)]^{+} + H^{+} \quad (8)$$

$$[Pd(P\text{-}P)(OH)]^{+} + CO \rightleftharpoons [Pd(P\text{-}P)\{C(O)OH\}]^{+} \rightarrow [Pd(P\text{-}P)H]^{+} + CO_2 \quad (9)$$

$$[Pd(P\text{-}P)H]^{+} + CO + 2\,CH_2{=}CH_2 \rightarrow\rightarrow [Pd(P\text{-}P)\{CH_2CH_2C(O)CH_2H_3\}]^{+} \quad (10)$$

We also examined the efficiency of in situ catalyst preparation in methanol for some other palladium diphosphane systems. It was found that mixing of equimolar amounts of $Pd(OAc)_2$ and dppbz in methanol at room temp. also initially affords a mixture of monochelate $[Pd(dppbz)(OAc)_2]$ (**5**; δ = 60.3 ppm) and bischelate $[Pd(dppbz)_2](OAc)_2$ (**6**; δ = 56.0 ppm) in a ratio of about 20:80. Subsequent conversion of **6** and unreacted $Pd(OAc)_2$ into **5** proceeded about four times slower ($k = 0.037\ h^{-1}$) than for the dppe counterpart and was inevitably accompanied by plating, as unprotected $Pd(OAc)_2$ is not stable in methanol. As a result, no complete conversion of **6** into **5** took place. As for **1**, the occurrence of autoionization of **5** in methanol was discarded in a separate experiment. No conversion was observed of **5** into **6** and $Pd(OAc)_2$ (h-scale).

Preparation of $[Pd(dppp)(CF_3CO_2)_2]$ in methanol via Equation (1) and (2) was found to proceed smoothly, and no species other than the desired one was observed by ^{31}P NMR spectroscopy. This does not necessarily imply that the bischelate $[Pd(dppp)_2](OAc)_2$ is not an intermediate in the first step. $[Pd(dppp)]_2(OAc)_2$ prepared in situ was found to convert instantaneously into the monochelate $[Pd(dppp)(OAc)_2]$ upon addition of an equimolar amount of $Pd(OAc)_2$, indicating its *kinetic stability* to be much lower than that of its C_2-bridged diphosphane counterparts **2** and **6**.

An anomalous feature was observed whilst monitoring in situ preparation of $[Pd(bdompp)(CF_3CO_2)_2]$ {bdompp = 1,3-bis[di-(*o*-methoxyphenyl)phosphanyl]propane}, the catalyst employed in the manufacture of polyketone on a commercial scale.[9] Mixing $Pd(OAc)_2$ and bdompp in methanol does not afford the monochelate $[Pd(bdompp)(OAc)_2]$ nor the bischelate $[Pd(bdompp)_2](OAc)_2$ as the kinetic product, but a complex mixture of palladium-diphosphane species. It is assumed that these species are oligomeric in nature, but all attempts to characterize these species unambiguously (by NMR spectroscopy and electrospray-MS) failed. Upon standing, the complex mixture slowly converted into monomeric $[Pd(bdompp)(OAc)_2]$. Almost complete conversion (>95%) took more than 16 h at ambient temperature and was accompanied by some plating.

In conclusion, it has been shown that in situ preparation of palladium diphosphane catalysts is not a trivial affair. Instead of the desired mononuclear monochelate catalyst, $Pd(P\text{-}P)X_2$, undesired formation of inactive bischelate (dppe, dppbz) or oligomeric species (bdompp) may occur. This problem may be overcome by rational selection of the solvent in which the catalyst is prepared, or by synthesis and isolation of the $[(P\text{-}P)Pd(OAc)_2]$ intermediate prior to anion exchange in methanol.

Experimental Section

General: The ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded on Varian GEMINI-300 and Varian INOVA-400 spectrometers operating at 300.1 and 400.0 for ^1H, at 75.5 MHz and 100.6 MHz for ^{13}C, and at 121.5 MHz and 161.9 MHz for ^{31}P. Deuterated solvents were used as internal reference, and the ^{31}P data are given in δ units relative to triphenylphosphane (δ = −6 ppm). All chemicals were reagent grade and were used without further purification for synthetic and spectroscopic purposes. The diphosphanes 1,2-bis(diphenylphosphanyl)ethane (dppe), 1,3-bis(diphenylphosphanyl)propane (dppp) and 1,2-bis(diphenylphosphanyl)-benzene (dppbz) were purchased from Strem Chemicals. The diphosphane 1,3-bis[di-(*o*-methoxyphenyl)phosphanyl]propane (bdompp) was synthesized according to literature procedures.[10] The CO/ethene copolymerization reactions were carried out in a 250 mL, magnetically stirred AISI-316 steel batch autoclave.

Synthesis of $[Pd(dppe)(OAc)_2]$ (1): $Pd(OAc)_2$ (0.50 g; 2.23 mmol) was dissolved in 30 mL of dichloromethane and dppe (0.89 g, 2.23 mmol) was added to the filtered red solution, which turned yellow. After 10 min half of the solvent was removed under vacuum and a pale yellow solid precipitated upon addition of diethyl ether. This solid was isolated by filtration and washed twice with diethyl ether. Yield: 1.18 g (85%). $C_{30}H_{30}O_4P_2Pd$ (622.9): calcd. C 57.84, H 4.85; found C 57.89, H 4.91. ^1H NMR (CD_3OD): δ = 1.56 [s, 6 H, $CH_3C(O)O$], 2.58 (m, 4 H, CH_2P), 7.60 (m, 12 H), 7.89 (dd, 8 H) ppm. $^{31}P\{^1H\}$ NMR (CD_3OD, 20 °C): δ = 63.4 ppm.

Synthesis of $[Pd(dppe)_2](OAc)_2$ (2): dppe (0.32 g; 0.80 mmol) was added to a solution of the isolated complex **1** (0.50 g; 0.80 mmol) in 30 mL of methanol. After 10 min the solution was concentrated to half of the original volume and diethyl ether was added resulting in the precipitation of a yellow solid, which was isolated by filtration and washed twice with diethyl ether. Yield: 0.74 g (90%). $C_{56}H_{54}O_4P_4Pd$ (1021.3): calcd. C 65.85, H 5.33; found C 65.79, H 5.28. ^1H NMR (CD_3OD): δ = 1.78 [s, 6 H, $CH_3C(O)O$], 2.79 (m, 8 H, CH_2P), 7.26 (m, 16 H), 7.44 (t, 16 H), 7.61 (t, 8 H) ppm. $^{31}P\{^1H\}$ NMR (CD_3OD, 20 °C): δ = 58.7 ppm.

Copolymerization of Carbon Monoxide and Ethene: *Catalyst preparation*. The catalyst was either prepared in situ (run A) by mixing $Pd(OAc)_2$ (2.5 mg, 11 μmol) and dppe (5.6 mg, 12 μmol) in methanol (2 mL), followed by the addition of trifluoroacetic acid (7.8 mg, 68 μmol) after 15 min, or (run B) by mixing isolated $Pd(dppe)(OAc)_2$ (**1**, 7 mg, 11 μmol) and trifluoroacetic acid (7.8 mg, 68 μmol) in methanol (2 mL).

Copolymerization. The reactor was charged with catalyst solution and with 98 mL of a methanol/water mixture (98:2 v/v). After purging the reactor with nitrogen, it was charged with ethene (2.5 MPa) and carbon monoxide (2.5 MPa), and heated to 90 °C. After 2.5 h the reaction was stopped by cooling the reactor rapidly to room temperature and venting the remaining gases. The reaction product was collected by filtration and dried at 55 °C for one day under nitrogen. The isolated grey (run A) or slightly grey copolymer (run B) was weighed and characterized by ^{13}C NMR spectroscopy in C_6D_6/1,1,1,3,3,3-hexafluoro-isopropanol, using $Cr(acac)_3$ as a relaxation reagent, providing M_n, and the methyl ester (**E**) to ethyl ketone (**K**) end-group ratio.[2]

Yield (run A) = 1.08 g, rate = 390 g/g Pd·h, M_n = 6600 Da, **E/K** ratio = 42:58, bulk density = 210 g/L; Yield (run B) = 2.27 g, rate = 910 g/g Pd·h, M_n = 4100 Da, **E/K** ratio = 45:55, bulk density = 108 g/L.

Acknowledgments

We thank Prof. Dr. E. Drent for his stimulating interest and Shell International Chemicals B. V. for giving permission to publish this paper.

Encapsulation of Copper(II) Complexes with Pentadentate N_3O_2 Schiff Base Ligands in a Pillared Layered Clay

Rita Ferreira,[a] Cristina Freire,*[a] Baltazar de Castro,*[a] Ana P. Carvalho,[b] João Pires,[b] and Manuela B. de Carvalho[b]

Keywords: Clays / Microporous materials / Copper / Schiff bases

Two copper(II) complexes with five-coordinate Schiff-base ligands derived from acetylacetone and with a N_3O_2 coordination sphere, namely bis(acetylacetonate)-3-amino-bis(propyldiimine) and bis(acetylacetonate)-3-methylamino-bis(propyldiimine), were entrapped in the interlayers of a pillared layered clay (PILC). A two-step process in the liquid phase was used: (i) adsorption of copper(II) acetylacetonate in the porous structure of the PILC, and (ii) in situ Schiff condensation of the copper(II) precursor complex with the corresponding triamine. The new materials were characterised by chemical analysis, surface techniques (SEM and XPS), X-ray powder diffraction, nitrogen adsorption isotherms and spectroscopic methods (FTIR, UV/Vis). These data indicate conclusively that the Cu^{II} complexes are encapsulated in the PILC, and that the entrapped complexes exhibit structural and electronic properties that are different from those of the free complexes. These differences can arise from distortions caused either by steric effects imposed by the structure of pillared clay, or by strong interactions with the matrix.

Introduction

Transition metal complexes have been proven to be efficient catalysts in several industrial chemical reactions.[1−3] A particularly strong area of research in catalysis is the immobilization of metal complexes used in homogeneous catalysis onto solid supports such as zeolites,[4,5] polymers,[6,7] carbons,[8−10] and other porous-structured materials.[11−13] This heterogenization often combines the homogeneous catalytic properties of metal complexes with some characteristics of the heterogeneous catalysts, such as shape selectivity, ease of separation from reaction media, and reusability without appreciable loss of catalytic activity.

Pillared layered clays (PILCs) are a recently developed family of porous materials obtained by exchanging the interlayered cations of swelling clays with bulky inorganic polyoxo and polyhydroxy cations.[14,15] Upon calcination they are converted into metal oxide clusters creating an interlayer space of molecular dimensions and a well-defined pore system.[14−17] Introduction of pillars between layers is an attractive route for the preparation of porous materials in which pore size and thermal stability can be tailored by the appropriate choice of the polyoxo and polyhydroxy cations.[17]

The most widely used polycation is $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$, usually denoted as Al_{13}, mainly because its polymerisation is better understood than that of other cations. Consequently, the alumina-pillared clays (Al-pillared clays) are by far the best documented pillared clays.[15] Although metallic polyoxo or polyhydroxo cations of Al^{3+} and also of other ions, namely Zr^{4+}, Ti^{4+}, Cr^{3+}, Fe^{3+}, or Ga^{3+}, are the most widely used intercalating species, several coordination and organometallic compounds have recently been considered for this purpose.[19−21]

The catalytic properties of PILCs are mainly related to their acid character,[15,18] as seen by their uses in hydrogenation, hydrotreating and isomerisation reactions. The incorporation of transition metal elements to the composition of Al PILCs not only increases their Brönsted acidity, but also allows them to be used in catalytic redox reactions.[15,18]

In recent years, pillared clays have also been used as supports for transition metal compounds, typically their salts, which are deposited on pillared clays by ionic exchange, incipient wetness, or dry impregnation of calcined samples. Copper, vanadium, and platinum have been the preferred active phases, and, to a lesser extent, molybdenum, cobalt, and other elements.[15] Nevertheless, the use of pillared clays to act as hosts for coordination and organometallic compounds is poorly documented,[22] in contrast with what is found for other aluminosilicates, such as zeolites[4,5] and swelled clays.[23]

We have been interested in the heterogenisation of transition metal complexes in zeolites[24,25] and activated carbons[8−10] and have shown that the methodologies used

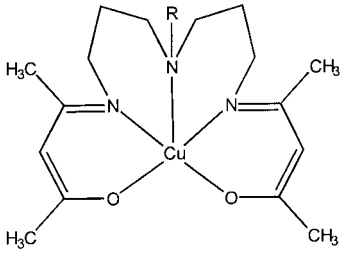
for immobilisation/anchorage of the metal complexes are largely determined by the supports. The analogy between PILCs and zeolites NaX and NaY prompted us to explore the properties of the former as supports for the encapsulation of transition metal complexes. Here we use a pillared clay, denoted as BENAVILA (named after the region in Portugal from where the clay was obtained), which has been extensively characterised previously.[26] We have chosen to encapsulate two copper Schiff-base complexes, since their in situ preparation has been worked out for their immobilisation in FAU zeolites.[24,25]

The two copper(II) complexes with pentadentate N_3O_2 Schiff-base ligands derived from acetylacetone − bis(acetylacetonate)-3-amino-bis(propyldiimine) and bis(acetylacetonate)-3-methylamino-bis(propyldiimine) (Scheme 1) − were encapsulated in the pores of BENAVILA using a procedure similar to that used in the encapsulation of the same complexes in NaX and NaY zeolites.[24,25] This methodology involves in situ Schiff condensation between a Cu^{II} precursor complex, [Cu(acac)$_2$], and the corresponding triamine.



Scheme 1. [Cu(acac$_2$trien)], R = H; [Cu(acac$_2$Metrien)], R = CH_3

The BENAVILA with entrapped complexes was characterised by chemical analysis, surface techniques (SEM and XPS), X-ray powder diffraction, nitrogen adsorption isotherms and spectroscopic methods (FTIR and UV/Vis). Our data indicate that copper complexes in the PILC exhibit structural and electronic properties that are different from those of the free complexes, caused either by steric effects imposed by the structure of the pillared clay, or by strong interactions with the matrix.

Results and Discussion

Morphology and Cu Content of the Modified BENAVILA

The modified PILC with [Cu(acac)$_2$], denoted as [Cu(acac)$_2$]@BEN, was not purified by Soxhlet extraction, as the precursor square-planar complex [Cu(acac)$_2$], due to its dimensions, can diffuse out of the supporting material. Soxhlet extraction was performed only for the modified BENAVILA with the complexes [Cu(acac$_2$trien)] and [Cu(acac$_2$Metrien)]; these materials {denoted as [Cu(acac$_2$trien)]@BEN and [Cu(acac$_2$Metrien)@BEN} did not change colour after extensive extraction, and after the last extraction no bands due to copper species could be detected in the extracting solvent. These results indicate that the resulting metal complexes are too large to diffuse out of the PILC layers, and that encapsulation of metal complexes after in situ Schiff condensation has taken place.

Analysis of the SEM micrographs of the parent and modified BENAVILA indicates that there is no change in the BENAVILA morphology and structure upon complex encapsulation. In the SEM micrograph of all samples, exemplified in Figure 1 for [Cu(acac$_2$Metrien)]@BEN, two types of particles with different morphology and dimen-

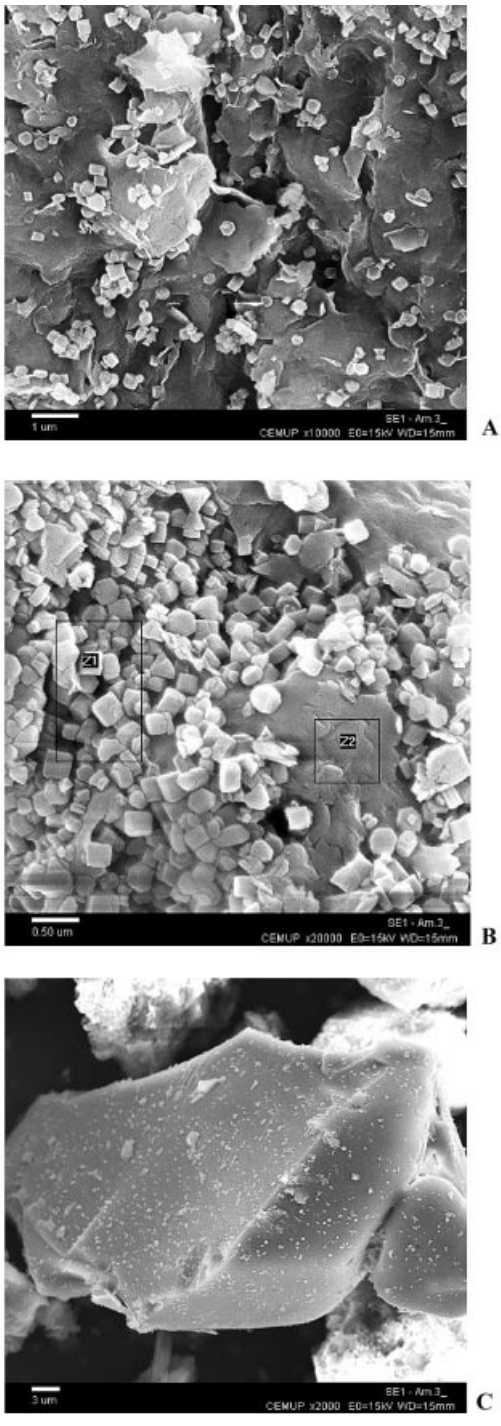


Figure 1. SEM photographs of [Cu(acac$_2$Metrien)]@BEN with different resolutions: × 10000 (A); × 20000 (B) and × 2000 (C)

sions can be observed: (i) small crystalline particles with dimensions of roughly 0.2 μm, and (ii) particles with lamellar morphology and larger dimensions (Figure 1A). By semi-quantitative EDS analysis of the different particles (Figure 1B) it is possible to assign the latter particles to the pillared clay (Figure 1C). As the small crystalline particles have high aluminium and oxygen content relative to the general composition of BENAVILA particles, we propose them to be probably aluminium oxides originating in the pillaring process. Furthermore, no crystals due to adsorbed metal complexes could be detected in any of the modified pillared clays, suggesting that the metal complexes are evenly distributed throughout the PILC.

A comparison of the X-ray diffractograms of the parent BENAVILA with those of modified PILCs (Figure 2) indicates that the structure of the PILC is retained upon metal complex immobilisation, as revealed by the proximity of the basal spacing, which is 1.8 nm for the nonencapsulated material and 1.73 nm for the encapsulated samples. As can be seen from this figure no appreciable changes are seen in the characteristic diffraction peak after encapsulation.

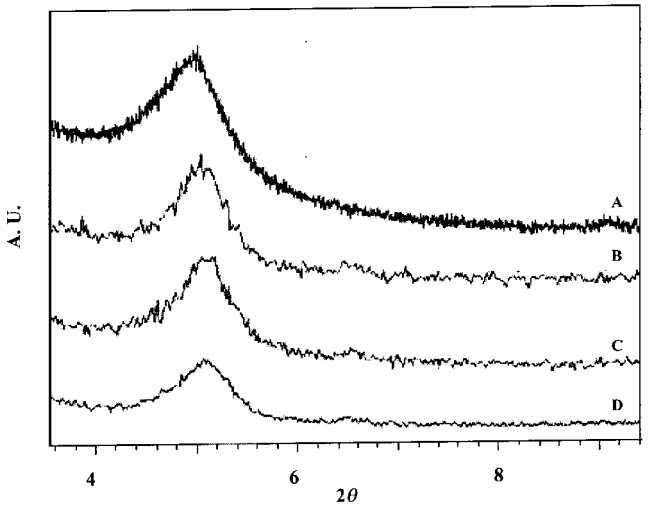

Figure 2. X-ray diffractograms for the BEN PILC: before encapsulation (A) and after encapsulation with [Cu(acac)$_2$] (B); [Cu(acac)$_2$trien] (C) and [Cu(acac)$_2$Metrien] (D)

The Si/Al, Cu/Si and Cu/Al molar ratios obtained by bulk chemical analysis and by XPS are presented in Table 1. A comparison of the Si/Al ratios obtained by chemical analysis and XPS reveals that the surface of the clay is, in general, enriched in silicon upon immobilisation of the complexes, as has been observed in several zeolites with occluded metal complexes.[27,28]

A comparison between the copper content determined by chemical analysis (Table 1) in [Cu(acac)$_2$]@BEN with that in the samples resulting from the Schiff condensation suggests that practically all adsorbed [Cu(acac)$_2$] complexes have reacted with the triamines and have became trapped inside the PILC. The Cu/Si and Cu/Al ratios obtained by chemical analysis and XPS do not differ markedly, although the values of XPS for [Cu(acac$_2$trien)]@BEN and [Cu(acac$_2$Metrien)]@BEN are slightly lower than those obtained by CA. This result suggests that upon reaction with triamines the copper complexes are located preferentially in inner pores.

Table 1. Si/Al, Cu/Si and Cu/Al ratios determined by chemical analysis (CA) and XPS in BENAVILA

Samples	Si/Al		Cu/Si		Cu/Al	
	CA	XPS	CA	XPS	CA	XPS
BENAVILA	1.16	1.17	–	–	–	–
[Cu(acac)$_2$]@BEN	1.17	1.22	0.017	0.017	0.020	0.014
[Cu(acac$_2$trien)]@BEN	1.18	1.19	0.017	0.014	0.020	0.012
[Cu(acac$_2$Metrien)]@BEN	1.22	1.21	0.020	0.016	0.024	0.013

A comparison between Cu content in BENAVILA with that in NaX[25] and in NaY[24] zeolites indicates that the loading of metal complexes occurs to a larger extent in the PILC. Despite its lower micropore volume, the PILC has a more open structure than the faujasite zeolites. Two factors can account for this behaviour: on the one hand the heights of the galleries, which have been estimated as 8.4 Å, are larger than the supercage entrances of Y and X zeolites (7.3 Å). On the other hand, the nature of the network of PILCs microporosity, in which the spacing between the pillars is not absolutely regular, can lead to the existence of regions of lower pillar density that can favour the accommodation of large molecules. Moreover, few studies have been made on the cross-linking between the pillars and the clay sheets, which leaves as an open question the possibility of the pillars also being distorted to some degree.[29]

The N_2 adsorption isotherms for parent and modified BENAVILA (Figure 3) are typical of solids which are mainly microporous, although the existence of hysteresis loops suggests some degree of mesoporosity, which is a consequence of the secondary structure of the clay particles. It is interesting to note that the loops are similar in all samples, which means that the encapsulation process does not modify the original mesoporosity of the PILC.

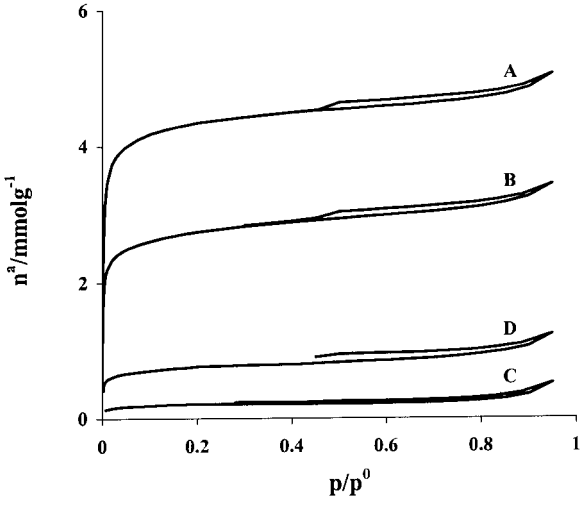

Figure 3. Nitrogen adsorption-desorption isotherms at 77 K of the samples BENAVILA (A), [Cu(acac)$_2$]@BEN (B), [Cu(acac$_2$trien)]@BEN (C), and [Cu(acac$_2$Metrien)]@BEN (D)

As expected, a decrease in adsorption capacity of the PILC was observed after immobilisation of [Cu(acac)$_2$] (to around 53% of the initial value), and a much more drastic decrease (up to 3−12% of the initial value) after Schiff-base condensation. The micropore volumes (obtained by the t-method) and the BET surface are presented in Table 2. The large reduction in micropore volume observed in the Cu-encapsulated BENAVILA is interpreted as arising from the presence of the copper compounds in the interlayers. As the copper content in all samples is roughly the same (Table 1), the observed lowering of micropore volume on going from [Cu(acac)$_2$] to [Cu(acac$_2$Metrien)] and [Cu(acac$_2$trien)] must be attributed to the larger volume of the latter complexes, thus providing indirect confirmation that Schiff condensation took place within the PILC.

Table 2. Textural properties for parent and copper-modified BENAVILA

Samples	A_{BET} (m^2/g)	V_{micro}[a] (cm^3/g)
BENAVILA	350	0.115
[Cu(acac)$_2$]@BEN	221	0.066
[Cu(acac)$_2$trien]@BEN	17	0.003
[Cu(acac)$_2$Metrien]@BEN	61	0.014

[a] Estimated using the t-method.

FTIR Spectra

Vibrational spectroscopy can provide information on both the encapsulated metal complexes and on the crystallinity of the host material. The FTIR spectra of the parent and modified BENAVILA are shown in Figure 4. The spectra of all samples are dominated by the very intense bands of BENAVILA in the range 3700−3300 cm^{-1}, due to surface hydroxyl groups, and in the range 1300−450 cm^{-1} which are assigned to lattice vibrations (Figure 4, I).[30] The bands due to the complexes are much weaker, as they are diluted in the PILC, and can only be observed in the region 1620−1200 cm^{-1}, where the BENAVILA matrix does not absorb (Figure 4, II).

No shift or broadening of the PILC structure-sensitive vibrations was observed upon inclusion of the complexes, which provides evidence, at the molecular level, that the matrix remains unchanged upon encapsulation of the copper complexes.

The IR bands of adsorbed [Cu(acac)$_2$] in the range 1620−1200 cm^{-1}, which are assigned to the coupled C=O and C=C stretching vibrations and to bending vibrations of methyl groups, occur at frequencies which are shifted by between 5 and 9 cm^{-1} from those shown by the free complex (Figure 4, II-B, E).[31] Furthermore, some changes in relative band intensities can also be observed in these bands. These observations confirm the presence of [Cu(acac)$_2$] in the PILC, and suggest that the structure of the adsorbed complex is distorted when compared with that of the square-planar free complex. This is a consequence of

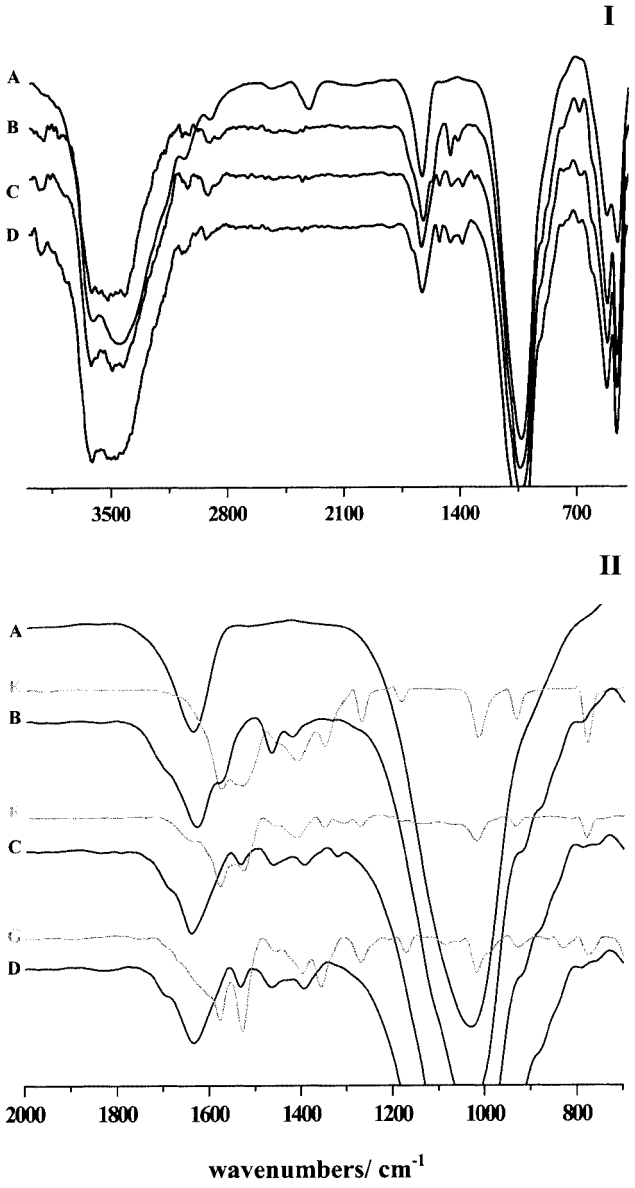

Figure 4. FTIR spectra: (I) in the range 4000−400 cm^{-1}: BENAVILA (A), [Cu(acac)$_2$]@BEN (B), [Cu(acac$_2$trien)]@BEN (C), and [Cu(acac$_2$Metrien)]@BEN (D); (II) in the region 2000−700 cm^{-1}: BENAVILA (A), [Cu(acac)$_2$]@BEN (B), [Cu(acac$_2$trien)]@BEN (C), [Cu(acac$_2$Metrien)]@BEN (D), and the free complexes [Cu(acac)$_2$] (E), [Cu(acac$_2$trien)] (F), and [Cu(acac$_2$Metrien)] (G)

host-guest interactions with the PILC, eventually to the extent of the formation of a chemical bond to the framework, as the PILC can act as a ligand to copper through its matrix oxygen atoms.

The IR spectra of [Cu(acac$_2$trien)]@BEN and [Cu(acac$_2$Metrien)]@BEN (Figure 4, II-C, D) clearly show the absence of the characteristic coupled ν(C=O) + ν(C=C) vibration of [Cu(acac)$_2$], as expected after Schiff condensation with the triamines within the PILC. The trapped complexes exhibit IR bands at 1527−1533, 1466−1464 and 1394 cm^{-1} which are similarly shifted by between 5 and 10 cm^{-1} relative to those of the free complexes (Figure 4, II-F, G). These variations in band frequency can also be at-

tributed to distortion of the complexes induced by the PILC porous structure, or to coordination of the complexes to the oxygen matrix through the sixth (free) coordination position.

UV/Vis Spectroscopy

The parent pillared layered clay exhibits, in the range 1300−200 nm, several medium-intensity broad bands at λ_{max} =265, 482 and 630 nm. These bands occur in the same range as some of the expected d-d bands for the copper complexes, which prevents a direct observation of their electronic spectra due not only to their low concentration but also to their small extinction coefficients (Figure 5).

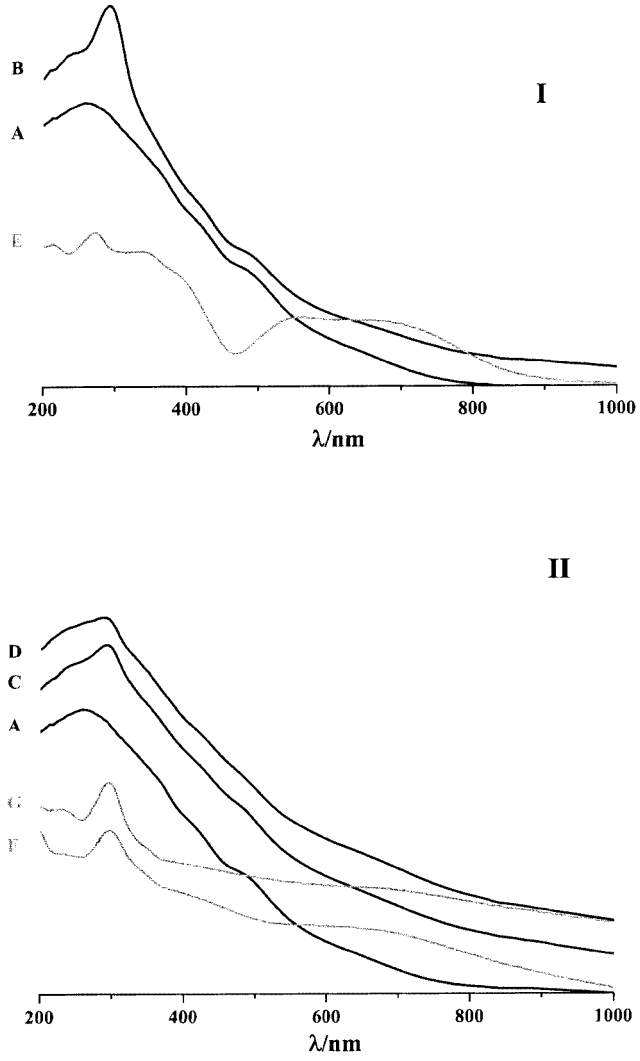

Figure 5. UV/Vis spectra: (I) BENAVILA (A), [Cu(acac)$_2$]@BEN (B), and [Cu(acac)$_2$] (E); (II) BENAVILA (A), [Cu(acac$_2$trien)]@BEN (C), [Cu(acac$_2$Metrien)]@BEN (D), [Cu(acac$_2$trien)] (F), and [Cu(acac$_2$Metrien)] (G)

The visible electronic spectrum of [Cu(acac)$_2$]@BEN is similar to that of parent BENAVILA as the d-d bands at 450−600 nm, typical of the square-planar free complex,[33] are completely masked by the PILC electronic bands, (Figure 5, I). However, a charge-transfer band due to the complex can be detected at λ_{max} = 294 nm and can be taken as a proof of the presence of the complex inside the PILC. Similarly, the visible-region spectra of [Cu(acac$_2$trien)]@BEN and [Cu(acac$_2$Metrien)]@BEN are dominated by the same features as parent BENAVILA (Figure 5, II): no d-d bands typical of pentacoordinate complexes could be observed at $\lambda \approx$ 450 and 650 nm.[33] However, as the latter band usually tails into the near-IR region, and BENAVILA does not absorb in this region, the increase in absorbance observed in the range 800−1000 nm for [Cu(acac$_2$trien)]@BEN and [Cu(acac$_2$Metrien)]@BEN, can be taken as an indication of the presence of the complexes inside the BENAVILA. Similarly to the spectrum of [Cu(acac)$_2$]@BEN, it is possible to observe one charge-transfer band at $\lambda_{max} \approx$ 290 nm in the spectra of [Cu(acac$_2$trien)]@BEN and [Cu(acac$_2$Metrien)]@BEN due to the trapped complexes, again providing a proof of the presence of the complexes inside the PILC. Due to the lack of resolution of the electronic spectra of the resulting materials, no information on the structure of the entrapped complexes could be derived from this technique.

Conclusions

By combining surface analysis and spectroscopic data it was possible to conclude that [Cu(acac$_2$trien)] and [Cu(acac$_2$Metrien)] can be encapsulated in the interlayers of BENAVILA by in situ Schiff condensation between pre-adsorbed [Cu(acac)$_2$] and the corresponding triamine, without damage of the main matrix or loss of its crystallinity. It was shown that the complex loading in the PILC is larger (approximately 0.12 mmol·g^{-1}) than for the faujasite zeolites NaX and NaY.

FTIR data suggest that copper(II) complexes entrapped in BENAVILA exhibit structural properties that are different from those of the complexes encapsulated in FAU zeolites (NaX and NaY), which have been shown to be mainly physically entrapped in the FAU supercages and with no significant interaction with the zeolite matrix. In the case of PILCs the occluded complexes exhibit distortion induced either by the porous structure or by strong interactions with the oxygen atoms of the host matrix.

The strategy used for the encapsulation of copper complexes can be extended to other metals with known catalytic properties. These novel materials may thus be used as heterogeneous catalysts, indicating that is possible to extend the potential applications of pillared clays in the field of catalysis.

Experimental Section

Reagents and Solvents: All solvents were obtained from Merck (grade *pro analysi*); copper(II) acetylacetonate was obtained from Aldrich and used as received, bis(3-aminopropyl)amine (trien) and bis(3-aminopropyl)methylamine (Metrien) were obtained from Aldrich and were distilled prior to use. The complexes [Cu-

($acac_2$trien)] and [Cu($acac_2$Metrien)] were prepared by published procedures.[32]

The BENAVILA PILC was prepared following the procedure described by Pires et al.[26] The parent material was collected from a soil in Benavila, Portugal, and purified according to published methods, with the difference that the clay was not purified by sedimentation, but only by sieving. The pillaring was achieved as described elsewhere.[26] Briefly, an oligomer solution was prepared from $AlCl_3$ and NaOH (both 0.2 M), with an OH/Al ratio of two. After mixing and aging for 2 hours the pH was increased to 6. This oligomer solution was added dropwise to the clay dispersion (2.5 g of clay in 500 mL of water) at 80 °C, whilst stirring, refluxed for 3 h and kept overnight at 25 °C. After centrifugation the solid was washed in a dialysis tube until a conductivity of less than 1 $mS \cdot m^{-1}$. After being freeze dried and calcined at 350 °C the PILC BENAVILA, with alumina pillars, was obtained. Physical properties: specific surface area of 350 m^2/g and a microporous volume of 0.115 cm^3/g. From the d_{001} reflections, which indicated a basal spacing of 1.8 nm, and subtracting the height of the sheets from the basal spacing, the heights of the galleries of this PILC were estimated to be 0.84 nm.[26]

Sample Preparation

Preparation of [Cu(acac)$_2$]@BEN: [Cu(acac)$_2$] (0.2 mmol) was dissolved in 40 cm^3 of dichloromethane and added to 1.2 g of the PILC BENAVILA (the amount of copper corresponds to about 10^{20} Cu^{2+} ions per gram of PILC). After 7 hours refluxing, the blue colour of the [Cu(acac)$_2$] solution had disappeared indicating that the complex was adsorbed by the clay, although no significant alteration of the original brown-orange colour of BENAVILA was observed. The solid material, denoted as [Cu(acac)$_2$]@BEN, was collected by filtration and dried under vacuum at 90 °C for 1 hour.

Preparation of [Cu($acac_2$trien)]@BEN and [Cu($acac_2$Metrien)]@BEN: [Cu(acac)$_2$]@BEN (0.4 g) in 40 cm^3 of dichloromethane, was refluxed for 3 h with a twofold excess of bis(3-aminopropyl)amine (trien) or bis(3-aminopropyl)methylamine (Metrien). The pillared clays changed their colour to a brownish green, providing a first indication that the Schiff condensation had taken place and the complexes [Cu($acac_2$trien)] and [Cu($acac_2$Metrien)] formed. After filtration, the solid materials, denoted as [Cu($acac_2$trien)]@BEN and [Cu($acac_2$Metrien)]@BEN, were dried under vacuum at 90 °C for 1 hour. To remove any excess triamine, unchanged [Cu(acac)$_2$] and residual Cu^{II} complexes physically adsorbed on the external surface, the solids were Soxhlet extracted with dichloromethane (4 hours) and then with acetone (4 hours). The solids were dried at 90 °C, under vacuum, for 8 hours.

Characterisation Procedures: The elemental chemical analyses (Si, Al, and Cu) were performed by Kingston Analytical Services, UK, using inductively coupled plasma atomic emission spectroscopy. X-ray photoelectron spectroscopy and scanning electron microscopy were obtained at the Centro de Materiais da Universidade do Porto (CEMUP), Porto, Portugal, on a VG Scientific ESCALAB 200A spectrometer using a non-monochromatized Mg-K_α radiation (1253.6 eV), and on a JSM-6301F Scanning Microscope with EDS (NORAN Voyager), respectively

Nitrogen adsorption measurements were performed at 77 K, using an automated apparatus (ASAP 2010). Prior to the adsorption measurements, the samples were outgassed (under vacuum) at 125 °C for 2.5 hours.

FTIR spectra were obtained at room temperature using a Shimadzu Mattson spectrometer in the 4000−400 cm^{-1} range. The transmission spectra of the samples were recorded using KBr (Merck spectroscopic grade) pellets with 32 scans and 4 cm^{-1} resolution. Diffuse reflectance electronic spectra were registered on a Shimadzu UV/3101PC spectrophotometer in the range 1500−200 nm.

X-ray diffractograms were obtained with oriented mounts, on a Philips PX 1820 instrument. To prepare the oriented films, the solids were dispersed in distilled water by ultrasound and then deposited on glass slides.

Acknowledgments

Dr. Carlos Sá performed the SEM and XPS measurements at Centro de Materiais da Universidade do Porto (CEMUP), Porto, Portugal. This work was supported by the Fundação para a Ciência e a Tecnologia (FCT, Lisboa) through Project no. POCTI/42931/QUI/2001. R. F. thanks FCT for a fellowship.

Synthesis and Structural Characterisation of a Novel Chiral *ansa*-Cobaltocenium Hexafluorophosphate

Shona Fox,[a] John P. Dunne,[a] Matthias Tacke,*[a] Dieter Schmitz,[b] and Richard Dronskowski[b]

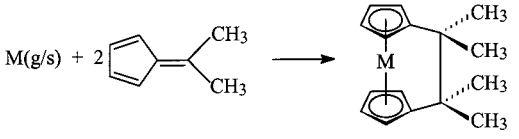
Keywords: Metallocenes / Structural analysis / Density functional calculations / Cobalt

trans-[(1,2-Diphenyl-1,2-dicyclopentadienyl)ethanediyl]-cobalt(III) hexafluorophosphate (**1**) was synthesised and its structure derived by X-ray crystallography and spectroscopic methods in conjunction with theoretical calculations. To gain an insight into the effect of these bridging atoms and the exocyclic substituents on the sandwich structure, a study was undertaken in which comparisons were drawn between this *ansa*-cobaltocenium ion and other previously reported structurally characterised metallocenes and *ansa*-metallocenes. DFT calculations were also performed to provide further data for this analysis, including reaction energies for the formation of, and breaking of, the bridging C–C bond to ascertain the extent to which this moiety imposes strain on the system.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

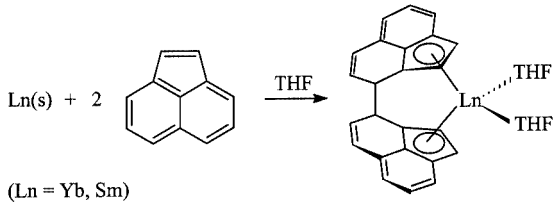
Introduction

The reductive dimerisation of either symmetrically or unsymmetrically substituted fulvenes leads to achiral or, in the latter case, chiral *ansa*-metallocenes. These direct syntheses can be carried out under cocondensation conditions using metal atoms like Sn, Pb[1] or Fe[2] or with electropositive metal powders like Ca,[3] Yb or Sm,[4] which reductively couple the fulvene in solution.



(M = Sn, Pb, Fe, Ca, Yb, Sm)

The activated metallic lanthanides Yb and Sm also form *ansa*-lanthanocenes in which the exocyclic moiety of the fulvene ligand is held in position due to its incorporation into an aromatic ring system.[5]



(Ln = Yb, Sm)

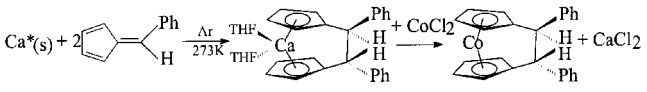
The metallocenes of the transition metals have been the subject of extensive research, especially in the area of catalysis.[6,7] Many of these compounds contain an *ansa*-bridge, which restricts the geometry of the rings and therefore changes the electronic properties of the metallocene.[8,9] The rings can be the same, as in bis-cyclopentadienyl,[10,11] bis-indenyl,[12] bis-fluorenyl[13] or bis-tetrahydroindenyl[14] systems, but they can also consist of different ligands as in the case of the fluorenyl-cyclopentadienyl metallocene.[15]

We wish to report the synthesis and structural characterisation of the *trans*-[1,2-$(Ph)_2C_2H_2(\eta^5\text{-}C_5H_4)_2$]$Co^+$ cation, which was isolated as its PF_6^- salt **1**. The synthesis first involves the production of an intermediate, [1,2-$(Ph)_2C_2H_2\{\eta^5\text{-}C_5H_4\}_2$]$Ca(THF)_2$ (**2**),[16] by reacting the ligand 6-phenylfulvene with Rieke calcium. From this point, it is possible to obtain a variety of *ansa*-metallocenes,[17] simply by carrying out a transmetallation using the appropriate anhydrous metal chloride, in this case $CoCl_2$.



The air-sensitive, paramagnetic [1,2-$(Ph)_2C_2H_2(\eta^5\text{-}C_5H_4)_2$]Co (**3**) is then oxidised to give the cation **1**. As this compound is isoelectronic with ferrocene and its analogues, a study can be undertaken, both theoretically and experimentally, to understand the effects of the two-atom bridge on the structure of the metallocene when compared with its unbridged counterpart.

Results and Discussion

The synthesis of **1** was obtained by performing a transmetallation reaction between **2** and anhydrous $CoCl_2$ analogously to a method reported by Shapiro.[16] 6-Phenylfulvene[18] is the ligand of choice for this synthesis, undergoing reductive coupling to give solely the bridged metallocene. As reported earlier[19] this fulvene produces a radical anion that is readily formed and selective enough to give exclusive formation of the bridging moiety, thus eliminating the possibility of any unbridged metallocenes forming as an inseparable impurity.

The molecular structure of **1** (Figure 1) was determined by X-ray diffraction. Selected bond lengths can be found in Table 1, with diagrams depicting these values in Figure 2 and 3. Selected bond angles are presented in Table 2 and collection and refinement data in Table 3. From this, it can be seen that the cobalt is coordinated to the cyclopentadienyl rings in an η^5-fashion and the phenyl groups on the ethano bridge are in a *trans* position with respect to one another. Compound **1** is present only as the *S*,*S* stereoisomer, but there is no reason to believe that the *R*,*R* form is not also present as crystals and it is only the chance selection of the crystals that lead to the *S*,*S* form. The cation exhibits C_2 symmetry only, with a bridge length of 1.540 Å. In order to accommodate this bond, ring tilting from the parallel arrangement occurs, resulting in different Co^+-C bond lengths and hence a bent sandwich structure, with a ring centroid-Co^+-ring centroid angle of 163.1°. The unit cell is shown in Figure 4 where it can be seen that each PF_6^- anion is surrounded by four *ansa*-metallocene cations. The interaction between these oppositely charged ions occurs between both the cyclopentadienyl and phenyl hydrogens, and two of the fluorides.

Structural Analysis

X-ray Crystallography

The inclusion of a two-carbon interannular bridge between the two cyclopentadienyl rings of a metallocene results in structural modification such as bending and lowering the symmetry of the metallocene. This can be demonstrated by comparing an unbridged and a bridged metallocene, namely ferrocene[20] and 1,1′-tetramethylethyleneferrocene (**4**).[21] In ferrocene, the metal is sandwiched equidistantly between the two parallel cyclopentadienyl rings, with the Fe−C distance being 2.045 Å. At room temperature, the rings adopt a staggered conformation, around 3.320 Å apart from each other with a C−C bond length of 1.403 Å. However, the presence of a two-carbon bridge in **4** introduces not only C_2 symmetry, but also a considerable amount of strain into the system, resulting in a C−C bond

of 1.584 Å. In order to accommodate this bond, the rings are forced to tilt by an angle (α) of 23.2° relative to one another (Table 2 and Figure 5). This, in turn, results in an

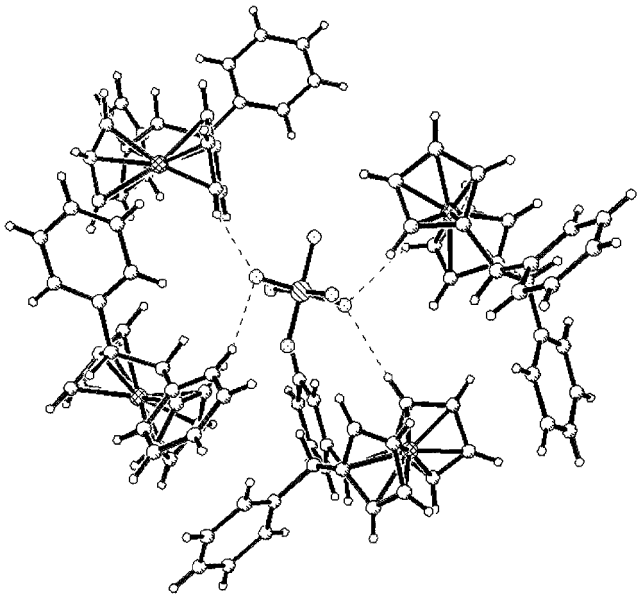

Figure 4. Crystal packing in the unit cell

angle between the metal and the ring centroids (δ) of 156.8°. The deviation from the fully eclipsed position (τ) of one ring with respect to the other is between 9.0° and 10.0°, so they are still very close to being eclipsed. As in ferrocene, the average Fe-ring C distance is 2.039 Å, but looking at each individual bond length reveals that this value actually varies from 1.965 Å to 2.099 Å. This is also the case with the inter-ring distance: the two carbons bonded to the bridge are pulled closer together (at 2.070 Å) than the carbons on the opposite side of the rings (3.600 Å and 3.650 Å). The C−C bond lengths of the rings themselves show a slight increase in going from 1.401 Å to 1.464 Å but this is still similar to ferrocene. Further evidence of strain is visible in the angles (β) occurring between the rings and the exocyclic bonds, 10.0° and 12.0°, which would not be present in an unstrained system. The two CMe_2 units of the bridge are displaced from the eclipsed arrangement by torsion angles (ε) of 26.0° and 28.0°.

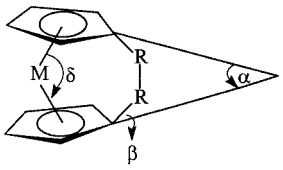

Figure 5. Selected angles from Table 2

A comparison of the structures of 1,1′-bis(benzhydryl)cobaltocenium (**5**)[22] and **1** further demonstrates the effect of the bridge. Again, the metal is sandwiched equidistantly between two parallel cyclopentadienyl rings in the unbridged metallocene, with Co-ring carbon lengths ranging from 2.016 Å to 2.068 Å. On insertion of the ethano bridge, this range increases to between 1.963 Å and 2.060 Å in order to accommodate this bond. The C−C bond lengths in the

rings vary little, however, in going from the former (1.392 Å to 1.482 Å) to the latter (1.392 Å to 1.465 Å). As **1** is isoelectronic with **4**, comparisons can be made. The C−C bond length of the bridging moiety is 1.540 Å, indicating that the substituents present around this bond do not impose a strain on it, and therefore it maintains a normal C−C single bond length. This isn't the case for **4**, where a lengthening of the bridge occurred. In addition, a less-strained situation is seen for the rest of the structure due to the differing bridge substituents between this compound (**1**) and **4**. The tilt angle (α) is found to be 22.9° which is quite similar to the above-mentioned ferrocene derivative, while the ring centroid-metal-ring centroid angle (δ) increases to 163.1°, leading to a more parallel arrangement of the cyclopentadienyl groups. As before, the twist angle (τ) is 9.0° but a slight decrease occurs in the range of the metal to ring carbon distances (1.963 Å to 2.060 Å) as a result of the less-bent structure. No further change appears to have occurred in the ring C−C bond lengths (1.392 Å to 1.465 Å). Likewise the β angles of 12.3° and 12.6° remain relatively constant. The greatest structural change to occur is in the torsion angles, ε, which are 37.2° and 37.4°, but this is mainly due to the different bridging units $(CPhH)_2$.

The types of atoms present in the bridge also influence the degree to which structural changes occur. Five important angles from the structures of cyclic ferrocenyldisilane,[23] $[Fe(\eta\text{-}C_5H_4)_2(SiMe_2)_2]$ (**6**) and 1,2-distanna(2)ferrocenophane,[24] $[Fe(\eta\text{-}C_5H_4)_2(SnMe_2)_2]$ (**7**) were examined and in almost in all cases these vary greatly from those for 1,1′-tetramethylethyleneferrocene. The length increases in going from the disilanyl bridge (2.353 Å) to the distannyl bridge (2.762 Å), due to the increase in size of these atoms. The effect of this bridge lengthening can be seen from the ring-M-ring angle (δ). The angle for **6** is 176.4° and for **7** is 179.4°, with the cyclopentadienyl rings being almost parallel in both cases. The tilt angle (α) also decreases, going from 4.2° to 0.7°. The rings are also much closer to being fully eclipsed when the bridge length is increased. Evidence of this is found from the twist angle (τ), which is 6.0° for **6** and 2.9° for **7**. The bridging units themselves, adopt a more eclipsed arrangement, ε is 7.9° and 8.4° for the silane units and decreases to 5.2° and 5.5° for the stannyl units. However, there is one set of values that remains the same and this is the angle β between the exocyclic bond and the ring plane: in **6** it is 10.8° and in **7** it is 10.3° and 10.6°.

Finally, the bonds between the bridge and the cyclopentadienyl rings also increase with replacement of the bridging moieties by larger atoms. They are found to be 1.548 Å and 1.543 Å, 1.852 Å and 1.866 Å and 2.149 Å and 2.134 Å for the C_2 (**1**), Si_2 (**6**) and Sn_2 (**7**) bridges respectively.

Theoretical Calculations

In order to get a deeper understanding of the nature of metallocene formation, a series of density functional theory (DFT) calculations were performed in which iron atoms were reacted with selected fulvenes. These calculations provide structural data and enthalpies of formation and allow a discussion of the effect of varying the substituted fulvenes, namely 6,6-dimethylfulvene, 6-phenylfulvene and 6,6-diphenylfulvene. These calculations were extended to include the reaction of the *ansa*-metallocenes **9** and **11** and the bis-fulvene complex **13** with hydrogen gas to form unbridged ferrocenes. Similar calculations were also carried out on **1**, the accuracy of which can be seen by comparing the calculated bond lengths (Table 4 and Figure 6) with the experimental values (Table 1), the difference between the two sets of results being only around 0.02 Å. Although the range of the cyclopentadienyl ring carbon bond lengths C1−C5 is shorter (1.423 Å to 1.439 Å) than the experimental values (1.392 Å to 1.465 Å) they mimic the results: bond elongation to the *ipso* carbon with shorter C−C bonds for the rest of the ring. The calculated M-ring carbon bonds also clearly show how the metallocene is bent due to the bridging moiety (1.584 Å), which is slightly longer than the actual length of 1.540 Å. As was found in the experimental values, the shortest Co^+-ring carbon bond is to the *ipso* carbon

[a] Calculation performed at the B3LYP level using 3-21G as the basis set. [b] Calculation performed at the B3LYP level using 6-311G** as the basis set.

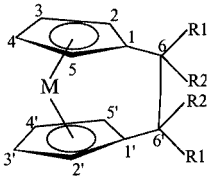

Figure 6. Numbering scheme for observed and calculated metallocene structures

(1.980 Å) and the longest to the two carbons furthest away from this (2.074 Å and 2.080 Å).

The bridged and unbridged ferrocenes that were measured were derived from 6,6-dimethylfulvene, 6-phenylfulvene and 6,6-diphenylfulvene (unbridged only). For the unbridged tetramethylferrocene (**8**), the C−C bonds in the cyclopentadienyl rings range from 1.425 Å to 1.433 Å, and are very similar to those of the bridged tetramethylferrocene **9** (1.426 Å to 1.442 Å). The difference between these two compounds is found in their Fe-ring carbon bonds (2.048 Å to 2.075 Å, compared to 1.975 Å to 2.087 Å for the bridged structure). This is a result of the C6−C6′ bridge of 1.631 Å distorting the sandwich structure of **9**. Again, these values show a slight elongation compared to the measured experimental bond lengths for 1,1′-tetramethylethyleneferrocene (**4**), whose bridge length is 1.584 Å.

In the case of the unbridged **10** and bridged diphenylferrocene **11**, the ring carbon bond lengths are very similar (1.427 Å to 1.431 Å and 1.427 Å to 1.439 Å respectively). As before, the longest bonds are to the *ipso* carbon, although the presence of a bridge (1.570 Å) causes the M-ring carbon distances to change from 2.052 Å to 2.059 Å — a parallel arrangement — to 1.974 Å to 2.089 Å — a bent structure.

The third group of calculations involved 6,6-diphenylfulvene as the ligand. Only the unbridged tetraphenylferrocene **12** was studied, as bridge formation in this case is not possible due to the large steric overload that would result.[25] As for the previous two ferrocenes, the bond lengths lie within a very similar range: the cyclopentadienyl carbon-carbon bonds are between 1.426 Å and 1.432 Å and the metal-carbon distances are between 2.048 Å and 2.073 Å.

The role of the substituents is evident from these results. In order to synthesise an *ansa*-metallocene, the groups present on the exocyclic carbon must not be so sterically demanding that they prevent dimerisation occurring, as in the case of 6,6-diphenylfulvene. Despite its suitability for radical anion stabilisation,[19] the steric hindrance between the four phenyl rings results in the sole production of the unbridged metallocene. Changing the phenyl groups for methyl groups reduces these clashes and bridge formation occurs. However, the structure still possesses substantial strain and so to compensate the C_2 bridge is elongated to 1.631 Å. Replacing the methyl groups for a phenyl and a hydrogen decreases the strain even further and this is reflected in the bridge length of 1.570 Å. This effect can also be seen in the formation energies of the respective molecules (Table 5). In both the bridged and unbridged cases, going from the tetramethylferrocene to the diphenylferrocene results in a lowering of the energy of these compounds. The energy of the unbridged tetraphenylferrocene is lower still, despite having large substituents, as these are responsible for producing the most stable radical anion. The enthaplies of bridge formation for **9** and **11** were also calculated (Scheme 1 and 2) and found to be −101.3 kcal/mol and −129.2 kcal/mol respectively. From this, it can be seen that the formation of **11** is energetically more favourable. Further ΔH values were calculated for the breaking of the bridging moiety, to give the unbridged metallocene, namely −30.2 kcal/mol (**8**) and −28.2 kcal/mol (**10**). These values show that not only does the bridge impose a strain on the metallocene, but the substituents do as well. The presence of four methyl groups on the bridge imposes greater stress on the structure than two phenyls and two hydrogens, occupying the *trans* position. Hence breaking this bond releases more energy (−30.2 kcal/mol) and thus removes the strain in the system. The ΔH value for the formation of **12** was also measured and found to be −124.3 kcal/mol (Scheme 3). This too shows that the synthesis of **12** is viable but is the lowest of the three values, for **8** the value is −131.5 kcal/mol and for **10** it is −157.4 kcal/mol.

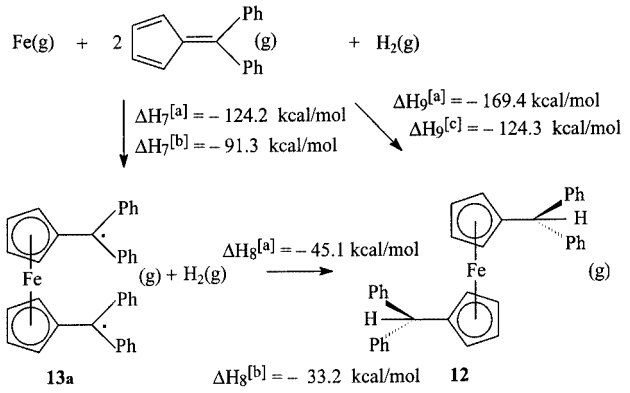
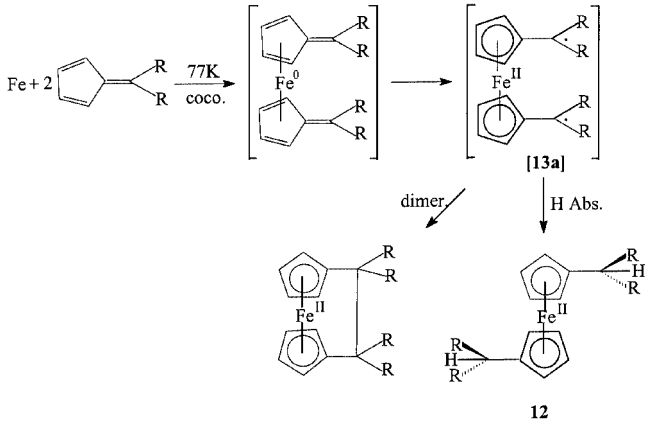


Scheme 3. Calculated reaction enthalpies for the formation of **12** and **13a**, using 6,6′-tetraphenylferrocene as the starting ligand [a] Calculations performed using the 3-21G basis set. [b] Correction factor applied to the results from the 3−21G basis set to give corresponding values from the 6-31G** basis set. [c] Calculations performed using the 6-31G** basis set

It was previously proposed[26] that a further intermediate is involved in the synthesis of these metallocenes, namely a bis-fulvene complex. This intermediate was thought to form initially from the reaction of metal atoms with fulvenes to give a complex whose metal centre has an oxidation state of zero. The next step is an electron transfer — one electron goes to each ring — resulting in an M^{2+} ion centred between two radical anions, which can then dimerise to give the *ansa*-metallocene or undergo hydrogen abstraction yielding the unbridged compound (Scheme 4). Proof of this postulate was obtained from the X-ray structure of a bis(6,6-diphenylfulvenyl)iron intermediate **13**.[26] A theoretical examination of this complex can give a further insight into its role in the reaction mechanism. The structure was calculated to obtain a minimum in the singlet state, **13a**, but this had to be performed using 3-21g* as the basis set to save calculation time. This revealed C−C ring lengths of 1.431 Å to 1.475 Å and M−C distances of 2.028 Å to 2.224 Å. These are similar to the experimentally found values of 1.406 Å to 1.452 Å for the cyclopentadienyl C−C bonds and 2.035 Å to 2.209 Å for the M−C lengths. Using these values, it can be determined whether or not **13** is really a bis-fulvene complex or a ferrocene derivative. To be the former of the two, the cyclopentadienyl rings should consist of alternating single and double bonds, with the two phenyl substituents located at the exocyclic double bond. These bond lengths should mirror the values determined both theoretically[19] and experimentally[26] for the 6,6-diphenylfulvene. Alternatively, to be the ferrocene derivative, the cyclopentadienyl rings should be more aromatic in character due to their reduction by the iron centre. The structure of the 6,6-diphenylfulvene radical anion has previously been calculated, using the 6-31G** basis set.[19] It can clearly be seen that the C−C bonds in the cyclopentadienyl ring are no longer comprised of distinct single and double bonds and lie in the range of 1.387 Å to 1.446 Å. The exocyclic bond has elongated to 1.434 Å, showing increased single bond character. A study of the crystal structure of **13** reveals that the equivalent bond in this complex is 1.408 Å and there is no clear distinction between what were formally single and double bonds in the ring. Therefore, structurally, **13** is a complex in which an Fe^{II} centre is coordinated to two fulvene radical anions with the two formally unpaired electrons in the C6 and C6′ positions. The crystal geometry also shows that the phenyl substituents are eclipsed with respect to one another, despite the steric crowding. As stated earlier, theoretical calculations found the optimised structure in the singlet state. This indicates that there is coupling occurring between the two electrons, hence allowing such an arrangement to occur, satisfying the 18 VE rule. The ΔH values for the formation of complex **13a** and the ultimate formation of **12** were also calculated at this lower level (Scheme 3). Formation of the singlet was exothermally favourable at −124.2 kcal/mol and the overall enthalpy of formation of the unbridged ferrocene was −169.4 kcal/mol. There is a considerable difference between this latter value and the original one calculated using the higher basis set (−124.3 kcal/mol). The ratio difference between these two is 1.36 and this can be used as a correction factor to get a more accurate value for the formation of the singlet. This was calculated to be −91.3 kcal/mol, and since this is too low to result in the formation of a C−C bond (−100 kcal/mol is necessary), only the unbridged metallocene is seen.



Scheme 4. Reaction mechanism for the synthesis of metallocenes, showing the role of the bis-fulvene complex **13a**

Conclusion

The formation of **1** was achieved and it was isolated as a PF_6^- salt. Theoretical calculations were also carried out in order to obtain a geometry optimised structure, and from this it was seen that these results mirror the experimental values very closely. The main difference was found in the length of the bridging moiety, which the calculations had over-estimated by about 0.04 Å. This too was also the case for the other *ansa*-metallocene calculations. Despite this, the effect of the bridge on the structure and the effect of the substituents on the bridge can be seen. From both experimental and theoretical data, it is apparent that the presence of four methyl groups on the bridge of **9** imposes strain

on the bond, elongating it. This then has a knock-on effect on the structure, causing the rings to tilt more away from the parallel and a smaller δ angle. Replacing the groups with ones that produce less steric hindrance as in **1**, results in a bridge with a normal C−C bond length. This less-strained structure is also reflected in the more parallel arrangement of the rings and the larger ring centroid-M-ring centroid angle, with respect to **9**. Finally, the structure of **13** has been proposed to be that of a ferrocene derivative, with the iron centre donating two electrons to the cyclopentadienyl rings, where they occupy the C6 and C6′ positions. Here they experience a degree of coupling which results in an eclipsed arrangement of the phenyl substituents.

Experimental Section

Synthetic Work. General: The preparation of **2** was carried out according to a literature procedure.[16] THF was dried over and distilled from Na/benzophenone prior to use. Air- and moisture-sensitive compounds were stored and handled in an argon glove box and manipulations of these substances were carried out with standard Schlenk techniques using argon to avoid calcium nitride formation.

NMR spectra were recorded on a VARIAN 300 MHz spectrometer. Chemical shifts are reported in ppm and are referenced to TMS, except for the ^{31}P NMR spectra, which are referenced to external triphenylphosphate.

The mass spectra were measured on a Finnigan MAT Incos 50 B mass spectrometer in EI mode.

Computational Study: DFT calculations were performed using the GAUSSIAN 98[27] programme implemented on an Origin 200 eight-processor cluster (SGI 180 MHz CPU/2 GB RAM). These were carried out at the B3LYP level, using either the 6-31G** or the 3-21G basis sets. The calculated electronic energies (*E*) of the complexes studied are presented in Table 5 in Hartrees. A correction value, namely the zero-point energy (ZPE), must be added to these values to give the overall energies (*E*′) of the molecules. Finally, the reaction enthalpies in Table 5 have been calculated from the energy differences between the reactants and the products. For the formation of the *ansa*-metallocenes, this was found to be the difference between the bridged ferrocene and the combined energy of the iron atom with the desired fulvene. Two pathways were studied for the unbridged metallocene: direct reaction between the iron, selected fulvene and hydrogen gas and the breaking of the bridging moiety of the *ansa*-ferrocene with subsequent reaction with the hydrogen.

Synthesis of *ansa*-Cobaltocenium Hexafluorophosphate (1): A freshly made solution of **2** was prepared according to literature methods[16] and an equimolar amount of $CoCl_2$ (0.422 g, 3.25×10^{-3} mol) was added to it under argon. This was refluxed for eight hours, producing a dark green solution of **3**. After filtration, the solution was cooled to −30 °C to produce **3** as a lime green powder, which was then dried under vacuum. Principle IR absorptions (nujol): $\tilde{\nu}$ = 2950 cm^{-1} (m), 2865 (m), 1580 (w), 1304 (w), 1260 (s), 1092 (s), 1021 (s), 867 (w), 798 (s), 722 (m). MS (EI): *m*/*z* = 367.1 (54) [M$^+$], 308.1 (8.2) [M$^+$ − Co$^+$], 306.1 (51.3) [M$^+$ − Co$^+$ − 2H$^+$], 212.9 (8.2) [M$^+$ − $C_{12}H_{10}$], 154.1 (57) [$C_{12}H_{10}$], 153.1 (100) [$C_{12}H_{10}$ − H$^+$], 58.9 (2.3) [Co$^+$]. UV/Vis (CH_3CN): λ_{max} = 364 nm. The powder was redissolved in 6 M HCl (65 mL), while exposing the solution to air. This was stirred until the olive green colour changed to yellow-green. The mixture was then filtered and the filtrate was washed with diethyl ether. The aqueous layer was separated and a saturated aqueous solution of NH_4PF_6 was added dropwise. An orange precipitate was seen to slowly drop out of the solution and upon filtration gave 0.72 g of an orange/yellow powder (yield: 43%). ^{1}H NMR (CD_3CN, 25 °C): δ = 5.20 (s, 2 H, PHC*H*Cp), 5.33, 5.71, 6.43, 6.71 (m, 8 H, C_5H_4), 7.23−7.41 (m, 10 H, C_6H_5) ppm. ^{13}C NMR (CD_3CN, 25 °C): δ = 57.1 (Ph*C*HCp), 84.1, 84.9, 89.1, 90.0, 130.9 (C_5H_4), 128.1, 128.7, 129.5, 140.3 (C_6H_5) ppm. Principle IR absorptions (KBr): $\tilde{\nu}$ = 3117 cm^{-1} (m), 3063 (m), 3015 (m), 1548 (w), 1496 (s), 1398 (s), 1032 (s), 927 (m), 836 (s), 820 (m), 777 (m), 726 (s), 704 (m). $C_{24}H_{20}CoF_6P$ (512.3): calcd. C 56.26, H 3.93, Co 11.50, F 22.25, P 6.04; found C 55.95, H 4.03, Co 11.21, F 19.91, P 5.21. MS (EI): *m*/*z* = 367.1 (54) [M$^+$ − PF_6], 213.02 (8.8) [M$^+$ − $C_{12}H_{10}$], 154.1 (48) [$C_{12}H_{10}$], 153.1 (100) [$C_{12}H_{10}$ − H$^+$], 58.9 (20) [Co$^+$]. UV/Vis (CH_3CN): λ_{max} = 422.0 nm. Crystals were grown by the slow evaporation of acetonitrile at room temperature.

X-ray Crystallography: The crystals grown were found to be suitable for X-ray diffraction. The orange cross-shaped crystals that were obtained belong to the $P2_1$ space group and the crystallographic parameters are presented in Table 3. Data were collected on an Enraf−Nonius CAD4 four-circle diffractometer with monochromatized Mo-K_α radiation. An absorption correction turned out to be unnecessary. The crystal structure was solved by direct methods[28] and refined using a least-squares method.[29] All non-hydrogen atoms were refined with anisotropic displacement parameters. The H atoms were placed at idealised positions and refined with coupled, isotropic displacement parameters. The absolute structure could be determined because of a definite Flack parameter.

CCDC-190062 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows two conformations of the chiral chelate cation $[\{\kappa\text{-P(Mes)}_2\text{CH}_2\text{CH(OH)CH}_2\text{-}\kappa\text{-P(Ph}_2\}\text{Rh}(\eta^4\text{-COD})]^+$ which is active as an enantioselective hydrogenation catalyst. The δ- and λ-twist conformations of the six-membered diphosphane chelate cycle are shown together with a projection of the hypersurface relevant to the transition between these enantiomeric forms. The hypersurface is generated by force field calculations. The specific force field is derived by refinement of the relevant force field parameters by genetic algorithms on the basis of eleven compounds of this type. The predictions made by this model are in almost quantitative agreement with the experimental data: The λ-form is calculated to be 3.1 kJ•mol^{-1} more stable than the δ-form (experimental: 3.4 kJ•mol^{-1}). The δ ⇔ λ transition is predicted to be accompanied by a coupled rotation of the mesityl groups (color code in the cover picture) in full agreement with the experimental results. The upper threshold of the activation barrier of the transition is calculated to be 69.1 kJ•mol^{-1}; the experimental value is 64.4•kJ mol^{-1}. This novel approach to molecular modeling is described in the article by G. Huttner et al. on p. 3111 ff. The quantitative NMR analysis of the structure and dynamics of compounds containing six-membered diphosphane chelate cycles is presented in the accompanying article by G. Huttner et al. on p. 3129 ff.

Organometallic Chemistry: Structural Isomerization Reactions in Confined Environments

Neil J. Coville*[a] and Demetrius C. Levendis[a]

Keywords: Isomerization / Solid-state reactions / Surfaces / Organometallic chemistry / Rhenium

Reactions in the solution phase have dominated the development of chemistry. In recent years, however, the area of solid-state organic chemistry has undergone a renaissance, although the related area of organometallic chemistry is still in its infancy. Indeed, only a limited number of systematic studies on the reactions of organometallic compounds in a confined environment (on a surface, in a zeolite pore, in the bulk phase) have been reported. Herein we summarize some recent results on a specific reaction type in a confined environment, namely the isomerization reaction.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The synthesis and characterization of ferrocene is regarded as the event that brought to life the area of organometallic chemistry.[1−3] This event, which took place in 1951, has led to the synthesis of many tens of thousands of organometallic complexes.[4,5] By the late 1980's many of the principles governing the synthesis and reactivity patterns in the discipline of organometallic chemistry had been established and the exotic complexes that had constantly been prepared were found to fit classical bonding patterns and theories.[6]

Much of this early chemistry was studied in solution, brought about by the ready availability of techniques such as IR and NMR spectroscopy. Studies in confined environments such as the solid state were more limited. While X-ray diffractometers were available, use of this technique was time consuming and studies were predominantly undertaken to determine the atom connectivity in complexes. The emphasis was certainly not on the study of reactions *in* the solid state. Developments in the last two decades in diffractometer design (such as the charge coupled device) have resulted in the determination of crystal structures now be-

Neil Coville obtained his BSc (Hons) and MSc degrees at the University of the Witwatersrand (''Wits'') before proceeding to McGill University, Montreal where he obtained his PhD (1973) under the supervision of Ian Butler. After postdoctoral work at Harvard University with (the late) John Osborn he returned to Wits in 1976 where he has remained. He is currently the Director of the Molecular Sciences Institute and holds the Chair of Inorganic Chemistry in the School of Chemistry. His current research interests include Fischer−Tropsch chemistry, synthetic routes to carbon (and other) nanotubes, hard material synthesis and organometallic chemistry in the solid state.

Demi Levendis obtained his BSc (Hons) and MSc degrees at the University of the Witwatersrand. After obtaining his Honours degree he worked at the CSIR in Pretoria for three years, and returned to Wits to complete his PhD (1985). Thereafter he spent two years as a postdoctoral researcher with Philip Coppens at SUNY, Buffalo, New York and the Synchrotron (NLS) at Brookhaven National Laboratories. He went back to Wits to take up a full-time lecturing position. After a one year sabbatical with Ivan Bernal at the University of Houston, Texas, USA, he was promoted to Associate Professor, and in due course became team leader of the Jan Boeyens Structural Chemistry Laboratory and of the Structural and Computational Chemistry programme in the Molecular Sciences Institute of the School of Chemistry.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

ing viewed as a routine analytical procedure in organometallic chemistry. Coupled to this has been the development of commercially available thermal equipment (examples include differential thermal analysis, differential scanning calorimetry, thermal gravimetric analysis, temperature programmed reduction) and surface equipment (atomic force microscopy, scanning tunneling microscopy). These and other related techniques have permitted studies of the composition/reactivity of *molecular* solids that was not available 20 years ago.

Classical inorganic complexes have been studied in the solid state for many years. Further, as pointed out by Braga and co-workers,[7] solid-state organic chemistry also has a long and rich history. The same, however, cannot be said for the area of organometallic chemistry.[8,9] The time thus seems appropriate for the development of the field of organometallic chemistry in confined environments,[10] with particular emphasis on reactions in the solid state.

There are a number of possibilities that need to be considered when describing a "confined" environment and these are listed below.

Supported Molecules

Much work has been carried out on supporting reagents on both inorganic and organic supports, for example on polymers,[11] dendrimers[12] and surfaces.[13] The study of the *chemical* interaction of molecules/ions with a surface has led to the development of SOMC (Surface Organometallic Chemistry), and the information that has been obtained has important implications for the generation of heterogeneous catalysts from organometallic precursors.[14−16] The methodology has also been exploited for the synthesis of organometallic complexes that can subsequently be extracted from surfaces.[17]

Matrix Isolated Complexes

This area of chemistry[18] constitutes another example of solid-state chemistry. In these studies, reactant molecules are generally isolated from each other by a matrix at low temperatures. Reactions are brought about typically by photolytic means and the surrounding matrix acts to modify the reactions of the deposited molecules. The information obtained has been used in the identification of reaction intermediates and pathways.

Molecules Encapsulated in Zeolites and Mesoporous Solids

The variable cavities, all of the same dimension, found in various zeolites and larger pore materials (e.g. MCM-41) provides a means of studying isolated, confined molecules.[19] The cavities range from 3−4 Å to 40−60 Å in width and thus reactions of small to very large molecules are possible.

Crystalline/Amorphous Materials

A molecule in the solid state is considered confined in a cavity generated by the other molecules surrounding it. The molecule is held rigidly in place. This type of solid contains two "types" of molecules: those in the bulk and those at the surface or situated at defects. When solids are heated they can undergo intra-atom/ligand rearrangements as well as inter-molecule rearrangements (e.g. phase changes). Interactions in the solid state *between molecules*, such as H-bonding and dipole-dipole interactions, can have similar energies to those found in covalent/ionic bonds. Braga and others have shown how interactions in organometallic molecular solids lead to the generation of 3-D networks,[7] and thus links directly to the area of supramolecular chemistry.[20]

Much of the focus of this Microreview will be on reactions in the solid state as opposed to reactions on a solid support. It will focus on isomerization reactions entailing physical (not chemical) interactions with the surrounding molecules. Others have highlighted the advantages/disadvantages in performing studies on organic materials in confined environments (e.g. the solid state). These include: solvent free synthesis, the use of enantioselective cavities, and modified reactivity patterns.[21,22] The same factors will apply to the study of organometallic chemistry in confined environments. Furthermore, the study of reversible gas adsorption by organometallic complexes in the solid state could expand the area of sensor studies,[23] while the polymerization of functional groups associated with ligands attached to metals could lead to the generation of new types of polymers.[24]

Isomerization Reactions of $[(CpMe)Re(CO)_2Br_2]$ — The Breakthrough

As with many entries into new areas of chemistry, serendipity played a crucial role for us. For many years we had been fascinated by the steric control displayed by cyclopentadienyl ligands in reactions.[25] This led us to consider methods of quantifying the size of substituted cyclopentadienyl ligands and to correlate steric measures (cone angle, solid angle) with physical parameters associated with the molecules under investigation. As part of our study we prepared a series of $[(CpR)Re(CO)_2Br_2]$ complexes and wished to determine the impact of the R group on the *cis*/*trans* isomer ratio of the complexes.[26] In attempting to purify *trans*-$[(CpMe)Re(CO)_2Br_2]$ by vacuum sublimation we noticed that the material that sublimed onto the cold probe was the *cis* isomer. We soon found that the isomerization reaction did not take place in the gas phase but occurred when the solid sample was simply heated in a flask at a temperature lower than the melting point of either of the isomers. Also surprising was the observation that in solution the isomerization reaction went in the *opposite direction* to that observed in the solid state i.e. the *cis* isomer converted into the *trans* isomer. It was clear that we had discovered a phase-dependent isomerization reaction (Figure 1). This suggested that the environment surrounding the molecule that was to rearrange (or more precisely, the cavity in which the molecule was situated) played a key role in the reaction.

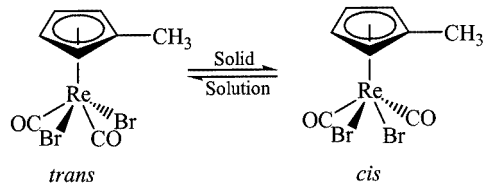

Figure 1. *cis* and *trans* isomers of $[(CpMe)Re(CO)_2Br_2]$

A procedure was developed to monitor the above solid-state reaction. This entailed placing small amounts of reactant in a degassed capillary or NMR tube and immersing the tube in an oil bath pre-set at the required temperature. At the end of a pre-determined time the material was removed from the oil bath and was ready for analysis (powder XRD, NMR or IR spectroscopy). The reaction was also monitored by optical microscopy using a specially designed temperature-controlled cell that allowed study under nitrogen.

Before proceeding with our follow up studies, it is worth digressing to indicate studies that had been undertaken by others prior to our finding, as well as some related current studies of pertinence to this Microreview.

Isomerization Reactions in the Solid State

Inorganic Molecules

Reactions of covalent molecules in the solid state have been studied for over 100 years and continue to be studied. Excellent reviews are available that have summarized the early work and thus these early studies will not be discussed in any detail here.[27,28]

Three types of isomerization reactions have been studied: racemization, *cis*/*trans* isomerization and linkage isomerization.

The *cis*/*trans* isomerization of simple four-coordinate compounds such as $[Pd(NH_3)_2X_2]$ (X = Cl, Br, I) continues to provide information on the isomerization reaction mechanism. In this specific case the reaction proceeds from the *cis* to the *trans* isomer in a process that entails the "breaking of Pd−X and Pd−N bonds".[29] Numerous six-coordinate Cr and Co compounds have also been studied.[30] It appears that the presence of water assists the *cis*/*trans* isomerization reaction of Co complexes, with dehydration playing a key role. Extensive studies, including single crystal studies, on the NO_2-ONO interconversion in complexes of the type $[Co(NH_3)_5NO_2]^{2+}$ have generated data on the role of pressure, light and cavity size on the reaction.[31] These studies provide a reference point for the study of organometallic complexes viz. typical reaction energies and reaction pathways.

Organic Molecules

Scientific investigations of solid-state organic chemistry dates back to (at least) the early 1800's but Schmidt and co-workers have been credited with the field's revival after their extensive investigations that led to the formulation of the topochemical principle.[32] One of the classic reactions that they described was the photodimerization of *ortho*-ethoxy-*trans*-cinnamic acid, a reaction that depends on which crystal polymorph is irradiated. It is cited in many reviews and textbooks, but a recent detailed analysis of three forms of *ortho*-ethoxycinnamic acid[33] has shown that factors other than the topochemical principles enunciated by Schmidt may apply. These other important factors that influence the course of solid-state reactions include the presence of solvates, planar defects, phase-transitions,[33] disorder and even crystal morphology.[34]

To date, several hundred high-yield solid-state syntheses involving numerous organic reaction types have been reported.[21] Two incentives driving the rapid development are the advantages of "solvent-free syntheses"[14] and the possibility of achieving novel or stereoselective products as a consequence of reactions in a constrained crystalline environment.

One of the predominant reaction types occurring in organic crystals is photo-dimerization/photo-polymerization, but since the 1980's many accompanying (and unique) isomerization reaction types have been reported.[35−37] These include thermal or photochemical interconversion between geometrical isomers, conformers and *E*/*Z* configurations. The interconversion between conformational isomers can occur with relatively low energy barriers in the solid, an occurrence that is sometimes referred to as conformational polymorphism.[38] However, the more space and energy demanding *E*/*Z* isomerization reactions do not generally obey the topochemical principle, and often proceed unidirectionally, either from the *Z* to *E* or from the *E* to *Z* configuration.[39] Mechanisms of solid-state isomerizations have been the subject of intense deliberation in recent years,[39−41] particularly since the application of new techniques such as scanning near field optical microscopy (SNOM) and atomic force microscopy (AFM), which have suggested, for example "phase-rebuilding" mechanisms.[39]

Organometallic Molecules

Three types of reactions can be envisaged for organometallic complexes: (i) isomerization of a ligand, (ii) isomerization at the metal, and (iii) isomerization in the crystal (phase change).

Isomerization of a Ligand

One of the earliest investigations of an isomerization/racemization reaction of an organometallic complex was the report by Ohashi and Sasada on the X-ray induced racemization reaction shown in Figure 2a [base = (*S*)-α-methylbenzylamine].[42] Of significance was the observation that the reaction occurred without crystal decay and this permitted a study of the mechanism of the reaction in a single crystal. Many publications, in which both the organic group and the base have been varied, have emanated from studies by Ohashi and co-workers since this report (Figure 2b). In these later papers they have shown:

a) racemization can be induced by exposure to a xenon lamp.[43,44]

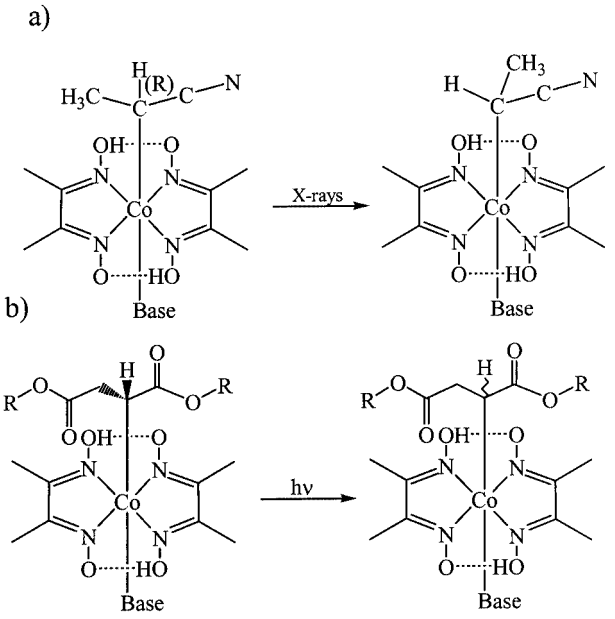

Figure 2. Cobaloxime racemization reactions: (a) X-ray induced [Base = (*S*)-α-methylbenzylamine, pyridine, PMe_2Ph etc.]; (b) light induced (bases as above, R = CH_3, C_2H_5, $CH{=}CH_2$)

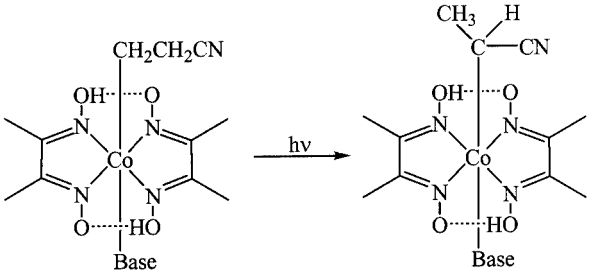

Figure 3. Cobaloxime isomerization reaction (e.g. B = 3-Mepyridine) (ref.[46])

b) isomerization reactions, for example of β-cyanoethyl to α-cyanoethyl ligands, with production of a scalemic chiral complex from a pro-chiral complex (Figure 3).[45,46]
c) asymmetric synthesis in a "cavity" i.e. generation of a preferred isomer from a racemic mixture.[47]
d) the detailed mechanism of the reaction by neutron diffraction studies entailing deuterium labelling experiments.[48–50]

By varying the R group and the base (situated below the cobaloxime ring) the ability of the R group to racemise or isomerise has been correlated with the concept of a reaction cavity.[51,52] In particular, the studies have shown that the reaction does not correlate with the density of the crystal (i.e. the packing of the whole molecule) but rather with the packing of the reactive group. The reaction cavity was defined as "*the space limited by a concave surface of spheres of the surrounding atoms around the reactive group in the crystal*".[51,52] Cavity volumes have been calculated and it has been observed that, in general, the larger the cavity volume the greater the reaction rate. For example, in a number of the complexes studied there are two crystallographically different molecules in the unit cell (i.e. two molecules per asymmetric unit). Comparison of volume data for the two independent molecules, A and B (Table 1), contained in the same crystal, reveals that inversion of the ligand only occurs when the cavity size exceeds a certain dimension and that selective reaction occurs, typically for the "B" molecules.[52] This relationship between reaction cavity size and reaction rate also holds for structures that contain only one molecule in the asymmetric unit (Table 1).

However, the *shape* of the cavity can also play a role. This is shown, for example, by studies on (cobaloxime)-Co[(*R*)-1,2-bis(ethoxycarbonyl)ethyl] (*S*)-1-phenylethylamine L complexes (Table 1).[43] Thus, the complex with L = pyridine racemizes on exposure to light, while the complex with L = PPh_2Me, with an equivalent cavity volume, does not. A detailed comparison of the shapes of the cavities revealed that movement of the ligand atoms in the cavity for L = PPh_2Me is not possible if an intact single crystal is to be maintained.

Isomerization at the Metal

Isomerization of six-coordinate complexes *in the ligand sphere* are also known. The first "organometallic-type" complexes to show *cis*/*trans* isomerization in the solid state

Table 1. Cavity volumes for cobaloxime complexes[a]

R	Base	*V* (Å^3) A	B	Molecule racemised	Ref
(*R*)-1-cyanoethyl[b]	4-cyanopyridine	7.97	10.37	B only	[51]
PPh_2Me	17.08	18.01	A and B	[51]	
3-methylpyridine	10.24	14.29	B > A	[51]	
piperidine	7.0	14.2	B	[47]	
(*R*)-1,2-bis(ethoxycarbonyl)ethyl[c]	(*S*)-1-phenylethylamine	68.8	–	none	[43]
pyridine	76.5	–	yes	[43]	
propylamine	58.9	–	none	[43]	
PPh_2Me	75.8	–	none[d]	[43]	
(*R*)-1,2-bis(methoxycarbonyl)ethyl	PPh_2Me	47.4	55.0	B only	[44]

[a] Structures are given in Figure 2. [b] Two independent molecules were found per asymmetric unit (A and B). Each has a different cavity size and the reaction only occurs in the larger cavity (ref.[51]). [c] Structures given in Figure 2b. [d] Reaction expected, but shape of the cavity did not allow for reaction.

were reported by Nelson and co-workers.[53,54] In this study a series of Ru complexes underwent *trans* to *cis* rearrangements, as shown in Figure 4, and the solution data suggested the movement of the bulky phosphane group in the isomerization reaction (ttt to ccc and ccc to cct, Figure 4a). In the solid state the reaction could occur via the interchange of only two small groups. We have recently measured the activation energy of the isomerization reaction (ttt to cct) in the solid state for a range of these complexes and find that the values fall in the range 70 ± 20 kJ·mol^{-1}, values that are consistent with a simple ligand-rotation process.[55]

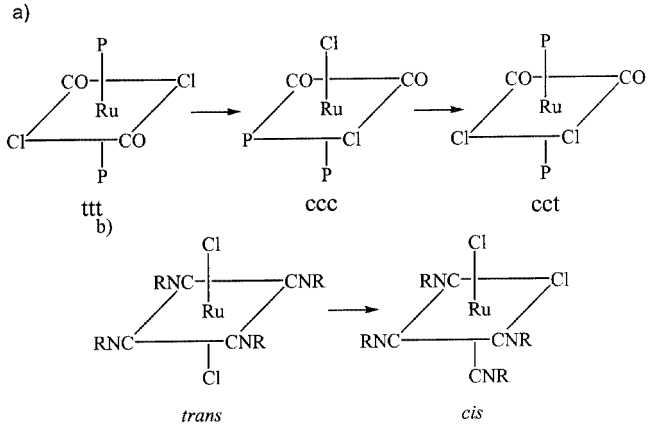

Figure 4. Solid-state isomerization reactions: (a) $[Ru(CO)_2P_2Cl_2]$ (P = phosphane) and (b) $[RuCl_2(RNC)_4]$

In a related study some Ru isocyanide complexes (Figure 4b) were also shown to undergo *trans* to *cis* isomerization in the solid state.[56]

Another type of isomerization reaction that occurs in the solid state is the η^1-acetylene to vinylidene rearrangement

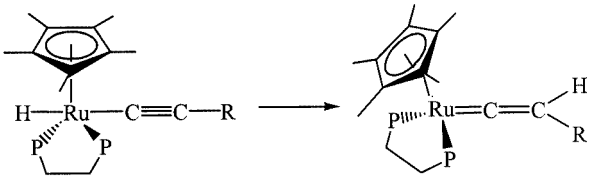

Figure 5. An η^1-alkynyl to vinylidene conversion of $[(C_5Me_5)RuH(diphos)(\eta^1\text{-}CCR)]$ in the solid state

reaction (Figure 5).[57] This reaction involves the migration of an H-atom from the metal to the ligand. Numerous examples of this reaction type have been reported.[9]

Isomerization in the Crystal

It appears that this is a little explored area in the field of solid-state organometallic chemistry. The relationship between phase transitions and chemical reactions has been the subject of continued debate.[38] One well-known example is that of ferrocene, which can exist in three distinct configurations, [staggered (D_{5d}), eclipsed (D_{5h}) and D_5] in the crystalline form, and can transform between these configurations as the crystals undergo phase transitions between different stable polymorphs.[38] In more recent work, Braga et al. reported on the fascinating solid-solid phase transition and solid-state reaction of bis(formyl)ferrocene.[58]

Isomerization of $CpML_4$ Complexes in the Solid State

The discovery of the solid-state isomerization reaction of $[(CpMe)Re(CO)_2Br_2]$ posed many interesting questions — how general is the reaction?, what are the factors that determine the direction of the reaction?, what is the mechanism of the reaction? These and other questions have provided the basis for our ongoing investigation into this area of organometallic chemistry.

Generality of the Reaction

The first issue addressed was to establish the breadth of the reaction.

Variation of the Substituents on the Cyclopentadienyl Ring

A series of $[(CpR)Re(CO)_2Br_2]$ (R = $SiMe_3$, *t*Bu, Et, C_6H_{11}) complexes was prepared but none of these complexes underwent *trans*/*cis* isomerization in the solid state.[26] Indeed, melting occurred prior to isomerization and *isomerization was found to occur in the melt.* Interestingly reaction also occurred from the *trans* to the *cis* isomer in the melt. Later studies have shown that for R = *i*Pr, a solid-state reaction does take place (Table 2).[59] Attempts to extend the reaction to disubstituted ring complexes such as $[\{Cp(SiMe_3)_2\}Re(CO)_2Br_2]$ were also made, but again the new complexes did not isomerise in the solid state.[60]

Variation of the L Groups

Substitution of CO in $[(CpR)Re(CO)_2Br_2]$ (R = Me, *t*Bu, $SiMe_3$) by L (L= phosphanes, phosphites and isocyanides) using NMe_3O-induced CO displacement techniques[61] readily gave the $[(CpR)Re(CO)LBr_2]$ complexes in good yield. Typically more than 80% of the product was synthesized as the *trans* isomer (Table 2).[62] These complexes all isomerize completely in the solid state — in every instance from the *trans* to the *cis* isomer. This is the same direction as found for the solution state isomerization reaction.

Variation of the Metal

Extension of the reaction to complexes of the type $[(CpR)M(CO)_2LX]$ (Figure 6; M = Mo, W; R = Me, Et etc.; L = phosphites, phosphanes, isocyanides; X = Br, I) has also been achieved.[63,64] Reaction of $[(CpR)M(CO)_3X]$ with L (in the presence of NMe_3O) gave a mixture of *cis*/*trans* isomers that could be separated by column chromatography. Reactions performed on either the pure *cis* or *trans* isomers gave the same *cis*/*trans* isomer equilibrium ratio (typically 65:35) in the solid state. The reaction goes from either direction to yield equilibrium mixtures of the two isomers, but the reaction is accompanied by decomposition (see below).

Interestingly, there have been two other reports of solid-state reactions of similar group 6 metal complexes in the literature. In a short comment Barnett and co-workers reported that $[CpMo(CO)_2\{P(nBu)_3\}I]$ isomerizes from the

Table 2. Thermal solid-state isomerization reactions of $[(CpR)Re(CO)LX_2]$[a]

[a] Reaction goes from the *trans* to the *cis* isomer.

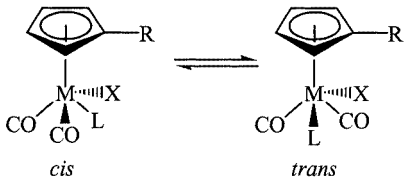

Figure 6. *cis* and *trans* isomers of $[(CpR)M(CO)_2LX]$ (M = Mo, W; L = phosphane, phosphite, isocyanide; X = halide)

cis to the *trans* isomer on standing at room temperature.[65] Also, while our work was in progress, Filippou and coworkers reported on the isomerization reaction (*cis* to *trans*) of $[(C_5R_5)W(CO)_2(PMe_3)GeCl_3]$ (R = H, Me) and $[(C_5Me_5)\text{-}Mo(CO)_2(PMe_3)GeCl_3]$ in the solid state.[66]

Variation of the Halide

$[(CpMe)Re(CO)_2I_2]$ was synthesized (see below) and, remarkably, this complex isomerized from the *cis* to the *trans*

isomer (>90%) — the reverse of the reaction for [(CpMe)Re(CO)$_2$Br$_2$].[67] The isomerization reaction, which takes place in the melt, and possibly the solid state, is more rapid for the iodo complex than for the bromo complex.[26][68] The mixed-halide complex [(CpMe)Re(CO)$_2$IBr] has also been synthesized and isomerizes from the *trans* (dihalide) to the *cis* (dihalide) isomer. More interestingly, reaction of [(CpMe)Re(CO)$_2$IBr] with 2,6-Me$_2$C$_6$H$_3$NC (RNC) yields [(CpMe)Re(CO)(RNC)IBr], a complex with *five different* substituents. This complex also undergoes a *trans* to *cis* isomerization reaction in the solid state (Table 2) and should provide interesting information on subtle features associated with the reaction mechanism (see below).[59]

From the above it can be seen that the reaction type is quite general and no doubt many other "pseudo" five-coordinate complexes will be discovered that will show solid-state isomerization behavior. However, no obvious pattern can be established that indicates which complexes will indeed isomerize and even the direction undertaken in the isomerization reaction. The data do however indicate that: (a) the isomerization can occur in the solid state if the temperatures of the melting point and the isomerization reaction are well separated, but that this in itself is not a sufficient criterion for isomerization to occur, and (b) reaction occurs from the complex with the lower melting point to that with the higher melting point.

Factors that Drive the Reaction

General Considerations

If a unidirectional isomerization reaction occurs in the solid state it suggests that the *kinetic* product is obtained during the precipitation reaction and that the *thermodynamic* product is formed on heating the solid. Either inter- or intramolecular interactions or, combinations of both factors, can drive the reaction to the thermodynamically favored product in the solid state. A more important question that has to be addressed is: does the isomerization reaction drive the change in the overall structure or do changes in the bulk structure drive the isomerization reaction?

Further, the reaction can be viewed as occurring by independent individual reactions in cavities (topotactic reaction[69]) *or* by a concerted process in which a rearrangement within a molecule (or between molecules) drives molecules in close proximity to rearrange.[70] In this latter instance the surface and defects will play an important role in the reaction.

Intramolecular Factors

Here both steric and electronic factors could play a role in determining the favored isomer. Indeed, reactions in solution are normally rationalized using these factors (e.g. *cis* and *trans* effects, cone angles, solid angles etc.). Data need to be evaluated from crystallographic analyses and it can be expected that even small *inter*molecular effects could be difficult to eliminate in the analysis.

Intermolecular Effects

The close proximity of atoms in the solid state can lead to attractive forces that could lead to the preference of one structure (e.g. isomer) over another; these forces could override intramolecular factors. These effects can, in principle, be detected by unit cell volume changes, measurement of bond lengths/angles and phase changes.

Attempts to Determine Factors that Influence the Isomerization Reaction

X-ray structural analyses

Structure determinations were undertaken for both isomers of a series of Re complexes in an attempt to evaluate the factors responsible for the reaction direction.[71−73] Three pairs of *cis*/*trans* isomers were chosen for study. The structures covered the range in which isomerization occurred with {[(CpMe)Re(CO)$_2$Br$_2$]} and without {[(CpMe)-Re(CO){P(OPh)$_3$}Br$_2$]} single crystal disintegration, and a *cis*/*trans* pair in which no isomerization was detected {[(Cp*t*Bu)Re(CO)$_2$Br$_2$]}.

Table 3. Structural parameters for *cis* and *trans* isomers of [(CpR)Re(CO)LBr$_2$] complexes [R = *t*Bu, Me; L = CO, P(OPh)$_3$] (taken from refs.[71−73])

Complex	Space group		V (Å^3)[a]		Dir[b]
	cis	trans	cis	trans	
[(CpMe)Re(CO)$_2$Br$_2$]	$P2_1/c$	$P\bar{1}$	1078	535	t→c
[(Cp*t*Bu)Re(CO)$_2$Br$_2$]	$P2_1/a$	Pbca	1375	2829	nr
[(CpMe)Re(CO){P(OPh)$_3$}Br$_2$]	$P2_1/c$	$P2_1/c$	2468	2481	t→c

[a] Note that in some instances there are half the number of molecules per unit cell. [b] Dir = direction of the isomerization reaction in the solid state.

Key data are shown in Table 3. Analysis of this data reveals that:

a) No correlation between volume changes and the isomerization reaction/direction is apparent.

b) No unusual inter-atomic bond lengths are noted (see refs.[71−73]).

c) A change in space group does not rule out an isomerization reaction.

d) The single crystal to single crystal reaction of [(CpMe)Re(CO){P(OPh)$_3$}Br$_2$] occurs in the same space group but this is not a necessary requirement for a single crystal reaction to occur.

Powder diffraction studies carried out on [(CpMe)Re-(CO)$_2$Br$_2$] revealed that the *cis* isomer generated by heating the *trans* isomer is identical to the *cis* isomer prepared independently in the solution reaction. Thus, no polymorphs were produced in the reaction.[72]

Molecular Mechanics Calculations

Attempts were made to determine the preferred isomer of [(CpMe)Re(CO)$_2$Br$_2$] by use of molecular mechanics and

semi-empirical methods, both for the isolated molecules and for the crystalline form. The data did not distinguish between the two isomers.[74] The failure of this analysis related to our inability to correctly allow for the evaluation of intermolecular interactions in our calculations. More sophisticated analyses may assist here.

Differential Scanning Calorimetry (DSC) Data

An extensive DSC study of selected Re samples revealed that the position and shape of exotherms, corresponding to the isomerization reaction, were influenced by both heating rates and crystal dimensions.[75] Indeed, at high heating rates (e.g. 20 °C/min) simultaneous melting and isomerization reactions could be detected.

Initially it appeared that the DSC technique could be used to screen isomers for their ability to transform in the solid state. However, some recent results obtained from studies on [(CpMe)Mo(CO)$_2$LI] [L = PPh$_3$, P(O*i*Pr)$_3$] have indicated cases in which isomerization occurs in the solid state but without the presence of an accompanying exotherm being detected by DSC. When the above reactions are monitored by NMR spectroscopy at temperatures below 100 °C, isomerization is noted yet no DSC exotherm is detected in the DSC profile.[63][64] The exotherms noted at temperatures above 100 °C correspond to decomposition reactions. A combination of DSC, powder XRD, solution NMR studies of reactants and optical microscopy studies of the Mo complexes reveals that isomerization commences prior to decomposition of the *cis* isomer to give as yet unidentifiable Mo complexes and OPPh$_3$.[64]

The inability to detect a DSC exotherm corresponding to a chemical reaction has been commented on by Dunitz[76] and reveals the danger of using only one technique to evaluate changes in a reaction.

Optical Microscopy Studies

An optical microscopy study of the Re complexes indicated that both crystal fragmentation and the presence of single crystal to single crystal reactions could be detected by this procedure. Two examples are described. In the first instance the isomerization of *trans*-[(CpMe)Re(CO)$_2$Br$_2$] was monitored as a function of time, and pictures taken at t = 0.5 h, 1 h, 3 h, 3 h (expanded) are shown in Figure 7. Disintegration of the crystal can be seen on the crystal edges after 1 h and indeed darkening (formation of the *cis* isomer) within the crystal can also be detected. The isomerization occurs with formation of a *new crystalline material*, as seen in Figure 7d, which is an expanded portion of the top left hand corner of Figure 7c.

Figure 8 shows the isomerization reaction of *trans*-[(CpMe)Re(CO)(2,6-Me$_2$C$_6$H$_4$NC)Br$_2$] with time (t = 0 h, 2 h, 6 h, 17 h). Darkening (corresponding to formation of the *cis* isomer) can be seen to occur at the surface as well as at cracks on the surface. The surface becomes rough with time but essentially the crystal remains single. No obvious pattern relating to the isomerization can be detected at this magnification. However, studies by Kaupp, using scanning tunneling microscopy (STM) on reactions in organic crystals, have suggested that "phase rebuilding" should be expected in many solid-state reactions, and indeed could be occurring here.[77]

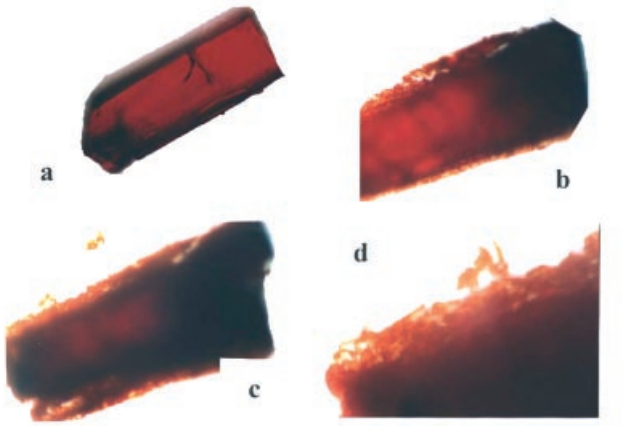

Figure 7. The isomerization of *trans* [(CpMe)Re(CO)$_2$Br$_2$] as a function of time (a = 0.5 h, b = 1 h, c = 3 h, c = 3 h − at higher magnification)

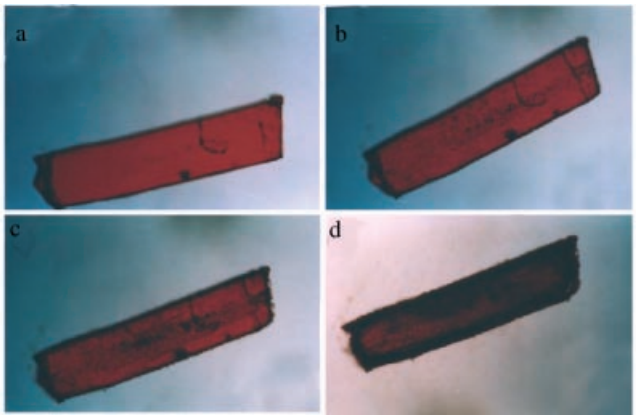

Figure 8. The isomerization of *trans*-[(CpMe)Re(CO)(2,6-Me$_2$C$_6$H$_4$NC)Br$_2$] as a function of time (a = 0 h, b = 2 h, c = 6 h, d = 17 h)

In the case of [(CpMe)Re(CO){P(OPh)$_3$}Br$_2$] (data not shown) the crystal retained its crystallinity throughout the isomerization reaction as determined by optical microscopy. Interestingly, when the crystal appeared to be completely converted, as detected by a homogeneous dark surface coloring under the optical microscope, only 22% of the *cis* isomer was detected by X-ray crystallography.

All the data is thus consistent with reactions commencing at the surface (or at defects). For all three Re compounds the pictures clearly reveal the heterogeneous nature of the reaction.

Reaction Mechanism

Two extreme mechanisms can be envisaged: (a) all ligands are attached to the metal atom, or (b) some ligands dissociate/re-associate (either as ions, atoms or molecules) in the reaction.

The reaction mechanism for the solution state *cis-trans* isomerization reaction of $[CpMo(CO)_2LX]$ complexes was studied in the 1970's by Faller,[78,79] Poilblanc[80] and coworkers. Faller proposed a mechanism based on a variation of a Berry pseudorotation model. The lowest energy pathway in the reaction involves a trigonal bipyramidal intermediate with the Cp ring and the L group in axial positions (Figure 9). In this mechanism all groups move extensively, a situation made possible in a solvent.

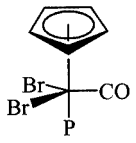

Figure 9. A proposed intermediate/transition state for the *cis*/*trans* isomerization reaction of $[CpMo(CO)_2LX]$ (ref.[79])

In an early attempt to evaluate the mechanism of the isomerization reaction in the solid state we carried out a structure correlation analysis of a wide range of ML_5 complexes using the Cambridge Structural Database.[81] Our data indicated that a modified Berry−Turnstile mechanism could fit the data (see Figure 10). For example, the isomerization of $[(CpMe)Re(CO)\{P(OPh)_3\}Br_2]$ could be rationalized with a mechanism that requires the two bulky groups [Cp, $P(OPh)_3$] to act as pivots while the movement of the three small groups undergoes rotation around a threefold axis through the metal. Some motion of the bulky groups (e.g. flexing) to accommodate the isomerization reaction is possible but the key feature entails rotation of the three non-bulky groups in the reaction.

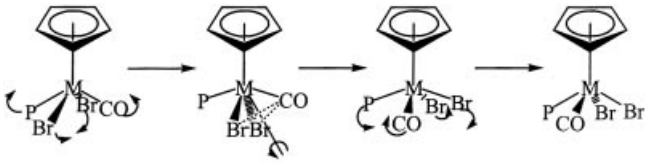

Figure 10. Proposed isomerization reaction for $[(CpMe)Re(CO)\{P(OPh)_3\}Br_2]$ based on the movement of three ligands. (ref.[81])

A recent study has led to a more detailed understanding of the reaction mechanism.[73] The single crystal to single crystal reaction of $[(CpMe)Re(CO)\{P(OPh)_3\}Br_2]$ was monitored by X-ray crystallography as a function of time. A consideration of the electron density changes indicated that only *one* of the Br ligands exchanges with the CO ligand. This suggests that the mechanism for the isomerization reaction entails rotation of the CO and one of the Br groups by 180° around an axis through the metal (Figure 11). This unexpected result relates to the size of the "cavity" in which a $[(CpMe)Re(CO)\{P(OPh)_3\}Br_2]$ molecule is confined. The second Br group is close to the ring Me group and appears to be sterically constrained in the lattice. A plot of the unit cell down the *b* axis suggests that there is a cavity of sufficient size to allow for the two-atom rotation. Notwithstanding this, the optical microscopy study also suggests that the reaction may be initiated from the "cavity surface" by a phase rebuilding process (see above).

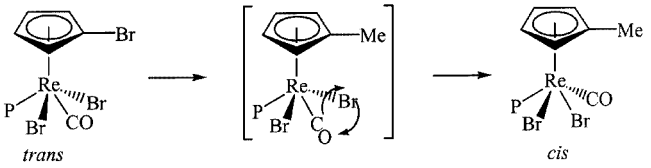

Figure 11. Proposed isomerization reaction for $[(CpMe)Re(CO)\{P(OPh)_3\}Br_2]$ based on the movement of two ligands

The electron density maps recorded as a function of isomer conversion suggested that the rotation occurs such that the CO (not the Br) ligand approaches the ring. In the rotation process, the other ligands could flex to allow for formation of a larger cavity. Indeed, the issue of a fixed versus flexible cavity *in general* is topical and currently under investigation.[82]

The *trans* to *cis* isomerization reaction of $[(CpMe)Re(CO)\{P(OPh)_3\}Br_2]$ has been monitored as a function of temperature (115−150 °C) (Figure 12).[83] The kinetic study suggests that the reaction is first order, but that two first order terms are required to give a good fit to the data. The smaller term derived from the rate expression has tentatively been assigned to an annealing process that follows the isomerization reaction.[73] An activation energy of 100 ± 9 $kJ \cdot mol^{-1}$ has been measured for the reaction.[83]

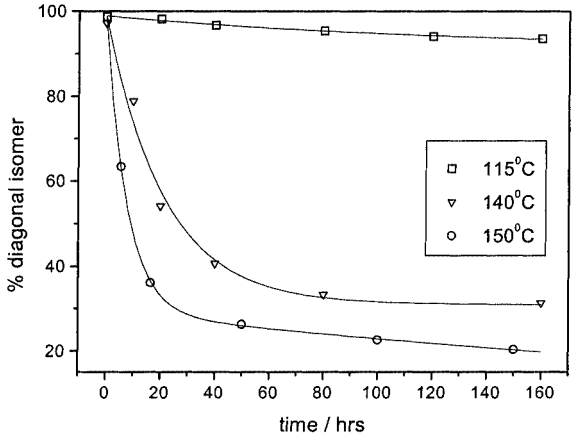

Figure 12. The *trans* to *cis* isomerization reaction of $[(CpMe)Re(CO)\{P(OPh)_3\}Br_2]$ as a function of temperature (115−150 °C)

These data do not as yet differentiate between the possibility of a process in which the two exchanging atoms (Br, CO) are bonded at all times to Re and one in which the Re−Br bond is cleaved and then reforms. (It is unlikely that CO dissociates during the reaction as the high temperatures required to induce isomerization, typically 110 °C to 145 °C, would result in loss of CO from the crystal).

Experiments to evaluate the possibility of halide-metal bond cleavage occurring during the isomerization reaction were performed. Reaction of *trans*-$[(CpMe)Re(CO_2)Br_2]$ with NaI (excess) gave *trans*-$[(CpMe)Re(CO_2)I_2]$ in quantit-

ative yield.[26] Although this suggests a mechanism entailing halide exchange the finding may not have bearing on the isomerization reaction. Studies on [(CpMe)Re(CO)$_2$BrI] are currently underway to evaluate this issue further.

Isomerization of CpML$_4$ Complexes in Matrices

Hill and co-workers have investigated photochemically induced isomerization reactions in frozen matrices for a range of CpML$_4$ complexes.[84−88] The results of the investigations can be summarized as follows:

i) For complexes of the type [CpRe(CO)$_2$Br$_2$] and [CpM(CO)$_2$LX] (Mo, W), photolysis induces *CO loss* and the intermediates formed at low temperature (e.g. 12 K) either retained (Mo, W) or lost (Re) the geometry of the starting isomer. At higher temperatures (100 K) the Mo and W *cis*/*trans* isomers inter-converted (Figure 13).[84]

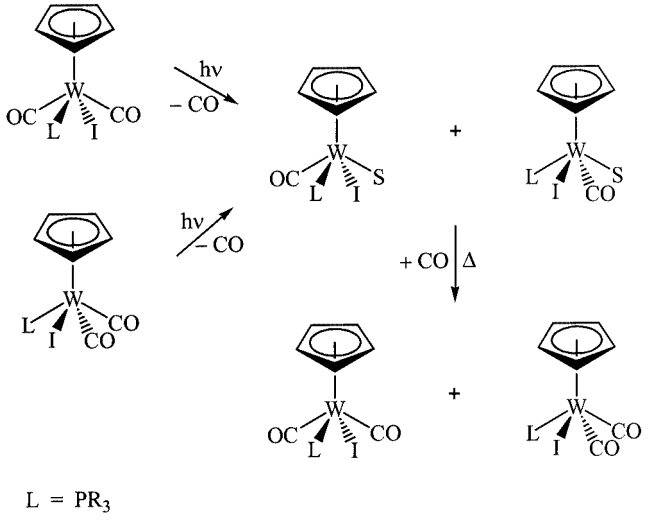

Figure 13. Photolysed low temperature *cis*/*trans* isomerization reaction of [CpW(CO)$_2$LI] (ref.[84])

ii) The isomerization ratio was similar to data observed in solution.

These data again indicate the powerful role played by the reaction cavity in the reaction. In this instance, the cavity acts to limit movement of CO away from the metal, but even under the conditions studied, preferential isomerization is seen to occur.

Isomerization of CpML$_4$ Complexes on Surfaces

Surfaces provide a range of active functional groups with which a molecule can interact. Indeed, chemical reactions between a molecule and a surface (chemisorption) provide a means to synthesize both catalysts and new reagents. To the best of our knowledge this interaction has not been exploited in isomerization reactions. However, the exploitation of the interaction of a molecule with a surface via weak dipole or van der Waals interactions to induce isomerization reactions has been reported (see below).

Hill and co-workers [88] have studied the photolytic isomerization of [(C$_5$Me$_5$)Re(CO)$_2$Br$_2$] on Si (111) surfaces at low temperature. The reaction occurred from the *cis* to the *trans* isomer, the same direction as found in solution. Photolysis of the intermediate produced at low temperature generated a second unsaturated isomer that gave the *cis* isomer on warming. (Figure 14).

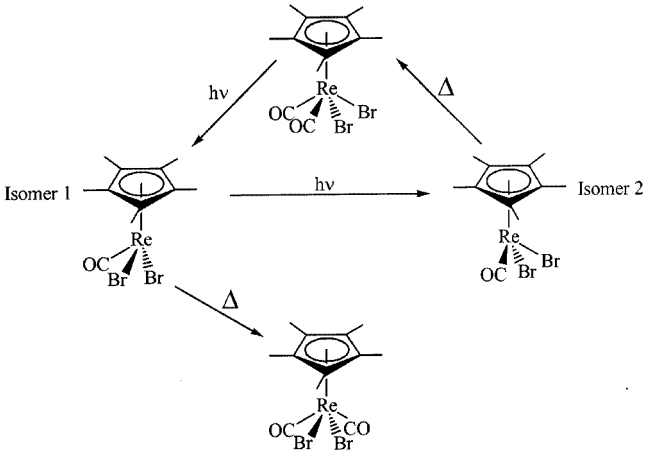

Figure 14. *cis*/*trans* isomerization reactions of [(C$_5$Me$_5$)Re(CO)$_2$Br$_2$] (film) on the surface of Si (111); irradiation of the *cis* isomer (at 77 K) gives isomer 1 which then generates both the *trans* isomer (on warming) and isomer 2; isomer 2 on warming reverts back to the *cis* isomer (ref.[88])

Addition of *cis* or *trans* isomers of [(CpR)Re(CO)$_2$X$_2$] (R = H, Me; X = Br, I)[68] and [{Cp(SiMe$_3$)$_2$}Re(CO)$_2$Br$_2$][60] to silica supports, followed by room temperature photolysis with a 200 W light source, has resulted in isomerization of the isomers to equilibrium isomer mixtures. After reaction the material can be extracted from the support to yield the isomer mixture in good yield (typically >85%). Reactions to evaluate the reaction mechanism were performed:

a) Selective removal of the surface OH groups with Me$_2$SiCl$_2$ gave a reaction that correlated with the amount of OH groups retained on the surface.

b) Irradiation of the reactants in the absence of support gave no isomerization reaction.

c) Irradiation of [(CpMe)Re(CO)$_2$Br$_2$]/NaI (excess) on SiO$_2$ gave *cis* and *trans*-[(CpMe)Re(CO)$_2$I$_2$].

d) Irradiation of a 50:50 mixture of *cis*/*trans* [(CpMe)Re(CO)$_2$Br$_2$]/[(CpMe)Re(CO)$_2$I$_2$] on SiO$_2$ gave a mixture of products that included both isomers of [(CpMe)Re(CO)$_2$BrI].

These data are consistent with interaction between the Br ligand and the surface OH groups. However, they do not distinguish between a radical or an ionic mechanism. A possible ionic mechanism involving Br interaction with a silica OH group is shown in Figure 15.[68] The kinetics of the reaction have been monitored and the data can be interpreted in terms of first order kinetics.[89] The isomerization rate on the surface follows the order [CpRe(CO)$_2$I$_2$] > [CpRe(CO)$_2$Br$_2$] > [(CpMe)Re(CO)$_2$Br$_2$], with the activation energy for all of the reactions lying in the range 60−75 kJ·mol^{-1}.

Table 4. Summary of isomerization reaction data in a confined environment[a]

Complex	Crystal/ powder	Melt	Solution	On support
$[(CpMe)Re(CO)_2Br_2]$	$t \rightarrow c$	$(t \rightarrow c)$[b]	$c \rightarrow t$	$t \rightarrow c$
$[(CpEt)Re(CO)_2Br_2]$	na	$t \rightarrow c$[c]	$c \rightarrow t$	$t \rightarrow c$
$[(CpMe)Re(CO)_2I_2]$	$c \rightarrow t$[d]	$c \rightarrow$ t	$c \rightarrow t$	$c \rightarrow t$
$[(CpMe)Re(CO)\{P(OPh)_3\}Br_2]$	$t \rightarrow c$	na	$t \rightarrow c$	$t \rightarrow c$
$[CpW(CO)_2\{P(OiPr)_3\}I]$	$t \rightleftarrows c$[e]	na	$t \rightleftarrows c$[f]	

[a] t = *trans*, c = *cis*; na = not applicable. [b] Reaction occurs in the solid. However, when the reaction is monitored by DSC at high heating rates, it appears that a reaction can be induced in the melt. [c] An equilibrium is established (ca. 65:35 *cis*/*trans*). [d] It is possible that a reaction in the solid state precedes the reaction in the melt. [e] Reaction proceeds from either isomer to yield a 30:70 *cis*/*trans* ratio of isomers. [f] In benzene (reflux) the equilibrium ratio is 70:30 *cis*/*trans*.

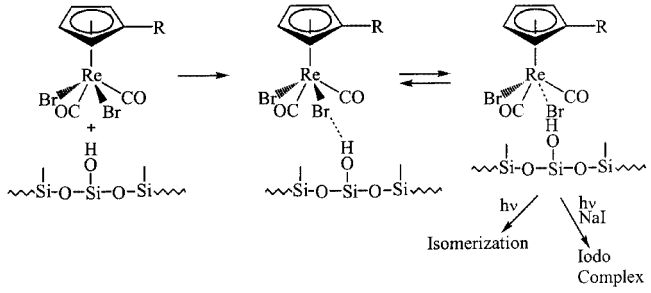

Figure 15. Possible ionic mechanism for the *trans* to *cis* isomerization of $[(CpMe)Re(CO)_2Br_2]$ on the surface of silica (ref.[67])

Isomerization of $CpML_4$ Complexes on Zeolite/Mesoporous Surfaces

The reaction described above has also been performed on high surface area MCM-41 zeolite whose pores (42 Å) are large enough to accommodate the Re molecules.[89] The data were obtained for $[(CpR)Re(CO)_2Br_2]$ (R = H, Me; both isomers) In all instances reaction occurred to yield equilibrium mixtures favoring the *cis* isomer. Only pure silica zeolites could be used, as reactions on *acidic* alumina generate $[(CpR)Re(CO)_3]$ from the $[(CpR)Re(CO)_2Br_2]$.[89]

A small-pore zeolite would only function as support by use of the external zeolite surface as the pores are too small to accommodate the reagent molecules.

Conclusions and Future Prospects

This Microreview has concentrated on a limited area of solid-state organometallic chemistry. A summary of some of the results obtained indicates the influence of the reaction environment and the reactant on the direction of a reaction (Table 4). The study has also indicated that the reaction mechanism may be different from that found in solution. Indeed, a host of mechanisms have been proposed/detected for the simple *cis*/*trans* isomerization reaction in different environments.

Clearly much work is still required to put in place the rules that permit the prediction of the reaction direction.

Other reaction types such as ligand replacement, ligand addition and ligand conversion have also been little explored in the solid state, and it is expected that such studies will yield mechanisms different from that observed in solution.

Extension of solid-state synthetic studies in organometallic chemistry to reagent mixing in the solid state to generate solventless chemical procedures has not been systematically explored to date and so the area is open for development.[90] Furthermore, the possibility of performing reactions between solids/liquids, solids/gases and carrying out reactions in the melt are still in their infancy.[9]

The remarkable success currently being achieved in the area of solid-state organic chemistry attests to the importance of the general area of solid-state chemistry. It is hoped that the same may be found true for the area of organometallic chemistry.

Acknowledgments

We would like to acknowledge the many postgraduate students in our group who have contributed to the development of this area of chemistry and in particular to Lin Cheng whose initial observations were so critical to what has since been discovered. We are also thankful to our funding sources for continued support (THRIP, SASTECH, NRF and the University of the Witwatersrand).

1- and 2-D Coordination Networks Based on Porphyrin and Copper: an Example of Supramolecular Isomerism

Bertrand Zimmer,[a] Véronique Bulach,[a] Mir Wais Hosseini,*[a] André De Cian,[a] and Nathalie Kyritsakas[b]

Keywords: Porphyrin / Pyridine / Isonicotinoyl / Coordination network / Copper / Atropoisomerism

A high-yield synthesis of atropoisomers of the *meso*-tetrakis(*o*-isonicotinoylamidophenyl)porphyrin was achieved. Depending on the crystallising solvent system, the $\alpha_2\beta_2$ atropoisomer leads to the formation of either 1-D or 2-D coordination networks in the presence of $Cu(OAc)_2$.

Introduction

The design of coordination networks, i.e. infinite structures formed upon interconnection of organic tectons by metal centres, is a topic of current interest.[1] The formation of such a molecular assembly results from the interplay between the organic and the metallic tectons. With respect to the design of the organic tecton, one may use the porphyrin core which presents several interesting features. Being a tetradentate macrocycle, it binds a variety of metal cations and the resulting complex offers tuneable redox as well as photochemical properties. Furthermore, the porphyrin backbone may be functionalised either at the β-pyrrolic or *meso* positions. Thus, using this preorganised unit, one may design a variety of tectons upon anchoring additional coordination sites such as pyridine, nitrile, carboxylate etc. The porphyrin core has been widely used in materials chemistry[2] and the formation of coordination networks based on a porphyrin bearing pyridyl units directly connected at the *meso* positions has been demonstrated.[3] On the other hand, discrete polynuclear species have been also obtained when using pyridine-bearing porphyrin derivatives.[4]

Results and Discussion

Continuing our effort towards the formation and design of new types of coordination networks,[5] we thought that the porphyrin-based tecton **1** (Scheme 1) bearing four isonicotinoyl units may be of interest for the formation of coordination networks when associated with connecting transition metal complexes possessing two linearly disposed coordination sites. The tecton **1** is based on the *meso*-tetraphenylporphyrin bearing four pyridyl units. The connection between the latter and the phenyl ring is ensured at the *ortho* position through an amide junction using the *para* position of the pyridyl unit. It is worth noting that, owing to the bulkiness of the isonicotinoyl unit, four separable atropoisomers ($\mathbf{1}\alpha_4$, $\mathbf{1}\alpha_3\beta$, $\mathbf{1}\alpha_2\beta_2$, and $\mathbf{1}\alpha\beta\alpha\beta$) may be formed.[6] In terms of design principles, as previously demonstrated for catechol-bearing porphyrins,[7] this aspect is interesting since using the same units one may generate four different tectons. Although the synthesis of **1**, based on the condensation of a statistical mixture of all four atropoisomers of the amino derivative **2** with isonicotinoyl chloride, was previously reported,[8] as mentioned by the authors, the separation procedure leading to the pure atropoisomers is extremely tedious and may only be achieved by preparative thin layer chromatography affording thus small quantities of the desired species. For those reasons we developed our own strategy based on the condensation, in the presence of Et_3N and in dry THF, of purified atropoisomers of the amino derivative **2** with isonicotinoyl chloride. Thus, $\mathbf{1}\alpha_2\beta_2$,

1αβαβ, and **1**α_4 could be obtained in 68, 43 and 78% yields, respectively.

Here we report on the formation of supramolecular isomeric 1-D and 2-D coordination networks formed between **1**$\alpha_2\beta_2$ and copper acetate.

Since the tecton **1**$\alpha_2\beta_2$ possesses four isonicotinoyl moieties (two adjacent pyridine units located on each face of the porphyrin), in order to generate a stair-type network the choice of a metallic tecton adopting a linear coordination geometry was obvious. Therefore, we used $Cu(OAc)_2$ which is present as a binuclear neutral complex formed upon bridging of the two Cu^{II} centres by four acetate anions.[9] This complex has been previously exploited in the formation of coordination networks using urotropine.[10]

Upon slow diffusion of compound **1**$\alpha_2\beta_2$ (5 mg) in $CHCl_3$ (0.6 mL) into a solution of $Cu(OAc)_2$ (19 mg, 25-fold excess) in 2-propanol (1.8 mL) violet crystals were obtained at room temp. over a period of one month and studied by X-ray diffraction (Figure 1). The crystal (triclinic system, $P\bar{1}$ as the space group) is composed of **1**$\alpha_2\beta_2$, Cu atoms, acetate anion, $CHCl_3$, H_2O and 2-propanol solvent molecules. Both $CHCl_3$ molecules present in the unit cell are disordered with all Cl atoms distributed over two positions. Among the 10 water molecules present, two of them are also disordered over two positions. For the organic tecton **1**$\alpha_2\beta_2$, the planar porphyrin macrocycle binds a Cu^{2+} cation adopting a square-planar coordination geometry (d_{Cu-N} = 1.99 Å). The Cu^{2+} ion, generated upon decomplexation of the copper acetate, occupies the centre of symmetry. The phenyl rings at the *meso* positions are, as expected, tilted with respect to the plane of the porphyrin with C−C−C−C dihedral angles of −67.3 and 76.6°. All four amide junctions (d_{C-N} = 1.31 and 1.36 Å; $d_{C=O}$ = 1.21 and 1.25 Å, N−C−O angle of 123 and 124°) are in *trans* configuration with the C=O fragments outwardly oriented. The pyridine units are not coplanar with the amide junctions but tilted (N−C−C−C dihedral angle of −18.2 and 44.2°). The consecutive substituted porphyrins are interconnected through the binding by all four isonicotinoyl moieties to the copper centres (average N−Cu distance of 2.17 Å) of four neutral $Cu_2(OAc)_4$ dimers leading thus to a stair-type 1-D coordination network. The structural characteristics of the bridging $Cu(OAc)_2$ dimer (O−Cu distance varying between 1.94 and 2.00 Å and Cu−Cu distance of 2.62 Å) are similar to those previously observed.[9] The 1-D networks are packed in a parallel fashion (Figure 1) with solvent molecules occupying the free space with no specific interactions between the networks and solvents. The same 1-D network was also obtained when *i*PrOH was replaced by MeOH. However, in that case the MeOH molecules were also strongly disordered.

In order to study the role played by the solvent system, the crystallisation of the same molecular components was carried out using different solvent mixtures. Upon slow diffusion of the compound **1**$\alpha_2\beta_2$ (5 mg) in 1,1′,2,2′-tetrachloroethane (TCE) (0.6 mL), or 1,2-dichlorobenzene or a TCE/$CHCl_3$ (1:1) mixture, into a solution of $Cu(OAc)_2$ (19 mg, 25 fold excess) in EtOH (1.8 mL) reddish crystals were obtained at room temp. over a period of 1 month. The single crystals were subject to X-ray diffraction which revealed, unexpectedly, the formation of a 2-D coordination network in all three solvent systems used (Figure 2).

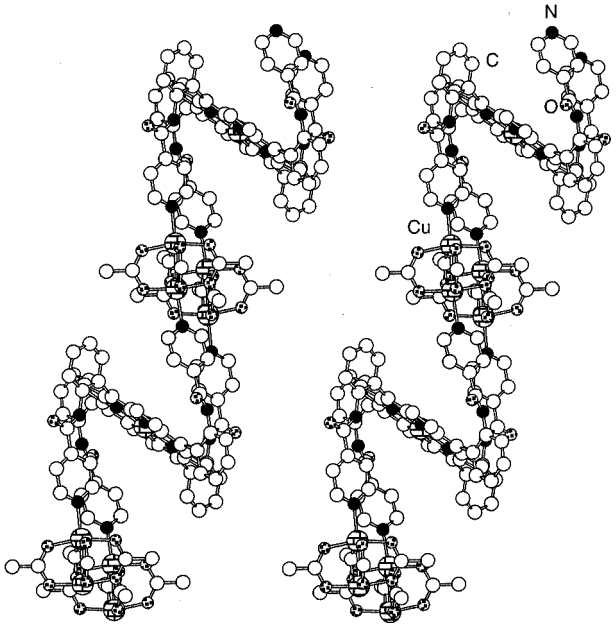

Figure 1. A portion of the crystal structures of the 1-D coordination network formed by the self-assembly of **1**$_{\alpha2\beta2}$ and copper in *i*PrOH/$CHCl_3$ showing the stair-type arrangement and the packing of two consecutive networks; solvent molecules and H atoms are not represented for clarity; for bond lengths and angles see text

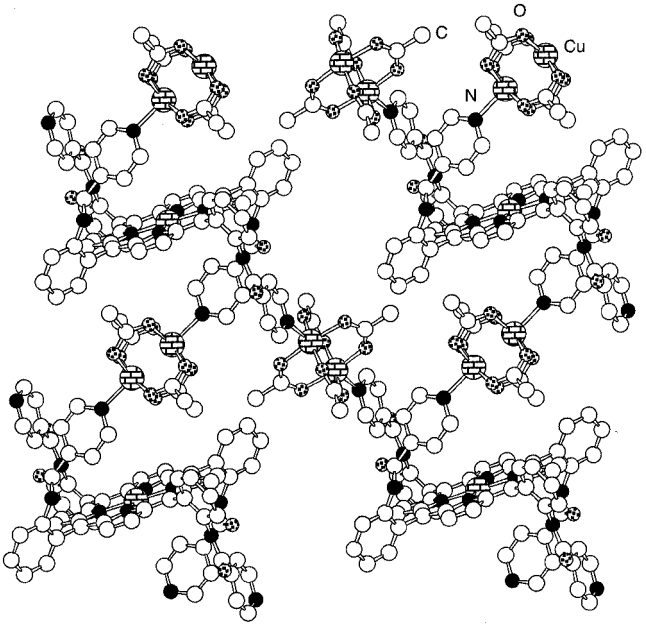

Figure 2. A portion of the crystal structures of the 2-D coordination network formed by the self-assembly of **1**$_{\alpha2\beta2}$ and copper ions in EtOH/TCE showing the connection of Cu−metallaporphyrin by $Cu_2(OAc)_4$ dimers; solvent molecules and H atoms are not represented for clarity; for bond lengths and angles see text:

The crystal (triclinic system, $P\bar{1}$ as the space group) is composed of $\mathbf{1}\alpha_2\beta_2$, Cu atoms, AcO^- anions, and TCE solvent molecules. In that case, the TCE molecules present in the lattice are not disordered and no specific interactions between them and the network structure can be spotted. Dealing with the organic tecton $\mathbf{1}\alpha_2\beta_2$, again the porphyrin macrocycle remains planar and binds a Cu^{2+} cation, formed upon decomplexation of the acetate complex, which occupies the centre of symmetry and again adopts a square-planar coordination geometry (d_{Cu-N} = 1.99 Å). The phenyl rings at the *meso* positions are differently tilted (C−C−C−C dihedral angles of −114.4 and 77.5°) with respect to the above-mentioned case . All four amide junctions (average $d_{C-N} \approx 1.35$ Å; average $d_{C=O} \approx 1.21$ Å, average N−C−O angle of ca. 124.4°) are again in *trans* configuration. The pyridine units are again not coplanar with the amide junctions but tilted (N−C−C−C dihedral angle of −17.0 and 33.3°). In marked contrast with the above-mentioned case for which the pyridine units located on the same face of the porphyrin ring are oriented almost parallel to each other, in the present case, whereas one of the two pyridine rings is almost perpendicular to the porphyrin plane, the other one is strongly tilted. As the consequence of this peculiar disposition of the coordination sites on each face of the tecton, the consecutive units are again interconnected through coordination bonds between the nitrogen atom of the isonicotinoyl moieties and the copper centres (average N−Cu distance of ca. 2.15 Å) of four neutral $Cu_2(OAc)_4$ dimers leading to a 2-D coordination network (Figure 2). Again, the structural characteristics of the bridging $Cu(OAc)_2$ dimer are similar to those obtained in the case of the 1-D network mentioned above. The packing of the 2-D networks generates channels which are filled with TCE solvent molecules with no specific interactions between the networks and the solvents molecules. As mentioned above, the same 2-D network was also obtained when TCE was replaced by 1,2-dichlorobenzene or by a mixture of TCE/$CHCl_3$ (1:1) while using EtOH.

The two networks obtained are clearly not polymorphs since they differ in their composition. However, they constitute an example of supramolecular[11] or structural[12] isomerism since both networks are based on the same molecular units and the passage from the 1-D to the 2-D network takes place through a rotational process (Figure 3).

In summary, upon self-assembly of the $\alpha_2\beta_2$, atropoisomer of the porphyrin **1** bearing four isonicotinoyl moieties and $Cu(OAc)_2$, depending on the solvent systems used, 1-D and 2-D coordination networks containing two different types of Cu^{2+} centres were formed and structurally characterised by X-ray diffraction on single crystals. The two networks obtained may be regarded as supramolecular or structural isomers. The formation of coordination networks using the other atropoisomers of **1** as well as other transition metal cations is under current investigation.

Experimental Section

Synthesis of $\mathbf{1}_{a2b2}$: 0.10 g (0.15 mmol) of $\mathbf{2}_{a2b2}$ [13] and 0.40 g (2.23 mmol, 15 equiv.) of the hydrochloride salt of isonicotinoyl chloride were placed in a round-bottom flask. 620 μL of NEt_3 (4.44 mmol, 30 equiv.) and 50 mL of freshly distilled and degassed THF were added under argon. The mixture was cooled to 0 °C and sonicated to obtain a clear solution. The course of the reaction was monitored by TLC (SiO_2, CH_2Cl_2). After ca. 3.5 h, the starting porphyrin was completely consumed. Volatiles were removed and the residue was dissolved in CH_2Cl_2 (100 mL), washed with 10% aqueous NaOH (1 × 100 mL), H_2O until neutralisation (5 × 500 mL) and finally dried with Na_2SO_4. Interestingly, due to the low solubility of $\mathbf{1}_{a2b2}$, the purification could be achieved simply by washing the solid with Et_2O (500 mL) and hexane (100 mL). The pure compound $\mathbf{1}_{a2b2}$ was obtained as a purple solid in 68% yield (0.11 g). ^{1}H NMR ($CDCl_3$, 300 MHz, 25 °C): δ = −2.65 (s, 2 H, NH pyrrole), 6.47 (dd, 8 H, J = 1.5 Hz and J = 4.4 Hz, $H_{pyridine}$), 7.61 (m, 8 H, $H_{phenyl+NHCO}$), 7.64 (broad s, 4 H, NHCO), 7.85 (dd, 8 H, J = 1.5 Hz and J = 4.4 Hz, $H_{pyridine}$), 7.90 (m, 8 H, H_{phenyl}), 8.79 (d, 4 H, J = 7.8 Hz, H_{phenyl}), 8.92 (s, 4 H, $H_{β\text{-}pyrrolic}$), 8.95 (s, 4 H, $H_{β\text{-}pyrrolic}$) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz, 25 °C): δ = 114.9, 119.7, 121.9, 124.2, 130.3, 131.2, 135.2, 137.4, 140.9, 149.8, 163.3 (NH**C**O) ppm. UV/Vis ($CHCl_3$): λ_{max} (ε) = 423 (1.8 × 10^5), 517 (1.2 × 10^4), 550 (4.3 × 10^3), 590 (4.4 × 10^3), 650 (2.3 × 10^3) nm. $C_{68}H_{46}N_{12}O_4{\cdot}CH_2Cl_2$ (1180.14): calcd. C 70.21, H 4.11, N 14.24; found C 70.12, H 4.25, N 14.06.

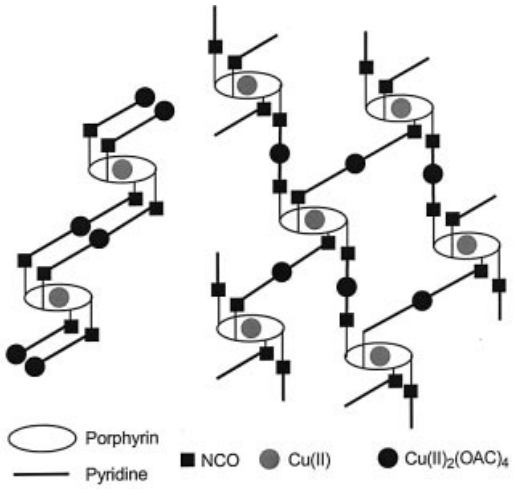

Figure 3. Schematic representation of the two supramolecular isomers based on the 1-D (left) and 2-D (right) coordination networks obtained with the same molecular components but in two different solvent systems

Crystal Structure Characterisation: X-ray diffraction data collection was carried out with a Kappa CCD diffractometer equipped with an Oxford Cryosystem liquid N_2 device, using graphite-monochromated Mo-K_α radiation. For all structures, diffraction data were corrected for absorption and analysed using the OpenMolen package.[14] All non-H atoms were refined anisotropically. Crystallographic data for the 1-D network based on $\mathbf{1}_{\alpha2\beta2}$ and $Cu_2(OAc_4)$ (violet crystals, 173 K): $C_{84}H_{68}Cu_5N_{12}O_{20}{\cdot}2CHCl_3{\cdot}10H_2O{\cdot}4C_3H_7O$, M = 2538.51, triclinic, a = 214.7082(4), b = 15.9643(4) c = 17.8289(6) Å, α = 106.851(5), β = 97.638(5), γ = 117.560(5)°, V = 3371.4(2) Å^3, space group $P\bar{1}$, Z = 1, $D_{calcd.}$ = 1.25 g cm^{-3}, μ = 0.964 mm^{-1}, 6534 data with $I > 3\sigma(I)$, R = 0.109, Rw = 0.142. Crystallographic data for the for 2-D network based on $\mathbf{1}_{\alpha2\beta2}$ and $Cu_2(OAc_4)$ (red crystals, 173 K): $C_{84}H_{68}Cu_5N_{12}O_{20}{\cdot}8C_2H_2Cl_4$, M = 3226.05, triclinic, a = 12.2094(4), b = 16.1597(5), c = 17.6546(6) Å, α = 76.557(5), β = 73.767(5), γ = 83.554(5)°, V = 3248.6(2) Å^3, space group $P\bar{1}$,

$Z = 1$, $D_{calcd.} = 1.65\ g\ cm^{-3}$, $\mu = 1.529\ mm^{-1}$, 6049 data with $I > 3\sigma(I)$, $R = 0.072$, $Rw = 0.102$. CCDC-185378 and -185379 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic data Center, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The combination of the $[Co^{III}(Cl_2\text{-bpy})_3]^{3+}$ complex with the $[Ni(dmit)_2]^-$ anion is a one-step reaction, which results in the partially oxidised $Ni(dmit)_2$-based material $[Co^{II}(Cl_2\text{-bpy})_3][Ni(dmit)_2]_5$ with a paramagnetic Co^{II} cation, as proven by Raman, EPR and XAS, exemplifying a, for $M(dithiolene)_2$ compounds new, synthetic strategy that may give access to a large variety of new $[Co^{II}(N,N\text{-imine})_3][M(dithiolene)_2]_n$ ($n > 2$, M = Ni, Pd) type magnetic conductors.

Introduction

One of the important relatively recent challenges in the design of molecular conductors is the combination of magnetic and conducting properties.[1] In the area of $M(dmit)_2$-based (M = Ni, Pd; dmit = 2-thioxo-1,3-dithiole-4,5-dithiolate) compounds, attempts to obtain these multiple-property materials have been made by combination of the $M(dmit)_2$ anion with either an organic radical cation[2−4] or with a paramagnetic transition-metal cation. Apart from $Cu_{0.39}[Ni(dmit)_2]$ reported by Sakai et al.,[5] no previously published $M(dmit)_2$-based material contains both (1) a paramagnetic transition-metal cation and (2) an $[M(dmit)_2]^{x-}$ anion with a non-integer formal charge ($0 < x < 1$), which is the best electronic situation for optimal conductivity.[6] Most reported $M(dmit)_2$-based materials containing a transition-metal cation are $[M'(Cp^*)_2][M(dmit)_2]$ (M′ = Fe, Mn, Ni) type compounds[7−10] with monovalent anions. These compounds exhibit various magnetic properties. Nevertheless, they can be considered precursors that need further oxidation, required to obtain a species with a non-integer formal charge. However, the major problem of these precursor materials is their poor solubility in most organic solvents, making subsequent chemical or electrolytic oxidation of the anion, virtually impossible.

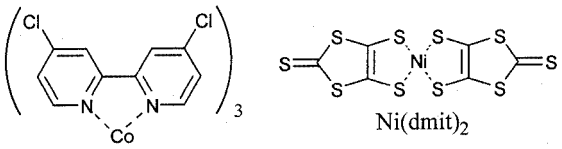
Here we present an elegant and powerful solution to this problem: combination of the $[M(dmit)_2]^{1-}$ anion with an oxidant that becomes a paramagnet upon its reduction and that subsequently precipitates together with the oxidised $[M(dmit)_2]^{x-}$ ($0 < x < 1$) anion, resulting in a fractionally oxidised, $M(dmit)_2$-based material containing a paramagnetic cation.

There are only a few examples in the literature where this concept of using a counter ion as an oxidant for the potentially conducting species has been exploited. $[BEDT\text{-}TTF]_{3.6}[MnCl_4]$ is an insulating compound. Replacement of some $[Mn^{II}Cl_4]^{2-}$ anions ($S = 5/2$) by $[Fe^{III}Cl_4]^-$ anions ($S = 5/2$) results in the Fe-doped salt $[BEDT\text{-}TTF]_{3.6}[(MnCl_4)_{1-x}(FeCl_4)_x]$ ($x = 0.05$) with strongly reduced resistivity and a magnetic behaviour composed of the Curie−Weiss contribution of the anions and Pauli contribution of mobile electrons in the donor lattice.[11] The semiconducting ($\sigma_{rt} = 0.025\ S\ cm^{-1}$) antiferromagnet $TMTSF(FeCl_4)$ is the product of the oxidation of the neutral TMTSF molecule to the $TMTSF^{\cdot+}$ radical cation by two $Fe^{III}Cl_3$ units that are converted into the paramagnetic counteranion $[Fe^{III}Cl_4]^-$ and "waste product" $Fe^{II}Cl_2$.[12] The compounds $(TTF)_6(Et_4N)(HPMo_{12}O_{40})$ and $(TTF)_6(Et_4N)(HPW_{12}O_{40})$ ($\sigma_{rt} = 10^{-3}-10^{-4}\ S\ cm^{-1}$) also are the result of a redox reaction between the $[PM_{12}O_{40}]^{3-}$ (M = W, Mo) anions that act as oxidants for the neutral TTF donor.[13] The redox reaction generates a paramagnetic $[PM_{12}O_{40}]^{4-}$ anion and a radical cation $TTF^{\cdot+}$. Already in 1980 some semiconducting $[CuL](TCNQ)_2$ and $[CuL_2](TCNQ)_2$ compounds ($\sigma_{rt} = 10^{-7}-1.9\ S\ cm^{-1}$) have been reported with L = en, bpy, phen. Some of these $Cu^{II}L$ and $Cu^{II}L_2$ complexes act as oxidants for the TCNQ anions, resulting in compounds with a charge distribution be-

 © 2002 WILEY-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim 1434−1948/02/1212−3083 $ 20.00+.50/0

tween $Cu^{II}Ln(TCNQ^{-})_2$ and $Cu^{I}Ln(TCNQ^{-})(TCNQ^{0})$, which eliminates the paramagnetism of some of the Cu^{II} species, since the Cu^{I} d^{10} species are diamagnetic. However, these compounds do display coexistence of magnetic and conducting properties.[14−17] In the case of the $[Cu^{I}\{bis(2\text{-pyridyl})amine\}_2][TCNQ]_2$ this redox reaction is total, resulting in fractionally oxidized anions and a diamagnetic cation.[18,19]

In this communication we present, for the first time with the $[Ni(dmit)_2]^{-}$ anion, such a redox reaction, where the oxidant, a cobalt(III) cation, becomes the paramagnetic species and the $[Ni(dmit)_2]^{-}$ complex anion, the fractionally oxidised, potentially conducting species. Octahedral cobalt(III) complexes with 6 nitrogen donor atoms are d^6 systems with in general a low-spin $t_{2g}^{6}e_g^{0}$ ($S = 0$) ground state. The Co^{II} equivalent, however, is a d^7 system with a high-spin $t_{2g}^{5}e_g^{2}$ ($S = 1.5$) ground state.[20] Therefore, reduction of the Co^{III} starting compound is absolutely indispensable in order to obtain a paramagnetic cation. The electron for this reduction can be provided by the $[Ni(dmit)_2]^{-}$ anion, which then can be oxidised to its neutral form. This species then can recombine with other anions[21] to form an array of $Ni(dmit)_2$ units with formal fractional charge $x-$ ($0 < x < 1$), an optimal situation for conductivity. The desired redox reactions are described in Scheme 1.



$[Co(III)(Cl_2\text{-bpy})_3]^{3+} + e^{-} \dashrightarrow [Co(II)(Cl_2\text{-bpy})_3]^{2+}$ $E_{1/2} = 0.60$ V

$1/(1\text{-}x)\ [Ni(dmit)_2]^{1-} \dashrightarrow 1/(1\text{-}x)\ [Ni(dmit)_2]^{x-} + e^{-}$ $E_{ox} = 0.24$ V

Scheme 1. Structure and redox reactions of $[Co^{III}(Cl_2\text{-bpy})_3]^{3+}$ ($E_{1/2}$ determined here) and $[Ni(dmit)_2]^{-}$ (E_{ox} redetermined here; see also ref.[22])

Below are the results of the combination of the $[Ni(dmit)_2]^{-}$ with a cationic complex that possesses these extraordinary capabilities: the $[Co^{III}(Cl_2\text{-bpy})_3]^{3+}$ complex (Cl_2-bpy = 4,4′-dichloro-2,2′-bipyridine). The $[Co^{III}(bpy)_3]^{3+}$ also has been used for comparison.

Results and Discussion

The electrochemical potentials of the starting compounds $[Co^{III}(Cl_2\text{-bpy})_3](PF_6)_3(H_2O)$, $[Co^{III}(bpy)_3](PF_6)_3(H_2O)$ and $[Bu_4N][Ni(dmit)_2]$ have been (re)determined[22,23] with cyclic voltammetry (WE, CE: Pt; RE: Ag/AgCl; CH_3CN/Bu_4NPF_6). Figure 1 shows their cyclic voltammograms. The half-wave potentials $E_{1/2,Co(III/II)}$ of $[Co(bpy)_3]^{3+}$, $E_{1/2} = 0.33$ V vs. Ag/AgCl, and $[Co(Cl_2\text{-bpy})_3]^{3+}$, $E_{1/2} = 0.60$ V vs. Ag/AgCl, are both higher than the oxidation-wave potential E_{ox} of the $[Ni(dmit)_2]^{1-/x-}$ oxidation, $E_{ox} = 0.24$ V vs. Ag/AgCl. The difference between the half-wave potential of the oxidant and the reductant, $\Delta E = E_{1/2}([Co(L)_3]^{3+/2+}) - E_{ox}([Ni(dmit)_2]^{x-/1-})$ should be at least $\Delta E > 0.1$ V,[24]

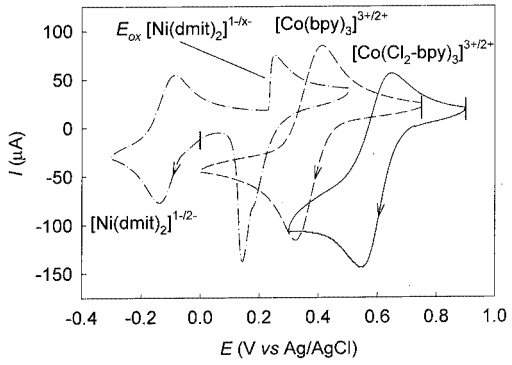


Figure 1. Cyclic voltammograms (WE, CE: Pt; RE: Ag/AgCl; CH_3CN/Bu_4NPF_6) of $[Bu_4N][Ni(dmit)_2]$ (−·), $[Co^{III}(bpy)_3](PF_6)_3{\cdot}H_2O$ (−−) and $[Co^{III}(Cl_2\text{-bpy})_3](PF_6)_3{\cdot}H_2O$ (−)

in order to have a charge transfer from anion to cation. The potential differences for $[Co(bpy)_3]^{3+}$ are $\Delta E = 0.09$, too small for this complex to be an oxidant for the $[Ni(dmit)_2]^{1-}$ anion, and for $[Co(Cl_2\text{-bpy})_3]^{3+}$ $\Delta E = 0.36$ V. Therefore, the redox reactions shown in Scheme 1 were expected to occur only for the latter cation complex. The electron-withdrawing effect of the chlorine substituents on the bpy ligand in $[Co^{III}(Cl_2\text{-bpy})_3]^{3+}$ apparently makes the difference between a normal counter cation and an effective oxidant for the $Ni(dmit)_2$ species.

Solutions of $[Co^{III}(Cl_2\text{-bpy})_3](PF_6)_3(H_2O)$ or $[Co^{III}(bpy)_3](PF_6)_3(H_2O)$ and $[Bu_4N][Ni(dmit)_2]$ in acetone have been mixed and the resulting black precipitates (product A or B, respectively) have been filtered off and washed with acetone.

In order to determine whether $[Ni(dmit)_2]^{-}$ is oxidised in the products A and B, Raman spectroscopy has been performed. Raman is a useful tool to determine the effective charge on an $Ni(dmit)_2$ anion, because of the almost linear correlation between the frequency of the ν(C=C) vibration of the dmit ligand and the charge on the anion complex.[25] The cobalt oxidation state was determined using EPR and X-ray absorption spectroscopy (XAS) at the Co $L_{2,3}$ edges. XAS is a spectroscopic technique that is very sensitive to differences in charge and spin state of a metal cation.[26]

The Raman spectra of A, [$\tilde{\nu}$(C=C) = 1331 cm^{-1}], B [$\tilde{\nu}$(C=C) = 1391 cm^{-1}] and reference $[Bu_4N][Ni(dmit)_2]$ [$\tilde{\nu}$(C=C) = 1394 cm^{-1}] (Figure 2) indicate the presence of an oxidised $Ni(dmit)_2$ species in A and a normal monovalent anion in B. This suggests that oxidation of the anion occurred only during the formation of A. The effective charge on the oxidised species in A should be 0.03− based on the previously reported correlation.[25] The asymmetry of the 1331 cm^{-1} band may indicate some variation in charge on the oxidised $Ni(dmit)_2$ species. Also some signals with low intensity are present around 1390 cm^{-1} and higher, indicating an inhomogeneous charge distribution over the $Ni(dmit)_2$ complexes in product A.

Since the Co^{III} starting compounds are diamagnetic, the equivalent Co^{II} complexes have been used as references for the EPR spectra of A and B (X-band, dpph as a standard, $T = 77$ K), that are shown together with the spectrum of

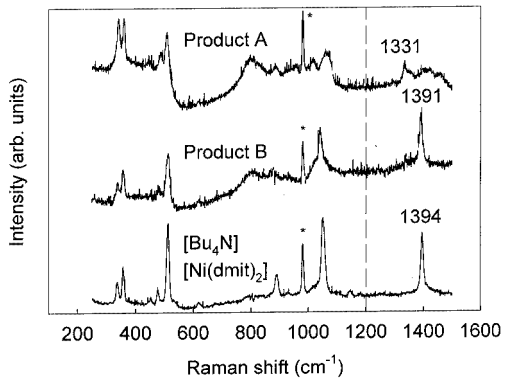

Figure 2. Raman spectra of powdered samples in rotated K_2SO_4 (*) pellets of products A ($\lambda_{exc.}$ = 514.5 nm), B and $[Bu_4N][Ni(dmit)_2]$ ($\lambda_{exc.}$ = 488 nm); right of the dotted line (> 1200 cm^{-1}) are the ν(C=C) signals of the compounds

$[Bu_4N][Ni(dmit)_2]$. The spectrum of A (Figure 3) clearly shows a signal at g = 2.06 of the radical anion $[Ni(dmit)_2]^-$ and a very broad signal with its maximum at g = 5.5, as pointed out by an arrow, indicating that a Co^{II} species must be present in A. In the spectrum of B (Figure 4) however, this signal is absent and only the anion signal is visible, which is almost identical to the signal of $[Bu_4N][Ni(dmit)_2]$. When considering the intensity of the Co^{II} EPR signal of A, no quantitative conclusions concerning the Co^{II} concentration in A can be drawn, because the intensity of the, normally very broad, Co^{II} EPR signals is, among others, strongly influenced by the relaxation times, that can differ between Co^{II} compounds.[27]

The conclusions concerning the cation charge in A and B based on the EPR spectra are confirmed by the XAS results. The spectrum (Figure 5) of A resembles very much a high-spin Co^{II} spectrum, whereas the spectrum of B agrees with a pure low-spin Co^{III} spectrum.[26]

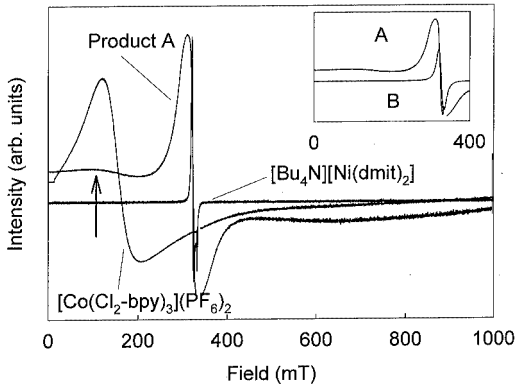

Figure 3. Powder sample EPR spectra at T = 77 K of $[Bu_4N][Ni(dmit)_2]$, $[Co(Cl_2\text{-}bpy)_3](PF_6)_2$ and product A; the inset shows comparison of spectra of products A and B

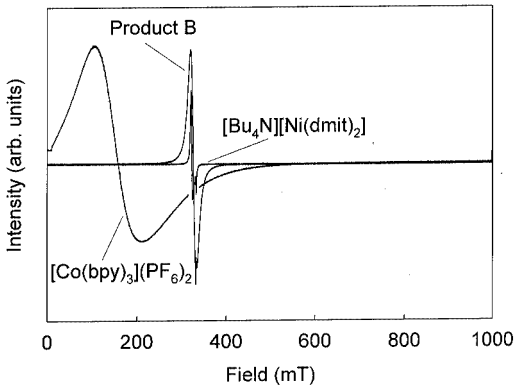

Figure 4. Powder sample EPR spectra at T = 77 K of $[Bu_4N][Ni(dmit)_2]$, $[Co(bpy)_3](PF_6)_2$ and product B

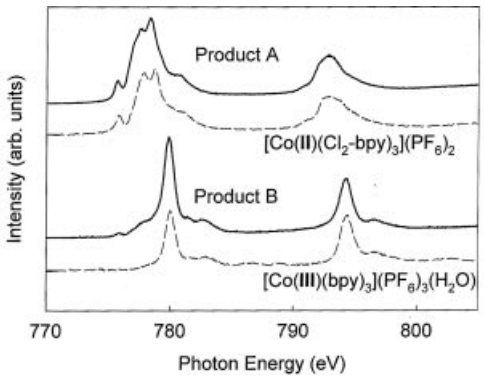

Figure 5. XAS spectra of A and B (——) and of $[Co^{II}(Cl_2\text{-}bpy)_3](PF_6)_2$ and $[Co^{III}(bpy)_3](PF_6)_3(H_2O)$ (----) as reference compounds

Product B has a cation/anion ratio of 1:3, as indicated by elemental analysis. For product A this is somewhat more difficult to determine. The elemental analysis suggests a ratio of 1:5.4, whereas the AAS indicates a ratio 1:4.5. This discrepancy between the two results is significant, but may still be within the margin of error for compounds with non-integer stoichiometries, like many $M(dmit)_2$-based compounds. It is evident that the cation/anion ratio of A, which is assumed to be 1:5 here, is significantly lower than that of B, also, like the Raman results, implying the presence of $Ni(dmit)_2$ species with formal charge x ($0 < x < 1$) in A.

The room-temperature powder conductivities of A and B are both around $\sigma_{rt} = 2 \cdot 10^{-3}$ S/cm. This similarity is remarkable considering the differences in stoichiometry and $Ni(dmit)_2$ oxidation state of the two compounds; A was expected to have a higher conductivity than B. However, the two-point powder conductivity technique is quite inaccurate for determining the true intrinsic conductivity of a compound. Contact resistance and inter-grain electron hopping in the compressed powder pellet inhibit an accurate measurement. Only single-crystal conductivity measurements can give this true intrinsic conductivity of these compounds. Studies of the magnetic properties of these materials are in progress.

Further efforts to obtain single crystals and studies on combining other $Co^{III}(N,N\text{-imine})_3$ complexes with $M(dmit)_2$ (M = Ni, Pd) are ongoing.

First findings show, that also for $Pd(dmit)_2$ anions the above described strategy is a successful one, resulting in compounds with a paramagnetic Co^{II} cation and $Pd(dmit)_2$ an-

ions with a non-integer formal charge. More detailed studies are in progress.

Conclusion

In conclusion can be stated, that combination of the appropriate ($\Delta E > 0.1$ V) $Co^{III}(N,N\text{-imine})_3$ complex with an $M(dmit)_2$ anion (M = Ni, Pd) allows the preparation of a partially oxidised, $M(dmit)_2$-based material, with a paramagnetic cation. Variation of the bis(imine) ligand enables fine tuning of the redox potential of the cobalt cation complex. In this way the oxidative power of the Co^{III} complex can be controlled.

In general can be concluded, that these $Co^{III}(N,N\text{-imine})_3$ complexes can be combined with a great variety of different $M(dithiolene)_2$ anions with a suitable $E_{ox,1-/x-}$ oxidation wave potential. A large number of such anions is already known.[6] This strategy may give access to a whole new series of compounds, all consisting of a paramagnetic cobalt(II) cation and a partially oxidised bis(dithiolato)metallate.

Experimental Section

General Remarks: Resonance Raman spectra were recorded with a Dilor XY spectrometer using a Spectra Physics 2040E Ar+ laser as excitation source. Co $L_{2,3}$ XAS data were recorded in the Fluorescence Yield mode at the SRRC Dragon beamline. The electrochemical analyses have been performed using an Autolab PGSTAT10 potentiostat, Pt working and counter electrodes and an Ag/AgCl reference electrode.

$[Bu_4N][Ni(dmit)_2]$: This starting compound has been prepared according to the well-developed procedure first described by Steimecke[28] and modified by Lindqvist.[29]

$[Co^{III}(X_2\text{-bpy})_3](PF_6)_3\cdot H_2O$ (X=H, Cl): The ligand 2,2′-bipyridine (bpy) is commercially available and has been used as received. The 4,4′-dichloro-2,2′-bipyridine ligand (Cl_2-bpy) has been synthesized according to a slightly adapted procedure described in the literature.[30] The two Co^{III} complexes have been prepared according to the literature.[31,32]

$[Co(Cl_2\text{-bpy})_3][Ni(dmit)_2]_5$ (A) and $[Co(bpy)_3][Ni(dmit)_2]_3$ (B): The cation exchange reactions to obtain products A and B involve mixing of a 2 mM solution of $[Bu_4N][Ni(dmit)_2]$ in acetone with a 2 mM $[Co^{III}(X_2\text{-bpy})_3](PF_6)_3\cdot H_2O$ solution in acetone, in a 3:1 molar ratio. The resulting black precipitates have been washed in acetone in an ultrasonic bath to wash out any enclosed starting compound, filtered off and dried under vacuum. A: Yield 50% with respect to $[Bu_4N][Ni(dmit)_2]$. IR (KBr): $\tilde{\nu}$ = 1654, 1560 (m, Cl_2-bpy), 1296 (m), 1246, 1058 (s, dmit), 922, 856, 827, 777, 747 (w, dmit), 667 (m, dmit), 497 (m, dmit) cm^{-1}. Elemental analysis found (calculated 1:5.4 cation/anion): C 22.56 (23.63), H 0.55 (0.57), N 2.53 (2.65), S 51.63 (54.59); calculated values with optimal C/N and S/N ratios. AAS found (calculated 1:4.5 cation/anion) Co 2.32 (2.17), Ni 10.25 (9.49); Co/Ni ratio 1:4.5. B: Yield 63% with respect to $[Bu_4N][Ni(dmit)_2]$. IR (KBr): $\tilde{\nu}$ = 1603, 1560 (w, bpy), 1446 (m, bpy), 1345, 1059 (s, dmit), 1025 (m, dmit), 920 (s, dmit), 757 (m, bpy), 511 (m, dmit) cm^{-1}. Elemental analysis found (calculated): C 30.29 (30.64), H 1.23 (1.29), N 4.51 (4.47), S 50.61 (51.12).

Regio-Directed Synthesis of a $Zn^{II}Fe^{III}$ Complex from an Unsymmetrical Ligand and Its Relevance to Purple Acid Phosphatases

Catherine Belle,*[a] Isabelle Gautier-Luneau,[a] Lydia Karmazin,[a] Jean-Louis Pierre,[a] Sabine Albedyhl,[b] Bernt Krebs,[b] and Michel Bonin[c]

Keywords: Heterometallic complexes / Zinc / Iron / Unsymmetrical ligands / Phosphatases

A new heterodinuclear $Zn^{II}Fe^{III}$ μ-phenoxy complex has been prepared and isolated from the unsymmetrical ligand 2-{[bis(2-hydroxybenzyl)]amino}methyl-6-{[2-pyridinylmethyl)amino]methyl}-4-methylphenol (H_3L^1), which provides two distinct N- and O-rich donor sets. The regioselective complexation is confirmed in solution by ^1H NMR studies (comparison of the spectra obtained from H_3L^1 and HL^2 – a ligand with only the N-donor set available – and a zinc salt). The crystal structure of the bis(μ-diphenylphosphato)$Zn^{II}Fe^{III}$ complex $[ZnFeL^1\{O_2P(OPh)_2\}_2]$ (**1**) is reported. The NO_5 coordination sphere around the Fe^{III} reproduces, for the first time, the oxygen-rich coordination sphere around iron(III) in red kidney bean purple acid phosphatase (KBPAP).

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Purple acid phosphatases (PAPs) are non redox-active dinuclear metalloenzymes representing a group of widely distributed phosphomonoesterases. Purple acid phosphatases require acidic conditions for optimum activity and are characterized by an intense purple color ($\lambda_{max} \approx 550$ nm) due to a charge-transfer transition from a tyrosine group to the iron(III).[1] Mammalian PAPs contain an $Fe^{II}Fe^{III}$ center at the active site while the most studied plant enzyme, isolated from red kidney bean (KBPAP), contains a $Zn^{II}Fe^{III}$ center. The X-ray structure of KBPAP (resolution 2.65 Å) shows that the two metal ions are 3.26 Å apart and bridged by Asp_{164}; each metal center has octahedral coordination.[2] The iron is further coordinated by Tyr_{167}, His_{325} and Asp_{135} residues, and zinc by His_{323}, His_{286} and Asn_{201} residues (Figure 1A). Three exogenous ligands are also included in the X-ray model to complete the coordination sphere: one terminal hydroxy ligand to iron, one terminal water ligand to zinc, and one hydroxy bridge between the metal ions. An important role is assigned to such unsymmetrical coordination, providing selective substrate binding and stereochemical control during the catalytic cycle.[2] The crystal structure of KBPAP with a coordinated μ-phosphate (the product of the hydrolysis reaction) (resolution 2.7 Å; Figure 1B) or with a μ-tungstate inhibitor (resolution 3.0 Å) have also been reported.[2b] Phosphate or tungstate oxoanions bind in a bidentate bridging mode to the two metals ions. The intermetallic distances have been refined to 3.33 Å and 3.20 Å, respectively.

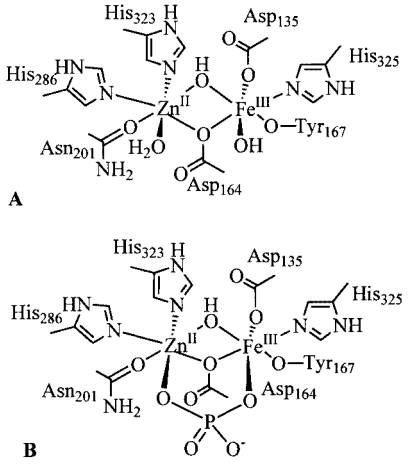

Figure 1. The active site of kidney bean purple acid phosphatase (KBPAP) (A) and of its phosphate adduct (B) from X-ray crystallography[2b]

Although the metal ions in KBPAP are in two chemically distinct environments, the heterodinuclear $Zn^{II}Fe^{III}$ complexes described as models for the active site of KBPAP[3–8] have been prepared from symmetrical ligands. Only limited examples of unsymmetrical $Zn^{II}Fe^{III}$ complexes have been

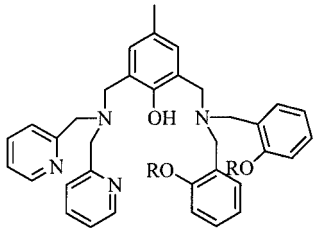
reported. They involve constitutionally unsymmetrical ligands with an alkoxy bridge but with identical chemical environments (two N_3O coordination spheres) around the metal ions.[9,10] The only example characterized by an X-ray structure has iron and zinc atoms bridged by an arsenate group[10] and with two different coordination environments (N_3O_3 and N_3O_2 for Fe and Zn, respectively). Currently, there is great interest in the development of new $Zn^{II}Fe^{III}$ complexes which may be used as models for enzyme-substrate/inhibitor intermediates.

We have used the known binucleating ligand H_3L^1 (Scheme 1),[11] which involves two different coordination sites connected by a phenol spacer: a hard site {a [bis(2-hydroxybenzyl)amino]methyl moiety} suited for iron(III) complexation and a softer site {a [bis(2-pyridinylmethyl)-amino]methyl moiety}, suited for zinc(II) complexation. We report here a regiodirected preparation of a heterodinuclear $Zn^{II}Fe^{III}$ complex and the X-ray structure of a diphenylphosphate adduct.



R = H (H_3L^1) or R = CH_3 (HL^2)

Scheme 1

Results and Discussion

Mononuclear zinc(II) complexes were prepared in solution in an NMR tube with either H_3L^1 or HL^2. HL^2 is the bis-methoxy derivative of H_3L^1 (Scheme 1)[12] where the terminal phenolate donor set has been suppressed and only one coordination site remains for metal ion complexation. The zinc complex of this ligand shows spectroscopic features for the complexation of Zn^{2+} by a bis(2-pyridinylmethyl)amino moiety. The complexation processes were monitored by ^1H NMR spectroscopy. The ligand resonances shifted progressively upon addition of a solution of $Zn(ClO_4)_2 \cdot 6H_2O$ in CD_3CN (Figure 2). Interestingly, the spectrum recorded for solutions containing a mixture of the ligand and the complex show that the two species are in slow exchange on the NMR time scale. Although different species are observed during the addition of the zinc salt only one species is present after addition of one molar equivalent of the zinc salt. The spectrum remains unchanged after the addition of a further equivalent of the zinc salt. The mononuclear zinc complexes prepared independently from H_3L^1 and HL^2 or obtained upon addition of the zinc salt to the ligand in the NMR tube are the same, as seen by their NMR spectra. Comparison of the spectra obtained with one molar equivalent of zinc salt and H_3L^1 instead of HL^2 reveals the similarity of the environment

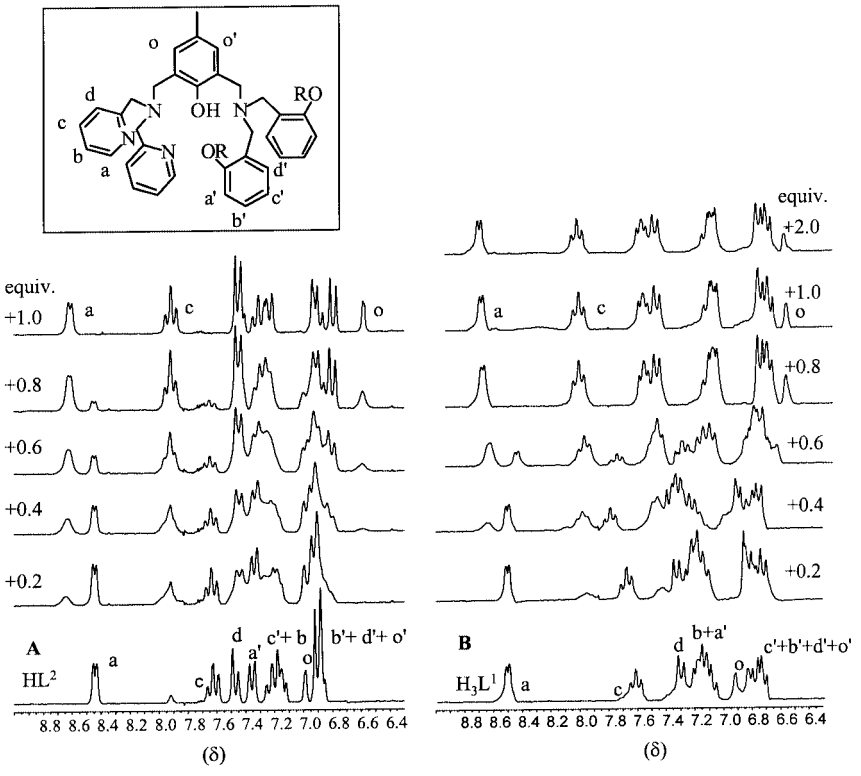


Figure 2. ^1H NMR spectra (200 MHz, CD_3CN) monitoring the formation of the mononuclear zinc complexes in the aromatic region, from HL^2(A) and H_3L^1(B) upon progressive addition of the zinc perchlorate salt; inset: ligand numbering scheme

around the zinc(II) center in the two mononuclear complexes (Figure 2). In particular, the well-resolved *ortho*- and *para*-pyridinyl resonances (protons *a* and c respectively in Figure 2) show the same behavior. In a similar manner, the resonance for the proton in the *ortho* position on the central phenyl ring and close to the pyridyl arms (signal *o* on Figure 2) appears near $\delta = 7.0$ ppm for both free ligands and is shifted to $\delta = 6.7$ ppm after complexation. Accordingly, it appears that the zinc ion is regioselectively complexed by the bis-pyridyl site of the dinucleating ligand H_3L^1.

The neutral heterobinuclear $[ZnFeL^1\{O_2P(OPh)_2\}_2]$ (**1**) complex was obtained from H_3L^1 by stepwise addition (in methanol) of zinc(II) perchlorate (1 equiv.) followed by addition of triethylamine (3 equiv.), and iron(III) perchlorate (1 equiv.). After addition of diphenylphosphate (2 equiv.) complex **1** precipitated as a violet powder. Recrystallisation by vapor diffusion of methanol into an acetonitrile solution of **1** gave crystals suitable for an X-ray diffraction study. The electronic absorption spectrum of **1** in CH_3CN displays a main feature at 501 nm ($\varepsilon \approx 3077$ M^{-1} cm^{-1}). Comparison of this spectrum with those of iron(III) complexes of μ-phenolato ligands leads to the assignment of the latter band to charge-transfer transitions from the terminal and the bridging phenolates to the iron(III).[4] The native Zn^{II}-Fe^{III} red kidney bean phosphatase displays a visible spectrum with a λ_{max} of 560 nm ($\varepsilon \approx 3360$ M^{-1} cm^{-1}).[13]

The crystal structure of **1** reveals that the two metallic atoms are triply bridged by the phenoxo group (O1) of the ligand and two μ-diphenylphosphato groups leading to the intermetallic distance of 3.7402(7) Å. An ORTEP view is shown on Figure 3, and selected bond lengths and angles are given in Table 1. The octahedral coordination geometry of the metal centers is completed by the tertiary amine (N2) and two pyridine nitrogens (N3 and N4) for Zn^{II} and by the tertiary amine (N1) and two phenolate oxygens (O2 and O3) for Fe^{III}. The distances in the $[NO_5]$ coordination sphere of the iron(III) are in the range of 1.918(2) to 2.222(3) Å and are more asymmetric than those of Zn^{II} for which the distances in the $[N_3O_3]$ coordination sphere are ranged between 2.037(3) and 2.182(3) Å. The Fe−O(phenolate) bond lengths [1.918(2) and 1.919(2) Å] are slightly longer than in the $[Fe_2L^1(\mu\text{-OMe})(OMe)]^+$ complex[14] [1.872(5) and 1.850(5) Å] where the iron has a pentacoordinate coordination sphere. The Zn···Fe distance of 3.7402(7) Å is slightly longer than in other complexes where the metals are linked by three bridges, one phenoxy and two μ-diphenylphosphate groups. In $[ZnFe(BPMP)\{O_2P(OPh)_2\}_2]^{2+}$ and $[ZnFe(BPMOP)\{O_2P(OPh)_2\}_2]^{2+}$ the intermetallic distances are 3.695(1) Å[3] and 3.7030(7) Å,[5] respectively.

Although the Zn−O1 [2.124(2) Å] and Fe−O1 [2.035(3) Å] bond lengths in complex **1** are similar to those observed in the previously cited complexes, the Zn−O1−Fe bond angle is larger [128.1(1)°] {$[ZnFe(BPMP)\{O_2P(OPh)_2\}_2]^{2+}$: Zn−O1 = 2.176(2) Å, Fe−O1 = 2.031(2) Å, Zn−O1−Fe = 122.8(1)°; $[ZnFe(BPMOP)\{O_2P(OPh)_2\}_2]^{2+}$: Zn−O1 = 2.168(2) Å, Fe−O1 = 2.047(2) Å, Zn−O1−Fe = 122.9(1)°}. Moreover, the Zn−O1−Fe angle is similar to that observed in $[ZnFe(BPBP)(MoO_4)_2]$[8] [127.4(2)°] where, due to the longer Mo−O distance [average 1.788 Å, compared to the P−O distance (average 1.478

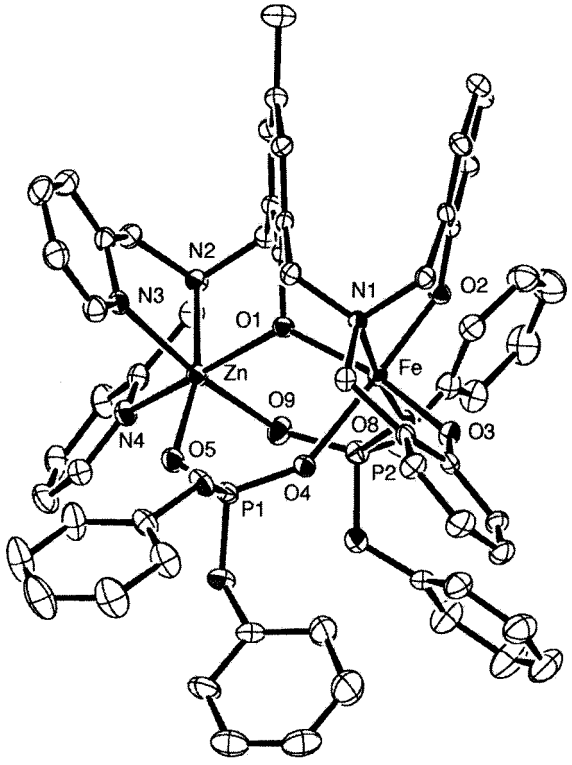

Figure 3. ORTEP plot of $[ZnFeL^1(O_2P(OPh)_2]_2]$ (**1**), with atom labels and numbering scheme; hydrogens are omitted for clarity; ellipsoids are drawn at the 30% probability level

Å)], the Fe−O1 [2.156(5) Å] and Zn−O1 [2.104(5) Å] bonds are longer, leading to an intermetallic distance of 3.819(4) Å. All these structures indicate a remarkable structural flexibility of the intermetallic distance, which may be important for the catalytic activity. In native KBPAP with one coordinated phosphate, the Fe···Zn distance has been refined to 3.33 Å.[2b] The bridging mode of the phosphate is nearly symmetrical (with Fe−O−P and Zn−O−P angles of 120° and 127° respectively), whereas in complex **1** the angles are larger and ranged between 124.0(1)° and 147.1(1)°. Larger angles are also observed in $[ZnFe(BPMP)\{O_2P(OPh)_2\}_2]^{2+}$ and in $[ZnFe(BPMOP)\{O_2P(OPh)_2\}_2]^{2+}$ complexes.

Conclusion

The use of an unsymmetrical ligand possessing both a hard and a softer coordination site may be considered as an interesting strategy to prepare heterobinuclear complexes in a directed, non-statistical way. This paper describes a predictable and controlled synthesis of a $Zn^{II}Fe^{III}$ complex. The zinc was complexed first and solution studies revealed that zinc(II) is bound exclusively by the N-rich donor set.; the O-rich donor remains available for the subsequent complexation of iron(III). This regiocontrolled synthesis has allowed us to describe and characterize the first example of a phosphate-bridged species with a $Zn^{II}Fe^{III}$ core in an unsymmetrical, octahedral environment. The NO_5 coordination sphere around the iron(III) models the oxygen-rich coordination sphere for this ion in KBPAP.

Experimental Section

H_3L^1 and HL^2 were synthesized as reported previously.[11−12]

$[ZnFeL^1\{O_2P(OPh)_2\}_2]$ (1): A solution of $Zn(ClO_4)_2\cdot 6H_2O$ (0.0664 g, 0.178 mmol) in methanol (3 mL) was added dropwise to a solution of H_3L^1 (0.100 g, 0.178 mmol) dissolved in methanol (4 mL). The solution was stirred for 1 h and NEt_3 (0.712 mmol) was added. After 15 min a solution of $Fe(ClO_4)_2\cdot 9H_2O$ (0.0632 g, 0.178 mmol) in methanol (3 mL) was added, and the solution, which turned dark-red, was stirred for 1 h. Diphenylphosphate (0.0893 g, 0.356 mmol) dissolved in methanol (4 mL) was then added, and the solution turned dark and a purple powder precipitated. This precipitate was collected by filtration (79.2 mg, 38%). Crystals of X-ray quality were obtained by vapor diffusion of methanol into an acetonitrile solution of **1**. $C_{59}H_{53}FeN_4O_{11}P_2Zn\cdot CH_3OH$: calcd. C 59.59, H 4.75, Fe 4.62, N 4.63, P 5.12, Zn 5.41; found C 59.49, H 4.47, Fe 4.62, P 5.13, N 4.69, Zn 5.00. UV/Vis (CH_3CN): λ_{max} = 501 nm (ε = 3077 $M^{-1}\,cm^{-1}$). FAB-MS (NBA): m/z = 1176 $[M + H]^+$.

The mononuclear zinc(II) complexes were isolated as pale yellow powders after addition of diethyl ether to a methanol solution of $Zn(ClO_4)_2\cdot 6H_2O$ (1 equiv.) and H_3L^1 (or HL^2) (1 equiv.). FAB-MS (NBA): from H_3L^1, m/z = 623 $[H_3L^1 + Zn - 2H]^+$; from HL^2, m/z = 651 $[HL^2 + Zn - 2H]^+$.

X-ray Crystallographic Study A single crystal of $[ZnFeL^1\{O_2P(OPh)_2\}_2]$ was mounted at 170 K on a Stoe IPDS diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). $[ZnFe(C_{35}H_{33}N_4O_3)\{O_2P(OC_6H_5)_2\}_2]$ M = 1177.26, dark purple platelet (0.045 × 0.08 × 0.23 mm), monoclinic, space group $P2_1/c$, a = 19.338(4), b = 16.850(3), c = 16.851(3) Å, β = 99.12(3)°, U = 5421(2) Å^3, Z = 4, D_c = 1.44 g cm^{-3}, μ = 0.835 mm^{-1}. 43028 Reflections (10794 independent reflections) were collected and corrected for Lorentz and polarization effects but not for absorption. The structures were solved by direct methods and refined using the teXsan software package.[13] All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were generated in idealized positions, riding on the carrier atoms, with isotropic thermal parameters. Final cycle refinement, including 703 parameters, converged to $R(F)$ = 0.035 and $Rw(F)$ = 0.028 [for 6130 $F > 2\sigma(F)$] [s = 1.11, (Δ/σ_{max} = 0.07, $\Delta\rho_{max}$ = 0.36 e·Å^{-3}, $\Delta\rho_{min}$ = −0.26 e·Å^{-3}]. CCDC-179245 contains the supplementary crystallographic data for this paper. Astonishing Alkylation and Unusual Reduction Reactions of Anionic Titanium(II) Isopropoxide Complexes: Evidence for SET Processes in Transition-Metal Oxidative Additions[‡]

John J. Eisch*[a] and John N. Gitua[a]

Keywords: Titanium / Subvalent compounds / Oxidative addition / Alkylation / Electron transfer

A mixture of titanium(II) isopropoxide and lithium isopropoxide (1:2), generated in THF by the treatment of titanium(IV) isopropoxide with two equivalents of *n*-butyllithium, has been shown to be an unexpected alkylating agent as well as an unusual reducing agent for a wide variety of organic substrates. Since titanium(II) isopropoxide, which is free of any lithium isopropoxide, neither causes alkylation of any of the same substrates nor is such a powerful reductant, it is proposed that the lithium isopropoxide activates titanium(II) isopropoxide for such unusual reactions by the formation of the lithium salt coordination complex $Li_2Ti[OiPr]_4$. Illustrative of the unprecedented alkylations are the transformations, after hydrolysis, of various substituted benzonitriles to isopropyl-substituted phenyl ketones, of (dichloromethyl)benzene to, principally, 2-methyl-1-phenyl-1-propene and of (trichloromethyl)benzene to isopropyl phenyl ketone. By comparing the reducing actions of $Li_2Ti[OiPr]_4$ and $Ti[OiPr]_2$ individually, it has been shown that, generally, the lithium salt is the more powerful reductant for epoxides, benzylic halides and conjugated olefins. From the reactions of $Li_2Ti[OiPr]_4$ with the benzonitriles, styrene, the isomeric stilbene oxides and *cis*-stilbene, cogent evidence is marshaled for the operation of SET processes, sensitive to steric hindrance, in such alkylations and reductions.

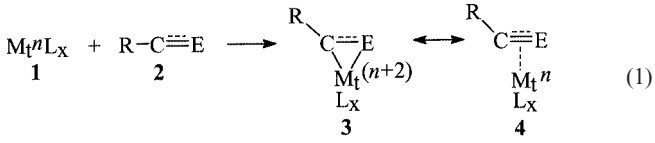
Introduction

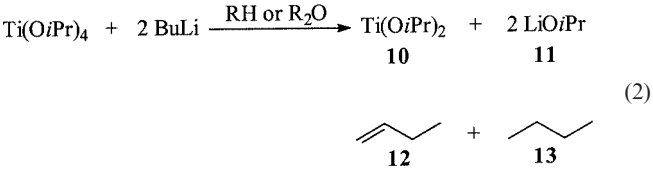
The oxidative addition of subvalent transition metals or metal salts, $M_t^nL_x$ (**1**), where *n* is the oxidation number, to π-bonded organic substrates (**2**) with the formation of a metallacyclic intermediate (**3**) has been termed epimetallation [Equation (1)].[2]



(1)

Since metallacycle **3** is one extreme of resonance structures ranging to the other extreme of a π-complex structure **4**, the term epimetallation implies that the adduct of **1** and **2** displays chemical reactions in better accord with **3**, possessing two sigma C−M_t bonds, than with **4**. The chemical behavior of **5** — the adduct of benzophenone and $Li^+CrH_2^-$ — towards D_2O[3] and towards CO_2 [2] illustrates clearly why **5** should be viewed as an oxachromacyclopropane rather than as the π-complex **6**. Were the π-complex **6** involved in the reaction with CO_2, then simple ligand displacement and reduction of CO_2 to **7** should have ensued (Scheme 1). Instead, the observed products of deuterium oxide cleavage (**8**) and of carbonation (**9**) are unambiguous proof for the presence of a C−Cr bond in **5**.

In exploring the applicability of epimetallation for organic synthesis, we have recently generated titanium(II) isopropoxide (**10**) according to Equation (2) and have employed **10** for the epimetallation of terminal alkenes, alkynes and selected carbonyl derivatives.[4]



(2)

Particularly noteworthy are the by-products formed in the production of **10**, namely lithium isopropoxide (**11**), which remains in solution regardless of whether the reaction is conducted in hexane or THF, and the one equivalent of 1-butene (**12**) which is epimetallated in situ by **10** with the formation of **14** (Scheme 2). The presence of **14** was demonstrated by its chemical trapping with benzonitrile

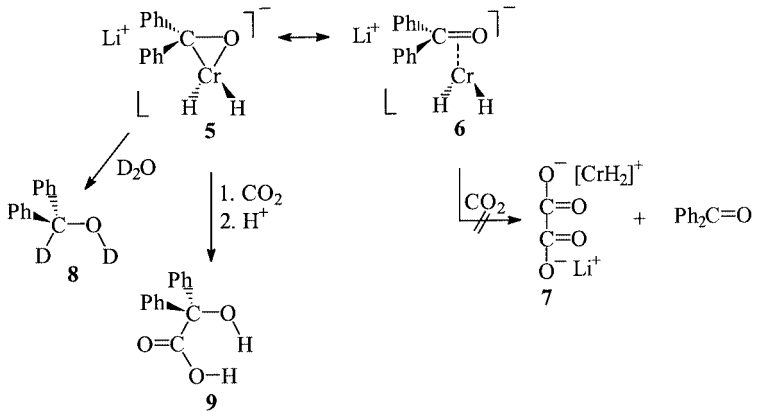
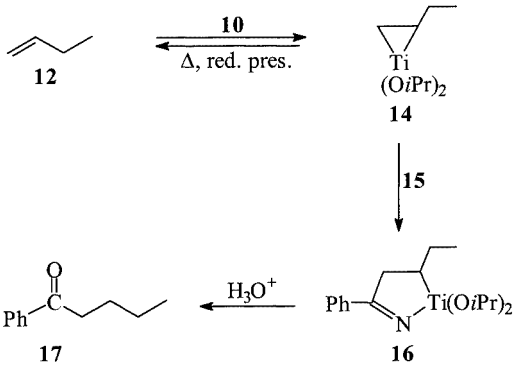


Scheme 1

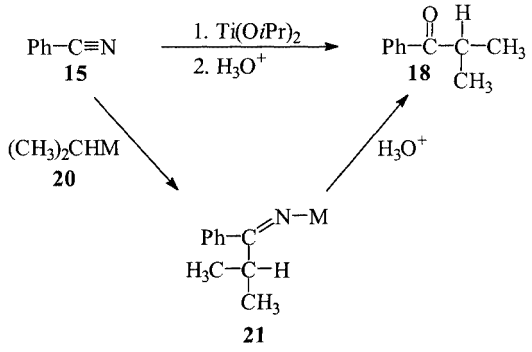
(**15**) to provide **16**, whose subsequent hydrolysis yielded *n*-butyl phenyl ketone (**17**).[4] Only if the solvent is removed by warming and reduced pressure can **14** be decomposed.



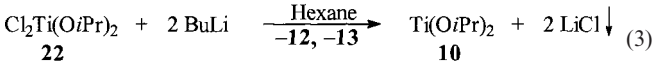
Scheme 2

Results and Discussion

In order to learn whether titanium(II) isopropoxide itself, free of any of the adduct **14**, could epimetallate benzonitrile (**15**), a solution of **10** generated in THF was freed of solvent under reduced pressure at 70°. To the black residue of **10** and **11** an equivalent of benzonitrile in toluene was then added and the solution heated at reflux. To our astonishment, upon hydrolytic workup such a reaction mixture gave 92% of isopropyl phenyl ketone (**18**) but only a small amount of **17** and a trace of 2,2-dimethyl-1,3-diphenyl-1,3-propanedione (**19**)[5] [Scheme 3, Table 1]. The formation of **18** raised the possibility that heating solutions of **10** might have produced an isopropylmetallic agent **20**, which would then have added to **15** to yield **21**, a prehydrolysis intermediate to the observed final product. That the lithium isopropoxide by-product **11** plays an essential role in this unexpected reaction was demonstrated in the following way. Recently we have reported that titanium(II) isopropoxide, free of lithium isopropoxide, can be prepared by treating titanium dichloride diisopropoxide (**22**) in hexane with two equivalents of *n*-butyllithium[6] [Equation (3)]. In this case, the lithium chloride formed is a much weaker base and more ionic salt and precipitates completely from the mixture. When this $Ti(OiPr)_2$, free of lithium isopropoxide, was heated with benzonitrile in toluene and then hydrolyzed, analogous to the reaction in Scheme 3, no trace of **18** was found whatsoever.[7] Thus, a combination of **10** and **11** is a prerequisite for the formation of isopropyl phenyl ketone (**18**) from benzonitrile (**15**).

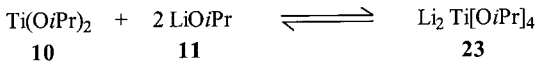


Scheme 3



(3)

In establishing the role of **11** in activating **10** for this unusual reaction, it should be noted that titanium(II) salts form anionic complexes with alkali metal salts.[8] Therefore, **10** and **11** can be expected to be in equilibrium with complexes such as **23** [Equation (4)].



(4)

That four isopropoxyl groups can be sterically accommodated around the titanium(II) center in **23** is corroborated by the existence of stable titanium(IV) isopropoxide. One possibility for the formation of the requisite isopropyl-

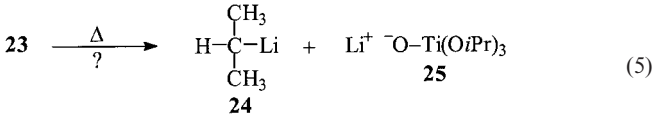
[a] All reactions involved 10.0 mmol of $Ti(OiPr)_2$ containing the LiO*i*Pr by-product and 5.0 mmol of the organic substrate in 40 mL of THF at 25 °C for 24 h unless otherwise specified. [b] Percent yields of products were obtained from the integrated ^1H NMR spectra; recovered starting substrate = 100% −% of products. [c] The reaction was conducted at reflux for 4−8 h. [d] The reaction was conducted at 25 °C for 12 h.

ating agent **20** would be an intraanionic oxidative addition that might occur upon heating **23** that would produce isopropyllithium (**24**) and the lithium salt of the titanium(IV) complex **25** [Equation (5)]. However, the fatal flaw in this proposal is that isopropyllithium is an extremely active lithium reagent that attacks ethers and is thereby destroyed, with lithium alkoxide elimination, even at 25 °C.[9] Under the reaction conditions used to prepare a mixture **10** and **11** for reaction with benzonitrile (**15**), according to Scheme 3, no isopropyllithium would have been expected to survive.



(5)

The remaining possibility, therefore, is that the ionic complex **23** itself is the actual isopropylating agent for benzonitrile (**15**). In order to evaluate this hypothesis, a series of polar substrates, ranging from substituted benzonitriles through benzylic and aryl halides to epoxides and finally to aryl-conjugated acetylenes and olefins, were individually treated with lithium complex **23**, prepared according to Equation (2). The resulting products are tabulated in Table 1.

Because of the equilibrium possible between **10** and **23** [depicted in Equation (4)], it became important to ascertain which reactions reported in Table 1 are unambiguously attributable to reagent **23** and which could equally be caused by reagent **10**. To this end, titanium(II) isopropoxide, which was essentially free of lithium isopropoxide (**11**) and hence of any **23**, was generated according to Equation (3). Reagent **10** was then individually allowed to react with many of the same polar substrates, which had previously been treated with reagent **23**, and the results are listed in Table 2.

Through a comparison of the reaction products from individual substrates towards reagent **23** (Table 1) and towards reagent **10** (Table 2), the following conclusions can be reached. First of all, only reagent **23**, not reagent **10**, can introduce an isopropyl group into any of the organic substrates, as it does with benzonitriles **15**, **26** and **27** (entries 1,2,3), (dichloromethyl)benzene (**29**, entry 5) and (trichloromethyl)benzene (**30a**, entry 6 in Table 1) [cf. Scheme 3 and Equation (6) and (7)]. Secondly, with respect to the isopropylation of benzonitriles by **23**, it is most noteworthy that some substituted benzonitriles, such as the 2-methoxy (**26**, entry 2, Table 1) and 4-methoxy (**27**, entry 3) derivat-

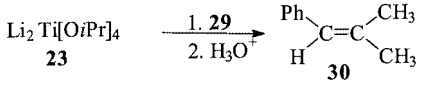
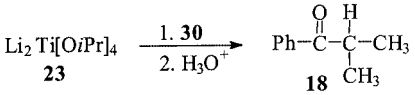
[a] Identical reaction conditions involving titanium(II) isopropoxide, prepared according to Equation (3), as those specified in footnote [a] of Table 1. [b] The percent yields of products were obtained from the integrated ^{1}H NMR spectra; recovered starting substrate = 100% − % of products.

ives underwent the isopropylation reaction readily,[5] but the 2,6-dimethyl derivative (**28**, entry 4) did not react at all. The failure of **28** to react with **23** can readily be ascribed to steric hindrance to the close approach of **23** to the C≡N group in **28** because of the flanking CH_3 groups.

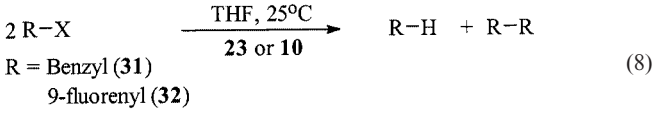


(6)

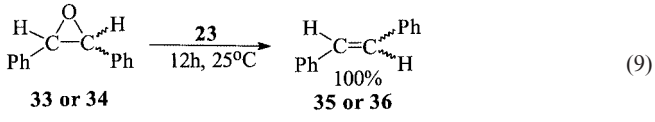


(7)

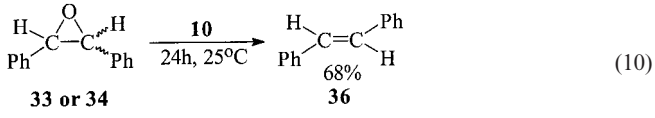
Thirdly, in those cases where no isopropylation of the organic substrate takes place, reagents **23** and **10** can effect monomolecular and bimolecular reductions, deoxygenations or dehalogenations to various degrees. Although not without exception, the results given in Table 1 and 2 indicate that reagent **23** is a more active reductant than reagent **10**. Thus in the reduction of benzyl chloride (**31**) or of 9-bromofluorene (**32**) the monomolecular and bimolecular reduction depicted in Equation (8) is complete in 12 h with **23** but requires 24 h with **10** (entries 7 and 8, Table 1, versus entries 4 and 5, Table 2). In another instance, the deoxygenation of *cis*- or *trans*-stilbene oxide (**33** or **34**) proceeds more cleanly and rapidly to the stilbenes **35** or **36** with **23** than with **10** (entries 10 and 11, Table 1, versus entry 7, Table 2; Equation (9) and (10)]. But with other substrates, such as diphenylacetylene (**37**) and the stilbenes **35** and **36**, the extent of reduction with either **23** or **10** is not markedly different. The behavior of 4-bromoanisole is anomalous in this regard, being much more readily reduced by **10** than by **23** (entry 6 in Table 2 versus entry 9 in Table 1).



(8)



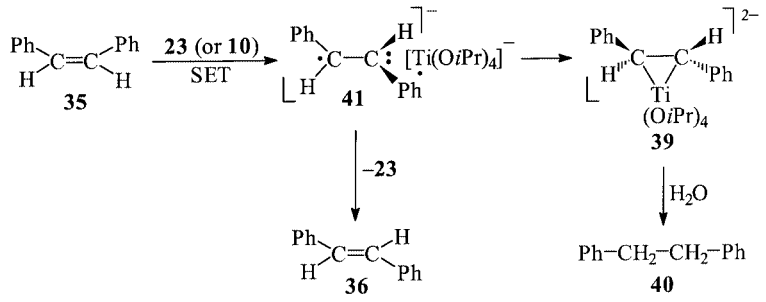
(9)



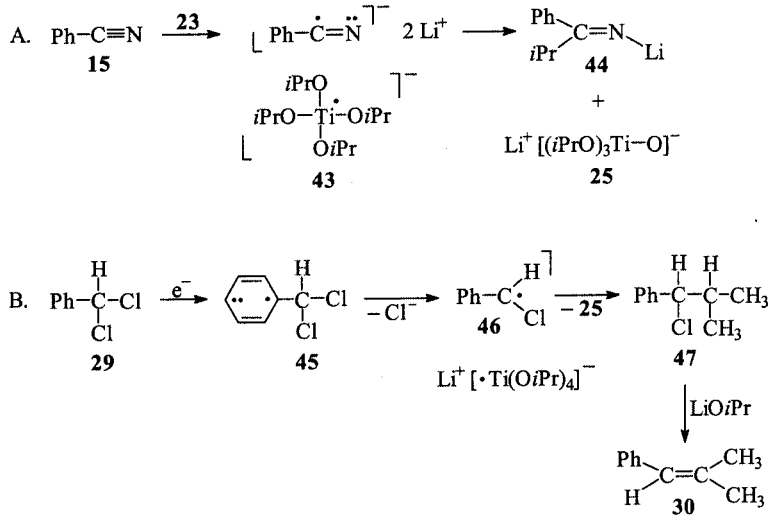
(10)

The final valuable conclusion deducible from these reductions by reagents **10** or **23** concerns their underlying mechanism of reaction. First, that *cis*-stilbene (**35**) undergoes extensive isomerization to *trans*-stilbene (**36**) in the course of epimetallation to **39** is consistent with the formation of the biradical intermediate **41** by single-electron transfer (SET). This intermediate can then either ring-close to **39** or reeliminate **23** to form the *trans*-isomer **36** (Scheme 4).[10]

Furthermore, that the *cis*- and *trans*-stilbene oxides (**33** and **34**) undergo non-stereoselective deoxygenation[11] to give chiefly *trans*-stilbene (**36**) again strongly supports an isomerizable radical ion intermediate (**42**), which can lead principally to the more stable *trans*-olefin **36** [Equation (11)]. Finally, that styrene undergoes polymerization much more rapidly than epimetallation with **23**, compared with **10**, further corroborates the superior SET donor character of **23** in forming the styrene radical-anion intermediate, crucial in such polymerization. Compelling precedents for SET mechanisms for both olefin isomerization and

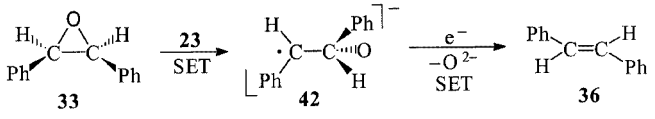


Scheme 4



Scheme 5

conjugated olefin polymerization are available in the work of Swarc and co-workers on the "living polymerizations" of diolefins by alkali metals.[12]



(11)

Conclusions

In light of the foregoing unexpected isopropylations of carbon centers and the nature and stereochemistry of many of the observed reductions, we conclude that the actual reagent in most of these reactions is dilithium tetraisopropoxytitanate(II) (**23**) and not titanium(II) isopropoxide (**10**) alone, and that such processes involve SET pathways. The mode of action of **23** as an isopropylating agent towards benzonitrile (**15**) is proposed in Scheme 5, Part A. The caged radical-anions formed by SET (**43**) can then undergo an isopropyl-radical transfer to the sterically accessible nitrile carbon to form the final adduct **44**. In Part B, (dichloromethyl)benzene (**29**) undergoes SET with **23** to form radical-anion **45**, which loses a Cl anion to form radical **46**. Radical **46** accepts an isopropyl radical from the caged Ti^{III} radical to form **47**. Simple dehydrohalogenation by LiO*i*Pr leads to the final product **30**.

In summary, a most unusual intramolecular oxidative addition of an ionic titanium(II) alkoxide (**23**), leading to a complex of titanium(IV), probably **25**, has been observed to occur with a variety of reducible organic substrates. The organic substrate undergoes either simple reduction or isopropylating reduction via pathways most likely involving SET processes.

Experimental Section

Instrumentation, Analysis and Starting Reagents: All reactions were carried out under a positive pressure of anhydrous, oxygen-free argon. All solvents employed with organometallic compounds were dried and distilled from a sodium metal-benzophenone ketyl mixture prior to use.[13] The IR spectra were recorded with a Perkin−Elmer instrument (model 457) and samples were measured either as mineral oil mulls or as KBr films. The NMR spectra (^1H and ^{13}C) were recorded with a Bruker spectrometer (model EM-360) and tetramethylsilane (Me_4Si) was used as the internal standard. The chemical shifts reported are expressed on the δ scale in parts per million (ppm) from the Me_4Si reference signal. The GC/MS measurements and analyses were performed with a Hewlett−Packard GC 5890/Hewlett−Packard 5970 mass-selective-

detector instrument. The gas chromatographic analyses were carried out with a Hewlett−Packard instrument (model 5880) provided with a 2-m OV-101 packed column or with a Hewlett−Packard instrument (model 4890) having a 30 m SE-30 capillary column. Melting points were determined on a Thomas-Hoover Unimelt capillary melting point apparatus and are uncorrected.

Preparation of Titanium(II) Isopropoxide (10, Free of LiO*i*Pr): *n*BuLi (1.28 g, 12.5 mL, 1.6 M solution in hexane, 20 mmol) was added slowly at −78 °C to a stirred solution of titanium(IV) chloride (1.89 g, 10 mmol) in THF (40 mL) under an argon atmosphere and the mixture stirred for 30 minutes at this temperature. Then the slow addition of isopropyl alcohol (1.20 g, 1.53 mL, 20 mmol) was performed at the same low temperature. The resulting reaction mixture was allowed to warm to 25 °C over 10 h to yield a dark brown suspension, which was then cooled to −78 °C and a further two equivalents of *n*BuLi (20 mmol) were slowly added at the same temperature. The resulting dark brown suspension was then allowed to warm to 25 °C over a 10 h period to yield a black solution of titanium(II) isopropoxide (1.66 g, 100%) from which white LiCl precipitated on standing.

Preparation of Titanium(II) Isopropoxide (23, Containing LiO*i*Pr): *n*BuLi (1.28 g, 12.5 mL, 1.6 M solution in hexane, 20 mmol) was added slowly at −78 °C to a stirred solution of titanium(IV) isopropoxide (2.84 g, 10 mmol) in THF (40 mL) under an argon atmosphere and the mixture stirred for 2 h at this temperature. The resulting light-brown reaction mixture was then allowed to warm to 25 °C over 10 h to yield a dark brown-black solution of titanium(II) isopropoxide (1.66 g, 100%).

Chem.* **1994**, *620*, 801−804) and $Na_2Ti_3Cl_8$ (D. J. Hinz, G. Meyer, T. Dedecke, W. Urland, *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 71−73).
[9] P. D. Bartlett, S. Friedman, M. Stiles, *J. Am. Chem. Soc.* **1953**, *75*, 1771−1772: Isopropyllithium reacts with diethyl ether exothermally at room temperature to form lithium ethoxide and ethylene:

$$i\text{PrLi} + \text{Et}_2\text{O} \longrightarrow \text{PrH} + \text{LiOEt} + \text{H}_2\text{C=CH}_2$$

The excess *i*PrLi then adds to the ethylene to form isoamyllithium, which can be trapped with CO_2 to give, after hydrolysis, the observed diisoamyl ketone:

$$i\text{PrLi} + \text{H}_2\text{C=CH}_2 \longrightarrow i\text{Pr–CH}_2\text{–CH}_2\text{Li}$$

$$2\ i\text{Pr–CH}_2\text{–CH}_2\text{Li} \xrightarrow[2.\ \text{H}_2\text{O}]{1.\ \text{CO}_2} (i\text{Pr–CH}_2\text{–CH}_2)_2\text{C=O}$$

[10] Solutions of **23** and **10** in THF are paramagnetic as shown by ESR spectroscopic measurement at room temperature. In fact, solutions of **23** give a strong triplet signal, consistent with the presence of two unpaired electrons. However, from the magnitude of the spin coupling, the two electrons are not on the same titanium atom, and probably not even on adjacent titanium centers. (Studies in progress with Professor D. C. Doetschman).

The First Two Novel Metallomacrocycles Constructed from Cubane-Like Cu_4I_4 Cluster Units and Ditopic Diamines

Rui-Hu Wang,[a] Mao-Chun Hong,*[a] Jun-Hua Luo,[a] Rong Cao,*[a] and Jia-Bao Weng[a]

Keywords: Amine ligands / Copper / Metallacycles / X-ray diffraction

Two novel metallomacrocycles made up of difunctional 4,4′-diaminodiphenylmethane (DADPM) or 4,4′-diaminodiphenyl ether (DADPE) and cubane-like Cu_4I_4 cluster units have been prepared by the reaction of CuI and DADPM or DADPE in $MeCN/H_2O$. The X-ray crystal structural analyses show that the topology of the cubane-like Cu_4I_4 cluster units is maintained in the assembly process.

Introduction

Much effort has been devoted to the design and construction of metal-containing supramolecular and coordination polymers from building blocks possessing useful properties such as nonlinear optical properties, bulk magnetism, light emission and porosity.[1−8] Metallomacrocycles based on specific building blocks have recently received a great deal of attention in chemistry and material science owing to their potential applications in various materials.[9−24] A number of discrete macrocycles have been constructed by ditopic or oligotopic ligands, in particular di- or polypyridyl ligands and suitable metal ions.[15−23] For instance, discrete square or rectangular metallomacrocycles with nanometer-sized cavities have been obtained by the assembly of pyridine-based ligands, such as 4,4-bipyridine or its derivatives, and metal ions with square-planar coordination geometry, such as Pd^{II} or Pt^{II}.[15−21] However, discrete macrocycles consisting of metal clusters and organic ligands are less well-known.[23,24]

It is known that the reaction of copper(I) iodide with aniline derivatives, such as *p*-toluidine, *p*-chloroaniline, *p*-anisidine, *o*-ethylaniline, 2,6-dimethylaniline or 6-ethyl-*o*-toluidine, produces complexes containing a single cubane-like Cu_4I_4 cluster in which the aniline derivatives act as the terminal ligands coordinating to copper(I) centers.[25−28] Thus, it is reasonable to expect the formation of macrocyclic complexes constructed from Cu_4I_4 cluster units by replacing the aniline derivatives with difunctional diamine ligands containing suitable spacers. Considering the flexibility and electronic structures of diamine ligands, such as 4,4′-diaminodiphenylmethane (DADPM) and 4,4′-diaminodiphenyl ether (DADPE), we recently began work on the reaction of diamine ligands and Cu^I, with the hope of isolating some interesting complexes constructed by cubane-like Cu^I cluster units. Herein, we report two novel macrocyclic complexes $[(Cu_4I_4)(MeCN)_2(DADPM)]_2{\cdot}2MeCN$ (**1**) and $[(Cu_4I_4)(MeCN)_2(DADPE)]_2{\cdot}2MeCN$ (**2**) assembled from DADPM, DADPE and CuI, respectively. To the best of our knowledge they are the first two discrete macrocyclic complexes constructed from cubane-like Cu_4I_4 clusters.

Results and Discussion

Complex **1** was synthesized in a high yield from the reaction of DADPM and CuI with a metal-to-ligand ratio of 1:1 in $MeCN/H_2O$ at 60 °C. Single crystal X-ray diffraction analysis revealed that **1** is a discrete metallomacrocycle possessing a crystallographic center of symmetry, in which two cubane-like Cu_4I_4 cluster units are linked by two DADPM ligands (Figure 1).

Each DADPM ligand acts as a μ_2-bridge linking two cubane-like Cu_4I_4 units through its two nitrogen atoms. The dihedral angle of the two phenyl rings and the C(4)−C(5)−C(6) bond angle in the DADPM ligand are 89.2° and 112.7(10)°, respectively, resulting in a twisted-rhombus macrocycle. Two opposite phenyl rings in the macrocycle are parallel to each other at a distance of 10.53 Å, while the distance between the C(7)−C(8)−I(4A) and C(7A)−C(8A)−I(4) planes is 4.04 Å. Thus the dimension of the distorted macrocycle is 10.53 × 4.04 Å which compares well with the value of 8.36 × 4.10 Å for the macrocycle formed from DADPM and Cu^{II} ions.[22] Two uncoordinated MeCN molecules lie in two sides of the macrocycle as space fillers. Each Cu_4I_4 unit displays a cubane-like arrangement with Cu^I and iodide atoms occupying alternate corners of the cube; no crystallographic symmetry element is present for this unit. All Cu^I centers are in a distorted NI_3 tetrahedral geometry in which the coordination geometry of

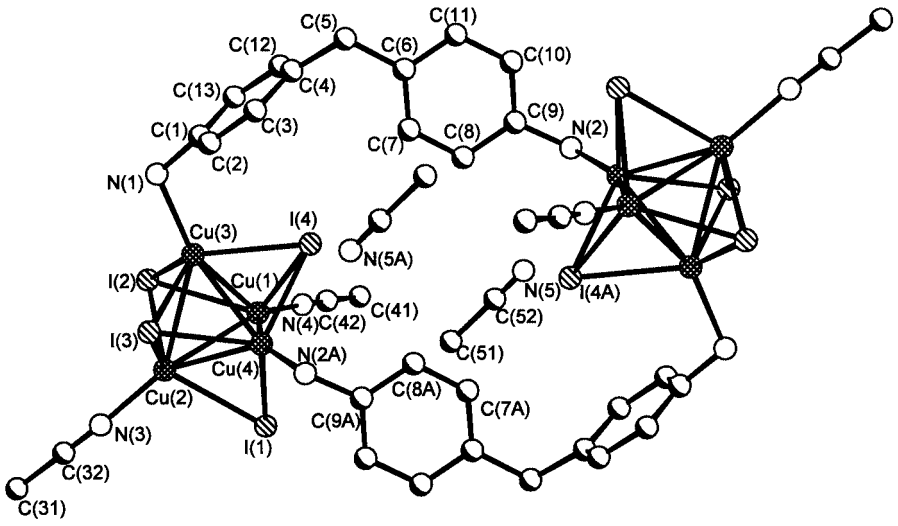

Figure 1. A view of the macrocyclic structure of **1**

two of the Cu^I ions is completed by the nitrogen atoms of two MeCN ligands and that of the other two Cu^I ions is completed by the nitrogen atoms of different DADPM ligands. All the bond lengths and bond angles of the Cu_4I_4 units in **1** are normal.[25−28] The Cu−Cu bond lengths, ranging from 2.670(3) to 2.777(3) Å (average value 2.724 Å), are within the range suggested by Mehrotra and Hoffman.[29]

Complex **2** was obtained in an analogous procedure except that DADPE was used instead of DADPM. The X-ray crystallographic analysis reveals that its structure is very similar to that of complex **1**, consisting of a centrosymmetrical metallomacrocycle formed from two cubane-like Cu_4I_4 cluster units and two bridging DADPE ligands. As shown in Figure 2, each DADPE ligand acts as a μ_2-bridge linking two Cu_4I_4 cluster units, the dihedral angle of two phenyl rings and the C(4)−O(1)−C(5) bond angle in DADPE are 90.4° and 117.1(7)°, respectively, resulting in a twisted-rhombus metallomacrocycle with dimensions of 9.99 × 3.88 Å. This is slightly smaller than in **1**, but larger than in other complexes obtained from the reaction of transitional metal ions and 1,2-bis(4-pyridyl)ethane.[19−21]

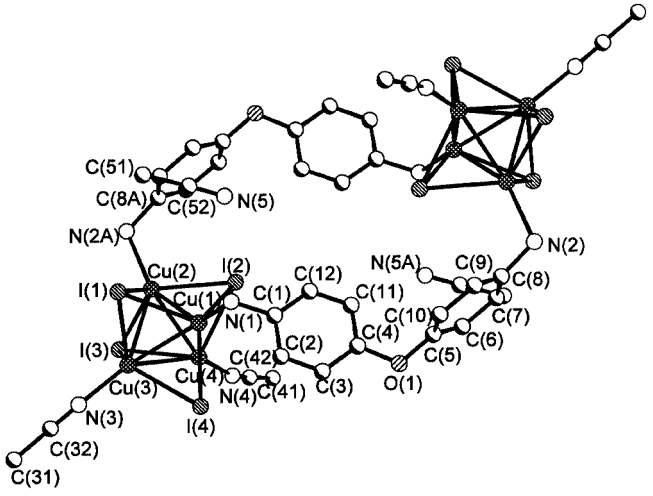

Figure 2. A view of the macrocyclic structure of **2**

There are no apparent differences in the bond lengths and bond angles in the Cu_4I_4 cluster units in complexes **1** and **2** and in the reported $[Cu_4I_4L_2(MeCN)_2]$ (L = aniline derivatives) complexes.[25−28] This result suggests that the topology of the cubane-like Cu_4I_4 cluster units is maintained during the assembly process and is not influenced by the linker ligands used.

In the solid state, the emission spectra for **1** and **2** were recorded after irradiating with light at a wavelength of 310 nm. Compounds **1** and **2** show a similar emission band in the 320−630 nm range despite the fact that free DADPM and DADPE have different emission spectra at the same excitation wavelength. Compared with single cubane-like $[Cu_4I_4L_2(MeCN)_2]$ (L = aniline derivatives) complexes[25,26] and luminescent Cu^I complexes,[30−33] the high energy emission at 350−460 nm might be ascribed to an intraligand interaction, and the weak emission which appears as a shoulder at around 500 nm might be ascribed to a metal-centered transition.

Conclusion

We have successfully assembled cubane-like Cu_4I_4 cluster units and difunctional diamines containing a spacer to form two discrete metallomacrocycles in which the topology of the Cu_4I_4 clusters is maintained. Previous reports have predicted that the tetranuclear chalcogenide Cu_4 or Ag_4 d^{10} clusters are good building blocks for the formation of materials with desirable physical and chemical properties.[33] Our report may open a new way to assembly Cu_4 clusters into desirable materials.

Experimental Section

General: All chemicals were purchased from Acros and used as received. The IR spectra were recorded as KBr discs on a Magna 750 FT-IR spectrophotometer. Elemental analyses were determined on an Elementar Vario ELIII elemental analyzer by the elemental analysis laboratory of this institute. NMR spectra were recorded on a Varian Unity 500 spectrophotometer. The fluorescent data were collected on an Edinburgh FL-FS920 TCSPC system by the Spectroscopy Laboratory of Fuzhou University.

Synthesis of $[(Cu_4I_4)(MeCN)_2(DADPM)]_2\cdot 2MeCN$ (1): A solution of DADPM (0.10 g, 0.5 mmol) in H_2O (10 mL) was added slowly to a solution of CuI (0.10 g, 0.5 mmol) in MeCN (20 mL). The reaction mixture was stirred at 60 °C for 30 min and gave a colorless solution, which was then filtered. The gray crystals of complex **1** were obtained by allowing the resulting solution to stand in the air for three days. Yield: 0.107 g, (0.049 mmol, 79% based on CuI). Addition of CuI and DADPM in a 2:1 ratio under otherwise identical experimental conditions gave the same complex. $C_{38}H_{46}Cu_8I_8N_{10}$ (2166.37): calcd. C 21.07, H 2.14, N 6.47; found C 21.23, H 2.17, N 6.54. IR (KBr): $\tilde{\nu}$ = 3396m, 3321s, 3265s, 3228m, 3140w, 3030w, 2922w, 2904w, 1612m, 1587m, 1510vs, 1433w, 1242m, 1178w, 1095w, 1018s, 985s, 941m, 850w, 825w, 812m, 777w, 766w, 704w, 577m, 515m cm^{-1}. ^1H NMR ([D_6]DMSO): δ = 2.08 (m, 9 H, MeCN), 3.68 (s, 2 H, -CH_2-), 4.33 (s, 4 H, NH_2), 6.83 and 6.37 (m, 8 H, -C_6H_4-) ppm.

Synthesis of $[(Cu_4I_4)(MeCN)_2(DADPE)]_2\cdot 2MeCN$ (2): The experimental procedure was similar to the synthesis of complex **1** except that DADPE (0.10 g, 0.5 mmol) was used instead of DADPM. Yield: 0.086 g (0.040 mmol, 63% based on CuI). Changing the metal-to-ligand ratio has no influence on the product of the reaction. $C_{36}H_{42}Cu_8I_8N_{10}O_2$ (2170.32): calcd. C 19.92, H 1.95, N 6.46; found C 20.07, H 2.03, N 6.57. IR (KBr): $\tilde{\nu}$ = 3315s, 3253s, 3128w, 3061w, 3018w, 1572m, 1498vs, 1441w, 1284m, 1265s, 1221s, 1165w, 1090w, 1014m, 978s, 926w, 877w, 843w, 825m, 785m, 552w, 517w, 503w cm^{-1}. ^1H NMR ([D_6]DMSO): δ = 2.09 (m, 9 H, MeCN), 4.29 (s, 4 H, NH_2), 6.66 and 6.43 (m, 8 H, -C_6H_4-) ppm.

[a] Symmetry transformations used to generate equivalent atoms: A: $-x$, $-y$, $-z$.

X-ray crystallography: The crystal data and a structure determination summary for **1** and **2** are listed in Table 1. Selected bond lengths and bond angles for **1** and **2** are listed in Table 2 and 3, respectively. Intensity data for **1** and **2** were measured on a CAD4 four-circle and Siemens Smart CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 298 K, respectively. Empirical absorption corrections were applied by using the SADABS program. The structures were solved by direct methods and all calculations were performed using the SHELXL PC program. The positions of the H atoms were generated geometrically (C−H bond fixed at 0.96 Å), assigned isotropic thermal parameters, and allowed to ride on their parent carbon atoms before the final cycle of refinement. The structure was refined by full-matrix least-squares minimization of $\Sigma(F_o - F_c)^2$ with anisotropic thermal parameters for all atoms except the H atoms. CCDC-175784 (**1**) and CCDC-175785 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Lanthanide Triple Helical Complexes with a Chiral Bis(benzimidazole)pyridine Derivative

Gilles Muller,[a,b] James P. Riehl,[b] Kurt J. Schenk,[c] Gérard Hopfgartner,[d] Claude Piguet,[e] and Jean-Claude G. Bünzli*[a]

Keywords: Lanthanides / Tridentate ligands / Chirality / Luminescence / Stability constants

The ligand neopentyl 2,6-bis[(1-methylbenzimidazol-2-yl)]-pyridine-4-carboxylate ($\mathbf{L^{12}}$) has been synthesised to test the effect of the chiral neopentyl ester group in the 4-position of the pyridine ring on (i) the helical wrapping, (ii) the diastereomeric induction and (iii) the thermodynamic and photophysical properties of the $[Ln(\mathbf{L^{12}})_3]^{3+}$ complexes. The crystal structure of ligand $\mathbf{L^{12}}$ shows the expected *trans-trans* conformation of the tridentate binding unit. The ligand forms stable 1:3 complexes in anhydrous acetonitrile ($\log\beta_3$ in the range 17.3–19.0, $\log K_3$ in the range 2.9–4.6). The triple helical structure in solution is responsible for the four times larger specific rotary dispersion measured in the complexes. Circularly polarised luminescence of the Eu triple helical complex displays a weak effect, suggesting a small diastereomeric excess in solution. Ligand $\mathbf{L^{12}}$ appears to favour a $^3\pi\pi^*$-to-Ln energy transfer process for Eu, but temperature-dependent nonradiative processes lead to a very small quantum yield. High-resolution luminescence spectra indicate that the Eu complex has a distorted D_3 local symmetry at the metal ion site.

Introduction

During the last two decades, lanthanide ions Ln^{III} have proved to be powerful luminescent and magnetic probes in biology and medicine.[1−4] In the latter field, applications range from diagnosis (e.g. fluoroimmunoasssays,[5−7] luminescent specific imaging agents for tissues,[8,9] contrast agents for magnetic resonance imaging[10]) to therapeutic tools.[11] In addition, these ions are also good catalysts for the selective hydrolysis of DNA and RNA.[12,13]

These applications require the introduction of the Ln^{III} ions into functional molecular edifices able to preserve or better enhance the metal ion physicochemical properties.[14] One strategy proposed to meet this goal is the formation of induced cavities obtained by the self-assembly of carefully tailored multidentate ligands and podands.[15] A judicious design of the ligands results in weak noncovalent interstrand interactions stabilizing the molecular edifices. We have shown that tridentate aromatic ligands $\mathbf{L^1}$−$\mathbf{L^9}$, $\mathbf{L^{11}}$ derived from bis(benzimidazole)pyridine (Scheme 1) lead to triple helical assemblies displaying sizeable ππ-stacking interactions, whose structural, photophysical and thermodynamic properties can be tuned by varying the substituents R^1, R^2 and R^3.[16−18] Substitution in the R^2 position of the benzimidazole rings essentially controls the stability and the final structure of the complexes, while substitution in the R^1 and R^3 positions affects the electronic and photophysical properties.

So far, limited attention has been devoted to the inherent chirality of triple helical complexes, which often appear as racemic mixtures both in the solid state and in solution. However, Riehl et al. have shown that the $[Ln(dpa)_3]^{3-}$ racemate equilibrium (H_2dpa = dipicolinic acid) can be perturbed by adding chiral sugars.[19] Moreover, a small excess of one enantiomer can be induced in the excited state with the use of circular polarised excitation light.[20] Chiral lanthanide complexes are of potential great interest because of their use as probes for the sensing of chirality in biological substrates.[21,22] Since the high lability of the Ln^{III} ions favours easy racemisation of triple helical complexes, we are exploring the possibility of producing edifices in which the

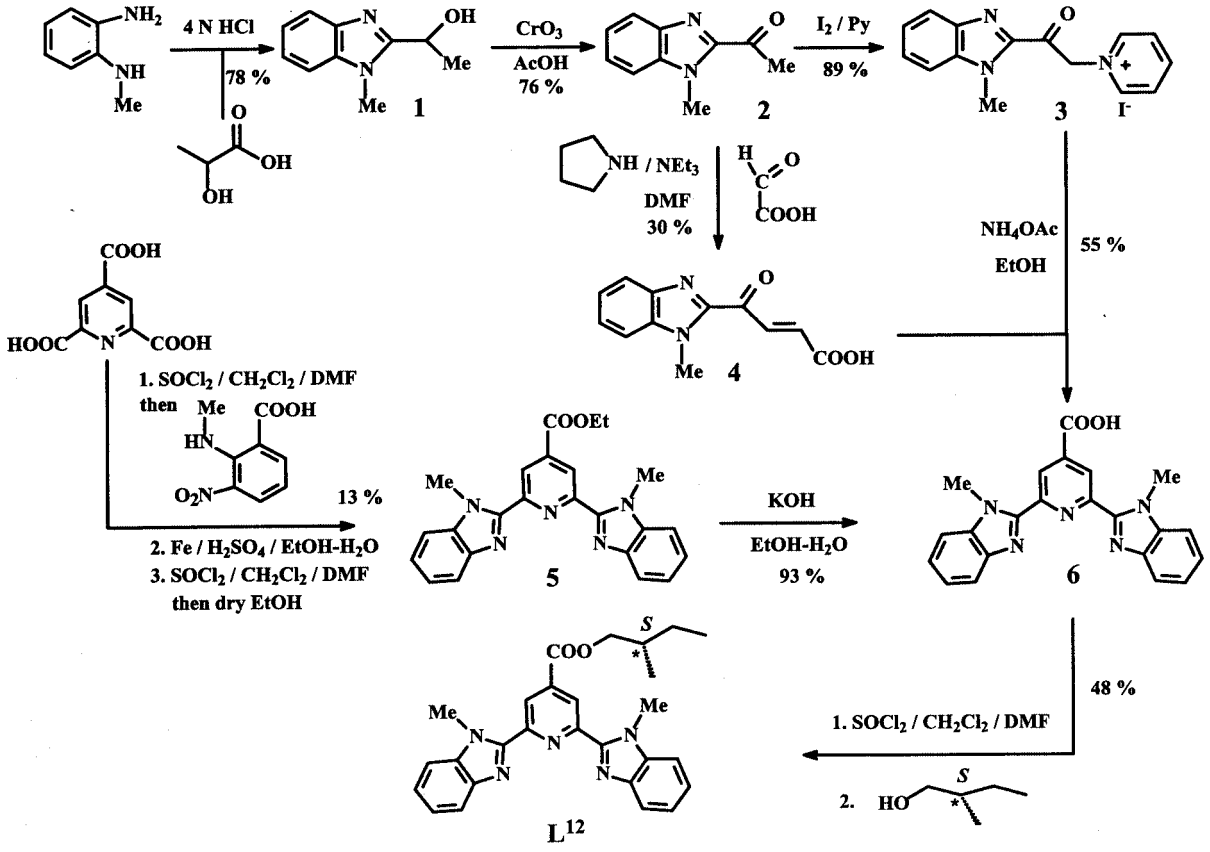
chirality is brought about by the ligands, a method which can only be used if the diastereoisomers have a large enough energy difference.

Working along these lines, we have introduced a chiral substituent onto the benzimidazole side arms of bis(benzimidazole)pyridine to yield $\mathbf{L^{11}}$. Unfortunately, the bulky neopentyl group precludes the formation of stable triple helical complexes.[18] On the other hand, introducing a bulky chiral substituent in the 4-position (R^3) of a pyridine 2,6-dicarboxamide (**L***, Scheme 1) results in (i) helical wrapping of the three ligand strands around the Ln^{III} ion, (ii) thermodynamically stable 1:3 complexes ($\log K_3$ in acetonitrile is in the range 5.1−5.3), and (iii) a small excess of one diastereoisomer.[23] To further our understanding of the influence of helical wrapping on diastereomeric induction, we introduce here a chiral neopentyl ester group in the pyridine R^3 position of $\mathbf{L^1}$ ($\mathbf{L^{12}}$, Scheme 1), and investigate its influence on the thermodynamic, chiro-optical and luminescent properties of the resulting tris complexes with Ln^{III} ions.

Results and Discussion

Synthesis and Characterisation of the Ligand and its Complexes

Ligand $\mathbf{L^{12}}$ was synthesised in a 48% yield from 2,6-bis[(1-methylbenzimidazol-2-yl)]pyridine-4-carboxylic acid (**6**) by esterification with (−),(*S*)-2-methyl-1-butanol (Scheme 2), while **6** was initially obtained by a four-step



Scheme 2

procedure involving a modified double Phillips coupling reaction to form the benzimidazole unit.[24] Using an excess of *N*-ethyl-2-nitroaniline and 2,4,6-pyridinetricarboxylic acid favoured the formation of by-products such as the triamide, and significantly decreased the yield of the Phillips reaction. Consequently, we turned to a different strategy based on a procedure similar to that reported for the synthesis of $\mathbf{L^7}$ and $\mathbf{L^8}$,[25] and made use of the Kröhnke reaction[26] for the construction of the 4-substituted central pyridine ring. The required pyridinium salt **3** was prepared by an Ortoleva−King reaction[27] from 2-acetyl-1-methylbenzimidazole (**2**), while 4-(1-methylbenzimidazol-2-yl)-4-oxo-2-butanoic acid (**4**) was obtained by a Knoevenagel condensation.[26,28] Finally, **4** was synthesised by treating **2** with a mixture of glyoxylic acid monohydrate, triethylamine and pyrrolidine, which gave a better yield (30%) and resulted in an easier isolation process than the originally proposed method based on UV-irradiation.[29]

The specific rotary dispersion of $\mathbf{L^{12}}$ in degassed anhydrous acetonitrile, $[\alpha]_D^{25} = 8.1 \pm 0.4$ deg dm^2 mol^{-1}, confirms the chirality arising from the asymmetric carbon atom. At room temperature, the ^{1}H and ^{13}C NMR spectra in $CDCl_3$ (5×10^{-3} M) display 13 and 17 signals, respectively, indicating a local pseudo twofold symmetry for the bis(benzimidazole)pyridine part of the molecule (Figure 1, Figure S1). These spectra coupled with {^{1}H-^{1}H} COSY, DEPT-135, {^{1}H-^{13}C} HSQC experiments and NOE effects observed between H^4 and N−Me (NOE effects do not exist between H^5 and N−Me), clearly suggest that $\mathbf{L^{12}}$ has a *trans-trans* conformation, similar to that observed in $\mathbf{L^{11}}$. This conformation also prevails in the solid state, as demonstrated by the X-ray crystal structure (Table 1, Figure 2). The unit cell contains two independent molecules A and B, the bond lengths and angles of which differ only slightly (Table S1). All aromatic groups are planar, but the benzimidazole units are not coplanar with the pyridine group, the interplanar angles being either very similar (16.6° and 10.9°) or largely different (36.3° and 14.2°) in molecules A and B, respectively (Table S2). These angles result in an optimal packing coefficient. Finally, no noteworthy hydrogen-bonding or π-stacking interactions exist in the structure, which seems to be an example of a pure van der Waals packing.

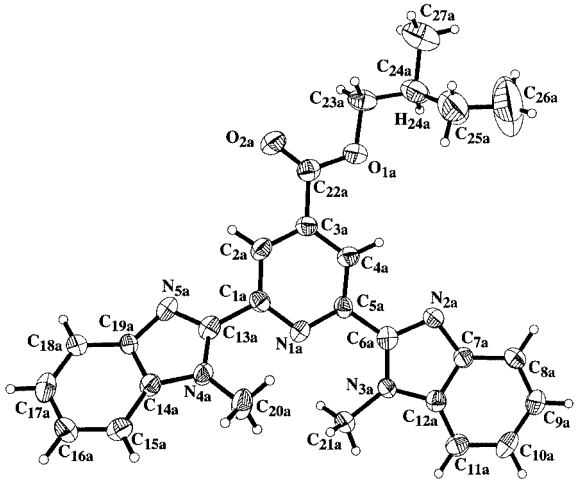

Figure 2. Molecular structure and atom numbering scheme for the two types of $\mathbf{L^{12}}$ molecules found in the unit cell.

The 1:3 complexes were obtained in 70−80% yields, by adding a solution of $\mathbf{L^{12}}$ in CH_2Cl_2 to solutions of lanthanide perchlorates in a mixture of MeCN and CH_2Cl_2. Evidence for complexation is the blue shift of the ν_{CO} and the two $\nu_{C=C}$ pyridine and benzimidazole vibrations by 4−6 cm^{-1} and 2−6 cm^{-1}, respectively. All perchlorate ions are ionic; hence the complexes are most probably nine-coordinate (see below). Single crystals for X-ray structure determination could not be obtained.

Interactions between $\mathbf{L^{12}}$ and the $\mathbf{Ln^{III}}$ Ions

The various species in solution were first identified by ESI-MS. Solutions of $\mathbf{L^{12}}$ (10^{-4} M in anhydrous acetonitrile) were titrated with $Ln(ClO_4)_3 \cdot xH_2O$ ($x = 0.2-0.6$) at 298 K, for ratios $R = [\mathbf{L^{12}}]_t/[Ln^{III}]_t = 0-3$. The spectra clearly show the successive formation of 1:*n* ($n = 1-4$) species, some of which had solvation molecules and/or were in the

Eu	8.0 ± 0.3	[b]	6.4 ± 0.4	[b]	4.6 ± 0.5	[b]
Lu	8.0 ± 0.3	7.9 ± 0.2	6.4 ± 0.4	6.5 ± 0.3	2.9 ± 0.4	3.1 ± 0.3

[a] Values of log K_1 and log K_2 were fixed. [b] Not determined.

form of perchlorate adducts (Table 2, Table S3). For La and Eu, the 1:3 complex ($R = 3$) is most abundant, while for Lu, this species coexists in solution with the 1:2 complex. In parallel, the proportion of the $[Ln(\mathbf{L^{12}})_4]^{3+}$ species is relatively important for the larger ions (La, Eu), but this species is not seen for Lu. Such complexes have been observed for ligands derived from pyridine 2,6-dicarboxamide and were assigned to an outer-sphere association of a fourth ligand with a 1:3 complex.[23,30] The ES-MS data clearly point to the presence of stable 1:3 complexes with La and Eu, while the formation of this species with Lu appears to be less favoured.

To confirm the speciation, the titration of $\mathbf{L^{12}}$ (10^{-3} M in CD_3CN) with La^{III} and Lu^{III} ions has been monitored by 400 MHz ^1H NMR spectroscopy. Chemical shifts are reported in Table 3, while Figure S2 (see Supporting Information) presents the aromatic part of the spectra obtained with Lu. Signals for the 1:1, 1:2, and 1:3 complexes could clearly be identified for both ions. When R reaches 3, the tris species is the major complex in solution for La (> 68%) and Lu (50%); the other species in solution is the 1:2 complex. This observation confirms that the bulky neopentyl ester group increases the steric constraint in the triple helical complexes with the smaller lanthanide ions. The stability constants extracted from ^1H NMR spectroscopic data and analysed with MINEQL$^+$ [31] are reported in Table 4. The apparent ease with which the 1:3 complex forms contrasts with the situation observed with $\mathbf{L^{11}}$, and indicates that the substitution in the R^3 position of the central pyridine is less detrimental to the formation of the helical complexes compared with substitution on the benzimidazole rings.[18]

To quantify the $Ln^{III}-\mathbf{L^{12}}$ interaction further, we have performed spectrophotometric titrations of $\mathbf{L^{12}}$ with $Ln(Otf)_3$ (Ln = La, Eu, Lu; Otf = trifluoromethanesulfonate) at 298 K in MeCN, in the presence of 0.1 M Et_4NClO_4, under anhydrous conditions ($[H_2O] < 30$ ppm). Factor analysis[32] indicates the presence of three or four absorbing species and the data can be fitted to Equations (1)−(3), where solvation and anion coordination has been omitted.

$$Ln^{3+} + \mathbf{L^{12}} \rightleftarrows [Ln(\mathbf{L^{12}})]^{3+} \quad \log\beta_1 \tag{1}$$

$$Ln^{3+} + 2\,\mathbf{L^{12}} \rightleftarrows [Ln(\mathbf{L^{12}})_2]^{3+} \quad \log\beta_2 \tag{2}$$

$$Ln^{3+} + 3\,\mathbf{L^{12}} \rightleftarrows [Ln(\mathbf{L^{12}})_3]^{3+} \quad \log\beta_3 \tag{3}$$

A model including $[Ln(\mathbf{L^{12}})_4]^{3+}$ does not improve the fit, in agreement with the postulated outer-sphere nature of this species detected in the gas phase. Electronic spectra of the three complexes are correlated, which renders the fitting process difficult and generates relatively large uncertainties in the $\log\beta_i$ values (Table 4). The stability constants are in a good agreement with those extracted from NMR spectroscopic data. The interactions between $\mathbf{L^{12}}$ and the Ln^{III} ions are stronger than those with $\mathbf{L^{11}}$, as indicated by $\Delta\log K_3(\mathbf{L^{12}}-\mathbf{L^{11}}) = 2.6$ and 3.7 for La and Eu, respectively.[18] According to previous studies with ligands derived from bis(benzimidazole)pyridine,[17] the methyl substituents bound to the benzimidazole side arms in $\mathbf{L^{12}}$ favour the formation of a tight cavity around the lanthanide ions. This is not the case for the neopentyl groups in $\mathbf{L^{11}}$. This observation also confirms the large influence of the alkyl N-substituents on the formation of the 1:3 complexes. However, the size-discriminating effect along the lanthanide series, and the stability of the $[Ln(\mathbf{L^{i}})_3]^{3+}$ complexes, are largely influenced by the substituents on the benzimidazole and

Table 3. ^1H NMR shifts observed (ppm) for $\mathbf{L^{12}}$ in $CDCl_3$ and for its 1:1, 1:2, and 1:3 complexes with Ln^{III} ions in CD_3CN (10^{-3} M, 298 K).

central pyridine groups; the latter acting on the electron density of the pyridyl N atom. The introduction of an electron-attracting neopentyl ester group in **L12** decreases the electronic density on the pyridyl N atom, which reduces the electrostatic interaction, as indicated by $\Delta\log K_3(\mathbf{L^1}-\mathbf{L^2}) = 1.0-1.1$, but the size-discriminating effect is retained.[17]

The specific rotary dispersion of solutions of the $[Ln(\mathbf{L^{12}})_3]^{3+}$ complexes (10^{-3} M in anhydrous acetonitrile) is 33.5 ± 0.5 (La) and 31.0 ± 0.3 deg dm^2 mol^{-1} (Eu). This is about four times larger than those measured for the free ligand. We assign the greater rotary dispersion with respect to that generated by three free ligands to a structural contribution such as the formation of triple helical complexes in solution, as observed for **L***.[23] As a comparison, relatively little or no (4−5 deg dm^2 mol^{-1}) structural contribution was observed for the 1:1 and 1:2 complexes with **L11**.[18] The circularly polarised luminescence (CPL) spectrum of a 5×10^{-3} M solution of $[Eu(\mathbf{L^{12}})_3]^{3+}$ is plotted in Figure 3 in the spectral range of the $^5D_0 \rightarrow {}^7F_1$ transition,

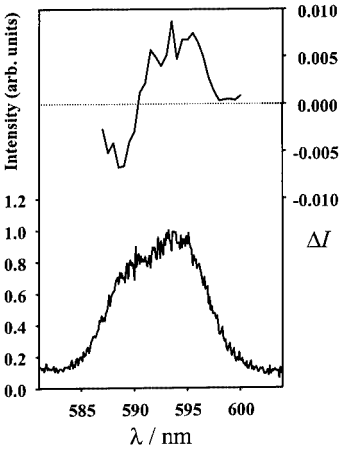

Figure 3. CPL spectrum of the $^5D_0 \rightarrow {}^7F_1$ transition of $[Eu(\mathbf{L^{12}})_3]^{3+}$ (5×10^{-3} M in anhydrous MeCN at 295 K), on ligand excitation at 386 nm.

which is particularly well-suited for CPL measurements since it satisfies the magnetic-dipole selection rule, $\Delta J = 0, \pm 1$. The spectrum depends on the polarisation of the excitation light, indicating the presence of two species in solution.[33] At the concentrations used, 93% of the Eu^{III} ion is in the form of the 1:3 complex, and 7% in the form of the 1:2 species, which is expected to generate a smaller chiral effect. The second species could also be a complex in which partial decomplexation of a ligand strand is induced by the interaction with one water molecule (see below). In conclusion, the CPL data are consistent with the presence of a small excess of one diastereoisomer in solution, on the short time scale of optical measurements, as previously observed for the corresponding complex with **L***.[23]

Photophysical Properties

The electronic spectrum of **L12** in MeCN displays two intense bands centred around 33950 and 29590 cm^{-1}, with a shoulder at higher energy (Table 5, Figure 4). Irradiation in the UV region at room temperature yields one broad unresolved fluorescence band, centred around 22885 cm^{-1} and originating from the $^1\pi\pi^*$ level (Figure 5). At 77 K, the fluorescence band is more structured and emission from the

[a] x = n or π. [b] At the concentration used, 67−85% of the metal ion is in the form of the 1:3 complex and 15−33% in the form of the 1:2 complex; Logε values are given in parentheses. [c] The 0-phonon transition is given in italics for frozen solutions in acetonitrile. [d] sh = shoulder. [e] not observed because of the **L12**-to-Ln energy transfer process.

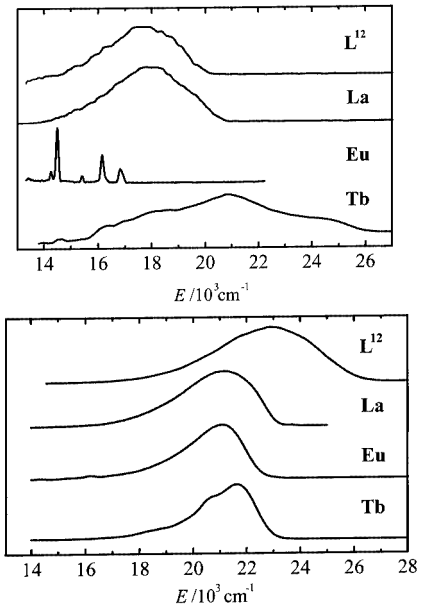

Figure 5. Top: Time-resolved emission spectra of $\mathbf{L^{12}}$ and $[Ln(\mathbf{L^{12}})_3]^{3+}$ in the solid state at 77 K and recorded with time delays of 0.01 (Eu), 0.1 (Tb) and 10 ms ($\mathbf{L^{12}}$, La). Bottom: Emission spectra of $[Ln(\mathbf{L^{12}})_3]^{3+}$ and $\mathbf{L^{12}}$ (10^{-3} M in MeCN at 293 K).

$^3\pi\pi^*$ state appears with a maximum around 17670 cm^{-1}. The decay of the latter is a single exponential with a lifetime of 210 ± 3 ms, in the range of values previously reported for similar ligands (160−323 ms).[16,34]

The higher energy component observed in the electronic (or reflectance) spectrum of $\mathbf{L^{12}}$ at 33950 cm^{-1} (33670 cm^{-1}) is only slightly modified on complexation with Ln^{III} ions, while the other band centred at 29590 cm^{-1} (27100 cm^{-1}) undergoes an important red shift (Table 5, Figure 4). This observation reflects the electronic transformations associated with the *trans-trans→cis-cis* conformational change and the complexation of the lanthanide metal ions to the tridentate binding unit.[16,25,34] On complexation of $\mathbf{L^{12}}$ to La^{III}, the 0-phonon transitions of the singlet and triplet states are red-shifted by 1470 and 1170 cm^{-1}, respectively (frozen MeCN solution, 77 K, see Figure 5), and the $^3\pi\pi^*$ lifetime decreases to 144 ± 1 ms. Emission from the $^1\pi\pi^*$ state of the ligand is still visible for the Eu and Tb complexes, suggesting an incomplete intersystem crossing. Emission from the $^3\pi\pi^*$ state disappears for the Eu solution, with a concomitant observation of the metal-centred emission bands. This is not the case for the Tb solution for which little or no ligand-to-Tb energy transfer takes place because the energy of the ligand donor level (19750 cm^{-1} in the La complex at 77 K) is located below the metal $^5D_4$ acceptor level (20350 cm^{-1}). Weak emission from the Tb^{III} ion can only be seen on direct excitation of the metal states (Figure S3, Supporting Information), and the short and temperature-dependent Tb($^5D_4$) lifetime (decreasing from 0.38 to 0.12 ms between 13 and 55 K) indicates that energy back transfer occurs in this complex.

In order to gain information on the chemical environment around the Eu^{III} ion, we have measured the high-resolution emission spectra of a solid state sample of $[Eu(\mathbf{L^{12}})_3](ClO_4)_3{\cdot}2H_2O$ (**8**) at low temperature since this complex is only faintly luminescent at room temperature. The lifetime of the $^5D_0$ level, 0.85 ± 0.01 ms, is constant between 13 and 77 K. This is shorter than the lifetimes reported for $[Eu(\mathbf{L^1})_3]^{3+}$ (1.85 ms in the range 4−77 K)[35] and $[Eu(\mathbf{L^{11}})_3]^{3+}$ (2.03 ms at 10 K),[36] but similar to that found for $[Eu(ClO_4)_2(H_2O)(\mathbf{L^{11}})_2]^+$ (0.65 ms at 10 K).[36] Therefore, we cannot rule out the interaction of one water molecule in the first coordination sphere. The decrease in the Eu($^5D_0$) lifetime from 0.85 ms to 0.27 ms between 77 and 295 K indicates temperature-dependent quenching mechanisms, e.g. a ligand-to-metal charge transfer as demonstrated for $[Eu(\mathbf{L^1})_3]^{3+}$,[37,38] and as reported for other Eu^{III} complexes[39] or other intermolecular interactions. In acetonitrile solution (10^{-3} M) at 295 K, the lifetime is longer, reaching 0.96 ± 0.01 ms; since in addition to the hydration of **8** the solvent contains about 2 mM H_2O, inner-sphere water interaction could occur. Using Horrocks equation, $q = 1.05\,(k_{H2O}-k_{D2O})$[40] and taking k_{D2O} equal to 0.51 ms^{-1} (average of the values for the anhydrous tris species with $\mathbf{L^1}$ and $\mathbf{L^{11}}$),[35,36] we find $q = 0.56$. This points to an equilibrium in solution between an anhydrous species and a monohydrate, as has been observed for triple helical complexes with terpyridine derivatives.[41] Alternatively, it has been demonstrated that fast diffusing outer-sphere H_2O molecules can contribute 0.25 ms^{-1} to the quenching of the Eu^{III} ion in complexes with cyclen derivatives.[42] Applying a similar correction for **8** results in a reduction of q by approximately a factor of 2. Therefore, given the uncertainties linked to this type of correlation, it is difficult to determine from the lifetime data whether or not a water molecule interacts in the inner coordination sphere. On the other hand, it is clear that the introduction of an electron-attracting group in the R^3 position weakens the Ln−N(py) bond, consistent with the relatively high energy of the $^5D_0 \leftarrow {}^7F_0$ transition (17258 cm^{-1} at 295 K). Using the correlation proposed by Frey and Horrocks[43] and the nephelauxetic parameter $\delta_{N(het)} = -15.3$ cm^{-1} that we reported previously,[44] we get $\delta_{N(py)} = -8.1$ cm^{-1}, a value much lower than those proposed (−12 to −17 cm^{-1}).[43,45]

The emission spectra recorded at 13 K on excitation through the ligand band, or direct laser excitation of the $^5D_0 \leftarrow {}^7F_0$ transition, display fairly broad bands which are compatible with a distorted D_3 symmetry environment for the metal ion (Figure S4). The relative intensities of the $^5D_0 \rightarrow {}^7F_J$ transitions are 0.07, 1.00, 1.28, <0.01 and 4.11 for $J = 0$, 1, 2, 3, and 4, respectively. The $^5D_0 \rightarrow {}^7F_1$ transition displays two main components, one of them appearing as a doublet with a splitting of 17 cm^{-1}, while the $^5D_0 \rightarrow {}^7F_2$ transition shows two doublets with a splitting of 13 and 14 cm^{-1}, respectively. Finally, the $^5D_0 \rightarrow {}^7F_4$ transition displays four main components, three of them having a very weak intensity, again compatible with a distorted D_3 local symmetry.

To get a better insight into the various energy conversion processes occurring in the $[Ln(\mathbf{L^{12}})_3]^{3+}$ complexes, we have determined the quantum yields of both the ligand- and

metal-centred luminescence of 10^{-3} M solutions at 295 K, and the ratio between the integrated triplet and singlet state emissions, $I^{(T)}/I^{(S)}$ for the free ligand and its La^{III} complex at 77 K. The quantum yield of $[La(\mathbf{L^{12}})_3]^{3+}$ (Q^F = 5.5%) decreases by a factor of 9 with respect to that of the free ligand (Q^F = 51%), and the ligand-centred phosphorescence increases, as indicated by $I^{(T)}/I^{(S)}$ which increases from 8×10^{-5} to 9.8×10^{-3} on complexation of $\mathbf{L^{12}}$ with La^{III}, that is by a factor of 122. The better intersystem crossing (isc) efficiency in the La^{III} complex may be explained by (i) the reduced energy gap between the $^1\pi\pi^*$ and $^3\pi\pi^*$ states: 2350 cm^{-1}, determined from the energy of the 0-phonon transitions, in contrast to 2650 cm^{-1} in the free ligand (Figure 6) and (ii) the spin-orbit mixing of the singlet and triplet states induced by the complexation with La^{III}.[46] The quantum yield of the metal-centred luminescence of $[Eu(\mathbf{L^{12}})_3]^{3+}$ obtained on ligand excitation remains very small, $Q_L^{Eu} = 5 \times 10^{-3}$ %, not only because the efficiency of the isc process stays small, but most probably because of photoinduced electron transfer processes, as already pointed out for the triple helical complex with $\mathbf{L^1}$.[37,38]

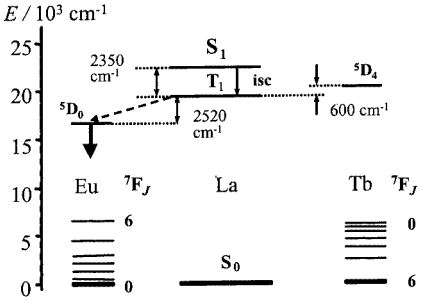

Figure 6. Schematic energy diagram for $[Ln(\mathbf{L^{12}})_3]^{3+}$ complexes. Data for S_1 and T_1 are those of the La^{III} complex in the solid state at 77 K (0-phonon transitions).

Conclusion

The introduction of a chiral neopentyl ester group in the 4-position of the central pyridine ring of ligand $\mathbf{L^1}$ to yield $\mathbf{L^{12}}$ leads to the formation of thermodynamically stable 1:3 complexes with lanthanide ions in acetonitrile, as shown by the logK_3 values in the range 2.9−4.6. Chiro-optical data clearly suggest the helical wrapping of the ligand strands around the Ln^{III} ions. As a comparison, the bulky neopentyl groups grafted onto the benzimidazole side arms in $\mathbf{L^{11}}$ precluded helical wrapping, a fact confirmed by the specific rotary dispersion measurements.[18] Although only a small excess of one diastereoisomer is induced in solution by the chiral ligand $\mathbf{L^{12}}$, as was observed for complexes with $\mathbf{L^*}$,[23] this work reveals that structural chirality may be induced in triple helical complexes by a suitable design of the ligand. The substitution also significantly modifies the photophysical properties of the tris complexes, compared with those with $\mathbf{L^{11}}$.[36] In particular, the ligand-to-metal energy transfer is amplified for Eu, but cancelled for Tb.

Therefore, this study demonstrates that, in addition to the electronic and photophysical properties which may be modulated by varying the substituent in the R^3 position, a diastereomeric excess can be induced in solution if this substituent is chiral. The combination of these properties opens new perspectives for the design of lanthanide triple helical complexes acting as probes for chiral recognition.

Experimental Section

Solvents and Starting Materials: Acetonitrile, dichloromethane, chloroform, tetrahydrofuran, pyridine and triethylamine were purified in the usual way.[47] Silica gel (Merck 60, 0.04−0.06 mm) was used for preparative column chromatography. Other products were purchased from Fluka AG (Buchs, Switzerland) or Merck and used without further purification. 2,4,6-pyridinetricarboxylic acid was prepared according to a literature procedure.[48] Lanthanide perchlorates were obtained as described previously.[49]

Caution: Dry perchlorates and their complexes with aromatic amines may easily explode and should be handled in small quantities and with extreme caution.[50]

Spectroscopic and Analytical Measurements: Electronic spectra in the UV/Vis range were recorded at 293 K with a Perkin−Elmer Lambda 900 spectrometer and 1.0 and 0.1 cm quartz cells. Reflectance spectra were recorded on finely ground powders dispersed in MgO (5%), with MgO as the reference, on the same spectrometer equipped with a Labsphere PELA-1000 integration sphere. Specific rotary dispersion values were measured from 10^{-3} M solutions in degassed anhydrous acetonitrile at 298 K with the help of a JASCO DIP-370 polarimeter (sodium D line). IR spectra were obtained from KBr pellets with a Mattson α-Centauri FT-IR spectrometer. Pneumatically assisted electrospray (ESIMS) mass spectra were recorded from MeCN solutions on API III or API 3000 tandem mass spectrometers (PE Sciex) by infusion at 10 μL min^{-1}. The spectra were recorded under low up-front declustering or collision-induced dissociation (CID) conditions, typically ΔV = 0−30 V between the orifice and the first quadrupole of the spectrometer. ^1H, ^{13}C NMR spectra and 2-D experiments were recorded at 25 °C on Bruker AM-360 or Bruker AVANCE 400-DRX spectrometers. Chemical shifts are reported in parts per million with respect to TMS. Ligand excitation and emission spectra were recorded on a Perkin−Elmer LS-50B spectrometer equipped for low temperature (77 K) measurements. The experimental procedures for high resolution, laser-excited luminescence studies have been published previously.[51] Emission spectra are corrected for the instrumental function. Quantum yields of the ligand-centred emission were measured relative to quinine sulfate in 0.05 M H_2SO_4 (A_{347} = 0.05, absolute quantum yield: 0.546).[52] Quantum yields of the metal-centred emission were determined as described previously[53] at excitation wavelengths at which (i) the Lambert−Beer law is obeyed and (ii) the absorption of the reference $[Ln(terpy)_3]^{3+}$ closely matches that of the sample. CPL measurements were made on an instrument described previously, operating in a differential photon-counting mode.[33] Elemental analyses were performed by Dr H. Eder (Microchemical Laboratory, University of Geneva).

Spectrophotometric Titrations: The electronic spectra in the UV/Vis range were recorded at 298 K from 10^{-4} M solutions in acetonitrile containing Et_4NClO_4 (0.1 M) as the inert electrolyte with a Perkin−Elmer Lambda 7 spectrometer connected to an external computer and in quartz cells of 0.100 cm path length. Solutions were prepared in a thermostatted vessel (Metrohm 6.1418.220) and the titrant solution was added with an automated burette from Me-

trohm (6.1569.150 or .210) fitted with an anti-diffusion device. In a typical experiment, 5−10 cm^3 of **L^{12}** were titrated with a solution of Ln^{III} triflate (10^{-4} M) in acetonitrile. After each addition of 0.20 cm^3 and a delay of 2 min, the spectrum was measured and transferred to the computer. In some instances, reverse titrations, i.e. with **L^{12}** as the titrating species, were also performed to confirm the values of the stability constants. All the experiments were conducted in a dry box and the water content of the solutions, measured at the end of the titration by the Karl Fischer method, was always <30 ppm. Factor analysis and stability constant determinations were carried out with the program SPECFIT, version 2.10.[54]

Crystal Structure of L^{12}: The pale yellowish, lathlike crystals were directly transferred from the mother liquor into a drop of Hostinert 216 oil kept at 210 K. A specimen was selected and placed in a glass capillary. The data collection, at 170 K, took place on a Stoe IPDS system equipped with Mo-K_α radiation (Table 1). The image plate − crystal distance was set to 80 mm, and a φ interval of 1° was chosen. Two hundred images were then exposed for 20 min each. Inspection of the reciprocal space revealed that about three quarters of the diffraction spots could be accounted for by the cell given in Table 1. The integration was based on an effective mosaic spread of 0.012 and a profile between 11 and 21 pixels. A peak overlap of 2 pixels was tolerated in order to retain the maximum number of reflections. Nevertheless, over 2700 reflections were eliminated because of severe peak overlap. The intensities were corrected for Lorentz and polarisation effects. No absorption correction could be applied since the crystal was all but invisible in the frozen oil, but the absorption coefficient appeared to be small. The decay during the measurement was negligible. The structure was solved in the space group $P2_12_12_1$ with the help of SIR 97.[55] The oxygen and nitrogen atoms were refined anisotropically and the carbon and hydrogen atoms isotropically; the latter were allowed to ride on their associated carbon atoms. The refinement seems to favour the *S* configuration for the chirality centre C24 for both molecules, as expected from the synthesis and the observed rotary dispersion, but the value of Flack's parameter (2 ± 2) is not conclusive.[56] CCDC-186842 contains the supplementary crystallographic data for this paper, which can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Preparation of the Ligand. (±)-2-(1-Hydroxyethyl)-1-methylbenzimidazole (1): A mixture of *N*-Methyl-1,2-phenylenediamine (0.93 cm^3, 8.18 mmol) and (±)-2-hydroxypropionic acid (0.91 cm^3, 12.21 mmol) was refluxed for 45 min in 4 N hydrochloric acid (10 cm^3). After cooling, the mixture was neutralised to pH = 7.1 with NH_4OH (25%). The resulting brown crude solid was filtered, washed with water and recrystallised from hot water to give 1.13 g of **1** (6.41 mmol, 78%). M.p. 106−108 °C. ^{1}H NMR (360 MHz, CD_3OD): δ = 1.73 (d, ^3J = 7.0 Hz, 3 H), 3.94 (s, 3 H), 4.93 (s, 1 H), 5.20 (q, ^3J = 7.0 Hz, 1 H), 7.25−7.34 (m, 2 H), 7.50 (m, 1 H), 7.66 (m, 1 H) ppm. ^{13}C NMR (360 MHz, CD_3OD): δ = 21.65, 30.67, 64.15, 110.79, 119.59, 123.33, 124.06, 137.37, 142.35, 157.45 ppm. IR (KBr): $\tilde{\nu}$ = 1105 ($\nu_{C\text{-}OH}$) cm^{-1}. ESI-MS (MeOH): *m*/*z* = 177.2 [L + H]$^+$.

2-Acetyl-1-methylbenzimidazole (2): A solution of chromium trioxide (494 mg, 4.94 mmol) in water (3 cm^3) was added dropwise to a solution of **1** (1.13 g, 6.41 mmol) in glacial acetic acid (5 cm^3) at 90 °C. The reaction mixture was heated at 100 °C for 10 min and poured into water (60 cm^3). The resulting precipitate was extracted with dichloromethane (3 × 30 cm^3), and the combined extracts dried (Na_2SO_4) and the solvents evaporated. The resulting crude solid was recrystallised from methanol to give 849 mg of **2** (4.87 mmol, 76%) as white crystals. M.p. 72−74 °C. ^{1}H NMR (360 MHz, $CDCl_3$): δ = 2.83 (s, 3 H), 4.11 (s, 3 H), 7.33−7.37 (m, 1 H), 7.41 (m, 2 H), 7.87 (m, 1 H) ppm. ^{13}C NMR (360 MHz, $CDCl_3$): δ = 28.18, 32.38, 110.64, 122.02, 123.82, 126.06, 137.07, 141.71, 146.28, 193.46 ppm. IR (KBr): $\tilde{\nu}$ = 1684 (ν_{CO}) cm^{-1}. ESI-MS (MeOH): *m*/*z* = 175.1 [L + H]$^+$.

1-{[(Methylbenzimidazol-2-yl)carbonyl]methyl}-1-pyridinium Iodide (3): **2** (211 mg, 1.21 mmol) and I_2 (307 mg, 1.21 mmol) were dissolved in dry distilled pyridine (4 cm^3) under an inert atmosphere. After 20 min at room temp., the mixture was heated at 100 °C for 15 h, then cooled to room temperature. The resulting brown precipitate was filtered, washed once with pyridine/diethyl ether (1:1, 5 cm^3) and twice with diethyl ether (10 cm^3). The dried crude product was recrystallised from ethanol with charcoal to give 410 mg of **3** (1.08 mmol, 89%) as dark yellow needles. M.p. 205−207 °C. ^{1}H NMR (360 MHz, [D$_6$]DMSO): δ = 4.11 (s, 3 H), 6.54 (s, 2 H), 7.46 (m, 1 H), 7.56 (m, 1 H), 7.84 (m, 1 H), 7.94 (m, 1 H), 8.30 (m, 2 H), 8.76 (m, 1 H), 9.03 (m, 2 H) ppm. ^{13}C NMR (360 MHz, [D$_6$]DMSO): δ = 31.96, 66.56, 111.86, 121.22, 124.22, 126.47, 127.74, 136.65, 141.07, 143.47, 145.56, 146.46, 184.43 ppm. IR (KBr): $\tilde{\nu}$ = 1705 (ν_{CO}) cm^{-1}. FAB-MS (MeOH): *m*/*z* = 252.1 [L − I]$^+$.

4-(1-Methylbenzimidazol-2-yl)-4-oxobut-2-enoic Acid (4): Glyoxylic acid monohydrate (1 g, 10.86 mmol), triethylamine (1.52 cm^3, 10.86 mmol) and pyrrolidine (0.33 cm^3, 3.8 mmol) were sequentially added to a solution of **2** (631 mg, 3.62 mmol) in DMF (10 cm^3). The mixture was stirred at room temp. for 48 h and 1% hydrochloric acid was then added until pH = 1. The solution was extracted with diethyl ether (3 × 20 cm^3) and the combined organic layers were dried (Na_2SO_4) and the solvents evaporated. The resulting crude solid was redissolved with 10% $NaHCO_3$ (5 cm^3) to pH = 8 and washed with dichloromethane (2 × 10 cm^3). The aqueous phase was acidified to pH = 1 by addition of 10% hydrochloric acid and extracted with diethyl ether (3 × 10 cm^3). The combined organic layers were washed with water (2 × 30 cm^3), dried (Na_2SO_4) and the solvents evaporated. The resulting crude solid was recrystallised by slow diffusion of hexane into an ethyl acetate solution to give 251 mg of **4** (1.09 mmol, 30%) as brownish-red needles. M.p. 194−196 °C. ^{1}H NMR (360 MHz, [D$_6$]DMSO): δ = 4.15 (s, 3 H), 6.83 (d, ^3J = 15.9 Hz, 1 H), 7.39 (m, 1 H), 7.50 (m, 1 H), 7.75 (m, 1 H), 7.88 (m, 1 H), 8.28 (d, ^3J = 15.9 Hz, 1 H) ppm. ^{13}C NMR (360 MHz, [D$_6$]DMSO): δ = 32.18, 111.64, 121.45, 123.85, 126.32, 132.46, 136.65, 137.03, 141.22, 146.17, 166.24, 181.66 ppm. IR (KBr): $\tilde{\nu}$ = 1707, 1670 (ν_{CO}) cm^{-1}. ESI-MS (MeOH): *m*/*z* = 231.2 [L + H]$^+$.

Ethyl 2,6-Bis[(1-methylbenzimidazol-2-yl)]pyridine-4-carboxylate (5): A mixture of 2,4,6-pyridinetricarboxylic acid (1 g, 4.7 mmol), freshly distilled thionyl chloride (15 cm^3, 207 mmol) and DMF (0.12 cm^3) was refluxed for 90 min in dry dichloromethane (40 cm^3), evaporated and dried under vacuum for 60 min. The resulting solid was dissolved in dry dichloromethane (45 cm^3), and a mixture of 2-nitro-*N*-ethylaniline (1.08 g, 7.1 mmol) and triethylamine (6.6 cm^3, 47 mmol) in dry dichloromethane (30 cm^3) was added dropwise under inert atmosphere. The solution was stirred for 2 h at room temperature, refluxed for 6 h and the solvents evaporated. The brown residue was partitioned between dichloromethane (3 × 100 cm^3) and half-saturated aqueous NH_4Cl solution (100 cm^3). The combined organic phases were dried (Na_2SO_4) and the solvents evaporated. The crude product was dissolved in a mixture of ethanol/water (250:55 cm^3), and freshly activated iron powder (8 g,

143 mmol) and 25% hydrochloric acid (45.7 cm^3, 352 mmol) were added. The solution was refluxed for 8 h under inert atmosphere. The excess of iron was filtered off, and the ethanol was distilled off under vacuum. Water was then added to bring the total volume to 100 cm^3. The resulting solution was poured into dichloromethane (150 cm^3). $Na_2H_2edta{\cdot}2H_2O$ (84 g, 236 mmol) in 150 cm^3 water was then added, and the resulting mixture was neutralised to pH = 7 with 5 M aqueous potassium hydroxide; 30% H_2O_2 (1 cm^3) was added and the pH adjusted to 8.3. After vigorous stirring for 30 min, the organic layer was separated and the aqueous phase extracted with dichloromethane (3 × 150 cm^3). The combined organic phases were dried (Na_2SO_4) and the solvents evaporated. The resulting crude solid was dissolved in dry dichloromethane (40 cm^3), then freshly distilled thionyl chloride (15 cm^3, 207 mmol) and DMF (0.12 cm^3) were added. The mixture was refluxed for 90 min, evaporated and dried under vacuum for 60 min. The crude product was cooled to 0 °C, then dry ethanol (20 cm^3) was added dropwise. The resulting solution was allowed to stand at room temperature, stirred for 60 min, evaporated and dried under vacuum for 60 min. The residue was partitioned between dichloromethane (3 × 40 cm^3) and half-saturated aqueous NH_4Cl solution (40 cm^3). The combined organic phases were dried (Na_2SO_4) and the solvents evaporated. The resulting brownish-red crude solid was purified by column chromatography (silica gel, CH_2Cl_2/MeOH, 100:0 → 99:1) to give 251 mg of **5** (0.61 mmol, 13%). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.46 (t, ^3J = 7.0 Hz, 3 H), 4.25 (s, 6 H), 4.49 (q, ^3J = 7.0 Hz, 2 H), 7.39 (m, 4 H), 7.48 (m, 2 H), 7.91 (m, 2 H), 8.95 (s, 2 H) ppm. ^{13}C NMR (400 MHz, $CDCl_3$): δ = 14.97, 33.24, 62.89, 110.69, 121.05, 123.78, 124.66, 125.26, 137.91, 141.03, 143.36, 150.32, 151.33, 164.85 ppm. IR (KBr): $\tilde{\nu}$ = 1712 (ν_{CO}), 1597, 1562 ($\nu_{C=C}$) cm^{-1}. ESI-MS (MeCN): *m*/*z* = 412.2 $[L + H]^+$.

2,6-Bis[(1-methylbenzimidazol-2-yl)]pyridine-4-carboxylic Acid (6). Procedure A: 3 (410 mg, 1.08 mmol), **4** (226 mg, 0.98 mmol) and ammonium acetate (3 g, 38.92 mmol) were dissolved in ethanol (25 cm^3). The mixture was refluxed for 24 h under an inert atmosphere, and then slowly cooled to room temperature. The resulting white crystals were separated by filtration and recrystallised from hot methanol to give 230 mg of **6** (0.60 mmol, 55%). **Procedure B:** A solution of **5** (251 mg, 0.61 mmol) in a mixture of ethanol/water, 1:4 (5:20 cm^3) containing potassium hydroxide (17 g, 303 mmol) was refluxed for 24 h. Ethanol was distilled off and the aqueous phase acidified to pH = 3 with 25% hydrochloric acid. The resulting precipitate was filtered off and washed with water to give 218 mg of **6** (0.57 mmol, 93%) as a white powder. M.p. >260 °C. ^{1}H NMR (360 MHz, $[D_6]$DMSO): δ = 4.37 (s, 6 H), 7.38−7.47 (m, 4 H), 7.78 (m, 2 H), 7.87 (m, 2 H), 8.81 (s, 2 H) ppm. ^{13}C NMR (360 MHz, $[D_6]$DMSO): δ = 36.51, 114.78, 123.45, 126.27, 127.10, 128.81, 141.06, 146.18, 146.70, 153.00, 154.41, 166.54 ppm. IR (KBr): $\tilde{\nu}$ = 1716 (ν_{CO}), 1617, 1560 ($\nu_{C=C}$) cm^{-1}. ESI-MS (MeCN): *m*/*z* = 384.2 $[L + H]^+$, 767.4 $[2L + H]^+$.

Neopentyl 2,6-Bis[(1-methylbenzimidazol-2-yl)]pyridine-4-carboxylate (L^{12}): A mixture of **6** (430 mg, 1.12 mmol), freshly distilled thionyl chloride (3.62 cm^3, 50 mmol) and DMF (0.03 cm^3) was refluxed for 90 min in dry dichloromethane (10 cm^3), evaporated and dried under vacuum for 60 min. A solution of (−)-(*S*)-2-methyl-1-butanol (1.2 cm^3, 11.2 mmol) dried on molecular sieves was added to the resulting crude solid. After stirring for 30 min at room temp., the resulting violet solution was evaporated and the residue was redissolved in $CHCl_3$ (10 cm^3). The organic phase was washed with water (3 × 20 cm^3), then with half-saturated aqueous NH_4Cl (20 cm^3), dried (Na_2SO_4) and the mixture evaporated to dryness. The resulting crude solid was purified by column chromatography (silica gel, CH_2Cl_2/MeOH, 100:0 → 99:1) and recrystallised by slow diffusion of hexane into a dichloromethane solution to give 245 mg of $\mathbf{L^{12}}$ (0.54 mmol, 48%) as white crystals. M.p. 186−188 °C. ^{1}H NMR (360 MHz, $CDCl_3$): δ = 0.97 (t, ^3J = 7.3 Hz, 3 H), 1.04 (d, ^3J = 6.8 Hz, 3 H), 1.29 (m, ^3J = 7.3 Hz, 1 H, ^2J = 13.6 Hz), 1.56 (m, ^3J = 7.3 Hz, 1 H, ^2J = 13.6 Hz), 1.95 (1 H, pseudo-oct., ^3J = 6.3−7.3 Hz), 4.23 (dd, 1 H, ^3J = 6.3 Hz), 4.24 (s, 6 H), 4.32 (dd, 1 H, ^3J = 6.3 Hz), 7.35−7.43 (m, 4 H), 7.48 (m, 2 H), 7.90 (m, 2 H), 8.92 (s, 2 H) ppm. ^{13}C NMR (360 MHz, $CDCl_3$): δ = 11.35, 16.59, 26.20, 32.68, 34.34, 70.96, 110.15, 120.60, 123.20, 124.10, 124.68, 137.35, 140.51, 142.79, 149.78, 150.79, 164.44 ppm. IR (KBr): $\tilde{\nu}$ = 1730 (ν_{CO}), 1587, 1564 ($\nu_{C=C}$) cm^{-1}. ESI-MS (MeCN): *m*/*z* = 454.2 $[L + H]^+$. $C_{27}H_{27}N_5O_2{\cdot}0.11CH_2Cl_2$: calcd. C 70.3, H 5.9, N 15.1; found C 70.3, H 6.0, N 15.1.

Preparation of the Complexes: The 1:3 complexes $[Ln(\mathbf{L^{12}})_3](ClO_4)_3{\cdot}xH_2O$ (La, *x* = 2, (7); Eu, *x* = 2, (8); Tb, *x* = 3, (9)] were prepared by mixing $\mathbf{L^{12}}$ with stoichiometric amounts of $Ln(ClO_4)_3{\cdot}nH_2O$ (Ln = La, Eu, Tb and *n* = 0.2−0.6) in dichloromethane/acetonitrile. The complexes may be crystallised in 70−80% yields by slow diffusion of *tert*-butyl methyl ether into an acetonitrile solution. [$C_{81}H_{81}N_{15}O_{18}Cl_3La{\cdot}2H_2O$: found C 53.2, H 4.6, N 11.6, calcd. C 53.1, H 4.7, N 11.5; $C_{81}H_{81}N_{15}O_{18}Cl_3Eu{\cdot}2H_2O$: found C 52.5, H 4.7, N 11.4, calcd. C 52.7, H 4.6, N 11.4; $C_{81}H_{81}N_{15}O_{18}Cl_3Tb{\cdot}3H_2O$: found C 51.9, H 4.5, N 11.1; calcd. C 52.0, H 4.7, N 11.2]. IR (KBr): $\tilde{\nu}$ = 1736 (La), 1735 (Eu), 1734 (Tb), (ν_{CO}); 1593, 1568 (La), 1591, 1570 (Eu), 1589, 1570 (Tb), ($\nu_{C=C}$) and 1092, 625 (ionic ClO_4^-) cm^{-1}.

Acknowledgments

This work is supported through grants from the Swiss National Science Foundation. We thank Prof. Pierre Vogel for the use of his polarimeter, Dr. Anne-Sophie Chauvin for her help in the ligand synthesis and the Fondation Herbette (Lausanne) for the gift of spectroscopic equipment.

How to Model the Conformational Behaviour of Saturated Diphosphane Chelate Cycles: The Conformational Rearrangement Processes of [{κ-$PAr_2CH_2CH(OH)CH_2$-κ-PAr'_2}Rh-(η^4-COD)]$^+$

Volker Schulz,[a] Axel Frick,[a] and Gottfried Huttner*[a]

In memoriam Dr. Laszlo Zsolnai[†]

Keywords: Rhodium / Phosphane ligands / Chelates / Molecular modelling / Conformation analysis

Eleven solid state structures of eight compounds **1**–**8** of the type [{κ-$PAr_2CH_2CH(OH)CH_2$-κ-PAr'_2}Rh-(η^4-COD)]$^+PF_6^-$ are used as a basis for deriving a force field model for this class of compound by Genetic Algorithms. By a complete search in the conformational space of [{κ-$PMes_2CH_2$-$CH(OH)CH_2$-κ-PPh_2}Rh-(η^4-COD)]$^+PF_6^-$ (**1**) it is shown that the model is not only capable of reproducing the structures but as well capable to predict the stability of individual conformers and the conformational reaction pathways in full agreement with experimental observations. The model predicts that the λ twist conformation is the most stable conformation of **1**. The δ twist conformation is calculated 3.1 kJ·mol^{-1} above this minimum. The experimental value is 3.4 kJ·mol^{-1}. The model predicts that there are two mechanistic pathways for the λ ⇄ δ isomerization process. Both of them are characterised by a strictly coupled rotation of the mesityl groups of the $PMes_2$ entity of **1**. These two pathways differ only in the sense of this rotation. The activation enthalpy for the λ ⇄ δ isomerization process as a whole is calculated as $\Delta H^{\#}$ = 69.1 kJ·mol^{-1}. The experimental value is $\Delta H^{\#}$ = 64.4 kJ·mol^{-1}. It is concluded therefore that the novel type of approach as described leads to models of very high predictive power.

Introduction

Molecular mechanics has been established to be a highly efficient tool in understanding the conformational manifold of small organic molecules.[1,2] In coordination chemistry these methods should work as well, once the force field parameters describing the metal ligand interactions would be known. The fact, however, that there are many different metals along the periodic table and that all these metals may engage with the ligands in different geometries makes the molecular mechanics approach in general a cumbersome one.[3−5] Nevertheless different types of general force fields have been described which are in fact able to overcome many of these difficulties and are able to predict conformations of inorganic and organometallic compounds.[6,7] Such force fields are, however, limited in the accuracy with which they predict the energy differences between individual conformers. If, on the other hand, conformational pathways are at the focus of a molecular mechanics analysis and if the calculated energy differences are small and are to be compared to experimentally determined reaction enthalpies these generalised force fields do not reproduce energies to the desired and necessary accuracy.[8]

As an alternative to generalised force fields specific force fields may be developed for a specific class of compounds.[3−5] It may be hoped that such specific force fields might be able to reproduce not only the geometry but as well the relative energy of the conformational manifold in agreement with experimental data.[9,10] Such force fields, if developed in the traditional way, have been shown to correctly reproduce conformations while the energies of these conformations are still generally not reliable enough to compare small energy differences to experimental data. It is common practice to adjust force field parameters of a specific class of compound by hand such that a known structure is correctly reproduced and to optimise the parameters by trial-and-error on the basis of a few experimentally determined structures of the specific class of compounds analysed. Parameters thus obtained may be taken as such or may be used as a starting point for further optimisation. The optimisation procedures used in this case are local ones, i.e. they will lead to a locally optimised set of parameters which need not necessarily be the optimal solution of the global problem.

With this in mind optimisation procedures have been developed which − starting from a randomly selected point in parameter space − allow for a global search of the optimal

set of parameters.[11−16] While optimisation procedures which will solve this type of problem with certainty within an finite amount of time are not available, optimisation by Genetic Algorithms has been found to be an efficient way around this problem in many situations.[17−19] It has in fact been shown that force fields derived by this strategy are well suited to predict structures as well as energy differences in agreement with experimental observations.[11−16] This kind of approach has been applied to analyse and predict the conformational properties of *tripod*-$Mo(CO)_3$ compounds [*tripod* = $RCH_2C(CH_2PR'_2)(CH_2PR''_2)(CH_2PR'''_2)$]. By this method it was possible to predict NOE-distances of compounds such as $CH_3C[CH_2P(R')(CH_2Ph)]_3Mo(CO)_3$ (R′ = Ph, 3,5-Xylyl) to within an rms of less than 0.3 Å with respect to the experimental values.[15] The same type of approach was used to predict the activation barriers of the conformational isomerisation of compounds $[CH_3C\{CH_2P(Ph)_2\}_{3-n}\{CH_2P(o\text{-Tol})_2\}_n]Mo(CO)_3$ (n = 1−3) to within less than 5 kJ·mol^{-1}.[16]

The quality of these results suggests that it might be worthwhile to apply a similar strategy to more complicated problems. 'More complicated' in this context means that there is a larger number of torsional degrees of freedom which cover a wide spread of torsion angles. In the *tripod* metal compounds analysed by now the chelate scaffolding of the bicyclo[2.2.0.]octane type is such that the individual six-membered chelate cycles are forced to adopt boat or twist conformations with any chair conformation excluded by the rigidity of the framework. In this sense the conformations of compounds of the type $[\{\kappa\text{-}PAr_2CH_2CH(OH)CH_2\text{-}\kappa\text{-}PAr'_2\}Rh\text{-}(\eta^4\text{-}COD)]^+PF_6^-$ are more complicated since the six-membered chelate cycles − which are not a part of a chelate cage − can adopt boat, twist or chair conformations.

Compounds of this type have been shown to be efficient precatalysts in the enantioselective hydrogenation of olefins.[20] The solid state structures of eleven members of this family of compounds are known[20] which are well suited as a basis to derive appropriate force field parameters by Genetic Algorithms. In addition, the solution structures of four of these compounds are known as well as the activation barriers for different types of conformational rearrangements.[8] With all these data given this class of compounds presents an ideal object for evaluating the power of the modelling approach as sketched above. In addition the problem is of some chemical interest since the conformational properties of six-membered diphosphane chelate cycles have not been analysed in detail, while, of course, it is just these properties which will control the stereochemical result of reactions mediated by chelate compounds containing these cycles.

Results and Discussion

The paper deals with the following problems:

"Definition of the Force Field"

− How to describe the forces which imply contributions by the metal?

"Optimisation of Force Field Parameters"

− How to optimise this description by Genetic Algorithms?

"Grid Search Analysis of 1−3"

− How to do a complete scan of the conformational hypersurface?

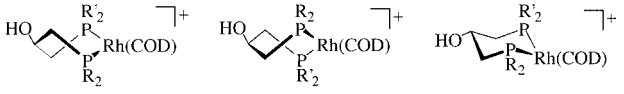
"Energy − Reaction Pathway"

− How to analyse conformational pathways and how to derive activation energies for these pathways?

"Force Field Model and Experimental Reality − Comparison of Results and Conclusion"

− How do the calculated results compare to the experimental ones?

The compounds **1**−**8** on which the analysis of these questions is based are shown in Figure 1. For some compounds δ and λ twist forms where found in one and the same crystal. In these cases the two crystallographically independent conformations have been dealt with as independent individual molecules.



Compound	Structure	PR_2	PR'_2	X-ray		Chirality
1	**1a**	$PMes_2$	PPh_2	twist	δ	(S)
1	**1b**	$PMes_2$	PPh_2	twist	λ	(S)

Figure 1. Compounds **1**−**8**; the sequence in which the compounds are labelled is such that compounds **1**−**3** are the ones which are extensively analysed in this paper. For compounds **1**, **2**, **4**, **5** quantitative solution structures are available.[8] Qualitative NMR spectroscopic data for dynamic processes are available for **6**, **7**.[20] The numbering scheme follows this hierarchy.

Definition of the Force Field

Parameters describing interactions within the organic parts of the molecules were taken from the standard MM2* force field.[1,21,22] Parameters describing C−P−C angles

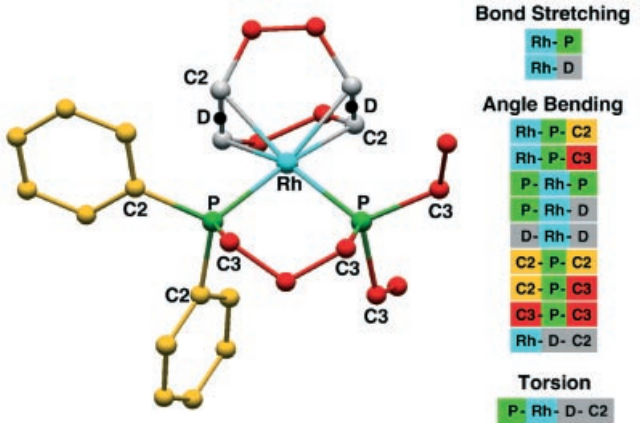

Figure 2. Illustration of the force field parameters which were refined; the colours refer to the individual atom types (C2: sp^2-carbon; C3: sp^3-carbon). The label D designates a dummy atom placed at the centre of a double bond of the COD ligand. Only the parameters which are listed in Figure 2 were allowed to refine.

(Figure 2) were defined as usual − they were however refined (see below). All parameters involving the rhodium atom were refined. Conventional descriptions were used to describe distances, angles and torsion angles (see Exp. Sect.).

Parameters involving parts of the COD coligand and the metal atom where defined as follows: dummy atoms were defined at the centre of each coordinated double bond (Figure 3). The distances between the dummy atoms and the rhodium centre (r_d, Figure 3) as well as the angles D−Rh−D (β, Figure 3) and D−Rh−P (γ, Figure 3) were described by conventional functionals (see Exp. Sect.). The angles enclosed by the rhodium centre, the dummy atoms and any of the two carbon atoms of the double bond adjacent to the dummy atom Rh−D−C2 (α, Figures 2 and 3) were as well modelled by the standard functional for valence angles (see Exp. Sect.). To define the rotational position of the π-ligands with respect to the rest of the molecule the rotation of the double bond around the axis Rh−D was defined by the torsion angle around this axis. The reference axis was defined as a Rh−P vector. Of the two Rh−P vectors the one was chosen whichever had the smaller D−Rh−P angle. The torsion angle (see Exp. Sect.) was defined with respect to one of the vectors D−C2 (Figures 2 and 3). The energy function for this angle (τ, Figure 3) was

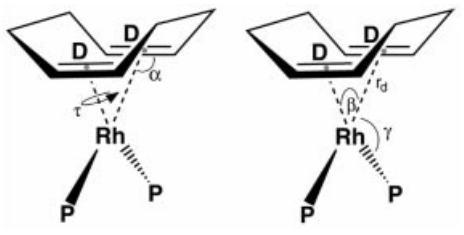

Figure 3. Definition of π bonds within the force field approach. Dummy atoms at the centre of the coordinated double bonds were used to define the parameters r_d, α, β, γ, and τ. The forces acting on the dummy atoms were distributed to the two carbon atoms of the respective double bonds. Half of the force acting upon D was assigned to each of these atoms.

chosen as $E(\tau) = k_{t2}\cdot[1 - \cos(2\tau)]$. τ values of ±90° correspond to an orientation of the double bond vertical to the coordination plane of the rhodium atom. These positions correspond to minima in the torsional potential function $E(\tau) = k_{t2}\cdot[1 - \cos(2\tau)]$ where the force constant k_{t2} has hence to be negative. τ values of ±90° correspond to the situation sketched in Figure 3 which is a minimum situation with cos(2τ) being −1. The forces on the dummy atoms have to be transferred to the carbon atoms of the double bonds to which they refer. The force field thus defined was incorporated in the body of the force field program YAMMP[23] (see Exp. Sect.).

This type of approach is similar to the one be taken by B. Bosnich and C. R. Landis et. al. for the force field description of coordinated Cp ligands.[24,25] Similar methods have been developed by van Gunsteren[26] for the force field description of proteins and by C. R. Landis et. al. for descriptions of different types of π-ligands.[27]

Optimisation of Force Field Parameters

In order to describe conformational behaviour by force field methods an algorithmic machinery is needed which correctly models the experimentally determined behaviour. Such a machinery has to be built up with appropriate functions and parameters. Once the functions are defined it is the parameters which have to be tuned. Tuning means to adapt the parameters such that the observed conformational properties of the molecule are correctly reproduced by the machinery. The conformational property chosen in most cases is the 'structure' of the molecule. Structures, however, are in general taken from crystallographic studies; this means that the molecule is embedded in a crystal and subject to external forces acting upon it from the neighbouring molecules. If force field parameters are fitted to reproduce such structures it is the solid state structures which they reproduce. Only if it is evident that these structures, even though determined in the solid state, are almost completely due to the inner molecular potential with vanishing contributions from the external forces, this approach will lead to a force field which models the inner molecular potential. If a large number of a family of crystal structures is known the question of whether these structures are by and large uninfluenced by crystal forces can be addressed by statistical analysis. In the first report on the use of Genetic Algorithms in the refinement of force field parameters which dealt with modelling the behaviour of *tripod*-$Mo(CO_3)$ compounds[14] statistical analysis by a variety of methods including Neural Network analysis had shown that these premises are met in this case.[11] Refinement of the force field parameters on the basis of solid state structures has been highly successful in this case.[14] In the present case there are too few individual structures available for a meaningful statistical test. A practical approach in this case is then to assume that the crystal structures are due to the inner molecular potentials, to refine the force field parameters on this basis and possibly to remove outliers if there are any. It is assumed in this case that structures which are less well reproduced than the average are influenced by

crystal forces acting on the molecules in the crystal lattice. This approach is taken in this paper.

Genetic Algorithms were applied to tune the force field parameters such that twelve crystallographically determined structures of the eight compounds (Figure 1) were reproduced to the best possible extent. A short explanation of how Genetic Algorithms work, may help to appreciate that the methodology is very simple indeed. The first thing to do is to make a guess for the numerical range which the individual parameters may possibly adopt. To give an example: it is known that the valence force constants can adopt values up to a maximum of 20 mdyn·Å^{-1} and, of course, that such force constants have to be greater than zero. In this case setting the range for this type of constant to $0 \leq k \leq 20$ covers all possible values. If it is known that the specific force constant k refers to a weak bond this range might be much smaller of course. Once the numerical range is determined it is divided in $2^{(n-1)}$ equally spaced intervals. The position of each specific interval may then be clearly defined by a binary number in the range $0 \leq 2^{n-1}$. The binary number may thus be taken as a representation of a numerical interval within the range allotted to the parameter. It may be decoded into the numerical value of this parameter with the resolution depending on the size of the interval.[28]

To start the optimisation process binary representations of the values of the individual parameters are generated stochastically. The binary representations of the individual parameters are combined in one binary string where the positions on the string clearly indicate to which parameter each part of the string belongs. A whole set of such parameter strings is generated; in the Genetic Algorithm idiom it is called a population (Figure 4). Each parameter string is decoded to produce the numerical values of the individual parameters. The parameters are fed into the force field program and the experimentally determined structures are subject to refinement. The quality of a given set of parameters is deduced by their capability to produce a set of refined structures in close agreement with the experimentally determined conformations. By some formalism this quality is expressed as a number. In the example given (Figure 4) a small number is meant to indicate a high quality and a large one to correspond to a low quality parameter set. The numerical values by which the sets are ranked are called the fitness values in the Genetic Algorithm idiom. For each individual within a given population this fitness is evaluated on the basis of all observations. With the problem at hand this means that for a given set of force field parameters each of the structures in the data base has to be optimised. This has to be done for all individuals of a population within each generation over and over again and thus is the really time consuming part within optimisations based on Genetic Algorithms. Optimisation itself is achieved by creating a next generation of parameter sets from the forgoing one such that the population of this next generation has a high probability to contain bit strings or parts of bit strings which had already been shown to produce high fitness values in the foregoing generation. This is achieved by making fit individuals produce offspring with higher probability than the less fit ones. Offspring is generated by exchanging parts of bit strings between the parents (Figure 4) that is by crossover. The idea behind this is that pieces of information (bit strings) which have already been found to be well adapted to solve the problem will accumulate from generation

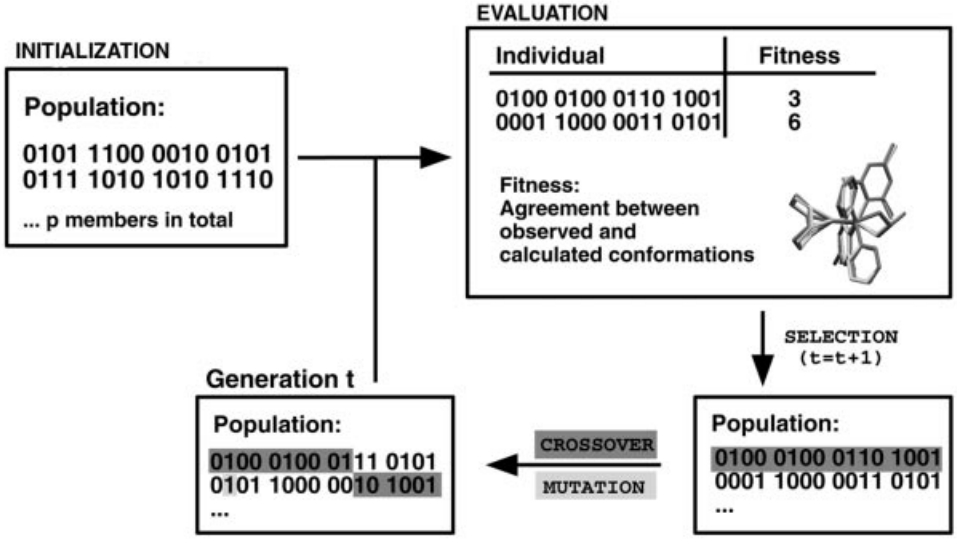

Figure 4. Refinement of the force field parameters by Genetic Algorithms. The parameters which are to be refined are encoded as binary strings. The sections within these strings refer to individual parameters. The values of these parameters are represented by the binary numbers within these sections. The first generation of such strings is generated at random. Each of these parameter strings is evaluated with respect to the quality with which it is capable of reproducing the structures of all compounds in the data basis by molecular mechanic calculations. The parameters which have a high 'fitness value' are preferentially selected to produce offspring by crossover and mutation. The next generation thus produced is subject to the same procedure of evaluation and offspring production. Iteration of this process leads to optimised parameters.

to generation such that the populations as a whole and their individual members will be more and more adapted to the problem from generation to generation. In order to avoid that the selection procedure leads to a suboptimal solution mutations are induced once in a while by inverting randomly selected bits (Figure 4).[29,30]

The optimisation by Genetic Algorithm (GA-optimisation) is generally an efficient optimisation strategy converging to optimal solutions also in those cases where traditional optimisation procedures fail.[31−33] A specific advantage of the underlined algorithmic scheme is that the time consuming step (evaluation of the fitness) may be performed independently on different processors, i.e. the algorithm is naturally parallel. With the problem at hand reasonable computing times can only be achieved if optimisations are performed on a parallel computer.

With the problem at hand GA-optimisation led to force field parameters, which when fed into the molecular mechanics program, were able to reproduce the observed structures. It was found that the agreement between calculated and observed structures was quite good for eleven members of this set (**1**−**8**) while one structure {**2b**: [{κ-PPh_2CH_2CH-$(OH)CH_2$-κ-P(*o*-Tol)$_2$}Rh-(η^4-COD)]$^+PF_6^-$} was less well reproduced. Analysis of the crystal structure indicated that the observed conformation might be biased by crystal forces and structure **2b** was therefor excluded from the data basis.[34] Refinement based on the optimisation of the eleven remaining structures led to satisfactory agreement for all the members of the set (Table 1 and Figure 5).

Table 1. RMS deviations of structures **1a**−**8a**

Structure[a]	RMS_{mm2_rms} [Å]	RMS_{mm2_int} [Å]
1a	0.343	0.368
1b	0.212	0.256
2a	0.384	0.441
3a	0.238	0.267
4a	0.357	0.249
5a	0.253	0.242
5b	0.286	0.284
6a	0.191	0.190
6b	0.195	0.187
7a	0.136	0.165
8a	0.196	0.284
average	0.254	0.267

[a] The column with the suffix mm2_rms was obtained on the basis of parameters calculated by using the RMS deviations between observed and calculated atom positions as the criteria to evaluate the fitness. The column labelled mm2_int refers to a parameter set which was obtained by basing the evaluation of fitness on the agreement between calculated and experimental values of a set of selected internal coordinates (optimised distances, angles, and torsion angles).

Expressed as the RMS deviation between observed and calculated atom positions the agreement is between 0.14 and 0.38 Å. Table 1 refers to two different procedures used for the evaluation of fitness during Genetic Algorithm refinement. The column with the suffix mm2_rms was obtained on the basis of parameters calculated by using the RMS deviations between observed and calculated atom positions as the criteria to evaluate the fitness. The column labelled mm2_int refers to a parameter set which was obtained by basing the evaluation of fitness on the agreement between calculated and experimental values of a set of selected internal coordinates (optimised distances, angles, and torsion angles). Independent of the criteria on which the evaluation of fitness was based, the refined parameter sets were able to reproduce the structures quite well. Figure 5 shows an overlay of observed and calculated conformations for an unbiased (cf. Table 1) selection of compounds.

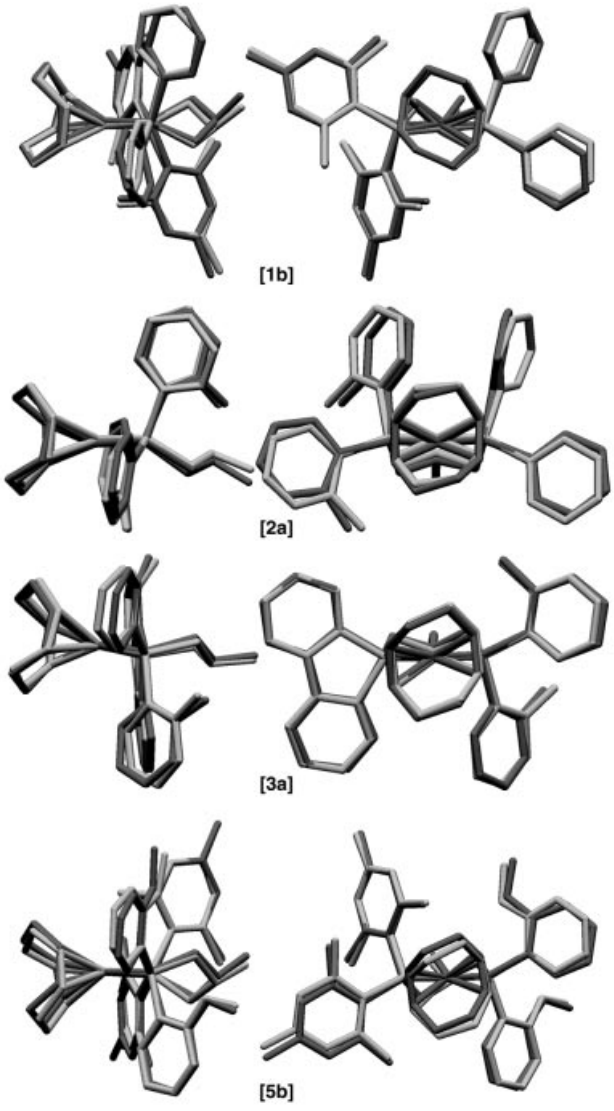

Figure 5. Illustration of the quality of agreement between calculated and observed conformations. From the compounds shown **2a** is the one with the lowest quality of reproduction (Table 1). The other compounds shown are of average quality.

Numerical values of force constants optimised by this approach have their meaning only as a whole: due to the interdependence of the internal coordinates which are used to describe the mechanical model within a force field program there is in general not just one optimal solution to the optimisation but there may be families of optimal solutions with quite different numerical values for the individual force

constants. When fed into a molecular modelling program as a whole these numerically different solutions will equally well reproduce the structures.

Table 2 shows the quality of agreement with respect to internal coordinates. The columns labelled average in Table 2 show that the average of the values for individual types of distances, angles and torsion angles taken over all structures are well reproduced by the two parameter sets. The force field mm2_int derived by minimising the discrepancy between observed and calculated values of internal coordinates is found to reproduce such internal coordinates (distances, angles, and torsion angles) somewhat better than the mm2_rms which minimises the discrepancy between atom positions (Table 2). The columns labelled rmsd represent the RMS deviation between calculated and observed values in each case. These deviations must be larger than the deviations between corresponding average values (Table 2) since in calculating the average positive and negative deviations may cancel each other while in calculating the RMS deviation (rmsd) they are accumulating independent of sign. From the numbers given in Table 2 it is seen for set mm2_rms that some valence angles are systematically too large or too small in comparison with the observed structures. Nevertheless valence angles are reproduced to an accuracy between 2° and 5°. Torsion angles do not appear to be biased. The accuracy with which they are reproduced is in the range of 3° and 8°. The accuracy of the force field is thus well within the range reported to be achievable by molecular modelling methods.[27,35,36]

Table 2. Agreement between calculated and experimental values of characteristic internal coordinates (distances [Å]; angles [°]

[a]	X-ray$_{av}$	mm2_rms$_{av}$	rmsd	mm2_int$_{av}$	rmsd

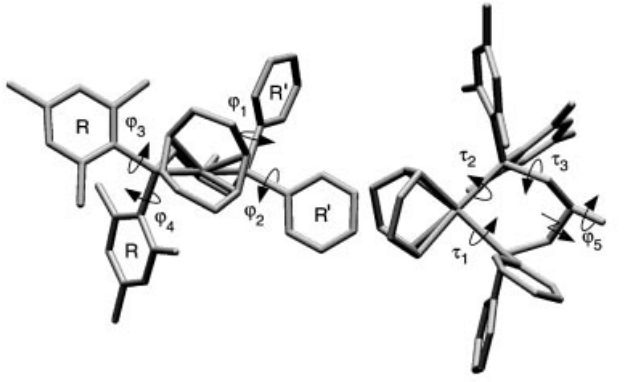
[a] The data in column X-ray$_{av}$ represent the average value of the corresponding internal coordinate over all eleven structures contained in the data basis. mm2_rms$_{av}$ and mm2_int$_{av}$ refer to the two sets of force field parameters reported in this paper. The numbers given under these column headers represent the mean of the corresponding internal coordinates for the calculated structures. The rms values given in each case represent the rms deviations for each class of internal coordinates as obtained by comparing calculated and experimentally observed values of each member of the corresponding set.

Grid Search Analysis of 1−3

A detailed analysis of the conformational space of molecules **1−3** is described in the following paragraphs. The analysis is based on the force field mm2_rms. To adequately scan the conformational space grids are defined as shown in Figure 6.



Compounds	PR_2	PR'_2		rotated fragments
1	$PMes_2$	PPh_2	τ_1	PR'_2CH_2

sense of positive rotation

ring closure bond

Figure 6. Conformational parameters of **1−3**. For a complete conformational search the actively driven conformational coordinates were chosen as shown. The four aryl rotations ($\varphi_1-\varphi_4$) were driven by using the rubberband protocol.[37] In order to relate the origin of the rotation to the coordination scaffolding the orientations where an aryl ring is parallel to the bisector of the P−Rh−P angle (vertical to the paper plane in the left hand side of the figure respectively horizontal in the right hand side of the figure) were defined as ±90°. The sense of rotation was taken as shown in the left hand diagram in Figure 6. By this definition an edge orientation is characterised by an φ value of ±90° while a face orientation corresponds to φ values of ±0°. The conformational coordinates ($\tau_1-\tau_3$) were as well actively driven using the ring closure bond protocol.[38] The rotational position of the OH group (φ_5) completes the coordinates of the eight dimensional conformational space.

The grid intervals for aryl rotations are set to the values in Table 3 upon detailed inspection of the experimentally determined structures of the relevant molecules. The resolutions were chosen such that any feasible rotational positions could be reached from the starting points. The conformations observed in the X-ray structures are selected as starting points in each case. To generate the starting conformations the 'rubberband' protocol was used which had already been found to be efficient with other compounds for which steric crowding did not allow for a direct rotation of their aryl groups.[37] The OH group was allowed to occupy the

Table 3. Definition and results of the grid search for compounds **1**−**3**

Compound	$\varphi_{1,2}$		$\varphi_{3,4}$		τ_{1-3}		φ_5		No. of starting geometries	No. of total minima	No. of minima in the range of $\Delta E \leq 50$ kJ·mol^{-1}
	range	step	range	step	range	step	range	step			
1	0°-180°	3	0°-180°	2	0°-360°	6	0°-360°	3	23328	91	82
2	0°-180°	2	0°-360°	3	0°-360°	6	0°-360°	3	23328	177	177
3	0°-360°	3	0°-360°	1	0°-360°	12	0°-360°	3	46656	92	92

three classical staggered positions. To construct chelate cycles with the appropriate torsion angles the 'ring closure' protocol was used.[38] Under this protocol the appropriate C−C bond is removed and reinstalled after adjusting the torsion angles to the selected values.

From the ten thousands of starting geometries (Table 3) force field minimisations lead to the same number of local minima, but many of them being the same. A comparison of these minimised structures leads to 91 independent minima for compound **1** and 92 of them in the case of **3**. For compound **2** there are 177 independent minima altogether reflecting the lower symmetry and the less strained situation in **2** as compared to the once in compounds **1** and **3**. From these local minima only a subset of 82, 177, and 92 is within a range of 50 kJ·mol^{-1} at or above the corresponding global minimum for compounds **1**−**3** in that sequence (Table 3).

To sort the conformations into classes with respect to the conformations adopted by their chelate cycles a Neural Network analysis of the Kohonen type was applied.[39] The six torsion angles characterising the conformations of the six-membered chelate cycles were used as the components of the input vectors. Self organisation of the 5 × 5 Kohonen network clearly revealed twelve individual classes in a two dimensional map.

The classes which lie within a energy window of 20 kJ·mol^{-1} are shown for **1** in Figure 7. It is seen that these classes conform to the standard classification of six-membered cycles. This means that the standard classification scheme is 'reinvented' by the Neural Network. If the different conformations are ranked according to the lowest energy calculated for the members of each specific class, the diagram as shown in Figure 7 results. It is satisfying to find that the λ and δ twist-boat conformations are at the lowest

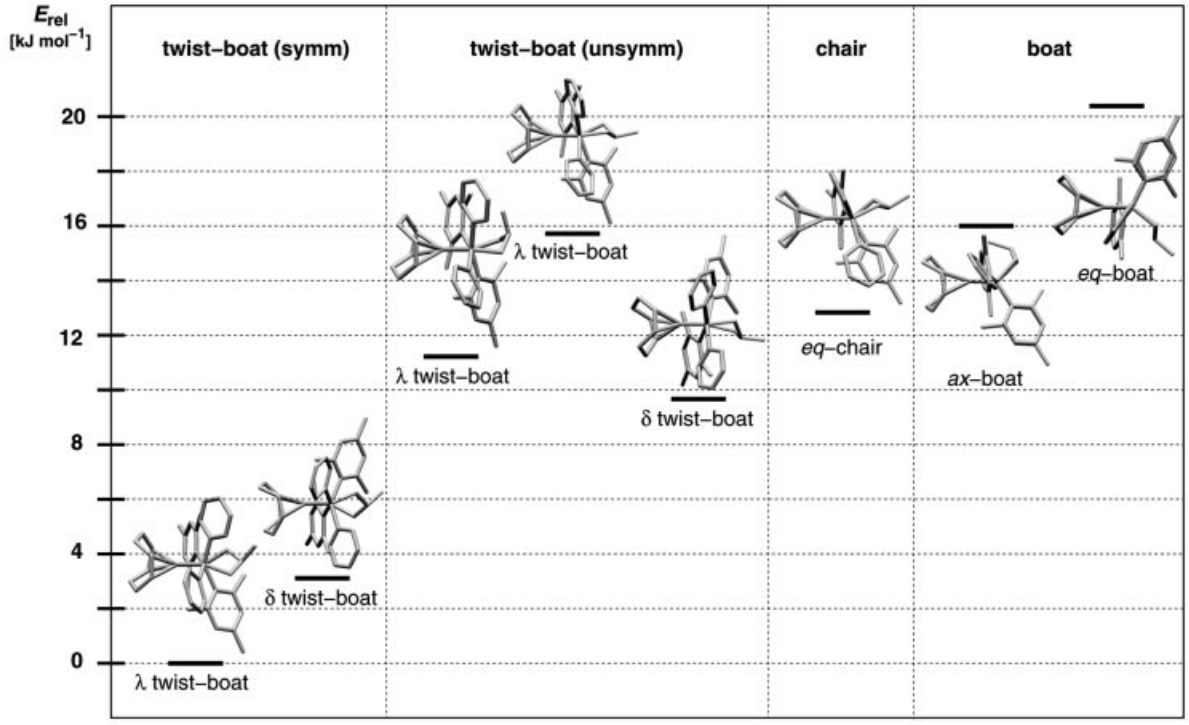

Figure 7. Classification of the conformations of the chelate cycle of **1**. The 91 independent local minima were sorted into the classes shown by Neural Network analysis. The energy scale refers to the lowest energy conformer in each class.

energy (Figure 7) since these are the conformations which are observed in the crystal of molecule **1**.

The same procedure when applied to the conformations which result as local energy minima from the analysis of **3** (Table 3) results in the diagram shown in Figure 8.

In this case the chair conformation − which almost exactly corresponds to the conformation of compound **3** in the solid state − has the lowest energy. It is however seen that other conformations are energetically almost equal to the one observed in the crystal such that the conformation

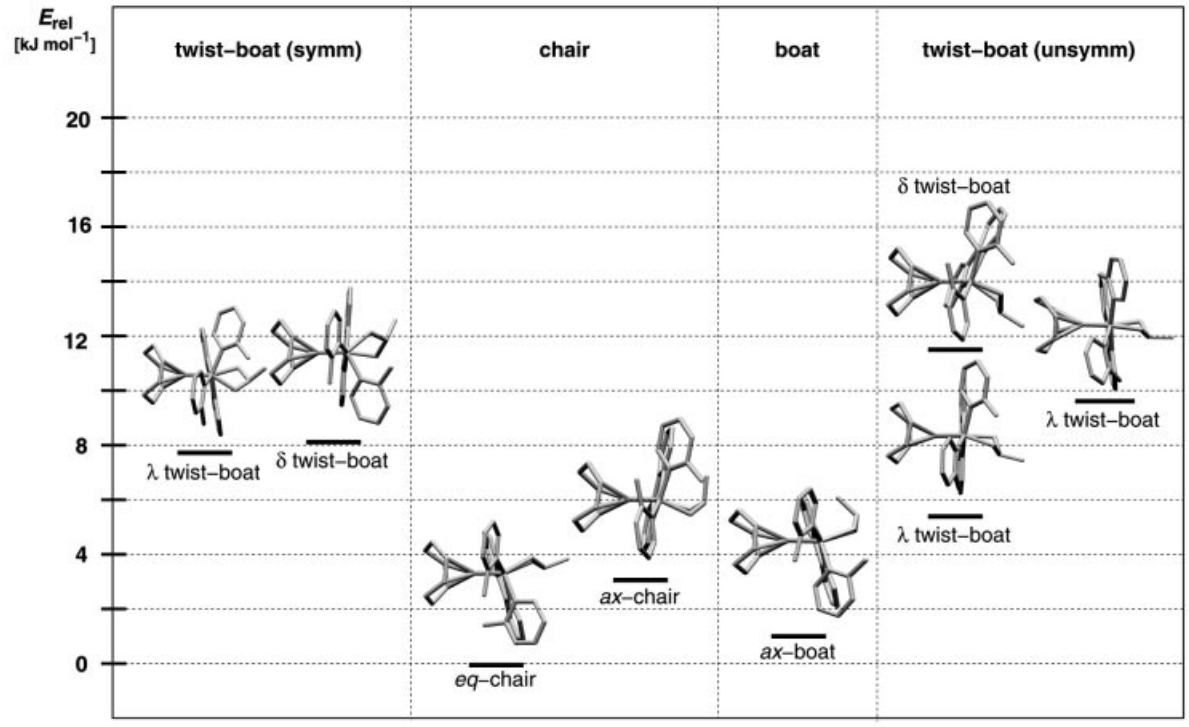

Figure 8. Classification of the conformations of the chelate cycle of **3**. The 92 independent local minima were sorted into the classes shown by Neural Network analysis. The energy scale refers to the lowest energy conformer in each class.

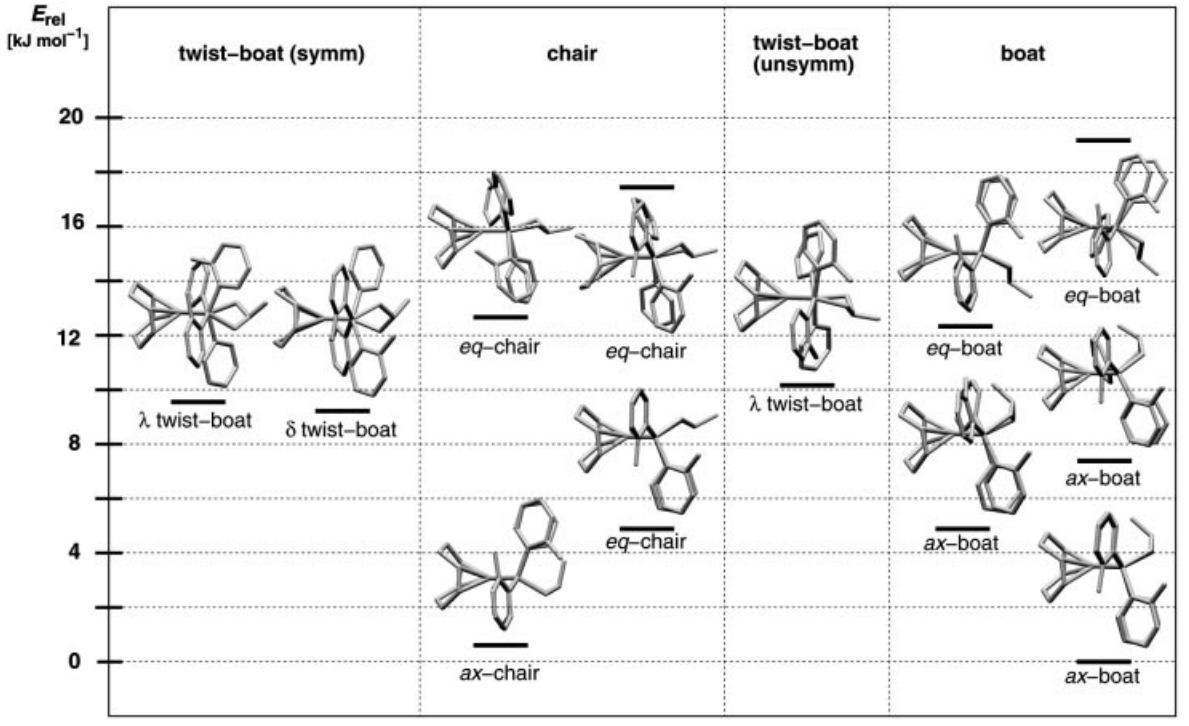

Figure 9. Classification of the conformations of the chelate cycle of **2**. The 177 independent local minima were sorted into the classes shown by Neural Network analysis. The energy scale refers to the lowest energy conformer in each class.

which should be found in the crystal cannot really be predicted. One would expect, however, that it should be one of the low energy molecular conformations which build up the crystal and it is in fact the one with the lowest calculated energy.

Figure 9 shows the same type of analysis for compound **2** where it is seen that the conformation observed in the crystal (chair, Figure 1) is amongst the conformations of the lowest energy of this compound but lies some 5 kJ·mol^{-1} above the global minimum.[40]

In comparing Figures 7−9 it is obvious that twist conformations are only preferred with **1** while **2** and **3** appear to prefer non-twisted conformations (chair or boat). Site differentiation by the two different PAr_2 groups is obviously largest for molecule **1** which prefers a twist conformation while the difference in the repulsive forces acting on the chelate cycle from the two different PAr_2 groups in **2** and **3** do not overcome the intrinsic preference of the more symmetric chair and boat conformations.

Energy − Reaction Pathway

With the approach taken in deriving force constants describing the potentials with respect to internal coordinates which involve the rhodium atom as a contributor there is no explicit reference to an energy scale (see paragraph Optimisation of Force Field Parameters). The reference is only implicit and the scale results by virtue of the scale intrinsic to the MM2* part of the force field. This part of the force field is thoroughly adapted to energy differences observed for organic molecules which means that it is capable of reproducing conformational pathways in organic chemistry not only with respect to structures but also with respect to relative energies. Since, with the molecules analysed, the interactions between their organic parts dominate it is expected that the force constants derived for the 'inorganic' part of the molecules by GA-optimisation will adapt to the major forces exerted by their organic part such that the scale of relative energies as calculated by the force field as a whole will be on scale with the observations. These expectations have been born out by similar analyses in related cases.[14−16] If the energies are on scale with the observations it must be possible to calculate conformationally relevant energies and to compare these with experimental values wherever available. The only molecule within the set studied for which experimental data relating to the relative stability of different conformers and to activation energies of conformational rearrangements are available is molecule **1**.[8] A more detailed analysis of the implications to be drawn from the force field calculations is therefore restricted to **1**.

An indication for the appropriateness of the energy scale is the finding (Figure 7) that the λ twist-boat conformation of **1** is calculated to be 3.1 kJ·mol^{-1} more stable than the δ twist-boat conformation. Experimentally it is observed that the energy difference between these conformers is $\Delta H =$ 3.4 kJ·mol^{-1} with the λ twist conformer being the more stable one.[8] The modelling approach hence predicts the correct sequence of relative stabilities and, even more, the calculated energy difference is in agreement with experiment.

NMR analysis shows that the conformational reaction pathway of the λ ⇄ δ interconversion of **1** is a complicated one.[8] It may or may not be accompanied by rotational rearrangements of the mesityl groups where on the other hand such mesityl rotations can only occur during λ ⇄ δ twist interchange.[8] If the force field approach is an appropriate one it should correctly predict this behaviour. To address this point contour maps were constructed in order to delineate the corresponding reaction path. To construct these maps with sufficient resolution with respect to the internal coordinates, which should best describe the pathway, grid points were calculated at a higher resolution (torsion angles $\tau_1-\tau_3$, rotational angles $\varphi_1-\varphi_4$, see Figure 6).

The diagrams (Figures 10−13, and 15) showing projections onto the τ_i/τ_j-planes ($i = 1-3$; $j = 2, 3$; $i \neq j$) were constructed in the following way: for any combination of the three τ-values (resolution in τ-space = 12°) the remaining coordinates ($\varphi_1-\varphi_5$) were allowed to refine in the same way as used in the global conformational search (see above). The lowest energy conformation from the stack of conformations thus obtained for each grid point was taken to represent the grid point in energy as well as in structure.

Figure 10 shows the isoenergy contour plot in a projection onto the τ_1/τ_3-plane. The λ and δ conformations which are the most stable conformations are shown on the left hand side of the diagram. A least energy pathway for the interconversion of these conformers along the τ_1/τ_3-plane is shown as a black line in the diagram. Individual conformations at the grid points corresponding to points along or close to this line are shown in sequence around the contour plot.

From this sequence of structural models it may be inferred that the rotation of the mesityl groups should occur at around $\tau_1 = 12°$; $\tau_3 = 24°$ (asterisk in the Figure 10) along the λ ⇄ δ interconversion pathway. It has already been stated that a whole stack of conformations has to be calculated for every grid point such that the one with the lowest energy can be chosen as a representative for each grid point. The conformations shown in Figure 10 are the ones having the lowest energy in each corresponding stack. For any conformation shown there is a pendant with an approximately opposite orientation of the mesityl groups, i.e. it is an orientation for which the aryl rotations ($\varphi_1-\varphi_4$ in Figure 6) are approximately equal in their absolute value but opposite in sign (compare $\mathbf{a_4}$ and $\mathbf{b_4}$ in Figure 10). The area around the point marked with an asterisk in Figure 10 is the one where the energy difference between these rotamers is the lowest one along the pathway i.e. less than 1 kJ·mol^{-1} against 10−80 kJ·mol^{-1} for the other grid points along the black line.

Figure 11 shows the isomerisation pathway in a projection onto the τ_1/τ_2- and τ_2/τ_3-planes. The values of the coordinates at which the concerted flip of the mesityl groups will occur are again (Figure 10) marked by an asterisk in each case.

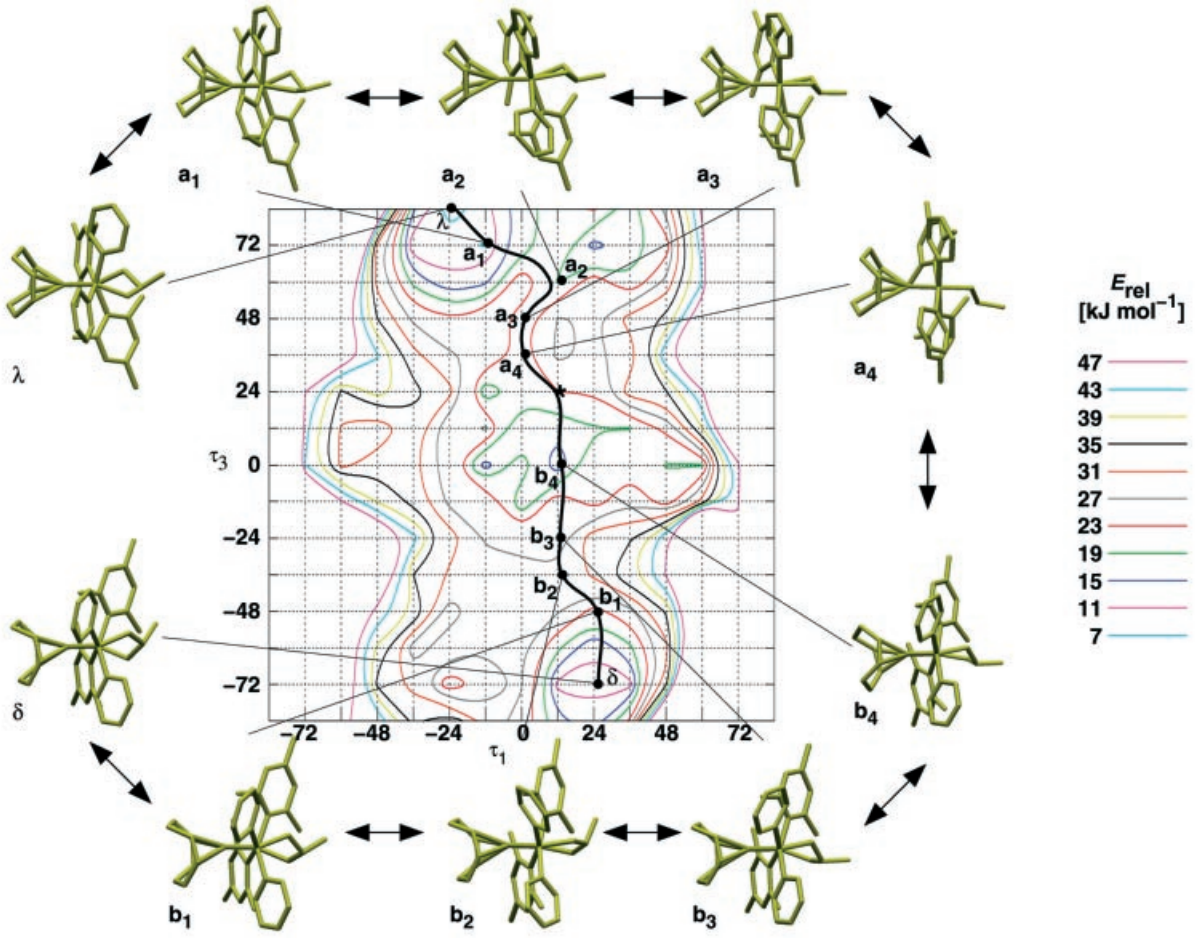

Figure 10. Projection of the energy hypersurface of **1** onto coordinates τ_1/τ_3, which characterise the conformation of the chelate cycle. To derive the contour plot the energy of the lowest energy conformation from each stack of conformations referring to each grid point was chosen as a representative. The reaction pathway (black line) was constructed such that it is a lowest energy route from the λ to the δ isomer. The conformations which characterise individual grid points are shown as molecular models around the contour plot. The conformations labelled **a** have an orientation of the aryl groups which corresponds in its sense to the one observed in the λ isomer. The conformations referenced by the label **b** have a different orientation which is similar to the one observed for the δ isomer. The region around the point marked with an asterisk is the one where the flip of the aryl rotation occurs.

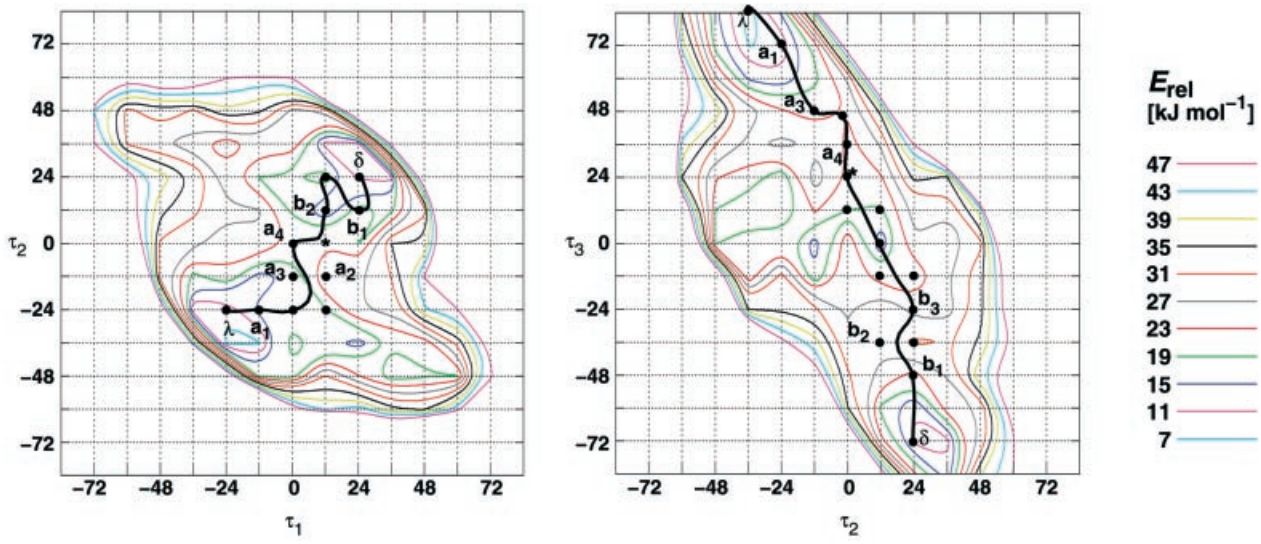

Figure 11. Projection of the energy hypersurface onto the τ_1/τ_2- and τ_2/τ_3-planes. The contour plots were constructed as described in the text and in the legend of Figure 10. The symbols **a**, **b**, λ, and δ refer to the conformations shown in Figure 10. The black lines indicate the projection of the reaction pathway for the $\lambda \rightleftarrows \delta$ isomerization. The asterisks pinpoint the region where the flip of the aryl rings occurs.

The reaction pathway, indicated by a black line in each case, corresponds to a smooth transition from one isomer into the other with all τ and φ values changing gradually along these curves. Only at the transition point marked by an asterisk there is a concerted flip of both mesityl groups by around 70° within a very short interval along the τ scale.

The kind of coupled rotation of the mesityl groups is evident from Figure 12 which shows the dependence of the energy on the rotational positions of the two mesityl groups. The diagram refers to the corresponding relative energies as calculated with τ_1, τ_2, and τ_3 fixed at 12°, 0°, and 24° respectively, i.e. at that point in τ-space (asterisk in Figures 10 and 11) which was found to induce the flip of the two mesityl groups.

It is found that the diagram shows pronounced minima at discrete positions which are labelled by **A** and **B**. The molecular models shown in Figure 12 illustrate the mutual arrangement of the mesityl groups. The conformation of the chelate cycle is the same in each case and corresponds to the specific triple of τ coordinates which was found to characterise the flip situation in τ space (asterisk in Figures 10 and 11). The energy minima labelled **A** correspond to a rotational position of the mesityl groups which is characteristic for the λ conformer. The labels **B** correspondingly refer to the rotational position of the mesityl groups as characteristic for the δ conformer. This means that all conformations labelled **A** will relax to the conformation of the λ isomer as soon as the τ values are allowed to refine. The conformations labelled **B** will correspondingly refine to the δ isomer upon relaxation of the constraints in τ space. Since the analysis of the τ-space diagrams (Figures 10 and 11) makes clear that any δ/λ transition and its reverse is necessarily accompanied by a concerted flip of the two mesityl groups the interpretation of Figure 12 is straightforward: A λ conformer (**A**) has two possibilities to change into a δ one. Starting from $\mathbf{A_1}$ as an example (Figure 12) there are two low energy pathways either to $\mathbf{B_1}$ or to $\mathbf{B_3}$. The rotational position of the mesityl groups corresponding to minima of type **B** is the one which corresponds to a δ isomer. This means that starting from the λ isomer ($\mathbf{A_1}$) a δ conformation can be reached on two ways: Either there will be a saddlepoint between $\mathbf{A_1}$ and $\mathbf{B_1}$ or a saddlepoint between $\mathbf{A_1}$ and $\mathbf{B_3}$. The barrier heights for these two types of transition are slightly different (Figure 12) while the energy of all the λ isomers (**A**) is necessarily the same but different from the energy of the δ isomers (**B**) which are again of equal energy for all members of the group. The only difference between energetically equal conformations such as $\mathbf{B_1}$ and $\mathbf{B_3}$ is then that the mesityl groups − even though they occupy fully equivalent positions in $\mathbf{B_1}$ and $\mathbf{B_3}$ as a whole − find themselves rotated by 180° on going from $\mathbf{B_1}$ to $\mathbf{B_3}$ (see colour coding of the conformations in Figure 12). The

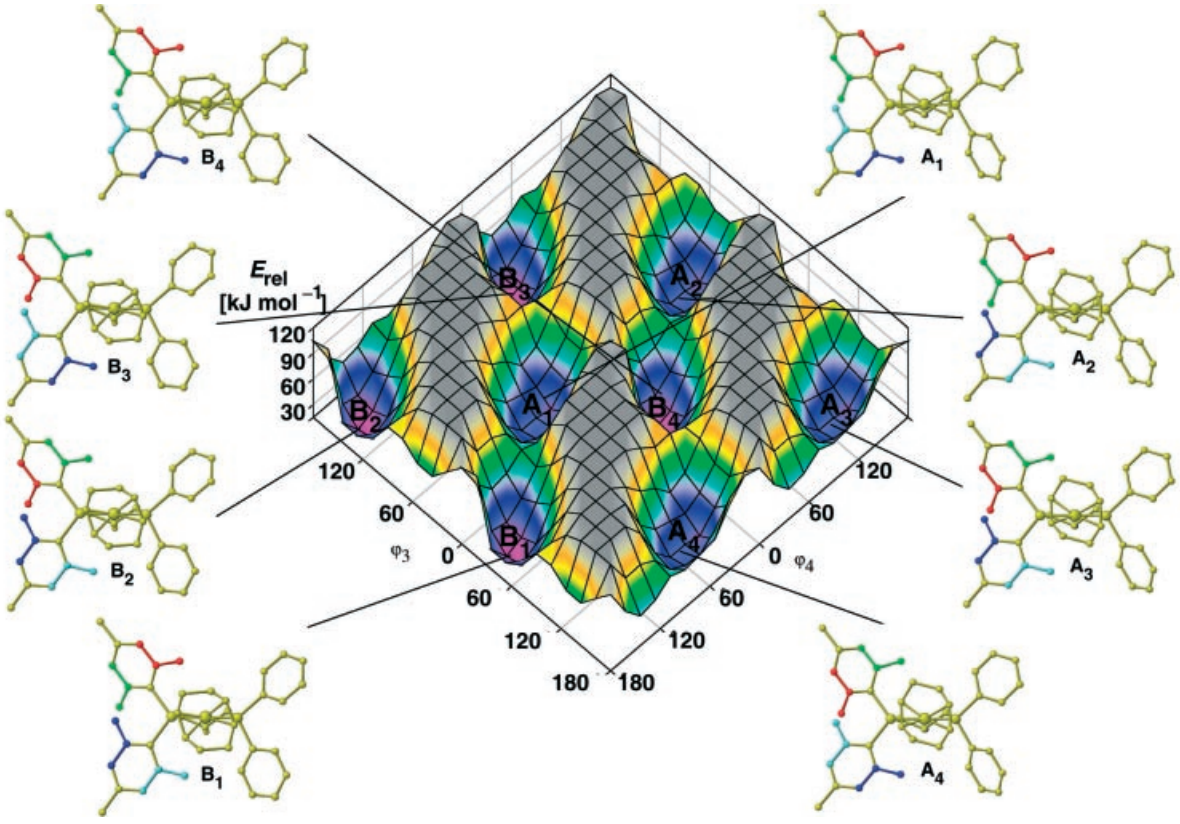

Figure 12. Energy diagram illustrating the pathways of rotational rearrangements of the $PMes_2$ entity of **1** during λ ⇄ δ isomerization. The translation symmetry of the graph is 180° in φ_3 and φ_4. The minima labelled **A** are characteristic for the λ isomer. The minima **B** likewise refer to the δ isomer. The molecular models $\mathbf{A_{1-4}}$ and $\mathbf{B_{1-4}}$ illustrate the rotational position of the mesityl groups for each of the eight minima shown. It is seen that the rotation of the mesityl groups at the $PMes_2$ entity is strictly coupled such that the groups have to rotate in mutually opposite sense.

conformations $\mathbf{B_1}$ and $\mathbf{B_3}$ are energetically fully equivalent; the ways however on which they are formed starting from $\mathbf{A_1}$ are different.

The energy diagram shown in Figure 12 has of course a translation period of 180°. The graph itself consists of four symmetrically independent unit cells. The fact that the mesi-

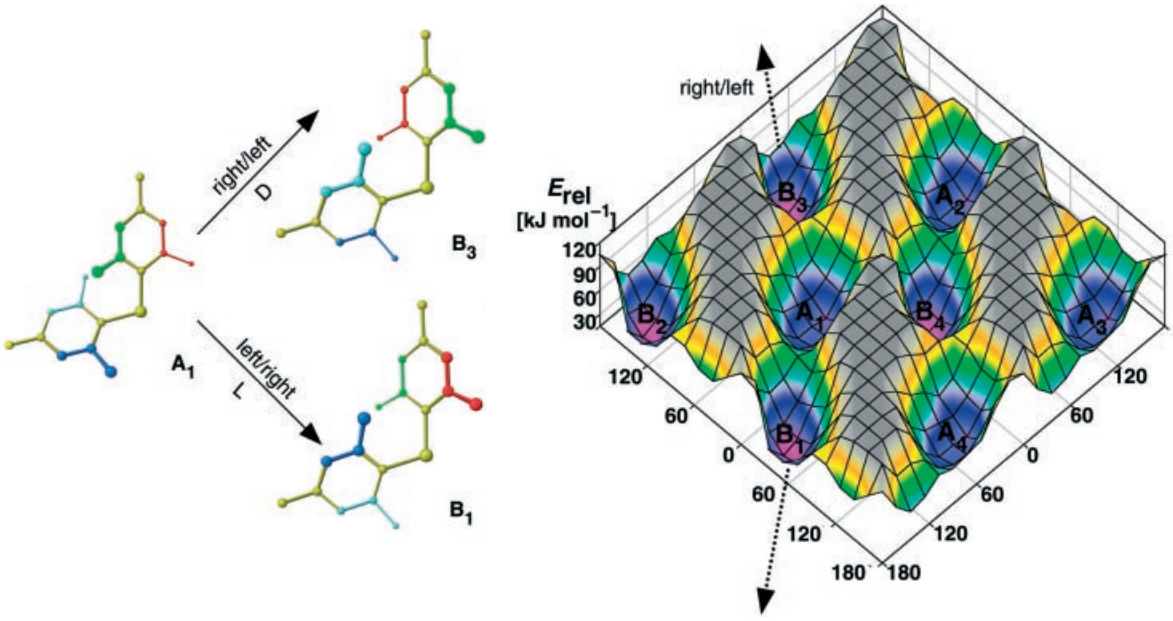

Figure 13. Illustration of the two energetically different pathways on which the $\lambda \rightleftarrows \delta$ isomerization of **1** may occur. The two pathways of $\lambda \rightleftarrows \delta$ isomerization are characterised by strictly coupled and countersense rotations of the mesityl groups at the $PMes_2$ entity. Depending on the sense of this coupled rotation different activation barriers have to be overcome. The two pathways labelled right/left (D) and left/right (L) are illustrated by molecular models.

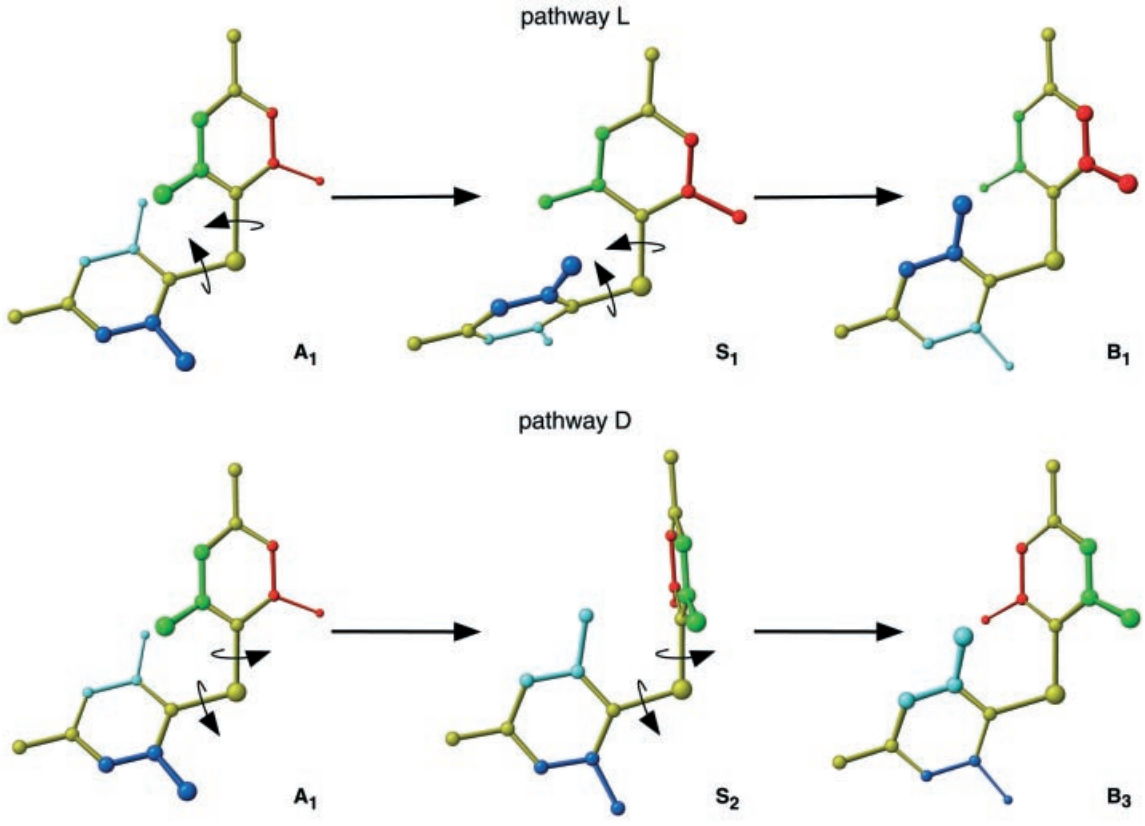

Figure 14. The one ring flip processes characterising the reorientation of the mesityl groups at the $PMes_2$ entity of **1** during $\lambda \rightleftarrows \delta$ isomerization. For the meaning of **A** and **B** see Figures 12 and 13. $\mathbf{S_1}$ and $\mathbf{S_2}$ correspond to the rotational positions of the mesityl groups at the saddlepoints (Figures 12 and 13).

tyl groups can only change their rotational positions as a strictly coupled pair is evident from Figure 12 as well. Only if the mesityl groups rotate in opposite sense the coupled rotation is allowed by low energy pathways. With the labelling scheme chosen $\mathbf{A_{(odd)}}$ can only interchange with $\mathbf{B_{(odd)}}$ and correspondingly $\mathbf{A_{(even)}}$ and $\mathbf{B_{(even)}}$ can interchange with each other. The corresponding reaction channels $\mathbf{B_1} \rightarrow \mathbf{A_1} \rightarrow \mathbf{B_3} \rightarrow \mathbf{A_3}$ are evident from Figure 12 where the minimum $\mathbf{A_3}$ is shown in a symmetrically equivalent position at the corner of the diagram (a phase shift in φ_3 by plus 180° will place $\mathbf{A_3}$ adjacent to $\mathbf{B_3}$). The channel $\mathbf{A_4} \rightarrow \mathbf{B_4} \rightarrow \mathbf{A_2} \rightarrow \mathbf{B_2}$ is likewise apparent in Figure 12 (a phase shift of −180° will place $\mathbf{B_2}$ adjacent to $\mathbf{A_2}$). A transition from a position on the pathway labelled by an uneven number subscript to any position on the pathway labelled by an even number subscript would correspond to either the rotation of just one mesityl group or to the coupled rotation of the two mesityl groups in the same rotational direction. Both possibilities are excluded by high potential barriers (grey barriers running vertical in Figure 12).

The rotational pathways taken by the mesityl groups upon $\lambda \rightleftarrows \delta$ isomerization are illustrated in Figure 13 in a different way. As an example the λ conformer $\mathbf{A_1}$ is taken as starting point. The mesityl groups labelled by φ_3 and φ_4 together with the phosphorus atom to which they are bonded are shown in a projection which keeps the $C_{ipso}-P-C_{ipso}$ fragment in the same orientation in each case (in the molecules themselves the pseudo-axial and pseudo-equatorial positions of the mesityl groups with respect to the coordination plane will exchange during the $\lambda \rightleftarrows \delta$ isomerization).

Following the pathway $\mathbf{A_1}$ to $\mathbf{B_3}$ (pathway D in Figure 12) the λ conformer transforms into the δ conformer such that φ_3 makes a clockwise rotation while φ_4 rotates in counterclock sense. This process needs a somewhat higher energy than the $\lambda \rightleftarrows \delta$ transformation from $\mathbf{A_1}$ to $\mathbf{B_1}$ (pathway L in Figure 13) which is accompanied by a counterclockwise rotation of φ_3 and a clockwise rotation of φ_4. These two pathways are labelled right/left for pathway D and left/right for pathway L respectively in Figure 13.

The two pathways L and D are illustrated in Figure 14 in yet another way. On the way from $\mathbf{A_1}$ to $\mathbf{B_1}$ (pathway L) the rotational arrangement corresponding to the saddlepoint (Figures 12 and 13) is the one shown ($\mathbf{S_1}$). The view taken in this Figure 14 is along the bisector of the P−Rh−P entity (Figure 6). The orientation is chosen such that one of the $P-C_{ipso}$ axes is vertical in each case in Figure 14.

The saddlepoint on the way from $\mathbf{A_1}$ to $\mathbf{B_3}$ (pathway D, Figures 12 and 13) is shown as well and labelled $\mathbf{S_2}$. It is

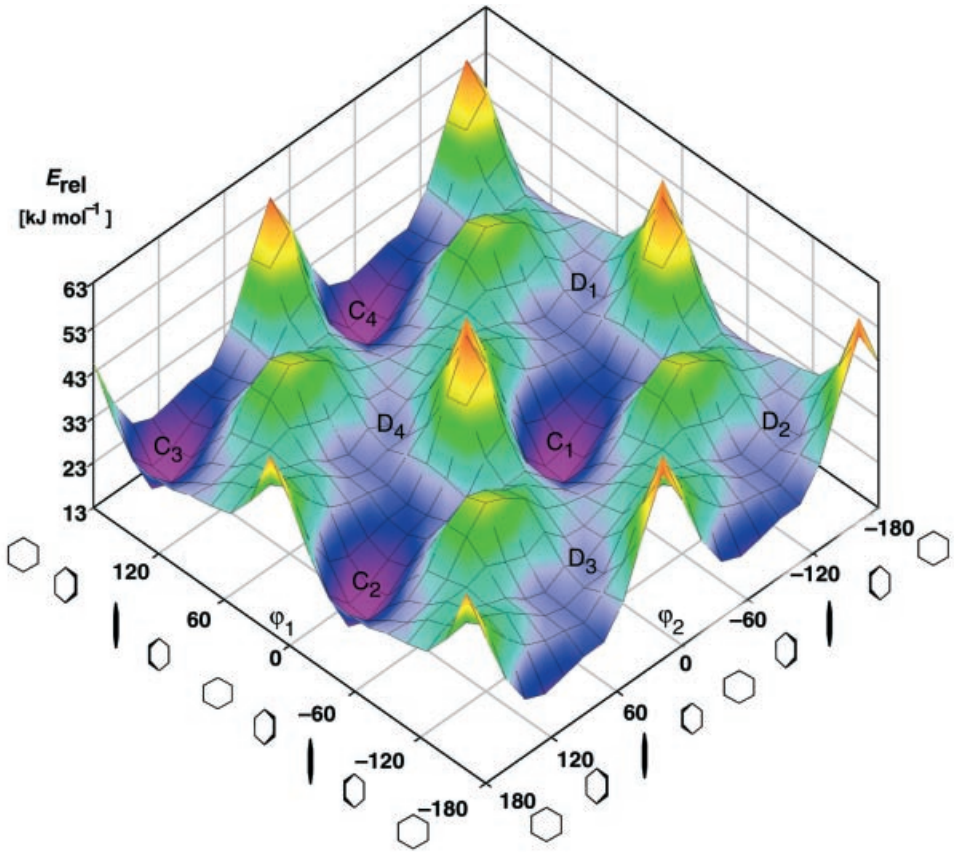

Figure 15. Energy diagram illustrating the ease of phenyl rotation at the PPh_2 group of **1**. The minima **C** are isoenergetic as are the flat minima **D**. The translation period of the graph is 180° in both axes. The energy scale is magnified with respect to the scale used in Figures 12 and 13. This larger magnification allows the illustration of the inherent asymmetry due to the chirality of **1**. The diagram is not symmetric with repect to the main diagonals (vertical in Figure 15).

seen that on both pathways the transition state corresponds to a situation where one of the aryl rings is almost vertical. The transitions thus correspond to a one ring flip process.[41]

The rotation of the phenyl groups at the PPh_2 entity is far less energy demanding than the rotation of the mesityl groups at the $PMes_2$ entity. The projection of the energy hypersurface onto the axes describing the rotation of the phenyl groups (φ_1, φ_2) is shown in Figure 15. This diagram is in principle analogous to the one shown in Figures 12 and 13. The energy scale and the energy profile are however quite different: In Figures 12 and 13 the barriers between the reaction channels (vertical reefs) are higher than 120 $kJ{\cdot}mol^{-1}$ (relative to the energy of the global minimum; Figures 12 and 13) and transition between different rotational positions is only energetically feasible along the two reaction channels.

The rotation of the phenyl groups on the other hand is far less restricted. The energy scale shown in Figure 15 is limited to 63 $kJ{\cdot}mol^{-1}$ with the highest barriers (orange) being covered within this range.

While a continuous reef separates the left hand and the right hand part of the Figures 12 and 13, in Figure 15 there are only isolated mountains and valleys between them. The positions of the minima **C** and **D** (Figure 15) are similar to the ones of **B** and **A** in Figures 12 and 13. This means that the low energy rotational positions of the aryl groups at the $PMes_2$ group and at the PPh_2 group are rather similar. There are however many energetically accessible pathways for concerted as well as for unconcerted phenyl rotations (Figure 15) while the mesityl groups can only rotate in a strictly concerted way (Figures 12 and 13). The barrier heights for the pathways reflecting the phenyl rotation are in the range of 12−15 $kJ{\cdot}mol^{-1}$ (Figure 15) while the barrier heights along the pathway of the strictly concerted rotation of the mesityl groups (pathways L and D, Figures 12 and 13) are in the range of 70−80 $kJ{\cdot}mol^{-1}$.

Force Field Model and Experimental Reality − Comparison of Results and Conclusion

The conformational behaviour of compounds **1**−**7** has been thoroughly analysed by NMR methods.[8] For compound **1** the quantitative details relating to the relative stability of its isomeric forms and to the pathways of isomerization and the activation enthalpy of this process are all available. It is found that the λ form of **1** is by 3.4 $kJ{\cdot}mol^{-1}$ more stable than its δ form.[8] Force field analysis calculates this energy difference as 3.1 $kJ{\cdot}mol^{-1}$ in almost exact numerical agreement (Figure 16). NMR exchange spectroscopy reveals that there are two different pathways for the isomerization of **1**.[8] Both pathways are characterised by a coupled rotation of the mesityl groups at the $PMes_2$ entity of **1**. The only difference between these two pathways is the opposite sense of this strictly coupled rotation.[8] The activation enthalpy for the enantiomerisation process as a whole is found to be $\Delta H^{\#}$ = 64.4 $kJ{\cdot}mol^{-1}$.[8] Force field calculations of **1** show that there are two pathways for λ ⇄ δ isomerization which comprise the strictly coupled countersense rotation of the mesityl groups at the $PMes_2$ entity and which differ only in the sense of rotation. The calculated activation enthalpy of the lower energy pathway is 69.1 $kJ{\cdot}mol^{-1}$, again in close nu-

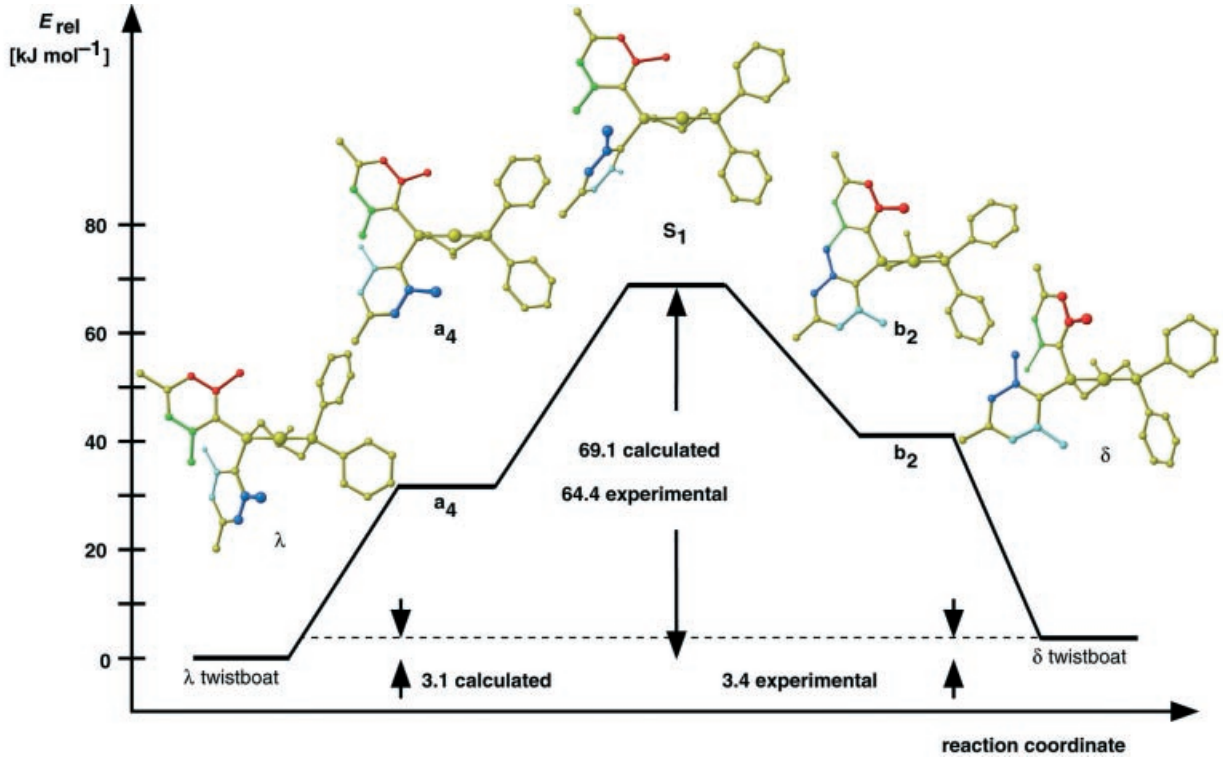

Figure 16. Comparison of experimental and calculated results for the λ ⇄ δ isomerization of **1**.

merical agreement with the experimental value (Figure 16). This type of quantitative and qualitative agreement between calculation and experiment lends quite some credit to the calculation procedures as reported. The force field calculations identify the conformation of the chelate ring at the saddlepoint as an unsymmetrical twist conformation. Starting from the λ isomer this transition state geometry is reached via a halfboat conformation (**a**$_4$ in Figure 16). Starting from the δ isomer a twist conformation (**b**$_2$ in Figure 16) is the intermediate.

It appears that the approach taken in deriving a force field model is a very promising one. The optimisation of the force field parameters on the basis of as many solid state structures as available for a class of compound had already been shown to lead to models of high predictive power.[14−16] The case studied here is the most complicated one of the ones analysed by this method so far and at the same time the one for which pathways and energies have been experimentally determined to the maximum possible extent.[8] It is highly satisfying to observe that the model is capable of predicting the types of conformational rearrangement processes as well as the energy differences associated with them.

Experimental Section

Force Field Calculations

The force field program used is based on the program set YAMMP[23] written by R. K. Z. Tan et al. in "C" which is available as a public domain source code.[42] The force field potentials were adapted to the units used in MacroModel MM2*.[21] Data transfer between MacroModel and YAMMP was accomplished by appropriate converters and YAMMP was embedded in a number of shells which make it available at different types of single processor machines (Pentium, SGI) and parallel computing systems (Parsytec GC, CRAY T3E).

The rms deviation between two structural models was calculated as the square root of the sum of the squares of the deviations between all n corresponding pairs of atoms divided by the square root of n (Hydrogen atoms were included in these calculations during GA optimisation). An overlay of the two structures was computed by a least-squares fitting procedure based on a program of D. Heisenberg[43] and implemented into YAMMP by K. Allinger.[14]

The following expressions were used for the potential energy:

Bond Length Deformation:

$$E(r) = 1/2\,k((r-r_0)^2 - (r-r_0)^3) \quad (1)$$

where r_0 represents the ideal bond length (minimum of the curve) and r represents the actual distance. This potential curve has a artificial maximum at large ($r-r_0$) values. For such large values only the quadratic term is used.

Valence Angle Deformation:

$$E(\alpha) = 1/2\,k((\alpha-\alpha_0)^2 + k'(\alpha-\alpha_0)^6) \quad (2)$$

α_0 and α have a similar meaning as r_0 and r above. The force constants k ank k' refer to the contributions of the harmonic and the unharmonic parts of the potential function to the energy.

Torsion Angle Deformation:

$$E(\tau) = k_{t1}(1+\cos\tau) + k_{t2}(1-\cos(2\tau)) + k_{t3}(1+\cos(3\tau)) \quad (3)$$

The variable τ describes the torsion angle. k_{t1}, k_{t2}, and k_{t3} are the force constants describing potential terms with twofold, fourfold and sixfold symmetry in this series.

π-Bonds: π-bonding was incorporated by defining a dummy atom D at the centre of the coordinated double bond (Figure 3). The position of the olefinic carbon atoms was then expressed as a function of r_d, α, β, γ, and τ (Figure 3). The terms needed in a molecular mechanics calculation are however of the type $\delta E/\delta x$ (x being any coordinate of any atom in real space) and not of the type $\delta E/\delta p$ (p being any internal coordinate). The potentials on the other hand are defined as $E = f(p)$ and it is necessary therefor to transform $\delta E/\delta p$ into $\delta E/\delta x$. This problem is solved for the standard set of conformational coordinates (distance, angle, torsion angle ...) in any standard molecular mechanics program. It is not incorporated, however, for parameters such as r_d, α, β, γ, and τ which were used to define a π bond (Figure 3). In principle the solution is given by differential calculus by $\delta E/\delta x = (\delta E/\delta p)\cdot(\delta p/\delta x)$. With the parameters r_d, α, β, γ, and τ the application of this rule is rather tedious. For this reason and since the corresponding expressions cannot be found in the literature the results are given here for the derivatives with respect to the x-coordinate in each case. The derivatives for the other coordinates are easily obtained from these expressions by cyclic permutation.

If a_x represents the x coordinate of the real atom (rhodium in Figure 3) and d_x the x coordinate of the dummy atom (D in Figure 3) the expression relating to r_d is:

$$\delta E/\delta d_x = -\delta E/\delta a_x = k\Delta r_d \cdot (a_x - d_x)/|r_d| \quad (4)$$

The term Δr_d means ($|\vec{r_0}| - |\vec{r}|$ where $|\vec{r}|$ is the distance r_d and $|\vec{r_0}|$ is the distance at the minimum of the potential function.

In order to derive the expressions relating to α, β, and γ (Figure 3) the following definition is used (Figure 17).

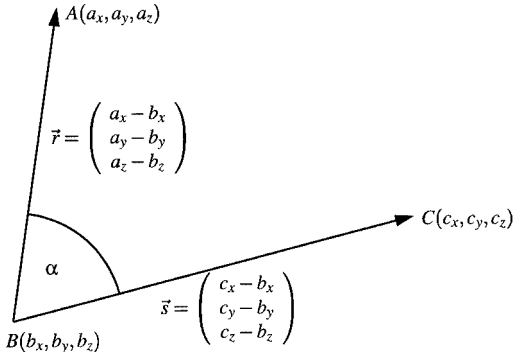

Figure 17. Definitions used in calculating derivatives with respect to angles.

If the potential function $E(\alpha) = {}^1/_2k\cdot[(\alpha - \alpha_0)^2 + k_{unh}\cdot(\alpha - \alpha_0)^6]$ is defined as above the derivatives with respect to the x coordinates of the points A, B, and C are:

$$\frac{\delta E(\alpha)}{\delta a_x} = k_{angle}\cdot\Delta\alpha\cdot\left(1+3\cdot k_{unh}\cdot(\Delta\alpha)^4\right)\cdot\frac{-1}{\sin\alpha} \cdot\frac{|\vec{r}|^2\cdot(c_x-b_x)-\vec{r}\cdot\vec{s}\cdot(a_x-b_x)}{|\vec{r}|^3\cdot|\vec{s}|}$$

$$\frac{\delta E(\alpha)}{\delta b_x} = k_{angle}\cdot\Delta\alpha\cdot\left(1+3\cdot k_{unh}\cdot(\Delta\alpha)^4\right)\cdot\frac{-1}{\sin\alpha} \cdot\frac{\vec{r}\cdot\vec{s}\cdot|\vec{s}|^2\cdot(a_z-b_x)-(a_x-2b_x+c_x)\cdot|\vec{r}|^2\cdot|\vec{s}|^2+\vec{r}\cdot\vec{s}\cdot|\vec{r}|^2\cdot(c_x-b_x)}{|\vec{r}|^3\cdot|\vec{s}|^3} \quad (5)$$

$$\frac{\delta E(\alpha)}{\delta c_x} = k_{angle}\cdot\Delta\alpha\cdot\left(1+3\cdot k_{unh}\cdot(\Delta\alpha)^4\right)\cdot\frac{-1}{\sin\alpha} \cdot\frac{|\vec{s}|^2\cdot(a_x-b_x)-\vec{r}\cdot\vec{s}\cdot(c_x-b_x)}{|\vec{r}|\cdot|\vec{s}|^3}$$

The term $\Delta\alpha$ means ($\alpha - \alpha_0$) in each case (see above).

For analysing $\delta E/\delta\tau$ (Figure 3) the definitions shown in Figure 18 are used.

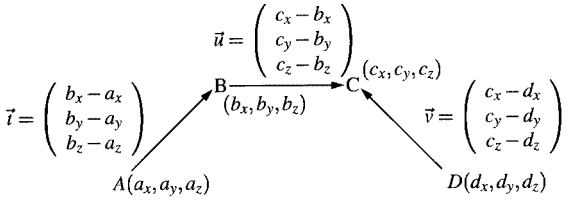

Figure 18. Definitions used in calculating derivatives with respect to torsion angles.

Two additional vectors are defined as:

$$\vec{r} = \vec{t}\times\vec{u} \text{ and } \vec{s} = \vec{u}\times\vec{v} \quad (6)$$

With a_x, b_x, c_x, and d_x being the x coordinates of the points A, B, C, and D in that sequence the following expressions result:

$$\frac{\delta E(\tau)}{\delta a_x} = \left(k_{t1}\cdot(1+\cos\tau)+k_{t2}\cdot(2\cos^2\tau-1)+k_{t3}\cdot(4\cos^3\tau-3\cos\tau)\right) \cdot\frac{|\vec{r}|\cdot|\vec{s}|\cdot(u_z s_y-u_y s_z)-\vec{r}\cdot\vec{s}\cdot\frac{|\vec{s}|}{|\vec{r}|}\cdot(r_y u_z-r_z u_y)}{|\vec{r}|^2\cdot|\vec{s}|^2}$$

$$\frac{\delta E(\tau)}{\delta b_x} = \left(k_{t1}\cdot(1+\cos\tau)+k_{t2}\cdot(2\cos^2\tau-1)+k_{t3}\cdot(4\cos^3\tau-3\cos\tau)\right) \cdot\left(\frac{|\vec{r}|\cdot|\vec{s}|\cdot(s_y(-t_z+u_z)+r_y v_z+s_z(-u_y+t_y)-r_z v_y)}{|\vec{r}|^2\cdot|\vec{s}|^2} -\frac{\vec{r}\cdot\vec{s}\cdot\left(\frac{|\vec{r}|}{|\vec{s}|}\cdot(r_y(u_z-t_z)+r_z(-u_y+t_y))+\frac{|\vec{r}|}{|\vec{s}|}\cdot(s_y v_z-s_z v_y)\right)}{|\vec{r}|^2\cdot|\vec{s}|^2}\right) \quad (7)$$

$$\frac{\delta E(\tau)}{\delta c_x} = \left(k_{t1}\cdot(1+\cos\tau)+k_{t2}\cdot(2\cos^2\tau-1)+k_{t3}\cdot(4\cos^3\tau-3\cos\tau)\right) \cdot\left(\frac{|\vec{r}|\cdot|\vec{s}|\cdot(r_y(-v_z+u_z)+s_y t_z+r_z(-u_y+v_y)-s_z t_y)}{|\vec{r}|^2\cdot|\vec{s}|^2} -\frac{\vec{r}\cdot\vec{s}\cdot\left(\frac{|\vec{r}|}{|\vec{s}|}(s_y(u_z-v_z)+s_z(v_y-u_y))+\frac{|\vec{r}|}{|\vec{s}|}\cdot(r_y t_z-r_z t_y)\right)}{|\vec{r}|^2\cdot|\vec{s}|^2}\right)$$

$$\frac{\delta E(\tau)}{\delta d_x} = k_{t1}\cdot(1+\cos\tau)+k_{t2}\cdot(2\cos^2\tau-1)+k_{t3}\cdot(4\cos^3\tau-3\cos\tau) \cdot\frac{|\vec{r}|\cdot|\vec{s}|\cdot(u_y r_z-u_y r_y)-\vec{r}\cdot\vec{s}\cdot\frac{|\vec{r}|}{|\vec{s}|}\cdot(s_z u_y-s_y u_z)}{|\vec{r}|^2\cdot|\vec{s}|^2}$$

Optimisation by GA

The procedures already explicitly described elsewhere[14] based on the use of the program GAPAO which itself uses functions of the

[a] Parameter set mm2_rms was obtained by calculating the fitness on the basis of the distance between pairs of atoms, one atom belonging to the experimentally observed structure and the constitutionally equivalent atom belonging to the calculated structure. Parameter set mm2_int was obtained by evaluating the fitness on the basis of the internal coordinates as shown. Only parameters marked with an asterisk were refined. Harmonic potentials were used for the bond length deformation. The unharmonic term k_{unh} of the valence angle deformation (see text) was set at $k_{unh} = 0.754$ rad^{-4} throughout.

PGA-Genetic Algorithm Package[44] were applied. These functions are fully parallelised and are based on the Message Passing Interface Library[45] and thus GAPAO runs in single processor as well as in parallel processor environments.

The force constants as derived by optimisation on the basis of eleven structures are shown in Table 4.

Conformation Analysis

The procedure used was similar to the one described in detail elsewhere.[15] Two dimensional and pseudo-three dimensional contour plots were produced by using the program *SigmaPlot*.[46] Neural Network analyses were calculated and visualised by the program kmap.[47] The calculations were performed by using the modified program YAMMP as a minimizer and a shell around it which allowed to run the program on parallel processor environments. The standard program YAMMP was augmented by a part, written in "C", implementing a grid search algorithm. All calculations were performed on a Cray T3E.

Acknowledgments

Financial support by the German Science Foundation (DFG HU 151/24-1 and DFG HU 151/29-1), the Fonds der Chemischen Industrie and the Graduiertenkolleg "Selektivität in der organischen und metallorganischen Synthese und Katalyse" is gratefully acknowledged. The computations were made possible by grants of computing time at PARSYTEC (IWR Heidelberg) and CRAY [John von Neumann Institut (NIC)] parallel computing environments. We are indebted to J. Gasteiger, Erlangen, for the allowance to use the program kmap written by the Erlangen group.

[28] The conventional binary code has the disadvantage that occasionaly more than one bit has to be changed in going from the binary representation of n to $n + 1$ (cf.: $n = 3$, code = 011; $n = 4$, code = 100). In applying Genetic Algorithms this would mean that it is more probable to change a 4 into a 5 (100; 101) than it is to change a 3 into a 4. 'Grey coding' avoids this problem by assigning a binary code such that only one bit has to be inverted in going from n to $n + 1$ throughout.

[34] The structure contains one molecule CH_2Cl_2 and half a molecule Et_2O per formula unit. Both of these solvate molecules as well as PF_6^- counterions are disordered. Relatively short contacts between the hydroxy oxygen of the ligand and some of the fluorine substituents of the counterion PF_6^- (2.8 Å) and some of the chlorine atoms of the dichloromethane solvate (3.3 Å) indicate that the structure of the ligand might be biased by these contacts.

Interconversion of δ and λ Forms of Six-Membered Chelate Cycles − A Quantitative NMR Spectroscopic Study of (Diphosphane)rhodium Compounds

Axel Frick,[a] Volker Schulz,[a] and Gottfried Huttner*[a]

Prof. Dr. Matthias Drieß in recognition of his outstanding contributions to inorganic chemistry

Keywords: Conformational analysis / Diphosphanes / Rhodium / Kinetics / Thermodynamics

The stereochemical flexibility of six-membered chelate cycles containing phosphorus donor groups has not yet been analysed in detail. With a number of compounds of the type $[\{\kappa\text{-}PR_2CH_2CH(OH)CH_2\text{-}\kappa\text{-}PR'_2\}Rh(\eta^4\text{-}COD)]^+PF_6^-$ at hand, and since the solid state structures and the catalytic properties of these compounds are known, an ideal opportunity to study this topic was available. After assigning all of the important ^1H, ^{13}C, and ^{31}P NMR spectroscopic resonances by a combination of one- and two-dimensional NMR spectroscopic methods quantitative interpretation of the 2D NOESY/EXSY spectra was achieved for four compounds [PR_2 = $PMes_2$; PR'_2 = PPh_2 (**1**), DBP (**2**), PEt_2 (**3**), P(*o*-anisyl)$_2$ (**4**)]. It is found that the conformations that these compounds adopt in solution are similar to the ones observed for them in the solid state. The conformational ensemble in solution comprises λ twist and δ twist forms; λ and δ isomers are clearly differentiated by quantitative NOE-based structure analysis (distance geometry). Since the sense of chirality of the ligand is known, an absolute assignment of these conformations is possible. The equilibrium constants at 298 K for the δ ⇄ λ isomerisation of compounds **1**–**4** are not very different from one another, with reaction enthalpies ranging from −8 to −2 kJ mol^{-1} and the reaction entropies in the range of −10 to 8 J K^{-1} mol^{-1}. The activation barriers are again similar for **1**–**4** and lie at $\Delta H^{\neq} \approx 64$ kJ mol^{-1}. It is observed that the mesityl entities at the $PMes_2$ donor groups behave as coupled rotors with two rotational pathways open to them during the δ ⇄ λ interconversion while they are rotationally fixed in the λ and δ conformations themselves. Comparing the above results with the enantioselective discrimination found for the same compounds in hydrogenation experiments it becomes clear that there is no direct correlation between the preference of one twist form over the other in the precatalyst and its chiral performance.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Enantiopure chelate ligands play an important role in metal-mediated enantioselective catalyses. Amongst chelate ligands which contain a saturated carbon chain as a linker between the donor groups, the ones forming five-membered cycles have been found to be most effective.[1] These cycles have only one torsional degree of freedom as soon as three valence angles and five distances are defined, such that their conformational behaviour may easily be controlled, e.g. DIPAMP.[2,3] If larger chelate cycles have been found to be effective in enantioselective catalyses they almost inevitably contain unsaturated parts such that the number of independent coordinates of torsional freedom is still low due to the fixed conformation at the double bonds, e.g. BINAP.[4] In some other cases where the conformation of the chelate cycle is almost inflexible, by the nature of the covalent framework, enantiodiscrimination ensues from the chirality of substituent groups at the chelate cycle, e.g. PHOX.[5] It is not astonishing therefore that chelate ligands containing a saturated three-carbon chain as a linker between the donor groups have not been studied much as coligands in enantioselective catalyses. The six-membered cycles derived from them have an additional degree of torsional freedom with respect to five-membered cycles, once the six distances and four valence angles are defined.[6] Nevertheless, it has been found that six-membered diphosphane chelate cycles may be quite efficient in enantioselective catalyses.[7,8] Transfer of the chiral information from the chelate metal template to the substrates must then occur via the chirally induced preference of one of the chiral conformations of the chelate cycle over the others. If six-membered chelate cycles are generally found to be inefficient in enantioselective catalyses the reason for this might well be that the diastereoselection of one ring conformation over the others is less efficient in six-membered cycles as compared to the one in five-membered ones. Since quantitative information about the conformational enantiomerisation of phos-

phorus-containing six-membered chelate cycles is still missing, it appeared worthwhile to study such conformational enantiomerisation processes in more detail. In this paper we report on an NMR analysis of several compounds of the type $[\{\kappa\text{-}PR_2CH_2CH(OH)CH_2\text{-}\kappa\text{-}PR'_2\}Rh(\eta^4\text{-}COD)]^+PF_6^-$ which results in precise estimates of the thermodynamic and kinetic parameters which control the conformational inversion of their six-membered chelate cycles.

Results

The syntheses and catalytic properties of compounds **1**−**7** (Figure 1) are described in the literature.[8] The solid state structures of these compounds are well known with the exception of the structures of **3** and **7**.[8]

Figure 1. Compounds **1**−**7**[a]
[a] The formulae indicate the constitution of compounds **1**−**7** as well as the three basic types of conformations (λ twist, δ twist, chair) which characterise the folding of the six-membered chelate cycle as found by X-ray analyses of crystals of the compounds. [b] The items in this column refer to the chirality of the ligand used for preparing the crystal material to which the X-ray data refer and from which the solutions for NMR spectroscopic analyses were prepared. [c] In the original paper[8] the sense of chirality of **2** was erroneously assigned as (*S*).

The structures of these latter two compounds have been determined for the racemates of compounds **3** and **7**.[9] The spread of substitution patterns in **1**−**7** and the fact that two conformational isomers are generally observed for these compounds in NMR studies[8] appeared to warrant a detailed NMR analysis of their conformational behaviour. Since, in addition, the solid state structures of the compounds are known, dissolving the crystals at low temperatures should produce solutions that contain the compounds in the same conformation as pertinent to the crystal. These conformations might well be metastable in solution at low temperatures and might thus help assign NMR signals to individual conformations. In the following paragraphs the procedures of complete assignment of all the relevant NMR signals of **1**−**4** will be described first (*Assignment of the NMR Spectra of **1**−**4***).

An EXSY analysis of the exchange processes between different ring conformations is described next (*Dynamic Exchange Processes*).

The information obtained by dissolving crystalline samples of **1**−**7** at low temperatures is given in the following paragraph (*Results from Dissolving Crystals of **1**−**7** at Low Temperatures*).

The last paragraph deals with the quantitative (distance geometry) NOE structure analysis of **1**−**4** (*Quantitative NMR Structure Analysis*).

Assignment of the NMR Spectra of 1−4

The general procedure of the assignment is given here for **1**. The procedures used for assigning the NMR resonances of **2**−**4** are, mutatis mutandis, the same. A view of the λ and δ conformations of **1** as found in the crystal[8] is shown in Figure 2.

The scheme adopted for referencing individual nuclei is shown in Figure 3.

The equilibrium between the λ and δ forms, that is observed in solution necessarily exchanges the positions that the substituents of the chelate ligand occupy with respect to the chelate cycle (Figure 4).

Thus, the mesityl group that is in a pseudo-axial position in the λ isomer (Figure 4, left) will be in a pseudo-equatorial position when the λ conformation transforms into the δ isomer. The same type of exchange occurs not only for the PR_2 groups, but also for the CH_2 protons of the chelate cycle (Figure 4). Referring to Figure 4 it is clear that the labelling scheme has been chosen, such as to identify the protons of the chelate cycle in the λ isomer by an unprimed number and refer to the same protons in the δ isomer by a primed number. The pseudo-axial or pseudo-equatorial position of these protons may always be extracted by inspecting Figure 4. If necessary, the atom identifier has been additionally labelled by the suffix *ax* or *eq* respectively.

A solution of **1** in CD_2Cl_2 contains two isomeric forms of **1** in a ratio of approximately 5:1, at 298 K. This had already been inferred from ^{31}P NMR spectroscopy.[8] The assignment of the individual nuclei of these two isomers is based on a combination of one- and two-dimensional NMR techniques including ^1H-^{31}P HMBC,[10] ^1H-^{13}C HSQC,[11] ^1H-^{13}C HMBC,[10] ^1H-^1H DQF-COSY,[12] and ^1H-^1H NOESY/EXSY.[13] DQF-COSY spectra at 298 K show the signals referring to the two isomers in an intensity ratio of 5:1 and allow one to clearly separate the data referring to one or the other isomer.

^1H-^{31}P HMBC spectra show that the mesityl groups are bonded to P1 (strong correlations to all of the protons of the mesityl groups). The protons H31,35 and H37,41 (Figure 3) are strongly correlated with P2 and must thus be the *ortho*-protons of the phenyl groups at the PPh_2 entity. Their correlations with the *meta*- and *para*-protons of the respective phenyl groups are evident from the COSY data (Table 3). The same type of correlation is found for the minor isomer.

The ^{13}C NMR signals of **1** were assigned by their ^1H-^{13}C correlations using ^1H-^{13}C HSQC and ^1H-^{13}C HMBC techniques. So far the assignment cannot differentiate be-

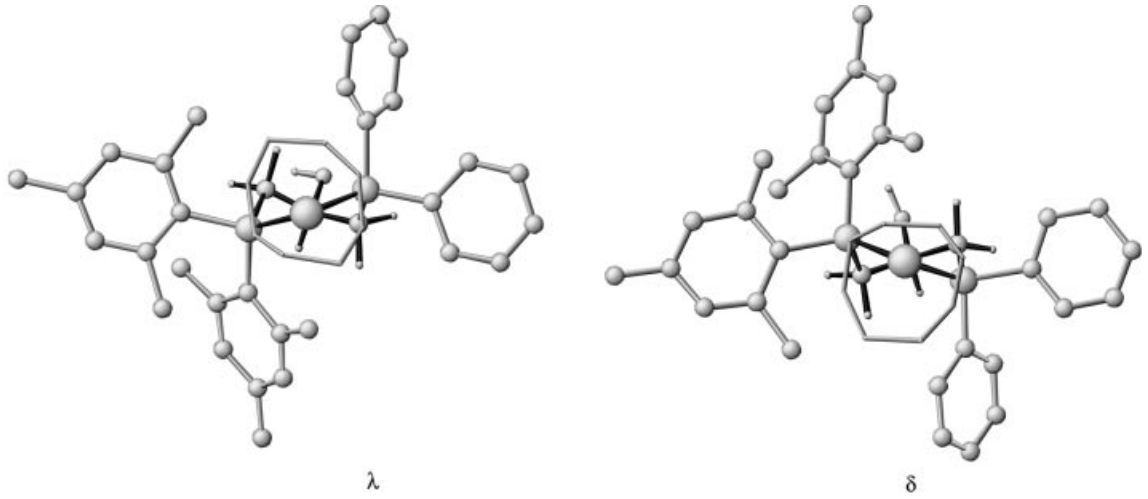

Figure 2. λ twist and δ twist isomers as found for independent constituents in the crystal of **1**; left-hand side: λ isomer; right-hand side: δ isomer; fFor the sake of clarity bonds to the carbon atoms of the COD ligands are not shown; hydrogen atoms are only shown for the chelate cycles

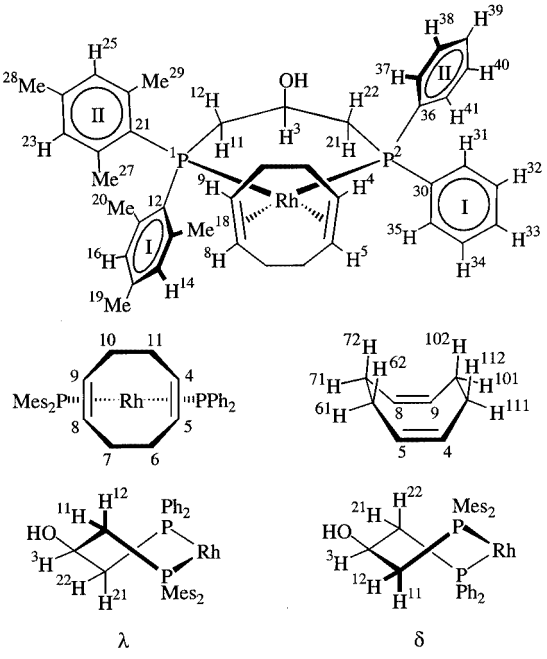

Figure 3. Labelling scheme used for **1**; the same numeric label as the hydrogen atoms to which they are bound, in general, designates the individual carbon atoms; carbon atoms belonging to the CH_2 groups of the COD ligand have labels which are numerically related to the labels used for the hydrogen atoms to which they are connected (e.g. C7−H71/H72, see figure); the carbon atoms of the three-carbon chain of the chelate ligand are numbered accordingly such that C1 binds to H11/H12, C2 to H21/H22, and C3 to H3; the labelling of the carbon atoms of the aryl groups is such that the carbon atoms have the same label as the respective protons; thus, C23 is bonded to H23, etc.; the carbon atoms are labelled with consecutive numbers around the cycles; the sense in which the numbers increase is evident from the labels assorted to the arene protons. The *ipso*-carbon atoms bonded to the phosphorus atoms have the lowest number in each case (C12, C21 for the mesityl groups; C30, C36 for the phenyl groups

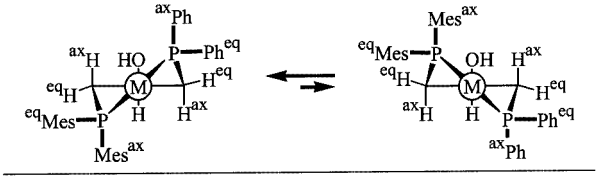

major isomer (λ)				minor isomer (δ)

H^{eq}	H22	Ph^{eq}	H31–H35	H^{ax}	H22′	Ph^{ax}	H31′–H35′
H^{ax}	H21	Ph^{ax}	H37–H41	H^{eq}	H21′	Ph^{eq}	H37′–H41′

Figure 4. Labelling scheme for the two conformational isomers of **1**; the labelling scheme was chosen such that it refers to the identity of the specific atoms; this means that a proton that may occupy a pseudo-axial position in one isomer may find itself in a pseudo-equatorial position in the other one; the NMR spectroscopic signals referring to this specific proton will therefore find themselves at two distinctly different positions; throughout the paper the convention is adopted to assign unprimed numbers to the protons of the λ isomer and use primed numbers for the ones of the δ isomer. The pseudo-axial or pseudo-equatorial position of a proton, be it primed or unprimed, may be unequivocally inferred from the figure as given; for the ease of reading, the suffixes *ax* and *eq* are added to the labels wherever confusion might arise

tween e.g. nuclei in pseudo-axial and pseudo-equatorial groups, i.e. between different positions relative to the conformation of the chelate cycle. This differentiation is possible by NOE spectroscopy. Taking the λ and δ conformations observed for **1** in the crystal (Figure 2) as the ruler for distance based arguments the observed NOE cross-peaks can be consistently assigned.

The major isomer is found to correspond to the λ form of the chelate cycle (see below). The results are easily interpreted with respect to Figure 2 (left-hand side) which shows the structure of the λ isomer as found in the crystal. Referring to this figure the qualifiers left, right, top, and bottom make definite sense. The NOE analysis allows one to discriminate between the positions of individual groups with respect to these qualifiers. There are chains of contacts that link the top and bottom half of the molecule. A link on the rear side of the molecule (Figure 2, left) between the left-

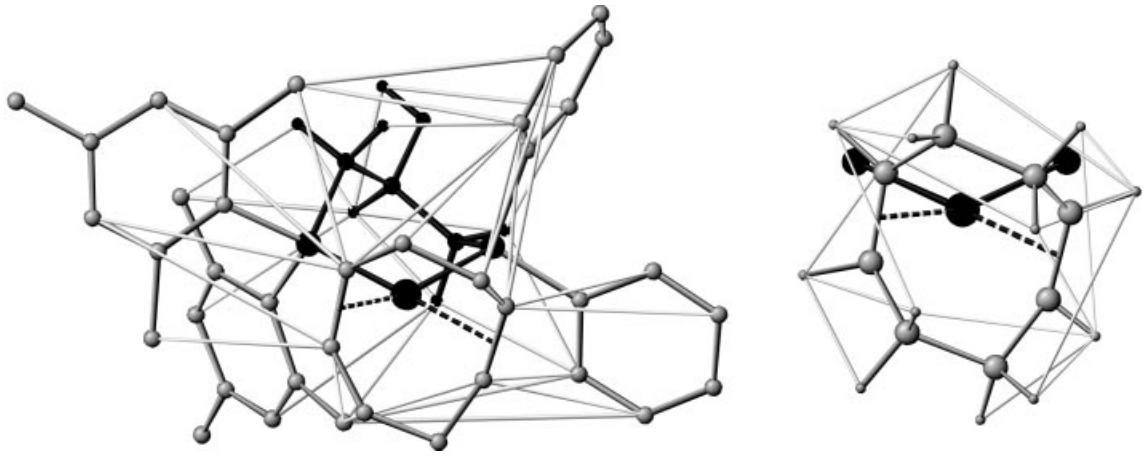

Figure 5. Scaffolding of NOE contacts characterising the λ twist conformer of **1**; NOE contacts are shown as light-grey shaded rods; right-hand side: conformationally relevant contacts within the COD coligand; left-hand side: contacts characterising the conformation of **1** as a whole (only a subset of observed contacts is shown; the full set is given in Table 8)

and the right-hand part of the molecule is formed by a number of contacts each of them involving the protons of the $CH_2-CH(OH)-CH_2$ linker (see above). On the front side of the molecule the left- and right-hand sides are also bridged by some interproton contacts (H18···H5, H18···H31,35; Figure 2 and 3). A tight scaffolding is therefore built up by the NOE contacts.

This scaffolding is shown in Figure 5 for the major isomer. The pertinent numeric information obtained by transforming NOE volume integrals into distances is given in Table 8. The NOE analysis of the minor isomer follows steps analogous to the ones used for the analysis of the major isomer. Due to the 1:5 ratio between the concentrations of the two isomers at the measuring temperature (298 K) a smaller number of contacts is observed. With the combination of methods described so far all the relevant ^1H-, ^{13}C-, and ^{31}P NMR signals of **1** can unequivocally be assigned (Table 3, 4, and 5). The details of the assignment of **1** are given in the Supporting Information.

Analogous procedures were used to assign individual nuclei in compounds **2**−**4**. The results pertaining to the assignment of **2**−**4** are shown in Table 5 and the Supporting Information.

Dynamic Exchange Processes

Dynamic exchange processes had already been found by variable-temperature 1D NMR spectroscopy for compounds of the type **1**−**7**.[8] To further elucidate these processes and to quantify activation barriers, 2D EXSY spectroscopy was applied to compounds **1**−**4**. Figure 6 shows parts of the 2D ^1H EXSY spectrum which characterises the dynamic exchange occurring for **1** in a CD_2Cl_2 solution at 298 K.

It is seen (Figure 6, left-hand side) that H3 exchanges with H3′; H11 is involved in a dynamic exchange process with H11′; H12 exchanges with H12′ and H22 is seen to exchange with H22′. It is clear from these observations that the shape of the chelate cycle switches between two conformations. With respect to the solid state structure of **1** which contains the λ and the δ isomers (Figure 2) the most

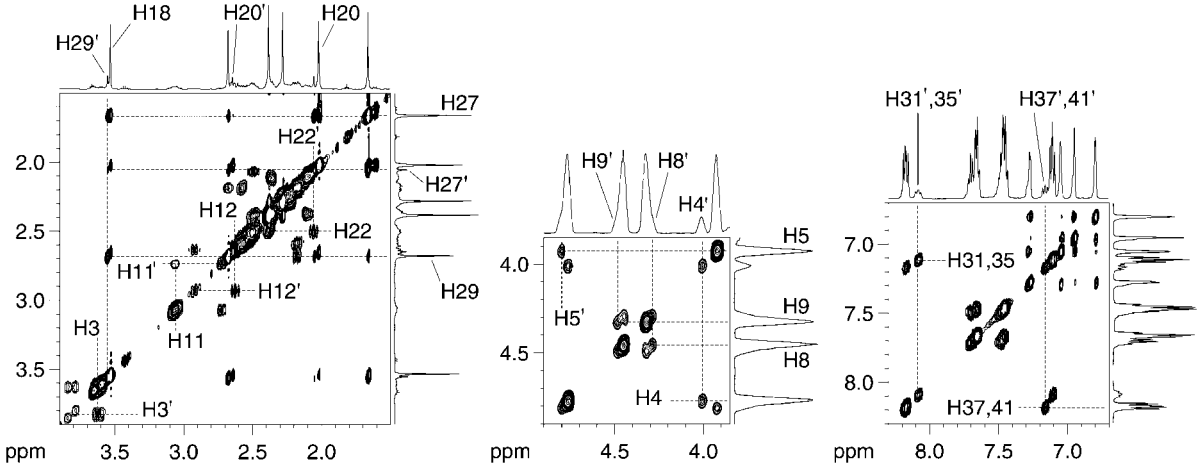

Figure 6. ^1H EXSY spectrum of **1** at 298 K; mixing time: 400 ms; all parts of the NOESY/EXSY spectrum of **1** are shown for which EXSY peaks can be observed; NOE peaks are suppressed in the figures shown

probable working hypothesis is to assume that the NMR observations pertain to the dynamic exchange between these two conformations (Figure 4). This hypothesis is proved by a series of further arguments including quantitative modelling of the conformations (see below). The part of the spectrum that characterises the dynamic behaviour of the COD coligand is shown in the center of Figure 6; H4 and H4′, as well as H5 and H5′, are in exchange with each other and so are H8/H8′ as well as H9/H9′. Exchange of the olefinic protons is hence only observed between protons at one and the same double bond. There is no cross-exchange between protons of the two different double bonds and any exchange process corresponding to a rotation of the COD coligand can therefore be ruled out. The observed process must then be due to an exchange of the surroundings of these olefinic protons such that, technically spoken, the COD coligand serves as a spectator ligand. Referring to Figure 2 it is seen that the position of the olefinic protons with respect to the PR_2 groups is just exchanged in the two isomers. In the course of the dynamic exchange between the two twist conformations (Figure 2) the substituents at the PR_2 groups must exchange their position with respect to their pseudo-axial or pseudo-equatorial positions. It is then expected that the phenyl *ortho*-protons H31,35 of one conformational isomer will exchange with the phenyl *ortho*-protons H31′,35′ of the other isomer (Figure 3 and 4). As Figure 6 (right-hand side) shows, this is in fact observed. The phenyl groups are free to rotate around their $P-C_{ipso}$ axes as is evident from the observation of just one signal for both *ortho*-protons of each of the phenyl groups. The mesityl groups on the other hand show well-separated sharp signals for each of their *ortho* and *meta* substituents in the one-dimensional ^1H NMR spectra. EXSY spectroscopy shows (Figure 6, left) that the exchange process includes an exchange of the mesityl groups as a whole. During this exchange process the mesityl groups are free to rotate since EXSY correlations are observed between H29′ and H29 as well as H27. The fact that each of the *ortho*-methyl groups at one mesityl group of one isomer is found to exchange with both of the *ortho*-methyl groups of the other mesityl residue in the other isomer, implies that at some stage of the isomerisation pathway the mesityl groups are free to rotate around their $P-C_{ipso}$ axes. As the corresponding exchange peaks are of different intensity, it follows that the probability of their rotation to either side is unequal. Some exchange is also observed between the *ortho*-methyl groups of the mesityl residues which is not accompanied by their switching between pseudo-axial and pseudo-equatorial positions, i.e. within one and the same isomer (Figure 6, left; H18/H20, H27′/H29′). This exchange process is again too slow to be apparent in the corresponding one-dimensional ^1H NMR spectra.

Quantitative analysis of the EXSY data (Exp. Sect.) reveals the dynamics of the system in quite some detail. The equilibrium $\delta \rightleftarrows \lambda$ has an equilibrium constant of $K = 4.7$ at 298 K. The rate constant determined for the conversion of the δ form into the λ form is $k_{\delta\rightarrow\lambda} = 1.8\ s^{-1}$, the reverse reaction shows $k_{\lambda\rightarrow\delta} = 0.4\ s^{-1}$ (Table 7). These rate constants have been derived from a whole series of ^1H-^1H EXSY experiments, with similar values stemming from ^{31}P-^{31}P EXSY spectra (see Exp. Sect.).

The transformation of the λ isomer into the δ isomer and the transformation of the δ isomer back into the λ isomer follows two different pathways with respect to the rotational motion of the mesityl groups. On both these pathways the mesityl groups are found to rotate in opposite directions around their $P-C_{ipso}$ axes. These motions are found to be strongly coupled (Figure 7).

Figure 7 illustrates the observed position of the respective methyl groups that ensues from the two different ways of $\lambda \rightleftarrows \delta$ transformation. The rotational pathway illustrated by the right-hand side of Figure 7 is deliberately assigned the label *D*. Pathway *D* refers to the clockwise rotation of the pseudo-equatorial mesityl group II around its $P-C_{ipso}$ axis that accompanies the $\lambda \rightleftarrows \delta$ transformation. EXSY analysis can of course not differentiate between a clockwise rotation of x degrees and a counter-clockwise rotation of $360 - x$ degrees. It can, however, clearly differentiate between the individual positions of the mesityl groups in the two isomers. The absolute positions are unequivocally established by NOE data and correspond to the ones shown in Figure 7. The left-hand side of Figure 7 illustrates the second pathway on which a $\lambda \rightleftarrows \delta$ isomerisation can occur. It is labelled *L* with respect to the counter-clockwise rotation of the pseudo-equatorial mesityl group II. EXSY data also demonstrate the strongly coupled and counter-sense rotation of the two mesityl groups on this second pathway. The probability of which pathway is taken is determined as $P_L = 0.8$ and $P_D = 0.2$ (the total probability that either of the two pathways will be taken during the transformation of the λ into the δ isomer ($\lambda \rightarrow \delta$) − and the reverse transformation ($\delta \rightarrow \lambda$) − is, of course, equal to 1). These probabilities are extracted from 2D ^1H EXSY measurements of the individual rate constants and are accurate to within 10% (Exp. Sect.).

Figure 8 illustrates the overall process. Starting from a λ isomer the two isoenergetic δ isomers, δ_L and δ_D, are formed. The only difference between these two forms is a 180° rotation of the mesityl groups around their $P-C_{ipso}$ axes.

The pathways shown in Figure 8 are illustrated with respect to the transformation of a λ into a δ isomer. During the back-transformation of a δ isomer into a λ one the same pathways are, of course, taken such that the δ_L as well as the δ_D isomer will again have the choice between two different pathways when transforming back into the λ conformation. The diagram in Figure 8 illustrates the reaction sequence $\lambda \rightarrow \delta \rightarrow \lambda$. The same arguments, as illustrated for this type of process, apply to the corresponding process starting from δ passing by λ and landing again at δ. In other words, if in the diagram every λ is replaced by a δ and every δ is replaced by a λ the corresponding probabilities remain unchanged. EXSY cross-peaks that refer to the pathways illustrated in Figure 8 are observed for $\lambda_{LD}/\lambda_{DL}$ as well as for the couple δ_{LD}/δ_{DL}. The two-step transformations from λ into λ_{LL} and λ_{DD} correspond to peaks on the diagonal and

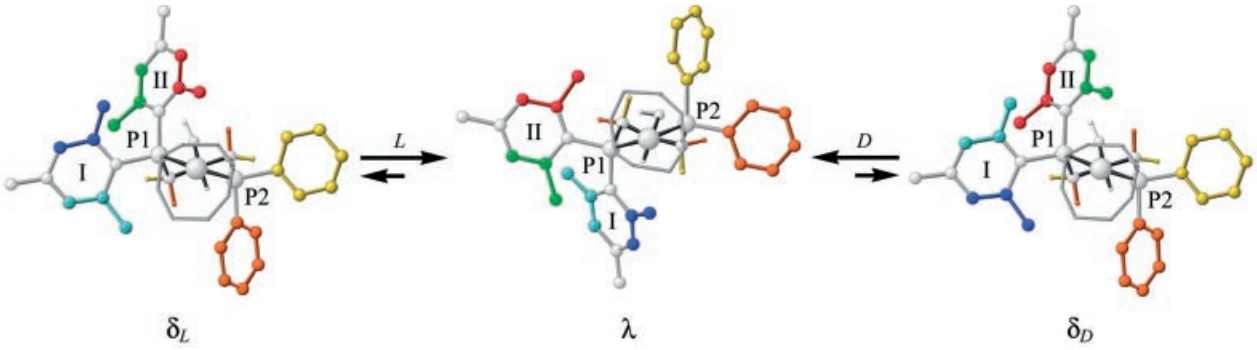

Figure 7. Coupling between λ ⇄ δ isomerisation and mesityl rotation; the rotation of the mesityl groups at a $PMes_2$ entity is strongly coupled; labels *L* and *D* for the pathways of the λ ⇄ δ isomerisation refer to the sense of this rotational process

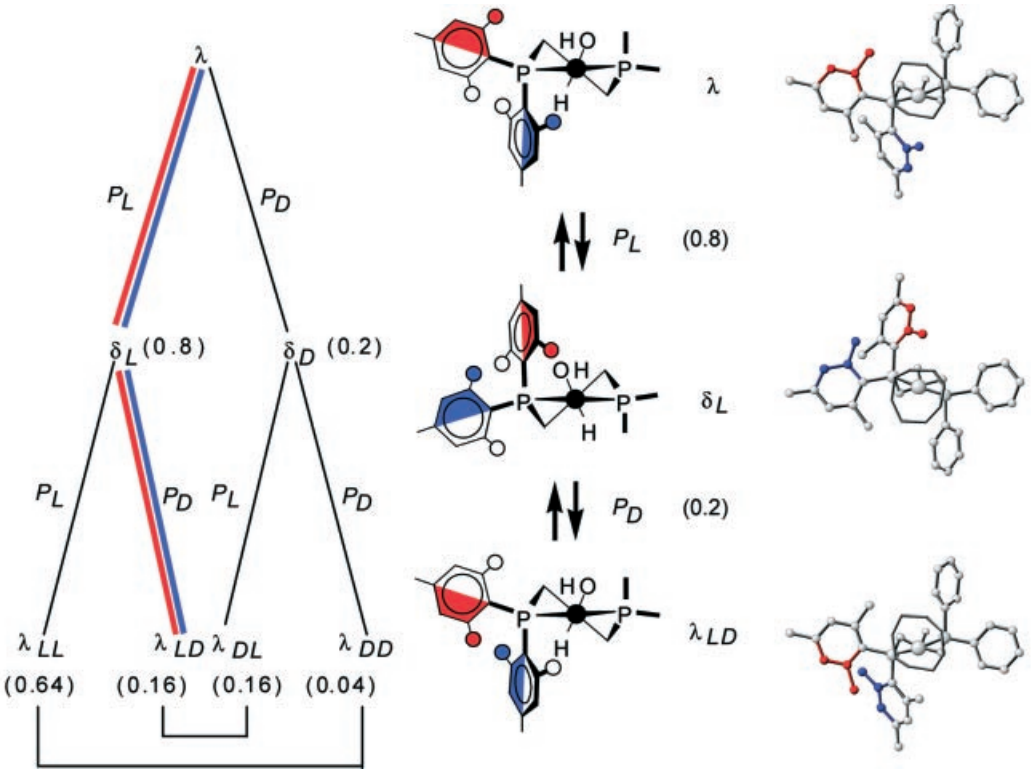

Figure 8. Probability of individual rotational motions of the mesityl groups during λ → δ/δ → λ isomerisation for **1**

are not seen directly. The fact that the couple $\lambda_{LD}/\lambda_{DL}$ can only ensue from λ by a sequence of two exchange steps is already clearly apparent from the time dependence of the corresponding 2D ^{1}H EXSY cross-peak intensity. If EXSY spectra are taken with different mixing times, single exchange processes are apparent by their nonzero slope at mixing time $\tau_m = 0$ s as well as by the linear dependence of the size of the corresponding integrals on mixing time over a range of short mixing times. Double exchange processes are, on the other hand, characterised by a zero slope at mixing time $\tau_m = 0$ s. The dependence of the corresponding integrals on time is close to parabolic instead of linear. The EXSY signals corresponding to the two-step processes $\lambda_{LD}/\lambda_{DL}$ and δ_{LD}/δ_{DL} show this parabolic dependence and zero slope at $\tau_m = 0$ s. The time dependence of the corresponding signals is correctly reproduced by the rate constants and reaction probabilities which were derived from the analysis of single-step processes (Table 7, Exp. Sect.).

With respect to the conformation of the $PMes_2$ group both pathways *D* and *L* involve a one-ring flip process.[14] This process is illustrated in Figure 9. The top half of this figure sketches the rotational reorientation undergone by the mesityl groups during a λ ⇄ δ isomerisation process following pathway *L* (major pathway). The bottom half correspondingly refers to pathway *D* (minor pathway). The diagrams show snapshots of these transformations. These snapshots have been obtained by a linear interpolation of the Rh−P−C_{ipso}−C_{ortho} torsion angles between their values in the λ and the δ isomers (X-ray structures taken as a basis). The graphs were obtained by orienting the $PMes_2$ group as a whole such that the pseudo-axial mesityl groups of the λ and δ isomers are close to vertical with the interme-

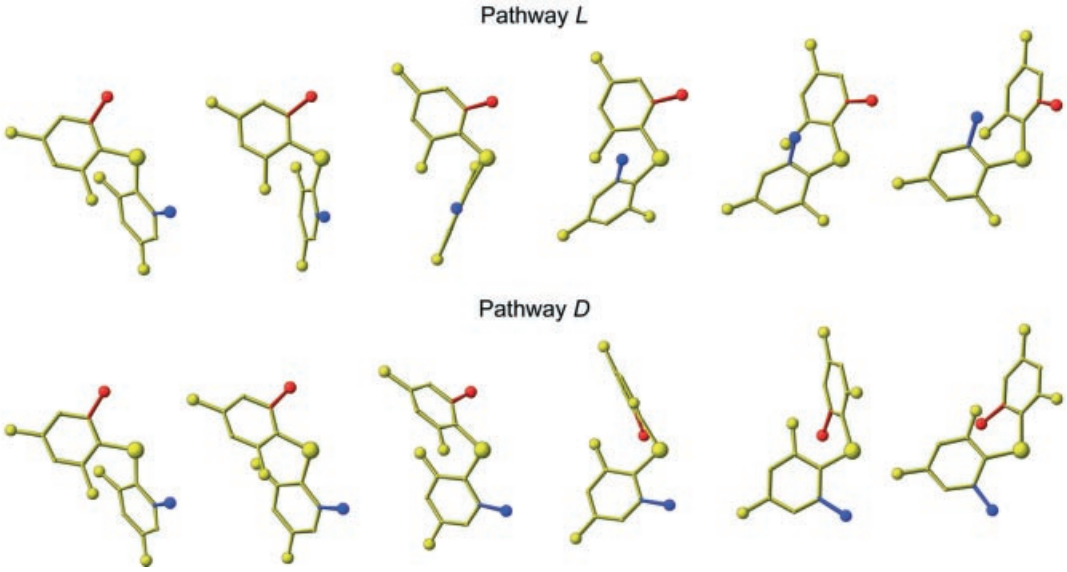

Figure 9. Illustration of the one-ring flip processes accompanying the λ ⇄ δ isomerisation for **1**; the labels *D* and *L* refer to the rotational pathways as illustrated in Figure 7

diate rotational positions again obtained by linear interpolation. The direction of view taken stays constant throughout Figure 9 and corresponds to a view along the pseudo-C_2 axis of the chelate framework. The sketches thus obtained are not to be taken as snapshots along the minimum energy pathway but they serve well to illustrate the fact that, whatever the real pathway looks like, it has to incorporate a one-ring flip process in each case.

The conformational isomerisation of **1** may thus be described as follows: δ and λ isomers interchange with one another with different rate constants (Table 7), with the λ isomer being the more stable one. The exchange process follows two different pathways with respect to the motion taken by the mesityl groups at the $PMes_2$ entity (Figure 9). There are two different types of motions both of which are such that the rotation of one mesityl group is strictly coupled to the rotation of the other mesityl group in each case (Figure 9). The barriers which correspond to these different pathways differ by approximately 4 kJ mol^{-1} at 298 K.

The same type of procedure as explicitly described for **1** was applied to compounds **2**−**4**. The corresponding data are given in the Exp. Sect. In the solid state **2** exists as just one conformational isomer [δ twist, (*R*) ligand; Figure 1].[15] For the purpose of further discussion, the argument is based on the (*S*) enantiomer of the ligand. The crystal structure of this isomer would of course correspond to the λ form (since the NMR experiments conducted are such that they do not differentiate between enantiomers in an absolute sense, this shift of reference frame has no further physical consequence; it is, however, indicated by the quest for a uniform illustration). NMR spectra show that two isomeric forms of **2** equilibrate with each other in solution. NMR structure analysis (see below, Exp. Sect.) proves that these two isomers are the λ and δ forms of the compound. At room temperature the λ isomer is the more stable one (K_{298} = 6.8). The activation barrier for the δ → λ transition amounts to $\Delta G^{\neq}_{298}$ = 68.1 kJ mol^{-1}; the barrier for the reverse transition is $\Delta G^{\neq}_{298}$ = 72.7 kJ mol^{-1} (Table 7). The process of δ ⇄ λ isomerisation is again coupled with a one-ring flip transition at the $PMes_2$ group. The process is as described for **1** and illustrated in Figure 7−9 for the case of **1**. The preference of one pathway over the other (*L* over *D*, Figure 7 and 8) is the same as observed for **1** with the relative probabilities of P_L and P_D amounting to 0.9 and 0.1.

The structure of compound **3** (Figure 1) has been determined for a crystal of the racemic compound.[9] In the solid state **3** exists as a 1:1 mixture of λ and δ forms. For the sake of a homogeneous description of the results, the arguments in this paper are based on the (*S*) enantiomer of the ligand; λ and δ isomers are clearly apparent in the NMR spectra of **3**. NMR structure analysis (see below and Exp. Sect.) shows that the λ isomer is the more stable one (K_{298} = 5.9). The barrier for the δ → λ transition is $\Delta G^{\neq}_{298}$ = 73.0 kJ mol^{-1}, and the barrier for the reverse process is $\Delta G^{\neq}_{298}$ = 77.4 kJ mol^{-1} (Table 7). As already observed for **1** and **2**, two different one-ring flip transitions are encountered along the isomerisation pathway. With respect to the illustrations given for **1** (Figure 7−9) the pathway labelled *L* is only slightly preferred over pathway *D* (P_L = 0.6, P_D = 0.4) in the case of **3**.

Compound **4** (Figure 1) exists as a 1:1 mixture of λ and δ isomers in the solid state.[8] The two isomers are also present in solution with a preference of 3:1 of the λ isomer over the δ isomer at 298 K. The activation barriers are $\Delta G^{\neq}_{298}$ = 71.6 kJ mol^{-1} for the δ → λ process and $\Delta G^{\neq}_{298}$ = 74.5 kJ mol^{-1} for the reverse transition (Table 7). With the ligand of **4** containing a $P(o\text{-anisyl})_2$ and a $P(mesityl)_2$ group different rotational orientations of the aryl groups at the PR_2 entities might in principle be apparent for both of the PR_2 groups. EXSY spectra indicate that there is also some exchange with respect to a rotation of the anisyl

groups. The corresponding EXSY peaks are an order of magnitude smaller than the ones referring to the analogous rotation of the mesityl groups. The smallness of the corresponding exchange peaks and their partial overlap with other signals excludes the quantitative analysis of this exchange. If these minor peaks are ignored and the exchange referring to the anisyl groups is correspondingly modelled as a two-site exchange process (Exp. Sect.) the resulting rate constants agree with the overall rates for the $\delta \rightleftarrows \lambda$ isomerisation process within the limits of error (Table 7). The individual probabilities for the pathways *L* and *D* are found to be $P_L = P_D = 0.5$.

Results from Dissolving Crystals of 1−7 at Low Temperatures

Crystals of **1**−**7** have been found to contain either just one conformational isomer (**2**: twist; **6**, **7**: chair) or two of them in equal amounts (**1**, **3**, **4**, **5**: λ, δ twist). If the activation barriers for the conformational isomerisation are high enough, dissolution of the crystals at low temperature should produce metastable solutions which would in the optimal case contain the conformational isomers in the same ratio as they are present in the crystals. This way an independent assignment of conformations could thus be possible. Another benefit of this type of experiment is that the rate constants of the processes as well as their dependence on temperature could be obtained in independent experiments. ^{31}P NMR spectroscopy was used as the experimental tool throughout.

As crystals of **1** contain a 1:1 mixture of λ and δ isomers, dissolution of these crystals at low temperatures is expected to produce a solution that contains the two isomers in a 1:1 ratio. The activation barriers for the $\delta \rightarrow \lambda$ and $\lambda \rightarrow \delta$ isomerisation have already been found to be above 70 kJ mol^{-1} (see above) such that at the lowest feasible temperature using CD_2Cl_2 as a solvent, isomerisation should be very slow. It is in fact observed that between 175 and 200 K the ratio with which the λ and δ isomers are contained in the solution is 1:1 [Figure 10; $\ln(c_\lambda/c_\delta) = 0$]. Above this temperature an increase of the concentration of one isomer over the other is observed. This increase upon warming the solution is observed in the temperature range between 200 and 230 K (Figure 10). From then on by rising the temperature further the isomer ratio follows an opposite trend. This behaviour is shown in Figure 10 in an $\ln(c_\lambda/c_\delta)$ vs. T^{-1} diagram.

The linear slope of the curve above 230 K indicates that an equilibrium between the two species is established at every measuring point. At the same time it is clear that the appearance of the sigmoidal curve as the temperature increases between 200 and 230 K relates to the fact that an equilibrium cannot be reached in this temperature interval within the time allotted to the experiment (ca. 3 h). The same conclusion is reached by cooling the solution from about 300 to 170 K. In the range of 300 to 230 K the slope of the $\ln(c_\lambda/c_\delta)$ vs. T^{-1} curve is linear, as was already found

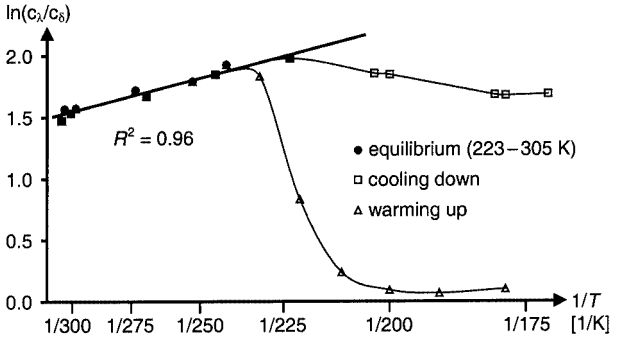

Figure 10. Isomeric ratio of **1**; the sigmoidal curve in the plot refers to ratios observed after dissolving crystals of **1** at low temperature and gradually warming these solutions (triangles); the points along the bold-face line correspond to experiments where thermal equilibrium has been reached; the open squares correspond to situations for which during cooling down equilibrium conditions could not be met; the abscissa is scaled as 1/*T*, the ordinate has a logarithmic scale

in the experiment where the temperature was increased from 230 to 300 K (Figure 10). From about 220 K on the measured ratios no longer follow the straight line but tend to level out at a value of $\ln(c_\lambda/c_\delta)$ of around 1.7 (c_λ/c_δ = 5.4). This behaviour must be due to the fact that at temperatures below 220 K equilibrium can no longer be achieved within the time given. From the slope of the straight line part of the diagram the ΔH and ΔS values relating to ΔG may be extracted; ΔS is found to be close to zero (ΔS = 1.7 J K^{-1} mol^{-1}) and ΔH amounts to −3.4 kJ mol^{-1} (Table 1).

Some information about the kinetics of the process is obtained by monitoring the time dependence of the concentration ratio c_λ/c_δ at low temperatures during the warming up experiment. From the equilibrium constant it is known that the rate constant of the forward process $\delta \rightarrow \lambda$ is about ten times larger than the rate constant referring to the back reaction. At low temperatures the mixture is far from equilibrium and the concentrations of both isomers are about equal. Evaluation of the time dependence of the c_λ/c_δ ratio at intervening temperatures leads to rate constants at these temperatures (see Exp. Sect.) such that the activation parameters for $\delta \rightleftarrows \lambda$ interconversion may be estimated (Table 1); $\delta \rightarrow \lambda$ isomerisation corresponds to $\Delta H^{\neq}$ = 60.5 kJ mol^{-1}, $\Delta S^{\neq} = -37$ J K^{-1} mol^{-1}, with the reverse reaction being characterised by $\Delta H^{\neq}$ = 64.4 kJ mol^{-1}, $\Delta S^{\neq} = -36$ J K^{-1} mol^{-1} (Table 1).

Similar experiments have been performed for compounds **2**−**7** (see Supporting Information) leading to estimates of thermodynamic and kinetic parameters as given in Table 1.

Quantitative NMR Spectroscopic Structure Analysis

While all NMR spectroscopic data show that compounds **1**−**7** exist as mixtures of two conformational isomers in solution, it is not clear from the beginning which conformation corresponds to which isomer. In the case of **2** the experiments referring to the dissolution of a crystalline

sample of **2** at low temperatures (see preceding paragraph) could decide between the λ and δ forms of this compound and an absolute assignment was thus possible.

As a general tool to assign definite conformations to the different isomers, distance geometry (DG) methods were applied to compounds **1**−**4**. Based on the ^{1}H NOE data (Table 8, Figure 5) restraints on interproton distances were defined in each case. The initial structural models were chosen as the λ and δ conformations, the structure of which is basically known from X-ray data. It was found that the results obtained were quite independent of whether those starting conformations were taken as the X-ray determined conformations themselves or as the appropriate conformations as modelled by the ESFF force field.[16] It was also found that when starting from a modelled chair conformation, which is quite improbable on the basis of the X-ray results, the final distance geometry determined conformations were the same as the ones reached from the other starting points. For the final calculations the X-ray determined models were used as the starting point. These calculations were performed for the major and for the minor isomer in each case. For each of the two conformational isomers observed in solution for compounds **1**−**4** both λ and δ twist conformations were chosen as the starting points.

For distance geometry refinement different strategies can be applied dependent on the amount of variation allowed to the NOE-derived restraints. With weak restraints, corresponding to a large amount of variation being permitted, λ and δ forms can interchange into one another. In order to discriminate between the two principle possibilities the resulting optimised conformations have to be sorted into λ and δ classes after refinement. The calculated NOE distances for these refined structures may then be compared with the experimental ones in order to decide whether λ or δ gives the better fit. Another strategy that was applied throughout for the calculations reported here consists of using strong NOE restraints, i.e. variations allowed only to within ±5% with respect to the NOE determined distances. With this strategy λ and δ forms cannot change into one another such that two sets of optimised structures are finally obtained, one exclusively containing conformations with a λ twist and the other one with only δ conformations. In the case of the major isomer it was observed for all compounds **1**−**4** that the rms values as calculated by the error function of the DG programme[17,18c,29a] were about one order of magnitude different for the two classes. The class relating to the lower rms values should then be the one to which the isomer belongs. Different types of qualifiers may be used to ascertain this decision (Exp. Sect.). All of them unequivocally lead to the same result, i.e. the λ isomer is the more stable one throughout (Exp. Sect., Table 8, 9). This result shows the power of distance geometry methods in assigning conformations. There is only one proton (H3;

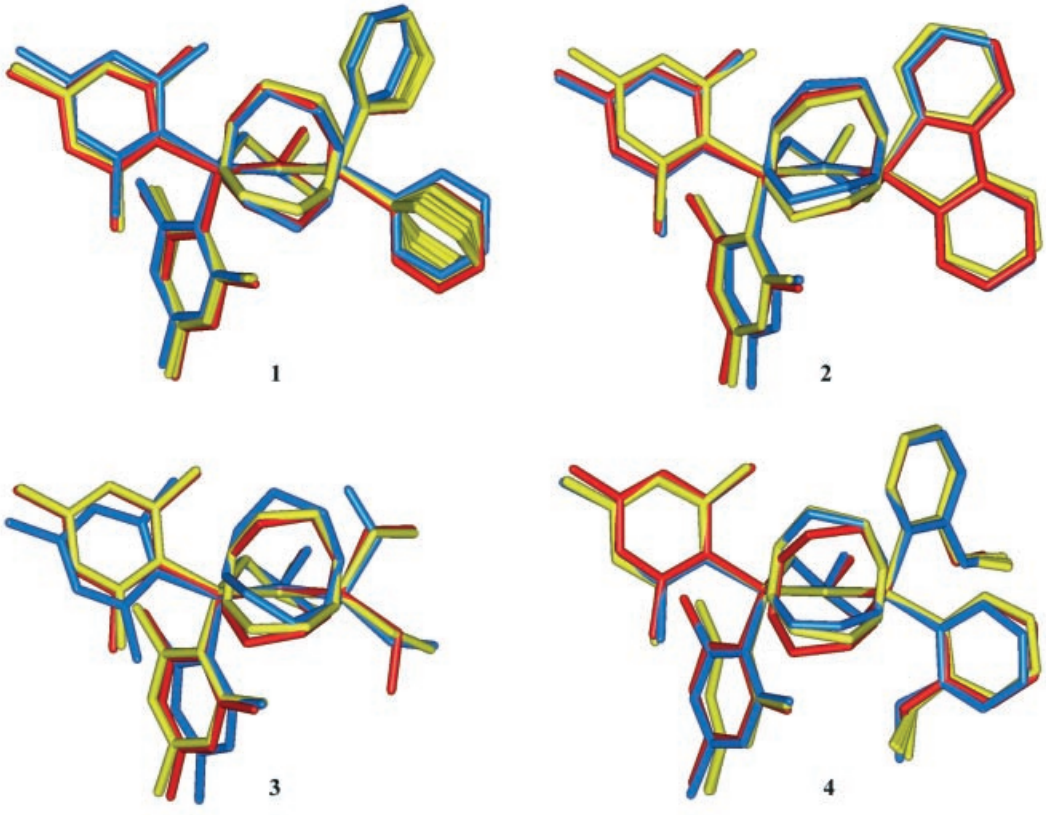

Figure 11. Overlay of the conformations of **1**−**4** (λ twist form) as inferred by different techniques; colour code: blue: X-ray structure; red: optimal single conformation as derived from force field refinement; yellow: DG-derived conformations

Figure 2 and 3 and 5), the proton at the chiral carbon atom, that directly pinpoints to λ and δ conformations. A sufficient number of NOE contacts involving H3 could be determined for each of the compounds **1**−**4** for the major isomer, and these contacts are most important in differentiating between λ and δ forms. For the minor isomer only a smaller number of contacts was experimentally accessible in each case. Nevertheless, applying the same procedure as described for the major isomer did not lead to any contradiction of the conclusive results obtained for the major isomer in each case. Whenever the major isomer was found to have a λ conformation, as was the case for each of the compounds **1**−**4**, the set of solutions obtained for the minor isomer by distance geometry refinement had a better fit for the models with δ conformation than for the ones with λ conformation (Exp. Sect., Table 9). This means that even with the small number of NOE contacts found for the minor isomer in each case, distance geometry methods are able to differentiate between λ and δ forms of the chelate cycle.

It is found throughout (Figure 11) that the average structure in solution conforms nicely to the structure in the solid state. This is shown in Figure 11 for all compounds **1**−**4** for the major isomer. The scatter of conformations as inferred from the results of DG runs is also shown in Figure 11.

It is seen that the only parts that are rotationally flexible to a higher or lesser degree, are the phenyl residues (**1**), the ethyl groups (**3**), and the methoxy groups (**4**). It is also seen that the conformations of **2** containing the DBP residue show no scatter at all. The graphs in Figure 11 also show a comparison with the structure of the least-energy model obtained in each case by force field refinement. Again, the difference between the solid state conformations and the force field calculated conformations is quite small in all cases; all three models, X-ray, DG refinement, and force field refinement are almost exactly congruent for **2** which means that due to steric repulsions and the fixed geometry of the DBP group this conformation finds itself in a minimum of the corresponding energy hypersurface which has steep ascents in all directions.

Discussion

An important result of this study is that it is found that structures determined by X-ray methods in the solid state and structures characterising the ensembles of molecules in solution are congruent within the limits of error. This gives much credit to the application of NMR spectroscopic structure analysis − which has been so successful in protein structure assignment[18] − also with small molecules. Even if the number of discriminative NOE contacts is much smaller in small molecules than it is in proteins (due to the fact that amino acids, which are far apart in a sequence,

[a] The estimated standard deviation in units of the least significant digit is given in parentheses. [b] The signs of the thermodynamic parameters refer to the process minor isomer ⇄ major isomer. [c] Values refer to Eyring plots which were based on the rate constants measured at higher temperatures by EXSY methods (Table 7) and rate constants determined under nonequilibrium conditions (**1**: T [K], $k_{\delta\rightarrow\lambda}$ [s^{-1}], $k_{\lambda\rightarrow\delta}$ [s^{-1}]: 221, 2.4·10^{-4}, 0.3·10^{-4}; 232, 1.8·10^{-3}, 0.3·10^{-3}; **3**: T [K], $k_{\delta\rightarrow\lambda}$ [s^{-1}], $k_{\lambda\rightarrow\delta}$ [s^{-1}]: 212, 1.3·10^{-5}, 0.2·10^{-5}; 224, 7.1·10^{-5}, 1.0·10^{-5}; 235, 5.2·10^{-4}, 0.8·10^{-4}). The $\Delta G^{\neq}_{298}$ values thus calculated are in close agreement to the ones determined from EXSY measurements alone. [d] A: minor isomer, B: major isomer; the exact geometry in solution has not been determined. For the solid state structures see Figure 1. [e] Activation parameters refer to Eyring plots based on rate constants determined by line shape analysis of ^{31}P NMR spectra.

may be in close contact to each other due to the folding of the proteins while constituents of a small molecule which are separated by a far smaller number of intervening atom−atom distances are rarely found to be in close contact to each other) this small number of contacts is still sufficient to determine the structure of small molecules as well.

The refinement of structural models as developed by DG methods has to make use of force field calculations. It appears that the general ESFF force field[16] is well parameterised for this purpose as seen by refining the X-ray derived models by these methods. Almost negligible changes of the conformations are observed in this case. It is also satisfying to note that the energy differences between the λ and δ isomers as calculated by the force field approach in each case are in the same order of magnitude as the ones which have been experimentally determined (Table 1). The calculated energy differences are $\Delta E = E_\lambda - E_\delta = 2.1$, -0.2, 6.1, and -2.5 kJ mol^{-1} in the series of compounds **1**−**4**. Comparison with the experimental ΔH values in Table 1, shows that the calculated values do not correctly predict which of the two forms is the more stable one nor do they rank the compounds correctly with respect to these energy differences. Since force field methods have been found to be quite appropriate for the calculation of such small energy differences in the stereochemistry of organic ring compounds[19] it is evident that it is not the force field method in itself which leads to wrong results in the case of **1**−**4** but that the parameterisation of these methods is not yet good enough for metal-containing compounds.

As far as the energy differences between the two conformers are concerned they are found to be in a small range for all compounds **1**−**7**. It is seen that the larger the steric discrimination between the two different PR_2 groups is [$PMes_2/PEt_2$ (**3**), $PMes_2/PPh_2$ (**1**), $PMes_2/P(o\text{-anisyl})_2$ (**4**)] the more the equilibrium will lie on the side of the λ twist form (Table 1). The λ twist form is even more preferred by **2** with its $PMes_2$ substituent on one side and a dibenzophospholyl group on the other side. The rigidity of the DBP residue obviously causes less interference within the molecule than even a PEt_2 group (Table 1). The almost 1:1 equilibrium between the two forms of **5** [$P(o\text{-anisyl})_2/PMes_2$] indicates that the steric influence of these two groups onto the chelate cycle is not greatly different. For compounds **6** and **7** [$P(o\text{-Tol})_2/PPh_2$ (**6**), $P(o\text{-Tol})_2/PEt_2$ (**7**)] the lesser steric demand of PEt_2 in comparison to PPh_2 again mirrors itself in the equilibrium constants with the equilibrium referring to **7** being more biased ($K = 2.7$) than the one referring to **6** ($K = 1.6$). Due to the differences in the entropic terms the ΔG_{298} values show a smaller difference amongst the series of compounds than do the ΔH values such that the equilibrium constants K_{298} are in the narrow range of 1.2−6.3.

Throughout the series of compounds **1**−**4** the λ isomer is the more stable one. The reason for this is intuitively clear from looking at the structural models (Figure 11) where it is seen that the C−O bond at the central carbon atom of the ligand is tilted such as to orient it away from the mesityl side of the compounds, i.e. away from the bulkier of the two PR_2 groups (Figure 11).

The activation barriers are higher than those normally found in saturated organic ring compounds (ca. 30 kJ mol^{-1} higher than in cyclohexane).[20] The activation entropies are definitely negative for the two compounds for which they could be determined (**1**, **3**). This indicates that sterically highly crowded situations are met along the transition pathway.

For all compounds **1**−**7** data about the efficiency in catalysing the enantioselective hydrogenation of (*Z*)-2-acetamidocinnamic acid are available.[8] No direct correlation between the reported *ee* values[8] and any of the thermodynamic and kinetic data reported in this paper is apparent. Thus, it has been found that compound **5** is the most enantiodiscriminating catalyst leading to *ee* values of the hydrogenation product of up to 85% *ee*[8] while the two isomers of this compound are present in a close to 1:1 ratio at the temperature of catalysis (298 K). Compounds **1** and **2** which show a strong predominance of the λ conformation (Table 1) produce *ee* values of only 40−60%.[8] Compound **6**, for which both conformations have equal enthalpies (Table 1) and for which the major/minor equilibrium is close to 1:1, yields the hydrogenation product with around 50% *ee*.[8] It is thus clear that the thermodynamic equilibrium of the λ and δ forms of the precatalyst has no direct bearing on the chirality of the transition state of the hydrogenation reaction. Table 1 and the data published on the catalytic activity of **1**−**7**[8] allow for the following hypothesis. Since both compounds **6** and **7** have a chair conformation in the solid state and are at the same time least efficient in enantiodiscrimination it appears probable that twist conformations are a prerequisite for an efficient enantioselective catalyst. Compounds **1**−**5** show twist conformations in their solid state structures. For compounds **1**−**4** the persistence of twist conformations in solution is proved in this paper. For compound **5** this persistence is not proven by NMR spectroscopic analysis but highly probable. Compound **5** is the most efficient enantioselective catalyst amongst compounds **1**−**5**. On the other hand **5** is a compound where the two forms (presumably λ and δ twist) are of almost equal stability (Table 1). A high degree of enantioselectivity as found for **5** can therefore not ensue from the predominance of one of the two chiral forms of **5** over the other. Enantiodiscrimination must then be due to an induced fit between the prochiral substrate and the chiral coordination scaffolding.[21] For this type of fit, as induced by the substrate, consisting of switching from λ to δ twist conformations or vice versa, it is seen from Table 1 that amongst the enantiodiscriminating catalysts **1**−**5** compound **5** is the one with the lowest activation barrier for this switching process. It may then be argued that a prerequisite for an efficient enantiodiscriminating catalyst is the intrinsic stability of its λ and δ twist forms as well as a low barrier for the transformation between these forms such that a prochiral substrate may easily induce the appropriate fit.

Conclusion

Compounds $[\{\kappa\text{-}PR_2CH_2CH(OH)CH_2\text{-}\kappa\text{-}PR'_2\}Rh(\eta^4\text{-}COD)]^+PF_6^-$ exist as λ and δ conformers when at least one of their PR_2 groups is a $PMes_2$ entity. As shown by quantitative NMR spectroscopic structure analysis their conformations in solution correspond to the conformations adopted by them in the solid state. From the two conformations the one which is preferred is that which keeps the central C−O bond of the chelate ligand away from the mesityl side. The experimentally determined difference between the enthalpy of the two isomers is found to lie within a few kJ mol^{-1} with ΔS values in the range of ± 10 J K^{-1} mol^{-1}. The free energies of activation for the conformational changes (δ → λ and λ → δ) are around 70 kJ mol^{-1}. Negative activation entropies indicate the steric strain along the reaction pathway. The mesityl groups at the $PMes_2$ entity behave as coupled rotors, their rotation is only possible in the transformation between λ and δ forms. Due to the chirality of the compounds the probabilities with which rotation in either sense will occur are not generally equal. The rotational pathways taken correspond to one-ring flip processes in each case. The precise thermodynamic data worked out in this paper may serve as criteria to evaluate force field models that describe the compounds in the sense of a mechanical molecular machine.[22]

Experimental Section

General Remarks: Bruker instruments of the type DPX200 operating at 200.13 (^{1}H), 81.014 MHz (^{31}P), DRX300 at 300.13 MHz (^{1}H), 75.468 (^{13}C), 121.495 MHz (^{31}P), and DRX500 at 500.13 (^{1}H), 125.758 (^{13}C), 202.456 MHz (^{31}P) were used throughout. Chemical shifts are given in ppm with respect to CD_2Cl_2 (^{1}H: δ = 5.32 ppm; ^{13}C: δ = 53.5 ppm) as internal standard. ^{31}P chemical shifts are expressed in ppm with respect to an aqueous solution of H_3PO_4 (85%) as external standard. All measurements were performed on samples dissolved in CD_2Cl_2 under argon in sealed NMR tubes. The dissolution of crystalline material at low temperature was performed as follows: NMR tubes were fixed to a vacuum line. The crystalline sample was introduced into the tube under argon and the tube was immersed into a liquid N_2 bath. CD_2Cl_2 was condensed onto it and the tube was sealed. The solid material (sample and CD_2Cl_2) was allowed to warm up to 160 K and transferred at this temperature into the NMR probehead. The temperature of the probehead was gradually increased until the shape of the ^{31}P NMR resonances showed that the sample had completely dissolved. The temperature was calibrated using [D_4]methanol (99.8%) and ethylene glycol samples.[23]

Measurement Techniques and Assignment: Standard pulse sequences were applied throughout. The acronyms given in Table 2 refer to the standard Bruker pulse sequence library. By a combination of 1D and 2D NMR spectroscopic experiments (Table 2) unequivocal assignment of the NMR resonances of the two isomers was possible for **1**−**4**. NMR spectroscopic data referring to **1** are shown in Table 3 and 4. NMR spectroscopic data for **2**−**4** are available as Supporting Information. For compounds **5**−**7** analysis was based on ^{31}P NMR spectra alone. The complete set of ^{31}P NMR spectroscopic assignments for **1**−**7** is given in Table 5. The peak volumes of 2D NMR spectra were measured by the volume integration algorithm supplied with the FELIX NMR spectroscopic processing software package.[24] 2D ^{1}H NOESY/EXSY data were collected with different mixing times (see Table 2) at 298 K throughout. For the purpose of quantitative interpretation of the ^{1}H NOE data the initial rate approximation was chosen.[25] The dependence of the peak volumes on mixing time was first analysed by the inspection of the corresponding graphs (Figure 12, right). Based on this inspection it was decided how many measuring points should be included for obtaining the slope in a linear fit. The peaks above and below the diagonal were analysed separately. Further evaluation was based on the one of the two graphs that showed the larger slope. In general the volume of the corresponding peaks above and below the diagonal were in good agreement (Figure 12, right).^{1}H EXSY peaks were evaluated by the same type of procedure (Figure 12, center), where the average of the volume integrals of the peaks above and below the diagonal, was used. To evaluate the rate constants the slope based on the values obtained for a mixing time of $\tau_m = 50$ ms was used throughout, since it was found that internal consistency of the rate data decreases if longer mixing times within the "linear" first part of the curve (Figure 12, center) are incorporated in calculating the slope. The volume integrals of the diagonal peaks showed the expected continuous decrease with increasing mixing time as seen from the curves in Figure 12 (left). A single exponential fit (solid line) is not completely appropriate especially at short mixing times. It was decided therefore to use the two integrals corresponding to the shortest and the next shortest mixing times (Figure 12, left) in a linear extrapolation in order to estimate the integral value at mixing time $\tau_m = 0$ s. 2D ^{31}P EXSY data were collected with mixing times of 100−600 ms at 298, 300, and 305 K. Volume integrals collected with mixing times of up to 400 ms were found to be far enough away from saturation such as to allow kinetic data to be extracted from them.

Coupling Constants: Since the experiments on **1**−**4** make it clear that the major isomer corresponds to the λ twist conformation of the chelate ring in each case and since the structure of the twist conformations is known from X-ray analysis as well as from modelling and NOE data, the torsion angles H−C−C−H, H−C−C−P

and H−C−P−C can be calculated for both the λ twist and δ twist forms of each of the compounds **1**−**4**. The torsion angles allow the degree of ^3J coupling to be predicted in each case. Determination of the corresponding coupling constants is in part possible by 2D NMR spectroscopic experiments. Even in the case where a numerical value of an individual coupling constant cannot be obtained with sufficient accuracy, the relative degree of coupling may be inferred from the size of the corresponding volume integrals. If the observed degree of coupling is ranked as strong (*s*), medium (*m*) and weak (*w*) a comparison of the ranking derived from calculated torsion angles and the ranking derived from NMR spectroscopic experiments is possible. This type of comparison is shown in Table 6 for the λ twist isomer of **1** as an example. It is seen that on the basis of $^3J_{H,H}$ coupling the agreement between calculated and experimental degrees of coupling is definitely better for the values calculated for the λ twist isomer than for the ones derived from the geometry of the δ twist isomer. It is also seen that the $^3J_{HP}$ and $^3J_{HC}$ couplings do not differentiate between the two twist isomers. If on the other hand a chair conformation of the chelate cycle is chosen as the basis of comparison (Table 6) almost all of the experimental $^3J_{HX}$ couplings show a definite misfit. It is seen then that the $^3J_{HX}$ couplings strongly indicate that the solution structure of the major isomer of **1** adopts a twist conformation while only the $^3J_{H,H}$ couplings involving H3 (Figure 3) allow to differentiate between its λ twist and δ twist forms. The λ twist form that in fact corresponds to the conformation of the major isomer gives the best agreement, as expected. The same type of analysis, when performed for the minor isomer of **1,** shows a better fit for the δ twist isomer ($^3J_{H,H}$ coupling constants 6.2, 6.7, 11.3, 9.1 Hz in the sequence shown in Table 6, ranking of couplings: *m*, *m*, *s*, *m*). For compounds **2**−**4** the observed degree of $^3J_{HX}$ coupling is also in agreement with the conformations assigned to the individual isomers in each case (see Supporting Information).

Evaluation of Kinetic Data and Thermodynamic Parameters: The rate constants for the overall process of δ ⇄ λ isomerisation were evaluated by the method of exchange between two unequally populated sites.[26] In the case of the ^{31}P EXSY data this evaluation was based on the molar fraction approach.[26] For the ^{1}H EXSY data this approach as well as the evaluation using the integral values at zero mixing time were used, with only slight differences in the resulting rate constants which were found to be within the margins of error.

The protons of the mesityl groups are involved in a four-site exchange throughout. The mesityl groups are allowed to rotate only in connection with a δ ⇄ λ exchange; thus, in one exchange step a specified mesityl proton may exchange with two mesityl protons of the product; a consequent reverse reaction will then lead to an exchange with a proton of the mesityl group in the starting conformation. The rate data corresponding to these processes were evaluated by finding the solution to the four corresponding linear differential equations according to standard methods.[27] For the corresponding matrix operations MATHEMATICA[28] was used as the tool.

[a] The degree of coupling is ranked as strong (*s*), medium (*m*) and weak (*w*). With respect to torsion angles the ranking is as follows: 0−14°, 165−180°: *s*; 15−74°, 105−164°: *m*; 75−104°: *w*.

The rate constants referring to the two individual pathways with respect to the mesityl rotation on which δ ⇄ λ exchange can occur must add to the rate constants of the overall process as determined by the analysis of the two-site exchange processes (Table 7). Within the margins of error this is in fact the case for all of the four-site exchange processes in compounds **1**−**4**. The rotational pathways which the mesityl groups take as a coupled pair in each case have been described as *L* and *D* (Figure 7−9). From the corresponding rate constants the probabilities with which these pathways are taken were calculated and are shown in Table 7. Rate constants for temperatures other than the ones listed in Table 7 were determined for two compounds by analysis of the behaviour of solutions of these compounds containing the isomers in nonequilibrium concentrations. These solutions were prepared by dissolving crystals of these compounds at low temperatures (see Figure 10). At certain temperatures during the warming up period (**1**: 221, 232 K; **3**: 212, 224, 235 K) the time dependence of the concentration ratio of the two isomers was measured at T = const. The time dependence of this ratio was evaluated by making use of the solution of the corresponding differential equations (see Supporting Information) which is Equation (1) (k: rate constant [s^{-1}]; t_x: time [s]; K: equilibrium constant; r_0: concentration ratio at t = 0 s; r_x: concentration ratio at $t = x$ s). From these k values at different temperatures $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values, relating to the rate constants pertinent to compounds **1** and **3** were evaluated. From the temperature dependence of the equilibrium constants (Figure 10) the ΔH and ΔS values as shown in Table 1 were obtained.

$$-\frac{1}{(K+1)}\cdot\ln\frac{(r_0+1)\cdot(r_x-K)}{(r_x+1)\cdot(r_0-K)}=k\cdot t_x \qquad (1)$$

NMR Spectroscopic Structure Refinement: In order to transform NOE volume integrals into distances[25] some volume integrals referring to known distances had to be selected. The selection used (Table 8) was based on the inspection of the 2D NOE maps with the selection principle allowing only those volume integrals which were free from disturbance by other peaks to be incorporated. The resulting interproton distances for the major isomer of compound **1** as an example are shown in Table 8. These distances were used to define the distance matrix[29] on the basis of the known solid state structures of the compounds.[8,9] Distance geometry calculations were based on a model with λ conformation and another one with δ conformation in each case. From each of the two distance matrices one hundred conformations were allowed to evolve.

[a] The kinetic data presented in this column are the average of the corresponding rate constants as obtained by evaluating all EXSY peaks stemming from all the protons which show a two-site exchange excluding the ones of the mesityl groups (see table) which are engaged in a four-site exchange (see text). The numbers in parentheses give the estimated standard deviation in units of the least significant digit in each case. [b] Based on the estimated standard deviations of the rate constants a statistical test (student's test[32]) reveals that the values for k_L and k_D refer to two different distributions about different mean values within a confidence limit > 99.9% for compounds **1**−**3**. This means that there are in fact two different pathways *L* and *D* (Figures 7−9) of strongly coupled mesityl rotations. The estimated standard deviation in units of the least significant digit is given in parentheses. [c] P*L*, P*D* are the probabilities of pathways *L* and *D* (Figures 7−9) as inferred from k_L and k_D for each compound.

The initial restraints with respect to NOE-determined distances were set to an allowed variation of ±5% (major isomer) and ±10% (minor isomer) throughout. For those groups for which individual protons could not be assigned the "pseudoatom approach" was used.[30] Methyl groups, the three protons of which lead to one and the same signal, were modelled by a pseudoatom at the centre of the plane formed by the three hydrogen atoms. With respect to NOE distances, which involve these groups, the upper bounds of the corresponding distance intervals were increased by 1 Å. Phenyl groups which were found to be freely rotating (**1**) were described by replacing the pair of *ortho*-protons as well as the pair of *meta*-protons by corresponding pseudoatoms placed on the C_2 axis of the phenyl groups. The upper bound of NOE distances involving these protons was increased by 1.5 Å to 2.0 Å. Methylene protons (COD coligand for **1**−**4**, ethyl groups for **3**) for which the diastereotopic differentiation was found to be insufficient to resolve individual signals for each proton were modelled by a pseudoatom placed in the middle of these protons. The upper bound for NOE distances involving these protons was increased by 0.5 Å. These distance corrections for pseudoatoms as quoted were checked for their appropriateness by inspection of the starting models. The 2 × 100 conformations obtained by DG refinement were finally allowed to refine in the ESFF force field[16] with no NOE restraints imposed on them. Since many of the DG refined conformations relax into one and the same force field optimised conformation only a small number of different conformations remained from the 100 conformations in the starting set. These remaining conformations were found to be very similar to each other for the major isomer. Larger differences between these conformations occurred only with respect to dihedral angles involving methyl groups or phenyl *ortho* positions as the termini (**1**: phenyl; **3**: ethyl; **4**: OMe). For **2** with its DBP ligand constituent only one conformation remained since there are no rotational groups of this kind in this compounds. Only one type of orientation was found for the mesityl groups in each case. The conformation concerning the $PMes_2$ part of the compounds **1**−**4** was found to be roughly the same in each case (Figure 11). In order to decide whether the λ or the δ form was the one to give rise to the NOE data, the following procedure was adopted. The rms values as given by the DG program package which refer to a weighted sum of squares of different classes of distances[17] were taken as one of these criteria. It was found that for the major isomer these rms values were an order of magnitude smaller for the λ conformation than for the δ conformation, i.e. that the major isomer should be the λ one. The minor isomer must then be the δ one. The rms values obtained by DG runs on the minor isomer confirmed this expectation. The quality of agreement between the NOE distances calculated for the best DG structures and the NOE distances inferred from

[a] Distances as inferred from NOE measurements. [b] Distances referring to the λ isomer (correct) and those referring to the δ isomer (wrong!) in the solid state structure are given in that sequence separated by a slash. [c] Distances referring to the optimal model from DG refinement. [d] Distances referring to the optimal model from force field refinement. [e] The designators refer to Figures 3 and 4. [f] Contacts used as reference distances. [g] Root mean square (rms) deviations between distances obtained from NOE experiments and distances derived from model structures for selected sets of contacts.

measurement is shown as column DG in Table 8 for the λ isomer of **1**, which is the major isomer in this case as in the cases of **2**−**4**. This is shown in Table 8 for all of the 64 NOE contacts that could be measured for **1**-λ including those contacts that are fixed by the covalent framework. Contacts that may serve as reference contacts have the numbers 1−5 in Table 8. Contacts No. 1 and 2 were used in the transformation of NOE integrals into distances. The rms value relating to all NOE distances is 0.45 Å, the one relating to the potential reference distances is 0.22 Å as shown in Table 8. Distances No. 6−21 (Table 8) refer to 1−3 or 1−4 contacts which are, while being comparatively well fixed by the covalent framework, subject to variation on torsion angles and are therefore not so well suited as reference distances. The rms value for this group of distances is only 0.13 Å. For the comparison of distances involving methyl groups out of the three protons of such a group the one was chosen which had the shortest contact. This principle was also applied to make the proper choice between the two *ortho*- and *meta*-protons of the phenyl groups (Table 8). Contacts No. 22−64 will respond to the conformation, to a larger or lesser extent, due to the fact that there are quite a number of "long" distances above 3.5 Å which, by the nature of the experiment, are less well determined. The agreement is somewhat lower for this set of distances and is found to amount to an rms value of 0.53 Å. When the same type of comparison is made for the structural models derived by force field methods (column FF, Table 8) or from X-ray analysis of the λ isomer (column X-ray, Table 8) the overall agreement is good (Table 8 and rms values given in this table). This means that the average structure in solution is very close to the force field calculated minimum structure that is again very close to the structure determined by X-ray methods in the solid state. When the distances determined for the major isomer are compared with the ones calculated for the δ conformation (known from X-ray structure analysis) the agreement is worse for those classes of distances which contain distances that respond to conformational changes (of course not different for covalently fixed distances), i.e. for the group of all distances No. 1−64 and for the group of distances No. 22−64 (Table 8).

The most discriminating distances are found to be the ones radiating from H3 (Figure 3) as expected. The rms values based on this subset of distances (No. 22−27, Table 8), as calculated by comparison with the λ conformer and the δ conformer of the X-ray structure, are given in Table 8 and show that there can be no doubt about the fact that it is the λ form which corresponds to the conformation of the major isomer.

When the minor isomer of **1** is treated in the same way this same type of rms value is again maximally discriminating. It is found to be 0.31 Å for the correct assignment (δ) and 0.76 Å for the incorrect one (λ) (Table 9). This means that, even though, due to its low concentration, the NOE data for the minor isomer are less accurate and smaller in number, it is possible to discriminate between the two forms for the minor isomer. The same procedure, as explicitly described for **1**, was applied to compounds **2**−**4** leading to the result that, beyond doubt, the major isomer corresponds to the λ conformation in each case. The rms values with respect to the contacts radiating from H3 and referring to the differences between these distances as inferred from NOE measurements and the distances calculated either for the λ or the δ conformer of the X-ray structure, are collected in Table 9.[31] It is seen that these rms values are significantly different for the two assignments in all cases. The correct assignment is the one where the δ conformation is the one corresponding to the minor isomer and the λ conformation corresponds to the average structure of the major isomer. The agreement between the rms values as calculated on the basis of structural models derived from X-ray data or from DG refinement or also from force field refinement (Table 9 ROWSEP="YES") is found to be equally good for **2**−**4** as already observed for **1**.

Table 9. Discrimination between λ and δ isomers on the basis of rms values

[a]	No. of contacts	Major X-ray λ/δ	(λ) DG λ	FF λ	No. of contacts	Minor X-ray δ/λ	(δ) DG δ	FF δ
1	64	0.29/0.52	0.45	0.36	19	0.35/0.46	0.37	0.35
	6	0.20/1.23	0.16	0.33	3	0.31/0.76	0.25	0.33
2	73	0.39/0.75	0.38	0.36	14	0.39/0.41	0.33	0.36
	7	0.25/0.87	0.25	0.22	2	0.20/0.59	0.11	0.16
3	70	0.72/0.77	0.50	0.55	21	0.61/0.74	0.38	0.89
	6	0.10/1.04	0.14	0.09	5	0.22/0.79	0.05	0.37
4	60	0.36/0.50	0.33	0.44	27	0.25/0.30	0.17	0.36
	7	0.52/1.28	0.47	0.44	3	0.24/0.41	0.13	0.19

[a] Column headers have the same meaning as given in the footnote of Table 8. The first line refers to the corresponding rms values as calculated for the total of all the NOE contacts measured in this case, the second line refers only to those contacts which radiate from H3 in each case.

CH/π Interactions Implicated in the Crystal Structure of Transition Metal Compounds − A Database Study[‡]

Hiroko Suezawa,*[a] Takashi Yoshida,[a] Yoji Umezawa,[b] Sei Tsuboyama,[c] and Motohiro Nishio*[c]

Keywords: Hydrogen bonds / Noncovalent interactions / π interactions / Supramolecular chemistry

A statistical study was carried out to investigate the role of the CH/π interaction in the crystal structure of transition metal compounds. Thus, short CH/π distances were surveyed in crystal structures deposited in the Cambridge Structural Database. Among organometallic entries bearing C_6 or C_5 aromatic rings, a substantial part of the structures has been found to have intermolecular CH/π contacts shorter than the van der Waals distance. Further, in many structures short intramolecular CH/π contacts have been found. Interligand and intraligand CH/π interactions were also surveyed in coordination compounds bearing the typical ligands 1,10-phenanthroline, 2,2′-bipyridine, and 2,2′:6′,2′′-terpyridine, as well as triphenylphosphane complexes of ruthenium, rhenium, and rhodium. The results were discussed in the context of the CH/π interaction in controlling the crystal packing and the molecular structure of transition metal compounds. The compact structure with CH/π interactions is a general aspect in coordination and organometallic chemistry.

Introduction

Sigel and his co-workers studied the conformation of a number of ternary metal complexes with aromatic and aliphatic ligands such as M(bipy)(AA), M(phen)(AA)[1] and M(ATP)(AA)[2] [M = Cu^{2+} or Zn^{2+}, bipy = 2,2′-bipyridine, phen = 1,10-phenanthroline, ATP = adenosine triphosphate, AA = $RCH(NH_2)COOH$]. In every case, the alkyl group R (isopropyl, isobutyl, etc.) in AA was found to curl over the aromatic rings to form a folded rather than an extended conformation. A number of examples have been provided by these workers where, in complexes including nucleotides and amino acids as ligands, the structures displaying alkyl/arene as well as arene/arene interactions prevail in solution.[3] The results imply that an attractive interaction operates between these moieties.

Okawa first recognized the importance of CH/π interaction in the stereoselective formation of several metal complexes.[4] The relevance of the CH/π interaction[5] in coordination and organometallic chemistry has since been shown by a number of workers.[6] For instance, Brunner studied the crystal and solution structure of a series of ruthenium compounds with a cyclopentadienyl and/or benzene unit as ligand. One of the isomers in a half-sandwich complex, where a hydrogen atom of the η^5- or η^6-arene ligand points to an aromatic group in the neighboring ligand, has been shown to be more stable than the diastereoisomeric congener. They termed this the "β-phenyl effect",[7] and the phenomenon is now understood on the grounds of the CH/π hydrogen bond.[8] His finding has an obvious implication for the mechanism of enantioselective catalysis.[9]

The CH/π interaction is the weakest extreme of nonconventional hydrogen bonds[10] and is recognized to be the interaction between soft acids and soft bases,[11] in contrast to the ordinary hydrogen bond, that is the interaction between hard acids and hard bases. Though weak, the CH/π hydrogen bond plays significant roles in various fields of chemistry such as the conformation of molecules,[12] self-assembly[13] as well as chiral recognition.[14] The electronic substituent effect on the stereoselectivity of complex formation,[15] conformational equilibrium,[16] crystal packing,[17] and enantioselectivity[18] has demonstrated that the CH/π interaction is by no means merely a dispersion force. According to high-level ab initio calculations, the most important stabilization comes from the correlation energy.[19] The electrostatic interaction also contributes, but is a minor factor (ca. 20%)[20] in the CH/π interaction. Hence, the CH/π interaction is nonpolar and is effective in water unlike the conventional hydrogen bond and Coulomb force. This

point is of supreme importance when considering the role of CH/π interaction in biological environments. Evidence has in fact been presented for the ubiquity of CH/π bonds in the interaction involving protein[21,22] or DNA.[23]

CH/π interactions are often reported to occur in crystal packing[24] of organometallic compounds and in clathrates.[25] Braga and co-workers reported on a Cambridge Structural Database (CSD) study of organometallic entries including XH/π (X = O, N C) bonds and demonstrated the hydrogen bond character of these interactions.[26] Previously we showed, by analyzing structures in the CSD,[27] the prominence of CH/π interactions in the packing of organic crystals[28] and host/guest compounds.[29] To investigate the significance of the CH/π interaction in coordination and organometallic chemistry, we extended our approach to the crystal structure of transition metal compounds.

Method

The CSD version 5.21 and 5.22 (April and October 2001 release) were used. The 6- and 5-membered aromatic ring systems were chosen in view of their abundance in the database. The method of exploring CH/π interactions in the CSD was described in detail in our previous papers.[12a,28,29] For surveying CH/π interactions in compounds bearing an arene ring, several kinds of distance and angle parameters were defined to cover every possibility. This is necessary since a C−H group may interact in regions where the hydrogen atom is slightly offset out of the π-plane. Figure 1 illustrates the method for a six-membered arene ring. Nonbonding contacts were sought with appropriate cut-off values for the distance and angle parameters. Interatomic distances shorter than the sum of the van der Waals radii[30] were considered as relevant for the presence of CH/π interaction.[31] In practice, the software QUEST3D was used to find CH/π contacts within the above constraints.

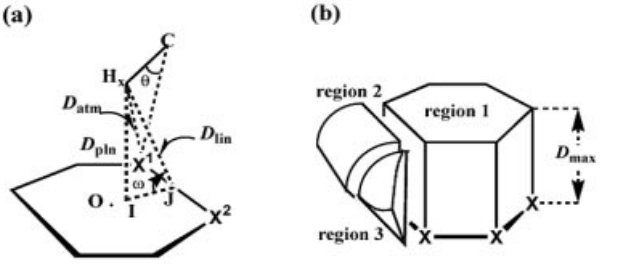

Figure 1. Method of surveying CH/π contacts with a 6-membered aromatic ring: (a) O: center of the plane; X^1 and X^2: nearest and second nearest sp^2 atoms, respectively, to H; ω: dihedral angle defined by X^1OX^2 and HX^1X^2 planes; θ: HCX^1; D_{pln}: H/π-plane distance (H/I); D_{atm}: interatomic distance (H/X^1); D_{lin}: distance between H and line X^1X^2 (H/J); (b) the program was run to search for H/π distances shorter than a cut-off value D_{max} in every region; $D_{pln} < D_{max}$, $\theta < 60°$, for the region just above the ring (region 1); $D_{lin} < D_{max}$, $\theta < 60°$, $90° < |\omega| < 130°$ for the region slightly offset from the ring (region 2); $D_{atm} < D_{max}$, $\theta < 60°$, $50° < \varphi < 90°$ for another possible region φ: HX^1I (region 3)

Results and Discussion

Intermolecular Interactions

First, coordinates determined by the neutron diffraction method were examined. Table 1 shows the results for entries bearing at least a C_6 aromatic group. The mean intermolecular CH/π distance D_{atm} increases to a larger value when the cut-off distance is longer. The proportion of hit entries, however, does not increase appreciably. The interatomic distance was then surveyed, separately, for sp^2- and sp^3-CH/π interactions. The aromatic CH groups interact with the π-system at a shorter distance than the alkyl groups.

Table 1. Intermolecular CH/π interactions in the crystal structure of organometallic compounds bearing a C_6 arene ring, determined by neutron diffraction (71 entries)

	Hit[a]	Ratio[b] (%)	D_{atm}/Å[c] (fragment)[d]
D_{max}			
3.05 Å	55	77	2.87 ± 0.13 (514)
sp^2-CH	35	49	2.86 ± 0.13 (226)
sp^3-CH	28	39	2.89 ± 0.12 (101)
3.20 Å	58	82	2.94 ± 0.17 (684)
3.50 Å	59	83	3.03 ± 0.23 (874)

[a] Number of entries with short CH/Ar contacts. [b] Proportion of hits. [c] Mean atomic distance. [d] Number of observations.

Intermolecular CH/π distances were then sought from the entire CSD (Table 2). Only error-free, nondisordered structures with $R < 10\%$ were accepted. Among 39570 organometallic entries with C_6 arene ring(s),[32] 28363 crystal structures (ca. 72%) have been found to have at least one CH/π distance shorter than 3.05 Å.[33] This proportion is a conservative estimate, since in the above 39570 entries, structures bearing no hydrogen coordinates are counted. The CH groups may also interact with nonbenzenoid π-systems such as heteroaromatics, cyclopentadienyl groups, or multiple bonds such as C≡C, C=O, etc. Further, the CH/π interaction may operate at a distance longer than 3.05 Å. D_{atm} shifted to a longer value for a larger D_{max} but the number of hits did not increase remarkably. Table 2 includes data obtained by surveying compounds with C_5 aromatic rings as the CH acceptor. D_{atm} is not appreciably distinct from the C_6 case; the results suggest that the π-donating property is not very different between these rings. The ratio of hits, on the other hand, is smaller in C_5 than in C_6 arenes. This probably reflects the smaller surface area of a cyclopentadienyl group than that of the C_6 aromatic compounds. Several database subsets were edited for 1st, 2nd, and 3rd row transition elements and surveyed. No appreciable difference has been noted between these subsets.

Figure 2 shows histograms recorded by surveying CH hydrogen atoms interacting with the C_6 aromatic ring. We see many distances shorter than the van der Waals distance. In Figure 3, positions of the hydrogen atoms are projected onto the C_6 π-plane.[34] It is remarkable that the C−H bond

tends to point toward the center of the aromatic ring; this is consistent with our earlier experiences on organic crystals. Braga et al. also noticed the directionality of the XH/π-type interactions.

Intramolecular Interactions

Table 3 gives the results obtained by examining intramolecular interactions; here the entries are limited to neutron diffraction data. We found that these structures have CH/π contacts both between and within the ligands.[35] Both the interligand and intraligand CH/π interactions seem to play an important part in controlling the shape of metal complexes.

Table 4 summarizes the results obtained by surveying the entire CSD. Among 39570 entries, 20738 crystal structures (ca. 52%) have been found to have at least one short CH/π intramolecular distance. Examples are given in Figure 4. Tables 3 and 4 show that the value of D_{atm} increases on going to a larger number of covalent bonds (N) separating the relevant H and C(sp^2) atom. The greater the value of N, the longer the CH/π interatomic distance. This is reasonable, since with a smaller N the position of CH is greatly restricted. The value of D_{atm} coalesces finally to that of the intermolecular interaction. Intramolecular interactions involving the C_5 aromatic ring as the CH acceptor are very scarce (ca. 6%). The exact reason remains unclear, but it may be pointed out that in these cyclopentadienyl compounds, ligands generally have few moieties that can make intramolecular contacts with the C_5 aromatic part.

Interactions Involved in Complexes with Certain Heteroaromatic Ligands

We then examined interactions among complexes bearing 1,10-phenanthroline, 2,2′-bipyridine, and 2,2′:6′,2′′-terpyridine as ligands. The importance of these ligands as supramolecular motives is well known.[36] In these surveys, six-membered heteroaromatic rings also acted as the CH acceptor. Table 5 lists the results. The proportion of hits in these complexes is lower than in the general cases reported in Table 4. This is probably because such nitrogen-containing flat ligands often form an offset π/π-stacked structure.[37,38] Representative examples are given in Figure 5. CH/π contacts are often found between an *ortho*-hydrogen atom of a pyridine moiety and an sp^2 atom of a nearby ring.

Interactions Involved in Complexes with Triphenylphosphane Ligands

Rhenium, rhodium, and ruthenium compounds bearing triphenylphosphane as ligands were also examined in view of their potent use as catalysts in the enantioselective reaction. Table 6 lists the results. The ratio of hits is considerably higher in these complexes than in the other cases. This certainly reflects the propensity of PPh_3 to form CH/π bonds within the ligand or with a nearby part of the complex. Figure 6 gives representative examples. Short contacts

are found between CH groups of an alkyl chain as well as aromatic groups and a phenyl ring in the triphenylphosphane moiety. Dance and Scudder studied the interaction involved in both PPh_3 complexes [39] and Ph_4P^+ salts[40] in organometallic entries. They found many edge-to-face interactions and termed such a motif the "multiple phenyl embrace". These motifs seem to make the crystal structures compact and stable. Our suggestion is that this tight structure is achieved by a cooperative use of the aromatic CH/π interaction.[41]

Figure 6. Conclusion

To summarize, CH/π interactions are ubiquitously found in crystals of transition metal compounds. In other words, the CH/π-interacted crystal packing and the compact molecular structure are general aspects in coordination and organometallic chemistry. Janiak examined interactions involved in metal complexes with nitrogen-containing aromatic ligands[37] and found that the π/π-stacking[42] seldom occurs at a perfect parallel-stack geometry of the opposing parts. Nitrogen-containing flat ligands generally form an offset π/π-stacked structure. This is compatible with the present results that, for 1,10-phenanthroline complexes etc., aromatic CH/π interactions prevail but the ratio of hits is somewhat smaller than in the general cases. There are ample data in the literature demonstrating that the folded crystal conformation of metal compounds is maintained in solution.[43] The present statistical data suggest that these findings are not necessarily fortuitous, but exhibit a part of the general phenomenon. It is pertinent to point out in this regard that Taylor et al. presented unequivocal evidence by a CSD study that the so-called crystal packing forces do not provide systematic influence on molecular conformations.[44]

The enthalpy of one unit CH/π bond is certainly the smallest (around 1 kcal mol^{-1})[45] among the nonconventional hydrogen bonds. A notable feature of this molecular force, however, is that many CH groups can participate cooperatively in an interaction with π-bases. Besides, the CH/π interaction is entropically advantageous in that CH and π groups are generally arranged in a certain symmetric structure to make a persistent (stable and flexible) organization of molecules or molecular aggregates. We conclude that the concept of a CH/π hydrogen bond is vital in understanding various issues of chemistry and biochemistry of the transition metal compounds.

[31] D_{max} 3.05 Å: 2.9 Å [(1.2 Å for C−H plus 1.7 Å for a half width of the aromatic ring) × 1.05] was used throughout the study unless otherwise noted; sp^2-C and -N atoms were not discriminated in the present survey. The C−H bond length and angle were normalized to standard values in the QUEST3D program, unless only coordinates from neutron studies are analyzed.

[32] The entries include metal complexes as well as organometallic compounds (screen −57 in the QUEST3D program) bearing at least one C_6 aromatic ring.

[33] In the hit entries, we note crystal structures of inorganic salts such as carbonylmetal complexes pairing with Ph_4P^+ as the counter ion.

[34] D_{max} 2.90 Å: Hydrogen atoms are limited to aromatic CH groups to minimize the chemical inhomogeneity.

[35] It is difficult in the present search to distinguish the intraligand and interligand CH/π interaction. Occurrence of intraligand interaction is not frequent, but we often note interactions within a ligand in certain ligands such as triphenylphosphane.

Reaction of $[(Cp_2TiCH_3)(THF)^+][BPh_4^-]$ with Tripeptide Derivatives: Formation of Cationic (Peptide)titanocene Complexes

Dirk Harmsen,[a] Gerhard Erker,*[a] Roland Fröhlich,[a][‡] and Gerald Kehr[a]

Keywords: Bioinorganic chemistry / Peptides / Metallocenes / Titanium / Cations

A series of Z- and Boc-protected tripeptide methyl esters [Z-/Boc-**5** to -**12**(pept)] was prepared using the amino acids glycine, alanine and valine. In both the alanine and the valine series a single glycine unit was introduced and its position inside the tripeptide framework was systematically varied. Reaction of these 16 tripeptide derivatives with the organometallic reagent $[Cp_2TiCH_3(THF)^+][BPh_4^-]$ (**13**) resulted in the formation of methyl(peptide)titanocene cation complexes that contained the strongly electrophilic $[Cp_2TiCH_3^+]$ cation moiety coordinated to a single carboxamide carbonyl oxygen atom. Mostly, the carbonyl oxygen atom of the central amino acid residue was specifically attached to yield the coordination products **5**–**12**(coord[7]). In a few specific cases, formation of the κO-adduct between the $[Cp_2TiCH_3^+]$ cation and the *N*-terminal amino acid moiety was also observed, especially in the cases of the *N*-terminal glycine derivatives. In one case we observed the migration of the $[Cp_2TiCH_3^+]$ group along the chain from the C4=O to the C7=O position. Subsequent thermally induced CH_4 elimination of the products **5**–**12**(coord) gave the cationic peptide chelate derivatives **5**–**12**(chel). These are characterized by the presence of a five-membered κ*O*,κ*N*-chelate with an anellated four-membered κ*N*,κ*O*-chelate. This is mostly centered around the central amino acid unit [products **5**–**12**(chel^B)], but in some cases the *N*-terminal amino acid, together with the *N*-terminal protective group, also forms this type of a stable peptide titanocene cation chelate complex [products **5**–**12**(chel^A)]. The selective formation of these series of (peptide)metallocene cation complexes was readily analyzed by means of their very characteristic ^1H and ^{13}C NMR spectra.

Introduction

Peptides represent interesting chiral ligand systems. Therefore, some of them have been used in organometallic chemistry and catalysis, although mostly such complexes derived from the middle or late transition metals are reported so far.[1−3] The usually rather oxophilic early metals, especially those of group 4 (and the f-elements), are not easily "tamed" to allow unrestricted bonding to the multifunctional oligopeptide frameworks. Some Cp group-4 metal complexes have found use in peptide synthesis.[4,5] A few (amino acid or peptide)cyclopentadienylzirconium complexes were previously described, and some catalytic features were reported;[6−10] *C*-terminal carboxylate-bonded amino acid derivatives were found useful in titanocene chemistry with regard to the development of novel antitumor pharmaceuticals.[11]

A cationic zirconocene complex of a dipeptide derivative (**2**) was first prepared by treatment of "Jordan's cation"[12] $[Cp_2ZrCH_3)(THF)^+][BPh_4^-]$ (**1a**) with the dipeptide isocyanate derivative. Addition of the $Zr-CH_3$ functionality to the *N*-terminal heterocumulene cleanly gave the $\kappa^2O,\kappa N$-chelate (dipeptide)zirconocene cation **2a** (see Scheme 1).[13] The typical metallatricyclic σ-framework of complex **2** was characterized by X-ray diffraction. The NMR spectroscopic analysis of **2** revealed typical spectroscopic features of this type of bonding, such as a strong shift of the $^{13}C4$ carbonyl resonance to larger δ values ($\Delta\delta \approx 8-10$ ppm) relative to the respective neutral noncoordinated peptides.[13] Treatment of the dipeptide derivative Boc-Ala-Val-OMe with **1** furnished the analogous zirconocene cation complex **3** (after loss of methane), that was characterized by an X-ray crystal structure analysis. It revealed the formation of a

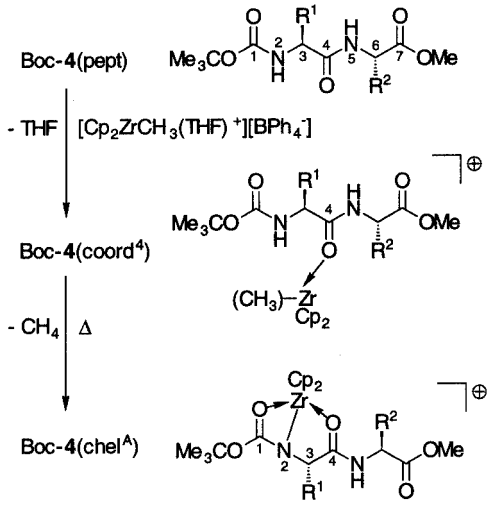
[‡] X-ray crystal structure analyses.
Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

metallatricyclic structure analogous to **2** (see Scheme 1), that again exhibits very typical ^1H and ^{13}C NMR features.[14]

A series of experiments using different di- and tripeptide systems revealed that $[Cp_2ZrCH_3^+]$ was in all the cases first attached to the C4 carbonyl oxygen atom under kinetic control, followed by migration of the metallocene unit along the chain. Subsequent intramolecular NH deprotonation with loss of CH_4 usually led to the formation of complex **4**(chel) (with a few exceptions), which is the thermodynamic product in the series investigated[14] (see Scheme 2).



Scheme 2

We have now systematically examined the reaction of the titanium analog $[(Cp_2TiCH_3)(THF)^+][BPh_4^-]$[15] with peptides, employing two series of tripeptide derivatives (details see below), and found some similarities and some noteworthy differences in the formation of the cationic (peptide)titanocene complexes and in their chemical behavior.

Results and Discussion

Synthesis and Characterization of the Tripeptide Derivatives Employed in this Study

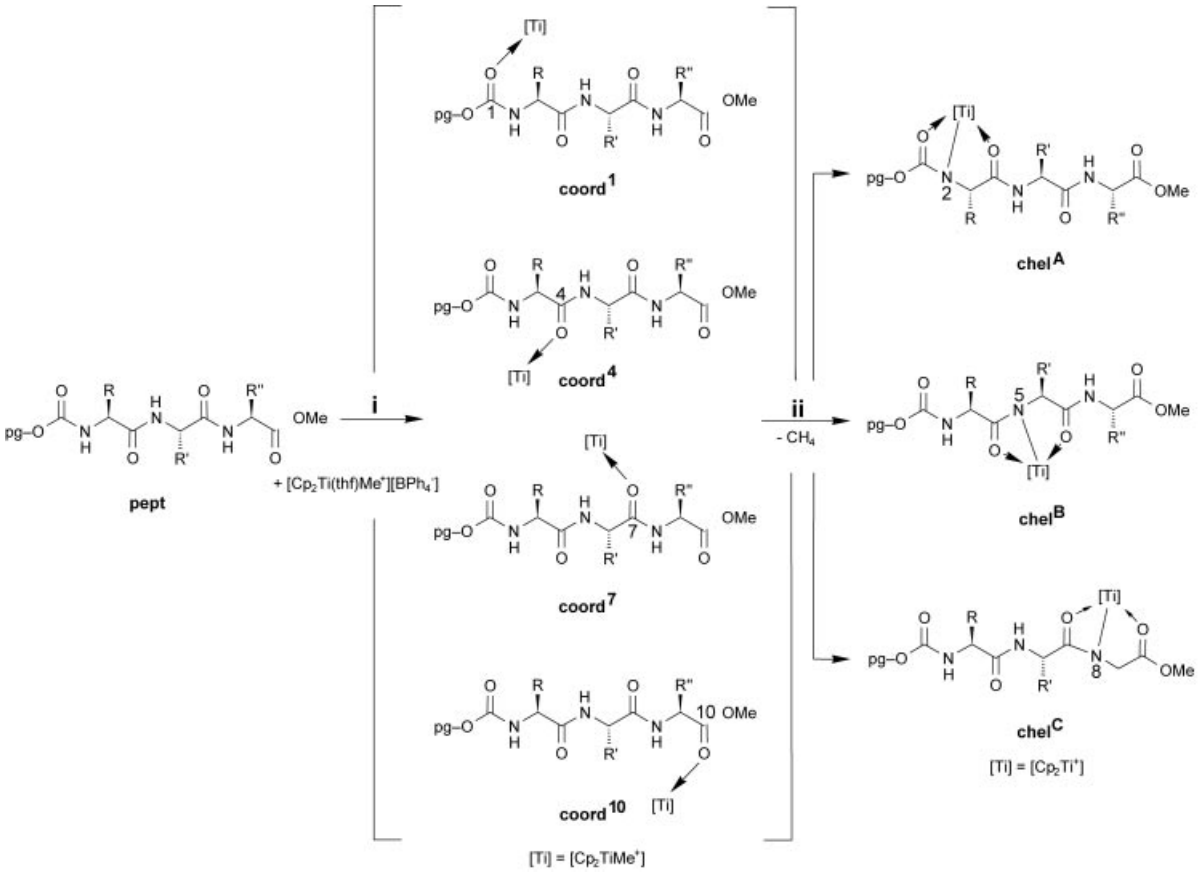
We have used two series of tripeptides in this study. The first involved a systematic combination of the natural amino acids glycine (Gly) and alanine (Ala) with a variation of the two *N*-terminal protecting groups benzyloxycarbonyl (Z)[16] and *tert*-butoxycarbonyl (Boc);[17] the *C*-terminal carboxylic acid was protected by a methyl ester group in each case. A single Gly amino acid was moved from the *N*-terminus through the center position to the *C*-terminus, and we used the corresponding $(Ala)_3$ systems for comparison. The Z-protected systems were prepared from the commercially available Z-dipeptide acids, to which the corresponding amino acid methyl esters were coupled using the IIDQ method.[18] The Boc-protected systems were synthesized in a similar way, although, the respective Boc-protected dipeptides were prepared by a variation using DCC.[19] In this way the eight tripeptide derivatives Z-**5**(pept) (= Z-Gly-Ala-Ala-OMe) to Boc-**8**(pept) (= Boc-Ala-Ala-Ala-OMe) were obtained[20] (for a compilation see Table 3).

The series of eight glycine- and valine-containing tripeptides Z-**9**(pept) (= Z-Gly-Val-Val-OMe) to Boc-**12**(pept) (= Boc-Val-Val-Val-OMe) were prepared analogously (for details see the Exp. Sect. and Table 3).

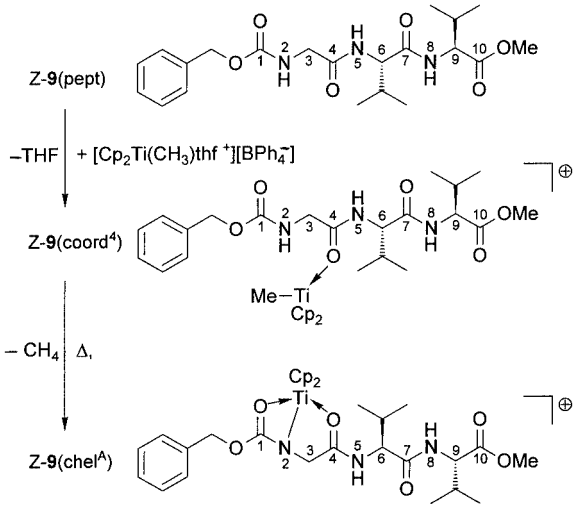
The ^1H and ^{13}C NMR chemical shifts of these 16 tripeptide derivatives were determined using 1D and 2D NMR spectroscopy. These data are presented in Table 4 in the Exp. Sect. It shows that the characteristic NMR features of the peptide backbones are largely independent of the protecting groups. Val and Ala building blocks give rise to characteristic alterations of the ^{13}C NMR chemical shifts at C3, C6, and C9. Glycine, of course, influences these δ values even more and also shows a small systematic decrease in the corresponding δ(C=O) values (see Table 4). The numbering scheme that we have used for characterization of the peptide backbones throughout this paper is depicted in Scheme 4.

Two of the tripeptide derivatives were characterized by X-ray diffraction. They belong to different structural types; Z-**5**(pept) (= Z-Gly-Ala-Ala-OMe) contains two independent molecules in the unit cell, that are only markedly different with regard to the conformational orientation of the phenyl group of the benzyloxycarbonyl protecting group at the *N*-terminus (see Figure 1). Compound Z-**5**(pept) shows no *intramolecular* hydrogen bonds, only *trans*-peptide linkages are found and all torsional angles ω (i.e. $C_\alpha-C_{(o)}-N-C_\alpha$) are close to 180°. However, this peptide derivative exhibits two types of *intermolecular* hydrogen bonds (between the carbonyl oxygen atom O2 and N2*−H of an adjacent molecule *and* between N8−H and C=O7*). This leads to the specific supramolecular peptide framework that is depicted in Figure 1.

Compound Z-**6**(pept) (i.e. Z-Ala-Gly-Ala-OMe) contains the amino acid glycine in the central position. Glycine allows for a fair amount of conformational flexibility inside the peptide chain. Compound Z-**6**(pept) is found to adopt a β-turn-type structure in the solid state (see Figure 2). It requires the involvement of four amino acid residues to complete the typical hydrogen-bonded β-turn ten-membered ring structure, that makes up the almost 180° turn of the peptide backbone structure.[21] In the tripeptide derivative Z-**6**(pept), the carbonyl group of the benzyloxycarbonyl protecting group Z at the *N*-terminus serves as a substitute for the missing fourth amino acid building block. The ten-membered ring in Z-**6**(pept) is then closed between N8−H and the Z-carbonyl oxygen atom C1=O2 (see Figure 2). The β-turn structure of Z-**6**(pept) in the solid state is characterized by the torsional angles φ_{i+1} (i.e. C1−N2−C3−C4) = −57.5(3)°, ψ_{i+1} (N2−C3−C4−N5) = 136.4(2)°, φ_{i+2} (C4−N5−C6−C7) = 71.3(3)°, and ψ_{i+2} (N5−C6−C7−N8) = 8.2(4)°. This is similar to the values for the most commonly observed βII-turn (ideal values: $\varphi_{i+1} = -60°$, $\psi_{i+1} = 120°$, $\varphi_{i+2} = 80°$, $\psi_{i+2} = 0°$).[22]



Scheme 3 . The series of possible primary and secondary products formed by the reaction between the tripeptide derivatives **5**−**12**(pept) with the $[Cp_2TiCH_3(THF)^+]$ salt **13**



Scheme 4

Compound Z-**6**(pept) is characterized by the formation of two additional *intermolecular* hydrogen bonds, namely between N2−H2 and the carbonyl group C7*=O7* (N−H: 0.85 Å; H···O*: 2.04 Å; N−H···O angle: 164°) and between N5−H5 and C*4=O4* (N−H: 0.82 Å; H···O* 2.09 Å; angle 160°), in addition to the *intramolecular* N8−H8···O2 hydrogen bond. This results in the formation of a μ-H-bridged supramolecular structure of the tripeptide derivative Z-**6**(pept), as depicted in Figure 3.

The Cationic Titanocene Complexes

The *N*-protected tripeptide derivatives Z- and Boc-**5**(pept) to -**12**(pept) (see Table 3) were treated with the metallocene cation reagent $[Cp_2TiCH_3(THF)^+][B(C_6F_5)_4^-]$ (**13**).[15] Similarly, as previously observed for the related zirconocene system, the THF ligand is rapidly replaced at low temperature (< 0 °C). In contrast to the zirconium systems,[13,14] the resulting $[\kappa O\text{-}Cp_2Ti(CH)_3(peptide)^+]$ cation complexes are more stable. It usually required several hours at room temperature to allow for the subsequent methane elimination reaction to go to completion. Typically, reaction of the respective peptide derivative with reagent **13** was carried out at ca. −20 °C, and the resulting coordination products [**5**(coord) to **12**(coord)] were characterized by NMR spectroscopy at −5 °C. The samples were then kept overnight at room temperature to cleanly yield the final methane elimination products [**5**(chel) to **12**(chel)]. The latter compounds were all isolated and fully characterized.

The reaction of the protected tripeptides with **13** primarily proceeds by the replacement of the stabilizing THF ligand from the reactive oxophilic methyltitanocene cation, and coordination of the peptide through one of its carbonyl groups. In principle, this could result in the formation of

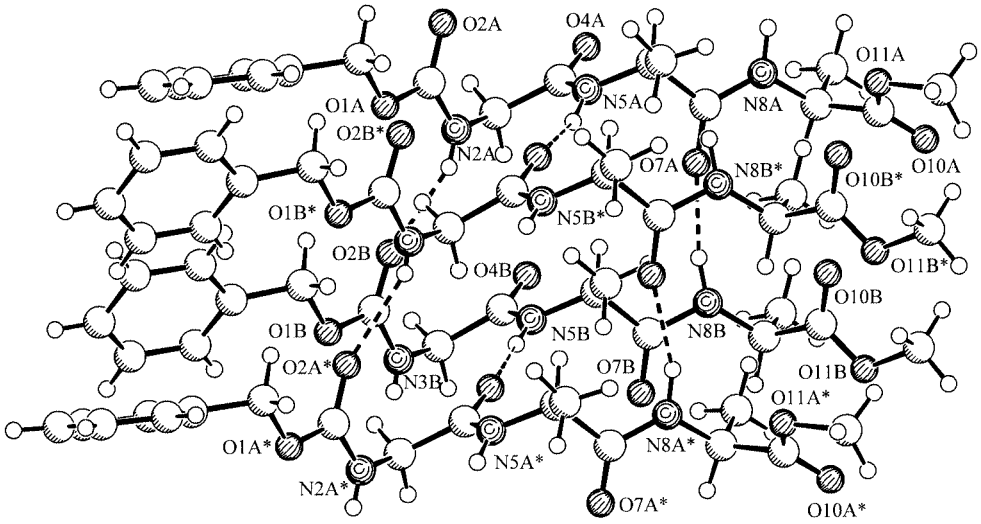


Figure 1. Molecular framework structure of Z-Gly-Ala-Ala-OMe [Z-**5**(pept)] in the solid state; the specific hydrogen bonding pattern between two pairs of Z-**5**(pept) molecules is depicted

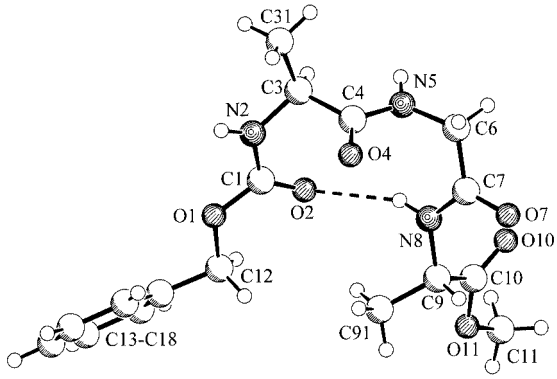

Figure 2. A view of the β-turn-like structure of compound Z-**6**(pept) in the crystal

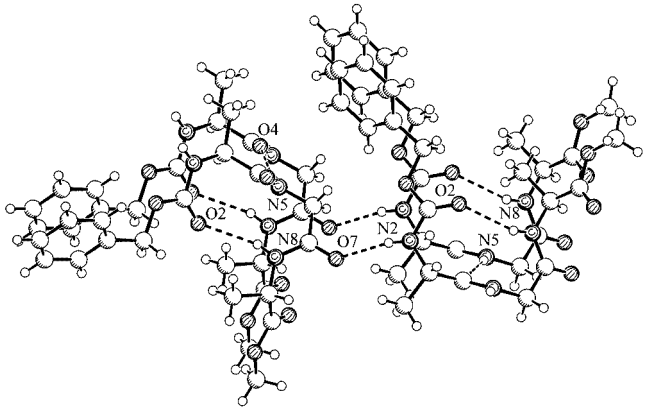

Figure 3. Supramolecular hydrogen-bridged network structure of Z-**6**(pept) in the solid state

four coordination products, which we will name e.g. Z-**5**(coord[1]), -**5**(coord[4]), -**5**(coord[7]), and -**5**(coord[10]), with the superscript denoting the atom number of the coordinating carbonyl group (see Scheme 3). Subsequent thermally induced methane elimination can then result in the formation of three different organometallic products, where the peptide ligand is bonded to the remaining titanocene unit in the typical chelate fashion. We will name these three products accordingly, e.g. Z-**5**(chel^{A}), -**5**(chel^{B}), and -**5**(chel^{C}). Here, the superscript denotes whether the chelate is formed by participation of the carbonyl-containing *N*-terminal protecting group (chel^{A}), the carbonyl group of the *C*-terminal ester (chel^{C}), or just the central peptide bonds (chel^{B}) (see Scheme 3).

The previously described detailed characterization of some of the zirconium complexes[13,14] enabled us to assign the structures of this large (and, as we will see, in some cases, quite complicated) series of (peptide)titanocene cation complexes. A rather simple example may serve as a demonstration. The peptide derivative Z-**9**(pept) (i.e. Z-Gly-Val-Val-OMe) reacts cleanly with **13** to give a single primary carbonyl coordination product, which is identified as Z-**9**(coord[4]).

The ^{13}C and, to a lesser extent, the ^{1}H NMR spectra reveal that in this case the [$Cp_2TiCH_3^+$] moiety is selectively coordinated to the C=O4 carbonyl oxygen. Very characteristically, the ^{13}C NMR resonance of the C4 carbonyl carbon atom is shifted by $\Delta\delta = +8.6$ ppm to a *larger* δ value [(Z-**9**(pept): δ = 169.6 (C4) vs. Z-**9**(coord[4]): δ = 178.2 (C4)]. In contrast, the other three carbonyl carbon chemical shifts are only marginally affected by [$Cp_2TiCH_3^+$] coordination. As expected, metallocene coordination to the C=O4 carbonyl group leads to some spectral changes for the atoms in the direct vicinity of this carbonyl group, most notably the anisotropy effects in the ^{1}H NMR spectra caused by the spatial vicinity of the aromatic Cp-ring systems.

Thus, the glycine 3-H/3-H′ ^{1}H NMR resonances shift to a lower δ value on complex formation, namely from δ = 3.90 ppm [(Z-**9**(pept)] to δ = 1.71 ppm [Z-**9**(coord[4])]. A similar effect is observed for the N2−H proton NMR resonance [δ = 5.92 ppm (pept) vs. δ = 4.23 ppm (coord[4])], and the rather remote C6−H signal [δ = 4.45 ppm (pept) vs. δ = 3.48 ppm (coord[4])], whereas the opposite effect is

observed for the N5−H resonance [δ = 7.05 ppm (pept), but δ = 7.48 ppm (coord[4])]. Coordination of the titanocene unit results in a diastereotopic splitting of the Cp resonances in **Z-9**(coord[4]) [δ = 6.19 ppm, 6.15 ppm (^{1}H)]. The methyl group at the titanium atom gives rise to a ^{1}H NMR singlet at δ = 1.14 ppm (^{13}C NMR resonance at δ = 52.0 ppm).

Overnight at room temperature, complex **Z-9**(coord[4]) looses 1 equiv. of methane to selectively form a single chelate (peptide)titanocene cation complex. The ^{1}H NMR spectrum shows that the *N2*-bound hydrogen atom is eliminated during this process. Its signal does not appear in the product spectrum and, consequently, we must assume that the [Cp_2Ti^+] unit is κ*N2*-bonded in the product. The overall coordination is likely to be κ^2(*O1*,*O4*),κ*N2*, i.e. the peptide is bound in a chelate fashion to the group-4 metal center, as had been previously demonstrated for the related zirconium systems. In the product **Z-9**(chel[A]), this specific type of bonding leads to very characteristic NMR features. The C4 ^{13}C NMR carbonyl resonance is shifted to larger δ values [δ = 175.3 ppm (chel[A])] relative to the parent peptide derivative [δ = 169.6 ppm (pept)], as is the C3 methylene carbon resonance [δ = 52.2 ppm (chel[A]) vs. δ = 44.8 ppm (pept)]. Remarkably, the κ*O*,κ*N* chelate moiety in this type of product typically leads to the observation of a slightly decreased ^{13}C NMR δ(C1=O) shift [(δ = 151.9 ppm (chel[A]) vs. δ = 156.9 ppm (coord[4]) vs. δ = 157.0 ppm (pept)], which probably results from an electronic compensation effect within the chelating κ*O*,κ*N* peptide anion moiety.[13,14] Of course, the Ti−methyl resonances are no longer observed in the spectra of **Z-9**(chel[A]), and the Cp_2Ti unit gives rise to resonances assigned to a pair of diastereotopic η^5-cyclopentadienide ligands [δ = 6.07 ppm and 6.00 ppm (^{1}H), δ = 118.8 ppm and 118.7 ppm (^{13}C NMR)].

In most other cases, the situation is more complicated than in the titanocene coordination chemistry of **Z-9**(pept). Often, other primary coordination products were obtained, sometimes mixtures of two compounds. In about half of the cases studied, mixtures of two final chelate products were obtained after subsequent methane elimination. In all these cases, the typical ^{1}H and, more importantly, ^{13}C NMR spectra allowed for a clear identification of the individual metal complexes in these mixtures. In the case of the primary [$Cp_2TiCH_3^+$] coordination products, the amino acid to which the metallocene residue was κ*O*-coordinated, could easily be identified, primarily by observing the typical marked downfield shift of the respective ^{13}C NMR carbonyl resonance. Eight examples in our series (for details see Table 2 and the Exp. Sect.) have the alkylmetallocene cation coordinated to the glycine residue on the **5**−**12**(coord) primary product stage. Their respective Gly(*C*=O) ^{13}C NMR chemical shifts are shifted to larger δ values by Δδ ≈ +8.6 and +10.6 (average: $\Delta\delta_{av}$ = +9.3). Similarly, $\Delta\delta_{av}$ = +11.4 for Ala(*C*=O) coordination (6 examples ranging from individual Δδ = +10.2 to +15.8), and $\Delta\delta_{av}$ = +10.4 for Val(*C*=O) coordination (6 individual examples with Δδ between +10.0 and +10.8). The NMR chemical shifts of the adjacent ^{1}H and ^{13}C nuclei are smaller; however, the Δδ ranges are similar to those described above for the selected example of complex **Z-9**(coord). For statistical details see Table 1 and Scheme 5.

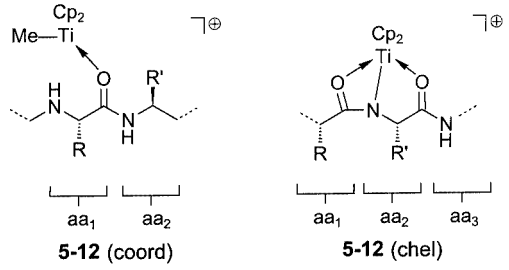

Scheme 5

Similarly, characteristic Δδ values are observed for the pairs of adjacent amino acid moieties that coordinate to the [Cp_2Ti^+] unit after CH_4 elimination in the products **5**−**12**(chel). In all cases strong Δδ effects are observed for the ^{13}C NMR resonances of the carbonyl group, *and* its adjacent α-carbon atom of the amino acid unit AS_2 (see Scheme 5) inside the five-membered chelate ring of the overall metallabicyclic structural subunits. The average ^{13}C NMR Δδ(*C*=O) values are about +5.7 ppm (see Table 2). The shielding effect is even larger for the α-*C*HR ^{13}C NMR resonance, with $\Delta\delta_{av}$ values between +9.0 and +10.3 ppm (see Table 2). The Δδ values of the *C*=O group in the anellated four-membered κ*O*,κ*N*-chelate is again much smaller because of the "carboxamide compensation effect". This is similar to that observed for the analogous zirconium complexes.[13,14]

With these characteristic NMR spectroscopic data it is possible to analyze the resulting product mixtures in a rather straightforward manner. The results are listed in Table 2. It can be seen that coordination of the intact

[$Cp_2TiCH_3^+$] cation to the amido carbonyl oxygen atom of the central amino acid building block of the tripeptide framework is favored in the majority of the cases. A single such product is formed in the cases of Z- and Boc-**6**, -**7**, -**8**, -**10**, and -**11**(coord^7). Deviations from this behavior are observed in the cases where the small glycine building block is located at the *N*-terminus of the tripeptide. Pure Z- and Boc-**9**(coord^4) adducts are formed in the PG-Gly-Val-Val-OMe series, and mixtures of the respective Z- and Boc-**5**(coord^4) and -**5**(coord^7) adducts are found in the PG-Gly-Ala-Ala-OMe cases (see Table 3).

The situation is similar for the final products obtained after subsequent thermally induced methane elimination, although in some cases it is slightly more complicated. Once again, it can be seen from Table 3 that coordination to the central section of the tripeptide framework is by far favored, i.e. the dominating products are Z- and Boc-**5**−**11**(chel^B), where the chelate structure is formed by the involvement of two adjacent amino acid moieties, without any participation of the carbonyl groups of the *N*-terminal protecting group nor the *C*-terminal ester. However, in many cases, mixtures of (chel^B) and (chel^A) (mostly minor) are found. Only in the extreme cases of Z- and Boc-Gly-Val-Val-OMe did we find the selective formation of the otherwise less favored **9**(chel^A) products that involve glycine and the RO−CO protective functionality in chelate bonding (see Table 3). The products (coord^1), (coord^{10}), or (chel^C) (see Scheme 3) were never observed in this series of experiments.

Methane elimination from the cationic primary coordination products [(coord)] is much slower in the case of the titanocene complexes than for the previously described zirconocene relatives. In one case, this has allowed for the observation of a rearrangement process at the stage of the formation of the κ*O*-[$Cp_2TiCH_3^+$] coordination products. The peptide Z-Val-Val-Val-OMe [Z-**12**(pept)] forms a 3:2 mixture of the two [$Cp_2TiCH_3^+$] coordination products Z-**12**(coord^4) and Z-**12**(coord^7). After 4 h at −5 °C, this changed to a ratio of Z-**12**(coord^4)/Z-**12**(coord^7) of 1:3. In the case of the Boc-protected system, Boc-**12**, the situation is even more pronounced. A Boc-**12**(coord^4)/Boc-**12**(coord^7) mixture of 4:1 is initially formed at −5 °C, that changed to a 1:3 ratio in favor of the generally thermodynamically favored internal coordination product after 4 h at −5 °C (see Scheme 6).

Table 3. A compilation of the products formed by the reaction of the tripeptide derivatives **5**−**12** with [$Cp_2TiCH_3^+$][BPh_4^-] (**13**)

Peptide (pept):	Coordination product (coord^4)/(coord^7)	Chelate product (chel^A)/(chel^B)

Conclusions

We had previously shown that the "Jordan cation" $[Cp_2Zr(CH_3)(THF)^+]$[12] reacts with oligopeptide derivatives by displacement of THF and addition of the methylzirconocene cation to a peptide C=O moiety. Subsequently, rapid methane elimination was observed to yield the $[(peptide)Cp_2Zr^+]$ chelate complexes.[13,14] We have now shown that the reagent $[Cp_2Ti(CH_3)(THF)^+]$ reacts with Z- or Boc-protected tripeptide esters in a similar way; first, coordination to a peptide carbonyl oxygen atom is observed [(coord) product formation]; subsequently a thermally induced CH_4 elimination is observed to yield the respective (chel) products.

However, there are notable differences between the zirconocene- and titanocene-based reactions that make the latter more interesting and probably more important. The methylzirconocene cation reagent is much more reactive. Consequently, a dominating (coord^4) product formation was observed, followed by a rather rapid CH_4 elimination to predominately yield the chelate product that involved bonding of the C=O group of the respective alkoxycarbonyl protective group at the *N*-terminus of the peptide. In this respect, the Cp_2Zr^+-derived chemistry is not to be regarded as simple and typical peptide framework chemistry, but rather as a combination of general peptide and specific protective group chemistry.

This is significantly different in the Cp_2Ti^+ systems described here. We have predominately observed the formation of a purely peptide-derived internal chelate product (chel^B) that involves only a pair of adjacent amino acid moieties of the peptide framework. In a few cases, the (chel^A) product that involves bonding of the protective group is observed as a minor component of the product mixture. Only in cases where there is a significant difference in the steric bulk of the backbone units (see Table 3) was the (chel^A) product dominant. A similarly significant difference between the Cp_2Zr^+- and Cp_2Ti^+-derived systems is observed in the regioselectivity of the primary attack. In almost all cases, the internal coordination product (coord^7) was obtained at low temperature. Only in very few specific cases was (coord^4) product formation observed for titanium, in contrast to zirconium where this dominated. The Cp_2Ti^+ adducts are, in some cases, "just resistant enough" to allow a secondary rearrangement to be observed experimentally. The products Z-**12**(coord^4) and Boc-**12**(coord^4) seem to be formed under kinetic control, but then slowly rearrange to form their favored isomers Z-**12**(coord^7) and Boc-**12**(coord^7), respectively. For the first time it seems that we have observed the (intra- or intermolecular) migration of a group-4 metallocene cation derivative along an oligopeptide chain, with the metallocene actively searching for the best resting place available at the peptide backbone, before undergoing further reactions. We will see if this might serve as a first step towards the development of achieving the selective information transfer between a typical biomolecule chain and a catalytically active transition metal center.

Experimental Section

General: All reactions involving organometallic compounds were carried out under argon using a modified Schlenk technique or a glovebox. Melting points were determined with a differential scanning calorimeter TA-Instruments 2010 and the infrared spectra were recorded in KBr with a Nicolet 5 DXC FT IR spectrometer. A Perkin−Elmer polarimeter 241 was used to determine the optical rotations (25 °C; λ = 589 nm). Elemental analyses were performed with a Foss-Heraeus CHNO-Rapid apparatus. NMR spectra were recorded in CD_2Cl_2 at −5 °C with a 600 MHz Varian UNITYplus spectrometer. Chemical shifts (δ) are given in ppm, coupling constants (*J*) in Hz. Commercially available reagents were used as purchased. The reagents HCl·H-Gly-OMe,[23] HCl·H-Ala-OMe,[24] HCl·H-Val-OMe,[25] Boc-Gly-Ala-OH,[26] Boc-Gly-Val-OH,[27] Boc-Ala-Gly-OH,[28] Boc-Ala-Ala-OH,[29] Boc-Val-Gly-OH,[30] Boc-Val-Val-OH,[31] Z-Ala-Ala-OH,[32] and $[Cp_2TiCH_3(THF)^+][BPh_4^-]$ (**13**)[15] were prepared as described in the literature.

General Procedure of the Preparation of the Protected Tripeptides:[20c,33] Two separated ice-cooled solutions were prepared. In the first case triethylamine (0.69 mL, 506 mg, 5.00 mmol) was added to an ice-cooled solution of 20 mL of chloroform and the hydrochloride of the amino acid methyl ester (5.00 mmol). The second was prepared by adding IIDQ (1.52 g, 5.00 mmol) to the Boc- or Z-protected dipeptide (5.00 mmol) in 20 mL of chloroform while stirring. After stirring for 10 min at 0 °C, both solutions were com-

bined. The mixture was allowed to warm up to room temperature overnight. The reaction mixture was filtered and then extracted with 30 mL of aqueous 10% citric acid, 5% $NaHCO_3$ solution and water. The organic solution was dried with $MgSO_4$. The solvent was then removed in vacuo. Recrystallization of the crude product from ethyl acetate/cyclohexane (1:10) or purification by column chromatography gave the pure products. The characteristic NMR features of the 16 tripeptide derivatives prepared and used in this study are listed in Table 4.

[a] First line ^1H, second line $^{13}C\{^1H\}$ NMR spectroscopic data; the different amino acid fragments are illustrated by different colors: white (glycine or C1), light grey (alanine), dark grey (valine)

Representative Experimental Procedure of the Reaction of $[Cp_2TiCH_3(THF)^+][BPh_4^-]$ (13) with the Tripeptides (Monitored by NMR Spectroscopy): Equimolar amounts of **13** and the respective tripeptide derivative (ca. 20 mg, both in 0.5 mL CD_2Cl_2) were combined at −20 °C. After stirring for 10 min, the reaction mixture was decanted to a precooled NMR tube. The reaction was monitored by NMR spectroscopy at −5 °C and the resulting products identified. The reaction mixture was then stored for 12 h at room temperature to complete the formation of the chelate products. Only NMR spectroscopic data of the cations are listed below since the $[BPh_4^-]$ resonances are equivalent in all examples: ^1H NMR (tetraphenylborate): δ = 7.35 (m, 8 H, *ortho*-H), 7.06 (m, 8 H, *meta*-H), 6.92 (m, 4 H, *para*-H) ppm. ^{13}C NMR: δ = 164.6 (q, $^1J_{CB}$ = 49 Hz, C-*ipso*), 136.3 (C-*ortho*), 126.0 (C-*meta*), 122.1 (C-*para*) ppm. ^1H NMR (THF): δ = 3.70 (m, 4 H, α-H), 1.83 (m, 4 H, β-H). ^{13}C NMR: δ = 68.2 ppm (C-α), 26.0 (C-β).

General Procedure of the Preparation of the (Tripeptide)titanium Complexes: Reagent **13** (0.371 mmol), dissolved in 5 mL of CH_2Cl_2, was added to a solution of the respective tripeptide (0.371 mmol) in 5 mL of CH_2Cl_2 at −20 °C. The reaction mixture was allowed to warm to room temperature overnight. After removal of the solvent in vacuo, an orange-red residue was obtained. The solid was washed with 20 mL of pentane (2 ×), and dried under vacuum to yield the respective chelate (peptide)Ti cation complex. Only selected NMR spectra of the (coord)- and (chel)-type metal complexes are listed below. A complete compilation of data from the 1D and 2D NMR spectroscopic analysis is provided as Supporting Information.

Z-5(pept) (Z-Gly-Ala-Ala-OMe): Reaction of Z-Gly-Ala-OH (1.00 g, 3.57 mmol) with HCl·H-Ala-OMe (498 mg, 3.57 mmol) , triethylamine (0.50 mL, 3.57 mmol), IIDQ (1.08 g, 3.57 mmol) yielded 1.02 g (78%) of Z-**5**(pept). Single crystals were obtained by recrystallization from ethyl acetate. M.p. (DSC) 131 °C. $[\alpha]_D = -21$ (c = 1.0, CH_2Cl_2). IR (KBr): $\tilde{\nu}$ = 3321 (br. s, NH), 3063 (w), 2998 (w), 2953 (w), 1734 (vs, COO), 1692 (vs, CON), 1661 (vs, CON), 1530 (br. s), 1456 (m), 1344 (m), 1271 (br. s), 1150 (m), 1057 (m), 733 (m), 661 (w) cm^{-1}. $C_{17}H_{23}N_3O_6$ (365.4): calcd. C 55.88, H 6.34, N 11.50; found C 55.76, H 6.41, N 11.32.

X-ray Crystal Structure Analysis: Formula $C_{17}H_{23}N_3O_6$, M = 365.38, colorless crystal 0.45 × 0.20 × 0.05 mm, a = 6.135(1), b = 8.222(3), c = 18.418(3) Å, α = 84.94(2), β = 87.14(2), γ = 83.38(2)°, V = 918.5(4) $Å^3$, $\rho_{calcd.}$ = 1.321 g cm^{-3}, μ = 8.46 cm^{-1}, empirical absorption correction with ψ-scan data ($0.702 \leq T \leq 0.959$), Z = 2, triclinic, space group $P\bar{1}$ (no. 1), λ = 1.54178 Å, T = 223 K, ω/2θ scans, 4018 reflections collected ($\pm h$, $+k$, $\pm l$), [(sinθ)/λ] = 0.62 $Å^{-1}$, 4018 independent and 1688 observed reflections [$I \geq 2\,\sigma(I)$], 493 refined parameters, R = 0.057, wR^2 = 0.123, Flack parameter −0.2(4), max. residual electron density 0.24 (−0.21) e $Å^{-3}$, hydrogen atoms at the nitrogen atoms from difference Fourier calculations, others calculated and all refined as riding atoms.

Reaction of Z-5(pept) with 13

Z-5(coord^4)/Z-5(coord^7) = 2:1. Z-5(coord^4): ^1H NMR: δ = 7.55 (br., 1 H, 5-H), 7.37 [m, 5 H, 1-$OCH_2(C_6H_5)$], 6.46 (br. d, ^3J = 7.0 Hz, 1 H, 8-H), 6.20 and 6.17 (Cp-H and Cp′-H), 5.06 [AB, ^2J = 12.5 Hz, 2 H, 1-$OCH_2(C_6H_5)$], 4.44 (m, 1 H, 9-H), 4.34 (AB*X*, 1 H, 2-H), 3.73 (s, 3 H, 10-OCH_3), 3.66 (m, 1 H, 6-H), 1.98 (*AB*X, 2 H, 3-H and 3-H′), 1.42 (d, ^3J = 7.3 Hz, 3 H, 9-CH_3), 1.30 (d, ^3J = 7.2 Hz, 3 H, 6-CH_3), 1.12 (s, 3 H, Ti−CH_3) ppm. ^{13}C NMR: δ = 178.0 (C-4), 172.9 (C-10), 168.4 (C-7), 157.2 (C-1), 138.7 to 122.0 {1-$OCH_2(C_6H_5)$ and $[BPh_4]^-$}, 116.7 and 116.6 (C-Cp and C-Cp′), 67.7 [1-$OCH_2(C_6H_5)$], 52.9 (10-OCH_3), 52.3 (Ti−CH_3), 49.8 (C-9), 48.4 (C-6), 44.8 (C-3), 18.2 (6-CH_3), 17.6 (9-CH_3) ppm. **Z-5(coord^7):** ^1H NMR: δ = 8.63 (br. d, ^3J = 8.4 Hz, 1 H, 5-H), 7.37 [m, 5 H, 1-$OCH_2(C_6H_5)$], 6.08 (br., 1 H, 8-H, not visible), 6.27 and 6.26 (Cp-H and Cp′-H), 5.26 (AB*X*, 1 H, 2-H), 5.05 [AB, ^2J = 12.6 Hz, 2 H, 1-$OCH_2(C_6H_5)$], 3.83 (m, 1 H, 6-H), 3.78 (s, 3 H, 10-OCH_3), 3.66 (m, 1 H, 9-H), 3.38 (*AB*X, ^2J = 16.7 Hz, 2 H, 3-H and 3-H′), 1.44 (d, ^3J = 7.2 Hz, 3 H, 6-CH_3), 1.13 (s, 3 H, Ti−CH_3), 0.96 (d, ^3J = 7.3 Hz, 3 H, 9-CH_3) ppm. ^{13}C NMR: δ = 188.0 (C-7), 182.3 (C-10), 169.7 (C-4), 158.2 (C-1), 138.7−122.0 {1-$OCH_2(C_6H_5)$ and $[BPh_4]^-$}, 116.9 and 116.8 (C-Cp and C-Cp′), 67.8 [1-$OCH_2(C_6H_5)$], 53.3 (10-OCH_3), 51.7 (Ti−CH_3), 49.8 (C-9), 48.4 (C-6), 45.2 (C-3), 16.7 (9-CH_3), 15.9 (6-CH_3) ppm.

Product Z-5(chel^B): Reaction of Z-**5**(pept) (113 mg, $3.09 \cdot 10^{-4}$ mol) with **13** (181 mg, $3.09 \cdot 10^{-4}$ mol) yielded 248 mg (93%) of orange-red Z-**5**(chel^B). M.p. (DSC): 46 °C (dec.). $[\alpha]_D = -29$ (c = 1.0,

CH_2Cl_2). $[Yb(THF)_3(C_5H_4PPh_2)_2W(CO)_4]\cdot 0.5THF$ and $^1_\infty[Yb(THF)(C_5H_4PPh_2)_2(\mu\text{-}OC)W(CO)_3]$: Two New Heterobimetallic Complexes Containing Yb^{II} and W^0

Klaus Müller-Buschbaum,*[a,b] Glen B. Deacon,[b] and Craig M. Forsyth[b]

Keywords: Heterometallic complexes / Ytterbium / Tungsten / Carbonyl ligands

The reaction of bis(diphenylphosphanylcyclopentadienyl)-ytterbium(II) with tungsten hexacarbonyl in tetrahydrofuran yields $[Yb(THF)_3(C_5H_4PPh_2)_2W(CO)_4]\cdot 0.5THF$ (**1**), whilst $[Yb(THF)(C_5H_4PPh_2)_2(\mu\text{-}OC)W(CO)_3]$ (**2**) is obtained from toluene. Complex **1** contains nine-coordinate bis(η^5-diphenylphosphanylcyclopentadienyl)tris(tetrahydrofuran)-ytterbium(II) units. Complex **2** has eight-coordinate ytterbium(II) with one carbonyl group showing an *iso*-carbonyl linkage to ytterbium (W–C≡O–Yb), thereby forming a structure of infinite chains. The $Yb(\eta^5\text{-}C_5H_4PPh_2)_2$ units in both **1** and **2** bind to tungsten through the phosphorus atoms giving an octahedral *cis*-$W(CO)_4P_2$ arrangements.

Introduction

Early lanthanoid-d-block bimetallic complexes such as $[Yb(THF)(C_5Me_5)_2Co(CO)_4]$[1] and $[Yb(C_5Me_5)_2Fe_3(CO)_{11}]$[2] involve the coordination of a transition metal carbonylate to the lanthanoid through a carbonyl oxygen. The introduction of the diphenylphosphanylcyclopentadienyl ligand ($CpPPh_2$) into organolanthanoid chemistry with $Yb(CpPPh_2)_2$ [3] enabled the preparation of the first lanthanoid-d-block bimetallic complex with the f-block element in the donor part of the molecule. Subsequently, other divalent[4–7] and trivalent[8–14] (diphenylphosphanylcyclopentadienyl)lanthanoid complexes have been prepared, including a Sm^{III} complex with four different ligands,[15] and a limited number of further bimetallics.[4,9,12] Crystallographically characterized derivatives are relatively scarce (see also the related $[Yb(THF)_2(C_4Me_4P)_2Ru(H)_2(PPh_3)_2]$[16]). $[Yb(THF)_2(CpPPh_2)_2Mo(CO)_4]\cdot THF$ and $[Yb(THF)(CpPPh_2)_2Mo(CO)_4]\cdot PhMe$ were prepared with carbonyls of Group 6 transition metals, and the latter was proposed to contain an *iso*-carbonyl–Yb linkage, although no crystal structures were determined.[4] By preparing the tungsten carbonyl analogs, we have succeeded in crystallizing the key complexes $[Yb(THF)_3(CpPPh_2)_2W(CO)_4]\cdot 0.5THF$ (**1**) and $[Yb(THF)(CpPPh_2)_2(\mu\text{-}OC)W(CO)_3]$ (**2**) whose structures illuminate the nature of the $Yb(CpPPh_2)_2$/Group 6 tetracarbonyl bimetallics.

Results and Discussion

Reaction of $[Yb(THF)(CpPPh_2)_2]$[4] with $W(CO)_6$ in THF initially at room temperature and then at elevated temperatures yielded $[Yb(THF)_3(CpPPh_2)_2W(CO)_4]\cdot 0.5THF$ (**1**) [Equation (1)]. Single crystals were also obtained from the same solvent, and readily underwent decomposition when taken out of the mother liquor precluding opportunity for microanalysis.

$$[Yb(thf)(CpPPh_2)_2] + W(CO)_6 \xrightarrow{THF} [Yb(thf)_3(CpPPh_2)_2W(CO)_4]\cdot 0.5THF\ (\mathbf{1}) + 2\ CO \quad (1)$$

The infrared spectra of the product in Nujol and in THF show four ν(CO) absorptions consistent with a *cis*-$W(CO)_4$ moiety, with values quite similar to those (2010, 1900, 1880, 1845 cm^{-1})[4] for the proposed complex $[Yb(THF)_2(CpPPh_2)_2Mo(CO)_4]\cdot THF$ in Nujol. Although the complex is almost insoluble in toluene (see below) the spectrum of the light green solution shows ν(CO) absorptions similar to the values for the complex in THF, suggesting dissolution of some of the complex as unchanged **1**. The ^1H NMR spectrum in $[D_8]THF$ confirmed the presence of the diphenylphosphanylcyclopentadienyl ligand. A similar ^{31}P resonance was observed for **1** in $[D_8]THF$ and in C_6D_6 (sparing solubility at room temperature) consistent with the similar IR spectra for the compound in THF and toluene. As expected for a P–W coordination, a major shift of the ^{31}P resonance to higher frequencies (δ = 9–10 ppm) than the value for $[Yb(THF)_2(CpPPh_2)_2]$ (δ = −20.5 ppm[4]) is observed, although this change is not as marked as that seen upon coordination of the $Yb(CpPPh_2)_2$ ligand to $Ni(CO)_2$, $PtMe_2$, or $Mo(CO)_4$ (δ =

17−20 ppm).[4] Further evidence for P−W bonding comes from observation of W−P coupling (see Exp. Sect.) within the usual range for $^1J_{W,P}$.[17,18]

Complex **2** can be obtained as single crystals from the same reactants as **1** but by heating in toluene. Its identity was established as a Yb−O≡C−W-bridged complex [Equation (2)]. Although some **1** dissolves in toluene, the bulk gives dark colored insoluble $[Yb(THF)(CpPPh_2)_2(\mu\text{-}OC)W(CO)_3]$ (**2**) [Equation (3)].

$$[Yb(THF)(CpPPh_2)_2] + W(CO)_6 \xrightarrow{\text{toluene}} [Yb(THF)(CpPPh_2)_2(\mu\text{-}OC)W(CO)_3]\ (\mathbf{2}) + 2\ CO \quad (2)$$

$$[Yb(THF)_3(CpPPh_2)_2W(CO)_4]\cdot 0.5THF\ (\mathbf{1}) \xrightarrow{\text{toluene}} [Yb(THF)(CpPPh_2)_2(\mu\text{-}OC)W(CO)_3]\ (\mathbf{2}) + 2\ THF \quad (3)$$

The formation of **2** releases THF into toluene enabling the resulting solution to dissolve a little of **1** unchanged. The IR spectrum of solid **2** also displays four carbonyl absorptions indicative of a *cis*-$W(CO)_4$ arrangement. One of these bands (1758 cm^{-1}) is in the region for a bridging or *iso*-carbonyl group, and even lower than the corresponding value (1790 cm^{-1}) for the related molybdenum complex $[Yb(THF)(CpPPh_2)_2Mo(CO)_4]\cdot PhMe$.[4] Crystals of **2** are extremely unstable outside the mother liquor making a fast characterization by a low temperature X-ray determination necessary and precluding elemental analysis.

Although the compositions of **1** and **2** differ only in their THF content, the structures are very different. In complex **1** a formally nine-coordinate ytterbium atom is surrounded by three THF oxygen atoms and two η^5-bonded $CpPPh_2$ ligands, which chelate through the phosphorus atoms to a $W(CO)_4$ moiety in *cis* positions (Figure 1). The resulting nine-coordination is extremely unusual for $Ln^{II}(Cp')_2$-thf complexes which are normally eight-coordinate $[Ln(Cp')_2(THF)_2]$,[19−21] apart from $[Sm(ind)_2(THF)_3]$ (ind = indenyl).[22] It may be considered that **1** is more remarkable than the Sm^{II} complex[22] since the nine-coordinate ionic radius is 0.12 Å smaller for Yb^{2+} than Sm^{2+}.[23] It is possible that the electron-withdrawing effect of the $CpPPh_2$ ligands[24] more than compensates for the bulkiness of the PPh_2 substituent. The best-fit polyhedron[25] for the three oxygen donors and the centroids (cent) of the $CpPPh_2$ ligands around ytterbium is a distorted square-based pyramid with O(6) apical. The difference from a trigonal bipyramidal arrangement is best seen in the angle difference of a best-fit polyhedron calculation,[26] which is $\Delta = 14.4°$. For a trigonal bipyramidal arrangement the expected value would be 60° and 0° for an undistorted square-based pyramid. However, describing spherical phenomena such as Cp rings by single points representing the centroids of those rings has to be viewed cautiously. Tungsten shows a slightly distorted octahedron of two *cis* phosphorus and four carbon donor atoms.

In complex **2** each ytterbium is eight-coordinate and surrounded by two η^5-$CpPPh_2$ ligands, a THF oxygen and a carbonyl oxygen, with the two phosphorus atoms chelating

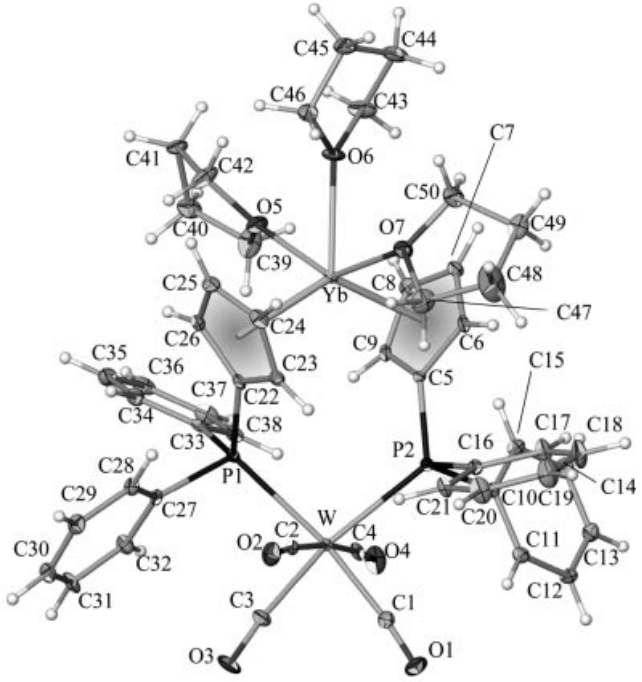

Figure 1. The molecular structure of $[Yb(THF)_3(CpPPh_2)_2W(CO)_4]\cdot 0.5THF$ (**1**); η^5-interactions between Yb and Cp are represented by bonds towards centroids of shaded Cp rings; the thermal ellipsoids here and in Figure 2 are scaled to a probability density of 50%

(*cis*) to a $W(CO)_4$ unit, one oxygen of which bridges to the adjacent ytterbium. The best-fit polyhedron[25] for the disparate oxygen donors and the $CpPPh_2$ centroids is a tetrahedron, whilst tungsten again shows a slightly distorted octahedral geometry (Figure 2). Only one other structure of a Ln−O≡C−W arrangement could be found in a search of the Cambridge Crystallographic Data Base, viz. $[Ce(Cp')_2(\mu\text{-}OC)_2W(CO)Cp]$ [$Cp' = C_5H_3(SiMe_3)_2$-1,3, $Cp = C_5H_5$],[27] although analogous molybdenum complexes are more numerous and include Mo−C≡O−Yb-bonded systems.[28−31]

Whilst complex **1** is molecular, complex **2** shows a one-dimensional chain structure running along [100] with neighbouring molecules connected via iso-carbonyl bridges (Figure 3). Complex **2** can therefore be described by the Niggli formula $^1_\infty[Yb(THF)(C_5H_4PPh_2)_2(\mu\text{-}OC)W(CO)_3]$.

Selected bond lengths and angles for **1** and **2** are given in Table 1. The average Yb−C distances (276 pm and 270 pm for **1** and **2** respectively) differ, as expected, for eight- and nine-coordinate Yb^{2+}.[23] In addition, the value for **2** corresponds to the average Yb−C bond length (271 pm) of eight-coordinate $[Yb(THF)_2(CpPPh_2)_2Z]\cdot thf$ {$Z = Ni(CO)_2$, $PtMe_2$}.[4] Although different methods for the calculation of ionic radii are present in the literature, subtraction of ionic radii from distances offers valuable data for comparison. Based on the values[23] for eight- and nine-coordinate Yb^{2+} the subtraction from[32,33] <Yb−C> distances gives a value of 156 pm, which is similar to values for analogous bimetallic complexes.[4] The attached $CpPPh_2$ ligands in **1** show a slight tilt associated with a difference in Yb−C distances of

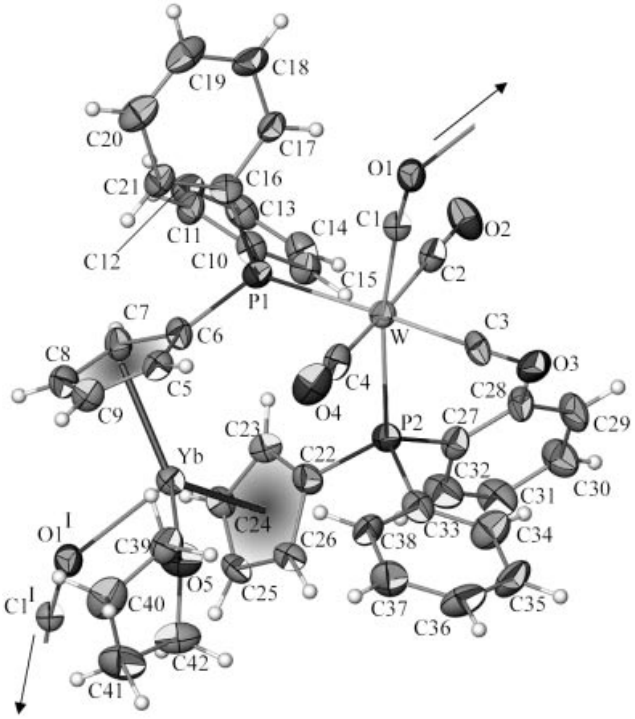

Figure 2. The molecular structure of $^{1}_{\infty}$[Yb(THF)($C_5H_4PPh_2$)$_2$(μ-OC)W(CO)$_3$] (**2**); η^5-interactions between Yb and Cp are represented by bonds towards centroids of shaded Cp rings; the *iso*-carbonyl-bridging to a neighbouring molecule is indicated by arrows

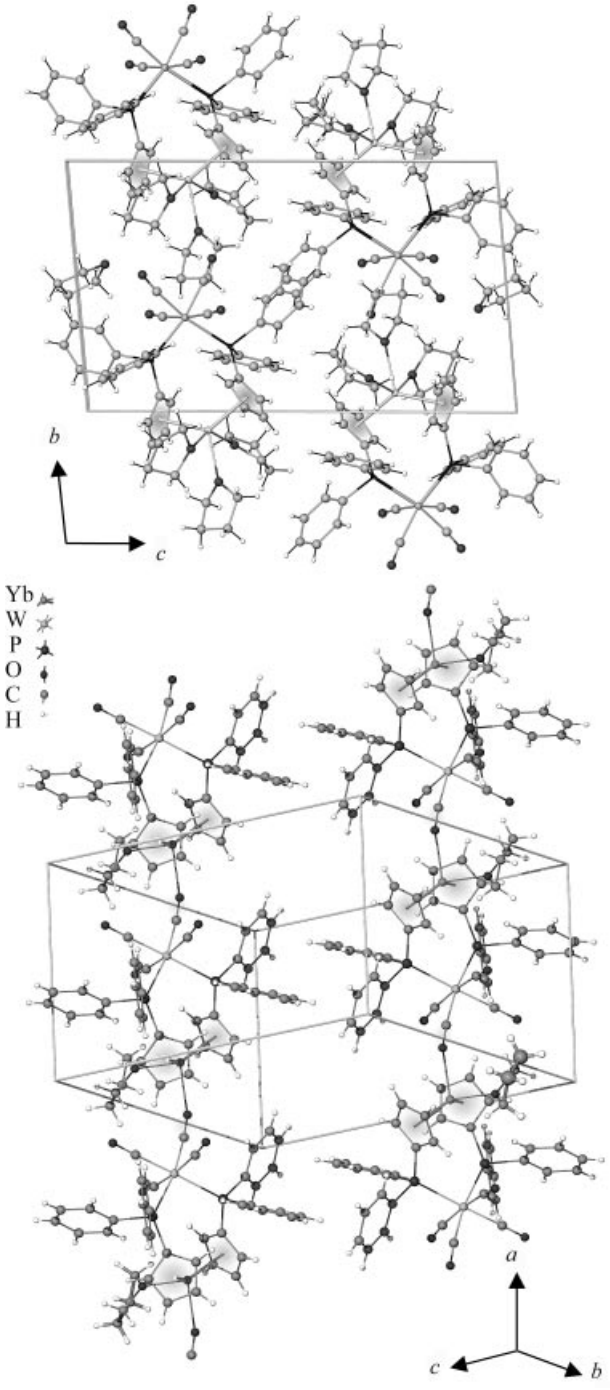

Figure 3. The crystal structures of [Yb(THF)$_3$($C_5H_4PPh_2$)$_2$-W(CO)$_4$]·0.5THF (**1**, above) and [Yb(THF)($C_5H_4PPh_2$)$_2$(μ-OC)W(CO)$_3$] (**2**, below); the unit cells are shown; whilst **1** is a packing of isolated molecules, **2** is a packing of infinite chains of molecules connected via *iso*-carbonyl bridges underlain in light grey

only 12 pm. Thus, there is no significant trend towards η^3-attachment, as subtraction of the ionic radius from the longest Yb−C distance gives a normal value[32,33] of 162 pm. The Ln−C distance variation is much less than that of [Er(η^5-CpPPh$_2$)$_3$(OPPh$_3$)].[7] The Yb−O(THF) distance of **2** corresponds well with those of [Yb(THF)$_2$(CpPPh$_2$)$_2$Ni(CO)$_2$] [242.4(4), 242.9(4) pm][4] and is marginally longer than <Yb−O> of the PtMe$_2$ analog (240 pm).[4] On the other hand the Yb−O distances of **1** show a wide variation. One is as short as that of eight-coordinate **2**, and two are much longer so that the average (253 pm) exceeds the value for **2** by more than the expected amount for the coordination number variation. As the shortest distance, Yb−O(6), is for the ligand that is apical in the Yb(cent)$_2$O$_3$ square pyramid (as best-fit polyhedron) whilst the other two THF ligands are *transoid* to each other, a *trans* influence may be invoked for the lengthening of Yb−O(5,7). Such influences are now well established in lanthanoid chemistry despite the ionic nature of the bonding.[34−37] Subtraction of an appropriate Yb^{2+} ionic radius from the Yb−O distances gives a value of 130 pm for **2**, which is at the short end of the range 134 ± 5 pm for ether complexes of organolanthanoids,[38] whilst the longer Yb−O distances of **1** give a value of 138−141 pm, which is at the higher end and greater than the expected ionic radius difference of about 6 pm due to the variation in coordination number. In contrast the shortest Yb−O distance of **1** gives a value of 124 pm, which is well below the normal range, reflecting the absence of any ligand *transoid* to oxygen. In addition, the CpPPh$_2$ ligand is electron withdrawing[24] and is known to cause bond-shortening upon attachment of coligands.[7] Unfortunately the precision of the [Sm(ind)$_2$(THF)$_3$] structure determination[22] is insufficient to be able to compare the Sm−O bond lengths with the present Yb−O bond lengths. Thus **1** provides currently unique data. The Yb−O(C) distances in **2** lie within the range 238−256 pm reported for recent *iso*-carbonyl-bonded ytterbium complexes[30,31,39−41] (cf. 225 pm for ytterbium(III) in two earlier structures[1,2]).

Table 1. Selected distances (pm) and angles(°) for $[Yb(THF)_3(CpPPh_2)_2W(CO)_4]\cdot 0.5THF$ (**1**) and $[Yb(THF)(CpPPh_2)_2(\mu\text{-}OC)W(CO)_3]$ (**2**); standard deviations are given in brackets

[a] cent1 = centroid of the $CpPPh_2$ rings with the C atoms C(5)−C(9). [b] cent2 = centroid of the $CpPPh_2$ rings with the C atoms C(22)−C(26). [c] I: $x-1, y, z$. [d] II: $x+1, y, z$.

The coordination sphere around tungsten shows the expected features. Opening of the P−W−P angles of **1** and **2** by up to 12° from the normal value of 90° in response to the bulky substituents on phosphorus parallels a similar behavior in recently reported $WP_2(CO)_4$ complexes,[42−44] but is less than the 18.35° observed with bulky *cis*-PPh_2(*o*-Me-OC_6H_4) ligands.[42] On the other hand the W−P distances are close to those (256, 257 pm) with this bulky phosphane, and larger than those (247, 251 pm) of the less crowded [*cis*-$W(CO)_4(Ph_2PH)_2$].[43] Although the shorter W−C bonds in both **1** and **2** are located *trans* to phosphorus, consistent with a greater *trans* influence of CO than R_3P in W^0 complexes,[45] the differences are within a three esd range and hence are of limited significance. Coordination of the carbonyl group to Yb in **2** has no significant effect within error limits on the W−C bond lengths or W−C−O angles (Table 1), in contrast to $[Ce(Cp')_2(\mu\text{-}CO)_2WCp(CO)_2]$ [Cp′ = $C_5H_3(SiMe_3)_2$-1,3, Cp = C_5H_5] for which $W-C-O_{ter}$ is bent relative to near linear $W-C-O_{br}$.[27] The Yb−O−C angle is at the lower end for *iso*-carbonylytterbium complexes and is close to that of $[Yb(NCMe)_3(\mu\text{-}CO)_3Fe(CO)]_n$ (145.75°)[38] and quite different from the Ce−O−C angles (174.8, 154.4°) of $[Ce(Cp')_2(\mu\text{-}CO)_2WCp(CO)_2]$ [Cp′ = $C_5H_3(SiMe_3)_2$-1,3, Cp = C_5H_5].[27] Overall the W−C distances (bridging or terminal) of the cerium complex are much shorter than those of **1** and **2**,

consistent with a weaker trans influence of Cp than R_3P or CO in W^0 complexes.[45]

Conclusions

Observation of nine-coordinate ytterbium in $[Yb(THF)_3(CpPPh_2)_2W(CO)_4]\cdot 0.5THF$ (**1**) is a major surprise in view of the ubiquitous nature of eight-coordinate $[Yb(THF)_2(Cp')_2]$ complexes[19−21] and the presence of eight-coordinate Yb in $[Yb(THF)_2(CpPPh_2)_2PtMe_2]\cdot THF$ and $[Yb(THF)_2(CpPPh_2)_2Ni(CO)_2]$.[4] Accordingly, the proposal[4] that the analytically similar $[Yb(THF)_2(CpPPh_2)_2Mo(CO)_4]\cdot THF$ contains eight-coordinate $Yb(THF)_2(CpPPh_2)_2$ units may be questioned and it is likely that this complex also contains nine-coordinate $Yb(THF)_3(CpPPh_2)_2$ moieties. A single-crystal structure determination is therefore desirable. The only prior example of a nine-coordinate $[Ln(THF)_3(Cp')_2]$ complex, $[Sm(ind)_2(THF)_3]$,[22] is also unexpected given the bulky indenyl ligands, although lack of bond length data frustrates examination of possible slippage towards η^3 coordination

On the other hand, the structure of **2** with the *iso*-carbonyl−Yb linkage provides validation of the proposal of similar bonding in $[Yb(THF)(CpPPh_2)_2Mo(CO)_4]\cdot PhMe$ and indeed in $[Yb(THF)(CpPPh_2)_2Ni(CO)_2]$.[4] Accordingly, the structures of **1** and **2** are of strategic importance in understanding the behavior of $Yb(CpPPh_2)_2$ derived bimetallic complexes.

Experimental Section

All reactions were carried out under dry nitrogen using dry box and standard Schlenk techniques due to the air- and moisture-sensitivity of **1** and **2**. Solvents were dried by distillation from sodium wire/benzophenone. IR data (4000−650 cm^{-1}) were recorded either for Nujol mulls sandwiched between NaCl plates or as THF or PhMe solutions in a solution cell with AgBr plates using a Perkin−Elmer 1600 Fourier transform infrared spectrometer. NMR spectra were obtained on a Bruker AC300 instrument. ^{31}P spectra are referenced to external 85% H_3PO_4. Deuterated solvents were degassed and distilled from Na/K alloy prior to use. $W(CO)_6$ was purchased from Aldrich and used as received whilst $[Yb(THF)(CpPPh_2)_2]$ was prepared according to the literature procedure.[3]

$[Yb(THF)_3(CpPPh_2)_2W(CO)_4]\cdot 0.5THF$ (1): A Schlenk flask was charged with $W(CO)_6$ (1.2 mmol), $[Yb(THF)(CpPPh_2)_2]$ (0.7 mmol) and THF (40 mL) giving an intense dark red solution. The reaction mixture was stirred and heated to 60 °C for 48 h and then stirred for a further 48 h at room temperature. Hexane was added until a permanent precipitate formed. Upon heating, the solid re-dissolved and slow cooling to −20 °C gave dark red crystals of **1** and some colorless crystals of $W(CO)_6$. Subsequent warming to room temperature dissolved the colorless material and the remaining red crystals were collected by filtration and dried under vacuum at room temperature for 1 h to give a yield of 0.3 g (45%). Rapid decomposition outside the mother liquor, however, made it preferable to collect the product from solution. IR (Nujol): $\tilde{\nu}$ = 2005vs, 1894vs, 1872vs, 1849vs [all ν(CO)], 1570w, 1440s, 1204w, 1177m, 1153w, 1087m, 1045s, 1031s, 917w, 881m, 742m, 695m; (THF) ν(CO): 2015s, 1914s, 1893s, 1880sh, (PhMe) ν(CO) 2015s, 1917s, 1892s(br), 1868sh cm^{-1}. ^1H NMR (300 MHz, $[D_8]$THF): δ = 5.93 (br s, 4 H, β-C_5H_4), 6.17 (br s, 4 H, α-C_5H_4,), 7.37 [br s, 12 H, *m*-,*p*-*H*(Ph)], 7.59 [br s, 8 H, *o*-*H*(Ph)] ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $[D_8]$THF): δ = 9.67 ($^1J_{W,P}$ = 237 Hz); (C_6D_6): 9.00 ($^1J_{W,P}$ = 232 Hz) ppm.

$[Yb(THF)(CpPPh_2)_2(\mu\text{-}OC)W(CO)_5]$ (2): (a) A glass ampoule was charged with $W(CO)_6$ (0.14 mmol), $[Yb(THF/DME)(CpPPh_2)_2]$ (0.14 mmol), and PhMe (1.5 mL) and then degassed and sealed under vacuum. Heating at 130 °C for 127 h gave a dark red solution. Upon cooling, very dark red crystals of **2** deposited, together with $W(CO)_6$ and some green crystals which disappeared on subsequent heating. Several of the dark red crystals were mounted for X-ray crystallography. The remaining material decomposed within hours in the inert drybox atmosphere also indicating instability outside the mother liquor.

(b) Red crystals of **1** were washed with successive amounts of PhMe (3 × 5 mL) until the washings were colorless. The remaining dark colored powder was dried under vacuum at room temperature for 1 h. IR (Nujol): $\tilde{\nu}$ = 2016vs, 1910vs, 1883vs [all $\nu(CO)_{ter}$], 1758vs [$\nu(CO)_{br}$], 1305w, 1177m, 1156w, 1085m, 1036s, 1027m, 894w, 756s, 737s, 694s, cm^{-1}.

X-ray Crystal Structure Determination: The data collection for single crystal X-ray determination of **1** was carried out on a κ-CCD diffractometer (Enraf Nonius), and the data collection for **2** on an IPDS-I diffractometer (STOE). Structure solution: SHELXS-86;[46] structure refinement: SHELXL-97.[47] Integrity of symmetry and geometry: PLATON.[48] All non-hydrogen atoms were refined anisotropically. Some hydrogen atoms of **1** were deduced from the Fourier map while most hydrogen atoms were placed in calculated positions and assigned to an isotropic displacement parameter of 1.2-times the size of the isotropic displacement parameter of the parent carbon atom. Two THF molecules of **1** show a split position of the carbon atom opposite to the oxygen atom of the THF rings in a ratio of about 2:1. In addition the free THF molecule is split by centers of symmetry.

Crystallographic Data for $C_{52}H_{56}O_{7.5}P_2WYb$ (1): Triclinic, $P\bar{1}$, Z = 2, T = 123(2) K, a = 1024.76(1) pm, b = 1255.72(1) pm, c = 2054.38(3) pm, α = 89.154(1)°, β = 75.803(1)°, γ = 68.069(1)°, V = 2368.7(5)·10^6 pm^3, μ = 45.1 cm^{-1}, Mo-K_α, 5.16 ≤ 2θ ≤ 56.56°, −13 ≤ h ≤ 13, −16 ≤ k ≤ 16, −24 ≤ l ≤ 27, F(000) = 1204, R_1 = 0.0340 for 9407 reflections [$I > 2\sigma(I)$], R_1 = 0.0482 and wR_2 = 0.0805 for 11547 unique reflections, GOOF on F^2 = 1.042.

Crystallographic Data for $C_{42}H_{36}O_5PWYb$ (2): Triclinic, $P\bar{1}$, Z = 2, T = 170(1) K, a = 1008.2(4) pm, b = 1195.0(5) pm, c = 1750.4(8) pm, α = 105.06(5)°, β = 97.98(5)°, γ = 106.18(5)°, V = 1904(2)·10^6 pm^3, μ = 55.9 cm^{-1}, Mo-K_α, 4.46 ≤ 2θ ≤ 50.0°, −11 ≤ h ≤ 11, −14 ≤ k ≤ 14, −20 ≤ l ≤ 20, F(000) = 1004, R_1 = 0.0564 for 3960 reflections [$I > 2\sigma(I)$], R_1 = 0.0868 and wR_2 = 0.1399 for 6299 unique reflections, GOOF on F^2 = 0.924. CCDC-177663 (**1**) and CCDC-177664 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Variety in the Coordination Modes of the Ligand Hexakis(pyrazol-1-yl)benzene (Hpzb) to Pd^{II}, Pt^{II} and Cu^{I} Centres

Ana M. Guerrero,[a] Félix A. Jalón,*[a] Blanca R. Manzano,[a] Rosa M. Claramunt,[b] María Dolores Santa María,[b] Consuelo Escolástico,[b] José Elguero,[c] Ana M. Rodríguez,[d] Miguel A. Maestro,[e] and José Mahía[e]

Keywords: N ligands / Conformational analysis / Palladium / Platinum / Copper / Coordination chemistry

The structure and conformational analysis of eight complexes derived from hexakis(pyrazol-1-yl)benzene (hpzb) have been carried out by means of X-ray crystallography and NMR spectroscopy. The metallic fragments [$Pd(C_6F_5)_2$, [$Pd(\eta^3$-2-Me-$C_3H_4)]^+$, $PtCl_2$ and $Cu(PMe_3)^+$] coordinate with two adjacent pyrazole residues yielding complexes with one, two or three metallic centres. The crystal and molecular structures of [{$Pd(C_6F_5)_2$}$_2$(hpzb)], [{$Pd(\eta^3$-$C_4H_7)$}$_2$-(hpzb)]$(TfO)_2$, [{$Cu(PMe_3)$}$_2$(hpzb)]$(BF_4)_2$ and [{$Pd(\eta^3$-$C_4H_7)$}$_3$(hpzb)]$(TfO)_3$ have been determined. The structure of each of the complexes depends on the fact that the metal atoms, when two or three are present, prefer to be situated on opposite faces of the benzene ring. Evidence for restricted rotation of the uncoordinated pyrazolyl groups has been found for the free ligand and monometallic derivatives, while free rotation of these groups at room temperature has been observed for the dimetallic complexes. Furthermore, the derivative {[$Cu(PMe_3)]_2$(hpzb)}$(BF_4)_2$ and probably [{$Pd(\eta^3$-$C_4H_7)$}$_2$(hpzb)]$(TfO)_2$ exhibit metallotropy on the NMR time scale.

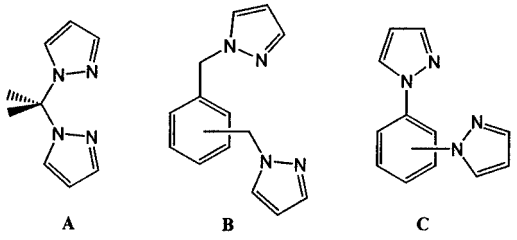
Introduction

The use of *N*-substituted pyrazoles as ligands is very common, with the three main types of derivatives being polypyrazolylborates (scorpionates), polypyrazolylmethanes **A** and polypyrazolylazines (pyridines, pyrimidines, *s*-triazines, etc.). On the other hand, polypyrazolylbenzenes have seldom been used if one excludes the (pyrazol-1-ylmethyl) derivatives **B** (“coelenterands”),[1−17] which have structures intermediate between pyrazolylalkanes and (pyrazol-1-yl)benzenes **C** (Scheme 1).

Only five ligands derived from **C** have been used in coordination chemistry: **D**,[18] **E**,[19] **F**,[20] **G** [21] and **H** [22−23] (Scheme 2). However, hexakis(pyrazol-1-yl)benzene (hpzb, **1**), which belongs to the “propellene” class of ligands that we have studied systematically,[24−29] has never previously been used.



Scheme 1

In this paper, we will discuss the coordination chemistry of **1** (hpzb) to different metal atoms with two vacant coordination sites with special emphasis on its conformational aspects. Compound **1**, like other biphenyl-like compounds, has two rotational barriers: the planar barrier, due to steric effects, and the perpendicular one, due to the loss of conjugation. In propellenes the first barrier is much larger than the second one. Therefore, these compounds can be described as having the six azolyl residues librating about the perpendicular conformations, either (*P*) or (*M*) [plus (*P*) or minus (*M*) refers to the sense of rotation, clockwise or counterclockwise, with respect to a perpendicular orientation of the pyrazole and the benzene ring]. We are interested in determining whether in solution, not only in the free ligand but also in the complexes having non-coordinated pyrazolyl groups, free or restricted rotation of these rings exists. Concerning the metallic complexes we were also inter-

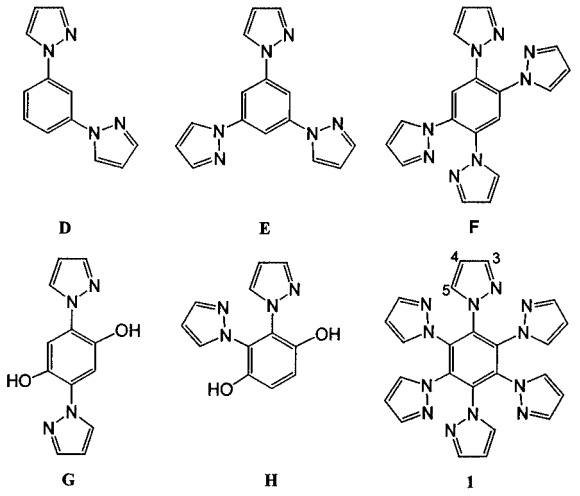


Scheme 2

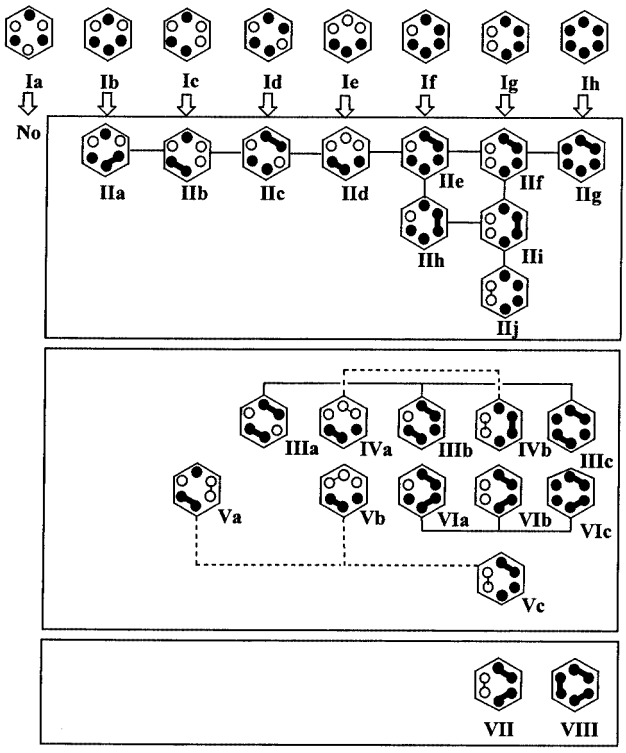
ested in studying the following points: i) The number of metal atoms that is possible to introduce for each hpzb ligand. ii) The disposition of these metal atoms around the six pyrazolyl groups. For example, it was of interest to determine the possibility of having two or more metal atoms at the same side of the benzene plane or two metal atoms bonded to two contiguous pyrazolyl rings. It was foreseeable that the steric requirements of the metallic fragment considering the size and orientation of the ancillary ligands could play an important role in these two points. iii) The presence of fluxional behaviour due to metallotropic shifts and the factors that influence it. iv) Where possible, we also have an interest in analysing the solid-state structure. Interesting points concerning this aspect could be: similarity between complexes of different metals, cooperativity in the orientation of the pyrazolyl groups and correspondence between the solid-state and solution structures. We chose different fragments with late transition metals: $Pd(C_6F_5)_2$, $PtCl_2$, $[Pd(\eta^3\text{-}2\text{-}Me\text{-}C_3H_4)]^+$, and Cu^+/PMe_3. The first two examples with different metals and ancillary ligands of different size were supposed to exhibit a typical square-planar coordination. The allyl fragment had a different orientation of this group that could reduce the symmetry of the derivatives obtained increasing the number of possible isomers. The copper centre was chosen to analyse a case with a different metallic geometry (tetrahedral or trigonal-planar were open possibilities).

Results and Discussion

Conformational Analysis

Before describing the synthesis and characterisation of the new derivatives it would be useful to analyse the different isomers that could exist for the ligand and the mono-, di- and trinuclear complexes depending on the relative orientation of the metallic fragments and the uncoordinated pyrazolyl rings.

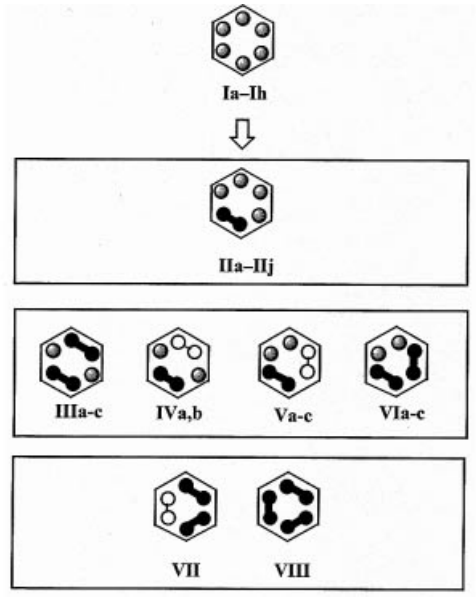
In derivative **1**, and according to our previous discussion, each pyrazol-1-yl group can adopt two perpendicular conformations depending on whether the N-2 lone pair is *up* (*u*, black dot) or *down* (*d*, white dot). This situation results in the eight isomers **Ia**−**Ih**, neglecting enantiomerism (**Ic** is chiral), which we have represented at the top of Scheme 3. The hpzb ligand exists in the solid state in two conformations (polymorphism) − *ududud* (**Ia**) and *udduud* (**Ic**).[25] According to AM1 and SAM calculations, these conformations have torsion angles close to 90°, with the most stable conformer being **Ia** followed, at about 9 kJ mol^{-1} higher, by **Ib**, **Ic** and **Id**, all of which have the same energy.[28]



Scheme 3. Conformational description of ligand **1** and all possible mono- di- and trimetallic derivatives

The main difficulty concerning the conformation of **1** and its bidentate chelate complexes is to decide between a fixed *up-down* conformation and a free-rotating situation. If we represent a free-rotating pyrazole with a grey dot, we obtain the situation depicted in Scheme 4. In both Schemes we suppose that the metallic fragment does not reduce the symmetry of the complex. It should be noted, however, that free rotation does not signify that all conformations are equally populated. The classifications shown in Scheme 4 are only rigorously true when the *up* and *down* conformations have the same energy.

The formation of a bidentate chelate complex κ^2-*N*1*N*2-hpzb (**II**) is not possible for conformation **Ia** but is feasible for all the others, which are related by *u*/*d* rotations of the uncoordinated pyrazol-1-yl residues (ten conformers **IIa**−**IIj**). The formation of a second chelation could lead to four different isomers, **III**−**VI**, two with κ^4-*N*1*N*2,*N*4*N*5-



Scheme 4. Conformational description of ligand **1** and all possible mono-, di- and trimetallic derivatives assuming free rotation of the uncoordinated pyrazoles

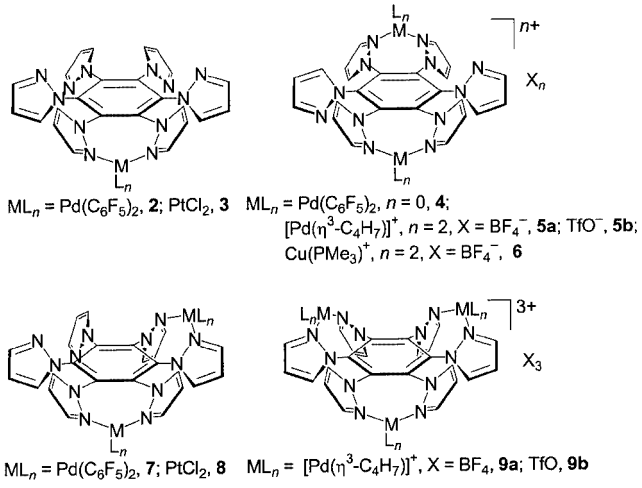
hpzb coordination (three conformers **IIIa**−**IIIc** and two conformers **IVa**, **IVb**) and two with κ⁴-*N*1*N*2,*N*3*N*4-hpzb coordination (three conformers **Va**−**Vc** and three conformers **VIa**−**VIc**). Finally, the third and final chelation could lead to only two isomers κ⁶-*N*1*N*2,*N*3*N*4*N*5*N*6-hpzb (**VII** and **VIII**) without any rotational freedom (they are identical in Schemes 3 and 4).

Synthesis of Complexes

In order to follow the discussion more easily we have included the molecular structures of the new complexes in Scheme 5.

(a) Pd Complexes 2, 4, 5, 7 and 9

The reaction between hpzb and $[Pd(C_6F_5)_2(cod)]$ led to a mixture of three compounds whose relative proportions depended on the stoichiometry used:



Scheme 5

1 hpzb + 0.5 $[Pd(C_6F_5)_2(cod)]$ → **2** + hpzb

1 hpzb + 1 or 2 $[Pd(C_6F_5)_2(cod)]$→ **2** + **4** + **7**

1 hpzb + 3 or 6 $[Pd(C_6F_5)_2(cod)]$ → **4** + **7**

When **4** and **7** are present in a reaction mixture, their relative ratio is near 50:50. The reaction corresponding to a 1:6 stoichiometry was only carried out in an NMR tube and the attempt to obtain a compound with three Pd centres (analogous to **9**) failed. In order to increase the yield of **2** we used a ratio of 1:0.5. Although **2** was the only metallic complex formed in this reaction we were not able to obtain it in a pure form because it was partially transformed into **4** and **7** in the crystallisation process. Compound **4** (previously separated by crystallisation) was dissolved in $(CD_3)_2CO$ and its ^1H NMR spectrum showed an approximately 50:50 mixture of **4** and **7**. This important result shows that structures of type κ⁴-*N*1*N*2,*N*4*N*5-hpzb (**IV**) and κ⁴-*N*1*N*2,*N*3*N*4-hpzb (**V**) rapidly equilibrate in solution.

On the other hand, the reactions with $[Pd(\eta^3\text{-}C_4H_7)(THF)_2]TfO$ or $[Pd(\eta^3\text{-}C_4H_7)(cod)]BF_4$ also depend on the proportions used. In the case of the reaction with $[Pd(\eta^3\text{-}C_4H_7)(cod)]BF_4$, the use of a 1:1 or 1:0.5 stoichiometry gives rise to a solid that could not be characterised as a pure product (see below for NMR in solution). Attempts to crystallise this solid failed. The elemental analyses of the crystallised sample were intermediate between those corresponding to mononuclear and dinuclear complexes.

On using 2 or 3 equiv. of the allyl derivatives, the only isolated metallic compound was **9**, which has three palladium centres (**9a** and **9b** differ only in the counteranion: BF_4^- for **9a** and TfO^- for **9b**).

1 hpbz + 2 $[Pd(\eta^3\text{-}C_4H_7)(cod)]BF_4$ → **9a** + hpzb

1 hpbz + 2 or 3 $[Pd(\eta^3\text{-}C_4H_7)(THF)_2]TfO$ → **9b** (+ hpzb)

The crystallisation of **9b** led not only to crystals of this trinuclear compound but also to a small amount of crystals of a complex of stoichiometry $[\{Pd(\eta^3\text{-}C_4H_7)\}_2(hpzb)](TfO)_2$ (**5b**).

(b) Pt Complexes 3 and 8

The different stoichiometries used correspond to two Equations:

hpzb + 0.5 or 1 $[PtCl_2(PhCN)_2]$ → **3** + **8** + hpzb

hpzb + 2 or 3 $[PtCl_2(PhCN)_2]$ → **8**

These reactions only reach completion after two weeks at room temperature. On using shorter reaction times the benzonitrile was not completely displaced from the Pt reagent and heating produced decomposition of Pt^{II} into Pt^0. Mono- and dimetallic derivatives can be separated by chromatography, with the mononuclear complex being eluted

first. We have verified that **8** does not dissociate into **3** and $PtCl_2$ in an acetone solution.

(c) Cu Complex 6

This compound was obtained according to the following Equation:

hpzb + 2 or 3 $[Cu(NCCH_3)_4](BF_4)$ + 2 or 3 $PMe_3 \rightarrow$ **6**

The same derivative was obtained when 2 equiv. of PMe_3 per Cu^+ were used.

The new derivatives are soluble in acetone, THF, chloroform and dichloromethane but are insoluble in pentane, hexane and diethyl ether.

Mass Spectrometry

The main information obtained by this technique concerns the number of metal centres in a given complex. Thus, the MAS-FAB$^+$ spectrum of **3** shows peaks at 740 $[M]^+$, 705 $[M - Cl]^+$, 638 $[M - pz - Cl]^+$, 602 $[M - pz - 2\ Cl]^+$ and 475 $[M - (PtCl_2)]^+$. The mixture of isomers **4** and **7** did not show the molecular ion peak, only fragments at 1188 $[M - C_6F_5]^+$, 1020 $[M - 2\ (C_6F_5)]^+$ and 513 $[M - pz - Pd - 4\ (C_6F_5)]^+$. Analogously, the most significant fragments in the case of **6** are 841 $[M - BF_4]^+$, 613 $[M - 2\ BF_4 - Cu(PMe_3)]^+$ and 537 $[M - 2\ BF_4 - Cu(PMe_3) - PMe_3]^+$, and for **8**, 1006 $[M]^+$, 933 $[M - 2\ Cl - H]^+$, 740 $[M - PtCl_2]^+$, 638 $[M - pz - Pt - 3\ Cl]^+$, 602 $[M - Pt - 4\ Cl]^+$ and 475 $[M - 2\ (PtCl_2)]^+$. The trinuclear complex **9b** presents a characteristic spectrum with peaks at 1257 $[M - TfO]^+$, 947 $[M - 2\ TfO - \{Pd(\eta^3\text{-}C_4H_7)\}]^+$ and 635 $[M - 3\ TfO - 2\ \{Pd(\eta^3\text{-}C_4H_7)\}]$.

X-ray Structural Characterisation of Complexes 4, 5b, 6 and 9b

A number of problems were encountered in the NMR spectroscopic study, including the difficulty in differentiating between the coordinated and noncoordinated pyrazoles. Hence, it is appropriate to discuss the crystallographic study first.

Crystallographic and selected structural data are compiled in Tables 1 and 2, respectively. ORTEP plots of the structures are shown in Figures 1−4. The bad quality of the crystals and the failure of obtaining new crystals made it impossible to obtain an adequate refinement for **5b**. However, the data indicate unambiguously the position of the two palladium fragments.

Pd or Cu atoms are in an approximately square- or trigonal-planar environment, respectively. The bite angle of hpzb for the Cu complex **6** is small (93.14°) for a trigonal-planar disposition, which indicates a marked difference in the angles of the coordination plane.

The molecular structures for complexes **4** (Figure 1), **5b** (Figure 2) and **6** (Figure 3) show the two metallic units in a coordination type **IV** (κ^4-*N*1*N*2,*N*4*N*5-hpzb) with one metal atom *up* and the other *down.* The existence, in these derivatives, of a crystallographic inversion centre in the geometric central point of the molecule ensures that the uncoordinated pyrazole rings are oppositely oriented with respect to the benzene plane (*up* and *down*). As a consequence, conformer **IVa** is the only one present in the solid state for

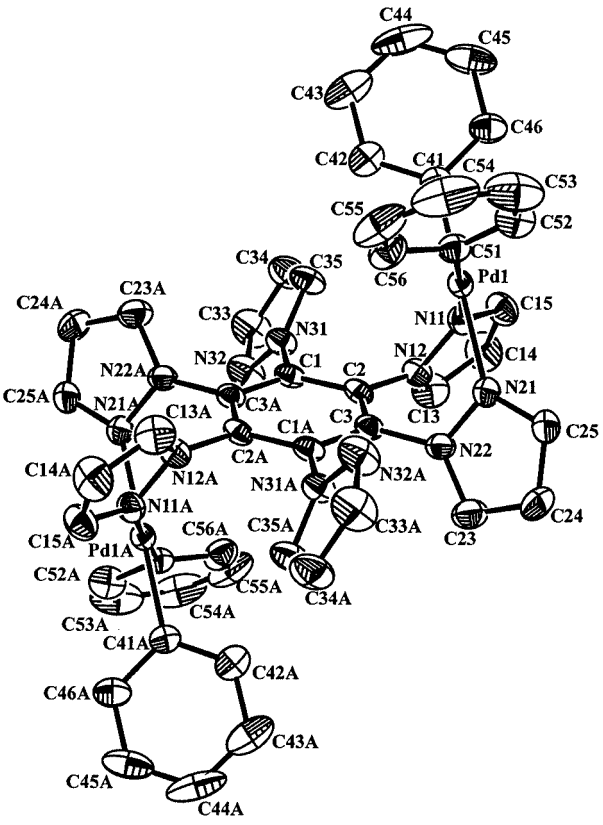

Figure 1. ORTEP view with atomic numbering of **4** (30% probability ellipsoids); the F atoms have been omitted for clarity

these dinuclear compounds. This is not the only similarity between the three structures: (i) Firstly, the uncoordinated pyrazole rings, which are in *para* positions with respect to one another, adopt a conformational orientation suitable for minimising the steric hindrance with the neighbouring rings, in such a way that the six pyrazole rings are distributed in two sets: three twisted (*P*) and three twisted (*M*). (ii) The dihedral planes of the pyrazole rings and the benzene rings are very similar (58−68°, Table 2), not only in **4** and **6** but also in one of the polymorphic forms of the free hpzb ligand.[25] (iii) The N−Pd−N bite angles do not differ greatly (84−93°). (iv) As a consequence of the two preceding statements the central cores, including the hpzb and the metallic centres, are practically superimposable for these three structures.

The structure of complex **4** (Figure 1) shows the two $Pd(C_6F_5)_2$ fragments oriented *up* and *down* in relation to the benzene ring and pointing in towards the core of the molecule. Considering this orientation and the considerable volume of this metallic fragment, it is very unlikely that three metallic units of this type could be coordinated with the same hpzb ligand and this hypothesis is in accordance with the experimental observations.

The trimetallic derivative $[\{Pd(\eta^3\text{-}C_4H_7)\}_3(hpzb)](TfO)_3$ (**9b**) (Figure 4) has a structure of type κ^6-*N*1*N*2,*N*3*N*4,*N*5*N*6-hpzb with two (allyl)palladium units on the opposite side to that of the third, with respect to the plane of the benzene ring (isomer type **VII**). The three methylallyl groups are oriented away from the molecule. This orientation, in conjunction with the considerably smaller volume of the (allyl)palladium unit with respect to the other groups used in this work, allows the coexistence of two vicinal metallic centres on the same side of the benzene ring. The small size of the crystals obtained precluded a final refinement of the structure, but a general overview of the backbone is possible. Bite and torsional angles of the pyrazole rings are in the range found for structures described previously. This structure is also preserved in solution (vide infra).

In summary, when more than one metal atom is present they prefer to be situated on opposite faces of the benzene ring. A reasonable extension to complexes **7** and **8** is that they adopt a **Va**, **Vb** or **Vc** disposition.

NMR Spectroscopic Studies in Solution

Before a discussion on the NMR spectroscopic data is undertaken, it is useful to classify the different conformations of Schemes 3 and 4 according to their symmetry point groups and the expected number of different pyrazole rings (see Table 3). There is a one-to-one correspondence between the point group and the number of pyrazole rings with the exception of the C_s case where, depending on whether the symmetry plane lies between two *ortho*-pyrazole rings or through two *para*-pyrazole rings, the number of expected signals is 1:1:1 or 1:2:2:1, respectively.

Free Ligand hpzb (1)

This ligand can exist in the eight perpendicular conformations (**Ia**−**Ih**) shown in Scheme 3. When the ^{1}H NMR spectrum was recorded in $CDCl_3$ (4 mg/0.6 mL), signals of only one type of pyrazole ring could be observed (Table 4). This could correspond to the highly symmetric *ududud* (**Ia**) or *uuuuuu* (**Ih**) conformations or the average conformation

Table 3. Point groups and patterns of the signals in NMR spectra (see Schemes 3 and 4)

Conformation	Point group	No of pz rings	Conformation	Point group	No. of pz rings

Ia−Ih. Conformation **Ih** can be excluded on the basis of its very high energy.[25,28] The difficult problem remains in deciding between the static (except for librations) conformation **Ia** or the dynamic one **Ia−Ih**.

When the spectrum of this compound was recorded in $(CD_3)_2CO$, in which the compound is rather insoluble, one or two isomers were observed depending on the concentration. In a very dilute solution (2 mg/0.6 mL) signals of only one kind of pyrazole ring was observed, as was the case in $CDCl_3$. However, in a more concentrated solution (saturated, i.e. about 6 mg/0.6 mL), two isomers were observed (the signals are narrow in all cases). The most abundant isomer (60%) corresponds to that already described above. The minor isomer (40%), however, has two kinds of pyrazole rings in a 1:2 ratio. First conclusion: the average **Ia−Ih** dynamic system shown in Scheme 4 can definitely be ruled out at room temperature on the NMR time-scale. A low-temperature ^{1}H NMR spectrum (193 K), in which signal splitting was not observed, also confirmed this statement. Consequently, the major isomer is **Ia** and the signals of the minor isomer, according to Table 3, should correspond either to conformer **Id** or **Ie**. Since the second conformer is much higher in energy,[25] we conclude that the minor isomer is the *uuduud* compound **Id**. It should be noted that this isomer has also been observed in a small amount in other hexakis(azol-1-yl)benzenes.[28]

The following discussion refers to the new complexes **2−9**.

(a) ^{1}H NMR Spectroscopy

The ^{1}H-^{1}H coupling constants, which are higher for 5-H/4-H than for 4-H/3-H, were used to differentiate the corresponding signals. In cases where different pyrazolyl groups were observed for a specific compound, COSY experiments allowed the signals belonging to the same pyrazole ring to be identified (Table 5).

For the mononuclear complexes **2** and **3**, three different types of pyrazole rings were evident, a situation in agreement with conformations **IIc**, **IIg**, **IIi** or **IIj** in Scheme 3 or with the dynamic situations **IIa−IIj** in Scheme 4 (see Table 3). In the low-temperature spectrum (193 K) of **2**, evidence for splitting of the signals was not observed. On extrapolating the result to **3**, we propose a static situation for both derivatives, similar to that found in the free ligand. If the orientation of two contiguous free pyrazolyl groups towards the same side of the benzene ring is considered less stable (see ref.[25] for energy calculations for the free ligand), **2** and **3** should have the structure of conformer **IIc**.

Three different situations have been found in the NMR spectra of the dinuclear compounds: (i) In complex **4** two kinds of pyrazole signals were observed in a ratio of two (coordinated) to one (noncoordinated). The existence of conformers **IIIa** or **IIIc** or the dynamic equilibria **IIIa/IIIb/IIIc** or **IVa/IVb** are consistent with the experimental data. However, according to the X-ray results the steric hindrance that will arise from the orientation of two $Pd(C_6F_5)_2$ fragments on the same side of the benzene ring allows us to rule out conformers of type **III** and, consequently, the equilibrium **IVa/IVb** is proposed. Moreover, the dynamic situ-

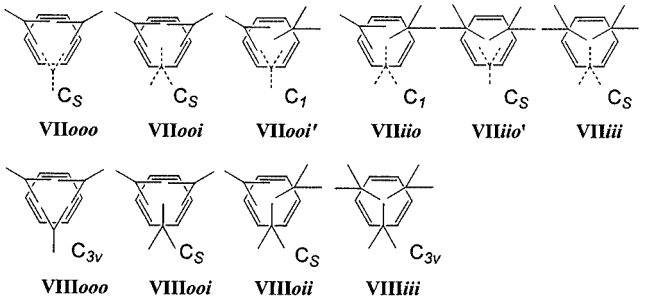
[a] T = 293 K if not indicated; δ in ppm; J in Hz,; solvent = $(CD_3)_2CO$. See formula **1** in Scheme 2 for numbering. Unless specified, the signals are singlets; d = doublet, br. s = broad singlet, m = multiplet, pt = pseudotriplet. [b] Signal partially overlapped. [c] T = 183 K. [d] T = 213 K. The signals marked with * have not been unequivocally assigned to one specific pyrazole ring.

ation is confirmed by a low-temperature NMR spectrum (193 K). The resonances of the coordinated pyrazole rings are broad at 233 K and a splitting is finally observed at lower temperatures. Although the resonances of the noncoordinated pyrazole rings are less sensitive to temperature, the corresponding 5-H signal also broadens and splits at low temperature. (ii) In complexes **7** and **8** three different pyrazole rings in a 1:1:1 ratio are observed; two for each pair of coordinated pyrazole rings and a third for the noncoordinated system. If we again exclude conformers that have the two metallic fragments on the same side of the benzene plane (**VIb**, **VIc** and **VIa/VIb/VIc**) the possible conformers would be: **IVa**, **IVb**, **Va**, **Vb** or the equilibrium **Va/Vb/Vc** (see Table 3). In the case of complex **7**, conformers **IVa** and **IVb** are not possible because the equilibrium **IVa/IVb** is the only possibility for **4** and is observed separately from **7**. Splitting of some signals is observed in both derivatives at low temperature. Consequently, the equilibrium **Va/Vb/Vc** is proposed for **7** and **8** at room temperature. (iii) In **6**, other dynamic processes must operate in addition to pyrazolyl rotation. Only broad signals due to one type of pyrazole ring are observed, some of which remain broad even at 203 K. A metallotropic process by exchange of the metal atoms between the pyrazole rings must take place and averaged signals are observed.

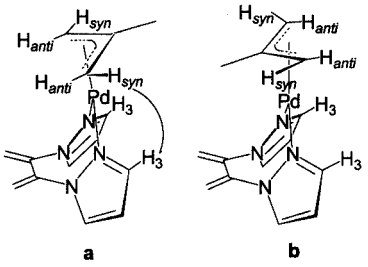
For the solid obtained in the reaction between hpzb and $[Pd(\eta^3\text{-}C_4H_7)(cod)]BF_4$ (1:0.5 or 1:1 ratio), one broad signal for 4-H and two broad and overlapped signals for 3-H and 5-H are observed at room temperature. The spectrum at 323 K exhibits narrower signals and a very complex spectrum is observed at low temperature (193 K). We propose that a mixture of complex **5a** (analogous to **5b** with a BF_4^- anion), adopting some of the possible structural configurations, (**III**−**VI** of Scheme 3) and free hpzb are present in equilibrium at room temperature by a metallotropic process. The concomitant presence of a mononuclear complex cannot be excluded.

A particularly interesting case is that of complex **9**. Three kinds of pyrazole rings are observed in a 1:1:1 ratio. Although some signal overlap seems to occur in the allylic region, at low temperature three separate H_{anti} signals (1:1:1 ratio) are observed. It is necessary to consider that the methyl group of the 2-methylallyl group can point inside (*i*) or outside (*o*) the benzene ring. This reduction in symmetry of the (allyl)Pd fragment when compared with that of the previously described MX_n groups, makes the symmetry considerations in Table 3 not strictly applicable in this case. Scheme 6 shows representations of the isomers derived from structures **VII** (six isomers) and **VIII** (four isomers). The symmetry point group is indicated in each case. When the symmetry is C_{3v}, one type of pyrazole ring is expected, but six types would occur if the symmetry is C_1 and three if it is C_s. Consequently, the experimental data only fit with the conformers of C_s symmetry. Several NOE experiments were carried out at room temperature (**9a** and **9b**): upon irradiation of H_{anti} (*anti*) an NOE effect was observed with H_{syn} (*syn*) and when H_{syn} was irradiated the NOE effect was observed not only on H_{anti} but also on the three signals of 3-H (closer to H_{syn} than 5-H) (Scheme 7). This confirms the previous assignment of these pyrazolic protons but, more importantly, indicates that the three allyl groups have an outside orientation. Consequently, if we consider the con-

formers of C_s symmetry, only conformer **VII*ooo*** fits with the NOE data and we propose this structure for complex **9** in solution. The fact that interchange of the (allyl)palladium fragments between the pyrazolyl groups is not observed, in contrast to **5**, could be due to the absence of free pyrazolyl rings in this derivative.



Scheme 6. Representation of the isomers corresponding to structures **VII** and **VIII**



Scheme 7. **a** and **b** represent the outside and inside orientations, respectively, of the allyl group; only in **a** the NOE observed in compound **9** (indicated with an arrow between H_{syn} and 3-H of the pyrazolyl group is possible

Conclusions concerning the possible conformers in solution for complexes **2**−**9** are collected in Table 6. The conformation of the molecule in the solid state is also included in cases where it is known. The first conclusion is that structures found in the solid state are consistent with those in solution in the cases of complex **9** (one conformer) and with one of the possible conformations of **4**−**6**. A static behaviour has been found in the free ligand and the monometallic derivatives while in the dimetallic complexes free rotation of the uncoordinated pyrazolyl groups is observed at room temperature. A slowing down of this rotation is observed at low temperature. In derivatives **5** and **6** the occurrence of other fluxional processes has prevented the study of this phenomenon.

are in agreement with those presented in Table 5: **3** (1:1:1), **4** (1:2), **6** (fluxional behaviour), **7**, **8** and **9** (1:1:1).

(c) ^{19}F NMR Spectroscopy

In accordance with the expected symmetry, and as deduced from the number of F_{para} signals observed, one kind of C_6F_5 ring exists in compounds **2** and **4** and two kinds (1:1 ratio) in derivative **7**. These belong to C_6F_5 groups either close to the other metal centre or close to a noncoordinated pyrazole ring. The F_{ortho} or F_{meta} signals are broad in some cases, indicating a certain degree of restricted rotation (Table 8).

Conclusions

After the reaction of the ligand hpzb (**1**) with different metallic fragments {$[Pd(C_6F_5)_2]$, $[Pd(\eta^3\text{-}2\text{-}Me\text{-}C_3H_4)]^+$, $PtCl_2$ and $Cu(PMe_3)^+$} we have synthesised new mono-, di- and trinuclear derivatives. We have carried out an analysis of the complex energy hypersurface that these complexes present, reporting many examples which describe fairly well its multidimensional aspect. The incorporation of three metallic centres was only possible with the smaller group $[Pd(\eta^3\text{-}C_4H_7)]^+$, a clear indication of the influence of steric effects. We have found that the metallic fragments, when two or three are present, prefer to be situated on opposite faces of the benzene ring. As far as the fluxionality of the compounds is concerned, we observed two types of behaviour on the NMR spectroscopic time-scale: metallotropic processes and rotation of the uncoordinated pyrazolyl groups. The former process was found in the dimetallic derivatives **5** and **6** with (allyl)palladium and $Cu(PMe_3)$ fragments, respectively. The second process described was the free rotation of the uncoordinated pyrazolyl groups that was found in the rest of the dimetallic complexes (**4**, **7** and **8**) at room temperature, although the process slows down at low temperature. Restricted rotation was observed in the monometallic derivatives and the free ligand even at room temperature. For complex **9**, where all the pyrazole rings are involved in coordination to the metal centre, a fluxional process is not observed. Finally, on a much slower timescale, when the Pd^{II} derivative **4** was dissolved in $(CD_3)_2CO$ an approximately 50:50 mixture of **4** and **7** was obtained. This fact shows that structures of type κ^4-*N*1*N*2,*N*4*N*5-hpzb (**IV**) and κ^4-*N*1*N*2,*N*3*N*4-hpzb (**V**) equilibrate in solution (isomerism). The X-ray structure of three dimetallic derivatives (**4**, **5b** and **6**) and the trinuclear derivative **9b** was undertaken. All the structures with two metallic centres were of the type κ^4-*N*1*N*2,*N*4*N*5-hpzb (**IV**) and the central core (hpzh ligand and metal centre) was near superimposable. Cooperative rearrangement of the pyrazolyl rings to minimize the steric hindrance was found in these dinuclear derivatives. When allyl ligands were present, they had the methyl group pointing away from the molecule. In all cases, the structures determined in the solid state were in accordance with the situations found in solution.

Experimental Section

General Comments: All manipulations were carried out under dry oxygen-free nitrogen using standard Schlenk techniques. Solvents were distilled from the appropriate drying agents and degassed before use. The ligand hexakis(pyrazol-1-yl)benzene (hpzb, **1**) has been previously described.[25,27] $[Pd(C_6F_5)_2(cod)]$ (cod = 1,5-cyclooctadiene) was synthesised as described in the literature for similar complexes.[30] $[PtCl_2(PhCN)_2]$ was prepared according to Kharasch,[31] $[Pd(\eta^3\text{-}C_4H_7)(\mu\text{-}Cl)]_2$ according to Wilkinson [32] and $[Cu(CH_3CN)_4](BF_4)$ according to Kubas.[33] Elemental analyses were performed with a Perkin−Elmer 240 B microanalyser. IR spectra were recorded in Nujol mulls with a Perkin−Elmer 883 (4000−200 cm^{-1} range) spectrophotometer. ^1H, ^{13}C, and ^{19}F NMR spectra were recorded with a Varian Unity 300 spectrometer using, unless specified, $(CD_3)_2CO$ as solvent. Standard experimental conditions were employed.[34,35] Mass spectra (position of the peaks in Da) were recorded with a VG Autospec spectrometer (University of Zaragoza) using the FAB^+ technique and *m*-nitrobenzylic alcohol as matrix.

Preparation of Compounds

(a) $[Pd(C_6F_5)_2(hpzb)]$ (2) and $[\{Pd(C_6F_5)_2\}_2(hpzb)]$ (4 and 7): We have carried out the reaction using different metal/ligand stoichiometries (0.5, 1, 2 or 3). Different mixtures (white colour) of the three isomers were obtained accordingly with the results specified in the previous section. Here we report the experiment with a 1:3 stoichiometry. $Pd(C_6F_5)_2(cod)$ (242 mg, 0.42 mmol) was added to a solution of hpzb (70.0 mg, 0.14 mmol) in THF (20 mL). The mixture was stirred for 7 h. The solution was then concentrated to near dryness and pentane (10 mL) was added, a white solid precipitated that was filtered, washed with pentane to eliminate the cod and dried. Yield of **4** + **7**: 80% (155 mg). IR: $\tilde{\nu}$ = 1639−1627, 1510−1500, 1070−1054, 975−950, 798, 796 and 787 cm^{-1} (C_6F_5).

Although **2** was the only metallic complex (in a mixture with hpzb) formed in the reaction with a metal/ligand ratio of 0.5, we were not able to obtain it in a pure form because in the crystallisation process, it was partially transformed into **4** and **7**. Compound **7** was never isolated, only a mixture of **4** and **7** without **2** was obtained. **4 +7:** $C_{48}H_{18}F_{20}N_{12}Pd_2 \cdot 1/2C_4H_8O$ (1399.62): calcd. C 42.91, H 1.58, N 12.01; found C 43.13, H 1.53, N 11.75. From the mixture of the 1:3 reaction, a pure sample of **4** was obtained when preparing crystals for X-ray diffraction by diffusion with acetone/hexane.

(b) [($PtCl_2$)(hpzb)] (3) and [($PtCl_2$)$_2$(hpzb)] (8): 1 equiv. of $PtCl_2(PhCN)_2$ (74.6 mg, 0.16 mmol) under nitrogen was added to a solution of hpzb (75.0 mg, 0.16 mmol) in dry acetone (20 mL). The mixture was stirred at room temperature for 2 weeks. The solution was concentrated to near dryness and pentane (10 mL) was added, a yellow solid precipitated that was filtered, washed with pentane and dried. The mixture of **3** and **8** were separated by flash chromatography (silica gel; eluent: methanol) and a small amount of both derivatives was obtained. IR: $\tilde{\nu}$ = 347 cm^{-1} [ν(Pt−Cl)] for both complexes. **3**: $C_{24}H_{18}Cl_2N_{12}Pt$ (740.49): calcd. C 38.93, H 2.45, N 22.70; found C 38.79, H 2.37, N 22.60.

(c) [($PtCl_2$)$_2$(hpzb)] (8): The synthesis was carried out as described above, except that 2 equiv. of $PtCl_2(PhCN)_2$ {hpzb (37.9 mg), [$PtCl_2(PhCN)_2$] (75.5 mg)} were used. In this way a pure sample of **8** was obtained after washing the yellow precipitate with pentane. Yield: 86% (68.0 mg). $C_{24}H_{18}Cl_4N_{12}Pt_2$ (1006.48): calcd. C 29.63, H 1.80, N 16.61; found C 29.17, H 1.91, N 16.36. The use of a 1:3 stoichiometry again affords **8**.

(d) [{Pd(η^3-C_4H_7)}$_2$(hpzb)](X)$_2$ (5) and [{Pd(η^3-C_4H_7)}$_3$(hpzb)](X)$_3$ (9) [X = BF_4^- (a), TfO^- (b)]: We have carried out the reaction with different ligand/metal stoichiometries and using the solvate [Pd(η^3-C_4H_7)(THF)$_2$]TfO (TfO: triflate, trifluoromethylsulfonate) or the derivative [Pd(η^3-C_4H_7)(cod)]BF_4 as metallic precursors (see discussion of the results). Here we report on the experiment with a 1:3 stoichiometry and the solvate precursor. First, a solution of [Pd(η^3-C_4H_7)(THF)$_2$]TfO was prepared from [Pd(η^3-C_4H_7)(μ-Cl)]$_2$ (87.1 mg, 0.22 mmol) and AgTfO (113 mg, 0.44 mmol) in freshly distilled THF (20 mL). The mixture was stirred for 2 h and protected from light. The solution was filtered through Celite to eliminate AgCl. The addition to this solution of the ligand (70.0 mg, 0.15 mmol) produced a white precipitate and the suspension was stirred for 3 h. The solid was filtered and washed with diethyl ether. The solid was crystallised in acetone/pentane to obtain crystals of **9b**. IR: $\tilde{\nu}$ = 835 [ν(C−CH_3) of the allyl group], 1282, 1165, 1031, 767 and 638 cm^{-1} (TfO^- anion). Yield: 75% (155 mg). $C_{39}H_{39}F_9N_{12}O_9Pd_3S_3$ (1406.22): calcd. C 33.31, H 2.79, N 11.95; found C 33.01, H 2.08, N 11.53. When the crystallisation was carried out in acetonitrile/diethyl ether, crystals of [{Pd(η^3-C_4H_7)}$_2$(hpzb)](TfO)$_2$ (**5b**) were obtained.

(e) [{Cu(PMe_3)}$_2$(hpzb)](BF_4)$_2$ (6): PMe_3 (0.30 mmol, 0.30 mL, 1 M solution in toluene) was added to a solution of [Cu($NCCH_3$)$_4$](BF_4) (94.4 mg, 0.30 mmol) in dry acetone (30 mL). The colourless solution was stirred for 15 min, then hpzb (71.1 mg, 0.15 mmol) was added and the resulting pale yellow solution was stirred for 4 h, concentrated to dryness and washed with diethyl ether. A yellow solid was obtained. Yield: 81% (113 mg). $C_{30}H_{36}B_2Cu_2F_8N_{12}P_2$ (927.36): calcd. C 38.84, H 3.91, N 18.11; found C 38.22, H 4.02, N 18.07. IR: $\tilde{\nu}$ = 1084 and 520 cm^{-1} (BF_4 anion). The crystals for X-ray diffraction were obtained by crystallisation in dichloromethane/pentane.

X-ray Data Collection, Structure Determination, and Refinement of Complexes 4, 5b, 6 and 9b:[36] Crystal data and basic information about the data collection and structure refinement are listed in Table 1. The diffraction experiments were carried out with a CAD4-MACH3 diffractometer (**4** and **5b**) with ω-2θ scan technique to a maximum value of 56° and a Bruker Smart CCD based diffractometer (**6** and **9b**) by using graphite-monochromated Mo-K_α radiation with ψ-ω scan technique (**6** and **9b**). For **4**, the asymmetric unit comprises two half molecules, and for **5b** and **6,** one independent half molecule. Data were corrected for Lorentz and polarisation effects and absorption correction was made for **6** and **9b**. The structures were solved by direct methods (SHELXS)[37] and refined first isotropically by full-matrix least squares using SHELXL-97[38] program and then anisotropically by blocked full-matrix least squares for all the non-hydrogen atoms. The hydrogen atoms were included in calculated positions and refined "riding" on their parent carbon atoms.

Synthesis, Microstructural Characterisation and Magnetic Study of Two New One-Dimensional Members of the $(A_3ZnMnO_6)_\alpha$ $(A_3Mn_3O_9)_\beta$ Homologous Series (A = Ba, Sr)

María Hernando,*[a] Khalid Boulahya,[a] Marina Parras,[a] and José M. González-Calbet[a]

Keywords: Electron diffraction / Electron microscopy / One-dimensional oxides / Magnetic properties / Twinned microstructure

Two new members of the $(A_3ZnMnO_6)_\alpha(A_3Mn_3O_9)_\beta$ one-dimensional homologous series have been synthesised with the compositions $Sr_4Mn_2ZnO_9$ and $Ba_5Mn_3ZnO_{12}$. Their structures can be described as a hexagonal array of infinite 1D-chain polyhedra, running parallel to the *c*-axis, formed by two face-sharing octahedra linked by one trigonal prism for $Sr_4Mn_2ZnO_9$, and one more octahedron between prisms for $Ba_5Mn_3ZnO_{12}$. Both oxides have a twinned microstructure as evidenced by SAED and HREM. $Sr_4Mn_2ZnO_9$ shows a pronounced antiferromagnetic character with a broad susceptibility maximum at 100 K due to short-range ordering. At low temperature, the susceptibility data suggest a transition to a 3D long-range ordering.

Introduction

The family of one-dimensional oxides structurally related to the 2H hexagonal perovskite ABO_3 [1] has been widely studied due to their striking magnetic properties. This structure and the K_4CdCl_6 [2] structural type define the two end-members of this 1D family. Both structures are formed by a hexagonal array of infinite chains of face-sharing polyhedra running parallel to the *c*-axis. In the 2H hexagonal type, $[BO_6]$ octahedra (O_h) constitute the polyhedra chains, whereas in K_4CdCl_6 ($A_3A'BO_6$) one $[BO_6]$ octahedron alternates with one $[A'O_6]$ trigonal prism (TP) in an ordered sequence. Between both structures, an unlimited number of one-dimensional related structures can be generated by varying the octahedron/trigonal-prism ratio.[3−6] There are several ways to describe the different members of this family. Among them, a very useful approach is to consider these structures as being formed by the ordered intergrowth of the structural units building up the two end-members. This building principle gives rise to the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ general formula, where α and β denote the number of $A_3A'BO_6$ and 2H-ABO_3 structural blocks, respectively, in each member.[7] A large number of oxides belonging to this family have already been reported. Usually, the A cation is an alkaline earth metal whereas the chemical nature of A′ and B is much wider since alkali, alkaline earth, transition, rare earth or main group metals can occupy such positions.

A wide range of magnetic properties are observed in these oxides. When both trigonal prism and octahedral sites contain magnetic cations, the system presents a 1D magnetic behaviour that can induce a 3D ordered state at low temperature.[8−10] However, this 1D character can be lost — a 3D character appearing — when diamagnetic cations separate the paramagnetic ones in the chain.[9,11] In this case, the superexchange pathways between such paramagnetic cations are not significantly shorter than those between metals located at different chains, hence the intrachain and interchain interactions are of comparable magnitude.

Up to now, only two phases have been stabilised in the A−Mn−Zn system (A = Ca and Ba), *viz.* Ca_3MnZnO_6 [9] and $Ba_6Mn_4ZnO_{15}$.[12] The former adopts the K_4CdCl_6 structure corresponding to the (α = 3 β = 0) member of the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ homologous series. The structure can be regarded as infinite 1D-chains, running along the *c*-axis, made up of alternate $[ZnO_6]$ face-sharing trigonal prisms and $[MnO_6]$ octahedra (Figure 1a). The magnetic cations are only located in the octahedral holes and, consequently, the $(Mn\text{-}Mn)_{intrachain}$ distances (5.3 Å) are similar to the $(Mn\text{-}Mn)_{interchain}$ distances (5.6 Å), giving rise to a 3D magnetic system.

$Ba_6Mn_4ZnO_{15}$,[12] which is isostructural to $Sr_6Co_5O_{15}$,[13] shows a different magnetic behaviour. This 1D-oxide corresponds to the (α = 3 β = 3) member of the above-mentioned homologous series. The chains are now made up of four face-sharing octahedra linked by one trigonal prism (Figure 1d). The cationic distribution in the different polyhedra is only partially ordered. Zn and Mn occupy the trigonal prismatic site in equal concentrations, with the re-

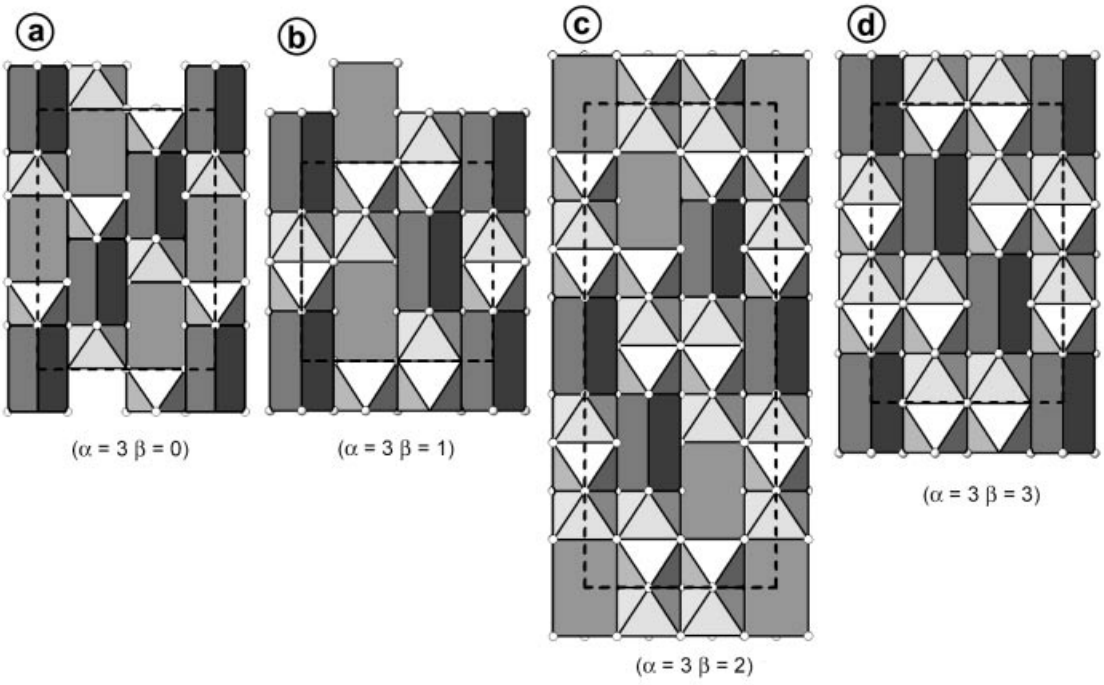

Figure 1. Schematic structures of Ca_3MnZnO_6 (a) and $Ba_6Mn_4ZnO_{15}$ (d), the ($\alpha = 3\,\beta = 0$) and ($\alpha = 3\,\beta = 3$) members of the $(A_3ZnMnO_6)_\alpha(A_3Mn_3O_9)_\beta$ homologous series; ideal structures correspond to intermediate phases of this series: the ($\alpha = 3\,\beta = 1$) (b) and the ($\alpha = 3\,\beta = 2$) (c) members; the unit cells are indicated by dotted lines

maining Zn and Mn distributed in the octahedral sites. A 1D magnetic ordering along the chains is observed due to antiferromagnetic interactions between Mn^{IV} ions. However, the presence of nonmagnetic Zn^{2+} cations in the octahedral environment suppresses the intrachain interaction between Mn atoms and, consequently, magnetic trimers, dimers and isolated $[Mn^{IV}O_6]$ octahedra are created. Uncompensated magnetic moments of the trimers and the isolated octahedra are responsible for the rise in the magnetic susceptibility at low temperature.

Between Ca_3MnZnO_6 ($\alpha = 3\,\beta = 0$) and $Ba_6Mn_4ZnO_{15}$ ($\alpha = 3\,\beta = 3$), two intermediate members can be envisaged. Actually, Figure 1b and 1c correspond to the ideal structures of the ($\alpha = 3\,\beta = 1$) and ($\alpha = 3\,\beta = 2$) terms of the above family. Therefore, in order to synthesise these novel 1D phases containing Mn as the only magnetic cation, we have explored the A−Mn−Zn−O system (A = Ba, Sr,) which has resulted in the stabilisation of $Sr_4Mn_2ZnO_9$ ($\alpha = 3\,\beta = 1$) as a single phase. Attempts to isolate the ($\alpha = 3\,\beta = 2$) term have been successful for the $Ba_5Mn_3ZnO_{12}$ composition although some impurities have been detected. Structurally, both phases can be regarded as a hexagonal array of infinite 1D-chains of face-sharing polyhedra running parallel to the crystallographic *c*-axis. In $Sr_4Mn_2ZnO_9$, two octahedra are linked by one trigonal prism, whereas in $Ba_5Mn_3ZnO_{12}$ one more octahedron is incorporated between the trigonal prisms in the polyhedra rows. The synthetic conditions, microstructural characterisation and magnetic properties are discussed.

Results and Discussion

Figure 2a shows the powder XRD pattern corresponding to $Sr_4Mn_2ZnO_9$. The whole pattern can be indexed on the basis of a trigonal unit cell (*P*321) with parameters $a = 0.9592(1)$ and $c = 0.7823(1)$ nm. On the other hand, the XRD pattern corresponding to $Ba_5Mn_3ZnO_{12}$ (Figure 2b), can be also indexed in a trigonal ($P\bar{3}c1$) unit cell with $a = 1.0060(1)$ and $c = 2.0812(1)$ nm. In fact, both patterns show the characteristic profile of one-dimensional oxides corresponding to the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ homologous series,[7] although some broad reflections are observed.

The SAED study sheds more light on the microstructural features of both compounds. For this purpose, it is helpful to consider these one-dimensional oxides as commensurate modulated superstructures of the 2H-hexagonal type. As we have previously reported, the superstructure direction can be expressed as $[\alpha+\beta\ \alpha+\beta\ i\ 2\alpha]^*_{2H}$ [7] and, thus, is related to the number of α and β blocks constituting every phase. The superstructure direction is determined from the $[1\bar{2}10]$ zone axis, which provides the most useful structural information.

$Sr_4Mn_2ZnO_9$

Figure 3a corresponds to the above-mentioned $[1\bar{2}10]$ zone axis of the $Sr_4Mn_2ZnO_9$ sample. All the observed crystals show the same features. The most intense spots correspond to hexagonal 2H planes (referred as sub-index 2H in the figure). The modulation direction, marked with an ar-

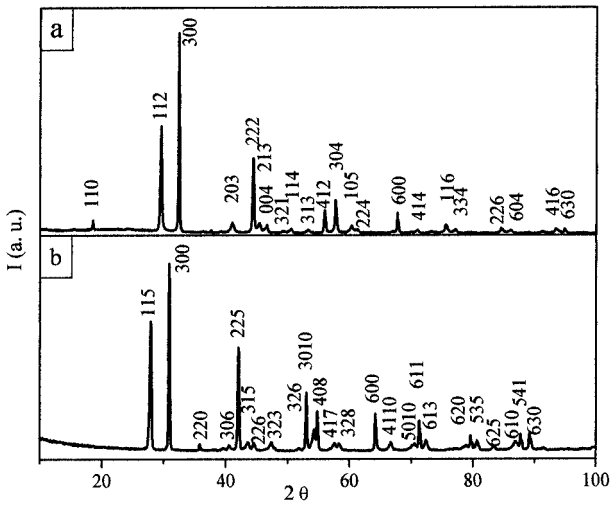

Figure 2. Powder XRD patterns of $Sr_4Mn_2ZnO_9$ (a) and $Ba_5Mn_3ZnO_{12}$ (b)

row, follows the reciprocal $[44\bar{8}6]^*_{2H}$ direction, according to the ($\alpha = 3$ $\beta = 1$) values. However, the features of this SAED pattern also indicate that the microstructure of this 1D-phase must be more complex than that shown by other isostructural oxides. Actually, if this reciprocal plane is compared to the same reciprocal net corresponding to the $(Sr_{0.5}Ca_{0.5})_4Co_3O_9$ isostructural oxide[14] (Figure 3b), some differences can be appreciated. Both SAED patterns present the same structural characteristics but the intensity distribution of the superstructure spots is clearly different. The modulated intensity of such spots, as observed in $(Sr_{0.5}Ca_{0.5})_4Co_3O_9$, is typical of this structure. Following the $[44\bar{8}6]^*_{2H}$ direction, the first-order satellite reflections are the most prominent ones, the intensity decreasing as the satellite order increases. On the contrary, in $Sr_4Mn_2ZnO_9$, such a modulation is not only noticeable along the $[44\bar{8}6]^*_{2H}$ direction but also at 90°, i.e., following the $[\bar{4}\bar{4}86]^*_{2H}$ direction. This feature could be due to twinning, as previously observed in isostructural $Sr_4CuIr_2O_9$.[15]

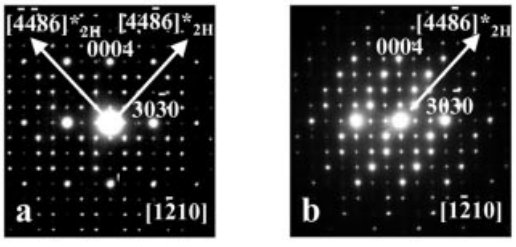

Figure 3. SAED patterns along the $[1\bar{2}10]$ zone axis of $Sr_4Mn_2ZnO_9$ (a) and $(Sr_{0.5}Ca_{0.5})_4Co_3O_9$ (b)

The multitwinned microstructure was confirmed by HREM. The image taken along the $[1\bar{2}10]$ zone axis is shown in Figure 4a. Several domains, tilted 90° to one another around the *c*-axis, are clearly evident. In each domain, d-spacings of 0.83 and 0.78 nm along the *a* and *c* axes, respectively, are observed and these correspond to d_{100} and d_{001} of the ($\alpha = 3$ $\beta = 1$) one-dimensional oxide. The contrast variation in each domain is also characteristic of this member of the series. This is clearly seen in the magnification of one of them (Figure 4b), where it can be observed that, following the *c*-axis, one bright dot alternates with two less-intense ones. We have previously reported that, in all these 1D oxides, the metal columns in the trigonal interstices and the Sr atoms are imaged as bright dots.[16] Therefore, the contrast sequence in this experimental image is as expected for the ...O_hO_hTP... polyhedral sequence in the 1D-chains. The calculated image (inset of Figure 4b) shows a good fit with the experimental one for $\Delta t = 6$ nm and $\Delta f = -65$ nm. It is worth mentioning that the domains are quite narrow, not exceeding approx. 2−3 nm along one direction. The small size of the domains is responsible for the broad reflections observed in the XRD pattern. In addition, the HREM image shows that the twins are coherent since no relative displacement is observed at the twin boundaries. This is outlined in Figure 5 and illustrated in the inset, where a schematic model of two domains of the ($\alpha = 3$ $\beta = 1$) structure meet at the (0001) twin plane. It can be appreciated that both domains are rotated 180° to one another around the twin plane.

The optical Fourier transforms corresponding to domains A and B (Figure 4a) are depicted in Figure 4c and Figure 4d, respectively. In domain A, the superstructure direction follows the $[44\bar{8}6]^*_{2H}$ reciprocal direction, while in domain B, tilted 90° with regard to the former, the satellite reflections are located along the $[\bar{4}\bar{4}86]^*_{2H}$ direction. In both domains, the intensity distribution of the spots is as expected for a modulated superstructure. The juxtaposition of both patterns (Figure 4e) corresponds to the experimental SAED shown in Figure 3a.

In the [0001]* reciprocal plane (Figure 6a) the reflections are distributed in a hexagonal array corresponding to a lattice parameter close to 0.9 nm. All the reflections are visible according to the trigonal *P*321 space group. The corresponding HREM (Figure 6b) also shows the presence of domains tilted by 60°, which are related to the previous twinning. Actually, in this image domains at 60° can be seen around the twin plane ($11\bar{2}0$); this is probably due to a mismatch between the chains.

$Ba_5Mn_3ZnO_{12}$

The SAED study of the title sample shows that it is not a single phase. It is worth noting that, in these 1D-phases, the most intense diffraction maxima are those corresponding to the 2H-subcell and, thus, they appear at very close d-spacings. This fact makes it difficult to detect small amounts of other members of the series that might be present as impurity phases in very small proportion by XRD. However, the SAED study reveals that, although almost all crystals correspond to the expected ($\alpha = 3$ $\beta = 2$) member of this series, a small fraction, presenting the structural features of the ($\alpha = 3$ $\beta = 3$) member, is also detected; such a

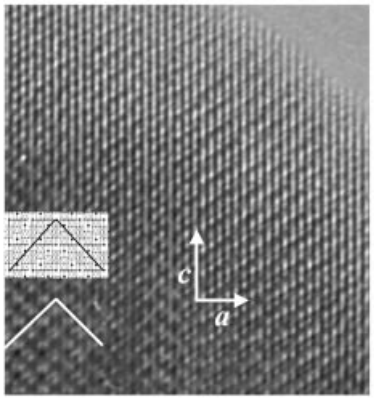

Figure 5. A magnification of the HREM image along [1$\bar{2}$10] showing a coherent twin structure; the twin boundary is labelled; a schematic model illustrating the twin boundary between two (α = 3 β = 1) domains is shown in the inset

member corresponds to the previously reported $Ba_6Mn_4ZnO_{15}$.[12] In spite of this, the majority of the phase corresponds to the new (α = 3 β = 2) member of the series and, therefore, we have performed the microstructural study of this phase.

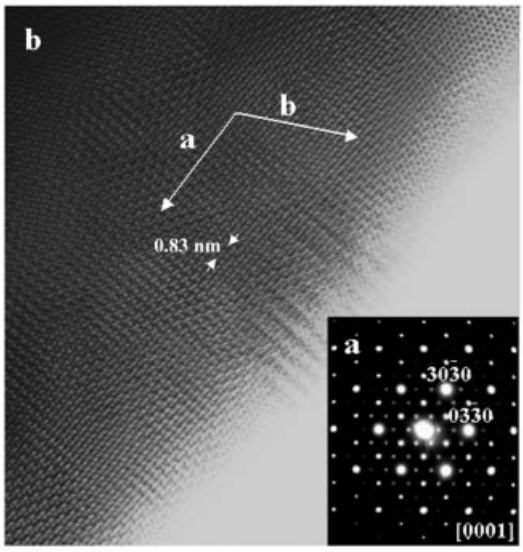

Figure 6. (a) SAED pattern corresponding to $Sr_4Mn_2ZnO_9$ along [0001]; (b) corresponding HREM image

The SAED pattern along the [1$\bar{2}$10] zone axis of the majority phase is shown in Figure 7a. EDS analysis performed on these crystals is in agreement with the nominal cationic ratio. The structural features of this pattern are those corresponding to the (α = 3 β = 2) member. Actually, only the 00l, $l = 2n$ reflections are visible ($P\bar{3}c1$ space group) and the modulation direction follows the $[55i6]^*_{2H}$ reciprocal axis. Once again, the intensity distribution of the spots suggests a twinned microstructure. As can be seen, satellite reflections appear not only along the $[55i6]^*_{2H}$ direction, as expected for this structure, but also along $[\bar{5}\bar{5}i6]^*_{2H}$ in a similar manner to that observed for $Sr_4Mn_2ZnO_9$. The presence of domains, tilted nearly 90° to each other, is clearly visible in the HREM taken along the [1$\bar{2}$10] direction (Figure 7b). Each domain shows the characteristic image of this (α = 3 β = 2) member and the calculated image (inset) is in agreement with the experimental one for Δt = 3.5 nm and Δf = −70 nm. The twin plane follows the [0001] direction, as in the previous case, but the domain size is much larger.

Taken together the SAED and HREM results indicate that both 1D oxides present a twinned microstructure. In order to establish if such a feature is a general characteristic of all Zn−Mn 1D oxides, we also studied oxide $Ba_6Mn_4ZnO_{15}$,[12] i.e., the (α = 3 β = 3) member of the series, by means of SAED and HREM. This oxide incorporates one more octahedron between the trigonal prisms than the previous $Ba_5Mn_3ZnO_{12}$ phase. The unit cell has rhombohedral symmetry ($R32$) with parameters a = 1.004 and c = 1.283 nm. The corresponding SAED pattern along [1$\bar{2}$10] is shown in Figure 8a. The superstructure spots appear not only along the $[66i6]_{2H}$ direction but also along the $[\bar{6}\bar{6}i6]_{2H}$ reciprocal direction and, consequently, a pseudotrigonal symmetry results. Once again, this is related to the presence of twinning as evidenced in the HREM along the

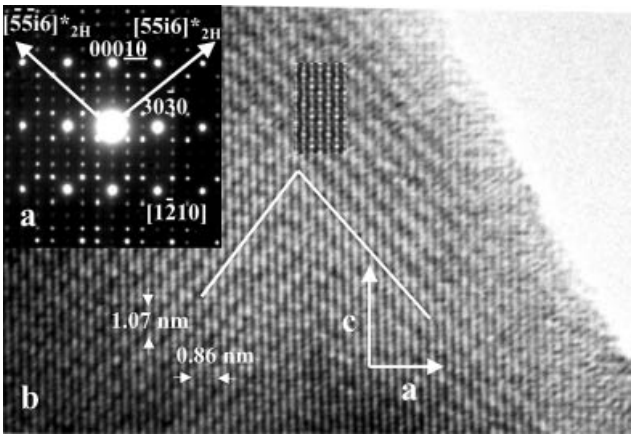

Figure 7. (a) SAED pattern corresponding to $Ba_5Mn_3ZnO_{12}$ along [1$\bar{2}$10]; (b) corresponding HREM image

same zone (Figure 8b). All the crystals checked exhibit the same features.

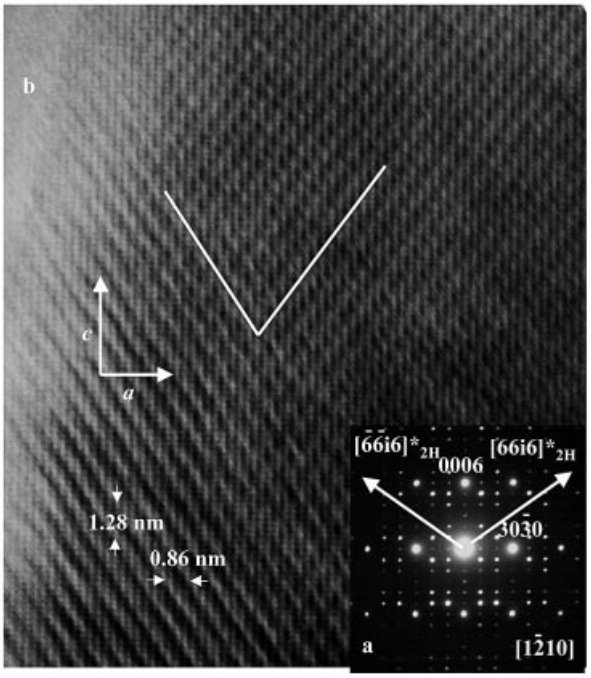

Figure 8. (a) SAED pattern corresponding to $Ba_6Mn_4ZnO_{15}$ along the [1$\bar{2}$10] zone axis; (b) corresponding HREM image; a twin plane is outlined

The stabilisation of one-dimensional oxides in the A−Mn−O system is a new example of the flexibility of the oxygen polyhedra chain in accommodating metal cations of very different size. The small size of Mn^{4+} (r_i = 0.53 Å) when compared with Zn^{2+} (r_i = 0.74 Å)[17] should give rise to a regular distribution of both transition metals in such a way that Zn would occupy the TP sites while Mn would be located in the octahedral ones. This is the case for Ca_3ZnMnO_6,[9] where [MnO_6] octahedra and [ZnO_6] trigonal prisms form a 1D chain with no sign of disorder between the metals over the two different sites. However, when the number of octahedra between trigonal prisms increases, it seems that both transition metals can be accommodated in the same oxygen environment. Neutron diffraction data on $Ba_6Mn_4ZnO_{15}$ [12] indicate that Mn^{4+} and Zn^{2+} ions are distributed in equal concentration in the trigonal prismatic polyhedra; consequently, Zn must also located in the octahedral sites.

The origin of the twinning cannot be easily determined, although it could be related to the cationic disorder in the structure. In this sense, it is worth noting that the presence of twinning related to cationic disorder has been previously reported in Sr_3CuPtO_6.[18] This compound crystallises in a distorted monoclinic structure (*C*2/*c*) closely related to the trigonal unit cell corresponding to the (α = 3 β = 0) member of this 1D homologous series. In this oxide, in which the single crystal X-ray diffraction data indicate that some disorder between Cu and Pt cations could exist, all crystals appear heavily twinned. Moreover, it is also noticeable that Ca_3ZnMnO_6,[9] in which an ordered distribution of Zn (into the TP sites) and Mn (into the O_h ones) is achieved, is the only 1D Zn/Mn-containing oxide that does not present a twinning microstructure. Figure 9 shows the SAED pattern corresponding to Ca_3ZnMnO_6 along the [1$\bar{2}$10] zone axis. A threefold superstructure is visible along the $[33i6]_{2H}$ reciprocal direction, corresponding to the (α = 3 β = 0) member of the series. The lack of superstructure maxima along the $[\bar{3}\bar{3}i6]_{2H}$ direction indicates that this is an untwinned compound. Although we do not have direct evidence of the cationic distribution in the new reported phases, it seems plausible to assume that increasing the number of octahedra between the trigonal prisms could facilitate the interchange between cations, giving rise to some cationic disorder. Such a disorder could be accompanied by local structural deformations which introduce some structural strain that is compensated by twin formation, as observed by HREM. The structural foundation of this observation will be further studied by neutron diffraction.

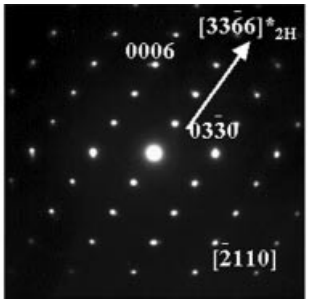

Figure 9. SAED pattern corresponding to Ca_3MnZnO_6 along [1$\bar{2}$10].

On the other hand, when the micrographs corresponding to $Ba_6Mn_4ZnO_{15}$ (Figure 8b), $Ba_5Mn_3ZnO_{12}$ (Figure 7b) and $Sr_4Mn_2ZnO_9$ (Figure 4a) are compared, it can be appreciated that the domain size decreases as the TP/O_h ratio increases. Actually, the highest concentration of twin planes is attained when the number of polyhedra per row and unit cell is lower. This feature seems to indicate that the struc-

tural strains are more pronounced when the Zn^{2+} ions can be distributed over a smaller number of octahedral sites. In addition, the smaller size of Sr^{2+}, in comparison to the Ba^{2+} cations, generates polyhedral sites of smaller volume, which increase the structural strain originating from the incorporation of Zn into the octahedral holes, thus supporting the small domain size in $Sr_4Mn_2ZnO_9$.

Magnetic Properties

The temperature dependence of the magnetic susceptibility corresponding to the single phase $Sr_4Mn_2ZnO_9$ measured at $H = 1000$ Oe is depicted in Figure 10a. The ZFC and FC data overlap in the temperature range measured and show a broad maximum at a temperature close to 100 K. At lower temperature (below 40 K), a sharp increase of the susceptibility is observed. The susceptibility curve cannot be fitted by a Curie−Weiss law over any temperature range.

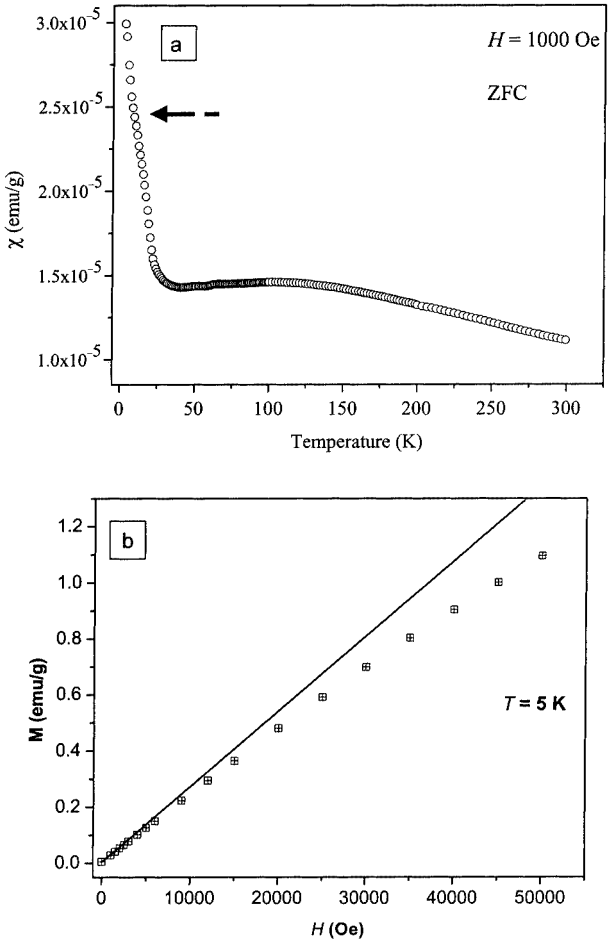

Figure 10. (a) Temperature dependence of the magnetic susceptibility of $Sr_4Mn_2ZnO_9$ at H = 1000 Oe; (b) magnetisation vs. applied field at 5 K; a nonlinear magnetisation field dependence is clearly observed

The magnetic behaviour of this 1D oxide is quite similar to that observed in $Ba_6Mn_4ZnO_{15}$,[12] although, in this case, the broad maximum is shifted to lower temperatures (50 K). The presence of such a maximum is characteristic of a 1D magnetic behaviour and it represents the onset of the 1D ordering along the chains. Such an ordering corresponds to antiferromagnetic interactions between Mn^{4+} in the chain, and therefore low magnetic susceptibility values are obtained in the measured temperature range. The increase of the number of octahedra between prisms seems to result in a weakening of the intrachain interactions and, consequently, the broad maximum is shifted to lower temperatures.

On the other hand, as can be observed in Figure 10a, the susceptibility passes through a local minimum and increases below 40 K. This rise of the magnetic susceptibility has also been observed in $Ba_6Mn_4ZnO_{15}$ and is associated with the presence of uncompensated magnetic moments that result from the irregular distribution of Mn^{4+} and Zn^{2+} in the polyhedra chains. Thus, these results agree with the presence of cationic disorder in the polyhedra chains in this new phase.

Unlike $Ba_6Mn_4ZnO_{15}$,[12] in which the 3D ordering is not observed in the magnetic susceptibility, the susceptibility curve corresponding to $Sr_4Mn_2ZnO_9$ shows a very small inflexion (marked in Figure 10a with an arrow) at about 7 K. This feature can be associated with a transition from 1D to 3D magnetic ordering. This weak interchain interaction is confirmed by slight nonlinear magnetisation-field dependence (Figure 10b). This different behaviour could be a consequence of the smaller interchain distance in the Sr compound due to their smaller size compared to Ba oxides.

It is worth recalling that a similar 1D-3D transition has previously been reported in Ca_3MnNiO_6.[9] The temperature-dependence susceptibility curve for this oxide is analogous to that corresponding to $Sr_4Mn_2ZnO_9$. Actually, a broad peak at around 100 K, attributed to a 1D antiferromagnetic ordering, and a small inflexion at 20 K, associated with a 3D ordering, are observed. This long range (3D) ordering has been confirmed by a neutron diffraction study.

Experimental Section

Polycrystalline $Sr_4Mn_2ZnO_9$ and $Ba_5Mn_3ZnO_{12}$ were synthesised by the ceramic procedure by heating stoichiometric amounts of ACO_3 (A = Sr, Ba; Aldrich, 99.9+%), $MnCO_3$ (Aldrich, 99.9+%) and ZnO (Aldrich, 99.99%) in air. The former was treated at 875 °C for five days and the latter at 1050 °C for six days with intermediate grindings. In both cases the products were quenched to room temperature.

The average cationic composition was determined by ICP while the local composition in every crystal was established by X-ray Energy Dispersive Spectroscopy (EDS). For this purpose, a JEOL 2000 FX electron microscope equipped with a OXFORD ISIS 300-analyser system was employed. Chemical compositions are consistent with the nominal ones.

Powder X-ray diffraction (XRD) patterns were collected with Cu-K_α radiation at room temperature on a PHILIPS X′PERT diffractometer equipped with a graphite monochromator.

Selected-area electron diffraction (SAED) was carried out using a JEOL 2000FX electron microscope fitted with a double-tilting

goniometer stage (±45°). High resolution electron microscopy (HREM) was performed on a JEOL 4000EX electron microscope fitted with a double-tilting goniometer stage (±25°). Simulated HREM images were calculated by the multislice method using the MacTempas software package.

Magnetic susceptibility was measured with a SQUID magnetometer in a temperature range from 5 to 300 K, under a maximum applied magnetic field of 5 T.

Preparation and Electrochemical Properties of Polynuclear Organometallic Complexes Derived from Ferrocene-Containing Bidentate Ligands

Ryo Horikoshi,[a] Tomoyuki Mochida,*[a] Reiko Torigoe,[a] and Yasuhiro Yamamoto[a]

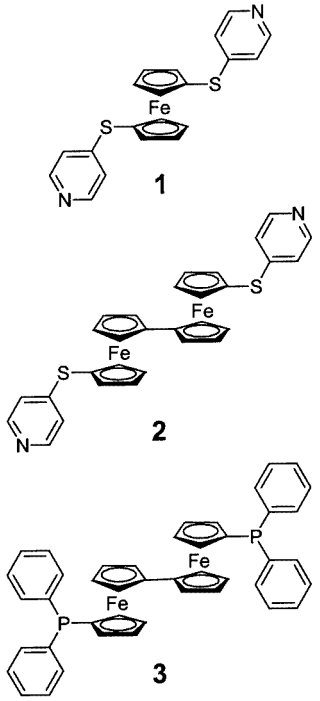
Keywords: Bridging ligands / Cyclic voltammetry / Ruthenium / Rhodium / Iridium / Metallocenes

The reaction of the ferrocene-containing bridging ligands 1,1′-bis(4-pyridylthio)ferrocene (**1**), 1′,1‴-bis(4-pyridylthio)biferrocene (**2**), and 1′,1‴-bis(diphenylphosphanyl)biferrocene (**3**), with the chloro-bridged dinuclear complexes $[(p\text{-cymene})RuCl(\mu\text{-}Cl)]_2$ and $[Cp^*MCl(\mu\text{-}Cl)]_2$ (M = Rh, Ir) affords trinuclear and tetranuclear metal complexes in good yields: $[\{(p\text{-cymene})RuCl(\mu\text{-}Cl)\}_2(\mu\text{-}L)]$ (**4**: L = **1**; **7**: L = **2**; **10**: L = **3**), $[\{Cp^*MCl(\mu\text{-}Cl)\}_2(\mu\text{-}L)]$ (**5**: L = **1**, M = Rh; **6**: L = **1**, M = Ir, **8**: L = **2**, M = Rh; **9**: L = **2**, M = Ir; **11**: L = **3**, M = Rh; **12**: L = **3**, M = Ir). The molecular structures of **3** and **5** have been determined by X-ray structure analysis. These complexes show quasi-reversible redox processes of the bridging ligands as well as irreversible redox processes of the terminal metal ions. Reaction of $[\{Cp^*MCl(\mu\text{-}Cl)\}_2(\mu\text{-}\mathbf{1})]$ with $AgPF_6$ affords $[\{(Cp^*M)_4(\mu\text{-}Cl)_4\}(\mu\text{-}\mathbf{1})_2](PF_6)_4$ (**13**: M = Rh, **14**: M = Ir), which are chloro-bridged polynuclear complexes.

Introduction

Metal-containing supramolecules and coordination polymers have attracted much interest in recent years, and a variety of supramolecular compounds have been prepared by the spontaneous self-assembly of metal ions and spacer ligands.[1−10] Recently it has been shown that supramolecular architectures can be constructed in a stepwise manner, using organometallic compounds.[11−16] Molecular squares and boxes have been synthesized by combining bidentate ligands, which have organometallic building blocks containing octahedral metals of Ru,[11,12] Rh[13,14] or Ir[15,16], with arene, cyclopentadienyl or pentamethylcyclopentadienyl (Cp*) groups.

The redox activities of ferrocene and biferrocene derivatives are well documented,[17] and we have recently synthesized redox-active bridging ligands containing ferrocene and have characterized their coordination polymers.[18] The syntheses of organometallic polynuclear compounds of Ru, Rh, and Ir with ferrocene- and biferrocene-based bidentate ligands are reported here. These compounds may be useful as redox-active building blocks for supramolecules showing multi-step redox properties. This paper describes the preparation and electrochemical properties of a series of tri- and tetranuclear organometallic complexes containing bidentate ligands of 1,1′-bis(4-pyridylthio)ferrocene (**1**), 1′,1‴-bis(4-pyridylthio)biferrocene (**2**), and 1′,1‴-bis(diphenylphosphanyl)biferrocene (**3**), as shown in Scheme 1: $[\{(p\text{-cymene})RuCl(\mu\text{-}Cl)\}_2(\mu\text{-}L)]$ (**4**: L = **1**; **7**: L = **2; 10**: L = **3**), $[\{Cp^*MCl(\mu\text{-}Cl)\}_2(\mu\text{-}L)]$ (**5**: L = **1**, M = Rh; **6**: L = 1, M = Ir, **8**: L = **2**, M = Rh; **9**: L = **2**, M = Ir; **11**: L = **3**, M = Rh; **12**: L = **3**, M = Ir). Coupling reactions of the trinuclear complexes were also investigated; treatment of **5** or **6** with $AgPF_6$ afforded $[\{(Cp^*M)_4(\mu\text{-}Cl)_4\}(\mu\text{-}\mathbf{1})_2](PF_6)_4$ (**13**: M = Rh, **14**: M = Ir), which are chloro-bridged polynuclear complexes.



Scheme 1. Ferrocene-based bridging ligands: 1,1′-bis(4-pyridylthio)-ferrocene (**1**), 1′,1‴-bis(4-pyridylthio)biferrocene (**2**), and 1′,1‴-bis(diphenylphosphanyl)biferrocene (**3**)

Results and Discussion

Preparation and Properties of the Bridging Ligands 1, 2, and 3

The bidentate ligands 1,1′-bis(4-pyridylthio)ferrocene (**1**), 1′,1‴-bis(4-pyridylthio)biferrocene (**2**), and 1′,1‴-bis(diphenylphosphanyl)biferrocene (**3**) were chosen so as to generate bridged polynuclear complexes, rather than chelate ones. The ligand **1** was synthesized as reported previously,[18] and **2** and **3** were synthesized from dilithiobiferrocene. The ligand **3** is a biferrocene analogue of 1,1′-bis(diphenylphosphanyl)ferrocene (dppf), although dppf mostly forms chelate complexes.[17,19−23] The molecular structure of **3** has been characterized by X-ray crystallography. An ORTEP[24] view of the compound is shown in Figure 1 along with the numbering scheme. The molecule sits on a crystallographic inversion centre and the phosphorus atoms are arranged in opposite directions, demonstrating the versatility of this ligand as a bidentate. The distances from the iron atom to the Cp planes are approximately 1.64 Å, which is typical for neutral ferrocene. The bond lengths and angles around the phosphorus atom are similar to those found in dppf.[25]

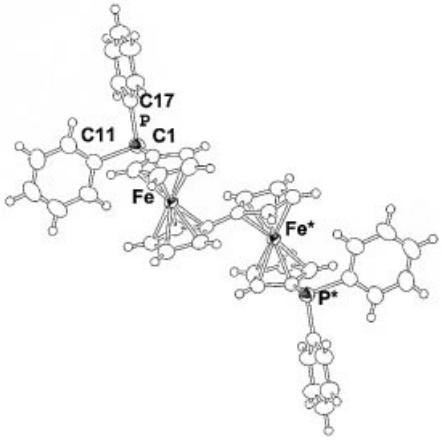

Figure 1. An ORTEP drawing of the molecular structure **3** with the atom numbering scheme; displacement ellipsoids are shown at the 50% probability level; selected bond lengths (Å) and angles (°): P(1)−C(1) 1.815(3), P(1)−C(11) 1.847(2), P(1)−C(17) 1.836(2), C(1)−P(1)−C(11) 99.4(1), C(1)−P(1)−C(17) 102.1(1), C(11)−P(1)−C(17) 101.2(1)

The redox properties of **2** and **3** were investigated by cyclic voltammetry. Complex **2** shows two quasi-reversible redox waves of the biferrocenyl moiety at $E_{1/2}$ = 0.14 V and 0.37 V (vs. $FeCp_2/FeCp_2^+$), exhibiting slight positive shifts relative to biferrocene, due to the electron-withdrawing effect of the pyridinethio moieties. The complex **3** exhibits several complicated redox waves; these could not be analyzed, although peaks corresponding to the oxidations of the biferrocene moiety were identified at $E_{1/2}$ = 0.03 V and 0.40 V (vs. $FeCp_2/FeCp_2^+$). The redox behaviour might be analogous to that of dppf,[26] in which oxidation is accompanied by reactions such as intermolecular coupling of the phosphorus groups, giving rise to complicated behaviour.

Preparation and Characterization of the Polynuclear Complexes

Reactions of the ferrocene-containing ligands **1**−**3** with the chloro-bridged dinuclear complexes [(*p*-cymene)RuCl(μ-Cl)]$_2$ and [Cp*MCl(μ-Cl)]$_2$ (M = Rh, Ir) produced tri- and tetranuclear metal complexes **4**−**12**, in good yields. Satisfactory analytical data were obtained for all products. The NMR spectroscopic and elemental analysis data confirm the 2:1 molar ratio of the organometallic moieties and the bridging ligands. These compounds are air-stable and are soluble in common polar organic solvents.

The trinuclear molecular structure of **5** was confirmed by X-ray structure analysis. An ORTEP view of the trinuclear complex is shown in Figure 2, along with the numbering scheme. The coordination environment of the rhodium atom is pseudooctahedral, with N(1)−Rh(1)−Cl(1), N(1)−Rh(1)−Cl(2), N(2)−Rh(2)−Cl(3), N(2)−Rh(2)−Cl(4) angles of 88.7(3), 87.0(2), 89.1(3), and 86.8(3) °, respectively, and Rh(1)−N(1) and Rh(2)−N(2) distances of 2.117(8) and 2.127(9) Å, respectively. The cyclopentadienyl rings are located ca. 1.77 Å away from the rhodium atom. The conformation of the two ferrocenyl rings is synclinal (eclipsed) with an S···S separation of ca. 4.26 Å. The ferrocenyl rings are planar and located 1.65 Å away from the iron atom.

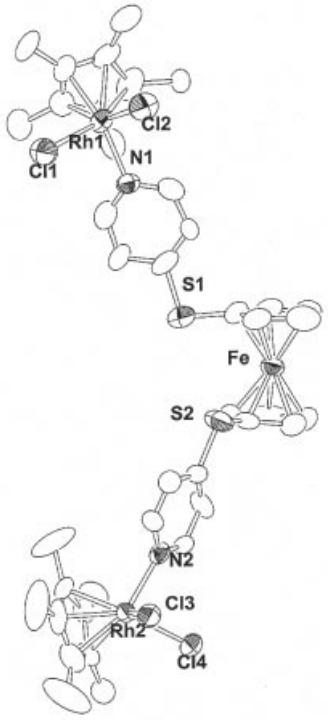

Figure 2. An ORTEP drawing of the molecular structure **5** with the atom numbering scheme; displacement ellipsoids are shown at the 50% probability level; selected bond lengths (Å) and angles (°): Rh(1)−N(1) 2.117(8), Rh(2)−N(2) 2.127(9), S(1)−C(1) 1.743(13), S(1)−C(11) 1.782(11), S(2)−C(6) 1.711(13), S(2)−C(16) 1.766(11), C(1)−S(1)−C(11) 103.5(6), C(6)−S(2)−C(16) 104.6(6)

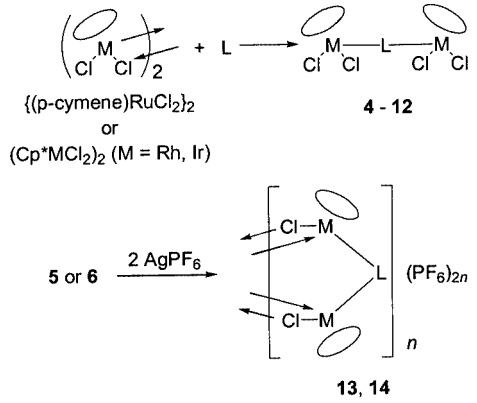
The ^{1}H NMR spectra of the pyridine-ligated complexes **4**−**9** show two doublets at around δ(H_α) = 8.6 and δ(H_β) =

6.8 ppm, which are assigned to the metal-coordinated pyridine ring protons. The chemical shifts of the pyridyl α-protons are shifted downfield by 0.3−0.4 ppm relative to those of the free ligands of **1** [$\delta(H_\alpha)$ = 8.31, $\delta(H_\beta)$ = 6.89 ppm][18] and **2** [$\delta(H_\alpha)$ = 8.24, $\delta(H_\beta)$ = 6.83 ppm]. The NMR spectroscopic signals of the ferrocenyl protons in complexes **4**−**10** are observed at almost identical positions to those of the corresponding free ligands **1**−**3**. The signals of the ferrocenyl protons in **11** and **12** are very broad at room temperature, and become sharper when the temperature is lowered to −60 °C.

The ^{31}P NMR spectroscopic signals of the phosphane-ligated complexes **10**−**12** are observed at δ = 18.99, 22.33 and −8.53 ppm, respectively, and show significant low-field shifts relative to the free ligand **3**. The chemical shifts have reasonable values for metal-coordinated phosphorus atoms.[27−29]

Self-coupling reactions of the trinuclear complexes **5** or **6** were performed by treating these complexes with $AgPF_6$. The yields were low — 27% and 16% for **13** and **14**, respectively — and recovery of the starting materials was mainly observed, with no significant side products. Based on the spectroscopic data, elemental analysis data, and the 18-electron rule, these products are considered to be chloro-bridged polynuclear complexes. Infrared spectra of the products exhibit characteristic P−F stretching vibrations at 1112, 848 and 558 cm^{-1}, showing the presence of the PF_6^- anion. The ^1H NMR spectroscopic signals of the Cp* protons are observed at higher fields than those of the precursors **5** and **6**, which may be a consequence of changes in the electron density on the metal centres. The ^1H NMR spectroscopic signals of the bridging moieties are observed at slightly lower fields than the precursors. Although we could not determine the crystal structures of **13** and **14**, we speculate that these complexes are most likely to have dimeric structures, i.e. n = 2 in Scheme 2, because of their close resemblance to the tetranuclear chloro-bridged complexes of $[\{Cp^*M(\mu\text{-}Cl)\}_4L_2]X_4$ (M = Rh, Ir).[13,14] The present complexes are soluble in common organic solvents such as dichloromethane, acetonitrile, and methanol, suggesting that they are oligomers and not coordination polymers.[18]



Scheme 2. General reaction scheme

Electrochemical Properties of the Trinuclear and Tetranuclear Complexes

The redox properties of complexes **4**−**10** were investigated by cyclic voltammetry. Figure 3 and 4 show the cyclic voltammograms in dichloromethane solutions. The redox potentials are listed in Table 1. Cyclic voltammetry studies on complex **4** revealed that there are two oxidation waves at 0.50 and 0.93 V (vs. $FeCp_2/FeCp_2^+$), and one reduction wave at 0.34 V. The redox waves around 0.4 V are assigned to the redox processes of the ferrocene moiety, and the oxidation wave at 0.93V is assigned to that of the Ru^{II} to Ru^{III} process.

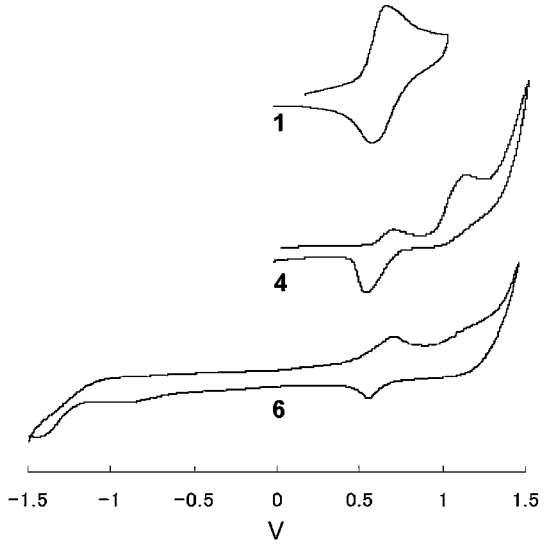


Figure 3. Cyclic voltammograms (vs. Ag/Ag^+) of **1**, **4** and **6**

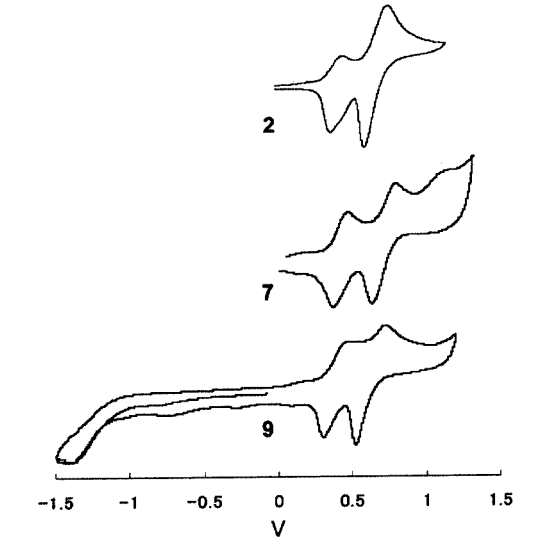

Figure 4. Cyclic voltammograms (vs. Ag/Ag^+) of **2**, **7** and **9**

The cyclic voltammogram of complex **5** exhibits an irreversible reduction wave of the Rh^{III} state at −1.60 V, and a quasi-reversible redox wave of the bridging ligand at $E_{1/2}$ = 0.45 V. Similarly, the cyclic voltammogram of the iridium

Table 1. Redox potentials (in V vs. $FeCp_2/FeCp_2^+$)

10		–	0.02	–	0.30	0.73

[a] Several unresolved redox waves were also present

complex **6** exhibits an irreversible reduction wave of the metal ion at −1.54 V, and a quasi-reversible redox wave of the bridging ligand at $E_{1/2} = 0.47$ V. It seems that the redox potentials of the ferrocene moiety roughly increase in the order $E_{1/2}$ (**1**) < $E_{1/2}$ (**5**: M = Rh) < $E_{1/2}$ (**6**: M = Ir). This tendency is consistent with the stronger electron-withdrawing nature of the Ir complex than that of the Rh complex.

The biferrocene-containing ruthenium complex **7** shows two quasi-reversible and one irreversible oxidation wave. The reversible ones [$E_{1/2}(1) = 0.17$ V, $E_{1/2}(2) = 0.44$ V] are assigned to the redox processes of the biferrocene moiety, and the irreversible one ($E_{pa} = 0.84$ V) to that of the ruthenium ion. The rhodium and iridium complexes of **8** and **9** show two quasi-reversible and one irreversible reduction wave on scanning from 0 to −1.5 V. It seems that the redox potentials of the biferrocene moiety roughly increase in the order $E_{1/2}$ (**2**) < $E_{1/2}$ (**8**: M = Rh) < $E_{1/2}$ (**9**: M = Ir), showing a similar tendency to the derivatives of **1**. Since the redox spectra of the terminal metal ions exhibit only one wave in **4**−**9**, it follows that interactions between the terminal metal ions through the bridging ligand are negligible.

The diphenylphosphanyl-coordinated complexes **10**−**12** show highly complicated redox behaviours compared with the pyridine-coordinated complexes **4**−**9**. The redox behaviour of complex **10** is slightly clearer than that of its precursor **3**; three oxidation processes for the biferrocene moiety and the Ru^{II} centre can be discerned, although these are irreversible. It is conceivable that the addition of the end-capping groups prevents chemical reactions such as intermolecular coupling,[26] which complicate the redox processes of **3**. The first oxidation process of the biferrocene moiety in **10** is quasi-reversible on scanning from 0 to 0.15 V, although both the first and the second waves become irreversible on scanning from 0 to 0.40 V. In complexes **4**−**9**, the redox processes of the ferrocene moiety are only slightly affected by the coordination of the metal ions. This is probably because the sulfur bridge terminates the conjugation between the ferrocene moiety and the pyridyl group. By contrast, coordination of the metal ions to the phosphorus atom in **3** leads to significant interaction between the metal ions and the ferrocene moieties, which could complicate the redox behaviour of **10**−**12**.

Experimental Section

General Remarks: All reactions were carried out by Schlenk techniques under nitrogen. Reagent grade solvents were dried, distilled, and stored under a nitrogen atmosphere. The starting complexes [(*p*-cymene)RuCl(μ-Cl)]$_2$ [30] and [Cp*MCl(μ-Cl)]$_2$ (M = Rh, Ir),[31,32] and the bridging ligand **1**[18] were prepared by a published procedure.

Elemental analyses were performed using a Yanagimoto C−H−N recorder (MT-3) and Elementar Vario EL. Infrared spectra were recorded on a JASCO FT-IR 230 spectrometer as KBr pellets in the 4000−400 cm^{-1} range. NMR spectra were recorded on a JEOL JNM-ECL-400 spectrometer. Chemical shifts are cited relative to $SiMe_4$ (^1H) and 85% H_3PO_4 (^{31}P). Cyclic voltammograms were obtained with an ALS/chi electrochemical-analyzer, model 600A. The working electrode was a glassy disk electrode with an Ag/Ag^+ reference electrode. NBu_4ClO_4 and CH_2Cl_2 were used as the supporting electrolyte and solvent, respectively.

Synthesis of 1′,1‴-Bis(4-pyridylthio)biferrocene (2): A THF solution (10 mL) of 4,4′-dipyridyl disulfide (660 mg, 3 mmol) was added dropwise to a suspension of dilithiobiferrocene, prepared from dibromobiferrocene (528 mg, 1 mmol), in THF (30 mL) at −80 °C for 4 h, and left to stir at room temperature for 4 h. The resulting brown solution was filtered, the solvent evaporated, and the orange residue dissolved in chloroform. Concentration of the solution to ca. 10 mL and addition of diethyl ether gave **2** as an orange solid. Further purification was achieved by recrystallization from chloroform/acetonitrile (1:1 v/v) as an orange solid that was obtained in a yield of 53% (312 mg). $C_{30}H_{24}Fe_2N_2S_2$ (588.36): calcd. C 61.20, H 4.11, N 4.76; found C 60.91, H 4.12, N 4.56. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 4.16 (m, 4 H), 4.26 (m, 4 H), 4.34 (m, 4 H), 4.51 (m, 4 H), 6.83 (m, 4 H), 8.24 (m, 4 H) ppm. IR (KBr): $\tilde{\nu}$ = 3094 cm^{-1} (m), 1575 (s), 1479 (m), 1409 (m), 802 (m), 705 (s), 494 (m), 418 (m).

Synthesis of 1′,1‴-Bis(diphenylphosphanyl)biferrocene (3): The procedure was similar to that described for the preparation of **2**, except that diphenylphosphanyl chloride (0.54 mL, 3 mmol) was used instead of 4,4′-dipyridyl disulfide. The product **3** was obtained in 68% (502 mg) yield. Crystals suitable for X-ray measurements were grown by slow diffusion of diethyl ether into a solution of **3** in chloroform at ambient temperature. $C_{44}H_{36}Fe_2P_2$ (738.41): calcd. C 71.56, H 4.91; found C 71.47, H 4.91. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 3.87 (m, 4 H), 4.01 (m, 4 H), 4.11 (m, 4 H), 4.18 (m, 4 H), 7.37−7.27 (m, 20 H) ppm. ^{31}P NMR (160 MHz, $CDCl_3$, 25 °C): δ = −16.09 ppm. IR (KBr): $\tilde{\nu}$ = 3053 cm^{-1} (m), 1477 (m), 1433 (s), 1159 (m), 1033 (m), 836 (m), 829 (m), 805 (m), 742 (s), 697 (s), 495 (s), 419 (s).

Synthesis of [{(*p*-cymene)RuCl(μ-Cl)}$_2$(μ-1)] (4): A dichloromethane solution (10 mL) of 1,1′-bis(4-pyridylthio)ferrocene (20 mg, 0.05 mmol) was added to a solution of [(*p*-cymene)RuCl(μ-Cl)]$_2$ (31 mg, 0.05 mmol) in dichloromethane (5 mL), and the mixture was stirred for 5 h at room temperature. The resulting orange solution was evaporated to dryness and the red residue recrystallized from dichloromethane/diethyl ether (1:1 v/v). The orange solid of **4** was obtained in a yield of 74% (38 mg). $C_{40}H_{44}Cl_4FeN_2Ru_2S_2$ (1016.73): calcd. C 47.25, H 4.36, N 2.76; found C 46.95, H 4.42, N 2.85. ^1H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.29 (d, 12 H),

2.10 (s, 6 H), 2.97 (sept, $J_{H,H}$ = 7.0 Hz, 2 H), 4.47 (m, 4 H), 4.58 (m, 4 H), 5.19 (d, $J_{H,H}$ = 3.0 Hz, 4 H), 5.41 (d, $J_{H,H}$ = 3.0 Hz, 4 H), 6.86 (m, 4 H), 8.66 (m, 4 H) ppm. IR (KBr): $\tilde{\nu}$ = 3045 cm^{-1} (m), 2965 (m), 2872 (m), 1594 (s), 1481 (m), 1417 (m), 1219 (m), 1110 (m), 1061 (m), 815 (m), 724 (m), 514 (m), 418 (m).

Synthesis of [{Cp*RhCl(μ-Cl)}$_2$(μ-1)]·CH_2Cl_2 (5): The procedure was similar to that described for the preparation of **4**, except that [Cp*RhCl(μ-Cl)]$_2$ (31 mg, 0.05 mmol) was used instead of [(*p*-cymene)RuCl(μ-Cl)]$_2$. The orange solid of **5** was obtained in a yield of 95% (47 mg). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.57 (s, 30 H), 4.47(m, 4 H), 4.58 (m, 4 H), 6.92 (m, 4 H), 8.62 (m, 4 H) ppm. $C_{41}H_{48}Cl_6FeN_2Rh_2S_2$ (1107.35): calcd. C 44.47, H 4.27, N 2.53; found C 44.4, H 4.5, N 2.5. ^{1}H NMR (400 MHz, [D$_6$]DMSO, 25 °C): δ = 1.66 (s, 30 H), 4.61 (m, 4 H), 4.66 (m, 4 H), 6.93 (m, 4 H), 8.31 (m, 4 H) ppm. IR (KBr): $\tilde{\nu}$ = 1636 cm^{-1} (m), 1592 (s), 1479 (m), 1417 (m), 1375 (m), 1216 (m), 1109 (m), 1062 (m), 1025 (m), 896 (m), 817 (m), 726 (m), 504 (m), 419 (s).

Synthesis of [{Cp*IrCl(μ-Cl)}$_2$(μ-1)] (6): The procedure was similar to that described for the preparation of **4**, except that [Cp*IrCl(μ-Cl)]$_2$ (39 mg, 0.05 mmol) was used instead of [(*p*-cymene)RuCl(μ-Cl)]$_2$. The yellow solid of **6** was obtained in a yield of 87% (51 mg). $C_{40}H_{46}Cl_4FeIr_2N_2S_2$ (1201.04): calcd. C 40.00, H 3.86, N 2.33; found C 39.73, H 3.89, N 2.20. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.56 (s, 30 H), 4.49 (m, 4 H), 4.58 (m, 4 H), 6.88 (d, $J_{H,H}$ = 3.4 Hz, 4 H), 8.61 (d, $J_{H,H}$ = 3.2 Hz, 4 H) ppm. ^{1}H NMR (400 MHz, [D$_6$]DMSO, 25 °C): δ = 1.63 (s, 30 H) 4.61 (m, 4 H), 4.67 (m, 4 H), 6.95 (m, 4 H), 8.31 (m, 4 H) ppm. IR (KBr): $\tilde{\nu}$ = 2917 cm^{-1} (m), 1636 (m), 1595 (s), 1478 (m), 1419 (m), 1380 (m), 1215 (m), 1111 (m), 1061 (m), 1029 (m), 896 (m), 816 (m), 728 (m).

Synthesis of [(*p*-cymene)RuCl(μ-Cl)}$_2$(μ-2)](7): The procedure was similar to that described for the preparation of **4**, except that **2** (30 mg, 0.05 mmol) was used instead of **1**. The orange solid of **7** was obtained in a yield of 52% (31 mg). $C_{50}H_{52}Cl_4Fe_2N_2Ru_2S_2$ (1200.75): calcd. C 50.00, H 4.37, N 2.33; found C 49.71, H 4.46, N 2.44. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.27 (d, 12 H), 2.07 (s, 6 H), 2.95 (sept, $J_{H,H}$ = 7.0 Hz, 2 H), 4.12 (m, 4 H), 4.27 (m, 4 H), 4.35 (m, 4 H), 4.49 (m, 4 H), 5.14 (d, $J_{H,H}$ = 3.0 Hz, 4 H), 5.36 (d, $J_{H,H}$ = 3.0 Hz, 4 H), 6.80 (m, 4 H), 8.58 (m, 4 H) ppm. IR (KBr): $\tilde{\nu}$ = 3085 cm^{-1} (w), 3037 (w), 2961 (w), 2870 (w), 1593 (s), 1480 (m), 1418 (m), 1111 (m), 1059 (m), 1026 (m), 890 (m), 816 (m), 725 (m), 500 (m), 419 (m).

Synthesis of [Cp*RhCl(μ-Cl)}$_2$(μ-2)]·CH_2Cl_2 (8): The procedure was similar to that described for the preparation of **5**, except that **2** (30 mg, 0.05 mmol) was used instead of **1**. The orange solid of **8** was obtained in a yield of 52% (32 mg). $C_{51}H_{56}Cl_6Fe_2N_2Rh_2S_2$ (1291.37): calcd. C 47.43, H 4.37, N 2.17; found C 47.6, H 4.5, N 2.1. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.54 (s, 30 H), 4.12 (m, 4 H), 4.27 (m, 4 H), 4.35 (m, 4 H), 4.50 (m, 4 H), 6.86 (m, 4 H), 8.55 (m, 4 H) ppm. IR (KBr): $\tilde{\nu}$ = 2870 cm^{-1} (w), 1636 (m), 1592 (s), 1478 (m), 1417 (m), 1374 (m), 1215 (m), 1165 (m), 1109 (m), 1061 (m), 1024 (m), 890 (m), 817 (m), 725 (m), 499 (m).

Synthesis of [{Cp*IrCl(μ-Cl)}$_2$(μ-2)]·$(CH_2Cl_2)_{1.5}$ (9): The procedure was similar to that described for the preparation of **6**, except that **2** (30 mg, 0.05 mmol) was used instead of **1**. The yellow solid of **9** was obtained in a yield of 67% (46 mg). $C_{51.5}H_{57}Cl_3Fe_2Ir_2N_2S_2$ (1370.65): calcd. C 40.90, H 3.80, N 1.85; found C 41.20, H 3.89, N 1.72. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 1.54 (s, 30 H), 4.14 (m, 4 H), 4.28 (m, 4 H), 4.36 (m, 4 H), 4.51 (m, 4 H), 6.82 (m, 4 H), 8.58 (m, 4 H) ppm. IR (KBr): $\tilde{\nu}$ = 3075 cm^{-1} (w), 2913 (w), 1595 (s), 1479 (m), 1420 (m), 1377 (m), 1215 (m), 1167 (m), 1111 (m), 1062 (m), 1031 (m), 891 (m), 822 (m), 727 (m), 500 (m).

Synthesis of [{(*p*-cymene)RuCl(μ-Cl)}$_2$(μ-3)]·CH_2Cl_2 (10): The procedure was similar to that described for the preparation of **4**, except that **3** (37 mg, 0.05 mmol) was used instead of **1**. The orange solid of **10** was obtained in a yield of 45% (32 mg). $C_{65}H_{66}Cl_6Fe_2P_2Ru_2$ (1435.73): calcd. C 54.37, H 4.63; found C 54.63, H 4.71. ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 0.96 (d, 12 H), 1.75 (s, 6 H), 2.52 (sept, $J_{H,H}$ = 7.0 Hz, 2 H), 3.61 (m, 4 H), 3.89 (m, 4 H), 4.00 (m, 4 H), 4.30 (m, 4 H), 5.07 (s, 8 H), 7.43−7.37 (m, 12 H), 7.85−7.80 (m, 8 H) ppm. ^{31}P NMR (160 MHz, $CDCl_3$, 25 °C): δ = 18.99 ppm. IR (KBr): $\tilde{\nu}$ = 3044 cm^{-1} (w), 2958 (w), 2868 (w), 1482 (m), 1437 (s), 1384 (m), 1159 (m), 1095 (m), 1032 (s), 825 (s), 742 (s), 694 (s), 540 (m), 517 (s), 472 (s), 450 (s).

Synthesis of [{Cp*RhCl(μ-Cl)}$_2$(μ-3)]·$(CH_2Cl_2)_{0.5}$ (11): The procedure was similar to that described for the preparation of **5**, except that **3** (37 mg, 0.05 mmol) was used instead of **1**. The orange solid of **11** was obtained in a yield of 79% (54 mg). $C_{64.5}H_{67}Cl_5Fe_2P_2Rh_2$ (1398.95): calcd. C 55.38, H 4.83; found C 55.8, H 5.0. ^{1}H NMR (400 MHz, $CDCl_3$, −60 °C): δ = 1.27 (s, 30 H), 3.93−3.70 (m, 4 H), 4.28−4.02 (m, 8 H), 4.50 (m, 4 H), 7.55−7.30 (m, 12 H), 8.10−7.82 (m, 8 H) ppm. ^{31}P NMR (160 MHz, $CDCl_3$, 25 °C): δ = 22.33 (d) ppm. IR (KBr): $\tilde{\nu}$ = 2359 cm^{-1} (w), 1483 (m), 1434 (s), 1373 (m), 1305 (m), 1192 (m), 1159 (m), 1113 (m), 1094 (m), 1023 (m), 834 (m), 748 (m), 697 (m), 540 (s), 479 (m).

Synthesis of [{Cp*IrCl(μ-Cl)}$_2$(μ-3)] (12): The procedure was similar to that described for the preparation of **6**, except that **3** (37 mg, 0.05 mmol) was used instead of **1**. The orange solid of **12** was obtained in a yield of 71% (54 mg). $C_{64}H_{66}Cl_4Fe_2Ir_2P_2$ (1535.12): calcd. C 50.07, H 4.33; found C 49.8, H 4.3. ^{1}H NMR (400 MHz, $CDCl_3$, −60 °C): δ = 1.25 (s, 30 H), 3.82−3.75 (m, 4 H), 4.20−3.90 (m, 8 H), 4.60−4.25 (m, 4 H), 7.50−7.20 (m, 12 H), 8.10−7.70 (m, 8 H) ppm. ^{31}P NMR (160 MHz, $CDCl_3$, 25 °C): δ = −8.53 (s) ppm. IR (KBr): $\tilde{\nu}$ = 3072 cm^{-1} (w), 2912 (w), 1636 (m), 1435 (s), 1374 (m), 1159 (m), 1098 (m), 1085 (m), 1030 (m), 836 (m), 749 (m), 697 (m), 545 (s), 518 (m), 476 (m).

Synthesis of [{(Cp*Rh)$_4$(μ-Cl)$_4$}(μ-1)$_2$](PF$_6$)$_4$·CH_2Cl_2 (13): A diethyl ether solution (30 mL) of $AgPF_6$ (26 mg, 0.1 mmol) was added to a solution of **5** (52 mg, 0.05 mmol) in dichloromethane (30 mL), and the mixture was stirred for 12 h at room temperature. The resulting orange solution was filtered, the solvents evaporated to dryness and the red residue recrystallized from dichloromethane/diethyl ether (1:1 v/v). The orange solid of **13** was obtained in a yield of 27% (21 mg). $C_{81}H_{94}Cl_6F_{24}Fe_2N_4P_4Rh_4S_4$ (2567.81): calcd. C 37.89, H 3.69, N 2.18; found C 38.08, H 3.34, N 2.02. ^{1}H NMR (400 MHz, [D$_6$]DMSO, 25 °C): δ = 1.54 (s, 60 H), 4.72 (m, 8 H), 4.76 (m, 8 H), 7.31 (m, 8 H), 8.36 (m, 8 H) ppm. IR (KBr): $\tilde{\nu}$ = 1596 cm^{-1} (s), 1482 (m), 1422 (m), 1377 (m), 1112 (m), 1062 (m), 1023 (m), 844 (s).

Synthesis of [{(Cp*Ir)$_4$(μ-Cl)$_4$}(μ-1)$_2$](PF$_6$)$_4$ (14): The procedure was similar to that described for the preparation of **13**, except that **6** (61 mg, 0.05 mmol) was used instead of **5**. The yellow solid of **14** was obtained in a yield of 16% (16 mg). $C_{80}H_{92}Cl_4F_{24}Fe_2Ir_4N_4P_4S_4$ (2840.14): calcd. C 33.83, H 3.26, N 1.97; found C 33.44, H 3.00, N 2.18. ^{1}H NMR (400 MHz, [D$_6$]DMSO, 25 °C): δ = 1.55 (s, 60 H), 4.73 (m, 8 H), 4.77 (m, 8 H), 7.31 (m, 8 H), 8.43 (m, 8 H) ppm. IR (KBr): $\tilde{\nu}$ = 1598 cm^{-1} (s), 1483 (m), 1458 (m), 1425 (m), 1387 (m), 1230 (m), 1140 (m), 1115 (m), 1061 (m), 1031 (m), 848 (s).

X-ray Crystallographic Study: Crystals of compound **3** or **5** were mounted on a glass fibre and transferred to the diffractometer. The X-ray data were collected with a Rigaku AFC-5S four-circle diffractometer (**3**) or a Rigaku Mercury CCD diffractometer (**5**) using graphite-monochromated Mo-K_α radiation. Crystal data, data col-

Table 2. Crystal data and structure refinement of **3** and **5**

	3	**5**
Empirical formula	$C_{44}H_{36}Fe_2P_2$	$C_{41}H_{48}Cl_6FeN_2Rh_2S_2$

[a] $R1 = \Sigma||F_0| - |F_c||/\Sigma|F_0|$; $wR2 = [\Sigma w(F_0^2 - F_c^2)^2/\Sigma w(F_0^2)^2]^{1/2}$.

lection parameters, and analysis statistics for **3** and **5** are listed in Table 2. All calculations were performed using the teXsan crystallographic software package.[33] The structures were solved by direct methods (SIR 92[34] and SHELX-97[35]) and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically, and absorption correction was applied. The hydrogen atoms were inserted at the calculated positions and allowed to ride on their respective parent atoms.

CCDC-181949 (**3**) and CCDC-184341 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to Prof. Tadashi Sugawara and Dr. Michio M. Matsushita (The University of Tokyo) for help with X-ray measurements. We thank Mr. Jouji Seta (Toho University) for help with ^{31}P NMR spectroscopy measurements. We also thank Prof. Hiroshi Moriyama (Toho University) for his assistance and Ms. Yumiko Sato (Toho University) the for elemental analyses. We are indebted to Mr. Masaru Nakama (WarpStream Ltd., Tokyo) for the Web-DB computer system.

Reactivity of a Triruthenium Ynenyl Cluster Complex with Diynes: Cluster-Mediated Combination of up to Three Substituted Butadiyne Molecules into a Carbon-Rich Hydrocarbyl Ligand

Javier A. Cabeza,*[a] Ignacio del Río,[a] Marta Moreno,[a] Santiago García-Granda,[b] Mónica Pérez-Priede,[b] and Víctor Riera[a]

Keywords: Ruthenium / Clusters / Alkynes / C-C bond formation / N ligands

The triruthenium ynenyl cluster complex $[Ru_3(\mu_3\text{-}\eta^2\text{-apyr})(\mu\text{-}\eta^3\text{-MeCH=CC}\equiv\text{CMe})(\mu\text{-CO})_2(CO)_6]$ (**2**; Hapyr = 2-aminopyrimidine) has been prepared in two steps from $[Ru_3(CO)_{12}]$, 2-aminopyrimidine and 2,4-hexadiyne. Its reactivity with two conjugated diynes has been studied. With 2,4-hexadiyne, it affords $[Ru_3(\mu_3\text{-}\eta^2\text{-apyr})\{\mu\text{-}\eta^5\text{-MeC}\equiv\text{CC=CMeC(=CHMe)-C}\equiv\text{CMe}\}(\mu\text{-CO})_2(CO)_5]$ (**3**), which contains a diynedienyl ligand that arises from the coupling of 2,4-hexadiyne with the hex-2-yn-4-en-4-yl ligand of **2**, whereas the reaction of complex **2** with diphenylbutadiyne gives $[Ru_3(\mu_3\text{-}\eta^2\text{-apyr})\{\mu_3\text{-}\eta^7\text{-PhC}\equiv\text{CC=CPhCMe=CC(=CHMe)C(C}\equiv\text{CPh)=CPh}\}(\mu\text{-CO})(CO)_6]$ (**4**). Complex **4** contains an unprecedented diynetetraentriyl ligand that arises from the coupling of two diphenylbutadiyne molecules with the hex-2-yn-4-en-4-yl ligand of **2**.

Introduction

In previous studies, it was observed that 2-amidopyridine-bridged hydrido triruthenium carbonyl complexes[1] activate alkynes, rendering derivatives of the type $[Ru_3(\mu_3\text{-}\eta^2\text{-apy})(\mu\text{-}\eta^2\text{-alkenyl})(\mu\text{-CO})_2(CO)_6]$ (apy = 2-amidopyridine-type ligand).[2,3] These alkenyl derivatives have been recognized as catalytic precursors for the hydrogenation,[4,5] dimerization,[6] polymerisation[6] and hydroformylation[7] of selected alkynes.

The natural evolution of these investigations led us to study the reactivity of apy-bridged hydrido triruthenium complexes with diynes. In this field, we have already reported that the complex $[Ru_3(\mu\text{-H})(\mu_3\text{-}\eta^2\text{-ampy})(CO)_9]$ (Hampy = 2-amino-6-methylpyridine) reacts with diphenylbutadiyne and 1,6-diphenoxy-2,4-hexadiyne to give ynenyl complexes of the type $[Ru_3(\mu_3\text{-}\eta^2\text{-ampy})(\mu\text{-}\eta^3\text{-RCH=CC}\equiv\text{CR})(\mu\text{-CO})_2(CO)_6]$ (R = Ph, CH_2OPh). These ynenyl compounds are prone to react with alkynes and diynes to give interesting coupling products, including η^5-cyclopentadienyl and η^5-ruthenacyclopentadienyl derivatives.[8] However, the analogous ynenyl complex derived from $[Ru_3(\mu\text{-H})(\mu_3\text{-}\eta^2\text{-ampy})(CO)_9]$ and 2,4-hexadiyne could not be isolated and, therefore, its reactivity could not be studied.[9]

We report herein that the use of 2-aminopyrimidine (Hapyr) as a ligand precursor, instead of 2-amino-6-methylpyridine, leads to the isolation of a trinuclear ynenyl derivative of 2,4-hexadiyne, $[Ru_3(\mu_3\text{-}\eta^2\text{-apyr})(\mu\text{-}\eta^3\text{-MeCH=CC}\equiv\text{CMe})(\mu\text{-CO})_2(CO)_6]$, and allows the study of the reactivity of the latter complex with diynes. We also report that a product of one of these reactions contains an unprecedented hydrocarbyl ligand that arises from the coupling of three diyne molecules.

Results and Discussion

Synthesis of Compounds 1 and 2

The reaction of $[Ru_3(CO)_{12}]$ with 2-aminopyrimidine in THF at reflux temperature leads to the trinuclear derivative $[Ru_3(\mu\text{-H})(\mu_3\text{-}\eta^2\text{-apyr})(CO)_9]$ (**1**) (Scheme 1). The compound was characterised by its mass spectrum, which shows the molecular ion, and by its IR and NMR spectra, which are similar to those of $[Ru_3(\mu\text{-H})(\mu_3\text{-}\eta^2\text{-ampy})(CO)_9]$.[10] Thus, the behaviour of 2-aminopyrimidine in its reaction with $[Ru_3(CO)_{12}]$ is similar to that of 2-aminopyridines.

The thermal reaction (refluxing THF) of 2,4-hexadiyne with compound **1**, in a 1:1 mol ratio, leads to a mixture of compounds from which the major product, the ynenyl derivative $[Ru_3(\mu_3\text{-}\eta^2\text{-apyr})(\mu\text{-}\eta^3\text{-MeCH=CC}\equiv\text{CMe})(\mu\text{-CO})_2(CO)_6]$ (**2**) (Scheme 1), could be separated by TLC.

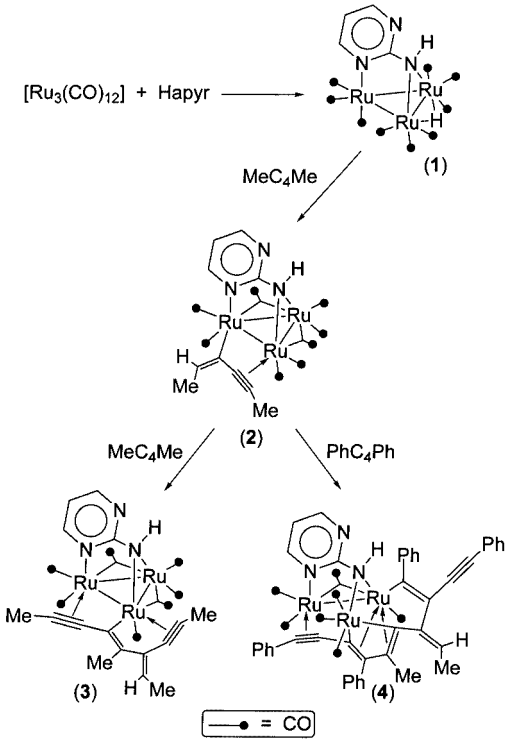

Scheme 1

The mass spectrum of **2** shows the corresponding molecular ion. Its IR spectrum indicates the presence of bridging CO ligands. The ^{1}H NMR spectrum also confirms the insertion of the original diyne into a Ru−hydride bond of **1** to give an ynenyl ligand. The multiplicity of the signal of this hydrogen atom in **2** (quadruplet, J = 6.5 Hz) indicates that it is adjacent to a methyl group. The structure depicted for this compound in Scheme 1, which shows a bridging three-electron donor hex-2-yn-4-en-4-yl ligand, is also supported by the similarity of its spectroscopic data with those of the compounds [$Ru_3(\mu_3$-η^2-ampy)(μ-η^3-RCH=CC≡CR)(μ-CO)$_2$(CO)$_6$] (R = Ph, CH_2OPh), the structures of which have been determined by X-ray diffraction methods.[8]

We have recently reported that the isolation of the 2-amido-6-methylpyridine derivative [$Ru_3(\mu_3$-η^2-ampy)(μ-η^3-MeCH=CC≡CMe)(μ-CO)$_2$(CO)$_6$] could not be achieved. Although this complex was spectroscopically detected in the reaction of [$Ru_3(\mu$-H)(μ_3-η^2-ampy)(CO)$_9$] with 2,4-hexadiyne, mixtures of inseparable products were always obtained, regardless of the ratio of the reactants.[9] This prevented the study of its derivative chemistry. As desired, the slightly different polarity of analogous ampy and apyr derivatives allows the successful TLC separation of complex **2**.

Considering the asymmetry of each triple bond of hexa-2,4-diyne, the insertion of one of its triple bonds into a Ru−H bond of **1** could lead to two different products. As occurred with [$Ru_3(\mu$-H)(μ_3-η^2-ampy)(CO)$_9$],[9] the reaction is selective in the sense that only the insertion product containing a hex-2-yn-4-en-4-yl ligand, (compound **2**) is formed. The alternative product would have a hex-2-yn-4-en-5-yl ligand. This selectivity has also been observed previously for the reaction of compound **1** with 1,6-diphenoxy-2,4-hexadiyne,[8] but not with diphenylbutadiyne.[9,11] A mechanistic proposal accounting for the formation of compounds similar to **2** from conjugated diynes and hydrido trinuclear clusters has been reported.[8]

Apart from the above-mentioned ynenyl compounds derived from [$Ru_3(\mu$-H)(μ_3-η^2-ampy)(CO)$_9$],[8] only a few more ynenyl derivatives have heretofore been reported as products of reactions of carbonylruthenium clusters with diynes, i.e. the compounds [$Ru_2(\mu$-N=CPh$_2$)(μ-η^2-CH$_2$=CCH$_2$C≡CSiMe$_3$)(CO)$_6$],[12] [$Ru_3(\mu_3$-η^2-pyNMe)(μ-η^3-PhCH=CC≡CPh)(μ-CO)$_2$(CO)$_6$],[11] and [$Ru_4(\mu$-η^2-dmpz)(μ_4-η^4-MeCH=CC≡CMe)(μ-CO)(CO)$_{10}$] (Hdmpz = 3,5-dimethylpyrazole).[13] The cluster complex [Ru_3{μ-NS(O)MePh}(μ-η^3-PhCH=CC≡CPh)(CO)$_9$] also contains an ynenyl ligand, but in this case the ligand arises from an alkynyl−vinylidene coupling.[14]

Reactions of Compound 2 with Diynes

Treatment of compound **2** with 2,4-hexadiyne in THF at reflux temperature leads to [$Ru_3(\mu_3$-η^2-apyr){μ-η^5-MeC≡CC=CMeC(=CHMe)C≡CMe}(μ-CO)$_2$(CO)$_5$] (**3**) in quantitative yield (Scheme 1). Its analytical and spectroscopic data, although indicating the presence of the apyr ligand, the existence of bridging and terminal CO ligands, and the incorporation of the new 2,4-hexadiyne molecule, did not reveal its molecular structure, which was determined by X-ray diffraction.

Figure 1 shows a view of compound **3**. A selection of bond lengths is given in Table 1. The new ligand, which can be described as a 5-methyl-6-(ethylidene)nona-2,7-diyn-4-en-4-yl ligand, behaves as a five-electron donor. It spans the longest edge of the metal triangle [Ru(1)−Ru(3): 2.8874(9) Å], and is attached to Ru(1) through a C≡C triple bond (two-electron π-type interaction) and to Ru(3) through the remaining C≡C triple bond (two-electron π-type interac-

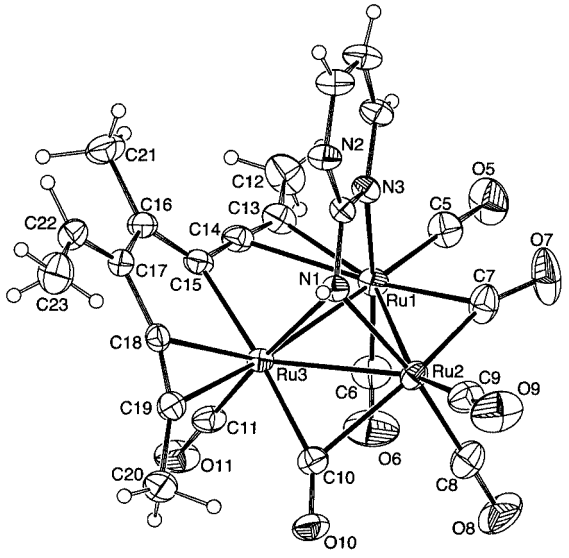

Figure 1. Molecular structure of compound **3**; thermal ellipsoids are drawn at a 40% probability level

tion) and the C(15) carbon atom (one-electron σ-type interaction). The remaining edges of the metal triangle are shorter [Ru(1)−Ru(2): 2.7846(9) Å, Ru(2)−Ru(3): 2.6662(8) Å], and each one is asymmetrically bridged by a CO ligand. The apyr ligand caps the Ru_3 triangle, and is attached to the Ru(2)−Ru(3) edge through the exocyclic N(1) atom and to the Ru(1) atom through the heterocyclic N(3) atom. The cluster shell is completed with five terminal CO ligands. Thus, the compound is a closed-shell 48-electron cluster. Overall, the structure resembles that of the related ampy derivative, which contains an analogous diynedienyl ligand.[9]

The reaction of complex **2** with one equivalent of diphenylbutadiyne, in THF at reflux temperature, led only to intractable mixtures. However, the use of a 1:2 ratio of the reactants led to a mixture of compounds from which the trinuclear derivative [$Ru_3(\mu_3$-η^2-apyr){μ_3-η^7-PhC≡CC=CPhCMe=CC(=CHMe)C(C≡CPh)=CPh}(μ-CO)$(CO)_6$] (**4**) could be separated by TLC. X-ray diffraction was necessary to determine its structure, since its analytical and spectroscopic data, although suggesting the incorporation of two diphenylbutadiyne molecules to complex **2**, did not allow a structural assignment.

Figure 2 shows a view of compound **4**. A selection of bond lengths is given in Table 2. While the Ru(1)−Ru(3) distance [2.8341(5) Å] corresponds to a metal−metal bond, the Ru(1)−Ru(2) and Ru(2)−Ru(3) distances [4.0288(5) Å and 3.0929(5) Å respectively] are too long to be assigned to Ru−Ru bonds. The new ligand spans the two long Ru−Ru edges and is attached to Ru(1) through a C≡C triple bond (two-electron π-type interaction). It is involved in a ruthenacyclopentadiene fragment with Ru(2), to which it is bonded through the carbon atoms C(18) and C(24) (two one-electron σ-type interactions). It also binds to Ru(3) through both double bonds of the ruthenacyclopentadiene fragment (two two-electron π-type interactions) and the C(12) carbon atom (one-electron σ-type interaction). This hydrocarbyl ligand, which can be systematically named as a 1,4,9-triphenyl-5-methyl-7-ethyliden-8-(phenylethynyl)nona-1-yn-3,5,8-trien-3,6,9-triyl ligand, behaves as a nine-electron donor. The apyr ligand is attached to the Ru(2) and Ru(3) atoms through the exocyclic N(1) atom and to Ru(1) through the heterocyclic N(3) atom. The Ru(1)−Ru(3) edge is asymmetrically bridged by a CO ligand. The complex shell is completed with six terminal CO ligands. Thus, the compound is a 52-electron species.

Although a few hydrocarbyl ligands resulting from the coupling of two diyne molecules at metal cluster cores have

been reported,[8,9,15] complex **4** is the first example of a hydrocarbyl ligand resulting from the coupling of three diyne molecules.

The compounds $[Ru_3(\mu_3\text{-}\eta^2\text{-ampy})(\mu\text{-}\eta^3\text{-RCH=CC}\equiv\text{CR})(\mu\text{-CO})_2(CO)_6]$ (R = Ph, CH_2OPh), structurally analogous to **2**, are the only ynenyl derivatives whose reactivity with alkynes and diynes has been studied. They systematically give trinuclear products containing η^5-ruthenacyclopentadienyl fragments which arise from the coupling of the coordinated ynenyl ligands with a C≡C triple bond of the new reagent (alkyne or diyne).[8] It is noteworthy that the reactions of **2** with 2,4-hexadiyne and diphenylbutadiyne do not give related products, but instead give compounds **3** and **4**. At this stage, it seems that this different reactivity is not due to steric reasons, but it is not yet clear whether it may be caused by the different substituents of the ynenyl ligands, the different capping *N*-donor ligands or a combination of both.

We also studied the reactions of **2** with some monoalkynes, but complex mixtures, from which we could not isolate and characterise any product, were formed in all cases.

Experimental Section

General Remarks: Solvents were dried over sodium diphenyl ketyl (THF, hydrocarbons) or calcium hydride (dichloromethane) and distilled under nitrogen prior to use. The reactions were carried out under nitrogen, using Schlenk and vacuum line techniques, and were routinely monitored by solution IR spectroscopy (carbonyl stretching region) and by spot TLC (silica gel). All reagents were purchased as analytically pure samples. IR: Perkin−Elmer Paragon 1000 FT spectrometer. NMR: Bruker AC-200, AC-300 or DPX-300 spectrometers, room temperature, $SiMe_4$ as internal standard. Microanalyses were obtained from the University of Oviedo's Analytical Service. FAB-MS were obtained from the University of Santiago de Compostela's Mass Spectroscopic Service; data given refer to the most abundant molecular ion isotopomer.

$[Ru_3(\mu\text{-H})(\mu_3\text{-}\eta^2\text{-apyr})(CO)_9]$ (1): A mixture of $[Ru_3(CO)_{12}]$ (300 mg, 0.468 mmol) and 2-aminopyrimidine (71 mg, 0.749 mmol) in THF (50 mL) was stirred at reflux temperature for 90 min. After concentration under reduced pressure to approximately 2 mL, the solution was applied to the top of a chromatography column (10 × 2 cm) packed with activity I neutral alumina in hexane. Hexane/dichloromethane (1:1) eluted two bands. The first, yellow, contained some $[Ru_4H_4(CO)_{12}]$ product (IR identification). The second band, yellow-orange, afforded compound **2** after solvent removal (150 mg, 48%). $C_{13}H_5N_3O_9Ru_3$ (650.44): calcd. C 24.01, H 0.77, N 6.46; found C 23.85, H 0.76, N 6.38. FAB-MS: *m*/*z* = 652 [M^+]. IR (CH_2Cl_2): ν(CO) = 2084 (m), 2054 (s), 2030 (vs), 1998 (s), 1964 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.42 (dd, *J* = 5.1, 2.4 Hz, 1 H), 8.20 (dd, *J* = 5.1, 2.4 Hz, 1 H), 6.76 (t, *J* = 5.1 Hz, 1 H), 4.55 (br. s, 1 H), −11.31 (s, 1 H) ppm.

$[Ru_3(\mu_3\text{-}\eta^2\text{-apyr})(\mu\text{-}\eta^3\text{-MeCH=CC}\equiv\text{CMe})(\mu\text{-CO})_2(CO)_6]$ (2): A solution of complex **1** (150 mg, 0.230 mmol) and 2,4-hexadiyne (20 mg, 0.256 mmol) in THF (20 mL) was stirred at reflux temperature for 60 min. The colour changed from yellow to red. After concentration under reduced pressure to approximately 2 mL the solution was applied to preparative silica gel TLC plates. Repeated elution with hexane/dichloromethane (3:1) allowed the separation of two bands. The second band, orange, contained a small amount of compound **3** (9 mg, 5%). The first band, orange, gave compound **2** (51 mg, 30%) upon extraction with dichloromethane. $C_{18}H_{11}N_3O_8Ru_3$ (700.54): calcd. C 30.86, H 1.58, N 6.00; found C 30.91, H 1.63, N 5.84. FAB-MS: *m*/*z* = 702 [M^+]. IR (CH_2Cl_2): ν(CO) = 2064 (s), 2030 (vs), 2022 (vs), 1994 (s), 1969 (w), 1873 (w), 1820 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.00 (m, 2 H), 6.50 (t, *J* = 5.4 Hz, 1 H), 6.43 (q, *J* = 6.5 Hz, 1 H), 4.05 (br. s, 1 H), 2.94 (s, 3 H), 2.45 (d, *J* = 6.5 Hz, 3 H) ppm.

$[Ru_3(\mu_3\text{-}\eta^2\text{-apyr})\{\mu\text{-}\eta^5\text{-MeC}\equiv\text{CC=CMeC(=CHMe)C}\equiv\text{CMe}\}(\mu\text{-CO})_2(CO)_5]$ (3): A solution of complex **2** (15 mg, 0.021 mmol) and 2,4-hexadiyne (2 mg, 0.025 mmol) in THF (10 mL) was stirred at reflux temperature for 60 min. The original yellow colour of the solution darkened slightly. The solvent was removed under reduced pressure and the residue was washed with hexane (2 mL) to give compound **3** (14 mg, 89%) as a yellow-orange solid. $C_{23}H_{17}N_3O_7Ru_3$ (750.65): calcd. C 36.80, H 2.28, N 5.60; found C 36.76, H 2.12, N 5.59. FAB-MS: *m*/*z* = 752 [M^+]. IR (CH_2Cl_2): ν(CO) = 2064 (vs), 2012 (s), 1980 (s), 1955 (w), 1876 (w), 1815 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 7.92 (dd, *J* = 4.3, 2.1 Hz, 1 H), 7.73 (dd, *J* = 5.5, 2.1 Hz, 1 H), 6.36 (dd, *J* = 5.5, 4.3 Hz, 1 H), 6.09 (q, *J* = 7.6 Hz, 1 H), 4.22 (br. s, 1 H), 3.12 (s, 3 H), 2.84 (s, 3 H), 2.15 (s, 3 H), 2.11 (d, *J* = 7.6 Hz, 3 H) ppm.

$[Ru_3(\mu_3\text{-}\eta^2\text{-apyr})\{\mu_3\text{-}\eta^7\text{-PhC}\equiv\text{CC=CPhCMe=CC(=CHMe)-C(C}\equiv\text{CPh)=CPh}\}(\mu\text{-CO})(CO)_6]$ (4): A solution of complex **2** (45 mg, 0.064 mmol) and diphenylbutadiyne (29 mg, 0.143 mmol) in THF (30 mL) was stirred at reflux temperature for 150 min. The colour changed from yellow to brown. After concentration under reduced pressure to approximately 2 mL, the solution was applied to preparative silica gel TLC plates. Multiple elution with hexane/dichloromethane (2:1) allowed the isolation of compound **4** (10 mg, 15%) from the major band, orange, upon extraction with dichloromethane. $C_{49}H_{31}N_3O_7Ru_3$ (1077.05): calcd. C 54.64, H 2.90, N 3.90; found C 54.34, H 2.80, N 3.77. FAB-MS: *m*/*z* = 1023 [M^+ − 2CO]. IR (CH_2Cl_2): ν(CO) = 2092 (s), 2029 (vs), 2013 (m), 1963 (m), 1809 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.05 (d, *J* = 7.4 Hz, 1 H), 7.95 (dd, *J* = 4.4, 2.5 Hz, 1 H), 7.82 (dd, *J* = 5.4, 2.5 Hz, 1

H), 7.6−7.1 (m, 19 H), 6.48 (q, J = 7.4 Hz, 1 H), 6.28 (dd, J = 5.4, 4.4 Hz, 1 H), 4.01 (br. s, 1 H), 2.29 (s, 3 H), 2.18 (d, J = 7.4 Hz, 3 H) ppm.

X-ray Crystallographic Studies: Selected crystal and refinement data are given in Table 3. Crystals of compound **3** were obtained by slow diffusion of pentane into a solution of the complex in dichloromethane. Crystals of **4** were obtained by slow diffusion of pentane vapor into a solution of the complex in 1,2-dichloroethane. Diffraction data were obtained on Nonius CAD4 (**3**) and KappaCCD (**4**) diffractometers. Absorption corrections were applied using DIFABS[16] (for **3**) or XABS2[17] (for **4**). Maximum and minimum transmission factors 0.631 and 0.480 (for **3**) and 0.131 and 0.062 (for **4**). The structures were solved by Patterson interpretation using DIRDIF-96.[18] Isotropic and full-matrix anisotropic least-squares refinements were carried out using SHELXL-97.[19] All non H-atoms were refined anisotropically. All the hydrogen atoms of **3** were found and refined. For **4**, the NH hydrogen atom was located and its position was refined, while the remaining hydrogen atom positions were calculated and refined riding in their parent atoms. The molecular plots were made with the EUCLID program package.[20] The WINGX program system[21] was used throughout the structure determinations.

CCDC-185400 (**3**) and CCDC-185401 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Formation and Structure of the Novel Heptanuclear Lead(II) Oxo Cluster $[Pb_7(\mu_3\text{-}O)(\mu_4\text{-}O)(\mu_3\text{-}OMe)_4(\mu_2\text{-}I)_4]I_2$ with an Unprecedented Cage Structure

Yu-Jun Shi,[a] Yan Xu,[a] Xue-Tai Chen,*[a] Ziling Xue,[b] and Xiao-Zeng You*[a]

Keywords: Lead / Cluster compounds / Alkoxides / Oxo ligands / Crystal structure

A novel lead(II) cluster $[Pb_7(\mu_3\text{-}O)(\mu_4\text{-}O)(\mu_3\text{-}OMe)_4(\mu_2\text{-}I)_4]I_2$ (**1**) has been isolated from the reaction mixture of PbI_2 and pyrazine in DMF/MeOH solvent with a reasonable yield (46%). The X-ray crystallography shows that **1** exhibits a novel unprecedented cage structure with centered μ_3-O and μ_4-O atoms and four different coordination environments of lead atoms. It is the first structurally characterized example of a lead compound containing bridging oxo, methoxide and iodide ligands. Compound **1** crystallizes in the tetragonal space group $P42_1m$, $a = b = 11.7768(13)$, $c = 9.8606(16)$ Å, $Z = 2$, $V = 1367.6(3)$ Å^3.

Introduction

Lead(II) alkoxides and oxo alkoxides have been extensively studied for their uses as molecular precursors to lead-containing metal oxide materials via chemical routes such as MOCVD and sol-gel processes.[1] There has been much research interest focused on the synthesis and spectroscopic characterization of lead alkoxide and oxoalkoxide complexes. However, only a limited number of crystal structures have been reported for lead alkoxides and oxoalkoxides. These include oxygen-free, monomeric, trimeric, and one-dimensional $Pb(OR)_2$ (R = 2,6-di-*tert*-butyl-4-methylphenyl,[2] *t*Bu,[3] *i*Pr,[3] and CH_2CH_2OMe[3]), and two oxygen-centered, regular polyhedral clusters $[Pb_4(\mu_4\text{-}O)(OSiPh_3)_6]$[4] and $[Pb_6(\mu_3\text{-}O)_4(\mu_3\text{-}O\textit{i}Pr)_4]$.[5] Sita and coworkers[6] recently reported a novel lead(II) oxoalkoxide cluster $[Pb_7(\mu_3\text{-}O)(\mu_4\text{-}O)(\mu_2\text{-}OSiMe_3)_{10}]$ containing $Pb_4(\mu_4\text{-}O)$ and $Pb_3(\mu_3\text{-}O)$ units. Obviously the structures of lead alkoxides are highly dependent on the R groups and the method of preparation.

We have recently become interested in the construction of supramolecular structures using PbX_2 as the building blocks and have reported a novel 2-D coordination polymer $[PbI_2(4,4'\text{-bpy})]$ from the reaction of 4,4-bipyridine and PbI_2 in DMF/MeOH.[7] We intended to extend this chemistry from 4,4-bipyridine to pyrazine with the expectation of preparing a similar PbI_2 complex containing pyrazine ligands. We were surprised that the mixture of PbI_2 and pyrazine in MeOH/DMF gave a cluster complex $[Pb_7(\mu_3\text{-}O)(\mu_4\text{-}O)(\mu_3\text{-}OMe)_4(\mu_2\text{-}I)_4]I_2$ (**1**) reproducibly in 46% isolated yield, which contains bridging oxo, methoxide and iodide ligands. Lead(II) dimethoxide has been reported previously, although it was only poorly characterized due to its low solubility and air- and moisture-sensitivity.[8] To the best of our knowledge, there have been no lead oxomethoxide complexes reported in the literature. Herein we report the preparation of the unusual heptanuclear lead oxo cluster **1** and its unprecedented cage structure.

Results and Discussion

The syntheses of **1** and our previously reported cluster are summarized in Scheme 1, indicating how different products can be isolated by varying the ligand from 4,4-bipyridine to pyrazine. The formation of **1** can be rationalized as follows. As the basicity of pyrazine is greater than that of 4,4′-bipyridine, pyrazine could act as a stronger proton acceptor than 4,4-bipyridine in abstracting the proton of MeOH and H_2O and enhance coordination between lead(II) and the oxo and methoxide ligands. The low solubility of **1** might also favor its isolation from solution. A nitrogen-containing heterocyclic ligand plays a similar role in the preparation of transition metal clusters, for example $[Fe_{13}O_4F_{24}(OMe)_{12}]^{5-}$,[9] which was isolated from $FeF_3{\cdot}3H_2O$ and pyridine in MeOH.

Compound **1** is insoluble in common organic solvents, which prevents its characterization in solution. The crystal structure of **1** was determined by X-ray crystallography. A labeled ORTEP diagram of the cluster cation of **1** is shown in Figure 1 and bond lengths and bond angles are listed in Table 1. The structure of the cluster **1** exhibits C_{2v} symmetry with a C_2 axis through Pb(3), O(3) and O(1). There are four symmetrically different sets of lead atoms which vary in the type and number of coordinated ligands. The pyramidal Pb(2) and Pb(2A) are three-coordinate with one μ_4-O and two μ_3-OMe ligands, while Pb(1) and Pb(1A) are in an inverted square-pyramidal configuration surrounded by one μ_4-O, one μ_3-O, and two μ_3-OMe ligands. More interesting is the mixed coordination environment around Pb(4) and Pb(4A), and Pb(3). Pb(4) and Pb(4A) are coordinated by two μ_3-OMe and two iodide ligands, and the unique Pb(3) is in an inverted square pyramidal I_4O environment. The coordination spheres of all four Pb atoms in **1** are strongly distorted as a result of the presence of the stereochemically active $6s^2$ lone-pair electrons on the Pb^{II} cations. The Pb−O bond lengths fall into three different categories depending on the environments of the O atoms. The mean bond lengths of Pb-(μ_3-O), Pb-(μ_4-O), and Pb−OMe are 2.20(3), 2.28(2), 2.439(17) Å, respectively. The Pb−I bond lengths of 3.198(2)−3.302(3) Å are normal.[10−12] *The cage structure of **1** can also be viewed as being built-up from a Pb_4(μ_4-O) unit bonded to Pb(4), Pb(4A) and Pb(3) through four μ_3-OMe groups, a μ_3-O and four iodide atoms. The μ_4-O(1) atom tetrahedrally bridges Pb(2), Pb(2A), Pb(1), and Pb(1A). The planar μ_3-O is surrounded by Pb(1), Pb(1A) and Pb(3). A similar three-coordinate planar configuration has been observed in the lead(II) thiolate cluster $[Pb_5O(SR_F)_8]\cdot 2C_7H_8$ [R_F = 2,4,6-trsi(trifluromethylphenyl)].[13]

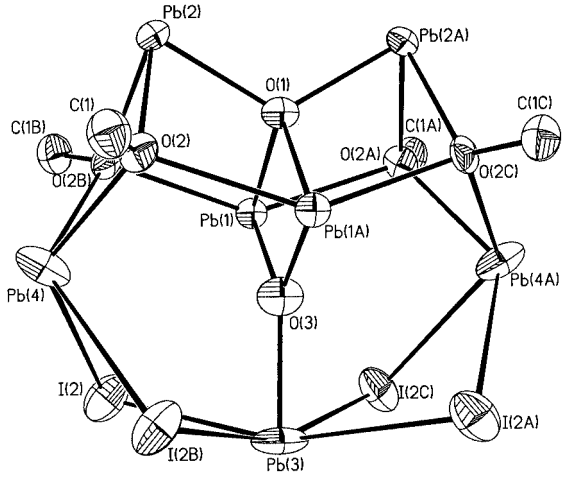

Figure 1. The ORTEP diagram of cluster cation of **1**

The Pb^{II} atoms of the cluster cation are involved in weak interactions with the anion I^- as shown in Figure 2, where each I^- anion links three cationic clusters to form an extensive three-dimensional supramolecular assembly through the six weak interactions [I(1)···Pb(1a)(1 − *y*, *x* − 1, 1 − *z*), 3.63(2); I(1)···Pb(2), 3.68(2); I(1)···Pb(2a) (*y*, 1 − *x*, 1 − *z*), 3.49(2); I(1)···Pb(2b) (1 − y, −1 + *x*, 1 − *z*), 3.49(2); I(1)···Pb(3a) (*y*, 1 − *x*, 1 − *z*), 4.01(2) and I(1)···Pb(4), 3.48(2) Å].

The isolation of **1** implies that a suitable choice of base and alkoxide ligand could lead to the formation of novel mixed-coordinate lead clusters.

Experimental Section

Materials and Methods: All chemicals are commercially available and were used without further purification, except PbI_2, which was prepared by the reaction of PbO with HI 35%. C, H and N analyses were carried on a Perkin−Elmer 240C elemental analyzer. IR spectra were recorded on a Bruker Optik Gmbh spectrophotometer (range: 400−4000 cm^{-1}) as KBr pellets.

Preparation of 1: Single crystals of **1** were grown at room temperature by using a layered solution approach. The bottom solution layer, contained within a long straight tube, consisted of PbI_2 (0.239 g, 0.5 mmol) dissolved in DMF. A mixed-solvent layer of methanol/DMF (1:1) was carefully placed on top of the PbI_2 solution using a syringe. Finally, pyrazine (a stoichiometric quantity relative to the PbI_2) dissolved in methanol was added to the top of the buffer. As the layers slowly mixed, well-formed crystals of **1** appeared that were suitable for X-ray single-crystal analysis. Yield 77.8 mg, 46% (based on PbI_2). $C_4H_{12}I_6O_6Pb_7$ (2368.0): calcd. C, 2.03, H 0.51; found C 2.22, H 0.63. IR (KBr): $\tilde{\nu}$ = 603.86 cm^{-1} (vs), 682.04 (m), 750.83 (w), 838.09 (w), 1401.10 (s), 1608.43 (m).

X-ray Crystallographic Analysis: X-ray data were collected at 293 K on a Bruker Apex CCD diffractometer equipped with graphite-monochromated Mo-K_α radiation (λ = 0.7103Å) by using the $\theta/2\theta$ scan mode. An empirical absorption correction was applied to the data, and structure solution and refinement on F^2 were done. The structures were solved by direct methods by using SHELXS 97[14] and refined by full-matrix least-squares calculation on F^2 with SHELXL 97.[15] All non-hydrogen atoms were refined anisotropically, whereas the hydrogen atoms were generated geometrically. Crystal data, data collection parameters, and refinement statistics for **1** are listed in Table 1. Relevant bond lengths and bond angles for **1** are collected in Table 2.

CCDC-184695 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structure, Properties and Cytostatic Activity of Triorganotin (Aminoaryl)carboxylates

Florian P. Pruchnik,*[a] Małgorzata Bańbuła,[a] Zbigniew Ciunik,[a] Henryk Chojnacki,[b] Małgorzata Latocha,[c] Barbara Skop,[c] Tadeusz Wilczok,[c] Adam Opolski,[d] Joanna Wietrzyk,[d] and Anna Nasulewicz[d]

Keywords: Tin / Cytostatic agents / Antitumor activity / O ligands

The properties of vinyltin and phenyltin complexes $[Sn(CH=CH_2)_3\{\mu\text{-}OOCC_6H_3(NH_2)_2\text{-}3,4\}]_n$ (**1**), $[Sn(C_6H_5)_3\{OOCC_6H_3(NH_2)_2\text{-}3,4\}]$ (**2**), $[Sn(C_6H_5)_3\{OOC\text{-}2\text{-}C_6H_4N{=}NC_6H_4N(CH_3)_2\text{-}4\}]$ (**3**) and $[Sn(CH=CH_2)_3\{OOC\text{-}2\text{-}C_6H_4N{=}NC_6H_4N(CH_3)_2\text{-}4\}]$ (**4**) have been investigated. The structures of complexes **1**, **2**, and **3**, have been determined by X-ray crystallography. Compound **1** is a distorted trigonal-bipyramidal complex and compounds **2** and **3** adopt a distorted tetrahedral structure. Complex **1** is a single-strand polymer with a bridging 3,4-diaminobenzoato ligand coordinating via the O(1) atom of the carboxylato group and the nitrogen atom of the *para*-amino group. The oxygen and nitrogen atoms occupy the axial coordination sites. The Sn(1)–N(2A) bond is weak. In complexes **2** and **3** the carboxylato ligands are strongly coordinated to the central atom via one oxygen atom, and the Sn(1)–O(2) distances are considerably longer. Weak interactions of the central atom with the amino group in complex **1**, and with the O(2) atoms in complexes **2** and **3**, as well as the hydrogen bonds, stabilize the crystal structure. The complexes are effective cytostatic agents.

Introduction

Coordination and organometallic compounds belong to the very important group of antitumor agents.[1,2] Many platinum complexes and other transition metal compounds, as well as organometallic compounds of the main group metals show high cytostatic activity. A number of organotin compounds have been shown to be active against various types of cancers. A series of organotin dipeptide compounds and a number of diorganotin halides containing amino ligands $[SnR_2X_2L_2]$ have displayed modest antitumor activity.[3,4] Many di-*n*-butyl-, tri-*n*-butyl-, and triphenyltin hydroxycarboxylates, oxycarboxylates, and fluorocarboxylates display interesting antitumor activities.[5−15] However, only few tin carboxylates with amino groups have been investigated. These complexes comprise pyridinocarboxylato and aminosalicylato organotin compounds.[5] Here, we report on the synthesis, properties, structure, and in vitro cytostatic activity of trivinyltin and triphenyltin complexes with 3,4-diaminobenzoate and 2-[4-(dimethylamino)phenylazo]benzoate.

Results and Discussion

The complexes $[Sn(CH=CH_2)_3\{\mu\text{-}OOCC_6H_3(NH_2)_2\text{-}3,4\}]_n$ (**1**), $[Sn(C_6H_5)_3\{OOCC_6H_3(NH_2)_2\text{-}3,4\}]$ (**2**), $[Sn(C_6H_5)_3\{OOC\text{-}2\text{-}C_6H_4N{=}NC_6H_4N(CH_3)_2\text{-}4\}]$ (**3**) and $[Sn(CH=CH_2)_3\{OOC\text{-}2\text{-}C_6H_4N{=}NC_6H_4N(CH_3)_2\text{-}4\}]$ (**4**) are soluble in ethanol, methanol, acetone, chloroform, dichloromethane, and in other polar organic solvents, and are slightly soluble in aqueous ethanol (50%). The vinyl complexes **1** and **4** have been obtained by the reactions of $SnO(CH=CH_2)_2$ and the appropriate acid in ethanol, while complexes **2** and **3** have been prepared by the reactions of $SnO(C_6H_5)_2$ or $\{Sn(C_6H_5)_3\}_2O$ with the acids. Thus, in the reactions of $SnO(CH=CH_2)_2$ and $SnO(C_6H_5)_2$ with the acids, the vinyl or phenyl groups are transferred. Other products obtained were SnO(R)(OOCR′), $Sn(OH)_2R(OOCR')$ and similar monoorganotin(IV) compounds, however, these compounds were not pure enough.

O(2)−C(1)	1.241(4)	O(2)−Sn(1)−C(31)	149.18(13)

The structures of complexes **1**, **2** and **3** are shown in Figures 1, 2, and 3, and selected bond lengths and angles are given in Tables 1, 2, and 3, the lengths and angles of the hydrogen bonds in the solid compounds in Tables 4, 5, and 6, and the crystallographic data in Table 8. Compound $[Sn(CH{=}CH_2)_3\{OOCC_6H_3(NH_2)_2\text{-}3,4\}]$ (**1**) is a distorted trigonal-bipyramidal complex, it consists of three vinyl ligands and a bridging 3,4-diaminobenzoato ligand, which is coordinated via one oxygen atom and the nitrogen atom of the *para*-amino group. The monodentate coordination of the carboxylate group is reflected in the short Sn(1)−O(1) bond [2.1353(19) Å] and the different C(7)−(O1) and C(7)−O(2) distances of 1.310(3) and 1.240(4) Å, respectively. The Sn−O(2) bond [2.955(3) Å] is much longer than the Sn−O(1) bond [2.1353(19) Å], thus the interaction of the O(2) atom with the central atom is very weak. The fifth

Table 6. Lengths [Å] and angles [°] of weak C−H···π hydrogen bonds in solid complex **3**

C−H···Ph[a]	H···Ph	Offset	C−H···Ph
C(13)−H(13)···Ph5	3.07	0.91	134
C(3)−H(3)···Ph4^{i}	2.54	0	155
C(213)−H(213)···Ph3^{ii}	3.07	1.04	144
C(315)−H(315)···Ph1^{iii}	2.63	0.32	168

[a] Ph1 is defined by C(2), C(3), C(4), C(5), C(6), and C(7) atoms; Ph3 by C(111), C(112), ..., C(116) atoms; Ph4 by C(211), C(212), ..., C(216) atoms; Ph5 by C(311), C(312), ..., C(316) atoms. Symmetry code superscript: (none) x, y, z; (i) $x + 1, y, z$; (ii) $x - 1, y, z$; (iii) $x, y - 1, z$.

coordination site is occupied by the N(2A) atom of a neighboring molecule (Figure 1). Thus, complex **1** is a single-strand polymer in the solid state. The Sn(1)−N(2A) distance is 2.685(3) Å and the O(1)−Sn(1)−N(2A) angle is 178.76(7)°. The angles C(1)−Sn(1)−C(3) [113.18(12)°] and C(1)−Sn(1)−C(5) [112.63(12)°] are considerably smaller, and the C(3)−Sn(1)−C(5) angle [130.87(12)°] is substantially larger than those expected for a regular trigonal bipyramid. A relatively strong Sn(1)−N(2A) bonding interaction is important for the stabilization of the crystal structure of complex **1**. The crystal structure is also stabilized by the relatively strong hydrogen bond N(2)−H(4N)···O(2)(i) and the weaker hydrogen bonds N(2)−H(3N)···C(2)(ii), N(1)−H(1N)···X1A(C1/C2)(iii), and N(1)−H(2N)···X1B-(C3/C4)(iv) (Table 4). In complex **2**, the central atom has a distorted tetrahedral geometry, with the Sn(1)−O(1) bond length of 2.069(2) Å, the Sn(1)−C bond lengths of 2.121(3)−2.146(3) Å, and the considerably longer Sn(1)−O(2) distance of 2.680(3) Å. The C(11)−Sn(1)−C(31) and C(21)−Sn(1)−C(31) angles are 108.51(13) and 109.21(13)°, respectively, and the C(11)−Sn(1)−C(21) angle is 119.14(13)°. The interaction of the oxygen atom O(2) with the central atom Sn(1) is relatively strong in comparison with analogous interactions in complex **1**. The O(2)−Sn(1)−C(31) angle is 149.18(13)°, while the O(2)−Sn(1)−C(11) and O(2)−Sn(1)−C(21) angles are 84.67(13) and 86.38(13)°, respectively. The structure of complex **2** is similar to that of $[Sn(C_6H_5)_3(OOCC_6H_5)]$, in which the O(2)−Sn distance is 2.674(3) Å.[7,16] The crystal structure of the complex **2** is stabilized not only by the Sn(1)−O(2) interaction, but also by intermolecular hydrogen bonds, namely, N(1)−H(2N)···N(2)(ii) and N(2)−H(3N)···O(2)(iii) (Table 5). Complex **3** has a molecular structure similar to that of compound **2**, with the Sn(1)−O(1) bond length of 2.054(2) Å, Sn(1)−C bond lengths of 2.117(4)−2.126(4) Å and Sn(1)−O(2) bond length of 2.827(3) Å. Thus, in this compound the interaction between the Sn(1) and O(2) atoms is weaker than in complex **2**. However, the crystal structure of compound **3** is also stabilized by weak C−H···Ph intermolecular and intramolecular hydrogen bonds (Table 6), as well as by intermolecular stacking interactions between parallel C(2)−C(7) and C(8)(i)−C(13)(i) phenyl rings of the two neighboring molecules. The distance between these rings is 2.49 Å and the offset is 1.42 Å. There are three intermolecular and one intramolecular C(13)−H(13)···Ph5 (C311,C312, ..., C316 ring) hydrogen bonds (Table 6). Two bonds with short distances between the hydrogen donor atom and the phenyl centroid (Ph1 and Ph4) have a short offset, which is defined as the distance from the ring centroid to the projection of the H-atom position on the plane of the ring.[17] These bonds are also more linear than long hydrogen bonds. Intermolecular hydrogen bonds link all the molecules located along the [100] and [010] directions in the crystal. Short lattice vectors ***a*** and ***b***, relative to ***c***, suggest that analyzed weak hydrogen bonds control the growth of the crystals. The same was observed earlier in the case of other compounds.[18]

Infrared spectra of all investigated complexes are consistent with X-ray data for compounds **1**, **2**, and **3**. The presence of $\nu_{as}(COO)$ and $\nu_s(COO)$ in the ranges 1600−1614 cm^{-1}, and 1334−1368 cm^{-1}, respectively, and therefore the large $\Delta\nu = \nu^{as}_{COO} - \nu^{s}_{COO}$ values are consistent with the presence of the asymmetrically coordinated carboxylato group in complexes **1**, **2**, **3**, and **4**. The ν(SnC) bands for the vinyl compounds (**1** and **4**) are observed in the range 496−542 cm^{-1}, and are similar to the values in other vinyl−Sn^{IV} compounds.[19] The substituent-sensitive r-modes for the phenyl groups were observed at 620 cm^{-1} and 588 cm^{-1} for complex **2**, and 636 cm^{-1}, 610 cm^{-1}, and 590 cm^{-1} for compound **3**, and the y-modes at 452 cm^{-1} and 442 cm^{-1} for **2**, and 457 cm^{-1} and 444 cm^{-1} for **3**. These values agree well with the data for $Sn(C_6H_5)_4$.[19]

The ^1H chemical shift ranges for the trivinyl, triphenyl moieties and the carboxylato ligands were deduced from resonance intensities and $^nJ(^1H\text{-}^1H)$ coupling constants. Both chemical shifts and coupling constants for complexes **1**−**4** agree well with the data found for $[Sn(C_6H_5)_3(OOCC_6H_5)]$,[7] $[Sn(C_6H_5)_3(OOCC_6H_4NH_2)]$, and other triphenyltin(IV) compounds,[20,21] $[Sn(CH{=}CH_2)_2X_2]$ and $[Sn(CH{=}CH_2)_3X]$,[22−24] and with the spectra of 3,4-diaminobenzoic and 2-[(4-dimethylamino)phenylazo]benzoic acid and their metal salts. The first-order spectra of the vinyl ligands of the $[Sn(CH{=}CH_2)_3(OOCR)]$ complexes **1** and **4** consist of three quadruplets with $^{119/117}Sn$ satellites. The chemical shifts of H^7, H^8, and H^9 and the $^3J(H^7H^9)$, $^3J(H^7H^8)$, and $^2J(H^8H^9)$ coupling constants in chloroform solution are slightly higher than those found for $[Sn(CH{=}CH_2)_3X]$ (X = Cl, Br, I). It has been found that the ^1H chemical shifts and the $^nJ(^1H\text{-}^1H)$ coupling constants of the vinyltin halides depend on the electronegativity of the halide.[22] Thus, deshielding of H^1, H^2, and H^3 and a slight increase in the $^nJ(^1H\text{-}^1H)$ coupling constants are caused by the higher electronegativity of the RCOO ligand in comparison with that of the ligands Cl, Br, and I. The chemical shift differences $[\delta(H^7) - \delta(H^8)]$ for complexes **1** and **4** are also greater because of the higher electronegativity of the carboxylato ligand. These differences increase in more polar solvents. They are equal to δ = 0.24 ppm in $CDCl_3$ and 0.36 ppm in $(CD_3)_2CO$ and $(CD_3)_2SO$. The ^{119}Sn chemical shifts are higher for four-coordinate compounds than for the five-coordinate complexes. The values of $\delta(^{119}Sn)$ in the latter are shifted upfield over a wide range.[20−22,24] The ^{119}Sn chemical shifts for compounds **1** and **4** in acetone are δ = −167.9 and −168.9 ppm, respectively. They are lower than the chemical shift for $Sn(CH{=}CH_2)_4$ (δ = −157.4 ppm),[24] and greater than for $[Sn(CH{=}CH_2)_2(OOCPh)_2]$ in $CDCl_3$ (δ = −317.7 ppm).[23] The value of the $^1J(^{119/117}Sn\text{-}^{13}C^7)$ coupling constant for complex **4** in chloroform is 600.2/574.9 Hz and is similar to that found for complex $[Sn(CH{=}CH_2)_3Cl]$ in $CDCl_3$ (594.7/568.2 Hz). Thus, the ^1H, ^{13}C, and ^{119}Sn NMR spectra indicate that complexes **1** and **4** in chloroform solution are tetrahedral molecules, and that the coordination of acetone, methanol or dimethyl sulfoxide with tin compounds is rather weak. The formation of weak adducts of complexes **2** and **3** with

polar solvents is also confirmed by the ^{13}C and ^{119}Sn NMR spectra. The $^{1}J(^{119}Sn\text{-}^{13}C)$ coupling constants for tetrahedral $SnPh_3X$ (X = Cl, RCOO, etc.) complexes in chloroform solution are in the range 550−650 Hz, while for five-coordinate complexes, they are often in the range 770−850 Hz. The $^{2}J(^{119}Sn\text{-}^{13}C)$ coupling constants do not depend on the coordination number of tin and have values of 47.6−50.0 Hz, and the $^{3}J(^{119}Sn\text{-}^{13}C)$ and $^{4}J(^{119}Sn\text{-}^{13}C)$ coupling constants are slightly greater for five-coordinate compounds than for four-coordinate complexes and are in the range 63−73 Hz and 12.7−14.6 Hz, respectively.[20−22,24] Small differences between five-coordinate and four-coordinate triphenyltin(IV) compounds were found in the values of the chemical shifts $\delta(^{13}C^{i})$ of the carbon atoms in the *ipso*-positions of the phenyl groups. The values of the $\delta(^{13}C^{i})$ for the five-coordinate complexes are shifted downfield from those of four-coordinate tin compounds by several ppm.[20] The ^{13}C chemical shifts and $^{n}J(^{119}Sn\text{-}^{13}C)$ coupling constants for complexes **2** and **3** in chloroform are in the range characteristic of tetrahedral triphenyltin compounds since $\delta(^{13}C^{i})$ = 138.88 ppm and $^{1}J(^{119/117}Sn\text{-}^{13}C^{i})$ = 651.0/621.8 Hz for the *ipso*-carbon atoms of complex **2**, and $\delta(^{13}C^{i})$ = 138.48 ppm and $^{1}J(^{119/117}Sn\text{-}^{13}C^{i})$ = 644.6/618.5 Hz for those of compound **3**. The chemical shift $\delta(^{13}C^{i})$ is slightly higher in more polar solvents, thus for complex **2** in $(CD_3)_2CO$ a value of δ = 140.69 ppm is observed and for compound **3** in CD_3OD, a value of δ = 140.12 ppm is observed. The values of $\delta(^{119}Sn)$ in $CDCl_3$ for **2** and **3** are δ = −118.9 and −108.6 ppm, and are similar to those found for complexes $[SnPh_3(OOCC_6H_4NH_2\text{-}4)]$ and $[SnPh_3(OOCC_6H_4NH_2\text{-}2)]$ (δ = −122.6 and −116.8 ppm).[20] The $\delta(^{119}Sn)$ values for complex **2** in acetone (δ = −123.1 ppm) is ca. 4 ppm greater than that in chloroform. These data also confirm the formation of weak adducts of compounds **2** and **3** with polar solvents.

The molecular and electronic structures of a single molecule of $[Sn(CH{=}CH_2)_3(OOCC_6H_3(NH_2)_2\text{-}3,4)]$ with C_1 symmetry has been studied by both semiempirical and nonempirical ab initio methods. The quantum chemical calculations were performed using the PM3 of the MOPAC2000 package,[25] and the GAUSSIAN-98 computer program.[26]

The geometry optimization in the first case was performed at the PM3 level and in the second case within the 3-21G basis set and MP2 formalism. The evaluated Sn−O1 bond length with PM3 is found to be 2.019 Å and the Sn···O2 distance 2.685 Å. The respective ab initio results are 2.071 Å and 2.609 Å, whereas the relevant crystallographic values are 2.1353(19) Å and 2.955(2) Å, respectively. This discrepancy results from the formation of the weak Sn(1)−N(2A) bond and the distorted trigonal-bipyramidal coordination of the tin atom in the solid state. In complex **2**, in which the Sn−N bond in the solid state is not formed, the Sn(1)−O(1) bond [2.069(2) Å] and the Sn(1)−O(2) bond [2.680(3) Å] are very similar to those calculated with semiempirical and ab initio methods. Thus, these methods can most likely be applied for the calculations of the interactions of Sn^{IV} compounds with nucleotides and other molecules important for the explanation of the biological activity of tin compounds. The theoretical dipole moment is 1.543 D, the ionization energy is 8.572 eV, and the heat of formations is estimated to be 9.98 kJ/mol.

Complexes **1**, **2**, **3**, and **4** belong to the efficient cytostatic agents (Table 7). Compound **2** is very active against HCV29T cells (ID_{50} = 0.0072 μmol/dm^3). The activity of the compounds against the HCV29T cell line decreases in the order **2** > **1** > **3** > **4**. It is worth noting that the complexes are also very active in ethanol solution. Cytostatic activity of complexes **1** and **2** against the A549 and CACO-2 lines is relatively high, although lower than that against HCV29T cells. Thus, these compounds are promising cytostatic agents against some tumor lines in vitro.

Conclusion

Investigations of the structures of the complexes $[Sn(CH{=}CH_2)_3\{\mu\text{-}OOCC_6H_3(NH_2)_2\text{-}3,4\}]_n$ (**1**), $[Sn(C_6H_5)_3\{OOCC_6H_3(NH_2)_2\text{-}3,4\}]$ (**2**), and $[Sn(C_6H_5)_3\{OOC\text{-}2\text{-}C_6H_4N{=}NC_6H_4N(CH_3)_2\text{-}4\}]$ (**3**) reveal that the coordination of the central atom in complex **1** is distorted trigonal-bipyramidal, and in complexes **2** and **3** distorted tetrahedral. Complex **1** is a regular single-strand polymer. The vinyl

ligands are coordinated in the equatorial positions and the bridging 3,4-diaminobenzoato ligands occupy the axial coordination sites, and form a strong Sn−O bond and a weak Sn−N bond with the *para*-amino group, the Sn(1)−O(1) and Sn(1)−N(2A) distances are 2.1353(19) and 2.685(3) Å, respectively. In complexes **2** and **3**, the carboxylato ligand is strongly coordinated to the central atom via one oxygen atom and the Sn(1)−O(2) distances are considerably longer. However, these weak interactions, as well as the N−H···O, N−H···C, N−H···N hydrogen bonds, and in the case of complex **3** the C−H···Ph hydrogen bonds, stabilize the crystal structure of these complexes. The crystal structure of complex **3** is additionally stabilized by the intermolecular stacking interaction between parallel C(2)−C(7) and C(8)(i)−C(13)(i) phenyl rings of the 2-[4-(dimethylamino)-phenylazo]benzoato ligand of two neighboring molecules. The IR and NMR spectra reveal that the structure of complex **4** is analogous to that of the complexes **2** and **3**. The molecular and electronic structure of a single molecule of complex **1** [$Sn(CH=CH_2)_3(OOCC_6H_3(NH_2)_2$-3,4)], calculated both with semiempirical and ab initio methods, reveal that coordination about the tin atom is similar to that in complex **2**. Thus, the relatively long Sn(1)−O(1) bond in complex **1**, relative to that in compounds **2** and **3**, results from the weak interaction between the Sn atom and the N atom of the *para*-amino group of the 3,4-diaminobenzoato ligand. The complexes are effective cytostatic agents against HCV29T, A549 and CACO-2 tumor lines.

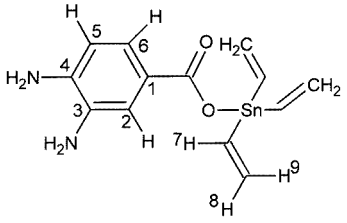
Experimental Section

Materials and Methods

Compounds: 3,4-diaminobezoic acid was obtained from Aldrich, 2-[4-(dimethylamino)phenylazo]benzoic acid from POCH (Poland), diphenyltin dichloride and divinyltin dichloride from Strem and used without further purification. Diphenyltin oxide, triphenyltin oxide, and divinyltin oxide were prepared from diphenyltin dichloride, triphenyltin chloride, and divinyltin dichloride with sodium hydroxide in aqueous ethanol solution. Syntheses were carried out under nitrogen. Infrared spectra (KBr pellets) were recorded with a Bruker IFS 113v, and ^{1}H NMR spectra were recorded with a Bruker AMX 300 and a Bruker Avance 500. C,H,N analyses were performed with a Perkin−Elmer 2400 CHN analyzer, and Sn was determined using ICP-AES with an ARL 3410.

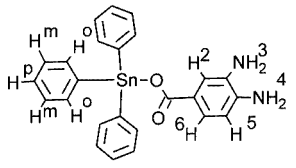
Synthesis of Complexes

$[Sn(CH=CH_2)_3\{OOCC_6H_3(NH_2)_2$-3,4$\}]$ (1): A suspension of $Sn(CH=CH_2)_2O$ (0.75 g, 3.95 mmol) and $HOOCC_6H_3(NH_2)_2$ (0.60 g, 3.95 mmol) in ethanol (10 mL) was refluxed with stirring for 5 h. The dark-brown solid was filtered and the filtrate was concentrated to dryness. The dry residue was extracted with chloroform. The light beige solid was filtered. The filtrate was concentrated and the obtained solid was crystallized from hot toluene. The light brown product $[Sn(CH=CH_2)_3\{OOCC_6H_3(NH_2)_2$-3,4$\}]$ (**1**) was filtered and washed with cold toluene. Yield 0.32 g (46%). $C_{13}H_{16}N_2O_2Sn$ (350.95): C 44.49, H 4.59, N 7.98, Sn 33.82; found: C 44.06, H 4.50, N 7.65, Sn 33.43. Single crystals were grown by concentration of a toluene solution of the compound. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3412 s (ν_{NH2}), 3348 s (ν_{NH2}), 3048 w (ν_{CH}), 2984 w (ν_{CH}), 2940 w (ν_{CH}), 1614 vs (ν_{COO}), 1599 s ($\nu_{C=C}$), 1590 s, 1584 s, 1570 s, 1556 vs (ν_{COO}), 1520 s, 1442 m, 1396 s, 1362 vs (ν_{COO}), 1332 vs(ν_{COO}),1304 vs, 1248 vs, 1152 m, 1096 w, 1004 s, 956 s, 904 w, 820 m, 784 s, 648 m, 588 m, 542 m (ν_{SnC}), 498 m (ν_{SnC}), 451 m, 389 m. ^{1}H NMR ($CDCl_3$, ppm): δ = 7.50 [dd, $^3J(H^5H^6)$ = 8.1, $^4J(H^2H^6)$ = 1.8 Hz, H^6], 7.43 (d, H^2), 6.65 [d, H^5], 6.59 [dd, $^3J(H^7H^8)$ = 13.5, $^3J(H^7H^9)$ = 20.4, $^2J(^{119/117}SnH^7)$ = 125.9/120.4 Hz, H^7], 6.32 [dd, $^2J(H^8H^9)$ = 2.6, $^3J(^{119/117}SnH^8)$ = 236.2/226.0 Hz, H^8], 5.96 [dd, $^3J(^{119/117}SnH^9)$ = 115.9/110.9 Hz, H^9], 3.47, 3.69 (2s, H^3, H^4). ^{1}H NMR [$(CD_3)_2CO$, ppm]: δ = 7.60 [dd, $^3J(H^5H^6)$ = 8.3, $^4J(H^2H^6)$ = 1.9 Hz, H^6], 7.20 (d, H^2), 6.74 (d, H^5), 6.62 [dd, $^3J(H^7H^8)$ = 13.6, $^3J(H^7H^9)$ = 20.4, $^2J(^{119/117}SnH^7)$ = 129.0/122.9 Hz, H^7], 6.26 [dd, $^2J(H^8H^9)$ = 2.9, $^3J(^{119/117}SnH^8)$ = 239.5/228.2 Hz, H^8], 6.01 [dd, $^3J(^{119/117}SnH^9)$ = 114.9/109.9 Hz, H^9], 3.47, 3.69 (H^3, H^4). ^{119}Sn NMR [$(CD_3)_2CO$, ppm]: δ = −167.9.

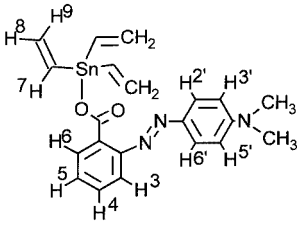


$[Sn(C_6H_5)_3\{OOCC_6H_3(NH_2)_2$-3,4$\}]\cdot 0.5C_6H_5CH_3$ (2). Method a: A mixture of $Sn(C_6H_5)_2O$ (0.58 g, 2.01 mmol) and $HOOCC_6H_3(NH_2)_2$ (0.31 g, 2.03 mmol) in toluene/ethanol (3:1) (10 mL) was refluxed with stirring for 4 h. The light brown solid was filtered. The yellow filtrate was slowly concentrated giving yellow crystals of complex **2**. The solid was washed with cold ethanol and dried in vacuo. Yield 0.32 g (56%). $C_{28,5}H_{26}N_2O_2Sn$ (547.24): C 62.55, H 4.79, N 5.12, Sn 21.69; found C 62.50, H 4.85, N 5.40, Sn 22.02. Single crystals for X-ray investigations were prepared by slow concentration of a toluene/ethanol solution of the complex. **Method b:** A mixture of $\{Sn(C_6H_5)_3\}_2O$ (0.716 g, 1.0 mmol) and $HOOCC_6H_3(NH_2)_2$ (0.31 g, 2.03 mmol) in ethanol (15 mL) was refluxed with stirring for 0.3 h. The red-brown solution was filtered. The filtrate was concentrated, giving a yellow polycrystalline precipitate of complex **2**. The solid was recrystallized from toluene and washed with cold ethanol and dried in vacuo. Yield 0.652 g (65%). IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3408 s (ν_{NH2}), 3320 s (ν_{NH2}), 3295 w (ν_{NH2}), 3250 w (ν_{NH2}), 3200 w (ν_{NH2}), 3075 w (ν_{CH}), 3070 w (ν_{CH}), 3064 w (ν_{CH}), 1632 s (δ_{NH2}), 1600 vs (ν_{COO}), 1572 vs, (ν_{COO}), 1518 s, 1480 s, 1446 w 1430 vs, 1368 vs (ν_{COO}), 1334 vs (ν_{COO}),1300 vs, 1246 vs, 1192 w, 1152 s, 1112 w, 1076 s, 1060 w, 1024 w, 956 vw, 898 w, 836 m, 778 s, 732 vs, 700 vs, 658 s, 620 w (r-mode SnC), 588 w (r-mode SnC), 512 m, 468 w, 452 m (y-mode SnC), 442 s (y-mode SnC), 402 m. $C_{28,5}H_{26}N_2O_2Sn$ (547.24): C 62.55, H 4.79, N 5.12, Sn 21.69; found C 62.40, H 4.65, N 5.30, Sn 21.92. ^{1}H NMR ($CDCl_3$, ppm): δ = 7.78−7.84 [m, $^3J(^1H$-$^{119/117}Sn)$ = 63.6 Hz, H^o], 7.60 [dd, $^3J(H^5H^6)$ = 8.1, $^4J(H^2H^6)$ = 1.8 Hz, H^6], 7.50 (d, H^2), 7.43−7.49 (m, $H^{m,p}$), 7.29 [H^m(toluene)], 7.19 [$H^{o,p}$(toluene)], 6.63 (d, H^5), 3.38, 3.69 (2s, $H^{3,4}$), 2.37 [s, CH_3(toluene)]. ^{13}C NMR ($CDCl_3$, ppm): δ = 173.34 (COO), 140.39 (C^4) 138.88 , [$^1J(^{13}C$-$^{119/117}Sn)$ = 651.0/621.8 Hz, C^i], 136.88 [$^2J(^{13}C$-$^{119/117}Sn)$ = 48.0 Hz, C^o], 133.20 (C^3), 129.93 [$^4J(^{13}C$-$^{119/117}Sn)$ = 13.0 Hz, C^p], 128.78 [$^3J(^{13}C$-$^{119/117}Sn)$ = 62.7 Hz, C^m], 124.49 (C^6), 120.91 (C^1), 119.46 (C^2), 114.73 (C^5); toluene: 137.82 (C^i), 128.99 (C^o), 128.19 (C^m), 125.26 (C^p), 21.41 (CH_3). ^{13}C NMR [$(CD_3)_2CO$, ppm]: δ = 172.14 (COO), 141.79 (C^4), 140.69 (C^i), 137.65 [$^2J(^{13}C$-$^{119/117}Sn)$ = 47.5 Hz, C^o], 134.61 (C^3), 130.61 [$^4J(^{13}C$-$^{119/117}Sn)$ = 13.2 Hz, C^p], 129.50 [$^3J(^{13}C$-$^{119/117}Sn)$ = 64.4 Hz,C^m], 123.57 (C^6), 119.71 (C^1),

118.43 (C^2), 114.24 (C^5); toluene: 129.73 (C^o), 129.01 (C^m) 126.09 (C^p), 21.43 (CH_3). ^{119}Sn NMR ($CDCl_3$, ppm): δ = −118.9, [$(CD_3)_2CO$, ppm]: δ = −123.1.



[$Sn(C_6H_5)_3${OOC-2-C_6H_4N=$NC_6H_4N(CH_3)_2$-4}] (3). Method a: A mixture of $Sn(C_6H_5)_2O$ (0.58 g, 2.01 mmol) and 2-[4-(dimethylamino)phenylazo]benzoic acid [$HOOCC_6H_4N$=$NC_6H_4N(CH_3)_2$-4] (0.58 g, 2.01 mmol) in ethanol (15 mL) was refluxed with stirring for 4 h. The red solid was filtered. The red filtrate was slowly concentrated, giving red crystals of complex **3**. The solid was washed with cold hexane and dried in vacuo. Yield 0.32 g (50%). $C_{33}H_{29}N_3O_2Sn$ [$Sn(C_6H_5)_3${OOC-2-C_6H_4N=$NC_6H_4N(CH_3)_2$-4}] (618.33): C 64.10, H 4.73, N 6.80, Sn 19.20; found C 64.80, H 4.95, N 7.15, Sn 18.85. **Method b:** A mixture of $\{Sn(C_6H_5)_3\}_2O$ (0.716 g, 1.0 mmol) and) and 2-[(4-dimethylamino)phenylazo]benzoic acid [$HOOCC_6H_4N$=$NC_6H_4N(CH_3)_2$-4] (0.54 g, 2.01 mmol) in ethanol (15 mL) was refluxed with stirring for 0.3 h. The red solution was filtered. The red filtrate was slowly concentrated, giving a red product. The solid was washed with cold hexane and dried in vacuo. Yield 0.841 g (68%). $C_{33}H_{29}N_3O_2Sn$ [$Sn(C_6H_5)_3${OOC−2-C_6H_4N=$NC_6H_4N(CH_3)_2$-4}] (618.33): C 64.10, H 4.73, N 6.80, Sn 19.20; found C 64.40, H 4.85, N 7.04, Sn 18.94. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3068 w (ν_{CH}), 3048 w, 3020 vw, 1640 m, 1600 vs (ν^{as}_{COOH}), 1560 w, 1520 s, 1480 m, 1442 w, 1432 m, 1416 w, 1406 m, 1366 vs (ν^{s}_{COOH}), 1340 s (ν^{s}_{COOH}), 1312 m, 1276 w, 1250 w, 1232 w, 1190 vw, 1144 vs, 1088 w, 1076 w, 1020 vw, 996 wm, 944 m, 860,w, 820 ms, 784 w, 760 m, 746 w, 736 s, 726 s, 696 s, 676 w 636 w (r-mode SnC), 610 vw (r-mode SnC), 590 vw (r-mode SnC), 570 vw, 546 m, 510 wvw, 494 vw, 464 w, 457 m (y-mode SnC), 444 m (y-mode SnC), 390 w. ^1H NMR (CD_3OD, ppm): δ = 7.78−7.86 [m, $^3J(^1H$-$^{119/117}Sn)$ = 63 Hz, H^o], 7.62 [d, $^3J(H^{2'}H^{3'})$ = 9.1 Hz, $H^{2'}$ + $H^{6'}$], 7.48−7.59 (m, H^3 + H^6), 7.30−7.46 (m, H^4 + H^5 + H^m + H^p), 6.71 [d, $^3J(H^{5'}H^{6'})$ = 9.1 Hz, $H^{3'}$ + $H^{5'}$], 3.08 (s, CH_3). ^{13}C NMR ($CDCl_3$, ppm): δ = 174.47 (COO), 152.88 (C^2), 152.43 ($C^{4'}$), 143.89 ($C^{1'}$), 138.48 [$^1J(^{13}C$-$^{119/117}Sn)$ = 644.6/618.5 Hz, C^i], 136.99 [$^2J(^{13}C$-$^{119/117}Sn)$ = 48.0 Hz, C^o], 131.50 (C^1, C^4), 130.31 (C^6), 129.91 [$^4J(^{13}C$-$^{119/117}Sn)$ = 13.0 Hz, C^p], 128.76 [$^3J(^{13}C$-$^{119/117}Sn)$ = 63.5 Hz, C^m], 128.06 (C^5), 125.48 ($C^{2'}$, $C^{6'}$), 118.36 (C^3), 111.36 ($C^{3'}$, $C^{5'}$), 40.25 (NCH_3). ^{13}C NMR (CD_3OD, ppm): δ = 173.25 (COO), 154.45 (C^2), 152.54 ($C^{4'}$), 144.76 ($C^{1'}$), 140.12 (C^i), 137.76 [$^2J(^{13}C$-$^{119/117}Sn)$ = 48.1 Hz, C^o], 132.57 (C^1), 131.62 (C^4), 130.36 (C^p), 130.05 (C^6), 129.58 (C^m), 129.11 (C^5), 126.62 ($C^{2'}$, $C^{6'}$), 118.23 (C^3), 112.63 ($C^{3'}$, $C^{5'}$), 40.45 (NCH_3). ^{119}Sn NMR ($CDCl_3$, ppm): δ = −108.6.



[$Sn(CH$=$CH_2)_3${OOC-2-C_6H_4N=$NC_6H_4N(CH_3)_2$-4}] (4): A mixture of $Sn(CH$=$CH_2)_2O$ (0,38 g, 2.0 mmol) and 2-[4-(dimethylamino)phenylazo]benzoic acid $HOOCC_6H_4N$=$NC_6H_4N(CH_3)_2$-4 (0.54 g, 2.0 mmol) in ethanol (15 mL) was refluxed with stirring for 4 h. The red solid was filtered. The red filtrate was concentrated, giving a red solid that was crystallized from a hot dioxane/toluene mixture (1:4, v/v). Red needles of complex **4** were separated and washed with diethyl ether and dried in vacuo. Yield 0.22 g (47%). $C_{21}H_{23}N_3O_2Sn$ [$Sn(CH$=$CH_2)_3${OOC-2-C_6H_4N=$NC_6H_4N(CH_3)_2$-4}] (468.15): C 53.88, H 4.95, N 8.98, Sn 25.36; found C 53.40, H 4.65, N 9.05, Sn 24.69. X-ray Crystallographic Study: All measurements were performed at low temperature using an Oxford Cryosystem device with a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo-K_α radiation (Table 8). The crystal was positioned at 65 mm from the CCD camera. 612 frames were measured at 0.75Θ intervals with a counting time of 20 s. Accurate cell parameters were determined and refined by least-squares fit of the strongest reflections. The data were corrected for Lorentz and polarization effects. No absorption correction was applied. Data reduction and analysis were carried out with the Oxford Diffraction, Poland (formerly Kuma Diffraction Wrocław, Poland), programs. The structure was solved by direct methods (program SHELXS-97[27]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97[28] programs. Non-hydrogen atoms were refined with anisotropic vibrational parameters; hydrogen atoms were included from the geometry of the molecules and Δρ maps and were refined with isotropic vibrational parameters. CCDC-176692, -176693, and -176694 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge

Cytostatic Activity in vitro: Human cell lines HCV29T, A549 (lung adenocarcinoma) and CACO-2 were used for the proliferation assay. The experiments were repeated in triplicate for each tested Sn compound concentration. Statistical significance was tested using Student's t-test ($p < 0.05$ was considered statistically significant). The in vitro tests against all cell lines were performed as described previously.[29−31] The results of cytotoxic activity in vitro were expressed as ID_{50} − the dose of compound that inhibits proliferation rate of the tumor cells by 50% as compared with untreated control cells.

Experimental and Computational Study on a Variety of Structural Motifs and Coordination Modes in Aluminium Complexes of Di(2-pyridyl)amides and -phosphanides

Matthias Pfeiffer,[a] Alexander Murso,[a] Lepakshaiah Mahalakshmi,[a] Damien Moigno,[b] Wolfgang Kiefer,[b] and Dietmar Stalke*[a]

Keywords: Aluminium / Computational chemistry / Conformation analysis / N ligands / P ligands

The $(2\text{-Py})_2N^-$ ligand shows much more conformational freedom than the $(2\text{-Py})_2P^-$ anion in aluminium coordination. The two isomers $[Al\{(NPy)Py\}_3]$ (**1a**) and $[Al\{(NPy)Py\}_2(Py_2N)]$ (**1b**) were isolated, the former containing exclusively *cis-trans* ligands, and the latter *cis-trans* ligands together with a *trans-trans* ligand. The energy differences in the noncoordinated anions $(2\text{-Py})_2E^-$ (E = N, P) were determined by computational methods to be low in the amide. While the N→Al donor bond energy is appreciable (96 kJ/mol), that of the P→Al donor bond is much lower (45 kJ/mol). This explains why the P-analogous donor-acceptor complex to $Et_2Al(2\text{-Py})_2N{\rightarrow}AlEt_3$ could never be isolated. The P-centred systems are much better π-donors to soft metals than σ-donors to hard metals.

Introduction

Since the historic discovery of Ziegler−Natta catalysts for polymerisation reactions, the industrial importance of organoaluminium compounds has expanded into several other fields, including applications as ceramic precursors, as volatile organometallic precursors for semiconducting materials in electronic industry, and as selective reagents in organic synthesis.[1] Furthermore, current knowledge of the important role of cationic group-13 complexes in catalytic chemistry has resulted in a resurgence of interest in the field of catalytic chemistry.[2] On the other hand, interest in aluminium amide chemistry is due to the potential for the preparation of aluminium nitride thin films.[3] The aluminium nitride can adopt a great variety of structural motifs, oligomerisation through the bridging amido nitrogen atom normally being observed.[4] Suitable tuning of steric factors, however, can prevent such oligomerisation, resulting in monomeric aluminium complexes, as reported by several research groups[5] ($[Al\{N(SiMe_3)_2\}_3]$[5a] and $[AlH_2\{N\text{-}CMe_2CH_2)_2CH_2\}(NMe_3)]$[5b]). Heteroaromatic substituted amides capable of intramolecular side arm donation were found to be able to give rise to several different coordination modes.[6] The presence of diverse donor groups integrated in the ligand periphery can provide electronic and steric stabilisation to the aluminium atom.[5c,5d] During our study on the reactivity and coordination behaviour of 2-pyridyl-based ligand systems[6] − 2-pyridyl derivatives of methane,[7] amines,[8,9] phosphanes,[9,10] arsanes,[10b] phosphanylamines,[11,12a] iminophosphoranes[11,12] and aminoiminophosphoranes[11] − we have isolated several aluminium complexes. The structural variety and large number of coordination modes possible in the case of pyridylamide-based systems[8,9,13] prompted us to carry out a detailed structure and bonding study of dipyridylamide-based aluminium complexes. This paper deals with both crystallographic and theoretical investigations into the structures of some of the aluminium complexes isolated in this group.

Results and Discussion

Syntheses and Crystal Structure of $[Al\{(NPy)Py\}_3]$ (1a) and $[Al\{(NPy)\ Py\}_2\ (Py_2N)]$ (1b)

$LiAlH_4$ is extensively used as a reagent in organic chemistry.[14a,14b] Nöth et al. described the reaction of secondary aliphatic amines with $LiAlH_4$,[14c] we reported the isolation of the intermediate product obtained in the reaction between $(Me_3Si)_2NH$ and $LiAlH_4$ in 1992,[14d] and analogous reactions between $LiAlH_4$ and primary and secondary aromatic amines were reported by Roesky et al. in 1997.[14e] In continuation of our research into the reactivity of $LiAlH_4$ we investigated its reaction behaviour with $(2\text{-Py})_2NH$.

In a reaction similar to that reported by Raston et al.,[13e] treatment of $(2\text{-Py})_2NH$ with $LiAlH_4$ in Et_2O, replacement

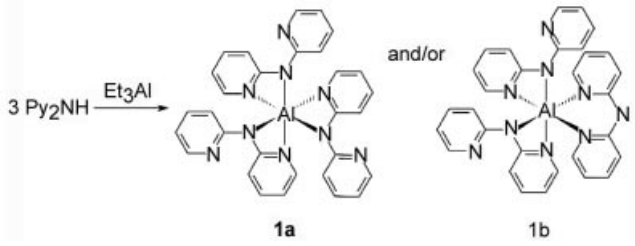
of the solvent by pyridine, subsequent filtration of the undissolved material, and cooling of the solution to 0 °C gives the aluminium triamide [Al{(NPy)Py}$_3$] (**1a**). However, a significantly higher yield of **1a** is obtained on treatment of (2-Py)$_2$NH with Et$_3$Al in Et$_2$O at −78 °C. Stirring for 2 d at room temperature and storage of the resulting solution at −40 °C give crystals of **1a** in 90% yield (Scheme 1). Raston et al.[13e] observed dynamic behaviour of **1a** in solution, as a consequence of which they were unable to distinguish the coordinated and uncoordinated nitrogen atoms of the pyridyl rings in NMR experiments. This dynamic behaviour can be explained by the rearrangement process associated with the ligands, confirmed by the isolation of the isomer **1b** in our studies. In this work, however, eight signals in the ^{1}H NMR and ten signals in the ^{13}C NMR could, as expected, be detected in the solid state structure for the coordinated and the uncoordinated pyridyl rings.



Scheme 1. Synthesis of [Al{(NPy)Py}$_3$] (**1a**) and [Al{(NPy)Py}$_2$-(Py$_2$N)] (**1b**)

Figure 1 shows the molecular structure of **1a**. The geometric features correspond to data obtained from crystals grown after the reaction between (2-Py)$_2$NH and LiAlH$_4$. Three uncoordinated pyridine molecules are present in the asymmetric unit of **1a**. The aluminium amide was isolated several times under different reaction conditions and from various solvents, with the same structural data being obtained in each case. The details show that **1a** incorporates various lattice solvents in different amounts, either as [Al{(NPy)Py}$_3$] + 3PyH (**1a**), [Al{(NPy)Py}$_3$] + thf (space group $P\bar{1}$) or solvent-free [Al{(NPy)Py}$_3$] (space group $P2_1/n$).

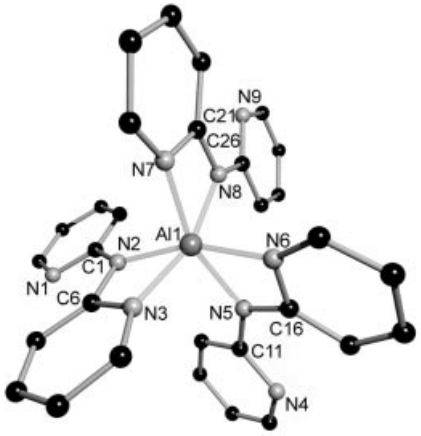


Figure 1. Structure of [Al{(NPy)Py}$_3$] (**1a**) in the solid state; the three pyridine molecules in the lattice have been omitted for clarity

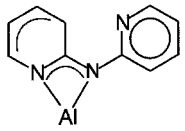
In the solid state, **1a** is a monomer. Each of the three Py$_2$N$^-$ ligands in **1a** adopts a *cis-trans* conformation and exhibits a chelating coordination mode to the aluminium atom. Each Py$_2$N$^-$ ligand coordinates to the metal atom through one pyridyl nitrogen atom and the bridging nitrogen atom of the ligand. The geometry around the aluminium atom is distorted octahedral [N−Al−N angles 66.7(7)−160.37(7)°; Table 1]. The average bond length of 197.3(2) pm for Al1−N(bridge) is slightly shorter than the average bond length of 200.6(2) pm for Al1−N(pyridyl). Both distances, however, are considerably longer than the amidic Al−N single-bond length of 178 pm found in tricoordinate aluminium amide systems such as [Al{N(SiMe$_3$)$_2$}$_3$],[5a] which is due to the higher coordination number of six found in **1a**. On the other hand, the bond lengths are on average 7 pm shorter than in a purely dative Al←N(PyH) bond, with a length of 206 pm in [(PyH)$_3$AlCl$_3$][5e] or 205.7 pm in [Me$_3$Al(Py$_3$P)].[6,10]

The Py$_2$N$^-$ anion in [Al{(NPy)Py}$_3$] (**1a**) coordinates to the metal atom in a *cis-trans* conformation, as previously found in [Me$_2$Tl{(NPy)Py}]$_n$ (see Scheme 2).[8] The Py$_2$N$^-$ ligand is nearly planar, as the angle between the two pyridyl ring planes is only 9° on average, leaving the bridging nitrogen atom sp^2-hybridised. The aluminium atom is displaced at an average distance of 7.5 pm out of the plane of the coordinating rings. NMR spectroscopic studies show that the structure in solution emulates that in the solid state. The ^{1}H NMR spectrum obtained in C$_6$D$_6$ shows the expected eight signals in the aromatic region, while the ^{13}C NMR spectrum displays ten resonances. Dynamic behaviour was not detected at room temperature.



Scheme 2. Mesomeric structure of Py$_2$N$^-$ in [Al{(NPy)Py}$_3$] (**1a**)

Slow evaporation of the deuterated NMR solvent from a sample of **1a** at room temperature resulted in the recrystallisation of a aluminiumtris[di(2-pyridyl)]amide that turned out to be a different conformational isomer [Al{(NPy)Py}$_2$(Py$_2$N)] (**1b**). This isomer contains two C$_6$D$_6$ molecules in the asymmetric unit rather than the three pyridine molecules in **1a**.

In the solid state, **1b** is found to be a monomer similar to **1a**. The three Py$_2$N$^-$ ligands chelate the aluminium atom and the metal centre exists in a distorted octahedrally coordinated polyhedron [N−Al−N angles vary from 64.69(17) to 167.8(2)°]. However, one of the Py$_2$N$^-$ ligands in [Al{(NPy)Py}$_2$(Py$_2$N)] (**1b**) now adopts a *trans-trans* conformation and coordinates to the aluminium atom through both pyridyl nitrogen atoms, leaving one bridging nitrogen atom uncoordinated (Figure 2, Table 2). The bond parameters of the *cis-trans* ligand containing N1 to N3 indicate a bonding situation similar to that of the Py$_2$N$^-$ ligands in **1a**.

Table 1. Selected average bond lengths [pm] and angles [°] in [Al{(NPy)Py}$_3$] (**1a**); the tabulated structural parameters correspond to the average values for the di(2-pyridyl)amide ligand according to the numbering scheme

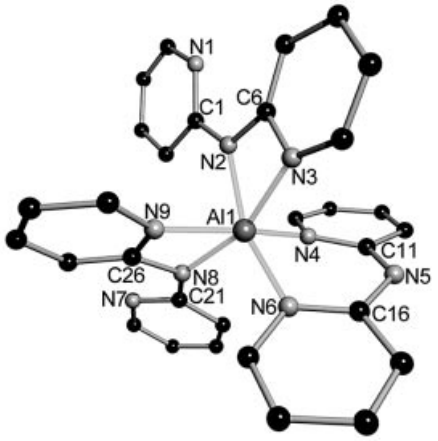

Figure 2. Structure of [Al{(NPy)Py}$_2$(Py$_2$N)] (**1b**) in the solid state; the two C_6D_6 molecules in the lattice have been omitted for clarity

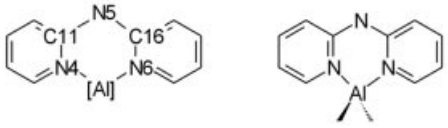
The situation in the second *cis-trans* ligand, between the atoms from N7 to N9, is quite different from that in **1a**. The variance of the two Al−N bonds is larger [Al1−N8 197.0(5) and Al1−N9 202.5(4) pm]. This indicates a greater accumulation of charge density at the bridged nitrogen atom N8, which is further supported by the angle defined by the best planes between the two pyridyl rings. This large angle of 17.7°, in contrast to the average 9° in **1a** and 7.2° in the previous ligand (N1 to N3) in **1b**, points to more pronounced sp^3 hybridisation at the bridging nitrogen atom N8. The aluminium atom is found at a distance of 31.5 pm out of the heteroallyl system plane, in contrast to the analogous distance of just 7.5 pm in **1a**.

Similarly, the *trans-trans* conformation of the Py$_2$N$^-$ ligand in [Al{(NPy)Py}$_2$(Py$_2$N)] (**1b**) shows another structural feature different to that found in [Me$_2$Al(Py$_2$N)] (Scheme 3).[8] Although both ligands show similar coordination to the metal atom, with the N−C bond lengths in [Me$_2$Al(Py$_2$N)] indicating a symmetric charge distribution over both pyridyl rings, they are unsymmetrical in **1b**. This can be seen in all the N(bridge)−C(*ipso*), C(*ipso*)−N(pyridyl) and Al−N bond lengths. Regardless of the fact that both pyridyl rings take part in the metal coordination, the greater part of the electron density is accumulated in only one of them (C11−C15 and N4). This results in shorter Al1−N4 [196.9(4) compared to 200.9(5) pm for Al1−N6] and N5−C11 bonds [134.2(7) in comparison to 139.3(7) pm for N5−C16]. In solution, **1b** converts into the conformational isomer **1a**, and so no difference is observed in the spectroscopic data. Conformer **1b** seems to be energetically disfavoured in comparison to **1a**, but can be crystallised under the conditions described in the Exp. Sect.



Scheme 3. The *trans-trans* conformation of Py$_2$NH$^-$ in [Al{(NPy)Py}$_2$(Py$_2$N)] (**1b**) and [Me$_2$Al(Py$_2$N)]

Syntheses and Crystal Structure of [(PyH)$_2$AlCl$_2${(NPy)Py}] (2)

A solution of di(2-pyridyl)amine and aluminium trichloride, when treated with *n*-butyllithium and allowed to warm to room temperature, gives [(PyH)$_2$AlCl$_2${(NPy)Py}] (**2**) (Scheme 4). Colourless crystals of **2** were isolated after 4 d at 0 °C. The crystals were found to decompose at 50 °C.

Compound **2** exists as a monomer in the solid state (Figure 3). Di(2-pyridyl)amide coordinates to the aluminium atom through one of the pyridyl ring nitrogen atoms and the bridging central nitrogen atom. The coordination sphere is completed by the coordination of two chloro ligands and the nitrogen atoms of two pyridine molecules to give a distorted octahedral geometry around the aluminium centre (N5−Al1−N4 174.4°, Cl1−Al1−Cl2 137.5°, N2−Al1−N3 65.9°). Because of the absence of steric strain the two pyridyl rings are coplanar.

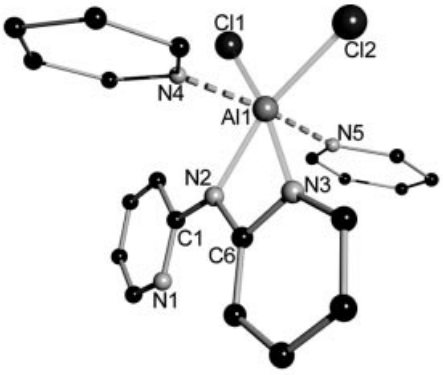

Figure 3. Structure of [(PyH)$_2$AlCl$_2${(NPy)Py}] (**2**) in the solid state

The di(2-pyridyl)amide ligand in **2** adopts a *cis-trans* conformation, as in the cases of **1a** and [Me$_2$Tl{(NPy)Py}]$_n$ [8] (Figure 3, Table 3). The distance between the coordinated central nitrogen atom and the pyridyl nitrogen atom is 218.1 pm. In the octahedral coordination sphere, the aluminium atom lies nearly in the plane of the di(2-pyridyl)amide ligand (7.6° angle between the pyridyl ring planes) in the Al1−Cl1−Cl2 plane. This is the first example of *cis-trans* coordination of the monoanionic di(2-pyridyl)amide in a monomeric metal complex. As in **1a** and **1b**, the *cis*−*cis* conformation is precluded due to the greater $N_{ring}\cdots N_{ring}$ distance, while in a hypothetical planar *trans-trans* conformation there would be steric interaction between the hydrogen atoms of the ring and the chlorine atoms, due to their closer proximity. Hence, by adopting the *cis-trans* conformation, the system avoids such disadvantageous steric factors (Scheme 5). Because of the coordination through the central nitrogen atom N2 and through the pyridyl nitrogen atom N3 of the di(2-pyridyl)amide, different electronic situations exist in the pyridyl rings. The distances from the bridging nitrogen atom N2 to the *ipso*-carbon atoms (N2−C1 139.3 and N2−C6 136.8 pm) deviate significantly in the same way as seen for the $C_{ipso}-N_{ring}$ distance (C6−N3 136.8 and C1−N1 134.2 pm). The N2−C6 bonding exhibits a more pronounced double bond character, in contrast to N2−C1. Furthermore, C6−N3 is shorter than C1−N1. The charge of the anionic ligand is predominantly localised at the N3 nitrogen atom of the coordinated pyridyl ring (Scheme 6).

				C7−C6−N2	135.4(4)

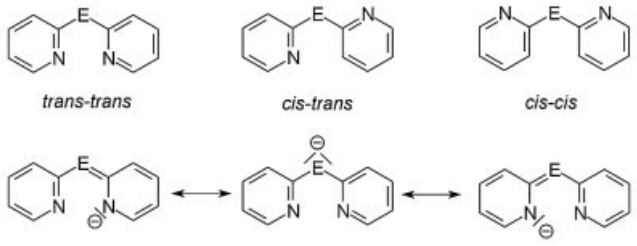
The aluminium−nitrogen and aluminium−chloride distances in **2** can be compared with those in the following compounds: $[Cl_2Al(PyH)_4][AlCl_4]$ (Al−N 206, Al−Cl 227 pm),[5e] $Cl_3Al(PyH)_3$ (Al−N 206, Al−Cl 227 pm),[5e] and $Cl_2Al(bpy)_2$ (Al−N 203, Al−Cl 225 pm).[5f] The Al1−N4 (205.9 pm) and Al1−N5 (207.7 pm) bond lengths in the donating pyridine molecules correspond to the dative aluminium−nitrogen bonding in $[Cl_2Al(PyH)_4][AlCl_4]$[5e] and $[Cl_3Al(PyH)_3]$,[5f] each with an Al−N distance of 206 pm. The aluminium−nitrogen bonds in the monoanionic di(2-pyridyl)amide ligands are substantially shorter. Because of the higher charge density at the pyridyl ring nitrogen atom N3, the Al1−N3 bond length (198.4 pm) is shorter than the Al1−N2 bond length (202.7 pm).

Both aluminium−chloride bond lengths lie in the range expected for Al−Cl bond lengths (226 pm). However, Al1−Cl1 (223.7 pm) is shorter than Al1−Cl2 (226.2 pm). The different Al−N distances result from the difference in the dipole moment parallel to Al1−N3 and Al1−N2. Thus, the Al−Cl bond length is likewise different. As a compensation for these differences a shortening of the Al1−Cl1 bond and a lengthening of the Al1−Cl2 bond results.

The ^1H and the ^{13}C NMR spectra at room temperature do not resolve the magnetic and chemical differences of the pyridyl substituents. Because of the overlap of the signals in the ^1H NMR spectrum, no exact assignment could be made. Eight signals are observed in the ^{13}C NMR spectrum of **2**; three correspond to the pyridine molecules and four to the di(2-pyridyl)amide ligand [δ = 116.6 (C5), 117.7 (C3), 123.6 (C_{para}), 139.7 (C_{meta}), 141.5 (C4), 142.7 (C_{ortho}), 144.1 (C6), 152.8 (C2) ppm]. NMR experiments conducted at −60°C show no further splitting of the signal pattern.

Comparison of Structural Parameters for Compounds 1a, 1b and 2

Structural comparison of the various complexes shows that the Py_2N^- ligand is flexible enough, depending on the electronic and steric demand, to suit different coordination modes, giving rise to a variety of metal complexes. Scheme 7 illustrates the different possible coordination modes for the dipyridyl amide ligand. Furthermore, the negative charge density at the bridging nitrogen atom of the Py_2N^- ligand is more or less delocalised over the pyridyl ring. The degree of delocalisation and density accumulation depends on the coordinated metal atom, the degree of aggregation and the conformation of the ligand. This has a distinct effect on the geometrical parameters of the ligand, accounting for the significant perturbation of the aromatic ring systems.



Scheme 7. The different possible coordination modes of the di(2-pyridyl)amide and -phosphanide ligand (top) and the mesomeric structures for the ligand in the *trans-trans* coordination mode (bottom)

Table 4 gives an overview of the structural parameters of the Py_2N^- ligand for compounds **1a**, **1b** and **2**, in comparison with PyH (**A**),[17] $(2\text{-Py})_2NH$ (**B**),[15] $[Me_2Al(Py_2N)]$ (**C**),[8] $[Et_2Al(2\text{-}Py_2N)AlEt_3]$ (**D**),[9] Py_2PH (**E**),[9] $[Me_2Al(Py_2P)]$ (**F**)[10a][10b] and $[Et_2Al(Py_2P)]$ (**G**).[9] The structural parameters shown in Table 4 follow the ordering scheme shown in the Figure. Three different kinds of polymorphs are known for the $(2\text{-Py})_2NH$ molecule; a hydrogen-bridging dimer exists in the orthorhombic[18a] and triclinic[18b] polymorphs, while on the other hand, the hydrogen bridging produces a tetramer in the case of the monoclinic[9] polymorph. Distinct and strong differences exist in the torsion angles (the angle β between the pyridyl planes) of the various polymorphs found in $(2\text{-Py})_2NH$. The angles are 73, 40 and 0° in the triclinic, orthorhombic and monoclinic forms, respectively. However, the bond lengths in the different polymorphs are identical. The free electron pair in neutral $(2\text{-Py})_2NH$ is also partly delocalised over the pyridyl ring. The bridging nitrogen atom has sp^2 character. Assessment of the electronic structure in di(2-pyridyl)amide li-

gands in various metal complexes is possible by comparison with $(2\text{-}Py)_2NH$.

Theoretical Studies of the $(2\text{-}Py)_2P^-$ and $(2\text{-}Py)_2N^-$ Anions

To obtain deeper insights [e.g., the energetic differences between the conformers and the quantification of an Al−N(amide) versus Al←N(donor) bond energy contribution in the light of the related $(2\text{-}Py)_2P^-$ phosphanide system] into these structures, we performed DFT calculations. Coordination modes with the *cis-cis*, *cis-trans* and *trans-trans* conformers are documented for both $(2\text{-}Py)_2E^-$ anions (E = N, P).[7,10] Although the bridging nitrogen atom in $Et_2Al(2\text{-}Py)_2N$ might be employed in an additional N→Al donor bond towards $AlEt_3$ to give the adduct $Et_3Al{\leftarrow}N(2\text{-}Py)AlEt_2$, Lewis acid/base pairing was precluded with the related phosphanide $Et_2Al(2\text{-}Py)_2P$.[9] However, the di(2-pyridyl)phosphanide ligand shows a metal-dependent coordination response and is involved in a highly unusual σ/π interaction with the soft metal caesium.[10c] The phosphorus atom in the anion is sufficiently Lewis basic to bridge two soft organometallic iron centres. In this context, the different conformers of $(2\text{-}Py)_2N^-$ and $(2\text{-}Py)_2P^-$ were analysed by DFT calculations (Figure 4).

As anticipated, the *cis-trans* conformers of both $(2\text{-}Py)_2E^-$ anions are more stable than the *trans-trans* and *cis-cis* conformers. The twisted *trans-trans* conformer of Py_2N^- is only 1.4 kJ/mol more stable than the twisted *cis-cis* form (each av. dihedral angle 52°), while the twisted *cis-cis* form of the Py_2P^- anion (each av. dihedral angle 42°) is significantly more stable than the twisted *trans-trans* form (11.42 kJ/mol, Figure 4). This allows full conjugation throughout the heteroallylic system and intramolecular $N^{\delta-}\cdots{}^{\delta+}H(C)$ hydrogen bonding. While the N(bridge)−C(*ipso*) distances from the calculated anions match those in the experimental contact ion pairs **1a**, **1b** and **2** almost exactly, the P(bridge)−C(*ipso*) distances seem to be marginally too long (compare Tables 1−3 and 5). While the C−E−C angle in the amides is widened to values considerably larger than 120°, it is much sharper in the phosphanides, and smaller even than the value expected for an sp^3-hybridised phosphorus atom. Both features match the experimentally found values in the contact ion pairs. Closer examination of the bond lengths reveals partially localised double bonds in the pyridyl rings at the 3- and 5-positions. The small energetic differences between the *trans-trans* and the *cis-trans* conformers − 7.4 kJ/mol for the Py_2N^- and 23.2 kJ/mol for the Py_2P^- anion − can easily be overcompensated by metal coordination.

Theoretical Studies of the E→Al Donor Bond (E = N, P)

The next challenge was to determine the E→Al donor-acceptor bond energies in the experimentally verified complex $Et_2Al(2\text{-}Py)_2NAlEt_3$ and the model compounds $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ and $Me_2Al(2\text{-}Py)_2P{\rightarrow}AlMe_3$, since $Et_2Al(2\text{-}Py)_2P$ does not form the adduct $Et_2Al(2\text{-}Py)_2P{\rightarrow}AlEt_3$ with a second equivalent of $AlEt_3$. One difference between the Lewis-type donor-acceptor bond and a covalent bond is that dissociation of the former yields two

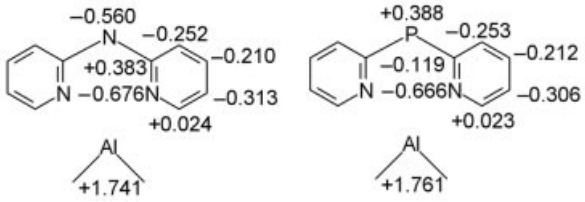
closed-shell fragments with an electron lone-pair donor and an electron-pair acceptor, while the latter gives two open-shell fragments.[19] Another difference is that the bond length of a covalent bond would not usually change much in different aggregation states, while donor-acceptor bonds frequently show larger interatomic distances in the gas phase than in the solid state. As we wanted to investigate the above-mentioned donor-acceptor complexes by theoretical methods, we first tested them by employing the molecular structures of the complexes $Me_3N{\rightarrow}AlMe_3$ and $Me_3P{\rightarrow}AlMe_3$, which have already been determined structurally in the gas phase.[20] Their donor-acceptor bond dissociation energies were determined experimentally. The theoretical parameters calculated at the CBS-4, MP2/6-31+G(d) and BPW91/6-31+G(d) levels of theory were evaluated and compared to the experimental values obtained by Haaland. As expected, the most powerful computational methods CBS-4M and MP2/6-31+G(d) gave the best match with the experimentally ascertained structures and energies. The BPW91/6-31+G(d) method calculates the N→Al and P→Al donor-acceptor bond lengths as being

slightly too long, and the resulting bond dissociation energies are too low (Figure 5).

To force the central donating atom into the sp^2 hybridisation of an amide or phosphanide we performed calculations for $H_2C{=}(Me)N{\rightarrow}AlMe_3$ and $H_2C{=}(Me)P{\rightarrow}AlMe_3$, since these models should be more consistent with $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ and $Me_2Al(2\text{-}Py)_2P{\rightarrow}AlMe_3$. In contrast to the shortening of the Al−N bond, by 1 and 5 pm, the P−Al interatomic distances surprisingly lengthened by 5 and 10 pm by the MP2 and BPW91/6-31+G(d) methods, respectively. Furthermore, the calculated bond dissociation energies at the most reliable MP2 level of theory were determined in these cases to be 95.7 and 44.9 kJ/mol for $H_2C{=}(Me)N{\rightarrow}AlMe_3$ and $H_2C{=}(Me)P{\rightarrow}AlMe_3$, respectively (Figure 5). Consequently, the sp^2 hybridisation of the heteroatom and the coupling of the charge to the substituents has a strong effect on the dissociation enthalpy of the E→Al bond, and particularly in the phosphanide adduct. While the energy is only decreased by a factor of one fifth in the amide adduct, it is halved in the phosphanide adduct. In addition, the "hard" aluminium atom prefers the "hard" nitrogen donor rather than the "soft" phosphane function. Population analysis schemes, such as Natural Population Analysis,[21] assign most pronounced negative partial charges to the ring nitrogen atoms in $Me_2Al(2\text{-}Py)_2N$ and $Me_2Al(2\text{-}Py)_2P$. In the latter, the divalent P^{III} centre even shows a partial positive charge. (Scheme 8).



Scheme 8. Calculated natural charges in $[e]^-$ for the complexes $Me_2Al(2\text{-}Py)_2N$ and $Me_2Al(2\text{-}Py)_2P$, determined by natural population analysis

The s and p_π populations of the atomic orbitals of the bridging phosphorus and nitrogen atoms are significantly different. The 3s orbital in the phosphorus atom is more highly populated than the 2s orbital of the nitrogen atom, while the charge density in the p orbitals of the phosphorus atom is depleted relative to the bridging nitrogen atom.

Since this suggests the formation of a metal−nitrogen bond rather than a metal−phosphorus bond, we became interested in quantitatively evaluating the E→Al bond energies in the model compounds $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ and $Me_2Al(2\text{-}Py)_2P{\rightarrow}AlMe_3$. Selected bond lengths and angles for these compounds are reported in Table 6, in comparison

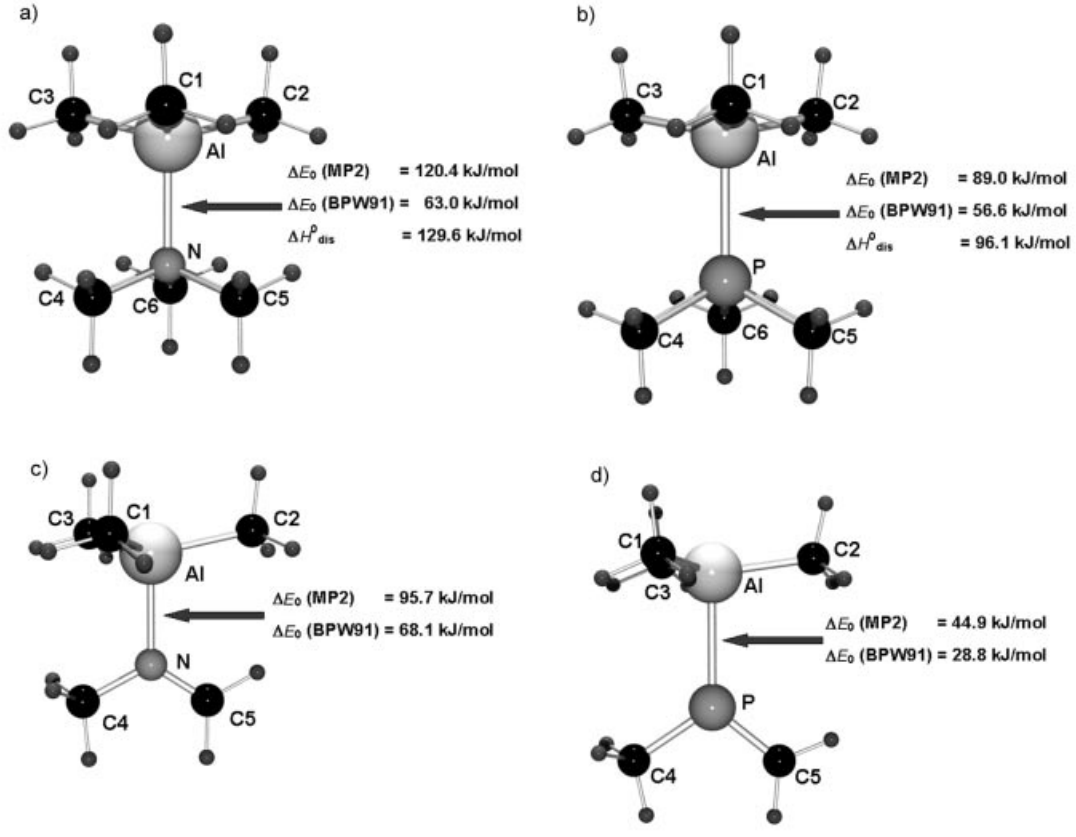


Figure 5. Optimised geometries for the adducts $Me_3N{\rightarrow}AlMe_3$ (a), $Me_3P{\rightarrow}AlMe_3$ (b), $H_2C{=}(Me)N{\rightarrow}AlMe_3$ (c) and $H_2C{=}(Me)P{\rightarrow}AlMe_3$ (d), with the related E→Al donor bond energies

Table 6. Selected calculated bond lengths [pm] and angles [°] of $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ and $Me_2Al(2\text{-}Py)_2P{\rightarrow}AlMe_3$ in comparison to the experimentally ascertained data for $Et_2Al(2\text{-}Py)_2N{\rightarrow}AlEt_3$

to the experimentally determined values for the complex $Et_2Al(2\text{-}Py)_2N{\rightarrow}AlEt_3$. Because of the coordination of the additional $AlMe_3$ fragment by the bridging nitrogen atom, the $Me_2Al(2\text{-}Py)_2N$ moiety adopts an accentuated butterfly conformation analogous to that of $Me_2Al(2\text{-}Py)_2P$. Furthermore, the heteroatom in the bridging position seems to become a pseudo-sp^3-hybridised centre, giving rise to a displacement of the $AlMe_3$ fragment from the plane containing the N1, E and N2 atoms. Surprisingly, comparison between the model compounds $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ and $Me_2Al(2\text{-}Py)_2P{\rightarrow}AlMe_3$ reveals a different position of the $AlMe_3$ fragment relative to the second aluminium atom of the $Me_2Al(2\text{-}Py)_2E$ butterfly moiety. While both metal atoms are located on the same side in the nitrogen complex, they are positioned on opposite sides in the phosphorus complex (Figure 6).

The experimentally determined Al2→N bond length of 201.0(3) pm in $Et_2Al(2\text{-}Py)_2NAlEt_3$ is significantly longer than a covalent bond and about 5 pm shorter than a pure dative bond.[9] The calculated Al2→N bond length of 212.9 pm in the model complex $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ is much longer, possibly due to the gas-phase nature of the simulation.

The calculated E→Al bond energies at the MP2/6-31+G(d) level for the complexes $Me_3E{\rightarrow}AlMe_3$ (E = N, P) differ from the experimentally determined values only by less than 10 kJ/mol. Consequently, a single-point calculation at the MP2 level of theory was performed for the $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ and $Me_2Al(2\text{-}Py)_2P{\rightarrow}AlMe_3$ complexes. The fully optimised geometry from the BPW91/6−31+G(d) calculations was employed. The calculated bond dissociation energy for the complex $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ (125.4 kJ/mol) is very close to the experimentally determined value for $Me_3N{\rightarrow}AlMe_3$ (129.6 kJ/mol), but the donor-acceptor bond energy of 75.4 kJ/mol in $Me_2Al(2\text{-}Py)_2P{\rightarrow}AlMe_3$ is considerably lower (by 20.7 kJ/mol) than the experimentally determined value for $Me_3P{\rightarrow}AlMe_3$ (96.1 kJ/mol).

In summary, all di(2-pyridyl)amides and -phosphanides coordinate the R_2Al^+ fragment through at least one ring nitrogen atom. This in itself suggests that the charge density in the anions is coupled into the rings and accumulated at the ring nitrogen atoms. The Lewis basicity of the central nitrogen atom in $Me_2Al(2\text{-}Py)_2N$ is still high enough to coordinate a second equivalent of $AlEt_3$ to form the Lewis acid/base adduct $Et_2Al(2\text{-}Py)_2N{\rightarrow}AlEt_3$. All these findings confirm the formation of metal nitrogen rather than of metal−phosphorus bonds even in reaction pathways, as established by Budzelaar for reactions between (2-pyridyl)-phosphanes and methyllithium.[22] The theoretical results presented show that while the bridging nitrogen atom in the amides (E = N) is still a typical Lewis base, the situation in

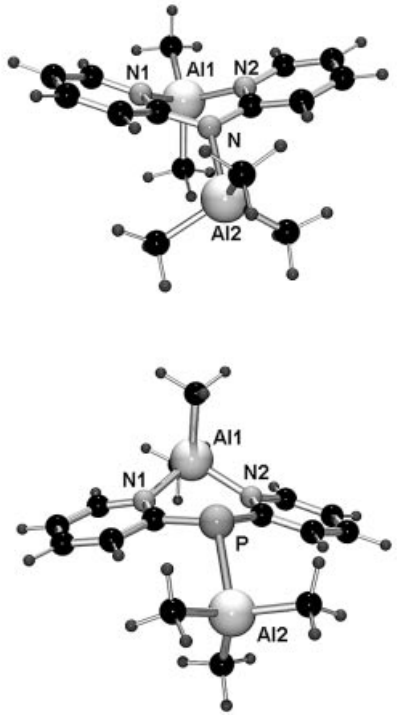

Figure 6. BPW91/6-31+G*-optimised geometries of $Me_2Al(2\text{-}Py)_2N{\rightarrow}AlMe_3$ (top) and $Me_2Al(2\text{-}Py)_2P{\rightarrow}AlMe_3$ (bottom)

the corresponding phosphanides (E = P) is different. Here, nearly all the charge density couples into the pyridyl rings, leaving the central phosphorus atom attractive only for soft metals, in the form of a π-acid-type of coordinating centre to reinforce the otherwise poor phosphorus donor bond energy, shown in the P−N−C allylic coordination to the soft Cs atom.[10c]

Conclusion

The competition between the amidic bridging nitrogen atom and the pyridyl nitrogen atoms for the charge density in Py_2N^- provides for greater conformational variety than in the analogous Py_2E^- systems (E = CH,[7a,7b] P,[10a,10b] As[10b]). The former system shows considerable Lewis basicity at the bridging nitrogen atom, while the charge density at the bridging phosphorus atom is depleted and coupled into the rings. The small energy differences of about 8 kJ/mol between the *cis-trans*, *trans-trans* and *cis-cis* conformers in the Py_2N^- anion can easily be overcome by various crystallisation techniques from different solvents at different temperatures (**1a** from pyridine at 0 °C or from diethyl ether at −40 °C, **1b** from C_6D_6 at room temperature). The 23 kJ/mol by which the *trans-trans* conformer in Py_2P^- is disfavoured against the *cis-trans* form can easily be compensated for by coordination to the hard organometallic Me_2Al^+ fragment. The energy gained from the E→Al donor bonds, in which the charge density at E = N or P can be delocalised to an adjacent carbon atom, is only half the amount with phosphorus than with nitrogen. Hence, the P-centred systems are much better π-donors to soft metals than σ-donors to hard metals. We found computational methods extremely helpful for interpreting the coordination behaviour of di(2-pyridyl)amides and -phosphanides.

Experimental Section

General Remarks: All manipulations were performed under dry N_2 with Schlenk techniques or under argon in a glove box. All solvents were dried with Na/K alloy and distilled prior to use. NMR spectra were obtained in C_6D_6 or $CDCl_3$ as solvent, with $SiMe_4$ or H_3PO_4 as external reference, with a Bruker AMX 250 MHz spectrometer. Mass spectra were recorded with a Finnigan Mat 8230 or Varian Mat CH5 spectrometer. Elemental analyses were performed by the Analytisches Laboratorium, Universität Würzburg.

$[Al\{(NPy)Py\}_3]$ (1a) and/or $[Al\{(NPy)Py\}_2(Py_2N)]$ (1b)

1a. Method a: A solution of Py_2NH (4.00 g, 23.3 mmol) in Et_2O (20 mL) was added dropwise to a suspension of $LiAlH_4$ (220 mg, 5.8 mmol) in Et_2O (20 mL), cooled to 0 °C. After the mixture had been stirred at room temp. for 2 d, the diethyl ether was replaced by PyH (20 mL). The reaction mixture was filtered through Celite to remove the undissolved solids, and the clear solution was allowed to stand at 0 °C. After 1 d, crystals of **1a** suitable for single-crystal X-ray diffraction were isolated. For analytic and spectroscopic analysis the crystals were washed twice with hexane (10 mL) and dried under vacuum. Yield: 1.03 g (50%). **Method b:** Py_2NH (2 g, 11.6 mmol) in Et_2O (25 mL) was cooled to −78 °C. Et_3Al (5.95 mL of 15% solution in hexane, 3.83 mmol) was added dropwise to the cooled mixture, which was allowed to gradually attain room temp. Stirring at room temp. was continued for 2 d. Crystals of **1a** suitable for X-ray diffraction study were isolated from the reaction mixture stored at −40°C. For analytical and spectroscopic analysis the crystals were washed twice with hexane (10 mL each time) and dried under vacuum. Yield: 1.85 g (90%). Decomposition point: 83 °C; The ^1H and ^{13}C NMR spectra show different resonance peaks for the coordinated pyridyl ring and noncoordinated pyridyl rings. An unambiguous assignment of all the resonances was not possible. ^1H NMR (C_6D_6): δ = 6.13 (dd, $^3J_{H\text{-}H}$ = 6.2, $^3J_{H\text{-}H}$ = 6.3, 1 H), 6.45 (s_{br}, 1 H,) 7.01 (s_{br}, 2 H, 5-H, 5-H′, 4-H and 4′-H), 7.26 (d, $^3J_{H\text{-}H}$ = 6.6, 1 H,), 7.77 (s_{br}, 1 H), 7.83 (s_{br}, 1 H), 8.12 (s_{br}, 1 H, 3-H, 3′-H, 6-H and 6′-H) ppm. ^{13}C NMR (C_6D_6): δ = 112.0 (s), 113.7 (s), 114.5 (s), 116.3 (s, C-5, C-5′, C-4 and C-4′), 137.5 (s), 138.2 (s), 139.0 (s), 148.1 (s, C-3, C-3′, C-6 and C-6′), 154.1 (s), 160.8 (s, C-2 and C-2′) ppm. EI-MS: *m/z* (%) = 170.1 (100) [Py_2N], 78.1 (24.9) [Py]. $C_{30}H_{24}AlN_9$ (537.56): calcd. C 67.1, H 4.50, N 23.5; found C 65.7, H 4.70, N 23.1.

1b: Compound **1a** was dissolved in C_6D_6 for spectroscopic studies. Reducing the volume of the solution slowly gives rise to crystals of the isomer **1b**. In solution, **1b** converts into **1a**, and hence the spectroscopic data are identical.

$[(PyH)_2AlCl_2\{(NPy)Py\}]$ (2): A mixture of di(2-pyridyl)amine (0.50 g, 2.90 mmol) and aluminium trichloride (0.39 g, 2.90 mmol) in pyridine (30 mL) was cooled to −40 °C. An equimolar quantity of *n*-butyllithium (1.90 mL of a 1.6 M solution in *n*-hexane) was added dropwise to this mixture, which was gradually allowed to attain room temp. by standing overnight. Stirring of the resulting clear solution at room temp. was continued for 2 d. Needle-shaped, colourless crystals suitable for single-crystal diffraction studies were isolated from the solution after 4 d at 0 °C. After removal of the mother liquor, the crystals were further washed several times with hexane (10 mL) and vacuum-dried for analytic and spectroscopic

studies. Yield: 0.87 g (70.2%). Decomposition point: 50 °C. ^{1}H NMR ($CDCl_3$): δ = 7.04−8.70 (m, 18 H, Py-H) ppm. ^{13}C NMR ($CDCl_3$): δ = 116.6 (s, C-5), 117.7 (s, C-3), 126.6 (s, C_{para}), 139.7 (s, C_{meta}), 141.5 (s, C-4), 142.7 (s, C_{ortho}), 144.1 (s, C-6), 152.8 (s, C-2) ppm. EI-MS: *m*/*z* (%) = 170.1 (12.8) [Py_2N], 119.1 (0.10) [(AlPyN)], 105.1 (0.12) [(AlPy)], 79.1 (100) [PyH]. $C_{20}H_{18}AlCl_2N_5$ (426.28): calcd. C 56.4, H 4.26, N 16.43; found C 54.7, H 4.53, N 15.84.

Crystal Structure Determination: Crystallographic details pertaining to data collection and refinement are presented in Table 7. The data for **1a** and **2** were collected with an Enraf−Nonius CAD4 four-circle diffractometer, and the data for **1b** with a Stoe-IPDS single-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 71.073 pm). All data were collected at low temperatures, using oil-coated shock-cooled crystals.[23] After determination and refinement of the cell parameters for **1a** and **2**, the intensity of the reflections was detected by the background-peak-background method.[24] All reflections were collected by the 2θ/ω-scan method for **1a** and **2**, while in the case of **1b** the reflections were detected by the φ-scan mode with stepwise rotation of every 1°. All structures were solved by direct methods by use of the SHELXS-97 program for compounds **1a** and **1b** and SHELXS-96 for **2**.[25a] Refinement of the structures was performed by full-matrix, least-squares methods against F^2 with SHELXL-97[25b] (for **1a** and **1b**) and SHELXL-96[25c] (for **2**). All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were assigned ideal positions and refined isotropically with a riding model with U_{iso} constrained to 1.2 times of U_{eq} of the parent atom. Structure refinement: Compound **1a** crystallises in the centrosymmetric triclinic space group $P\bar{1}$. The [Al{(NPy)Py}$_3$] (**1a**) molecule shows almost threefold symmetry. In the asymmetric unit, three non-coordinated pyridine molecules are present as solvent from crystallisation. They are not disordered and do not give rise to any hydrogen-bonding pattern. Single-crystal data for compound **1a** in this conformation were obtained in different solvents. Compound **1a** has also been reported by another research group.[13e] The different forms show varying cell parameters, and a comparison of these parameters is listed in the Supporting Information. Compound **1b**, which is a conformational isomer of **1a**, crystallises in the centrosymmetric monoclinic space group $P2_1/c$. Two noncoordinated C_6D_6 solvent molecules are present in the asymmetric unit. The donating pyridine molecules in compound **2** were refined with ADP and distance restraints. Selected bond lengths and angles are summarised in Tables 1−3. The CCDC numbers listed in Table 7 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: The calculations were carried out with the GAUSSIAN98 program package.[26] For the evaluation of the donor-acceptor bond energies of the complexes $Et_2Al(2\text{-}Py)_2N\rightarrow AlEt_3$ and $Et_2Al(2\text{-}Py)_2P\rightarrow AlEt_3$, calculations at the BPW91,[27] MP2[28] and CBS-4[29] levels of theory were carried out. The 6-31+G(d) basis set was used for the calculations.[30] Because of the

relatively large size of the bipyridyl complexes, the geometries were fully optimised at the BPW91/6-31+G(d) level and used to compute vibrational harmonic wavenumbers and zero-point corrections. In order to obtain more reliable total energies and bond energies, MP2/6-31+G(d) energy calculations were also performed with the BPW91/6-31+G(d)-optimised geometries, and this type of calculation is designated by the standard notation MP2/6-31+G(d)//BPW91/6-31+G(d).

Si−H-Functionalized Ferriodisiloxanes: Synthesis from the Ferriodimethylsilanols $C_5R_5(OC)_2Fe-SiMe_2OH$ (R = H, Me) and Photoinduced Transformation into μ_2-Disiloxanediyl-Bridged Dinuclear Iron Complexes[‡]

Wolfgang Malisch,*[a] Marco Hofmann,[a] Günter Kaupp,[a] Harald Käb,[a] and Joachim Reising[a]

Keywords: Iron / Metallacycles / Oxidative addition / Silicon / Siloxanes

Hydrolysis of the ferriochlorosilanes $C_5R_5(OC)_2Fe–SiMe_2Cl$ [R = H (**1a**), Me (**1b**)] in the presence of Et_3N yields the corresponding ferriosilanols $C_5R_5(OC)_2Fe–SiMe_2(OH)$ (**2a** and **2b**). In addition, **2b** is also obtained by oxo-functionalization of $C_5Me_5(OC)_2Fe–SiMe_2H$ (**3**) with dimethyldioxirane. The ferriosilanol **2a** can be converted into the ferriodisiloxanes $Cp(OC)_2Fe–SiMe_2OSiR_3$ [R_3Si = $Me_2(H)Si$ (**5a**), $pTol_2(H)Si$ (**5b**), Me_3Si (**5c**) and *p*Tol(Me)(H)Si (**5d**)] by condensation with the chloro(organo)silanes R_3SiCl (**4a**–**d**). Irradiation of **5a** and **5b** results in CO elimination, followed by dimerization to give the cyclic 1,5-diferratetrasiloxanes $[\mu_2\text{-}SiMe_2OSi(R)_2]_2[Fe(H)(CO)Cp]_2$ [R = Me (**6a**) and *p*Tol (**6b**)]. Compounds **2b** and **6b** have been characterized by single-crystal X-ray structure determination.

Introduction

Transition metal substituted silicon compounds have attracted great attention in recent years, especially with regard to the effect of the metal component on the reactivity of the silicon unit.[2−5] In the context of our systematic studies on the reactivity of functionalized silicon−transition metal complexes[6−13] we have shown that metallosilanols with a direct M−Si bond of the general type $L_nM-Si(R)_{3-n}(OH)_n$ (n = 1−3)[14−30] are characterized by remarkably high stability towards self-condensation, due to the electron-releasing effect of the metal fragment. This property has permitted the isolation of a number of transition metal substituted silanols,[14−26] mainly of the chromium and iron groups, including examples with stereogenic metal and silicon atoms[26] and even of metallosilanediols[27,28] and -silanetriols.[29,30]

The reactivity of this special class of silanols has so far not been explored in detail. However, preliminary studies showed facile condensation with chlorosilanes as an efficient route to metallosiloxanes.[22−24,26−30] In particular, those bearing an SiH function at the γ-silicon atom offer high synthetic potential in terms of the oxidative addition of the SiH unit to electronically unsaturated metal centres to provide access to Si−O−Si-bridged dinuclear metal complexes.[27]

This was strong motivation to perform the synthesis of novel metallosilanols, especially with the well-known iron fragments $C_5R_5(OC)_2Fe$ (R = H, Me), and condensation reactions to afford the corresponding disiloxanes. Furthermore, the SiH-functional derivatives were used for photoinduced transformation, providing novel eight-membered cyclic dimetallasiloxanes.

Results and Discussion

Access to the ferriodimethylsilanols **2a** and **2b**, the precursors for synthesis of the ferriodisiloxanes, is given by two procedures − hydrolysis of chloroferriosilanes[14,18] and oxo-functionalization of ferriosilanes.[16,20]

Hydrolysis of the chloroferriodimethylsilanes **1a** and **1b** in diethyl ether in the presence of the auxiliary base Et_3N at room temperature afforded the metallated silanols **2a** and **2b** in good yields [89% (**2a**), 70% (**2b**)] [Equation (1), route a]. The C_5Me_5-substituted complex **1b** undergoes ligand exchange (48 h) significantly more slowly than the Cp compound **1a**. This difference can be associated with the reduced electrophilicity of the silicon atom, deriving from the greater electron-releasing effect of the permethylated Cp ring. Controlled Cl/OH exchange can be performed without an auxiliary base, as demonstrated for **2a**, indicating that the Fe−Si bonds in both **1a** and **2a**, in contrast to those in

[‡] Synthesis and Reactivity of Silicon Transition Metal Complexes, 51. Metallo-Silanols and Metallo-Siloxanes, 23. Part 50/22: Ref.[1]

[a] Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, 97074 Würzburg, Germany

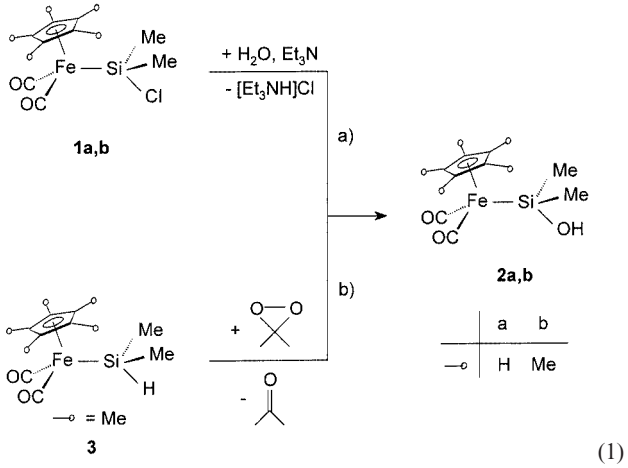
trialkylferriosilanes, are resistant towards cleavage with HCl.

In addition, the C_5Me_5-substituted ferriosilanol **2b** was obtained by oxygenation of the corresponding ferriodimethylsilane **3** with dimethyldioxirane [Equation (1), route b]. This method gave shorter reaction times and a more convenient workup procedure than the hydrolysis route. However, the yield was significantly lower (36%), presumably due to oxidation of the transition metal centre.[31]



(1)

The ferriodimethylsilanols **2a** and **2b** were obtained as slightly air-sensitive, pale yellow solids, showing good solubility in all kinds of organic solvents. Compounds **2a** and **2b** did not undergo self-condensation at room temperature even in the presence of Et_3N.

In order to gain an insight into the solid-state structure of the ferriodimethylsilanols **2a** and **2b**, especially with respect to hydrogen-bonded aggregation, an X-ray structure determination of **2b** was performed. Two molecules were found in the asymmetric unit (Figure 1). For the central iron atom a pseudo-octahedral coordination sphere is indicated by the ligand−iron−ligand angles, which are close to 90°. A larger angle exists between the carbonyl carbon atoms [98.3(3)°], while those between the CO ligands and the silicon atom are diminished [83.1(2)°/84.1(2)° and 83.9(2)°/84.0(2)°]. Newman projection along the Fe−Si bond reveals a staggered conformation of the substituents, with one of the methyl groups *trans* to the C_5Me_5 ring and the OH group consequently occupying the space between the C_5Me_5 ring and one carbonyl ligand. The Fe−Si distances [2.313(2) Å and 2.319(2) Å] lie within the range observed in known iron−silicon compounds.[32,33] The Si−O bond lengths [1.676(9) Å and 1.653(6) Å] are slightly greater than those in organosilanols,[34] indicating some electronic saturation of the silicon atom by the transition metal component. The silicon atoms show a distorted tetrahedral coordination with reduced angles between the methyl and hydroxy substituents [104.8(3)−106.2(4)°] and enlarged ones to the metal component [111.6(4)−115.5(3)°]. Triorganosilanols often show interesting hydrogen-bonded superstructures, forming chains,[35,36] tetramers[37] or dimers,[38−40] depending on the steric demand of the organic substituents. A few examples show that, as far as the formation of hydrogen bonds is concerned, the transition metal components show an effect analogous to that of organic substituents, the difference being that the acidity of the OH hydrogen atom is reduced and the basicity of the oxygen atom is increased.[16,22] Compound **2b**, because of the bulkiness of the metal component, prefers hydrogen-bonded "dimerization", indicated by an oxygen−oxygen distance of 2.889 Å. This arrangement is similar to that found in $C_5Me_5(OC)_2Ru-Si(o\text{Tol})_2OH$.[22]

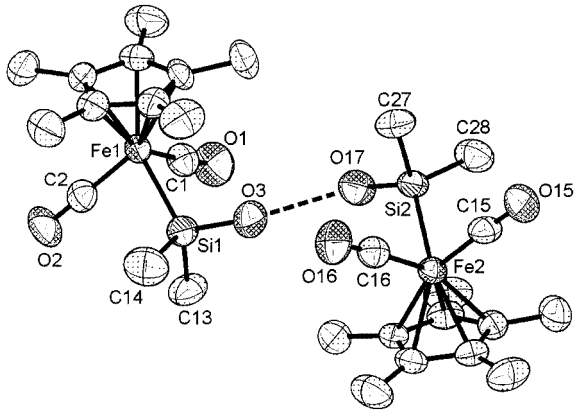


Figure 1. ORTEP Plot of **2b** (O···O bond is dashed); selected bond lengths [Å], angles [°] and torsion angles [°]: Fe1−C1 1.731(8), Fe1−C2 1.755(7), Fe1−Si1 2.313(2), O3−Si1 1.676(9), Si1−C14 1.864(7), Si1−C13 1.871(7), Fe2−C15 1.732(7), Fe2−C16 1.743(8), Fe2−Si2 2.319(2), Si2−O17 1.653(6), Si2−C28 1.864(7), Si2−C27 1.894(7); C1−Fe1−C2 98.3(3), C1−Fe1−Si1 83.1(2), C2−Fe1−Si1 84.1(2), O3−Si1−C14 105.2(5), O3−Si1−C13 106.2(4), C14−Si1−C13 104.9(4), O3−Si1−Fe1 111.6(4), C16−Fe2−C15 98.3(3), C15−Fe2−Si2 83.9(2), C16−Fe2−Si2 84.0(2), O17−Si2−C28 105.1(3), O17−Si2−C27 106.0(3), C28−Si2−C27 104.8(3), O17−Si2−Fe2 113.5(2), C28−Si2−Fe2 113.8(2), C27−Si2−Fe2 112.8(2); C1−Fe1−Si1−O3 74.0(4), C2−Fe1−Si1−O3 173.1(4), C15−Fe2−Si2−O17 −177.0(3), C16−Fe2−Si2−O17 −77.9(3)

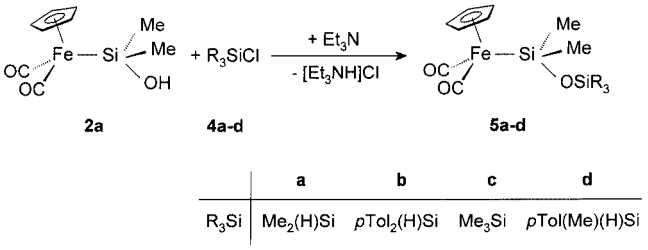
Due to their high stabilities with respect to self-condensation, the ferriosilanols **2a** and **2b** are excellent starting materials for further reactions. Among these, condensation with chlorosilanes is of special interest for investigation of the transition metal effect on the Si−O−Si bonding system and the γ-silicon atom of the resulting ferriodisiloxanes. Treatment of **2a** with the chloro(organo)silanes **4a**−**d** in Et_2O in the presence of the auxiliary base Et_3N at room temperature afforded the ferriodisiloxanes **5a**−**d** [34% (**5c**) to 95% (**5b**) yield] after 1−12 h, these compounds being isolated as pale yellow (**5c**) or orange (**5a**, **5b**, **5d**) oils displaying high solubility in benzene and *n*-pentane [Equation (2)].

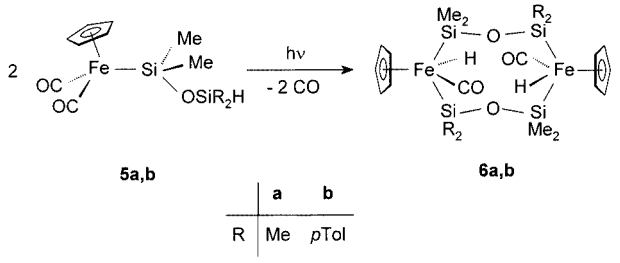
Compounds **5a** and **5d** were also obtained in the absence of triethylamine, but the reaction rate was significantly lower [70% (**5a**)/10% (**5d**) conversion after 7 d].

Comparison of the spectroscopic data of the ferriosilanol **2a** and of the ferriosiloxanes **5a**−**d** shows no significant effect concerning the $\nu(CO)_{sym}$ and $\nu(CO)_{asym}$ frequencies of the CO ligands, while for the ^{29}Si NMR resonance a high-field shift for the iron-bound silicon atom from δ = 66.05 ppm (**2a**) to δ = 58.73 (**5a**), 61.45 (**5b**) or 59.97 ppm (**5d**) is



(2)

found. The $\tilde{\nu}$(SiH) absorptions of **5a**, **5b** and **5d** (2123−2112 cm^{-1}) lie in the normal range of Si−H functional organosilanes or organosiloxanes, showing that the "transition metal effect" on the silicon atom in the γ-position is negligible. This finding implies that for these systems the known reactivity behaviour of Si−H-functional silanes − photoinduced oxidative addition of SiH functions to coordinatively unsaturated metal centres, for example, resulting in the formation of M(H)−Si units − may be expected.[5] Indeed, irradiation of **5a** and **5b** with UV light in cyclohexane for 7 h/20 h resulted in controlled CO elimination, followed by Si−H addition to the iron atom. The resulting eight-membered cyclic ferriodisiloxanes **6a** and **6b** were obtained as white (**6a**) and beige (**6b**) solids in 19% (**6a**) and 10% (**6b**) yields [Equation (3)].



(3)

The structures of **6a** and **6b** were confirmed by the Fe−H resonance in the ^{1}H NMR at δ = −13.31 (**6a**)/−12.54 ppm (**6b**), with ^2J(HFeSi) coupling constants of 23.6 (**6a**)/24.0 Hz (**6b**) excluding agostic FeHSi interaction.[5] In addition, the ^{29}Si{^{1}H} NMR spectra show singlets at δ = 45.11 (**6a**) and 46.71 (**6b**) ppm, indicating chemical equivalence of the methyl-substituted silicon atoms.

Intramolecular cyclization to the four-membered *cyclo*-ferradisiloxanes Cp(OC)(H)Fe-($SiMe_2OSiR_2$-κ^2-Si)[41−45] can be ruled out, as shown by the X-ray structure determination of **6b**. This type of siloxane is obviously disfavoured, due to high ring strain.

Figure 2 shows that **6b** can be regarded as deriving from the well-known cyclic organotetrasiloxanes by replacement of the oxygen atoms in the 1- and 5-positions with the isolobal iron fragment Cp(OC)(H)Fe.[46]

The Fe−Si bond lengths of 2.339(1) Å (Fe1−Si1) and 2.311(1) Å (Fe1−Si2) show the expected decrease on going from the methyl- to the tolyl-substituted metal−silicon unit

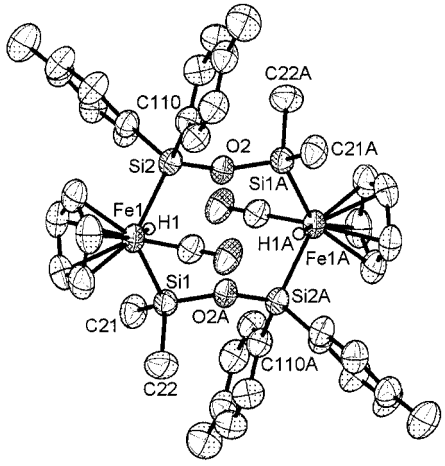


Figure 2. ORTEP Plot of **6b**; selected bond lengths [Å], angles [°] and torsion angles [°]: Fe1−Si1 2.339(1), Fe1−Si2 2.311(1), Fe1−H1 1.4644(5), Si1−O2A 1.636(2), Si2−O2 1.635(2), Si1−C21 1.868(4), Si2−C110 1.891(3); Si1−Fe1−Si2 109.43(4), Si2−Fe1−H1 55.88(3), Si1−Fe1−H1 62.03(3), C1−Fe1−H1 102.4(2), Si2−O2−Si1A 153.6(1), Fe1−Si1−O2A 110.81(9); Fe1−Si2−O2 111.75(9), Fe1−Si1−C21 116.0(2), C21−Si1−C22 107.5(3), Fe1−Si2−C110 114.4(1), Fe1−Si2−O2−Si1A −128.18(8), H1−Fe1−Si2−O2 −51.09(8), Si1−Fe1−Si2−O2 −18.29(7)

and lie within the range of known bis(silyl)iron complexes.[47,48] The Si−O distances [1.636 (Si1) and 1.635 Å (Si2)] are significantly shorter than those in four-membered *cyclo*-metalladisiloxanes {e.g., $(Ph_3P)_2$(OC)(H)Ir($SiMe_2O$-$SiMe_2$-κ^2-Si) [*d*(Si−O) = 1.690/1.678 Å][44] or (dppe)Pt(Si-Me_2OSiMe_2-κ^2-Si) [*d*(Si−O) = 1.693/1.689 Å][49]} and imply a partial double bond character for the Si−O bond.[50−55] The value of 153.6(1)° for the Si−O−Si angle is similar to that in cyclic organotetrasiloxanes.[32] The iron atoms show a pseudo-square-pyramidal arrangement, with the Cp ligand in the apical position and the two Si atoms at the tetragonal base arranged *trans* to each other [Si1−Fe1−Si2 109.43(4)°] as well as the CO and H ligands [C1−Fe1−H1 102.4(2)°]. The silicon atoms show distorted tetrahedral coordination with different Fe−Si−C angles depending on the nature of the organic ligand [114.4(1)/111.3(1)° Fe−Si−C(*p*Tol); 116.0(2)/109.2(2)° Fe−Si−C(Me)], with the Fe−Si−C(Me) angles showing stronger deviation from the ideal value.

For $(R_2SiO)_4$ rings a variety of conformations (C_i chair, C_2 boat, S_4 boat) has been found in the solid state,[32] with $(t Bu_2SiOSiMe_2O)_2$ representing an exception, due to the planarity of the ring.[56] The eight-membered $Fe_2Si_4O_2$ arrangement of **6b** adopts a chair conformation with both metal components bent in opposite directions out of the plane defined by the four silicon atoms (Figure 3). An identical situation holds for the oxygen atoms.

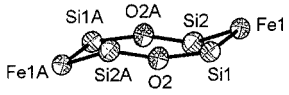

Figure 3. Chair conformation of the eight-membered ring of **6b**

Conclusions

The γ-SiH-functionalized ferriodisiloxanes presented in this paper proved to be synthetically valuable precursors for the simple synthesis of Si−O−Si-bridged homodinuclear iron complexes. Further investigation is currently being directed towards heteronuclear derivatives with metal complexes characterized by a high tendency towards oxidative addition of SiH functions, such as Pt or Ir. Another aspect concerns the introduction of hydroxy groups at the γ-silicon atom, giving access to metallosiloxanols. These compounds are of special interest for further condensation to afford transition metal fragment substituted oligosiloxanes. We regard these species as model compounds for catalytic systems immobilized on a silica surface.

Experimental Section

General Remarks: All reactions were performed under purified nitrogen. Solvents were dried by conventional procedures, distilled and saturated with N_2 prior to use. ^1H, $^{13}C\{^1H\}$ and $^{29}Si\{^1H\}$ NMR spectra were recorded with Jeol FX 90Q, Bruker AC 200 and Bruker AMX 400 spectrometers; $\delta(^{29}Si)$ chemical shifts are measured relative to external Me_4Si; $\delta(^1H)/(^{13}C)$ are reported downfield from Me_4Si, referenced to the residual proton signal (^1H) or natural-abundance carbon signal of C_6D_6 (^{13}C). Infrared spectra were recorded with a Perkin−Elmer 283 grating spectrometer. The solutions were measured in NaCl cells of 0.1 mm path length with a resolution of about 2 cm^{-1}. Melting points: differential thermal analysis (Du Pont 9000 Thermal Analysis System). Literature procedures were employed to synthesize $Cp(OC)_2Fe-SiMe_2Cl$ (**1a**)[57] and dimethyldioxirane.[58] $Me_2Si(H)Cl$ (**4a**), Me_3SiCl (**4c**), Et_3N and 18-crown-6 were obtained commercially and were distilled prior to use.

1. Chloro[dicarbonyl(η^5-pentamethylcyclopentadienyl)ferrio]dimethylsilane (1b): Me_2SiCl_2 (1680 mg, 13.03 mmol) was added to a suspension of $Na[Fe(CO)_2C_5Me_5]$ (880 mg, 3.26 mmol) in 50 mL of cyclohexane and the mixture was vigorously stirred for 40 h at room temperature. After filtration, the solvent was removed in vacuo, the red residue was extracted three times with 10 mL of *n*-pentane, and **1b** crystallized at −78 °C. Yield 410 mg (37%). Orange, microcrystalline powder. M.p. 96 °C. ^1H NMR (60 MHz, [D$_6$]benzene): δ = 1.60 [s, 15 H, $(H_3C)_5C_5$], 0.97 ppm (s, 6 H, H_3CSi). IR (*n*-pentane): $\tilde{\nu}$ = 1993 cm^{-1} (vs), 1941 (vs) [ν(CO)]. $C_{14}H_{21}ClFeO_2Si$ (340.74): calcd. C 49.35, H 6.23, Cl 10.40; found C 49.07, H 5.91, Cl 10.60.

2. [Dicarbonyl(η^5-pentamethylcyclopentadienyl)ferrio]dimethylsilane (3): The preparation was as described under 1., from $Na[Fe(CO)_2C_5Me_5]$ (700 mg, 2.59 mmol) and $Me_2Si(H)Cl$ (735 mg, 7.77 mmol) in 100 mL of cyclohexane (20 h). Further purification of **3** was performed by sublimation at 83−85 °C (10^{-2} Torr). Yield 420 mg (53%). Yellow, microcrystalline powder. M.p. 43 °C. ^1H NMR (60 MHz, [D$_6$]benzene): δ = 4.72 [sept, ^3J(HSiCH) = 3.6 Hz, 1 H, HSi], 1.50 [s, 15 H $(H_3C)_5C_5$], 0.62 ppm [d, ^3J(HCSiH) = 3.6 Hz, 6 H, $(H_3C)_2Si$]. $^{13}C\{^1H\}$ NMR (50 MHz, [D$_6$]benzene): δ = 217.27 (s, CO), 94.57 [s, $C_5(CH_3)_5$], 9.45 [s, $(CH_3)_5C_5$], 2.79 ppm [s, $(CH_3)_2Si$]. $^{29}Si\{^1H\}$ NMR (18 MHz, [D$_6$]benzene): δ = 28.36 ppm (s). IR (cyclohexane): $\tilde{\nu}$ = 2043 cm^{-1} [w, ν(SiH)], 1984 (vs), 1931 (vs) [ν(CO)]. $C_{14}H_{22}FeO_2Si$ (306.3): calcd. C 54.90, H 7.24; found C 54.72, H 6.95. MS (30 °C): *m*/*z* (%) = 306 (3) [M$^+$], 278 (36) [M − CO$^+$], 248 (26) [$C_5Me_5(CO)Fe$ − SiH$^+$], 191 (100) [$C_5Me_5Fe^+$].

3. [Dicarbonyl(η^5-cyclopentadienyl)ferrio]dimethylsilanol (2a): $Cp(OC)_2Fe-SiMe_2Cl$ (**1a**, 256 mg, 0.96 mmol), dissolved in 25 mL of Et_2O, was treated with Et_3N (144 mg, 1.44 mmol) and H_2O (100 mg, 5.55 mmol). After 45 min of stirring at room temperature, the precipitate of $[Et_3NH]Cl$ was separated, the orange solution was concentrated to dryness, and the resulting ferriosilanol was washed five times with 2 mL of *n*-pentane and dried in vacuo. Yield 215 mg (89%). Light yellow, microcrystalline powder. M.p. 45 °C (decomp.). ^1H NMR (200 MHz, [D$_6$]benzene): δ = 4.27 (s, 5 H, H_5C_5), 1.77 (br. s, 1 H, HO), 0.70 ppm (s, 6 H, H_3C). $^{29}Si\{^1H\}$ NMR (18 MHz, [D$_6$]benzene): δ = 66.05 ppm (s). IR (cyclohexane): $\tilde{\nu}$ = 3690 cm^{-1} [br, w, ν(OH)], 1998 (s), 1947 (vs) [ν(CO)]. $C_9H_{12}FeO_3Si$ (252.13): calcd. C 42.88, H 4.80; found C 42.14, H 4.79.

4. Synthesis of 2a in the Absence of an Auxiliary Base: H_2O (1000 mg, 55.6 mmol) was added to a solution of $Cp(OC)_2Fe-SiMe_2Cl$ (**1a**, 270 mg, 1.00 mmol) in Et_2O (20 mL). After 2 h of stirring at room temperature, the organic layer was separated and concentrated in vacuo. The resulting **2a** was washed twice with 2 mL of *n*-pentane and dried in vacuo. Yield 242 mg (96%).

5. [Dicarbonyl(η^5-pentamethylcyclopentadienyl)ferrio]dimethylsilanol (2b): The preparation was as described under 3., from $C_5Me_5(OC)_2Fe-SiMe_2Cl$ (**1b**, 235 mg, 0.69 mmol), H_2O (12 mg, 0.69 mmol) and Et_3N (730 mg, 7.2 mmol) (48 h). Yield 155 mg (70%). Yellow microcrystalline powder. M.p. 72 °C (decomp.). ^1H NMR (400 MHz, [D$_6$]benzene): δ = 1.55 [s, 15 H, $(H_3C)_5C_5$], 1.02 (s, 1 H, HO), 0.67 ppm [s, 6 H, $(H_3C)_2Si$]. $^{13}C\{^1H\}$ NMR (101 MHz, [D$_6$]benzene): δ = 217.62 (s, CO), 95.13 [s, $C_5(CH_3)_5$], 9.96 [s, $(CH_3)_2Si$], 9.80 ppm [s, $(CH_3)_5C_5$]. $^{29}Si\{^1H\}$ NMR (80 MHz, [D$_6$]benzene): δ = 66.83 ppm (s). IR (toluene): $\tilde{\nu}$ = 3629 cm^{-1} [w, br, ν(OH)], 1979 (vs), 1922 (vs) [ν(CO)]. $C_{14}H_{22}FeO_3Si$ (322.26): calcd. C 52.18, H 6.88; found C 52.63, H 7.15.

6. Synthesis of 2b by Oxygenation of $C_5Me_5(OC)_2Fe-SiMe_2H$ (3) with Dimethyldioxirane: A solution of dimethyldioxirane in acetone (0.10 M, 10 mL) was added dropwise at −78 °C to a solution of $C_5Me_5(OC)_2Fe-SiMe_2H$ (**3**, 265 mg, 0.87 mmol) in 20 mL of toluene. After 1 h of stirring, the mixture was allowed to warm to room temperature and the solvent was evaporated in vacuo. The orange residue was extracted with 10 mL of *n*-pentane, and **2b** crystallized at −78 °C. Yield 100 mg (36%).

7. Chlorobis(4-methylphenyl)silane (4b): A Grignard solution, freshly prepared from Mg (2.43 g, 0.1 mol) and 4-bromotoluene (1.71 g, 0.1 mol) in 50 mL of diethyl ether, was added dropwise over 1 h to a cooled solution (0 °C) of $HSiCl_3$ (6.77 g, 0.05 mol) in 100 mL of Et_2O. After the mixture had been stirred for 1 h at room temperature, the precipitate was filtered off and the resulting dark brown, oily residue was fractionally distilled. Yield 12.69 g (51%). Colourless liquid. B.p. 105−107 °C/0.01 Torr. ^1H NMR (60 MHz, [D$_6$]benzene): δ = 7.53 [d, $^3J_{HCCH}$ = 8.0 Hz, 4 H, H-3/5 of H_4C_6], 6.97 [d, $^3J_{HCCH}$ = 8.0 Hz, 4 H, H-2/6 of H_4C_6], 5.90 (s, 1 H, HSi), 1.92 ppm (s, 6 H, H_3C). IR (cyclohexane): $\tilde{\nu}$ = 2159 cm^{-1} [s, ν(SiH)].

8. 1-[Dicarbonyl(η^5-cyclopentadienyl)ferrio]-1,1,3,3-tetramethyldisiloxane (5a)

a) From $Cp(OC)_2Fe-SiMe_2OH$ (2a), $Me_2Si(H)Cl$ (4a) and Et_3N: A solution of $Cp(OC)_2Fe-SiMe_2OH$ (**2a**, 224 mg, 0.89 mmol) in 20 mL of Et_2O was treated with Et_3N (101 mg, 1.00 mmol) and $Me_2Si(H)Cl$ (**4a**, 308 mg, 2.84 mmol). After the mixture had been stirred for 1 h at room temperature, the precipitate of $[Et_3NH]Cl$

was filtered off and all volatiles were removed in vacuo. The red oily residue was extracted with 3 mL of *n*-pentane, the solvent was removed, and **5a** was dried in vacuo. Yield 218 mg (79%).

b) From $Cp(OC)_2Fe-SiMe_2OH$ (2a), NaH and $Me_2Si(H)Cl$ (4a): A cooled solution (−78 °C) of $Cp(OC)_2Fe-SiMe_2OH$ (**2a**, 100 mg, 0.40 mmol) in 10 mL of toluene was treated with NaH (10 mg, 0.40 mmol) and 18-crown-6 (10 mg) and stirred for 30 min. After addition of $Me_2Si(H)Cl$ (**4a**, 47 mg, 0.50 mmol) the mixture was allowed to warm to room temperature and stirred for another 10 min. After filtration through a Celite pad, the solvent was removed and **5a** was washed at −78 °C with 3 mL of *n*-pentane and dried in vacuo. Yield 104 mg (84%). Orange oil. M.p. −37 °C. ^{1}H NMR (400.1 MHz, [D$_6$]benzene): δ = 5.04 [sept, ^3J(HSiCH) = 2.7, $^1J_{SiH}$ = 202.0 Hz, 1 H, HSi], 4.12 (s, 5 H, H_5C_5), 0.63 (s, 6 H, H_3CSiFe), 0.23 ppm [d, ^3J(HSiCH) = 2.7 Hz, 6 H, H_3CSiH]. ^{29}Si{^{1}H} NMR (79.5 MHz, [D$_6$]benzene): δ = 58.73 (s, SiFe), −8.27 ppm (s, SiH). IR (*n*-pentane): $\tilde{\nu}$ = 2117 cm^{-1} [w, ν(SiH)], 1998 (s), 1957 (vs) [ν(CO)]. $C_{11}H_{18}FeO_3Si_2$ (310.28): calcd. C 42.58, H 5.85; found C 42.29, H 5.82.

9. 1-[Dicarbonyl(η^5-cyclopentadienyl)ferrio]-1,1-dimethyl-3,3-bis(4-methylphenyl)disiloxane (5b): The preparation was as described under 8a., from $Cp(OC)_2Fe-SiMe_2OH$ (**2a**, 699 mg, 2.77 mmol), Et_3N (722 mg, 7.14 mmol) and $(p\text{Tol})_2Si(H)Cl$ (**4b**, 1026 mg, 4.16 mmol) in 60 mL of diethyl ether (5 h). Yield 1214 mg (95%). Orange oil. M.p. −20 °C. ^{1}H NMR (400.1 MHz, [D$_6$]benzene): δ = 7.69 [d, $^3J_{HCCH}$ = 6.8 Hz, 2 H, H-3/H-5 of H_4C_6], 7.07 [d, $^3J_{HCCH}$ = 6.8 Hz, 2 H, H-2/H-6 of H_4C_6], 5.87 [s, $^1J_{SiH}$ = 211.3 Hz, 1 H, HSi], 4.13 (s, 5 H, H_5C_5), 2.11 (s, 6 H, $H_3CC_6H_4$), 0.71 ppm (s, 6 H, H_3CSi). ^{13}C{^{1}H} NMR (100.6 MHz, [D$_6$]benzene): δ = 215.42 (s, CO), 140.00 (s, C-1 of C_6H_4), 134.76 (s, C-3/C-5 of C_6H_4), 133.48 (s, C-4 of C_6H_4), 129.11 (s, C-2/C-6 of C_6H_4), 83.64 (s, C_5H_5), 21.52 (s, $CH_3C_6H_4$), 11.08 ppm (s, CH_3Si). ^{29}Si{^{1}H} NMR (79.5 MHz, [D$_6$]benzene): δ = 61.45 (s, SiFe), −22.76 ppm [s, Si(*p*Tol)$_2$H]. IR (*n*-pentane): $\tilde{\nu}$ = 2123 cm^{-1} [w, ν(SiH)], 2000 (vs), 1949 (vs) [ν(CO)], 1252 [vw, ν(SiCH$_3$)], 1042 [m, br, ν_{as}(-SiOSi)], 597 [s, ν_s(SiOSi)]. $C_{23}H_{26}FeO_3Si_2$ (462.474): calcd. C 59.73, H 5.67; found C 59.84, H 5.80.

10. 1-[Dicarbonyl(η^5-cyclopentadienyl)ferrio]-1,1,3,3,3-pentamethyldisiloxane (5c): The preparation was as described under 8a., from $Cp(OC)_2Fe-SiMe_2OH$ (**2a**, 366 mg, 1.43 mmol), Et_3N (211 mg, 2.09 mmol) and Me_3SiCl (**4c**, 244 mg, 2.25 mmol) in 15 mL of Et_2O (12 h). Further purification of **5c** was performed by distillation at 50 °C (10^{-4} Torr). Yield 153 mg (34%). Pale yellow oil. M.p. −32 °C. ^{1}H NMR (60 MHz, [D$_6$]benzene): δ = 4.21 (s, 5 H, H_5C_5), 0.63 [s, 6 H, $(H_3C)_2SiFe$], 0.19 ppm [s, 9 H, $(H_3C)_3Si$]. ^{29}Si{^{1}H} NMR (79.5 MHz, [D$_6$]benzene): δ = 55.50 (s, SiFe), 5.44 ppm (s, $SiMe_3$). IR (benzene): $\tilde{\nu}$ = 1994 cm^{-1} (vs), 1936 (vs) [ν(CO)]. $C_{12}H_{20}FeO_3Si_2$ (324.31): calcd. C 44.44, H 6.22; found C 44.90, H 5.77. MS: *m*/*z* = 324 [M$^+$].

11. 1-[Dicarbonyl(η^5-cyclopentadienyl)ferrio]-1,1,3-trimethyl-3-(4-methylphenyl)disiloxane (5d): The preparation was as described under 8a., from $Cp(OC)_2Fe-SiMe_2OH$ (**2a**, 302 mg, 1.20 mmol), Et_3N (203 mg, 2.01 mmol) and *p*Tol(Me)Si(H)Cl (**4d**, 420 mg, 2.46 mmol) in 20 mL of Et_2O (1 h). Further purification of **5d** was performed by column chromatography (20 × 2 cm, Al_2O_3, activity IV, cyclohexane). Yield 270 mg (70%). Orange oil. M.p. 4 °C. ^{1}H NMR (60 MHz, [D$_6$]benzene): δ = 7.64 [d, $^3J_{HCCH}$ = 8.5 Hz, 2 H, H-3/5 of H_4C_6], 7.12 [d, $^3J_{HCCH}$ = 8.5 Hz, 2 H, H-2/6 of H_4C_6], 5.47 [q, ^3J(HSiCH) = 2.8, $^1J_{SiH}$ = 207.0 Hz, 1 H, HSi], 4.08 (s, 5 H, H_5C_5), 2.10 (s, 3 H, $H_3CC_6H_4$), 0.68, 0.67 (2 s, 6 H, H_3CSiFe), 0.49 ppm [d, ^3J(HSiCH) = 2.8 Hz, 3 H, H_3CSiH]. ^{13}C{^{1}H} NMR (50 MHz, [D$_6$]benzene): δ = 215.49 (s, CO), 139.75 (s, C-1 of C_6H_4), 134.98 (s, C-4 of C_6H_4), 133.91 (s, C-2/6 of C_6H_4), 129.06 (s, C-3/5 of C_6H_4), 83.55 (s, C_5H_5), 21.48 (s, $CH_3C_6H_4$), 11.03 (s, CH_3SiFe), 1.02 ppm (s, CH_3SiH). ^{29}Si{^{1}H} NMR (18 MHz, [D$_6$]benzene): δ = 59.97 (s, SiFe), −15.39 ppm (s, SiH). IR (cyclohexane): $\tilde{\nu}$ = 2112 cm^{-1} [w, ν(SiH)], 1999 (s), 1947 (vs) [ν(CO)]. $C_{17}H_{22}FeO_3Si_2$ (386.38): calcd. C 52.85, H 5.74; found C 52.17, H 5.78.

12. Treatment of $Cp(OC)_2Fe-SiMe_2OH$ (2a) with $Me_2Si(H)Cl$ (4a) or *p*Tol(Me)Si(H)Cl (4d) in the Absence of an Auxiliary Base: A solution of $Cp(OC)_2Fe-SiMe_2OH$ (**2a**, 151 mg, 0.60 mmol) and either $Me_2Si(H)Cl$ (**4a**, 300 mg, 3.17 mmol) or *p*Tol(Me)Si(H)Cl (**4d**, 258 mg, 1.51 mmol) in 15 mL of Et_2O was stirred at room temperature. After 7 d, conversion into **5a/5d** was 70%/10% complete.

13. Bis(μ-1,1,3,3-tetramethyldisiloxane-1,3-diyl)bis[carbonyl(η^5-cyclopentadienyl)hydridoiron(IV)] (6a): A solution of $Cp(OC)_2Fe-SiMe_2OSiMe_2H$ (**5a**, 581 mg, 1.87 mmol) in 40 mL of cyclohexane was irradiated with UV light (quartz lamp TQ 718, 700 W, Hanau) for 7 h. After removal of the solvent in vacuo, the residue was purified by column chromatography (20 × 1 cm, silica gel, 0.063−0.2 mm, 20 °C, cyclohexane/benzene, 2:1). The eluate from the yellow zone was concentrated to dryness, the residue was stirred with 2 mL of ice-cold *n*-pentane, and the precipitate of **6a** separated and dried in vacuo. Yield: 100 mg (19%). White microcrystalline powder. M.p. 126 °C (decomp.). ^{1}H NMR (60 MHz, [D$_6$]benzene): δ = 3.94 (s, 10 H, H_5C_5), 0.80 (s, 12 H, H_3C), 0.65 (s, 12 H, H_3C), −13.31 ppm [s, ^2J(HFeSi) = 23.6 Hz, 2 H, HFe]. ^{13}C{^{1}H} NMR (50 MHz, [D$_6$]benzene): δ = 212.98 (s, CO), 82.46 (s, C_5H_5), 13.37 (s, CH_3), 12.97 ppm (s, CH_3). ^{29}Si{^{1}H} NMR (18 MHz, [D$_6$]benzene): δ = 45.31 ppm (s). IR (cyclohexane): $\tilde{\nu}$ = 1955 cm^{-1} [vs, ν(CO)], 1257 (m), 1247 (m) [ν(SiCH$_3$)], 1070 (s), 1065 (m, sh) [ν_{as}(-SiOSi)], 576 (m), 565 (m) [ν_s(SiOSi)]. $C_{20}H_{36}Fe_2O_4Si_4$ (564.542): calcd. C 42.55, H 6.43; found C 42.24, H 6.50.

14. Bis[μ-1,1-dimethyl-3,3-bis(4-methylphenyl)disiloxane-1,3-diyl]-bis[carbonyl(η^5-cyclopentadienyl)hydridoiron(IV)] (6b): The preparation was as described under 13., from $Cp(OC)_2Fe-SiMe_2OSi(p\text{Tol})_2H$ (**5b**, 998 mg, 2.16 mmol) in 40 mL of cyclohexane (20 h). Crystallization of **6b** occurred at −78 °C in *n*-pentane. Yield: 90 mg (10%). Beige, microcrystalline powder. M.p. 179 °C (decomp.). ^{1}H NMR (60 MHz, [D$_6$]benzene): δ = 8.01, 7.90 [2 d, $^3J_{HCCH}$ = 7.7/7.6 Hz, 8 H, H-3/H-5 of H_4C_6], 7.25, 7.19 [2 d, $^3J_{HCCH}$ = 7.6/7.7 Hz, 8 H, H-2/H-6 of H_4C_6], 3.93 (s, 10 H, H_5C_5), 2.26, 2.19 (2 s, 12 H, $H_3CC_6H_4$), 0.70, 0.63 (2 s, 12 H, H_3C), −12.54 ppm [s, ^2J(HFeSi) = 24.0 Hz, 2 H, HFe]. ^{13}C{^{1}H} NMR (50 MHz, [D$_6$]benzene): δ = 213.17 (s, CO), 142.97, 142.22 (2 s, C-1 of C_6H_4), 138.14, 138.03 (2 s, C-4 of C_6H_4), 135.38, 134.61 (2 s, C-3/C-5 of C_6H_4), 128.72, 128.37 (2 s, C-2/C-6 of C_6H_4), 83.99 (s, C_5H_5), 21.47, 21.43 (2 s, $CH_3C_6H_4$), 13.57, 13.17 ppm (2 s, CH_3Si). ^{29}Si{^{1}H} NMR (18 MHz, [D$_6$]benzene): δ = 46.71 ppm [s, $Si(CH_3)_2$], Si(*p*Tol)$_2$ signal not detected. IR (cyclohexane): $\tilde{\nu}$ = 1956 cm^{-1} (vs), 1945 (m, sh) [ν(CO)], 1258 [m, br, ν(SiCH$_3$)], 1051 (s, br), 1020 (m, br) [ν_{as}(SiOSi)], 574 (m), 565 (w) [ν_s(SiOSi)]. $C_{44}H_{52}Fe_2O_6Si_2$ (868.929): calcd. C 60.82, H 6.03; found C 60.85, H 5.88.

15. X-ray Crystal Structure Determination of 2b: Colourless crystals of **2b** suitable for X-ray diffraction were grown by slow diffusion of *n*-pentane into a benzene solution of **2b** at room temperature. Crystal data: $C_{28}H_{44}Fe_2O_6Si_2$, *M* = 644.52, monoclinic, space group $P2_1$ (no. 5), *a* = 9.042(10) Å, *b* = 13.941(5) Å, *c* = 13.125(9) Å, β = 104.14(4)°, *V* = 1604.2(22) Å^3, *Z* = 4, $d_{calcd.}$ = 1.334

g·cm^{-3}, CAD4 diffractometer (Enraf−Nonius), radiation type: Mo-K_α, wavelength: λ = 0.71073 Å, graphite monochromator, crystal size: 0.19 × 0.10 × 0.07 mm, temperature: 293 K, ω/Θ-scan, scale range: 1.60° < Θ < 22.50°, $F(000)$ = 680, total reflections: 2373, independent reflections: 2211 with $I > 2.0\sigma(I)$, absorption coefficient: μ = 1.018 mm^{-1}, empirical absorption correction ($T_{min.}/T_{max.}$ = 0.8779/0.9978), structure solution: SHELXS-86[59] by direct methods, structure refinement: SHELXL-93[60] (369 parameters), R_1 = 0.0293, wR_2 = 0.0683. The positions of the OH hydrogen atoms were located and isotropically refined, while the remaining hydrogen atoms were geometrically positioned and subsequently refined with a riding model. CCDC-158196 contains the supplementary crystallographic data for this compound. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

16. X-ray Crystal Structure Determination of 6b: Pale yellow crystals of **6b** suitable for X-ray diffraction were grown by slow diffusion of *n*-pentane into a toluene solution of **6b** at −35 °C. Crystal data: $C_{26}H_{31}FeO_2Si_2$, M = 487.54, triclinic, space group: $P\bar{1}$ (no. 2), a = 8.882(3) Å, b = 9.241(6) Å, c = 15.243(9) Å, α = 87.423(12)°, β = 79.07(2)°, γ = 86.49(2)°, V = 1225.5(11) Å^3, Z = 2, $d_{calcd.}$ = 1.321 g·cm^{-3}, CAD4 diffractometer (Enraf−Nonius), radiation type: Mo-K_α, wavelength: λ = 0.71073 Å, graphite monochromator, crystal size: 0.50 × 0.40 × 0.20 mm, temperature: 293 K, ω/Θ-scan, scale range: 2.20° < Θ < 26.91°, $F(000)$ = 514, total reflections: 5545, independent reflections: 4314 with $I > 2\sigma(I)$, absorption coefficient: μ = 0.735 mm^{-1}, empirical absorption correction (T_{min}/T_{max} = 0.9433/0.9965), structure solution: SHELXS-86[59] by direct methods, structure refinement: SHELXL-93[60] (371 parameter), R_1 = 0.0405, wR_2 = 0.1189. The positions of all hydrogen atoms except those of the *p*Tol methyl groups were located and isotropically refined, while the remaining hydrogen atoms were geometrically positioned and subsequently refined with a riding model. In addition, one toluene molecule with a disordered CH_3 group was found in the unit cell. CCDC-158197 contains the supplementary crystallographic data for this compound. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structural Characterization and Reactivity of the (Ferriomethyl)silanols $C_5R_5(OC)_2Fe-CH_2-SiMe(R')OH$ (R = H, Me; R′ = Me, Ph)[‡]

Wolfgang Malisch,*[a] Marco Hofmann,[a] Martin Nieger,[b] Wolfgang W. Schöller,[c] and Andreas Sundermann[c]

Keywords: Silicon / Iron / Oxygenation / (Metalloalkyl)silanols / Density functional calculations

The novel (ferriomethyl)-substituted silanols $C_5R_5(OC)_2Fe–CH_2–SiMe(R')OH$ [R = H, R′ = Me (**4a**), Ph (**4b**); R = Me, R′ = Me (**4c**)] are obtained by hydrolysis of the chloro(ferriomethyl)silanes $C_5R_5(OC)_2Fe–CH_2–SiMe(R')Cl$ [R = H, R′ = Me (**3a**), Ph (**3b**); R = Me, R′ = Me (**3c**)] in the presence of Et_3N. Another access to this class of compounds is offered by the oxygenation of Si–H-functional (ferriomethyl)silanes with dimethyldioxirane, as shown for **4a** by the oxo-functionalization of the (ferriomethyl)silane $Cp(OC)_2Fe–CH_2–SiMe_2H$ (**3d**). **4a–c** have been characterized spectroscopically and by X-ray structure analyses showing the formation of tube- or chain-like arrangements in the solid state caused by hydrogen bonding. In addition, the bonding situation in the related (ferriomethyl)silanol $Cp(OC)_2Fe–CH_2–SiH_2OH$ has been analyzed on the basis of density functional calculations. **4a** shows self-condensation to give the 1,3-bis(ferriomethyl)disiloxane $[Cp(OC)_2Fe–CH_2–SiMe_2]_2O$ (**5**), which is also obtained by the reaction of **4a** with **3a**. Analogous treatment of **4a** with the chloro(organo)silanes R(R′)Si(Me)Cl (R = H, R′ = Me, *p*-Tol; R = R′ = Me) yields the monometalated disiloxanes $Cp(OC)_2Fe–CH_2–Si(Me)_2OSi(Me)(R)R'$ [R = H, R′ = Me (**6a**), *p*-Tol (**6b**); R = R′ = Me (**6c**)].

Introduction

Transition metal substituted siloxanes represent attractive model compounds for catalytically active transition metal complexes anchored on silica surfaces.[2–5] They offer an opportunity to determine the reaction mechanisms of heterogeneous catalyzed reactions on a molecular level in order to improve the selectivity, activity and lifetime of a heterogeneous catalyst. As a consequence many of those model compounds have been synthesized in the last few years often starting from stable organosilanetriols[6–10] or incompletely condensed silsesquioxanes[11–18] which can react with various metal complexes resulting in the formation of metallosiloxanes with the structural unit $L_nM-O-Si$, i.e. a silanolate ligand sphere around the transition metal centre.

Another approach to transition metal substituted siloxanes involves the synthesis of metallosilanols of the general type $L_nM-Si(R)_{3-n}(OH)_n$ (n = 1–3)[19–34] and their extensive condensation with chlorosilanes giving access to metallosiloxanes with a direct metal–silicon bond. In this context, metallosilanols containing the metal fragments $C_5R_5(OC)_2(Me_3P)M$ (M = Mo, W; R = H, Me),[19–24] $C_5R_5(OC)_2M$ (M = Fe, Ru; R = H, Me),[23–27] $(Ph_3P)_2(OC)(Cl)Os$,[28] $(OC)_5Cr$,[29] (dcpe)(Ph)Pt,[30] $(Et_3P)_2(Cl)(H)Ir$[33] and $Cp_2(H)Mo$[34] have been realized. Due to the strong electron-releasing effect of the metal fragment the acidity of the Si–OH proton and the tendency towards self-condensation are strongly decreased. This situation offers the possibility of isolating metal derivatives with an $Si(OH)_3$ unit,[20,28] which are synthetically useful for the generation of well-defined metallosiloxanes by controlled co-condensation processes.

In recent years, two routes – hydrolysis of chloro(metallo)silanes in the presence of an auxiliary base[23–25] and oxo-functionalization of hydrido(metallo)silanes with the mild oxidizing agent dimethyldioxirane[31,32,35–37] – proved to be most efficient for the generation of metallosilanols. The electrophilic oxygen insertion is especially productive for metallosilanes with electron-rich Si–H bonds provided by metal fragments with high donor capacity. For these sys-

tems the hydrolysis of the analogous chloro(metallo)silanes fails since the electrophilicity of the silicon atom is too weak.

Our interest has now turned to silanols having the Si−OH moiety separated from the metal fragment by a methylene group in order to check the "transition metal effect" on silanol units that are not directly bound to the transition metal atom. The spacer group should also help to suppress undesirable decomposition reactions involving "β-hydrogen abstraction" from the Si−OH group, observed for ferriosilanols of the type $Cp(OC)_2Fe-Si(R)(R')OH$ (R, R′ = alkyl, aryl).[38]

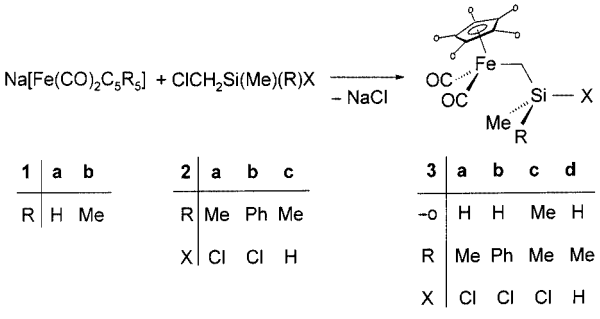
Although the Me_3SiCH_2 ligand has found wide application in transition metal chemistry due to its inertness with respect to β-hydride abstraction,[39−41] only a few examples exist in the literature with a silylmethyl ligand having one or more functional groups at the silicon atom.[42−52] These compounds have been used as precursors in the synthesis of silene transition metal complexes, which were originally proposed by Pannell[42] as intermediates in the β-elimination reaction of $Cp(OC)_2Fe-CH_2-SiMe_2H$ and were spectroscopically observed by Wrighton et al. by low-temperature near-UV photolysis of $C_5R_5(OC)_3W-CH_2-SiMe_2H$ (R = H, Me)[46] and $C_5Me_5(OC)_2Fe-CH_2-SiMe_2H$.[47] The chloro-functional (silylmethyl)tungsten complex $Cp_2W(Cl)-CH_2-SiMe_2Cl$ has been used by Berry et al. to generate a stable silene transition metal complex by reductive dechlorination with magnesium.[48]

No attempts so far have been made to generate or isolate any (metallomethyl)-substituted silanols from these silicon-functional complexes. Here we report on the synthesis of the first (ferriomethyl)-substituted silanols bearing a methylene group between the silanol and the iron fragment.

Results and Discussion

Synthesis of Si−Cl- and Si−H-Functional (Ferriomethyl)silanes (3a−d)

The chloro-functional (ferriomethyl)silanes $C_5R_5(OC)_2Fe-CH_2-SiMe(R')Cl$ [R = H, R′ = Me (**3a**), Ph (**3b**); R = Me, R′ = Me (**3c**)] are obtained by nucleophilic metallation of the organosilanes $ClCH_2SiMe(R')Cl$ [R′ = Me (**2a**); Ph (**2b**)] with the sodium ferrates $Na[Fe(CO)_2C_5R_5]$ [R = H (**1a**), Me (**1b**)] in THF or cyclohexane after reaction periods of 16−36 h at room temperature (Scheme 1).[53] The heterogeneous method using cyclohexane as a solvent proved to be advantageous over the homogeneous one using THF because of the formation of considerable amounts of undesirable by-products in the latter case.



Scheme 1. Synthesis of the (ferriomethyl)silanes **3a−d**

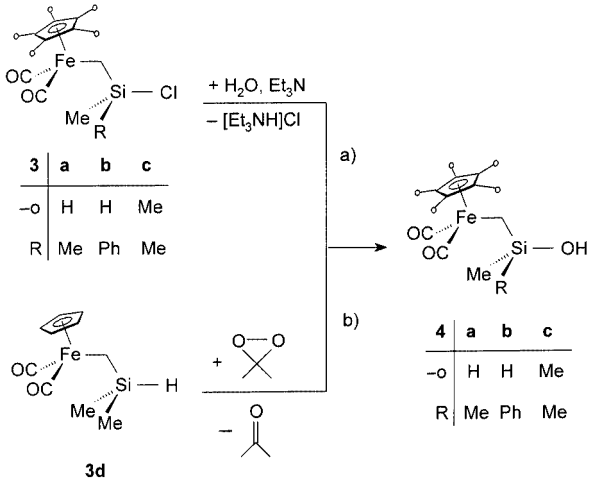
In the synthesis of **3a**,**b** metallation of **2a**,**b** occurs primarily at the silicon atom. The initially formed ferriosilanes $Cp(OC)_2Fe-SiMe(R')(CH_2Cl)$ [R′ = Me (**3a′**), Ph (**3b′**)] can be subsequently converted into the chloro(ferriomethyl)-silanes **3a**,**b** by thermal rearrangement at 120 °C. In the case of **3a** this rearrangement is nearly quantitative after 1 h,[44,45] whereas in the other case a mixture of the two isomers is produced after heating for 3 h (**3b**/**3b′** ≈ 80:20), from which **3b** can be separated by crystallization at −78 °C from *n*-pentane. Prolonged heating and a higher temperature lead to extensive decomposition of **3b**.

In the metallation of **2a** with the pentamethylcyclopentadienyl-substituted ferrate **1b** no isomer of **3c** is detected; **3c** is obtained directly at room temperature after appropriate workup in a moderate yield of 33% due to the formation of considerable amounts of $C_5Me_5(OC)_2Fe-Cl$, which are removed by repeated fractional crystallization at −20 °C.

The Si−H-functional (ferriomethyl)silane **3d** is obtained analogously by nucleophilic metallation of $ClCH_2SiMe_2H$ (**2c**) with **1a** in THF.[42,43]

Synthesis of (Ferriomethyl)silanols (4a−c)

The (ferriomethyl)silanol $Cp(OC)_2Fe-CH_2-SiMe_2OH$ (**4a**) is available by hydrolysis of **3a** in diethyl ether in the presence of the auxiliary base Et_3N. It can be isolated after 2 h at room temperature in 89% yield (Scheme 2, route a). A second approach to **4a** involves oxygenation of **3d** with dimethyldioxirane in acetone after 2 h (−78 °C to room temp.) in 67% yield (Scheme 2, route b). The oxygenation route guarantees a more convenient workup procedure but proved to be inferior to the hydrolysis route with respect to the lower yield of the resulting silanol **4a**, presumably due to oxidative decomposition reactions at the metal fragment.



Scheme 2. Synthesis of the (ferriomethyl)silanols **4a−c** by hydrolysis or oxygenation

For the synthesis of the (ferriomethyl)silanols $C_5R_5(OC)_2Fe-CH_2-Si(Me)(R')OH$ [R = H, R′ = Ph (**4b**); R = Me, R′ = Me (**4c**)] only the hydrolysis route (Scheme 2, route a) has been applied; **4b**,**c** can be isolated after reaction periods of 4 h at room temperature in the presence of Et_3N in yields of 74% (**4b**) and 40% (**4c**), respectively.

The (ferriomethyl)silanols **4a**−**c** are obtained as slightly air-sensitive yellow-brown waxy solids [m.p. 38 °C (**4a**), to 89 °C (**4c**)], which show good solubility in diethyl ether and aromatic solvents like benzene and toluene and are rather soluble even in aliphatic solvents like *n*-pentane. They are characterized in the IR spectrum by the OH stretching band at $\tilde{\nu}$ = 3698 cm^{-1} (**4a**), 3682 cm^{-1} (**4b**) and 3703 cm^{-1} (**4c**) (*n*-pentane solution), and in the ^1H NMR spectrum (C_6D_6) by a broad signal for the hydroxy proton at δ = 0.95 (**4a**), 1.28 (**4b**) and 0.92 (**4c**) ppm. The characteristic upfield signal of the CH_2 protons is detected at δ = −0.42 (**4a**) and −0.62 (**4c**) ppm. In the case of **4b**, the asymmetric silicon atom leads to diastereotopic CH_2 protons which are detected as pair of doublets at δ = −0.09 and −0.38 ppm. In the ^{13}C NMR spectra the signals for the CH_2 group are observed between δ = −12.4 (**4c**) and −24.5 (**4b**) ppm. The chemical shifts in the ^{29}Si NMR spectra [δ = 21.8 (**4a**), 11.7 (**4b**), 21.1 (**4c**) ppm] reveal a decreased influence of the transition metal fragment on the silicon atom in the β-position. For example, in the case of **4a**, the signal is shifted by approximately 44 ppm to a higher field compared with its counterpart $Cp(OC)_2Fe-SiMe_2OH$ (δ = 66.1 ppm)[1] without a methylene bridge.

X-ray Analyses of 4a−c

Final evidence for the structural assignments of **4a**−**c** is given by single-crystal X-ray structure determinations (Figures 1−3). In the case of **4a**, two crystallographically independent molecules have been found in the asymmetric unit.

The crystal structures of **4a**−**c** reveal a pseudo-octahedral coordination sphere at the iron atom, indicated by the ligand−iron−ligand angles close to 90°. The largest one is in all cases found between the carbonyl carbon atoms lying between 97.52(9)° (**4c**) and 93.15(7)° (**4a**), while the angles between the methylene carbon atom and the CO ligands are slightly smaller [92.00(8)° (**4c**), to 85.94(7)° (**4a**)].

The conformation along the iron−methylene bond reveals a distorted staggered pseudo-ethane arrangement. In the case of **4a**,**b** the SiR_3 substituent adopts a nearly "*anti*" position to one of the CO groups [C2−Fe1−C8−Si1 164.21(11)/150.30(11)° (**4a**), −161.32(11)° (**4b**)] and is positioned between the cyclopentadienyl and the other carbonyl ligand, but as the dihedral angles indicate in the case of **4a**, that a major difference exists concerning the orientation in the two different molecules of the asymmetric unit (see also below).

Looking at **4c**, the silanol group is positioned between the two carbonyl ligands [C1B−Fe1−C11−Si1 41.70(12)°; C1A−Fe1−C11−Si1 −55.91(12)°] in a mutually "*anti*" position to the pentamethylcyclopentadienyl group, which is in sharp contrast to **4a**,**b** and probably a consequence of the higher steric demand of the C_5Me_5 ligand.

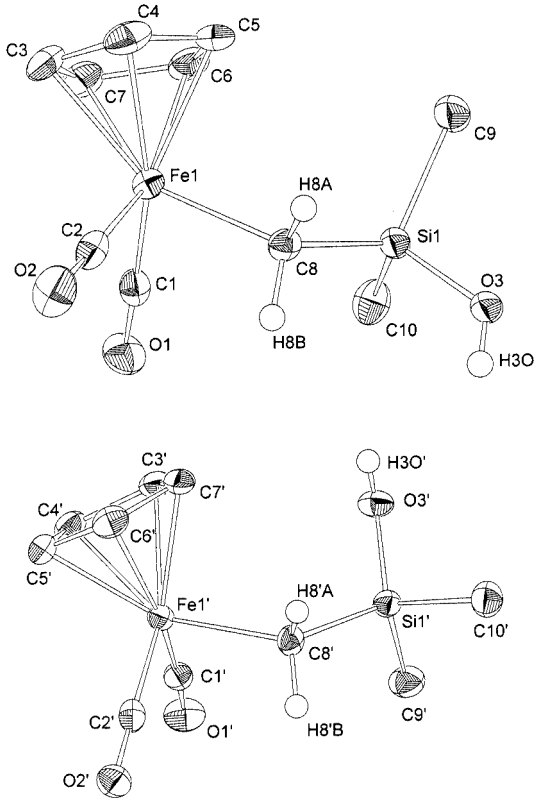


Figure 1. ORTEP view of $Cp(OC)_2Fe-CH_2-SiMe_2OH$ (**4a**), showing the two crystallographically independent molecules; hydrogen atoms have been omitted for clarity (except for those at C8 and O3); selected bond lengths [Å] and angles [°]: Fe1−Cp(Z) 1.728(2)/1.730(2), Fe1−C8 2.0896(16)/2.0863(17), C8−Si1 1.8451(17)/1.8508(16), Si1−O3 1.6599(13)/1.6558(13), Si1−C10 1.8596(19)/1.8686(19), Si1−C9 1.8668(17)/1.8508(18); C1−Fe1−C2 93.61(8)/93.15(7), C1−Fe1−C8 89.38(8)/92.32(8), C2−Fe1−C8 87.20(7)/85.94(7), Cp(Z)−Fe1−C1 126.8(2)/126.3(2), Cp(Z)−Fe1−C2 125.1(1)/126.5(1), Cp(Z)−Fe1−C8 123.4(1)/121.6(1), Fe1−C8−Si1 120.36(8)/120.51(8), C8−Si1−O3 108.41(7)/114.90(7), C9−Si1−O3 102.63(7)/104.03(8); selected torsion angles [°]: Fe1−C8−Si1−O3 −174.24(8)/40.09(12), C1−Fe1−C8−Si1 70.57(11)/57.31(11), Fe1−C8−Si1−C9 71.72(12)/−77.92(12)

The lengths of the iron−methylene bonds lie in a close range between 2.0931(18) (**4b**) and 2.0775(16) Å (**4c**) and are similar to other $C_5R_5(OC)_2Fe-CR_3$ complexes bearing an sp^3-carbon atom at the iron atom.[54−56]

The Fe−C−Si bond angle is in all cases wider than the tetrahedral angle and is up to 124.89(9)° for **4c**, which is in agreement with a higher s-character of the carbon orbital interactions with the more electropositive iron and silicon atoms according to Bent's rule,[57,58] but also shows the higher steric demand of the iron and silanol groups in comparison to the H atoms at the methylene carbon atom. This finding parallels that for the complexes $Cp(OC)(Ph_3P)Fe-CH_2-SiMe_3$ [Fe−C−Si 122.8(2)°],[59] $Cp(OC)_2Fe-CH_2-SiMe_2-SiMe_2-Fe(CO)_2Cp$ [Fe−C−Si 123.4(2)°][60] and *meso*-$[Cp(OC)_2Fe-CH_2-Si(Me)(Ph)]_2$ [Fe−C−Si 120.5(1)°][61] which, to the best of our know-

Figure 2. Figure 3. ORTEP view of $C_5Me_5(OC)_2Fe-CH_2-SiMe_2OH$ (**4c**); hydrogen atoms have been omitted for clarity (except for those at C11 and O1); selected bond lengths [Å] and angles [°]: Fe1−C_5Me_5(Z) 1.759(2), Fe1−C11 2.0775(16), C11−Si1 1.8477(17), Si1−O1 1.6589(12), Si1−C12 1.859(2), Si1−C13 1.865(2); C1B−Fe1−C1B 97.52(9), C1B−Fe1−C11 92.17(7), C1A−Fe1−C11 92.00(8), C_5Me_5(Z)−Fe1−C1A 122.2(1), C_5Me_5(Z)−Fe1−C1B 124.1(1), C_5Me_5(Z)−Fe1−C11 120.7(1), Fe1−C11−Si1 124.89(9), C11−Si1−O1 106.66(7), C12−Si1−O1 106.39(8), C11−Si1−C12 113.72(9), O1−Si1−C13 107.53(10), C11−Si1−C13 114.29(10), C12−Si1−C13 107.78(13); selected torsion angles [°]: C1B−Fe1−C11−Si1 41.70(12), C1A−Fe1−C11−Si1 −55.91(12), Fe1−C11−Si1−O1 169.61(10), Fe1−C11−Si1−C12 −73.43(13), Fe1−C11−Si1−C13 50.93(16)

ledge, are the only other structurally characterized compounds with a $CpL_2Fe-CH_2-SiR_3$ (L = CO, PPh_3) moiety.

The Si−O bond lengths with values between 1.6645(13) (**4b**) and 1.6558(13) Å (**4a**) are nearly identical and lie within the range of other organo- and metallo-substituted silanols.[19−34,62−65] The silicon atom shows in all cases a distorted tetrahedral arrangement of substituents with the expected smaller angle between the OH and CH_3 group[57,58] [106.39(8) (**4c**) to 102.63(7)° (**4a**)] and enlarged ones to the methylene carbon atom [114.89(8) (**4b**) to 114.29(10)° (**4c**)].

Looking at the arrangement of the substituents along the methylene−silicon bond, in the case of **4b** there is a nearly ideal "*anti*" arrangement of the iron fragment and the phenyl group, with a small deviation of only about 6° [Fe1−C8−Si1−C10 173.59(8)°], whereas in the case of **4c** the hydroxy group adopts the "*anti*" position to the iron fragment [Fe1−C11−Si1−O1 169.61(10)°] with a deviation of about 10°.

The situation in the case of **4a** is a bit more complex. The two different molecules are characterized by a nearly ideal "*anti*" position of the iron atom and the hydroxy group [Fe1−C8−Si1−O3 −174.24(8)] in the one case and a "*gauche*" position of these ligands with a more significant deviation from ideal conformation of about 20° [Fe1−C8−Si1−O3 40.09(12)°] in the other. This situation is clearly a consequence of the formation of a polymeric arrangement of the molecular subunits based on hydrogen bonding (see also below).

Triorganosilanols often show interesting hydrogen-bonded superstructures, the pattern of which depends on the nature of the organic substituents.[65] In contrast to the structures of other diorgano(metallo)silanols L_nM-SiR_2OH, which prefer hydrogen-bonded "dimerization", e.g. $C_5Me_5(OC)_2Fe-SiMe_2OH$[1] and $C_5Me_5(OC)_2Ru-Si(o\text{-Tol})_2OH$,[26] in the case of the (ferriomethyl)silanols **4a**,**b** strong intermolecular OH···O bridges lead to the formation of discrete tetrameric units in the solid state, indicated by O···O distances of 2.7320(16)/2.7410(17) (**4a**) and 2.6965(17) Å (**4b**). This arrangement is similar to that found for Ph_3SiOH.[62]

Looking at **4a**, the tetramers consist of the two types of staggered conformers, concerning the C8−Si bond (see above). They are formed by an alternating arrangement of

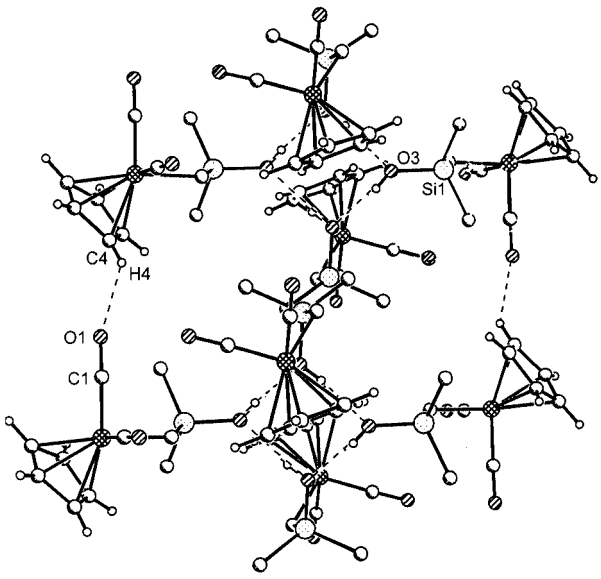

Figure 4. Ladder-type connection of **4a** between the "*anti*" conformers of neighboring tetramers via CH···OC bridges

the "*anti*" and "*gauche*" conformers and exhibit a centre of symmetry.

The tetrameric units are connected to each other in a ladder-type fashion by weak CH···OC interactions of the Cp and one CO ligand [C4···O1 3.358(3) Å] between two "*anti*" conformers of neighbouring units, as depicted in Figure 4. This kind of hydrogen bonding, although very rare, has recently been found by Braga et al. in the structures of $[Cp(CO)_2Fe]_2$ and $Cp_2Fe_2(CO)_2(\mu\text{-}CO)(\mu\text{-}CHMe)$.[66,67]

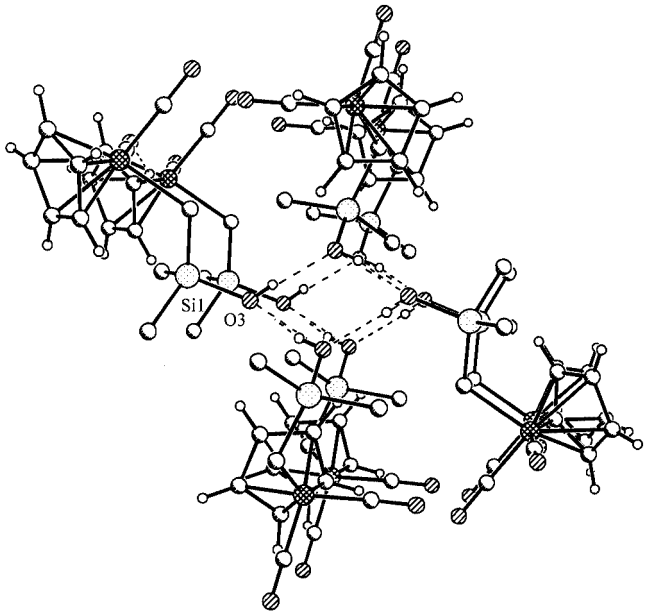

Figure 5. View inside the tube-like arrangement of the tetrameric units of **4a**

The tetrameric units are stacked on top of each other in the same way, resulting in a tube-like arrangement of the Si−OH moieties, which can be seen from Figure 5. The tubes can be considered as hydrophilic channels inside a lipophilic shape of the remaining (ferriomethyl) fragments. Between atoms of different tubes there are no or only marginal interactions, indicated by C···O distances of more than 3.70 Å.

In the case of **4b**, the situation is similar, but in contrast to **4a** there are no conformational isomers in the crystal structure, but two pairs of enantiomers which form the tetramer. The enantiomers are linked in an alternate fashion by hydrogen bonding to produce the centrosymmetric tetra-

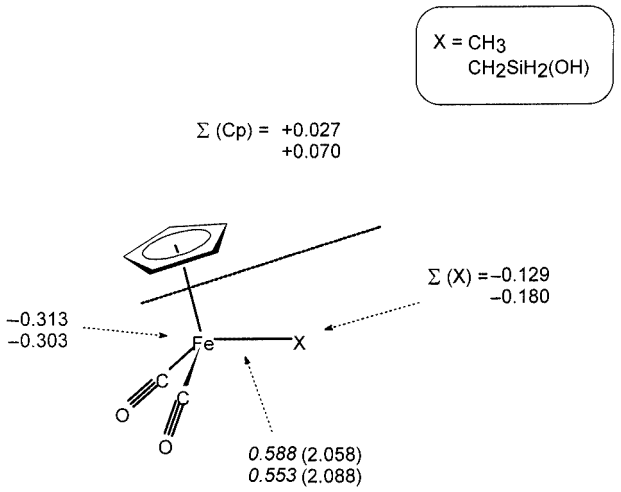

Figure 9. Population analysis of $Cp(OC)_2Fe-X$ (X = CH_3, CH_2SiH_2OH), NBO charges and Wiberg bond indices (in italics); in parentheses are Fe−X equilibrium distances

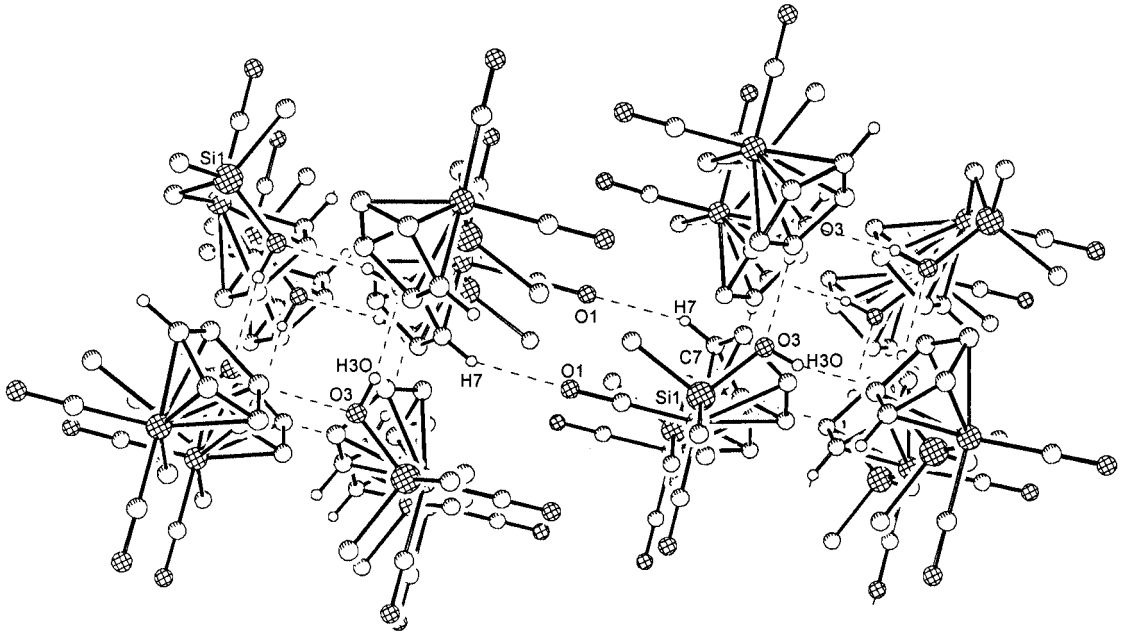

Figure 6. View inside the tube-like arrangement of the tetrameric units of **4b** with connection of the tubes via CH···OC bridges; hydrogen atoms (except for those involved in hydrogen bonding) as well as the phenyl carbon atoms (except for the *ipso* carbon atom) have been omitted for clarity

mer. Like **4a**, the tetramers are stacked on top of each other to produce a tube-like arrangement (Figure 6). These tubes are linked by weak CH···OC interactions of the Cp and one CO ligand of two enantiomers with the same configuration of neighboring tubes [C7···O1 3.406(2) Å].

The situation for the (ferriomethyl)silanol **4c** is somehow different. The molecules are connected by OH···O bridges giving rise to the formation of an infinite chain structure. This arrangement is a result of a "flip mechanism" of the disordered Si−OH proton[68] which guarantees the linkage of the molecules in two directions (intermolecular O···O distance 2.751/2.789 Å). This connection via hydrogen bonding is repeated in an infinite fashion to result in the formation of a linear chain structure, as depicted in Figure 7.

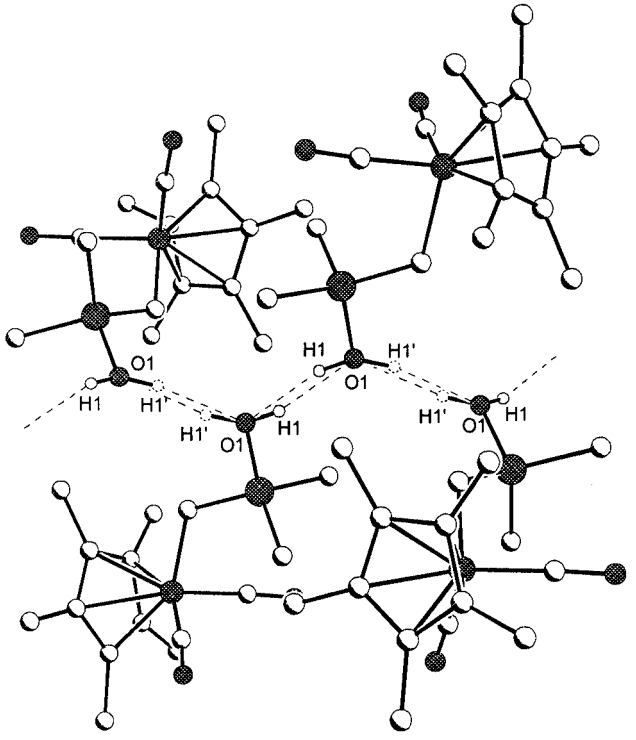

Figure 7. Chain structure of **4c** via OH···O bridges of the disordered SiOH proton

These chains interact by weak CH···OC contacts of the C_5Me_5 and one CO ligand with intermolecular C···O distances lying between 3.409(2) and 3.632(3) Å (Figure 8).

DFT Calculations

In order to analyze the bonding situation in the (ferriomethyl)silanol **4a** in more detail, we performed density functional calculations[69] on the model compounds $Cp(OC)_2Fe-X$ (X = CH_3, CH_2SiH_2OH). Plots of their equilibrium structures, determined at BP86/SBK(d) level,[70−73] are shown in Figure 9, together with the results of a natural bond orbital population analysis (NBO).[74]

The bonding parameters for X = CH_2SiH_2OH are in agreement with the X-ray investigation on **4a** (Fe−C: computed 2.088 Å, experimental 2.089 Å). The calculations also predict a widened valent angle at the carbon atom [X = $CH_2SiH_2(OH)$: Fe−C−Si = 115.7°], in agreement with the expectations from Bent's rule.[57,58] It is of interest to analyze the electron density distributions within the calculated structures. The substituent X (CH_3, CH_2SiH_2OH) is only weakly bound to the metal atom (Wiberg bond index for Fe−C 0.59 vs. 0.55), as compared with a stronger coordination of the carbonyl units (bond index 0.89 vs. 0.90). Interestingly, the iron atom accumulates negative charge, although the overall metal fragment releases electron density to X. The electron-withdrawing effect of X (−I) is more strongly pronounced for X = CH_2SiH_2OH than for X = CH_3.

Condensation Behavior of 4a

Although **4a** can be stored at −20 °C for several months without any self-condensation, at room temperature, this process slowly starts even in the solid state, leading to the 1,3-bis(ferriomethyl)disiloxane **5**.[43] The disiloxane formation also occurs in solution, which was proven by monitoring a C_6D_6 solution by NMR spectroscopy. In this case, **5** is formed in 33% yield after 30 d.

The disiloxane **5** is additionally obtained by the reaction of **4a** with the chloro(ferriomethyl)silane **3a** in diethyl ether in the presence of the auxiliary base Et_3N after a reaction period of 3 d at room temperature (Scheme 3).

Disiloxanes with only one iron fragment are available in the same manner using the chlorosilanes R(R′)Si(Me)Cl (R = H, R′ = Me, *p*-Tol; R = R′ = Me) (Scheme 4). The (ferriomethyl)-substituted disiloxanes **5** and **6a**−**c** are obtained in good yields of 76−85% as orange-brown (**5**) and yellow-brown oils (**6a**−**c**), respectively, which can be stored under nitrogen at room temperature for several months without decomposition.

The dinuclear disiloxane **5** shows a characteristic upfield shift of δ = 9 ppm in the ^{29}Si NMR spectrum compared to the silanol **4a** [δ = 12.8 (**5**) versus 21.8 (**4a**) ppm], which finds its counterpart in the resonances of triorganosilanols and the corresponding disiloxanes.[75]

In accordance with this finding, the ^{29}Si NMR resonances of the β-Si atom of **6a**−**c** are observed at δ = 15.9 (**6a**), 17.0 (**6b**) and 13.8 (**6c**) ppm. The Si−H-functionalized disiloxanes **6a**,**b** offer the possibility of further functionalization. In this context, experiments to effect Si−H/Si−OH transformation are under investigation, as well as oxidative addition reactions to electronically unsaturated metal fragments.

Conclusion

The results of this paper demonstrate that (ferriomethyl)-substituted silanols are accessible either by Cl/OH exchange at the silicon atom of chloro(ferriomethyl)silanes or by oxygen insertion into the Si−H bond of the corresponding (ferriomethyl)silanes. They show interesting structural features, like aggregation to tetramers and the formation of tube- or

Scheme 4. Synthesis of the (ferriomethyl)disiloxanes **6a**–**c**

chain-like arrangements, which is a consequence of intermolecular hydrogen bonding.

The stability of this type of metal fragment substituted silanols with respect to self-condensation is reduced, compared with the ferriosilanols $C_5R_5(OC)_2Fe-SiMe_2OH$ (R = H, Me)[1] bearing the Si–OH unit directly at the transition metal atom. As a consequence, the silanol **4a** undergoes condensation to a disiloxane, which is well known from triorganosilanols. Apart from that, these compounds are ideal precursors to perform controlled reactions with chlorosilanes to generate novel transition metal containing siloxanes.

Current work deals with the generation of (ferriomethyl)-substituted silanediols and silanetriols in order to check the capability of these species to create metal-substituted oligo- or polysiloxanes by controlled self-condensation reactions.

Experimental Section

General Remarks: All operations were performed under purified and dried nitrogen using Schlenk-type techniques. Solvents were dried according to conventional procedures, distilled and saturated with N_2 prior to use. NMR: Jeol Lambda 300 (300.4 MHz, 75.5 MHz, and 59.6 MHz for ^1H, ^{13}C, and ^{29}Si, respectively). [D_6]Benzene as a solvent: δ_H = 7.15 ppm, δ_C = 128.0 ppm; for ^{29}Si rel. to TMS external. IR: Perkin–Elmer 283 grating spectrometer. Melting points: differential thermo analysis (Du Pont 9000 Thermal Analysis System). Elemental analyses were performed in the laboratories of the Institut für Anorganische Chemie der Universität Würzburg. Starting materials were prepared according to literature procedures: $Na[Fe(CO)_2Cp]$,[76] $Na[Fe(CO)_2C_5Me_5]$,[77] $ClCH_2Si(Me)(Ph)Cl$,[78] $Cp(OC)_2Fe-CH_2-SiMe_2H$,[43] $Cp(OC)_2Fe-CH_2-SiMe_2Cl$,[45] $ClSi(Me)(p\text{-Tol})H$[79] and dimethyldioxirane.[37] $ClCH_2SiMe_2Cl$, $ClSiMe_2H$ and $ClSiMe_3$ were purchased commercially and distilled prior to use.

1. Chloro{[dicarbonyl(η^5-cyclopentadienyl)ferrio]methyl}methyl(phenyl)silane (3b): A stirred suspension of $Na[Fe(CO)_2Cp]$ (**1a**)

(1329 mg, 6.65 mmol) in cyclohexane (40 mL) was treated with $ClCH_2Si(Me)(Ph)Cl$ (**2b**) (2157 mg, 10.51 mmol) and stirred for 36 h at room temperature in the dark. The reaction mixture was filtered through a Celite pad and the filtrate concentrated in vacuo. Excess **2b** was distilled off at 90 °C (10^{-2} Torr) and the remaining dark brown oil was heated to 120 °C for 3 h. After cooling to room temperature, the mixture was suspended in *n*-pentane (20 mL) and filtered off from insoluble decomposition products through a Celite pad. The filtrate was reduced to a volume of 8 mL and **3b** was crystallized at −78 °C and dried in vacuo. Yield: 1093 mg (47%). Orange-brown, waxy solid. M.p. 55 °C. ^{1}H NMR: δ = 7.69 (m, 2 H, H_5C_6Si), 7.20 (m, 3 H, H_5C_6Si), 3.97 (s, 5 H, H_5C_5), 0.75 (s, 3 H, H_3C), −0.02 (d, $^2J_{H,H}$ = 12.9 Hz, 1 H, H_2C), −0.05 ppm (d, $^2J_{H,H}$ = 12.9 Hz, 1 H, H_2C). $^{13}C\{^1H\}$ NMR: δ = 216.99 (s, CO), 216.96 (s, CO), 139.7 (s, C-1 of C_6H_5), 133.7 (s, C-2, C-6 of C_6H_5), 129.9 (s, C-4 of C_6H_5), 128.2 (s, C-3, C-5 of C_6H_5), 84.8 (s, C_5H_5), 3.3 (s, CH_3), −24.9 (s, CH_2) ppm. $^{29}Si\{^1H\}$ NMR: δ = 27.9 (s) ppm. IR (*n*-pentane): $\tilde{\nu}$ = 1999 (s, CO), 1962 cm^{-1} (vs, CO). $C_{15}H_{15}ClFeO_2Si$ (346.75): calcd. C 51.97, H 4.36; found C 51.60, H 4.64.

2. Chloro{[dicarbonyl(η^5-pentamethylcyclopentadienyl)ferrio]methyl}dimethylsilane (3c): A stirred suspension of $Na[Fe(CO)_2C_5Me_5]$ (**1b**) (1315 mg, 4.87 mmol) in cyclohexane (40 mL) was treated with $ClCH_2SiMe_2Cl$ (**2a**) (1087 mg, 7.60 mmol) and stirred for 20 h at room temperature in the dark. The reaction mixture was filtered through a Celite pad and the filtrate concentrated in vacuo. The orange-red residue was treated with *n*-pentane (15 mL) and stored at −20 °C overnight to crystallize the by-products $[C_5Me_5(OC)_2Fe]_2$ and $C_5Me_5(OC)_2FeCl$. The supernatant liquid was separated and the volume reduced in vacuo to 10 mL. Remaining $C_5Me_5(OC)_2FeCl$ was crystallized at −20 °C and filtered off. The filtrate was reduced in vacuo to 5 mL and **3c** was crystallized at −78 °C, washed twice with *n*-pentane (each 1 mL) at this temperature and dried in vacuo. Yield: 571 mg (33%). Orange-brown, waxy solid. M.p. 60 °C (decomp.). ^{1}H NMR: δ = 1.25 [s, 15 H, $(H_3C)_5C_5$], 0.66 (s, 6 H, H_3CSi), −0.43 (s, 2 H, H_2C) ppm. $^{13}C\{^1H\}$ NMR: δ = 219.5 (s, CO), 95.7 [s, $C_5(CH_3)_5$], 9.1 [s, $(CH_3)_5C_5$], 4.7 (s, CH_3Si), −12.0 (s, CH_2) ppm. ^{29}Si NMR: δ = 35.5 (non, $^2J_{Si,H}$ = 6.7 Hz) ppm. IR (cyclohexane): $\tilde{\nu}$ = 1983 (s, CO), 1931 cm^{-1} (vs, CO). $C_{15}H_{23}ClFeO_2Si$ (354.75): calcd. C 50.79, H 6.53; found C 50.51, H 6.30.

3. {[Dicarbonyl(η^5-cyclopentadienyl)ferrio]methyl}dimethylsilanol (4a). a) Hydrolysis of $Cp(OC)_2FeCH_2SiMe_2Cl$ (3a) in the Presence of Et_3N: A stirred solution of **3a** (237 mg, 0.83 mmol) in Et_2O (30 mL) was treated with Et_3N (730 mg, 7.21 mmol) and H_2O (100 mg, 5.55 mmol). After addition, stirring was continued for 2 h at room temperature. Precipitated $[Et_3NH]Cl$ and excess H_2O were removed by filtration through Na_2SO_4. The filtrate was concentrated in vacuo, leaving yellow-brown oily **4a**, which was crystallized from *n*-pentane (3 mL) at −78 °C and dried in vacuo. Yield: 197 mg (89%). **b) Oxygenation of $Cp(OC)_2FeCH_2SiMe_2H$ (3d) with Dimethyldioxirane:** A stirred solution of **3d** (238 mg, 0.95 mmol) in acetone (10 mL) was treated dropwise at −78 °C with a solution of dimethyldioxirane (1.22 mmol,16 mL, 0.076 M) in acetone. After addition, the reaction mixture was stirred for 1 h at this temperature and an additional 1 h at room temperature. All volatiles were removed in vacuo, leaving brown oily **4a**, which was crystallized from *n*-pentane (3 mL) at −78 °C and dried in vacuo. Yield: 170 mg (67%). Yellow-brown, waxy solid. M.p. 38 °C. ^{1}H NMR: δ = 4.24 (s, 5 H, H_5C_5), 0.95 (br. s, 1 H, HO), 0.23 (s, 6 H, H_3C), −0.42 (s, 2 H, H_2C) ppm. $^{13}C\{^1H\}$ NMR: δ = 218.0 (s, CO), 84.8 (s, C_5H_5), 3.2 (s, CH_3), −23.1 (s, CH_2) ppm. $^{29}Si\{^1H\}$ NMR: δ = 21.8 (s) ppm. IR (*n*-pentane): $\tilde{\nu}$ = 3698 (w, OH), 2000 (s, CO), 1959 cm^{-1} (vs, CO). $C_{10}H_{14}FeO_3Si$ (266.15): calcd. C 45.13, H 5.30; found C 45.11, H 5.21.

4. {[Dicarbonyl(η^5-cyclopentadienyl)ferrio]methyl}methyl(phenyl)silanol (4b): According to 3.a) obtained from **3b** (352 mg, 1.02 mmol), Et_3N (219 mg, 2.16 mmol) and H_2O (100 mg, 5.56 mmol) in Et_2O (20 mL) after 4 h at room temperature. Yield: 247 mg (74%). Yellow-orange, crystalline solid. M.p. 60 °C. ^{1}H NMR: δ = 7.63 (m, 2 H, H_5C_6Si), 7.26 (m, 3 H, H_5C_6Si), 4.18 (s, 5 H, H_5C_5), 1.28 (br. s, 1 H, HO), 0.44 (s, 3 H, H_3CSi), −0.09 (d, $^2J_{H,H}$ = 12.8 Hz, 1 H, H_2C), −0.38 (d, $^2J_{H,H}$ = 12.8 Hz, 1 H, H_2C) ppm. $^{13}C\{^1H\}$ NMR: δ = 217.8 (s, CO), 217.6 (s, CO), 142.9 (s, C-1 of C_6H_5), 133.5 (s, C-2, C-6 of C_6H_5), 129.1 (s, C-3, C-5 of C_6H_5), 128.0 (s, C-4 of C_6H_5), 84.8 (s, C_5H_5), 1.8 (s, CH_3), −24.9 (s, CH_2) ppm. $^{29}Si\{^1H\}$ NMR: δ = 11.7 (s) ppm. IR (*n*-pentane): $\tilde{\nu}$ = 3682 (w, br, OH), 1995 (s, CO), 1952 cm^{-1} (vs, CO). $C_{15}H_{16}FeO_3Si$ (328.23): calcd. C 54.89, H 4.91; found C 54.60, H 5.06.

5. {[Dicarbonyl(η^5-pentamethylcyclopentadienyl)ferrio]methyl}dimethylsilanol (4c): According to 3.a) obtained from **3c** (126 mg, 0.36 mmol), Et_3N (365 mg, 3.60 mmol) and H_2O (200 mg, 11.1 mmol) in Et_2O (20 mL) after 4 h at room temperature. Precipitated $[Et_3NH]Cl$ and excess H_2O were removed by filtration through Na_2SO_4. The filtrate was concentrated in vacuo and treated with *n*-pentane (5 mL). The by-products $C_5Me_5(OC)_2FeCl$ and $[C_5Me_5(OC)_2Fe]_2$ were crystallized at 0 °C and separated by filtration through a Celite pad. The filtrate was reduced to 2 mL and **6c** was crystallized at −78 °C and dried in vacuo. Yield: 48 mg (40%). Yellow-orange solid. M.p. 89 °C (decomp.). ^{1}H NMR: δ = 1.35 [s, 15 H, $(H_3C)_5C_5$], 0.92 (br. s, 1 H, HO), 0.40 (s, 6 H, H_3CSi), −0.62 (s, 2 H, H_2C) ppm. $^{13}C\{^1H\}$ NMR: δ = 220.1 (s, CO), 95.2 [s, $C_5(CH_3)_5$], 9.2 [s, $(CH_3)_5C_5$], 3.2 (s, CH_3Si), −12.4 (s, CH_2) ppm. $^{29}Si\{^1H\}$ NMR: δ = 21.1 (s) ppm. IR (*n*-pentane): $\tilde{\nu}$ = 3703 (w, OH), 1988 (s, CO), 1936 cm^{-1} (vs, CO). $C_{15}H_{24}FeO_3Si$ (336.29): calcd. C 53.57, H 7.19; found C 53.82, H 7.05.

6. 1,3-Bis{[dicarbonyl(η^5-cyclopentadienyl)ferrio]methyl}-1,1,3,3-tetramethyldisiloxane (5). a) Self Condensation of $Cp(OC)_2FeCH_2SiMe_2OH$ (4a): In an NMR sample tube **4a** (20 mg, 0.08 mmol) was dissolved in C_6D_6 (0.6 mL). After 30 d at room temperature, **5** was formed in 33% yield as determined by ^{1}H NMR spectroscopy. **b) Reaction of $Cp(OC)_2FeCH_2SiMe_2OH$ (4a) with $Cp(OC)_2FeCH_2SiMe_2Cl$ (3a): 3a** (103 mg, 0.48 mmol) in Et_2O (20 mL) was added dropwise to a stirred solution of **4a** (108 mg, 0.41 mmol) in Et_2O (20 mL). After stirring for 3 d in the dark at room temperature, all volatiles were removed in vacuo. The residue was suspended in *n*-pentane (15 mL) and filtered through a Celite pad. The volume of the filtrate was reduced in vacuo to 3 mL and **5** crystallized at −78 °C. Solid **5** melts upon warming to room temperature. Yield: 163 mg (77%). Orange-brown oil. ^{1}H NMR: δ = 4.24 (s, 10 H, H_5C_5), 0.36 (s, 12 H, H_3C), −0.25 (s, 4 H, H_2C) ppm. $^{13}C\{^1H\}$ NMR: δ = 218.0 (s, CO), 84.9 (s, C_5H_5), 4.0 (s, CH_3), −22.4 (s, CH_2) ppm. $^{29}Si\{^1H\}$ NMR: δ = 12.8 (s) ppm. IR (*n*-pentane): $\tilde{\nu}$ = 2003 (s, CO), 1961 cm^{-1} (vs, CO). $C_{20}H_{26}Fe_2O_5Si_2$ (514.29): calcd. C 46.71, H 5.09; found C 46.37, H 5.32.

7. 1-{[Dicarbonyl(η^5-cyclopentadienyl)ferrio]methyl}-1,1,3,3-tetramethyldisiloxane (6a): According to 6.b) obtained from **4a** (866 mg, 3.26 mmol), Et_3N (1186 mg, 11.50 mmol) and $Me_2Si(H)Cl$ (694 mg, 10.26 mmol) in Et_2O (60 mL) after stirring in the dark at room temperature for 12 h. The residue was suspended in *n*-pentane (40 mL) and filtered through a Celite pad. The filtrate was concentrated in vacuo, leaving **6a**. Yield: 900 mg (85%). Yellow-

brown oil. ^{1}H NMR: δ = 5.05 (sept, $^3J_{H,H}$ = 2.4, $^1J_{H,Si}$ = 201.6 Hz, 1 H, HSi), 4.19 (s, 5 H, H_5C_5), 0.28 [s, 6 H, $(H_3C)_2SiCH_2$], 0.22 [d, $^3J_{H,H}$ = 2.4 Hz, 6 H, $(H_3C)_2SiH$], −0.39 (s, 2 H, H_2C) ppm. $^{13}C\{^1H\}$ NMR: δ = 217.9 (s, CO), 84.8 (s, C_5H_5), 3.4 [s, $(CH_3)_2SiCH_2$], 1.2 [s, $(CH_3)_2SiH$], −23.0 (s, CH_2) ppm. $^{29}Si\{^1H\}$ NMR: δ = 15.9 (s, $SiCH_2Fe$), −8.0 (s, SiH) ppm. IR (*n*-pentane): $\tilde{\nu}$ = 2116 (w, br, SiH), 2003 (s, CO), 1961 cm^{-1} (vs, CO). $C_{12}H_{20}FeO_3Si_2$ (324.30): calcd. C 44.44, H 6.21; found C 44.09, H 6.21.

8. 1-{[Dicarbonyl(η^5-cyclopentadienyl)ferrio]methyl}-1,1,3-trimethyl-3-(*p*-tolyl)disiloxane (6b): According to 7. obtained from **4a** (296 mg, 1.11 mmol), Et_3N (219 mg, 2.16 mmol) and (*p*-Tol)(Me)(H)SiCl (189 mg, 1.11 mmol) in Et_2O (40 mL) after stirring for 24 h in the dark at room temperature. After workup the crude product was dried for 6 h at 5 × 10^{-5} Torr. Yield: 338 mg (76%). Brown oil. ^{1}H NMR: δ = 7.63 (d, $^3J_{H,H}$ = 7.4 Hz, 2 H, H_4C_6), 7.08 (d, $^3J_{H,H}$ = 7.4 Hz, 2 H, H_4C_6), 5.47 (q, $^3J_{H,H}$ = 2.8, $^1J_{H,Si}$ = 206.4 Hz, 1 H, HSi), 4.16 (s, 5 H, H_5C_5), 2.10 (s, 3 H, $H_3CC_6H_4$), 0.47 (d, $^3J_{H,H}$ = 2.8 Hz, 3 H, H_3CSiH), 0.31 [s, 6 H, $(H_3C)_2SiCH_2$], −0.35 (s, 2 H, H_2C) ppm. $^{13}C\{^1H\}$ NMR: δ = 217.8 (s, CO), 139.8 (s, C-1 of C_6H_4), 135.0 (s, C-4 of C_6H_4), 134.0 (s, C-2, C-6 of C_6H_4), 129.1 (s, C-3, C-5 of C_6H_4), 84.8 (s, C_5H_5), 21.5 (s, $CH_3C_6H_4$), 3.5 [s, $(CH_3)_2SiCH_2$], 0.1 (s, CH_3SiH), −23.1 (s, CH_2) ppm. ^{29}Si NMR: δ = 17.0 (m, $SiCH_2Fe$), −14.6 (dsext, $^1J_{Si,H}$ = 206.4, $^2J_{Si,H}$ = 6.4 Hz, SiH) ppm. IR (*n*-pentane): $\tilde{\nu}$ = 2119 (w, br, SiH), 2002 (s, CO), 1960 cm^{-1} (vs, CO). $C_{18}H_{24}FeO_3Si_2$ (400.41): calcd. C 53.99, H 6.04; found C 54.00, H 5.97.

9. 3-{[Dicarbonyl(η^5-cyclopentadienyl)ferrio]methyl}-1,1,1,3,3-pentamethyldisiloxane (6c): According to 7. obtained from **4a** (213 mg, 0.80 mmol), Et_3N (219 mg, 2.16 mmol) and Me_3SiCl (257 mg, 2.37 mmol) in Et_2O (30 mL) after stirring for 24 h in the dark at room temperature. Yield: 204 mg (79%). Yellow-brown oil. ^{1}H NMR: δ = 4.21 (s, 5 H, H_5C_5), 0.28 [s, 6 H, $(H_3C)_2Si$], 0.18 [s, 9 H, $(H_3C)_3Si$], −0.36 (s, 2 H, H_2C) ppm. $^{13}C\{^1H\}$ NMR: δ = 217.9 (s, CO), 84.9 (s, C_5H_5), 3.8 [s, $(CH_3)_2Si$], 2.3 [s, $(CH_3)_3Si$], −22.5 (s, CH_2) ppm. ^{29}Si NMR: δ = 13.8 (m, $SiCH_2Fe$), 6.2 [dec, $^2J_{Si,H}$ = 7.0 Hz, $Si(CH_3)_3$] ppm. IR (Et_2O): $\tilde{\nu}$ = 2000 (vs, CO), 1953 cm^{-1} (vs, CO). $C_{13}H_{22}FeO_3Si_2$ (338.33): calcd. C 46.15, H 6.55; found C 46.80, H 6.63.

X-ray Crystal Structure Analyses of 4a−c: Table 1 contains details of the structures. The intensities were measured with a Nonius-Kappa CCD diffractometer (Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator) at T = −150 °C. The structures were solved by direct methods (Patterson methods)[80] (SHELXS-97) and refined by least-squares methods based on F^2 with all measured reflections (SHELXL-97) (full-matrix least-squares on F^2,[81]). Non-hydrogen atoms were refined anisotropically, H atoms localized by difference electron density and refined using a "riding" model [H(O) free]. An empirical absorption correction was applied. CCDC-115086 (**4a**), -148145 (**4b**) and -156552 (**4c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We gratefully acknowledge financial support from the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm "Spezifische Phänomene in der Siliciumchemie") as well as from the Fonds der Chemischen Industrie. M. N. wants to thank the DAAD for financial support.

[68] The difference electron density determination [after refinement taking H(C) into account, which was also localized by difference electron density determination and refined using a riding model] shows two difference peaks in a reasonable O−H distance, also with reasonable intermolecular H−O distances forming hydrogen bonds (to Si−OH in two different molecules).

There is a significant gap between those two peaks and the remaining peaks in the difference density map. Using HFIX 87, HFIX 147 and HTAB in the SHELXL-97 refinement two possible H(O) positions, very close to the low localized density peaks, are indicated. This all suggests a disorder (50:50) of the Si−OH group with "flipping" hydrogen bond pattern. In addition, data are collected at 123 K and the quality is "not so bad", which even improves the possibility of localization of disordered H atoms.

Stable $Rh_2(MTPA)_4$ Phosphane Adducts − The First Example of *P*-Chirality Recognition by ^{103}Rh NMR Spectroscopy

Damian Magiera,[a] Wolfgang Baumann,[b] Ivan S. Podkorytov,[c] Jan Omelanczuk,[d] and Helmut Duddeck*[a]

Keywords: Phosphanes / Rhodium / NMR spectroscopy / Chirality / Chiral discrimination

The optimal parameters for ^{31}P-detected ^{103}Rh HMQC NMR spectroscopy of AMX spin systems (A = ^{31}P; M and X = ^{103}Rh) have been derived and applied to adducts of $Rh_2[(R)\text{-MTPA}]_4$ with PPh_3 (**1**) and a chiral phosphane (**2**). It is shown that all nuclei (^1H, ^{13}C, ^{31}P, and ^{103}Rh) reflect the diastereomerism of the latter complex.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

In a series of papers[1] we have studied the potential of the dirhodium complex $Rh_2[(R)\text{-MTPA}]_4$ (**Rh***; MTPA-H = methoxytrifluoromethylphenylacetic acid, Mosher's acid) as a chiral solvating agent for the chiral recognition of various chiral monofunctional ligands **L**, i.e. for the determination of enantiomeric ratios.[2] We have shown that our "dirhodium method" is particularly suitable for soft-base functionalities where the classical method of chiral lanthanide-shift reagents (CLSR)[3] usually fails. Typically, **Rh*** and **L** form kinetically labile adducts so that only averaged NMR signals can be observed (in analogy to the CLSR method) for the **L** molecules in equilibria as depicted in Scheme 1.

Although the ^{103}Rh nucleus has some advantageous properties (spin 1/2 and 100% natural abundance), it is not easy to monitor by direct ^{103}Rh NMR measurement because of its low receptivity (18% of that of ^{13}C) and rather long spin-lattice relaxation times.[4−6] So far, only one study has reported the ^{103}Rh chemical shift for the bis(trimethylphosphite) adduct of dirhodium tetraacetate (δ = 6694 ppm).[7] In our dirhodium system, however, any direct ^{103}Rh NMR spectroscopy is impossible due to the relatively low solubility of **Rh*** in $CDCl_3$.

Results and Discussion

Very recently, we reported the "dirhodium method" as the first to discriminate enantiomeric phosphane sulfides ($R_3P{=}S$) in a direct way; as for any other previously studied ligand,[1] the adducts (Scheme 1) are kinetically unstable.[8] However, when we later turned to phosphanes (R_3P) as ligands we were surprised to find that phosphane adducts are kinetically stable, i.e., the lifetimes of these adducts are long with respect to the NMR timescale. Thus, for the first time we were able to see the [**Rh***←phosphane] adducts in the ambient temperature ^{31}P NMR spectra without any averaging; the ^{31}P signals are doublets of doublets due to one- and two-bond ^{103}Rh couplings (adducts with **1**, see Scheme 2 and Table 1 and Table 2). In the case of chiral phosphanes, such as **2**, a further doubling of the signal is caused by diastereomeric dispersion.

For the first time in our dirhodium project, this offers the possibility of indirect ^{103}Rh observation by ^{31}P-detected ^{103}Rh HMQC NMR experiments. Experiments of this kind — or analogous ^1H-detected ^{103}Rh HMQC — have not been described very frequently as they require special equipment.[5,6,9] Furthermore, it was thought that if more

than one such insensitive nucleus (e.g., ^{103}Rh) is coupled to the sensitive detection nucleus (^{1}H or ^{31}P), triple-quantum effects may modulate the intensities and even the positions of the cross-peaks because all of the involved nuclei are ubiquitous (100% natural abundance) and rules valid for simple AX spin systems might not be applicable.[10,11] Therefore, we first had to explore the correct parameters in the HMQC experiment for our first-order AMX spin system (A = ^{31}P; M and X = ^{103}Rh). This is described in the Appendix.

^{31}P-Detected ^{103}Rh HMQC NMR Spectroscopy

Despite the low solubility of the complexes, we succeeded in obtaining ^{103}Rh correlation signals by ^{31}P-detected HMQC spectroscopy (Figure 1 and 2). The choice of the transfer delay d_2 according to Equations (7) and (8) (see Appendix) allows the discrimination and selection of signals originating from Rh(1) or Rh(2). Using the coupling constants $^{n}J(^{103}Rh,^{31}P)$ for the complex [Rh(2)−Rh(1)←**1**] (Figure 1), we obtained a first maximum for Rh(1) at d_2 = 5 ms, $f_1(0.005) = 0.940$, while Rh(2) cannot be observed: $f_2(0.005) = 0.024$. The reverse situation occurs at d_2 = 21 ms, $f_1(0.021) = 0.002$, $f_2(0.021) = 0.990$, thus only a correlation signal for Rh(2) is observable. These predictions were verified experimentally. As exemplified in Figure 1, the choice of other delays allows the simultaneous observation

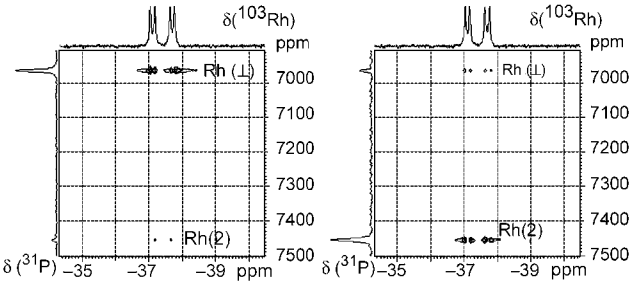

Figure 1. $^{31}P,^{103}Rh\{^{1}H\}$ HMQC NMR spectra of [**Rh*←1**] at ca. 298 K, magnitude representation.; left: transfer delay d_2 = 2.6 ms, selection of Rh(1): $f_1(0.0026) = 0.692$, $f_2(0.0026) = 0.125$; right: transfer delay d_2 = 11.6 ms, selection of Rh(2): $f_1(0.0116) = -0.234$, $f_2(0.0116) = -0.671$; calculated from J_1 = 95.5, J_2 = 21.7 Hz

of both signals, although with a somewhat reduced intensity.

In the F_2 dimension (^{31}P), the signals appear as doublets of doublets, split by the coupling constants $^{1}J(^{103}Rh,^{31}P)$ and $^{2}J(^{103}Rh,^{31}P)$, as expected. An additional splitting of ca 10 Hz is observed in the F_1 dimension (^{103}Rh), provided

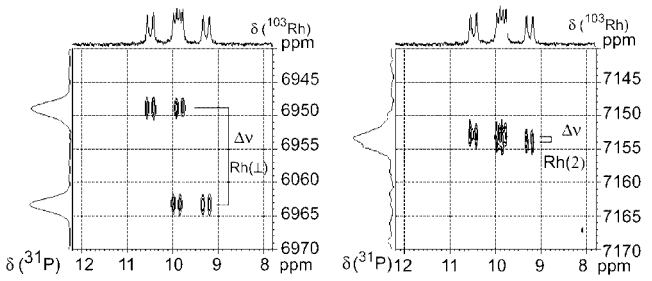

Figure 2. Sections of ^{31}P,^{103}Rh{^{1}H} HMQC NMR spectra of [**Rh*←2**] at ca. 298 K; digital resolution in F_1 is 2.9 Hz per point; top: transfer delay d_2 = 4.5 ms, selection of Rh(1): $f_1(0.0045) = 0.95$, $f_2(0.0045) = 0.02$; bottom: transfer delay d_2 = 19.0 ms, selection of Rh(2): $f_1(0.019) = -0.001$, $f_2(0.019) = 0.967$; calculated from J_1 = 105.2, J_2 = 22.0 Hz

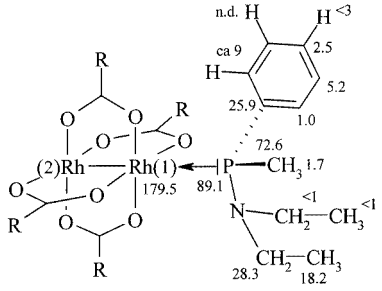
the digital resolution is sufficient. We attribute this to the homonuclear coupling $^{1}J(^{103}Rh,^{103}Rh)$ which is to be regarded as a "passive coupling" with respect to the ^{31}P,^{103}Rh spin pair under observation and should show up in F_1. For the related symmetric phosphite adduct $[Rh_2(\mu\text{-}OAc)_4][P(OMe)_3]_2$ this coupling was determined to be 8 Hz.[7] Another origin for this splitting is unlikely as the protons are decoupled and a coupling to the fluorine atoms is not observable: the ^{19}F{^{1}H} NMR signal of (**Rh*←1**) is a singlet at δ = −72 ppm with a half-width of 3 Hz (including 1 Hz line broadening by exponential multiplication).

^{1}H, ^{13}C, ^{31}P, and ^{103}Rh NMR Parameters of 1 and 2 and Chiral Recognition

All chemical shifts and coupling constants of the phosphanes **1** and **2**, as free ligands and as their adducts with **Rh***, are listed in Table 1 and Table 2. In addition, the complexation shifts [Δδ = δ(adduct) − δ(free)] are given, and Table 2 shows the dispersion effects Δν (in Hz), which are the signal splittings due to the existence of two diastereomeric complexes. Dispersion values are field-dependent and refer to B_0 = 11.74 Tesla corresponding to 500 MHz ^{1}H (except for the ^{103}Rh values: B_0 = 9.4 Tesla, see Scheme 3).

Strong complexation shifts Δδ are observed for the phosphorus atom and for carbons nearby, and numerous ^{31}P,^{1}H and ^{31}P,^{13}C coupling constants are changed significantly as well, up to threefold or down to one half. This is clearly



Scheme 3. Diastereomerism dispersions (Δν, in Hz) of **Rh*←2**, in $CDCl_3$ at 11.74 Tesla (^{103}Rh at 9.4 Tesla); R = MTPA; the two ethyl groups are not diastereotopic due to rapid interchange by nitrogen inversion; in contrast, the hydrogen atoms of the CH_2 groups are diastereotopic

a consequence of the above-mentioned strong interaction between the phosphanes and the rhodium atoms they are ligated to. Even a deshielding of 3.2 ppm for the *para*-carbon in **2** and one of 1.9 ppm for **1** can be noticed indicating that the inductive effect of the phosphorus atom on the benzene system is severely changed by adduct formation.

As can be seen in Scheme 3, strong dispersions appear at the phosphorus and the carbon atoms of **2**. Thus, enough nuclei exist for a safe, direct determination of the enantiomeric ratio of the phosphane (chiral recognition). Interestingly, the ^{1}H atoms in the phosphane do not show well-resolved signals in these phosphanes, except for the P-CH_3 signal — although this nucleus is generally favourable for chiral recognition — and measurements of further nuclei are often not required.[1,8] Currently, we are investigating a great variety of further chiral phosphanes to see whether or not this is a general rule.

It should be noted that dispersions of **Rh*** signals can be observed in the phosphane adducts with **2** as well, namely those of the ^{1}H and the ^{13}C signal of the methoxy group in the MTPA ligands (^{1}H: δ = 2.99 and 2.97 ppm, Δν = 12.1 Hz; ^{13}C: $\delta = 54.6_0$ and 54.5_6 ppm, Δν = 4.0 Hz). This is another proof for the fact that the adducts **Rh*←1** and **Rh*←2** are kinetically stable. If the complexes were kinetically unstable (as usually occurs for ligands other than phosphanes), only one time-averaged signal each would be visible.

As mentioned above, ^{103}Rh NMR spectroscopy is not straightforward. Only a few reports seem to exist approaching stereochemical problems by ^{103}Rh NMR spectroscopy, all on mononuclear complexes. They cover studies on catalytically active species, for example on diastereomeric enamide complexes,[12] on the stereoselectivity of the hydrogen addition to them,[13] or on the relation between δ(^{103}Rh) and changes in the ligand sphere affecting catalytic activity.[9f,9j]

In our study, the rhodium atoms reflect the diastereomerism of the **Rh*←2** adducts (Figure 2). The directly attached rhodium atom [Rh(1)] shows a large chemical shift difference of 14 ppm for the two diastereomeric complexes, corresponding to a dispersion (Δν) of 182 Hz whereas, expectedly, the remote one [Rh(2)] is much less sensitive; the correlation peaks can show a slight dispersion of 9 Hz, whereas the ^{103}Rh signal in the F_1 projection cannot resolve it (Figure 2, right). This proves the sensitivity of the rhodium nuclei in the chiral recognition experiment. Further molecular systems are currently under investigation in our laboratory.

Conclusion

For the first time, a methodology was derived for observing ^{103}Rh resonances in dirhodium-phosphane adducts (AMX spin systems) based on ^{31}P-detected ^{103}Rh HMQC NMR spectroscopy. It is shown that not only ^{31}P and ^{13}C but also ^{103}Rh signals reflect the stereochemistry of the complexes with chiral phosphanes with great sensitivity.

Experimental Section

Compounds: The synthesis of **Rh*** has been described before.[1a] Triphenylphosphane (**1**) is commercially available. *N*,*N*-Diethylamino-(methyl)(phenyl)phosphane (**2**) was synthesized according to a known procedure: Bis(*N*,*N*-diethylamino)phenylphosphane [$PhP(NEt_2)_2$], prepared from dichloro(phenyl)phosphane and diethylamine,[14] was reacted with dichlorophenylphosphane as described[15] (although without solvent) to produce *N*,*N*-diethylamino-(chloro)(phenyl)phosphane [$PhP(NEt_2)Cl$]. This compound was converted into **2** by reaction with MeLi in diethyl ether according to the procedure described by Nöth et al.[16] Yield 74%.

NMR Spectroscopy: ^1H (500.1 MHz), ^{13}C (125.8 MHz), and ^{31}P NMR measurements (202.4 MHz) of the free ligands **1** and **2** in the absence and presence of **Rh*** were performed on a Bruker DRX-500 spectrometer equipped with a broad-band probe head. Solutions were about 0.05−0.06 M in $CDCl_3$. Standards were internal tetramethylsilane ($\delta = 0$) for ^1H and ^{13}C, and external aqueous H_3PO_4 (85%) ($\delta = 0$) for ^{31}P. Digital resolutions were 0.27 Hz/point in the ^1H, 0.48 Hz/point in the ^{13}C and 0.43 Hz/point in the ^{31}P NMR spectra. ^{19}F NMR (235.4 MHz) of [**Rh***←**1**] was measured on a Bruker AC 250 spectrometer with the shift referenced against CCl_3F.

Typically, the samples were prepared by mixing 48.6 mg of **Rh*** (0.043 mmol) and a molar equivalent of **1** in 0.75 mL $CDCl_3$; 7 μL (1 drop) of [D_6]acetone were added to increase the solubility of **Rh***.[1e,8]

The unequivocal signal assignments in the ^1H and ^{13}C NMR spectra of **1** and **2** were assisted by H,H COSY, and ^1H-detected ^{13}C HMQC and HMBC NMR experiments using standard Bruker software. In cases where signal splittings due to ^{31}P-coupling had to be differentiated from dispersion effects (Δν), spectra were recorded at different B_0 (9.40 and 11.74 Tesla). (Δν values are field-dependent, coupling constants are not.)

^{103}Rh NMR spectroscopy was carried out on a Bruker ARX 400 spectrometer, equipped with a commercial triple-resonance probe, by "inverse detection" with ^{31}P as the sensitive nucleus. The standard four-pulse HMQC sequence with continuous proton decoupling was applied,[17,18] the choice of the transfer delay (d_2) was according to criteria described in the text. The chemical shifts were referenced against Ξ (^{103}Rh) = 3.16 MHz.[19] The samples of both complexes had a tetramethylsilane proton frequency of 400.130010 MHz, leading to a rhodium reference frequency, $\delta(^{103}Rh) = 0$, of 12.644108 MHz. Each experiment was performed *at least* twice with a variation of the rhodium offset and the t_1 increment to ensure that the signals in the F_1 dimension (^{103}Rh) are not folded. The digital resolution in this direction was better than 0.5 ppm in the final spectra that were recorded for shift determination. Rhodium shifts were reproducible to within ±2 ppm; we attribute observed variations to slight temperature changes (rhodium shifts have a pronounced temperature coefficient[9e][19b]). Although the data were acquired with TPPI phase cycling, a proper phasing of the signals was not always possible (regardless of whether an additional refocusing delay of duration d_2 was inserted between the last HF pulse and the data acquisition or not), hence some spectra presented in this paper are in the magnitude mode.

For a given spin system, the effect of varying experimental parameters on the HMQC spectra was tested by simulation with the NMR-SIM program (Bruker Rheinstetten). In all cases, results were as predicted by Equations (1)−(9) (see Appendix), and they were compatible with the experimental results.

APPENDIX

Signal Intensities and Multiple-Quantum Coherences in HMQC Spectroscopy of First-Order AMX Spin Systems (A = ^{31}P; M and X = ^{103}Rh): The following discussion holds for the standard four-pulse HMQC experiment, $\pi/2(^{31}P) - d_2 - \pi/2(^{103}Rh) - d_0/2 - \pi(^{31}P) - d_0/2 - \pi/2(^{103}Rh) -$ acquisition[17] in its simple as well as in its phase-sensitive (TPPI) version. The behaviour of the three-spin system ^{31}P-$^{103}Rh(1)$-$^{103}Rh(2)$ with $J[P,Rh(1)] = J_1$ and $J[P,Rh(2)] = J_2$ under the influence of this sequence can be described as follows. At the beginning of the evolution period d_0, just after the first $\pi/2(^{103}Rh)$ pulse ($t = d_2$), the state of the three-spin system is given by the density operator:

$$\sigma = (0Rh) + (1Rh_1) + (1Rh_2) + (2Rh) \quad (1)$$

where

$$(0Rh) = P(\pi/2)f_0(d_2) \quad (2)$$

$$(1Rh_1) = -2P(0)Rh_1(\pi/2)f_1(d_2) \quad (3)$$

$$(1Rh_2) = -2P(0)Rh_2(\pi/2)f_2(d_2) \quad (4)$$

$$(2Rh) = -4P(\pi/2)Rh_1(\pi/2)Rh_2(\pi/2)f_{12}(d_2) \quad (5)$$

with

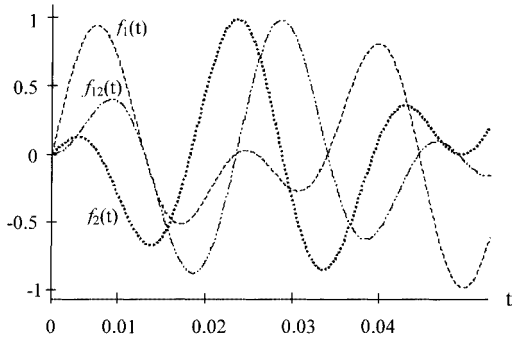
$$f_0(t) = \cos(\pi J_1 t)\cos(\pi J_2 t) \quad (6)$$

$$f_1(t) = \sin(\pi J_1 t)\cos(\pi J_2 t) \quad (7)$$

$$f_2(t) = \cos(\pi J_1 t)\sin(\pi J_2 t) \quad (8)$$

$$f_{12}(t) = \sin(\pi J_1 t)\sin(\pi J_2 t) \quad (9)$$

The ^{31}P chemical shift frequency is set to zero in these equations, and the notation follows that given in ref.:[11] $P(\varphi)$ and $Rh_i(\varphi)$ denote the phosphorus and rhodium, Rh(i), spin operators for arbitrary phase φ. The zero- and two-spin rhodium coherences ($0Rh$) and ($2Rh$) are suppressed by complete phase cycling. The single-rhodium terms ($1Rh_1$) and ($1Rh_2$) produce the desired 2D peaks at true rhodium chemical shifts in the F_1 dimension. The magnitude of these correlation signals is defined by the trigonometric factors $f_1(t)$ and $f_2(t)$, see Equations (7) and (8) and Scheme 3. It is important to note that the extreme points of $f_1(t)$ and $f_2(t)$ do not coincide with the extreme points of $\sin(\pi J_1 t)$ and $\sin(\pi J_2 t)$. They cannot be deduced from the equation $d_2 = (2J)^{-1}$, as is normal for HMQC, as this might lead to complete lack of signal intensity in unfavourable cases (see Scheme 4)! A homonuclear coupling between the rhodium atoms would lead to a splitting along F_1 by J(Rh,Rh) solely of the ($1Rh$) correlation signals. This has been tested by simulation (see Exp. Sect.).



Scheme 4. Time dependence of the trigonometric factors $f_n(t)$ [Equations (7)−(9)] in a three-spin system ^{31}P-^{103}Rh-^{103}Rh, calculated for $J_1 = 95.5$ Hz and $J_2 = 21.6$ Hz (values applicable for [**Rh***←**1**])

Synthesis, Characterisation and Reactivity towards Pd^{II} and Pt^{II} of *ortho*-, *meta*- and *para*-Xylyl-Based Phosphorus-Containing Macrocycles

Lluis Escriche,*[a] José Antonio Muñoz,[a] Raikko Kivekäs,[b] Reijo Sillampää,[c] and Jaume Casabó[a]

Keywords: Macrocycles / Palladium, Platinum / S ligands / Phosphanes

The new *meta*- and *para*-xylyl-based phosphadithiamacrocycles 6-phenyl-6-phospha-3,9-dithiabicyclo[9,3,1]pentadeca-1(15),12,14-triene (L2) and 6-phenyl-6-phospha-3,9-dithiabicyclo[9,2,2]pentadeca-1(13),12,14-triene (L3) have been synthesised and characterised. The reactivity of these ligands and the previously described *ortho*-xylyl macrocycle 6-phenyl-6-phospha-3,9-dithiabicyclo[9,4,0]pentadeca-1(11),12,14-triene (L1) with $[PdCl_2(cod)]$ and $K_2[PtCl_4]$ has been studied. $[MCl_2(L)]$ complexes have been obtained and characterised by NMR spectroscopy. X-ray structural analyses have been carried out in the case of $[PdCl_2L2]\cdot CH_3CN$ (**2·CH$_3$CN**) and $[PdCl_2L3]$ (**3**). In both compounds the Pd^{II} ion adopts a slightly distorted square-planar coordination defined by one *S*-thioether, the P-phosphane atoms of the ligand and two chlorine atoms, which are oriented in a mutual *cis* position, whereas the second *S*-thioether atom of the ligand remains uncoordinated. According to the spectroscopic data, the same coordination mode is found for the Pt^{II} complexes.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The synthesis and chemical properties of phosphamacrocycles are less developed and studied than those of their oxygen or nitrogen equivalents.[1] This is partially due to the air-sensitivity of the reagents used in their preparations and problems in isolating the final products, especially in the case of homoleptic polyphosphamacrocycles,[2] which are usually obtained by template methods.[3] Phosphathiamacrocycles are more accessible as free ligands and several examples can be found in the literature.[4−6] Generally, the interest in asymmetric phosphorus-sulfur donor ligands, which has recently been reviewed,[7] is focused mainly towards their ability to act as hemilabile ligands and their potential use in catalytic processes.[8] Other interesting possibilities are found when these P−S donor systems are integrated in macrocyclic systems, such as the documented ability of their phosphoryl[9,10] and thiophosphoryl[11] derivatives to interact selectively with ionic species, thus acting as chemical sensors for anions.

As part of our work in this field, we report here the synthesis of the new xylyl-based phosphadithiamacrocycles 6-phenyl-6-phospha-3,9-dithiabicyclo[9,3,1]pentadeca-1(15),12,14-triene (L2) and 6-phenyl-6-phospha-3,9-dithiabicyclo[9,2,2]pentadeca-1(13),12,14-triene (L3), and the reactions of these compounds and the previously described 6-phenyl-6-phospha-3,9-dithiabicyclo[9,4,0]pentadeca-1(11),12,14-triene (L1),[12] with $[PdCl_2(cod)]$ and $K_2[PtCl_4]$.

Results and Discussion

The ligands L2 an L3 were obtained by reaction of 3-phenyl-3-phosphapenta-1,5-dithiolate (generated in situ)

and the appropriate α,α′-dichloro-xylene (Scheme 1) in similar conditions to those described for the synthesis of L1.[12] The yields of L2 and L3 (17% and 15%, respectively) were lower than that reported for L1 (23%), which reflects the steric hindrance imposed by the *meta* and *para* substitution of the xylyl unit to obtain the [1+1] macrocyclic compound.

The $^{31}P\{^1H\}$ NMR spectra of L2 and L3 show singlet at δ = −23.7 and −27.2 ppm, respectively, corresponding to the intraannular phosphorus atom. These values are similar to that previously reported for the ligand L1 (δ = −21.4 ppm)[12] and other similar phosphorus-containing macrocycles.[13,24] As can be seen, there is a small, but systematic, high-field shift of the P-resonances through the *ortho*, *meta* and *para* sequence, which probably reflects the increasing interaction between the aromatic π-system of the xylene ring and the phosphorus nucleus as a consequence of the different structural requirements in this series of macrocycles.

The ^1H NMR spectra of both macrocycles exhibit a complex pattern due to the high inversion energy barrier of the phosphane group,[14] which makes the geminal methylene protons non-equivalent. In both cases the aromatic protons of the phenyl rings appear as a complex multiplet between δ = 7 and 7.5 ppm, whereas the -S−CH_2-Ar methylene protons appear as a doublet of doublets (AB system) centred at δ = 3.74 and 3.80 ppm for L2 and L3, respectively. The two remaining methylene groups give four groups of complex signals between δ = 1.0 and 2.4 ppm. This reflects a coupling between all four protons and the phosphorus atom defining an ABMNX system similar to that found in the L1 ligand[12] and in other related phosphorous-containing macrocyclic molecules,[15,24] which makes the assignment of these signals difficult

The $^{13}C\{^1H\}$ NMR spectra of L2 and L3 are similar and only show one signal for each different carbon atom in the molecule, split in some cases by P−C coupling. The -S−C−Ar carbon atoms appear as a sharp singlet at δ = 35.0 and 36.6 ppm for L2 and L3, respectively, whereas the -S−C−C−P carbon atoms appear as a doublet of doublets centred at δ = 26.0 ($J_{P,C}$ = 20.3 Hz) and 26.9 ppm ($J_{P,C}$ = 22.2 Hz) for L2, and δ = 25.5 ($J_{P,C}$ = 18.7 Hz) and 28.6 ppm ($J_{P,C}$ = 16.4 Hz) for L3. According to literature data for the P−C(13) coupling constants[16] and the observed chemical shift of similar phosphane-containing ligands,[12,17,24] we assigned the first and second doublets to the carbon atoms located in the α- and β-positions, respectively, with respect to the phosphorus atom.

The Pd^{II} complexes $[PdCl_2L1]$ (**1**), $[PdCl_2L2]\cdot CH_3CN$ (**2·CH$_3$CN**) and $[PdCl_2L3]$ (**3**) were obtained by reaction of equimolar amounts of $[PdCl_2(cod)]$ dissolved in methanol (**1**) or acetonitrile (**2**, **3**) and a dichloromethane solution of the corresponding ligand (Scheme 1).

The compound **1** containing the *o*-xylyl based macrocycle L1 was obtained as an amorphous yellow material highly insoluble in all tested solvents and no additional measurements could be done. However, compounds **2** and **3** are sufficiently soluble in acetonitrile to allow their slow crystallisation from the reaction mixture if large quantities of solvent are used in the synthesis. These complexes are also sufficiently soluble in DMSO to record their NMR spectra.

The $^{31}P\{^1H\}$ NMR spectra of **2** and **3** only show one signal each at δ = 73.7 and 69.3 ppm, respectively, which suggests the presence of a unique species in solution. The positions of these resonances are similar to those found in other *cis*-$[PdCl_2L]$ complexes where L is a macrocyclic[18] or open-chain ligand[19] containing a phosphane-thioether donor-set of atoms coordinated to the Pd atom forming a five-membered chelate ring. It is well-known that chelating phosphanes in a five-membered ring are deshielded (by about 25−35 ppm) in the ^{31}P NMR spectrum, whereas in a six-membered ring they are shielded (by about 5−15 ppm), relative to related nonchelating ligands.[5,20]

The ^1H NMR spectra of both compounds are significantly more complex than those of the corresponding ligands, especially between δ = 0.3 and 3.5 ppm where the number of broad signals seems to indicate that all eight -S−CH_2−CH_2−P- protons become nonequivalent. The region between δ = 3.7 and 5.0 ppm, where the -S−CH_2−Ph-methylene proton resonances appear, is more informative regarding the coordinating behaviour of these macrocycles. Complex **2** shows two pairs of doublets in this area, indicating the presence of four nonequivalent protons (Figure 1b). The first high-field pair of doublets has an average position (δ = 3.87 ppm) similar to that found in the free ligand (δ = 3.74 ppm), and the same coupling constant ($J_{H,H}$ = 13.8 Hz), although the chemical shift difference between the centre of gravity of both doublets increases from 0.08 ppm in L2 to 0.18 ppm in **2** (Figure 1a). The second pair of doublets ($J_{H,H}$ = 13.8 Hz) is centred at δ = 4.51 ppm with a Δδ value of 0.59 ppm. This situation is similar for **3**, although a more complex spectrum is obtained. This is a result of the small difference in the chemical shift of three of the four doublets, which appear between δ = 3.84 and 4.02 ppm. To clarify this situation we performed a simulation of the above-mentioned spectra. Figure 1d and 1c show the experimental spectrum and the spectrum fitted with the gNMR simulation software,[21] respectively, for **3** in this region. The coincidence between them permits the calculation of the values of δ and the coupling constants for both pairs of doublets, which are centred at δ = 4.22 ppm (Δδ = 0.59 ppm, $J_{H,H}$ = 12.4 Hz) and δ = 3.97 ppm (Δδ = 0.06 ppm, $J_{H,H}$ = 11.7 Hz). As observed for **2**, the position and the appearance of the first high-field pair of doublets of **3** is similar to that found in free L3 (δ = 3.81 ppm, Δδ = 0.07 ppm). These data indicate a loss of symmetry in ligands L2 and L3 when they coordinate to the Pd^{II} ion, making the two -S−CH_2-Ph methylene groups nonequivalent. The fact that one of these CH_2 groups appears centred at a similar chemical shift to the free ligand in both complexes, whereas the other, more deshielded, shows a significant increase in the Δδ value between the two geminal protons suggests that only one of the *S*-thioether atoms is involved in coordination to the Pd^{II} atom. The structural information provided by the NMR spectra of **2** and **3** indicates that the behaviour of L2 and L3 as ligands with the Pd^{II} cation implies the simultaneous coordination of

one *S*-thioether and the P-phosphane atoms, forming a five-membered chelate ring and leaving the remaining *S*-thioether atom uncoordinated.

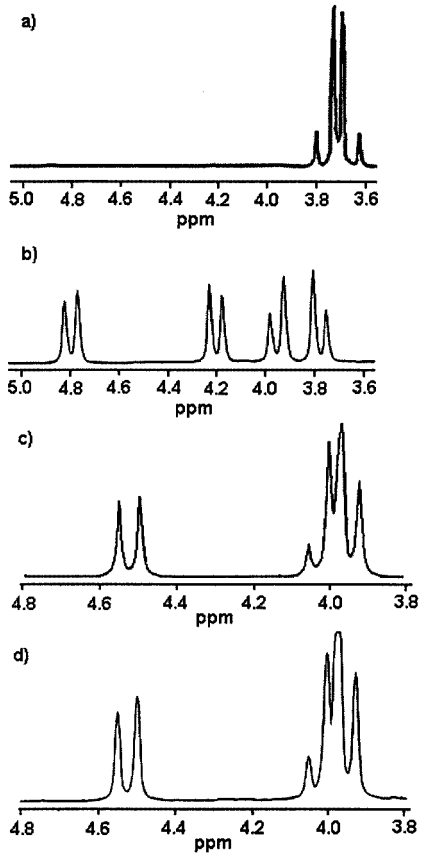

Figure 1. ^{1}H NMR spectra showing the -S−CH_2-Ar proton signals corresponding to: (a) the free ligand L2, (b) complex **2·CH_3CN**, (c) the simulation obtained with the gNMR software for **3** and (d) the complex **3**

The Pt^{II} complexes [$PtCl_2$L1] (**4**), [$PtCl_2$L2] (**5**) and [$PtCl_2$L3] (**6**) were obtained in a similar manner to that described for the Pd^{II} complexes using nitromethane solutions of $K_2[PtCl_4]$ as starting material. These complexes are significantly less soluble than their Pd^{II} equivalents. The $^{31}P\{^1H\}$ NMR spectra of **5** and **6** show a singlet, with satellites corresponding to the ^{195}Pt-^{31}P coupling, at δ = 46.4 ppm ($J_{Pt,P}$ = 3583 Hz) and δ = 41.2 ppm ($J_{Pt,P}$ = 3674 Hz), respectively. These values are similar to those found in related [*cis*-$PtCl_2$(P−S)] complexes where the P−S ligand forms a five-membered chelate ring.[18−20,22] The ^{1}H NMR spectra of both compounds show the same pattern as those recorded for **2** and **3**. Taking these data into account, it can be concluded that the platinum complexes **5** and **6** are isostructural with the Pd complexes **2** and **3**.

The X-ray diffraction analysis of **2·CH_3CN** and **3** confirms these structural deductions. The ORTEP diagrams for **2** and **3** are shown in Figure 2 and 3, respectively. Crystallographic data for both structures are listed in Table 1, and selected bond lengths and angles are summarised in Table 2. The coordination geometry around the Pd atom in both complexes is a slightly distorted square-plane defined by one *S*-thioether, the P-phosphane atoms of the ligand and two chlorine atoms, which are oriented in a mutual *cis* position. The distortion from ideal geometry around the Pd metal ions is evidenced by the P−Pd−S1 angles [87.44(5)° and 87.79(6)° for **2·CH_3CN** and **3** respectively]; this distortion can be attributed to the bite angle of the chelating ligand. In both complexes, the two Pd−Cl distances [2.3851(12) Å and 2.3118(14) Å for **2**, 2.3874(18) Å and 2.3094(18) Å for **3**] differ significantly. The Pd−Cl distance *trans* to the phosphorus atom is larger, reflecting the stronger *trans* effect of the phosphorus ligand atom relative to sulfur. The values of these Pd−Cl distances and the Pd−P and Pd−S distances lie in the same range as those found in related *cis*-[$PdCl_2$L] compounds, where L is a *P,S*-chelating ligand.[18,19,23] An interesting feature of the L3 ligand skeleton in **3** is the marked distortion observed around the *para*-substituted xylene ring as seen by the significant displacement of the methylene carbon atoms C1 and C8 out of the plane defined by the aromatic ring [0.32(1) Å and 0.40 (1) Å, respectively]. This fact reflects the steric constraint imposed on this ligand by the *P,S*-chelate ring

formation, which forces the xylene unit to interact with the aliphatic chain.

[a] C(Ar) = C(6) for **2·CH$_3$CN** and C(5) for **3**.

Conclusion

X-ray diffraction analysis of compounds **2·CH$_3$CN** and **3** shows an exocyclic coordination to Pd^{II} by these phosphorus- and sulfur-containing *meta*- and *para*-xylyl-based macrocyclic ligands. This coordination involves only one sulfur atom of the ligand and the P-phosphane unit. The coordination sphere is completed by two chlorine atoms. A comparative experimental and theoretical study of the ^{1}H, ^{13}C{^{1}H} and ^{31}P{^{1}H} NMR spectra of compounds **2**, **3**, **5** and **6**, especially in the region in which the proton methylene resonances of the -S−CH$_2$-Ph unit appear, allowed us to assign the same coordination mode to the corresponding Pt^{II} compounds. The insolubility of **1** and **4** prevents further structural characterisation, but the similarity observed between the related ligands L2 and L3 in their coordinating behaviour permits us to extend it to the *o*-xylyl-based ligand L1.

Experimental Section

General Remarks: All syntheses were carried out using standard Schlenk techniques under a dry dinitrogen atmosphere. The solvents were dried by conventional methods and distilled under dinitrogen before use. Dilithium 3-phenyl-3-phosphapenta-1,5-dithiolate[24] and 6-phenyl-6-phospha-3,9-dithiabicyclo[9,4,0]pentadeca-1(11),12,14-triene (L1)[12] were prepared according literature procedures. Elemental analyses were performed using a Carlo Erba EA-1108 instrument in the Chemical Analysis Service of the Universitat Autònoma de Barcelona. All NMR spectra were run by the NMR Service of the Universitat Autònoma de Barcelona. ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded using a Bruker 400 MHz AM instrument and the ^{31}P{^{1}H} NMR spectra were recorded using a Bruker 250 MHz AC instrument with chemical shifts given in ppm relative to 85% H_3PO_4. COSY and HETCOR ^{1}H-^{13}C experiments were made in order to assign the ^{1}H and ^{13}C spectra by using general standard parameters. Mass spectra were recorded using a HP298S GC/MS system.

6-Phenyl-6-phospha-3,9-dithiabicyclo[9,3,1]pentadeca-1(15),12,14-triene (L2): A solution of dilithium 3-phenyl-3-phosphapenta-1,5-dithiolate in THF (100 mL, 0.18 M) and a solution of α,α′-dichloro-*m*-xylene (3.13 g, 18 mmol) in THF (100 mL) were added simultaneously to THF (500 mL) over a period of five hours at room temperature under a dinitrogen atmosphere. The resulting mixture was then stirred for a further 48 h. The THF was removed under vacuum and the resulting oily yellow residue was treated with diethyl ether (150 mL). The LiCl precipitate was filtered off and the filtrate was evaporated to a final volume of 5 mL and chromatographed over neutral Al_2O_3. The fraction eluting with toluene/CH_2Cl_2 (1:1) was collected and evaporated to obtain L2 as a colourless oil. Yield 1.02 g, 17%. $C_{18}H_{21}PS_2$ (332.5): calcd. C 65.04, H 6.37, S 19.26; found C 64.9, H 6.2, S 19.1. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.66−1.84 (m, 4 H, -S−C*H*$_2$−CH$_2$-), 2.08−2.42 (m, 4 H, -S−CH$_2$−C*H*$_2$−P-), 3.71 (d, $J_{H,H}$ = 13.1 Hz, 2 H, -S−C*H*$_2$-Ph), 3.77 (d, $J_{H,H}$ = 13.1 Hz, 2 H, -S−C*H*$_2$-Ph), 7.07−7.45 (m, 9 H, Ar) ppm. ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$): δ = 26.0 (d, $J_{P,C}$ = 20.3 Hz, S−CH$_2$-*C*H$_2$−P-), 26.9 (d, $J_{P,C}$ = 22.2 Hz, −S-*C*H$_2$−CH$_2$−P-), 35.1 (-S-*C*H$_2$-Ph), 127.8 (-CH$_2$-*Ph*−CH$_2$-), 128.2 (s, P-Ph), 128.3 (d, $J_{P,C}$ = 7.4 Hz, P-Ph), 130.3 (-CH$_2$-*Ph*−CH$_2$-), 130.5 (-CH$_2$-*Ph*−CH$_2$-), 131.4 (d, $J_{P,C}$ = 16.6 Hz, P-Ph), 136.7 (d,

$J_{P,C}$ = 12.9 Hz, P-Ph), 137.3 (-CH_2-*Ph*−CH_2-) ppm. $^{31}P\{^1H\}$ NMR (101 MHz, $CDCl_3$): δ = −23.7 ppm. MS: (EI): *m*/*z* = 332 [M^+].

6-Phenyl-6-phospha-3,9-dithiabicyclo[9,2,2]pentadeca-1(13),12,14-triene (L3): The compound was prepared by the same procedure as for L2 using α,α′-dichloro-*p*-xylene (3.13 g, 18 mmol). Yield 0.89 g, 15%. $C_{18}H_{21}PS_2$ (332.5): calcd. C 65.04, H 6.37, S 19.26; found C 65.1, H 6.3, S 19.0. ^1H NMR (400 MHz, $CDCl_3$): δ = 0.98−1.42 (m, 4 H, -S−C*H*$_2$−CH_2-), 2.32 (m, 4 H, -S−CH_2−C*H*$_2$−P-), 3.77 (d, $J_{H,H}$ = 13.1 Hz, 2 H, -S−C*H*$_2$-Ph), 3.84 (d, $J_{H,H}$ = 13.1 Hz, 2 H, -S−C*H*$_2$-Ph), 7.12−7.45 (m, 9 H, Ar) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ = 25.5 (d, $J_{P,C}$ = 18.7 Hz, S−CH_2-*C*H_2−P-), 28.7 (d, $J_{P,C}$ = 16.4 Hz, -S-*C*H_2−CH_2−P-), 36.6 (-S-*C*H_2-Ph), 128.2 (d, $J_{P,C}$ = 4.7 Hz, P-Ph), 128.4 (s, P-Ph), 130.4 (-CH_2-*Ph*−CH_2-), 131.8 (d, $J_{P,C}$ = 18.7 Hz, P-Ph), 136.6 (-CH_2-*Ph*−CH_2-), 136.9 (d, $J_{P,C}$ = 16.4 Hz, P-Ph) ppm. $^{31}P\{^1H\}$ NMR (101 MHz, $CDCl_3$): δ = −27.2. MS (EI): *m*/*z* = 332 [M^+].

[$PdCl_2$L1] (1): A solution of L1 (50 mg, 0.15 mmol) in dichloromethane (5 mL) was slowly added to a solution of [$PdCl_2$(cod)] (43 mg, 0.15 mmol) in methanol (10 mL). The yellow complex obtained was filtered off, washed with diethyl ether and vacuum dried. Yield 0.057 g, 74%. $C_{18}H_{21}Cl_2PPdS_2$ (509.8): calcd. C 42.53, H 4.17, S 12.59; found C 42.3, H 4.1, S 12.3.

[$PdCl_2$L2]·CH_3CN (2·CH_3CN): A solution of L2 (230 mg, 0.69 mmol) in dichloromethane (3 mL) was slowly added to a solution of [$PdCl_2$(cod)] (198 mg, 0.69 mmol) in acetonitrile (200 mL). The resulting mixture was refluxed for 48 h and cooled down slowly to room temperature. A yellow crystalline material suitable for X-ray diffraction analysis was filtered off, washed with diethyl ether and vacuum dried. Yield 0.266 g, 70%. $C_{20}H_{24}Cl_2NPPdS_2$ (562.9): calcd. C 43.72, H 4.41, N 2.55, S 11.65; found C 43.6, H 4.3, N 2.5, S 11.5. ^1H NMR [400 MHz, $(CD_3)_2SO$]: δ = 0.95−3.44 (m, 8 H, -S−C*H*$_2$−C*H*$_2$−P), 3.78 (d, $J_{H,H}$ = 13.8 Hz, 1 H, −S−C*H*$_2$-Ph), 3.96 (d, $J_{H,H}$ = 13.8 Hz, 1 H, −S−C*H*$_2$-Ph), 4.21 (d, $J_{H,H}$ = 13.1 Hz, 1 H, -S−C*H*$_2$-Ph), 4.80 (d, $J_{H,H}$ = 13.1 Hz, 1 H, −S−C*H*$_2$-Ph), 7.26−8.43 (m, 9 H, Ar) ppm. $^{13}C\{^1H\}$ NMR [100 MHz, $(CD_3)_2SO$]: δ = 24.6 (d, $J_{P,C}$ = 24.0 Hz, S-*C*H_2−CH_2-), 27.9 (s, -CH_2-*C*H_2−P-), 28.1 (s, -CH_2-*C*H_2−P-), 33.7 (d, $J_{P,C}$ = 33.3 Hz, S-*C*H_2−CH_2-), 38.6 (s, -S-*C*H_2-Ph), 40.7 (s, -S-*C*H_2-Ph), 127.1, 128.5, 128.6, 129.3, 129.9, 131.1, 131.9 132.3, 132.4, 133.26, 142.1 (Ar) ppm. $^{31}P\{^1H\}$ NMR [101 MHz, $(CD_3)_2SO$]: δ = 73.7 ppm.

[$PdCl_2$L3] (3): This compound was prepared by the same procedure as for **2** using L3 as ligand. Yield 0.270 g, 70%. $C_{18}H_{21}Cl_2PPdS_2$ (509.8): calcd. C 42.53, H 4.17, S 12.59; found C 42.2, H 4.0, S 12.4. ^1H NMR [400 MHz, $(CD_3)_2SO$]: δ = 0.33−3.25 (m, 8 H, -S−C*H*$_2$−C*H*$_2$−P), 3.84 (d, $J_{H,H}$ = 11.7 Hz, 1 H, -S−C*H*$_2$−Ph), 3.95 (d, $J_{H,H}$ = 12.4 Hz, 1 H, -S−C*H*$_2$−Ph), 4.02 (d, $J_{H,H}$ = 11.7 Hz, 1 H, -S−C*H*$_2$−Ph), 4.51 (d, $J_{H,H}$ = 12.4 Hz, 1 H, -S−C*H*$_2$-Ph), 7.32−8.75 (m, 9 H, Ar) ppm. $^{13}C\{^1H\}$ NMR [100 MHz, $(CD_3)_2SO$]: δ = 23.9 (s, -CH_2-*C*H_2−P), 26.5 (d, $J_{P,C}$ = 16.6 Hz, -S-*C*H_2−CH_2-), 28.9 (s, -CH_2-*C*H_2−P-), 34.8 (s, -S-*C*H_2-Ph), 36.1 (d, $J_{P,C}$ = 33.3 Hz, -S-*C*H_2−CH_2-), 42.1 (s, -S-*C*H_2-Ph), 127.3, 128.23, 128.55, 128.6, 130.9, 131.4, 131.8, 131.9, 132.29, 132.5, 132.8, 135.8, 137.8 (Ar) ppm. $^{31}P\{^1H\}$ NMR [101 MHz, $(CD_3)_2SO$]: δ = 69.3 ppm.

[$PtCl_2$L1] (4): A solution of L1 (100 mg, 0.30 mmol) in dichloromethane (2 mL) was slowly added to a solution of $K_2[PtCl_4]$ (125 mg, 0.30 mmol) in nitromethane (100 mL) and the resulting mixture was refluxed for 3 h. A white precipitate of **4** mixed with KCl appeared which was filtered off, washed with water (50 mL) and diethyl ether (50 mL) and vacuum dried. Yield 0.173 g, 96%. $C_{18}H_{21}Cl_2PPdS_2$ (509.8): calcd. C 36.18, H 3.55, S 10.71; found C 35.9, H 3.5, S 10.6.

[$PtCl_2$L2] (5): A solution of L2 (190 mg, 0.57 mmol) in dichloromethane (2 mL) was slowly added to a solution of $K_2[PtCl_4]$ (237 mg, 0.57 mmol) in nitromethane (100 mL) and the resulting mixture was refluxed for 48 h. The solvent was then removed under vacuum and the residue treated with dichloromethane (100 mL). The KCl precipitate was filtered off and the remaining solution was then evaporated to a final volume of 50 mL. A microcrystalline solid appeared, which was filtered off and recrystallised from acetonitrile. Yield 0.240 g, 70%. $C_{18}H_{21}Cl_2PPdS_2$ (509.8): calcd. C 36.18, H 3.55, S 10.71; found C 36.0, H 3.5, S 10.7. ^1H NMR [400 MHz, $(CD_3)_2SO$]: δ = 0.71−3.53 (m, 8 H, -S−C*H*$_2$−C*H*$_2$−P), 3.74 (d, $J_{H,H}$ = 13.4 Hz, 1 H, -S−C*H*$_2$-Ph), 3.90 (d, $J_{H,H}$ = 13.4 Hz, 1 H, -S−C*H*$_2$-Ph), 4.35 (d, $J_{H,H}$ = 13.4 Hz, 1 H, -S−C*H*$_2$-Ph), 4.75 (d, $J_{H,H}$ = 13.4 Hz, 1 H, -S−C*H*$_2$-Ph), 7.22−8.43 (m, 9 H, Ar) ppm. $^{13}C\{^1H\}$ NMR [100 MHz, $(CD_3)_2SO$]: δ = 23.2 (d, $J_{P,C}$ = 23.1 Hz, -S-*C*H_2−CH_2-), 26.5 (s, -CH_2-*C*H_2−P), 28.1 (s, -CH_2-*C*H_2−P-), 31.5 (d, $J_{P,C}$ = 38.8 Hz, S-*C*H_2−CH_2-), 37.5 (s, -S-*C*H_2-Ph), 38.8 (s, -S-*C*H_2-Ph), 125.3, 127.34, 127.52, 128.1, 128.5, 128.6, 130.3, 130.7, 130.8, 131.2, 131.37, 131.43, 140.7 (Ar) ppm. $^{31}P\{^1H\}$ NMR [101 MHz, $(CD_3)_2SO$]: δ = 46.4 (t, $J_{Pt,C}$ = 3583 Hz).

[$PtCl_2$L3] (6): This compound was prepared by the same procedure as for **5** using L3 as ligand. Yield 0.233 g, 68%. $C_{18}H_{21}Cl_2PPdS_2$ (509.8): calcd. C 36.18, H 3.55, S 10.71; found C 36.0, H 3.2, S 10.6. ^1H NMR [400 MHz, $(CD_3)_2SO$]: δ = 0.43−3.07 (m, 8 H, -S−C*H*$_2$−C*H*$_2$−P), 3.85−4.71 (m, 4 H, -S−C*H*$_2$-Ph), 7.28−8.48 (m, 9 H, Ar) ppm. $^{31}P\{^1H\}$ NMR [101 MHz, $(CD_3)_2SO$]: δ = 41.2 ppm (t, $J_{Pt,C}$ = 3674 Hz) ppm.

X-ray Crystallographic Study: Single-crystal data collections for compounds **2·CH_3CN** and **3** were performed at ambient temperature on a Rigaku AFC5S diffractometer using graphite-monochromatised Mo-K_α radiation. The unit cell parameters for both compounds were determined by least-squares refinement of 25 carefully centred reflections. Both sets of data obtained were corrected for Lorentz and polarisation effects, and for dispersion. Corrections for empirical absorption (ψ scan) were also applied. A total of 4267 and 3566 reflections giving 3980 and 3462 unique reflections (R_{int} = 0.0199 and 0.0257) were collected by ω/2θ scan mode ($2\theta_{max}$ = 50°) for **2·CH_3CN** and **3**, respectively.

Both structures were solved by direct methods by using the SHELXS-86 program[25] and least-squares refinements were performed using the SHELX-97 program system.[26] For both complexes non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in the calculations at the fixed distances from their host atoms and treated as riding atoms using the SHELX-97 default parameters.

CCDC-193056 (**2·CH_3CN**) and -193057 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A Novel Chiral Silver(I) Complex from the Reaction of Thiazolidinethione with AgOAc

Min Shi,*[a] Jian-Kang Jiang,[a] and Gui-Ling Zhao[a]

Keywords: Silver / Cluster compounds / S ligands / Structure elucidation

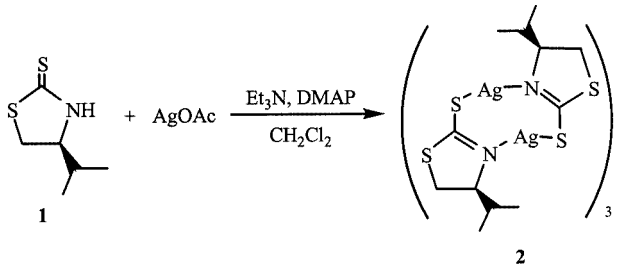
A novel chiral silver(I) complex was successfully synthesized from the reaction of chiral (*S*)-4-isopropylthiazolidine-2-thione ligand (**1**) with AgOAc in dichloromethane in the presence of Et_3N and DMAP at room temperature. Its unique crystal structure was unambiguously disclosed by X-ray analysis. The six silver atoms and six (*S*)-4-isopropylthiazolidine-2-thione ligands present in the complex are connected through the S and N atoms to form a cluster containing a silver octahedron with six faces of the octahedron capped by ligands.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Historically, the chemistry of metal-sulfur-nitrogen cluster complexes has been a very active field for organometallic chemists because of the novelty and versatility of the structures and reactivities of such clusters, as well as their potential applications as models for the active site in nonheme proteins such as the ferredoxins.[1] In addition, many cluster complexes bearing chiral ligands can be used as catalysts in asymmetric reactions.[2] Recently, during our investigations on the utilization of thiazolidine-2-thione as a chiral auxiliary, we found that the nitrogen atom and sulfur atom of the thiocarbonyl group of thiazolidine-2-thione can readily coordinate to a metal center to afford the corresponding chiral metal complex. In particular, with AgOAc as the metal source we found that a very unusual chiral metal cluster was formed under very mild reaction conditions. This novel cluster has a silver octahedron with six faces of the octahedron capped by chiral ligands. Herein, we wish to report the synthesis and crystal structure of this novel chiral Ag^I cluster complex.

Results and Discussion

The chiral ligand (*S*)-4-isopropylthiazolidine-2-thione (**1**) was prepared according to a literature procedure.[3] The reaction of **1** with AgOAc gave a novel Ag^I complex **2** in the presence of Et_3N and DMAP in dichloromethane under very mild reaction conditions (Scheme 1). The structure of **2** was established by spectroscopic data and microanalysis.



Scheme 1

We believe that the formation of **2** is caused by the fact that (*S*)-4-isopropylthiazolidine-2-thione (**1**) is in equilibrium with its tautomer **1′**, which reacts directly with AgOAc to give the corresponding Ag^I complex **2** (Scheme 2).[4] In order to clarify the crystal structure of **2** by X-ray analysis, we recrystallized **2** from dichloromethane and petroleum ether (1:5) to obtain a yellowish single crystal of **2** in which one molecule of CH_2Cl_2 was included (see the microanalysis data of **2** in the Exp. Section). The crystal structure is shown in Figure 1. Selected bond lengths and bond angles are shown in Table 1 and the crystal data of **2** are summarized in Table 2.

The chiral Ag^I complex **2** is an air- and moisture-stable solid which crystallizes in the space group *P*2(1)3. Six (*S*)-4-isopropylthiazolidine-2-thione (**1**) ligands and six Ag^I atoms form a cluster possessing a silver octahedron with six faces of the octahedron capped by ligands that alternate in

their orientation (Figure 1): two adjacent ligands take an anti-parallel direction using their S and N atoms to coordinate to the Ag center forming the Ag/S,N core network. Each Ag atom is coordinated by two sulfur atoms with bond lengths of 2.4527(16) and 2.5121(16) Å and a nitrogen atom with a bond length of 2.247(5) Å. In addition, the Ag^I-Ag^I distances are 2.9811(6), 3.2071(6), 3.3269(8), and 3.2071(6) Å. This distance is within the sum of the van der Waals radii of Ag of 3.44 Å (Ag = 1.72 Å[5]). The six silver atoms and six sulfur atoms present in complex **2** are connected with S and N atoms with the bond angles shown in Table 2. The Ag/S,N core forms a six-silver network. Two faces located at opposite sites of the cluster **2** are open. Based on a powder XRD analysis of the **2** obtained directly from the solvent after column chromatography (Figure 2) and of a single crystal of **2** obtained after recrystallization from dichloromethane and petroleum ether (1:5) (Figure 3), we can conclude that both samples are essentially the same. It is impossible to form by-products such as clusters of different nuclearity or coordination polymers from solution.

Compared to the metal-metal distances in the open-shell metallic silver in cluster **2** as well as to the rather underestimated sum of van der Waals radii (Ag−Ag = 3.44), we believe that a closed-shell d^{10}-d^{10} metallophilic interaction (argentophilic interaction) may exist in the above clusters[6] as the Ag−Ag distance is close to the upper van der Waals limit.[7] Assignment of these metal-metal contacts to crystal packing forces is unwarranted since the M−M vectors have a specific directionality. In addition, the M−M interactions do not seen to be dictated by ligand-packing effects. No π-

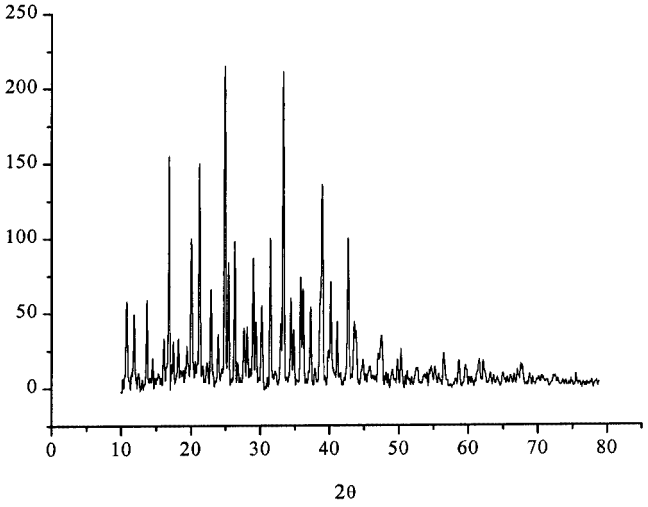

Figure 2. The powder XRD spectrum of **2** obtained directly by column chromatography

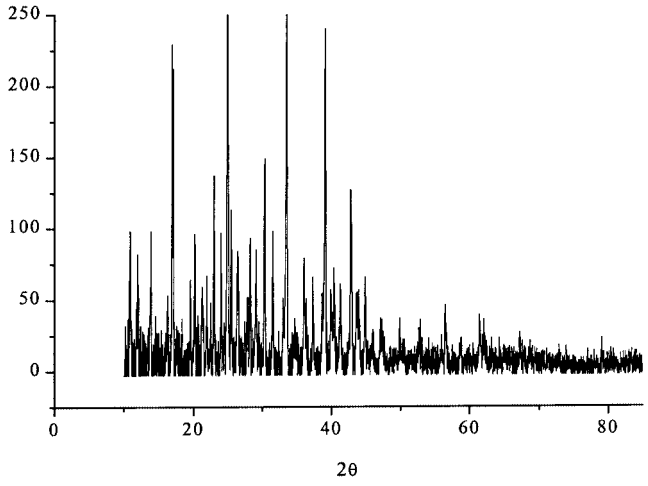

Figure 3. The powder XRD spectrum of **2** obtained after recrystallization

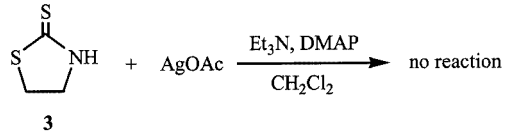
stacking or hydrogen-bonding interactions are apparent in the crystal structures of **2**.

It should be emphasized here that when using the simplest thiazolidine-2-thione **3** as the substrate under the same reaction conditions, no reaction occurred (Scheme 3). We believe that this may be due to the fact that the tautomer of **3** is very unstable and the equilibrium between **3** and its tautomer lies almost completely in the direction of **3**.

Yamamoto and co-workers have reported many catalytic enantioselective reactions using chiral phosphane ligand·Ag^I complexes as the catalyst, although they did not disclose the nature of the active species.[8] Therefore, we also



Scheme 3

tried to use this novel chiral cluster in some catalytic asymmetric reactions. Unfortunately we found that these reactions are very sluggish. We are now looking for suitable reaction conditions for these catalytic asymmetric reactions.

In conclusion, we have isolated a novel Ag^I/S,N metal cluster from the reaction of (*S*)-4-isopropylthiazolidine-2-thione (**1**) with AgOAc and determined its structure by X-ray analysis. This result also confirms that silver(I) can easily form an unexpected polymeric metal cluster with an S,N ligand. Such a chiral metal cluster should be very interesting in the synthesis of novel metal complexes for asymmetric catalysis. Work in this direction is currently in progress.

Experimental Section

Melting points were obtained with a Yanagimoto micro melting point apparatus and are uncorrected. Optical rotations were determined in a solution of $CHCl_3$ or methanol at 20 °C by using a Perkin−Elmer-241 MC digital polarimeter; $[\alpha]_D$ values are given in units of 10^{-1} deg·cm^2·g^{-1}. ^{1}H NMR spectra were determined for solutions in $CDCl_3$ with tetramethylsilane (TMS) as internal standard on a Bruker AMX-300 spectrometer; *J* values are in Hz. IR spectra were determined on a Perkin−Elmer 983 spectrometer. Mass spectra were recorded with an HP-5989 instrument. All solid compounds reported in this paper gave satisfactory CHN microanalyses. The chiral starting materials (*S*)-4-isopropylthiazolidine-2-thione (**1**) and thiazolidine-2-thione (**3**) were prepared according to literature procedures.[3]

(*S*)-4-Isopropylthiazolidine-2-thione (1): Yield 300 mg, 96%; mp: 66−67 °C; $[\alpha]_D^{20}$ = −35.4 (*c* = 0.96, $CHCl_3$). ^{1}H NMR ($CDCl_3$, 300 MHz, TMS): δ = 1.0 (d, *J* = 7.2 Hz, 3 H, CH_3), 1.03 (d, *J* = 7.2 Hz, 3 H, CH_3), 1.96 (quintet, *J* = 7.2 Hz, 1 H, CH), 3.33 (dd, *J* = 11.2, 8.5 Hz, 1 H, CH), 3.52 (dd, *J* = 11.2, 5.5 Hz, 1 H, CH), 4.0−4.10 (m, 1 H, CH), 7.62 (s, 1 H, NH) ppm. The physical data and ^{1}H NMR spectroscopic data are consistent with those reported in the literature.[3c]

Thiazolidine-2-thione (3): Yield 450 mg, 95%. ^{1}H NMR ($CDCl_3$, 300 MHz, TMS): δ = 3.58 (t, J = 7.6 Hz, 2 H, CH_2), 4.01 (t, J = 7.6 Hz, 2 H, CH_2), 8.27 (s, 1 H, NH) ppm. The physical data and ^{1}H NMR spectroscopic data are consistent with those reported in the literature.[3c]

Preparation of Chiral Silver(i) Complex 2: (*S*)-4-isopropylthiazolidine-2-thione (**1**) (65 mg, 0.5 mmol), AgOAc (84 mg, 0.5 mmol) and DMAP (6.0 mg, 0.05 mmol) were added to a Schlenk tube under argon atmosphere. CH_2Cl_2 (5.0 mL) and Et_3N (61 mg, 0.6 mmol) were added successively and the reaction mixture was stirred at room temperature for 24 h. After filtration, the filtrate was washed with water (10 mL) and the organic layer was dried with anhydrous $MgSO_4$. The solvent was removed under reduced pressure and the residue was purified by silica gel column chromatography (length: 20 cm, φ: 2 cm) to give the complex **2** as a yellowish solid (eluent: EtOAc/petroleum ether, 1:4). 120 mg, 83%; m.p. 158−160 °C (dec.); $[\alpha]_D^{20}$ = +251 (*c* = 0.11, $CHCl_3$). IR (KBr): $\tilde{\nu}$ = 1265, 1421, 1541 cm^{-1}. ^{1}H NMR ($CDCl_3$, 300 MHz, TMS): δ = 0.94 (d, *J* = 6.7 Hz, 3 H, CH_3), 0.97 (d, *J* = 6.7 Hz, 3 H, CH_3), 2.22−2.40 (m, 1 H, CH), 3.30 (d, *J* = 9.7 Hz, 2 H, CH_2), 4.20−4.32 (m, 1 H, CH) ppm. ESI-MS: *m/z* = 1259 [M^+] (acetone/acetonitrile, 2:1) $C_{36}H_{60}Ag_2N_6S_{12}\cdot CH_2Cl_2$ (1693.77): calcd. C 26.24, H 3.69, N 4.96; found C 26.45, H 3.64, N 4.94.

X-ray Crystallography: A suitable crystal was mounted on the top of a glass capillary. Crystal data and details of data collection and structure refinement are given in Table 2. Data were collected on a CCD area detector with graphite-monochromated Mo-K_α radiation (λ= 0.71073 Å) using the ω-2θ technique at 20 °C. A total of 4896 unique reflections was collected. The data were collected for Lorentz polarization effects. The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically by full-matrix least-squares. All hydrogen atoms were included in their calculated positions. All calculations were performed using the SHELXS-97 (Sheldrick, 1990) crystallographic software package. Final *R* and R_w values were 0.0329 and 0.0655. CCDC-177953 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Cyclic and Polycyclic Gallium-Antimony Compounds: Synthesis and Crystal Structures of $[GaCl(PnPr_2Ph)(SbSiiPr_3)]_2$ and $[(GaCl)_4(SbSiiPr_3)_4(PnPr_2Ph)_2]$

Carsten von Hänisch,*[a] Petra Scheer,[a] and Birgit Rolli[a]

Keywords: Gallium / Antimony / Polycycles / Heterocycles / Semiconductors

The reaction of $[(DME)LiE(SiMe_3)_2]$ (E = As, Sb) with iPr_3SiCl in DME yields the mixed silylated compounds $iPr_3SiE(SiMe_3)_2$ (**1**: E = As, **2**: E = Sb). Compounds **1** and **2** were characterised by multinuclear NMR spectroscopy and mass spectrometry. The antimony compound **2** reacts with $[GaCl_3PnPr_2Ph]$ to give the cyclic compound $[GaCl(PnPr_2Ph)(SbSiiPr_3)]_2$ (**3**). The polycyclic Ga-Sb compound $[(GaCl)_4(SbSiiPr_3)_4(PnPr_2Ph)_2]$ (**4**) can be obtained from a solution of **3** in benzene. The central structural motif of **3** is a folded Ga_2Sb_2 four-membered ring. Compound **4** consists of a ladder-like Ga_4Sb_4 unit and is the first polycyclic Ga-Sb compound described. Compounds **3** and **4** were characterised by single crystal X-ray diffraction. The thermal decomposition of both compounds results in the formation of the binary phase GaSb.

Introduction

In the last few years different groups have reported the synthesis of four- and six-membered Ga-Sb ring compounds of the general formula $[R_2GaSbR'_2]_n$ (R = alkyl, chloride; R′ = alkyl, silyl; n = 2, 3).[1] In these compounds the Ga and Sb atoms have the coordination number four. Cyclic compounds with lower coordinated Ga and/or Sb atoms or polycyclic molecules are unknown so far. In contrast, several cyclic or polycyclic gallium phosphorus or gallium arsenic compounds with low-coordinate Ga and P/As atoms have been described.[2,3] We obtained the cyclic and polycyclic Ga-Sb compounds $[GaCl(PnPr_2Ph)(SbSiiPr_3)]_2$ (**3**) and $[(GaCl)_4(SbSiiPr_3)_4(PnPr_2Ph)_2]$ (**4**) from the reaction of the mixed silylated antimony compound $iPr_3SiSb(SiMe_3)_2$ (**2**) with the gallium chloride phosphane complex $[GaCl_3PnPr_2Ph]$. The structure of compounds **3** and **4** was determined by X-ray crystal structure analysis.[4]

Results and Discussion

The reaction of $[(DME)LiE(SiMe_3)_2]_2$ (E = As, Sb) with iPr_3SiCl in DME at 0 °C yields the mixed silylated compounds $iPr_3SiE(SiMe_3)_2$ (**1**: E = As, **2**: E = Sb). These compounds are highly viscous liquids which solidify to a glass-like solid when cooled to −78 °C. Both compounds were characterised by multinuclear NMR spectroscopy and mass spectrometry. Whereas the arsenic compound **1** shows no reaction towards gallium chloride phosphane complexes the antimony compound **2** reacts with the phosphane complex $[GaCl_3PnPr_2Ph]$ in diisopropyl ether to give the cyclic compound **3** as illustrated in Equation (1). Compound **3** can be obtained in crystalline form by cooling the reaction mixture to 6 °C.

$$2\,[GaCl_3{\cdot}PnPr_2Ph] + 2\,iPr_3SiSb(SiMe_3)_2 \rightarrow [GaCl(PnPr_2Ph)(SbSiiPr_3)]_2\,(\mathbf{3}) + 4\,Me_3SiCl \quad (1)$$

Compound **3** crystallises with an orthorhombic unit cell containing four molecules in the space group $Pna2_1$, and has been refined as an inversion twin (Figure 1). The central structural motif is a folded Ga_2Sb_2 four-membered ring in which the Sb atoms are trigonal pyramidally coordinated by two Ga atoms and one $SiiPr_3$ group. The gallium centres have a distorted tetrahedral geometry consisting of a chloride atom, a $PnPr_2Ph$ ligand and the two Sb atoms. Due to the mutual repulsion of the sterically demanding $PnPr_2Ph$ and $SiiPr_3$ groups they are orientated on different sides of the ring. The shape of **3** is therefore similar to the recently described gallium phosphorus and gallium arsenic compounds $[GaCl(PtBu_2Me)(ESiMe_3)]_2$ (E = P, As).[2b] The clear folding of the ring — the Sb−Ga−Sb planes have an angle of 139.0° to each other — is caused by the lower coordination number at the Sb atoms and by the *cis* orientation of the sterically demanding $SiiPr_3$ and $PnPr_2Ph$ groups. The Ga−Sb bonds in **3** are 264.1 pm on average and therefore shorter than in the Ga−Sb ring compounds with coordination number four at the gallium and the antimony atoms (267−277 pm) mentioned above. This shortening can be explained by the lower coordination number of the Sb atoms and the purely covalent character of the Ga−Sb bonds in **3**. A Ga−Sb bond length of 264.8(1) pm, however, can be observed in the acyclic compound $[LGaEt_2{-}Sb(SiMe_3)_2]$ [L = 4-(dimethylamino)pyridine], also featuring coordination number three at the anti-

mony and four at the gallium atom.[5] The endocyclic angles in **3** are 98.7° at the gallium and 75.2° at the antimony atoms. The Ga−Cl bonds are, on average, 225.2 pm long, and the exocyclic dative P−Ga bond is 244.2 pm long. Compound **3** is stable in the mother liquor but decomposes over a period of two weeks time with release of the phosphane ligands and the formation of a brown residue when isolated.

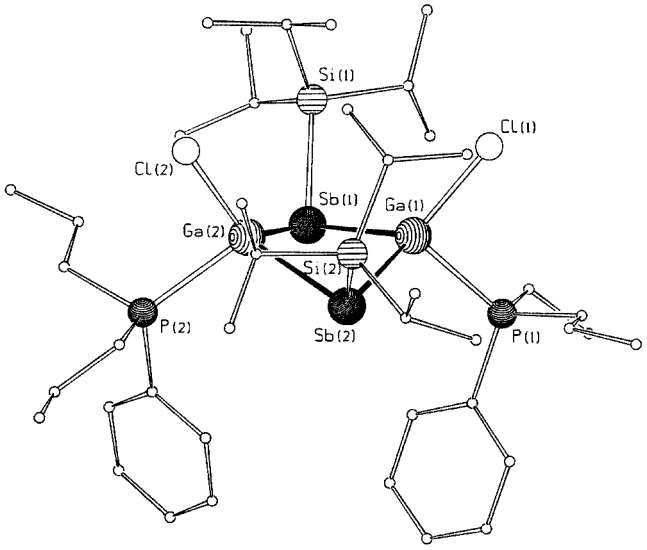

Figure 1. Molecular structure of **3**; selected bond lengths (pm) and bond angles (°): Ga(1)−Sb(1) 264.1(1), Ga(1)−Sb(2) 265.1 (1), Ga(2)−Sb(1) 263.5 (1), Ga(2)−Sb(2) 263.6(1), Ga(1)−Cl(1) 224.8(2), Ga(1)−P(1) 244.8(2), Ga(2)−Cl(2) 225.6(2), Ga(2)−P(2) 243.6(2), Sb(1)−Si(1) 258.1(2), Sb(2)−Si(2) 258.2(2); Ga(1)−Sb(1)−Ga(2) 75.3(1), Ga(1)−Sb(2)−Ga(2) 75.1(1), Sb(1)−Ga(1)−Sb(2) 98.4(1), Sb(1)−Ga(2)−Sb(2) 99.0(1), Cl(1)−Ga(1)−P(1) 93.7(1), Cl(2)−Ga(2)−P(2) 92.3(1), Si(1)−Sb(1)−Ga(1) 107.5(1), Si(1)−Sb(1)−Ga(2) 116.0(1), Si(2)−Sb(2)−Ga(1) 117.1(1), Si(2)−Sb(2)−Ga(2) 105.9(1)

Red crystals with the composition $[(GaCl)_4(SbSi\text{-}i Pr_3)_4(P n Pr_2Ph)_2]$ (**4**) · 2 C_6H_6 were obtained from a solution of **3** in benzene over a period of three days. Obviously compound **3** undergoes a condensation reaction to give **4** and two free phosphane molecules [Equation (2)].

$$2\,[GaCl(P n Pr_2Ph)(SbSi i Pr_3)]_2 \rightarrow [(GaCl)_4(SbSi i Pr_3)_4(P n Pr_2Ph)_2]\,(\mathbf{4}) + 2\,P n Pr_2Ph \quad (2)$$

The molecular structure of **4** (Figure 2), which contains an inversion centre, consists of a central planar Ga_2Sb_2 four-membered ring in which the silyl groups and the Cl atoms are *trans* orientated. Two slightly folded Ga_2Sb_2 rings with an all *cis* orientation of the silyl groups and the Cl atoms are connected to the central ring on opposite sides. These three Ga_2Sb_2 rings are not coplanar, instead the three moieties form a chair-like structure. A similar structure has been observed for the aluminium-phosphorus compound $[(AlCl)_4(PR)_4(OEt_2)_2]$ (R = Si*i*Pr$_3$, Si*i*Pr$_2$Me) which was recently obtained by reaction of $AlCl_3$ with Li_2PR in diethyl ether.[6]

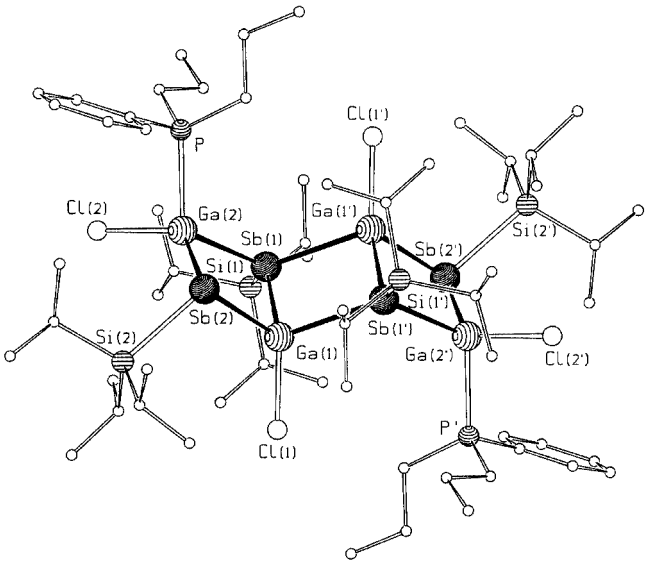

Figure 2. Molecular structure of **4**; selected bond lengths (pm) and bond angles (°): Ga(1)−Sb(1) 271.7(1), Ga(1)−Sb(1′) 269.1(1), Ga(1)−Sb(2) 264.4(1), Ga(2)−Sb(1) 266.2(1) Ga(2)−Sb(2) 261.8(1), Ga(1)−Cl(1) 222.5(2), Ga(2)−Cl(2) 222.9(2), Ga(2)−P: 242.9(2), Sb(1)−Si(1) 258.9(2), Sb(2)−Si(2) 259.1(2); Ga(1)−Sb(1)−Ga(2) 80.4(1), Ga(1)−Sb(1)−Ga(1′) 86.3(1), Ga(1′)−Sb(1)−Ga(2) 117.7(1), Ga(1)−Sb(2)−Ga(2) 82.6(1), Sb(1)−Ga(1)−Sb(2) 97. 0(1), Sb(1)−Ga(1)−Sb(1′) 93.7(1), Sb(1′)−Ga(1)−Sb(2) 110.9(1), Sb(1)−Ga(2)−Sb(2) 99.0(1), Cl(2)−Ga(2)−P 93.3(1)

The coordination sphere of the outer Ga atoms [Ga(2) and Ga(2′)] in **4** is completed by the phosphane ligands, so that all Ga atoms have coordination number four. The Sb atoms in **4** have two different coordination numbers: the Sb atoms of the central ring [Sb(1) and Sb(1′)] have a coordination number of four, whereas the outer Sb atoms are trigonal pyramidal coordinated. The Ga−Sb bond lengths in **4** vary greatly. In the central ring they are 269.1(1) to 271.7(1) pm long, whereas the Ga(1)−Sb(2) and the Ga(2)−Sb(1) bond lengths are 264.4(1) and 266.2(1) pm, respectively. The shortest Ga−Sb bond known so far can be observed between Ga(2) and Sb(2) [261.8(1) pm].

The UV/Vis spectrum of the yellow compound **3** shows a first absorption maxima at 425 nm. The red compound **4** reveals the first absorption maxima at 450 nm. In the IR spectra of both compounds the typical peaks of the P*n*Pr$_2$Ph ligands and the Si*i*Pr$_3$ groups are observed.

Thermogravimetric analysis of compound **3** under vacuum shows a one-step decomposition in the temperature range of 110 to 160 °C. The on-line mass spectra of the cleavage products shows the phosphane ligands and the silyl groups. The overall mass loss is 70.0% (calculated for the formation of GaSb: 66.9%). Powder X-ray diffraction measurements of the grey residue obtained display only the reflections of cubic GaSb. From element analyses the carbon content of the residue was determined to be 1.5(5)%. Analogous thermogravimetric experiments on **4** show a two-step decomposition. In a first step, between 75 and 120 °C, the cleavage of the crystal solvent can be observed (mass

loss: calcd. 7.5%, observed 7.1%). At 180 °C all volatile constituents have been eliminated and the formation of cubic GaSb occurs.

Experimental Section

All manipulations were performed with rigorous exclusion of oxygen and moisture using a Schlenk line and nitrogen atmosphere. Solvents were dried and freshly distilled before use. $[(DME)LiE(SiMe_3)_2]_2$ was prepared according to a literature procedure.[7] $GaCl_3$ (99.99%) and iPr$_3$SiCl (97%) were obtained from Aldrich and used as received.

iPr$_3$SiAs(SiMe$_3$)$_2$ (1): A mixture of iPr$_3$SiCl (12.1 g) in DME (20 mL) was added to a solution of $[(DME)LiAs(SiMe_3)_2]_2$ (20 g, 63 mmol) in DME (200 mL) over a period of two hours at 0 °C. Subsequently the reaction mixture was stirred for an additional 16 hours at room temperature and then filtered. All volatile components were then removed under vacuum and the resulting residue was fractionally distilled to give **1** as a highly viscous liquid at 90−100 °C and 10^{-3} mbar. Yield: 15.5 g (65%). ^{1}H NMR (C_6D_6): δ = 0.52 (s, 18 H, SiMe$_3$), 1.29 (m, 21 H, SiiPr$_3$) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 5.7 (s, SiMe$_3$), 15.8 [s, CH(CH$_3$)$_2$], 20.3 [s, CH(CH$_3$)$_2$] ppm. ^{29}Si{^{1}H} NMR (C_6D_6): δ = 2.4 (s, SiMe$_3$), 25.0 (s, SiiPr$_3$) ppm. MS (EI, 70 eV): m/z (%) = 378 (30) [M$^+$], 363 (0.5) [M$^+$ − Me], 335 (1) [M$^+$ − iPr], 293 (0.7) [M$^+$ − iPr, − CH$_2$CHCH$_3$], 251 (0.7) [M$^+$ − 2iPr − CH$_2$CHCH$_3$], 206 (22) [M$^+$ − Me − SiiPr$_3$], 157 (18) [SiiPr$_3$], 73 (100) [SiMe$_3$].

iPr$_3$SiSb(SiMe$_3$)$_2$ (2): A mixture of iPr$_3$SiCl (10.5 g) in DME (20 mL) was added to a solution of $[(DME)LiSb(SiMe_3)_2]_2$ (20 g, 55 mmol) in DME (200 mL) over a period of two hours at 0 °C. Subsequently the reaction mixture was stirred for an additional 16 hours at room temperature and then filtered. All volatile components were removed under vacuum and the resulting residue was fractionally distilled to give **2** as a highly viscous liquid at 110−120 °C and 10^{-3} mbar. Yield: 13.5 g (58%). ^{1}H NMR (C_6D_6): δ = 0.58 (s, 18 H, SiMe$_3$), 1.27 (m, 21 H, SiiPr$_3$) ppm. ^{13}C{^{1}H} NMR (C_6D_6): δ = 6.0 (s, SiMe$_3$), 15.4 [s, CH(CH$_3$)$_2$], 20.6 [s, CH(CH$_3$)$_2$] ppm. ^{29}Si{^{1}H} NMR (C_6D_6): δ = −10.2 (s, SiMe$_3$), 27.1 (s, SiiPr$_3$) ppm. MS (EI, 70 eV): m/z (%) = 424 (4) [M$^+$], 409 (0.4) [M$^+$ − Me], 252 (5) [M$^+$ − Me − SiiPr$_3$], 157 (30) [SiiPr$_3$], 73 (100) [SiMe$_3$].

3: PnPr$_2$Ph (0.94 g, 4.88 mmol) was added to a solution of $GaCl_3$ (0.43 g, 2.44 mmol) in 30 mL of iPr$_2$O. After stirring for one hour iPr$_3$SiSb(SiMe$_3$)$_2$ (1.04 g, 2.44 mmol) was added. The reaction mixture was then stirred for an additional 24 hours. Subsequently the resulting red solution was filtered to remove small amounts of insoluble residues and the volume was reduced to 10 mL under vacuum. After addition of 5 mL heptane and cooling to 6 °C yellow crystals of **3** formed over a period of two days. Yield: 0.59 g (42%). $C_{42}H_{80}Cl_2Ga_2P_2Sb_2Si_2$ (1157.02): calcd. C 43.60, H 6.97; found C 43.16, H 6.98. ^{31}P{^{1}H} NMR (C_6D_6/PnPr$_2$Ph): δ = −30.5 (s) ppm. IR (KBr): $\tilde{\nu}$ = 3077(w), 3049(w), 2960(s), 2937(vs), 2860(vs), 1983(vw), 1959(vw), 1906(vw), 1806(vw), 1758(vw), 1484(m), 1463(vs), 1437(vs), 1407(m), 1380(m), 1364(w), 1358(w), 1226(m), 1105(w), 1068(s), 1027(m), 995(vs), 918(m), 882(s), 842(w), 828(m), 770(w), 746(vs), 693(s), 658(vs), 634(s), 557(vs), 503(m), 489(w), 459(s), 393(w) cm^{-1}. UV/Vis (suspension in mineral oil): λ_{max} = 425 nm (sh), 370 (sh), 260, 220.

4: Compound **3** (0.2 g) was dissolved in 2 mL benzene and stirred for two hours at room temperature. Subsequently the solution was cooled to 6 °C. After three days red crystals of **4** formed from this solution. Yield: 0.1 g (54%). $C_{60}H_{122}Cl_4Ga_4P_2Sb_4Si_4 \cdot 2\ C_6H_6$ (2081.77): calcd. C 41.54, H 6.49; found C 41.38, H 6.96. ^{31}P{^{1}H} NMR (C_6D_6): δ = −20.2 (s) ppm. IR (KBr): $\tilde{\nu}$ = 3087(vw), 3059(w), 3033(vw), 2960(s), 2939(vs), 2862(vs), 1959(vw), 1859(w), 1816(vw), 1459(vs), 1437(s), 1413(w), 1384(m), 1365(w), 1292(w), 1224(m), 1105(w), 1083(m), 1069(m), 1020(s), 993(s), 918(m), 878(vs), 846(w), 802(w), 740(m), 690(m), 693(s), 658(m), 639(s), 564(s), 520(w), 494(vs), 458(m) cm^{-1}. UV/Vis (suspension in mineral oil): λ_{max} = 450 nm, 380 (sh), 300.

Synthesis and Structure of the Decanuclear Gold(I) Cluster Cation $[Au_8(AuCl)_2\{\mu_3\text{-}P(t\text{Bu})\}_2\{\mu\text{-}P(t\text{Bu})=C(NMe_2)_2\}_6]^{4+}$ with Bridging Phosphaalkene and Phosphanediide Ligands

Lothar Weber,*[a] Ulrich Lassahn,[a] Hans-Georg Stammler,[a] Beate Neumann,[a] and Konstantin Karaghiosoff[b]

Keywords: Cluster compounds / Gold / Phosphaalkenes / Phosphinidenes

Reaction of the inversely polarized phosphaalkene HP=C(NMe$_2$)$_2$ (**1**) with [AuCl(PPh$_3$)] (**2a**) in a molar ratio of 2:1 in THF led to the formation of complex [Au{HP=C(NMe$_2$)$_2$}$_2$]Cl (**3**) as a pale yellow solid. In contrast to this, treatment of **2a** with two molar equivalents of *t*BuP=C(NMe$_2$)$_2$ (**4**) afforded a mixture of [Au{P(*t*Bu)=C(NMe$_2$)$_2$}$_2$]$^+$Cl$^-$ (**5**) and [{(Me$_2$N)$_2$C=(*t*Bu)PAu}$_2$(μ-Cl)]$^+$Cl$^-$ (**6**). In CH_2Cl_2 solution this mixture was slowly converted into the novel decanuclear complex $[Au_8(AuCl)_2\{\mu_3\text{-}P(t\text{Bu})\}_2\{\mu\text{-}P(t\text{Bu})=C(NMe_2)_2\}_6]^{4+}(Cl^-)_4$ (**7**) featuring six edge-bridging phosphaalkene ligands and two μ_3-*tert*-butylphosphanediide ligands. In solution the cluster **7** shows a high order $^{31}P\{^1H\}$ NMR spectrum of the $[AB_2C]_2$ type. According to the X-ray structural analysis the Au_{10} framework may be described as a slightly puckered ladder constructed of three quadrangles. The central Au_4 parallelogram is capped on both faces by a pair of [*t*BuPAuCl] units.

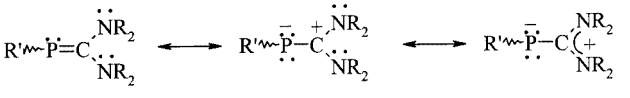
Introduction

The chemistry of multinuclear complexes has been studied by several research groups for academic reasons as well as for potential industrial applications.[1] In contrast to a wide variety of chalcogen-bridged gold complexes,[2] gold clusters with phosphorus-containing ligands in bridging positions are rare. Cluster cations with "naked" phosphorus atoms are $[P(AuL)_4]^+$,[4] $[P(AuL)_5]^{2+}$,[5] $[P(Au_5L_6)]^{2+}$,[6] $[P(AuL)_6]^{3+}$,[7] $[Au\{P(AuL)_4\}_2]^{3+}$.[3] In $[arylP(AuL)_3]^+$ [5a,8] and $[arylP(AuL)_4]^{2+}$ [8] phosphinidene ligands are bridging the Au atoms and the terminal ligands (L) are tertiary phosphanes. The chemistry of gold(I) phosphanides is also poorly developed. Apart from polymeric $[\{Au(\mu\text{-}PR_2)\}_n]$ (R = phenyl, substituted phenyl, ethyl, or *n*-octyl),[9] structurally characterized dinuclear complex anions $[(AuX)_2(\mu\text{-}PPh_2)]^-$ (X = Cl, Br, I)[10,11] are known. Laguna et al. have recently reported the synthesis of dinuclear Au^{III} complexes $[\{Au(C_6F_6)_3\}_2(\mu\text{-}PPh_2)]^-$, $[Au_2(C_6F_5)_4(\mu\text{-}PPh_2)_2)]$[13] as well as the trinuclear $Au^{III}-Au^{I}$ phosphanido-bridged derivatives $[\{(C_6F_5)_3Au(\mu\text{-}PPh_2)\}_2Au]^-$,[14] $[\{C_6F_5Au(\mu\text{-}PPh_2)\}_2Au(C_6F_5)_2]^-$,[15] $[\{(Ph_3P)Au(\mu\text{-}PPh_2)\}_2Au(C_6F_5)_2]^+$ [15] and the tetranuclear complex $[\{Au(C_6F_5)_2(\mu\text{-}PPh_2)_2Au\}_2]$.[15] Structurally characterized polynuclear ($n > 4$) and homometallic μ-phosphanido clusters of gold are without precedent to the best of our knowledge.

C-Amino-substituted phosphaalkenes $R'P=C(NR_2)_2$ are zwitterions in which the negatively charged phosphanide unit is stabilized by an adjacent carbenium center[16,17] (Scheme 1).



Scheme 1. Limiting formulae of amino-substituted phosphaalkenes

In the context of the present work, the question as to whether phosphaalkenes with an inverse distribution of π-electron density can function as bridging ligands in polynuclear gold complexes was intriguing.

Results and Discussion

The reaction of the gold complexes [Au(Cl)L] (**2**) (**a**: L = PPh_3, **b**: tetrahydrothiophene (THT), **c**: CO) with two molar equivalents of phosphaalkene **1** in THF at ambient temperature leads to the precipitation of the yellow mononuclear complex **3** (Scheme 2).

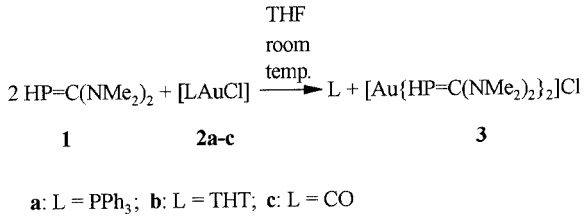
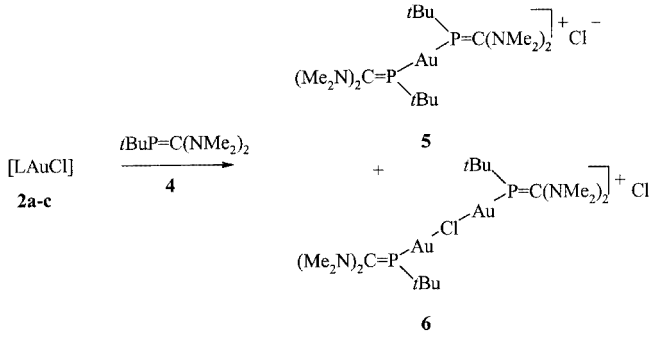


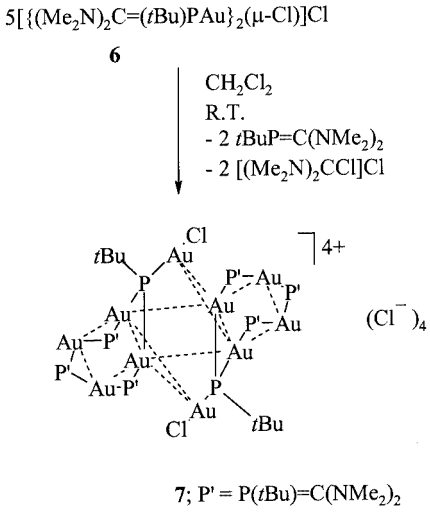
Scheme 2. Reaction of $HP{=}C(NMe_2)_2$ with [LAuCl]

Compound **3** is readily soluble in dichloromethane. The ^{31}P NMR signal in the proton-coupled spectrum of **3** at $\delta = -90$ ppm (d, $^1J_{P,H} = 219$ Hz) is shifted to higher field with respect to the free ligand **1** ($\delta = -73$ ppm, d, $^1J_{P,H} = 156$ Hz). A peak at $m/z = 461$ in the electrospray-ionization mass spectrum (ESI-MS) is assigned to the cation of **3**. The reaction of **2** with the more bulky and more basic phosphaalkene tBuP=C(NMe$_2$)$_2$ (**4**) under analogous conditions produces an amorphous green-yellow precipitate, which according to an ESI mass spectrum contains the complex cations **5** (m/z =573) and **6** (m/z =805) (Scheme 3).



Scheme 3. Reaction of tBuP=C(NMe$_2$)$_2$ with [LAuCl]

The $^{31}P\{^1H\}$ NMR spectrum of the mixture displays a broad signal at $\delta = 37$ ppm, which again is considerably shielded with respect to the free ligand ($\delta = 81$ ppm). In the ^1H NMR spectrum of the same sample, broad singlets at $\delta = 3.62$ and 1.42 ppm are attributed to the protons of the dimethylamino functions and the *tert*-butyl groups. In free **4** the corresponding resonances are observed at $\delta =$ 2.83 and 1.19 ppm. Thus ligand exchange between cations **5** and **6** in solution is obvious. Attempted separation of these salts on a preparative scale was unsuccessful. Also, attempts to separate the components by crystallization from dichloromethane led to the complete transformation of **5** and **6** into the yellow salt **7** with a decanuclear complex cation (Scheme 4). The cation $[(Me_2N)_2CCl]^+$ was formed by an unprecedented nucleophilic cleavage of a P=C double bond by a chloride. This cation was identified from its $^{13}C\{^1H\}$ NMR spectrum, where singlets at $\delta = 44.5$ and 157.9 ppm appeared (ref.:[18] $\delta = 45$ and 159 ppm). The same transformation of **5** and **6** was observed when using acetonitrile as a solvent.



Scheme 4. Formation of **7** from **6** (idealized)

Compound **7** is readily soluble in acetonitrile and water but only moderately soluble in dichloromethane.

In the $^{31}P\{^1H\}$ NMR spectrum of cluster **7** three groups of signals are observed at $\delta = 42.2$, 34.0, and 20.3 ppm with a relative intensity of 2:1:1 respectively.. The pattern of the signals indicates the presence of an $[AB_2C]_2$ spin system. This is also consistent with the symmetry of the compound as derived from the X-ray diffraction study. The signal at $\delta = 34.0$ ppm shows only four lines and, in a first approximation, may be regarded as the A-part of an AB_2 spectrum, implying that the A nucleus is only coupling with the B nuclei (but not with the B′ nuclei). Thus, the signal at $\delta =$ 34.0 ppm is assigned unambiguously to the peripheral phosphorus atoms P_A and $P_{A'}$ in Figure 1.

The signal at $\delta = 42.2$ ppm with the highest intensity is attributed to P_B; consequently, the resonance at $\delta =$ 20.3 ppm is caused by P_C. The interaction between both AB_2C parts occurs exclusively through the coupling between the nuclei P_C and $P_{C'}$ and causes the splitting of the higher order signals of P_B and P_C. Within the AB_2C parts $^2J_{PP}$ couplings are observed, whereas between both AB_2C halves of the cation a $^3J_{PP}$ coupling is present, which is also reflected by the different signs of the coupling constants. The relative signs result from the iterative fitting of the spectrum assuming positive values for the two-bond P-P couplings. The relatively large $^2J_{PP}$ coupling constants agree with a trans-arrangement of the coupling P atoms.

The fourfold positive charge of the cation is compensated for by four chloride ions. Accordingly, the ESI mass spectrum features a peak at m/z =836.0, indicating a mass of 3344 Dalton for the cation $[C_{62}H_{144}Au_{10}Cl_2N_{12}P_8]^{4+}$; this peak shows the correct isotopic pattern.

X-ray Structural Analysis of 7·14CH$_2$Cl$_2$

Bright yellow single crystals of **7** as a solvate with 14 molecules of CH_2Cl_2 were grown over two weeks from a solution of **7** in dichloromethane layered with *n*-hexane at 4 °C. The X-ray structural analysis (Figure 2) shows a cation

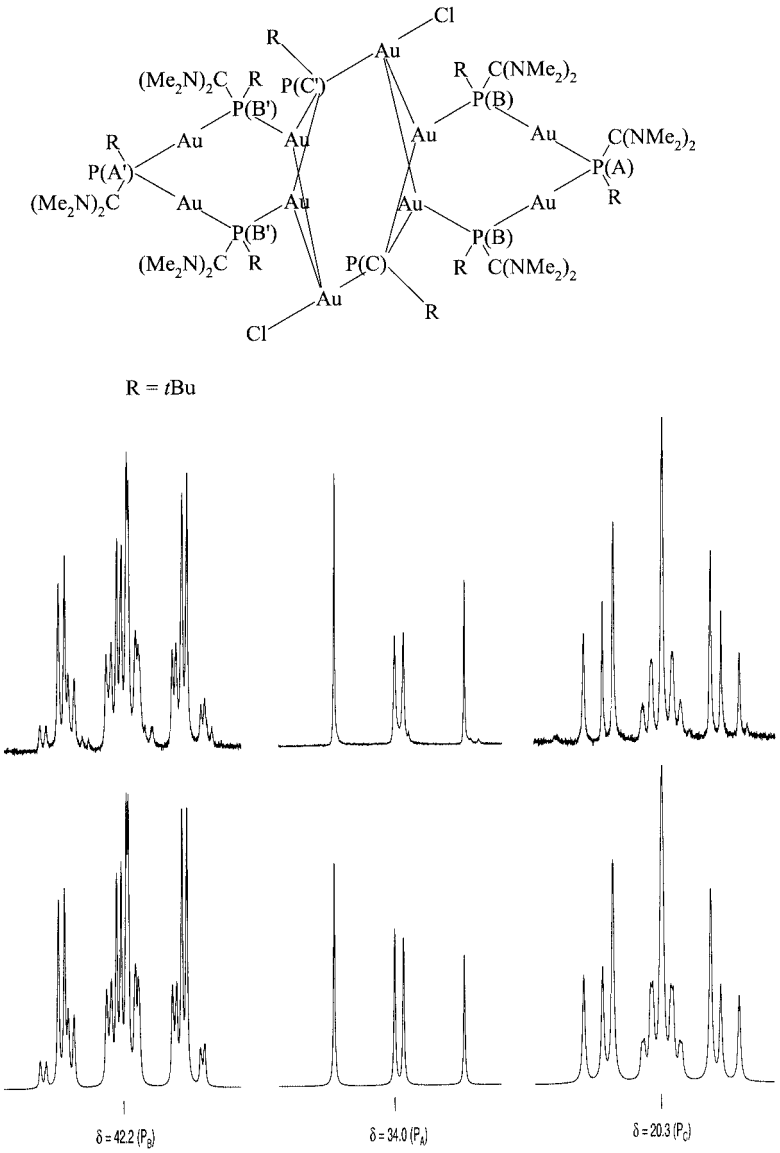


Figure 1. Observed and simulated $^{31}P\{^{1}H\}$ NMR spectrum of **7**

containing ten gold atoms. Eight atoms [Au(1) to Au(4) and Au(1a) to Au(4a)] form a puckered ladder made up of three quadrangles [Au(1)−Au(2)−Au(3) = 158.22(2)°, Au(2)−Au(3)−Au(4) = 159.43(2)°].

The central quadrangle — a parallelogram defined by the atoms Au(2), Au(2a), Au(3), and Au(3a) — is capped on both faces by a [*t*BuPAuCl] entity, which leads to the triangles Au(2),Au(3a),P(2a); Au(2a),Au(3),P(2); Au(2),Au(3a),Au(5a); and Au(2a),Au(3),Au(5). The center of this parallelogram is located on a crystallographic center of inversion. In pairs, the three edges of both peripheral quadrangles Au(1)−Au(4a), Au(1a)−Au(4), Au(1)−Au(2), Au(1a)−Au(2a), Au(3)−Au(4), and Au(3a)−Au(4a) are bridged by six phosphaalkene ligands via their P atoms. The Au−Au distances vary from 3.030(1) Å [Au(2a)−Au(5), Au(2)−Au(5a)] to 3.426(1) Å [Au(1)−Au(4a), Au(1a)−Au(4)] and have to be regarded as weak aurophilic contacts. The Au(5)−P(2a) and Au(5a)−P(2) bond lengths within the [P(*t*Bu)AuCl] units [2.272(4) Å] are similar to the Au−P distances in $[(Ph_3PAu)_6C]^{2+}$ [2.269(1)−2.274(1) Å][19] but they are significantly shorter than the Au−P contacts to the μ-phosphaalkene ligands [2.306(4)−2.324(3) Å]. The Au−P−Au valence angles at the P atoms of the phosphaalkene bridges vary from 90.9(1)° at P(3) to 91.6(1)° at P(1), and to 95.7(1)° at P(4). They are significantly compressed in comparison to the ideal tetrahedral angle. The same holds for the Au(2a)−P(2)−Au(3) angle, which is 92.7(1)°. In contrast to this the Au(3)−P(2)−Au(5a) [119.7(2)°] and Au(2a)−P(2)−Au(5a) [116.4(2)°] angles are significantly widened. The P−Au−P angles at the atoms Au(1) and Au(4) average 170.5° — close to linearity. Similarly the P(2a)−Au(5)−Cl(1) angle is 173.8(1)°. The Au−Cl bond lengths in **7** [2.332(4) Å] exceed those in [tBu$_3$PAuCl] [2.28(6) Å][20] and [Au(CO)Cl] [2.2261(5) Å].[21] The

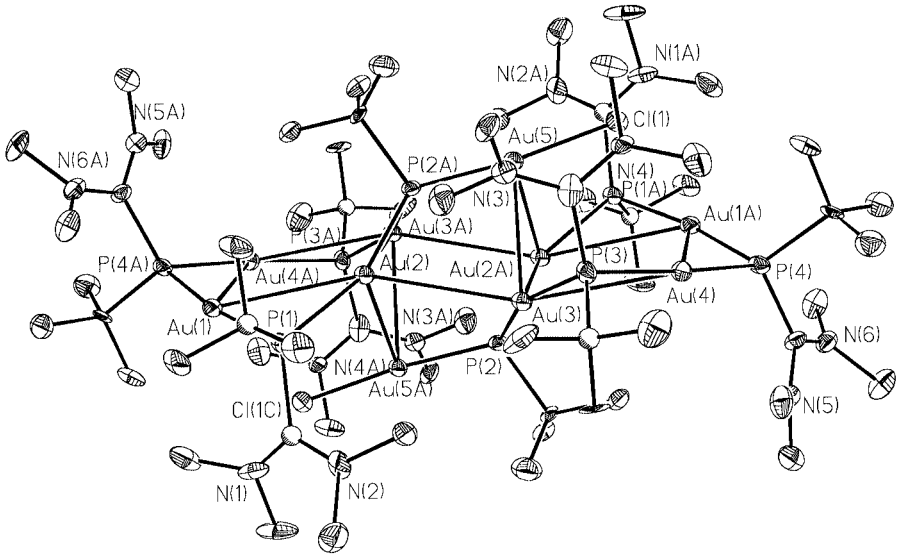

Figure 2. Structure of the cation of **7** in the crystal; selected bond lengths [Å] and angles [°]: Au(1)−Au(2) 3.323(1), Au(2)−Au(3) 3.285(1), Au(3)−Au(4) 3.303(1), Au(4)−Au(1a) 3.426(1), Au(2)−Au(3a) 3.372(1), Au(2)−Au(5a) 3.030(1), Au(3)−Au(5) 3.102(1), Au(1)−P(1) 2.313(4), Au(2)−P(1) 2.322(3), Au(3)−P(3) 2.324(4), Au(4)−P(3) 2.310(4), Au(4)−P(4) 2.316(4), Au(1a)−P(4) 2.306(4), Au(2)−P(2a) 2.332(3), Au(3a)−P(2a) 2.330(3), Au(5)−P(2a) 2.272(4), Au(5)−Cl(1) 2.332(4); Au(4a)−Au(1)−Au(2) 89.31(2), Au(1)−Au(2)−Au(3a) 90.34(2), Au(2)−Au(3a)−Au(4a) 90.59(2), Au(3a)−Au(4a)−Au(1) 89.74(2), Au(2)−Au(3)−Au(2a) 87.51(2), Au(3)−Au(2)−Au(3a) 92.49(2), Au(2a)−Au(5)−Au(3) 66.71(2), Au(5)−Au(3)−Au(2a) 55.62(2), Au(3)−Au(2a)−Au(5) 57.67(2), Au(1)−P(1)−Au(2) 91.60(13), Au(3)−P(3)−Au(4) 90.91(13), Au(1)−P(4a)−Au(4a) 95.67(14), Au(2)−P(2a)−Au(3a) 92.66(12), Au(2)−P(2a)−Au(5) 116.41(16), Au(3a)−P(2a)−Au(5) 119.72(15). P(2a)−Au(5)−Cl(1) 173.77(12), P(4a)−Au(1)−P(1) 170.60(12), P(4)−Au(4)−P(3) 170.41(14)

P=C double bond of precursor **4** {C−P in **1**: 1.740(1) Å[22]} is elongated to single bond length upon incorporation into the cluster cation **7** [1.849(16)−1.877(14) Å]. A similar bond length [1.8751(17) Å] was observed after the ligation of $[Tp^*(CO)_2Mo{\equiv}C-P{=}C(NMe_2)_2]$ to two [AuCl] units to give $[Tp^*(CO)_2Mo{\equiv}C-P(AuCl)_2C(NMe_2)_2]$ {Tp^*= $HB(3,5\text{-}Me_2pz)_3$}.[17] The three-coordinate carbon atoms of the phosphaalkenes remain planar. π-Conjugation to the N-atoms of the dimethylamino groups results in short $C(sp^2)-N(sp^2)$ bonds [1.292(18)−1.358(19) Å] with respect to the standard value for a C−N single bond (1.45 Å).[22] The formation of cluster **7** is remarkable for several reasons:

1) It is the first polynuclear gold compound with bridging phosphaalkene ligands.

2) The degradation of a phosphaalkene to a tBuP^{2-} ligand and a chloroformamidinium ion by chloride ions in the coordination sphere of a metal is without precedent.

3) The structural architecture is new for Au_{10} derivatives.

The metal frameworks in $[Au(AuNCO)(AuPPh_3)_8]Cl$[23] and $[Au(AuCl)(AuPPh_3)_8]^+$ [24] are derived from a square antiprism with a gold atom in the center of the cage. One square-face of the anti-prism is capped by the AuNCO or the AuCl moiety. The cluster $[Au_{10}(C_6F_5)_4(PPh_3)_5]$ is of toroidal geometry,[25] whereas the Au_{10} skeleton of $[PtAu_{10}\{Ph_2P(CH_2)_3PPh_2\}_5](NO_3)_2$ [26] and $[Pt(AuPEt_3)_{10}](BPh_4)_2$ [27] are segments of an icosahedron. In the cation $[Au_{10}Se_4(dppm)_4]^{2+}$ [dppm = $(Ph_2P)_2CH_2$], eight Au atoms form an irregular puckered octagon with two additional Au atoms in the center.[27] The Au_{10} skeleton of $[Au_{10}(AsPh)_4(PhAsSiMe_3)_2(PnPr_3)_6]$ can be described as an edge-shared bioctahedron, the four vertices of which are linked by pairs.[28] The cation $[Au_{10}Se_4(dppf)_4]^{2+}$ (dppf = 1,1′-diphenylphosphanylferrocene) consists of two [Au{Se(Au_2dppf)}] subunits, which are combined via aurophilic interactions.[2k] The structure of the cation $[Au_{10}\{\mu\text{-}Ph_2PN(nPr)PPh_2\}_4(\mu\text{-}S)_4]^{2+}$ is similar to a propeller.[2h]

Experimental Section

General: All manipulations were performed under dry argon. Organic solvents were rigorously dried with an appropriate drying agent and freshly distilled before use. The following compounds were prepared as described in the literature: $[AuCl(PPh_3)]$ (**2a**),[29] [AuCl(THT)],[30] [AuCl(CO)],[31] $HP{=}C(NMe_2)_2$ [32] (**1**), tBuP= $C(NMe_2)_2$ [33] (**4**). IR spectra: Bruker FTIR Vector 22, Bruker FTIR IFS66. ^1H, ^{13}C, ^{31}P NMR spectra: Bruker Avance DRX 500 (^1H: 500.13 MHz, ^{13}C: 125.76 MHz, ^{31}P: 202.46 MHz); references: $SiMe_4$ (^1H, ^{13}C), 85% H_3PO_4 (^{31}P). For solution and simulation of the ^{31}P NMR spectrum of **7** the PERCH program package[34] was used. 754 of the 890 allowed transitions were assigned to experimentally observed lines. The simulation converged at an RMS value of 0.95. MS: Esquire 3000/Tune-ESI.MS

$[Au\{HP{=}C(NMe_2)_2\}_2]Cl$ (3): A solution of $[AuCl(PPh_3)]$ (**2a**) (0.30 g, 0.6 mmol) in 10 mL of tetrahydrofuran (THF) was treated at ambient temperature with of $HP{=}C(NMe_2)_2$ (**1**; 0.15 g, 1.15 mmol). After stirring for 2 h the light yellow slurry was filtered, the solid washed with THF (3 × 10 mL), and dried in vacuo to give 0.26 g (85%) of **3**. IR (KBr): $\tilde{\nu}$ = 2949w cm^{-1}, 2328m [ν(PH)], 1558s, 1507w, 1465m, 1410m, 1385s, 1286m, 1173m, 1109m, 919m. ^1H NMR (CD_2Cl_2): δ = 3.27(s, 24 H, NMe_2), 3.71(d, $^1J_{P,H}$=219 Hz, PH) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ =

44.5 (br. s, NCH_3), 197.6 (d, $^1J_{P,C}$=56 Hz, P=CN_2) ppm. MS-ESI: *m*/*z* = 461.1 [Au{HP=$C(NMe_2)_2$}]$^+$. $C_{10}H_{26}AuClN_4P_2$ (496.71): calcd. C 24.18, H 5.28, N 11.28; found C 24.34, H 5.00, N 10.94.

$[Au_8(AuCl)_2\{\mu_3\text{-}P(t\text{Bu})\}_2\{\mu\text{-}P(t\text{Bu})\text{=}C(NMe_2)_2\}_6]^{4+}(Cl^-)_4$ (7): Neat *t*BuP=$C(NMe_2)_2$ (**4**) (0.75 g, 3.98 mmol) was added to a solution of [AuCl(PPh_3)] (**2a**) (1.00 g, 2.02 mmol) in THF (50 mL) at 20 °C. The resulting yellow slurry was stirred for 1 h and then filtered. The isolated solid was washed with THF (2 × 5 mL) and dried in vacuo to give 0.95 g of a mixture of **5** and **6**. ^{1}H NMR (CD_2Cl_2): δ = 1.42 (s, 9n H, *t*Bu), 3.62 (s, 12n H, NMe_2) ppm. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 37 (s, br) ppm. MS-ESI: *m*/*z* (%) = 805.1 (19) [$Au_2Cl\{t\text{BuP=}C(NMe_2)_2\}_2$]$^+$, 573.2 (100) [Au{*t*BuP=$C(NMe_2)_2\}_2$]$^+$. A sample of this mixture (0.85 g) was dissolved in dichloromethane (40 mL) and then *n*-hexane was added dropwise until a slight cloudiness of the liquid phase persisted. Stirring at 20 °C was continued for three days before the solution was concentrated to about 25% of its volume resulting in the separation of **7** as a yellow powder. The mother liquor was syringed off and the residue was dried to yield 0.58 g (82% yield with respect to **2a**) of **7**. ^{1}H NMR (CD_3CN): δ = 1.34, 1.37, 1.41 (3s, 72 H, *t*Bu), 3.28 (s, 12 H, NMe_2), 3.66 (br. s, 48 H, NMe_2), 4.29 (s, 12 H, NMe_2) ppm. $^{31}P\{^1H\}$ NMR (CD_3CN): $(AB_2C)_2$-type spectrum: δ(A) = 34.0 (P4, P4a), δ(B) = 42.2 (P1, P1a, P3, P3a), δ(C) = 20.3 (P2, P2a) ppm; $^2J_{AB} = {}^2J_{A'B'}$ = 221.6, $^2J_{BC} = {}^2J_{B'C'}$ = 197.4, $^3J_{BC'} = {}^3J_{B'C}$ = −3.6, $^3J_{CC'}$ = −94.5 Hz. MS-ESI: *m*/*z* = 836.0 [$Au_8(AuCl)_2(t\text{BuP})_2\{t\text{BuP=}C(NMe_2)_2\}_6$]$^{4+}$. The salt is solvated with varying amounts of dichloromethane. Samples isolated from acetonitrile crystallize with three molecules of CH_3CN as shown by ^{1}H NMR spectroscopy. $C_{62}H_{144}Au_{10}Cl_6N_{12}P_8\cdot 3CH_3CN$ (3611.26): calcd. C 22.62, H 4.27, N 5.82; found C 22.78, H 4.54, N. 5.81.

X-ray Structural Analysis of $7\cdot 14CH_2Cl_2$: Yellow single crystals of $7\cdot 14CH_2Cl_2$ were grown from a CH_2Cl_2/*n*-hexane solution at +4 °C over 2 weeks; 0.29 × 0.28 × 0.20 mm^3, *T* = 100 K, Nonius Kappa CCD, Mo-K_α (graphite monochromator, λ = 0.71073 Å), empirical formula $[C_{62}H_{144}Au_{10}Cl_2N_{12}P_8]Cl_4\cdot 14CH_2Cl_2$, monoclinic space group $P2_1/n$; unit cell dimensions *a* = 13.1890(1) Å, *b* = 16.627(2) Å, *c* = 33.4040(3) Å, β = 95.2320(5)°; *V* = 7294.76(12) Å^3, d_{calcd} = 2.129 g/cm^{-3}, *Z* = 2; μ = 10.762 mm^{-1}; range for data collection: 2.9 < θ < 25.0°; index ranges: −15 ≤ *h* ≤ 15, −18 ≤ *k* ≤ 19, −39 ≤ *l* ≤ 39; reflections collected 88813; unique reflections 12561 (R_{int} = 0.098); parameters 661; absorption correction: multi-scan min/max transmission 0.2221/0.1464; Program used: SHELXL-97; structure refinement: full-matrix least-squares on F^2, wR_{F^2} = 0.1405 (all data), R_F = 0.059, wR_F = 0.1314 based on 9916 unique reflections with $I > 2\sigma(I)$. GOOF(F^2) = 1.098; maximum residual electron density 4.099 e·Å^{-3}, 1.01 Å nearby Au(3). Disorder of Cl(4) on two positions (48:52), disorder of Cl(11) on two positions (65:35). CCDC-183582 (**7**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2/1EZ, UK; Fax: (internat.)+44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

Hydrogenperoxo-[(bztpen)Fe(OOH)]$^{2+}$ and Its Deprotonation Product Peroxo-[(bztpen)Fe(O_2)]$^{+}$, Studied by EPR and Mössbauer Spectroscopy − Implications for the Electronic Structures of Peroxo Model Complexes

Olivier Horner,*[a] Claudine Jeandey,[a] Jean-Louis Oddou,[a] Pierre Bonville,[b] Christine J. McKenzie,[c] and Jean-Marc Latour[a]

Dedicated to the memory of Prof. William E. Hatfield

Keywords: EPR spectroscopy / Iron / Mössbauer spectroscopy / Peroxo ligands

The purple hydrogenperoxo species [Fe(bztpen)(OOH)]$^{2+}$ (**1**) can be generated in methanol solution by treatment of [Fe(bztpen)Cl]$^{3+}$ with a large excess of hydrogen peroxide [A. Hazell, C. J. McKenzie, L. P. Nielsen, S. Schindler, M. Weitzer, *J. Chem. Soc., Dalton Trans.* **2002**, 310–317]. Addition of 30 equivalents of triethylamine to a solution of [Fe(bztpen)(OOH)]$^{2+}$ gives the [Fe(bztpen)(O_2)]$^{+}$ (**2**) species, in which it has been proposed that the peroxo ligand is coordinated in the η^2 mode. We have synthesized both 100% ^{57}Fe-enriched non-heme Fe^{III} peroxo species and studied them by EPR and Mössbauer spectroscopy. Species **1** displays a typical S = 1/2 low-spin ferric EPR spectrum, the g values of which have been analysed in terms of the Griffith model [J. S. Griffith, *Proc. R. Soc. London, A* **1956**, *234*, 23–36]. We have thus obtained insight into the electronic structure of **1**. The EPR spectrum of **2** is characteristic of a high-spin Fe^{III} species in a nearly axial ligand field. We have determined all Mössbauer parameters for both complexes by a numerical treatment of applied field Mössbauer data. Species **1** exhibits an isomer shift $\delta_{/Fe}$ = 0.16 mm/s and a quadrupole splitting ΔE_Q = −2.08 mm/s (T = 4.2 K). In the case of **2**, we obtain an isomer shift $\delta_{/Fe}$ = 0.63 mm/s and a quadrupole splitting ΔE_Q = 1.12 mm/s (T = 4.2 K). These values are close to those published very recently by Bill et al. for [Fe(trispicMeen)(OOH)]$^{2+}$ (**3**) and [Fe(trispicMeen)(η^2–OO)]$^{+}$ (**4**) species, where bztpen and trispicMeen ligands differ by a noncoordinating group [A. J. Simaan, F. Banse, J.-J. Girerd, K. Wieghardt, E. Bill, *Inorg. Chem.* **2001**, *40*, 6538–6540]. We have also used the extension of the Griffith model developed by Lang et al. for Mössbauer spectroscopy [W. T. Oosterhuis, G. Lang, *Phys. Rev.* **1969**, *178*, 439–456] to evaluate the ^{57}Fe hyperfine tensor of **1** and reproduce the experimental data. On comparison with the Mössbauer data available for η^2-peroxo Fe^{III} complexes, our Mössbauer study of **2** agrees well with a high-spin Fe^{III} side-on peroxo complex. Very characteristic $\delta_{/Fe}$ and ΔE_Q ranges for hydrogenperoxo and side-on peroxo Fe^{III} species are now available, which should aid in the detection of comparable species formed in biological systems.

Introduction

There is currently great interest in non-heme peroxo species, since they are suspected to be key intermediates in several enzymatic or metabolic processes.[1] Detailed spectroscopic characterizations of peroxo species for diiron enzymes such as ribonucleotide reductase and methane monooxygenase are available in the literature.[1b] Where non-heme mononuclear peroxo intermediates are concerned, a well known example is the antitumor drug bleomycin: when this protein is exposed to dioxygen, a transient activated form involved in DNA-cleaving activity is formed. This has been demonstrated to be a hydrogenperoxo FeOOH species.[2] Peroxo species have also been proposed for mononuclear, non-heme, Fe-based superoxide dismutase[3] and more recently, from pulsed radiolysis studies, for the product of superoxide reductase reaction with superoxide.[4] In the recent past, several non-heme mononuclear peroxo model complexes, generated in solution, have been described in the literature.[5] Raman spectroscopy has been fruitful for gaining insight into the peroxo ligand binding mode; hydrogenperoxo and side-on (η^2) peroxo coordination geometries have been characterized.[5i] These two species have very different reactivities. Hydrogenperoxo species

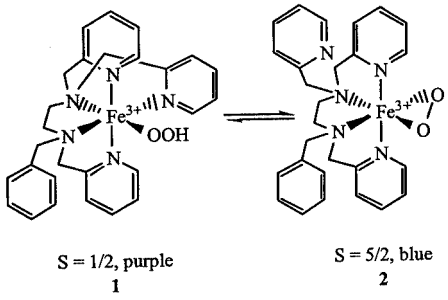
are believed to intervene in oxidation and hydroxylation reactions of substrates, and are likely to operate by the cleavage of the activated O−O bond to generate a catalytically active high-valent iron intermediate. In contrast, the O−O bond in a side-on peroxo complex is not activated for direct cleavage and the species is relatively stable, but can react as a nucleophile towards protonation, probably to produce highly reactive species.[6] No η^2-FeO_2 peroxo species has yet been characterized by Mössbauer spectroscopy in biological systems. A well known example of an η^2-FeO_2 peroxo model complex is $[Fe(edta)(O_2)]^{3-}$, which has been studied by many spectroscopic techniques,[6] including a recently detailed Mössbauer spectroscopy study.[7]

Indeed, Mössbauer spectroscopy is particularly well adapted for the study of iron compounds.[8] Nevertheless, few Mössbauer data for non-heme peroxide species are currently available in the literature.[7,9] We therefore decided to study the hydrogenperoxo complex $[^{57}Fe(bztpen)(OOH)]^{2+}$ (**1**) and its deprotonation product $[^{57}Fe(bztpen)(O_2)]^{2+}$ (**2**) [bztpen stands for *N*-benzyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)-ethane-1,2-diamine[10]] by Mössbauer spectroscopy. The two complexes **1** and **2** can be interchanged by a protonation-deprotonation sequence as shown in Scheme 1.



Scheme 1

While this work was nearing completion, Bill et al. published a detailed Mössbauer study of non-heme Fe^{III} hydrogenperoxo $[Fe(trispicMeen)(OOH)]^{2+}$ (**3**) and η^2-peroxo $[Fe(trispicMeen)(O_2)]^{+}$ (**4**) complexes [trispicMeen stands for *N*-methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine].[9b]

In this article we report the complete Mössbauer spectroscopy study of complexes **1** and **2**. The characteristic Mössbauer parameters obtained for each compound are in full agreement with Bill's results[9b] and give clear Mössbauer signatures for both non-heme mononuclear hydrogenperoxo and side-on peroxo species. This should aid in the detection of comparable species formed in biological systems.

Results

The ligand bztpen was prepared as described previously.[10] For the synthesis of $[^{57}Fe(bztpen)Cl](ClO_4)_2$, $^{57}FeCl_3{\cdot}6H_2O$ was used as a starting compound. Addition of $NaClO_4{\cdot}H_2O$ resulted in the immediate precipitation of the complex $[^{57}Fe(bztpen)Cl](ClO_4)_2$. The purple hydrogenperoxo complex **1** was generated in solution by treatment of $[^{57}Fe(bztpen)Cl]^{2+}$ with a large excess of hydrogen peroxide. Addition of 30 equivalents of triethylamine to this solution gave **2**, in which it has been proposed that the peroxo ligand is coordinated in the η^2 mode.[10] Both species were studied in detail by EPR and Mössbauer spectroscopy as described below.

EPR Spectroscopy

The hydrogenperoxo species **1** was studied by X-band EPR spectroscopy at low temperature. Figure 1 shows the EPR spectrum of **1** in methanol at $T = 6.3$ K; it is typical of a $S = 1/2$ low-spin Fe^{III} species, with g values observed at $g_{max} = 2.22$, $g_{inter} = 2.18$ and $g_{min} = 1.97$.

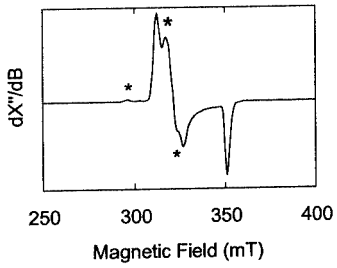


Figure 1. X-band EPR spectrum of **1** in methanol. EPR conditions : temperature 6.3 K, microwave frequency 9.678 GHz, power 2 mW, modulation 1.0 mT/100 kHz. The asterisks denote the components of a minor amount of $[^{57}Fe^{III}(bztpen)(OCH_3)]^{2+}$.

The stars in Figure 1 denote the components of the EPR signal arising from a minor amount (less than 1%) of a precursor species, which corresponds to the low-spin $[Fe^{III}(bztpen)(OCH_3)]^{2+}$.[10]

The 4.2 K X-band EPR spectrum of **2**, shown in Figure 2, exhibits signals at $g = 7.6$ and $g = 5.8$ and a broad unresolved signal in the $g = 4.5$ region.

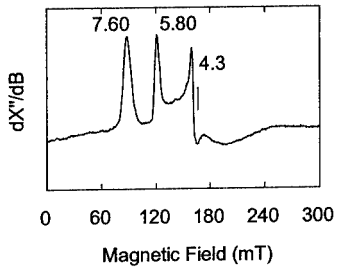

Figure 2. X-band EPR spectrum of **2** in methanol. EPR conditions: temperature 6.3 K, microwave frequency 9.678 GHz, power 20 mW, modulation 1.0 mT/100 kHz.

In addition, an EPR signal arising from a high-spin Fe^{III} contaminant in a rhombic ligand field is seen at $g = 4.3$, but the EPR signal of **1** has completely disappeared, indicating its quantitative transformation upon addition of triethylamine (data not shown). The spectrum of **2** is characteristic of a $S = 5/2$ Fe^{III} complex in a nearly axial ligand field and was analyzed by the rhombogram method.[11] For an $S = 5/2$ spin multiplet, observation of resonances at $g =$

Table 1. Mössbauer parameters for **1** and **2** at $T = 4.2$ K; published spin Hamiltonian parameters for non-heme Fe^{III} peroxo complexes with nitrogen ligands are also given for purposes of comparison; for **1**, with $g_x = -2.18$, $g_y = 2.22$ and $g_z = -1.97$, $A_x = 4.30$ T, $A_y = 6.26$ T and $A_z = 42.26$ T are obtained in the fitting procedure (n.a.: not available)

7.6, 5.8 and 4.5 is consistent with E/D ≈ 0.08. In particular, the signal at $g = 7.6$ arises from the $M_s = \pm 1/2$ Kramers doublet and the signal at $g = 5.8$ arises from the $M_s = \pm 3/2$ Kramers doublet. The temperature dependence of these signals is consistent with the $M_s = \pm 1/2$ doublet being the highest in energy (Supporting Information; see also footnote on the first page of this article). Consequently, the zero-field splitting parameter D must be negative for **2**, as for $[Fe(edta)O_2]^{3-}$ and **4** (Table 1).

Mössbauer Spectroscopy

The hydrogenperoxo complex **1** was studied by Mössbauer spectroscopy at low temperature in one low and two high magnetic fields applied parallel to the propagation direction of the Mössbauer γ-rays. Figure 3 shows Mössbauer spectra of **1** at $T = 4.2$ K ($H = 50$ mT, $H = 3$T) and $T = 10$ K ($H = 7$ T).

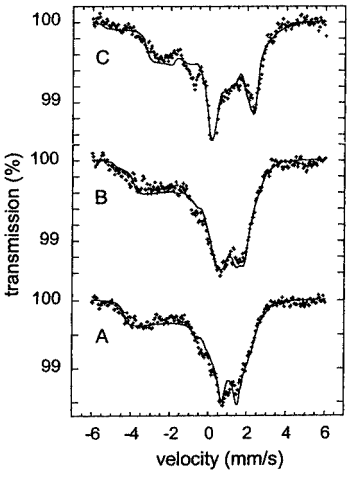

Figure 3. Mössbauer spectra in **1** in methanol. The experimental spectra taken at $T = 4.2$ K in an applied parallel field of 50 mT (A) and 3 T (B) and at $T = 10$ K in an applied parallel field of 7.0 T (C), were fitted (solid curves) with the parameters set of Table 1.

The rather featureless spectra obtained can be fitted simultaneously in the slow relaxation limit within the spin Hamiltonian formalism using a unique set of parameters. We were not fully able to reproduce the shape of the feature at velocity of about −1 mm/s in the 7 T spectrum (Figure 3, curve C). No high-spin Fe^{III} impurity was detected on a higher velocity scale (data not shown). The minor amount of precursor species $[Fe^{III}(bztpen)(OCH_3)]^{2+}$ discernible in the EPR spectrum of **1** was not taken into account in the Mössbauer fitting data. The g-values were taken as positive and fixed to the values obtained by EPR spectroscopy, with $g_x = 2.18$, $g_y = 2.22$ and $g_z = 1.97$ (vide infra). This is not a restriction, as a Mössbauer spectrum is only sensitive to the sign of the products $A_i \cdot g_i$, $i = x, y, z$[12] The Mössbauer parameters obtained from the fit are listed in Table 1.

At $T = 4.2$ K, complex **1** exhibits an isomer shift $\delta_{/Fe} = 0.17$ mm/s. This parameter, which is typical for a low-spin Fe^{III} complex, is similar to those published for hydrogenperoxo complexes with nitrogen ligands (Table 1). The quadrupole splitting $\Delta E_Q = -2.07$ mm/s is large and negative, and the asymmetry parameter $\eta = 0.26$ is low. Our fit was improved by introducing an Euler angle $\alpha = 64°$ between the [A] and [V] tensors. This means that the [A], [g] and [V] tensors share the same principal z axis. These experimentally ascertained values are close to those obtained for **3**[9b] and for the hydroperoxo complex $[Fe(N_4Py)(OOH)]^{2+}$, where N_4Py stands for *N*-[bis(2-pyridyl)methyl]-*N*,*N*-bis(2-pyridylmethyl)amine.[9a]

Complex **2** was studied by Mössbauer spectroscopy at low temperature in one small and one high magnetic field applied parallel to the propagation direction of the Mössbauer γ-rays. Figure 4 shows the Mössbauer spectra obtained at $H = 50$ mT ($T = 4.2$ K and 10 K) and at $H = 7$ T ($T = 4.2$ K).

These spectra were simultaneously fitted at the slow relaxation limit within the spin Hamiltonian formalism using a unique set of parameters. The Mössbauer parameters ob-

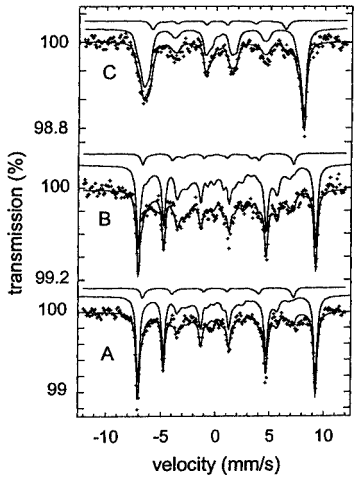

Figure 4. Mössbauer spectra in **2** in methanol. The experimental spectra taken at $T = 4.2$ K (A) and $T = 10$ K (B) in an applied parallel field of 50 mT, and at $T = 4.2$ K in an applied parallel field of 7.0 T (C), were fitted (solid curves) with the parameters set of Table 1. A Fe^{III} impurity (9.4 %) is also present. The solid curves located above the experimental spectrum show the contribution of both species (dashed lines).

tained from the fit are given in Table 1. The spectra of **2** are superimposed by the sextuplet spectra of a minor (9.4%) high-spin Fe^{III} component ($D = +2.9$ cm^{-1}, $E/D = 0.33$, $g = 2.0$, $[A]/g_n\beta_n = -18.0$ T), probably a degradation product of the peroxo complex.

At $T = 4.2$ K under a small applied field ($H = 50$ mT), complex **2** exhibits a sextuplet Mössbauer spectrum. The internal field can be evaluated from its overall splitting and is about 54 T. This is typical for a high-spin Fe^{III} complex. The axial zero-field parameter D is found to be of the order of -1 cm^{-1}, and is close to the D values already published for $[Fe(edta)(O_2)]^{3-}$ and for **4** (Table 1). For $E/D = 0.08$ (zero-field splitting parameter $D < 0$), the lower Kramers doublet $M_s = \pm 5/2$ is uniaxial (it has an easy axis of magnetization along z) and yields a sextuplet Mössbauer spectrum.[13] At $T = 4.2$ K, the levels of population of the upper doublets are much smaller than that of the ground doublet. Therefore, the observed Mössbauer spectrum at $T = 4.2$ K is attributed to the $M_s = \pm 5/2$ doublet and measures the V_{zz} component of the electric field gradient tensor [V]. It can be seen from the experimental spectrum that V_{zz} is positive, as the inner transitions are shifted to the left of the spectrum, and so ΔE_Q is positive for **2**.[13] A Mössbauer spectrum of **2** recorded at higher temperature should give an insight into the other components of the electric field gradient V_{xx} and V_{yy} and allow the asymmetry parameter $\eta = (V_{xx} - V_{yy})/V_{zz}$ to be determined.[7,13] The spectrum recorded at $T = 10$ K and $H = 50$ mT is shown in Figure 4, part B: several additional features appear as the contributions of the middle and upper Kramers doublets (which are not uniaxial) increase. By simultaneous fitting of the three experimental spectra, a value of $\eta = 0$ and a large positive quadrupole splitting $\Delta E_Q = +1.12$ mm/s were determined for **2**. A large isomer shift value $\delta_{/Fe} = 0.63$ mm/s is obtained for this high-spin Fe^{III} complex. The hyperfine coupling tensor of **2** is negative ($A_{av}/g_n\beta_n = -21$ T) because of the main contribution of the Fermi contact term and slightly anisotropic, as for $[Fe(edta)(O_2)]^{3-}$, **4** and the η^2-peroxo complex $[Fe(N_4Py)(O_2)]^+$ (Table 1).

Discussion

The theoretical model developed by Griffith[14] and adapted by Taylor[15] is commonly used to evaluate the tetragonal and rhombic field parameters Δ/λ and V/λ, respectively (where λ is the spin-orbit coupling constant), of low-spin ferric complexes from their g-values determined by EPR spectroscopy. Such a calculation assumes a symmetry not lower than rhombic, a condition not always met, as discussed below for **1**. Therefore, in this model the electronic [g] tensor, the magnetic hyperfine [A] tensor and the electric field gradient [V] tensor are assumed to have a common axis system.[12] Moreover, the orbital reduction factor k is taken to be equal to 1.[14] Following the proposal of Girerd et al. for **3**, the product $g_x.g_y.g_z$ is taken to be positive (with $g_x = -2.18$, $g_y = 2.22$, $g_z = -1.97$),[5] as initially shown by Burger et al.[16] We selected the system of axes described by Taylor, such that $|V| < (2/3)|\Delta|$, where the three real coefficients a, b and c of the ground Kramers doublet are given by the following Equations:[15]

$$\begin{aligned} a &= (g_z + g_y)[8(g_z + g_y - g_x)]^{-1/2} \\ b &= (g_z - g_y)[(g_z + g_y - g_x)]^{-1/2} \\ c &= (g_y - g_x)[(g_z + g_y - g_x)]^{-1/2} \end{aligned} \quad (1)$$

From the experimental g values, we obtain: $a = 0.0567$, $b = 0.0476$ and $c = 0.9979$, which in turn give the field parameters $\Delta/\lambda = -10.10$ and $V/\lambda = 1.85$.[5g,5i,15] This set of values implies that the unpaired electron is located in an orbital with a predominant d_{xy} character, which is strongly destabilized by an antibonding interaction with the π^* orbital of the OOH ligand.[5g,5i] The field parameters of **1** are close to those obtained by Girerd et al. for the hydrogenperoxo complex **3** involving a nitrogen ligand with a similar coordinating environment.[5g,5i] These results agree with a $(d_{xz})^2(d_{yz})^2(d_{xy})^1$ low-spin Fe^{III} electronic configuration, which gives a large negative V_{zz} value (and a large negative ΔE_Q) and a small asymmetry parameter, as found experimentally (Table 1).

By use of the extension of the Griffith model developed by Lang et al. for Mössbauer spectroscopy, one can evaluate the ^{57}Fe hyperfine tensor; the hyperfine tensor values are given by:[17]

$$A_x = -P[-4bc - (1 + \kappa)(a^2 - b^2 - c^2) + 3/7(a^2 - 3b^2 - 3c^2 + 2ab + 2ac)]$$

$$A_y = -P[4ac - (1 + \kappa)(a^2 - b^2 + c^2) + 3/7(3a^2 - b^2 + 3c^2 - 2ab - 2bc)]$$

$$A_z = -P[4ab - (1 + \kappa)(a^2 + b^2 - c^2) + 3/7(3a^2 + 3b^2 - c^2 - 2ac - 2bc)]$$

where a, b and c are given by Equation (1), κ is a parameter characterizing the isotropic contact contribution ($\kappa =$

0.35 for low-spin ferric heme proteins) and P is a scaling factor accounting for the radial distribution of the valence electrons of the Fe^{III} ion ($P/g_n\beta_n \approx -62$ T for low-spin ferric heme proteins).[18] It was possible to reproduce the anisotropic experimental [A] tensor by choosing $\kappa = 0.35$ and $P/g_n\beta_n = -50.3$ T.

[A]/$g_n\beta_n$ (−3.92; 6.09; 42.15) was obtained ($A_{iso}/g_n\beta_n$ = 14.8 T). The low value obtained for P indicates higher covalency for the low-spin iron ion in **1** than for low-spin ferric ions in heme proteins and activated bleomycin.[16]

It is worth noting that different approaches are used in the literature to deal with the signs of the g-values to be employed within the Griffith model. In the case of "activated bleomycin" $Fe^{III}OOH$, Solomon et al. concluded that the three g-values should be taken to be positive.[19] Indeed, they argued that other signs of the g-values would produce crystal field parameters V and Δ that would not allow the experimentally determined higher-energy intra-t_{2g} transition to be reproduced ($E_{exp} \approx 3800$ cm^{-1}). They used an axis system in which the z-axis (which corresponds to the y-axis in this paper) was taken along the Fe−hydrogenperoxo bond. On the other hand, different signs ($g_x = -2.17$; $g_y = 2.26$; $g_z = -1.94$) were obtained by Girerd et al.[5i] for "activated bleomycin" under the same assumption as made by Scholes et al.[20] that $g_xg_yg_z$ is positive. Moreover, upon using the crystal field parameters determined from the latter g-values, one obtains a higher-energy intra-t_{2g} transition at 3900 cm^{-1} (using a covalently reduced spin-orbit coupling constant[19] of 380 cm^{-1} for Fe^{III}). This value is very close to that of 3950 cm^{-1} predicted from field parameters with g_x, g_y and g_z taken to be all positive,[19] and not in contradiction with the near IR MCD results. To probe this point further, we carried out simultaneous fitting of the Mössbauer data for **1** with g_x, g_y and g_z all positive, z being along the Fe−hydrogenperoxo bond. Identical fits were obtained, but with Mössbauer parameters expressed in the new coordinate system.

As noted by Münck et al.[18b] and reemphasized in the case of **3** by Bill et al.,[9b] the Griffith-Taylor model might not be fully valid when the symmetry is less than rhombic. It can be seen in the EPR spectrum of **1** (Figure 1) that the $g_z = 1.97$ resonance does not exhibit any ^{57}Fe magnetic hyperfine splitting. On the other hand, a large component of the hyperfine coupling tensor along the z-axis of the [A] proper axis system is determined experimentally. These conflicting observations can be reconciled if the principal axis frames of the [A] and [g] tensors of **1** are rotated relative to each other. Such a case has already been observed for the low-spin Fe^{III} centre in the active nitrile hydratase.[18b]

Finally, it must be noted that the isomer shift and the quadrupole splitting of **1** are within the range observed for hydrogenperoxo Fe^{III} complexes ($\delta_{/Fe} = 0.16-0.19$ mm/s and a large and negative $\Delta E_Q \approx -2.0$ mm/s at $T = 4.2$ K). These parameters match those of activated bleomycin ($\delta_{/Fe} = 0.16$ mm/s and $\Delta E_Q = -2.96$ mm/s at T = 4.2 K),[16] substantiating the proposition that **1** is a relevant model for these biological hydroperoxo non-heme iron species.

The isomer shift value $\delta_{/Fe} = 0.63$ mm/s obtained for **2** is large for a high-spin Fe^{III} complex but is located in the 0.61−0.65 mm/s range that characterizes high-spin Fe^{III}-η^2O_2 complexes, as shown in Table 1. The side-on peroxo complexes in Table 1 are also characterized by positive ΔE_Q values in the 0.72−1.37 mm/s range ($T = 4.2$ K). Isomer shifts above 0.60 mm/s up to 0.68 mm/s have also been reported in the literature for dinuclear Fe^{III} peroxo complexes, which generally exhibit ΔE_Q values greater than 1.50 mm/s, although some exceptions exist.[22] An isomer shift $\delta_{/Fe}$ = 0.67 mm/s ($T = 4.2$ K) has also been reported for the high-spin porphyrin Fe^{III} η^2-O_2 complex $[Fe(OEP)(O_2)]^-$ (OEP stands for the octaethylporphyrin dianion ligand).[23] In addition, a large quadrupole splitting is observed for **2**, as for the series of side-on peroxo complexes in Table 1. This specific feature is probably due to the 3d anisotropy introduced by the η^2-FeO_2 binding mode, as suggested by theoretical calculations.[24]

Conclusion

The Mössbauer parameters obtained for **1** and **2** in this study agree with the proposal of McKenzie et al. that **1** is a hydrogenperoxo complex and **2** an η^2-peroxo Fe^{III} complex.[10] The coordination number of Fe^{III} in **2** (7 or 6) still remains unknown, the latter being obtained with the decoordination of a picolyl arm of bztpen; the isolation and crystallization of such a species would be useful.

Table 1 shows that non-heme hydrogenperoxo and side-on peroxo Fe^{III} complexes exhibit very characteristic and unambiguous isomer shift values, and $\delta_{/Fe}$ and ΔE_Q ranges are now available for both types of mononuclear peroxo complexes. In particular, no confusion is possible between a mononuclear Fe^{III} species of biological interest with nitrogen/oxygen or sulfur ligands and a mononuclear Fe^{III}-η_2O_2 species. This should make the Mössbauer identification of such species possible in biological systems.

In addition, the Mössbauer parameters obtained here reemphasize both the peculiarity of peroxo Fe^{III} derivatives among ferric complexes and their similarity with their nitrosyl analogues. Indeed, η_2-O_2 iron complexes and $[FeNO]^7$ ($S = 3/2$) species display high isomer shifts, and theoretical descriptions show in both cases that the metal-ligand bond involves a strong σ bonding and a weak additional Π interaction.[24,25]

Experimental Section

EPR spectra were recorded on a Bruker EMX spectrometer. For low-temperature studies, an Oxford Instruments continuous-flow helium cryostat and a temperature control system were used.

All Mössbauer measurements were performed with a constant acceleration spectrometer calibrated with hematite, and isomer shifts are reported relative to an Fe metal standard at room temperature. Variable-temperature experiments were carried out with the sample placed in the tail section of a variable-temperature cryostat. The

temperature of the sample was regulated to within 0.2 K with a conventional PID system. The samples for Mössbauer spectroscopy contained ≈ 4 mM ^{57}Fe in a 200 μL nylon cell. The Mössbauer spectra were analysed with the WMOSS (WEB Research, Edina, MN) software package. For the analysis, the Hamiltonian **H** describing the system is used:

$$\mathbf{H} = D[\mathbf{S}_z^2 - (1/3)S(S+1) + (E/D)(\mathbf{S}_x^2 - \mathbf{S}_y^2)] + \beta_e \cdot \mathbf{S} \cdot [g] \cdot \mathbf{B} + \langle \mathbf{S} \rangle \cdot [A] \cdot \mathbf{I} - g_n \beta_n \mathbf{B} \cdot \mathbf{I} + \mathbf{H_Q}$$

where D and E are the axial and rhombic zero field splitting parameters, respectively, β_e the electronic Bohr magneton, [g] the electronic g-tensor, $\langle \mathbf{S} \rangle$ the appropriately taken spin expectation value, [A] the magnetic hyperfine tensor, g_n the nuclear g-factor, β_n the nuclear Bohr magneton and $\mathbf{H_Q}$ the quadrupolar interaction Hamiltonian.

Synthesis of [^{57}Fe(bztpen)Cl](ClO$_4$)$_2$ and of Complexes 1 and 2

Caution: Although no problems were encountered in the preparation of the perchlorate salts, care should be taken when handling such potentially hazardous compounds.

The ligand bztpen was synthesized as previously described.[10] The $^{57}FeCl_3 \cdot 6H_2O$ starting compound was obtained as recently published.[7] Methanol was purchased from Prolabo, $NaClO_4$ from Sigma, hydrogen peroxide and triethylamine from Aldrich, and all were used without further purification. For the synthesis of [^{57}Fe(bztpen)Cl](ClO$_4$)$_2$, $^{57}FeCl_3 \cdot 6H_2O$ (53.2 mg, 0.197 mmol) in dry methanol (1 mL) was added to a solution of bztpen (83.3 mg, 0.197 mmol) in 2 mL of dry methanol. A yellow precipitate formed immediately and redissolved spontaneously after 2 minutes. Addition of $NaClO_4$ (72.6 mg, 0.591 mmol) resulted in precipitation of a yellow product, which was isolated by filtration. Treatment of this yellow compound, dissolved in dry methanol, with hydrogen peroxide (30%, 300 equivalents) generated the purple species **1**. Addition of triethylamine (99%, 30 equivalents) produced a blue solution of **2**.

Syntheses of Zinc Complexes with Multidentate Nitrogen Ligands: New Catalysts for Aldol Reactions

Tamis Darbre,*[a] Christian Dubs,[a] Eduard Rusanov,[b] and Helen Stoeckli-Evans[b]

Keywords: Aldol reaction / Catalysis / N ligands / N,O ligands / Zinc

The ligands 2,6-bis{[(pyrid-2-ylmethyl)amino]methyl}-pyridine with an N_5 pattern and (6-{[(pyrid-2-ylmethyl)amino]methyl}pyrid-2-yl)methanol with an N_3O pattern were synthesized. Zn^{II} complexes of the two ligands could be obtained, and the single-crystal X-ray structure of (2,6-bis{[(pyrid-2-ylmethyl)amino]methyl}pyridine)zinc chloride showed Zn coordination to all five nitrogen atoms. The strong complexation of 2,6-bis{[(pyrid-2-ylmethyl)-amino]methyl}pyridine and (6-{[(pyrid-2-ylmethyl)amino]-methyl}pyrid-2-yl)methanol with Zn^{II} were demonstrated by ^1H NMR spectroscopic studies and electrospray mass spectrometry. The coupling of 2-hydroxyacetophenone and benzaldehyde was studied in the presence of the prepared Zn complexes, and it was shown that the coupling product was obtained at room temperature in up to 60% yield with 7.5 mol % of the zinc catalyst. The present complexes mimic the active site of the zinc-dependent class II aldolases, where Zn^{II} is coordinated to three nitrogen atoms.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The aldol reaction is of central importance for construction of C−C bonds in organic chemistry.[1] It is therefore not surprising that several catalysts and reagents have been developed in order to achieve efficient condensation with high diastereomeric and enantiomeric selectivity.[2] Furthermore, due to its importance for organic synthesis, the asymmetric aldol reaction has become, without doubt, one of the most important topics in modern catalytic synthesis.

From the several methods available for the aldol reaction, the direct condensation of an aldehyde with a ketone[3] is a most attractive approach since it does not require the isolation of preformed enolates.[4] Therefore, the development of new catalysts for the direct condensation is a field of considerable importance.

In nature, aldol reactions also constitute an important reaction class that is mediated by aldolases, ubiquitous enzymes that catalyze among other reactions, the reversible aldol cleavage of fructose-1,6-bis(phosphate) (FBP) in glycolysis. Aldolases are divided into two distinct classes according to their enzymatic mechanism. Whereas the class I aldolases form a Schiff base intermediate between the e-amino group of a lysine residue and the carbonyl carbon atom of the substrate, class II aldolases are zinc-dependent.[5] Three histidine side chains and a carboxylate group of a glutamic acid are coordinated to the Zn^{II} ion in class II fuculose 1-phosphate aldolase produced by *E. coli*.[6] Upon substrate binding, the carboxylate group dissociates from the Zn^{II} reaction center and moves away, providing space for the hydroxy ketone to bind to the Zn^{II} ion and at the same time deprotonating the carbon atom in the α-position to the carbonyl group. The resulting enediolate is proposed to be stabilized through binding to the zinc ion and to act as a nucleophile (Figure 1).[6]

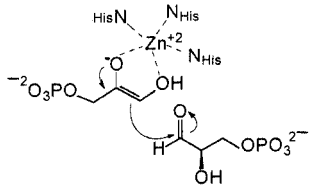

Figure 1. Proposed mechanism for the aldol reaction catalyzed by type II aldolase[6]

Although it has been demonstrated that Zn^{II} salts catalyze the aldol condensation,[7] Zn complexes with nitrogen ligands have not been explored much as catalysts for aldol reactions. In a structural model for aldolases, a modified tris(pyrazolyl)borate ligand[8] was used to mimic the three nitrogen atoms in the enzyme's active site. A model with four nitrogen atoms and a carbonyl group bound to the zinc ion has also been developed.[9] Proline has been used as an asymmetric catalyst,[10,11] and some early work has shown that the Zn^{II} ion coordinated to pyridine and bi- and ter(pyridine)s can catalyze the reaction of aldehydes and ketones to give unsaturated ketones.[12]

Chiral dinuclear Zn complexes with chiral binol as ligand as well as other oxygen-containing ligands have been re-

cently reported to catalyze asymmetric aldol reactions.[13−18]

Inspired by the Zn^{II} coordination site in the active site of the class II aldolases, we have prepared ligands containing nitrogen-binding sites in order to develop novel catalysts for the aldol reaction.

Here we report on the efficient synthesis of ligands containing nitrogen as binding sites (N_5 and N_3O), the synthesis of new Zn^{II} complexes where the zinc center is coordinated to nitrogen atoms, and our first results on the activity of the new zinc complexes as catalysts for the condensation of benzaldehyde and 2-hydroxyacetophenone.

Results and Discussion

The syntheses of the ligands with N_5 and N_3O coordination sites (**6** and **9**) are shown in Scheme 1. Synthesis of tosylamine **3** was achieved by treatment of 2-(aminomethyl)-pyridine with NaOH and tosyl choride in a two-phase system (H_2O/diethyl ether) in 89% yield.[19] Coupling of **3** with 2,6-bis(bromomethyl)pyridine (**4**), also in a two-phase system and nBu_4NBr as a phase-transfer catalyst, gave product **5**, which could be isolated after chromatography in 86% yield. The tosyl group was removed by heating the tosylate **5** with concentrated sulfuric acid to yield the ligand **6** in 94% yield. The three-step synthesis gives **6** in an overall yield of 72%. There are two reports in the literature of compounds related to **6**; in the first the tetraammonium salt of **6** is prepared by a different procedure,[20] and in the second G. Newkome et al.[19] report the synthesis of **6** in 28% yield. The latter authors describe the product obtained as an unstable oil whereas we isolated **6** as a brownish, stable solid.

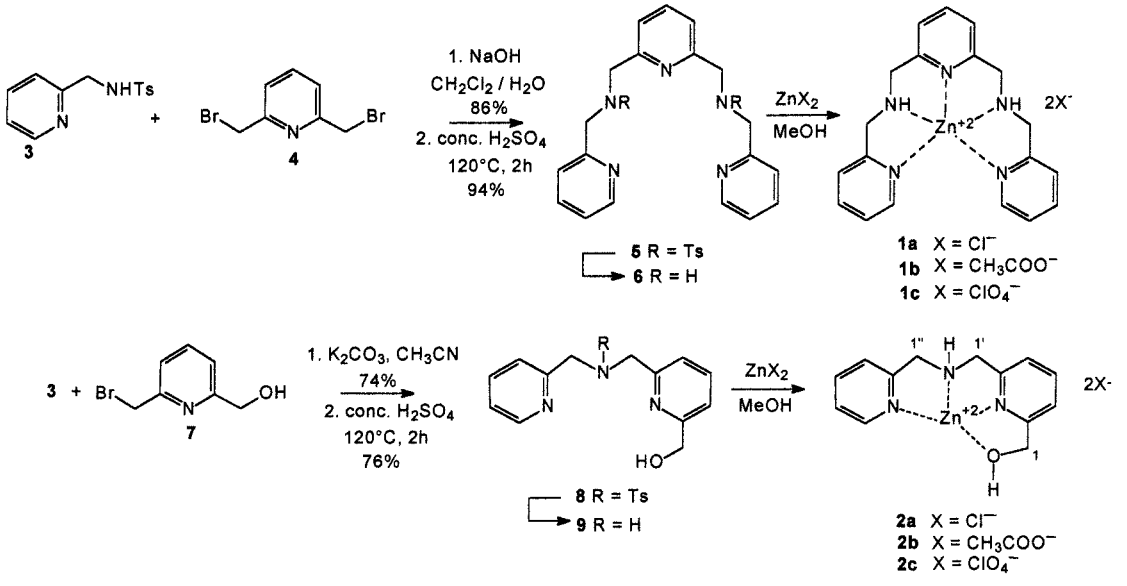
For the synthesis of the new ligand **9**, the tosylamine **3** was alkylated with [6-(bromomethyl)pyrid-2-yl]methanol (**7**) in the presence of K_2CO_3 in acetonitrile to give **8** in 74% yield. The latter was deprotected in the same way as **5** to give **9** in 76% yield (Scheme 1).

The ligands **6** and **9** became readily available in a few steps and high yields by the syntheses developed here.

Complexation of 6 and 9 with Zn Salts

Having the two ligands **6** and **9** at hand, we have prepared a series of Zn^{II} complexes to test their ability to act as catalysts for aldol reactions. Thus, ligand **6** was refluxed with $ZnCl_2$, $Zn(CH_3COO)_2{\cdot}2H_2O$ or $Zn(ClO_4)_2{\cdot}6H_2O$ in a 1:1 ration in MeOH to give the corresponding complexes **1a**, **1b** and **1c** in 64%, 82% and 81% yield, respectively. All three complexes could be identified by their ^1H and ^{13}C NMR spectra, and ESI-MS. The ^1H NMR spectrum in CD_3OD of **1a**, **1b**, **1c** showed shifts of the signals for the pyridine hydrogen atoms as well as for the two methylene groups [the signals of the $pyCH_2N$ methylene groups appear at δ = 3.97 ppm (8 H) for the ligand **6** and at δ = 4.28 ppm (4 H) and δ = 4.39 ppm (4 H) for the acetate complex **1b**]. The ESI-MS data showed for the three complexes, **1a**, **1b** and **1c**, peaks at *m*/*z* = 382, 384, 386, that can be assigned to [**6** − H^+ + Zn^{II}], with relative intensities of 100:59:41 for **1a**, 100:61:38 for **1b** and 100:59:41 for **1c**, in good agreement with the calculated intensities of 100:60:42 for the three zinc isotopes. Furthermore, the peaks for [**6** + Zn^{II} + Cl^-] at *m*/*z* = 418, 420 and 422 are also observed for **1a**, as well as the peaks for the [**6** + Zn^{II} + CH_3COO^-] at *m*/*z* = 442,444 and 446 and for the [**6** + Zn^{II} + ClO_4^-] at *m*/*z* = 482, 484 and 486 for **1b** and **1c**, respectively. The free ligand **6**, however, could not be detected in the ESI-MS.

Insight into the geometry of the complexes and the binding mode of the zinc atom with the ligand **6** was obtained by single-crystal X-ray analysis. The reaction of **6** with $ZnCl_2$ gave two pseudo-polymorphs, **1a**·CH_3OH solvate and **1a**·$2H_2O$. Here the Zn^{II} ion is coordinated to the five



Scheme 1

nitrogen atoms of the ligand and to a chloride anion, producing complexes with pseudo-C_2 symmetry (for example, see Figure 2). The zinc atoms and the pyridine rings of the side chain are almost co-planar. The amine N atoms, N2 and N4, are displaced above this plane towards the central pyridine ring. The reaction of **6** with $Zn(ClO_4)_2$ gave **1c**, in which the metal ion is pentacoordinate, with all five nitrogen atoms coordinated to the metal (Figure 3). Due to the lack of a sixth ligand, the two pyridine rings are bent downwards, but the complex retains the pseudo-C_2 symmetry. The bond angles N1−Zn−N3 and N3−Zn−N5 have an average value of 128.3° relative to 89.3° for the two hexacoordinate **1a** complexes. The zinc−N bond lengths in **1c** are notably shorter than those observed in complexes **1a**·CH_3OH and **1a**·$2H_2O$. These differences are particularly important for the central Zn−N(pyridine) distance (ca. 0.1 Å) and the outer Zn−N(pyridine) distances (ca. 0.15 Å). Selected bond lengths and angles for the three structures are given in Table 1.

Complexes **2a**, **2b** and **2c** were obtained by refluxing the zinc salts and **9** in a 1:1 ratio in methanol. Partial evaporation of the solvent and addition of diethyl ether gave [(6-{[(pyrid-2-ylmethyl)amino]methyl}pyrid-2-yl)methanol]zinc dichloride (**2a**), [(6-{[(pyrid-2-ylmethyl)amino]methyl}-pyrid-2-yl)methanol]zinc diacetate (**2b**) and [(6-{[(pyrid-2-ylmethyl)amino]methyl}pyrid-2-yl)methanol]zinc diperchlorate (**2c**) as white solids (Scheme 1), in 41, 62 and 66% yields, respectively.

The complexes **2a**, **2b**, **2c** were characterized by ^1H and ^{13}C NMR spectroscopy, and ESI-MS. The ^1H NMR spectrum in [D_4]methanol of **9**, **2b** and **2c** are shown in Figure 4. In general, we can see that for the three methylene groups a strong downfield shift is observed upon complexation, whereas the aromatic protons are less influenced by the Zn coordination. For ligand **9**, three signals for the 6 H atoms in the positions 1, 1′ and 1′′ (see numbering in Scheme 1) can be seen; a singlet at δ = 4.72 ppm (2 H1), and two close singlets (δ = 3.95 and 3.96 ppm) corresponding to four protons (2 H1′ and 2 H1′′). After complexation, five signals appeared for the same six hydrogen atoms and the two H1, two H1′ and two H1′′ atoms, became nonequivalent. We observe two broad signal at δ = 5.05 and 4.97 ppm for the two H1 atoms, a broad signal at δ = 4.54 ppm for two hydrogen atoms (1 H1′ and 1 H1′′) and two broad doublets at δ = 4.16 and 3.82 ppm for the remaining two hydrogen atoms (1 H1′ and 1 H1′′). For **2c** the signals are well defined.

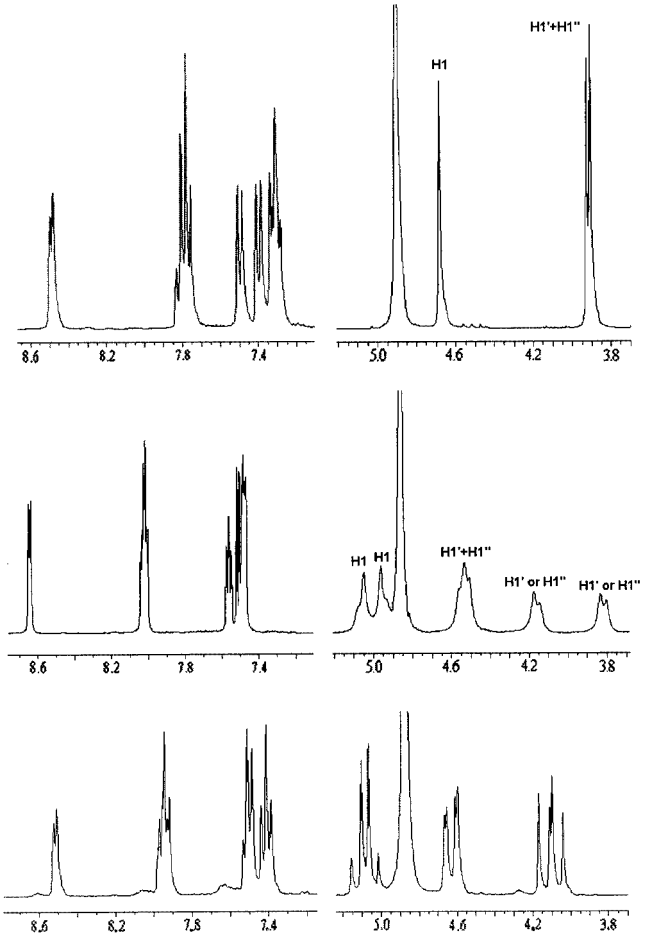

Figure 4. Top: ^{1}H NMR in CD_3OD of ligand **9**; center: ^{1}H NMR spectrum, in CD_3OD, of complex **2b**; bottom: ^{1}H NMR spectrum in CD_3OD of complex **2c**; the aromatic region and the methylene groups are shown (in ppm)

The assignment of the hydrogen signals in the ^{1}H NMR spectrum of complex **2b** was determined by a ^{1}H-^{1}H COSY measurement.

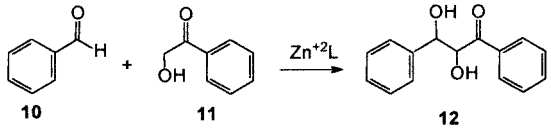
The electrospray mass spectra of **2a**, **2b** and **2c** show the peaks corresponding to [**9** − H^+ + Zn^{II}] at m/z = 292, 294 and 296 in the expected relative intensities, consistent with the structure shown in Scheme 1. The peaks corresponding to [**9** − H^+ + Zn^{II} + Cl^-] for **2a** and [**9** − H^+ + Zn^{II} + CH_3COO^-] for **2b** are also present. Similar to the complexes of **6**, the peak corresponding to the free ligand **9** is not observed in the ESI-MS.

The structures for the complexes **2a**, **2b**, **2c** in Scheme 1 indicate a protonated hydroxy group, although deprotonation cannot be excluded. The presence of a hydroxy group was inferred by the fact that the ^{1}H NMR spectrum of the acetate complex **2b** showed six protons for two acetate anions, indicating the presence of two counter-anions in **2b**.

The acetates **1b** and **2b** proved to be soluble in a variety of organic solvents, an important property for efficient catalysis of organic reactions. The acetate anion can also act as a base to deprotonate a ketone in the aldol reaction. Therefore, the preliminary reactivity studies described below were conducted with the acetates.

Reactivity Studies

In order to explore the ability of the new zinc complexes to act as catalysts for aldol reactions, the zinc-catalyzed reaction of benzaldehyde (**10**) with 2-hydroxyacetophenone (**11**) to give 1,3-diphenylpropan-1-one (**12**) was investigated (Scheme 2).



Scheme 2

The results are summarized in Tables 2−4. The aldol product **12** was formed when a mixture of 1.0 equiv. of benzaldehyde (**10**) and 1.5 equiv. of 2-hydroxyacetophenone (**11**) reacted in the presence of 7.5 mol % of either **6** or **9** and 7.5 mol % of zinc acetate.[21] The reaction took place in THF but also in a protic solvent, methanol, and the yields improved with addition of 0.5 equiv. of triethylamine. The ligand **9** was the more efficient of the two ligands studied, giving the addition product in 53% in methanol and 56% in THF. The conversion was higher when diethylzinc was added to **9** (62%, Entry 7, Table 3). The preformed complexes **1b** and **2b** could also catalyze the aldol reaction; **2b** gave the higher yield (59%) of **12**. We have also observed that an excess of benzaldehyde or 2-hydroxyacetophenone can lead to better yields (51−52%) when **1b** is the catalyst (Entries 4 and 7 in Table 4). The *syn*/*anti* ratio of **12**, determined by ^{1}H NMR spectroscopy for the reactions shown in the tables, was 1:1 for all the experiments with exception of Entry 4 inTable 3 (1.5:1 *syn*/*anti* ratio) and Entry 5 in Table 3 (3:1 *syn*/*anti* ratio).

Table 2. Aldol reaction using the ligands **6** and **9** and zinc salts as catalysts in MeOH (in all experiments, 0.5 mmol of benzaldehyde, 0.75 mmol of 2-hydroxyacetophenone and 0.05 mmol of catalyst were used; **12** was obtained as a 1:1 *syn*/*anti* mixture and the yields and diastereomeric ratios were determined by ^{1}H NMR spectroscopy; Py: pyridine; Im: imidazole; Et_3N: triethylamine)

Entry	Catalyst (7.5 mol %)	Additives	Yield of **12** (%)
1	**6**		0
2	**6**, $Zn(Ac)_2$		37
3	**6**, $Zn(CH_3COO)_2$	0.25 mmol Et_3N	45

8[a]	2b	MS	41
9[a]	**2b**	0.25 mmol Et_3N, MS	59
10[a]	2b		29
11[a]	**2b**	Na_2SO_4	23

[a] 0.5 mmol benzaldehyde, 0.75 mmol 2-hydroxyacetophenone. [b] 1 mmol benzaldehyde, 0.25 mmol 2-hydroxyacetophenone. [c] 1.5:1 *syn*/*anti*. [d] 3:1 *syn*/*anti*. The yields and diastereomeric ratios were determined by ^{1}H NMR spectroscopy. MS: molecular sieves. Py: pyridine; Et_3N: triethylamine. [e] 0.25 mmol benzaldehyde, 0.75 mmol 2-hydroxyacetophenone. In all experiments 0.05 mmol of catalyst was used. **12** was obtained as a 1:1 *syn*/*anti* ratio with the exception of footnotes [c] and [d].

Further studies of the catalytic system developed with other substrates and screening for reaction conditions that will lead to improved yields are now under way.

Conclusions

In a search for new Zn^{II} complexes that can act as catalysts for aldol reactions, we have prepared novel zinc complexes with N_5 and N_3O coordination. For that, the ligands **6** and **9** were synthesized in a few steps with high yields. The complexes prepared catalyze the reaction of hydroxyacetophenone and benzaldehyde to give 2,3-diphenylpropan-1-one in yields of 60% when **9** plus diethylzinc or the preformed zinc complex **2b** were the catalysts.

Experimental Section

General Remarks: All reactions were carried out, unless mentioned, in open flasks, without exclusion of O_2 or H_2O. Technical solvents were distilled prior to use. Chemicals were purchased from commercial suppliers (FLUKA and Aldrich) and, unless otherwise stated, used without further purification. Acetonitrile was refluxed under nitrogen for 2 h in the presence of CaH_2, distilled and kept over molecular sieves. Column chromatography (CC): silica gel 60 from FLUKA; thin layer chromatography (TLC): silica gel plates Alugram® Sil G/UV254; visualization was made with a UV lamp (λ = 254 nm) or with 10% ninhydrin solution in 90% ethanol. NMR spectra: Bruker AC-300 spectrometer, 300 MHz for ^{1}H and 75 MHz for ^{13}C. Chemical shifts δ are given in ppm and were calibrated against the deuterated solvent. The multiplicity of the ^{13}C NMR peaks were determined by ^{13}C NMR DEPT spectra and the expected chemical shifts; the *J* values are in Hz. Mass spectra were provided by the Service of Mass Spectrometry of the Department of Chemistry and Biochemistry in Bern. Infrared spectroscopy was performed with a Perkin-Elmer 1600 series FTIR spectrometer. Frequencies $\tilde{\nu}$ are given in cm^{-1} (s strong, m medium, w weak).

Caution: Perchlorates are potentially explosive and should be handled with the necessary precautions.[22]

2-[(Tosylamino)methyl]pyridine (3): Prepared as described.[19] Tosyl chloride (14.12 g, 74 mmol) in diethyl ether (14 mL) was added to a mixture of 2-(aminomethyl)pyridine (8 g, 74 mmol) and NaOH (4.4 g, 110 mmol) in water (20 mL). The two-phase reaction mixture was stirred in a closed flask for 18 h. The ether was then evaporated and the pH of the aqueous phase adjusted to 7 with 1 M HCl solution. The precipitated white solid was filtered, dried and dissolved in ethanol. The ethanol was evaporated to yield **3** as a white solid (17.36 g, 89% yield). ^{1}H NMR ($CDCl_3$): δ = 2.39 (s, 3 H, CH_3Ts), 4.24 (d, *J* = 5.49, 2 H, NCH_2Py), 5.90 (br. t, 1 H, NH), 7.14−7.19 (m, 2 H, 3-pyH and 5-pyH), 7.23−7.26 (m, 2 H, 3-phH), 7.61 (ddd, 1 H, 4-pyH), 7.74 (d, *J* = 7.7, 12 H, 2-phH), 8.45 (d, *J* = 4.77, 1 H, 6-pyH) ppm. ^{13}C NMR ($CDCl_3$): δ = 22.17 (q), 48.05 (t), 122.65 (d), 123.29 (d), 127.91 (d), 130.8 (d), 137.52 (d), 144.04 (q), 149.57 (d), 155.47 (q) ppm.

2,6-Bis(bromomethyl)pyridine (4) and [6-(Bromomethyl)pyrid-2-yl]-methanol (7): 2,6-bis(hydroxymethyl)pyridine (2 g,14.4 mmol) was heated for 15 h in 48% HBr solution (20 mL). The solution was cooled with an ice bath and 10 M NaOH was added until pH = 12 was reached. After extraction with ether (3 × 60 mL), the ether phase was dried with $MgSO_4$, filtered and the ether evaporated to give a white solid. The products were separated by column chromatography (diethyl ether/hexane, 3:7) to give two fractions. Fraction A: **4** (1.94 g, yield 51%) as white needle-like crystals. R_f = 0.4 (diethyl ether/hexane, 3:7). ^{1}H NMR ($CDCl_3$): δ = 4.55 (s, 4 H, CH_2Py), 7.39 (d, *J* = 7.74 Hz, 2 H, 3-pyH), 7.72 (ap. t, *J* = 7.73 Hz, 1 H, 4-pyH) ppm. ^{13}C NMR ($CDCl_3$): δ = 33.45 (t), 122.79 (d), 138.11 (d), 156.73 (s) ppm. Fraction B: **7** (720 mg, yield 24%) as white needle-like crystals. R_f = 0.05 (diethyl ether/hexane, 3:7). ^{1}H NMR ($CDCl_3$): δ =3.66 (br. s, 1 H, OH), 4.56 (s, 2 H, OCH_2py), 4.77 (s, 2 H, $BrCH_2$py), 7.18 (d, *J* = 7.7 Hz, 1 H,), 7.36 (d, *J* = 7.5 Hz, 2 H), 7.61 (app t, *J* = 7.7 Hz, 1 H, 4-pyH) ppm. By adding more HBr after 15 h and refluxing for a longer time, the yield of **4** could be increased to 69%. By stopping the reaction immediately after all the 2,6-bis(hydroxymethyl)pyridine had disappeared on the TLC the yield of **7** could be increased to 37%.

2,6-Bis{[(pyrid-2-ylmethyl)(tosyl)amino]methyl}pyridine (5): $n$$Bu_4NBr$ (6.48 g) and KOH (80 g) in water (240 mL) was added to 2-[(tosylamino)methyl]pyridine (**3**) (8 g, 30.4 mmol) in dichloromethane (800 mL). The reaction mixture was heated to reflux and 2,6-bis(bromomethyl)pyridine (**4**) (4 g, 15.2 mmol) in dichloromethane was added at once. The reaction mixture was refluxed for 14 h. The

two phases were separated and the dichloromethane was evaporated to leave a brown oil. Column chromatography (hexane/ethyl acetate, 1:1 with 1% triethylamine) yielded **5** as a brown viscous oil (8.25 g, yield 86%). R_f = 0.1 (hexane/ethyl acetate, 1:1). ^{1}H NMR ($CDCl_3$): δ = 2.39 (s, 3 H, $TsCH_3$), 4.36 (s, 4 H, $pyCH_2$), 4.49 (s, 4 H, $pyCH_2$), 7.05−7.09 (m, 4 H,3,5-pyH), 7.23 (d, J = 8.1 Hz, 4 H, phH), 7.31 (d, J = 7.92 Hz, 2 H, 3,5-pyH), 7.36 (ap. t, J = 7.71 Hz, 1 H, 4-pyH), 7.53 (ddd, J = 7.63, J = 1.6 Hz, 2 H, 4-pyH), 7.65 (d, J = 8.2 Hz, 4 H, phH), 8.34 (d, J = 4.2 Hz, 2 H, 6-pyH) ppm. ^{13}C NMR ($CDCl_3$): δ = 22.16 (q), 54.31 (t), 54.56 (t), 121.83 (d), 123.02 (d), 123.36 (d), 128.06 (d), 130.24 (d), 137.26 (d), 137.61 (d), 144.03 (s), 149.44 (d), 156.42 (s), 157.14 (s) ppm.

2,6-Bis{[(pyrid-2-ylmethyl)amino]methyl}pyridine (6): **5** (7.6 g, 12.1 mmol) was dissolved in 98% H_2SO_4 (10 mL) and heated to 120 °C for 3 h. The liquid turned black. The solution was poured into a brine/NaOH solution (20 mL) and the pH of the solution was adjusted to 12 with an NaOH solution The aqueous solution was extracted with dichloromethane (4 × 100 mL). The organic phase was dried with $MgSO_4$, filtered and the dichloromethane evaporated to give **6** as a brown solid (3.65 g, yield 94%). ^{1}H NMR ($CDCl_3$): δ = 2.32 (s, 2 H, NH), 3.96 and 3.98 (2s, 8 H, CH_2py), 7.13−7.15 (m, 2 H, pyH), 7.21 (d, J = 7.71, 2 H, pyH), 7.35 (d, J = 7.71 Hz, 2 H, 3,5-pyH), 7.57−7.66 (m, 3 H, 4-pyH), 8.54 (d, J = 4.8 Hz, 2 H, 6-pyH) ppm. ^{13}C NMR ($CDCl_3$): δ = 55.31 (t) 55.44 (t), 121.15 (d), 122.63 (d), 123.01 (d), 137.15 (d), 137.59 (d), 149.96 (d), 159.70 (s), 160.31 (s) ppm. IR ($CHCl_3$): ṽ = 3425 s, 1604 m, 1215 s, 742 s, 668 s cm^{-1}. MS: m/z (%) = 319 (1.6) [M$^+$], 241 (2.6), 227 (3.0), 213 (71), 107 (88), 93 (100). FAB (DTT/DTE): m/z = 320 [M + 1]. HRMS: calculated for $C_{19}H_{21}N_5$ 319.179696, found 319.179690.

[6-{[(Pyrid-2-ylmethyl)(tosyl)amino]methyl}pyrid-2-yl]methanol (8): A mixture of **3** (1.9 g, 7.2 mmol), **7** (1.5 g, 7.2 mmol) and K_2CO_3 (2.7 g) in acetonitrile (140 mL) was refluxed for 6 h. The precipitate was collected by vacuum filtration and washed with acetonitrile. The acetonitrile was evaporated to give an orange oil. Chromatography using a gradient (ethyl acetate/hexane/triethylamine, 1000:100:1 to ethyl acetate/methanol/triethylamine, 1000:100:1) gave **8** as a colorless viscous oil (2.05 g, yield 74%). R_f = 0.62 (ethyl acetate/methanol, 25:2). ^{1}H NMR ($CDCl_3$): δ =2.42 (s, 3 H, CH_3Ts), 4.54−4.56 (3 s, 6 H, CH_2py), 6.98 (d, J = 7.8 Hz, 1 H, 3-pyH), 7.06−7.10 (m, 1 H, 5-pyH), 7.16 (d, J = 7.35 Hz, 1 H, 5-pyH), 7.27 (d, J = 7.71 Hz, 2 H, phH), 7.35 (d, J = 8.1 Hz, 1 H, 3,5-pyH), 7.48- 7.58 (m, 2 H, 4-pyH), 7.70 (d, J = 8.34 Hz, 2 H, phH), 8.33 (d, J = 4.77 Hz, 1 H, 6-pyH) ppm. ^{13}C NMR ($CDCl_3$): δ = 22.17 (q), 54.01 (t), 54.61 (t), 64.40 (t), 119.65 (d), 122.03 (d), 123.04 (d), 123.44 (d), 127.98 (d), 130.30 (d), 137.20 (d), 137.31 (s), 137.79 (d), 144.15 (s), 149.57 (d), 155.70 (s), 157.12 (s), 159.99 (s) ppm. IR ($CHCl_3$): ṽ = 3018 m, 1597 s, 1576 s, 1339 s, 1159 s, 1091 m, 756 s, 668 m cm^{-1}. MS: m/z (%) = 207 (11), 162 (27), 155 (30), 134 (33), 105 (30), 91 (52), 69 (69), 57 (100). FAB-NBA: m/z = 384 [M + 1]. High resolution LSIMS: calculated for $C_{20}H_{22}N_3O_3S$ 384.138189; found 384.13812.

[6-{[(Pyrid-2-ylmethyl)amino]methyl}pyrid-2-yl]methanol (9): The tosylate **8** (2.0 g, 5.2 mmol) was dissolved in 98% H_2SO_4 (10 mL) and heated to 120 °C for 3 h. The liquid turned black. The solution was poured into a brine/NaOH solution (20 mL), and the pH was adjusted to 12 with NaOH solution. The water phase was extracted with dichloromethane (4 × 100 mL). The organic phase was dried with $MgSO_4$, filtered and the dichloromethane evaporated to give **9** as an oil with a slight orange color (0.91 g, yield 76%). ^{1}H NMR ($CDCl_3$): δ = 3.15 (br. s, 2 H, OH + NH), 3.95 and 3.96 (2 s, 4 H, CH_2py), 4.72 (s, 2 H, $pyCH_2O$), 7.10 (d, J = 7.71 Hz, 1 H, 3-pyH), 7.14−7.18 (m, 1 H, 5-pyH), 7.23 (d, J = 7.71 Hz, 1 H, 3-pyH), 7.33 (d, J = 7.7 Hz, 1 H, 5-pyH), 7.59−7.66 (m, 2 H, 4-pyH), 8.55 (d, J = 4.05 Hz, 1 H, 6-pyH) ppm. ^{1}H NMR(CD_3OD): δ = 3.91 and 3.93 (2 s, 4 H), 4.69 (s, 2 H), 7.25−7.34 (m, 2 H), 7.40 (d, J = 7.74 Hz, 1 H), 7.50 (d, J = 7.71 Hz, 1 H), 7.72−7.85 (m, 2 H), 8.49 (d, J = 4.02 Hz, 1 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 54.97 (t), 55.24 (t), 64.68 (t), 119.34 (d), 121.44 (d), 122.74 (d), 123.08 (d), 137.23 (d), 137.81 (d), 149.98 (d), 159.02 (s), 159.37 (s), 159.99 (s) ppm. IR ($CHCl_3$): ṽ = 3016 w, 1595 m, 1576 m, 1216 s, 754 s, 668 m cm^{-1}. FAB-NBA: m/z = 230 [M + 1]. High resolution ESI-TOF-MS: calculated for $C_{13}H_{16}N_3O$: 230.1293; found 230.1288.

(2,6-Bis{[(pyrid-2-ylmethyl)amino]methyl}pyridine)zinc Dichloride (1a): 2,6-bis{[(pyrid-2-ylmethyl)amino]methyl}pyridine (**6**) (200 mg, 0.63 mmol) and $ZnCl_2$ (85 mg, 0.63 mmol) were dissolved in methanol (15 mL) and chloroform (3 mL). The solution was refluxed for 3 h. The methanol was reduced to 3 mL, and complex **1a** could be obtained as crystals (183 mg; yield 64%) by gradually adding (day by day 0.3−0.5 mL) diethyl ether. ^{13}C NMR ($CDCl_3$): δ = 52.29 (t), 54.28 (t), 123.32 (d), 125.49 (d), 125.97 (d), 142.01 (d), 142.64 (d) 148.83 (d), 155.32 (s), 157.87 (s) ppm. IR: ṽ = 3462 s, 3196 s, 1653 w, 1627 w, 1603 s, 1586 m, 1434 s, 1097 m, 915 m, 781 m, 771 s, 760 s cm^{-1}. ESI-MS: m/z (%) = 382 (86) [**6**-H$^+$ + ^{64}Zn], 384 (51) [**6**-H$^+$ + ^{66}Zn], 386 (35) [**6**-H$^+$ + ^{68}Zn], 418 (100) [**6** + ^{64}Zn + ^{35}C] , 420 (92) [**6** + ^{64}Zn+ ^{37}Cl, **6** + ^{66}Zn+ ^{35}Cl], 422 (65) [**6** + ^{66}Zn + ^{37}Cl, **6** + ^{68}Zn + ^{35}Cl]. High resolution ESI-TOF-MS: $C_{19}H_{20}N_5Zn$ calcd. 382.1010, found 382.1005; $C_{19}H_{20}ClN_5Zn$ calcd. 418.0776; found 418.0742. For X-ray structure see X-ray section.

(2,6-Bis{[(pyrid-2-ylmethyl)amino]methyl}pyridine)zinc Diacetate (1b): **6** (150 mg, 0.5 mmol) and $Zn(CH_3COO)_2$ (108 mg, 0.5 mmol) were dissolved in methanol (5 mL). After refluxing for 3 h, the methanol was evaporated to leave the **1b** complex as a brown viscous oil (200 mg, yield 82%). The complex was soluble in various organic solvents (THF, acetonitrile, dichloromethane and methanol). ^{1}H NMR (MeOD): δ = 1.83 (s, $COOCH_3$, 6 H), 4.28 and 4.39 (2 br. s, 8 H, CH_2py), 7.34−7.43 (m, 4 H, pyH), 7.54 (d, J = 7.71 Hz, 2 H, pyH), 7.87−7.99 (m, 3 H, pyH), 8.49 (d, J = 3.66 Hz, 2 H, 6-pyH) ppm. ^{13}C NMR (CD_3OD): δ = 23.46 (q), 52.54 (t), 54.14 (t), 122.91 (d), 124.95 (d), 125.30 (d), 140.95 (d), 141.81 (d), 148.87 (d), 155.68 (s), 157.62 (s) ppm. IR: ṽ = 3447 s, 1653 m, 1560 s, 1419 m, 1215 w, 770 s cm^{-1}. FAB MS (matrix: 3-NBA): m/z (%) = 382 (100) [**6**-H$^+$ + ^{64}Zn], 384 (61) [**6**-H$^+$ + ^{66}Zn], 386 (38) [**6**-H$^+$ + ^{68}Zn], 442 (34) [**6** + ^{64}Zn + CH_3COO^-], 444 (19) [**6** + ^{66}Zn + CH_3COO^-], 446 (12) [**6** + ^{68}Zn + CH_3COO^-]. HR ESI-TOF-MS: $C_{19}H_{20}N_5Zn$ calcd. 382.1010, found 382.1027; $C_{21}H_{24}N_5O_2Zn$ calcd. 442.1221, found 442.1226.

(2,6-Bis{[(pyrid-2-ylmethyl)amino]methyl}pyridine)zinc Diperchlorate (1c): **6** (150 mg, 0.5 mmol) and $Zn(ClO_4)_2$ (175 mg, 0.5 mmol) were dissolved in methanol (4 mL) The solution was refluxed for 3 h. By addition of the $Zn(ClO_4)_2$ a white solid immediately precipitated. The methanol was evaporated to leave **1c** as a white solid (235 mg, yield 81%). The solid was dissolved in acetonitrile and upon slow evaporation crystals were obtained. ^{1}H NMR (DMSO): δ = 4.10 (br. s, 4 H, CH_2py), 4.57 (br. d, 4 H, CH_2py), 5.77 (br. t, N−H, 2 H), 7.43 (d, J = 7.71 Hz, 2 H, 5-pyH), 7.58 (t, J = 6.26 Hz, 2 H, 3-pyH), 7.66 (d, J = 7.71 Hz, 2 H, 3,5-pyH), 7.97 (t, J = 7.73 Hz, 1 H, 4-pyH), 8.10 (dd, J = 7.71, J = 1.47 Hz, 2 H, 6-pyH) ppm. ^{13}C NMR (CD_3OD): δ =60.84 (t), 62.47 (t), 131.26 (d), 133.70 (d), 133.94 (d), 150.27 (d), 150.55 (d), 157.00 (d), 163.09 (s), 165.96 (s) ppm. IR ($CHCl_3$): ṽ = 3500 s, 1610 s, 1450 s, 1100 s, 770 s, 620 s cm^{-1}. ESI-MS: m/z (%) = 382 (22) [**6**-H$^+$ + ^{64}Zn], 384 (13) [**6**-H$^+$ + ^{66}Zn], 386 (9) [**6**-H$^+$ + ^{68}Zn], 482 (100) [**6** +

$^{64}Zn+ {}^{35}ClO_4$], 484 (95) [**6** + ^{64}Zn + $^{37}ClO_4$, **6** + ^{66}Zn + $^{35}ClO_4$, 486 (63) [**6** + ^{66}Zn + $^{37}ClO_4$, **6** + ^{68}Zn + $^{35}ClO_4$]. HR ESI-TOF-MS: $C_{19}H_{21}N_5O_4ClZn$ calcd. 482.0573, found 482.0586; $C_{19}H_{20}N_5Zn$ calcd. 382.1010, found 382.1035.

(6-{[(Pyrid-2-ylmethyl)amino]methyl}pyrid-2-yl]methanol)zinc Chloride (2a): 9 (150 mg, 0.66 mmol) and $Zn(Cl)_2$ (89 mg, 0.66 mmol) were dissolved in methanol (15 mL) and refluxed for 1 h. The methanol was reduced to 3−4 mL and by addition of diethyl ether **2a** precipitated as a white amorphous solid (98 mg, 41%). Recrystallization from ethanol/dichloromethane gave crystals that were too small to perform X-ray analysis. ^1H NMR (CD_3OD): δ = 3.77 (br. d, 1 H, CH_2py), 4.23 (br. d, 1 H, CH_2py), 4.45−4.66 (br. m, 2 H, CH_2py), 5.05 (br. d, 2 H, $pyCH_2O$), 7.51−7.66 (m, 4 H, 3,5-pyH), 8.09 (dd, *J* = 7.80, *J* = 5.31 Hz, 2 H, 4-pyH), 8.61 (d, *J* = 5.3 Hz, 1 H, 6-pyH) ppm. ^{13}C NMR (CD_3OD): δ = 51.69 (t), 52.85 (t), 61.86 (t), 122.28 (d), 123.86 (d), 124.94 (d), 126.04 (d), 142.34 (d), 142.60 (d), 148.79 (d), 155.81 (s), 157.69 (s), 158.10 (s) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 3414 s, 3223 s, 2908 m, 1604 s, 1575 m, 1465 m, 1452 m, 1444 m, 1285 w, 1063 s, 1012 s, 802 m, 767 s, 644 w cm^{-1}. ESI-MS: *m*/*z* (%) = 292 (100) [**9**-H^+ + ^{64}Zn], 294 (57) [**9**-H^+ + ^{66}Zn], 296 (38) [**9**-H^+ + ^{68}Zn], 328 (24) [**9** + ^{64}Zn + $^{35}Cl^-$], 330 (21) [**9** + ^{64}Zn+ $^{37}Cl^-$, **9** + ^{66}Zn+ $^{35}Cl^-$], 332 (14) [**9** + ^{66}Zn+ $^{37}Cl^-$, **9** + ^{68}Zn+ $^{35}Cl^-$]. HR ESI-TOF-MS: $C_{13}H_{14}N_3OZn$ calcd. 292.0428, found 292.0429; $C_{13}H_{15}ClN_3OZn$ calcd. 328.0195, found 328.0214.

[(6-{[(Pyrid-2-ylmethyl)amino]methyl}pyrid-2-yl)methanol)]zinc Acetate (2b): 9 (150 mg, 0.66 mmol) and $Zn(CH_3COO)_2$ (143 mg, 0.66 mmol) in methanol (15 mL) were refluxed for 1 h. The methanol was reduced to 3−4 mL and the complex precipitated by addition of diethyl ether to give **2b** as a white amorphous solid (168 mg, 62% yield). ^1H NMR (MeOD): δ = 1.93 (s, $COOCH_3$, 6 H), 3.82 (br. d, 1 H, CH_2py), 4.16 (br. d, 1 H, CH_2py), 4.47−4.60 (br. m, 2 H, CH_2py), 5.01 (br. d, 2 H, $pyCH_2O$), 7.43−7.58 (m, 4 H, 3,5-pyH), 7.97−8.06 (m, 2 H, 4-pyH), 8.64 (d, *J* = 4.77, 1 H, 6-pyH) ppm. ^{13}C NMR (MeOD): δ = 22.98 (q), 52.09 (t), 52.78 (t), 62.64 (t), 121.87 (d), 123.20 (d), 124.56 (d), 125.63 (d), 141.78 (d), 142.00 (d), 148.97 (d), 155.68 (s), 157.97 (s), 159.03 (s), 180.89 (s) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 3406 m, 2924 w, 1606 s, 1385 s, 1080 m, 1014 m, 668 w cm^{-1}. ESI-MS: *m*/*z* (%) = 292 (100) [**9**-H^+ + ^{64}Zn], 294 (55) [**9**-H^+ + ^{66}Zn], 296 (33) [**9**-H^+ + ^{68}Zn]. HR ESI-MS-TOF: $C_{13}H_{14}N_3OZn$ calcd. 292.0428, found 292.0438.

[(6-{[(Pyrid-2-ylmethyl)amino]methyl}pyrid-2-yl)methanol]zinc Perchlorate (2c): 9 (400 mg, 1.74 mmol) and $Zn(ClO_4)_2·6H_2O$ (650 mg, 1.74 mmol) in methanol (25 mL) were refluxed for 1 h. The methanol was reduced to 3−4 mL and the complex precipitated by addition of diethyl ether to give **2b** as a white amorphous solid (565 mg, 66% yield). ^1H NMR (CD_3OD): δ = 4.04−4.17 (2 d, 2 H, CH_2py), 4.50−4.70 (2 d, 2 H, CH_2py), 5.00−5.16 (2 d, 2 H, $pyCH_2O$), 7.40−7.53 (m, 4 H, 3,5-pyH), 7.92−8.00 (m, 2 H, 4-pyH), 8.51 (d, 1 H, 6-pyH) ppm. ^{13}C NMR (CD_3OD): δ = 53.99 (t), 54.70 (t), 61.40 (t), 121.78 (d), 123.28 (d), 125.23 (d), 125.85 (d), 141.60 (d), 142.04 (d), 148.04 (d), 154.49 (s), 155.18 (s), 156.70 (s) ppm. IR: $\tilde{\nu}$ = 3331 s, 2739 s, 2330 w, 2023 w, 1615 s, 1486 s, 1109 s, 658 s cm^{-1}. ESI-MS: *m*/*z* (%) = 292 (100) [**9**-H^+ + ^{64}Zn], 294 (58) [**9**-H^+ + ^{66}Zn], 296 (37) [**9**-H^+ + ^{68}Zn]. HR ESI-TOF-MS: $C_{13}H_{14}N_3OZn$ calcd. 292.0428, found 292.0418.

X-ray Crystallography: Intensity data for crystals of **1a**·CH_3OH solvate (0.25 × 0.15 × 0.15mm), **1a**·$2H_2O$ (0.25 × 0.18 × 0.15 mm), and **1c** (0.40 × 0.35 × 0.35 mm), were collected at 153 K with a Stoe Image Plate Diffraction System[23] using Mo-K_α graphite-monochromated radiation. Image plate distance 70 mm, φ oscillation scans 0−180° or 0−200°, step Δφ = 1.2°, 1.5° and 2°, respectively. 2θ range 3.27−52.1°, $d_{max.}-d_{min.}$ = 12.45−0.81 Å. The structures were solved by direct methods using the program SHELXS-97.[24] Refinement and all further calculations were carried out using SHELXL-97.[25] The H atoms were located from difference maps and refined isotropically. In **1a**·CH_3OH, the solvent H atoms were included in calculated positions and treated as riding atoms using SHELXL default parameters. The non-H atoms were refined anisotropically, using weighted full-matrix least squares on F^2. The molecular structure and crystallographic numbering schemes are illustrated in the PLATON[26] figures. Further crystallographic data are summarized in Table 5. CCDC-183956 (**1a**·CH_3OH), -183957 (**1a**·$2H_2O$) and -183958 (**1c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cam-

Reactivity Tests: All reactivity tests were performed using the 12 place Carousel Reaction Station with Reflux Heads from Radleys Discovery Technologies (RR98030) or the Cooled Carousel Reaction Station from Radleys Discovery Technologies (RR99900). All the reactions were performed under nitrogen at room temperature in 5 mL of solvent. For more details refer to the result section. The benzaldehyde was distilled prior to use and 2-hydroxyacetophenone was purified on a silica gel column (hexane/ethyl acetate, 1:1). Procedure A (Entry 7, Table 2): diethylzinc (46 μL, 1.1 M) in toluene was added to ligand **9** (11.5 mg, 0.0.05 mmol) in dry THF (5 mL). After 10 min, benzaldehyde (53 mg, 0.5 mmol), and hydroxyacetophenone (90 mg, 0.66 mmol) were added, and the reaction mixture was stirred under N_2 for 48 h. The solvent was evaporated and the products analyzed by ^{1}H NMR spectroscopy. The coupling product **12** was formed in 62% yield. The ^{1}H NMR spectroscopic yields were determined by the ratio of the areas of the following peaks: benzaldehyde (δ = 10.03 ppm, 1 H), 2-hydroxyacetophenone (δ = 4.90 ppm, 2 H) and the four doublets corresponding to the two diastereomers of **12** (*anti*: δ = 5.41 ppm, 1 H and δ = 5.08 ppm, 1 H; *syn*: δ = 5.24 ppm, 1 H and δ = 4.95 ppm, 1 H).[27] Procedure B: Benzaldehyde (53 mg, 0.5 mmol), 2-hydroxyacetophenone (90 mg, 0.66 mmol), **2b** (20.1 mg, 0.049 mmol) and 35 μL of triethylamine in dry methanol (5 mL) were stirred at room temperature under N_2 for 48 h. The reaction mixture was analyzed as described above to give 59% of product **12**.

Synthesis, Crystal Structures, and Magnetic Properties of Two New 1D Copper(II) Coordination Polymers Containing Fumarate(−2) and Chelating N,N′-Donor as Ligands

Sudipta Dalai,[a] Partha Sarathi Mukherjee,[a] Guillaume Rogez,[b] Talal Mallah,*[b] Michael G. B. Drew,[c] and Nirmalendu Ray Chaudhuri*[a]

Keywords: Coordination polymers / Copper / Magnetic properties / N ligands

Two new polynuclear complexes of Cu^{II}, $[Cu_2(fum)(\mu\text{-}OH)(bpy)_2(H_2O)](NO_3)\cdot 2H_2O$ (**1**) (fum = fumarate dianion, bpy = 2,2′-bipyridine) and $[Cu(fum)(tmen)]\cdot 2H_2O$ (**2**) (tmen = *N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine), have been synthesized and structurally characterized by X-ray crystallography. Complex **1**, $C_{24}H_{27}Cu_2N_5O_{12}$, crystallizes in a triclinic system, space group $P\bar{1}$, with a = 10.168(14), b = 11.347(14), c = 14.74(2) Å, and Z = 2; complex **2**, $C_{10}H_{22}CuN_2O_6$, crystallizes in an orthorhombic system, space group *Pbca*, with a = 14.701(19), b = 14.899(19), c = 26.90(3) Å, and Z = 16. Compound **1** is an alternating chain compound, with alternate repetition of bis(monodentate) (μ_2) and bis(bidentate) (μ_4) bridging modes of fumarate, showing ferromagnetic interaction between Cu^{II} ions through hydroxo bridges with a Cu–O–Cu angle of 108.5°. Compound **2** is a linear 1D zig-zag polymer. There are two copper(II) ions with equivalent coordination and geometry in the asymmetric unit, each of them bonded to a bidentate tmen ligand and to two different fumarate moieties. Magnetic susceptibility data were measured in the 300–2 K temperature range. The magnetic data for **1** were fitted by use of a ferromagnetic/antiferromagnetic alternating S = 1/2 chain system and show the following results: J_F = +5.4 cm^{-1}, J_{AF} = −0.25 cm^{-1}, g = 1.96. The susceptibility data of **2** were fitted by use of the Bonner–Fisher expression for antiferromagnetically coupled S = 1/2 local spins, giving the parameters J = −1.81 cm^{-1}, g = 2.03.

Introduction

The chemistry of metal complexes containing paramagnetic metal ions and exhibiting extended structures is at the forefront of modern research, due to these compounds' potential applications in molecular magnetism.[1−4] The most useful strategy by which to construct such extended systems is to employ appropriate bridging ligands capable of binding metal centers through direct bond formation, promoting magnetic interactions. Di- and polycarboxylates are good candidates as bridging ligands for the construction of such extended systems. Previous reports have revealed that dicarboxylic acids can coordinate to metal centers either in the chelating bis(bidentate) mode or as bridging bis(monodentate) ligands.[5−7] Although the use of various dicarboxylic acids to form bridges between paramagnetic metal centers has been extensively studied with terephthalate, malonate, oxalate, maleate, etc.,[8−12a] systems with fumarate as bridging ligand are much fewer in number,[12b] due to their poor solubilities in all common organic solvents. Our current attention to the use of fumarate dianion as an organic coupler with which to obtain polymetallic complexes[1,4,13,14] is due to its versatile coordination mode (Scheme 1). We have recently reported a few fumarate-bridged Cu^{II} and Ni^{II} systems.[13,14] Here we report the synthesis and structural characterization of two different kinds of copper(II) fumarate systems that make use of N-donor ligands − 2,2′-bipyridine (bpy) and *N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine (tmen) − as blocking ligands. Both were magnetically characterized, interestingly showing different kinds of magnetic behavior. Complex **1** is a chain of $[Cu_2(fum)(\mu\text{-}OH)(bpy)_2(H_2O)](NO_3)\cdot 2H_2O$ (fum = fumarate dianion, bpy = 2,2′-bipyridine) with alternate repetition of bis(monodentate) (μ_2) and bis(bidentate) (μ_4) fumarate bridging modes. It represents the first molecular system with both bis(monodentate) and bis(bidentate) bridging fumarate. Magnetic studies show the existence of ferromagnetic exchange coupling between the Cu^{II} ions through the hydroxo bridge. To the best of our knowledge, this is the first report of a ferromagnetic interaction between Cu^{II} ions through a hydroxo bridge with a Cu−O−Cu angle as large

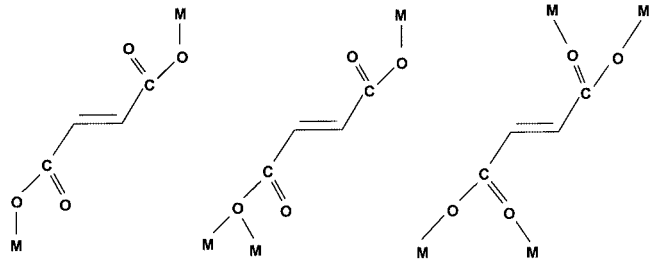
as 108.5°. Complex **2** is a one-dimensional zig-zag polymer of composition $[Cu(fum)(tmen)]\cdot 2H_2O$. Here, fumarate coordinates in bis(monodentate) bridging fashion, and a weak antiferromagnetic interaction (300−2 K) is observed between the two Cu^{II} centers. The attainment of magnetic ordering generally requires the organization of transition metal centers into three-dimensional networks, but reduced dimensionalities (one- and two-dimensional) are preferable for development of the necessary theoretical models required for better interpretation of the magnetic properties of three-dimensional coordination polymers. In this context, one-dimensional systems (such as complexes **1** and **2**) are being thoroughly investigated from both experimental and theoretical viewpoints.



Scheme 1

Results and Discussion

Description of the Structures

$[Cu_2(fum)(\mu\text{-}OH)(bpy)_2(H_2O)]\ (NO_3)\cdot 2H_2O$ (1)

This complex is a one-dimensional polymeric chain made up of dinuclear (bpy)CuOHCu(bpy) units linked together by fumarate anions. The fumarate ligand adopts two bridging coordination modes through the chain, bis(monodentate) and bis(bidentate) (Figure 1). The two Cu^{II} ions in the asymmetric unit are in square-pyramidal environments each with one additional weak bond (shown as dotted line in Figure 1) to complete the octahedron. Thus, Cu(1) is bonded to the bridging hydroxide O(1) at 1.921(5) and to the two nitrogen atoms of the bipyridine ligand at 2.005(5) and 2.030(4) Å. It is also bonded to O(31) [at 2.026(5) Å] and O(41) [at 2.196(5) Å] from bridging fumarate ligands, the latter being the axial position. The second axial site is completed with a weak interaction to O(33) [2.800(2) Å]. The Cu(2) atom is bonded to the bridging hydroxide ion at 1.926(5) Å, to two nitrogen atoms of the bipyridine ligand at 2.010(5) and 2.027(6) Å, to an oxygen atom belonging to the bridging fumarate ligand at 1.940(4) Å, and to a water molecule at 2.420(6) Å in the axial position. The sixth coordination site is completed with a weak bond to a fumarate ligand oxygen atom O(31) at 2.720(2) Å. The Cu···Cu distance in complex **1** is 3.1212 Å. The

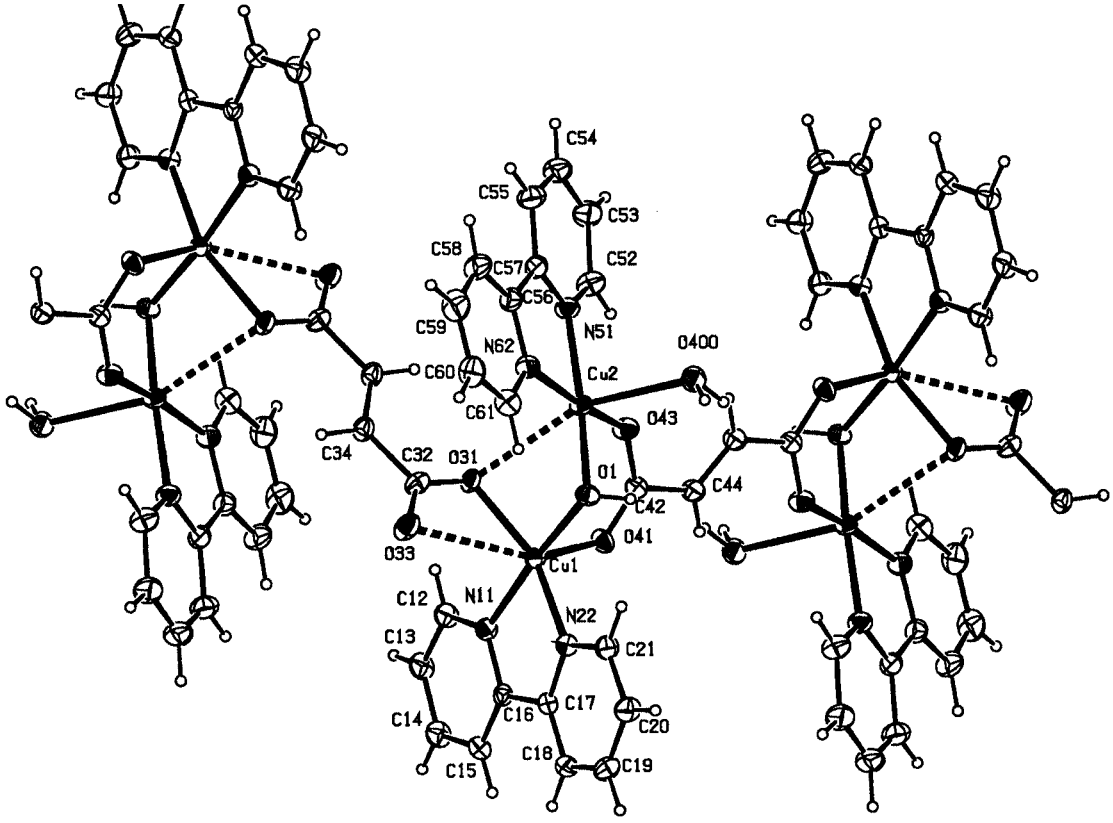


Figure 1. The polymeric structure of **1** at 20% probability; weak bonds in the metal coordination spheres are shown as dotted lines; the nitrate anion and the lattice water molecules in the asymmetric unit are not shown

structure is stabilized by an extensive hydrogen bond network with the water molecules and nitrate anion. The alternate repetition of the bidentate and tetradentate bridging modes of the fumarate makes the compound unique.

[Cu(fum)(tmen)]·2H$_2$O (2)

The structure of **2** is shown in Figure 2, together with its atom numbering scheme. In this complex the copper atoms are each in a four-coordinate square-planar environment, the asymmetric unit possessing two metal atoms. Each has equivalent coordination and geometry and each is part of a self-contained quasi-one-dimensional zig-zag polymer (Figure 3). Each metal ion is bonded to a bidentate tmen ligand and to two different fumarate ligands. The ligands are centrosymmetric. The carboxylate groups can be considered to be monodentate, with distances of 1.985(4)/2.015(4) and 2.001(4)/1.987(4) Å in the two coordination spheres, but the other oxygen atoms are weakly bonded at distances ranging from 2.450(5) to 2.592(5) Å, and could be considered to complete a distorted octahedral coordination sphere. The Cu···Cu distances in complex **2** are Cu−Cu (interchain) 7.3526 Å and Cu−Cu (intrachain) 9.0421 Å.

Magnetic Results

Variable-temperature magnetic susceptibility data for complexes **1** and **2** were collected in the 300−2 K temperature range with a SQUID magnetometer. For complex **1**, the $\chi_M T$ value at room temperature corresponds to what is expected for isolated $S = 1/2$ spins (0.73 cm^{3}mol^{-1}K, $g = 1.96$). On cooling down, $\chi_M T$ increases, reaches a maximum of 0.83 cm^{3}mol^{-1}K at $T = 4$ K, and then rapidly decreases (Figure 4). This behavior can be explained by the existence of a ferromagnetic interaction between the Cu^{II} ions within the hydroxo- and carboxylato-bridged dinuclear unit and a much weaker antiferromagnetic interaction between the dinuclear units through the fumarate bridges. The magnetic data were therefore fitted by use of a ferromagnetic/antiferromagnetic alternating[15−16] $S = 1/2$ chain system and gave the following results: $J_F = +5.4$ cm^{-1}, $J_{AF} = -0.25$ cm^{-1}, $g = 1.96$, and an agreement factor $R = 6{\cdot}10^{-6}$. The ferromagnetic exchange coupling between the Cu^{II} ions is surprising because of the presence of a hydroxo bridge with a Cu−O−Cu angle of 108.5°. The presence of a carboxylato bridge within the dinuclear unit might produce a counter-complementarity between the two bridges, which could explain the ferromagnetic interaction. However, this cannot reasonably be operative since the oxygen atom O(41) of the bridging carboxylate group linked to Cu(1) is in an apical

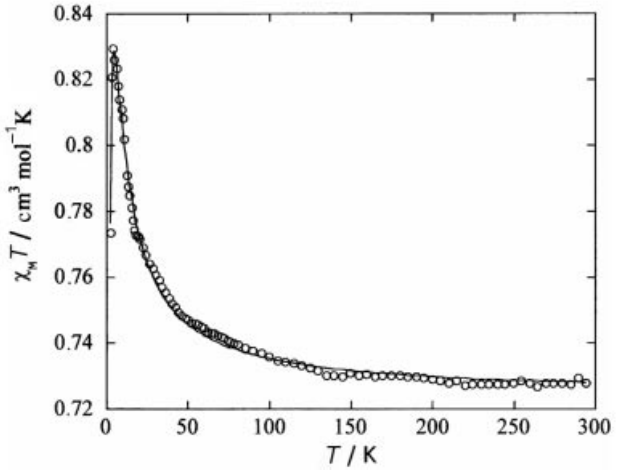

Figure 4. Plot of $\chi_M T$ versus T for complex **1**; the solid line shows the best fit obtained

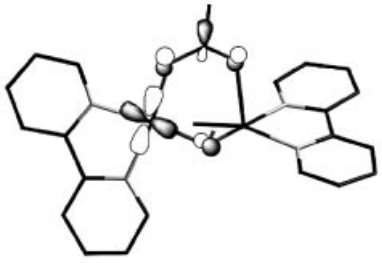
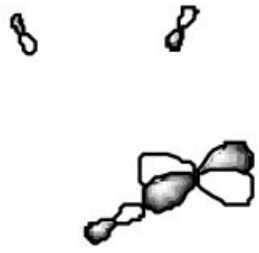
position and the carboxylate bridge does not participate much in the magnetic coupling. In order to understand the experimentally observed ferromagnetic interaction, we carried out semiempirical calculations on the dinuclear unit.[17] The results show that the two single electrons are described by molecular orbitals (Schemes 2 and 3) mainly localized on each copper atom.[18]



Scheme 2



Scheme 3

From a structural viewpoint, complex **2** is a homogeneous chain of Cu^{II} with fumarate bridging. The geometry of each Cu^{II} is distorted octahedral. A plot of $\chi_M T$ against T is given in Figure 5, and shows a gradual decrease in $\chi_M T$ value with decreasing temperature, revealing the existence of antiferromagnetic interaction within the chain. The temperature dependence of the susceptibility data was analyzed by use of the Bonner−Fisher expression for antiferromagnetically coupled $S = 1/2$ spins.[19]

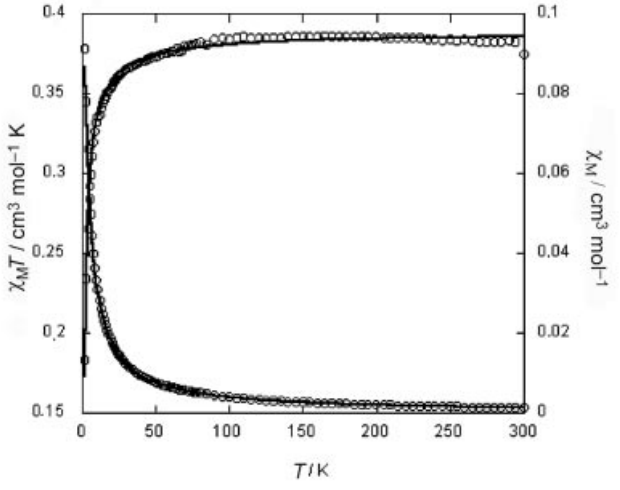


Figure 5. Plot of $\chi_M T$ versus T for complex **2** with solid lines showing the best fit obtained

The Hamiltonian for the isotropic interaction between nearest neighbor ions is

$$H = -J\sum_{i=1}^{n-1} S_i \cdot S_{i+1}$$

and according to Bonner and Fisher[20] the molar susceptibility is given by

$$\chi = \frac{Ng^2\beta^2(0.25 + 0.074975x + 0.075235x^2)}{kT(1 + 0.9931x + 0.172135x^2 + 0.757825x^3)}$$

where $x = |J|/kT$ and J is the exchange coupling parameter describing the magnetic interaction between any two nearest-neighbor $S = 1/2$ spins. The results of the best fit (Figure 5) are $J = -1.81\text{cm}^{-1}$, $g = 2.03$, and $R = 2.9\cdot10^{-5}$ (R is the agreement factor defined as $R = [(\chi_M)_{obsd.} - (\chi_M)_{calcd.}]^2/[(\chi_M)_{obsd.}]^2$). The very low J value is obviously due to a long-range superexchange pathway and this result agrees with previously reported results.[1e,4]

Conclusion

Fumarate(−2) has been employed as a bridging ligand, because of its potential for the construction of coordination polymers with different structures and its possible combination with bidentate bridging (and not chelating) N,N′-donors, as in previous work by our group.[1e,4] We present here the synthesis, single-crystal X-ray structure, and magnetic behavior of two fumarate-bridged Cu^{II} complexes. Complex **1** is a one-dimensional polymeric chain made up of dinuclear (bpy)CuOHCu(bpy) units linked together by fumarate anions. The fumarate ion adopts two coordination bridging modes through the chain, bis(monodentate) and bis(bidentate). The magnetic data were thus fitted by use of a ferromagnetic/antiferromagnetic alternating $S = 1/2$ chain system, with the result $J_F = +5.4\ \text{cm}^{-1}$, $J_{AF} = -0.25\ \text{cm}^{-1}$, $g = 1.96$, and an agreement factor $R = 6\cdot10^{-6}$. The ferromagnetic exchange coupling between the Cu^{II} ions is unusual because of the presence of a hydroxo bridge with a Cu−O−Cu angle of 108.5°. Compound **2** is a 1D zig-zag chain of Cu^{II} in which the fumarate ion binds in a bis(monodentate) fashion and the diamine is a blocking ligand. Fitting of the temperature-dependent susceptibility data (300−2 K) by use of the Bonner−Fisher equation gives $J = -1.81\ \text{cm}^{-1}$.

Experimental Section

Synthesis

$[Cu_2(fum)(\mu\text{-}OH)(bpy)_2(H_2O)](NO_3)\cdot2H_2O$ (1): $Cu(NO_3)_2\cdot3H_2O$ (1 mmol) dissolved in water/methanol (50:50) solution (15 mL) was mixed with 2,2′-bipyridine (1 mmol). A water/methanol (50:50) solution (10 mL) of fumaric acid (1 mmol) and triethylamine (2 mmol) was added, and the mixture was heated under reflux for 1 h at 80 °C. A sky-blue solid separated, and this remained insoluble in all common organic solvents. It was dissolved in a minimum amount of dilute (4 N) ammonia and allowed to crystallize. After

a week, suitable green single crystals of X-ray diffraction quality were obtained. Yield ca. 60%. $C_{24}H_{27}Cu_2N_5O_{12}$ (704.59): calcd. C 40.8, H 3.8, N 9.9; found C 40.9, H 3.6, N 9.8.

[Cu (fum)(tmen)]·2H$_2$O (2): A methanolic solution (10 mL) of $Cu(NO_3)_2·3H_2O$ (1 mmol) and tmen (1 mmol) was added dropwise, with constant stirring, to a water/methanol (50:50) solution (10 mL) of fumaric acid (1 mmol) and triethylamine (2 mmol). Suitable blue single crystals of X-ray diffraction quality were obtained after a week on keeping the resulting blue solution in a refrigerator. Yield ca. 65%. $C_{10}H_{22}CuN_2O_6$ (329.81): calcd. C 36.5, H 6.4, N 8.6; found C 36.3. H 6.6, N 8.4.

Crystallographic Data Collection and Refinement: Intensity data were collected with Mo-K_α radiation by use of the MAR research Image Plate System. The crystals were positioned at 70 mm from the Image Plate. 100 frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program.[21] The structures were solved by direct methods with the SHELX-86 program.[22] In both structures, the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. The structures were refined on F^2 by use of SHELXL-93.[23]. Selected bond lengths and angles are given in Table 1 (complex **1**) and Table 2 (complex **2**). Selected crystallographic data are summarized in Table 3 and hydrogen bonds of complex **1** are shown in Table 4. CCDC-165333 and -185540 for complexes **1** and **2**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Effect of HCl on the Copper(II) Chloride/Pyridine/Water System: Synthesis, Properties and Crystal Structure of $[(pyH)_2CuCl_4]$ and $[(pyH)_2Cu_3Cl_8(H_2O)_2]_n$

Mátyás Czugler,[a] László Kótai,*[a] Bojja Sreedhar,*[b] Antal Rockenbauer,[a] István Gács,[a] and Sándor Holly[a]

Keywords: Copper / IR spectroscopy / EPR spectroscopy / Hydrogen bonds

Bis(pyridinium) tetrachlorocuprate monomer **1** and bis(pyridinium) octachlorodiaquatricuprate polymer **2** were synthesized and their crystal structures were determined. Both complexes contain pyridinium cations with bifurcated H-bridges. These H-bridges stabilize the monomeric structure of the tetrachlorocuprate anion together with the steric demand of the relatively large pyridinium ions in the crystal lattice of **1**. Conversely, at the lower pyridinium ion:copper(II) ratio of **2**, the bifurcated hydrogen bonds reduce the electron density on the chloride ions in such a way that the electron repulsion decreases and coordination spheres with more ligand interactions develop. Obviously, water may be a successful competitor for ligand sites in **2** as well. The octahedral and square-pyramidal structural units condense into polymeric chains which are stabilized by the interchain hydrogen bond networks of the water molecules. The structure motif of SP-5-[*OC-6-SP-5-SP-5*]-OC-6 (–$CuCl_5$-[$CuCl_4(OH_2)_2$-$CuCl_5$-$CuCl_5$]-$CuCl_4(OH_2)_2$-) were observed in **2**, and the two neighboring square-pyramidal units were found to be localized in a *transoid* position. The IR and ESR spectroscopical characterization of complexes was also performed.

Introduction

Due to their structural variety, modes of coordination and application in chemical and material sciences[1–4] a great deal of attention has been paid to the study of copper(II) halide complexes. The plasticity of the coordination sphere of the copper cations and the bridge-forming ability of the halide anions can lead to a variety of crystalline architectures with different coordination numbers, geometries and nuclearities.[2] The copper(II) ion in these complexes exhibits normal coordination as well as semi-coordination. In the latter case, the bond lengths are 0.3–1.0 Å longer. The coordination numbers may vary from four to six (with typically distorted geometries). The building species form chains of edge-sharing monomers with halide bridges between the neighboring copper(II) ions. The coordination spheres of the copper atoms in these chains are frequently supplemented with other ligands.

Pyridinium salts of chlorocuprate anions are of special interest both from a theoretical and a practical point of view. This is attributed to the fact that protonation of the pyridine ring decreases its coordination ability, and hydrogen-bond-forming properties of the N–H hydrogen atom introduces additional structure-building possibilities, hence pyridinium cations are capable of stabilizing MX_4^{2-} layer-type structures.[3]

Although the structure and properties of several chlorocuprate(II) compounds of substituted pyridine bases have been documented,[4] no X-ray crystal structure of unsubstituted pyridinium chlorocuprate(II) compounds has yet been reported. In this paper the synthesis, properties and crystal structures of monomeric bis(pyridinium) tetrachlorocuprate(II) (**1**) and polymeric bis(pyridinium) octachlorodiaquatricuprate(II) dihydrate (**2**) are reported.

Results and Discussion

Synthesis of Pyridinium Chlorocuprates

The protonation of pyridine ligand led to the formation of complexes **1** and **2**. The key to the formation of these two compounds in the $CuCl_2/C_5H_5N/HCl/H_2O$ system in the presence of excess hydrochloric acid lies in the distribution of the pyridinium cations between chlorocuprate anions. One of the chlorocuprate compounds may contain one copper(II) ion, while the other may have three copper(II) ions. Thus, formation of equimolar amounts of **1** and **2** is possible due to the 1:1 pyridine:copper molar ratio in the polymeric $[CuCl_2(py)]_n$ starting material. Decreasing the amount of HCl in the reaction leads to an increase in the

amount of **2** formed and to a decrease in the amount of **1**. The increased yield of **2** can be attributed to an incomplete release of pyridine from the $[CuCl_2(py)]_n$ polymer, since the neutral pyridine ligand may form other compounds with $CuCl_2$.[5,9] This way, the molar ratio of pyridinium ion:copper(II) can be lower than 1:1 and formation of the 2:3 pyridinium complex **2** becomes possible. Consequently, complex **1**, which has a pyH:Cu(II) stoichiometry of 2:1, can form in only a small amount.

In order to check the polymer complex, we reproduced some earlier experiments.[5] The reaction of copper(II) chloride and pyridine hydrochloride in a molar ratio of 3:2 in conc. HCl led to the precipitation of **2**, and only a small amount of **1** was formed. If a stoichiometric amount of HCl was used for the reaction only the $[CuCl_2(py)]_n$ polymer was obtained.[5] Further addition of HCl, however, led to the dissolution of the $[CuCl_2(py)]_n$ polymer and the complexes mentioned above could be obtained.

ESR Spectral Characterization of Pyridinium Chlorocuprate Complexes

The ESR spectra of both compounds were recorded at 77 K and 300 K. No significant effect of the temperature on the signal positions and splittings could be observed.

The tetrachlorocuprate anion in **1** gives a single broad ESR signal at $g = 2.209$. The lack of anisotropy can be explained either by a dynamic Jahn−Teller effect or by strong spin-exchange between centers that are randomly distorted by the static Jahn−Teller interaction. The temperature-independent line-width makes the latter mechanism more likely. The large *g*-factor suggests anionic ligand-to-metal bonds.

Complex **2** has a broad anisotropic ESR signal at $g_{zz} = 2.49$ and $g_{xx} = g_{yy} = 2.126$. The large *g*-factors indicate ionic bonds, the order of *g*-factors reveals a $d_x^2 - {}_y^2$ ground state for the $3d^9$ electron configuration. This ground state is compatible with square-planar or square-pyramidal coordination. Magnetic interactions between neighboring Cu^{II} centers should be strong, since no hyperfine splitting is observed. Presumably the dipolar interactions dominate over the exchange interactions, since the bonds are not covalent.

IR Spectroscopic Investigations of 1 and 2

In order to assign the internal vibrations, it was presumed that the proton acts as a complex-forming ligand and the pyridinium ion is a quasi-metallic complex of the pyridine and the hydrogen ion wherein the central pseudo-metallic hydrogen atom can also interact with other atoms. In the IR spectra of both compounds we could identify the IR-active bands of the pyridine ring as well as the stretching vibrations of the N−H bond. The positions of the assigned vibrations were compared with the vibrations of non-complexed free pyridine base and with the vibrations of pyridine-coordinated $MCl_2(py)_2$ complexes.[10]

The values of the coordination-sensitive stretchings of pyridine were found to be up to 640 and 440 cm^{-1}, respectively; these values are similar to the values of transition metal complexes.[10] Based on the band shifts, the binding force of the proton in these compounds is very similar to the binding force of copper(II) to the pyridine in $[CuCl_2(py)_2]$. This strong coordination ability of the H^+ to the pyridine nitrogen atom may induce the formation of a pyridinium salt instead of an HCl complex of the pyridine-coordinated copper(II) chloride complexes as has been assumed previously.[5] Owing to the similar binding ability of H^+ and Cu^{2+} to the pyridine N-atom, however, the formation of N-coordinated Cu-chloro complexes or pyridinium-chlorocuprate complexes depends strongly on the HCl concentration of the $CuCl_2$/pyridine/HCl/H_2O system.

The coordination of the proton to the pyridine N atom generally causes higher band-shifts of the ring-atoms than in the metal complexes. The IR spectra of **1** and **2** are very similar, the position of the C−H out-of plane and in-plane stretchings and ring-stretchings or breathing bands show almost the same frequencies in both spectra. Characteristic bands of the pyridinium ion ($\tilde{\nu}$ = 1540, 1327, 1295 and 1250 cm^{-1}) can be seen in both spectra, although the degree of degeneracy is lower in **2** due to the more complicated multidendate hydrogen-bonding network structure. Symmetric N−H stretchings are lowered from 3200 cm^{-1} to 2850 cm^{-1} due to the presence of well-defined hydrogen bonds.[11] The OH vibrations in **2** give well-defined bands at $\tilde{\nu}$ = 3300 and 3400 cm^{-1}.

The γ(NH) band at around 900 cm^{-1} is very sensitive to the presence of hydrogen bonds. There is one band in compound **1** at 905 cm^{-1}, and an irregular triplet is present at 875, 900 and 905 cm^{-1} in the spectrum of **2**. This also indicates the presence of characteristic hydrogen bonds. The strength of the hydrogen bonds of **1** and **2** is similar to the strength of the N−H···Br bond in [pyNH]Br.[11]

The bands of the Cu−Cl and Cu−O vibrations fall outside the detection limit of our IR spectrometer (400 cm^{-1}). The broad Cu−N bands between 400 and 440 cm^{-1}could not be observed in the IR spectra of either compound. The narrow band at 405 cm^{-1} is a characteristic pyridine-ring vibration.[10]

X-ray Crystal structures of 1 and 2

The structural chemistry of chlorocuprate(II) salts was studied recently.[1−4] In tetrachlorocuprate(II) compounds the Cu−Cl distances vary between 2.205 Å and 2.265 Å and the *trans*-Cl bond angles vary from 104.5 to 180° (i.e. between the limiting values of tetrahedral and square-planar geometry). In **1** (Figure 1 and Table 1) the Cu−Cl(3) bond is slightly shorter [2.233(1) Å] than the Cu−Cl(2) bond [2.251(1) Å, Table 2]. Both chloride ions take part in the network of the hydrogen bonds (Table 2), and form a bifurcated bridge to the cationic proton of the pyridinium ion. The crystal structure of compound **1** is composed of discrete $CuCl_4^{2-}$ polyhedra and isolated pyridinium cat-

ions. The copper atom sits on a crystallographic twofold axis.

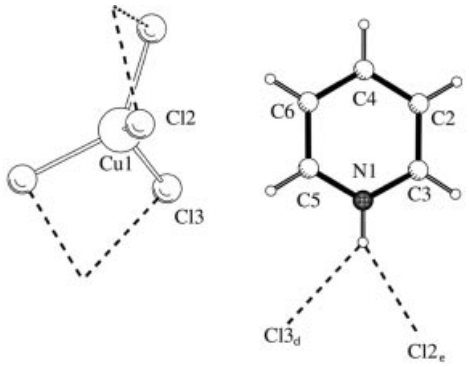

Figure 1. Molecular structure of bis(pyridinium) tetrachlorocuprate(II) (**1**) with atomic numbering and hydrogen-bond contacts indicated in broken lines

The Cl−Cu−Cl bond angles in **1** vary between 97.83(2) and 132.05(2)° showing a geometry intermediate between square planar and tetrahedral coordination. The 0.695 packing coefficient of **1** indicates close packing. The mean plane of the chloride anions lies perpendicular to the *b* crystallographic axis, and the pyridinium ions lie almost perpendicular to the Cu−Cl(2) vector. These data together with the crystal packing (Figure 2) show the basic forces directing crystal growth. Packing appears as separate columns of cations and anions. The cations are oriented so as to minimize electrostatic repulsion between identical charges and simultaneously maximize attraction between opposite ones. The steric demand of the pyridinium cations neighbouring to each tetrachlorocuprate(II) anion, their hydrogen bonds and the shielding as a joint effect isolates the tetrachlorocuprate anions in the monomeric form. Since the nearest non-covalent Cu−Cu and the shortest Cl···Cl distances are both longer than the sum of the respective van der Waals radii, there is no visible interaction between the tetrachlorocuprate(II) anions.

Table 2. Coordination geometry and normalized hydrogen bonding data (Å, °) with their esd's for non-hydrogen atoms in (**1**)

M−X	M−X(Å)	X−M−X	X−M−X(°)[a]

The structure of **2** shows a very distinct pattern (Figure 3). The tetrachlorocuprate anions polymerize with the formation of a condensed Cl-bridged chain-structure by complementing the coordination sphere with water. The building block of the crystal may be described as an endless concatenation of edge-sharing five-coordinate square-pyramidal (MX_4Y type *SP*) and hexacoordinate octahedral (MX_4Y_2 type *OC*) metal centers. The *SP*-[*OC*-*SP*-*SP*]-*OC* sequence is repeated throughout the crystallographic trans-

lation along the *c* axis. The *OC*-*SP* link occurs through the edge sharing of the axial ligands of both the *SP* and the *OC* polyhedra. Consequently, edge-sharing occurs between the connected *SP*-*SP* polyhedra through the equatorial positions. The coordination geometry of the two independent Cu^{II} ions forming the asymmetric unit is different not only in their ligating relationships but also in the water that coordinates solely to the hexacoordinate Cu^{II}. Pentacoordinate Cu(1) binds only to chlorides. This latter polyhedron has approximately equal and ideal equatorial distances ranging from 2.267(1) Å to 2.313(1) Å, while the axial distance is longer [2.675(1) Å], due to a Jahn−Teller effect. The shape of the coordination polyhedron is intermediate but relatively close to a square-pyramid conformation (τ descriptor[12] is 0.20). The value of 85.2% of the Berry pseudorotation from the trigonal bipyramid form to the *SP* one is also in agreement with this conclusion. The pyridinium cation behaves as if it would replace a missing sixth coordination site opposite the true ligand, the axial Cl(4) chloride ion. The SP-coordinated polyhedron is capped from this second axial ligand position (see Figure 3). The other metal [Cu(2)] has an apparently more regular coordination. Symmetry dependence makes the polyhedron more symmetric on the one hand, and distorted from the coordination distances on the other (Table 3). The long axial distance occupied by Cl(3) [2.874(1) Å] is the longest observed here, while the water has a rather short equatorial distance. The other equatorial distance pair [2.279(1) Å] maintained by the Cl(4) is in agreement with the expected value of approx. 2.3 Å. The alternating Cu(1)···Cu(1)···Cu(2)···Cu(1) metal centers are displaced by 3.597(1) Å−3.411(1) Å−3.597(1) Å from each other. The polymeric chains running in the *c* direction at $x = 0$ and $x = 1/2$ are crosslinked by hydrogen bonds (Table 3, Figure 4). Both edge-sharing anions of the hexacoordinate metal are involved in four acceptor interactions, while the pentacoordinated one assumes five acceptor interactions, four of which are common to the hexacoordinated one. One of the three chloride anions [Cl(5)] does not take part in any hydrogen bonds as it is shielded in the central edge-sharing between the two neighboring *SP* polyhedra. Three of these six H-bridges are of the weaker C−H···Cl type. Interestingly, these three bridges also serve as cross-links between the two *ortho*- and the *para*-positioned hydrogen atoms of the pyridinium cations. Analogously to **1** the cationic proton of the pyridinium ion appears in the bifurcated hydrogen bridge.

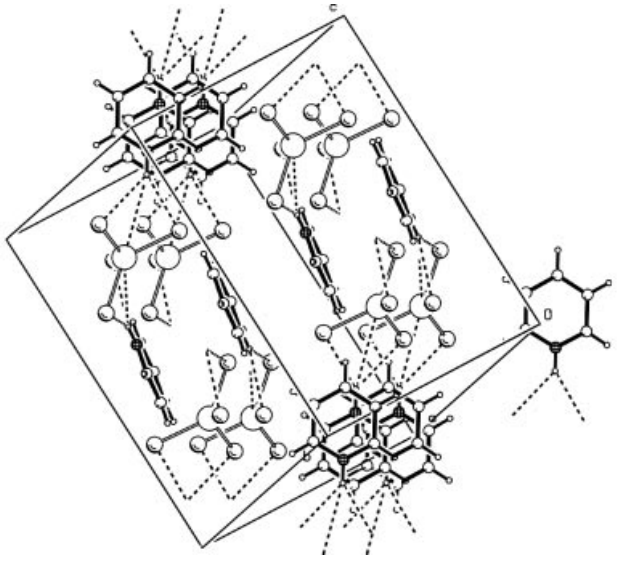

Figure 3. Crystal structure of bis(pyridinium) octachlorodiaquatricuprate(II) (**2**); only the atoms forming the asymmetric unit are numbered; polymeric contacts are shown by broken lines

The dielectric role of both ligand types (pyridinium and water molecules) in insulating the octahedral and square-pyramidal copper coordination centers is such that they effectively and simultaneously shield and compensate for opposite charges. Since the hydrogen bond network removes the charges of the chloride ions, the anion may relax back towards the square-planar geometry favored by crystal-field effects.[10] Other factors may have an influence on the size and nature of the distortions of the octahedral units of the CuX_4Y_2 octahedra, for instance the Jahn−Teller distortion and the difference between the donor strength of the axial water ligands and the equatorial chloro-bridges may be the main reasons for the tetragonal distortion of the OC-6 units in **2**.[13,14] The 0.732 packing coefficient of **2** indicates fairly close packing in the crystal.

Conclusions

Based on the results of the chemical analysis, the IR, the Raman and the ESR spectroscopic studies and the single crystal investigations, the structure of water-soluble compounds formed in the $CuCl_2$/pyridine/HCl/H_2O system has been determined. The two compounds, namely bis(pyridinium) tetrachlorocuprate monomer **1** and bis(pyridinium) octachlorodiaquatricuprate polymer **2** are formed in an obviously pH-dependent manner. The effect of steric and electronic supplements in building the structural units can be

[a] Only non-redundant and symmetry-unconstrained angles are shown. Constrained angles (such as Cl3−Cu2−$Cl3_{ii}$ = 180, Cl4−Cu2−$Cl4_{ii}$ = 180 and O1−Cu2−$O1_{ii}$ = 180) are not given explicitly. [b] $i = -x, 1-y, -z$. [c] $ii = -x, 1-y, 1-z$. [d] $iii = x, 1/2-y, 1/2+z$. [e] $iv = 1-x, 1-y, 1-z$. [f] $v = 1+x, 1/2-y, 1/2+z$. [g] $vi = -x, -1/2+y, 1/2-z$.

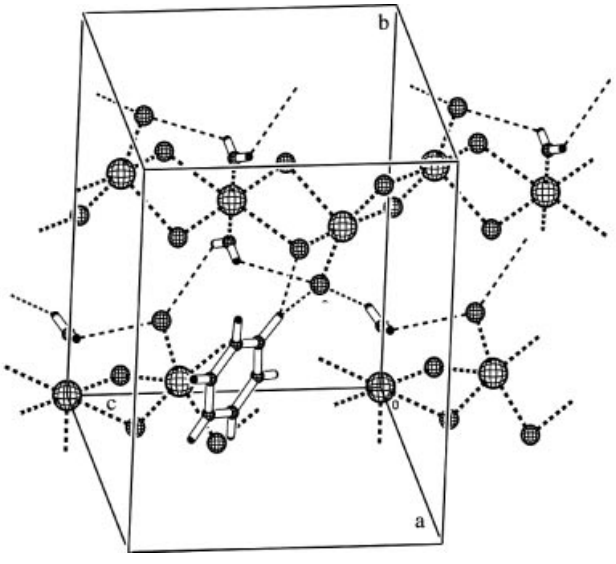

Figure 4. Packing viewed down c^* in bis(pyridinium) octachlorodiaquatricuprate(II) (**2**), with hydrogen bonds indicated by broken lines

rationalized on the basis of their crystal structures. Both complexes contain pyridinium cations in bifurcated H-bridges. As the HCl concentration increases the coordinating ability of the pyridine-nitrogen decreases due to protonation, with a concomitant enhancement of the H-bond formation ability. These H-bridges stabilize the monomeric structure of the tetrachlorocuprate anion together with the steric demand of the relatively large pyridinium ions in the crystal lattice of **1**. Conversely, at the lower pyridinium ion:copper(II) ratio of **2**, the bifurcated hydrogen bonds reduce the electron density on the chloride ions in such a way that the electron repulsion decreases and coordination spheres with more ligand interactions develop. Obviously, water may be a successful competitor for ligand sites in **2** as well. The octahedral and square-pyramidal structural units condense into the polymeric chains, which are stabilized by the interchain hydrogen bond networks of the water molecules. In **2** the two neighboring pyramidal units are localized in the *transoid* positions. To the best of our knowledge the SP-5-[*OC-6-SP-5-SP-5*]-OC-6 -$CuCl_5$-[$CuCl_4(OH_2)_2$-$CuCl_5$-$CuCl_5$]-$CuCl_4(OH_2)_2$- structural motif observed in **2** has not been detected yet.

Experimental Section

General: Analytical grade $CuCl_2 \cdot 2H_2O$, conc. HCl (35% by wt.) and pyridine (99.8%, anhydrous) were purchased from Aldrich. Anhydrous copper(II) chloride (13.5 g, 0.1 mol) obtained by thermal treatment of $CuCl_2 \cdot 2H_2O$ at 150 °C in a dry HCl stream was mixed

with equimolar amount of pyridine (0.1 mol, 8 mL) in dry acetone. The blue solution formed was refluxed for 3 h.[5] The gray precipitate formed was filtered off, then dissolved in 500 mL of conc. hydrochloric acid. From the solution obtained nearly equal amounts of compound **1** (green prisms or brownish microcrystals) and compound **2** (yellow plates) crystallized concurrently.

The carbon, hydrogen and nitrogen contents of compounds **1** and **2** were determined with a Fisons CHN 1018S elemental analyser. The chloride content was determined by argentometric microtitration using a chloride-selective electrode, and the copper content was determined by an ICP spectrometer (Atomscan 25, Thermo Jarrel Ash).

Results of the elemental analysis: **1**: $(C_5H_5NH)_2[CuCl_4]$ (365.57): calcd. C 32.85, H 3.30, N 7.66, Cl 38.79, Cu 17.38; found C 33.49, H 3.35, N 7.68, Cl 41.11, Cu 17.68. **2**: $(C_5H_5NH)_2[Cu_3Cl_8(H_2O)_2]$ (670.47); calcd. C 17.91, H 2.40, N 4.18, Cl 42.30, Cu 28.43; found C 17.98, H 2.41, N 4.18, Cl 42.21, Cu 28.18.

Diffraction-quality single crystals of **1** and **2** were obtained by slow crystallization from the hydrochloric acid solution. For the diffraction measurements the single crystals (**1** and **2**) were placed into glass capillaries. The single-crystal X-ray diffraction data were recorded by means of an Enraf−Nonius CAD4 diffractometer (graphite monochromator; Mo-K_α radiation, $\lambda = 0.71070$ Å) at 295(2) K in the range of $2.95 < \theta < 34.96°$ for **1** and $2.53 < \theta < 34.94°$ for **2** using $\omega/2\theta$ scans. The intensities of three standard reflections were monitored regularly in both cases. In order to establish the final structure models, the initial structures obtained by direct methods were refined by standard procedures (anisotropic full-matrix least-squares refinement on F^2 for all non-hydrogen atoms, riding H atoms except the N−H ones which were found in difference electron-density maps).[6] Figures and geometry analyses were done by means of PLATON.[7]

Cell parameters were determined by least-squares of the setting angles of 25 standard reflections (**1**: $8.67 \leq \theta \leq 17.3°$; **2**: $15.34 \leq \theta \leq 16.70°$). In the case of **1**, the intensities of the standard reflections remained constant within experimental error throughout the data collection. A total of 6900 reflections were collected of which 3254 were unique [R(int) = 0.0226, $R(\sigma) = 0.0415$]; the intensities of 1725 reflections were greater than $2\sigma(I)$. Completeness to $2\theta = 100\%$. No absorption correction was applied. Final model yielded $R_1 = 0.0385$ and $wR^2 = 0.0915$ for 1725 [$I > 2\sigma(I)$] and $R_1 = 0.0869$ and $wR^2 = 0.1018$ for all 3254 intensity data (goodness-of-fit = 0.925; the maximum and mean shift/esd 0.008 and 0.001). The maximum and minimum residual electron density in the final difference map was 0.706 and −0.474 e·Å^{-3}.

In the case of **2** the intensities of the standard reflections indicated a crystal decay of 4% (the data were corrected for decay). A total of 5143 reflections were collected of which 4769 were unique [R(int) = 0.0249, $R(\sigma) = 0.0370$]; the intensities of 3033 reflections were greater than $2\sigma(I)$. Completeness to $2\theta = 99.7\%$. An empirical (psi scan)[8] absorption correction was applied to the data (the minimum and maximum transmission factors were 0.6767 and 1.000). Final model gave $R_1 = 0.056$ and $wR^2 = 0.134$ for 3033 [$I > 2\sigma(I)$] and $R_1 = 0.088$ and $wR2 = 0.144$ for all 4769 intensity data [goodness-of-fit = 0.942; the maximum and mean shift/esd 0.009 and 0.002; extinction coefficient 0.027(2)]. The maximum and minimum residual electron density in the final difference map was 1.851 and −1.954 e·Å^{-3}. The crystallographic data and refinement results for **1** and **2** are collected in Table 1.

CCDC-192665 (**1**) and -192666 (**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Infrared spectra were recorded by the diffuse reflectance method in KBr. Measurements were carried out between 4000−400 cm^{-1} by means of a Nicolet 170SX FT-IR spectrometer with a resolution of 1 cm^{-1}. ESR spectra were recorded by a JEOL JES-FE/3X ESR spectrometer (upgraded for data acquisition with an IBM PC Pentium I), in the X microwave band with 100 kHz field modulation. Manganese(II)-doped magnesium oxide powder was used as a standard for calibration of the g-values.

Steric Control of Cyclometallation Reactions in Schiff-Base Complexes of Cobalt(I) Containing an Anchoring Diphenylphosphanyl Group

Hans-Friedrich Klein,*[a] Robert Beck,[a] Ulrich Flörke,[b] and Hans-Jürgen Haupt[b]

Keywords: Cyclometallation / Cobalt / P ligands / Schiff bases / Regioselectivity

2-(Diphenylphosphanyl)alkyliminobenzaldehydes (2-$Ph_2PC_6H_4CHNR$) react with $[CoCH_3(PMe_3)_4]$ forming five-membered metallacycles in complexes [(2-$Ph_2PC_6H_4CNR$-*C,P*)$Co(PMe_3)_3$] [**1**: R = C_2H_5, **2**: R = $CH(CH_3)_2$, **3**: R = *cyclo*-C_6H_{11}] while the *ortho*-metallation pathway is selectively followed in the formation of [{2-$Ph_2PC_6H_3(CHNR)$-C^1,*P*}$Co(PMe_3)_3$] [**4**: R = $C(CH_3)_3$]. The presence of a four-membered cobaltocycle in the molecular structure of **4** was confirmed by X-ray analysis. Carbonylation of **2** and **3** gives the monocarbonyl derivatives [(2-$Ph_2PC_6H_4CNR$-*C,P*)Co(CO)$(PMe_3)_2$] [**5**: R = $CH(CH_3)_2$, **6**: R = *cyclo*-C_6H_{11}] while **4** undergoes ring expansion by insertion forming [{2-$Ph_2PC_6H_3(CHNR)CO$-*C,P*}$Co(CO)(PMe_3)_2$] [**7**: R = $C(CH_3)_3$]. Monosubstitution occurs under 1 bar of ethene giving the π-ethene complexes [(2-$Ph_2PC_6H_4CNR$-*C,P*)$Co(C_2H_4)(PMe_3)_2$] [**8**: R = $CH(CH_3)_2$, **9**: R = *cyclo*-C_6H_{11}] and [{2-$Ph_2PC_6H_3(CHNR)$-C^1,*P*}$Co(C_2H_4)(PMe_3)_2$] [**10**: R = $C(CH_3)_3$]. The molecular structure of **9** shows an equatorial π-ethene ligand. Iodomethane oxidizes **2** and **3** to afford the cobalt(II) complexes [(2-$Ph_2PC_6H_4CNR$-*C,P*)$CoI(PMe_3)_2$] [**11**: R = $CH(CH_3)_2$, **12**: R = *cyclo*-C_6H_{11}] and oxidatively adds to **4** to give *mer-trans*-[{2-$Ph_2PC_6H_3(CHNR)$-C^1,*P*}$CoI(CH_3)(PMe_3)_2$] [**13**: R = $C(CH_3)_3$].

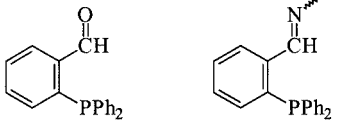
Introduction

Methylnickel complexes have been shown to activate the CHO function of 2-diphenylphosphanylbenzaldehyde forming acylnickel compounds.[1]



A **B**

We have recently described cobalt(I) complexes containing soft/hard P,N-chelating ligands,[2] where the introduction of an imino ligand function increases the softness of the N-donor. The isoelectronic relationship between 2-diphenylphosphanyl benzaldehyde **A** and its Schiff base derivatives **B** raises the possibility of a cyclometallation route to iminoacyl metal complexes. The coordination modes of iminoacyl complexes, which depend on the number of metal valence electrons and steric limitations, show an active participation of the neighbouring N-donor whenever needed.

Therefore, in Schiff-base complexes of transition metal ions six-membered rings are the dominant structural features, and complexes of the chelating ligands **B** are no exception, as shown by the few reported examples of complexes of these ligands with cobalt,[3] molybdenum,[4] rhodium,[5] and iridium.[6] Preferred coordination of the N-donor would appear to prevent an attack of the metal at the C−H bond which would explain the scarcity of iminoacyl metal complexes arising from C−H activation.[7] However, in cyclometallation reactions with $[CoMe(PMe_3)_4]$ there is evidence for steric control being dominant.[8] Consequently we have studied the effect of a bulky N-substituent in our investigation of the prechelate species **B**.

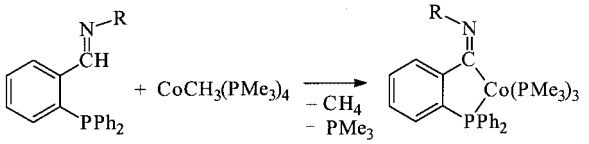
Results and Discussion

Metallation Reactions

An iminoacyl side-chain containing an N-donor function and an activated C−H bond was attached to one of the six *ortho*-positions of triphenylphosphane to give the Schiff-base compounds 2-(diphenylphosphanyl)alkyliminobenzaldehyde. Reaction with [$CoMe(PMe_3)_4$] proceeded at −70 °C in THF [Equation (1)] and afforded the C-metallated complexes **1**−**3**.



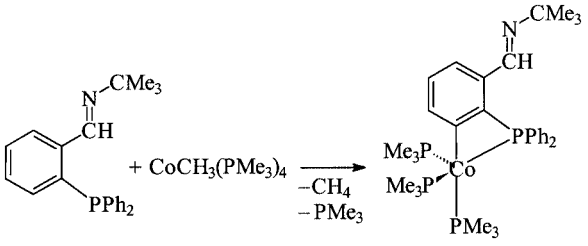
(1)

	1	2	3
R	C_2H_5	$CH(CH_3)_2$	*cyclo*-C_6H_{11}

Black quadrangular crystals of **1** and **2** were obtained from pentane solution while **3** formed dark brown scales. Decomposition was noticed above 109−113 °C under argon. The ν(C=N) absorptions in the IR spectra are shifted bathochromically (by about 100 cm^{-1}) with respect to those of the free ligands upon metallation. The ^{31}P NMR spectra of **1**−**3** show little variation in the dominant signals. A large low-field shift of the PPh_2 resonances is compatible only with five-membered cobaltocycles, and two doublets of doublets for one axial and two equatorial P-donor atoms with almost identical $J_{P,P}$ values indicate a tbp-coordinated cobalt in **1**−**3**. Only in the spectrum of **1** (Figure 1) are all the resonances accompanied by those of an isomer (12%) with quite different coupling constants.

Angular distortions of the tbp geometry can be expected in a configuration [(*E*)-alkyliminoacyl] where the ethyl substituent is sterically accommodated within the ligand sphere. Therefore the larger substituents in **2** and **3** are exclusively arranged in the opposite *Z*-configuration.

At first glance 2-diphenylphosphanyl-*tert*-butylbenzimide appeared to react similarly as evolution of a gas was observed at −70 °C. The reaction mixture became a slightly deeper red colour than **1**−**3**, and eventually dark red rhombic crystals of **4** were obtained from pentane. However, upon metallation there is almost no shift in the infrared absorption of the C=N band (1626 cm^{-1}), and in the ^1H NMR spectrum a singlet resonance (δ = 7.95 ppm) clearly represents an aldimine proton. The ^{31}P NMR spectrum shows a pattern of resonances well-known from *ortho*-metallated complexes,[8] strongly suggesting a regioselective cyclometallation reaction [Equation (2)].

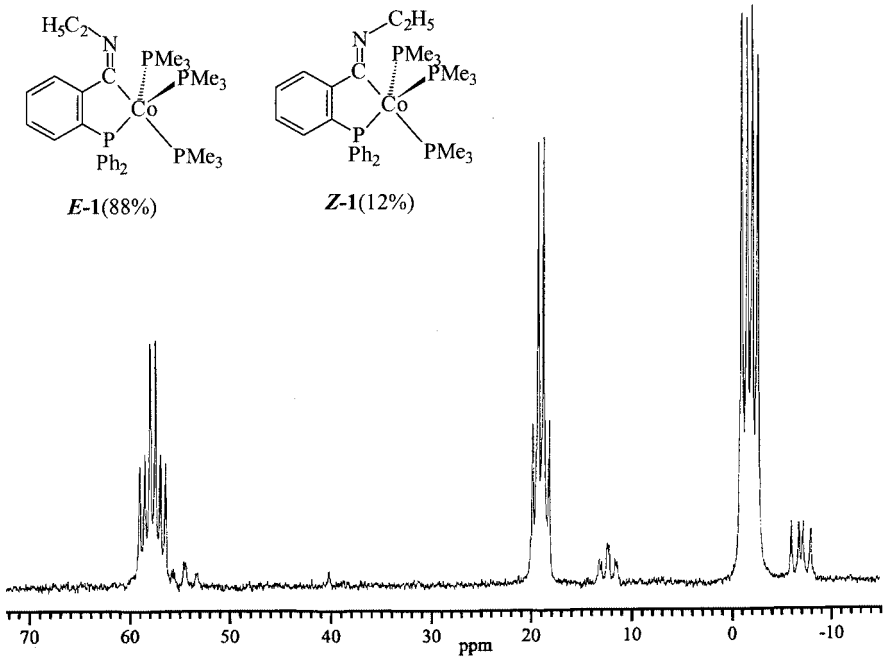


(2)

4

The presence of a four-membered cobaltocycle in **4** was confirmed by elucidation of the molecular structure (Figure 2).

The cobalt atom occupies the central position of a trigonal bipyramid with an axial C1 atom and a PMe_3 group



E-**1**(88%) *Z*-**1**(12%)

Figure 1. ^{31}P NMR spectrum of **1** (81 MHz, [D_8]THF, 203 K)

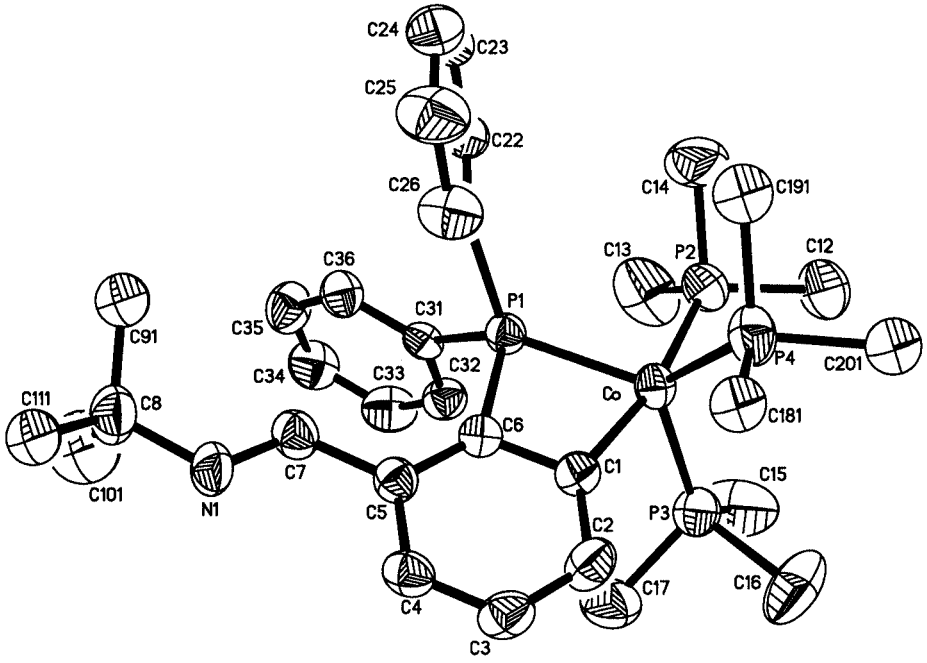


Figure 2. Molecular structure of **4**, only one position of disordered *t*Bu and PMe_3 groups shown (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C1 1.977(4), Co−P1 2.2075(12), Co−P2 2.1997(15), Co−P3 2.1836(14), Co−P4 2.1821(15), P1−C6 1.802(4), C1−C6 1.403(5); C1−Co−P1 71.09(12), C1−Co−P2 167.82(12), C1−Co−P3 87.92(12), C1−Co−P4 90.78(12), P1−Co−P2 97.11(5), P1−Co−P3 124.02(5), P1−Co−P4 113.76(5), P2−Co−P3 96.66(6), P2−Co−P4 96.96(6), P3−Co−P4 117.93(6)

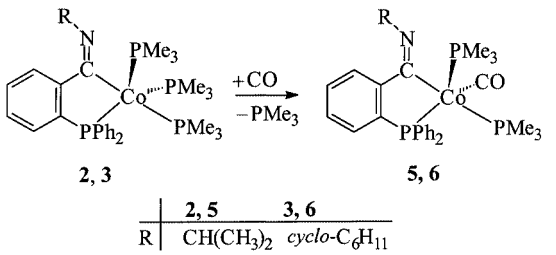
(P2). A planar [C,P] metallacycle (sum of internal angles = 360°) spans the axial and equatorial positions with a narrow bite-angle [C1−Co−P1 = 71.09(12)°]. Except for one of the equatorial PMe_3 groups (P4), which shows rotational disorder, the Co−C, Co−P, and P−C bond lengths are close to the average of reported values in arylcobalt compounds. The bond lengths and angles resemble those found in the unsubstituted parent compound.[8]

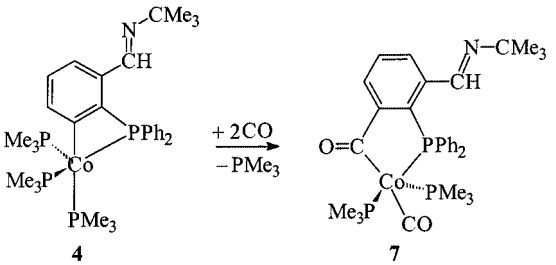
The bulky CMe_3 substituent appears to prevent a close approach of the CH=N group to the cobalt and causes complete switching of the metallation reaction onto the selective *ortho*-pathway where the four *ortho* positions of the PPh_2 group are not involved.[2]

Reactions with Carbon Monoxide

An experimental distinction between four- and five-membered cobaltocycles was achieved by placing solutions of **2**−**4** under a pressure of 1 bar CO at 20 °C. While the iminoacyl complexes **2** and **3** undergo monosubstitution [Equation (3)], compound **4** takes up two equivalents of CO and undergoes a ring expansion [Equation (4)].



(3)



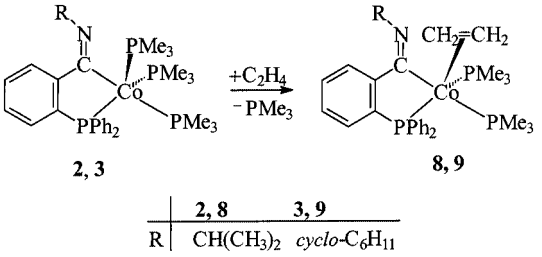
(4)

The iminoacyl(carbonyl)cobalt complexes **5** and **6** are yellow solids that can be handled in air for several hours and under argon are thermally stable up to 165 °C. They are insoluble in pentane or diethyl ether and show moderate solubility in THF. Their IR spectra display characteristic bands around 1876 cm^{-1} for terminal carbonyl ligands and around 1539 cm^{-1} for exocyclic C=N groups; these are hypsochromically shifted by about 18 cm^{-1} with respect to **2** and **3**. The ^{31}P NMR spectra show three resonances as doublets of doublets which are compatible with trimethylphosphane in axial and equatorial positions and an equatorial CO ligand.

The acyl(carbonyl)cobalt complex **7** is soluble in pentane or diethyl ether. In the IR spectrum the acyl and carbonyl groups are represented by new bands that fall precisely in the positions expected for a tbp molecular configuration with axial acyl and CO ligands.[2] The NMR spectroscopic data confirm this configuration in solution, and isomers with equatorial CO ligands are not detected.

Reactions with Ethene

Red-brown solutions of **2** or **3** under 1 bar C_2H_4 turned orange red within 5 min indicating that a reaction had taken place [Equation (5)].



2, 3 **8, 9** (5)

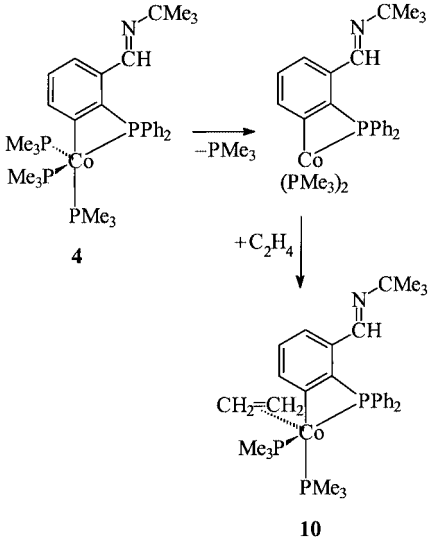
R	2, 8	3, 9
	$CH(CH_3)_2$	*cyclo*-C_6H_{11}

Short orange rods of **8** or orange rhombs of **9** were obtained from pentane that release ethene while decomposing above 93 °C under argon. The ^{31}P NMR spectra consist of three doublets of doublets with $J_{P,P}$ coupling constants of between 24 and 36 Hz, indicating P-nuclei of trimethylphosphanes in axial and equatorial positions leaving an equatorial position free for coordination of the ethene ligand.

In the crystal **9** has a molecular structure showing the expected configuration (Figure 3).

A cobalt atom in the centre of a trigonal bipyramid is coordinated to an equatorial ethene and two trimethylphosphanes in axial and equatorial positions. A five-membered metallacycle spans the C-axial and P-equatorial positions with a C7−Co−P1 bite angle of 79.11(9)° and considerable bending (sum of internal angles = 520.7° as compared with 540° for a planar arrangement). The side-on coordinated ethene shows the expected increase of 5 pm in the C8−C9 bond relative to free ethene. The Co−C1 and Co−P bond lengths fall in the typical range reported for arylcobalt complexes.

When compared with the isoelectronic (2-diphenylphosphanyl)benzoyl complex derived from the prechelate system **A**, in which cobalt fails to coordinate ethene, the iminoacyl group places enough electron density on the metal centre to support olefin binding. As was observed earlier a four-membered cobaltocycle induces weaker olefin coordination.[2] Compound **4** forms a π-ethene compound **10** [Equation (6)] only after thermal pretreatment.



4 **10** (6)

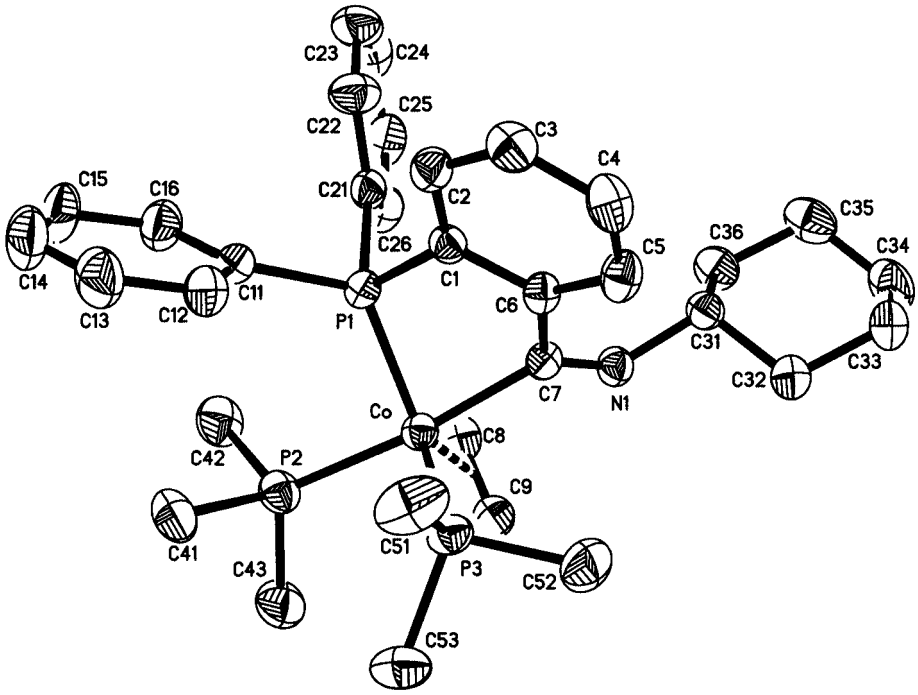


Figure 3. Molecular structure of **9** (ORTEP plot with hydrogen atoms omitted); selected bond lengths [Å] and angles [°]: Co−C7 2.014(3), Co−C8 2.055(3), Co−C9 2.046(3), Co−P1 2.1748(10), Co−P2 2.2232(12), Co−P3 2.1985(11), P1−C1 1.803(3), C1−C6 1.401(4), C6−C7 1.507(4), C8−C9 1.397(5); C7−Co−P1 79.11(9), C7−Co−P2 173.14(9), C7−Co−P3 87.17(9), P1−Co−P2 95.40(4), P1−Co−P3 113.32(4), P2−Co−P3 98.84(4), Co−C7−C6 114.3(2), C1−C6−C7 114.3(3), C6−C1−P1 110.4(2)

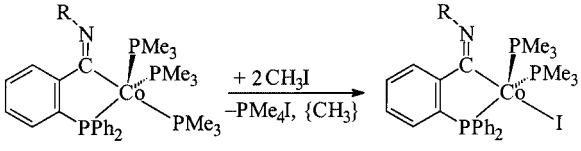
The orange crystals of **10** are readily soluble in diethyl ether or pentane. Before melting under argon at 105−107 °C with decomposition they turn red brown. This behaviour indicates a tetracoordinate intermediate which, however, could not be isolated as an analytically pure compound. The spectroscopic data of **10** are in agreement with an overall replacement reaction of one equatorial trimethylphosphane ligand by ethene.

Reactions with Iodomethane

Complexes **2** and **3** react with two molar equivalents of iodomethane in tetrahydrofuran [Equation (7)] to form the iodocobalt(II) complexes **11** and **12** with formal loss of a methyl group.



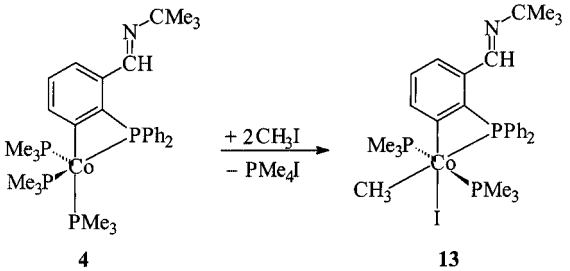
2, 3 **11, 12** (7)

	2, 11	3, 12
R	$CH(CH_3)_2$	*cyclo*-C_6H_{11}

Dark brown crystals with a magnetic moment of 1.98 were obtained. A diamagnetic cobalt(III) intermediate as described earlier[2] could not be isolated from reactions in less polar diethyl ether or pentane solvents.

This particular reactivity has been observed with type **A** systems where structural proof of a tbp molecular structure was obtained with acyl and iodo groups in axial positions.[1] On the basis of their mutual *trans*-influences a *trans*-arrangement of the iminoacyl and iodo ligands would suggest itself also for **11** and **12**.

Under otherwise similar conditions **4** oxidatively adds iodomethane with substitution and quaternization of a trimethylphosphane ligand [Equation (8)].The dark red crystals of **13** melt at 117−119 °C with decomposition and with no indication of the formation of a paramagnetic iodocobalt(II) complex as an intermediate. Solutions in THF slowly decompose at 273 K, but at 203 K the ^{31}P NMR spectroscopic data confirm a *mer-trans* arrangement of the six ligand functions.



4 **13** (8)

The steric influence of the alkylimino group in **13** does not affect the coordination sphere of cobalt, therefore the stereoselective oxidative *cis*-addition proceeds with retention of the metallacycle, as with other ring substituents.[1] As the iminoacyl group remains uncoordinated, it retains an *E*-configuration.

Experimental Section

General Procedures and Materials: All air-sensitive and volatile materials were handled using standard vacuum techniques and were kept under argon. Microanalyses: Kolbe Microanalytical Laboratory, Mülheim/Ruhr, Germany. Melting points/decomposition temperatures: Sealed capillaries, uncorrected values. Chemicals (Merck/Schuchardt) were used as purchased. Literature methods were followed in the preparation of 2-(diphenylphosphanyl)-benzaldehyde,[9,10] 2-(diphenylphosphanyl)-*N*-alkyliminobenzaldehyde,[5,11] and $[CoMe(PMe_3)_4]$.[12] IR: Nujol mulls between KBr discs, Bruker spectrophotometer type FRA 106. ^1H and ^{13}C NMR spectra (300 MHz and 75 MHz, respectively) were recorded with a Bruker ARX-300 spectrometer, ^{31}P NMR spectra (81 MHz) with a Bruker AM-200 instrument. ^{13}C and ^{31}P resonances were obtained with broad-band proton decoupling. Magnetic susceptibility data were obtained by the Faraday method using a Cahn D 200 torsion balance (Bruker) at 1.5 Tesla.

[(*E,Z*)-2-(Diphenylphosphanyl)-*N*-ethylbenzimino-*C,P*]tris-(trimethylphosphane)cobalt(I) (1): 2-(Diphenylphosphanyl)-*N*-ethylbenzimide (377 mg, 1.18 mmol) in 30 mL of THF was combined at −70 °C with $[CoMe(PMe_3)_4]$ (450 mg, 1.18 mmol) in 80 mL of THF. During warm-up evolution of gas was noticed and the mixture became red brown. The mixture was kept at 20 °C for 18 h. The volatiles were then removed in vacuo, and the solid residue was extracted with two 70 mL portions of pentane. The solution was cooled to −27 °C to afford dark crystals of **1**. Yield 322 mg (45%); m.p. 109−111 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1542 cm^{-1} (C=N). ^1H NMR (300 MHz, $[D_8]$THF, 296 K): δ = 0.89 (br. s, 9 H, PCH_3), 1.18 (br. s, 18 H, PCH_3), 1.29 (t, ^3J = 6.9 Hz, 3 H, CH_3), 3.65 (q, ^3J = 6.9 Hz, 2 H, CH_2), 6.90 (t, ^3J = 7.2 Hz, 1 H, CH), 7.01 (t, ^3J = 7.3 Hz, 1 H, CH), 7.18−7.29 (m, 8 H, CH), 7.47−7.53 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, $[D_8]$THF, 296 K): δ = 17.9 (s, CH_3), 23.0 (m, PCH_3), 24.8 (m, PCH_3), 50.5 (s, CH_2), 123.4 (d, $^2J_{P,C}$ = 17.8 Hz, CH), 125.8, 126.2 (s, CH), 128.1 (d, $^2J_{P,C}$ = 7.2 Hz, CH), (s, CH), 131.1 (s, CH), 133.8 (d, $^2J_{P,C}$ = 12.2 Hz, CH), 142.2 (s, C) ppm. ^{31}P NMR (81 MHz, $[D_8]$THF, 203 K): *E*-**1** (88%) δ = −1 (dd, $^2J_{P,P}$ = 84 and 44 Hz, 2 P, PCH_3), 18 (dd, $^2J_{P,P}$ = 45 and 44 Hz, 1 P, PCH_3), 57 (dt, $^2J_{P,P}$ = 84 and 45 Hz, 1 P, PPh_2); *Z*-**1** (12%) δ = −6 (dd, $^2J_{P,P}$ = 95 and 63 Hz, 2 P, PCH_3), 12 (dt, $^2J_{P,P}$ = 63 and 15 Hz, 1 P, PCH_3), 56 (dt, $^2J_{P,P}$ = 95 and 15 Hz, 1 P, PPh_2) ppm. $C_{30}H_{46}CoNP_4$ (603.2): calcd. [(*E*)-2-(Diphenylphosphanyl)-*N*-*tert*-butylbenzimide-*C^1,P*]tris-(trimethylphosphane)cobalt(I) (4): 2-(Diphenylphosphanyl)-*tert*-butylbenzimide (530 mg, 1.50 mmol) in 50 mL of THF was combined at −70 °C with [CoMe(PMe$_3$)$_4$] (570 mg, 1.50 mmol) in 50 mL of THF and a gas evolved. After 16 h at 20 °C all volatiles were removed from the mixture in vacuo, and the solid residue was extracted with 80 mL of pentane. From the solution 250 mg of dark red rhombic crystals were obtained which proved suitable for X-ray diffraction. Upon cooling to −27 °C a second fraction of **4** was collected and combined with the first. Yield 790 mg (83%); m.p. 114−116 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1625 cm^{-1} (C=N). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.91 (s, 9 H, CH_3), 1.11 (d, $^2J_{P,H}$ = 6.4 Hz, 9 H, PCH_3), 1.28 (t′, $|^2J_{P,H} + {}^4J_{P,H}|$ = 4.7 Hz, 18 H, PCH_3), 6.70 (t, ^3J = 7.4 Hz, 1 H, CH), 6.90 (m, 1 H, CH), 7.13 (d, ^3J = 7.0 Hz, 1 H, CH), 7.25−7.30 (m, 6 H, CH), 7.74−7.82 (m, 4 H, CH), 7.95 (s, 1 H, NCH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 21.7−22.9 (m, PCH_3), 27.3 (s, CH_3), 55.6 (s, CMe_3), 115.4 (s, CH), 126.5 (d, $^3J_{P,C}$ = 7.8 Hz, CH), 126.8, 127.5 (s, CH), 131.7 (d, $^2J_{P,C}$ = 12.9 Hz, CH), 138.0, 138.6 (s, C), 152.2 (d, $^2J_{P,C}$ = 6.9 Hz, NCH) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = −28 (dt, $^2J_{P,P}$ = 90 and 71 Hz, 1 P, PPh_2), −3 (dd, $^2J_{P,P}$ = 90 and 48 Hz, 2 P, PCH_3), 21 (dt, $^2J_{P,P}$ = 71 and 48 Hz, 1 P, PCH_3) ppm. $C_{32}H_{50}CoNP_4$ (631.2): calcd. C 60.86, H 7.98, N 2.22, P 19.62; found C 60.55, H 7.98, N 2.21, P 19.98.

[(*E*)-2-(Diphenylphosphanyl)-*N*-isopropylbenzimino-*C,P*]carbonylbis-(trimethylphosphane)cobalt(I) (5): A sample of **2** (430 mg, 0.69 mmol) in 70 mL of diethyl ether was kept stirring under 1 bar of CO for 30 min to form a light yellow precipitate. The volatiles were then removed in vacuo, and the solid residue of **5** was washed with 20 mL of cold diethyl ether and dried in vacuo. Yield 368 mg (93%); m.p. 185−187 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1874 cm^{-1} (C≡O), 1538 cm^{-1} (C=N). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 1.05 (br. s, 18 H, PCH_3), 1.30 (m, 6 H, CH_3), 4.30 (m, 1 H, NCH), 7.09 (m, 2 H, CH), 7.29−7.31 (m, 8 H, CH), 7.43−7.58 (m, 2 H, CH), 8.22−8.28 (m, 2 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 19.9 (m, PCH_3), 23.1 (s, CH_3), 8.5 (s, NCH), 127.5 (d, $^2J_{P,C}$ = 16.5 Hz, CH), 128.2 (d, $^2J_{P,C}$ = 15.9 Hz, CH), 129.1 (d, $^2J_{P,C}$ = 7.0 Hz, CH), 143.1 (m, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 203 K): δ = −4 (dd, $^2J_{P,P}$ = 63 and 53 Hz, 1 P, PCH_3), 21 (dd, $^2J_{P,P}$ = 53 and 36 Hz, 1 P, PCH_3), 68 (dd, $^2J_{P,P}$ = 63 and 36 Hz, 1 P, PPh_2) ppm. $C_{29}H_{39}CoNOP_3$ (569.2): calcd. C 61.16, H 6.90, N 2.46, P 16.32; found C 60.97, H 6.87, N 2.45, P 16.20.

[(*E*)-2-(Diphenylphosphanyl)-*N*-cyclohexylbenzimino-*C,P*]-carbonylbis(trimethylphosphane)cobalt(I) (6): Carbonylation of **3** (510 mg, 0.77 mmol) in 50 mL of diethyl ether was carried out as in the preparation of **5** to afford **6** as a yellow solid. Yield 449 mg (95%); m.p. 165−167 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1880 cm^{-1} (C≡O), 1540 cm^{-1} (C=N). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 1.04 (br. s, 18 H, PCH_3), 1.26−1.86 (m, 10 H, CH_2), 3.99 (m, 1 H, NCH), 7.04 (m, 2 H, CH), 7.29−7.31 (m, 8 H, CH), 7.41−7.43 (m, 2 H, CH), 8.00−8.03 (m, 2 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 21.9 (m, PCH_3), 24.7, 25.2, 26.8, 34.5 (s, CH_2), 68.8 (s, NCH), 125.5 (d, $^2J_{P,C}$ = 16.5 Hz, CH), 128.2 (d, $^3J_{P,C}$ = 3.9 Hz, CH), 128.7 (s, CH), 129.1 (d, $^2J_{P,C}$ = 7.1 Hz, CH), 133.8 (m, C) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 203 K): δ = −4 (dd, $^2J_{P,P}$ = 61 and 54 Hz, 1 P, PCH_3), 21 (dd, $^2J_{P,P}$ = 54 and 39 Hz, 1 P, PCH_3), 69 (dd, $^2J_{P,P}$ = 61 and 39 Hz, 1 P, PPh_2) ppm. $C_{32}H_{43}CoNOP_3$ (609.2): calcd. C 63.05, H 7.11, N 2.30, P 15.24; found C 61.62, H 6.35, N 2.06, P 16.49. (Crystals of the analytical sample contained ca. 3% of trimethylphosphane oxide.)

[(*E*)-2-(Diphenylphosphanyl)benzoyl-3-*N*-*tert*-butylimidomethyl-*C,P*]carbonylbis(trimethylphosphane)cobalt(I) (7): A sample of **4** (520 mg, 0.82 mmol) in 70 mL of diethyl ether was kept stirring under 1 bar of CO for 1 h during which time the colour of the mixture turned from red brown to orange. The volatiles were removed in vacuo, and the solid residue was extracted with two 50 mL portions of pentane. Crystallization at −27 °C afforded dark red rhombs of **7**. Yield 380 mg (75%); m.p. 123−125 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1906 cm^{-1} (C≡O), 1630 cm^{-1} (C=N), 1540 cm^{-1} (C=O). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.76 (s, 9 H, CH_3), 1.04 (t′, $|^2J_{P,H} + {}^4J_{P,H}|$ = 7.3 Hz, 18 H, PCH_3], 7.28−7.34 (m, 6 H, CH), 7.46 (dt, ^3J = 7.6, ^4J = 2.6 Hz, 1 H, CH), 7.54 (dd, ^3J = 6.4, ^4J = 1.6 Hz, 1 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 17.9 (m, PCH_3), 27.8 (s, CH_3), 56.1 (s, CMe_3), 68.8 (s, NCH), 125.5 (d, $^2J_{P,C}$ = 20.5 Hz, CH), 126.8 (s, CH), 127.3 (d, $^3J_{P,C}$ = 8.8 Hz, CH), 129.8 (d, $^2J_{P,C}$ = 11.4 Hz, CH), 137.1 (s, C), 138.5 (d, $^1J_{P,C}$ = 30.7 Hz, CH), 139.7 (d, $^2J_{P,C}$ = 23.9 Hz, CH), 153.3 (s, C), 159.1 (s, NCH) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 233 K): δ = 9 (d, $^2J_{P,P}$ = 79 Hz, 1 P, PCH_3), 79 (t, $^2J_{P,P}$ = 79 Hz, 1 P, PPh_2) ppm. $C_{31}H_{41}CoNO_2P_3$ (611.2): calcd. C 60.89, H 6.76, N 2.29, P 15.20; found C 61.03, H 7.52, N 2.28, P 14.85.

[(*E*)-2-(Diphenylphosphanyl)-*N*-isopropylbenzimino-*C,P*]ethenebis-(trimethylphosphane)cobalt(I) (8): A sample of **2** (650 mg, 1.05 mmol) in 50 mL of diethyl ether was kept stirring under 1 bar of C_2H_4 for 30 min to form an orange solution. The volatiles were removed in vacuo, and the solid residue was extracted with two 50 mL portions of pentane. Crystallization at −27 °C afforded orange crystals of **8**. Yield 365 mg (61%); m.p. 105−107 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1541 cm^{-1} (C=N). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.69 (d, $^2J_{P,H}$ = 6.2 Hz, 9 H, PCH_3), 1.02 (d, ^3J = 5.9 Hz, 6 H, CH_3), 1.10 (d, $^2J_{P,H}$ = 6.1 Hz, 9 H, PCH_3), 1.67 (m, 2 H, CCH_2), 2.25 (m, 2 H, CCH_2), 3.98 (septet, $^2J_{P,H}$ = 6.2 Hz, 1 H, NCH), 6.79 (dd, ^3J = 5.7, ^4J = 1.4 Hz, 1 H, CH), 6.93 (dd, ^3J = 7.5, ^4J = 1.4 Hz, 1 H, CH), 7.03 (m, 1 H, CH), 7.26−7.30 (m, 6 H, CH), 7.74−7.83 (m, 4 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 17.5 (d, $^1J_{P,C}$ = 13.3 Hz, PCH_3), 21.1 (d, $^1J_{P,C}$ = 23.0 Hz, PCH_3), 23.9 (s, CH_3), 48.2 (d, $^2J_{P,C}$ = 20.4 Hz, CCH_2), 52.1 (d, $^2J_{P,C}$ = 13.9 Hz, CCH_2), 54.1 (s, NCH), 122.5 (d, $^2J_{P,C}$ = 15.2 Hz, CH), 126.8 (s, CH), 127.9−134.0 (s, CH), 134.9

(d, $^2J_{P,C}$ = 12.1 Hz, CH), 138.3 (m, CH), 139.2 (d, $^2J_{P,C}$ = 9.6 Hz, CH), 140.2 (d, $^1J_{P,C}$ = 22.4 Hz, CH) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 203 K): δ = 8 (dd, $^2J_{P,P}$ = 30 and 26 Hz, 1 P, PCH_3), 16 (dd, $^2J_{P,P}$ = 30 and 36 Hz, 1 P, PCH_3), 67 (dd, $^2J_{P,P}$ = 36 and 26 Hz, 1 P, PPh_2) ppm. $C_{30}H_{43}CoNP_3$ (569.2): calcd. C 63.27, H 7.61, N 2.46, P 16.32; found C 63.40, H 7.80, N 2.41, P 15.80.

[(*E*)-2-(Diphenylphosphanyl)-*N*-cyclohexylbenzimino-*C,P*]ethenebis(trimethylphosphane)cobalt(I) (9): A sample of **3** (680 mg, 1.03 mmol) in 50 mL of pentane was kept stirring under 1 bar of C_2H_4 for 20 min to form a yellow solid. The supernatant solution was decanted and kept at −4 °C to afford yellow crystals of **9**. The solid was recrystallised from pentane. Combined yields 460 mg (73%); m.p. 93−95 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1557 cm^{-1} (C=N). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.66 (d, $^2J_{P,H}$ = 6.3 Hz, 9 H, PCH_3), 1.07 (d, ^3J = 6.1 Hz, 9 H, PCH_3), 1.24−1.99 (m, 10 H, CH_2), 1.80 (m, 2 H, CCH_2), 2.19 (m, 2 H, CCH_2), 3.41 (septet, $^3J_{P,H}$ = 3.8 Hz, 1 H, NCH), 6.83 (dd, ^3J = 5.5, ^4J = 1.5 Hz, 1 H, CH), 7.00 (dt, ^3J = 7.3, ^4J = 1.5 Hz, 1 H, CH), 7.26−7.30 (m, 6 H, CH), 7.34 (dt, ^3J = 5.2, ^4J = 0.9 Hz, 1 H, CH), 7.44 (ddd, ^3J = 5.7, 5.0, ^4J = 1.1 Hz, 2 H, CH), 7.98 (ddd, ^3J = 9.5, ^4J = 1.9, 1.5 Hz, 2 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 18.0 (d, $^1J_{P,C}$ = 13.2 Hz, PCH_3), 20.6 (d, $^1J_{P,C}$ = 22.8 Hz, PCH_3), 24.9, 25.2, 27.2, 35.2, 36.0 (s, CH_2), 48.3 (d, $^2J_{P,C}$ = 18.4 Hz, CCH_2), 51.5 (d, $^2J_{P,C}$ = 11.3 Hz, CCH_2), 60.3 (s, NCH), 122.5 (d, $^3J_{P,C}$ = 16.0 Hz, CH), 125.1 (d, $^4J_{P,C}$ = 4.4 Hz, CH), 126.8 (s, CH), 128.0 (d, $^3J_{P,C}$ = 8.7 Hz, CH), 128.5 (d, $^3J_{P,C}$ = 7.6 Hz, CH), 129.1 (d, $^3J_{P,C}$ = 8.6 Hz, CH), 134.5 (d, $^2J_{P,C}$ = 10.1 Hz, CH), 134.9 (d, $^2J_{P,C}$ = 12.1 Hz, CH), 138.8 (d, $^2J_{P,C}$ = 9.8 Hz, CH), 139.2 (d, $^2J_{P,C}$ = 9.6 Hz, CH), 141.1 (d, $^1J_{P,C}$ = 22.8 Hz, C], 146.7 (d, $^1J_{P,C}$ = 44.9 Hz, C), 156.4 (dd, $^1J_{P,C}$ = 43.5, $^2J_{P,C}$ = 10.4 Hz, NC) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 203 K): δ = 7 (dd, $^2J_{P,P}$ = 30 and 24 Hz, 1 P, PCH_3), 16 (dd, $^2J_{P,P}$ = 30 and 36 Hz, 1 P, PCH_3), 66 (dd, $^2J_{P,P}$ = 36 and 24 Hz, 1 P, PPh_2) ppm. $C_{33}H_{47}CoNP_3$ (609.2): calcd. C 65.02, H 7.77, N 2.30, P 15.24; found C 64.79, H 7.39, N 2.22, P 15.30.

[(*E*)-2-(Diphenylphosphanyl)-*N*-*tert*-butylbenzimide-*C^1,P*]ethenebis(trimethylphosphane)cobalt(I) (10): A sample of **4** (640 mg, 1.01 mmol) was kept at 100 °C in vacuo for 5 h. After cooling 30 mL of diethyl ether was condensed upon the red brown solid, and at 20 °C the solution was kept stirring under 1 bar of ethene for 1 h. The volatiles were removed in vacuo, and the solid residue was extracted with two 30 mL portions of pentane. Crystallization at −4 °C afforded orange crystals of **10**. Yield 236 mg (40%); m.p. 105−107 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1633 cm^{-1} (C=N). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.82 (s, 9 H, CH_3), 0.90 (d, $^2J_{P,H}$ = 6.3 Hz, 9 H, PCH_3), 1.05 (d, ^3J = 6.2 Hz, 9 H, PCH_3), 1.61 (m, 2 H, CCH_2), 1.80 (m, 2 H, CCH_2), 5.99 (m, 1 H, CH), 6.44 (m, 1 H, CH), 6.75 (dt, ^3J = 7.5, ^4J = 2.0 Hz, 1 H, CH), 7.17−7.19 (m, 3 H, CH), 7.29 (s, 1 H, NCH), 7.34−7.36 (m, 3 H, CH), 7.71−7.77 (m, 2 H, CH), 7.92−7.98 (m, 2 H, CH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF, 296 K): δ = 16.8 (d, $^1J_{P,C}$ = 17.9 Hz, PCH_3), 19.1 (d, $^1J_{P,C}$ = 17.9 Hz, PCH_3), 24.9 (s, CH_3), 25.2 (s, CMe_3), 33.2 (m, CCH_2), 35.3 (m, CCH_2), 109.5 (s, CH), 125.8 (d, $^2J_{P,C}$ = 15.6 Hz, C), 126.6 (d, $^3J_{P,C}$ = 7.9 Hz, CH), 126.8 (d, $^2J_{P,C}$ = 8.4 Hz, CH), 127.2, 128.8 (s, CH), 132.1 (d, $^2J_{P,C}$ = 12.3 Hz, CH), 132.9 (d, $^2J_{P,C}$ = 12.6 Hz, CH), 169.1 (s, NCH) ppm. ^{31}P NMR (81 MHz, [D$_8$]THF, 203 K): δ = −21 (dd, $^2J_{P,P}$ = 51 and 47 Hz, 1 P, PPh_2), 9 (dd, $^2J_{P,P}$ = 47 and 32 Hz, 1 P, PCH_3), 17 (dd, $^2J_{P,P}$ = 32 and 51 Hz, 1 P, PCH_3) ppm. $C_{31}H_{45}CoNP_3$ (583.2): calcd. C 63.81, H 7.77, N 2.40, P 15.92; found C 63.46, H 7.30, N 2.36, P 16.48.

[(*E*)-2-(Diphenylphosphanyl)-*N*-isopropylbenzimino-*C,P*]iodobis(trimethylphosphane)cobalt(II) (11): A sample of **2** (850 mg, 1.37 mmol) in 50 mL of THF at −70 °C was combined with iodomethane (488 mg, 3.44 mmol). After 3 h at 20 °C an off-white solid of tetramethylphosphonium iodide (IR) was filtered off, and the filtrate was evaporated to dryness. Extraction with three 80 mL portions of diethyl ether and cooling to 4 °C afforded dark brown platelets of **11**. Yield 440 mg (48%); m.p. 130−132 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1554 cm^{-1} (C=N). Magnetic moment: μ_{eff} = 1.98 μ_B. $C_{28}H_{39}CoINP_3$ (668.1): calcd. C 50.32, H 5.88, N 2.10, P 13.90; found C 50.56, H 6.58, N 2.02, P 13.88.

[(*E*)-2-(Diphenylphosphanyl)-*N*-cyclohexylbenzimino-*C,P*]iodobis(trimethylphosphane)cobalt(II) (12): A sample of **3** (790 mg, 1.20 mmol) in 80 mL of THF at −70 °C was combined with iodomethane (375 mg, 2.64 mmol). After 3 h at 20 °C workup proceeded as in the preparation of **11** to afford dark brown platelets of **12**. Yield 505 mg (63%); m.p. 128−134 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1547 cm^{-1} (C=N). Magnetic moment: μ_{eff} = 1.98 μ_B. $C_{31}H_{43}CoINP_3$ (708.1): calcd. C 52.56, H 6.12, N 1.98, P 13.12; found C 52.60, H 5.74, N 1.98, P 12.58.

***mer-trans*-[(*E*)-2-(Diphenylphosphanyl)-*N*-*tert*-butylbenzimide-*C^1,P*]iodo(methyl)bis(trimethylphosphane)cobalt(III) (13):** A sample of **4** (920 mg, 1.45 mmol) in 50 mL of diethyl ether at −70 °C was combined with excess iodomethane (455 mg, 3.20 mmol). After 1 h at 20 °C the solution became red. An off-white solid of tetramethylphosphonium iodide was filtered off, and the solution at 4 °C afforded red crystals of **13**. Yield 518 mg (51%); m.p. 117−119 °C (dec.). IR (Nujol): $\tilde{\nu}$ = 1633 cm^{-1} (C=N). ^{1}H NMR (300 MHz, [D$_8$]THF, 296 K): δ = 0.54 (m, 3 H, $CoCH_3$), 0.80 (s, 9 H, CCH_3), 1.04 (br. s, 18 H, PCH_3), 7.51−7.56 (m, 6 H, CH), 7.74−7.79 (m, 4 H, CH), 8.20 (s, 1 H, NCH) ppm. ^{13}C NMR (75.4 MHz, [D$_8$]THF,

Helical 1D Coordination Polymers − Structure and Magnetic Properties of *catena*-Poly[chloro(μ-({2-[(hydroxyimino)methyl]phenoxy}acetato-*N*,*O*,*O*,O′)copper(II)]

Sergiu Shova,*[a] Ghenadie Novitchi,[b] Maria Gdaniec,[c] Andrea Caneschi,[d] Dante Gatteschi,[d] Ludmila Korobchenko,[e] Violeta K. Voronkova,[e] Yurii A. Simonov,[a] and Constantin Turta[f]

Keywords: Copper / EPR spectroscopy / Magnetic properties / N ligands / O Ligands

A new compound $[CuHLCl]_n$, where H_2L is the product of the condensation reaction between 2-formylphenoxyacetic acid and hydroxylamine, has been synthesized and its crystal structure determined. The copper(II) atom is in an O_3NCl coordination environment and the helical chains of the complex are formed by square-pyramidal copper(II) ions bridged by *anti-anti* carboxylate ligands in basal-apical positions. The chloride ion acts as monodentate ligand and is involved in intramolecular hydrogen bonding to the oxime group. The results of magnetic susceptibility and EPR measurements performed on the polycrystalline sample over a wide temperature range are presented. The magnetic susceptibility data have been fitted by use of the linear chain model and $J = -2.5$ cm^{-1} as the value of antiferromagnetic interaction. The value of the exchange exceeds the Zeeman energy difference for two adjacent magnetically nonequivalent copper centers, and signals of these centers are averaged out. The temperature dependence of the EPR spectra shows increases in the linewidth and the shifts of the signals as the temperature decreases, indicating a short-range-order effect in the chain. Shifts of the EPR signals in the Q-band were discovered for the orientations perpendicular to the chain direction as the temperature decreased below 10 K. The nature of this shift is discussed.

Introduction

The quasi-one-dimensional magnetic systems of transition metal ions (metallopolymers) are of particular interest for physicists and chemists because of their special properties resulting from the nature of the magnetic ions. On the other hand, one-dimensional polymeric helical motifs are also attracting increased attention in supramolecular chemistry,[1−4] which certainly originates from the observed importance of these motifs in biological systems and enantioselective catalysis.[5−7]

This paper reports the synthesis, crystal structure, and magnetic properties of an anhydrous copper(II) complex existing in crystals in the form of a helical polymeric chain of formula $[Cu(HL)Cl]_n$, where H_2L is the product of the condensation reaction between 2-formylphenoxyacetic acid and hydroxylamine. There is currently renewed interest in copper(II) complexes with carboxylic ligands[8−13] because carboxylic groups can exhibit several different coordination modes to the central atom, giving rise to compounds with ferromagnetic or antiferromagnetic properties[14,15] depending on the copper magnetic orbitals involved in bonding and the coordination mode of the carboxylic group. Studies of structure and magnetic exchange interactions in this type of compounds are aimed at understanding of the structural and chemical features determined by the magnitude and sign of the exchange interaction.

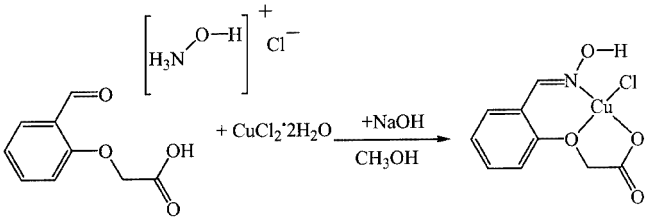
Results and Discussion

Synthesis

The template synthesis of the copper(II) coordination compound was carried out according to Scheme 1.

Copper(II) chloride and acetate were used for the reaction, but the yield was less when the acetate was used instead of the chloride. The compound [Cu(HL)Cl] was also formed when copper(II) chloride reacted directly with the oxime.



Scheme 1

IR Spectra

The IR spectrum of $[Cu(HL)Cl]_n$ does not contain absorption bands attributable to the vibration of the aldehyde group of 2-formylphenoxyacetic acid [ν(CH=O): $\tilde{\nu}$ = 1754, 1712 cm^{-1}], but it does show the vibration bands of the coordinated imino group [ν(C=N): $\tilde{\nu}$ = 1604 cm^{-1}], indicating that the template reaction is accompanied by condensation between 2-formylphenoxyacetic acid and hydroxylamine.[16] In addition, the IR spectrum of the complex shows the characteristic absorption bands of the carboxyl group of the formylphenoxyacetic fragment [$\nu_{as}(COO^-)$: $\tilde{\nu}$ = 1570 cm^{-1}; $\nu_s(COO^-)$: $\tilde{\nu}$ = 1414cm^{-1}], which were assigned according to ref.[17] The 156 cm^{-1} difference in the wavenumbers of the absorption bands $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ suggests the bidentate bridge mode of coordination. The shift of the $\nu_s(C-O-C)$ absorption band (1164 cm^{-1}) of the ether group by 52 cm^{-1} in the lower wavenumber range and of the $\nu_{as}(C-O-C)$ band (1244 cm^{-1}) by 4 cm^{-1} in the higher wavenumber range (relative to their counterparts in 2-formylphenoxyacetic acid) confirm the participation of the ether oxygen atom in coordination. The presence of the absorption band of the stretching frequency ν(OH) at $\tilde{\nu}$ = 3100−3300 cm^{-1} testifies to the presence of the protonated aldoxime group.

Structure

The crystal of the complex $[Cu(HL)Cl]_n$ consists of infinite helical chains directed along the *b* axis. Two antiparallel enantiomorphic helices in the crystal are shown in Figure 1, together with the atom-labeling scheme. The monomeric units of the $[Cu(HL)Cl]_n$ chain are sequentially bridged by *anti-anti* carboxylate groups. The monodeprotonated HL^- anion acts as a tridentate ligand towards one copper(II) ion and as a monodentate ligand towards another copper(II) center. The copper(II) ions each exist in distorted square-pyramidal coordination with the O_3NCl atom-donor set. The basal coordination sites are occupied by three donor atoms of the ligand [Cu−O(1) 2.089(3), Cu−O(2) 1.908(3) and Cu−N(1) 1.966(3) Å] and the chlorine atom [Cu−Cl 2.245(1) Å], whereas the carboxylate O(3) atom of the ligand from the adjacent monomeric unit along the chain resides in the apical position [Cu−O(3)′ 2.189(3) Å]. Thus, each *anti-anti* carboxylate group is located in the basal-apical positions of the coordination polyhedra and bridges two copper(II) ions. The Cu atom is displaced by 0.208 Å from the OONCl plane toward the axially coordinated O(3)′ atom. The distance between the nearest Cu atoms along the chain, 5.845 Å, is longer than those observed in similar helical chains but with the *syn-anti* carboxylate coordination mode.[12] The H-atom of the oxime group is involved in intramolecular hydrogen bonding [O(4)···Cl 3.058 Å, H···Cl 2.34 Å, OHCl 150°], closing a five-membered ring. No intermolecular hydrogen bonds are formed in this crystal; however, there is some overlap of the aromatic rings belonging to adjacent helical chains, with the distances between the ring atoms being in the 3.22−3.62 Å range, suggesting that π-π interactions may be of some importance in stabilizing this crystal structure (Figure 1). In the lattice, right- and left-handed helices alternate, resulting in an optically inactive racemic crystal, spontaneous resolution of two isomers being rare.[11,12]

Magnetic Susceptibility

The temperature dependence of the magnetic susceptibility and χT is presented in Figure 2. The value of χT (see a in Figure 2) decreases as the temperature decreases, indicating antiferromagnetic behavior. The Hamiltonian appropriate for a Heisenberg linear chain of S = 1/2 spins is given by Equation (1).

$$H = J\Sigma S_i \cdot S_{i+1} \quad (1)$$

The experimental data for the variation of susceptibility with temperature can be satisfactorily fitted into the analytic expression introduced to represent the Bonner−Fisher model[18] for a uniformly spaced Heisenberg chain of spins with S = 1/2 [Equation (2)].[19]

$$\chi = \left(Ng^2\beta^2/kT\right)\left\{\frac{0.25 + 0.074975x + 0.075235x^2}{1.0 + 0.9931x + 0.172135x^2 + 0.757825x^3}\right\} \quad x = |J/kT| \text{ with.} \quad (2)$$

The solid line in Figure 2 (part b) is the curve calculated according to Equation (2) with J = 2.5 cm^{-1}, g = 2.15. It shows good agreement between experimental data and calculated $\chi(T)$. Although the decrease in $\chi(T)$ in the temperature range studied is not observed experimentally, the measured values of $\chi(T)$ in the low-temperature range (inset in part b of Figure 2) would allow the presence of the maximum in this range. We considered the one-dimensional model, neglecting the interaction between the chains, as the distances between the paramagnetic copper centers in adjacent chains (R = 9.50 Å) exceed the intrachain copper distance (R = 5.85 Å) and there are no channels for indirect exchange between neighboring chains. Hence the antiferromagnetic interaction is produced only inside the chains.

It should be noted that the given data are in good agreement with a model chain of equally spaced copper(II) ions. In fact, the bridging fragments between the copper complexes in the chains coincide completely, although the chain is built up of magnetically nonequivalent copper centers: square-pyramidal copper(II) polyhedra $CuClNO_3$ are rotated with respect to each other along the direction of the chain. This chain structure results in a small value for the

antiferromagnetic interaction between the copper centers in the chains.

The value of the isotropic exchange interaction is determined by the overlap integral between ground-state orbitals, which for an indirect exchange is produced through intermediate orbitals of bridging ligands (the ground state of a square-pyramidal copper complex is the $d_{x^2-y^2}$ orbital). A weak antiferromagnetic coupling is justified by the small overlap of the magnetic orbitals according to the Goodenough−Kanamori rule.[20−22]

EPR Investigation

EPR spectra of the polycrystalline sample are shown in Figures 3 and 4. The spectrum is typical for the state $S = 1/2$ with the rhombic symmetry of the $\{g\}$ tensor. The temperature dependence of the spectra at the Q-band indicates the change of the values of the {g} tensor: $g_1 = 2.239 \pm 0.002$, $g_2 = 2.159 \pm 0.002$, $g_3 = 2.060 \pm 0.002$ at $T = 293$ K; $g_1 = 2.236 \pm 0.002$, $g_2 = 2.129 \pm 0.002$, $g_3 = 2.044 \pm 0.002$ at $T = 4.2$K.

The X-band anisotropy of the spectra is not resolved completely, but computer analysis of the spectra has allowed the temperature dependence of the g factor anisotropy and linewidths to be estimated. The temperature dependence of the linewidth for the high-field signal (Figure 5) shows that the appreciable changes are already detectable at $T = 10$ K and that the effect increases as the temperature decreases.

As we have already noted, the principal axes of g tensors of the neighboring copper ions are rotated with respect to each other. As the exchange interaction exceeds the difference of Zeeman energies for two magnetically inequivalent molecules, collapse of the lines occurs and for this spectrum the temperature dependence of the g tensor is detectable due to the merging effect. In principle, the temperature de-

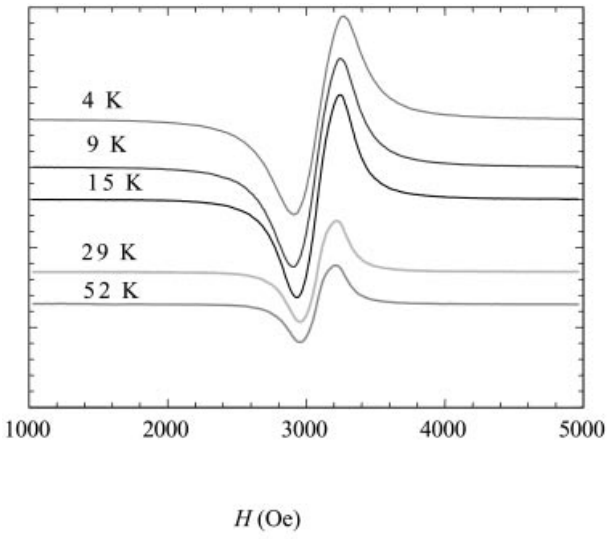

Figure 3. Temperature dependence of the EPR spectra of the polycrystalline sample of $[Cu(HL)Cl]_n$ at the *X*-band

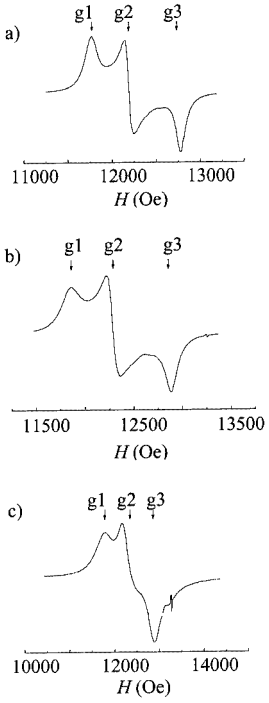

Figure 4. The EPR spectra at the *Q*-band at 298 K (a), 77 K (b), 4.2 K (c)

pendence of the positions of the signals may be due to small structural changes and to short-range order effects in the chain. Consider the correlation between observed g_1, g_2, g_3 components and molecular $\{g\}$ tensors. On the assumption of the axial symmetry of the molecular *g* tensor ($g_\parallel$, $g_\perp$) the resulting components of the *g* tensor are given by Equation (3).[23]

$$g_3 = g_\perp$$
$$g_1 = (g_\parallel^2 \cos^2\gamma + g_\perp^2 \sin^2\gamma)^{1/2} \quad (3)$$
$$g_2 = (g_\parallel^2 \sin^2\gamma + g_\perp^2 \cos^2\gamma)^{1/2}$$

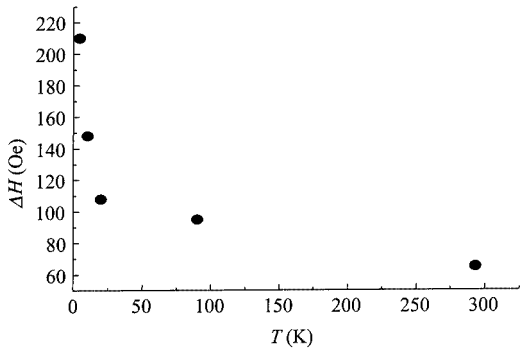

Figure 5. The temperature dependence of the linewidth of the high-field signal at the *X*-band

The 2γ term is the angle between the g_z directions of two neighboring complexes. It might be expected that this angle should be equal to the angle between the directions of the apical Cu−O bonds of two consecutive copper positions. According to Equation (3), for $\gamma \approx 36°$ and typical values of $g_\parallel$ and $g_\perp$ for the square-pyramidal copper complexes it would be expected that the change in the g_2 value due to possible small structural changes with temperature should not exceed the change of the g_1 value. However, the g_1 value is practically independent of the temperature and the supposition about the temperature dependence of the *g* value due to the availability of the short-range order effect is preferable. Analysis of the expressions of Equation (3) indicates that the g_1 component corresponds to the orientation of the magnetic field along the chain and the $g_{2,3}$ components are perpendicular to the chain direction.

The temperature dependence of the EPR spectra unequivocally shows that the linewidth for all orientations increases as the temperature decreases, and that the *g* factors shift for orientations perpendicular to the direction of the chain. No shift of the signal relative to the direction of the magnetic field along the direction of the chain is observed. The effects of the increase in the linewidth and the shifts of the signals for quasi-one-dimensional systems as the temperature approaches the value of the exchange interaction inside a chain have previously been explained in terms of the availability of the short-range order and the presence of the preferable direction for antiferromagnetic or ferromagnetic ordering due to the anisotropy of the interaction.[24−26] Changes of different signs were observed for the g factor, depending on the direction of a magnetic field: parallel or perpendicular to the direction of the chain. These experimental data are satisfactorily described by the assumption that the anisotropy of the interaction has a dipole-dipole character.

The $[Cu(HL)Cl]_n$ crystal provides an example of a new type of behavior of magnetic properties close to the temperature $T \approx J$. The change in behavior is probably connected with the change of the nature of the anisotropy of the interaction. For $[Cu(HL)Cl]_n$, the distance between the copper centers in a chain (R = 5.85 Å), allows us to assume that the main role is played by the anisotropy of the exchange interaction, including the antisymmetric interaction. For

the orientations of the magnetic field in the plane perpendicular to the direction of the chain, as the temperature decreases in the range $T \approx J$, the EPR signals shift to higher fields.

In principle, interaction between copper ions of adjacent chains in the plane perpendicular to the direction of the chains could give a similar effect. Because of the absence of the channels for such indirect exchange between copper ions of neighboring chains, however, this supposition is improbable. Measurements on single crystals would be necessary for more detailed investigation, because the spectrum of the polycrystalline sample contains only the signals corresponding to appropriate orientations of the magnetic field along the principal axes of the *g* tensor.

Experimental Section

Synthesis of [Cu(HL)Cl]$_n$: 2-Formylphenoxyacetic acid (0.9 g, 0.005 mol) was added to $CuCl_2 \cdot 2H_2O$ (0.85 g, 0.005 mol) in methanol (20 mL). A mixture of hydroxylamine−hydrochloride (0.35 g, 0.005mol) and NaOH (0.4 g, 0.01 mol) in methanol (25 mL) was then added, with stirring, to the resulting solution. The obtained solution was heated in a water bath at 50 °C for 30 min. The dark blue crystals, precipitating after cooling, were filtered, washed with cold methanol, and dried in air. Yield: 1.025 g, 70%. $C_9H_8ClCuNO_4$ (293): calcd. C 36.86, H 2.73, Cl 12.12, Cu 21.67, N 4.78; found C 36.93, H 2.76, Cl 12.09, Cu 21.78, N 4.80.

IR Spectra: These were recorded as oil suspensions with a Specorde M-80 spectrometer in the 4000−400 cm^{-1} range.

X-ray Crystal Structure Analysis: The crystal used for measurements was a prism of approximate dimensions 0.4 × 0.4 × 0.2 mm. The crystal was a non-mesohedral twin with the twin matrix [1 0 0 0 −1 0 −0.5 0 −1]. The data were collected with a Kuma Diffraction KM4 diffractometer by use of graphite-monochromatized Cu-K_α radiation. Lattice parameters were obtained from the least-squares refinement of 27 reflections with 16° ≤ 2θ ≤ 70°. The intensities were measured by the ω/2θ scan technique up to $2\theta_{max}$ = 129.6°. The intensities of three reflections were checked every 100 measurements to monitor instrument and crystal stability. Their intensity variation was within 3%. The structure was solved by direct methods with SHELXS-86[27] and refined by full-matrix, least squares on F^2 with SHELXL-93.[28] Instruction HKLF5 from SHELXL-93 was used for the refinement, because half of all the reflections belonged to both twin domains while the second half belonged to one domain. The non-hydrogen atoms were refined by the least-squares method in the anisotropic approximation. The positions of H atoms bonded to C atoms were calculated by assuming C−H distances of 0.96 Å. Positional parameters of the oxime H atom were obtained from difference Fourier syntheses and verified by the hydrogen bond geometric parameters. Isotropic displacement parameters of H atoms were fixed at 1.2 × U_{eq} for the relevant C and O atoms. The main crystallographic parameters and structure refinement details are summarized in Table 1, bond lengths and angles in Table 2. CCDC-182198 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

EPR and Magnetic Measurements: The measurements were carried out on the polycrystalline sample of [Cu(HL)Cl]$_n$. The static magnetic susceptibility was measured over the 2−300 K temperature range. The data were corrected for a diamagnetic contribution by use of Pascal constants.[29] The magnetization vs. *B* was recorded

Synthesis of New Pd^{II} Complexes Containing Thioether−Pyrazole Hemilabile Ligands − Structural Analysis by ^1H and ^{13}C NMR Spectroscopy and Crystal Structures of $[PdCl_2(bddo)]$ and $[Pd(bddo)](BF_4)_2$ [bddo = 1,8-Bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane]

Jordi García-Antón,[a] Josefina Pons,*[a] Xavier Solans,[b] Mercè Font-Bardia,[b] and Josep Ros*[a]

Keywords: Hemilabile ligands / N ligands / Palladium / S ligands

Treatment of the ligands 1,6-bis(3,5-dimethyl-1-pyrazolyl)-2,5-dithiahexane (bddh), 1,7-bis(3,5-dimethyl-1-pyrazolyl)-2,6-dithiaheptane (bddhp), 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane (bddo) and 1,9-bis(3,5-dimethyl-1-pyrazolyl)-3,7-dithianonane (bddn) with $[PdCl_2(CH_3CN)_2]$ produces $[PdCl_2(L)]$ or $[Pd_2Cl_4(L)]$ complexes, depending on the stoichiometry. Treatment of the complexes $[PdCl_2(bddo)]$ and $[PdCl_2(bddn)]$ with $AgBF_4$ gives $[Pd(bddo)](BF_4)_2$ and $[Pd(bddn)](BF_4)_2$. These Pd^{II} complexes have been characterised by elemental analyses, conductivity measurements, IR and ^1H and ^{13}C NMR spectroscopy where possible. The X-ray structures of the complexes $[PdCl_2(bddo)]$ and $[Pd(bddo)](BF_4)_2$ have been determined. In $[PdCl_2(bddo)]$ the thioether–pyrazole ligand is coordinated through the azine nitrogen atoms to the metal atom, which completes its coordination with two chloride ions in a *trans* disposition. In $[Pd(bddo)](BF_4)_2$ the metal atom is tetracoordinated by the two thioether sulfur atoms and the two azine nitrogen atoms of the pyrazole rings. Complexes $[PdCl_2(bddo)]$ and $[PdCl_2(bddn)]$ were obtained again when the complexes $[Pd(bddo)](BF_4)_2$ and $[Pd(bddn)](BF_4)_2$ were heated under reflux in a solution of Et_4NCl in CH_2Cl_2/MeOH (1:1).

Introduction

The chemistry of hemilabile ligands has been widely studied in recent years.[1] The term ''hemilabile ligand'', introduced in 1979 by Jeffrey and Rauchfuss,[2] refers to polydentate chelates containing at least two types of bonding groups displaying different properties in substitution reactions (one labile and one inert). Thus, one group bonds strongly to a metal centre and the other group is weakly bonded and easily displaced by coordinating ligands. This makes them very attractive for catalytic purposes.

In recent years, we have studied and reported on the properties of hemilabile ligands based on the pyrazolyl group and on some other groups, containing N,[3] P[4] or O[5] atoms. This article is the initial part of a study of ligands containing pyrazolyl and thioether groups.

The literature describes the use of low molecular mass coordination compounds (with cations such as Ni^{II}, Cu^{I}, Cu^{II}, Co^{II}, Zn^{II}, Cd^{II} and Ag^{I}) with ligands of this kind for the modelling of metalloprotein-active centres in the bioinorganic field.[6−9] Our goal is to extend these studies to include the potential hemilabile capability of ligands that coordinate Pd^{II}.

Here we report the synthesis of the ligand 1,7-bis(3,5-dimethyl-1-pyrazolyl)-2,6-dithiaheptane (bddhp). We have also studied the reactivity towards Pd^{II} of the previously described ligands 1,6-bis(3,5-dimethyl-1-pyrazolyl)-2,5-dithiahexane (bddh),[6] 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane (bddo)[7] and 1,9-bis(3,5-dimethyl-1-pyrazolyl)-3,7-dithianonane (bddn)[8] (Scheme 1). We have isolated the following complexes: $[PdCl_2L]$ with L = bddh (**1**), L = bddhp (**2**), L = bddo (**3**) and L = bddn (**4**), and $[Pd_2Cl_4L]$ with L = bddhp (**5**), L = bddo (**6**) and L = bddn (**7**). Treatment of **3** and **4** with $AgBF_4$ affords $[Pd(bddo)](BF_4)_2$ (**8**) and $[Pd(bddn)](BF_4)_2$ (**9**). NMR studies and the X-ray crystal structures of **3** and **8** are also presented.

Results and Discussion

The pyrazole ligands bddh, bddo and bddn were synthesised as described in the literature.[6−8] The bddh ligand was further purified by chromatography (silica gel 60) with methanol/dichloromethane (1:9) as eluent; bddo and bddn were purified by extraction ($CHCl_3$/H_2O/NaOH).

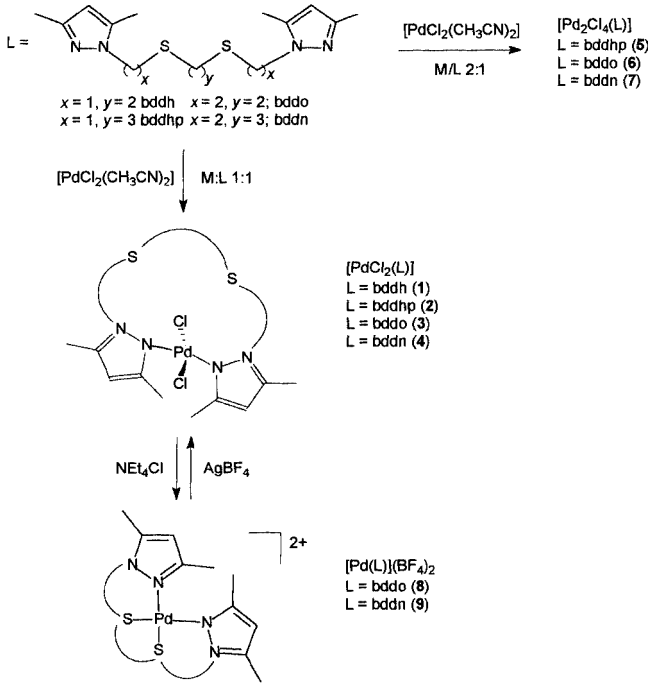

Scheme 1

Ligand bddhp, not previously reported in the literature, was prepared by a synthetic route similar to that used for the ligand bddh.[6a] Treatment of 2-(hydroxymethyl)-3,5-dimethylpyrazole with thionyl chloride gave 2-(chloromethyl)-3,5-pyrazolium chloride. This compound, on treatment with 1,3-propanedithiol in the presence of sodium hydroxide, yielded the desired product. The ligand bddhp was characterised by elemental analysis, mass spectrometry and IR, ^{1}H and ^{13}C NMR spectroscopy.

Complexes $[PdCl_2L]$ [L = bddh (**1**), bddhp (**2**), bddo (**3**) and bddn (**4**)] were obtained by treatment of the corresponding ligand either with $[PdCl_2(CH_3CN)_2]$ or with [PdCl$_2$(COD)] in a 1:1 M/L ratio. Complexes $[Pd_2Cl_4L]$ [L = bddhp (**5**), bddo (**6**) and bddn (**7**)] were obtained by use of a 2:1 M/L ratio.

Treatment of **3** and **4** with $AgBF_4$ gave compounds of formula $[PdL](BF_4)_2$ [L = bddo (**8**) and bddn (**9**)]. In contrast, use of the same reaction conditions with complexes **1** and **2** gave decomposition products. When complexes **8** and **9** were heated under reflux in a solution of Et_4NCl in CH_2Cl_2/MeOH (1:1) for 24 h, complexes **3** and **4** were obtained again.

The elemental analyses of products **5**, **6** and **7** are consistent with the formulas $[Pd_2Cl_4L]$. The low solubilities of the complexes were sufficient for their conductivity and ^{1}H NMR spectra to be measured, but their ^{13}C NMR spectra could not be recorded.

Conductivity values in acetonitrile for complexes **1**−**4**, and in DMSO for complexes **5**−**7**, are in agreement with non-electrolyte natures (Table 4). Conductivity values in methanol for complexes **8** and **9** are in agreement with 2:1 electrolytes. The reported values for 10^{-3} M solutions of non-electrolyte complexes are lower than 120 $\Omega^{-1}cm^2mol^{-1}$ or 50 $\Omega^{-1}cm^2mol^{-1}$ in acetonitrile or DMSO, respectively, while the range of conductivity values for 10^{-3} M solutions of 2:1 electrolyte compounds in methanol is between 160 and 220 $\Omega^{-1}cm^2mol^{-1}$.[10]

The IR spectra of all complexes are similar to those of the ligands, the most characteristic bands being those attributable to the pyrazolyl group: ν(C=C) and ν(C=N) between 1564−1554 cm^{-1} and $\delta(C-H)_{oop}$ between 820 and 778 cm^{-1}. The ν(B−F) band at 1061 cm^{-1} is characteristic for **8** and **9**.[11]

The IR spectra of the complexes in the 500−100 cm^{-1} region were also studied. Complexes $[PdCl_2L]$ (**1**−**4**) show two well-defined bands corresponding to ν(Pd−Cl) at 340−326 cm^{-1} and ν(Pd−N) at 473−448 cm^{-1}. For the $[Pd_2Cl_4L]$ complexes **5**−**7**, three bands can be observed. One of these can be assigned to ν(Pd−N) at 459−452 cm^{-1}. The number and energy of the other two bands are consistent with the presence of terminal (366−360 cm^{-1}) and bridging (335−299 cm^{-1}) Pd−Cl bonds. For complexes **8** and **9** the ν(Pd−N) and ν(Pd−S) bands can be attributed to the signals appearing between 461−456 and 238−247 cm^{-1}, respectively.[12]

NMR Experiments

The ^{1}H and ^{13}C NMR spectra of complexes **1**−**4**, **8** and **9** show the signals of coordinated ligands. NMR spectroscopic data are shown in the Exp. Sect. NMR spectra of compounds **3**, **4**, **8** and **9** were studied in more detail.

Study of the S−CH$_2$−CH$_2$−N fragment (in **3** and **4**) as an AA′XX′ system gave a set of coupling constants for each compound. These constants were consistent with the simulated spectra for compounds **3** and **4**, obtained with the aid of the *g* NMR program.[13] All these results are reported in Table 1. Figure 1 shows the experimentally determined and simulated spectra for **3**.

Table 1. ^{1}H NMR results: chemical shifts (ppm) and ^{1}H,^{1}H coupling constants (Hz) for **3** and **4** in $CDCl_3$

Compound	**3**	**4**
δ(CH$_2$) (6)	4.93	4.89
δ(CH$_2$) (7)	3.08	3.14
^2J(6a,6b)	−12.28	−12.87
^2J(7a,7b)	−12.28	−14.32
^3J(6a,7a) = ^3J(6b,7b), ^3J(6a,7b) = ^3J(6b,7a)	4.81, 13.01	4.87, 12.39

The Karplus equation cannot be used directly to calculate the dihedral angle between adjacent hydrogen atoms if the ethylenic fragments are α-substituted by heteroatoms (O, S, NR). In such cases, coupling constants are dependent on the electronegativity of the α-heteroatom substituent as well as on the dihedral angle.[14] Here, we have used a program based on the Karplus equation but which takes account of the electronegativity of the fragments connected

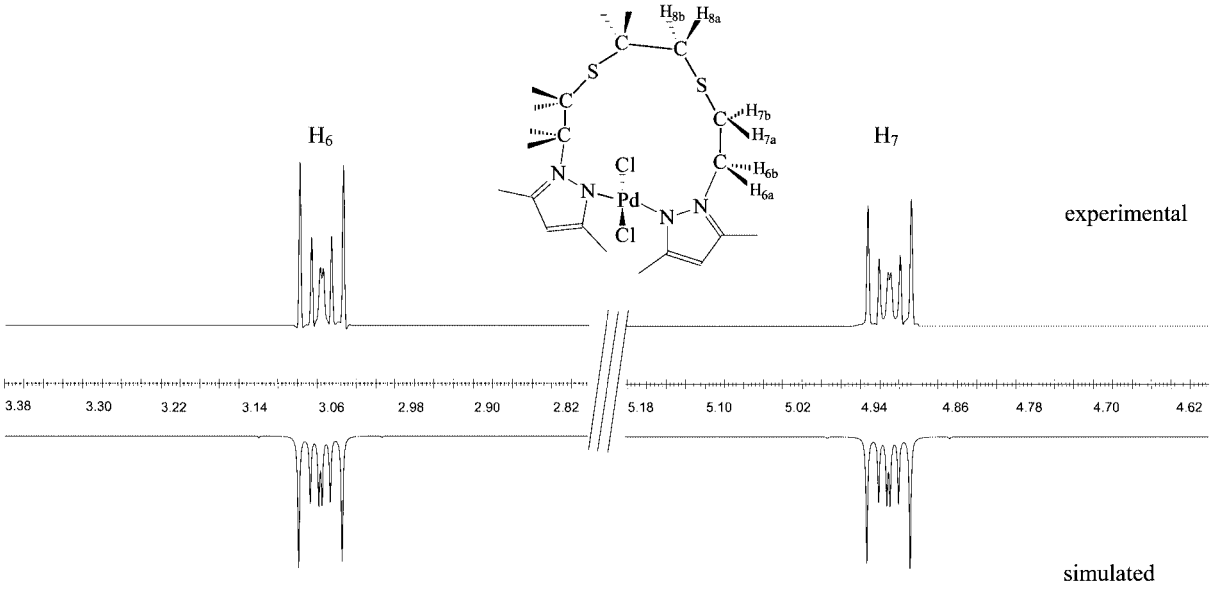

Figure 1. The 400-MHz ^1H NMR and the simulated *g* NMR spectra for the NCH_2CH_2S fragment of $[PdCl_2(bddo)]$ (**3**)

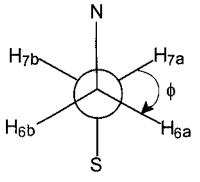
to the two carbon atoms involved.[15] Although this program was designed for organic molecules, in our case it works correctly when our ligands are coordinated to Pd^{II}. By use of this program, the dihedral angles corresponding to the observed adjacent coupling constants ($^3J_{6a,7a}$ = 4.81 and 4.87 Hz for **3** and **4**, respectively) are 51° and 52° for **3** and **4**, respectively. These values are in both cases consistent with an *anti* conformation (Figure 2).



$[PdCl_2(bddo)]$ $\phi = 52°$
$[PdCl_2(bddn)]$ $\phi = 51°$

Figure 2. Dihedral angles for the NCH_2CH_2S fragment of $[PdCl_2(bddo)]$ (**3**)

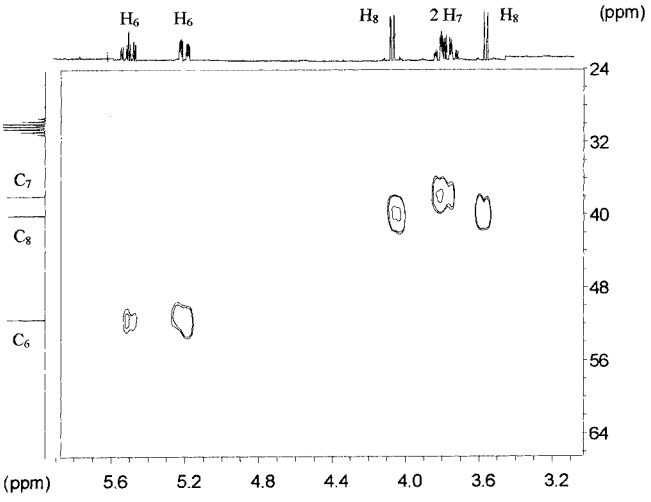


Figure 3. The 250-MHz 2D HMQC spectrum of $[Pd(bddo)](BF_4)_2$ (**8**)

The two different chains $[S-(CH_2)_2-N$ and $S-(CH_2)_x-S$; x = 2 for **8** and x = 3 for **9**] were studied separately. HMQC spectra were used to assign the signals of protons H_6, H_7 and H_8 for **8** and H_6, H_7, H_8 and H_9 for **9** (Figure 3). Simulated ^1H NMR spectra of both chains were obtained by use of the *g* NMR program.[13] The coupling constants are reported in Table 2.

Because of the symmetry of **8**, the two CH_2 units in the $S-CH_2-CH_2-S$ fragment are equivalent. The two protons of each CH_2, though, are diastereotopic and can be assigned to the two doublets found at δ = 3.52 and 4.04 ppm. The signal of H_8 for the $S-(CH_2)_3-S$ chain in compound **9** is superposed on that of H_7 and could not be further studied.

Table 2. ^1H NMR results: chemical shifts (ppm) and $^1H,^1H$ coupling constants (Hz) for **8** and **9** in $[D_6]$acetone

Compound	**8**	**9**
δ(H) (6*R*), δ(H) (6*S*)	5.19, 5.50	5.23, 5.58
δ(H) (7*S*), δ(H) (7*R*)	3.72, 3.78	3.52, 3.92
δ(H) (8*R*), δ(H) (8*S*)	3.52, 4.04	3.53
δ(H) (9*R*), δ(H) (9*S*)	−	2.70

^2J(7*R*,7*S*)	−13.70	−4.40
^3J(6*R*,7*R*), ^3J(6*S*,7*S*),	2.11, 3.17,	2.92, 10.28,
^3J(6*R*,7*S*), ^3J(6*S*,7*R*)	3.84, 12.45	15.24, 15.52
^2J(8*R*,8*S*)	−8.04	−

For complexes **8** and **9**, the two protons of each CH_2 group in the $S-CH_2-CH_2-N$ chain are diastereotopic, thus giving rise to four groups of signals, each attributable to a single hydrogen atom. This happens because of the rigid conformation of the ligand when it is complexed. In this way, each group of signals can be assigned as a double double doublet. In **8**, the two signals of lower δ value appear partially superimposed. Figure 4 shows the experimental and the simulated spectra for **8**.

Crystal Structure of [$PdCl_2$(bddo)] (3)

The structure of **3** (Figure 5) consists of discrete [$PdCl_2$(bddo)] units. The palladium atom is coordinated by two pyrazole nitrogen and two chlorine atoms in a distorted square-planar geometry. The tetrahedral distortion can be observed in the mean separation [±0.174(3)] of the atoms coordinated to the Pd atom in relation to the mean plane. Tetrahedral distortion of the square-planar geometry can

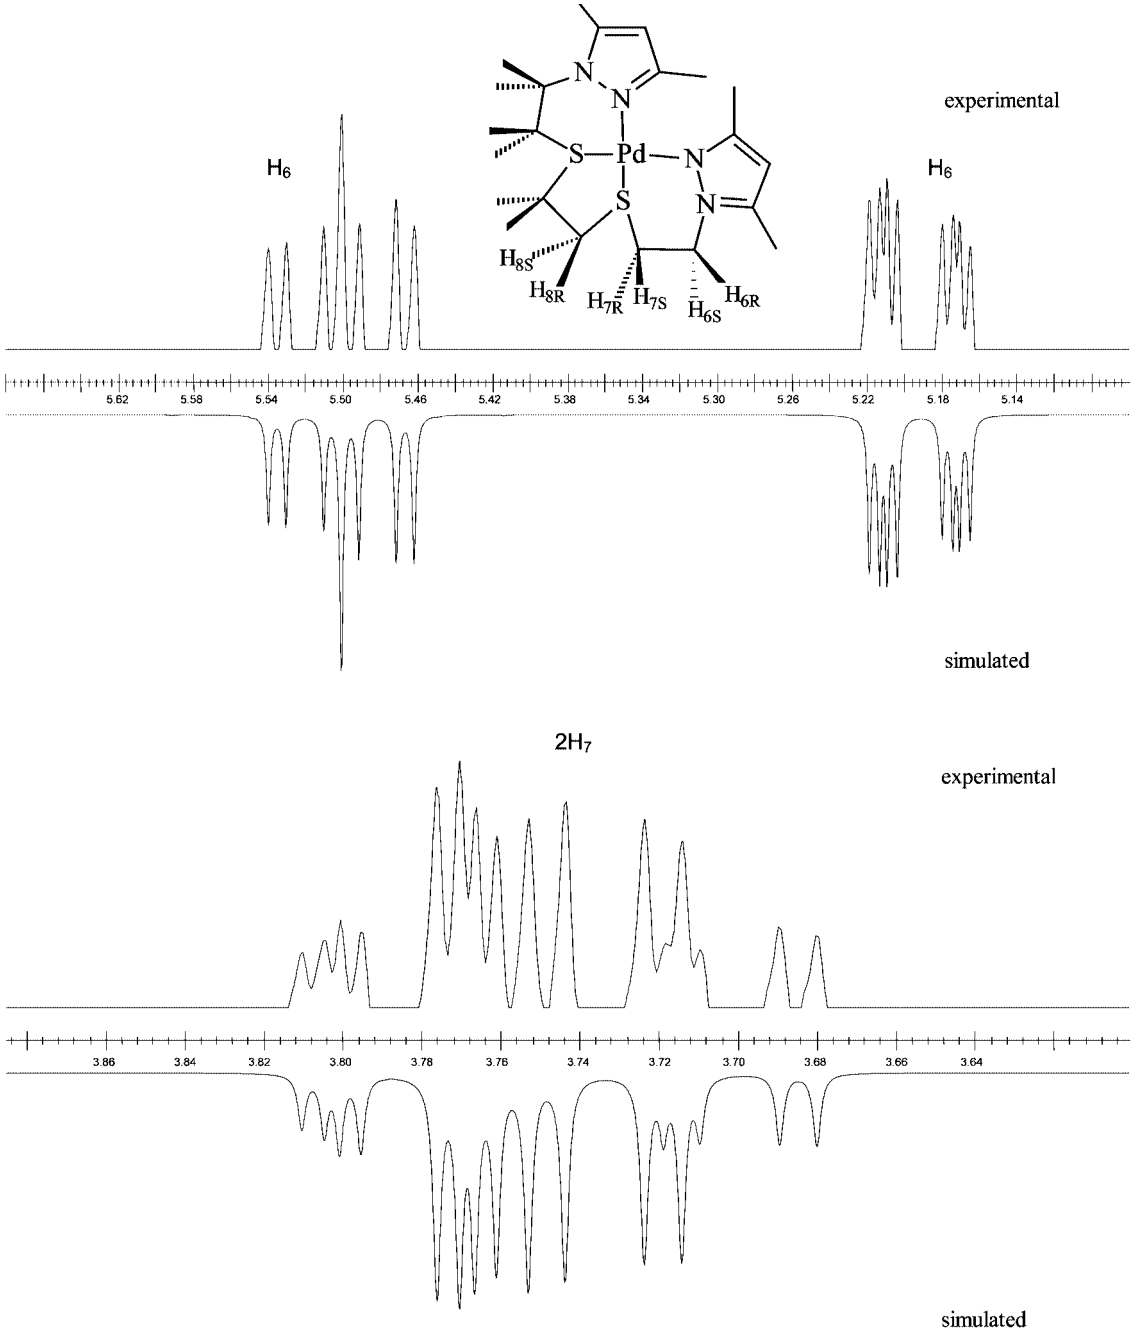

Figure 4. The 400-MHz ^1H NMR and the simulated *g* NMR spectra for the H_6 and H_7 protons of the NCH_2CH_2S fragment of [Pd(bddo)]$(BF_4)_2$ (**8**)

also be observed in the angles Cl(1)−Pd−Cl(2) and N(1)−Pd−N(3), of 172.47(4) and 168.65(9)°, respectively. The dihedral angle between the planes N(1)−Pd−Cl(1) and N(3)−Pd−Cl(2) is 13.5(1)°.

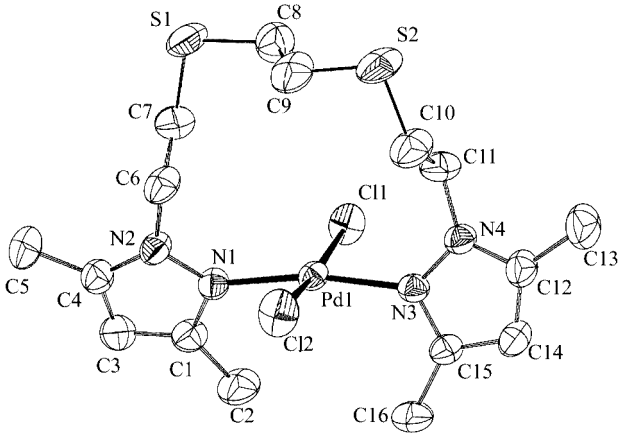

Figure 5. ORTEP drawing of $[PdCl_2(bddo)]$ (**3**, 273 K determination) showing all non-hydrogen atoms and the atom-numbering scheme; 50% probability amplitude displacement ellipsoids are shown

The pyrazolyl groups are *trans* to each other. The PdN_2Cl_2 core (containing pyrazole nitrogen atoms and terminal chloride ions) is found in 11 complexes described in the literature (seven of the complexes found had *trans* geometry and five were *cis*).[16] Both the Pd−N and the Pd−Cl bond lengths in **3** are of the same order as those found in the literature.[17] The palladium atom does not interact with the sulfur atoms, the Pd−S distances being 5.02(8) and 5.16(8) Å, respectively. The SCH_2CH_2S bridging segment is disordered in the crystal.

The structure of **3** is similar to that found for the complex $[CuCl_2(bddo)]$,[7b] but the copper complex shows greater distortion of the square-planar geometry. This can be observed in the dihedral angle between the planes N(1)−Cu−Cl(1) and N(3)−Cu−Cl(2), which is 27°. Table 3 lists some selected bond lengths and angles for this complex.

Table 3. Selected bond lengths (Å) and angles (°) for **3** and **8**, with estimated standard deviations (e.s.d.) in parentheses

Crystal Structure of $[Pd(bddo)](BF_4)_2 \cdot H_2O$ (8)

The structure of **8** (Figure 6) consists of cationic units of $[Pd(bddo)]^{2+}$, BF_4^- anions and solvent molecules (H_2O). Two nitrogen atoms of the pyrazolyl groups and two thioether groups coordinate the palladium atom in a slightly distorted square-planar geometry. The pyrazolyl groups are *cis* to each other. The tetrahedral distortion of the square-planar geometry can be observed in the mean separation of the atoms linked to Pd from the mean plane, which is ±0.050(3) Å. The dihedral angle between the planes N(1)−Pd−N(4) and S(1)−Pd−S(2) is 3.79(9)°. Some selected bond lengths and bond angles for this complex are listed in Table 3.

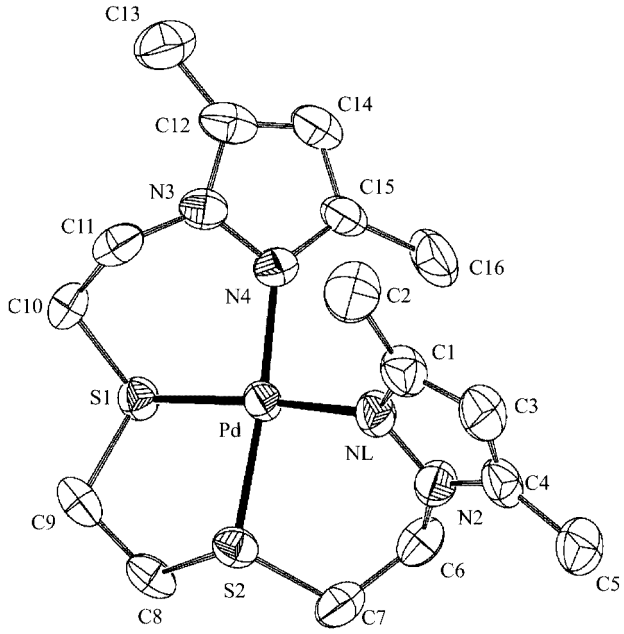

Figure 6. ORTEP drawing of $[Pd(bddo)](BF_4)_2$ (**8**, 273 K determination) showing all non-hydrogen atoms and the atom-numbering scheme; 50% probability amplitude displacement ellipsoids are shown

The PdN_2S_2 core (N in aromatic amine and S thioether) is found in five complexes in the literature.[18] The Pd−N and Pd−S distances in complex **8** are of the same order as those found in the literature for this kind of complexes.[17]

Ligand bddo acts as a tetradentate chelate and forms two Pd−N−N−C−C−S six-membered rings and one Pd−S−C−C−S five-membered ring. All of these have half-chair configurations. For the six-membered rings the N(4)−Pd−S(1) and N(1)−Pd−S(2) bite angles are 86.8(1) and 86.2(1)°, respectively. For the five-membered ring, the S(1)−Pd−S(2) bite angle is 89.75(6)°. These bite angles are similar to those reported in the literature for $[Pd(pdto)](ClO_4)_2$ [pdto = 1,8-bis(2-pyridyl)-3,6-dithiaoctane] (N−Pd−S bite angles are 86.9 and 87.2° and the S−Pd−S bite angle is 89.4°).[18d] This is the only compound with a PdN_2S_2 core similar to that presented in this paper, with two six-membered rings and one five-membered ring.

The half-chair distortions in the six-membered rings are ΔC_S(Pd) = 10.9(4)° and 17.0(4)° and ΔC_S[S(1)−C(10)] = 11.95(5)°, ΔC_S[S(2)−C(7)] = 14.0(6)° for Pd−S(1)−C(10)−C(11)−N(3)−N(4) and Pd−S(2)−C(7)−C(6)−N(2)−N(1), respectively.

Conclusion

We have shown that thioether−pyrazole N_2S_2 ligands can coordinate Pd^{II} centres in different ways. Treatment of $[PdCl_2(CH_3CN)_2]$ with these ligands gave complexes in which the Pd^{II} centre is bonded to two pyrazole rings and two chloride ions in a *trans* disposition. Abstraction of the chloride components in **3** and **4** with $AgBF_4$ gave complexes **8** and **9** with the $Pd^{II}N_2S_2$ core. These kinds of complexes were not obtained with bddh and bddhp ligands, probably because of the imposed geometry of the hypothetical PdNNCS metallacycle, which would induce steric hindrance between the methyl groups of the pyrazole rings. The Cl_2N_2 and N_2S_2 coordination modes of Pd^{II} can be interconverted. Thus, if **8** and **9** are heated under reflux in solutions with Et_4NCl, **3** and **4** are formed again. This reactivity is confirmation of the hemilabile behaviour of these thioether−pyrazole ligands in the complexation of Pd^{II}.

Experimental Section

Generals Remarks: Preparations were performed by use of conventional vacuum line and Schlenk techniques. All reagents were commercial grade materials and were used without further purification. Acetonitrile and dichloromethane were dried and distilled by standard methods and deoxygenated in the vacuum line in advance. Samples of $[PdCl_2(CH_3CN)_2]$[19] and $[PdCl_2(COD)]$[20] were prepared as described in the literature. 1,6-Bis(3,5-dimethyl-1-pyrazolyl)-2,5-dithiahexane (bddh),[6a] 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane (bddo)[7a] and 1,9-bis(3,5-dimethyl-1-pyrazolyl)-3,7-dithianonane (bddn)[8] were prepared according to the published methods. Analyses (C, H, N, S) were performed in our analytical laboratory with a Carlo Erba CHNS EA-1108 instrument. Conductivity measurements were performed at room temperature in 10^{-3} M acetonitrile, DMSO or methanol solutions, with the aid of a Crison micro CM 2200 conductimeter. Infrared spectra were recorded as KBr pellets or polyethylene mulls under nitrogen over the 4000−100 cm^{-1} range. The ^1H, $^{13}C\{^1H\}$ NMR and HMQC spectra were obtained either with Bruker 250-MHz or 400-MHz instruments. Chemical shifts (δ) were determined relative to internal TMS and are given in ppm. Mass spectra were obtained with an HP 5989A apparatus.

1,7-Bis(3,5-dimethyl-1-pyrazolyl)-2,6-dithiaheptane (bddhp): 2-(Chloromethyl)-3,5-pyrazolium chloride[6a] (720 mg, 3.98 mmol) and 1,3-propanedithiol (0.20 mL, 1.97 mmol) were dissolved in dry DMF (6 mL) and the mixture was then heated to 90 °C. After the mixture had been maintained at this temperature for 15 min, sodium hydroxide (500 mg, 12.1 mmol), dissolved in water (7 mL), was added dropwise. Heating was stopped; after 15 min, additional water (7 mL) was added. After cooling to room temperature, the reaction mixture was extracted four times with $CHCl_3$ (15 mL). The collected organic layers were dried with anhydrous sodium sulfate and removed under vacuum. The product was purified by chromatography (silica gel 60) with methanol/dichloromethane (1:9) as eluent to give a white solid. Yield: 0.46 g (72%). M.p. 30−32 °C. IR (NaCl, cm^{-1}): $\tilde{\nu}$ = 2918 [ν(C−H)$_{al}$], 1558 [ν(C=C), ν(C=N)], 1455 [$\delta(CH_3)_{as}$], 1378 [$\delta(CH_3)_s$], 779 [δ(C−H)$_{oop}$]. ^1H NMR (250 MHz, $CDCl_3$ solution): δ = 1.76 (q, ^3J = 7 Hz, 2 H, $CH_2-CH_2-CH_2$), 2.22 (s, 6 H, *Me*), 2.31 (s, 6 H, *Me*), 2.67 (t, ^3J = 7 Hz, 4 H, $S-CH_2-CH_2$), 5.05 (s, 4 H, pz-CH_2−S), 5.86 (s, 2 H, pz-CH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$ solution, 63 MHz): δ = 11.6 (*Me*), 13.9 (*Me*), 29.4 ($CH_2-CH_2-CH_2$), 30.3 (S-CH_2-CH_2), 50.3 (pz-CH_2−S), 106.9 (pz-CH), 139.4 (pz-C), 148.1 (pz-C) ppm. Synthesis of the Pd^{II} Complexes

Complexes $[PdCl_2L]$ with L = bddh (1), bddhp (2), bddo (3) and bddn (4): A solution of $[PdCl_2(CH_3CN)_2]$ or $[PdCl_2(COD)]$ (0.36 mmol) in dichloromethane (30 mL) was added to a solution of the appropriate ligand (0.36 mmol) in dichloromethane (10 mL). After the mixture had been stirred for 12 h, most of the solvent was removed under vacuum. Diethyl ether was then added to induce precipitation. The resulting precipitate was then filtered and washed with diethyl ether, yielding the desired compound.

Complex 1: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2951 [ν(C−H)$_{al}$], 1562 [ν(C=C), ν(C=N)], 1462 [$\delta(CH_3)_{as}$], 1380 [$\delta(CH_3)_s$], 778 [δ (C−H)$_{oop}$]. IR (polyethylene, cm^{-1}): $\tilde{\nu}$ = 459 [ν(Pd−N)$_{as}$], 326 [ν(Pd−Cl)]. ^1H NMR (400 MHz, $CDCl_3$ solution): δ = 2.35 (s, 6 H, *Me*), 2.85 (s, 6 H, *Me*), 3.96 (s, 4 H, $S-CH_2-CH_2-S$), 5.96 (s, 2 H, pz-CH), 5.98 (s, 4 H, pz-CH_2−S) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$ solution): δ = 12.5 (*Me*), 16.3 (*Me*), 31.6 ($S-CH_2-CH_2-S$), 48.8 (pz-CH_2−S), 108.9 (pz-CH), 144.8, 152.5 (pz-C) ppm.

Complex 2: IR (KBr, cm^{-1}): $\tilde{\nu}$ =3130 [ν(C−H)$_{ar}$], 2923 [ν(C−H)$_{al}$], 1559 [ν(C=C), ν(C=N)], 1464 [$\delta(CH_3)_{as}$], 1381 [$\delta(CH_3)_s$], 800 [δ(C−H)$_{oop}$]. IR (polyethylene, cm^{-1}): $\tilde{\nu}$ = 448 [ν(Pd−N)$_{as}$], 338 [ν(Pd−Cl)]. ^1H NMR (400 MHz, $CDCl_3$ solution): δ = 2.38 (s, 6 H, *Me*), 3.01 (s, 6 H, *Me*), 3.13 (m, 2 H, $CH_2-CH_2-CH_2$), 3.22 (m, 4 H, $S-CH_2-CH_2$), 5.84 (s, 4 H, pz-CH_2−S), 6.02 (s, 2 H, pz-CH) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$ solution): δ = 12.7 (*Me*), 16.4 (*Me*), 27.2 ($CH_2-CH_2-CH_2$), 31.4 ($S-CH_2-CH_2$), 48.3 (pz-CH_2−S), 109.7 (pz-CH), 144.6, 151.4 (pz-C) ppm.

Complex 3: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3129 [ν(C−H)$_{ar}$], 2918 [ν(C−H)$_{al}$], 1557 [ν(C=C), ν(C=N)], 1469 [$\delta(CH_3)_{as}$], 1393 [$\delta(CH_3)_s$], 820 [δ(C−H)$_{oop}$]. IR (polyethylene, cm^{-1}): $\tilde{\nu}$ = 453 [ν(Pd−N)$_{as}$], 340 [ν(Pd−Cl)]. ^1H NMR (400 MHz, $CDCl_3$ solution): δ = 2.28 (s, 6 H, *Me*), 2.95 (s, 6 H, *Me*), 3.08 (m, 4 H, CH_2-CH_2−S), 3.20 (s, 4 H, $S-CH_2-CH_2$−S), 4.93(m, 4 H, pz-CH_2-CH_2), 5.94 (s, 2 H, pz-CH) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$ solution): δ = 12.1 (*Me*), 15.5 (*Me*), 30.8 (S-CH_2-CH_2−S), 34.0 (CH_2-CH_2−S), 51.1 (pz-CH_2-CH_2), 108.8 (pz-CH), 142.9, 150.6 (pz-C) ppm.

Complex 4: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3126 [ν(C−H)$_{ar}$], 2917 [ν(C−H)$_{al}$], 1554 [ν(C=C), ν(C=N)], 1469 [$\delta(CH_3)_{as}$], 1390 [$\delta(CH_3)_s$], 789 [δ(C−H)$_{oop}$]. IR (polyethylene, cm^{-1}): $\tilde{\nu}$ = 473 [ν(Pd−N)$_{as}$], 335 [ν(Pd-Cl)]. ^1H NMR (400 MHz, $CDCl_3$ solution): δ = 2.28 (s, 6 H, *Me*), 2.97 (s, 6 H, *Me*), 1.72 (q, 2 H, $CH_2-CH_2-CH_2$), 2.84 (t, 4 H, $CH_2-CH_2-CH_2$), 3.14 (m, 4 H, CH_2-CH_2−S), 4.89 (m, 4 H, pz-CH_2-CH_2), 5.94 (s, 2 H, pz-CH) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$ solution): δ = 12.1 (*Me*), 15.6 (*Me*), 29.5, 29.6, 30.6 (pz-CH_2-CH_2−S, $CH_2-CH_2-CH_2$, $CH_2-CH_2-CH_2$), 50.7 (pz-CH_2-CH_2), 108.8 (pz-CH), 143.1, 150.9 (pz-C) ppm.

Complexes $[Pd_2Cl_4L]$ with L = bddhp (5), bddo (6) and bddn (7): A solution of $[PdCl_2(CH_3CN)_2]$ (0.36 mmol) in dichloromethane

(30 mL) was added to a solution of the appropriate ligand (0.18 mmol) in dichloromethane (10 mL). After the mixture had been stirred for 12 h, a precipitate had formed. This precipitate was filtered off, washed with diethyl ether and dried under vacuum, yielding the desired compound. No Pd^{II} complex of this stoichiometry with bddh as ligand could be isolated.

Complex 5: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3129 [ν(C−H)$_{ar}$], 2967 [ν(C−H)$_{al}$], 1564 [ν(C=C)], 1463 [ν(C=N), $\delta(CH_3)_{as}$], 1392 [$\delta(CH_3)_s$], 808 [δ(C−H)$_{oop}$]. IR (polyethylene, cm^{-1}): $\tilde{\nu}$ = 452 [ν(Pd−N)$_{as}$], 366 [ν(Pd−Cl)], 335 [ν_B(Pd−Cl)]. ^{1}H NMR (400 MHz, [D$_6$]DMSO solution): δ = 2.16 (s, 6 H, *Me*), 2.34 (s, 6 H, *Me*), 2.69 (br, 2 H, $CH_2-CH_2-CH_2$), 2.97 (br, 4 H, $S-CH_2-CH_2$), 5.67 (br, 4 H, pz-CH_2−S), 5.97 (s, 2 H, pz-CH).

Complex 6: IR (KBr, cm^{-1}): 3120 [ν(C−H)$_{ar}$], 2967 [ν(C−H)$_{al}$, ν(C=C)], 1554 [ν(C=N)], 1467 [$\delta(CH_3)_{as}$], 1395 [$\delta(CH_3)_s$], 797 [δ(C−H)$_{oop}$]. IR (polyethylene, cm^{-1}): 456 [ν(Pd−N)$_{as}$], 367 [ν(Pd−Cl)], 322 [ν_B(Pd−Cl)]. ^{1}H NMR (400 MHz, [D$_6$]DMSO solution): δ = 2.36 (s, 6 H, *Me*), 2.43 (s, 6 H, *Me*), 2.79 (br, 4 H, CH_2-CH_2−S), 4.23 (br, 4 H, S−CH_2-CH_2−S), 4.92 (br, 4 H, pz-CH_2-CH_2), 6.19 (s, 2 H, pz-CH) ppm.

Complex 7: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3126 [ν(C−H)$_{ar}$], 2958 [ν(C−H)$_{al}$], 1560 [ν(C=C), ν(C=N)], 1470 [$\delta(CH_3)_{as}$], 1400 [$\delta(CH_3)_s$]. IR (polyethylene, cm^{-1}): $\tilde{\nu}$ = 459 [ν(Pd−N)$_{as}$], 360 [ν(Pd−Cl)], 319 [ν_B(Pd−Cl)]. ^{1}H NMR (400 MHz, [D$_6$]DMSO solution): δ = 2.25 (s, 6 H, *Me*), 2.80 (s, 6 H, *Me*), 2.05 (br, 2 H, $CH_2-CH_2-CH_2$), 2.42 (br, 4 H, $CH_2-CH_2-CH_2$), 4.50 (br, 4 H, CH_2-CH_2−S), 4.90 (br, 4 H, pz-CH_2-CH_2), 6.20 (s, 2 H, pz-CH) ppm.

Complexes [Pd(bddo)](BF$_4$)$_2$·H$_2$O (8) and [Pd(bddn)](BF$_4$)$_2$ (9): A solution of $AgBF_4$ (0.86 mmol) was added dropwise with vigorous stirring to a solution of [PdCl$_2$(L)] (L = bddo or bddn, 0.43 mmol) in dichloromethane (10 mL) and methanol (10 mL). The reaction was carried out in the dark to prevent reduction of Ag^I to Ag^0. After 5 min, stirring was stopped, and AgCl was filtered off. When the volume of the resultant solution had been reduced to roughly 5 mL, the product precipitated as a yellow solid. This solid was filtered and washed with dichloromethane.

Complex 8: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3141 [ν(C−H)$_{ar}$], 2956 [ν(C−H)$_{al}$], 1553 [ν(C=C), ν(C=N)], 1470 [$\delta(CH_3)_{as}$], 1395 [$\delta(CH_3)_s$], 1061 [ν(B−F)], 791 [δ(C−H)$_{oop}$]. IR (polyethylene, cm^{-1}): $\tilde{\nu}$ = 461 [ν(Pd−N)$_{as}$], 238 [ν(Pd−S)]. ^{1}H NMR (400 MHz, [D$_6$]acetone): δ = 1.99 (s, 6 H, *Me*), 2.52 (s, 6 H, *Me*), 3.72/ 3.78/ 5.19/ 5.50 (pz-CH_2-CH_2), 6.26 (s, 2 H, pz-CH) ppm. ^{13}C{^{1}H} NMR (100 MHz, [D$_6$]acetone): δ = 11.9 (*Me*), 13.3 (*Me*), 31.4 (S−CH_2-CH_2), 48.3 (pz-CH_2-CH_2−S), 109.0 (pz-CH), 147.0, 152.1 (pz-C) ppm.

Complex 9: IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3129 [ν(C−H)$_{ar}$], 2985−2928 [ν(C−H)$_{al}$], 1549 [ν(C=C), ν(C=N)], 1472 [$\delta(CH_3)_{as}$], 1393 [$\delta(CH_3)_s$], 1061 [ν(B−F)], 810 [δ(C−H)$_{oop}$]. IR (polyethylene, cm^{-1}): $\tilde{\nu}$ = 456 [ν(Pd−N)$_{as}$], 247 [ν(Pd−S)]. ^{1}H NMR (400 MHz, [D$_6$]acetone): δ = 1.85 (s, 6 H, *Me*), 2.52 (s, 6 H, *Me*), 3.52/3.92/ 5.23/5.58 (pz-CH_2-CH_2), 6.24 (s, 2 H, pz-CH) ppm. ^{13}C{^{1}H} NMR (100 MHz, [D$_6$]acetone): δ = 11.3 (*Me*), 12.7 (*Me*), 22.8 ($CH_2-CH_2-CH_2$), 31.2 (pz-CH_2-CH_2), 36.4 ($CH_2-CH_2-CH_2$), 49.9 (pz-CH_2-CH_2), 108.9 (pz-CH), 146.1, 152.1 (pz-C) ppm.

Tables 1 and 2 show coupling constants for complexes **3**, **4**, **8** and **9**; Table 4 shows other analytical and physical data for all complexes.

X-ray Crystallographic Study: Crystals of compounds **3** and **8** suitable for X-ray diffraction experiments were obtained by crystallisation from CH_2Cl_2 and MeOH, respectively. The data for **3** were collected with an Enraf−Nonius CAD$_4$ four-circle diffractometer, by the Ω/2θ scan technique. The data for **8** were collected with an MAR345 diffractometer with an image plate detector, by the φ-scan technique. Both crystals were subjected to graphite-monochromated Mo-K_α radiation. The structures were solved by direct methods with the SHELXS 97 computer program[21] and refined by full-matrix, least squares with the SHELXL 97 program.[22] All hydrogen atoms were computed and refined by use of a riding model. The final *R* (on *F*) factor and ω*R* (on F^2) values, as well as the numbers of parameters refined and other details concerning the refinement of the crystal structure are presented in Table 5. CCDC-185048 (**3**) and -185049 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cam-

Formation and Characterization of Zwitterionic Stereoisomers from the Reaction of $B(C_6F_5)_3$ and NEt_2Ph: (*E*)- and (*Z*)-[$EtPhN^+=CHCH_2$-$B^-(C_6F_5)_3$]

Nicolas Millot,[a] Catherine C. Santini,*[a] Bernard Fenet,[b] and Jean Marie Basset[a]

Keywords: Boranes / Aniline / Zwitterions / NMR spectroscopy

The stoichiometric reaction of $B(C_6F_5)_3$ and NEt_2Ph **I**, at room temperature, in an aromatic solvent, has been investigated by 1D and 2D NMR spectroscopy (^1H, ^{11}B,^{13}C, ^{15}N and ^{19}F). No $Et_2PhN{\cdot}B(C_6F_5)_3$ adduct was observed. An equilibrium between free $B(C_6F_5)_3$, NEt_2Ph, $[HB(C_6F_5)_3]^-(HNEt_2Ph)^+$ and two zwitterionic stereoisomers (*E*)- and (Z)-[$EtPhN^+=CH$-CH_2-$B^-(C_6F_5)_3$] (30%) in an *E*/*Z* ratio of 3:2 was observed. Whatever the protic reagent Z-OH [Z = H, $SiPh_3$, (c-$C_5H_9)_7O_{12}Si_8$, or silanol group of silica], all the equilibria involved in solutions of **I** are quantitatively displaced towards the ionic form $[Z\text{-}O\text{-}B(C_6F_5)_3]^-(HNEt_2Ph)^+$. In the case of dimethylaniline, besides free $B(C_6F_5)_3$ and Me_2NPh, the 1:1 adduct $(C_6F_5)_3B{\cdot}NMe_2Ph$ and an iminium salt $[PhCH_3N=CH_2]^+[HB(C_6F_5)_3]^-$ have been identified.

Introduction

In homogeneous metallocene-based olefin polymerization catalysis, ammonium salts are known to activate neutral alkyl precursors into highly active metallocenium cations by irreversible protonolysis. These salts are generally composed of a tertiary ammonium cation $[HNR_2R']^+$ (R = Me, Et; R′ = Ph, Et) and various non-coordinating anions such as metallacarboranes[1] or borates.[2−6] From the latter, the non-coordinating character of pentafluorophenylborates {$[XB(C_6F_5)_3]$, X = -C_6F_5,[7] -OH,[8] -OR,[9] (c-$C_5H_9)_7O_{12}Si_8$ [10]}, and their resistance towards anion decomposition, even though pentafluorophenylborates are far less stable towards decomposition when X = OR,[11] have allowed the successful enhancement of the activity of metallocenium catalysts.[12]

$$Cp_2ZrMe_2 + [HNR_2R']^+[B(C_6F_5)_4]^- \rightarrow [Cp_2ZrMe]^+[B(C_6F_5)_4]^- + MeH + NR_2R'$$

Interestingly, despite the fact that anilines are commonly used with tris(pentafluorophenyl)borane $[B(C_6F_5)_3]$ in the preparation of heterogeneous cocatalysts for olefin polymerization,[13−16] no reports exist on the Lewis acid/base reactivity of such compounds in solution and the possible formation of aniline·$B(C_6F_5)_3$ adducts. Like boron trihalides,[17,18] the strong Lewis acid $B(C_6F_5)_3$ is known to form stable adducts with amines or pyridines.[19]

We report in this paper the results obtained by multinuclear 1D and 2D NMR spectroscopy (^1H, ^{11}B, ^{13}C, ^{15}N, ^{19}F) on stoichiometric solutions of $B(C_6F_5)_3$ and NR_2Ph (R = Et, Me).

Results and Discussion

The addition of one equivalent of NEt_2Ph to $B(C_6F_5)_3$ in aromatic solvents led instantaneously to a pink coloration of the solution **I**. The ^{11}B NMR spectrum of **I** shows three resonance at δ = −13.7, −23.6 and 60 ppm indicating the presence of at least three different species in the reaction mixture. In order to determine their structure, a study was performed using multinuclear ^1H, ^{11}B, ^{13}C, ^{15}N and ^{19}F NMR spectroscopy.

In the ^1H NMR spectrum of solution **I** (Figure 1), the major peaks at δ = 0.82 (CH_3), 2.8 (CH_2) and 6.5−7 ppm

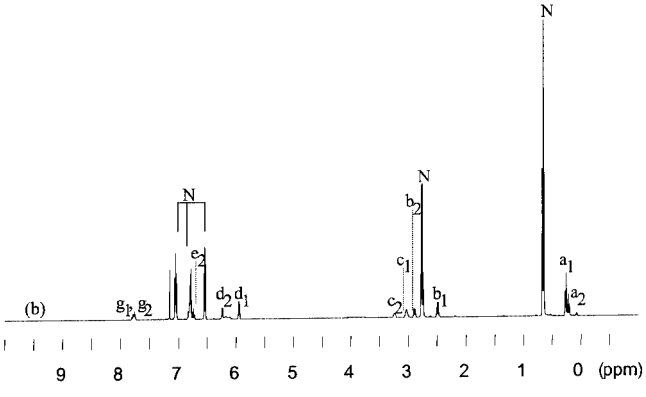

Figure 1. ^1H NMR spectrum (500 MHz, 25 °C, C_6D_6) of solution **I**; N indicates peaks due to free Et_2NPh

(aromatic protons) are characteristic of the free amine in solution. Additional peaks appear in the region of methyl (a_1, a_2), methylene (b_1, b_2; c_1, c_2) and aromatic (d_1, d_2, e_2) protons. Two deshielded overlapping triplets (g_1, g_2) and a very broad signal are also observed at $\delta = 7.8$ and 3.9 ppm, respectively. The intensities of these peaks, relative to those of the free amine, do not exceed 30%, and are sensitive to the concentration of the solution, suggesting the existence of an equilibrium or equilibria between NEt_2Ph and other species in solution. In all experiments, a ratio of 3:2 is observed for the areas of the peaks x_1/x_2 (x = a−g).

In the 2D-COSY NMR spectrum of **I** (Figure 2) the triplets a_1 and a_2 are correlated to the quadruplets b_1 and b_2, respectively, supporting the fact that two different -$CH_{2\text{-}b}$-$CH_{3\text{-}a}$ fragments are present. A correlation is also detected between (c_1, c_2) and (g_1, g_2), indicating that the H_g protons are coupled to the -$CH_{2\text{-}c}$-X fragments (Figure 2a). Analysis of the aromatic proton region of the spectrum (Figure 2b) shows the presence of two types of non-equivalent phenyl groups (in a d_1/d_2 ratio of 3:2). At lower levels, a weak correlation can be detected between the (b_1, b_2) quadruplets and the (g_1, g_2) triplets.

The solution ^{13}C NMR spectrum of **I** (Figure 3) shows the characteristic peaks for the methyl ($\delta = 11.4$ ppm), methylene ($\delta = 49.4$ ppm) and aromatic carbons ($\delta = 116-142$ ppm) of diethylaniline, as well as doublets representative of the pentafluorophenyl carbons ($\delta = 138-149$ ppm) of $B(C_6F_5)_3$. As in the ^1H NMR spectrum, two sets of additional peaks appear in the ^{13}C NMR spectrum of **I** for each methyl, methylene and aromatic carbon atom. Two new peaks are also present near $\delta = 190$ ppm that can be attributed to a C=Y group, where Y is an electron-withdrawing center (O, N).

The upfield shift of the methyl and *ipso* carbons, as well as the downfield shifts of the methylene, *ortho* and *para* carbons of the diethylaniline (see Exp. Sect.) could indicate a protonation[20,21] or a weakly coordinative interaction between NEt_2Ph and $B(C_6F_5)_3$, as described for other boron-aniline complexes.[17]

More accurate structural information on the species present in **I** can be obtained by a ^1H-^{13}C HSQC NMR experiment (Figure 4). The carbons of the methyl (a_1, a_2) and methylene (b_1, b_2) groups of the two -$CH_{2\text{-}b}$-$CH_{3\text{-}a}$ fragments can be assigned. The two broad methylene protons (c_1, c_2) are correlated to a broad carbon resonance at $\delta = 34.5$ ppm, suggesting the proximity of a boron atom. The aromatic resonances associated with the *ortho* (d_1, d_2), *meta* (e_1, e_2) and *para* (f_1, f_2) hydrogen atoms confirm the presence of two distinct phenyl groups in addition to the phenyl ring of the free aniline (Figure 4b). The two most deshielded carbons ($\delta = 190$ ppm) exhibit a correlation with the triplets (g_1, g_2, $\delta = 8$ ppm), supporting the presence of an H_g-C=Y group (Y = O, N). In accordance with the results obtained by ^1H-^1H COSY NMR experiments, the ^1H-^{13}C HSQC NMR experiment confirms the existence of two different -$CH_{2\text{-}b}$-$CH_{3\text{-}a}$, phenyl and H_g-(C=Y)-$CH_{2\text{-}c}$-X fragments.

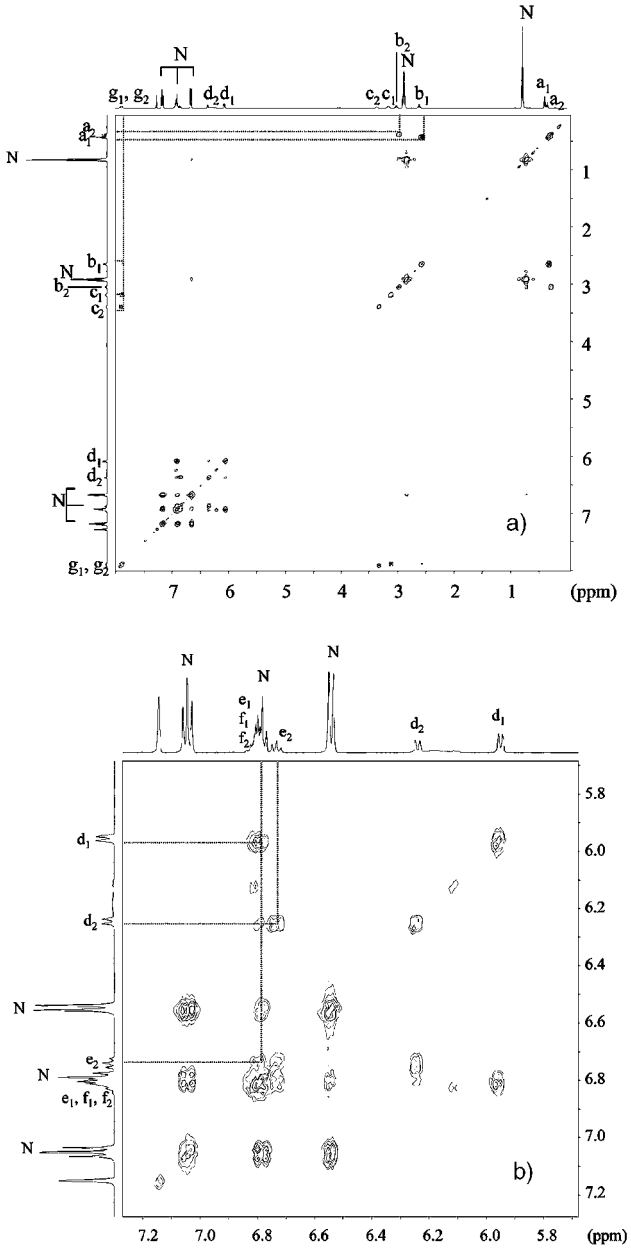

Figure 2. a) ^1H-^1H COSY NMR spectrum (500 MHz, 25 °C, C_6D_6) of solution **I**; b) expanded [$\delta = 7.2-5.7$ ppm] region

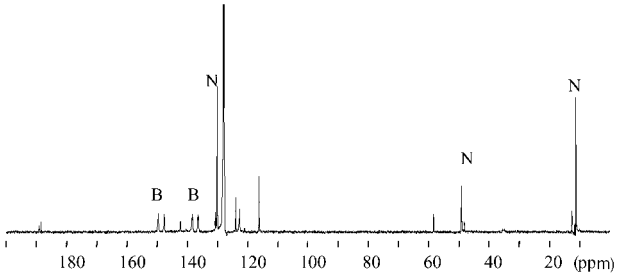

Figure 3. ^{13}C NMR spectrum (500 MHz, 25 °C, C_6D_6) of solution **I**; N and B indicate peaks due to free Et_2NPh and $B(C_6F_5)_3$, respectively

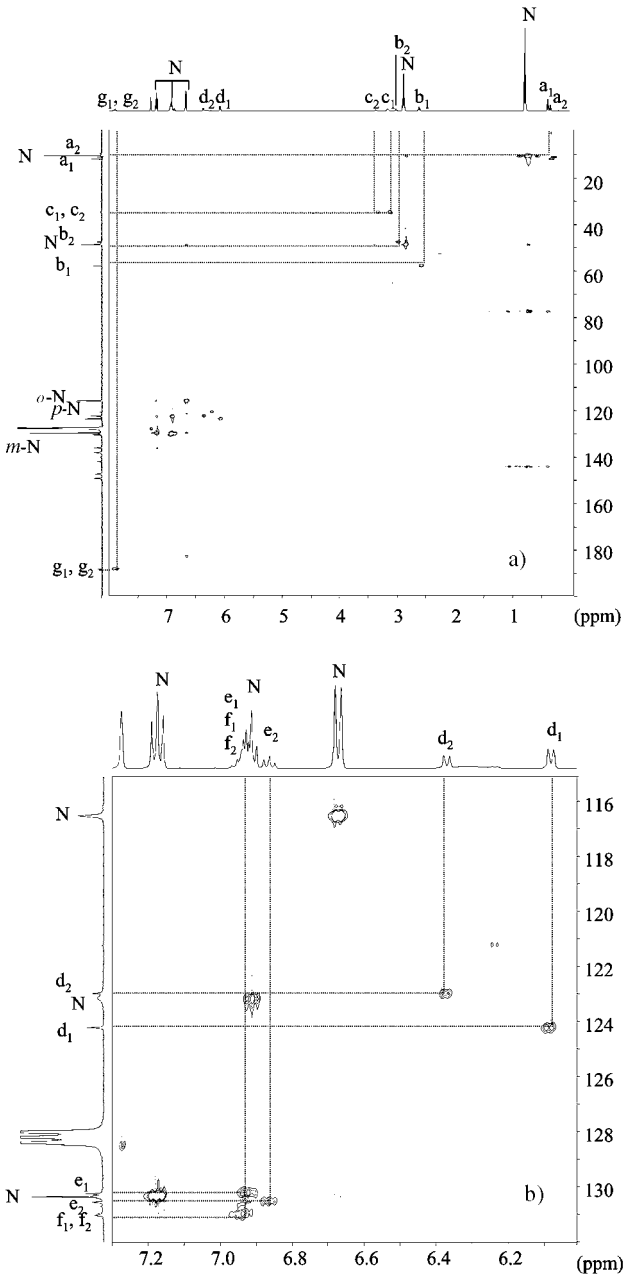

Figure 4. a) ^{1}H-^{13}C HSQC NMR spectrum (500 MHz, 25 °C, C_6D_6) of solution **I**; b) expanded [δ = 7.3−6.0/δ = 132−115 ppm] region

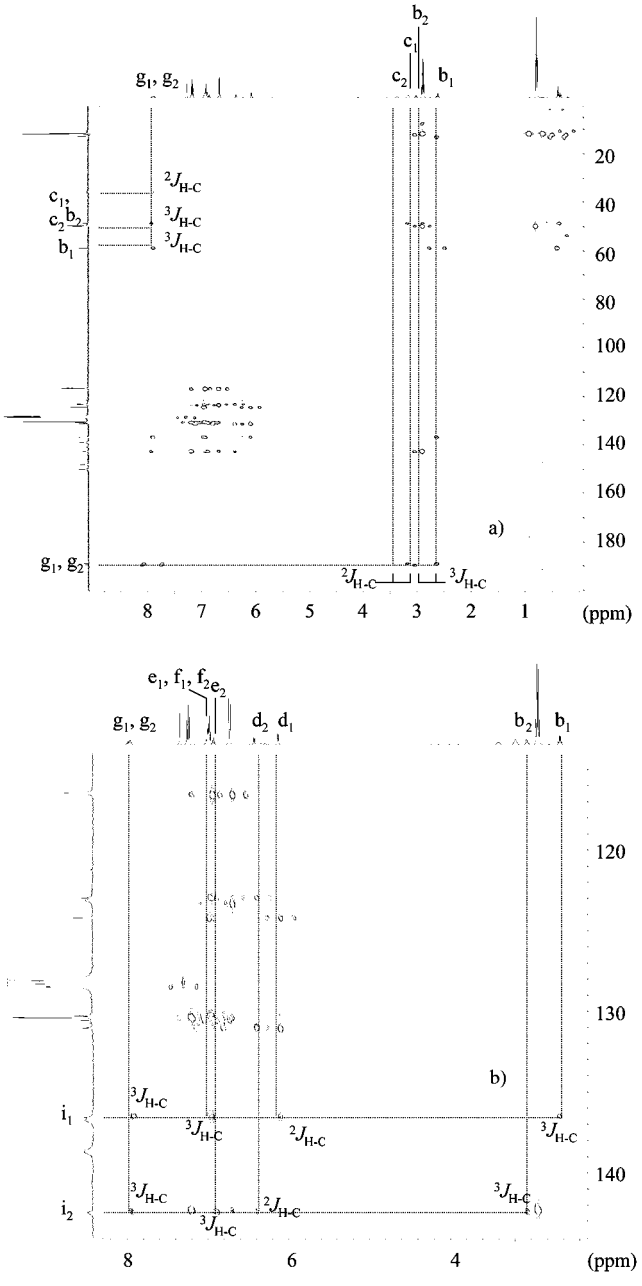

Figure 5. a) ^{1}H-^{13}C HMBC NMR spectrum (500 MHz, 25 °C, C_6D_6) of solution **I**; b) expanded [δ = 8.3−2.3/δ = 144 to −114 ppm] region

The ^{1}H-^{13}C HMBC NMR experiments on **I** (Figure 5) allow the *ipso* carbons of the two distinct phenyl rings to be assigned (Figure 5b), and show their couplings with the methylene protons (b_1, b_2 − $^{3}J_{C\text{-}H}$), with the deshielded triplets (g_1, g_2 − $^{3}J_{C\text{-}H}$), and with aromatic *meta* (e_1, e_2 − $^{3}J_{C\text{-}H}$) and *ortho* (d_1, d_2 − $^{2}J_{C\text{-}H}$) hydrogens. The coupling between the deshielded triplets (g_1, g_2 − $^{3}J_{C\text{-}H}$) and methylene protons (b_1, b_2 − $^{3}J_{C\text{-}H}$) and, (c_1, c_2 − $^{2}J_{C\text{-}H}$) is also evident (Figure 5a).

The ^{11}B NMR spectrum of **I** on a 300 MHz spectrometer shows two sharp peaks at δ = −13.7 and −23.6 ppm, characteristic of tetracoordinate anionic boron centers[22] and a broad resonance at δ = 60 ppm assigned to free $B(C_6F)_3$ [23−25] (Figure 6). No resonance characteristic of a $(C_6F_5)_3B{\cdot}NEt_2Ph$ adduct is observed in the region between 0 and −5 ppm.[22] The resonance at δ = −23.6 ppm is unambiguously assigned to $[HB(C_6F_5)_3]^-$ due to the observed ^{11}B-^{1}H coupling constant ($^{1}J_{B\text{-}H}$ = 77.5 Hz[22,26]). This assignment is consistent with the presence of a broad signal at δ = 3.9 ppm characteristic of the hydride[27] in the ^{1}H NMR spectrum of **I**. The third resonance at δ = −13.7 ppm is assigned by comparison to related

systems[8,28–30] to a $[R\text{-}B(C_6F_5)_3]^-$ fragment (where R is an alkyl group with an sp^3 carbon bound to boron). The ^{11}B NMR spectrum of **I** on a 500 MHz spectrometer shows that there are two signals at $\delta = -13.1$ (B_2) and -13.5 ppm (B_1) in an approximate B_2/B_1 ratio of 2:5 (Figure 6). This indicates the presence of two types of anionic boron compound in which the boron atoms are located in very similar environments.

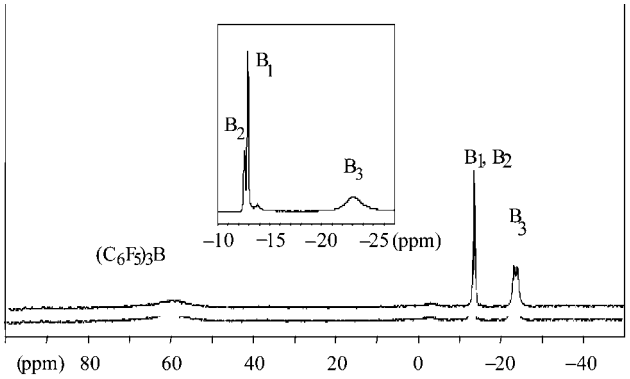

Figure 6. ^{11}B NMR spectrum (500 MHz, 25 °C, C_6D_6) of solution **I**

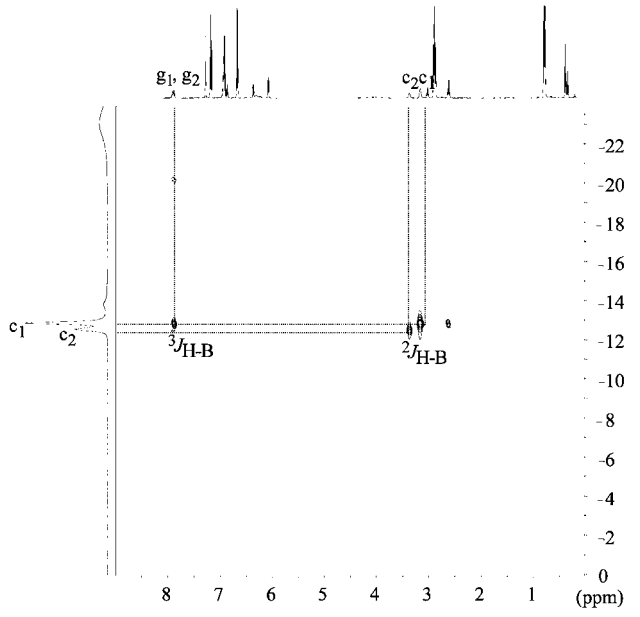

Figure 7. ^1H-^{11}B NMR HMBC NMR spectrum (500 MHz, 25 °C, C_6D_6) of solution **I**

^1H-^{11}B HMBC NMR experiments show a $^2J_{B\text{-}H}$ coupling between the $[R\text{-}B(C_6F_5)_3]^-$ boron atoms and the (c_1, c_2) protons (Figure 7). In spite of the short T_2 of the quadrupolar ^{11}B nucleus, ^1H-^{11}B HMBC experiments were attempted to confirm the linkage of the $\text{-}CH_2\text{-}B(C_6F_5)_3$. The quality of the 2D matrix was surprisingly good and allowed us to attribute the broad resonances c_1 and c_2 in the ^1H ($\delta c_1 = 3.15$, $\delta c_2 = 3.45$ ppm) and ^{13}C NMR spectra ($\delta c_1, c_2 = 34.5$ ppm) to be attributed to the $\text{-}CH_2\text{-}B(C_6F_5)_3$ moieties.[30–32] A $^3J_{B\text{-}H}$ coupling of the $[\text{-}CH_2\text{-}B(C_6F_5)_3]^-$ boron atoms with the (g_1, g_2) protons is an additional proof for the structure of $H\text{-}(C{=}X)\text{-}CH_2\text{-}B(C_6F_5)_3$. Furthermore, a third coupling is observed between the major boron resonance B_1 and the methylene protons b_1, while there is no correlation between B_2 and the methylene protons b_2.

^1H-^{15}N HMBC NMR experiments indicate that three different nitrogen resonances are present at $\delta = 74$, 209.5 and 210.2 ppm (Figure 8 and 9). The major peak at $\delta = 74$ ppm (N) corresponds to the nitrogen atom of NEt_2Ph. The resonances at $\delta = 209.5$ for (N_1) and $\delta = 210.2$ ppm (N_2) are characteristic of an sp^2-hybridized nitrogen atom, such as an iminium center.[22] Correlations are observed between these peaks and the methyl (a_1, a_2 – $^3J_{N\text{-}H}$), the methylene (b_1, b_2 – $^2J_{N\text{-}H}$; c_1, c_2 – $^3J_{N\text{-}H}$), the *ortho* (d_1, d_2 – $^3J_{N\text{-}H}$) and imino (g_1, g_2 – $^2J_{N\text{-}H}$) protons, indicating the existence of two types of iminium center in slightly different environments, as observed in the ^{11}B NMR spectrum.

The ^{19}F NMR spectrum of **I** reveals a complex pattern of non-equivalent pentafluorophenyl groups at ambient temperature, three types of pentafluorophenyl ligand (**a**, **b**, **c**) bound to anionic boron centers are present[32] (Table 1). No pentafluorobenzene is formed in solution.

Thus, multinuclear NMR studies indicate that in solutions containing equimolar amounts of $B(C_6F_5)_3 + NEt_2Ph$ (**I**) at ambient temperature, several species are present: $B(C_6F_5)_3$, NEt_2Ph, $[HB(C_6F_5)_3]^-(HNEt_2Ph)^+$ and two new species (A_1, A_2 in Scheme 1) in a constant A_1/A_2 ratio of 3:2. In none of the experiments is formation of the $(C_6F_5)_3B{\cdot}NEt_2Ph$ adduct observed. The zwitterionic stereoisomeric species A_1 (*E* isomer) and A_2 (*Z* isomer) come closest to explaining the 2D NMR experimental data.

In the ^1H-^{11}B HMBC NMR spectra, the long range coupling between the boron resonance B_1 and the methylene protons b_1 is only possible for the *trans*-isomer A_1 (*E* isomer) in a particular conformation. According to the relative intensities of the peaks associated with A_1 in the ^1H, ^{11}B and ^{15}N NMR spectra, this result definitively proves that A_1 (*E* isomer) is the major species, as expected on the basis of steric considerations.

Multinuclear NMR studies performed on **I** at ambient temperature enable the other boron species, besides unchanged $B(C_6F_5)_3$, to be identified as $[HB(C_6F_5)_3]^-$ and the two stereoisomers A_1 and A_2 of $[RCH_2\text{-}B(C_6F_5)_3]^-$. The formation of the $[HB(C_6F_5)_3]^-$ anion can be explained by a reversible abstraction of the α-hydrogen from NEt_2Ph by $B(C_6F_5)_3$ affording the iminium cations (B) (reaction 1 in Scheme 2). This hydride abstraction by $B(C_6F_5)_3$ could be facilitated by conjugation with the lone pair of the nitrogen atom, and has already been reported for organic substrates[33] and for organometallic complexes.[26,27] However, there is no evidence for the presence of the iminium cations (B) in solution. It is likely that, in the presence of NEt_2Ph, the iminium salt (B) initially formed is rapidly converted into enamine (C) and an anilinium salt (reaction 2, Scheme 2). The conversion of tertiary iminium salts into enamines in presence of a base is well documented.[34] At this stage, an electrophilic addition of $B(C_6F_5)_3$ to the enamine intermediate yields the zwitterions (A_1, A_2) (reaction

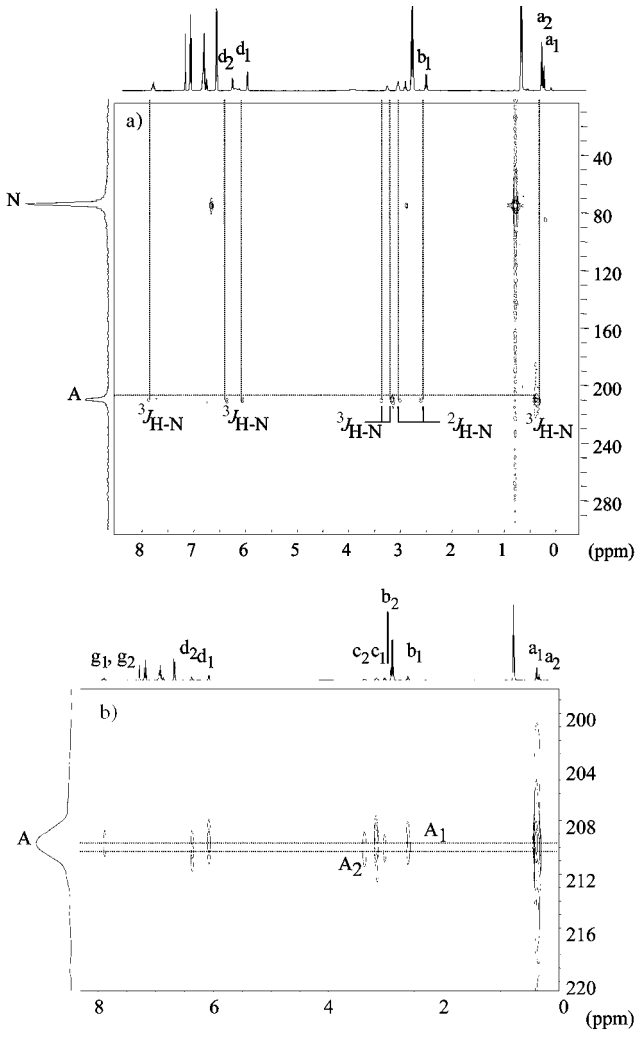

Figure 8. a) ^1H-^{15}N NMR HMBC NMR spectrum (500 MHz, 25 °C, C_6D_6) of solution **I**; b) expanded [δ = 199−220 ppm] region

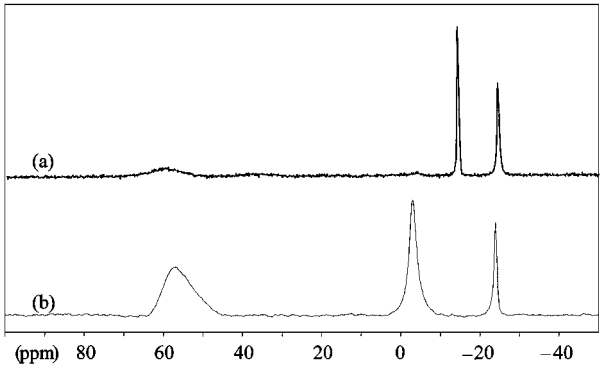

Figure 9. ^{11}B NMR spectrum (300 MHz, 25 °C, C_6D_6) of: a) solution **I**; b) solution $\mathbf{I_{Me}}$

3, Scheme 2), as already reported for other Lewis acids such as $GeCl_4$, $SnCl_4$,[35] and $TiCl_4$.[36,37]

The involvement of the iminium ion (B) as an intermediate is demonstrated by using dimethylaniline as a base instead of diethylaniline. The reaction of equimolar amounts of $B(C_6F_5)_3$ and NMe_2Ph in concentrated [D_6]benzene solution was monitored by ^{11}B NMR spectroscopy at room temperature. The spectra of the pale pink solution of $\mathbf{I_{Me}}$ show the presence of a sharp peak at δ = −24 ppm characteristic of the $[HB(C_6F_5)_3]^-$ anion. This indicates the formation of the iminium (B_{Me}) by α-hydrogen abstraction with $B(C_6F_5)_3$ (reaction 5, Scheme 3). It should be noted that there is also a peak at δ = −3 ppm which is assigned to the Lewis acid-base complex $(C_6F_5)_3B{\cdot}NMe_2Ph$ (**V**). The fact that no peak characteristic of zwitterions A_1 and A_2 is present at δ = −13 ppm proves that electrophilic addition of $B(C_6F_5)_3$ does not proceed for dimethylaniline. This can be rationally explained by the fact that formation of an enamine intermediate is not possible in the case of dimethylaniline. Thus, the reaction pathway is stopped at the stage of the formation of the ternary iminium salt (B_{Me}).

The overall equilibria observed in solutions **I** and $\mathbf{I_{Me}}$ are summarized in reaction 4 (Scheme 2) and reaction 6 (Scheme 3) respectively. It should be noted that in the ^{11}B NMR spectrum of **I** (Figure 9) the intensity ratio of 1:0.9 between the two sharp peaks at δ = −13.7 and −23.6 ppm, that is $[CH_2\text{-}B(C_6F_5)_3]^-/[HB(C_6F_5)_3]^-$, is in good agreement with the stoichiometry expected from reaction 4 in Scheme 2. However, in all cases, the reaction of R-OH compounds [R = H, Ph_3Si, (c-$C_5H_9)_7O_{12}Si_8$ or silanol group of silica] with [$B(C_6F_5)_3$ + NEt_2Ph] solutions leads quantitatively to the formation of $[RO\text{-}B(C_6F_5)_3]^-(HNEt_2Ph)^+$ confirming that all equilibria involved in solutions of **I** are displaced towards the ionic form $[RO\text{-}B(C_6F_5)_3]^-(HNEt_2Ph)^+$ in the presence of protic compounds.[39]

Table 1. ^{19}F NMR chemical shifts of C_6F_5 ligands in **I**

Attribution	Chemical shifts[a]			$\Delta(\delta_{m,p})$

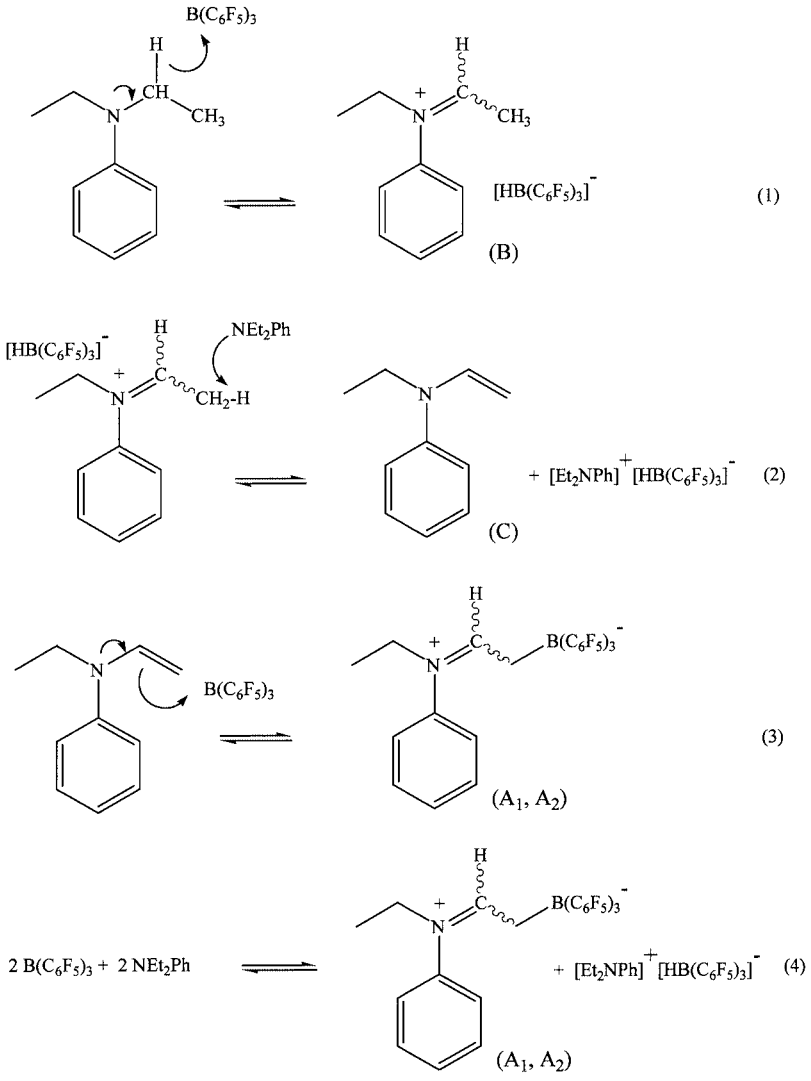
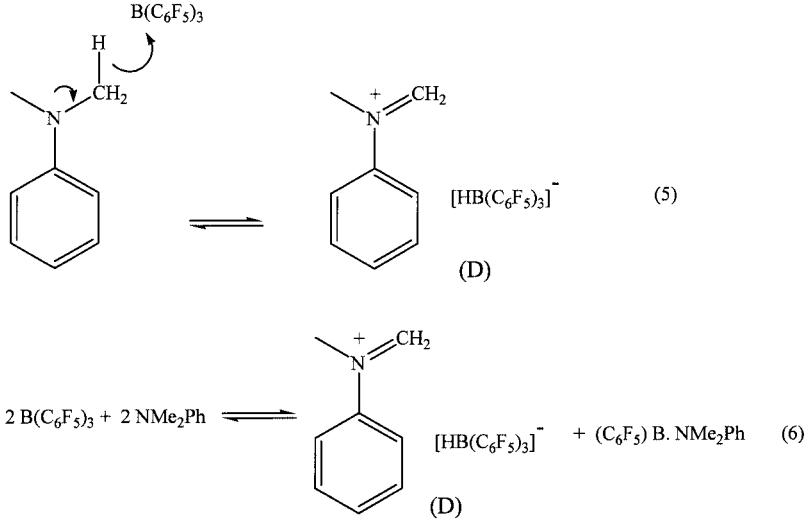


Scheme 2. Proposed mechanism to explain the formation of stereoisomers (A_1) and (A_2)



Scheme 3. Structure of the compounds of the reaction of $B(C_6F_5)_3$ and Me_2NPh, solution $\mathbf{I_{Me}}$

Conclusion

The presence of several species in equilibrium in a solution of $(C_6F_5)_3B$ and R_2NPh (1: 1) has been established by several NMR experiments. In the case of dimethylaniline, besides free $B(C_6F_5)_3$ and Me_2NPh, the 1:1 adduct $(C_6F_5)_3B{\cdot}NMe_2Ph$ and an iminium salt $[PhCH_3N{=}CH_2]^+[HB(C_6F_5)_3]^-$ have been identified. With diethylaniline, 40% of the products were unchanged $(C_6F_5)_3B$ and Et_2NPh, 30% were the iminium salt $[HB(C_6F_5)_3]^-(HNEt_2Ph)^+$, and the remaining 30% were converted into the zwitterionic stereoisomers (*E*)- and (*Z*)-$[PhEtN^+{=}CH\text{-}CH_2B^-(C_6F_5)_3]$ in a 3:2 ratio. In the presence of a protic compound this equilibrium is totally displaced towards the ionic form $[RO\text{-}B(C_6F_5)_3]^-[HNEt_2Ph]^+$.

Experimental Section

All operations were carried out under an argon atmosphere using glovebox (Jacomex or MBraun) or vacuum-line techniques. Toluene and pentane were distilled under argon from Na/K alloy, degassed and stored under argon over Na (toluene) or 3 Å molecular sieves (pentane). C_6D_6 (SDS − 99.6%) and CD_2Cl_2 (SDS − 99.6%) were degassed by three "freeze-pump-thaw" cycles and dried over freshly regenerated 3 Å molecular sieves. NEt_2Ph (Aldrich Chemicals, 98%) and NMe_2Ph (Aldrich Chemicals, 99%) were dried over KOH, distilled under vacuum and used immediately. $B(C_6F_5)_3$ (Merck Chemicals, > 97%) was dried using Me_3SiCl,[38] purified by vacuum sublimation and controlled by ^{19}F NMR spectroscopy before use. The NMR spectra were recorded with Bruker AC 200 MHz (^{19}F), AC 300 MHz (^1H, ^{13}C), DRX 300 MHz (^{11}B) and DRX 500 MHz (^1H, ^{13}C, ^{11}B, ^{15}N 2D NMR) spectrometers. Chemical shifts are reported in ppm and referenced to residual solvent resonances (C_6D_6: δ = 7.15 ppm for ^1H, δ = 128 ppm for ^{13}C; CD_2Cl_2: δ = 5.32 ppm for ^1H, δ = 53.8 ppm for ^{13}C), or external standards (^{19}F: $CFCl_3$; ^{11}B: $BF_3{\cdot}OEt_2$; ^{15}N: *N*,*N*-dimethylformamide).

2D COSY experiments were acquired with the standard Bruker COSYgp experiment and processed in absolute mode. 2D HSQC experiment were acquired with the standard Bruker inviegts experiment and processed in phases mode. 2D HMBC experiment were acquired with the standard Bruker inv4gplrnd and processed in absolute mode, as shown in Table 2.

Reactions of Equimolar Amounts of $[B(C_6F_5)_3{+}NEt_2Ph]$ (I) and $[B(C_6F_5)_3{+}NMe_2Ph]$ (I_{Me})

Preparation of I: In an NMR tube, $B(C_6F_5)_3$ (75 mg, 0.15 mmol) was dissolved in 0.4 mL of C_6D_6. NEt_2Ph (23.3 μL, 0.15 mmol) was then added with a syringe to give a pink solution after agitation.

NEt_2Ph: ^1H NMR (C_6D_6): δ = 7.17 (dd, $^3J_{H\text{-}H}$ = 7.9 Hz, 2 H, *m*-C_6H_5), 6.9 (t, $^3J_{H\text{-}H}$ = 7.2 Hz, 1 H, *p*-C_6H_5), 6.66 (d, $^3J_{H\text{-}H}$ = 8.2 Hz, 2 H, *o*-C_6H_5), 2.80 (q, $^3J_{H\text{-}H}$ = 7.1 Hz, 4 H, CH_2), 0.82 (t, $^3J_{H\text{-}H}$ = 7.1 Hz, 6 H, CH_3) ppm. ^{13}C NMR: δ = 142.4 (s, *i*-C_6H_5), 130.3 (s, *m*-C_6H_5), 123.1 (br. s, *p*-C_6H_5), 116.4 (s, *o*-C_6H_5), 49.4 (s, CH_2), 11.4 (s, CH_3) ppm. ^{15}N NMR: δ = 71 (s, NEt_2Ph) ppm.

$B(C_6F_5)_3$: ^{11}B NMR: δ = 59 (br. s, $B(C_6F_5)_3$] ppm. ^{13}C NMR: δ = 148.8 (d, $^1J_{C\text{-}F}$ = 243 Hz, *o*-C_6F_5), 141.5 (d, $^1J_{C\text{-}F}$ = 230 Hz, *p*-C_6F_5), 137.7 (d, $^1J_{C\text{-}F}$ = 247 Hz, *m*-C_6F_5) ppm. ^{19}F NMR: δ = −128.6 (br. s, 6 F, *o*-C_6F_5), −141.7 (br. s, 3 F, *p*-C_6F_5), −160.0 (br. s, 6 F, *m*-C_6F_5) ppm.

[A_1, (*E*)-isomer]: ^1H NMR (20%): δ = 7.88 (t, $^3J_{H\text{-}H}$ = 7.9 Hz, 1 H, H-C=N), 6.92 (m, *m*- and *p*-C_6H_5), 6.17 (d, $^3J_{H\text{-}H}$ = 7.2 Hz, 2 H, *o*-C_6H_5), 3.15 (br. m, 2 H, CH_2-B), 2.60 (q, $^3J_{H\text{-}H}$ = 7.25 Hz, 2 H, CH_2), 0.40 (t, $^3J_{H\text{-}H}$ = 7.2 Hz, 3 H, CH_3) ppm. ^{11}B NMR: δ = −12.9 (s, [-CH_2-$B(C_6F_5)_3]^-$) ppm. ^{13}C NMR: δ = 188.6 (s, C=N), 136.5 (s, i-C_6H_5), 131 (s, *m*-C_6H_5), 130.2 (s, *p*-C_6H_5), 124.2 (s, *o*-C_6H_5), 58.5 (s, CH_2), 34.5 (br, CH_2-B), 12.7 (s, CH_3) ppm; C_6F_5 signals not resolved. ^{15}N NMR: δ = 209.5 (s, $EtPhN^+{=}CH$-) ppm. ^{19}F NMR: δ = −132.6 (d, $^3J_{F\text{-}F}$ = 19 Hz, 6 F, *o*-C_6F_5), −158.6 (br. s, 3 F, *p*-C_6F_5), −164.8 (br. s, 6 F, *m*-C_6F_5) ppm.

[A_2, (*Z*)-isomer]: ^1H NMR (10%): δ = 7.91 (t, $^3J_{H\text{-}H}$ = 8.5 Hz, 1 H, H-C=N), 6.92 (m, *m*-C_6H_5), 6.85 (t, $^3J_{H\text{-}H}$ = 7.7 Hz, 1 H, *p*-C_6H_5), 6.36 (d, $^3J_{H\text{-}H}$ = 7.9 Hz, 2 H, *o*-C_6H_5), 3.45 (br.m, 2 H, CH_2-B), 3.10 (q, $^3J_{H\text{-}H}$ = 7.4 Hz, 2 H, CH_2), 0.35 (t, $^3J_{H\text{-}H}$ = 7.2 Hz, 3 H, CH_3) ppm. ^{11}B NMR: δ = −12.6 (s, [-CH_2-$B(C_6F_5)_3]^-$) ppm. ^{13}C NMR: δ = 189.2 (s, C=N), 142.4 (s, *i*-C_6H_5), 130.9 (s, *m*-C_6H_5), 130.5 (s, *p*-C_6H_5), 122.9 (s, *o*-C_6H_5), 48.3 (s, CH_2), 34.5 (br, CH_2-B), 11.8 (s, CH_3) ppm; C_6F_5 signals not resolved. ^{19}F NMR: δ = −132.6 (d, $^3J_{F\text{-}F}$ = 19 Hz, 6 F, *o*-C_6F_5), −158.6 (br. s, 3 F, *p*-C_6F_5), −164.8 (br. s, 6 F, *m*-C_6F_5) ppm. ^{15}N NMR: δ = 210.2 (s, $EtPhN^+{=}CH$-) ppm.

$[HB(C_6F_5)_3]^-$: ^1H NMR: δ = 3.90 (br, 1 H) ppm. ^{11}B NMR: δ = −23.6 (d, $^1J_{B\text{-}H}$ = 77.5 Hz) ppm. ^{19}F NMR: δ = −132.2 (d, $^3J_{F\text{-}F}$ = 22 Hz, 6 F, *o*-C_6F_5), −159.5 (t, $^3J_{F\text{-}F}$ = 22 Hz, 3 F, *p*-C_6F_5), −164.3 (m, 6 F, *m*-C_6F_5) ppm; δ = −133.5 (br. m, 6 F, *o*-C_6F_5), −161.2 (br. m, 3 F, *p*-C_6F_5), −165.4 (br. m, 6 F, *m*-C_6F_5) ppm.

Preparation of I_{Me}: In an NMR tube, $B(C_6F_5)_3$ (97 mg, 0.19 mmol) was dissolved in 0.4 mL of C_6D_6. NMe_2Ph (24 μL, 0.19 mmol) was then added with a syringe to give a pale pink solution.

NMe_2Ph: ^1H NMR: δ = 7.31 (dd, $^3J_{H\text{-}H}$ = 7.0 Hz, 2 H, *m*-C_6H_5), 6.88 (t, $^3J_{H\text{-}H}$ = 7.0 Hz, 1 H, *p*-C_6H_5), 6.72 (d, $^3J_{H\text{-}H}$ = 8.5 Hz, 2 H, *o*-C_6H_5), 2.62 (s, 3 H, CH_3) ppm. ^{15}N NMR: δ = 43.7 (s, NMe_2Ph) ppm.

$(C_6F_5)_3B{\cdot}NMe_2Ph$: ^1H NMR: δ = 7.17 (d, $^3J_{H\text{-}H}$ = 8.5 Hz, 2 H, *o*-C_6H_5), 6.8 (t, $^3J_{H\text{-}H}$ = 8.2 Hz, 1 H, *p*-C_6H_5), 6.67 (t, $^3J_{H\text{-}H}$ = 8.4 Hz, 2 H, *m*-C_6H_5), 2.55 (s, 6 H, CH_3) ppm. ^{11}B NMR: δ = −2.9 (s, $(C_6F_5)_3B$-NMe_2Ph) ppm. ^{15}N NMR: δ = 52.3 [s, $(C_6F_5)_3B$-NMe_2Ph] ppm. ^{19}F NMR: δ = −132.7 (d, $^3J_{F\text{-}F}$ = 20 Hz, 6 F, *o*-C_6F_5), −159.1 (t, $^3J_{F\text{-}F}$ = 20 Hz, 3 F, *p*-C_6F_5), −165.4 (m, 6 F, *m*-C_6F_5) ppm.

$[PhMe(N{=}CH_2)]^+[HB(C_6F_5)_3]^-$: ^{11}B NMR: δ = −23.9 (s, $[HB(C_6F_5)_3]^-$) ppm. ^{19}F NMR: δ = −132.1 (d, $^3J_{F\text{-}F}$ = 22 Hz, 6 F, *o*-C_6F_5), −159.7 (t, $^3J_{F\text{-}F}$ = 22 Hz, 3 F, *p*-C_6F_5), −164.4 (m, 6 F, *p*-C_6F_5); δ = −133.3 (br. m, 6 F, *o*-C_6F_5), −161.6 (br. m, 3 F, *p*-C_6F_5), −165.4 (br. m, 6 F, *m*-C_6F_5) ppm.

Acknowledgments

We thank Dr. R. Andersen, Pr. M. Ciufolini and Pr. A. Smith for fruitful discussions. We are also grateful to CNRS and ESCPE Lyon for financial support, and to the French Ministry for Education and Research for a fellowship (N. M.).

Metallation of Unactivated Methyl Groups − Platinum(II) Derivatives with 6-Alkyl-2,2′-bipyridines

Antonio Zucca,*[a] Sergio Stoccoro,[a] Maria Agostina Cinellu,[a] Giovanni Minghetti,[a] Mario Manassero,[b] and Mirella Sansoni[b]

Keywords: Platinum / N ligands / Cyclometallation

The reaction of $K_2[PtCl_4]$ with three 6-alkyl-2,2′-bipyridines HL, ($N_2C_{10}H_7R$; R = CH_2Me, HL^{et}; $CHMe_2$, HL^{ip}; CH_2CMe_3, HL^{np}) affords five- and six-membered cyclometallated complexes [Pt(L)Cl] where L is a terdentate *N,N,C* anionic ligand which originates from HL through direct activation of a C(sp^3)–H bond. In the case of HL^{ip}, metallation generates a stereogenic carbon atom β to the metal. Complex **5**, [$Pt(L^{np})Cl$], having an uncommon six-membered ring containing a Pt–C(sp^3) bond, was studied in depth in solution, by means of 1- and 2- dimensional NMR spectroscopy, and in the solid state by X-ray diffraction. Differences are observed in the behaviour of these ligands: thus with HL^{et} an adduct, [$Pt(HL^{et})Cl_2$], was also isolated and its structure was determined by X-ray diffraction. In the metallated species, the fourth ligand, Cl, can easily be substituted by neutral or anionic ligands (CO, PPh_3, CN^-). The metallated species react with potentially bidentate ligands L′–L′′ [$Ph_2PCH_2PPh_2$ (dppm), $Ph_2P(CH_2)_2PPh_2$ (dppe), $Ph_2P(CH_2)_2AsPh_2$ (dppae)] to give, with different Pt:L ratios, mononuclear [Pt(L)(L′–L′′)]$^+$ or dinuclear [(L)Pt(μ–L′–L′′)Pt(L)]$^{++}$ cationic species. In the second case an uncommon unsupported L′–L′′ bridge is present. The cyclometallated species are stable in air and moisture, and the *N,N,C* system is rather robust.

Introduction

Cyclometallated compounds, in particular those derived from nitrogen ligands, have attracted considerable interest as a consequence of the wide range of their potential applications in many areas including organic synthesis,[1] homogeneous catalysis[2] (even asymmetric), photochemistry[3], and the design of new metallomesogens[4], sensors[5] and antitumour drugs.[6]

In recent years, in addition to the classical bidentate N,C systems, attention has also been devoted towards potentially terdentate-bound anionic ligands able to coordinate through different sets of donor atoms (e.g. *N,N,C*,[7] *N,C,N*,[8] *C,N,C*[9]). The sequence of coordinating atoms, the size of the metallacycles and the type of metallated carbon atom can be tuned to obtain complexes with different properties.

Although cyclometallation reactions, especially those concerning metals of the platinum group, have been extensively studied, the factors that control the process are not completely understood. Whereas for Pd^{II} the most common mechanism is electrophilic, in the case of Pt^{II} both electrophilic and nucleophilic behaviour has been ascertained.[10] The reaction, besides the obvious electronic and steric factors, seems to be affected by a number of factors: we have shown in previous papers that even subtle differences in the substituents of the ligands can drive the cyclometallation reactions towards unpredictable results.[7a]

In general, nitrogen donor ligands show a strong tendency to form five-membered rings, although a few six-membered rings are known. The great majority of papers in this field concern C(sp^2)−H bond activation, in spite of the present interest in activation of alkyl groups. Only few cyclometallated species containing nitrogen ligands and C(sp^3)−Pt bonds are known and, to the best of our knowledge, only two six-membered cyclometallated species with a Pt−C(sp^3) bond have been described,[11] but none of them derives from a true C−H activation.

Here we describe a series of platinum(II) complexes containing terdentate bound anionic ligands with an *N,N,C*(sp^3) sequence of donor atoms obtained by the direct activation of a methyl group of 6-alkyl-2,2′-bipyridines. The substituents on the bipyridines have been chosen in order to compare five and six-membered rings. In addition, one of the ligands (HL^{ip}, $N_2C_{10}H_7CHMe_2$–6), is potentially able to give a stereogenic carbon atom directly by metallation.

Depending on the ligand and the reaction conditions both adducts [$Pt(HL)Cl_2$] and five- or six-membered cyclo-

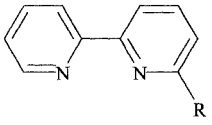
metallated species, [Pt(L)Cl], can be obtained from $K_2[PtCl_4]$. The chloride ligand in the metallated species has been found to be rather substitution labile, so that its replacement by anionic or neutral ligands as CN^-, CO or PPh_3 has been studied. We also report on the reaction with the potentially chelating ligands L′−L′′ [$Ph_2PCH_2PPh_2$ (dppm), $Ph_2P(CH_2)_2PPh_2$ (dppe), $Ph_2P(CH_2)_2AsPh_2$ (dppae)] with 1:1 and 2:1 Pt/L′−L′′ molar ratios.

The behaviour of $[PtCl_4]^{2-}$ is compared with that of $[PdCl_4]^{2-}$, which is previously described.[7a]

Results and Discussion

The ligands 6-ethyl-2,2′-bipyridine (HL^{et}), 6-isopropyl-2,2′-bipyridine (HL^{ip}) and 6-neopentyl-2,2′-bipyridine (HL^{np}) were obtained as previously described.[12]



R	
CH_2CH_3	HL^{et}
$CH(CH_3)_2$	HL^{ip}
$CH_2C(CH_3)_3$	HL^{np}

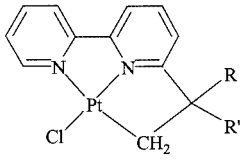
The activation of one C(sp^3)−H bond was achieved with HL^{ip} and HL^{np}, in high yields (ca. 90%), by reacting the ligand with $K_2[PtCl_4]$ in aqueous HCl under refluxing conditions. In the case of HL^{et} the metallation, possibly owing to the presence of only one methyl group, is more difficult and a mixture of the metallated complex [Pt(L^{et})Cl] (**2**) and the adduct [Pt(HL^{et})Cl_2] (**1**), is obtained. We recently reported[7a] that the analogous reactions of these ligands with $Na_2[PdCl_4]$ give only the adducts [Pd(HL)Cl_2]: C−H activation however can be easily obtained from [Pd($OAc)_2$]. A peculiar behaviour is observed with a forth ligand HL^{tb} (R = $C(CH_3)_3$]: activation of a methyl group by reaction with $[PdCl_4]^{2-}$ occurs even at room temperature, whereas refluxing conditions are needed with $[PtCl_4]^{2-}$.

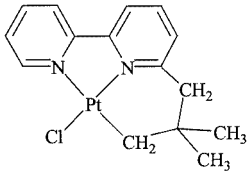
The adduct [Pt(HL^{et})Cl_2], **1**, can also be synthesised from *cis*-[Pt($DMSO)_2Cl_2$] (see the Exp. Sect.) in fairly good yields. The ^{1}H NMR spectrum (see Table 1) shows all the expected resonances: in particular the 6′-H and the CH_2 protons are strongly deshielded with respect to the free ligand ($\Delta\delta$ = 0.95 and 0.83 ppm, respectively) as is often observed when a chlorine atom is coordinated in their proximity. In addition the 6′-H is strongly coupled to platinum ($^3J_{Pt\text{-}H}$ = 40 Hz), providing evidence for the coordination of the nitrogen atom of the unsubstituted pyridine ring. Complex **1** was characterised in the solid state by X-ray diffraction.

The structure consists of the packing of [Pt(HL^{et})Cl_2] molecules with no unusual van der Waals contacts. There are two crystallographically independent molecules, A and B, in the asymmetric unit. Selected bond lengths and angles for the two molecules are reported in Table 4. An ORTEP view of molecule A is shown in Figure 1. The platinum atom displays a square-planar coordination with a slight square-pyramidal distortion. The displacement of the metal atom from the best plane of atoms Cl(1), Cl(2), N(1), and N(2) is 0.090(1) Å in molecule A and 0.111(1) Å in molecule B. Corresponding bond lengths and angles in the two molecules are all very similar (see Table 4). The Pt−Cl(1) and Pt−Cl(2) distances, (average 2.298 and 2.284 Å, respectively) are both in good agreement with the Pt−Cl bond length, 2.299(2) Å, found in [PtCl(Me)(HL^{et})], compound **19**.[13] The Pt−N(2) distance, average 2.050 Å, is longer than the Pt−N(1) one, average 1.996 Å, and the Cl(1)−Pt−N(2) angle, average 100.5°, is much larger than the Cl(2)−Pt−N(1) angle, average 92.7°. Both effects are probably due to the steric hindrance of the ethyl substituent on atom C(10). An even larger Cl−Pt−N(2) angle, 103.1(1)°, had been found in **19**. It must be observed that in compound **19** a clear intramolecular hydrogen bond was found between a CH_2 hydrogen atom and the Cl ligand (Cl···H 2.28 Å, C(11)−H···Cl angle 160.4°, see ref.[13]). There is no such hydrogen bond in either of the two present independent molecules, which exhibit different conformations of the ethyl substituent, with a shortest Cl(1)···H distance of 2.52 Å and a C(11)−H···Cl(1) angle of 126.6° in molecule B.

Metallated Compounds

From $K_2[PtCl_4]$ the metallated compounds [Pt(L^{ip})Cl] (**3**) and [Pt(L^{np})Cl] (**5**) have been obtained in pure form, whereas isolation of complex **2** requires separation from adduct **1** by column chromatography. The synthesis of complex **4** has been previously reported.[7b]





2 R = R′ = H

3 R = H, R′ = CH_3

4 R = R′ = CH_3

5

Metallation entails a C(sp^3)−H activation to give a five-membered cycle in the case of compounds **2**, **3** and **4**, and a less common six-membered ring in the case of complex **5.** To the best of our knowledge this is the first six-membered cyclometallated species of platinum(II) with nitrogen donors originating directly from an unactivated C(sp^3)−H bond: two precedent reports involved a benzylic C−H bond[11a] and an acidic C−H group in the presence of alkali.[11b]

The metallated species were fully characterised by analytical and spectroscopic methods. In particular NMR spectroscopy (^{1}H and ^{13}C{^{1}H}) gives evidence for a methylenic

[a] Room temperature, solvent $CDCl_3$, chemical shifts in ppm from internal $SiMe_4$, coupling constants in, $J_{Pt,H}$ in square brackets, $J_{P,H}$ in braces; n.r. = not resolved. [b] Solvent: CD_2Cl_2. [c] In all the phosphane complexes the 6′-H is strongly shielded. [d] Complex pattern from δ = 1.18 to 2.84 ppm, due CH_2-Pt, CH_2 (dppe), CH_2(bipy), 8 H.

group strongly coupled to the metal ($^2J_{Pt,H}$ = 80−90, $^1J_{Pt,C}$ = 668−743 Hz, see Table 1 and 2).

In complexes **2−5** the signals of the 6′-H protons are strongly deshielded and coupled to the metal ($^3J_{Pt,H}$ = ca. 10 Hz). In the series of palladium(II) and platinum(II) *N,N,C* cyclometallated compounds derived from 6-substituted 2,2′-bipyridines[7a−7g] (see Scheme 1) the chemical shifts of 6′-H appear to be strongly dependent on the nature of the metal and of the fourth ligand as well as on the size of the metallated cycle.

Coordinated halides exert a strong deshielding effect. At variance, the chemical shifts are not remarkably affected by the nature of the carbon atom, $C(sp^3)$ or $C(sp^2)$, bonded to the metal.

For platinum(II) compounds, in the case of 5,5 fused rings, values of ca. δ = 9.20 ppm are typical, whereas for 5,6 fused rings more deshielded resonances (ca. 9.60 ppm) are usually observed. In the analogous palladium species the same trend is observed, but all the signals are less deshielded (ca. 0.4 ppm) than in the corresponding platinum

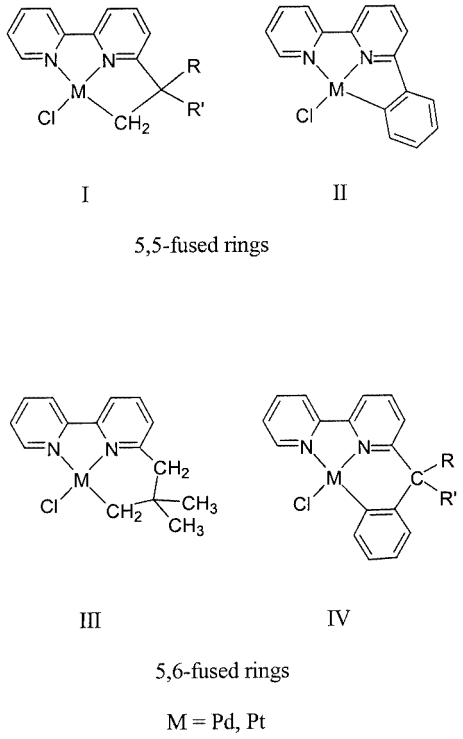

Scheme 1

complexes. Similar trends have also been recently observed for analogous gold(III) cationic species $[Au(N,N,C)Cl]^+$ [7g] for which, however, less experimental data are available.

The $^{13}C\{^1H\}$ spectra of **2**−**5** deserve comments: the chemical shifts of the CH_2−Pt resonances depend mainly on the degree of substitution on the carbon β to the metal, irrespective of the cycle [e.g. Pt−CH_2−$C(CH_3)_2$−, ca. 18−19 ppm (**4** and **5**), Pt−CH_2−$CH(CH_3)$−, ca. δ = 10 ppm (**3**), and Pt−CH_2−CH_2-, −1.2 ppm (**2**)] reflecting only electronic effects. At variance, the $^1J_{Pt,C}$ values are higher for the five-membered rings (ca 740 Hz, **2**−**4**) than for the six-membered one (668 Hz in **5**).

In the analogous palladium compounds the CH_2−Pd resonances are shifted downfield (e.g. Pd(L^{tb})Cl, δ = 32.8 ppm; Pd(L^{np})Cl, δ = 34.9 ppm).[7a]

In the case of compound **5**, taking into account the rarity of six-membered cyclometallated rings containing C(sp^3)−Pt bonds, complete assignment of ^1H and ^{13}C signals was accomplished by 2D NMR studies (COSY and HETCOR experiments, see experimental). The coupling constants $J_{Pt,C}$ in the inner pyridine ring are much larger than those of the outer one [e.g.: ^3J(Pt−C(3) = 33 Hz, ^3J(Pt−C(3′)] not observed, ^4J(Pt−C(4) = 45 Hz, ^4J(Pt−C(4′) not observed] indicating that the pyridine involved in the cyclometallation is more tightly bonded than the other one, in agreement with the X-ray data.

The crystal structure of **5**·$CHCl_3$ consists of the packing of [Pt(L^{np})Cl] and $CHCl_3$ molecules in a 1:1 molar ratio with no unusual van der Waals contacts. Selected bond parameters are listed in Table 5. An ORTEP view of **5** is shown in Figure 2. The Pt atom is in a square-planar coordination with a very slight square-pyramidal distortion. It is displaced by only 0.026(1) Å from the best plane of atoms Cl(1), N(1), N(2), and C(13). A comparison can be made between compound **5** and the corresponding Pd derivative,

[PdL^{np}Cl], compound **20**.[7a] The Pt−Cl, Pt−N(1), and Pt−N(2) distances, 2.309(1), 2.116(3), and 2.020(3) Å, respectively, are slightly shorter than the corresponding ones involving palladium, 2.314(1), 2.138(2), and 2.046(2) Å, respectively. This is in keeping with the recent observation that platinum is slightly smaller than palladium.[7a,14] On the contrary, the Pt−C(13) bond, 2.040(4) Å, is slightly longer than the Pd−C(13) one, 2.022(3) Å. As pointed out in ref.[7a], this can be due to the different packing forces in the two nonisomorphous crystals. The conformation of the Pd−N(2)−C(10)−C(11)−C(12)−C(13) six-membered ring is irregular, as previously found in **20**, ref.[7a]. Atoms Pt, N(2), C(10), and C(13) are approximately planar (maximum distances from their best plane are +0.033(3) Å for N(2) and −0.023(4) Å for C(10)], with atoms C(11) and C(12) lying at −0.336(4) and +0.471(4) Å from this best plane.

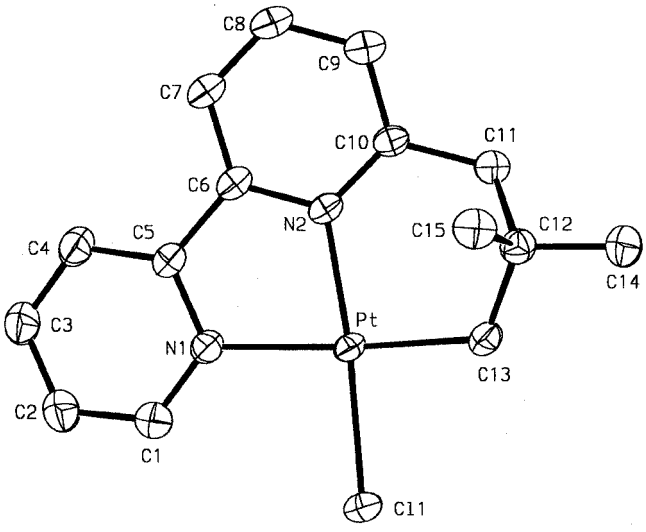

Figure 2. ORTEP view of compound **5**. Thermal ellipsoids as in Figure 1.

In the case of compound **3**, the activation of the methyl group directly generates a stereogenic carbon atom β to the metal atom, a result still rare,[7a] even if not unprecedented. In agreement, the ^1H NMR spectrum shows two diastereotopic hydrogens α to the metal atom (δ_A = 2.66, dd; δ_B = 3.07, dd).

Reactivity of the Metallated Species

In contrast with the behaviour of the analogous cyclometallated species containing Pt−C(sp^2) bonds,[7d] displacement of the chloride ligand in complexes **2**−**5** is easily accomplished in mild conditions by both neutral (e.g. CO, PPh_3) and anionic ligands (e.g. CN^-)

Derivatives **7**−**12** were obtained in good yields in the presence of $[BF_4]^-$ and characterised by analytical and spectroscopic methods. In particular the carbonyl derivatives [Pt(L)CO][BF_4], **7** and **8**, show strong IR absorptions in the region around 2100 cm^{-1} [$\tilde{\nu}_{max}$ (cm^{-1}) = 2107, **7**; 2100, **8**)].

In the ^1H and $^{13}C\{^1H\}$ NMR spectra of **7**, the $^2J_{Pt\text{-}H}$ and $^1J_{Pt\text{-}C}$ values relevant to the metallated methylene group are small ($J_{Pt,H}$ = 66 and 52 Hz; $J_{Pt\text{-}C}$ = 567 Hz) in comparison with those of the chloride species **5** (J = 89, 79 and 736 Hz, respectively), as previously observed when a strong π acceptor ligand is *cis* to the metal−carbon bond.[7b]

Compounds **9−11**, $[Pt(L)(PPh_3)][BF_4]$, can be obtained both with a Pt/P 1:1 or 1:2 molar ratio, showing that the terdentate *N,N,C* system is rather robust. The ^{31}P NMR spectra (see Table 3) are in agreement with a phosphorus *trans* to a nitrogen atom: the $^1J_{Pt,P}$ values in the five-membered compounds **9** and **10**, as well as in $[Pt(L^{tb})(PPh_3)][BF_4]$,[7b] are in the range 4000−4100 Hz, whereas in the six-membered species **11** a greater value, 4453 Hz is found. Similar values (4400−4471 Hz) have been observed in the case of the *N,N,C*(sp^2) six-membered compounds derived from substituted benzylbipyridines[7d] (see Scheme 1, compounds of type IV, M = Pt).

The reactivity of compound **5** with the potentially bidentate ligands L′−L′′ ($Ph_2P(CH_2)PPh_2$, dppm, $Ph_2P(CH_2)_2PPh_2$, dppe, and $Ph_2P(CH_2)_2AsPh_2$, dppae) was studied with the aim of establishing whether square-planar (mono- or dinuclear) or five-coordinated complexes were formed.

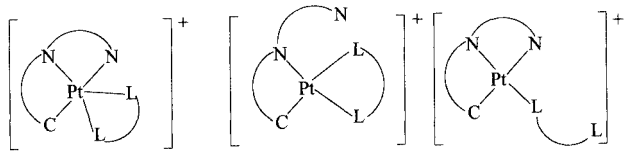
The reaction was investigated both with a 1:1 and a 2:1 Pt/L′−L′′ molar ratio: in the first case mononuclear cationic species of the general formula $[Pt(L)(L'-L'')]^+$ were formed, whereas dinuclear species containing a not so common unsupported L′−L′′ bridging unit were isolated in the second case.

The dinuclear species $[(L)Pt(\mu\text{-}L'-L'')Pt(L)]^{2+}$, **12−15**, were characterised mainly on the basis of ^1H and $^{31}P\{^1H\}$ NMR spectroscopy. In particular the $^{31}P\{^1H\}$ NMR spectra of **12−15** deserve comments: the chemical shifts rule out a chelating behaviour of the ligands L′−L′′ and support a bridging coordination.[15] In the analysis of the ^{31}P NMR spectra, due to the presence of ^{31}P (100% natural abundance) and ^{195}Pt (33.8% natural abundance) nuclei, four isotopomers have to be considered.

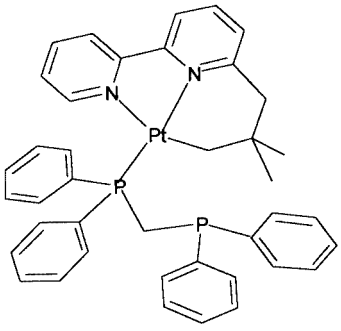
I	$Pt_A\text{-}P_A \frown P_B\text{-}Pt_B$	43.8%
II	$^{195}Pt_A\text{-}P_A \frown P_B\text{-}Pt_B$	22.4%
III	$Pt_A\text{-}P_A \frown P_B\text{-}^{195}Pt_B$	22.4%
IV	$^{195}Pt_A\text{-}P_A \frown P_B\text{-}^{195}Pt_B$	11.4%

In symmetric species, such as **12** and **14**, the ^{31}P NMR spectra should consist of a singlet due to isotopomer I located in the centre of a satellite system. If the complex pattern due to IV is ignored owing to its low natural abundance, the satellite system is governed by species II−III, which in symmetric species, are equivalent. Isotopomers II and III give rise to an ABX spin system (X = ^{195}Pt) and the ^{31}P spectrum can be described as being formed by two AB subspectra.[16] Two different situations are shown by the dppm and dppe bridging systems, respectively: in the former case no $^2J_{P\text{-}P}$ has been resolved, but a $^3J_{Pt\text{-}P}$ (32 Hz) is observed, whereas in the latter case a $^3J_{P\text{-}P}$ = 52 Hz is present but the $^4J_{Pt,P}$ is negligible. The reaction with dppe has also been carried out on complex **3**, $[Pt(L^{ip})Cl]$: in this case, due to the presence of a couple of stereogenic centres two diastereomers are expected, and this is reflected by the complex pattern of the ^1H NMR spectrum,. It is also worth noting that in these dinuclear complexes the $^1J_{Pt,P}$ is very different in the six- and five-membered species ($^1J_{Pt,P}$ = 4020 Hz, **13**, and $^1J_{Pt,P}$ = 4412 Hz, **14**). Compound **15**, $[(L^{np})Pt(\mu\text{-dppae})Pt(L^{np})][BF_4]_2$, at variance with compounds **12−14**, is no longer symmetric so that resonances relevant to two different bipy units are present in the ^1H NMR spectrum (Table 1).

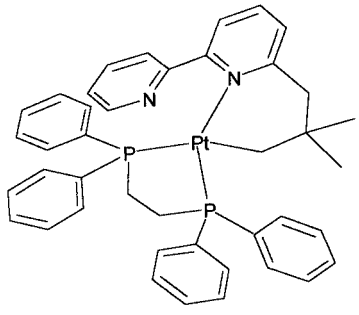
When the reaction is carried out with a Pt/L′−L′′ 1:1 molar ratio at least three different species should be considered: a pentacoordinated, (A), and two square-planar compounds (B and C).



A B C



16



17

In the case of dppm a type C species, **16**, is formed as indicated, inter alia, by the $^{31}P\{^1H\}$ NMR spectrum which shows two different signals, corresponding to a coordinated (δ = 7.69 ppm, doublet, $^1J_{Pt,P}$ = 4421, $^2J_{P,P}$ = 83 Hz), and to an uncoordinated phosphorus atom (δ = −25.9 ppm doublet, $^3J_{Pt,P}$ = 94, $^2J_{P,P}$ = 83 Hz). The ^1H NMR spectrum, as expected, is almost coincident with that of $[Pt(L^{np})(PPh_3)]^+$ (e.g. CH_2−Pt, δ = 1.60 ppm, **11**; 1.69, **16**). At variance, with dppe a type-B complex is obtained, **17**: in the $^{31}P\{^1H\}$ NMR spectrum two sets of signals, centred at δ = 44.84 ppm ($^1J_{Pt\text{-}P}$ = 1912 Hz) and 32.37 ppm, ($^1J_{Pt\text{-}P}$ = 4138 Hz), are consistent with phosphorus atoms *trans* to a carbon and a nitrogen nucleus, respectively. The ^1H NMR spectrum is complex, which is likely due to the crowded environment, all the protons of the four CH_2 groups are not equivalent anymore.

The nature of complex **17** has been confirmed by the resolution of the structure.

The crystal consists of the packing of $[Pt(L^{np})(dppe)]^+$ cations, $[BF_4]^-$ anions and CH_2Cl_2 molecules in the molar ratio 1:1:1 with no unusual van der Waals contacts. Principal bond parameters are listed in Table 6. An ORTEP view of the cation is shown in Figure 3. The Pt atom displays a square-planar coordination with a slight tetrahedral distortion, with maximum distances from the best plane of −0.084(2) and +0.1035(3) Å for atoms C(13) and N(2), respectively. The Pt−P(1) distance, 2.314(1) Å, is markedly longer than the Pt−P(2) one, 2.209(1) Å, because of the strong *trans* influence of the C(13) alkyl atom. Also the Pt−C(13), 2.115(3) Å, and Pt−N(2), 2.127(2) Å, bond lengths are elongated by the *trans* influence of atoms P(1) and P(2), respectively. The Pt−N(2)−C(10)−C(11)−C(12)−C(13) ring is in a boat conformation, with atoms N(2), C(11), C(12), and C(13) approximately planar [maximum distances from their best plane are −0.068(2) Å for N(2) and +0.074(3) Å for C(10)] and atoms Pt and C(11) lying at −1.289(1) and −0.615(3) Å from the best plane, respectively. The P(1)−Pt−N(2) angle, 100.9(1)°, is larger than the P(2)−Pt−C(13) one, 92.4(1)°, probably as a result of the steric hindrance of the noncoordinated pyridine ring. The two pyridine rings are planar and form a dihedral angle of 29.2(2)°.

Table 6. Selected bond lengths (Å) and angles (°) with e.s.d.s in parentheses for cation **17**

Pt−P(1)	2.314(1)	Pt−P(2)	2.209(1)
Pt−N(2)	2.127(2)	Pt−C(13)	2.115(3)
P(1)−Pt−P(2)	85.5(1)	P(1)−Pt−N(2)	100.9(1)
P(1)−Pt−C(13)	173.5(1)	P(2)−Pt−N(2)	173.0(1)
P(2)−Pt−C(13)	92.4(1)	N(2)−Pt−C(13)	81.6(1)

The spectroscopic evidences for **18**, $[Pt(L^{np})(dppae)][BF_4]$, indicate a monodentate P coordination of dppae, as for dppm, so that the *N,N,C* coordination environment is retained. The $^{31}P\{^1H\}$ NMR resonance at δ = 15.22 ppm, is indicative of a nonchelating behaviour of dppae and the $^1J_{Pt,P}$ = 4382 Hz is typical for a P nucleus *trans* to a pyridinic nitrogen atom. In the ^1H NMR spectrum the signals of the pyridine rings as well as those of the CH_2−Pt groups are almost superimposable to those of compounds **11** and **16**, providing further evidence for the terdentate behaviour of the *N,N,C* ligand. In crowded species such as **16**−**18**, it is reasonable to deem that either the different size or the coordinating ability of the As atom with respect to P can direct the reaction towards a different outcome.

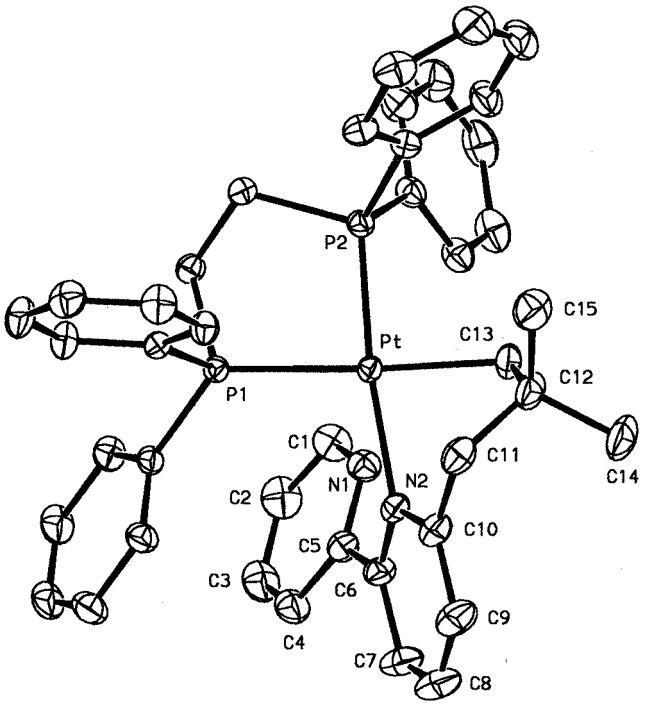


Figure 3. ORTEP view of compound **17**; thermal ellipsoids as in Figure 1

Conclusions

In this paper we have shown that organoplatinum(II) compounds containing an *N,N,C*(sp^3) terdentate ligand are readily formed from $K_2[PtCl_4]$ through a direct C(sp^3)−H bond activation of an unactivated aliphatic chain. Among the species obtained, $[Pt(L^{np})Cl]$, having a rare six-membered cyclometallated N,C(sp^3) cycle, and $[Pt(L^{ip})Cl]$, where a stereogenic centre has been directly formed through metallation, are of particular interest. The ligands studied have different reactivities: with HL^{et} the metallation can be achieved with difficulty and an adduct species, which can be regarded as an intermediate in the cyclometallation, has been isolated in the solid state and studied by X-ray diffraction. Also the structure of $[Pt(L^{np})Cl]$ has been solved, allowing comparisons to be made with the analogous Pd^{II} six-membered N,C(sp^3) metallacyle. NMR spectroscopic data seem to indicate that in the six-membered $[Pt(N,N,C)L]^{n+}$ species (L = neutral, n = 1; or anionic ligand, n = 0) the Pt−C bond is weaker and the Pt−L (L = PR_3) bond is stronger than in the five-membered ones, as indicated by $^1J_{Pt,C}$ in **2**−**5** and by $^1J_{Pt,P}$ in **9**−**18**.

In the course of the study on the reactivity of these species the chloride ligand has been shown to be rather labile whereas the *N*,*N*,*C* system is rather robust. The chloride ligand can easily be removed by anionic and neutral ligands: in the case of neutral bidentate ligands both mono- and binuclear species can be obtained. Only in one case (with dppe) has the external nitrogen atom of the terdentate *N*,*N*,*C* ligand been displaced from the metal to give a crowded $[Pt(N,C)(P,P)]^+$ compound whose structure has been resolved in the solid state.

All the new species are remarkably stable towards air and moisture, even in solution, and so all the reactions can be performed in air.

Experimental Section

The ligands HL were prepared according to literature methods.[12] $K_2[PtCl_4]$ (43.035% Pt) was obtained from Engelhard S.r.l. and $[(DMSO)_2PtCl_2]$ was synthesised as described in ref[17]. All the solvents were purified before use according to standard methods.[18] Elemental analyses were performed with a Perkin−Elmer Elemental Analyser 240B by Mr. A. Canu (Dipartimento di Chimica, Università di Sassari). Conductivities were measured with a Philips PW 9505 conductimeter. Infrared Spectra were recorded with a Perkin−Elmer 983 using Nujol mulls. ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded with a Varian VXR 300 spectrometer operating at 299.9, 75.4 and 121.4 MHz respectively, and are collected in Table 1−3.

Chemical shifts are given in ppm relative to internal TMS (^1H, ^{13}C) and external 85% H_3PO_4 (^{31}P). The 2D experiments were performed by means of standard pulse sequences.

The mass spectrometric measurements were performed on a VG 7070EQ instrument, equipped with a PDP 11−250 J data system and operating under positive ion fast atom bombardment (FAB) conditions with 3-nitrobenzyl alcohol as supporting matrix.

Preparations

$[Pt(HL^{et})Cl_2]$ (1): a) *cis*-$[(DMSO)_2PtCl_2]$ (215 mg, 0.51 mmol) was added to a solution of HL^{et} (92 mg, 0.50 mmol) in $CHCl_3$ (50 mL). The yellow solution was stirred for 36 h, then evaporated to dryness. The resulting solid was crystallised from CH_2Cl_2/Et_2O to give the analytical sample as a yellow solid. Yield 85% (191 mg). The reaction can also be carried out in other solvents (e.g. EtOH).

b) $K_2[PtCl_4]$ (43.035% Pt, 1.297 g, 2.86 mmol) was dissolved in H_2O (30 mL) and filtered. HL^{et} (523.7 mg, 2.85 mmol) and of 2 M HCl (5 mL) were added to the solution. The mixture was stirred at room temperature until the solution became colourless. The precipitate that formed was filtered, washed with H_2O, EtOH and Et_2O and recrystallised from CH_2Cl_2/Et_2O to give the analytical sample. Yield 30% (384 mg). M.p. 220 °C. $C_{12}H_{12}Cl_2N_2Pt$ (450.2): calcd. C 32.01; H 2.69; N 6.22 ; found C 31.97; H 2.65; N 6.11%. IR (Nujol): $\tilde{\nu}$ = 1600 s 1558 w, 1375 s, 335 w cm^{-1}.

$[Pt(L^{et})Cl]$ (2): HL^{et} (184 mg, 1.00 mmol) and 2 M HCl (3.5 mL) were added to an aqueous solution (30 mL) containing $K_2[PtCl_4]$ (1.00 mmol) in water. The mixture was heated in a water bath for 1 d: the precipitate that formed was filtered, washed with water, EtOH and Et_2O and recrystallised from CH_2Cl_2/Et_2O. The crude obtained (362 mg) was a mixture ca. 1:1 of compounds **1** and **2** (NMR criterion). The products were separated by column chromatography on silica gel, using a mixture of CH_2Cl_2/acetone 20:1 as eluent. Complex **2** was obtained with a 30% yield. M.p. 258−260 °C (dec). $C_{12}H_{11}ClN_2Pt$ (413.8): calcd. C 34.83, H 2.68, N 6.77; found C 35.44, H 2.80, N 6.50%. IR (Nujol): $\tilde{\nu}$ = 1597 s 1556 w, 328 s cm^{-1}. FAB^+: *m*/*z* = 413 $[M^+]$, 378 [M − Cl], 791 $[M_2-Cl]$.

$[Pt(L)Cl]$ ($L = L^{ip}$, 3; $L = L^{np}$, 5): HL (1.00 mmol) and 2 M HCl (3.0 mL) were added to an aqueous solution (30 mL) containing K_2PtCl_4 (1.00 mmol). The mixture was heated in a water bath until a colourless solution was obtained and an orange precipitate formed. The suspension was filtered off, washed with water, ethanol and diethyl ether and recrystallised from CH_2Cl_2/Et_2O

3: Yield 91% (389 mg), m.p. 245 °C. $C_{13}H_{13}ClN_2Pt$ (427.8): calcd. C 36.50, H 3.06, N 6.55; found C 36.50, H 3.05, N 6.25%. IR (Nujol): $\tilde{\nu}$ = 1596 s, 1552 w, 332 s cm^{-1}. FAB^+: *m*/*z* = 427 $[M^+]$, 392 [M − Cl], 819$[M_2-Cl]$.

5: Yield 90% (410 mg), m.p.: 233 °C (dec). $C_{15}H_{17}ClN_2Pt$ (455.8) calcd. C 39.52, H 3.76, N 6.15; found C 39.27, H 3.84, N 6.04%. IR (Nujol): $\tilde{\nu}$ = 1600 s, 1564 w, 328 s cm^{-1}. FAB^+: *m*/*z* = 455 $[M^+]$.

$[Pt(L^{ip})(CN)]$ (6): Complex **3** (175 mg, 0.41 mmol) was added to a methanolic solution (25 mL) of KCN (27 mg, 0.41 mmol) whilst stirring. The mixture was stirred for 1 day, then evaporated to dryness and the solid residue recrystallised from CH_2Cl_2/Et_2O to give the analytical sample as a yellow solid. Yield 56% (96 mg), m.p. 115 °C. $C_{14}H_{13}N_3Pt$ (418.3) calcd. C 40.19, H 3.13, N 10.04; found C 39.67, H 3.06, N 9.62%. IR (Nujol): $\tilde{\nu}$ = 2105 m, 1595 s, 1557 w cm^{-1}.

$[Pt(L)(CO)]$ $[BF_4]$ ($L = L^{ip}$, 7; $L = L^{np}$, 8): $NaBF_4$ (121 mg, 1.00 mmol) was added to a solution of the relevant [Pt(L)Cl] (0.25 mmol) in acetone (20 mL) whilst stirring and carbon monoxide, at atmospheric pressure, was bubbled through the solution. After 6 h the solvent was evaporated to dryness and the solid residue was crystallised from CH_2Cl_2/Et_2O.

7 Yield 70% (89 mg), m.p.: 235 °C. Λ_M ($5\cdot10^{-4}$ M, acetone) = 138 ohm^{-1} cm^2 mol^{-1}. $C_{14}H_{13}BF_4N_2OPt$ (507.2): calcd. C 33.16, H 2.58, N 5.52; found C 33.28, H 2.60, N 5.30%. IR (Nujol): $\tilde{\nu}$ = 2107 s 1598 s 1563 s 1050 b. FAB^+: *m*/*z* = 420 $[M^+]$, 392 [M − CO].

8: Yield: 76% (102 mg), m.p.182−184 °C. Λ_M (5.10^{-4} M, acetone) = 157 ohm^{-1} cm^2 mol^{-1}. $C_{16}H_{17}BF_4N_2OPt$ (535.2): calcd. C 35.91, H 3.20, N 5.23; found C 35.40, H 3.06, N 5.11%. IR (Nujol): $\tilde{\nu}$ = 2100 s, 1600 s, 1560 w, 1050 s cm^{-1}.

$[Pt(L)(PPh_3)][BF_4]$ ($L = L^{et}$, 9; $L = L^{ip}$, 10; $L = L^{np}$, 11): PPh_3 (0.22 mmol) and $NaBF_4$ (100 mg, 0.900 mmol) were added to a solution of the relevant [Pt(L)Cl] (0.20 mmol) in acetone (30 mL) whilst stirring. The mixture was stirred at room temperature, then evaporated to dryness and crystallised from CH_2Cl_2/Et_2O.

9: Yield 90% (131 mg), m.p. 253 °C. Λ_M ($5\cdot10^{-4}$ M acetone) = 150 ohm^{-1} cm^2 mol^{-1}. $C_{30}H_{26}BF_4N_2PPt$ (727.4): calcd. C 49.54, H 3.60, N 3.85; found C 48.93, H 3.55, N 3.71%. FAB^+: *m*/*z* = 640 $[M^+]$, 378 $[M - PPh_3]$.

10: Yield 76% (113 mg), m.p. 275 °C. Λ_M ($5\cdot10^{-4}$ M, acetone) = 130 ohm^{-1} cm^2 mol^{-1}. $C_{31}H_{28}BF_4N_2PPt$ (741.4): calcd. C 50.22, H 3.81, N 3.78; found C 50.34, H 3.91, N 3.63%. IR (Nujol): $\tilde{\nu}$ = 1598 s, 1564 w, 1102 s, 1050br, s. FAB^+: *m*/*z* = 654 $[M^+]$ 392 $[M - PPh_3]$.

11: Yield: 77% (118 mg), m.p. 263 °C. Λ_M ($5\cdot10^{-4}$ M, acetone) = 150 ohm^{-1} cm^2 mol^{-1}. $C_{33}H_{32}BF_4N_2PPt$ (769.5): calcd. C 51.51,

H 4.19, N 3.64%; found C 51.26, H 4.09, N 3.65%. IR (Nujol): $\tilde{\nu}$ = 1602 s, 1568 w, 1050 s, 540 w. FAB$^+$: *m*/*z* = 682 [M$^+$].

[Pt$_2$(L^{np})$_2$(μ-dppm)] [BF$_4$]$_2$ (12): A mixture containing **5** (42 mg, 0.092 mmol), dppm (17.4 mg, 0.046 mmol) and NaBF$_4$ (43 mg) in acetone (30 mL) was stirred at room temperature for 4 days, then evaporated to dryness and recrystallised from CH_2Cl_2/Et_2O, to give the analytical sample as a yellow solid. Yield: 59% (34 mg), m.p 168 °C (dec.). Λ_M (5 10^{-4} M, acetone) = 260 ohm^{-1} cm^2 mol^{-1}. $C_{55}H_{56}B_2F_8N_4P_2Pt_2{\cdot}0.5CH_2Cl_2$ (1441.2): calcd. C 46.25, H 3.99, N 3.89 ; found C 46.37, H 4.03, N 3.96%. IR (Nujol): $\tilde{\nu}$ = 2100 s, 1600 s, 1560 w, 1050 br s cm^{-1}. FAB$^+$: *m*/*z* = 1224 [M$^+$], 1311 [M$^+$ + BF$_4$].

[Pt$_2$(L)$_2$(μ-dppe)] [BF$_4$]$_2$ (L = L^{ip}, 13; L = L^{np}, 14): dppe (0.20 mmol) and NaBF$_4$ (150 mg) were added to a suspension of the relevant [Pt(L)Cl] (0.40 mmol) in acetone (25 mL) whilst stirring. The mixture was stirred for a few hours, then evaporated to dryness and crystallised by CH_2Cl_2/Et_2O to give the analytical sample.

13: Yield 75% (203 mg); m.p. 280 °C. Λ_M (5.10^{-4} M, acetone) = 202 ohm^{-1} cm^2 mol^{-1}. $C_{52}H_{50}B_2F_8N_4PPt_2$ (1356.7): calcd. C 46.04, H 3.71, N 4.13; found C 45.74, H 3.74, N 4.01%. (IR (Nujol): $\tilde{\nu}$ = 1598 s 1564 w, 1050 broad cm^{-1}.

14: (yellow) Yield 93% (279 mg); m.p. 184 °C (dec). Λ_M (5 10^{-4} M, acetone) = 248 ohm^{-1} cm^2 mol^{-1}. $C_{56}H_{58}B_2F_8N_4P_2Pt_2{\cdot}CH_2Cl_2$ (1497.7): calcd. C 45.71, H 4.04, N 3.74 ; found C 46.26, H 4.18, N 3.71%. IR (Nujol): $\tilde{\nu}$ = 1602 s, 1569 w, 1050 br s cm^{-1}.

[Pt$_2$(L^{np})$_2$(μ-dppae)] [BF$_4$]$_2$ (15): A mixture containing **5** (39 mg, 0.085 mmol), dppae (18.8 mg, 0.0425 mmol) and NaBF$_4$ (50 mg) in acetone (30 mL) was stirred at room temperature for 1 day, then evaporated to dryness and crystallised from CH_2Cl_2/Et_2O, to give the analytical sample as a yellow solid. Yield 80% (51 mg), m.p. 250−255 °C. $C_{56}H_{58}AsB_2F_8N_4Pt_2P{\cdot}0.5CH_2Cl_2$ (1499.2): calcd. C 45.26, H 3.97, N 3.74; found C 45.02, H 3.98, N 3.68%.

[Pt(L^{np})(L′−L′′)][BF$_4$] (L′−L′′ = dppm, 16, L′−L′′ = dppe, 17, L′−L′′ = dppae, 18): NaBF$_4$ (120 mg) was added to an acetone solution (30 mL) of **5** (103 mg, 0.25 mmol) and L′−L′′ (0.25 mmol) whilst stirring. The mixture was stirred for 4 h, then evaporated to dryness. The solid obtained was crystallised from CH_2Cl_2/Et_2O to give the analytical sample as a yellow solid.

L′−L′′ = dppm, **16**, pale-yellow. Yield: 90% (201 mg); m.p. 238−240 °C. $C_{40}H_{39}BF_4N_2P_2Pt$ (891.6): calcd. C 53.88, H 4.41, N 3.14; found C 53.40, H 4.53, N 3.07%.

L′−L′′ = dppe, **17**, yellow. Yield: 88% (199 mg). M.p. 182−5 °C (dec). Λ_M (5 10^{-4} M, acetone) = 133 ohm^{-1} cm^2 mol^{-1}. $C_{41}H_{41}BF_4N_2P_2Pt$ (905.6): calcd. C 54.38, H 4.56, N 3.09; found C 54.42, H 4.56, N 3.11%. IR (Nujol): $\tilde{\nu}$ = 1600, 1580 w, 1050 s, 540 s cm^{-1}.

Final *R* and *R′*[a]	0.030, 0.037	0.023, 0.028	0.024, 0.033
No. of variables	308	209	496
Goodness of fit[b]	1.40	0.94	1.19

[a] $R = [\Sigma(|F_o - k|F_c||)/\Sigma F_o]$, $R' = [\Sigma w(F_o - k|F_c|)^2/\Sigma w F_o^2]^{1/2}$. [b] $[\Sigma w(F_o - k|F_c|)^2/(N_o - N_v)]^{1/2}$, where $w = 1/[\sigma(F_o)]^2$, $\sigma(F_o) = [\sigma^2(F_o^2) + (0.04F_o^2)^2]^{1/2}/2F_o$, N_o is the number of observations, N_v the number of variables.

L′−L′′ = dppae, **18**, yellow. Yield: 84% (199 mg), m.p. 205−213 °C (dec). Λ_M (5 10^{-4} M, acetone) = 147 ohm^{-1}cm^{2}mol^{-1}. $C_{41}H_{41}AsBF_4N_2PPt$ (949.6): calcd. C 51.86, H 4.35, N 2.95; found C 51.47, H 4.39, N 2.97%. IR (Nujol): $\tilde{\nu}$ = 1600 s, 1560 w, 1050 br, 530 s cm^{-1}.

X-ray Data Collection and Structure Determination: Crystal data and other experimental details are summarised in Table 7. The diffraction experiment concerning **1** was carried out on an Enraf−Nonius CAD-4 diffractometer at room temperature using Mo-K_α radiation (λ = 0.71073 Å) with a graphite crystal monochromator in the incident beam. A periodic monitoring of three standard reflections did not reveal any crystal decay. The diffracted intensities were corrected for Lorentz, polarisation, and absorption effects (empirical correction).[19]

The diffraction experiments concerning **5**·$CHCl_3$ and **17**[BF_4]·CH_2Cl_2 were carried out on a Bruker SMART CCD area-detector diffractometer at room temperature using Mo-K_α radiation (λ = 0.71073 Å) with a graphite crystal monochromator in the incident beam. Cell parameters and orientation matrix were obtained from the least-squares refinement of 69 reflections (for **5**·$CHCl_3$) and of 148 reflections (for **17**[BF_4]·CH_2Cl_2) measured in three different sets of 15 frames each, in the range $3 < \theta < 23°$. At the end of data collections the first 50 frames, containing 171 and 362 reflections (for **5**·$CHCl_3$ and **17**[BF_4]·CH_2Cl_2, respectively) were recollected to have a monitoring of crystal decay, which was not observed, so that no time-decay correction was needed. The collected frames were processed with the software SAINT,[20] and an empirical absorption correction was applied (SADABS[21]) to the collected reflections. Scattering factors and anomalous dispersion corrections were taken from ref.[22].

The calculations were performed on a Pentium III PC using the Personal Structure Determination Package[23] and the physical constants tabulated therein.

The structures were solved by Patterson and Fourier methods and refined by full-matrix least-squares, minimising the function $\Sigma\omega(F_o - k|F_c|)$ (refinement on *F*). In compound **17**[BF_4]·CH_2Cl_2 three fluorine atoms of the BF_4^- anion are disordered. Anisotropic thermal factors were refined for all the non-hydrogen atoms. Hydrogen atoms were placed in their ideal positions (C−H: 0.97 Å, B: 1.10 times that of the carbon atom to which they are attached) and not refined . The final Fourier maps showed maximum residuals of 1.34(19) e/Å^3 at 0.87 Å from Pt_A (in compound **1**), 1.22(11) e/Å^3 at 0.96 Å from Pt (in compound **5**·$CHCl_3$), and of 1.18(9) e/Å^3 at 0.83 Å from Pt (in compound **17**[BF_4]·CH_2Cl_2). The atomic coordinates of the structure models have been deposited with the Cambridge Data File.

CCDC-181834 (**1**), -181835 (**5**·$CHCl_3$) and -181836 (**17**-[BF_4]·CH_2Cl_2) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Magnetochemistry, and Spectroscopy of Heterometallic Trinuclear Basic Trifluoroacetates $[Fe_2M(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ (M = Mn, Co, Ni)

Konstantin S. Gavrilenko,[a] Attila Vértes,[b] Gyorgy Vanko,[b] Laszlo F. Kiss,[c] Anthony W. Addison,*[d] Thomas Weyhermüller,[e] and Vitaly V. Pavlishchuk*[a]

Keywords: Heterometallic complexes / Carboxylate ligands / Magnetic properties / Iron / Manganese / Cobalt / Nickel / Trinuclear complexes

Three new μ_3-oxo(trifluoroacetato) complexes $[Fe_2^{III}M^{II}(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ [M = Mn (**1**), Co (**2**), Ni (**3**)] have been prepared. Compounds **1** and **2** crystallize in the monoclinic space groups *C*2/*c* [*a* = 22.002(5), *b* = 13.647(3), *c* = 24.767(4) Å, β = 98.23(3)°] and *C*2/*m* [*a* = 21.426(4), *b* = 15.100(2), *c* = 14.815(3) Å, β = 117.99(2)°], respectively. The coordination spheres of the metal ions are essentially octahedral, with the Fe–O distances [1.870(5) Å] falling in the usual range for these systems. Magnetochemical studies reveal the presence of antiferromagnetic exchange in the isosceles triangular skeletons of the polynuclear species. Application of the isotropic spin Hamiltonian $H = -2J_{FeM}[S_{Fe1}S_M + S_MS_{Fe2}] - 2J_{FeFe}[S_{Fe1}S_{Fe2}]$ gives the fitting parameters: $g_{Fe} = g_{Mn} = 2.00$, $J_{Fe\text{-}Fe} = -56.50(7)$ and $J_{Fe\text{-}Mn} = -16.23(4)$ cm^{-1} (**1**), $g_{mol} = 2.09(1)$, $J_{Fe\text{-}Fe} = -42.8(3.5)$ cm^{-1}, $J_{Fe\text{-}Co} = -17.8(1.4)$ cm^{-1} (**2**) and $g_{Fe} = 2.00$, $g_{Ni} = 2.215(2)$, $J_{Fe\text{-}Fe} = -45.60(1)$ and $J_{Fe\text{-}Ni} = -16.96(2)$ cm^{-1} (**3**). A Mössbauer investigation confirms that no electron transfer from Mn^{II} or Co^{II} to Fe^{III} occurs during the syntheses of these complexes.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Polynuclear carboxylates of the 3d transition metals have been attracting renewed interest because of their intramolecular magnetic exchange interactions[1,2] and their application as simple models of oligonuclear active sites in metalloproteins.[3−6] Particular attention is being paid to polynuclear complexes behaving as single-molecular magnets.[7−9] Trinuclear (carboxylato)(oxo) complexes are also found within supramolecular arrays of higher nuclearity, and thus are of interest as building blocks ("*molecular Legos*™") with regard to modern magnetic materials.[10,11]

The first heterometallic trinuclear acetates of tripositive iron and chromium $[X_2^{III}Z^{III}(\mu_3\text{-}O)(CH_3COO)_6(H_2O)_3]^+$ (where X_2Z = Fe_2Cr, Cr_2Fe)[12] and of mixed-valence metals $[Fe_2^{III}M^{II}(\mu_3\text{-}O)(CH_3COO)_6(H_2O)_3]$ (where M = Co, Mn, Ni, Zn)[13] were synthesized by Weiland. Difficulties in the synthesis and in the interpretation of the physicochemical properties of these heterometallic trinuclear carboxylates discouraged their extensive investigation.[14] Nonetheless, the consequences of straightforward variations in their structures, such as substitution of the acetate group by other functionalised carboxylates, appear to be fundamental in the development of new materials derived from them. This class of compounds is also active with respect to alkane activation, the catalytic activity being dependent on the carboxylate and metal identities.[15,16]

Thus, it is attractive to combine this property of superacidity and catalytic activity of trinuclear (carboxylato)(μ_3-oxo) complexes using strong acids such as trifluoroacetic acid as the ligand source. We present here the syntheses, structures and investigation of the spectroscopic and magnetic behaviour of the trinuclear heterometallic basic trifluoroacetates $[Fe_2^{III}M^{II}(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]$ (M = Mn, Co, Ni).

Results and Discussion

Synthesis

The heteronuclear basic trifluoroacetates $[Fe_2^{III}M^{II}(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ [M = Mn (**1**), Co (**2**), Ni (**3**)]

were synthesized by metathesis reaction between trifluoroacetate and the acetate trimers. The reactions proceeded smoothly in aqueous trifluoroacetic acid as the solvent without any destruction of the oxo-bridged trinuclear skeleton of the Mn, Co, or Ni complexes, despite the substantial acidity of trifluoroacetic acid [Equation (1)].

$$[Fe_2^{III}M^{II}(\mu_3\text{-}O)(CH_3COO)_6(H_2O)_3]\cdot 3H_2O + 6\,CF_3COOH \rightarrow [Fe_2^{III}M^{II}(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O + 6\,CH_3COOH + 2\,H_2O \quad (1)$$

Similar metathesis reactions have also been applied successfully to higher-nuclearity carboxylates.[17] All the trifluoroacetate compounds are readily soluble in water and a variety of organic solvents, so that growing single crystals of **1**−**3** by concentration, vapour diffusion or liquid diffusion was limited to certain solvent combinations, as reflected by the compositions of the crystals described below.

Description of Structures

Molecular structures of $[Fe_2Mn(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot 2MeNO_2\cdot H_2O$ (**1′**) and $[Fe_2Co(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot 3Me_2CO\cdot 1/2Mes$ (**2′**) were examined under cryogenic conditions (100 K). An ORTEP diagram of $[Fe_2Co(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]$ is presented in Figure 1. The principal lattice matrices of the complexes are listed in Table 6, while bond lengths and angles of **2′** are presented in Table 1.

$[Fe_2Co(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot 3Me_2CO\cdot 1/2Mes$ (Mes = 1,3,5-trimethylbenzene) (2′)

The monoclinic unit cell of the complex contains 4 molecules of the trinuclear complex, 12 molecules of acetone, and 2 molecules of mesitylene. In the crystal structure of **2′**, all the trinuclear molecules are located in parallel layers of sequence *ABAB*. Hence the molecules of the third layer occupy positions precisely above those of the first layer. The absence of interlayer trimer−trimer cohesion forces (e.g. through the lack of any intertrimer hydrogen bonds) allows the solvent molecules to readily penetrate and occupy the interlayer volume. The interstices between trinuclear species are occupied by molecules of acetone and mesitylene, the aromatic ring planes of mesitylene being perpendicular to the trimetal planes. The *R* factor (0.0857) for this structure is somewhat raised by the disorder in the trifluoromethyl groups, as well as in the mesitylene (lying on the C_2 axes) and acetone molecules (lying on the symmetry planes).

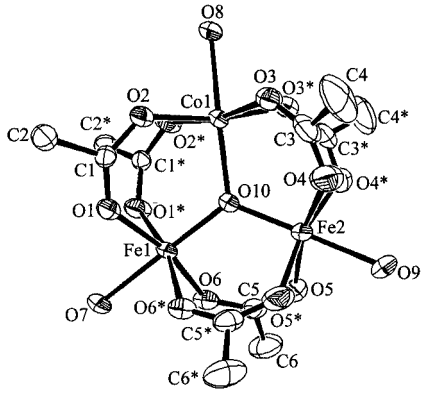

Figure 1. ORTEP plot of the structure of the skeleton of complex **1′**; thermal ellipsoids are shown at the 20% level for clarity; H and F atoms are omitted for clarity of presentation

[a] The positions of the atoms with an asterisk are defined by the appropriate symmetry operations. The standard deviations are reported in parentheses.

The molecular structure of the complex is based on an isosceles triangular Fe_2Co fragment, with a μ_3-bridging oxide oxygen atom μ_3-O(O10) at the centre of the triangle made up by two iron(III) atoms and a cobalt(II) atom. Six μ-trifluoroacetate anions also join the metal atoms through carboxylate oxygen atoms (O_c), reinforcing the triangular framework: in each case the carboxylate groups have a μ-O,O′ coordination. The oxygen donor atoms of the water molecules bring the coordination number of each metal 3d-ion to 6, so that each Fe^{3+} and Co^{2+} ion manifests a distorted octahedral environment of oxygen atoms. The coplanarity of the μ_3-oxygen atom with the triangle of the

metal ions shows that it is an sp^2-hybridised oxide ion, removing the ambiguity associated with a possible μ_3-OH^- bridge. The average μ_3-O−Fe distance of 1.870(5) Å is typical for $Fe^{3+}-O^{2-}$ bonds in trinuclear (carboxylato)(μ_3-oxo) complexes.[18] Comparison of this value with corresponding distances in $[Fe^{III}_2Fe^{II}(\mu_3\text{-}O)(CH_3COO)_6(4\text{-Et-py})_3]$ (μ_3-O−Fe^{2+} 2.01 Å, μ_3-O−Fe^{3+}, 1.86 Å at 163 K)[19] favours the assumption that the oxidation state of the iron atoms in **2** remains +3. If the μ_3-O^{2-} ionic radius is taken as 1.22 Å,[20] the ionic radius of Fe^{3+} can be estimated to be 0.64 Å, somewhat smaller than the value reported at room temperature (0.78 Å[20]). The μ_3-O−Co distance [1.993(5) Å] is greater than μ_3-O−Fe, due to the larger ionic radius of Co^{2+}.[20] For each Fe^{3+} ion, three sets of values of the Fe−O bond lengths are found: short μ_3-O−Fe distances (1.87 Å), two intermediate Fe−O_c distances (2.03 Å for Fe−O1 and Fe1−O1*), and three longer Fe−O_c and Fe−OH_2 bonds (ranging from 2.05 Å for Fe2−O5 and Fe2−O5*, to 2.08 Å for Fe1−O7 and Fe2−O9, where O_c are oxygen atoms of the carboxylate bridges). For the Co^{2+} ion, the differences between the Co−O_c bond lengths [2.069(4) and 2.078(4) Å] are less significant than the corresponding bond lengths in analogous trinuclear acetato complexes. This can be rationalised by a weaker donor power of the trifluoroacetate ion (due to the inductive effect of the CF_3− group) in comparison with the acetate group. All the M−OH_2 bond lengths are 2.08 Å.

In the acetato complex $[Fe_2Co(\mu_3\text{-}O)(CH_3COO)_6(H_2O)_3]\cdot 2H_2O$, which crystallises in a monoclinic system ($Z = 8$),[21] disorder causes the metal atoms to appear to be arranged at the corners of an equilateral triangle, hence concealing the identities of the individual Fe^{3+} and Co^{2+} ions. In the present trifluoroacetate case, the observed C_{2v} symmetry of the trimetal unit allows the distinction between Fe^{3+} and Co^{2+} to be made.

$[Fe_2Mn(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot 2MeNO_2\cdot H_2O$ (**1′**)

This complex also crystallises in a monoclinic space group. The parallel layers of trinuclear species are arranged in an *ABCDEABCDE* sequence. The overall *R* factor for the structure is quite large because of substantial disordering of the trifluoromethyl groups and solvent molecules. However, the trinuclear skeleton is confirmed and certain details are clearly apparent. The structure of **1′** is not identical to that of **2′**, the trimetal moiety forms a slightly distorted isosceles triangle: [Fe1−Mn 3.328(2) Å; Fe2−Mn 3.368(2) Å; Fe−Fe 3.273(2) Å]. The coordination spheres of the metal ions are essentially octahedral, with the Fe−μ_3-O distances in the typical range for these systems: the μ_3-O−Fe bond lengths (1.86 and 1.87 Å for atoms Fe1 and Fe2, respectively) differ slightly from the corresponding values in **2′**, while a similar effect is seen for the Fe−OH_2 bond (2.10 and 2.06 Å for Fe1 and Fe2, respectively). The Fe−O_c distances vary from 2.01 to 2.07 Å, similar Fe−O_c distances have been found in analogous compounds.[22] Meanwhile, the μ_3-O−Mn (2.02 Å), Mn−O_c and Mn−OH_2 distances (2.11−2.15 Å) are in a range consistent with the persistence of Mn^{2+} under the conditions of synthesis. In consonance with this, the Mössbauer spectrum of this compound (vide infra) testifies to the presence of iron(III) rather than iron(II) in **1′**.

Mass Spectra

FAB mass spectra clearly indicate the trinuclear nature of complexes **1**−**3**, as well as the persistence of the $Fe_2M^{II}(\mu_3\text{-}O)$ skeletons. Although ions such as $[Fe_2M^{II}(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_2]^+$ or $[Fe_2M^{II}(\mu_3\text{-}O)(CF_3COO)_5]^+$ are not immediately apparent, intense peaks associated with partially solvated $[Fe_2M^{II}(\mu_3\text{-}O)(CF_3COO)_5(H_2O)_2]^+$ cations are present in each case (Table 2). The spectra also display fragmentation patterns corresponding to consecutive loss of trifluoroacetate groups and water molecules. The relative intensities suggest a greater lability for trifluoroacetate than for water.

Table 2. FAB-MS data for the complexes $[Fe_2M(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ (M = Mn, Co, Ni)

Ion composition	*m/z*

$[Fe_2M(\mu_3\text{-}O)(CF_3COO)_4]^+$	635	639	638
$[Fe_2M(\mu_3\text{-}O)(CF_3COO)_3(H_2O)]^+$	541	545	544
$[Fe_2M(\mu_3\text{-}O)(CF_3COO)_3]^+$	522	526	525
$[Fe_2M(\mu_3\text{-}O)(CF_3COO)_2(H_2O)_2]^+$	447	451	450
$[Fe_2M(\mu_3\text{-}O)(CF_3COO)_2(H_2O)]^+$	428	432	431
$[Fe_2M(\mu_3\text{-}O)(CF_3COO)(H_2O)_2]^+$	334	338	337

IR Spectra

The IR absorption bands for **1**−**3** (Table 3) are consistent with those reported in the literature for the acetate analogues[22,23] and are similarly assigned: $\nu(COO^-)_s$ and $\nu(COO^-)_{as}$ in **1**−**3** are shifted to a lower energy by 40−50 cm^{-1} relative to the trinuclear basic acetates,[22] indicating

Table 3. IR data for trinuclear carboxylates [cm^{-1}]

Complex	$\nu(M_3O)_{as}$	$\nu(COO^-)_s$	$\nu(COO^-)_{as}$	$\Delta\nu$[a]
$[Fe_2Mn(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$	622	1470	1640	170
$[Fe_2Co(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$	627	1475	1630	155
$[Fe_2Ni(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$	630	1475	1645	170

[a] $\Delta\nu = \nu(COO^-)as - \nu(COO^-)s$.

that the replacement of the CH_3 radical by the more powerfully electron-accepting CF_3 moiety weakens the metal$-O_c$ force constant.

The splitting of the symmetric and asymmetric valence vibrations ($\Delta\nu$, Table 3) signals bidentate bridging carboxylate groups around the $Fe_2M(\mu_3\text{-}O)$ fragment,[12] while the bands at 600−650 cm^{-1} are assigned to vibrations of the $Fe_2M(\mu_3\text{-}O)$ skeleton.

Electronic Spectra

The electronic spectra of **1**−**3** (Table 4) are similar to those reported for other trinuclear basic carboxylates containing iron(III),[22] and are useful in revealing the spin states of the metal ions. At longer wavelengths, absorbance bands are observed which are characteristic of d−d transitions from the $^6A_{1g}$ ground state of a distorted octahedral high-spin Fe^{3+} ion. For instance, the band at 17500 cm^{-1} is assigned to the $^6A_{1g}\rightarrow{}^4A_{2g}$ d−d transition, the intensity of which is enhanced due to the influence of exchange interactions[24] inside the trinuclear moiety. The remaining Fe^{3+} d−d transitions are obscured by intense absorbance bands near 29000 and 22000 cm^{-1} (ε = 1500−3000 $dm^3\cdot mol^{-3}\cdot cm^{-1}$) associated with the ligand-to-metal charge-transfer transitions which are characteristic of such iron(III) systems.[25,26] The electronic spectrum of $[Fe_2Ni(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ (**3**) exhibits an absorbance band at 13580 cm^{-1} (Table 4). The position and intensity of this band are consistent with a $^3A_{2g}\rightarrow{}^3T_{2g}$ assignment for an octahedral Ni^{2+} chromophore.[25] The intensity of this band in **3** is slightly enhanced relative to similar bands in mononuclear Ni^{2+} complexes, which is likely to be related to the exchange interactions in the $Fe_2Ni^{2+}(\mu_3\text{-}O)$ moiety.[24] Literature data for various other basic carboxylates[22,24] also confirm that the exchange interactions are generally orders of magnitude less than the differences amongst the term energies of the individual ions.

Magnetic Studies

Temperature dependencies of the magnetic susceptibilities of complexes **1**−**3** were measured in the 5−300 K range.

Complex $[Fe_2Mn(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ (1)

With decreasing temperature, $\chi_M T$ (in $cm^3\cdot K\cdot mol^{-1}$, where χ_M is per mol of trimer) decreased smoothly from 4.51 at 300 K to 3.19 at 5 K (Figure 2). The observed $\chi_M T$ value for this complex, even at room temperature, is significantly lower than the expected spin-only $\chi_M T$ value (13.125 $cm^3\cdot K\cdot mol^{-1}$) for a non-interacting $g = 2$ high-spin set of one manganese(II) and two iron(III) ions. This clearly indicates strong antiferromagnetic coupling within the Fe_2Mn framework. In general, two high-spin iron(III) ions with $S = 5/2$ and one manganese(II) ion with $S = 5/2$ can couple to give a total molecular spin (S_T) ranging from 1/2 to 15/2. Magnetic data were analysed according to the exchange Hamiltonian [Equation (2)], and the coupling pathways are presented in Scheme 1.

$$H = -2J_{FeM}[S_{Fe1}S_M + S_MS_{Fe2}] - 2J_{FeFe}[S_{Fe1}S_{Fe2}] \quad (2)$$

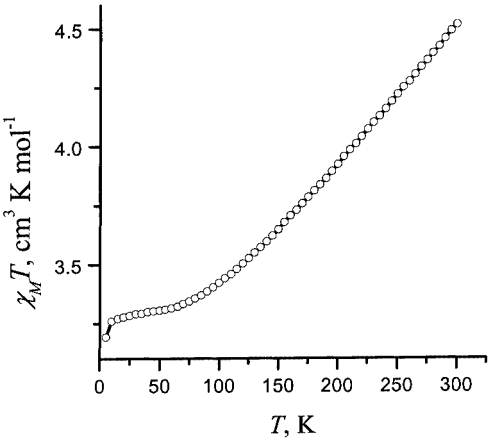

Figure 2. Temperature dependence of the magnetic susceptibility of **1**, plotted as χT vs. T; the solid line is the least-squares fit

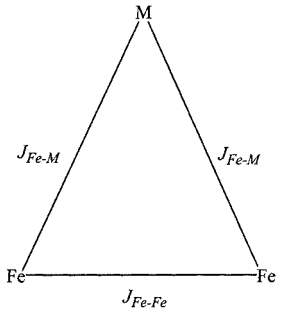

Scheme 1. Magnetic exchange pathways in the trinuclear core

The zero-field energy levels for the Fe_2M complexes were calculated according to Equation (3),[5] where $S_{Fe} = 5/2$; S_M is the spin of M^{II} (5/2 for Mn^{II}, 3/2 for Co^{II}, and 2/2 for Ni^{II}); $S^* = S_{Fe} + S_{Fe}$; $S_T = S^* + S_M$ according to Kambe's notation.[27]

$$E(S_T, S^*) = J_{FeM}[2S_{Fe}(S_{Fe} + 1) - S_T(S_T + 1)] + J_{FeFe}[S_T(S_T + 1) + S_M(S_M + 1) - S^*(S^* + 1)] \quad (3)$$

Within this approach, S^* ranges integrally from 0 to 5, so that for instance, when $S^* = 1$, S_T for the Co^{II}-containing molecule may take values of 1/2, 3/2, or 5/2. Substitution

of the eigenvalues for the spin-states derived from the above exchange Hamiltonian into the van Vleck equation results in an expression for the $\chi_M T$ values for the Fe_2Mn complex [Equation (4)], where $a = -25J_{Fe\text{-}Mn} - 12.5J_{Fe\text{-}Fe}$; $b = -10J_{Fe\text{-}Mn} - 12.5J_{Fe\text{-}Fe}$; $c = 3J_{Fe\text{-}Mn} - 12.5J_{Fe\text{-}Fe}$; $d = 14J_{Fe\text{-}Mn} - 12.5J_{Fe\text{-}Fe}$; $e = 23J_{Fe\text{-}Mn} - 12.5J_{Fe\text{-}Fe}$; $f = 30J_{Fe\text{-}Mn} - 12.5J_{Fe\text{-}Fe}$; $\gamma = -20J_{Fe\text{-}Mn} - 2.5J_{Fe\text{-}Fe}$; $h = -7J_{Fe\text{-}Mn} - 2.5J_{Fe\text{-}Fe}$; $\omega = 4J_{Fe\text{-}Mn} - 2.5J_{Fe\text{-}Fe}$; $j = 13J_{Fe\text{-}Mn} - 2.5J_{Fe\text{-}Fe}$; $\kappa = 20J_{Fe\text{-}Mn} - 2.5J_{Fe\text{-}Fe}$; $l = 25J_{Fe\text{-}Mn} - 2.5J_{Fe\text{-}Fe}$; $m = -15J_{Fe\text{-}Mn} + 5.5J_{Fe\text{-}Fe}$; $n = -4J_{Fe\text{-}Mn} + 5.5J_{Fe\text{-}Fe}$; $o = 5J_{Fe\text{-}Mn} + 5.5J_{Fe\text{-}Fe}$; $p = 12J_{Fe\text{-}Mn} + 5.5J_{Fe\text{-}Fe}$; $q = 17J_{Fe\text{-}Mn} + 5.5J_{Fe\text{-}Fe}$; $r = 20J_{Fe\text{-}Mn} + 5.5J_{Fe\text{-}Fe}$; $s = -10J_{Fe\text{-}Mn} + 11.5\ J_{Fe\text{-}Fe}$; $t = -J_{Fe\text{-}Mn} + 11.5J_{Fe\text{-}Fe}$; $u = 6J_{Fe\text{-}Mn} + 11.5J_{Fe\text{-}Fe}$; $v = 11J_{Fe\text{-}Mn} + 11.5J_{Fe\text{-}Fe}$; $w = 14J_{Fe\text{-}Mn} + 11.5J_{Fe\text{-}Fe}$; $x = -5J_{Fe\text{-}Mn} + 15.5J_{Fe\text{-}Fe}$; $y = 2J_{Fe\text{-}Mn} + 15.5J_{Fe\text{-}Fe}$; $z = -7J_{Fe\text{-}Mn} + 15.5J_{Fe\text{-}Fe}$; $\varphi = 17.5J_{Fe\text{-}Fe}$.

$$\chi_M T = (Ng^2\beta^2/3k)(1020e^{-a/kT} + 682.5e^{-b/kT} + 429e^{-c/kT} + 247.5e^{-d/kT} + 126e^{-e/kT} + 52.5e^{-f/kT} + 682.5e^{-\gamma/kT} + 429e^{-h/kT} + 247.5e^{-\omega/kT} + 126e^{-j/kT} + 52.5e^{-\kappa/kT} + 15e^{-l/kT} + 429e^{-m/kT} + 247.5e^{-n/kT} + 126e^{-o/kT} + 52.5e^{-p/kT} + 15e^{-q/kT} + 1.5e^{-r/kT} + 247.5e^{-s/kT} + 126e^{-t/kT} + 52.5e^{-u/kT} + 15e^{-v/kT} + 1.5e^{-w/kT} + 126e^{-x/kT} + 52.5e^{-y/kT} + 15e^{-z/kT} + 52.5e^{-\varphi/kT})/(16e^{-a/kT} + 14e^{-b/kT} + 12e^{-c/kT} + 10e^{-d/kT} + 8e^{-e/kT} + 6e^{-f/kT} + 14e^{-\gamma/kT} + 12e^{-h/kT} + 10e^{-\omega/kT} + 8e^{-j/kT} + 6e^{-\kappa/kT} + 4e^{-l/kT} + 12e^{-m/kT} + 10e^{-n/kT} + 8e^{-o/kT} + 6e^{-p/kT} + 4e^{-q/kT} + 2e^{-r/kT} + 10e^{-s/kT} + 8e^{-t/kT} + 6e^{-u/kT} + 4e^{-v/kT} + 2e^{-w/kT} + 8e^{-x/kT} + 6e^{-y/kT} + 4e^{-z/kT} + 6e^{-\varphi/kT}) \quad (4)$$

Despite the deviation of this complex from an exact isosceles triangle, a satisfactory fit was achieved using two J parameters. The best fit was obtained with fixed values of $g_{Fe} = g_{Mn} = 2.00$, giving $J_{Fe\text{-}Fe} = -56.50(7)$ and $J_{Fe\text{-}Mn} = -16.23(4)$ cm^{-1} [$R^2 = 1.85\cdot10^{-5}$ where $R^2 = \Sigma(\chi_{obs}-\chi_{calc})^2/\Sigma\chi^2_{obs}$]. An energy diagram (Figure 3) for the spin states of **1** reveals that the ground state is a quadruplet (S_T, S^*) = (3/2, 1), with a low-lying sextuplet (5/2, 0) 0.61 cm^{-1} above it. The experimental $\chi_M T$ value at 5 K (3.19) is intermediate between the calculated values for these two spin-states: 1.88 cm^3·K·mol^{-1} for a quadruplet and 4.38 cm^3·K·mol^{-1} for a sextuplet ground state, and the $\chi_M T$ data thus betoken Boltzmann distribution over these two states. Previously, Blake et al. reported that $S_T = 3/2$ is the ground state for $[Fe_2Mn(\mu_3\text{-}O)(CH_3COO)_6(py)_3]\cdot0.7py$.[24]

Complex $[Fe_2Co(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ (2)

In general, the magnetic properties of **2** resembled those of the manganese analogue (Figure 4). On cooling, $\chi_M T$ for this complex decreased from 4.76 cm^3·K·mol^{-1} at 300 K to 2.00 at 5 K (Figure 4). The observed χ_MT value at room temperature is less than one half of the spin-only χ_MT value (10.61 cm^3·K·mol^{-1}) for a non-interacting FeCoFe ion set. Again, this directly testifies for the existence of strong antiferromagnetic coupling within the Fe_2Co framework. Two high-spin irons(III) ions and one high-spin ($S = 3/2$) cobalt(II) ion can couple to give spins ranging from $S_T = 1/2$ to $S_T = 13/2$. The experimental data were fitted according to the isotropic spin-Hamiltonian [Equation (2)] to give Equation (5), where $a = -15J_{Fe\text{-}Co} - 12.5J_{Fe\text{-}Fe}$; $b = -2J_{Fe\text{-}Co} - 12.5J_{Fe\text{-}Fe}$; $c = 9J_{Fe\text{-}Co} - 12.5J_{Fe\text{-}Fe}$; $d = 18J_{Fe\text{-}Co} - 12.5J_{Fe\text{-}Fe}$; $e = -12J_{Fe\text{-}Co} - 2.5J_{Fe\text{-}Fe}$; $f = -J_{Fe\text{-}Co} - 2.5J_{Fe\text{-}Fe}$; $\gamma = 8J_{Fe\text{-}Co} - 2.5J_{Fe\text{-}Fe}$; $h = 15J_{Fe\text{-}Co} - 2.5J_{Fe\text{-}Fe}$; $\omega = -9J_{Fe\text{-}Co} + 5.5J_{Fe\text{-}Fe}$; $j = 5.5J_{Fe\text{-}Fe}$; $\kappa = 7J_{Fe\text{-}Co} + 5.5J_{Fe\text{-}Fe}$; $l = 12J_{Fe\text{-}Co} + 5.5\ J_{Fe\text{-}Fe}$; $m = -6\ J_{Fe\text{-}Co} + 11.5J_{Fe\text{-}Fe}$; $n = J_{Fe\text{-}Co} + 11.5J_{Fe\text{-}Fe}$; $o = 6J_{Fe\text{-}Co} + 11.5J_{Fe\text{-}Fe}$; $p = 9J_{Fe\text{-}Co} + 11.5J_{Fe\text{-}Fe}$; $q = -3J_{Fe\text{-}Co} + 15.5J_{Fe\text{-}Fe}$; $r = 2J_{Fe\text{-}Co} + 15.5J_{Fe\text{-}Fe}$; $s = 5J_{Fe\text{-}Co} + 15.5J_{Fe\text{-}Fe}$; $t = 17.5J_{Fe\text{-}Fe}$.

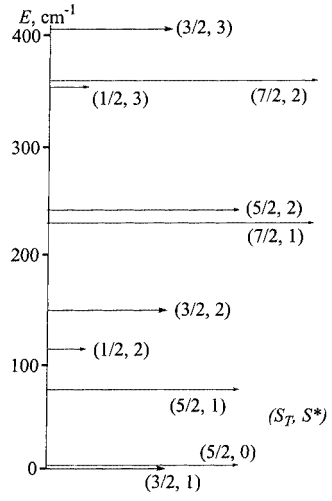

Figure 3. Energy diagram for low-lying spin levels of **1**

$$S_T = [(Ng_{mol}^2\beta^2/3k)(682.5e^{-a/kT} + 429e^{-b/kT} + 247.5e^{-c/kT} + 126e^{-d/kT} + 429e^{-e/kT} + 247.5e^{-f/kT} + 126e^{-\gamma/kT} + 52.5e^{-h/kT} + 247.5e^{-\omega/kT} + 126e^{-j/kT} + 52.5e^{-\kappa/kT} + 15e^{-l/kT} + 126e^{-m/kT} + 52.5e^{-n/kT} + 15e^{-o/kT} + 1.5e^{-p/kT} + 52.5e^{-q/kT} + 15e^{-r/kT} + 1.5e^{-s/kT} + 15e^{-t/kT})/(14e^{-a/kT} + 12e^{-b/kT} + 10e^{-c/kT} + 8e^{-d/kT} + 12e^{-e/kT} + 10e^{-f/kT} + 8e^{-g/kT} + 6e^{-h/kT} + 10e^{-\omega/kT} + 8e^{-j/kT} + 6e^{-\kappa'/kT} + 4e^{-l/kT} + 8e^{-m/kT} + 6e^{-n/kT} + 4e^{-o/kT} + 2e^{-p/kT} + 6e^{-q/kT} + 4e^{-r/kT} + 2e^{-s/kT} + 4e^{-t/kT})](1 - \rho) + S(S+1)(Ng^2\beta^2/3k)\rho + TIP \quad (5)$$

Here, ρ is the fraction of a mononuclear ferric paramagnetic ($S = 5/2$) impurity, and g_{mol} is for the trinuclear complex.

The best fit was obtained with $g_{mol} = 2.09(1)$; $J_{Fe\text{-}Fe} = -42.8(3.5)$ cm^{-1}; $J_{Fe\text{-}Co} = -17.8(1.4)$ cm^{-1}; $\rho = 0.031(5)$ and $TIP = 0$ ($R^2 = 6.17\cdot10^{-6}$). Fixing g_{Fe} at 2.00 gave $g_{Co} = 2.27$ according to $3g_{mol} = (2\ g_{Fe} + g_{Co})$. The associated spin ladder energy diagram reveals a (1/2, 1) ground state with a (3/2, 0) state 3.2 cm^{-1} above it (Figure 5). These states are well-separated from the second excited state (3/2, 1), which is 50 cm^{-1} above them.

Complex $[Fe_2Ni(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ (3)

For this complex, the $\chi_M T$ value monotonically decreased from 3.03 cm^3·K·mol^{-1} at 300 K to about 1.15

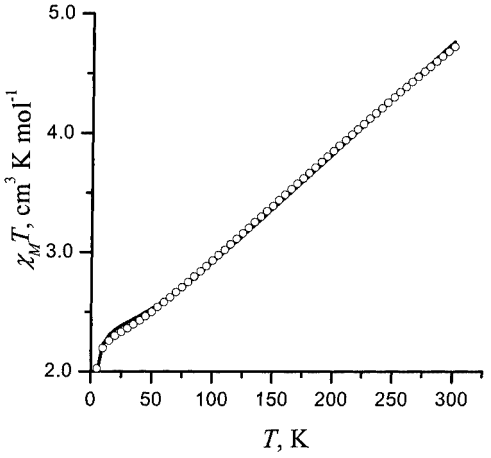

Figure 4. Temperature dependence of the magnetic susceptibility of **2**, plotted as χT vs. T; the solid line is the least-squares fit

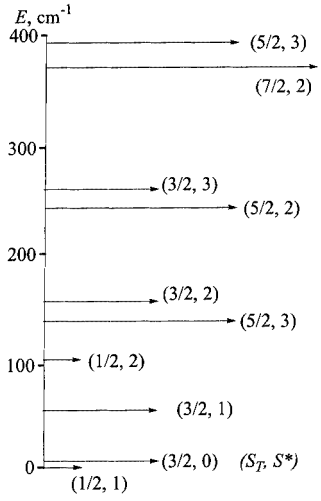

Figure 5. Energy diagram for low-lying spin levels of **2**

cm^3·K·mol^{-1} at 32 K, and after passing through a broad minimum at 50−20 K, increased somewhat again as T approached 5 K Figure 6). Comparison with the calculated spin-only $\chi_M T$ value (9.73 cm^3·K·mol^{-1}) for non-interacting ions again indicates strong antiferromagnetic exchange within the trimetallic species. Two high-spin S = 5/2 iron(III) ions and one high-spin S = 1 nickel(II) ion can couple to give S_T values ranging from 0 to 12/2. Magnetic data were fitted in agreement with the exchange Hamiltonian [Equation (2)] and the expression for $\chi_M T$ [Equation (6)], where $a = -10J_{Fe\text{-}Ni} - 12.5J_{Fe\text{-}Fe}$; $b = 2J_{Fe\text{-}Ni} - 12.5J_{Fe\text{-}Fe}$; $c = 12J_{Fe\text{-}Ni} - 12.5J_{Fe\text{-}Fe}$; $d = {}_{Fe\text{-}Ni} - 2.5J_{Fe\text{-}Fe}$; $e = 2J_{Fe\text{-}Ni} - 2.5J_{Fe\text{-}Fe}$; $f = 10J_{Fe\text{-}Ni} - 2.5J_{Fe\text{-}Fe}$; $\gamma = -6J_{Fe\text{-}Ni} + 5.5J_{Fe\text{-}Fe}$; $h = 2J_{Fe\text{-}Ni} + 5.5J_{Fe\text{-}Fe}$; $\omega = 8J_{Fe\text{-}Ni} + 5.5J_{Fe\text{-}Fe}$; $j = -4J_{Fe\text{-}Ni} + 11.5J_{Fe\text{-}Fe}$; $\kappa = 2J_{Fe\text{-}Ni} + 11.5J_{Fe\text{-}Fe}$; $l = 6J_{Fe\text{-}Ni} + 11.5J_{Fe\text{-}Fe}$; $m = -2J_{Fe\text{-}Ni} + 15J_{Fe\text{-}Fe}$; $n = 2J_{Fe\text{-}Ni} + 15.5J_{Fe\text{-}Fe}$; $o = 4J_{Fe\text{-}Ni} + 15.5J_{Fe\text{-}Fe}$; $p = 17.5J_{Fe\text{-}Fe}$.

$$\chi_M T = (Ng_{mol}^2\beta^2/3k)\cdot(546e^{-a/kT} + 330e^{-b/kT} + 180e^{-c/kT} + 330e^{-d/kT} + 180e^{-e/kT} + 84e^{-f/kT} + 180e^{-\gamma/kT} + 84e^{-h/kT} + 30e^{-\omega/kT} + 84e^{-j/kT} + 30e^{-\kappa/kT} + 6e^{-l/kT} + 30e^{-m/kT} + 6e^{-n/kT} + 6e^{-p/kT})/(13e^{-a/kT} + 11e^{-b/kT} + 9e^{-c/kT} + 7e^{-d/kT} + 11e^{-e/kT} + 9e^{-f/kT} + 7e^{-\gamma/kT} + 5e^{-h/kT} + 9e^{-\omega/kT} + 7e^{-j/kT} + 5e^{-\kappa/kT} + 3e^{-l/kT} + 7e^{-m/kT} + 5e^{-n/kT} + 3e^{-o/kT} + e^{-p/kT}) \quad (6)$$

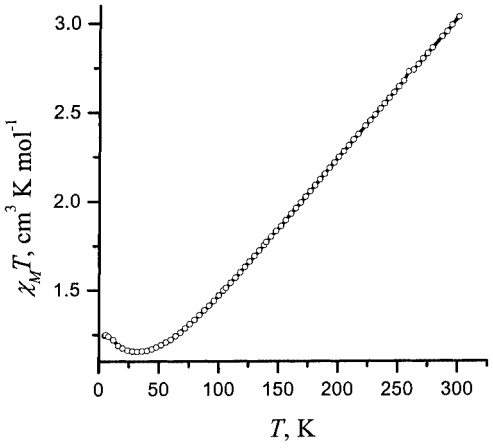

Figure 6. Temperature-dependence of the magnetic susceptibility of **3**, plotted as χT vs. T; the solid line is the least-squares fit

The best fit was obtained with a fixed g_{Fe} value of 2.00 and g_{Ni} = 2.215(2); $J_{Fe\text{-}Fe}$ = −45.60(1) and $J_{Fe\text{-}Ni}$ = −16.96(2) cm^{-1} ($R^2 = 8.54\cdot10^{-5}$). The unexpected shape of the $\chi_M T$ vs. T curve can be clarified from the associated energy diagram for the spin-states (Figure 7). This reveals a (1, 0) ground state, succeeded by the first two excited states (0, 1) and (1, 1), so that there is a diamagnetic state between the two lowest-lying triplet states. When the temperature is decreased, the singlet first excited state becomes populated and the higher states with $S_T \geq 1$ become less populated, reducing $\chi_M T$. However, a further decrease in temperature depopulates this singlet level, in favour of the triplet ground state, so that the reduction in the $\chi_M T$ value with decreasing temperature is thus arrested and reversed.

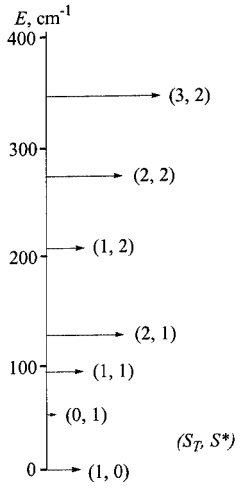

Figure 7. Energy diagram for low-lying spin levels of **3**

When comparing the magnetochemical characteristics of **1**−**3**, one notes that $J_{Fe\text{-}M}$ (M = M^{II}) is insensitive to the identity of M^{II}, whereas the $J_{Fe\text{-}Fe}$ values are affected by the nature of the third metal ion in the triangular skeleton. These results are in agreement with observations by Blake et al.[24] that $J_{Fe\text{-}Fe}$ increases significantly in Fe_2M^{II} relative to that in similar trinuclear (carboxylato)(oxo)iron(III) complexes. It is noteworthy that trinuclear pivalate complexes[28] also show significant antiferromagnetic exchange.

Mößbauer Spectra

The electronic properties of complexes **1**−**3** were examined by ^{57}Fe Mößbauer spectroscopy at 80 and 300 K (Figure 8, Table 5). Each of the spectra display one quadrupole-split doublet. The values of the isomer shifts (IS, δ) and quadrupole splittings (QS) for **1**−**3** are close to those reported previously for similar heterometallic trinuclear complexes,[29] and correspond to a high-spin iron(III) ion. Second-order Doppler effects (an increase in the isomer shift at cryogenic temperature[30]) and Goldanskii−Karyagin anisotropy[30] (manifested by the different relative intensities of the two peaks of the doublet at higher temperatures) are minor, but detectable in the spectra. The data indicate that there is no occurrence of any intermetallic redox process during or subsequent to the synthesis − i.e. there is no electron transfer from M^{2+} (especially from the more readily oxidizable Co^{2+} and Mn^{2+}) to Fe^{3+}. However, the isomer shifts in **1**−**3** are smaller than in some other[31] heterotrinuclear complexes (Table 5), which may be accounted for by the electron-withdrawing nature of the CF_3 group; the decreased donor ability of the carboxylate group thus reduces the electron density in the 3d subshell.[30] Similar effects have been reported for other homopolynuclear iron(III) species.[32,33] The relatively high quadrupole splitting in **1**−**3** also reflects the significant electron-density transfer from the iron(III) centre to the trifluroacetate anion. Previous work[22,31] indicates that quadrupole splitting increases with Fe^{III}−carboxylate bond ionicity.

The Mössbauer results reveal no spin-spin interactions which would be indicative of the exchange coupling that is so compellingly suggested by the magnetic susceptometry.

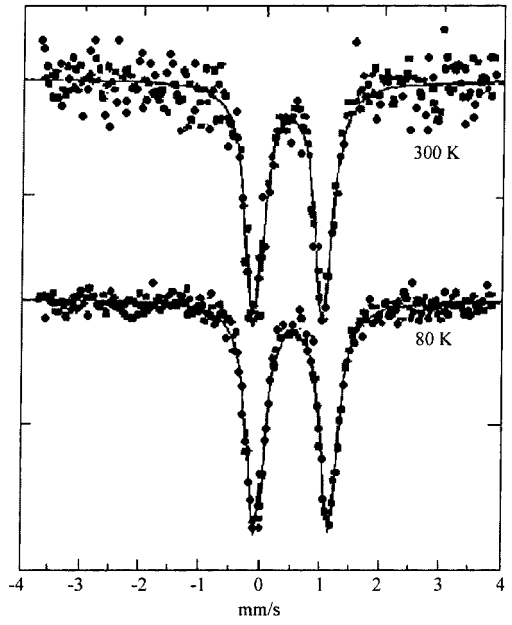

Figure 8. ^{57}Fe Mössbauer spectrum of **1**; the solid line is the least-squares fit; isomer shifts are referred to α-iron at room temperature

The relatively high J values alone lead to the expectation that a "coupled" spectrum might be observed at 80 K. However, similar apparently paradoxical results have been reported by Rentschler and co-workers,[28] who pointed out that they are a consequence of the difference in the experimental time scales of the phenomena on which the two types of measurements are based; the magnetic exchange occurs on a timescale that is too fast to be detected by ^{57}Fe Mößbauer spectroscopy.

Conclusion

Three new heterometallic trinuclear basic trifluoroacetates $[Fe_2M^{II}(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ (M = Mn, Co, Ni) have been prepared. The crystal structures of two complexes were obtained at 100 K. FAB-MS data, IR and UV/

Table 5. Mössbauer spectroscopic parameters of complexes **1**−**3**

Vis spectra, along with magnetochemical and Mössbauer studies were interpreted in terms of the trinuclear nature of the compounds. The complexes exhibit substantial intramolecular antiferromagnetic exchange. The absence of any iron(II) centre, as proved by the Mössbauer investigation, showed that no electron transfer from Mn^{II} or Co^{II} to Fe^{III} occurred in these complexes. Increased values of quadrupole splittings are a result of the electron-withdrawing abilities of the CF_3- group in the trifluoroacetate anions.

Experimental Section

General: Reagents and solvents (UkrReaKhim and Merck) were generally used as received. The precursory acetate complexes $[Fe_2^{III}M^{II}(\mu_3\text{-}O)(CH_3COO)_6(H_2O)_3]\cdot 3H_2O$ (M = Mn, Co, Ni) were prepared as described elsewhere.[24]

$[Fe^{III}_2M^{II}(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$ (M = Mn, Co, Ni): The initial acetato complex $[Fe_2^{III}M^{II}(\mu_3\text{-}O)(CH_3COO)_6(H_2O)_3]\cdot 3H_2O$ (1.3 g, ca. 2 mmol) was dissolved in aqueous trifluoroacetic acid (15 mL of a 60% solution), and the resulting solution was refluxed for 1 h. After cooling, the reaction mixture was diluted with an equal volume of acetone. Slow concentration of the reaction mixture at room temperature over several days resulted in the formation of red-brown crystals, which were filtered, washed with cold water and dried in vacuo with KOH. Yield: 60−80%.

$[Fe^{III}_2Co(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$: $C_{12}H_8CoF_{18}Fe_2O_{17}$ (936.77): calcd. C 15.4, H 0.85, Co 6.30, Fe 11.9; found C 15.3, H 0.83, Co 6.42, Fe 11.6. Yield 1.43 g (75%).

$[Fe^{III}_2Ni(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$: $C_{12}H_8F_{18}Fe_2NiO_{17}$ (936.54): calcd. C 15.4, H 0.86, Ni 6.27, Fe 12.0; found C 15.3, H 0.80, Ni 6.40, Fe 11.7. Yield 1.38 g (72%).

$[Fe^{III}_2Mn(\mu_3\text{-}O)(CF_3COO)_6(H_2O)_3]\cdot H_2O$: $C_{12}H_8F_{18}Fe_2MnO_{17}$ (932.76): calcd. C 15.4, H 0.86, Mn 5.89, Fe 12.0; found C 15.4, H 0.88, Mn 5.80, Fe 12.1. Yield 1.26 g (66%).

Physical Measurements: Electronic absorption spectra were recorded with a Carl-Zeiss-Jena Specord-M40 spectrophotometer, IR spectra with a Carl-Zeiss-Jena Specord-75. C,H,N contents were determined using a Carlo Erba 1106 microanalyzer. Mass spectra were obtained with a VG-ZABHF instrument, using 2-nitrobenzyl alcohol as the matrix for the FAB mode. The temperature and field dependencies of the magnetic susceptibilities were measured with an MPMS-5S SQUID magnetometer, Pascal's diamagnetic corrections were applied according to a standard text.[2] Magnetisation experiments were performed at 5 and 300 K. Möβbauer spectra were measured in the transmission mode on conventional spectrometers, a temperature-controlled Leybold cryostat was used for low-temperature spectra. A $3\cdot10^9$ Bq $^{57}Co(Rh)$ sample was used as the γ-ray source, while isomer shifts were referred to α-iron at room temperature. Spectra were deconvoluted using the MossWin program.[34]

X-ray Crystallographic Study: Crystals suitable for crystallography were grown from CH_3NO_2/mesitylene (for the Mn complex) or from $CH_3NO_2/(CH_3)_2CO$/mesitylene layering (for the cobalt complex). A dark red single crystal of **2′** was coated with perfluoropolyether, picked up with a glass fibre and immediately mounted in the cold nitrogen stream to prevent loss of solvent. Intensity data were collected with a Siemens SMART diffractometer at 100 K using graphite-monochromated Mo-K_α radiation (λ= 0.71073 Å). Final cell constants were obtained from a least-squares fit of 4419 reflections. Data collection was performed by hemisphere runs taking frames at 0.3°. A semiempirical absorption correction using the program SADABS[35] was performed on the data set of **2**. Crystallographic data are listed in Table 6. The Siemens SHELXTL1 software package was used for solution, refinement and artwork of the structure. The structure was readily solved by direct methods and difference Fourier techniques. All non-hydrogen atoms except atoms in disordered parts were refined anisotropically and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. Split atom models were used to account for the disorder of the CF_3COO groups and a mesitylene solvent molecule lying on the crystallographic mirror plane. The C−F and F−F distances of the CF_3 groups were re-

Hydrothermal Syntheses, Structures, and Properties of First Examples of Lanthanide(III) 2,3-Pyrazinedicarboxylates with Three-Dimensional Framework

Xiang-Jun Zheng,[a] Lin-Pei Jin,*[a] and Shao-Zhe Lu[b]

Keywords: Hydrothermal synthesis / Lanthanides / Coordination polymer / N ligands / O ligands

Lanthanide 2,3-pyrazinedicarboxylate complexes with three-dimensional frameworks, $[Ln_2(pzdc)_3(H_2O)]_x \cdot 2xH_2O$ [Ln = Pr (**2**), Nd (**3**), and Eu (**4**)], were obtained by hydrothermal reactions of 2,3-pyrazinedicarboxylic acid (H_2pzdc) and the lanthanide(III) chlorides, while $[La_2(pzdc)_3(H_2O)]_x \cdot 2xH_2O$ (**1**) was obtained by hydro(solvo)thermal reaction of $LaCl_3 \cdot 7H_2O$ and 2,3-pyrazinedicarboxylic acid. They are isomorphous and exhibit complicated 3-D structures based on $[Ln_2(pzdc)_3(H_2O)]$ building blocks. In the asymmetric unit, the two Ln^{3+} ions are both nine-coordinate, but with different coordination environments. The ligand pzdc coordinates to the central Ln^{3+} ions in a tetradentate, hexadentate, or heptadentate manner. Utilizing the characteristic of Eu^{3+} ion to act as a conformational probe, we determined the high-resolution spectra of **4**, which show that there are two Eu^{3+} ion sites in the coordination polymer. This is also in agreement with the results of the X-ray single-crystal diffraction study. It was concluded that there are two La^{3+}, two Pr^{3+} and two Nd^{3+} ion sites in polymers **1**, **2**, and **3**, respectively. The thermogravimetric analyses of these complexes show that all coordinated and uncoordinated water molecules were lost at the first weight loss above 240 °C.

Introduction

The field of coordination polymers has undergone an explosive growth since numerous one-, two-, and three-dimensional structures have been obtained.[1−8] Much attention in this area has been focussed on coordination polymers with multifunctional ligands as the presence of different functional groups allows for the incorporation of interesting properties into the resulting coordination networks. Such polymeric structures are generally neutral, which simplifies the ability to control their structures and increases the chances of obtaining porous solids.[6] 2,3-Pyrazinedicarboxylic acid is a commonly used multifunctional ligand. Its complexes with d-block transition metals have been synthesized and their structures have been obtained.[9−16] However, the lanthanide complexes of this ligand are relatively unexplored. Up to now, no structural characterization of the lanthanide complexes of 2,3-pyrazinedicarboxylic acid has been reported. In light of the fact that lanthanide and d-block transition metal ions differ in their coordination number, pzdc may coordinate with them in a different manner, resulting in a characteristic structure. As these complexes have potential applications as new materials, we synthesized the lanthanide coordination polymers of pzdc by hydrothermal and hydro(solvo)thermal syntheses. Here, we report on their crystal structures and their properties.

Results and Discussion

Crystal Structures

The three coordination polymers are isomorphous. Only the structure of **4** will be described in detail. The asymmetric unit of **4** consists of two europium(III) ions, three 2,3-pyrazinedicarboxylate groups, one coordinated water and two lattice water molecules (Figure 1). There are three coordination modes for the three bridging 2,3-pyrazinedicarboxylate groups, as shown in Scheme 1. The three pyrazine rings are orientated differently in the crystal. The dihedral angles between the pyrazine rings are 70.8, 76.3, and 14.4°, owing to the steric effects in the formation of lanthanide coordination polymers. Although Eu1 and Eu2 are both nine-coordinate, the coordination environments around them are different. A hexadentate and a tetradentate pzdc ligand coordinate to Eu1 in a bidentate chelating mode through a nitrogen atom N(2A) of the pyrazinyl group and an oxygen atom O(4A) of an adjacent carboxylate group, and through N(3) and O(5).

In addition, Eu1 is coordinated to two oxygen atoms [O(1), O(2)] from a μ_2,η^3-carboxylate group of a hexadent-

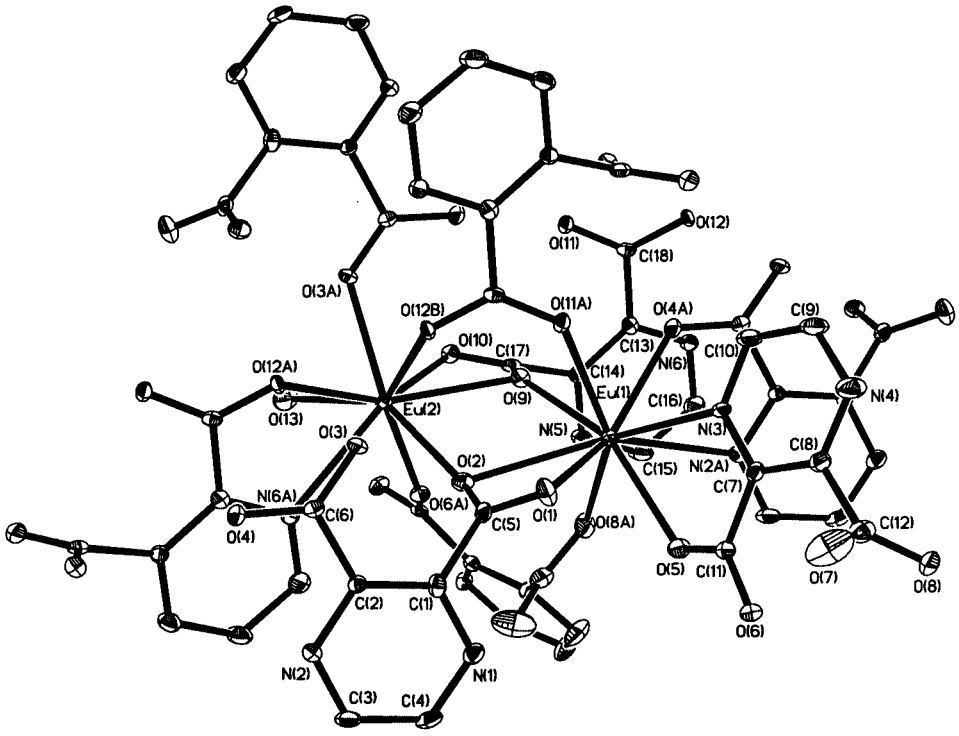

Figure 1. Coordination environment of complex **4**; the asymmetric unit and the related coordination atoms are labeled; lattice water molecules and all hydrogen atoms are omitted for clarity; thermal ellipsoids are shown at the 30% probability level

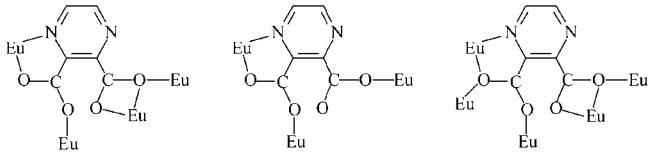

Scheme 1. The coordination modes of the pzdc ligand in complex **4**

ate pzdc ligand, one oxygen atom [O(8A)] from the carboxylate group of a tetradentate ligand, one oxygen atom [O(11A)] from the μ_2,η^2-carboxylate group of a heptadentate pzdc ligand and one oxygen atom [O(9)] from the μ_2,η^3-carboxylate group of another heptadentate pzdc ligand. Compared with Eu1, there is only one heptadentate pzdc ligand that is coordinated to Eu2 through one nitrogen atom [N(6A)] of pyrazinyl group and one carboxylate oxygen atom [O(12A)]. Eu2 is also coordinated to two oxygen atoms [O(9), O(10)] of a carboxylate group from a heptadentate pzdc ligand, four oxygen atoms[O(2), O(3A), O(6A), O(12B)] from the carboxylate groups of two hexadentate, one tetradentate, and another heptadentate pzdc ligands. An oxygen atom [O(13)] from a water molecule coordinates to Eu2 to complete the coordination number of nine. Altogether, there are six pzdc ligands bound to every Eu^{3+} ion. Eu1 is coordinated to two tetradentate, two hexadentate, and two heptadentate pzdc ligands, while Eu2 is coordinated to two hexadentate, one tetradentate, and three heptadentate pzdc ligands, as well as a water molecule. However, their modes of coordination differ, as mentioned above.

The framework structure of **4** is constructed from an $Eu_2(pzdc)_3H_2O$ unit. Firstly, two hexadentate and two heptadentate pzdc ligands link two dieuropium building units to form a parallelogram, the four vertices of which are occupied by four Eu^{3+} ions (Figure 2). The two heptadentate pzdc ligands are located above and below the plane of the parallelogram and link the four Eu^{3+} ions, resulting in a "cage-like" motif. The distances between Eu1 and Eu2, and Eu1 and Eu2B are 4.08 Å and 6.04 Å, respectively, and that between Eu2 and Eu2B is 4.22 Å. Four tetradentate pzdc ligands then link every parallelogram with four adja-

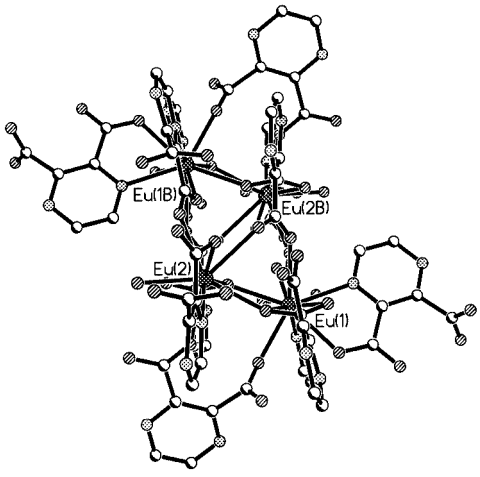

Figure 2. Perspective view of the parallelogram motif along the *a* axis formed by linking two dieuropium building blocks of **4** through tetradentate and hexadentate pzdc ligands

cent parallelograms which are orientated in a different manner. The parallelograms extend infinitely on the plane (100). Simultaneously, along the *a* axis, the parallelograms are linked by the hexadentate and heptadentate pzdc ligands forming a pillar of parallelograms, as shown in Figure 3. Thus, a complicated three-dimensional architecture is built with many cavities along the *a* axis.

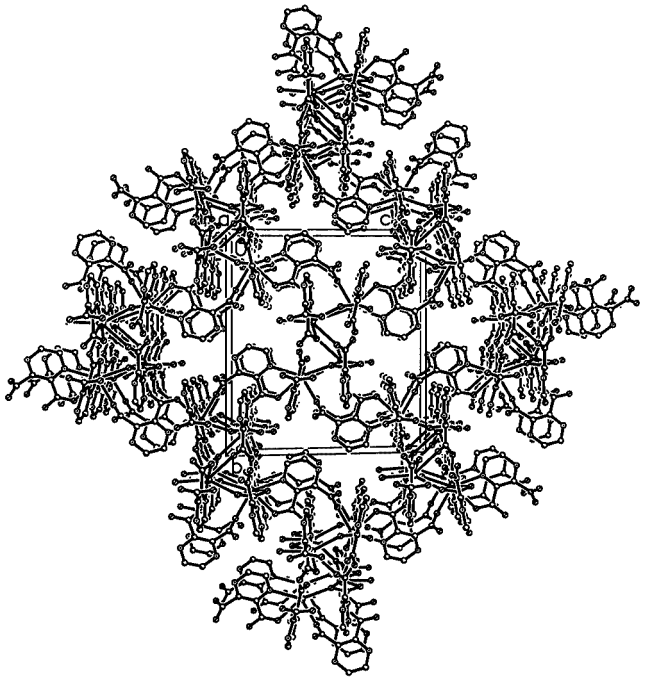

Figure 3. 3-D framework of **4** viewed along the *a* axis; all hydrogen atoms and uncoordinated water molecules are omitted for clarity

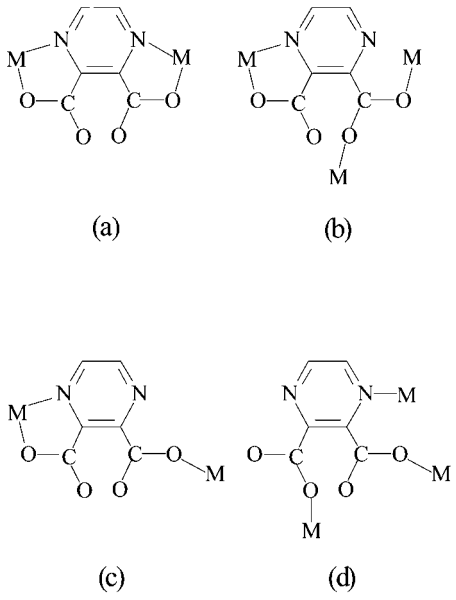
Although we have not determined the crystal structure of **3**, we can conclude that **3** has the same 3-D structure as complexes **1**, **2**, and **4** since they have the same components based on elemental analyses; furthermore, complexes **1**, **2**, and **4** are isomorphous and Nd is situated between La, Pr, and Eu in the lanthanide series. The pzdc ligands in **1**, **2**, and **3** have the same bridging modes, as shown in Scheme 1. In the reported binary d-block transition metal complexes with pzdc, there are four bridging modes for pzdc, as shown in Scheme 2. In $[M(pzdc)(H_2O)_2]_x{\cdot}2xH_2O$ (M = Co, Ni, Cu),[16] $[Co(pzdc)(H_2O)_2]_x$[17] and $[Cu(pzdc){\cdot}HCl]_x$,[13] the pzdc ligands bridge the metal ions through 1,4-diazine links that are supported by forming chelates to both metal ions, as depicted in Scheme 2 (a).

In $[M(pzdc)(H_2O)_2]_x{\cdot}2xH_2O$ (M = Fe,[9] M = Mn[15]) and $[Zn(pzdc){\cdot}3H_2O]_x$,[18] the pzdc ligands chelate to a metal ion in one chain and bridge two metal ions in the second chain by O−C−O links of a second carboxylate group of the same pzdc ligand, as shown in Scheme 2 (b). While in $[M(pzdc)(H_2O)_3]_x{\cdot}xH_2O$ (M = Zn,[19] M = Cd[15]), the pzdc ligand links one metal ion forming a chelate and bridges another metal ion with a second carboxylate group in a monodentate fashion, as depicted in Scheme 2 (c). In $[NH_4]_x[Ag(pzdc)]_x$,[14] besides one Ag^+ ion coordinated by one nitrogen atom of 1,4-diazine, two carboxylate groups of pzdc coordinate to one Ag^+ ion in a monodentate fashion, as seen in Scheme 2 (d). Generally speaking, in the above reported d-block transition metal complexes, the pzdc ligand adopts only one bridging mode in every complex. While in the title complexes, pzdc adopts three bridging modes in every complex, and its bridging mode is much more complicated than those in the d-block transition metal complexes (see Scheme 1). This can be attributed to the larger radii and greater positive charge of the Ln^{III} ions, and hence the large coordination number and different coordination modes required by the lanthanide ions.



Scheme 2. Coordination modes of the pzdc ligand in the reported binary d-block transition metal complexes

In addition, two types of hydrogen bonds exist in the crystal. A hydrogen bond forms between the lattice water molecules, and another between the coordinated water molecule and the lattice water molecule. These hydrogen bonds stabilize the crystal.

Photophysical Properties of $[Eu_2(pzdc)_3(H_2O)_x]{\cdot}2xH_2O$

Figure 4 illustrates the high-resolution emission spectrum of **4** excited at 355 nm at 77 K, corresponding to the $^5D_0 \rightarrow {}^7F_J$ ($J = 0-4$) transitions. From Figure 4 it can be seen that the intensity ratio of $^5D_0 \rightarrow {}^7F_2/{}^5D_0 \rightarrow {}^7F_1$ is 3.2, which indicates that the Eu^{III} ions are not in an inversion center. The number of components of the $^5D_0 \rightarrow {}^7F_1$ transition indicates the presence of more than one chemically different Eu^{III} ion sites. The intensity of the $^5D_0 \rightarrow {}^7F_0$ transition is relatively weak and the emission band is not symmetrical. The non-homogeneous broadening of the $^5D_0 \rightarrow {}^7F_0$ emission band arises from the site to site variation in the local field acting on the ions, and has consequently been studied by selective excitation techniques.

Among the transitions from the lowest emission state $^5D_0$ to the ground state ^7F_J ($J = 0-6$), the $^5D_0 \rightarrow {}^7F_2$ transition

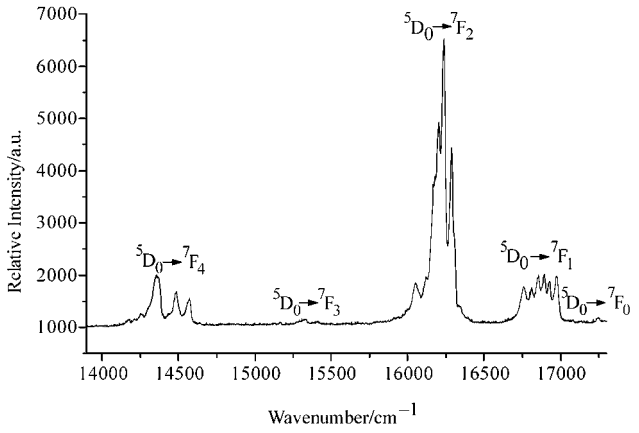


Figure 4. Emission spectrum of **4** corresponding to the $^5D_0 \rightarrow {}^7F_J$ ($J = 0-4$) transitions at 77 K, $\lambda_{exc} = 355$ nm

is the electronic dipole transition which is hypersensitive, and is greatly affected by the coordination environment. On the other hand, the $^5D_0 \rightarrow {}^7F_1$ transition is the magnetic dipole transition and is much less sensitive to the coordination environment. Therefore, the time-resolved spectra of complex **4** in the range of 16500−15900 cm^{-1} (corresponding to $^5D_0 \rightarrow {}^7F_2$ transition) were recorded and are shown in Figure 5. From Figure 5 it can be seen that the relative intensity of the emission peaks change. With a time delay, the peaks marked with "a" decay sharply relative to those marked with "b", which indicates that they arise from the Eu^{III} ion sites with different life-times. However, the less-developed bands show that it is difficult to obtain the exact life-time of each Eu^{III} ion site because they have slightly different chemical environments. Therefore, they may be simultaneously excited, or there may be an energy transfer between the Eu^{III} ion sites when excited, resulting in averaged life-times.

The excitation spectra of **4** (Figure 6) were recorded at 77 K, the analyzing wavenumbers were 16178, 16195, 16216, and 16304cm^{-1}. There are two main peaks located at 579.52 nm and 579.75 nm in every spectrum, which indicates that there are two Eu^{III} ion sites in the complex. This is in agreement with the results of the X-ray single-crystal diffraction study. It is worth noting that the excitation peaks are not narrow enough, and this is possibly a result of the slightly different chemical environments of the Eu^{III} ions in coordination polymers.

Thermogravimetric Analyses

Thermogravimetric analyses of the four complexes were carried out to examine their thermal stabilities. The data of the thermogravimetric analyses for **1**−**4** are listed in Table 1. All four complexes undergo loss of their coordinated and uncoordinated water molecules at the first weight loss.

Their dehydration temperatures range from 240 to 310 °C. They began to decompose beyond 430 °C. Looking at **1** as an example, the TGA curve shows that the first weight

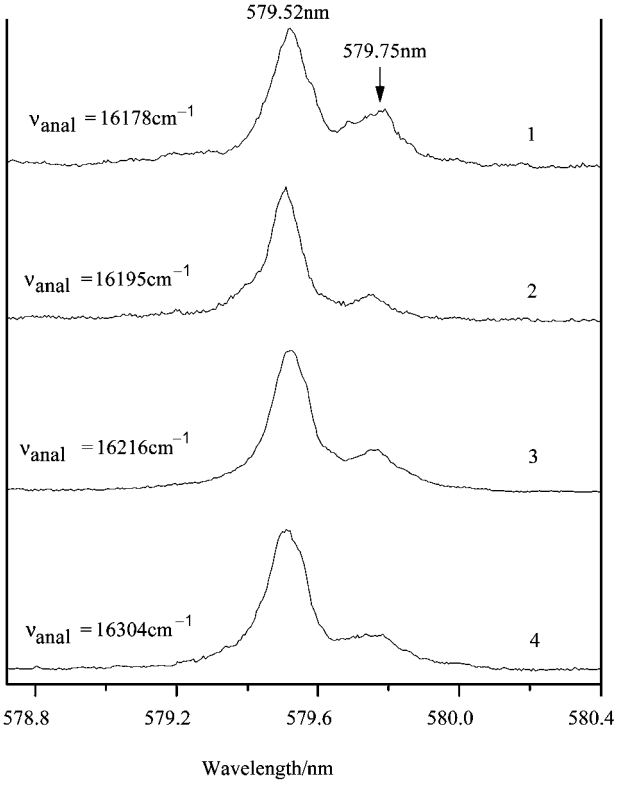

Figure 6. Excitation spectra of **4** at 77 K; analyzing wavenumber: 16178 cm^{-1} (1), 16195 cm^{-1} (2), 16216 cm^{-1} (3), and 16304 cm^{-1} (4)

Table 1. Thermogravimetric analyses of **1**−**4**

	1	**2**	**3**	**4**
Dehydration temperature [°C]	242.3−277.2	259.5−294.7	263.7−293.1	276.2−309.7
Loss of water:				
Calculated [%]	6.5	6.5	6.4	6.3
Found [%]	6.2	6.4	6.2	5.8
Further decomposition temperature [°C]	443	429.7	432.2	421.2

loss of 6.2%,which occurs between 242.3 and 277.2 °C corresponds to the loss of two uncoordinated water molecules and one coordinated water molecule (calculated: 6.5%). Further decomposition of **1** occurs above 443 °C (see Table 1).

Conclusion

Complexes **1**−**4** exhibit the same 3-D structures because they are isomorphous. The pzdc ligands in the complexes all adopt tetradentate, hexadentate and heptadentate bridging modes. By utilizing the characteristic of Eu^{3+} to act as a conformational probe, two Eu^{3+} ion sites have been observed in the coordination polymer **4**. In the coordination polymers, the La^{3+}, Pr^{3+}, and Nd^{3+} ions may have similar coordination environments to that of Eu^{3+}. Therefore, a conclusion could be reached that in polymers **1**, **2**, and **3**, there are two La^{3+} ion sites, two Pr^{3+} ion sites, and two Nd^{3+} ion sites, respectively. The four complexes are relatively stable. They all lose their coordinated and lattice water molecules at the first weight loss, above 240 °C.

Experimental Section

General: $LaCl_3{\cdot}7H_2O$, $NdCl_3{\cdot}6H_2O$, and $EuCl_3{\cdot}6H_2O$ were prepared by dissolving their oxides in concentrated hydrochloric acid and the solvents were evaporated to dryness. The stock solution of $PrCl_3$ was prepared by dissolving Pr_6O_{11} in concentrated hydrochloric acid and diluted to 0.49 mol/L. All the other reagents were commercially available and used without further purification. Elemental analyses were performed with an Elementar Vario EL analyzer. The IR spectra were recorded with a Nicolet Avatar 360 FT-IR spectrometer using the KBr pellet technique. Thermogravimetric analyses were performed with a ZRY-2P Thermal Analyzer.

$[La_2(pzdc)_3(H_2O)]_x{\cdot}2xH_2O$ (1): A solution of $LaCl_3{\cdot}7H_2O$ (0.111 g, 0.3 mmol), 2,3-pyrazinedicarboxylic acid (0.077 g, 0.45 mmol), H_2O (6.0 mL), ethanol (1 mL), and aqueous NaOH (1.6 mL, 1.04 mmol) was sealed in a 25-mL stainless steel reactor with Teflon liner and heated at 190 °C for 96 h. Colorless crystals of **1** were obtained in a 72.3% yield (0.09 g). $C_{18}H_{12}La_2N_6O_{15}$ (830.16): calcd. C 26.04, H 1.46, N 10.12; found C 25.64, H 1.08, N 9.73. IR data (KBr pellet, $\tilde{\nu}$ [cm^{-1}]): 3501 m, 1618s, 1558 s,1448 s, 1366 s, 1119 s, 895 m, 837 m, 443 m.

$[Pr_2(pzdc)_3(H_2O)]_x{\cdot}2xH_2O$ (2): An aqueous solution of $PrCl_3$ (0.61 mL, 0.3 mmol), 2,3-pyrazinedicarboxylic acid (0.077 g, 0.45 mmol), H_2O (6.5 mL), and aqueous NaOH (1.6 mL, 1.04 mmol) was sealed in a 25-mL stainless steel reactor with Teflon liner and heated at 190 °C for 62 h. Green crystals of **2** were obtained in a 79.9% yield (0.1 g). $C_{18}H_{12}Pr_2N_6O_{15}$ (834.16): calcd. C 25.92, H 1.45, N 10.07; found C 25.79, H 1.02, N 9.84. IR data (KBr pellet, $\tilde{\nu}$ [cm^{-1}]): 3492 m, 1619 s, 1558 s, 1447 s, 1366 s, 1120 s, 891 m, 843 m, 837 m, 444 m.

$[Nd_2(pzdc)_3(H_2O)]_x{\cdot}2xH_2O$ (3): A solution of $NdCl_3{\cdot}6H_2O$ (0.108 g, 0.3 mmol), 2,3-pyrazinedicarboxylic acid (0.077 g, 0.45 mmol), H_2O (7 mL), and aqueous NaOH (1.46 mL, 0.95 mmol) was sealed in a 25-mL stainless steel reactor with Teflon liner and heated at 190 °C for 62 h. Purple crystals of **3** were obtained in a 79.2% yield (0.1 g). $C_{18}H_{12}Nd_2N_6O_{15}$ (840.76): calcd. C 25.71, H 1.44, N 10.00; found C 25.39, H 1.12, N 9.84. IR data (KBr pellet, $\tilde{\nu}$ [cm^{-1}]): 3492 m, 1621 s, 1558 s, 1448 s, 1366 s, 1120 s, 891 m, 837 m, 445 m.

$[Eu_2(pzdc)_3(H_2O)]_x{\cdot}2xH_2O$ (4): A solution of $EuCl_3{\cdot}6H_2O$ (0.11 g, 0.3 mmol), 2,3-pyrazinedicarboxylic acid (0.077 g, 0.45 mmol), H_2O (8.4 mL), and aqueous NaOH (1.4 mL, 0.91 mmol) was sealed in a 25-mL stainless steel reactor with Teflon liner and heated at 190 °C for 88 h. Colorless crystals of **4** were obtained in a 77.8% yield (0.1 g). $C_{18}H_{12}Eu_2N_6O_{15}$ (856.26): calcd. C 25.25, H 1.41, N 9.81; found C 24.78, H 1.10, N 9.43. IR data (KBr pellet, $\tilde{\nu}$ [cm^{-1}]): 3486 m, 1627 s, 1561 s, 1449 s, 1368 s, 1122 s, 898 m, 845 m, 838 m, 449 m.

Measurement of the High-Resolution Luminescence Spectra: The excitation light source was a YAG:Nd laser that emits at 1.064 μm, and the excitation wavelength was 355 nm. The sample was placed in a Dewar bottle and cooled with liquid nitrogen. The fluorescence emitted was collected at right angles through a Spex 1403 monochromator with a photomultiplier tube, then averaged with a Boxcar integrator and finally the data were transferred to a computer.

X-ray Data Collections and Structure Determinations: The X-ray single-crystal data collections for complexes **1**, **2**, and **4** were performed with a Bruker Smart 1000 CCD diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Semi-empirical absorption corrections were applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least squares on F^2 using the SHELXTL-97 program.[16] All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were generated geometrically and treated by a mixture of independent and constrained refinements. Experimental details for X-ray data collection of **1**, **2**,
