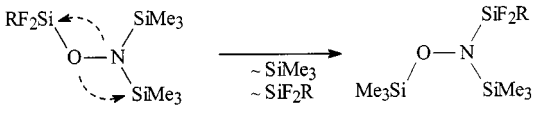
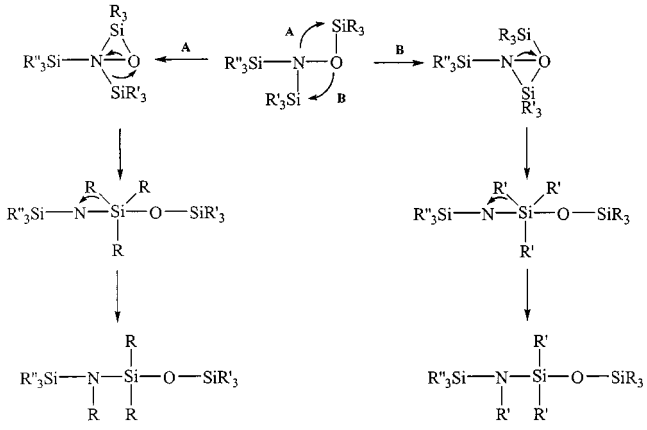
(fluorosilyl)-*N*,*O*-bis(trimethylsilyl)hydroxylamines and found it to be irreversible.[5] Ab initio and density functional calculations were consistent with the dyotropic course of the isomerisation.



(3)

R = alkyl, aryl

In a thermal rearrangement, which proceeds at temperatures up to 200 °C, tris(organosilyl)hydroxylamines undergo an intramolecular isomerisation involving the insertion of a silicon moiety into the bond between the nitrogen and the oxygen atom and the transfer of an organyl group from the silicon to the nitrogen atom, thereby forming silylaminodisiloxanes.[1,2,6,12]



(4)

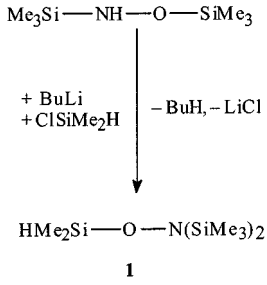
This conversion occurs in high yields. We studied rearrangements of *N*-(fluorosilyl)-*N*,*O*-bis(organylsilyl)hydroxylamines and found that the insertion of a silicon moiety into the N−O bond exclusively involves the silicon moiety that was bonded to the nitrogen atom. The insertion of an SiF_2 unit into the N−O bond has not been observed.

For a better understanding of our results, we report herein on quantum chemical investigations of the isomerisations of tris(silyl)hydroxylamines based on several model compounds and the thermal rearrangements of two *N*,*N*,*O*-tris(silyl)hydroxylamines with formation of the isomeric silylaminodisiloxanes.

Results and Discussion

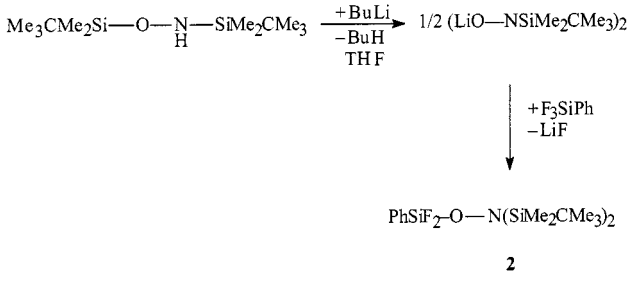
Experimental

O-Lithio-*N*,*N*-bis(trimethylsilyl)hydroxylamide reacts with $ClSiMe_2H$ to give *O*-(dimethylsilyl)-*N*,*N*-bis(trimethylsilyl)hydroxylamine (**1**) [Equation (5)].



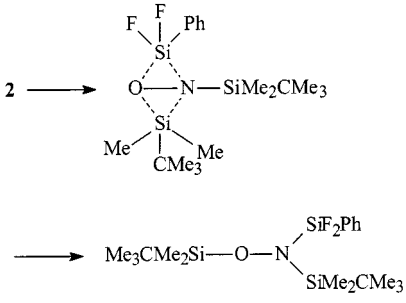
(5)

The lithium salt of *N*,*O*-bis(*tert*-butyldimethylsilyl)hydroxylamine crystallises from THF as dimeric *N*,*N*-bis(*tert*-butyldimethylsilyl)hydroxylamide[7] and reacts with trifluoro(phenyl)silane at 0 °C with formation of *N*,*N*-bis(*tert*-butyldimethylsilyl)-*O*-[difluoro(phenyl)silyl]hydroxylamine (**2**).



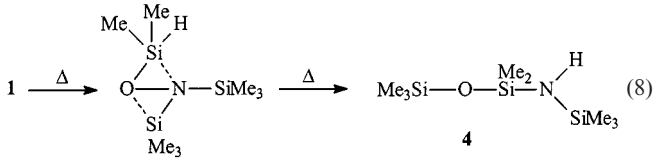
(6)

Product **2** could be isolated following the removal of LiF in a centrifuge by virtue of the low reaction temperature and the bulky $SiMe_2CMe_3$ groups. In solution, even at room temperature, the onset of the dyotropic rearrangement of **2** into the isomeric *N*,*O*-bis(*tert*-butyldimethylsilyl)-*N*-difluorophenylsilyl)hydroxylamine (**3**) can be observed by means of NMR spectroscopy. The conversion of **2** to **3** is found to be quantitative within a few hours in boiling THF. The softer Lewis acid F_2SiPh migrates to the softer Lewis base nitrogen, while the harder Lewis acid $SiMe_2CMe_3$ migrates to the harder Lewis base oxygen.

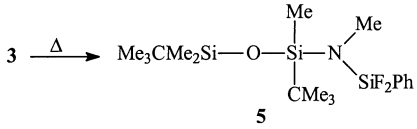


(7)

When heated under reflux for 3 d, **1** and **3** undergo a thermal rearrangement to form the silylaminodisiloxanes **4** and **5**, respectively. The conversion of **1** to **4** was monitored by ^1H NMR spectroscopy. It was found that a structural isomer of **1**, namely *N*-(dimethylsilyl)-*N*,*O*-bis(trimethylsilyl)hydroxylamine, was formed initially, which could not be isolated under the given reaction conditions.



(8)



(9)

The formation of **4** involves the insertion of an $SiMe_2$ moiety into the N−O bond and a hydrogen atom transfer from the silicon to the nitrogen atom, whereas the formation of **5** involves the insertion of an $SiMeCMe_3$ moiety into the N−O bond and the migration of a CH_3 group from the silicon to the nitrogen atom.

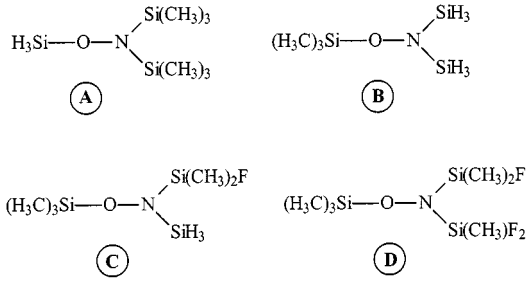
Quantum Chemical Study on the Isomerisation of Tris(silyl)hydroxylamines

In order to gain more insight into the mechanisms governing the thermal isomerisation reactions of tris(silyl)hydroxylamines, quantum chemical calculations have been carried out.

Methodology

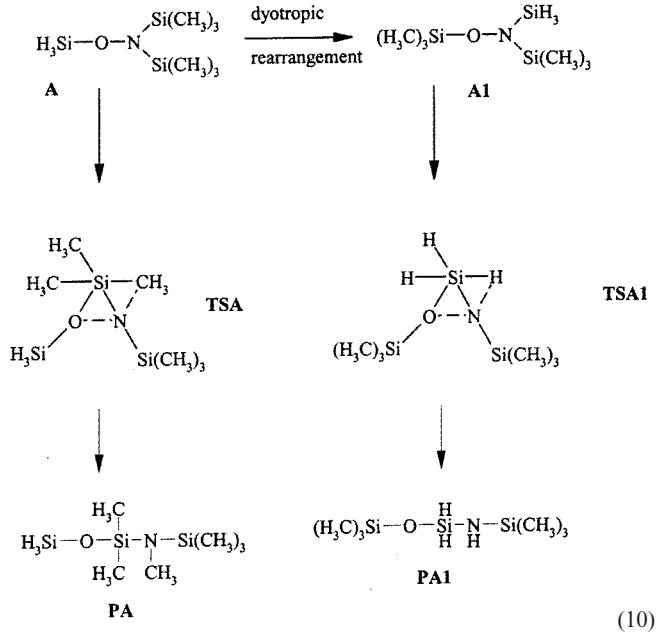
The program package GAUSSIAN-98[13] was employed throughout. The geometries of the minima and first-order saddle points on the potential energy surfaces (PES) were calculated using the density functional variant B3LYP, which is a hybrid method employing Becke's exchange functional[14] and the Lee, Yang, and Parr correlation functional.[15] The 6-31G* basis set was used. The calculated stationary points on the PES were characterised by the Hessian matrices. The obtained harmonic vibrational frequencies were used to calculate the zero-point energy contributions. The saddle points were further characterised using the TS routine in GAUSSIAN-98 (intrinsic reaction coordinate method).[16]

Using the B3LYP/6-31G* methodology, we have recently studied various isomerisation reactions in silylhydrazine chemistry.[17−21] The calculated structures were compared with available X-ray diffraction data and good agreement was found throughout.

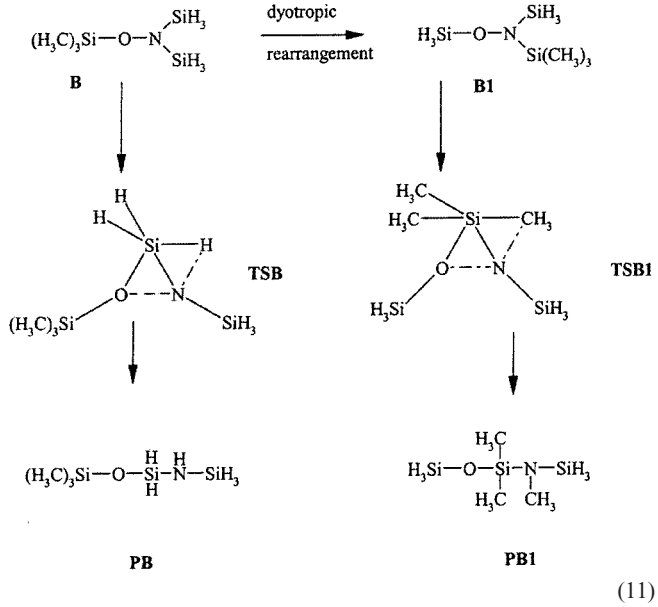


Here, four different model compounds are investigated in detail: *N*,*N*-bis(trimethylsilyl)-*O*-(silyl)hydroxylamine (**A**), *N*,*N*-bis(silyl)-*O*-(trimethylsilyl)hydroxylamine (**B**), *N*-(fluorodimethylsilyl)-*N*-silyl-*O*-(trimethylsilyl)hydroxylamine (**C**), and *N*-(fluorodimethylsilyl)-*N*-(difluoromethylsilyl)-*O*-(trimethylsilyl)hydroxylamine (**D**).

In all four cases, insertion of a silicon atom initially located at the nitrogen atom into the N−O bond occurs. For **A** and **B**, only one product (**PA** and **PB**, respectively) is possible for symmetry reasons. However, **A** and **B** can undergo a dyotropic rearrangement yielding structures **A1** and **B1**. Starting from these isomers, a silicon atom from the nitrogen site can be inserted into the N−O bond yielding products **PA1** and **PB1**, respectively.

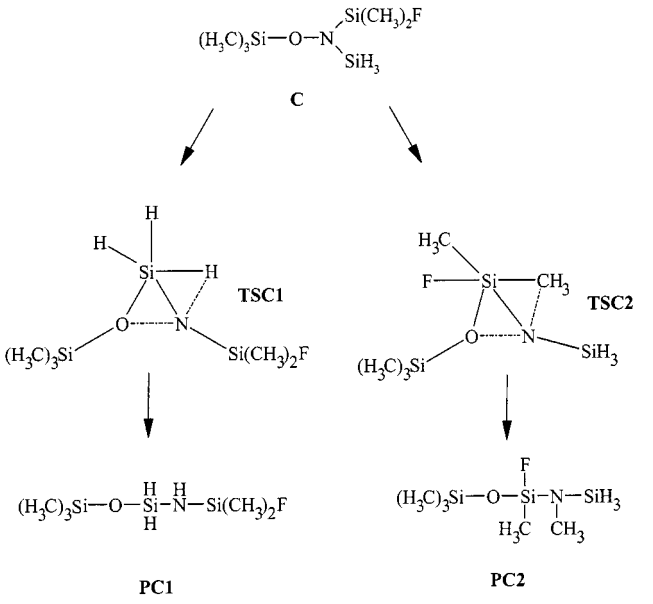


(10)

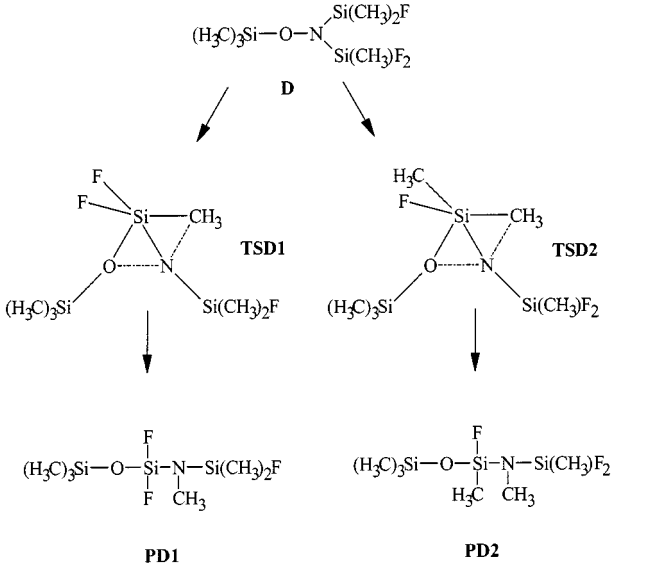


(11)

For **C** and **D**, two different reaction pathways are possible, yielding products **PC1/PC2** and **PD1/PD2**, respectively.



(12)



(13)

The transition states corresponding to these reactions are denoted as follows: **TSdA** and **TSdB** are the dyotropic transition states in the isomerisations **A** → **TSdA** → **A1** and **B** → **TSdB** → **B1**. The transition states leading to the silylaminodisiloxanes **PA**, **PA1**, **PB**, **PB1**, **PC1**, **PC2**, **PD1**, and **PD2** are denoted by **TSA**, **TSA1**, **TSB**, **TSB1**, **TSC1**, **TSC2**, **TSD1**, and **TSD2**, respectively.

Structures

In Table 1, the B3LYP/6-31G* equilibrium geometries for the hydroxylamines **A**, **A1**, **B**, **B1**, **C**, and **D** are given. **A** and **B** exhibit C_s symmetry with the Si−O−N chain contained in the symmetry plane. The O−N bond length is calculated to be within the range 147−150 pm. Electron-withdrawing (e.g. fluorosilyl) groups shorten the O−N bond. Depending on the substituents at the silicon atom, the Si−O bond lengths range from 169 to 172 pm and the Si−N bond lengths from 173 to 179 pm. The Si−O−N angles are in the range 109 to 118°, indicating pure sp^3 to sp^2 hybridisation of the oxygen atom. The angles O−N−Si, on the other hand, clearly show that the nitrogen atom is sp^3-hybridised. Depending on the steric demand of the silyl groups, the Si−N−Si angles are between 122 and 129°. As can be seen from the torsional angles Si−O−N−Si, all hydroxylamines adopt a *trans* conformation.

Table 1. The geometries of the two saddle points corresponding to the dyotropic transition states **TSdA** and **TSdB** are given in Table 2. The structure of **TSdB** is shown graphically in Figure 1. The steric demand of the bicyclic structures is considerable because both three-membered rings exhibit acute O−Si−N angles of ca. 45° and thus underlie strong ring tension. It should be noted that the first calculations on dyotropic transition states in silylhydroxylamines were carried out by Müller.[5] Compared to the reactants **A** and **B**, the O−N bonds are only slightly longer by 4.6 and 5.3 pm, respectively. In both transition states, the hydroxylamine Si−O bonds are considerably stretched (by 39.7 pm and 46.1 pm for **TSdA** and **TSdB**, respectively). The original and the newly formed Si−O bonds are almost

Table 2. B3LYP/6-31G(d) geometries of the dyotropic transition states **TSdA** and **TSdB**; bond lengths in pm, angles in °; bond angles are denoted by α, torsional angles by θ

equal in length. On the contrary, the hydroxylamine Si−N bonds are stretched by only ca. 10 pm, and the newly formed endocyclic Si−N bond lengths are 7 pm longer that the original ones. The exocyclic Si−N bond is slightly elongated in the dyotropic TS compared to the Si−N bonds in hydroxylamines. The angle between the two three-membered rings is given by the torsional angle $\theta(Si_1ONSi_2)$, which is calculated to be 122 and 123° in **TSdA** and **TSdB**, respectively. The geometries are in very good agreement with the results for $H_3SiO-N(SiH_3)_2$ reported in ref.[5]

In Table 3, the equilibrium structures of the eight silylaminodisiloxanes **PA**, **PA1**, **PB**, **PB1**, **PC1**, **PC2**, **PD1**, and **PD2** are given. These structures may be compared with the structures of the diazasilacyclopropanes discussed in refs.[17,18] The triangular O−Si−N structural motif is analogous to the SiN_2 ring; however, the N−O bond is broken (distance 272 to 286 pm) and the nitrogen atom bears an additional substituent. The O−Si bonds are considerably shortened compared to those in the hydroxylamines, on average by 4 pm. The shortest O−Si bond length is calculated to be only 162 pm. The Si−N bonds are also slightly shorter in the disiloxanes, but the effect is less pronounced compared to the situation with the Si−O bonds. The central silicon atom is clearly sp^3-hybridised (as is the case for the diazasilacyclopropanes[17,18]). The Si−O−Si angles, however, are between 138 and 153°, and indicate sp^2 hybridisation of the oxygen atom with a tendency towards sp hybridisation. The Si−N−Si angles are in the range 124 to 132°. The sum of the angles at the nitrogen centre amounts to almost 360° throughout, clearly indicating sp^2 hybridisation.

Table 3. B3LYP/6-31G(d) equilibrium geometries of the silylaminodisiloxanes (products **PA**, **PA1**, **PB**, **PB1**, **PC1**, **PC2**, **PD1**, and **PD2**); bond lengths in pm, angles in °; bond angles are denoted by α, torsional angles by θ; R = H for **PA1**, **PB** and **PC2**; R = Me otherwise values in parentheses give the equilibrium geometry of structure **PB** obtained at the B3LYP/6-31+G(d) level of theory

Table 4 gives the geometrical parameters of the saddle points corresponding to transition states **TSA**, **TSA1**, **TSB**, **TSB1**, **TSC1**, **TSC2**, **TSD1**, and **TSD2**. As an example, the structure **TSC1** is shown graphically in Figure 2. The O−N bonds (between 203 and 212 pm) are markedly elongated (by more than 30 pm) compared with the corresponding bonds in the reactant structures. The exocyclic Si−O bond length is only slightly greater than the corresponding bond length in the products. The newly formed O−Si bond is relatively long (up to 20 pm longer than that in the silylaminodisiloxanes). The exocyclic N−Si bond length is slightly greater than the corresponding bond length in the product. The Si−N bond bridging to the oxygen atom is only slightly shorter than that in the silylaminodisiloxanes, and much shorter than that in the hydroxylamines. The acute central

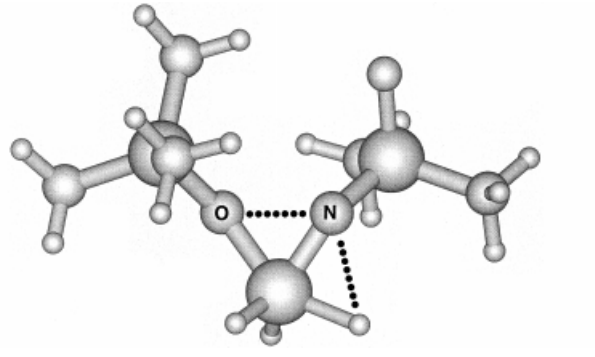

Figure 2. Structure of the saddle point **TSC1** (SiH_3 insertion into the O−N bond; see text for details)

O−Si−N angle is between 68 and 76°. The Si−O−Si and Si−N−Si angles are between 131 and 142°.

The transition states are bicyclic structures with the first ring formed by the NO moiety and the inserting silicon atom, while the second ring is formed by the central silicon atom, the nitrogen atom, and the group R transferred from the silicon atom to the nitrogen atom (see Figure 2). The transferred group (R) is either a hydrogen atom or a methyl group. The silicon, the oxygen, the nitrogen, and the hydrogen atom (or the methyl carbon atom) are almost coplanar. At the saddle point, the reacting Si−R bonds are considerably stretched. Thus, the reacting Si−C bond in **TSA** is 19.2 pm longer than the other two Si−C bonds (198.2 pm) at the same silicon atom. The Si−H bond in **TSA1** is 11.7 pm longer compared to the other two Si−H bond lengths (148.8 pm). However, the new bond to the nitrogen atom has yet to be formed at the saddle point. The N−C distance in **TSA** is 248.0 pm and the N−H distance in **TSA1** amounts to 212.7 pm; these are much longer than the corresponding distances in the silylaminodisiloxanes (Table 3). Thus, the saddle points reported in Table 4 may be classified as *early* transition states. The N−O bond is not yet fully broken and the interaction between the nitrogen atom and the transferred moiety is only weak. The bicyclic first-order saddle point structures for silicon insertion into the N−O bond are analogous to the dyotropic transition states **TSdA** and **TSdB** (the bond between the central silicon atom and the nitrogen atom adopts the role of the N−O bond in the dyotropic TS). The B3LYP/6-31G(d) structures of all compounds described in this quantum chemical study can be obtained from one of the authors (sschmat@gwdg.de).

The influence of diffuse basis functions [6-31+G(d) basis set] on the geometries of the stationary points was investigated for structures **B**, **PB**, and **TSB** (see Tables 1, 3, and 4). The only remarkable deviation from the B3LYP/6-31G(d) results was found for the Si−O−Si angle in the silylaminodisiloxane **PB**, which is widened by 25°. The Si−O−Si unit becomes almost linear (178.4°) when the additional diffuse functions are taken into account. However, the energetics are hardly affected. The saddle point **TSB** is found at 38.3 kcal·mol^{-1} above **B** [38.2 kcal·mol^{-1} with 6-31G(d)], whereas the product **PB** is located at 84.9 kcal·mol^{-1} below **B** [83.8 kcal·mol^{-1} with 6-31G(d)].

Energetics

In Table 5, the energetics of the dyotropic transition state **TSdA** and silylhydroxylamine **A1** relative to species **A** are given. **A1** is more stable than **A** by ca. 3 kcal·mol^{-1}, and zero-point energy effects enhance its stability. Energetically, the dyotropic TS is located at 33 kcal·mol^{-1} above the reactant. This is of the same order of magnitude as reported by Wolfgramm et al.[5] The dyotropic **TSdB** is calculated to be 36 kcal·mol^{-1} above the reactant **B** (Table 6). The isomer **B1** is 1.5 kcal·mol^{-1} higher in energy than **B**. This indicates that configurations with silyl groups at the nitrogen atom and trimethylsilyl groups at the oxygen site are energetically favoured.

In Figures 3−6, the potential energy profiles of the isomerising tris(silyl)hydroxylamines **A**, **B**, **C**, and **D** are displayed graphically as functions of the reaction coordinate. Note that the stationary points are connected by a smooth curve; the "reaction coordinate" in Figures 3−6 does not have any quantitative physical significance. The influence of zero-point vibrational energy (at the harmonic level; reaction coordinate at saddle points not included) is given in Tables 5−8. The effect of finite temperature (298 K) is also highlighted in these tables (reaction enthalpies $\Delta_R H°$). As can be seen from Figure 3, the insertion of an SiH_3 group into the N−O bond is favoured compared to $SiMe_2$ insertion. In addition to the thermodynamic control ($|\Delta E_{\mathbf{PA1}}| > |\Delta E_{\mathbf{PA}}|$), the reaction is also kinetically controlled (by the barriers to isomerisation $\Delta E_{\mathbf{TSA1}} < \Delta E_{\mathbf{TSA}}$). Silylhydroxylamine **A** first has to undergo isomerisation via the dyotropic transition state **TSdA**, for which the activation energy (barrier height $\Delta E_{\mathbf{TSdA}}$) is very similar to the corresponding value for the silyl group insertion ($\Delta E_{\mathbf{TSA1}}$). The larger reaction enthalpy and the lower isomerisation barrier determine the course of the reaction (**A** → **PA1**).

A similar conclusion can be drawn from Figure 4. Here, reaction **B** → **PB** (SiH_3 insertion) is favoured both thermodynamically and kinetically. The barrier $\Delta E_{\mathbf{TSdB}}$ for the dyotropic rearrangement **B** → **B1** is smaller than the barrier $\Delta E_{\mathbf{TSB1}}$ for $SiMe_3$ insertion **B1** → **PB1**.

In Figure 5, insertion of a silyl group is compared with that of a fluorodimethylsilyl group. Again, SiH_3 insertion (**C** → **PC1**) is favoured both thermodynamically and kinetically (Table 7).

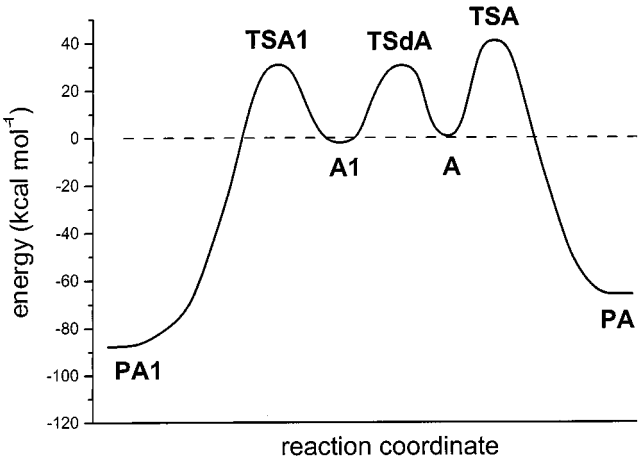

Figure 3. Potential energy diagram for reaction **A** (schematic)

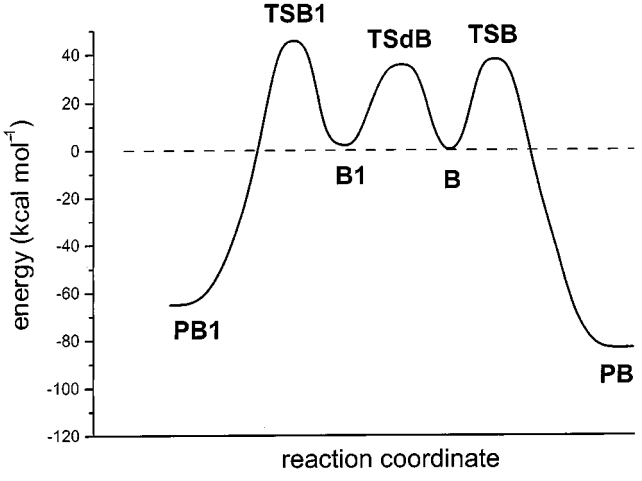

Figure 4. Potential energy diagram for reaction **B** (schematic)

Figure 6 shows the thermal rearrangement of *N*-(difluoromethyl)-*N*-(fluorodimethylsilyl)-*O*-(trimethylsilyl)-hydroxylamine. Insertion of the difluorosilyl group has a slightly smaller associated barrier height ΔE_{TSD1} than insertion of the monofluorosilyl group. However, the product **PD2** is energetically favoured by 1.3 kcal·mol^{-1} (Table 8). The reaction is clearly subject to thermodynamic control. This is in keeping with the conditions of preparation of the silylaminodisiloxane, i.e. heating of a fluoro-substituted tris(silyl)hydroxylamine up to 200 °C and keeping it at this temperature for several hours.

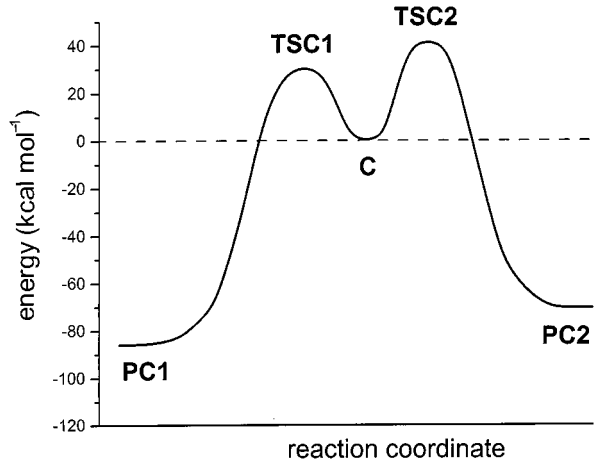

Figure 5. Potential energy diagram for reaction **C** (schematic)

It should be noted that the theoretical results are in nice agreement with the experimental finding that during the conversion of **1** to **4** a structural isomer of **1** was monitored. This isomer is formed by a dyotropic rearrangement. After this step, the $SiHMe_2$ group inserts instead of the $SiMe_3$ group.

It remains to be considered how well hybrid DFT methods, e.g. B3LYP, can predict transition-state geometries and barrier heights. Hybrid DFT involves mixing various amounts of the Hartree−Fock non-local exchange operator with DFT exchange-correlation functionals, and it has been observed that the fraction needed for an accurate prediction of thermochemical data differs from the optimal fraction for predicting accurate barrier heights. Recently, Lynch and Truhlar[22] reported DFT calculations of barrier heights in 22 reactions and found a mean unsigned error of 3.4−4.2 kcal·mol^{-1} (depending on the basis set) in comparison with best estimates derived from experimental data. Møller−Plesset second-order perturbation theory (MP2) performed slightly less well. Lynch and Truhlar recommend their own hybrid method MPW1K,[23] which gave a mean unsigned error of only 1.5 kcal·mol^{-1}. However, all of the 22 reactions involve free radicals and the transfer of a hydrogen atom, and all but one are bimolecular reactions. Since the empirical data are as yet only limited, and since, in the present work, we focus on the energetic *differences* between several reaction pathways, we are confident that the B3LYP method yields reliable results.

[a] At B3LYP/6-31G(d) geometry.

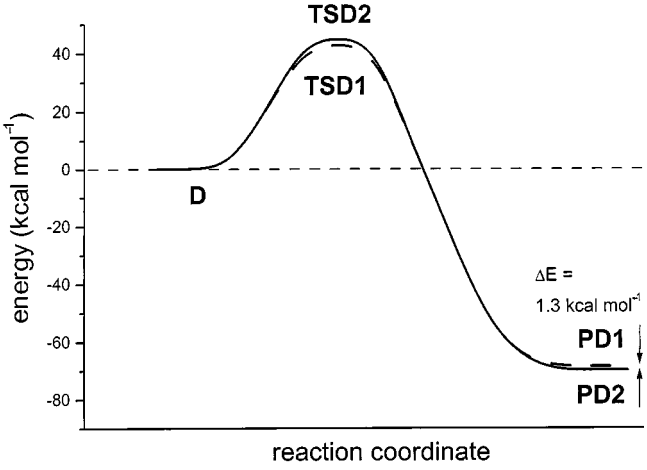

Figure 6. Potential energy diagram for reaction **D** (schematic)

In order to study the influence of polarization and diffuse basis functions on the energetics of the four systems, we performed B3LYP/6-311+G(2d,p) calculations on the B3LYP/6-31G(d) geometries (see Tables 5−8). Overall, the results are in good agreement with those obtained employing the smaller basis set. The products **PA1**, **PB**, and **PC1** are lowered in energy because the additional diffuse and polarization functions allow for a better description of the SiH_2−NH unit in these cases.

We also carried out MP2 calculations with the 6-31G(d) and 6-31+G(d,p) basis sets at the optimized B3LYP geometries (see Tables 5−8). The energetic differences between reactants and products are very close to the DFT results. The two saddle points describing the dyotropic transition states are slightly lower in energy than the corresponding saddle points from the MP2 calculations. However, all other MP2 saddle points are much higher in energy. This can be explained by the fact that the dyotropic transition states (TS) can be classified as "tight" TS, whereas the other TS (Table 4) are "loose" TS with considerably stretched bonds. MP2 does not include a major fraction of the non-dynamical correlation energy and is not capable of describing such loose structures. In particular, the order of the two saddle points in reaction according to eq. 13 is reversed at the MP2 level of theory.

Normal Modes of Transition States

The harmonic vibrational frequencies ω_{TS} of the reactive normal modes Q_{TS} at the various saddle points are given in Table 9. The two dyotropic transition states have rather similar imaginary frequencies and corresponding reduced masses μ_{TS}. In both cases, a silyl group and a trimethylsilyl group undergo simultaneous migration. However, the motion along Q_{TS} is governed by the oxygen atom, which is much lighter than the heavy silyl groups (see Figure 7). From the viewpoint of reaction dynamics, the term "silyl group migration" is somewhat misleading.

Table 9. Harmonic vibrational frequencies in cm^{-1} of the reactive normal coordinates Q_{TS} of the transition states; the corresponding reduced mass in a.m.u. is denoted by μ_{TS}

	TSdA	TSA	TSA1	TSdB	TSB	TSB1	TSC1	TSC2	TSD1	TSD2
ω_{TS}	278*i*	558*i*	505*i*	267*i*	559*i*	617*i*	613*i*	527*i*	509*i*	546*i*
μ_{TS}	8.96	2.78	8.46	8.04	7.04	2.48	2.40	7.04	8.99	8.80

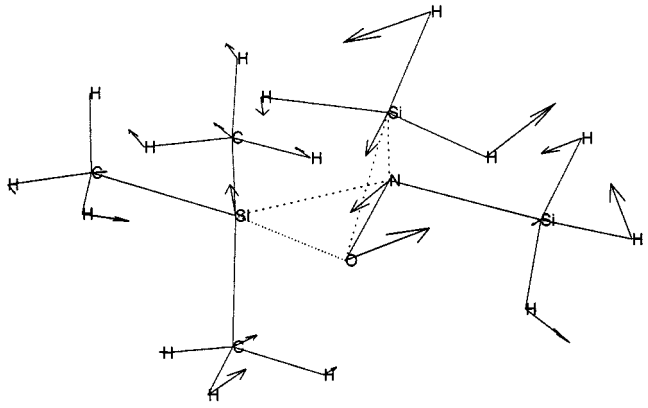

Figure 7. The reaction coordinate Q_{TS} at the saddle point **TSdB**, i.e. the normal coordinate of the mode with the imaginary vibrational frequency ω_{TS}

The transition states for SiH_3 group insertion into the N−O bond (**TSA**, **TSB1**, and **TSC1**) exhibit very similar characteristic ω_{TS} and μ_{TS} data for the reactive normal modes Q_{TS}. Inspection of the remaining saddle points (**TSA1**, **TSB**, **TSC2**, **TSD1**, and **TSD2**) reveals that substitution of an $SiMe_3$ group by $SiMe_2F$ or $SiMeF_2$ has only a small influence on the nuclear dynamics in the saddle-point region of the PES (the curvature of the saddle point, given by $\mu_{TS}\,\omega_{TS}^2$, is relatively similar). The reactive motion is described by the fission of the N−O bond and the insertion of the silicon atom (see Figure 8). The bond between the transferred group (H or CH_3) is considerably stretched. The nitrogen atom moves towards the transferred group and forms a new bond.

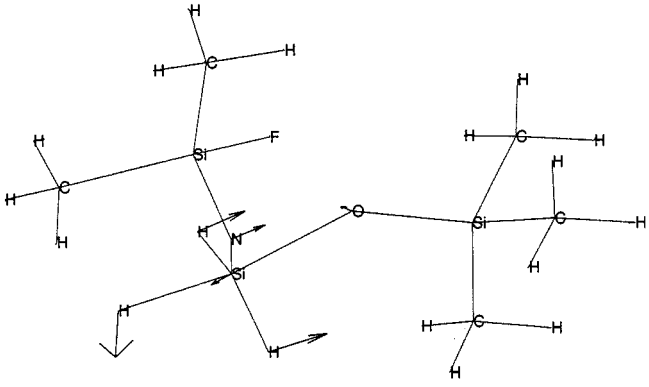

Figure 8. The reaction coordinate Q_{TS} at the saddle point **TSC2**, i.e. the normal coordinate of the mode with the imaginary vibrational frequency ω_{TS}

In summary, it has been shown that the insertion of a silyl group into the N−O bond is energetically favoured if it occurs from the nitrogen atom. Furthermore, a monofluorosilyl group inserts into the N−O bond whereas the difluorosilyl group does not. Insertion of SiH_2 stabilises the product by 86 kcal·mol^{-1} whereas insertion of $SiMe_2$, SiMeF, or SiF_2 yields a stabilisation of 66, 70, and 69 kcal·mol^{-1}, respectively. The transition state for SiH_2 insertion is located at 35±3 kcal·mol^{-1} above the tris(silyl)hydroxylamines, whereas the transition state for insertion of $SiMe_2$, SiMeF, and SiF_2 is ca. 10 kcal·mol^{-1} higher (44±3 kcal·mol^{-1}).

Experimental Section

General: All experiments were performed in oven-dried glassware using standard inert gas and vacuum-line techniques. NMR spectra were recorded from samples in $CDCl_3$ with $SiMe_4$ and C_6F_6 (^{1}H, ^{13}C, ^{19}F, ^{29}Si) as internal and $MeNO_2$ (^{15}N) as external references. Mass spectral data are reported in mass-to-charge units (*m*/*z*). The progress of the reactions was monitored by ^{19}F NMR spectroscopy. The compounds were obtained in analytically pure form.

***O*-(Dimethylsilyl)-*N*,*N*-bis(trimethylsilyl)hydroxylamine (1):** To a solution of *N*,*N*-bis(trimethylsilyl)hydroxylamine (8.8 g, 0.05 mol) in *n*-hexane (70 mL), *n*BuLi (1.6 M solution in *n*-hexane, 0.05 mol) was slowly added. After heating under reflux for 2 h, the reaction mixture was cooled to room temperature, whereupon $ClSiMe_2H$ (0.05 mol, 4.7 g) was added. LiCl was removed on a frit and **1** was purified by distillation; yield 73%; b.p. 63 °C/0.01 mbar. ^{1}H NMR ($CDCl_3$): δ = 0.11 [s, 18 H, $Si(CH_3)_3$], 0.22 [d, $^3J_{H,H}$ = 2.9 Hz, 6 H, $Si(CH_3)_2$], 4.7 (sept, $^3J_{H,H}$ = 2.9 Hz, 1 H, SiH). ^{13}C NMR ($CDCl_3$): δ = −1.22 (SiC_3), 0.76 (SiC_2). ^{29}Si NMR ($CDCl_3$): δ = 8.27 [$Si(CH_3)_3$], 13.43 (SiH). MS (EI): *m*/*z* (%) = 235(21) $[M]^+$, 220(8) $[M - CH_3]^+$. IR: $\tilde{\nu}$ = 2131.6 cm^{-1} (SiH). $C_8H_{25}NOSi_3$ (235.55): calcd. C 40.79, H 10.70; found C 40.53, H 10.32.

***N*,*N*-Bis(*tert*-butyldimethylsilyl)-*O*-(difluorophenylsilyl)hydroxylamine (2):** F_3SiPh (8.1 g, 0.05 mol) was added to *N*,*N*-bis(*tert*-butyldimethylsilyl)-*O*-lithiohydroxylamine[6] (13.0 g, 0.5 mol) at 0 °C and the mixture was slowly allowed to warm to room temperature. **2** was freed of LiF by centrifugation; yield 76%; b.p. 100 °C/0.05 mbar. ^{1}H NMR ($CDCl_3$): δ = 0.23 (t, $^6J_{HF}$ = 0.56 Hz, 12 H, $NSiCH_3$), 1.01 [s, 18 H, $NSiC(CH_3)_3$], 7.0−7.2 (C_6H_5). ^{13}C NMR ($CDCl_3$): δ = −2.91 (t, $^5J_{C,F}$ = 1.51 Hz, NSiC), 20.03 ($NSiCC_3$), 27.89 ($NSiCC_3$), 125.04 (t, $^2J_{C,F}$ = 26.7 Hz, C-1 of Ph), 128.47 (t, $^4J_{C,F}$ = 0.7 Hz, C-3,5 of Ph), 132.25 (C-4 of Ph), 134.72 (t, $^3J_{C,F}$ = 119 Hz, C-2,6 of Ph). ^{19}F NMR ($CDCl_3/C_6F_6$): δ = 29.5. ^{29}Si NMR ($CDCl_3$): δ = −65.02 (t, J_{SiF} = 278.7 Hz, OSiF), 14.85 (NSi). MS (EI): *m*/*z* (%) = 388(8) $[M - CH_3]^+$, 346(100) $[M - C(CH_3)_3]^+$.

***N*,*O*-Bis(*tert*-butyldimethylsilyl)-*N*-(difluorophenylsilyl)hydroxylamine (3):** A solution of **2** (20.2 g, 0.05 mol) in THF (50 mL) was refluxed for 3 d (^{19}F NMR control). Thereafter, the **3** obtained was distilled in vacuo. yield 67%. ^{1}H NMR ($CDCl_3$): δ = 0.12 (s, 6 H, $OSiCH_3$), 0.16 (s, 6 H, $NSiCH_3$), 0.28 [s, 9 H, $OSiC(CH_3)_3$], 0.88 [s, 9 H, $NSiC(CH_3)_3$], 7.2−7.8 (m, 5 H, C_6H_5). ^{13}C NMR ($CDCl_3$): δ = −6.37 ($NSiCH_3$), −5.49 ($OSiCH_3$), 17.82 [$NSiC(CH_3)_3$], 18.12 [$OSiC(CH_3)_3$], 25.84 [$NSiC(CH_3)_3$], 26.39 [$OSiC(CH_3)_3$]. ^{19}F NMR ($CDCl_3$): δ = 27.19 (OSiF). ^{29}Si NMR ($CDCl_3$): δ = −51.02 (t, $^1J_{SiF}$ = 271.19 Hz, NSiF), 15.49 (NSi), 24.56 (OSi). MS (EI): *m*/*z* (%) = 403(2) $[M]^+$, 388(8) $[M - CH_3]^+$, 346(100) $[M - CMe_3]^+$. $C_{18}H_{35}F_2NOSi_3$ (403.20): calcd. C 53.62, H 8.75; found C 53.16, H 8.49.

Compounds 4 and 5: The respective tris(silyl)hydroxylamine **1** or **3** (0.03 mol) was heated under reflux without a solvent for 3 d. Compounds **4** and **5** produced were purified by distillation in vacuo.

1,1,1,3,3-Pentamethyl-3-[(trimethylsilyl)amino]-1,3-disiloxane (4): Yield 82%; b.p. 63 °C/10 mbar. ^{1}H NMR ($CDCl_3$): δ = 0.04

[$Si(CH_3)_2$], 0.06 [$NSi(CH_3)_3$], 0.07 [$OSi(CH_3)_3$], 0.42 (NH). ^{13}C NMR ($CDCl_3$): δ = 1.97 [$OSi(CH_3)_3$], 2.30 [$NSi(CH_3)_3$], 2.46 [$Si(CH_3)_2$]. ^{15}N NMR ($CDCl_3$): δ = −344.71 (NH). ^{29}Si NMR ($CDCl_3$): δ = −11.24 (NSi), 2.12 (OSiN), 6.08 (SiO). MS (EI): *m*/*z* (%) = 235(4) $[M]^+$, 220(100) $[M - CH_3]^+$. $C_8H_{25}NOSi_3$ (235.55): calcd. C 40.79, H 10.70; found C 40.31, H 10.35.

1,3-Di-*tert*-butyl-3-[(difluorophenylsilyl)methylamino]-1,1,3-trimethyl-1,3-disiloxane (5): Yield 67%; b.p. 101 °C/0.05 mbar. ^1H NMR ($CDCl_3$): δ = 0.14 (3 H, $OSiCH_3$), 0.15 (3 H, $OSiCH_3$), 0.36 (3 H, $SiCH_3$), 0.97 [9 H, $SiC(CH_3)_3$], 1.04 [9 H, $SiC(CH_3)_3$], 2.68 (t, $^4J_{HF}$ = 1.15 Hz, 9 H, NCH_3), 7.4−7.8 (m, 5 H, C_6H_5). ^{13}C NMR ($CDCl_3$): δ = −2.92 ($OSiCH_3$), −2.90 ($OSiCH_3$), −5.66 (t, $^4J_{HF}$ = 2.53 Hz, $SiCH_3$), 18.27 [$SiC(CH_3)_3$], 18.37 [$SiC(CH_3)_3$], 25.84 [$SiC(CH_3)_3$], 26.67 [$SiC(CH_3)_3$], 33.72 (t, $^3J_{C,F}$ = 2.45 Hz, NCH_3), 128.04 (C-1 of Ph), 128.27 (C-3,5 of Ph), 131.57 (C-4 of Ph), 134.72 (t, $^3J_{C,F}$ = 1.26 Hz, C-2,6 of Ph). ^{19}F NMR ($CDCl_3$): δ = 24.71−26.55 (NSiF). ^{29}Si NMR ($CDCl_3$): δ = −47.22 (t, $^1J_{SiF}$ = 268.35 Hz, NSiF), 8.95 (t, $^3J_{SiF}$ = 1.53 Hz, NSiO), 11.62 (OSi). MS (EI): *m*/*z* (%) = 403(2) $[M]^+$, 388(8) $[M - CH_3]^+$, 346(100) $[M - CMe_3]^+$. $C_{18}H_{35}F_2NOSi_3$ (403.20): calcd. C 53.62, H 8.75; found C 53.74, H 8.92.

Acknowledgments

S. S. is indebted to Professor Peter Botschwina for continuous support. We would like to thank Dr. Rainer Oswald for his help with Figures 7 and 8. Helpful discussions with Dr. Thomas Müller (University of Frankfurt/Main) are gratefully acknowledged. Most of the calculations were carried out on workstations of the Gesellschaft für wissenschaftliche Datenverarbeitung Göttingen (GWDG). Support through Sonderforschungsbereich 357 "Molekulare Mechanismen unimolekularer Prozesse" is gratefully acknowledged. We are grateful to the Deutsche Forschungsgemeinschaft and Fonds der Chemischen Industrie for support of this work.

Syntheses, Structures, and Spectroscopic Properties of Cobalt(III) Complexes Containing 3- or 4-Pyridyl-Substituted Nitronyl and Imino Nitroxide Ligands

Masahiro Ogita,[a] Youhei Yamamoto,[a] Takayoshi Suzuki,[a] and Sumio Kaizaki*[a]

Keywords: Nitroxides / Radicals / Cobalt / NMR spectroscopy / Deoxygenation

Several new cobalt(III) complexes incorporating 4,4,5,5-tetramethyl-2-(3- or 4-pyridyl)imidazolin-1-oxyl 3-oxide (NIT*n*py) (*n* = 3 or 4) or 4,4,5,5-tetramethyl-2-(3- or 4-pyridyl)-imidazolin-1-oxyl (IM*n*py) have been prepared. The X-ray crystallographic analyses and the spectroscopic investigations have revealed that the nitronyl or imino nitroxides with the radical character are bound through the pyridyl-N atom to a Co^{III} center. There are some influences from the radical unpaired electron toward the Co^{III} complex moiety and those from the coordination of the Co^{III} ion toward the nature of these radicals which can be detected by ^{59}Co NMR and UV/Vis spectroscopy. Such observed changes coincide with the proposed spin density on the N atom of the pyridyl substituent. Furthermore, it was found that *trans*-[Co(acac)$_2$(PPh$_3$)(NIT4py)]$^+$ in methanol was gradually converted into the corresponding IM4py complex, while free NIT4py is stable in methanol. The Co^{II} species formed on the partial decomposition of the NIT4py complex in methanol seems to catalyze the deoxygenation of NIT4py to IM4py.

Introduction

In the last two decades, the chemistry and magnetic properties of transition metal complexes containing imidazolin-1-oxyl 3-oxide (abbreviated as nitronyl nitroxide; NIT) or imidazolin-1-oxyl (imino nitroxide; IM) radicals have been examined extensively.[1−11] These studies have been aimed mainly at investigating the magnetic exchange interactions between the metal d (or f) and the radical unpaired electrons, and at designing and synthesizing molecular ferro/ferrimagnets. Therefore, most of the complexes studied were of paramagnetic metal ions such as Mn^{II}, Cu^{II}, Ni^{II},[1−5] Cr^{III},[5a] Co^{II},[6−8] and lanthanide(III).[9] Among the nitronyl or imino nitroxide radicals, the pyridyl-substituted derivatives are especially attractive and are utilized successfully, because the auxiliary donor ability of the pyridyl-N atom tends to assemble extended coordination compounds by binding to metal ions.[2a,10] The suitability of such pyridyl-substituted nitroxides with the metal ions has afforded new aspects of their paramagnetic and diamagnetic metal complexes. In our previous papers concerning paramagnetic metal radical complexes, we have reported on the structures, magnetic, and spectroscopic (UV/Vis absorption, MCD, resonance Raman, NMR) properties of the 2-pyridyl-substituted nitronyl nitroxide (NIT2py) or imino nitroxide (IM2py) complexes of Cr^{III}, Ni^{II}, Co^{II}, and Mn^{II}.[5,6] For diamagnetic metal complexes Oshio et al. have observed a large ferromagnetic or antiferromagnetic interaction between the two imino nitroxides through a diamagnetic metal center in tetrahedral Cu^{I}, Ag^{I} and square-planar Pd^{II} complexes.[11] Wei et al. have found a fairly large antiferromagnetic interaction in a polymeric Hg^{II} chain compound.[10] Recently, we described the X-ray structures and magnetic properties of the IM2py Zn^{II} complex and related complexes.[6] On the other hand, substitution-inert Co^{III} complexes incorporating the pyridyl-substituted nitronyl or imino nitroxides (NIT*n*py or IM*n*py) would exhibit a variety of coordination modes of the 3- or 4-pyridyl-substituted nitroxide radicals, or exert an influence from nonradical coligands. Such nitroxide radical Co^{III} complexes are expected to afford moderately or slightly magnetically coupled systems, where the spectroscopic properties could be regulated, as observed for the Ni^{II} and Cr^{III} complexes.[5] This is in contrast to semiquinone radical Co^{III} complexes, which are susceptible to reduction to Co^{II}.[12] Here, we report on the synthesis and structural characterization of *trans*-[Co(acac)$_2$(NO$_2$-κ*N*)(L)], *trans*-[Co(acac)$_2$(PPh$_3$)(L)]PF$_6$, and [Co(acac)(tdmme)(L)](PF$_6$)$_2$ [acac = pentane-2,4-dionate; tdmme = 1,1,1-tris(dimethylphosphanylmethyl)-ethane; L = NIT4py, NIT3py, IM4py, and IM3py] (Scheme 1). We also report on the novel deoxygenation reaction of NIT4py in *trans*-[Co(acac)$_2$(PPh$_3$)(NIT4py)]PF$_6$, and on the attempts to prepare the bis(nitroxide) Co^{III} complexes.

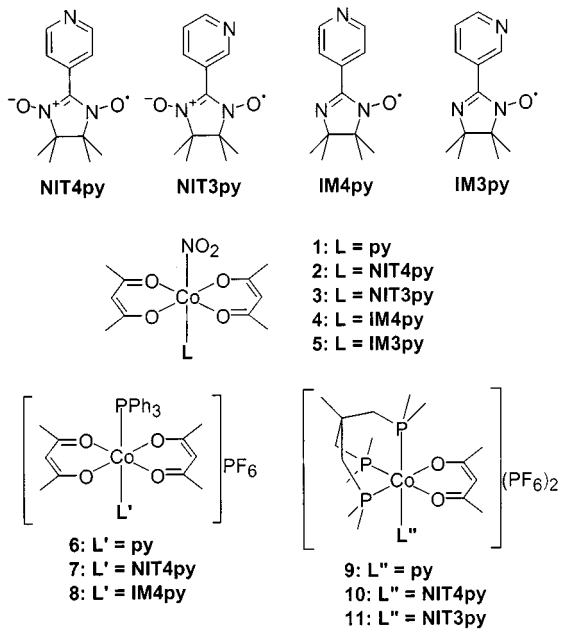

Scheme 1. The nitronyl and imino nitroxides and their Co^{III} complexes, together with the reference pyridine complexes, prepared in this study

Results and Discussion

Bis(pentane-2,4-dionato)(nitrito-κ*N* or triphenylphosphane) Complexes

Although both 4- and 3-pyridyl-substituted nitroxide complexes, *trans*-$[Co(acac)_2(NO_2\text{-}\kappa N)(L)]$ [L = NIT4py (**2**), IM4py (**4**), NIT3py (**3**), and IM3py (**5**)], were prepared from *trans*-$Na[Co(acac)_2(NO_2\text{-}\kappa N)_2]$, the reaction of *trans*-$[Co(acac)_2(PPh_3)_2]PF_6$ with the nitroxides gave only the 4-pyridyl-substituted complexes, *trans*-$[Co(acac)_2(PPh_3)(L')]PF_6$ [L′ = NIT4py (**7**) and IM4py (**8**)]. The formation of the 3-pyridyl-substituted nitroxide (NIT3py or IM3py)/PPh_3 complexes was not observed due to steric factors (vide infra). The *trans* geometry of the nitroxide complexes, as well as of the corresponding pyridine complexes of **1** and **6** was determined by ^1H NMR spectroscopy in $CDCl_3$. The spectra showed only one methyl and one methine proton resonances of the acac moiety with an intensity ratio of 6:1 (Table 1).

Table 1. ^1H NMR chemical shifts of the acac moiety in the Co^{III} complexes **1**−**8**

Compound	$-CH_3$[a]	$=CH-$[a]
1	2.12	5.33
2	2.11	5.33
3	2.19	5.35
4	2.12	5.33
5	2.12	5.32
6	1.78	4.89
7	1.74	4.91
8	1.79	4.90

[a] In $CDCl_3$. Chemical shifts (δ scale) are relative to TMS. For all compounds listed the intensity ratio of $-CH_3$ to $=CH-$ was found to be 6:1.

The structures of complexes **5**, **7**, and **8** were confirmed by X-ray analysis. The molecular structures of *trans*-$[Co(acac)_2(NO_2\text{-}\kappa N)(IM3py)]$ (**5**) and *trans*-$[Co(acac)_2(PPh_3)(NIT4py)]^+$ in **7**·CH_2Cl_2 are shown in Figure 1. The crystal of **8**·CH_2Cl_2 is isomorphous to that of **7**·CH_2Cl_2 and the molecular structure of *trans*-$[Co(acac)_2(PPh_3)(IM4py)]^+$ in **8**·CH_2Cl_2 (Figure S1, Supporting Information) is very similar to that of the NIT4py complex, except for the absence

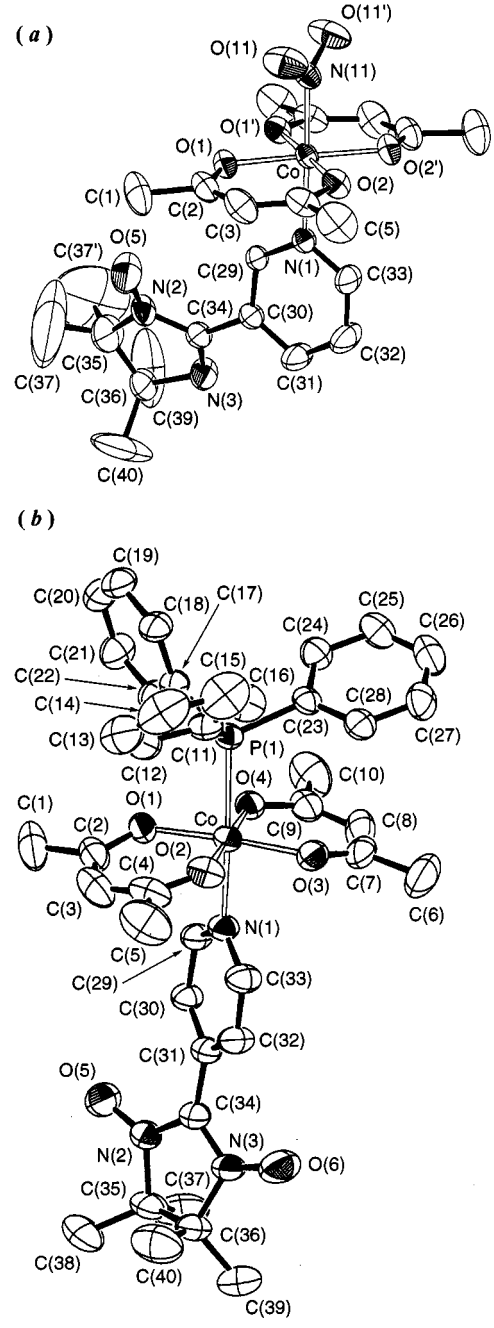

Figure 1. Perspective views of (*a*) *trans*-$[Co(acac)_2(NO_2\text{-}\kappa N)(IM3py)]$ (**5**) (40% probability level) and (*b*) *trans*-$[Co(acac)_2(PPh_3)(NIT4py)]^+$ in **7**·CH_2Cl_2 (50% probability level); hydrogen atoms are omitted for clarity

of one O atom from the nitronyl nitroxide moiety. The pyridyl-substituted nitronyl or imino nitroxide is bound to a Co^{III} center via a pyridyl-N atom at the position *trans* to NO_2-κ*N* or PPh_3.

Selected bond lengths, bond angles, and dihedral angles between the least-squared planes are listed in Table 2. The structural parameters of the NIT4py moiety in **7** are similar to those of free NIT4py,[7b,13] and those of the other complexes containing monodentate pyridyl-N donating NIT4py.[1,2b,2c] The dihedral angle between the nitronyl nitroxide mean plane and the pyridyl ring in **7** [28.8(1)°] is slightly larger than those in free NIT4py (24.7°[7b] or 22.8°[13]). The N−O bond lengths in **7** [1.276(3) and 1.260(3) Å] are close to the typical bond lengths in the free nitronyl nitroxides.[7b,13,14] In contrast, the structural parameters of IM4py in **8**, IM3py in **5**, and the free 5-pyrimidyl or *m*-nitrophenyl imino nitroxide (IM5pym or IM*m*NP)[14a,15] are fairly different from one another. For example, the N−O bond length becomes shorter in the order **8** [1.295(6) Å] > **5** [1.273(6) Å] > IM5pym [1.268(4) Å] > IM*m*NP (average 1.246 Å). The dihedral angle between the imino nitroxide mean plane and the pyridyl ring is 29.2(2) and 22.5(2)° for **5** and **8**, respectively, 19.1° for IM5pym,[14a] and 44.7 and 13.0° for two crystallographically independent IM*m*NP molecules.[15]

Table 2. Selected bond lengths [Å], bond angles [°], and dihedral angles [°] between the least-squared planes for the complexes

plane(Co−4O) vs. plane(phenyl 2)	−	72.7(1)	69.0(1)
plane(Co−4O) vs. plane(phenyl 3)	−	23.5(1)	22.8(1)
plane(py) vs. plane(nitroxide)	29.2(2)	28.8(1)	22.5(2)

[a] Plane(Co−4O) was defined by O(1), O(2), O(3 or 1′) and O(4 or 2′); plane(acac 1) by O(1), O(2), and C(2)−C(4); plane(acac 2) by O(3), O(4), and C(7)−C(9); plane(py) by N(1) and C(29)−C(33); plane(phenyl 1) by C(11)−C(16); plane(phenyl 2) by C(17)−C(22); plane(phenyl 3) by C(23)−C(28).

The structures of the *trans*-$Co(acac)_2(PPh_3)$ moiety in **7** and **8** are similar to those in *trans*-$[Co(acac)_2(PPh_3)(H_2O)]PF_6$[16a] and *trans*-$[Co(acac)_2(PPh_3)(atmp)]PF_6$ (atmp = 4-amino-2,2,6,6-tetramethylpiperidine-κN^4).[16b] In particular, the acac ligands in the equatorial positions bend away from the axial PPh_3 group, due to the steric effects presented by the bulky axial PPh_3 group. The dihedral angle between the two acac planes are 24.3(1) and 26.8(2)° in **7** and **8**, respectively. The Co−P bond lengths, 2.2723(7) in **7** and 2.269(1) Å in **8**, are similar to those in *trans*-$[Co(acac)_2(PPh_3)(H_2O)]PF_6$ [2.243(1) Å] and *trans*-$[Co(acac)_2(PPh_3)(atmp)]PF_6$ [2.295(2) Å].

The pyridyl ring of NIT4py or IM*n*py in **5**, **7**, and **8** is oriented toward the cleft between the two equatorial acac ligands (Figure 1 and Figure S1). This orientation would minimize the sterically repulsive interaction between the planar pyridyl moiety of the nitroxide and the equatorial acac planes. Comparison with the structures of complexes **5**, **7**, and **8** suggests that in the hypothetical complex, *trans*-$[Co(acac)_2(PPh_3)(NIT3py \text{ or } IM3py)]^+$, severe steric interaction exists between the nitroxide part of the coordinated NIT3py or IM3py and the equatorial acac planes which would bend away from the axial PPh_3 group due to steric hindrance. This seems to be the reason for the unsuccessful syntheses of the 3-pyridyl-substituted nitroxide complexes for PPh_3 derivatives.

(Tripodal tridentate phosphane)(pentane-2,4-dionato) Complexes

For spectroscopic purposes (vide infra), we have also attempted to prepare the NIT4py and NIT3py complexes which incorporates tripodal tridentate phosphane,

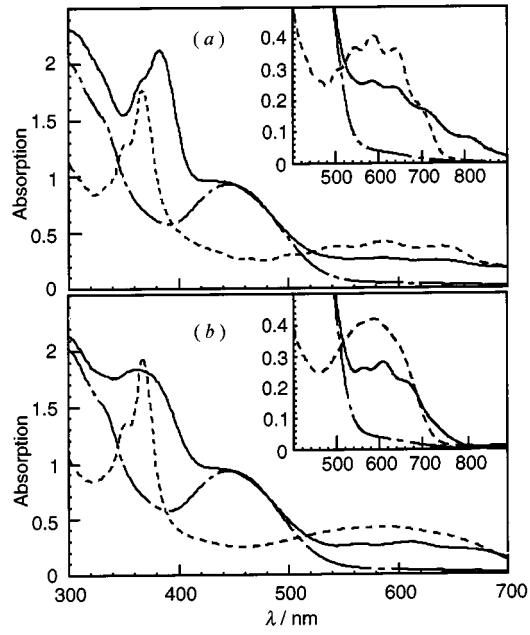

Figure 2. UV/Vis spectra in the solid state: (*a*) complex **9** (− · −), complex **10** (——), and NIT4py (− − − −); (*b*) complex **9** (− · −), complex **11** (——), and NIT3py (− − − −)

tdmme.[17] The reaction of [Co(acac)(tdmme)-(CH_3CN)](PF_6)$_2$ (**12**) and L′′ (L′′ = py, NIT4py, or NIT3py) in methanol afforded powder products of [Co(acac)(tdmme)(L′′)](PF_6)$_2$ (**9**−**11**). The UV/Vis spectra of the products in the solid state showed distinct changes from the superimposed spectra of the starting materials (Figure 2 and Table 3). These compounds were insoluble in dichloromethane, chloroform, and methanol, and fairly soluble in acetonitrile. However, the absorption spectra of compounds **9**−**11** in acetonitrile showed apparent shifts from those in the solid, and coincided with the superimposed spectra of complex **12** and free L′′. These facts indicate that in acetonitrile NIT*n*py (or py) dissociates from the Co^{III} center giving a mixture of the acetonitrile complex **12** and free L′′. This lability is probably due to the strong *trans* influence of tdmme.[17]

Deoxygenation of NIT4py to IM4py in the PPh_3 Complex

Ullman reported that heating nitronyl nitroxides with PPh_3 in benzene affords the corresponding imino nitroxides in high yields.[18] In view of this fact, the successful synthesis of complex **7** from *trans*-[Co(acac)$_2$(PPh_3)$_2$]PF_6 seems to be strange since free PPh_3 is produced in the reaction mixture. Under the experimental conditions employed (in dichloromethane at room temperature for several hours), detectable deoxygenation of NIT*n*py to IM*n*py was not observed. Further, refluxing NIT4py with PPh_3 in dichloromethane, chloroform, or methanol for several hours did not result in any UV/Vis spectral change. The isolated complex **7** was also stable on refluxing in dichloromethane or chloroform for several hours. However, when a methanol solution of **7** was allowed to stand at room temperature for 1 d, the UV/Vis and ESR spectra of the solution changed to those corresponding to the IM4py complex **8**. On refluxing the methanol solution, deoxygenation of NIT4py in complex **7** was completed within 10 min (Figure 3). A prolonged reaction in boiling methanol resulted in the decomposition of IM4py; a very weak ESR signal of IM4py was seen after 1 d.

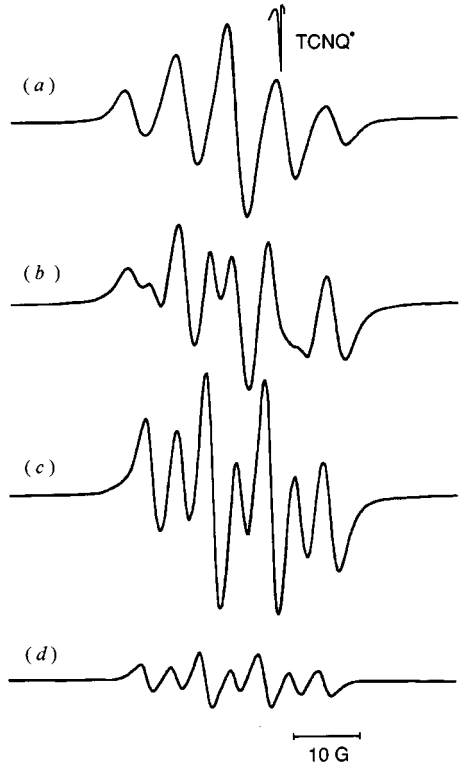

Figure 3. The ESR spectra of complex **7** (*a*) in dichloromethane, (*b*) in methanol, (*c*) in refluxing methanol for 10 min, and (*d*) in refluxing methanol for 24 h

The reagent that is responsible for the deoxygenation of NIT4py in complex **7** was investigated. As described above, a methanol solution of NIT4py alone, or together with PPh_3, did not result in such a deoxygenation reaction. The following Sephadex LH-20 chromatographic behavior in methanol suggests that complex **7** exists as a dissociated equilibrium mixture. Of the two bands separated from the

[a] Shoulder. [b] These data were measured qualitatively.

adsorbed products, the faster developing green band was a mixture of complex **7** and *trans*-[Co(acac)$_2$(PPh$_3$)(H$_2$O)]PF$_6$,[16a] whereas the slower developing blue eluate was free NIT4py. Thus, the aquated complex, [Co(acac)$_2$(PPh$_3$)(H$_2$O)]$^+$ would mainly contribute to the deoxygenation of NIT4py. In fact, NIT4py itself is catalyzed to form deoxygenated IM4py by a methanol solution of the triphenylphosphane complex *trans*-[Co(acac)$_2$(PPh$_3$)(H$_2$O)]PF$_6$, but not by a methanol solution of the dimethylphenylphosphane complex *trans*-[Co(acac)$_2$(PMe$_2$Ph)(H$_2$O)]PF$_6$ and the Co^{II} complex [Co^{II}(acac)$_2$(H$_2$O)$_2$]. The Co^{III}−PPh$_3$ complex, *trans*-[Co(acac)$_2$(PPh$_3$)(H$_2$O)]PF$_6$ slowly decomposes to give Co^{II} species, while *trans*-[Co(acac)$_2$(PMe$_2$Ph)(H$_2$O)]PF$_6$ is stable in methanol.[16a,19] Thus, the decomposed, yet uncharacterized Co^{II} products may be a catalyst for the deoxygenation process.

Attempts to Prepare Bis(nitronyl or imino nitroxide)bis(pentane-2,4-dionato) Complexes

Although the reaction of *trans*-[Co(acac)$_2$(PPh$_3$)$_2$]PF$_6$ with NIT3py in dichloromethane did not proceed, a similar reaction with twice the equimolar amounts of NIT3py in methanol showed a gradual change in color from dark red to brown. The elemental analysis and the spectroscopic data of the brown product indicate the formation of a complicated mixture of bis(NIT3py)-, (NIT3py)(IM3py)-, and bis(IM3py)-bis(acac)cobalt(III) complexes (Figure S2, Supporting Information), as suggested from the reaction conditions for the deoxygenation of NIT3py to IM3py as described above. The formation of IM3py could not be avoided under these reaction conditions.

An attempt to oxidize an ethanolic solution of *trans*-[Co^{II}(acac)$_2$(NIT*n*py or IM*n*py)$_2$][7b] with acidic PbO$_2$ resulted in the formation of a mixture of bis(NIT*n*py or IM*n*py) complexes (Figure S2), as in the case started from the Co^{III} complex. It is noted that in the reactions with PbO$_2$, NIT*n*py still deoxygenates to give IM*n*py.

ESR Spectra and Magnetic Properties

The ESR spectra of the Co^{III} NIT*n*py (**2**, **3**, **7**) and IM*n*py (**4**, **5**, **8**) complexes give a well-resolved quintuplet and septuplet signal, respectively (Figure S3, Supporting Information), as observed for free NIT*n*py and IM*n*py.[1,21] The *g* and *A* values of the Co^{III} complexes are close to those of the free nitroxide (Table 4). This fact indicates that the radical unpaired electron of the nitroxide is not significantly influenced by the coordination to a diamagnetic Co^{III} ion through the substituted pyridyl-N atom. This is also suggested by the variable-temperature magnetic measurements in the solid state, the overall profiles of the temperature dependence of the molar magnetic susceptibilities of the Co^{III} complexes are found to be similar to those of the free nitroxides (Figure S4, Supporting Information).

NMR Spectra

The ^{1}H NMR signals of the acac or PPh$_3$ moiety in the Co(acac)$_2$(NO$_2$-κ*N* or PPh$_3$) unit of **2**, **3**, **7**, and **8** were found to become broad. Since the observed broad signals did not show any shift from those of the parent complexes (Table 1), the line-broadening on coordination of NIT*n*py or IM*n*py via the pyridyl-N atom results from the dipolar relaxation (through space) mechanism, but not from the contact (through bond) mechanism. This is also related to the difference in broadening between the NIT3py and NIT4py complexes, the former being larger than the latter. The distance from the radical moiety in NIT3py to the protons in the coligands is shorter than for NIT4py, and accounts for the difference in line broadening in terms of the dipolar relaxation.

Table 4. ESR spectral parameters

[a] Chemical shifts (δ scale) are relative to K$_3$[Co(CN)$_6$]. [b] Could not be isolated.

Table 5 presents the ^{59}Co NMR parameters of the pyridine and nitroxide complexes. The ^{59}Co NMR chemical shifts of the PPh$_3$ complexes with py, NIT4py, and IM4py are located at a higher field than those of the corresponding NO$_2$-κ*N* complexes. The ^{59}Co NMR resonances of the nitroxide complexes are relatively broader as compared with the py complexes. For the NIT*n*py complexes **2**, **3**, and **7**, the ^{59}Co NMR signals on coordination of NIT3py and NIT4py shift to a higher and lower field, respectively, from those of the corresponding py complexes. The line-broadening for the NIT3py complex is small and considerably larger for the NIT4py complex (Figure S5, Supporting Information). These observations coincide with the ^{1}H

NMR behavior of the *meta*- and *para*-protons in the phenyl group of NITPh[22] and NITPhOH,[23] and also with the experimental and theoretical spin density (and sign) at these positions.[14,24]

The ^{59}Co NMR resonances of the IM*n*py complexes **3**, **4**, and **8** show slightly higher field shifts with less broadening than the corresponding NIT*n*py complexes. This also coincides with the difference in the spin density between the imino and nitronyl nitroxides.[14,15] Thus, the ^{59}Co NMR chemical shifts reflect the spin density and sign on the pyridyl-N atom of NIT*n*py or IM*n*py, although the shift values are relatively small, in accordance with the small spin density on the N atom.

UV/Vis Absorption Spectra

The UV/Vis spectra of complexes **2**−**5**, **7**, and **8** give a complicated pattern due to the overlap with the intraligand bands for the nitroxides and the Co(acac)$_2$(NO$_2$-κ*N* or PPh$_3$) moieties (Figure S6, Supporting Information). Thus, it is difficult to evaluate the coordination effect on the ligand-field d−d transitions of the Co^{III} ion and on the intraligand transitions of the radical moiety in these complexes by comparison with the spectra of the py complexes **1** and **6**. This difficulty may be overcome if the d−d bands are shifted to a shorter wavelength where the nitronyl nitroxides are transparent. This can be achieved with the use of a tripodal tridentate phosphane tdmme instead of PPh$_3$ and one acac ligand, since the ligand-field strength of tdmme is much larger than that of PPh$_3$ and acac.[17] Since the complexes [Co(acac)(tdmme)(L′′)](PF$_6$)$_2$ (**9**−**11**) are unstable in acetonitrile, the following UV/Vis spectra were measured in the solid state. The ligand-field d−d band of the py complex **9** appears at 22200 cm^{-1}, as expected from the difference in the ligand-field strengths between tdmme and (acac)(PPh$_3$). It is noted that the d−d transition of the NIT*n*py complex **10** or **11** is observed at the same position as that of the py complex **9** (Figure 2). Therefore, the radical unpaired electron of NIT*n*py exerts no influence on the d−d transition energy of the Co^{III} complexes. However, there are explicit perturbations for the broad vibronic band at 15000−18000 cm^{-1} upon coordination, and a very sharp strong band following the higher energy component around 27000 cm^{-1}, due to the n→π* and π→π* transitions of the nitronyl nitroxide moiety, respectively.[1] In the NIT4py complex **10** [Figure 2 (*a*)], the n→π* and π→π* bands are red-shifted by 1300 and 1100 cm^{-1}, respectively. In contrast, the NIT3py complex **11** [Figure 2 (*b*)] gives a slightly red-shifted (500 cm^{-1}) n→π* transition band, however, the π→π* band is shifted by a negligible amount, but is remarkably broad.

This perturbation is confirmed by subtracting the UV/Vis spectra of the NIT*n*py complexes from the py complex, which gives the spectrum of the perturbed nitroxide in the complex. For the NIT*n*py complexes, comparisons of both the difference spectra of complexes **2** (subtracted from **1**) and **3** (subtracted from **1**) with the spectra of free nitroxides (Figure 4) gives a similar result as the above tdmme complexes. Further, the difference spectrum of the PPh$_3$ complex **7** (subtracted from **6**) gives the same result (Figure S7, Supporting Information). Thus, it is concluded that the n→π* and π→π* transition bands are red-shifted (by ca. 800 cm^{-1}) on coordination of NIT4py to the Co^{III} ion via the pyridyl-N atom, while these bands show a slight shift and band-broadening when NIT3py is coordinated. These differences in perturbation between the NIT4py and NIT3py complexes may result from the difference in spin density (and sign) at the pyridyl-N atom, as found in the ^{59}Co NMR chemical shifts of complexes **2** and **3** (vide supra). Another reason is considered to be related to the difference in perturbation on the NIT*n*py SOMO π* orbitals through π-back-bonding from the Co^{III} t_{2g} orbital to the pyridyl π* orbital, in view of the plausible inherent interaction of the π-systems between the NIT*n*py and the pyridyl group. This interaction is suggested by the lower frequency shift of both the n→π* and π→π* transitions by 1000−2000 cm^{-1}, on going from NITMe to NIT*n*py.[1]

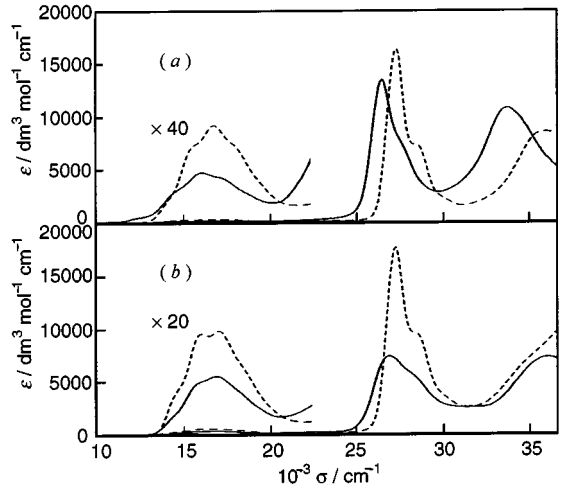

Figure 4. The difference absorption spectra of (*a*) complex **2** − complex **1** and (*b*) complex **3** − complex **1** (——), together with the UV/Vis spectra of NIT4py and NIT3py (− − − −), respectively

We have also made a similar analysis for the IM*n*py complexes (Figure S8, Supporting Information). Although the n(N−O)→π* transition band in the IM4py complexes **4** and **8** shows a distinct red-shift and that in the IM3py complex **5** does not shift, the results are not so clear, because the absorption spectra are much more complicated.

The intensity enhancement of the spin-forbidden $^1A_1 \rightarrow {}^3T_2$, $^3T_1$ ligand-field transitions is expected as a result of the magnetic exchange coupling with the doublet ground state of the nitroxide radical and the triplet excited state of Co^{III}. This intensity enhancement is also found for the intraligand singlet−triplet transition in diamagnetic bipyridine, due to the nearby paramagnetic Cr^{III} ion in [Cr(mal)$_2$(bpy)]$^-$.[25] However, in the predicted region for the $^1A_1 \rightarrow {}^3T_2$, $^3T_1$ transitions, only one shoulder is observed for complexes **2**, **7**, and **11** near 12500 cm^{-1}, which belongs to the lowest frequency vibronic component of the n→π* NIT*n*py intraligand transition, in terms of the above difference spectra. It is seen that the magnetic exchange coupling

in this kind of nitroxide complex is not large enough to observe the spin-forbidden transition intensity enhancement. The chelated NIT2py or IM2py Co^{III} complexes may be such a candidate to give observable intensity enhancement. The research in this direction is currently under way in our laboratory.

Conclusion

Explicit perturbations are found in the ^{59}Co NMR chemical shifts resulting from the radical unpaired electron, and on the n→π* and π→π* transition bands of the nitroxide moieties as a result of coordination to the Co^{III} center, in several newly prepared Co^{III} complexes bearing 3- or 4-pyridyl-substituted nitronyl or imino nitroxides. The structural and magnetic properties do not show any significant changes from the corresponding pyridine complexes and/or from the free nitroxides. These perturbed properties reflect the radical spin density and sign on the pyridyl-N atom of NIT*n*py or IM*n*py and/or the π-back bonding which is fine-tuned by coordination. Attempts to prepare bis(NIT*n*py or IM*n*py) Co^{III} complexes resulted in the formation of a mixture of the NIT*n*py and IM*n*py complexes, due to the deoxygenation of NIT*n*py to IM*n*py, and the decomposition of the IM*n*py radicals.

Experimental Section

General Remarks: The nitronyl and imino nitroxides, NIT4py, NIT3py, IM4py, and IM3py,[18,20,21a,26] and the starting Co^{III} complexes, *trans*-Na[Co(acac)$_2$(NO$_2$-κ*N*)$_2$],[27a] *trans*-[Co(acac)$_2$(PPh$_3$)$_2$]PF$_6$,[19a] and [CoCl(acac)(tdmme)]PF$_6$,[17a] and the pyridine (py) complex, *trans*-[Co(acac)$_2$(NO$_2$-κ*N*)(py)] (**1**),[27b] were prepared by the literature methods. UV/Vis spectra were measured with a Perkin−Elmer Lambda 19 spectrophotometer at room temperature. The solid-state spectra in the form of Nujol mulls were obtained according to the method described by Lee et al.[28] The ^1H and ^{59}Co NMR spectra were recorded with a JEOL EX-270 or Lambda 500 spectrometer at 30 °C. The ^{59}Co chemical shifts were referenced from external [Co(acac)$_3$] (in CDCl$_3$; δ = 12625).[16a,29] The ESR spectra were obtained with a JEOL JES-FE or JES RE1X spectrometer at ambient temperature. The magnetic susceptibility data were collected with a SQUID-based sample magnetometer using a QUANTUM Design model MPMS instrument. Data were corrected for the magnetization of the sample holder and for the diamagnetic contributions, which were estimated from Pascal's constants.

***trans*-[Co(acac)$_2$(NO$_2$-κ*N*)(L)] {L = NIT4py (2), NIT3py (3), IM4py (4), and IM3py (5)}:** A methanol solution (10 mL) of **L** (1.00 mmol) was added to an aqueous solution (50 mL) of *trans*-Na[Co(acac)$_2$(NO$_2$-κ*N*)$_2$] (1.00 mmol). The mixture was stirred at 30 °C for 10 min, and then cooled in an ice bath. The resulting red-brown precipitate was collected by filtration, and washed with a small amount of methanol and with diethyl ether. The crude product was recrystallized from chloroform/diethyl ether. **2**: Dark red-brown prismatic crystals, yield 0.38 g (70%). $C_{22}H_{30}CoN_4O_8$ (537.4): calcd. C 49.17, H 5.63, N 10.42; found C 48.09, H 5.50, N 10.20. **3**: Dark red-brown needle crystals, yield 0.27 g (50%). $C_{22}H_{30}CoN_4O_8$ (537.4): calcd. C 49.17, H 5.63, N 10.42; found C 48.15, H 5.65, N 10.24. **4**: Red powder, yield 0.42 g (80%). $C_{22}H_{30}CoN_4O_7$ (521.4): calcd. C 50.68, H 5.80, N 10.74; found C 49.90, H 5.66, N 11.15. **5**: Red columnar crystals, yield 0.26 g (50%). $C_{22}H_{30}CoN_4O_7$ (521.4): calcd. C 50.68, H 5.80, N 10.74; found C 49.92, H 5.66, N 10.68.

***trans*-[Co(acac)$_2$(PPh$_3$)(L′)]PF$_6$·*x*CH$_2$Cl$_2$ {L′ = py (6): *x* = 0, NIT4py (7): *x* = 1, and IM4py (8): *x* = 1}: L′** (1.00 mmol) was added to a red-purple dichloromethane solution (100 mL) of *trans*-[Co(acac)$_2$(PPh$_3$)$_2$]PF$_6$ (1.00 mmol) while stirring; the color of the mixture turned brown immediately. The solution was concentrated to dryness under reduced pressure, and the residue was thoroughly washed with diethyl ether (100 mL). The obtained brown solid was recrystallized either from dichloromethane/hexane or from dichloromethane/diethyl ether. **6**: Dark brown columnar crystals from CH$_2$Cl$_2$/C$_6$H$_{14}$, yield 0.67 g (90%). $C_{33}H_{34}CoF_6NO_4P_2$ (743.5): calcd. C 53.31, H 4.61, N 1.88; found C 52.98, H 4.52, N 2.10. **7**: Dark brown trigonal columnar crystals from CH$_2$Cl$_2$/Et$_2$O, yield 0.88 g (90%). $C_{41}H_{47}Cl_2CoF_6N_3O_6P_2$ (983.6): calcd. C 50.07, H 4.82, N 4.27; found C 49.54, H 4.80, N 4.42. **8**: Red plate crystals from CH$_2$Cl$_2$/C$_6$H$_{14}$, yield 0.87 g (90%). $C_{41}H_{47}Cl_2CoF_6N_3O_5P_2$ (967.6): calcd. C 50.89, H 4.90, N 4.34; found C 50.65, H 4.80, N 4.74.

[Co(acac)(tdmme)(L′′)](PF$_6$)$_2$·*x*H$_2$O {L′′ = py (9): *x* = 0, NIT4py (10): *x* = 1, and NIT3py (11): *x* = 1}: A methanol solution (15 mL) of AgPF$_6$ (1.61 mmol) was added to a solution of [Co(acac)Cl(tdmme)]PF$_6$ (1.60 mmol) in a mixture of methanol and acetonitrile (1:1, 50 mL) while stirring. The mixture was stirred in the dark for 2 h at room temperature, and the resulting white precipitate was filtered off. The precipitate was washed with acetonitrile (10 mL × 2), and the filtrate and washings were combined and concentrated to ca. 5 mL under reduced pressure. Diethyl ether vapor was diffused into the filtered concentrate in a desiccator, depositing red prismatic crystals of [Co(acac)(tdmme)(CH$_3$CN)](PF$_6$)$_2$ (**12**), yield 1.08 g (91%). $C_{18}H_{37}CoF_{12}NO_2P_5$ (741.3): calcd. C 29.17, H 5.03, N 1.89; found C 29.11, H 4.95, N 1.84. Compound **12** (1.00 mmol) was dissolved in acetonitrile (40 mL), and ligand **L′′** (4.00 mmol of py or 1.00 mmol of NIT*n*py) was added to the solution. After stirring for 20 min at room temperature, the solvents were evaporated to dryness under reduced pressure. The residue was thoroughly washed with methanol (10 mL) and dried in vacuo. **9**: Red powder, yield 0.38 g (95%). $C_{21}H_{39}CoF_{12}NO_2P_5$ (779.3): calcd. C 32.37, H 5.04, N 1.80; found C 32.21, H 4.95, N 1.85. **10**: Green powder, yield 0.89 g (96%). $C_{28}H_{52}CoF_{12}N_3O_5P_5$ (952.5): calcd. C 35.31, H 5.50, N 4.41; found C 35.29, H 5.32, N 4.36. **11**: Green powder, yield 0.90 g (96%). $C_{28}H_{52}CoF_{12}N_3O_5P_5$ (952.5): calcd. C 35.31, H 5.50, N 4.41; found C 34.82, H 5.33, N 4.23.

***trans*-[Co(acac)$_2$(py)$_2$]PF$_6$:** The bis(pyridine) complex *trans*-[Co(acac)$_2$(py)$_2$]PF$_6$ was prepared as follows. Acetic acid (1 mL) and PbO_2 (7.78 mmol) were added to an ethanol solution (200 mL) of *trans*-[Co^{II}(acac)$_2$(py)$_2$] (3.05 mmol). The mixture was stirred for 2 h at room temperature, and then filtered. The filtrate was concentrated to ca. 50 mL under reduced pressure, and an excess amount of solid NH_4PF_6 was added to the concentrate with vigorous stirring. The resulting pale brown precipitate was collected by filtration, and recrystallized from acetone/diethyl ether, affording red-brown needle crystals, yield 0.51 g (30%). $C_{20}H_{24}CoF_6N_2O_4P$ (560.3): calcd. C 42.87, H 4.32, N 5.00; found C 43.33, H 4.34, N 5.02.

Attempts To Prepare Bis(nitroxide) Complexes. − Method A: NIT*n*py (2.00 mmol) was added to a green methanol solution (150 mL) of *trans*-[$Co(acac)_2(PPh_3)_2$]PF_6 (1.00 mmol). The mixture was stirred at room temperature for 1 d, and the solvents evaporated to dryness under reduced pressure. The residue was extracted with a minimum amount of methanol, and diethyl ether was added to the filtered extract. The resulting precipitate was collected by filtration and washed with diethyl ether. − **Method B:** Acetic acid (1 mL) and PbO_2 (1.00 mmol) were added to an ethanol solution (150 mL) of *trans*-[$Co^{II}(acac)_2(L)_2$] (1.00 mmol), which was prepared from [$Co(acac)_2(H_2O)_2$] and **L** in methanol in a molar ratio of 1:2.[7b] The mixture was stirred for 2 h in an ice bath and then filtered. The filtrate was concentrated to ca. 30 mL under reduced pressure, mixed with an excess amount of a saturated ethanol solution of $NaBPh_4$ or $LiBF_4$, and stored in a refrigerator overnight. The crystalline product deposited was collected by filtration, and recrystallized either from acetone/diethyl ether (BPh_4 salt) or from acetonitrile/diethyl ether (BF_4 salt).

X-ray Crystallographic Study:[30] A suitable crystal of each compound **5**, **7**·CH_2Cl_2, **8**·CH_2Cl_2 was coated with enamel and used for an X-ray diffraction study. The X-ray intensities were measured with an automated Rigaku four-circle diffractometer AFC-5R or -7R [23 °C, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), 2 θ_{max} = 60°]. Absorption corrections were made by an empirical Ψ-scan method.[30a] The structures were solved by the usual heavy-atom method using the SHELXS-86 program,[30b] and refined on F^2 by full-matrix least squares with all independent reflections using the SHELXL-97 program.[30c] All non-hydrogen atoms were refined anisotropically, and hydrogen atoms were treated by riding models. All calculations were carried out using the teXsan software package.[30d] Selected crystallographic data are summarized in Table 6. The structures of **7**·CH_2Cl_2 and **8**·CH_2Cl_2 were successfully solved on the assumption of a centrosymmetric space group $P\bar{1}$. For the analysis of **8**·CH_2Cl_2, there is no electron density (larger than 1 e·Å^{-3}) around the imino-N, N(3), site of IM4py, although from the crystal packing point of view there is no difference between the O(5) and O(6) sites of the NIT4py group in **7**·CH_2Cl_2. For **5**, the Laue symmetry check and systematic absences (0kl, $k + l$ = odd; hk0, h = odd) indicated the space group was either *Pnma* or *Pn*2_1a. Initially the structure was solved based on the centrosymmetric space group *Pnma* with Z = 4. It was suggested that the complex possessed a crystallographically imposed plane of symmetry, on which Co, N(11) of nitrito-κ*N*, all atoms [N(1) and C(29)−C(33)] of the pyridyl ring, atoms C(34) and C(35) were located. The imino nitroxide moiety of IM3py was almost planar, but the plane was twisted against the pyridyl ring; this twist forces the N(2), N(3), O(5), C(36), C(39) and C(40) atoms to be positionally disordered over two positions related to the symmetry plane. Even though the space group was deduced to be the non-centrosymmetric *Pn*2_1a, such disorders could not be resolved. Consequently, the space group *Pnma* was adapted. The O atom of the nitroxide group was located at the *endo* position [N(2) site] relative to the Co atom, no electron-density (larger than 1 e·Å^{-3}) was observed at the corresponding *exo* position [N(3) site]. CCDC-168533 to -168535 (**5**, **7**·CH_2Cl_2, **8**·CH_2Cl_2) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Crystal Structure and Magnetic Properties of the Helical-Chain Compounds $[M_2(O_2CC_{12}H_8CO_2)_2(H_2O)_8]$ [M = Cobalt(II), Nickel(II)]

Jean-Michel Rueff,[a] Sébastien Pillet,[b] Nicolas Claiser,[b] Gautier Bonaventure,[a] Mohamed Souhassou,[b] and Pierre Rabu*[a]

Keywords: Carboxylate ligands / Hydrothermal synthesis / Nickel / Cobalt / Magnetic properties

New 1D complexes are obtained from the reaction of 1,1′-biphenyl-2,2′-dicarboxylic acid (diphenic acid) with KOH and $[Co(NO_3)_2{\cdot}6H_2O]$ or $[Ni(NO_3)_2{\cdot}6H_2O]$ under hydrothermal conditions. Compounds **1** and **2** are isostructural and their structure consists of stacked helical chains of octahedral metal(II) ions. Magnetic measurements show that the Co^{II} atoms in compound **1** are quasi-isolated. In compound **2**, the Ni^{II} chains exhibit a ferromagnetic behaviour. From a simple model derived from the scaling theory of phase transition, the exchange coupling between neighbouring Ni^{II} atoms is evaluated at $J = +1.06$ K. A zero-field splitting effect is observed below 16 K.

Introduction

Low-dimensional magnetism (1D, 2D) is an important research field for chemists interested in the design of new magnetic materials and a better understanding of the mechanisms responsible for their magnetic behaviours.[1−4] Correlations between the magnetic properties of molecule-based solids and their structure or the nature of the chemical bond is largely used for the design of new materials, including high T_C magnets.[5−8] In this context, helicate structures are of current interest in supramolecular coordination chemistry, mainly for their similarity with the structure of the DNA molecule.[9−11] Very few of these studies discuss the effect of the helical arrangement of spin carriers on the magnetic properties[12−14] even though chirality is known to induce photo-magnetic effects.[15] For the design of new coordination compounds with extended structures, the solvo- or hydrothermal route is currently being developed by several research teams involved in solid-state coordination chemistry,[16,17] and organic-inorganic materials,[18−20] including helical chain compounds[21,22] and mesoporous (possibly magnetic) materials.[23−25] In this approach, the organic ligand acts as a template, the structure of the product being closely related to the geometry and the number of coordination sites provided by the ligand. Important results have recently been obtained in the field of low dimensional magnetic materials exhibiting unusual behaviours.[26−29]

The present paper describes the crystal structure and the magnetic properties of new Ni^{II} and Co^{II} coordination polymers synthesised by using self-assembly in hydrothermal conditions and exhibiting helical chains based on an inexpensive ligand, the 1,1′-biphenyl-2,2′-dicarboxylate.

Results and Discussion

Compounds **1** and **2** were synthesised by the hydrothermal method from cobalt(II) nitrate, and nickel(II) nitrate, respectively, with diphenic acid, potassium hydroxide and water in a 2:3:8:120 ratio, at 170 °C during 72 h (see Exp. Sect.). The title compounds are obtained in good yields, and crystallise as large (mm size), thin platelets. In the case of compound **1**, another phase is also observed as purple needle-shaped crystals, whose structure and properties will be reported elsewhere. The synthetic conditions can be optimised in order to favour compound **1**, and pure compound **1** is easily obtained by manual separation of the largest crystals. The formula of both compounds **1** and **2** has been checked by chemical analysis, and ancillary characterisation techniques, and their structure has been determined by single crystal X-ray diffraction at room and low temperature (see Exp. Sect.). The principal distances are reported in Table 1.

Compounds **1** and **2** are isostructural. The crystal cell parameters of **2** are slightly smaller than for **1**[30] in agreement with the smaller metal−oxygen bond lengths for the nickel(II) ions compared to cobalt(II) as also found in aqua complexes and η^1-carboxylates.[31] The molecular structure consists of divalent metal atoms, located in slightly distorted octahedral sites (Figure 1 and Table 1). Water molecules (O1 to O4) are located at the four basal positions [mean Co−O = 2.1249(14) Å, mean Ni−O = 2.0778(13) Å] whereas the apical ones [mean Co−O = 2.0547(12) Å, mean Ni−O = 2.0332(10) Å] are occupied by oxygen atoms of carboxylate groups (O5 and O6). Only one oxygen of each carboxylate group is coordinated to a metal atom, the other one being involved in short hydrogen bonds with hydrogen atoms of the neighbouring water molecules [O8···O3(H14), $O8^{ii}$···O4(H8), in Table 1 (A in Figure 2), and O7···O4(H15) (B in Figure 3)]. The M^{2+} ions form helical chains running along the *b* axis (Figure 3). These ions

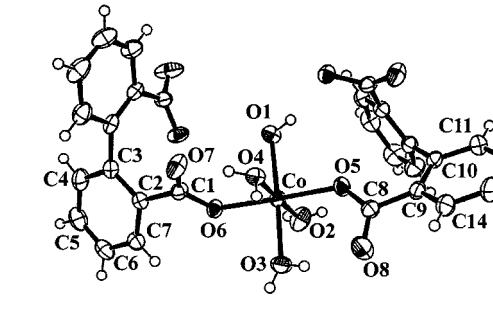

Figure 1. Molecular structure and atomic labels (asymmetric unit only) of the non-H atoms for compound **1**; both biphenyldicarboxylate ligands have been completed using the $1/2 - x$, $y - 1/2$, $1/2 - z$ symmetry element; compound **2** exhibits the same structure, with Ni instead of Co

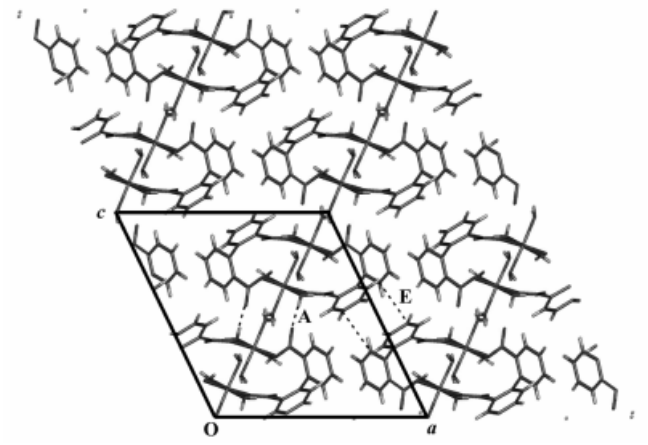

Figure 2. Perspective view of the molecular packing along the *b* axis, showing the helical stacking (H atoms omitted for clarity); inter-chain hydrogen bonds between $O8^{ii}$ and H8 [$O8^{ii}$···O4(H8)] are drawn as dashed lines (label A); inter-chain short $C6^{iv}$···C11 interactions are drawn as dashed lines (label E); symmetry codes given in Table 1

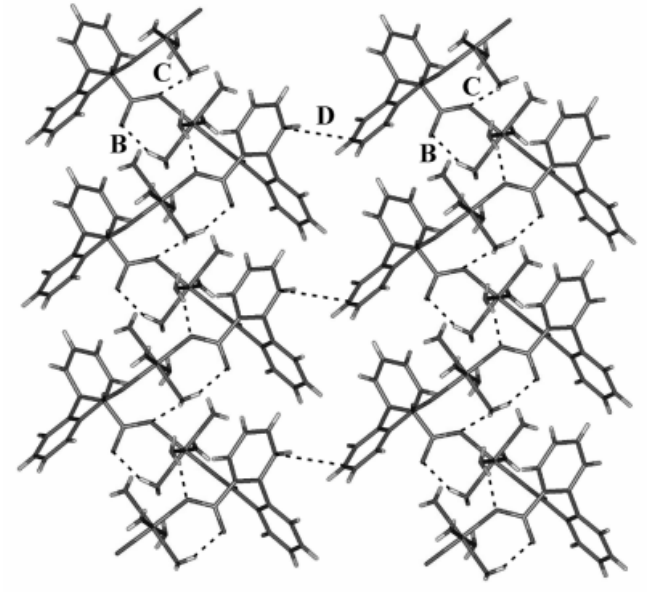

Figure 3. View of two neighbouring M^{II} helical chains; in one chain, the shortest M−M distance is 4.9981(3) Å for M = Co, and 4.9373(3) Å for M = Ni; intra-chain short hydrogen bonds between O7 and H15 [O7···O4(H15)] and between $O6^{i}$ and H6 [$O6^{i}$···O1(H6)] are drawn as dashed lines (B and C respectively); inter-chain short $C4^{iii}$···C13 contacts are drawn as dashed lines (D); symmetry codes given in Table 1

are connected through the biphenyldicarboxylate ligand, the shortest M···M distance along the chain being 4.9981(3) Å and 4.9373(3) Å, for Co and Ni, respectively. The shortest exchange pathway involves a short intra-chain hydrogen bond (C in Figure 3) between $O6^{i}$ and H6 [$O6^{i}$···O1(H6) = 2.705(2) Å in **1** and $O6^{i}$···O1(H6) = 2.684(2) Å in **2**]. The two aromatic rings of each ligand are tilted around the C3−C10 bond by 85.96(8)° and 87.2(1)° for **1** and **2**, respectively. Moreover, the chains are connected by inter-chain hydrogen bonds (A in Figure 2) to form planes quasi perpendicular to the [1 0 $\bar{1}$] direction. The metal atoms are arranged in a zigzag manner between the planes. Phenyl-phenyl contacts in a T-shape arrangement (cf. D,E in Figure 2 and 3, and $C6^{iv}$···C11, $C4^{iii}$···C13 distances in Table 1) ensure inter-plane connections. In E contacts, the corresponding aromatic rings stack almost perpendicular to each other, the dihedral angle between the best planes corresponding to the two rings is 86.10(6)° for **1** and 85.46(6)° for **2**. Contacts D involve similar inter-plane contacts, the corresponding dihedral angles being 115.47(6)° and 113.82(4)° for **1** and **2**, respectively. In each of these inter-plane contacts, the positively charged C−H groups of one aromatic ring probably interact with the negatively charged π-electron cloud of the other aromatic ring.[32] No parallel π−π stacking of the phenyl rings results from the present geometrical configuration.

The IR spectra of both compounds exhibit the same features, as would be expected from their structural homology. The frequency difference between the symmetric and antisymmetric carboxylate vibrations, $\Delta\nu$ = 141 cm^{-1}, is small but in agreement with the unidentate coordination mode of the carboxylate groups;[33] this small value can be explained by the occurrence of hydrogen bond involving the oxygen atom that is not linked to the metal atom, thus giving a bidentate character to the carboxylate groups. The presence of two broad ν(O−H) bands in the range 3200−3400 cm^{-1} is due to the two hydrogen-bonded *aqua* ligands. As for the UV spectra shown in Figure 4, it corroborates the octahedral geometry of Co^{II} and Ni^{II} ions.[34,35] The values of *Dq* (1050 cm^{-1} for **1** and 877 cm^{-1} for **2**) and Racah's parameter *B* (862 cm^{-1} for **1** and 1005 cm^{-1} for **2**), deduced from the transitions observed, agree with a low crystal field (Dq/B = 1.2 for **1** and Dq/B = 0.9 for **2**) and an octahedral high-spin configuration for the metal centres, which can also be inferred from the magnetic findings (see below).

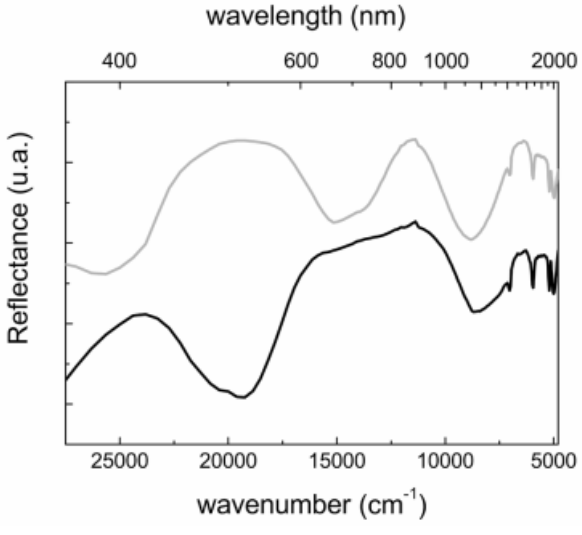

Figure 4. UV spectra of compounds **1** (below) and **2** (upper curve)

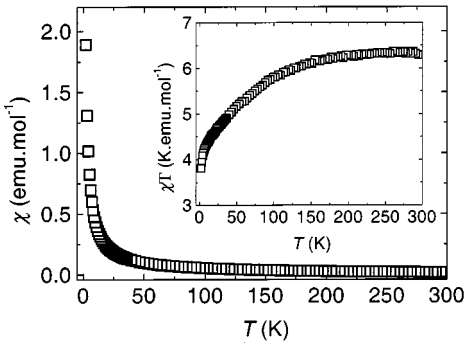

Figure 5. Magnetic susceptibility and χT product of compound **1**

The magnetic properties of **1** and **2** were investigated as described in the Exp. Sect.. The temperature variation of the magnetic susceptibilities χ of **1** is shown in Figure 5, after correction for diamagnetic contributions. Upon cooling down, $\chi = f(T)$ increases continuously up to a maximum of 1.9 emu·mol^{-1} at 2 K. The χT product exhibits a regular decrease from 6.36 emu·K·mol^{-1} at 300 K to 3.81 emu·K·mol^{-1} at 2 K. The inverse susceptibility varies linearly with the temperature in the high temperature regime ($T > 180$ K) and is well fitted in this region by using the Curie−Weiss law, giving C = 6.55 emu·K·mol^{-1} and θ = −8.63 K. The calculated effective moment per metal ion, $\mu_{eff} = (8 \times 1/2 \times C)^{1/2}$ = 5.12 μ_B/Co, agrees with that expected for octahedral high spin Co^{II} ions.[36,37] In accordance with this, the magnetisation vs. field curve at 2 K is characteristic of a paramagnetic phase, with a saturation moment per cobalt(II) ion of Ms = 2.5 $\mu_B mol^{-1}$ (expected, 2−3 μ_B per cobalt ion).[36,37]

The decrease of the χT product together with the negative value of θ are well explained by the effect of the spin-orbit coupling for isolated Co^{II} ions in an octahedral crystal field, which results in the splitting of the energy levels arising from the $^4T_{1g}$ ground term, stabilising the $J = \pm 1/2$ doublet that is well separated from the excited states.[36] An antiferromagnetic coupling could also contribute, although this is expected to be very small since the value measured at 2 K (1.9 emu·K per Co^{II} mol) is close to that expected for isolated metal ions in an O_h crystal field (≈1.8 emu·K per Co^{II}).[36] An analytical expression of the susceptibility for isolated Co^{II} ions is reported in the literature,[36] but corresponds to the particular case of a cubic crystal field and it is stated that the magnetic behaviour of such an ion is highly sensitive to site distortion and crystal field variations. Attempts to use this expression for the present compound give not particularly satisfactory results. Likewise no expression is available for Co^{II} chains taking into account the spin-orbit coupling. Thus the fitting of the experimental

data to an appropriate model is rather complex for compound **1**, although its behaviour is qualitatively very well explained on the basis of quasi-isolated magnetic centres.

The magnetic behaviour of compound **2** is presented in Figure 6. The $1/\chi = f(T)$ curve fits well the Curie−Weiss law at high temperature ($T > 100$ K) with $C = 2.289$ emu·K·mol^{-1}, in agreement with the value expected for isolated Ni^{II} ions in an octahedral ligand field (giving $\mu_{eff} = 3.03\ \mu_B$/Ni), and $\theta = +1.08$ K, pointing to weak ferromagnetic interactions. Accordingly, the χT product is almost constant from ambient temperature down to about 150 K at a value of approximately 2.3 emu·K·mol^{-1}. Below 150 K, a slight increase up to a maximum of 2.49 emu·K·mol^{-1} at 16 K and a drop down to 1.69 emu·K·mol^{-1} at 2 K are observed. Zero-field splitting is known to occur for nickel(II) ions, and for isolated ions may induce either an increase or a decrease of χT, at very low temperature, depending on the site distortion.[4] It cannot give rise to both at the same time however. The observed behaviour is thus characteristic of the occurrence of ferromagnetic interactions within the chains. The drop to zero below 16 K can be related to antiferromagnetic coupling between the chains together with the effect of zero-field splitting. The absence of any maximum in the χ vs. T curve is rather in favour of the latter mechanism. Moreover, the magnetisation versus field measurement exhibits a paramagnetic-like behaviour. As expected for divalent metal ions, the saturation magnetisation at 2 K is 2 μ_B per nickel, and neither metamagnetic nor spin-flop transitions are observed, suggesting that no 3D antiferromagnetic order is reached at this temperature.

In order to evaluate the exchange interaction between neighbouring nickel(II) atoms, the susceptibility measurements were fitted in the high temperature region by using a simple model for Heisenberg $S = 1$ ferromagnetic regular chains. In this approach, the zero-field splitting for nickel(II) is not taken into account, assuming that its effect is significant only at low temperatures ($T < 16$ K).[38]

The spin-exchange Hamiltonian of the system [Equation (1)] can be solved numerically only for ring chains involving a limited number of spins N. The study of the variation of the susceptibility as a function of the reduced temperature $T_r = T/[S(S + 1)J]$, for chains of various size (up

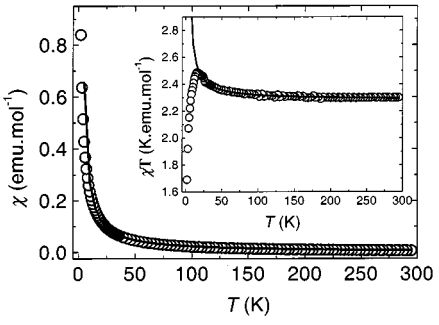

Figure 6. Magnetic susceptibility and χT product of compound **2**; the full line corresponds to the best fit to the expression calculated for a ferromagnetic Heisenberg chain of $S = 1$ spins

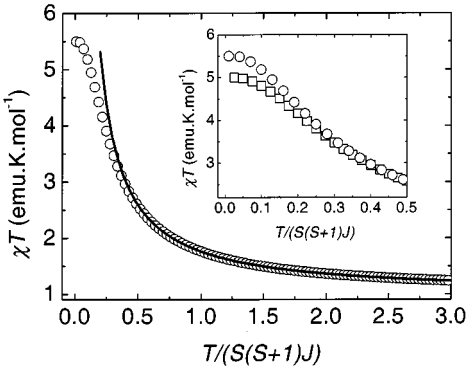

Figure 7. Variation of the χT product as a function of reduced temperature for a Heisenberg chain of 10 (square) and 9 (circle) $S = 1$ spins; the full line corresponds to the best fit of the $N = 10$ system to the power law expression given in the text; the inset is a zoom at low temperature showing the discrepancy between $N = 9$ and $N = 10$ spin chains

to $N = 10$) shows that data corresponding to N and $N + 1$ chains coincide in a wide range down to a limiting value at low temperatures (inset in Figure 7). This value decreases when N increases and corresponds to the temperature limit above which the calculation for N spins is the exact solution for the infinite chain. Moreover, following the approach developed within the frame of the scaling theory by Soulétie,[39,40] the χT product for a regular ferromagnetic $S = 1$ chain can be described in the high temperature range by the power law[41] shown in Equation (2):

$$\hat{H}_{ex} = -J\sum_{i=1}^{N}\hat{S}_i\hat{S}_{i+1} - g\mu_B\sum_{i=1}^{N}\hat{S}_i\vec{H} \quad (1)$$

$$\chi T = C(1 - T_c/T_r)^{-\gamma} \quad (2)$$

where C is the Curie constant $[g^2\mu_B^2S(S + 1)/3k]$, T_c the reduced critical temperature and γ is a critical exponent. With this relation, the $\chi T = f(T_r)$ data for $N = 10$ have been fitted from high temperatures down to the limit ($T_r \approx 0.6$) where it does not coincide with the $N = 9$ calculation (Figure 7) giving the general relation for $S = 1$ Heisenberg ferromagnetic chains shown in Equation (3):

$$\chi T = (g^2\mu_B^2S(S + 1)/3k)(1 - 0.59679/T_r)^{-1.2322} \quad (3)$$

Finally, this simple expression fits very well with the experimental susceptibility of compound **2** (Figure 6), giving $g = 2.13$, and $J = +1.06$ K, which is weak and in agreement with the value of θ deduced above.

The crystal structure of the present compounds indicates that the exchange pathways between neighbouring magnetic centres involve the biphenyldicarboxylate ligands and hydrogen bonds. Both are known to promote weak exchange interactions. Indeed, the binuclear 1,1′-biphenyl-2,2′-dicarboxylate transition metal complexes reported in the literature[42] exhibit a quasi-paramagnetic behaviour, and the coupling through hydrogen bonds in molecular materials is

likewise very weak.[43] The low efficiency of these exchange pathways explains this behaviour of **1** and also the weak ferromagnetic behaviour observed for **2**, although the magnetic centres are relatively close to each other.

Conclusion

New one-dimensional cobalt(II) and nickel(II) compounds have been synthesised as large single crystals by hydrothermal methods. Their structures have been solved and consist of stacked helical chains, which are generated by using the simple 1,1′-biphenyl-2,2′-dicarboxylate ligand as an efficient template. From the magnetic point of view this ligand appears to be fairly poor for magnetic exchange coupling, as shown by the results obtained for compound **1** where the cobalt(II) ions are quasi-isolated. Nevertheless, in the isostructural compound **2**, the nickel(II) ions are coupled and form ferromagnetic $S = 1$ chains. The present compounds are not chiral since both right hand and left hand orientations of the helical chain are present in the structure. Further work is in progress on related systems in order to isolate enantiomerically pure forms. The purple phase obtained as needle crystals with the compound **1** is currently under investigation.

Experimental Section

General Remarks: Thermogravimetric experiments were performed using a Setaram TG92 instrument (heating rate of 2 °C/min, air stream). FT-IR studies were performed with an ATI Mattson Genesis computer-driven instrument (0.1 mm thick powder samples in KBr). UV/Vis-NIR studies were performed with a Perkin−Elmer Lambda 19 instrument (spectra recorded by reflection with a resolution of 4 nm and a sampling rate of 480 nm/min). Magnetic studies were carried out using a (Quantum Design XMPMS) SQUID magnetometer. Susceptibilities were measured at H = 2000 Oe, in the field range of the linear variation of magnetization versus H.

Bis{cobalt(II)-tetraaqua-biphenyl-2,2′-η¹,η¹-dicarboxylate} (1): $C_{28}H_{32}Co_2O_{16}$ (**1**) was synthesised by the hydrothermal method from $[Co(NO_3)_2{\cdot}6H_2O]$ (98% Aldrich), diphenic acid (1,1′-Biphenyl-2,2′-dicarboxylic acid, 98% Acros), and KOH (85%, SDS). The starting mixture corresponding to the molar composition 2:3:8:120 of $[Co(NO_3)_2{\cdot}6H_2O]$, $C_{14}H_{10}O_4$, KOH and H_2O was homogenised and transferred (170 °C, 72 h, autogenous pressure) to a sealed hydrothermal bomb (23 cm^3 bomb volume) walled with a Teflon liner. Pink plates were obtained, washed and rinsed with deionised water (18.2 MΩcm) and absolute ethyl alcohol (Carlo Erba) (yield > 60% on the basis of $[Co(NO_3)_2{\cdot}6H_2O]$). The purity was confirmed by elemental analysis (EA) {$C_{28}H_{32}Co_2O_{16}$ (742.4): calcd. C 44.6, H 7.5; found C 44.3, H 7.5}, oxidising pyrolysis (OP) {heating in air from 20 to 700 °C at 2 °C/min, 30 min at 700 °C to transform cobalt into Co_3O_4,[44−45] and cooling to 20 °C at 10 °C/min: calcd. Co 15.88; found 15.64}, and ATG weight loss at 172 °C titration of water {calcd. 19.4; found 19.2 }. IR (KBr pellet): $\tilde{\nu}$ = 3612 cm^{-1} (ν OH), 3440 (ν OH−O), 3197 (ν OH−Co), 1598 (ν C−C), 1576 (ν C−C), 1539 (ν_{as} C=O), 1496 (ν C−C), 1440 (ν C−C), 1398 (ν_s C−O), 1267 (in plane δ_b C−H), 1151 (in plane δ_b C−H), 1108 (in plane δ_b C−H), 1049 (in plane δ_b C−H). UV/Vis (reflectance for octahedral coordination of Co^{II}): λ = 1190 nm ($^4T_{1g} \rightarrow {}^4T_{2g}$), 520 nm ($^4T_{1g} \rightarrow {}^4T_{1g}(P)$].

Bis{nickel(II)-tetraaqua-biphenyl-2,2′-η¹,η¹-dicarboxylate} (2): $C_{28}H_{32}Ni_2O_{16}$ (**2**) was synthesised by the hydrothermal method from $[Ni(NO_3)_2{\cdot}6H_2O]$ (98% Aldrich), diphenic acid (1,1′-Biphenyl-2,2′-dicarboxylic acid, 98% Across), and KOH (85%, SDS). The starting mixture corresponding to the molar composition 2:3:8:120 of $[Ni(NO_3)_2{\cdot}6H_2O]$, $C_{14}H_{10}O_4$, KOH and H_2O was homogenised and transferred (170 °C, 72 h, autogenous pressure) to a sealed hydrothermal bomb (23 cm^3 bomb volume) walled with a Teflon liner. Pale green plate crystals were obtained (yield > 90% on the basis of $[Ni(NO_3)_2{\cdot}6H_2O]$), washed and rinsed with deionised water (18.2 MΩcm) and absolute ethyl alcohol (Carlo Erba). The purity was confirmed by elemental analysis (EA) {$C_{28}H_{32}Ni_2O_{16}$ (742.0): calcd. C 45.33, H 4.35; found C 45.3, H 4.35}, oxidising pyrolysis (OP) {heating in air from 20 to 700 °C at 2 °C/min, 30 min at 700 °C to transform nickel into NiO,[44] and cooling to 20 °C at 10 °C/min: calcd. Ni 15.82; found 16.0}, and ATG titration of water {weight loss (%) at 200 °C: calcd. 19.41; found 19.32}. IR (KBr pellet): $\tilde{\nu}$ = 3608 cm^{-1} (ν OH), 3432 (ν OH−O), 3180 (ν OH−Ni), 1598 (ν C−C), 1575 (ν C−C), 1539 (ν_{as} C=O), 1496 (ν C−C), 1442 (ν C−C), 1398 (ν_s C−O), 1269 (in plane δ_b C−H), 1151 (in plane δ_b C−H), 1109 (in plane δ_b C−H), 1049 (in plane δ_b C−H). UV/Vis (reflectance for octahedral coordination of Ni^{II}): λ = 1140 nm ($^3T_{2g} \rightarrow {}^3A_{2g}$), 720 nm ($^1E_g \rightarrow {}^4A_{2g}$), 653 nm ($^3T_{1g}(F) \rightarrow {}^3A_{2g}$), 391 nm ($^3T_{1g}(P) \rightarrow {}^3A_{2g}$).

X-ray Crystallographic Study: $C_{28}H_{32}Co_2O_{16}$, (**1**), M_r = 742.40, monoclinic, $P2_1/n$ (No. 14), a = 14.3800(4) Å, b = 7.5373(2) Å, c = 15.6142(5) Å, β = 115.3850(10)°, V = 1528.96(8) $Å^3$, Z = 2, D_x = 1.613 g cm^{-3}, μ (Mo-K_α) = 1.155 mm^{-1}, F(000) = 764, T = 293(2) K. A total of 5173 independent reflections (N_{tot} = 36455, R_{int} = 4.70%) were measured on a Nonius Kappa CCD. Absorption corrections were performed by Gaussian integration (ABSORB, DeTitta, 1985[46]) using the crystal shape (T_{min} = 0.688, T_{max} = 0.850), $R[F^2 > 2\sigma(F^2)]$ = 0.056, $wR(F^2)$ = 0.083. The structure was solved by direct methods (SHELXS, Sheldrick 1997[47]) and refined on F^2 by using full-matrix least-squares techniques (SHELXL, Sheldrick 1997[48]). All H atoms were located in the difference Fourier map and refined isotropically, all non-H atoms were refined anisotropically.

$C_{28}H_{32}Ni_2O_{16}$, (**2**), M_r = 741.96, monoclinic, $P2_1/n$ (No. 14), a = 14.3092(4) Å, b = 7.4605(2) Å, c = 15.4260(5) Å, β = 115.4540(10)°, V = 1486.93(8) $Å^3$, Z = 2, D_x = 1.612 g cm^{-3}, μ (Mo-K_α) = 1.345 mm^{-1}, F(000) = 768, T = 110(2) K. A total of 8129 independent reflections (N_{tot} = 48871, R_{int} = 4.80%) were measured on a Nonius Kappa CCD. Absorption corrections were performed by Gaussian integration (ABSORB, DeTitta, 1985) using the crystal shape (T_{min} = 0.701, T_{max} = 0.908), $R[F^2 > 2\sigma(F^2)]$ = 0.042, $wR(F^2)$ = 0.091. The structure was solved by direct methods (SHELXS, Sheldrick 1997[47]) and refined on F^2 using full-matrix least-squares techniques (SHELXL, Sheldrick 1997[48]). All H atoms were located in the difference Fourier map and refined isotropically, all non-H atoms were refined anisotropically.

A Calix[4]arene-Based Bipyridine Podand as Versatile Ligand for Transition Metal Cations

Jean-Olivier Dalbavie,[a] Jean-Bernard Regnouf-de-Vains,*[a] Roger Lamartine,[b] Monique Perrin,[b] Sylvain Lecocq,[b] and Bernard Fenet[c]

Keywords: Calixarenes / Bipyridines / Podands / Cobalt / Nickel / Zinc / Copper

The calix[4]arene-based podand **1** which incorporates two 2,2′-bipyridine units and two benzyl units in alternate positions at the lower rim has been subjected to complexation studies with copper(I), copper(II), cobalt(II), nickel(II), and zinc(II). The reaction of **1** with $Cu(MeCN)_4PF_6$ afforded the expected mononuclear Cu^I complex. With cobalt(II), nickel(II), and zinc(II) chloride, **1** gave dinuclear tetrahedral complexes in which each bipyridine unit is associated to two chlorine atoms around the metal centre. With Zn^{II}, replacing the chloride ion for the trifluoromethanesulfonate ion resulted in the formation of the mononuclear complex species. The complexes thus obtained were fully characterised, notably by NMR techniques and, for the dinuclear cobalt, nickel and zinc species, by X-ray crystal structure analyses.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

1. Introduction

The abundant literature related to calixarenes illustrates their important role in supramolecular chemistry,[1] and particularly, as recently reviewed by Asfari et al.[2] or by Matt et al. or Roundhill et al.,[3] as ligands for metal cations. Their complexation properties are attractive in the development of selective extracting agents for metallic cations, notably for rare metals. This can be accomplished through their own binding sites (oxygen atoms, aryl rings), or by their ability to act as carriers and spatial organisers of various types of chelating agents, such as ethers, esters, amides and their thio analogues, ketones, alkenes, ammonium species, amino acids, phosphanes, or heterocycles.

Among these chelating subunits, introduced at the upper or lower rims at the calix[4]arene platform, the biheterocyclic systems have been moderately studied, with a major attention brought to the 2,2′-bipyridine group,[4] and to the corresponding Ru^{II}, Cu^I, and Ag^I complexes. Other contributions have been devoted to ligands incorporating 2,2′-bithiazole[5] or 2,2′-bipyrazine,[6] and their Cu^I complexes.

Depending on the nature, the number and the position of the chelating units, such podands should be able to provide different coordination geometries. We thus attempted to employ this behaviour in a selective metal extraction process based on the use of the tetrahedral geometry. In this sense, we have recently demonstrated the interest of such kinds of complexing structures with the bis(bipyridyl) ligand **1** displaying in alternate positions two opposing 2,2′-bipyridyl chelating subunits and two opposing lipophilic pendant benzyl groups. Complex **1** showed a very interesting selective and quantitative extraction behaviour towards Ag^I against Pb^{II} from neutral aqueous media.[7]

The objective of the present report was to verify the complexing behaviour of **1** toward various transition metal cations. We found this necessary because, on the one hand, except for the above-mentioned metallic cations, the coordinating behaviour of such ligands towards transition metal species has not been reported until now, and on the other hand our extraction study necessitated a better knowledge of the other available complexes.

As assessed by X-ray crystallographic study of its picolyl parent compound **A**,[8] complex **1** should give a mononuclear Cu^I pro-helicoidal tetrahedral complex, which should also be encountered with Ag^I in complex **B**.[7,9] With $CoCl_2$, we recently reported the synthesis and X-ray crystal structure determination of a mononuclear complex involving a calix[4]arene podand at the upper rim by a 2,2′-bipyridyl unit, and in which the metal centre was coordinated in a tetrahedral mode by the two chloride ions and the two bipyridyl nitrogen atoms.[4f] This structure was proposed some years ago by Newkome et al. for 6,6′-dimethyl-2,2′-bipyridine and $CoCl_2$, $NiCl_2$, $ZnCl_2$, $CuCl_2$, as well as less common metal species.[10] With the two close bipyridyl units of

1, one may expect the two coordinating chlorine atoms to be replaced by the second bipyridine unit, thus affording mononuclear complexes with Co^{II}, Ni^{II}, Zn^{II}, and Cu^{II}; however, dinuclear complexes could be obtained.

2. Synthesis and Analysis of Complexes

The bis(benzyl) bis(bipyridyl) podand **1** was prepared as previously reported.[7] The air-stable orange copper(I) complex, **2**, was synthesised by mixing stoichiometric amounts of ligand **1** and $Cu(CH_3CN)_4PF_6$ in CH_3CN. It was obtained in a pure state with a yield of 90% after chromatography on alumina with CH_2Cl_2 as eluent. The ML stoichiometry was preliminarily determined by UV titration, with the appearance of the characteristic MLCT (Metal-to-Ligand Charge Transfer) band at 447 nm; the ε value of 5500 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$, measured with a CH_2Cl_2 solution of **2**, is similar to those of the parent complexes.[4b,4e] Electrospray mass spectrometry (positive mode, 60 V) showed the presence of the monocharged 1:1 adduct [**1** + Cu]$^+$, characterised by a base peak at 1257.7 amu, and elemental analysis was consistent with the proposed formula. ^{1}H NMR study of **2** (Figure 1) showed strong similitude with parent species,[4e] and with its picolyl analogue **A**,[8] for which the racemic pro-helicoidal metal-centred structure was demonstrated by X-ray analysis. More particularly, the helicoidal arrangement of the two bipyridine units was evident by the presence of an AB system at δ = 5.00, 6.35, attributed to the two corresponding anchoring methylene groups. In the grooves thus generated, the benzyl groups should have place, resulting in the discrimination of the two enantiotopic OCH_2 protons, characterised by a strong AB system at δ = 3.82, 4.01.

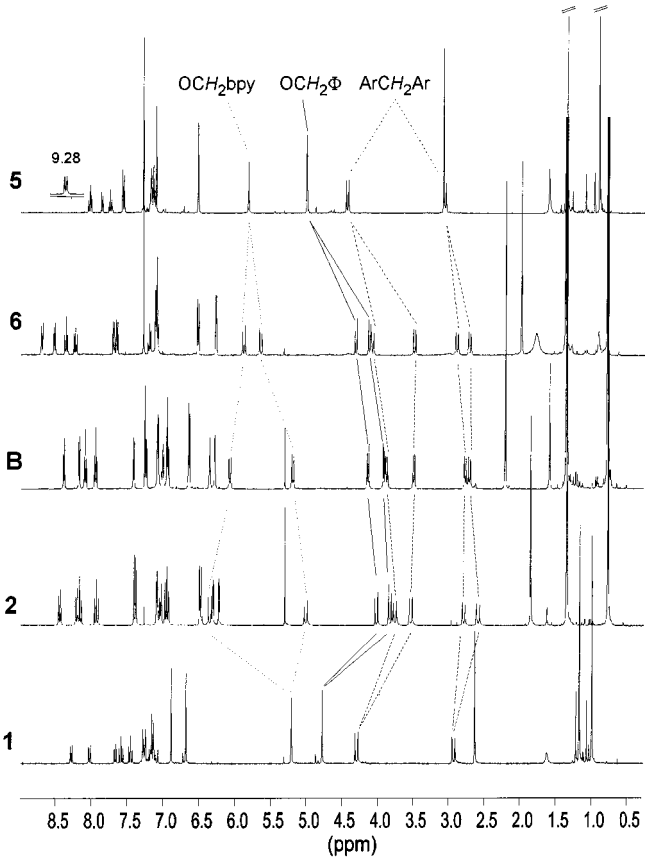

Figure 1. ^{1}H NMR spectra of **1**, **2**, **B**, **6** and **5** (500 MHz, $CDCl_3$, room temp.)

As previously experienced at the upper rim of the calix[4]arene (complexes **C** and **D**) and assessed by a crystal structure (complex **C**),[4f] the cobalt(II) chloride can be complexed by a bipyridine unit in a tetrahedral mode involving two chloride ions and the two bipyridyl nitrogen atoms.[10]

The blue-green complex **3** was prepared by adding an excess of $CoCl_2$ to **1** in a mixture of CH_3CN and CH_2Cl_2 at room temperature; due to its good solubility in CH_2Cl_2, **3** was easily separated from excess $CoCl_2$ in a highly pure form. The dinuclear nature of **3** was indicated by UV/Vis spectroscopy, which showed the presence of the expected metal-centred transition at 658 cm^{-1}, with a molar extinction coefficient of ca. 1000 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$, twice the value reported for complex **C**, and identical to that of complex **D**. Elemental analysis was consistent with the formula $C_{82}H_{88}Co_2Cl_4N_4O_4$. Electrospray mass spectrometry (positive mode, 252 V) showed notably the presence of the expected mono-charged species [**1** + 2 $CoCl_2$ − Cl]$^+$ at 1417.5 amu (10%), accompanied by the "decomplexed" species, such as [**1** + $CoCl_2$ − Cl]$^+$ at 1287.5 amu (40%), [**1** + Na]$^+$

at 1216.7 amu (100%), $[\mathbf{1} + H]^+$ at 1193.7 amu (60%), and by various fragmentation products.

In the standard ^1H NMR spectrum of **3** ($\delta = 0-15$), the absence of some resonance signals confirmed the paramagnetic nature of the [Co/bpy] subunit, as was previously observed.[4f] Recording data in a larger frequency domain (65000 Hz; $\delta = 216$ at 300 MHz, $\delta = 130$ at 500 MHz) showed 11 new resonance signals that were correlated by a COSY experiment (Figure 2): two groups of three singlets integrating 2 H each at $\delta = 72.93$ ($\Delta\nu_{1/2} = 32$ Hz), 42.28 ($\Delta\nu_{1/2} = 34$ Hz), −6.75 (s, $\Delta\nu_{1/2} = 77$ Hz), and $\delta = 72.72$ (s, $\Delta\nu_{1/2} = 25$ Hz), 49.18 (s, $\Delta\nu_{1/2} = 28$ Hz), −14.76 (s, $\Delta\nu_{1/2} = 21$ Hz) were attributed to the bipyridyl groups; one group of two singlets integrating 4 H each at $\delta = -9.70$ (s, $\Delta\nu_{1/2} = 40$ Hz) and $\delta = -3.05$ (s, $\Delta\nu_{1/2} = 22$ Hz) was attributed to the Ar-CH_2-Ar protons. No correlation was found between the groups of bipyridyl aromatic protons and signals corresponding to the OCH_2 and CH_3 groups. Nevertheless, due to their chemical shifts and their integration values, the large singlets found at $\delta = -42.49$ (br. s, $\Delta\nu_{1/2} = 317$ Hz, 4 H) and −22.60 (br. s, $\Delta\nu_{1/2} = 196$ Hz, 6 H) were assigned to the latter, respectively. Finally, the sharp singlet ($\Delta\nu_{1/2} = 4$ Hz) found at $\delta = -1.72$ and integrating 18 H was assigned to two of the four *tert*-butyl groups.

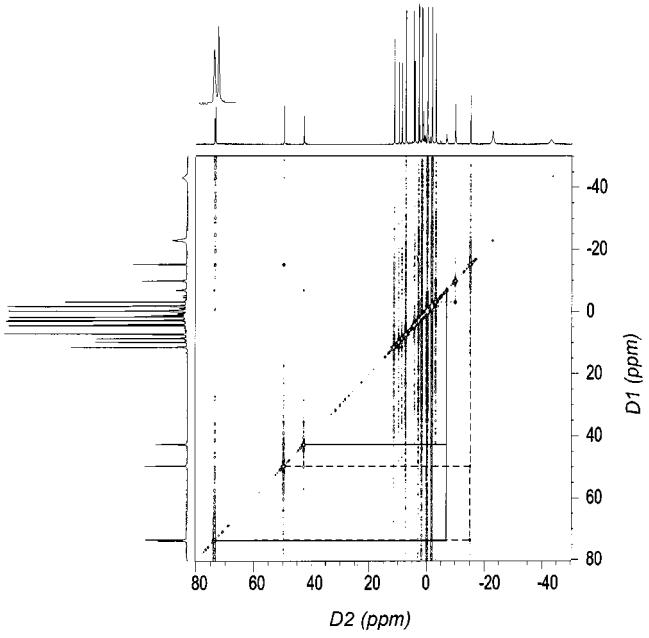

Figure 2. 2D COSY spectrum of cobalt complex **3** (500 MHz, 298 K, $CDCl_3$)

A preliminary study of the complexation of the nickel(II) cation was conducted in solution by UV/Vis titration of **1** with $NiCl_2{\cdot}6H_2O$ in CH_3CN/CH_2Cl_2 (95:5) (Figure 3). The new ligand-centred absorption band that appeared at 318 nm upon complexation increased, up to exactly 2 equiv. of the metal ion, confirming the formation of a dinuclear complex. Two close isosbestic points (offset) were observed at 300.5 nm (curves a−d; 0.0−0.8 equiv. of $NiCl_2{\cdot}6H_2O$) and 295.5 nm (curves f−i; 1.2−2.0 equiv. of $NiCl_2{\cdot}6H_2O$), which correspond to the formation of the mono- and the dinuclear species, respectively. Attempts to isolate the former have failed until now.

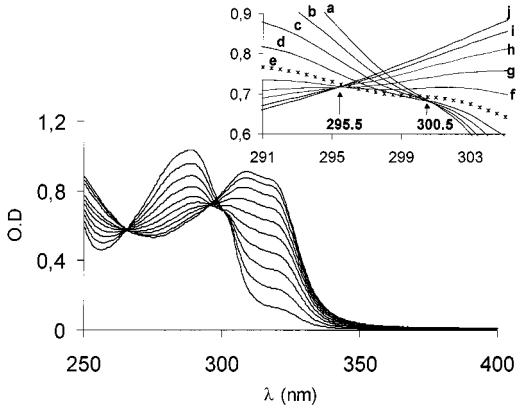

Figure 3. UV/Vis titration of **1** by $NiCl_2{\cdot}6H_2O$ [CH_3CN/CH_2Cl_2 (95:5); a−d: 0.0−0.8 equiv. of $NiCl_2{\cdot}6H_2O$; f−i: 1.2−2.0 equiv. of $NiCl_2{\cdot}6H_2O$]

The reaction of **1** with 2 equiv. of $NiCl_2{\cdot}6H_2O$ at room temp., followed by evaporation of solvents, re-dissolution in $CHCl_3$ and precipitation with hexane, afforded **4** as a salmon-pink microcrystalline solid. Elemental analysis was consistent with the formula $C_{82}H_{88}Cl_4N_4Ni_2O_4{\cdot}0.5CHCl_3$. Electrospray mass spectrometry (positive mode, 234 V) showed, as for the cobalt complex **3**, the presence of the expected mono-charged species $[\mathbf{1} + 2\ NiCl_2 - Cl]^+$ at 1413.5, 1415.5, 1416.5, 1417.5, 1419.5 amu (10%), accompanied by the "decomplexed" species, such as $[\mathbf{1} + NiCl_2 - Cl]^+$ at 1285.5, 1287.5 amu (30%), $[\mathbf{1} + Na]^+$ at 1216.7 amu (100%), $[\mathbf{1} + H]^+$ at 1193.7 amu (80%), and by various fragmentation products. Expecting that, as for the cobalt complex **3**, the paramagnetic nature of the nickel(II) ion should only influence the bipyridine unit resonance signals, **4** was analysed by NMR at 500 MHz. The ^1H NMR spectrum, recorded in a large frequency domain ($\delta = 0-85$) showed the presence of 18 resonance signals with $\Delta\nu_{1/2}$ varying from 9 to 392 Hz. Among them, two sharp singlets ($\Delta\nu_{1/2} = 9$ Hz) integrating 18 H each at $\delta = 1.97$ and 2.03 were attributed to the *tert*-butyl groups; four singlets integrating 2 H each located at $\delta = 58.22$ ($\Delta\nu_{1/2} = 46$ Hz), 63.80 ($\Delta\nu_{1/2} = 38$ Hz), 80.41 ($\Delta\nu_{1/2} = 80$ Hz), and 84.72 ($\Delta\nu_{1/2} = 90$ Hz) were suspected to be bipyridyl resonance signals. A 2D COSY experiment (Figure 4) confirmed this hypothesis, allowing us to build in two groups of three singlets at $\delta = 84.72$ ($\Delta\nu_{1/2} = 90$ Hz), 58.22 ($\Delta\nu_{1/2} = 46$ Hz), 16.75 ($\Delta\nu_{1/2} = 87$ Hz), and $\delta = 80.41$ ($\Delta\nu_{1/2} = 80$ Hz), 63.80 ($\Delta\nu_{1/2} = 38$ Hz), 22.50 ($\Delta\nu_{1/2} = 26$ Hz). Another correlation was found between two signals located at $\delta = 10.75$ (s, $\Delta\nu_{1/2} = 57$ Hz) and 5.60 (s, $\Delta\nu_{1/2} = 50$ Hz), integrating 4 H each,

which were attributed to the Ar-CH_2-Ar groups (Figure 4, offset). The residual signals were not precisely assigned.

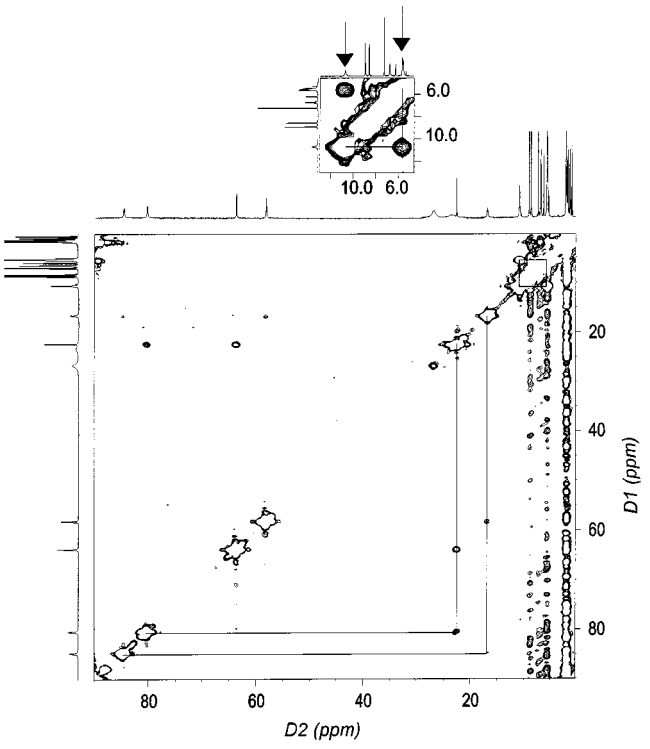

Figure 4. 2D COSY spectrum of nickel complex **4** (500 MHz, 298 K, $CDCl_3$)

Since zinc(II) accepts a tetrahedral geometry with 6,6′-dimethyl-2,2′-bipyridine,[10] we attempted to prepare the dinuclear complex **5**, in which, as for its cobalt and nickel parents **3** and **4**, each metallic centre should be coordinated to one bipyridine unit and to two chloride ions. The complexation of $ZnCl_2$ by ligand **1** was studied by UV/Vis titration, which showed the presence of two close isosbestic points at 299.4 and 303 nm. The two new ligand-centred absorption bands that appeared at 310 and 321 nm upon addition of $ZnCl_2$ increased, up to exactly 2 equiv. of metal ion, confirming the formation of the expected dinuclear species **5**. The latter was prepared as a white microcrystalline solid by mixing the ligand **1** and an excess of $ZnCl_2$ in MeOH and CH_2Cl_2 at room temp., followed by filtration of unchanged $ZnCl_2$ and slow concentration of the filtrate. Surprisingly, with regards to complexes **3** and **4**, electrospray mass spectrometry (positive mode, 80 V) gave poor information on the complex composition, with the presence of one partially "decomplexed" species at 1255.8, 1258.7, and 1259.8 amu [**1** + Zn^{2+} − H^+]$^+$, and the presence of a fragment of ligand at 1032.9, 1033.8, and 1034.9 amu [**1** − 2 ($CH_2C_6H_5$) + Na^+]$^+$. Elemental analysis was consistent with the formula $C_{82}H_{88}Cl_4N_4O_4Zn_2{\cdot}0.5CH_2Cl_2$. Due to its diamagnetism, complex **5** gave a perfectly well-resolved ^{1}H NMR spectrum (Figure 1) between δ = 0 and 10, displaying notably an AB system at δ = 3.12, 4.48 (J_{AB} = 12.9 Hz) assigned to the Ar-CH_2-Ar groups. Both benzyl and bipyridyl methylene groups appear as singlets at δ = 5.02 and 5.81, respectively, indicating the absence of conformational constraint on these pendant arms. All the resonance signals were attributed with the help of a COSY experiment. ^{13}C NMR Ar-*C*H_2-Ar resonance signal was found at δ = 31.56, in the range accepted for the cone conformation.[11]

With the aim of preparing a mononuclear zinc(II) complex displaying structural features equivalent to the above-mentioned copper(I) and silver(I) complexes **2** and **B**, we changed the chloride ions to the noncoordinating trifluoromethanesulfonate ion. UV/Vis titration of **1** by $Zn(Tfo)_2$ (Tfo = $CF_3SO_3^-$) in CH_2Cl_2 resulted in the bathochromic shift of the ligand-centred transition from 288 to 317 nm, and confirmed the formation of the expected mononuclear species. Complex **6** was thus prepared by mixing **1** and 1 equiv. of $Zn(Tfo)_2$ in CH_2Cl_2 and methanol at room temperature. Evaporation of the solvents and dissolution of the residue in $CHCl_3$, followed by filtration and addition of hexane afforded **6** as a white precipitate, in a yield of 90%. Electrospray mass spectrometry (positive mode, alcohol-free CH_2Cl_2, +90 V) showed the presence of the expected mono-charged mononuclear species at 1405.7, 1409.6, 1410.7, and 1413.9 amu ([**1** + Zn + Tfo]$^+$), accompanied by a fragment resulting from the loss of one $C_6H_5CH_2O$ group at 1301.8, 1303.8, 1304.8, and 1306.8 amu ([**1** + Zn + Tfo − $C_6H_5CH_2O$ + H]$^+$); working at a lower voltage (45 V) resulted in the appearance of a base peak at 628.5, 629.4, and 630.0 amu attributed to the doubly-charged species ([**1** + Zn]$^{2+}$/2. Elemental analysis was consistent with the formula $C_{82}H_{88}N_4O_4{\cdot}(CF_3SO_3)_2{\cdot}Zn{\cdot}CHCl_3$. The two Ar-C$H_2$-Ar ^{13}C NMR resonance signals located at δ = 32.37 and 32.87 indicated that **6** was in a distorted cone conformation.[11] A ^{1}H NMR 2D COSY experiment allowed the full assignment of the resonance signals of **6**. As for the tetrahedral species **2** and **B** (Figure 1), the Ar-CH_2-Ar resonance signals appear as two AB systems at δ = 2.67, 3.40 and 2.84, 4.02, indicating a distortion of the conic calixarene platform; the benzyl methylene groups also appear as an AB system at δ = 4.06, 4.21, resulting from an environmental difference generated by the helicoidal complex substructure. The latter is also characterised by a strong AB system located at δ = 5.55, 5.78, attributed to the OCH_2-bpy groups. All attempts to obtain crystals suitable for a convenient X-ray analysis have failed until now.

In parallel, attempts to prepare, on the base of the results obtained with zinc(II), the mononuclear cobalt(II) and nickel(II) species by anion metathesis were unsuccessful.

On the other hand, the different experiments performed to obtain a di- or mononuclear copper(II) complex species resulted in the slow partial to full formation of red copper(I) species. This phenomenon had been previously observed, but as a spontaneous reaction, during the study of **A**[8] and was explained by an oxido reduction process involving an oxidisable substrate and a base in the presence of

copper(II) and the bipyridyl calixarene podand. This particular reactivity is currently under investigation.

3. X-ray Crystal Structure Analyses

At the end of the above-mentioned investigations developed in solution, we obtained single crystals suitable for X-ray analysis with the dinuclear cobalt, nickel and zinc complexes **3**, **4** and **5**. In each case the results of the X-ray crystal structure analyses confirmed that two divalent metal ions are complexed by a podand unit in the expected, more or less distorted, tetrahedral mode,[4f,10] with the participation of the two nitrogen atoms of each bipyridine unit and two coordinating chloride ions.

The study of the calixarene platform subunit shows that the three compounds display a similar cone conformation. The inclination angles versus the mean plane of the methylene groups are very similar: two of the phenolic rings are near 90° (values between 90.8 and 98.5°) and the two others carrying the bipyridine units lie outside (values between 129.9 and 135.7°; Figure 5, ORTEP view of nickel complex **4**).

The bipyridine units are very planar (χ^2 from 0.01 to 0.08), but the angles between their planes are different, increasing from 24.8(1)° for **3**, to 31.65(7)° for **5** and 47.39(9)° for **4**. Distances from the metal ion to the mean plane of each bipyridine unit vary from 0.006 Å to 0.103 Å, while the chloride distances vary from 1.626 Å to 2.311 Å.

Distances and angles have been calculated around each metal ion (Tables 1 and 2). The geometry is very similar with a mean angle value N−metal−N of 81.6°. Mean distances metal−N have values of 2.033 Å in **3**, 2.005 Å in **4** and 2.050 Å in **5**, while the mean value for metal−Cl is 2.21 Å for the 3 compounds.

Comparison of cobalt complex subunits in **C** and **3** shows a high similarity in the coordination mode; in **3**, the Co1 coordination appears less distorted than that of Co2 and that in **C**. A similar difference in distortion is also observed between the two complex subunits in **4** and in **5**.

In each compound, one of the benzyl groups (E) is always found in the same position, in such a way that the benzene ring is almost parallel to the corresponding phenolic ring of the calixarene. The second benzyl group (F) is oriented out of the cone (Figure 6).

In the study of the packing of the zinc complex **5**, we can note some π−π interactions between one ring of a bipyridine unit (B) and another one (D) of the macrocycle obtained by a 2_1 axis (Figure 7). The same situation is found in **3**.

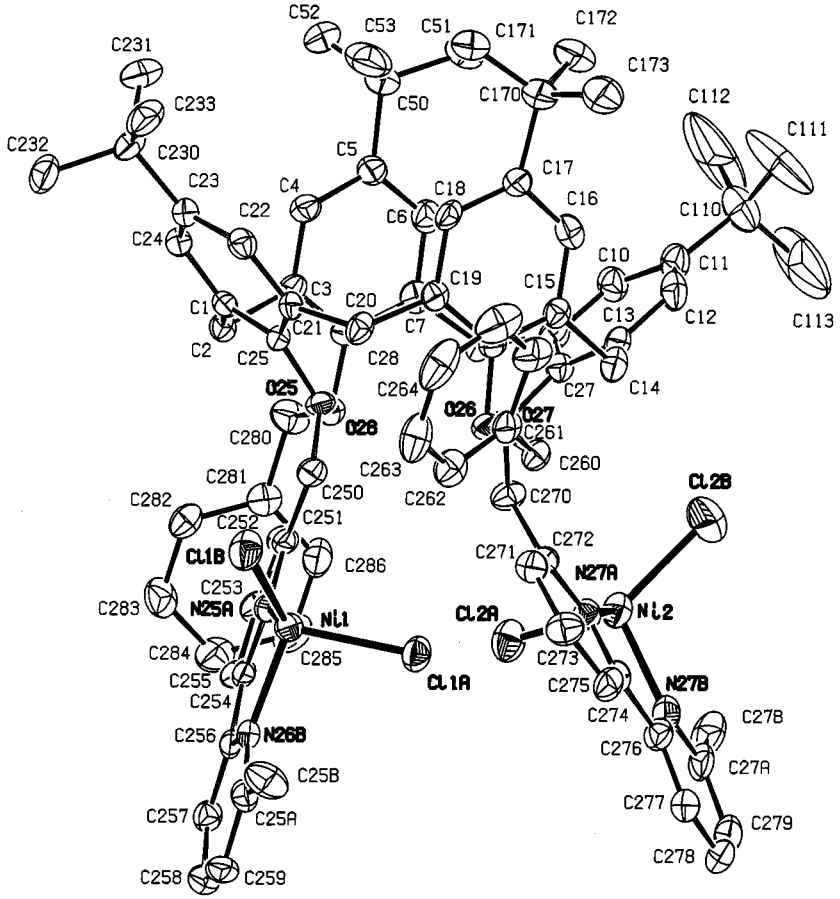

Figure 5. ORTEP side-view and numbering scheme of complex **4** (carbon atoms 8, 9, 26, 225 and 226 are omitted for clarity)

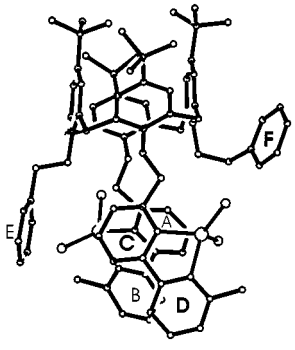

Figure 6. Side views of complex **4** and labelling of pendant bipyridyl and benzyl arms[14]

The nickel complex **4**, which crystallises in the triclinic system, shows interactions between bipyridine units A and B on one part, and pyridine rings C and D on another part.

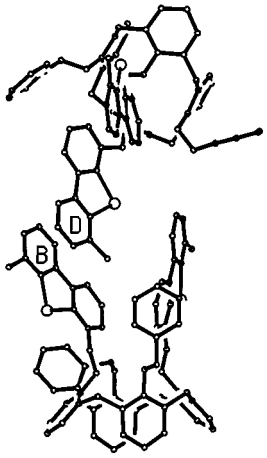

Figure 7. Interactions between rings B and D in complex **5** (*tert*-butyl groups and chlorine atoms were omitted for clarity

The corresponding calixarenes are obtained both by the centre of symmetry and by translation along *b* axis (Figure 8).

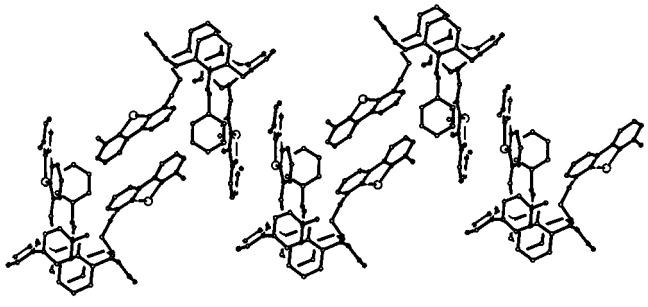

Figure 8. Interactions between the bipyridine units A and B, and C and D in nickel complex **4** (solvent atoms, *tert*-butyl groups and chlorine atoms are omitted for clarity)

Each complex crystallises with solvents which are not shown in the figures: **4** with three molecules of toluene, **3** with one molecule of dichloromethane, and **5** with two molecules of dichloromethane and two of ethanol. For the latter, one of the ethanol molecules displays a short contact

with a chlorine atom of one dichloromethane molecule (Cl···O = 3.208 Å).

Conclusion

The bipyridyl-containing calix[4]arene podand **1** described in this report shows interesting versatile complexing properties towards various common transition metal cations, giving in all cases complexes with tetrahedral coordination geometry. Depending on the nature of the cation, but also of the coordinating ability of the counter-anion, these complexes are of the L/M or L/M_2 stoichiometry, as demonstrated by UV/Vis spectroscopy, high resolution NMR spectroscopy and X-ray diffraction analysis. This versatile behaviour is currently the subject of competitive extraction studies, which necessitates developing in parallel the synthesis of the corresponding heterodinuclear complexes.

Experimental Section

General: Melting points (°C, uncorrected values) were determined with an Electrothermal 9100 (capillary apparatus). ^1H and ^{13}C NMR spectra were recorded with a Bruker AM 300 or DRX 300 and DRX 500 ($CDCl_3$, TMS as internal standard, chemical shifts in ppm). Mass spectra (electrospray, ES) were recorded with a Platform Micromass apparatus at the Service Central d'Analyse du CNRS, Solaize. Infrared spectroscopy was performed with a Mattson 5000 FT apparatus (KBr, ν in cm^{-1}) and UV spectra were recorded with a Shimadzu UV 2401 PC or a SAFAS UV mc^2 apparatus, λ_{max} in nm, ε in $dm^3 \cdot mol^{-1} \cdot cm^{-1}$. Elemental analyses were performed at the Service Central de Microanalyse, Ecole Supérieure de Chimie, Montpellier. Macherey−Nagel TLC plates were used for chromatography analysis (SiO_2, Polygram SIL G/UV254, ref. no. 805021). All commercially available products were used without further purification unless otherwise specified.

Mononuclear Copper(I) Hexafluorophosphate Complex 2: A solution of 0.0156 g of $Cu(CH_3CN)_4PF_6$ ($4.2\ 10^{-5}$ mol) in 5 mL of acetonitrile was added to a suspension of 0.05 g of **1** ($4.2\ 10^{-5}$ mol) in 20 mL of acetonitrile. Upon complexation, **1** was dissolved, giving an orange-coloured solution. The solvent was evaporated to dryness and the residue was chromatographed (Al_2O_3, CH_2Cl_2) to give **2** (0.055 g, 90%). Orange powder. M.p. 308 °C. IR: $\tilde{\nu}$ = 1570 (C−N), 2960 (C−H). UV/Vis (CH_2Cl_2): λ = 266 (29900), 302 (34700), 447 (5500, MLCT). ^1H NMR (300 MHz, $CDCl_3$): δ = 0.76 (s, 18 H, *Me*$_3$C), 1.34 (s, 18 H, *Me*$_3$C), 1.85 (s, 6 H, *Me*bpy), 2.58, 3.75 ("q", AB, J_{AB} = 13.3, 4 H, Ar-C*H*$_2$-Ar), 2.78, 3.53 ("q", AB, J_{AB} = 12.6, 4 H, Ar-C*H*$_2$-Ar), 3.82, 4.01 ("q", AB, J_{AB} = 11.5, 4 H, OC*H*$_2$C$_6$H$_5$), 5.00, 6.35 ("q", AB, J_{AB} = 12.9, 4 H, OC*H*$_2$bpy), 6.22, 6.30 (AB, J_{AB} = 2.0, 4 H, Ar*H*), 6.47 (dd, *J* = 7.7 *J* = 1.4, 4 H, C$_6$*H*$_5$), 7.02, 7.09 (AB, J_{AB} = 2.0, 4 H, Ar*H*), 7.06−7.29 (m, 6 H, C$_6$*H*$_5$), 7.39 (d, *J* = 7.7, 4 H, bpy), 7.93 (t, *J* = 8.1, 2 H, bpy), 8.16 (t, *J* = 8.1, 2 H, bpy), 8.19 (d, *J* = 8.1, 2 H, bpy), 8.44 (d, *J* = 8.1, 2 H, bpy). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 23.7 (*Me*bpy), 31.8, 32.4 (Ar-C*H*$_2$-Ar), 31.1, 31.7 (*Me*$_3$C), 33.6, 34.2 (Me$_3$*C*), 77.4 (OCH$_2$C$_6$H$_5$), 79.3 (O*C*H$_2$bpy), 119.8, 121.9, 124.1, 124.54, 125.50, 126.7, 126.9, 127.8, 127.9, 128.9, 138.7, 139.0 (aromatic *C*H), 131.1, 131.4, 134.8, 135.8, 137.0, 144.5, 145.9, 151.96, 151.98, 152.1, 154.0, 157.7, 157.8 (aromatic *C*). ES-MS (pos. mode): *m*/*z* = 1255.6 [**1** + Cu^I]$^+$. $C_{82}H_{88}CuF_6N_4O_4P \cdot 0.8CH_2Cl_2$ (1470.09): calcd. C 68.30, H 6.08, N 3.77; found C 68.06, H 6.03, N 3.86.

Dinuclear Cobalt(II) Chloride Complex 3: A solution of 0.016 g of $CoCl_2$ ($1.26\ 10^{-4}$ mol) in 5 mL of acetonitrile was added to a solution of 0.05 g of **1** ($4.2\ 10^{-5}$ mol) in 10 mL of CH_2Cl_2. The resulting blue-green solution was stirred at room temp. during 1 h and then concentrated to dryness. The residue was treated with 5 mL of CH_2Cl_2 and the excess of $CoCl_2$ was removed by filtration. Slow concentration of the filtrate gave blue-green crystals of **3** (0.060 g, 98%). M.p. 235 °C. IR: $\tilde{\nu}$ = 1570, 1601 (C−N), 2956 (C−H). UV/Vis (CH_2Cl_2): λ = 317 (30700), 568 (550), 658 (1000). ^1H NMR (500 MHz, $CDCl_3$): δ = −42.49 (br. s, $\Delta\nu_{1/2}$ = 317 Hz, 4 H, OC*H*$_2$bpy), −22.60 (br. s, $\Delta\nu_{1/2}$ = 196 Hz, 6 H, *Me*bpy), −14.76 (s, $\Delta\nu_{1/2}$ = 21 Hz, 2 H, bpy), −9.70 (s, $\Delta\nu_{1/2}$ = 40 Hz, 4 H, 2 Ar-C*H*$_2$-Ar), − 6.75 (s, $\Delta\nu_{1/2}$ = 77 Hz, 2 H, bpy), −3.05 (s, $\Delta\nu_{1/2}$ = 22 Hz, 4 H, 2 Ar-C*H*$_2$-Ar), −1.72 (s, $\Delta\nu_{1/2}$ = 4 Hz, 18 H, *Me*$_3$C), −0.13 (s, $\Delta\nu_{1/2}$ = 6 Hz, 18 H, *Me*$_3$C), 1.75 (s, $\Delta\nu_{1/2}$ = 6 Hz, 4 H, Ar*H*), 1.78 (s, $\Delta\nu_{1/2}$ = 6 Hz, 4 H, Ar*H*), 4.17 (s, $\Delta\nu_{1/2}$ = 18 Hz, 4 H, 2 OC*H*$_2$C$_6$H$_5$), 8.63 (s, $\Delta\nu_{1/2}$ = 22 Hz, 4 H, C$_6$*H*$_5$), 9.77 (s, $\Delta\nu_{1/2}$ = 12 Hz, 2 H, C$_6$*H*$_5$), 11.38 (s, $\Delta\nu_{1/2}$ = 22 Hz, 4 H, C$_6$*H*$_5$), 42.28 (s, $\Delta\nu_{1/2}$ = 34 Hz, 2 H, bpy), 49.18 (s, $\Delta\nu_{1/2}$ = 28 Hz, 2 H, bpy), 72.72 (s, $\Delta\nu_{1/2}$ = 25 Hz, 2 H, bpy), 72.93 (s, $\Delta\nu_{1/2}$ = 32 Hz, 2 H, bpy). ES-MS (pos. mode, 252 V): *m*/*z* = 1417.5 [**1** + 2 ($CoCl_2$) − Cl^-]$^+$, 1288.5 [**1** + $CoCl_2$ − Cl^-]$^+$, 1215.7 [**1** + Na]$^+$, 1193.7 [**1** + H]$^+$. $C_{82}H_{88}Cl_4Co_2N_4O_4$ (1453.32): calcd. C 67.77, H 6.10, N 3.86; found C 68.00, H 6.25, N 3.65.

Dinuclear Nickel(II) Chloride Complex 4: A solution of 0.020 g of **1** ($1.67\ 10^{-5}$ mol) and 0.0081 g of $NiCl_2 \cdot 6H_2O$ ($3.35\ 10^{-5}$ mol) in a mixture of CH_2Cl_2 (1 mL), acetonitrile (10 mL) and methanol (1 mL) was stirred at room temp. during 1 h. The resulting salmon-pink solution was concentrated to dryness; the residue was dissolved in $CHCl_3$ and the addition of 10 mL of hexane resulted in the precipitation of **4** as a pink microcrystalline solid (0.017 g; 71%). M.p. 295 °C. IR: $\tilde{\nu}$ = 2957 (CH), 1574, 1603 (C−N). UV/Vis (CH_2Cl_2): λ = 310 (40200), 488 (325). ^1H NMR (500 MHz, $CDCl_3$): δ = 1.97 (s, $\Delta\nu_{1/2}$ = 9 Hz, 18 H, *Me*$_3$C), 2.03 (s, $\Delta\nu_{1/2}$ = 9 Hz, 18 H, *Me*$_3$C), 5.60 (s, 4 H, Ar-C*H*$_2$-Ar), 10.75 (s, $\Delta\nu_{1/2}$ = 57 Hz, 4 H, Ar-C*H*$_2$Ar), 16.75 [s, $\Delta\nu_{1/2}$ = 87 Hz, 2 H, bpy(1)], 22.50 [s, $\Delta\nu_{1/2}$ = 26 Hz, 2 H, bpy(2)], 58.22 [s, $\Delta\nu_{1/2}$ = 46 Hz, 2 H, bpy(1)], 63.80 [s, $\Delta\nu_{1/2}$ = 38 Hz, 2 H, bpy(2)], 80.41 [s, $\Delta\nu_{1/2}$ = 80 Hz, 2 H, bpy(2)], 84.72 [s, $\Delta\nu_{1/2}$ = 90 Hz, 2 H, bpy(1)],1.72 (s, $\Delta\nu_{1/2}$ = 28 Hz, 6 H), 5.32 (s, 4 H), 5.67 (s, 4 H), 6.25 (s, $\Delta\nu_{1/2}$ = 16 Hz, 2 H), 6.77 (s, $\Delta\nu_{1/2}$ = 28 Hz, 4 H), 8.60 (s, $\Delta\nu_{1/2}$ = 14 Hz, 4 H), 8.94 (s, $\Delta\nu_{1/2}$ = 12 Hz, 4 H), 26.82 (s, $\Delta\nu_{1/2}$ = 392 Hz, 4 H) (*Me*bpy, OC*H*$_2$C$_6$H$_5$, C$_6$*H*$_5$, Ar*H*, OC*H*$_2$bpy). ES-MS (pos. mode, 234 V): *m*/*z* = 1417.5 [**1** + 2 ($NiCl_2$) − Cl^-]$^+$, 1287.5 [**1** + ($NiCl_2$) − Cl^-]$^+$, 1215.7 [**1** + Na]$^+$. $C_{82}H_{88}Cl_4N_4Ni_2O_4 \cdot 0.5CHCl_3$ (1512.52): calcd. X-ray Crystallographic Study of Complexes 3, 4 and 5: The data were collected with a Nonius Kappa CCD diffractometer using monochromated Mo-K_α radiation. Structures were solved by direct methods and refined using full-matrix least squares with SHELXS97 [12] and SHELXL97 programmes.[13] All non-H atoms were refined anisotropically. Hydrogen atoms were calculated at their idealised positions and refined isotropically riding on previous atoms. Details for the experimental conditions, cell data, structure and refinement data are given in Table 3. CCDC-167144 (**3**), -167143 (**4**) and -167145 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to the MRES for financial support, especially J.-O. D. for a PhD fellowship; to SAFAS (Monaco) and BRUKER S. A. for UV spectroscopy and WinNMR facilities, respectively. The authors thank Mrs. Nicole Marshall for correcting the manuscript.

Structural and Spectroelectrochemical Studies on (2,2′-Bidipyrrinato)copper(II) and -palladium(II) Complexes

Martin Bröring,*[a] Carsten D. Brandt,[a] Jordi Bley-Escrich,[b] and Jean-Paul Gisselbrecht*[b]

Keywords: Porphyrinoids / N ligands / Copper / Palladium / Electrochemistry

Copper(II) and palladium(II) complexes of two 2,2′-bidipyrrin ligands were prepared and examined, in comparison with the known nickel(II) complexes of these ligands, by means of X-ray crystallography, cyclic voltammetry, and spectroelectrochemistry. All compounds are of helical geometry with coordination environments of the metal centres displaying very small tetrahedral distortions for palladium and very large ones for copper complexes. Porphyrinoid behaviour was found for the one- and two-electron oxidations of all complexes studied, as well as for the reductions of the Pd^{II} species. On the other hand, the reduction of the Cu^{II} complexes shows some special features, which may be explained from the results of spectroelectrochemical studies as related to the particular non-planarity of these compounds.

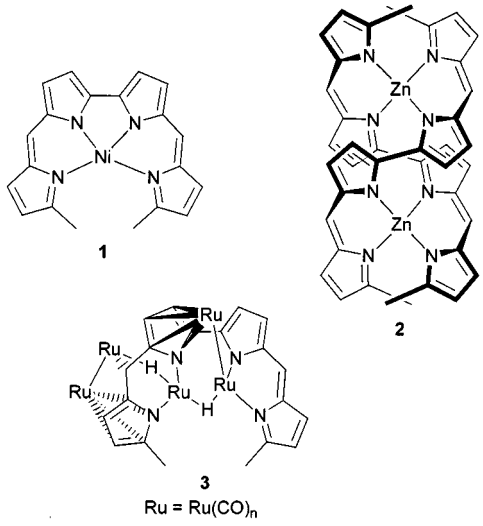
Introduction

As part of an ongoing project to study the coordination chemistry of open-chain oligopyrrolic ligands, we recently became interested in the tetrapyrrolic 2,2′-bidipyrrins.[1,2] Topologically, 2,2′-bidipyrrins resemble the porphyrins both in their build-up (from two connected dipyrrin units) and their expected dianionic character when serving as ligands in metal complexes.[3] Our initial studies on a set of (2,2′-bidipyrrinato)nickel(II) complexes showed that this tetrapyrrole formed conformatively stable helicates, which may be resolved chromatographically into the separate enantiomers. In addition to this, the delocalized π system of 2,2′-bidipyrrin ligands largely determines the electrochemical behaviour of the Ni^{II} complexes, in that only ligand centred oxidation and reduction steps could be observed. This finding, in particular, qualifies 2,2′-bidipyrrins as open-chain analogues of the porphyrins.[4]

The higher flexibility of the 2,2′-bidipyrrin ligand with respect to the porphyrins, however, has tremendous impact on its coordination chemistry, as was recently shown by the X-ray crystallographic characterization of two non-porphyrinoid coordination modes (Scheme 1).[5,6] Therefore, a prediction of how this tetrapyrrole would interact with a given metal ion is not trivial. In the early 1960s, the Johnson group reported the first palladium and copper complexes of 2,2′-bidipyrrins. From molecular mass determination, the latter were deduced to exist in two different, interchangeable forms, namely the coordination modes displayed by **1** and **2** (Scheme 1).[7]



Scheme 1. Coordination modes of 2,2′-bidipyrrins

In this context, we had two important questions. Firstly, what is the impact of elongated M−N bonds of e.g. Pd^{II} vs. Ni^{II} complexes of 2,2′-bidipyrrins on the stability of the helical conformation? Secondly, how does the typical structural lability for Cu^{II} complexes influence the coordination mode, the ligand structure, and the redox behaviour of these complexes? In this paper we try to answer these questions using structural and electrochemical arguments.

Results and Discussion

Preparation and Characterization of Complexes 6−9

The copper(II) and palladium(II) complexes **6−9** were prepared from the 2,2′-bidipyrrins **4** and **5** by treatment with a methanolic solution of excess metal acetate (Scheme 2). The complexation reactions were complete after 30 min at room temperature. The copper complexes **6** and **7** were purified by several washings of the resulting solutions with water, and recrystallization from dichloromethane/*n*-hexane. In the case of the palladium complexes **8** and **9**, convenient purification could be achieved by chromatographic filtration through silica and subsequent recrystallization from the above solvent mixture. The observed yields were good (78−92%). Only one copper(II) complex was formed from either ligand by this method, namely the M_1L_1 compound of type **1**.

Ph	Ni	**11**

Scheme 2. Syntheses of (2,2′-bidipyrrinato)metal(II) complexes

All new compounds gave correct analyses, and were further characterized by EIMS. In addition, proton and carbon NMR measurements were carried out on the palladium derivatives **8** and **9**, showing the expected sharp signals for **8** and broadened resonances for **9** due to the steric encumbrance of the peripheral substituents. The same line broadening was observed earlier on a set of related (2,2′-bidipyrrinato)nickel(II) complexes like **11**.[3] The splitting of the signals of the *meso*-phenyl substituents indicates the expected helical conformation of **9** in solution at room temperature.

Molecular Structures of 6 and 8

Crystals of **6** and **8** were obtained from slow concentration of the respective solutions in dichloromethane/*n*-hexane. As in the case of the nickel(II) complex **10** of the same ligand, complexes **6** and **8** crystallized in the monoclinic system, space group $P2_1/c$, with $Z = 4$. Both compounds show helically distorted ligand frameworks in the solid, and both enantiomers co-crystallize in the same unit cell. Figures 1 and 2 show the molecular structures of **8** and **6**, and Table 1 summarizes structural parameters of **6**, **8**, and **10**.

For the palladium derivative **8**, the Pd−N bond lengths of 1.956(3)−2.045(3) Å appear in the range found for other (tetrapyrrole)palladium(II) complexes,[8−12] and indicate a larger N_4 core as compared with the Ni^{II} derivative **10**. As a consequence of these elongations, the coordination sphere of the metal ion becomes significantly more trapezoidal. This is clearly visible in the reduced internal N−M−N angles (by 1.37−2.05° with respect to **10**), and a widened N(1)−Pd−N(4) angle of 105.44°. The ligand itself was found to expand upon coordination of the Pd^{II} ion. This

was deduced from the fact that the inner bond angles of the bipyrrole linkage N(2)−C(9)−C(10) and N(3)−C(10)−C(9) as well as those at the *meso* carbon atoms C(4)−C(5)−C(6) and C(13)−C(14)−C(15) became larger. In summary, the changes result in reduced overlap of the terminal methyl groups, and thus in diminished helicity of the ligand and enhanced planarity of the metal centre {rms deviation of MN_4 fragments from planarity: Pd 0.151 Å, Ni 0.203 Å; angle between the planes [N(2),N(3),M] and [N(1),N(4),M]: for **8** 14.0°, for **10** 19.9°; angles N(1)−M−N(3) and N(2)−M−N(4): Pd 164.02(11) and 162.69(11)°, Ni 161.72(7) and 163.08(7)°; Figure 3}. The distance between the terminal methyl groups, however, increased in the Pd^{II} complex from 3.34 to 3.48 Å. Obviously, this value is not a good indicator for the helical topology of the tetrapyrrole perimeter in chelates with different metal ions. Despite the more open structure of **8** with respect to **10**, the helical arrangement is still quite pronounced and

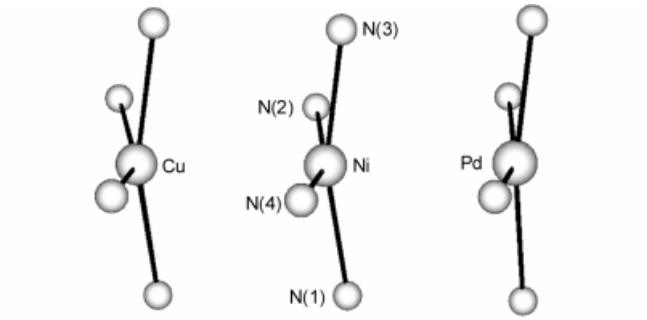

Figure 3. Comparison of coordination geometries found in **6**, **8**, and **10**

stable. Further support to this statement is provided by the fact, that the diphenyl derivative **9** of (2,2′-bidipyrrinato)-palladium(II) could be separated into the enantiomers by HPLC on an analytical scale, and by the observation, that in the ^1H NMR spectrum the splitting of the signals of the *meso*-phenyl groups of **9** remained unchanged up to 90 °C.

The Cu−N bond lengths of the copper(II) complex **6** of 1.9250(17)−1.9794(16) Å are normal for copper(II) complexes of tetrapyrrolic ligands,[9,13−16] and are therefore again longer than the Ni−N bond length of **10**. The same conclusions as with the palladium derivative **8** above can thus be drawn concerning the changes found for the inner bond angles and the overlap of the terminal methyl groups of the tetrapyrrole ligand. In contrast to **8**, however, the more open structure of complex **6** results in enhanced helicity of the ligand and reduced planarity of the metal coordination sphere. This difference is caused by the pronounced tetrahedral distortion imposed by the metal centre as measured by the N(1)−Cu−N(3) and N(2)−Cu−N(4) angles of 159.28(7) and 157.97(7)°, respectively. The difference could be monitored in the enlarged deviation of the CuN_4 fragment from planarity (0.234 Å) as well as in the angle between the planes [N(2),N(3),Cu] and [N(1),N(4),Cu] of 22.0° (Figure 3). The flexibility of 2,2′-bidipyrrin ligands thus allows different metal centres to accommodate the coordination geometry within some range, even if the same coordination mode is established.

Cyclic Voltammetry

As we have shown earlier, the redox characteristics of (2,2′-bidipyrrinato)nickel(II) complexes resemble those of porphyrinoid nickel(II) complexes. In both cases, two one-electron transfer steps occurred upon oxidation or reduction, and all could be shown to be ligand centred.[4] The values detected for the potentials of (2,2′-bidipyrrinato)-nickel(II) complex oxidations and reductions, however, are more closely related to those of the chlorinato- and bacteriochlorinato complexes than to the metalloporphyrins themselves.[17,18]

Cu^{II} and Pd^{II} complexes **6**−**9** were studied in benzonitrile with 0.1 M $n Bu_4NPF_6$, and gave well-defined signals (Fig-

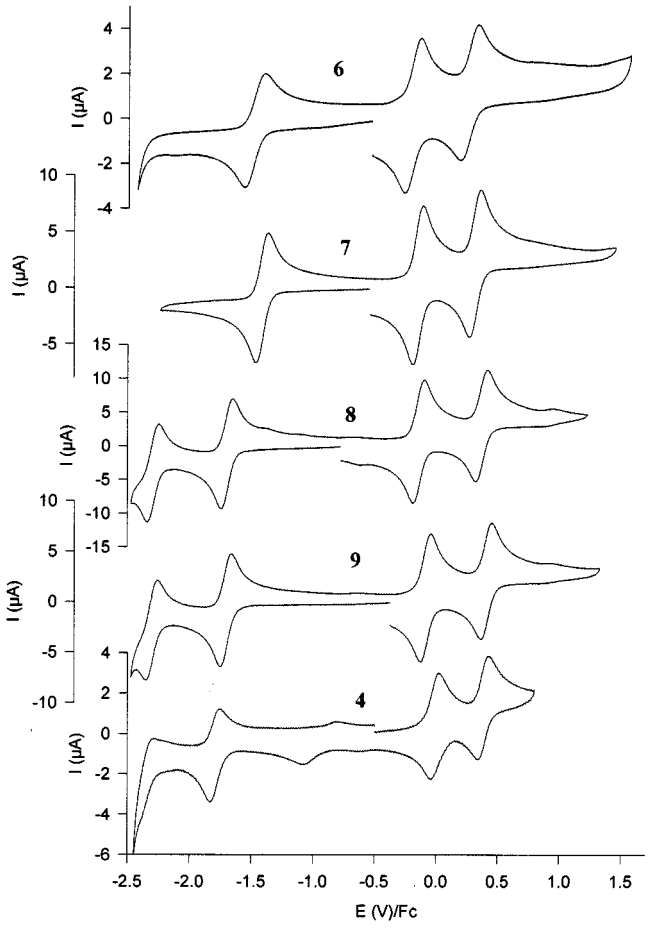

Figure 4. Cyclic voltammetry of **4**, **6**, **7**, **8**, and **9** in PhCN with 0.1 M Bu_4NPF_6 on a platinum working electrode; sweep rate: v = 0.2 V s^{-1}

ure 4). All derivatives underwent two reversible one-electron oxidations at rather low potentials. In reduction, the first reduction step (one-electron reversible step) was well resolved, whereas the second reduction step occurred close to the electrolyte discharge for the Pd^{II} complexes and could not be observed for the Cu^{II} complexes. The potentials of all accessible electron transfers are collected in Table 2.

Table 2. Electrochemical data for free base **4** and complexes **6**−**11**

[a] Measured on a platinum electrode in PhCN solution with 0.1 M nBu_4NPF_6. Values are given in V relative to the Fc^+/Fc couple. [b] HOMO−LUMO gap (= $E_{Ox.\ 1} - E_{Red.\ 1}$). [c] Electronegativity values taken from ref.[19] [d] Not observed.

The redox behaviour of the palladium complexes **8** and **9** is similar to that of the respective nickel complexes **10** and **11**, and all four redox waves were in analogy assigned to ligand-centred electron transfer processes. The phenyl substituents of **9** and **11** shifted the oxidation potentials to more positive values, whereas the first reduction became slightly more negative. Such shifts are not expected for donor substitution. It seems much more likely that the electronic effect of the phenyl moiety is superimposed by a structural one. X-ray crystallographic work on *meso*-aryl-substituted nickel(II) complexes shows a reduced bite angle of both dipyrrin units due to the higher congested periphery. This structural difference may be responsible for the effect in **9** and **11**.

For the two one-electron oxidation steps of the copper(II) derivatives **6** and **7**, the above discussion still holds true, and both electron transfers are therefore assigned to ligand-centred processes. The interpretation of the reduction behaviour of **6** and **7**, however, is more difficult. A comparison of the obtained data clearly shows, that the potentials of the first reduction step of the copper complexes are at less negative values than those of the nickel and palladium species. However, even if the first reduction is facilitated, the second reduction step is not observed in the available potential range. This peculiar behaviour is again probably due to geometric reasons, since Cu^{II} can more easily adopt and support the non-planar coordination geometry imposed by the ligand, in contrast to Ni^{II} or Pd^{II}, which prefer square-planar environments. The easier reduction of the copper complexes **6** and **7** is most likely a consequence of strain release, and does not seem to result from a possible reduction of the metal ion. Spectroelectrochemical studies discussed below further strengthen this conclusion.

Since structural effects have a strong impact on the redox characteristics of 2,2′-bidipyrrinato complexes, it is obvious that metal-dependent trends known from metalloporphyrin electrochemistry cannot be expected to hold true for the open-chain analogues. Correlations like the potential evolution vs. metal electronegativity,[19] or the energy of the HOMO−LUMO gap vs. the potential difference between the first oxidation and first reduction potential,[20−22] which are typical for metalloporphyrins and other rigid porphyrinoid complexes, strongly depend on structural factors and are therefore not valid for complexes **6**−**11** (Table 2).

Spectroelectrochemical Investigations

Spectroelectrochemical studies were carried out on the complexes **7**, **9**, and **11**, as well as on the free base **4**. The time-resolved UV/Vis spectra recorded during spectroelectrochemical studies are given in Figures 5 and 6, and the UV/Vis data for all species are summarized in Table 3. It has to be mentioned that in all cases after the first reduction, as well as after the first oxidation, the initial spectrum could be recovered quantitatively. After the second oxidation step, the reduction to regenerate the radical cation was not quantitative, and only 60 to 75% of the radical cation could be recovered for the studied complexes. The second oxidation step of the free base was irreversible on the time scale of spectroelectrochemistry.

Since the UV/Vis spectra and redox potentials of free base 2,2′-bidipyrrins **4** differ significantly from those of the respective metal complexes, the spectroelectrochemical data of **4** are only of limited value as a reference. One important trend, however, is easily seen in Figure 5: the one-electron oxidised and reduced ligand species are both characterized by new and quite narrow bands in the optical spectra. For the two-electron oxidised species, on the other hand, only broad absorptions were detected.

The UV/Vis spectra of the metal complexes **7**, **9**, and **11** also changed dramatically upon reduction or oxidation, and the different electrogenerated species show the same trends within the series (Figure 6). As for the free base ligand **4**, rather sharp absorptions were found after one-electron oxidation and reduction, and only broad bands were observed for the two-electron oxidised members. These similarities are best explained by the assumption of ligand-centred redox reactions throughout the series. The reduction of the copper(II) complex **7**, however, produced an extra distinct band at 706 nm, which was missing in the spectra of the other chelates. This band inhibits a simple comparative analysis of the data. We believe that a ligand-centred one-electron step occurs also in the case of Cu^{II} rather than a reduction to Cu^{I}, since upon reduction of **7** the other bands evolve in a similar fashion to those of **9** and **11**, and because these bands obviously belong to transitions of the tetrapyrrole ligand π system.

In order to identify the site of the one-electron reduction of the copper complexes **6** and **7**, further electrochemical experiments were performed. Upon changing the solvent from benzonitrile to dichloromethane very similar results were obtained for **6**, and all redox processes remained perfectly reversible. On the time scale of spectroelectrochemistry (i.e. ca. 20 min), however, the one-electron reduced $\mathbf{6}^{-\cdot}$ reacted irreversibly with the solvent, leading to a different UV/Vis spectrum with respect to the one obtained in benzonitrile. In fact, by cyclic voltammetry, in the presence of a large excess of the better electrophile *n*-propyl bromide (1000 equiv.), the first reduction step of **6** remained reversible at sweep rates higher than 1 V/s and became irreversible, and dielectronic at sweep rates lower than 0.1 V/s. Such a behaviour is characteristic for an ECE mechanism (*E*lectrochemical *C*hemical *E*lectrochemical) in the presence of a sufficient amount of an electrophile. The generated anion (electrochemical step) is reacting with *n*-propyl bromide (chemical step) to generate a new species, which is again one-electron reduced in another electrochemical step. Since four-coordinate Cu^{I} is a poor nucleophile, the outcome of this experiment strongly supports the hypothesis of a ligand radical anion character of $\mathbf{6}^{-\cdot}$. Similar experiments have been performed before on metalloporphyrins.[23]

In addition to the electrochemical investigations, chemical reduction of **6** using NaHg was attempted and was monitored by proton NMR and EPR spectroscopy. In THF (or [D_8]THF) the one-electron reduction of **6** proceeded slowly at room temperature and could be conveniently followed through the colour change from orange-red to red-violet. In NMR spectroscopy, the reduction of **6** was accompanied by an additional line broadening and the entire loss of any residual signal fine structure, which was detected even in the spectrum of **6** for the most distant CH_3 groups only.[24] This observation is again indicative of the presence of a π-radical on $\mathbf{6}^{-\cdot}$ that has no magnetic coupling with the

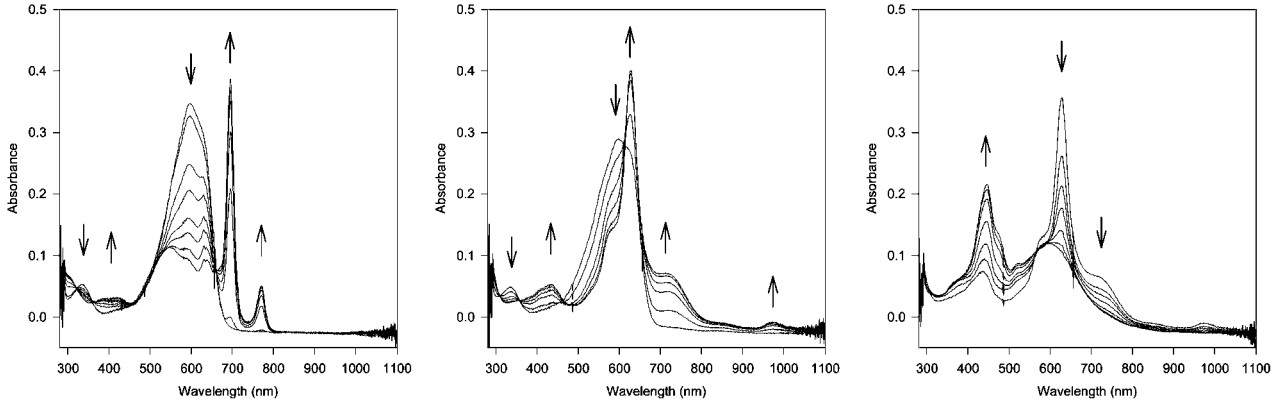

Figure 5. Time-resolved UV/Vis spectroelectrochemical measurements of free base 2,2′-bidipyrrin **4** in PhCN with 0.1 M Bu_4NPF_6; first column: Red. 1, second column Ox. 1, third column Ox. 2

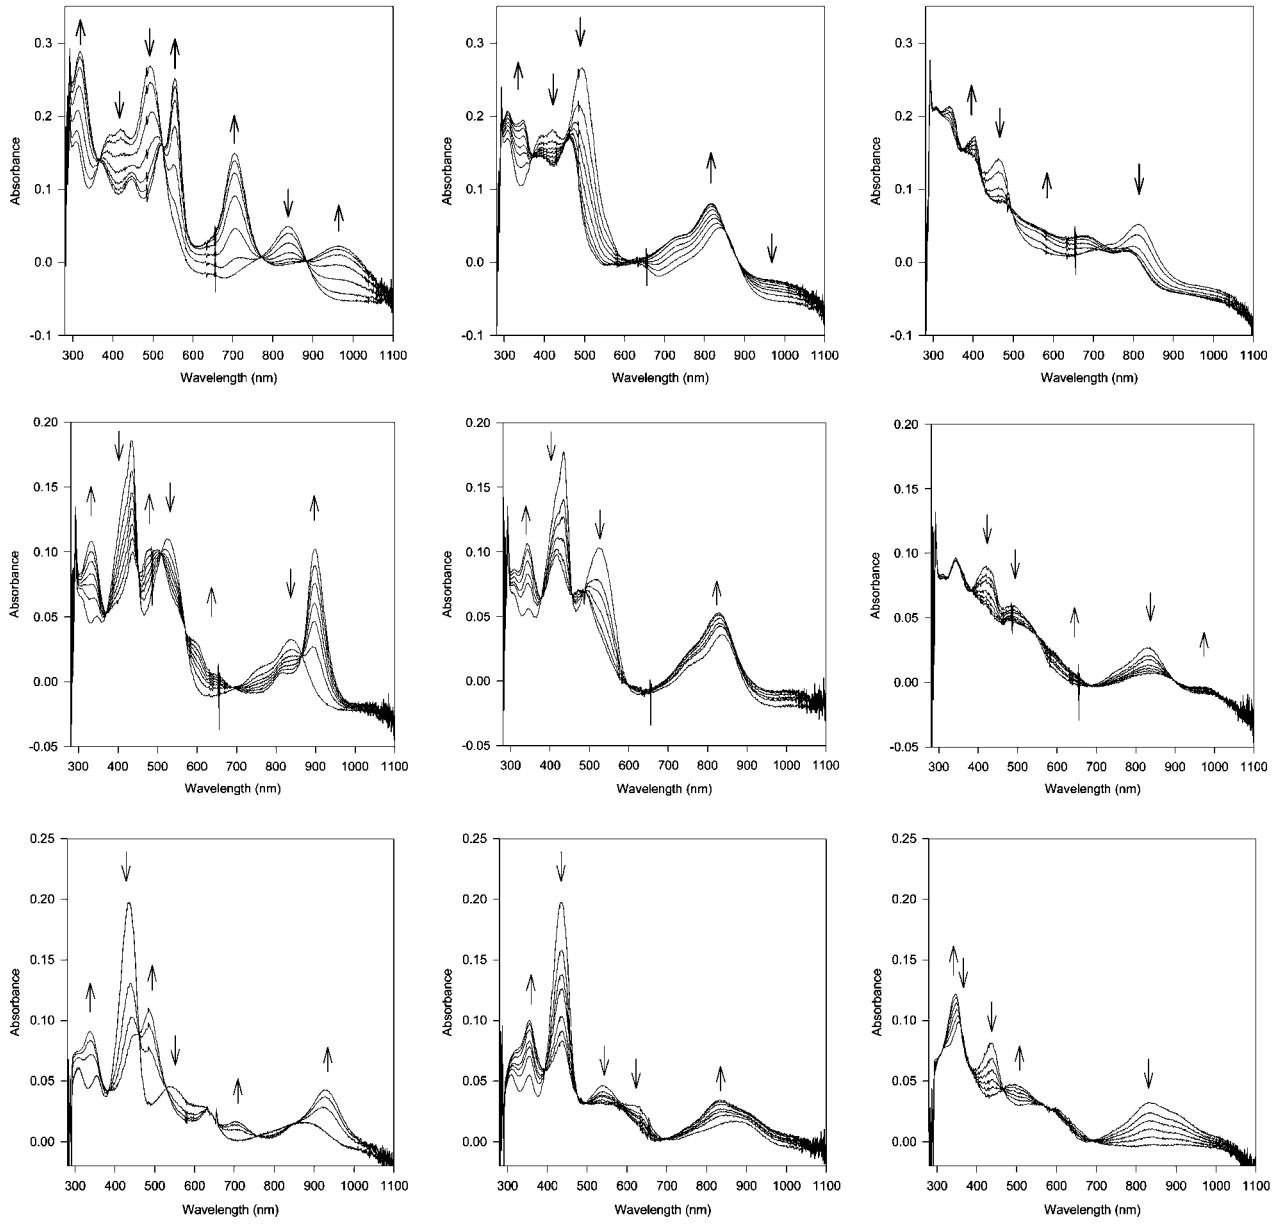

Figure 6. Time-resolved UV/Vis spectroelectrochemical measurements of 2,2′-bidipyrrinato complexes **7** (first row), **9** (second row), and **11** (third row) in PhCN with 0.1 M Bu_4NPF_6; first column: Red. 1, second column Ox. 1, third column Ox. 2

d-electron of the metal centre.[25] The EPR spectroscopic investigation of the reduction of **6** (X-band at 9.76 GHz, room temperature) gave the spectra depicted in Figure 7. Complex **6** shows an EPR spectrum similar to that of a related (porphyrinato)copper(II) complex,[26] with a g_0 value of 2.092 and a Cu hyperfine splitting of 82.6 G. The expected splitting of the signals by the nitrogen donors was not resolved. After chemical reduction, the signal for the Cu^{II} ion was still present and found shifted to $g_0 = 2.073$ with an enlarged splitting of 104.6 G. For $\mathbf{6}^{-\cdot}$ the hyperfine splitting by the nitrogen atoms is well resolved (line distance 16.6 G), and the theoretically possible nine lines (assuming, that all four nitrogen atoms are equivalent) can be found in two overlapping sets. The signal for the π-radical, however, is broad and heavily obscured by the signals of the single 3d-electron. The *g* value for this electron of ca. 2.00 is close to that of a free electron, which is expected for a porphyrinoid π-radical.[27]

Conclusion

(2,2′-Bidipyrrinato)copper(II) and -palladium(II) complexes belong to the same structural type as the respective nickel(II) complexes. The porphyrinoid M_1L_1 coordination mode generally leads to a helical distortion of the ligand scaffold, which is stable to helix inversion in all cases studied. The open-chain tetrapyrrolic ligand, however, is sufficiently flexible to accommodate different bonding situ-

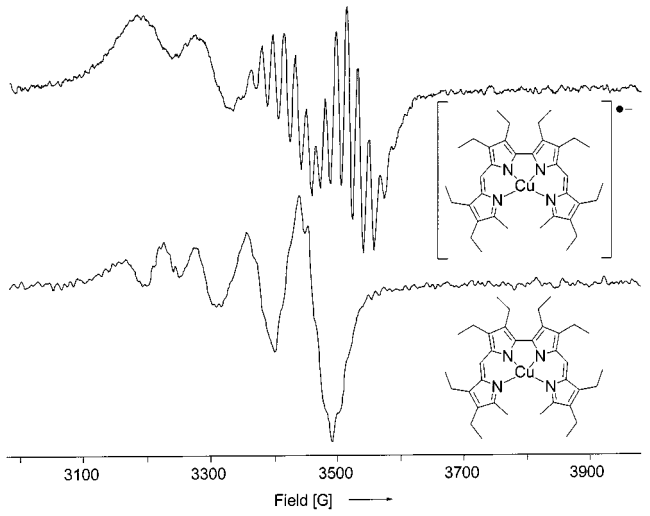

Figure 7. Solution EPR spectra of **6** and $\mathbf{6}^{-\cdot}$ in THF at X-band (9.76 GHz)

ations for metal ions with square-planar or distorted tetrahedral coordination preferences. Electrochemically, 2,2′-bidipyrrinato complexes are enormously robust, so that even spectroelectrochemical analyses of electrogenerated oxidised and reduced species could be performed. The electrochemical behaviour of these complexes is strongly dependent on structural parameters, which almost always superimpose the electronic effects typical for the electrochemistry of metalloporphyrins.

Experimental Section

General: All reagents and solvents were purchased from commercial sources and used as received. NMR spectra were obtained in $CDCl_3$ solution with a Bruker AC 200 spectrometer. Chemical shifts (δ) are given in ppm relative to residual protio solvent resonances (^1H spectra) or to chloroform (^{13}C). Mass spectra (EI, 70 eV or FAB) were recorded with a Finnigan 90 MAT instrument; *m*/*z* values are given for the most abundant isotopes only. Melting points were measured by DTA with a Thermoanalyzer DuPont 9000. Elemental analyses (C, H, N) were effected at the microanalytical laboratory of the Institut für Anorganische Chemie, Universität Würzburg. Solution EPR spectra were measured in THF at ambient temperature with a Bruker ESP 300 spectrometer at X-band (9.76 GHz). Chiral HPLC was performed with a Pirkle-type column (D-phenylglycine on spherical silica gel; 25 cm × 4.6 mm, 5 μ particle size), using a Latek P402 chromatographic system and 2% acetone in *n*-hexane as the eluent. The fractions were detected by single point UV absorption at 400 nm. Electrochemical studies were carried out in benzonitrile containing nBu$_4$NPF$_6$ as supporting electrolyte (0.1 M). Benzonitrile (Aldrich) was dried with anhydrous $CaCl_2$ for 2 d, and further distilled from P_2O_5 under a reduced pressure of argon. nBu$_4$NPF$_6$ (Fluka, electrochemical grade) was dried under vacuum at 65 °C. Before use, the 0.1 M solution of nBu$_4$NPF$_6$ in benzonitrile was purified in a glove box on activated neutral alumina (Merck). The measurements were carried out in the glove box using a classical three-electrode cell. The working electrode was a platinum disk (2 mm in diameter), the pseudo reference electrode and the counter electrode being platinum wires. All potentials are given against the ferrocene/ferrocenium couple used as internal standard. The cell was connected to an EG&G PAR potentiostat (Model 273) interfaced with a computer (type PC). The studies were carried out by cyclic voltammetry (CV), at sweep rates ranging from 0.02 to 5 V/s, and by steady state voltammetry (SSV), on a platinum rotating disk electrode. Spectroelectrochemical measurements were performed in an air-tight closed quartz cell (1 mm) through an optically transparent thin-layer electrode (OTTLE) made of a Pt mini-grid (1000 mesh). The auxiliary electrode and the pseudo-reference electrode were Pt wires placed in separate compartments. The cell was filled with the electrolyte and the species to be studied, and hermetically closed in the glove-box. The cell was then removed from the glove-box and placed in a Hewlett Packard diode-array UV/Vis spectrometer model 8453. The OTTLE cell was connected to a Bruker potentiostat (model EI30M) for control and measurement of the electrochemical parameters.

Preparation of Complexes

(2,2′-Bisdipyrrinato)copper Complexes 6 and 7. − General Procedure: 2,2′-Bidipyrrin **4** or **5** (0.1 mmol) in 30 mL of dichloromethane was treated with a solution of copper(II) acetate hydrate (399 mg, 2 mmol) in 30 mL of methanol, and the resulting solution was stirred for 30 min (colour change from deep blue to brownish-orange). The reaction mixture was extracted four times with 100 mL of water, dried with sodium sulfate, and the solvent removed in vacuo. Recrystallization from dichloromethane/methanol yielded the title compounds as dark green, shiny crystals.

(3,3′,4,4′,8,8′,9,9′-Octaethyl-10,10′-dimethyl-2,2′-bidipyrrinato)copper (6): Yield 48.6 mg (81%); m.p. 192 °C (decomp.). MS (70 eV, EI): m/z = 599 [M^+]. $C_{36}H_{48}CuN_4$ (600.34): C 72.02, H 8.06, N 9.33; found C 71.88, H 8.04, N 9.20.

Crystallographic Data for 6: $C_{36}H_{48}CuN_4$, green plates obtained by slow concentration of a CH_2Cl_2/*n*-hexane solution, crystal size: 0.40 × 0.40 × 0.20 mm, monoclinic, space group $P2_1/c$, a = 12.580(3), b = 20.030(4), c = 13.316(3) Å, β = 108.721(4)°, V = 3177.8(11) Å^3, $\rho_{calcd.}$ = 1.255 g cm^{-3}, Z = 4, $2\theta_{max}$ = 50°, Mo-K_α radiation, λ = 0.71073 Å, scan mode: ω-scans, T = 173(2) K, 44776 measured, 5576 independent reflections, 5019 reflections observed for $I > 2\sigma(I)$, μ = 0.718 mm^{-1}, solved by Patterson method (SHELXS-97: G. Sheldrick, University of Göttingen), refined with full-matrix least squares on F^2 (SHELXL-97: G. Sheldrick, University of Göttingen), 380 parameters, H atoms refined with isotropic temperature factors. R = 0.0379, wR = 0.0964, residual electron density ρ = 0.438/−0.207 e Å^{-3}. CCDC-170387 (**6**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

(3,3′,4,4′,8,8′,9,9′-Octaethyl-10,10′-dimethyl-6,6′-diphenyl-2,2′-bidipyrrinato)copper (7): Yield 58.7 mg (78%); m.p. 249 °C (decomp.). MS (70 eV, EI): m/z = 751 [M^+]. $C_{48}H_{56}CuN_4$ (752.54): C 76.61, H 7.50, N 7.45; found C 76.28, H 7.29, N 7.19.

(2,2′-Bisdipyrrinato)palladium Complexes 8 and 9. − General Procedure: 2,2′-Bidipyrrin **4** or **5** (0.1 mmol) in 30 mL of dichloromethane was treated with a solution of palladium(II) acetate (80 mg, 0.4 mmol) in 30 mL of methanol, and the resulting solution was stirred for 30 min (colour change from deep blue to deep red). The reaction mixture was extracted with 100 mL of water, dried with sodium sulfate, and the solvent removed in vacuo. Chromato-

graphic filtration with dichloromethane on silica gave the product as a red, major band. Recrystallization from dichloromethane/methanol yielded the title compounds as green, shiny crystals.

(3,3′,4,4′,8,8′,9,9′-Octaethyl-10,10′-dimethyl-2,2′-bidipyrrinato)-palladium (8): Yield 59.2 mg (92%); m.p. 212 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.90 (t, 6 H, ^3J = 7.5 Hz, 2×CH_3), 1.03 (t, 6 H, ^3J = 7.5 Hz, 2×CH_3), 1.06 (t, 6 H, ^3J = 7.5 Hz, 2×CH_3), 1.08 (t, 6 H, ^3J = 7.5 Hz, 2×CH_3), 2.11 (q, ^3J = 7.5 Hz, 4 H, 2×CH_2CH$_3$), 2.31−2.39 (m, 12 H, 6×CH_2CH$_3$), 2.59 (s, 6 H, terminal CH_3), 6.18 (s, 2 H, H_{meso}). ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 14.3, 16.7, 16.8, 17.2, 17.3, 17.6, 17.7, 18.1, 18.4, 120.1, 128.1, 130.9, 131.6, 136.1, 138.5, 148.0, 150.1, 165.8. Chelate Complexes of Functionalized Cycloheptatrienyl Ligands: 17- and 18-Electron Molybdenum Complexes with Linked Cycloheptatrienyl−Phosphane Ligands and Their Use in Transition Metal Catalysis

Matthias Tamm,*[a] Kim Baum,[a] Thomas Lügger,[a] Roland Fröhlich,[b] and Klaus Bergander[b]

Keywords: Cycloheptatrienyl complexes / Molybdenum / Ligand functionalization / Ring-opening polymerization / Metathesis

The synthesis of *P*-functionalized molybdenum chelate complexes incorporating the linked cycloheptatrienyl–phosphane ligand [2-(diphenylphosphanyl)phenyl]cycloheptatrienyl, *o*-$Ph_2P–C_6H_4–C_7H_6$, is described. The air-stable ligand precursor [2-(cyclohepta-2,4,6-trienyl)phenyl]diphenylphosphane (**2**) can be obtained in large quantities by addition of lithiated 2-$BrC_6H_4PPh_2$ (**1**) to the tropylium cation $C_7H_7^+$. Hydride abstraction employing the trityl cation, Ph_3C^+, results in the formation of the tricyclic phosphonium salt **3**. The *P*-functionalized cycloheptatriene **2** acts as an eight-electron ligand on reaction with $Mo(CO)_6$ to afford the cycloheptatriene–phosphane complex [(*o*-$Ph_2PC_6H_4$-η^6-C_7H_7)$Mo(CO)_2$(*P–Mo*)] (**4**) as a single, chiral regioisomer, which undergoes clean hydride abstraction on treatment with $(Ph_3C)BF_4$. The resulting cationic cycloheptatrienyl–phosphane complex **5** reacts with sodium bromide to yield the uncharged "chiral-at-metal" complex [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CO)Br(*P–Mo*)] (**6**). This 18-electron complex can be oxidized with 0.5 equiv. of Br_2 to give the paramagnetic dibromo complex **7**, which is a versatile starting material for the preparation of the 17-electron mono- and dialkyl complexes [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)$Mo(CH_2SiMe_3)$X(*P–Mo*)] (X = Br, **8**; X = CH_2SiMe_3, **9**). In combination with Me_3SiCH_2MgCl, complexes **7** and **9** prove to be active catalysts for the ring-opening metathesis polymerization of norbornene. In addition, the X-ray crystal structures of **2**, **4**, **5**·CH_2Cl_2, **7**·$CHCl_3$, **8**, and **9**·C_6H_{14} are reported.

Introduction

η-Cyclopentadienyl complexes, (η-C_5R_5)M, as well as η-arene complexes, (η-C_6R_6)M, are among the most important classes of compounds in organotransition metal chemistry.[1] In particular, the widespread use of cyclopentadienes as organometallic ligands is due to the large number of ring-substituted derivatives, which have been synthesized since the serendipitous synthesis and discovery of ferrocene. Successive replacement of hydrogen atoms by alkyl or aryl substituents alters the steric and electronic properties of the Cp ring and gives rise to increased steric bulk, solubility and stability of the resulting complexes.[2] Numerous routes to ring-substituted Cp derivatives are known to date, and stable cyclopentadienyl complexes of almost any element have been synthesized. It has recently been estimated that about 80% of all organometallic compounds of the transition metals are cyclopentadienyl complexes.[2a] Consequently, cyclopentadienyl complexes are now ubiquitous and indispensable in research areas such as homogeneous catalysis,[3] organic synthesis[4] and materials science.[5] In contrast, η-cycloheptatrienyl transition metal complexes, (η-C_7R_7)M, have been much less thoroughly studied, and with a few exceptions, the use of cycloheptatrienyl ligands had been confined to the parent C_7H_7 system.[6] Only recently have we been able to report on the syntheses and properties of the first heptamethylcycloheptatrienyl (CHT*) complexes[7] and of complexes derived from sterically demanding tropylium salts of the type (1,3,5-$C_7H_4R_3$)BF_4 (R = *tert*-butyl, $SiMe_3$).[8]

Another concept, which has been extremely successful, in particular in cyclopentadienyl chemistry, is ligand functionalization, whereby an additional coordinating site is linked to the periphery of the five-membered ring via a suitable bridging moiety. This prospering area has produced a large number of novel cyclopentadienyl ligands bearing pendant *N*-,[9,10] *O*-,[11] *P*-, *As*-, and *S*-donor groups.[12] If properly designed, these ligands can coordinate to a transition metal center in a chelating η^5:η^1-fashion, and several of these complexes have played a key role in homogeneous catalysis as so-called constraint-geometry catalyst sys-

tems.[3] In cycloheptatrienyl transition metal chemistry on the other hand, ligand functionalization is an almost unknown concept, and we have recently started to apply this concept to the preparation of cycloheptatrienyl complexes bearing pendant phenolate,[13] amine, and phosphane donor groups (Figure 1). The reasons for our interest in the development of such ligand systems are twofold. Firstly, donor-functionalization can in general lead to the formation of chelate complexes of significantly enhanced stability, which can allow the preparation and isolation of complexes of previously unknown structural types and reactivities. For instance, since the coordination of the cycloheptatrienyl ring to a transition metal center is often much more difficult than the introduction of a cyclopentadienyl group, the donor group can serve as a *Trojan horse*, which binds to a metal ion first followed by the formation of the metal−carbon bonds. Secondly, some of the donor groups might only coordinate in a labile fashion or could be converted into hemilabile groups, which offers the possibility of reversibly providing free coordination sites for other molecules or substrates.

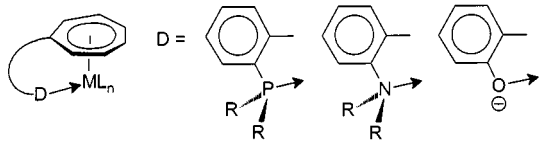

Figure 1. Cycloheptatrienyl complexes bearing pendant *P*-, *N*-, and *O*-donors

To the best of our knowledge, no complexes with donor-functionalized cycloheptatrienyl ligands coordinating in a chelating η^7:η^1-fashion have been reported prior to our work,[13] whereas a few examples are known, in which the functional group is directly attached to the seven-membered ring allowing the cycloheptatrienyl ligand to only bridge two different metal centers.[14−16] For instance, lithiation of [(η-C_7H_7)Ti(η-C_5H_5)] with *n*BuLi occurs preferentially at the seven-membered ring,[14] and the consecutive reaction with chlorodiphenylphosphane allows the selective functionalization of the cycloheptatrienyl ring to yield [(η^7-$C_7H_6PPh_2$)Ti(η-C_5H_5)], which has been used as a monodentate phosphane ligand forming bimetallic complexes.[15] Dimetalation of [(η-C_7H_7)Ti(η-C_5H_5)] can also be achieved, and the reaction with $ClPR_2$ (R = Me, Ph) produces [(η^7-$C_7H_6PR_2$)Ti(η^5-$C_5H_4PR_2$)], which can react with various carbonylmetal complexes to produce a series of complexes with the bifunctionalized sandwich unit acting as a chelating or bridging diphosphane ligand.[16] In this respect, bimetallic sesquifulvalene derivatives can also be regarded as complexes containing cyclopentadienyl-functionalized cycloheptatrienyl ligands, and various complexes have been reported, in which the five- and seven-membered rings are coordinated in a bridging μ-η^7:η^5-mode.[17,18]

With this contribution, we introduce, for the first time, phosphorus-functionalized cycloheptatrienyl ligands, which are capable of binding the metal center in a chelating η^7:η^1-fashion (Figure 1), and we wish to report on the syntheses of a series of molybdenum complexes of the type [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)$MoLL'(P-Mo)$] containing a cycloheptatrienyl ligand with a linked 2-(diphenylphosphanyl)-phenyl substituent. The *ortho*-phenylene moiety had been chosen as the bridging unit between the seven-membered ring and the *P*-donor group, as it will lead to the formation of complexes with a very rigid, C_s-symmetric ligand backbone and will additionally allow the alteration of their steric and electronic properties by modification of the aryl fragment. Furthermore, the synthesis and use of 17-electron complexes of the type [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)-$MoX_2(P-Mo)$] (X = Br, CH_2SiMe_3) for the ring-opening metathesis polymerization of norbornene will be described, which is among the first reports on the application of cycloheptatrienyl complexes to homogeneous transition metal catalysis.

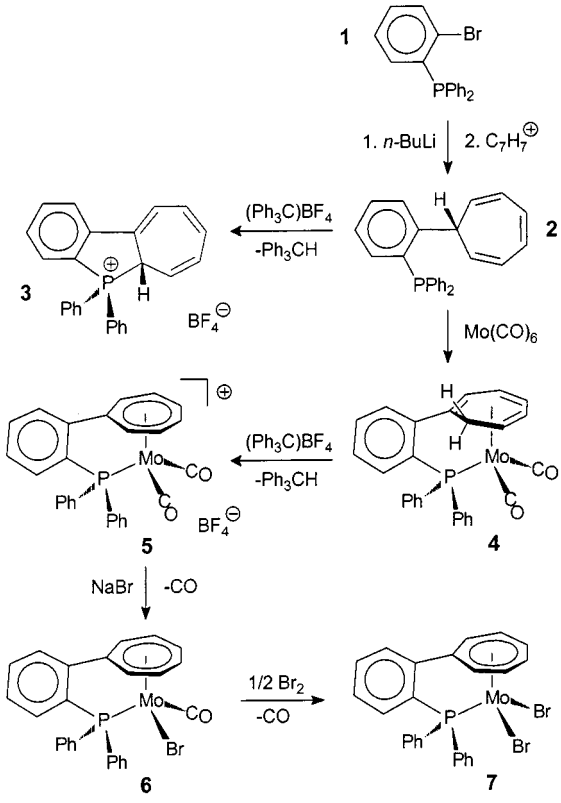
Results and Discussion

Ligand Synthesis

Although a large number of phosphorus-functionalized cyclopentadienyl systems are known,[12] we are only aware of a few related cyclopentadienyl complexes, in which the phosphane group is attached to the five-membered ring via a bridging *ortho*-phenylene moiety.[19−21] For instance, Trost and co-workers have obtained the ligand precursor [2-(diphenylphosphanyl)phenyl]cyclopentadiene by the reaction of (2-bromophenyl)diphenylphosphane (**1**) with 1 equiv. of *n*-butyllithium followed by addition of 2-cyclopentenone.[19] Similarly, one should be able to obtain the related cycloheptatriene−phosphane ligand precursor **2** (Scheme 1) by addition of 2-(diphenylphosphanyl)phenyllithium[22] to the tropylium cation $C_7H_7^+$.[23] In fact, careful monolithiation of 1,2-dibromobenzene and reaction with $ClPPh_2$ led to 2-$BrC_6H_4PPh_2$ (**1**),[22,24] which was successively treated with *n*BuLi and (C_7H_7)BF_4 to afford the air-stable ligand precursor [2-(cyclohepta-2,4,6-trienyl)phenyl]diphenylphosphane (**2**) in large quantities.

The ^{31}P NMR spectrum of **2** exhibits one single resonance at δ = −15.9, which is about 10 ppm up-field from the resonance observed for triphenylphosphane under identical conditions.[25] The molecular structure of **2** could be established by X-ray diffraction (Figure 2, top) confirming the *ortho* linkage between the phosphorus atom and the cycloheptatriene moiety, which bears the PPh_2 residue in the allylic 1-position. As anticipated,[26] the seven-membered ring adopts a boat conformation, and all bond lengths and angles fall in the expected ranges.

As we have recently developed a method for the quantitative complexation of tropylium salts by an arene exchange reaction employing [(η-*p*-xylene)$Mo(CO)_3$],[8,18a] we sought for the synthesis of a phosphanyl-functionalized tropylium salt by hydride abstraction using triphenylcarbenium tetrafluoroborate, (Ph_3C)BF_4. The direct reaction of **2** with (Ph_3C)BF_4, however, did not result in a clean reaction, presumably due to steric hindrance at the allylic position of the seven-membered ring created by the 2-(diphenylphos-



Scheme 1

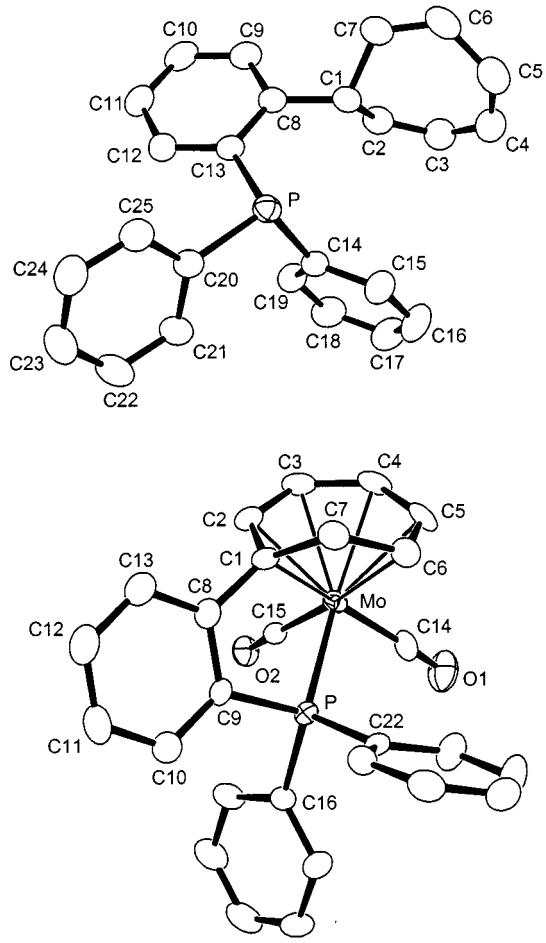


Figure 2. ORTEP drawings of **2** (top) and **4** (bottom) with thermal ellipsoids drawn at 50% probability

phanyl)phenyl substituent. Therefore, **2** was heated in DMF at 150 °C to undergo a thermal rearrangement through consecutive 1,5-sigmatropic hydrogen migrations.[18b,27] The resulting isomeric mixture was treated with $(Ph_3C)BF_4$ to afford Ph_3CH and a colorless tetrafluoroborate salt, which turned out to be the tricylic phosphonium salt **3**, formed by intramolecular nucleophilic attack of the tethered phosphane group at the seven-membered ring in the intermediate [2-(diphenylphosphanyl)phenyl]cycloheptatrienylium tetrafluoroborate (Scheme 1). A similar ring-closure has been observed for a linked cycloheptatrienyl−phenolate system.[13] As expected for asymmetric **3**, the ^1H NMR spectrum exhibits six different resonances for the allylic and vinylic cycloheptatrienyl protons, and the ^{31}P NMR spectrum displays a resonance at $\delta = 43.8$ indicative of a deshielded phosphonium center.[25]

Synthesis of 18-Electron Cycloheptatrienyl−Phosphane Complexes

Attempts to use **3** for the direct synthesis of the linked cycloheptatrienyl−phosphane complex **5** were unsuccessful, and the reaction with various $Mo(CO)_3$ transfer reagents such as $[(CH_3CN)_3Mo(CO)_3]$ or $[(\eta\text{-}p\text{-xylene})Mo(CO)_3]$ did not result in ring-opening of the phosphonium salt and insertion of the molybdenum complex fragment into the P−CH bond. More conveniently, the cycloheptatriene−phosphane ligand can be used as a multidentate ligand, and the reaction with $Mo(CO)_6$ in refluxing methylcyclohexane leads to the substitution of four carbonyl groups and the formation of cycloheptatriene−phosphane complexes of the type $[(o\text{-}Ph_2PC_6H_4\text{-}\eta^6\text{-}C_7H_7)Mo(CO)_2(P\text{−}Mo)]$. In comparison to the reaction of cycloheptatriene, C_7H_8, with $Mo(CO)_6$, the reaction described here proceeds much faster and no sublimation of hexacarbonylmolybdenum out of the flask into the reflux condenser was observed indicating that the phosphane group adds rapidly to the molybdenum center to form an involatile material followed by coordination of the cycloheptatriene moiety. If the reaction mixture is kept at 100 °C overnight, complex **4** crystallizes from the solution, upon cooling with dry ice, as the only detectable regioisomer (Scheme 1). The formation of **4** must have resulted from thermal rearrangement of the coordinated cycloheptatriene ring involving, in principle, two consecutive 1,5-hydrogen shifts.[28] In its ^1H NMR spectrum **4** exhibits five resonances due to the vinylic protons and two resonances due to the allylic *exo* and *endo* protons (Figure 3). The ^{31}P NMR resonance is observed at $\delta = 64.5$ revealing that the phosphorous atom is coordinated to the metal center. As **4** is obtained as a racemic mixture of two enantiomers, two different sets of resonances are observed for the diastereotopic phenyl groups in the ^{13}C NMR spectrum. Accordingly, two doublets are found for the ^{13}CO

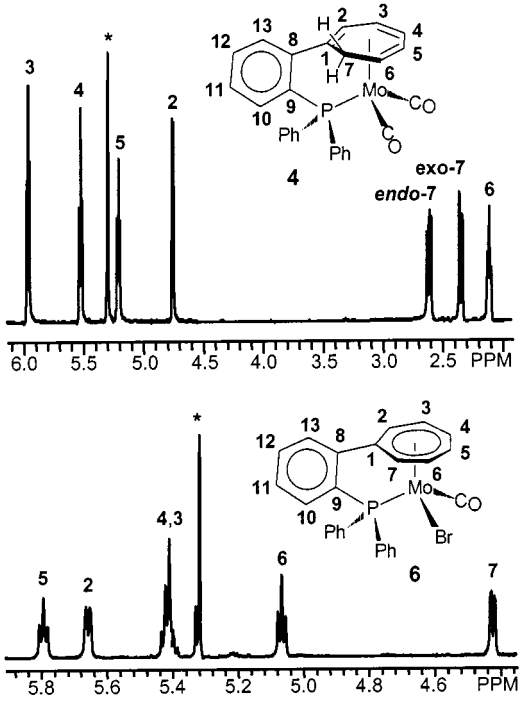

Figure 3. Selected parts of the ^{1}H NMR spectra (600 MHz, CD_2Cl_2) of **4** (top) and **6** (bottom)

carbonyl resonances at δ = 227.2 ($^2J_{C,P}$ = 10 Hz) and 223.9 ($^2J_{C,P}$ = 12 Hz), respectively.

In order to confirm the spectroscopic results, the molecular structure of **4** was established by X-ray diffraction analysis, and Figure 2 (bottom) shows an ORTEP diagram of one enantiomer. The 2-(diphenylphosphanyl)phenyl substituent is indeed attached to the vinylic carbon atom C1, which is next to the CH_2 group, and the cycloheptatriene−phosphane ligand binds to the metal center in a chelating η^6:η^1 fashion. If compared to the molecular structures of related (cycloheptatriene)molybdenum complexes, e.g. [(η^6-C_7H_8)Mo(CO)$_3$][29] and [(η^6-C_7H_8)Mo(CRR′)(CO)$_2$] (R = OEt, R′ = *o*-tolyl),[30] the bond lengths and angles within the seven-membered ring fall in the expected ranges (Table 1). The distances between the molybdenum atom and the cycloheptatriene carbon atoms, however, differ significantly with the shortest bond to C3 [2.296(3) Å] and the longest bond to C6 [2.468(3) Å], which is probably due to the asymmetry of the linked cycloheptatriene−phosphane ligand as well as the mixed set of co-ligands (one phosphane and two carbonyl ligands) about the molybdenum center.[30]

In **4** the *exo* hydrogen atom is accessible to the trityl cation for hydride abstraction, and the cycloheptatrienyl−phosphane complex [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CO)$_2$(*P*−*Mo*)]BF_4 (**5**) is formed almost quantitatively upon treatment with $(Ph_3C)BF_4$ (Scheme 1). With removal of the hydrogen atom from the CH_2 group, **5** becomes C_s-symmetric and exhibits three cycloheptatrienyl resonances in its ^{1}H NMR spectrum at δ = 6.06, 6.00, and 5.59 in a 2:2:2 ratio. Accordingly, the ^{13}C NMR spectrum displays four resonances for the C_7H_6 carbon atoms together with ten resonances for the phenyl and phenylene carbon atoms. The ^{13}CO resonance for the magnetically equivalent carbonyl groups is observed as a doublet at δ = 212.7 ($^2J_{P,C}$ = 25 Hz), and the ^{31}P resonance at 59.9 is slightly shifted to higher field in comparison with **4**. To unambiguously confirm the formation of the first cycloheptarienyl−phosphane chelate complex, a single-crystal of **5**·CH_2Cl_2 was subjected to X-ray diffraction analysis, and the molecular structure of the cation in **5** is depicted in Figure 4 (top). One recognizes that the ligand does indeed act as a chelate ligand in an η^7:η^1 fashion with almost perfectly perpendicularly oriented six- and seven-membered rings (interplanar angle of 85.8°). The molybdenum atom is symmetrically η^7-coordinated with the shortest bond to C1 [2.262(2) Å] and the longest bond to C6 [2.323(2) Å] (Table 1). On average, these distances are similar to those found for [(η-C_7H_7)Mo(CO)$_3$]BF_4 (mean 2.31 Å),[31] [(η-C_7H_7)Mo(CO)$_2$X] (X = Cl, mean 2.31 Å; X = Br, mean = 2.32 Å)[32] and [(η-C_7H_7)Mo(CO)$_2$(C_6F_5)] (mean = 2.32 Å).[33] No significant deviation from planarity can be observed for the seven-membered ring in **5**, and the mean and maximum deviations from the least-squares plane (C1−C7) are 0.028 and −0.058 Å (for C1), respectively. In order to allow chelate formation, the six-membered ring bends slightly down towards the metal center, and the angle between the centroid of the seven-membered ring, C1 and C8 deviates by 10.3° from a perfectly linear orientation. On the other hand, this out-of-plane displacement observed for C8 could also be attributed to a reorientation of the large seven-membered ring favoring a better metal overlap (vide infra). In addition, the phenylene bridge also leads to a somewhat distorted tetrahedral environment about the phosphorous atom with the angle Mo−P−C13 [105.95(8)°] being smaller than the adjacent angles Mo−P−C16 [116.53(7)°] and Mo−P−C22 [119.12(7)°].

It has previously been demonstrated that monophosphane complexes of the type [(η-C_7H_7)M(CO)X(PR_3)] (M = Mo, W; X = halide) allow the introduction of various nucleophiles by halide substitution reactions and are suitable precursors for studying organometallic transformations supported by the (cycloheptatrienyl)molybdenum and -tungsten fragments.[34] Therefore, **5** was treated with an excess of NaBr in THF at elevated temperature leading to the direct, high-yield formation of [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CO)Br(*P*−*Mo*)] (**6**). Due to chelation by the linked cycloheptatrienyl−phosphane ligand, complex **6** seems to be significantly more stable than related unbridged phosphane halide complexes, and chromatographic purification is possible under ambient conditions using alumina (4% H_2O). In **6**, the pseudotetrahedrally coordinated molybdenum center has four different ligands, and the complex is thus obtained as a racemic mixture of two enantiomers. Since this new representative of so-called "chiral-at-metal" half-sandwich compounds[35,36] is configurationally stable, the diastereotopic cycloheptatrienyl hydrogen atoms give rise to six different ^{1}H NMR resonances. This portion of

the 600-MHz NMR spectrum is shown in Figure 3. Accordingly, seven ^{13}C NMR resonances are observed for the C_7H_6 carbon atoms together with six resonances for the phenylene bridge and eight resonances for the diastereotopic phenyl groups. The assignment of all ^1H and ^{13}C NMR resonances in **6** is supported by two-dimensional NMR spectroscopy (COSY and NOE experiments). The ^{13}CO carbonyl resonance in **6** is observed as a doublet at $\delta = 232.3$ ($^2J_{C,P} = 15.6$ Hz), and one single ^{31}P NMR resonance is found at $\delta = 49.1$. As expected, the IR spectrum of **6** exhibits one CO absorption at 1946 cm^{-1}, which is in good agreement with the stretching frequency of 1944 cm^{-1} reported for the closely related, unbridged analogue [(η-C_7H_7)Mo(CO)Br(PPh_3)].[34a] Single crystals of **6**·$CHCl_3$ could be obtained by recrystallization from a $CHCl_3$ solution allowing the molecular structure of **6** to be established by X-ray crystal structure determination.[37]

Synthesis of 17-Electron Cycloheptatrienyl−Phosphane Complexes

Ng et al. have recently reported on the ring-opening metathesis polymerization of norbornene promoted by (η-cycloheptatrienyl)molybdenum and -tungsten complexes of the type [(η-C_7H_7)MLI_2] (M = Mo, W; L = CH_3CN, PPh_3).[38] This is one of the first reports on the application of cycloheptatrienyl complexes to homogeneous transition metal catalysis.[6] Activated by Me_3SiCH_2MgCl, these 17-electron complexes give high molecular weight poly(1,3-cyclopentylenevinylene). The synthesis of such complexes has been developed by Green and co-workers, during the last decade, employing the sandwich compound [(η-C_7H_7)M(η^5-C_7H_9)] (M = Mo, W), which can be obtained in a one-pot reaction from cycloheptatriene, sodium amalgam and $MoCl_5$ or WCl_6, respectively. Treatment of these complexes with chlorine, bromine or iodine in the presence of Lewis bases provides a convenient route to half-sandwich derivatives such as [(η-C_7H_7)MLX_2] (M = Mo, W; L = CH_3CN, THF, PPh_3, PMe_3; X = Cl, Br, I).[39,40] Moreover, the magnetic properties of several of these paramagnetic compounds have been studied in detail.[41]

Herein, we present a new route to analogous 17-electron complexes containing linked cycloheptatrienyl−phosphane ligands. If [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CO)Br(*P−Mo*)] (**6**) is treated with 0.5 equiv. of bromine in CH_2Cl_2 a rapid color change from green to brown-red is observed together with the evolution of gas. After stirring for 1 h at ambient temperature, paramagnetic [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)-$MoBr_2$(*P−Mo*)] (**7**) can be isolated as an air-stable brown dichloromethane adduct after precipitation with hexane (Scheme 1). The formation of **7** is obtained by oxidation of **6** with 0.5 equiv. of bromine to give the labile odd-electron intermediate [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CO)Br(*P−Mo*)]-

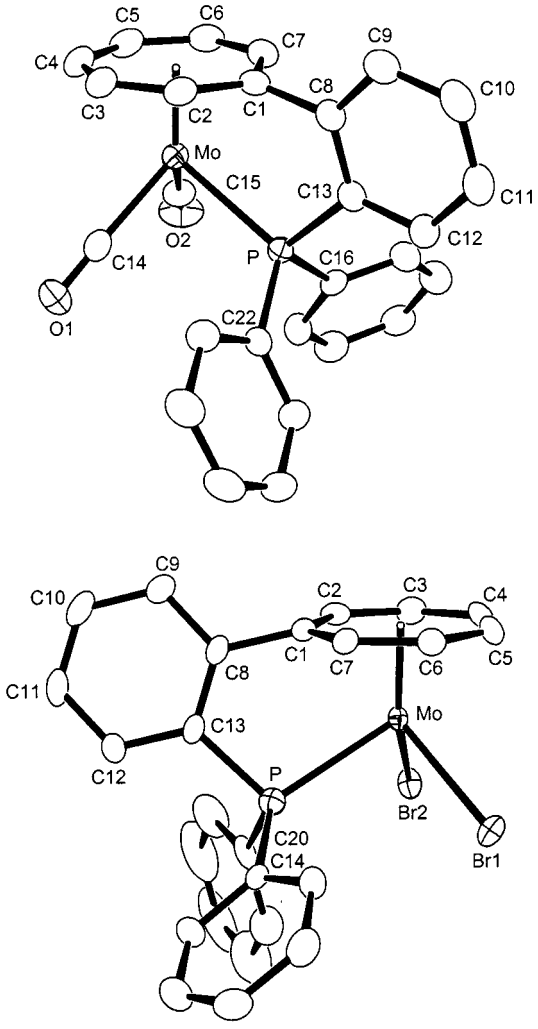

Figure 4. ORTEP drawings of the cation in **5**·CH_2Cl_2 (top) and of **7** in **7**·CH_2Cl_2 (bottom) with thermal ellipsoids drawn at 50% probability

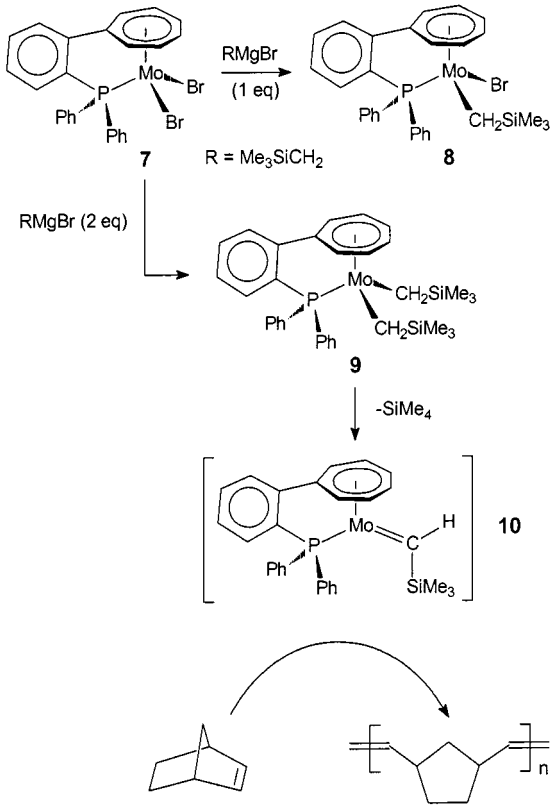
Br, which rapidly undergoes carbonyl substitution by bromide to give complex **7** in high yield. Due to the unpaired electron in **7**, the compound was only characterized by mass spectrometry and by ^{31}P NMR spectroscopy revealing a resonance at $\delta = 38.5$, and the purity was additionally checked by elemental analysis.

Recrystallization from chloroform afforded single crystals of **7**·$CHCl_3$, which were suitable for structure determination by X-ray diffraction. The molecular structure is shown in Figure 4 (bottom). The Mo−C distances range from 2.239(3) to 2.310(3) Å (mean 2.27 Å, Table 1), which are similar to those in the 17-electron complexes [(η-C_7H_7)Mo(CH_3CN)I_2] [2.258(5)−2.280(5), mean 2.27 Å][41] and [(η-C_7H_7)Mo(THF)I_2] [2.23(2)−2.29(2), mean 2.25 Å],[42] and they are, on average, shorter than the corresponding values observed in 18-electron complexes such as **5** [2.262(2)−2.323(2), mean 2.31 Å] (vide supra). In contrast, the Mo−P bond length of 2.5763(9) Å is significantly longer than that in **5** [2.4183(6) Å]. Again, the cycloheptatrienyl ring in **7** is almost perfectly planar, and the mean and maximum deviations from the least-squares plane (C1−C7) are 0.012 and −0.020 Å (for C2), respectively. The structural features of the ligand backbone are quite similar to those found for the molecular structure of **5**, with an interplanar angle between the least-squares planes containing C1−C7 and C8−C13 of 78.2° and an angle between the centroid of the seven-membered ring, C1 and C8 of 169.4°.

As indicated above, it has been observed that, on activation with Me_3SiCH_2MgCl, molybdenum complexes such as [(η-C_7H_7)MoLI_2] (M = Mo, W; L = CH_3CN, PPh_3) catalyze the ring-opening metathesis polymerization of norbornene. It was concluded that these reactions presumably involve the intermediate carbene complexes [(η-C_7H_7)Mo(=$CHSiMe_3$)L], which could have been generated by α-deprotonation of the initially formed dialkyl complexes [(η-C_7H_7)Mo(CH_2SiMe_3)$_2$L].[38] Although precedents for similar reaction sequences can be found in the literature,[43] the formation of 17-electron dialkyl(cycloheptatrienyl) complexes has not yet been confirmed. As the formation of metal−alkyl bonds is essential for most industrially important catalytic processes[3,4] and since cycloheptatrienyl complexes bearing alkyl ligands are generally a rare class of compounds,[6,44] we sought to isolate the first 17-electron alkyl(cycloheptatrienyl) complexes by the reaction of the dibromide [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)MoBr_2(*P*−*Mo*)] (**7**) with Me_3SiCH_2MgCl (1.0 M solution in diethyl ether). Treatment of **7** with 2 equiv. of the Grignard reagent resulted, after extraction with hexane, in a mixture of two compounds as indicated by the observation of two ^{31}P NMR resonances. Recrystallization from hexane afforded orange crystals of [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CH_2SiMe_3)Br(*P*−*Mo*)] (**8**), which contains only one trimethylsilylmethyl group, in moderate yield (Scheme 2). Transfer of the mother liquor to a chromatography column (SiO_2) and elution with diethyl ether/petroleum ether (1:1) led to the collection of an orange-yellow fraction, from which the dialkyl complex [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CH_2SiMe_3)$_2$(*P*−*Mo*)] could be isolated in low yield. Presumably, the introduction of the second alkyl substituent to form **9** is obstructed by steric hindrance produced by the first neosilyl (CH_2SiMe_3) group in **8**. In order to selectively prepare the monoalkyl derivative, the dibromide **7** can be treated with just 1 equiv. of the Grignard reagent to obtain **8** in about 60% yield. Complete dialkylation can be achieved by employing a large excess (about tenfold based on **7**) of the Grignard solution to afford excellent yields of the dialkyl complex **9**. The purity of the two paramagnetic compounds was only checked by elemental analysis and by ^{31}P NMR spectroscopy to reveal one resonance each at $\delta = 51.9$ for **8** and at $\delta = 54.6$ for **9**. Both compounds are air-stable and highly soluble in nonpolar solvents such as hexane or toluene as well as in THF and diethyl ether. As indicated above, **9** can even be purified by chromatography on silica without any significant loss of material by decomposition.

The molecular structures of both complexes could additionally be established by means of X-ray diffraction. **9** crystallizes with one molecule of hexane per formula unit,



Scheme 2

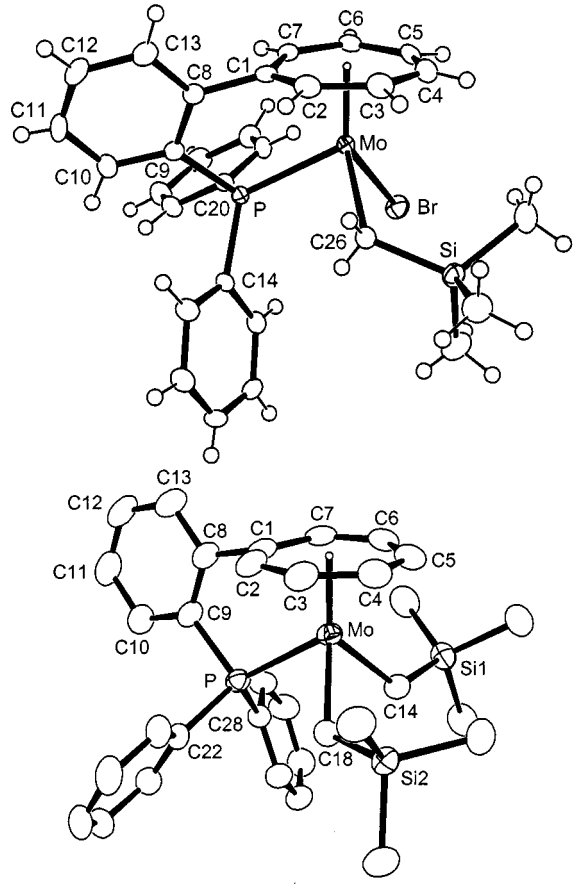


Figure 5. ORTEP drawings of the cation in **8** (top) and **9** in **9**·C_6H_{14} (bottom) with thermal ellipsoids drawn at 50% probability

and Figure 5 shows ORTEP presentations of **8** (top) and of **9** in **9**·C_6H_{14} (bottom). Successive substitution of the two bromine atoms in **7** by the sterically more demanding Me_3SiCH_2 group does not seem to have great consequences on the structural parameters of the cycloheptatrienyl−phosphane scaffold in **8** and **9**. Thus, the Mo−C distances range from 2.234(3) to 2.361(3) Å (mean 2.29 Å) in **8** and from 2.261(2) to 2.324(4) Å (mean 2.30 Å) in **9** and are only slightly elongated in comparison to those in **7** [2.239(3)−2.310(3) Å (mean 2.27 Å] (Table 1). In contrast, the Mo−P bond length slightly decreases on going from **7** [2.5763(9) Å] to **8** [2.5484(8) Å] and **9** [2.5427(7) Å]. The cycloheptatrienyl rings in **8** and **9** remain planar, and the mean and maximum deviations from the least-squares plane (C1−C7) together with the dihedral angle between the best planes containing C1−C7 and C8−C13 are summarized in Table 1. The metal-to-alkyl carbon distances observed for compounds **8** [2.211(3) Å] and **9** [2.225(2), 2.228(2) Å] are rather large but still comparable to those found in other alkylmolybdenum complexes, which lie in the range 2.08−2.20 Å.[45] The bond angles Mo−C−Si of 121.71(16)° in **8** and 124.62(13) and 129.34(12)° in **9** are significantly larger than expected for sp^3-hybridized carbon atoms, although similar bond angles have also been found in neosilylmolybdenum(VI) and -tungsten(VI) complexes.[43,45] It should be noted that the positions of all hydrogen atoms could be refined for **8**. Therefore, it is possible to establish the angles between the centroid of the cycloheptatrienyl ring, the C_7 carbon atoms and the adjacent hydrogen atoms revealing a significant out-of-plane displacement for the C_7 hydrogen atoms. The average bending is about 9° toward the molybdenum center, and such a deviation has been attributed to a reorientation of the large seven-membered ring for a better metal overlap.[6,46]

Ring-Opening Metathesis Polymerization (ROMP) of Norbornene

Homogeneous metathesis polymerization is dominated by well-defined alkylidene complexes of group-VI and group-VIII transition metals,[47,48] some of which have been neosilyl (M−CH_2SiMe_3) or neosilylidene complexes (M=$CHSiMe_3$), respectively.[43,45] Encouraged by the report on the ability of complexes of the type [(η-C_7H_7)MLI_2] (M = Mo, W; L = CH_3CN, PPh_3) to promote the ring-opening metathesis polymerization of norbornene,[38] we were prompted to test the ROMP activity of our 17-electron cycloheptatrienyl−phosphane complexes. Hence, the dibromo complex **7** was treated with 300 equiv. of norbornene in toluene. After addition of an excess amount of Me_3SiCH_2MgCl (6 equiv. of a 1.0 M solution in diethyl ether), the reaction mixture, which gradually became viscous, was heated for 12 h at 40 °C to ensure completion of the polymerization. The formed poly(1,3-cyclopentylenevinylene) was obtained as a colorless, fibrous material after

quenching with a few drops of benzaldehyde and dropwise addition of the hot solution to vigorously stirred methanol. Initial ^{13}C NMR and IR spectroscopic studies show in comparison with the literature data,[49,50] that about 80% of the double bonds in the polymer are in the *trans* configuration.

As we have demonstrated, that [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CH_2SiMe_3)$_2$(*P*−*Mo*)] (**9**) is actually formed by the reaction of Me_3SiCH_2MgCl with **7**, we anticipated that **9** might be an active single-source catalyst, from which the active species [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_7)Mo=$CHSiMe_3$-(*P*−*Mo*)] (**10**) could be generated by intramolecular α-deprotonation and elimination of Me_4Si (Scheme 2). The formation of this alkylidene complex would then allow the course of the metathesis polymerization to be described by the Chauvin mechanism.[51] Treatment of **9** with norbornene in different solvents at various temperatures, however, did not give detectable amounts of polymer. On the other hand, addition of 1 equiv. of Me_3SiCH_2MgCl to such a reaction mixture resulted in a rapid and quantitative formation of medium molecular weight polynorbornene (M_n = $2.6 \cdot 10^4$ g/mol, PDI = M_w/M_n = 6.7, approx. 80% *trans* double bonds). A standard procedure is described in the Exp. Sect. It should be noted, that we have ruled out the possibility of the Grignard reagent alone reacting as a ROMP catalyst by independent control experiments, and at this stage, the mechanism as well as the active catalyst in our system remains unclear. Further work will be directed toward the synthesis and isolation of paramagnetic alkylidene complexes such as **10**, which might then dimerize to form interesting bis(μ-alkylidene) species containing metal−metal bonds. Substitution of the neosilyl by other alkyl groups, e.g. by neopentyl groups, as well as modification of the residues of the R_2P donor moiety will allow fine tuning of the activity of this catalyst system and adjustment of the electronic and steric requirements of the resulting complexes according to future challenges.

Conclusion

With this contribution, chelate complexes of functionalized cycloheptatrienyl ligands bearing a pendant phosphane donor group have been reported for the first time, and we have presented a high-yielding protocol for the synthesis of a series of 17- and 18-electron molybdenum complexes containing linked cycloheptatrienyl−phosphane ligands. These complexes are archetypal for the new class of donor-functionalized cycloheptatrienyl complexes,[13] that will emerge from our laboratory in the near future. Although the preliminary results on the use of the 17-electron complexes presented herein as catalyst systems for olefin metathesis polymerization are by no means spectacular, these findings indicate that cycloheptatrienyl complexes can be potentially useful for applications in homogeneous transition metal catalysis. Hence, we are currently pursuing a general study on the utilization of these systems in various areas of application in view of our general objectives in order to extend the chemistry of cycloheptatrienyl complexes and to raise their level of significance in comparison with that of cyclopentadienyl and benzene complexes.

Experimental Section

General: All operations were performed in dry argon by using Schlenk and vacuum techniques. Solvents were dried by standard methods and distilled prior to use. (2-bromophenyl)diphenylphosphane (**1**),[24] tropylium tetrafluoroborate,[52] and triphenylcarbenium tetrafluoroborate,[53] were prepared according to published procedures. Elemental analyses (C, H, N) were performed with a Heraeus CHNO-Rapid elemental analyzer. EI and ESI mass spectra were recorded with a Varian MAT 212 or with a Micromass Quattro LCZ mass spectrometer, respectively. ^1H and ^{13}C NMR spectra were measured with Bruker AC 200, Bruker AMX 400 or Varian U 600 spectrometers using the solvent as internal standard, whereas ^{31}P NMR spectroscopic measurements were run with a Bruker AC 200 spectrometer using aqueous H_3PO_4 (85%) as an external reference. IR spectra were recorded with a Bruker Vector 22 instrument. The assignment of all ^1H and ^{13}C NMR resonances has been supported by two-dimensional NMR spectroscopy (COSY and NOE experiments). For the atomic numbering schemes used in the Exp. Sect., see Figure 3.

[2-(Cyclohepta-2,4,6-trienyl)phenyl]diphenylphosphane (2): A solution of **1** (9.62 g, 28.20 mmol) in THF (140 mL) was treated with *n*-butyllithium (12.2 mL of a 2.5 M solution in hexane, 30.5 mmol). After stirring for 45 min, solid (C_7H_7)BF_4 (5.01 g, 28.16 mmol) was added at −78 °C, and the resulting reaction mixture was slowly warmed to room temperature (3 h). It was then diluted with a saturated aqueous NH_4Cl solution (100 mL) and extracted with diethyl ether (100 mL) and dichloromethane (2 × 50 mL). The combined organic extracts were dried with $MgSO_4$. Evaporation of the solvents and purification by column chromatography on silica using petroleum ether/dichloromethane (1:1) as eluent afforded **2** as a colorless, crystalline solid. Yield: 7.41 g (75%). ^1H NMR ($CDCl_3$, 400 MHz): δ = 7.66 (dd, 1 H, 13-H), 7.49 (t, 1 H, 12-H), 7.40−7.28 (m, 10 H, C_6H_5), 7.24 (t, 1 H, 11-H), 6.98 (dd, 1 H, 10-H), 6.65 (t, 2 H, 4,5-H), 6.11 (m, 2 H, 3,6-H), 5.26 (dd, 2 H, 2,7-H), 3.66 (m, 1 H, 1-H). ^{31}P NMR ($CDCl_3$, 81 MHz): δ = −15.9. MS (EI): *m*/*z* (%) = 352 (100) [M^+], 351 (94) [M − H]$^+$, 262 (25) [PPh_3]$^+$. $C_{25}H_{21}P$ (352.42): calcd. C 85.20, H 6.01; found C 84.93, H 6.27.

Phosphonium Salt 3: Prior to hydride abstraction, the phosphane **2** was thermally rearranged by heating in *N*,*N*-dimethylformamide at 150 °C overnight. After evaporation of the solvent, the mixture was purified by chromatography as described above. A solution of this isomeric mixture (0.82 g, 2.33 mmol) in acetonitrile (35 mL) was treated with (Ph_3C)BF_4 (0.69 g, 2.09 mmol) at 0 °C. After it was warmed to room temperature, the reaction mixture was warmed to reflux for 2 h. The solvent was removed by evaporation, and the residue was washed with diethyl ether to remove Ph_3CH and recrystallized from dichloromethane/petroleum ether at 0 °C to afford **3** as a yellow, crystalline solid. Yield: 0.64 g (70%). ^1H NMR (CD_2Cl_2, 400 MHz): δ = 8.02−7.66 (m, 14 H, C_6H_5 + 10,11,12,13-H), 7.28 (m, 1 H, C_7 ring: CH), 6.98 (dd, 1 H, C_7 ring: CH), 6.85 (dd, 1 H, C_7 ring: CH), 6.43 (m, 1 H, C_7 ring: CH), 4.89 (m, 1 H, C_7 ring: CH), 3.89 (m, 1 H, C_7 ring: CHP). ^{31}P NMR (CD_3CN, 81 MHz): δ = 43.8. MS (ESI): *m*/*z* (%) = 351 (100) [M − BF_4]$^+$. $C_{25}H_{20}BF_4P$ (438.21): calcd. C 68.52, H 4.60; found C 68.24, H 4.70.

[(*o*-$Ph_2PC_6H_4$-η^6-C_7H_7)Mo(CO)$_2$(*P*−*Mo*)] (4): The phosphane **2** (9.72 g, 28.58 mmol) and $Mo(CO)_6$ (7.65 g, 28.98 mmol) were dissolved in methylcyclohexane (250 mL) and slowly heated to 120 °C within 2 h. Heating was continued at this temperature while stirring for 10 h. The solvent and unchanged $Mo(CO)_6$ were removed in vacuo, and the residue was recrystallized from dichloromethane/hexane at 0 °C. After 12 h, **4** was isolated as a red crystalline solid by filtration. Yield: 8.84 g (64%) − ^{1}H NMR (CD_2Cl_2, 600 MHz): δ = 7.66 (m, 2 H, *o*-C_6H_5), 7.47 (dd, 1 H, 13-H), 7.42 (m, 6 H, C_6H_5), 7.38 (m, 3 H, C_6H_5 + 12-H), 7.31 (t, 1 H, 11-H), 7.27 (t, 1 H, 10-H), 5.97 (t, 1 H, 3-H), 5.53 (t, 1 H, 4-H), 5.22 (t, 1 H, 5-H), 4.77 (d, 1 H, 2-H), 2.62 (dd, 1 H, 7-*endo*-CH_2), 2.35 (dd, 1 H, 7-*exo*-CH_2), 2.12 (tt, 1 H, 6-H). ^{13}C NMR (CD_2Cl_2, 150.7 MHz): δ = 227.2 (d, $^2J_{C,P}$ = 10.2 Hz, CO), 223.9 (d, $^2J_{C,P}$ = 12.1 Hz, CO), 153.6 (d, $^2J_{C,P}$ = 27.5 Hz, C-8), 151.3 (d, $^1J_{C,P}$ = 40.9 Hz, C-9), 142.0 (d, $^1J_{C,P}$ = 36.4 Hz, *i*-C_6H_5), 138.1 (d, $^1J_{C,P}$ = 40.2 Hz, *i*-C), 133.4 (s, C-10), 133.1 (d, $^2J_{C,P}$ = 12.8 Hz, *o*-C), 132.8 (d, $^2J_{C,P}$ = 11.5 Hz, *o*-C), 130.3 (s, C-12), 129.8 (s, *p*-C), 129.6 (s, *p*-C), 128.7 (d, ^3J = 9.6 Hz, *m*-C), 128.4 (d, ^3J = 10.1 Hz, *m*-C), 127.4 (d, ^3J = 12.8 Hz, C-13), 127.3 (d, ^3J = 5.8 Hz, C-11), 104.7 (s, C-5), 98.8 (s, C-2), 90.9 (s, C-3), 86.3 (s, C-4), 86.0 (s, C-1), 54.8 (s, C-6), 33.6 (s, CH_2-7). ^{31}P NMR ($CDCl_3$, 81 MHz): δ = 64.5. MS (EI): *m*/*z* (%) = 504 (12) [M^+], 476 (4) [M − CO]$^+$, 448 (100) [M − 2 CO]$^+$. IR (KBr): ν(CO) = 1905 (shoulder), 1889, 1873, 1816 cm^{-1}. $C_{27}H_{21}MoO_2P$ (504.38): calcd. C 64.30, H 4.20; found C 64.90, H 4.30.

[(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CO)$_2$(*P*−*Mo*)]BF_4 (5): A solution of **4** (8.84 g, 17.53 mmol) in dichloromethane (200 mL) was treated with $(Ph_3C)BF_4$ (5.20 g, 15.75 mmol) at 0 °C, and the resulting mixture was subsequently heated to reflux for 30 min. The solution was reduced in volume to about 50 mL and added dropwise to rapidly stirred diethyl ether at 0 °C to precipitate **5**, which was isolated as an orange crystalline solid by filtration, washing with diethyl ether and drying in vacuo. Yield: 8.34 g (90%). ^{1}H NMR (CD_2Cl_2, 600 MHz): δ = 7.88 (dd, 1 H, 13-H), 7.71 (t, 1 H, 12-H), 7.59 (t, 1 H, 11-H), 7.55−7.59 (m, 6 H, *p*- + *m*-C_6H_5), 7.43−7.39 (m, 4 H, *o*-C_6H_5), 7.38 (t, 1 H, 10-H), 6.06 (m, 2 H, 3,6-H), 6.00 (m, 2 H, 4,5-H), 5.59 (dd, 2 H, 2,7-H). ^{13}C NMR (CD_2Cl_2, 150.7 MHz): δ = 212.6 (d, $^2J_{C,P}$ = 25.3 Hz, CO), 146.7 (d, $^2J_{C,P}$ = 25.5 Hz, C-8), 141.5 (d, $^1J_{C,P}$ = 47.3 Hz, C-9), 133.3 (s, C-10), 132.8 (d, $^4J_{C,P}$ = 2.6 Hz, C-12), 132.3 (d, $^2J_{C,P}$ = 12.1 Hz, *o*-C), 132.1 (d, $^1J_{C,P}$ = 47.2 Hz, *i*-C), 132.0 (d, $^4J_{C,P}$ = 2.6 Hz, *p*-C), 131.0 (d, $^3J_{C,P}$ = 6.4 Hz, C-11), 129.9 (d, $^3J_{C,P}$ = 10.9 Hz, *m*-C), 127.3 (d, $^3J_{C,P}$ = 11.5 Hz, C-13), 126.7 (d, $^3J_{C,P}$ = 3.2 Hz, C-1), 98.2 (s, C-3,6), 96.0 (s, C-4,5), 94.7 (d, $^4J_{C,P}$ = 3.6 Hz, C-2,7). ^{31}P NMR ($CDCl_3$, 81 MHz): δ = 59.9. MS (ESI): *m*/*z* (%) = 503 (100) [M − BF_4]$^+$. IR (KBr): ν(CO) = 2032, 1988 cm^{-1}. IR (CH_2Cl_2): ν(CO) = 2035, 1994 cm^{-1}. $C_{27}H_{20}BF_4MoO_2P$ (590.17): calcd. C 54.95, H 3.42; found C 54.16, H 3.48.

[(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CO)Br(*P*−*Mo*)] (6): A solution of **5** (2.40 g, 4.07 mmol) in acetone (160 mL) was treated with NaBr (3.04 g, 29.55 mmol), and the resulting mixture was subsequently heated to reflux for 14 h. After evaporation of the solvent, the residue was transferred to a silica chromatography column. Elution with dichloromethane produced a green band that was collected to give **6** as a green, crystalline solid. Yield: 0.72 g (35%). ^{1}H NMR (CD_2Cl_2, 600 MHz): δ = 7.79 (dd, 1 H, 13-H), 7.71 (dd, 2 H, *o*-C_6H_5), 7.53 (t, 1 H, 12-H), 7.47 (t, 1 H, 11-H), 7.44 (t, 1 H, 10-H), 7.43−7.33 (m, 6 H, *p*- + *m*-C_6H_5), 7.20 (dd, 2 H, *o*-C_6H_5), 5.80 (t, 1 H, 5-H), 5.66 (d, 1 H, 2-H), 5.42 (t, 1 H, 4-H), 5.40 (t, 1 H, 3-H), 5.07 (t, 1 H, 6-H), 4.42 (d, 1 H, 7-H). ^{13}C NMR (CD_2Cl_2, 150.7 MHz): δ = 232.3 (d, $^2J_{C,P}$ = 15.6 Hz, CO), 150.4 (d, $^2J_{C,P}$ = 29.4 Hz, C-8), 141.5 (d, $^1J_{C,P}$ = 45.3 Hz, C-9), 134.5 (d, $^1J_{C,P}$ = 42.1 Hz, *i*-C), 134.2 (d, $^2J_{C,P}$ = 12.1 Hz, *o*-C), 132.7 (d, $^1J_{C,P}$ = 37.7 Hz, *i*-C), 132.2 (s, C-10), 131.6 (d, $^2J_{C,P}$ = 12.1 Hz, *o*-C), 130.6 (d, $^4J_{C,P}$ = 1.9 Hz, C-12), 130.5 (d, $^4J_{C,P}$ = 2.6 Hz, *p*-C), 129.8 (d, $^4J_{C,P}$ = 1.9 Hz, *p*-C), 129.1 (d, $^3J_{C,P}$ = 5.8 Hz, C-11), 128.5 (d, $^3J_{C,P}$ = 9.6 Hz, *m*-C), 128.3 (d, $^3J_{C,P}$ = 10.2 Hz, *m*-C), 127.5 (d, $^3J_{C,P}$ = 9.6 Hz, C-13), 107.3 (d, $^3J_{C,P}$ = 2.2 Hz, C-1), 99.4 (d, $J_{C,P}$ = 1.3 Hz, C-3), 99.2 (s, C-2), 98.5 (d, $J_{C,P}$ = 5.3 Hz, C-4), 93.6 (d, $J_{C,P}$ = 5.1 Hz, C-5), 89.5 (s, C-7), 80.9 (s, C-6). ^{31}P NMR ($CDCl_3$, 81 MHz): δ = 49.1. MS (EI): *m*/*z* (%) = 527 (11) [M − CO]$^+$, 447 (9) [M − CO − Br]$^+$. IR (KBr): ν(CO) = 1946 cm^{-1}. IR (CH_2Cl_2): ν(CO) = 1956 cm^{-1}. $C_{26}H_{20}BrMoOP$ (555.26): calcd. C 56.24, H 3.63; found C 55.30, H 3.64.

[(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)$MoBr_2$(*P*−*Mo*)] (7): A solution of **6** (4.92 g, 8.86 mmol) in dichloromethane (120 mL) was treated with a solution of bromine (0.24 mL, 4.68 mmol) in dichloromethane (10 mL) at 0 °C, and the resulting mixture was subsequently stirred for 1 h at ambient temperature. The solution was reduced in volume to about 50 mL and added dropwise to rapidly stirred hexane to precipitate **7**, which was isolated as a brown, crystalline solid by filtration, washing with hexane and drying in vacuo. Purification was possible by recrystallization from dichloromethane to afford crystals of **7**·CH_2Cl_2. Yield: 5.30 g (86%). ^{31}P NMR ($CDCl_3$, 81 MHz): δ = 38.5. MS (EI): *m*/*z* (%) = 607 (16) [M^+], 527 (68) [M − Br]$^+$, 448 (21) [M − 2 Br]$^+$. $C_{26}H_{22}Br_2Cl_2MoP$ (692.09): calcd. C 45.12, H 3.20; found C 45.72, H 3.13.

[(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CH_2SiMe_3)Br(*P*−*Mo*)] (8): A solution of **7**·CH_2Cl_2 (200 mg, 0.29 mmol) in THF (20 mL) was treated with Me_3SiCH_2MgCl (0.3 mL of a 1.0 M solution in diethyl ether, 0.3 mmol) at −78 °C, and the resulting mixture was allowed to warm to room temperature and was subsequently stirred for 12 h at ambient temperature. The solvent was evaporated, and the residue was extracted with hexane (20 mL). Keeping the filtrate in the refrigerator for 24 h at 0 °C afforded orange crystals of **8**. Yield: 110 mg (62%). ^{31}P NMR ($CDCl_3$, 81 MHz): δ = 51.9. $C_{29}H_{31}BrMoPSi$ (614.47): calcd. C 56.69, H 5.09; found C 56.97, H 5.11.

[(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)Mo(CH_2SiMe_3)$_2$(*P*−*Mo*)] (9): A solution of **7**·CH_2Cl_2 (500 mg, 0.72 mmol) in THF (20 mL) was treated with a large excess of Me_3SiCH_2MgCl (7.2 mL of a 1.0 M solution in diethyl ether, 7.2 mmol) at −78 °C, and the resulting mixture was allowed to warm to room temperature and was subsequently stirred for 12 h at ambient temperature. The solvent was evaporated, and the residue was extracted with hexane (20 mL). Purification was possible by column chromatography on silica using diethyl ether/petroleum ether (1:1) as eluent to isolate **8** as an orange-yellow, crystalline solid. Yield: 420 mg (93%). ^{31}P NMR ($CDCl_3$, 81 MHz): δ = 54.6. $C_{33}H_{42}MoPSi_2$ (621.78): calcd. C 63.75, H 6.81; found C 63.35, H 6.74.

X-ray Crystallography:[37,54] Data sets were collected at −75 °C (for **2**, **4**, and **5**) with an Enraf−Nonius KappaCCD or at −120 °C (for **6**−**9**) with a Bruker AXS APEX diffractometer both equipped with a rotating anode using Mo-K_α radiation (λ = 0.71073 Å). Empirical absorption correction with SORTAV[55] (for **2**, **4**, and **5**) or SADABS[56] (for **6**−**9**) was applied to the raw data. Structure solution was performed in all cases with SHELXS[57] and refinement with SHELXL[58] with anisotropic thermal parameters for all atoms. Hydrogen atoms were added to the structure models on calculated positions and were refined as riding atoms (**2**, **4**, and **5**) or are unrefined for **6**, **7**, and **9**. Hydrogen atoms for **8** were located in the difference Fourier map and were refined with isotropic ther-

mal parameters. ORTEP[59] was used for all drawings. Additional crystallographic data are listed in Table 2 and in ref.[37]

Metathesis Studies: A solution of norbornene (750 mg, 7.97 mmol) and the bis(neosilyl) complex **9** (16.5 mg, 26.5 μmol) in chlorobenzene (60 mL) was treated with Me_3SiCH_2MgCl (30 μL of a 1.0 M solution in diethyl ether, 30 μmol), and the resulting mixture was heated at 40 °C for 12 h. After quenching with a few drops of benzaldehyde, the viscous mixture was heated to 80 °C and then added dropwise to rapidly stirred methanol (400 mL) to precipitate a white, fibrous material, which was collected by filtration and dried in vacuo. Yield: 650 mg (87%). The molecular weights of the poly(1,3-cyclopentylenevinylene) samples thus obtained were determined by GPC with THF as eluent using refraction index detection and polystyrene as standard ($M_n = 2.6 \cdot 10^4$ g/mol, PDI = $M_w/M_n = 6.7$, approx. 80% *trans* double bonds as indicated by ^{13}C NMR[49] and IR[50] measurements).

Acknowledgments

This work was financially supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the government of North Rhine-Westphalia (Bennigsen-Foerder-Preis 2000 to M. T.). We are indepted to Tania Pape for excellent technical assistance and to Dr. Victoria Urban and to Bernd Dreßel for considerable support during the preparation of the manuscript.

Octagallane (tBu$_3$Si)$_6$Ga$_8$ and Its Reduction to (tBu$_3$Si)$_6$Ga$_8^{2-}$ – On the Existence of Isomeric Gallium Clusters[‡]

Nils Wiberg,*[a] Thomas Blank,[a] Heinrich Nöth,[a][‡‡] Max Suter,[a][‡‡] and Markus Warchhold[a][‡‡]

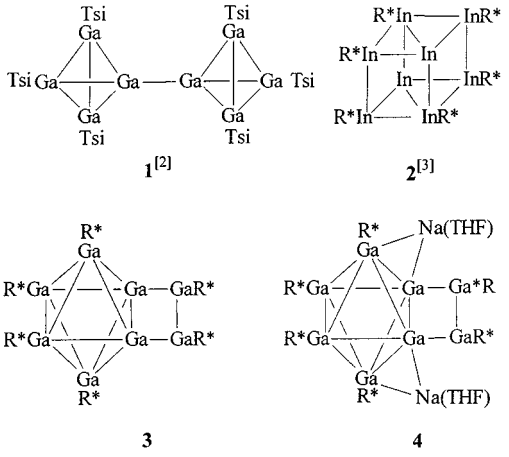
Keywords: Clusters / Gallium / Isomers / Silicon

Thermolysis of the trigallanyl radical R*$_4$Ga$_3^{\cdot}$ in heptane at 60 °C leads to the dark blue octagallane R*$_6$Ga$_8$ (R* = supersilyl SitBu$_3$), as well as the digallanyl radical R*$_3$Ga$_2^{\cdot}$ and the *tetrahedro*-tetragallane R*$_4$Ga$_4$. In addition, supersilyl radicals R*$^{\cdot}$ are formed which stabilize themselves either by dimerization or by addition of hydrogen atoms. R*$_6$Ga$_8$ can be reduced in THF with NaC$_{10}$H$_8$ to the dark-red octagallanediide Na$_2$Ga$_8$R*$_6$·2THF. According to an X-ray structure analysis of R*$_6$Ga$_8$ and R*$_6$Ga$_8^{2-}$ one finds that the Ga atoms of four R*Ga moieties, together with two "naked" Ga atoms, occupy the corners of a distorted octahedron; the "naked" Ga atoms themselves are located, along with Ga atoms of two further R*Ga moieties, at the corners of a distorted square. The reduction of R*$_6$Ga$_8$ leads only to a negligible shortening of the Ga–Ga distances from 2.64 to 2.61 Å (mean values) in R*$_6$Ga$_8^{2-}$. Both the octagallanes possess Ga$_8$ frameworks previously unknown for group 13 clusters. They are isomeric to the recently described Ga$_8$ framework of the octagallane Tsi$_6$Ga$_8$ [Tsi = trisyl C(SiMe$_3$)$_3$]. Hence, not only boron but also the heavier group 13 atoms form isomeric clusters.

Introduction

Cluster compounds R$_m$E$_n$ of the heavier group 13 metals Al, Ga, In, Tl — unlike those of B — became accessible only recently when it was realized that the tendency of R$_m$E$_n$ to disproportionate into R$_3$E and E (or R$_2$ and E) can be stopped by employing bulky substituents such as trisyl (Tsi) [C(SiMe$_3$)$_3$], hypersilyl (Hsi) [Si(SiMe$_3$)$_3$] or supersilyl (R*) [Si(CMe$_3$)$_3$]. In fact, numerous clusters of Ga — the subject of this publication — have been isolated within the last few years (for more than 30 gallium cluster compounds see ref.[1]).

Schnöckel and co-workers[2] recently reported the preparation of hexatrisyloctagallane Tsi$_6$Ga$_8$ (**1**) with a framework of two *tetrahedro*-tetragallanyl moieties connected by a Ga–Ga bond (see Scheme 1). We now report the isolation of hexasupersilyloctagallane R*$_6$Ga$_8$ (**3**) as well as its reduction product disodium hexasupersilyloctagallanediide-tetrahydrofuran(1/2) Na$_2$Ga$_8$R*$_6$·2THF (**4**), the Ga$_8$ frameworks of which are isomeric with the Ga$_8$ cluster of Tsi$_6$Ga$_8$ (Scheme 1). It is worth mentioning here that the In$_8$ framework of hexasupersilyloctaindane R*$_6$In$_8$ (**2**; Scheme 1), reported some years ago by us,[3] has a structure different to the structures of Tsi$_6$Ga$_8$ and R*$_6$Ga$_8$.



Scheme 1. Compounds with isomeric group 13 E$_8$ cluster frameworks [Tsi = C(SiMe$_3$)$_3$, R* = SitBu$_3$]

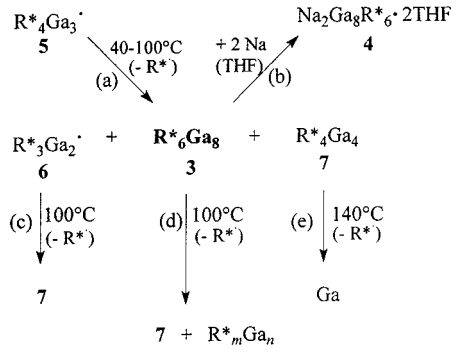
Results and Discussion

Syntheses of R*$_6$Ga$_8$ (3) and Na$_2$Ga$_8$R*$_6$·2THF (4)

The dark green radical R*$_4$Ga$_3^{\cdot}$ (**5**), which may be synthesized, via isolable intermediates, from gallium trichloride GaCl$_3$, supersilyl sodium NaR*, and supersilyl bromide R*Br,[4] slowly decomposes in heptane at 40 °C with formation of the dark blue radical R*$_3$Ga$_2^{\cdot}$ (**6**) and the dark violet *tetrahedro*-tetragallane R*$_4$Ga$_4$ (**7**) [see Scheme 2, Equation

[‡] Compounds of Silicon and Homologues, 152; Compounds of Boron and Homologues, 19. – Parts 151 and 18: Ref.[7]
[‡‡] X-ray structure analyses
[a] Department Chemie der Universität München, Butenandtstraße 5–13 (Haus D), 81377 München, Germany

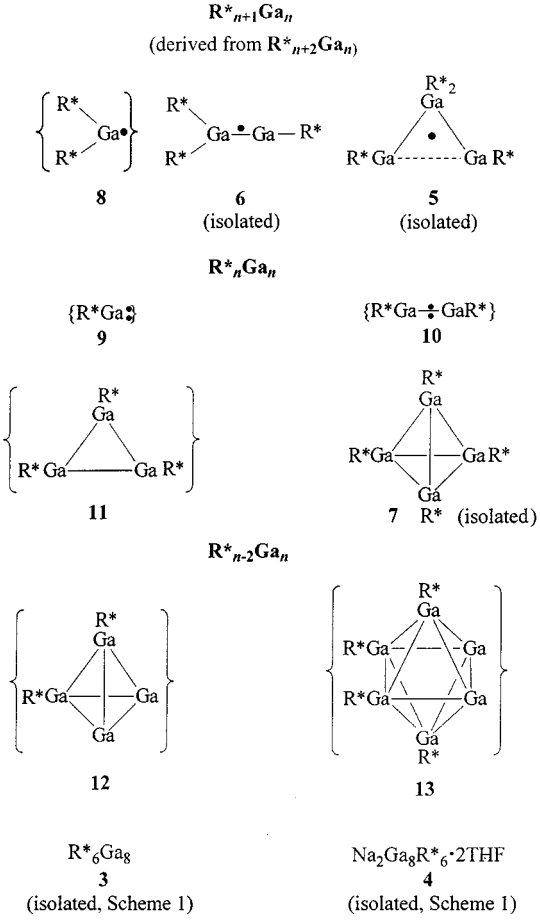
(a); for the structures see Scheme 3].[4] The radical **6** transforms quantitatively at 100 °C in heptane into the tetrahedrane **7** [Scheme 2, Equation (c)] which decomposes as a solid at 322 °C and in solution at 140 °C to metallic gallium [Scheme 2, Equation (e)].[5] The supersilyl radicals R*· obtained in reactions (c) and (e) dimerize to give superdisilane molecules R^*_2, which at higher temperatures transform via R*· into supersilane R*H.[6]



Scheme 2. Decomposition of **5** (the produced supersilyl radical R* stabilizes with formation of R^*_2 and/or R*H; R* = Si*t*Bu$_3$)

The thermolysis of **5** in addition leads to the octagallane $R^*_6Ga_8$ (**3**) [Scheme 2, Equation (a); maximum yields at about 60 °C], which itself decomposes in benzene at 100 °C to give the tetrahedrane **7** (main product) as well as unidentified cluster compounds R_mGa_n [Scheme 2, Equation (d)]. The octagallane **3** can be reduced in THF with $NaC_{10}H_8$ to give the octagallanediide $Na_2Ga_8R^*_6$·2THF (**4**) [Scheme 2, Equation (b)]. Reduction of the tetragallane **7** in THF with sodium occurs analogously to produce the tetragallanediide $Na_2Ga_4R^*_4$·2THF.[7]

To date our insight into the pathways of the formation and thermolysis of **3** is still incomplete. It is possible that compounds **8**−**13**, which are shown in Scheme 3 along with the isolated products **3**−**7**, may play the role of intermediates (cf. ref.[4] for formation of **3**, and the following for thermolysis of **3**). Radical **5** can react with cleavage of Ga−Ga bonds to form **6** and **9**, as well as **8** and **10**, and with cleavage of a Ga−Si bond to form **11** and R*·; radical **8**, after dimerization and R* elimination, transforms into isolable **6** (cf.[4]), and radical **6**, after elimination of R*, into non-isolable **10**. The formed gallylene **9** and the digallene **10** tetramerize and dimerize, respectively, to give isolable **7**. It is also possible that the cyclotrigallane **11** may eliminate R* and then dimerize with formation of the hitherto non-isolated hexagallane **13** which, on adding **10**, might form the isolable octagallane **3**. This compound decomposes on gentle heating to give the isolable tetrahedrane **7** and the non-isolable tetragallane **12** which possibly stabilizes with formation of unidentified oligogallanes (see above). Support for this suggestion is based on the formation of decagallanide $R^*_6Ga_{10}^-$ [8] as an isolable adduct of **12** and **13** [see also Hsi_6Ga_{10}, Hsi = Si(SiMe$_3$)$_3$ [8]] as well as the formation of dodecaindane $R^*_8In_{12}$ [9] from two molecules of the In analog of **13** (Hexaindane $R^*_4In_6$ — an obvious intermediate in the formation of $R^*_8In_{12}$ — has been observed by NMR spectroscopy[9].) In addition, a cluster formed from two equivalents of **12** with In/Dmp instead of Ga/R* has been synthesized[10] (Dmp = 2,6-Mes*$_2$C$_6$H$_3$ with Mes* = 2,4,6-*t*Bu$_3$C$_6$H$_2$). The preparation and isolation of hexagallane **13** is the next challenge for group 13 cluster chemists.



Scheme 3. Isolated and postulated products of the thermolysis of **5** as well as the reduction product **4** of **3** (R* = Si*t*Bu$_3$)

Characterization and Structures of $R^*_6Ga_8$ (3) and $Na_2Ga_8R^*_6$·2THF (4)

Hexasupersilyloctagallane (**3**) crystallizes from benzene as water- and air-sensitive dark blue prisms (monoclinic, space group $P2_1/c$) which are thermolabile at elevated temperatures. Disodium hexasupersilyloctagallanediide-tetrahydrofuran(1/2) (**4**) crystallizes from benzene as extremely water- and air-sensitive dark red prisms (triclinic, space group $P\bar{1}$).

The molecular structures of the molecules **3** and **4** in the crystal are shown in Figure 1 and 2, respectively. In both compounds the Ga atoms of four R*Ga moieties occupy the corners of a distorted octahedron together with two "naked" Ga atoms. The "naked" Ga atoms are located next to each other, along with the Ga atoms of two further R*Ga moieties, at the corners of a distorted square. The Ga

atoms that form the Ga_6 octahedron and the anellated Ga_4 square lie almost in a plane together with the Si atoms of the four connected R* groups. All quadrangle surfaces Ga1Ga2Ga7Ga8/Ga5Ga6Ga7Ga8/Ga3Ga5Ga4Ga7/Ga3Ga6Ga4Ga8 in **3** and **4** are planar (angles sum ca. 360°). The Si atoms connected at the apices of the Ga_6 octahedron are tilted towards the square. The two Na(THF) moieties of **4** bridge opposite edges between the Ga atoms of the apex and the central plane of the Ga_6 octahedron. Surprisingly, Na(THF) is not located above and below the Ga_4 square, probably due to steric reasons. $(Hsi)_6Ga_{10}$, which is derived from **4** after exchange of supersilyl for the sterically less crowded hypersilyl $Si(SiMe_3)_3$ and $Na(THF)^+$ by "isoelectronic" Ga^+, shows a Ga_{10} framework built from two anellated Ga_6 octahedrons. Scheme 4 shows the structural relationships between the octagallanediide $R_6Ga_8^{2-}$ (isolated as **4**) and the decagallane R_6Ga_{10} [isolated as $(Hsi)_6Ga_{10}$][8] via the nonagallanide $R_6Ga_9^-$ {isolated as $[Na(THF)_6]^+(Hsi)_6Ga_9^-$},[8] which are formally derived from $R_6Ga_8^{2-}$ by successive "neutralization" of the dianion with Ga^+ cations (it remains to be seen whether $R^*_6Ga_8^{2-}$ is transformed in the presence of a Ga^I compound into $R^*_6Ga_{10}$ via $R^*_6Ga_9^-$).

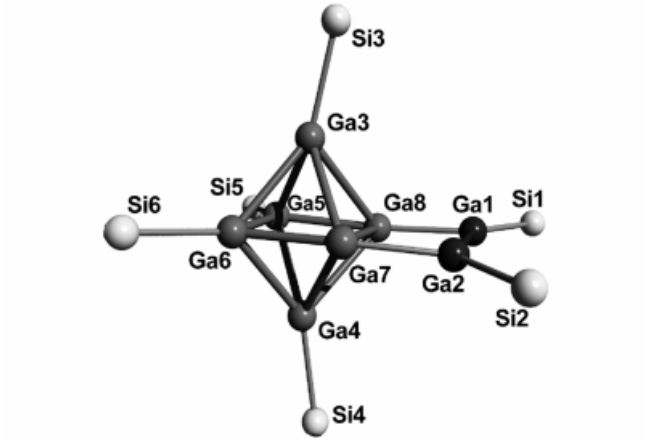


Figure 1. View of a molecule of **3** in the crystal (tBu groups excluded for clarity); for bond lengths and angles see Table 1

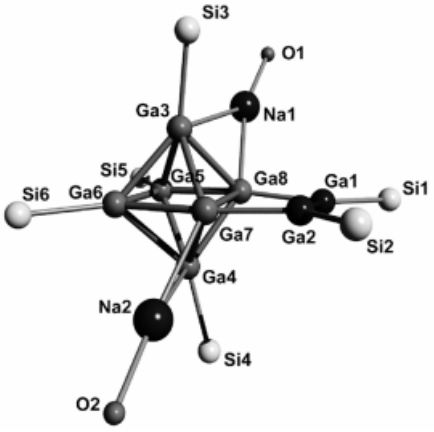

Figure 2. View of a molecule of **4** in the crystal (tBu and CH_2 groups excluded for clarity); for bond lengths and angles see Table 1

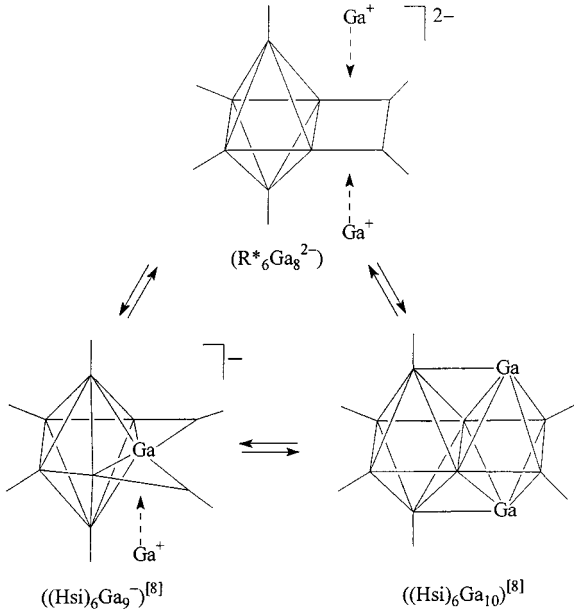

Scheme 4. Topological relation between $R^*_6Ga_2^{2-}$, $(Hsi)_6Ga_9$, and $(Hsi)_6Ga_{10}$ [R* = SitBu$_3$, Hsi = Si(SiMe$_3$)$_3$]

Table 1 presents selected bond lengths [Å] and angles [°] of **3** and **4**. The Ga−Ga distances (2.41−2.93 Å for **3** and 2.45−2.76 for **4**) lie in the typical range observed in other gallium cluster compounds such as $R^*_4Ga_4$ [5] and $R^*_8Ga_{18}/R^*_8Ga_{22}$.[1] On reduction of **3** to **4** some of the Ga−Ga bonds lengthen and some shorten, but on average they remain practically constant (mean bond length of 2.64 Å in **3** and 2.61 Å in **4**). Although the reductions of **3** and **7** with sodium in THF formally proceed in the same manner ($R^*_6Ga_8/R^*_4Ga_4$ + 2 Na + 2 THF → $Na_2Ga_8R^*_6$·2THF/$Na_2Ga_4R^*_4$·2THF), in the first case very little structural change is observed, whereas in the second case a drastic structure change and significant Ga−Ga bond shortening occurs.[7] The Ga_8 framework of **3** is less symmetric than that of **4** (cf. Ga−Ga distances). The Na−GaR*, Na−Ga, and Na−O distances are 3.52 Å (mean value), 2.99 Å, and 2.31 Å (angles sum at Na 357°, mean value of the Ga−Na−Ga angles 46°), respectively.

Compounds **3** and **4** possess a framework of eight Ga atoms that was previously unknown for clusters of the group 13 elements B − Tl. The isolation of $R^*_6Ga_8$ (**3**) and Tsi_6Ga_8 (**1**)[2] shows for the first time that the heavier group 13 elements can also form isomeric clusters that hitherto were thought to be restricted to boron.

Compound **3** can be described as a *conjuncto*-octagallane, based on hexagallane $R^*_4Ga_6$ (**13**) and digallene $R^*_2Ga_2$ (**10**). Considering the Wade−Mingos rules[11] compound **13** may therefore be classified as a doubly capped *tetrahedro*-tetragallane, that is a *hypoprecloso*-hexagallane [**13** possesses 10 cluster electrons ($2n$ − 2 with n = number of cluster atoms), giving 1 electron for Ga and two electrons for GaR*], although this description does not agree at all with the structure obtained for **3** by X-ray crystallography (see Table 1).

[a] Compound numbering from Figures 1 and 2. [b] Apex = Ga3, Ga4; basis = Ga5, Ga6, Ga7, Ga8.

However, **3** may also be derived from the hexagallane $R^*_6Ga_6$ − that should not be preparable for steric reasons − by substituting two neighbouring R* groups for digallanediyl -R*Ga−GaR*-. According to its 12 ($2n$) cluster electrons, $R^*_6Ga_6$ should be classified as a monocapped trigonal-bipyramidal *closo*-Ga_5 cluster, that is a *pre-closo*-hexagallane. This description agrees with the solid-state structure found for **3** (Table 1). The long Ga8−Ga3/Ga4/Ga7 distances of the $R^*_4Ga_6$ moiety of **3** suggest that $R^*_4Ga_6$ contains a trigonal-bipyramidal Ga3Ga4Ga5-Ga6Ga7 cluster with Ga8 as the edge-bridging atom. By the same reasoning, the octagallanediide **4** may be described as a derivative of the *closo*-octagallanediide $R^*_6Ga_6^{2-}$ [14 ($2n + 2$) cluster electrons] by substituting two neighbouring R* groups for -R*Ga−GaR*-, and in fact the $R^*_4Ga_6^{2-}$ moiety of **4** shows a more regular (octahedral) Ga_6 framework than the $R^*_4Ga_6$ moiety of **3** (Table 1).

Information about the structures of **3** and **4** in solution is still limited. Only one (broad) NMR signal is found for the six R* groups of **3** in benzene, whereas three NMR signals (ratio of areas 1:1:1) are found for **4** in benzene. This either means that **3** gives equal NMR shifts for the nonequivalent R* groups, or that it is fluxional. Low temperature NMR studies of **3** in solution are planned. In addition, NMR studies of **4** in donor solvents D may confirm the expected dissociation of the cluster into $Na(D)_n^+$ and $R^*_6Ga_8^{2-}$ ions.

Experimental Section

All experiments were carried out in flame-dried glass apparatus with standard Schlenk techniques under dry argon or nitrogen. Air and moisture were strictly excluded. The solvents (heptane, ben-

zene, THF) were dried with sodium plumbide or sodium in the presence of benzophenone. Available for use: C_6D_6. The following compounds were synthesized according to literature procedures: R*$_4$Ga$_3$ (**3**),[4] $NaC_{10}H_8$ in THF.[12]

NMR Spectra: Jeol GX-270 (^{1}H/^{13}C/^{29}Si: 270.17/67.94/53.67 MHz), Jeol EX-400 (^{1}H/^{13}C/^{29}Si: 399.78/100.54/79.43 MHz). The NMR spectra were recorded with the INEPT and DEPT pulse sequences using empirically optimized parameters for the mentioned groups.

Synthesis of R*$_6$Ga$_8$ (3): A solution of **5** (0.151 g, 0.130 mmol) in 5 mL of heptane was kept 25 h at 60 °C, after which time it had quantitatively decomposed into R*H,[13] R*$_2$,[13] **6**,[4] **7**,[5] and **3** (ratio of ^{1}H NMR signal areas of the R* groups of molecules R*H, R*$_2$, **7**, **3** about 1:1:5:3, corresponding to a mol ratio of the compounds of about 4:2:5:2) according to ESR, and ^{1}H, ^{13}C and ^{29}Si NMR spectroscopy. After the removal of all volatile compounds under vacuum and dissolving the residue in 2 mL of benzene, compound **3** (0.115 g, 0.066 mmol, 15%) was obtained after eight days at 8 °C as water- and air-sensitive dark-blue crystals. ^{1}H NMR (C_6D_6): δ = 1.28 (broad, 162 H, 6 SitBu$_3$). ^{13}C{^{1}H} NMR (C_6D_6): δ = 25.6/33.6 (broad/broad, 18 C/54 C, 18 CMe$_3$/18 CMe_3). ^{29}Si NMR (C_6D_6): δ = 58.7 (broad, 6 Si, 6SitBu$_3$). X-ray structure analysis: see Figure 1 (blue prisms from benzene). *Note*: The relative yields of **6** (seen only by ESR spectroscopy), **7** and **3** (seen only by NMR spectroscopy) depend, amongst others, on the reaction temperature. According to the NMR spectra, **7** and **3** are formed from **5** in heptane after 25 h at 40 or 60 or 100 °C in the mol ratio of about 99:1 or 71:29 or 100:0 (**3** is thermolabile at 100 °C).

Thermolysis of R*$_6$Ga$_8$ (3): A solution of **3** (0.073 g, 0.042 mmol) in 0.6 mL of C_6D_6 was kept for 14 h at 100 °C. After this time, according to the ^{1}H/^{13}C/^{29}Si NMR spectra, **3** had quantitatively decomposed into R*H,[13] R*$_2$,[13] **7**,[5] and an unidentified compound R$_m$Ga$_n$ (ratio of ^{1}H NMR signal areas of the R* groups of molecules R*H, R*$_2$, **7**, R$_m$Ga$_n$ about 2:1:10:(4+2), corresponding to a mol ratio of R*H, R*$_2$ and **7** of about 4:1:5). In addition, an insoluble product was formed (oligogallane ?). Characterization of the dissolved R$_m$Ga$_n$: ^{1}H NMR (C_6D_6): δ = 1.39 (broad). ^{13}C{^{1}H} NMR (C_6D_6): δ = 25.59/26.01 (s/s, 2x C/x C, 2x CMe$_3$/x CMe$_3$), 30.27/33.45 (s/s, 6x C/3x C, 2x CMe_3/x CMe_3). ^{29}Si NMR (C_6D_6): δ = 43.28/56.70 (s/s, 2x Si/x Si, 2x SitBu$_3$/x SitBu$_3$). *Note*: Octagallane R*$_6$Ga$_8$ with the structure of R*$_6$In$_8$ (**2**) should give a ratio of SitBu$_3$ NMR signal areas of 2:1).

Synthesis of Na$_2$Ga$_8$R*$_6$·2THF (4): A solution of $NaC_{10}H_8$ (0.11 mmol) in 1.5 mL of THF was added dropwise to a solution of **3** (0.05 mmol) in 10 mL of THF at −78 °C. After 5 h stirring at −78 °C all volatile components were removed from the reaction mixture under vacuum at −45 °C and the residue was dissolved in 3 mL of C_6D_6. This solution was concentrated to 0.8 mL and water- and air-sensitive red crystals of **4** were obtained after two months at 5 °C. ^{1}H NMR (C_6D_6): δ = 1.289/1.367/1.380 (s/s/s, 54 H/54 H/54 H, 2 SitBu$_3$/2 SitBu$_3$/2 SitBu$_3$), 1.124/3.325 (m/m, 8 H/8 H, 4 CH$_2$/4 CH$_2$O). ^{29}Si{^{1}H} NMR (C_6D_6): δ = 43.8/47.1/51.2 (s/s/s, 2Si/2Si/2Si, 2 SitBu$_3$/2 SitBu$_3$/2 SitBu$_3$). X-ray structure analysis: see Figure 2 (red prisms from benzene).

X-ray Structure Determinations: Data collection was performed with a Siemens P4 diffractometer equipped with an area-detector (Mo-K_α radiation λ = 0.71073 Å). Crystals were mounted in perfluoropolyether oil and data collected at T = 188(2) (**3**) and 193(2) K (**4**). The structures were solved by direct methods (SHELXS-97) and refined with full-matrix procedures against F^2 for all observed reflections. All non-hydrogen atoms were refined anisotropically and H atoms were included in the final refinement at calculated positions using a riding model and fixed isotropic U$_i$ values. A semiempirical absorption correction was applied by using the program SADABS. The structures of **3** and **4** are shown in Figure 1 and 2, crystallographic details are summarized in Table 2.
CCDC-165237 (**3**) and CCDC-165238 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Structural Characterization of (Carbene)ruthenium Complexes Binding Nucleobases

Jean-Luc Fillaut,*[a] Isaac de los Rios,[b] Dante Masi,[b] Antonio Romerosa,[c] Fabrizio Zanobini,[b] and Maurizio Peruzzini*[b]

Keywords: Carbenes / Ruthenium / Adenine / Uracil / X-ray crystallography / Aminophosphanes

The new (carbene)ruthenium(II) nucleobase derivatives *fac*,*cis*-[(PNP)RuCl{C($NHC_4H_3N_2O_2$)(CH_2Ph)}]Cl (**5**) and *fac*,*cis*-[(PNP)RuCl{C($NHC_5H_3N_4$)(CH_2Ph)}]Cl (**6**) [PNP = $CH_3CH_2CH_2N(CH_2CH_2PPh_2)_2$] were synthesised by treating (vinylidene)ruthenium(II) complex *fac*,*cis*-[(PNP)$RuCl_2${C=C(H)Ph}] (**1**) with 5-aminouracil or adenine, respectively. Both complexes were characterized by spectroscopic techniques (IR and NMR) and elemental analyses, which confirmed the formation of the aminocarbene moieties incorporating 1 equiv. of the nucleobase in the complex framework. Crystal and molecular structure determination by X-ray diffraction analysis of the uracil derivative **5** revealed a very unusual *O*-coordination of the exocyclic C=O group on the C(4) atom of the uracil ring to the ruthenium atom leading to an unprecedented six-membered aminocarbene metallacycle.

Introduction

The chemistry of organotransition metal complexes containing biologically important molecules as ligands constitutes a recent research field of general interest relevant to aspects such as DNA condensation,[1] heavy metal toxicity and mutagenicity,[2] and, in a broader sense, to topics related to the subject of supramolecular architectures where metal-to-ligand coordination bonds are intimately combined with H-bonding interactions. These supramolecular bio-organometallic aggregates have potential implications for the design of new metal-based drugs[3] as well as in material chemistry.[4]

The presence of metal ions in these systems introduces additional variables, whose effects remain largely to be explored in detail. These include inter alia the overall charge of the complex, the oxidation state of the metal atom, the electronic and steric properties of the coligands and also, in charged compounds, the nature of the counterion.[5] Among transition metal ions, ruthenium has unique properties making it particularly useful in drug design.[6] A ruthenium anticancer agent showing promising activity against otherwise resistant tumours and a low systemic toxicity has recently entered clinical trials.[7] Remarkably, bio-organometallic compounds conjugating nucleobases with typical metal−carbon multiple bond species such as carbenes and carbynes have not yet been described in spite of the enormous interest in this class of compounds[8] and the steadily increasing attention paid to the search of new routes to ruthenium species bio-conjugated with nucleobases.

Herein, we wish to report on our results in this area describing the first examples of transition metal carbenes incorporating nucleobases in their molecular structure. Noticeably, an unprecedented bonding mode of the uracil moiety to a transition metal ion has been ascertained by X-ray analysis.

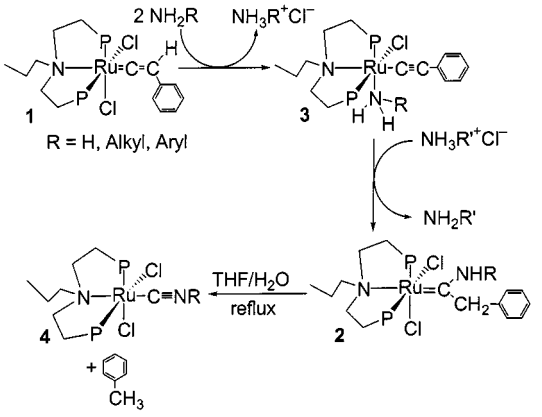
Results and Discussion

Synthesis and Characterization of the (Carbene)ruthenium Nucleobase Derivatives *fac*,*cis*-[(PNP)RuCl{C($NHC_4H_3N_2O_2$)-(CH_2Ph)}]Cl (5) and *fac*,*cis*-[(PNP)RuCl{C($NHC_5H_3N_4$)(CH_2Ph)}]Cl (6)

In recent years, some of us reported that the reaction of the (vinylidene)ruthenium(II) complex *fac*,*cis*-[(PNP)-$RuCl_2${C=C(H)Ph}] (**1**) [PNP = $CH_3CH_2CH_2N$-$(CH_2CH_2PPh_2)_2$] with a variety of primary amines is a simple general method to synthesising the neutral aminocarbene complexes *fac*,*cis*-[(PNP)$RuCl_2${C(NHR)(CH_2Ph)}]

(**2**) in excellent yields via the intermediary aminoalkynyl compounds **3**.[9] The aminocarbene complexes are air- and thermally stable in the solid state but slowly decompose in boiling THF eliminating toluene and forming the corresponding isocyanide complexes *fac*,*cis*-[(PNP)$RuCl_2$-(C≡NR)] (**4**) (Scheme 1).

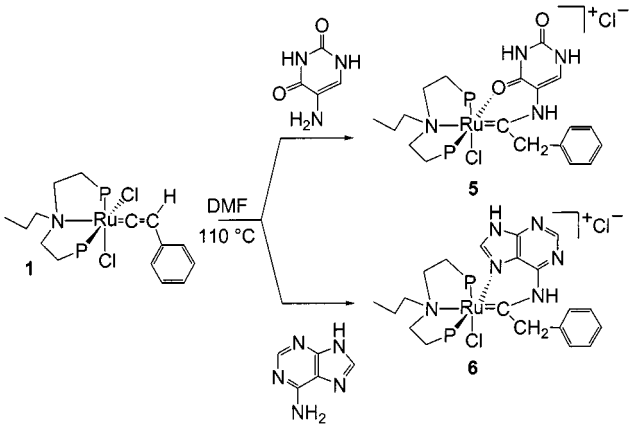


Scheme 1

We were intrigued by the generality of the reaction of **1** with primary amines, and so decided to investigate the possibility of introducing biologically relevant molecules such as 5-aminouracil and adenine into the skeleton of the ruthenium−carbene moiety. The incorporation of both 5-aminouracil and adenine in the ruthenium complex would lead to the building of bifunctional organometallic moieties that could exploit their potential to act as ligands capable of recognising complementary nucleobases trough hydrogen bond interactions.

With these ideas in mind, we have examined the reactivity of the vinylidene complex **1** with a slight excess of 5-aminouracil or adenine. This was done by adapting our general preparation of the aminocarbene complexes **2** for both the insolubility of these nucleobases in common organic solvents and the reluctance of these weak bases to interact with the Ru=C=C fragment under less forceful conditions. A straightforward reaction was obtained by allowing **1** to react with an excess of either 5-aminouracil or adenine in distilled dimethylformamide at ca. 110 °C where both the nucleobases and the ruthenium precursors are soluble enough. Concentration of the hot solution to dryness under vacuum left a yellowish residue which was taken up with a mixture of dichloromethane/ethanol to yield, after workup, a crop of light-yellow microcrystals of *fac*,*cis*-[(PNP)-$RuCl\{C(NHC_4H_3N_2O_2)(CH_2Ph)\}]Cl$ (**5**) or orange platelets of *fac*,*cis*-[(PNP)$RuCl\{C(NHC_5H_3N_4)(CH_2Ph)\}]Cl$ (**6**), respectively (Scheme 2). The uracil derivative could be recrystallized in air as lemon-yellow needles suitable for an X-ray diffraction study from dichloromethane/petroleum ether mixtures. In contrast, several attempts to grow crystals of **6** (either as chloride or tetraphenylborate salt) were unsuccessful.

Apart from conventional spectroscopic techniques (IR and NMR spectroscopy) and elemental analysis (see Exp. Sect.), which confirmed the incorporation of one equiv. of



Scheme 2

nucleobase and the formation of the expected aminocarbene moiety in the complex framework of both **5** and **6**, precious information that shed light on their structures was inferred from chemical tests. A complete X-ray diffraction analysis was also obtained for **5** (see below).

Unambiguous evidence for the presence of the aminocarbene ligands in **5** and **6** was provided by NMR spectroscopy ([D_6]DMSO) that showed the typical ^{13}C NMR absorptions of the aminocarbene carbon atom at $\delta = 257.9$ (t, $^2J_{C,P} = 13.9$ Hz) for **5** and $\delta = 284.5$ (t, $^2J_{C,P} = 19.2$ Hz) for **6**. The magnitude of the coupling constants, which are in the expected range for Fischer-type (carbene)ruthenium(II) complexes points to a *trans* disposition of the carbene ligand and the nitrogen donor atom of the PNP ligand. The IR spectra contained a broad absorption in the N−H stretching region (3500−3400 cm^{-1}), while the uracil derivative, in addition, exhibited medium-to-strong bands at 1720, 1643 and 1621 cm^{-1}, which were assigned to the stretching of the oxo groups in position 2 and 4 and to the C(5)−C(6) double bond in the uracil residue, respectively. In the ^1H NMR spectra, the hydrogen atoms of the benzyl substituents are diastereotopic and thus give rise to an AB multiplet, whereas the NH proton of the aminocarbene moiety appears as a very broad singlet at $\delta = 11.70$ (**5**) and $\delta = 13.90$ (**6**) due to the presence of the quadrupolar ^{14}N-nucleus.

In keeping with a *facial* arrangement of the PNP ligand and an inequivalent chemical environment of the two phosphane ends, the $^{31}P\{^1H\}$ NMR spectra in [D_6]DMSO showed slightly perturbed second-order AB splitting patterns with homonuclear geminal coupling constants $^2J_{P,P}$ equal to 32.5 and 27.5 Hz, respectively. The inequivalence of the two P-donor atoms in both **5** and **6** was quite unexpected in view of the *facial* geometry adopted by the aminodiphosphane ligand ($\delta_P > 39$)[10] and of the absence of any chiral element in the frame of the nucleobases incorporated in the complexes.[9] While a ^{31}P NMR singlet could be anticipated for a *fac*,*cis*-PNP(carbene)Ru complex, the occurrence of an AB system could not be simply explained. On the basis of the elemental analysis, confirming two chloride ligands for each ruthenium atom, a reasonable structural

hypothesis suggested that one of the two chloride ligands was no longer coordinated to the metal centre, therefore acting as the counteranion in a charged complex. In agreement with this hypothesis, both **5** and **6** readily exchanged one of the two chloride ions with tetraphenylborate when their solutions in CH_2Cl_2/EtOH were treated with excess $NaBPh_4$. Elemental analysis, IR and NMR spectroscopy, as well as solution conductivities (1,2-dichloroethane) clearly indicated that the tetraphenylborate complexes *fac*,*cis*-[(PNP)RuCl{C($NHC_4H_3N_2O_2$)(CH_2Ph)}]BPh_4 (**5-BPh$_4$**) and *fac*,*cis*-[(PNP)RuCl{C($NHC_5H_3N_4$)(CH_2Ph)}]BPh_4 (**6-BPh$_4$**), were quantitatively produced by metathetical chloride substitution.

Crystal Structure of *fac,cis*-[(PNP)RuCl{C($NHC_4H_3N_2O_2$)(CH_2Ph)}]Cl·CH_3OH·H_2O (5·CH_3OH·H_2O)

The easy formation of the tetraphenylborate salts of **5** and **6** raised the question of which structure is attributed to carbenes **5** and **6** where a nucleobase is incorporated with a (carbene)ruthenium moiety. This makes it of paramount importance to attain single crystals suitable for an X-ray diffraction analysis. While for **6** we were unable to grow well-shaped crystals, the thermal and air robustness of the uracil derivative makes it feasible to grow crystals of **5** for the diffraction study from a saturated dichloromethane/methanol solution in air. Thus, in order to collect geometrical information on this class of aminocarbenes, an X-ray analysis was carried out on a single crystal of **5**. An ORTEP drawing of the complex is shown in Figure 1 with the adopted atomic numbering scheme. A list of selected bond lengths and angles is given in Table 1.

In the structure of *fac*,*cis*-[(PNP)RuCl{C($NHC_4H_3N_2O_2$)(CH_2Ph)}]Cl·CH_3OH·H_2O (**5·CH_3OH·H_2O**), formed by *fac*,*cis*-[(PNP)RuCl{C($NHC_4H_3N_2O_2$)(CH_2Ph)}]$^+$ cations, chloride anions and interspersed solvate molecules of methanol and water in a 1:1:1:1 ratio, the arrangement of the non-hydrogen atoms about the metal atom in the cation is approximately octahedral with the aminodiphosphane ligand occupying three facial coordination sites. A chloride ligand and one aminocarbene group incorporating the 5-aminouracil fragment and located *trans* to the PNP nitrogen donor, are also coordinated to the metal centre. The coordination polyhedron about the ruthenium atom is completed by O-coordination from the exocyclic C=O group on the C(4) atom of the uracil ring. The arrangement found in **5** does not significantly differ from that established in the related aminocarbene derivative *fac*,*cis*-[(PNP)$RuCl_2${C[NH(*S*)-(−)-CH(Me)(1-naphthyl)](CH_2Ph)}], which was also authenticated by X-ray methods,[9] as well as in other PNPruthenium(II) complexes.[10,11] Bond lengths and angles match well with the data reported for other (aminocarbene)ruthenium complexes.[9,12] Cocrystallised molecules of methanol and water, the latter likely taken from the air, contribute to the stability of the crystal lattice. As a matter of fact, a net of hydrogen bonding interactions involves the uracil N(4), the methanol O(3) and the water O(4) atoms, the most important contacts being N(4)···O(3) 2.79 Å and O(3)···O(4) 2.72 Å. Additionally, the O(4) water atom shows weak interactions

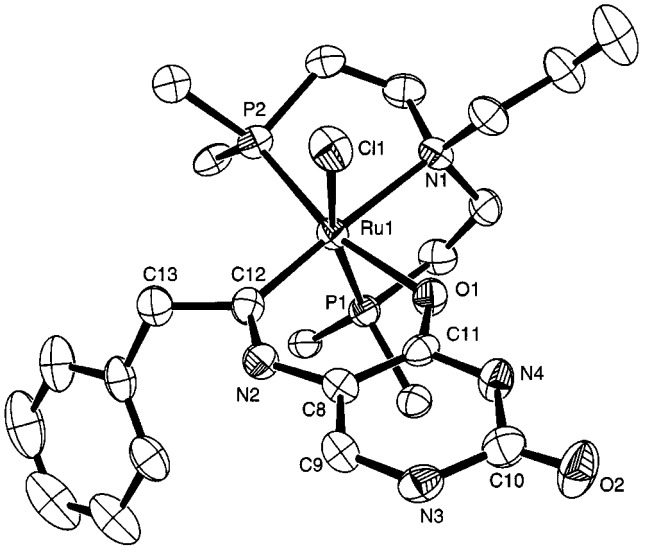


Figure 1. ORTEP drawing of the complex cation *fac*,*cis*-[(PNP)RuCl{C($NHC_4H_3N_2O_2$)(CH_2Ph)}]$^+$; only the *ipso*-carbon atoms of the PNP phenyl substituents are shown for the sake of clarity

Table 1. Selected bond lengths [Å] and angles [°] for *fac*-[(PNP)RuCl{C($NHC_4H_3N_2O_2$)(CH_2Ph)}]Cl·CH_3OH·H_2O (**5**·CH_3OH·H_2O)

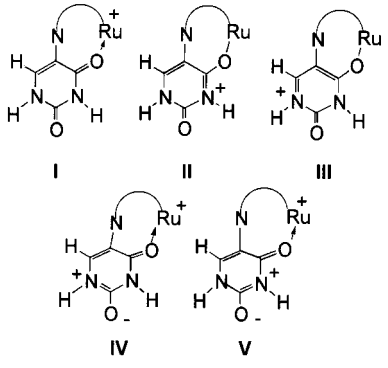
with both chlorine atoms [3.24 Å with Cl(1), 3.31 Å with Cl(2)].

The most notable feature of the crystal structure of **5** is the unexpected metallation of the C=O group at the 4-position of the uracil moiety, that, therefore, behaves as an η^1-monodentate ligand through the exocyclic oxygen atom. The complexation of one of the carbonyl groups of the uracil ligand to the ruthenium centre was quite surprising and has no precedents in this series of PNP(carbene)Ru derivatives. In this regard, it is remarkable to underline that the reaction of **1** with several α,ω-diamines parallels that established for simple monoamines and resulted in the synthesis of (aminocarbene)ruthenium complexes with a pendant, noncoordinated, amino arm.[13]

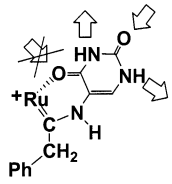
Although few examples of transition metal complexes containing uracil residues have been described so far,[5a,14a] the arrangement found in **5**, where the nucleobase metallates through one carbonyl group, is unprecedented.[14] The C(11)−O(1) bond length [1.240(6) Å] of the carbonyl group involved in the intramolecular interaction with the ruthenium atom [the O(1)−Ru separation is 2.126(4) Å], even if longer than in free uracil [1.227(2) Å],[15] does not significantly differ from that observed in the known uracil derivatives containing metal complexes.[5a,14a] This points to a weak interaction between the uracil moiety and the ruthenium centre. The two rings deriving from the adopted geometry of the (aminocarbene)ruthenium complex with 5-aminouracil are virtually planar. In order to analyse the influence of the coordination of one uracil carbonyl group to the ruthenium centre, the bond lengths of the uracil ring in **5** have been compared with those determined for the free ligand.[15] Five different valence isomers may be drawn in which the positive charge is moved from the metal atom to the nitrogen atoms N(3) and N(4) (Scheme 3).



Scheme 3. Structure of the possible valence isomers for the metal modified uracil ring in **5**

A perusal of the bond lengths listed in Table 1, suggests that both **IV** and **V**, in which the oxygen atom O(2) bears a negative charge, do not provide a major contribution to the representation of **5**, and, in keeping with this hypothesis, the "distal" C(10)−O(2) separation (1.203 Å), which is typical of a C=O double bond, is shorter in **5** than in the free uracil molecule [1.218(2) Å].[15] In contrast, the C(10)−N(4) bond length is definitely longer than all the other C−N distances pertaining to the uracil residue in **5**, which rules out the occurrence of a ketoimine equilibrium involving N(4) and O(2). The closeness of two positive charges in **V** also agrees with this observation. In accordance with a significant contribution from the structures **II** and **III**, both C(9)−N(3) and C(11)−N(4) bond lengths are slightly shorter in **5** than in the free uracil while the separations C(9)−C(8) and C(8)−C(11) are longer and shorter, respectively, with respect to the free nucleobase. On the basis of all these findings, it is conceivable that form **I** corresponds to the closest representation of the cationic complex **5**.

Although one of the two carbonyl groups of the uracil moiety is blocked by coordination to the ruthenium centre, preventing H-bonding, **5** still presents a potential hydrogen bond donor/hydrogen bond acceptor/hydrogen bond donor arrangement (DAD),[16] capable of forming hydrogen bonds with molecules containing complementary ADA or AD ends (Scheme 4).



Scheme 4

The formation of centrosymmetric [2+2] "dimer pairs" by association of N−H···O hydrogen bonds between an amide N−H group of one molecule of **5** with the "free" carbonyl oxygen atom of a second molecule of **5** and vice versa could be expected. Actually, the analysis of the crystal packing of **5** does not permit us to detect any links via hydrogen bonds between independent molecules, even if geometrical complementarity is unaltered.

NMR Spectroscopic Studies of the H-Binding Properties of the (Aminocarbene)ruthenium Complexes 5 and 6

Because of coordination to the metal centre in **5** (and **6**), it is evident that the "usual" H bonding at the uracil (or adenine) fragment is not possible. Nevertheless, the new aminocarbenes **5** and **6** bear appropriate hydrogen bonding molecular recognition sites, which could, in principle, still form non-covalent host-guest assemblies with suitable substrates.[5a,17] Therefore, in order to assess this property, we decided to study how the ^{1}H NMR chemical shift of the N−H protons of **5** and **6** change as a function of the sample concentration and of the presence of substrates with complementary hydrogen-bonding recognition sites.[18] At first, we noticed that, independently from the solvent used, (CD_2Cl_2 or CD_3CN), the N−H chemical shift of both **5** and **6** is not concentration-dependent. Whereas this fact is quite intriguing and suggests that dimerisation of these nucleobase aminocarbenes does not occur through hydrogen bonding, it can be related with the information derived from the X-ray study of **5**. This behaviour does not have a clear explanation as electrostatic repulsions between cationic organometallic species, steric hindrance due to the

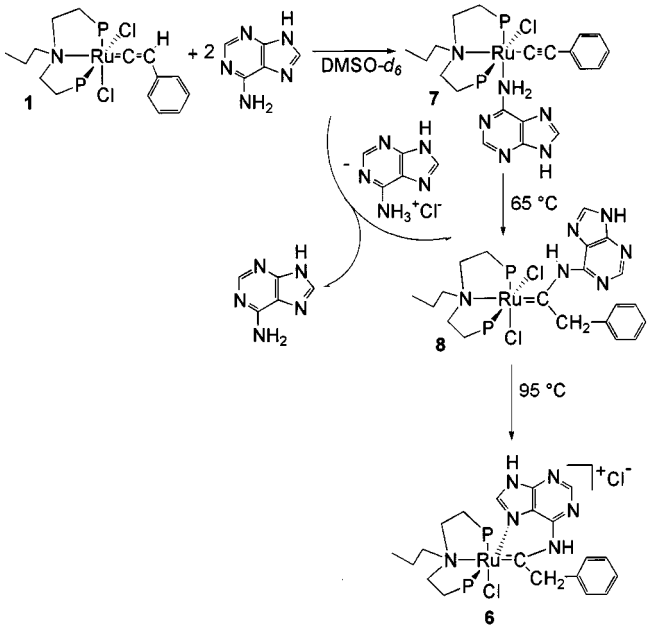
presence of bulky ancillary ligands,[19] or even changes in the electronic distribution in the metal-bounded nucleobases,[20] could be responsible. In order to understand better this piece of evidence, we unsuccessfully attempted to detect by ^{1}H NMR spectroscopy the formation of hydrogen bonding adducts of **5** in the presence of adenine. The latter could indeed act as a neutral sterically nondemanding molecule with a DA (DA = donor/acceptor)[16] motif capable of utilising only one hydrogen bond acceptor and donor motif of the uracil derivative **5** in a Watson−Crick manner.[16,17] This negative result could suggest that either electrostatic repulsions or steric hindrance at the approaching of a complementary motif to the metal-modified uracil are not decisive. In any case, it can be anticipated that O-binding of the uracil ring to a metal ion significantly disturbs its electronic complementarity with the adenine partner.

Mechanism of the Formation of the Nucleobase Carbene Complexes

The mechanism accounting for the formation of the vast family of PNP aminocarbene derivatives by nucleophilic attack of primary amines to the (vinylidene)ruthenium complex **1** encompasses a well-established pathway requiring 2 equiv. of amine.[9,10] In summary, the first amine equivalent deprotonates the vinylidene C_β carbon atom, while the second one coordinates the metal centre prior to be transferred, by an intramolecular nucleophilic attack, on the C_α carbon atom of the alkynyl intermediate (Scheme 1).

The synthetic route to both **5** and **6** most likely goes through a related pathway with the obvious changes expected by the formation of the metallated aminocarbenes. In the case of **6**, the N(7) atom of the adenine is responsible for chelation at the ruthenium centre affording the unprecedented cyclic adeninylcarbene **6**. Remarkably, once formed, **5** is much more robust than **6** indicating that the Ru−O=C interaction involving the uracil system is much more stable than the Ru−N(7) interaction of the aminocarbene deriving from adenine.

Monitoring the reaction between **1** and adenine in an NMR tube via ^{1}H and ^{31}P NMR spectroscopy is a straightforward method to providing experimental evidence for the proposed mechanism as well as confirming that for **6,** the final reaction product is an N(7)-metallated adeninylcarbene (Scheme 5). In the case at hand, when 2 equiv. of adenine are dissolved in a 5-mm NMR tube containing a solution of **1** in [D_6]DMSO and the solution is monitored by ^{31}P NMR spectroscopy, a neat reaction takes place at room temperature affording a single compound displaying a well-resolved AB spin system at δ = 53.90 and 52.01 with $J_{P,P}$ = 35.2 Hz. The latter derives from the chemical inequivalence of the two PPh_2 groups in the adenine complex *fac*,*cis*-[(PNP)RuCl(C≡CPh)($NH_2C_5H_3N_4$)] (**7**) that forms after the substitution of one chloride ligand by an amine. Attempts to isolate **7** by stripping off DMSO at room temperature leave a yellowish residue whose ^{31}P NMR spectrum denies a simple analysis owing to the accompanying presence of several unidentified products. Nevertheless, the IR spectrum of this solid species exhibits a sharp IR absorption at 2050 cm^{-1} assigned to the phenylethynyl ligand in **7**. Heating the [D_6]DMSO solution of **7** at 65 °C turns the light yellow colour to greenish yellow as **7** transforms into a new compound still exhibiting an AB spin system in the phosphorus NMR spectrum. The formation of this latter species, assigned to the nonmetallated neutral (aminocarbene)ruthenium complex *fac*,*cis*-[(PNP)$RuCl_2${C($NHC_5H_3N_4$)(CH_2Ph)}] (**8**), is accompanied by the appearance of the final metallated derivative **6**. In keeping with the accepted mechanistic hypothesis, on transforming **7** into **8** (and then into **6**), the informative AB system of the diastereotopic benzylic CH_2 protons and the featureless NH signal of the aminocarbene (δ = 11.91) rises in the ^{1}H NMR spectrum indicating that the intramolecular ruthenium-mediated attack of the adenine-NH_2 end has just occurred along the C=C moiety of the vinylidene ligand. The conversion of **8** into **6** is not completed at 65 °C in 1 d and goes to completion only after prolonged heating at 95 °C. A perusal of the collected pieces of evidence makes it reasonable to assign **6** to a structure similar to that ascertained in **5** by X-ray methods.



Scheme 5

Conclusions

In this paper we have described the first examples of transition metal carbenes incorporating nucleobases such as adenine and 5-aminouracil. Surprisingly these novel bio-organometallic derivatives exploit a new coordination mode towards a ruthenium centre. Thus, in the 5-aminouracil derivative a six-membered ring is closed by metallation of the oxo group on C(4) while in the adenine complex the aminocarbene uses the nitrogen atom N(7) to coordinate the ruthenium atom. This behaviour is quite surprising and has no precedents either in the series of PNP(carbene)Ru

derivatives, or, to the best of our knowledge, in the coordination chemistry of these nucleobases. As a final consideration, it can be stressed that the present coordination mode of the two nucleobases has an important influence on their hydrogen-bonding pattern.

Experimental Section

General Procedures: Dimethylformamide (DMF), *n*-hexane and dichloromethane were purified by distillation under nitrogen over molecular sieves, sodium and P_2O_5, respectively. Adenine and 5-aminouracil were purchased from Aldrich and used as received. All the other reagents and chemicals were reagent grade and, unless otherwise stated, were used as received from commercial suppliers. All reactions and manipulations were routinely performed under dry nitrogen by using standard Schlenk-tube techniques. The solid complexes were collected on sintered glass-frits and washed with light petroleum ether (b.p. 40−60 °C) before being dried in a stream of nitrogen. The ligand $CH_3CH_2CH_2N(CH_2CH_2PPh_2)_2$ (PNP)[21] and the vinylidene complex *fac*,*cis*-[(PNP)RuCl$_2${C=C(H)Ph}] (**1**),[10b] were prepared as described in the literature. [D$_6$]DMSO for NMR measurements (Aldrich) was dried with molecular sieves (0.4 nm). ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded with Varian VXR 300 or Bruker AC200 spectrometers operating at 299.94 or 200.13 MHz (^{1}H) and 75.42 or 50.32 MHz (^{13}C), respectively. Peak positions are relative to tetramethylsilane and were calibrated against the residual solvent resonance (^{1}H) or the deuterated solvent multiplet (^{13}C). ^{13}C-DEPT-135 experiments were run with the Bruker AC200 spectrometer. ^{31}P{^{1}H} NMR spectra were recorded with the same instruments operating at 121.42 and 81.01 MHz, respectively. Chemical shifts were measured relative to external 85% H_3PO_4 with downfield values taken as positive. Infrared spectra were recorded as Nujol mulls with a Perkin−Elmer 1600 series FT-IR spectrometer between KBr plates. The molar conductivities were measured with an AMEL model 134 conductance cell connected with a model 101 conductivity meter. The conductivity data were obtained at sample concentration of 10^{-3} M in 1,2-dichloroethane solution at room temperature (22 °C). Elemental analyses (C,H,N) were performed using a Carlo Erba model 1106 elemental analyser.

Synthesis of *fac*,*cis*-[(PNP)RuCl{C(NHC$_4$H$_3$N$_2$O$_2$)(CH$_2$Ph)}]Cl (5): A fourfold excess of 5-aminouracil (0.27 g, 2.12 mmol) was added in small portions at room temperature to a stirred suspension of the vinylidene complex **1** (0.40 g, 0.53 mmol) in 30 mL of dichloromethane. The reaction mixture was stirred for 30 min and then DMF (15 mL) was added and the temperature gently raised to evaporate all the dichloromethane and then to about 110 °C. Heating was continued for 30 min to afford a light yellow solution, which was concentrated to dryness under vacuum. The crude yellowish material was taken with two portions (10 mL each) of a 1:2 mixture of ethanol and dichloromethane and the excess of unchanged 5-aminouracil was separated by filtration of the hot solutions. The filtered yellow solutions were collected in an Erlenmeyer flask and concentrated to ca. 5 mL. Addition of petroleum ether (3 mL) and slow concentration in air gave lemon-yellow crystals of the aminocarbene complex **5** that were recrystallised from dichloromethane and methanol in air to yield the solvate salt **5·CH$_3$OH·H$_2$O**. Yield ca. 82%. $C_{44}H_{49}Cl_2N_4O_4P_2Ru$ (931.16): calcd. C 56.72, H 6.01, N 5.30; found C 56.39, H 5.89, N 6.10. IR: $\tilde{\nu}$ = 3400 (br, m, ν_{NH}), 1720 (s, $\nu_{C=O}$), 1643 (s, $\nu_{C=O-Ru}$), 1621 (sh, $\nu_{C=C}$) cm^{-1}. ^{31}P{^{1}H} NMR (22 °C, [D$_6$]DMSO, 121.42 MHz): AB system: δ_A = 55.24, δ_B = 50.14, $^2J(P_A,P_B)$ = 32.5 Hz. ^{1}H NMR (22 °C, [D$_6$]DMSO, 299.94 MHz): δ = 12.4 [br, 2 H, NH(uracil)], 11.70 [s, 1 H, NH(aminocarbene)], 8.04 [s, 6-H, 1 H, CH(uracil)], 5.13 (CH_2Ph), 4.75 [AB system, $^3J_{H,H}$ = 16.9 Hz, 2 H]. ^{13}C{^{1}H} NMR (22 °C, [D$_6$]DMSO, 75.42 MHz): δ = 257.9 [t, $^2J_{C,P}$ = 13.9 Hz, Ru=*C*], 161.3 [*C*=O(uracil)], 149.1 (s, C-2 and C-4), 118.0 [s, C-6, C=*C*H(uracil)], 66.0 [br d, $^3J_{C,P}$ = 2.2 Hz, *C*H$_2$Ph].

Synthesis of *fac*,*cis*-[(PNP)RuCl{C(NHC$_5$H$_3$N$_4$)(CH$_2$Ph)}]Cl (6): A threefold excess of adenine (0.22 g, 1.63 mmol) was added at room temperature to a stirred suspension of the vinylidene complex **1** (0.40 g, 0.53 mmol) in 20 mL of DMF. The reaction mixture was stirred for 10 min and then gently heated to about 110 °C. Heating was continued for 30 min to afford a light orange solution, which was concentrated to dryness under vacuum. The crude orange material was combined with two portions (10 mL each) of hot dichloromethane and the excess of unchanged adenine was separated by filtration through a cotton plug. Addition of *n*-hexane (8 mL) and concentration of the orange solution under nitrogen gave orange yellowish crystals of the aminocarbene complex **6** that were recrystallised from dichloromethane/*n*-hexane (2:1). Yield ca. 74%. $C_{44}H_{46}Cl_2N_6P_2Ru$ (892.81): calcd. C 59.19, H 5.19, N 9.41; found C 58.87, H 5.20, N 9.22. IR: $\tilde{\nu}$ = 3480−3350 cm^{-1} (br, ν_{NH}). ^{31}P{^{1}H} NMR (22 °C, [D$_6$]DMSO, 81.01 MHz): AB system: δ_A 47.74, δ_B 39.21, $^2J(P_A,P_B)$ = 27.5 Hz. ^{1}H NMR (22 °C, [D$_6$]DMSO, 299.94 MHz): δ = 13.9 [br. d, $J_{H,P}$ = 12.4 Hz, 1 H, NH(aminocarbene)], 8.75 [s, 1 H, NH(adenine)], 8.62 [CH(adenine)], 7.90 (s, 2 H, 2-H + 8-H), 5.88 (CH_2Ph), 5.25 [AB system, $^3J_{H,H}$ = 16.8 Hz, 2 H]. ^{13}C{^{1}H} NMR (22 °C, [D$_6$]DMSO, 75.42 MHz): δ = 284.5 [t, $^2J_{C,P}$ = 19.2 Hz, Ru=*C*], 154.7 [s, C-5(adenine)], 152.6 [s, C-2(adenine)], 146.8 [s, C-4(adenine)], C-8(adenine) not observed, likely masked by aromatic resonances, 56.3 (s, *C*H$_2$Ph).

Synthesis of *fac*,*cis*-[(PNP)RuCl{C(NHC$_4$H$_3$N$_2$O$_2$)(CH$_2$Ph)}](BPh$_4$) (5-BPh$_4$) and *fac*,*cis*-[(PNP)RuCl{C(NHC$_5$H$_3$N$_4$)(CH$_2$Ph)}](BPh$_4$) (6-BPh$_4$): Metathetical reaction of **5** or **6** with $NaBPh_4$ (2 equiv.) in CH_2Cl_2/EtOH (2:1) yielded the tetraphenylborate salts *fac*,*cis*-[(PNP)RuCl{C(NHC$_4$H$_3$N$_2$O$_2$)(CH$_2$Ph)}](BPh$_4$) **(5-BPh$_4$)** and *fac*,*cis*-[(PNP)RuCl{C(NHC$_5$H$_3$N$_4$)(CH$_2$Ph)}](BPh$_4$) **(6-BPh$_4$)** in almost quantitative yields. **5-BPh$_4$:** $C_{67}H_{63}BClN_4O_2P_2Ru$ (1165.54): calcd. C 69.04, H 5.45, N 4.81; found C 69.67, H 5.65, N 4.59. **6-BPh$_4$:** $C_{68}H_{66}BClN_6P_2Ru$ (1176.59): calcd. C 69.42, H 5.65, N 7.14; found C 69.56, H 5.42, N 6.84. $\Lambda_{M(5\text{-}BPh4)}$ = 26 Ω^{-1} cm^2 mol^{-1} (295 K, in 1,2-dichloroethane). $\Lambda_{M(6\text{-}BPh4)}$ = 24 Ω^{-1} cm^2 mol^{-1} (295 K, in 1,2-dichloroethane).[22] IR: $\tilde{\nu}$ = 612 cm^{-1} (m, ν_{BC}).

In situ NMR Spectroscopic Study of the Reaction of 1 and Adenine: A 5-mm NMR tube was filled under nitrogen with **1** (20 mg, 0.026 mmol), adenine (7 mg, 0.052 mmol) and [D$_6$]DMSO (0.8 mL). ^{31}P{^{1}H} NMR monitoring of the reaction showed the fast and complete conversion of **1** into *fac*,*cis*-[(PNP)RuCl(C≡CPh)(NH$_2$C$_5$H$_3$N$_4$)] (**7**). After 2 h, when **7** was the only ruthenium complex, the temperature of the probehead was raised to 65 °C and the NMR analysis showed a slow conversion of **7** into a mixture of *fac*,*cis*-[(PNP)RuCl$_2${C(NHC$_5$H$_3$N$_4$)(CH$_2$Ph)}] (**8**) and **6** {after 12 h: **8** (68%), **6** (30%), *mer*,*trans*-[(PNP)RuCl$_2$(CO)] (2%)}. Heating to 95 °C completed the transformation of **8** into **6** in 24 h, but caused the formation of several unidentified compounds {after 24 h at 95 °C: **6** (81%), **8** (5%), *mer*,*trans*-[(PNP)RuCl$_2$(CO)] (3%), *fac*,*cis*-[(PNP)RuCl$_2$(CO)] (2%), unidentified compounds (9%, δ = 46.9, 36.5, 34.9 all singlets)}.

***fac*,*cis*-[(PNP)RuCl(C≡CPh)(NH$_2$C$_5$H$_3$N$_4$)] (7):** ^{31}P{^{1}H} NMR (22 °C, [D$_6$]DMSO, 121.42 MHz): AB system: δ_A 53.90, δ_B 52.01,

$^2J(P_A,P_B)$ = 35.2 Hz. ^1H NMR (22 °C, [D$_6$]DMSO, 299.94 MHz): δ = 3.21 (br. s, 2 H, NH_2, superimposed to aliphatic resonances of PNP ligand), , 8.60 [NH(adenine) and CH(adenine)], 8.52, 7.85 (all s, NH, 2-H, 8-H, 3 H).

***fac*,*cis*-[(PNP)RuCl$_2${C(NHC$_5$H$_3$N$_4$)(CH$_2$Ph)}] (8):** $^{31}P\{^1H\}$ NMR (22 °C, [D$_6$]DMSO, 121.42 MHz): AB system: δ_A 49.69, δ_B 37.99, $^2J(P_A,P_B)$ = 28.0 Hz. ^1H NMR (22 °C, [D$_6$]DMSO, 299.94 MHz): 11.91 [br. s, 1 H, NH(aminocarbene)], , 8.88 [NH(adenine) + CH(adenine)], 8.56, 8.21 (all s, NH, 2-H, 8-H, 3 H), 5.04 (CH_2Ph), 4.87 [AB system, $^3J_{H,H}$ = 17.1 Hz, 2 H]. $^{13}C\{^1H\}$ NMR (22 °C, [D$_6$]DMSO, 75.42 MHz): 279.9 [t, $^2J_{C,P}$ = 13.6 Hz, Ru=*C*], 163.7 [s, C-5(adenine)], 156.1 [s, C-2(adenine)], 141.3 [s, C-4(adenine)], C-6(adenine) and C-8(adenine) not observed, likely masked by aromatic resonances, 62.6 [t, $^3J_{C,P}$ = 1.9 Hz, *C*H$_2$Ph].

X-ray Diffraction Study of *fac*,*cis*-[(PNP)RuCl{C(NHC$_4$H$_3$N$_2$O$_2$)(CH$_2$Ph)}]Cl·CH$_3$OH·H$_2$O (5·CH$_3$OH·H$_2$O): A lemon-yellow crystal of **5·CH$_3$OH·H$_2$O** was chosen for an X-ray analysis. A summary of crystal and intensity data for the compound is presented in Table 2. Experimental data were recorded at room temperature with an ENRAF-NONIUS CAD4 diffractometer using graphite-monochromated Mo-K_α radiation. A set of 25 carefully centred reflections in the range 7.5° ≤ θ ≤ 9° was used for determining the lattice constants. As a general procedure, the intensity of three standard reflections was measured periodically every 2 h for orientation and intensity control. This procedure did not reveal any decay of intensities. The data were corrected for Lorentz and polarisation effects. Atomic scattering factors were those tabulated by Cromer and Waber[23] with anomalous dispersion corrections taken from ref.[24] An empirical absorption correction was applied via Ψ scan with transmission factors in the range 1.0−0.9. All the calculations were performed using the WINGX package[25] SIR97,[26] SHELX97[27] and ORTEP-III.[28] Final atomic coordinates with equivalent isotropic thermal parameters of all atoms and structure factors are available as supplementary material. All the non-hydrogen atoms were found through a series of F_0 Fourier maps. Refinement was done by full-matrix least-squares calculations, initially with isotropic thermal parameters, and then, in the last least-squares cycle, with anisotropic thermal parameters for all atoms, except the solvents ones. All of the phenyl rings were treated as rigid bodies with D_{6h} symmetry and C−C distances fixed at 1.39 Å. Hydrogen atoms of the PNP ligand were introduced in calculated positions, but not refined. At an advanced stage of the refinement, two solvent molecules, one of methanol and the other of water, were located in the Fourier map and successfully refined. CCDC-172155 (**5·CH$_3$OH·H$_2$O**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Three Novel End-to-End Single Azido-Bridged Ferromagnetic Copper(II) Chains: Synthesis, Crystal Structure, and Magnetic Behavior

Partha Sarathi Mukherjee,[a] Tapas Kumar Maji,[a] Albert Escuer,*[b] Ramon Vicente,[b] Joan Ribas,[b] Georgina Rosair,[c] Franz A. Mautner,[d] and Nirmalendu Ray Chaudhuri*[a]

Keywords: Copper / N ligands / Azido bridge / Magnetic properties

Three new single end-to-end azido-bridged copper(II) chains $[Cu(L1)(N_3)]_n(ClO_4)_n$ (**1**), $[Cu(L2)(N_3)]_n(ClO_4)_n$ (**2**), and $[Cu(L3)(N_3)]_n(ClO_4)_n$ (**3**) using three different tridentate Schiff bases L1, L2, and L3, obtained from condensation of pyridine-2-carbaldehyde with *N*,*N*-dimethylethane-1,2-diamine, *N*,*N*-diethylethane-1,2-diamine, and 4-(2-aminoethyl)morpholine, respectively, have been synthesized, and their crystal structures have been determined by X-ray diffraction methods. Complex **1**, $C_{10}H_{15}CuN_6ClO_4$, crystallizes in an orthorhombic system, space group $P2_12_12_1$, with a = 7.434(3), b = 12.047(4), c = 17.404(6) Å, and Z = 4; complex **2**, $C_{12}H_{19}CuN_6ClO_4$, crystallizes in an orthorhombic system, space group $Pna2_1$, with a = 14.723(5), b = 13.829(5), c = 8.002(5) Å, and Z = 4 and complex **3**, $C_{12}H_{17}CuN_6ClO_5$, crystallizes in an orthorhombic system, space group $Pna2_1$, with a = 13.837(15), b = 14.804(2), c = 8.050(4) Å, and Z = 4. Each structure consists of a single end-to-end azido-bridged copper(II) 1D chain where each copper(II) center possesses a square pyramidal geometry. Magnetic susceptibility data, measured from 4 to 300 K, show weak ferromagnetic interaction through the end-to-end bridging azido pathway in all the complexes. The magnetic data were fitted to a high temperature series-expansion for a one-dimensional system with $S = {}^1/_2$ local spin based on the Hamiltonian $H = -J\Sigma S_i \cdot S_{i+1}$ for all the complexes**,** giving the parameters J = +2.15 cm^{-1}, g = 2.23 for **1**, J = +3.61 cm^{-1}, g = 2.16 for **2**, and J = +2.06 cm^{-1}, g = 2.17 for **3**. This unusual magnetic behavior through the end-to-end bridging azido pathway has been correlated to the structural parameters.

Introduction

Recently, chemists as well as physicists have concentrated their efforts on the study of multinuclear molecular-based magnetic materials from the need to understand the fundamental science associated with magnetic interactions between the paramagnetic metal ions and the bridging ligands to develop the magneto-structural correlation enabling the design synthesis of interesting magnetic materials.[1−4] These molecular-based magnets can be designed to yield dimer, tetramer, mono-, bi-, and three-dimensional extended structures[5−8] with the paramagnetic metal ions using suitable bridging ligands which act as a superexchange pathway between paramagnetic centers and determine the strength of magnetic interactions i.e., the coupling parameter (J). The construction of molecular-based magnetic materials with ferromagnetic ordering is one of the major challenges in magneto-chemistry. The proper choice of the bridging ligand, which determines the magnetic behavior of the molecule, is an important task to the chemist for synthesizing such type of materials.

The azido ligand is an efficient superexchange pathway for propagating magnetic interaction between the paramagnetic centers such as copper(II), giving dimeric, tetranuclear, cubane, 1D, 2D, and 3D complexes.[9−17] The versatility of this ligand is due to its diverse binding modes leading to a variation in the magnetic properties that depend on its orientation with respect to the magnetic centers.[18] In general, the bridging modes observed for the azido group are end-to-end with anti-ferromagnetic interaction[19,20] and end-on with ferromagnetic interaction.[21] However, the magnetism of the latter is dependent on the M−N−M angle.[22−27] For copper(II) systems, ferromagnetic interaction is observed for complexes having Cu−N−Cu angles less than 108°. For angles above this value, molecules show antiferromagnetic interaction.[27] Hoffmann et al.[28] and later Ribas et al.[29] showed the possibility of even ferro-

magnetic interaction through an end-to-end azido pathway on the basis of theoretical calculations. This theory has been successfully tested in a scarce number of complexes. Only a few structurally solved M^{II} systems, showing weak ferromagnetic interaction through the end-to-end bridging azido pathway have recently been reported in the literature.[30−33] One of them is a 1D chain of Ni^{II} with an end-to-end azido-bridge using a nonchelating capping co-ligand[30] and the second one is a dimer of Ni^{II} using a chelating co-ligand.[31] Recently this laboratory reported the first observation of a ferromagnetic interaction through end-to-end azido pathways in a copper(II) system.[32,33] This unusual result prompted us to synthesize more and more such complexes types. In the present paper we report on the synthesis, X-ray crystal structures of three new 1D single azido-bridged copper(II) chains, $[Cu(L1)(N_3)]_n(ClO_4)_n$ (**1**), $[Cu(L2)(N_3)]_n(ClO_4)_n$ (**2**), and $[Cu(L3)(N_3)]_n(ClO_4)_n$ (**3**) where L1, L2, and L3 are three different Schiff bases obtained from the condensation of pyridine-2-carbaldehyde with *N*,*N*-dimethylethane-1,2-diamine, *N*,*N*-diethylethane-1,2-diamine, and 4-(2-aminoethyl)morpholine, respectively, and observation of unusual ferromagnetic interaction through the end-to-end azido pathway.

Results and Discussion

IR Spectroscopy

The presence of strong bands at 2062, 2075, and 2070 cm^{-1} in the IR spectrum of complexes **1**, **2**, and **3,** respectively, are due to asymmetric stretching of azide. Peaks at 1662, 1659, and 1674 cm^{-1} in the IR spectrum of **1**, **2**, and **3**, respectively, are due to the stretching of the C=N group in these complexes.

Description of the Structures

All the structures consist of 1D copper(II)-azido chain isolated by a ClO_4^- anion. In the chain structures, each copper(II) atom is coordinated by one tridentate (NNN donor) Schiff base ligand and two bridging azido ligands in a square pyramidal geometry.

$[Cu(L1)(N_3)]_n(ClO_4)_n$ (1)

A labeled scheme of **1** is shown in Figure 1. The main bond lengths and angles are listed in Table 1. Other distances and angles may be found in the deposited information (Cambridge database; see reference at the end of the

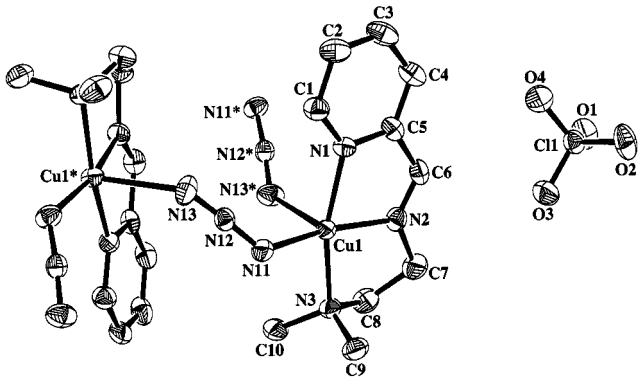

Figure 1. View of the $[Cu(L1)(N_3)]_n(ClO_4)_n$ (**1**) with atom labeling scheme showing 50% probability thermal ellipsoids for all non-hydrogen atoms

Exp. Sect.). The structure of **1** consists of copper $Cu(L1)(N_3)$ units bridged by an end-to-end azido resulting in a chain system with perchlorate counter anions. The basal plane of each copper atom consists of one tridentate L1 ligand, Cu(1)−N(1) 2.051(4), Cu(1)−N(2) 1.953(4), Cu(1)−N(3) 2.058(3) Å, and one nitrogen atom N(11) of the azido ligand *trans* to N(2) with a Cu(1)−N(11) distance of 1.947(3) Å and the apical coordination site occupied by the N(13)* atom from another azido-bridging ligand, Cu(1)−N(13)* 2.355(4) Å. One oxygen atom from the perchlorate counter anion weakly interacts with the copper atom, Cu(1)−O(1) 2.914(4) Å in a *trans* position to N(13)*. The L1 ligand is roughly planar, with N(2) and N(3) displaced 0.120(1) and 0.036(4) Å from the mean plane defined by the aromatic ring. Bond angles between N(2)−Cu(1)−N(11) and N(1)−Cu(1)−N(3) are 168.2(2)° and 163.3(2)° and the bond angles between the apical equatorial coordination sites are greater than 90°, suggesting a square pyramidal arrangement. Azido ligand acts as a single end-to-end bridge between the copper atoms, showing the Cu(1)−N(11)−N(12) and Cu(1)−N(13)* −N(12)* bond angles of 126.5(3)° and 131.2(4)°. The torsion angle Cu(1)−N(11)−N(12)−N(13)−Cu(1)* has a value of 97.8(4)° and the CuN_4 neighboring mean planes an angle of 34.6(1)°.

$[Cu(L2)(N_3)]_n(ClO_4)_n$ (2) and $[Cu(L3)(N_3)]_n(ClO_4)_n$ (3)

The labeled scheme of complexes **2** and **3** are shown in Figures 2 and 3, respectively. The main bond lengths and angles of complexes **2** and **3** are listed in Tables 2 and 3, respectively. Other distances and angles may be found in the deposited information (Cambridge database). The structures of **2** and **3** consist of $Cu(L2)(N_3)$ and $Cu(L3)(N_3)$ units, respectively, bridged by end-to-end azido resulting in a 1D coordination chain and perchlorate counter anions. Each copper atom in the polymeric chain is in a square pyramidal geometry. The local environment of the copper atoms in both the complexes consists of one tridentate Schiff base ligand and the two azido-bridging ligand. In both the complexes all three nitrogen atoms of the tridentate ligands (L2 and L3) are occupied in the basal plane of

the square pyramid. In the case of complex **2** the bond lengths in the basal plane are Cu(1)−N(8) 1.961(3), Cu(1)−N(7) 2.039(3), Cu(1)−N(10) 2.068(3), and Cu(1)−N(3) 1.965(3) Å. The axial position of Cu(1) is occupied by N(1)* of the azido of the neighboring $[Cu(L2)(N_3)](ClO_4)$ moiety with a Cu(1)−N(1)* distance of 2.311(3) Å for **2**. While for complex **3** the basal plane bond lengths are Cu(1)−N(30) 1.939(7), Cu(1)−N(20) 2.064(6), Cu(1)−N(10) 2.030(6), and Cu(1)−N(3) 1.951(7) Å which is in a *trans* position to N(30) and the axial position of Cu(1) is occupied by N(1) of the azido of the neighboring $[Cu(L3)(N_3)](ClO_4)$ moiety with a Cu(1)−N(1) distance of 2.270(5) Å. The Cu(1)−N(3)−N(2)−N(1)−Cu(1)* torsion angle is 50.0(4)° and the normals to the two copper equatorial coordination planes are inclined at 15.9(1)° for **2**. For complex **3** the Cu(1)−N(1)−N(2)−N(3)*−Cu(1)* torsion angle is 40.4(8)° and the normals to the two copper equatorial coordination planes are inclined at 14.2(2)°. The intrachain copper−copper distance is 5.630(2) and 5.540(2) Å for complexes **2** and **3,** respectively, and each copper(II) in the chain has square pyramidal geometry with the Cu atom displaced towards the axial azide ligand by 0.1681(15) and 0.241(3) Å out of the equatorial plane. One of the perchlorate oxygen atoms has an intermolecular contact to copper approximately *trans* to N(1)* with a Cu(1)−O(3) distance of 3.405(5) Å in **2** and the similar contact distance in **3** is 3.398(6) Å. Such long Cu−O contact distances are beyond the bonding region.

Magnetic Results

The variable temperature magnetic susceptibility data for complexes **1−3** were recorded between 300 and 4 K. Plots of $\chi_M T$ versus T for compounds **1−3** are similar (Figure 4), showing a constant increase of the $\chi_M T$ when the temperature decreases, reaching $\chi_M T$ values between 0.68 and 0.86 $cm^3 \cdot K \cdot mol^{-1}$ per copper atom respectively, suggesting ferromagnetic interactions. On the basis of structural features of complexes **1−3** the magnetic data were fitted as chains using the one-dimensional $S = {}^1/_2$ expression based on the Hamiltonian $H = -J\Sigma S_i \cdot S_{i+1}$. A high-temperature series-

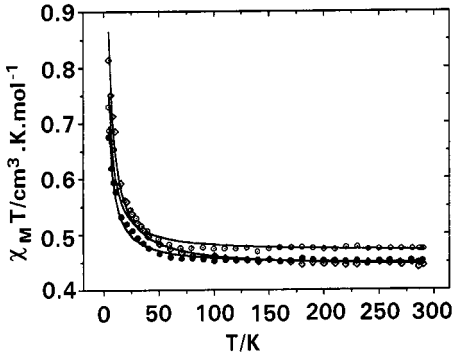

Figure 4. Plots of $\chi_M T$ vs. T (K) data for **1** (open circles), **2** (open rhombus), and **3** (filled circles); the solid lines correspond to the best fit obtained

expansion, valid for both positive and negative J values, has been proposed.[41−42] The results of the best fit, shown as the solid lines in Figure 4, were $J = +2.15$ cm^{-1}, $g = 2.23$, $R = 1.5 \cdot 10^{-4}$ for complex **1**; $J = +3.61$ cm^{-1}, $g = 2.16$, $R = 1.3 \cdot 10^{-4}$ for complex **2**; and $J = +2.06$ cm^{-1}, $g = 2.17$, $R = 1.3 \cdot 10^{-4}$ for complex **3**. These J values are of the same order as that of previously reported results for a similar compound with a tridentate Schiff base.[32]

From the EPR spectra, the g values for complexes **1**−**3** are (at 4 K): $g_{\|} = 2$, 19, 2.22, 2.22 and $g_{\perp} = 2.08$, 2.12, 2.07, respectively. The three spectra are very similar as may be expected from structural data. On cooling from room temperature down to 4 K the g values are practically constant, but the line-width becomes larger due to dipolar effects along the ferromagnetic chain for all of them.

Superexchange Mechanism

Ferromagnetic interactions for azido-bridged metal complexes are generally associated with an end-on coordination mode whereas end-to-end coordination modes of the azido bridge generally allows antiferromagnetic coupling for a large number of Cu^{II}, Ni^{II}, Co^{II}, or Mn^{II} systems reported to date.[41,43] For copper systems, the magnitude of the antiferromagnetic component of the superexchange parameter J is strongly dependent on two main factors, i.e. the atomic orbitals of the copper atoms involved in the superexchange pathway and on the M−N−N angle α and on the M−N_3−M torsion angle θ in the bridging region.

The coupling may be strongly AF when the end-to-end azido ligands are bonded to the equatorial coordination sites of the two copper atoms, in which case the atomic orbitals involved in the superexchange mechanism are the two $d_{x^2-y^2}$ orbitals. In contrast, very low coupling interactions should be expected when the interaction is between axial-equatorial coordination sites and the atomic orbitals involved are the $d_{x^2-y^2}$ and d_{z^2} respectively. The different magnetic behavior is related to the low unpaired electronic density found in the d_{z^2} atomic orbital in the square pyramidal or octahedrally coordinated copper atoms. Classical attempts to relate the magnitude of the superexchange coupling and the structural data for the axial-equatorial case conclude a greater anti-ferromagnetic coupling for the trigonal bipyramidal arrangement in agreement with the greater mixing of the $d_{x^2-y^2}$ and d_{z^2} atomic orbitals.[44] In our case, complexes **1**−**3** exhibit a square pyramidal geometry of the copper(II) with one nitrogen of the bridging azido linked to the equatorial position of one copper(II) whereas the other end nitrogen of the same azide is linked to the axial site of the neighboring copper(II) center, indicating that the spin unpaired electron is mainly located in the basal $d_{x^2-y^2}$ orbital whereas the d_{z^2} orbital contains spin paired electrons. The consequence is that there is a good delocalization of the electron density of one of the copper(II) atoms towards the bridging azido, while the delocalization from the second copper is poor because azide

occupies an apical position with a longer distance and so, a weak interaction should be expected, which is also observed experimentally.[8]

The nature of this low interaction may be ferro or antiferromagnetic, as a function of the bond parameters in the bridging region. The AF component of the superexchange may be drastically reduced for large M−N−N bond angles or large M−N_3−M torsion angles.[29] The effect of the M−N−N bond angle is not determinant in our case because the Cu−N−N bond angles, in all cases, lie below 140°, but the effect of the θ torsion angles should be considered. The maximum antiferromagnetic component is found for θ = 180 or 0° and quickly diminishes with an increase in θ and becomes zero (accidental orthogonality) for θ = 90°.[29] In compound **1** the Cu−N−N angles are 126.6 and 131.3° and the torsion angle defined by the Cu(1)−N(11)−N(12)−N(13) and the N(11)−N(12)−N(13)−Cu(1)* mean planes is 97.8°. In compound **2** the Cu−N−N angles are 131.2(3) and 139.1(3)° and the Cu−N_3−Cu torsion angle is 50.4(4)°. In compound **3** the Cu−N−N angles are 132.2(5) and 139.0(5)° and the Cu−N_3−Cu torsion angle θ is 40.4(8)°. The large Cu−N_3−Cu torsion angles, along with the axial-equatorial bridging mode of the azido ligand and the square-pyramid geometry in all these complexes orient the magnetic orbitals in almost orthogonal fashion to nullify the antiferromagnetic component of the superexchange resulting in a net weak ferromagnetic interaction.

Conclusions

We have presented here the synthesis, single crystal structure and magneto-structural correlation of three novel end-to-end single azido-bridged 1D copper(II) chains, using three different tridentate (NNN-donor) Schiff base ligands and the observation of unusual ferromagnetic interaction through end-to-end azido pathways in a copper(II) system. Fitting of the $\chi_M T$ versus T data in the temperature range between 300 and 4 K using a high temperature series-expansion for $S = {}^1/_2$ local spin lead to the coupling parameters, $J = +2.15$ cm^{-1} for **1**, $J = +3.61$ cm^{-1} for **2**, and $J = +2.06$ cm^{-1} for **3**. Positive J values as well as the nature of $\chi_M T$ versus T plot clearly indicate the existence of an intrachain ferromagnetic interaction in all of the complexes **1**−**3**. Such an unusual magnetic behavior through an end-to-end azido pathway is explained on the basis of the axial-equatorial bridging mode as well as the bond parameters like the Cu−N_3−Cu torsion angle.

Experimental Section

Caution! Perchlorate and azido complexes of metal ions in the presence of organic ligands are potentially explosive. Only a small amount of the materials should be prepared, and it should be handled with care.

Synthesis

L1, L2, and L3 Ligands: The three Schiff bases were prepared by reflux of 2 mmol of pyridine-2-carbaldehyde and 2 mmol of *N*,*N*-dimethylethane-1,2-diamine, or *N*,*N*-diethylethane-1,2-diamine, or 4-(2-aminoethyl)morpholine, respectively, in 10 mL of methanol, according to the literature methods.[34−35]

$[Cu(L1)(N_3)]_n(ClO_4)_n$ (1): A methanolic solution (10 mL) of copper(II) perchlorate hexahydrate (2 mmol) was added to the hot methanolic solution (10 mL) of the L1 (2 mmol) ligand. To the resulting deep blue cold solution, an aqueous solution (5 mL) of sodium azide (2 mmol) was added dropwise with continuous stirring and filtered. Suitable single crystals for structure determination were obtained by slow evaporation of this solution in air. Yield ca. 60%. $C_{10}H_{15}ClCuN_6O_4$: calcd. C 31.4, H 4.0, N 22.0; found C 32.0, H 4.1, N 22.3%.

$[Cu(L2)(N_3)]_n(ClO_4)_n$ (2): A methanolic solution (10 mL) of copper(II) perchlorate hexahydrate (2 mmol) was added to the hot methanolic solution (10 mL) of the L2 ligand (2 mmol). To the resulting bluish-green cold solution, an aqueous solution (5 mL) of

sodium azide (2 mmol) was added dropwise with continuous stirring. Suitable green single crystals for structure determination were obtained after a few days by slow evaporation of this dark green solution in air. Yield ca. 80%. $C_{12}H_{19}ClCuN_6O_4$: calcd. C 35.0, H 4.7, N 20.5; found C 35.2, H 4.6, N 20.2%.

$[Cu(L3)(N_3)]_n(ClO_4)_n$ (3): This complex was synthesized following the strategy adopted for complexes (**1**) and (**2**) using the ligand L3. Suitable single crystals for X-ray diffraction were obtained by slow evaporation of the final solution in a refrigerator. Yield ca. 75%. $C_{12}H_{17}ClCuN_6O_5$: calcd. C 33.9, H 4.0, N 19.8; found C 34.2, H 4.2, N 19.5%.

Crystallographic Data Collection and Refinement: The X-ray single-crystal data for compound **1** was collected on a modified STOE four-circle diffractometer. While the crystals of **2** and **3** were covered in nujol and mounted with vacuum grease on a glass fiber and transferred to a Bruker AXS P4 diffractometer[36] and data were measured at 293 K. The crystallographic data, the conditions for the intensity data collection and some features of the structure refinements are listed in Table 4. Graphite-monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) and the ω-scan technique for **1** and ψ- scan technique for **2** and **3** were used to collect the data sets. The accurate unit-cell parameters were determined from automatic centering of 54 reflections ($9.4° < \theta < 13.7°$) for **1**, 37 reflections ($2.76° < \theta < 20.82°$) for **2** and 30 reflections ($4.75° < \theta < 12.49°$) for **3** and refined by least-squares method. A total of 2755 reflections (2709 independent reflections, $R_{int} = 0.0238$) for **1**; 3244 reflections (2740 independent reflections, $R_{int} = 0.0323$) for **2**; and 1960 reflections (1707 independent reflections, $R_{int} = 0.0221$) for **3**,were collected in the range $2.89° < \theta < 30.00°$, $2.02° < \theta < 25.00°$, and $2.75° < \theta < 25.00°$ for **1**, **2**, and **3** respectively. The structures were solved by direct methods using the SHELXS-86[37] computer program, and refined by full-matrix least-squares methods on F^2, using the SHELXL-93[38] program incorporated in the SHELXTL/PC V 5.03[39] program library and the graphics program PLATON.[40] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were located on calculated positions by use of the HFIX utility of the SHELXL-93 program. For complexes **1**, **2**, and **3,** respectively, the final *R* indices for all observed reflections are 0.0426, 0.0341, and 0.0469. Maximum and minimum peaks in the final difference Fourier syntheses were 0.29 and −0.44 e·Å^{-3} for **1**, 0.31 and −0.30 e·Å^{-3} for **2**, and 0.53 and −0.84 e·Å^{-3} for **3**. Significant bond parameters are given in Tables 1−3.

Physical Measurements: IR spectra (4000−400 cm^{-1}) were recorded from KBr pellets on a Nicolet 520 FT-IR spectrometer. Magnetic measurements were carried out with a DSM8 pendulum susceptometer equipped with a helium continuous-flow cryostat, working in the temperature range 300−4 K. The applied external magnetic field was 1.5 T. Diamagnetic corrections were estimated from Pascal constants. Electronic Spin Resonance spectra of the polycrystalline samples have been recorded at X-band frequency by using a Bruker ESP 300 E automatic spectrometer from room temperature to 4 K.

CCDC-168803, -168804, and -168805 for complexes **1**, **2**, and **3**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A New μ_4-Oxo Tetranuclear Magnesium Compound: Coordination Effects of the Azolato Ligands

Nadia C. Mösch-Zanetti,*[a] Marilena Ferbinteanu,[b] and Jörg Magull[a]

Keywords: N ligands / Magnesium / Coordination modes

The μ_4-oxo tetranuclear magnesium compound $[Mg_4(\mu_4\text{-oxo})(\mu\text{-tz})_6]$ **1** (tz = 3,5-*i*Pr_2-1,2,4-triazolato) with six η^1-η^1-bridging triazolato ligands was prepared in a one-step reaction between $MgBr_2$ and tzK. The solid state structure was determined by X-ray diffraction analysis showing the tetrahedral arrangement of the Mg_4O core. The reaction of $MgBr_2$ with pzK and pzH gave $[Mg(pz)_2(pzH)_2]$ **2** (pz = 3,5-*t*Bu_2-pyrazolato), which contains hydrogen bonds between two different ligands, as established by X-ray crystal structure analysis. In solution, compound **2** shows a dynamic behavior involving two different processes. Line shape analysis of variable temperature NMR experiments suggests that the interconversion occurs via an η^2-coordination of the pyrazolato ligand.

Introduction

The structural chemistry of magnesium amido and imido compounds is becoming an increasingly active area of research. The main reason for this recent interest is their use as reagents in numerous organic transformations.[1−7] Stimulated by the desire to elucidate the mechanisms of such reactions, several magnesium bisamido species have been structurally characterized as dimeric units of the type $[R_2NMg(\mu\text{-}NR_2)_2MgNR_2]$;[8−10] monomeric compounds are formed in the presence of sterically demanding amido ligands or additional donors.[11−14] However, polynuclear species with a higher magnesium atom count are still relatively limited. The rather unusual nitrogen-centered hexameric amido species $[Mg_6(\mu_6\text{-}N)(NHtBu)_9]$ was reported as early as 1980.[15] More than 10 years later, hexameric[16] and trimeric arrangements[17,18] were found with bifunctional amido ligands. With imido ligands, hexagonal prismatic structures of the type $[\{(THF)MgNR\}_6]$ (R = Ph, 1-naphthyl) have been reported.[19,20] In addition to these pure magnesium species a nice series[21,22] of mixed alkali metal magnesium compounds including oxide-captured examples such as $[Li_2Mg_2\{N(SiMe_3)_2\}_4(O_2)_x(O)_y]$[23] and $[K_2Mg_2[N(SiMe_3)_2]_4(O_2)\}_8]$[24] has been reported by Mulvey and co-workers. In addition to these amido species, the oxo-centered lithium magnesium cresylate cage $[LiMg_4OR_7\cdot 4THF]$ [R = *o*-$Me(C_6H_4)O^-$] has been reported.[25]

Pyrazolates and triazolates are known to be good bridging ligands for the synthesis of polynuclear complexes[26] and have proven to coordinate to magnesium in a μ_2-bridging mode[27,28] as well as an η^2-fashion[29] forming dimeric units. This prompted us to investigate whether these ligands are suitable for the construction of unusual polynuclear magnesium species. Herein, we present the synthesis and X-ray crystal structure determination of the μ_4-oxo tetranuclear magnesium compound $[Mg_4(\mu_4\text{-oxo})(\mu\text{-tz})_6]$ **1** (tz = 3,5-*i*Pr_2-1,2,4-triazolato) with six η^1-η^1-bridging triazolato ligands. Due to a structural pattern similar to those known for divalent transition metal ions, compound **1** is an appropriate model for the investigation of structural factors that are independent of the *d*-electron configuration. The second compound $[Mg(pz)_2(pzH)_2]$ **2** (pz = 3,5-*t*Bu_2-pyrazolato) employing a more sterically demanding pyrazolato ligand features both protonated and deprotonated ligands allowing an in-depth study of the coordination capabilities of these versatile ligands.

Results and Discussion

The general route for the synthesis of the triazole ligand starts from 4-NH_2-3,5-*i*Pr_2-1,2,4-triazole[30] (4-NH_2-tz) followed by diazotization to produce, after standard workup, tzH in high yield (Scheme 1). Sublimation under reduced pressure at 110 °C gave the analytically pure ligand. The analogous triazole ligand with *tert*-butyl substituents was not accessible since its higher steric demand prevents the formation of the heterocycle. The deprotonation of tzH was achieved with stoichiometric amounts of elemental potas-

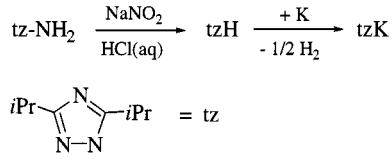
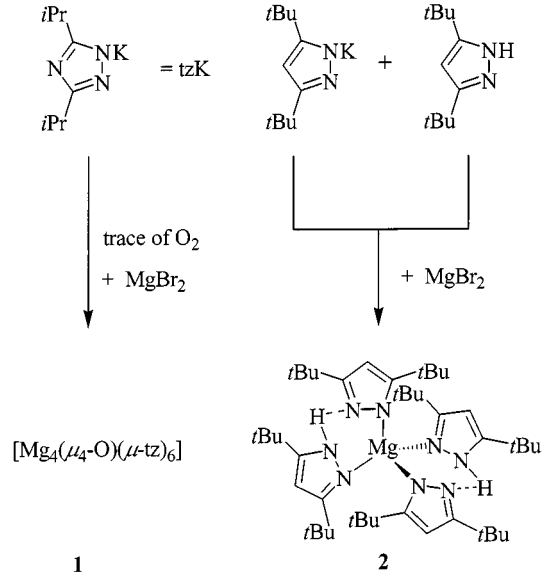
sium in refluxing THF. The white powders of tzK thus obtained were analytically pure and used without further purification. The potassium salt is slightly soluble in THF, readily soluble in acetonitrile and insoluble in hydrocarbon solvents. The ^{1}H NMR spectrum of the dried compound in CD_3CN shows no coordinated THF molecules.



Scheme 1

The reaction of magnesium bromide with two equivalents of tzK in THF at room temperature for 48 h afforded **1** in moderate yield (Scheme 2). The compound is only soluble in polar solvents such as THF, and can be separated from the finely dispersed KBr precipitate by centrifugation. Recrystallization from cold THF gave **1** as large colorless crystals. The NMR spectroscopic data in CD_3CN show signals for one kind of ligand coordinated in a symmetric fashion.



Scheme 2

The source of the oxygen anion cannot be unambiguously identified although several experiments along this line have been carried out. Repeated syntheses under more rigorous anhydrous conditions always led to the isolation of **1** arguing against the source being adventitious water. To avoid contamination with water due to residual $MgBr_2{\cdot}H_2O$, the magnesium bromide was prepared from the elements according to literature procedures.[31] The incorporation of oxygen due to a reaction with the employed grease could be ruled out by using commercially available non-silicon grease (Lithelen, Leybold Vakuum GmbH). Such a reaction is not unprecedented, although entire $O-SiMe_3$ or $O-SiMe_2$ units are usually transferred.[32–34] The cleavage of THF, which cannot be replaced due to insolubility in hydrocarbon solvents, seems unlikely. Cleavage of alkyl aryl ethers by Grignard reagents has been reported but usually requires drastic conditions,[35,36] except for certain crown ethers, where cleavage of an O–Me bond was found within 1 h at room temperature.[37] In addition, an NMR experiment in [D_8]THF ($MgBr_2$, 2 equiv. tzK and 10 equiv. THF) did not show any by-products of the cleavage. Replacement of the ethereal solvent by acetonitrile led to unidentified reaction mixtures, from which no uniform product crystallized. Incorporation of KOH remains a possibility, since the parent triazole is deprotonated by the reaction with elemental potassium. However, the yield of **1** argues against it since the potassium metal was freshly cut inside a well-maintained glove box prior to use. Finally, molecular oxygen might be a possible source as its complete exclusion is difficult to accomplish by routine Schlenk techniques. Reactions of organomagnesium compounds with oxygen are known to give peroxide[23,24] and oxide species.[38] Although this is a hint for a reaction with O_2, the oxygen source cannot be pinned down conclusively to one of the above reasons.

A structural analysis of **1** reveals a slightly distorted tetrahedral oxo-centered arrangement of four Mg atoms bridged by six η^1-η^1-triazolato ligands. Figure 1 shows an ORTEP view of **1**, crystallographic data are given in Table 1 and selected bond lengths and angles in Table 2. The Mg_4O unit is embedded in a matrix of 10 disordered molecules of THF, none of which is coordinated to a metal atom. This is consistent with the NMR spectroscopic data of the isolated and dried material in CD_3CN, where no THF signals are detectable. This is similar to the situation with the structures of proteins surrounded by disordered water molecules. Therefore, the structural parameters of the THF molecules were only approximately refined. The geometry at the four-coordinate Mg atoms is distorted tetrahedral, unlike the trigonal-bipyramidal geometry in the inorganic species [$Mg_4(\mu_4\text{-}O)(\mu\text{-}Br)_6{\cdot}4Et_2O$] published in 1964 by Stucky and Rundle,[38] where each Mg atom is additionally coordinated by an Et_2O molecule. The smaller coordination number in **1** apparently does not influence the Mg–O bond lengths {1.937(2)–1.950(2) Å in **1**; 1.95 Å in [$Mg_4(\mu_4\text{-}O)(\mu\text{-}Br)_6{\cdot}4Et_2O$][38]}. Similar structural features are exhibited by complexes of beryllium in the basic acetates [$Be_4(\mu_4\text{-}O)(RCO_2)_6$],[39] for example, and even in well-known transition metal systems such as [$Co_4(\mu_4\text{-}O)(\mu\text{-}pz)_6$],[40,41] suggesting that the formation of **1** arises from geometrical packing and ionic effects rather than from the electronic configuration of the metal. The structure of **1** should also be compared with that of the cresylate species [$LiMg_4(\mu_5\text{-}O)R_7{\cdot}4THF$] (R = *o*-Me($C_6H_4$)$O^-$),[25] where a $Mg_4(\mu_4\text{-}O)$ core is additionally coordinated by a lithium cresylate. This leads to an oxo-centered, trigonal bipyramidal $LiMg_4(\mu_5\text{-}O)$ core. Unlike in **1**, all the Mg atoms are coordinated by one molecule of THF. The Mg–O(central) bonds are slightly longer [2.002(4) to 2.041(2) Å], presumably due to the higher coordination number.

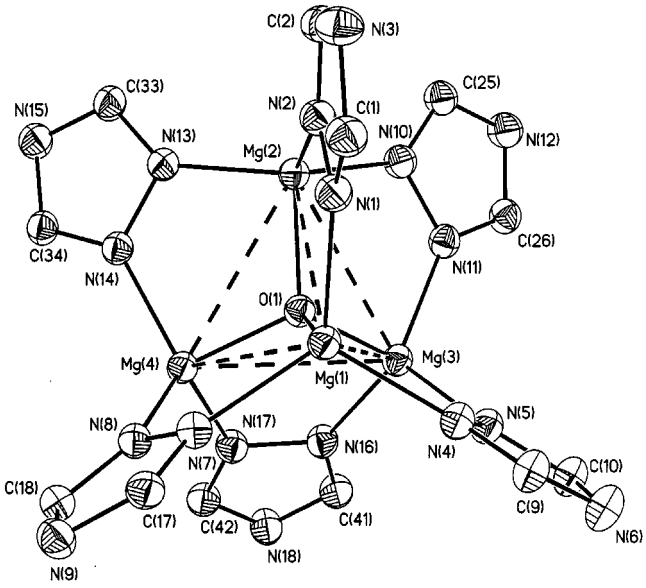


Figure 1. Molecular view of $[Mg_4(\mu_4\text{-oxo})(\mu\text{-tz})_6]$ (**1**); *iso*-propyl groups have been omitted for clarity

The $MgON_3$ tetrahedra show a pronounced trigonal distortion with the Mg atom lying almost within the N_3 plane [O(1)−Mg(1)−N(1) = 100.71°]. This structure ensures a perfect alignment of the lone pairs of the N atoms toward the metal and, in addition, obeys Bent's rules:[42,43] the hybrid orbitals pointing towards the less electronegative atom acquire a higher *s* character and therefore increased angles [N(1)−Mg(1)−N(4) = 117.16°]. The $MgON_3$ tetrahedron can be modeled with $s^{1+x/3}p^{3-x/3}$ hybrid orbitals in the Mg−N directions and with $s^{1-x}p^{3+x}$ orbitals for the Mg−O axis. From this, the N−Mg−N bond angles are arccos[−(1 + *x*/3)/(3 − *x*/3)]. Thus, the experimental angles yield an estimation of $x = 0.73$, showing a distinct redistribution of *s* vs. *p* character compared to the sp^3 reference.

Compound **2** may be prepared by two different routes. The more straightforward method involves the addition of two equiv. of pzH[44] and pzK[45] each to $MgBr_2$ in THF (Scheme 2). The product is soluble in most organic solvents, including hexane and toluene. Compound **2** may also be prepared by the addition of water to a hexane solution containing $[\{Mgpz_2\}_2]$, a species recently reported by Winter.[29] During the reaction with water, a white precipitate is formed and **2** is found exclusively in solution. Evaporation of the solvent gave pure **2** in 40% yield (based on the amount of pzK). The ^{1}H NMR spectrum in C_6D_6 of the precipitate shows six different signals in the *t*Bu region pointing to a mixture of compounds. At this point it is unclear whether one of these species is the compound $[Mg_4(\mu_4\text{-O})(\mu\text{-pz})_6]$, similar to **1**, although mass spectrometry points to its existence.[46] An interesting experiment would be a similar reaction with the triazolato ligand to find out whether water is the oxo anion source; however tzK and $MgBr_2$ do not react at all in toluene or hexane due to their insolubility in these solvents.

The solid state structure of **2** determined by X-ray crystallography shows the magnesium atom tetrahedrally surrounded by two η^1-coordinated pyrazole and two pyrazolato ligands. Figure 2 shows an ORTEP view of **2**, crystallographic data are given in Table 1 and selected bond lengths and angles in Table 2. A particular feature are the intramolecular hydrogen bonds between two pairs of different ligands [N(4)−H(4)···N(2) 2.7448(17) Å, 153(3)°] preventing the possibility of η^2-coordination [Mg(1)−N(1) 2.038(1) Å vs. Mg(1)−N(2) 2.737(1) Å] although a preference for such a coordination even in a sterically congested six-coordinate species has been previously found.[29]

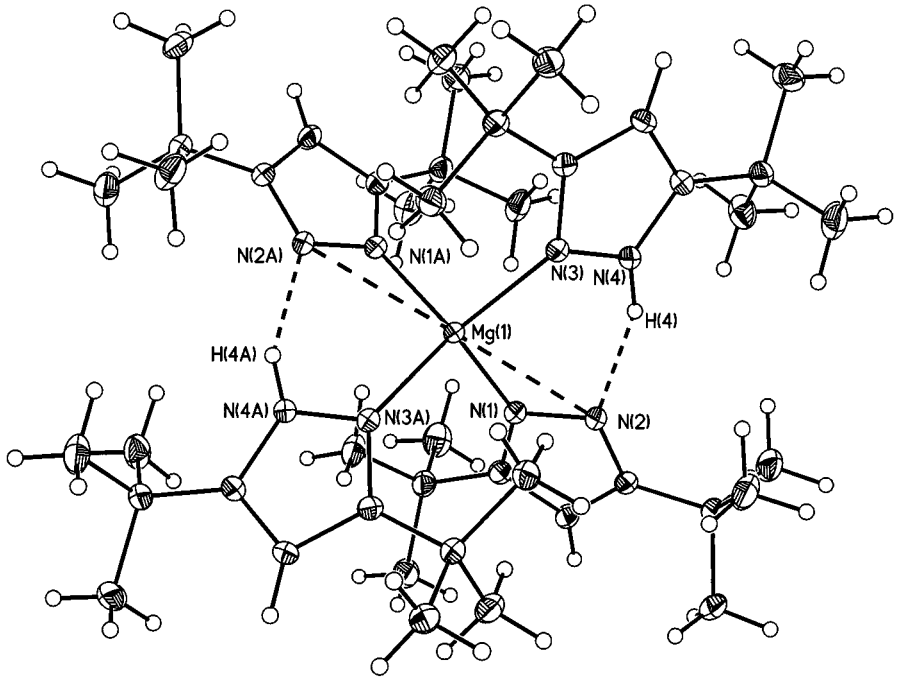

Figure 2. Molecular view of $[Mg(pz)_2(pzH)_2]$ (**2**)

The ^{1}H NMR spectrum of **2** at room temperature shows broad resonances for one kind of ligand, indicating a dynamic process. As the sample was cooled to 183 K the individual resonances of the four *t*Bu, two CH and one NH protons appeared, consistent with the structure in the solid state at 133 K (Figure 3). The temperature dependent behavior of the *t*Bu region can be modeled with two separate exchanges $A_1 \rightleftarrows B_1$ with rate constant k_τ (coalescence temperature ≈243 K) as well as $A_1(B_1) \rightleftarrows A_2(B_2)$ with rate constant k_H (coalescence temperature ≈290 K) (Figure 3). This is consistent with a rapid interchange of the A_1 and B_1 signals of the deprotonated ligand. The process coalescing at higher temperatures corresponds to the exchange of the bridging proton between different ligands interchanging A_1 in A_2 and parallel B_1 in B_2 (with equal rate constant k_H).

The rates were measured by line shape analysis by solving the following matrix:[47−49]

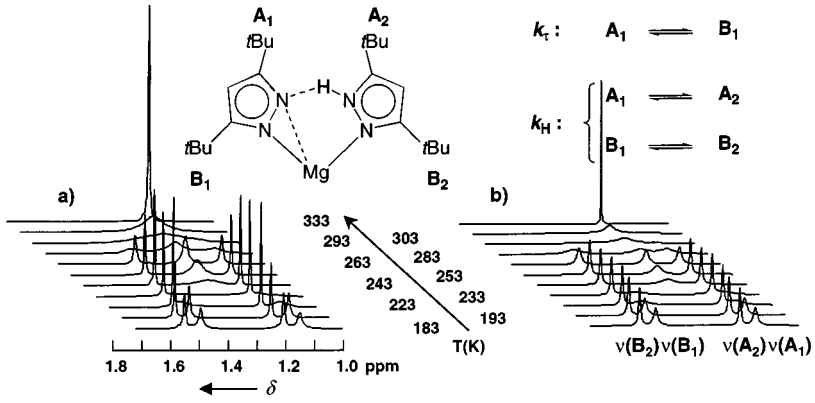

Figure 3. a) Variable temperature ^{1}H NMR spectra (500 MHz, [D$_8$]toluene) of **2** showing the *t*Bu resonances; b) computer simulated spectra and proposed kinetic processes

$$\begin{pmatrix} \nu(A_1)+\alpha T+ik_\tau(T)+ik_H(T) & 0 & -ik_\tau(T) & 0 \\ -ik_H(T) & \nu(A_2)+\alpha T+ik_H(T) & 0 & 0 \\ -ik_\tau(T) & 0 & \nu(B_1)+\alpha T+ik_\tau(T)+ik_H(T) & -ik_H(T) \\ 0 & 0 & -ik_H(T) & \nu(B_2)+\alpha T+ik_H(T) \end{pmatrix}$$

where ν denotes the chemical shift of the four types of protons.

The real part of the eigenvalues corresponds to the position of the peaks, while the imaginary part corresponds to their bandwidths. The solutions of this matrix were used to form the spectrum as the sum of four Lorentzian peaks. In addition, a slight shift of the barycenter of the experimental signals with temperature required a linear adjustment αT, which was added to each diagonal element. This is probably due to a general modification of the average Mg−N bond lengths with temperature. Targeting only a qualitative simulation, kinetic terms corresponding to spin-lattice relaxation were not ascribed. Both the chemical shift ν and the rate constant *k* have the common meaning of a frequency and therefore, in this case, *k* is defined in units of the chemical shifts. The coalescence appears when the frequency of the chemical exchange becomes similar to those of the magnetic resonance.

A fit of the chemical rate constants to the Arrhenius equation yielded activation energies of E_τ = 8.3 kcal/mol and E_H = 15.2 kcal/mol; use of the Eyring form gave similar results (E_τ = 8.0 kcal/mol and E_H = 14.7 kcal/mol). The low value of E_τ points to an interchange of the two N atoms of the deprotonated ligand via η^2-coordination. Surprisingly, in previously reported magnesium η^2-pyrazolato complexes dynamic processes were proposed, but seem to be faster than the NMR time scale.[29] The value of E_H is consistent with a facile exchange of the proton between two ligands favored by an N−H···N hydrogen bond established in the low temperature structure. These intramolecular rearrangements are complex processes at the quantum level. However, the employed classical rate laws allow a semi-quantitative statement that, due to the possible η^1- and η^2-coordination modes, the pseudo-rotation of the deprotonated ligand is more rapid than the intramolecular proton exchange.

Conclusion

Here, we present a μ_4-oxo tetranuclear main group metal compound with azolato ligands. Due to the lack of *d*-electrons, compound **1** represents a model for this structural prototype allowing the conclusion that the forces to build this structure pattern are mainly of an ionic nature and that *d-d* electron interactions seem not to play a role. In addition, our investigations of **2** offer an illustration for the paradigm used in supramolecular concepts stating that hydrogen bonds and coordination effects compete in the same range of bonding energies.

Experimental Section

General Remarks: All preparations were carried out under an atmosphere of dry nitrogen. All common reagents and solvents were purchased from commercial suppliers and used without further purification unless otherwise indicated. Melting points were determined on a Büchi B-540 melting point apparatus in sealed glass tubes and are uncorrected. NMR spectra were recorded on Bruker Avance 200 or Bruker Avance 500 spectrometers. The chemical shifts are referenced to external $SiMe_4$.

tzH: 4-NH_2-3,5-*i*Pr_2-triazole was synthesized according to a published method from *i*PrCOOH and hydrazine hydrate at 180 °C. Subsequently, a solution of 4-NH_2-3,5-*i*Pr_2-triazole (4.28 g, 0.025 mol) in aqueous HCl (6 M, 5.5 mL) was treated with a solution of $NaNO_2$ (2.01 g, 0.029 mol) in 30 mL of water and stirred until evolution of N_2 ceased. The temperature was kept in the range 20−30 °C by occasional cooling with an ice bath. After neutralization, extraction with CH_2Cl_2 and evaporation of the solvent the pure product was obtained as colorless crystals (3.42 g, 88%). m.p. 154 °C. ^{1}H NMR (C_6D_6, 200.1 MHz):δ = 12.98 (br. s, NH, 1 H), 3.19 [hept, C*H*$(CH_3)_2$, 2 H], 1.35 [d, CH$(CH_3)_2$, 12 H]. ^{13}C NMR (C_6D_6, 125.8 MHz):δ = 164.0 (C ring), 27.6 [*C*H$(CH_3)_2$], 21.5

[$CH(CH_3)_2$]. $C_8H_{15}N_3$ (153.2): calcd. C 62.71, H 9.87, N 27.42; found C 62.79, H 9.61, N 27.23.

tzK: A solution of tzH (1.65 g, 10.8 mmol) in 60 mL of THF was treated with one equivalent of potassium metal (0.43 g). The solution was stirred under reflux for 5 h after which all the metal had reacted. The solvent was removed under reduced pressure to give the product as a white powder that was pure enough for further reactions (1.92 g, 93%). m.p. > 300 °C ^{1}H NMR (CD_3CN, 200.1 MHz):δ = 2.84 [hept, 2 H, C*H*(CH_3)$_2$], 1.18 [d, 12 H, CH(C*H*$_3$)$_2$]. $C_8H_{14}KN_3$ (191.3): calcd. C 50.22, H 7.38, N 20.44; found C 49.88, H 7.29, N 20.42.

[Mg_4(μ_4-oxo)(μ-tz)$_6$] (1): Freshly distilled THF (20 mL) was added to a mixture of $MgBr_2$ (0.21 g, 1.14 mmol) and tzK (0.43 g, 2.25 mmol). The resulting suspension was stirred for 48 h at room temp. The fine precipitate was then centrifuged and the solution decanted. After evaporation of the solvent to a volume of approximately 10 mL, colorless crystals of **1** formed overnight (0.11 g, 38% based on Mg). ^{1}H NMR (CD_3CN, 200.1 MHz, room temp.): δ = 3.07 [sept, $^3J_{H,H}$ = 7 Hz, 2 H, C*H*(CH_3)$_2$], 1.16 [d, $^3J_{H,H}$ = 7, 12 Hz, CH(C*H*$_3$)$_2$]. ^{13}C NMR (CD_3CN, 125.8 MHz, room temp.): δ = 171.11 (C ring), 29.71 [*C*H(CH_3)$_2$], 23.13 [CH(*C*H$_3$)$_2$]. $C_{48}H_{84}Mg_4N_{18}O$ (1026.5): calcd. C 56.16, H 8.25, N 24.56; found C 55.78, H 8.41, N 24.03.

[Mg(pz)$_2$(pzH)$_2$] (2): Freshly distilled THF (20 mL) was added to a mixture of $MgBr_2$ (0.16 g, 0.87 mmol), pzK (0.38 g, 1.74 mmol) and pzH (0.31 g, 1.72 mmol). The resulting suspension was stirred for 48 h at room temp. The solvent was then removed under reduced pressure and the resulting white residue was extracted with hexane. After removal of hexane, the powder was recrystallized from toluene at −25 °C to give **2** as colorless crystals (0.21 g, 32%). ^{1}H NMR (C_6D_6, 500.1 MHz, 193 K): δ = 13.22 (s, 1 H, NH), 6.15 (s, 1 H, CH), 6.05 (s, 1 H, CH), 1.60 [s, 9 H, C(CH_3)$_3$], 1.54 [s, 9 H, C(CH_3)$_3$], 1.22 [s, 9 H, C(CH_3)$_3$], 1.16 [s, 9 H, C(CH_3)$_3$].). ^{13}C NMR (C_6D_6, 125.8 MHz, room temp.): δ = 159.57 (CH ring), 98.72 (C ring), 31.76 [*C*(CH_3)$_3$], 30.991 [C(*C*H$_3$)$_3$]. $C_{44}H_{78}MgN_8$ (743.5): calcd. C 70.25, H 10.54, N 14.90; found C 70.70, H 10.52, N 14.96.

X-ray Crystal Structure Analysis: The data were collected on a Stoe IPDS II-array detector system instrument with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods and refined against F^2 on all data by full-matrix least-squares procedures with SHELX-97.[50]
1: To verify the complex composition of **1**·10THF and especially the connectivity in the 10 solvent molecules, complete crystal structure determinations were carried out with five different crystals. The best results are presented in this paper. All THF molecules are disordered and refined with restraints. In the Mg_4 unit two *i*Pr groups are disordered.

CCDC-166225 (**1**) and CCDC-166226 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[49] The formation of the matrix can be intuitively described as follows: i) The real part of the matrix elements corresponds to the spin Hamiltonian; the diagonal elements contain only chemical shifts without coupling between different types of protons. ii) The imaginary part is related to the kinetic equations; nondiagonal elements -*ik*H or -*ik*t are added at intersections between the lines and columns of the corresponding interchange. iii) The sum of the imaginary parts on each diagonal element must contain all the rate constants that affect a given species. iv) The sum of the imaginary terms of each row or column must be zero.

Synthesis of the First 2*H*-1,2-Azaphosphole Complexes with P,C and P,N Ylide Functional Groups

Rainer Streubel,*[a] Nils Hoffmann,[a] H.-M. Schiebel,[a] Frank Ruthe,[a] and Peter G. Jones[a]

Dedicated to Professor Wolfgang W. Schoeller on the occasion of his 60th birthday

Keywords: Ylides / Phosphorus heterocycles / Tungsten / Cyclization

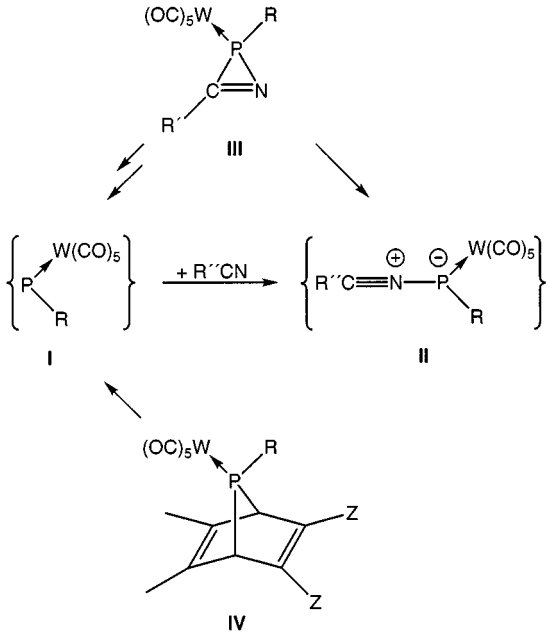
The first C^5-functionalized 2*H*-1,2-azaphosphole complexes have been obtained by the reactions of P,C and P,N ylide substituted carbonitriles and terminal phosphanediyl complexes involving transiently formed nitrilium phosphanylide complexes.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The transition metal promoted synthesis of P-heterocycles is of current interest because of the frequently observed outstanding reaction selectivities and product yields.[1] Recently, we presented a new concept in phosphorus heterocycle synthesis, which relies on the use of short-lived 1,3-dipole species that are stabilized through metal coordination, viz. nitrilium phosphanylide complexes **II**.[2] Complexes **II** may be formed by 1,1-addition of thermally generated terminal phosphanediyl complexes **I**[2,3] to carbonitriles, which is a weakly exothermic reaction according to theoretical calculations,[4] or by ring-opening of 2*H*-azaphosphirene complexes **III** (Scheme 1).[2,4] To date, the 1,1-addition of terminal phosphanediyl complexes **I** to carbonitriles has been demonstrated using two different precursor systems for **I**, namely 2*H*-azaphosphirene complexes **III**[2] and 7-phosphanorbornadiene complexes **IV**.[3,5] The former is especially useful for the transient formation of bulky *P*-substituted derivatives of **I** having a bis(trimethylsilyl)methyl (**1a**) or pentamethylcyclopentadienyl group (**1b**) attached to the phosphorus atom, whereas the latter can be employed to generate derivatives of **I** with small and/or functional substituents at the phosphorus atom.

Only two different intramolecular trapping reactions of transient nitrilium phosphanylide complexes **II** have hitherto been observed, which were shown to be very sensitive to the substituent at the phosphorus atom. For example, complex **2a** isomerized to the 2*H*-azaphosphirene complex **4a**[6] while complex **3** led to the C,N,P cage complex **5**[7] through an intramolecular [2+1] cycloaddition of the phosphanediyl phosphorus center of **3** to the Cp* π-system (Scheme 2).



Scheme 1. Generation of terminal phosphanediyltungsten complexes **I** and (nitrilium phosphanylide)tungsten complexes **II** using precursors **III** and **IV**

Furthermore, we showed that *C*-dialkylamino-, *C*-alkyl-, or *C*-aryl-substituted nitrilium phosphanylide complexes **II** reacted with electron-deficient alkynes such as dimethylacetylene dicarboxylate (DMAD) to furnish 2*H*-1,2-azaphosphole complexes through [3+2]-cycloaddition reactions.[2,8,9] It is noteworthy that only complex **2b**, which has

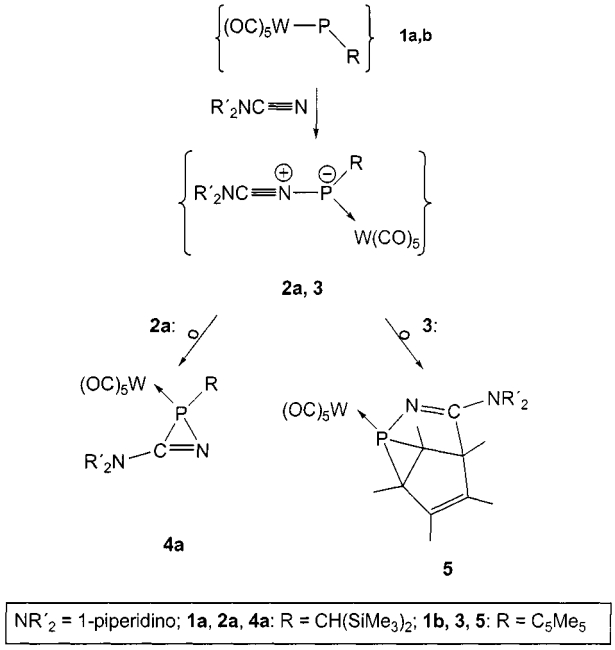
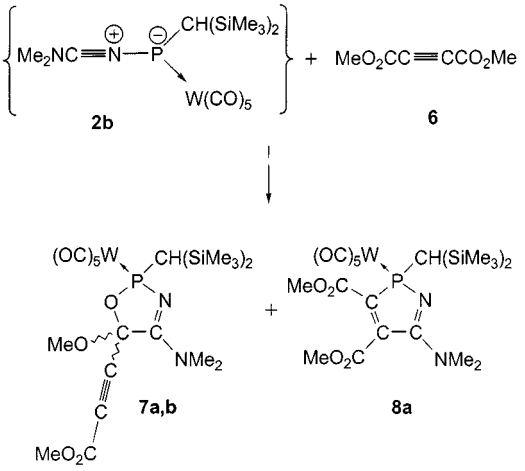


Scheme 2. Generation and intramolecular reactions of (nitrilium phosphanylide)tungsten complexes **2a** and **3**

the dimethylamino group at the carbon atom and a bulky substituent at the phosphorus atom, reacted with DMAD (**6**) to give both the Δ^3-1,3,2-oxazaphospholene complexes **7a**,**b** and the 2*H*-1,2-azaphosphole complex **8a** (Scheme 3).[10]

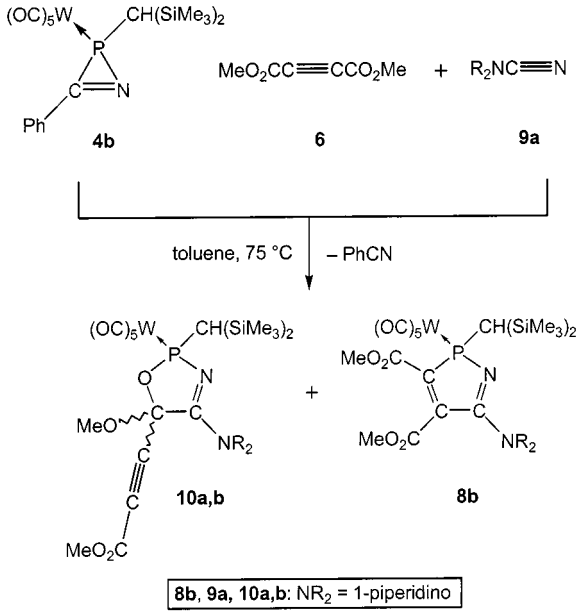


Scheme 3. Reaction modes of transiently formed (nitrilium phosphanylide)tungsten complex **2b** towards DMAD

We report herein on a comparative study of the stereoelectronic effects of various strong π-donor *C*-substituents of transiently formed [nitrilium bis(trimethylsilyl)methylphosphanylide]tungsten complexes **II** on ring-closure reactions of **II** to **III** (e.g. **1a** → **3**) and on the reactivity of **II** towards electronically activated alkynes. In view of the known electronic stabilizing effect of P,C ylide substituents in low-coordinated phosphorus compounds such as thioxophosphanes or selenoxophosphanes of the formula RPX [R = $Ph_3PC(R')$; X = S, Se[11]] we decided to include $Ph_3PC(H)CN$[12] and Ph_3PNCN[13] in this study, the latter for comparison purposes. Furthermore, we have also sought an optimized synthesis of 2*H*-1,2-azaphosphole complexes, whereby such systems can be obtained bearing new P,C and P,N ylide functional groups. The first results concerning new three-component reactions are reported herein.

Results and Discussion

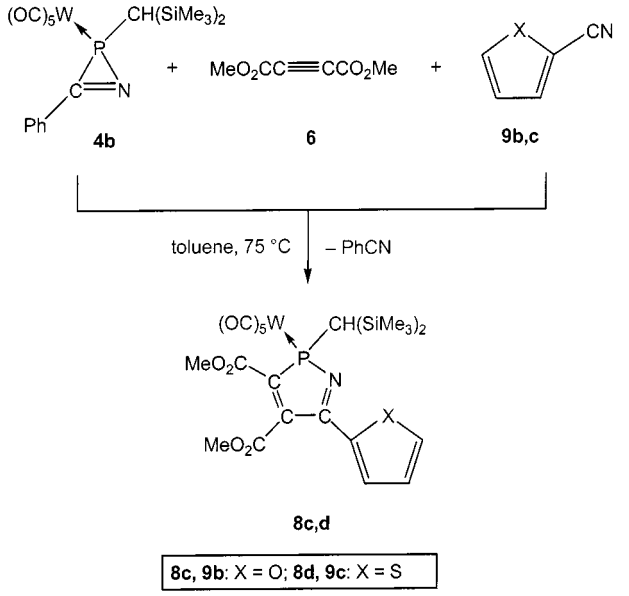
Thermal reaction of the (2*H*-azaphosphirene)tungsten complex **4b**[14] with piperidinocarbonitrile (**9a**) and DMAD (**6**) furnished the Δ^3-1,3,2-oxazaphospholene complexes **10a**,**b** and the 2*H*-1,2-azaphosphole complex **8b** in a 1:1:1 ratio as the phosphorus-containing products. Although only complexes **10a** and **8b** could be isolated by column chromatography, complex **10b** was readily identified by its ^{31}P NMR spectroscopic data (δ = 191.8, $^1J_{W,P}$ = 305.7 Hz) (Scheme 4).



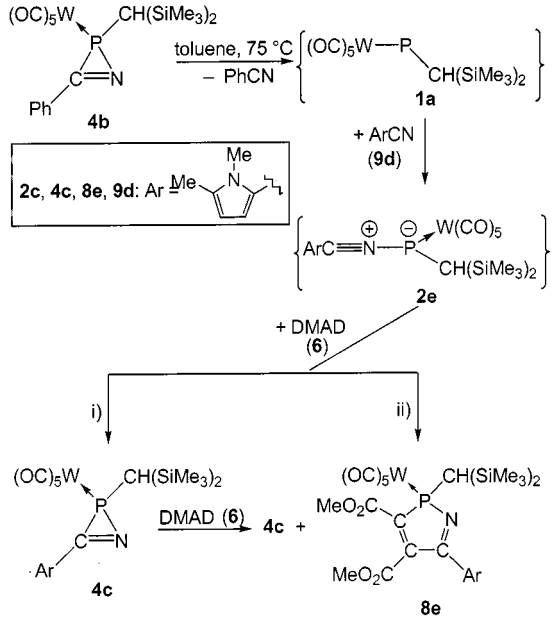
Scheme 4. Three-component reaction of 2*H*-azaphosphirene complex **4b** with DMAD and 1-piperidinocarbonitrile (**9a**)

Very selective reactions were observed with **4b**, 2-furylcarbonitrile (**9b**) or 2-thienylcarbonitrile (**9c**), and **6**. In this case, we obtained exclusively the 2*H*-1,2-azaphosphole complexes **8c**,**d** and no side-reactions leading to Δ^3-1,3,2-oxazaphospholene complexes were observed; complexes **8c**,**d** were isolated and fully characterized (Scheme 5).

To our surprise, reaction of the 2*H*-azaphosphirene complex **4b** (1 equiv.) with the pyrrolyl-substituted carbonitrile **9d** (2 equiv.) and DMAD (2 equiv.) led exclusively to the 2*H*-azaphosphirene complex **4c** (**i**). Even more surprising was that we had to change the ratio of 2*H*-azaphosphirene complex **4b**/pyrrolyl-substituted carbonitrile **9d**/DMAD to 1:4:2 in order to obtain the 2*H*-azaphosphirene complex **4c** and the 2*H*-1,2-azaphosphole complex **8e** in a 1:10 ratio (**ii**) (Scheme 6). This finding was completely counterintuitive. It was also very remarkable that a 2*H*-azaphosphirene complex was formed in a three-component reaction with DMAD; this had not been observed previously. This points



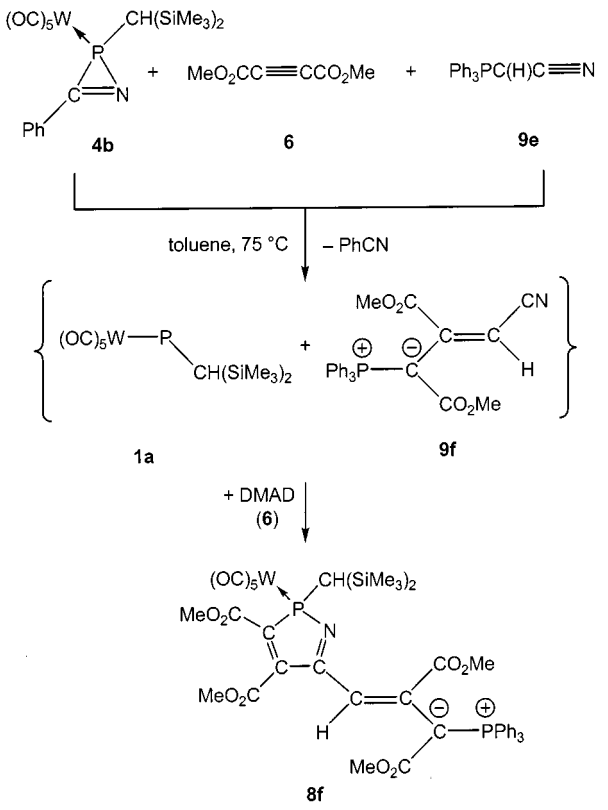
Scheme 5. Three-component reactions of 2*H*-azaphosphirene complex **4b** with DMAD and hetarene-substituted carbonitriles (**9b**,**c**)



Scheme 6. Two- and three-component reactions of 2*H*-azaphosphirene complex **4b** with DMAD and pyrrolecarbonitrile (**9d**) (for explanations of **i** and **ii**, see text)

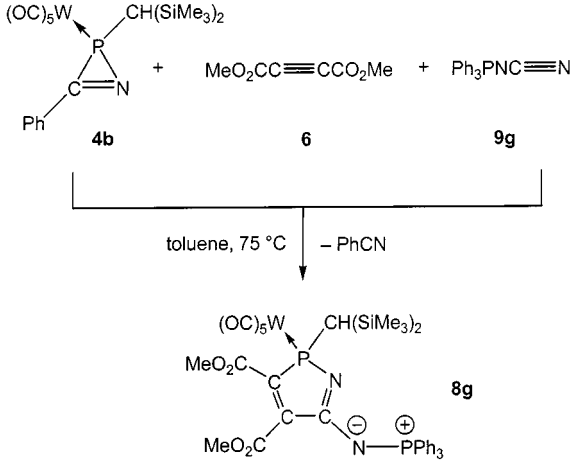
to an increased tendency of nitrilium phosphanylide complex **2e** to isomerize to **4c**, even under such conditions. Furthermore, the pure complex **4c** displayed an enhanced thermal stability in solution and underwent rapid ring-opening to transient **2c** only beyond 78 °C to yield complex **8e** with DMAD (Scheme 6).

The course of the reaction of the 2*H*-azaphosphirene complex **4b** with $Ph_3PC(H)CN$ (**9e**) and DMAD appeared to be more complicated under the same reaction conditions, although the outcome was in some respects not very surprising. Primarily, and at ambient temperature, rapid formation of the carbonitrile derivative **9f** was observed.[15] Nevertheless, this nitrile then selectively led to the 2*H*-1,2-azaphosphole complex **8f** (Scheme 7). Neither formation of Δ^3-1,3,2-oxazaphospholene complexes nor of a 2*H*-azaphosphirene complex was observed.



Scheme 7. Three-component reaction of 2*H*-azaphosphirene complex **4b** with DMAD and $Ph_3PC(H)CN$ (**9e**)

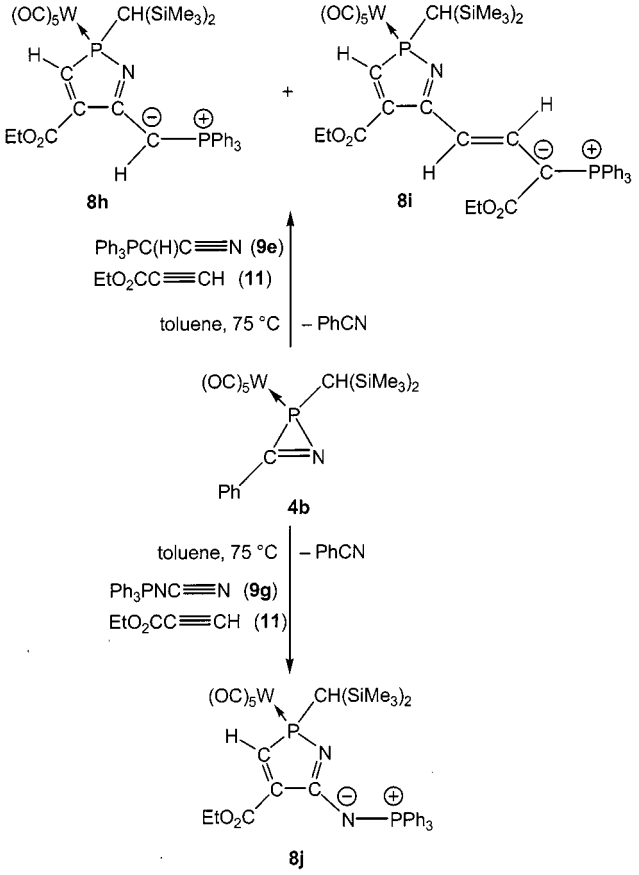
Also very selective was the reaction of the 2*H*-azaphosphirene complex **4b** with Ph_3PNCN (**9g**) and DMAD (1:1:1 ratio). ^{31}P NMR spectroscopic monitoring of the reaction showed exclusively the formation of the 2*H*-1,2-azaphosphole complex **8g** as the sole phosphorus-containing product, which was isolated in good yields by column chromatography (Scheme 8).



Scheme 8. Three-component reaction of 2*H*-azaphosphirene complex **4b** with DMAD and Ph_3PNCN (**9g**)

As our former studies on the regioselectivity of reaction of transiently generated nitrilium phosphanylide complexes

2a,**b**[8] and **2c**−**e**[9] with ethyl acetylenecarboxylate (**11**) showed, these highly reactive species always yield two regioisomeric 2*H*-1,2-azaphosphole complexes, with formation of the 4-ethoxycarbonyl-substituted 2*H*-1,2-azaphosphole complexes being favored. This was established by X-ray crystal structure analysis of a 5-(1,5-dimethylpyrrol-2-yl)-substituted 2*H*-1,2-azaphosphole complex.[9] Furthermore, we found that the regioisomer ratios showed a marked dependence on the C^5 substituent, e.g., 2-furanyl (3:1 ratio), 2-thienyl (5:1 ratio), and 2-(1,5-dimethylpyrrolyl) (8:1 ratio). Therefore, we were interested in examining the regioselectivity of transiently generated nitrilium phosphanylide complexes **2f**,**g** of the general formula RCNP[CH(SiMe$_3$)$_2$]W(CO)$_5$ [**2f**: R = Ph$_3$PC(H); **2g**: R = Ph$_3$PN] towards the terminal alkyne derivative **11**. Applying the aforementioned reaction protocols to the reactions of 2*H*-azaphosphirene complex **4b** with the carbonitriles **9e**,**h** and **11** led to the exclusive formation of only one regioisomer in each case, namely the 4-ethoxycarbonyl-substituted 2*H*-1,2-azaphosphole complexes **8h** and **8j**, which, in the case of **8h**, partially underwent subsequent reaction with the alkyne **11** to additionally yield complex **8i** (Scheme 9). All complexes were isolated in pure form by column chromatography. Related reactions of phosphonium ylides with activated alkynes have been reported previously and were interpreted as [2+2] cycloadditions with subsequent electrocyclic ring-opening, thus leading to new acyclic phosphonium ylides.[15,16]



Scheme 9. Three-component reactions of 2*H*-azaphosphirene complex **4b** with carbonitriles **9e**/**9g** and ethyl acetylenecarboxylate (**11**)

Although spectroscopic data for 1*H*-1,2-azaphosphole derivatives are available in the literature,[17,18] we will not make any comparisons with these because of the significantly different bonding situations. 1*H*-1,2-azaphosphole derivatives can be regarded as 6π-heteroaromatic systems,[19] whereas 2*H*-1,2-azaphosphole derivatives can be expected to have no such aromaticity.[20] The salient NMR spectroscopic data of the 2*H*-1,2-azaphosphole ring atoms of complexes **8b**−**8j** are collected in Table 1. Besides the typical chemical shifts of the ^{31}P NMR resonances, which are associated with the nature of the element directly bonded to the C^5 ring atom, the resonances show tungsten−phosphorus couplings but no phosphorus−phosphorus couplings. The $^{13}C\{^1H\}$ NMR spectra each feature three resonances due to the 2*H*-1,2-azaphosphole ring with different phosphorus−carbon coupling constant magnitudes. The assignments of the resonances and thus the regiochemistry of the rings of **8g**−**8j** were unambiguously established by means of DEPT experiments. Besides the typical small $|J(^{31}P,^{13}C)|$ values for the C^5 atoms, we observed that the magnitudes of the phosphorus−carbon coupling constants of the C^4 atoms were always greater than those of the C^3 atoms, even though the latter are directly bonded to the phosphorus atoms. This means that the $|^{2+3}J(^{31}P,^{13}C)|$ values are considerably larger than the $|^{1+4}J(^{31}P,^{13}C)|$ values! In the case of complexes **8g**,**h** and **8j**, the proposed constitutions were also established through additional phosphorus−carbon couplings of the C^4 atom with the ylide phosphorus atom of about 40 to 50 Hz, which were absent in complexes **8f** and **8i** as a consequence of the greater distances of the through-bond coupling pathways.

The ^{1}H NMR spectra of **8h**−**8j** show the typical parameters for the protons bonded to the C^3 atoms with chemical shifts of $\delta \approx 8.1$ and phosphorus−proton couplings $|^2J(^{31}P,^1H)|$ of ca. 31 Hz. In the case of complexes **8h** and **8j**, long-range couplings $|^5J(^{31}P,^1H)|$ of ca. 3−4 Hz are also seen, but these are absent in the case of complex **8i**. Selected NMR parameters of the ylide functional groups are collected in Table 2; further confirmation of the proposed structures comes from the fact that the $^{13}C\{^1H\}$ NMR spectroscopic data of the side-chain and ylide functionalities are all as expected.[15] The UV/Vis spectra lend further support to the constitutions of **8f**−**8j** by displaying additional absorptions for complexes **8g**, **8h**, and **8j** at $\lambda \approx 420-430$ nm ($\lg \varepsilon \approx 3.8$) and for complexes **8f** and **8i** at $\lambda = 470-510$ nm ($\lg \varepsilon \approx 4.1$), and an additional broad band at $\lambda = 558$ nm ($\lg \varepsilon \approx 3.8$) for complex **8f** (Figure 1). These bands additionally show the existence of more elongated π-systems.[16]

EI mass spectrometric experiments revealed that all of these 2*H*-1,2-azaphosphole complexes lose carbon monoxide following the ionization process as one important fragmentation pathway. Apart from this, other fragmentation pathways can occur, which are highly dependent on the C^5 substituent, e.g. cleavage of the tungsten−phosphorus bond in the case of complex **8g**. In this case, the initially formed

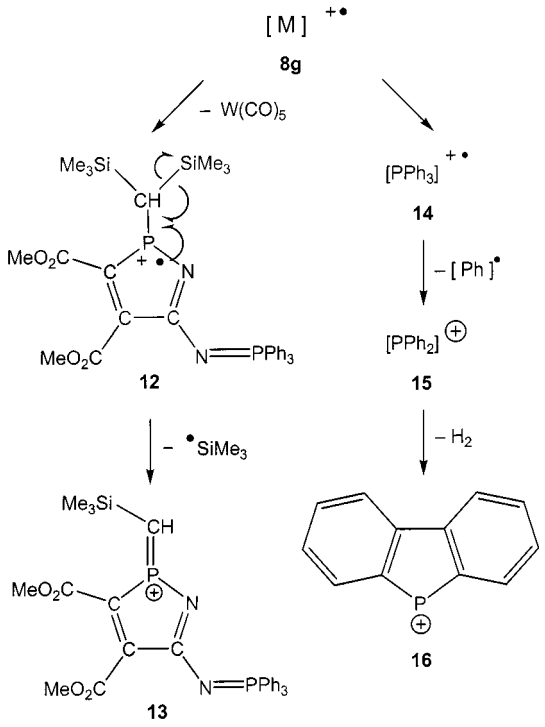
radical cation **12** undergoes C−Si bond cleavage to yield **13** (Scheme 10). Furthermore, the complexes **8g**−**8j** were seen to undergo cleavage of the P−C or P−N ylide bonds of the C^{5} substituent, e.g. in the case of complex **8g**, thus generating $[Ph_3P]^{+\cdot}$ (**14**) and neutral species such as carbenes and nitrenes. The further degradation of **14** to $[Ph_2P]^{+}$ (**15**) and **16** has been reported previously.[21]

We were able to confirm the constitutions of complexes **4c** (Figure 2, Table 3), **8d**,**8e**, and **8g** by single-crystal X-ray structure analyses (Figure 3, Figure 4, and Figure 5 and



Scheme 10. Fragmentation pathway of complex **8g**

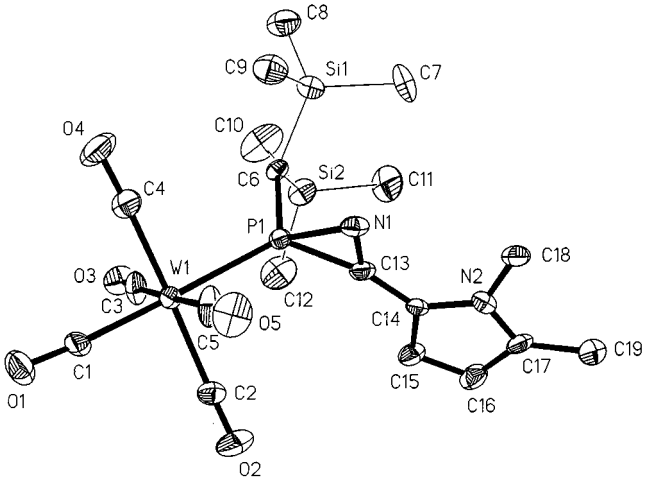


Figure 2. Molecular structure of one of the two independent molecules of **4c** in the crystal (ellipsoids represent 30% probability levels; hydrogen atoms are omitted for clarity); selected bond lengths [Å] and angles [°] (values for both molecules are given): W1−C1 1.980(13), 1.977(14), W1−P1 2.485(3), 2.488(3), P1−N1 1.800(10), 1.785(11), N1−C13 1.313(14), 1.307(14), C13−C14 1.411(16), 1.403(16); W1−P1−C6 120.8(4), 120.7(4), N1−C13−P1 70.7(7), 69.5(7), C13−C14−C15 126.0(12), 126.4(11)

Table 3 and Table 4). The molecular structure of complex **4c** shows an approximately coplanar arrangement of the two ring systems (interplanar angles 12.0° and 6.0° in two independent but closely similar molecules), thus enabling effective electronic interactions between the two rings. This is manifested in a shortened C(13)−C(14) bond of 1.411(16) Å, 1.403(16) Å and an elongated C(13)−N bond of 1.313(14) Å, 1.307(14) Å [compared to analogous C−C and C−N bond lengths of 1.457(7) Å and 1.272(7) Å in the C^3-phenyl-substituted (2*H*-azaphosphirene)tungsten complex].[14] It is also noteworthy that the NMe group adopts a position below the C−N double bond, thus pointing away from the phosphorus atom. This is interesting in the light of the observation that two alternative orientations seem to exist in *ortho*-substituted phenyl derivatives, depending on the *ortho* substituent.[22,23] We are currently trying to understand and exploit this aspect of the stereochemistry of 2*H*-azaphosphirene complexes.

The 2*H*-1,2-azaphosphole rings of complexes **8d**, **8e** and **8g** showed no unusual interatomic distances between the ring atoms, nor to the externally bonded atoms (Table 4). In all cases, the 2*H*-1,2-azaphosphole rings are approximately planar (largest mean deviation 0.014 Å in **8e**) and the bis-(trimethylsilyl)methyl group adopts the same preferred relative orientation towards the tungsten center and thus towards the ring as reported previously for other structures of related phosphorus heterocycle complexes. A further common structural motif is that the ester groups bonded to the C^{13} atoms adopt an approximately in-plane orientation, whereas the ester groups bonded to the C^{14} atoms adopt an out-of-plane orientation. The interplanar angles in **8d**, **8e** (22.3° and 24.6°, respectively) and the torsion angle of N(1)−C(15)−N(2)−P(2) of −18.9° in **8g** should, in all cases, enable electronic interactions between the two ring systems or the substituent. It is also noteworthy that in **8g** the $NPPh_3$ group adopts an *s-cis* configuration with respect to the C(15)−N(2) bond and seems to induce a slight elongation of the phosphorus−tungsten bond.

The following short contacts are observed: **8d**: S···O9 3.312 Å (operator $1 + x, y, z$); **8e**: C24−H24···O9 2.39 Å (angle at H 147°, operator $1 + x, y, z$); **8g**: C17−H17···O9 2.34 Å (angle at H 162°, operator $-x, 2 - y, -z$).

Concluding Remarks

We have shown that the chemistry of transiently generated nitrilium phosphanylide complexes can be further exploited, especially by using reactions of P,C and P,N ylide substituted carbonitriles and terminal phosphanediyl complexes, ultimately leading to the first C^5-functionalized 2*H*-1,2-azaphosphole complexes. It is also remarkable that no products were observed that may conceivably have arisen from initial attack of the transiently formed electrophilic terminal phosphanediyl complex at the nucleophilic ylide carbon or nitrogen atoms, which can probably be attributed to steric shielding of these centers. Therefore, the carbonitrile nitrogen atoms are predisposed to act exclusively as efficient donor centers towards the phosphorus atom of the electrophilic terminal phosphanediyl complex. In view of the lack of diazaphosphole complex formation, we conclude that the nitrile/nitrile exchange is a dissociative process (cf. ref.[6]) and, therefore, that the generation of the nitrilium phosphanylide complexes has to be described as 1,1-addition (cf. ref.[3]). With regard to the possible competition of the trapping reagents, nitriles and alkynes, the selectivity of the P,N ylide substituted nitrilium phosphanylide complexes towards alkynes is remarkable. Furthermore, the

finding that such 1,3-dipoles do not tend to form 2*H*-azaphosphirene complexes is very interesting, and, although no calculations were carried out on such systems, one may assume that the $Ph_3PC(H)$ and Ph_3PN ylide substituents stabilize nitrilium phosphanylide complexes more effectively than 2*H*-azaphosphirene complexes.[4,24] It is also remarkable that no cross-reactions and/or side-reactions of the transiently formed nitrilium phosphanylide complexes were detected, i.e. cycloaddition reactions involving the P−C and/or P−N bond − common organic 1,3-dipoles show

such cycloaddition reactions with phosphorus ylides such as $Ph_3PC(H)CN$.[16] Overall, very bulky ylide-substituted carbonitriles seem to be very interesting candidates for the generation of stable nitrilium phosphanylide complexes.

We are currently trying to exploit such ylide-substituted carbonitriles in other three-component reactions and to use the ylide functionalities in 2*H*-1,2-azaphosphole complexes to construct more extended N,P-heterocycle ligand structures, e.g. by using Wittig and aza-Wittig reactions.

Experimental Section

General Procedures: All reactions and manipulations were carried out under deoxygenated dry nitrogen in conventional glassware using standard Schlenk techniques. Solvents were dried according to standard procedures. NMR spectra were recorded with a Bruker AC-200 spectrometer (200 MHz for ^1H; 50.3 MHz for ^{13}C; 81.0 MHz for ^{31}P) using [D]chloroform or [D_6]benzene as solvent and internal standard; shifts are given relative to external tetramethylsilane (^1H, ^{13}C) or 85% H_3PO_4 (^{31}P); only coupling constant magnitudes are given. Electron impact (EI) (70 eV), chemical ionization (CI) (ammonia), and fast atom bombardment (FAB) (xenon) mass spectra were recorded with a Finnigan MAT-8430 double-focusing mass spectrometer. Infrared spectra were recorded with a Biorad FT-IR 165 spectrometer (selected data given). UV/Vis spectra were recorded with a Hewlett Packard HP 8452 spectrophotometer. Melting points were obtained with a Büchi 535 capillary apparatus. Elemental analyses were performed using a Carlo Erba analytical gas chromatograph. The *κP* notation in the nomenclature is intended to differentiate between P and N coordination of the relevant heterocycle to the metal ion.

{2-[Bis(trimethylsilyl)methyl]-3-(1,5-dimethylpyrrol-2-yl)-2*H*-azaphosphirene-*κP*}pentacarbonyltungsten(0) (4c): A solution of the (2*H*-azaphosphirene)tungsten complex **4b** (0.62 g, 1 mmol) and 1,5-dimethyl-2-pyrrolecarbonitrile **(9d)** (0.617 g, 5 mmol) in toluene (10 mL) was heated at 72 °C for 2 h with slow stirring. Thereafter, the solvent was removed in vacuo (ca. 0.01 mbar) and the product was separated by low-temperature column chromatography (SiO_2, −15 °C, 10 × 2 cm, *n*-pentane/diethyl ether, 70:30). Evaporation of the solvents from the second fraction yielded **4c** as a yellow solid. Yield 220 mg (36%); m.p. 131 °C (decomp.). ^1H NMR ($CDCl_3$): δ = 0.07 (s, 9 H, $SiMe_3$), 0.15 (s, 9 H, $SiMe_3$), 0.33 [d, $^2J_{P,H}$ = 1.3 Hz, 1 H, C*H*($SiMe_3$)$_2$], 2.23 (s, 3 H, CH_3), 3.60 (s, 3 H, NCH_3), 5.89 (d, $^3J_{H,H}$ = 3.4 Hz, 1 H, 3-H), 6.66 (d, $^3J_{H,H}$ = 3.9 Hz, 1 H, 4-H). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 1.2 (d, $^3J_{P,C}$ = 3.2 Hz, $SiMe_3$), 2.0 (d, $^3J_{P,C}$ = 3.1 Hz, $SiMe_3$), 12.4 (s, C*C*H_3), 27.0 [d, $^1J_{P,C}$ = 24.3 Hz, *C*H($SiMe_3$)$_2$], 32.1 (s, NCH_3), 110.8 (s, $C5_{aryl}$), 119.2 (d, $^2J_{P,C}$ = 19.4 Hz, $C2_{aryl}$), 122.0 (s, $C3_{aryl}$), 135.4 (s, $C4_{aryl}$), 177.4 (d, $^{1+2}J_{P,C}$ = 8.5 Hz, PCN), 196.0 (d, $^2J_{P,C}$ = 9.0 Hz, *cis*-CO), 198.1 (d, $^2J_{P,C}$ = 35.2 Hz, *trans*-CO). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −131.4 (s, $^1J_{P,W}$ = 294.2 Hz). MS (pos. CI, ^{184}W): *m/z* = 634 (1) $[M]^{+\cdot}$.

General Procedure for the Preparation of Complexes 8b−8e: To a solution of the (2*H*-azaphosphirene)tungsten complex **4b** (0.62 g, 1 mmol) in toluene (10 mL), the respective carbonitrile **9b−9e** (4 mmol) and dimethyl acetylenedicarboxylate (**6**; 0.245 mL, 2 mmol) were added and the resulting mixture was heated at 75 °C for 3.5 h with slow stirring. Thereafter, all volatile components were removed in vacuo (ca. 0.01 mbar) and the products were separated by low-temperature column chromatography (SiO_2, −10 °C, 10 × 2 cm, *n*-pentane/diethyl ether, 70:30). Evaporation of the solvents from the respective second fractions yielded **10a** and **8b** as yellow solids and **8c−8e** as red solids.

{2-[Bis(trimethylsilyl)methyl]-4-methoxy-4-(2-methoxycarbonylethynyl)-5-piperidino-Δ^3-1,3,2-oxazaphospholene-*κP*}pentacarbonyltungsten(0) (10a,b): Yield 84 mg (11%); m.p. 144 °C (decomp.). ^1H NMR ($CDCl_3$): δ = 0.01 (s, 9 H, $SiMe_3$), 0.15 (s, 9 H, $SiMe_3$), 1.49 [s, 1 H, C*H*($SiMe_3$)$_2$], 1.54 (m_c, 6 H, $NCH_2CH_2CH_2$), 3.44 (m_c, 4 H, $NCH_2CH_2CH_2$), 3.63 (s, 3 H, OCH_3), 3.80 (s, 3 H, OCH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 2.0 (d, $^3J_{P,C}$ = 2.4 Hz, $SiMe_3$), 2.3 (s, $SiMe_3$), 24.3 (s, $NCH_2CH_2CH_2$), 24.7 (s, $NCH_2CH_2CH_2$), 36.8 [d, $^1J_{P,C}$ = 5.9 Hz, *C*H($SiMe_3$)$_2$], 48.1 (s, $NCH_2CH_2CH_2$), 52.8 (s, OCH_3), 53.2 (s, OCH_3), 77.2 (s, C*C*CO_2Me), 79.9 (s, *C*CCO_2Me), 99.0 (d, $^{2+3}J_{P,C}$ = 7.2 Hz, POC), 152.7 (s, PNC), 156.7 (s, *C*O_2Me), 197.2 (d, $^2J_{P,C}$ = 8.6 Hz, *cis*-CO), 201.1 (d, $^2J_{P,C}$ = 28.4 Hz, *trans*-CO). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 198.3 (s, $^1J_{P,W}$ = 300.9 Hz). General Procedure for the Preparation of Complexes 8f−8j: To a solution of the 2*H*-azaphosphirene complex **4b** (0.62 g, 1 mmol) in toluene (6 mL), the appropriate carbonitrile **9e** or **9h** (1 mmol) and the appropriate alkyne **6** or **11** (1 mmol) were added and the resulting mixture was heated at 75 °C for 2 h with slow stirring. Thereafter, all volatile components were removed in vacuo (ca. 0.01 mbar) and the products were separated by low-temperature column chromatography (SiO_2, −10 °C, 10 × 2 cm, *n*-pentane/diethyl ether, 70:30). Evaporation of the solvents from the respective second fractions yielded **8f** and **8i** as red solids, **8g** and **8h** as yellow solids, and **8j** as a pale-brown solid.

X-ray Crystallography: The structure of **4c** was determined with a Siemens P4 diffractometer, while the structures of **8d**, **8e**, and **8g** were determined with a Bruker SMART 1000 CCD diffractometer. The structures were solved by the heavy atom method and refined anisotropically by full-matrix least-squares on F^2.[25] CCDC-168172 (**4c**), -168173 (**8d**), -168174 (**8e**), and -168175 (**8g**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Equilibrium, Kinetic and Leaving Group Effect Studies on Ligand Substitution Reactions of a Simple Model for Coenzyme B_{12}

Basam M. Alzoubi,[a] Mohamed S. A. Hamza,[a][‡] Carlos Dücker-Benfer,[a] and Rudi van Eldik*[a]

Keywords: Enzyme models / Equilibrium / Kinetics / Ligand effects / Leaving group effect / Volume profile

The ligand substitution reactions of *trans*-$[Co^{III}(en)_2(Me)H_2O]^{2+}$ and *trans*-$[Co^{III}(en)_2(Me)NH_3]^{2+}$ were studied for CN^-, SCN^-, N_3^-, and NH_3 as entering nucleophiles. These nucleophiles displace the coordinated H_2O and NH_3 molecules *trans* to the methyl group and form the six-coordinate complex *trans*-$[Co(en)_2(Me)L]$. The complex-formation constant for the displacement of H_2O by NH_3 was found to be 17.4 ± 1.1 M^{-1} at 20 °C, and those for the displacement of NH_3 by SCN^- and N_3^- were found to be 4.4 ± 1.5 and 3.1 ± 0.4 at 10 °C, respectively. From temperature and pressure dependence studies, activation parameters ($\Delta H^{\neq}$, $\Delta S^{\neq}$ and $\Delta V^{\neq}$) for the reaction of *trans*-$[Co^{III}(en)_2(Me)H_2O]^{2+}$ with NH_3 were found to be 62 ± 1 kJ mol^{-1}, $+3 \pm 5$ J K^{-1} mol^{-1} and $+5.7 \pm 0.3$ cm^3 mol^{-1}, respectively, compared to 79 ± 2 kJ mol^{-1}, $+40 \pm 6$ J K^{-1} mol^{-1} and $+9.0 \pm 0.4$ cm^3 mol^{-1} for the reverse aquation reaction of *trans*-$[Co^{III}(en)_2(Me)NH_3]^{2+}$. Based on the reported kinetic and activation parameters, the substitution of coordinated H_2O by NH_3 follows an I_d mechanism in which the entering nucleophile participates in the transition state. The substitution of NH_3 by SCN^-, N_3^- and CN^- proceeds via the intermediate aqua complex such that aquation of the amine complex becomes the rate-determining step at high entering ligand concentration. A detailed comparison with available data in the literature is made.

Introduction

Model complexes for vitamin B_{12} have played an important role in understanding the behavior of the ligand substitution reactions of vitamin B_{12} and the role of the Co−C bond in the coenzyme vitamin B_{12}.[1,2] Many octahedral organometallic complexes of Co^{III}, such as cobaloxime[2−10] and Costa's complex[11] (a mixed Schiff base/oxime complex with a uni-negative N_4 equatorial ligand), those with a Schiff base,[12,13] *N*,*N*′-ethylenebis(actylacetoneiminato),[14] *N*,*N*′-ethylenebis(salicylideneiminato)[15] and the dianion of disalicylidene-*O*-phenylenediamine[15] as ligands, have been suggested as models for the vitamin B_{12} coenzyme, to mimic either the nature of the active site or a specific function of the enzyme. These model complexes have shown that the ligand in the *trans* position to the Co−C bond can affect the kinetics and thermodynamic stability of this bond.[16] We recently studied the reaction of cyanide with different alkylcobalamins (RCbl, where R = CF_3, CF_3CH_2, CF_2H, CH_3, CH_2Br) and found that the nature of the alkyl group has an influence on the thermodynamic equilibrium constants, kinetics and mechanism of the substitution reactions of the axial ligand *trans* to the alkyl group.[17]

The simplest model for coenzyme B_{12} was synthesized by Kofod in 1995[18] and consists of a Co^{III} metal center surrounded by five ammine groups and one methyl group as ligands. This complex is only stable in aqueous solution in the presence of a high ammonia concentration (ca. 3 M). We recently suggested that the $[Co(NH_3)_5(Me)]^{2+}$ cation is not favored in being used as a model for vitamin B_{12} due to the necessary presence of a high ammonia concentration and the unfavorable pH.[19] $[Co(NH_3)_5(Me)]^{2+}$ undergoes a rapid ligand substitution reaction with ethylenediamine (en) to form *cis*-$[Co(en)_2(Me)NH_3]^{2+}$, which slowly isomerizes to the more stable and isolable *trans* isomer.[19] The kinetic and activation parameters for the displacement of the four ammonia ligands by two ethylenediamine (en) chelates confirmed the operation of a limiting dissociative reaction mechanism under limiting concentration conditions. The activation parameters also confirmed the operation of a dissociative mechanism for the subsequent *cis* to *trans* isomerization reaction.

A potential advantage of the planar bis(ethylenediamine) arrangement around the Co^{III} center is the flexibility of the chelates, an aspect that has been suggested to be important for the biological activity of the coenzyme.[20] We studied the ligand substitution reactions of *trans*-$[Co^{III}(en)_2(Me)H_2O]^{2+}$ with CN^- and imidazole. Activation parameters ($\Delta H^{\neq}$, $\Delta S^{\neq}$ and $\Delta V^{\neq}$) for the reaction of *trans*-$[Co^{III}(en)_2(Me)H_2O]^{2+}$ with cyanide were found to be 49 ± 4 kJ mol^{-1}, -38 ± 15 J K^{-1} mol^{-1} and $+7.0 \pm 0.6$

$cm^3\ mol^{-1}$, respectively, compared to 53 ± 2 kJ mol^{-1}, −22 ± 7 J K^{-1} mol^{-1} and +4.7 ± 0.1 $cm^3\ mol^{-1}$ for the reaction with imidazole.[21] Based on the reported activation volumes, these reactions follow a dissociative (interchange dissociative, I_d, or limiting dissociative, D) mechanism in which the entering nucleophile could be weakly bound in the transition state.[21] By way of comparison, ligand substitution reactions of vitamin B_{12} in general follow a dissociative (I_d or D) type of mechanism.[22−36] In the case of the coenzyme, however, evidence for an associative substitution mode was reported.[37] In order to gain further insight into the reasons for this unexpected mechanistic changeover, we have now investigated substitution reactions of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ and *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ to study the effect of the leaving group on the axial ligand substitution mechanism of these model complexes that include a cobalt−carbon σ-bond. These complexes allow us to mimic the active site of the coenzyme since the ammine ligand *trans* to the Co−Me bond represents the dimethylbenzimidazole moiety in the coenzyme.

Results and Discussion

As mentioned before, the pK_a value of coordinated water in *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ is higher than 12, since there was no change observed in the pH titration curve up to that pH.[21] Furthermore, it was found that *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ decomposes upon exposure to UV light, suggesting that the Co−C bond can be cleaved photochemically. This was observed for most of the Co^{III} complexes containing alkyl groups coordinated to the cobalt atom in the axial position.[16] Preliminary experiments showed that decomposition of this complex by the light beam of the spectrophotometer was negligible. Despite the lower light sensitivity of this complex as compared to other alkylcobalamins, special care was taken to protect this complex from photochemical decomposition.

In the present study, we investigated the displacement of the axial H_2O molecule in *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ by NH_3 in order to make comparisons with our earlier study on the reactions of cyanide and imidazole with this complex.[21] Subsequently, we investigated the displacement of NH_3 in *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ by SCN^-, N_3^- and CN^-, in order to obtain more information on leaving group effects in such systems. The investigated reaction is shown in Equation (1), where X = H_2O for L = NH_3, and X = NH_3 for L = CN^-, SCN^-, N_3^-.

$$\textit{trans}\text{-}[Co(en)_2(Me)X]^{2+} + L \underset{k_b}{\overset{k_a}{\rightleftharpoons}} \textit{trans}\text{-}[Co(en)_2(Me)L]^{2+} + X \quad (1)$$

Reaction of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ with NH_3

Equilibrium Measurements

The UV/Vis spectrum of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ in buffers at pH = 11 shows characteristic bands at 364 (125 $M^{-1}\ cm^{-1}$) and 472 nm (74 $M^{-1}\ cm^{-1}$). Addition of NH_3 shifts the bands to 354 (133 $M^{-1}\ cm^{-1}$) and 464 nm (67 $M^{-1}\ cm^{-1}$) with a shoulder at 290 nm (166 $M^{-1}\ cm^{-1}$). These changes in the UV/Vis spectra are accompanied by distinct isosbestic points, indicating that a simple equilibrium exists under these conditions. These observations suggest that the aqua ligand in the *trans* position to the methyl group is displaced by ammonia to form the six-coordinate *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ complex.

Preliminary experiments in which the UV/Vis spectrum was scanned in the range 250 to 600 nm, showed that at pH = 11, NH_3 reacts rapidly with *trans*-$[Co(en)_2(Me)H_2O]^{2+}$. Equilibrium (1) was established within the time required for mixing the solutions and recording the spectra. The values of the overall equilibrium constant K were determined spectrophotometrically (in duplicate experiments) by titrating ca. 3×10^{-3} M *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ (I = 0.1 M, $NaClO_4$) with a concentrated stock solution of NH_3 to minimize dilution effects.

The spectrophotometric titration of NH_3 was monitored by following the increase in absorbance at 326 nm or the decrease in absorbance at 380 nm, where the largest change in absorbance occurred. Typical data for the reaction with NH_3 are shown in Figure 1. The solid line represents the fit of the experimental data to Equation (2), where A_o and A_∞ represent the absorbance at 0 and 100% formation of *trans*-$[Co(en)_2(Me)L]^{2+}$, respectively, and A_x is the absorbance at any given ligand concentration [L].

$$A_x = A_o + A_\infty K[L]/(1 + K[L]) \quad (2)$$

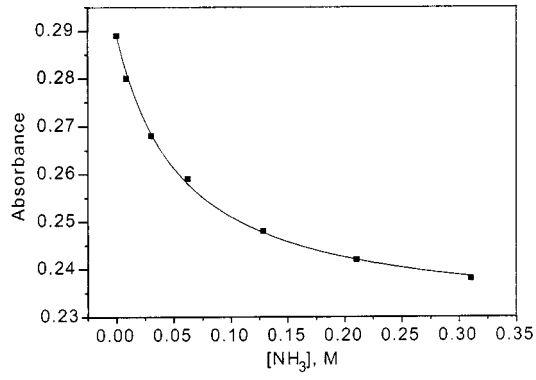

Figure 1. Changes in absorbance at 380 nm on addition of NH_3 to *trans*-$[Co(en)_2(Me)H_2O]^{2+}$; the solid line is a fit of the data to Equation (2) in the text

The values of K and A_∞ were calculated from a non-linear least-squares fit of the data to Equation (2). The data were subsequently also analyzed by plotting log $(A_x - A_o)/(A_\infty - A_x)$ versus log[L], which resulted in a linear plot with slope of 0.99 ± 0.06 for NH_3, indicating that only one ligand (L) is coordinated to the cobalt complex. The intercept of the linear plot gives the value of log K, which is in excellent agreement with the directly determined value described above.

The value of $K(NH_3)$ was found to be 17.4 ± 1.1 M^{-1} at 20 °C. The value of K for the binding of NH_3 to $[Co(corrin)(Me)H_2O]^{2+}$ was reported to be 0.1 M^{-1},[38] from which it follows that the affinity of NH_3 for *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ is almost 200 times higher than for $[Co(corrin)(Me)H_2O]^{2+}$. This comparison demonstrates the *cis* effect, i.e. the influence of the equatorial ligand on the substitution reaction of the axial ligand *trans* to the alkyl group. The observed trend in the formation constants for the equatorial ligands is corrin < $(en)_2$.

Kinetic Measurements

The reaction between *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ and excess NH_3 at pH = 11 ($[NH_3]$ = 0.1 to 1.25 M, I = 0.1 M using $NaClO_4$) was studied at different temperatures. The results are shown in Figure 2, from which it follows that good linear plots with significant intercepts are obtained within the experimental error limits. Furthermore, the plots do not indicate any saturation at high $[NH_3]$ values. This behavior can be expressed by the rate law given in Equation (3), where k_a and k_b represent the rate constants for the forward and reverse reactions in Equation (1), respectively, L represents NH_3 and X is H_2O (the concentration of water is a constant and taken into k_b). It should be noted that the intercepts in Figure 2 are subjected to large error limits and an alternative procedure was used to determine the rate constant for the reverse reaction more accurately (see further Discussion). The values of k_a and k_b as a function of temperature, along with the corresponding activation parameters are summarized in Table 1.

$$k_{obs} = k_a[L] + k_b \quad (3)$$

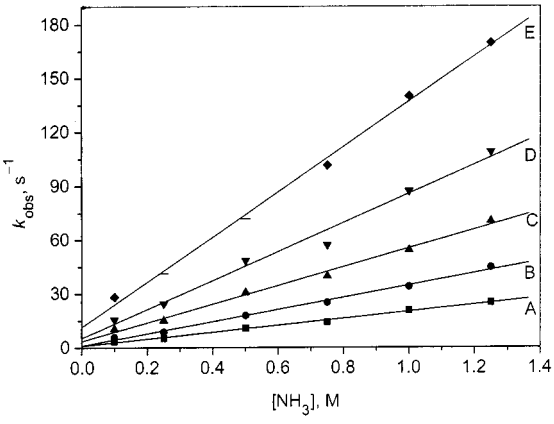

Figure 2. Plot of k_{obs} versus $[NH_3]$ for the reaction between *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ and NH_3 as a function of temperature; experimental conditions: $[Co^{III}]$ = 0.0045 M, pH = 11, I = 0.1 M $NaClO_4$ and temperature = 5.0 (A), 10.0 (B), 15.0 (C), 20.0 (D) and 25.0 °C (E)

The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the forward reaction (k_a) were found to be 62 ± 1 kJ mol^{-1} and 3 ± 5 J K^{-1} mol^{-1}, respectively, whereas those for the reverse reaction (k_b) were found to be 85 ± 13 kJ mol^{-1} and 60 ± 43 J K^{-1} mol^{-1}, respectively.

Table 1. Kinetic data for the reaction of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ with NH_3 as a function of temperature (experimental conditions see footnotes)

T [°C]	k_a [M^{-1} s^{-1}][a]	k_b [s^{-1}][b]	k_b [s^{-1}][c]
5.0	19.1 ± 0.8	1.0 ± 0.6	1.33 ± 0.03
10.0	33.6 ± 1.3	1.1 ± 1.0	2.28 ± 0.06
15.0	51.8 ± 2.1	3.5 ± 1.6	4.45 ± 0.04
20.0	82.2 ± 5.4	4.7 ± 4.1	7.5 ± 0.6
25.0	125.5 ± 3.7	11.5 ± 2.8	13.8 ± 0.9
$\Delta H^{\neq}$ [kJ mol^{-1}]	62 ± 1	85 ± 13	79 ± 2
$\Delta S^{\neq}$ [J K^{-1} mol^{-1}]	+3 ± 5	+60 ± 43	+40 ± 6

[a] $[Co(en)_2(Me)H_2O]$ = 4.5 × 10^{-3} M, pH = 11, I = 0.1 M $NaClO_4$. [b] Values were calculated from the intercepts in Figure 2. [c] Values were calculated from the direct reaction of 9 × 10^{-3} M $[Co(en)_2(Me)NH_3]^{2+}$ in the presence of 0.3 M NH_3, at pH = 11 and 0.1 M $NaClO_4$, with 0.5 M HCl.

We determined the rate and activation parameters for the aquation (k_b) of *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ (in the presence of 0.3 M NH_3) directly by treating this amine complex with 0.5 M HCl to protonate ammonia to form *trans*-$[Co(en)_2(Me)H_2O]^{2+}$. This reaction was found to be independent of the acid concentration as long as the acid is in excess under the selected conditions, and the results for k_b are included in Table 1. The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were found to be 79 ± 2 kJ mol^{-1} and 40 ± 6 J K^{-1} mol^{-1}, respectively, and are more accurate than those determined from the intercepts of Figure 2.

The values of k_a and k_b can be used to calculate K (= k_a/k_b), which turns out to be 11.0 ± 1.6 M^{-1} at 20 °C. The kinetically determined value of K is in close agreement with that obtained spectrophotometrically at the same temperature, viz. 17.4 ± 1.1 M^{-1}.

The high lability of coordinated water in *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ is also seen in the relatively low activation enthalpy for the substitution by NH_3, as compared to the higher activation enthalpy for the aquation reaction of the ammonia complex (i.e. back reaction). The value of the activation enthalpy for the reaction with NH_3 (63 ± 1 kJ mol^{-1}) is close to that obtained previously[21] for the reaction with CN^- and imidazole (50 ± 4 kJ mol^{-1} and 53 ± 2 kJ mol^{-1}, respectively). The activation entropy for the formation of *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ was found to be close to zero, compared to a significantly positive value for the back reaction. It is known that $\Delta S^{\neq}$ is usually subjected to large error limits because of the intrinsic extrapolation involved in its determination, such that small absolute numbers are not very significant in terms of the assignment of a mechanism.[39] The significantly positive value found for the reverse aquation reaction, points to a dissociatively activated transition state.

The pressure dependence of the reaction of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ with NH_3 was investigated and the data are summarized in Table 2. Plots of ln k_a versus pressure gave a good linear plot from which $\Delta V^{\neq}$ was found to be +5.7 ± 0.3 cm^3 mol^{-1}. The pressure dependence of the aquation reaction of *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ (in the

Table 2. Kinetic data for the reaction of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ with NH_3 as a function of pressure at 5 °C (experimental conditions see footnotes)

p [MPa]	k_a [M^{-1} s^{-1}][a][b]	k_b [s^{-1}][c]
10	3.88 ± 0.16	1.74 ± 0.04
50	3.43 ± 0.22	1.50 ± 0.01
90	3.08 ± 0.12	1.25 ± 0.02
130	2.73 ± 0.22	1.10 ± 0.04
$\Delta V^{\neq}$ [cm^3 mol^{-1}]	+5.7 ± 0.3	+9.0 ± 0.4

[a] $[Co(en)_2(Me)H_2O] = 4.5 \times 10^{-3}$ M, $[NH_3] = 1.5$ M, pH = 11, 5 °C, $I = 0.1$ M $NaClO_4$. [b] Calculated from the equation: $k_{obs} = k_b + k_a[NH_3]$. [c] Determined from the reaction of 1.8×10^{-2} M $[Co(en)_2(Me)NH_3]^{2+}$ in the presence of 0.3 M NH_3 at pH = 11, 0.1 M $NaClO_4$ and 5 °C, with 0.5 M HCl.

presence of 0.3 M NH_3) was also investigated by the direct reaction of 1.8×10^{-2} M $[Co(en)_2(Me)NH_3]^{2+}$ with 0.5 M HCl to protonate the ammonia. A plot of ln k_b versus pressure gave a good linear relationship, from which $\Delta V^{\neq}$ was calculated to be +9.0 ± 0.4 cm^3 mol^{-1} (the data are summarized in Table 2; see Supporting Information, Figure S-1). From the values of $\Delta V^{\neq}$ it is possible to construct a volume profile for the substitution of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ by NH_3 (see Figure 3), from which it can be concluded that the substitution process is dissociatively activated, since the transition state has a significantly higher partial molar volume than the reactant state. Similar results were reported for reactions of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ with CN^- and imidazole[21] and also for the reaction of aquacobalamin with different ligands such as HN_3, N_3^-, pyridine and its derivatives, and thiourea and its derivatives.[30–32] In all these cases, $\Delta V^{\neq}$ was found to be in the range of +4 to +8 cm^3 mol^{-1}, i.e. similar to the value found for the reaction of NH_3 with *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ in this study, and was interpreted in terms of an I_d mechanism. These values are significantly smaller than those reported for substitution reactions of (porphyrin)cobalt(III) systems. There it was found that $\Delta V^{\neq}$ for ligand substitution on $[Co(TMPP)(H_2O)_2]^{5+}$ and $[Co(TPPS)(H_2O)_2]^{3-}$, where TMPP = *meso*-tetrakis(4-*N*-methylpyridyl)porphine and TPPS = *meso*-tetrakis(*p*-sulfonatophenyl)porphine, are +14.4 and +15.4 cm^3 mol^{-1}, respectively,[40,41] and these were assigned to a limiting D mechanism. It follows from this comparison that the introduction of a single cobalt–carbon bond significantly labilizes the coordinated water molecule in *trans*-$[Co(en)_2(Me)H_2O]^{2+}$, as reflected by its high pK_a value, but apparently does not induce a limiting D mechanism on the basis of the reported $\Delta V^{\neq}$ data.

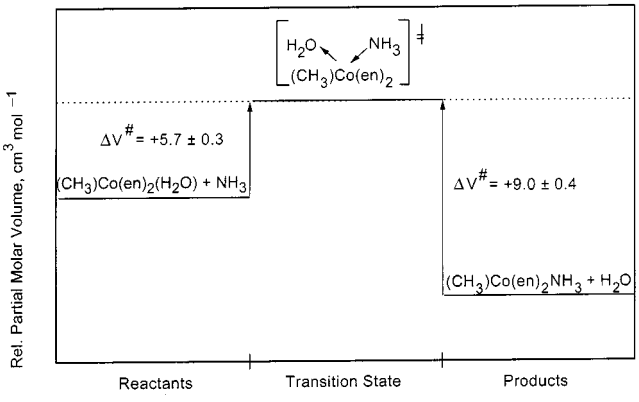

Figure 3. Volume profile for the reaction *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ + NH_3 ⇄ *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ + H_2O

On the basis of the volume of activation data and the constructed volume profile, it is reasonable to conclude that the reaction of *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ with NH_3 follows an I_d mechanism, where the entering nucleophile partially participates in the transition state. The volume changes during the complex-formation reaction are controlled by the lengthening of the Co–OH_2 bond that should be independent of the nature of L.

Reaction of *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ with CN^-, SCN^- and N_3^-

The UV/Vis spectrum of *trans*-$[Co(en)_2(Me)NH_3]^{2+}$, dissolved in buffers at pH = 11 in the presence of 1 M NH_3, showed bands at 354 (133 M^{-1} cm^{-1}) and 464 nm (67 M^{-1} cm^{-1}) with a shoulder at 290 nm (166 M^{-1} cm^{-1}). Addition of SCN^- shifts the UV/Vis bands to 356 (208 M^{-1} cm^{-1}) and 464 nm (97 M^{-1} cm^{-1}), whereas addition of N_3^- shifts the UV/Vis bands to 364 (182 M^{-1} cm^{-1}) and 472 nm (98 M^{-1} cm^{-1}).

Spectrophotometric titrations for the reactions with SCN^- and N_3^- were performed in the presence of 1 M NH_3 at 10 °C, and monitored by the increase in absorbance at 461 and 467 nm, respectively. The values of K were calculated from a non-linear least-squares fit of the data to Equation (2) and found to be 4.4 ± 1.5 and 3.0 ± 0.4, respectively. The data were also analyzed by plotting log $(A_x - A_o)/(A_\infty - A_x)$ versus log[L], which resulted in linear plots with slopes of 0.99 ± 0.04 and 0.99 ± 0.09 for SCN^- and N_3^-, respectively, indicating that only one ligand (L) is coordinated to the cobalt complex.

Figure 4 shows a plot of k_{obs} versus $[CN^-]$ for the reaction of *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ (in the presence of 1 M NH_3) with CN^- at pH = 11 ($[CN^-] = 0.05$ to 1 M), $I = 1$ M ($NaClO_4$) and 10 °C. This plot shows saturation kinetics (a limiting value of k_{obs} (= k_3) is reached at high $[CN^-]$ values) and exhibits no intercept, indicating that the reverse reaction does not contribute significantly. The suggested mechanism in reaction (4) involves the dissociative formation of a six-coordinate aqua intermediate, followed by the reaction with the entering ligand L. The data in Figure 4 were fitted to Equation (5), and resulted in $k_3 = 2.79 \pm 0.02$ s^{-1}, $k_{-4} \approx 0$ and $k_4/k_{-3} = 73 \pm 3$. The value of k_{obs} increases with increasing cyanide concentration due to the fact that $k_3 >> k_{-4}$. The value of k_4/k_{-3} represents the efficiency of CN^- compared with NH_3 to scavenge the six-coordinate aqua intermediate. The rate law is presented in Equation (5)

$$\begin{aligned} &trans\text{-}[Co(en)_2(Me)NH_3]^{2+} + H_2O \rightleftarrows \\ &\quad trans\text{-}[Co(en)_2(Me)H_2O]^{2+} + NH_3 \quad k_3,k_{-3} \\ &trans\text{-}[Co(en)_2(Me)H_2O]^{2+} + L \rightleftarrows \\ &\quad trans\text{-}[Co(en)_2(Me)L]^{+} + H_2O \quad k_4,k_{-4} \end{aligned} \tag{4}$$

$$k_{obs} = \{k_3k_4[L] + k_{-3}k_{-4}[NH_3]\}/\{k_4[L] + k_{-3}[NH_3]\} \tag{5}$$

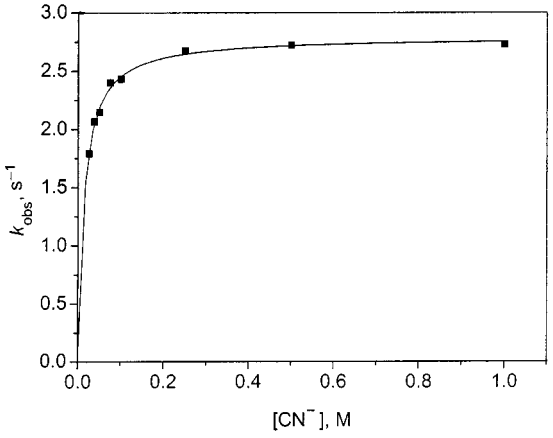

Figure 4. k_{obs} versus $[CN^-]_{total}$ for the reaction between *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ and CN^- at pH = 11, $[NH_3]$ = 1 M, 10 °C and I = 1 M ($NaClO_4$); the best fit of the data (solid line) to Equation (5) gives $k_3 = 2.79 \pm 0.02$ s^{-1}, $k_4/k_{-3} = 73 \pm 3$

The reactions of SCN^- and N_3^- with *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ were studied at 10 °C, using a buffer at pH = 9 and I = 1 M $NaClO_4$. Interestingly, the plot of k_{obs} versus $[SCN^-]$ results in a decrease of k_{obs} with increasing ligand concentration presumably due to the fact that $k_3 << k_{-4}$ as shown in Figure 5. A Similar plot was obtained for the reaction with N_3^- (see Supporting Information, Figure S-2). This is characteristic for the dissociative formation of an intermediate and the occurrence of an efficient back reaction. A similar nucleophile concentration dependence was reported for several reversible dissociative ligand substitution reactions, such as the reaction of $[Co(NH_3)_5(Me)]^{2+}$ with ethylenediamine,[19] the reaction of (*N*-methylimidazole)cobalamin with *N*-methylimidazole,[27] and other reactions reported in the literature.[42–46] A nonlinear least-squares fit of the data for SCN^-, revealed that $k_3 = 3.1 \pm 0.2$ s^{-1}, $k_{-4} = 19 \pm 4$ s^{-1} and $k_4/k_{-3} = 34 \pm 13$, and those obtained for N_3^- are $k_3 = 3.1 \pm 0.3$ s^{-1}, $k_{-4} = 23 \pm 5$ s^{-1} and $k_4/k_{-3} = 16 \pm 7$. The values of k_4/k_{-3} represent the efficiency of SCN^- and N_3^- compared with NH_3 to scavenge the six-coordinate intermediate. The complex-formation constant $K = k_3k_4/k_{-3}k_{-4}$ obtained from the kinetic data for the reaction with SCN^- and N_3^- are 5.6 ± 0.5 and 2.2 ± 0.5, respectively, which are in good agreement with the thermodynamically determined values of 4.4 ± 1.5 and 3.0 ± 0.4, respectively.

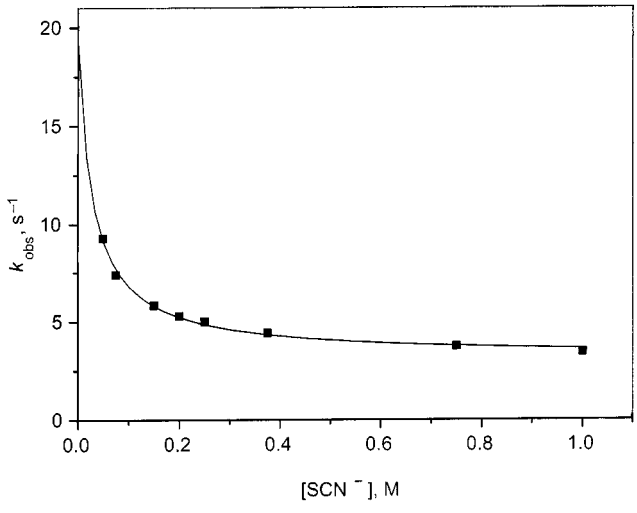

Figure 5. k_{obs} versus $[SCN]_{total}$ for the reaction between *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ and SCN^- at pH = 9, $[NH_3]$ = 1 M, 10 °C and I = 1 M $NaClO_4$; the best fit of the data (solid line) to Equation (5) gives $k_3 = 3.1 \pm 0.2$ s^{-1}, $k_{-4} = 19 \pm 4$ M^{-1} s^{-1}, $k_4/k_{-3} = 34 \pm 13$

By way of comparison, the value of k_3 for the reaction of *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ with $[CN^-]$ (2.79 ± 0.02 s^{-1}) is close to that obtained when L is SCN^- and N_3^-, viz. 3.1 ± 0.2 and 3.1 ± 0.3 s^{-1}, respectively, and also in agreement with that obtained for the aquation of *trans*-$[Co(en)_2(Me)NH_3]^{2+}$ (viz. 2.28 ± 0.06 s^{-1}) at 10 °C. This suggests that the limiting rate constant reached at high nucleophile concentration for all these reactions, is for aquation of the ammine complex that is controlled by the release of NH_3 (i.e., k_3), for which the mechanism has been discussed above.

The value of k_{-4} for the reaction of $[Co(en)_2(Me)CN]^+$ with NH_3 is close to zero. However, k_{-4} for the reaction of the SCN^- and N_3^- complexes with NH_3 is 19 ± 4 and 23 ± 5 M^{-1} s^{-1}, respectively. These values indicate that the back reaction contributes significantly in the case of the weaker nucleophiles SCN^- and N_3^-, and that the reaction is irreversible in the case of the stronger nucleophile CN^-.

The ratio of k_4/k_{-3} for the reaction of CN^- with $[Co(en)_2(Me)NH_3]^{2+}$ was found to be 73 ± 3, significantly higher than for the reactions with SCN^- and N_3^-, viz. 34 ± 13 and 16 ± 7, respectively. The higher ratio in the case of CN^- is due to its stronger nucleophilicity than SCN^- and N_3^-, and is therefore a better scavenger for the six-coordinate aqua intermediate in its competition with NH_3 as nucleophile. We conclude that aquation of the ammine complex controls the ligand substitution reactions with the studied nucleophiles and proceeds according to the mechanism outlined in Equation (4).

Experimental Section

Materials: All chemicals were of p.a. grade and used as received. Taps buffer (pH = 9) and Caps buffer (pH = 11) were purchased from Sigma. $NaClO_4$ was purchased from Fluka. NaSCN, NaN_3, NH_3 and NaCN were purchased from Merck. Ultra pure water

was used for all measurements. All preparations and measurements were carried out in diffuse light since the complexes were found to be light sensitive. *trans*-$[Co(en)_2(Me)NH_3]S_2O_6$ was prepared as described by Kofod[47] by treating Co^{II} nitrate with methylhydrazine in the presence of NH_3 to give $[Co(NH_3)_5Me](NO_3)_2$. This complex was treated with ethylenediamine to give *cis*-$[Co(en)_2(Me)NH_3]^{2+}$, followed by a slow isomerization to give *trans*-$[Co(en)_2(Me)NH_3]^{2+}$, which can be isolated in the solid form; *trans*-$[Co(en)_2(Me)H_2O]^{2+}$ was prepared by dissolving *trans*-$[Co(en)_2(Me)NH_3]S_2O_6$ in water at 60 °C for 2 h as previously described. The complexes were characterized by elemental analyses, UV/Vis and NMR spectroscopy, and the results were in agreement with literature data.[47]

Instrumentation: The pH of the solution was measured using a Mettler Delta 350 pH meter. The pH meter was calibrated with standard buffer solutions at pH = 7 and 10. UV/Vis spectra were recorded with Shimadzu UV-2101 and Cary 5 spectrophotometers. Kinetic measurements were carried out with an Applied Photophysics SX 18MV stopped-flow instrument coupled to an online data acquisition system. At least eight kinetic runs were recorded under all conditions, and the reported rate constants represent the mean values. All kinetic measurements were carried out under pseudo-first order conditions, i.e. the ligand concentration was in at least tenfold excess. Measurements at high pressure were carried out using a homemade high-pressure stopped-flow unit.[48] Kinetic data were analyzed with the OLIS KINFIT (Bogart, GA, USA) program. All instruments used were thermostated to the desired temperature (± 0.1 °C). Equilibrium measurements: $3-5 \times 10^{-3}$ M *trans*-$[Co(en)_2(Me)NH_3]S_2O_6$ or *trans*-$[Co(en)_2(Me)H_2O]S_2O_6$, dissolved in Taps buffer pH = 9 or caps buffer pH = 11 (I = 0.1 M using $NaClO_4$), was placed in a 1.0-cm path length cuvette in the thermostated cell block of the spectrophotometer for ca. 20 min. This solution was titrated by addition of small volumes of a concentrated stock solution of the ligand, using a Hamilton syringe. The ligand solution was prepared in the same buffer and the ionic strength was also adjusted to 0.1 M using $NaClO_4$. The titrations were carried out in duplicate and were monitored at several wavelengths where the largest change in absorbance occurred. The values of the equilibrium constant, K, were obtained by fitting the absorbance versus concentration curve to the appropriate equation, after correction for dilution (see further Discussion).

Di- and Tetranuclear Dawson-Derived Sandwich Complexes: Synthesis, Spectroscopic Characterization, and Electrochemical Behavior

Laurent Ruhlmann,[a] Louis Nadjo,*[a] Jacqueline Canny,[b] Roland Contant,[b] and René Thouvenot*[b]

Keywords: Polyoxometalates / Sandwich complexes / Synthesis / NMR spectroscopy / Electrochemistry

The reaction of α-$[P_2W_{15}O_{56}]^{12-}$ with divalent cations M^{2+} leads to sandwich complexes of the formula $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ ($M_4P_4W_{30}$) where M = Mn^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II}, or Cd^{II}. An Fe^{III} tetranuclear sandwich complex has also been obtained. Full details are reported concerning procedures by which the pure sandwich complexes can be obtained in good yield. A pure dinuclear trivalent Dawson-derived sandwich complex of the formula $[(H_2O)_2Na_2Fe^{III}_2(P_2W_{15}O_{56})_2]^{16-}$ has also been prepared as a water-soluble sodium salt. All the compounds have been characterized by IR spectroscopy, elemental analysis, and ^{31}P NMR spectrometry. The acid-base equilibria of the $M_4P_4W_{30}$ series have been studied. The electrochemical behavior of this series of sandwich complexes in aqueous solution has been investigated and systematic comparisons have been made. All these compounds exhibit successive reduction processes of the W atoms in a negative potential range, but in some cases the electrochemistry also involves redox reactions originating from the substituent transition metal (M), such as the reduction of Fe^{III} and Cu^{II} and the oxidation of Mn^{II}.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The possibility of modifying the redox and chemical properties of heteropolyanions by replacing one or many elements renders them particularly attractive for catalytic and electrocatalytic applications.[1] For instance, a cluster such as $[P_2W_{18}O_{62}]^{6-}$ may be modified under hydrolytic conditions to give lacunary complexes containing one, three, or more vacant sites.[2] The action of metallic cations on the trivacant heteropoly ligand $[P_2W_{15}O_{56}]^{12-}$ (derived from the Dawson structure $[P_2W_{18}O_{62}]^{6-}$; Scheme 1) leads to metal-heteropolyanions that can be formulated as $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{n-}$ (where M = Mn^{II}, Fe^{III}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II}, or Cd^{II}, and n = 16, except in the case of Fe^{III}, where n = 12). These constitute an extensive series of compounds in which a tetranuclear cluster $M_4O_{14}(H_2O)_2$ is encapsulated between two trivacant fragments.[3] Of the four metal atoms, two reside in a pseudooctahedral environment with one coordination site occupied by a labile water molecule, which can be replaced by other ligands.

This series of sandwich polyoxoanions with four d-electron transition metal cations appears quite promising as a potential class of catalysts because both the four central metal ions and, in principle, the heteroatoms in the trivacant polyoxoanions units can be varied considerably. Thus, they can be used in catalytic reactions as inorganic analogues of porphyrins with the advantage of being more robust and inert toward an oxidizing environment and more thermally stable than systems based on organic ligands.[4]

We report herein on a new route for the synthesis of a tetranuclear Co Dawson-derived sandwich complex as well as of a dinuclear Fe Dawson-derived sandwich complex[3i,3j] of the formula $[(H_2O)_2Na_2Fe_2(P_2W_{15}O_{56})_2]^{16-}$, which have been obtained when operating in acidic media.

We also present in the following a systematic spectroscopic investigation by ^{31}P NMR of the para- and diamagnetic sandwich complexes of the composition $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$, as well as a study of their electrochemical behavior.

These sandwich complexes exhibit at least three consecutive processes involving oxo-tungsten based reduction in a negative potential range, but in some cases the electrochemistry also involves redox reactions originating from the substituent transition metal (M), such as the reduction of Fe^{III} and Cu^{II} and the oxidation of Mn^{II}.

Interestingly, for the compounds $[Fe_4(H_2O)_2P_4W_{30}O_{112}]^{12-}$ and $[(H_2O)_2Na_2Fe_2P_4W_{30}O_{112}]^{16-}$, the Fe-centered redox processes are fully reversible prior to reduction of the polyanions. Splitting of this wave is often seen.

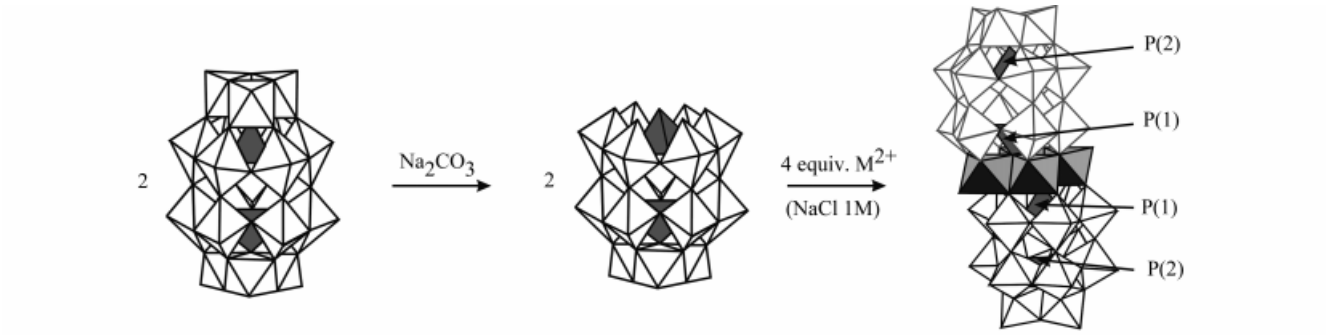

Scheme 1

Intriguingly, the Fe^{III}/Fe^{II} couples in $[(H_2O)_2Na_2Fe_2P_4W_{30}O_{112}]^{16-}$ ($Fe_2P_4W_{30}$) were found to be pH dependent; this is rather unusual for Fe-centered redox processes, for which the redox potential is usually almost pH-independent at low pH.[5] Assuming that $Fe_2P_4W_{30}$ has the molecular structure recently reported by Hill et al.,[3i,3j] with the two external sites of the sandwich structure occupied by Na^+ cations, the unusual pH dependence can be tentatively explained in terms of a stepwise exchange of the Na^+ cations by H^+ during the consecutive reduction of the two Fe^{III} centers.

To the best of our knowledge, such a complete investigation of Dawson sandwich species has not been published previously.

Results and Discussion

Synthesis

The first objective of this work was the large-scale, high-yielding preparation of very pure tetranuclear sandwich complexes of the composition $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$. This polyanion consists of an oxo-aqua tetranuclear metal core, $M_4O_{14}(H_2O)_2$, sandwiched by two trivacant α-Dawson moieties, α-$[P_2W_{15}O_{56}]^{12-}$. The polyanion has C_{2h} symmetry (see Scheme 1).

Key factors in the strategy that led to the results described below included: (i) use of the pure lacunary precursor α-$[P_2W_{15}O_{56}]^{12-}$, (ii) extensive use of ^{31}P NMR spectroscopy to survey different conditions in optimizing the route to pure $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ products, (iii) careful control of the solution pH, and (iv) control of the stoichiometry of M^{n+} vs. α-$[P_2W_{15}O_{56}]^{12-}$ in order to obtain pure compounds.

The complexes were readily prepared in ca. 50−90% isolated yields and in high purity. The best preparation is similar to that cited in the literature for sandwich polytungstophosphate complexes $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$, where M = Mn^{II}, Zn^{II}, or Cd^{II}.

However, to obtain pure $[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ it is necessary to operate in an acidic medium. Actually, as is evident from Figure 1, which shows the ^{31}P NMR spectra of $Co_4P_4W_{30}$ prepared by the literature method (neutral medium) and at ca. pH 3, the best preparation of pure $Co_4P_4W_{30}$ is undoubtedly achieved at pH 3. From the ^{31}P analysis, it appears that the preparation in neutral media, as described in the literature, invariably gives a mixture of several species, and that two different types of crystals, one green-brown and the other gray, are deposited from such solutions on crystallization. In contrast, the synthesis in acidic solution (ca. pH 3) leads exclusively to one major species as green-brown crystals with a purity of 95% (A in Figure 1).

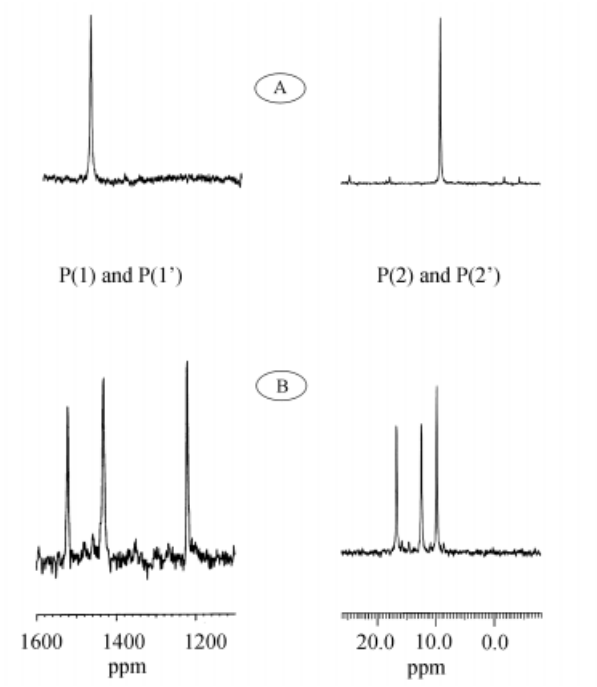

Figure 1. 121.5 MHz ^{31}P NMR spectra of $Co_4P_4W_{30}$ (0.02 M in 0.5 M aqueous LiCl): (A) sample prepared at pH 3; (B) sample prepared in neutral medium; left part: P(1) region; experimental conditions: spectral width 125 kHz; pulse width 2 μs (ca. 40° flip angle); 8K data points; acquisition time 33 ms; ca. 10K transients acquired without relaxation delay; line-broadening factor 40 Hz; right part: P(2) region; experimental conditions: spectral width 9 kHz; pulse width 2 μs (ca. 40° flip angle); 4K data points; acquisition time 0.23 s; ca. 1000 transients acquired without relaxation delay; line-broadening factor 4 Hz

The ^{31}P NMR spectrum of the mixture obtained following the synthesis in a neutral medium exhibits three "pairs"

[a] Unless otherwise noted, 0.02 M solution in 0.5 M LiCl. [b] P(1) and P(2) in the PW_6 and PW_9 subunits, respectively. [c] In ppm with respect to 85% H_3PO_4. [d] In Hz. [e] Not observed. [f] In a mixture as obtained from the synthesis medium (see text). [g] As for f, but in 0.1 M AcONa/AcOH buffer (pH 4.7).

of resonances (see Table 1 and B in Figure 1). The pair at δ = 1459 and 9.8 correspond to the two resonances of the pure $Co_4P_4W_{30}$ synthesized at pH 1 (see A in Figure 1). The four other signals will be considered below.

In more acidic solution (0.1 M AcONa/AcOH buffer), the ^{31}P NMR spectrum evolves by a concomitant decrease in the four resonances (at δ = 1590, 1201, 16.7, and 10.1). After one day, only the two peaks at δ = 1473 and 8.8 remain, which are characteristic of the pure $Co_4P_4W_{30}$ compound.

The chemical shift variations observed between neutral and acidic solutions can be attributed to deprotonation of the aqua ligands in neutral media (see below).

Because they disappear simultaneously at the expense of the $Co_4P_4W_{30}$ signals, the four resonances (at δ = 1590, 1201, 16.7, and 10.1) are most probably due to a single species, which contains four non-equivalent P atoms and should be structurally related to the symmetrical sandwich compound $Co_4P_4W_{30}$ (C_{2h}). Two unsymmetrical structural isomers of $Co_4P_4W_{30}$, both of C_s symmetry, can be considered, resulting from either (i) the formal π/3 rotation of the polar cap of one P_2W_{15} moiety, leading to a β-P_2W_{15} subunit (see Scheme 1) or (ii) the formal rotation of a whole α-P_2W_{15} subunit leading to both α-type and β-type junctions at the Co_4 tetrad.

Thus, in neutral solution, the synthesis of the Dawson sandwich species gives a mixture of symmetrical (δ = 1459 and 9.8) and unsymmetrical (δ = 1551, 1242, 16.7 and 12.3) complexes in relative proportions of 38 and 62% (by integration of the NMR resonances).

In acidic solution, only the symmetrical isomer is formed, which suggests that this isomer is the thermodynamic product obtained at pH 3 and that slow transformation occurs on decreasing the pH. Finke et al.[3b] described a similar behavior for $[Zn_4(H_2O)_2P_4W_{30}O_{112}]^{16-}$, where thermal isomerization was observed with the appearance of additional ^{31}P resonances. On the other hand, the temperature is not a factor in the present isomerization since the same temperature is used for the syntheses in acidic and neutral solutions. This result may suggest a control of the isomerization by the pH of the medium.

Di- and tetrairon sandwich polyoxoanions were prepared in 67% and 52% isolated yields, respectively, using essentially the same procedure. Actually, powdered α-$Na_{12}[P_2W_{15}O_{56}]$ dissolves readily at room temperature in an aqueous solution of iron(III) chloride (pH 3) without the formation of any insoluble intermediate. However, the optimal synthetic conditions were found when operating in more acidic media (pH 1) at high temperature (80 °C) and under vigorous stirring. With only one equivalent of α-P_2W_{15} added to the iron(III) solution, i.e. with one equivalent of Fe^{3+}, the diiron sandwich complex is obtained and can be isolated in high purity.

Conversely, with a stoichiometry of one equivalent of α-P_2W_{15} to two equivalents of Fe^{3+}, only the tetrairon sandwich compound is obtained as a pure species. This suggests an equilibrium between the di- and tetrairon sandwich polyoxoanions [Equation (1)]:

$$(H_2O)_2Na_2Fe^{III}_2(P_2W_{15}O_{56})_2^{16-} + 2\,Fe^{3+} \rightleftarrows Fe^{III}_4(H_2O)_2(P_2W_{15}O_{56})_2^{12-} + 2\,Na^+ \quad (1)$$

Accordingly, the "unsaturated" diiron species must be formed first and exists predominantly at low Fe^{3+}/α-P_2W_{15} ratios. It is converted to the "saturated" tetrairon species in the presence of an excess of iron.

IR Characterization

The IR spectrum of $Zn_4P_4W_{30}$ is shown Figure 2 and is compared with those of the parent anions α-P_2W_{15} and α-P_2W_{18}.

Apart from the W−O bands, which appear at low wavenumbers (< 1000 cm^{-1}), the IR spectra of phosphorus-centered polyoxotungstates are characterized by well-separated P−O stretching vibrations between 1200 and 1000 cm^{-1}.[6]

According to the local symmetry of the PO_4 group, the triply-degenerate mode F_2 (for T_d symmetry) may split into two or three absorption bands for C_{3v} or C_s symmetry, respectively; the splitting depends on the deviation from ideal symmetry. Hence, for the lacunary anions $[PMo_{11}]$ and $[PW_{11}]$, and for the substituted metallophosphates $[PMMo_{11}]$ and $[PMW_{11}]$ (M = first row transition metal), it was shown that the splitting Δν decreases when the metal M interacts more strongly with the oxygen atom of the PO_4 tetrahedron.[7] For lacunary or substituted unsymmetrical Dawson species, the situation is more intricate due to the overlap of vibrational absorption bands arising from two different PO_4 tetrahedra; in favorable cases, however, it is possible to discriminate between the bands arising from the unperturbed subunit PW_9 and those arising from the PW_xM_y moiety.[8] For example, α-P_2W_{15}, like α-P_2W_{18}, ex-

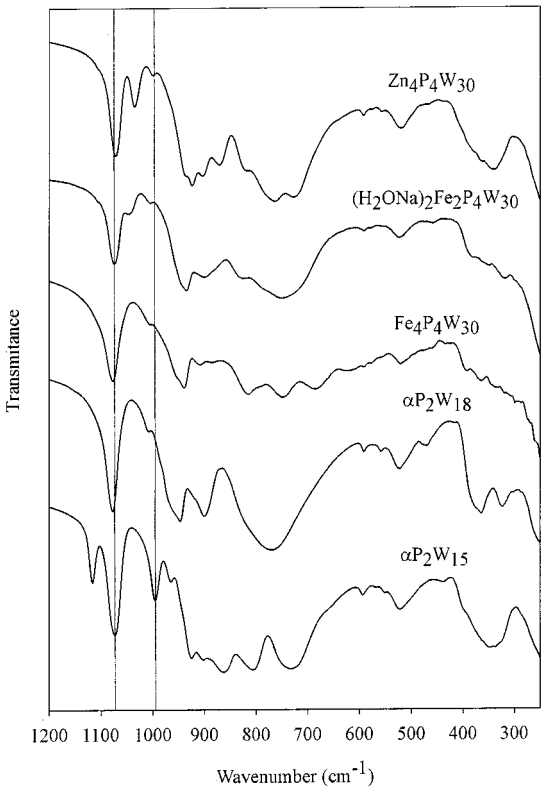

Figure 2. Comparison of the IR spectra (KBr) of the hydrated sandwich compounds $Zn_4P_4W_{30}$, $Fe_2P_4W_{30}$, $Fe_4P_4W_{30}$, and of their precursors

hibits two bands at around 1080 and 1010 cm^{-1} (assigned to PW_9), as well as an additional band at high wavenumbers (1131 cm^{-1}), which can be attributed to the PW_6 subunit. The corresponding vibrational mode may be described as a stretching of the $P-O_{ter}$ bond along the ternary axis (A_1-type in the C_{3v} point group) and the relatively high frequency is related to the large force constant of this bond, which has some P=O double bond character. This band is not observed for the sandwich compounds $M_4P_4W_{30}$, in agreement with the fact that the oxygen atom has contracted bonds with some M atoms, which results in a decrease of the k_{P-O} force constant. Actually, it appears that the band associated with the PW_6 subunit is correspondingly shifted to low wavenumbers and all of the tetrametallic sandwich compounds, except for $Fe_4P_4W_{30}$, exhibit a band at about 1055 cm^{-1}. The IR spectra of the Mn, Co, Ni, Cu, Zn, and Cd derivatives are nearly identical, which indicates a structural similarity throughout the whole $M_4P_4W_{30}$ series. Finally, we note that terminal W−O and bridging W−O−W stretching bands are located in the range 970−700 cm^{-1}, at lower wavenumbers than for the parent saturated α-P_2W_{18} anion.

Let us return to the case of the iron compounds: in the phosphate stretching region, the IR spectrum of $Fe_4P_4W_{30}$ exhibits the same pattern as that of P_2W_{18}, and no band is present at around 1060 cm^{-1} (Figure 2). This indicates that both PO_4 groups in the PW_6 and PW_9 moieties are becoming nearly equivalent, most probably because of the stronger M−O interaction exerted by the trivalent Fe^{3+} ions as compared with those of the divalent Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Cd^{2+} cations. For $[Fe_2P_4W_{30}]$, however, only two iron atoms may interact with the oxygen atom of the phosphate, which is insufficient to restore the equivalence of the two PO_4 groups belonging to the two subunits; this accounts for the presence of the small absorption band at almost the same wavenumber as seen for the $M_4^{II}P_4W_{30}$ species.

^{31}P NMR Characterization

^{31}P NMR spectroscopy is particularly well-suited for checking the purities of polyoxometallate species and for characterizing the nature of the substituting elements. The ^{31}P NMR spectroscopic data for the sandwich complexes $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ (M = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Cd^{2+}), $[Fe_4^{III}(H_2O)_2(P_2W_{15}O_{56})_2]^{12-}$ and $[(H_2O)_2Na_2Fe_2^{III}(P_2W_{15}O_{56})_2]^{16-}$ ($Fe_2P_4W_{30}$), and their parent compounds are reported in Table 1. The ^{31}P NMR spectra of the diamagnetic species $Cd_4P_4W_{30}$ and $Zn_4P_4W_{30}$ show two lines, consistent with the presence of a single isomer (Figure 3); the most shielded line, at about $\delta = -14$, is assigned to P(2) of the PW_9 unit. The deshielded line, at about $\delta = -4$, corresponds to P(1) in the PW_6M_3 unit; its integrated intensity appears smaller than that of P(2) because of a slow relaxation rate (large T_1).

In comparison with the diamagnetic complexes, the spectra of the paramagnetic compounds are characterized by broad signals and large frequency shifts. For paramagnetic species, the signals can be assigned according to the following rule: the most broadened and shifted resonances correspond to the atoms nearest to the paramagnetic centers. Then, for each sandwich compound, the sharper line, with a chemical shift close to those seen for diamagnetic metallophosphates (between $\delta = +20$ and $\delta = -20$) is assigned to P(2), the P atom furthest from the M^{n+} ions. The P(1) atom, which is very close to the paramagnetic elements, is responsible for the broad and strongly deshielded resonances. For $Ni_4P_4W_{30}$, the broadening of the P(1) signal makes the line difficult to discern accurately from base-line artifacts. Figures 1, 3, and 4 show typical ^{31}P NMR spectra of $M_4P_4W_{30}$ and $Fe_2P_4W_{30}$ Dawson sandwich complexes.

For the series of sandwich complexes, the observed line widths, $\Delta\nu_{1/2}$, for the P(1) resonance are as follows: for the diamagnetic Zn^{2+} and Cd^{2+} complexes the signal is very narrow ($\Delta\nu_{1/2} < 5$ Hz); for Co^{2+} complexes it is relatively narrow ($\Delta\nu_{1/2} = 420$ Hz), while for tetrametallic Fe^{3+} and Ni^{2+} complexes it is very broad ($\Delta\nu_{1/2} = 2500$ Hz and 3400 Hz, respectively). In the case of Cu^{2+} and Mn^{2+}, as well as for the diiron species, the signals from P(1) are probably too broad to be observed. As a consequence, the spectra of these complexes feature only one resonance, corresponding to the P(2) atom.

The same trend in line width is also observed for the P(2) signal (the P atom furthest from the M^{n+} ions). The line width $\Delta\nu_{1/2}$ for P(2) varies as follows: for the diamagnetic Zn^{2+} and Cd^{2+} complexes the signal is very narrow ($\Delta\nu_{1/2} < 3$ Hz), it remains relatively narrow for Co^{2+} and Ni^{2+} (in

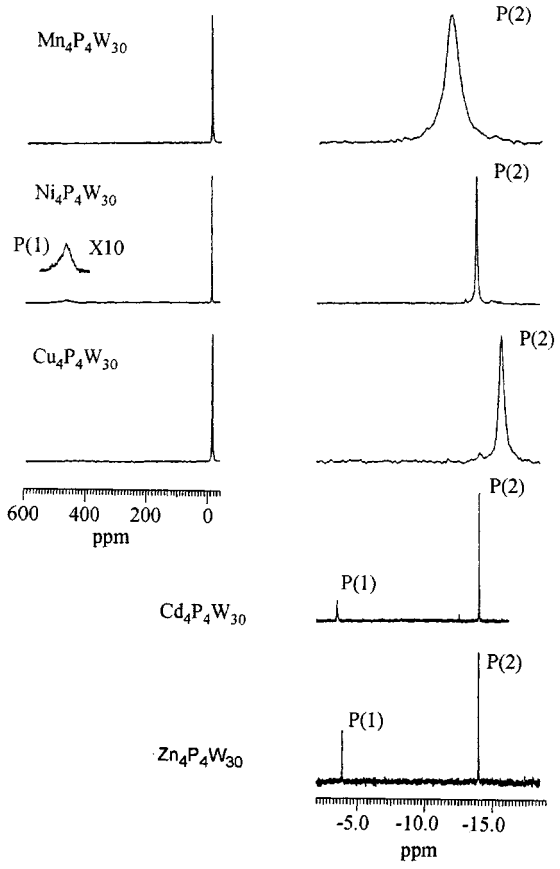

Figure 3. 121.5 MHz ^{31}P NMR spectra of various $M_4P_4W_{30}$ species (0.02 M in 0.5 M aqueous LiCl); experimental conditions for the left part: spectral width 166 kHz; pulse width 2 μs (ca. 40° flip angle); 4K data points; acquisition time 13 ms; ca. 70K transients acquired without relaxation delay; line-broadening factor 80 Hz; experimental conditions for the right part: $Cd_4P_4W_{30}$ and $Zn_4P_4W_{30}$: spectral width 2.5 kHz; 8K data points; acquisition time 1.6 s; ca. 300 transients acquired without relaxation delay; line-broadening factor 0.6 Hz; $Mn_4P_4W_{30}$, $Ni_4P_4W_{30}$, and $Cu_4P_4W_{30}$: spectral width 6 kHz; 4K data points; acquisition time 0.3 s; ca. 2000 transients acquired without relaxation delay; line-broadening factor 20 Hz (Mn), 3 Hz (Ni), and 10 Hz (Cu)

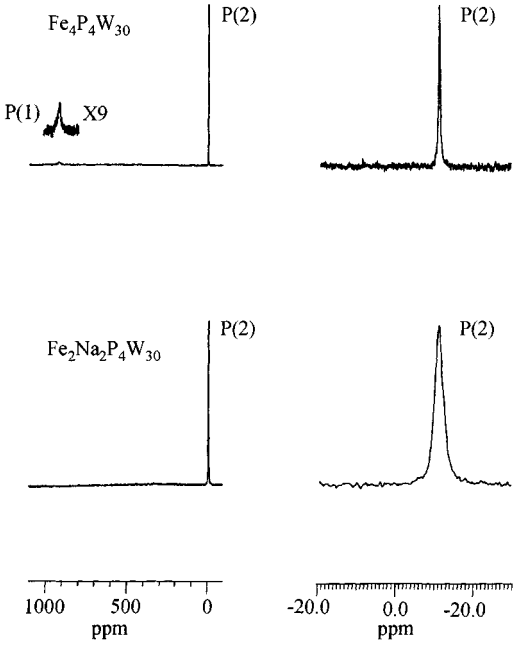

Figure 4. 121.5 MHz ^{31}P NMR spectra of $Fe_4P_4W_{30}$ and $Na_2Fe_2P_4W_{30}$ (0.02 M in 0.5 M aqueous LiCl); experimental conditions for the left part: spectral width 166 kHz; pulse width 2 μs (ca. 40° flip angle); 4K data points; acquisition time 13 ms; ca. 70K transients acquired without relaxation delay; line-broadening factor 80 Hz; experimental conditions for the right part: spectral width 10 kHz; 4K data points; acquisition time 0.2 s; ca. 3000 transients acquired without relaxation delay; line-broadening factor 10 Hz ($Fe_4P_4W_{30}$) and 10 Hz ($Na_2Fe_2P_4W_{30}$)

the range 15−20 Hz), but is markedly broadened for Mn^{2+} ($\Delta\nu_{1/2}$ = 130 Hz) and for the diiron species ($\Delta\nu_{1/2}$ = 220 Hz). For Cu^{2+} and for the tetrairon species, the signal is of intermediate width ($\Delta\nu_{1/2}$ = 60 Hz and 55 Hz, respectively).

A similar variation in ^{31}P line width has previously been observed by Baker et al. for Keggin and Dawson monosubstituted polytungstates.[9] Baker noted that complexes containing paramagnetic ions with orbitally nondegenerate ground states (i.e. Mn^{2+}, $^6A_{1g}$) are those giving very broad ^{31}P signals. Orbitally nondegenerate states have long electronic relaxation times, which lead to very fast nuclear relaxation of the nearby nuclei (short T_1 and T_2). Therefore, in accordance with the relationship $\Delta\nu_{1/2} = 1/\pi T_2$, the NMR resonances are very broad. On the contrary, for orbitally degenerate ground states, such as Co^{2+} ($^4T_{1g}$), the fast electronic relaxation rate leads to relatively slow nuclear relaxation, which explains the relatively narrow NMR lines.[9]

pK_a Determination

In the sandwich compounds, the sixth coordination position of the external metal atoms is occupied by a labile water molecule. According to the pH, this aqua ligand can be easily deprotonated, successively giving the hydroxo-aqua and the dihydroxo forms [Equations (2) and (3)].

$$M_4^{II}(H_2O)_2P_4W_{30}O_{112}^{16-} + H_2O \rightleftarrows M_4^{II}(H_2O)(OH)P_4W_{30}O_{112}^{17-} + H_3O^+ \quad pKa_1 \tag{2}$$

$$M_4^{II}(H_2O)(OH)\,P_4W_{30}O_{112}^{17-} + H_2O \rightleftarrows M_4^{II}(OH)_2P_4W_{30}O_{112}^{18-} + H_3O^+ \quad pKa_2 \tag{3}$$

The dihydroxo forms of the M^{II} sandwich complexes were obtained directly from their syntheses in neutral solutions, except in the case of the Co^{II} species. For the titration, the hydroxo-aqua form of $Co_4P_4W_{30}$, as obtained from the synthesis at ca. pH 3, was initially converted to its dihydroxo form by adding a stoichiometric amount of NaOH.

Acidification curves of the dihydroxo complexes do not depend on the concentration and show the successive protonation of the two hydroxo groups. Actually, the diacid character of the sandwich complex could be confirmed by a pH jump in the presence of two equivalents of HNO_3.

The titration curves are characteristic of diacid behavior where pK_{a1} and pK_{a2} are close.

K_{a1} and K_{a2} were calculated from experimental points using the following relationship (A):

$$[H_3O^+] = \frac{-(1-x)Ka_1 + \sqrt{Ka_1^2(1-x)2 + 4xKa_1Ka_2(2-x)}}{2(2-x)} \quad (A)$$

where x is the number of mol of HNO_3 per mol of complex. The values of pK_{a1} and pK_{a2} are reported in Table 2.

Table 2. Acidity constants for the sandwich species $M_4P_4W_{30}$ and $Fe_2P_4W_{30}$

Compound	pK_{a1}	pK_{a2}
$Mn_4P_4W_{30}$	3.5 ± 0.1	5.3 ± 0.1
$Fe_4P_4W_{30}$	3.6 ± 0.1	5.6 ± 0.1
$Fe_2P_4W_{30}$	3.6 ± 0.1	5.6 ± 0.1
$Co_4P_4W_{30}$	3.5 ± 0.1	5.3 ± 0.1
$Ni_4P_4W_{30}$	—[a]	—[a]
$Cu_4P_4W_{30}$	3.2 ± 0.1	5.0 ± 0.1
$Zn_4P_4W_{30}$	3.2 ± 0.1	5.2 ± 0.1
$Cd_4P_4W_{30}$	3.6 ± 0.1	5.4 ± 0.1

[a] Degradation occurred during the titration.

In the case of iron(III) complexes, as their syntheses were conducted in acidic solutions, they were obtained as diaqua species. Therefore, their acidity constants were determined from the titration of their diaqua forms with NaOH. This corresponds to the successive deprotonation of the two aqua ligands. pK_{a1} and pK_{a2} were obtained by analysis of the basification curves using the following relationship (B):

$$[H_3O^+] = \frac{(1-x)Ka_1 + \sqrt{Ka_1^2(1-x)2 + 4xKa_1Ka_2(2-x)}}{2x} \quad (B)$$

where x is the number of mol of NaOH per mol of complex.

Electrochemistry

General Electrochemical Behavior

The electrochemical behavior of sandwich complexes of the composition $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ ($M_4P_4W_{30}$) was mainly studied in aqueous solutions by cyclic voltammetry (CV). $M_4P_4W_{30}$ complexes are stable in aqueous media in the pH range 1−6 (with the exception of the $Ni_4P_4W_{30}$ sandwich, for which slow degradation was observed during the titration).

Beyond this pH range, the complexes become unstable due to hydrolytic decomposition.

These sandwich complexes exhibit at least three successive processes involving W in a negative potential range. Some of them also undergo redox reactions originating from the substituent transition metal (M), such as the reduction of Fe^{III} and Cu^{II} at less negative potentials and the oxidation of Mn^{II} at a more positive potential. In general, the reduction of heteropolyanions is accompanied by protonation at low pH, and hence the pH of the solution has a great effect on the electrochemical behavior of the sandwich. For the three couples corresponding to oxo W-based reduction, the cathodic peak currents are almost proportional to the square root of the scan rate up to 500 mV s^{-1}, which indicates that the electrode reaction of $M_4P_4W_{30}$ is diffusion controlled.

All electrochemical data acquired at pH 2.52 are gathered in Table 3 and typical cyclic voltammograms are presented in Figures 5−9.

$M_4P_4W_{30}$ Complexes with Electrochemically Silent Heterometallic Ions, M = Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}

The electrochemical behavior of all $M_4P_4W_{30}$ complexes with M = Co^{2+}, Ni^{2+}, Zn^{2+}, or Cd^{2+} is very similar. Therefore, only the characteristics of the Co compound will be described in detail. CVs of $Co_4P_4W_{30}$ in aqueous solutions at pH 2.52 are presented in Figure 5. $Co_4P_4W_{30}$ is stable in aqueous solution in the pH range 1−6. At pH > 6, the cyclic voltammogram becomes ill-defined and the peak current is much smaller; such an observation has previously been reported by Dong et al. in relation to Keggin-type polyoxometallates;[10] this behavior may be due to a repulsion of the 18^- charge of $Co_4P_4W_{30}$ at the glassy carbon electrode surface.

In the pH range 1−6, three well-defined redox waves originating from the oxo-tungsten framework are seen between −0.30 and −0.95 V. These three redox couples with equal heights all relate to four-electron reaction processes, as determined by coulometry. At more acidic pH (in the range 1−3), the redox potentials of the three four-electron waves become more negative; the first and the last four-electron waves for M = Co^{2+} or Ni^{2+} split into two two-electron waves (see B in Figure 5). Thus, in the pH range 1−3, the formal potentials of all three pairs of waves are pH dependent; the slopes of plots of the formal potentials vs. pH lie in the range 80−95 mV per pH unit, which indicates the addition of two or four H^+ ions to the reduced form of each redox couple. Above pH 3, the formal potentials for the two first redox couples are influenced by pH to a lesser degree, and they are shifted only slightly to more negative values with increasing pH. On the contrary, the formal potential of the third redox process is shifted slightly in the positive direction at pH > 3. These results show that H^+ does not participate in the redox reaction at pH > 3.

In addition, a fourth reduction wave is observed in the more negative range, between −1.00 and −1.20 V. It is an irreversible multi-electron wave that overlaps with the hydrogen evolution, and is not shown in the figure. In the more positive potential range between +1.60 and −0.30 V, however, no redox waves are observed, suggesting that the four sandwich complexes with Co, Ni, Zn, and Cd divalent

transition metal cations are not electroactive under our experimental conditions.

$Fe_2P_4W_{30}$ and $M_4P_4W_{30}$ Complexes with Electroactive Substituent Metals, M = Mn^{2+}, Cu^{2+}, Fe^{3+}

$[Mn_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ ($Mn_4P_4W_{30}$): CVs of the compound ($Mn_4P_4W_{30}$) at pH 2.52 are shown in Figure 6.

Three couples of oxo-tungsten based reduction processes can be seen at negative potentials in Figure 6, close to those of other $M_4P_4W_{30}$ species (M = Co, Ni, Zn, and Cd). The fourth reduction wave is a multi-electron wave that overlaps with the hydrogen evolution and is not shown in the figure. A new pair of redox process is observed at positive potentials of 1.00 V for oxidation and 0.80 V for reduction, which must correspond to the Mn-centered reaction (see B in Figure 6).[11] Controlled-potential electrolysis oxidation at +1.20 V (pH 2.52) resulted in the passage of 8.2 electrons per molecular anion, whereas subsequent reduction at +0.60 V consumes 4.2 electrons. These results show that the Mn-centered anodic peak corresponds to an eight-electron process, which suggests simultaneous oxidation of the four Mn^{II} heterometals to Mn^{IV} at +1.00 V and reduction of Mn^{IV} to Mn^{III} at 0.80 V. When the pH is increased, the peak potentials of both W- and Mn-centered redox waves of $Mn_4P_4W_{30}$ shift in the negative direction, indicating that they are all accompanied by protonation. Additionally, a new cathodic peak appears at −0.08 V.

Figure 6 (A) shows that the appearance of the new cathodic peak is closely related to the Mn oxidation state. This new cathodic peak appears in the CVs only after the Mn-centered redox wave. It can be seen that as the preconditioning time at +1.00 V increases, the new cathodic peak at −0.08 V grows gradually, the peak current of the first Mn-centered reduction at 0.80 V increases simultaneously, while the W-based peak currents remain unchanged.

Similar results have also been obtained for α_2-MnP_2W_{17} and $ZnW_{11}Mn$ polyanions.[10] The present results suggest the oxidation of Mn^{II} to Mn^{IV} at ca. 1.00 V followed by the

Figure 6. Figure 7. (A) Cyclic voltammograms of 1 mM $Fe_4P_4W_{30}$ in 0.5 M Na_2SO_4 + H_2SO_4 at pH 2.52 with different negative potential limits: −0.13 V, −0.30 V, −0.39 V, −0.47 V, −0.69 V, and −0.95 V; scan rate 20 mV s^{-1}; inset: differential pulse voltammetry; scan rate 25 mV s^{-1}; (B) half-wave potential vs. pH plots for the $Fe^{III/II}$ redox couples (● and ▼) and the first (◆), second (■), and third tungsten redox couples (●)

reduction of Mn^{IV} to Mn^{III} at ca. 0.80 V and reduction of Mn^{III} to Mn^{II} at ca. −0.08 V on the reverse scan.

$[Fe_4^{III}(H_2O)_2(P_2W_{15}O_{56})_2]^{12-}$ ($Fe_4P_4W_{30}$): This species is stable in aqueous solution in the pH range 0.24−6.0, but at pH > 4 the cyclic voltammogram becomes ill-defined and the peak current is much smaller. No redox process is seen between 0.30 and 1.60 V; on the cathodic part, three or (depending on the pH) four $Fe^{III/II}$ reduction waves and three W reduction waves are observed. The positions of these three tungsten oxo reduction waves were studied as a function of pH; the formal potentials were found to shift by 87−95 mV per pH unit, which indicates the addition of one or two protons to the reduced forms of each redox couple.

In contrast, the three Fe-centered waves are almost pH independent. These results show that H^+ does not participate in the Fe-centered redox reaction in the pH range 0.24−6.00. At pH 2.52, two reversible one-electron and one reversible two-electron waves appear (Figure 7) with $E^{\circ\prime}$ values of +0.187 V, +0.110 V, and −0.028 V (ΔE_p = 74, 68, and 112 mV, respectively). Controlled potential electrolysis at −0.20 V in a medium at pH 2.52 and under continuous argon bubbling indicated the involvement of 4.10 electrons per molecule.

The reduction processes of $Fe_4P_4W_{30}$ can be represented as follows [Equations (4)−(6)].

$$[Fe_4^{III}(H_2O)_2(P_2W_{15}O_{56})_2]^{12-} + e^- \leftrightharpoons [Fe_3^{III}Fe^{II}(H_2O)_2(P_2W_{15}O_{56})_2]^{13-} \quad (4)$$

$$[Fe_3^{III}Fe^{II}(H_2O)_2(P_2W_{15}O_{56})_2]^{13-} + e^- \leftrightharpoons [Fe_2^{III}Fe_2^{II}(H_2O)_2(P_2W_{15}O_{56})_2]^{14-} \quad (5)$$

$$[Fe_2^{III}Fe_2^{II}(H_2O)_2(P_2W_{15}O_{56})_2]^{14-} + 2e^- \leftrightharpoons [Fe_4^{II}(H_2O)_2(P_2W_{15}O_{56})_2]^{16-} \text{ (at pH} < 3.5) \quad (6)$$

$[(H_2O)_2Na_2Fe_2(P_2W_{15}O_{56})_2]^{16-}$ ($Fe_2P_4W_{30}$): This species is stable in aqueous solution in the pH range 0.24−7.00. As shown in Figure 8, at pH 2.52 it also exhibits three four-electron waves at negative potentials close to those of $M_4P_4W_{30}$ (M = Co, Ni, Zn, and Cd). The positions of these three tungsten oxo reduction waves were found to be pH dependent. The slopes of plots of the formal potential vs. pH vary in the range 55−80 mV per pH unit. This is indicative of the addition of four protons to the reduced forms of each redox couple.

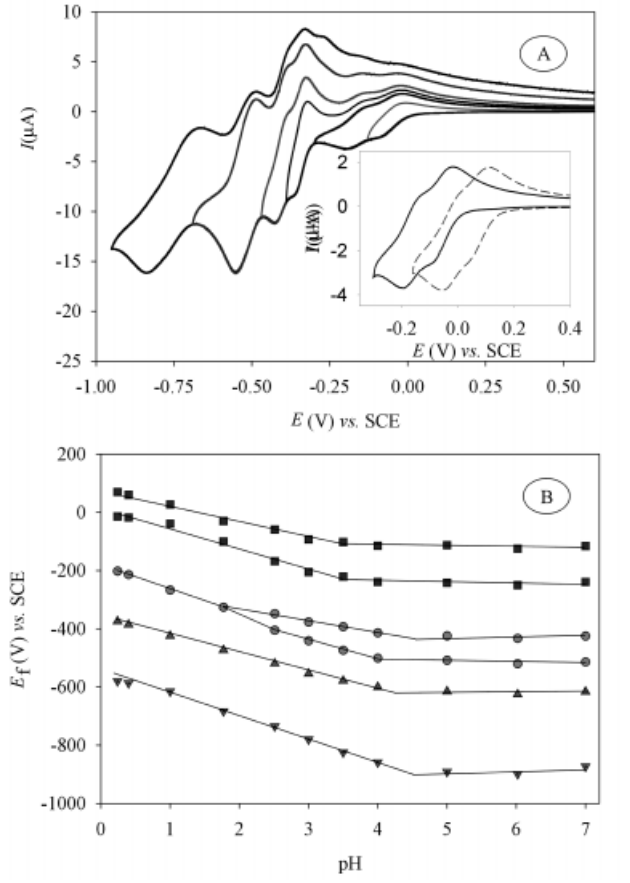

Figure 8. (A) Cyclic voltammograms of 1 mM $Na_2Fe_2P_4W_{30}$ in 0.5 M Na_2SO_4 + H_2SO_4 at pH 2.52 with different negative potential limits: −0.13 V, −0.30 V, −0.39 V, −0.47 V, −0.69 V, and −0.95 V; scan rate 20 mV s^{-1}; (B) half-wave potential vs. pH plots for the $Fe^{III/II}$ redox couples (■), and the first (●), second (▲), and third tungsten redox couples (▼); inset: the voltammograms are restricted to the first waves of the cathodic patterns, which corresponds to the $Fe^{III/II}$ couples; solid line: pH 2.52; dotted line: pH 0.24

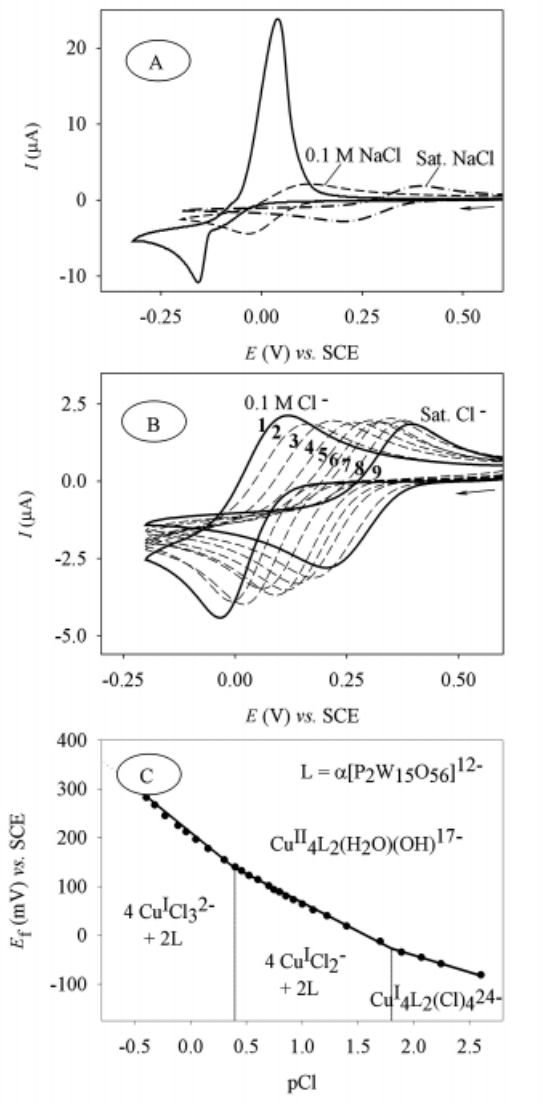

Figure 9. (A) Cyclic voltammograms of 1 mM $Cu_4P_4W_{30}$ in 0.5 M Na_2SO_4 + H_2SO_4 at pH 4.57; scan rate 20 mV s^{-1}; (1) without NaCl (—), (2) in the presence of 0.1 M NaCl (----), and (3) in the presence of saturated NaCl (-.-); (B) evolution of the voltammograms (Cu-centered reduction, Cu^{II}/Cu^{I}) with increasing chloride ion concentration: **1**. 0.1 M NaCl; **2**. 0.2 M NaCl; **3**. 0.4 M NaCl; **4**. 0.8 M NaCl; **5**. 1.2 M NaCl; **6**. 1.6 M NaCl; **7**. 2.0 M NaCl; **8**. 2.8 M NaCl; **9**. saturated solution of NaCl; scan rate 20 mV s^{-1}; pH 4.57; (C) plot of $E_f = (E_{pa} + E_{pc})/2$ vs. pCl (scan rate 20 mV s^{-1}, pH 4.57)

As for $Mn_4P_4W_{30}$, other redox processes can be identified at more positive potentials: at pH 2.52, two reversible one-electron waves are observed at −0.060 V and −0.164 V (ΔE_p = 66 and 68 mV, respectively). Controlled-potential coulometry at −0.245 V in a medium at pH 2.52 and under continuous argon bubbling and stirring consumes 2.10 electrons per molecule, consistent with the reduction of the two Fe^{III} cations.

These waves must thus be attributed to the successive reduction of both Fe^{3+} cations.[12] The couple Fe^{III}/Fe^{II} in $Fe_2P_4W_{30}$ remains fully reversible in the pH range 0.24−7.00, as shown in the inset of Figure 9 and the *E* vs. pH diagram (B in Figure 8). The stability of $Fe_2P_4W_{30}$ was checked by comparison of the CVs obtained immediately after the preparation of the solution and after it had been set aside for at least 4 hours. No variation in current intensities or in the potentials of the different waves was observed; this reproducibility was considered as a sufficient test of the stability of $Fe_2P_4W_{30}$ complexes in these media. The peak currents for the tungsten-based reduction waves and the metal-based reduction waves were seen to vary linearly with the square root of the scan rate up to 500 mV s^{-1} at pH 2.52, which indicates that the electrode reaction is a diffusion-controlled process.

At more acidic pH, i.e. in the pH range 0.24−3.50, Fe-centered redox waves show a negative shift, indicating that they are all accompanied by protonation. It could be shown that the variations in the potentials were of the order of 50−55 mV per pH unit (B in Figure 8), which corresponds to the exchange of one proton.

This result is rather unusual in the case of the Fe-centered redox processes, for which, at low pH, the redox potential is generally almost pH independent.[12c,13]

Assuming that $Fe_2P_4W_{30}$ has the molecular structure recently reported by Hill et al.,[3i,3j] with the two external sites of the sandwich structure occupied by Na^+ cations, the unusual pH dependence can be tentatively explained as follows [Equation (7)−(8)].

At pH < 3.50:

$$[(H_2O)_2Na_2Fe^{III}_2(P_2W_{15}O_{56})_2]^{16-} + e^- + H^+ \leftrightarrows [(H_2ONa)(H_3O)Fe^{III}Fe^{II}(P_2W_{15}O_{56})_2]^{17-} + Na^+ \quad (7)$$

$$[(H_2ONa)(H_3O)Fe^{III}Fe^{II}(P_2W_{15}O_{56})_2]^{17-} + e^- + H^+ \leftrightarrows [(H_3O)_2Fe^{II}_2(P_2W_{15}O_{56})_2]^{18-} + Na^+ \quad (8)$$

$[Cu_4(OH)_2(P_2W_{15}O_{56})_2]^{18-}$ ($Cu_4P_4W_{30}$): Figure 9 shows CVs of 1 mM $Cu_4P_4W_{30}$ at pH 4.57. An irreversible broad peak is observed at −0.15 V, along with an unusual sharp redox anodic peak at about 0.04 V. Similar results have been reported elsewhere for Dawson-type α_2-$P_2W_{17}Cu$ and $ZnW_{11}Cu$.[10]

The sharp anodic peak current increases with the preconditioning time at −0.20 V vs. SCE and with the scan rate. This redox wave is assigned to reduction and oxidation of the transition metal Cu. It is reasonable to expect that both the Cu^{II} and Cu^{I} cations within $Cu_4P_4W_{30}$ will be destabilized by the six-coordinate geometry imposed by the polyoxometallate framework, favoring reduction to Cu^0. In fact, upon reduction, deposition of metallic Cu is observed on the glassy carbon electrode surface, which demonstrates the irreversible dissociation of the complex into α-P_2W_{15}. The anodic peak at 0.04 V should correspond to the reoxidation of Cu^0 to Cu^{2+}. The α-P_2W_{15} anion is not stable in this medium and therefore further decomposition occurs. This accounts for the fact that the W-based waves are irreversible and ill-defined.

Addition of chloride ions to the solution leads to dramatic changes in the electrochemical behavior of $Cu_4P_4W_{30}$, as shown in Figure 9 (B,C). The irreversible cathodic peak at −0.15 V becomes reversible. As this wave, corresponding to copper reduction, is well-separated from the tungsten waves, it is reasonable to assume that this redox process is associated with a $Cu^{II}/Cu^{I}(Cl)_n^{(n-1)}$ couple. The redox potential becomes more negative on increasing the chloride ion concentration. Figure 9 (C) shows a plot of the formal potential vs. pCl. The slopes amount to 64 mV per pCl unit above pCl = 1.8, 121 mV per pCl unit between 1.8 and 0.4, and 177 mV for pCl < 0.4. These results suggest that the Cu-centered reaction mechanism in presence of chloride can be described by Equations (9)−(11).

$$[Cu^{II}_4(H_2O)(OH)(P_2W_{15}O_{56})_2]^{17-} + 4e^- + 4\,Cl^- \leftrightarrows [Cu^{I}_4Cl_4(P_2W_{15}O_{56})_2]^{24-} + OH^- + H_2O\,E_1^{0'}$$
$$[Cu^{I}_4Cl_4(P_2W_{15}O_{56})_2]^{24-} \leftrightarrows 4Cu^{I}Cl(s) + 2\,\alpha\text{-}[P_2W_{15}O_{56}]^{12-} \quad (9)$$

$$[Cu^{II}_4(H_2O)(OH)(P_2W_{15}O_{56})_2]^{17-} + 4e^- + 8\,Cl^- \leftrightarrows 4Cu^{I}Cl_2^- + 2\,\alpha\text{-}[P_2W_{15}O_{56}]^{12-} + OH^- + H_2O\,E_2^{0'} \quad (10)$$

$$[Cu^{II}_4(H_2O)(OH)(P_2W_{15}O_{56})_2]^{17-} + 4e^- + 12\,Cl^- \leftrightarrows 4Cu^{I}Cl_3^{2-} + 2\,\alpha\text{-}[P_2W_{15}O_{56}]^{12-} + OH^- + H_2O\,E_3^{0'} \quad (11)$$

The six-coordinate geometry imposed by the polyoxoanion framework might favor the extraction of the stable $Cu^{I}Cl_n^{(n-1)}$ complex, where n = 1, 2, or 3.

Apparent standard potentials can be calculated from the E_f vs. pCl plot: $E_1^{0'}$ = −0.217 V, $E_2^{0'}$ = −0.109 V, and $E_3^{0'}$ = −0.086 V.

Summary and Concluding Remarks

It is well-known from the literature that the reaction of α-$[P_2W_{15}O_{56}]^{12-}$ with divalent cations M^{2+} leads to sandwich complexes of the general formula $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ ($M_4P_4W_{30}$). However, in the case of the Fe^{III} and Co^{II} complexes, preparations according to the literature methods, that is in neutral media, invariably give a mixture of several species. In contrast, we have shown that performing the synthesis at low pH leads exclusively to one major isomer with high purity.

The electrochemical behavior of the $M_4P_4W_{30}$ compounds has been investigated systematically at various pH values. All the compounds exhibit three couples due to W-centered reduction processes with slightly different peak potentials from one complex to the next. Two types of sandwich complexes can be distinguished:

(i) For those with Co^{II}, Ni^{II}, Zn^{II}, and Cd^{II}, the metallic centers are electrochemically silent in the potential domains explored in this work.

(ii) For those with Mn^{II}, Fe^{III}, and Cu^{II}, redox reactions originating at the metals M are seen.

The Mn^{II} complex shows an oxidation and two reduction processes, which correspond to oxidation of Mn^{II} to Mn^{IV}, followed, in the reverse scan, by the reduction of Mn^{IV} to Mn^{III} and reduction of Mn^{III} to Mn^{II}. The compound $Cu_4P_4W_{30}$ exhibits a deposition process accompanied by decomposition of the copper complex. Extraction of the copper(I) complexes $Cu^{I}Cl_n^{(n-1)}$ (n = 1−3) can also be observed upon reduction of the polyoxoanions in the presence of chloride ions.

Finally, the compounds $[Fe_4(H_2O)_2(P_2W_{15}O_{56})_2]^{12-}$ and $[(H_2O)_2Na_2Fe_2(P_2W_{15}O_{56})_2]^{16-}$ both exhibit Fe-centered redox processes prior to reductions of the polyanions. Splitting of this wave often occurs.

This series of sandwich polyoxoanion complexes would appear to be quite promising in relation to electrocatalytic reactions; in particular, the Mn^{II} sandwich complex is a potential candidate for both oxidative and reductive catalysis. $[(H_2O)_2Na_2Fe_2(P_2W_{15}O_{56})_2]^{16-}$ also appears to be quite promising and may find application in the preparation of pure mixed sandwich complexes of the type $[M^{II}_2Fe^{III}_2(H_2O)_2(P_2W_{15}O_{56})_2]^{14-}$.

Electrocatalytic processes of this type, both in aqueous solution and in organic media, and the preparation of new $[M^{II}_2Fe^{III}_2(H_2O)_2(P_2W_{15}O_{56})_2]^{14-}$ complexes are currently under investigation.

Experimental Section

General: Most common laboratory chemicals were reagent grade, as purchased from commercial sources, and were used without further purification.

Preparation of the Compounds: The potassium salt of α-$[P_2W_{18}O_{62}]^{6-}$ and the sodium salt of α-$[P_2W_{15}O_{56}]^{12-}$ were prepared by published methods.[2] An extensive series of tetranuclear divalent Dawson-derived sandwich complexes of the formula $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ (where M = Mn^{II}, Ni^{II}, Zn^{II}, Cd^{II}) were prepared as described elsewhere.[3] All samples were recrystallized as described in the original procedures and were characterized by IR spectroscopy and ^{31}P NMR spectrometry.

$Na_{16}[(H_2O)_2Na_2Fe_2(P_2W_{15}O_{56})_2]\cdot 53H_2O\cdot 4NaCl$: $FeCl_3\cdot 6H_2O$ (0.34 g, 1.25 mmol) was dissolved in 1 M aq. NaCl/0.1 M aq. HCl (pH 1) (50 mL) with stirring. α-$Na_{12}P_2W_{15}O_{56}\cdot 24H_2O$ (5.00 g, 1.13 mmol) was then added under vigorous stirring. The solution was heated at 80 °C until the volume had been reduced to ca. 12.5 mL. It was then filtered hot and the filtrate was left to stand in air. After evaporation of the solvent, 1 M aq. NaCl (5 mL) was added with stirring. A yellow solid was precipitated, which was collected by filtration and dried in air; yield 3.49 g (0.38 mmol; 67%). $Cl_4Fe_2Na_{22}O_{112}P_4W_{30}\cdot 55H_2O$: calcd. Fe 1.22, P 1.35, W 60.08, H_2O 10.79; found Fe 1.24, P 1.35, W 59.89, H_2O 10.76.

The purity of the compound was checked by ^{31}P NMR in D_2O, which showed a single resonance [P(2)] at δ = −11.2 ($\Delta\nu_{1/2}$ = 220 Hz). The signal of the phosphorus atom nearest to the paramagnetic Fe^{III} ions [P(1)] was not observed.

$Na_{11}H[Fe^{III}_4(H_2O)_2(P_2W_{15}O_{56})_2]\cdot 45H_2O$: This complex was prepared as follows by a modification of the literature method:[3i] $FeCl_3\cdot 6H_2O$ (0.82 g, 3.01 mmol) was dissolved in 1 M NaCl/0.1 M HCl (pH ≈ 1) (40 mL) with stirring. α-$Na_{12}P_2W_{15}O_{56}\cdot 24H_2O$ (6.00 g, 1.36 mmol) was then slowly added under vigorous stirring. The solution was heated at 80 °C until the volume had been reduced to ca. 12.5 mL. It was then filtered hot and the filtrate was left to stand in air. After evaporation of the solvent, 1 M aq. NaCl (5 mL) was added with stirring. A yellow solid precipitated, which was collected by filtration, dried in air, and recrystallized from 2 M aq. NaCl; yield: 3.09 g (0.35 mmol; 52%). $Fe_4Na_{11}HO_{112}P_4W_{30}\cdot 47H_2O$: calcd. Fe 2.55, P 1.41, W 63.00, H_2O 9.67; found Fe 2.69, P 1.38, W 62.98, H_2O 9.78.

The purity of the compound was checked by ^{31}P NMR, which showed two resonances at δ = −11.7 [P(2); $\Delta\nu_{1/2}$ = 55 Hz] and δ = +915 [P(1); $\Delta\nu_{1/2}$ = 2500 Hz].

$Na_{17}[Co_4(H_2O)(OH)(P_2W_{15}O_{56})_2]\cdot 51H_2O\cdot 2NaCl$: $Co(NO_3)_2\cdot 6H_2O$ (0.73 g, 2.25 mmol) was dissolved in 1 M aq. NaCl/0.1 M aq. HCl (50 mL) with stirring. α-$Na_{12}P_2W_{15}O_{56}\cdot 24H_2O$ (5.00 g, 1.13 mmol) was then slowly added under vigorous stirring. The solution was heated at 40 °C for 15 min (pH 3), then filtered hot and the filtrate was left to stand in air. After evaporation of the solvent, 1 M aq. NaCl (5 mL) was added with stirring. A pale green-brown solid was precipitated, which was collected by filtration and dried in air; yield 3.99 g (0.44 mmol, 78%). $Cl_2Co_4Na_{18}P_4W_{30}O_{112}\cdot OH\cdot 52H_2O$: calcd. Co 2.59, P 1.35, W 60.34, H_2O 10.87; found Co 2.77, P 1.30, W 60.10, H_2O 11.16.

The purity of the compound was checked by ^{31}P NMR, which showed two resonances at δ = 9.9 [P(2); $\Delta\nu_{1/2}$ = 20 Hz] and δ = 1483 [P(1); $\Delta\nu_{1/2}$ = 420 Hz].

$Na_{16}Cu[Cu_4(OH)_2(P_2W_{15}O_{56})_2]\cdot 53H_2O$: This complex was prepared, as follows, by a method slightly different from that reported elsewhere:[3c] $CuCl_2$ (0.35 g, 2.50 mmol) was dissolved in 1 M aq. NaCl (50 mL) with stirring. α-$Na_{12}P_2W_{15}O_{56}\cdot 24H_2O$ (5.00 g, 1.13 mmol) was then slowly added under vigorous stirring. The solution was heated at 40 °C until the P_2W_{15} had completely dissolved. It was then filtered hot and the filtrate was left to stand in air for one day at room temperature and then cooled to 5 °C. Pale-green crystals were deposited after two days, which were collected by filtration and dried in air; yield (3.20 g, 0.35 mmol, 62%). $Cu_5Na_{12}O_{112}P_4W_{30}\cdot 2(OH)\cdot 53H_2O$: calcd. Cu 3.52, P 1.37, W 60.87, H_2O 10.58; found Cu 3.43, P 1.37, W 60.88, H_2O 10.26.

The purity of the compound was checked by ^{31}P NMR, which showed a single resonance at δ = −16.2 ($\Delta\nu_{1/2}$ = 60 Hz). This line was assigned to P(2), the more distant P atom from the Cu^{II} center. The signal from the phosphorus atom designated P(1) nearest to the paramagnetic Cu^{II} ions was not observed.

NMR, IR, and Potentiometric Measurements: ^{31}P NMR spectra were recorded from sample solutions in 5 mm o.d. tubes on a Bruker AC 300 spectrometer operating at 121.5 MHz in Fourier-transform mode (equipped with a QNP probe for ^{31}P NMR). The ^{31}P chemical shifts were measured at 300 K using 0.02 M solutions of the polyanions in 0.5 M aqueous LiCl (50% D_2O) solutions and were referenced to external 85% H_3PO_4 (IUPAC convention) by the substitution method.

IR spectra were recorded on a Bio-Rad FTS 165 FTIR spectrophotometer from samples in KBr pellets.

Potentiometric measurements were made on a Tacussel PHN330T pH meter. Constant ionic strength (μ = 0.1 M, $NaNO_3$) was used in the titrations. In potentiometric titrations, the dilution was less than 2%.

Electrochemical Experiments

Chemicals, Equipment, and Apparatus: Pure water was used throughout. It was obtained by passing water through a Milli-RO_4 unit and subsequently through a Millipore Q water purification set. H_2SO_4 and Na_2SO_4 were commercial products (Prolabo). The pH 2 electrolyte was made up from 0.5 M Na_2SO_4 and the pH was adjusted by the addition of 0.5 M (H_2SO_4 + Na_2SO_4). Other pHs were obtained by the addition of H_2SO_4 or NaOH (Prolabo) as appropriate. The solutions were thoroughly deaerated for at least 30 min by bubbling pure argon and were kept under argon pressure during the experiments.

The source, mounting, and polishing of glassy carbon (GC, Tokai, Japan) have been described previously.[14] The glassy carbon samples for use as electrodes had a diameter of 3 mm. The electrochemical set-up consisted of an EG&G 273 A potentiostat driven by a personal computer with 270 software. Potentials are quoted with respect to a saturated calomel electrode (SCE). The counter-electrode was a platinum gauze of large surface area. All voltammetric experiments were carried out at room temperature.

Analyses: Elemental analyses were performed by classical gravimetric, potentiometric, and spectrophotometric methods.

The anions were first decomposed in boiling concentrated hydrochloric acid solution. Tungsten and phosphorus were then precipitated together by adding cinchonium hydrochloride. They were determined simultaneously as WO_3 and P_2O_5 by gravimetry after calcination of the cinchonium salt. Cobalt, which remained in the filtrate, was complexed with ammonia and then titrated as hexacyanocobaltate(III) complex by potentiometry. Phosphorus was determined by spectroscopy of the molybdovanadophosphate.[15] Water content was determined by thermogravimetric analysis. The other metallic elements (Fe, Cu) were analyzed by atomic absorption spectroscopy.

Supporting Information (see footnote on the first page of this article): Comparison of the IR spectra (KBr) of the hydrated sandwich heteropolyanion series.

Acknowledgments

This work was supported by the CNRS and by the Universities Paris XI and Paris VI. We are also grateful to Martine Richet for performing the microanalyses.

A New Cu^{I} Complex that Mimics the Cresolase Reaction of Tyrosinase and the Crystal Structure of its Oxygenated Cu^{II} Complex

Vieri Fusi,*[a] Antoni Llobet,*[b] José Mahía,[c] Mauro Micheloni,[a] Paola Paoli,[d] Xavi Ribas,[b] and Patrizia Rossi[d]

Keywords: Bioinorganic chemistry / Copper / Macrocyclic ligands / O-O activation / Tyrosinase

A new dinuclear Cu^{II} complex with a unique structural arrangement and containing a doubly bridged macrocyclic ligand has been prepared from two different routes, one of which involves the reaction of oxygen and a Cu^{I} precursor, thus mimicking the cresolase activity of tyrosinase

Introduction

The synthesis, structural elucidation and characterization of the reactivity of copper-dioxygen compounds obtained from the interaction of molecular oxygen with Cu^{I} complexes is an important goal in the comprehension of the fundamental chemistry involved in oxidase and oxygenase reactions of synthetic and biological copper-containing catalysts.[1] Within this context, tyrosinase is a monooxygenase enzyme with a binuclear copper active-site and is responsible for the *ortho* hydroxylation of the existing hydroxyl group of substrates as shown in Equation (1).[2–5]

$$\text{R-Ph-OH} \xrightarrow[O_2]{\text{tyrosinase}} \text{R-Ph-(OH)}_2 \qquad (1)$$

A number of xylene-substituted ligands, including amines[6–11] and imines,[12,13] have been used to prepare binuclear Cu^{I} complexes that successfully mimic this reaction. The ligand influence in the modelling of such reactions is of great importance in order to elucidate the detailed pathways that can lead to the activation of the Cu complex towards the oxidation of C–H bonds, and therefore has implications in the understanding of metalloenzymes and other catalysts.[14,15]

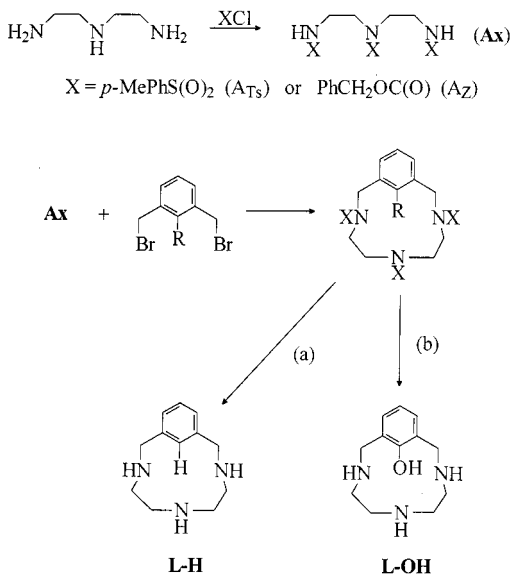
In this paper we present a new example of a Cu^{I} complex that is capable of producing an intramolecular hydroxylation reaction. We also report an alternative synthesis directly from the hydroxylated ligand and Cu^{II} that generates the same final complex. Furthermore, this oxygenated complex constitutes the first example of a macrocyclic ligand that does not contain pendant arms, and that doubly bridges the Cu metal[16–18] with an unusual geometry.[19]

Results and discussion

The synthetic strategy for the preparation of the new ligands L-H and L-OH is outlined in Scheme 1, and in both cases is based on the condensation of the protected triamine



(a) R = H, X = Z : H_2 (Pd/C); (b) R = OMe, X = Ts : Li/NH_3 (l)

Scheme 1. Synthetic strategy

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434–1948/02/0404–0987 $ 17.50+.50/0

with 1,3-dibromoxylene or 1,3-dibromoanisole. The L-OH ligand was isolated after simultaneous deprotection of the amine and phenol groups with lithium in liquid ammonia.

The reaction of stoichiometric amounts of L-H and $[Cu^{I}(MeCN)_4](PF_6)$ in acetonitrile presumably produces a dinuclear complex $[Cu_2(L\text{-}H)_2]^{2+}$ in equilibrium with different conformers, as seen by variable temperature ^1H NMR and ESI spectroscopy. Molecular models clearly show that the monomeric species $[Cu(L\text{-}H)]^+$ contains two fused five-membered rings highly constrained due to the rigidity imposed by the *meta*-substituted phenyl group. On the other hand, the dimer contains only one five-membered ring per ligand and thus the steric strain is much lower. Solution equilibrium studies with Cu^{II} and the L-OH ligand, performed by potentiometric methods, are also in agreement with this behaviour.[20]

The formation constant value of this dinuclear complex [Equation (2)] is $\log K = 38.47$, more than twice that of the mononuclear species ($\log K = 17.53$), indicating that the association process of two mononuclear species is highly favoured.

$$2\,Cu^{2+} + 2\,L\text{-}OH \longrightarrow [Cu_2(L\text{-}O)_2]^{2+} \quad (2)$$

Bubbling oxygen through an acetonitrile solution of the colourless complex $[Cu^{I}_2(L\text{-}H)_2]^{2+}$ at low temperatures (−40 °C) generates a blue intermediate, whose nature is currently under investigation, which upon warming to room temperature turns green [Equation (3)]. Addition of ether to this solution and cooling to 5 °C overnight produces green crystals of the binuclear Cu^{II} bisphenolate complex $[Cu^{II}_2(L\text{-}O)_2]^{2+}$ in 22% isolated yield.

$$[Cu_2(L\text{-}H)_2]^{2+} + O_2 \rightleftharpoons [Cu_2(L\text{-}O)_2]^{2+} + 2\,H^+ + 2\,e^- \quad (3)$$

Exactly the same dicationic complex can be obtained in quantitative yield by the direct reaction of the L-OH ligand and $CuCl_2$ or $Cu(ClO_4)_2$.

The crystal structure of $[Cu_2(L\text{-}O)_2](PF_6)_2$ was determined by X-ray crystallography and its ORTEP diagram is shown in Figure 1.

The molecule sits on a centre of symmetry that transforms one macrocyclic ligand into the other. The Cu_2O_2 core atoms lie in a plane forming a rhomboidal arrangement. Each copper atom has a slightly distorted square-pyramidal geometry (with a τ factor of 0.21).[21] The base of the pyramid is occupied by two N atoms from one of the macrocyclic ligands together with a third N atom and a phenoxo O atom from the other macrocyclic ligand. The apical position is occupied by a phenoxo O atom from the former macrocyclic ligand and therefore the copper centres become doubly bridged by each macrocyclic ligand. The oxygen atoms of the phenoxo groups bridge the copper centres so that the apical oxygen atom from one pyramid is also the base of the other pyramid. As a result, the geometry of the complex consists of two square pyramids sharing a base-to-apex edge with the bases nearly parallel to one another. The constraint imposed by the macrocyclic ligand in this bis(μ-phenoxo)dicopper complex gives rise to long Cu−O [1.927(2) Å, 2.201(2) Å], Cu−Cu [2.864(1) Å] and O−O [2.988(1) Å] distances relative to unconstrained systems.[14]

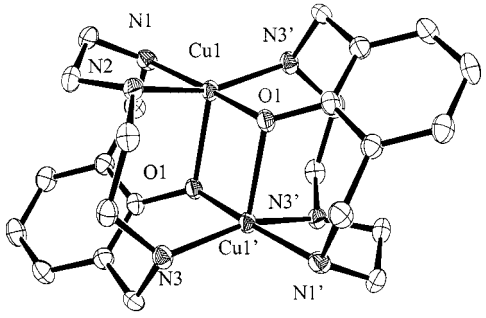


Figure 1. ORTEP view of the molecular structure of complex $[Cu_2(L\text{-}O)_2]^{2+}$ (ellipsoids at 50% probability); H atoms are omitted for clarity; selected bond lengths (Å) and angles (°): Cu1−N1 2.026(3), Cu1−N2 20142(3), Cu1−N3′ 2.044(3), Cu1−O1′ 1.927(2), Cu1−O1 2.201(2), Cu1−Cu1′ 2.864(1), O1−O1′ 2.988(1); Cu1−O1′−Cu1′ 92.44(9), O1−Cu1−O1′ 87.56(9), N1−Cu1−N2 85.13(11), N1−Cu1−N3′ 99.53(11), N2−Cu1−O1′ 86.41(10), O1−Cu1−N3′ 87.97(10), N2−Cu1−N3′158.78(11), N1−Cu1−O1′ 171.48(10), N1−Cu1−O1 89.51(10), N2−Cu1−O1 96.17(11), N3′−Cu1−O1 104.51(11)

The complex $[Cu_2(L\text{-}O)_2]^{2+}$ constitutes the first example of a complex bearing a macrocyclic ligand that does not contain pendant arms, and that doubly bridges the Cu centres. In the structure the Cu pyramids have an unusual parallel bases type of relative arrangement due to the constraints imposed by the macrocyclic ligand. The driving force for the doubly bridged disposition of $L\text{-}O^-$ is due to both the tendency of phenoxo groups to act as bridging ligands and to the release of steric strain that would otherwise exist if the $L\text{-}O^-$ ligand had all three N atoms coordinating to the same Cu metal centre. Molecular models clearly show that the corresponding oxygenated dinuclear Cu^{I} complex has the adequate geometry, thanks to the specific coordination of the macrocyclic ligand, to undergo oxygen insertion into the aromatic C−H bond, as indeed occurs in our case. This reaction is of importance since it results in a low molecular weight complex capable of mimicking the reactivity exhibited by tyrosinase in its cresolase activity.

Experimental Section

Materials and Instruments: All reagents used in the present work were obtained from Aldrich Chemical Co. and were used without further purification. Reagent-grade organic solvents were obtained from SDS. IR spectra were recorded with a Mattson Satellite FT-IR spectrometer on KBr pellets. UV/Vis spectroscopy was performed with a Cary 50 Scan (Varian) UV/Vis spectrophotometer with 1-cm quartz cells. The ^1H-NMR spectroscopy was performed with a Bruker DPX 200 MHz or a Bruker 400 MHz. Samples were

run in $CDCl_3$, CD_2Cl_2 or deuterium oxide with internal references (residual protons and/or tetramethylsilane). Elemental analyses were performed using a CHNS-O Elemental Analyzer EA-1108 from Fisons. FAB-MS experiments were run with a Fisons VG-Quattro and the ESI-MS experiments with a Navigator LC/MS chromatography from ThermoQuest. X-ray analyses were carried out using a Siemens Smart CCD diffractometer.

Ligand L-H: The protected linear amine A_z (1.75 g, 3.46 mmol), Cs_2CO_3 (2.82 g, 8.66 mmol) and α,α′-dibromo-*m*-xylene (0,.914 g, 3.46 mmol) were heated to reflux in CH_3CN (180 mL) under a N_2 atmosphere for 14 h. After cooling to room temperature, the mixture was filtered and the solvent removed under reduced pressure. The protected triazamacrocycle was then purified by column chromatography using silica as the chromatographic support and CH_2Cl_2/EtOAc (98:2) as the eluting agent to give the protected amine (0.469 g, 0.73 mmol, 22.3% isolated yield). Deprotection was achieved by hydrogenation with H_2/Pd(C) in methanol at 0 °C. The product was then purified by column chromatography using silica as the chromatographic support and CH_2Cl_2/MeOH/NH_4OH (75:25:7) as the eluting agent to obtain ligand L-H in 62.3% yield. ^1H NMR (200 MHz, $CDCl_3$, 298 K, TMS): δ = 2.01 (s, 3 H), 2.08 (m, 4 H), 2.71 (t, *J* = 3.0 Hz, 4 H), 3.90 (s, 4 H), 6.99−7.26 (m, 3 H), 8.26 (s, 1 H). MS (FAB): *m*/*z* = 206 [M + H^+]. $C_{12}H_{19}N_3$ (205.3): C 70.2, H 9.3, N 20.3; found C 69.9, H 9.4, N 20.1.

Ligand L-OH·3HCl: This ligand was prepared according to a published synthetic procedure.[22] ^1H NMR (200 MHz, D_2O, pH 3, 298 K, HOD): δ = 3.22 (t, *J* = 12.4 Hz, 4 H), 3.32 (t, *J* = 12.4, 4 H), 4.44 (s, 4 H), 7.04 (t, *J* = 7.3, 1 H), 7.53 (d, *J* = 7.3, 2 H). MS (FAB): *m*/*z* = 222 [M + H^+]. $C_{12}H_{22}Cl_3N_3O$ (330.7): C 43.6, H 6.7, N 12.7; found C 43.5, H 6.7, N 12.6.

$[Cu_2(L\text{-}H)_2(MeCN)_2](PF_6)_2$: L-H (21.6 mg, 0.105 mmol) and [Cu(MeCN)$_4$](PF_6) (39.2 mg, 0.105 mmol) were placed in a Schlenk tube under an argon atmosphere, 2 mL of CH_2Cl_2 were added and the solution stirred for 5 min. Addition of Et_2O (approx. 5 mL) to the resulting light yellow solution produced a white solid which was filtered, and dried under vacuum (38.3 mg, 80.0%). ^1H NMR (200 MHz, CD_2Cl_2, 300 K): δ = 1.50 (br. s, 2 H), 2.22 (br. s, 2 H), 2.49 (br. s, 2 H), 2.76 (br. s, 2 H), 3.50 (br. s, 2 H), 4.25 (br. s, 2 H), 7.1−7.3 (m, 3 H), 8.78 (s, 1 H). The resonances in the aromatic region were sharp with a clear hyperfine structure whereas the other resonances were broad. Upon lowering the temperature all resonances progressively broadened but no splitting was observed even at 210 K. FT-IR (KBr): $\tilde{\nu}$ = 2253cm^{-1} (C≡N), 846 (PF_6^-), 559 (PF_6^-).

Complex $[Cu_2(L\text{-}O)_2](PF_6)_2$: The ligand L-H (0.02 g, 0.097 mmol) and $[Cu^I(CH_3CN)_4]PF_6$ (0.036 g, 0.097 mmol) were dissolved in 1 mL of degassed, anhydrous CH_3CN under an argon atmosphere. The resulting colorless solution was cooled to −20 °C and O_2 was bubbled through at this temperature for 10min, during which time the solution turned blue. The mixture was then warmed to room temp. whilst stirring overnight. Slow diffusion of diethyl ether into the resulting solution allowed the formation of green crystals of the final product in 20% yield (0.0084 g, 0.010 mmol). FT-IR (KBr): $\tilde{\nu}$ = 3337 cm^{-1} (NH), 3291 (NH), 1595 (Ph-O), 1455 (C=C), 1297 (O-Ph), 843 (PF_6^-), 559 (PF_6^-). UV/Vis (CH_3CN): λ_{max} (ε) = 406 nm (542), 578 (323). ESI-MS (CH_3CN): *m*/*z* = 711 $[Cu_2(L\text{-}O)_2(PF_6)]^+$, 283 $[(L\text{-}O)Cu^{II}]^+$. $C_{24}H_{36}Cu_2F_{12}N_6O_2P_2$ (857.6): C 33.6, H 4.2, N 9.8; found C 34.0, H 4.5, N 9.7.

Crystal Data for $[Cu_2(L\text{-}O)_2](PF_6)_2$: $C_{24}H_{36}Cu_2F_{12}N_6O_2P_2$, *M* = 857.61, green crystals, triclinic, space group $P\bar{1}$ (no. 2), *a* = 8.818(4), *b* = 9.696(3), *c* = 10.801(6) Å, *Z* = 1, α = 113.89(5)°, β = 113.20(2)°, γ = 90.28(3)°, *V* = 761.0(6) Å^3, D_c = 1.871 g cm^{-3}, *T* = 173(2) K, Mo-K_α radiation (λ = 0.71073 Å), 4306 reflections measured, 3653 unique (R_{int} = 0.0212) which were used in all calculations. *R* = 0.0429, *Rw* = 0.0954.

CCDC-137239 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

COVER PICTURE

The cover picture shows the structure of the bis[citrato(3−)]-silicate dianion, a hexacoordinate silicon species with two tridentate ligands derived from citric acid. This complex has been synthesized and structurally characterized in context with studies on silica biomineralization. Details are discussed in the Short Communication by R. Tacke et al. on p. 1025 ff.

Activation of Organic Substrates on Multi-Metallic Sites of Transition Metal Polyhydride Clusters Having C_5Me_5 Groups as Auxiliary Ligands

Hiroharu Suzuki[a]

Keywords: Cluster compounds / Hydride ligands / Iron / Ruthenium

An overview of the chemistry of the di- and trinuclear transition metal polyhydride complexes containing only C_5Me_5 groups as auxiliary ligands is presented. The synthesis of a series of η^5-C_5Me_5 polyhydride clusters and their reactivities centered about some typical examples of "multi-metallic activation" including the cleavage of carbon–hydrogen bonds of alkanes, carbon-carbon bond of cyclopentadiene, and carbon–carbon double bond of 1,1-disubstituted alkenes, achieved on the reaction site of the polyhydride-bridged clusters, are reported.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

1. Introduction

The reactivity of transition metal cluster complexes has been of special interest recently, in the area of organometallic chemistry, because of their potential applicability to organic synthesis.[1] The advantageous properties of multi-metallic systems over a mono-metallic ones in the substrate activation step are their capability for multiple coordination of the substrate to the metal clusters, and the multi-electron transfer between the substrate and the cluster. Transition metal clusters have therefore been intensively investigated, in the quest to develop new and effective organic transformations achieved by the synergetic effect of the metal centers. A large number of studies on the reaction chemistry of clusters have been reported, to date using mostly carbonylmetal clusters. However, most of the metal clusters used in these studies have been binary carbonylmetal complexes or clusters directly derived from them, $M_m(CO)_n$ or $L_kM_m(CO)_n$, and it is hard to say that the reactions developed are really characteristic of the metal cluster. Although selectivity and efficiency of the reactions are modified in some cases, the mode of the reaction is sometimes similar to that achieved by using mononuclear metal complexes. In contrast, there have been a relatively small number of reported examples of metal polyhydride clusters – probably due to their instability. Furthermore, an effective synthetic method for obtaining polyhydride clusters that is applicable to the many ligand/metal combinations has not been developed thus far.

Electron density at the metal centers in the metal hydride cluster is most certainly higher than that in the polycarbonylmetal or polycarbonylmetal hydride clusters. The metal polyhydride clusters are, therefore, expected to be much more active than the carbonylmetal clusters toward oxidative addition of substrates. In addition, a metal polyhydride cluster, particularly a polyhydride-bridged cluster, is considered to be a suitable and versatile precursor of the active species for multi-metallic activation. We have used the term

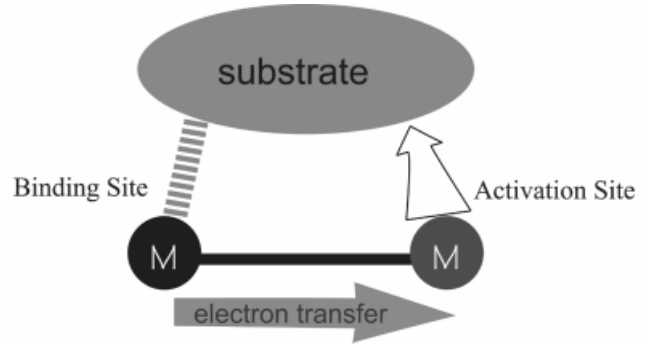
Hiroharu Suzuki was born in Gifu, Japan, in 1948 and studied chemistry at Nagoya University. In 1976, he obtained his Ph.D. degree from Nagoya University on a study on organometal–nitrogen bonds, under the supervision of Prof. Yoshio Ishii. Upon graduation, he moved to the Research Laboratory of Resources Utilization at Tokyo Institute of Technology and was offered a position of Assistant Professor. After a post-doctoral stay with Prof. Tobin J. Marks at Northwestern University (1982–1983), he returned to Tokyo and became Associate Professor in 1984. In 1991, he was promoted to his current position of Professor. He is concurrently serving as Research Director of the "CREST Molecular Architecture of Metal Hydride Cluster" Project of Japan Science and Technology Corporation (JST). His research interests are concentrated on the chemistry of transition metal polyhydride clusters, in particular development of new synthetic methods for polyhydride clusters, and activation of unreactive substrates such as alkanes and dinitrogen on multimetallic sites.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

"multi-metallic activation" to refer to a mode of activation achieved as a result of cooperative action of many metal centers. Liberation of bridging hydride ligands from the metal cluster gives rise, spontaneously, to vacant coordination sites on the adjacent metal centers, and the substrate taken in the reaction site likely interacts with the resulting vacant metal centers all together. In such a situation, the metal centers probably cooperate in activating the substrate as a binding site and an activation site. This must be the origin of the cluster effect in the substrate activation.



There had been several reported examples of multinuclear polyhydride-bridged complexes having tertiary phosphanes as auxiliary ligands,[2] while no polyhydride clusters having only cyclopentadienyl ligands as auxiliaries were known at the end of the 1980s. Unfortunately, the reaction chemistry of the phosphane polyhydride clusters is not as remarkable or unique as that of a polycarbonylmetal cluster.

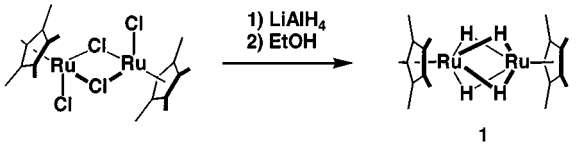
A cyclopentadienyl ligand, especially the C_5Me_5 ligand, is strongly electron-releasing and almost inert towards substitution, unlike tertiary phosphanes. Introduction of C_5Me_5 groups into the cluster framework, therefore, increases the electron density at the metal centers and, as a result, makes the cluster much more reactive to oxidative addition. Even carbonyl clusters become highly reactive and therefore often reveal really unique reactivity when cyclopentadienyl ligands are introduced into the cluster framework.[3] Introduction of cyclopentadienyl ligands affects not only the activity but also the selectivity. An empty space surrounded by the C_5Me_5 ligands becomes a reaction site in which substrates are activated in a shape-selective manner, due to the steric repulsion among the substrates and the C_5Me_5 groups.

We now describe the synthesis of a series of η^5-C_5Me_5 polyhydride clusters and some typical examples of "bi- and trimetallic activation" achieved on the reaction site of the polyhydride-bridged clusters.

2. Synthesis of Transition Metal Polyhydride Clusters Having C_5Me_5 Groups

2.1 Synthesis and Structure of a Dinuclear Tetrahydride Complex of Ruthenium

Ruthenium is a fascinating metal from the standpoint of electron transfer between the substrate and the metal atom because of its wide diversity of oxidation states, from −2 (d^{10}) to +8 (d^0). We therefore attempted to synthesize a new class of polyhydride complex having only C_5Me_5 groups as the auxiliary ligands.



1 (1)

A dinuclear tetrahydride-bridged complex of ruthenium $\{(C_5Me_5)Ru\}_2(\mu\text{-}H)_4$ (**1**) was synthesized by treatment of $\{(C_5Me_5)RuCl_2\}_2$ [4] with $LiAlH_4$ followed by workup with ethanol [Equation (1)].[5] To the best of our knowledge, only two examples have been reported for the dinuclear tetrahydride-bridged complexes $L_mM(\mu\text{-}H)_4ML_n$,[6] while related trihydride-bridged complexes such as $[\{(C_6Me_6)Ru\}_2(\mu\text{-}H)_3]^+$ are known.[7] Complex **1** is the first dinuclear tetrahydride-bridged complex having no phosphane or arsane ligands.

An X-ray diffraction study of **1** showed that the four hydride ligands were essentially arrayed at the vertices of an approximate square, and were placed perpendicularly to the Ru−Ru vector (Figure 1). The average H−H distance of 1.46 Å and the T_1 value of 2.28 s were deemed to be sufficient to characterize the complex as a classical metal polyhydride.[8] Although the short Ru−Ru distance [2.463(1) Å] and the 18-electron rule applied to the dimer **1** require a triple bond between the ruthenium atoms, a theoretical study performed by Morokuma et al. showed the absence of a direct metal−metal bond.[9] The short Ru−Ru distance is most likely due to four 3c-2e M−H−M bonds.

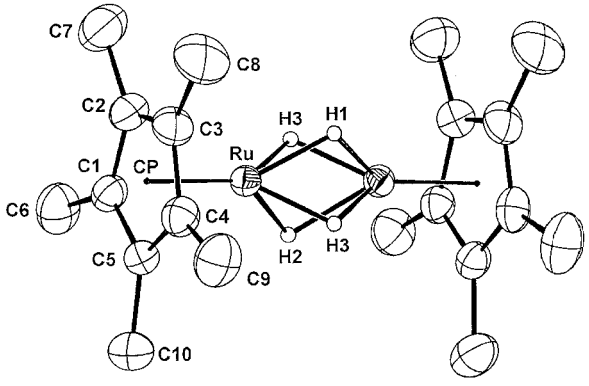


Figure 1. Molecular structure of $\{(C_5Me_5)Ru\}_2(\mu\text{-}H)_4$ (**1**)

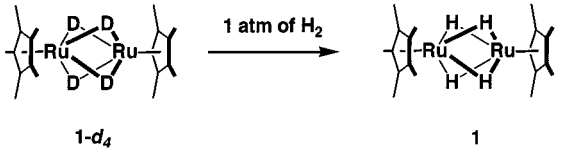
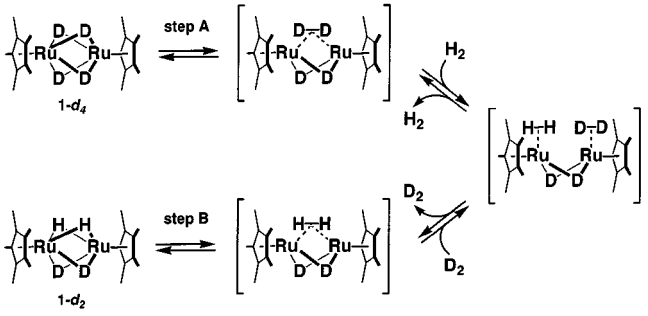
The hydride ligands of **1** undergo an intermolecular exchange reaction with dihydrogen under mild conditions. Exposure of a toluene solution of an isotopomer **1**-d_4 to an atmospheric pressure of dihydrogen resulted in the quantitative exchange of the deuteride ligands for hydride, affording **1**-h_4 [Equation (2)].



(2)

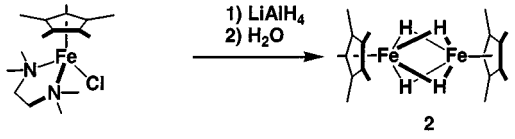
The mechanism shown in Scheme 1 possibly accounts for the H/D exchange reaction of **1** with H_2, which presumably involves a dihydride/dihydrogen equilibrium (step A and step B). With regard to the chemistry of η^2-dihydrogen complexes, such an equilibrium is proposed on the basis of VT-^{1}H NMR studies.[10]



Scheme 1

2.2 Synthesis and Structure of Dinuclear Tetrahydride Complex of Iron

According to the vertical trends associated with the transition elements, the metal−metal and metal−ligand bond enthalpies decrease up a period and the complexes become substitutionally active. The iron analogue of diruthenium tetrahydride **1** is, therefore, expected to be much more reactive than **1**.



(3)

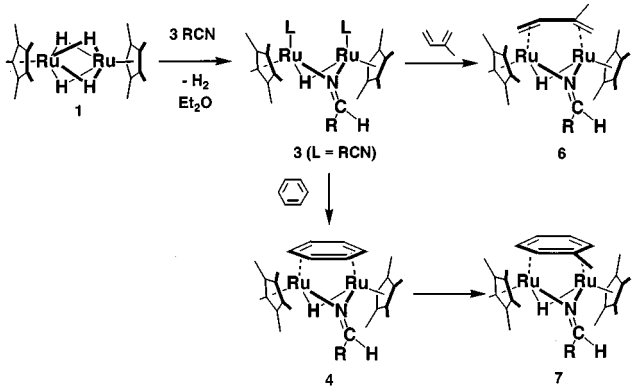
Treatment of $(C_5Me_5)FeCl(tmeda)$[11] with $LiAlH_4$, followed by workup with H_2O, gave the dinuclear iron tetrahydride $\{(C_5Me_5)Fe\}_2(\mu\text{-}H)_4$ (**2**) [Equation (3)].[12] The X-ray analysis clearly showed structural identity between **1** and **2**. The presence of four bridging hydride ligands are probably responsible for the short Fe−Fe distance of 2.202(1) Å.

We concluded that compound **2** was a classical metal hydride similar to **1** on the basis of the long H−H distance (av. 1.60 Å) and the large T_1 value of 0.63 s (−80 °C) for the hydride ligands. The iron tetrahydride **2** has also been shown to undergo H/D exchange between hydride ions and added dihydrogen. As anticipated, the reaction proceeded much faster than that of the corresponding ruthenium analogue. Since tetrahydride **2** is stable enough in solution not to release dihydrogen even under reduced pressure, the H/D exchange must be an associative process.

2.3 Dinuclear Polyhydride Clusters Bridged by a Ligand Containing a Heteroatom

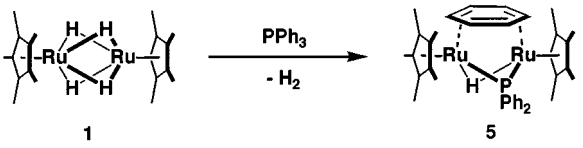
Introduction of a bridging ligand containing a heteroatom into a dinuclear complex possibly affects the electronic and steric environment of the bimetallic reaction sites and, therefore, modifies the complex with regard to both reactivity and selectivity.

A dinuclear μ-alkylideneamide complex $\{(C_5Me_5)Ru\}_2(NC{-}R)_2(\mu\text{-}N{=}CHR)$ (**3**) was exclusively generated in the reaction of **1** with R−CN in diethyl ether, as a result of insertion of the nitrile into an Ru−H bond (Scheme 2).[13] The coordinated nitrile molecule in **3** was readily replaced with arene to form an (alkylideneamide)(η^2:η^2-arene) complex $\{(C_5Me_5)Ru\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-arene})(\mu\text{-}N{=}CHR)$ (**4**). Complex **4** was directly synthesized by the reaction of **1** with nitrile in an appropriate arene solution.



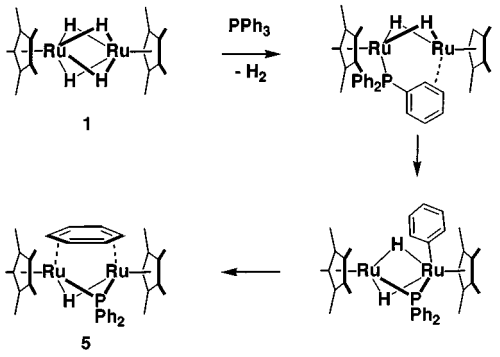
Scheme 2

A phosphide-bridged dinuclear complex $\{(C_5Me_5)Ru\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}C_6H_6)(\mu\text{-}PPh_2)$ (**5**) was prepared by applying a P−C(aromatic) bond cleavage reaction to PPh_3. Treatment of **1** with PPh_3 in toluene led to the formation of **5** as a result of the P−C bond cleavage [Equation (4)].[14]



(4)

The formation of **5** is reasonably elucidated by a sequence of reactions depicted in Scheme 3. Coordination of PPh_3 and reductive elimination of H_2 would form an intermediary (dihydrido)(monophosphane) complex $\{(C_5Me_5)Ru\}_2(H)_2(PPh_3)$. Cleavage of a P−C bond of the coordinated PPh_3 ligand by one of the ruthenium centers would be expected to yield a μ-phosphido species that would then undergo reductive elimination of benzene and subsequent coordination of the benzene molecule in a $\mu\text{-}\eta^2\text{:}\eta^2$ mode to give **5**. For the cluster-mediated P−C bond cleavage of tertiary phosphane, a similar mechanism has been proposed.[15]

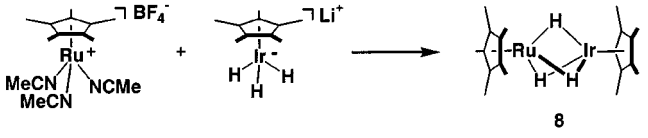


Scheme 3

A series of dinuclear μ-phosphido complexes $\{(C_5Me_5)Ru\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}C_6H_6)(\mu\text{-}PRR')$ were synthesized in a similar manner.[16] As a result, modification of the electronic environment of the bimetallic reaction sites might be achieved by changes in the substituents on the bridging phosphido ligand. It is noteworthy that arene molecules coordinated both in **4** and **5** were readily replaced by the added organic substrates and therefore, they are considered to be a suitable precursor of the active species for bimetallic activation. For example, addition of isoprene to a solution of **4** in tetrahydrofuran resulted in the exclusive formation of a (μ-alkylideneamide)(η^2:η^2-isoprene) complex $\{(C_5Me_5)Ru\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-isoprene})(\mu\text{-N=CHR})$ (**6**). Similarly, the coordinated benzene was substituted with toluene to yield $\{(C_5Me_5)Ru\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-toluene})(\mu\text{-N=CHR})$ (**7**) when **5** was heated at 60 °C in toluene.

2.4 Synthesis of Heterobimetallic Polyhydride Complexes

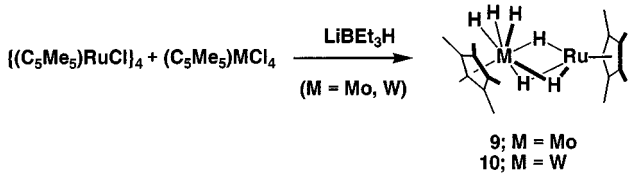
As an extension to multimetallic activation by homonuclear cluster complexes, we focused our attention on the synthesis of a heterometallic polyhydride cluster, thereby making the reaction sites electronically anisotropic. Enhancement of the anisotropic character of the reaction sites likely causes changes in regioselectivity at the stage of substrate activation. Although a number of heterobimetallic polyhydride cluster complexes have been synthesized,[17] there have only been a few reported examples of successful achievement of heterobimetallic activation of organic substrates.[18]



(5)

The reaction of $[(C_5Me_5)Ru(CH_3CN)_3](BF_4)$[19] with an anionic iridium hydride complex $Li[(C_5Me_5)IrH_3]$[20] led to a new heterobimetallic hydride cluster $(C_5Me_5)Ru(\mu\text{-}H)_3Ir(C_5Me_5)$ (**8**) [Equation (5)].[21]

The longitudinal relaxation time T_1 for the hydride ligands was determined to be 3.34 s at −80 °C, which is sufficient to characterize the complex as a classical trihydride complex. The hydride ligands of **8**, as well as the methyl group of the C_5Me_5 ligand coordinated to iridium, underwent an intermolecular H/D exchange reaction with C_6D_6. Interestingly, the H/D exchange of the bridging hydride ions preceded that of the methyl hydrogen atoms of the C_5Me_5 group, and the H/D exchange of the methyl hydrogen atoms selectively occurred on the C_5Me_5 ligand bound to the iridium center. The H/D exchange between the bridging hydride ions and that of the methyl hydrogen atoms on the C_5Me_5 group likely proceed via an intermediary η^2-C_6D_6 complex and an η^6-1,2,3,4-tetramethylfulvene or η^1:η^6-tetramethylcyclopentadienylmethyl intermediate, respectively. The latter process is proposed for the reversible hydrogen shift from a ring methyl group to the titanium center in $(C_5Me_5)_2Ti$.[22]



(6)

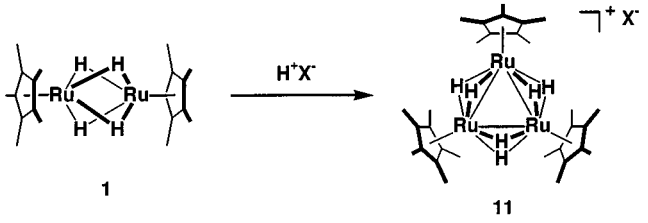
Heterobimetallic polyhydride complexes containing ruthenium and electron-deficient group-6 metal atoms, $(C_5Me_5)MH_3(\mu\text{-}H)_3Ru(C_5Me_5)$ (**9**: M = Mo; **10**: M = W), were obtained by the treatment of a 1:1 mixture of $\{(C_5Me_5)RuCl\}_4$ [19] and $(C_5Me_5)MCl_4$ [23] with $LiBEt_3H$ [Equation (6)].[24]

The X-ray diffraction studies of **9** and **10** clearly establish the dinuclear structure with 3 terminal hydride ions and the three bridging hydride ions. The signals for the six hydride ions of **10** were observed to be equivalent above −40 °C due to a rapid exchange of the hydride ions among the terminal sites on the molybdenum center and the bridging sites. The hydride ligands of **9** were more mobile than those of the tungsten analogue **10**, and the signal for the terminal and the bridging hydride ions de-coalesced at −110 °C. On the basis of the T_1 value, both **9** and **10** were concluded to be the classical hydride complexes.

Heterobimetallic polyhydride clusters with different metal/metal combinations, such as Ru/Rh,[25] Ru/Os,[26] and Ru/Re[27] were also synthesized and characterized.

2.5 Synthesis of a Trinuclear Polyhydride Cluster of Ruthenium

The reactivity of a cluster complex most probably depends on the ease of the electron transfer between complex and substrate. The number of transferable electrons between the cluster complex and the substrate must be changed by the nuclearity of the cluster: the more nuclei there are in the cluster, the more effectively electrons are transferred. As an extension of bimetallic activation, the trimetallic polyhydride cluster has attracted some attention.

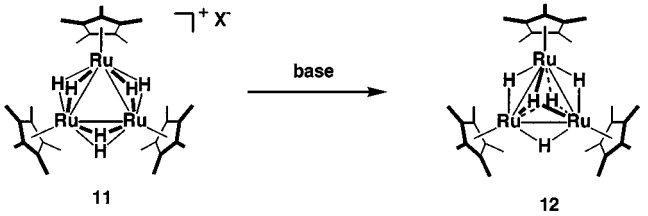


(7)

A cationic triruthenim hexahydride cluster $[\{(C_5Me_5)Ru(\mu\text{-}H)_2\}_3](X)$ (**11**) was obtained by the reaction of **1** with an acid HX in excellent yields [Equation (7)].[28,29] Compound **11** is stable enough to be stored in chloroform for several hours without decomposition.

The T_1 value of 0.387 s for the hydride resonance of **11** lies within the range of those for the classical hydride complexes. This result is consistent with the relatively long distance (average 1.81 Å) between the two hydrogen atoms bridging the same Ru−Ru bond observed in the X-ray structure.

Treatment of the cationic cluster **11** with an appropriate base such as sodium methoxide afforded a neutral pentahydride cluster $\{(C_5Me_5)Ru\}_3(\mu\text{-}H)_3(\mu_3\text{-}H)_2$ (**12**) [Equation (8)].[29]



(8)

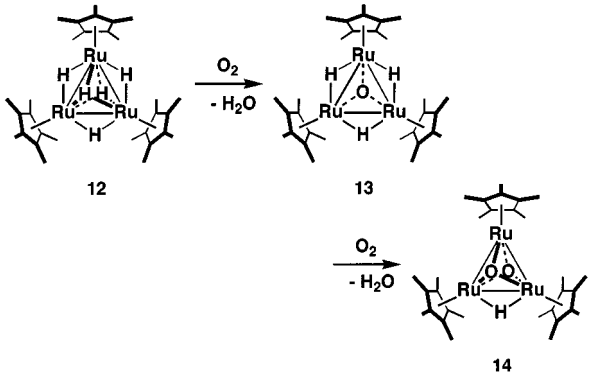
The VT-^{1}H NMR study has shown the rapid exchange of the hydride ions among the coordination sites, on an NMR timescale in the temperature range from 20 to −120 °C. The T_1 value of 2.55 s (−80 °C) for the hydride signal of **12** is significantly large in comparison with that of the hydride signal of the cationic cluster **11**. Cluster **12** was also concluded to be a classical hydride complex based on this T_1 value.

Triruthenium pentahydride **12** is an unsaturated 44-electron cluster and is able to capture a weakly coordinating substrate such as dihydrogen or benzene in a triangular reaction site. As a result, **12** readily underwent an H/D exchange reaction between the hydride ligands and D_2 or C_6D_6.

Unlike the cationic cluster **11**, the neutral cluster **12** is much more reactive because of high electron density at the metal center to activate even a chemically inert alkane molecule (vide infra).

2.6 Trinuclear Polyhydride Clusters with a Triply Bridged Ligand Containing a Heteroatom

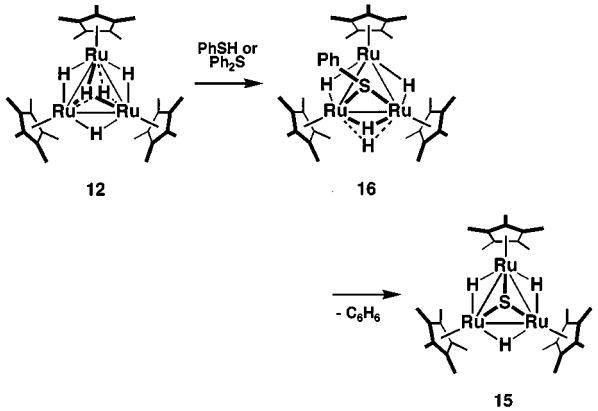
Introduction of a triply bridging ligand on to the Ru_3 core allowed control over the reactivity of the cluster due to change in the electronic environment of the reaction site. It is of utmost importance to introduce one bridging ligand onto one side of the Ru_3 core. If both faces of the Ru_3 plane are covered with the two bridging ligands, there is no space for the substrate activation on the Ru_3 plane. Cluster **12** is stable enough not to undergo fragmentation of the Ru_3 framework even in the reaction with various reactive small molecules such as dioxygen and pressurized dihydrogen. A new class of trinuclear polyhydride cluster with a triply bridging ligand has therefore been synthesized by using pentahydride **12** as the starting material.



(9)

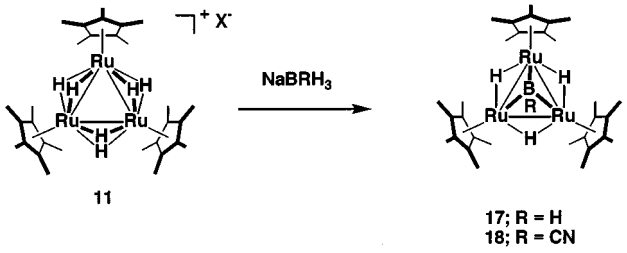
Cluster **12** was converted into a mono-μ_3-oxo complex $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}O)(\mu\text{-}H)_3$ (**13**) and a di-μ_3-oxo complex $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}O)_2(\mu\text{-}H)$ (**14**), successively, by the reaction with dioxygen at low temperature [Equation (9)].[29] The mono-μ_3-oxo complex was isolated in high yield by controlling the reaction conditions such as the O_2/**12** ratio and the temperature.

The sulfur analogue of **13**, $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}S)(\mu\text{-}H)_3$ (**15**), was selectively synthesized by the reaction of **12** with an equimolar amount of thiophenol or diphenyl sulfide [Equation (10)].[30] An intermediary μ-(phenyl sulfide) complex $\{(C_5Me_5)Ru\}_3(\mu\text{-}SPh)(\mu\text{-}H)_4$ (**16**) was isolated in the reaction, which underwent S−C(aromatic) bond cleavage to afford **15**.



(10)

Reaction of **12** with excess diphenyl sulfide yielded a bi-capped cluster $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}S)_2(\mu\text{-}H)$, which was almost inactive toward various unsaturated hydrocarbons because both faces of the Ru_3 core were covered with the μ_3-S groups.



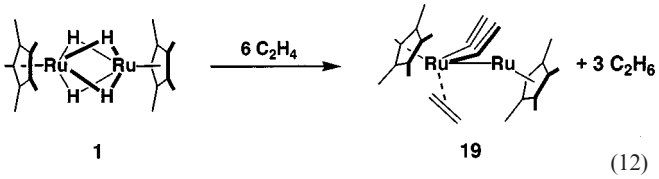
(11)

Bridging ligands containing not only an electronegative element but also an electropositive one were introduced into the Ru_3 core. The reaction of a cationic polyhydride cluster **11** with $NaBH_4$ resulted in the exclusive formation of $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}BH)(\mu\text{-}H)_3$ (**17**) [Equation (11)].[31] A cluster having a μ_3-BCN ligand, $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}BCN)(\mu\text{-}H)_3$ (**18**), was similarly prepared by using $NaB(CN)H_3$.[31] Complexes **17** and **18** are both an unprecedented type of a μ_3-borylene cluster, namely, "single-faced μ_3-borylene cluster", having a spacious reaction site on the reverse side of the μ_3-borylene ligand with respect to the Ru_3 plane.

3 Multimetallic Activation of Hydrocarbon Molecules on the Reaction Site of a Polyhydride Cluster

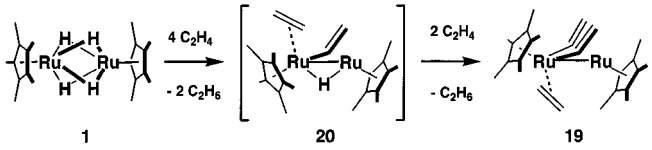
3.1 Reactions of a Dinuclear Polyhydride Cluster with Ethylene and Diphenylacetylene

The reaction of **1** with ethylene under atmospheric pressure proceeded at ambient temperature to form a dinuclear di-μ-η^1:η^2-vinyl complex $\{(C_5Me_5)Ru\}_2(CH_2CH_2)(\mu\text{-}CHCH_2)_2$ (**19**) in excellent yield [Equation (12)].[5b] The GLC analysis of the gas phase of the reaction revealed the formation of ca. 270% of ethane together with a small amount of 1-butene. This result suggests that the coordinatively unsaturated sites are generated on **1** by way of a hydride transfer from the ruthenium center to the ethylene ligand, i.e., hydrogenation of ethylene.



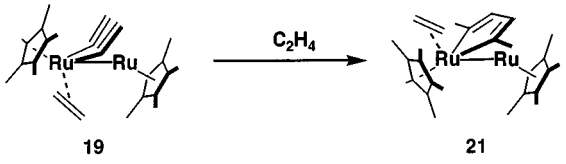
(12)

Monitoring the reaction by NMR spectroscopy showed the formation of an intermediary mono-μ-vinyl complex $\{(C_5Me_5)Ru\}_2(CH_2CH_2)(\mu\text{-}CHCH_2)(\mu\text{-}H)$ (**20**). Monovinyl complex **20** was highly reactive owing to coordinative unsaturation at the metal centers and could be readily converted into **19** in the presence of excess amounts of ethylene (Scheme 4).

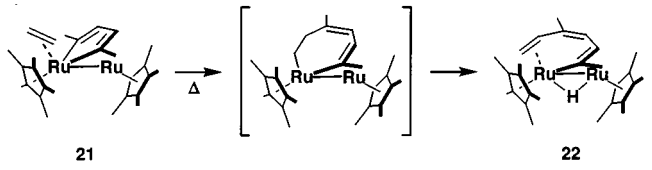


Scheme 4

Subsequent reaction proceeded to yield a 2,5-dimethylruthenacyclopentadiene complex **21** when **19** was heated in the presence of ethylene under atmospheric pressure [Equation (13)]. Ruthenacycle **21** was further converted into a μ-η^2:η^2:η^2-5-methylhepta-2,4,6-trien-2-yl complex **22** (Scheme 5). The formation of **22** is reasonably elucidated by the mechanism involving an insertion of the coordinated ethylene ligand into one of the Ru−C σ bonds of **21**. Subsequent β-H elimination from the resulting intermediary ruthenacycloheptadiene would yield **22**.

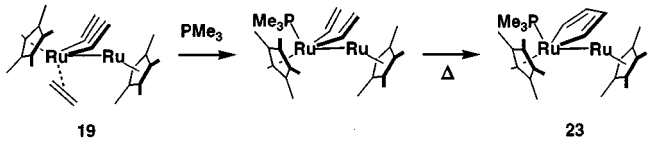


(13)



Scheme 5

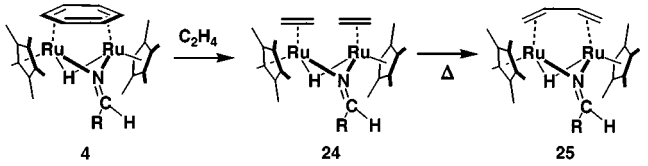
Interestingly, dinuclear divinyl complex **19** underwent dehydrogenative C−C coupling between the terminal carbon atoms of the bridging vinyl groups to generate a ruthenacyclopentadiene complex **23** upon heating in the presence of trimethylphosphane (Scheme 6).[32]



Scheme 6

Introduction of a bridging ligand onto the bimetallic reaction site caused changes in reactivity due to changes in the electronic and steric environment around the metal centers. The (μ-alkylidene)(amide) complex **4** could easily open a pair of vacant coordination sites in solution to generate an active species for bimetallic activation. The reaction of **4** with 1 atm of ethylene proceeded at ambient temperature

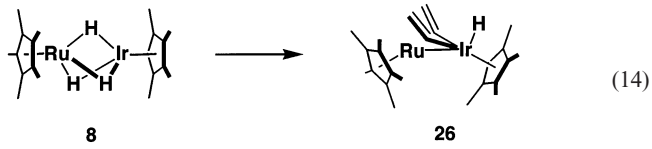
to give a bis(η^2-ethylene)ruthenium complex **24**.[13] When **24** was heated at 80 °C, a μ-η^2:η^2-*s*-*cis*-butadiene complex **25** was exclusively formed by a dehydrogenative coupling of the coordinated ethylene molecule (Scheme 7).



Scheme 7

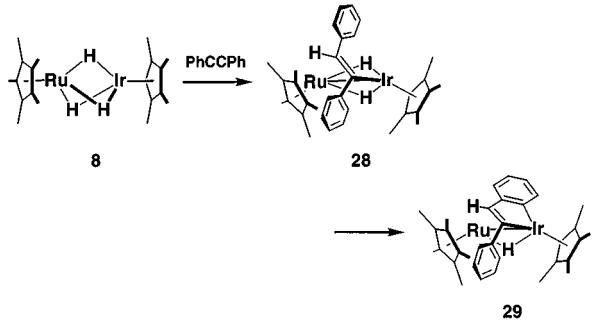
The butadiene complex **25** could be directly synthesized from **4** by treatment with 1 atm of ethylene in refluxing toluene.

The reaction of the heterobimetallic complex **8** with ethylene revealed the site selectivity of the heterobimetallic system toward an organic substrate. The reaction of **8** with ethylene led to the exclusive formation of a di-μ-η^1:η^2-vinyl complex **26** [Equation (14)].[21] A notable feature of this reaction is the site selectivity in which C−H bond cleavage exclusively took place at the iridium center. The ruthenium center most likely plays the role of a coordination site.

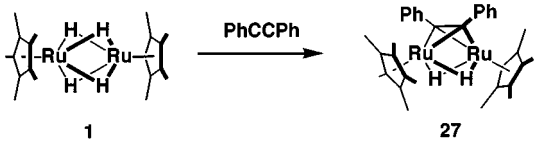


(14)

The reactivity of the heterobimetallic cluster **8** is significantly different from that observed for homonuclear cluster **1**. While the reaction of **1** with diphenylacetylene resulted in the formation of a dinuclear complex bridged by a perpendicularly coordinated diphenylacetylene, {(C_5Me_5)Ru}$_2$(μ-η^2:η^2-PhCCPh)(μ-H)$_2$ (**27**) [Equation (15)],[33] complex **8** smoothly reacted with diphenylacetylene to produce a μ-η^1:η^2-alkenyl complex, (C_5Me_5)Ir{μ-η^1:η^2-(*Z*)-CPh=CHPh}(μ-H)$_2$Ru(C_5Me_5) (**28**) (Scheme 8).[21] The formation of **28** is most likely due to an initial μ-η^2:η^2-alkyne coordination perpendicular to the Ir−Ru vector and subsequent *trans*-addition of Ir and a hydride ion to the carbon−carbon triple bond. The bridging alkenyl complex **28** was quantitatively converted into a dinuclear benzoiridacyclopentadiene complex **29**, as a result of intramolecular activation of the C(*ortho*)−H bond, upon heating at 80 °C.

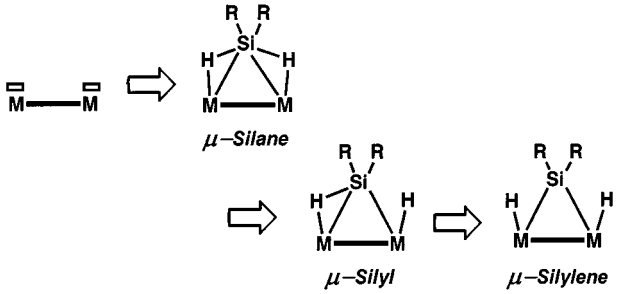


Scheme 8



(15)

The reaction of **1** with various organosilanes provided evidence for the concerted activation of the Si−C and Si−H bonds, in which the two ruthenium atoms cooperatively affect the silane molecule. In the reaction of **1** with secondary silanes, a stepwise transformation of the silane from the μ-silane complex to a μ-silylene complex by way of the μ-silyl complex was observed, and each metal center mutually took the role of a binding site and an activation site (Scheme 9).[12,34]

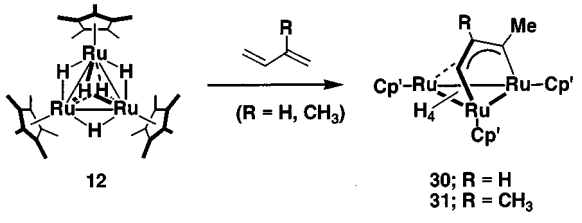


Scheme 9

3.2 Reactions of a Trinuclear Polyhydride Cluster with Acyclic 1,3-Dienes

The reaction of **12** with acyclic conjugated dienes such as butadiene and isoprene affords a novel trinuclear μ_3-η^2:η^2-*s*-*cis*-1,3-diene complexes having an agostic Ru−H−C interaction.

Treatment of **12** with excess butadiene (1 atm) in tetrahydrofuran led to the formation of a trinuclear 1-methyl-1,3-dimetalloallyl complex {(C_5Me_5)Ru}$_3$(H)$_4$(μ_3-η^3-C(Me)-CHCH} (**30**).[35] The reaction of **12** with isoprene proceeded in a similar manner at ambient temperature to form the corresponding μ_3-dimetalloallyl complex **31** [Equation (16)].



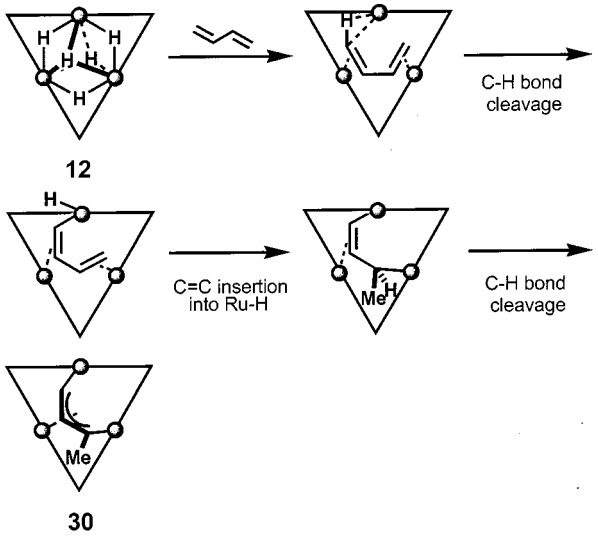
(16)

The molecular structure of **30** was proven by X-ray crystallography. Monitoring the reaction of **12** with 1 equiv. of isoprene in [D_6]benzene at room temperature by ^{1}H and ^{13}C NMR spectroscopy showed the formation of an intermediary trinuclear μ_3-η^2:η^2-*s*-*cis*-isoprene complex **33** in the initial stage of the reaction. Complex **33** involved an agostic interaction among the terminal carbon and hydrogen atoms and one of the ruthenium atoms. The small C(sp^2)−H

coupling constant (J_{CH} = 107 Hz) and the upfield shift (δ = −9.33) of the resonance for the terminal methylene proton of the diene ligand in **33** lie within the range of structurally well-established agostic complexes and unambiguously indicate the presence of a three-center two-electron Ru−H−C interaction.[18d,36] An intermediary agostic complex **32** was similarly detected in the reaction of **12** with butadiene by means of NMR spectroscopy.

The intermediates **32** and **33** underwent activation of the agostic C−H bond to ultimately form the 1,3-dimetalloallyl complexes **30** and **31**, respectively. These results show that 2 of the 3 ruthenium centers in **12** act as coordination sites, and the third metal atom takes the role of an activation site by agostic interaction in the reaction with 1,3-diene. This is a typical example showing the activation process performed by the concerted action of three metal centers.

Formation of the μ_3-η^2:η^2-*s*-*cis*-1,3-diene complexes **32** and **33** suggests the mechanism shown in Scheme 10 for the reaction of **12** with acyclic conjugated dienes leading to the exclusive formation of the μ_3-1,3-dimetalloallyl complexes. When the 1,3-diene is incorporated into the triangular reaction site, the diene ligand is forced to adopt the *s*-*cis* conformation to minimize the steric repulsion between the substrate and the C_5Me_5 groups. The agostic intermediate likely undergoes activation of the carbon−hydrogen bond to form a μ_3-η^1:η^2:η^2-dienyl complex. Insertion of the terminal carbon−carbon double bond into an adjacent Ru−H bond followed by carbon−hydrogen cleavage at the allylic position of the resulting dimetallocyclopentene would give the μ_3-1,3-dimetalloallyl complex as a final product.



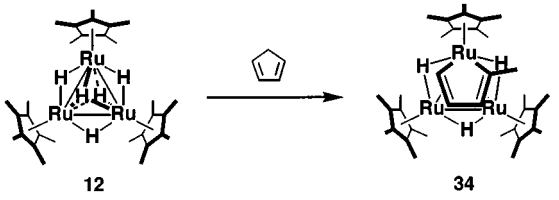
Scheme 10

As the trimetallic reaction site of **12** is surrounded by the three C_5Me_5 groups, steric repulsion between the C_5Me_5 ligand and the substrate strongly influences the incorporation step of the substrate into the trimetallic site. As a result, remarkable shape selectivity for the incorporation of the substrate was observed in the reaction of **12** with a series of substituted 1,3-diene. While complex **12** readily reacted with monosubstituted 1,3-butadienes such as isoprene, 1,3-pentadiene, and 1,3-hexadiene to generate the corresponding μ_3-1,3-dimetalloallyl complexes exclusively, the reaction of **12** with disubstituted butadiene such as 2,3-dimethyl-1,3-butadiene, 2-methyl-1,3-pentadiene, 3-methyl-1,3-pentadiene, and 2,4-hexadiene resulted in the recovery of the starting complex **12** and the diene.

3.3 Reactions of a Trinuclear Polyhydride Cluster with Cyclic 1,3-Dienes

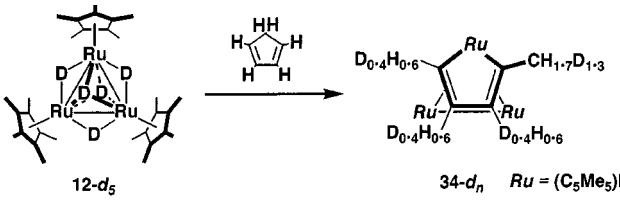
The size and shape of cyclopentadiene fit well with those of the reaction site of **12**. Whereas C−H bond cleavage took place at the terminal carbon atom of the diene in the reaction of **12** with acyclic 1,3-diene, the reaction of **12** with cyclopentadiene resulted in selective C−C bond cleavage in cooperation with the three metal centers.

The reaction of **12** with cyclopentadiene in tetrahydrofuran at room temperature led to the quantitative formation of the trinuclear 2-methylruthenacyclopentadiene $\{(C_5Me_5)Ru\}_3(\mu\text{-}H)_3\{\mu_3\text{-}\eta^4\text{-}C(Me)=CHCH=CH\}$ (**34**) as a result of the $C(sp^2)-C(sp^3)$ bond cleavage of the cyclopentadiene [Equation (17)].[37] To the best of our knowledge, this is the first example of the selective activation of an unactivated carbon−carbon bond in cooperation with three metal centers. Kinetic parameters of $\Delta H^{\ddagger}$ = 12.7(3) kcal mol^{-1} and $\Delta S^{\ddagger}$ = −30.0(10) cal mol^{-1} K^{-1} for this reaction indicate that incorporation of the cyclopentadiene into the trimetallic reaction site is the rate-determining step.



(17)

Monitoring the reaction of **12** with 5 equiv. of cyclopentadiene in [D_8]tetrahydrofuran at room temperature by ^{1}H NMR spectroscopy showed the formation of an intermediary ruthenacyclohexadiene **35** during the initial stage of the reaction. Although **35** could not be isolated, it was unambiguously characterized by means of NMR spectroscopy.

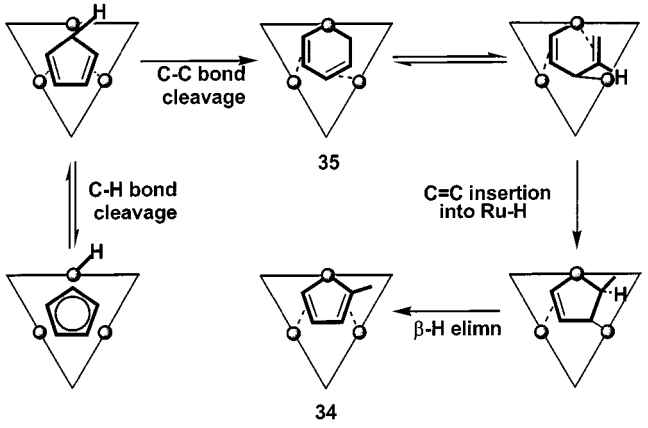


(18)

To elucidate the reaction mechanism, a labeling experiment was performed by use of triruthenium pentadeuteride complex **12**-d_5. The reaction of **12**-d_5 with cyclopentadiene-h_6 smoothly proceeded at room temperature to give an iso-

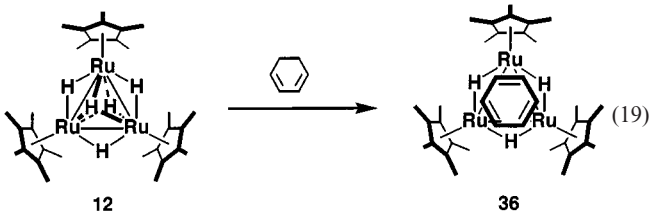
topomer of the 2-methylruthenacyclopentadiene **34**-d_n, in which the deuterium atoms were uniformly scrambled over the ruthenacycle [Equation (18)]. This result indicates that the activation of the carbon−hydrogen bond at the allylic position of cyclopentadiene leading to a μ_3-cyclopentadienyl intermediate takes place prior to the carbon−carbon bond cleavage.

One plausible reaction mechanism involving a pre-equilibrium between a μ_3-η^2:η^2-cyclopentadiene complex and a μ_3-η^5-cyclopentadienyl complex is illustrated in Scheme 11. Cyclopentadiene incorporated into the Ru_3 core is bound to two of the three ruthenium centers of **12** through μ-η^2:η^2 coordination to form the μ_3-cyclopentadiene complex. In the intermediary μ_3-cyclopentadiene complex, both the allylic C−H bond and the C(sp^3)−C(sp^2) bond are nicely oriented towards the third metal atom for the bond cleavage. Ruthenacyclohexadiene formed as a result of the C(sp^3)−C(sp^2) bond cleavage is in equilibrium with a μ_3-penta-1,4-diene-1,3-diyl complex, which undergoes insertion of the carbon−carbon double bond into Ru−H to yield a μ_3-5-methylruthenacyclopent-2-ene complex.



Scheme 11

The space of the triangular reaction site in **12** is large enough to accommodate a C_6-ring compound. The reaction of **12** with 5 equiv. of 1,3-cyclohexadiene in tetrahydrofuran resulted in the quantitative formation of a face-capping benzene complex $\{(C_5Me_5)Ru)_3(\mu\text{-}H)_3(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}C_6H_6)$ (**36**) by C−H bond cleavage at the allylic carbon atoms [Equation (19)].[38]

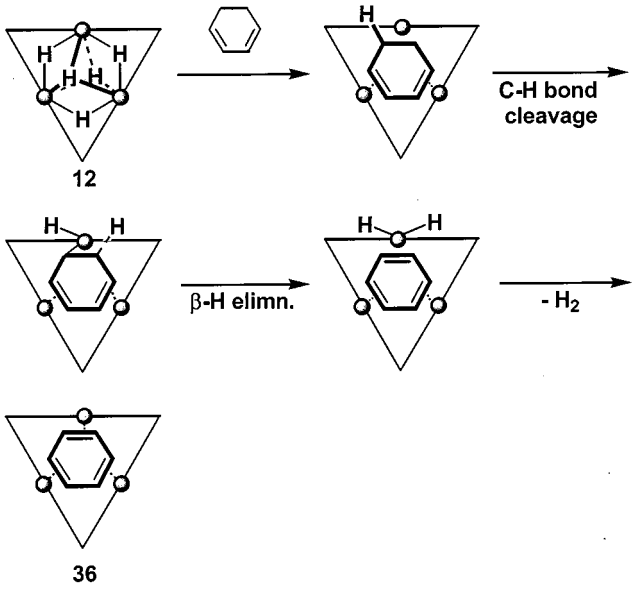


(19)

The shift of the ^1H and ^{13}C NMR resonances for the coordinated benzene ligand, respectively, are much higher than those observed in the carbonyl clusters $Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}C_6H_6)$[39] and $Os_3(CO)_9$ (μ_3-η^2:η^2:η^2-C_6H_6).[40]

The μ_3-η^2:η^2:η^2 coordination of the benzene ring was unequivocally confirmed by an X-ray diffraction study. The reaction of **12** with 1,3-cyclohexadiene to give **36** is first-order in both **12** and cyclohexadiene [$k_{obs} = 2.7(1) \times 10^{-3}$ mol^{-1} s^{-1} at 66 °C] with $\Delta H^{\ddagger} = 13.5(8)$ kcal mol^{-1} and $\Delta S^{\ddagger} = -30.6(3)$ cal mol^{-1} K^{-1}. The value of the activation entropy is similar to that for the reaction of **12** with cyclopentadiene, as mentioned above. The negative large value of $\Delta S^{\ddagger}$ and the relatively small value of $\Delta H^{\ddagger}$ indicate that fitting into the size and shape between the substrate and the reaction site surrounded by the three C_5Me_5 groups is essential for the progress of the reaction.

In an attempt to observe intermediates by NMR spectroscopy, the reaction was performed in an NMR tube at 0 °C. Although no resonance signal except for those attributable to **12**, **36**, and H_2 was observed, the reaction most likely proceeds via an intermediary μ_3-η^2:η^2-cyclohexadiene complex. One plausible reaction mechanism for the reaction of **12** with cyclohexadiene leading to the μ_3-η^2:η^2-cyclohexadiene complex **37** is illustrated in Scheme 12. In the present reaction, two of the three metal centers in **12** act as coordination sites, and the third metal atom plays the role of an activation site to cleave an allylic C−H bond as observed in the reaction of **12** with butadiene or isoprene.

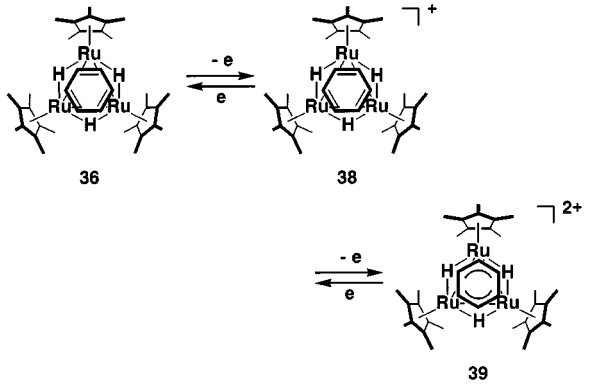


Scheme 12

In the trimetallic reaction site of the triruthenium pentahydride **12**, conjugated dienes with the appropriate size and shape could be effectively activated due to the concerted action of the three metal centers. The reaction of **12** with 1,4-cyclohexadiene or 1,3-cycloheptadiene, however, required heating at 60−100 °C to complete, because the orientation of two carbon−carbon double bonds or the ring size of the substrate is not suitable for the coordination to the Ru_3 site.

It is noteworthy that oxidation of the face-capping C_6H_6 complex **36** induces change in the coordination mode of the benzene ligand. The electrochemistry of **36** displays two

reversible one-electron oxidations at −490 and −224 mV vs. Ag/AgCl. To examine changes in the coordination mode of the face-capping benzene ligand due to changes in the oxidation state, oxidation of **36** with a ferricinium salt was examined (Scheme 13).



Scheme 13

Treatment of **36** with 1 equiv. of $[(C_5H_5)_2Fe]PF_6$ in toluene quantitatively yielded a paramagnetic monocationic complex $[\{(C_5Me_5)Ru\}_3(\mu\text{-}H)_3(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-}C_6H_6)]PF_6$ (**38**). The X-ray diffraction study established the μ_3-η^2:η^2:η^2 coordination of benzene in **38**. As was anticipated from the electrochemical study, a diamagnetic complex $[\{(C_5Me_5)Ru\}_3(\mu\text{-}H)_3(\mu_3\text{-}\eta^3\text{:}\eta^3\text{-}C_6H_6)](PF_6)_2$ (**39**) was obtained by two-electron oxidation of **36**. The most striking structural feature of **39** is the μ_3-η^3:η^3 coordination of the C_6 ring (Figure 2). Thus far, there have been a few precedents of trinuclear μ_3-η^3:η^3-C_6H_6 complexes.[41] Complex **36** is, however, the first example that exhibits the hapticity change in the face-capping benzene ligand induced by a redox process.

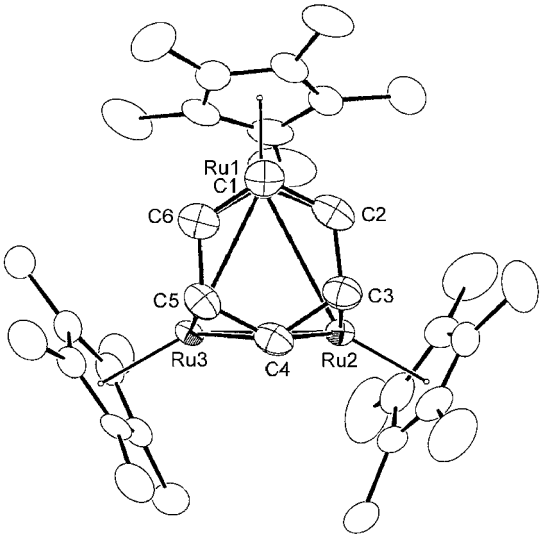


Figure 2. Molecular structure of $[\{(C_5Me_5)Ru\}_3(\mu\text{-}\eta^3\text{:}\eta^3\text{-}C_6H_6)]^{2+}$ (**39**)

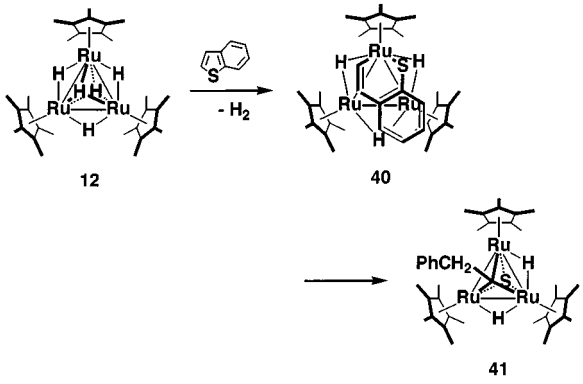
3.4 Reactions of a Trinuclear Polyhydride Cluster with Benzothiophene and Dibenzothiophene

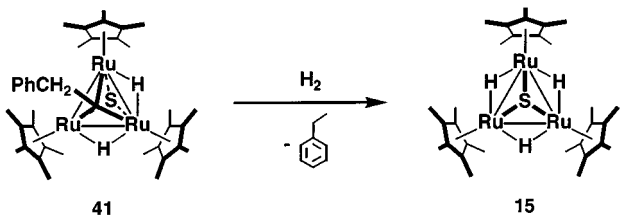
Cleavage of the C−S bond of thiophenes by transition metal complexes has attracted the attention of many inorganic and organometallic chemists in connection with hydrodesulfurization (HDS) from petroleum feedstock. While there is a vast chemistry of organosulfur−transition metal complexes, successful examples of C−S bond cleavage of benzothiophene and dibenzothiophene by mono- and dinuclear transition metal complexes have been limited.[42]

Interestingly, the trimetallic hydride cluster **12** could effectively activate benzothiophene and dibenzothiophene to cleave their C−S bonds selectively. The reaction of **12** with benzothiophene in toluene quantitatively afforded a (μ_3-phenethylidyne)(μ_3-sulfido) complex $\{(C_5Me_5)Ru\}_3(\mu\text{-}H)_2(\mu_3\text{-}S)(\mu_3\text{-}CCH_2Ph)$ (**41**) as a result of the successive cleavage of two C−S bonds (Scheme 14).[43]



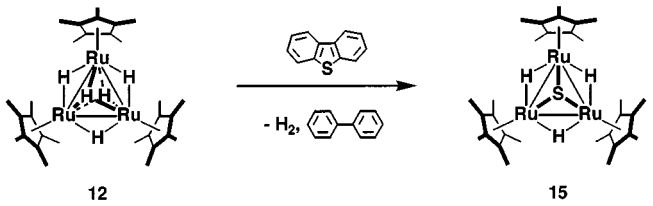
Scheme 14

Monitoring the reaction by means of ^{1}H NMR spectroscopy revealed formation of an intermediary thiaruthenacyclohexadiene complex **40**, which was isolated from the resulting mixture at −30 °C. The structure of the intermediary thiaruthenacyclohexadiene **40** was confirmed in comparison with that of the analogous thiaruthenacycle derived by the reaction of μ_3-borylene complex **17** with benzothiophene.[31] Complex **41** underwent hydrogenolysis by treatment of **41** with dihydrogen (7.2 atm) to produce ethylbenzene and the μ_3-sulfido complex **15** [Equation (20)].



(20)

Complex **12** shows reactivity for the cleavage of the C−S bonds in dibenzothiophene. The reaction of **12** with dibenzothiophene proceeded at 110 °C to form **15** and biphenyl in high yield [Equation (21)].

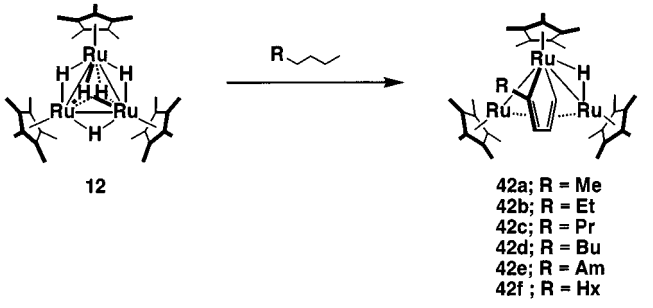


(21)

3.5 Reactions of a Trinuclear Polyhydride Cluster with Alkanes

Activation of an alkane C−H bond mediated by late transition metal complexes has been the focus of recent studies in organometallic chemistry because of its potential applicability to the functionalization of alkanes.[44] We have dealt with C−H bond activation of alkanes on the multimetallic site and found that trinuclear clusters **12** and **15** effectively activated alkanes in a thermal reaction.

Heating a solution of **12** in various alkanes at 170 °C resulted in the formation of novel trinuclear *closo*-ruthenacyclopentadiene complexs **42** (**a**: R = Me; **b**: R = Et; **c**: R = Pr; **d**: R = Bu; **e**: R = Am; **f**: R = Hx) in reasonable yield [Equation (22)].[45]

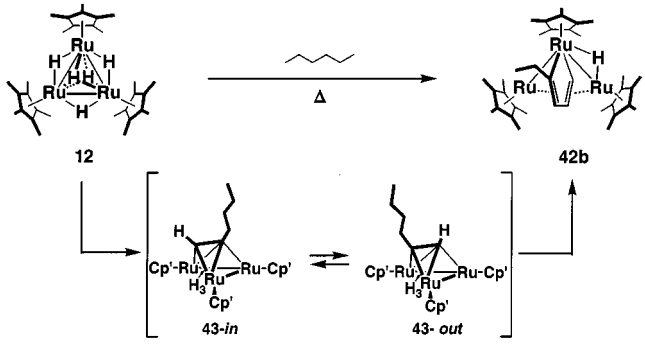


(22)

It is clear that the carbon framework of 2-alkylruthenacyclopentadiene in **42** originates from the *n*-alkane used as the solvent. In this reaction, six C−H bonds of the alkanes were successively cleaved on the trimetallic site, and these results strongly suggest the potential applicability of transition metal cluster complexes, especially polyhydrido metal clusters, to the functionalization of alkanes.

The *n*-alkane molecule is most likely incorporated into the triangular reaction site from one of the methyl termini at the initial stage of the reaction. This was confirmed through the H/D exchange between the hydride ligands in **12** and the deuterated methyl group in octane-d_{18} observed in the temperature range of 140−160 °C.

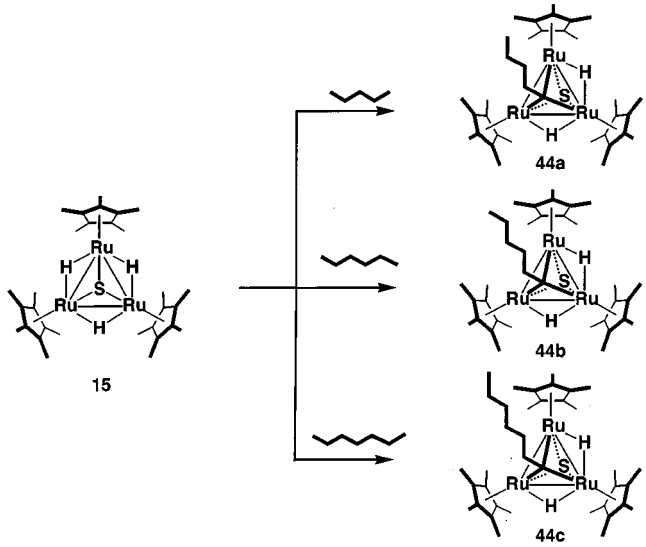
Monitoring the reaction by means of ^{1}H NMR spectroscopy showed signals for several reaction intermediates. They finally converged into thermodynamically stable products **42**. When the reaction of **12** with hexane was monitored at 170 °C by ^{1}H NMR spectroscopy, formation of an equilibrated mixture of perpendicularly coordinated μ_3-hexyne complexes, $\{(C_5Me_5)Ru\}_3(\mu\text{-}H)_3\{\mu_3\text{-}\eta^1\text{:}\eta^2\text{:}\eta^2\text{-}HCCC_4H_9\}$ (**43**-*in*) and $\{(C_5Me_5)Ru\}_3(\mu\text{-}H)_3\{\mu_3\text{-}\eta^1\text{:}\eta^2\text{:}\eta^2\text{-}C_4H_9CCH\}$ (**43**-*out*), was detected in a complex mixture of intermediates (Scheme 15). The intermediacy of the alkyne complex **43** was confirmed by use of an authentic complex independently prepared by treatment of **12** with 1-hexyne.



Scheme 15

To modify the regioselectivity of the triruthenium cluster mediated alkane C−H bond activation, a triply bridging sulfido ligand was introduced into the Ru_3 core by the reaction of **12** with thiophenol. The μ_3-sulfido group introduced was expected to reinforce the Ru_3 framework and to prevent Ru−Ru bond cleavage in the course of the reaction with the alkane.

Heating a solution of **15** in hexane at 170 °C for 107 h led to the quantitative formation of a μ_3-hexylidyne complex $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}S)(\mu\text{-}H)_2\{\mu_3\text{-}C(CH_2)_4CH_3\}$ (**44b**) as a result of C−H bond cleavage at the terminal carbon atom while the reaction of **12** with hexane afforded a *closo*-ruthenacyclopentadiene complex **42**.[46] The results of the reactions of **15** with a series of alkanes are summarized in Scheme 16.

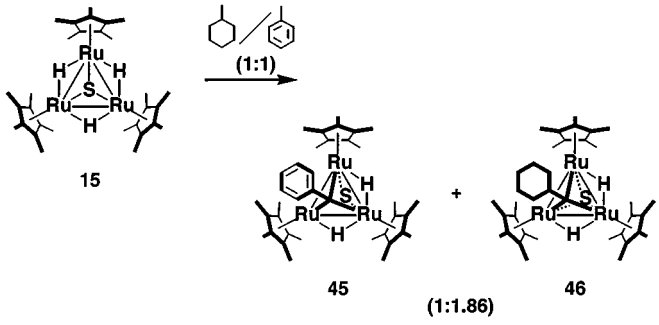


Scheme 16

A notable feature of the reaction is its regioselectivity such that no metal insertion products into the secondary C−H bonds were detected in spite of the clear advantage

over that of the primary C−H bonds, judging from the bond dissociation energy, ca. 95 kcal/mol vs. ca. 98 kcal/mol. The steric repulsion between the substrates and the C_5Me_5 fences surrounding the reaction site would be responsible for the highly primary-selective C−H bond activation because it impedes the access of the secondary C−H bonds to the metal center. The oxidative addition of the C−H bond at the less-hindered methyl group exclusively took place in the reaction with a 5-methylhexane to yield a 5-methylhexylidyne complex despite the statistical disadvantage.

Complex **15** was active toward cleavage of both aromatic and benzylic C−H bonds of toluene. When complex **15** was heated in [D_8]toluene at 130 °C, H/D exchange took place among the hydride ligands of **15** and the aromatic C−D bonds of [D_8]toluene. However, a tolyl intermediate resulting from the aromatic C−D bond cleavage could not be detected because it is presumably unstable due to the steric repulsion with the C_5Me_5 group. Heating a toluene solution of **15** at 170 °C, however, led to the exclusive formation of a thermally stable μ_3-benzilidyne complex $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}S)(\mu\text{-}H)_2(\mu_3\text{-}CC_6H_5)$ (**46**) as a result of C−H bond cleavage at the benzylic carbon.



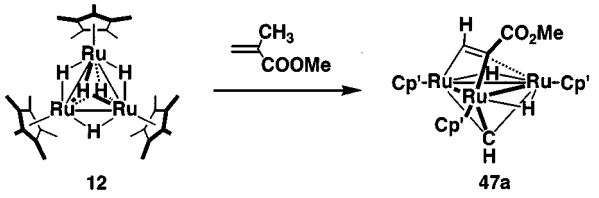
(23)

A competition experiment with a 1:1 mixture of toluene and methylcyclohexane was carried out to elucidate the mechanism. While the accessibility of the methyl group of these two substrates to the reaction site seem to be of similar extent in terms of the steric bulk of the substrate, the C(methyl)−H bond dissociation energy of toluene (ca. 88 kcal/mol) is much smaller than that of methylcyclohexane (ca. 98 kcal/mol). From a thermodynamic point of view, the μ_3-benzylidyne complex should be exclusively formed if the reaction proceeded via homolysis of the C−H bond. In spite of this, heating a solution of **15** in the mixed solvent at 170 °C for 142 h resulted in the formation of **45** and **46** in the ratio of 1:1.86 [Equation (23)]. This result implies that a radical mechanism seems unlikely for these reactions.

3.5 Reactions of a Trinuclear Polyhydride Cluster with 1,1-Disubstituted Alkenes

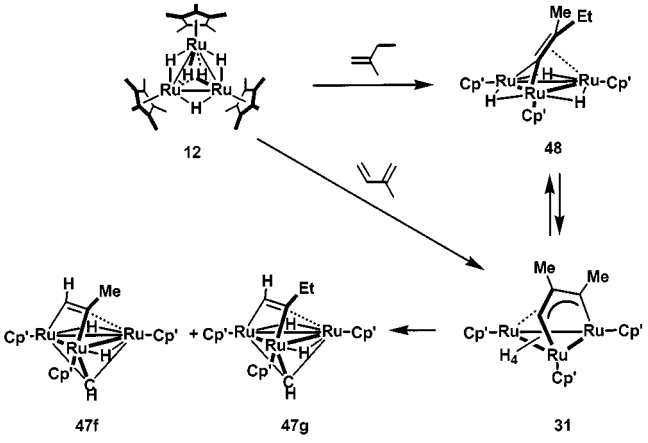
In comparison with the C−H bond cleavage reaction, there have been a relatively small number of successful examples of C−C bond cleavage mediated by mononuclear transition metal complexes.[44h,47] However, the remarkable properties of a multimetallic system, namely its capability of multiple coordination and multi-electron transfer, enabled us to activate not only a C−C single bond[37,48] but also a double bond.

The reaction of **12** with excess methyl methacrylate at 80 °C resulted in the quantitative formation of $\{(C_5Me_5)Ru\}_3(\mu_3\text{-}\eta^2\text{:}\eta^2\text{-}CH{=}CCO_2Me)(\mu_3\text{-}CH)(\mu\text{-}H)_2$ (**47a**) [Equation (24)].[49] The reaction of **12** with a 1,1-disubstituted alkene such as α-methylstyrene, methylenecyclopentane, methylenecyclohexane, and α-methylene-γ-butyrolactone proceeded similarly, leading to the exclusive formation of the corresponding (μ_3-alkyne)(μ_3-methylidyne) complexes **47b**−**47e**.



(24)

Formation of **47** evidently shows that the C−C double bond is cleaved, and the resulting two fragments are converted into the μ_3-methylidyne and the μ_3-alkyne moieties. When the reaction of **12** with the alkene was conducted under milder conditions, formation of an intermediary μ_3-vinylidene complex **48** was detected. Interestingly, heating a solution of the dimetalloallyl complex **31** derived from isoprene resulted in the formation of a 1:1 mixture of **47f** and **47g** by way of the μ_3-vinylidene complex. These observations are consistent with the reaction path involving a reversible isomerization between the μ_3-vinylidene complex and the μ_3-1,3-dimetalloallyl complex, followed by C−C bond cleavage that is likely associated with metal−metal bond cleavage and recombination (Scheme 17).



Scheme 17

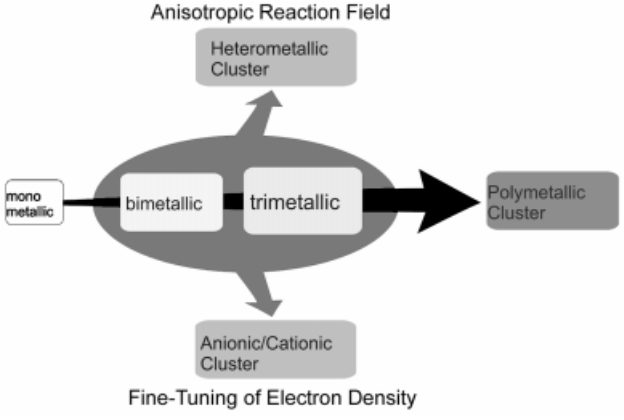
4. Conclusion

The reaction chemistry of metal polyhydride clusters has been a relatively unexplored field in comparison with that

of polycarbonyl clusters. However, the newly developed cyclopentadienylmetal polyhydride system has brought about several great changes in the reactivity of the clusters. Metal polyhydride clusters, especially those having C_5Me_5 groups, reveal remarkable reactivity, that is, an unprecedented mode of C−C bond cleavage, C−C double bond cleavage of terminal alkenes, alkane C−H bond cleavage, and so on.

Among the intrinsic properties of metal clusters, their capability of multi-electron transfer and multiple coordination discriminate their reactivity from that of mononuclear metal complexes. Particularly, the latter is most probably essential for the multimetallic activation. The metal−metal distances of the polyhydride clusters appearing in this review are in the range of 2−3 Å, and these metal−metal separations would be suitable for cooperation of multiple metal atoms in the activation step of the substrate. In the above-mentioned polyhydride clusters, metal centers are tightly bound to each other by multiple bridging hydride ions and, therefore, the clusters are stable enough not to undergo fragmentation during the reaction. As a result, each metal center mutually takes the role of a binding site and an activation site and activates the substrate concertedly.

We are now exploring the following three subjects: (1) synthesis of clusters with higher nuclearity, (2) modification of the electronic and steric environment of the reaction site by introducing a variety of bridging ligands into the core of the cluster, and (3) synthesis of heterometallic polyhydride clusters.



Systematic, namely both experimental and theoretical studies of the multimetallic activation would be a shortcut to the successful development of really new and versatile methods of transformation of the organic substrates.

Bis[citrato(3−)-O^1,O^3,O^6]silicate: A Dianionic Complex with Hexacoordinate Silicon(IV) and Two Tridentate Dioato(2−)olato(1−) Ligands

Reinhold Tacke,*[a] Martin Penka,[a] Friedrich Popp,[a] and Ingo Richter[a]

Keywords: Silicon / Silicates / Coordination modes / Biomineralization

Simple preparative methods for the synthesis of a hexacoordinate silicate dianion with two tridentate citrato(3–) ligands have been developed. Thus, treatment of tetramethoxysilane with two molar equivalents of citric acid and two molar equivalents of tri(*n*-butyl)amine in tetrahydrofuran yielded tri(*n*-butyl)ammonium bis[citrato(3–)-O^1,O^3,O^6]silicate (**10**). Alternatively, **10** was prepared by treatment of tetrachlorosilane with two molar equivalents of citric acid and six molar equivalents of tri(*n*-butyl)amine in acetonitrile. Compound **10** was characterized by elemental analyses (C,H,N), solid-state ^{29}Si VACP/MAS NMR studies, solution NMR experiments (^{1}H, ^{13}C; CD_3CN), and a crystal structure analysis.

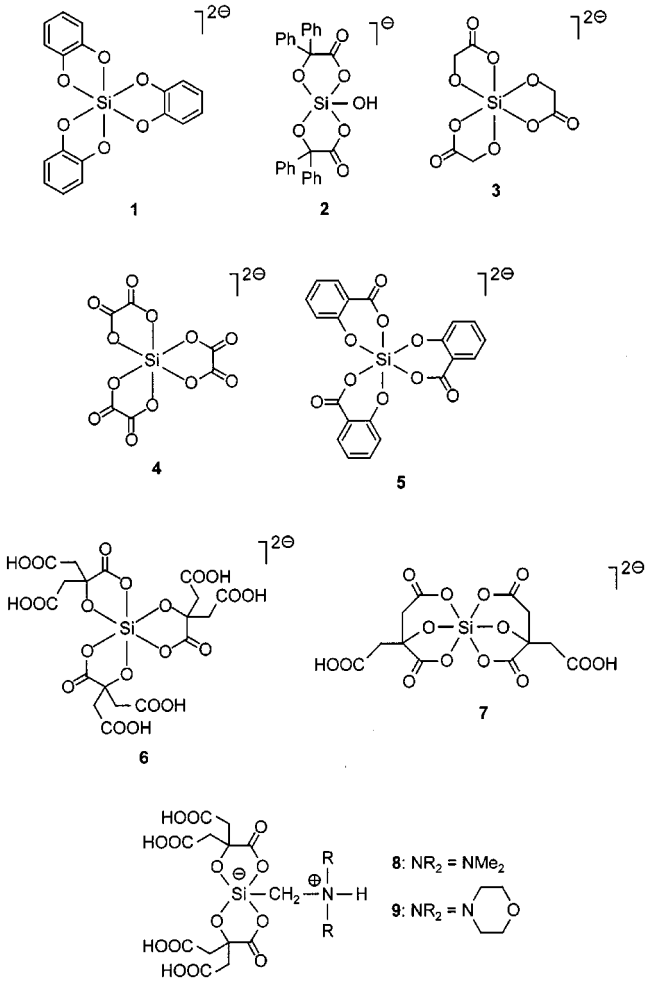
Introduction

In recent years, biochemistry and molecular biology have made significant contributions to the understanding of silica biomineralization.[1] However, almost nothing is known about how silicon acts in biological systems at the molecular level. Two decades ago it was speculated that organosilicates with chelate ligands derived from organic hydroxy compounds may play a role in silicon chemistry in the biosphere, controlling the transport of silicon, its concentration as a soluble silicon pool, and its deposition as silica.[2] In this context, chelate complexes with tetra-, penta-, or hexacoordinate silicon(IV) may be promising candidates.[3] In continuation of our studies on penta- and hexacoordinate silicates with bidentate ligands derived from organic dihydroxy compounds (mono- or dianionic complexes, such as **1**,[3c] **2**,[3d] **3**,[4,5] **4**,[4,5] and **5**[5]), we have attempted to synthesize the tris[citrato(2−)]silicate dianion **6**.[6]

Results and Discussion

To prepare the hexacoordinate silicate dianion **6** according to the strategy applied to the synthesis of **1**−**5**, tetramethoxysilane or tetrachlorosilane were treated with three molar equivalents of citric acid in acetonitrile in the presence of a tertiary amine. However, to our great surprise we did not observe the formation of **6**, but instead obtained the dianionic bis[citrato(3−)-O^1,O^3,O^6]silicate **7** in which two tridentate dioato(2−)olato(1−) ligands are bound to the silicon(IV) center. It is interesting to note that the reaction of



$(MeO)_3SiCH_2NR_2$ (NR_2 = NMe_2 or morpholino) with two molar equivalents of citric acid leads to the zwitterionic sil-

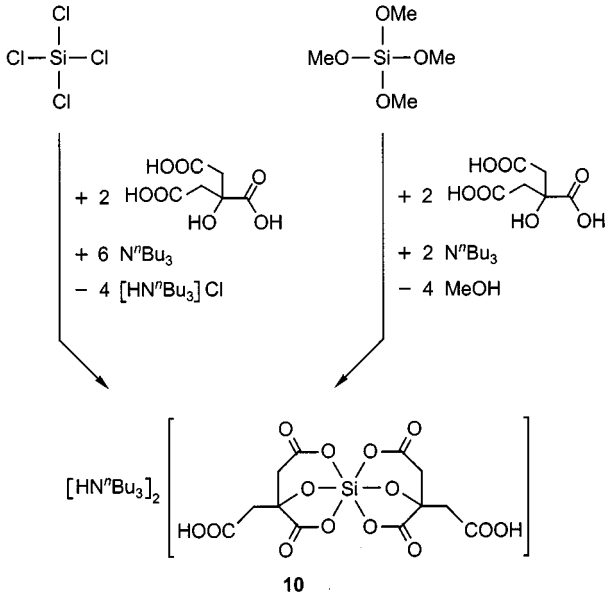
icates **8**[3a] and **9**,[7] with two bidentate citrato(2−) ligands that exhibit chelating properties as in the hypothetical dianion **6**.

We report here on the synthesis of tri(*n*-butyl)ammonium bis[citrato(3−)-O^1,O^3,O^6]silicate (**10**), starting from tetramethoxysilane or tetrachlorosilane (Scheme 1). Compound **10** was isolated in 93% and 40% yield, respectively, as a colorless crystalline solid. To the best of our knowledge, complexes with hexacoordinate silicon(IV) and two tridentate dioato(2−)olato(1−) ligands have not yet been described in the literature.[8]



Scheme 1. Synthesis of compound **10**

As shown by single-crystal X-ray diffraction, the Si-coordination polyhedron of **10** is a distorted octahedron, with maximum deviations of 3.41(5)° and 5.59(5)° from the ideal 90° and 180° O−Si−O angles, respectively (Figure 1). The two tridentate citrato(3−) ligands are coordinated to the silicon atom each with two carboxylato oxygen atoms (O2/O3, O5/O6) and one alcoholato oxygen atom (O1, O4), forming two bicyclic moieties each with a five-, six-, and seven-membered ring. The Si−O(carboxylato) distances are in the range 1.7952(10)−1.8151(10) Å, whereas the Si−O(alcoholato) distances amount to 1.7163(10) Å (Si−O1) and 1.7330(10) Å (Si−O4). The carbon atoms C1 and C7 are stereogenic centers with identical absolute configurations (chiral dianion), and compound **10** crystallizes as a racemate (space group $P2_1/n$). It is interesting to note that related mononuclear hexacoordinate aluminum(III)[9,10] and gallium(III)[10] complexes with two tridentate citrato(3−) or citrato(4−) ligands crystallize as *meso* isomers (achiral dianion, center of inversion).

The isotropic ^{29}Si chemical shift ($\delta = -167.4$) determined by solid-state ^{29}Si VACP/MAS NMR experiments and the ^{13}C VACP/MAS NMR spectroscopic data of compound **10** are in excellent agreement with its crystal structure. However, the situation in solution (solvent: CD_3CN) appears to be more complicated since the ^{1}H and ^{13}C NMR

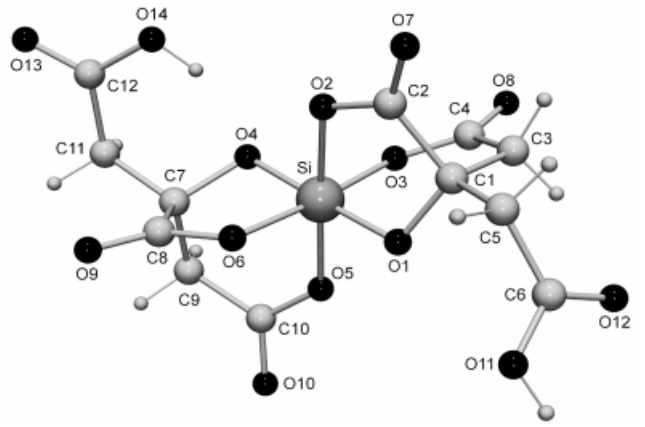


Figure 1. Structure of the silicate dianion in the crystal of **10**; selected bond lengths [Å] and angles [°]: Si−O1 1.7163(10), Si−O2 1.8151(10), Si−O3 1.8001(10), Si−O4 1.7330(10), Si−O5 1.7952(10), Si−O6 1.8116(10); O1−Si−O2 88.49(5), O1−Si−O3 92.78(5), O1−Si−O4 178.56(5), O1−Si−O5 88.25(5), O1−Si−O6 92.76(5), O2−Si−O3 90.62(5), O2−Si−O4 90.22(5), O2−Si−O5 176.62(5), O2−Si−O6 88.74(5), O3−Si−O4 86.59(5), O3−Si−O5 90.41(5), O3−Si−O6 174.41(5), O4−Si−O5 93.05(5), O4−Si−O6 87.85(5), O5−Si−O6 90.54(5), Si−O1−C1 109.95(8), Si−O2−C2 112.92(8), Si−O3−C4 127.73(9), Si−O4−C7 109.80(8), Si−O5−C10 127.71(9), Si−O6−C8 113.37(9); hydrogen-bonding system in the crystal: intermolecular bifurcate N1−H···O3/O8 and N2−H···O5/O10 hydrogen bonds; intermolecular O11−H···O12 interaction; intramolecular bifurcate O14−H···O2/O4 hydrogen bond[11]

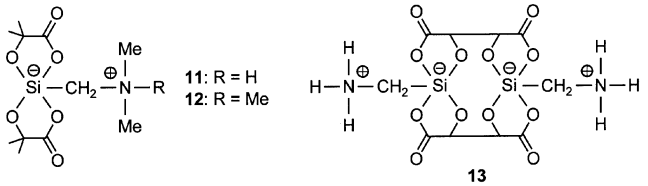
spectroscopic data (^{1}H,^{1}H and ^{1}H,^{13}C correlation experiments) point to the existence of more than one silicate species. The ^{1}H and ^{13}C NMR spectra of the major species are in accordance with the crystal structure of **10**, and the solution and solid-state ^{13}C NMR spectroscopic data show an excellent agreement. However, the solution NMR spectra do not allow a differentiation between C_2 symmetry (chiral silicate dianion) and C_i symmetry (achiral silicate dianion). All attempts to record a solution ^{29}Si NMR spectrum of **10** have failed so far.

Upon dissolution of **10** in water, spontaneous hydrolysis occurred, meaning that the expected chelation effect of the two tridentate ligands of the bis[citrato(3−)]silicate complex is not strong enough to stabilize this species in water.[12] Starting from a 0.2 M aqueous solution of **10** (pH 3.6, 20 °C), gel formation was observed after a period of two weeks. In this context it is interesting to note that the zwitterionic pentacoordinate silicon compounds **8**,[3a] **9**,[3a] **11**,[13] **12**,[13] and **15**[14] could be recovered almost quantitatively from aqueous solutions by crystallization at room temperature. Taking into account all these findings, it remains an open question as to whether or not α-hydroxycarboxylic acids (including citric acid) have any potential relevance for silicon biochemistry.



Experimental Section

General: All syntheses were carried out under dry nitrogen. The organic solvents used were dried and purified according to standard procedures and stored under nitrogen. Melting points were determined with a Büchi Melting Point B-540 apparatus using samples in sealed capillaries. The ^{1}H, ^{13}C, and ^{29}Si solution NMR spectra were recorded at 22 °C on a Bruker DRX-300 NMR spectrometer (^{1}H: 300.1 MHz; ^{13}C: 75.5 MHz; ^{29}Si: 59.6 MHz). CD_3CN was used as solvent. Chemical shifts (ppm) were determined relative to internal CHD_2CN (^{1}H: δ = 1.94), internal CD_3CN (^{13}C: δ = 1.27), and external TMS (^{29}Si: δ = 0). Assignment of the ^{13}C NMR spectroscopic data was supported by DEPT 135 experiments. Solid-state ^{29}Si VACP/MAS NMR spectra were recorded at 22 °C on a Bruker DSX-400 NMR spectrometer with bottom layer rotors of ZrO_2 (diameter 7 mm) containing ca. 300 mg of sample [79.5 MHz; TMS as external standard (δ = 0); spinning rate, 5 kHz; contact time, 5 ms; 90° ^{1}H transmitter pulse length, 3.6 μs; repetition time, 4 s].

Synthesis of Tri(*n*-butyl)ammonium Bis[citrato(3−)-*O*^{1},*O*^{3},*O*^{6}]silicate (10). Method 1: Tetramethoxysilane (1.00 g, 6.57 mmol) and tri(*n*-butyl)amine (2.43 g, 13.1 mmol) were added one after another at 20 °C to a solution of citric acid (2.52 g, 13.1 mmol) in THF (10 mL). The mixture was stirred for 2 min and then kept undisturbed for 2 days at 20 °C. The resulting crystalline product was isolated by filtration, washed with diethyl ether (10 mL), and then dried in vacuo (0.01 Torr, 20 °C, 1 h). Yield: 4.73 g (6.07 mmol, 93%). M.p. 188 °C (dec.). ^{1}H NMR (CD_3CN): δ = 0.89−0.99 (m, 18 H, CH_3), 1.28−1.43 (m, 12 H, CH_2), 1.55−1.69 (m, 12 H, CH_2), 2.46−2.81 (m, 8 H, CH_2), 3.02−3.12 (m, 12 H, NCH_2), 8.0 (br. s, 2 H, NH), 11.6 (br. s, 2 H, OH). ^{13}C NMR (CD_3CN):[15] δ = 13.8 (CH_3), 20.4 (CH_2CH_3), 26.0 ($NCCH_2$), 41.2 (CH_2CO), 44.0 (CH_2CO), 53.3 (NCH_2), 74.0 (OCC_3), 171.3 (C=O), 172.5 (C=O), 178.2 (C=O). ^{13}C VACP/MAS NMR: δ = 13.8 (CH_3), 13.9 (CH_3), 14.8 (CH_3), 15.0 (CH_3), 15.2 (CH_3), 15.4 (CH_3), 19.0 (CH_2CH_3), 20.0 (CH_2CH_3), 20.3 (CH_2CH_3), 20.5 (CH_2CH_3), 20.6 (CH_2CH_3), 21.4 (CH_2CH_3), 24.4 ($NCCH_2$), 26.4 ($NCCH_2$), 27.8 ($NCCH_2$), 27.9 (2 C) ($NCCH_2$), 29.1 ($NCCH_2$), 39.3 (CH_2CO), 41.2 (CH_2CO), 42.5 (CH_2CO), 44.2 (CH_2CO), 45.6 (NCH_2), 53.8 (NCH_2), 54.2 (2 C) (NCH_2), 56.3 (NCH_2), 57.8 (NCH_2), 74.1 (2 C) (OCC_3), 171.8 (C=O), 176.4 (2 C) (C=O), 177.0 (C=O), 178.0 (C=O), 181.5 (C=O). ^{29}Si VACP/MAS NMR: δ = −167.4. $C_{36}H_{66}N_2O_{14}Si$ (779.01): calcd. C 55.51, H 8.54, N 3.60; found C 55.4, H 8.1, N 3.6.

Method 2: Tri(*n*-butyl)amine (2.89 g, 15.6 mmol) was added at 20 °C to a stirred suspension of citric acid (1.00 g, 5.20 mmol) in acetonitrile (20 mL) (formation of a clear solution), followed by addition of tetrachlorosilane (442 mg, 2.60 mmol) over a period of 10 min. The mixture was stirred at 20 °C for 1 day, the solvent removed in vacuo, and acetone (15 mL) added to the stirred oily residue. The resulting solid was isolated by filtration and then purified by twofold recrystallization from acetonitrile/diethyl ether [1:1 (v/v); addition of diethyl ether to a solution of **10** in acetonitrile at 20 °C]. Yield: 807 mg (1.04 mmol, 40%). M.p. 188 °C (dec.). Identical NMR spectroscopic data as described above. $C_{36}H_{66}N_2O_{14}Si$ (779.01): calcd. C 55.51, H 8.54, N 3.60; found C 55.4, H 8.1, N 3.6.

Crystal Structure Analysis of 10: A suitable single crystal was mounted in inert oil (perfluoroalkyl ether, ABCR) on a glass fiber and then transferred to the cold nitrogen gas stream of the diffractometer (Stoe IPDS; graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å). The structure was solved by direct methods (SHELXS-97) and refined by full-matrix least-squares on F^2 with all unique reflections (SHELXL-97).[16] For the CH hydrogen atoms, a riding model was employed. The positions of the NH and OH hydrogen atoms were localized in difference Fourier syntheses and refined freely. Selected data: single crystal (0.5 × 0.5 × 0.4 mm) obtained by recrystallization from acetonitrile/diethyl ether (see synthesis), $C_{36}H_{66}N_2O_{14}Si$, M_r = 779.00, analysis at 173(2) K, monoclinic, space group $P2_1/n$, a = 10.647(2), b = 15.612(3), c = 24.923(5) Å, β = 96.11(3)°, V = 4119.1(14) Å^3, Z = 4, $\rho_{calcd.}$ = 1.256 g cm^{-3}, μ = 0.122 mm^{-1}, $F(000)$ = 1688, $2\theta_{max}$ = 49.46°, 51175 collected reflections, 7033 unique reflections (R_{int} = 0.0597), 496 parameters, R_1 = 0.0305 [$I > 2\sigma(I)$], wR_2 (all data) = 0.0757, S = 1.013, largest difference peak and hole +0.404/−0.194 e Å^{-3}. CCDC-175178 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Structure of the First Fe^{II} Heterometallic Alkoxide $[(THF)NaFe(O\mathit{t}Bu)_3]_2$ – a Possible Precursor for New Materials

Yurii K. Gun'ko,*[a] Ute Cristmann,[a] and Vadim G. Kessler[b]

Keywords: Iron / O ligands / Heterometallic complexes / Alkali metals / Materials science

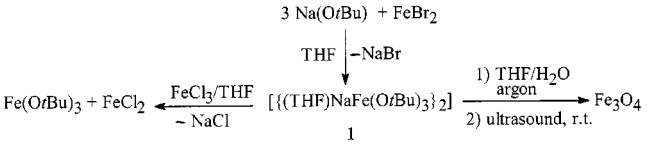
The reaction of $FeBr_2$ with three equivalents of $NaO\mathit{t}Bu$ in THF affords the first heterometallic Fe^{II} alkoxide, $[(THF)NaFe(O\mathit{t}Bu)_3]_2$ (**1**), to be structurally characterised. The central core of the structure is an $M_2O_6M'_2$ fragment with C_2 symmetry. The compound is shown to be promising as a new precursor for magnetic iron oxide Fe_3O_4.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Iron(III) alkoxides have been studied quite extensively. They show a quite unusual structural diversity and possess many interesting physical properties.[1] In contrast, the chemistry of Fe^{II} alkoxides is very poorly developed,[2,3] even though Fe^{II} complexes might be very promising precursors for the preparation (by MOCVD or sol-gel technology) of important iron-based compounds and materials. Here we report the synthesis, structure, and some selected reactions of the first Fe^{II} heterometallic alkoxide $[(THF)NaFe(O\mathit{t}Bu)_3]_2$.

Results and Discussion

The reaction of $FeBr_2$ with three equivalents of $NaO\mathit{t}Bu$ in THF at ambient temperature proceeds with the precipitation of NaBr to afford the heterometallic Fe^{II} alkoxide $[(THF)NaFe(O\mathit{t}Bu)_3]_2$ (**1**). The preparation of **1** and further reactions are summarised in Scheme 1. Compound **1** gave a satisfactory C, H, N analysis and was characterised by IR and ^1H NMR spectroscopy. The structure of **1** was also studied by X-ray single crystal diffraction.



Scheme 1. Synthesis and selected reactions of $[\{(THF)NaFe(O\mathit{t}Bu)_3\}_2]$ (**1**)

[a] The Department of Chemistry, Trinity College Dublin, Dublin 2, Ireland
[b] Department of Chemistry, Swedish University of Agricultural Sciences, Box 7015, 75007 Uppsala, Sweden

The IR spectrum of **1** in nujol shows the characteristic C–O stretching bands for metal alkoxides at 1286, 1227 and 1195 cm^{-1} and M–O stretching bands at 618, 574 and 538 cm^{-1}. The ^1H NMR spectrum of **1** in C_6D_6 displays broad, paramagnetically shifted signals for the bridging $O\mathit{t}Bu$ groups (δ = 11.71 and −4.08) and THF (δ = 12.90 and 6.27).

X-ray quality crystals of **1** were crystallised from a concentrated solution in THF at ambient temperature. The central fragment of the molecule **1** (Figure 1) is an $Na_2O_6Fe_2$ cage-like unit with C_2 symmetry. A similar fragment (Figure 2) is found in several heterometallic alkoxides, for example in $[LiNbO(OEt)_4(EtOH)]_2$,[4] $[NaWO(OEt)_5(EtOH)_2]_2$,[5] $[MSn(O\mathit{t}Bu)_3]_2$ (M = Li, Na),[6] $[LiTi(O\mathit{i}Pr)_5]_2$,[7] $[KTi(O\mathit{t}Bu)_5]_2$,[8] and $[LiHf(O\mathit{i}Pr)_5]_2$.[9] In **1** the M positions in the central metal-oxygen core, which are occupied by alkali metals in the majority of above-mentioned complexes (Figure 2), are occupied by Fe atoms, and the M′ positions, which are occupied by Sn or multivalent transition metals (e.g. Ti, Hf, Zr, Mo, W) in the previously reported compounds, are occupied by alkali metal (Na) atoms. Such an uncommon arrangement of metal atoms has earlier been observed in the structures of, for example, $[LiNbO(OEt)_4(EtOH)]_2$,[4] $[NaMoO_2(OC_2H_4OMe)_3]_2$,[10] and $[NaWO_2(OC_2H_4OMe)_3]_2$.[11] In **1** each of the Fe atoms is coordinated by two μ_2- and two μ_3-$O\mathit{t}Bu$ bridging groups with O–Fe–O angles that vary between 78.0(7)° and 150.7(9)°. Because of this the coordination polyhedron around the Fe atom could be described as either a very distorted tetrahedron or, alternatively, as an octahedron in which *cis* apices are missing. A similar geometry around the Fe^{II} atom has been observed before in $[Fe(OCPh_3)_2(THF)_2]$.[2] As expected, the Fe–O(μ_3) bond lengths [2.074(16) and 2.061(14) Å] are longer than the Fe–O(μ_2) ones [1.923(14) and 1.829(19) Å]. There is an asymmetry in the Fe–O bond lengths, which is particularly significant for the Fe–O(μ_2) bonds [Δ(Fe–O) = 0.094 Å].

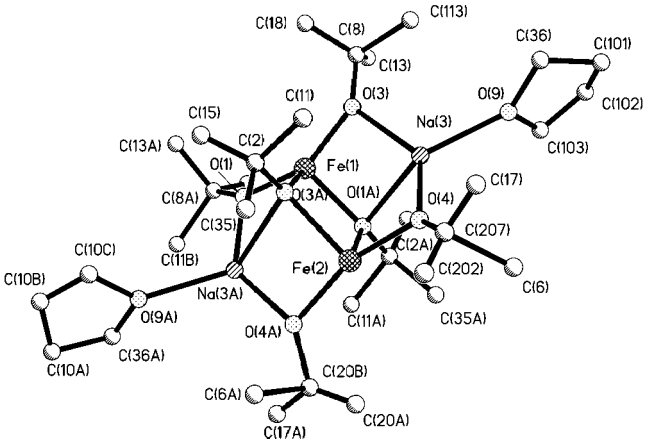


Figure 1. X-ray crystal structure of [{(THF)NaFe(O*t*Bu)$_3$}$_2$] (**1**); selected bond lengths (Å) and angles (°): Fe(1)−O(3) 1.923(14), Fe(1)−O(3A) 1.923(14), Fe(1)−O(1A) 2.074(16), Fe(1)−O(1) 2.074(16), Fe(1)−Na(3) 2.988(7), Fe(1)−Na(3A) 2.988(7), Fe(2)−O(4) 1.829(19), Fe(2)−O(4A) 1.829(19), Fe(2)−O(1A) 2.061(14), Fe(2)−O(1) 2.061(14), Fe(2)−Na(3A) 3.114(8), Fe(2)−Na(3) 3.114(8), Na(3)−O(3) 2.138(18), Na(3)−O(10) 2.370(11), Na(3)−O(4) 2.425(19), Na(3)−O(1A) 2.468(8); O(3)−Fe(1)−O(3A) 150.7(9), O(3)−Fe(1)−O(1A) 195.2(5), O(3A)−Fe(1)−O(1A) 1107.6(4), O(3)−Fe(1)−O(1) 107.6(4), O(3A)−Fe(1)−O(1) 95.2(5), O(1A)−Fe(1)−O(1) 78.0(7), O(4)−Fe(2)−O(4A) 150.0(10), O(4)−Fe(2)−O(1A) 99.1(5), O(4A)−Fe(2)−O(1A) 104.1(6), O(4)−Fe(2)−O(1) 104.1(6), O(4A)−Fe(2)−O(1) 99.1(5), O(1A)−Fe(2)−O(1) 78.5(8), O(3)−Na(3)−O(10) 112.4(10), O(3)−Na(3)−O(4) 132.2(5), O(10)−Na(3)−O(4) 114.6(11), O(3)−Na(3)−O(1A) 79.4(6), O(10)−Na(3)−O(1A)134.3(4), O(4)−Na(3)−O(1A) 74.5(6); Fe(1)−O(1)−Fe(2) 101.8(3)

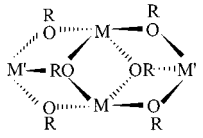

Figure 2. Schematic presentation of the M′$_2$O$_6$M$_2$ unit in heterometallic alkoxides (R = *t*Bu or *i*Pr)

In general the Fe−O(*t*Bu) bond lengths in **1** are similar to the corresponding ones in other Fe^{II} alkoxy derivatives: [Fe(OCPh$_3$)$_2$(THF)$_2$] [1.883(1) Å],[2] [Fe$_4$(DBCat)$_4$(py)$_6$] [from 1.974(6) to 2.236(5) Å] and [Fe$_2$(DBCat)$_2$(py)$_n$] [from 1.936(4) to 2.326(4) Å] (DBCat = 3,5-di-*tert*-butylcatechol, n = 4, 6).[3] The Fe···Fe distance of 3.208 Å is also quite close to those in the tetranuclear Fe^{II} complex [Fe$_4$(DBCat)$_4$(py)$_6$] [from 3.079(2) to 3.481(2) Å] and in the binuclear complex [Fe$_2$(DBCat)$_2$(py)$_n$] [3.223(3) and 3.195(3) Å].[3] The sodium atom in **1** is coordinated by the oxygen atoms of two μ_2- and one μ_3-O*t*Bu groups and one THF molecule, in a distorted tetrahedral arrangement. The O−Na−O angles vary between 74.5(6)° and 132.2(5)° and the Na−O(*t*Bu) bond lengths between 2.138(18) Å (μ_2-O) and 2.468(8) Å (μ_3-O). Surprisingly, one of the Na−O(μ_2) bonds is substantially longer, at 2.425(19) Å, than the other one, and is in fact very close to an Na−O(μ_3) bond length; this causes a significant asymmetry in the molecule. The observed structure can also be considered as a dimer of [(THF)Na(O*t*Bu)$_2$Fe(O*t*Bu)$_2$Na(THF)] held together by additional metal/O*t*Bu bonds.

It was of great interest to us to investigate the chemical properties of **1** as a potential precursor for other iron-containing compounds and materials. The reaction of **1** with two equivalents of FeCl$_3$ in THF at ambient temperature (24 h) gave FeCl$_2$ and Fe(O*t*Bu)$_3$, which were separated by fractional crystallisation and clearly identified by elemental analysis (Scheme 1). This reaction demonstrates the labile nature of **1**.

Fe^{II} compounds have recently been reported to be very good precursors for the preparation of Fe$_3$O$_4$ nanoparticles by sol-gel and sonochemical methods.[12−14] For this reason a solution of **1** in THF was hydrolysed with doubly distilled water under argon, followed by ultrasonic treatment (Scheme 1). The black product was characterised by X-ray powder diffraction (XRD). The reflections of the XRD patterns (2θ from 5 to 70°) for the sample show d spacing values and relative intensities of the peaks that coincide exactly with the JCPDS data of magnetite (Fe$_3$O$_4$). The product was also characterised by Mössbauer spectroscopy at room temperature. The Mössbauer spectrum of the Fe$_3$O$_4$ sample shows combined magnetic and quadrupole splittings. A least-squares fit to the experimental data indicates that the lines are characteristic of nonstoichiometric magnetite, with a small line-broadening due to a distribution of hyperfine magnetic fields caused by the different iron environments in the structure, and a small contribution from paramagnetic Fe^{3+}. The most plausible mechanism of the magnetite formation in this reaction involves an oxidation of Fe^{II} into Fe^{III} by oxygen from the water during the hydrolysis and subsequent ultrasonic treatment. Ultrasonically generated radical and peroxide species from water might also contribute to the oxidation of Fe^{II}, as has been reported recently.[13,14]

The above reactions demonstrate that the new iron(II) alkoxide **1** can be used as a promising precursor for the facile preparation of magnetite. Work on the further development of this research is currently in progress.

Experimental Section

General: All manipulations were carried out under vacuum or dry argon by Schlenk techniques. Solvents were purified and degassed by standard procedures. FeBr$_2$ and NaO*t*Bu were obtained from Aldrich. Microanalyses were carried out by Medac Ltd. The ^{1}H NMR spectra were recorded using a Varian-400 (^{1}H, 400 MHz) instrument. Deuteriated benzene was dried with a K metal mirror and distilled prior to use. IR spectra (500−4000 cm^{-1}) were recorded in Nujol, using KBr discs and a Perkin Elmer instrument.

[(THF)NaFe(O*t*Bu)$_3$]$_2$ (1): NaO*t*Bu (5.27 g, 54.9 mmol) was added to FeBr$_2$ (3.95 g, 18.3 mmol) in THF (300 mL) at ca. 0 °C. The mixture was stirred for 24 h at ambient temperature and was then filtered. The filtrate was concentrated in vacuo to give grey crystals of **1**. Yield: 4.27 g (64%). C$_{32}$H$_{70}$Fe$_2$Na$_2$O$_8$ (740.6): calcd. C 51.8, H 9.45; found C 51.7, H 9.39. ^{1}H NMR (400 MHz, C$_6$D$_6$, 22 °C): δ = −4.08 (v. br., 18 H, μ_3-O*t*Bu), 6.27 (br, 8 H, THF), 11.71 (v.

br., 36 H, μ_2-O*t*Bu), 12.90 (br, 8 H, THF). IR (Nujol): $\tilde{\nu}$ = 2709 (s), 1657 (w), 1570 (w), 1356 (w), 1286 (w), 1227 (s), 1195 (w), 1055 (s), 968 (w), 775 (w), 618 (w), 574 (w) 538 (w) cm^{-1}.

Fe_3O_4: A solution of **1** (2.3 g, 3.1 mmol) in THF (100 cm^3) was carefully hydrolysed with doubly distilled water (40 cm^3) under argon. The resultant mixture was then ultrasonically (Ultrasonic bath Grant XB6, 30 kHz, 130 W) irradiated at ambient temperature for one hour under argon. The dark precipitate was filtered and washed five times with distilled water. The product was then dried in vacuum for five hours at room temperature giving a black powder of Fe_3O_4 (0.44 g, 92%) characterised by X-ray powder diffraction (XRD) and Mössbauer spectroscopy.

X-ray Crystallography

A single crystal of **1** was placed in a glass capillary and sealed under vacuum. Data were measured on a SMART CCD 1 K diffractometer using monochromated Mo-K_α radiation. Corrections for absorption were made using the Bruker SADABS program.[15] The crystal was found to be a merohedral twin, with the centre of symmetry as an external symmetry element not belonging to the true symmetry group. Structure solutions were made using the SHELXTL program package Version 5.3. The structure was solved by direct methods and was refined first in an isotropic and then an anisotropic (all non-hydrogen atoms) approximation. The positions of the hydrogen atoms were calculated geometrically and included in the final cycles of the refinement in an isotropic approximation.

Crystal Data for 1: $C_{32}H_{70}Fe_2Na_2O_8$, M = 740.56, monoclinic, a = 18.822(7), b = 12.516(5), c = 9.262(3) Å, β = 91.179 (6)°, U = 2181.4(14) $Å^3$, T = 295(2) K, space group $C2$, Z = 2, ρ = 1.127 Mg/m^3, μ(Mo-K_α) = 0.723 mm^{-1}, 3446 reflections collected, 1675 independent reflections [R(int) = 0.0870], R_1 = 0.0815 for reflections with $I > 2\sigma(I)$, wR_2 = 0.2191 (all data). CCDC 170603 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization of Soluble Axially Substituted Tetra-(*tert*-butyl)gallium(III)phthalocyanines

Yu Chen,[a] Lakshminarayanapuram R. Subramanian,[a] Markus Barthel,[a] and Michael Hanack*[a]

Keywords: Gallium / Nitrogen heterocycles / Nonlinear optics / Phthalocyanines

The synthesis and characterization of the highly soluble tetra(*tert*-butyl)gallium(III) phthalocyanines (tBu)$_4$PcGaCl (**2**) and (tBu)$_4$PcGa(*p*-TMP) (**3**) is described. They were characterized by IR, UV/Vis, MS, and ^{1}H, ^{13}C, and ^{19}F NMR spectroscopy.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Phthalocyanines (Pcs) and their analogs have been intensively investigated for many technological applications due to their remarkable photophysical, optoelectronic, conductive properties, and biological activities, as well as their wide variety of architectural flexibility.[1−3] In recent years we have concentrated our efforts on studying the influence of different axial substituents on the nonlinear optical (NLO) properties, particularly on the optical limiting (OL) properties of soluble peripherally alkyl-substituted phthalocyaninato-and naphthalocyaninatoindium(III) complexes. We have synthesized, for example, a series of soluble axially substituted indium(III)phthalocyanines (tBu)$_4$PcInX with X = Cl, Br, I, *p*-trifluoromethylphenyl (*p*-TMP), *m*-TMP, *p*-fluorophenyl, and pentafluorophenyl, amongst others.[4−6]

In comparison to the chloro compounds, each of the (phthalocyaninato)indium complexes studied showed very promising results, such as higher nonlinear absorption coefficients, lower limiting thresholds, and an earlier onset of the optical limiting behavior.[5,7,8] Furthermore, soluble axially substituted indium naphthalocyanines have been prepared[9] that show a similar optical limiting behavior.[10]

Peripherally unsubstituted gallium phthalocyanines with an axial chloro, fluoro or hydroxy ligand (PcGaX, X = Cl, F, OH) were the first phthalocyanines to be investigated for their third order (χ^3) nonlinear behavior;[11] values of the order of 10^{-11} esu were found. The greatest disadvantage of peripherally unsubstituted phthalocyanines is their poor solubility in organic solvents. For this reason, we report here the synthesis of the highly soluble chlorogallium(III) 2,(3)-tetra(*tert*-butyl)phthalocyanine [(tBu)$_4$PcGaCl] (**2**), and its reaction with R′MgBr (R′ = *p*-TMP) leading to the σ-bonded aryl(phthalocyaninato)gallium(III) complex (tBu)$_4$PcGa(*p*-TMP) (**3**). The aryl substituent should introduce greater steric crowding than the chloro ligand and should reduce the tendency, which is common in Pc's, to form aggregates.[12]

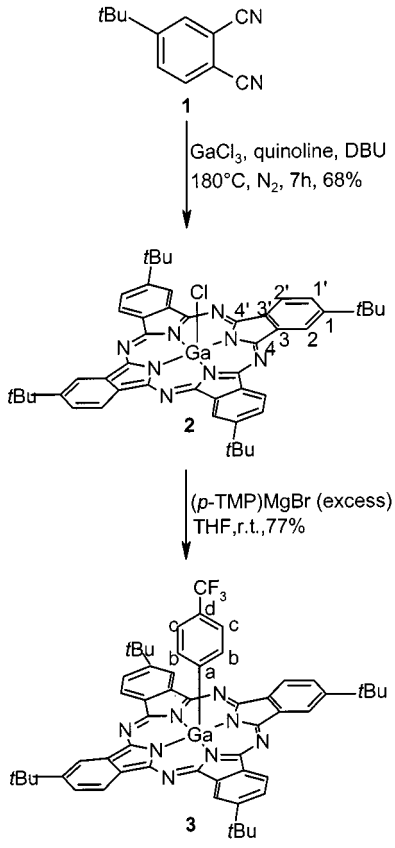
Results and Discussion

The synthetic pathway to **2** and **3**, together with the numbering of the atoms of the macrocycles and the axial *p*-TMP ligand, is shown in Scheme 1. Compound **2** was obtained by the reaction of 4-*tert*-butylphthalonitrile with anhydrous $GaCl_3$ (molar ratio, 4:1.05) in doubly distilled, deoxygenated quinoline at 180 °C in the presence of catalytic amounts of the nonnucleophilic base 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU). Compound **3** was synthesized by the reaction of a freshly prepared 10-fold excess of *p*-TMP Grignard reagent with (tBu)$_4$PcGaCl. Products **2** and **3** were further purified by column chromatography and recrystallization; they are highly soluble in common organic solvents.

The UV/Vis spectra of **2** and **3** in $CHCl_3$ are shown in Figure 1; it can clearly be seen that they are almost identical. The introduction of electron-donating *tert*-butyl groups in the periphery of the macrocycle of **2** leads to a red-shift of about 8 nm of the Q-band maximum with respect to the unsubstituted PcGaCl (Fluka product). The axial *p*-TMP ligand has little influence on the position of the Q-band maximum in comparison with compound **2**. The observed red-shift is only of the order of 1.5 nm. Similar results with (tBu)$_4$PcInCl and (tBu)$_4$PcIn(*p*-TMP) have been reported by us earlier.[4] The UV/Vis spectra of (tBu)$_4$PcGaCl (**2**) and (tBu)$_4$PcInCl are almost identical, with a $\Delta\lambda$ value of 2−3 nm. (tBu)$_4$PcIn(*p*-TMP), on the



Scheme 1

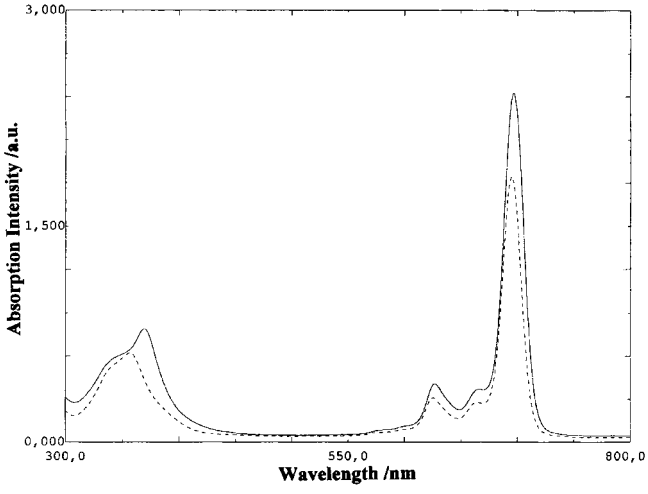


Figure 1. The UV/Vis spectra of $(t\text{Bu})_4$PcGaCl (dashed line) and $(t\text{Bu})_4$PcGa(*p*-TMP) (solid line) in $CHCl_3$.

other hand, shows a bathochromically shifted Q-band (1.5 nm) relative to the gallium compound **3**.

The greater solubility of compound **3** than of the chloro analog **2** shows that the usual tendency of phthalocyanines to form aggregates can be effectively suppressed by axial substitution.[4] Similar to the aryl axially substituted indium(III)phthalocyanines,[5] the shape of the UV/Vis spectrum of **3** is almost independent of the concentration of the solution and shows no aggregation. However, for the chlorogallium phthalocyanine **2**, a concentration-dependent increase of the absorption on the red side of the Q-band indicates a somewhat larger degree of aggregation. A comparison of the UV/Vis absorption spectra of thin film and dilute solutions of **2** and **3** in $CHCl_3$ shows that the absorption spectra of thin films of **2** and **3** are broader. Upon comparing the thin film and dilute solution UV/Vis spectra of **2**, it is observed that the position of the Q-band maximum is shifted slightly by about 2.5 nm towards longer wavelength. In the case of **3**, the same comparison shows that the position of the Q-band maximum is almost unchanged, which is consistent with relatively weak aggregation of **3** in solution.

The field desorption (FD) mass spectrum of **2** shows a cluster of peaks centered at *m*/*z* (%) = 842.3 (100), assigned to the molecular peak, which is almost identical to the calculated intensity pattern for **2** [*m*/*z* (%) = 840.3 (90), 841.3 (50), 842.3 (100), 843.3 (52), 844.3 (33) and 845.3 (12)]. Likewise, the molecular peak of **3** at *m*/*z* (%) = 951.4 (100) is also detected in the FD mode. The mass spectrum of **3** measured in the FAB modes shows a peak at *m*/*z* = 958 which is assigned to an $[M^+ + Li]$ peak.

The IR spectrum of **2** is similar to that of $(t\text{Bu})_4$PcInCl.[4] The Ga−Cl stretching vibration is shifted from 431 cm^{-1} in unsubstituted PcGaCl[13] to 351 cm^{-1} in **2**, while the ν_{In-Cl} band in $(t\text{Bu})_4$PcInCl appears at 336 cm^{-1}.[4] For **3**, some new absorption bands, which do not appear in the spectrum of $(t\text{Bu})_4$PcGaCl (**2**), were observed (see Exp. Sect.).

The ^{1}H NMR spectra of **2** and **3** in $CDCl_3$ confirm the presence of the expected mixtures of structural isomers of tetrasubstituted phthalocyanines. The numbering of the atoms of the macrocycle and the axial *p*-TMP ligand is shown in Scheme 1. In **2** the aromatic signals appear as two broad multiplets [δ = 9.4−8.9 (8 H, H-2,2′) and δ = 8.4−8.2 (4 H, H-1)], the singlet of the *tert*-butyl group appears at δ = 1.9 (36 H) and is split because of the structural isomers; the signals are located almost in the same range as those of $(t\text{Bu})_4$PcInCl.[4,5] For compound **3**, the σ-bonded *p*-TMP ligand causes a slightly stronger deshielding of the aromatic protons, especially those closer to the heteroaromatic 18-π-electron system (H-2,2′), than does the chloro ligand in **2**. The proton signals of the *p*-TMP ligand are shifted upfield due to the diamagnetic ring-current of the phthalocyanine macrocycle. They appear at δ = 7.1 (d, ^3J = 8.9 Hz, 2 H, H-c,c′) and 6.8 (d, ^3J = 8.7 Hz, 2 H, H-b,b′), compared to δ = 7.5(H-c,c′) and 7.6 (H-b,b′) in pure *p*-trifluoromethylphenyl bromide (*p*-TMPBr). This is a smaller upfield shift than in $(t\text{Bu})_4$PcIn(*p*-TMP) due to the different central metal atom.[4,5]

The ^{13}C NMR spectra of **2** and **3** are also similar to the ^{13}C NMR spectra of $(t\text{Bu})_4$PcInCl and $(t\text{Bu})_4$PcIn(*p*-TMP),[4] and show seven signals for the aromatic carbon atoms and two signals for the *tert*-butyl group. The aromatic signals are broadened due to the structural isomers,

and the carbon signals of the *p*-TMP ligand are split on account of C−F coupling and are of very low intensity. However, additional signals can be observed at δ = 113.9, 127.5−127.8 and 133.3, and are assigned to C-d, C-c,c′ and C-a of the axial ligand, respectively.

The ^{19}F NMR spectrum of **3** provides evidence for the attachment of the *p*-TMP ligand at the gallium atom: only one narrow singlet at δ = −62.8 was observed for the axial ligand, whereas the ^{19}F signal of pure α,α,α-trifluorotoluene appears at δ = −63.9.[5] Similarly to **3**, the ^{19}F signal of (tBu)$_4$PcIn(*p*-TMP) appears at δ = −64.1.[4,5] The difference in chemical shifts of the fluorine atoms in (tBu)$_4$PcIn(*p*-TMP) and (tBu)$_4$PcGa(*p*-TMP) **3** is due to the different electronic effects of indium(III) and gallium(III).

Experimental Section

General: The operations for synthesis prior to the termination reaction were carried out under purified dry nitrogen. Solvents were purified, dried and distilled under dry nitrogen. FT-IR: Perkin−Elmer Spectrum 1000. UV/Vis: Shimadzu UV-365. MS: Varian Mat 711(FD: temperature of the ion source 30 °C; FAB: temperature of the ion source 50 °C); ^1H,^{13}C NMR: Bruker AC 250 (^1H: 250.131 MHz, ^{13}C: 62.902 MHz). ^{19}F NMR: Bruker Avance DRX 250 (235.334 MHz); elemental analyses: Carlo−Erba Elemental Analyser 1104, 1106.

Chlorogallium(III) 2,(3)-Tetra(*tert*-butyl)phthalocyanine [(tBu)$_4$PcGaCl] (2): A mixture of anhydrous gallium(III) chloride (0.75 g, 4.26 mmol), 4-*tert*-butylphthalonitrile (**1**; 3 g, 16.3 mmol), quinoline (15 mL, doubly distilled over CaH_2), and DBU (1 mL) was stirred at 180 °C for 7 h. The solvent was then removed by distillation under reduced pressure, leaving a dark green residue, which was chromatographed on silica gel using a gradient of toluene and chloroform 100:0 to 0:100 in order to remove metal-free phthalocyanine and a large portion of polar impurities. The blackish green fraction ($R_f \geq 0$) was collected, the solvent evaporated, and the crude compound recrystallized from a mixture of CH_2Cl_2/MeOH (v/v 4:3) by slowly evaporating the more volatile dichloromethane in a rotary evaporator at 40−60 °C under slightly reduced pressure. To complete the crystallization, the mixture was kept in a refrigerator overnight. The complex was collected by filtration, washed twice with methanol and dried at 80 °C in vacuum for 10 h. Yield 2.35 g (68.5%) of **2** as a blackish green powder. FD-MS ($C_{48}H_{48}ClGaN_8$): calcd. 842.14; found 842.3(100). UV/Vis ($CHCl_3$): λ_{max} (nm) = 695, 664.5 (sh), 625, 356. FT-IR (KBr): $\tilde{\nu}$ = 3068 cm^{-1} vw, 2958 s, 2866 m, 1734 w, 1682 w, 1615 m, 1507 m, 1483 m, 1406 m, 1394 m, 1364 m, 1334 vs, 1281 m, 1258 s, 1201 m, 1149 m, 1087 vs, 1052 m, 1024 w, 967 w, 929 s, 895 w, 831 m, 765 m, 750 s, 694 m, 670 m, 602 vw, 566 vw, 532 m, 444 vw, 350.5 w [ν(Ga-Cl)]. ^1H NMR ($CDCl_3$): δ = 1.9 (m, 36 H, tBu), 8.2−8.4 (m, 4 H, H-1), 8.9−9.4 (m, 8 H, H-2, -2′). ^{13}C NMR ($CDCl_3$): δ = 31.1−32.1 (tBuCH$_3$), 36.2 (CMe$_3$), 119.1−119.6 (C-2′), 122.6−122.9 (C-2), 128.5−128.6 (C-1), 133.7−133.9 (C-3), 135.9−136.2 (C-3′), 150.4−151.1 (C-4, -4′), 154.2−154.6 (C-1′). $C_{48}H_{48}ClGaN_8$ (842.1): calcd. C 68.46, H 5.74, N 13.31, Cl 4.21; found C 66.50, H 5.63, N 12.36, Cl 4.15.

***p*-(Trifluoromethyl)phenylgallium(III) 2,(3)-Tetra(*tert*-butyl)phthalocyanine [(tBu)$_4$PcGa(*p*-TMP)] (3):** A freshly prepared solution of R′MgBr (R′ = *p*-trifluoromethylphenyl) in THF (20 mL, 0.18 M R′MgBr) was added dropwise to a stirred solution of (tBu)$_4$PcGaCl (**2**; 300 mg, 0.356 mmol) in dry THF (25 mL). The reaction was monitored by TLC and stopped when all of the chloro complex **2** had been consumed. The deep green mixture was poured onto ice and then extracted several times with diethyl ether. The combined organic layers were washed with water and dried with $MgSO_4$. After evaporation of the solvent, the residue was rapidly subjected to column chromatography (silica gel/toluene). Light was strictly excluded during this step. Further purification of the complex was achieved by recrystallization from a mixture of CH_2Cl_2/MeOH (v/v 1:1) by slowly evaporating the more volatile dichloromethane in a rotary evaporator at 40−60 °C under slightly reduced pressure. To complete crystallization, the mixture was kept in a refrigerator overnight. The complex was collected by filtration, washed twice with methanol and dried at 70 °C in vacuum for 6 h. Yield 260 mg (77%) of **3** as a green powder. FD-MS ($C_{52}H_{52}F_3GaN_8$): calcd. 951.14; found 951.4 (100). FAB-MS (*m*/*z*): 958 [M$^+$ + Li], 864, 857, 842, 823, 805 [(tBu)$_4$PcGa$^+$], 789, 749, 637, 539, 489, 481, 469, 385, 342, 281, 269, 253. cis-[$PtCl_2(NH_3)$\{2-(2-hydroxyethyl)pyridine\}] − an Analogue of the Anticancer Drug AMD473: Unusual Hydrolysis Rates and pK_a Values for the Diaqua Adduct

Keywords: Platinum / Antitumor agents / Hydrolysis / Molecular modelling

The X-ray crystal structure of *cis*-[$PtCl_2(NH_3)$\{2-(2-hydroxyethyl)pyridine\}] shows that it has similar structural features to the 2-picoline analogue, the anticancer drug AMD473 (ZD0473), but undergoes aquation much more rapidly. The diaqua adduct has unusually low pK_a values which have been rationalised by molecular modelling.

Introduction

cis-[$PtCl_2(NH_3)$(2-picoline)] (AMD473) is a new anticancer drug which entered phase I clinical trials in 1997.[1,2] It is active against cisplatin-resistant cell lines, and appears to circumvent thiol-mediated resistance mechanisms whilst still maintaining the ability to form cytotoxic lesions with DNA.[2,3] In reactions of cisplatin with DNA, hydrolysis is known to be the rate-limiting step. The steric influence of 2-picoline plays an important role in decreasing the rates of hydrolysis and substitution reactions of AMD473,[4,5] and also in promoting high stereoselectivity in the formation of a GG intrastrand adduct with a 14-mer DNA duplex.[6] In order to elucidate further the role of pyridine substituents in determining the reactivity of platinum(II) picoline complexes, we have studied the hydrolysis rates of the AMD473 analogue *cis*-[$PtCl_2(NH_3)$\{2-(2-hydroxyethyl)pyridine\}] (**1**) and determined the pK_a values of its monoaqua and diaqua adducts by [^1H,^{15}N] NMR studies of complex **1** labelled with $^{15}NH_3$. The side-chain hydroxyl group introduces the potential for second coordination sphere interactions which may affect both the rate of hydrolysis and the acidity of the mono and diaqua adducts. Molecular mechanics modelling was therefore used to investigate possible hydrogen bonding between the side-chain hydroxyl group and am(m)ine or aqua ligands. The results show how both first and second coordination sphere interactions can have a major influence on the kinetic and thermodynamic properties of Pt^{II} complexes. These interactions probably also affect their anticancer activities.

Results and Discussion

X-ray Structure

cis-[$PtCl_2(NH_3)$\{2-(2-hydroxyethyl)pyridine\}] (**1**) was synthesised using a procedure reported previously for mixed am(m)ine complexes. The crystal structure of **1** (Figure 1) shows a square-planar complex with angles close to the ideal values of 90° and 180°. The angle between the two planes defined by Cl(1)−Pt−Cl(2) and N(1)−Pt−N(2) is 4.1°. The pyridine ring of complex **1** is nearly perpendicular to the platinum plane (76°) and the α-CH_2 group is very close to the platinum atom (H_2C···Pt 3.16 Å). These structural features are similar to those of the 2-picoline complex AMD473 (103° and H_3C···Pt 3.22 Å).[4] The Pt−N1 distance (2.028 Å) is also similar to that of the 2-picoline complex (2.017 Å). No intramolecular hydrogen bonding is observed between the hydroxyl group and the two Cl ligands. The 2-hydroxyethyl group is rotated away from the Pt atom, probably due to crystal packing effects. The pattern of intermolecular hydrogen bonding observed in the crystal packing of complex **1** (Supplementary Figure S1) is different from that observed previously for AMD473. For complex **1**, the packing is dominated by intermolecular NH_3···Cl hydrogen bonding [e.g. NH(2A)···Cl(1) 2.54 Å]. Additional intermolecular hydrogen bonding involves NH_3···OH [NH(2C)···O(23) 2.20 Å], and the OH group and a Cl ligand [OH(23)···Cl(1) 2.33 Å]. The X-ray diffraction data for the diiodo analogue **6** were of much poorer quality but were sufficient to define the connectivities. The complex

is again almost square-planar, with a slight lengthening of the Pt−N bonds to 2.08 and 2.10 Å due to the stronger *trans* influence of I versus Cl. There is no significant H-bonding to the coordinated halide, and interactions involving the side-chain OH are much weaker. This demonstrates the flexibility of the side-chain and that the conformation is determined by both inter- and intramolecular interactions. An overlay of the structures of complexes **1** and **6** is shown in Supplementary Figure S2.

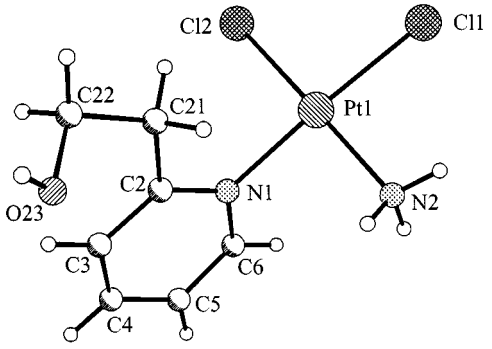

Figure 1. X-ray crystal structure of complex **1**

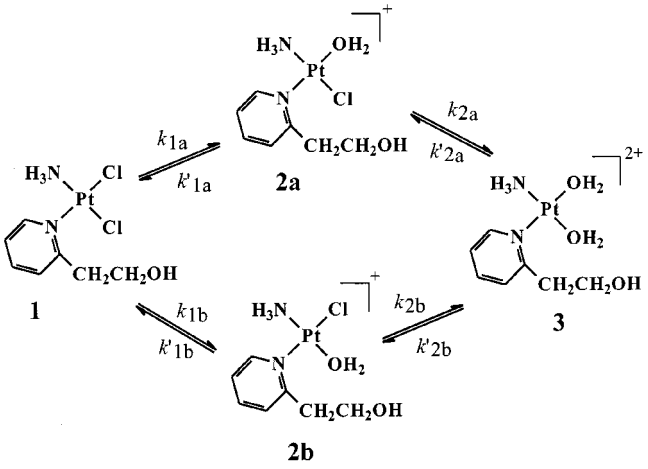
Hydrolysis and pK_a Values

2D [^{1}H, ^{15}N] HSQC NMR spectroscopy was used to monitor the hydrolysis of $^{15}NH_3$-labelled **1** in 0.1 M $NaClO_4$ for a period of 16 h at 298 K. Four major cross-peaks were observed in the first 2D NMR spectrum, recorded after 15 min. The assignments of the cross-peaks are based on the ^{15}N chemical shifts, which are diagnostic of the *trans* ligands,[4] and the time-dependent intensity changes of the cross-peaks. The assignments are consistent with the reaction pathway summarised in Scheme 1. The cross-peak at δ = 4.22 (^{1}H)/−65.59 (^{15}N) gradually decreased in intensity, and was assigned to the starting complex **1**. The intensity of the cross-peak at δ = 4.48/−63.30 was significantly lower than that of the cross-peak at δ = 4.40/−86.47. The ^{15}N chemical shift of the former is consistent with the assignment to the mono-aqua complex **2a** with a ^{15}N atom *trans* to Cl, while the latter peak is assignable to the monoaqua complex with the ammine trans to water (**2b**). The fourth peak at δ = 4.47/−78.07, assignable to the diaqua complex **3**, has a ^{15}N chemical shift typical of $^{15}NH_3$ *trans* to O. These shifts are similar to those observed for the 2-picoline complex AMD473.[4]

Two minor additional cross-peaks at δ = 4.34/−68.70 (complex **4**, NH_3 *trans* to N or Cl) and δ = 4.65/−82.60 (complex **5**, NH_3 *trans* to O) were present during the later stages of the aquation reaction. However, they disappeared when the pH of the solution was lowered and were therefore assigned to hydroxy-bridged species. These species were ignored in the kinetic calculations. The possibility of the formation of species containing a chelate ring by deprotonation of the hydroxyethyl side-chain and ring closure of complex **2b** was considered. Such a chelated complex would, however, contain high levels of steric strain on account of the severe steric clash between the pyridine *ortho* protons and the protons of the *cis* ammonia ligand.



Scheme 1

The time-dependence of the concentrations of species detected during hydrolysis of complex **1** (as determined by integration of NMR cross-peaks) is shown in Figure 2. Remarkably, the cross-peak for the diaqua adduct was already intense after 15 min, and the shape of the signal was very distorted in the early stages of the hydrolysis due to the lowering of pH which accompanied the hydrolysis. The percentages of the species present after ca. 16 h at 298 K were **1**: 26.4%, **2a**: 15.5%, **2b**: 30.1%, **3**:23.1%, **4**:4.6% and **5**:0.3%. The diaqua adduct is formed much faster than for the analogous 2-picoline complex. For the latter it appears only after 2.5 h even at the higher temperature of 310 K, and less than half as much is formed after 16 h.[4]

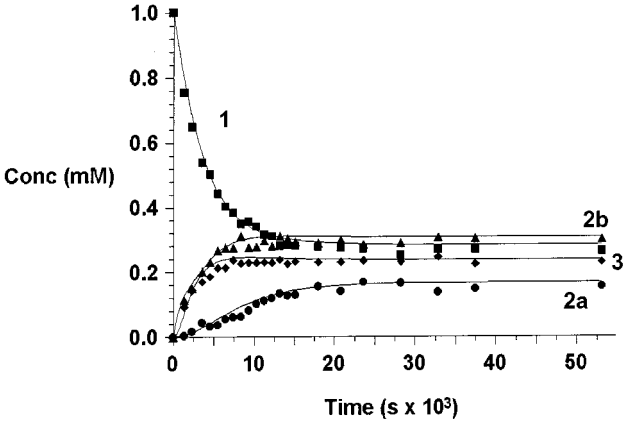


Figure 2. Dependence of the concentrations of complex **1** and its hydrolysis products on time as determined by NMR spectroscopy; labels: complex **1** (■), monoaqua complexes **2a** (•) and **2b** (▲), and diaqua complex **3** (◆); the curves represent the calculated best fits based on the rate constants given in Table 2 (see Scheme 1)

The assignments of the peaks for the mono- and diaqua complexes were further confirmed by pH titrations (Figure 3). As expected, the ^{1}H and ^{15}N chemical shift changes during the pH titration are larger for an ammine ligand

trans to an aqua ligand than when *trans* to a chloride ligand. The pK_a values of the mono- and diaqua complexes obtained by fitting the titration curves are listed in Table 1 and compared with those for the analogous 2-picoline and 3-picoline complexes, and with cisplatin.

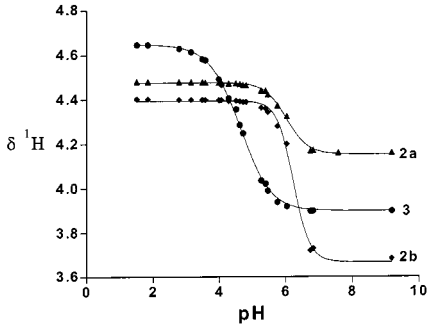

Figure 3. Dependence of the ^{1}H NMR chemical shifts of the NH_3 ligand in the monoaqua complexes **2a** and **2b** and diaqua complex **3** on pH; the curves represent best fits based on the pK_a values listed in Table 1

The rate of aquation for the chloride ligand *cis* to the pyridine ligand is much faster for complex **1** than for the 2-picoline complex AMD473 (8 × even at a temperature 12 K lower: k_{1b}, Scheme 1, Table 2). Since the X-ray crystal structures suggest that the steric effects of the pyridine side-chains are similar in the ground states of complex **1** and the 2-picoline analogue, the faster hydrolysis must arise from a lowering of the energy of the five-coordinate transition state. This may arise from H-bonding between the 2-hydroxyethyl side-chain and an incoming water ligand. The slower rate of aquation for the Cl ligand *trans* to the pyridine ligand in complex **1** in the first step of the aquation reaction (k_{1a}, Scheme 1, Table 2) is slower than for the ammine, 2-picoline or 3-picoline analogues in line with the basicities of the *trans* ligand, for which the pK_a values are in the order: NH_3 (9.29)[7] > 2-picoline (6.1), 3-picoline (6.0) > 2-(2-hydroxyethyl)pyridine (4.52).[8]

The pK_a values of the two monoaqua species of complex **1** (6.01, 6.23) are similar to those of the 2- and 3-picoline complexes (Table 1). However, the pK_a values for the diaqua adduct of complex **1** (3.90, 4.78) are significantly lower than those of the 2- and 3-picoline analogue complexes. It seems likely that a cooperative interaction between the hydroxyethyl side-chain and the H_2O/OH ligands in the diaqua complex is involved since the pK_a values for the monoaqua complexes are normal.

Molecular Modelling

The potential for hydrogen-bonding between the hydroxyl side-chain and am(m)ine or aqua ligands and its possible influence on the deprotonation of the aqua ligands was investigated by molecular mechanics modelling. A view of a molecular model of *cis*-[$Pt(NH_3)${2-(2-hydroxyethyl)pyridine}$(H_2O)_2$]·H_2O is shown in Figure 4A. The planar picoline ligand adopts an orientation perpendicular to the coordination plane. The first methylene of the hydroxyethyl side chain is necessarily disposed toward the Pt atom, but the remainder of this chain is free to adopt orientations that map out an arc lying above the coordination plane. At the two extremes of this arc, close contacts with the ligands *cis* to the picoline ligand occur and, depending on the orientation of the hydroxyl group, this contact can take the form of a hydrogen bond. The hydroxyl group can act as a hydrogen bond acceptor or hydrogen bond donor, and in the latter role would stabilise a hydroxo

Table 1. Values of pK_a for the mono- and diaqua adducts of *cis*-[$PtCl_2(NH_3)${2-(2-hydroxyethyl)pyridine}] (**1**), *cis*-[$PtCl_2(NH_3)$(2-picoline)], *cis*-[$PtCl_2(NH_3)$(3-picoline)] and cisplatin[4,23]

Adduct	**1**	*cis*-[$PtCl_2(NH_3)$(2-picoline)]	*cis*-[$PtCl_2(NH_3)$(3-picoline)]	cisplatin

Table 2. Rate constants determined for the hydrolysis of platinum complexes at 298 K (I = 0.1 M), unless otherwise stated (see Scheme 1); the errors represent one standard deviation

Complex	Rate constant (x 10^{-6} s^{-1}) (Anation rate constants × 10^{-3} M^{-1} s^{-1})[a]			
Complex **1**	k_{1a} 8.6 ± 4.5 (k'_{1a} 55.7 ± 50.3)	k_{1b} 167.9 ± 6.1 (k'_{1b} 144.1 ± 27.5)	k_{2a} 89.8 ± 58.3 (k'_{2a} 95.9 ± 26.8)	k_{2b} 737.9 ± 120.4 (k'_{2b} 95.5 ± 17.4)
AMD473[b]	k_{1a} 31.9 ± 1.5	k_{1b} 22.1 ± 1.4	k_{2a} 73.0 ± 14.0	k_{2b} 3.5 ± 2.5
3-picoline[b]	k_{1a} 44.7 ± 1.9	k_{1b} 103.0 ± 4.0	k_{2a} 35.0 ± 1.7	k_{2b} 78.0 ± 60.0
Cisplatin[c]	k_{1a} 51.8 ($k1$)	-	-	-

[a] Obtained from best fits to the curves shown in Figure 2 (see Scheme 1). The anation rates are subject to large errors because the reverse reactions are relatively fast. [b] Ref.[4] 310 K. [c] Ref.[24]

ligand in the *cis* position. Thus, it has the potential to promote deprotonation of the *cis* aqua ligand and contribute to the unusually low pK_a value. No stable orientation of the hydroxyethyl side chain resulted in a close contact with the ligand lying *trans* to the picoline ligand, primarily because of the unfavourably short contacts between the side-chain and the Pt atom that result from any disposition toward the *trans* ligand. Therefore an alternative explanation for its low pK_a was sought. A water molecule, added to the second coordination sphere close to the coordination plane and in a position to form hydrogen bonds with both aqua ligands, moved away from this plane toward the hydroxyethyl side chain on energy minimisation. In the final model (Figure 4B), this water molecule acts as a hydrogen bond acceptor to the aqua ligand *cis* to the picoline ligand and a hydrogen bond donor to both the hydroxyethyl group and the aqua ligand *trans* to the picoline. This is but one of many arrangements that might be considered, but it shows that the 2-hydroxyethyl side chain can be viewed as providing an environment conducive to the close association of a water molecule with the *cis*-[Pt{2-(2-hydroxyethyl)-pyridine}$(NH_3)(OH_2)_2]^{2+}$ complex. The Pt···OH_2 interaction is long (3.33 Å) but may provide an additional electrostatic contribution to bonding, as previously described for other Pt^{II} ammine complexes.[9,10] Hydrogen bonding between the Pt and a water molecule would be expected to stabilise the hydroxo form of the aqua ligands. In addition, the hydrophilic environment created by the 2-hydroxyethyl side chain would promote deprotonation of the aqua ligands and so contribute to their unusually low pK_a values.

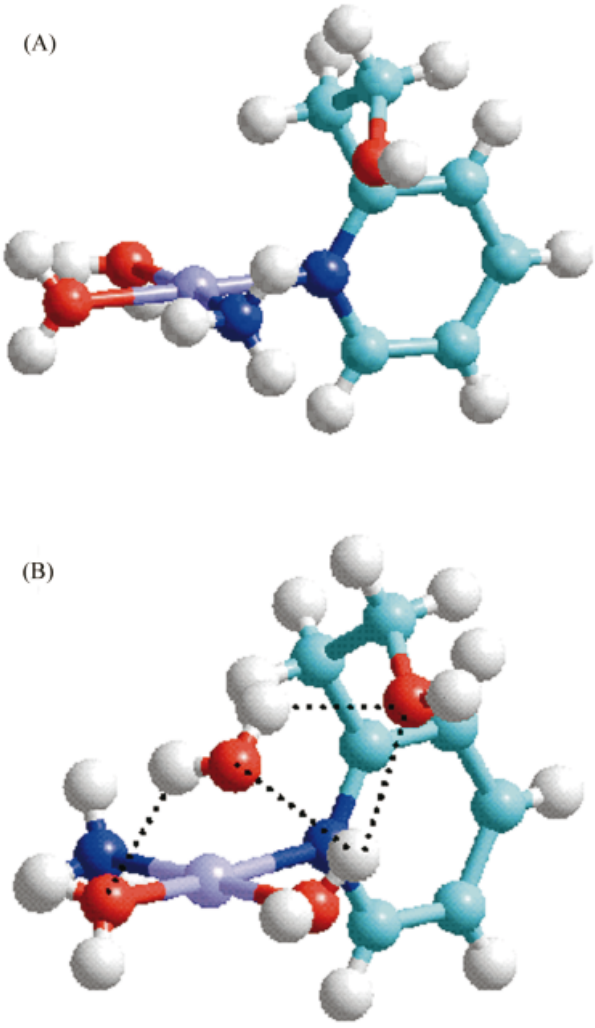

Figure 4. (A) A ball and stick view of a molecular model of *cis*-[Pt(NH_3)\{2-(2-hydroxyethyl)pyridine\}$(OH_2)_2]^{2+}$; colour code: H (white), C (cyan), O (red), Pt (dark blue), N (blue); (B) energy-minimised model of [Pt(NH_3)\{2-(2-hydroxyethyl)-pyridine\}$(OH_2)_2]^{2+}\cdot H_2O$, showing that the water molecule acts as a hydrogen bond acceptor to the aqua ligand *cis* to the picoline ligand and a hydrogen bond donor to both the hydroxyethyl group and the aqua ligand *trans* to the picoline ligand; colour code: H (white), C (green), O (red), Pt (light blue), N (dark blue)

In conclusion, complex **1** is an interesting new analogue of the anticancer drug AMD473, and it will now be interesting to investigate the effects of the rapid hydrolysis of complex **1** and low pK_a values of the diaqua adduct on its biological activity in comparison with AMD473.

Experimental Section

Materials and Preparations: 2-(2-Hydroxyethyl)pyridine was purchased from Aldrich. *cis*-[$PtCl_2(^{15}NH_3)$\{2-(2-hydroxyethyl)-pyridine\}] (**1**) and the iodide analogue **6** were prepared by a similar procedure to that described in the literature for natural abundance, mixed-ligand am(m)ine Pt^{II} complexes.[11] Crystals suitable for X-ray diffraction were obtained by recrystallisation from water, in the case of **1** by very slow evaporation of solvent in the presence of 0.5 M NaCl.

pH Measurements: These were obtained on a Corning 145 pH meter equipped with an Aldrich micro combination electrode calibrated with Aldrich buffer solutions of pH 4, 7 and 10. The values of pH were adjusted with 1 M $HClO_4$ or NaOH as appropriate.

NMR Spectroscopy: NMR spectra were recorded on a Bruker DMX500 instrument using 5 mm tubes, as described previously.[4] The chemical shift references were sodium trimethylsilyl[D_4]propionate for ^1H, and $^{15}NH_4Cl$ in 1.5 M HCl for ^{15}N (external).

X-ray Crystallography

Crystal Data for Complex 1: $C_7H_{12}Cl_2N_2OPt$, M = 406.18, monoclinic, space group $P2_1/c$; a = 9.608(5), b = 10.722.(6), c = 10.608(5) Å, β = 100.72(5)°, V = 1073.8(9) $Å^3$, Z = 4, ρ_c = 2.512 g cm^{-3}, $F(000)$ = 752, μ(Mo-K_α) = 13.53 mm^{-1}, yellow block 0.38 × 0.24 × 0.12 mm^3. Data were collected to 2θ = 50° at 220 K in the manner described above. An absorption correction was applied by Gaussian integration following refinement of the crystal dimensions and face indices against a set of ψ-scans (Stoe X-SHAPE;[12] range of T: 0.364−0.737). The structure was solved by Patterson methods (DIRDIF)[13] and refined against F^2 using SHELX-97. H-atoms were treated as described above. The refinement converged to $R1$ = 2.98% [for 1552 data with $F > 4\sigma(F)$], $wR2$ = 6.36% (for all 1908 unique data), S = 1.021. The final difference map extremes were +1.39 and −1.02 $eÅ^{-3}$.

Crystal Data for Complex 6: $C_7H_{12}I_2N_2OPt$, M = 589.08, monoclinic; space group $P2_1/c$; a = 7.253(4), b = 20.702.(9), c = 8.834(5) Å, β = 113.68(4)°, V = 1213.4 $Å^3$, Z = 4, ρ_c = 3.225 g cm^{-3}, $F(000)$ = 1040, μ(Mo-K_α) = 16.62 mm^{-1}, yellow lath 0.43 × 0.18 × 0.10 mm^3. Data were collected to 2θ = 50° in ω-θ mode at 220 K

on a Stoe Stadi-4 diffractometer equipped with an Oxford Cryosystems low-temperature device. The diffraction peaks had irregular profiles and high, uneven backgrounds; perhaps for this reason, intensity versus ψ plots derived from azimuthal scans showed significantly different intensities for reflections differing in ψ by 180°. Not surprisingly, an attempt to perform an absorption correction based on these was unsuccessful, and so a DIFABS[14] correction was applied during refinement at isotropic convergence (T = 0.129−0.599). Therefore, while these data establish chemical connectivity, the displacement parameters are liable to be systematically in error as a result of the absorption correction procedure. The structure was solved by direct methods and refined by full-matrix least-squares against F^2 (SHELX-97).[15] The OH and NH_3 groups were treated as rotating rigid groups, while other H-positions were calculated and treated using a riding model. Anisotropic displacement parameters were refined for all non-H atoms, similar restraints being applied to those of directly-bonded light atoms. The refinement converged to $R1$ = 5.96% [for 1434 data with $F > 4\sigma(F)$], $wR2$ = 14.71% (for all 2149 unique data), S = 1.045. The final difference map extremes were +2.18 and −2.12 e·Å^{-3}.

CCDC-136876 (**1**) and -136877 (**6**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Molecular Mechanics Modelling: The starting models were generated using the HyperChem program[16] and energy minimised using the MOMECPC-95[17] program and a force field based on one described elsewhere.[18−22] All models were subjected to energy minimisation using MOMECPC-95 until convergence (all shifts < 0.001 Å) was achieved.

Kinetic Measurements: Peak volumes and relative concentrations from the NMR spectra recorded during the hydrolysis of complex **1** were calculated for each time point. Appropriate differential equations were integrated numerically. A nonlinear optimisation procedure using the program SCIENTIST® (version 2.01, MicroMath Inc) was employed to determined the rate constants. The errors represent one standard deviation.

Acknowledgments

We thank the EPSRC, BBSRC, Wolfson Foundation and Royal Society for their support for this work. We thank Professor Jan Reedijk (Leiden) and other members of EC COST D8/D20 for encouragement and stimulating discussions.

N,*N*-Dilithioarylamines as New Building Blocks in Amide Chemistry; the Structure of a Carbanion-Stabilized $[C_2N_5Li_{10}]^{2-}$ Cluster

Christine Neumann,[a] Axel Schulz,[a] Thomas Seifert,[a] Wolfgang Storch,*[a] and Martina Vosteen[a]

Keywords: Amines / Tin / Lithium / Clusters / Structure elucidation

2-Biphenylamine reacts with (dimethylamino)trimethylstannane in a 2:1 molar ratio, undergoing transamination to the distannylamine **1a**. The extremely air and moisture sensitive (2-biphenyl)-*N*,*N*-dilithium amide **2a** is obtained by the stannazane cleavage reaction of **1a** with *n*BuLi in MeO*t*Bu. Compound **2a** is the first example of a highly reactive, doubly metallated amine that can be used as a precursor in inorganic synthesis under fairly mild conditions. For example, both lithium atoms can be substituted by boryl or silyl groups, which cannot be introduced using other routes. Amide **2a** crystallizes as a cluster containing five $RNLi_2$ units, and is unexpectedly stabilized by two methanide anions. When the methanide ions are included, the lattice of the central $C_2N_4Li_8$ unit represents a section of the antiisomorphic lattice of the CaF_2-type. DFT (B3LYP) calculations and population analysis (NBO) have been carried out to get further insights into the thermodynamics of several dilithioamines $(RNLi_2)_n$ (R = H, CH_3, Ph; n = 1–6).

Introduction

Lithium amides are of widespread importance as precursors in the synthesis of novel main group element-nitrogen compounds and as deprotonating agents.[1] Their synthesis from secondary amines and alkyllithium compounds,[1] as well as their structural features in solution and the solid state, have been documented in numerous examples.[2] In contrast, little information is available about synthetic routes to doubly lithiated primary amines and the molecular structures of these compounds. Apart from powder diffraction studies on $LiNH_2/Li_2NH$ in the early fifties,[3] only the complex structure of the dilithiated α-naphthylamine has been reported.[4] This metal amide crystallizes as a cyclo-oligomeric aggregate containing ten molecular units with intermolecular Li−N bridging bonds. Dilithiated species have been postulated as intermediates in the decomposition of metallated amines, although their existence has not yet been confirmed.[5]

Recently we reported the synthesis and structures of monometallated organostannylamides of the type $RN(SnMe_3)M$.[6] In this paper we want to describe the synthesis of the first example of a highly reactive dilithiated primary amine, its unexpected molecular structure and its promising use as a building block.

Results and Discussion

The dilithium organylamides **2** are obtained by stannazane cleavage reactions of the distannylamines **1** with lithium alkyls in a 1:2 molar ratio according to Equation (1) and (2) under kinetically controlled conditions in good yield.[7] The deprotonation reaction of primary amines with metal alkyls does not lead to dimetallated amides. These reactions are usually not straightforward and lead to a mixture of products owing to unintentional C−H bond-cleavage reactions.

$$R\text{–}NH_2 \xrightarrow[-\ 2\ Me_2NH]{+\ 2\ Me_3SnNMe_2} \underset{\mathbf{1}}{R\text{–}N(SnMe_3)_2} \quad (1)$$

$$R\text{–}N(SnMe_3)_2 \xrightarrow[-2\ Me_3SnR']{+\ 2\ R'Li} \underset{\mathbf{2}}{1/n\ [R\text{–}NLi_2]_n} \quad (2)$$

The distannazanes **1** can be obtained from the transamination of Me_3SnNR_2 (R = Me, Et) with primary amines [Equation (1)] according to well-known procedures.[8a,8b] The progress of the reaction [Equation (2)] can be monitored by ^1H and ^{119}Sn NMR spectroscopy by following the change of the signal intensity of the cleavage product tetraalkylstannane as well as of the signal of **1**.

The extremely air- and moisture-sensitive dilithium amides **2** can only be isolated as colorless powders when butyllithium is used as the metalating agent in a 1:1 mixture of hexane and diethyl ether. Monomeric species of **2** could

not be detected in solution even when temperature-dependent NMR spectroscopy methods were applied. In most cases complex multiplet signals (^{7}Li or ^{13}C NMR) were detected, or the low concentration of compounds remaining in solution after cooling the reaction mixture did not allow the detection of nuclei with low natural abundance. This holds particularly for ^{15}N NMR studies, which are essential for the elucidation of structural features in solution. The signal pattern and the chemical shift of the nuclei measured (^{1}H, ^{7}Li, ^{13}C, ^{14}N) point to aggregation even in the presence of chelating amine ligands (pmdta, tmeda) for complexation of the lithium ions. These findings are in contrast to the properties of the respective precursors, the monolithium stannylamides.[6] Depending on the reaction conditions mono- or dinuclear units can be detected in solution, confirmed by their excellent resolved spin-spin coupling pattern of $^{1}J(^{6}Li,^{15}N)$ and $^{2}J(^{6}Li,^{119}Sn)$ and by an X-ray structure determination in the solid state. Although the predominant ionic character of the Li−N bond is indisputable, the values of the coupling constants mentioned above indicate a significant degree of covalency in that bond. Previous theoretical investigations of the hypothetical structure of the monomeric $HNLi_2$ [2d] suggested a considerable amount of p_π overlap in the Li−N bond, which has not been proved to be a good description.

The tendency of metal amides to form polynuclear aggregates should increase on going from mono- to dilithiated amides owing to the increase of electron density at the nitrogen center and the change of the ionic character in the Li−N bonds. To obtain an insight into the aggregation of dilithioamines, several species of the type $(RNLi_2)_n$ (R = H, CH_3, Ph; n = 1−6) have been studied by DFT (B3LYP)[9] calculations and population analysis (NBO).[10] These results are summarized in Table 1. They confirm that all the examined aggregation reactions are exothermic. For each substituent R attached to the nitrogen atom the calculated reaction enthalpy reveals the same trend. Starting with the dimer up to the hexamer, with R = H, the reaction enthalpy is smallest (largest stability) for the formation of the trimer (**C** in Figure 1).

The energy values of the exothermic oligomerization for different reactions decrease along the series R = H > CH_3 > Ph (Table 1).[11] According to NBO analysis the Li−N bonds are highly polar with significant amounts of covalent bonding [e.g. in the trimer (**C**): only 90% of the σ(Li−N) orbital is localized at the N atom]. In general, the polarity of the Li−N bonds increases with growing cluster size. In all cluster units each nitrogen atom interacts with four lithium centers. The lithium atoms, however, show a strong

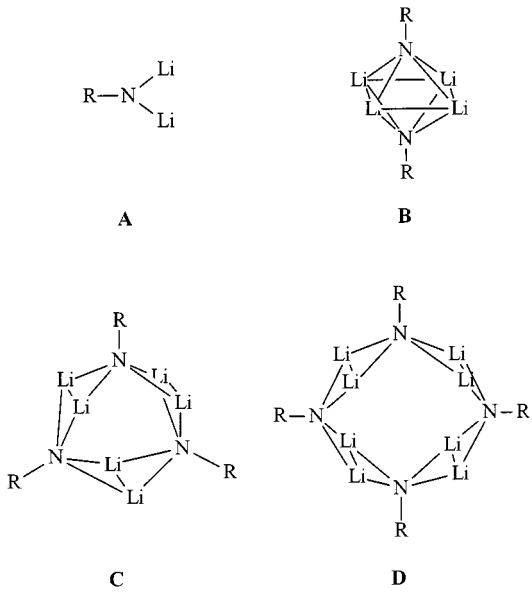

Figure 1. Schematic representation of di-, tetra-, hexa- and octanuclear Li clusters of the type ($[RNLi_2]_n$ for n = 1−4)

interaction with one adjacent lithium center and two weak interactions with two additional lithium centers [e.g. **C**: d(Li−Li) = 2.11 Å vs. 2.63 Å]. The calculated covalent (atom-atom NLMO) bond orders for this type of Li···Li interaction lie in the range between 0.03 and 0.04. Consequently, edge-linked square pyramids, containing four lithium atoms in the square positions and a nitrogen in the apical position, represent the predominant structural element (**B**−**D** in Figure 1). It therefore becomes evident that there is a positively charged area perpendicular to the rings formed by linked pyramids (see **C** and **D)** which is suitable for the attack of Lewis bases. The title molecule **2a**, the *N*-arylated species 2-dilithioaminobiphenyl, represents the product of such a formal Lewis acid-base reaction.

The X-ray structure determination of **2a** revealed an overall composition of $(C_{12}H_9NLi_2)_5{\cdot}2LiCH_3{\cdot}5OEt_2$ with a central $Li_8N_4C_2$ unit (Figure 2).[12] This structural feature is nicely in agreement with our theoretical prediction that the formation of oligomeric species (trimers and tetramers, respectively) is energetically preferred to the formation of monomeric or polymeric entities. Large R values are obtained due to the disorder of ether molecules in the crystal and the insufficient reflection properties of such a light atom cluster compound.[13] A detailed discussion of bond lengths and bond angles must therefore be carried out with care. However, the topological framework and the peculiar-

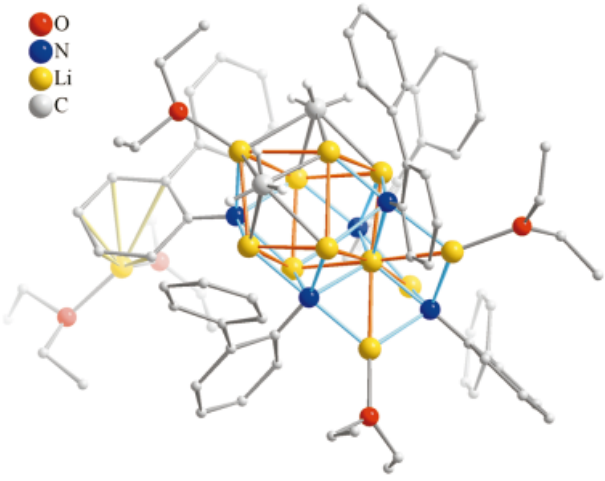

Figure 2. Molecular structure of [(2-Biphenyl-NLi_2)$_5$·2MeLi·5Et_2O] **2a**; the hydrogen atoms attached to the aryl groups are omitted for clarity, and the size of the carbon atoms of the aryl groups has been decreased.

ities of the cluster structure could be determined unambiguously. We should stress here that the results of the X-ray structure determination have been reproduced by the investigation of different single crystals deriving from several experiments. The most striking structural feature is the peculiar stabilization of the central Li_8N_4 aggregate (Figure 3) by the introduction of two methanide ions, each of them coordinating to four lithium centers. The eight lithium ions occupy the corners of a cube. The four organyl nitrogen and the two methanide anions compensate the positive charge of the cube by occupying the apical positions of six square pyramids. The six squares of the pyramids composed of lithium atoms form a cube as shown in Figure 3b. The two reactive sites in the tetrameric aggregate **D** are no longer available for further attack of the Biph-NLi_2 moiety, which would lead to the formation of larger aggregates, because of the introduction of the two methanide ions. However, the large biphenyl group of the amide center cannot prevent one additional BiphNLi_2 species from attaching itself to the periphery of the polyhedron stabilized by a lithium ion originally belonging to one of the methanide groups. Consequently the coordination number of three nitrogen centers of the polyhedron is extended to six. The Li cation of the second methanide ion is attached to a peripheral phenyl group of the biphenyl substituent by an η^6 π-

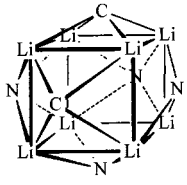

Figure 3. Central entity of the molecular structure of **2a** [without substituents R at the nitrogen atoms, the fifth $RNLi_2$ unit and the coordinating ether molecules]

interaction and additionally coordinates to two ether molecules. The lithium centers are three- and four-coordinate. The fourth position is predominantly occupied by an η^2 π-coordination with the aryl ligands (not shown in Figure 2)

When the methanide ions are included, the arrangement of the atoms in the central cluster unit represents a section of the antiisomorphic lattice of the CaF_2-type (Figure 3).[14] The positions of the fluoride ions at the corners of the cube are occupied by the lithium ions and the calcium positions above the centers of the edges of the cube are filled with $(R\text{-}N)^{2-}$ and CH_3^- ions. The same arrangement of atoms is found in the lattice of Li_2O. The bond lengths in the cluster **2a** are summarized in Table 2. With the reservations mentioned above they can be compared to the interatomic distances of already known lithium amides and alkyllithium compounds to see if there is a small or large deviation from normal values. The Li−N bond lengths of 1.942(5)−2.149(6) Å are in the range of the values determined by ab initio calculations of the mono lithiated $(LiNH_2)_4$ [$d_{(LiN)}$: 1.99−2.06 Å].[2b] The structural features of the latter are similar to the cluster of $(MeLi)_4$, where the positions of the methyl groups are occupied by the amino groups instead. In general the Li−N distances are significantly shorter in **2a**, probably due to the change of the electron density at the doubly metallated nitrogen atom. The Li−C bond lengths of 2.156(6)−2.445(7) Å of the methyl carbanions are similar to the values determined for tetrameric MeLi {$d_{(LiC)}$: 2.36 Å[15] and 2.236 Å according to recent ab initio studies[2b]}. Moreover, the Li−Li distances of 2.329(7)−2.611(7) Å are in good agreement with the values of 2.420 Å calculated by ab initio studies of $(MeLi)_4$.[15] Finally, the sufficient agreement of the bond lengths in **2a** with those in similar compounds confirms the topology of this unusual cluster.

Table 2. Range of selected bond lengths [Å] of the cluster **2a**

Li−N	1.942(5)−2.149(6)	Li−Li	2.329(7)−2.611(7)
Li−O	1.921(6)−1.992(6)	Li−CH_3	2.156(6)−2.445(7)
Li···$C_{biphenyl}$	2.291(6)−2.786(6)		

The origin of MeLi, which was not used as the metalating agent, can be explained indirectly by the presence of the alkyl stannanes Me_2SnBu_2 and $SnMe_4$. This points to exchange reactions according to Equation (3) followed by the Sn−N cleavage reaction of **1a** according to Equation (4).

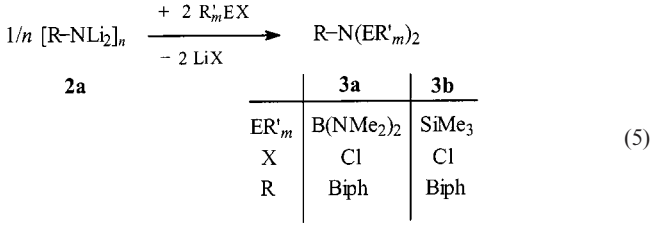
$$Me_3SnBu + LiBu \rightleftharpoons Me_2SnBu_2 + LiMe \quad (3)$$

$$R\text{-}N(SnMe_3)_2 + LiMe \longrightarrow R\text{-}N(SnMe_3)Li + SnMe_4 \quad (4)$$

However, it was not possible to detect MeLi in the cooled reaction mixture by means of ^{1}H and ^{13}C NMR spectroscopy, probably due to the Sn−N cleavage reactions proceeding very rapidly under these conditions. The equilibrium in Equation (3) was proved by reaction of Me_3SnBu with BuLi in a 1:1 molar ratio at −20 °C. The ^{1}H and ^{119}Sn NMR spectra showed that only ca. 30% of the products were formed under these conditions.[7]

The similarities in the lattices of **2a** and Li_2O may indicate that the Li−N bond is predominantly ionic in character despite a significant amount of covalent bonding as confirmed by our DFT studies. Additionally, Li−Li interactions may stabilize the cluster **2a**.

Astonishingly, the cluster compound **2a** is easily split into reactive cluster fragments, which makes it an ideal precursor for the formation of new element-nitrogen compounds. A convenient method of using the dilithium amide in solution even at low temperatures (−40 °C to −50 °C) is the reaction of **2a** with element halides according to Equation (5). A crucial condition for this procedure is the formation of the cluster compound in methyl *tert*-butyl ether (mtbe) as solvent and with methyllithium in ether as reagent.



(5)

Using this technique diborylamines (**3a**) or disilylamines (**3b**) are accessible under mild conditions [Equation (5)]. These compounds are not easily synthesized by existing techniques and, to the best of our knowledge, routes including Si−N or Sn−N cleavage reactions do not yield satisfactory results.[7] The application of the synthetic potential of **2a** is not restricted to the examples described in this paper, it is also suitable for a variety of element halides as well as organyl groups R (e.g. R = *t*Bu, Me_3Si, Me_3Sn, C_6H_5, 2,6-*i*$Pr_2C_6H_3$, etc.). The extreme reactivity of the R-N^{2-} group is revealed by the existence of protonation reactions [Equation (6) and (7)] upon allowing the reaction mixture to warm to ambient temperature.[7]

Experimental Section

General Remarks: Due to the moisture sensitivity of the compounds, some extremely so, all experiments and manipulations were carried out under argon purified by passage through a BTS catalyst. Reactions were performed by using standard Schlenk techniques and using dried, thoroughly deoxygenated solvents. The starting materials 2-aminobiphenyl, Me_3SiCl (all Aldrich) were used after redestillation. Me_3SnNMe_2[19] was prepared according to a literature procedure from Me_2NLi and Me_3SnCl. However, the yield could be improved by separation of surplus Me_2NLi before the addition of the exact stochiometric amount of Me_3SnCl. (2-Biphenyl)$N(SnMe_3)_2$[8c] and $(Me_2N)_2BCl$,[20] were prepared according to literature procedures. NMR spectra were recorded with Jeol GSX270 and Jeol EX400 spectrometers. A Perkin-Elmer Paragon 1000 PC spectrophotometer was used to record the IR spectra; solid substances were examined as Nujol mulls between KBr plates (vs: very strong, s: strong, m: medium, w: weak, vw: very weak, sh. shoulder).

(2-Biphenyl)dilithium amide (2a): A 1.1 mL portion of a solution of 2-biphenyl-$N(SnMe_3)_2$ (1.5 g, 3 mmol) dissolved in Et_2O (20 mL) was treated dropwise at −50 °C with *n*BuLi (3.75 mL, 1.6 M in hexane) diluted with 10 mL of hexane, resulting in a yellow solution. An orange solid precipitated from the solution, which redissolved (complete at −20 °C) upon allowing the reaction mixture to slowly warm to 0 °C. After removal of a sample for NMR investigations [$\delta^{7}Li$ = 3.5 (broad); $\delta^{119}Sn$ = 0.2 ($BuSnMe_3$), 2.6 ($SnMe_4$); signal ratio 100:12], the orange solution was cooled to −20 °C again, concentrated to a volume of ca 1.5 mL, diluted with 10 mL of Et_2O and stored at −78 °C for a fortnight. Some of the orange single crystals obtained by this procedure and suitable for X-ray structure analysis were isolated from the cooled solution. After separation of the solid from the solution, the crystalline material was dried in vacuo (10 °C/10^{-3} Torr). The residual yellow powder (0.31 g, 57%; m.p. > 280 °C, decomp.), which burns upon contact with air or moisture, changed color to dark brown when attempting to isolate a sample for elemental analysis, even under an argon atmosphere, hence the reported data are fairly inaccurate (ca. 12.5% too low). ^{1}H NMR (C_6D_6): δ = −1.31 [s, $(CH_3Li)_n$], 0.83 [t, $^{3}J_{H,H}$ = 7.0 Hz, $(CH_3CH_2)_2O$], 2.98 [q, $^{3}J_{H,H}$ = 7.0 Hz, $(CH_3CH_2)_2O$], 6.5−7.8 (unresolved m, aryl-*H*). ^{7}Li NMR (C_6D_6): δ = −4.9, −0.9 (very broad, signal ratio 11:100). ^{13}C NMR (C_6D_6): δ = −4.6 [s, $(CH_3Li)_n$], 14.9 [$(CH_3CH_2)_2O$], 65.2 [$(CH_3CH_2)_2O$], 120.7−155.8 (ca. 20 signals, aryl area, diphenyl groups). IR (nujol): $\tilde{\nu}$ = 3048 cm^{-1} w, 3034 w, 2972 m, 2929 m, 2871 m, 1573 s, 1443 s, 1411 vs, 1309 s, 1293 s, 1249 s, 1184 m, 1093 m, 987 m, 840 m, 762 m, 738 m, 600 m, 532 m, 497 m. $C_{12}H_9NLi_2$ (181.1): calcd. C 79.59, H 5.01, N 7.73; found C 69.57, H 4.34, N 6.66.

Bis[bis(dimethylamino)boryl](2-biphenyl)amine (3a): BuLi (3.1 mL, 1.6 M in hexane) was added dropwise at −55 °C to a stirred solution of 2-biphenyl-$N(SnMe_3)_2$ (**1a**; 1.1 g, 2.5 mmol) in mtbe (25 mL). The suspension turned to an orange solution at −30 °C. After stirring for 2 h at −30 °C, $(Me_2N)_2BCl$ (0.7 mL, 5 mmol), dissolved in hexane (12 mL), was added. After allowing the yellow suspension to warm to ambient temp. and stirring for a further 48 h the colorless solid was filtered off (G4-frit). [NMR spectroscopic data of the filtrate: $\delta^{11}B$ = 24.0, 28.6 (br, 2-Biph-$N[B(NMe_2)_2]_2$ **3a**); $\delta^{119}Sn$ = −3.6 (Bu_2SnMe_2), 0.2 ($BuSnMe_3$), 2.3 ($SnMe_4$), signal ratio: 24:100:24]. After removal of all volatile components in vacuo (40 °C/10^{-3} Torr), **3a** (0.66 g, 72%, bp. 87 °C/10^{-5} Torr) could be isolated as a yellow oil. ^{1}H NMR (C_6D_6): δ = 2.45 [broad, 24 H, $(Me_2N)_2$], 6.77 (m, 1 H, 3-H), 6.95 (m, 1 H, 5-H), 7.09−7.28 (m,

5 H, 2′- 6′-H), 7.49 (m, 2 H, 4-H/6-H). ^{11}B NMR (C_6D_6): δ = 29.1. ^{13}C NMR (C_6D_6): δ = 39.4 [broad, ($Me_2N)_2$], 121.2 (C3), 126.3 (C5), 127.2 (C1), 128.3 (C2′, C6′), 128.7 (C3′, C5′), 129.0 (C6), 132.2 (C4), 135.1 (C4′), 142.4 (C1′), 148.5 (C2). IR (nujol): $\tilde{\nu}$ = 3073 cm^{-1} w, 2992 m, 2896 s, 2791 m, 1580 w, 1510 s, 1388 s, 1349 s, 1246 m, 1224 s, 1136 m, 1122 m, 1064 m, 1028 m, 862 s, 744 m, 702 m. $C_{20}H_{32}B_2N_5$ (365.1): calcd. C 65.79, H 9.11, N 19.18; found C 63.69, H 8.94, N 18.18. MS: *m*/*z* = 365 [M$^+$].

Bis(trimethylsilyl)(2-biphenyl)amine (3b): BuLi (4.19 mL, 1.6 molar in hexane) was added dropwise at −55 °C to a stirred solution of the distannylamine **1a** (1.66 g, 3.35 mmol) dissolved in mtbe (25 mL) at the same temperature. After 1 h stirring at −10 °C the orange colored solution was cooled to −30 °C. Me_3SiCl (0.84 mL, 6.7 mmol) dissolved in hexane (12 mL) was then added dropwise and the solution was allowed to attain ambient temp. within 2 h. After additional stirring for 12 h the solid components were separated by filtration (0.35 g, 120% according to LiCl, G4-frit). The volatile compounds of the filtrate were removed in vacuo (30 °C/10^{-2} Torr) and **3b** (0.7 g, 67%, 80 °C/10^{-3} Torr, solidifying after 12 h) was obtained by distillation as a colorless liquid from the residual viscous, brown oil. ^{1}H NMR (400 MHz, C_6D_6): δ = 0.08 (s, 18 H, Me_3Si), 6.81 (m, 1 H, 3-H), 6.96 (m, 1 H, 5-H), 7.11−7.24 (m, 5 H, 2′-H/6′-H), 7.36−7.49 (m, 2 H, 4-H/6-H) ^{13}C NMR: δ = −0.01 (s, Me_3Si), 115.7 (C3), 118.3 (C5), 127.3 (C1), 128.0 (C2′, C6′), 128.8 (C3′, C5′), 129.2 (C6), 129.7 (C4), 130.6 (C4′), 131.1 (C1′), 144.8 (C2). ^{29}Si NMR: δ = 5.9. $C_{18}H_{27}N_1Si_2$ (313.6): calcd. C 68.94, H 8.68, N 4.47; found C 68.32, H 8.43, N 4.21. MS: *m*/*z* = 313 [M$^+$].

Computational Methods: The structural and vibrational data of several lithium-nitrogen clusters $(RNLi_2)_n$ (R = H, CH_3, Ph; *n* = 1−6; for CH_3 and Ph *n* = 1−4) were calculated by using the hybrid density functional theory (B3LYP) with the program package Gaussian 98.[9] For all elements a standard 6-31G(d,p) basis set was used. The computations were carried out at the DFT level using the hybrid method B3LYP which includes a mixture of Hartree−Fock exchange with hybrid DFT exchange correlations. Becke's three parameter functional where the non-local correlation is provided by the LYP expression (Lee, Yang, Parr correlation functional) was used as implemented in Gaussian 98. An NBO population analysis was carried out to investigate the bonding in these species.[10]

[13] Cluster compounds with such a composition of elements frequently show a drastic decrease in the number of reflections at larger decline angles Θ when small crystals (edge length < 0.1 mm) of low quality are measured. As a consequence the standard deviations of atom distances and bond angles increase, as do the conventional *R* value and the weighted *R* value, wR_2. Even exposures of 40 s/frame (ΔΦ and Δω = 0.3°) only result in a slight improvement of the data.

The First Case of Local *cis* versus *trans* Coordination as the Controlling Factor for the Overall Structure in Dinuclear Assemblies

Guillem Aromí,[a] Patrick Gamez,[a] Olivier Roubeau,[a] Paula Carrero-Berzal,[a] Huub Kooijman,[b] Anthony L. Spek,[b] Willem L. Driessen,[a] and Jan Reedijk*[a]

Keywords: Stereochemistry / Self assembly / O ligands / Manganese / Nickel

The preparation and structure of two dinuclear assemblies $[M_2(HL)_2(py)_4]$ (M^{II} = Mn, Ni) with the phenol bis-β-diketone H_3L are presented. The octahedral N_2O_4 coordination environments around the metals are in *cis* and *trans* configuration for Mn and Ni, respectively, leading to structurally different assemblies. These results represent the first example where the overall structure of a complicated coordination architecture is controlled by the local stereochemistry imposed at the metal ions.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

In the creation of complicated coordination supramolecular assemblies, the information leading to the final architecture is contained in the structural and electronic properties of the ligands as well as in the specific requirements of the transition metals.[1] This is best illustrated by cases where very different structures are obtained when all but one of the parameters of the system are maintained constant.[2−7] For example, a ligand has been reported whose molecular information is expressed in form of either a circular or a cross-shaped dodecanuclear assembly depending on the set of metals that is allowed to react with it, and this is dictated by the coordination geometry imposed by them.[6] In a different example, small differences in the spacer between donor sites in polynucleating ligands determine whether a grid-like complex or a helicate is obtained from the same transition metal.[3,4] The understanding and control of the factors that lead to each particular architecture are paramount to bring about the ambitious potential technological applications of this field. We report here a unique example where the preferred *cis*/*trans* stereochemistry at the metal centers determines the overall architecture of the dinuclear complexes that they form with the same ligand.

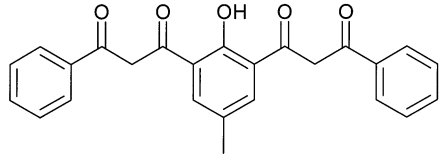
Results and Discussion

The ligand H_3L[8] has been prepared recently[9] (Scheme 1) and its coordination properties with a variety of transition metals are just starting to be explored. The versatility provided by the presence of a phenol and two β-diketone units in this molecule has already afforded a diversity of supramolecular architectures.[10,11]



Scheme 1. H_3L in its ketonic form and *syn-syn* conformation

The X-ray structure of H_3L has been determined[12] using single crystals obtained from a solution in acetone and it is presented in this report (Figure 1). Consistent with the solution ^1H NMR spectroscopic data, the Fourier maps of this diffraction experiment also revealed the β-diketone groups to lie completely in their enolic form. In one of these units, the acidic H is found to be disordered between the oxygen atoms. One apparent and striking feature of this essentially flat molecular structure is the *anti-syn* conformation displayed by the β-diketone units with respect to the phenol group. No intermolecular hydrogen bonding or π-π contacts have been identified in the crystal lattice, suggesting this conformation to be the result of intramolecular

interactions, as supported by molecular modeling calculations performed on H_3L.[13] Presumably, this nuclear topology allows for the most favorable interactions between the numerous local electric dipoles present in this molecule.

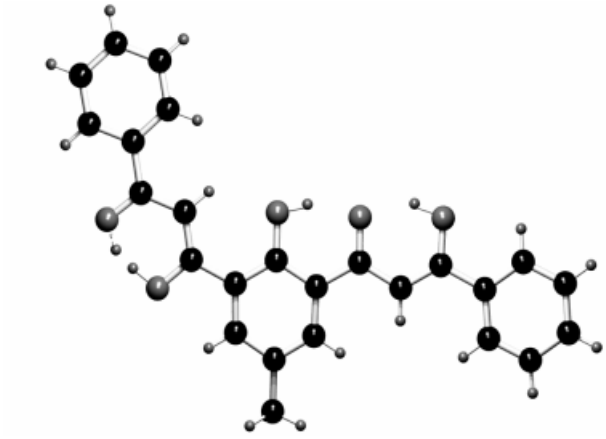


Figure 1. Pov-ray drawing of the X-ray structure of H_3L displaying its enolic form and *anti-syn* conformation

The reaction of equimolar amounts of H_3L and $Mn(OAc)_2$ or $Ni(OAc)_2$ in pyridine produced high yields of orange or green crystals of $[M_2(HL)_2(py)_4]$ (M = Mn, **1**; Ni, **2**) upon addition of Et_2O (**1**) or after layering the reaction mixture with toluene (**2**). Both types of crystals were suitable for X-ray crystallography and analyzed satisfactorily.[14]

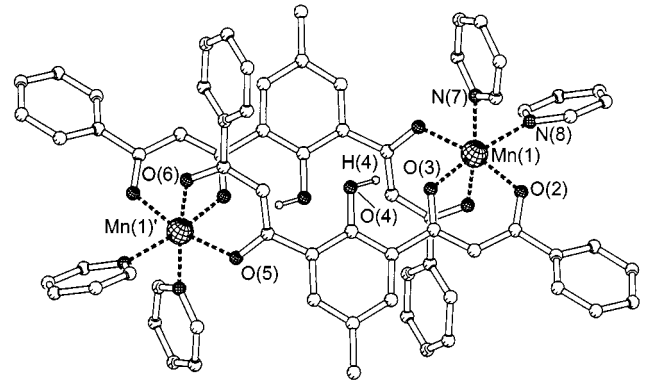

Figure 2. Platon drawing of $[Mn_2(HL)_2(py)_4]$ (**1**); selected bond lengths (Å): Mn(1)−O(2) 2.1522(15), Mn(1)−O(3) 2.1651(14), Mn(1)′−O(5) 2.1557(13), Mn(1)′−O(6) 2.1337(14), Mn(1)−N(7) 2.2415(17), Mn(1)−N(8) 2.2631(16), Mn(1)···Mn(1)′ 9.3018(13), O(3)···O(4) 2.4753(19)

The structure of **1**[12] (Figure 2) consists of a centrosymmetric complex of two Mn^{II} ions, chelated and bridged by two crystallographically equivalent HL^{2-} ligands. Interestingly, the ligands in this complex lie in the same conformation as that of the free ligand in the solid state, although much more removed from planarity [the angle between the idealized planes containing both β-diketonate groups is 40.74(9)° in **1** and 7.53(11)° in H_3L]. In addition, the presence of intramolecular hydrogen bonding between O(3) and O(4) is revealed in this structure [O(3)···O(4) = 2.4753(19) Å], where H(4) has been refined. The metals in this assembly are separated by a distance of 9.3018(13) Å, and are accommodated in a slightly distorted octahedral geometry. An oxidation state of 2+ has been assigned to Mn based on charge considerations, and is consistent with the magnetic properties of **1** (vide infra).

X-ray diffraction analysis performed on crystals of **2**[12] showed this compound to be an assembly of two Ni^{II} centers bridged by two HL^{2-} chelating ligands, with the coordination around each metal completed by two pyridine ligands (Figure 3). A crystallographic center of symmetry is also present in the middle of the molecule in this case. In contrast to **1**, however, the polynucleating ligands in this complex are found in the *syn-syn* conformation. This leads to an overall architecture that is completely different to that in **1** despite the fact that these two compounds share the same formulation, with the exception of the nature of the metals. A closer examination of the structure of **2** allows one to conclude that this major structural change is the consequence of the local stereochemistry at the metal centers. The coordination geometry around Ni is octahedral with a slight tetragonal elongation. Comparing **1** with **2**, it can be seen that the N_2O_4 coordination sphere around Ni^{II} is in a *trans* configuration, as opposed to the *cis* stereochemistry with Mn^{II}. The HL^{2-} ligand in **2** is not completely planar [the β-diketonate planes form an angle of 46.61(7)°] and also shows the same [O−H···O] interaction [O(3)···O(4) = 2.5047(15) Å] as in **1**. Furthermore, the conformational disparity between **1** and **2** leads to a markedly shorter metal-metal distance in the latter complex, the Ni···Ni distance being 7.9210(8) Å. The same arguments as for **1** are used for the assumption about the oxidation state of Ni in **2**. Crystals of the related complex $[Ni_2(HL)_2(py)_2(THF)_2]$ were also analyzed and show the same structural features as **2**. Details of this determination are included in the Supporting Information (see footnote on the first page of this article).

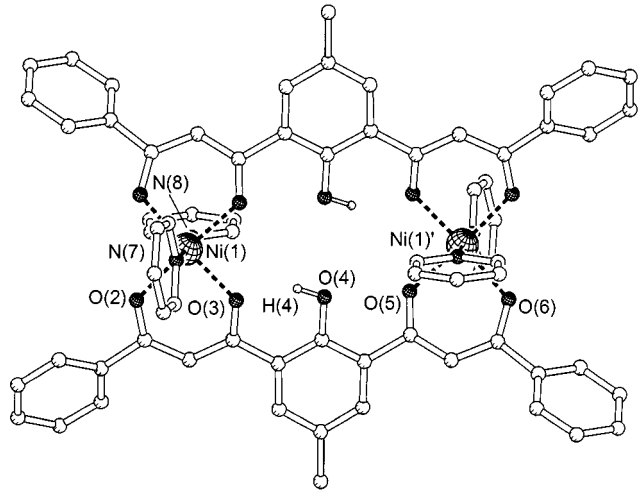

Figure 3. Platon drawing of $[Ni_2(HL)_2(py)_4]$ (**2**); selected bond lengths (Å): Ni(1)−O(2) 2.0297(10), Ni(1)−O(3) 2.0241(10), Ni(1)′−O(5) 2.0092(10), Ni(1)′−O(6) 2.0295(10), Ni(1)−N(7) 2.1067(13), Ni(1)−N(8) 2.1136(13), Ni(1)···Ni(1)′ 7.9210(8), O(3)−O(4) 2.5047(15)

The structural difference between **1** and **2** is not mirrored in their magnetic properties, as shown by bulk magnetization measurements in the 2−300 K temperature range at a constant field of 1 kG. In both cases, the magnetic susceptibility data could be fitted with a model that considers two noninteracting M^{II} centers, yielding ionic *g* values of 2.01 and 2.10 for Mn^{II} and Ni^{II}, respectively.

The local *trans* configuration preferred in complex **2** is ascribed to the larger crystal field stabilization energy that results from this donor distribution, one that is observed in the vast majority of Ni^{II} complexes with an equivalent set of ligands.[15] This thermodynamic argument does not apply to high-spin Mn^{II} (d^5). Therefore, the *cis* stereochemistry is observed at the metal ions in **1**, most probably because it is the one that allows for the most stable conformation of the polynucleating ligand. To the best of our knowledge, this is the first example where the overall structure of a polynuclear assembly is determined solely by the difference in the local *cis*/*trans* configuration of the metals. A related precedent exists where a dinucleating ligand delivers either a helicate or a mesocate, depending on the metal used, the structure of the assembly being dictated by the chirality at the coordination centers.[16] Additional examples of the simple principle manifested experimentally for the first time in the present work are currently under investigation with different metals. A thorough study will be published in due course.

[12] Crystal structure determinations were carried out at 150 K. Data were measured on a Nonius KappaCCD diffractometer with a rotating anode (Mo-K_α radiation, graphite monochromator, $\lambda = 0.71073$ Å). Structures were solved by direct methods (SHELXS-86) and refined on F^2 with SHELXL-97. The coordinates of the hydroxyl hydrogen atoms were refined; other hydrogens were included in the refinement at calculated positions riding on their carrier atoms. No absorption correction was applied.
Data for $\mathbf{H_3L}$: $C_{25}H_{20}O_5$, $M_r = 400.41$, yellow, needle-shaped crystal (0.05 × 0.12 × 0.40 mm), orthorhombic, space group $Pna2_1$ (no. 33) with $a = 7.625(2)$, $b = 22.540(6)$, $c = 11.193(2)$, Å $V = 1923.7(8)$ Å^3, $Z = 4$, $D_c = 1.383$ g cm^{-3}, μ(Mo-K_α) = 0.096 mm^{-1}, 14561 reflections measured ($1.6° < \theta < 27.47°$), 2317 independent (Friedel pairs were averaged), $R_{int} = 0.0657$. A hydrogen atom was found to be disordered between O5 and O6; the coordinates of both positions were refined. The occupancy of the major component refined to 0.59(11). 285 parameters were refined, $wR2 = 0.0873$, $R1 = 0.0383$ [for 1796 reflections with $F_o > 4\sigma(F_o)$] $S = 1.020$, $-0.25 < \Delta\rho < 0.15$ e Å^{-3}.
Data for **1**: $C_{70}H_{56}Mn_2N_4O_{10}\cdot 5C_5H_5N$, $M_r = 1618.62$, orange, needle-shaped crystal (0.1 × 0.1 × 0.3 mm), monoclinic, space group $C2/c$ (no. 15) with $a = 25.215(3)$, $b = 15.166(2)$, $c = 21.295(2)$ Å, $\beta = 91.455(9)°$, $V = 8140.8(16)$ Å^3, $Z = 4$, $D_c = 1.321$ g cm^{-3}, μ(Mo-K_α) = 0.398 mm^{-1}, 72705 reflections measured ($1.6° < \theta < 25.21°$), 7323 independent, $R_{int} = 0.0761$. Electron density in a disordered solvent area containing 2.5 unique pyridine molecules was taken into account in the refinement via PLATON/SQUEEZE. Where relevant, the data cited above are given with the contribution of this disordered solvent. 393 parameters were refined, $wR2 = 0.1100$, $R1 = 0.0423$ [for 5551 reflections with $F_o > 4\sigma(F_o)$] $S = 1.066$, $-0.28 < \Delta\rho < 0.28$ e Å^{-3}.
Data for **2**: $C_{70}H_{56}N_4Ni_2O_{10}\cdot 2C_7H_8\cdot 2C_5H_5N$, $M_r = 1574.04$, light green, block-shaped crystal (0.15 × 0.20 × 0.30 mm), triclinic, space group $P\bar{1}$ (no. 2) with $a = 11.0980(10)$, $b = 12.0326(12)$, $c = 15.5168(15)$ Å, $\alpha = 88.854(10)°$, $\beta = 78.382(10)°$, $\gamma = 79.478(10)°$, $V = 1995.2(3)$ Å^3, $Z = 1$, $D_c = 1.309$ g cm^{-3}, μ(Mo-K_α) = 0.537 mm^{-1}, 58280 reflections measured ($1.6° < \theta < 27.49°$), 9138 independent, $R_{int} = 0.0414$, 510 parameters, $wR2 = 0.0840$, $R1 = 0.0321$ [for 7934 reflections with $F_o > 4\sigma(F_o)$] $S = 1.044$, $-0.49 < \Delta\rho < 0.53$ e Å^{-3}.

Synthesis, Stereochemistry and Ligating Properties of Tetraalkyl-Substituted Ethanedithioamides − Evidence for the Lowering of High-Energy Rotation Barriers under the trans Influence of Pt-σ-Bonded Aryl Groups

Santo Lanza,*[a] Francesco Nicolò,[a] and Giuseppe Tresoldi[a]

Keywords: C−C hindered rotation / C−N hindered rotation / (*E*)/(*Z*) isomerisation / Tetraalkylethanedithioamides

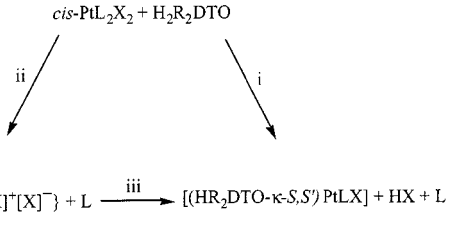
The structural and coordinating properties of five tetrasubstituted tetraalkyldithioxamides (R_4DTO) have been studied: tetraethyldithioxamide (Et_4DTO, **1**), tetrabenzyldithioxamide (Bz_4DTO, **2**), (*E*,*E*)-*N*,*N*′-dibenzyl-*N*,*N*′-diethyldithioxamide [(*E*,*E*)-Bz_2Et_2DTO, **3**], (*E*,*Z*)-*N*,*N*′-dibenzyl-*N*,*N*′-diethyldithioxamide [(*E*,*Z*)-Bz_2Et_2DTO, **4**], (*Z*,*Z*)-*N*,*N*′-dibenzyl-*N*,*N*′-diethyldithioxamide [(*Z*,*Z*)-Bz_2Et_2DTO, **5**]. The solid structure of **4**, determined by single-crystal X-ray diffraction, is characterised by two planar thioamide groups positioned almost orthogonally to each other, connected by a C–C single bond. Each of these dithioxamides showed high-energy barriers to rotation around both the C–N and the central C–C bond. This latter is a chiral torsion, so that R_4DTO species exist as pairs of enantiomers. Compounds **3**, **4** and **5** slowly isomerised in solution to give equimolar mixtures of the three isomers; the activation enthalpy of the process was 30.0 kcal mol^{-1}. The ligands **1**–**5** reacted with [$Pt(Me_2SO)_2X_2$] (X = Cl, Br, Me, Ph) to give chiral chelate complexes [(R_4DTO-κ-*S*,*S*′)PtX_2], but **3** (and also **4** and **5**) provided a mixture of three isomeric platinum chelates in which the *S*,*S*′-coordinated ligands showed the (*E*,*E*), (*E*,*Z*) and (*Z*,*Z*) conformations. Furthermore, the presence of small amounts of the platinum complexes *cis*-[$Pt(Me_2SO)_2Ph_2$] or [(Et_4DTO-κ-*S*,*S*′)$PtPh_2$] caused the fast isomerisation of large quantities of a given isomerically pure ligand. We have explained the collapse of the R_4DTO rotational barriers by assuming that a release of electrons from the metal atom to incoming ligands in the transition state twists these into a partially reduced, dithiolenic form.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

We have previously found that the reactions (Scheme 1) between H_2R_2DTO (*N*,*N*′-dialkyldithioxamides) and *cis*-[PtL_2X_2]-type complexes (L = Me_2SO, Me_2S; X = Cl, Me, Ph) give rise to (i) rubeanate compounds or (ii) tight ion pairs in high yield, depending on starting material and/or reaction medium.

In fact, when X = Me or Ph, methane or benzene leaves the coordination sphere of platinum(II),[1] while when X = Cl and the reaction is carried out in low-polar, noncoordinating solvents, hydrochloric acid (HCl) remains as a guest in the ion pair.[2] HCl can be easily removed from this ion pair by means either of Lewis nitrogen bases or of Brønsted basic solvents (iii).



Scheme 1

Furthermore, we have previously observed that the tetraethyldithioxamides (Et_4DTO) react with *cis*-[$Pt(Me_2SO)_2X_2$] similarly to other common neutral chelating ligands to give rise to [(Et_4DTO-κ-*S*,*S*′)PtX_2] complexes.[3]

Clearly, the different reaction course of *N*,*N*′-dialkyldithioxamides with respect to the tetraalkyl-substituted ones is due to the two amide hydrogen atoms allowing loss of Cl^- in the Werner substrates *cis*-[PtL_2Cl_2], and cleavage of the Pt−C bond in the corresponding organometallic complexes *cis*-[PtL_2R_2].

Another, perhaps more relevant, difference between the *N*,*N*′-dialkyl- and tetraalkyldithioxamides arises from their conformations in solution: the energy barrier around the C(=S)−C(=S) axis in the H_2R_2DTO species is low, while the same barrier is of high energy in R_4DTO molecules. Thus, tetraalkyldithioxamides, because of the tilted array of the two NCS moieties, exist as pairs of enantiomers.

Both classes of compounds display high-energy achiral torsion barriers around the C−N bonds, and the secondary dithioxamides are locked in the more favourable (*Z*) forms.[4]

The conformational differences seen in the free ligands are still evident in their platinum complexes [(HR_2DTO-κ-*S*,*S*′)PtLX] (**I**), {[(H_2R_2DTO-κ-*S*,*S*′)PtLX]$^+$,[Cl^-]} (**II**) and [(Et_4DTO-κ-*S*,*S*′)PtX_2] (**III**). In the rubeanate complexes **I**, the S−C−C−S skeleton is planar, owing to the loss of one of the two amide hydrogen atoms. In the ion pairs **II**, dithioxamides act as neutral ligands, and this implies that the two NCS moieties are twisted relative to one another, because of repulsion of amide hydrogen atoms.[5] The torsion angle between amide planes (about 40°), measured by X-ray diffraction in several metal complexes, seems to be independent of the metal centre (Zn, Cu, Sn and Bi) and coordination geometry (square-planar, tetrahedral, octahedral, bipyramidal),[6] and it is therefore probably a structural characteristic of neutral chelating secondary dithioxamides. In solution, however, the amide planes flip rapidly (on the NMR timescale) because of the low-energy torsion barrier around the C(=S)−C(=S) axis.

In contrast, the compounds **III** display chiral torsion barriers as high in energy in solution as in the free ligand, and each of these complexes exists as a pair of potentially isolable enantiomers. We have already highlighted the significance of **III** as a new class of chiral chelate complexes,[3] in acknowledgment of the fact that this particular aspect in the chemistry of tetrasubstituted dithioxamide derivatives should be emphasised on account of the importance of metal complexes of chiral chelate ligands in asymmetric catalysis.[7]

Here we report a more extended series of R_4DTO platinum(II) coordination and organometallic complexes for achieving a better understanding of the chiral properties of such systems.

Results and Discussion

The synthetic route to the ligands started from dialkylamines and oxalyl chloride. The resulting oxamides were then treated with phosphorus pentasulfide to yield tetraalkyldithioxamides. Both oxamides and dithioxamides show barriers to rotation around both the amide bond and the central carbon−carbon (the pivot bond).[8] However, the barrier around the C−N bond is high in energy in both classes of compounds, while rotation around the pivot bond is hindered only in tetraalkyldithioxamides, the oxamide C(=O)−C(=O) barrier being of low energy (< 10 kcal/mol). As a consequence, the twisted dithioxamides are chiral molecules, as one can see from the resonances of the prochiral probes $-CH_2-C_6H_5$ and $-CH_2-CH_3$ in Table 1.

The barrier to rotation around the C−N bond means that both oxamides and dithioxamides with different substituents at each nitrogen atom display (*E*)/(*Z*) isomerism.

Actually, the synthesis of *N*,*N*′-dibenzyl-*N*,*N*′-diethyloxamide provides all possible geometrical isomers [(*E*,*E*), (*E*,*Z*), (*Z*,*Z*)] in equimolar ratio. The oxamide isomer mixture, on treatment with P_2S_5, is transformed into the corresponding isomers: (*E*,*E*)- (*E*,*Z*)- and (*Z*,*Z*)-*N*,*N*′-dibenzyl-*N*,*N*′-diethyldithioxamide. Each of these isomers exists as a pair of enantiomers, as a consequence of the twisting of the NCS fragments around the pivot bond.

By taking advantage of the different solubilities of the geometrical isomers in ethanol, we were able to obtain the pure (*E*,*E*) isomer **3** (insoluble in ethanol), as well as the (*E*,*Z*) isomer **4** (which crystallised from ethanol after ca. 1 h.) and the (*Z*,*Z*) isomer **5** (soluble in ethanol).

NMR spectroscopy provided useful information to establish the geometries of the isomers. Thus, compound **4**, the

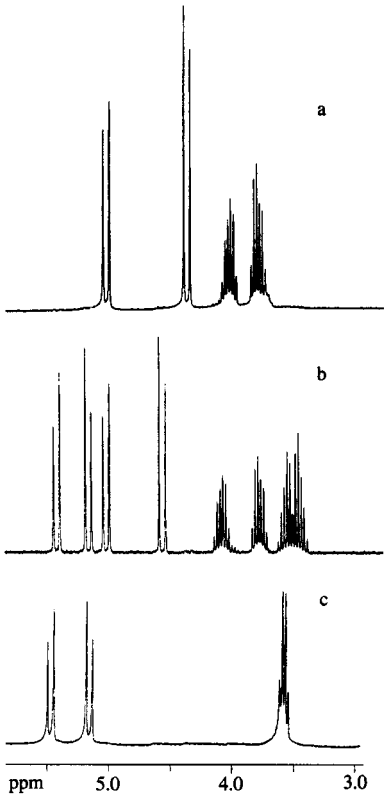

Figure 1. ^{1}H NMR spectra (methylene region) in $CDCl_3$ at 298 K of: a) (*E*,*E*)-Bz_2Et_2DTO (**3**), b) (*E*,*Z*)-Bz_2Et_2DTO (**4**) and c) (*Z*,*Z*)-Bz_2Et_2DTO (**5**)

enantiomeric couple in which the −CSNBzEt fragments have opposite (*E*,*Z*) geometries, showed in its ^{1}H NMR spectrum (Table 1 and Figure 1) two AB quadruplets, corresponding to the nonequivalent benzyl methylene protons, and two ABX_3 schemes featuring the ethyl hydrogen atoms as well.

Furthermore, studies of long-range coupling,[9] intramolecular nuclear Overhauser effects,[10] paramagnetic contact shifts[11] and benzene dilution[12] have shown that, in amides in which rotation about the N−CO bond is restricted, protons *cis* to the carbonyl groups are shielded more strongly than those in a "*trans*" arrangement, at least in the case of freely rotating alkyl substituents. In contrast, the corresponding thioamides display opposite magnetic anisotropies.[13] Thus, the (*E*,*E*) isomer **3**, insoluble in ethanol, showed the methylene proton signals of the ethyl group at lower fields in the ^{1}H NMR spectrum (and those of the benzyl group at higher field) than the corresponding resonances in **5**.

The preparative-scale separation of the above isomers offered an ideal opportunity to confirm the NMR assignment of their geometries by crystallographic analysis. For this reason, we grew a single crystal from a chloroform/ethanol (9:1, v/v) solution of **3**. Unfortunately, the crystal selected for the structural analysis was found to be (*E*,*Z*)-Bz_2Et_2DTO. This unexpected result indicated that spontaneous isomerisation of **3** had occurred in solution.

We observed afterwards that **3**, and also **4** and **5**, all became equimolar mixtures of the three enantiomeric couples within a few days when allowed to stand in chloroform at room temperature.

Kinetic monitoring of the above isomerisation process by ^{1}H NMR revealed a consecutive reversible process. This was a first-order reaction during the time in which the appearance of isomer **5** was negligible; we therefore measured the specific constants of the first-order process at 298, 310 and 323 K (Table 2). From these kinetic measurements, the activation enthalpy was estimated as 30.0 kcal mol^{-1}. This value agrees with the $\Delta H^{\ddagger}$ values for the (*Z*)/(*E*) isomerisation of several thioamides, determined by NMR spectroscopy, which have been found to be[14] in the range of 18−30 kcal mol^{-1}. Finally, the presence of **3**, **4** and **5** in equimolar quantities in the mixture indicated that the free-energy differences ΔG between the geometrical isomers were very small.

X-ray Structure of 4

The crystal structure of compound **4** consists of discrete molecules of the ligand $[(C_2H_5)(C_6H_5{-}CH_2)NCS{-}]_2$, packed together by van der Waals interactions. The crystallographic asymmetric unit is represented by one molecule, shown with the corresponding atom-labelling scheme in Figure 2. It was not possible to determine the absolute con-

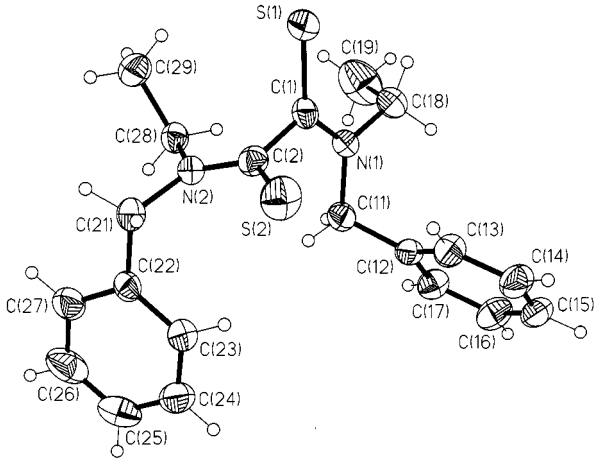

Figure 2. Molecular structure of **4** with the numbering scheme

figuration, expected from the crystallographic space group and spectroscopic evidence, despite the good quality of diffraction data and the structure model definition. In fact, the enantiomorph parameter of Flack,[15] included in the last cycle of the model refinement, converged stably to 0.55(9), a value in the middle of the theoretical extremes of 0.0 for the correct and 1.0 for the incorrect absolute configuration, respectively. This ambiguous situation has already been investigated[16] and the corresponding crystal sample was described as "inversion twin": a solid packing that is a perfect twin formed by the co-crystallisation of both enantiomers.

The ligand scheme comprises a central bulk made up of a dithionic fragment that carries an *N*-benzyl-*N*-ethylamine unit bonded to each carbon atom. On comparison of the geometric data of the two thioamides, the two $(C_2H_5)(C_6H_5{-}CH_2)NCS$ fragments appear to be very similar. The ethyl groups show some difference, which may be related to the disorder of the terminal methyl group [C(19)], as clearly evidenced by its significantly larger displacement parameters, when compared with the corresponding values for C(29). Electronic delocalisation inside each thioamide fragment is limited, as evidenced by the bond data for the almost flat geometry observed for each nitrogen atom. Both the C(1)C(2) bond length of 1.500(4) Å, denoting a single σ-bond, and the S=C−C=S torsion angle of 87.8(3)°, indicating the orthogonal disposition of the dithionic groups, point to the total absence of conjugation between the two thioamide fragments. This staggered arrangement is largely due both to steric and to electronic effects, as we have already pointed out in our previous work on an *N*,*N*,*N*′,*N*′-tetraethyl derivative,[3] in which the geometric parameters of the central N(=S)C−C(=S)N moiety are comparable. Hindrance effects play an important role in determining the disposition of substituents on both thioamide nitrogen atoms.

Metal Complexes of R_4DTO Ligands

S,*S*′−Pt chelation is postulated for all the complexes, since *N*,*N*′−Pt coordination is an unfavourable coordination mode both for steric and for electronic reasons. In fact, the nitrogen lone pairs are barely available for the coordination, because of their involvement in the CN partial double bond, especially since they are protected by bulky alkyl groups. Furthermore, *N*,*N*′−Pt coordination should be a disfavoured hard chelate ligand−soft metal interaction.

$(R^1_2R^2_2DTO)PtX_2$ compounds have been obtained as pure microcrystalline powders if $R^1 = R^2 =$ Et or Bz, X = Ph, Cl, Br.

In solution, all these complexes displayed well-resolved double ABX_3 (Et_4DTO derivatives) and AB (Bz_4DTO compounds) spectral schemes (Table 3). This means that the chiral torsion barriers around the pivot bonds, as well as the achiral torsion barriers around amide bonds, were of high energy even when tetraalkyldithioxamides were linked to platinum(II) fragments.

The Me derivative **11** was unstable and was characterised only in solution.

The three Bz_2Et_2DTO isomers displayed unexpected behaviour when they were treated with *cis*-$[Pt(Me_2SO)_2Ph_2]$ species; when one of the isomers (any one of the three) was treated with an equimolar quantity of the platinum complex, there was a mixture obtained containing the isomeric metal complexes [(*E*,*E*)-, (*E*,*Z*)-, (*Z*,*Z*)-Bz_2Et_2DTO)$PtPh_2$] in an equimolar ratio, together with the three isomers of the free ligand and the starting *cis*-$[Pt(Me_2SO)_2Ph_2]$. In other words, the equilibrium according to Scheme 2 took place and caused the isomerisation of the given pure isomer of Bz_2Et_2DTO.

Actually, the presence of catalytic amounts of *cis*-$[Pt(Me_2SO)_2Ph_2]$ complexes produced fast isomerisation of large amounts of a pure isomer (Table 2).

In turn, starting complex *cis*-$Pt(Me_2SO)_2Cl_2$, when treated with a stoichiometric amount of an isomerically pure ligand, quantitatively gave the three isomeric complexes [(*E*,*E*)-, (*E*,*Z*)-, (*Z*,*Z*)-Bz_2Et_2DTO)$PtCl_2$]. However, an excess of isomerically pure ligand, if present, isomerises at a similar rate of the spontaneous isomerisation process.

These findings supported the idea that chelation of a tertiary dithioxamide to a PtX_2 fragment lowered the energy of the barriers to rotation around CN and (S)C−C(S) bonds.

[a] $[D_7]$DMF. [b] The complexes **6** and **8** have already been published,[3] but the NMR-spectroscopic data are included for comparison. [c] Protons *trans* to the sulfur atom. [d] Protons *cis* to the sulfur atom. [e] C_6D_6. [f] Three overlapped ABX_3 systems, $^2J_{H,H}$, for protons *trans* to sulfur, not calculated. [g] $CDCl_3$. [h] Overlapped signals.

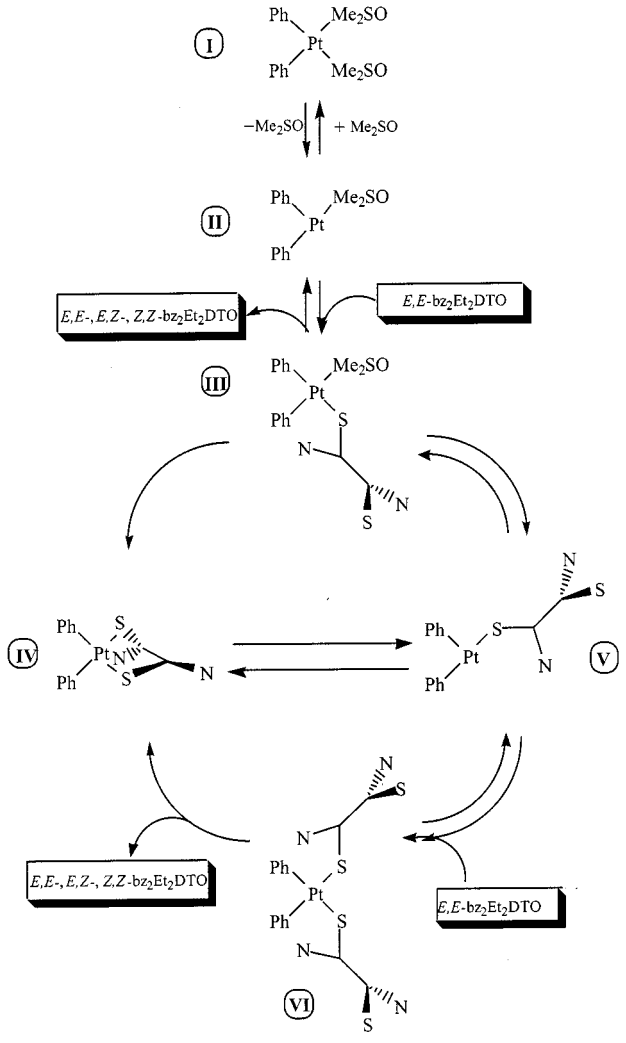
$$bz_2Et_2DTO + cis\text{-}[Pt(Me_2SO)_2Ph_2] \rightleftharpoons (EE\text{-},EZ\text{-},ZZ\text{-}\ bz_2Et_2DTO)PtPh_2 + 2Me_2SO$$

Scheme 2

We assumed that, when the dithioxamide molecule approached the platinum atom in the transition state, a transfer of electron density from the metal centre to the ligand was able to occur, and the ligand was consequently able, in the transition state, to approach the planar dithiolenic form, this obviously bringing about the collapse of both CN and central C−C barriers. The subsequent evolution of the transition state toward the products, or also toward the reagents, restored the dithioxamides, free or coordinated, in all the possible isomeric forms.

The organometallic complexes *cis*-$[Pt(Me_2SO)_2Ph_2]$ and $[Pt(R_4DTO)Ph_2]$, but not the classical Werner compounds *cis*-$[Pt(Me_2SO)_2Cl_2]$ and $[Pt(R_4DTO)Cl_2]$, were able to catalyse the isomerisation of isomerically pure ligand (Table 2). The difference in the behaviour of the two classes of compound can be attributed to the great *trans* influence of the phenyl groups in **I** (Scheme 3), which favours the dissociation of one sulfoxide molecule and gives rise to an intermediate of reduced coordination number. The chemistry of such kinds of intermediate is well understood.[17]

In the absence of external sulfoxide, the proposed intermediate **II** can be saturated by one sulfur "tooth" of an isomerically pure dithioxamide molecule; the subsequent ring-closure process to give the chelate **IV** requires the collapse of both C−C and C−N rotational barriers, as evidenced by the spectral analysis of **IV** (Table 3). Further dissociation of **IV** produces **V** as a three-coordinated intermediate, which takes a new isomerically pure molecule and



Scheme 3. Catalytic cycle for the isomerisation of (*E,E*)-Bz_2Et_2DTO ligand; the ligand input occurs in the steps II → III and V → VI, the output in the steps III → II and VI → IV

forms **VI** as a saturated intermediate. This, upon chelation, restores **IV** together with the equivalent quantity of (*E*,*E*)-, (*E*,*Z*)- and (*Z*,*Z*)-Bz_2Et_2DTO isomers. The alternative paths − **V** → **III** → **II** or **V** → **III** → **IV** − appear unlikely under the actual experimental conditions because of the exceedingly high [(*E*,*E*)-Bz_2Et_2DTO]/[Me_2SO] ratio. As evidence, the isomerisation rate of the (*E*,*E*) isomer when *cis*-[$Pt(Me_2SO)_2Ph_2$] was the catalyst ([DTO]/[Pt] = 30) was similar to that observed when [$Pt(Et_4DTO)Ph_2$] was used as catalyst ([DTO]/[Pt] = 30) and the sulfoxide path did not exist.

It is therefore possible to envisage a catalytic cycle in which the three-coordinate intermediates (**II** and **V** in Scheme 3) produce the input of isomerically pure dithioxamide, while the saturated intermediates (**VI** and **III**) produce the output of the isomerised mixture of ligands.

Studies on coordination of tetraalkyldithioxamides with various $Mo(CO)_{4-x}(PR_3)_x$ led tom Dieck to make the interesting assertion that dithioxamide links the metal atom as dithione−Mo^0 or dithiolene−Mo^{II}, depending on the electronic disposal at the metal centre.[18]

This proposal was supported by Wedd et al., who provided X-ray and NMR evidence for the dithiolenic coordination of Et_4DTO in *trans*-[$Mo(CO)_2(PR_3)_2$-(Et_4DTO)].[19]

These literature references support our hypothesis of a dithiolenic transition state as the key step in the isomerisation process of Bz_2Et_2DTO.

Unfortunately, the easy isomerisation of R_4DTO ligands as a consequence of their linkage with PtX_2 fragments indicates that the resolution of optically pure R_4DTO species through metal complexation is probably impracticable, in spite of the fact that the barrier around the pivot bond is of an energy high enough to allow, in principle, the separation of the two enantiomers.

Experimental Section

General Remarks: The precursors *cis*-$Pt(Me_2SO)_2Cl_2$,[20] *cis*-$Pt(Me_2SO)_2Br_2$,[20] *cis*-$Pt(Me_2SO)_2Ph_2$,[21] *cis*-$Pt(Me_2SO)_2Me_2$,[21] the ligands tetraethyldithioxamide (Et_4DTO) (**1**)[22] and tetrabenzyldithioxamide (Bz_4DTO) (**2**)[22] and the complexes [(Et_4DTO)$PtCl_2$] (**6**)[3] and [(Et_4DTO)$PtPh_2$] (**8**)[3] were prepared according to literature procedures. Solvents and other chemicals were of the highest purity grade commercially available and were used as purchased. ^1H and ^{13}C NMR spectra were recorded at 298 K unless stated otherwise, with a Bruker AMX-R 300 spectrometer at 300.13 and 75.47 MHz, respectively (δ in ppm relative to TMS, *J* in Hz). ^1H- and ^{13}C-NMR-spectroscopic data for the new ligands are given in Table 1 and for the complexes in Table 3. Compound **11** was not isolated in the solid state, and its characterisation was restricted to solution only.

Synthesis of (*E*,*E*)-*N*,*N*′-Dibenzyl-*N*,*N*′-diethyldithioxamide [(*E*,*E*)-Bz_2Et_2DTO, 3], (*E*,*Z*)-*N*,*N*′-Dibenzyl-*N*,*N*′-diethyldithioxamide [(*E*,*Z*)-Bz_2Et_2DTO, 4] and (*Z*,*Z*)-*N*,*N*′-Dibenzyl-*N*,*N*′-diethyldithioxamide [(*Z*,*Z*)-Bz_2Et_2DTO, 5]: Oxalyl chloride (6.346 g, 0.05 mol) and *N*-benzyl-*N*-ethylamine (27.042 g, 0.2 mol) were dissolved in benzene (120 mL). After the reaction mixture has stood overnight, diethylamine hydrochloride was filtered off, and benzene was distilled in vacuum from the filtrate to leave the crude *N*,*N*′-dibenzyl-*N*,*N*′-diethyloxamide as a mixture of (*E*,*E*), (*E*,*Z*) and (*Z*,*Z*) isomers. Phosphorus pentasulfide (3.825 g, 0.02 mmol) was added in small increments to a refluxing xylene solution (80 mL) of the crude oxamide. After the reaction mixture had been refluxed for 4 h, it was cooled and filtered from a black residue. Xylene was removed from the filtrate in vacuo, and a dithioxamide isomer mixture was obtained. This product was dissolved in ethanol (60 mL); the white, microcrystalline compound that remained undissolved provided the pure isomer **3**. The ethanolic filtrate, when allowed to stand, gave pure crystals of the isomer **4**. Finally, the pure isomer **5** was obtained when the solvent was removed from the ethanolic solution in vacuo.

Isomer 3: Yield 4.99 g (28%). $C_{20}H_{24}N_2S_2$ (356.55): calcd. C 67.37, H 6.78, N 7.86; found C 67.30, H 6.80, N 7.90.

Isomer 4: Yield 4.63 g (26%). $C_{20}H_{24}N_2S_2$ (356.55): calcd. C 67.37, H 6.78, N 7.86; found C 67.40, H 6.80, N 7.80.

Isomer 5: Yield 3.92 g (22%). $C_{20}H_{24}N_2S_2$ (356.55): calcd. C 67.37, H 6.78, N 7.86; found C 67.20, H 6.90, N 7.80.

Synthesis of [(Et_4DTO-κ-*S*,*S*′)$PtBr_2$] (7): Et_4DTO (0.232 g, 1 mmol) was added as solid to a stirred suspension of *cis*-$Pt(Me_2SO)_2Br_2$ (0.511 g, 1 mmol) in chloroform (60 mL) at ambient temperature. A deep red solution was obtained, and within a few minutes a red solid precipitated in high yield. The compound was washed with dichloromethane/diethyl ether (1:1) and dried in vacuo. Yield 0.499 g (85%). $C_{10}H_{20}Br_2N_2PtS_2$ (587.30): calcd. C 20.45, H 3.43, N 4.77; found C 20.40, H 3.50, N 4.70.

Synthesis of [(Bz_4DTO-κ-*S*,*S*′)$PtCl_2$] (9): The synthetic procedure was essentially the same as described above for **7**, from Bz_4DTO (0.481 g, 1 mmol), *cis*-$Pt(Me_2SO)_2Cl_2$ (0.422 g, 1 mmol) and chloroform (80 mL). The compound was obtained as red solid. Yield 0.597 g (80%). $C_{30}H_{28}Cl_2N_2PtS_2$ (746.69): calcd. C 48.26, H 3.78, N 3.75; found C 48.20, H 3.80, N 3.75.

Synthesis of [(Bz_4DTO-κ-*S*,*S*′)$Pt(C_6H_5)_2$] (10): Bz_4DTO (0.481 g, 1 mmol) and *cis*-[$Pt(Me_2SO)_2(C_6H_5)_2$] (505 mg, 1 mmol) were stirred in chloroform (60 mL). The resulting red solution was concentrated in vacuo (ca 20 mL), and hexane (40 mL) was then added. The compound precipitated as a red powder. Yield 0.564 g (68%). $C_{42}H_{38}N_2PtS_2$ (829.99): calcd. C 60.78, H 4.61, N 3.38; found C 60.40, H 6.70, N 3.30.

In situ Preparation of [(Bz_4DTO-κ-*S*,*S*′)$PtMe_2$] (11): Bz_4DTO (0.0252 g, 0.05 mmol) and *cis*-$Pt(Me_2SO)_2(CH_3)_2$ (0.0190 g, 0.05 mmol) were stirred in $CDCl_3$ (2 mL) for 1 h. The ^1H NMR spectrum of the solution was then recorded.

Synthesis of [Bz_2Et_2DTO-κ-*S*,*S*′)$PtCl_2$] (12) [Equimolar Mixture of the (*E*,*E*), (*E*,*Z*) and (*Z*,*Z*) Isomers]: The pure isomer (*E*,*E*)-Et_2Bz_2DTO (0.356 g, 1 mmol) and *cis*-$Pt(Me_2SO)_2Cl_2$ (0.422 g, 1 mmol) were stirred in chloroform (60 mL). The solution became red, and the compound, which was a mixture of three isomers, precipitated as deep red microcrystals. Yield 0.404 g (65%). $C_{20}H_{24}Cl_2N_2PtS_2$ (622.54): calcd. C 38.59, H 3.89, N 4.50; found C 38.40, H 3.90, N 4.40.

Synthesis of [(Bz_2Et_2DTO-κ-*S*.S′)$PtPh_2$] (13) [Equimolar Mixture of (*E*,*E*), (*E*,*Z*) and (*Z*,*Z*) Isomers]: *cis*-$Pt(Me_2SO)_2Ph_2$ (0.505 g,

1 mmol) and the pure isomer (*E*,*E*)-Bz_2Et_2DTO (1.068 g, 3 mmol) were stirred in chloroform (60 mL). The solution became red and the compound precipitated as red solid. Satisfactory analytical data were not obtained, due to the presence of the free ligand.

X-ray Data Collection and Structure Refinement of 4: Suitable crystals of compound **4** were obtained by slow concentration of a chloroform/ethanol (90:10, v/v) solution of **3**, which underwent spontaneous isomerisation during the crystallisation (see Discussion). Diffraction data were collected at room temperature with a Siemens P4 automatic four-circle diffractometer, by use of graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Lattice parameters were obtained from least-squares refinement of the setting angles of 40 reflections with $11° \leq 2\theta \leq 30°$. No sign of crystal deterioration was found during the data collection up to $2\theta = 50°$ with variable-speed 2θ-ω scan type. The intensities of the 2340 measurements were evaluated by a 2θ profile procedure[23] and then corrected for Lorentz dispersion effects. An absorption correction was applied by fitting a pseudo-ellipsoid to the azimuthal scan data of 12 high c reflections[24] (R_{int} = 0.9%). The systematic absences unambiguously indicated the space group $P2_12_12_1$ of the orthorhombic system [a = 7.978(2), b = 12.777(2), c = 19.075(3) Å, Z = 4, D_c = 1.218 g/cm^3, μ = 22.77 cm^{-1}]. The structure was solved by Direct Methods with the SHELXTL-PLUS system[25] (also used to perform data reduction) and subsequently completed by a combination of least-squares techniques and Fourier syntheses. Whereas several hydrogen atoms were located on the final ΔF map, the H atoms were included in the refinement according to the "riding model" method with the X−H bond geometry depending on the parent atom X and with a unique common fixed isotropic displacement parameter (0.070 Å^2). The refinement, with all non-hydrogen atoms anisotropic and the function $w(F_o^2 - F_c^2)^2$ minimised for all the 2229 unique reflections, was carried out by the full-matrix, least-squares technique, based on F^2, with SHELXL93.[26] The model converged to the final residual $R(F_o) = [\Sigma||F_o| - |F_c||]/\Sigma|F_o| = 0.0279$, $wR(F_o^2) = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2} = 0.0525$ and $GoF = [\Sigma w(|F_o| - |F_c|)^2/(N_{obsd.} - N_{var})]^{1/2} = 1.022$ with the final weighting scheme $w = \exp(\sin\theta/l)^2/[\sigma^2(F_o)^2 + \{0.0090 \times [\max(F_o^2,0) + 2F_c^2]\}^2]$ for 1546 reflections with $F \geq 4\sigma(F)$. A parameter for extinction correction was included in the last refinement cycles and assumed the final value $53(8)\cdot10^{-4}$. In the last difference Fourier map, the density residuals were not significant [range −0.11, 0.09 eÅ^{-3}]. The enantiomorph parameter[15] was included in the last refinement cycles of the structure model, and quickly converged to 0.55(9). Neutral atom scattering factors and anomalous dispersion correction were from ref.[27] Final geometrical calculations and drawings were carried out with the PARST program[28] and the XP utility of the Siemens package, respectively. CCDC-170711 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Aluminum / N ligands / Pyrazolato ligands / Structural elucidation

The chelating aluminum complex [{3,5-N-*t*Bu$_2$pz-N′–CH=C(SiMe$_3$)}AlR$_1$R$_2$] [R^1 = R^2 = Me (**2**); R^1 = R^2 = H (**3**); R^1 = R^2 = I (**4**)] was prepared in modest yield from an organoaluminum dichloride precursor [{3,5-N-*t*Bu$_2$pz-N′–CH=C(SiMe$_3$)}AlCl$_2$] (**1**). Compounds **2** and **3** were obtained from the reaction of **1** with MeLi in Et$_2$O or with LiAlH$_4$ in THF, respectively. Reaction of **2** or **3** with I$_2$ in toluene gave **4**. In addition, the reaction of **1** with two equivalents of water yielded the hydrolyzed product H[3,5-N-*t*Bu$_2$pz-N′–CH=C(SiMe$_3$)] (**5**). All compounds were characterized by elemental analysis, NMR spectroscopy, and mass spectrometry. The X-ray structure analysis shows that complex **2** exhibits one fused five-membered AlC$_2$N$_2$ ring and one pyrazolato ring system.

Introduction

Organoaluminum compounds have been explored widely owing to their importance in a variety of applications.[1] The chemistry of sterically hindered neutral derivatives of organoaluminum halides, hydrides and alkyls is especially important as they are key starting materials for a variety of compounds with unusual bonding and oxidation states, as well as unique structures.[2] Recent progress in aluminum chemistry has shown that aluminum halides with a bulky ligand may be used as precursors for synthesizing low-valent Al^{I} species.[3] Additionally, the reaction of aluminum alkyls with extremely strong Lewis acids such as B(C$_6$F$_5$)$_3$ leads to the formation of low-coordinate cationic compounds that are potential catalysts for olefin polymerization.[4] Furthermore, organoaluminum hydrides have been shown to be ideal starting materials for preparing various unusual compounds that were difficult to synthesize by other routes.[5,6] Obviously, the sterically demanding ligands play a crucial role during the formation of these compounds. In the course of the reaction of aluminum pyrazolato compounds and trimethylsilylacetylene, an unusual compound [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}AlCl$_2$] (**1**) was formed. It has been shown that the Al−Cl bonds in **1** are readily cleaved and can be substituted by other functional groups.[7] Apparently, the chelating [3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)]$^-$ ligand in compound **1** is more sterically demanding than the simple 3,5-di-*tert*-butylpyrazole. Due to the interest in precursors of sterically demanding aluminum halides, alkyls and hydrides, reactions using **1** as a starting material have been examined.

Results and Discussion

A solution of **1** and two equivalents of MeLi in Et$_2$O was stirred at −78 °C for 3 h and then at ambient temperature for 15 h to give [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}AlMe$_2$] (**2**) in fair yield (ca. 70%; Scheme 1).[8] Compound **2** is extremely soluble in *n*-hexane and it can be purified in two steps. First, the resulting residue was sublimed at 0.01 mbar and 100 °C and then recrystallized from *n*-hexane at −26 °C to afford colorless crystals. The mass spectrum (EI) shows **2** to be monomeric {*m*/*z* (%) = 334 (10) [M$^+$], 319 (100) [M$^+$ − Me]}. The ^{1}H NMR spectrum shows a set of resonances for the chelating moiety {δ = 0.37 [Si(C*H*$_3$)$_3$], 1.00 [C(3)−C(C*H*$_3$)$_3$], 1.28 [C(1)−C(C*H*$_3$)$_3$], 5.86 [C(2)*H*], 7.63 [=C(4)*H*]} and one signal for the protons of the Al−Me groups at δ = −0.15, clearly indicating the formation of **2**. However, the ^{27}Al NMR resonance is too broad to be distinguished.

The crystallographic data of **2** are listed in Table 1. It crystallizes in the monoclinic crystal system, space group *C*2/*c* (Figure 1). The similar cell parameters of [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}AlMe$_2$] (**2**) and [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}AlCl$_2$] (**1**) indicate a structural relationship between these two compounds.[7] As in

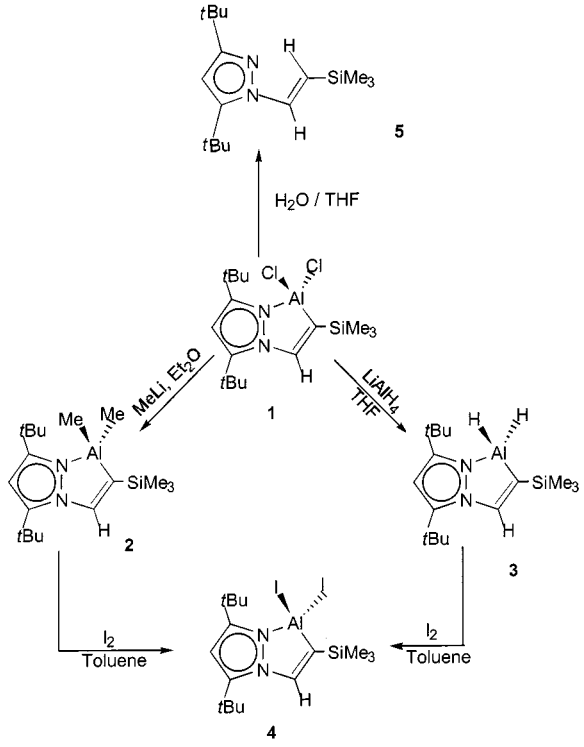

Scheme 1. Synthesis of compounds **2**–**5**

compound **1**, the geometry at the aluminum atom is a distorted tetrahedron [N1–Al1–C5 = 84.90(9)° and C21–Al1–C22 = 115.24(11)°] due to the strain imposed by the chelate ring. The fused five-membered AlC_2N_2 ring and the pyrazolato moiety are approximately coplanar. The C=C bond length of the inserted trimethylsilylacetylene molecule is significantly increased [C4–C5 = 1.328(3) Å] but is slightly shorter than the C=C double bonds of the σ complex of $AlCl_3$ with tetramethylcyclobutadiene [1.387(3) Å][9] and 1,4-dichloro-2,3,5,6-tetramethyl-1,4-dialumina-2,5-cyclohexadiene [1.367(3) Å].[10] The terminal Al(1)–C bond lengths [1.971(2) Å] are similar to those in [(η^1,η^1-3,5-*t*Bu_2pz)(μ-$AlMe_2$)]$_2$ [Al–C = 1.962(2) Å].[11]

Treatment of **1** with 2.1 equivalents of $LiAlH_4$ in THF at −30 °C yielded [{3,5-N-*t*Bu_2pz-N′–CH=C($SiMe_3$)}-AlH_2]·$(THF)_2$ [**3**·$(THF)_2$] as a white solid (Scheme 1) that is only slightly soluble in common organic solvents, except THF. Compound **3**·$(THF)_2$ is sensitive to oxygen and water. The mass spectrum (EI) suggests that **3**·$(THF)_2$ is a monomer {*m*/*z* (%) = 306 (100) [M^+]}, probably because of the sterically demanding chelating ligand [3,5-N-*t*Bu_2pz-N′–CH=C($SiMe_3$)]$^-$. The THF molecules of **3**·$(THF)_2$ can be removed by heating at 50 °C under high vacuum for 15 hours to give **3** {δ = 0.14, 1.410, 1.415, 3.80 (br.), 6.21 and 7.60 in [D_8]THF}. The ^{1}H NMR spectrum ([D_8]THF) reveals a set of resonances for the chelating moiety and a broad Al–H signal (δ = 3.80, $W_{1/2}$ = 85 Hz). The ^{27}Al NMR spectrum shows one signal at δ = 106.4, implying a coordination number of four at the Al atom. The two resonances of the protons of the nonequivalent *t*Bu groups are close to each other (δ = 1.410 and 1.415). The IR spectrum exhibits two strong bands in the expected range for Al–H stretching bands (1780 and 1812 cm^{-1}) implying terminal Al–H bonds in the solid state.[12] However, whether the THF molecules in **3**·$(THF)_2$ coordinate directly to the aluminum center or are incorporated in the crystal lattice is currently unknown.

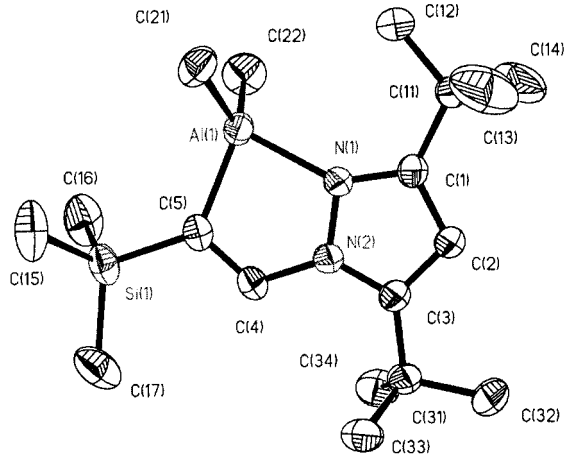

Figure 1. Perspective view of compound **2**, showing the numbering scheme and the thermal ellipsoids at the 50% probability level: Al(1)–C(5) 1.993(3), Al(1)–C(21) 1.971(2), Al(1)–C(22) 1.971(3), Al(1)–N(1) 2.016(3), C(4)–C(5) 1.328(3) Å; C(5)–Al(1)–N(1) 84.90(9)°, C(21)–Al(1)–C(22) 115.24(11)°

The reaction of **2** with two equivalents of I_2 in toluene afforded the compound [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}AlI$_2$] (**4**) after refluxing for 24 h (Scheme 1).[13] Compound **4** is readily soluble in toluene but only slightly soluble in *n*-hexane and can be readily purified by crystallization from toluene at −26 °C to give small pale crystals. The mass spectrum is in good agreement with the formulation of **4** as a monomer {*m*/*z* (%) = 558 (4) [M$^+$], 553 (15) [M$^+$ − Me], 431 (100) [M$^+$ − I]}. The ^{1}H NMR spectrum shows one set of resonances for the chelating moiety [3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)]$^-$ (δ = 0.42, 082, 1.43, 5.81 and 7.36 in C_6D_6), indicating the formation of **4**. Alternatively, **4** can also be prepared by the reaction of **3** and two equivalents of I_2 under mild conditions (room temp.). The reaction of **3** with I_2 gives higher yields than that with **2**.[14] It is essential that the THF molecules in the precursor **3**·(THF)$_2$ are removed prior to the reaction of **3** with I_2 as otherwise the product is difficult to separate from the oily residue.

The reaction of [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}-AlCl$_2$] (**1**) with two equivalents of water in THF led to the formation of the free ligand [3,5-N-*t*Bu$_2$pz-N′−CH=CH(SiMe$_3$)] (**5**) (Scheme 1), which could be purified by sublimation at 90 °C under high vacuum (0.01 mbar). Compound **5** is soluble in both aliphatic and aromatic solvents at ambient temperature. The mass spectrum (EI) {*m*/*z* (%) = 278 (20) [M$^+$], 263 (100) [M$^+$ − Me]} and elemental analysis are in accordance with a monomeric formula for **5**. The ^{1}H NMR spectrum in C_6D_6 shows two doublets at δ = 6.77 and 7.48 (^2J = 16.3 Hz) for the two hydrogen atoms of the inserted TMS(H$_a$)C=(H$_b$) group. No proton resonance was observed in the range δ = 10−12 [the resonance of an N$_{(pyrazole)}$−H proton is usually found between δ = 10 and12 in C_6D_6],[15] confirming that the added H$_a$ atom is found in a terminal position at the TMS(H$_a$)C= group. Unfortunately, no lithium salt of **5** could be isolated from our attempts to deprotonate **5** with *t*BuLi at −78 °C or at ambient temperature. The reason why compound **5** is resistant to deprotonation is as yet unclear.

Conclusion

In summary, this paper reports the preparation of three aluminum complexes **2**−**4**, with an unusual chelating ligand containing a bulky 3,5-di-*tert*-butylpyrazolato unit, and the formation of ligand **5**, all from the readily accessible aluminum dichloride complex **1**. We have also shown that the Al−Cl bonds of **1** can be easily substituted partly[7] or completely by various basic substituents under different conditions, while the metallaheterocycle in these compounds seems to be rather stable. We are interested in a variety of aluminum complexes that have unique binding modes due to their potential applications as catalysts.[2] Compounds **1**−**4** are therefore ideal starting materials for further studies.

Experimental Section

General: All reactions were performed using standard Schlenk and dry box techniques. Solvents were appropriately dried and distilled under dinitrogen prior to use. All NMR spectra were obtained in 5-mm tubes with dry degassed [D$_6$]benzene as solvent (except for **3**, which was measured in [D$_8$]THF), referenced to external SiMe$_4$. Elemental analyses were performed by the Analytisch-Chemisches Laboratorium des Instituts für Anorganische Chemie, Göttingen.

Compound **1** was prepared according to the published method.[7]

Synthesis of [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}AlMe$_2$] (2): MeLi (4 mL, 4 mmol) in Et$_2$O (20 mL) was added slowly at −78 °C to a suspension of **1** (0.74 g, 2.0 mmol) in Et$_2$O (40 mL). The solution was allowed to warm to room temperature and then stirred for 15 h. The solvent was removed and the resulting residue sublimed at 100 °C under high vacuum (0.01 mbar) to give a white powder mainly consisting of **2**. Pure **2** was obtained by recrystallization from *n*-hexane at −26 °C (ca. 0.46 g, 70%). Crystals suitable for X-ray diffraction analysis were obtained from *n*-hexane at 4 °C. M.p. 157 °C. ^{1}H NMR (200.130 MHz, C_6D_6): δ = −0.15 (s, 6 H, Al−C*H*$_3$), 0.37 [s, 9 H, Si(C*H*$_3$)$_3$], 1.00 [s, 9 H, C(3)−C(C*H*$_3$)$_3$], 1.28 [s, 9 H, C(1)−C(C*H*$_3$)$_3$], 5.86 [s, 1 H, C(2)*H*], 7.63 [s, 1 H, =C(4)*H*]. ^{13}C NMR (125.758 MHz, C_6D_6): δ = −7.1 [br, Al-*C*(5)=], −0.9 (Al−*C*H$_3$), −0.01 [Si−*C*(16)], 29.7 [*C*(12,13,14)], 30.6 [*C*(11)], 31.4 [*C*(32,33,34)], 32.6 [*C*(31)], 103.2 [*C*(4)], 132.7 [*C*(2)], 150.7 [*C*(1)], 161.9 [*C*(3)]. MS (EI): *m*/*z* (%) = 334 (10) [M$^+$], 319 (100) [M$^+$ − Me]. $C_{18}H_{35}AlN_2Si$ (334.55): calcd. C 64.62, H 10.54, N 8.37; found C 64.3, H 10.1, N 8.2.

Synthesis of [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}AlH$_2$] (3): A solution of **1** (0.74 g, 2.0 mmol) in THF (20 mL) was added slowly at −30 °C to a suspension of LiAlH$_4$ (0.16 g, 4.2 mmol) in THF (30 mL). The suspension was stirred for an additional 15 h at room temperature and then filtered through celite. The solution was concentrated to ca. 8 mL and **3**·(THF)$_2$ crystallized as a white crystalline solid at −26 °C. After the removal of THF molecules of **3**·(THF)$_2$ at 50 °C under high vacuum for 15 h, **3** was obtained as a white powder (0.35 g, 57%). M.p.: 134 °C. ^{1}H NMR (200.130 MHz, [D$_8$]THF): δ = 0.14 [s, 9 H, Si−(C*H*$_3$)$_3$], 1.410 [s, 9 H, C(3)−C(C*H*$_3$)$_3$], 1.415 [s, 9 H, C(1)−C(C*H*$_3$)$_3$], 3.80 (br, s, 2 H, Al−*H*), 6.21 [s, 1 H, C(2)*H*], 7.60 [s, 1 H, =C(4)*H*]. ^{13}C NMR (125.758 MHz, [D$_8$]THF): δ = −0.01 [Si−*C*(16)], 29.9 [*C*(12,13,14)], 30.2 [*C*(11)], 32.4 [*C*(32,33,34)], 32.8 [*C*(31)], 104.2 [*C*(4)], 135.1 [*C*(2)], 143.6 (br, Al−*C*=), 152.0 [*C*(1)], 162.3 [*C*(3)]. ^{27}Al NMR (65.170 MHz, [D$_8$]THF): δ = 106.4. ^{29}Si NMR (99.362 MHz, [D$_8$]THF): δ = −6.2. MS (EI): *m*/*z* (%) = 306 (100) [M$^+$], 291 (70) [M$^+$ − Me]. IR (KBr, nujol mull): ν_{Al-H} = 1780 (ms), 1812 (ms) cm^{-1}. $C_{16}H_{31}AlN_2Si$ (306.50): calcd. C 62.70, H 10.19, N 9.14; found C 61.8, H 9.9, N 9.0

Synthesis of [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}AlI$_2$] (4). Method 1: A solution of I_2 (1.00 g, 4.0 mmol) in toluene (40 mL) was added slowly at room temperature to a solution of **2** (0.66 g, 2.0 mmol) in toluene (20 mL). The solution was stirred for 15 h at room temperature and then refluxed for 12 h. The solution was filtered through celite and then concentrated to ca. 10 mL to give small colorless crystals at −26 °C (0.82 g, 73%).

Method 2: A solution of I_2 (1.00 g, 4.0 mmol) in toluene (40 mL) was added slowly to a suspension of **3** (0.61 g, 2.0 mmol) in toluene (20 mL) and then stirred for 12 h at room temperature until the brown color disappeared. The solution was filtered through celite and the filtrate was concentrated to about 10 mL. Compound **4** crystallized as a pale solid at −26 °C (0.49 g, 43%). M.p.: 192 °C.

^{1}H NMR (200.130 MHz, C_6D_6): δ = 0.42 [s, 9 H, Si(CH_3)$_3$], 0.82 [s, 9 H, C(3)−C(CH_3)$_3$], 1.43 [s, 9 H, C(1)−C(CH_3)$_3$], 5.81 [s, 1 H, C(2)*H*], 7.36 [s, 1 H, =C(4)*H*]. ^{13}C NMR (125.758 MHz, C_6D_6): δ = 0.09 [Si−*C*(16)], 29.4 [*C*(12,13,14)], 31.39 [C(11)], 31.44 [*C*(32,33,34)], 33.3 [C(31)], 105.0 [*C*(4)], ca. 128 (br, Al−C=, overlapped by C_6D_6 signals), 134.7 [*C*(2)], 153.5 [*C*(1)], 165.3 [*C*(3)]. ^{29}Si NMR (99.362 MHz, C_6D_6): δ = −6.4. MS (EI): *m*/*z* (%) = 558 (4) [M^+], 543 (15) [M^+ − Me] , 431 (100) [M^+ − I]. $C_{16}H_{29}AlI_2N_2Si$ (558.29): calcd. C 34.42, H 5.24, N 5.02; found C 33.8, H 5.1, N 5.2.

Synthesis of [{3,5-N-*t*Bu$_2$pz-N′−CH=C(SiMe$_3$)}H] (5): 0.036 mL of a solution of water (2.0 mmol) in THF (10 mL) was added slowly to a solution of compound **1** (0.75 g, 2.0 mmol) in THF (30 mL) at room temperature. After stirring for 15 h at room temperature, the solvent was removed in vacuo. The resulting residue was sublimed at 90 °C under high vacuum (0.01 mbar) to afford the colorless solid **5** (0.39 g, 70%). M.p.: 173 °C. ^{1}H NMR (200.130 MHz, C_6D_6): δ = 0.12 [s, 9 H, Si(CH_3)$_3$], 1.17 [s, 9 H, C(3)−C(CH_3)$_3$], 1.44 [s, 9 H, C(1)−C(CH_3)$_3$], 6.01 [s, 1 H, C(2)*H*], 6.77 [d, $^2J_{H,H}$ = 16.3 Hz, 1 H, C(5)*H*], 7.48 [d, $^2J_{H,H}$ = 16.3 Hz, 1 H, =C(4)*H*]. ^{13}C NMR (125.758 MHz, C_6D_6): δ = −1.3 [Si−*C*(16)], 30.0 [*C*(12,13,14)], 30.3 [*C*(11)], 30.9 [*C*(32,33,34)], 33.1 [*C*(31)], 101.2 [*C*(4)], 111.2 [*C*(5)], 135.7 [*C*(2)], 150.8 [*C*(1)], 161.4 [*C*(3)]. MS (EI): *m*/*z* (%) = 278 (20) [M^+], 263 (100) [M^+ − Me]. $C_{16}H_{30}N_2Si$ (278.51): calcd. C 69.00, H 10.86, N 10.06; found C 70.4, H 11.0, N 10.3.

X-ray Crystallography: Crystals of **2** (*M* = 334.55) were grown from a concentrated *n*-hexane solution cooled to 4 °C. **2** crystallized in the monoclinic crystal system with space group *C*2/*c*. Relevant details and data are summarized in Table 1. The crystals were mounted on a glass fiber in a rapidly cooled perfluoropolyether.[16] Diffraction data were collected on a Stoe−Siemens four-circle diffractometer coupled to a Siemens CCD area detector at 200(2) K, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods using SHELXS-96[17] and refined against F^2 on all data by full-matrix least-squares with SHELXS-97.[18] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included in the model at their geometrically calculated positions and refined using a riding model. CCDC-170473 (**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Pyrrolylaldiminato Complexes of Zn, Mg and Al

Haijun Hao,[a] Sonali Bhandari,[a] Yuqiang Ding,[a] Herbert W. Roesky,*[a] Jörg Magull,[a] Hans-Georg Schmidt,[a] Mathias Noltemeyer,[a] and Chunming Cui[a]

Dedicated to Professor Rüdiger Mews on the occasion of his 60th birthday

Keywords: Zinc / Magnesium / Aluminum / N ligands

The reaction of 2-(2,6-*i*$Pr_2C_6H_3N$=CH)-5-R-C_4H_2NH (R = H, L^1H; R = *t*Bu, L^2H) with one equivalent of $ZnMe_2$ or Mg*n*Bu_2 in toluene or *n*-hexane afforded the bis(pyrrolylaldiminato) complexes ZnL^1_2 (**1**), ZnL^2_2 (**2**) and MgL^2_2 (**3**). Crystalline MgL^1_2·THF (**4**·THF) was formed by treatment of LiL^1 with MeMgCl in THF followed by recrystallization from *n*-hexane. L^1AlMe_2 (**6**) and L^2AlMe_2 (**7**) were readily prepared by refluxing L^1H and L^2H with $AlMe_3$ in toluene or *n*-hexane for several hours. However, the reaction of LiL^1 with $AlCl_3$ in a 1:1 molar ratio provided L^1_2AlCl (**8**), while the reaction of KL^2 with $AlCl_3$ afforded L^2AlCl_2 (**9**). Compounds **2**, **3**, **5**, and **8** were characterized by a single-crystal X-ray structural analysis. Compounds **2**, **3**, and **5** all have a tetrahedral geometry around the metal atom, while the five-coordinate aluminum in **8** has a trigonal bipyramidal geometry.

Introduction

There are only a few reports on pyrrolylaldiminato complexes.[1,2] Bischelating pyrrolylaldiminato ligands with bulky substituents have not drawn as much attention as salicylaldiminato ligands, which have been shown to be excellent ligands for zirconium and nickel complexes that act as olefin polymerization catalysts.[3,4] Very recently, salicylaldiminato zinc compounds have been reported to be active for the copolymerization of CO_2 and epoxides.[5]

Both pyrrolylaldiminato and salicylaldiminato ligands are easily prepared and have similar steric demands; their steric and electronic properties may be varied by simply changing the substituents. The chelating pyrrolylaldiminato ligand forms five-membered ring systems with metal ions, whereas salicylaldiminato complexes tend to form six-membered rings (Scheme 1).

Here we present the synthesis and structures of divalent Zn, Mg and trivalent Al compounds ligated by the pyrrolylaldiminato ligands [2-(2,6-*i*$Pr_2C_6H_3N$=CH)-C_4H_3N]$^-$ (L^1) and [2-(2,6-*i*$Pr_2C_6H_3N$=CH)-5-*t*Bu-C_4H_2N]$^-$ (L^2).

Results and Discussion

Synthesis and Spectroscopic Characterization of Compounds 1−9

Initially we attempted to prepare monoalkyl zinc and magnesium compounds, since there are plenty of monoalkyl zinc or magnesium compounds known that contain much less bulky amide groups,[6] and which are important precursors for various transformations.[5,7] However, the reaction of L^1H or L^2H with one equivalent of $ZnMe_2$ or Mg*n*Bu_2 in toluene or *n*-hexane resulted in the formation of the bis(pyrrolylaldiminato) compounds **1**−**3** (Scheme 2).

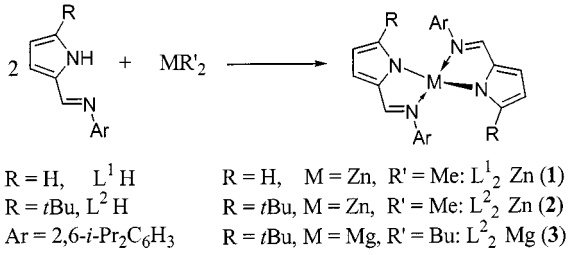
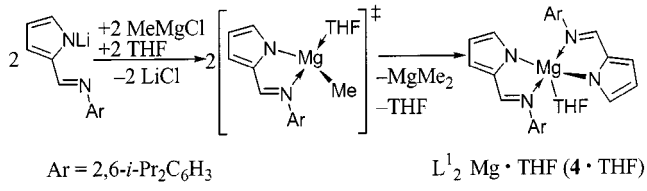
Darensbourg et al. have reported the preparation of mono(salicylaldiminato)methyl zinc compounds;[5] under similar conditions we were not able to isolate any mono(pyrrolylaldiminato) species. We attributed this failure to prepare methylzinc or -magnesium species to the stronger acidity of the pyrrole proton relative to that of the amine hydrogen, and the enhanced basicity of methyl in the monoalkyl intermediate relative to that in MR_2.[8–10] Attempts to prepare the methylmagnesium compounds from the reaction of LiL^1 with MeMgCl afforded the compound MgL^1_2·THF (**4**·THF), which is presumably derived from the dismutation of transient $[L^1MgMe]^‡$ to **4**·THF and $MgMe_2$ (Scheme 3), even though we were not able to isolate $MgMe_2$ from this reaction. Furthermore, compounds **1**–**4** do not react with $ZnMe_2$ or $MgMe_2$ in conventional solvents such as toluene or diethyl ether.



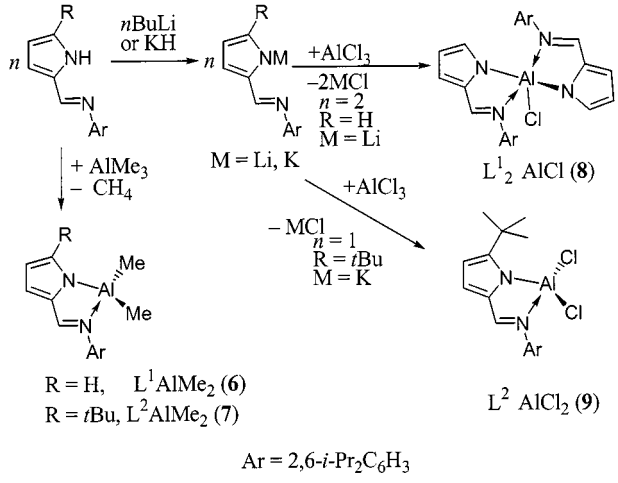
Scheme 2



Scheme 3

The reaction of KL^2 with MeMgCl, after workup and keeping the solution at room temperature for 24 h, provided a small amount of fine colorless crystals. Although the amount of product isolated was too low to calculate the yield, it was sufficient for microanalysis. The EI-MS, ^1H NMR spectrum and X-ray structural analysis revealed that this compound is the methoxy-bridged dimer $(L^2Mg)_2(\mu\text{-}OMe)_2$ (**5**). The reaction was repeated twice. In the ^1H NMR spectrum, the hydrogen resonance of the methoxy group appears at $\delta = 3.58$ as a singlet. The elemental analysis is also in good agreement with this formula. Since we were not able to detect any mono(pyrrolylaldiminato)methylmagnesium in the products, we suppose that this compound is derived from the inadvertent presence of MeOMgCl in the Grignard reagent, or perhaps from small amounts of water present in the solvents. Exposure of **5** to air resulted in an unidentifiable amorphous powder. Due to the potential uses of mono(alkyloxy)magnesium species as catalysts for the ring-opening polymerization of lactides,[11] we tried to prepare **5** in high yield from the reaction of $MgMe_2$ with one equivalent of methanol, followed by reaction with L^2H. This led to a mixture containing L^2H, **3**, and **5** as indicated by EI-MS. Attempts to synthesize **5** from a one-pot reaction of MeMgCl with one equivalent of methanol followed by reaction with LiL^2, or from the metathesis reaction of **3** with $Mg(OMe)_2$, were also unsuccessful.

The reaction of L^1H and L^2H with $AlMe_3$ provided the corresponding dimethylaluminum complexes **6** and **7**, which apparently have a four-coordinate tetrahedral geometry around the Al atoms (Scheme 4), while the reaction of LiL^1 with one equivalent of $AlCl_3$ in THF provided the five-coordinate L^1_2AlCl (**8**) instead of the expected mono(pyrrolylaldiminato) aluminum dichloride L^1AlCl_2. However, treatment of KL^2 with $AlCl_3$ in diethyl ether followed by evaporation resulted in a brown-purple product. After extraction with toluene and recrystallization from diethyl ether, pale yellowish microcrystals were isolated in relatively low yield; they were subsequently characterized as L^2AlCl_2 (**9**). The reaction of **6** or **7** with bromine or iodine led to unidentifiable products.



Scheme 4

Compounds **1**–**9** were fully characterized by EI-MS, ^1H NMR spectroscopy and elemental analysis. The EI-MS showed the molecular ion peaks in all cases. In the ^1H NMR spectra, the resonances for the methyl groups of the isopropyl substituents in **2**, **3**, and **8** appeared as four distinguishable doublets, while for the remaining compounds only two doublets were observed. These observations indicate that in **2**, **3**, and **8** the metals have more congested environments than the others in the series due to the *t*Bu substituents in **2** and **3** and the higher coordination number in **8**. Similar to the salicylaldiminato zinc complexes,[12] compounds **1**–**3** are chiral complexes with only C_2 symmetry; the other enantiomer is also formed in the product. Since the molecules have only C_2 symmetry, the isopropyl methyl groups of **1** display two sets of doublets even when rotation about the $N-C_{(phenyl)}$ bond is rapid at room temperature. In compounds **2** and **3**, the methyl groups of the isopropyl substituents display four sets of doublets due to the steric influence of the *t*Bu group causing a slow rotation about

the $N-C_{(phenyl)}$ bond on the NMR timescale. The ^1H NMR spectrum of the ligand in **4** resembles that of **1**, indicating that the coordinated THF has no observable influence on the rotation about the $N-C_{(phenyl)}$ bond at room temperature.

X-ray Single Crystal Analysis for 2, 3, 5, and 8

Compounds **2** and **3** crystallize in a triclinic system, space group $P\bar{1}$. Their structures exhibit a distorted tetrahedral geometry around the metal center with four nitrogen atoms arranged at the vertices (Figure 1 and 2, respectively). In compound **2** the $Zn-N_{(pyrrole)}$ (av. 2.00 Å) and $Zn-N_{(imine)}$ (av. 2.06 Å) bonds are shorter than the Mg−N bonds in **3** (av. 2.05 Å and 2.11 Å, respectively) leading to a slightly wider angle formed by the bischelating nitrogens and the metal atom (av. 85.56° in **2** vs. av. 84.72° in **3**). The $Zn-N_{(imine)}$ bond lengths are similar to those in bis(salicylaldiminato) zinc complexes (range 1.99−2.00 Å), while the $Zn-N_{(pyrrole)}$ bond lengths (av. 2.00 Å) are slightly longer than the Zn−O bond lengths (range 1.91−1.95 Å) in bis(salicylaldiminato) zinc complexes.[5]

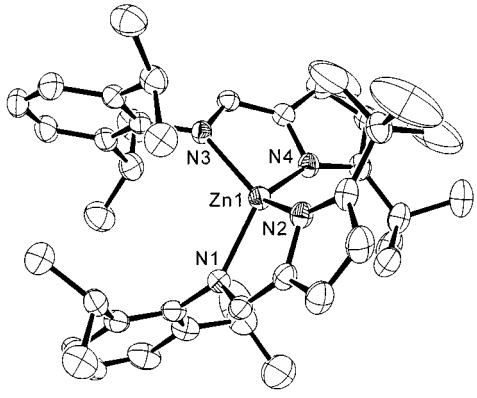


Figure 1. Molecular structure of **2** (hydrogen atoms are omitted for clarity)

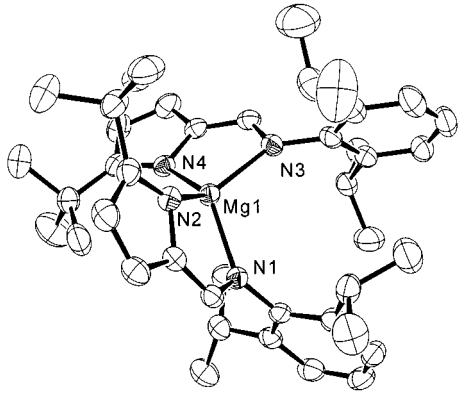

Figure 2. Molecular structure of **3** (hydrogen atoms are omitted for clarity)

Compound **5** is a centrosymmetric dimer with each magnesium atom having a tetrahedral geometry (Figure 3). The magnesium and oxygen atoms form a four-membered coplanar ring and there is a C_2 axis passing through the two Me−O bonds. The Mg−O−Mg−O ring is perpendicular to the Mg1−N1−N2 plane. The Mg−N bond lengths [Mg1−N2: 2.043(2) Å; Mg1−N1: 2.100(2) Å] are similar to those in **3**. The Mg−O bond lengths (av. 1.94 Å) are nearly the same as those in $[Mg(\mu\text{-}OMe)\{\eta^2\text{-}(i\text{Pr}_2)ATI\}]_2$ (av. 1.94 Å, ATI = *N*,*N*′-diisopropylaminotroponiminate).[13]

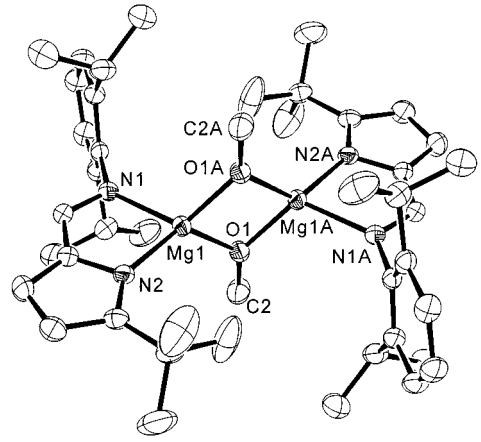

Figure 3. Molecular structure of **5** (hydrogen atoms are omitted for clarity)

The molecular structure of **8** (Figure 4) is best described as a distorted trigonal bipyramidal geometry around the aluminum atom with the N2 and N2A atoms located at the top of the vertex [N2−Al1−N2A: 165.16(8)°], and the chlorine atom, N1 and N1A atoms arranged at the equatorial positions (the Al1, Cl1, N1 and N1A atoms are essentially coplanar). There is a C_2 axis passing through the Al−Cl bond. The average $Al-N_{(imino)}$ bond length is 1.993 Å, slightly longer than those found in salicylaldiminato aluminum complexes (range 1.94−1.98 Å).[14,15] The $Al-N_{(pyrrole)}$ bond length (av. 1.96 Å) is slightly longer than that (av. 1.90 Å) in the recently reported compound $AlCl_2\{C_4H_3N(CH_2NMe_2)\text{-}2\}$ (**A**),[16] while the Al−Cl bond length [2.1582(8) Å] is slightly shorter than that in **A**. This can be attributed to a partial conjugation between the imine C and N atoms and the aromatic pyrrole ring.

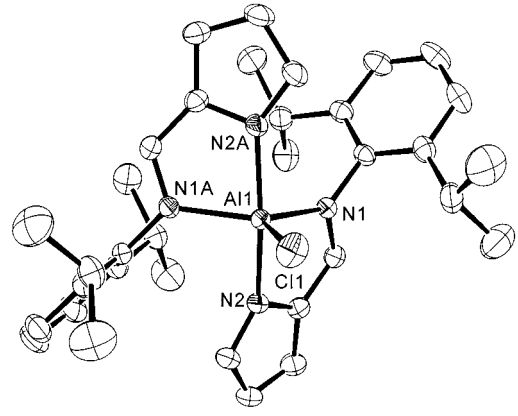

Figure 4. Molecular structure of **8** (hydrogen atoms are omitted for clarity)

The N−M−N angles associated with the bite of the pyrrolylaldiminato ligand in **2**, **5** and **8** (range 84−86° for Zn, 81.57(5)° for Al), are evidently more acute than the corresponding O−M−N angles in salicylaldiminato zinc[12] and aluminum[14,15] compounds (range 95−100° for Zn and 93−98° for Al). The M−N bond lengths (av. 2.00 Å for Zn in **2**, av. 1.96 Å for Al in **8**) are longer than the M−O distances (range 1.87−1.96 Å for Zn,[5,12] and 1.75−1.78 Å for Al[14,15] in salicylaldiminato complexes).

Conclusion

In summary, we have synthesized a series of pyrrolylaldiminato compounds of Zn, Mg, and Al. The structural investigations illustrate that the substituents at the 5-position of the pyrrole significantly enhance the steric demand. The variability of the steric properties of pyrrolylaldiminato ligands enhances the potential of these systems for catalytic processes.

Experimental Section

General Remarks: All experiments were carried out under an atmosphere of dry dinitrogen using standard Schlenk techniques. All solvents were dried by common methods and freshly distilled prior to use. Aluminum trichloride, trimethyl aluminum, di-*n*-butylmagnesium, methylmagnesium chloride and bromide, and dimethylzinc were purchased commercially. LiL^1 and LiL^2 were prepared according to the literature method.[1] KL^2 was prepared by the reaction of L^2H with KH in THF followed by filtration, evaporation in vacuo, and washing with *n*-hexane, and was used without further characterization. ^1H NMR spectra were recorded on Bruker AS-250 or Bruker AM-200 spectrometers. IR spectra were recorded on a Bio-Rad FTS-7 spectrometer as nujol mulls between KBr plates. EI-mass spectra were obtained on a Finnigan MAT8230 or a Varian MAT CH5 spectrometer.

ZnL^1_2 (1): A solution of L^1H (0.50 g, 2.0 mmol) in *n*-hexane (20 mL) was added to a solution of $ZnMe_2$ (1.0 mL of a 2.0 M solution in toluene, 2.0 mmol) diluted with *n*-hexane (20 mL) at −78 °C. After the addition the mixture was warmed slowly to ambient temperature and was then stirred at room temperature for 36 h. The volatiles were removed in vacuo and the residue was recrystallized from a mixed solvent of toluene and *n*-hexane (10:1) at −32 °C to afford a white solid. Yield: 0.45 g (20% based on L^1H). M.p. 221−224 °C. ^1H NMR (200.131 MHz, C_6D_6): δ = 0.6 (d, *J* = 6.8 Hz, 12 H, CH*Me*$_2$), 1.06 (d, *J* = 6.8 Hz, 12 H, CH*Me*$_2$), 3.13 (sept, *J* = 6.8 Hz, 4 H, C*H*Me$_2$), 6.54 (dd, *J* = 3.6, 1.7 Hz, 2 H, pyrrole), 6.83 (dd, *J* = 3.6, 1.0 Hz, 2 H, pyrrole), 6.85−7.10 (m, 8 H, aryl and pyrrole), 7.12 (d, *J* = 1.0 Hz, 2 H, pyrrole), 7.49 (d, *J* = 1.0 Hz, 2 H, N=C*H*). EI-MS: *m*/*z* (%) = 570 (100) [M^+]. $C_{34}H_{42}N_4Zn$ (572.11): calcd. C 71.38, H 7.44, N 9.79; found C 71.20, H 7.44, N 9.94.

ZnL^2_2 (2): A solution of L^2H (1.0 g, 3.2 mmol) in toluene (20 mL) was added to an excess of $ZnMe_2$ (2 mL of a 2.0 M solution in toluene, 4.0 mmol) diluted with toluene (20 mL) at −78 °C with stirring. The solution was warmed slowly to ambient temperature and stirred at room temperature for 16 h. After removal of all volatiles the residue was extracted with 10 mL of hot *n*-hexane. Colorless crystals formed while cooling the hot extract slowly to ambient temperature. Yield: 0.73 g (33% based on L^2H). M.p. 228−250 °C. ^1H NMR (200.13 MHz, C_6D_6): δ = 0.25 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 0.97 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.05 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.12 (d, *J* = 6.8 Hz, 6 H, C*H*Me$_2$), 1.33 (s, 18 H, *t*Bu), 2.78 (sept, 2 H, *J* = 6.8 Hz, C*H*Me$_2$), 3.76 (sept, 2 H, *J* = 6.8 Hz, C*H*Me$_2$), 6.50 (d, *J* = 3.8 Hz, 2 H, pyrrole), 7.00−7.18 (m, 8 H, aryl, pyrrole), 7.47 (s, 2 H, N=C*H*). EI-MS: *m*/*z* (%) = 682 (100) [M^+]. $C_{42}H_{58}N_4Zn$ (684.29): calcd. C 73.72, H 8.54, N 8.19; found C 73.76, H 8.43, N 8.21.

MgL^2_2 (3): A solution of L^2H (0.93 g, 3.0 mmol) in *n*-hexane (30 mL) was added to an excess of Mg*n*Bu$_2$ (3.0 mL of a 1.0 M solution in toluene, 3.0 mmol) diluted with *n*-hexane (20 mL) at −78 °C whilst stirring. The solution was warmed slowly to ambient temperature and stirred at room temperature for 16 h. After filtration and washing the precipitate with *n*-hexane (20 mL), the combined filtrate was concentrated and stored at 0 °C in the refrigerator for 24 h to afford colorless crystals suitable for X-ray structural analysis. Yield: 0.58 g (30% based on L^2H). M.p. 240−242 °C. ^1H NMR (200.13 MHz, C_6D_6): δ = 0.28 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.01 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.08 (d, *J* = 6.9 Hz, 6 H, CH*Me*$_2$), 1.18 (d, *J* = 6.8 Hz, 6 H, C*H*Me$_2$), 1.33 (s, 18 H, *t*Bu), 2.81 (sept, 2 H, *J* = 6.8 Hz, C*H*Me$_2$), 3.57 (sept, 2 H, *J* = 6.9 Hz, C*H*Me$_2$), 6.45 (d, *J* = 3.6 Hz, 2 H, pyrrole), 6.88 (d, *J* = 3.6 Hz, 2 H, pyrrole), 6.90−7.00 (m, 8 H, aryl, pyrrole), 7.53 (s, 2 H, N=C*H*). EI-MS: *m*/*z* (%) = 642 (100) [M^+], 627 (50) [M^+ − Me]. $C_{42}H_{58}MgN_4$ (643.23): calcd. C 78.42, H 9.09, N 8.71; found C 78.34, H 9.11, N 8.69.

MgL^1_2·THF (4·THF): MeMgCl (0.67 mL of a 1.0 M solution in THF, 2.0 mmol) was added dropwise to a suspension of LiL^1 (0.50 g, 2.0 mmol) in THF (30 mL) at −78 °C. After the addition the mixture was warmed slowly to ambient temperature and stirred at room temperature for 16 h. The mixture was stripped of all volatiles and the residue was extracted with *n*-hexane (20 mL). The *n*-hexane extract was stored at 0 °C to afford colorless crystals. Yield: 0.35 g (29%). M.p. 208−210 °C. ^1H NMR (200.131 MHz, C_6D_6): δ = 1.03 (br, 4 H, THF), 1.15 (d, *J* = 6.9 H, CH*Me*$_2$), 1.18 (d, *J* = 6.9 Hz, 12 H, CH*Me*$_2$), 3.17 (sept, *J* = 6.9 Hz, 4 H, C*H*Me$_2$), 3.37 (br, 4 H, THF), 6.23 (d, *J* = 1.6 Hz, 2 H, pyrrole), 6.33 (dd, *J* = 3.4, 1.6 Hz, 2 H, pyrrole), 6.80 (dd, *J* = 3.4, 1.6 Hz, 2 H, pyrrole), 7.08−7.20 (m, 6 H, Aryl), 7.76 (d, *J* = 1.1 Hz, 2 H, C*H*=N). EI-MS: 530.2 (95) [M^+], 464.2 (100) [M^+ − 2Pr]. $C_{38}H_{50}MgN_4O$ (602.14, including one molecule of THF): calcd. C 75.67, H 8.66, N 9.29; found C 75.11, H 8.65, N 9.22.

$(L^2Mg)_2(\mu\text{-}OMe)_2$ (5): A solution of KL^2 (0.68 g, 2.0 mmol) in THF (20 mL) was added dropwise to a solution of MeMgCl (0.68 mL of a 3 M solution in THF, 2.0 mmol) in THF (20 mL) at −78 °C. After the addition it was warmed slowly to ambient temperature and stirred at room temperature for 16 h. After the removal of all volatiles, the residue was washed with *n*-hexane (20 mL) and extracted with toluene (40 mL). Colorless crystals of **5** formed on allowing the toluene solution to stand. The amount of **5** was small but sufficient for microanalysis. The reaction was repeated twice. M.p. 295−297 °C. ^1H NMR (200.131 MHz, C_6D_6): δ = 1.04 (d, *J* = 6.8 Hz, 12 H, CH*Me*$_2$), 1.18 (s, 18 H, *t*Bu), 1.20 (d, *J* = 6.8 Hz, 12 H, CH*Me*$_2$), 3.10 (sept, 4 H, C*H*Me$_2$), 3.58 (s, 6 H, OC*H*$_3$), 6.42 (d, *J* = 3.6 Hz, 2 H, pyrrole), 6.85 (d, *J* = 3.6 Hz, 2 H, pyrrole), 7.00−7.20 (m, 6 H, aryl), 7.63 (s, 2 H, N=C*H*). EI-MS: *m*/*z* (%) = 728 (100) [M^+]. $C_{44}H_{64}Mg_2N_4O_2$ (729.61): calcd. C 72.43, H 8.84, N 7.68; found C 71.97, H 8.79, N 7.53.

L^1AlMe_2 (6): A solution of L^1H (2.54 g, 10 mmol) and $AlMe_3$ (5.3 g of a 16% solution in *n*-hexane, 11 mmol) in toluene (40 mL)

was refluxed for 4 h. The solution was then cooled to ambient temperature. Subsequently, all volatiles were removed in vacuo. The residue was recrystallized from *n*-hexane at −32 °C to afford colorless crystals. Yield: 1.77 g (57%). M.p. 83−85 °C. ^{1}H NMR (200.13 MHz, C_6D_6): δ = −0.77 (s, 6 H, Al*Me*$_2$), 1.01 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.11 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 3.01 (sept, *J* = 6.8 Hz, 2 H, C*H*Me$_2$), 6.39 (d, *J* = 3.6 Hz, 1 H, pyrrole), 6.92 (dd, *J* = 3.6 Hz, 1 H, pyrrole), 7.05−7.20 (m, 4 H, Aryl), 7.26 (m, 1 H, pyrrole-*H*), 7.76 (d, *J* = 1.1 Hz, 1 H, N=C*H*). EI-MS: *m*/*z* (%) = 310 (0.1) [M$^+$], 295 (100) [M$^+$ − Me].

L^{2}AlMe$_2$ (7): A solution of L^{2}H (6.2 g, 20 mmol) in *n*-hexane (50 mL) was added dropwise to a solution of $AlMe_3$ (12 g of a 15% solution in *n*-hexane, 25 mmol) in *n*-hexane (50 mL). After the addition the resulting solution was warmed slowly to ambient temperature and stirred at room temperature for 16 h. After the removal of all volatiles the residue was extracted with *n*-hexane (20 mL). Cooling the extract to −32 °C for 16 h afforded colorless crystals. Yield: 6.3 g (86%). M.p. 117−119 °C. ^{1}H NMR (200.13 MHz, C_6D_6): δ = −0.23 (s, 6 H, Al*Me*$_2$), 0.92 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.15 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.35 (s, 9 H, *t*Bu), 3.20 (sept, *J* = 6.8 Hz, 2 H, C*H*Me$_2$), 6.34 (d, *J* = 3.8 Hz, 1 H, pyrrole), 6.78 (d, *J* = 3.8 Hz, 1 H, pyrrole), 7.00−7.18 (m, 4 H, aryl, pyrrole), 7.44 (s, 1 H, N=C*H*). EI-MS: *m*/*z* (%) = 366 (20) [M$^+$], 351 (100) [M$^+$ − Me]. $C_{23}H_{35}AlN_2$ (366.52): calcd. C 75.37, H 9.62, N 7.64; found C 75.38, H 9.67, N 7.56.

L$^1_2$AlCl (8): A solution of LiL^1 (1.3 g, 5.0 mmol) in THF (20 mL) was added dropwise to a solution of $AlCl_3$ (0.67 g, 5.0 mmol) in THF (20 mL) at −78 °C. After complete addition the resulting solution was warmed slowly to ambient temperature and stirred at room temperature for 16 h. After removal of all volatiles the residue was extracted with toluene (20 mL). Cooling the extract to −32 °C for 20 h afforded yellow crystals. Yield: 2.36 g (83% based on the ligand). M.p. 190−213 °C. ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.72 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 0.96 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.01 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.42 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 2.89 (sept, *J* = 6.8 Hz, 2 H, C*H*Me$_2$), 3.67 (sept, *J* = 6.8 Hz, 2 H, C*H*Me$_2$), 6.01 (dd, *J* = 3.7 Hz, 2 H, pyrrole), 6.16 (m, 2 H, pyrrole), 6.57 (dd, *J* = 3.7 Hz, 2 H, pyrrole), 6.85−7.10 (m, 12 H, Ar−*H*), 7.53 (d, *J* = 1.16 Hz, 2 H, N=C*H*). MS: *m*/*z* (%) = 568 (100) [M$^+$]. $C_{34}H_{42}AlClN_4$ (569.15): calcd. C 71.75, H 7.74, N 9.84; found C 72.05, H 7.63, N 9.90.

L^{2}AlCl$_2$ (9): A suspension of KL^2 (5.70 g, 16.0 mmol) in THF (20 mL) was added to a solution of $AlCl_3$ (2.13 g, 16.0 mmol) in THF (20 mL) at −90 °C whilst stirring. The resulting solution was warmed slowly to ambient temperature and was stirred at room temperature for 16 h. After the removal of all volatiles the residue was extracted with diethyl ether and the extract was stored at −32 °C to afford pale white microcrystals. Yield: 2.54 g (39%). M.p. 187−190 °C. ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.89 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.27 (d, *J* = 6.8 Hz, 6 H, CH*Me*$_2$), 1.35 (s, 9 H, *t*Bu), 3.40 (sept, *J* = 6.8 Hz, 2 H, C*H*Me$_2$), 6.19 (d, *J* = 3.9 Hz, 1 H, pyrrole), 6.61 (d, *J* = 3.9 Hz, 1 H, pyrrole), 6.95−7.15 (m, 6 H, Ar−H), 7.27 (s, 1 H, N=C*H*). MS: *m*/*z* (%) = 406 (100) [M$^+$]. $C_{21}H_{29}AlCl_2N_2$ (407.36): calcd. C 61.92, H 7.18, N 6.88; found C 61.20, H 7.21, N 6.41.

X-ray Crystallographic Study: Single crystals of **2**, **3**, **5**, and **8** were taken from the flask under nitrogen gas and mounted on a glass fiber in a rapidly cooled perfluoropolyether.[17] Diffraction data for **2**, **3**, and **8** were collected on a Stoe−Siemens−Huber four-circle diffractometer coupled to a Siemens CCD area detector at 200(2) K while those for **5** were collected on a Stoe two-circle diffractometer at 133(2) K, with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods (SHELXS-96 for **2**, **3**, and **8**; SHELXS-97 for **5**)[18] and refined against F^2 using SHELXL-97.[19] All non-hydrogen atoms were refined anisotropically with similarity and rigid-bond restraints. All hydrogen atoms were included in the refinement in their geometrically ideal positions. Crystallographic data for **2**, **3**, **5**, and **8** are given in Table 1 and selected bond lengths and angles in Table 2. CCDC-171433 (**2**), CCDC-171434 (**3**), CCDC-171435 (**5**) and CCDC-171436 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structure and Dehalogenation of the Disilene RClSi=SiClR [R = (tBu$_3$Si)$_2$MeSi][‡]

Nils Wiberg,*[a] Wolfgang Niedermayer,[a] Gerd Fischer,[a][‡‡] Heinrich Nöth,[a][‡‡‡] and Max Suter[a][‡‡‡]

Dedicated to Professor Hans Bürger on the occasion of his 65th birthday

Keywords: Disilene / Disilyne / Silicon / Silylene / X-ray structure analysis

The reaction of R*$_2$MeSi–SiX$_2$X′ (X/X′ = Cl/Br, Br/Cl) with NaR* (R* = supersilyl SitBu$_3$) leads, probably via the silylenes R*$_2$MeSi–SiX, to the *trans*-configurated disilene (R*$_2$MeSi)ClSi=SiCl(SiMeR*$_2$), which could be isolated as orange-red crystals. According to an X-ray structure analysis, the central SiClSi=SiClSi framework of the disilene – the formation mechanisms of which are discussed – is planar. The Si=Si double bond is as short as 2.163(4) Å and shows a band in the Raman spectrum at 589 cm^{-1}. Due to its insolubility in organic solvents, no NMR spectra of the disilene in solution were obtained. The spatially overcrowded disilene is stable towards H_2O, MeOH, HF, and NaR*. It melts at 228 °C with decomposition. Reduction of the disilene occurs with $LiC_{10}H_8$ in THF with formation of a reaction mixture containing a chlorine-free product that gives a low field ^{29}Si NMR signal at δ = 91.5 (the region for unsaturated Si atoms). It transforms in solution with traces of oxygen into a substance which, according to mass spectrometry (chemical ionization), shows a mass for the disilyne R*$_2$MeSi–Si≡Si–SiMeR*$_2$ plus two oxygen atoms.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Searching for a way to synthesize a disilyne RSi≡SiR, we recently tried to transform 1,2-bis[(disupersilyl)silyl]disilane R*$_2$HSi−SiH$_2$−SiH$_2$−SiHR*$_2$ into its tetrabromo derivative R*$_2$HSi−SiBr$_2$−SiBr$_2$−SiHR*$_2$ (R* = supersilyl SitBu$_3$),[1] as the latter might be a good starting point for the synthesis of the disilyne R*$_2$HSi−Si≡Si−SiHR*$_2$ (for a discussion of the disilyne problem see ref.[2]). Unfortunately, the spatially overcrowded 1,2-bis[(disupersilyl)silyl]disilane could only be dibrominated, probably for steric reasons (Scheme 1). The debromination of 1,2-dibromo-1,2-bis[(disupersilyl)silyl]disilane (**1**) with supersilylsodium, NaR*, leads to the disilene **2** as the main product, which was isolated as yellow, oxygen- and water-sensitive crystals [cf. Scheme 1; δ(^{29}Si) = 144.3 for the unsaturated silicon atoms].[3] Compound **2** slowly decomposes even at −20 °C with formation of the colorless product **3**.

Besides the above-mentioned yellow crystals, red crystals of the cyclotetrasilene **4** were also obtained (Scheme 1).[3] This compound may be formed by the elimination of two molecules of hydrogen bromide in the presence of NaR*, possibly via the desired disilyne R*$_2$HSi−Si≡Si−SiHR*$_2$ as a short-lived intermediate, although, of course, other pathways for the formation of **4** are also possible.

Obviously, the steric overcrowdedness of the (disupersilyl)silyl groups SiHR*$_2$ used as substituents is not sufficient to stabilize a disilyne against further reactions. Therefore, we turned to the sterically more overcrowded methyldi(supersilyl)silyl group SiMeR*$_2$ and first tried to prepare a disilene (R*$_2$MeSi)HalSi=SiHal(SiMeR*$_2$), the dehalogenation of which might lead to an isolable disilyne R*$_2$MeSi−Si≡SiMeR*$_2$. Here we report on the synthesis, structure and dehalogenation of the disilene (R*$_2$MeSi)ClSi=SiCl(SiMeR*$_2$).

(NB: We also make use of the sterically overloaded trimesitylsilyl group SiMes$_3$ and prepared a disilane Mes$_3$Si−SiH$_2$−SiH$_2$−SiMes$_3$.[4] Unfortunately, the extreme insolubility of this compound has prevented further experiments for the present.)

Results and Discussion

Synthesis of (R*$_2$MeSi)ClSi=SiCl(SiMeR*$_2$)

Whereas R*$_2$HSi−SiH$_2$−SiH$_2$−SiHR*$_2$ is easily prepared by dehalogenation of R*$_2$HSi−SiH$_2$Cl with so-

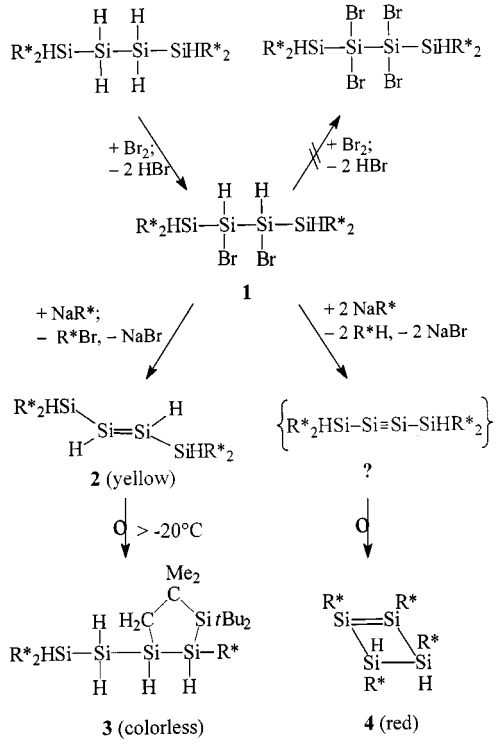
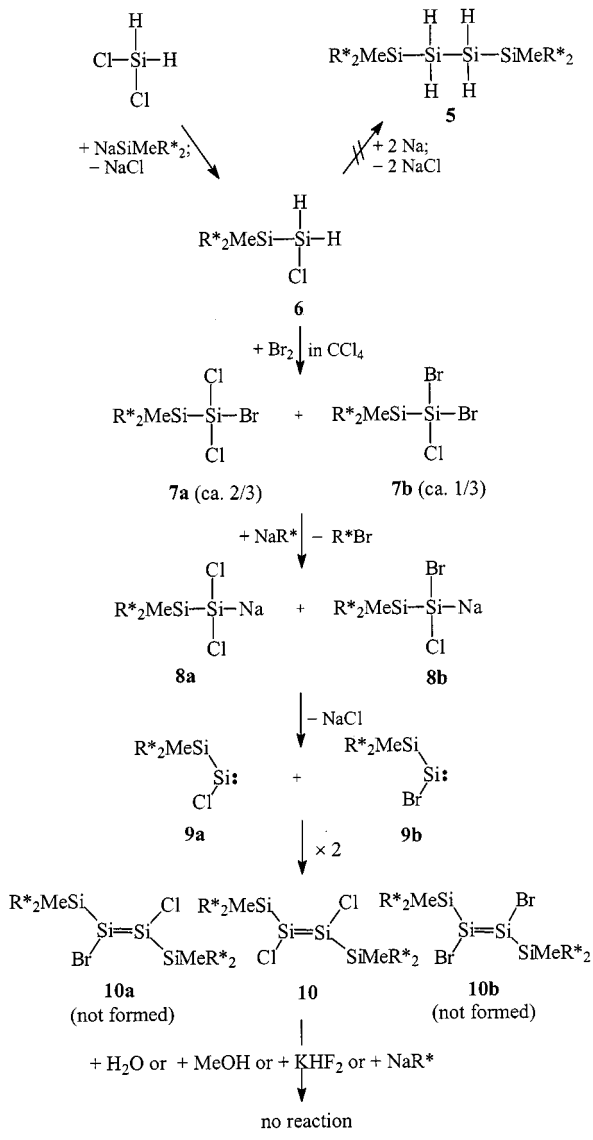


Scheme 1. Synthesis of the bis(silyl)disilane **1** and its reaction with supersilylsodium NaR* with formation of the disilene **2** (thermolysis under isomerization into product **3**) and the cyclotetrasilene **4** (R* = Si*t*Bu$_3$)

dium,[1] the same reaction is unsuitable for synthesizing R*$_2$MeSi−SiH$_2$−SiH$_2$−SiMeR*$_2$ (**5**) from R*$_2$MeSi−SiH$_2$Cl (**6**) and sodium (Scheme 2), probably for steric reasons. As a consequence, the reactions that lead to a disilene and, possibly, to a disilyne with SiHR*$_2$ substituents (Scheme 1) are not practicable to obtain the corresponding compounds with SiMeR*$_2$ substituents. However, we recently found that disilenes R*XSi=SiXR* (X = Cl, Br, I) are intermediates in the reactions of silanes R*SiX$_3$ with supersilylsodium NaR*.[5,6] We therefore tried to synthesize R*$_2$MeSi−SiX$_3$ compounds and then to transform these into disilenes (R*$_2$MeSi)XSi=SiX(SiMeR*$_2$). Indeed, the bromination of compound **6**, which was prepared by reaction of NaSiMeR*$_2$ and SiH$_2$Cl$_2$,[6] with bromine in CCl$_4$ at 0 °C leads to a mixture of R*$_2$MeSi−SiCl$_2$Br (**7a**) and R*$_2$MeSi−SiClBr$_2$ (**7b**) in a molar ratio of ca. 2:1 (Scheme 2), which we were not previously able to separate into its components by fractional crystallization.[1] Obviously, CCl$_4$ also acts as a halogenating agent for **6**. Heating a mixture of NaR* and **7** (mole ratio ca. 1.1:1) in tetrahydrofuran (THF) from −78 °C to room temperature causes the initial dark-red solution to become orange, and an orange residue precipitates slowly (in hours) leaving a nearly colorless solution. According to the mass spectrum, the amorphous residue is the disilene (R*$_2$MeSi)ClSi=SiCl(SiMeR*$_2$) (**10**). This disilene forms crystals suitable for X-ray structure analysis (see below) after warming the residue for several weeks in benzene at 50 °C.



Scheme 2. Synthesis of the silylsilanes **7** and their reactions with NaR* with formation of the bis(silyl)disilene **10** (R = Si*t*Bu$_3$)

We have not studied in the mechanism of formation of **10** in detail. although we believe that the first step of the action of NaR* on **7** must involve an exchange of bromine for sodium with formation of the deep-red silanides **8**, which then eliminate NaCl with formation of the silylenes **9**. This proposal is supported by the extensively studied reaction of R*SiCl$_2$Br (the same is valid for R*SiBr$_3$, R*SiI$_3$) with NaR* in THF which leads, at −78 °C, to the deep-colored silanide NaSiCl$_2$R* (no exchange of chloride for sodium has been observed).[5,6] NaSiCl$_2$R* then eliminates NaCl at about −50 °C to give the silylene R*SiCl, which inserts into the Na−Si bond of its precursor with formation of the disilanide Na−R*SiCl−SiCl$_2$R*.[6] The latter finally eliminates NaCl above −20 °C to give R*ClSi=SiClR* as a short-lived intermediate.[7] An insertion of the silylenes **9** into the Na−Si bond of their precursors **8**, with formation

of disilanides possessing four-coordinate central Si atoms, is unlikely for steric reasons (see below), therefore it makes sense that the disilene **10** is the product of a silylene dimerization (Scheme 2).

Of the three disilenes **10**, **10a**, **10b** conceivable as products of the dehalogenation of **7** with NaR* (cf. Scheme 2), only one disilene (**10**) is obtained. Furthermore, compound **10** precipitates from the THF solution only after several hours, but then is basically insoluble. These facts point to the existence of relatively long-lived silylenes **9** in solution at room temperature, whereby **9a**, which is obviously stable in the presence of NaR* (see below), slowly dimerizes to give **10**. The reaction of **9b** with **9a** or another molecule of **9b** is excluded for steric reasons, although excess NaR* may debrominate **9b** (see below). These proposals are confirmed by recently published results,[8] which show that the silylene $[(Me_3Si)_3C]BrSi{\cdot}D$ [D = THF or, more probably, Br^-; prepared from $(Me_3Si)_3C-SiBr_3$ and $LiC_{10}H_8$; trapped by alcohols or dienes] is metastable in THF at room temperature.

Characterization of $(R^*_2MeSi)ClSi{=}SiCl(SiMeR^*_2)$

The disilene **10** is the first silicon compound with halogen atoms bound to unsaturated silicon atoms to be isolated as a pure substance. Its characterization (see below) improves our knowledge of disilenes, whose syntheses, reactivity and geometric and electronic structures have been thoroughly studied in the last 20 years. In fact, up to date ca. 40 disilenes have been isolated and many disilenes are proved as intermediates (cf. in this connection the reviews, summarized in refs.[9–14]).

The disilene **10** forms orange-red crystals that are practically insoluble in organic solvents such as alkanes, benzene and THF. As a consequence, we have not yet been able to obtain NMR spectra for **10** even at slightly raised temperatures (see below). The orange solution that is first obtained after warming a mixture of **7** and NaR* to room temperature shows three ^{29}Si NMR signals in regions expected for unsaturated silicon atoms: δ = 153.9 (less intense), 140.9 (more intense) and 91.5 (less intense). The signals at δ = 153.9 and 140.9 are probably not due to the disilene **10** or a mixture of disilenes **10**, **10a**, **10b** as one would expect only one low-field ^{29}Si signal for **10**, and four signals for **10**, **10a** and **10b** (the normal regions for >Si=Si< with four aryl substituents, two aryl and two silyl substituents or four silyl substituents are δ = 60–90, 90–130 and 140–160, respectively[14,15]). If, on the other hand, the reaction mixture contained the silylenes **9a** and **9b**, one would expect two low-fied ^{29}Si signals (the normal regions for >Si**:** with aminyl substituents or alkyl substituents are δ = 70–100 and >500, respectively[16]). For a discussion of the signal at δ = 91.5 see below.

In the Raman spectrum the Si=Si double bond vibration occurs at 589 cm^{-1} (for comparison:[14,15,17] $Mes_2Si{=}SiMes_2$: 539 cm^{-1}; Mes(*t*Bu)Si=Si(*t*Bu)Mes: 522 cm^{-1}; R*PhSi=SiPhR*: 592 cm^{-1}. See also ref.[18]).

The disilene **10** is unreactive towards water, methanol, or hydrogen fluoride and decolorizes very slowly (over several days) when exposed to air. A change of the disilene **10** with three-coordinate central Si atoms to disilanes with four-coordinate central Si atoms is not favorable for steric reasons. In addition, **10** does not react with NaR*. Moreover, it is much more thermally stable than the previously mentioned bis[(disupersilyl)silyl]disilene **2** and only melts at 228 °C with decomposition. Obviously, the methyl(disupersilyl)silyl groups $SiMeR^*_2$ are much better substituents for stabilizing the disilenes RXSi=SiXR than the (disupersilyl)silyl groups $SiHR^*_2$, and probably the same must be valid for disilynes. Although, there is only a small difference between $SiHR^*_2$ and $SiMeR^*_2$ its effect is much larger.

Dehalogenation of $(R^*_2MeSi)ClSi{=}SiCl(SiMeR^*_2)$

To dehalogenate the disilene **10** we combined a suspension of **10** in THF at −78 °C with lithium naphthalenide ($LiC_{10}H_8$) in THF. After heating the reaction mixture to room temperature, all volatile products were evaporated under an oil pump vacuum and the residue was treated with benzene to obtain an orange-red solution with insoluble components (among others LiCl and unchanged **10**). The question then arises: does this oxygen-sensitive solution contain the disilyne $R^*_2MeSi-Si{\equiv}Si-SiMeR^*_2$? We have so far been unable to grow crystals from the solution suitable for an X-ray structure analysis. However, the ^{29}Si NMR spectrum of the solution has a signal at δ = 91.5, along with various other signals. This signal appears in a region that might be reasonable for disilyne Si atoms. It is worth mentioning here that the orange solution that is first obtained after warming the mixture of **7** and NaR* to room temperature also shows a less-intense ^{29}Si NMR signal at δ = 91.5 (see above). This could indicate that the dehalogenation of **7** with NaR* might in part not stop at silylenes or disilenes.

The mass spectrum of the solution obtained in chemical ionization mode indicates the presence of chlorine-free molecules with the mass of the desired disilyne $R^*_2MeSi-Si{\equiv}Si-SiMeR_2$ plus two oxygen atoms. The dehalogenation of **10** in THF might, in fact, give a disilyne in solution, which, due to its extreme sensitivity towards air, might react with molecular oxygen when transferring it into the mass spectrometer. This result corresponds to the observation that the mass spectrum of a solution of tetrasupersilyl-*tetrahedro*-tetrasilane[19] shows a mass peak for the tetrahedrane dioxide $R^*_4Si_4O_2$, as well as for the expected tetrahedrane $R^*_4Si_4$.[7]

Structure of $(R^*_2MeSi)ClSi{=}SiCl(SiMeR^*_2)$

Figure 1 shows the structure of the disilene **10** (local symmetry C_i) in the crystal (orange-red prisms, triclinic, $P\bar{1}$) together with selected bond lengths and angles.

The central SiClSi=SiClSi framework of **10** is practically planar (torsion angles at >Si=Si< ca. 0°, angles sum at >Si= ca. 360°) with both the chlorine atoms and the $SiMeR^*_2$ groups in *trans*-positions. Only a few disilenes (*trans*-RR′Si=SiR′R with R/R′ = Mes/*t*Bu, 2,4,6-*i*$Pr_3C_6H_2$/*t*Bu or 2,4,6-*i*$Pr_3C_6H_2$/$SiMe_3$) have similar struc-

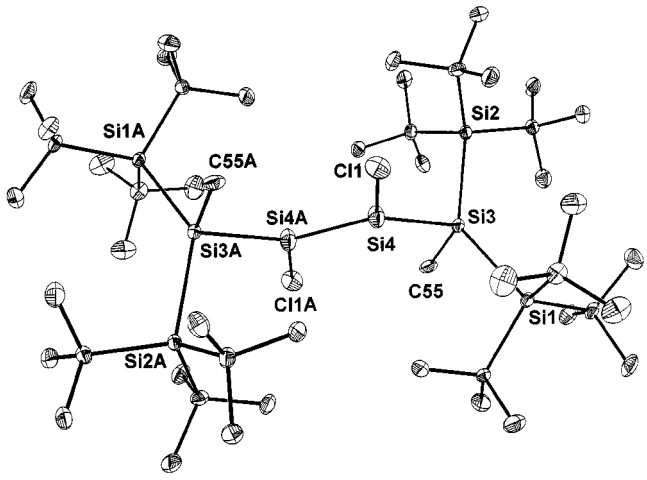


Figure 1. View of the molecule **10** (local symmetry C_i) in the crystal (ORTEP; H atoms excluded for clarity); selected bond lengths [Å] and angles [°]: Si1−Si2 2.553(3), Si2−Si3 2.531(3), Si3−Si4 2.401(3), Si4−Si4A 2.163(4) Si4−Cl1 2.091(3), Si3−C55 1.900(7), Si−C (mean value) 1.96; Si1−Si3−Si2 136.3(1), Si1−Si3−Si4 105.9(1), Si2−Si3−Si4 102.9(1), Si3−Si4−Si4A 132.0(2), Cl1−Si4−Si3 120.8(1), Cl1−Si4−Si4A 106.8(2), C55−Si3−Si1 101.3(2), C55−Si3−Si2 104.1(2), C55−Si3−Si4 102.0(3), C−Si−C (mean value) 109.7, C−Si−Si (mean value) 109.2; Si3−Si4−Si4A−Si3 180.0, Cl1−Si4−Si4A−Cl1A 180.0, Cl1−Si4−Si4A−Si3A 7.5, Cl1−Si4−Si3−C55 179.2, C55−Si3−Si3A−C55A 180.0, Cl1−Si4−Si3−Si1 73.6, Cl1−Si4−Si3−Si2 73.1, Si4A−Si4A−Si3−C55 9.2

tures, the other structurally studied disilenes show *trans*-bent angles between the >Si planes and the Si=Si vectors of up to 35° and/or twist angles of the >Si planes around the Si=Si bond of up to ca. 25°.[14,15] Obviously, the planar conformation of the central structural element of **10** is a consequence of a special three dimensional expansion of the SiMeR*$_2$ substituents at the Si=Si double bond. As mentioned previously, we believe that **10** is formed by dimerization of the silylene (R*$_2$MeSi)ClSi**:** (**9a**) which, as is normal for silylenes, should be in the singlet state (cf. Scheme 2 and ref.[6]). The approach of two such species must occur on the reaction coordinate with a *trans*-bent orientation of the silylene planes;[15] this requires a slowing down of the rate of dimerization.

The Si atom of one R* group of each SiMeR*$_2$ substituent is found above the Si atom of the other R* group below the central SiClSi=SiClSi plane, whereas the C atom of the Me group of each SiMeR*$_2$ substituent is located in the SiClSi=SiClSi plane. These Me groups are *trans* to each other (Me and Cl in *cis*-position). The same is true for the Si−Si−Si planes of both the SiMeR*$_2$ substituents, where the angle between the SiClSi=SiClSi and Si−Si−Si planes is 86.7°.

The Si=Si double bond in **10** is short (2.16 Å), despite the steric overcrowdedness of the SiMeR*$_2$ substituents. The Si=Si distances of acyclic tetraorganyl- or diorganyldisilyldisilenes lie typically in the range 2.14−2.16 Å, whereas the Si=Si distances in acyclic tetrasilyldisilenes can be as long as 2.25 Å.[9,14,15] Obviously, **10** possesses a comparatively strong double bond (see also the section describing the Raman spectrum above).

As a consequence of steric hindrance the R*$_2$MeSi−Si distances (2.40 Å) and especially the R*−Si (2.54 Å) and Si−Cl distances (2.09 Å) exceed the normal Si−Si and Si−Cl single bond lengths of 2.34 Å and 2.03 Å,[20] respectively. In addition, the Si−Si=Si and the Si−Si−Si angles (132.0° and 136.3°) are large. The central saturated Si atom of the =Si***Si***MeR*$_2$ moiety forms a flat pyramid (angles sum 345°) with its three Si neighbors, whereby the Me group at the top of the ***Si***Si$_3$ pyramid is nearly symmetrically placed with regard to the three other Si atoms (C−Si−Si angles 101−104°).

Experimental Section

All experiments were carried out in flame-dried glassware using standard Schlenk techniques under dry argon or nitrogen. Air and moisture were strictly excluded. The solvents (pentane, benzene, THF) were distilled from sodium/lead or sodium/benzophenone. Br_2, MeOH, KHF_2, C_6D_6 are available commercially and were used without further purification. The following compounds were synthesized according to literature procedures: **6**,[1] NaR*·2THF,[21] $LiC_{10}H_8$/THF.[22]

NMR Spectra: Jeol GX-270 (^{1}H/^{13}C/^{29}Si: 270.17/67.94/53.67 MHz) and a Jeol EX-400 (^{1}H/^{13}C/^{29}Si: 399.78/100.54/79.43 MHz). The NMR spectra were recorded conventionally or with the INEPT and DEPT pulse sequences using empirically optimized parameters for the mentioned groups. Mass Spectra: Jeol MStation JMS 700. The mass spectra were recorded by electron ionization (EI) or chemical ionization (CI; NH_3 and $Me_2C{=}CH_2$ as ionization agents). Raman Spectra: Perkin−Elmer, 2000 NIR FT-Raman with Na-YAG Laser (1064 nm).

Synthesis of 7a/7b: These compounds were synthesized as described elsewhere[1] by adding Br_2 (3.37 mmol) dropwise to a solution of **6** (1.69 mmol) in CCl_4 (15 mL) at 0 °C. After 5 min all volatile components were removed with an oil-pump vacuum. The remaining residue consisted of **7a**, **7b** and R*$_2$MeSiBr in the mol ratio ca. 6:3:2 (R*$_2$MeSiBr is possibly formed by Si−Si bond cleavage of **6**; identification of the products was by comparison with authentic samples[1]). The mixture could not be separated by recrystallization.

Synthesis and Characterization of the Disilene 10: A solution of NaR*·2THF (22 mmol) in THF (40 mL) was dropped slowly into a solution of **7a/7b** (ca. 20 mmol, 12.4 g; ca. 13.7 mmol **7a** and 5.9 mmol **7b** according to the NMR spectrum) in pentane (7 mL) at −78 °C (as stated above, the mixture of **7a/7b** also contains some R*$_2$MeSiBr) to give a dark-red reaction mixture (possibly due to the formation of silanides **8** and of NaSiMeR*$_2$). In the course of warming this mixture to room temperature, the color changed to orange-red (formation of silylenes **9**?). An insoluble precipitate was slowly formed from the solution over several hours and the color lightened. After removing all the volatile components under an oil-pump vacuum, the residue was extracted for 4 h with 10 mL of boiling benzene. The disilene *trans*-1,2-dichloro-1,2-bis[methyl(di-supersilyl)silyl]disilene (**10**) (1.20 g, 1.19 mmol; ca. 12%) precipitated from this benzene extract upon cooling, and was isolated at room temperature by filtration (m.p. 228 °C with decomposition). The disilene **10**: (i) is practically insoluble in benzene, alkanes or THF, (ii) does not react with either water or methanol, (iii) reacts very slowly with oxygen (decolorization in air only after eight

days), and (iv) is also unreactive towards HF (used as KHF_2) and NaR* (no reaction after 3 weeks at 60 °C in THF). Disilene **10** crystallizes after warming to 50 °C in benzene for several weeks. As a consequence of the insolubility of **10**, no NMR spectra of the disilene could be obtained. MS (EI): *m/z* (%) = 1012/1010/1008 (24) [M^+], 955/953/951 (33) [$M^+ - t$Bu], 869/867/865 (15) [$M^+ - t$Bu $- 2C_3H_7$], 813/811/809 (56) [M^+ − R*], 775/773 (32) [M^+ − R*H − Cl], 755/753/751 (15) [M^+ − R*H − *t*Bu], 613/611/609 (28) [M^+ − R*H − R*], 575/573 (100) [M^+ − R*Cl − R*]; all isotopic patterns agree well with the calculated spectrum. Raman (Nujol mull): $\tilde{\nu}$ = 123 cm^{-1} s, 277 w, 295 w, 559 m, 589 s (Si=Si), 647 w, 816 m, 1180 s, 1451 w, 1469 w, 2852 w. No analytic data were obtained. For the X-ray structure analysis see Figure 1.

Remarks: As mentioned previously, **10** precipitates only slowly from the reaction mixture of **7** and NaR* in pentane/THF at room temperature. The freshly prepared solution shows three ^{29}Si NMR signals in the low-field region (as well as other signals at higher field) at δ = 153.9, 140.9, 91.5 as discussed above.

Reaction of the Disilene 10 with $LiC_{10}H_8$: A solution of $LiC_{10}H_8$ (0.154 mmol) in THF (1.4 mL) was added dropwise to a suspension of **10** (0.079 g, 0.078 mmol) in THF (3 mL) at −78 °C to give a dark-red reaction mixture. The color of this mixture changed to light orange whilst warming to room temperature. After removal of all the volatile components under an oil-pump vacuum (including naphthalene), the remaining residue was combined with 1 mL of C_6D_6. After 4 weeks at 6 °C the obtained suspension contained no crystals suitable for X-ray structure analysis. The solution showed one ^{29}Si NMR signal in the low-field region (besides other signals at higher field): δ = 91.5 (see above). The MS of the solution after filtration indicated the presence of one type of chlorine-free molecule with the mass M = (**10** − Cl_2 + O_2) = 970.7: MS (CI with $Me_2C{=}CH_2$): *m/z* (%) = 971 (100) [M^+], 914 (38) [$M^+ - t$Bu], 772 (26) [M^+ − R*], 740 (40) [M^+ − R* − C_3H_6], 442 (25) [$R^*_2MeSi^+$]. MS (CI with NH_3): *m/z* (%) = 972 (20) [M^+ + H], 914 (2) [$M^+ - t$Bu], 459 (43) [$R^*_2MeSi^+ + NH_3$], 442 (92) [$R^*_2MeSi^+$], 217 (100) [$R^{*+} + NH_3$]. The MS of the components that are insoluble in benzene indicated the presence of **10** as well as **10** − Cl_2 + O_2.

X-ray Structure Determination of 10: Orange-red prisms, 0.1 × 0.1 × 0.1 mm, $C_{50}H_{114}Cl_2Si_4$, M_r = 1011.04, triclinic, space group $P\bar{1}$, *a* = 9.020(1), *b* = 12.150(1), *c* = 14.767(1) Å, α = 80.580(2)°, β = 89.118(2)°, γ = 71.221(2)°, *V* = 1510.4(3) $Å^3$, *Z* = 2, $\rho_{calcd.}$ = 1.112 Mg m^{-3}, μ = 0.297 mm^{-1}, *F*(000) = 560. Data collection: 2θ = 3.60−43.44°, $-9 \le h \le 9$, $-12 \le k \le 12$, $-15 \le l \le 15$, 5854 reflections of which 2997 were independent (R_{int} = 0.0496) and 2116 [$F > 4\sigma(F)$] refined. All non-hydrogen atoms were refined anisotropically and the H atoms were included in calculated positions. R_1 = 0.0681, wR_2 = 0.1648 [$F > 4\sigma(F)$], GOOF (F^2) = 1.031; max./min. residual electron density 1.377/−0.474 $Å^3$.

The intensities were measured with a Siemens SMART Area-detector (Mo-K_α, λ = 0.71073 Å). The crystals were mounted in perfluoropolyether oil at 193(2) K. The structure was solved by direct methods and refined against F^2 for all observed reflections. Structure solution with SHELXS-97 (Sheldrick, 1990), and refinement with SHELXL-97 (Sheldrick, 1997).

CCDC-171748 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for support of our research, T. Blank for helpful preparations and K. Karaghiosoff for the attempt to get NMR spectra of the disilene **10**.

Magnetic Behaviour in the System $La_{1.33}Na_xMn_xTi_{2-x}O_6$

Ana Isabel Ruiz,*[a] Javier Campo,[b] María Luisa López,[a] José Luis Martínez Peña,[c] Carlos Pico,[a] and María Luisa Veiga[a]

Keywords: Perovskite phases / Neutron diffraction / Magnetic properties

A series of perovskite-type complex oxides of general formula $La_{1.33}Na_xMn_xTi_{2-x}O_6$ (x = 0.66, 0.55 and 0.44) have been obtained and characterised. Magnetic susceptibility measurements on these phases follow a Curie–Weiss-like dependence at high temperatures, although a more complex variation is observed at lower temperatures. The thermal variation of M/H from zero-field-cooled and field-cooled susceptibility measurements shows irreversible processes and magnetisation isotherms that differ from typical ferromagnetic behaviour. Neutron diffraction data collected at low temperature show no extra magnetic contribution in the nuclear peaks nor extra reflections. All the measurements carried out on this series, such as magnetic susceptibility (dc and ac), magnetisation and neutron diffraction can be interpreted as being due to a spin-glass behaviour.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Perovskite-type oxides have the general formula ABO_3 and it is well-known that this structure allows a great number of cation substitutions at the A and/or B sites. In this way, both A and B sites can accommodate two different metal ions, with different oxidation states, that are expressed by the nominal compositions $AA'B_2O_6$,[1,2] $A_2BB'O_6$ [3,5] and $AA'BB'O_6$.[6–8] These systems have been the subject of intense research efforts due to the fact that they exhibit a wide variety of electrical and magnetic properties (high temperature superconductors, ferromagnetic and piezoelectric materials, magnetoresistors, etc.) that depend on variations in the chemical composition, stoichiometry and structure of the material.

In particular, hole-doped perovskite-type manganese oxides have attracted considerable interest in recent years motivated by the apparition of colossal magnetoresistance and the great variety of magnetic and transport properties in this class of materials.[9] Among the La-based systems, the ground state of the stoichiometric parent compound $LaMnO_3$ shows remarkable insulating A-type antiferromagnetic properties, which are attributed to a cooperative effect of orbital ordering and superexchange interactions.[10]

For these reasons, we have carried out previous research on the system $La_{1.33}Na_xMn_xTi_{2-x}O_6$ (x = 0.66, 0.55 and 0.44) oriented towards structural characterization by neutron diffraction[6] and electrical properties.[11] The aim of the present work was to analyse additional physical properties of these compounds by studying their magnetic behaviour.

Results and Discussion

Chemical Composition and Structural Results

Samples of the series $La_{1.33}Na_xMn_xTi_{2-x}O_6$ (x = 0.66, 0.55 and 0.44) were synthesised as polycrystalline powders. Table 1 gathers the Mn^{III} and Mn^{IV} concentrations present for the different compositions, which agree well with the respective nominal manganese content. From these results it is deduced that the amounts of Mn^{IV} are practically negligible in the x = 0.55 and 0.44 samples.

Table 1. Composition of manganese in the series $La_{1.33}Na_xMn_xTi_{2-x}O_6$

x	Mn^{III}	Mn^{IV}
0.66	0.55	0.11
0.55	0.50	0.05
0.44	0.39	0.05

All these compounds have characteristic diffraction patterns of the perovskite structure, in which some reflections are split indicating a noticeable distortion from the ideal cubic symmetry. It can be seen from neutron powder diffraction data[6] that an interesting structural transition be-

tween the orthorhombic (space group *Ibmm*) and rhombohedral (space group $R\bar{3}c$) symmetries takes place between 400 and 600 K in the $x = 0.66$ sample. In contrast, the phases $x = 0.55$ and 0.44 adopt a rhombohedral symmetry (space group $R\bar{3}c$) as is deduced from the X-ray diffraction results.[6]

These materials do not show any superlattice lines corresponding to an ordered distribution of the cations at the A and B sites. Taking into account the structural results, both lanthanum and sodium cations and vacancies are located at the A-sites, and manganese and titanium cations occupy, at random, the B-sites of the perovskite structure.

Magnetic Properties

Magnetic measurements were carried out on all the above compounds. Figure 1 shows the temperature dependence of magnetic susceptibility (a) and its reciprocal (b). Reciprocal susceptibility data can be fitted to a Curie−Weiss law [M/H = C/(T − θ)] over a relatively narrow temperature range that decreases as the x value increases, from which the experimental and theoretical magnetic moments and parameters C and θ were obtained (Table 2). The experimental magnetic moment should diminish in the same way as the Mn^{3+} concentration in the sample. However, a noticeable difference between the calculated (3.85 μ_B) and observed (3.43 μ_B) values is encountered for the $x = 0.66$ phase,

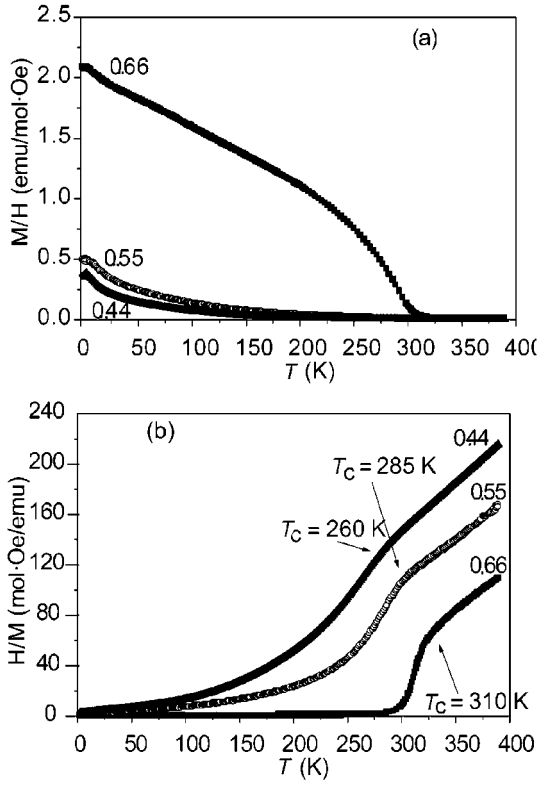

Figure 1. Susceptibility (a) and reciprocal susceptibility variations (b) for the system $La_{1.33}Na_xMn_xTi_{2-x}O_6$ ($x = 0.66$, 0.55 and 0.44)

Table 2. Magnetic data for $La_{1.33}Na_xMn_xTi_{2-x}O_6$

x	T range (K)	μ_{calc} (μ_B)	μ_{exp} (μ_B)	θ (K)
0.66	340−390	3.85	3.43	228
0.55	315−390	3.63	3.55	128
0.44	300−390	3.25	3.24	107

whereas both values are practically the same for the $x = 0.44$ composition. Thus, some magnetic interactions between the paramagnetic Mn^{3+} ions are to be expected in the first case and, possibly, in the intermediate composition $x = 0.55$. These assumptions seem to be supported by the fact that the respective Weiss constants are positive and decrease in good agreement with the Mn content in the sample. Figure 1b shows the increase in the value of the critical temperature, T_c, at which a magnetic phase-transition takes place; these increase as the manganese content increases (i.e., from 260 K for $x = 0.44$ to 310 K for $x = 0.66$). It is likely that this variation in T_c is due to magnetic dilution within the B sublattice.

In order to analyse the nature of the proposed cooperative interactions, field-cooled (FC) and zero-field-cooled (ZFC) susceptibility measurements are compared in Figure 2 for the $x = 0.66$ sample; they were obtained at an applied field (H_e) of 500 Oe. As the temperature is lowered from around 300 K, both FC and ZFC magnetisation curves increase and are basically identical in a wide region, $T_r \leq T \leq T_c$, implying a reversibility of the magnetisation. Below the temperature, T_r, at which the FC and ZFC graphs diverge, the ZFC magnetisation shows a broad maximum at 12.4 K that is taken as the spin freezing temperature, namely as T_{sg}, while the FC variation shows a bend and increases slightly. Thus the irreversibility appears far below T_c, a behaviour that is typical of reentrant spin-glass systems,[12] as in cluster-glass systems the irreversibility starts just below T_c and the difference between FC and ZFC magnetisation is usually much higher, reflecting the presence of ferromagnetic order within the clusters.[13]

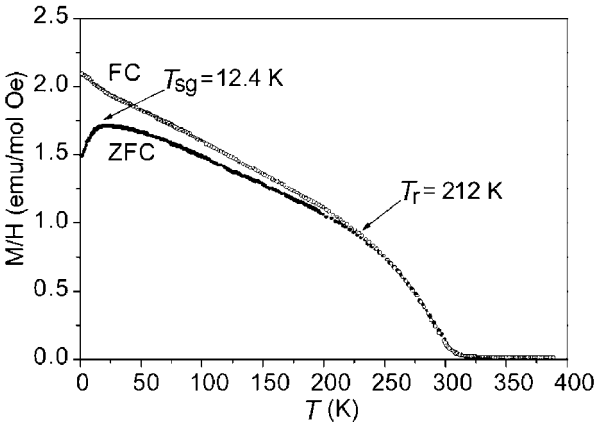

Figure 2. Temperature dependence of the magnetic susceptibility for $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$ measured after zero-field cooling (ZFC) and field cooling (FC)

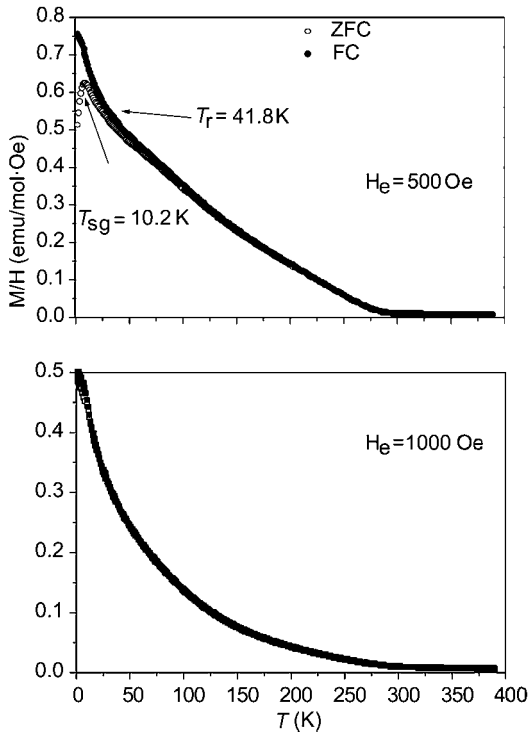

Figure 3. FC and ZFC M/H for $La_{1.33}Na_{0.55}Mn_{0.55}Ti_{1.45}O_6$ measured with an applied field (H_e) of 500 and 1000 Oe

With respect to the remaining compositions, Figure 3 shows the shape of the M_{FC} and M_{ZFC} curves for $x = 0.55$ at two different fields of 500 and 1000 Oe. Only a clear T_{sg} is detected for the lower field measurements; a similar behaviour was obtained for the sample $x = 0.44$ (not shown). However, when the manganese doping decreases in the sample, T_{sg} drops slightly and the respective cusp is less pronounced, suggesting that the magnetic interaction diminishes (12.4 K for $x = 0.66$ and 10.2 K for $x = 0.55$); the maximum is not observed for $x = 0.44$ at the same external field of 500 Oe. These changes suggest that the magnetic transitions below T_c in this system are very sensitive to the applied field and that they are completely suppressed by increasing H_e. Such a behaviour has also been reported for some other perovskite-type oxides[4,13,14] and was assumed to originate from the formation of a spin-glass.

Magnetisation measurements provide useful information about the magnetic behaviour of these systems and the isotherms obtained at different temperatures are depicted in Figure 4. Characteristic S-shaped curves were obtained in all cases and they do not saturate even in fields as high as 50 kOe. Curves below T_c show a clear ferromagnetic component with increasing importance when the temperature is lowered. Such a behaviour is evidence for a disordered spin-state (spin-glass-like state) induced by disorder and frustration due to competing ferro- and antiferromagnetic exchange interactions. The very narrow hysteresis loops indicate that these materials behave as weakly ferromagnetic. Finally, the low values of magnetisation could be explained

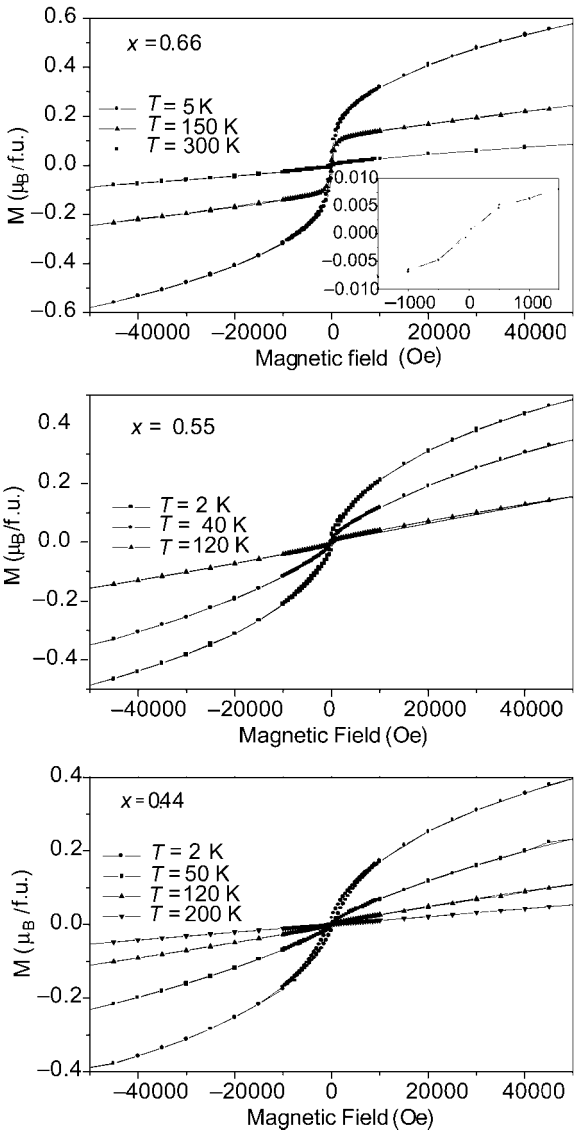

Figure 4. Magnetisation isotherms obtained at different temperatures for the system $La_{1.33}Na_xMn_xTi_{2-x}O_6$ ($x = 0.66$, 0.55 and 0.44)

by recalling that both paramagnetic Mn^{3+} and diamagnetic Ti^{4+} ions are randomly distributed over the B sites, thus preventing the establishment of a long-range ordering in these materials.[9]

In order to evaluate the importance of the above cooperative interactions, neutron diffraction experiments were carried out on these systems and Figure 5 shows thermal patterns for the sample $x = 0.66$ in the temperature range 1.6−262 K. Only a very weak ferromagnetic contribution could be observed near $2\theta = 70°$, whose intensity is practically negligible (see inset in Figure 5), so it was not possible to obtain a ferromagnetic component. Therefore it is more realistic to assume that no extra magnetic contributions (in the intensity of nuclear peaks nor extra peaks) are observed at low temperatures and, consequently, that there is no long range magnetic ordering in these materials.

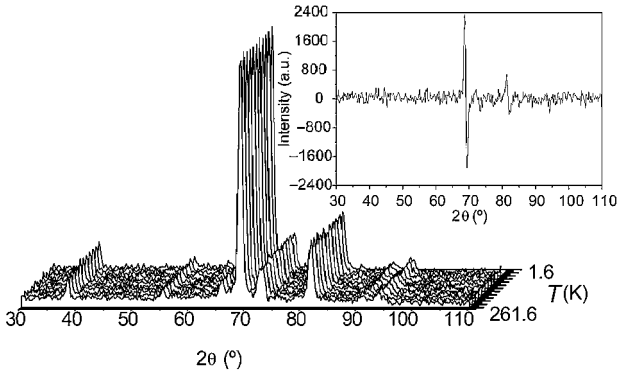

Figure 5. Neutron thermodiffractograms of $La_{1.33}Na_{0.66}Mn_{0.66}Ti_{1.34}O_6$ between 1.6 and 262 K and angular range 30−110°; the inset shows the difference diagram between 1.6 and 261.6 K (inset)

Finally, to gain a deeper insight into the spin-glass behaviour of this series, thermal variations of the ac susceptibility, χ_{ac}, at different frequencies were performed and they are depicted in Figure 6 for the sample $x = 0.66$. This demonstrates that the real part of χ_{ac} exhibits a broad maximum at about 67 K which decreases in intensity as the frequency increases (from 1 to 1000 Hz), as is expected for spin-glass systems,[15] thus confirming the above assumptions.

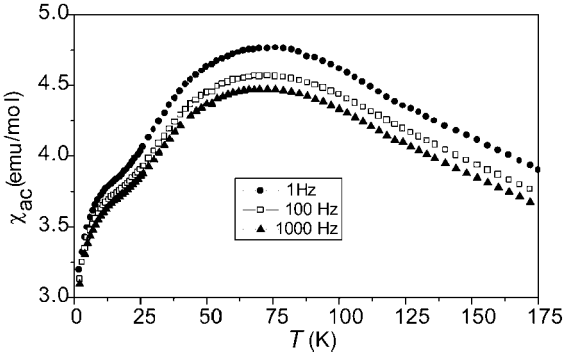

Figure 6. Thermal dependence of the ac susceptibility at different values of the excitation frequency

In summary, different magnetic and neutron diffraction measurements carried out on the series $La_{1.33}Na_xMn_xTi_{2-x}O_6$ ($x = 0.66$, 0.55, and 0.44) confirm a spin-glass behaviour that is attributed to cation disorder in the perovskite B sites. Such a disorder should contribute to the frustrated magnetic ground state and has also been found in related $AB_{1-x}B'_xO_3$ perovskite-type systems, in which the dilution of paramagnetic B cations seems to be crucial to the occurrence of spin-glass transitions at low temperatures. In the compounds under research the Ti^{4+}/Mn^{3+} ratio increases progressively from about 2 (for $x = 0.66$) to about 3.5 (for $x = 0.44$) and it becomes obvious that the effect of manganese dilution is crucial to the respective magnetic ordering. Similar features were previously observed in other related systems $LnMn_{1-x}B'_xO_3$, where lanthanum has been substituted by praseodymium or neodymium.[16,17]

Experimental Section

Polycrystalline samples of general composition $La_{1.33}Na_xMn_xTi_{2-x}O_6$ ($x = 0.66$, 0.55 and 0.44) were prepared by a classical ceramic method. Stoichiometric amounts of $La(NO_3)_3{\cdot}6H_2O$, $NaNO_3$, $C_{15}H_{21}MnO_6$ [manganese(III) acetylacetonate] and $C_{10}H_{14}O_5Ti$ [titanium(IV) acetylacetonate] were used as starting materials, and heated at 973 K for several days.

The Mn^{3+}/Mn^{4+} ratio was determined by redox titration with an excess of $FeSO_4$ solution and back titration with $KMnO_4$, with the samples being dissolved in H_2SO_4/H_2O (50:50). A known amount of $FeSO_4$ was introduced into the sample solution and the excess was determined with a standard $KMnO_4$ solution to give the total manganese ; the possible Mn^{4+} content was determined by the procedure described in ref.[10]

X-ray diffraction patterns were recorded with a Philips X'Pert-MPD diffractometer and a PW 3050/00 goniometer, using Ni-filtered Cu-K_α radiation and a 2θ step size of 0.05°, with a counting time of 12.5 s for each step. The goniometer was connected to a PC controlled by the commercial program PC-APD (Analytical Powder Diffraction Software, 4.0).

The neutron powder-diffraction data were recorded on the D1A high-resolution powder diffractometer (λ = 1.9110 Å) at the Institut Laue−Langevin (Grenoble, France). The neutron and X-ray diffraction patterns were analysed by the Rietveld method and the Fullprof program.[18] The multidetector D1B powder diffractometer with a wavelength of 2.52 Å was used for thermal patterns in the 1.6−300 K temperature range.

Magnetic measurements were obtained in a SQUID (Quantum Design, MPMS-XL model) with a sensitivity of 10^{-10} emu in the temperature range 2−400 K, applying a field of 500, 1000 Oe.

Preparation of Trifluorophosphaneruthenium(II) Complexes from η^3:η^3-Cyclooctadienediylruthenium(IV) Compounds as Precursors

Helmut Werner,*[a] Wolfram Stüer,[a] Stefan Jung,[a] Birgit Weberndörfer,[a] and Justin Wolf[a]

Dedicated to Professor Gerhard E. Herberich on the occasion of his 65th birthday

Keywords: Allyl complexes / Carbene complexes / Hydrido complexes / P ligands / Ruthenium

The dinuclear cyclooctadienediylruthenium(IV) compound [{$RuCl_2(\eta^3:\eta^3\text{-}C_{10}H_{16})$}$_2$] (**1**) reacts with PCy_3 in 2-propanol under an H_2 atmosphere to give the hydrido(dihydrogen) complex [$RuHCl(H_2)(PCy_3)_2$] (**2**) in nearly quantitative yield. Treatment of **1** with PCy_3, P*i*Pr$_3$ or P*i*Pr$_2$Ph under argon affords the mononuclear products [$RuCl_2(\eta^3:\eta^3\text{-}C_{10}H_{16})(PR_3)$] (**3**–**5**) by chloride-bridge cleavage. The corresponding compound **6** with PF_3 as phosphane ligand reacts with PCy_3 by nucleophilic attack of PCy_3 at the carbon atom C3 of the dienediyl chain to give the zwitterionic η^2:η^3-alkene(allyl)-ruthenium(II) complex [$RuCl_2\{\eta^2:\eta^3\text{-}CH_2{=}C(Me){-}CH(PCy_3)(CH_2)_2CHC(Me)CH_2\}(PF_3)$] (**7**) the crystal and molecular structures of which have been determined. The reaction of **7** with excess PCy_3 in the presence of H_2 affords the five-coordinate hydrido compound [$RuHCl(PF_3)(PCy_3)_2$] (**8**), which upon treatment with acetylene gives the vinyl derivative [$RuCl(CH{=}CH_2)(PF_3)(PCy_3)_2$] (**9**). The related cationic carbene complex [$RuCl(=CHCH_3)(PF_3)(PCy_3)_2$]$BF_4$ (**10**) is obtained by protonation of **9** with HBF_4 in ether.

Introduction

In the search for coordinatively unsaturated vinylideneruthenium(II) complexes with [Ru(P*i*Pr$_3$)$_2$] and [Ru(PCy$_3$)$_2$] as building blocks, we recently discovered that the six-coordinate non-octahedral dihydridoruthenium(IV) compounds [$RuH_2Cl_2(PR_3)_2$] (R = *i*Pr, Cy) are excellent precursors for the preparation of the target molecules [$RuCl_2(=C=CHR')(PR_3)_2$].[1] If, however, instead of [$RuH_2Cl_2(PR_3)_2$] the corresponding hydrido(dihydrogen)ruthenium(II) complexes [$RuHCl(H_2)(PR_3)_2$] are used as starting materials, the reaction with HC≡CR′ in the presence of Brönsted acids and chloride ions leads to the formation of the Grubbs-type ruthenium carbenes [$RuCl_2(=CHCH_2R')(PR_3)_2$].[1,2] Since the reactivity of these species depends on the type of phosphane and since, to the best of our knowledge,[3] complexes of the general composition [$RuCl_2(=CHCH_2R')(PR_3)(PX_3)$] with two *different* phosphanes have not been reported in the literature, we were tempted to prepare the respective precursors [$RuHCl(H_2)(PR_3)(PX_3)$] in order to find out whether they are appropriate starting materials for the synthesis of the desired ruthenium carbenes. While we failed to prepare neutral carbenes [$RuCl_2(=CHCH_2R')(PR_3)(PX_3)$], we found in the course of these studies a stepwise synthetic route to ruthenium complexes with [Ru(PF$_3$)(PCy$_3$)$_2$] as a molecular unit. In the present paper we describe details of this route and report on the reactivity of the mixed trifluorophosphane(tricyclohexylphosphane)ruthenium(II) compounds.

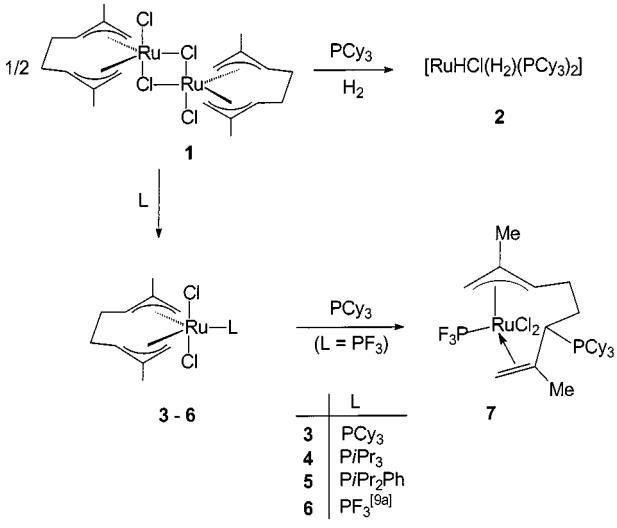
Results and Discussion

For the one-pot synthesis of the five-coordinate ruthenium carbenes [$RuCl_2(=CHCH_2R')(PR_3)_2$] (R = *i*Pr, Cy), recently developed in our laboratory, polymeric cyclooctadieneruthenium(II) dichloride [{$(\eta^4\text{-}C_8H_{12})RuCl_2$}$_n$] was used as the starting material.[4] By heating a suspension of this compound in 2-butanol for 6 h at 80 °C, in the presence of PCy_3 and H_2, the hydrido(dihydrogen) complex **2**[5] is formed. Since the conditions for the preparation of **2** with [{$(\eta^4\text{-}C_8H_{12})RuCl_2$}$_n$] as the precursor are rather severe, we decided to search for another starting material to generate **2**. The compound of choice was the dinuclear cyclooctadienediylruthenium(IV) complex **1**, which was first reported by Porri et al. in 1965[6] and in subsequent studies used as a catalyst for olefin metathesis.[7,8] Both Porri[6a] and others[9,10] have reported that the chloro bridges of **1** can easily be split by hard and soft Lewis bases to yield the mononuclear compounds [$RuCl_2(\eta^3:\eta^3\text{-}C_{10}H_{16})(L)$] (L = py, DMSO, CH_3CN, CN*t*Bu, CO, PPh_3, $P(OMe)_3$, PF_3 etc). It was also observed that the reaction of **1** with H_2 (1 bar,

25 °C) in dichloromethane leads quantitatively to the formation of 2,7-dimethylocta-2,6-diene.[6a]

Taking these results into consideration, we treated a suspension of **1** in 2-propanol with PCy_3 and replaced the argon atmosphere by dihydrogen. Upon stirring the suspension under these conditions at ca. 50 °C, an orange solid precipitated which was shown by comparison of the ^1H and ^{31}P NMR spectroscopic data to be **2**.[5] The isolated yield of **2** was 92%. If the reaction of **1** with PCy_3 was carried out in CH_2Cl_2 at −20 °C under argon (i.e., in the absence of H_2 and a hydrogen-transfer reagent such as 2-propanol), the cyclooctadienediylruthenium(IV) complex **3** was formed instead of **2** (Scheme 1). Other bulky tertiary phosphanes such as P*i*Pr$_3$ and P*i*Pr$_2$Ph behave analogously and afford the corresponding mononuclear compounds **4** and **5** in 89% and 91% yield, respectively. Compounds **3**−**5** are yellow to brownish solids that are only moderately air-sensitive but thermally quite labile and decompose both in solution and in the solid state at 40−50 °C. The ^1H NMR spectroscopic data of **3**−**5** and the ^{13}C NMR spectroscopic data of **4** and **5** are similar to those of the Ru(PF$_3$) complex **6**, the crystal and molecular structures of which have been determined crystallographically.[9b] The CH and CH_2 protons H1−H5 of **3**−**5** give rise to five resonances and the carbon atoms C1−C4 to four resonances in the NMR spectra (for assignment see Exp. Sect.), in agreement with the C_2 symmetry of the cyclooctadienediyl ligand.[6b][9b]



Scheme 1

The reactions of **4** and **5** with a slight excess of PCy_3 in the presence of H_2, undertaken with the aim to prepare the mixed-ligand compounds [RuHCl(H$_2$)(P*i*Pr$_2$R)(PCy$_3$)] (R = *i*Pr, Ph), led to a mixture of products that could not be separated by fractional crystallization or chromatographic techniques. When the reactions were monitored by ^1H or ^{31}P NMR spectroscopy, the formation of uncoordinated P*i*Pr$_3$ or P*i*Pr$_2$Ph was detected. Obviously, PCy_3 replaces the less bulky phosphanes and generates **3**, which upon treatment with PCy_3 and H_2 affords **2**.

In contrast to **4** and **5**, the related PF_3 derivative **6** reacts almost instantaneously with PCy_3, even in the absence of dihydrogen, to yield a single product **7**, the composition of which corresponds to a 1:1 adduct of the two starting materials. The pale-yellow, highly air-sensitive solid is soluble in chloroform and dichloromethane but decomposes in solution at room temperature quite rapidly. Whereas the ^1H and ^{13}C NMR spectra (measured at −50 °C in CD_2Cl_2) are rather complicated, the ^{31}P NMR spectrum displays a doublet at δ = 32.5 for the PCy_3 and a quadruplet of doublets at δ = 137.3 for the PF_3 phosphorus atoms. The rather small ^{31}P-^{31}P coupling constant of 19.3 Hz (for comparison see the data for **8**−**10**) indicate that only one phosphane molecule is coordinated to the metal center while the other is linked to the π-bonded chain-like ligand.

The result of the X-ray crystal structure analysis of **7** is shown in Figure 1. The coordination geometry around ruthenium can best be described as trigonal bipyramidal with the chlorine atoms occupying the apical positions of the bipyramid. The η^2:η^3-alkene(allyl) unit, formed by nucleophilic addition of PCy_3 at the allylic carbon atom C3 of the η^3:η^3-cyclooctadienediyl ligand, occupies two of the equatorial sites, while the third position is occupied by PF_3. In contrast to **6**,[9b] the PF_3 molecule of **7** is not disordered. The carbon atoms C1, C2, C7, C8, C10 and the phosphorus atom P1 lie in one plane, the largest deviation being found for C7 with 0.103(2) Å. Although **7** possesses two centers of chirality, the crystal contains only that pair of enantiomers in which the methyl group at C2 and the PCy_3 moiety are farthest apart. The bond angle between P1, Ru and the midpoint of the line between C7 and C10 is 122.5(2)° and thus deviates only slightly from the ideal value of 120°. The Ru−P1 bond length of 2.178(2) Å is somewhat shorter than in **6** [2.237(3) Å] but almost identical to the Ru−PF_3 distances in the octahedral compound [RuCl$_2$(PF$_3$)$_2$(PPh$_3$)$_2$] [2.160(2) and 2.180(2) Å].[9b] The olefinic fragment of the zwitterionic $C_{10}H_{16}$(PCy$_3$) ligand is unsymmetrically linked to the metal center, the bond lengths Ru−C1 and Ru−C2 pointing to a rather weak coordination compared to other alkeneruthenium complexes.[11] Similar Ru−C olefin distances are found in the compound [RuCl$_2$(η^3:η^2:η^3-C$_{12}$H$_{18}$)] which has been prepared from RuCl$_3$·3H$_2$O and butadiene.[12]

While we could not convert **7** to the desired hydrido(dihydrogen) complex [RuHCl(H$_2$)(PF$_3$)(PCy$_3$)], treatment of **7** in dichloromethane with excess PCy_3 under a hydrogen atmosphere leads to the formation of the five-coordinate hydridoruthenium(II) compound **8** in 63% isolated yield (Scheme 2). The presence of the hydrido ligand is clearly confirmed by the ^1H NMR spectrum, which displays a signal at high field (δ = −24.68). This signal is split into a doublet of triplets of quadruplets due to the coupling of the RuH proton with the ^{31}P and ^{19}F nuclei of the PCy_3 and PF_3 ligands.

The reactivity of the hydrido(trifluorphosphane)ruthenium(II) complex **8** is similar to that of the corresponding hydrido(carbonyl) derivatives [RuHCl(CO)(PR$_3$)$_2$]. By passing a slow stream of acetylene through a solution of **8** in

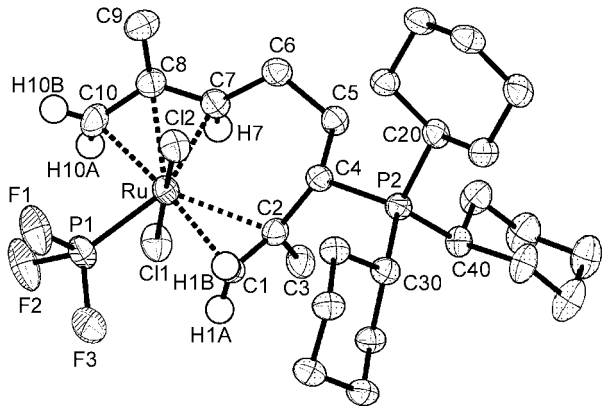


Figure 1. Molecular structure (SCHAKAL plot) of **7**; selected bond lengths [Å] and angles [°]: Ru−P1 2.178(2), Ru−Cl1 2.427(2), Ru−Cl2 2.433(2), Ru−C1 2.228(4), Ru−C2 2.360(4), Ru−C7 2.239(4), Ru−C8 2.246(4), Ru−C10 2.204(4), C1−C2 1.393(5), C2−C4 1.523(5), C7−C8 1.427(5), C8−C10 1.414(6), P2−C4 1.863(4); Cl1−Ru−Cl2 175.6(3), Cl1−Ru−P1 86.5(1), Cl1−Ru−C1 93.7(1), Cl1−Ru−C2 86.8(1), Cl1−Ru−C8 100.5(1), Cl1−Ru−C10 81.3(1), Cl2−Ru−P1 90.6(1), Cl2−Ru−C1 82.9(1), Cl2−Ru−C2 91.9(1), Cl2−Ru−C7 95.6(1), Cl2−Ru−C8 83.7(1), Cl2−Ru−C10 101.8(1), C1−C2−C3 117.5(3), C1−C2−C4 123.0(3), C2−C4−C5 113.1(3), C2−C4−P2 116.6(2), C5−C4−P2 108.7(2), C7−C8−C9 122.0(3), C7−C8−C10 119.6(3)

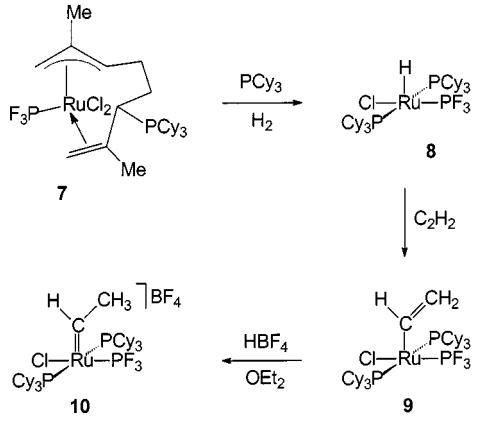

Scheme 2

hexane, a rapid change of color from yellow to bright-red occurs and, after removal of the solvent, the vinylruthenium(II) compound **9** is obtained in nearly quantitative yield. The ^{31}P NMR spectrum of **9** displays a doublet for the PCy_3 phosphorus atoms at δ = 24.3 and a quadruplet of triplets for the ^{31}P nuclei of coordinated PF_3 at δ = 119.2. Both the ^{31}P-^{31}P and ^{31}P-^{19}F coupling constants of 45.8 Hz and 1241 Hz, respectively, are of the same order of magnitude as for the hydrido complex **8**. The signals for the three vinyl protons of **9** appear in the ^1H NMR spectrum at δ = 8.51, 5.37 and 5.10 and are all shifted downfield relative to the related ruthenium carbonyl [RuCl(CH=CH_2)(CO)$(PCy_3)_2$].[13]

In analogy to the structurally related cationic vinylruthenium(II) derivative $[Ru(CH{=}CH_2)(CH_3CN)_2(PCy_3)_2]^+$, which reacts with HBF_4 in ether to generate the dicationic ruthenium carbene $[Ru(=CHCH_3)(CH_3CN)_2(PCy_3)_2](BF_4)_2$,[14] treatment of **9** with HBF_4 in CH_2Cl_2/OEt_2 gives the monocationic five-coordinate carbene compound **10** in moderate yield. The composition of **10** has been substantiated by elemental analysis and ^1H, ^{13}C, ^{19}F and ^{31}P NMR spectroscopy. Typical spectroscopic features of **10** are the signal for the RuCH proton at δ = 17.35 in the ^1H NMR spectrum and the multiplet for the carbene carbon atom at δ = 326.1 in the ^{13}C NMR spectrum. Similarly to **9**, the ^{31}P NMR spectrum of **10** exhibits two resonances at δ = 49.7 and 127.1, the splitting of which again corresponds to a doublet and a quadruplet of triplets. It should be noted that solutions of **10** (e.g., in dichloromethane or nitromethane) are stable only below −20 °C for a few hours; at room temperature decomposition occurs. While we failed to identify any Ru-containing decomposition products, the formation of the vinylphosphonium cation $[Cy_3PCH{=}CH_2]^+$ [with resonances for the vinyl protons at δ = 6.76 (dd), 6.35 (dd) and 6.15 (ddd) in the ^1H NMR spectrum] could be clearly confirmed.

In summary, the present work illustrates that with the dinuclear $\eta^3{:}\eta^3$-cyclooctadienediylruthenium(IV) compound **1** as the starting material and the unusual zwitterionic $\eta^3{:}\eta^3$-alkene(allyl)ruthenium(II) species **7** as an isolated intermediate five-coordinate hydrido-, vinyl- and carberuthenium complexes with PF_3 as a supporting ligand can be prepared. In contrast to the neutral ruthenium carbenes $[RuCl_2(=CHR)(PCy_3)_2]$,[3,15] the cation $[RuCl(=CHCH_3)(PF_3)(PCy_3)_2]^+$ is catalytically inactive in the ring-opening metathesis polymerization of cyclooctene, probably due to the ease of decomposition to give $[Cy_3PCH{=}CH_2]^+$. In this respect, the properties of the PF_3 derivative **10** are similar to those of the cationic carbene(carbonyl)ruthenium(II) complexes $[RuCl(=CHCH_2R)(CO)(P\mathit{i}Pr_3)_2]BF_4$ and $[RuCl(=CHCH_2R)(CO)(PCy_3)_2]BF_4$, the preparation and reactivity of which will be described in a forthcoming publication.

Experimental Section

All operations were carried out under argon using standard Schlenk techniques. The starting materials **1**[6b] and **6**[9a] were prepared as described in the literature. NMR spectra were recorded at room temperature on Bruker AC 200 and AMX 400 instruments, unless otherwise stated. Abbreviations used: s, singlet; d, doublet; t, triplet; q, quadruplet; m, multiplet; vt, virtual triplet; br, broadened signal; $N = {}^2J(PC) + {}^4J(PC)$. For assignment of protons and carbon atoms for the π-bonded ligands in compounds **3**−**5** and **7** see Figure 2. Melting and decomposition points were measured by differential thermal analysis (DTA).

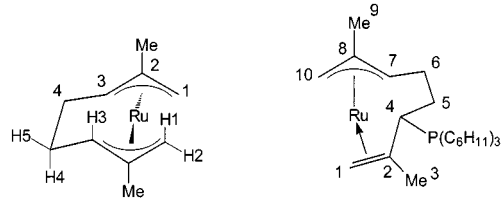

Figure 2. Assignment of proton and carbon atoms for the ligands in compounds **3**−**6** and **7**

Preparation of [RuHCl(H_2)(PCy_3)$_2$] (2) from 1: A suspension of **1** (510 mg, 0.827 mmol) in 2-propanol (40 mL) was treated with PCy_3 (1.86 g, 6.62 mmol) at room temperature. The Schlenk tube was evacuated and the argon atmosphere replaced by H_2. The suspension was warmed to ca. 50 °C and, after stirring for 40 min, an orange solid precipitated. This solid was separated from the mother liquor, washed twice with 20 mL portions of 2-propanol and dried. It was identified by comparing the ^{1}H and ^{31}P NMR spectra with those of an authentic sample;[5] yield 1.07 g (92%).

Preparation of [$RuCl_2$(η^3:η^3-$C_{10}H_{16}$)(PCy_3)] (3): A solution of PCy_3 (95 mg, 0.34 mmol) in CH_2Cl_2 (6 mL) was treated at −20 °C with **1** (104 mg, 0.17 mmol), leading to a change of color from violet to brown-yellow. After stirring the reaction mixture for 5 min, the solvent was evaporated in vacuo. The oily residue was treated with pentane (3 mL) and the suspension irradiated for 1 min in an ultrasound bath. A yellow solid precipitated which was separated from the mother liquor, washed twice with pentane (10 mL) and dried; yield 170 mg (85%); m.p. 46 °C (decomp). ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 5.14 (m, 2 H, H3), 4.69 (d, $^3J_{P,H}$ = 7.6 Hz, 2 H, H1 or H2), 3.55 (d, $^3J_{P,H}$ = 3.2 Hz, 2 H, H2 or H1), 3.32 (m, 2 H, H4 or H5), 2.64−2.45 (m, 8 H, H5 or H4 and C_6H_{11}), 2.16 (s, 6 H, Me), 2.20−2.00, 1.83−1.67, 1.40−1.24 (all m, 27 H, C_6H_{11}). ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 5.0 (s). $C_{28}H_{49}Cl_2PRu$ (588.7): calcd. C 57.13, H 8.39; found C 56.89, H 8.28.

Preparation of [$RuCl_2$(η^3:η^3-$C_{10}H_{16}$)(P*i*Pr_3)] (4): A solution of **1** (101 mg, 0.16 mmol) in CH_2Cl_2 (5 mL) was treated with P*i*Pr_3 (68 μL, 0.51 mmol) at room temperature, leading to a change of color from violet to red-brown. After stirring the reaction mixture for 30 min, the solvent was evaporated in vacuo. The oily residue was treated with pentane (5 mL) which after ca. 10 min led to the formation of a brownish solid. The solid was separated from the mother liquor, washed twice with 10 mL portions of pentane and dried; yield 137 mg (89%); m.p. 51 °C (decomp). ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 5.12 (m, 2 H, H3), 4.81 (d, $^3J_{P,H}$ = 7.6 Hz, 2 H, H1 or H2), 3.52 (d, $^3J_{P,H}$ = 3.2 Hz, 2 H, H2 or H1), 3.33 (m, 2 H, H4 or H5), 2.82 (m, 3 H, PC*H*CH_3) 2.55 (m, 2 H, H5 or H4), 2.17 (s, 6 H, Me), 1.46 (dd, $^3J_{P,H}$ = 12.0, $^3J_{H,H}$ = 7.1 Hz, 9 H, PCHC*H*$_3$), 1.39 (dd, $^3J_{P,H}$ = 12.8, $^3J_{H,H}$ = 7.1 Hz, 9 H, PCHC*H*$_3$). ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 124.9 (s, C2), 108.6 (d, $^2J_{P,C}$ = 9.1 Hz, C3), 62.6 (d, $^2J_{P,C}$ = 5.8 Hz, C1), 36.2 (s, C4), 28.8 (d, $^1J_{P,C}$ = 15.8 Hz, P*C*HCH$_3$), 20.7 (s, Me), 20.1 (d, $^2J_{P,C}$ = 3.0 Hz, PCH*C*H$_3$), 17.8 (br. s, PCH*C*H$_3$). ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 17.7 (s). $C_{19}H_{37}Cl_2PRu$ (468.5): calcd. C 48.72, H 7.96; found C 48.23, H 7.59.

Preparation of [$RuCl_2$(η^3:η^3-$C_{10}H_{16}$)(P*i*Pr_2Ph)] (5): This compound was prepared as described for **4**, using **1** (523 mg, 0.85 mmol) and P*i*Pr_2Ph (306 mg, 1.80 mmol) as starting materials. Yellow solid; yield 781 mg (91%); m.p. 42 °C (decomp). ^{1}H NMR(400 MHz, CD_2Cl_2): δ = 8.05 (m, 2 H, Ph), 7.41 (m, 3 H, Ph), 5.14 (m, 2 H, H3), 4.45 (d, $^3J_{P,H}$ = 8.8 Hz, 2 H, H1 or H2), 3.46 (d, $^3J_{P,H}$ = 3.2 Hz, 2 H, H2 or H1), 3.32 (m, 2 H, H4 or H5), 3.08 (m, 3 H, PC*H*CH_3) 2.57 (m, 2 H, H5 or H4), 2.16 (s, 6 H, Me), 1.40 (dd, $^3J_{P,H}$ = 14.4, $^3J_{H,H}$ = 7.2 Hz, 3 H, PCHC*H*$_3$), 1.32 (dd, $^3J_{P,H}$ = 13.2, $^3J_{H,H}$ = 7.2 Hz, 3 H, PCHC*H*$_3$), 1.22 (dd, $^3J_{P,H}$ = 14.0, $^3J_{H,H}$ = 7.0 Hz, 3 H, PCHC*H*$_3$), 1.17 (dd, $^3J_{P,H}$ = 13.8, $^3J_{H,H}$ = 7.0 Hz, 3 H, PCHC*H*$_3$). ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 134.2 (d, $J_{P,C}$ = 6 Hz, Ph), 132.9 (d, $J_{P,C}$ = 29.2 Hz, Ph), 129.6 (d, $J_{P,C}$ = 2 Hz, Ph), 127.8 (d, $J_{P,C}$ = 8 Hz, Ph), 126.0 (s, C2), 108.6 (d, $^2J_{P,C}$ = 9 Hz, C3), 63.8 (d, $^2J_{P,C}$ = 6 Hz, C1), 36.6 (s, C4), 27.6, 27.2 (both d, $^1J_{P,C}$ = 19.5 and 19.9 Hz, P*C*HCH$_3$), 21.0 (s, Me), 19.2, 18.5 (both s, PCH*C*H$_3$), 19.1, 18.5 [both d, $^2J_{P,C}$ = 2.6 and 2.7 Hz, PCH*C*H$_3$]. ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 16.9 (s). $C_{22}H_{35}Cl_2PRu$ (502.5): calcd. C 52.59, H 7.02; found C 53.14, H 6.91.

Preparation of [$RuCl_2${η^2:η^3-CH_2=C(Me)CH(PCy_3)$(CH_2)_2$CHC(Me)CH_2}(PF_3)] (7): A solution of **6** (112 mg, 0.34 mmol) in toluene (5 mL) was treated dropwise with a solution of PCy_3 (106 mg, 0.38 mmol) in toluene (5 mL) at room temperature. A slow precipitation of an orange oil was observed. After stirring the reaction mixture vigorously for 10 min, the oil was partly converted into a yellow solid, the precipitation of which was facilitated by addition of pentane (5 mL) and by cooling the Schlenk tube to −78 °C. The solid was filtered, washed twice with 5 mL portions of pentane (−20 °C) and dried; yield 172 mg (83%); m.p. 62 °C (decomp). ^{1}H NMR (200 MHz, CD_2Cl_2, −50 °C): δ = 4.22−4.11 (m, 2 H, L), 3.54−3.50 (m, 1 H, L), 3.48−3.24 (m, 2 H, L), 2.95 (s, 1 H, L), 2.94−2.72 (m, 1 H, L), 2.60−2.39 (m, 6 H, C_6H_{11}), 2.19, 1.97−1.60, 1.46−1.30 (all m, 36 H, C_6H_{11} and Me of L); L is the abbreviation for the η^2:η^3-alkene(allyl) ligand. ^{13}C NMR (100.6 MHz, CD_2Cl_2, −50 °C): δ = 120.6 (s, C8), 73.2 (s, C2), 72.8 (dq, $^2J_{P,C}$ = 43.0, $^3J_{F,C}$ ca. 3 Hz, C7), 59.8 (d, $J_{P,C}$ = 4.7 Hz, C1 or C10), 55.5 (s, C10 or C1), 38.2 (d, $J_{P,C}$ = 21.0 Hz, C4), 31.5 (d, $^1J_{P,C}$ = 34.3 Hz, C_6H_{11}), 31.1, 24.5 (both d, $J_{P,C}$ = 9.6 and 11.5 Hz, C5 and C6), 28.5, 21.5 (both s, C3 and C9), 27.1 (br. s, C_6H_{11}), 26.7, 26.5 (both d, $J_{P,C}$ = 11.4 and 11.5 Hz, C_6H_{11}), 25.0 (s, C_6H_{11}). ^{19}F NMR (376.4 MHz, CD_2Cl_2): δ = −17.3 (d, $^1J_{P,F}$ = 1362 Hz, PF_3). ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 137.3 (qd, $^1J_{P,F}$ = 1362 Hz, $J_{P,P}$ = 19.3 Hz, PF_3), 32.5 (d, $J_{P,P}$ = 19.3 Hz, PCy_3). $C_{28}H_{49}Cl_2F_3P_2Ru$ (676.6): calcd. C 49.70, H 7.30; found C 50.10, H 7.20.

Preparation of [RuHCl(PF_3)(PCy_3)$_2$] (8): A solution of **7** (125 mg, 0.19 mmol) in CH_2Cl_2 (4 mL) was treated with PCy_3 (312 mg, 1.11 mmol) and stirred for 2 h under an H_2 atmosphere (1 bar). A change of color from yellow to red occurred. After evaporation of the solvent in vacuo, the residue was suspended in acetone (4 mL) and the mixture stirred for 30 min. An orange-yellow solid precipitated, which was separated from the mother liquor, washed with acetone (4 mL) and dried in vacuo; yield 98 mg (63%); m.p. 40 °C (decomp). ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 2.63−1.21 (m, 66 H, C_6H_{11}), −24.68 (dtq, $^2J_{P^2,H}$ = 57.8, $^2J_{P^1,H}$ = 16.9, $^3J_{F,H}$ = 4.4 Hz, 1 H, RuH); P^1 and P^2 assigned to the phosphorus atoms of PCy_3 and PF_3, respectively. ^{19}F NMR (188.3 MHz, CD_2Cl_2): δ = −98.1 (d, $^1J_{P,F}$ = 1225 Hz). ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 128.7 (qm, $^1J_{F,P}$ = 1225 Hz, PF_3), 46.8 (d, $^2J_{P,P}$ = 45.8 Hz, PCy_3). $C_{36}H_{67}ClF_3P_3Ru$ (786.4): calcd. C 54.99, H 8.59; found C 54.99, H 8.73.

Preparation of [RuCl(CH=CH_2)(PF_3)(PCy_3)$_2$] (9): A slow stream of acetylene was passed for 10 s through a solution of **8** (88 mg, 0.11 mmol) in hexane (15 mL) at room temperature. A change of color from yellow to bright red occurred. The solvent was then evaporated in vacuo, and the remaining red solid washed with pentane (3 mL) and dried; yield 90 mg (99%); m.p. 88 °C (decomp). ^{1}H NMR (200 MHz, C_6D_6): δ = 8.51 (m, 1 H, C*H*=CH_2), 5.37 (m, 1 H, *cis*-H of CH=CH_2), 5.10 (dm, $^3J_{H,H}$ = 13.6 Hz, 1 H, *trans*-H of CH=CH_2), 2.85−1.11 (m, 66 H, C_6H_{11}). ^{13}C NMR (100.6 MHz, C_6D_6): δ = 153.9 (br. s, RuCH), 121.8 (br. s, =CH_2), 36.2 (vt, N = 17.4 Hz, C1 of C_6H_{11}), 30.8, 30.6 (both s, C3,5 of C_6H_{11}), 28.3, 28.1 (both s, C2,6 of C_6H_{11}), 27.0 (s, C4 of C_6H_{11}). ^{19}F NMR (188.3 MHz, C_6D_6): δ = −6.0 (d, $^1J_{P,F}$ = 1241 Hz). ^{31}P NMR (81.0 MHz, C_6D_6): δ = 119.2 (qt, $^1J_{F,P}$ = 1241, $^2J_{P,P}$ = 45.8 Hz, PF_3), 24.3 (d, $^2J_{P,P}$ = 45.8 Hz, PCy_3). $C_{38}H_{69}ClF_3P_3Ru$ (812.4): calcd. C 56.18, H 8.56; found C 56.59, H 8.06.

Preparation of $[RuCl(=CHCH_3)(PF_3)(PCy_3)_2]BF_4$ (10): A solution of **9** (80 mg, 0.10 mmol) in CH_2Cl_2 (2 mL) was treated with a 1.6 M solution of HBF_4 in ether (0.2 mL, 0.32 mmol) at room temperature. A change of color from red to yellow occurred. The solvent was evaporated in vacuo, the remaining yellow solid was washed twice with 3 mL portions of ether and dried; yield 45 mg (50%); m.p. 108 °C (decomp). ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 17.35 (br. s, 1 H, Ru=CH), 2.95 (s, 3 H, CH_3), 2.70−1.13 (m, 66 H, C_6H_{11}). ^{13}C NMR (50.3 MHz, CD_2Cl_2, −20 °C): δ = 326.1 (m, Ru=CH), 51.0 (s, CH_3), 35.1 (br. m, C1 of C_6H_{11}). 29.5 (s, C3,5 of C_6H_{11}), 27.2 (m, C2,6 of C_6H_{11}), 25.5 (s, C4 of C_6H_{11}). ^{19}F NMR (188.3 MHz, CD_2Cl_2): δ = −11.6 (d, $^1J_{P,F}$ = 1282 Hz, PF_3), −153.5 (br. s, BF_4). ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 127.1 (qt, $^1J_{F,P}$ = 1282, $^2J_{P,P}$ = 35.6 Hz, PF_3), 49.7 (d, $^2J_{P,P}$ = 35.6 Hz, PCy_3). $C_{38}H_{70}BClF_7P_3Ru$ (900.2): calcd. C 50.70, H 7.84; found C 50.25, H 7.31.

Determination of the X-ray Crystal Structure of 7: Single crystals were grown by cooling a saturated solution of **7** in acetone from 25 °C to −20 °C. Crystal data (from 5000 reflections, 2.49° < Θ < 28.23°): triclinic; space group $P\bar{1}$ (No. 2); a = 9.878(7), b = 13.93(1), c = 14.17(1) Å, α = 87.35(9)°, β = 84.80(9)°, γ = 74.22(9)°; V = 1868(2) Å^3, Z = 2; $d_{calcd.}$ = 1.410 g cm^{-3}; μ(Mo-K_α) = 0.686 mm^{-1}; crystal size 0.14 × 0.11 × 0.08 mm; IPDS (STOE), Mo-K_α radiation (0.71073 Å), graphite monochromator; T = 173(2) K; Θ-scan, max. 2Θ = 56.46°; 29465 reflections measured, 8456 independent ($R_{int.}$ = 0.0535), 6042 with $I > 2\sigma(I)$. Intensity data were corrected for Lorentz and polarization effects and an empirical absorption correction was applied. The structure was solved by direct methods (SHELX-97).[16] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares methods using SHELXL-97.[17] The asymmetric unit of **7** includes two molecules of acetone which were refined anisotropically with restraints. The hydrogen atoms H1a, H1b, H6a, H6b, H7, H10a and H10b were found in a difference-Fourier synthesis and refined with fixed temperature factors $U_{eq.}$ The positions of all other hydrogen atoms were calculated according to an ideal geometry and refined by the riding method. Conventional R = 0.0455 [for 6042 reflections with $I > 2\sigma(I)$], and weighted wR_2 = 0.1234 for all 8456 located reflections; reflection/parameter ratio 19.90; residual electron density +0.806/−1.074 eÅ^{-3}.

CCDC-175166 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347), BASF AG, and the Fonds der Chemischen Industrie. We are grateful to the latter in particular for a Ph.D. grant (to W. S.). Moreover, we thank Mrs. R. Schedl and Mr. C. P. Kneis (DTA and elemental analysis), Mrs. M.-L. Schäfer and Dr. W. Buchner (NMR spectra), and Mr. S. Stellwag for valuable experimental assistance.

Anderson-Type Heteropolymolybdates Containing Tris(alkoxo) Ligands: Synthesis and Structural Characterization

Bernold Hasenknopf,[a] Renaud Delmont,[a] Patrick Herson,[a] and Pierre Gouzerh*[a]

Keywords: Coordination modes / Molybdenum / Polyoxometalates / Tridentate ligands

Anderson-type molybdopolyanions containing tris(alkoxo) ligands $[MMo_6O_{18}\{(OCH_2)_3CR\}_2]^{3-}$ (M = Mn^{III}, Fe^{III}) and $[H_2MMo_6O_{18}\{(OCH_2)_3CR\}_2]^{2-}$ (M = Ni^{II}, Zn^{II}), (R = CH_3, NO_2, CH_2OH), were prepared by treatment of $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ with tris(hydroxymethyl)methane derivatives in the presence of manganese(III) acetylacetonate, iron(III) acetylacetonate, nickel(II) acetate, or zinc(II) acetate. The complexes were structurally characterized in solution, and also by single-crystal X-ray diffraction in the cases of $[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CNO_2\}_2]$, $[N(C_4H_9)_4]_2[H_2NiMo_6O_{18}\{(OCH_2)_3CCH_2OH\}_2]$, and $[N(C_4H_9)_4]_2[H_2ZnMo_6O_{18}\{(OCH_2)_3CCH_3\}_2]$. Two tris(alkoxo) ligands replace the six hydroxo groups usually found in Anderson polyanions of formula $[H_6MMo_6O_{24}]^{n-}$. The complex structures may be divided into two groups: In the first one the tris(alkoxo) ligands are bound entirely to the central heteroatom, while in the second one they cap a tetrahedral cavity.

Introduction

Heteropolymolybdates of the general formula $[H_x(MO_6)Mo_6O_{18}]^{n-}$ ($x = 0-6$, $n = 2-6$) occur with metallic or nonmetallic heteroatoms M.[1,2] Two isomers, α and β, are known; both consist of edge-sharing octahedra.[3,4] The β isomer corresponds to a nonplanar, bent arrangement, as in the structures of $[Mo_7O_{24}]^{6-}$ [5] and $[W_7O_{24}]^{6-}$.[6,7] In the more common α isomer, the so-called Anderson structure, six molybdenum atoms form a planar hexagon around the central heteroatom. Two types of the Anderson structure may be distinguished: the nonprotonated A type, with heteroatoms in high oxidation states, and the hexaprotonated B type, with heteroatoms in low oxidation states.[8] The six nonacidic protons are usually located on the six oxygen atoms bound to the central heteroatom,[9] although a different protonation pattern has been reported in one case.[4]

Several B-type Anderson structures in which the six protons have formally been replaced by two $(As_3O_3)^{3+}$ groups have been reported.[10,11] Analogously, it should be possible to incorporate alkoxo groups in place of the hydroxo groups of the B-type structure, thus formally replacing protons by carbon atoms. The synthesis of Anderson polyanions in alcoholic solvents (methanol or ethanol) has been reported,[12] but no incorporation of the alcohol was found. We therefore decided to investigate the reaction in the presence of tris(hydroxymethyl)methane derivatives $RC(CH_2OH)_3$, because the three alkoxo groups should ideally replace all three hydroxo groups on each side of the Anderson structure. This capping effect should enhance the stability of the complex formed. The residue R could further serve for the introduction of a variety of functionalities.

Results and Discussion

Synthesis

On the basis of our own experience and that of others[12] in polyoxometalate synthesis in organic solvents, and also our previous preparation of $[H_2Mo_8O_{24}\{R(CH_2O)_3\}_2]^{4-}$,[13] we decided to use the same $[\alpha\text{-}Mo_8O_{26}]^{4-}$ precursor and to operate in acetonitrile. The heteroatom should be introduced with a labile ligand, and we chose the acetylacetonate (acac) or acetate (OAc) complexes of Mn^{III}, Fe^{III}, Ni^{II}, and Zn^{II}. Thus, we treated 1 equiv. of $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ with 1.5 equiv. of $M(acac)_3$ (M = Mn^{III}, Fe^{III}) or $M(OAc)_2$ (M = Zn^{II}, Ni^{II}) and 3 equiv. of tris(hydroxymethyl)methane derivatives $RC(CH_2OH)_3$ (R = CH_3, NO_2, CH_2OH) in refluxing acetonitrile. The complexes formed (Table 1) were isolated from the solution as their tetrabutylammonium salts by slow ether vapor diffusion and recrystallization from DMF/ether. While Anderson-type polyoxomolybdates with Mn^{II}, Fe^{III}, Ni^{II}, and Zn^{II} have been reported in the literature,[1,2,12,14,15] compounds **1** appear to be the first with Mn in oxidation state +III.

Crystal Structures

Compounds **1b**, **3c**, and **4a** were characterized by single-crystal X-ray diffraction; crystal structure data are summar-

ized in Table 4. The molecular structures of these compounds belong to two groups, described below.

The structure of $[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CNO_2\}_2]\cdot 2DMF$ (**1b**·2DMF) is representative of the first group. It consists of three tetrabutylammonium cations, an $[MnMo_6O_{18}\{(OCH_2)_3CNO_2\}_2]^{3-}$ anion, and solvent molecules of crystallization. Two views of the anion are presented in Figure 1. The geometry of the polyanion is based on the common Anderson structure, with six MoO_6 octahedral edge-sharing units forming a hexagon around the central MnO_6 octahedron. All metal atoms essentially lie in a common plane, with a maximum deviation of 0.002 Å from the best least-squares plane. Selected bond lengths and angles are compiled in Table 2.

The six triply bridging oxygen atoms surrounding the Mn^{III} center belong to two $RC(CH_2O)_3$ residues. Thus, the organic alkoxide groups effectively replace the six hydroxide groups in B-type Anderson structures. They can be regarded as capping both sides of the planar metal arrangement. The coordination geometry of the central Mn^{III} ion is regular, with a mean Mn−O distance of 1.98(1) Å, and O−Mn−O bond angles of between 86° and 93°. The small distortions observed correspond to a slight compression of the octahedron, bringing the two faces capped by the organic ligands closer together. This distortion might arise from the expected Jahn−Teller effect for Mn^{III}. A similar small Jahn−Teller distortion, resulting in that case in the elongation of the central octahedron, has also been observed in the compound $[H_6CuMo_6O_{24}]^{4-}$.[16,17] The lack of flexibility of the Anderson polyoxometalate apparently prevents larger distortions. Thus, both chemical and crystallographic analysis are consistent with the presence of a Mn^{III} center. Preliminary EPR measurements are also in agreement with this conclusion. This series of compounds therefore represents the first Anderson molybdates with manganese in oxidation state +III. Only the analogous Mn^{II} molybdates have been reported previously.[14,15,18]

The MoO_6 octahedra are distorted, with Mo−O distances that fall into three ranges depending on the type of oxygen atoms bound. The longest distance is that towards the triply bridging alkoxide ligands (average 2.37 Å). The doubly bridging and the terminal oxygen atoms are at distances from the molybdenum atoms of 1.94 Å and 1.71 Å, respectively.

A single-crystal X-ray diffraction study of compound **1a** did not provide enough reflections to refine the structure satisfactorily. However, it was established without any doubt that the overall structure of the polyanion is identical

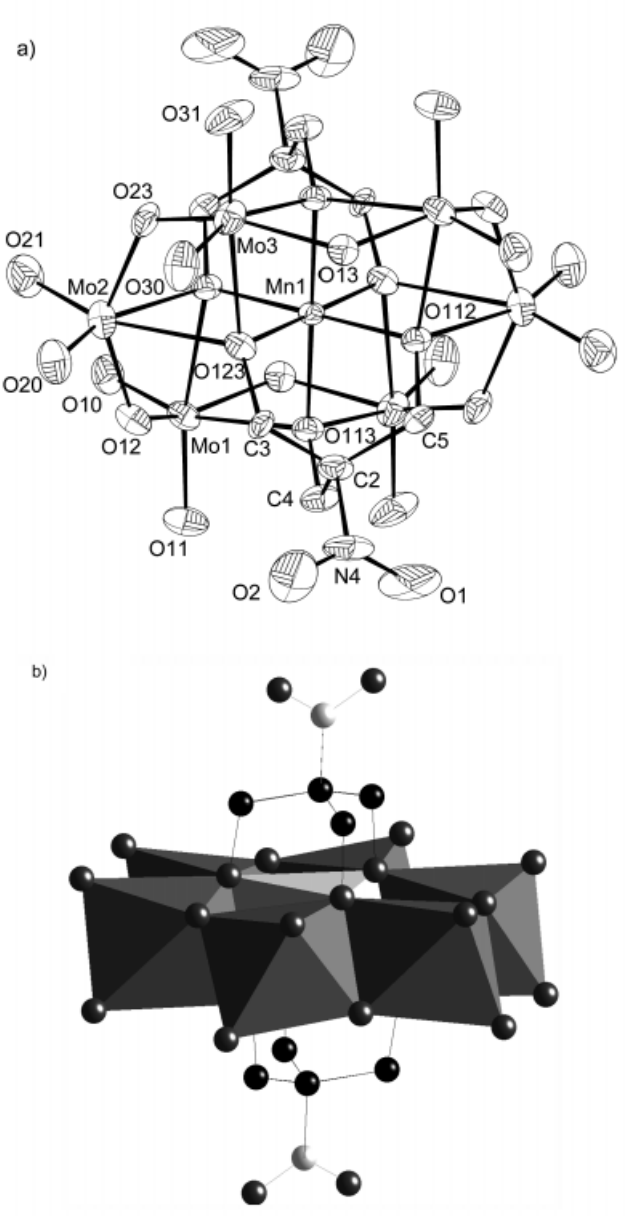

Figure 1. Structure and atom numbering of $[MnMo_6O_{18}\{(OCH_2)_3CNO_2\}_2]^{3-}$ (anion of **1b**); (a) thermal ellipsoids, (b) polyhedral representation

to that of **1b**; that is, the $CH_3C(CH_2O)_3$ residues cap the central Mn^{III} ion in the Anderson structure.

The structures of compounds **3c** and **4a** are representative of the second group. They both consist of a heteropolymolybdate − $[H_2MMo_6O_{18}\{(OCH_2)_3CR\}_2]^{2-}$ − that dif-

O(113)′ Mn(1)−O(123)	88.2(3)	O(113)−Ni(1)−O(123)′	81.8(1)	O(113)′ Zn(1)−O(123)	98.2(1)

fers remarkably from **1a** and **1b**. Yet again, the polyanion is based on the Anderson structure, with the heteroatom in the central cavity formed by six MoO_6 units. However, the organic ligands do not cap two faces of the central octahedron, but two tetrahedral cavities as shown in Figures 2 and 3. This causes the loss of the threefold symmetry as displayed in compounds **1a** and **1b**. The bond lengths (Table 2) are similar to those found in **1b**.

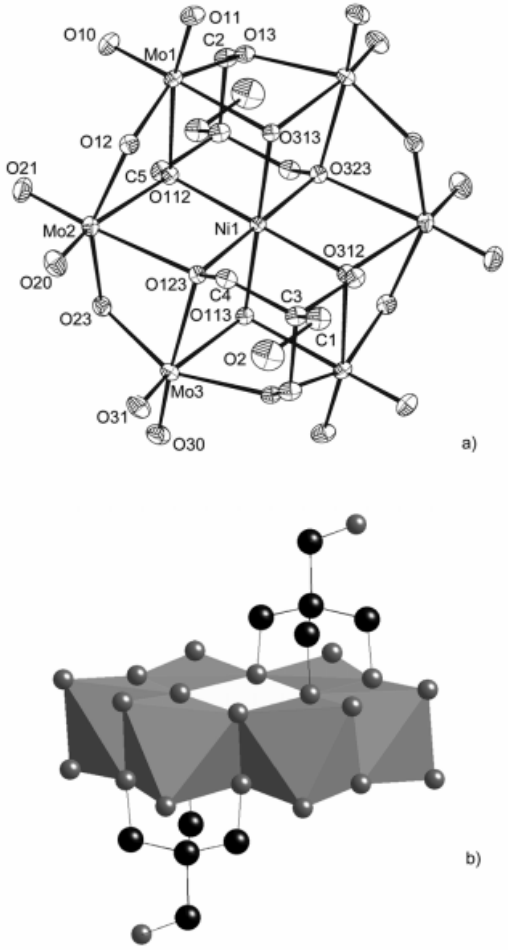

Figure 2. Structure and atom numbering of $[H_2NiMo_6O_{18}\{(OCH_2)_3CCH_2OH\}_2]^{2-}$ (anion of **3c**); (a) thermal ellipsoids, (b) polyhedral representation

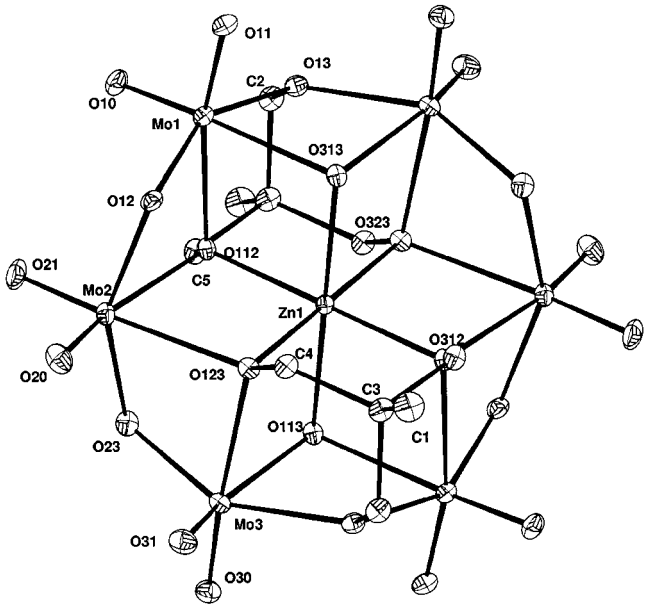

Figure 3. Structure and atom numbering of $[H_2ZnMo_6O_{18}\{(OCH_2)_3CCH_3\}_2]^{2-}$ (anion of **4a**), thermal ellipsoids

The crystals contain two $N(C_4H_9)_4$ cations per unit, thus indicating that the polyanions are doubly protonated. The quality of the X-ray diffraction data allowed the hydrogen atoms on the cations, anions, and the DMF molecules to be located. Furthermore, calculations of bond valence sums were performed in order to distinguish between O and OH ligands. It was clearly established that the remaining triply bridging oxygen atoms are protonated and form hydrogen bonds with the DMF oxygen atoms (distance 2.7 Å). The central metal is therefore coordinated to four μ_3-alkoxo and two μ_3-hydroxo ligands. The latter are at a slightly longer distance so that the coordination geometry of the central metal atom is an elongated octahedron.

It should be mentioned that the oxygen atoms bound to carbon atoms in **3c** and **4a** are protonated in the structure of $K_2[H_6\text{-}\alpha\text{-}PtMo_6O_{24}]\cdot 5H_2O$.[4] Thus, just as there are two different protonation patterns for B-type Anderson structures, there are two coordination modes for tris(hydroxymethyl)methane ligands. Below, we refer to the coordination mode in **1a** and **1b** as δ and in **3c** and **4a** as χ.

Spectroscopy

In order to assign the structures of the remaining compounds, and to determine their solution structures, we used NMR- and IR-spectroscopic methods.

The diamagnetic nature of compounds **4a**, **4b**, and **4c** allowed them to be investigated by multinuclear NMR. Selected NMR shifts are collected in Table 3; the complete description can be found in the Exp. Sect.

In order to interpret these results, one should discuss the expected pattern based on symmetry considerations [ignoring the atoms comprising R in the $RC(CH_2O)_3$ residues].

The δ form has an idealized D_{3d} symmetry. The methylene hydrogen and carbon atoms are chemically equivalent, as are the six molybdenum atoms. The oxygen atoms can be divided into three groups of terminal and doubly and triply bridging atoms.

The χ form, on the other hand, has a lower symmetry close to C_{2h}. The CH_2O hydrogen atoms can therefore be divided into three groups, and the carbon atoms into two. Furthermore, two types of molybdenum atoms and seven types of oxygen atoms are to be expected.

The ^{1}H and ^{13}C NMR spectra of compound **4b** in acetonitrile, which displayed only singlet signals (Table 3), clearly validated the δ form for the polyanion. Conversely, the spectra of **4a** and **4c** revealed the χ structure. In the latter, the CH_2O hydrogen atoms formed two ABX patterns, appearing as two doublets and one singlet of equal intensities. The corresponding carbon atoms gave rise to two signals of approximate 1:2 intensity. The molybdenum atoms were also observed, as expected, as two signals in a 2:4 ratio. The number of oxygen signals, however, was lower than expected. We found three signals of equal intensity (4 O) at $\delta \approx 900$, attributable to the three different terminal oxygen atoms by comparison with literature findings.[19] Four more signals should arise for the bridging oxygen atoms: four μ_3- and two μ_2-alkoxo, two μ_3-hydroxo and four μ_2-oxo ligands. Only two signals were observed, integrating as four and six oxygen atoms. There is no obvious assignment for these signals, but they are not incompatible with the proposed structure. Indeed, the chemical shifts fitted for bridging oxygen atoms, and hydroxy groups were not observed by ^{17}O NMR in other B-type heteropolymolybdates.[19]

Compound **4a** thus conclusively retains the χ form, as also found in the solid state, in solution. Compound **4c** has the same χ structure, but not compound **4b**, which adopts the δ form instead. This shows that the structure may vary with variation of the substituent R in the tris(hydroxymethyl)methane derivative. It should be mentioned that compound **4b** was obtained in significantly lower yield than **4a** and **4c**, and that it contained the $[\alpha\text{-}Mo_8O_{26}]^{4-}$ starting material as an impurity.

The paramagnetic compounds **1a**−**c**, **2a**−**c**, and **3a**−**c** were also investigated by ^{1}H NMR. In all cases, considerable line broadening was observed for the signals of the tetrabutylammonium cations. Signals for the organic ligand were observed only for compounds **1a**−**c**. They each displayed a broad singlet for the CH_2O groups at $\delta \approx 60$. This was suggestive of the δ structure, in which all CH_2O groups are at the same distance from the paramagnetic Mn^{III} center. In the χ structure, one CH_2O group of each ligand is not bound to the central Mn^{III}, and so these protons should be less deshielded.

In order to determine the structures of the remaining compounds in the series, we analyzed the IR spectra obtained in the solid state in detail. The two forms δ and χ are closely related, and their IR spectra were very similar; Figure 4 shows two representative examples (**1a** and **4a**) with the same tris(alkoxo) ligand. The spectra were typical of Anderson-type compounds,[12,15,20] with vibrational bands between 890 and 950 cm^{-1} for the terminal Mo=O units and between 660 and 710 cm^{-1} for the bridging Mo−O−Mo groups. The O−C bonds gave rise to bands between 1020 and 1120 cm^{-1}. The only difference detectable in the spectra of the compounds with known structures, established by the methods described above, concerned the bands around 700 cm^{-1}. The compounds with δ structure − **1a**, **1b**, and **4b** − each displayed a large and intensive band around 670 cm^{-1}, attributable to the vibration of the bridging Mo−O−Mo oxygen atoms. The reduction of the symmetry on passing to the χ form seemed to cause a splitting of this band. Indeed, **3c** and **4a** each displayed an additional signal of intermediate intensity, at 736 cm^{-1} and 732 cm^{-1}, respectively. On the assumption that an additional signal around 730 cm^{-1} exists in the spectra

of compounds with the χ arrangement, the structures containing the three-valent heteroatoms Mn^{III} and Fe^{III} are all identified as δ.

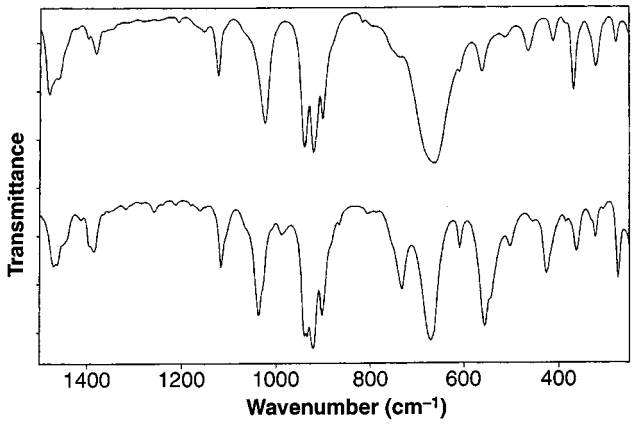

Figure 4. Infrared spectra of $[N(C_4H_9)_4]_3[MnMo_6O_{18}\{(OCH_2)_3CCH_3\}_2]$ (**1a**; top trace) and $[N(C_4H_9)_4]_2[H_2ZnMo_6O_{18}\{(OCH_2)_3CCH_3\}_2]$ (**4a**; bottom trace); note the splitting of the band around 700 cm^{-1} typical for the χ form

The Ni^{II}-containing compounds **3a** and **3b** each showed a very weak band in this region. This can be interpreted as resulting from a mixture of both form δ and form χ. This assumption was backed up by the elemental analyses of these compounds, which also correlated with mixtures of the two forms.

In summary, we have synthesized and structurally characterized a family of Anderson-type heteropolymolybdates containing tris(hydroxymethyl)methane derivatives. Two types of structures − δ and χ − differing in the site occupied by the alkoxide groups have been identified. In the presence of three-valent heteroatoms Mn^{III} and Fe^{III}, only the δ form occurred. The use of divalent heteroatoms Zn^{II} and Ni^{II} resulted in the formation of either δ or χ structures, or in mixtures of both. The reasons for preference for one or the other form are under investigation.

This work offers the potential to functionalize the heteropolymolybdates further by varying the R group on the $RC(CH_2OH)_3$ triol. If the R group were itself reactive, it should be possible to modify it while attached to the heteropolymolybdate. Thus, different functionalized polyoxometalates should be obtainable from a common precursor. Work in this area is in progress.

Experimental Section

Material: $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ was prepared by literature methods.[21] All other compounds, including solvents, were commercially available as reagent grade and used as received.

Spectroscopy: NMR spectra were recorded with Bruker AC 300 (^1H, ^{13}C) and Bruker AM 500 (^{95}Mo, ^{17}O) spectrometers. Deuterated solvent (CD_3CN unless otherwise stated) was used for ^1H and ^{13}C NMR. Chemical shifts (δ) are expressed in ppm relative to Me_4Si with residual solvent peak as standard. ^{13}C NMR spectra were recorded by use of an INEPT pulsing sequence. ^{17}O and ^{95}Mo NMR spectra were recorded at temperatures between 298 and 343 K at concentrations of 0.02 M in acetonitrile. Chemical shifts (δ) are expressed in ppm relative to water (^{17}O) and external aqueous alkaline Na_2MoO_4 (^{95}Mo). All compounds **4a**−**c** displayed the following signals for $N(C_4H_9)_4$ cations, integrating correctly for the number of cations required by the given formula. ^1H NMR: δ = 0.97 (t, $^3J_{H,H}$ = 7.3 Hz, 12 H, $NCH_2CH_2CH_2CH_3$), 1.38 (m, 8 H, $NCH_2CH_2CH_2CH_3$), 1.61 (m, 8 H, $NCH_2CH_2CH_2CH_3$), 3.10 (m, 8 H, $NCH_2CH_2CH_2CH_3$). ^{13}C NMR: δ = 13.8, 20.3, 24.3, 59.1. The signals were broadened in the case of paramagnetic compounds, without significant change in their chemical shifts. IR spectra were obtained on KBr pellets with a Bio-Rad FTS 165 spectrometer. All spectra contained the bands for tetrabutylammonium at 2960, 2874, 1472, and 1382 cm^{-1}. Relative intensities are given after the wavenumber as vs = very strong, s = strong, m = medium, w = weak, sh = shoulder, br = broad.

X-ray Crystal Structure Determination: A selected single crystal was set up on an automatic diffractometer. Unit-cell dimensions with estimated standard deviations were obtained from least-squares refinements of the setting angles of 25 well-centered reflections. Two standard reflections were monitored periodically; they showed no change during data collection. Crystallographic data and other pertinent information are summarized in Table 4. Corrections were made for Lorentz and polarization effects. Secondary extinction corrections were necessary. Computations were performed with the PC version of CRYSTALS.[22] Atomic form factors for neutral atoms were taken from tabulated values.[23] Real and imaginary parts of anomalous dispersion were taken into account. The structure was solved by direct methods[24] and successive Fourier maps. An absorption correction based on DIFABS[25] was applied. Non-hydrogen atoms were refined anisotropically. Least-squares refinements in full matrix were carried out by minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, in which F_o and F_c are the observed and calculated structure factors. Models reached convergence with $R = \Sigma(||F_o| - |F_c||)/\Sigma wF_o$ and $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2]^{1/2}$ having the values listed in Table 4. In the last stages of the refinement, each reflection was assigned a weight $w = w'\{1 - [(||F_o| - |F_c||)/6\sigma|F_o|]^2\}^2$ with $w' = 1/\Sigma_r A_r T_r(X)$ with three coefficients for a Chebyshev series, for which $X = F_c/F_c(\text{max.})$. Criteria for a satisfactory complete analysis were the ratio of rms shift to standard deviations being less then 0.2 and no significant features in the difference map. The ellipsoid views of the molecules were obtained with Cameron,[26] polyhedral representations were produced with CrystalMaker.[27] Ellipsoids are shown at the 20% probability level. CCDC-167626 (**1b**), -167627 (**3c**), and -167625 (**4a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis

General Method for the Complexes 1−4 a-c: A solution of $[N(C_4H_9)_4]_4[\alpha\text{-}Mo_8O_{26}]$ (1.1 g, 0.5 mmol) and 0.75 mmol of $M(acac)_3$ (M = Mn^{III}, Fe^{III}) or $M(OAc)_2$ (M = Zn^{II}, Ni^{II}) in 20 mL of acetonitrile was heated to reflux overnight (approximately 17 h). On cooling, a very small quantity of an unidentified solid separated and was discarded. On vapor diffusion of ether into the solution over 2 d, a solid crystallized and was filtered off, washed with ether, and air-dried. Recrystallization from DMF/ether gave analytically pure samples.

Studies of Phosphonic Acids Containing a π-Conjugated Ferrocenyl Unit Grafted on Metal Oxides − Mössbauer and Electrochemical Behaviour

Richard Frantz,*[b] Jean-Olivier Durand,[b] Gérard F. Lanneau,[b] Jean-Claude Jumas,[a] Josette Olivier-Fourcade,[a] Marc Cretin,[c] and Michel Persin[c]

Keywords: Mössbauer spectroscopy / Electrochemistry / Phosphorus / Sandwich complexes

The modification of metal oxide surfaces by π-conjugated ferrocene units has been performed. A phosphonic acid functionality was used to covalently anchor the π-conjugated ferrocene moiety to SnO_2 and TiO_2 particles. The covalent attachment and the monolayer coverage at the surface of the particles were confirmed by solid-state MAS ^{31}P NMR spectroscopy, microanalysis and electronic microscopy (EDX). The properties of the ferrocene-modified oxides were analysed by cyclic voltammetry, which confirmed the electroactivity of the material, and ^{57}Fe Mössbauer spectrometry, which provided information about the oxidation state and environment of the iron atoms.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The syntheses of materials with ferrocene units have attracted considerable interest in the last decades.[1] They have found increasing uses in many fields: molecular materials for non-linear optics,[1b] polymers for electrochemical applications,[1c] asymmetric catalysis,[1d] amperometric biosensors for glucose oxidase,[1e] and surfactant devices.[1f] The covalent coverage of surface oxides by organic molecules functionalised with ferrocene is particularly important for fundamental mechanistic studies,[2a] as well as for applications in the field of modified electrodes.[2b−2e] Great attention has been devoted to ferrocenes possessing a grafting function, such as a mercaptan[2c−2e] or a carboxylic acid,[2b] in order to achieve the preparation of new electrodes. Its application as electrochemical transducers for biosensors seems promising.[2f−2g] As the grafting of sophisticated molecules using a phosphonic acid functionality has been used for many purposes[3,2b] and is known to be very stable,[3c] we focused our attention to this functionality to covalently anchor ferrocene units to metal oxide particles. We have already described the preparation of phosphonic acids containing a π-conjugated ferrocenyl unit with a defined configuration of the conjugated backbone.[4] Analyses of their electrochemical properties in DMSO showed standard reversible redox waves assigned to the Fe^{II}/Fe^{III} couple.[4] Here, we present our studies on the grafting of these molecules on the surface of TiO_2 and SnO_2 particles. Electrochemistry is used as a powerful tool for detecting the electroactive species at the surface. ^{57}Fe Mössbauer spectroscopy informs us about the oxidation state of the iron atoms, the symmetry of its electronic environment and the nature of the chemical bonds involved. Additional information on the structural properties is obtained from the Mössbauer effect probability and its temperature dependence.

Results and Discussion

Two types of phosphonic acids with a π-conjugated ferrocenyl unit, **1** and **2**, have been synthesised (Scheme 1), and their electronic properties characterised in solution. We have shown that a better transmission of the electronic effects is obtained with the more conjugated phenylphosphonic acid **1** than the benzylphosphonic acid **2.**[4] The more conjugated phenylphosphonic acid **1** is a better electron-withdrawing group than the benzylphosphonic acid **2**. We then performed the grafting reaction of acids **1** and **2** (Scheme 1), in order to investigate the properties of the new hybrid organic-inorganic materials thus prepared, and particularly the modification of the electronic properties in the solid state. Three types of particle oxides were used. TiO_2 P25 Degussa (particle size of 21 nm) (**Ti**), SnO_2 synthesised by the sol-gel process[5] and pyrolysis at 700 °C (particle size 5−10 nm) (**Ss**), and SnO_2 Merck (particle size 20 nm) (**Sc**). The surface of the TiO_2 and SnO_2 particles were modi-

fied by refluxing with the phosphonic acid **1** or **2** for 3 d in MeOH/H_2O (4:1) at 65 °C. This mixture of solvents was chosen because of the low solubility of the acids **1** and **2**. A large excess of acid was used to ensure the total coverage of the particle surfaces. The solids were first analysed using energy-dispersive X-ray techniques, microanalysis, and solid-state ^{31}P NMR spectroscopy. Elemental analyses (Table 1) showed the presence of P and Fe in all the samples, indicating the presence of the molecules **1** and **2** at the surface of the particles. The P/Fe ratios were between 0.7 and 0.85, which confirmed that cleavage of the P−C bond did not occur. The microanalyses were corroborated by energy-dispersive X-ray analyses. Variation of the P/MO_2 ratio was not observed from one experiment to another on the same sample, which showed that the solids were homogeneous on a micrometric scale. From the low P/MO_2 ratio we have concluded that a monolayer coverage resulted at the surface of the oxide.[3c] Note that the proportion of the organic part was higher for **Ss1** than **Sc1** because of the higher specific surface area for **Ss1** (particle size 5−10 nm for **Ss1** versus 20 nm for **Sc1**). Solid-state ^{31}P NMR spectra of compounds **1** and **2** and materials **Ti1** and **Ti2** are presented in Figure 1. Phosphonic acids **1** and **2** show sharp signals at δ = 28.8 and 20, respectively, which is characteristic of well-crystallised homogeneous compounds. Signals of **Ti1** and **Ti2** are shifted upfield at δ = 22.3 and 13.6, respectively, which is characteristic of the formation of P−O−metal bonds. The peak width at half maximum is close to δ = 10, which indicates that the phosphorus atom has different environments on the surface of the oxide because of the different coordination modes. One, two, or three P−O−metal bonds are likely to be involved in the anchoring on the surface. In the case of materials **Sc1** and **Ss1** (Figure 2), we observed the same type of behaviour with an upfield shift at δ = 14 for the two materials. The signal was less symmetrical than for **Ti1** and **Ti2**, thus the

surface of SnO_2 is likely to be more carved than the surface of TiO_2.

Electrochemical Behaviour

After characterising the hybrid organic-inorganic materials, the electrochemical properties of the precursors and grafting materials were investigated by cyclic voltammetry by means of a potentiostat (E&GG model 273A). For the material powders, a modified electrode was prepared by pressing the particles on a flat pad made of stainless steel. A platinum electrode was used as the auxiliary electrode and a saturated calomel electrode was the reference, 0.1 M $LiClO_4$ was used as the electrolyte. The different voltammograms obtained are presented in Figures 3−5 and the half-wave potentials $E_{1/2}$ are gathered in Table 2. The electroactivity of the precursor **1** was first analysed in aqueous solution (Figure 3). We observed the quasi-reversible oxidation-reduction waves characteristic of the Fc^{II}/Fc^{III} couple. The oxidation and the reduction half-wave potentials were assigned at 150 mV/SCE and 200 mV/SCE, respectively. The electrochemical analyses, in the solid state, of the acid **1** and of the grafted TiO_2 powder (**Ti1**) are presented in Figure 4a. The non-reversibility of both systems is shown. In the solid state, the diffusion and the charge transfer processes do not obey the classical laws of electrochemistry in solution. The latter are, in many cases, slower than in solution, which explains the loss of the reversibility of the systems. The electrochemical behaviour of the acid **2** and of the grafted TiO_2 powder (**Ti2**) was studied after pressing the compounds on the stainless steel felt. The systems were non-reversible (Figure 4b), which confirmed the previous results. Moreover, comparison of the voltammograms of the grafted materials **Ti1** and **Ti2** shows that the oxidation and reduction potentials are close to those of the precursors **1** and **2**, respectively (Figure 4a,b). This confirms that the π-conjugated ferrocene unit was not damaged by the grafting on the oxide. The results obtained for the material **Ti2**, which differs from **Ti1** only by the presence of a CH_2 unit between the phenyl and phosphonic groups, confirms the ferrocene electroactivity. Furthermore, we observed the same behaviour as in a DMSO solution.[4] It is easier to oxidise acid **2** relative to acid **1** in the solid state (Table 2), due to the presence of the CH_2 group, which reduces the withdrawing effect of the phosphonic acid substituent. This effect is less visible on the grafted powders **Ti1** and **Ti2**. In Figure 5, the elec-

Table 2. $E_{1/2}$ of **1**, **2**, **Ti1**, **Ti2**, **Sc1**, **Ss1**

	Acid **1** Solution	Solid state	Powder **Ti1**	Powder **Sc1**	Powder **Ss1**	Acid **2** Solid state	Powder **Ti2**
$E_{1/2}$ [mV] Oxidation	150	285	260	200	200	260	260
$E_{1/2}$ [mV] Reduction	200	175	110	160	160	100	100

troactivity of the ferrocene unit on both grafted SnO_2 powders **Sc1** and **Ss1** is conserved. The $E_{1/2}$ values and the intensity recorded in the cyclic voltammograms confirms that the electroactivity of the ferrocene group is to be better on the SnO_2 grafted powder than on the TiO_2 grafted powder. Note also that the SnO_2-based system seems to be more reversible than the TiO_2-based system ($\Delta E_{Ti1}^{peak} = 430$ mV, $\Delta E_{Sc1}^{peak} = 390$ mV).

Mössbauer Spectrometry

^{57}Fe Mössbauer experiments were performed with an EG&G constant acceleration spectrometer in transmission mode. The source of nominal activity was 10 mCi of ^{57}Co in an Rh matrix. The velocity scale was calibrated using the standard magnetic sextuplet of a high-purity iron foil absorber. The origin of the isomer shift scale was determined from the centre of the α-Fe spectrum recorded at room temperature. The absorbers were prepared from approximately 200 mg of the powders in a specific cell.

^{57}Fe Mössbauer spectroscopy has been widely used to explore the charge density and symmetry of the charge distribution around the metal atom of ferrocenyl derivatives.[6] The Mössbauer spectra of low-spin Fe^{II} in ferrocenyl derivatives show isomer shifts δ in the range $0.45 < \delta < 0.55$ mms^{-1} and quadrupolar splittings Δ in the range $2.2 < \Delta < 2.5$ mms^{-1}. Spectra of acids **1** and **2** are presented in Figure 6. The characteristic doublet of the ferrocene units are at $\delta = 0.443$ and 0.449 mms^{-1}, respectively, and the quadrupolar splitting is at $\Delta = 2.268$ and 2.270 mms^{-1}, respectively. A secondary signal was also observed in the two spectra. The contribution of the signal to the spectra was 3.2% and 8.1%, respectively (Table 3). Isomeric shifts were in the range of the ferrocene species (0.44 and 0.49 mms^{-1}, respectively), but the quadrupole splittings are much smaller (in the range 0 to 0.38 mms^{-1}), indicating the presence of a "ferrocenium-like" low-spin Fe^{III} compound. It seems that a small fraction of ferrocene Fe^{II} has been oxidised to the Fe^{III} species. For the low-spin Fe^{II} and low-spin Fe^{III} species, the isomer shift is not very sensitive to the formal oxidation state of iron because the effective electric charges on the iron are not very different. In contrast, the quadrupole splitting of the ferrocenium ion $(C_5H_5)_2Fe^+$ decreases remarkably. For the two acids **1** and **2**, the Mössbauer parameters remain unchanged compared with unsubstituted ferrocene. The σ-bonded substituents on the cyclopentadienyl ring do not affect the π-bonds of the ferrocene unit. After compounds **1** and **2** were grafted on TiO_2, the materials **Ti1** and **Ti2** were analysed at room temperature (Figure 6). Major changes in the Mössbauer signals are observed, with only one broadened doublet. Respective values of the isomer shift are 0.40 and 0.38, in the range of ferrocenyl compounds. Quadrupole splitting values of about 0.6−0.7 mms^{-1} suggest the presence of some kind of electronic effect. The line broadening and the weak absorption are consistent with an averaged valence state of iron. This is not surprising, as TiO_2 is known to be a photooxidant. Sato[6−7] has observed the same type of behaviour by adsorbing ferrocene on silica. After standing in air, the Mössbauer spectra at room temperature only showed ferrocenium. By performing the measurements at 78 K, the signal of the ferrocene Fe^{II} species appeared, together with the signal of ferrocenium Fe^{III}. Materials **Ti1** and **Ti2** were therefore analysed at low temperature. At 78 K (Figure 4c), the spectra consist of an inner- and outer-doublet which are assigned to a "ferrocenium-like" Fe^{III} and a "ferrocene-like" Fe^{II} doublet, with a ratio of about 3:1. The characteristic signal of the ferrocene unit in its Fe^{II} form is observed for both **Ti1** ($\delta = 0.51$, $\Delta = 2.26$ mms^{-1}) and **Ti2** ($\delta = 0.63$, $\Delta = 2.43$ mms^{-1}), together with the ferrocenium species for both **Ti1** ($\delta = 0.50$, $\Delta = 0.67$) and **Ti2** ($\delta = 0.49$, $\Delta = 0.65$ mms^{-1}). These last measurements show the temperature dependence of the mixed-valence state, where the valence-state changes from an averaged to a trapped valence state. This effect proves that there is an interaction between the π-electrons of the cyclopentadienyl ring of ferrocene and the metal oxides (MO_2).

Conclusion

The covalent attachment of ferrocenyl π-conjugated compounds **1** and **2** on metal oxides has been efficiently achieved by using the phosphonic acid functionality. In this way an organic monolayer at the surface of the oxide was formed. Solid-state electrochemistry has confirmed the electroactivity of the supported ferrocene units, the electrochemical system was irreversible. Electroactivity seemed to be better with the SnO_2 grafted powders than the TiO_2

grafted powders, although coverage is higher on TiO_2 then on SnO_2. The support is effective and could be of importance for the final materials made. Mössbauer spectroscopy has shown that the ferrocene moiety was partially oxidised, and that the π-electrons of the ferrocene interact with the metal oxide. Potential applications in the field of modified electrodes and sensors are in progress.

Experimental Section

General: All reactions were performed under argon. Energy-dispersive X-ray analyses (EDX) were performed with an electronic scanning microscope Cambridge Stereoscan 360 equipped with a Link AN 10000 probe. Microanalyses were performed by the central analysis service at CNRS (Vernaison). The syntheses of the ferrocene π-conjugated phosphonic acids **1** and **2** have been described elsewhere.[4] SnO_2 was synthesised from $SnCl_4$ as described.[5] Commercial SnO_2 was purchased from Merck and TiO_2 P25 was furnished by Degussa. These oxides were functionalised by the following general procedure: The metal oxide was suspended in a mixture of MeOH (40 mL), H_2O (10 mL). Phosphonic acid **1** or **2** was added and the mixture heated at 65 °C for 3 d whilst stirring. The suspension was then cooled, filtered through a millipore membrane (0.45 μm), washed successively with water, MeOH, EtOH, acetone, ether and dried at room temp.

Material Ti1: TiO_2 P25: 600 mg (7.51 mmol), acid **1**: 200 mg (0.524 mmol). Solid-state ^{31}P NMR (hpdec, δ value): 13.6. Microanalysis (%): Fe 2.20, P 1.50, Ti 48.20; EDX (%)**:** Fe 4.14, P 3.99**.**

Material Ti2: TiO_2 P25: 600 mg (7.51 mmol), acid **2**:200 mg (0.543 mmol). Solid-state ^{31}P NMR (hpdec, δ value): 22.1. Microanalysis (%): Fe 2.20, P 1.75, Ti 48.80. EDX (%): Fe 3.5, P 4.07.

A Polymer-Supported β-Ketoesterate Complex of Palladium as an Efficient, Phosphane-Free, Air-Stable, Recyclable Catalyst for the Heck Reaction

Maria M. Dell'Anna,[a] Piero Mastrorilli,[a] Francesco Muscio,[a] Cosimo F. Nobile,*[a] and Gian P. Suranna[a]

Keywords: Heck reaction / Supported catalysts / Palladium

The coupling between aryl iodides and bromides with olefins (Heck reaction) has been studied with a polymer-supported palladium catalyst in the presence of sodium or potassium acetate. The reactions can be performed in air without any activating phosphorus ligands and with non dried solvents. Under suitable conditions the catalyst, which exhibits high activity and selectivity, is recyclable several times with negligible leaching of metal.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The Heck reaction[1] remains one of the most useful and versatile C−C bond forming reaction known. Although this vinylation of aryl halides has been widely studied in academia, there are not many industrial examples of its exploitation. The reasons for this are economic. Heck reactions are mostly catalysed by palladium complexes in homogeneous solution in the presence of phosphorus ligands, which are toxic and unrecoverable. In addition, these expensive catalysts give problems due to their instability at high reaction temperatures, and their separation and recovery after use. These problems can be overcome, however, by the use of heterogeneous systems,[2] made up of supported palladium complexes, which, moreover, are generally phosphane-free. Palladium metal colloids, in some cases stabilised by the presence of the support, appear to be the active species[3] for phosphane-free catalytic systems.

Polymer-supported palladium complexes have been used for the activation of aryl iodides by several research groups. An early report on a palladium catalyst based on triphenylphosphane-bonded polystyrene resin[4] describes the arylation of olefins by iodoarenes, although no studies on the activity of the recycled resin are reported. In a more recent paper, polymer-supported 1,2-bis(diisopropylphosphanyl)-benzene has been used for preparing a palladium catalyst for the reaction of iodobenzene with methyl acrylate.[5]

The reaction between Pd^{II} salts and a polypyrrole containing a phosphane-borane moiety resulted in another type of solid-supported palladium catalyst[6] that was moderately active in the coupling of iodobenzene with acrylic esters. The support could be recycled, though it needed to be recharged with $Pd(dba)_2$ in each subsequent run.

A palladium complex prepared from a triphenylphosphane amphiphilic resin and a palladium π-allyl chloride dimer has been used as an active catalyst for Suzuki cross-coupling and for the arylation of allylic acetates.[7]

All the heterogenised catalysts in which the support is a polymer with pendant phosphanes suffer from the same problem when used in Heck-type reactions: the irreversible loss of metal from the matrix due both to degradation of the phosphane moieties[2] and to the reaction mechanism itself.[8a] As an example, metal leaching was observed when palladium supported on glass beads was used as catalyst for Heck reactions, owing to the oxidation of phosphanes that bound the metal atoms onto the matrix.[9]

Various examples can be found in the literature concerning non-phosphinated organic polymers as supports for palladium-based catalysts. Among them, Pd^{II} coordinated to a pincer-type κ^3-S,C,S ligand attached to soluble organic polymers has been described as an active and recyclable catalyst for the olefination of iodoarenes at 95−110 °C under homogeneous[10] or liquid/liquid biphasic conditions.[11]

Polymer-supported carbene complexes of palladium have been used as recyclable catalysts for the Heck reaction of aryl bromides at 150 °C, although with significant loss of metal ($60\%_{wt}$) during the first run.[12]

Recently, a bis(pyrimidine)-based palladium polymer-supported catalyst for Heck-type reactions has been synthesised,[13] but no data on the activity of the recovered catalyst has been reported.

Another class of supports onto which catalytically active palladium is dispersed is represented by inorganic matrices. Pd on charcoal and Pd on different metal oxides have been found to be active catalysts for the Heck reaction of aryl

iodides.[2] Arai et al.[14] have studied the coupling between iodobenzene and methyl acrylate at 160 °C in the presence of 0.28−1.4 mol % of Pd supported on carbon or silica. Unfortunately, these conventional supported palladium catalysts are unselective when the substrates are bromoarenes, with dehalogenation being the dominant reaction. Pd particles supported on mesoporous silica have also been employed for the coupling of aryl bromides,[15] although satisfactory yields were obtained only with activated substrates such as *p*-bromonitrobenzene.

Very recently, Djakovitch et al. have described Pd-modified zeolites that are very active and recyclable catalysts for the Heck reaction of aryl bromides with olefins.[16]

Herein we report our studies on Heck reactions using a β-ketoesterato polymeric palladium complex (referred to as Pd-pol) as catalyst that exhibits satisfactory activities towards activated and nonactivated iodo- and bromoarene substrates. The supported complex (1.98%$_w$ Pd) was obtained by co-polymerisation of Pd(AAEMA)$_2$ [AAEMA$^-$ is the deprotonated form of 2-(acetoacetoxy)ethylmethacrylate] with ethyl methacrylate and ethylene glycol dimethacrylate.[17]

In this work we have considered the influence of solvent, base, temperature and additives on the performance and the recyclability of the catalyst.

Results and Discussion

Scheme 1 illustrates the scope of the investigated Heck reactions catalysed by Pd-pol. The molar ratio between the limiting substrate (aryl halide) and palladium was optimised at 1000 for reactions with aryl iodide and 500 for reactions with aryl bromides. A general feature of all the Pd-pol catalysed reactions is the simplicity of the set-up and work-up. All manipulations could be performed in an air atmosphere and with non-dried solvents because of the oxygen and moisture stability of the supported catalyst.

R' = $COOCH_3$, CN, C_6H_5

Scheme 1

The effect of the base was examined first. In preliminary experiments triethylamine (the typical base for many homogeneous and heterogeneous catalytic Heck reactions[1,2]) was used, but this organic base caused significant metal leaching. This is probably due to the higher coordination ability of trialkylamines towards palladium[18] than inorganic bases such as alkaline acetates or carbonates. For this reason, all subsequent tests were performed using inorganic bases such as potassium or sodium acetate. As for the choice of solvent, among those tested [toluene, *N*-methylpyrrolidine, dioxane, dimethyl sulfoxide, *N*,*N*-dimethylformamide (DMF), diethylene glycol (DEG)] the best results in terms of catalyst activity were obtained using DMF (with aryl iodides) and DEG (with aryl bromides).

Table 1. Heck coupling reactions of aryl iodides catalysed by Pd-pol; reaction conditions: a molar ratio of 1:1.2:2.4 was used for the aryl iodide (5 mmol):alkene:base (AcOK) in 6 mL DMF; T = 90 °C; molar ratio Pd/ArI = 1:1000; for all reactions the conversion of the aryl iodide was quantitative

Entry	Aryl iodide	Alkene	Additive	*t* (h)	Yield (%)[a] *trans*	*cis*

9	"		PPh_3[c]	2	95	5

[a] GLC yields. [b] Molar ratio Pd:DMG = 1:20. [c] Molar ratio Pd:PPh_3 = 1:5.

Table 1 summarises the results obtained in the reactions between activated and nonactivated aryl halides with different vinylic substrates. In all cases the conversions were quantitative.

The coupling between iodobenzene and styrene at 90 °C in the presence of 0.10 mol % of supported palladium gave, after 6 h, a 100% yield of stilbene (93% *trans*, 7% *cis*, entry 1). Under the same reaction conditions acrylonitrile afforded 99% cinnamonitrile with no selectivity between the *cis* and *trans* isomers (entry 2). The reaction between iodobenzene and methyl acrylate was faster, giving, at 90 °C, a 90% yield of *trans*-methyl cinnamate after 2 h (entry 3).

Reacting *p*-iodotoluene with styrene (entry 4), acrylonitrile (entry 5) or methyl acrylate (entry 6) resulted in quantitative yields of the desired coupling products.

The same reactions reported in entries 1, 2 and 3 of Table 1 were also carried out at 140 °C, in order to study the influence of the temperature. The reactions at 140 °C were slightly faster than those carried out at 90 °C. In particular, the reaction between iodobenzene and styrene was complete after 5 h, giving a 93% yield of *trans*-stilbene. The reaction between iodobenzene and methyl acrylate gave a quantitative conversion of the limiting substrate after 1 h with a 98% yield of *trans*-methyl cinnamate. The coupling

between iodobenzene and acrylonitrile was complete after 3 h giving a 76% yield of *trans*-cinnamonitrile and a 24% yield of *cis*-cinnamonitrile. In the two latter cases the selectivity was shifted towards the thermodynamically favoured *trans* adduct.

In order to study the influence of additives on the catalyst performance, the reactions of entries 1 and 2 were carried out in the presence of *N*,*N*-dimethylglycine (DMG), which is known to improve the activity and selectivity in the homogeneous phosphane-free Heck coupling of aryl bromides.[19] A slight improvement in the activity was observed. In fact, the TOFs for the reactions without DMG were 167 h^{-1} (entries 1, 2), whereas the TOFs for reactions carried out in the presence of a 20:1 DMG/Pd (mol/mol) ratio were 200 h^{-1} (styrene, entry 7) or 333 h^{-1} (acrylonitrile, entry 8).

The influence of a phosphorus additive, such as triphenylphosphane, was also investigated. The coupling between iodobenzene and methyl acrylate carried out in the presence of triphenylphosphane (5:1 P/Pd mol/mol) gave, after 2 h, a quantitative yield of methyl cinnamate (95% *trans* and 5% *cis*, entry 9), a result similar to that obtained in the phosphane-free reaction (entry 3). However, the presence of triphenylphosphane caused severe metal leaching from the supported catalyst.

In the case of the reaction of entry 9, the recovered catalyst became inactive after three cycles in the presence of PPh_3. On the contrary, the catalyst of the phosphane-free reaction described in entry 1 (Table 1) remained active for at least six cycles (Figure 1).

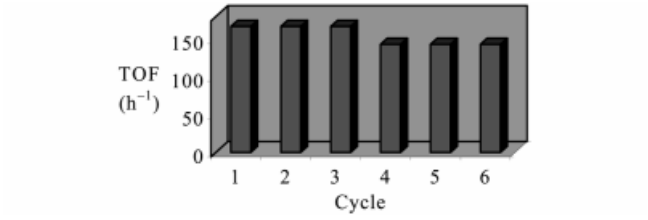

Figure 1. Recyclability of Pd-pol in Heck reactions between iodobenzene and styrene at 90 °C; in each reaction the conversion of iodobenzene was quantitative; TOF = [moles of coupling product (both isomers)]/[(moles of Pd) × (reaction time in hours)]

This behaviour was found to be general: the catalyst of all the phosphane-free reactions described in this work (including those in the presence of DMG) could be recycled at least three times with no loss of activity or selectivity.

The catalyst recycling was performed by filtration, washing with acetone and diethyl ether and with water (for removal of the excess base, its conjugate acid and the formed alkaline halides). This latter treatment did not affect the activity of the catalyst, as occurs in the case of palladium supported on zeolites and metal oxides.[20]

In addition, the mother liquor of all the described phosphane-free reactions (including those in the presence of DMG) showed negligible catalytic activity. On the other hand, the mother liquor of the reaction carried out in the presence of PPh_3 (entry 9) showed a moderate activity, giving a 50% conversion of fresh iodobenzene after 20 h reaction.

It is possible to explain the observed metal leaching in solutions containing PPh_3 as additive by referring to the commonly accepted mechanism.[1] Triphenylphosphane reduces palladium(II) to palladium(0) giving Ph_3PO and the coordinatively unsaturated $Pd(PPh_3)_2$, which can start the catalytic cycle through the oxidative addition of the aryl halide. Hence, the Pd^{II} centre must lose its counteranion (chloride, acetate, etc.) in order to enter the reaction cycle. Loss of the polymer-AAEMA$^-$ ligands, however, forms under-ligated palladium(0), which leaches irreversibly into solution.

Another mechanism, recently proposed by Amatore,[21] claims the intermediacy of anionic palladium complexes. In this case, the pre-activation step gives an anionic palladium(0) complex, which is able to start the catalytic cycle. This cycle is reported in Scheme 2 for the reaction promoted by Pd-pol in the presence of an *n*-fold excess PPh_3.

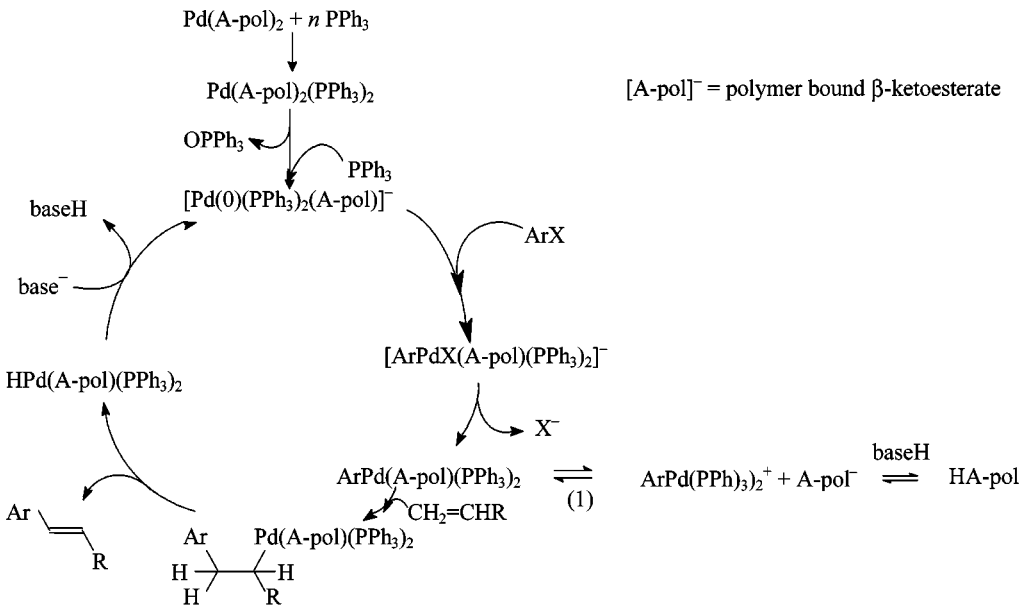
The anionic complex in our context should be $[Pd^0(PPh_3)_2(A\text{-}pol)]^-$ ([A-pol]$^-$ = polymer-bound β-ketoesterate). Following this type of mechanism the leaching should occur at the stage of the equilibrium (1) of Scheme 2.

In order to study the influence of equilibrium (1) on the metal leaching, one and two equivalents of base (respect to the olefin) were used in two parallel phosphane-assisted reactions. The reaction between iodobenzene and methyl acrylate carried out at 140 °C in the presence of one equivalent of base, 0.50 mol % of PPh_3 and 0.10 mol % of supported Pd, gave a 90% conversion and a 94% yield of *trans*-methyl cinnamate after 5 h. The same reaction carried out in the presence of two equivalents of base gave a quantitative conversion and a 98% yield of *trans*-methyl cinnamate after 1 h. In addition, the recovered resin of the former reaction (1 equiv. of base) was inactive for a second run, while the Pd-pol recovered after the second experiment (2 equiv. of base) was still active even after five further catalytic runs. However, contrary to what happens in phosphane-free reactions, the leaching is not completely inhibited even in the presence of 2 equiv. of base, since the mother liquor of the solution after each cycle revealed a high activity (80% of fresh iodobenzene converted after 3 h reaction).

The lower catalyst activity shown in the reaction carried out with 1 equiv. of base compared with that with 2 equiv. of base (the relevant TOF's are 200 h^{-1} and 1000 h^{-1}, respectively) can be ascribed to the formation of the less active[21a] cationic Pd complex $[ArPd(PPh_3)_2]^+$ generated through the equilibrium (1) of Scheme 2.

Although deeper mechanistic studies are required, these results seem to indicate that the reaction pathway proposed by Amatore is operative in our system.

The effect of the amount of base on metal leaching and on catalyst activity was observed by us also in the phosphane-free reactions. For example, the reaction between iodobenzene and styrene proceeded with TOFs of 83 h^{-1} or 167 h^{-1} when the molar ratio of olefin/base was 1 or 2, respectively. Furthermore, in the former case the copolymer leached out all its palladium loading after three cycles, whereas in the second case the metal content passed from



Scheme 2. Catalytic cycle via anionic palladium(0) complexes

1.98% before reaction to 1.67% after six cycles. It is possible to assume that the double amount of base inhibits the protonation of the polymer-supported β-ketoesterate ligand ($AAEMA^-$). Only if it remains anionic, in fact, is the polymeric ligand able to bind the palladium(II) and palladium(0) species involved in the different stages of the reaction cycle. The leaching of the metal could therefore be due to the protonation of the polymeric ligand by the acetic acid formed during the reaction.

In order to verify the influence of the presence of an acid in the reaction medium on metal leaching, the Suzuki reaction between aryl iodides and phenylboronic acid was carried out (Table 2). Quantitative yields of the corresponding coupling products were obtained starting from iodobenzene (entry 1) or *p*-iodotoluene (entry 2) with TOFs of 67 h^{-1} (iodobenzene) and 83 h^{-1} (*p*-iodotoluene). However, as expected, the initially yellow catalyst leached out all its palladium loading into solution and was inactive in subsequent runs.

Although in the case of the polymeric β-ketoesterato support the presence of a double amount of acetate results in increasing activity and recyclability of the supported catalyst, this effect is not generalizable.

The results reported in the literature seem to indicate that the amount of base and its nature can influence the metal leaching, *in function of the support used*. In fact, it has been recently claimed[22] that when Pd/alumina, Pd/C or sulfonated polystyrene-supported palladium are used to promote Heck reactions, the metal loss is enhanced by the presence of acetate ions (and of the aryl halide), presumably due to the formation of soluble $ArPdBr(OAc)_n$ or $ArPd(OAc)_n$ species.[8] Moreover, Arai et al.[14] reported that the Pd species leached out into the solvent during Heck reactions promoted by Pd/C or Pd/SiO_2 redeposited onto the surface of the supports at the end of the reaction only when 1 equiv. of Na_2CO_3 and 1 equiv. triethylamine were used at the same time.

Table 2. Suzuki and Sonogashira coupling reactions of aryl iodides catalysed by Pd-pol; typical reaction conditions: a molar ratio of 1:1.2:2.4 was used for ArI (5 mmol):phenyl boronic acid or phenylacetylene:base (AcOK) in 6 mL DMF; T = 90 °C; molar ratio Pd/aryl iodide = 1:1000; for all reactions the conversion of the aryl iodide was quantitative

[a] GLC yields.

The possibility of activating economically more interesting aryl bromides was also examined (Table 3). Pd-pol was used as catalyst for the Heck reaction of bromobenzene with styrene at 160 °C using a 1:500 Pd/substrate molar ratio, in the presence of DMG. Under these reaction condi-

tions the conversion of the substrate was quantitative after 12 h affording a 95% yield of *trans*-stilbene (entry 1). In the absence of DMG the conversion was quantitative after 24 h and the yield of *trans*-stilbene was 91% (entry 2). After the initial catalytic run, the resin used in the reaction of entry 1 was recovered, washed and recycled five times with negligible loss of activity (Figure 2).

Table 3. Heck coupling reactions of aryl bromides catalysed by Pd-pol; typical reaction conditions: a molar ratio of 1:1.2:2.4 was used for ArBr (5 mmol):alkene:base (NaOAc) in 6 mL DEG; T = 160 °C; molar ratio Pd/ArBr = 1:500

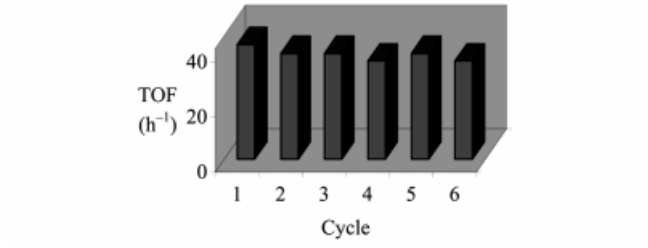

Figure 2. Recyclability of Pd-pol in Heck reactions between bromobenzene and styrene at 160 °C, in the presence of DMG; in each reaction the conversion of bromobenzene was quantitative; TOF = [moles of coupling product (both isomers)]/[(moles of Pd) × (reaction time in hours)]

The reactions of 4-bromonitrobenzene and 4-bromoacetophenone with styrene took 10 h to reach completion giving 90% (entry 3) and 92% yield (entry 4) of the *trans*-coupling adduct, respectively.

The possibility to use aryl chlorides as substrates in the Pd-pol catalytic system has also been examined. Unfortunately, the reactions between chlorobenzene and methyl acrylate or between *p*-chloronitrobenzene and styrene at 180 °C in the presence of DMG and Ph_4PCl[19b] were not effective, and only a small degree of dehalogenation occurred.

Finally, Pd-pol was used as catalyst for the coupling of aryl iodides with phenylacetylene at 90 °C (Sonogashira reaction), but the selectivities were poor (Table 2).

Experimental Section

All preparations, manipulations and reactions were carried out under air. All chemicals were purchased from Aldrich and used as received. The supported catalyst (Pd-pol) was prepared according to the procedure reported in ref.[17] The palladium content in the supported catalyst was determined by atomic absorption spectrometry using a Perkin−Elmer 3110 instrument. Chromatographic analyses were carried out on Hewlett Packard 6890 instruments using an HP-PLOT Molecular Sieve 5A (15.0m × 0.53 mm × 25.0 μm) column (injector temperature 280 °C, FID temperature 280 °C, carrier: nitrogen or helium). GCMS data (EI, 70 eV) were acquired on an HP 6890 instrument (injector temperature 280 °C, carrier: helium) using an HP-1 crosslinked methyl siloxane (60.0 m × 0.25 mm × 1.0 μm) capillary column coupled with a mass spectrometer HP 5973. The products were identified by comparison of their GC and GC-MS features with those of authentic samples. Conversions and yields were calculated by gas chromatography using *n*-dodecane as an internal standard calibrated to the corresponding pure compound. In the case of entry 1 of Table 1, the isolated yield was also assessed as described below.

General Procedure for the Heck, Suzuki and Sonogashira Reactions: A 50 mL pressure tube was charged with Pd-pol (1.98%$_w$ Pd), potassium or sodium acetate (12 mmol), aryl halide (5.0 mmol), olefin, alkyne or arylboronic acid (6.0 mmol), *n*-dodecane as internal standard, the additive (when present) and the solvent (DMF or DEG, 6 mL). The aryl iodide/Pd molar ratio was 1000, whereas the aryl bromide/Pd molar ratio was 500. The mixture was heated whilst stirring at the desired temperature until reaction completion as monitored by GLC and GCMS analyses. After reaction the catalyst was recovered by filtration, washed with acetone, water, acetone and diethyl ether, and dried under vacuum.

Isolation of *trans*-Stilbene: After separation of Pd-pol, the reaction mixture was diluted with CH_2Cl_2 (20 mL) and washed with H_2O (3 × 15 mL). After separation of the organic phase and drying over Na_2SO_4, the solution was concentrated under reduced pressure. Separation of the *cis*/*trans* isomers was carried out by silica gel chromatography with pentane/diethyl ether (1:1) solvent mixtures. The product was obtained in an analytically pure form after recrystallization from diethyl ether at −18 °C (0.808 g, isolated yield = 89.8%).

Catalytic Test for the Determination of the Activity of the Mother Liquor: The clear filtrate obtained from the catalyst was used as solvent for these experiments. This solution was obtained by filtration at 90 °C over celite, in order to remove the fine particles. Fresh reactants (5.0 mmol aryl halide, 6.0 mmol olefin, 12 mmol base) were added to the filtrate and the resulting mixture was heated at the desired temperature whilst stirring for 20 h. The reaction course (if any) was monitored by GLC as described above.

[8b] It is worth noting that when carrying out the vinylation of iodobenzene with 4 equiv. of acetate, the resin Pd-pol suffered from severe metal leaching. After one cycle the Pd content was reduced to a half, probably due to the substitution of the polymer-supported β-keto esterate ligand with the acetate.

Synthesis and Characterization of Methyltrioxorhenium(VII) Immobilized in Bipyridyl-Functionalized Mesoporous Silica

Carla D. Nunes,[a] Martyn Pillinger,[a] Anabela A. Valente,[a] Isabel S. Gonçalves,*[a] João Rocha,[a] Paula Ferreira,[b] and Fritz E. Kühn*[b]

Keywords: Rhenium / Supported catalysts / Mesoporous materials / Lewis base adducts

Methyltrioxorhenium(VII) (MTO) has been immobilized in the mesoporous silica MCM-41 functionalized with pendant bipyridyl (bpy) groups of the type 4-[(–O)$_3$Si(CH$_2$)$_4$]-4′-CH$_3$-2,2′-bipyridine. Powder X-ray diffraction and N_2 adsorption-desorption studies confirm that the regular hexagonal symmetry of the host is retained during the grafting reaction and that the channels remain accessible. Solid-state magic angle spinning NMR spectroscopy (^{29}Si, ^{13}C) was also used to monitor the coupling reactions. The formation of a tethered Lewis base adduct of the type CH$_3$ReO$_3$·bpy is confirmed by IR, Raman, and X-ray absorption fine structure (XAFS) spectroscopy. The XAFS results do, however, indicate that not all rhenium ions are present in this form, and this agrees with elemental analysis which gives an Re/N ratio of 1:1.1 (0.55 mmol Re g^{-1}). It is likely that the excess rhenium atoms are present as uncoordinated MTO molecules assembled in the MCM channels. The model complexes (4-alkyl-4′-methyl-2,2′-bipyridine)(methyl)trioxorhenium (alkyl = methyl, *n*-butyl) were also prepared and characterized.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Methyltrioxorhenium(VII) (MTO) has excellent catalytic properties in numerous oxy functionalizations,[1] some examples being the oxidation of olefins,[2] alcohols,[3] arenes,[4] and carbonylmetal compounds.[5] The epoxidation of olefins has received particular attention, using MTO to activate H_2O_2. Due to the Lewis acidity of the rhenium center, a major limitation of this system is the opening of the epoxide ring, leading to the formation of diols in the presence of water.[1,6] It was soon found, however, that amine additives, such as pyridine,[7] pyrazole,[8] and 3-cyanopyridine,[9] enhance the efficiency and selectivity of MTO-catalyzed oxidations. The aromatic N-base ligands work by coordinating to the metal center, thereby reducing the Lewis acidity of the catalyst and additionally accelerating the catalytic reactions. MTO forms trigonal-bipyramidal adducts with pyridines and related bases,[10a] and distorted octahedral adducts with bidentate Lewis bases, e.g. 4,4′-dimethyl-2,2′-bipyridine, 1,10-phenanthroline, and 2,2′-bipyrimidine.[10b] In the presence of H_2O_2 these complexes form very active and highly selective epoxidation catalysts.

Alternative strategies to improve MTO-catalyzed oxidations have involved host-guest inclusion chemistry. It was found that a urea/hydrogen peroxide complex is a very effective oxidant in heterogeneous olefin epoxidations and silane oxidations catalyzed by MTO.[11] With NaY-zeolite as host for these reactions also resulted in high yields and excellent product selectivities.[12] MTO has also been supported on silica functionalized with polyether tethers.[13] In the absence of an organic solvent, this catalytic assembly catalyzed the epoxidation of alkenes with 30% H_2O_2 with high selectivity compared to the ring-opened products observed in homogeneous media. In another example, MTO was heterogenized inside the porous system of a hybrid silica matrix by the sol-gel method using 4-[3-(triethoxysilyl)-propylamino]pyridine hydrochloride as a hydrolyzable ligand.[14] A supported catalyst of this type could, in principle, combine the advantages of a Lewis base adduct of MTO with the well-known benefits of a heterogeneous host-guest catalyst system.

Recently, we devised a stepwise procedure for the functionalization of the ordered mesoporous silica MCM-41 with pendant 4-alkyl-4′-methyl-2,2′-bipyridine groups.[15] Elemental analysis, powder X-ray diffraction (XRD), N_2 adsorption-desorption, solid-state magic angle spinning (MAS) NMR (^{13}C, ^{29}Si) and IR spectroscopy were used to monitor the different coupling reactions. The ligand−silica was subsequently examined as a support for the hetero-

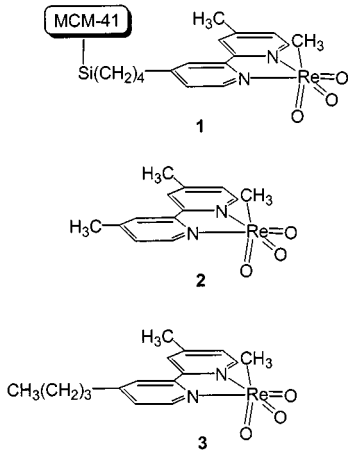
genization of the dioxomolybdenum(VI) complex $MoO_2Cl_2(THF)_2$. Instead of forming surface-bound monomeric complexes of the type $MoO_2Cl_2(bpy)$, weakly bound oxo-bridged dimers were formed with a metal−metal separation of 3.28 Å. In the present work, MTO is used as the oxometal species rather than the fragment MoO_2Cl_2, with the intention of forming surface-bound Lewis base adducts of the type **1**. The known MTO adduct **2**, containing the ligand 4,4′-dimethyl-2,2′-bipyridine, and also the novel complex **3**, containing the asymmetrical bipyridine ligand 4-(*n*-butyl)-4′-methyl-2,2′-bipyridine, have been prepared as model compounds. The hybrid material has been characterized by Raman spectroscopy and Re L-edge X-ray absorption fine structure (XAFS) spectroscopy, in addition to the techniques mentioned above.



Results and Discussion

The preparation and characterization of MCM-41 functionalized with bipyridyl groups has been described in a previous paper.[15] In the first step, the pristine calcined hexagonally ordered mesoporous host (d_{100} = 36.3 Å, a = 41.9 Å) is covalently grafted with (3-chloropropyl)trimethoxysilane. The second step comprises substitution of about 21% of pendant chloro groups by the anion [4-CH_2-4′-CH_3-2,2′-bipyridine]$^-$ to give a material containing about 0.3 mmol bipyridyl groups per gram, designated as MCM-41-bpy. Powder XRD and N_2 adsorption-desorption analysis demonstrate that the textural characteristics of the support are preserved during the grafting experiments and that the channels remain accessible (BET specific surface area 720 $m^2\ g^{-1}$, total pore volume 0.37 $cm^3\ g^{-1}$).

The heterogenization of MTO was carried out by treating the ligand−silica MCM-41-bpy (0.5 g) with a dichloromethane solution of MTO (0.046 M, 0.92 mmol) at room temperature. The resulting material, designated as MCM-41-bpy/MTO, was recovered by filtration and washed repeatedly with dichloromethane. Drying the product under vacuum at room temperature did not liberate (sublime) MTO from the MCM channels (pure MTO sublimes at 25 °C when using an oil-pump vacuum). The material is moderately air- and light-sensitive. Elemental analysis indicated a metal loading of 10.24 mass-% Re (0.55 mmol g^{-1}), giving an Re/N molar ratio of 1:1.1. If it is assumed that all Re is present as MTO, and knowing the specific total pore volume before and after introduction of MTO (see below), the volume occupied by MTO molecules in MCM-41-bpy/MTO is calculated to be 0.04 $cm^3\ g^{-1}$. It follows that the mass of MTO molecules per unit volume occupied is 3.5 g cm^{-3} [= 0.1024×(249.2/186.2)/0.04]. This value is similar to the density of bulk MTO (4.1 g cm^{-3}).

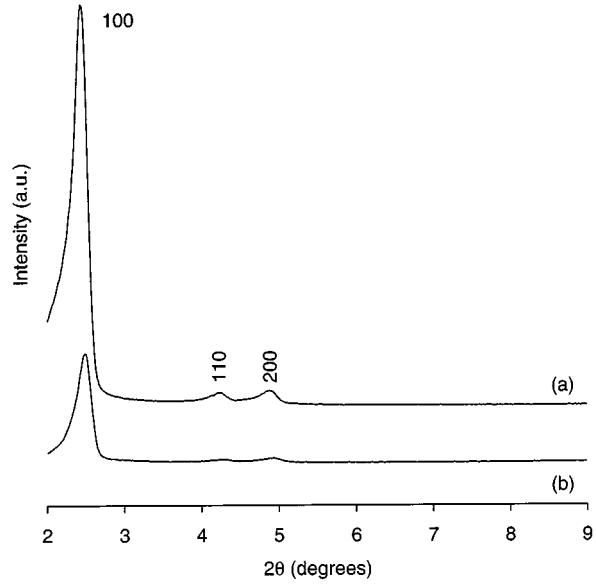


Figure 1. Powder XRD patterns of (a) MCM-41-bpy and (b) MCM-41-bpy/MTO

Figure 1 shows the powder XRD patterns of MCM-41-bpy and MCM-41-bpy/MTO. Three reflections are observed in the range 2θ = 2−8° for MCM-41-bpy, indexed assuming a hexagonal cell as (100), (110), and (200). The d value of the (100) reflection is 36.0 Å leading to a lattice constant of a = 41.6 Å. Three reflections are also observed for MCM-41-bpy/MTO, indicating retention of the long-range hexagonal symmetry. There is a slight contraction of the unit cell (d_{100} = 35.4 Å, a = 40.9 Å) and the intensities of the three reflections are considerably reduced compared to the starting ligand−silica. This is not interpreted as a severe loss of crystallinity. Instead, it is likely that there is a reduction in the X-ray scattering contrast between the silica wall and pore-filling material.[16] A similar phenomenon was observed for treatment of MCM-41-bpy with the complex $MoO_2Cl_2(THF)_2$,[15] and MCM-41 grafted with multiply bonded dimolybdenum complexes.[17]

Figure 2 shows the low-temperature N_2 adsorption-desorption isotherm for MCM-41-bpy/MTO. The corresponding isotherms for the pristine calcined MCM-41 host and the ligand−silica MCM-41-bpy are also shown for comparison. Each isotherm can be classified as type IV as defined by IUPAC,[18] characteristic of mesoporous solids (having pore widths between 2 and 50 nm). The isotherms show no evidence of hysteresis loops resulting from capillary condensation/evaporation, which has been attributed

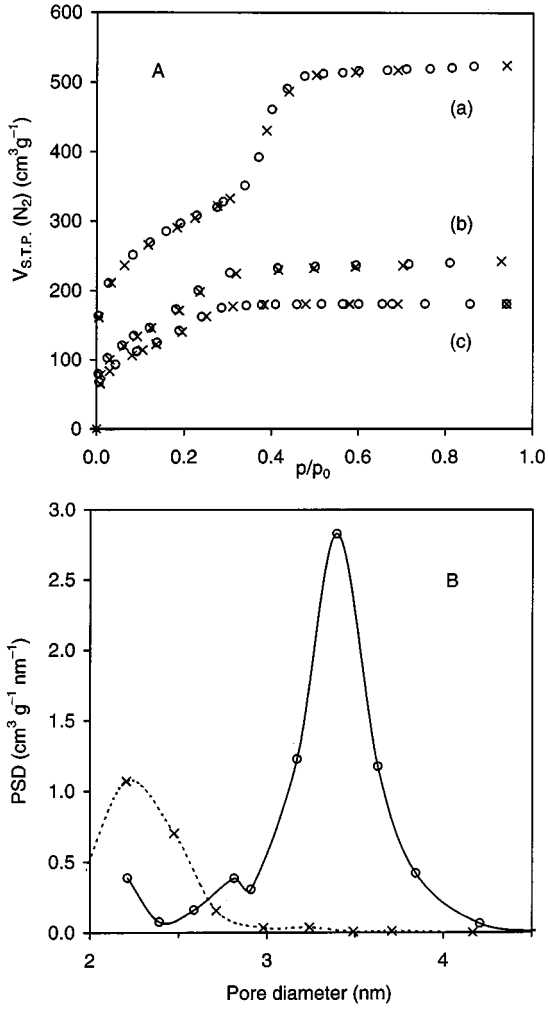

Figure 2. A: N_2 adsorption (×) and desorption (O) isotherms at 77 K of (a) pristine MCM-41, (b) MCM-41-bpy and (c) MCM-41-bpy/MTO; B: pore-size distribution profiles for pristine MCM-41 (——) and MCM-41-bpy/MTO (···)

to the instability of the liquid nitrogen meniscus.[18] Each of the modifications carried out to produce the two derivatized samples MCM-41-bpy and MCM-41-bpy/MTO leads to a decrease in the N_2 uptake at any given p/p_0, and both the BET specific surface area and pore volume decrease (Table 1). In the case of MCM-41, a pronounced step is observed between relative pressures of 0.32 and 0.42, arising from the condensation of nitrogen inside the primary mesopores. The sharpness of this step reflects the uniform pore size. A comparison of the pore size distribution (PSD) curves for MCM-41 and MCM-41-bpy/MTO reveals that the position of the maximum decreases from 34 to 23 Å (Figure 2). The decrease in the intensity of the maximum, together with an increase in the width at half height, indicates an increase in pore heterogeneity.

The material MCM-41-bpy/MTO was further characterized by thermogravimetric analysis (TGA), IR, Raman, MAS NMR, and XAFS spectroscopy. In order to assist the interpretation of these results, the known adduct **2** and the novel derivative **3** were prepared as model compounds. These complexes are readily obtained as yellow solids by

Table 1. Texture parameters of MCM-41 samples from N_2 isotherms at 77 K

Sample	S_{BET} [$m^2\ g^{-1}$]	ΔS_{BET} (%)[a]	V_P [$cm^3\ g^{-1}$]	ΔV_P (%)[b]
MCM-41	1029	–	0.81	–
MCM-41-bpy	718	−30	0.37	−54
MCM-41-bpy/MTO	574	−44	0.28	−66

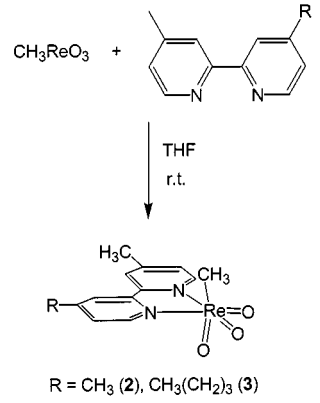
the reaction of MTO with 1 equiv. of bidentate N,N-ligand in tetrahydrofuran (THF) at room temperature (Scheme 1). Spectroscopic data (IR and ^1H NMR) for **2** are in agreement with that reported.[10b] The ^1H and ^{13}C NMR chemical shifts for the Re−CH_3 groups in **2** are located at δ = 1.20 and 25.9, respectively.[10b] The shifts in these resonances compared to those of uncoordinated MTO [δ(^{13}C) = 19.03; δ(^1H) = 2.67] are a consequence of electron donation to the Lewis-acidic metal center. In fact it has been shown that the weaker the donor ability of the Lewis base, the closer, in general, are the observed δ(^1H) and δ(^{13}C) values to those of uncoordinated MTO.[10] In the case of **3**, δ(^1H) and δ(^{13}C) of Re−CH_3 are located at δ = 1.09 and 26.0, respectively, and therefore the ligand in **3** can be considered as being a slightly stronger donor than that in **2**.



Scheme 1

TGA of MCM-41-bpy/MTO shows that the material decomposes in three steps up to 750 °C. It is stable under nitrogen up to about 50 °C, but then undergoes an abrupt mass loss, losing 6.0% up to 100 °C and a further 2.3% up to 200 °C. It is assumed that this is due to decomposition/sublimation of encapsulated MTO (MTO sublimes below 100 °C under TG conditions[19]). Further heating gives a residual mass of 81% at 750 °C. For comparison, the adduct CH_3ReO_3(4,4′-dimethyl-2,2′-bipyridine) (**2**) is stable under nitrogen up to 110 °C, then undergoes an abrupt mass loss of 24% up to 180 °C. This must correspond to rupture of the Re−N bond and sublimation of the now uncoordinated MTO. At 750 °C 42% remains as residual mass.

The IR spectrum of MCM-41-bpy/MTO contains one split band at 917 cm^{-1} (922 and 912 cm^{-1}) that is not observed in the spectrum of the ligand−silica MCM-41-bpy. This is attributed to an asymmetric Re=O stretching vibration. An associated symmetric stretching vibration should be present at higher frequency but is probably obscured by a broad band at 961 cm^{-1} arising from the silica host. The Raman spectrum shows more clearly the bands corresponding to the symmetric and asymmetric Re=O stretching vibrations (940 and 918 cm^{-1}, Figure 3). The model compound **3** displays very similar IR (940 and 919 cm^{-1}) and Raman (937 and 916 cm^{-1}) absorptions. From the IR data for **3** the force constant of the Re=O vibration can be calculated[20] to be 7.41 mdyn $Å^{-1}$. The corresponding bands for bulk MTO appear at 999 cm^{-1} (symmetric) and 957 cm^{-1} (asymmetric), yielding a force constant of 8.46 mdyn $Å^{-1}$.[10b] The decrease in the force constant indicates a weakening of the Re=O bonds, caused by electron donation from the coordinated bipyridyl groups to the Re^{VII} center.[10,21]

Further evidence for the formation of surface-bound adducts of the type $CH_3ReO_3(N-N)$ in MCM-41-bpy/MTO comes from the Raman bands of the tethered bipyridine groups. The precursor ligand−silica MCM-41-bpy displays bands at 1607 and 1559 cm^{-1} due to pyridyl ring stretching vibrations, and a band at 997 cm^{-1} due to an in-plane ring C−H deformation vibration (Figure 3). The corresponding ligand 4-(*n*-butyl)-4′-methyl-2,2′-bipyridine displays three identical bands. In complex **3** these bands shift to 1615, 1555 and 1030 cm^{-1}. Very similar results are obtained for the functionalized material MCM-41-bpy/MTO (bands at 1611, 1555 and 1031 cm^{-1}). The Raman spectrum of this material also contains a weak band at 997 cm^{-1}. This could be due to the ring C−H deformation vibration of uncoordinated bipyridyl groups, or alternatively to the Re=O symmetric stretching vibration of uncoordinated MTO molecules aggregated in the MCM channels. The Raman spectra of the complexes **2** and **3** contain a weak band at 555 cm^{-1} due to the Re−C stretching vibration (cf. 575 cm^{-1} for bulk MTO), and also a strong band at about 475 cm^{-1} that does not appear in the spectra of either the corresponding free ligand or bulk MTO. This latter band may be due to a C−Re=O deformation vibration.[22] While a band for the Re−C stretching vibration is not observed in the Raman spectrum of the material MCM-41-bpy/MTO, a band is clearly seen at 474 cm^{-1} that does not appear in the spectrum of MCM-41-bpy.

The ^{29}Si MAS and CP MAS NMR spectra of MCM-41-bpy/MTO are similar to those of the precursor MCM-41-bpy (Figure 4).[15] Two broad overlapping peaks at $\delta = -109.8$ and -102.0 are assigned to Q^4 and Q^3 units, respectively, of the silica framework, where $Q^n = Si(OSi)_n(OH)_{4-n}$. Two signals are also observed at $\delta = -58.7$ and -66.7, assigned to T^2 and T^3 organosilica species, respectively [$T^m = RSi(OSi)_m(OMe)_{3-m}$]. The ^{13}C CP MAS NMR spectrum of MCM-41-bpy/MTO is also largely unchanged compared to that of MCM-41-bpy (Figure 5).

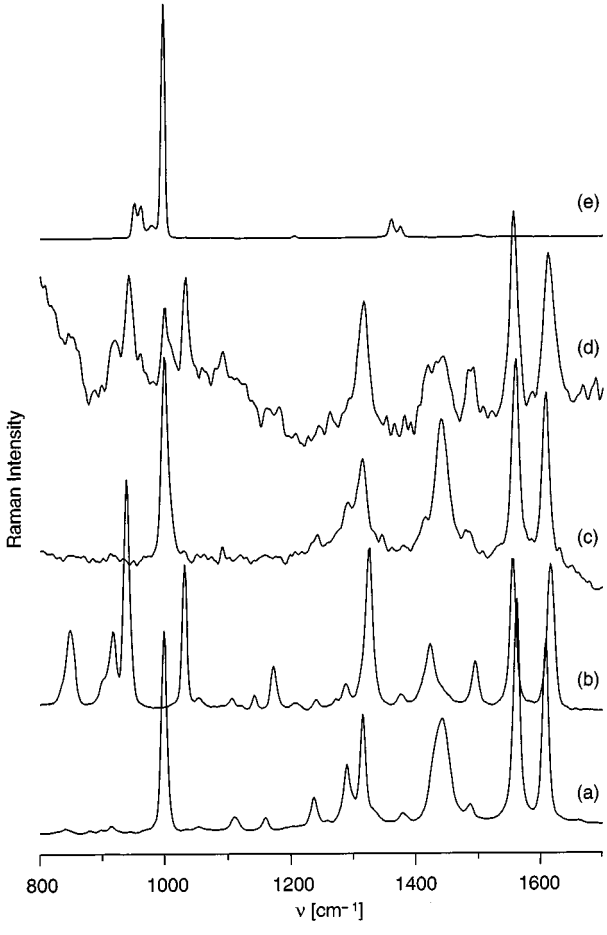


Figure 3. Raman spectra of (a) 4-(*n*-butyl)-4′-methyl-2,2′-bipyridine, (b) [4-(*n*-butyl)-4′-methyl-2,2′-bipyridine](methyl)trioxorhenium (**3**), (c) MCM-41-bpy, (d) MCM-41-bpy/MTO and (e) CH_3ReO_3

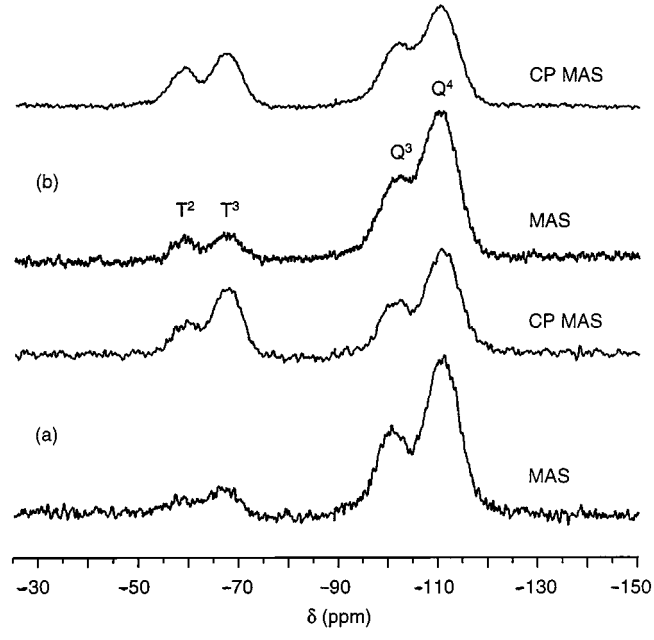

Figure 4. ^{29}Si MAS and CP MAS NMR spectra of (a) MCM-41-bpy and (b) MCM-41-bpy/MTO

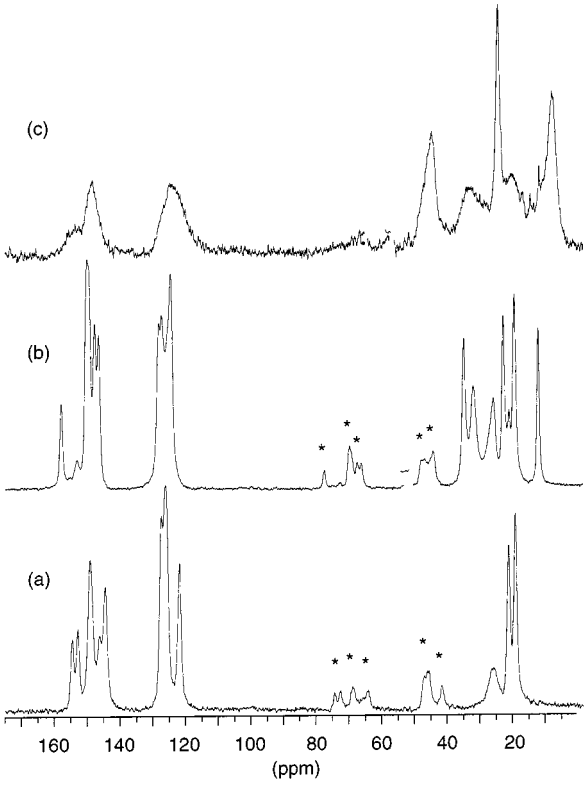

Figure 5. ^{13}C CP MAS NMR spectra of (a) (4,4′-dimethyl-2,2′-bipyridine)(methyl)trioxorhenium (**2**), (b) [4-(*n*-butyl)-4′-methyl-2,2′-bipyridine](methyl)trioxorhenium (**3**), and (c) MCM-41-bpy/MTO; asterisks denote spinning sidebands

Assignment of these spectra was supported by measuring the solution spectra of the ligand 4-(*n*-butyl)-4′-methyl-2,2′-bipyridine, and the MTO adduct of this ligand (**3**). Solid-state MAS NMR spectra were also recorded for **2** and **3** (Figure 5). In the ^{13}C CP MAS NMR spectrum of MCM-41-bpy/MTO, two broad peaks at δ = 149.3 and 125.7, and a shoulder at δ = 155.0, are assigned to the pyridyl ring carbon atoms. The other signals in the spectrum are attributed as follows: δ = 46.1 [Si(O*Me*)$_n$CH$_2$R and −*C*H$_2$Cl], 35.0 (−*C*H$_2$*C*H$_2$−bpy), 26.0 [Re−CH$_3$ and Si(OMe)$_n$CH$_2$*C*H$_2$−], 21.8 (*C*H$_3$−bpy), 9.6 [Si(OMe)$_n$-*C*H$_2$R]. Treatment of MCM-41-bpy with MTO produces only one measurable change in the ^{13}C NMR spectrum: the signal at δ = 123.3 shifts to δ = 125.7. A similar shift difference is observed for the corresponding resonances of the ligand 4-(*n*-butyl)-4′-methyl-2,2′-bipyridine and the MTO adduct of this ligand (**3**).

XAFS measurements at the Re L_I and L_{III} absorption edges were carried out at low temperature (20 K) for the Lewis base adduct **2** and MCM-41-bpy/MTO. The Re L_I X-ray absorption near edge structure (XANES) spectrum of **2** contains a weak pre-edge peak, caused by a 2s → 5d(Re) + 2p(O) electron transition (Figure 6).[23] With respect to the rhenium coordination, the intensity of this peak is usually strongest for systems with non-inversion symmetry, such as tetrahedral coordination. MTO, for example, exhibits an intense sharp pre-edge peak.[24] Any distortion of the regular tetrahedral symmetry leads to a decrease in the peak intensity. The XANES spectrum of **2** is therefore consistent with the expected rhenium coordination, i.e. distorted octahedral geometry. It is obvious that the XANES spectrum of MCM-41-bpy/MTO is quite different from that of **2**, in that the pre-edge peak is stronger and there are differences in the oscillations towards higher energy (Figure 6). In fact, the spectrum of MCM-41-bpy/MTO comes close to that reported for bulk MTO.[24]

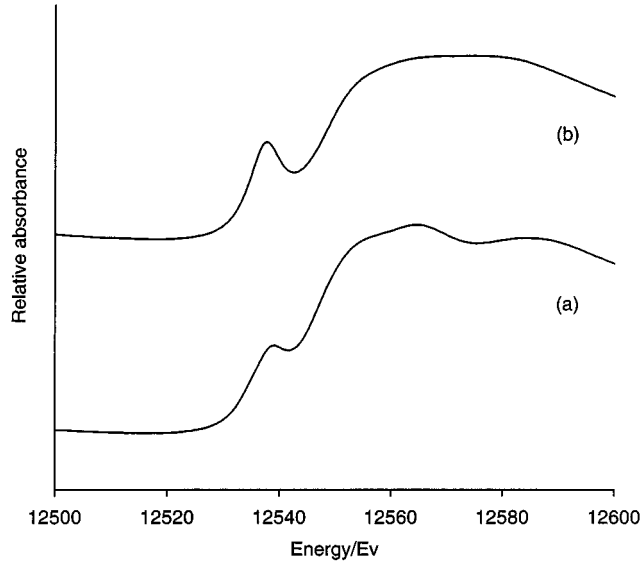

Figure 6. Re L_I-edge XANES spectra of (a) (4,4′-dimethyl-2,2′-bipyridine)(methyl)trioxorhenium (**2**), and (b) MCM-41-bpy/MTO

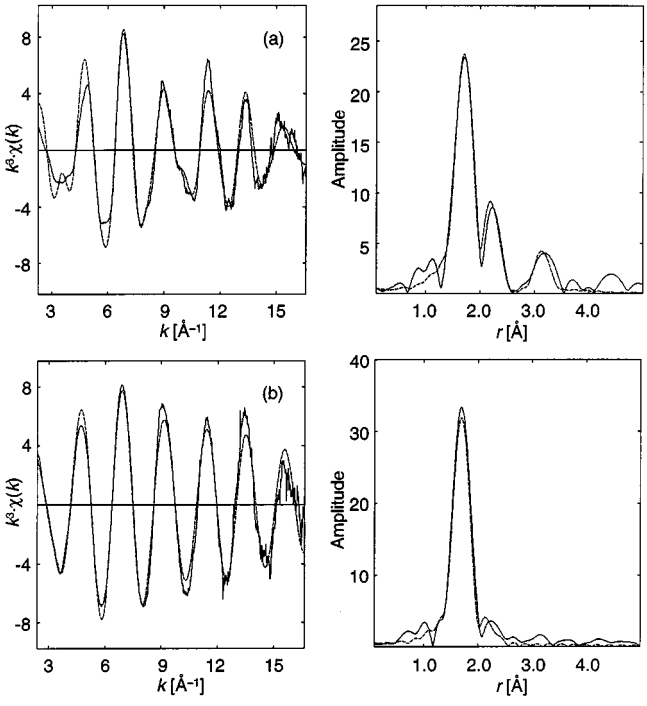

Figure 7. Re L_{III}-edge XAFS and Fourier transforms for (a) (4,4′-dimethyl-2,2′-bipyridine)(methyl)trioxorhenium (**2**), and (b) MCM-41-bpy/MTO; the solid line represents the experimental data and the dashed line shows the best fit using parameters given in Table 2

Table 2. Re L_{III}-edge XAFS-derived structural parameters for (4,4′-dimethyl-2,2′-bipyridine)(methyl)trioxorhenium (**2**) and MCM-41-bpy/MTO

Compound	Atom	CN[a]	r [Å]	$2\sigma^2$ [Å^2][b]	E_f [eV][c]	R (%)[d]
2[e]	O	3.0(1)	1.741(2)	0.0048(3)	−13.8(5)	27.2
	N	2.5(2)	2.246(5)	0.0052(8)		
	C	4.0(6)	3.192(11)	0.0078(19)		
MCM-41-bpy/MTO	O	3.3(1)	1.729(1)	0.0027(2)	−11.2(5)	19.0
	N	1.3(3)	2.216(11)	0.0091(24)		

[a] CN = Coordination number. Values in parentheses are statistical errors generated in EXCURVE. The true errors in coordination numbers are likely to be of the order of 20%; those for the interatomic distances ca. 1.5%.[25] [b] Debye−Waller factor; σ = root-mean-square internuclear separation. [c] E_f = edge position (Fermi energy), relative to calculated vacuum zero. [d] $R = (\int[\Sigma^{theory} - \Sigma^{exp.}]k^3 dk / [\Sigma^{exp.}]k^3 dk) \times 100\%$. [e] Compound **2** has been examined by single-crystal X-ray crystallography,[10b] but bond lengths and bond angles could not be determined reliably because the structure is disordered with respect to the position of the metal center.

Analysis of the Re L_{III} XAFS spectrum of **2** allowed three shells for O, N and C neighbors to be determined, in order of increasing distance from the absorbing atom (Figure 7, Table 2). The Re−O bond length of 1.74 Å is typical of all known (oxo)Re^{VII} complexes containing an Re=O double bond.[1f] Bidentate coordination of the bipyridyl ligand is confirmed by the presence of the other two shells for N (2.25 Å) and C (3.19 Å). The Re−N bond length is comparatively long, indicating a weak N→Re bonding interaction. Identical Re−N bond lengths were determined by single-crystal X-ray crystallography for the adducts $XReO_3$[4,4′-bis(*tert*-butyl)-2,2′-bipyridine] (X = Cl, Br).[26] The Re···N shell almost certainly includes a component for the carbon shell corresponding to Re−C, expected at about 2.1 Å. The similarity of the two elements as back-scatterers, together with the close proximity of the two shells, means that only one shell can be fitted. The Re L_{III} XAFS of MCM-41-bpy/MTO was initially fitted by a model comprising one shell of oxygen atoms. Both the refined distance (1.74 Å) and coordination number (3.3) are consistent with the presence of trioxorhenium species. Addition of a second shell for nitrogen atoms at 2.22 Å (coordination number = 1.3) reduced the R factor from 23.2 to 19.0% (Table 2, Figure 7). This shell was significant at the 99% level according to the statistical test of Joyner et al.[27] There was no evidence for a well-defined Re···Re outer coordination shell.

Conclusions

MCM-41 functionalized with bipyridyl groups has been successfully used as a support for the immobilization of methyltrioxorhenium(VII). Powder XRD and N_2 adsorption-desorption studies confirm that the regular hexagonal symmetry of the mesoporous host is retained during the grafting reaction and that the channels remain accessible. The formation of a tethered Lewis base adduct of the type CH_3ReO_3(bpy) is substantiated by IR, Raman, and XAFS spectroscopy. The latter technique does, however, indicate that not all rhenium atoms are present in this form and this is consistent with elemental analysis which gives an Re/N ratio of 1:1.1. It is likely that the excess rhenium atoms are present as uncoordinated MTO molecules assembled in the MCM channels. This phenomenon may be similar to that reported for MTO encapsulated in zeolite Y,[28] where it was proposed that each supercage contained a cluster of four MTO guest molecules aggregated by Re=O···Re intermolecular interactions.

Experimental Section

General: All manipulations were carried out using standard Schlenk techniques under nitrogen. Solvents were dried by standard procedures (THF, *n*-hexane and Et_2O with Na/benzophenone ketyl; CH_2Cl_2 with CaH_2), distilled under nitrogen and kept over 4 Å molecular sieves. Lithium diisopropylamide was prepared as described in the literature.[29] 4,4′-Dimethyl-2,2′-bipyridine was purchased from Aldrich and used as received. Microanalyses were performed at the Mikroanalytisches Laboratorium of the Technical University of Munich (M. Barth and co-workers). Powder XRD data were collected with a Phillips X'pert diffractometer using Cu-K_α radiation filtered by Ni. Nitrogen adsorption-desorption measurements were carried out at 77 K, using a gravimetric adsorption apparatus equipped with a CI electronic MK2-M5 microbalance and an Edwards Barocel pressure sensor. Before analysis, pristine calcined MCM-41 was degassed at 723 K overnight to a residual pressure of ca. 10^{-4} mbar. A lower degassing temperature of 413 K was used for the modified materials (to minimize destruction of the functionalities). The specific surface areas (S_{BET}) were determined by the BET method. The total pore volume (V_P) was estimated from the N_2 uptake at $p/p_0 \approx 0.95$, using the liquid nitrogen density of 0.8081 g cm^{-3}. The pore size distribution curves (PSD, the differential volume adsorbed with respect to the differential pore size per unit mass as a function of pore width) were computed from the desorption branch of the experimental isotherms, using a method based on the area of the pore walls.[18,30] Assuming open cylindrical pores of radius r_p, zero contact angle, and accounting for the statistical film thickness (t), r_p is given by the sum of the Kelvin radius and t.[18] The t values were derived from a standard nitrogen isotherm for nonporous hydroxylated silica (available from the literature[31]) using the Halsey equation.[18] Although it is known that such traditional methods based on the Kelvin equation underestimate the pore sizes in the range up to ca. 7.5 nm,[32] in this work these calculations are only intended to monitor changes in pore sizes after complexation, by comparing with the parent MCM-41. TGA studies were performed using a Perkin−Elmer TGA7 thermobalance system at a heating rate of 10 K min^{-1} under

nitrogen. IR spectra were measured with a Unican Mattson Mod 7000 FTIR spectrometer using KBr pellets. Raman spectra were recorded with a Bruker RFS 100/S FT Raman spectrometer using a 1064 nm excitation wavelength of the Nd/YAG laser. ^{1}H and ^{13}C solution NMR spectra were obtained with a Bruker AMX-300 spectrometer. ^{29}Si and ^{13}C solid-state NMR spectra were recorded at 79.49 and 100.62 MHz, respectively, with a (9.4 T) Bruker Avance 400P spectrometer. ^{29}Si MAS NMR spectra were recorded with 40° pulses, spinning rates 5.0−5.5 kHz and 60 s recycle delays. ^{29}Si CP MAS NMR spectra were recorded with 5.5 μs ^{1}H 90° pulses, 8 ms contact time, a spinning rate of 4.5 kHz, and 4 s recycle delays. ^{13}C CP MAS NMR spectra were recorded with a 4.5 μs ^{1}H 90° pulse, 2 ms contact time, a spinning rate of 8 kHz, and 4 s recycle delays. Chemical shifts are quoted in parts per million from tetramethylsilane (TMS). Re L_I- and L_{III}-edge X-ray absorption spectra were measured at 20 K in transmission mode on beamline BM29 at the ESRF (Grenoble), operating at 6 GeV in 2/3 filling mode with typical currents of 180−190 mA. One scan was performed for each sample and set up to record the pre-edge at 5 eV steps and the post-edge region in 0.025−0.05 Å^{-1} steps, giving a total acquisition time of ca. 40 min per scan. The order-sorting double Si(311) crystal monochromator was detuned to give 50% harmonic rejection. Solid samples were diluted with BN and pressed into 13 mm pellets. Air-sensitive samples were handled under an inert gas. Ionization chamber detectors were filled with Ar to give 30% absorbing I_o (incidence) and 70% absorbing I_t (transmission). The programs EXCALIB and EXBACK (SRS Daresbury Laboratory, UK) were used in the usual manner for calibration and background subtraction of the raw data. XAFS curve-fitting analyses, by least-squares refinement of the non-Fourier-filtered k^3-weighted XAFS data, were carried out using the program EXCURVE (version EXCURV98[33]) using fast curved-wave theory.[34] Theoretical phase shifts were obtained within this program using ab initio calculations based on the Hedin Lundqvist/von Barth scheme.

4-(*n*-Butyl)-4′-methyl-2,2′-bipyridine: Prepared by modification of a literature procedure.[29] A solution of 4,4′-dimethyl-2,2′-bipyridine (0.50 g, 2.71 mmol) in THF (15 mL) was added to a THF solution of lithium diisopropylamide (2.71 mmol). After 2 h, the orange-brown solution was cooled to −20 °C and $CH_3CH_2CH_2Br$ (0.25 mL) added. After 2 h, iced water was added to the green reaction mixture. The organic solution was dried with Na_2SO_4 and the solvent removed to give the crude product. The yellow residue was purified by recrystallization from diethyl ether to give a colorless solid. Yield: 0.55 g, 89%. $C_{15}H_{18}N_2$ (226.32): calcd. C 79.61, H 8.02, N 12.38; found C 79.48, H 7.98, N 12.18. IR (KBr): $\tilde{\nu}$ = 2957 m, 2925 s, 2870 m, 1596 s, 1553 m, 1460 s, 1376 m, 1104 m, 1023 m, 992 m, 824 s, 799 m, 670 m, 515 m cm^{-1}. Raman: $\tilde{\nu}$ = 3054 s, 2920 s, 2873 sh, 1607 s, 1561 s, 1487 w, 1442 m, 1379 w, 1315 m, 1290 m, 1237 m, 1159 w, 1110 w, 997 s, 737 m, 525 m, 344 w, 237 m cm^{-1}. ^{1}H NMR ($CDCl_3$, room temp., 300 MHz, TMS): δ = 0.86 (t, 3 H, CH_3), 1.29 (m, 2 H, CH_2), 1.60 (m, 2 H, CH_2), 2.36 (s, 3 H, py-CH_3), 2.62 (t, 2 H, py-CH_2), 7.05 (d, 2 H, py-H), 8.15 (s, 2 H, py-H), 8.47 (t, 2 H, py-H). ^{13}C {^{1}H} NMR ($CDCl_3$, room temp., 75.47 MHz, TMS): δ = 13.9 (CH_3CH_2), 21.2 (py-CH_3), 22.4 (CH_3CH_2), 32.5 (py-CH_2CH_2), 35.2 (py-CH_2), 121.3, 122.0, 123.9, 124.6, 148.9, 152.9, 156.0 (all py-C).

MCM-41 Functionalized with 4-[(−CH_2)$_4$]-4′-CH_3-2,2′-bipyridine (MCM-41-bpy): Prepared as described previously.[15] Raman: $\tilde{\nu}$ = 3057 m, 2899 s, 1607 s, 1559 s, 1440 s, 1314 s, 997 s, 732 w, 650 w, 238 m cm^{-1}.

MCM-41 Functionalized with Methyltrioxorhenium(VII) (MCM-41-bpy/MTO): To a suspension of MCM-41-bpy (0.50 g) in CH_2Cl_2 (5 mL) a solution of MTO (0.23 g, 0.92 mmol) in CH_2Cl_2 (10 mL) was added and the mixture stirred at room temperature for 24 h. The solution was filtered off and the pale yellow powder washed repeatedly with CH_2Cl_2 (4 × 20 mL), before drying under vacuum at room temperature for several hours; found C 11.80, H 2.40, Cl 3.34, N 0.83, Re 10.24, Si 27.70. IR (KBr): $\tilde{\nu}$ = 2938 w, 1559 w, 1438 w, 1384 w, 1233 sh, 1067 vs, 961 s, 921 vs, 913 vs, 801 s, 550 sh, 465 vs cm^{-1}. Raman: $\tilde{\nu}$ = 3069 w, 2913 m, 1611 m, 1556 m, 1484 w, 1442 w, 1317 m, 1031 m, 997 m, 941 m, 918 w, 733 w, 474 w, 237 w cm^{-1}. ^{29}Si MAS NMR: δ = −109.8, −102.0 (sh), −66.6, −58.5. ^{29}Si CP MAS NMR: δ = −109.8 (Q^4), −101.7 (Q^3), −66.7 (T^3), −58.7 (T^2). ^{13}C CP MAS NMR: δ = 9.6 [(−O)$_3$SiCH$_2$−], 21.8 (py-CH_3), 26.0 [(−O)$_3$SiCH$_2$*C*H$_2$− and Re−CH_3], 35.0 (py−CH_2CH_2−), 46.1 [Si(O*Me*)$_n$$CH_2$R and −$CH_2$Cl], 125.7, 149.3, 155.0 (all py-C).

(4,4′-Dimethyl-2,2′-bipyridine)(methyl)trioxorhenium (2): Prepared as described previously.[10b] Raman: $\tilde{\nu}$ = 3067 m, 2921 m, 1614 s, 1556 s, 1489 m, 1418 m, 1376 w, 1319 s, 1176 m, 1029 s, 937 vs, 912 s, 846 m, 833 m, 742 m, 668 w, 555 m, 474 s, 355 m, 343 m, 316 w, 271 m, 243 m, 196 m, 157 m cm^{-1}. ^{13}C CP MAS NMR: δ = 20.8 (py-CH_3), 22.8, 27.3 (Re−CH_3), 122.5, 126.8, 145.0, 149.4, 153.2, 154.7 (all py-C).

[4-(*n*-Butyl)-4′-methyl-2,2′-bipyridine](methyl)trioxorhenium (3): To a solution of MTO (0.56 g, 2.25 mmol) in CH_2Cl_2 (5 mL) 1 equiv. of 4-(*n*-butyl)-4′-methyl-2,2′-bipyridine was added. The resulting yellow solution was stirred for 1 h at room temperature. The solvent was evaporated, and the product washed with hexane and dried under vacuum. Yield: 1.02 g, 95%. $C_{16}H_{21}N_2O_3Re$ (475.56): calcd. C 40.41, H 4.45, N 5.89; found C 40.36, H 4.41, N 5.73. IR (KBr): $\tilde{\nu}$ = 3122 m, 3065 m, 3030 m, 2953 s, 2923 s, 2860 m, 1615 vs, 1555 s, 1492 s, 1466 m, 1419 s, 1375 m, 1310 s, 1243 m, 1030 s, 940 vs (Re=O), 918 vs (Re=O), 848 vs, 831 vs, 737 s, 555 m (Re−C), 540 m, 524 m, 480 m, 424 m, 358 s cm^{-1}. Raman: $\tilde{\nu}$ = 3070 m, 2921 s, 1615 s, 1555 s, 1495m, 1423 m, 1325 s, 1171 m, 1030 s, 937 vs, 916 m, 848 m, 743 m, 667 w, 555 w, 481 s, 352 m, 316 w, 265 m, 195 m cm^{-1}. ^{1}H NMR ($CDCl_3$, room temp., 300 MHz, TMS): δ = 0.98 (t, 3 H, CH_3), 1.09 (s, 3 H, Re−CH_3), 1.43 (m, 2 H, CH_2), 1.72 (m, 2 H, CH_2), 2.58 (s, 3 H, py-CH_3), 2.81 (t, 2 H, py-CH_2), 7.38 (d, 2 H, py-H), 8.09 (d, 2 H, py-H), 8.92 (m, 2 H, py-H). ^{13}C {^{1}H} NMR ($CDCl_3$, room temp., 75.47 MHz, TMS): δ = 13.8 (CH_3CH_2), 21.6 (py-CH_3), 22.3 (CH_3CH_2), 27.0 (Re−CH_3), 32.3 (py-CH_2CH_2), 35.4 (py-CH_2), 123.1, 123.8, 126.5, 127.2, 148.9, 150.2, 151.9, 156.7 (all py-C). ^{13}C CP MAS NMR: δ = 13.8 (CH_3CH_2), 21.1 (py-CH_3), 24.4 (CH_3CH_2), 27.4 (Re-CH_3), 33.5 (py-CH_2CH_2), 36.3 (py-CH_2), 125.2, 127.9, 128.7, 146.9, 148.0, 150.3, 153.3, 158.1 (all py-C).

Acknowledgments

This work was partly funded by FCT, POCTI and FEDER (Project PCTI/1999/QUI/32889). Financial support was also obtained from the Alexander von Humboldt foundation (to P. F.), Bayerische Forschungsstiftung (to I. S. G.), Deutsche Forschungsgemeinschaft and Fonds der Chemischen Industrie. A. A. V and M. P. thank FCT for post-doctoral grants, and C. N. thanks the University of Aveiro for a research grant. F. E. K. additionally thanks Prof. Dr. W. A. Herrmann for continuous and generous support. We are grateful to the director of the ESRF for the provision of facilities and to Stuart Ansell (local contact on BM29) for help in the XAFS

experiments. We also wish to thank Pedro Vaz for help with the Raman experiments and Marta Lopes for recording MAS spectra.

A New MnO_x Cathode Material for Rechargeable Lithium Batteries

Arno Perner,*[a] K. Holl,[a] D. Ilic,[a] and M. Wohlfahrt-Mehrens[b]

Keywords: Lithium batteries / Manganese oxides / Cathode materials

Different manganese oxide phases have been synthesized. Rietveld analysis of XRD profiles and galvanostatic cycling in 2025 coin cells were performed for structural and electrochemical characterization. A new two-phase product, containing α-MnO_2 and β-MnO_2 components, was found to deliver better electrochemical results than single phase α-MnO_2, β-MnO_2 or α/ramsdellite-MnO_2. It is shown that the β-MnO_2 phase is responsible for the high discharge capacities and that the α-MnO_2 is responsible for a stable structure during lithium intercalation and extraction, as the hollandite structure shows a small unit-cell volume change. This new cathode material is therefore a β-MnO_2 phase stabilized with α-MnO_2. Furthermore, the reaction of the new α/β-MnO_2 with LiOH was examined. Some lithium atoms of LiOH are intercalated within the channels as Li_2O in order to stabilize the structure, so that no capacity loss after the first cycle appears, whilst others form a $Li_2O{\cdot}MnO_2$ phase that delivers an additional structure stabilization and therefore a better cycling performance.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The development of secondary lithium batteries involves the use of high performance cathodic materials with numerous requirements such as high gravimetric and volume capacity, high density, high standard potential, fast electrode kinetics, reversible insertion reaction, satisfactory electronic conductivity, low solubility, a relatively low price for production, low toxicity, chemical compatibility with the electrolyte and good rechargeability. Therefore, intensive research has been carried out in the field of rechargeable positive electrodes.[1−9]

Manganese oxides are of interest as insertion electrodes for both primary and secondary lithium batteries.[10] The rechargeability of 3 V manganese oxide electrodes tends to be limited by the anisotropic expansion and contraction of the crystallographic unit cell when lithium is inserted into, and removed from, the manganese oxide. 3 V positive materials are used, for example, in button cells of different sizes for memory back-up (MBU) and bridging applications.[11]

The goal of this paper was to optimize 3 V cathode materials in order to improve the cycling stability and the discharge capacities. To fulfill these requirements we focused our efforts on stabilizing the α-MnO_2 structure with foreign phases. The structure of α-MnO_2 with the large [2 × 2] channels of the hollandite framework is not stable to lithium insertion/extraction. These [2 × 2] tunnels are usually occupied by cations (e.g. Ba^{2+}, K^+...) or water molecules (as OH^-) which hinder the lithium ion diffusion within the channels. As a consequence the α-MnO_2 framework must be stabilized by replacing these cations or water molecules with Li_2O[12,13] or by adding foreign phases[14] (e.g. ramsdellite-MnO_2, pyrolusite).

Thackeray proposed an α-MnO_2 (hollandite) structure stabilized with ramsdellite-MnO_2, which delivers higher discharge capacities than single-phase α-MnO_2 or ramsdellite-MnO_2.[14]

We report here a transformation of α/ramsdellite-MnO_2 when annealing at 350 °C. As a thermal transformation of ramsdellite to β-MnO_2 (pyrolusite) was observed by Ramsdell,[15] we assume a transformation of α/ramsdellite-MnO_2 to α/β-MnO_2. The structure and electrochemical properties of single-phase α-MnO_2, ramsdellite-MnO_2, β-MnO_2, α /ramsdellite-MnO_2 and the new α/β-MnO_2 are compared.

All these manganese oxides suffer from a large irreversible capacity loss after the first discharge (up to 30%) due to lithium trapped within the channels in order to stabilize the structure. The manganese oxides are chemically lithiated to reduce this irreversible capacity loss. We also observe that a reaction of the MnO_2 samples with LiOH results in a product consisting of lithium-stabilized MnO_2 with lithium intercalated within the channels [16] and an $Li_2O{\cdot}MnO_2$ phase.

Results and Discussion

Structure

The new α/β-MnO_2 was synthesized by annealing α/ramsdellite-MnO_2 at 350 °C for several hours. Figure 1 shows the TG/DSC graph of α/ramsdellite-MnO_2 with endothermic peaks at 100−150 °C and 170−220 °C due to the loss of surface adsorbed water and structural water, respectively. There is an additional endothermic peak at around 300 °C due to the transformation of α/ramsdellite-MnO_2 to α/β-MnO_2.

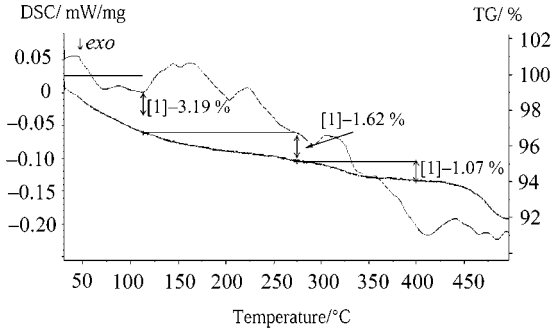

Figure 1. TG/DSC graph of α/Ramsdellite-MnO_2 with an endothermic peak at about 300 °C due to the transformation of α/Ramsdellite-MnO_2 to α/β-MnO_2

Figure 2 shows the different XRD patterns of single-phase α-MnO_2 with the hollandite structure, α/ramsdellite-MnO_2 [14] with the characteristic ramsdellite-MnO_2 Bragg line [110] at 22° and the new α/β-MnO_2. The pattern is characteristic of a two-phase product consisting of α-MnO_2 with a tetragonal unit cell (space group *I*4/*m*) and a β-MnO_2 phase with a pyrolusite structure (tetragonal symmetry).

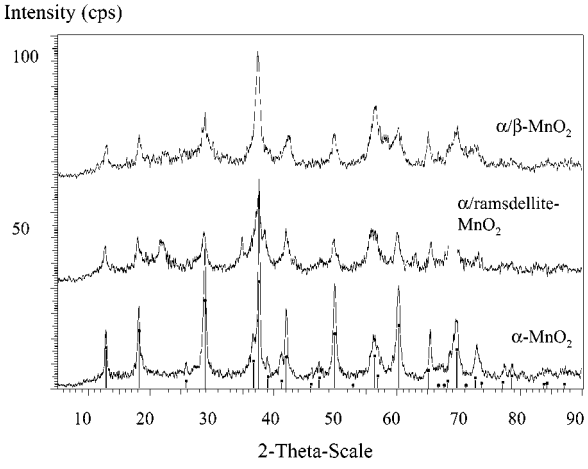

Figure 2. The different XRD patterns of single-phase α-MnO_2 with the hollandite structure, α/ramsdellite-MnO_2 with the characteristic Ramsdellite-MnO_2 reflex [110] at 22° and the new α/β-MnO_2

Table 1 compiles some characteristic reflexes of α-MnO_2 and β-MnO_2. The XRD lines at about 2θ = 28, 37, 42 and 56° of single phase α-MnO_2 coincide with the XRD lines of β-MnO_2. Figure 3 demonstrates that the [141], [600] and [521] lines recorded for α-MnO_2 are similar to the α/β-MnO_2 pattern, although there is an obvious difference in peak intensities. The XRD peak at about 56° of the synthesized α/β-MnO_2 shows a higher intensity than that of the single phase α-MnO_2 peak as the [211] line of β-MnO_2 coincides with the α-MnO_2 [600] line.

Table 1. Characteristic reflexes of α-MnO_2 and β-MnO_2

2θ (°)	Phase	*hkl*
12.781	α-MnO_2	[110]
18.112	α-MnO_2	[200]
28.882	α-MnO_2	[310]
28.670	β-MnO_2	[110]
37.488	α-MnO_2	[211]
37.342	β-MnO_2	[101]
41.993	α-MnO_2	[301]
42.800	β-MnO_2	[111]
49.847	α-MnO_2	[141]
56.356	α-MnO_2	[600]
56.645	β-MnO_2	[211]
60.253	α-MnO_2	[521]
59.363	β-MnO_2	[220]

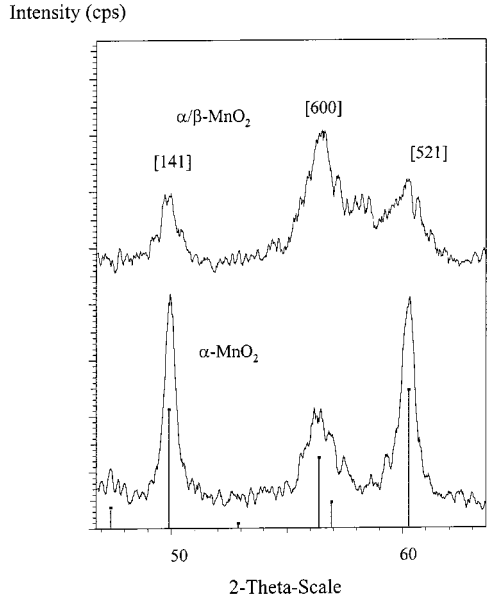

Figure 3. The [141], [600] and [521] reflexes of the measured XRD pattern of α-MnO_2 compared with the α/β-MnO_2 pattern

A [001] projection of the α-MnO_2 framework structure is given in Figure 4. The structure consists of [2×2] tunnels and of [1×1] tunnels with the pyrolusite structure. The structure of α/β-MnO_2 can be described by the model shown in Figure 5. It has an intergrown structure of layers of [2×2] channels and layers of [1×1] channels with disordered stacking. Layers with the hollandite structure alternate with several layers with the pyrolusite structure.

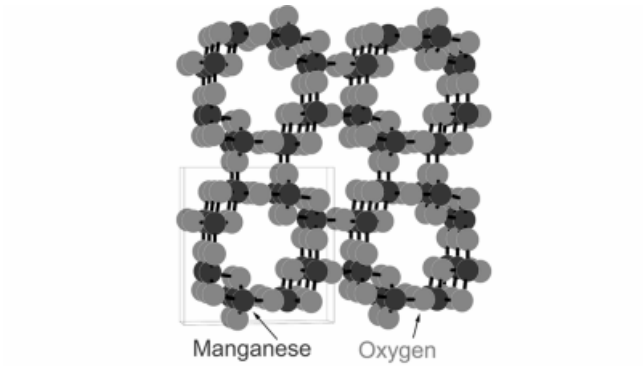

Figure 4. [001] projection of the α-MnO_2 framework structure

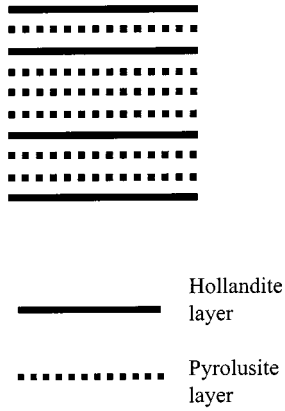

Figure 5. Proposed model of the α/β-MnO_2 structure

Figure 6 shows the Rietveld analysis (GOF: 1.35; *R*: 8.71) of the observed and calculated XRD pattern of α/β-MnO_2, assuming this structural model (α-MnO_2: PDF data 44−141; β-MnO_2: PDF data 24−735). There is quite a good agreement between the calculated pattern and the observed one. The cell parameters of a supposed tetragonal unit cell are: a = 9.791 Å and c = 2.862 Å. A peak can be observed at about 22° that doesn't belong either to the α-MnO_2 phase or to the β-MnO_2 phase. This peak can be assigned to ramsdellite-MnO_2 that has not completely transformed to β-MnO_2. As a consequence this new MnO_2 sample is a three-phase product consisting of α-MnO_2, β-MnO_2 and ramsdellite-MnO_2. The phase analysis yielded a composition of 56% α-MnO_2, 41% β-MnO_2 and 4% ramsdellite-MnO_2.

Electrochemistry

Figure 7 and 8 show the first discharge curves and the cycling behaviour, respectively, of single-phase α-MnO_2, β-MnO_2, ramsdellite-MnO_2 and the two-phase samples α/ramsdellite-MnO_2 and α/β-MnO_2. It is obvious that the stabilized α-MnO_2 delivers higher discharge capacities than single-phase α-MnO_2. Furthermore, β-MnO_2 and ramsdellite-MnO_2 show the highest discharge capacities. Single-phase α-MnO_2 shows an s-shaped discharge curve whereas β-MnO_2, ramsdellite-MnO_2 and the stabilized α-MnO_2 ex-

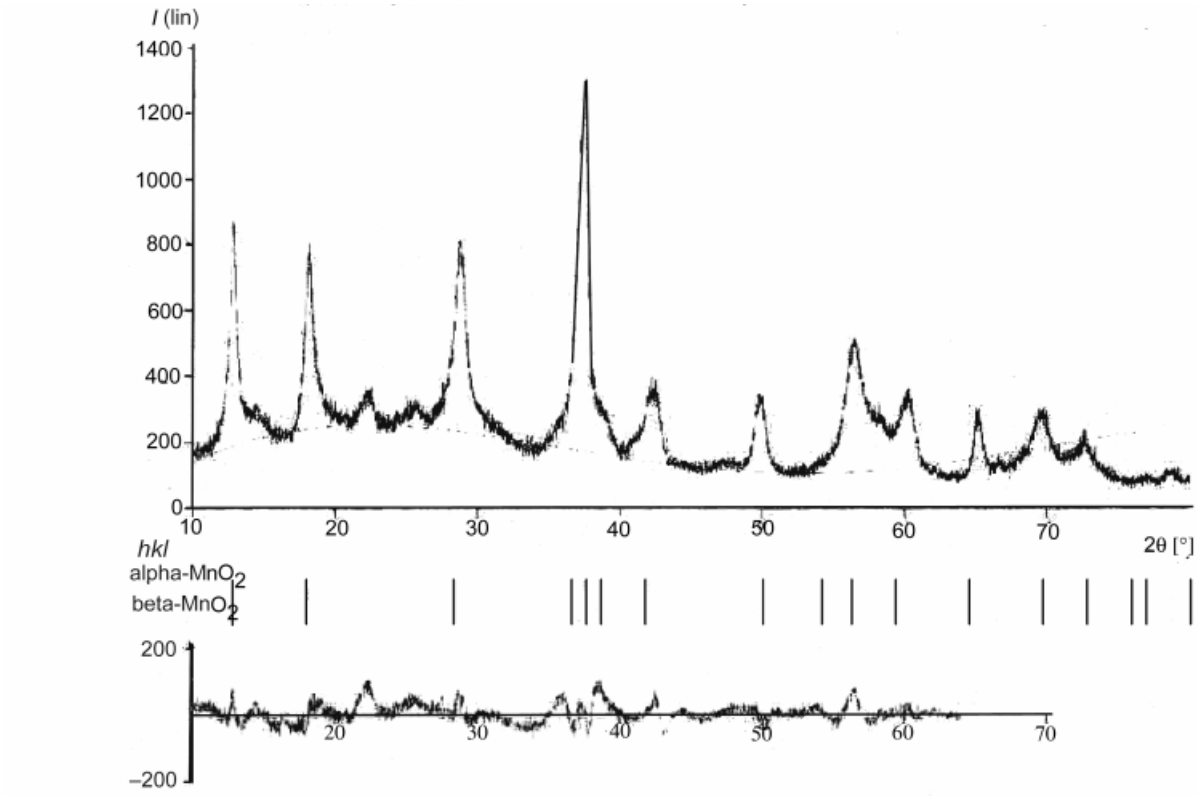

Figure 6. Observed and calculated (by Rietveld-method) XRD pattern of α/β-MnO_2 and the difference between these two patterns

hibit flat discharge curves with two voltage plateaux. The best cycling behaviour is obtained for single-phase α-MnO_2, due to small changes to the lattice parameters and unit cell volume,[18] single-phase ramsdellite-MnO_2 and the new α/β-MnO_2. The good cycling behaviour of ramsdellite-MnO_2 can be explained by a very small volume expansion and contraction during cycling, in contrast to other reports.[17] β-MnO_2 provides quite a good cycling performance even though it has always described as a cathode material for primary batteries.[19] Further work is underway to understand this feature in detail.

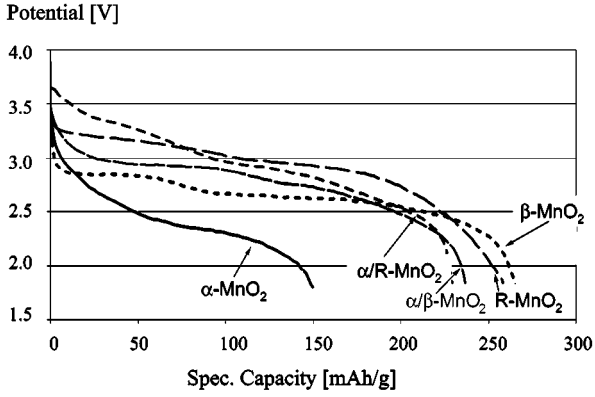

Figure 7. First discharge curves of single-phase α-MnO_2, β-MnO_2, ramsdellite-MnO_2 and the two-phase samples α/ramsdellite-MnO_2 and α/β-MnO_2

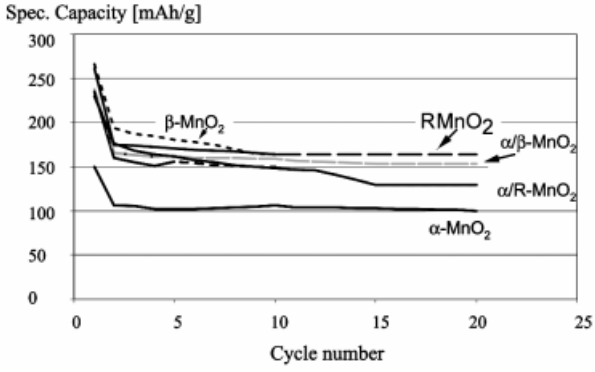

Figure 8. Cycling behaviour of single-phase α-MnO_2, β-MnO_2, ramsdellite-MnO_2 and the two-phase samples α/ramsdellite-MnO_2 and α/β-MnO_2

On the initial discharge the new α/β-MnO_2 electrode achieves a specific capacity of 237 mAh/g. After a decrease of the capacity to 168 mAh/g on the second discharge, the electrode shows good rechargeability, yielding 160 mAh/g after 10 cycles. The initial capacity loss of 30% suggests that about 0.3 mol of inserted lithium is used to provide the MnO_2 electrode with enhanced structural stability, and that this stabilizing lithium cannot easily be removed from the structure. Figure 9 shows the differential capacity plot of α/β-MnO_2 for the first and second cycle. The sharp intercalation peak at 2.9 V decreases in the second discharge due to partially irreversible intercalated lithium ions that stabilize the electrode structure during cycling. The extraction of the reversible ions from the [2×2] and [1×1] tunnel structure takes place at between 3.0 and 3.2 V, which is a higher deintercalation potential than the intercalation potential. This potential difference is mainly due to the slow kinetics of the lithium ions during extraction from the channels. The two voltage plateaux in the discharge profile of the two-phase α/β-MnO_2 are explained by the different intercalation sites.

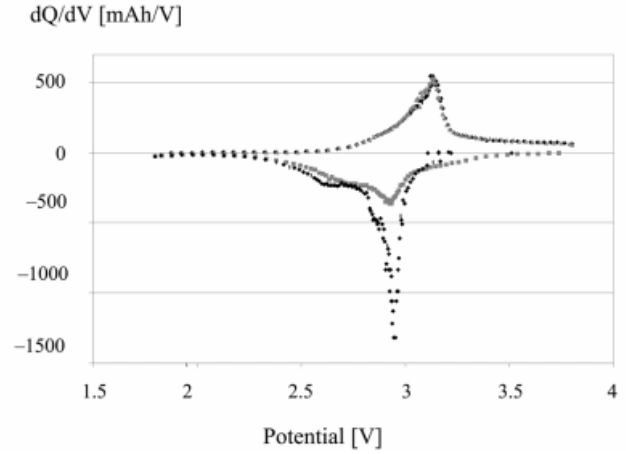

Figure 9. Differential capacity plot of α/β-MnO_2 (first and second cycle)

The high discharge capacities and the good cycling behaviour after the first cycle of this new two-phase product can be explained by the existence of interconnected α-MnO_2 and β-MnO_2 phase in the electrode structure. The β-MnO_2 is responsible for the high discharge capacities and flat discharge curve, whereas the α-MnO_2 is responsible for a stable structure during lithium intercalation and extraction, as the hollandite structure shows a small unit cell volume change. This new cathode material is therefore a β-MnO_2 stabilized with α-MnO_2.

Lithiated Manganese Oxides

In order to reduce the irreversible capacity loss after the first discharge the samples were lithiated with LiOH. Ohzuku et al. proposed a lithiation of EMD or heat-treated EMD with LiOH or other lithium salts.[21−23] This electrode material is a composite of γ-MnO_2 and β-MnO_2. Thackeray et al. described a lithiation of single-phase α-MnO_2 with LiOH.[18]

Figure 10 gives the XRD patterns of different lithiated α-MnO_2 samples. These patterns show two-phase products consisting of α-MnO_2 and a $Li_2O{\cdot}MnO_2$ (Li_2MnO_3) phase with the rock-salt structure ([002] peak at 18.7°). A different amount of $Li_2O{\cdot}MnO_2$ can be observed depending on the temperature and duration of the reaction with LiOH. There is only a small capacity loss of 5% observable after the first intercalation. The electrode structure is stabilized by Li_2O molecules introduced into the channels.[16] It appears that

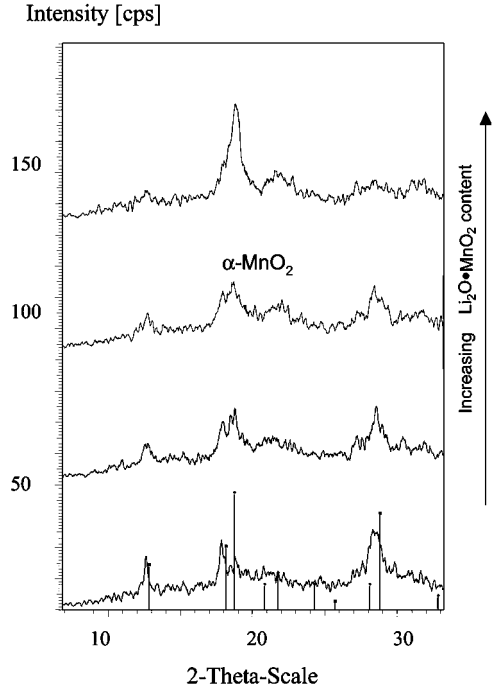

Figure 10. XRD patterns of α-MnO_2 with different Li_2MnO_3 content

no more lithium ions are trapped within the tunnels in order to stabilize the structure during electrochemical cycling. Our experiments proved that about 30% of the intercalation sites are necessary to stabilize the electrode structure. This stabilization can be done either electrochemically with lithium ions or chemically with Li_2O molecules (reaction with LiOH). It is therefore possible to insert/extract 0.7 mol of lithium reversibly.

The $Li_2O{\cdot}MnO_2$ phase provides an additional stabilization of the electrode that is responsible for a better cycling performance. The correlation between the amount of $Li_2O{\cdot}MnO_2$ and the cycling behaviour is shown in Figure 11. The capacity loss per cycle and the molar quantity of rechargeable lithium are plotted against the $Li_2O{\cdot}MnO_2$ content. The $Li_2O{\cdot}MnO_2$ phase stabilizes as a matrix (i.e. a stable rock salt structure) the large [2×2] channel structure of the α-MnO_2 framework. With increasing $Li_2O{\cdot}MnO_2$

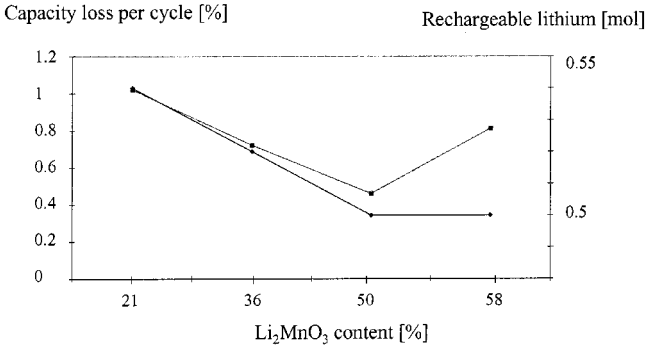

Figure 11. Correlation between Li_2MnO_3 content and cycling behaviour

content the rechargeable lithium decreases as $Li_2O{\cdot}MnO_2$ delivers only low discharge capacities.[20] We obtained the best electrochemical performance with about 30−40% $Li_2O{\cdot}MnO_2$.

The first discharge curves and the cycling behaviour of the lithiated α/β-MnO_2 in comparison to the other MnO_2 phases are shown in Figure 12 and 13, respectively. This lithiated α/β-MnO_2 is a MnO_2-based composite of α-MnO_2 and β-MnO_2 with Li_2MnO_3 as an additional phase. All the lithiated electrode materials show no, or only a small, capacity loss after the first cycle. The best electrochemical results were obtained with the lithiated α/β-MnO_2, which delivers a flat discharge curve and a good cycling stability with high discharge capacities (190 mAh/g after 10 cycles).

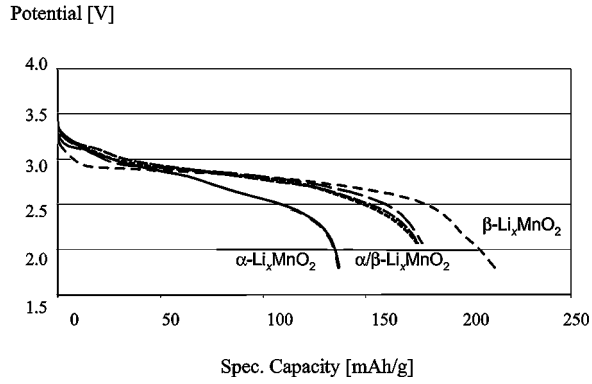

Figure 12. First discharge curves of lithiated manganese oxide phases

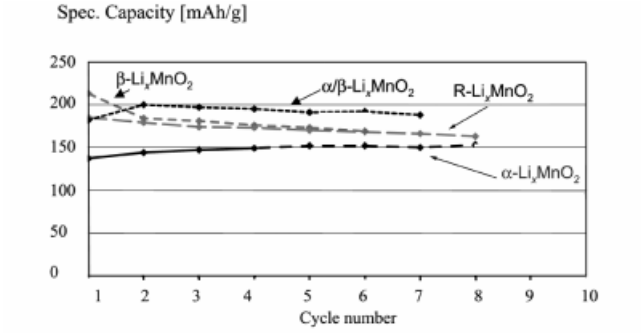

Figure 13. Cycling behaviour of the lithiated manganese oxide phases

The differential capacity plot of lithiated α/β-MnO_2 is displayed in Figure 14. There is no difference in peak intensities between the first and second cycles and there are two additional reduction/oxidation peaks in comparison to the non-lithiated α/β-MnO_2 phase. The peaks at 3.5 and 2.8 V are due to the presence of other lithium intercalation sites in the $Li_2O{\cdot}MnO_2$ framework.

Conclusion

We have demonstrated that a new synthesized α/β-MnO_2 electrode, containing α-MnO_2 and β-MnO_2 components,

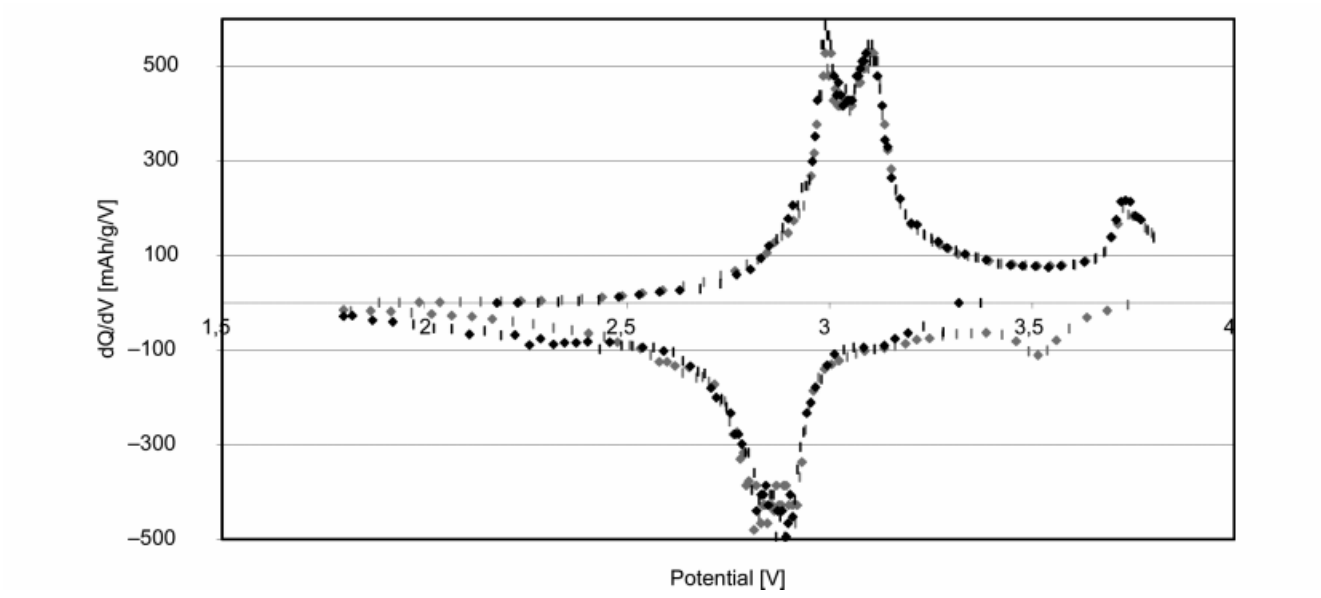

Figure 14. Differential capacity plot of lithiated α/β-MnO_2

exhibits better electrochemical features than either single phase α-MnO_2, β-MnO_2 or α/ramsdellite-MnO_2. Furthermore, it has been shown that a reaction of α-MnO_2 with LiOH forms a two-phase product consisting of a mixture of α-MnO_2 and a $Li_2O{\cdot}MnO_2$ phase. Some lithium ions of the LiOH are intercalated within the channels as Li_2O in order to stabilize the structure.[16] No capacity loss appears after the first cycle, and some lithium ions form a $Li_2O{\cdot}MnO_2$ phase that delivers an additional structure stabilization and therefore a better cycling performance. The electrochemical data indicate that lithiated α/β-MnO_2, which is a composite electrode of α-MnO_2, β-MnO_2 and Li_2MnO_3 as an additional phase, is an attractive 3 V electrode material that provides a betterr electrochemical performance than single-phase manganese oxides, with discharge capacities of 190 mAh/g after several cycles.

Experimental Section

Synthesis: The different α-MnO_2 samples were synthesized by treating α-Mn_2O_3 with sulfuric acid at different temperatures for several days with constant stirring. α-Mn_2O_3 (bixbyite-type structure) was obtained by heating EMD (Mitsui TAD 2) in air at 700 °C for 16 hours. Ramsdellite-MnO_2 was synthesized by treating a $LiMn_2O_4$ spinel with sulfuric acid. This ramsdellite-MnO_2 transforms to β-MnO_2 when heated to 350 °C for several hours. Lithiated samples were obtained by heat treatment of the different MnO_2 with LiOH between 300 and 400 °C for several hours.

Structural Characterization: X-ray diffraction profiles of the samples were determined with a Siemens D5000 diffractometer (Cu-K_α radiation). Scans were measured in the range from $2\theta = 5°$ up to 90° with a step size of 0.02°. Phase analysis was performed using the Bruker AXS software package Diffrac AT. Structural parameters were determined by Rietveld analysis of the diffraction profiles using the Bruker AXS program Win-Rietveld.

Electrochemical Characterization: Each electrode sample was prepared by grinding and mixing the active material with 4 wt.% carbon (Ketjenblack EC600) and 6 wt.% PTFE pressed into a tablet (diam 20 mm) under a pressure of 2 t/cm^2. The electrodes were dried for 16 h in vacuo at 120 °C. The separator was a polypropylene sheet (Celgard). The galvanostatic cycling took place in 2025 coin cells against metallic Li. As electrolyte a 1 M solution of $LiPF_6$ in ethylene carbonate (EC):ethylmethyl carbonate (EMC) (1:1) was used (Merck LP50). The cells were cycled galvanostatically between 3.8 and 1.8 V at a current density of 0.5 mA/cm^2 on a MACCOR test equipment. Cell assembly was performed in a glove box under argon atmosphere at room temperature.

TG/DSC measurements: The TG/DSC measurements were performed on a thermogravimetric analyser (TGA, Netsch STA 409, 5 K/min).

Keywords: Hydrogen bonds / X-ray diffraction / Raman spectroscopy / Transition metals

Some transition metal salts (Fe^{2+}, Co^{2+}, and Cu^{2+}) of 1,2,4,5-benzenetetracarboxylic acid (pyromellitic acid) have been synthesized: hexaaquairon(II) dihydrogen 1,2,4,5-benzenetetracarboxylate (**I**), hexaaquacobalt(II) dihydrogen 1,2,4,5-benzenetetracarboxylate (**II**), triaquacopper(II) dihydrogen 1,2,4,5-benzenetetracarboxylate trihydrate (**III**), and triaquacopper(II) 1,2,4,5-benzenetetracarboxylate tetrahydrate (**IV**). Single-crystal X-ray diffraction analysis of compound **III** has been performed. It crystallizes in the non-centrosymmetric space group *Pn* with two molecules per unit cell. Cu^{2+} and the ligand form an infinite linear chain. The metal atom is coordinated to five O atoms (three of the aqua ligand and two of the pyromellitate ligand) in a distorted trigonal-bipyramidal coordination. The carboxylic groups are involved in two medium intermolecular hydrogen bonds with water molecules. The O···O distances are 2.629(5) and 2.639(5) Å. The absolute structure parameter shows that the crystal and the atomic coordinate sets have the same polarity. Raman spectra of all the compounds and deuterated analogues of Fe^{2+} and Co^{2+} salts are reported. Spectral differences have been observed in the spectra of the compounds that present short hydrogen bonds (O···O distance less than 2.5 Å) in comparison to compounds that do not. In the crystal of compounds **I** and **II**, intramolecular short hydrogen bonds are present. Symmetric and asymmetric stretching vibrations of a short intramolecular hydrogen bond are observed at 307 and 874 cm^{-1} in salts **I** and **II**, respectively. The crystal structures of compounds **III** and **IV** do not show short hydrogen bonds, these bands are therefore not observed. These vibrational modes are tentative assignments by deuterium compounds and ab initio calculations of the dihydrogen pyromellitate ion.

Introduction

In general, a hydrogen bond, X−H···Y represents a relatively weak inter- or intramolecular interaction in which a positively charged hydrogen atom covalently bonded to X (the proton donor) is further attracted by a negative charge around Y (the proton acceptor). In most cases, the hydrogen atom in a hydrogen bond is more strongly bonded to one particular atom to form a clearly asymmetric hydrogen bond. Typically X and Y are electronegative elements such as N, O, F, Cl, etc. On the other hand, as the interaction H···Y becomes stronger, the X−H bond is successively elongated. Therefore, the H···Y distance becomes shorted and the hydrogen atom seems to be similarly attracted to both of them. In this situation, the donor−acceptor concept is not so clear. Anyhow, when a hydrogen bond is formed the contact between X···Y becomes closer than the sum of their van der Waals radii.[1] The hydrogen bond may be classified as: 1) strong, when the X···Y distance is short and the hydrogen atom is similarly attracted to X and Y atoms; 2) moderate, when the H atom is clearly bonded to X and electrostatically attracted to Y; 3) weak, when the H···Y interaction is weak, such that, the X···Y distance becomes long. For X = Y = oxygen atom, from the crystallographic point of view, the hydrogen bond is weak when the O···O distance is around 2.8−3.0 Å. The hydrogen bond is moderate when the O···O distance is somewhere between 2.5−2.8 Å and a hydrogen bond is short when the O···O distance is about 2.4−2.5 Å.

This work is part of a project involving crystallographic and spectroscopic studies of substances containing short hydrogen bonds (SHB). The 1,2,4,5-benzenetetracarboxylic acid, also known as pyromellitic acid [H_4Pm], is a very interesting system to study. At first, it can form different types of coordination compounds, due to the possibility of substitution of one to four hydrogen atoms. Therefore, it is possible to form intramolecular SHB, due to the proximity of the carboxylate and carboxylic groups. Some single-crystal structures of salts of this acid have been reported.[2−5] In most cases, there are SHB in these acid salt compounds. In Ni^{2+} and Co^{2+} acid salt compounds, two crystalline phases

have been identified. SHB have been observed in both phases. From the crystallographic point of view, in one phase (α) symmetric intramolecular SHB occur and in another phase (β) there are asymmetric intramolecular SHB. In the symmetric SHB, the H atom is located in a glide plane (*x*, 1/2, *z*). These complexes show potential practical interest such as detergent builders, catalysts, and heat stabilisers. The properties of these salts can be influenced by the presence of four carboxylic groups.[3] Multi-dentate complexing agents are able to form one-, two-, or three-dimensionally infinite connections between cations and anions. Due to the presence of four carboxylic groups in pyromellitic acid, its salts can coordinate in numerous ways and in different dimensionalities.

Various experimental and theoretical studies have reported on the nature of hydrogen-bonding systems.[6−8] Infrared spectroscopy has been very important in HB investigations. Spectra of a hydrogen-bonding system present broader, more intense and shifted bands than non-hydrogen-bonding systems.[6] However, hydrate compounds generally show some broad and intense envelope bands in the range of hydrogen-bond (HB) modes. In contrast, the water modes are very weak in Raman spectra. As a result of this, the Raman spectra of hydrate compounds are usually better than infrared spectra. Reid[9] interpreted the changes in the infrared spectra by making a semiempirical treatment of the hydrogen bond based on the Lippincott and Schroeder potential.[10] This treatment considers the coupling between the slow O···O stretching motion with the fast OH vibration. The O···O motion of two hydrogen-bonded oxygen atoms has been investigated much less than the O−H stretching mode, since it is in a range that is extremely difficult to separate from many other vibration modes. Reid used a harmonic oscillator approximation to calculate the O···O stretching frequency with respect to the O···O equilibrium distance. For a short O···O distance (< 2.5 Å), a frequency of ca. 850 cm^{-1} was found. Miller at al.[11] studied the O−H−O hydrogen bond in $CsH(CF_3CO_2)_2$ and $KH(CF_3CO_2)_2$. These compounds show very short O···O distances. They assigned the O···H···O mode at 798 and 792 cm^{-1} to Cs and K salts, respectively, by Raman spectroscopy. Hadzi, Orel, and Novak[12] also discussed the Raman and infrared spectra of the $MH(CX_3COO)_2$, where M = Na or K and X = H or F, and they assigned values of 720 and 320 cm^{-1} for the ν_{asym}(OHO) and ν_{sym}(OHO) bands, respectively. Luehrs et al.[13] investigated some salts of pyromellitic acid using infrared spectroscopy. They mentioned that an enlargement between 900 and 1800 cm^{-1} could be attributed to the presence of SHB.

In the present work, hydrogen bonds have been investigated in four salts: hexaaquairon(II) dihydrogen 1,2,4,5-benzenetetracarboxylate $\{[Fe^{2+}\cdot 6H_2O][C_{10}H_4O_8]^{2-}\}$ (FeH_2Pm) (**I**); hexaaquacobalt(II) dihydrogen 1,2,4,5 benzenetetracarboxylate $\{[Co^{2+}\cdot 6H_2O][C_{10}H_4O_8]^{2-}\}$ (CoH_2Pm) (**II**), triaquacopper(II) dihydrogen 1,2,4,5-benzenetetracarboxylate trihydrate $\{[Cu\cdot 3H_2O]C_{10}H_4O_8\cdot 3H_2O\}$ (CuH_2Pm) (**III**); triaquacopper(II) 1,2,4,5-benzenetetracarboxylate tetrahydrate $\{[Cu\cdot 3H_2O]_2C_{10}H_2O_8\cdot 4H_2O\}$ (Cu_2Pm) (**I**). From powder diffraction data, it can be concluded that FeH_2Pm and CoH_2Pm are isostructural. The crystal structure of CoH_2Pm was reported[3] earlier. These compounds show intramolecular SHB. The crystal structural investigation of CuH_2Pm is shown in this work and the crystal structure of Cu_2Pm was reported[2] elsewhere. These last two compounds show moderate intermolecular hydrogen bonds. All of these compounds are hydrated, with compounds **I**, **II**, and **III** having six water molecules in their structures, and compound **IV** showing ten water molecules. Due to this, Raman spectroscopy has been chosen to study spectral differences in short and long/medium HB modes. The SHB modes occur in a crowded region, thus Raman spectra of deuterated analogues of CoD_2Pm and FeD_2Pm have been obtained, and ab initio molecular orbital (MO) calculations have also been performed for the dihydrogen pyromellitate ion $[H_2Pm]^{2-}$ with the purpose of SHB mode assignment.

Results and Discussion

Description of Structures

Crystal Structure of CuH_2Pm

The crystal structure of CuH_2Pm is shown in Figure 1. Selected bond lengths and bond angles are listed in Table 1. The coordination number of Cu^{2+} is five, it is coordinated to three water molecules and two carboxyl groups of two ligand molecules $[H_2Pm]^{2-}$. The average of the Cu−O bonds is 1.944(2) Å to the ligand O atoms and 2.070(4) Å to the water molecules. The longest Cu−O bond length is Cu−O11 [2.235(4) Å]. At a first glance, Figure 1 could suggest a square-pyramidal oxygen atom arrangement around Cu^{2+}. The best least-squares plane through O1, Cu, $O5^i$, O9, and O10 shows that only the metal atom lies in this plane, however, O1, $O5^i$, O9, and O10 are on average 0.15(2) Å below and above that plane. The symmetry code of *i* is *x*, 1 + *y*, *z*. On the other hand, the best least-squares plane through the metal ion and the three oxygen atoms of the water molecules is the plane through Cu, O9, O10, and O11. All the atoms lie in this plane with an average distance of 0.005(3) Å. Therefore, it can be concluded that the oxygen arrangement around the metal ion is better described as a slightly distorted trigonal-bipyramidal structure. This geometry was observed in the Cu_2Pm crystal structure by Usubalieve et al.[2] The water molecules form the pyramid base and O−Cu−O angles are 165.4(2)° (O9,O10), 94.8(3)° (O9, O11), and 99.8(3)° (O10, O11). At the top and bottom of the coordination geometry O1 and O5 are attached to the ligand molecule. The average of O−Cu−O angles is 89.5(2)° and the O1−Cu−O5 angle is 176.3(2)°. Cu^{2+} atoms are bonded in a monodentate form to O1 and O5 atoms of different H_2Pm ligands. These O atoms are located on opposite sides of the benzene ring and the Cu^{2+}atoms are linked between ligand molecules. These bonds form an infinite linear chain, as can be seen from Figure 1.

Hydrogen bonds					
D−H···A	Distance D−A [Å]	Bond angles [°]	D−H···A	Distance D−A [Å]	Bond angles [°]°
O4−H4A−O12^{ii}	2.639(5)	175.9(4)	O11−H11A−O6^{ii}	2.757(7)	170.4(4)
O7−H7A−O12^i	2.629(5)	172.6(4)	O12−H12A−O1^{ii}	2.694(5)	165.7(5)
O9−H9A−O3	2.927(6)	146.6(4)	O12−H12B−O6^i	2.685(5)	152.1(4)
O9−H9B−O13^i	2.701(7)	149.1(5)	O13−H13A−O8^i	3.000(6)	141.4(4)
O10−H10A−O8^i	2.905(5)	154.4(4)	O13−H13B−O2^{ii}	2.891(6)	171.9(5)
O10−H10B−O14	2.731(6)	168.3(6)	O14−H14A−O5^{ii}	2.975(5)	165.8(5)

In the carboxyl groups the averages of C−O and C=O bonds are 1.294(4) and 1.222(4) Å, respectively. In the carboxylate groups O1−C7−O2 and O5−C9−O6 the difference between C−O and C=O bonds is smaller than usually in carboxylic groups due to the delocalization of the electrons as can be seen in Table 1. The average of the C−C−C, O−C−O, and C−C−O angles is 120(3)°. The benzene ring is planar with a maximum deviation of 0.006 Å. The distances of the carboxyl group atoms to the benzene plane are 0.003(6), 0.009(6), −0.197(7), 0.039(6), 1.175(7), −1.055(6), 0.075(8), −0.058(7), 0.834(7), −1.348(6), 0.183(8), and −0.082(7) Å to C7, C8, C9, C10, O1, O2, O3, O4, O5, O6, O7, and O8, respectively. The COOH planes are rotated against the mean plane through the benzene ring by −7.1 and −3.2°, and the COO^- planes are rotated by −87.1 and +95.4°. This conformation is similar to that found in pyromellitic acid (H_4Pm) for which the torsion angles are 17.9 and 74.4°.[14] CuH_2Pm crystallizes in a non-centrosymmetric space group, so the absolute structure could be obtained. The absolute structure parameter x, Flack parameter, may be determined for any non-centrosymmetric crystal. This parameter is a variable in the least-squares refinement.[15] The Flack parameter was refined to 0.01(2). The refined value of x is independent of

the starting values. Therefore, this value indicates that the crystal and atomic coordinates have the same polarity.[15]

The carboxylic groups present are not involved in SHB. There are three water molecules of crystallization in this structure (O12, O13 and O14). These water molecules are also involved in medium and long hydrogen bonds. The ligand H_2Pm is an acceptor of two medium (O12) and three long (O13 and O14) hydrogen bonds from water molecules. The O12···O1^{ii}, O12···O6^{i}, O13···O2^{ii}, O13···O8^{i}, and O14···O5^{ii} distances are 2.694(5), 2.685(5), 2.891(6), 3.000(6), and 2.975(5) Å, respectively. The coordination water molecules are donors to one medium (O11) and two long (O9, O10) hydrogen bonds. The O6^{ii}···O11, O8^{i}···O10, and O3···O9 distances are 2.757(7), 2.905(5), and 2.927(6) Å, respectively. Two medium hydrogen bonds between the water molecules were observed. The O10···O14 and O9···O13 distances are 2.731(6) and 2.701(7) Å, respectively. The H_2Pm ligand is the donor of two medium hydrogen bonds to waters of crystallisation (O12). The O7−O12^{i} and O4−O12^{ii} distances are 2.629(5) and 2.639(5) Å, respectively. The symmetry code of *ii* is 0.5 + *x*, −*y*, 0.5 + *z*.

Powder Diffraction Data

As described in the Exp. Sect., there was not a suitable single crystal for X-ray analysis of FeH_2Pm. Therefore, powder diffraction methods were used to identify iron compounds. In order to make sure that in the absence of a single crystal, powder diffraction techniques can be useful for identification of a structure type, some X-ray powder patterns are shown in Figure 4. The program XPOW[16] was used to generate X-ray powder patterns.

CuH_2Pm and Cu_2Pm Structures

The calculated X-ray powder patterns of CuH_2Pm are based on the cell parameters, atomic position, and displacements obtained from single-crystal structure refinement described in this present work. The X-ray powder pattern of Cu_2Pm was obtained from a single-crystal structure by Usubalieve et al.[2] In Cu_2Pm the water molecules of crystallisation are involved in medium and long hydrogen bonds with the ligand. The average O···O distances in medium and long hydrogen bonds are 2.69(1) and 2.85(5) Å, respectively. Cu_2Pm forms two cross infinite chains, where the Cu^{2+} is the link between the ligand molecules (Figure 2). Cu^{2+} shows the same coordination geometry as CuH_2Pm. The powder patterns are shown in Figure 4 (a).

CoH_2Pm and FeH_2Pm

There are two crystal phases reported for the Co^{2+} salt.[3,5] In both of them there are intramolecular SHB, and Co^{2+} is coordinated by six water molecules in an octahedral geometry. The carboxyl groups are involved in a short intramolecular hydrogen bond with an O···O distance of about 2.4 Å. From a crystallographic point of view, one of these phases (α) shows symmetric intramolecular SHB[3] and the other (β) shows asymmetric SHB.[5] The α phase crystal

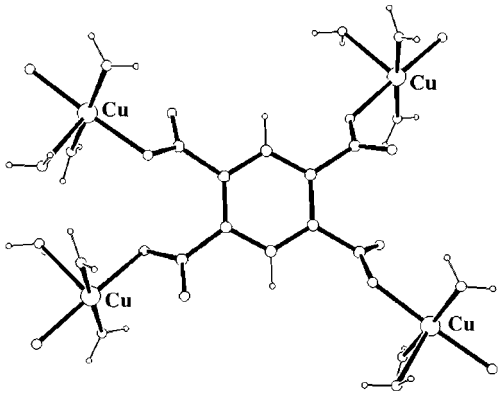

Figure 2. Crystal structure of Cu_2Pm

structure is shown in Figure 3. In the symmetric SHB, the H atom is located in a glide plane (*x*, 1/2, *z*). In the α phase the carboxyl groups are coplanar with the benzene ring while in the β phase the dihedral angles of the carboxyl group with the benzene ring are about 25°. In Figure 4 (b), experimental (Co^{2+} and Fe^{2+} salts) and calculated (α and β phase) X-ray powder patterns are shown. For the α phase the calculated pattern was obtained from single-crystal data by Ward and Luehrs.[3] For the β phase the calculated powder pattern has been performed from single-crystal data given by Rochon and Massarweh.[5]

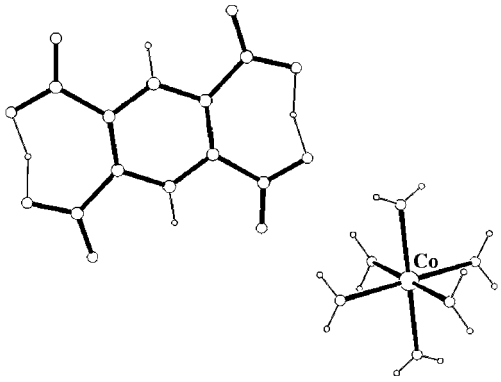

Figure 3. Crystal structure of the α phase of CoH_2Pm

Experimental FeH_2Pm and CoH_2Pm X-ray powder patterns are very similar, therefore, it can be concluded that they may be isostructural. This similarity shows that the Fe^{2+} and Co^{2+} salts obtained in this work have the same structure as the Co^{2+} salt published by Ward and Luehrs.[3]

Raman Spectroscopy and Vibrational Mode Assignment

Experimental Raman spectra of the compounds and a theoretical Raman spectrum of the H_2Pm^{-2} ion are displayed in Figures 5 and 6, and its deuterated counterpart for Fe^{2+} and Co^{2+} salts are shown in Figure 7. The Raman frequencies are shown in Tables 2 and 3.

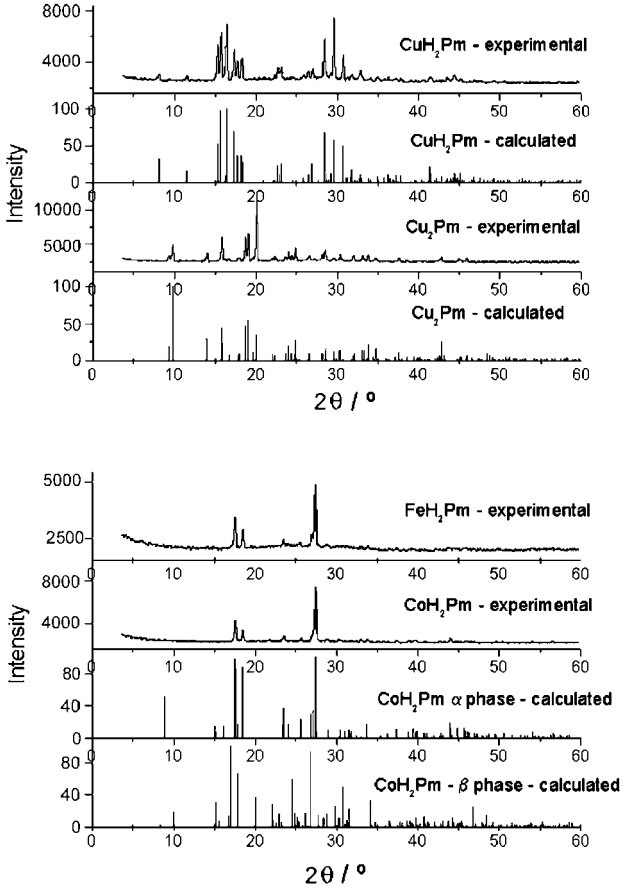

Figure 4. Experimental and calculated powder patterns of a) Cu_2Pm and CuH_2Pm and b) FeH_2Pm and CoH_2Pm

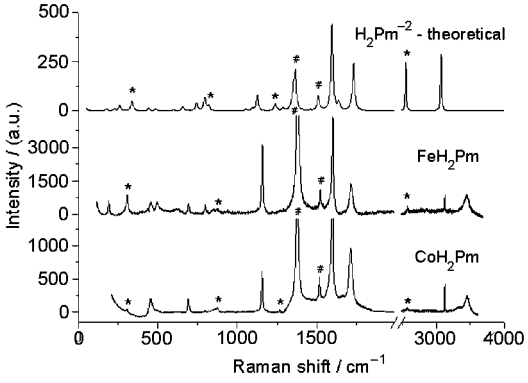

Figure 5. Raman spectra of Fe^{2+} and Co^{2+} salts of pyromellitic acid; the symbol * refers to bands relative to SHB vibrations; The symbol # refers to ν_{sym}(COO) and ν_{asym}(COO)

Carboxyl Modes

The stretching vibration of carboxyl groups is easily assigned as they are very intense and appear in a characteristic region. There are two stretching vibrations for the carboxylate group, one symmetric [ν_{sym}(COO)] and another asymmetric [ν_{asym}(COO)]. In CoH_2Pm and in FeH_2Pm the ν_{sym}(COO) and ν(C=O) are strongly coupled with δ(OH).

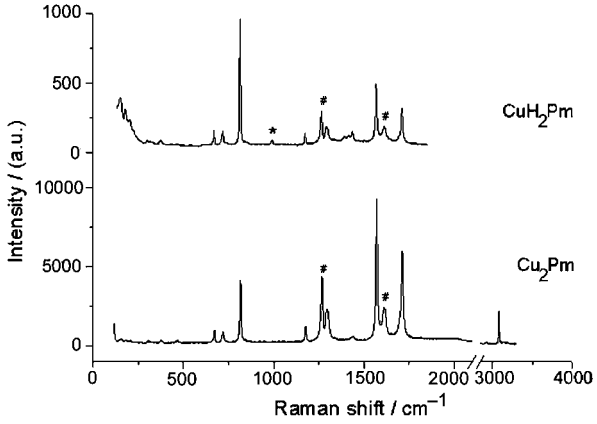

Figure 6. Raman spectra of copper salts of pyromellitic acid; the symbol * refers to γ(OH); the symbol # refers to ν_{sym}(COO) and ν_{asym}(COO)

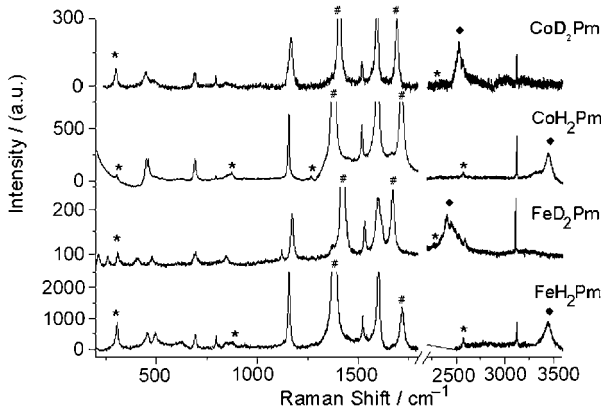

Figure 7. Raman spectra of the SHB region of FeH_2Pm, CoH_2Pm and deuterated analogues; the symbol * refers to bands relative to SHB vibrations; the symbol # refers to ν_{sym}(COO) and ν(C=O); the symbol ◆ refers to ν[OH(D)] from $H(D)_2O$

These couplings were confirmed by ab inito calculations and by the frequency shift of these bands in the Raman spectra of the deuterated analogues. In the CoH_2Pm salt the ν_{sym}(COO) and ν(C=O) were observed at 1378 and 1714 cm^{-1}, respectively, and they shift to 1406 and 1691 cm^{-1} after deuteration. Similar shifts were observed in the Fe^{2+} salt, ν_{sym}(COO) and ν(C=O) at 1381 and 1718 cm^{-1} respectively, and they shift to 1423 and 1670 cm^{-1}, respectively in the deuterated salt. These strong couplings and shifts were also observed in some hydrogen acetate salts.[12] The X-ray crystal data of CuH_2Pm show that Cu^{2+} is monodentately coordinated to the carboxylate groups of H_2Pm^{2-} and the carboxylic groups are involved in medium hydrogen bonds to water molecules, as seen in Figure 1. The ν_{sym}(COO) and ν_{asym}(COO) of the carboxylate groups were observed at 1260 and 1613 cm^{-1}. The ν(C−O) for carboxylic groups was assigned at 1318 cm^{-1} and ν(C=O) at 1694 and 1711 cm^{-1}. In Cu_2Pm, the ν_{sym}(COO) and ν_{asym}(COO) were observed at 1268 and 1611 cm^{-1} respectively, and the ν(C=O) at 1698 and 1713 cm^{-1}. In-plane bending [δ(COO)] occurs at 796, 798, 817, and 814 cm^{-1} for CoH_2Pm, FeH_2Pm, CuH_2Pm, and Cu_2Pm respectively, and

Frequencies of deuterated salts are in parentheses.

out-of-plane bending [γ(COO)] was observed at 854 and 845 cm^{-1} for CoH_2Pm and FeH_2Pm. The difference (Δ) between symmetric and asymmetric carboxylate stretching vibrations can be used as a parameter to identify the coordination type. In FeH_2Pm and CoH_2Pm the Δ values are 141 and 139 cm^{-1}, respectively, and in Cu^{2+} salts Δ is about 343 cm^{-1}. The crystal data show that Cu^{2+} has monodentate coordination, while Fe^{2+} and Co^{2+} do not coordinate to the dihydrogen pyromellitate ion. These results are in agreement with those of acetate compounds,[17] for which the Δ value is larger in monodentate complexes than in the free ion.

Benzene Ring and M−O Modes

The assignments for the aromatic ring moiety were based on that for substituted benzene[18,19] and are listed in Tables 2 and 3. The M−O stretching modes were observed at about 375 and 377 cm^{-1} for CuH_2Pm and Cu_2Pm, and 384 and 364 cm^{-1} to FeH_2Pm and CoH_2Pm respectively.[20]

O−H Modes

Crystal data shows that in the crystal structure of the Cu^{2+} salts SHB are not present, while in both Fe^{2+}, and Co^{2+} salts there are intramolecular SHB. In FeH_2Pm and CoH_2Pm, the O−H stretching of the carboxylic group was observed at 2575 and 2577 cm^{-1}, respectively. For free OH this mode occurs at 3700 cm^{-1}. These shifts to lower frequencies of the O−H carboxylic stretching are due to the formation of SHB. In the deuterated analogues, the ν(O−D) of SHB may be tentatively assigned to a very weak band at 2300 cm^{-1} in the Co^{2+} salt and at 2359 cm^{-1} in the Fe^{2+} salt. The ν_{OH}/ν_{OD} ratios are 1.12 and 1.09, respectively, for Co^{2+} and Fe^{2+} salts. The O−H stretching of water molecules was observed at 3143 cm^{-1} for Cu_2Pm, at 3444 cm^{-1} for FeH_2Pm, and 3450 cm^{-1} for CoH_2Pm. The ν(O−D) of water molecules are assigned to a very broad band near 2525 and 2400 cm^{-1} for Co^{2+} and Fe^{2+} salts, respectively. The ν_{OH}/ν_{OD} ratios are 1.36 and 1.44 for Co^{2+} and Fe^{2+} salts, respectively. These ratios are in agreement with the isotopic substitution effect. The γOH mode is very weak in Raman spectra and was only observed in CoH_2Pm and CuH_2Pm at 1267 and 991 cm^{-1}, respectively. In deuterated salts, the γOD could not be assigned.

O···H···O Modes

The SHB stretching modes in the FeH_2Pm and CoH_2Pm were tentatively assigned to very broad and weak bands at 874 cm^{-1} for the asymmetric stretching mode [ν_{asym}(O···H···O)], and at 307 cm^{-1} for the symmetric mode [ν_{sym}(O···H···O)] in both salts. These tentative assignments are in accordance with the semiempirical treatment of the hydrogen bond.[9] As these regions have many modes, tentative assignments were made using deconvolution methods, isotopic substitution (OH/OD) and ab initio calculations for H_2Pm^{2-}. Although ab initio calculations have been done in the gaseous phase and without a metallic cation, their results are in agreement with solid-state data. The dihydrogen pyromellitate ion (H_2Pm) is not coordinated to metallic Fe^{2+} and Co^{2+}, thus the crystal packing is more important for geometric and vibrational changes than metal coordination. The starting point of the ab initio calcula-

tions was the X-ray crystal structure of the CoH_2Pm α phase,[3] which minimises differences between theoretical (gaseous phase) and experimental (solid phase) data due to crystal packing. In ab initio calculations the symmetric and asymmetric stretching modes were obtained at 337 and 822 cm^{-1}, respectively.

In Raman spectra, the ν_{sym}(O···H···O) mode is symmetric about the H atom. The hydrogen atom does not move and no frequency shift due to mass difference is expected upon deuteration.[11] In the deuterated analogues, the ν_{sym}(O···D···O) was observed at 309 and 300 cm^{-1} for Co^{2+} and Fe^{2+} salts, respectively. In CoH_2Pm and FeH_2Pm, the ν_{asym}(O···H···O) was tentatively assigned to 874 cm^{-1}. As this region is crowded and SHB modes become a little broader in deuterated analogues, the assignment becomes more difficult. On the other hand, it is known that deuteration causes little shift in asymmetric O−H−O stretching as was observed in the infrared spectra of potassium hydrogen maleate[21] and lithium hydrogen phthalate monohydrate.[22] In contrast, in Cu^{2+} salts, which do not show any SHB, similar bands were not observed in these regions.

The ν(O···H···O) of long and medium hydrogen bonds are expected at low frequencies (about 120 cm^{-1}). However, this region has lattice and hydrogen-bond water modes, which makes it difficult to assign the O···H···O mode.

Computations

Vibrational modes of the short hydrogen bond occur in regions where there are other Raman-active modes. In this work, quantum-mechanical calculations were used in an attempt to observe and assign those specific hydrogen-bond modes.

Geometry optimization and frequency calculations were made for H_2Pm^{2-} with intramolecular SHB. The starting point of the geometry calculations was the α phase of CoH_2Pm, as described by Ward and Luehrs.[3] In spite of the fact that the calculations have been performed in the gas phase, they are in good agreement with the experimental values of the Co^{2+} salt.[3] Table 4 contains both theoretical and experimental geometric parameters for H_2Pm^{2-}. This good agreement between experimental and theoretical data is due to the fact that in the crystal structure of the α-phase CoH_2Pm, Co^{2+} does not coordinate to H_2Pm^{2-}, therefore it is an ionic compound. Co^{2+} is coordinated to six water molecules in an octahedral geometry. There is a weak interaction between H_2Pm^{2-} and coordinated water molecules. H_2Pm^{2-} is the receptor of three long hydrogen bonds involving the water molecules. This is a weak interaction, therefore the greatest difference between the crystal and the gaseous phase is the crystal packing. However, the geometry optimization was performed using the coordinates of the crystal structure, which reduce crystal packing effects. As a result, theoretical and experimental data, geometry and frequency calculations and X-ray crystal data and the Raman spectrum of the ionic salt CoH_2Pm, could be compared and were similar.

Table 4. Bond lengths and bond angles of dihydrogen pyromellitate ion − experimental and calculation data

	Exp.[3]	Calcd.
Distances [Å]		
C1−C2	1.394(1)	1.392
C2−C2′	1.414(2)	1.408
C2−C3	1.522(1)	1.538
C3−O1	1.286(1)	1.211
C3−O2	1.299(1)	1.274
Angles [°]		
C2−C1−C2′	124.76(6)	124.36
C1−C2−C2′	117.64(7)	117.83
C1−C2−C3	113.66(10)	114.31
C2′−C2−C3	128.69(5)	127.87
C2−C3−O1	118.97(9)	118.22
C2−C3−O2	119.92(9)	117.77
O1−C3−O2	121.09(8)	123.97
C1−C2−C3−O1	2.01(15)	−15.79
C2′−C2−C3−O2	−176.56(10)	−18.4

The maximum deviations between theoretical and experimental data were 2 and 6%, respectively, for angles and bond lengths. The computed C−C bonds and C−C−C angles are in excellent agreement with experimental values. The computed O···O distance for a short symmetric intramolecular hydrogen bond (2.336 Å) is in good agreement with the experimental value (2.381 Å). The experimental C−Obond values are larger than the computed ones, and the carboxyl groups are more planar. This occurs due to the fact that in the crystal structure the water coordination molecules are involved in medium hydrogen bonds with carboxyl groups. The frequency calculations are listed in Tables 2 and 3. The simulated and experimental Raman spectra of the compounds are shown in Figure 4. Theoretical wavenumbers listed in Table 2 are multiplied by a scale factor of 0.8929. This scale factor is an average from the comparison of several computed and experimental data.[23]

The frequencies (ν_i) and the vibrational intensities (A_i), obtained in the ab initio calculation, were fitted to a Lorentzian-type function to describe the vibrational spectra. In this process, the concentration was considered equal to $c = 1\cdot10^{-3}$ in the Raman spectrum where $l = 1$ cm. To simplify the procedure, a constant value for the full width at half maximum (ω) was considered in all spectral regions, $\omega = 15$ cm^{-1}. Equation (1) represents the absorbance for a given frequency, ν.

$$A(\nu) = \left[\ln\left(\frac{I_0}{I}\right)\right]_\nu = cl\sum_{i=1}^{3N-6}\left[A_i\left(\frac{2\omega_i}{\pi}\right)\right]\cdot\left\{\frac{1}{\left[4(\nu-\nu_i)^2+\omega\right]}\right\} \quad (1)$$

The theoretical Raman spectrum of H_2Pm^{-2} is very similar to the spectra of Fe^{2+} and Co^{2+} salts. The short hydrogen-bond modes were obtained at 822 for ν_{asym}(O···H···O), and 337 for ν_{sym}(O···H···O). The relative deviations of experimental data were 5.9 and 9.8%, respectively. In the fre-

quency calculations, a shift to low frequencies was observed for the O−H stretching of the carboxylic group (2551 cm^{-1}). This stretching is very sensitive to hydrogen-bond interactions and is in good agreement with the experimental data (2575 cm^{-1}). The O−H deformation modes were obtained at 1054 and 1539 cm^{-1} for out-of-plane and in-plane, respectively. Theoretical benzene ring deformation modes are strongly coupled with C−H and COO deformation modes.

Conclusion

Although the vibrational modes of hydrogen bonds are weak in Raman spectroscopy, it was possible to carry out a study of these types of interactions. The O···H···O modes lie in a crowed region of the spectrum, but these modes were identified and tentatively attributed with the aid of deconvolution techniques, isotopic substitution and ab initio calculations. The optimized geometry in the gas phase is in good agreement with the experimental X-ray crystal data. Information about different types of hydrogen bonds (short or long) can be obtained using Raman spectroscopy.

FeH_2Pm and CoH_2Pm have a very short intramolecular hydrogen bond with an O···O distance of about 2.4 Å. The short hydrogen bond stretching observed in the Raman spectra was tentatively assigned to a broad band of weak intensity at 874 cm^{-1} for the asymmetric mode [ν_{asym}(O···H···O)] and at 307 cm^{-1} for the symmetric [ν_{sym}(O···H···O)] one. In deuterated analogues the ν_{sym}(O···H···O) band appears not to shift and the ν_{asym}(O···H···O) band is unfortunately not possible to assign. The evidence of deuteration was observed by the shift in the frequency of ν_{sym}(COO) and ν(C=O) modes, which are strongly coupled with the δOH(D) mode, and by the shift of the ν(OH) of water molecules, whose ν_{OH}/ν_{OD} is 1.36 for CoH_2Pm and 1.43 for FeH_2Pm.

CuH_2Pm crystallizes in the non-centrosymmetric space group *Pn*. The carboxyl groups of the H_2Pm^{-2} ions form a linear polymeric structure. In this compound, two medium intermolecular hydrogen bonds [2.639(5) Å and 2.629(5) Å] were observed and in Cu_2Pm, the pyromellitate ion is a receptor of medium hydrogen bonds with water molecules. The ν(O···H···O) of long and medium hydrogen bonds is expected at low frequencies (about 120 cm^{-1}).

Experimental Section

Synthesis: Powders and single crystals of the compounds were obtained by slow concentration of aqueous solutions at room temperature.

Fe^{2+} Salt: To a hot aqueous solution of pyromellitic acid (3.3 mmol; Aldrich B400-7, 96%), iron powder(3.2 mmol; Merck 3819, 99.5%) was added. The final solution was heated until the total oxidation of the iron powder had occurred, filtered, and stored at room temperature. A yellow powder was obtained and characterised as hexaaquairon(II) dihydrogen 1,2,4,5-benzenetetracarboxylate (FeH_2Pm). $C_{10}H_{16}FeO_{14}$ (416.08): calcd. C 28.87, H 3.85, Fe 13.42; found C 28.86, H 3.46, Fe 12.64. Its deuterated derivative was obtained by the reaction of metallic iron (powder) with pyromellitic acid and recrystallised from D_2O.

Co^{2+} Salt: To a hot aqueous solution of pyromellitic acid (3.3 mmol; Aldrich B400-7, 96%), an aqueous solution of cobalt(II) nitrate hexahydrate (2.9 mmol; Aldrich 23,037-5, 99%) was added. The final solution was filtered and stored at room temperature. Pink crystals were obtained and characterised as hexaaquacobalt(II) dihydrogen 1,2,4,5 benzenetetracarboxylate (CoH_2Pm). $C_{10}H_{16}CoO_{14}$ (412.22): calcd. C 28.65, H 3.82, Co 14.06; found C 28.67, H 3.83, Co 14.04. Its deuterated derivative was obtained by repeated recrystallization of CoH_2Pm in D_2O.

Cu^{2+} Salts: In a hot aqueous solution of pyromellitic acid (3.2 mmol; Aldrich B400-7 96%), basic copper(II) carbonate (1.6 mmol; Aldrich 20,789-6) was dissolved. The final solution was filtered and stored at room temperature. Two types of crystals were obtained, one dark blue and the other light blue. The dark blue crystals were characterised as triaquacopper(II) 1,2,4,5-benzenetetracarboxylate tetrahydrate (Cu_2Pm). $C_{10}H_{16}Cu_2O_{15}$ (503.32): calcd. C 21.55, H 3.95, Cu 22.80; found C 22.04, H 3.38, Cu 26.79. The light blue crystals were characterised as triaquacopper(II) dihydrogen 1,2,4,5-benzenetetracarboxylate trihydrate (CuH_2Pm). $C_{10}H_{16}CuO_{14}$ (423.78): calcd. C 28.34, H 3.78, Cu 15.00; found C 29.56, H 3.61, Cu 14.20.

Powder: X-ray powder patterns were obtained with a Rigaku diffractometer using Cu radiation (λ = 1.541838 Å) with 4 °·min^{-1} speed.

Raman Spectroscopy: Raman spectra were obtained with a micro-Raman instrument Dillor X-Y triple monochromator equipped with a CCD detector at room temperature. The 514.5 nm line of an argon ion laser was used as the exciting radiation.

Calculation Methods: Ab initio MO calculations were performed with the Gaussian 98 program package[24] using a Digital workstation. All calculations were carried out at the Hartee−Fock (HF) level. The 6-31++G** basis set with polarised and diffuse functions added to all the atoms was employed. The X-ray structure of the Co^{2+} salt of pyromellitic acid (CoH_2Pm)[3] was used as a starting point for geometry optimisation, followed by vibrational analysis. These salts are isostructural to FeH_2Pm. The theoretical vibrational spectra were calculated using the SIMULAT program.[25]

X-ray Crystallographic Study: $C_{10}H_{16}CuO_{14}$, M = 423.78, monoclinic, a = 6.763(1), b = 10.923(1), c = 9.646(1) Å, β = 91.925(3)°, V = 801.58(4) $Å^3$, T = 298 K, space group *Pn* (no. 07), Z = 2, μ(Mo-K_α) = 13.9 mm^{-1}, d = 1.756 g·cm^{-3}, 3220 reflections measured, 3085 unique (R_{int} = 0.009) which were used to refine 229 parameters. Final $R(F)$ and $wR(F^2)$ were 0.037 and 0.114, respectively (all data). The crystal was mounted on a four-circle P4 Siemens diffractometer. XSCANS program[26] was used to refine the unit-cell parameters and to manage the data collection. Analytical absorption, Lorentz and polarisation effects were corrected using JANA'98,[27] with maximum and minimum transmission of 0.984 and 0.881, respectively. The structure was solved by Patterson methods in a non-centrosymmetric space group with the XS program.[16] This space group is non-polar, therefore, Cu fractional coordinates were used as the origin. Hydrogen atoms were located from successive Fourier difference maps. Their atomic coordinates were optimised and fixed. Anisotropic displacement parameters were assigned to all non-hydrogen atoms, the structure was refined using SHELXL-93.[28] An empirical isotropic extinction parameter x was refined, according to the method describe by Larson.[29] The

structure was drawn by ORTEP-3 for windows.[30] CCDC-167303 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to Dr. Marcelo Augusto Silva de Oliveira and Dr. Marcos Assunção Pimenta for the Raman spectroscopy data obtained with a micro-Raman spectrometer at the Departamento de Física of the Universidade Federal de Minas Gerais, and to the Centro de Desenvolvimento de Tecnologia Nuclear (CDTN) for providing the D_2O. This work has been supported by the Fundação de Amparo à Pesquisa do Estado de Minas Gerais, FAPEMIG (Grant CEX 1123/90). R. D. and H. A. A. are grateful to the CNPq for providing the graduate fellowship.

Coupling of Arylamines with Coordinated Arylazopyrimidines in Palladium(II) Complexes

Prasanta Kumar Santra,[a] Prithwiraj Byabartta,[a] Surajit Chattopadhyay,[b] Larry R. Falvello,[c] and Chittaranjan Sinha*[a]

Keywords: Nitrogen heterocycles / Palladium / N ligands / Aminations / X-ray structure / EHMO calculation

2-(Arylazo)pyrimidine (**1**) reacts with palladium chloride and gives Pd(aapm)Cl_2 (**2**) which undergoes a palladium(II)-mediated novel carbon–nitrogen bond formation reaction of the aromatic amines to the *ortho*-C–H function of the pendant aryl ring in the coordinated 2-(arylazo)pyrimidine. The reactant, Pd(papm)Cl_2 (**2a**) and the product, Pd(papm-N-C_6H_4-OCH_3-*p*)Cl (**5a**) have been characterised by X-ray crystal structure. The coupled products exhibit low energy transitions (NIR region) unlike the parent complex, Pd(aapm)Cl_2. The cyclic voltammogram shows an oxidation couple at positive potential to SCE. The EHMO calculation suggests that the spectral feature in Pd(aapm)Cl_2 (**2**) is due to the MLCT [d(Pd)→π*(azo)] whereas in Pd(aapm-N-C_6H_4-X-*p*)Cl (**3**–**6**) the transition at the NIR region is due to the intravalence charge transfer (IVCT) transition.

Introduction

Arylazoheterocycles are light-sensitive, redox-active, and efficient colorant materials.[1−9] Presence of an arylazo group at the *ortho* position of the N-heterocycles constitute an azoimine, −N=N−C=N−, function.[7−9] They have successfully been used to stabilise the low-valent metal redox state.[7−17] The coordination of arylazoheterocycles to a metal centre alter the electrophilic character of the ligand and provides a fascinating area in the metal-assisted organic synthesis. This has been observed in the metal complexes of 2-(arylazo)pyridines.[18−25] The complexes undergo different organic transformations at the pendant aryl ring such as hydroxylation,[18−20] thiolation,[21−23] and the C−N coupling[24,25] reaction with aromatic amines. This has encouraged us to design 2-(arylazo)pyrimidines [aapm (**1**)][13,14,19] that is more π-acidic than 2-(arylazo)pyridine due to the π-acidity order, pyrimidine > pyridine. Copper(I)[13] and isomers of ruthenium(II) complexes[14] of **1** have been reported from our group. Palladium(II) forms [2-(arylazo)pyrimidine]dichloropalladium(II) [Pd(aapm)Cl_2 (**2**)] and its reaction with OH^- in air or Tollen's reagent gives (azophenolatopyrimidine)palladium(II) complex.[19] This is believed to be formed by the hydroxylation of the C−H bond *ortho* to the azo group of 2-(arylazo)pyrimidine. Heterocyclic bases (e.g., pyridine and derivatives R-Py) react with Pd(aapm)Cl_2 and substitute the ligand followed by isomerisation to *trans*-Pd(R-Py)$_2Cl_2$.[26] In continuation of our work to explore the reactivity of palladium−aapm complexes, we discuss in this article the palladium(II)-mediated C−N coupling reaction of aromatic amines to the *ortho*-C−H function of the pendant aryl ring in the coordinated 2-(arylazo)pyrimidine. The reactant and product have been characterised by X-ray crystallography. The coupled products exhibit different electronic and redox behaviour from that of the reactants and have been accounted for by EHMO calculations.

Results and Discussion

Synthesis of Parent Complexes

The general abbreviation of 2-(arylazo)pyrimidine is aapm (**1**). 2-(Phenylazo)pyrimidine [papm (**1a**)], 2-(*p*-tolylazo)pyrimidine [tapm (**1b**)], and 2-(*p*-chloro-phenylazo)pyrimidine [Clpapm (**1c**)] are three ligands used in this work. They act as *N*,*N*′-bidentate chelators with an azoimine function, −N=N−C=N−, where N refers to N(8)(azo) and *N*′ refers to N(3)(pyrimidine). The reaction of aapm with Pd(MeCN)$_2Cl_2$ in MeCN has yielded orange-red Pd(aapm)Cl_2 (**2**) in high yield.[19,27]

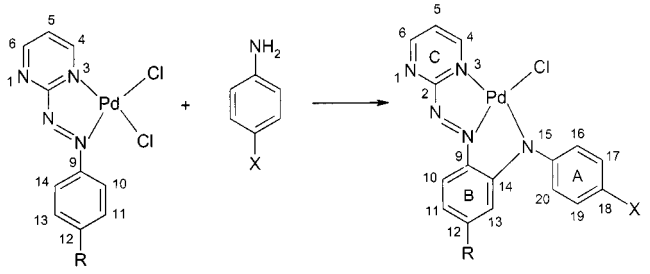
aapm, **1**

The C−N Coupling Reaction

Addition of $ArNH_2$ (in 1:1 stoichiometry) in an MeCN suspension of Pd(aapm)Cl_2 (**2**) under refluxing conditions, changes the intense orange-red colour to greenish-brown. Chromatographic purification of the reaction mixture separates an orange-brown band. The orange-brown band has been identified as an amine product coupled to Pd(aapm)Cl_2 and is abbreviated Pd(aapm-N-C_6H_4-X-*p*)Cl [where X= H (**3**), Me (**4**), OMe (**5**), Cl (**6**)]. The reaction is shown in Equation (1). The arylamination takes place at the *ortho* position of the aryl ring (B ring) of aapm to the azo function and forms a palladium(II) complex of tridentate *N*,*N*′,*N*′′-chelating ligand [where N is N(8)(azo); *N*′ is N(3)(pyrimidine); *N*′′ is N(15)(arylamine)]. Free ligands do not couple with arylamines even if forced but they react smoothly in the palladium(II) complex.



2 Pd(aapm-N–C_6H_4–X-*p*)Cl (**3** - **6**) (1)

Spectral Studies

Infrared spectra of Pd(aapm)Cl_2 (**2**) show two distinct Pd−Cl stretches [ν(Pd−Cl) = 340, 360 cm^{-1}] in agreement with *cis*-$PdCl_2$ configuration.[19,27] A sharp single band at 1400−1415 cm^{-1} corresponding to $\nu_{N=N}$ in the ligand is shifted to 1380−1385 cm^{-1} in Pd(aapm)Cl_2. This lowering of the frequency is due to N-coordination.[18] In the coupled products, Pd(aapm-N-C_6H_4-X-*p*)Cl (**3**−**6**), $\nu_{N=N}$ appears at 1290−1300 cm^{-1}; this significant reduction in azo stretching may be due to the intramolecular charge delocalisation from the fused N-C_6H_4-X-*p* fragment to the azo function (vide infra). A single stretch at 340−350 cm^{-1} in **3**−**6** supports the presence of a Pd−Cl bond. A chloroform solution of Pd(aapm)Cl_2 exhibits a strong absorption[19] at ca. 425 nm. On comparison with the free ligand solution spectra,[13] the transition has been assigned to the MLCT band which is also supported by an EHMO calculation (vide infra). The spectral structure changes abruptly in Pd(aapm-N-C_6H_4-X-*p*)Cl (**3**−**6**) and exhibits an intense band in the NIR region (750−1100 nm) with five/six well-defined transitions (Figure 1). The spectroscopic data are collected in Table 1. The transitions have been accounted from EHMO calculation and are assigned to HOMO→LUMO transitions where the HOMO has a major share from the arylamine group and the LUMO is dominated by the azo group (vide infra). The observed trend of the band maxima (λ_{max}) for the substituent in the aryl ring follows as *p*-chloroaniline (**6**) < aniline (**3**) < *p*-toluidine (**4**) < *p*-anisidine (**5**). The electron-donating substituent in the X-C_6H_4-N- fragment increased the energy of the HOMO[27,28] and in *p*-anisidine the energy was maximised. In *p*-choloroaniline the energy of the HOMO was reduced due to the electron-withdrawing effect of the Cl group. The substituent (R) in the arylazopyrimidine [R-C_6H_4-N=N-$C_4H_3N_2$ (**1**)] fragment also shifted the band maxima in the order Pd(Clpapm-N-C_6H_4-X-*p*)Cl (**c**) > Pd(papm-N-C_6H_4-X-*p*)Cl (**a**) > Pd(tapm-N-C_6H_4-X-*p*)Cl (**b**). This is due to the lowering of the energy of the LUMOs in **c** compared to **a** due to the electron-withdrawing power of Cl. The reverse case is seen in the complexes **b** due to the +I effect of the Me group that has a destabilising effect on the LUMOs.

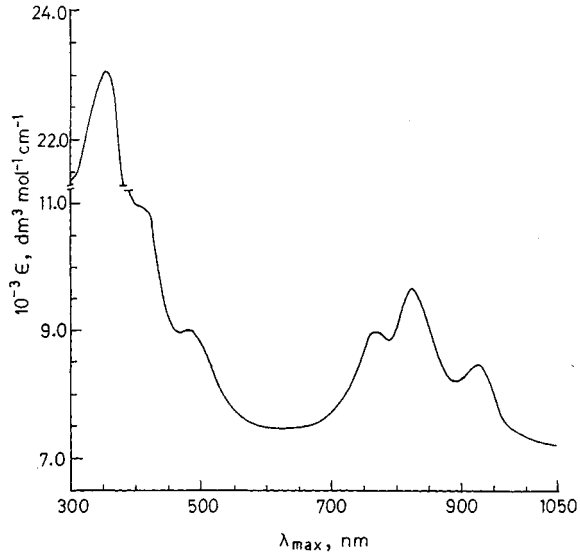


Figure 1. Electronic spectra of Pd(papm-N-OCH_3-*p*)Cl (**5a**) in $CHCl_3$

The ^{1}H NMR spectra of the complexes are compared in order to determine the bonding mode and stereochemistry. The ^{1}H NMR spectra of the ligands aapm (**1**) and Pd(aapm)Cl_2 (**2**) were reported from our group.[13,26] The signals were assigned on the basis of chemical shifts, spin-spin interaction and their effect on substitution. In Pd(aapm)Cl_2 the signals in general are downfield shifted compared to free ligand values.[26] Pd(aapm-N-C_6H_4-X-*p*)Cl show complex NMR spectra. The *N*-aryl (A-ring) and azoaryl (B-ring) proton signals appear on the upfield side. The effect of the substituent X (X-C_6H_4-N) on the signal movement of the arylamine protons (A-ring protons: 16-H to 20-H) is in accordance with the electronic property of X. It is observed that the electron-donating substituent (Me/OMe) moves the signals upfield while the electron-withdrawing group Cl moves them downfield with reference to

the unsubstituted system. A similar situation is also observed for the substituent R on the arylazopyrimidine (R-C_6H_4-N=N-$C_4H_3N_2$) protons of the B-ring (10-H to 13-H). The cross interactions i.e., the effect of substituent X at the *N*-aryl ring on the azoaryl protons or vice versa are not remarkable. Azoaryl signals (10-H to 13-H) are severely affected in Pd(aapm-N-C_6H_4-X-*p*)Cl relative to Pd(aapm)Cl_2 and are shifted upfield by 0.2−1.0 ppm. Pyrimidine protons (4-H to 6-H of C-ring) in **3**−**6** are shifted upfield by 0.1−0.5 ppm compared to the parent complex Pd(aapm)Cl_2 and are hardly affected by the substituents in the aryl rings (X or R). Coupling of arylamine with the aryl part of aapm (B-ring) has changed the electronic behaviour of the molecule. The azopyrimidine function is electron-deficient while the *N*-aryl (ring A) is a σ-donor and may cause an intramolecular charge-transfer transition. This may be the reason for the large upfield shifting of the arylazopyrimidine proton signals (4-H to 13-H). Solution electronic spectral properties also support this behaviour (vide supra).

X-ray Structure Studies

The X-ray structures of Pd(papm)Cl_2 (**2a**) and Pd(papm-N-C_6H_4-OCH_3-*p*)Cl (**5a**) have been determined. Perspective molecular views are shown in Figures 2 and 3 and the selected bond parameters are listed in Tables 2 and 3.

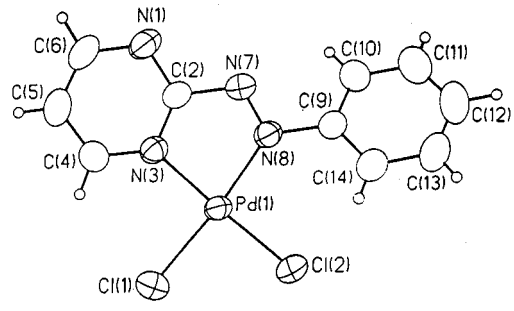

Figure 2. Drawing of Pd(papm)Cl_2 (**2a**), showing the atom numbering scheme; non-hydrogen atoms are represented by their 50% probability ellipsoids

a. Geometrical Features

The Pd(papm)Cl_2 has a *cis*-$PdCl_2$ configuration (Figure 2). The asymmetric unit of the crystal lattice consists of two molecules. These two molecules have parallel cores with a Pd···Pd separation of 3.4201(5) Å. The molecular packing diagram viewed down the *a* axis shows a Pd···Pd separation between asymmetric units of 3.9881(4) Å and the pendant phenyl rings are oriented in a parallel manner to ensure some sort of π-interaction. The packing also exhibits a benzene molecule at the special position and a weak Pd···Cl nonbonding intermolecular interaction (3.3−3.4 Å) where

Pd and Cl belong to two different molecules in the asymmetric unit. The two independent molecules are chemically similar. The PdN_2Cl_2 coordination sphere is planar with no atom deviating more than 0.06 Å from the mean plane. The chelate ring is planar (deviation < 0.04 Å) and the bond angle lies in the range 77.6±2°. This deviates from ideal square-planar angles. The Cl−Pd−Cl angle is ca. 90.2°. The pendant phenyl ring is no longer in plane with the chelated fragment and is twisted by ca. 42.5°.

The crystallographic asymmetry unit of Pd(papm-NC_6H_4-OCH_3-*p*)Cl contains 25 non-hydrogen atoms, of which 17 lie in a plane nearly perpendicular to the crystallographic *c* axis. These atoms comprise of two chelate rings, the aromatic groups fused to them, and the Pd and Cl atoms. The remaining atoms of the asymmetric unit comprise the methoxyphenyl group. The Pd atom lies in the square plane defined by the N_3Cl donor centres (deviation 0.02 Å). Two chelate planes Pd,N(3),C(2),N(7),N(8) (deviation < 0.01 Å) and Pd,N(15),C(14),C(9),N(8) (deviation < 0.01 Å) are coplanar and the chelate angles are 78.86(14) and 81.76(14)°, respectively. The pendant methoxyphenyl ring (A ring) is inclined at an angle of 54.99(15)° with the principal plane of 17 atoms.

b. Bond Parameters

In Pd(papm)Cl_2 the Pd−N(azo) bond length is slightly longer (ca. 2.03 Å) than that of the Pd−N(pyrimidine) (ca. 2.01 Å). This is the reverse in the case of other complexes. In copper(I) and ruthenium(II) complexes of papm, the M−N(azo) distance is significantly shorter than that of the M−N(pyrimidine) distance [Cu(papm)$_2$(ClO_4):[13] Cu−N(azo) 1.99 Å, Cu−N(pyrimidine) 2.03 Å; Ru(papm)$_2$$Cl_2$:[14] Ru−N(azo) 2.00 Å; Ru−N(pyrimidine) 2.06 Å]. This is due to π-back bonding involving metal t_2 and ligand π*(azo) orbitals.[7,13,14,29] The N=N bond length is 1.260(3) Å and is comparable with that of the copper(I)[13] complex but shorter than that of the ruthenium(II)[14] complexes. Efficient π-back bonding in (arylazopyrimidine)ruthenium(II) complexes enhances the N=N distance.[14] In Pd(papm-NC_6H_4-OMe-*p*)Cl the Pd−N(azo) [Pd−N(8)],

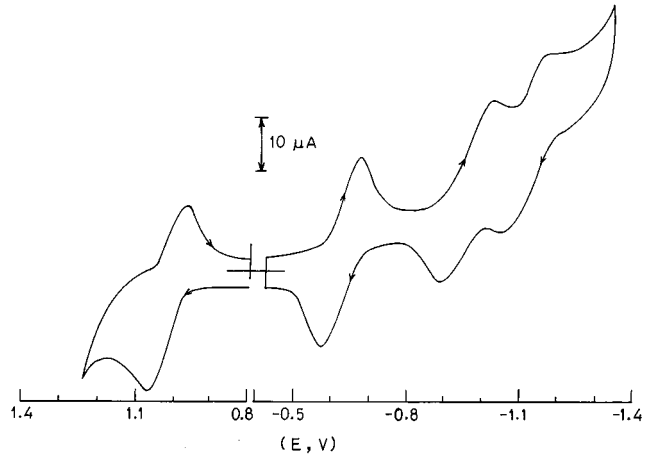

Figure 4. Cyclic voltammogram of Pd(papm-N-C_6H_4-OCH_3-*p*)Cl (**5a**) in MeCN (0.1 M Bu_4NClO_4) at 298 K

Pd−N(pyrimidine) [Pd−N(3)], and Pd−N(arylamine) [Pd−N(15)] distances are 2.028(4), 1.938(3), and 2.028(4) Å, respectively. The N=N length is 1.314(4) Å. The N=N distance is not available for the free ligand; however, the data available in some azo ligands[30−32] suggest that it is ca. 1.25 Å. In this case the N=N distance in **5a** is unusually long compared to the parent complex **2a**. This elongation may be due to intramolecular charge delocalisation from the arylamine fragment (vide supra) to the azopyrimidine.

Electrochemistry

The redox behaviour of **3**−**6** in acetonitrile solution was examined by cyclic voltammetry at a Pt-disk working electrode and the potentials are reported with reference to the SCE. The results are given in Table 1, and a representative voltammogram is shown in Figure 4. Pd(aapm)Cl_2 does not exhibit any redox response positive to the SCE and on the negative side a quasireversible redox couple ($\Delta E_P > 130$ mV) followed by an irreversible response at potential > -1.0 V is observed. Pd(aapm-N-C_6H_4-X-*p*)Cl (**3**−**6**) exhibited four successive redox couples: one of them at high positive potential (1.0−1.3 V) and three at the negative side of the SCE. Arylazopyrimidines are reduced at the negative potentials, −1.0 to −1.4 V.[13,14] The reduction is regarded as the electron accommodation in the LUMO characterised by the azoimine function. There are four successive redox-accessible levels in the azoimine function [Equations (2) to (5)]. In the present examples, three negative redox couples may correspond to three reductions [Equations (2) to (4)]. However, the couple at the positive potential is difficult to assign as Pd^{II} is redox-inactive. We suggest that this couple is due to oxidation of the ligand at the easily oxidisable azoarylamine chelated centre (chelate ring 2) [Equation (6)]. The first three redox couples [Equations (2), (3), and (6)] are quasireversible (ΔE_P = 70−100 mV) and the fourth response [Equation (4)] is irreversible in nature ($\Delta E_P > 130$ mV).

The oxidation of coordinated *ortho*-phenylenediamine to semibenzoquinone diimine and benzoquinone diimine are known in the literature and support this observation.[34,35] The redox potential varies in the usual manner with the substituent at the *N*-aryl (A-ring) and azoaryl (B-ring) ring.[13,19]

Electronic Structure − EHMO Calculation

In order to have an insight into the difference in electronic behaviour of Pd(aapm)Cl_2 and Pd(aapm-N-C_6H_4-X-*p*)Cl towards their spectral and electrochemical properties, the MO calculations have been performed in the framework of extended Hückel formalism on a model complex as shown in structures **i** and **ii** (shown in Table 4). Crystallographic data were used as the parameters for bond lengths and bond angles. The relative percentages of the atomic contributions to the MOs are given in Table 4. In complex

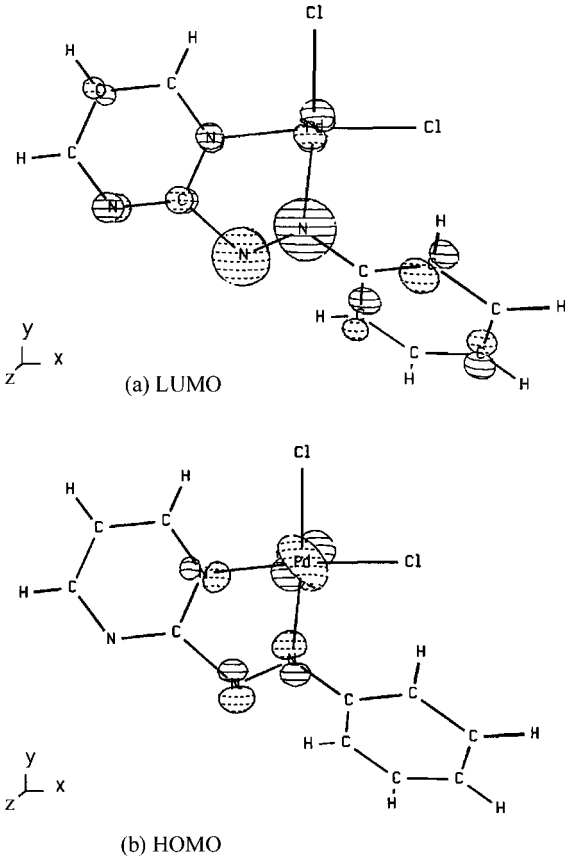

Figure 5. LUMO and HOMO of Pd(papm)Cl_2

Pd(aapm)Cl_2 the LUMO (47a) (Figure 5, a) is ligand-dominated with 67% character of azo (N=N), 5% of pyrimidine-N and a small contribution (9%) from the Pd d_{yz} orbital. The HOMO (46a) is mainly a metal orbital (83%) (Figure 5, b) and contributed from d orbitals (total 78%, of which d_z^2 41% and d_{xy} 37%) and a small part of the 4s orbital (5%). In complex Pd(aapm-N-Ar)Cl the LUMO

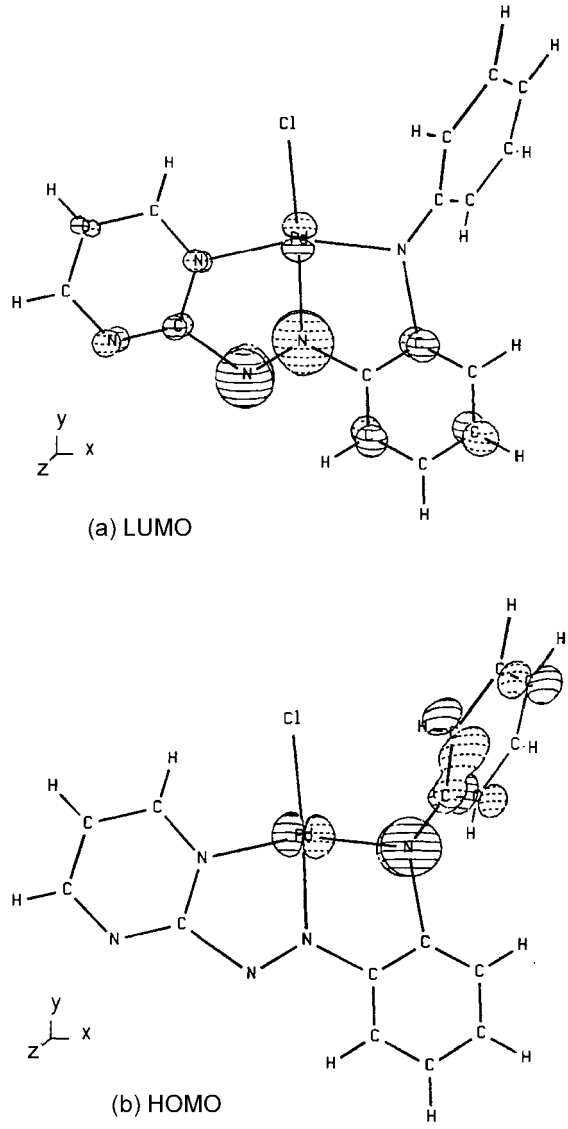

Figure 6. LUMO and HOMO of Pd(papm-N-C_6H_5)Cl

(60a) (Figure 6, a) is characterised by the azo group (68%), pyrimidine group (22%), and a small part of the metal orbital (d_{yz}, 9%). The HOMO (59a) (Figure 6, b) is computed from the admixture of the metal d_{xz} orbital (37%) and the *N*-aryl (ring A) (53%) and contributes to 90% of the character of the function.

Some experimental findings may be rationalised on the basis of EHMO results. The solution electronic spectra of complex **2** may exhibit a HOMO→LUMO (46a→47a) transition corresponding to the MLCT band. The first reduction will certainly be localised due to electron accommodation at the LUMO (47a) [π*(azo)] and the second electron will enter at the LUMO+1 (48a), which is purely pyrimidine in character (99%). Thus, the second reduction is irreversible in nature. The spectral and electrochemical behaviour of Pd(aapm-NAr)Cl is entirely different from the parent complex. The low-energy spectral band is associated with a HOMO→LUMO (59a→60a) charge transfer.[28,35,36] The HOMO is from a major portion (53%) of the N−Ar

group (ring A) and the LUMO shares 68% azo and 22% pyrimidine character. Thus, the transition is characterised as an intravalence charge-transfer transition (IVCT). Other spectral transitions may be characterised as HOMO−1 (58a)→LUMO (60a), HOMO−2 (57a)→LUMO (60a), HOMO (59a)→LUMO+1 (61a), etc. The redox behaviour at a positive potential to SCE may correspond to electron extraction from the HOMO (59a), which has a major share from the N−Ar group. The reductions correspond to sequential electron feeding at the LUMO (60a); LUMO+1 (61a) and LUMO+2 (62a).

Experimental Section

General Remarks: 2-(Arylazo)pyrimidines were prepared by the reported procedure.[13] $PdCl_2$ was purchased from Arora Matthey. Aniline, *p*-toluidine, *p*-anisidine, *p*-chloroaniline were received from the Sisco Research Lab. The purification of acetonitrile and preparation of tetrabutylammonium perchlorate (TBAP) for electrochemical work were done as before.[13] Dinitrogen was purified by bubbling through an alkaline pyrogallol solution. All other chemicals and solvents were of reagent grade and were used without further purification. Commercially available SRL silica gel (60−120 mesh) was used for column chromatography. Spectroscopic data were obtained using the following instruments: UV/Vis/NIR spectra: JASCO UV/Vis/NIR model V 570 and Hitachi U-3501. IR spectra (KBr disk, 4000−200 cm^{-1}): FTIR JASCO model 420. ^1H NMR spectra: Bruker (AC) 300 MHz FTNMR spectrometer. Electrochemical measurements were performed using a computer-controlled PAR model 270 VERSASTAT Electrochemical instruments with Pt-bead and GC-electrodes. All measurements were carried out under dinitrogen at 298 K with reference to a saturated calomel electrode (SCE) in acetonitrile. The reported potentials are uncorrected for junction potential.

Preparation of the Complexes: The dichloro[2-(arylazo)pyrimidine]-palladium(II) [Pd(aapm)Cl_2 (**2**)] complexes were prepared by a literature method[19] in the yield of 85−90%. A representative case is given in detail.

a. Dichloro[2-(phenylazo)pyrimidine]palladium(II) [Pd(papm)Cl_2 (2a)]: To an MeCN (10 mL) solution of $PdCl_2$ (0.18 g, 1.01 mmol), 2-(phenylazo)pyrimidine [papm (**1a**)] (0.2 g, 1.09 mmol) was added dropwise and the mixture was stirred for 1 h. The orange-red precipitate was filtered and washed with MeOH. The dried mass was dissolved in a minimum vol. of CH_2Cl_2 and purified by chromatography on a silica gel (60−120 mesh) column and the desired orange-red band was eluted with MeCN/benzene (30% v/v).Yield 85%. ***NOTE:*** Benzene is carcinogenic and precaution must be taken during its use!

b. Chloro[(2-(14-imidophenyl)phenylazo)pyrimidine-*N*,*N*′,*N*′′]palladium(II) [Pd(papm-N-C_6H_5)Cl (3a)]: To an acetonitrile solution (15 mL) of Pd(papm)Cl_2 (0.3 g, 0.83 mmol), an aniline (0.1 g, 1.08 mmol) solution in acetonitrile (10 mL) was slowly added. The reaction mixture was stirred and refluxed continuously for 4 h and the colour of the solution changed gradually from orange-red to greenish-brown. The solution was concentrated in air, and the residue was washed thoroughly first with water (2 × 5 mL) and then with 50% aqueous ethanol (3 × 5 mL). The residue was dissolved in dichloromethane (10 mL) and the solution was column-chromatographed on silica gel prepared in benzene. An orange-brown band was eluted with an acetonitrile/benzene (1:9) mixture. The eluted solution, on concentration in vacuo, gave a pure orange-brown compound, isolated in 45% yield. The orange-brown product is the desired coupled product, Pd(papm-N-C_6H_5)Cl. Pd(papm-N-C_6H_5)Cl (**3a**): $C_{16}H_{12}ClN_5Pd$ (416.2): calcd. C 46.16, H 2.89, N 16.83; found C 46.25, H 2.95, N 16.70. IR (cm^{-1}): $\nu_{Pd\text{-}Cl}$ 370, $\nu_{N=N}$ 1296, $\nu_{C=N}$ 1585. All the other compounds were prepared according to the same procedure, the yields varied between 40 and 65% for the orange-brown compound. Pd(papm-N-C_6H_4-Me-*p*)Cl (**4a**): $C_{17}H_{14}ClN_5Pd$ (430.2): calcd. C 47.45, H 3.26, N 16.28; found C 47.35, H 3.32, N 16.30. Molecular Orbital Calculations: Extended Hückel Molecular Orbital calculations[34,36] were performed using the ICON software package originally developed by Hoffmann. The orthogonal coordinate system chosen for the calculations are defined in Figures 5 and 6. The atomic parameters were taken from the crystallographic data (Table 5). For drawing figures and diagrams the graphic package CACAO was used.

X-ray Crystallography: Crystals of Pd(papm)Cl_2 suitable for X-ray work were grown by slow diffusion of benzene into a dichloromethane solution at 283 K. The crystal size was 0.26 × 0.25 × 0.23 mm. The crystals of Pd(papm-N-C_6H_4-OCH_3-*p*)Cl suitable for X-ray work were obtained from diffusion of hexane into a dichloromethane solution at 298 K. The crystal size was 0.22 × 0.19 × 0.10 mm. Crystal data and collection parameters are listed in Table 5. Data were gathered with a CAD4/PC V diffractometer with graphite monochrochromator (λ = 0.71073 Å) at 297(2) K. The crystals were mounted on glass fibres and covered with epoxy. Scan parameters were derived from ω-θ scans of 25 reflections. Three monitor reflections were measured after every 30 min of X-ray exposure as a check on experimental stability. The orientation of the crystal was checked after every 500 intensity measurements. Absorption corrections were based on ψ-scans of 12 reflections with bisecting-mode Eulerian χ values in the range of 0−86° for Pd(papm)Cl_2 and 2−83° for Pd(papm-N-C_6H_4-OCH_3-*p*)Cl. The structure was solved by direct methods and refined by full-matrix least squares. In Pd(papm)Cl_2 the asymmetric unit consists of two full molecules and a half molecule of benzene. Systematic absences are consistent

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^{1/2}]$. [c] GOF is defined as $[w|F_o - F_c|/(n_o - n_v)]^{1/2}$, where n_o and n_v denote the numbers of data and variable, respectively.

with the space group of $Pna2_1$ or the centric group *Pnma* for Pd(papm-N-C_6H_4-OCH_3-*p*)Cl. The refinement in the centric group (*Pnma*) leads to residuals of $R_1 = 0.12$ and $wR2 = 0.44$. In space group $Pna2_1$ the values are $R_1 = 0.0287$ and $wR2 = 0.0630$ and thus chosen as the correct space group. All data were corrected for Lorentz polarisation and an empirical absorption correction was done on the basis of azimuthal scans. Of 6435 reflections in $Pd(papm)Cl_2$ 6117 [$I > 2\sigma(I)$] were used for the structure solution. In Pd(papm-N-C_6H_4-OCH_3)Cl the unique reflections (2068) were used for the structure solution. Data were processed with an Alpha Station 2004/166 (open VMS/Alpha V 6.2) using the program XCAD4B and the commercial package SHELXTL Rel. 505/VMS. All non-hydrogen atoms were located from subsequent difference Fourier maps. CCDC-135187 and -135188 contain the supplementary crystallographic data for [$Pd(papm)Cl_2$] (**2a**) and [Pd(papm-N-C_6H_4-OMe-*p*)Cl] (5a), respectively. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Supporting Information: ^{1}H NMR spectroscopic data, a packing diagram, and Walsh diagrams are available (see footnote on the first page of this article).

Acknowledgments

We are thankful to the University Grants Commission, New Delhi for financial assistance. The Council of Scientific and Industrial Research, New Delhi provided a fellowship to P. B. Funding from the Directorate General of Higher Education and Scientific Research to the Departmento de Quimica Inorganica, Universidad de Zaragoza, Plaza San-Fransisco, S/NE-50009, Espana, for crystallographic work (grant PB 98-1593), is gratefully acknowledged.

Triaminoboranes and Their Metallation to *N*-Lithiotriaminoboranes[‡]

Ulrike Braun,[a][‡‡] Tassilo Habereder,[a] Heinrich Nöth,*[a] Hans Piotrowski,[a] and Marcus Warchhold[a]

Keywords: Boranes / Deprotonation / Lithium / Nitrogen / X-ray diffraction

In order to study the competition between deprotonation, borate formation, and B–N bond cleavage, six triaminoboranes bearing 1–3 NH functions were treated with butyllithium. The 2-anilino-1,3,2-diazaborolidine **1** was cleanly deprotonated, but the resulting *N*-lithio compound could not be crystallized. However, as a result of slow hydrolysis, the lithium 2-oxido derivative **7** was isolated in low yield as a dimeric ether solvate. Double deprotonation of 2-(dimethylamino)-1,3,2-benzodiazaborolidine (**9**) was accompanied by B–N bond cleavage. The dilithio derivative reacted with Me_3SiCl to produce 2-dimethylamino-1,3-bis(trimethylsilyl)-1,3,2-benzodiazaborolidine (**11**). Similarly, dianilino(diphenylamino)borane (**2**) was readily deprotonated to the insoluble dilithium compound. B–N bond cleavage also occurred, however, and the solvates $Ph_2NLi{\cdot}dme$ (**13**) and $Ph_2NLi{\cdot}2py$ (**14**) were isolated. These are dimeric, the former with a planar Li_2N_2 ring, the latter possessing an N–Li–N–Li chain structure. Triply metallated trianilinoborane (**15**) crystallized as dimeric $B(NLiPh)_3{\cdot}LiCl{\cdot}(OEt_2)_3$ (**15A**). Treatment of trianilinoborane (**3**) with LiBu in 1:1 and 1:2 ratios showed that the deprotonation was accompanied by the formation of anilino(butyl)borates. Treatment of the dilithio derivative of **3** with Me_3SnCl afforded $B[N(SnMe_3)Ph]_3$ (**23**), a result of substituent exchange. Tris(2-pyridylamino)borane (**4**), with a planar skeleton, reacted with BuLi both by deprotonation and by B–N bond cleavage. The metallated triaminoborane crystallized as dimeric $Li_4B(NR^*)_3NHR^*(THF)_3$ (**18**; R^* = 2-pyridyl). Tris(8-quinolylamino)borane (**5**) can also be triply lithiated according to ^{11}B and ^7Li NMR spectroscopic data. X-ray determination of the structures of compounds **1**–**3** showed the absence of N–H···N hydrogen bonding, which seems to be responsible for the planar structures of compounds **4** and **5**. The planarity of the BN_3 units in **3** and **4** was retained in the trilithiated compounds **15A** and **18**, as ascertained by X-ray structure determination.

Introduction

The metallation of aminoboranes $R_{3-n}B(NHR')_n$ by organolithium reagents LiR to give (lithioamino)boranes acts in competition with the formation of aminoborates $Li[R_{4-n}B(NHR')_n]$ and/or B−N bond cleavage. This was demonstrated by us in 1980,[2] after the first successful lithiation of a cyclic aminoborane.[3] As expected, (lithioamino)boranes are useful reagents for the syntheses not only of other metallated aminoboranes[2,4,5−7] by transmetallation reactions, but also for syntheses of diborylamines[8−10] and BN heterocycles.[5,6,11] So far, only a few structures of (lithioamino)boranes have been determined: the ionic $[Li(OEt_2)_3][mes_2B{=}N{=}Bmes_2]$,[12] the dimeric $Li(OEt_2)_2$-$Nmes{-}Bmes_2$,[7] and the solvent-free trimeric (lithioamino)-9-borabicyclonane.[13] In the presence of chelating ligands, monomeric molecular (lithioamino)boranes, such as $t Bu_2B(t BuN)Li{\cdot}tmen$ or $(Me_3Sn)N{-}BC_8H_{14}Li{\cdot}$pmdeta (pmdeta = pentamethyldiethylenetriamine),[14,15] were obtained and their structures determined. In comparison with lithium organylamides[16,17] the tendency of the lithium (diorganylboryl)amides to associate through Li−N bridges did not seem to be significantly altered. Dimetallation of bis(*tert*-butylamino)organylboranes was reported by Meller et al.,[6] whilst it is only recently that a threefold lithiation of the borazine $(PhB{-}NH)_3$ was successfully achieved, resulting in the compound $(PhBNLi)_3{\cdot}(LiPh)_3{\cdot}(THF)_3$, characterized by X-ray diffraction analyses.[18]

N-Lithiation of triaminoboranes offers a unique chance to study the influence of electronic and steric effects. One might expect that the metallation of triaminoboranes of type $(R_2N)_2B{-}(NHR)$ would proceed more readily than that of R_2BNHR,[5] as the amino groups make the boron atom less prone to attack by a nucleophile, thereby promoting the deprotonation of the NH group. On the other hand, double and triple deprotonation of aminoboranes $B(NHR)_3$ would probably become more difficult as the number of deprotonation steps increased, because introduction of an increasing number of lithium atoms would be expected to result in highly associated molecular aggregates through Li−N coordination. For this reason we synthesized

[‡] Chemistry of Boron, 250. Part 249: Ref.[1]

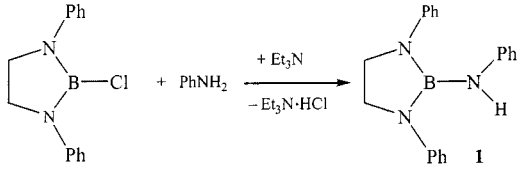
[a] Department of Chemistry, University of Munich, Butenandtstraße 5−13, 81377 München, Germany

a number of new triaminoboranes possessing NHR groups, studied their metallation with BuLi, and characterized their *N*-lithio derivatives.

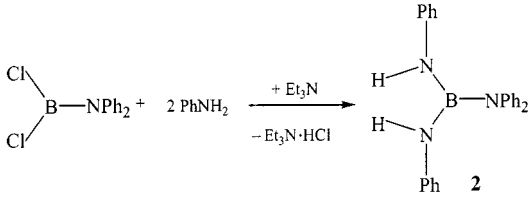
New Triaminoboranes

Synthesis

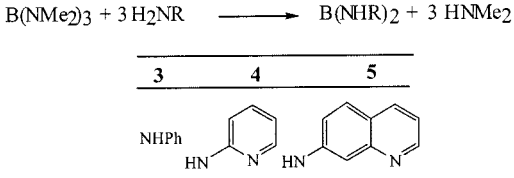
In order to study the competition between *N*-metallation, B−N bond cleavage, and borate formation, we first chose an aminoborane of type $(R_2N)_2BNHR$, with only one N−H bond. The molecule of choice was 2-anilino-1,3-diphenyl-1,3,2-diazaborolidine (**1**), obtained by treatment of 2-chloro-1,3-diphenyl-1,3,2-diazaborolidine with aniline in the presence of triethylamine as shown in Equation (1).



(1)



(2)



(3)

The preparation of dianilino(diphenylamino)borane (**2**) by aminolysis of $B(NMe_2)_3$ with diphenylamine (1:1 ratio), followed by aminolysis with aniline, was unsuccessful; we observed no reaction at reflux temperature between the tris(dimethylamino)borane and diphenylamine, although several successful syntheses of unsymmetrically substituted triaminoboranes by transamination reactions have been reported.[19,20] The low basicity of diphenylamine (pK_A = 0.9)[21,22] and steric effects may be responsible for the failure of this reaction, in spite of the fact that the resulting dimethylamine can readily be removed to drive the process towards the side of the transamination products. More surprising was the observation that $LiNPh_2$ did not react with $Cl-B(NMe_2)_2$ to produce $Ph_2N-B(NMe_2)_2$, either in THF or in toluene. However, dichloro(diphenylamino)borane reacted with aniline in the presence of triethylamine according to Equation (2) to give $Ph_2NB(NHPh)_2$ (**2**) in 71% yield.

Trianilinoborane (**3**) was readily obtained from aniline and $B(NMe_2)_2$,[19] whilst tris(2-pyridylamino)borane (**4**)[23] and tris(8-aminoquinolyl)borane (**5**) were prepared by the same procedure as shown in Equation (3).

Spectra

The NMR spectra (^1H, ^{11}B, ^{13}C, and ^{14}N) of compounds **1**−**5** were fully compatible with the suggested structures (e.g., chemically and magnetically equivalent anilino and amino heterocyclic groups). As was to be expected for triaminoboranes, the ^{11}B chemical shifts varied very little and were in the range typical of this class of compounds. The line widths, however, varied significantly. The sharpest signal was found for tris(2-pyridylamino)borane (**4**; $h_{1/2}$ = 220 Hz) and the broadest for the quinoline derivative **5** (450 Hz). Only a single broad ^{14}N resonance, at $\delta = -323$, was found for compound **2**, and one at $\delta = -292$ for compound **3**. On the other hand, the two types of N atoms in compounds **4** and **5** were readily recognizable. The resonances were at $\delta = -106$ and -79, respectively, for the heterocyclic N atoms, while those of the amino groups were observed at $\delta = -310$ and -327. This was consistent with ^{15}N NMR spectroscopic data of aminoboranes[24] and N-heterocycles.[25]

Interestingly, the ^1H resonances for the NH protons of the anilino groups were found as signals at $\delta = 4.65 \pm 0.14$, while those for **4** and **5** were observed at $\delta = 9.85$ and 8.15, respectively. We attribute this to intramolecular N−H···N interactions in the latter two compounds, and this was supported by the NH stretching vibrations found for these two aminoboranes at 3293 and 3340 cm^{-1}. In **1** to **3**, these vibrations were observed at higher wavenumbers (3384, 3387, and 3384 cm^{-1}). Obviously, the intramolecular N−H···N interaction was weaker in **5** than in **4**. This is consistent with the molecular structures of these compounds as determined by X-ray structure analysis.

Molecular Structures

The triaminoboranes **1**−**5** were characterized by X-ray structure analysis. Compound **1** crystallizes in the monoclinic system, space group *I*2/*a* and $Z = 8$. Figure 1 shows its molecular structure. The three B−N bonds are of equal lengths. Their common value (1.435 Å) corresponds very well with B−N bond lengths observed for other triaminoboranes.[26] All the N atoms and the B atom reside in planar environments, but because of the incorporation of the boron atom into a five-membered ring system a sharp N−B−N bond angle of 107.4(1)° results; this fits nicely for a five-membered ring system. Consequently, the other two N−B−N bond angles are wider than 120°. Typical for the structure of **1** is the propeller-like arrangement of the phenyl groups, with interplanar angles to the BN_3 plane of 31.6, 41.7, and 52.1°, the last being that made by the anilino group, which is more twisted than the other two phenyl groups. In the crystal there are neither intra- nor intermolecular N−H···N hydrogen bonds.

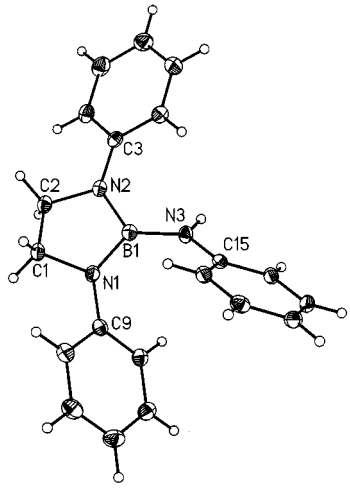


Figure 1. Molecular structure of **1** in ORTEP presentation; selected bond lengths and bond angles: B1−N1 1.436(2), B1−N2 1.437(2), B1−N3 1.433(2), N1−C9 1.409(2), N2−C3 1.402(2), N3−C15 1.400(2), N1−C1 1.473(2), N2−C2 1.471(2), C1−C2 1.523(2) Å; C1−N1−B1 109.0(1), C3−N2−B1 131.2(1), B1−N2−C2 108.9(1), C3−N2−C2 119.5(1), B1−N3−C15 127.5(1), N3−B1−N2 125.1(1), N1−B1−N2 107.4(1)°; torsion angle: N1−C1−C2−N2 −26.8°

Crystals of dianilino(diphenylamino)borane (**2**) are triclinic, space group $P\bar{1}$ with $Z = 2$. Figure 2 shows its molecular structure. In contrast to those in **1**, its B−N bond lengths differ significantly. The B−N bond of the diphenylamino group [1.470(3) Å] is longer than the B−N bonds to the anilino groups (average 1.425 Å). Since the angle between the BN_3 plane and the C1N1C2 unit of the diphenylamino group is at 26.6° only slightly larger than the interplanar angles to the anilino groups (24.5 and 23.5°), this longer B−N bond must be the result of the low basicity of the diphenylamine. Because of the steric requirement of the diphenylamino group, the phenyl groups of the anilino groups are pointing away from the Ph_2N substituent. This results in a *cisoidal* arrangement for the N−H units. The C−N−B bond angles of the anilino substituents are quite open (132.8° and 130.9°). This is not imposed by steric requirements of the diphenylamino group, as the same feature is also observed in compound **3**.

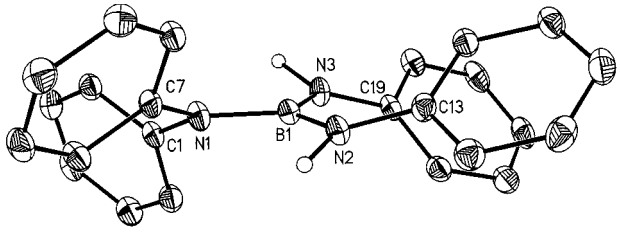

Figure 2. The molecular structure of **2** in the crystal; selected bond lengths and bond angles: B1−N1 1.470(3), B1−N2 1.422(3), B1−N3 1.427(3), N1−C1 1.330(3), N1−C7 1.423(3), N2−C13 1.415(3), N3−C19 1.414(3) Å; B1−N1−C1 120.7(2), B1−N1−C7 123.1(2), C1−N1−C7 116.2(2), B1−N2−C13 132.8(2), H2−N2−C13 113(1), H2−N2−B1 114(1), B1−N3−C19 130.9(2), H3−N3−C19 116(1), H3−N3−B1 113(1), N1−B1−N3 117.5(2), N2−B1−N3 125.9(2), N1−B1−N2 116.6(1)°

Trianilinoborane (**3**) crystallizes in the monoclinic system, space group $P2_1/c$, $Z = 4$. Its molecular structure is shown in Figure 3. Although one might expect that the three B−N bonds would be of equal lengths, one finds that this holds only for two of them (B1−N1 and B1−N2, average 1.430 Å), while the B1−N3 bond is slightly but significantly longer [1.442(2) Å]. As might be expected, the boron atom is sp^2-hybridized; the sum of its bond angles is 360°. As was also the case for the triaminoborane **2**, we observe B−N−C bond angles wider than the expected 120°. The three phenyl groups of **3** are arranged in a propeller-like fashion, and this has the effect that the N−H groups are *transoid* to each other. There are, however, no intermolecular N−H···N interactions.

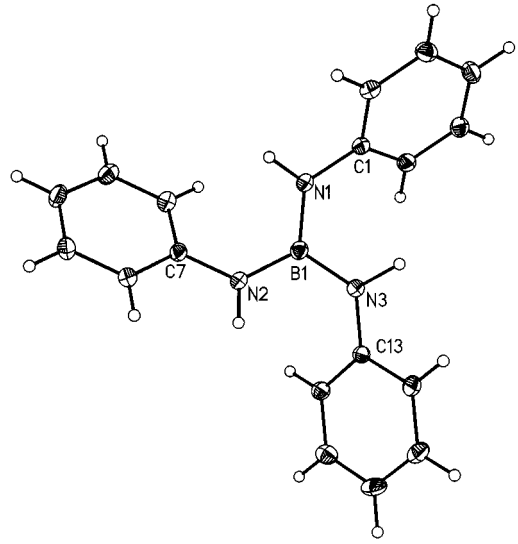

Figure 3. Structure representation of compound **3** in ORTEP description; selected bond lengths and bond angles: B1−N1 1.428(2), B1−N2 1.431(2), B1−N3 1.442(2), N1−C1 1.409(2), N2−C7 1.414(2), N3−C13 1.402(2) Å; N1−B1−N3 119.1(2), N2−B1−N3 119.5(2), N1−B1−N2 121.3(1), B1−N1−C1 127.8(1), B1−N2−C7 128.2(1), B1−N3−C13 129.0(1)°; angles between the planes of the phenyl groups: C1−C6/C7−C12 74.4, C1−C6/C13−C18 107.1, C7−C12/C13−C18 110.2°

The main difference between tris(2-pyridylamino)borane (**4**) and trianilinoborane (**3**) is that all atoms of the molecule of **4** lie in or close to a common plane (see Figure 4), the interplanar angles of the aminopyridine substituents to the BN_3 plane being less than 5.7°. All B−N bonds are of equal lengths (1.432 Å), and are typical of triaminoboranes.[26] Intramolecular N−H···N bridges are the most likely reason for the coplanarity of the molecule. On the other hand, the B−N−C bond angles lie between 130.5 and 132.0°. This certainly makes hydrogen bonds weaker, because a 120° B−N−C bond angle would allow a closer intramolecular N···N distance, which is actually 2.809 Å. The "hydrogen bond" bond angles range from 134 to 137°. This geometry therefore seems to be in better accord with a dipolar interaction N−H(δ+)···N(δ−). A similar structure has been observed for the hydrazinoborane $B(NH-NMe_2)_3$, which has a planar BN_6H_3 skeleton with the NC_2 group perpendicular

to the BN_6 plane. The N···N distance is 2.41(3) Å,[27] much shorter than in compound **4**.

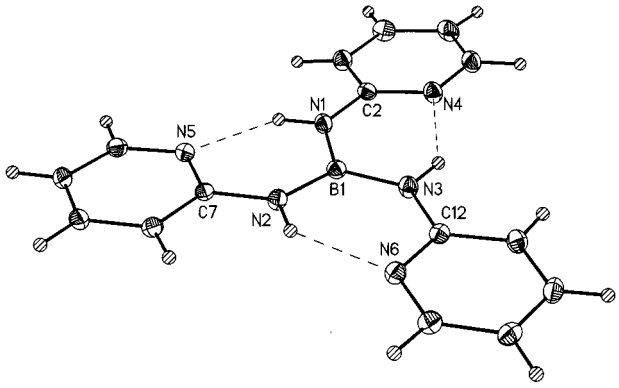

Figure 4. The molecular structure of **4** in the crystal; selected atom distances and bond angles: B1−N1 1.434(2), B1−N2 1.432(2), B1−N3 1.431(2), N1−C2 1.385(2), N2−C7 1.379(2), N3−C12 1.378(2), N5···H1 2.08, N4···H3 2.07, N6···H2 2.12 Å; B1−N1−C1 130.5(1), B1−N1−H1 114(1), B1−N2−C7 131.3(1), B1−N2−H2 115(1), H2−N2−C7 114(1), B1−N3−C12 132.0(1), B1−N3−H3 112(1), C12−N3−H3 116(1), N1−B1−N2 120.0(1), N1−B1−N3 119.9(1), N2−B1−N3 120.2(1)°

Tris(8-quinolylamino)borane (**5**) crystallizes in the triclinic system, space group $P\bar{1}$, $Z = 2$ (Figure 5). The molecular planes of the aminoquinoline substituents are not uniformly twisted relative to the BN_3 plane, but by 18.7° (N1), 33.9°(N3), and 24.4° (N5). Interactions between their N−H protons and the N atom of the heterocycle occur not between adjacent heterocycles as in compound **4**, but within its own heterocyclic system. The N···N distance is, at 2.720 Å, somewhat shorter than in **4**. As is to be expected for a five-membered "ring" (including a hydrogen bond), the angles at the bridging H atoms are sharp at ca. 100°.

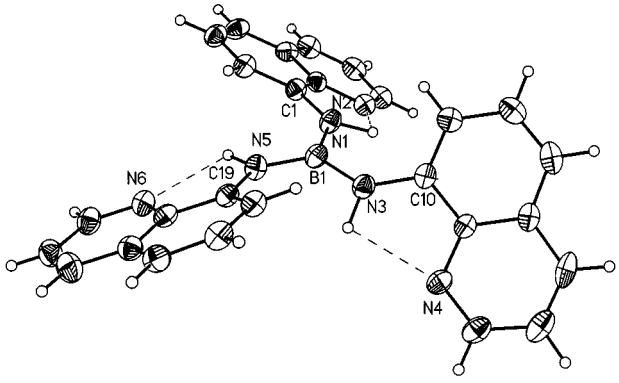

Figure 5. The molecular structure of **5** in the crystal; selected atom distances and bond angles: B1−N1 1.429(4), B1−N3 1.448(4), B1−N5 1.427(4), N1−C1 1.409(4), N3−C10 1.389(4), N5−C19 1.401(4), N2···H1−N 2.25, N4···H3−N 2.35, N6···H5−N 2.25 Å; B1−N1−C1 130.5(3), B1−N3−C10 131.2(3), B1−N5 C19 131.6(3), N1−B1−N3 119.3(3), N1−B1−N5 120.8(3), N3−B1−N5 119.6(3)°; torsion angle: C1−N1−C2−N2: −26.8

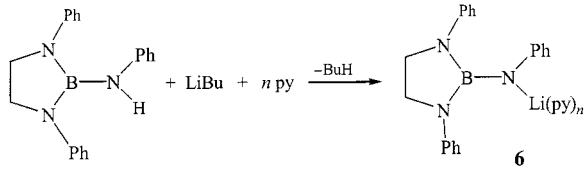
All B−N−C bond angles are wider than 130°, as found for all B(NHR) units in compounds **1**−**5**. However, it was surprising to find that one of the three B−N bonds of **5** is 0.02 Å longer than the other two. This indicates a somewhat weaker B−N bond with less π-bonding, and this longer bond is indeed associated with the substituent that shows the strongest twisting.

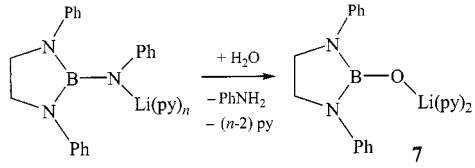
N-Lithiotriaminoboranes

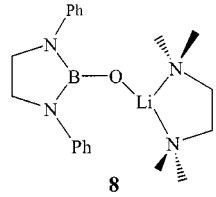
Synthesis

The triaminoboranes mentioned above were metallated with *n*-butyllithium under various conditions. In the case of **1**, the metallation proceeded smoothly, according to Equation (4). Monitoring of the deprotonation by ^{11}B NMR was not advisable, because the shielding of the boron nucleus did not change significantly (from $\delta^{11}B = 23.8$ to 23.0 in this case). On the other hand, the ^{11}B NMR spectrum ruled out both the formation of a borate and B−N bond cleavage. In the first of these two cases, a highfield shift should be observed, in the second case a shift to lower field should be expected.[28] Attempts to crystallize compound **6** from toluene failed. Crystals were obtained after addition of pyridine, but these proved to be the hydrolysis product **7** [see Equation (5)]. Tetramethylethylenediamine seemed to be a better ligand than pyridine for crystal formation. However, the "crystals" of **8** proved to be amorphous.[29]



(4)

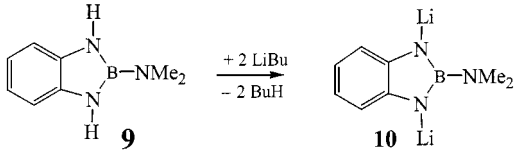




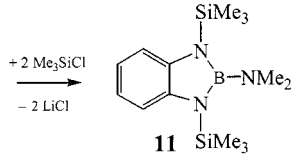
(5)

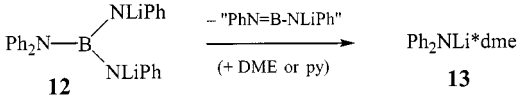
Double metallation of the benzodiazaborolidine **9** by 2 equiv. of LiBu at −78 °C occurred readily, only a single ^{11}B NMR signal being present after metallation ($\delta^{11}B = 29.3$). At −60 °C, however, a white solid separated from the gray-green suspension, and no ^{11}B NMR signals could any longer be observed in the solution. Obviously, the product **10** had become insoluble. For this reason it was impossible to grow single crystals, nor was it possible to obtain crystals from the solid dissolved in pyridine. On the other hand, the

elemental analysis of the precipitate was almost consistent with dimetallated **10** as far as the C/N ratio was concerned. In order to show that **10** had indeed been formed in the reaction described by Equation (6), the precipitate was treated with Me_3SiCl. As expected, the bis(trimethylsilyl) derivative **11** was obtained and characterized by NMR spectroscopy.

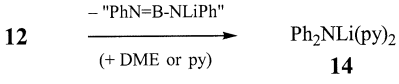


(6)





(7)



(8)

The lithiation of dianilino(diphenylamino)borane (**2**) by BuLi in the presence of dimethoxyethane (DME) produced a yellow orange solution, the ^{11}B NMR spectrum of which showed two signals at $\delta = 28.9$ and -10 in an intensity ratio of 85:15, provided that the spectrum was measured as rapidly as possible. We assigned the lowfield signal to the metallated product **12** and the highfield signal to a product containing tetracoordinated boron atoms. The orange solution turned brown within a few hours, with the formation of a white precipitate. No ^{11}B NMR signals could then be detected in the supernatant solution. Nevertheless, crystals separated slowly from the solution, and these were identified as $Ph_2NLi{\cdot}dme$ (**13**). Equation (7) describes a formal decomposition process for **12**.

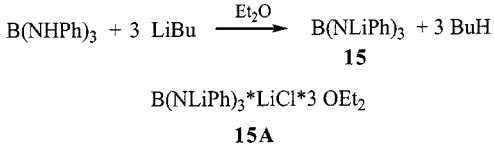
When pyridine was used to stabilize **12**, a clear yellow solution resulted. Its ^{11}B NMR spectrum, with signals at $\delta = -17.6$, -15.4, 0.2, 1.9, 3.0, and 43.2, demonstrated a much more complex reaction than that observed in the presence of DME. Obviously, aminoborates such as $Li[(PhLiN)_2B(NPh_2)Bu]$ or aminoborane–pyridine adducts such as $(PhHN)_2(Ph_2N)B{\cdot}py$ may form besides $BuB(NPh_2)(NLiPh)$. Crystals separated from the solution, and these proved to be $LiNPh_2{\cdot}(py)_2$ [**14**; see Equation (8)]. The lithium diphenylamides **13** and **14** were dimeric in the solid state (vide infra) but had different structures.

So far, the stoichiometry of the reaction has not been determined, as $LiNPh_2$ was almost certainly not the main product. We assume that B–N bond cleavage of **2** occurred, most probably at a stage after dimetallation of **2**.

It followed from the previous observations that multimetallation required a polar solvent, in order to prevent the rapid formation of insoluble products. The triple lithiation of $B(NHPh)_3$ was therefore studied in the presence of ether. The reaction, as in Equation (9), proceeded readily at low temperature. Two ^{11}B NMR signals were found at $\delta = 35.4$ and -3.5, the latter representing a minor component. The signal at $\delta = 35.4$ was assigned to compound **15**. However, the formation of a precipitate could not be prevented. The solid, on dissolution in THF, showed the same signals as the ether solution. Moreover, the ^1H NMR spectrum showed the absence of NH protons, a good indication of successful triple metallation. The minor component was, most probably, due to the formation of $LiBuB(NHPh)_3$ or $LiB(NHPh)_4$.[30] From the solution, compound **15** was isolated as $B(NLiPh)_3{\cdot}LiCl{\cdot}3OEt_2$ (**15A**) in 86% yield.[31]

The triple metallation of **4** was performed in THF as a solvent, as the solubility of the aminoborane in ether was rather low. The solution obtained after metallation showed a single but rather broad ^{11}B NMR signal at $\delta \approx 40$. This lowfield shift ($\delta = 15.8$) indicated a reaction according to Equation (10), since there was also a lowfield shift of $\delta = 11.2$ found for the triple lithiation of compound **4**. However, the product proved to be not **16**, but rather its adduct with LiNHR. Therefore, B–N cleavage as in Equation (11) must also have occurred, to produce $Li_4B(NR^*)_3(NHR^*)(THF)_3$ (**18**; R* = 2-pyridyl). Equations (10) to (13) summarize the results. The formation of borate **19** was indicated by an ^{11}B NMR signal at $\delta^{11}B = -9$.[5,28]

Although the composition of **18** might suggest the formation of a tetraaminoborate, this was not the case, as verified by the ^{11}B NMR spectrum and the determination of its molecular structure (vide infra).



(9)

(10)

(11)

(12)

(13)

R*NH = 2-pyridylamino group

In order to provide more insight into the metallation of **4**, reactions in a 1:1 and a 1:2 ratio were studied in addition to the 1:3 ratio. The observed ^{11}B NMR signals are summarized in Table 1. In all cases, two main products were formed. The signal at $\delta^{11}B = 23.3$ indicated that the environment about the tris(2-pyridylamino)borane was not greatly changed by the *N*-metallation. It may well be that the signals represented a mono- and a dilithiated **4**. On trimetallation, however, a noticeable deshielding indicated significant changes in triply metallated **4**. Since ^{11}B NMR signals at $\delta = -9.5$ were absent in the 1:1 and 1:2 reactions but one was observed in the 1:3 reaction, it appeared that this signal resulted from the anion $[Bu_3BNHR^*]^-$, as there was a sufficient supply of Bu^- anions under these conditions, and the observed chemical shift observed was similar to the value for $Na(Et_3BNH_2)$ ($\delta^{11}B = -9.8$).[28] The boron resonances at $\delta = -1.5$ and -3.3 (see Table 1) were consistent with the formation of $Li[BuB(NHR^*)_3]$ or/and $Li[BuB(NHR^*)_2(NLiR^*)]$.[28]

Table 1. ^{11}B NMR signals observed in reactions of tris(2-pyridylamino)borane with various ratios of BuLi; the resonances in italics represent the main species

Reagent ratio						Solvent
1:1	−3.3	−0.9	*−1.5*	1.4	*23.3*	THF
1:2	*−3.3*	*−0.9*	*1.2*	*1.4*	*23.5*	THF
1:3	*−9.5*			1.3	*39.6*	THF

	−24.6, *−28.6*					

[a] The only signal obtained on dissolving the precipitate in THF.

$$B(NHR^*)_3 + LiBu \longrightarrow \underset{\mathbf{20}}{(R^*NH)_2B(NLiR^*)} + BuH \quad (14)$$

$$(R^*HN)_2B(NLiR^*) + Me_3SnCl \xrightarrow[-LiCl]{} \underset{\mathbf{21}}{(R^*HN)_2B(NSnMe_3R^*)} \quad (15)$$

$$(R^*HN)B(NLiR^*)_2 + 2\,Me_3SnCl \xrightarrow[-\,2\,LiCl]{} \underset{\mathbf{22}}{(R^*HN)B(NSnMe_3R^*)_2} \quad (16)$$

To provide experimental evidence for the existence of monolithio compound **20**, stannylation by Me_3SnCl as in Equation (14) was attempted. The mono(trimethylstannyl) compound **21** was obtained, but could be characterized only by ^{119}Sn NMR spectroscopy.[32] However, the reaction of $R^*NH-B(NLiR^*)_2$ as shown in Equation (15) did not generate compound **22**. The solution showed ^{119}Sn and ^{11}B NMR signals, as observed in the stannylation of **20**, but there were additional signals in both NMR spectra. Amongst these were ^{119}Sn ($\delta = 9.2$) and ^{11}B resonances ($\delta = 30.2$) that we assigned to tris[2-pyridyl(trimethylstannyl)amino]borane (**23**), a compound that could be isolated and structurally characterized by X-ray crystallography. Obviously, the distannylated molecule **22** had exchanged Me_3Sn groups to give **23** and **21** as represented in Equation (17).

$$2\,(R^*NH)B(NSnMe_3R^*)_2 \longrightarrow \begin{matrix}(R^*NH)_2B(NSnMe_3R^* & \mathbf{21}\\ + & \\ B(NSnMe_3R^*)_3 & \mathbf{23}\end{matrix} \quad (17)$$

In contrast to the triple metallation of **4**, attempts to achieve the triple metallation of tris(8-quinolylamino)borane (**5**) in THF were futile. No single crystals separated from the violet-red solution, although a single broad ^{11}B NMR signal at $\delta = 32.9$ might have been indicative of the triple metallation. This assumption was supported by a single ^7Li resonance. However, the ^1H and ^{13}C NMR spectra were inconclusive.

Structures

The pyridine adduct of lithium 1,3-diphenyl-2-oxido-1,3,2-diazaborolidine (**7**) crystallizes in the triclinic space group $P\bar{1}$ with two independent dimeric molecules (Figure 6 depicts only one of the two molecules). Each molecule has a crystallographic center of inversion, generating four-membered planar Li_2O_2 rings. The Li−O bonds of the rings are significantly different, with bond lengths of 1.926(4) and 1.894(3) Å in molecule 1 and 1.912(4) and 1.966(3) Å in molecule 2. Moreover, the O−Li−O and Li−O−Li bond angles are different for the two molecules (97.8° and 82.2°, and 118.8° and 84.0°, respectively). Two pyridine molecules per Li ion complete the coordination shell around the Li centers, with N−Li−N bond angles of 96.0° (molecule 1) and 93.9° (molecule 2). Surprisingly, these angles are more acute than the O−Li−O bond angles, in spite of the fact

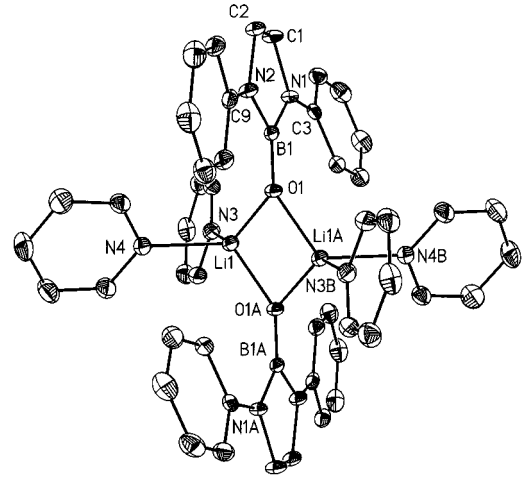

Figure 6. One of the two dimeric molecules of **7**; hydrogen atoms are omitted for clarity; selected bond lengths and bond angles: B1−O1 1.320(2), Li1−O1 1.926(4), Li1A−O1 1.894(3), B1−N2 1.467(3), B1−N1 1.478(3), N1−C3 1.391(3), N1−C1 1.466(2), C2−N2 1.455(2), N2−C9 1.386(3), Li1−N3 2.152(4), Li1−N4 2.128(4) Å; B1−O1−Li1 127.9(2), B1−O1−Li1A 146.4(2), Li1−O1−Li1A 82.2(2), O1−Li1−O1A 97.8(2), O1−Li1−N4 126.4(2), O1−Li1−N3 108.3(2),O1A−Li1−N3 117.1(2), N3−Li1−N4 95.0(2), O1−B1−O1A 128.0(2), O1−B1−N2 127.6(2), N1−B1−N2 104.4(2), C1−N1−C3 118.0(2), B1−N1−C3 129.9(2), B1−N1−C1 111.1(2), C2−N2−C9 118.5(2), B1−N2−C9 129.9(2), B1−N1−C2 111.4(2)°

that the N atoms are not part of a ring system. Consequently, the O−Li−N bond angles are more open, giving rise to Li ions with a rather distorted "tetrahedral" environment.

B−N bonds longer than those in compound **1** are found in **7**. The lengthening by ca. 0.04 Å is due to the negative charge at the oxygen atom. On the other hand, the B−O distance [1.320(3) Å] is shorter than those in $B(OMe)_3$, $(MeBO)_3$,[33] or $B_2(OMe)_4$,[34] and similar to the B−O distances of 1.317(6) Å found in $[thf{\cdot}LiOB(mes)_2]_2$ (mes = 2,4,6-trimethlphenyl)[35] and 1.345 Å in $[LiOB[CH(SiMe_3)_2]_2]_2$.[36] The B−O bond order in **7** is therefore higher than that in methylborates or trimethylboroxine, and this is also responsible for the longer B−N bonds.

The molecular structure of dimeric $Ph_2NLi{\cdot}dme$ (**13**) is shown in Figure 7. The centrosymmetric molecule has a four-membered, rhombic Li_2N_2 ring. Each Li ion is coordinated by two oxygen and two nitrogen atoms, with different Li−O and Li−N bond lengths, a sharp Li−N−Li bond angle (80(1)°], and a more open N−Li−N bond angle of 99(1)°.

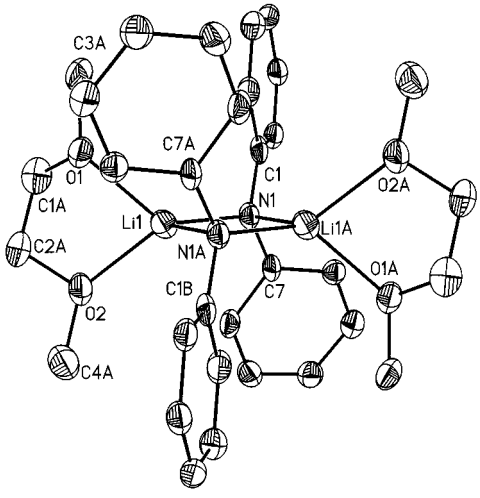

Figure 7. Molecular structure of the dimeric **13**; selected bond lengths and bond angles: Li1−N1 2.07(2), Li1A−N1 2.14(3), Li1−O1 2,07(2), Li1−O2 2.12(2), N1−C1 1.41(1), N1−C7 1.425(8) Å; Li1−N1−Li1A 80(1), N1−Li1−N1A 99(1), O1−Li1O2 79.7(7), O1−Li1−N1 125(1), Li1−N1−C7 124.2(5), C1−N1−C7 115.8(9)°

While the structure of **13** resembles the structures of dimeric $(smes)HNLi{\cdot}OEt_2$[37] [smes = 2,4,6-tris(*tert*-butyl)phenyl] or $(Me_3Si)[(Me_3Si)_3Si]NLi$[38] as far as the association through Li−N bonds is concerned, lithium amides with tetracoordinated Li centers are more common.[16] However, a much more interesting structure was found for dimeric $Ph_2NLi{\cdot}(py)_2$ (**14**), the molecular structure of which is shown in Figure 8. There are two kinds of Li ions. Li1 is surrounded by a plane of three nitrogen atoms in which the N1−Li1−N2 bond angle is quite open, at 139.8°. The longest Li−N bond is that formed with the pyridine nitrogen atom, followed by those with the nitrogen atom of the tetracoordinated Ph_2N group (2.042 Å), while the bond to the tricoordinated N2 atom is, as might be expected, even shorter (1.950 Å). While the Li1−N1−Li2 bond angle is almost tetrahedral, the C14−N1−C2 bond angle is more open, at 119.0(3)°. The tetracoordinated Li2 atom bears three pyridine molecules, with an average Li−N bond length of 2.111 Å. The phenyl rings at N2 form interplanar angles with the N_3Li plane of 17.6−0.7°, and the interplanar angle between $N2C_2$ and $Li1N_3$ at 95.6° shows an almost orthogonal orientation. This allows the pyridine ring N3 to adopt a staggered conformation not only with the phenyl groups at N2, but also with the plane around atom N1.

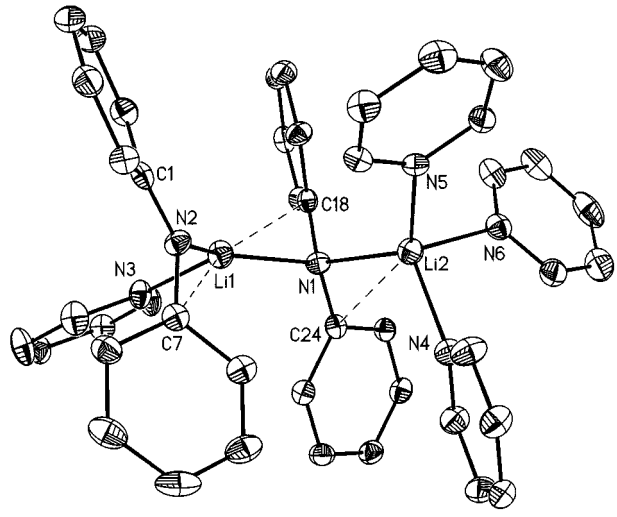

Figure 8. Molecular structure of dimeric **14**; selected bond lengths and bond angles: Li1−N1 2.042(6), Li1−N2 1.950(7), Li1−N3 2.054(7), Li2−N1 2.132(7), Li2−N4 2.137(7), Li2−N5 2.077(7), Li2−N6 2.119(6), C1−N2 1.368(4), C7−N2 1.393(4), C18−N1 1.405(4), C24−N1 1.410(4) Å; Li1−N1−Li2 108.1(3), Li1−N1−C18 95.3(3), Li1−N1−C24 121.0(3), Li2−N1−C18 111.7(3), Li2−N1−C24 101.8(2), C1−N2−C7 119.4(3), C1−N2−Li1 128.9(3), Li1−N2−C7 111.3(3), N1−Li1−N2 139.8(3), N1−Li1−N3 108.8(3), N2−Li1−N3 109.1(3), N5−Li2−N6 105.2(3), N1−Li2−N5 122.0(3), N1−Li2−N6 105.3(3), N4−Li2−N5 100.3(3), N4−Li2−N6 104.3(3), N1−Li2−N4 118.0(3)°

The triply lithiated trianilinoborane **15**, which crystallized as $B(NLiPh)_3{\cdot}LiCl{\cdot}3OEt_2$ (**15A**), once again proved to be dimeric in the solid state, its core structure containing eight Li atoms. Figure 9 shows the molecular structure. The dimeric molecule is centrosymmetric. Four Li atoms (Li1, Li1A, Li3, Li3A) are three-coordinated by one O, N, and Cl atom each, while the other four Li centers are tetracoordinated, atoms Li2 and Li2A by two N atoms, one O atom, and one Cl atom, and atoms Li4 and Li4A by three N atoms and one Cl atom. In order to describe the structure of **15A** it is best to start from the $B(NLiPh)_3$ unit. The core atoms of this molecule are shown in Figure 10.

The most important feature of compound **15A** is the planar BN_3 unit, which shows different B−N bond lengths of 1.429(9), 1.459(9), and 1.509(9) Å to atoms N1, N3, and N2, respectively. While B1−N1 is practically of the same length as in the parent compound **3**, the other two B−N

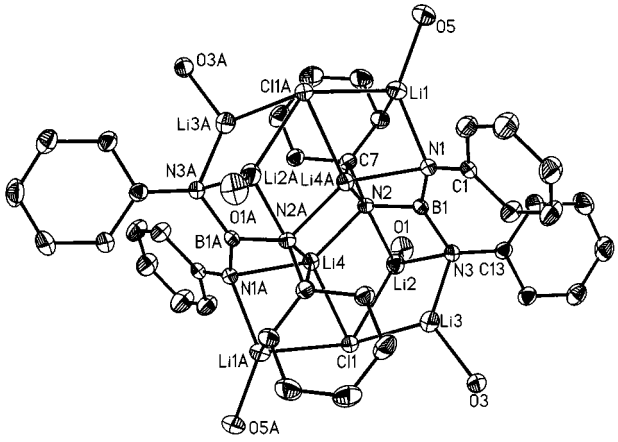

Figure 9. Molecular structure of compound dimeric **15A**; hydrogen atoms and C atoms of the ether molecules omitted for clarity

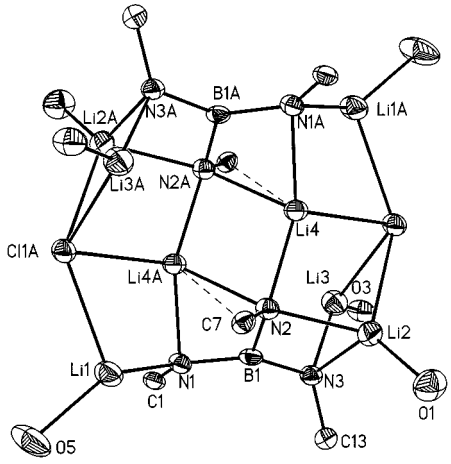

Figure 10. The core structure of $[B(NLiPh)_3{\cdot}LiCl{\cdot}3\ OEt_2]_2$ (**15A**)$_2$; only the *ipso*-C atoms of the phenyl rings are shown; the Et groups of the ether molecules have also been removed; selected bond lengths and bond angles: B1−N1 1.429(4), B1−N2 1.509(4), B1−N3 1.459(4), Li1 N1 2.021(6), N1−Li4A 2.029(5), Li3−N3 1.083(7), Li2−N3 1.983(7), Li4−N2 2.006(5), Li4A−N2 2.154(5), N1−C1 1.400(3), N2−C7 1.364(4), N3−C13 1.373(3). Cl1−Li2 2.564(5), Cl1−Li3 2.377(5), Cl1−Li4 2.362(5), Cl1A Li1 2.451(5), Li1−O1 1.901(6), Li2−O2 1.910(6), Li3−O3 1.925(6) Å; N1−B1−N3 132.9(3), N1−B1−N2 113.9(2), N3−B1−N2 112.1(2), Li1A−Cl1−Li3 121.1(2), Li1A−Cl1−Li2 130.2(2), Li4−Cl1−Li1A 64.7(2), Li4−Cl1−Li2 67.5(2), Li4−Cl1−Li3 88.7(2), Li2−Cl1−Li3 69.8(2)°

bonds are significantly elongated. Actually, the long B1−N2 bond corresponds to a single bond between sp^2-type B and N atoms. The reasons for these differences are the different N−B−N−C torsion angles and the number of coordinated Li atoms at the N atoms. Thus, the B1N1N2N3/B1N1C1 interplanar angle is 21.5°, which still allows for BN-π-bonding. While atom Li1 is part of the planar environment around atom N1 (sum of bond angles 357.8°), one may note that the atom Li4A has an N1−Li4A distance of 2.209(5) Å and lies 1.934 Å above the B1N1C1Li1 plane. However, the N1−Li1 distance is 2.961(6) Å, the same distance as found for N1−Li4A. The situation at atom N3 is similar to that at N1, but there is greater torsion, as demonstrated by the angle of 50.8° between the B1N1N3 and B1N3C13 planes. This has the consequence of weaker BN-π-bonding, as revealed by the longer B1−N3 bond. The distance from N3 to Li3 [1.983(7) Å] is shorter than that to Li2 [2.005(5) Å], but the B1N3C13Li3 atom system lies almost in a plane (B1 being −0.192 Å distant). Finally, the interplanar angle B1N1N2N3/B1N2C7 is 57.6°, and this seems to be a reason for the long B1−N2 bond to which the pentacoordinated atom N2 contributes. The coordination of Li2 and Li4A by two N atoms of the trianilidoborane unit is what most probably gives rise to an N1−B1−N3 bond angle as wide as 132.9(3)°.

As shown in Figure 10, the Cl anion is coordinated to the Li atoms of the $B(NLiPh)_3$ unit, with distances of 2.564, 2.377, and 2.362 Å to atoms Li2, Li3, and Li4, respectively. The presence of the chloride results in the formation of a distorted cubane unit in which one corner of the cube is missing. The Cl ion is surrounded by four Li ions. An unusually open coordination at Cl results, and this is best described as a strongly distorted trigonal bipyramid with a coordination partner missing in the equatorial plane. Atoms Li1, Li1A, Li3, and Li3A coordinate with three ligand atoms (O, N, Cl) in a nonplanar fashion.

The triply lithiated **4** crystallizes with one molecule of LiHNR* as $[Li_4B(NR^*)_3HNR^*(THF)_3]_2$ (**18**)$_2$. Its molecular structure is shown in Figure 11 and the monomeric unit is displayed in Figure 12. As may be noted, the metallation of compound **5** leaves the boron atom in a planar environment, the extra LiHNR* group not being bonded to atom B1 to generate a tetraamidoborate. One B−N bond of the $B(NLiR^*)_3$ unit is short, at 1.440(3) Å (B1−N1), while the other two are of almost equal lengths [1.476(3) for N2 and 1.467(3) Å for N3]. Thus, all B−N bonds are longer than those in the parent compound **4**. Each N atom of the BN_3 unit is coordinated to two Li atoms, but there is only one Li atom (Li3) that bridges two N atoms of the BN_3 unit. This gives rise to a small N1−B1−N3 bond angle of 111.8(2)°. The twisting of the CNB planes relative to the BN_3 plane is 24.4, 50.7, and 88.2° (at N1, N3, N2), respectively.

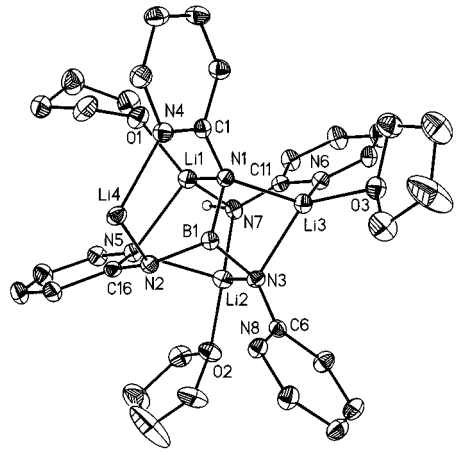

Figure 12. The asymmetric (monomeric) unit of **18**; bond lengths and bond angles: B1−N1 1.440(3), B1−N2 1.476(3), B1−N3 1.467(3), N1−C1 1.353(3), N2−C16 1.332(3), N3−C6 1.338(3), Li1−N1 2.114(5), Li3−N1 2.046(4), Li4−N2 2.065(4), Li2−N3 2.067(4) Å; N1−B1−N2 125.1(2), N1−B1 N3 111.8(2), N2−B1−N3 122.4(2), C1−N1−B1 123.9(2), C1−N1−Li3 138.3(2), C1−N1−Li1 106.8(2), B1−N2−C16 113.8(2), B1−N2−Li4 108.6(2), B1−N2−Li4A 104.7(2), Li4−N2−Li4A 78.4(2), Li4−N2−C16 117.7(2), Li4A−N2−C16 128.5(2), B1−N3−C6 122.9(2), B1−N3−Li2 96.5(2), B1−N3−Li3 87.6(2), C6−N3−Li2 123.3(2), C6−N3−Li3 125.4(2), Li2−N3−Li3 91.8(2)°

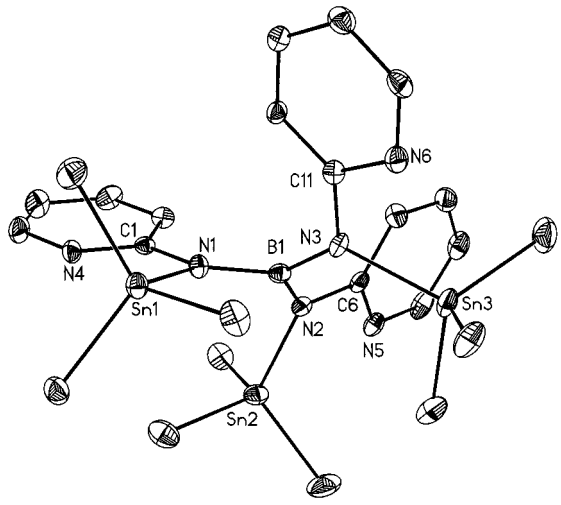

Figure 13. ORTEP plot of compound **23**; H atoms have been omitted for clarity; selected bond lengths and bond angles: B1−N1 1.443(7), B1−N2 1.435(6), B1−N3 1.457(6), N1−Sn1 2.109(4), N2−Sn2 2.119(4), N3−Sn3 2.110(3), Sn1···N4 2.717, Sn2···N5 2.703, Sn3···N6 2.672, N1−C1 1.396(5), N2−C6 1.383(6), N3−C11 1.385(5) Å; N1−B1−N2 121.2(4), N1−B1−N3 118.5(4), N2−B1−N3 120.3(4), B1−N1−C1 123.6(4), C1−N1−Sn1 108.2(3), B1−N1−Sn1 128.2(3), B1−N2−C6 123.7(4), C6−N2−Sn2 107.9(3), B1−N2−Sn2 128.4(3), B1−N3 C11 124.0(4), C11−N3−Sn3 107.8(3), B1−N3−Sn3 128.1(39, N1−Sn1−C16 104.6(2), N1−Sn1−C17 111.5(2), N1−Sn1−C18 113.0(2)°

The Li−N atom distances in $(\mathbf{18})_2$ span a range from 2.036(5) to 2.114(5) Å for the amino nitrogen atoms, and 2.038(4) to 2.155(4) Å for the pyridine nitrogen atoms, with the exception of the Li2−N5 distance of 2.286(4) Å. The reason for the long distance is most probably the specific situation at atom N5, since this atom in the only pyridine nitrogen atom that coordinates to two Li centers.

The (stannylamino)borane **23** crystallizes in the monoclinic system, its molecular structure being shown in Figure 13. The B−N bond lengths range from 1.435(6) to 1.457(6) Å. These are slightly longer than those in the parent compound **5**. All Sn−N bonds to the amino nitrogen atoms are of equal length. The pyridine nitrogen atoms are oriented towards the tin atoms of each Me_3SnNR^* unit. This may indicate the presence of Sn−N interactions. If there are any, then these must be quite weak, as the C−Sn−C bond angles deviate only slightly from the tetrahedral angle.

All amino nitrogen atoms reside in a planar environment, but the SnNC planes at N1, N2, and N3 are twisted relative to the BN_3 plane by 40.6, 38.1, and 46.1°, respectively. These torsion angles explain the lengths of the B−N bonds. The twisting results from the steric requirement of the trimethylstannyl groups and is the most striking difference on comparison of this structure with the parent compound **4**. As would be expected, the Sn−C bond lengths are in the typical range (2.12−2.15 Å).[39,40]

Discussion

The deprotonation of aminoboranes bearing RHN groups by butyllithium depends on the steric and electronic shielding of the boron atom, the structure of the aminoborane, and the solvent used. In almost all so far known cases, including the results presented here, there is competition between deprotonation and borate formation, as well as B−N bond cleavage. The last can be impeded if the boron atoms are part of a ring system, as shown for the triazaboradecalin system[3] or for borazines $(RB{=}NH)_3$.[18] However, an exocyclic B−N bond is comparatively easily cleaved, as demonstrated by compound **2**, while borate formation can be fully or at least partly suppressed by the use of *t*BuLi.[41] In the case of the double deprotonation of the aminoborane **2**, one observed the formation of a borate, most probably $Li[BuB(NPh_2)(NLiPh)_2]$, in solution besides $Ph_2NB(NLiPh)_2$. Both compounds might be the source of $LiNPh_2$, which was formed slowly. Isolated Ph_2NLi solvates form dimers, as is well known for various lithium diorganylamides. However, chain-like dimers of lithium diorganylamides are rare.[16,17]

Neither borate formation nor B−N bond cleavage was observed in the triple lithiation of trianilinoborane (**3**) in the presence of ether, unlike in the case of tris(2-pyridylamino)borane, in which B−N cleavage to give LiNHR* occurred. This amide cocrystallized with $B(NLiR^*)_3$ in a 1:1 ratio to give $(\mathbf{18})_2$, a cluster with an Li_8N_8 core. In addition, (2-aminopyridyl)butylborates were also formed. Nevertheless, deprotonation was the dominant reaction both for **3** and for **4**.

However, as we have seen for compound **18**, the metallated triaminoboranes did not add amide ions to form tetraaminoborates. These latter are scarce anyhow, and form readily only when the amido group is derived from a

heterocyclic system, such as the anions of pyrrole,[42] indole,[43] pyrazole,[44,45] or dihydropyridine.[46] In these cases, the parent triaminoborane is comparatively Lewis-acidic. This is obviously not the case for the tris(lithioamino)boranes; the negative charge at the nitrogen atoms reduces the Lewis acidity of the boron center. Therefore, an amide does not attack at the boron center, but rather forms coordinative Li−N bonds. The lithium atoms adopt coordination numbers ranging from 3 to 5. Therefore, in comparison with lithium amides,[16,17] the borylated lithium amides offer a much more versatile structural chemistry similar to that of lithiated silylamides[16] and aminophosphanes.[47] In addition, they are very useful reagents. This has been shown previously,[5−10,48] and we will report on this point in a forthcoming paper describing the synthesis and reactions of (*t*BuLiN)B(R)tmp (tmp = 2,2,6,6-tetramethylpiperidino) (see ref.[4]).

Experimental Section

General: All experiments required anhydrous conditions. Schlenk techniques were employed, with dinitrogen as a protecting gas. The amines are commercially available; the liquids were dried with either KOH or CaH_2 and distilled, and the solids were recrystallized before use. BuLi was obtained from Chemetall GmbH. NMR: Bruker ACP 200 (^{7}Li, ^{11}B, ^{119}Sn), JEOL GSX 270, and JEOL EX 400 (^{1}H, ^{13}C, ^{119}Sn) with Me_4Si, C_6D_6, $BF_3{\cdot}OEt_2$, and $SnMe_4$ as standards. Elemental analyses were performed in the microanalytical laboratory of this department. X-ray: Siemens P4 diffractometer equipped with a CCD area detector, graphite monochromator, and Mo-K_α source or a STOE IPS diffractometer (compounds **7** and **23**). Data sets were collected at −80 °C (Siemens LT2 device).

2-Anilino-1,3-diphenyl-1,3,2-diazaborolidine (1): Aniline (0.87 mL, 9.5 mmol) and triethylamine (1.32 mL) were added to a stirred solution of 2-chloro-1,3-diphenyl-1,3,2-diazaborolidine[48] (2.43 g, 9.50 mmol) in toluene (80 mL). A precipitate formed. The mixture was heated under reflux overnight, the solid was removed by filtration (glass frit), and the orange-yellow solution was concentrated to approximately 50 mL in vacuo. Needles of **1** separated from the solution. Yield: 2.7 g, 71%; m.p. 153 °C. NMR (in C_6D_6): δ^1H = 3.20 (s, 4 H, NCH_2), 4.49 (s br., 1 H, NH), 6.47 (d, $^3J_{H,H}$ = 7.3 Hz, 2 H, *o*-CH aniline), 6.66 (t, $^3J_{H,H}$ = 7.6 Hz, 1 H, *p*-CH aniline), 6.80 (t, ^3JH,H = 7.2 Hz, 2 H, *p*-H Ph), 6.90 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, *m*-CH aniline), 6.93 (d, $^3J_{H,H}$ = 7.6 Hz, 4 H, *o*-CH, Ph), 7.07 (t, $^3J_{H,H}$ = 8.8 Hz, 4 H, *m*-CH,Ph); δ^{13}C = 48.04 (CH_2), 119.5 (*o*-C, Ph), 119.6 (*o*-C, aniline), 120.2 (*p*-C, aniline), 120.9 (*p*-C, Ph), 128.8 (*m*-C, aniline), 129.0 (*m*-C, Ph), 143.1 (*i*-C, aniline), 146.6 (*i*-C, Ph); δ^{11}B = 23.0 ($h_{1/2}$ = 300 Hz). $C_{20}H_{20}BN_3$ (313.20): calcd. C 76.62, H 6.38, N 13.41; found C 76.31, H 6.67, N 13.31.

Dianilino(diphenylamino)borane (2): A solution of diphenylamine (4.23 g, 25.0 mmol) in toluene (150 mL) was cooled to −78 °C. A solution of BuLi in hexane (1.56 M, 16 mL) was added with stirring. A voluminous, white precipitate formed immediately, with some gas evolution. The suspension was allowed to attain ambient temperature. Stirring was continued for additional 3 h. After the mixture had again been cooled to −78 °C, a solution of BCl_3 in toluene (1.1 M, 22.7 mL, 25.0 mmol) was slowly added. Stirring was continued at ambient temperature overnight. The ^{11}B NMR spectrum taken after that time showed a signal at δ = 32.1 (**2**) and a tiny signal at δ = 41.1, corresponding to 2-butyl-1,3-diphenyl-1,3,2-diazaborolidine (ratio approximately 97:3). The solid was removed from the suspension by filtration. A mixture of aniline (4.6 mL, 50 mmol) and triethylamine (7.0 mL) was added at −78 °C to the slightly yellow filtrate. After the reaction mixture had been heated at reflux overnight and after removal of the solid, the filtrate was concentrated in volume to approximately 50 mL. Crystals separated from the solution within a few days. Crystallization from toluene yielded **2** (6.44 g, 71.0%), m.p. 185 °C. $C_{24}H_{22}BN_3$ (362.81): calcd. C 79.83, H 6.06, N 11.58; found C 78.09, H 6.21, N 11.08.

Trianilinoborane (3):[49] Aniline (5.5 mL, 60 mmol) was added to a solution of $B(NMe_2)_3$ (3.45 mL, 20 mmol) in toluene (70 mL). Gas evolution started, and became rapid on heating of the solution at reflux for 5 h. A single ^{11}B NMR signal at δ = 23.7 indicated a quantitative reaction. Crystals separated within a few hours. Half of the solvent was removed from the suspension in vacuo, and 6.6 g of **3** was isolated. Yield: 87%; m.p. 174 °C. NMR in C_6D_6: δ^1H = 4.83 (br. s, 3 H, NH), 6.75 (dd, $^3J_{H,H}$ =8.5, $^4J_{H,H}$ = 1.1 Hz,6 H, *o*-H), 6.80 (tt, $^3J_{H,H}$ = 7.6, $^4J_{H,H}$ = 1.2 Hz, 3 H, *p*-H), 7.06 (t, $^3J_{H,H}$ = 7.5 Hz, 6 H, *m*-H); δ^{13}C = 119.9, (*o*-C), 120.8 (*p*-C), 129.4 (*m*-C), 145.4 (*i*-C); δ^{11}B = 23.7 ($h_{1/2}$ = 214 Hz); δ^{14}N = −292.3.

Tris(2-pyridylamino)borane (4): 2-Aminopyridine (5.65 g, 59.4 mmol) and $B(NMe_2)_3$ (20.0 mmol) were heated under reflux in toluene (150 mL). Gas evolution (dimethylamine) rapidly started, and the amine was trapped at −78 °C. On cooling of the solution to ambient temperature, a white precipitate of **4** formed. After filtration, the filtrate was cooled to 0 °C. Colorless needles separated; these were suitable for X-ray structure determination. Yield: 5.2 g (90%), m.p. 121 °C. NMR in C_6D_6: δ^1H = 6.36 (ddd, $^3J_{H,H}$ = 8.5, $^3J_{H,H}$ = 5.4, $^4J_{H,H}$ = 0.8 Hz, 3 H, C5-H), 6.46 (dt, $^3J_{H,H}$ = 8.3, $^4J_{H,H}$ = 0.7 Hz, 3 H, C3-H), 6.99 (ddd, $^3J_{H,H}$ = 7.3, $^3J_{H,H}$ = 7.4, $^4J_{H,H}$ = 1.6 Hz, 3 H, C4r-H), 8.14 (ddm, $^3J_{H,H}$ = 5.3, $^4J_{H,H}$ = 1.8 Hz, 3 H, C6-H), 9.85(s, 3 H, NH); δ^{13}C = 113.6 (C3), 114.6 (C5), 137.4 (C4), 147.2 (C6), 159.6 (C2); δ^{11}B = 24.2 ($h_{1/2}$ = 218 Hz); δ^{14}N = −105.7 (pyN), −310.0 (NH). IR (Hostaflon, cm^{-1}): $\tilde{\nu}$ = 3293 (NH_2), 3090, 3059, 3043, 3022 (CH). $C_{16}H_{15}BN_5$ (290.13): calcd. C 57.14, H 5.71, N 26.62; found C 58.19, H 5.25, N 27.11.

Tris(8-quinolylamino)borane (5): Tris(dimethylamino)borane (1.8 mL, 19 mmol) was added to a suspension of 8-aminoquinoline (4.32 g, 30.0 mmol) in toluene (150 mL). The mixture was heated under reflux for 30 h. The red solution showed a broad ^{11}B NMR signal at δ = 24.7. After cooling of the solution to 0 °C, red needles separated within a few days. Yield: 3.75 g (85.3%), m.p. > 200 °C. NMR in C_6D_6: δ^1H = 6.74 (dd, $^3J_{H,H}$ = 3.7 Hz, 3 H, C3-H), 6.97 (d, br., $^3J_{H,H}$ = 7.8 Hz, 3 H, C5-H), 7.21 (dd, $^3J_{H,H}$ = 7.9, $^3J_{H,H}$ = 7.9 Hz, 3 H, C6-H), 7.54 (dd, $^3J_{H,H}$ = 8.4, $^4J_{H,H}$ = 1.8 Hz, 3 H, C4-H), 7.72 (d, $^3J_{H,H}$ = 7.5 Hz, 3 H, C7-H), 8.15 (s 3 H, NH), 8.48 (dd, $^3J_{H,H}$ = 4.0, $^4J_{H,H}$ = 1.5 Hz, 3 H, C2-H); δ^{13}C = 112.7 (C7), 116.6 (C5), 121.4 (C3), 129.2 (C10), 135.7(C9), 136.1, C6), 140.2 (C4), 143.4 (C8), 146.9(C2); δ^{11}B (in toluene) = 24.7 ($h_{1/2}$ = 450 Hz); δ^{14}N = −74.8 (ring N), −326.9 (NH). IR (Nujol, cm^{-1}): $\tilde{\nu}$ = 3340 (νNH). $C_{27}H_{21}BN_6$ (439.81): calcd. C 73.58, H 4.77, N 19.07; found C 73.33, H 482, N 18.61.

2-[Lithio(phenyl)amino]-1,3-diphenyl-1,3,2-diazaborolidine (6) and Formation of Lithium 2-Oxido-1,3-diphenyl-1,3,2-diazaborolidine (7): A solution of compound **1** (0.490 g, 1.56 mmol) in toluene (40 mL) was diluted with ether (10 mL), and the mixture was cooled to −78 °C. A solution of BuLi in hexane (1.0 mL, 1.56 mmol) was added by syringe, with stirring. The solution turned orange. At room temperature the solution showed only a single ^{11}B NMR sig-

nal at δ = 23.8 (**6**). The solid that was left on concentration of the solution also showed an ^{11}B NMR signal at δ = 23.8 in deuteriobenzene, which was assigned to **6**. Attempts to grow crystals from this solution failed. However, after addition of pyridine (3 mL) a few large crystals grew slowly at 0 °C over two weeks. These proved to be compound **7**, as also characterized by X-ray crystallography. **7:** NMR in C_6D_6: δ^1H = 3.47 (s, 4 H, NCH_2), 6.82 (d, $^3J_{H,H}$ = 8.5 Hz, 2 H, *p*-CH), 6.98 (t, $^3J_{H,H}$ = 7.6 Hz, 4 H, *o*-CH), 7.28 (t, $^3J_{H,H}$ = 7.8 Hz, 4 H, *m*-CH), 7.42 (t, $^3J_{H,H}$ = 8.6 Hz, 4 H, *p*-CH, py), 7.68 (t, $^3J_{H,H}$ = 7.6 Hz, 2 H, *p*-CH, py), 8.63 (d, $^3J_{H,H}$ = 4.5 Hz, 4 H, *o*-H, py); $\delta^{13}C$ = 43.0 (CH_2), 113.0 (*o*-C), 117.8 (*p*-C), 123.5 (*m*-C, py), 129.3 (*p*-C, py), 148.1 (ipso-C), 149.6 (*o*-C, py); $\delta^{11}B$ = 22.7 ($h_{1/2}$ = 350 Hz); δ^7Li = 1.59. $C_{24}H_{24}BLiN_4O$ (402.2): calcd. C 71.66, H 6.01, N 13.93; found C 68.37, H 6.35, N 12.07.

Double Metallation of 2-(Dimethylamino)-1,3,2-benzodiazaborolidine (9): The diazaborolidine **9**[50] (0.26 g, 1.6 mmol) was added to a solution of tetramethylethylenediamine (0.46 mL, 3.2 mmol) in tetrahydrofuran (80 mL). After this had been cooled to −78 °C, a hexane solution of BuLi (2.1 mL, 1.56 M) was added to the vigorously stirred solution. The color of the solution turned from yellow to gray-green. An ^{11}B NMR spectrum at −78 °C showed only one signal at δ = 29.3. On warming, a precipitate formed at about −60 °C, and no ^{11}B NMR signal was then observed in the supernatant solution at room temperature. When the solution was kept at −78 °C and the solvent was removed stepwise in vacuo, no crystals separated. The solid that was formed at −60 °C was dried in vacuo. Elemental analysis: C 48.12, H 5.88, N 17.92, corresponding to $C_8H_{11.6}N_{2.54}$ instead of $C_8H_{10}N_3(BLi_2)$ for **10**.

2-(Dimethylamino)-1,3-bis(trimethylsilyl)-1,3,2-benzodiazaborolidine (11): Me_3SiCl (0.34 mL) was added at −78 °C to **10** (1.35 mmol) in THF (80 mL). The stirred suspension was allowed to attain ambient temperature. All volatiles were removed from the gray-green solution in vacuo, and hexane (30 mL) was added to the oily residue. This resulted in a brown solution and a white insoluble product (LiCl). The solid was separated by filtration. From the filtrate all volatile material was removed. The liquid residue was dissolved in $CDCl_3$ and characterized as **11** by NMR spectroscopy. NMR: δ^1H = 0.55 (s, 18 H, SiMe), 2.67, (s, 6 H, NMe), 6.91 (m, 2 H, C3 H, C6-H), 7.25 (m, C4-H, C5-H); $\delta^{13}C$ = 1.9 SiMe, 41.4 (CMe=, 114.3, C3, C6), 118.9 (C4, C5), 142.0 (C1,C2); $\delta^{11}B$ = 32.0 (h_{12} = 227 Hz); $\delta^{27}Si$ = 4.7.

Double Metallation of Dianilino(diphenylamino)borane and Formation of $LiNPh_2$: Dimethoxyethane (0.41 g, 4.5 mmol) was added to compound **2** (1.63 g, 4.50 mmol) in toluene (80 mL). The solution was cooled to −78 °C. A hexane solution of LiBu (5.7 mL, 9.0 mmol) was added dropwise with stirring. After the yellow/orange solution had been allowed to attain ambient temperature, it showed two ^{11}B NMR signals at δ = 28.9 (**12**) and −10.0, in an intensity ration of 85:15. Solvent was removed in vacuo, to leave 10 mL of a solution. At 0 °C, colorless crystals separated within several days and proved to be $LiNPh_2$·dme (**13**). The supernatant liquid showed ^{11}B NMR signals at δ = −0.3 (weak), 30.8 (main signal), and 42.0

[a] $w^{-1} = \sigma^2F_o^2 + (xP)^2 + yP$; $P = (F_o^2 + 2F_c^2)/3$.

(weak, Bu_2BNPh_2). In a similar experiment, pyridine was added as an auxiliary base to the metallated solution of **2**. A yellow solution resulted. At 0 °C crystals separated, and proved on X-ray crystallography to be $LiNPh_2 \cdot 2$ py (**14**). The supernatant solution showed ^{11}B NMR signals at δ = −17.6, −16.4, 0.2, 1.9, 3.0, and 43.2. The last signal is most probably due to Bu_2BNPh_2 (compounds of type Bu_2B-NR_2 show resonances in the range of δ = 51−45).[18]

Triple Metallation of Trianilinoborane: Compound **3** (0.97 g, the compound contained chloride!) was dissolved in ether (80 mL) and cooled to −78 °C, and BuLi in hexane (1.56 M, 10.2 mmol, 6.5 mL) was added with stirring. After the solution had attained ambient temperature, a white precipitate appeared. The yellow solution showed an ^{11}B NMR signal at δ = 35.4 ($h_{1/2}$ = 640 Hz). Solvent was removed until 30 mL of a solution remained, from which crystals separated within a few hours at 0°. The crystals readily lost coordinated ether in vacuo; if drying was carried out carefully, however, the composition of the crystals was $B(NLiPh)_3 \cdot LiCl \cdot 3OEt_2$ (**15A**). The ^{11}B NMR spectrum of the solid, dissolved in THF, was the same as that of the solution. The NMR spectroscopic data were consistent with the formation of $B(NLiPh)_3 \cdot n OEt_2$. NMR in C_6D_6: δ^1H = 0.92 (t, $^3J_{H,H}$ = 7.0 Hz, 18 H, Me), 3.14 (q, $^3J_{H,H}$ = 6.9 Hz, 12 H, OCH_2), 6.85 (t, $^3J_{H,H}$ = 7.0 Hz, 3 H, *p*-H), 6.96 (d, $^3J_{H,H}$ = 7.5 Hz, 6 H, *o*-H), 7.23 (t, $^3J_{H,H}$ = 7.0 Hz), 6 H, *m*-H); $\delta^{13}C$ = 14.6 (Me), 64.9 (OCH_2), 117.7 (*p*-C), 125.8 (*o*-C), 128.8 (*m*-C), 160.0 (CNLi); $\delta^{11}B$ = 35.4 ($h_{1/2}$ = 640 Hz); δ^7Li = 1.24. $C_{30}H_{45}BClLi_4N_3O_3$(569.71): calcd. C 63.19, H 7.90, N 7.37; found C 62.09, H 7.78, N 7.89.

Triple Metallation of Tris(2-pyridylamino)borane and Formation of 18: Compound **4** (0.490 g, 1.69 mmol) was dissolved in THF (40 mL). The solution was cooled to −78 °C, stirred, and allowed to react with a hexane solution of BuLi (1.56 M, 3.3 mL). After the solution had attained ambient temperature, the slightly turbid, yellow solution showed ^{11}B NMR signals at δ = 1.3 and −9.5. Solvents were evaporated from the clear filtrate in vacuo to leave 30 mL of a solution, which was layered with hexane (20 mL) and kept at −20 °C. Within 1 d colorless crystals had separated. These rapidly became turbid on standing at ambient temperature, and did so more rapidly in vacuo; no elemental analysis was therefore performed. The identity of **18** was ascertained by X-ray structure determination. The same reaction was performed in ether instead of THF. In this case, more solid material separated. The solid, dissolved in THF, showed only a single ^{11}B NMR signal at δ = 35.0 ($h_{1/2}$ = 1330) corresponding to **18** was observed. The filtrate gave ^{11}B resonances at δ = 1.5, 0.6, −24.6, and −28.6.

Triple Metallation of Tris(8-quinolylamino)borane: In analogy to the lithiation of compound **4**, compound **5** (0.97 g, 2.2 mmol), dissolved in THF (90 mL), was metallated at −78 °C with BuLi in hexane (1.56 M, 4.2 mL). An intensively violet solution formed. At ambient temperature, one ^{11}B NMR signal at δ = 32.8 ($h_{1/2}$ = 1240 Hz) and a single ^7Li signal at δ = 2.46 were found. All attempts to induce crystallization by cooling or dissolving the residue (after removal of THF and hexane) in ether, toluene, ether/pyridine, or pyridine failed, only violet oils being observed. A solution of the oil in [D_8]THF revealed more ^1H NMR signals than expected.

Double Metallation of 4 and Formation of Tris(trimethylstannyl-2-pyridylamino)borane (23): A solution of **4** (0.40 g, 1.4 mmol) in THF (80 mL) was metallated at −78 °C with a hexane solution of LiBu (1.77 mL, 2.80 mmol). The solution at ambient temperature

[a] $w^{-1} = \sigma^2 F_o^2 + (xP)^2 + yP$; $P = (F_o^2 + 2F_c^2)/3$.

showed ^{11}B NMR signals at δ = 1.4, 1.2, −0.9, and −3.3, in addition to a dominant signal at δ = 23.5. While stirring, a solution of Me_3SnCl (0.28 g, 1.4 mmol) in THF was added. A ^{119}Sn NMR spectrum taken after 2 h showed signals at δ = 30.8, 26.2, and 9.2, the last signal resulting from **23**. The resonance at δ = 26.2 most probably corresponds to the monostannylation product **21**. Two signals were observed in the ^{11}B NMR spectrum, at δ = 30.9 and 22.9. THF was removed in vacuo. A waxy material was left behind, and was treated with toluene (20 mL). Crystals of **23** separated on cooling of the solution to −20 °C. Yield: 0.33 g (31%), m.p. 87 °C. NMR in C_6D_6: δ^1H = 0.39 (br., 27 H, Me), 6.18 [br., 3 H, C(5)H], 6.24 [m, 3 H, C(3)H], 7.84 [br., 3 H, C(6)H]; $\delta^{13}C$ = −0.87 (Me), 113.3 (C3), 137.3 (C4), 146.5 (C6); $\delta^{11}B$ = 30.9 ($h_{1/2}$ = 370 Hz); $\delta^{119}Sn$ = 9.2. $C_{24}H_{39}BN_6Sn_3$ (777.88): calcd. C 37.02, H 5.01, N 10.80; found C 37.16, H 5.16, B 10.62.

X-ray Structure Determinations: Crystals were covered with perfluoroether oil − those that readily lost coordinated solvent in precooled oil (approximately −40 °C). The selected crystal was placed on a glass fiber and mounted on the goniometer head. The reflections on five sets of frames were used for a preliminary determination of the unit cell, by use of the program implemented in SMART.[51] Data were collected in the hemisphere mode, and reduced with the SAINT program.[51] For absorption correction the SADABS[51] program was employed. The structures were solved by direct methods implemented in the SHELX97 program package.[52] Non-hydrogen atoms were refined in an isotropic description. Hydrogen atoms were placed in calculated positions and included in the final cycles of refinement by application of a riding model. One disordered ether molecule was found in the structure of compound **15A**, while compound **18** contains one uncoordinated THF molecule for each molecule of **18**. Tables 2 and 3 summarize data relevant to crystallography, data collection and refinement. CCDC-168322 to -168332 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Interaction of Uranyl Ions with Daunorubicin and Adriamycin

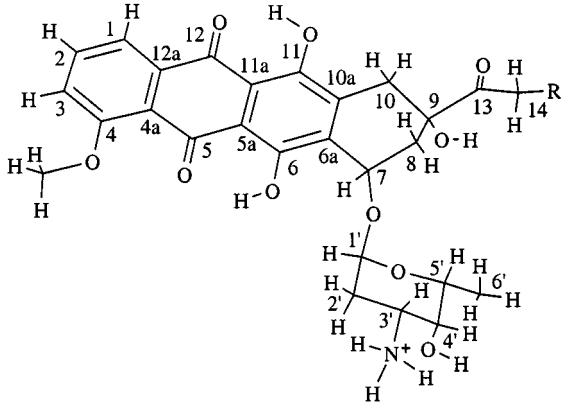
Athanasios Papakyriakou,[a] Angeliki Anagnostopoulou,[a] Arlette Garnier-Suillerot,[b] and Nikos Katsaros*[a]

Keywords: Antibiotics / Antitumor agents / Anthracyclines / O ligands / Uranium

The interaction of the uranyl(VI) ion (UO_2^{2+}) with two anthracyclines, adriamycin (Adr) and daunorubicin (Dnr), has been studied by absorption, circular dichroism, fluorescence and NMR spectroscopy. We have shown that both drugs can form two complexes with UO_2^{2+}, a process strongly dependent on the dielectric constant of the solvent, the metal-to-ligand ratio (R), and the pH. The first complex (**I**) involves coordination of the metal ion to the [C(11)–O$^-$, C(12)=O] chelating site, while the second complex (**II**) involves coordination to the [C(6)–O$^-$, C(5)=O] site. In aqueous solutions at pH 6.5, the formation of complex **I** takes place with two drug molecules per UO_2^{2+} ion. At higher pH or R values, complex **II** forms, and probably has a polymeric structure with one uranyl ion bridging two drug chromophores through both the keto-phenolate sites. In methanolic solutions the simultaneous formation of both complexes **I** and **II** is demonstrated by both CD and NMR spectroscopy. Dissociation of the complexes occurs upon interaction of the drug complexes with native DNA, with the free anthracyclines intercalating between the base pairs of the nucleotide.

Introduction

Adriamycin (Adr, or doxorubicin) and daunorubicin (Dnr, or daunomycin) are two representative members of the anthracycline antibiotic family. These antibiotics contain an anthraquinone chromophore and an amino glycoside sugar (Scheme 1).[1] Despite their severe cardiotoxicity and other side effects, they are both used clinically as chemotherapeutic agents, especially Adr, which exhibits a rather broad spectrum of activity.[2,3] Their antineoplastic activity has been attributed mainly to their strong interaction with DNA, either via an intercalation process of their chromophore into the base pairs of the minor groove, or via free-radical damage of the ribose through the redox cycle of the anthraquinone moiety.[4]



Scheme 1. Structures of daunorubicin (R = H) and adriamycin (R = OH) based on the crystal structure of Dnr[1]

Complexation of anthracyclines by metal ions has been suggested to provide less cardiotoxic compounds,[5,6] while their toxicity has also been related to the formation of reactive oxygen species generated by redox cycling of anthracycline metal complexes.[7,8] The uranyl ion has been used as a staining agent in electron microscopy,[9,10] mainly due to its high affinity for the phosphates of the DNA backbone.[11,12] In an effort to gain more information on the biological mechanisms of the action of anthracyclines we examined the interaction of UO_2^{2+} ion with both Adr and Dnr.

Results

The behavior of both daunorubicin (Dnr) and adriamycin (Adr) in the presence of uranyl (UO_2^{2+}) ions is almost identical. Therefore, we depict only the most characteristic results for either Dnr or Adr, indicating the potential differences for each case. We have also used the same symbols when referring to the corresponding complexes formed with the two drugs.

Formation of the Complexes in Aqueous Solution

Addition of uranyl nitrate to buffered solutions of the drugs at pH 6.5 resulted in a change of color from orange

to purple. Further addition of the metal ion gradually changed the color of the solutions to deep violet and then to blue, while a precipitate was formed. In order to characterize the species formed at this pH, titration of the drugs with increasing quantities of the metal was monitored by both absorption and CD spectroscopy. In the visible region of the absorption spectra, two new bands appeared at around 560 and 605 nm, while the main band of the free drug at 480 nm decreased in intensity. Two clear isosbestic points were observed at 408 and 529 nm (Figure 1) for solutions with a metal-to-ligand molar ratio (R) of up to 0.5. Upon further addition of metal, the two new bands were further shifted to 575 and 625 nm, and the isosbestic points were replaced by two other points at 426 and 572 nm, which were present up to R = 1.5 (Figure 2).

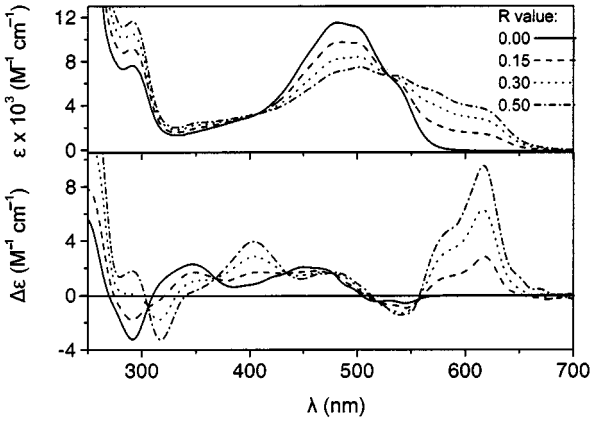

Figure 1. UV/Vis absorption (upper) and CD (lower) spectra of Adr and UO_2^{2+} in aqueous solutions at R < 0.5; [Adr] = 0.1 mM, Hepes buffer 0.01 M, pH = 6.5, NaCl = 0.01 M; the spectra were recorded 10 min after the addition of the metal ion at room temperature

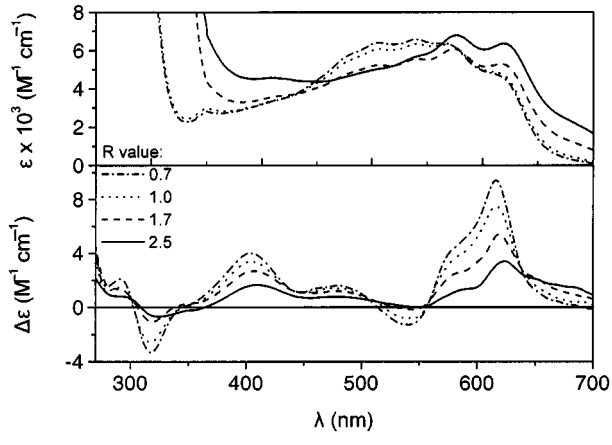

Figure 2. UV/Vis absorption (upper) and CD (lower) spectra of Adr and UO_2^{2+} in aqueous solutions at R > 0.5; [Adr] = 0.1 mM, Hepes buffer 0.01 M, pH = 6.5, NaCl = 0.01 M; the spectra were recorded 10 min after the addition of the metal ion at room temperature

The CD spectra of both drugs exhibited very characteristic changes upon addition of UO_2^{2+} at pH 6.5. The negative band at 290 nm decreased in intensity and moved to 317 nm. The positive band at 330 nm exhibited a red shift to 405 nm, and increased in intensity, while the 350 nm band also decreased in intensity and appeared as a shoulder at the same wavelength. In the visible region the band centered at 480 nm shifted by about 10 nm to higher wavelength, while the negative band at 540 nm increased in intensity (in the case of Adr, Δε increased in intensity almost threefold). Additionally, a band around 625 nm appeared with quite a high hyperchromic effect (Δε = 9.1 for Dnr at 626 nm and 9.5 for Adr at 618 nm) and a shoulder at about 585 nm. These changes occur with isodichroic points at 305, 368, 434, and 477 nm up to R = 0.5 (Figure 1). Further addition of UO_2^{2+} resulted in the hypochromicity of all the above bands, with isodichroic points at 343, 559, and 637 nm up to R = 1.5. At R > 2 a new band became visible at around 685 nm, while the bands at 350 and 317 nm gradually shifted by about 10 nm to higher wavelengths. At R = 3.0 the negative band at 535 nm had almost become positive (Figure 2).

In the solutions with R higher than two, a precipitate began to form after a couple of hours. This blue-violet precipitate was insoluble in either polar or nonpolar solvents. It readily dissolved in dilute HCl, accompanied by a color change to orange (probably due to dissociation to the free drug). Similar observations with such precipitates have been made previously with the Cu^{2+} [13] and Yb^{3+} [14] anthracycline complexes. In these cases, the authors suggested the formation of polymeric chain structure complexes, with the metal ion bound at both the keto-phenolate sites (C5/C6 and C11/C12) of two (or more) drug molecules.

The plots of ε and Δε versus R (molar ratio method, Figure 3) indicate the formation a 1:2 (metal:drug) complex at R ≈ 0.5 (**I**). This conclusion is supported mainly by the plot of ε at 575 nm, which is parallel to the *x*-axis up to R = 1.5. The plot at 625 nm exhibits a break point at R = 0.5 and continues to increase up to R = 1.5. The dependence of the CD bands upon the R value is also shown clearly in Figure 3b: the characteristics of the 1:2 complex fade out upon increasing R to above 0.5 (see Discussion). The 1:2 stoichiometry for complex **I** is also supported by the continuous variation method[15] (Job's method) applied to solutions with a total concentration of 50 μM. As shown in Figure 4a there is a clear maximum at a molar fraction of Dnr equal to 0.65 that corresponds to this stoichiometry.

The CD band at 625 nm has been used to monitor the pH dependence of the 1:2 species formed. As shown in Figure 4b, the complexation begins at pH > 4.5 and is completed at pH 6.5, a point above which the intensity of the band decreases. Furthermore, in solutions at pH higher than 7.5, a colored precipitate was formed. From this plot we can estimate that the pK_a for the complex formation is about 5.6, a value that is the same for both drugs.

The kinetics of the formation of the 1:2 species (complex **I**) is quite fast, whereas the intensity of the absorption band takes around 10 minutes to reach the maximum value. Both complexes are relatively stable, especially that of Dnr, which only dissociated by about 5% after four days at room temperature in the dark. Under the same conditions, the complex with Adr dissociated significantly more (about 35% as

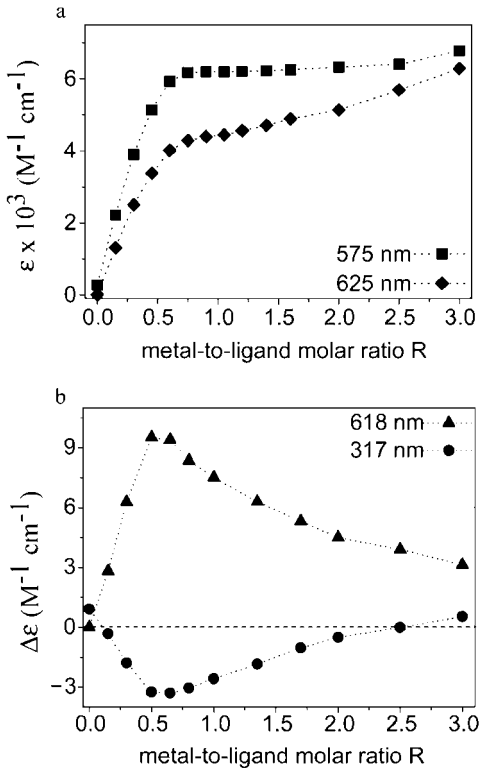

Figure 3. (a) Plots of ε at 625 and 575 nm and (b) Δε at 618 and 317 nm versus R (molar ratio method), of Adr titrated with UO_2^{2+}; experimental conditions as in Figure 1 and 2

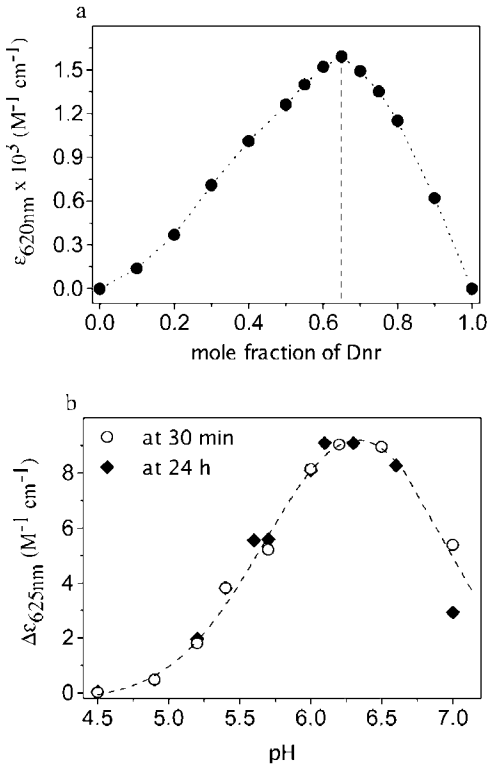

Figure 4. (a) Job's plot for Dnr 50 μM in Hepes buffer 0.01 M, NaCl 0.01 M, pH = 6.5 and (b) the pH dependence of the 1:2 UO_2^{2+}:Dnr complex monitored by the Δε at 625 nm; the pH of the solutions was measured just prior to the spectra acquisition, 30 min and 24 h after the addition of aliquots of NaOH (0.025 M) to solutions of Dnr 0.1 mM, with UO_2^{2+} 0.05 mM and NaCl 0.01 M; the dashed line is an empirical fit of the former data set

measured by the decrease in the intensities of the visible absorption bands).

The complexation with uranyl ions quenched the fluorescence of Dnr and Adr (Figure 5), as has been reported for most of the metal ions studied[16] (except the complex of Al^{3+} and Adr[17]).

From the decrease in the fluorescence intensity at λ_{max} = 555 nm (excitation at 480 nm) we have estimated the association constants K_s for the formation of the 1:1 species. Using Equation (1),[18] where F_o is the fluorescence intensity before the addition of the quencher, and F is the fluorescence intensity at concentration [Q] of uranyl ions, we obtained the linear plots shown in Figure 5. Their slope corresponds to the K_s values, calculated to be 25 mM^{-1} for Dnr and 14 mM^{-1} for Adr. At this anthracycline concentration (5μM) and up to an added [UO_2^{2+}] with R = 10, the linearity of these plots (> 0.997) indicates the formation of a species with a stoichiometry equal to 1:1.

$$F_o/F = 1 + K_s[Q] \quad (1)$$

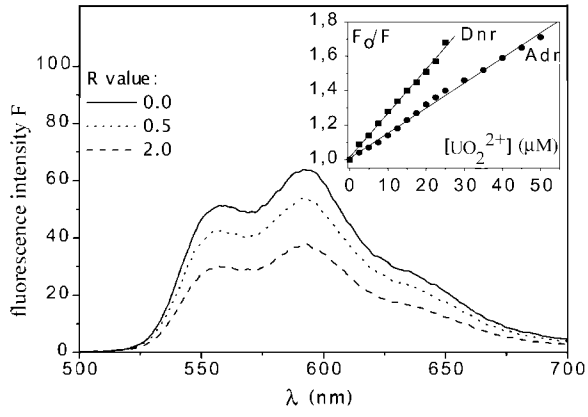

Figure 5. Uncorrected fluorescence spectra of Dnr and UO_2^{2+} at different R values recorded after 24 h (excitation wavelength at 480 nm); [Dnr] = 5 μM in Hepes buffer 0.01 M, pH = 6.5, NaCl 0.01 M; insert: plots of Fo/F at 555 nm versus the uranyl concentration added to solutions of the drugs made as above; the measurements were taken 1 min after the addition of the metal from a solution of [UO_2^{2+}] = 0.5 mM

Formation of the Complexes in 50% Methanolic Solutions

The complexation of UO_2^{2+} with Dnr and Adr was also studied in 50% (v/v) methanol/water solutions in order to examine the dependence of this process upon the aggregation state of the drugs. As has already been reported,[19] under such experimental conditions these compounds exist fully in the monomeric form, a fact that is reflected by the disappearance of the doublet centered at 480 nm in the CD spectra of the free anthracyclines, exhibiting only a positive band. The absorption spectral changes in the visible region of both drugs upon addition of uranyl (Figure 6) are very similar to those in pure water, with the main band at 480 nm decreasing in intensity and giving rise to the appearance of two new bands at 565 and 610 nm. These two

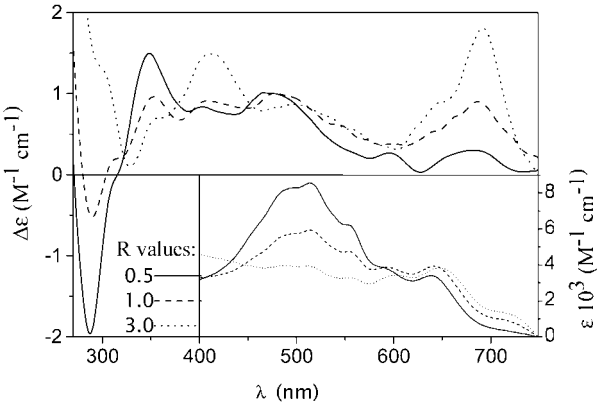

Figure 6. CD (upper) and visible absorption (lower) spectra of Adr and UO_2^{2+} in 50% MeOH solutions at different R values; [Adr] = 0.1 mM, Hepes buffer 0.01 M, pH = 6.5, NaCl 0.01 M

bands gradually shift by about 10 nm to lower energy when more metal is added (R > 2).

In contrast, the CD spectra exhibit much more informative changes following the addition of the metal ion. The negative peak at 290 nm readily decreased in intensity, and above R = 2 shifted to 330 nm. The positive band around 320 nm moved to 410 nm from an early stage of the titration (R ≈ 0.5) increasing in intensity, whereas the band at 350 nm gradually decreased in intensity and energy, shifting to 360 nm for R > 2. An intense red shift of the main band at 480 nm was also observed, yielding a broad band ranging from 600 to 700 nm. At low R values this band consists of a sharper band at 600 nm and a broader band centered at 660 nm, while at R > 2 the low energy band is formed at 675 nm and the high at 625 nm. At these high R values, a precipitate also formed with the same characteristics as those of the respective precipitates in pure aqueous media. There is no evidence for stacking of the drug molecules throughout the titration, at least as far as the spectra are concerned, which do not exhibit any negative band in the 530 nm region.

These changes indicate the formation of the same species as those in aqueous solutions, but with no clear step-points. Complex **I** (through the C11/C12 site) formation probably occurs along with complex **II** (through both the C11/C12 and C5/C6 sites), a possibility that is attested to by the appearance of a broad band at 600 to 700 nm from an early stage of the titration with the metal ion. Thus, the stoichiometry of both species could not be determined, since neither the molar ratio method nor the Jobs plot exhibited any clear break point. The intensity and the position of these CD bands can only support the conclusion that at low R values, complex **I** seems to be present in a higher concentration, while at higher R values (> 1) complex **II** begins to prevail, forming oligomers and polymers like those in pure water.

NMR Experiments in Methanol

Addition of UO_2^{2+} to aqueous solutions of Dnr and Adr in D_2O at pD > 5 resulted in an extensive line broadening of the acquired NMR spectra, therefore making the assignment of the peaks impossible. In order to examine the complexation process we performed NMR experiments in [D_4]methanol. Up to R = 10 one major complex was being formed (complex **I**), while increasing the R value above 20 resulted in the formation of another complex (complex **II**), which appears at lower fields. These two species are both present in the solution along with the free anthracycline, even at a hundredfold excess of UO_2^{2+} (Figure 7). The signals from the free anthracycline are still well resolved, suggesting that the drug is in slow exchange with its metal-bound form on the NMR time scale. The assignment has been successfully accomplished from the 800 MHz ^{1}H NMR spectra of the drugs at 10 mM concentration with UO_2^{2+} in excess (1 M). We have also performed 2D ^{1}H-^{13}C HMQC and HMBC experiments in order to assign the carbons of the anthracyclines and their complexes with UO_2^{2+}.

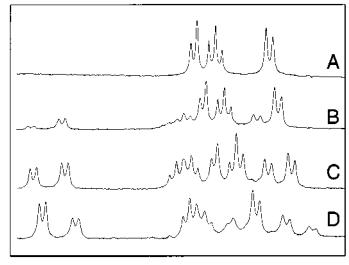

Figure 7. Expanded aromatic region of the 250 MHz ^{1}H NMR spectra of Dnr 10 mM titrated with UO_2^{2+} at R = 0 (A), 20 (B), 50 (C), and 100 (D)

Table 1 contains the ^{1}H NMR chemical shifts of free Dnr along with the chemical shifts of the two complexes formed and the uncomplexed Dnr present in the solution. From the peak intensities at R = 100 we can calculate the presence of the three species in the molar ratios of 2:3:5 (Dnr/complex **I**/complex **II**). The uncomplexed drug's protons present in these solutions exhibit a general upfield shift (0.1−0.2 ppm) upon addition of UO_2^{2+}. Complex **I** exhibits characteristic downfield shifts for H-1 (Δδ = 0.77 ppm) and for both H-10 protons (0.67 and 0.47 ppm for the equatorial and the axial proton, respectively). All other protons are also shifted downfield by 0.1−0.2 ppm. These observations indicate the complexation of Dnr to UO_2^{2+} through the [C(11)−O$^-$, C(12)=O] chelating site, given that the closest protons to C(11)−O$^-$ and C(12)=O are H-10 and H-1, respectively. Proton signals from complex **II** protons are shifted further downfield than those of complex **I** by 0.1−0.2 ppm, except H-1′, H-7, and 4-OCH$_3$, which exhibit rather large downfield shifts (0.84, 0.94, and 0.37 ppm, respectively, compared to free Dnr). These changes indicate the presence of a second UO_2^{2+} ion bound at the [C(6)−O$^-$, C(5)=O] donor site, since H-7, which shows the greatest downfield shift in complex **II** is the proton closest to C(6)−OH, while the 4-OCH$_3$ protons are less influenced by C(5)=O. As far as H-1′ is concerned, its rather large downfield shift in complex **II** reflects the change in the chemical environment around the sugar moiety upon

Table 1. ^{1}H chemical shift values (ppm) of Dnr and UO_2^{2+} in [D_4]methanol measured at 800 MHz and 25 °C; [Dnr] = 10 mM, [UO_2^{2+}] = 1 M; values in parenthesis are the calculated differences between the chemical shift values of the complexes and the respective uncomplexed drug present in the solutions; due to their signal overlapping, H-8 and H-2′ chemical shift values are given with lower accuracy

binding the second UO_2^{2+} ion. We have no indications for participation of the amino group in the complexation process, since no other proton of daunosamine exhibits any significant chemical shift upon addition of the metal ion.

From the 2D ^{13}C-^{1}H NMR experiments (Figure 8) we have managed to assign all the carbons of the free anthracyclines and most of the carbons of the complexes formed (Table 2). Both complexes exhibit remarkable changes in the ^{13}C chemical shifts of the keto-phenolate sites (3−15 ppm upfield shifts), especially those of C(6) and C(11) due to delocalization of the negative charge of the phenolic oxygen atoms upon complexation. This effect was expected to be more striking for C(5a) and C(11a), but this was not the case. None of the other ^{13}C chemical shifts exhibit significant changes (< 2 ppm). Unlike the ^{1}H chemical shifts, the carbons of both keto-phenolate sites in complexes **I** and **II** are similarly influenced by the presence of the metal ion, probably due to ring-current effects.

In the UV/Vis and CD spectra of this system (R = 100) two new bands appear in the absorption spectra at 575 and 620 nm, while the CD spectra is characterized by a red shift of the main band from 480 nm to 610 and 650 nm. It is quite evident from the bands exhibited that the species formed in methanol must be the same as in semi-aqueous MeOH solutions, despite the fact that in the first case the formation constants of the complexes are quite low and a higher excess of UO_2^{2+} is required for the respective changes to take place.

Interaction of the Complexes with DNA

Two different sets of experiments were carried out with native DNA in aqueous solutions. In the first set, a uranyl ion solution was added to a mixture of anthracyclines-DNA in solution at different r values (r = drug-to-nucleotide molar ratio). At r < 0.1, where total binding of the drugs

has been reported,[20] the addition of uranyl to solutions containing the DNA-bound drugs did not cause any changes in the CD spectra, even when a tenfold excess of UO_2^{2+} was added. On the other hand, addition of uranyl to the DNA-bound Dnr and Adr at $r > 0.3$ resulted in almost the same CD spectral features as in the case of complex **I**, probably because of the complexation of uranyl with the free anthracycline molecules. This observation is in agreement with the data reported for the Cu^{II}-Dnr system at $r > 0.1$.[21]

In the second set of experiments a mixture of drug-UO_2^{2+} solution was added to DNA solutions at several r values. In this case the 1:2 complex **I** was formed with both Dnr and Adr. In the presence of DNA, the complexes dissociated in a time-dependent procedure as free Dnr and Adr intercalated between the nucleotide base pairs. This is evident from the CD spectra of a typical experiment at $r = 0.1$ (Figure 9) where the band at 625 nm, associated with the complex decreases in intensity with time, while the negative band at 320 nm red shifts by approximately 10 nm. The characteristic spectra of the intercalated anthracyclines were obtained after 24 h, with bands at around 310, 380, and 500 nm.[22] The half-life of this process was estimated from the plot of $\Delta\varepsilon$ at 626 nm versus time to be 15 min, while for the Fe^{III}-Dnr system it was reported to be 18 h.[23] In the case of Adr, when concentrations above 0.1 mM were used, precipitation occurred, with the precipitate probably containing DNA and the metal-Adr complex, as it indicated by the color of the precipitate, which is the same as the deep-violet solution's color when R is greater than 2 or the pH is greater than 7. This observation is in accordance with the results already reported for Adr complexes with other metal ions.[24]

We have also measured the melting temperature (*T*m) of calf thymus DNA in the presence of both anthracyclines and their 1:2 UO_2^{2+} complexes. The values measured were dependent on r, and were in agreement with those already reported for the Dnr-DNA system,[20] taking into account the variations of the ionic strength. The Tm values in the presence of the complexes were only about 1 °C lower than the respective values for the free drug. Additionally, when the absorbance at 620 nm was monitored while increasing the temperature from 25 to 95 °C for solutions of the complexes in the absence of the DNA, we observed that at 55 °C the complexes had dissociated by about 50%. It is known that UO_2^{2+} solutions are only stable at low pH and that polynuclear complexes and uranyl hydroxide precipitates are formed at higher pH.[25] Thus, under our experimental conditions the released metal ions were bound to hydrolyse. It is not impossible, however, that some may bind to the phosphates, since it has been shown that their affinity for nucleotides is high and it has been proposed that UO_2^{2+} may bind by bridging phosphate groups on opposite strands of the minor groove of DNA.[12]

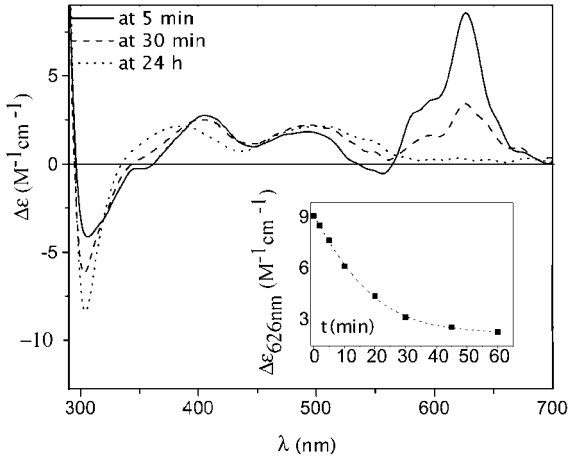

Figure 9. CD spectra of (UO_2^{2+}-Dnr_2)-DNA system as a function of time; [UO_2^{2+}-Dnr] = 50 μM, [DNA] = 0.5 mM, Hepes buffer 0.01 M, pH = 6.5, NaCl 0.01 M; insert: plot of $\Delta\varepsilon$ at 626 nm versus time elapsed after the addition of the nucleotide to the complex solution

Discussion

Our experience during the course of these studies with metal ion complexes of anthracyclines has shown the complexity of these systems.[26] Many conflicting reports have been published over the past 30 years, concerning either the stoichiometry of the complexes formed in solutions or their physicochemical characteristics. The formation of more than one species is evident for most of the metal ions examined, the predominance of which depends on the metal-to-ligand molar ratio, the pH, and the dielectric constant of the solvent. However, spectroscopic analysis, especially the CD spectra, can provide many detailed characteristics of the complexes formed,[27] while NMR spectroscopy has also proved to be a powerful tool for the study of these systems.[14,28]

In pure water and under our experimental conditions most anthracyclines exist in the fully protonated and dimeric state.[19,29] The formation of a major species with a stoichiometry of 1:2 (metal-to-drug) up to R = 0.5 is confirmed by both the clear isosbestic points in the absorption and CD spectra (Figure 1), as well as by the molar ratio and Job's method (Figure 3 and 4). The bathochromic shifts of the visible absorption and CD spectra bands show that complexation takes place to the drug's chromophore after deprotonation of either the C(11) or C(6) phenolic groups, in order of acidity.[19] The position of the absorption bands at 560−600 nm can account for the deprotonation of the first phenolic group[27] and coordination to UO_2^{2+} through the oxygens of the [C(11)−O^-, C(12)=O] donor site, forming a six-member chelate ring. In contrast, the red shift of the UV band from 290 to 320 nm in the CD spectra is characteristic of the deprotonation of the second phenolic group at C(6).[27]

A more detailed examination of these spectra reveal that this is not the case, however, since neither the red shift for the band at 350 nm nor the bathochromic shift of the main visible band from 450 to about 620 nm can account for this

deprotonation. Additionally, the intensity of the band at 317 nm is exactly the same as the original band at 290 nm, while C(6)−OH deprotonation is followed by a decrease in the intensity of this band.[27] Such a decrease in the energy of the $\pi\rightarrow\pi^*$ transitions along the sort axis of the chromophore has previously been observed in the case of Sn^{IV} with Adr.[30] The authors saw no evidence for participation of the phenolic groups, despite the fact that a shift of the band at 290 nm to higher wavelengths accompanied the complexation of Adr to Sn^{IV}. For this reason, it has been suggested that this occurs due to the aggregation of the drug molecules as in the case of Adr gels, for which the proposed structure is a supramolecular aggregate with Adr molecules stacked helically.[31,32] Additionally, when anthracyclines intercalate between the base pairs of DNA this band shifts to 305 nm. This observation can be attributed to a modification of the angle between the sugar moiety and the dihydroanthraquinone part, along with the influence of the hydrogen bonds between the C=O groups and their neighbors. This was confirmed by the crystal structure of Dnr complexed to d(CGTACG), in which the torsion angle around the O(7)−C(1′) bond was found to be 20° different from that of the free drug.[34] In our case the formation of the 1:2 species upon binding of UO_2^{2+} to Dnr and Adr at the [C(11)−O^-, C(12)=O] site probably promotes such a modification.

Upon increasing the metal-to-ligand ratio, the characteristic bands mentioned above decrease in intensity (Figure 2) and at $R > 2$ the appearance of a rather low-energy band at around 685 nm (shoulder), along with the continuous red shift of the band at 350 nm towards 360 nm, indicate further deprotonation of Dnr and Adr at C(6)−OH. As soon as UO_2^{2+} ions bind additionally at the [C(6)−O^-, C(5)=O] site, a precipitate was gradually formed from the blue solutions of the drugs. After 24 h Dnr and Adr have probably formed a polymeric complex, with UO_2^{2+} ions chelating two drug molecules through both the keto-phenolate sites of their chromophore. This has already been reported in the case of Cu^{2+} ions binding to Dnr and Adr,[13] and later in the case of Yb^{3+} binding to Adr,[14] both at high pH. Such a precipitation can occur with UO_2^{2+} at lower R values (< 2) when increasing the pH above 7, indicating that this process is strongly dependent on both the metal-to-ligand ratio and the proton concentration.

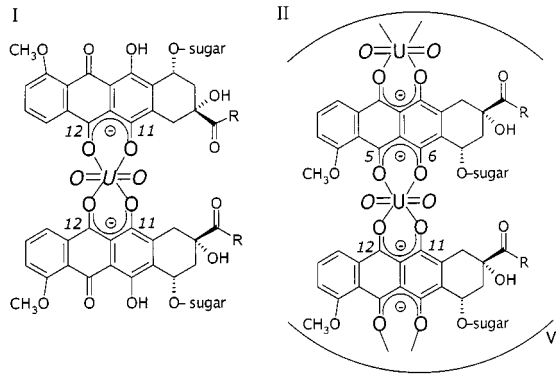
Decreasing the dielectric constant of water by adding 50% MeOH, at $R = 0.5$ at the same pH and ionic strength, resulted in significantly different CD features. First, no stacking interactions occur, as indicated by the absence of the negative band at 530 nm, while the UV band at 290 nm did not shift to higher wavelengths, but rather decreased in intensity. Although the absorption spectra exhibit the same characteristic bands at 565 and 610 nm as in the case of pure water, the CD spectra reveal the appearance of a band centered at 660 nm, which at $R = 3.0$ increased in intensity with a maximum at 675 nm (Figure 5). At this point, the band at 290 nm has red shifted to about 330 nm and the bands at 320 nm and 350 nm have shifted bathochromically to 410 nm and 360 nm, respectively. Therefore, the deprotonation of both the phenolic groups at C(11) and C(6) is demonstrated, a process that probably does not occur step-by-step, as is indicated by the appearance of a low energy band at around 660 nm even at low R values.

The parallel formation of more than one species is also supported by the NMR experiments in pure methanol. Up to $R = 10$ the formation of complex **I** took place with UO_2^{2+} binding to Dnr and Adr through the [C(11)−O^-, C(12)=O] chelating site, while at higher R ratios, complex **II** was also formed with participation of the [C(6)−O^-, C(5)=O] coordination site. The presence of both species is evident even under a very large excess of the metal ion, although complex **II** predominates at $R > 50$ (Figure 6). The participation of the amino group, as in the case of the Adr complexes of Pd^{II}, Pt^{II},[15,28] and Sn^{IV},[30] is excluded by the ^1H NMR chemical shifts of the daunosamine protons, which do not exhibit any significant change upon complexation to UO_2^{2+}, except the equatorial proton H-1′ in complex **II** (Table 1). This should also be true for the semi-aqueous MeOH solutions at $pH = 6.5$, where a gradual change of the CD spectra from the fully protonated to the fully deprotonated Dnr and Adr takes place as more UO_2^{2+} is added. No clear step-points were observed for this process, and as soon as both complexes (**I** and **II**) are present simultaneously in the solutions, the determination of their stoichiometry is very inaccurate.

Upon interaction of UO_2^{2+} with Dnr and Adr 1:2 complexes with calf thymus DNA ($r < 0.1$) at $pH = 6.5$, the complexes appeared to dissociate, with the free anthracyclines intercalating between the base pairs. This process is confirmed by the time-dependent change of their CD spectra (Figure 8) to the characteristic pattern of the intercalated drug. Additionally, no remarkable changes have been observed at the Tm values of the calf thymus DNA bound to the anthracyclines in the presence and absence of uranyl ions. This is probably due to the higher affinity of the drugs for DNA and that of uranyl ion for the phosphate groups of the DNA backbone.[12]

Conclusions

Uranyl ions form two complexes with Dnr and Adr, depending on the metal-to-ligand ratio, the pH, and the solvent. Complex **I** involves binding of UO_2^{2+} to the oxygen atoms of the drugs [C(11)−O^-, C(12)=O] donor site, while in complex **II** coordination also occurs through the [C(6)−O^-, C(5)=O] site. In aqueous solutions up to $R = 0.5$ and $pH = 6.5$ complex **I** is formed with the stoichiometry of 1:2 (metal-to-ligand), while at R above 0.5 or $pH > 7$ complex **II** formation takes place with drug molecules bridging two metal ions and forming oligomeric or polymeric structures (Scheme 2). In methanol these two complexes are formed at higher R values (> 10) and are both present in the solution as was shown by the NMR experiments.



Scheme 2. The proposed structures of the complexes formed upon interaction of UO_2^{2+} ions with Dnr [R = $CH(OH)CH_3$] and Adr [R = $CH(OH)CH_2OH$]; for both drugs, *sugar* = daunosamine

Experimental Section

Daunorubicin and adriamycin hydrochloride 99% were a gift from Pharmacia & Upjohn, Greece. Uranyl nitrate hexahydrate [$UO_2(NO_3)_2{\cdot}6H_2O$] (99%) was purchased from Merck, Hepes buffer 99.5% from Aldrich, while [D_4]methanol (99.9%) and calf thymus DNA were purchased from Sigma and used without further purification. Deionized and doubly-distilled water was used throughout the experiments.

Anthracycline solutions were prepared just prior to use and their concentrations determined by their absorption at 480 nm using ε = 11500 $M^{-1}cm^{-1}$.[25] Uranyl stock solutions were prepared in slightly acidified water to avoid hydrolysis. DNA stock solutions were prepared as described previously[34] and kept at 4 °C for no longer than a week. After dilution to the buffer, the nucleotide concentrations were determined by their absorption at 260 nm using ε = 6600 $M^{-1}cm^{-1}$ (expressed as phosphate).

Absorption spectra were recorded on a JASCO V-560 spectrophotometer. Circular dichroism (CD) measurements were made on a JASCO V-715 dichrograph. All spectra were recorded using a 1.0 cm cell and the following acquisition parameters: λ = 250−750 nm, step 0.5 nm, speed 200 nm min^{-1}, response 1.0 s, bandwidth 1.0 nm, accumulations 4−10. Methanol and aqueous buffer blanks were used as references, depending on the experimental conditions, while the temperature was kept constant at 25 °C. Results are expressed as ε (molar absorption coefficient) and $\Delta\varepsilon = \varepsilon_L - \varepsilon_R$ (differential molar absorption coefficient). Both ε and $\Delta\varepsilon$ values are expressed as molar concentration of anthracyclines.

All 1D ^1H NMR spectra were recorded either on a Bruker AC 250 MHz spectrometer or on a Bruker Avance 800 MHz spectrometer at 25 °C. The NMR spectroscopic data were transferred to a SGI O2 workstation (IRIX OS) and were processed using the XWIN NMR software (version 2.6, Bruker). A typical NMR sample contained 10 mM anthracycline in [D_4]methanol. ^1H and ^{13}C chemical shifts were referenced to the solvent peak at δ = 3.31 (25 °C).

The ^1H-1D experiments were recorded with presaturation of the H_2O/HDO signal during the recycling delay. Typical parameters used were: 64 K data domain size, 0.5 s recycling delay, 10 KHz spectral width and 64 transients. The 1D FIDs were multiplied by an exponential window function (0.3 Hz line broadening added) and zero filing was performed prior to Fourier transformation.

^1H-Detected heteronuclear multiple-quantum coherence HMQC [35] and ^1H-detected heteronuclear multiple bond correlation HMBC [36] (optimized for long range couplings with a low-pass J-filter to suppress one bond correlations) experiments were acquired at 800 MHz and at 25 °C. Data sets with 2048 × 512 complex points were acquired with a 9 KHz sweep width in the proton dimension and 40 KHz in the carbon dimension. $J_{C\text{-}H}$ was set to 140 Hz and the solvent signal was selectively irradiated for 1.0 s during the relaxation delay period. A total of 32 scans were collected per t_1 increment and the spectra were processed with an exponential weighting function.

Acknowledgments

The authors gratefully acknowledge Prof. Ivano Bertini and the EU Large Scale Facility at the Magnetic Resonance Center (CERM) of the University of Florence for the 800 MHz NMR experiments performed by Massimo Lucci and Dr. Georgios Spyroulias. We would also like to thank Pharmacia & Upjohn, Greece for the generous supply of the anthracyclines and Dr. Georgios Pistolis for the fluorescence measurements.

Influence of an Additional Gas on the Hydroformylation and Related Reactions

Mario Bianchi,[a] Piero Frediani,*[a] Franco Piacenti,[a] Luca Rosi,[a] and Antonella Salvini[a]

Keywords: Hydroformylation / Carbonyl ligands / Cobalt / Carbonylation / Dinitrogen complexes / Argon / Xenon

The initial rate of the catalytic carbonylations reported in this paper [the hydroformylation of olefins in the presence of $Co_2(CO)_8$, the carbonylation of orthoesters catalyzed by $Co_2(CO)_8$], and the formation of tetracarbonylhydridocobalt(I) from octacarbonyldicobalt and dihydrogen] was reduced by the addition of dinitrogen, argon, or xenon. The influence of xenon on the rate of hydroformylation was greater than that of dinitrogen or argon. Helium and neon, on the other hand, did not show any influence, as expected, in view of their chemical-physical features. The experimental data may be explained assuming that the additional gas competes with one or more reactants for a coordinatively unsaturated site responsible for their activation, thus affecting the reaction rate.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

In the mechanism for the hydroformylation reaction, Heck and Breslow proposed (Scheme 1)[1] that molecular hydrogen was involved in two steps of the catalytic cycle. In a first step (Scheme 1, step A) dihydrogen reacts with $Co_2(CO)_8$ to give $CoH(CO)_4$, while in a subsequent step (Step F) hydrogenolysis of an acylcarbonylcobalt intermediate gives the aldehyde, thus restoring the carbonylhydridocobalt. In an intermediate step (C) the olefin is activated by reaction with $CoH(CO)_3$. In this paper we report the results of some experiments aimed to collect evidence on the intermediates connected with the activation step of dihydrogen in the hydroformylation reaction. Taking into account the literature data, a dihydrogen metal complex should precede the oxidative addition of dihydrogen to the cobalt(0) complex (step A in Scheme 1).

Dihydrogen[2] and dinitrogen complexes[3] are well documented in the literature, the first dihydrogen complex $[W(\eta^2\text{-}H_2)(CO)_3(P\mathit{i}Pr_3)_2]$ being reported by Kubas et al.[2a] Preliminary data on xenon containing transition metal complexes have also been reported in a solid matrix, in liquid xenon, in supercritical fluids, and in gas phase.[4] Very recently, the first stable xenon complex $[AuXe_2^{2+}][Sb_2F_{11}^-]_2$ was characterized by X-ray crystal structure analysis.[5] The interactions in these non-classical complexes are relatively weak (between 1 and 10 kcal mol^{-1}).[4a,4g,6] Nevertheless, coordination may be considered as the initial step of an activation process by a metal-containing catalyst. For instance, dihydrogen complexes may be intermediates in the oxidative addition leading to a metal dihydride (Scheme 2).

Other weak interactions such as those between a transition metal and an alkyl group (agostic interactions $[M^{\cdots}H-C]$)[7] play an important role in catalytic processes, such as the polymerization of olefins.[8]

The identification of a dihydrogen-cobalt interaction in the photolysis of $CoH(CO)_4$ and in a solid H_2/Ar matrix[9] supports the suggestion that a dihydrogen cobalt complex may be the precursor of dihydrogen activation in the hydroformylation reaction. Dinitrogen was found to displace dihydrogen from the coordination of a cobalt(I) complex, as reported by Sacco and Rossi[3a] in the $CoH(H_2)(PR_3)_3$/$CoH(N_2)(PR_3)_3$ system and analogous equilibria are reported for Ru^{II} and Fe^{II} complexes.[3c,10] Taking into account these results we have investigated the influence of an appropriate "additional" gas, dinitrogen and others, on the rate of hydroformylation (and related reactions) and this paper reports new data on this subject.

Results and Discussion

The first additional gas employed in our experiments was dinitrogen and the investigation was then extended to rare gases such as helium, neon, argon, and xenon.[11] The initial rate for the hydroformylation of cyclohexene in the presence of an "additional gas" was established by determining the conversion of the substrate in isochronous experiments. An analogous methodology has been employed to study the carbonylation of orthoesters and the formation of $CoH(CO)_4$ from $Co_2(CO)_8$ and H_2.

Cyclohexene Hydroformylation

The influence of an additional gas on the rate of hydroformylation was determined by converting cyclohexene to the corresponding aldehyde (Scheme 3) in a set of experi-

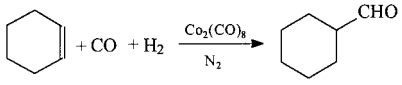
ments carried out under the same reaction conditions [100 °C, p(CO) 85 bar, p(H_2) 85 bar, reaction time 3 h], but under different pressures of dinitrogen (0−1000 bar).



Scheme 3

Preliminary results on this reaction have been reported,[11] and the data obtained are summarized in Table 1. A relevant amount of dinitrogen in the reaction medium due to a dinitrogen pressure of 1000 bar, reduced the initial rate of the reaction from 627 to 250 μmol h^{-1}. A reduction of the rate might also be due to a decrease in concentration of the catalyst and substrate resulting from the volume increase of the solution caused by the dissolution of the additional gas. It has been experimentally determined that the amount of dinitrogen dissolved in 7 mL of toluene at 100 °C under 1000 bar produce a volume increase of 1.4 mL. If the volume additivity holds, the molar fraction of dinitrogen[12] is 0.381, the total volume of the solution becomes 8.4 mL. The effect of the dilution on the initial rate of the hydroformylation has been determined by a reference test using 8.5 mL of solvent. As shown in Table 2, the initial rate of the hydroformylation is almost unchanged (595 μmol h^{-1}) (Table 2). By doubling the volume of the solution to 14 mL, the initial rate was reduced to 474 μmol h^{-1}. These data clearly show that although dilution reduces the conversion at a given time, the rate reduction observed in the hydroformylation test carried out under the high pressure of dinitrogen adopted is significantly greater. The hydroformylation of cyclohexene carried out in the presence of argon as additional gas shows a behavior analogous to that observed in the presence of dinitrogen, see Table 1. A specific chemical effect must therefore operate. A purely physical effect due to the increase of dinitrogen pressure should also be excluded since the same reaction carried out in the presence of helium under the same pressure does not show any significant change in the initial rate.

Table 1. Influence of additional gases on the initial rate of cyclohexene hydroformylation[11a]; reaction conditions: toluene 7 mL; $Co_2(CO)_8$ 0.149 mmol (51 mg); cyclohexene 6.15 mmol (500 mg); p_{CO} 70 ± 1 bar at 100 °C; p_{H2} 85 ± 2 bar at 100 °C; reaction time 3 h; T = 100 °C

[a] Initial rate reduction: $[(\text{Initial rate})_{0\ bar} - (\text{Initial rate})_{observed}]/(\text{Initial rate})_{0\ bar}$.

The observed reduction of the rate of hydroformylation may be ascribed to the formation of a cobalt complex containing dinitrogen (or argon). The formation of a similar complex does in fact reduce the concentration of the catalytically-active cobalt complex and consequently the initial rate of the reaction, see Scheme 4.

Table 2. Hydroformylation of cyclohexene to $C_6H_{11}CHO$; influence of dilution on the rate; solvent: toluene; $Co_2(CO)_8$ 0.149 mmol (51 mg); cyclohexene 6.15 mmol (500 mg); p_{CO} = 70 ± 1 bar at 100 °C; p_{H2} = 85 ± 2 bar at 100 °C; reaction time 3 h; T = 100 °C

Scheme 4

In other words, the reduced hydroformylation rate may be attributed to a lower concentration of the available active intermediate due to a competition between dinitrogen (or argon) and dihydrogen (or olefin) for the same vacant coordination site within the catalytically active species.

The ability of an electron-deficient cobalt complex to coordinate dinitrogen (or rare gases) may be related to the availability of outer shell electrons of this gas that is connected with the first ionization potential (IP).[13] Within rare gases, the IP decreases from helium to xenon. The large rare gases have been reported to coordinate a transition metal.[14,15]

The estimated bond dissociation enthalpy (BDE) for W−Xe in $W(CO)_5Xe$[16] is 35.1 ± 0.8 *k*J mol^{-1}. Furthermore, the estimated BDE's of the metal(0) pentacarbonyl derivatives[17] decrease from xenon (34.3 ± 4.2 *k*J mol^{-1}), to krypton (ca. 25 *k*J mol^{-1}), to argon (ca. 12 *k*J mol^{-1}).

In the hydroformylation of cyclohexene the initial rate was affected by the presence of xenon more than by argon or dinitrogen, while neon or helium had no effect, see Table 1, Table 3 and Table 4. The small difference in the observed rates when working in the presence of helium and neon may be attributed to their different solubility in toluene and therefore to the different volume increase. The concentration of N_2, Ar, Xe in toluene has been experimentally detected and the data are reported in the supplementary materials. The initial rate reduction evaluated for the same concentration of the additional gas in solution (Table 4), is 31.3 for Xe, 16.8 for N_2, and 8.2 [mM]$^{-1}$ for Ar.

Table 3. Influence of xenon on the initial rate of cyclohexene hydroformylation; toluene 7 mL; $Co_2(CO)_8$ 0.149 mmol (51 mg); cyclohexene 6.15 mmol (500 mg); reaction time 3 h; T = 100 °C

[a] Xenon 3.8 g. [b] The additional gas in solution was measured: see the supplementary materials.

The inhibiting effect of these additional gases (nitrogen, argon, or xenon) on the rate of hydroformylation may be considered as an indirect evidence of an interaction between these additional gases and a catalytically active cobalt complex. These interactions are presumably weak, and carrying out the hydroformylation of cyclohexene in heptane or toluene (Table 5) the initial rate is almost unaffected by the solvent although the solubilities of CO and H_2 differ significantly between heptane and toluene.[12]

Table 5. Hydroformylation of cyclohexene in different solvent; solvent 7 mL; $Co_2(CO)_8$ 0.149 mmol (51 mg); cyclohexene 6.15 mmol (500 mg); p_{CO} 70 bar at 100 °C; p_{H2} 85 bar at 100 °C; reaction time 3 h; T 100 °C

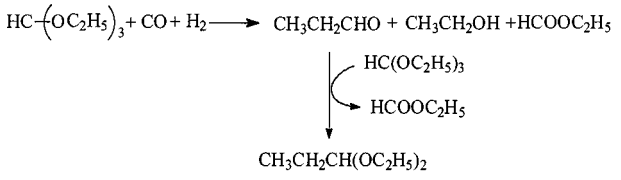
Carbonylation of Triethyl Orthoformate

The synthesis of aldehydes by carbonylation of orthoformic esters (Scheme 5) in the presence of $Co_2(CO)_8$ has the same kinetic dependence on CO and H_2 pressure, cata-



Scheme 5

lyst and substrate concentration as the hydroformylation of olefins.

The reaction proceeds through the protonation of one of the oxygen atoms of the ester,[18,19] followed by $RCo(CO)_4$ formation and collapse of the organic residue into ROH and HCOOR. Only one aldehyde is formed, due to the insertion of the formyl group onto the carbon atom of the alkyl group initially bound to the oxygen in the ester.

The aldehyde formed usually reacts through a fast reaction, with the orthoformic ester still present to provide the corresponding dialkyl acetal. The overall reaction is the formation of the acetal of the aldehyde (Scheme 5).

In this reaction no olefin is involved and there is no activation of the substrate by coordination to the metal atom of the catalyst. Coordination vacancies on the catalytically active intermediate should therefore be involved only for the activation of molecular hydrogen. The effect, if any, of the presence of the "additional gas" on the rate of this reaction, which uses the same catalyst as the hydroformylation, should therefore reveal the intervention of these gases on the specific activation steps of dihydrogen.

We have therefore tested the effect of the presence of "additional gases" on the carbonylation of orthoformic esters. The initial rate of the reaction was determined in isochronous (3 h) experiments carried out at 90 °C in the presence of an additional gas (pressure range: 0−1500 bar) through the conversion of triethyl orthoformate to 1,1-diethoxypropane, (see Scheme 5 and Table 6).

Table 6. Carbonylation of triethyl orthoformate: influence of additional gas on the initial rate; ethanol 8 mL; $Co_2(CO)_8$ 0.0789 mmol (27.0 mg); triethyl orthoformate 7.5 mmol (1.110 g); p_{CO} 50 ± 1 bar at 40 °C; p_{H2} 95 ± 2 bar at 90 °C; reaction time 3 h; T = 90 °C

	1500	100	81.5

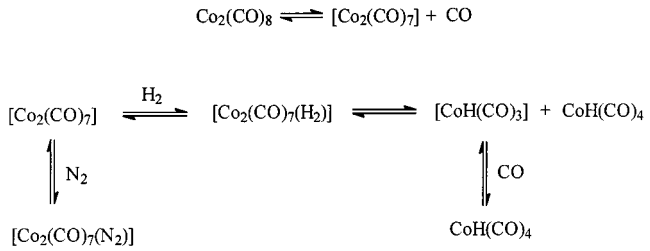
[a] Initial rate reduction: $[(\text{Initial rate})_{0\ bar} - (\text{Initial rate})_{observed}]/(\text{Initial rate})_{0\ bar}$.

The additional gas remarkably affects the rate of carbonylation of orthoesters as in the case of cyclohexene hydroformylation. Argon apparently has an even higher influence than dinitrogen.

These data suggest that the steps responsible for the activation of dihydrogen (Scheme 1, steps A, F) are involved in the competition between dihydrogen and the additional gas for the coordinatively unsaturated site.

Formation of $CoH(CO)_4$ from $Co_2(CO)_8$ and Dihydrogen

During the carbonylation of organic substrates in the presence of $Co_2(CO)_8$ as a catalytic precursor, the first reaction is the formation of the catalytically active tetracarbonylhydridocobalt(I). Its kinetic[20] and general considerations, however, on the necessary activation of dihydrogen suggest the following steps (Scheme 6).



Scheme 6

In order to get further evidence, although indirect, on the presence of a coordinatively unsaturated intermediate responsible for the activation of dihydrogen, we tested the effect of the presence of an additional gas on the rate of formation of $CoH(CO)_4$.

A solution of $Co_2(CO)_8$ in hexadeuterobenzene was heated at 50 °C under carbon monoxide (1 bar) to stabilize the carbonyl complex which, even in the absence of O_2 would decompose to $Co_4(CO)_{12}$.[21] The CO was also used to reduce the reaction rate, which in its absence is fast.[22] Dihydrogen and the additional gas were then added. The results are reported in Table 7. Dinitrogen shows a marked influence on the initial rate of the reaction. The conversion of $Co_2(CO)_8$ was almost suppressed in the presence of 1000 bar of dinitrogen: only a trace of $CoH(CO)_4$ was found to be present in solution. The presence of helium (1070 bar) did not affect the rate of this reaction: a conversion of 14−15% was observed under the same conditions. We assume that dinitrogen and dihydrogen compete for a coordinatively unsaturated site of an intermediate, tentatively indicated as $Co_2(CO)_7$ in Scheme 6.

Table 7. Formation of $CoH(CO)_4$ from $Co_2(CO)_8$ and dihydrogen; influence of the additional gas on the initial rate; hexadeuteriobenzene 4 mL; $Co_2(CO)_8$ 0.2339 mmol (80.0 mg); T = 50 °C; p_{CO} = 1 bar at room temp.; p_{H2} = 50 bar at 50 °C; reaction time 3 h

[a] Initial rate reduction: $[(\text{Initial rate})_{0\ bar} - (\text{Initial rate})_{observed}]/(\text{Initial rate})_{0\ bar}$

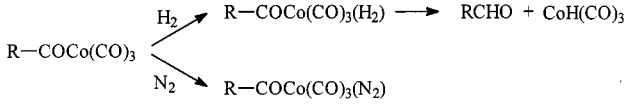
Conclusion

Several authors discussing the mechanism of the hydroformylation of olefins have indicated the reduction of an acylcarbonylcobalt intermediate as the rate determining step.[23,24] The negative influence of the pressure of carbon monoxide on the reaction rate[25] may be explained in terms of the shift of equilibrium D (Scheme 1) to the acyltricarbonylcobalt that was found to be more easily reducible than acyltetracarbonylcobalt.

The higher rate of hydroformylation under a low pressure of carbon monoxide may be attributed to the higher concentration in solution of the coordinatively unsaturated acyltricarbonylcobalt, necessary to activate dihydrogen, which is the predominant reducing agent in the system (Step F, Scheme 1).

Dihydrogen was suggested as the reducing agent[23,24] in consideration of its high concentration in solution when compared with that of the alternative reducing agent: tetracarbonylhydridocobalt(I).

Such an explanation is confirmed by the detected influence of the "additional gases" on the rate of hydroformylation. These gases do not take part in the formation of the product but compete with both dihydrogen and carbon monoxide for the coordinatively unsaturated site in the acyltricarbonylcobalt (Scheme 7). These interactions decrease the concentration of the intermediate available for the activation of dihydrogen and therefore retard its reaction with the acylcobalt complex that leads to the formation of the aldehyde.



Scheme 7

Experimental Section

General Methods: Quantitative GC analyses were performed with a Shimadzu mod. GC-14A instrument equipped with a PPG column ("Polypropylenglicol" LB-550-X on Chromosorb W at 15%, 1/8" i.d., 2 m) and a Shimadzu mod. C-R4A integrator. Unless otherwise stated, no correction factors were introduced, in consideration of the analogy of the products examined. Products were identified by GC-MS using a Shimadzu apparatus having a GC14A chromatograph equipped with a CP-Sil8 (50 m) capillary column and a QP2000 mass detector. Elemental analyses were performed using a Perkin−Elmer mod. 2400 Series II elemental analyzer. IR spectra were recorded with a Perkin−Elmer mod. 1760-X FT-IR spectrophotometer. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded using a Varian VXR300 spectrometer operating at 299.987 MHz for ^1H, and at 75.429 MHz for ^{13}C, using $SiMe_4$ as external standard.

$Co_2(CO)_8$ (m.p. 56 °C) was prepared according to Natta and Ercoli,[26] and recrystallized from hexane; cyclohexene (Fluka) was purified (99.9% purity by GC) through elution on an Al_2O_3 column and then distilled (b.p. 83 °C) under dinitrogen; triethyl orthoformate: (Fluka) was distilled under dinitrogen (b.p. 146 °C); toluene was heated under reflux over sodium for 5 h, then distilled under dinitrogen (b.p. 110 °C).[27] Heptane was dried by heating under reflux over $LiAlH_4$. Dinitrogen (Sol Centro, 99.996% purity), argon (Sol Centro, 99.998% purity), neon, (Rivoira, 99.997% purity), xenon (Rivoira, 99.997% purity), and helium (Sol Centro, 99.998% purity) were used as received.

The experiments were carried out in a stainless-steel rocking reactor, inner volume 24.5 mL, tested to a total pressure of 4000 bar. The vessel was equipped with a high-pressure Nova Swiss valve used for the introduction of gases and liquids. The temperature was measured using a Pt100 indicator and regulated with an accuracy of ±1 °C. The pressure was measured through a transducer (Sensotec, model Z Absolute) with an accuracy of ±1 bar. The experimental conditions are reported in Table 1−3 and Table 5−7. The amount of reagents were chosen to avoid relevant pressure drops during each experiment.

Hydroformylation of Cyclohexene: The same procedure was adopted for the hydroformylation of cyclohexene in the presence of dinitrogen, argon, or helium. The catalyst was placed in the stainless-steel autoclave under dinitrogen the vessel was sealed and the gas evacuated. A solution of the olefin was prepared in a Schlenk tube and introduced into the autoclave by suction. CO of up to 5 bar was then added. The reactor was rocked and heated at 100 °C. When the solution reached the predetermined temperature, further CO up to 75 bar was added, followed by dihydrogen up to a total pressure of 160 bar (partial pressure of H_2, 85 ± 2 bar). The additional gas was then rapidly introduced up to the required pressure. Only a few minutes were necessary to perform these operations. The reactor was rocked for 3 h, then rapidly cooled to room temperature. The gases were vented and the pale yellow solution analyzed by GC to evaluate the conversion of cyclohexene to the aldehyde. GC conditions adopted when the experiments were carried out in toluene were the following: 50 °C for 5 min than up to 110 °C at a rate of 4 °C/min and kept at this temperature for 50 min. When heptane was the solvent, GC conditions were the following: 35 °C for 20 min then up to 110 °C at a rate of 4 °C/min and keeping this temperature for 60 min. Cyclohexane, cyclohexene, toluene or heptane, and cyclohexanecarboxyaldehyde were determined by gas-chromatography. The amount of cyclohexane present was less than 1% of the starting cyclohexene in all experiments.

The experiments with xenon were carried out using a different procedure. After the introduction of both catalyst and solvent, CO up to 1 bar was added. Liquid xenon was introduced at room temperature from a pressure cylinder, followed by CO up to 53 bar at room temperature. The amount of xenon introduced was evaluated by weight difference. The reactor was heated at 100 °C and then pressurized with hydrogen. The subsequent procedures were identical to those reported above. The data in the presence of xenon were compared with a reference test performed, with the same procedure, in the presence of helium.

The results of the hydroformylation tests on cyclohexene are reported in Table 1−5.

Carbonylation of Triethyl Orthoformate: All conditions employed are reported in Table 6. The catalyst was placed in the autoclave under dinitrogen. The vessel was sealed and the gas evacuated. A solution of triethyl orthoformate in anhydrous ethanol was prepared in a Schlenk tube and introduced into the autoclave by suction. CO up to 50 bar was then added and the vessel heated at 90 °C. When the selected temperature was reached, hydrogen up to a total pressure of 145 bar was introduced (hydrogen partial pressure 95 ± 2 bar) followed rapidly by the additional gas. The reactor was rocked for 3 h, and then rapidly cooled to room temperature. The

gases were vented and the pale yellow solution analyzed by GC using heptanol as internal standard, to evaluate the conversion of triethyl orthoformate into 1,1-diethoxypropane. The following GC conditions were adopted: 50 °C for 5 min, then heated up to 70 °C at a rate of 5 °C/min and kept at this temperature for 15 min, then heated up to 120 °C at a rate of 5 °C/min and kept at this temperature for 20 min. Ethanol, ethyl formate, 1,1-diethoxypropane, and heptanol were separated and quantified by GC. The results are reported in Table 6.

Synthesis of $CoH(CO)_4$ from $Co_2(CO)_8$ and Hydrogen: The experimental conditions used are listed in Table 7. Under CO, a solution of octacarbonyldicobalt in [D_6]benzene was introduced into the autoclave, which was then sealed and heated up to 50 °C. Dihydrogen and the additional gas (helium or dinitrogen) were then introduced and the autoclave rocked for 3 h. The vessel was cooled at 0 °C, the gases were slowly vented (about 20 min) and the autoclave opened under dihydrogen. An aliquot of the solution (1 mL, 0 °C) was examined by ^1H NMR after addition of 21.0 mg (0.0146 mmol) of $Ru_4H_4(CO)_8(PBu_3)_4$ as internal standard [$CoH(CO)_4$, $\delta = -11.6$; $Ru_4H_4(CO)_8(PBu_3)_4$, $\delta = -16.7$] and the conversion of $Co_2(CO)_8$ into $CoH(CO)_4$ was detected (Table 7).

The loss of $CoH(CO)_4$ was estimated by carrying out an experiment in the absence of an additional gas under the conditions reported in Table 7. At the end of the reaction, helium was introduced up to a pressure of 930 bar, the gases were vented and the amount of $CoH(CO)_4$ evaluated as previously described. The initial rate of the transformation of $Co_2(CO)_8$ into $CoH(CO)_4$ is 5.6 μmol h^{-1}: 50% of the hydride present in the solution was lost.

Complexation of Lanthanide(III) Ions with Polyhydroxy Carboxylic Acids in Aqueous Solutions

Sébastien Giroux,[a] Sabrina Aury,[a] Bernard Henry,[a] and Patrice Rubini*[a]

Keywords: Lanthanides / Cations / Acidity / Complexation / NMR spectroscopy

The complexation of lanthanum(III), europium(III), dysprosium(III), erbium(III), and lutetium(III) with D-gluconic acid (LH) was studied by pH potentiometry and NMR. The set of complexes formed in aqueous solutions and their stability constants β were determined, and the results were compared to those previously found for praseodymium(III) (S. Giroux et al., Polyhedron **2000**, *19*, 1567). A regular evolution of the β values was observed along the lanthanide series, particularly for the neutral complex MLH_{-2} (where two hydroxy functions were deprotonated) with a selectivity similar to that of EDTA. For the ML_2^+ complex, where the ligand was coordinated via the carboxylate groups, the analysis of the ^{13}C NMR pseudocontact shift showed that the carboxylate group was not bidentate and that there was a participation of the α-hydroxy group in the coordination. The study of the complexation of Pr^{III} with other hydroxy carboxylic acids: glyceric, threonic, 2-hydroxybutanoic, and 3-hydroxybutanoic acids confirms that in the complex MLH_{-2} the deprotonated hydroxy groups, that intervene in the coordination with the metal ion, are those in α and γ positions relative to the carboxylate group.

Introduction

Polyhydroxycarboxylic acids, particularly D-gluconic acid (**I**), have good complexing properties, and find more and more practical applications in the industrial domain.[1] The complexing ability of gluconic acid towards metallic ions is well known[2−11] even if the structure of the complexes formed in solution is not always well reported. The determination of the role and the nature of the alcohol groups concerned by the coordination to the metal ion is a difficult problem to solve. The combination of several techniques (potentiometry, NMR, circular dichroism) has proved to be efficient in obtaining such information.[7,11]

Lanthanide(III) ions are hard acids and their interaction with carboxylate groups or deprotonated hydroxy functions is strong.[2,10−12] The complexation of the praseodymium(III) ion with D-gluconic acid in aqueous solutions has been thoroughly studied[11] by potentiometry, UV/Vis spectrophotometry, NMR, and circular dichroism (CD) experiments. It was shown that six different complexes are formed in solution. Among them there are species where deprotonated OH groups participate in the coordination. It must also be noted that at neutral pH values, the formation of a neutral complex takes place that could, using a more hydrophobic ligand, allow for the extraction of this species into an organic phase.[13]

This work is devoted to a study of the complexation of the La^{III}, Eu^{III}, Dy^{III}, Er^{III}, and Lu^{III} ions with D-gluconic acid in order to know if there is an evolution of the complexing ability of this ligand along the lanthanide series, and whether this induces a possible selectivity. The complexes and their stability constants were determined by pH potentiometry. An NMR study allowed us to draw conclusions on the structure of the complexes.

In order to enhance our knowledge on the binding sites of gluconic acid in complexes where alcohol functions are deprotonated, we also studied the complexation of the praseodymium(III) ion with glyceric acid (**II**), threonic acid (**III**), 2-hydroxybutanoic acid (**IV**), and 3-hydroxybutanoic acid (**V**). Gluconic acid and threonic acid are polyhydroxylated carboxylic acids with three or four carbon atoms, and two or three OH functions, respectively. The presence of a primary alcohol function in the β or γ position relative to the carboxylic function, instead of a secondary alcohol one in gluconic acid, may generate variations in the complexing abilities. The two studied butanoic acids have only one OH function in α or β position relative to the carboxylic function. It was interesting to see if the presence of only one OH group in the ligand considerably lowered the complexation power of these molecules.

Results

Complexes of La^{III}, Pr^{III}, Eu^{III}, Dy^{III}, Er^{III}, and Lu^{III} with D-Gluconic Acid

Potentiometric measurements were made on mixtures of lanthanide(III) cations and D-gluconic acid as a function of

pH and for several ligand to metal ratios. For ligand/metal ratios smaller than 5:1 a precipitate was observed at pH < 11 (Table 1). For higher ratios no precipitation occurred. In the case of the Dy^{III} and Er^{III} cations, for small ligand/metal ratios, high concentrations, and for pH > 9, the viscosity of the solutions increased with time, and the formation of a gel was observed after a few minutes or a few tens of minutes.

Table 1. pH of precipitation for solutions of gluconic acid (L) and lanthanide(III) ions (M) for different [L]/[M] ratios; the metal ion concentration was varied from ca. 1×10^{-3} to ca. 5×10^{-3} mol·L^{-1} for a nearly constant gluconic acid concentration of ca. $6-8 \times 10^{-3}$ mol·L^{-1}

[L]/[M]	La^{III}	Pr^{III}	Eu^{III}	Dy^{III}	Er^{III}	Lu^{III}
1:1	9.0	8.5	7.4	8.2	7.4	7.4
1.5:1	9.9	8.5	8.2	8.3	7.5	[a]
3:1	10.1	8.9	9.5	[b]	[b]	7.8
5:1	[b]	[b]	[b]	[b]	[b]	[b]

[a] Not measured. [b] No precipitation observed up to pH = 11.3.

These experiments allowed us to determine that the same set of six complexes was formed for the La^{III}, Eu^{III}, Dy^{III}, Er^{III}, and Lu^{III} cations as for the Pr^{III} cation:[11] ML^{2+}, MLH_{-1}^{+}, MLH_{-2}, ML_2^{+}, ML_2H_{-1}, and $ML_2H_{-3}^{2-}$, and in addition, the complex $M_2L_2H_{-5}^{-}$. There were two exceptions: $ML_2H_{-3}^{2-}$ could not be found for Eu^{III} and MLH_{-1}^{+} for Lu^{III}. The formation constants of all these species are summarized in Table 2.

Distribution diagrams of these complexes as a function of pH are represented by Figure 1. At pH = 4, and for a gluconic acid concentration of 0.5 mol·L^{-1}, and for large ligand/metal ratios, the complex ML_2 was formed in 100% yield.

A ^{13}C NMR study of this complex was performed. For the diamagnetic cations, La^{3+} and Lu^{3+}, no shifts relative to the free ligand were observed, but for the paramagnetic ions the peaks were considerably shifted and broadened. To observe the signals, large ligand/metal ratios (10:1 to 250:1) were used. Only one mean signal for each carbon atom was detected because of a rapid exchange between free and bound gluconic acid. With an excess of free ligand the signals are reasonably shifted and broadened.

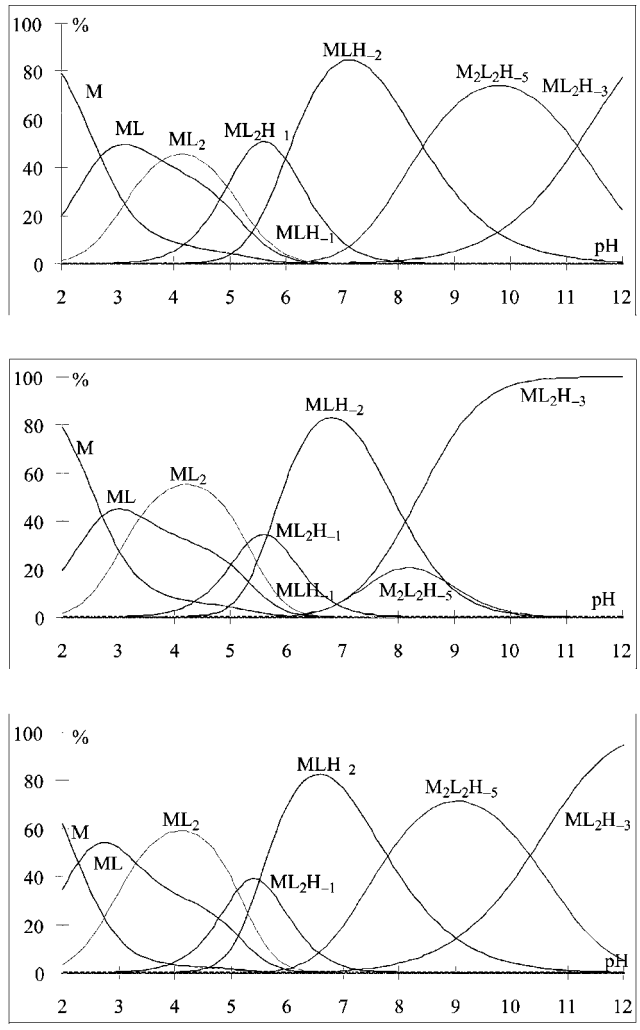

Figure 1. Distribution diagrams of the complexes formed at 25 °C between gluconic acid (5.10^{-3} mol·L^{-1}) and Dy^{III} (top), Er^{III} (center), and Lu^{III} (bottom) as a function of pH, for a ligand/metal ratio of 5:1

The chemical shift δ of the signals is related to the chemical shift of free (δ_f) and bound (δ_b) gluconic acid, as well as the molar fraction of free (p_f) and bound (p_b) ligand: $\delta = p_b\,\delta_b + p_f\,\delta_f$. As $p_f = 1 - p_b$, δ can be written as $\delta = \delta_f + p_b \cdot \Delta\delta$, where $\Delta\delta = \delta_b - \delta_f$.

Table 2. Formation constants (log β_{pqr}) for the different complexes formed in the system Ln^{III}/gluconic acid [T = 25 °C, I = 0.1 mol·L^{-1} ($NaClO_4$) determined from pH potentiometry measurements]

[a] From ref.[11]

The plot of δ as a function of p_b for each carbon atom for the Pr^{III}, Eu^{III}, and Dy^{III} complexes gives straight lines, the slope of which allows the determination of Δδ. An example of plot is given in Figure 2. The Δδ values are summarized in Table 3.

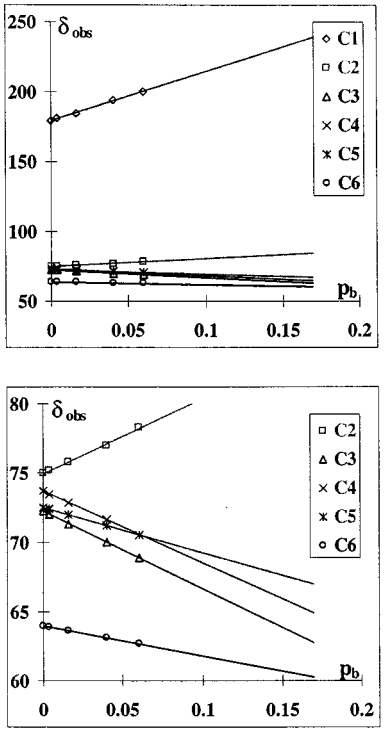

Figure 2. NMR chemical shifts of the different gluconic acid ^{13}C nuclei as a function of p_b, the molar fraction of gluconic acid bound to Dy^{III}

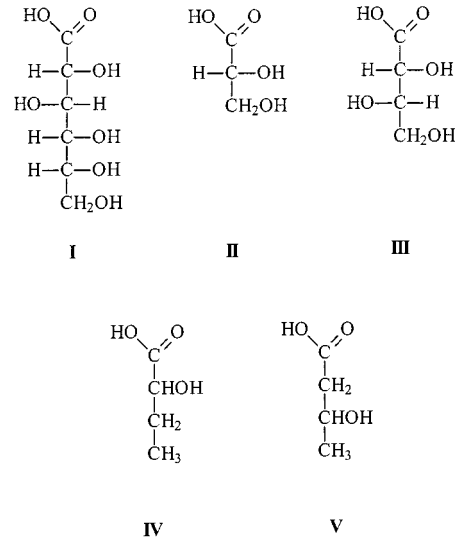
Complexation of Pr^{III} with Glyceric, Threonic, 2-Hydroxybutanoic and 3-Hydroxybutanoic Acids

In order to determine the influence of the number and the position of hydroxy groups on the complexation behaviour of the polyhydroxy carboxylic acids, a potentiometric study of the complexation of Pr^{III} by D-glyceric acid (**II**), L-threonic acid (**III**), 2-hydroxybutanoic acid (**IV**), and (*R*)-3-hydroxybutanoic acid (**V**) was performed (Scheme 1).



Scheme 1

The pK_a values of these acids are 3.52, 3.48, 3.64, and 4.34, respectively (gluconic acid: pK_a = 3.47). These values are in agreement with those reported in the literature. For glyceric acid, values of 3.32 (I = 0.1 mol·L^{-1}, KNO_3)[14] and 3.54 (I = 2 mol·L^{-1}, $NaClO_4$) are reported.[15] The pK_a value of 2-hydroxybutanoic acid from the literature data was found to be 3.70 or 3.80[16] at 25 °C and I = 0.1 mol·L^{-1}, that of 3-hydroxy-butanoic acid is reported to be 4.31 for an ionic strength of I = 0.5 mol L^{-1} in $NaClO_4$ at 25 °C[17] and 4.40 at 31 °C for I = 0.1 mol·L^{-1}.[18]

In the presence of Pr^{III}, the formation of a precipitate was observed at pH ≈ 8 for glyceric and threonic acids, and at pH ≈ 7 for the two butanoic acids. For **III**, **IV**, and **V** the complex ML was formed (the ligands, where the carboxylic function is not deprotonated, are noted LH) with log β_{110} = 2.76 ± 0.04, 2.56 ± 0.01, and 2.08 ± 0.02, respectively (2.78 ± 0.03 for gluconic acid[11]). It was the only complex that could be detected with **IV** and **V**. For **III**, the complexes MLH_{-1} and MLH_{-2} were also present (log β_{11-1} = −3.97 ± 0.03 and log β_{11-2} = −11.78 ± 0.02, compared to the corresponding values found for gluconic acid, −3.34 and −10.0[11]). Additionally the ML_2 species (log β_{120} = 5.19 ± 0.04) was also formed in the case of glyceric acid (log β_{120} = 5.11 ± 0.02; for gluconic acid, log β_{120} = 5.57). For **II**, in addition to ML_2, the complex ML_2H_{-2} and the binuclear species M_2L_2 and $M_2L_2H_{-2}$ were also detected (log β_{12-2} = −10.82 ± 0.06, log β_{220} = 7.79 ± 0.04, and log β_{22-2} = −6.61 ± 0.04, respectively). It should be noted that in this case, M_2L_2 and $M_2L_2H_{-2}$ could be replaced by ML and MLH_{-1}, but the fit is not as good, and the formation constant for ML is too low and not consistent with that of ML_2.

The ^1H and ^{13}C NMR study of these systems was made under conditions where the signals were not too broad nor significantly shifted, i.e. for large L/M ratios. For such L/M ratios, from the potentiometric results at pH < 7, the mean

species was ML_2 for glyceric acid, a mixture of ML and ML_2 (ML_2 predominant) for threonic acid, and ML for the butanoic acids (Figure 3). This study confirms the complexation by the carboxylate group. The most shifted ^{13}C NMR signals are those corresponding to the COO^- group and those corresponding to hydrogen atoms (^1H NMR) on the carbon atom adjacent to the carboxylate group.

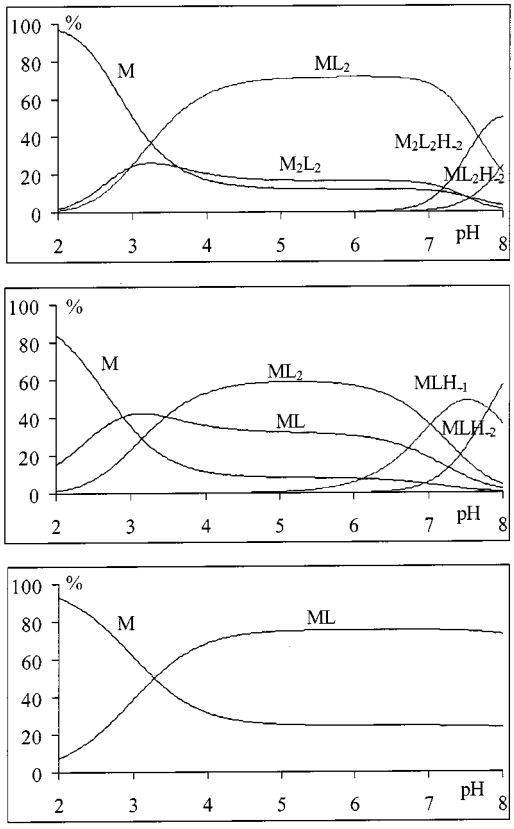


Figure 3. Distribution diagrams for the complexes formed at 25 °C between Pr^{III} and glyceric acid (top), threonic acid (center), and 2-hydroxybutanoic acid (bottom) as a function of pH; the concentration of the ligand was 0.01 mol·L^{-1} and the ligand/metal ratio was 5:1

Discussion

The systems of complexes formed between the six studied trivalent lanthanides and gluconic acid are very similar from one cation to another; only one species among seven is missing for Pr^{3+} ($M_2L_2H_{-5}$), Eu^{3+} (ML_2H_{-3}), and Lu^{3+} (MLH_{-1}). For an individual species, the formation constants are of the same order of magnitude, but show a regular increase along the lanthanide series with very few exceptions (Table 2). This can be put in relation with the increase in electrostatic interaction between the hard lanthanide ions, the radii of which decrease along the series, and the negatively charged oxygen atoms of the ligand that act as hard bases.

This continuous increase in the formation constants is shown for the complex MLH_{-2} in Figure 4. The amplitude in the variation from La^{3+} to Lu^{3+} is practically equal to five logarithmic units in this case, a value that can be compared to that obtained with the ethylenediamine tetraacetate ion (EDTA), 4.38.[19−20] The selectivity of gluconic acid towards lanthanide(III) ions through the formation of MLH_{-2} complexes is better than that of EDTA. This is important if one notes that MLH_{-2} is a non-charged species that can be extracted into an organic solvent. Gluconic acid, or a more hydrophobic form of this ligand, would be a good candidate for the liquid-liquid extraction of the trivalent lanthanide ions.[13]

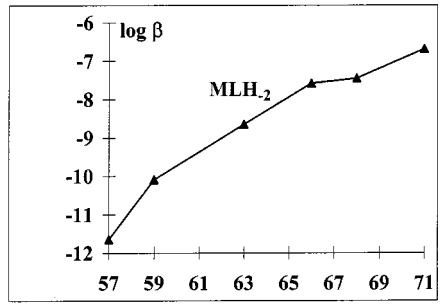

Figure 4. Variation of the log β_{11-2} value (MLH_{-2} complex) as a function of the lanthanide atomic number

The structure of the different Pr^{III} complexes has been largely discussed in a previous publication,[11] from potentiometric, NMR, UV/Vis, and CD experiments. For the ML_2 complex it is clear that the coordination takes place via the carboxylate group as demonstrated earlier,[11] but there is a presumption that the hydroxy group in α-position relative to the carboxylate group participates in the coordinating to the metal ion. Moreover, this OH function is that one that loses a proton, giving rise to the MLH_{-1} complex. The NMR study of systems with various paramagnetic cations may allow us to obtain more information on the structure of the ML_2 complex that can be formed at 100% without the presence of any other species at pH = 4.0. As was shown above, we could obtain the Δδ value for the different carbon atoms of gluconic acid ($\Delta\delta = \delta_b - \delta_f$). From these values it is possible to determine the part of the contact shift and that of the pseudo-contact shift in Δδ:[21−23]

$$\Delta\delta_i^j = f_i \langle S_z \rangle_j + D_j \cdot g_i.$$

The first term of the sum represents the contact shift, $\langle S_z \rangle_j$ is the projection of the total electron spin magnetization of the lanthanide j on the direction of the external magnetic field, and f_i is the product of the hyperfine coupling constant of carbon C_i and a coefficient. The second term is related to the dipolar (pseudo-contact) contribution. D_j is a constant for the lanthanide j, and g_i for a complex with an axial symmetry is defined as $g_i = k\,[3\cos^2(\theta - 1)]/r^3$, where k is a crystal field coefficient that is supposed to be constant along the lanthanide series; θ the angle between the principal axis of symmetry and the vector C_i-Ln^{3+} and r, the distance C_i-Ln^{3+}. The f and g coefficients can be determined from the plot $\Delta\delta_i^j/\langle S_z \rangle_j$ as a function of $D_i/\langle S_z \rangle_j$. In this case this plot must be a straight line, the slope of which is g_i. The structure of the complexes was not supposed to vary along the lanthanide series. The plot for the

C^1 (carboxylate) and C^2 carbon atoms are shown in Figure 5. The *f* and *g* values deduced from these plots and the corresponding contact and pseudo-contact contributions to the total shift are reported in Table 4. With the exception of the C^3 carbon atom, the pseudo-contact term is always larger than the contact term for the Pr^{3+} and Dy^{3+}ions. In the case of Eu^{3+}, the pseudo-contact part overcomes the contact term only for the C^1, C^4, and C^6 carbon atoms.

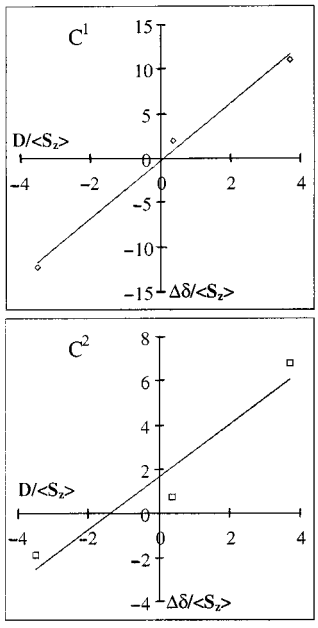

Figure 5. Plots $\Delta\delta/\langle S_z\rangle$ as a function of $D/\langle S_z\rangle$ for the C^1 (carboxylate) and C^2 carbon atoms of gluconic acid (L) in the complex PrL_2^+

Table 4. The *f* and *g* parameters for the ML_2 complex; contact and pseudo-contact contributions to the ^{13}C NMR chemical shift (M = Pr, Eu, and Dy)

	f	*g*	Pr^{III}		Eu^{III}		Dy^{III}

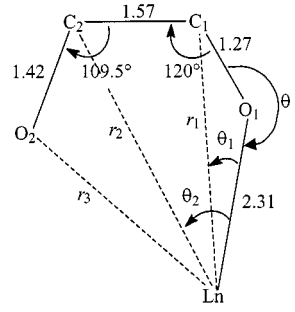
From the *g* value, structural information can be obtained for the ML_2 complex. The question arises whether the gluconic acid carboxylate group acts as a bidentate ligand, as observed in the case of the acetate ion,[24] or if it can be envisaged that there is a participation of the hydroxy group borne by the C^2 carbon atom, leading to a monodentate coordination of the carboxylate head. The second type of coordination was observed in the solid state for manganese(II) D-gluconate dihydrate[25] and lead D-gluconate,[26] where there is a strong interaction of the hydroxy group with the metal ions leading to the formation of a five-membered chelate ring; in this case the metal−oxygen distances are of the same order of magnitude either for one of the oxygen atoms of the carboxylate group or the oxygen atom of the α-hydroxy group.

In the solid $Pr(acetate)_3{\cdot}H_2O$, two acetate ions are bidentate (one of the oxygen atoms is bonded to a second Pr^{3+} ion) and the Pr−O−C−O planes are planar to within 0.06 Å.[24] If the situation is the same for the Pr gluconate system, the ratio of the *g* values for the C^1 and C^2 carbon atoms can be easily calculated; the angles θ for these two carbon atoms are the same regardless of the position of the principal axis of the complex (since the C^2 carbon atom is also in the Pr−O−C−O plane because of the planar structure of the carboxylate group). The distances *r* may be evaluated from the data of ref.[24] The calculated ratio is ca. 3.6, to be compared to the experimental value of 2.7 (Table 4). Obviously, the calculated value is too high, indicating that the C^2 carbon atom is probably closer to the lanthanide(III) ion in the gluconate complex than in the acetate complex. This leads us to propose a structure in which the carboxylate ion is monodentate and the α-hydroxy group interacts with the Ln^{III} ions. Nevertheless, this interaction in probably weaker than that observed in the solid state for the manganese(II) and lead(II) species, probably due to a competition with the hydrogen bonding of the water molecules. Indeed, no CD effect was observed for this complex in the case of Pr^{III} ion, indicating that the α-hydroxy group is not tightly bound to the cation. The position of the C^2 carbon atom (and that of the O^2 oxygen atom of



Scheme 2

the α-hydroxy group; see Scheme 2) may be evaluated from the g_1 and g_2 values ($g_1/g_2 \approx 2.7$). We made the assumption of an axial symmetry around the $Ln-O^1$ (acetate) bond, justified by fluxionality (rapid rotation) about this bond and by the fact that the coordination interaction with the carboxylate group is strong, compared to the other possible interactions.

The calculation of θ_1, θ_2, r_1, and r_2 was made by varying the angle θ, according to Scheme 2. The indicated angles and distances were estimated from the crystallographic structure discussed in ref.[26] for lead gluconate after correcting for the differences in the ionic radii of the Pb^{2+} and Pr^{3+} ions. There are two solutions for θ (130° and 210°), but only the second one gives rise to an interaction with the O^2 oxygen atom. The following values are consequently found: $\theta_1 = 10°$, $\theta_2 = 30°$; $r_1 = 3.46$ Å, $r_2 = 4.06$ Å, $r_3 = 3.39$ Å. It can be noted that the $Ln-O^2$ distance (ca. 3.4

Å) is much larger than the Ln−O^1 distance (2.3 Å), but that this weak interaction with the α-hydroxy group probably hinders the bidentate coordination of the carboxylate group and predisposes the OH group to be deprotonated in order to form the ML_2H_{-1} species.

The complexation of the lanthanide cations by hydroxy groups is important for the stability of the complex and it is probably a crucial stage before the deprotonation of these functions leading to an interaction with an alkoxide ion. We have just seen that in the complex ML_2 the complexation occurs via the carboxylate group, but that the cation also interacts with the α-hydroxy group. Previously, we concluded on the basis of CD results[11] that in the complex MLH_{-2} for the system Pr^{3+}/gluconic acid, the complexation occurred via a second deprotonated hydroxy function in addition to the deprotonated α-hydroxy group. Furthermore, this function was probably that in γ-position relative to the carboxylate group. If it is effectively the case, there is probably an interaction between the γ-hydroxy group and the cation, which occurs before the deprotonation of this function. If there is no tertiary alcohol function in γ-position, the complexation would undoubtedly occur via a β-hydroxy group, but it is probably energetically less favourable. In order to prove these assumptions, we studied some hydroxylated carboxylic acid ligands. The formation constants of the complexes ML and ML_2 for gluconic acid, threonic acid, and glyceric acid, which have nearly identical pK_a values, are very similar (practically identical for ML and slightly higher for ML_2 in the case of gluconic acid compared to the two other ligands with a difference of about 0.4 pK units).

It must be noted that all these ligands have a hydroxy function in α-position relative to the carboxylate group. For the two hydroxybutanoic acids the log β values are smaller than for the other ligands, contrary to what is generally observed: in the case of a hard base−hard acid interaction, log β(M + L → ML) usually increases when pK_a increases for ligands having comparable structures. The lower value observed for 2-hydroxybutanoic acid compared to **I**, **II** and **III**, seems to indicate that the OH groups other than those in the α-position also have a (weak) participation in complexation. The 3-hydroxybutanoic acid exhibits a significantly lower log β value because of the lack of an OH group in α-position relative to the carboxylate group. It must also be noted that the two hydroxybutanoic acids do not form MLH_{-1} and MLH_{-2} complexes.

The log β_{11-1} values ($M^{3+} + L^- \leftrightarrow MLH_{-1}^{+} + H^+$) for threonic acid is ca. 0.6 logarithm units lower than that for gluconic acid, indicating a small difference in the complexation strength of the two molecules. For gluconic acid, the γ-OH group plays a role in the complexation of Pr^{3+} in MLH_{-1} (this group deprotonates to form MLH_{-2}). For threonic acid the γ-OH group is not a secondary alcohol function, but a primary alcohol function with a higher acidity constant.

We can consider two possibilities: either the β-OH group intervenes in the complexation of the Pr^{3+} ion, inducing geometrical constraints due to the complexation of two consecutive OH functions (less favourable than those observed with the α- and γ-OH coordinations), or the γ-OH group interacts with the metal ion with a lower strength than in the case of gluconic acid. This second possibility would probably be due to the fact that there is a loss in hydrogen bonding with the solvent water molecules (there are no other OH groups in δ- and ε-positions unlike gluconic acid).

The difference in the complexation behaviour is amplified if we consider the formation of the MLH_{-2} complex: the β_{11-2} value for threonic acid is much lower than that for gluconic acid with a difference in the log β values of 1.8 logarithmic unit. All these remarks seem to prove that the hydroxy group in the γ-position is effectively the second deprotonated hydroxy function in gluconic acid.

Conclusion

This study confirms the view that gluconic acid is a good complexing agent towards the trivalent lanthanide ions. It also shows that the presence of five hydroxy functions in the chain is important for the stability of the complexes, either by their direct intervention in the complexation or by their interaction with solvent molecules in aqueous solutions. Polyhydroxy carboxylic acids with a smaller number of carbon atoms (and consequently of hydroxy functions) are less efficient.

The observation of a relative selectivity of complexation along the lanthanide series allows us to envisage using gluconic acid derivatives as extracting selective agents for lanthanides. For this purpose, hydrophobic derivatives must be synthesized − keeping the complexing ability of this molecule, but with a high solubility in organic solvents − for a use in liquid-liquid extraction. We already reported the preparation of hydrophobic derivatives of tartaric acid, HOOC−CHOH−CHOH−CONHR, where R is a long alkyl chain.[13] The preparation of hydrophobic ligands with a longer hydrophilic chain (with more OH functions) is in progress.

Experimental Section

Materials: Lanthanum, praseodymium, europium, dysprosium, and erbium nitrates (Strem Chem, 99.9%), lutetium perchlorate (Alfa Products, 99.9%), and sodium perchlorate (Fluka, 99%) were used without further purification. The concentration of the lanthanide(III) solutions was determined by a standard procedure using EDTA (Merck). pH-metric titrations were performed with NaOH (Merck or SDS) standard solutions. Potassium D-gluconate (99%), D-glyceric acid hemicalcium salt (≥ 98%), L-threonic acid hemicalcium salt (> 97%), and sodium 2-hydroxybutanoate (> 97%) were Fluka products. Sodium (*R*)-3-hydroxybutanoate (99%) was purchased from Aldrich.

pH-Metric Measurements: The acidity and complex formation constants were determined by pH-metric titrations at 298.0 ± 0.1 K and at an ionic strength I = 0.1 mol·L^{-1} ($NaClO_4$) under argon, using an automatic titration set, including a Metrohm Dosimat 665

autoburette and a Mettler Toledo Inlab 422 type combined glass electrode. The different equilibria were characterized by Equation (1), where M denotes the lanthanide(III) ion and L the ligand in the carboxylate form. Generally, charges were omitted, but they can be easily calculated.

$$pM + qL + rH \rightleftharpoons M_pL_qH_r$$

$$\beta_{pqr} = \frac{[M_p\ L_q\ H_r]}{[M]^p\,[L]^q\,[H]^r} \quad (1)$$

The description of the procedure for data evaluation using the PSEQUAD[27] computer program was described earlier.[28,29] The acidity and complex formation constants were determined, respectively, from four and six to eight independent titrations (about 100 data points per titration). The concentration of the ligands was about $5-8 \times 10^{-3}$ mol·L^{-1} and the ligand/metal (L/M) ratio was varied form 1:1 to 5:1. The pH-metric data between pH = 2 and 11.3 (or between pH = 2 and the pH of precipitation when precipitation occurred in the presence of a metal ion) were used for the evaluation of the acidity and complexation constants. The errors indicated for the complexation constants are those given by the PSEQUAD computer program. It was verified that the use of hemicalcium salts for glyceric and threonic acids had no consequence on the determination of the complexation constants. The acidity constants for compounds in the presence or absence of the calcium(II) ion are nearly identical. For the analysis of the titration curves, the formation of the hydroxo complex MOH^{2+} (MH_{-1}) was taken into consideration with the following values for the formation constant (log β_{10-1}): −9.33, −8.82, −8.58, −8.37, −8.26, and −8.17 for La^{III}, Pr^{III}, Eu^{III}, Dy^{III}, Er^{III}, and Lu^{III}, respectively.[30]

NMR Spectroscopy: ^{1}H and ^{13}C NMR spectra were recorded with a Bruker DRX400 apparatus at 400 and 100.6 MHz, respectively. The gluconic acid concentration, for the shift analysis, was 0.5 mol·L^{-1} and the L/M ratios varied from 10:1 to 250:1. The solvent was a mixture of H_2O/D_2O (80:20, v/v) and the pH was adjusted to 4.0 with NaOH or $HClO_4$. For the determination of the pseudocontact and contact contributions to the chemical shift, the parameters D and $\langle S_z \rangle$ are D = 2.972, −10.682, and −28.545, and $\langle S_z \rangle$ = 10.99, −4.05, and 100 for Pr ^{III}, Eu^{III}, and Dy^{III}, respectively.[22−23,31,32]

Acknowledgments

NMR spectra were recorded with the apparatus of the "Service Commun de RMN" of the University Henri Poincaré-Nancy 1. The authors are grateful to Stephane Parant for his technical assistance.

Photochemical Studies of *cis*(CO),*trans*(Cl)-[Ru(bpy)(CO)$_2$Cl$_2$] (bpy = 2,2′-bipyridine): Ligand Exchange Reactions in Methanol

Esa Eskelinen,[a] Toni-J. J. Kinnunen,[a] Matti Haukka,*[a] and Tapani A. Pakkanen[a]

Keywords: Photochemistry / Ruthenium / Cyclic voltammetry / N ligands / O ligands

The complex *cis*(CO),*trans*(Cl)-[Ru(bpy)(CO)$_2$Cl$_2$] (**1**) (bpy = 2,2′-bipyridine) complex was photoirradiated with visible light in methanol. Light-induced ligand substitution and alcohol coordination was observed under these conditions. The replacement of a carbonyl ligand with methanol is proposed to be the initial reaction step. The reaction product was characterized by NMR spectroscopy and cyclic voltammetry. The substitution of weakly bound alcohol occurred readily in acetonitrile, leading to the formation of more stable [Ru(bpy)(CO)(CH$_3$CN)Cl$_2$]. Extended (24 h) irradiation of *cis*(CO),*trans*(Cl)-[Ru(bpy)(CO)$_2$Cl$_2$] in methanol resulted in the formation of the dinuclear, mixed-valence complex [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl$_3$] (**2**). The structure of **2** consists of two Ru(bpy) moieties, which are linked by two methoxide bridges. These results showed that photoirradiation can be utilized in the synthesis of alkoxide-bridged ruthenium complexes.

Introduction

Alkoxides play an important role in organometallic chemistry owing to the increased need for the oxygenation of non-hydrocarbon ligands. The most straightforward way to synthesize metal alkoxides is the direct reaction of a main-group metal or metal complex with alcohols.[1,2] In the case of transition metals, the preparation of a metal−oxygen single bond is more complicated. The early transition metals tend to form more stable metal alkoxides than the late transition metals. The difference has been rationalized in terms of electronegativity: the more electropositive early transition metals form isolable alkoxo complexes.[2,3] Alkoxides are also hard, basic ligands while the late transition metals (groups 8−10) are seen as soft metals.[3]

In the course of the past ten years, the synthesis and reactions of (alkoxo)rhodium, -iridium, and -osmium complexes have been intensively studied.[4] However, much less attention has been paid to the ruthenium alkoxides, although complexes with the other related oxygen ligands such as aryloxo, or simple hydroxo, are well known.[4] Dinuclear, mixed-valence ruthenium complexes with bridging alkoxo ligands are even less common.[5−7] Mixed-valence complexes are of particular interest because they offer an opportunity to study electron transfer and electron delocalization in a dinuclear system.[8] Although alkoxy-bridged complexes are rare, there are several examples of other bridging ligand systems with mixed ruthenium valences. Probably the most familiar ones are the Creutz−Taube ion ($Ru^{II}Ru^{III}$) and dinuclear μ-oxo-ligated ruthenium complexes ($Ru^{III}Ru^{IV}$).[9]

Photoinduced reactions have been used as a synthetic route to the substituted (bipyridine)ruthenium(II) [Ru^{II}(bpy)] complexes. It is well known that in coordinating solvents such as CH_3CN, the photoirradiation of [Ru(bpy)(CO)$_2$Cl$_2$] leads to the replacement of monodentate ligands with a solvent molecule.[10−13] On the other hand, in weakly coordinating solvents such as CH_2Cl_2, the formation of the dimeric complex [Ru(bpy)(CO)Cl$_2$]$_2$ has been reported.[14] The solvent effects on Ru^{II}(bpy) complexes under UV/Vis irradiation have been studied and the coordination mode has been found to be associated with photoinduced oxidations and reductions.[15,16] It has also been shown that under steady-state irradiation the bipyridyl-based bridges in dinuclear Ru^{II} complexes are broken as a result of the photosolvation of acetonitrile or methanol.[17]

In the present paper we describe the photoirradiation of mono(bpy) complex *cis*(CO),*trans*(Cl)-[Ru(bpy)(CO)$_2$Cl$_2$] (**1**) in methanol. The stepwise reactions were monitored by means of cyclic voltammetry (CV) and spectroscopic methods.

Results and Discussion

Earlier studies[18,19] on the photochemical reactivity of the mono(bipyridine) complex [Ru(bpy)(CO)$_2$Cl$_2$] in a coordinating solvent (acetonitrile) showed that the initial photosubstitution takes place in two steps. In the first step, one

CO ligand is photosubstituted with CH_3CN, leading to the formation of $[Ru(bpy)(CO)(CH_3CN)Cl_2]$. When photoirradiation continues, further substitution occurs and the complex $[Ru(bpy)(CH_3CN)_3Cl]^+$ is formed.[18,19] On the other hand, photoirradiation in a noncoordinating solvent, CH_2Cl_2, is reported to lead to the dichloro-bridged dimer $[Ru(bpy)(CO)Cl_2]_2$ through a five-coordinate intermediate.[14]

Photoirradiation of *cis*(CO),*trans*(Cl)-[Ru(bpy)(CO)$_2$Cl$_2$] (1)

When the photoirradiation of complex **1** was performed in a closed, water-cooled vessel, a photoinduced loss of a carbonyl ligand was observed. During irradiation, the carbonyl ligand was probably replaced with methanol, forming $[Ru(bpy)(CO)(CH_3OH)Cl_2]$. The IR spectrum of the methanol solution of the initial complex **1** contained two strong carbonyl stretching bands at 2065 cm^{-1} and 2005 cm^{-1}. After 2 min of irradiation, a new peak at 1965 cm^{-1} was observed in the IR spectrum. The original CO peak pair disappeared completely after 30 min. The color of the methanol solution of **1** changed from pale yellow to dark orange during irradiation. Simultaneously, the absorption maximum in the visible-region spectra shifted from 340 nm to 492 nm, respectively. The similarities between the previously reported IR and absorption spectra of the *cis*(CO),*trans*(Cl)-$[Ru(bpy)(CO)_2Cl_2]$ irradiated in acetonitrile[19] and the current results in methanol, suggest the simple replacement of a carbonyl ligand by a neutral methanol ligand as the first reaction step.

The irradiation product was isolated as an orange-brown solid, which was dissolved in $[D_6]$DMSO and analyzed with ^{1}H NMR. The spectrum exhibited eight signals in the aromatic region, which are attributable to the two sets of aromatic protons. Such a pattern indicates that there are different ligands in *trans* positions to the bipyridine nitrogen atoms and that a structural rearrangement from *cis*(CO),*trans*(Cl)-$[Ru(bpy)(CO)_2Cl_2]$ to a less symmetrical product has occurred. Furthermore, the ^{1}H NMR spectrum also showed the characteristic peaks of methanol (see Exp. Sect.), indicating coordinated methanol and supporting $[Ru(bpy)(CO)(CH_3OH)Cl_2]$ as the first photoproduct.

The nature of the isolated photoproduct was further studied by dissolving it in strongly coordinating CH_3CN. The solution was then evaporated to dryness and the solid residue dried in a vacuum. The crystals obtained after this procedure were characterized by single-crystal X-ray crystallography. The X-ray analysis showed that the substitution of the MeOH ligand by CH_3CN had occurred, resulting in the formation of $[Ru(bpy)(CO)(CH_3CN)Cl_2]$. In this known structure,[19] the CH_3CN ligand is located in the *trans* position to the chloro ligand, which shows that a geometrical change takes place during the decarbonylation−acetonitrile coordination process.

The ligand replacement from CH_3OH to CH_3CN was also observed in CV studies. A clear, reversible-wave system ($E_{1/2}$ = 0.78 V, ΔE_p = 110 mV) was found with several weaker peak systems. It was found earlier that, after the irradiation of **1** in CH_3CN, a reversible-wave system appears at $E_{1/2}$ = 0.78 V, corresponding to the formation of $[Ru(bpy)(CO)(CH_3CN)Cl_2]$.[19] The ligand electrochemical parameter E_L (Lever parameter)[20] for $[Ru(bpy)(CO)(CH_3CN)Cl_2]$ was also calculated in order to find the most probable Ru^{II}/Ru^{III} potentials. The calculated value for $[Ru(bpy)(CO)(CH_3CN)Cl_2]$ is 0.70 V, which is reasonably close to the observed value. According to the CV data, no change in the oxidation state of the ruthenium metal was observed during the replacement of CH_3OH to CH_3CN. The preservation of the original oxidation state +II further supports the assumption of simple CO replacement by a neutral ligand, i.e., methanol, as the initial reaction step.

Prolonged Photoirradiation (24 h) of 1 and the Formation of [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl$_3$] (2)

The infrared spectrum of the solution after long (24 h) irradiation in a closed, water-cooled reaction vessel showed the loss of the carbonyl peaks. The absorption spectrum of the final solution contained only one absorption maximum, in the visible-light region at 419 nm. The changes in the IR and UV/Vis spectra during the stepwise photoirradiation are shown in Figures 1 and 2.

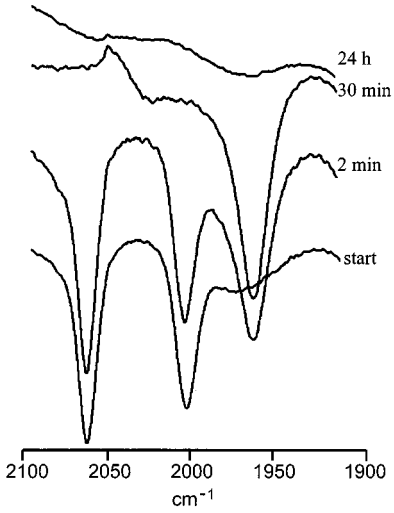

Figure 1. Changes in the ν(CO) region in methanol solution of *cis*(CO),*trans*(Cl)-Ru(bpy)(CO)$_2$Cl$_2$ (**1**) as a function of the photoirradiation time

The evaporation of solvent from the reaction mixture after 24 h of photoirradiation in a closed reaction vessel resulted in the formation of a brownish solid photoproduct, which shows a single carbonyl band at 1941 cm^{-1} in KBr. The same product was obtained in crystalline form by slow evaporation of the methanol in a refrigerator. The structure of this mixed-valence $Ru^{II}Ru^{III}$ dimer, $[\{Ru(bpy)\}_2(\mu\text{-}OMe)_2(CO)Cl_3]$ (**2**), is shown in Figure 3. In **2** the coordination environment surrounding the ruthenium center is octahedral. The Ru−O bond lengths of 2.040(2) Å and 2.087(2) Å are quite similar to the reported distances in the alkoxy-bridged Ru^{II} or Ru^{II}/Ru^{III} complexes in general.[5−8,21] The O−Me bond is slightly bent from the plane determined by Ru−Ru−O. In the closely related compound

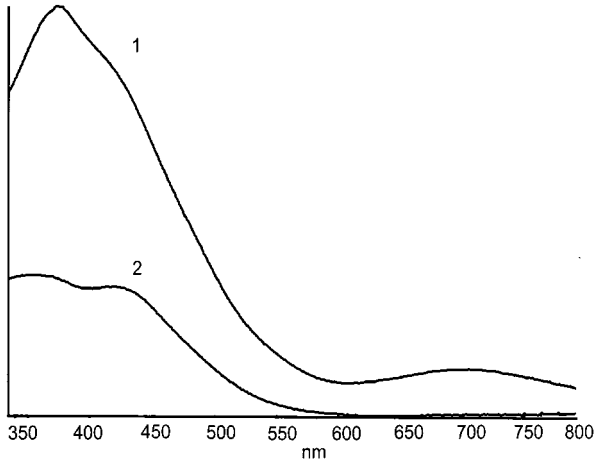

Figure 2. Absorption spectra of complex **1** after photoirradiation in open (1) and closed (2) reaction vessels measured directly from the methanol solutions

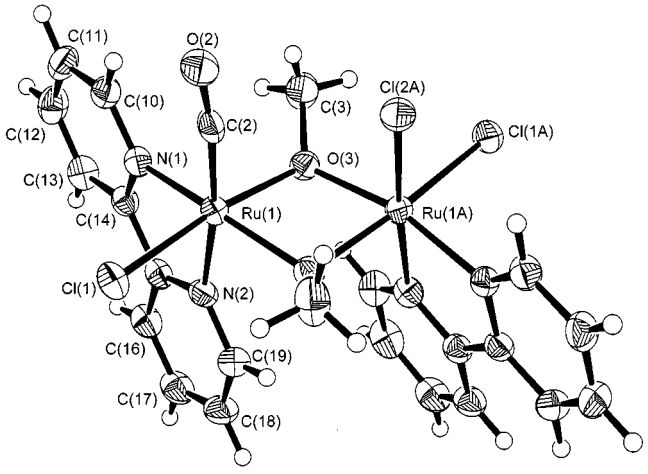

Figure 3. Structure of [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl$_3$]

[{Ru(bpy)$_2$}$_2$(OMe)$_2$](PF$_6$)$_2$ the corresponding Ru−Ru−O−C torsion angles are 167.0° and 169.0°.[21] However, the torsion angles of 137.7° and 138.8° found in complex **2** are comparable with the values found in the Ru^{II} complexes.[8,21]

The photoinduced chloride ligand exchange reactions of [(mono)bipyridine]ruthenium compounds in strongly coordinating solvents with extended irradiation have been reported earlier.[19] The photoinduced ejection of chloride is also required in the case of [Ru(bpy)(CO)(CH$_3$OH)Cl$_2$] to obtain the bimetallic complex [{Ru(bpy)}$_2$(μ-OMe)$_2$-(CO)Cl$_3$]. Figure 3 shows that isomerization has taken place at some point during the photoirradiation. The *trans*(Cl) geometry of the starting complex, [Ru(bpy)(CO)$_2$Cl$_2$], has been converted into the *cis*(Cl) isomer. This change occurs during the initial coordination of methanol, as was concluded in the case of 30 min of irradiation. Moreover, the deprotonation of methanol is needed to build up the methoxy bridges. The origin of this deprotonation process may lie in the photochemical basis, where the reaction intermediate abstracts protons from nucleophilic methanol molecules.

During the formation of the mixed-valence complex **2**, one of the ruthenium centers is oxidized. However, the detailed reaction mechanism for this redox reaction is not clear. The first examples of alkoxy-bridged dinuclear ruthenium(II) complexes were reported by Ward et al. in the 1990s.[8,21] It should be noted that Ward et al. synthesized the [{Ru(bpy)$_2$}$_2$(μ-OMe)$_2$](PF$_6$)$_2$ complex in refluxing methanol using added KOH, while in our case the photoirradiation in MeOH resulted directly in [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl$_3$] without any added hydroxide. The simple photoirradiation in alcohol is thus a convenient way to synthesize dinuclear alkoxy-bridged ruthenium complexes.

It is worth mentioning that the ν(CO) of [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl$_3$] at 1941 cm^{-1} was observed only in the solid samples measured in KBr. In solution, no IR peaks were found after 24 h of irradiation. However, when, after a prolonged irradiation in a closed vessel, the solution was allowed to stand overnight in the dark, a partial recovery of the CO band at 1965 cm^{-1} was observed. This phenomenon must be due to the presence of a labile, completely decarbonylated reaction product in solution. In the dark, the liberated CO is then able to recoordinate and the formation of carbonyl-containing [Ru(bpy)(CO)(CH$_3$OH)Cl$_2$] occurs. Experiments in an open reaction vessel prevented the CO recovery completely, indicating the absence of a recoverable species in solution. When an open system was used during irradiation, the absorption spectrum also gave a different maximum at 711 nm, instead of the 419 nm found in the closed-vessel experiments (Figure 2). In this case, no recovery of CO bands was observed, even after the solution was extensively bubbled with CO for several hours.

Experimental Section

Materials: Methanol (Riedel−de Haën, p.a. grade) was used without further purification. Acetonitrile (J. T. Baker, analytical grade) and tetrabutylammonium perchlorate (TBAP) were used as received. Monomeric *trans*(Cl)-[Ru(bpy)(CO)$_2$Cl$_2$] complex (**1**) (bpy = 2,2′-bipyridine) was prepared by a literature method.[22]

Spectroscopic Studies: The FTIR spectra were measured with a Nicolet Magna 750 spectrometer, ^{1}H NMR spectra with a Bruker AMX 400 (400 MHz) spectrometer in [D$_6$]DMSO, and UV/Vis spectra with a Perkin−Elmer Lambda 900 UV/Vis/NIR spectrometer. The elemental analyses were performed with an EA1110 CHNS-O (Carlo Erba Instruments) analyzer.

Photochemical Instrumentation and Procedure: In the photolysis experiments all of the samples were irradiated using a 450-W Xe discharge lamp (Oriel model 8540, UV light blocked out at 320 nm with a glass filter). The photolysis cell was water-cooled to prevent heating and the vessel was closed with a septum. When necessary, the CO was removed through a needle. The path length of the cell was 3 cm and the distance from the lamp was approximately 20 cm. Irradiation of the sample solutions (30 mg of [Ru(bpy)(CO)$_2$Cl$_2$] in 30 mL of solvent) was performed under air and monitored by the IR and UV/Vis spectra. The total period of irradiation was 24 h.

Electrochemical Instrumentation and Procedure: The CV was performed under argon at room temperature in a three-electrode cell using an Autolab PGSTAT20 potentiostat-galvanostat. The solutions for measurements were prepared by concentrating the photoproduct sample to dryness and dissolving this residue in 0.1 M TBAP/CH_3CN. The sample solutions were purged with argon prior to use. The working electrode was a platinum disk (Metrohm, area 1.28 cm^2), and the counter electrode a glassy carbon disk (Metrohm, area 0.28 cm^2). Potentials were referred to an Ag^+/Ag electrode (0.01 mol/dm^3 $AgNO_3$ in CH_3CN). Under the experimental conditions, the Fc^+/Fc couple potential was 0.01 V. In all of the experiments the potential scan rate was 100 $mV \cdot s^{-1}$. The cyclic voltammograms were mainly recorded in a positive region because in [mono(bpy)]ruthenium complexes the Ru^{II}/Ru^{III} redox reactions typically take place at the positive potentials versus the Ag/Ag^+ reference electrode. At the negative potentials all of the redox peaks were assigned to the bipyridine-based reactions.

Characterization of Complex [Ru(bpy)(CO)(CH_3OH)Cl_2]: FT-IR (CH_3OH): $\tilde{\nu}$ = 1965 cm^{-1} (vs, ν_{CO}). UV/Vis (CH_3OH): λ_{max} = 492 nm. ^1H NMR ([D_6]DMSO): δ = 9.53 (d, 1 6-H), 8.96 (d, 1 6′-H), 8.76 (d, 1 3-H), 8.67 (d, 1 3′-H), 8.38 (t, 1 4-H), 8.16 (t, 1 4′-H), 7.94 (t, 1 5-H), 7.61 (t, 1 5′-H), 4.12 (q, 1 H, CH_3OH), 3.17 (d, 3 H, CH_3OH). Note: satisfactory elemental analysis was not obtained for this complex owing to the small amounts of impurities, which could be seen in the NMR spectra.

Characterization of Complex [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl_3]: FT-IR (KBr): $\tilde{\nu}$ = 1941 cm^{-1} (vs, ν_{CO}). UV/Vis (CH_3OH): λ_{max} = 365 nm. [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl_3]·(CH_3OH) (742.98): calcd. C 38.80, N 7.54, H 3.53; found C 35.68, N 7.18, H 3.47. Note 1: ^1H NMR spectra measured in [D_6]DMSO revealed the different nature of the two aromatic bipyridine ligands and the non-equivalency of four pyridine rings. Note 2: The difference between the calculated and found values in the elemental analyses is due to the varying amounts of solvent or water present in the bulk material even though the sample was carefully dried in a vacuum. The crystal structure was solved with one CH_3OH molecule per [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl_3] unit.

Formation of [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl_3] Crystals, X-ray Data Collection, and Structure Solution for [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl_3]·(CH_3OH): Crystals of [{Ru(bpy)}$_2$(μ-OMe)$_2$(CO)Cl_3] suitable for structural characterization were formed from the photolyzed methanol solution of **1** after slow concentration in a refrigerator. The X-ray diffraction data were collected with a Nonius Kappa CCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å) and the Collect[23] data collection program. The Denzo-Scalepack[24] program package was used for cell refinements and data reduction. The structure was solved by direct methods using the SHELXS97[25] program and the WinGX[26] graphical user interface. The structural refinement was carried out by means of the SHELXL97[27] program. The structure was solved in the orthorhombic space group *Pbcn* and the asymmetric unit consisted of one half-molecule. The carbonyl ligand C(2)−O(2) and chloride Cl(2) were disordered and mixed in two positions with the equal population parameter 0.5. The solvent methanol was disordered around a special position with equal population parameter and was only refined isotropically. As a result of the disorder, the OH hydrogen atom of the solvent molecule was omitted. All of the other hydrogen atoms were placed in idealized positions and constrained to ride on their parent atom. The crystallographic data are summarized in Table 1. Selected bond lengths and angles are shown in Table 2. The molecular structure of the complex is presented in Figure 3. CCDC-168110 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

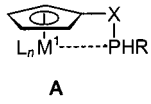
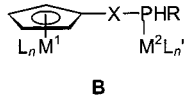
Introduction

Since the first report of a cyclopentadienyl transition metal complex in which the cyclopentadienyl ligand bears a donor-functionalized side chain, by Mathey et al. in 1978,[1] this area has expanded rapidly.[2] While numerous *O*- and *N*-functionalized cyclopentadienyl ligands are known, the number of cyclopentadienes with a *P*-functionalized alkyl or silyl side chain is still small,[1,3] and only recently have we reported the first such compounds in which the P atom has a reactive P−H bond, namely, 1-$SiMe_2PHCy$-2,3,4,5-Me_4C_5H, Li_2[(C_5Me_4)$SiMe_2PR$] [R = Cy, 2,4,6-$Me_3C_6H_2$ (Mes)], Li[(C_5H_4)CMe_2PHR] (R = Ph, *t*Bu) and Li_2[(C_5H_4)CH_2CH_2PPh].[4,5] The molecular structures of [Li(tmeda)]$_2$[(C_5H_4)CMe_2PPh][6] and [Li(tmeda)]-[(C_5H_4)CMe_2PR_2][7] (R = Ph, Me) were also reported. Such compounds are useful precursors for mono- or dianionic bifunctional ligands in transition metal chemistry. Thus, the monoanionic phosphanylalkylcyclopentadienyl ligands can act as chelating ligands towards one metal center (**A**) or they can bridge two (different) metal centers (**B**) (M = metal, $M^1 = M^2$ or $M^1 \neq M^2$, L = ligands, X = spacer (alkylidene, arylidene), R = alkyl, aryl).



A



B

We have recently shown that Li_2[(C_5Me_4)$SiMe_2PR$] (R = Cy, Mes) reacts with $ZrCl_4$ to give [{(η^5-C_5Me_4)$_2SiMe_2$}$ZrCl_2$] and $(PCy)_4$ or $(PHMes)_2$, while Li[(C_5H_4)CMe_2PHR] reacts with $ZrCl_4$ or [$TiCl_3(THF)_3$] to yield [{(η^5-C_5H_4)CMe_2PHR}$_2ZrCl_2$] or [{(η^5-C_5H_4)CMe_2PHR}$_2$TiCl] (R = Ph, *t*Bu).[5] However, these complexes slowly decompose in solution with formation of [{(η^5-C_5H_4)$_2CMe_2$}MCl_2] (M = Zr, Ti).[5] Erker et al. reported that the complexes [{CyPCMe_2(η^5-C_5H_4)}$M(NR_2)_2$] (M = Ti, R = Me; M = Zr, R = Et) are active catalysts for the polymerization of α-olefins.[8]

We now report the synthesis of the novel stable PH-functionalized ferrocene derivatives *rac*-[Fe{(η^5-C_5H_4)-CMe_2PHR}$_2$] [R = Ph (**2**), Mes (**3**)] and the heterotrinuclear complex *rac*-[Fe{(η^5-C_5H_4)$CMe_2PHPh(Cp^*TaCl_4)$}$_2$] (**4**) of type **B**.

Ferrocene derivatives usually show enhanced stability and are generally nontoxic. Thus, their industrial applications range from additives for heating oil to reduce formation of soot, iron-containing fertilizers, UV absorbers and protective coatings for rockets and satellites.[9]

Results and Discussion

Syntheses of Compounds 1−4.

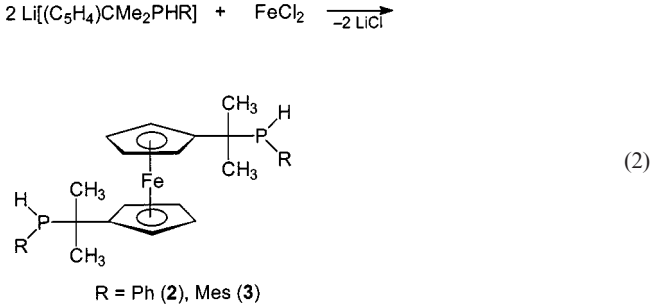
As a general synthetic route to cyclopentadienes with *P*-functionalized side chains, the addition of alkali metal phosphanides to fulvenes has been employed.[3a−3c,4,5] Accordingly, 6,6-dimethylfulvene reacts with LiPHMes in Et_2O at room temperature to give the highly air and water sensitive compound Li[$(C_5H_4)CMe_2PHMes$] (**1**) [Equation (1)].

(1)

1

The ^1H NMR spectrum of **1** indicates that the methyl groups in P−C(Me_2) are prochiral and thus diastereotopic. Therefore, the two nonequivalent Me groups appear as two doublets due to P−H coupling [δ = 1.43 ($^3J_{P-H}$ = 8.8 Hz); δ = 1.41 ($^3J_{P-H}$ = 13.0 Hz)]. However, in the ^{31}P NMR spectrum, the two Me groups are equivalent, and a doublet of septets is observed. As was observed for Li[$(C_5H_4)CMe_2PHR$] (R = Ph,[4] Cy[5]), the signal is shifted to low field by ca. 110 ppm, and the P−H coupling constant increases by ca. 10−15 Hz relative to the primary phosphane [**1**: δ = −45.6 ($^1J_{P-H}$ = 216 Hz); PH_2Mes:[10] δ = −154.8 ($^1J_{P-H}$ = 203 Hz)]. Similarly, the signal of the PH group is shifted to low field in the ^1H NMR spectrum by ca. 0.2−0.9 ppm relative to the phosphane (**1**: δ = 4.36; PH_2Mes:[10] δ = 3.53). Compared with the signals of 6,6-dimethylfulvene (Me: δ = 2.19; C_5H_4: δ = 6.53−5.45),[11] the corresponding signals in **1** are shifted to high field (δ = 1.41, 1.43 and 5.56).

The ferrocene derivatives [Fe{(η^5-C_5H_4)CMe_2PHR}$_2$] [R = Ph (**2**), Mes (**3**)] are obtained in high yield from the lithium reagents Li[$(C_5H_4)CMe_2PHR$] (R = Ph, Mes (**1**)] and $FeCl_2$ in THF at room temperature [Equation (2)].



(2)

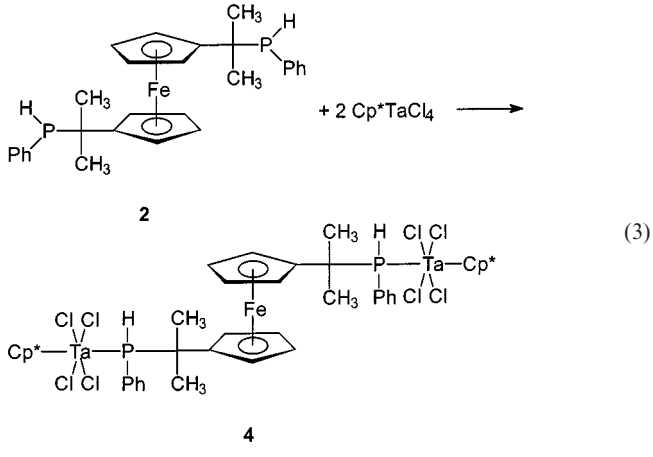
R = Ph (**2**), Mes (**3**)

After workup and repeated recrystallization from *n*-pentane (**2**) or toluene (**3**), the ferrocene derivatives are obtained as orange solids, which are air-stable, at least for a limited period of time. Due to the presence of two chiral phosphanyl groups, two diastereomers can be formed: the racemic form (*R*,*R* and *S*,*S* enantiomer) and the *meso* form (*S*,*R* enantiomer). As bulky substituents are present on the cyclopentadienyl rings, the antiperiplanar conformation is favored (see X-ray crystal structure determinations of **2**−**4** below).

No meaningful ^{31}P NMR spectra of the reaction mixture could be obtained due to the presence of small amounts of $FeCl_2$. However, the ^{31}P NMR spectra recorded for **2** at different stages of workup always indicated the presence of only one diastereomer. Thus, in the $^{31}P\{^1H\}$ NMR spectrum of crystalline **2**, only one signal is observed. However, in the ^{31}P NMR spectrum of **3**, obtained from *n*-hexane, two overlapping doublets of different intensity (ca. 4:1) are observed at δ = −33.4 and −33.9 with P−H coupling constants of 219 and 213 Hz, respectively, even at elevated temperature (340 K); this indicates the formation of both diastereomers, one of which is preferred. Recrystallization from toluene yields the preferred isomer (which was shown to be the *rac* isomer by crystal structure determination) as orange rod-like crystals. The *meso* isomer could not be obtained in pure form.

In the proton-coupled ^{31}P NMR spectrum of **2** and **3**, a doublet of multiplets is observed [**2**: δ = 8.8 ($^1J_{P-H}$ = 207 Hz); **3**: δ = −32.8 ($^1J_{P-H}$ = 214 Hz)], which are shifted to low field by ca. 10−13 ppm relative to Li[$(C_5H_4)CMe_2PHR$] (R = Ph, Mes). The complex coupling pattern in **2** arises from coupling of the protons of the Me and Ph groups. As was already observed for **1**, the ^1H NMR spectra of **2** and **3** indicate that the methyl groups in P−C(Me_2) are prochiral and thus diastereotopic. Thus, the two nonequivalent Me groups appear as two doublets due to P−H coupling [**2**: δ = 1.32 ($^3J_{P-H}$ = 12.0 Hz), 1.38 ($^3J_{P-H}$ = 12.4 Hz); **3**: δ = 1.39 ($^3J_{P-H}$ = 13.0 Hz), 1.45 ($^3J_{P-H}$ = 8.8 Hz)]. These signals and those of the P−H group are only slightly shifted relative to those of the lithium reagents, while a shift to high-field of ca. 1.8 ppm is observed for the C−H protons of the cyclopentadienyl rings.

At room temperature, the *ortho*-Me groups of the mesityl ring in **3** give a broad signal at δ = 2.27 in the ^1H NMR



2

(3)

4

spectrum, indicating that rotation around the P−C(mesityl) bond is hindered. At 340 K, only one sharp signal is observed for the Me groups, while below 263 K two separate signals are observed. From the coalescence temperature [T_c = 291(2) K] the activation enthalpy ($\Delta G^{\#}$ = 56 ± 1 kJ/mol)[12] was determined by using the Eyring equa-

tion.[13] Compound **2** reacts with [Cp*$TaCl_4$] in toluene at room temperature to give the heterotrinuclear complex *rac*-[Fe{(η^5-C_5H_4)CMe_2PHPh(Cp*$TaCl_4$)}$_2$] (**4**) [Equation (3)].

The trinuclear complex **4** is unstable in solution at room temperature. When brown crystals of **4** are dissolved in benzene or toluene at room temperature, a white precipitate forms after only a few minutes. Thus, for the NMR spectroscopic studies the crystals were cooled to −195 °C in an NMR tube and the solvent ([D_8]toluene or [D_6]benzene) was added at this temperature. The sample was warmed to ca. −50 °C prior to the NMR spectroscopic studies.

At −50 °C, two doublets are observed in the ^{31}P NMR spectrum at δ = 8.5 and 57.6 (ratio ca. 1:2), which collapse into one broad singlet at room temperature (δ = 33.7). Recrystallization from dichloromethane and toluene yielded small brown crystals suitable for crystal structure determination, which showed this to be the *rac* isomer.

Molecular Structures of 2−4

The ferrocene derivatives crystallize in the centrosymmetric monoclinic space group no. 14 [$P2_1/n$ (**2**, **3**) and $P2_1/c$ (**4**)]. For **2**, two molecules are present in the unit cell, while for **3** and **4**, four molecules are present.

In all three complexes, the substituted cyclopentadienyl rings adopt an antiperiplanar conformation, as expected for bulky substituents (see Table 1 for bond lengths and angles). An antiperiplanar conformation was also observed for [Fe{(η^5-C_5H_4)CH_2PPh_2}$_2$].[14]

In **2**, the Ph and cyclopentadienyl rings are almost coplanar [angle between plane of Ph ring and cyclopentadienyl ring 6.0(3)°]. The Fe atom is located on a crystallographic center of inversion. As the P−H proton is disordered over two positions (Figure 1), the configuration of the phosphanyl group could not be determined.

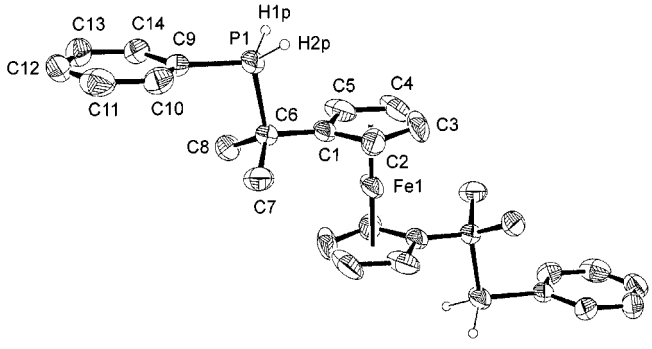

Figure 1. Molecular structure of *rac*-[Fe{(C_5H_4)CMe_2PHPh}$_2$] (**2**) showing the atom numbering scheme employed (ORTEP plot, 50% probability, SHELXTL PLUS; XP[23]); hydrogen atoms (other than P−H) are omitted for clarity; the P−H proton is disordered

In **3** (Figure 2) and **4** (Figure 3), the PH protons were located in the difference Fourier synthesis and refined isotropically. Only the *rac* isomer is present in the unit cell. As **4** is derived from **2**, in which the configuration could not be determined, the presence of the *rac* isomer can be deduced for **2**, too.

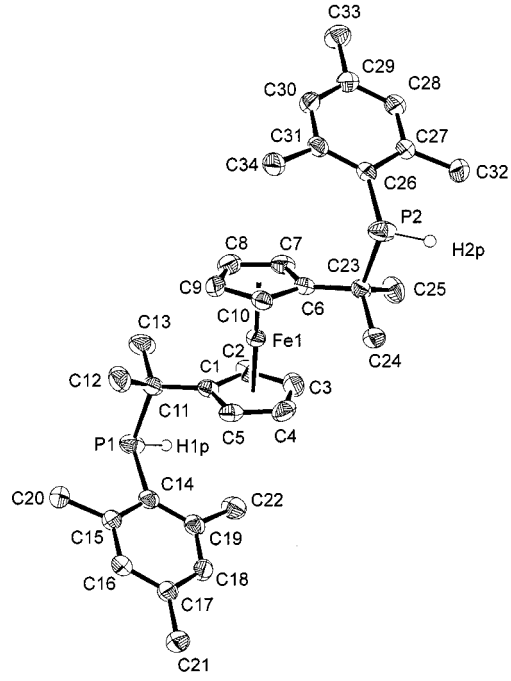

Figure 2. Molecular structure of *rac*-[Fe{(C_5H_4)CMe_2PHMes}$_2$] (**3**) showing the atom numbering scheme employed (ORTEP plot, 50% probability, SHELXTL PLUS; XP[23]); hydrogen atoms (other than P−H) are omitted for clarity; only the *R*,*R* isomer is shown.

In **3** and **4**, the aryl rings and the cyclopentadienyl rings adopt an angle of 31.2(1)° and 34.1(1)° (**3**) or 31.4(2)° and 33.3(2)° (**4**). In **4**, the Ta−P bond lengths of 2.758(1) and 2.798(1) Å are longer than those in the phosphane complex [Cp*$TaCl_4$(PH_2Ph)] [2.651(3) Å].[15] Apparently, replacement of the small H substituent by the bulky (C_5H_4)CMe_2 substituent at the P atom weakens the Ta−P bond. In **4**, the Ta atom is located 0.573(1) Å above the plane formed by the four Cl atoms. This distance is similar to that in [Cp*$TaCl_4$(PH_2Ph)] [0.602(2) Å] and smaller than that observed for [Cp*$TaCl_4$] [0.806(2) Å],[15] due to the higher steric demand of the phosphane ligands in [Cp*$TaCl_4$(PH_2Ph)] and **4**. Only one other trinuclear bis(phosphanylmethyl)ferrocene complex, namely [Fe{(η^5-C_5H_4)CH_2PPh_2[$RuCl_2$(η^6-1,2,3,4-Me_4C_6)]}$_2$], has been structurally characterized.[16,17]

The Fe−C bond lengths of 2.04−2.08 Å and the distance Fe−Cp^R_{center} of ca. 1.65−1.67 Å in **2**−**4** are in good agreement with those of related ferrocene derivatives.[14,16−19]

We are now extending these synthetic approaches to other cyclopentadienes with *P*-functionalized side chains and investigating their coordination properties towards other transition metals and main group metals.

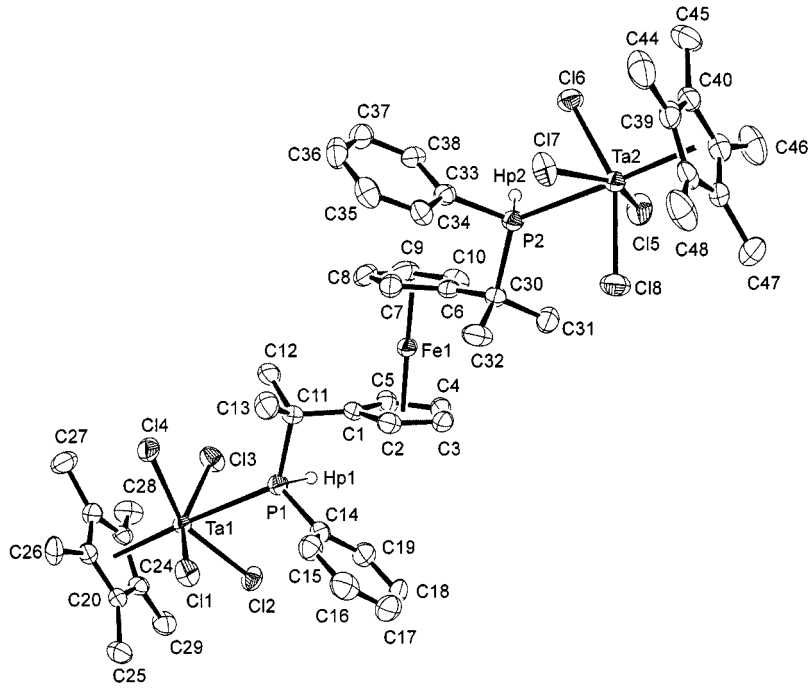

Figure 3. Molecular structure of *rac*-[Fe{(C_5H_4)CMe_2PHPh(Cp*$TaCl_4$)}$_2$] (**4**) showing the atom numbering scheme employed (ORTEP plot, 50% probability, SHELXTL PLUS; XP[23]); hydrogen atoms (other than P−H) are omitted for clarity; only the *S*,*S* isomer is shown

Experimental Section

General: All experiments were carried out under purified dry argon. Solvents were dried and freshly distilled under argon. The NMR spectra were recorded with an AVANCE DRX 400 spectrometer (Bruker), ^{1}H NMR (400 MHz): internal standard solvent, external standard TMS. ^{13}C NMR (100.6 MHz): external standard TMS, internal standard solvent. ^{31}P NMR (162 MHz): external standard 85% H_3PO_4. The IR spectra were recorded on an FT-IR spectrometer Perkin−Elmer System 2000 in the range 350−4000 cm^{-1}. MS: MAT 212 (Varian). The melting points were determined in sealed capillaries under argon and are uncorrected. 6,6-dimethylfulvene,[11] LiPHMes,[20] Li[(C_5H_4)CMe_2PHPh][4] and [Cp*$TaCl_4$][21] were prepared according to the literature procedures. $FeCl_2$ is commercially available (Aldrich).

Synthesis of Li[(C_5H_4)CMe_2PHMes] (1): 6,6-Dimethylfulvene (0.8 mL, 6.7 mmol) was added slowly in 0.1 mL portions to an orange suspension of LiPHMes (1.1 g, 6.7 mmol) in Et_2O (30 mL), and the resulting pale yellow reaction mixture stirred for 12 h. The resulting solid was isolated by filtration and washed twice with ca. 20 mL Et_2O, then twice with ca. 20 mL *n*-hexane and dried under vacuum to yield **1** as a white powder (1.4 g, 63%). M.p. 220 °C (dec.). ^{1}H NMR ([D$_8$]THF): δ = 1.41 (d, $^3J_{P-H}$ = 13.0 Hz, 3 H, CH_3 in CMe_2), 1.43 (d, $^3J_{P-H}$ = 8.8 Hz, 3 H, CH_3 in CMe_2), 2.19 (s, 3 H, *p*-CH_3 in Mes), 2.26 (s, 6 H, *o*-CH_3 in Mes), 4.36 (d, $^1J_{P-H}$ = 215.6 Hz, 1 H, PH), 5.56 (s, 4 H, CH in C_5H_4), 6.78 (s, 2 H, *m*-CH in Mes). ^{13}C NMR ([D$_8$]THF): δ = 21.0 (s, 1C, *p*-CH_3 in Mes), 23.9 (m, 2C, *o*-CH_3 in Mes), 30.4 (d, $^2J_{P-C}$ = 17.8 Hz, 1C, CH_3-C), 31.5 (d, $^2J_{P-C}$ = 9.7 Hz, 1C, CH_3−C), 37.2 (d, $^1J_{P-C}$ = 12.5 Hz, 1C, C−CH_3), 101.7 (d, $^3J_{P-C}$ = 3.5 Hz, 2C, C2, C5 in C_5H_4), 102.7 (s, 2C, C3, C4 in C_5H_4), 127.1 (d, $^2J_{P-C}$ = 9.6 Hz, 1C, C1 in C_5H_4), 129.1 (d, $^3J_{P-C}$ = 2.5 Hz, 2C, *m*-C in Mes), 132.6 (d, $^1J_{P-C}$ = 29.1 Hz, 1C, *ipso*-C in Mes), 137.3 (s, 1C, *p*-C in Mes), 143.8 (s, 2C, br, *o*-C in Mes). ^{31}P NMR ([D$_8$]THF): δ = −45.6 (d of m, $^1J_{P-H}$ = 216 Hz). IR (KBr): $\tilde{\nu}$ = 2337 (νPH, m), 1463 (νC=C m, br) cm^{-1}.

Synthesis of *rac*-[Fe{(η^5-C_5H_4)CMe_2PHPh}$_2$] (2): A solution of Li[(C_5H_4)CMe_2PHPh] (3.5 g, 15.6 mmol) in THF (30 mL) was slowly added to a suspension of $FeCl_2$ (1.0 g, 7.8 mmol) in THF. During the addition, $FeCl_2$ slowly dissolved, and the initially pale pink solution turned first yellow and finally red-brown. The solution was stirred for 16 h. The solvent was then evaporated under vacuum and the brown residue treated with Et_2O. The rust-brown powder was separated from the yellow solution by filtration and extracted repeatedly with Et_2O. The Et_2O fractions were combined and the solvent was evaporated under vacuum. The yellow residue was recrystallized repeatedly from *n*-hexane or *n*-pentane. At −20 °C orange needles of **2** were obtained. Yield: 2.2 g (59%), m.p. 97−100 °C (from *n*-pentane). ^{1}H NMR (C_6D_6): δ = 1.32 (d, $^3J_{P-H}$ = 12.0 Hz, 3 H, CH_3 in CMe_2), 1.38 (d, $^3J_{P-H}$ = 12.4 Hz, 3 H, CH_3 in CMe_2), 3.75−3.61 (m, 2 H, CH in C_5H_4), 3.95−3.91 (m, 2 H, CH in C_5H_4), 4.08 (d, $^1J_{P-H}$ = 206.7 Hz, 1 H, PH), 7.05 (m, 3 H, *o*- and *p*-CH in Ph), 7.16 (m, 2 H, *m*-CH in Ph). ^{13}C NMR (C_6D_6): δ = 28.4 (d, $^2J_{P-C}$ = 16.3 Hz, 1C, CH_3−C), 28.9 (d, $^2J_{P-C}$ = 16.0 Hz, 1C, CH_3−C), 33.6 (d, $^1J_{P-C}$ = 12.6 Hz, 1C, C−CH_3), 66.6 (s, 1C, C4 in C_5H_4), 67.1 (s, 1C, C3 in C_5H_4), 68.3 (d, $^3J_{P-C}$ = 21.0 Hz, 2C, C2, C5 in C_5H_4), 99.6 (d, $^2J_{P-C}$ = 7.2 Hz, 1C, C1 in C_5H_4), 126.6 (s, 1C, *p*-C in Ph), 129.3 (d, $^3J_{P-C}$ = 5.6 Hz, 2C, *m*-C in Ph), 135.5 (d, $^1J_{P-C}$ = 17.8 Hz, 1C, *ipso*-C in Ph), 137.0 (d, $^2J_{P-C}$ = 15.5 Hz, 2C, *p*-C in Ph). ^{31}P NMR (C_6D_6): δ = 8.8 (d of m, $^1J_{P-H}$ = 207 Hz). IR (KBr): $\tilde{\nu}$ = 2283 (νPH, m), 1463 and 1432 (νC=C, Ph, m), 741 and 697 (δC=C, Ph, st) cm^{-1}. EI MS: *m*/*z* (%) = 486 (15) [M$^+$], 377 (10) [M$^+$ − PHPh], 266 (100) [M$^+$ − 2 PHPh], 226 (5) [M$^+$ − 2 PHPh − CMe_2], and fragmentation products thereof. $C_{28}H_{32}FeP_2$ (486.3): calcd. C 69.1, H 6.6, P 12.7; found C 68.7, H 6.3, P 12.1.

Synthesis of *rac*-[Fe{(η^5-C_5H_4)CMe_2PHMes}$_2$] (3): A solution of Li[(C_5H_4)CMe_2PHMes] (1.6 g, 6.0 mmol) in THF (20 mL) was

slowly added to a suspension of $FeCl_2$ (0.4 g, 3.0 mmol) in THF (30 mL). During the addition, $FeCl_2$ slowly dissolved, and the initially pale pink solution turned first yellow and finally red-brown. The solution was stirred for 16 h. Then the solvent was evaporated under vacuum, and the brown residue treated with Et_2O (20 mL). The insoluble rust-brown powder was separated from the orange solution by filtration and extracted repeatedly with Et_2O. The Et_2O fractions were combined and the solvent was evaporated under vacuum. The yellow residue was recrystallized repeatedly from *n*-hexane, *n*-pentane or toluene. At −20 °C yellow platelets (from hexane) or orange rod-like crystals (from toluene) of **3** were obtained. Yield: 0.9 g (55%), m.p. 162 °C (from toluene). ^{1}H NMR (C_6D_6): δ = 1.39 (d, $^3J_{P-H}$ = 13.0 Hz, 3 H, CH_3 in CMe_2), 1.45 (d, $^3J_{P-H}$ = 8.8 Hz, 3 H, CH_3 in CMe_2), 2.08 (s, 3 H, *p*-CH_3 in Mes), 2.27 (br. s, 6 H, *o*-CH_3 in Mes), 3.87−3.60 (m, 4 H, CH in C_5H_4), 4.4 (d, $^1J_{P-H}$ = 216.1 Hz, 1 H, PH), 6.76 (s, 2 H, *m*-H in Mes). ^{13}C NMR (C_6D_6): δ = 21.7 (s, 1C, *p*-CH_3 in Mes), 24.8 (br. s, 2C, *o*-CH_3 in Mes), 29.3 (br. s, 1C, *C*H_3−C), 29.6 (br, 1C, *C*H_3−C), 35.7 (d, $^1J_{P-C}$ = 15.2 Hz, 1C, *C*−CH_3), 66.8 (s, 1C, C3 in C_5H_4), 67.3 (s, 1C, C4 in C_5H_4), 68.5 (d, $^3J_{P-C}$ = 12.2 Hz, 2C, C2, C5 in C_5H_4), 127.1 (d, $^2J_{P-C}$ = 9.6 Hz, 1C, C1 in C_5H_4), 129.1 (d, $^3J_{P-C}$ = 2.5 Hz, 2C, *m*-C in Mes), 132.6 (d, $^1J_{P-C}$ = 29.1 Hz, 1C, *ipso*-C in Mes), 137.3 (s, 1C, *p*-C im Mes), 143.8 (s, 2C, br, *o*-C in Mes). ^{31}P NMR (C_6D_6): δ = −32.8 (d of m, $^1J_{P-H}$ = 214 Hz). IR (KBr): $\tilde{\nu}$ = 2345 and 2310 (νPH, m) cm^{-1}. EI MS: *m*/*z* (%) = 570 (10) [M$^+$], 418 (8) [M$^+$ − PHMes], 313 (5) [M$^+$ − $C_5H_4CMe_2PHMes$], 266 (100) [M$^+$ − 2 PHMes], and fragmentation products thereof. $C_{34}H_{44}FeP_2$ (570.5): calcd. C 71.6, H 7.8, P 10.9; found C 71.1, H 8.3, P 10.3.

Synthesis of *rac*-[Fe{(η^5-C_5H_4)CMe_2PHPh(Cp*$TaCl_4$)}$_2$] (4): A solution of **2** (0.7 g, 1.4 mmol) in toluene (15 mL) was added dropwise to a suspension of [Cp*$TaCl_4$] (1.3 g, 2.8 mmol) in toluene (30 mL). The color of the reaction mixture changed from orange to brown. The mixture was then heated to 70 °C for 2 h, allowed to cool, and stirred at room temperature overnight. The solid was separated from the solution by filtration. Cooling to −20 °C gave unconverted [Cp*$TaCl_4$], which was also separated by filtration. The solvent was evaporated under vacuum, and the resulting brown residue was extracted with CH_2Cl_2. The dichloromethane solution was concentrated. Cooling to −20 °C gave a fine brown solid, which was recrystallized repeatedly from toluene. Finally, small brown crystals were obtained together with a brown powder. Yield: 0.9 g (45%), m.p. 162−167 °C (from toluene). ^{1}H NMR ([D$_8$]toluene): δ = 1.65 (d, $^3J_{P-H}$ = 12.0 Hz, 6 H, CH_3 in CMe_2), 2.24 (s, 30 H, CH_3 in Cp*), 3.49 (m, 4 H, CH in C_5H_4), 3.75 (m, 2 H, CH in C_5H_4), 4.32 (m, 2 H, CH in C_5H_4), 6.97−7.01 (m, 10 H, C*H* in Ph). ^{13}C NMR ([D$_8$]toluene and C_6D_6): δ = 13.7 (s, CH_3 in Cp*), 27.4 [br. s, C(*C*H_3)], 27.6 (br. s, C(*C*H_3)], 37.8 [s, *C*(CH_3)], 54 (br. s, ?), 67.2 (s, C3 and C4 in C_5H_4), 68.6 (s, C2 and C5 in C_5H_4), 100.4 (br., C1 in C_5H_4), 128.9 (s, *C*−CH_3 in Cp*), 129.7 (s, *m*-C in Ph), 133.9 (s, *ipso*-C in Ph), 137.3 (s, *o*-C in Ph); *p*-C in phenyl obscured by solvent. ^{31}P NMR ([D$_8$]toluene): T = 230 K: δ = 57.6 (d, $^1J_{P-H}$ = 364 Hz), 8.5 (d, $^1J_{P-H}$ = 204 Hz); T = 300 K: δ = 33.6 (br). IR (KBr): $\tilde{\nu}$ = 2965 (CH_3, m), 2286 (PH, m), 1463 and 1435 (C=C Ph, m), 742 and 697 (C=C Ph, st) cm^{-1}.

Data Collection and Structural Refinement of 2, 3, and 4: Data (Mo-K_α = 0.71073 Å) were collected with a Siemens CCD (SMART) diffractometer. All observed reflections were used for refinement (SAINT) of the unit cell parameters. Empirical absorption correction with SADABS.[22] The structures were solved by direct methods (SHELXTL PLUS).[23] Fe, Ta, P, Cl, and C atoms were refined anisotropically; H atoms were located by difference maps and refined isotropically. Table 2 lists crystallographic details.

Titanium Complexes Containing Bulky η^2-1,2,4-Triazolato Ligands

Nadia C. Mösch-Zanetti,*[a] Manuel Hewitt,[a] Thomas R. Schneider,[a] and Jörg Magull[a]

Keywords: N ligands / Titanium / Structure elucidation

The unusual η^2-coordination of a 1,2,4-triazolato ligand to a transition metal is described. The synthesized compounds $[Ti(\eta^2\text{-tz})_4]$ (**1**), $[(C_5Me_4CH_2Ph)Ti(\eta^2\text{-tz})Cl_2]$ (**2**), $[Cp^*Ti(\eta^2\text{-tz})Cl_2]$ (**3**) and $[Cp^*Ti(\eta^2\text{-tz})_3]$ (**4**) (tzH = 3,5-diisopropyl-1,2,4-triazole) were characterized by ^1H and ^{13}C NMR spectroscopy and, in the case of **1** and **2**, by X-ray crystallography. Both structures confirm the η^2-coordination of the ligand. In compound **1** all four ligands coordinate in an η^2 fashion leading to a metal center surrounded by eight nitrogen atoms. The core of the fragment formed by the central atom and the triazolato planes exhibits a distorted D_{2d} symmetry. A variable temperature NMR spectroscopy experiment performed on **1** confirms the occurrence of two different isopropyl groups at low temperature. The structure of compound **2** shows the geometry of the molecule in a distorted C_s symmetry, with the mirror plane perpendicular to the cyclopentadienyl and triazolato rings. The tz ligand is oriented in a *transoid* position relative to the benzyl substituent of the $C_5Me_4CH_2Ph$ group.

Introduction

Pyrazoles and triazoles represent a class of molecules with ideal ligand properties that allow a wide variety of structures and bonding options.[1−4] The preparation of the parent heterocycle is in most cases achieved by straightforward organic reactions, enabling easy tuning of the substituents attached to the five-membered ring.[5,6] In addition, they may act as neutral or monoanionic ligands. All these factors explain their extensive use in coordination chemistry. The most common bonding modes in these complexes are η^1, bridging between two metal atoms in a μ_2-η^1:η^1 fashion, or a μ_3-η^1:η^1:η^1 fashion for triazolato ligands. However, many different bonding modes have been found in recent years.[4,7−9] With pyrazolato ligands, an η^2-coordination has been found in complexes of f-block[10−15] and, quite unexpectedly, d-block metals[16−22] as well as with main group elements.[23−27] However, with triazolato ligands only one crystallographically established η^2-coordination has been reported, namely in a benzo-1,2,3-triazolato potassium salt, where an η^2-interaction was found in the solid-state structure.[28] No example of an η^2-1,2,4-triazolato ligand has been described as yet.[29]

Herein, we present a series of compounds that contain the unusual η^2-coordination of a 1,2,4-triazolato ligand. The complexes $[Ti(\eta^2\text{-tz})_4]$ (**1**), $[(C_5Me_4CH_2Ph)Ti(\eta^2\text{-tz})Cl_2]$ (**2**), $[Cp^*Ti(\eta^2\text{-tz})Cl_2]$ (**3**) and $[Cp^*Ti(\eta^2\text{-tz})_3]$ (**4**) (tz = 3,5-diisopropyl-1,2,4-triazolato) have been synthesized by the appropriate metathesis reaction and characterized by NMR spectroscopy, mass spectrometry and elemental analysis. In addition, the solid state structures of **1** and **2** were determined by X-ray crystallography.

Results and Discussion

Preparation of Titanium Compounds

The requirements for an ideal ligand system for high oxidation state early transition metals are steric bulk, to avoid oligomerization, and/or electron donating properties to stabilize the electrophilic metal center. Sterically demanding alkyl groups seem to meet those premises. We recently described the synthesis of a triazole ligand bearing bulky isopropyl groups in the 3,5-positions.[30]

The reaction of tetrakis(dimethylamido)titanium(IV) with four equivalents of tzH in toluene at room temperature gave $[Ti(\eta^2\text{-tz})_4]$ (**1**), isolated as yellow crystals from hexane in good yield [Equation (1)].

$$[Ti(NMe_2)_4] + 4\ tzH \xrightarrow[-\,4\ NHMe_2]{toluene} [Ti(\eta^2\text{-tz})_4] \quad \mathbf{1}\ (68\ \%) \qquad (1)$$

The reaction is fast, as the formation of $HNMe_2$ was immediately apparent. The compound is highly soluble in hydrocarbon solvents, and thus had to be crystallized from concentrated solutions at low temperatures. The highest peak in the mass spectrum was assignable to the monomeric molecular ion. This is consistent with the solid-state structure determined by X-ray crystallography (vide infra).

The ^1H and ^{13}C NMR spectra at room temperature each exhibit one set of signals, indicating a highly symmetric coordination of the ligands. However, a variable temperature ^1H NMR spectroscopy experiment shows the signals to split into two sets with a coalescence temperature of approx. 200 K, pointing to an asymmetric coordination of the ligands at low temperature (Figure 1).

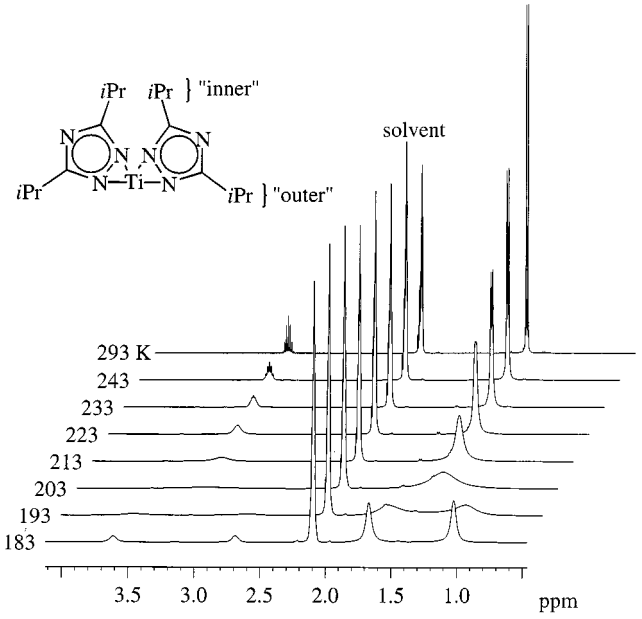

Figure 1. VT NMR spectra of **1** in [D_8]toluene; a fragment of **1** consisting of two coplanar triazolato ligands shows the two types of isopropyl groups

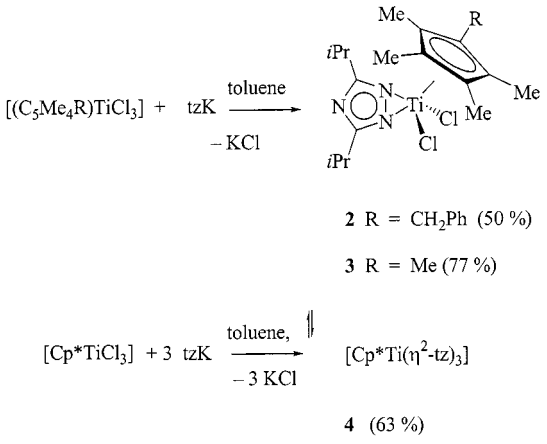
The spectrum at 183 K shows two relatively broad signals for six protons each (δ = 1.02 and 1.67) and two signals for one proton each (δ = 2.69 and 3.61) for two different isopropyl groups. A COSY NMR spectrum at 183 K reveals cross-peaks between the methyl signal at δ = 1.02 and the CH signal at δ = 2.69, while the resonance at δ = 1.67 has a cross-peak with that at δ = 3.61. The temperature could not be decreased further due to freezing of the solvent (toluene) thereby presumably preventing sharper signals that show the expected doublets and septuplets. With increasing temperature the structure apparently becomes more dynamic so that the room temperature spectrum shows only one averaged set of signals. The low-temperature spectrum is consistent with the solid-state structure determined by X-ray crystallography at 133 K, which shows two triazolato rings almost coplanar to each other, with the other two perpendicular to them. Two of the four nitrogen atoms coordinated to Ti in one plane form a large N−Ti−N angle [e.g. 169.25(6)° for N1−Ti1−N7], whereas the other two form a small one [e.g. 92.77(6)° N2−Ti1−N8]. This coordination leads to magnetically nonequivalent "inner" and "outer" isopropyl groups, which give rise to the two sets of signals.

The reaction of [($C_5Me_4CH_2Ph$)$TiCl_3$] and [Cp*$TiCl_3$], respectively, with one equivalent of tzK in toluene at room temperature afforded the complexes [($C_5Me_4CH_2Ph$)Ti(η^2-tz)Cl_2] (**2**) and [Cp*Ti(η^2-tz)Cl_2] (**3**) as red crystalline materials in medium to good yields (Scheme 1). The ^1H and ^{13}C NMR spectra show the coordination of one triazolato ligand in a symmetric fashion. The occurrence of an η^2-coordinated ligand was confirmed by the X-ray crystal structure analysis of **2** (vide infra). In the mass spectrum, the molecular ion could be detected indicating a thermal stability of the species.



Scheme 1

The analogous Cp derivative [CpTi(η^2-tz)Cl_2] can be formed by the same reaction procedure as above, producing orange crystals. The X-ray crystal structure determination confirms the connectivity as well as the η^2-coordination of the triazolato ligand, although the insufficient quality of the structural analysis due to disorder and twinning problems prevents the discussion of bond lengths and angles. These are general problems in these mixed Cp/tz as well as Cp*/tz systems, as several attempts with different crystals did not improve the structures. The combination of the steric properties of the two ligands seems to lead to disordered and twinned structures that can only be avoided by the substitution of a methyl by a benzyl group at the Cp* ring. The behavior of [CpTi(η^2-tz)Cl_2] in solution is unclear. NMR spectra of crystalline material in C_6D_6 show several signals in the Cp and isopropyl group region pointing to an instability in solution. Presumably the steric protection provided by the Cp group and the isopropyl groups is not large enough, giving rise to oligomeric structures in solution.

The treatment of [Cp*$TiCl_3$] with three equivalents of tzK in refluxing toluene for 2 h afforded the orange compound [Cp*Ti(η^2-tz)$_3$] (**4**) in high yield as shown in Scheme 1. NMR spectroscopic data as well as an attempted X-ray crystal structure analysis are consistent with the formation of a compound that contains three η^2-coordinated triazolato ligands. The addition of only two equivalents of tzK to [Cp*$TiCl_3$] gave mixtures of **3** and **4**, but no evidence was found for the formation of the monochloride species [Cp*Ti(η^2-tz)$_2$Cl] either by NMR spectroscopy or mass spectrometry.

Structural Studies

X-ray crystallography on a single crystal of **1** confirms a monomeric species with a titanium atom in a distorted

tetrahedral environment, assuming the triazolato ligands occupy only one coordination site. All four ligands coordinate in an η^2 fashion, leading to a metal center surrounded by eight nitrogen atoms. Figure 2 shows an ORTEP view of **1**; crystallographic data are given in Table 1 and selected bond lengths and angles in Table 2.

Table 2. Selected bond lengths (Å) and angles (°) for **1**

Ti1−N1	2.1289(16)	Ti1−N2	2.0338(15)
Ti1−N4	2.0284(15)	Ti1−N5	2.0816(16)
Ti1−N7	2.1285(16)	Ti1−N8	2.0151(16)
Ti1−N10	2.1019(16)	Ti1−N11	2.0591(16)
N1−Ti1−N2	38.73(6)	N1−Ti1−N7	169.25(6)
N2−Ti1−N8	92.77(6)	N1−Ti−N5	86.41(6)
N1−Ti−N10	91.87(6)	N4−Ti1−N5	39.43(6)

The triazolato rings can be grouped approximately into two, almost orthogonal planes. The average planarity in each group is satisfied within a few degrees, as evidenced by, for example, the torsion angles of 174.07(1)° (N1−N2−Ti1−N8) and 175.79(1)° (N5−N4−Ti1−N10). Whereas the core of the fragment formed by the central atom and the triazolato planes exhibits a symmetry close to D_{2d}, the steric hindrance between adjacent isopropyl groups leads to a deviation from the perfect arrangement. The eight coordinated nitrogen atoms may be considered as forming two tetrahedra, a very flattened, almost planar one, [N5−Ti1−N10 = 172.56(6)° and N1−Ti1−N7 = 169.25(6)] and another elongated one [N2−Ti1−N8 = 92.77(6) and N4−Ti1−N11 = 94.83(6)]. The bond lengths in the former tetrahedron are longer than in the latter by approx. 0.1 Å. The most interesting features of the structure are the three-membered TiN_2 metallacycles, with Ti−N bond lengths between 2.0151(16) and 2.1289(16) Å and N−Ti−N angles between 38.73(6)° and 39.43(6)°. Comparison of the structure of **1** with that of the η^2-pyrazolato species [Ti(η^2-3,5-Me_2pz)$_4$] employing a less bulky ligand, recently described by Winter and co-workers, reveals a similar geometry.[17] Apparently, steric hindrance seems not to be a prerequisite for the formation of the homoleptic species, whereas bulky substituents are important for the stability of the compounds **2**−**4**. Other titanium complexes with three-membered TiN_2 rings contain η^2-diazenido,[31] -diazo[32] or -hydrazido[33,34] ligands. Whereas the η^2-diazenido and -diazo ligands show similar structural features to those of **1**, the latter ones are slightly different in that the Ti−N bond lengths in η^2-hydrazido complexes differ by approx. 0.3 Å leading to a distinct tilting of the ligand.

The X-ray diffraction study of **2** confirms the η^2-coordination of the triazolato ligand. An ORTEP diagram is shown in Figure 3 and selected bond lengths and angles in

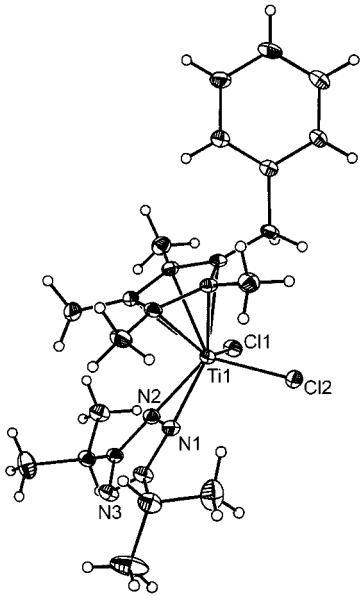

Figure 3. ORTEP view of **2** (thermal ellipsoids at the 50% probability level)

Table 3. Selected bond lengths (Å) and angles (°) for **2**

Ti1−N1	2.055(3)	Ti1−N2	2.061(3)
Ti1−Cl1	2.295(1)	Ti1−Cl2	2.284(1)
Ti1−C9	2.352(3)	Ti1−C10	2.357(4)
Ti1−C11	2.370(4)	Ti1−C12	2.384(4)
Ti1−C13	2.381(4)	N1−N2	1.372(4)
N1−Ti1−N2	38.95(12)	N1−Ti1−Cl1	123.97(10)
N2−Ti1−Cl1	91.91(10)	N1−Ti−Cl2	93.42(10)
N2−Ti1−Cl2	121.52(10)	Cl1−Ti1−Cl2	96.09(5)

Table 3. The structure shows the geometry of the molecule in a distorted C_s symmetry, with the mirror plane perpendicular to the Cp and tz rings.

The titanium atom is coordinated in a distorted tetrahedral geometry assuming that the Cp and tz ligand occupy only one coordination site. The tz ligand is oriented in a *transoid* position relative to the benzyl substituent of the Cp group for steric reasons. The bond lengths and angles of the three-membered TiN_2 ring are virtually identical to those in **1**, although the formal coordination number at Ti is smaller.

Conclusion

In summary, the unusual η^2-coordination of a triazolato ligand in a transition metal complex has been established. The formation of the symmetric homoleptic complex **1** as well as the less-symmetric heteroleptic systems **2**−**4** proves the relative stability of the η^2-pattern. The use of the potassium salt of the triazole enables a convenient route towards Ti^{IV} complexes for HSAB reasons.

Further investigations will concern the role of d electrons[22] in the stability of the η^2 pattern and an analysis of the related spectroscopic consequences, and we are also continuing to explore the coordination behavior and structural features of triazolato complexes of d-block metal ions.

Experimental Section

All preparations were carried out under an atmosphere of dry nitrogen. All common reagents and solvents were purchased from commercial suppliers and used without further purification unless otherwise indicated. Melting points were determined on a Büchi B-540 melting point apparatus in sealed glass tubes and are uncorrected. NMR spectra were recorded on Bruker Avance 200 and Bruker Avance 500 spectrometers (for the VT NMR experiment). The chemical shifts are referenced to external $SiMe_4$. Mass spectra were recorded on a Finnigan MAT 8230 or Varian MAT CH5 spectrometer.

Preparation of [Ti(η^2-tz)$_4$] (1): A solution of [Ti(NMe_2)$_4$] (0.58 g, 2.6 mmol) in toluene (75 mL) was added at room temperature to a suspension of tzH (1.59 g, 10.4 mmol) in toluene (20 mL). Evolution of dimethylamine was immediately apparent. The resulting yellow-brown solution was stirred overnight and then evaporated to dryness. The brown residue was extracted with hexane (50 mL) and filtered through Celite. The solvent was reduced to 10 mL and the product crystallized at −25 °C as yellow cubes (1.15 g, 68%). Crystals suitable for X-ray crystallography were grown from hexane at −25 °C. M.p. 98 °C. ^{1}H NMR (C_6D_6): δ = 1.30 [d, $^3J_{H,H}$ = 7 Hz, CH(CH_3)$_2$, 12 H], 3.14 [sept, $^3J_{H,H}$ = 7 Hz, CH(CH_3)$_2$, 1 H]. ^{13}C NMR (C_6D_6): δ = 21.9 [CH(*C*H$_3$)$_2$], 28.5 [*C*H(CH$_3$)$_2$], 163.1 (C ring). MS(EI): *m*/*z* (%) = 656 (5) [M$^+$], 504 (100) [M$^+$ − tz]. $C_{32}H_{56}N_{12}Ti$ (656.8): calcd. C 58.52, H 8.59, N 25.59; found C 58.07, H 8.64, N 25.15.

Preparation of [($C_5Me_4CH_2Ph$)Ti(η^2-tz)Cl$_2$] (2): A suspension of tzK (0.18 g, 0.94 mmol) in toluene (15 mL) was added at room temperature to a solution of [($C_5Me_4CH_2Ph$)$TiCl_3$] (0.32 g, 0.88 mmol) in 20 mL of toluene and the resulting red suspension was stirred overnight. The solvent was then removed, the residual solid extracted with hexane and filtered through Celite. The volume was reduced to 20 mL and 0.21 g (50%) of the red compound crystallized at −25 °C. M.p. 82 °C. ^{1}H NMR (C_6D_6): δ = 1.38 [d, $^3J_{H,H}$ = 7 Hz, CH(CH_3)$_2$, 12 H], 1.83 (s, CpCH_3, 6 H), 2.01 (s, CpCH_3, 6 H), 3.10 [sept, $^3J_{H,H}$ = 7 Hz, CH(CH$_3$)$_2$, 2 H], 4.06 (s, CH_2, 2 H), 6.84 (m, Ph, 2 H), 7.0 (m, Ph, 2 H), 7.12 (m, Ph, 1 H). ^{13}C NMR (C_6D_6): δ = 13.5 (CpMe), 14.1 (CpMe), 21.8 [CH(*C*H$_3$)$_2$], 28.7 [*C*H(CH$_3$)$_2$], 34.6 (CH_2), 126.8 (C_{para} Ph), 128.4 (C_{meta} Ph), 128.9 (C_{ortho} Ph), 134.67 (Cp ring), 134.88 (Cp ring), 136.4 (Cp ring), 139.5 (C_{ipso} Ph), 165.6 (tz ring). MS(EI): *m*/*z* (%) = 481 (20) [M$^+$], 329 (100) [M$^+$ − tz]. $C_{24}H_{33}Cl_2N_3Ti$ (482.4): calcd. C 59.77, H 6.90, N 8.71; found C 59.42, H 6.92, N 8.44.

Preparation of [Cp*Ti(η^2-tz)Cl$_2$] (3): The synthetic procedure used was analogous to **2** employing [Cp*$TiCl_3$] (0.51 g, 1.76 mmol) and tzK (0.36 g, 1.88 mmol). Yield: 0.55 g (77%). M.p. 132 °C. ^{1}H NMR (C_6D_6): δ = 1.37 [d, $^3J_{H,H}$ = 7 Hz, CH(CH_3)$_2$, 12 H], 1.87 (s, Cp*, 15 H), 3.07 [sept, $^3J_{H,H}$ = 7 Hz, CH(CH$_3$)$_2$, 2 H]. ^{13}C NMR (C_6D_6): δ = 13.6 (Cp* CH_3), 21.8 [CH(*C*H$_3$)$_2$], 28.6 [*C*H(CH$_3$)$_2$], 134.6 (Cp* ring), 165.5 (tz ring). MS(EI): *m*/*z* (%) = 405 (20) [M$^+$], 253 (100) [M$^+$ − tz]. $C_{18}H_{29}Cl_2N_3Ti$ (406.3): calcd. C 53.22, H 7.20, N 10.34; found C 53.68, H 7.24, N 10.10.

Preparation of [Cp*Ti(η^2-tz)$_3$] (4): Toluene (30 mL) was added to a mixture of [Cp*$TiCl_3$] (0.47 g, 1.62 mmol) and tzK (0.96 g, 5.03 mmol). The mixture was stirred under reflux for 2 h, the solvent removed, the residual solid extracted with hexane and filtered through Celite. The volume was reduced to 20 mL and the compound crystallized as yellow needles at −25 °C. Yield: 0.65 g (63%). M.p. 151 °C. ^{1}H NMR (C_6D_6): δ = 1.22 [d, $^3J_{H,H}$ = 6 Hz, CH(CH_3)$_2$, 12 H], 1.77 (s, Cp*, 15 H), 3.05 [sept, $^3J_{H,H}$ = 6 Hz, CH(CH$_3$)$_2$, 6 H]. ^{13}C NMR (C_6D_6): δ = 12.5 (Cp* CH_3), 22.3 [CH(*C*H$_3$)$_2$], 28.6 [*C*H(CH$_3$)$_2$], 129.9 (Cp* ring), 162.8 (tz ring). MS(EI): *m*/*z* (%) = 639 (5) [M$^+$], 504 [M$^+$ − Cp*] 487 (40) [M$^+$ − tz]. $C_{34}H_{57}N_9Ti$ (639.8): calcd. C 63.83, H 8.98, N 19.70; found C 63.25, H 8.98, N 19.70.

X-ray Crystallographic Studies: The selected crystals were covered with oil and mounted on a glass fiber. The data for **1** were collected on a Stoe−Siemens−Huber four-circle-diffractometer coupled to a Siemens CCD area-detector and for **2** on a Stoe IPDS II-array detector system instrument, in both cases with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods using SHELXS-97[35] and refined against F^2 on all data by full-matrix least-squares with SHELXL-97.[36] All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were included in the model at geometrically calculated positions and refined using a riding model.

CCDC-173074 (**1**) and CCDC-173075 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or

A Mössbauer Study of $[Fe(edta)(O_2)]^{3-}$ Agrees with a High-Spin Fe^{III} Peroxo Complex

Olivier Horner,*[a] Claudine Jeandey,[a] Jean-Louis Oddou,[a] Pierre Bonville,[b] and Jean-Marc Latour[a]

Keywords: Iron / Peroxo ligands / Mössbauer spectroscopy / N ligands

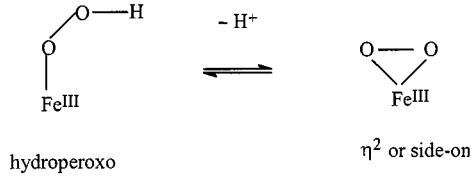
An isotopically enriched $[^{57}Fe(edta)(O_2)]^{3-}$ complex, formed by the addition of H_2O_2 to a $^{57}Fe^{III}$-edta (edta = ethylenediaminetetraacetic acid) complex at elevated pH (pH = 11.3), was studied by Mössbauer spectroscopy. All Mössbauer parameters were determined for this nonheme high-spin ferric peroxo complex with an η^2-FeO_2 (side-on) arrangement by a numerical treatment of applied field Mössbauer data. The peroxo complex exhibits an isomer shift $\delta_{/Fe}$ = 0.65(1) mm s^{-1} and a quadrupole splitting ΔE_Q = +0.72(2) mm s^{-1} (T = 4.2 K). The isomer-shift value is very similar to the value of $\delta_{/Fe}$ = 0.61 mm s^{-1} published for the side-on peroxo complex $[Fe^{III}(N_4Py)(\eta^2\text{-}OO)]^+$ (Py = pyridine) [V. Vrajmasu, E. Münck, R. Ho, L. Que, Jr., G. Roefles, B. L. Feringa, *J. Inorg. Biochem.* **2001**, *86*, 472]. The set of Mössbauer parameters obtained herein is expected to aid the characterization of analogous species that may appear during dioxygen activation by nonheme mononuclear iron enzymes.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The mechanism of dioxygen activation by nonheme iron systems has received much attention recently, and it has become clear that peroxo iron intermediates form a central part of these processes.[1] This has been thoroughly documented for diiron enzymes such as ribonucleotide reductase and methane monooxygenase, for which detailed spectroscopic characterizations of peroxo forms have been reported.[1b] Peroxo iron intermediates are also postulated for mononuclear nonheme iron enzymes, although their occurrence has been shown only in the antitumor drug bleomycin whose "activated" form was demonstrated to contain an Fe^{III}-OOH unit.[2] Similar species are likely to be involved in other mononuclear iron enzymes such as Fe-based superoxide dismutase,[3] and superoxide reductase.[4]

Great efforts are currently being made to obtain biologically relevant mononuclear nonheme iron(III) peroxide complexes. Some iron(III) hydrogenperoxo and peroxo complexes, which were proposed or demonstrated to contain a side-on peroxo group, have been identified in solution.[5] In some cases, these two forms can be interchanged by a protonation-deprotonation sequence (Scheme 1):[5a,5c,5d,5f]



Scheme 1

The reactivity of the enzymatic systems will be dictated by the decomposition mode of the peroxide, which obviously depends on its protonation state and coordination geometry. Therefore a detailed investigation of the electronic structure of peroxo-iron species is a prerequisite to understanding their chemistry.

The only nonheme Fe^{III}-peroxo complex studied in any detail is the $[Fe(edta)(O_2)]^{3-}$ complex, a side-on peroxo species.[5g] $[Fe(edta)(O_2)]^{3-}$ was recently characterized by a wide range of spectroscopic techniques, including electron paramagnetic resonance (EPR), low-temperature absorption, variable temperature variable field magnetic circular dichroism (VTVH MCD) and resonance Raman spectroscopy; all the spectroscopic results, together with theoretical calculations, gave insight into the electronic structure of the complex.[6]

Mössbauer spectroscopy has proven invaluable to characterize biological iron sites[7] and it has been instrumental in probing the mechanism of action of the iron-containing

component of ribonucleotide diphosphate reductase RNR R2,[8] and the hydroxylase component of methane monooxygenase MMOH[9] and stearoyl-ACP Δ^9-desaturase Δ9D.[10] Partial Mössbauer data have recently been published for the side-on peroxo complex $[Fe^{III}(N_4Py)(\eta^2\text{-}OO)]^+$ (Py = pyridine).[11] This prompted us to use Mössbauer spectroscopy to investigate the electronic structure of such complexes and their chemistry with respect to proton exchange. In this paper we report the Mössbauer characterization of the $[Fe(edta)(O_2)]^{3-}$ complex. Our study is a follow up from the work of Solomon et al.,[6] where Mössbauer spectroscopy was not used; we made use of their spectroscopic data [zero-field splitting (ZFS) parameters D and E]. The set of Mössbauer parameters obtained herein is expected to aid the characterization of analogous species that may appear during dioxygen activation by nonheme mononuclear iron enzymes.

Results and Discussion

The complex $[^{57}Fe(edta)(O_2)]^{3-}$ was synthesized following the procedure used by Solomon,[6] by adding H_2O_2 to a $^{57}Fe^{III}$-edta complex at elevated pH (a pH value of 11.3 was used) in buffered solution. It exhibits two weak EPR resonances at $g = 9.9$ and $g = 9.2$, and an intense derivation-type signal in the $g = 3-6$ region. Those resonances were shown to belong to an $S = 5/2$ system with rhombicity $E/D = 0.21$ and $D = -1.0 \pm 0.25$ cm^{-1}.[6,12]

The peroxo complex was studied by Mössbauer spectroscopy at low temperature in a low and a high magnetic field applied parallel to the propagation direction of the Mössbauer γ-rays. Figure 1 shows the Mössbauer spectra of $[Fe(edta)(O_2)]^{3-}$ in a 50 mT magnetic field (T = 4.2 K and 10 K), as well as the contribution of each Kramers doublet.

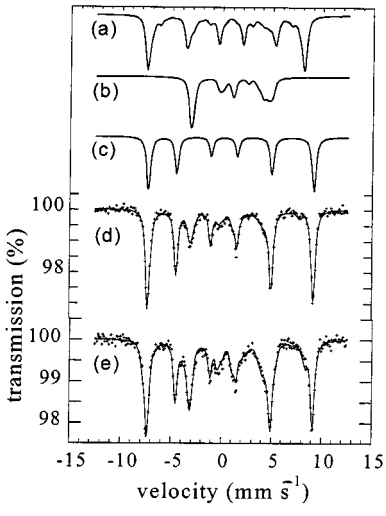

Figure 1. Mössbauer spectra of the $[Fe(edta)(O_2)]^{3-}$ complex; the experimental spectra shown in (d) and (e), taken at T = 4.2 K and T = 10 K, respectively in an applied parallel field of 50 mT, were fitted (solid curves) with the parameter set of Table 1; the solid curves in (a) – (c) show the contribution of each Kramers doublet

The peroxide complex Mössbauer spectrum was also recorded in a 7.0 T magnetic field (T = 4.2 K) and this is shown in Figure 2.

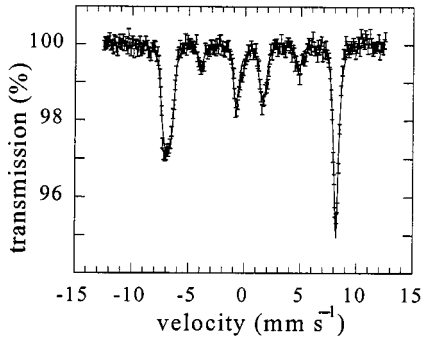

Figure 2. Mössbauer spectrum of the $[Fe(edta)(O_2)]^{3-}$ complex taken at 4.2 K in an applied parallel field of 7.0 T; the solid line corresponds to the fit of the spectrum with the set of Mössbauer parameters from Table 1

These spectra can be simulated within the spin-Hamiltonian formalism (see Exp. Sect. for details). All spectra were simultaneously fitted at the slow-relaxation limit using a unique set of parameters. The ZFS parameters were fixed to the values $D = -1.0$ cm^{-1} and $E/D = 0.21$.[6] The parameters obtained from the fits are shown in Table 1.

Table 1. Spin Hamiltonian parameters for the $[Fe(edta)(O_2)]^{3-}$ complex at T = 4.2 K; the electric field gradient (EFG) tensor, the hyperfine coupling tensor and the zero-field splitting tensor are colinear

	$[Fe(edta)(O_2)]^{3-}$
D (cm^{-1})	-1.0 cm^{-1} [6]
DE/D	0.21[6]
$g_x = g_y = g_z$	2.0
$A_x/g_n\beta_n$ (T)	$-23.1(3)$
$A_y/g_n\beta_n$ (T)	$-21.4(9)$
$A_z/g_n\beta_n$ (T)	$-20.8(1)$
η	0.4(2)
ΔE_Q (mm s^{-1})	+0.72(2)
$\delta_{/Fe}$ (mm s^{-1})	0.65(1)

Varying the ZFS parameter D from -1.25 cm^{-1} to -0.75 cm^{-1} changed the values of the set of parameters in Table 1 very slightly (except E/D, which was fixed at 0.21);[6] however, the best fit was obtained for $D = -1.0$ cm^{-1}.

For $E/D = 0.21$ ($D = -1.0$ cm^{-1}), the lower ("$M_S = \pm 5/2$") Kramers doublet of the $S = 5/2$ species is almost uniaxial and yields a sextuplet spectrum [Figure 1(c)]; the upper Kramers doublet ("$M_S = \pm 1/2$") is not uniaxial but also yields a sextuplet spectrum [Figure 1(a)]. The middle Kramers doublet ("$M_S = \pm 3/2$") is much more magnetically isotropic and yields a more complex-looking spectrum localized between -3.5 and $+6$ mm s^{-1} [Figure 1(b)].[13] At T = 4.2 K, the population of the upper doublet is significally less than that of the ground doublet. Therefore, the

contribution of the upper doublet to the experimental Mössbauer spectrum [Figure 1(d)] is negligible relative to the contribution from the lower and middle doublets. At T = 10 K, the populations of the upper and middle doublets and their contributions to the experimental spectrum increase [Figure 1(e)]. The intensity ratio of the spectral components is related to the Boltzmann factor and thus to the energy differences between the Kramers doublets, which, in turn, are related to the ZFS parameters D and E of the peroxo complex. At 77 K, the Mössbauer spectrum of the peroxo complex (50 mT applied magnetic field, data not shown) was poorly fitted at the slow relaxation limit, and at 200 K a broad unresolved spectrum was obtained (data not shown). This indicates that the fast relaxation limit is still not reached at this temperature.[14]

The $[Fe(edta)(O_2)]^{3-}$ complex exhibits an isomer shift $\delta_{/Fe}$ of 0.65 mm s^{-1} at 4.2 K and a quadrupole splitting $\Delta E_Q = +0.72$ mm s^{-1}. The former value is very similar to the value of 0.61 mm s^{-1} reported for the side-on peroxo complex $[Fe^{III}(N_4Py)(\eta^2\text{-}OO)]^+$.[11] Unfortunately, no quadrupole splitting value is available. Both parameters are also similar to those obtained by Mössbauer spectroscopy for the high-spin Fe^{III}-peroxo porphyrin $[Me_4N][Fe(OEP)O_2$ complex (OEP = octaethylporphyrin dianion);[15] this complex was suggested to contain a side-on peroxo group.[16] The porphyrin peroxo complex exhibits isomer shift and quadrupole splitting values (0.67 mm s^{-1} and + 0.62 mm s^{-1}, respectively, at 4.2 K) similar to those obtained for the $[Fe(edta)(O_2)]^{3-}$ complex, despite different iron environments. In addition, μ-1,2-peroxodiferric complexes exhibit isomer shifts in the range 0.60−0.66 mm s^{-1};[10] the isomer shift of the $[Fe(edta)(O_2)]^{3-}$ complex corresponds to the upper limit of this scale. The hyperfine coupling tensor of the peroxo complex is negative ($A_{av}/g_n\beta_n = -21.8$ T) because of the main contribution from the Fermi contact term (high-spin ferric iron case), and is also slightly anisotropic. For the $[Fe^{III}(N_4Py)(\eta^2\text{-}OO)]^+$ complex, a slighty anisotropic hyperfine tensor was also used with a similar average value ($A_{av}/g_n\beta_n = -21.1$ T).[11] For the $[Me_4N][Fe(OEP)O_2]$ complex, the hyperfine tensor was assumed to be isotropic ($A/g_n\beta_n = -23.3$ T).[14]

The absorbance of the peroxo complex at 520 nm (peroxo-to-iron ligand-to-metal charge transfer transition, LMCT band)[6] was recorded in solution at room temperature as a function of pH; it has been shown that this LMCT band reaches a plateau around pH = 10 (peroxide complex fully formed) and then collapses continuously to vanish at pH = 7.0.[17] In addition, no new bands appear between 400 and 800 nm (data not shown). It is thus not possible to generate, under those conditions, a hydrogenperoxo species by protonation of the peroxo complex, as discussed by Mc Kenzie et al,[5a] Girerd et al,[5c,5d] and Que et al.[5f] with nitrogen ligands.

In conclusion, we have fully characterized a mononuclear nonheme Fe^{III}-peroxo complex, where the peroxo group is coordinated to the iron center in a side-on way, by ^{57}Fe Mössbauer spectroscopy. The set of Mössbauer parameters obtained for the $[Fe(edta)(O_2)]^{3-}$ complex are close to those published for the high-spin ferric porphyrin complex $[Me_4N][Fe(OEP)O_2]$, which was suggested to contain a side-on peroxo group. The isomer shift value for the $[Fe(edta)(O_2)]^{3-}$ complex is also very close to the one reported by Münck et al. for the complex $[Fe^{III}(N_4Py)(\eta^2\text{-}OO)]^+$.[11] Therefore, our Mössbauer study of $[Fe(edta)(O_2)]^{3-}$ agrees with a high-spin Fe^{III} side-on peroxo complex. We are currently characterizing new mononuclear nonheme peroxo complexes by Mössbauer spectroscopy in our laboratory.

Experimental Section

All Mössbauer measurements were performed with a constant acceleration spectrometer calibrated with hematite, and isomeric shifts are reported relative to an Fe metal standard at room temperature. Variable temperature experiments were carried out with the sample placed in the tail section of a variable temperature cryostat. Temperatures of the sample were regulated to within ±0.2 K by a conventional PID system. The sample for Mössbauer spectroscopy contains about 4 mM ^{57}Fe. The Mössbauer spectra were analyzed, in a least-square fit procedure, by using the Hamiltonian **H** describing the system:

$$\mathbf{H} = D[\mathbf{S}_z^2 - (1/3)S(S+1) + (E/D)(\mathbf{S}_x^2 - \mathbf{S}_y^2)] + \beta_e\mathbf{.S.}[g]\mathbf{.B} + <\mathbf{S}>\mathbf{.}[A]\mathbf{.I} - g_n\beta_n\mathbf{B.I} + \mathbf{H_Q}$$

where D and E are the axial and rhombic zero field splitting parameters, respectively, β_e the electronic Bohr magneton, [g] the electronic tensor (considered here to be isotropic with a value fixed to 2), <**S**> the appropriately taken spin expectation value, [A] the magnetic hyperfine tensor, g_n the nuclear factor, β_n the nuclear Bohr magneton and $\mathbf{H_Q}$ the quadrupolar interaction Hamiltonian.[18] Each spectrum was then fitted with the set of parameters obtained when all the spectra were simultaneously fitted; the discrepancies found from this initial set allowed us to estimate the errors in each parameter.

Synthesis of the complex $[^{57}Fe(edta)(O_2)]^{3-}$

The $[^{57}Fe(edta)(O_2)]^{3-}$ complex was synthesized as reported recently.[8] Basically, a CHES (Sigma) buffered solution of fivefold excess ethylenediaminetetraacetic acid, tetrasodium salt (edta, Sigma) at pH = 11.3 was allowed to react with solid $^{57}FeCl_3{\cdot}6H_2O$. This mixture was heated until total dissolution of the solid material. The Fe^{III}-edta complex concentration was about 4 mM. The pH of the solution was then readjusted to 11.3 with sodium hydroxide and then filtered. The purple peroxo complex $[^{57}Fe(edta)(O_2)]^{3-}$ was formed by addition of a 10-fold excess of 30% H_2O_2 (Aldrich) to the former solution. For isotopic enrichment, the $^{57}FeCl_3{\cdot}6H_2O$ starting compound was obtained by dissolving $^{57}Fe_2O_3$ (AMT Ltd.) in 20 equivalents of concentrated HCl (Carlo Erba) under reflux and then by evaporating to dryness.

Acknowledgments

R. Vacher (CEA/Grenoble) is thanked for his help in the design and the building of the Mössbauer sample cells. J.-M. Mouesca (CEA/Grenoble) is thanked for useful discussions.

Synthetic, Structural, Magnetic, and Mössbauer Spectral Study of $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$ and Its Spin-State Crossover Behavior

Daniel L. Reger,*[a] Christine A. Little,[a] Mark D. Smith,[a] Arnold L. Rheingold,[b] Kin-Chung Lam,[b] Thomas L. Concolino,[b] Gary J. Long,*[c] Raphaël P. Hermann,[d] and Fernande Grandjean[d]

Keywords: Iron / N ligands / Spin crossover / Magnetic properties / Mössbauer spectroscopy

The complex $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$ (**1**) has been prepared from the reaction of FeI_2 and $HC(3,5\text{-}Me_2pz)_3$ (pz = pyrazolyl ring) in a 1:2 ratio. The complex is high-spin in both the solid state and in solution at ambient temperature. In the solid state, magnetic susceptibility and Mössbauer spectral studies indicate that samples of the complex that have been crystallized and dried change completely from high-spin to low-spin upon cooling below 195 K, with a substantial two-step thermal hysteresis in the transition. The spin-crossover properties of **1** are sample dependent: powder samples do not change to low-spin at low temperatures. Two crystalline forms of **1** have been identified by X-ray crystallography, one form containing no solvent of crystallization and the other containing solvent. In both, there is only one iron site, with average Fe–N bond lengths of 2.18 and 2.17 Å, values that confirm that the complex is high-spin. Single crystals of the nonsolvated form shatter at low temperatures whereas single crystals of the solvated form can be cooled to 110 K with no loss of crystallinity and remain fully high spin at this temperature. Crystallographic information: nonsolvated form is triclinic, $P\bar{1}$, a = 8.8062(2) Å, b = 10.3549(2) Å, c = 11.3549(2) Å, α = 104.0768(10)°, β = 110.2473(10)°, γ = 92.6385(11)°, Z = 1; solvated form is monoclinic $P2_1/c$, a = 10.3214(5) Å, b = 12.7753(7) Å, c = 20.1995(11) Å, α = 90°, β = 97.5380(10)°, γ = 90°, Z =2.

Introduction

The properties of octahedral iron(II) complexes, especially those with an FeN_6 coordination environment, that undergo thermal spin-state crossovers between the high-spin (HS, S = 2) and low-spin (LS, S = 0) states have been widely investigated.[1] In general, iron(II) complexes that are HS in the solid state at room temperature may show a spin-state crossover to the LS electronic state upon cooling, whereas, complexes that are LS at room temperature may show a spin-state transition to the HS electronic state upon heating.[1,2]

We have recently reported, by using a combination of NMR, X-ray structural, magnetic, and Mössbauer spectral results, that $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$ (pz = pyrazolyl ring) shows unusual spin-crossover behavior in the solid state.[3] Even though only one iron site is observed by X-ray crystallography at ambient temperature, the solid abruptly changes from all-HS above 206 K to a 50:50 mixture of HS and LS (in this form the Fe−N bond lengths are reduced by ca. 0.2 Å, as expected[1]) below 200 K, the composition of the lower temperature mixed spin-state does not change as the temperature is lowered to 4.2 K. This spin-state crossover is reversible and shows no thermal hysteresis. Herein we report the synthesis, NMR, X-ray structural, magnetic, and Mössbauer spectral studies of $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$ (**1**), a complex with the same dication as $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$, but paired with a different anion, a change that dramatically effects its properties.

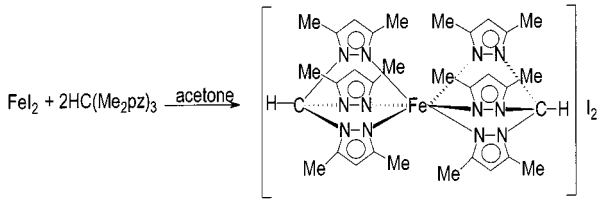
Results and Discussion

Synthesis and Characterization

The reaction of FeI_2 and $HC(3,5\text{-}Me_2pz)_3$ in a 1:2 ratio yields $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$ (**1**; Scheme 1). FeI_2 is black in solution. Upon addition of the ligand the homogeneous solution immediately becomes yellow and the desired product precipitates as a powder after several minutes. The solid is white as a powder and colorless as single crystals, indicat-



1

Scheme 1

ing that the iron(II) is HS at room temperature.[1] The solution ^{1}H NMR spectrum shows broad resonances shifted over the range from δ = 51.1 to −42.6, analogous to that previously reported for {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}(BF$_4$)$_2$ (**2**), indicating that the complex is also HS in solution.

The HS configuration of the iron(II) in **1** at ambient temperature was verified by the X-ray crystal structures (see Figure 1 and Table 1). Complex **1** crystallizes in two different forms under seemingly identical crystallization procedures. One form of these crystals contains no solvent molecules while the other form contains four molecules of CH_2Cl_2, the crystallization solvent, for every iron(II). In both cases, the crystals were found to fragment to microcrystals when taken out of solution. The crystals used for the X-ray structural studies were taken from a container that contained solvent and were immediately coated with an inert liquid.

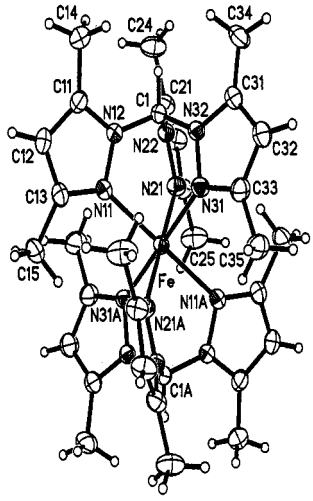


Figure 1. An ORTEP diagram of the cation of the solvated form of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}I$_2$

The structures of the cations in both forms of **1** are similar (Figure 1) and similar to the cation in **2**, which has been reported previously.[3] Table 1 gives selected bond lengths and angles for all of the structures. The average Fe−N bond lengths are 2.18 Å in the nonsolvated form of **1** and 2.17 Å in the solvated form of **1** and in **2**, clearly indicating that iron(II) is in the high-spin configuration at 295 K; average bond lengths of ca. 1.97 Å are typically observed in LS octahedral FeN$_6$ complexes.[1] In all of the structures the iron(II) is located on a center of symmetry and has an N$_6$ coordination environment. The chelate rings restrict the intraligand N−Fe−N angles to an average of 84.5° in both forms of **1** and 84.3° in **2**, restrictions that lead to trigonally distorted octahedral structures.

There are important differences in the behavior of crystals of the two forms of **1** and of **2** upon cooling. Crystals of **2** change from colorless above 206 K to purple below this temperature; they also undergo a phase change from monoclinic to triclinic. These crystals, when reheated above 206 K, again become colorless, returning to the monoclinic space group, with no apparent degradation of crystal quality. Crystals of **2** that have been cooled are still suitable for X-ray structural studies at ambient temperature.[3] In contrast, crystals of **1** in the nonsolvated form shatter when cooled below 195 K, a temperature below which the solid turns purple. After being cooled, the crystals are no longer suitable for single crystal X-ray studies at either low temperature or after reheating to ambient temperature, at which temperature the sample is again white. Crystals of **1** in the solvated form *do not undergo the spin-state transition* down to 110 K. The quality of the crystals does not change, they remain colorless at 110 K, and there is no phase change at lower temperatures.

There is an interesting and important difference between the structures of the two forms of **1** relating to the degree of tilting of the pyrazolyl rings away from an ideal C_{3v} type arrangement. In the absence of tilting, the FeN(n1)−N(n2)−C(n1) torsion angles, where n denotes the ring number, would be 180° and the metal atom would reside in the planes defined by the pyrazolyl rings. We have previously commented on the fact that in octahedral {M[HC(3,5-Me$_2$pz)$_3$]$_2$}$^{n+}$ and M[HB(3,5-Me$_2$pz)$_3$]$_2$ complexes this ring tilting increases with increasing size of the metal.[4] The tilting also changes when the same cation is paired with different anions.[4] We have solved the structure of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}(BF$_4$)$_2$ (**2**) at 220 K, where all of the cations are HS, and at 173 K, where half of the cations are HS and half LS. In the 220 K structure the torsion angle averages 169°, whereas for the HS form in the 173 K structure this torsion angle averages 162°. For the LS form of the 173 K structure this torsion angle averages 179°, reflecting the smaller size of LS iron(II). For the nonsolvated form of **1**, which changes to LS at low temperatures, this torsion angle averages 171°. In contrast, in the solvated form of **1**, the form that does not change to LS at low temperatures, it is 10° less at 161°.

Magnetic Susceptibility Studies

Both crystalline forms of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}I$_2$ (**1**) discussed in the X-ray section above fragment to microcrystals when dried or if even briefly removed from the crystallization solvents. This process makes it impossible to directly measure the magnetic properties of the single crystals used in the X-ray structural studies.

The effective magnetic moment of a sample originating from the nonsolvated, crystalline form of **1** as a function of temperature between 5 and 325 K is shown in Figure 2. A sample originating from the solvated, crystalline form of **1**,

Table 1. Selected bond lengths and angles for the cation in nonsolvated $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$, solvated $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2{\cdot}4CH_2Cl_2$ and $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}(BF_4)_2$ (**2**)

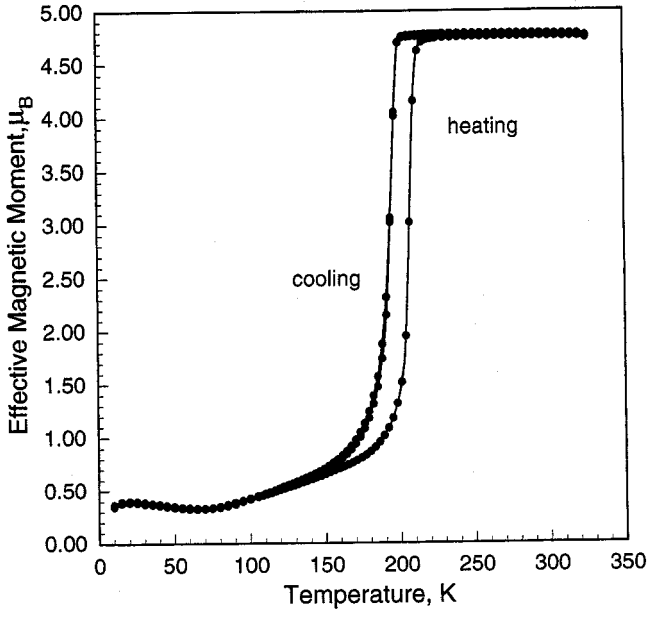

Figure 2. The effective magnetic moment as a function of temperature, measured by cooling, heating and recooling between 325 and 5 K, of crystallized $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$ (**1**)

that had been dried and shown by elemental analysis to lose the CH_2Cl_2 of crystallization, has essentially the same magnetic properties as shown in Figure 2. At higher temperatures **1** is clearly HS with an effective moment of ca. 4.8 μ_B, a value that is very close to the iron(II) spin-only value of 4.9 μ_B. Upon cooling below 195 K there is a dramatic drop in the moment as would be expected for a spin-state crossover to a LS iron(II) complex. Continued cooling to 5 K yields a very small moment, except at the lowest temperatures where a trace of paramagnetic iron(III) impurity leads to a very small increase in the magnetic susceptibility. The low-temperature moment of ca. 0.4 μ_B is typical of the temperature-independent paramagnetism observed in low-spin iron(II) complexes. Subsequent warming of the sample above 5 K reveals very similar behavior but with the presence of a reproducible hysteresis of ca. 15 degrees in the spin-crossover such that at ca. 210 K, the sample has completely returned to the HS state.

The magnetic properties of complex **1** are dependent on the history of the sample. Figure 3 shows the magnetic behavior of the solid that precipitated from acetone in the original reaction, a sample that is a white powder and is pure as indicated by elemental analysis and NMR spectroscopy. This solid was subsequently used to prepare the crystalline samples, which once dried were used to obtain the

magnetic results shown in Figure 2. For the solid that precipitated from acetone, only a small change in the magnetic moment was observed as the temperature was lowered. The high temperature moment of this sample is the same as observed for both crystallized samples. In contrast, for the sample of **1** that precipitated from acetone, there is only a small decrease in the magnetic moment from μ_{eff} = 4.85 μ_B at higher temperatures to μ_{eff} = 4.5 μ_B below 185 K. As with the results presented in Figure 2, a hysteresis of ca. 15 degrees is observed upon cooling and heating for the small changeover. Presumably, the decrease of ca. 0.4 μ_B is due to the presence of a small amount of microcrystalline **1** that is present in the sample.

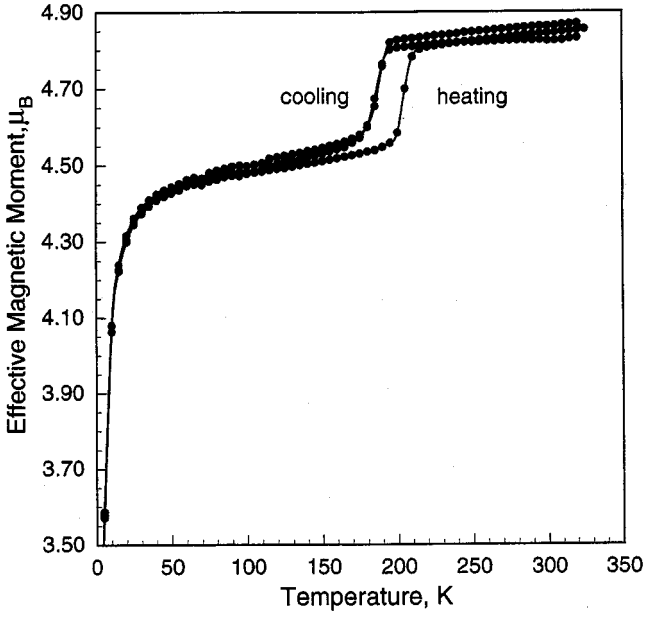

Figure 3. The effective magnetic moment as a function of temperature, measured by cooling, heating and recooling between 325 and 5 K, of a sample of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}I$_2$ that precipitated from the reaction mixture

There is a sharp drop in the effective moment below ca. 30 K (see Figure 3). This drop is not unexpected for a distorted octahedral iron(II) complex in which the low-symmetry component of the crystal field, in conjunction with electron delocalization and spin-orbit coupling, are known[5] to lead to a decrease in the observed moments at very low temperatures.

Mössbauer Spectral Analysis

The Mössbauer spectra of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}I$_2$ (**1**), measured on a sample that was crystallized from CH_2Cl_2/hexanes and dried, were obtained upon cooling from 295 to 4.2 K and upon warming from 175 to 215 K (Figures 4 and 5, respectively). Selected hyperfine parameters for this complex are given in Table 2. The complete temperature dependence of the isomer shift and quadrupole splittings for the HS and LS states are shown in Figures 6 and 7. As the sample is cooled, a dramatic change occurs in the spectra starting at ca. 190 K indicating a spin-state crossover from the HS to the LS state.[1] This change is clearly indicated by the appearance of a second doublet at ca. 0.5 mm/s. The change in population of the HS state, as reflected by the Mössbauer spectral absorption area of the HS component, is shown in Figure 8, and matches an analogous plot using data from the magnetic studies.

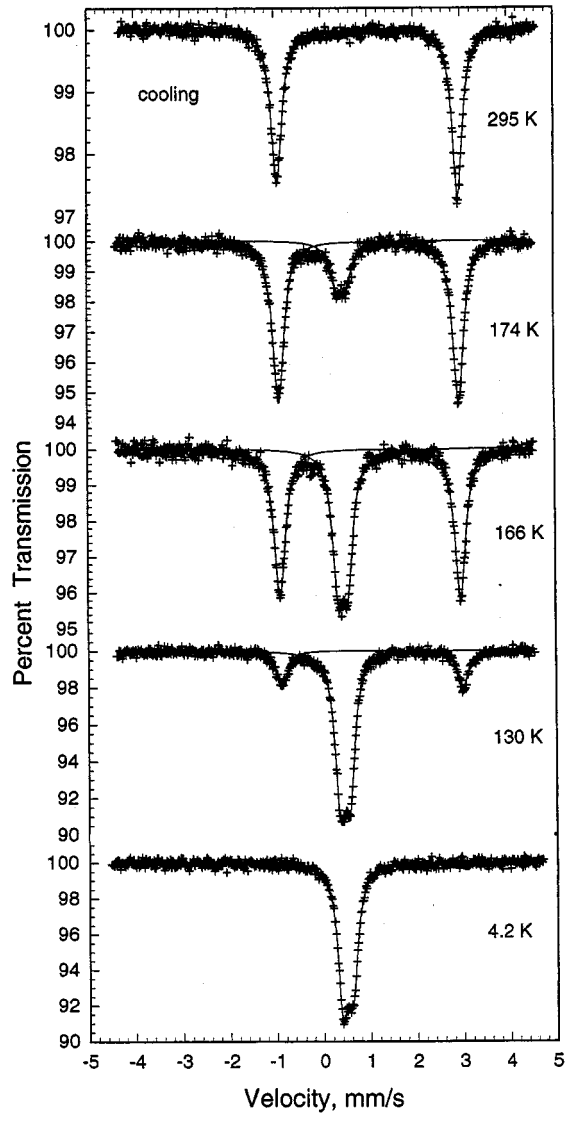

Figure 4. The Mössbauer spectra of crystallized {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}I$_2$ (**1**) obtained at the indicated temperatures upon cooling from 295 to 4.2 K

The hyperfine parameters reported in Table 2 are those expected for HS and LS iron(II) complexes with a distorted pseudooctahedral coordination geometry. The isomer shifts and quadrupole splittings for both the HS and LS states of **1** are virtually identical to those of the analogous complex {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}(BF$_4$)$_2$ (**2**), although the nature of the spin-crossover is different. In **1** the transition to the low-spin state is complete below 70 K but the transition occurs only to 75% in the temperature range from 70 to 150 K on cooling and 70 to 200 K on heating. The presence of a small amount of the HS complex in this temperature range is also

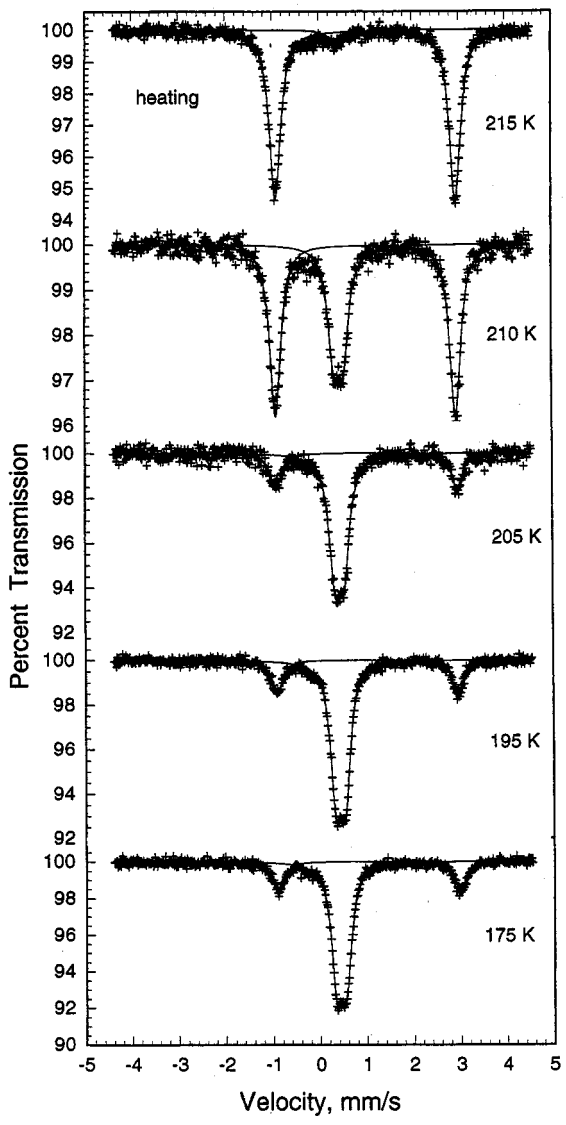

Figure 5. The Mössbauer spectra of crystallized {Fe[HC(3,5-$Me_2pz)_3]_2$}I_2 (**1**) obtained at the indicated temperatures upon heating from 4.2 K

[a] The isomer shifts are given relative to room temperature α-iron foil. [b] Data obtained on the nonsolvated crystallized sample during the initial cooling from 295 to 4.2 K. [c] Data obtained on the nonsolvated crystallized sample after cooling to 4.2 K. [d] Data obtained on a powder sample.

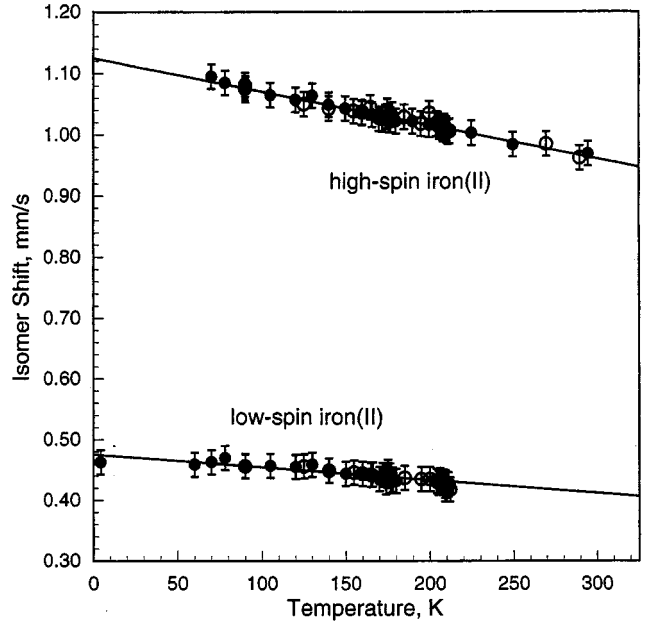

Figure 6. The temperature dependence of the Mössbauer spectral isomer shifts for {Fe[HC(3,5-$Me_2pz)_3]_2$}I_2 (**1**); the data obtained upon the initial cooling from 295 to 4.2 K are indicated by ● and the data obtained upon the subsequent heating from 4.2 K are indicated by ○

apparent in Figure 2 as a shoulder in the effective moment.

A comparison of Figure 2 with Figure 8 indicates that the temperature hysteresis observed in the magnetic measurements is approximately half that observed in the Mössbauer spectral studies. The exact reason for this difference is not apparent at this time, but is probably related to differences in sample preparation. We have shown that thermal equilibrium was achieved in the magnetic studies by stopping the change in temperature at a number of points in both the heating and cooling cycles around 200 K and observing no change of the magnetic moment with time.

Mössbauer spectra were obtained at 90 K and 295 K on the same sample that was used for the magnetic data shown in Figure 3, a sample that precipitated from acetone in the

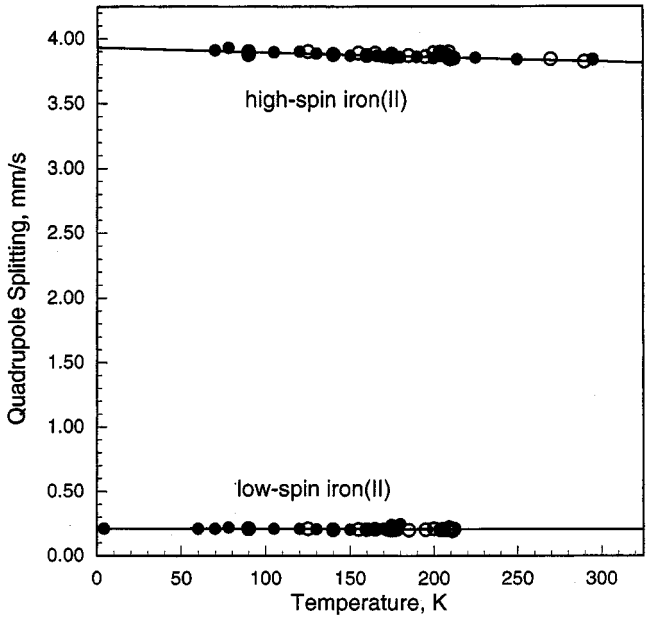

Figure 7. The temperature dependence of the Mössbauer spectral quadrupole splittings for {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}I$_2$ (**1**); the data obtained upon initial cooling from 295 to 4.2 K are indicated by ● and the data obtained upon the subsequent heating from 4.2 K are indicated by ○

original reaction. At 295 K the sample is fully HS with hyperfine parameters that match those observed with the crystallized samples. At 90 K, only 15% of the sample is LS, approximately the same amount that changes in the magnetic study.

Conclusions

The most interesting property of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}I$_2$ (**1**) is the temperature-dependent changes in spin-state behavior, changes which are a function of the history of the sample. These changes are observed both in the X-ray diffraction studies carried out on single crystals and in the magnetic and Mössbauer spectral studies carried out on the fragmented microcrystals that form when the single crystals are taken out of solution. Two crystalline forms of **1** have been identified by X-ray crystallography. Although the average Fe−N bond lengths and angles of the FeN$_6$ cores in the two structures are the same, there are substantial differences in the FeN(n1)−N(n2)−C(n1) torsion angles. In the structure of the nonsolvated form of **1**, measured at 298 K, this torsion angle averages 171°. These crystals shatter when cooled below 195 K, a temperature below which the solid turns purple, indicating a change to the LS form. In the structure of the solvated form of **1**, this torsion angle is 10° less, at 161°. As shown by X-ray crystallography, this crystalline form does not change to LS upon cooling to 110 K. It should be noted that in the low spin form of {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}(BF$_4$)$_2$ (**2**) observed at 173 K, the structure has a torsion angle of 179°, the angle expected for the LS form of iron(II) in this dication. Thus the failure of the solvated crystalline form of **1**, which has a much smaller average torsion angle, to undergo a spin-state change may well result from the unfavorable energetics required to dramatically change the torsion angle as well as the bond lengths. These energetic changes may well be large enough to prevent the spin-state crossover.

Both magnetic and Mössbauer spectral studies of the fragmented microcrystals that form when the single crystals of either crystalline form are taken out of solution, show that both samples are HS at ambient temperatures but change over to the LS form at low temperatures. These samples of complex **1** behave similarly to many other iron(II) complexes with an FeN$_6$ coordination environment[1] in changing completely to the LS state at low temperatures. Surprisingly, a pure sample of **1** that precipitates from the original reaction mixture changes only partially over to the LS form at low temperatures. As with the solvated, crystalline form of **1**, the energetics of the changeover are clearly different for different samples.

The behavior of complex **2** is different from that of **1** in that only half of the iron(II) sites change to LS at low temperatures, although all crystalline samples studied behave the same way. Another difference is that for **1** there is an ca. 15 degree hysteresis in the temperature dependence of the spin-state crossover, whereas no hysteresis is observed for **2**. Clearly the environment of the {Fe[HC(3,5-Me$_2$pz)$_3$]$_2$}$^{2+}$ dication within the ionic lattice and the crystalline form influence its spin-crossover behavior.

Experimental Section

General Procedure: All operations were carried out under a nitrogen atmosphere using either standard Schlenk techniques or in a

Vacuum Atmospheres HE-493 inert atmosphere dry box. All solvents were dried and distilled prior to use. Anhydrous FeI_2 (99.99%) was purchased from Aldrich Chemicals. Proton NMR chemical shifts are reported in ppm versus TMS. $HC(3,5\text{-}Me_2pz)_3$ was prepared according to our recently reported procedures.[6] Elemental analyses were performed by Robertson Microlit Laboratories, Inc.

Magnetic susceptibilities were measured at 5 kG using a Quantum Design MPMS XL SQUID magnetometer. Gelatin capsules were used as sample containers for measurements taken in the temperature range 5−400 K. The very small diamagnetic contribution of the gelatin capsule had a negligible contribution to the overall magnetization, which was dominated by the sample. The molar magnetic susceptibilities were corrected for the diamagnetism of the complexes, which were calculated from tables of Pascal's constants to be -445×10^{-6} emu/mol for $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$.

$\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$ (1): FeI_2 (0.19 g, 0.62 mmol) was dissolved in acetone (10 mL) and treated dropwise by cannula transfer with an acetone solution (10 mL) of $HC(3,5\text{-}Me_2pz)_3$ (0.370 g, 1.24 mmol). The solution turned yellow and after stirring for several minutes the desired product precipitated from solution as a white powder (0.47 g, 84%), dec. 333−339 °C. The crystals used for X-ray crystallographic studies were grown by layering a saturated dichloromethane solution with hexanes and allowing the two layers to slowly combine. Two forms of the crystals, a nonsolvated form and a solvated form of the formula $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2{\cdot}4CH_2Cl_2$ (as shown by X-ray crystallography, vide infra), are produced when this crystallization procedure is repeated under seemingly identical conditions. Both forms of these crystals fragment when dried, with the solvated form losing the CH_2Cl_2 of crystallization. Unless otherwise noted, these fragmented crystals were used in the magnetic and Mössbauer spectral studies. ^1H NMR (CD_2Cl_2): δ = −42.6 (v br, 2 H, *H*C), 41.1, 19.6 (v br, v br, 18 H, 18 H, Me_2), 51.1 (v br, 6 H, 4-*H* pz). $C_{32}H_{44}FeI_2N_{12}$ (906.4): calcd. C 42.40, H 4.89; found for the powder sample that precipitates from the reaction mixture: C 42.09, H 4.72; found for the nonsolvated crystalline form after drying: C 42.77, H 4.71; found for the solvated crystalline form after drying: C 42.47, H 4.78.

X-ray Structural Data

Nonsolvated Form of $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$: Colorless crystals were taken from solution and immediately coated with epoxy resin. Crystal, data collection, and refinement parameters are given in Table 3. There is no evidence of symmetry higher than triclinic, and *E*-statistics and the presence of an inversion center for the iron(II) cation suggest the centrosymmetric space group $P\bar{1}$ for **1**, a space group that yields a chemically reasonable and computationally stable refinement. The structure was solved using direct methods, completed by subsequent difference Fourier syntheses, and refined by full-matrix least-squares procedures. *SADABS* absorption corrections were applied to all data sets. The asymmetric unit contains half of the cationic iron(II) complex, which lies on an inversion center, and one of the iodide anions. All non-hydrogen atoms were refined with anisotropic thermal displacement coefficients. The hydrogen atom of C(1) was located from the difference map and allowed to refine, all other hydrogen atoms were treated as idealized contributions. All software and sources of the scattering factors are contained in the SHELXTL (5.10) program library (G. Sheldrick, Siemens XRD, Madison, WI).

Table 3. Crystallographic data for the structural analyses of nonsolvated $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2$ and Solvated $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2{\cdot}4CH_2Cl_2$

[a] Quantity minimized = $R(wF^2) = \Sigma[w(F_0^2 - F_c^2)^2/\Sigma w(F_0^2)^2]^{1/2}$; $R = \Sigma\Delta/\Sigma(F_o)$, $\Delta = |F_o - F_c|$

Solvated Form of $\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2{\cdot}4CH_2Cl_2$: A colorless needle was coated with inert oil, mounted on the end of a thin glass fiber and transferred to the cold stream of a Bruker SMART APEX CCD-based diffractometer system. The X-ray intensity data were measured at 190(2) K. Crystal quality and initial unit cell parameters were determined based on reflections taken from a set of three scans measured in orthogonal regions of reciprocal space. Subsequently a hemisphere of frame data was collected with a scan width of 0.3° in ω and an exposure time of 10 s per frame. The first 50 frames were re-collected at the end of the data set to monitor crystal decay. The raw data frames were integrated into reflection intensity files with the Bruker SAINT+ program,[7] which also applied corrections for Lorentz and polarization effects. The final unit cell parameters are based on the least-squares refinement of 9412 reflections with $I > 5\sigma(I)$ from the data set. Analysis of the data showed negligible crystal decay during data collection. An empirical absorption correction based on the multiple measurements of equivalent reflections was applied with the program SADABS.[8]

$\{Fe[HC(3,5\text{-}Me_2pz)_3]_2\}I_2{\cdot}4CH_2Cl_2$ crystallizes in the space group $P2_1/c$ as determined by the systematic absences in the intensity data. The structure was solved by a combination of direct methods and difference Fourier syntheses, and refined by full-matrix least-squares against F^2, using the SHELXTL software package.[8] The iron(II) ion is located on a special position, a center of symmetry; all other atoms are on general positions. The asymmetric unit consists of the iron(II), one $HC(3,5\text{-}Me_2pz)_3$ ligand, one iodide anion and two dichloromethane molecules. All non-hydrogen atoms were refined with anisotropic thermal displacement parameters; hydrogen atoms were placed in idealized positions and refined using a riding model.

CCDC-171226 (nonsolvated form) and CCDC-171227 (solvated form) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mössbauer Spectroscopic Data: The Mössbauer spectral absorber contained 47 mg/cm^2 of powder and the spectra were measured between 4.2 and 295 K on a constant-acceleration spectrometer which utilized a room temperature rhodium matrix cobalt-57 source and was calibrated at room temperature with an α-iron foil. The estimated absolute errors are ± 0.01 mm/s for the isomer shifts, ± 0.02 mm/s for the quadrupole splittings, and ± 0.5 percent for the relative areas of the high-spin and low-spin spectral components. The relative errors are estimated to be smaller by a factor of 2 to 5.

Acknowledgments

The authors acknowledge, with thanks, the help of Professor Hanno zur Loye and Katharine Stitzer for assistance in obtaining the magnetic data. The authors also thank the US National Science Foundation for grants CHE-0110493 to D. L. R. and DMR-9521739 to G. J. L. and the Petroleum Research Fund for grant 36368-AC3 to D. L. R. The Bruker CCD Single Crystal Diffractometer (at the University of South Carolina) was purchased with funds provided by the NSF Instrumentation for Materials Research Program through Grant DMR:9975623. Keywords: Rhenium / Cluster compounds / Structure elucidation / Cyanide ligands / XANES

Two novel octahedral rhenium(III) selenocyanide cluster complexes $[(n\text{Bu})_4\text{N}]_2\text{Ni}(\text{H}_2\text{O})_5[\text{Re}_6\text{Se}_8(\text{CN})_6]\cdot 2\text{H}_2\text{O}$ (**1**) and $[(n\text{Bu})_4\text{N}]_2\text{Mn}(\text{H}_2\text{O})_4[\text{Re}_6\text{Se}_8(\text{CN})_6]\cdot 2\text{H}_2\text{O}$ (**2**) have been prepared by the reaction of $K_4[Re_6Se_8(CN)_6]\cdot 3.5H_2O$, $(n\text{Bu})_4\text{NBr}$ and $Ni(OAc)_2$ (or $MnSO_4$) in aqueous solution. The complexes have been structurally solved in the orthorhombic unit cell *Pbca* with parameters: $a = 19.393(2)$, $b = 17.292(2)$, $c = 37.255(4)$ Å for **1**, and $a = 19.518(4)$, $b = 17.488(3)$, $c = 37.997(5)$ Å for **2**. The cluster anions and M^{2+} form ionic pairs $\{M(H_2O)_n[Re_6Se_8(CN)_6]\}^{2-}$ that are packed in the solid state with *n*-tetrabutylammonium cations. Coordinated and solvate water molecules as well as the nitrogen atoms of the anions form a network of hydrogen bonds in the structures. These compounds are isomorphous, although the coordination environments of the metal cations differ.

Introduction

The ability of CN ligands to form strong covalent bonds to *3d* transition metals is well-known and the coordination chemistry of mononuclear cyanometallates is well developed.[1] Complex cluster anions $[Re_6(\mu_3\text{-}Se)_8(CN)_6]^{4-}$ with terminal CN groups[2] can also interact with transition metals to form new polymeric cluster solids based on -Re−C≡N−M−N≡C−Re- bridges.[3,4] The type of polymeric compound formed and the coordination environment of the metal cation are influenced enormously by the nature of the additional cations present in the reaction mixture. We have found that an increase of cation size in the series $Cs^+ < Me_4N^+ < Et_4N^+ < n\text{Pr}_4N^+$ results in a reduction of the dimensionality of the formed solids. In the case of Cs^+,[3a] Me_4N^+ and Et_4N^+,[3b] a three-dimensional polymeric framework $\{M_3[Re_6Se_8(CN)_6]_2\}^{2-}$ is formed which includes these cations and water molecules in its cavities. In the case of $n\text{Pr}_4N^+$,[3c] polymeric chains or molecular-type structures built from complex anions and M^{2+} are obtained.

Here we report the synthesis and structures of two novel isomorphic complexes $(n\text{Bu}_4\text{N})_2\text{Ni}(\text{H}_2\text{O})_5[\text{Re}_6\text{Se}_8(\text{CN})_6]\cdot 2\text{H}_2\text{O}$ (**1**) and $(n\text{Bu}_4\text{N})_2\text{Mn}(\text{H}_2\text{O})_4[\text{Re}_6\text{Se}_8(\text{CN})_6]\cdot 2\text{H}_2\text{O}$ (**2**) obtained from the reaction of aqueous solutions of $K_4Re_6Se_8(CN)_6$ and M^{2+} (Mn^{2+} and Ni^{2+}) in the presence of Bu_4NBr. Although the space group, cell parameters and packing motifs in these structures are similar, the coordination spheres of Mn^{2+} and Ni^{2+} are quite different.

Results and Discussion

Structures of Compounds 1 and 2

The anion $[Re_6Se_8(CN)_6]^{4-}$ has the usual $Re_6X_8L_6$ environment (Figure 1). Six rhenium atoms form an Re_6 octahedron with the faces μ_3-capped by eight selenium atoms. The CN ligands are coordinated to rhenium atoms through the carbon atom. The bond lengths and angles in the anion (see Table 1) do not differ from those found in other salts with an Re_6Se_8 cluster core [$K_4Re_6Se_8(CN)_6\cdot 3.5H_2O$:[2] Re−Re = 2.633 Å; Re−Se = 2.526 Å; Re−C = 2.11 Å; C−N = 1.15 Å; $NaCs_3Re_6Se_8(CN)_6$:[4] Re−Re = 2.634 Å; Re−Se = 2.52 Å; Re−C = 2.10 Å; C−N = 1.17 Å; $Cs_4Re_6Se_8I_6$:[5] Re−Re = 2.625; Re−Se = 2.519 Å].

The cluster anion forms bridging Re−CN−M contacts at one nitrogen atom, with the other five CN groups remaining terminal, therefore we have an ionic pair containing an M^{2+} cation. The structures of the ionic pairs $\{M(H_2O)_n[Re_6Se_8(CN)_6]\}^{2-}$ for **1** and **2** are shown in Figure 2, with water molecules completing the coordination sphere of M^{2+}.

In compound **1** the coordination environment of Ni^{2+} is a slightly distorted octahedron (N + 5O), with Ni−N distances of 2.032(7) Å and Ni−O distances ranging from 2.033(6) to 2.118(7) Å. The hydrogen bond system can be

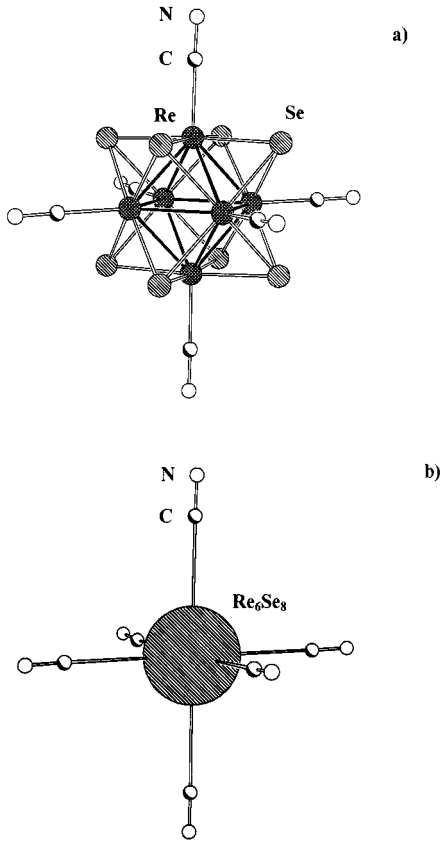

Figure 1. Structure of cluster anion $[Re_6(\mu_3\text{-}Se)_8(CN)_6]^{4-}$ (a) and its simplified presentation (b)

described as a superposition of two chains running along the *c* and *a* axes. The first of them consists of water molecules, O1 and O1w, and the terminal nitrogen atom N2 from the nickel-cluster ionic pair. The second includes O5, O2w and N6. The O···N and O···O distances are about 2.6−2.7 Å (Figure 3a).

In **2** the Mn^{2+} ion is coordinated by the nitrogen atom of the cluster anion and by four (rather than five) water molecules, with Mn−O distances ranging between 2.13(2) and 2.15(2) Å. Thus the coordination environment of Mn^{2+} is N + 4O and the coordination polyhedron is a distorted square pyramid (reversed umbrella) with an apex at the nitrogen atom. The manganese atom lies 0.55 Å out of the plane formed by the atoms O1, O2, O3, and O4. The next nearest water molecule, O1w, lies 3.65 Å from Mn1 (Figure 3b), forming a hydrogen bond with O3 (O···O distance of 2.70 Å). As in **1**, there are hydrogen bonded chains running roughly along *c* axis.

In the related compound $[(n\text{Pr})_4N]_2Mn(H_2O)_5[Re_6Se_8(CN)_6]\cdot H_2O$ (**3**), the environment of Mn^{2+} is different.[3c] An $\{Mn(H_2O)_5[Re_6Se_8(CN)_6]\}$ fragment of **3** is shown in Figure 2c and some bond lengths and angles are presented in Table 2 for comparison. In contrast to compounds **1** and **2**, the manganese(II) cation in **3** has a distorted octahedral coordination environment [1N + 5O(H_2O)] with an Mn−N−C angle of 158(5)° The reason for such a deviation from linearity is the different arrangement of the ionic pairs in the solid state. In **1** and **2** the ionic pairs are oriented along the *c* axis of the unit cell (Figure 3a and 3b) and have an arrangement similar to that in compound **3**.[3c] As in **3**, the cluster anions form a pseudo face-centred motif. In **1**

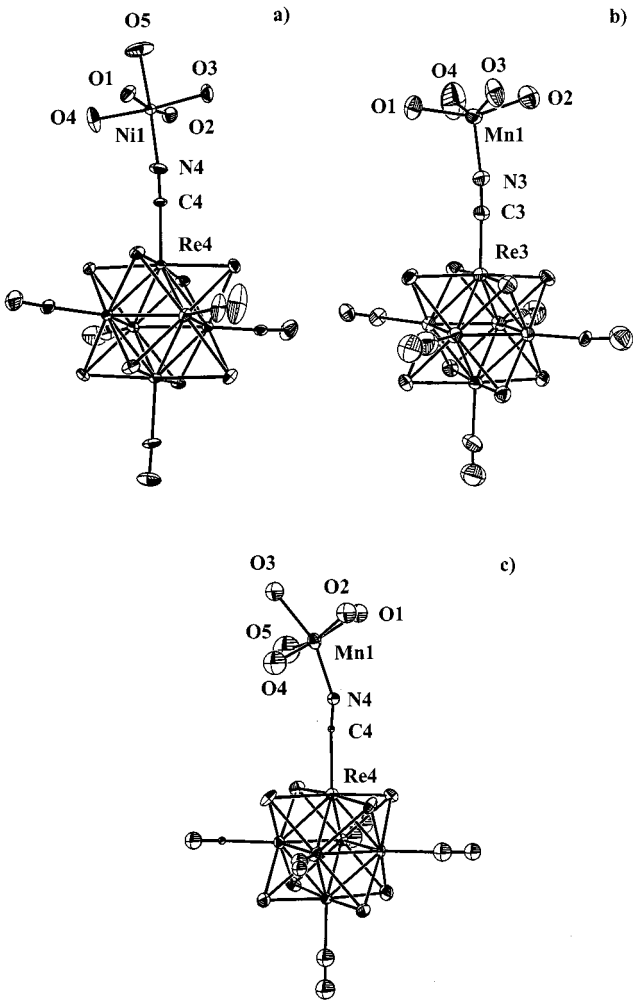

Figure 2. Structures of anionic pairs in compounds **1** (a), **2** (b) and **3** (c); thermal ellipsoids are drawn at a 50% probability level

the ionic pairs are connected by hydrogen bonds to the solvent water molecule O2w. The nickel atom has an almost regular octahedral environment and both the O5 and O2w water molecules form hydrogen bonds with normal distances (O5···O2w: 2.65 Å; O2w···N6: 2.76 Å) and angles (N6···O2w···O5: 131°). In **3** the ionic pairs interact directly through the O3···N2 hydrogen bond. This interaction forces a deviation of the C4−N4−Mn1 (158°) and N4−Mn1−O3 (159°) angles from linearity, thus allowing the O3 atom to form a normal hydrogen bond to N2 with an O−N distance of 2.77 Å and an Mn1−O3−N2 angle of 116°.

The space between the ionic pairs is occupied by Bu_4N^+ cations. Two crystallographically independent Bu_4N^+ cations have different conformations in the structure.

Although the coordination number of five for Mn^{2+} is known in the literature this environment is not usual for manganese and is mainly caused by steric factors, namely the volume of the organic ligands. Stelzig et al.[6] have reported the complexes $[Mn_2^{II}L^3(\mu_3\text{-OMe})(MeOH)]_2$ and $Na[Mn_3^{II}(L^3)_2(\mu_2\text{-OAc})]\cdot H_2O\cdot 0.25THF$, where L^3 = 1,5-bis(3-Cl, 5-NO_2-salicylideneamino)pentan-3-ol, a voluminous pentadentate ligand. The Mn^{2+} coordination arrangement here is 4O + N. It is also worthwhile to note the complex $[Mn_3(L^1O)_4(MeCN)][ClO_4]_2\cdot H_2O$, where L^1O is a deprotonated tridentate ligand (2-hydroxyphenyl)bis(pyrazolyl)methane.[7]

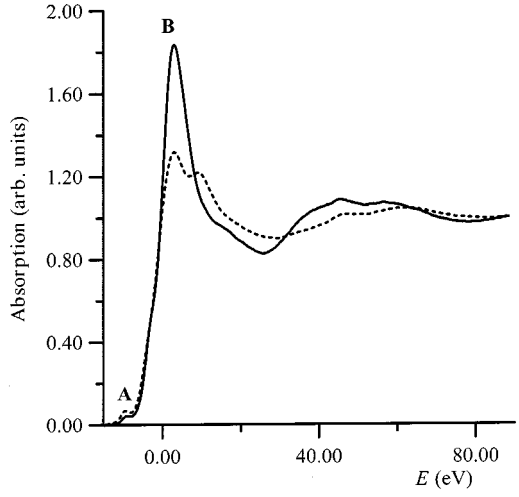

Figure 4. Mn-*K* XANES spectra of compounds **2** (dashed line) and **3** (solid line)

pounds (Figure 4). The maximum B in the spectra of **2** and **3** (Figure 4) corresponds to an electron transition from the Mn1s to the Mn4p level. The decrease of intensity of this maximum by a factor of two for compound **2** relative to compound **3** can clearly be seen. This decrease indicates a splitting of the 4p electronic levels due to substantially reduced symmetry for the first sphere of the Mn environment in **2**.[12] The pre-edge resonance (maximum A) corresponding to the quadrupole Mn1s−Mn3d transition (Figure 4) is sensible to symmetry distortion at the manganese atom. A noticeable increase of the intensity in **2** relative to **3** also indicates a symmetry lowering of the Mn environment in the former compound. These results are in accordance with the X-ray structural data for compounds **2** and **3**.

Experimental Section

Physical Measurements: Elemental analyses for C, H N, S (Carlo Erba 1106) were performed in the Laboratory of Microanalysis of the Institute of Organic Chemistry, Novosibirsk. Infrared spectra were measured on KBr disks with a Bruker IFS-85 Fourier spectrometer. For determination of water the curves of mass losses and TGD curves of the compounds were recorded at a heating rate of 3 °C/min (temperature range 20−300 °C) under an atmosphere of argon with a TGD-7000 RH thermal analysis controller (Sinku-Riku, Japan). Measurement of Mn-*K* XANES spectra were performed using synchrotron radiation of the VEPP-3 storage ring at the Budker Institute of Nuclear Physics at Novosibirsk. A channel-cut Si (111) single crystal was used as the two-crystal monochromator. The spectra were obtained using the transmission mode.

X-ray Structural Measurements: The structures of **1** and **2** were determined by X-ray structural analysis. Crystallographic data and details of diffraction measurements are given in Table 1. Both structures were solved by direct methods and refined by full-matrix least-squares methods on F^2.

Structural Studies of $[(n\text{Bu})_4N]_2Ni(H_2O)_5[Re_6Se_8(CN)_6]\cdot 2H_2O$ (1): The diffraction data were collected with a Stoe IPDS diffractometer with graphite-monochromated Mo-K_α radiation at T = 93(2) K using the φ-oscillation method. Absorption correction were applied using information from multiple scans. Anisotropic displacement parameters were refined for all non-H atoms. The final difference electron density map features were with no chemical meaning. Experimental crystal data are listed in Table 1. The calculations were performed with SHELX-97[8] and standard Stoe IPDS software.[9]

Structural Studies of $[(n\text{Bu})_4N]_2Mn(H_2O)_4[Re_6Se_8(CN)_6]\cdot 2H_2O$ (2): The diffraction data were collected with an Enraf−Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation at ambient conditions (T = 291 K). Reflection intensities were collected by standard techniques [θ/2θ scans with variable speed, ω range (deg.) = 0.9 + 0.35tg(θ)] and absorption corrections were applied by measuring azimuthal scan curves. Anisotropic displacement parameters were refined for all non-H atoms. The final difference electron density map features were with no chemical meaning. The calculations were performed with the standard Enraf−Nonius CAD4 programs (CD4CA0, CADDAT) and SHELX-93 (structure solution and refinement).[10]

Syntheses: The starting cluster compound $K_4[Re_6Se_8(CN)_6]\cdot 3.5H_2O$ was prepared from polymeric $Re_6Se_8Br_2$ [11] as described in refs.[2] All other reagents were employed as purchased.

$[(n\text{Bu})_4\text{N}]_2\text{Ni}(\text{H}_2\text{O})_5[\text{Re}_6\text{Se}_8(\text{CN})_6]\cdot 2\text{H}_2\text{O}$ (1): A mixture of $(n\text{Bu})_4\text{NBr}$ (160 mg, 0.48 mmol) and $\text{Ni(OAc)}_2\cdot 4\text{H}_2\text{O}$ (60 mg, 0.24 mmol) in 20 mL of water was gradually added to a hot solution of $\text{K}_4\text{Re}_6\text{Se}_8(\text{CN})_6\cdot 3.5\text{H}_2\text{O}$ (500 mg, 0.24 mmol) in 10 mL of water. The resulting mixture was stirred and heated for two hours. The fine orange precipitate was then washed with water (3 × 15 mL) and dried. Yield: quantitative (605 mg, 98%); $\text{C}_{38}\text{H}_{86}\text{N}_8\text{NiO}_7\text{Re}_6\text{Se}_8$ (2574.74): calcd. C 17.85, H 3.31, N 4.38; found C 18.10, H 3.46, N 4.49. Mass loss 4.4% at 105 °C (calcd 4.2% for six water molecules). IR: $\tilde{\nu}$ = 2109 (intense), 2142 (shoulder) (CN); 1620 cm^{-1} (weak) (H_2O).

$[(n\text{Bu})_4\text{N}]_2\text{Mn}(\text{H}_2\text{O})_4[\text{Re}_6\text{Se}_8(\text{CN})_6]\cdot 2\text{H}_2\text{O}$ (2): A mixture of $(n\text{Bu})_4\text{NBr}$ (160 mg, 0.48 mmol) and $\text{MnSO}_4\cdot 5\text{H}_2\text{O}$ (240 mg, 1 mmol) in 20 mL of water was gradually added to a hot solution of $\text{K}_4\text{Re}_6\text{Se}_8(\text{CN})_6\cdot 3.5\text{H}_2\text{O}$ (500 mg, 0.24 mmol) in 10 mL of water. The resulting mixture was stirred and heating for two hours. The fine orange precipitate was then washed with water (3 × 15 mL) and dried. Yield: quantitative (582 mg, 95%); $\text{C}_{38}\text{H}_{84}\text{MnN}_8\text{O}_6\text{Re}_6\text{Se}_8$ (2552.95): calcd. C 17.88, H 3.32, N 4.39; found C 18.00, H 3.49, N 4.45. IR: $\tilde{\nu}$ = 2108 (intense), 2130 (shoulder) (CN); 1649 cm^{-1} (weak) (H_2O).

Single Crystal Growth: Both compounds have low solubility and therefore crystals suitable for X-ray single crystal analysis were grown in a U-tube filled with silica gel as described in ref.[3a] The crystals were located near the middle part of the U-tube. The following reagents were used: $\text{K}_4\text{Re}_6\text{Se}_8(\text{CN})_6\cdot 3.5\text{H}_2\text{O}$, $n\text{Bu}_4\text{NBr}$, $\text{Ni(OAc)}_2\cdot 4\text{H}_2\text{O}$ for **1**, $\text{Mn(OAc)}_2\cdot 4\text{H}_2\text{O}$ for **2**. Octahedral red crystals can be easily separated from the silica gel manually. X-ray powder diffraction and IR spectroscopy confirmed the identity of these crystals.

CCDC-167585 (**1**) and CCDC-167586 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

On the Intra- and Intermolecular Bonding in Polyiodides

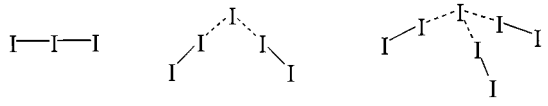
Lars Kloo,*[a] Jan Rosdahl,[a] and Per H. Svensson[a]

Keywords: Iodine / Polyhalides / Bond theory

The nature of intra- and intermolecular interactions of polyiodides has been investigated by means of quantum chemical methods and structural statistical data. In the region of "secondary bonds" the interaction is adequately described in terms of covalent bonding accompanied by dispersion. At greater distances the interaction is dominated by ion-quadrupole interactions between ionic and neutral iodine building blocks of the polyiodide structures.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Polyiodides have been extensively studied in the solid and liquid state and are characterized by a strong tendency to concatenation.[1] The solid structures may contain small, discrete polyiodides or large, extended anionic networks of interconnected units. Typically, polyiodides are described according to the stoichiometry of the discrete anions or the repeating units of the extended structures, such as triiodides **1**, pentaiodides **2**, heptaiodides **3** etc. Today, repeating units in complex networks have been claimed to contain up to almost 30 iodine atoms, for instance I_{29}^{3-} in $(Fc)_3I_{29}$ and I_{26}^{3-} in $(Me_3S)_3I_{26}$.[2,3] Almost all these structures can be described as consisting of only three fundamental building blocks: I^-, I_2 and I_3^-.



1 **2** **3**

In this context it is also worth noting that the triiodides occupy a special position in the sense that they typically contain discrete I_3^- ions with intermolecular I−I contacts near the van der Waals (vdW) distances, forming linear, zigzag or T-shaped packing patterns. Higher polyiodides can be regarded as constructed from the ions I^- or I_3^-, solvated by the neutral solvent molecules I_2, often into low-dimensional extended networks.

Depending on the extent of intermolecular bonding, I_2 displays I−I bond lengths between 2.69 and 2.80 Å. The triiodide ion is either centrosymmetric with an I−I bond length of about 2.91 Å or belongs to an asymmetric configuration with I−I distances between 2.85 and 3.00 Å. Thus, the intramolecular bond-length range for the fundamental building blocks can be defined as 2.69−3.00 Å. The sum of vdW radii for iodine is 4.3 Å and the I_2−I_2 vdW distance is normally set to 3.9−4.0 Å. With this in mind it is interesting to note the large number of intermolecular I−I contacts in the range between 3 and 4 Å. This was made clear by a structural statistical study of pentaiodides by Bittner.[4] I−I contacts in the intermediate range between typical intramolecular and vdW distances are normally referred to as "secondary bonds".

The assignment of an I−I contact as a secondary bond seems purely pragmatic. An arbitrary cut-off set to around 3.5 Å often allows a complicated network structure to be described in simpler terms (interconnected iodine molecules, pentaiodides etc.). However, polyiodide chemistry seems to have been focused on the search for larger and larger repeating units (i.e. higher I_2 contents) in recent years, and one can observe a progressive increase in the assigned distance cut-off. Is the secondary bond a completely artificial concept? Which type of interaction predominates at the typical intermolecular I−I distances between 3 and 4 Å? These questions were the motivation for this study.

For instance, pentaiodides (I_5^-) are found in three different forms irrespectively of whether they are discrete or part of an extended network: V-shaped $[(I^-)\cdot 2I_2]$, L-shaped $[(I_3^-)\cdot I_2]$ and linear $[(I^-)\cdot 2I_2]$. The bonding in these pentaiodides can be described in two principally different ways, in terms of either covalent interactions between mainly valence 5p orbitals or of closed-shell interactions (vdW interactions, charge-transfer interaction or dative bonds) between the building blocks.

The present study relies on statistical data for two archetypal structural fragments in polyiodide chemistry, employing the CSD database, and quantum chemical calculations providing potential energy surfaces (PES), bond order surfaces (BOS) and electron density maps of the same or similar fragments. The PES values obtained for

[a] Department of Inorganic Chemistry, Royal Institute of Technology,
10044 Stockholm, Sweden

Hartree−Fock (HF) and correlated levels are used to study the influence of correlation. The difference in energy between HF and correlated methods is axiomatically regarded as a measure of the correlation energy, thus providing information about the dispersion interaction. As pointed out in recent reviews, the interpretation of the PES is far from straightforward.[5,6] Although the explicit inclusion of the dynamic electron correlation provides insight into the intermolecular dispersion interaction, it also affects the intramolecular interactions. Therefore, difference PES values contain both intra- and intermolecular effects of correlation. The BOS values used in this work are based on a natural bond population analysis (NPA), although the very same information can be extracted from other types of population analyses, including the democratic method of Mulliken.[7]

Statistics

Figure 1 shows the histogram of the configuration in **4**. The histogram thus represents the "view" from an I_2 molecule with respect to both intra- and intermolecular contacts to another iodine atom. This representation is focused on "I_3^-" units in polyiodide structures and consequently is heavily dominated by the intramolecular contacts from 2.7−3.0 Å; the polyiodide structures are mainly triiodides (vide infra). The distribution of I−I contacts is largely uniform over the entire region of "secondary bonds", i.e. between 3 and 4 Å, whereas an increase is observed at distances greater than 4 Å. The latter effect can probably be attributed to purely statistical/sterical reasons, allowing more neighbours at greater distances. Ideally, an initial parabolic increase would be expected.

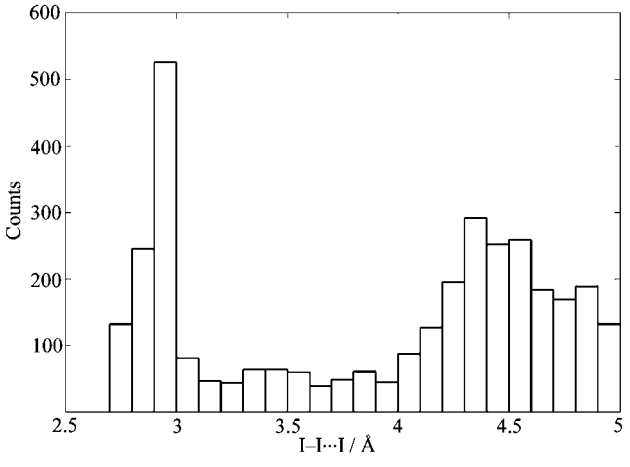


Figure 1. Histogram of the I−I distances from an I_2 fragment

4 **5**

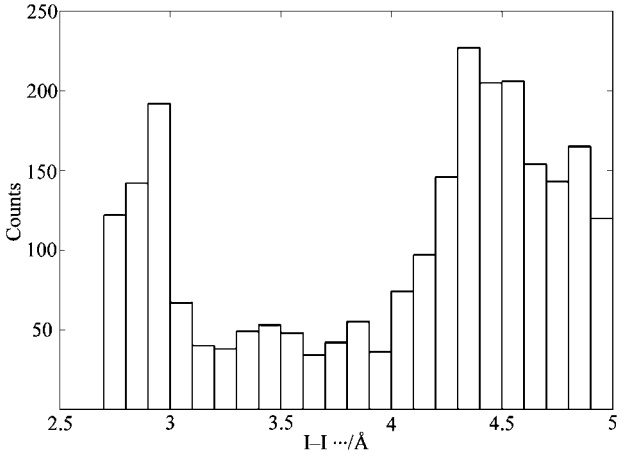

Figure 2. Histogram of the I−I distances from an I_3 fragment

Figure 2 shows the corresponding histogram for configuration **5**. Here, the diagram is completely dominated by intermolecular contacts from the "view" of a triiodide unit. Unfortunately, in the database there are quite a number of structures, in which the intramolecular I−I contacts have not been properly defined. As a result, these will also appear at short distances in this figure, making the overall distribution of I−I contacts very similar to that in Figure 1. Again, a very uniform distribution is observed between 3 and 4 Å.

The Triiodide System

The PES for I_3^- at the HF level is shown in Figure 3, corresponding to the configuration in **6**. Here, the distance *r1* and angle α are changed and the distance *r2* optimized at each point of the PES. It is clear that the preferred structure is centrosymmetrical (D_{ih}) with an I−I distance just below 3.0 Å. The intramolecular bonding in trihalide systems was extensively studied and the present results are in good agreement with previous work.[1,8] In order to estimate the influence of dynamic correlation, calculations at the MP2 and CCSD levels were also performed. The difference PES at MP2 level is given in Figure 4. Correlation at both levels gives an overall stabilization of the triiodide structure. A minimum valley (corresponding to a maximum in the

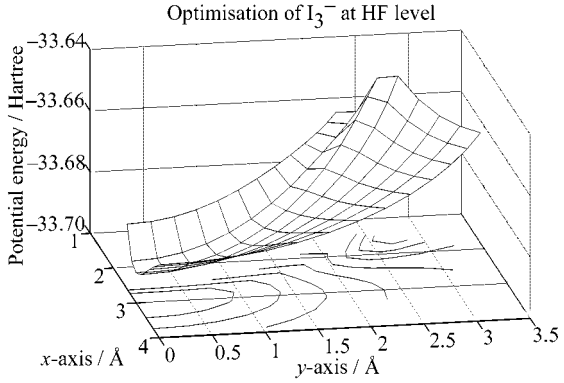

Figure 3. PES at HF level for the I_3^- ion

correlation stabilization) is observed near the optimum I−I distance (2.965, 2.943 and 2.964 Å for the HF, MP2 and CCSD levels, respectively). Remarkably enough, a minimum in the correlation energy seems to exist at a conformation corresponding to D_{3h} symmetry. However, this geometry is Jahn−Teller-unstable and not attainable by single-configuration methods. Nevertheless, this permits the conclusion that no obvious extra stabilization results from correlation at distances greater than the equilibrium intramolecular distance in I_3^-.

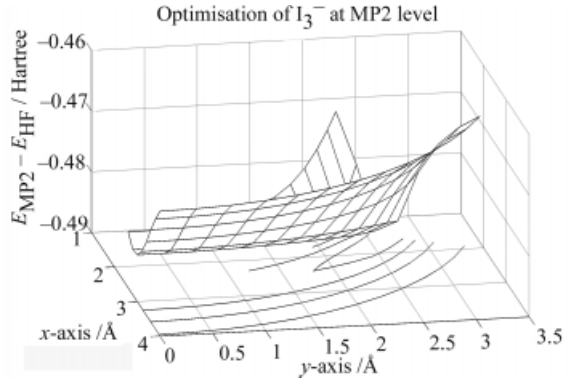

Figure 4. Difference PES between HF and MP2

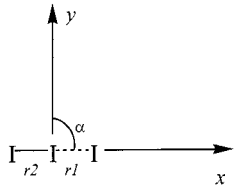

6

A plot of the NLMO/NPA BOS at the HF level is given in Figure 5. As expected, the bond order is close to 0.5 at the equilibrium distance and then progressively decreases as the I−I distance is increased. It is also notable that the decrease is less steep for the linear conformation, thus reflecting the behaviour of the corresponding PES. The BOS at the MP2 level is very similar, and the bond order at 4 Å is 0.046 and 0.087 at the HF and MP2 levels, respectively. A naive interpretation of these data suggests the postulation

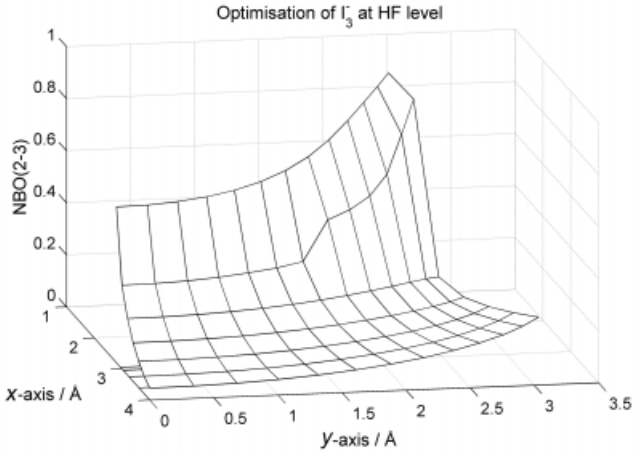

Figure 5. NLMO/NPA BOS for the I_3^- ion at HF level

of a weak covalent interaction between the I_2 and I^- fragments extending to the region of the so-called "secondary bonds". The interaction amounts to at least 15% − based on the overlap population data − of a "normal" I−I bond in I_3^-. This interpretation is also supported by the total electron density maps of $I_2\cdots I^-$ contacts at 5.0, 4.0 and 3.5 Å shown in Figure 6a−c. Below 4 Å there is a substantial electron density between the I_2 and I^- fragments. The difference electron density map in Figure 7 gives more detailed information about the bonding scheme. When brought into contact with an I_2 molecule (gradually from just above 4 Å), the I^- ion loses electron density from essentially a 5p orbital, and this electron density is transferred to the anti-

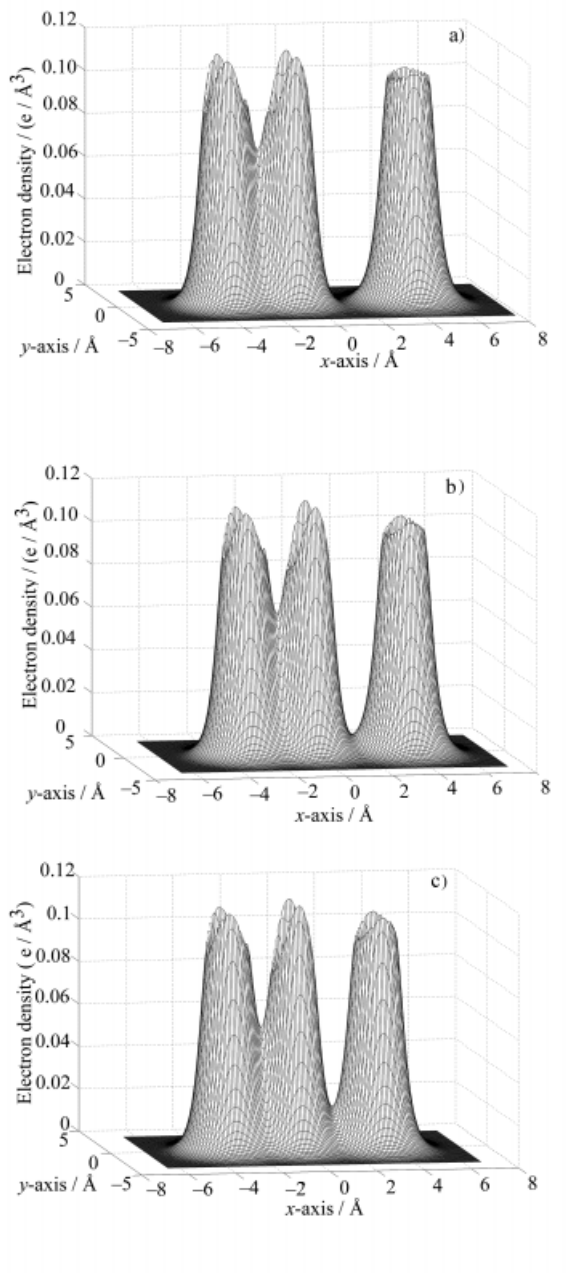

Figure 6. Total electron density of the $I^-\cdots I_2$ interaction in I_3^- at a) 5.0 Å, b) 4.0 Å and c) 3.5 Å

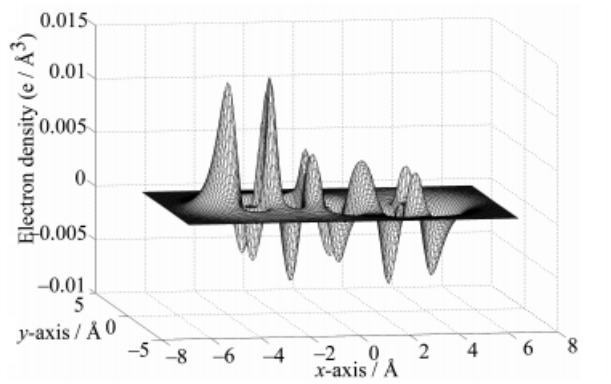

Figure 7. Difference electron density map of the $I^-\cdots I_2$ interaction in I_3^- at 3.5 Å (I^- on the right-hand side)

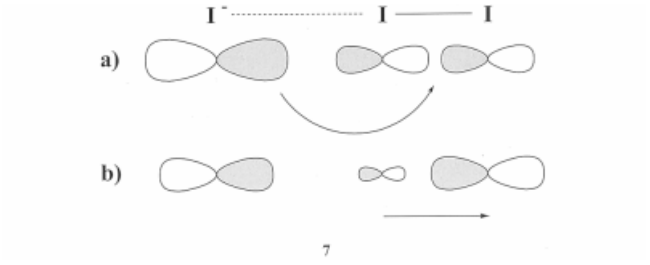

bonding LUMO of 5p−5p character in the I_2 fragment (a). As a secondary effect, the transferred electron density is polarized by the remaining negative charge on the I^- fragment (b), thus approaching the (−1/2)−(0)−(−1/2) charge distribution in the centrosymmetric I_3^- ion.

In order to further investigate the character of the bonding in I_3^-, the basis set superposition errors (BSSE) corrected interaction energy at the MP2 level was studied as a function of the distance between the centres of mass of the two fragments I_2 and I^- up to 20 Å separation. The BSSE at 4 Å is estimated to account for 2% of the total interaction energy, which gives an indication of the corrections involved in the present analysis. At greater distances the interaction is dominated by ion−quadrupole interactions because of the strong quadrupole moment of I_2 ($-1.17\ 10^{-38}$ Cm^2; MP2). The total interaction energy curve (IEC) is shown in Figure 8. The IEC is adequately described by ion−quadrupole, induction and dispersion interactions at distances greater than 7 Å. At shorter distances, the situation is of course complicated by the intramolecular interactions and charge-transfer effects. Here, a very simplistic approach is adopted: The long-range interactions are extrapolated down to the equilibrium I−I distance in I_3^- (about 3 Å). Although the induction and ion−quadrupole interactions were corrected for charges on the fragments, this is an oversimplification neglecting the damping of intermolecular interactions at shorter distances, especially concerning the dispersion interaction. Nevertheless, a maximum contribution to the total interaction energy in the "secondary bond" region may be estimated.

The remaining bonding interaction is assumed to arise mainly from intramolecular covalent and electrostatic interactions, which were modelled by a simple (exponential)

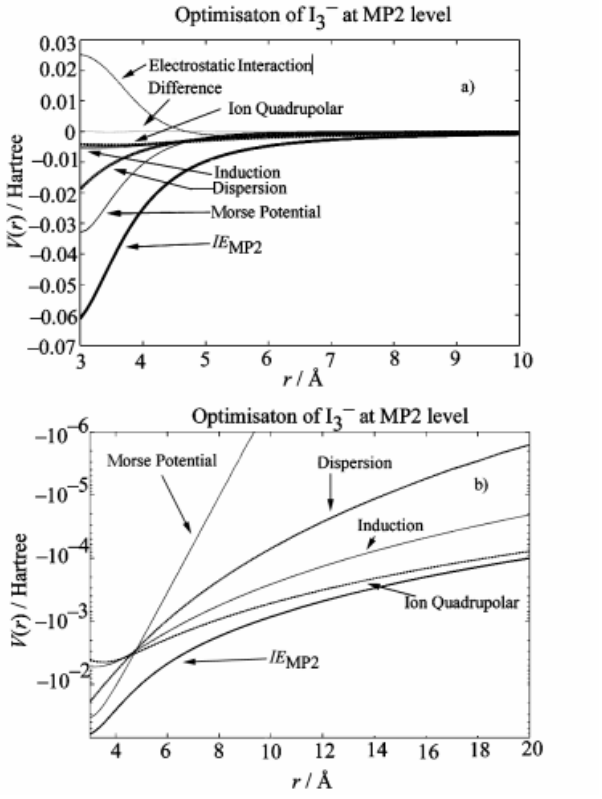

Figure 8. Interaction energy for the MP2 level and models as functions of the shortest distance between the fragments plotted in a) normal scale and b) logarithmic scale; the distance r refers to the distance between the centres of the iodide ion and the closest iodine atom in the I_2 molecule

Morse potential. The overall fit is excellent. Several fundamental conclusions can be drawn from the results.

Firstly, based on the Morse potential obtained the covalent interaction is significant up to distances of at least 5 Å. In Figure 8 the electrostatic interaction based on the NBO charges of the I^- and I_2 fragments is also included, although this was not used in the modelling of the total IEC. At greater distances the iodide ion induces a dipole on the iodine molecule, where polarization gives the closest iodine atom a partial positive charge and the most distant iodine atom a partial negative charge, resulting in a net attractive interaction. This situation prevails down to about 5 Å, where charge-transfer, inferring the beginning of orbital overlap, causes the repulsive factor to dominate. At shorter distances a strongly repulsive interaction is observed. The changeover from attractive to repulsive electrostatic interaction is at about 4.7 Å, thus giving an independent estimate of the extension of covalent interaction.

Secondly, in the region of "secondary bonds" (3−4 Å) the interaction energy is dominated by intramolecular and dispersion interactions. However, the dispersion contribution at these short distances is likely to be greatly overestimated. In addition, it is obvious from the repulsive electrostatic interaction that the covalent interaction compensates for extensive intramolecular ion−ion (or ion−dipole) repulsion. The results are very clear in one respect: There

is no specific justification based on bonding arguments for using a cut-off between intra- and intermolecular bonding somewhere in the region of "secondary bonds".

We are of course aware of the classical controversy regarding the bonding description of the X_2-X_2 interaction in condensed halogens, in particular that of Cl_2-Cl_2 (see for instance ref.[9]). The extensive literature on this subject, in many cases reduced to semantics rather than chemistry, clearly shows that different bonding models can be used to rationalize the interhalogen bonding. It is not our intention to revive this controversy with the present work. There are obvious similarities and differences between the bonding situation in "pure" halogens and the polyiodides, where the higher charge-transfer capability of the ionic fragments in polyiodides is the most important difference. This is emphasized by adopting a frontier orbital view: the HOMO energy of I^- (the 5p orbitals) is −3.33 eV, which should be compared with the HOMO (π_g) and LUMO (σ_u) energies of I_2 at −9.78 and −0.61 eV, respectively; here all values are taken from the results of the MP2 calculations. For the interactions in the region from primary to "secondary bonds" between the ionic and neutral building blocks of the polyiodides, the collective data from correlation effects, bond-order calculations, intermolecular interaction modelling and electron-density distributions thus lead us to propose that the bonding between 3 and 4 Å is dominated by covalent interactions, with additional dispersion interactions. Recently, a similar approach was used by Boese and co-workers in the rationalization of the crystal structure of ClF.[10]

The Pentaiodide System

The BSSE-corrected PES for a V-shaped I_5^- ion at the HF level is shown in Figure 9, corresponding to the configuration in **8** (*r2* optimized for each α and *r1*). As previously noted, the PES is very flat with respect to angular deformation. The optimum intermolecular ($I^-\cdots I_2$) distances and angles (*r1*/α) are 3.267 Å/110° and 3.048 Å/102° at HF and MP2 levels, respectively. This geometry and the structural data correspond well with those found experimentally. The difference PES at the MP2 level is shown in Figure 10. The

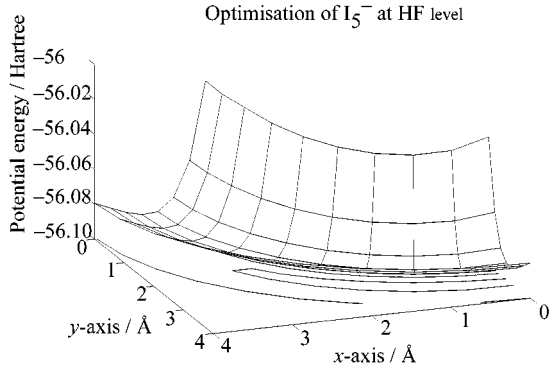

Figure 9. PES at the HF level for the V-shaped I_5^- ion (C_{2v} symmetry)

results of the theoretical study by Lin and Hall, where a decrease in intermolecular bond length is observed when dynamic correlation is taken into account, was taken as an indication of a substantial dispersion interaction.[11]

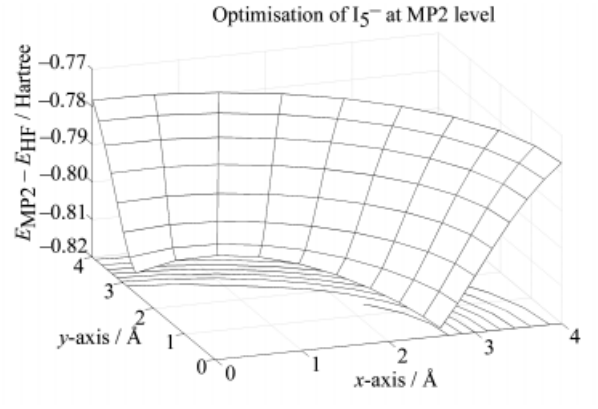

Figure 10. The difference PES between HF and MP2 levels for the V-shaped I_5^- ion

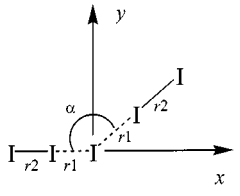

8

The same effect is seen in our results, where *r1* decreases for the MP2 level calculation. However, the difference PES values are similar to those for the I_3^- ion in being less informative on the intermolecular stabilization caused by the dispersion interaction. Again, both the NLMO/NPA BOS in Figure 11 and the total electron density map of an I_5^- ion at the optimized parameters in Figure 12 instead indicate a substantial charge transfer or covalent interaction in the range of "secondary bonding". Also, the difference electron density map shows a charge transfer from two independent 5p orbitals of the I^- fragment to the 5p−5p orbital-based LUMOs of the two I_2 fragments, thus mimicking the bonding situation in I_3^- (Figure 13). The V-shaped I_5^- ion can essentially be visualized as consisting of two I_3 legs with a common central iodine atom.

Conclusions

The present structural, statistical and computational data give no justification for the postulation of a "secondary bond" region other than for purely pragmatic reasons with respect to structural description and rationalization. The chemical bonding in the "secondary bond" region (between 3 and 4 Å) can be very adequately described in terms of intramolecular bonding with an additional dispersion interaction between the I^- and I_2 fragments in polyiodide compounds. The intramolecular interaction is comprised of attractive orbital overlap extending to almost 5 Å, compensating for a repulsive electrostatic interaction.

Databases and Calculational Details

The structural statistical data were retrieved from the Cambridge Structural Database system (CSD).[12] Only structures with I···I interactions within polyiodides were included (thus, for example, I···I−S and I···I−P interactions were excluded). Structures with disorder, errors and $R \geq 10\%$ were excluded from the statistics. The database contains approximately 300 triiodides and 40 higher polyiodides. All quantum chemical calculations were performed using Gaussian 98 (revision A.7).[13] An ECP-based basis set was used for iodine, employing the Stuttgart group *quasi*-relativistic ECP and an uncontracted valence space (7s6p3d2f), see Table 1.[14] Calculations were performed at Hartree−Fock (HF), 2nd-order Møller−Plesset perturbation theory (MP2) and, where possible, coupled cluster levels including single and double excitations (CCSD). The PES values obtained were corrected for basis set superposition errors (BSSE). However, previous results for the $I_3^-\cdots I_2$ and $AuI_2^-\cdots I_2$ interactions suggest that the main features of these weak interactions are obtained without correction for BSSE.[15] In an attempt to describe the $I^-\cdots I_2$ interaction, the interaction energy curve (IEC) at MP2 level out to 20 Å was determined, allowing the I−I distance of the iodine unit to relax at each step. The model interactions were fitted to the calculated IEC by least-squares methods. At greater distances the IEC was adequately described by ion−quadrupole ($1/r^3$), induction ($1/r^4$), and dispersion ($1/r^6$) interactions.[16] The long-range interactions were fitted in the region 7−20 Å, while a Morse potential, used to model intramolecular interaction, was fitted in the region 3−20 Å. The induction and ion−quadrupole interactions were compensated for the charge on I^- by means of calculated NBO charges.

Keywords: Platinum / P ligands / Terminal phosphides / Hydrides / Small ring systems

cis-$PtCl_2(PHCy_2)_2$ (**1**) reacts at 0 °C in toluene with sodium metal to give the dinuclear Pt^I complexes *cis*-[$(PHCy_2)$-$(H)Pt(\mu\text{-}PCy_2)]_2$ (**2**) and [$(PHCy_2)(Cl)Pt(\mu\text{-}PCy_2)Pt(PHCy_2)_2$]-(*Pt–Pt*) (**3**). On standing in solution, complex **3** isomerizes to *trans*-[$(PHCy_2)(Cl)Pt(\mu\text{-}PCy_2)_2Pt(PHCy_2)(H)$] (**4**). When treated with sodium at room temperature, complex **3** transforms into [$Pt(\mu\text{-}PCy_2)(PHCy_2)]_2$(*Pt–Pt*) (**5**). The sodium reduction of **1** carried out at room temperature leads to the direct formation of the phosphido bridged dinuclear complex [$Pt(\mu\text{-}PCy_2)(PHCy_2)]_2$(*Pt–Pt*) (**5**) along with the mononuclear platinum(II) complex [*trans*-$Pt(PCy_2H)_2(PCy_2)Cl$] (**6**). Complex **6**, which has also been obtained by reaction of **1** with $LiPCy_2$, unambiguously shows by single-crystal X-ray diffraction the presence of a pyramidal terminal phosphido ligand.

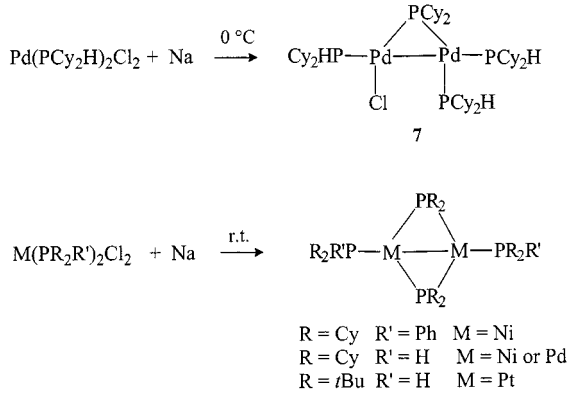
Introduction

The reaction of sodium metal with phosphanyl divalent group-10 halide complexes has been widely used to access molecules in which a transition metal atom exhibits a low-valent and somehow unusual oxidation state. In particular, NiP_2X_2 (P = PEt_3, P*n*Bu_3, PEt_2Ph; X = Cl, Br) was reduced under argon to the zero-valent tetracoordinated species NiP_4, whereas $Ni(PCy_3)_2X_2$ (X = Cl, Br) gave $Ni(PCy_3)_3$ or $[NiX(PCy_3)_2]_2$.[1] The chelating diphosphane complexes $Ni(dp)Cl_2$ [dp = 1,2-bis(diphenylphosphanyl)ethane (dppe), 1,2-bis(diethylphosphanyl)ethane (depe), 1,2-bis(dicyclohexylphosphanyl)ethane (dcpe), 1,3-bis(dicyclohexylphosphanyl)propane (dcpp), 1,4-bis(dicyclohexylphosphanyl)butane (dcpb)] afforded the 14- (dp = dcpe, dcpp, dcpb), 16- (dp = dcpe, dcpb), or 18-electron (dp = dppe, depe, dcpe) complexes Ni(dp), $Ni_2(dp)_3$, and $Ni(dp)_2$, respectively, depending on the diphosphane and on the reaction conditions.[2] Phosphido-bridged dinuclear metal(I) complexes have been accessed by sodium reduction of $Ni(PCy_2Ph)_2Cl_2$,[3] $Pt(PH\textit{t}Bu_2)_2Cl_2$,[4] and $M(PHCy_2)_2Cl_2$ (M = Ni, Pd).[5] Moreover, when the sodium reaction of $Pd(PHCy_2)_2Cl_2$ was carried out at 0 °C, the isolation of [$(PHCy_2)(Cl)Pd(\mu\text{-}PCy_2)Pd(PHCy_2)_2$](*Pd−Pd*) (**7**) was achieved (Scheme 1).



Scheme 1

In this paper we describe the reactivity of *cis*-$Pt(PHCy_2)_2Cl_2$ (**1**) towards sodium metal which was found to depend on the reaction temperature. At 0 °C the phosphido-bridged dinuclear platinum species *cis*-[$(PHCy_2)(H)Pt(\mu\text{-}PCy_2)]_2$ (**2**) and [$(PHCy_2)(Cl)Pt(\mu$-

$PCy_2)Pt(PHCy_2)_2](Pt-Pt)$ (**3**) were formed, whereas a mixture of $[Pt(\mu\text{-}PCy_2)(PHCy_2)]_2(Pt-Pt)$ (**5**) and the mononuclear (phosphido)platinum(II) complex [*trans*-$Pt(PHCy_2)_2(PCy_2)Cl]$ (**6**) was obtained when the reaction was carried out at room temperature.

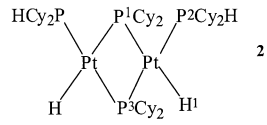
Results and Discussion

The reaction of *cis*-$PtCl_2(PHCy_2)_2$ (**1**) with sodium metal carried out in toluene at 0 °C resulted in the formation of two dinuclear complexes **2** and **3** in an approximately 4:1 ratio. Complex **2** is fairly stable in the air but air-sensitive in aromatic solvents, where it easily dissolves. Taking advantage of insolubility in alcohols it was isolated as a white powder from the reaction mixture by treatment with methanol.

Complex **2** exhibits in the IR spectrum two characteristic bands at 2299 and 1940 cm^{-1} due to P−H and Pt−H stretching, respectively. The $^{31}P\{^1H\}$ NMR spectrum of **2** recorded at room temperature consists of three signals, all flanked by ^{195}Pt satellites: two doublets (δ = 24.8 and δ = −170.6) and a triplet of doublets (δ = −123.0). The high-field signals at δ = −123.0 and δ = −170.6, which are mutually coupled [^2J(P-P) = 104 Hz], are typical for bridging phosphides involved in four-membered rings,[6] and strongly support a dinuclear structure for **2**, with two inequivalent phosphide groups bound to two platinum atoms without *Pt−Pt* linkage. Moreover, the pattern of the phosphide ^{31}P signals (triplet of doublets and doublet) and the value of the coupling constant between the phosphorus signal at δ = −123.0 and that at δ = 24.8 [J(P-P) = 308 Hz] both suggest a symmetrical dimeric structure in which two platinum atoms, each bearing a dicyclohexylphosphane ligand are bridged by two dicyclohexylphosphide groups. In the dimer the dicyclohexylphosphane ligands are *cis* with respect to each other and *trans* with respect to the bridging phosphide group resonating at δ = −123.0. ^1H and proton-coupled ^{31}P NMR spectroscopy experiments together with IR data indicate that, on each platinum atom, the *cis* positions with respect to the terminal dicyclohexylphosphane ligands are occupied by terminal hydride ligands. In addition to the resonances of aliphatic protons and a broad doublet which can be attributed to the hydrogen atom directly bound to P in the coordinated dicyclohexylphosphane [δ = 4.50; ^1J(P-H) = 317 Hz], the ^1H NMR spectrum shows a doublet of doublet of doublets [J(P-H) = 143, 20, and 9 Hz] with ^{195}Pt satellites centred at δ = −3.84 [^1J(Pt-H) = 905 Hz]. This latter signal could be attributed to two equivalent terminal hydride ligands, *cis* with respect to each other and *trans* with respect to the bridging phosphide group resonating at δ = −170.6 as suggested by the high value of ^2J(P-H) (143 Hz).

In the proton-coupled ^{31}P NMR spectrum the signal at δ = −123.0 (phosphide P^3Cy_2, see Table 1 for numbering) remains substantially unchanged while the signal at δ = 24.8 (phosphanes P^2Cy_2H) splits into a pseudo-triplet due to the additional direct coupling ^1J(P-H) = 317 Hz, and the signal at δ = −170.6 (phosphide P^1Cy_2) splits into a triplet of doublets due to the additional coupling with the *trans* hydride ligands [^2J(P-H) = 143 Hz].

Table 1. NMR parameters for complex **2** ([D_6]benzene, 295 K); chemical shifts (bold) are in ppm; coupling constants (normal) are in Hz



2

	P^1	P^2	P^3	H^1	Pt
P^1	**−170.6**	ca. 0	104	143	1322
P^2	ca. 0	**24.8**	308	20	1968
P^3	104	308	**−123.0**	9	2118
H^1	143	20	9	−3.84	905
Pt	1322	1968	2118	905	−4441

Finally, the value of ^1J(Pt-H) (905 Hz) and the position of the Pt−H stretching band in the IR spectrum both indicate terminal coordination for the hydride ligands. The dimeric structure of **2** formulated as *cis*-$[(PHCy_2)(H)Pt(\mu\text{-}PCy_2)]_2$ was also confirmed by the $^{195}Pt\{^1H\}$ NMR spectrum which consists of a doublet of doublets of doublets centred at δ = −4441 [^1J(Pt-P^1) = 1322, ^1J(Pt-P^2) = 1968 Hz, and ^1J(Pt-P^3) = 2118 Hz].

The minor product obtained in the sodium reduction of **1** at 0 °C, is a yellow-orange solid, the spectroscopic features and elemental analysis of which indicate the phosphido-bridged platinum(I) complex $[(PHCy_2)(Cl)Pt(\mu\text{-}PCy_2)Pt(PHCy_2)_2](Pt-Pt)$ (**3**), and represents the Pt analogue of the palladium complex **7**. In the region of the P−H stretching the IR spectrum of **3** shows the convolution of two bands of relative intensities 2:1 centred at 2295 cm^{-1} and 2255 cm^{-1}. The Pt−Cl band was found at 301 cm^{-1}. The $^{31}P\{^1H\}$ NMR spectrum of **3** recorded at room temp. shows signals centred at δ = 185.5, 37, and 16 and is reminiscent of that of **7**.

Among these signals, the only well-resolved one is that centred at δ = 185.5 (Figure 1) which does not significantly split in the proton coupled spectrum. This signal can be attributed to a bridging phosphide group involved in a three-membered Pt_2P ring[7] in which the two platinum atoms are inequivalent. The spectrum consists of a central doublet of triplets due to isotopomer **A**, which does not contain ^{195}Pt (43.8%) flanked by three different sets of satellites, two arising from isotopomers **B** and **C** (22.4% each), which contain only one ^{195}Pt nucleus and one due to isotopomer **D** (11.4%) which contains two ^{195}Pt nuclei. The coupling constants ^2J(P-P) = 231 and 26 Hz, which are clearly seen in the signal of isotopomer **A**, indicate that the phosphorus atom of the bridging phosphide group is coupled with a pseudo-*trans*- and two pseudo-*cis*-oriented phosphorus nuclei. The sets of satellites arising from both

isotopomers **B** and **C** appear as doublets of doublets of doublets. The couplings of P^1 with the two inequivalent platinum atoms gives the constants $^1J(Pt^2\text{-}P^1)$ = 3072 Hz and $^1J(Pt^1\text{-}P^1)$ = 3911 Hz whereas the coupling with P^2 and P^4 gives $^2J(P^1\text{-}P^2)$ = 34 Hz and $^2J(P^1\text{-}P^4)$ = 22 Hz (see Table 2 for P and Pt numbering). The third subset of signals due to the isotopomer **D** consists of a doublet of doublets of doublets of multiplets. The relevant coupling constants are $^1J(Pt^2\text{-}P^1)$ = 3080 Hz and $^1J(Pt^1\text{-}P^1)$ = 3916 Hz. Interestingly, the central signal appears as a doublet of triplets (instead of the expected ddd). This can be explained in terms of the isotopomer **A** having either coincident $^2J_{P,P}$ or a greater linewidth of the signal with respect to **B**, **C**, and **D**, due to difference in relaxation efficiency in different isotopomers. The latter explanation is in agreement with high-temperature spectra (82 °C) that also show the expected ddd for isotopomer **A**.[8]

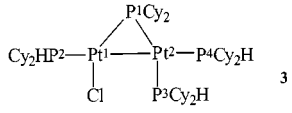
Table 2. NMR parameters for complex **3** ([D_8]toluene, 295 K); chemical shifts (bold) are in ppm; coupling constants (normal) are in Hz



3

	P^1	P^2	P^3	P^4
P^1	**185.5**	34	231	22
P^2	34	**16.3**	16	154
P^3	231	16	**37**	12
P^4	22	154	12	**15.8**

The other $^{31}P\{^1H\}$ NMR resonances of **3** are a very broad signal centred at δ = 37 and a broad multiplet centred at δ = 16. The signal at δ = 37 can be attributed to P^3 of the dicyclohexylphosphane pseudo-*trans* to the phosphide group. Dynamic $^{31}P\{^1H\}$ NMR spectroscopic experiments showed that the signal at δ = 37, which does not change significantly by lowering the temperature down to −38°C, splits into a broad doublet [$^2J(P^1\text{-}P^3)$ = 231 Hz] at high temperatures (> 50 °C) due to the coupling with the bridging phosphide group. The broadness of this signal at or below room temperature, can therefore be explained in terms of hindered rotation around the P^3−Pt bond originating in a set of slowly interconverting rotamers.

For the related palladium complex **7** the signal of the $PHCy_2$ ligand *trans* to the bridging phosphide group is already a broad doublet at room temperature[5] and becomes a very broad singlet by lowering the temperature down to −38 °C (Figure 2). This is in agreement with a more pronounced fluxionality of palladium with respect to platinum complexes.

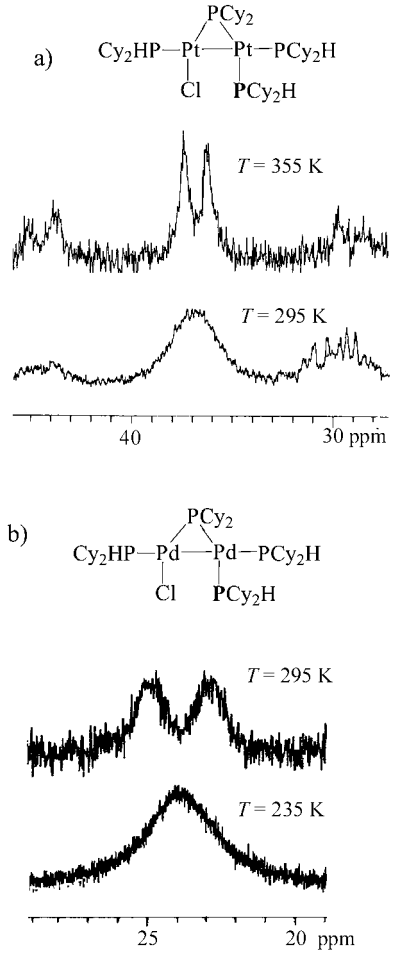


Figure 2. VT $^{31}P\{^1H\}$ NMR spectra of **3** and **7** in [D_8]toluene; (a) 202 MHz; (b) 81 MHz

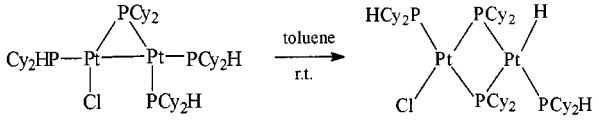
In the case of complex **3**, P^2 and P^4 (the two phosphorus atoms of the phosphane ligands *cis* to the bridging phosphide group) belong to a second-order spin system and a direct analysis of the spectrum was not obtained. The $^{31}P\{^1H\}$ NMR spectrum simulation for the isotopomer containing no ^{195}Pt (ABMX spin system, A and B being P^2 and P^4) agrees well with the experimental data for the fol-

lowing parameters: $\delta(P^2) = 16.3$, $\delta(P^4) = 15.8$, $^3J(P^2\text{-}P^4) = 154$, $^3J(P^2\text{-}P^3) = 16$, $^2J(P^3\text{-}P^4) = 12$ Hz (Table 2).

Complex **3** is different from its Pd analogue **7** in that it is not stable in solution and, with the rate depending on the temperature, undergoes an intramolecular oxidative addition of a P−H bond with the rupture of the Pt−Pt bond affording the new hydrido phosphido dinuclear platinum(II) complex *trans*-[(PHCy$_2$)(Cl)Pt(μ-PCy$_2$)$_2$Pt(PHCy$_2$)(H)] (**4**).

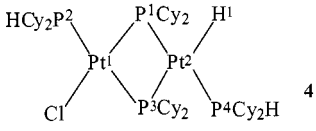


3 **4**

This complex shows one band at 281 cm^{-1} in the IR spectrum that is due to the Pt−Cl stretching, one broad band at 2301 cm^{-1} attributable to the P−H stretching, and one intense band at 1929 cm^{-1} due to the Pt−H stretching.

The $^{31}P\{^1H\}$ NMR spectrum of **4** consists of four signals, all flanked by ^{195}Pt satellites, centred at $\delta = 21.3$, $\delta = 12.5$, $\delta = -126.9$ and $\delta = -156.2$ (Table 3). The high-field signals at $\delta = -126.9$ and $\delta = -156.21$ indicate for **4**, as in the case of **2**, a dinuclear structure in which two phosphide groups are bound to two platinum atoms without Pt−Pt linkage.

Table 3. NMR parameters for complex **4** ([D$_6$]benzene, 295 K); chemical shifts (bold) are in ppm; coupling constants (normal) are in Hz



4

	P^1	P^2	P^3	P^4	H^1
P^1	**−126.9**	12	146	328	9
P^2	12	**12.5**	318		
P^3	146	318	**−156.2**	[a]	138
P^4	328		[a]	**21.3**	24
H^1	9		138	24	−3.19

[a] $^2J(P^3-P^4)$ not assessed because less than signal linewidth.

Moreover, proton-coupled ^{31}P NMR spectra show that, of the two phosphide groups, the phosphorus atom at $\delta = -156.2$ is strongly hydrogen-coupled [^2J(P-H) = 138 Hz]. The signals at $\delta = 21.3$ and $\delta = 12.5$ belong to two inequivalent terminally bound secondary phosphane ligands [^1J(P-H) = 320 and 314 Hz, respectively] with the first appearing as a doublet [^2J(P-P) = 328 Hz], and the second as a doublet of doublets [^2J(P-P) = 318 and 12 Hz]. These findings indicate that both of the terminal phosphane ligands are *trans* to a bridging phosphide group. From the ^{195}Pt satellites the coupling constants [^1J(Pt-P) = 2070 Hz, ^3J(Pt-P) = 124 Hz (phosphorus signal at $\delta = 21.3$), and ^1J(Pt-P) = 1760 Hz, ^3J(Pt-P) = 68 Hz (phosphorus signal at $\delta = 12.5$)] could be extracted.

The signals of the bridging phosphide groups at $\delta = -126.9$ and $\delta = -156.2$ are both doublets of doublets due to the mutual coupling [^2J(P-P) = 146 Hz] and also to the additional coupling of each of them with the *trans*-phosphane ligand. 2D COSY $^{31}P\{^1H\}$ NMR spectroscopic experiments enable one to clearly distinguish the satellites due to different couplings with Pt^1 and Pt^2 (such satellites, sixteen lines in total, are not unambiguously assigned in the monodimensional ^{31}P NMR spectrum) and the following values for the relevant coupling constants can be extracted: $^1J(P^1\text{-}Pt^1) = 2497$, $^1J(P^1\text{-}Pt^2) = 2239$, $^1J(P^2\text{-}Pt^1) = 1729$, $^1J(P^3\text{-}Pt^1) = 1766$, $^1J(P^3\text{-}Pt^2) = 1332$, $^1J(P^4\text{-}Pt^2) = 2070$ Hz.

The ^{1}H NMR spectrum shows, beside resonances due to aliphatic protons, two doublets centred at $\delta = 4.79$ and $\delta = 4.35$ as well as a doublet of doublets of doublets centred at $\delta = -3.19$ [J(H-P) = 138, 24, and 9 Hz]. The latter signal, which is flanked by ^{195}Pt satellites [^1J(Pt-H) = 912 Hz] is due to a terminal hydride ligand *cis* to P^4 (see Table 3 for P, H, and Pt numbering for **4**). Among the coupling constants shown by the hydride signal the largest one [^2J(H-P) = 138 Hz] is attributed to the coupling with *trans*-P^3, whereas the two smaller ones [^2J(H-P) = 24 and 9 Hz] are due to the couplings with *cis*-P^4 and *cis*-P^1, respectively.

When the Na reduction of **1** was carried out at room temperature (instead of at 0 °C), the reaction solution showed signals attributed to [Pt(μ-PCy$_2$)(PHCy$_2$)]$_2$(*Pt−Pt*) (**5**) and [*trans*-Pt(PHCy$_2$)$_2$(PCy$_2$)Cl] (**6**) in the $^{31}P\{^1H\}$ NMR spectrum. $^{31}P\{^1H\}$ NMR of **5** consists of two triplets centred at $\delta = 242.0$ and $\delta = 19.6$ [^2J(P-P) = 51 Hz] both with ^{195}Pt satellites.

The signal at $\delta = 242.0$ (Figure 3) which is flanked by two sets of satellites due to the isotopomers containing one or both NMR-active platinum atoms, does not change substantially in the proton-coupled spectrum, and belongs to the bridging phosphide groups that couple with the Pt nuclei [^1J(Pt-P) = 2598 Hz]. The low-field resonance of this bridging phosphide group indicates the presence of a three-membered Pt$_2$P ring[7a,7b] and, therefore, of a Pt−Pt bond in complex **5**. The triplet at $\delta = 19.6$ can be attributed to the terminal dicyclohexylphosphane ligands. The signal splits into a doublet of badly resolved triplets in the proton-coupled spectrum [^1J(P-H) = 318 Hz] and is flanked by satellites due to ^{195}Pt couplings [^1J(Pt-P) = 4811 Hz]. Neglecting signals due to the isotopomer containing two ^{195}Pt atoms, the main satellites each appear as a doublet of triplets due to the coupling with the phosphide groups [^2J(P-P) = 51 Hz] and with the other terminal phosphane ligand [^3J(P-P) = 70 Hz]. The relevant coupling constants found for the related complex [Pt{μ-P(SiMe$_3$)$_2$}(PEt$_3$)]$_2$(*Pt−Pt*) are: ^1J(Pt-P) = 4957, ^2J(P-P) = 63, and ^3J(P-P) = 66 Hz.[9]

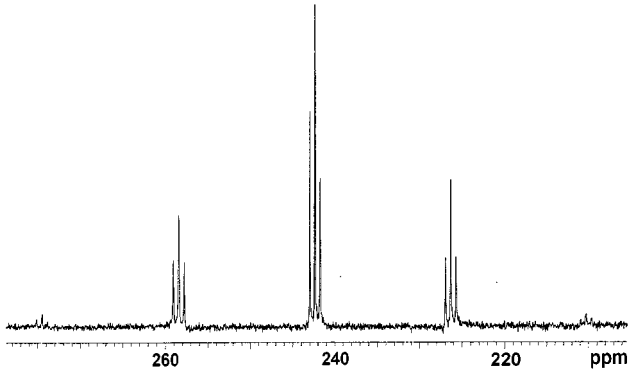


Figure 3. Phosphide region of the $^{31}P\{^{1}H\}$ NMR spectrum for **5** ([D_6]benzene, 81 MHz, 295 K)

The ^{1}H NMR spectrum of **5** shows the resonance of the hydrogen atoms directly bound to phosphorus atoms for the coordinated PCy_2H at low field. This resonance appears as a doublet of triplets [^{1}J(P-H) = 318 Hz and ^{3}J(μP-H) = 13 Hz] each broadened at the base due to H−Pt coupling (Figure 4). Moreover, each of the triplet components appears split into three peaks, due to the additional coupling with the cyclohexyl methyne protons, but the value of such coupling constants (< 4 Hz) could not exactly be assessed.

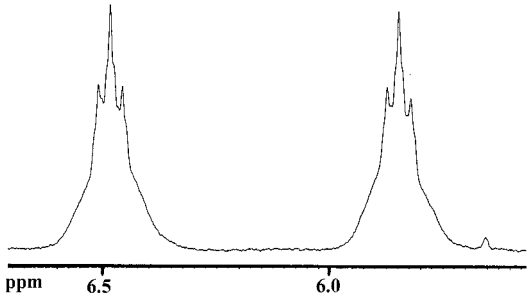

Figure 4. ^{1}H NMR spectrum in the low-field region for **5** ([D_6]benzene, 500 MHz, 295 K)

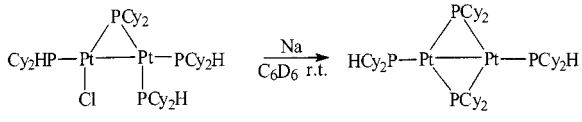
The IR spectrum of **5** shows a strong band at 2238 cm^{-1} attributed to the P−H stretching of the coordinated dicyclohexylphosphane ligand. Spectroscopically pure **5** was directly obtained in an NMR tube by treating **3** in [D_6]benzene with sodium at room temperature.



3 5

In the $^{31}P\{^{1}H\}$ NMR spectrum, complex **6** shows a doublet at δ = 27.6 and a triplet at δ = 20.6, in a 2:1 ratio (as assessed by the integrals in the proton coupled spectrum) with the same coupling constant of 41 Hz. The triplet at δ = 20.6, which does not substantially change in the proton-coupled spectrum, is flanked by satellites from which a coupling constant ^{1}J(P-Pt) = 931 Hz could be extracted. Therefore such a triplet can be ascribed to a terminal dicyclohexylphosphide group, coupled with two equivalent phosphorus atoms, directly bound to the platinum atom.

The doublet at δ = 27.6 is flanked by two satellites characterised by ^{1}J(P-Pt) = 3006 Hz. The pattern of the central signal (isotopomer without ^{195}Pt) in the proton-coupled spectrum is typical for the *A* part of a second-order spin system $(AXY_2)_2$[10] which is further coupled with a phosphorus atom [^{2}J(P-P) = 41 Hz]. In the present case *A* is ^{31}P, *X* is the proton bound to ^{31}P, and *Y* are the methyne protons of the cyclohexyl rings. In Figure 5 the experimental and simulated *A* part of the spectrum are reported. The spectroscopic features obtained through the analysis developed by Palmer and Whitcomb[10] are collected in Table 4. A similar pattern has been observed for the phosphorus atom of the coordinated secondary phosphane ligands in the palladium complexes [*trans*-$Pd(SPh)_2(PCy_2H)_2$][11] and [*trans*-$PdCl(CHCl_2)(PtBu_2H)_2$].[12]

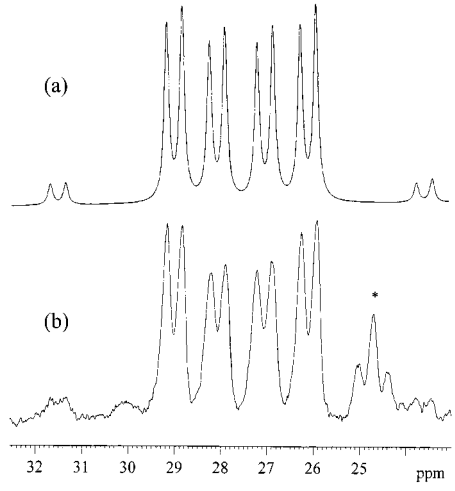


Figure 5. Proton-coupled ^{31}P NMR spectrum of complex **6** in the P^1 region ([D_6]benzene, 121 MHz, 295 K): (a) simulated, (b) experimental; the asterisked triplet belongs to P^2 satellites

The IR spectrum of **6** shows a strong band at 2324 cm^{-1} attributed to the P−H stretching of the coordinated dicyclohexylphosphane ligands and a medium 259 cm^{-1} band attributed to the Pt−Cl stretching. According to the above reported spectroscopic data, **6** can be formulated as [*trans*-$Pt(PHCy_2)_2(PCy_2)Cl$], a neutral terminal phosphido complex of platinum(II).

Due to the exceedingly high *trans*-effect of phosphido ligands, terminal (phosphido)platinum(II) complexes are quite rare, so that the pioneering work of Chatt and Davidson concluded that, at least in the case of diphenylphosphide, it seemed unlikely that such a ligand, terminally bound to platinum(II), could even exist.[13] Nevertheless, starting from the late 1980s, a number of terminal phosphido complexes of platinum(II) have been prepared. The first molecule of this type to be synthesised was the dichloro-

[a] $|^2J(P^1\text{-Pt})| = 50$ Hz. [b] $^3J(P^3\text{-}H^1) = 1$ Hz.

phosphide complex $[PtCl(PEt_3)(PCl_2)]$.[14] Other examples are the cations $[Pt\{PPh(CH_2CH_2PPh_2)_2\}(PR_2)]^+$ (R = Cy, Ph)[15] and $[(xp_3)Pt(PEt_2)]^+$ [xp_3 = $N(CH_2CH_2PPh_2)_3$, $P(CH_2CH_2PPh_2)_3$][16] and the neutral $[Pt(NCN)PPh_2)]$ [NCN = $C_6H_3(CH_2NMe_2)_2$-2,6] complex.[17] More recently, Glueck et al. have described a series of terminal (phosphido)platinum(II) complexes of the type $[Pt(dppe)Me(X)]^{n+}$ (X = primary or secondary phosphide, $n = 0$ or 1).[18]

In all of these terminal (phosphido)platinum complexes, the chemical shifts of the phosphido phosphorus atom fall in the range δ = −88.4 to δ = 56.7 and give scarce information about the character of the phosphorus ligand. On the other hand, the relatively small ^1J(Pt-P) coupling constant expected between platinum and a terminal phosphido ligand, rationalised in terms of low *s* character of the Pt−P bond,[18b] can be taken as diagnostic of the presence of such a ligand. The value of the relevant $^1J_{Pt,P}$ for the aforementioned complexes ranges from 767 Hz to 1305 Hz. The ^1J(Pt-P) = 931 Hz found for **6** supports our assignment as [*trans*-$Pt(PCy_2H)_2(PCy_2)Cl$].[19]

In order to gain insight into the structure of complex **6**, a crystallographic analysis was undertaken. The X-ray diffraction study revealed that **6** crystallises in the space group $P\bar{1}$ and contains a distorted square-planar platinum(II) centre (Figure 6 and Table 5), the largest angle between ligands being 99.87(11)° [P(3)−Pt−P(2)]. A tetrahedral distortion from planarity is also evident from the 172.46(12)° [P(3)−Pt−P(1) and 171.98(12)° [P(2)−Pt−Cl] angles, significantly differing from the ideal 180°.

The phosphide P atom is pyramidal as indicated by the sum of the angles at P(2) of 320.5° (compared to 328.5° for a tetrahedral and 360° for a planar atom). The hydrogen atoms bonded to the phosphorus atom were located in a Fourier difference synthesis. The two P−H bonds of the dicyclohexylphosphane ligands are both oriented toward the phosphido ligand; such orientation minimises the repulsions between the six cyclohexyl groups around the Pt atom. The relatively long[20] Pt−Cl bond [2.421(3) Å] indicates a pronounced *trans* effect of the terminal phosphide group. The P(2)−Pt bond length [2.326(3) Å] is slightly shorter than those reported for related terminal phosphido platinum(II) complexes. The Pt−P(phosphido) bond lengths of Pt(dppe)(Me)(PHMes*),[18b] Pt(dppe)(Me)(P-Mes_2),[18b] and Pt(*S*,*S*-Chiraphos)(Me)(PPhIs)[18d] [Mes* = 2,4,6-(tBu)$_3C_6H_2$, Mes = 2,4,6-$Me_3C_6H_2$, Chiraphos = 2,3-bis(diphenylphosphanyl)butane, Is = 2,4,6-(iPr)$_3C_6H_2$] are, in fact, 2.378(5), 2.351(2), and 2.3622(15) Å, respectively.

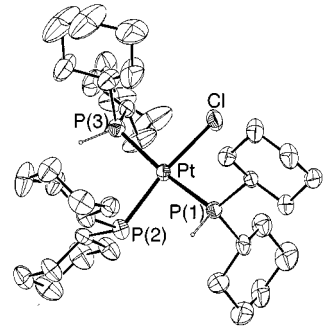

Figure 6. Displacement ellipsoid plot[29] of **6**; ellipsoids are scaled to 30% probability, H atoms are shown with arbitrary radii

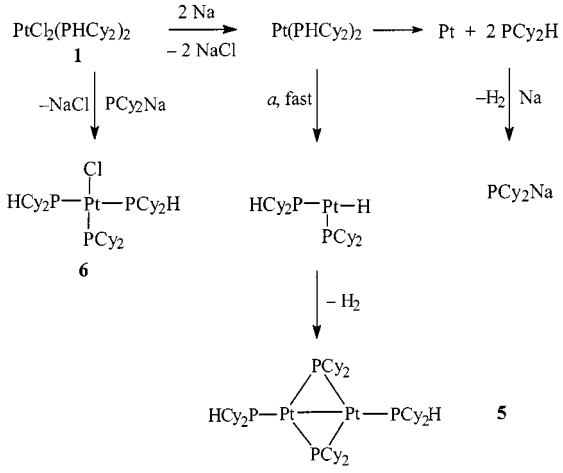
P(2)−Pt−Cl(1)	171.98(12)

A possible pathway for the reaction of **1** with sodium at room temp. could start with the abstraction of two subsequent chloride ions giving the dicoordinated Pt^0 complex $[Pt(PHCy_2)_2]$ (Scheme 2). This intermediate could lead to intramolecular electrophilic attack of one coordinated $PHCy_2$ yielding $[Pt(H)(PCy_2)(PHCy_2)]$ which, in turn, can dimerise to **5** via reductive elimination of hydrogen.[21]

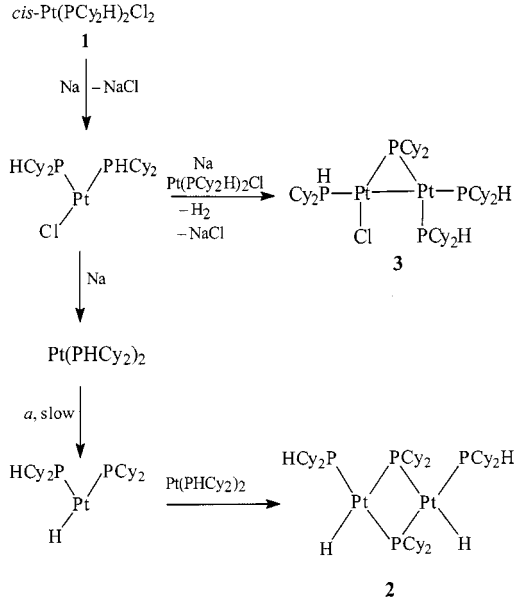
On the other hand, at room temperature, **1** could also react with sodium dicyclohexylphosphide (one of the products formed when **1** decomposes in the presence of sodium metal) giving **6** by substitution of the chloride ion with the dicyclohexylphosphide group (Scheme 2). A confirmation of this proposed mechanism came from the reaction between **1** and $LiPCy_2$ which gave pure **6**.[22]

The lack of formation of both **5** and **6** when the reaction of **1** with sodium metal is carried out at 0 °C can be explained by admitting that both chloride ion abstraction and intramolecular attack of a dicyclohexylphosphane ligand in $[Pt(PHCy_2)_2]$ leading to $[Pt(H)(PCy_2)(PHCy_2)]$ (Step *a* in Scheme 2) are temperature-sensitive and slow in the reac-



Scheme 2. Proposed mechanism for the sodium reduction of **1** at room temperature

tion at 0 °C. Under these conditions both intermediate $[PtCl(PHCy_2)_2]$ and $[Pt(PHCy_2)_2]$ could accumulate in the reaction medium (Scheme 3). Therefore $[Pt(PHCy_2)_2]$ may become the preferential target for the attack of $[Pt(H)(PCy_2)(PHCy_2)]$ which results in the formation of **2** (effectively found in the reaction solution at 0 °C as the major product). On the other hand, dimerization of $[PtCl(PHCy_2)_2]$ by HCl evolution (revealed as H_2 and NaCl formation in the presence of Na) could also account for the formation of compound **3** as the minor product.



Scheme 3. Proposed mechanism for the sodium reduction of **1** at 0 °C

Experimental Section

General Remarks: All manipulations were carried out under pure dinitrogen, using freshly distilled and oxygen-free solvents. All aromatic deuterated solvents were carefully dehydrated (Na) and deoxygenated (freeze and pump). Dicyclohexylphosphane was purchased from Strem and used as received. PCy_2Li[23] and $PtCl_2(PhCN)_2$[24] were prepared by literature methods. Infrared spectra were recorded with a Bruker Vector 22 spectrometer. Elemental analyses (C, H) were carried out using a Carlo Erba model EA 1108 instrument. The Cl and P contents (where reported) were determined by potentiometric titration with AgCl (716DMS Metrohm) and by spectrophotometric methods (Uvikon 942 Kontron, λ = 460 nm), respectively. NMR spectra were recorded with BRUKER Avance DRX500 (CARSO), BRUKER Avance DPX300, and VARIAN XL200 spectrometers; frequencies are referenced to Me_4Si (^1H and ^{13}C), 85% H_3PO_4 (^{31}P), and H_2PtCl_6 (^{195}Pt).

***cis*-Dichlorobis(dicyclohexylphosphane)platinum(II) (1):**[25] 1.45 g of dicyclohexylphosphane, dissolved in 10 mL of toluene, was added dropwise to a toluene solution of *trans*-$PtCl_2(PhCN)_2$ (1.7 g in 30 mL) kept at 60 °C. After 1.5 h, the resulting white suspension was cooled at room temp. and the solid filtered off, washed with toluene (5 mL), and dried under vacuum affording pure **1** as a colourless microcrystalline powder (2.03 g, 85% yield). IR (nujol mull): $\tilde{\nu}_{max}$ = 2351 w (P−H), 285 m (Pt−Cl) cm^{-1}. ^1H NMR ($CDCl_3$, 500 MHz): δ = 3.60 [m, ^1J(P-H) = 362, ^2J(Pt-H) = 96, ^2J(*H*P-C*H*) = 6 Hz, PH]. ^{31}P NMR ($CDCl_3$, 202 MHz): δ = 18.6 [s, ^1J(P-Pt) = 3402, ^1J(P-H) = 362, ^2J(P-P′) = 19, ^3J(P-H′) = 8 Hz]. $^{195}Pt\{^1H\}$ NMR ($CDCl_3$, 64 MHz): δ = −4540 [t, ^1J(P-Pt) = 3402 Hz]. $C_{24}H_{46}Cl_2P_2Pt$ (662.58): calcd. C 43.51, H 7.00, Cl 10.70, P 9.35; found C 43.48, H 7.10, Cl 10.75, P 9.27.

Reduction of 1 with Sodium at 0 °C: A suspension of *cis*-$PtCl_2(PHCy_2)_2$ (**1**) (0.98 g, 1.48 mmol) and sodium metal (0.067 g, 2.91 mmol) in toluene (40 mL) was vigorously stirred at 0 °C (ice bath) for 9 h. In the course of the reaction dihydrogen evolved, as revealed by gas chromatographic analysis. The resulting suspension was filtered (to remove 0.243 g of unchanged **1** and 0.104 g of platinum metal) and the solvent was removed at low temperature (0 °C). Treatment of the obtained solid with cold methanol afforded pure **2** (0.12 g, 13.7% yield) as a white powder and a yellow solution from which, after solvent removal and crystallisation of the residue from THF/*n*-hexane (1:1) at −30 °C, pure **3** precipitated as a yellow solid (28 mg, 3.1% yield). ^1H NMR spectroscopic features of **2** other than those reported in Table 1 ([D_8]toluene, 295 K): δ = 4.50 [br. d, ^1J(P-H) = 317 Hz, *H*-P^2). IR (nujol mull): $\tilde{\nu}_{max}$ = 2299 w (P−H), 1940 s (Pt−H) cm^{-1}. $C_{48}H_{92}P_4Pt_2$ (1183.34): C 48.72, H 7.84, P 10.47; found C 47.86, H 7.95, P 10.13. ^1H NMR spectroscopic features of **3** other than those reported in Table 2 ([D_8]toluene, 295 K): δ = 4.31 [d, ^1J(P-H) = 319 Hz, *H*-P^4], δ = 4.45 [d, ^1J(P-H) = 312 Hz, *H*-P^2], δ = 5.3 [br. d ^1J(P-H) = 320 Hz, *H*-P^3]. IR (nujol mull): $\tilde{\nu}_{max}$ = 2295 w and 2255 w (P−H), 301 w (Pt−Cl) cm^{-1}. $C_{48}H_{91}ClP_4Pt_2$ (1217.78): calcd. C 47.34, H 7.53, Cl 2.91; found C 46.87, H 7.27, Cl 2.85.

Isomerisation of 3 To Give 4: A toluene solution of **3** was stirred at 50 °C for 5 h causing the colour to lighten from yellow-orange to pale yellow. Evaporation of the solvent afforded a solid, which was washed with cold methanol and after crystallisation from toluene/*n*-hexane (2:1), **4** was obtained as white needles. IR (nujol mull): $\tilde{\nu}_{max}$ = 2301 w (P−H), 1929 w (Pt−H), 281 w (Pt−Cl) cm^{-1}. ^1H NMR spectroscopic features of **4** other than those reported in Table 3 ([D_6]benzene, 295 K): δ = 4.35 [d, ^1J(P-H) = 314, ^2J(Pt-H) = 98 Hz, *H*-P^2], δ = 4.79 [d, ^1J(P-H) = 320 Hz, *H*-P^4]. $C_{48}H_{91}ClP_4Pt_2$ (1217.78): calcd. C 47.34, H 7.53, Cl 2.91, P 10.17; found C 46.38, H 7.68, Cl 2.85, P 10.12.

Reduction of 1 with Sodium at Room Temperature: A suspension of *cis*-$PtCl_2(PHCy_2)_2$ (0.30 g, 0.45 mmol) and sodium metal (0.10 g, 4.3 mmol) in toluene (30 mL) was vigorously stirred at room temperature (25 °C) for 70 min. In the course of the reaction dihydrogen was evolved, as revealed by gas chromatographic analysis. The resulting suspension was filtered and the solvent was removed in vacuo from the yellow-orange filtrate. The residue was redissolved in deuterated benzene and used for NMR spectroscopic analysis, revealing the formation of **5** and **6** in an approximately 1:3 ratio.

Reduction of 3 with Sodium: A light yellow solution of complex **3** in [D_6]benzene was treated with sodium sand in an NMR tube at room temperature until the hydrogen evolution stopped (about 0.5 h). The resulting dark yellow solution was analysed by NMR spectroscopy giving signals due to **5** alone.

***trans*-Chloro(dicyclohexylphosphido)bis(dicyclohexylphosphane)-platinum(II) [$Pt(PHCy_2)_2(PCy_2)Cl$] (6):** A suspension of *cis*-[$Pt(PHCy_2)_2Cl_2$] (0.54 g, 0.82 mmol) and PCy_2Li (0.166 g, 0.82 mmol) in toluene (20 mL) was vigorously stirred at 0 °C until a yellow solution was obtained (about 8 h). LiCl was filtered and the solution concentrated in vacuo to ca. 5 mL. By cooling at −20 °C pale yellow crystals of **6** precipitated which were isolated by filtration (0.435 g, 65%). IR (nujol mull): $\tilde{\nu}_{max}$ = 2324 s (P−H), 259 m (Pt−Cl) cm^{-1}. $C_{36}H_{68}ClP_3Pt$ (824.40): calcd. C 52.45, H 8.31, Cl 4.30, P 11.27; found C 51.93, H 8.45, Cl 4.37, P 11.32.

X-ray Data Collection, Structure Solution, and Refinement of 6:[26] Crystal data and parameters for intensity data collection and structure refinement are compiled in Table 6. A pale yellow rod with the approximate dimensions of 0.15 × 0.11 × 0.03 mm was studied at room temperature with a BRUKER-AXS SMART Apex diffractometer. An empirical absorption correction[27] was applied (max. trans. 1.000, min. trans. 0.797). The structure was solved by direct methods and refined on F^2 with the SHELXTL[28] suite of programs.

Syntheses and First Crystal Structures of Rhenium Complexes Derived from ω-Functionalized Fatty Acids as Model Compounds of Technetium Tracers for Myocardial Metabolism Imaging

Christian M. Jung,[a] Werner Kraus,[b] Peter Leibnitz,[b] Hans-Jürgen Pietzsch,[a] Joachim Kropp,[c] and Hartmut Spies*[a]

Keywords: Rhenium / Technetium / Fatty acids / Drug research / Radiopharmaceuticals

In an attempt to develop new technetium-based radiopharmaceuticals for the noninvasive diagnosis of myocardial metabolism, we have synthesized three examples of novel metal-containing fatty acid derivatives according to the "3+1" mixed-ligand and the Schiff base/tricarbonyl design. The chelates contain the metal core in the oxidation states +5 and +1, respectively, and are attached to the end-position of a fatty acid chain. The complex formation was accomplished by ligand-exchange reactions with three different rhenium precursors, whereas the inactive rhenium metal was utilized as a surrogate of the technetium radionuclide. The molecular structures of the fatty acid complexes **7**, **10** and **14** were determined by single-crystal X-ray diffraction analyses and impressively show a general problem in technetium tracer research, namely the significant structural alterations of bioactive molecules by coordination even to small metal chelates. (© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Naturally occurring long-chain fatty acids serve as the main energy source of the normoxic myocardium. Regional alterations in the myocardial fatty acid oxidation may indicate ischemic heart diseases and cardiomyophaties at an early stage and therefore possess a remarkable diagnostic potential in nuclear medicine. Although radio-iodinated fatty acids such as 15-(*p*-[^{123}I]iodophenyl)pentadecanoic acid (IPPA) and its β-methyl-branched derivative BMIPP have proven their applicability for myocardial metabolism imaging in numerous clinical trials, fatty acid scintigraphy has not yet reached widespread application in nuclear medicine.[1] Compared to the technetium-99m-based perfusion tracers that are mainly applied at present, radiolabelled fatty acids allow more convincing scans of viable myocardium. However, logistical disadvantages and disproportionately high costs of the accelerator-produced radionuclide iodine-123 still conflict with a major acceptance of these tracers in routine cardiac diagnostics. On the other hand, the low-price availability from the ^{99}Mo/^{99m}Tc generator combined with its optimal radiophysical properties, and the commercial distribution of pre-prepared instant kits for various clinical examinations have made technetium-99m the preferred radiolabel in nuclear medicinal imaging.[2] The progress in ^{99m}Tc tracer design to monitor specific endogenic functions is nevertheless severely limited by the effect of the artificial radiometal and its coordination chemistry on the in vivo behaviour of labelled bioactive molecules.

The synthesis of technetium-containing long-chain fatty acids for accessing regional discrepancies in myocardial energy production has been a goal of many research groups since 1975.[3] Although a variety of different chelating moieties were used to attach the radiometal at the fatty acid skeleton, low myocardial extraction and poor recognition as a substrate for the β-oxidation in living cells has prevented an application of these ^{99m}Tc-labelled agents in nuclear medicine. A characteristic feature of almost all the technetium-99m fatty acid analogues described so far is the focus on polar tetradentate N_2S_2 chelates with a central oxometal(V) core. In our attempt to create new technetium-labelled fatty acids with an improved myocardial profile, we therefore concentrate on alternative coordination moieties according to the "*n*+1" mixed-ligand approach[4] and the Schiff base/tricarbonyl design.[5] Since working with radioactive compounds affords great care and is subjected to some restrictions, the third-row congener rhenium was used

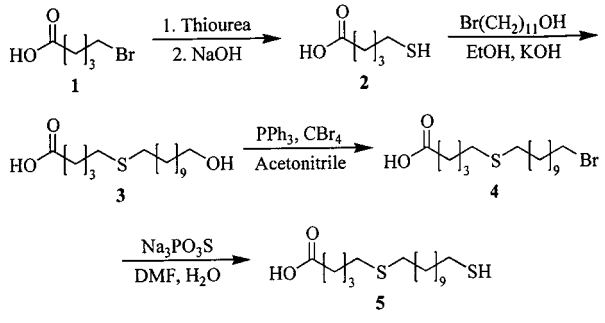
in our preliminary studies as a surrogate for the radioactive technetium.

Results and Discussion

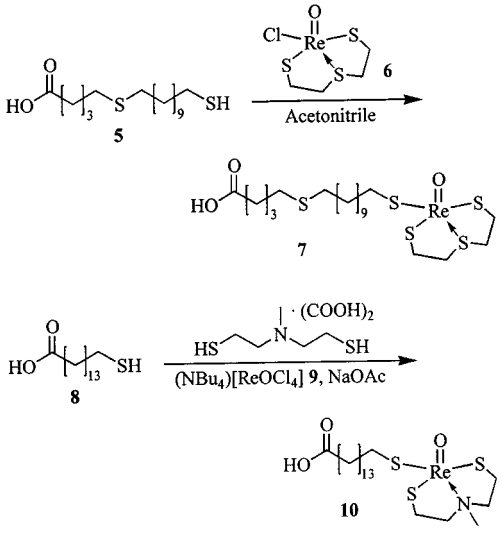
In this paper we report the synthesis and crystal structure of three new classes of rhenium-containing fatty acid analogues. From our point of view, success in the development of bioactive metal-based fatty acid tracers is primarily dependent on the choice of a suitable chelating moiety, which allows a strong binding of the bioligand to the metal centre but preserves the physiological integrity of the fatty acid. Since the carboxylic group probably plays a fundamental role in the substrate cognition in vivo we decided to functionalize fatty acid ligands in their ω-position. For the head structures we used the skeleton of the IPPA tracer,[6] which has been well tested in clinical trials, and the metabolism-blocking sulfur-inserted fatty acid analogue 14-(*R*,*S*)-[^{18}F]fluoro-6-thiaheptadecanoic acid (FTHA),[7] as well as the naturally occurring lauric acid.

Suitable ω-sulfanyl fatty acid ligands required for the "3+1" mixed-ligand concept were synthesized starting from the corresponding ω-bromo derivatives. Whereas the pentadecanoic acid starting material was reasonably accessible by acidic ring opening of the corresponding ω-hydroxylactone by hydrobromic acid,[8] the thia-inserted heptadecanoic acid analogue **4** was prepared in three steps starting from the commercially available 5-bromovaleric acid **1**. After nucleophilic substitution of the halide at the end position by a sulfanyl unit, the fatty acid body was built up by coupling to 11-bromo-1-undecanol under basic conditions. Conversion of the hydroxy group into a bromide was accomplished by an adopted version of the Appel reaction.[9] Sulfonyl groups in the ω-position of the fatty acids **5** and **8** were finally introduced by nucleophilic attack of sodium thiophosphate and subsequent acidic hydrolysis[10] (Scheme 1).



Scheme 1. Synthesis of ω-sulfanyl ε-thia fatty acid **5**

Coordination of the ω-sulfanyl fatty acid ligands **5** and **8** to the rhenium precursors **6**[11] and **9**[12] according the "3+1" approach offers access to the oxorhenium(V) complexes **7** and **10**, respectively. Preparation of **10** was accomplished in moderate yields by a one-pot synthesis of the tetrachlorooxorhenate **9**, the protected "SN(Me)S" tridentate and the ω-sulfanyl fatty acid **8** under basic conditions; complex **7** was obtained almost quantitatively by smooth chloride exchange of the thia fatty acid **5** at the preformed oxorhenium(V) precursor **6** (Scheme 2). The coordination sphere of these mixed-ligand complexes differs in the central donor atom of the tridentate chelator, being sulfur in the model compound **7** and nitrogen in complex **10**. Accompanied by the alteration of the tridentate ligand part is a change in colour from reddish-brown (for **7**) to dark green (for **10**). The infrared spectra of both complexes show a strong absorption band in the region of 955 cm^{-1}, which is distinctive of the central Re=O^{3+} moiety. In the ^{1}H NMR spectra of compound **7** the protons of the tridentate chelator give representative coupling patterns at δ_H = 4.27, 3.90, 3.09 and 1.95; the equivalent signals of the "SN(Me)S" ligand are partly widened and coincided and are observed between δ_H = 3.9−2.6.



Scheme 2. Syntheses of "3+1" mixed-ligand complexes **7** and **10**

Both complexes **7** and **10** were obtained as crystalline solids by slow solvent evaporation at room temperature and were investigated by X-ray analysis. As characteristic of "SSS"-coordinated "3+1" mixed-ligand complexes, **7** possesses a square-pyramidal coordination sphere around the central metal core. The distorted basal surface, stretched by the four sulfur donor atoms, exhibits a twisted orientation with respect to the planar arrangement of the fatty acid chain (Figure 1). An alteration of the tridentate to the "SN(Me)S" chelator results in a transition of the coordination sphere to a distorted trigonal-bipyramidal geometry. In **10** (Figure 2) the axial positions are occupied by the nitrogen donor of the tridentate ligand and the sulfur atom of the monodentate fatty acid derivative, respectively; the corner sites of the triangular plane, however, are taken up by the oxygen atom of the Re=O^{3+} unit and the two sulfanyl groups of the "SN(Me)S" ligand. In structures **7** and **10**, bond lengths and angles within the chelate moieties are of the order of magnitude expected for these types of rhenium coordination compounds (Table 1). However, a special order/disorder phenomenon was detected in the crystal packing of **10**. As frequently observed in this type of complexes

the "SN(Me)S" chelator can change its conformation by a flip-flop mechanism giving rise to a statistical distribution of two equal isomers within the crystal.[13]

Alberto et al. recently introduced the "*fac*-$[M(CO)_3]^+$" fragment as promising synthon for the labelling of biomolecules with technetium.[5] Due to the known tendency of the metal(I) core to interact strongly with soft donor compounds, bidentate aromatic Schiff base ligands are exceedingly suitable for coordinating the tricarbonylmetal(I) moiety. We therefore synthesized an appropriate fatty acid derivative; starting from commercially available ω-aminolauric acid (**11**), the corresponding Schiff base **12** was obtained by simple condensation of picolinaldehyde with the amino group of the analogous lauric acid salt. Since the resulting imines decompose even by neutralisation,[14] the protonation of the carboxyl function was carried out subsequent to the stabilizing attachment of the tricarbonylrhenium moiety. The two nitrogen donor atoms replace two bromide ions of the tricarbonylrhenium(I) precursor **13**.[15] The third halide substituent, however, is responsible for the compensation of the electrical charge and remains fixed in the coordination sphere of the metal(I) core (Scheme 3). Complex **14** was obtained as a deep orange compound and showed the characteristic carbonyl absorption bands at 2021 and 1902 cm^{-1} in the infrared spectrum. The imine proton of the fatty acid ligand was detected as a sharp singlet in the ^1H NMR spectrum at $\delta_H = 8.70$; the

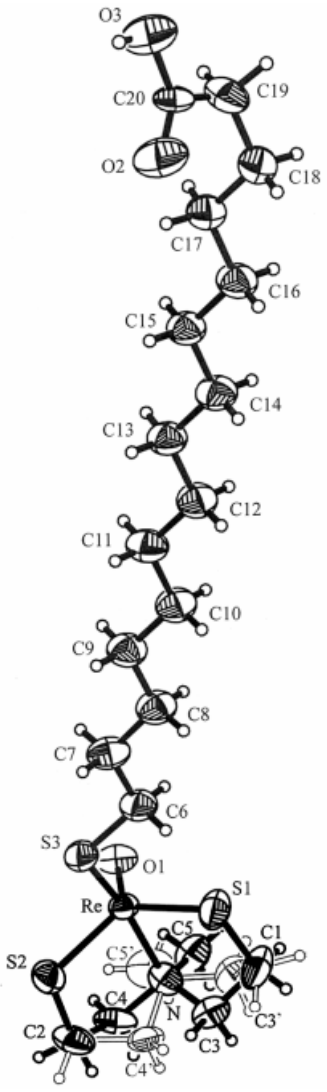

Figure 2. Molecular structure of "SN(Me)S"-coordinated "3+1" mixed-ligand complex **10**

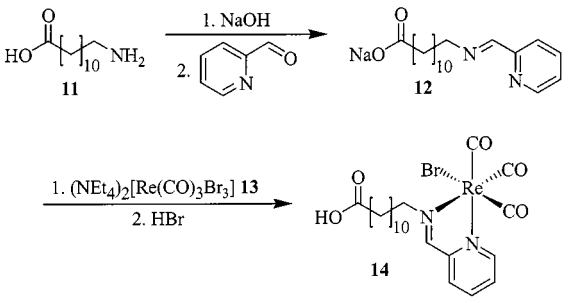
^{13}C signals of the three carbonyl substituents were observed at δ_C = 196.6, 195.8 and 186.1.



Scheme 3. Synthesis of tricarbonylrhenium(I) complex **14**

Compound **14** crystallized upon slow concentration of a saturated solution in acetonitrile. As expected for this type of complex, the molecular structure shows an octahedral coordination sphere around the central rhenium(I) core. The three carbonyl moieties are arranged facial to each other, and the remaining coordination sites are occupied by the bidentate Schiff base ligand and a bromine atom (Figure 3, Table 2).

Particularly conspicuous in the molecular structure of all three complexes, **7**, **10**, and **14**, are the proportions between the chelate moieties and the fatty acid ligands. The drastic structural alteration of the biomolecules, even by coordination to small-sized metal chelates, is certainly a main reason for the laborious progress in the development of new technetium-based radiotracers with the objective of assessment of specific endogenous processes and physiological functions. Nevertheless, structural integrity is only one of several parameters, besides others such as lipophilicity and polarity, that influence the in vivo behaviour of potential ^{99m}Tc radiotracers. Therefore further investigations concerning the biological profile of the technetium-99m analogues of **7**, **10** and **14** will be done to estimate the value of these compounds as potential radiotracers for myocardial metabolism imaging.

Experimental Section

General Remarks: All chemicals and solvents were of reagent grade and utilized without further purification, with the exception of picolinaldehyde, which was freshly distilled prior to use. 11-Bromo-1-undecanol and 12-aminolauric acid were purchased from Fluka. Sodium thiophosphate[16] and *N*-methyl-3-azapentane-1,5-dithiol−oxalic acid[17] were prepared according to the literature. The syntheses involving air-sensitive compounds were carried out under argon using the standard Schlenk technique. The standard workup procedure for product isolation was quenching the reaction mixture in an aqueous solution, followed by extracting thoroughly with $CHCl_3$, washing the extracts with saturated saline, drying owith $MgSO_4$ and evaporating the solvent under reduced pressure. Column chromatography was performed according to Still[18] by using Merck silica gel (0.040−0.063 mm). IR: Perkin−Elmer Specord 2000. NMR: Varian Inova-400. For ^1H NMR $CDCl_3$ (δ_H = 7.26) and CD_3OD (δ_H = 3.31) were used as solvents, for ^{13}C NMR $CDCl_3$ (δ_C = 77.0). Elemental analyses: LECO CHNS 932.

15-Sulfanylpentadecanoic Acid (8): 1.96 g (10.9 mmol) of sodium thiophosphate in 20 mL of H_2O was added to a solution of 1.75 g (5.45 mmol) of 15-bromopentadecanoic acid[8] in 50 mL of di-

methylformamide. The resulting slurry was stirred for 72 h while increasing the temperature from 25 to 50 °C. Afterwards, the mixture was quenched with 3.5% HCl (pH = 2) and stirred overnight. Dilution with additional 30 mL of H_2O and subsequent standard workup yielded a light yellow solid, which was purified by column chromatography (*n*-hexane/Et_2O/HOAc, 70:30:1). Yield: 1.22 g (82%). IR (KBr): $\tilde{\nu}$ = 1714 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.21−1.41 (m, 20 H, 10 × CH_2), 1.33 (t, ^3J = 7.7 Hz, 1 H, CH_2SH), 1.55−1.67 (m, 4 H, CH_2CH_2SH, CH_2CH_2COOH), 2.34 (t, ^3J = 7.5, 2 H, CH_2COOH), 2.52 (dt, ^3J = 7.4, CH_2SH, 2 H). $C_{15}H_{30}O_2S$ (274.47): calcd. C 65.46, H 11.02, S 11.68; found C 65.50, H 10.98, S 11.72.

5-Sulfanylvaleric Acid (2): A mixture of 5.00 g (27.6 mmol) of 5-bromovaleric acid (**1**) and 3.15 g (41.4 mmol) of thiourea in 50 mL of ethanol was heated under reflux for 16 h. After cooling off to room temperature, the solvent was evaporated under reduced pressure and the residue heated with 50 mL of 7.5 M NaOH for another 6 h. The mixture was carefully acidified with 2.5 M H_2SO_4, the organic layer separated and the aqueous phase extracted as usual. Purification of the remaining raw material was accomplished by distillation under vacuum. Yield: 3.04 g (82%). b.p. 102−104 °C/0.7 Torr. ^1H NMR ($CDCl_3$): δ = 1.35 (t, ^3J = 7.9, 1 H, CH_2SH), 1.59−1.80 (m, 4 H, $CH_2CH_2CH_2SH$), 2.37 (t, ^3J = 7.1, 2 H, CH_2COOH), 2.54 (dt, ^3J = 7.2, 2 H, CH_2SH), 10.2−11.3 (br, 1 H, COO*H*). ^{13}C NMR: δ = 23.3, 24.1 (CH_2S, CH_2CH_2COOH), 33.2, 33.4 (CH_2CH_2S, CH_2COOH), 179.8 (*C*OOH). $C_5H_{10}O_2S$ (134.20): calcd. C 44.75, H 7.51, S 23.89; found C 44.43, H 7.74, S 23.50.

17-Hydroxy-6-thiaheptadecanoic Acid (3): To a solution of 2.50 g (43.7 mmol) of KOH in 85 mL of ethanol was added, whilst stirring, 2.9 g (21.6 mmol) of **2** and subsequently 5.40 g (21.5 mmol) of 11-bromo-1-undecanol. After heating under reflux for 12 h, the mixture was acidified with 2.5 M H_2SO_4 and the solvent evaporated under reduced pressure. The residue was partitioned between 75 mL of H_2O and $CHCl_3$ and worked up by standard procedures. Crystallisation from MeOH at −15 °C yielded the pure fatty acid **3** as a colourless solid. Yield: 5.66 g (86%). IR (KBr): $\tilde{\nu}$ = 1690 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.19−1.39 (m, 14 H, 7 × CH_2), 1.47−1.76 (m, 8 H, CH_2CH_2OH, $CH_2CH_2SCH_2CH_2$, CH_2CH_2COOH), 2.33 (t, ^3J = 7.2, 2 H, CH_2COOH), 2.46 (t, ^3J = 7.4, 2 H), 2.48 (t, ^3J = 7.2, 2 H, CH_2SCH_2), 3.59 (t, ^3J = 6.7, 2 H, CH_2OH), 6.77 (br, 2 H, CH_2OH, COO*H*). $C_{16}H_{32}O_3S$ (304.49): calcd. C 63.11, H 10.59, S 10.53; found C 63.04, H 10.50, S 10.47.

17-Bromo-6-thiaheptadecanoic Acid (4): 646 mg (2.46 mmol) of PPh_3 was added, whilst stirring, to a solution of 817 mg (2.46 mmol) of CBr_4 and 250 mg (821 μmol) of **3** in 25 mL of acetonitrile at 0 °C. The mixture was allowed to reach ambient temperature and was stirred overnight. The solvent was evaporated under reduced pressure and the residue partitioned between 50 mL of H_2O and $CHCl_3$ followed by standard workup and column chromatography (*n*-hexane/Et_2O/HOAc, 75:25:1). Yield: 238 mg (79%). IR (KBr): $\tilde{\nu}$ = 1693 (C=O), 647 (C−Br) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.22−1.48 (m, 14 H, 7 × CH_2), 1.50−1.80 (m, 6 H, $CH_2CH_2SCH_2CH_2$, CH_2CH_2COOH), 1.85 (quint, ^3J = 7.1, 2 H, CH_2CH_2Br), 2.38 (t, ^3J = 7.2, 2 H, CH_2COOH), 2.49 (t, ^3J = 7.5, 2 H,), 2.52 (t, ^3J = 7.4, 2 H, CH_2SCH_2), 3.40 (t, ^3J = 6.9, 2 H, CH_2Br). $C_{16}H_{31}BrO_2S$ (267.39): calcd. C 52.31, H 8.50, S 8.73; found C 52.28, H 8.38, S 8.53.

17-Sulfanyl-6-thiaheptadecanoic Acid (5): ω-Sulfanyl ligand **5** was prepared from 200 mg (544 μmol) of **4** by the procedure described for **8**. Yield: 122 mg (70%). IR (KBr): $\tilde{\nu}$ = 1694 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.20−1.41 (m, 14 H, 7 × CH_2), 1.32 (t, ^3J = 7.8, 1 H, CH_2SH), 1.49−1.79 (m, 8 H, CH_2CH_2SH, $CH_2CH_2SCH_2CH_2$, CH_2CH_2COOH), 2.37 (t, ^3J = 7.2, 2 H, CH_2COOH), 2.44−2.55 (m, 6 H, CH_2SCH_2, CH_2SH). $C_{16}H_{32}O_2S_2$ (320.56): calcd. C 59.95, H 10.06, S 20.01; found C 59.97, H 10.08, S 20.12.

Oxorhenium(V) Complex 7: 50 mg (128 μmol) of chloro(3-thiapentane-1,5-dithiolato)oxorhenium(V) (**6**)[11] was dissolved in 6 mL of hot acetonitrile while stirring. To this mixture 45 mg (140 μmol) of the fatty acid **5** was added. The mixture was refluxed for 30 min and then concentrated to dryness. The residue was purified by flash chromatography ($CHCl_3$/EtOAc/HOAc, 60:40:1). Crystals suitable for single crystal analysis were obtained by slow evaporation of a saturated $CHCl_3$/acetonitrile solution of **7** at room temperature. Yield: 81 mg (94%). IR (KBr): $\tilde{\nu}$ = 1703 (C=O), 958 (Re=O) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.23−1.41 (m, 12 H, 6 × CH_2), 1.46−1.60 (m, 4 H), 1.64 (quint, ^3J = 7.3, 2 H), 1.74 (quint, ^3J = 7.4, 2 H, $CH_2CH_2SCH_2CH_2$, CH_2CH_2COOH, $CH_2CH_2CH_2SRe$), 1.88 (quint, ^3J = 7.6, 2 H, CH_2CH_2SReO"SSS"), 1.95 (ddd, J_1 = 4.9, J_2 = 9.9, J_3 = 14.6, 2 H, A-part ABCD system "SSS"), 2.38 (t, ^3J = 7.3, 2 H, CH_2COOH), 2.49 (t, ^3J = 7.3, 2 H), 2.52 (t, ^3J = 7.1, 2 H, $CH_2SCH_2CH_2CH_2$), 3.09 (dt, J_1 = 4.0, J_2 = 13.8, 2 H, B-part ABCD system "SSS"), 3.83 (t, ^3J = 7.5, 2 H, CH_2SReO"SSS"), 3.90 (dd, J_1 = 3.8, J_2 = 10.2, 2 H, C-part ABCD system "SSS"), 4.27 (dd, J_1 = 4.7, J_2 = 13.1, 2 H, D-part ABCD system "SSS"). $C_{20}H_{39}O_3ReS_4$ (674.06): calcd. C 35.64, H 5.83, S 23.79; found C 35.46, H 5.81, 23.86.

Oxorhenium(V) Complex 10: A mixture of 140 mg (510 μmol) of **8**, 109 mg (452 μmol) of *N*-methyl-3-azapentane-1,5-dithiol−oxalic acid, 265 mg (452 μmol) of tetrachlorooxorhenate **9**[12] and 4 mL of 1 M methanolic NaOAc in 25 mL of MeOH was stirred at 40 °C for 24 h. The solvent was removed under reduced pressure and the remaining brown solid partitioned between 25 mL of H_2O and $CHCl_3$. After standard workup, the pure complex was isolated by column chromatography ($CHCl_3$/EtOAc/HOAc, 50:50:1) and subsequent crystallisation from ethanol. Yield: 191 mg (68%). IR (KBr): $\tilde{\nu}$ = 1705 (C=O), 950 (Re=O) cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.20−1.38 (m, 18 H, 9 × CH_2), 1.47 (quint, ^3J = 7.4, 2 H, $CH_2CH_2CH_2SRe$), 1.63 (quint, ^3J = 7.4, 2 H, CH_2CH_2COOH), 1.85 (quint, ^3J = 7.4, 2 H, CH_2CH_2SRe"SNS"), 2.35 (t, ^3J = 7.6, 2 H, CH_2COOH), 2.63 (m, 2 H, "SNS"), 3.16−3.22 (m, 4 H, "SNS", CH_2SReO"SNS"), 3.35 (s, 3 H, NCH_3), 3.54 (m, 2 H, "SNS"), 3.5−3.9 (br, 2 H, "SNS"). $C_{20}H_{40}NO_3ReS_3$ (624.95): calcd. C 38.44, H 6.45, N 2.24, S 15.39; found C 38.52, H 6.65, N 2.21, S 15.47.

Sodium 12-{[(Pyridin-2-yl)methylene]amino}undecanoate (12): 200 mg (777 μmol) of amino fatty acid **11** was dissolved in 5 mL of MeOH, containing 31 mg (775 μmol) of NaOH. The solution was filtered and then concentrated to dryness. The residue was redissolved in 5 mL of MeOH and 125 mg (1.15 mmol) of freshly distilled picolinaldehyde was added whilst stirring at 0 °C. The mixture was stirred for additional 12 h at room temperature before removing the solvent and washing the residue carefully with several portions of acetone and Et_2O. Schiff base sodium salt **12** was obtained as a light brown powder without any further purification steps. Yield: 248 mg (87%). IR (KBr): $\tilde{\nu}$ = 1648 (CH=N), 1561 (C=O) cm^{-1}. ^1H NMR (CD_3OD): δ = 1.23−1.42 (m, 14 H, 7 × CH_2), 1.59 (m, 2 H), 1.73 (m, 2 H CH_2CH_2N, CH_2CH_2COONa), 2.14 (t, ^3J = 7.6, CH_2COONa, 2 H), 3.68 (t, ^3J = 7.0, 2 H, CH_2N), 7.48 (m, 1 H, $H_{5\text{-Ar}}$), 7.91 (m, 1 H, $H_{4\text{-Ar}}$), 7.99 (m, 1 H, $H_{3\text{-Ar}}$), 8.37 (s, 1 H, CH=N), 8.61 (m, 1 H, $H_{6\text{-Ar}}$). $C_{18}H_{27}N_2NaO_2$ (326.41): calcd. C 66.23, H 8.34, N 8.58; found C 65.94, H 8.53, N 8.87.

(Tricarbonyl)rhenium(I) Complex 14: 45 mg (130 μmol) of fatty acid ligand **12** was dissolved in 2 mL of MeOH and added to a solution of 100 mg (130 μmol) of tricarbonylrhenium(I) precursor **13**[15] in 1 mL of MeOH. The mixture immediately turned to a deep orange colour and became cloudy within 15 min. After stirring overnight at room temperature, the solvent was removed in a nitrogen stream. Then 1 mL of $CHCl_3$ and 1 mL of 4 M aqueous HBr were added and the mixture was vigorously stirred for another 24 h. Afterwards, the organic layer was separated and the aqueous phase thoroughly extracted in the usual manner. Purification of the obtained residue was accomplished by column chromatography ($CHCl_3$/EtOAc/HOAc, 100:25:4). Crystals of complex **14** suitable for single-crystal X-ray analysis were obtained by slow crystallization of **14** from an acetonitrile solution at room temperature. Yield: (74%). IR (KBr): $\tilde{\nu}$ = 2021, 1902 (C≡O), 1713 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.22−1.43 (m, 14 H, 7 × CH_2), 1.62 (quint, ^3J = 7.2, 2 H, CH_2CH$_2$COOH), 1.94−2.35 (m, 2 H, CH_2CH$_2$N), 2.34 (t, ^3J = 7.4, 2 H, CH_2COOH), 4.03 (m, 1 H), 4.26 (m, 1 H, CH_2N), 7.56 (m, 1 H, $H_{5\text{-Ar}}$), 7.90 (m, 1 H, $H_{4\text{-Ar}}$), 8.05 (m, 1 H, $H_{3\text{-Ar}}$), 8.70 (s, 1 H, CH=N), 9.04 (m, 1 H, $H_{6\text{-Ar}}$). $C_{21}H_{28}BrN_2O_5Re$ (654.57): calcd. C 38.53, H 4.31, N 4.28, Br 12.21; found C 38.40, H 4.35, N 4.24, Br 12.31.

X-ray Crystallographic Studies: Crystal data and details of structure determinations for complexes **7**, **10,** and **14** are listed in Table 3. Using Mo-K_α radiation, reflection intensities were collected at room temperature (293 K) with a Siemens SMART diffractometer, equipped with a CCD area detector. The structures were solved by direct methods using SHELXS-90 and refined with SHELXL-97.[19] An empirical absorption correction (Ψ-scan) was applied. All non-hydrogen atoms were refined anisotropically. The positions of hydrogen atoms were calculated corresponding to their geometrical conditions and refined using the riding model. Atomic numbering schemes are shown in Figure 1 (for **7**), Figure 2 (for **10**) and Figure 3 (for **14**). Selected bond lengths and angles are listed in Tables 1 and 2. For complex **7** only crystals of poor quality were available, reflected in a relatively high *R* value for this compound. CCDC-156312 (**7**), -172606 (**10**) and -172605 (**14**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Copper(I) as a Homogeneous Catalyst for the Ullmann Reaction in Aqueous Solutions − The Transformation of 2-Bromobenzoate into Salicylate

Magal Saphier,*[a,b] Alexandra Masarwa,[a] Haim Cohen,[a,b] and Dan Meyerstein[a,c]

Keywords: Copper(I) / Aromatic compounds / Catalysis / Ullmann reaction

The Cu^I-catalyzed transformation of 2-bromobenzoic acid (2-Br-BA) into salicylic acid (main product), benzoic acid, and diphenoic acid was studied. The reaction was monitored by UV/Vis spectroscopy, HPLC, and ESR. Up to 25 turnovers were achieved for low Cu^I concentrations. An intermediate was observed that was assigned to a complex between copper and a follow-up product of the aromatic acid, probably a complex with a copper–carbon σ-bond. The process is probably initiated by the formation of a d-π* complex of Cu^I with the aromatic ring of 2-Br-BA followed by the reaction with a second Cu^I ion. The effect of the addition of CH_3CN or NH_3 on the catalytic process is reported. Both were found to accelerate the process when present at relatively low concentrations and slow it down at higher concentrations. A side product, 2-aminobenzoate was observed in the presence of NH_3.

Introduction

Copper(I) complexes are key intermediates in a variety of catalytic processes in aqueous solutions, e.g. the catalytic substitution of halogens at the aromatic ring by nucleophiles in the presence of copper(I) (Ullmann reaction).[1] The expected steady-state concentration of Cu^+_{aq} is extremely low due to the disproportionation of Cu^+_{aq} [Equation (1)[2]] and the low solubility of cuprous oxide/hydroxide[2] and halides.[2] Moreover, atmospheric dioxygen, dissolved in water, reacts rapidly with copper(I) oxidizing it to copper(II). The addition of stabilizing ligands can increase the concentration of copper(I) in aqueous solutions and thus improve the efficiency of the catalytic process. However, these ligands are also expected to affect the reactivity of Cu^I, i.e. stabilizing ligands are in principle expected to decrease the Cu^I reactivity and therefore to slow down the catalytic process. A well-known method for the preparation of Cu^I solutions is the addition of CH_3CN.[2] Recently, it was reported that a series of aromatic compounds, such as 2-chlorobenzoic acid, form relatively stable d-π* complexes with Cu^I and thus increase Cu^I concentration in solution.[3]

$$Cu^{2+} + Cu^0 \leftrightarrows 2\,Cu^+_{aq} \quad K_{aq} = 1.00\cdot10^{-6}\ \text{M}^{-1} \qquad (1)$$

$$Cu^+_{aq} + L \leftrightarrows CuL^+_{aq} \qquad (2)$$

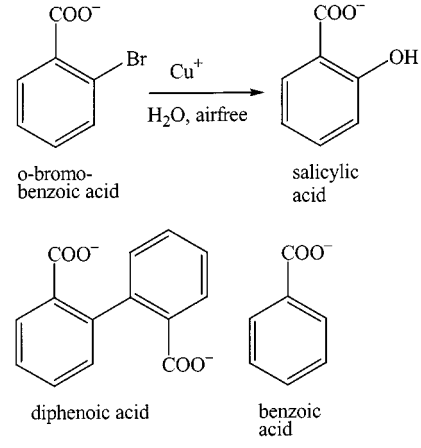
It was therefore of interest to study the implications, in terms of the mechanism of the catalytic process, of the addition of ligands in general and of Cu^I d-π* complex formation with aromatic compounds. In this study, the copper(I)-catalyzed substitution of halogen atoms at an aromatic ring was studied. As a model reaction, the transformation of 2-bromobenzoic acid into salicylic acid, benzoic acid, and diphenoic acid was chosen (Scheme 1).



Scheme 1

Results

On addition of Cu^I to deoxygenated aqueous solutions of 2-bromobenzoic acid (2-Br-BA) a relatively slow reaction takes place yielding salicylic, diphenoic, and benzoic acid. The kinetics of this process can be monitored by UV/Vis spectrophotometry. A peak at 296 nm grows in intensity,

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434−1948/02/0505−1226 $ 20.00+.50/0 *Eur. J. Inorg. Chem.* **2002**, 1226−1234

which is attributed to salicylate. The spectra of possible products of the reaction are shown in Figure 1. Moreover, organic products and the starting material can be identified and quantified by HPLC.

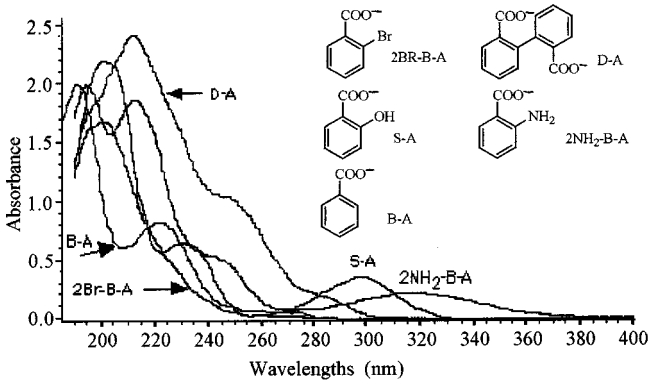


Figure 1. UV/Vis spectra of possible organic products and starting material (all 0.1 mM in aqueous solution)

The following sources of Cu^{I} were used in the course of this study:

1. Commercially available $Cu(CH_3CN)_4PF_6$ salt was added to deaerated aqueous solutions of *o*-bromobenzoic acid after addition of CH_3CN. Under these conditions, Cu(OH) precipitated (yellowish) only at pH > 9, whereas it precipitated already at pH = 7 without the addition of stabilizing ligands.

2. $[Cu(CH_3CN)_4]^{+}$ was prepared by the comproportionation of Cu^{II}_{aq} (source $CuSO_4$) and Cu^0 metal in deaerated aqueous solutions containing CH_3CN. Complete comproportionation was achieved when the concentration of acetonitrile was above 4%, in accordance with literature data.[4] This method can also be performed with different stabilizing ligands, e.g. higher concentrations of ammonia at basic pH.[2] The resulting Cu^{I} solution was subsequently injected into deaeraeted aqueous solutions of 2-bromobenzoic acid.

3. During the course of this study it emerged that Cu^{I} could also be prepared in situ by comproportionation of $CuSO_4$ and Cu metal in deaerated aqueous solutions containing 2-bromobenzoic acid. The bromobenzoic acid is expected to lead to comproportionation according to the measured stability constants.[3] Note that these stability constants increase with the increase in pH.[3] The comproportionation in this system was complete, as verified by the fact that the detected amounts of Cu^{I} were more than twofold the initial $CuSO_4$ concentration (as the catalytic cycle already starts with the addition of the 2-bromobenzoic acid).

Kinetics of Formation of Salicylic Acid Monitored by UV/Vis Spectrophotometry

Figure 2 shows typical spectral changes occurring during the initial phase of the reaction of 2-Br-BA and Cu^{I}. The absorbance at 296 nm increased, due to the formation of salicylic acid (SA), while the absorbance in the 310−430 nm region decreased during the course of about 1 h under the specific conditions used. It should be noted that time "zero" in these experiments is ca. 10 min after the solution was prepared. The spectral changes in the 310−430 nm region are attributed to the decomposition of an initially formed intermediate. The slow reaction can best be monitored when Cu^{I} is prepared in situ by comproportionation of $CuSO_4$ (0.001−0.01 M) and Cu^0 in 2-Br-BA solution. Figure 3 shows typical kinetic traces at 296 and 350 nm implying several overlying reactions.

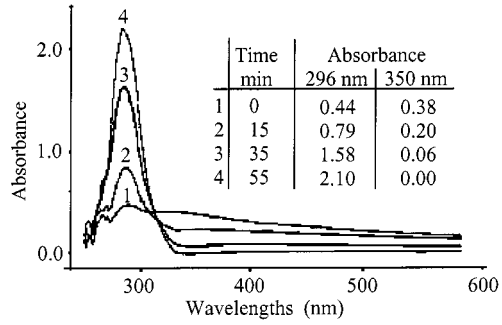

Figure 2. UV/Vis spectral changes during the reaction of 2-Br-BA with Cu^{+} [2-Br-BA (0.05 M), $CuSO_4$ (0.01 M), Cu^0, no air, pH_{init} = 7.0] (* 0-time is 10 min after mixing of the reactants, due to degassing time)

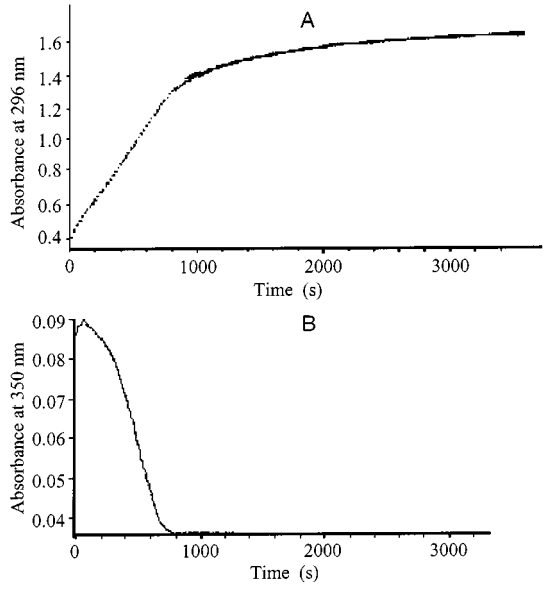

Figure 3. Kinetic traces monitored A) at 296 (SA) and B) at 350 nm (intermediate) during the reaction of 2-Br-BA with Cu^{+} [2-Br-BA (12.5 mM), $CuSO_4$ (0.1 mM), Cu^0, 4% MeCN, no air, pH_{init} = 6.7)] (* 0-time is 10 min after mixing of the reactants, due to degassing time)

During the disappearance of the intermediate, the formation of salicylic acid is fastest, but it continues after that time. The amount of salicylic acid formed within 2 h [calculated according to its absorption at 296 nm (ε = 3400 $M^{-1}cm^{-1}$), if necessary after dilution] was found to be proportional to the initial concentration of 2-Br-BA (Figure 4) under conditions of excess 2-Br-BA and a given Cu^{I} concentration. This Cu^{I} concentration was supplied by $Cu(CH_3CN)_4PF_6$ (without any addition of CH_3CN in this

case). The amount of salicylic acid formed was higher than the initial Cu^{I} concentration, implying a catalytic role of Cu^{I}. Moreover, varying the Cu^{I} salt concentration (employing ammonia as a stabilizing ligand) shows that the final amount of salicylic acid formed is independent of the initial Cu^{I} concentration (Figure 5), pointing again to its catalytic role. Up to 25 turnovers were achieved for the lowest Cu^{I} concentration and ca. 35% of the organic acid was converted under these specific conditions. The initial changes in salicylic acid (SA) concentration (d[SA]/dt calculated from the changes during the first 40 min of the reaction) are proportional to the square of the initial Cu^{I} concentration (Figure 6).

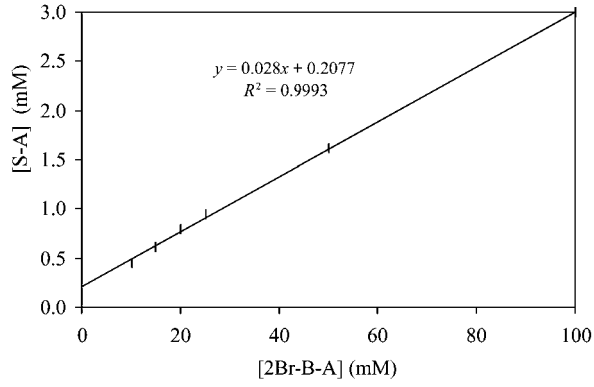

Figure 4. Dependence of SA production (after 120 min) on initial 2-Br-BA concentration {$Cu[MeCN]_4PF_6$ (0.33 mM), pH_{init} = 7.0}

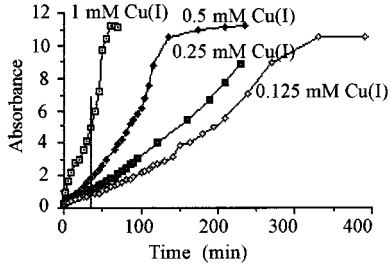

Figure 5. Kinetic traces monitored at 296 nm (SA) during the reaction of 2-Br-BA with Cu^{+} for different initial Cu^{+} concentrations {2-Br-BA (10 mM), $Cu[MeCN]_4PF_6$, NH_3 (0.0175 M), pH_{init} = 9.0} (* 0-time is 10 min after mixing of the reactants, due to degassing time)

Kinetics of the Formation of the Organic Products Monitored by HPLC

As the reaction is relatively slow, it is possible to monitor the formation of the organic products and decomposition of 2-Br-BA by HPLC. Figure 7 shows a typical kinetic run, with salicylic acid indeed being the main product of the process. Diphenoic acid formed with a similar kinetic profile, rate decreasing with the progress of the process, but with a significantly smaller yield. The formation of benzoic acid on the other hand was a slow but steady process, the final yield being similar to that of diphenoic acid, i.e. the relative yield of benzoic acid to that of salicylic, or diphenoic, acid increased with the progress of the reaction.

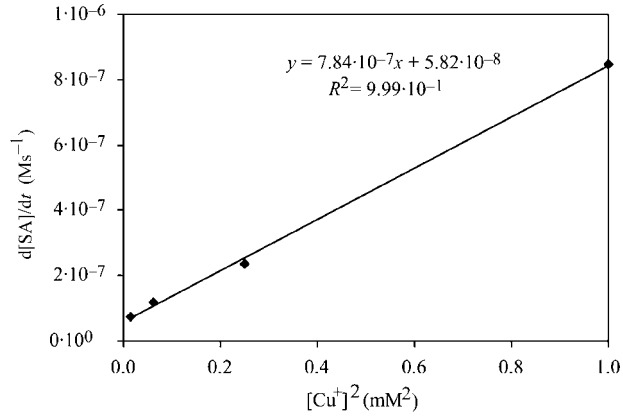

Figure 6. Dependence of SA production on the square of the initial Cu^{I} concentration {2-Br-BA (10 mM), $Cu[MeCN]_4PF_6$, NH_3 (0.0175 M), pH_{init} = 9.0}

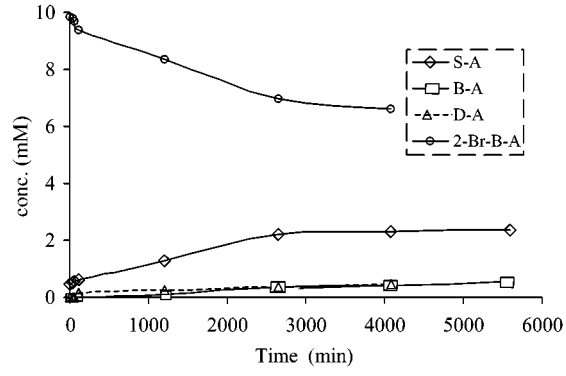

Figure 7. Kinetic traces of products and 2-Br-BA during the reaction of 2-Br-BA with Cu^{+} monitored using HPLC [2-Br-BA (10 mM), $CuSO_4$ (1 mM) + Cu^{0}, pH_{init} = 6.0]

pH Changes During the Process

Short-Term pH Changes

In recording the pH changes after the addition of Cu^{I} (salt or solution with acetonitrile as stabilizing ligand) to an acidic solution of 2-Br-BA (pH = 3−5) we observed an initial increase in pH over several 100 s (Figure 8) followed

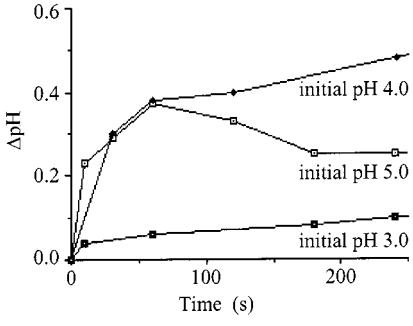

Figure 8. pH changes during the fast time scale of the reaction of 2-Br-BA with Cu^{+} {2-Br-BA (10 mM), $Cu[MeCN]_4PF_6$ (1 mM)}

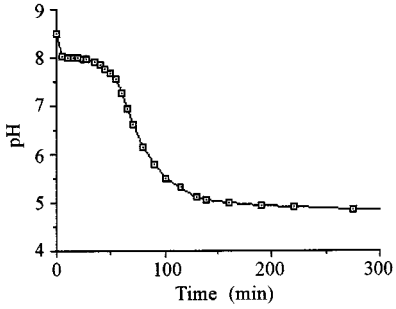

Figure 9. pH changes during the longer time scale of the reaction of 2-Br-BA with Cu^+ [2-Br-BA (10 mM), $CuSO_4$ (1 mM) + Cu^0]

by a slow decrease (Figure 9). The initial effect at pH = 3 was smaller than that for higher initial pH values, probably due to the buffer effect of 2-Br-BA (pK_a = 2.8).[5] Cu^I did not cause similar initial pH changes in the absence of 2-Br-BA, and we would rather expect an increase in acidity due to the addition of a metal salt to an aqueous solution. Furthermore, protons are released during the reaction of 2-Br-BA to form salicylic acid, see Equation (3), as was observed for longer reaction times.

$$\text{2-Br-BA} + H_2O\,[+\,Cu^+] \rightarrow \text{SA} + H^+ + \text{Br} \quad (3)$$

The initial increase in pH occurred over the same time span as the formation of the intermediate with the absorption around 350 nm, which was verified by simultaneous pH and UV/Vis measurements (employing fiber optics).

The increase in pH might in principle be due to an increase in the pK_a of the aromatic acid. Bonding of Cu^I to the aromatic ring (σ-donation from the HOMO of the π-system to Cu^I and π-back donation from Cu^I to the LUMO of the π-system) could cause such a change in pK_a. Indeed, excitation of aromatic acids induces a similar pK_a shift.[6] Assigning the intermediate with the absorption around 350 nm to a π-complex between Cu^I and 2-Br-BA poses several problems; no analogous complexes and no pH changes were detected when 2-Br-BA was replaced with benzoic acid. Furthermore, one expects that a complex formation of this kind should occur within a much shorter time. Alternatively, the formation of an intermediate with a σ-bond between the copper ion and a carbon atom of the aromatic ring (vide infra), might decrease the Cu^I–hydroxide interaction ($K_{sp} = 1 \cdot 10^{-14}$ M^2),[5] see Equation (4) where R$^\cdot$ is an aryl radical.

$$L_nCu^IOH + R^\cdot \rightarrow Cu^{II}\text{–}R + n\,L + OH^- \quad (4)$$

We investigated the effect of pH on the life time of the intermediate and found that the decay of the absorption at 350 nm was faster at lower pH values. Whereas the intermediate had a life time of a couple of 100 s at pH = 5–7 it seemed to be stable for more than 1 h at pH = 9.

Long-Term pH Changes

Over longer time scales (several 100 min) the pH of the Cu^I/2-Br-BA system dropped from the initial value (5–9) to 4.6. An example is shown in Figure 9. A titration pointed out that the yield of H_3O^+ equaled the yield of salicylic acid, as expected according to Equation (3).

Experiments were performed where the pH was kept constant by dropwise addition of 0.10 N NaOH or NH_3 during the reaction under argon (the reaction was monitored spectrophotometrically by using fiber optics). In both those experiments, more salicylic acid was produced than in parallel experiments without the addition of extra base. The yields were highest for the system with NH_3 addition.

When the system reached pH ≤ 4.7 a black precipitate formed on the Cu metal. The precipitate could be dissolved in a basic solution. According to the resulting spectrum and elemental analysis, this precipitate consisted of Br^- and Cu ions. No Cu ions remained in the reaction mixture after extraction of the covered Cu metal plate. Taking into account the fact that the relative yield of Cu/bromine was 1:1, by titrating the amount of dissolved Br (Vollhardt) and weighing the Cu plate before and after the reaction, we could conclude that nearly complete comproportionation took place. For example, 0.18 mM of Br^- was precipitated from an initial reaction solution containing 0.10 mM of Cu^{2+} (0.20 mM would have been expected for full comproportionation). A similar precipitate was also formed in experiments with 2-Cl-BA. According to the literature, such precipitates consist of mixed-valence Cu^I and Cu^{II} halides, e.g. $(CuBr)_n(CuBr_2)_m$.[7a,7b]

Influence of the Cu^{2+} Concentration on the Product Distribution

Figure 10 shows the dependence of the product distribution (measured after 24 h) on the initial Cu^{2+} concentration. Increasing the Cu^{2+} concentration favored the formation of salicylic acid on account of the dimer concentration. The effect on the yield of benzoic acid is negligible.

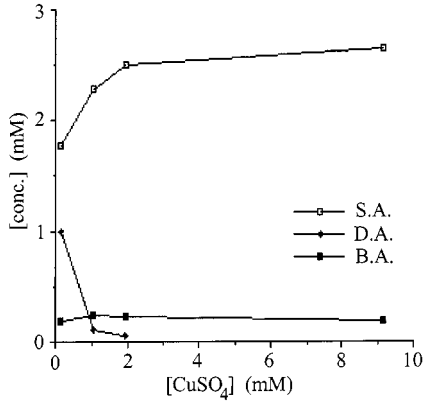

Figure 10. Dependence of the product distribution of the reaction of 2-Br-BA with Cu^+ (measured after 24 h) on the initial Cu^{2+} concentration [2-Br-BA (9 mM), Cu^I (2 mM) 5% MeCN, pH_{init} = 6.0]

ESR Measurements

In order to monitor the Cu^{2+} concentration during the reaction ESR spectroscopy was employed. Cu^{2+} (d^9) has an unpaired electron that makes it optimal for ESR studies, whereas Cu^{I} is ESR-silent (d^{10} system). A system containing Cu^{I} derived from comproportionation of Cu^{II} and Cu^0 metal in 4% CH_3CN did not produce an ESR signal, whereas a signal developed on addition of 2-Br-BA (g_{iso} = 2.16, see A and B in Figure 11). The final spectrum differs from that of Cu^{2+} with acetonitrile in aqueous solution and also from that of Cu^{2+} with 2-Br-BA (see A in Figure 12), but is very similar to that of Cu^{2+} with salicylic acid (see B in Figure 12).

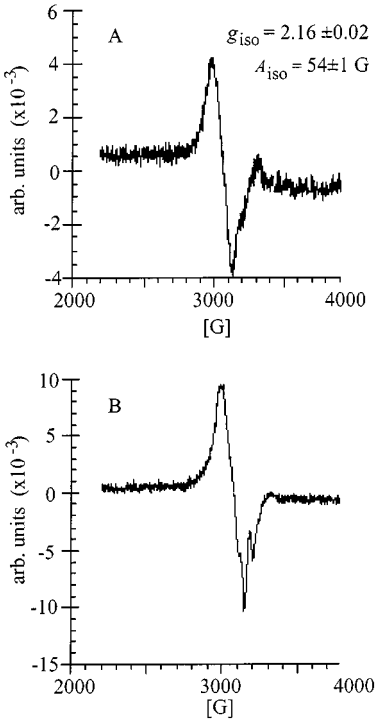

Figure 11. ESR spectra measured during the reaction of 2-Br-BA with Cu^{+}; A: after 120 s; B: after 24 h [2-Br-BA (10 mM), Cu^{I} (10 mM), 4% MeCN]

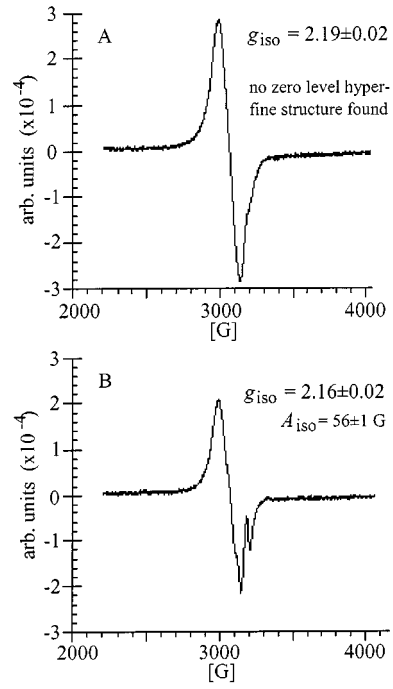

Figure 12. ESR spectra; A: 2-Br-BA (10 mM) with $CuSO_4$ (10 mM); B: SA (10 mM) with $CuSO_4$ (10 mM)

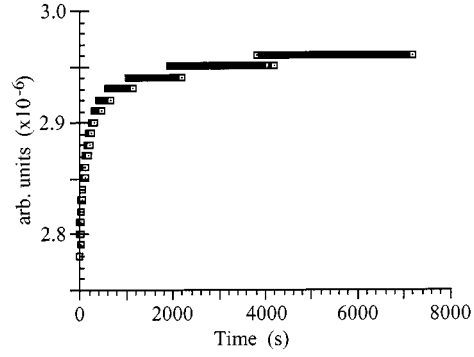

Figure 13. Time trace of ESR signal production due to Cu^{II} during the reaction of 2-Br-BA with Cu^{+} [2-Br-BA (10 mM), Cu^{I} (10 mM), 2% MeCN (* 0-time is 8 min after mixing of the reactants, due to technical reasons)]

Figure 13 shows a typical kinetic trace of the formation of the ESR signal in the Cu^{I}/2-Br-BA system. Under the experimental conditions necessary for the ESR measurements (relatively high concentrations of the reactants) most of the Cu^{2+} would have formed during the 8−10 min needed before the first measurement could be performed. Comparing the kinetics and form of the ESR signal with that of the Cu^{2+}/salicylic acid system it becomes obvious that the produced Cu^{2+} forms a complex with salicylic acid created during the reaction. The initial ESR spectrum (see A in Figure 11) differs slightly from the final spectrum, raising the possibility that initially Cu^{II} forms a complex with the intermediate. Unfortunately, ESR spectra taken at low temperatures could not assist in clarifying this assumption.

Influence of Different Ligands

The influence of different Cu^{I}-stabilizing ligands on the kinetics of the reaction was investigated.

Acetonitrile

A series of experiments in which Cu^{I} was formed by comproportionation under exclusion of dioxygen were performed for different concentrations of acetonitrile. The resulting Cu^{I} solutions were injected into solutions containing 2-Br-BA (under He). Figure 14 shows the change in absorbance due to SA formation at 296 nm (the absorbances were calculated from measurements in diluted solutions) after 2000 s as a plot of the CH_3CN percentage. For CH_3CN concentrations smaller than 4% the compropor-

tionation was incomplete, causing an increase in the formation of salicylic acid until about 4% CH_3CN. For concentrations > 4% CH_3CN there was a definite decrease in SA formation.

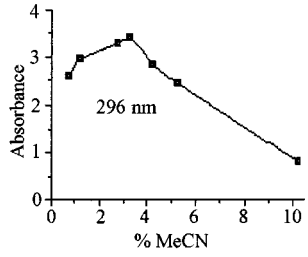

Figure 14. Change in absorbance due to SA formation at 296 nm after 2000 s as a plot of the CH_3CN percentage (the absorbances were calculated from measurements in diluted solutions) [2-Br-BA (25 mM), $CuSO_4$ (0.5 mM), Cu^0, MeCN, pH_{init} = 9]

In a similar experiment the formation of all organic products was investigated by HPLC (Figure 15). A decrease in the yield of all products with increasing CH_3CN concentration was observed. The influence on all the products is similar, therefore it is conceivable that CH_3CN plays a role in the first step of the reaction sequence.

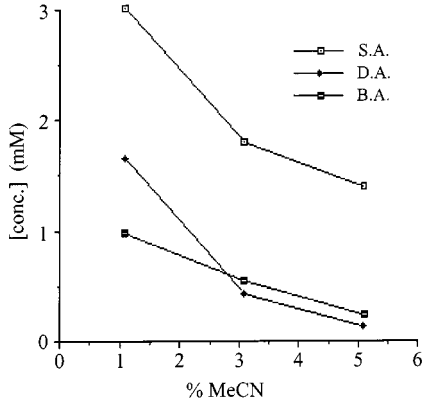

Figure 15. Changes in product distribution as a function of the CH_3CN percentage (the concentrations were determined after 24 h by HPLC) [2-Br-BA (10 mM), $CuSO_4$ (1 mM), Cu^0, MeCN, pH_{init} = 6]

Ammonia

NH_3 plays a major role in the formation of products. Its role cannot be explained solely by its stabilizing effect, as the reaction was also influenced at pH < 7, where NH_3 does not stabilize Cu^I anymore. A plot of the resulting absorbance at 296 nm vs. the concentration of NH_3 shows a similar pattern of increase and decrease of SA as for acetonitrile. At concentrations > 175 mM of NH_3 the formation of *o*-aminobenzoic acid was observed (verified by its absorbance at 318 nm, see Figure 1) in addition to the main product, SA.

Reaction with *o*-Chlorobenzoic Acid (2-Cl-BA)

In order to understand the influence of bromine, several parallel reactions with 2-Cl-BA instead of 2-Br-BA were studied. These reactions are considerably slower, but they seemed to follow a similar pathway.

Discussion

The above results for the Cu^I-catalyzed reaction of 2-Br-BA can be summarized by the following empirical observations:

1. As a first step an intermediate was formed with an absorbance in the 290−400 nm region. Transient complexes with copper−carbon σ-bonds[8a−8e] as well as d-π complexes of Cu^I [8d,9] with aromatic compounds are known to absorb in this wavelength region. For acidic starting pH values the pH initially rose during the formation of this intermediate. At acidic pH values (pH = 5) the intermediate was less stable than at basic pH values (pH = 9).

2. Several overlying reactions were observed at 296 nm, the absorption maximum of salicylic acid. The process can be divided into two time ranges so that the initial fast reaction covers the time when the concentration of the intermediate is relatively high.

3. During the fast time range the rate of reaction is linearly dependent on the 2-Br-BA concentration and quadratically dependent on the Cu^I concentration, implying the involvement of two Cu^I ions in the catalytic cycle.

4. During the reaction, Cu^{II} was formed, and most of it, according to the ESR measurements, during the initial phase. The ESR spectra of the final products indicate that most of the Cu^{II} is bound to salicylic acid.

5. pH dependence: The yield of the main product, salicylic acid, is considerably higher at basic pH than at acidic pH. The pH shifts during the reaction towards acidic pH and levels at pH ≈ 4.5. The proton yield stoichiometrically (1:1) equals the amount of salicylic acid formed. At pH = 4.5 a black precipitate, identified as $(CuBr)_n(CuBr_2)_m$,[7a,7b] forms and terminated the reaction. At pH values > 5 Cu^I apparently forms stronger complexes with the aromatic compounds.[3]

6. Excess Cu^{II} caused a relative decrease in the yield of the dimer and scarcely influenced the relative yields of salicylic and benzoic acids.

7. Influence of acetonitrile: Concentrations of more than 4% acetonitrile reduce the rate of formation of salicylic acid. For concentrations smaller than 3% the comproportionation was not yet complete, and therefore an increase in product formation was observed. Acetonitrile formed a complex with Cu^I and consequently was found to compete with 2-Br-BA for the Cu^I. At high acetonitrile concentrations the 2-Br-BA thus did not form the π-complex with 2-Br-BA. Alternatively, the formation of $Cu(CH_3CN)_n^+$ ($1 \leq n \leq 4$) shifted the redox potential of Cu^I anodically, leading to diminished reactivity.

8. Influence of ammonia: Similar to acetonitrile, ammonia also led to an increase in product formation at lower ammonia concentration, but to a decrease in rate at higher concentrations. Ammonia acted as a basic buffer and prevented the Cu^I ions from precipitating. Moreover, it formed

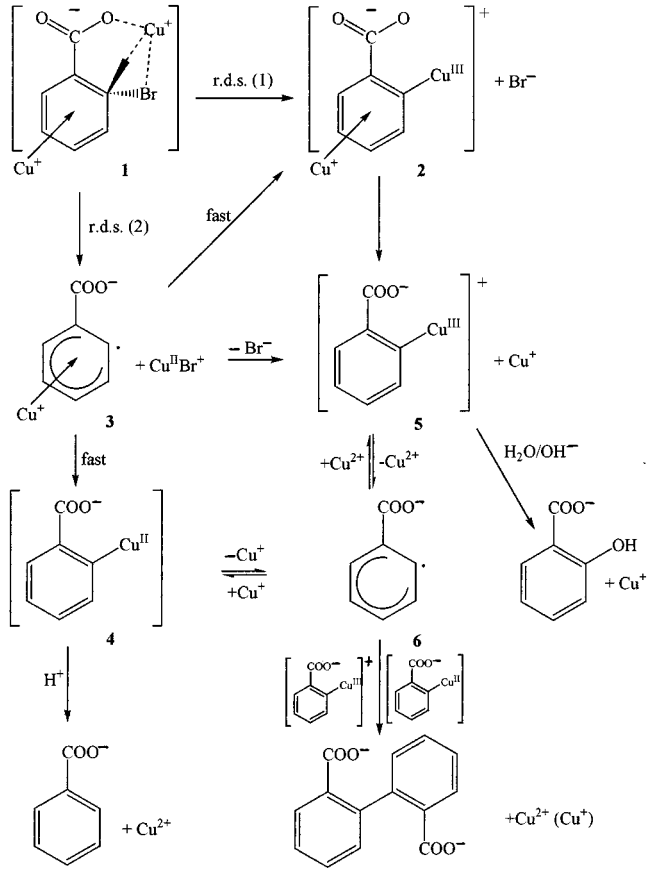
a σ-complex with Cu^{I} and thus changed its redox potential favorably, but a reaction of $Cu(NH_3)_2^+$ with a substrate requires a hybridization change probably from sp to sp^3. Such a hybridization change is endothermic and was recently shown to decrease the rate of reaction of Cu^{I} with $CCl_3CO_2^-$.[10]

9. The aromatic substrate, 2-Br-BA, induced comproportionation and catalyzed the formation of Cu^{I} by formation of a π-complex of Cu^{I} with the aromatic compound, thus shifting the equilibrium of the reaction according to Equation (1) to the Cu^{I} side.[3]

10. The isomers 3- and 4-Br-BA are considerably less reactive[1c,11,12] under the conditions used for the reaction of 2-Br-BA, implying that the interaction of Cu^{I} with Br as well as with the carboxylic substituent (chelate effect) is of importance.

11. A radical mechanism involving the $Ar^{\cdot}$ radical can be ruled out, as pulse radiolysis experiments (data not shown) point out that aryl radicals, produced in the presence of 2-Br-BA and Cu^{I}, reacted with the aromatic acid and not with Cu^{I}. The product of this reaction was the dimer bromodiphenoic acid, which is not a major product of the investigated catalytic process.

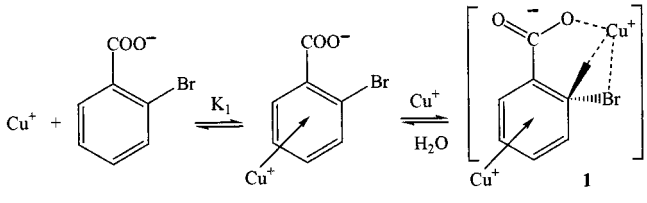
12. 2-Cl-BA reacted slower than 2-Br-BA, but otherwise followed the same pattern as discussed in the previous points, thus suggesting that the detachment of the halogen is the rate-determining step.



Scheme 3

The Proposed Mechanism

The results are consistent with the following mechanism for the formation of the reactive intermediate (Scheme 2). First a Cu^{I} ion forms a d-π* complex with the aromatic ring of 2-Br-BA followed by the interaction of a second Cu^{I} ion with the Br and carboxylate substituents.



Scheme 2

The aromatic ring of the intermediate is probably distorted as the carbon atom, bearing the Br substituent, attains tetrahedral character, in agreement with previous proposals from the literature.[12a–12c] The coordination of the Cu^{I} ion to the aromatic ring probably distorts it and also lengthens the C–Br bond,[13a–13f] thus facilitating the abstraction of Br. The proposed follow-up reactions, which fit all the observed results are summed up in Scheme 3.

The rate-determining step is obviously the bond breakage of the C–Br bond, as this step involves two Cu^{I} ions and therefore fits the second-order dependence on Cu^{I}, as was found experimentally. Moreover, this hypothesis is corroborated by the fact that 2-Cl-BA reacted in a similar manner to 2-Br-BA, only much slower.

The bond breakage of C–Br might follow two possible routes. In one a formal oxidation takes place to obtain intermediate **2** or **5**. In a second possibility, intermediate **3** is formed, which either reacts with the $Cu^{II}Br$ formed in a cage to yield intermediates **2** or **5**, or transforms immediately into intermediate **4**. Intermediates **2** and **5** can decompose by two different pathways. In the first the Cu–C bond breaks heterolytically to produce the main products of the reaction, salicylic acid, Cu^{I}, and a proton. On the other hand, intermediate **5** can decompose homolytically in a side reaction to form Cu^{II} and the radical **6**, which might dimerize to produce diphenoic acid. The radical **6** can also react with the intermediate **5** to produce the dimer and Cu^{II}, a termination step leading to loss of Cu^{I}. This reaction is more plausible as $[Cu^{III}C_6H_4CO_2^-] >> [C_6H_4CO_2^{\cdot -}]$. For high concentrations of Cu^{II} the equilibrium of the homolytic decomposition of intermediate **5** is shifted towards its formation and therefore less dimer is formed at high concentrations of Cu^{II}.

Intermediate **4** might decompose heterolytically, in an acid-catalyzed reaction, to form benzoic acid and Cu^{II}. This is a side reaction, in which Cu^{I} is removed from the reaction system stoichiometrically, and therefore the rate of the overall reaction (formation of salicylic acid) will slow down with time. Intermediate **4** can also react with the radical to form Cu^{I} and the dimer, in this pathway Cu^{I} is restored to the catalytic cycle. In addition, intermediate **4** can decompose homolytically and can thus be restored to the salicylic acid producing cycle.

According to the experimental observations, the reaction can be divided into at least two time scales. During the short time scale, seconds to minutes (depending on the relative concentrations of Cu^{I}, 2-Br-BA, initial pH, and initial Cu^{II} concentration), the intermediate is observed, as well as the increase in pH, second-order dependence on Cu^{I} and the yield of salicylic acid and the dimer are relatively high. At the same time, a rapid increase in Cu^{II} concentration is observed. During the slower phase, hours to days, a slow further increase in salicylic acid and a considerably slower increase in the dimer yield are observed; it seems that the rate of formation of benzoic acid is pH-dependent and thus its relative yield increases with time. The yield of Cu^{II} is especially low compared to the first phase. The absorption at 350 nm is nearly non-existent, and therefore the intermediate concentration as well as the Cu^{I} concentration are presumably low.

The origin of the two time scales is probably the fast formation of Cu^{II} on account of Cu^{I}. Cu^{II} is produced during the formation of the dimer and the benzoic acid. The dimer, which is formed mainly during the first time frame, when the steady-state concentrations of the intermediates **5**, **6**, and **4** are relatively high, is responsible for the majority of the Cu^{II} formed, later its formation is hindered by high Cu^{II} concentration. The decrease in Cu^{I} concentration, which also stems from the formation of insoluble CuBr, causes a decrease in the concentration of the intermediate and slows down the reaction. Moreover, the pH, that decreases during the reaction slows down the process, and finally at pH = 4.7 and relatively high Cu^{II} concentrations the formation and precipitation of a mixed-valence compound stops the catalytic reaction as a result of removing the rest of Cu^{I} from the reaction system.

Concluding Remarks

This study proves that Cu^{I} species are the catalysts in the Ullmann reaction. Furthermore, the results clearly point out that the addition of ligands that stabilize Cu^{I} in aqueous solutions, beyond a given optional concentration, slow down the catalytic process. This observation is attributed to the effect of the ligands on the Cu^{II}/Cu^{I} redox potential and thus on the Cu^{I} reactivity. (The latter might also be affected by the binding mode of the Cu^{I} ion to the ligand.[10]) Therefore, the use of CH_3CN or alkenes as solvents for Cu^{I}-catalyzed reactions is not recommended.

Experimental Section

Materials: All solutions were prepared from reagent grade chemicals or better. Distilled water was further purified by passing through a Milli Q Millipore setup, final resistivity > 10 MΩ/cm. All experiments were carried out at room temperature (22±2 °C). Cu^{I} solutions were prepared by comproportionation of Cu^{II} solutions (usually $CuSO_4$) with Cu^0 metal (activated by concentrated HNO_3). The solution was stirred for at least 24 h. All experiments involving Cu^{I} were carried out in strictly de-aerated solutions using the syringe technique and helium or argon gas. Aqueous solutions of the aromatic acids were prepared by completely dissolving the solids in basic solutions (NaOH) and acidifying to the desired pH by titration with $HClO_4$.

Techniques: The pH was measured with a Corning 220 or a Hanna (HI 9017) pH meter and adjusted with $HClO_4$ and/or NaOH.

UV/Vis: Spectra were recorded with a Hewlett Packard 8452A diode array spectrophotometer. Special cells for anaerobic studies were used. The concentration of Cu^{2+}(aq) and indirectly Cu^{+} (after oxidation to Cu^{2+} with atmospheric dioxygen) was determined spectrophotometrically by the addition of ammonia to form the complex $Cu(NH_3)_4^{2+}$, which has a molar absorption coefficient of 60 $M^{-1}cm^{-1}$ at 604 nm. Fast reactions were monitored by employing an SFA-11 Rapid Kinetics Accessory (Hi-Tech). In some cases, where pH and spectral measurements were performed simultaneously, fiber-optical connections by Phonetics were employed.

HPLC: Organic starting materials and products were separated and identified with the help of a Spectraphysics Analytic Inc. HPLC (SP Thermo Separation, A 0099-510) in conjunction with a Spectrophotometer, Spectra Series (p200) which operates in the 200−400 or 400−800 nm region (5 nm resolution). A Merck 50942 LiChroCart 125-4, LiChrospher 100 RP-8 (5 μm) column was utilized. A mixture of 35% MeCN (HPLC grade) and 65% 0.05 M phosphate buffer at pH = 3.5 was used as the eluent at a rate of 0.3 mL/min; chromatograms were thus collected within 10 min. Calibrations for starting materials and possible products were performed at 220, 260, and 295 nm (area of peaks) if applicable.

ESR: Spectra were recorded with a Bruker EMX 220 X-band ESR spectrometer. The different complexes of Cu^{II} with the aromatic compounds could be identified at 120 K. In some instances kinetics were measured at room temp. by using air-tight ESR tubes.

NMR: Spectra were recorded with a Bruker DPX 200 MHz. $Cu(CH_3CN)_4PF_6$ was used as a source of Cu^{I}, dissolved in 3% CH_3CN/D_2O.

Acknowledgments

This study was supported in part by a grant from the Budgeting and Planning Committee of The Council of Higher Education and the Israel Atomic Energy Commission. D. M. wishes to express his thanks to Mrs. Irene Evens for her ongoing interest and support.

The Preparation and Structures of Group 12 (Zn, Cd, Hg) Complexes of the Soft Tripodal Ligand Hydrotris(methimazolyl)borate (Tm)

Iain Cassidy,[a] Mark Garner,[a] Alan R. Kennedy,[a] Graeme B. S. Potts,[a] John Reglinski,*[a] Paul A. Slavin,[a] and Mark D. Spicer*[a]

Keywords: Tripodal ligands / N ligands / S ligands / Group 12 complexes

Complexes of the hydrotris(methimazolyl)borate ligand (Tm) have been prepared with zinc, cadmium and mercury halides. Complexes of type [M(Tm)X] were obtained and characterised by NMR and mass spectrometry. X-ray crystallographic analysis of [Zn(Tm)X] (X = Cl, Br, I) reveals a symmetrical coordination mode of the ligand, but no significant change with different halides, which sit on the approximate C_3 axes of the complexes. The structures of [M(Tm)Br] (M = Cd, Hg) are isomorphous with one another. Again, the ligand is symmetrically coordinated to the metal, but the halide is now significantly displaced from the approximate C_3 axis of the M(Tm) unit, resulting in what approximates to a trigonal pyramidal geometry. Unlike in most distorted mercury structures, little bond length expansion (towards two- or three-coordinate geometries) occurs. This is ascribed to the strong affinity of the thione donors for Hg.

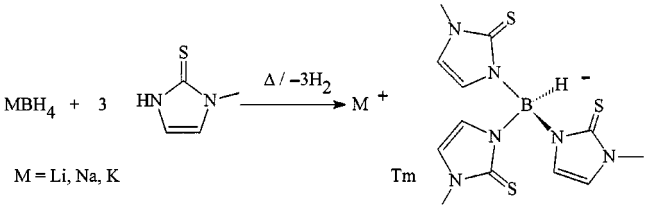
Introduction

The tripodal, anionic ligand hydrotris(pyrazolyl)borate (Tp) has been extensively studied since its preparation over 30 years ago.[1,2] Despite the relative ease of preparation of substituted analogues, and thus manipulation of the steric properties of the ligand, it is not possible to substantially alter the donor characteristics. To this end we have recently reported[3,4] the preparation of the novel, soft, anionic tripodal ligand hydrotris(methimazolyl)borate (Tm) (**1**) by adaptation of the method used by Trofimenko to prepare the Tp anion (Scheme 1).



Scheme 1

Tm is broadly analogous to Tp in that it also presents a face-capping donor set, but differs in that: i) the donor set is much softer in character (3 S donor atoms compared to 3 N donor atoms), and ii) the chelate ring size formed on complexation is eight (rather than six in Tp complexes). Tm can be considered to be the softest in a series of $6e^-$ donor, face-capping anionic ligands *viz* Tp, Cp and Tm.

[a] Department of Pure and Applied Chemistry, University of Strathclyde,
295 Cathedral Street, Glasgow, G1 1XL, UK

Our initial studies of the complexation of Tm with late transition metals and with lower main group metals have shown that although the analogy holds with respect to the tripodal bonding mode adopted by the ligand, the chemistry is modulated considerably on going from the hard Tp to the soft Tm ligand. This is manifested particularly in the stability and reactivity of the complexes obtained. For instance, with bismuth(III) we have obtained[5] both the octahedral $[Bi(Tm)_2]^+$ cation and a chloro-bridged dimer $[Bi(Tm)Cl(\mu\text{-}Cl)]_2$, while no examples of Tp complexes of bismuth have been reported. Indeed, in our hands, reaction of NaTp with $BiCl_3$ under identical conditions results in the reduction of the bismuth to its elemental state.[6] Likewise, iodine oxidation of $[Tl^I(Tm)]$ results in the formation of the $[Tl^{III}(Tm)_2]^+$ cation, while [Tl(Tp)] is not oxidised by iodine, but undergoes ligand decomposition.[7] A further difference in reactivity has been noted by Hill,[8] who in an attempt to prepare the Tm analogue of [Ru(R)-(CO)(PPh_3)(Tp)] observed intramolecular activation of the bridgehead B−H bond with formation of a metalloboratrane. In the latter example the reactivity apparently arises from the greater flexibility afforded by the eight-membered chelate rings formed by Tm in its metal complexes.

In an effort to further understand the bonding of Tm to metals we decided to investigate the zinc triad of metals. These elements only have a single accessible oxidation state, which should lessen the likelihood of side reactions (which in our experience are mostly redox driven). Furthermore, there has been extensive use of Tp in attempts to model the zinc coordination sphere in metalloenzymes such as carbonic anhydrase and liver alcohol dehydrogenase.[9,10] Recently, to this end, Parkin and Vahrenkamp have prepared

analogues of the Tm ligand either containing an NS_2 donor set[11,12] or with modified steric bulk,[13,14] have reported their zinc complexes and highlighted aspects of their mimicry of the biological system.

We have previously reported in brief the formation and crystal structure of [Zn(Tm)Br],[3] and the preparation of [Zn(Tm)X] (X = Cl, I).[4] The relatively simple tetrahedral structure seems to give an ideal system in which to investigate the effects of metal ion size and counterions on the structures adopted in the absence of problems arising from redox activity. Here we describe the preparation of the full series of group 12 metal halide complexes and analyses of their solid-state structures.

Results and Discussion

The complexes [M(Tm)X] (M = Zn, Cd) are readily prepared by reaction of the metal(II) halide with TlTm in dichloromethane [Equation (1)]; the resulting thallium halide precipitates and reasonably pure materials are obtained after filtration and evaporation of the solvent.

$$MX_2 \cdot n\,H_2O \;+\; Tl(Tm) \xrightarrow{CH_2Cl_2} [M(Tm)X] \;+\; TlX\,(+\,nH_2O) \qquad (1)$$

The mercury(II) complexes were less amenable to this method of preparation and so a route using NaTm in acetone was utilised instead. Apparently, the formation of the thallium halide is inhibited in the presence of Hg^{II}. The complexes thus obtained are white to pale yellow powders. The ^1H NMR spectra all show a singlet at about $\delta = 3.5$ (CH_3) and a pair of either singlets or doublets at about $\delta = 6.9$ and $\delta = 7.2$, as would be expected. These resonances are slightly shifted to high field from the free ligand and are generally broadened, suggesting some chemical exchange is taking place. Relatively low solubilities in solvents other than DMSO have ruled out variable temperature NMR studies to investigate this phenomenon. Their formulations are further confirmed by low resolution mass spectrometry. The complexes generally show rather weak parent ion peaks corresponding to [M(Tm)X], indeed in one case the parent is not observed at all. However in all complexes very strong peaks due to $[M(Tm)]^+$ are observed, which suggests relatively facile halide loss but significant stability of the $[M(Tm)]^+$ fragment under these conditions.

The X-ray crystal structures of a series of complexes [M(Tm)X] (where M = Zn and X= Cl, Br, I; M = Cd, Hg and X= Br) have been obtained giving data which allows assessment of the effects of both changing anion and changing metal cation. For the zinc complexes X-ray crystallography reveals the expected pseudo-tetrahedral geometry (Figure 1) with the zinc, halide and B−H all lying on an approximate (or in the case of [Zn(Tm)Br], crystallographic) threefold axis (Figure 2). The S−Zn−S angles are a little less than expected (105−108°) while the S−Zn−X angles are commensurately larger (110−115°). The Zn−S distances are in the narrow range 2.35−2.38 Å, a little longer than the values in Parkin's [$Zn(Tm^{Mes})$(HOMe)] (2.32−2.34 Å)[13] — possibly reflecting the relative donor abilities of halide and methanol ligands — and show no discernible alteration with changing halide. There are no other structurally characterised monomeric zinc complexes with S_3X (X = halide) donor sets. The only examples of such donor sets are in the zinc thiolate clusters [$Zn_4(\mu$-$SPh)_6X_4$],[15] which have Zn−S distances in the range 2.33−2.38 Å. The Zn−X distances, as expected, closely mirror the change in halide-ion radius. We conclude that there is little influence of the halide on the overall structure. However, changing the metal cation to cadmium or mercury has a profound effect.

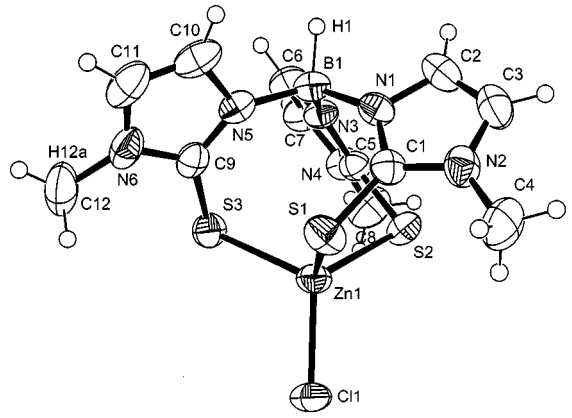


Figure 1. The X-ray Structure of [Zn(Tm)Cl]

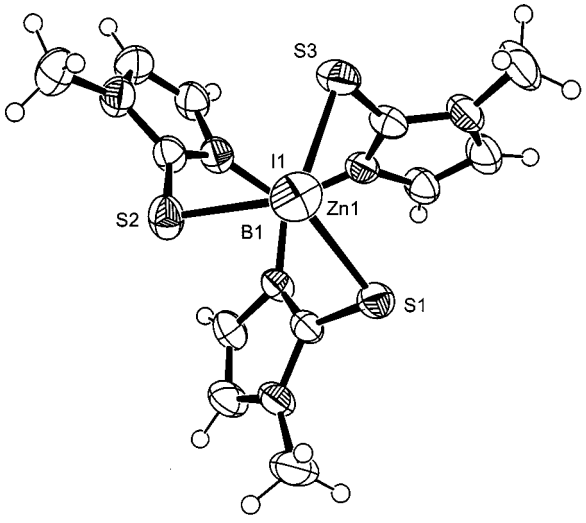

Figure 2. The X-ray Structure of [Zn(Tm)I], viewed down the approximate C_3 axis

The cadmium and mercury structures have remarkably similar structural parameters to one another, indeed it would appear that the compounds are crystallographically isomorphous. While the geometry is best described as

highly distorted tetrahedral (Figure 3), the Tm ligand remains symmetrically bound to the metal, with the S−M−S angles lying in the range 100−102°. This is somewhat less than in the corresponding zinc structures (vide supra) suggesting that the metal is displaced further from the ligand pocket. This is borne out by the increased B···M distances. The ligand further accommodates the larger cation by increasing the twist of the methimazole ring from the vertical (C_{3v}) arrangement as measured by the H−B−N−C torsion angles, with values of 36.7, 32.9 and 31.8° for the Zn structures and 40.1 and 40.3° for the Cd and Hg structures, respectively. This is further evidenced by the increase in the mean S···S nonbonded distances resulting from this twist, from 3.74, 3.76 and 3.77 Å in the Zn complexes to 3.97 and 3.98 Å in the Cd and Hg complexes, respectively. The metal and B−H unit are colinear, as in the zinc complexes. However, the halide no longer resides on this axis, but is markedly displaced. This results in a structure that tends towards a trigonal pyramid (Figure 4), with Br, S(1) and S(3) in the basal plane and S(2) in the apical position. The Br−M−S(1) and Br−M−S(3) angles are 120 and 125°, respectively. All the remaining angles are close to 100°.

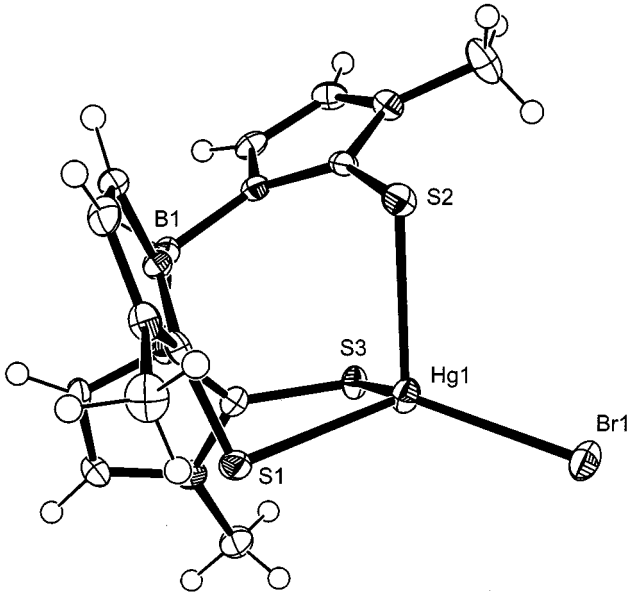

Figure 4. The X-ray Structure of [Hg(Tm)Br], emphasising the flattened trigonal pyramidal coordination geometry

Distorted structures are not uncommon in mercury chemistry, but are observed less frequently in cadmium chemistry. They are usually accompanied by significant lengthening of one or two metal-ligand bonds, tending towards either trigonal planar (e.g. [($Tp^{Me,Me}$)HgCN][16]) or linear (e.g. [{HOC(py)$_2$(*N*-MeIm)}HgMe][17]) coordination geometries. In this case, however, despite the distorted geometry, the variation of the metal-sulfur bond lengths (2.53−2.63 Å) is somewhat less than in other examples. We suppose that the strong affinity of mercury for sulfur donors (relative to the N-donors cited above) may in part explain this observation, although even in a complex with

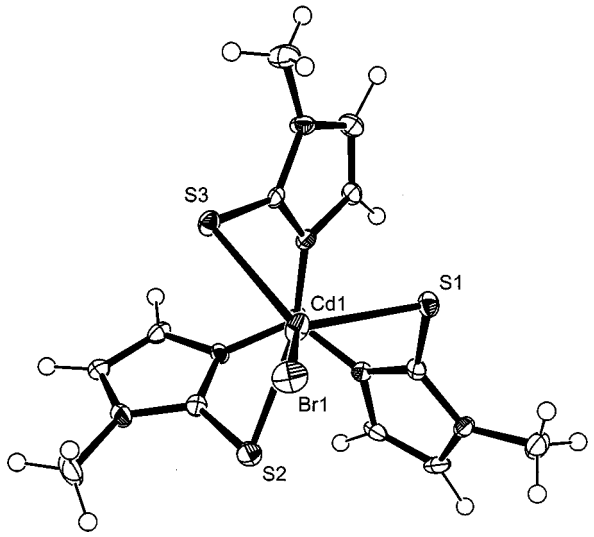

Figure 3. The X-ray Structure of [Cd(Tm)Br], showing the displacement of bromine from the H−B···M axis

an S_3X donor set, namely [{C(PSMe$_2$)$_2$(PSPh$_2$)}HgCl], the variation in bond lengths is 2.52−2.72 Å.[18]

Out of curiosity, the reaction of Hg_2Cl_2 with NaTm was also attempted. It was clear that disproportionation of the Hg_2^{2+} core had taken place by the immediate formation of a grey colouration and ultimately by the presence of small drops of metallic mercury. Analysis and NMR spectroscopy suggested that the product was not [Hg(Tm)Cl], and subsequently X-ray crystallography revealed the formation of the previously reported[19] dimer, [Hg(mt)(Hmt)(μ-mt)]$_2$ (Hmt = methimazole). We believe that the destruction of the Tm ligand is driven by the reducing nature of the B−H fragment, and its interaction with the redox active Hg_2^{2+} core.

What is clear from the crystallographic studies is that the Tm ligand binds strongly as a tridentate ligand to the metal centres, even towards metals that commonly exhibit lower coordination numbers. Because of the formation of eight-membered chelates in its metal complexes the ligand is able to show flexibility, adapting to the environment, with S−M−S angles able to vary from less than 90° in octahedral complexes such as [Tl(Tm)$_2$]$^+$ [7] and [Bi(Tm)$_2$]$^+$ [5] through to normal tetrahedral angles in the complexes reported here. While this results in versatility in terms of their ability to coordinate a range of metals, it also renders the ligands susceptible to interaction of the borohydride moiety with the metal and opens a potential route of decomposition, as observed in the reaction with Hg_2Cl_2.

Experimental Section

General: All reagents were obtained commercially and were used as received. NaTm and [Tl(Tm)] were prepared as described previously.[4] NMR spectra were recorded on a Bruker AMX400 spectrometer or a Jeol EX270 spectrometer. Electron Impact Mass Spectra were recorded on a JEOL JMS-AX505HA instrument.

[M(Tm)X] (M = Zn, Cd; X = Cl, Br, I). General Method: [Tl(Tm)] (0.200 g, 0.4 mmol) was suspended in acetone (30 mL) and a solution of the metal halide (0.4 mmol) dissolved in the minimum amount of acetone was slowly added. The mixture was stirred overnight at room temperature and the solid formed (TlX) was filtered off. The filtrate was taken to dryness and the resulting solid dried in vacuo. The crude product could be further purified by dissolving in the minimum amount of CH_2Cl_2 and cooling to −18 °C, whereupon colourless crystals were obtained. Crude yields were essentially quantitative, while yields of the recrystallised products were in the range 40−70%.

[Hg(Tm)X] (X = Cl, Br, I). General Method: The mercury(II) halide (2 mmol) and NaTm (2 mmol) were placed in a flask and acetone (25 cm^3) added. The mixture was stirred at room temperature for 20 h. The precipitate formed (NaX) was removed by filtration and the solvent removed in vacuo to yield crude product, which was recrystallised by slow diffusion of n-hexane into a saturated CH_2Cl_2 solution.

Reaction of Hg_2Cl_2 with NaTm: Hg_2Cl_2 (0.314 g, mmol) and NaTm (0.500 g, mmol) were placed in a flask with acetone (50 cm^3). The mixture was refluxed for 4 h and cooled. The solvent was removed on the rotary evaporator and the solid residue extracted with CH_2Cl_2 (3 × 20 cm^3). The solution was concentrated and the product precipitated as a white solid by addition of excess diethyl ether. Yield 0.5 g. Crystals for X-ray diffraction were obtained by slow evaporation of a CH_2Cl_2 solution.

Analytical and spectroscopic data for all the complexes are collected in Table 1.

X-ray Crystallography: Crystals of [Zn(Tm)Cl], [Zn(Tm)Br], [Zn(Tm)I], [Cd(Tm)Br] and [Hg(mt)(Hmt)(μ-mt)]$_2$ were obtained by slow evaporation of CH_2Cl_2 solutions at −18 °C, while crystals of the complex [Hg(Tm)Br] were obtained by diffusion of hexane into a solution of the complex in CH_2Cl_2. X-ray data were collected at 123 K on Rigaku AFC7S ([M(Tm)X], M = Zn; X= Cl, Br, I, M = Cd, X = Br) and Nonius Kappa-CCD ([Hg(Tm)Br]) diffractometers using graphite monochromated Mo-K_α radiation. The structures were solved by Patterson methods (SHELXS-86),[20] expanded by Fourier synthesis and refined by full-matrix least-squares refinement on F^2 with the exception of the Cd complex which was refined on F (SHELXL-97).[21] All calculations used the WinGX graphical interface.[22] Crystallographic data are collected in Table 2, selected bond lengths and angles in Table 3 and the structures shown in Figure 1−4.

COVER PICTURE

The cover picture shows the molecular structure of the first crystallographically characterized complex containing a silver–tin bond. The stabilization of divalent tin by the tripodal amido ligands allows the coordination of stannates(II) to highly oxidizing metal centres making them versatile "ligands" for a broad range of transition metals. Details are discussed in the Microreview by L. H. Gade on p. 1257 ff. We thank Prof. R. Welter (Strasbourg) for his help in producing the colour picture.

Tripodal Triamidometallates of the Heavy Group 14 Elements: Inorganic Cages with Remarkable "Ligand Properties"

Lutz H. Gade[a]

Keywords: Group 14 metals / Molecular cages / N ligands / Triamido metallates

Anionic main group metal donors with potentially interesting ligand properties are obtained if ate complexes of the heavy p-block metals are formed by coordination between tripodal amides and divalent group 14 metal centres. The limitations of this approach, due to the potential oxidation by the central transition metal atom, may in part be suppressed by the presence of electronegative substituents at the M^{II} centre, which makes the metallates less reducing. The considerable stability of the triamidostannates(II) towards Ag^{I} or $Au^{I–III}$ is testimony to the practical significance of this. The most characteristic structural consequence of the rigid amido cages is the well-defined orientation of the peripheral N-substituents, which gives rise to very large cone angles for the monodentate ligands in their transition metal complex derivatives. These angles considerably exceed those of "ordinary" metallate groups or of the isolobal neutral group 15 ligands, and so would be expected to favour low coordination numbers in transition metal complexes.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Molecular cages made up of main group metals, and also non-metals, have emerged as a basic structural principle in inorganic chemistry. They range from aggregates representing simple geometric bodies, such as the ubiquitous $\{M_4X_4\}$ cubes,[1] to very large, multi-shell "cluster" structures.[2]

Molecular fragments containing nitrogen and oxygen atoms, the components of amide, imide and alkoxide cages, have been studied in great detail. The field was comprehensively reviewed by Veith a decade ago,[3] and has reappeared in several more specialized overviews since.[4] In recent years, mixed-metal cage structures have attracted increased attention. Their rational synthesis (or at least an a posteriori rationalization of their assembly) remains a challenge and a current focus of research. In a perceptive analysis of the results of their work in this field, Wright et al. suggested that the p-block metals play the dominating role in dictating the structures of the mixed s-/p-block cage compounds.[5] This is thought to be the case since greater metal−ligand covalency of the metal−ligand interaction, and thus greater directionality of the bonding, results in more rigid metal coordination.

Several years ago, Veith and co-workers demonstrated that mixed metal alkoxide cages may be employed as (neutral) ligands in transition metal complexes.[6] Anionic main group metal donors with potentially interesting ligand properties are obtained if ate complexes of the heavy p-block metals are incorporated into such an array without "intra-cage" charge compensation. A conceptually simple

Lutz H. Gade is a full professor of chemistry at the Université Louis Pasteur, Strasbourg and the Head of the Laboratory of Organometallic Chemistry and Catalysis. After completing his undergraduate studies at the University of Bonn and the Technical University of Munich, he went to Cambridge to work for his Ph.D. with Jack Lewis. Having returned to Germany after completing his thesis in 1991, he joined the Chemistry Department at the University of Würzburg, where he finished his habilitation in 1996 and where he subsequently worked as a lecturer. In 1998 he moved to Strasbourg to take up his present position, and in summer 2000 he was elected a member of the Institut Universitaire de France. His research interests are in the fields of coordination chemistry, organometallic chemistry and catalysis.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

approach that employs this strategy is based on a polydentate ligand with podand topology coordinating to a low-valent p-block metal and thus forming the anionic keystone of a ligand cage. The tripodal amides, which we introduced to the coordination chemistry of the early transition metals in the early 1990s,[7] have proved to be ideally suited for the pursuit of this goal and offer straightforward means of ligand design based on the metal cages. The recent progress in this field is the topic of this overview.

Metallates of the Divalent Group 14 Metals

The structural chemistry of anionic trisubstituted metallate(II) compounds of group 14 elements has received considerable attention. It began to develop in the 1980s, thanks to significant improvements in crystal preparation techniques and low-temperature crystal data collection. Veith and co-workers characterized a whole series of lithium trialkoxygermanates(II), -stannates(II) and -plumbates(II) that displayed characteristic cage structures, such as [Li(μ-$C_4H_3O)_3Sn$] (**1**) and [{$Sn(OtBu)_3M$}$_2$] (**2**), shown in Figure 1.[8]

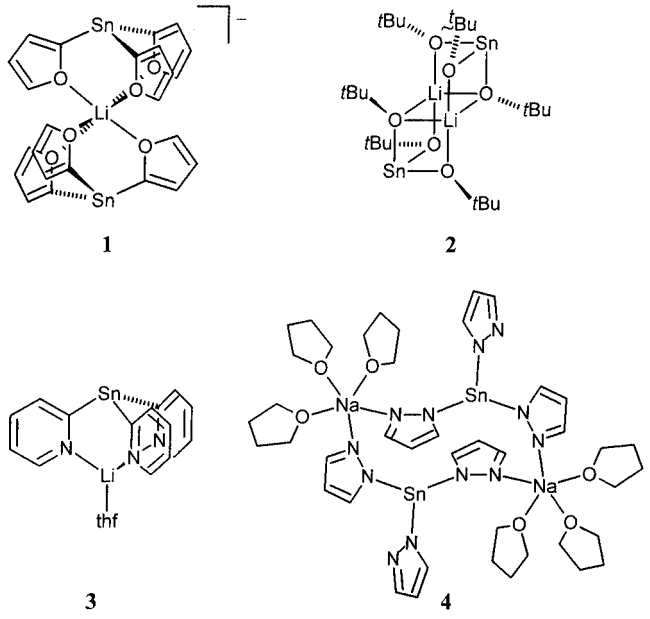

Figure 1. Four representative examples of cation−anion aggregation in stannates(II)

More recently, Wright et al. reported the structure of [Pb(2-py)$_3$Li(THF)] (**3**),[9] and Stalke and co-workers published the synthesis and X-ray diffraction study of several tris(pyrazolyl)germanates(II) and -stannates(II), such as [{$(Pz)_3SnNa(THF)_3(PzH)$}$_2$] (**4**), in which the heteroatom donor ligands at the p-block atom also serve as bridging units between the cations and metallate anions.[10]

A particularly interesting class of alkali metal group 14 and group 15 metallates are those containing a direct metal−metal contact between the cationic and the anionic metal centres, as found in the crystal structures of [$Ph_3Si-Li(THF)_3$] (**5**),[11] [Ph_3Sn-Li(pmdeta)] (**6**)[12] and [Ph_3Pb-Li(pmdeta)] (**7**)[13] (Figure 2).

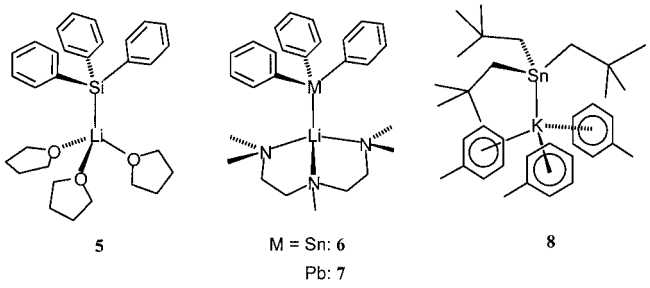

Figure 2. Metal−metal bonds between alkali metals and group 14 metals in trialkyl/aryl metallates(II)

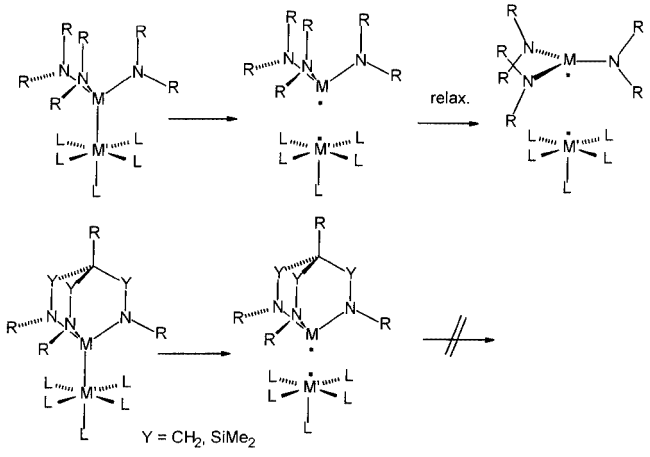
The presence of a direct K−Sn bond was established both by NMR spectroscopy (^{119}Sn-^{39}K coupling) and by X-ray diffraction for the complex [$(Me_3CCH_2)_3Sn-K(toluene)_3$] (**8**), isolated by Lappert and co-workers from the reaction between the distannane [$(Me_3CCH_2)_3Sn]_2$ and potassium metal.[14] The systematic synthesis and structural investigation of these heterodimetallic compounds has also been extended to the heavier group 15 elements.[15]

The Tripodal Triamido Metallate Cages as *Ligands*: Some Basic Conceptual Considerations

An important consequence of the integration of divalent group 14 metal centres into the rigid cage structures of the tripodal triamidometallates is the reinforced pyramidality of the M^{II} centre. Thus, structural relaxation and concomitant stabilization of the $M(NR_2)_3$ fragment upon homolytic cleavage of M−M′ (M′ = transition metal) bonds in derivatives of these compounds is inhibited (Scheme 1). As for the stabilization of the triamido transition metal fragment in the early−late heterodimetallic complexes previously studied by us, destabilization of the amido complex fragment therefore contributes to the thermodynamic stability

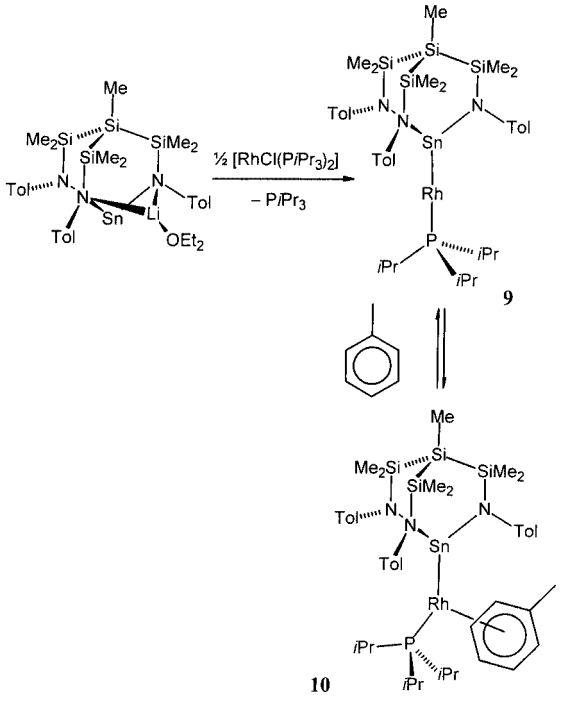


Scheme 1. Suppression of the structural relaxation of a triamido metal fragment upon homolytic cleavage of the M−M′ bond (M = group 14 metal, M′ = transition metal)

of the M−M′ complexes (or, viewed alternatively, to the stability of the complexation of M′ by the triamidometallate).[16]

The use of a divalent group 14 metallate as a ligand may in principle be limited by potential oxidation by the central transition metal atom. This may in part be suppressed by the presence of electronegative substituents at the M^{II} centre, which makes the metallates less reducing. Electronegative amido nitrogen atoms at the metal centre are therefore well suited for this purpose, and would be expected to match the established robustness of the halides and alkoxides. The considerable stability, discussed below, of the triamidostannates(II) studied in our group towards Ag^{I} or Au^{I-III} is testimony to the practical significance of this consideration.

The most characteristic structural consequence of the rigid amido cages is the well-defined orientation of the peripheral N-substituents, which gives rise to very large cone angles for the monodentate ligands in their transition metal complex derivatives. These angles considerably exceed those of "ordinary" metallate groups or of the isolobal neutral group 15 ligands, and thus should be expected to favour low coordination numbers in transition metal complexes. An illustrative example is the reaction product of $[Me\{SiMe_2N(p\text{Tol})\}_3SnLi(THF)_3]$ and the rhodium complex $[Rh_2Cl_2(P\textit{i}Pr_3)_4]$ (Scheme 2).[17]



Scheme 2. Synthesis of the Sn−Rh complex **10**, which is in equilibrium in solution with the 12-electron complex **9**

A low-temperature ^{31}P, ^{13}C and ^{1}H NMR study in $[D_8]$toluene indicated the existence of a free 12-electron dicoordinate species **9**, which appeared to be in rapid equilibrium with the 18-electron complex **10** bearing an η^6-toluene ligand. The molecular structure of the isolated, crystalline solid **10** was determined by an X-ray diffraction study (Figure 3).[17]

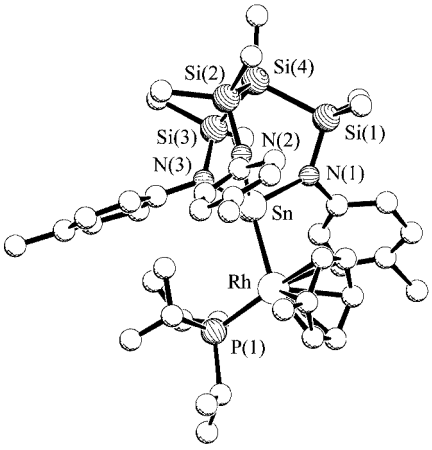


Figure 3. Molecular structure of $[Me\{SiMe_2N(p\text{Tol})\}_3Sn-Rh(P\textit{i}Pr_3)(\eta^6\text{-toluene})]$ (**10**)

The Structural Diversity of Lithium Triamidometallates Containing Tripodal Amido Ligands

As discussed above in more general terms, an interesting aspect of the structural chemistry of the lithium triamidometallates in solution and in the solid state is the type of interaction between the anionic cage and the counter-cation (in most cases solvated Li^+). Both solvent-separated salts and contact ions have been found. In the latter, the alkali metal ion is either directly bound to the group 14 metal (**I**) (Figure 4), in what is thought to be a primarily ionic metal−metal bonding interaction, or attached to the amido nitrogen atoms in a bridging coordination mode (**II**), thus breaking the overall threefold symmetry of the system.

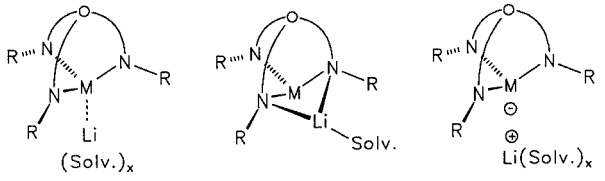

Figure 4. Three types of anion−cation association in lithium triamidometallates(II) of the group 14 elements

Treatment of the isolated lithium amides $[HC\{SiMe_2N(Li)(p\text{Tol})\}_3]$ and $[HC\{SiMe_2N(Li)[(S)\text{-1-(1-naphthyl)ethyl}]\}_3]$ with 1 mol-equiv. of $SnCl_2$ at 0 °C in diethyl ether/THF gave the lithium triamidostannates $[HC\{SiMe_2N(p\text{Tol})\}_3Sn-Li(THF)_3]$ (**11**)[18] and $[HC\{SiMe_2N[(S)\text{-1-(1-naphthyl)ethyl}]\}_3Sn-Li(THF)_3]$ (**12**), respectively.[12] Both compounds were characterized by single-

crystal X-ray structure analyses and found to possess direct Sn−Li bonds (**11**: 2.93 Å; **12**: 3.06 Å) (Figure 5).

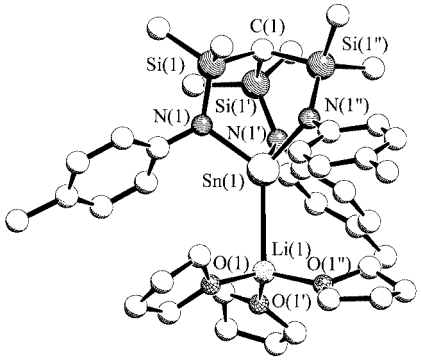

Figure 5. Molecular structure of $[HC\{SiMe_2N(p\text{Tol})\}_3SnLi(THF)_3]$ (**11**)

In the molecular structure of **11**, the Sn atom is displaced by 1.16(1) Å from the plane defined by the three amido nitrogen atoms, which have trigonal-planar geometry [$\Sigma\{<_N\} = 359.9(8)°$].[18] The average <(N−Sn−N′) of 93.3(4)° in the trigonal-monopyramidal SnN_3 unit indicates that Sn−N σ-bonding primarily involves the 4p orbitals of the tin atom, with the lone pair residing in a molecular orbital of essentially 4s character. However, it should be pointed out that the partially ionic nature of the Sn−N bonds may render orbital overlap and hybridization less important than in alkyl or aryl stannates. The absence of ionic conductivity of solutions of **11** in THF or diethyl ether indicates that the situation of a contact ion pair pertains even in a polar environment.

In view of the structure determined for **11**, it was of interest whether the presence of an additional stronger donor ligand would effect the disruption of the Sn−Li contact and produce an ion pair. The synthesis of compound **11** from the lithium amide and $SnCl_2$ in the presence of 2 mol-equiv. of pentamethyldiethylenetriamine (pmdeta) gave an anion−cation complex that was formulated as $[\{MeN(CH_2CH_2NMe_2)_2Li\}_2Cl][HC\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn]$ (**13**).[18,20] A single-crystal X-ray structure analysis of **13** revealed that the Li^+ counterion is indeed separated from the stannate anion $[HC(SiMe_2Np\text{Tol})_3Sn]^-$ through coordination by a pmdeta ligand and a ClLi(pmdeta) unit to generate the complex cation $[\{MeN(CH_2CH_2NMe_2)_2Li\}_2Cl]^+$ (Figure 6).

In the crystal, the cation rides in a "piggyback" fashion on the trisilylmethane side of the stannate anion, and there is no significant interaction with the tin atom.[20]

A molecular structure in which a contact ion pair adopts a type **II** arrangement, with the lithium ions attached to the amido nitrogen atoms in a bridging coordination mode, was found in the triamidoplumbate $[MeSi\{SiMe_2N(t\text{Bu})\}_3PbLi(THF)]$ (**14**).[18] In general, triamidoplumbates containing tripod-amido ligands were most conveniently synthesized by treatment of the lithium amides with plumbocene, which avoided the competing redox reactions found with use of $PbCl_2$ (Scheme 3).[21] An X-ray diffraction study of **14** revealed that the (tripod-amido)plumbate cage comprising the four silicon atoms of the trisilylsilane unit and the PbN_3 unit is significantly distorted, due to the coordination of the $(THF)Li^+$ "counterion" to two of the amido nitrogen atoms (Figure 7).

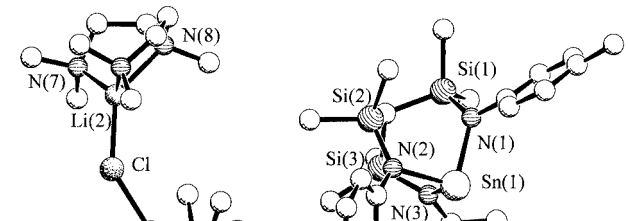

Figure 6. Representation of the molecular structure of $[\{MeN(CH_2CH_2NMe_2)_2Li\}_2Cl]$ $[HC\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn]$ (**13**), showing the relative cation−anion arrangement in the crystal

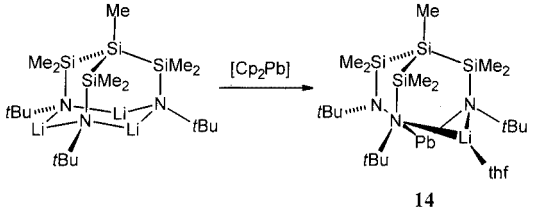

14

Scheme 3. Synthesis of the triamidoplumbate **14** by treatment of the lithium amide with plumbocene

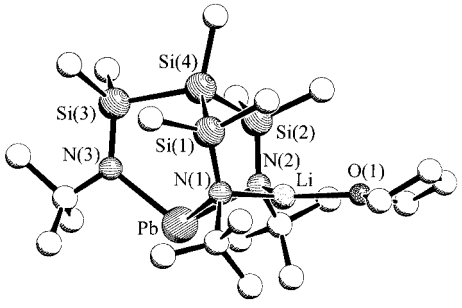

Figure 7. Molecular structure of the lithium triamidoplumbate $[MeSi\{SiMe_2N(t\text{Bu})\}_3PbLi(THF)]$ (**14**)

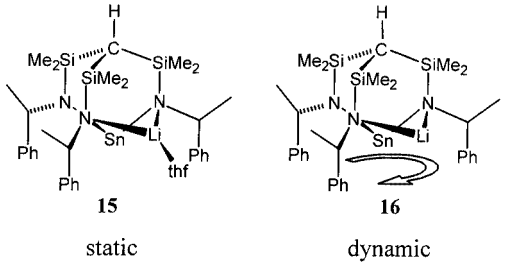
The molecule has idealized C_s symmetry, the virtual mirror plane being spanned by Si(4), Si(3), N(3), Pb(1), Li(1) and O(1). As a consequence of the binding of the (THF)Li group to the amido framework, the geometry of the two N-functions involved deviates from the trigonal planarity observed for the N(3) atom [$\Sigma\{<_{N(1)}\} = 346(2)°$, $\Sigma\{<_{N(2)}\} = 350(3)°$; however, $\Sigma\{<_{N(3)}\} = 359(3)°$]. Moreover, steric repulsion between the THF ligand and the N(1)- and N(2)-bonded *t*Bu groups forces the latter apart. On the other hand, the Li atom "ties" the two amido nitrogen atoms together to generate an N-donor atom arrangement that deviates from the otherwise more or less undistorted trigonal-monopyramidal arrangement of the N_3Pb unit

[<N(1)−Pb(1)−N(2) = 82.5(9)°, but <N(1)−Pb(1)−N(3) = 103(1)° and <N(2)−Pb(1)−N(3) = 109(1)°].

In the structure of **14**, the THF molecule coordinated to Li^+ is located between two of the peripheral N-substituents. This arrangement blocks potential cation mobility, which appears to require the absence of Li-bound co-ligands. We have been able to synthesize both the solvated (**15**) and the THF-free (**16**) lithium stannates of the C_3-chiral triamido cage $[HC\{SiMe_2N[(S)\text{-1-phenylethyl}]\}_3Sn]^-$ (Scheme 4), of which **15** was characterized by X-ray crystallography.[22]

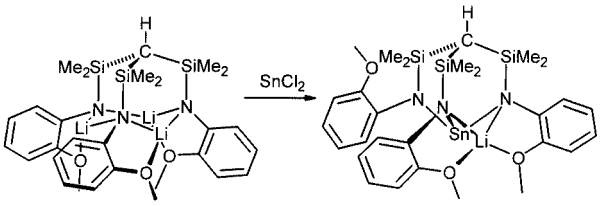


Scheme 4. "Locking" the cation mobility in a lithium triamidostannate by coordination of a co-ligand (THF)

While the signal patterns in the NMR spectra of **15** and **16** indicate closely related structures and are consistent with a retention in solution of the structural arrangement established for crystalline **15**, both compounds differ significantly with respect to dynamic behaviour in solution.[22] The coordinated THF ligand appears to "lock" the Li cation in the position between the two N atoms, thus conferring structural rigidity upon the molecules of **15** on the NMR timescale. On the other hand, the unsolvated compound **16** displays remarkable dynamic behaviour. As ^{1}H-EXSY studies have revealed, the Li atom appears to "rotate" around the N_3Sn unit, generating an effective threefold molecular symmetry at the fast exchange limit.[22,23] This intramolecular motion is reminiscent of the dynamic behaviour reported by Veith and co-workers for a tetraamidoindate, although it appears to take place much more rapidly in the latter case.[24]

The matter of which of the structural alternatives discussed above is observed in a given case was found to be largely unpredictable. It was therefore thought that the design of an amido tripod containing a specific binding site for the metal cation in the ligand periphery would yield "ion pairs" of predefined arrangement.

In an extension of our concept of the "active ligand periphery" in polydentate amides[25,26] containing additional donor functions for cation binding, we synthesised a tripod with peripheral 2-anisyl groups. The synthesis of the lithium stannate cage containing this ligand system (Scheme 5) did indeed give the expected aggregation pattern with intramolecular Li^+ solvation by two of the three *ortho*-anisyl groups, as confirmed by X-ray crystallography (Figure 8).[27]



Scheme 5. Synthesis of a triamidostannate possessing secondary donor function for intramolecular cation solvation

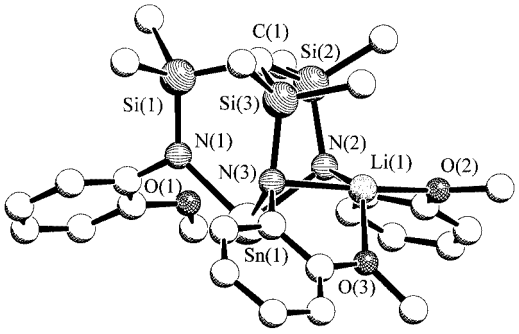


Figure 8. Intramolecular Li^+ solvation in the *ortho*-anisyl-substituted stannate $[HC\{SiMe_2N(2\text{-}MeOC_6H_4)\}_3SnLi]$

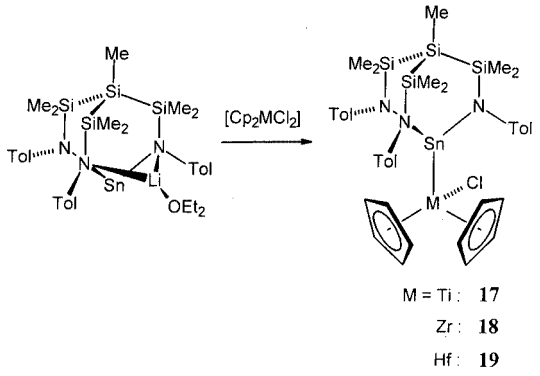
Triamidometallates Coordinated to Early Transition Metals

On going from the late to the early transition metals, the polarity and, concomitantly, the reactivity of the metal−metal bonds increase significantly.[28] Whereas group 4 M−Si compounds have found wide-ranging applications, such as in a variety of metal-mediated catalytic processes and in semiconductor growth,[29] their tin analogues remain extremely rare and thus poorly studied, despite numerous efforts to develop their chemistry.[30] A principal problem appears to be that many of the synthetic strategies employed for M−Sn bond formation do not work well when M is titanium, zirconium or hafnium.

A fundamental difficulty in group 4/group 14 metal−metal bond formation is the existence of energetically low-lying electron-transfer reaction pathways from the group 14 metal to the early transition metal. This problem is not unlike the situation in early−late heterodinuclear transition metal complexes, referred to above, in which metals from the two ends of the d-block are directly bonded to each other.[16]

With the aim of obtaining heterodinuclear complexes of greater stability than previously observed, the triamidostannate complex $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3SnLi(OEt_2)]$ was treated with the metallocene dichlorides $[Cp_2MCl_2]$ of all three titanium group metals.[31] Nucleophilic substitution of one of the chloro ligands in the metallocene dichlorides occurred cleanly in all three cases, yielding the corresponding dinuclear complexes as thermally stable solids (Scheme 6).



Scheme 6. Synthesis of the stable group 4/group 14 heterodimetallic complexes **17**–**19**

Single-crystal X-ray structure analyses of both **18** and **19** confirmed the molecular structures and established the presence of the group 4/group 14 metal–metal bonds (Figure 9).[31] The Zr–Sn bond length in compound **18** is, at 3.0231(2) Å, significantly longer than the sum of the covalent radii of the two metals as given by Pauling[32] (ca. 2.85 Å). However, it is in the same range as the Zr–Sn distances in $[Zr(CO)_5(SnMe_3)_2]^{2-}$ [3.011(3) Å] and $[Zr(CO)_4(dppe)SnMe_3]^-$ [3.061(2) Å] reported by Ellis and co-workers.[33] This observation is remarkable, since the latter compounds are low oxidation state zirconium complexes with high coordination numbers, and so should be expected to possess Zr–Sn bonds longer than those in **18**. It is quite likely that the length of the metal–metal bond in **18** is largely dictated by the repulsion of the ligand spheres of the two metal atoms.

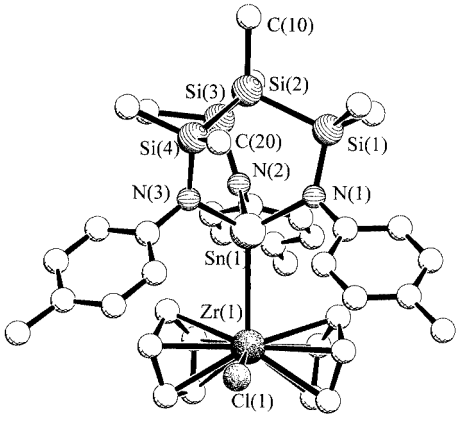


Figure 9. Molecular structure of the Zr–Sn heterodimetallic complex $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn–Zr(Cp)_2Cl]$ (**18**)

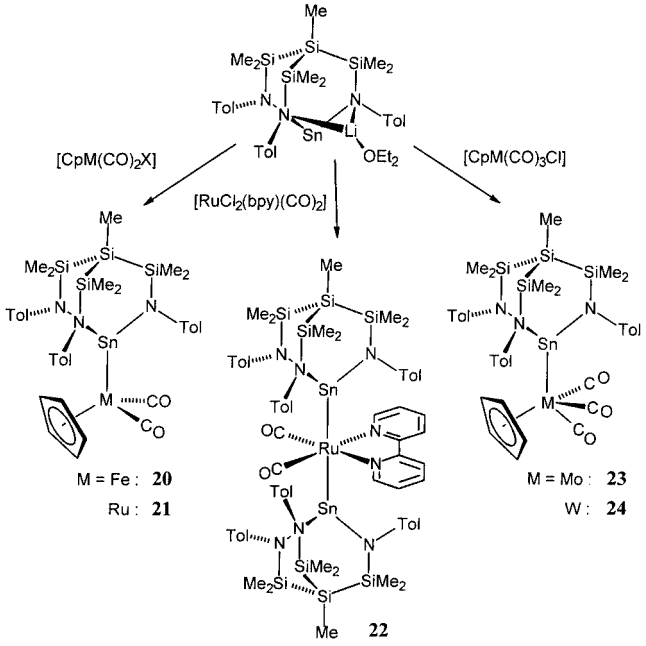
On comparing the molecular structure of complex **19** with that of **18**, it was interesting to note that all bonds to hafnium in **19** are significantly shorter than those to the zirconium centre in **18**. In particular, the Hf–Sn distance of 2.9956(3) Å is shortened by almost 0.03 Å relative to the analogous Zr–Sn bond and is very similar to the Hf–Sn bond lengths determined in $[(\eta^6\text{-}C_6H_5CH_3)_2Hf(SnMe_3)_2]$, reported by Green and co-workers.[34] There had been one previous study in which two analogous Zr–Sn and Hf–Sn complexes were structurally characterized by X-ray diffraction, and this revealed a very similar relationship between the metal–metal bond lengths in both complexes.[35]

In spite of the long Zr–Sn and Hf–Sn bonds, both compounds **18** and **19** are remarkably stable. No appreciable decomposition was observed when they were heated at reflux in toluene, and as solids they may be briefly handled in air, very probably due to the effective shielding of the highly polar metal–metal bond by the surrounding bulky ligand periphery.

Triamidometallates Coordinated to Late Transition Metals

The triamidostannate cages discussed in this review may readily be coupled with carbonyl halide complexes of the late transition elements, by the same approach as described for the group 4 derivatives in the previous section.[36] Several examples of such late transition metal tin complexes, all obtained by salt metathesis of a stannate with the respective chloro or bromo complexes, are summarized in Scheme 7.[37]



Scheme 7. Coordination of a tripodal triamidostannate to late transition metal complex fragments

In the molecular structure of **22**, depicted in Figure 10, the two $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn]^-$ ligands are bonded to the Ru centre in a nearly linear fashion [Sn(1)–Ru–Sn(2) 174.26(2)°] and are staggered with respect to their tolyl groups. The Ru–Sn bond lengths of 2.7085(5) and 2.7324(5) Å are slightly longer than the typical value for Ru–Sn bonds (2.55–2.69 Å)

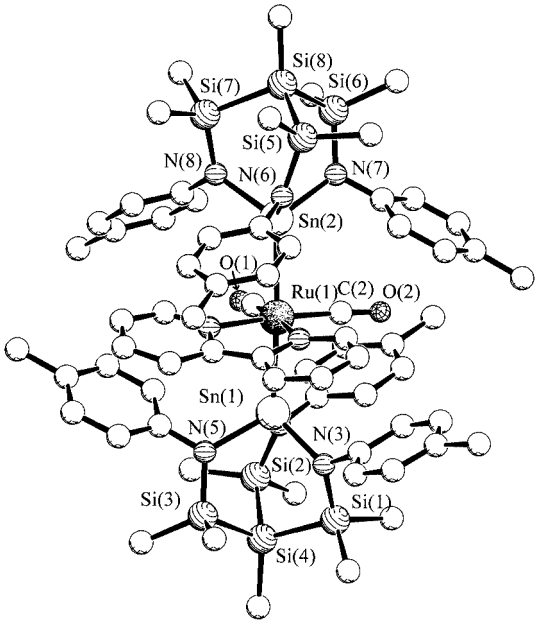


Figure 10. Molecular structure of the Sn−Ru−Sn complex **22**

.

Although the anionic complex $[(Ph_3Sn)Ni(CO)_3]^-$ was first reported by Kruck et al. in 1969, there had been no report of a crystal structure of an $[(R_3Sn)Ni(CO)_3]^-$ anion in the literature. Treatment of the chiral lithium stannate $[HC\{SiMe_2N[(S)\text{-1-phenylethyl}]\}_3Sn-Li(THF)]$ (**15**) with $[Ni(CO)_4]$ cleanly gave the Ni−Sn complex $[Li(THF)_4][HC\{SiMe_2N[(S)\text{-1-phenylethyl}]\}_3Sn-Ni(CO)_3]$ (**25**).[22] Crystals of **25** were found to be extremely air- and moisture-sensitive, and therefore had to be selected and mounted at ca. −80 °C. In the [2.2.2]bicyclooctane-derived cage, one of the bridgehead positions is occupied by the $Sn-Ni(CO)_3$ fragment (Figure 11).

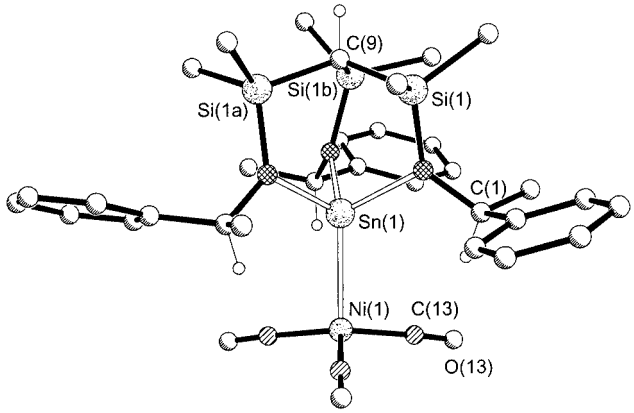

Figure 11. Molecular structure of the Ni−Sn complex $[HC\{SiMe_2N[(S)\text{-1-phenylethyl}]\}_3Sn-Ni(CO)_3]$ (**25**), containing a C_3-chiral triamidostannate

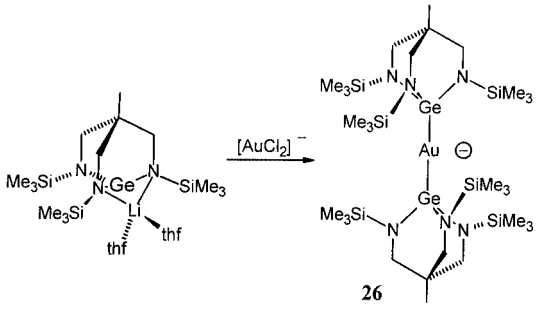
The Sn(1)−Ni(1) vector is aligned along the threefold crystallographic axis, imposing exact C_3 symmetry upon the anion. The Sn−Ni bond length of 2.492(2) Å is unexceptional; however, we note that the coordination of the Lewis acidic $Ni(CO)_3$ fragment to the Lewis basic stannate effects a significant shortening of the Sn−N distances [Sn(1)−N(1) 2.086(6) Å] in comparison to those in the lithium stannate **15** [average Sn−N 2.174(6) Å]. The stannate ligand is readily displaced from the nickel by better donors such as phosphanes and isocyanides.[22]

Triamidometallates Coordinated to the Coinage Metals: Copper, Silver and Gold(I, II and III) Complexes

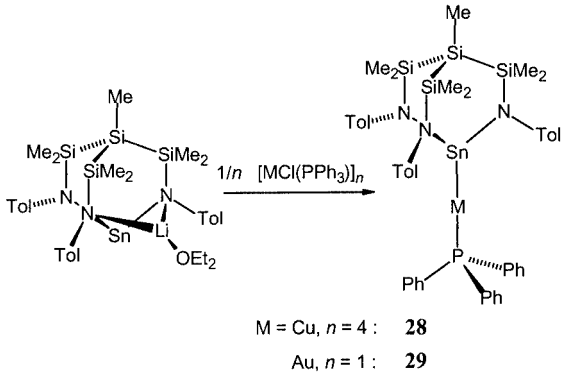
In contrast to the extensive investigations into the chemistry of organometallic complexes of the coinage metals, there have, until recently, been comparatively few compounds containing direct metal−metal bonds between copper, silver or gold and the heavier group 14 elements.[38]

We were able to provide the first crystallographically characterized example of a digermanylaurate (**26**) by treatment of the triamidogermanate(II) $[MeC(CH_2NSiMe_3)_3Ge-Li(THF)_2]$ with $[Ph_4P][AuBr_2]$, the corresponding Sn−Au−Sn analogue also being accessible by the same route (Scheme 8).[39]



Scheme 8. Synthesis of the first digermanylaurate **26**

Treatment of the stannate $[MeSi\{SiMe_2N(4-CH_3C_6H_4)\}_3SnLi(OEt_2)]$ (**27**) with 0.25 mol-equiv. of $[CuCl(PPh_3)]_4$ or 1 equiv. of $[AuCl(PPh_3)]$ in toluene at room temperature gave the corresponding Sn−Cu and Sn−Au complexes $[MeSi\{SiMe_2N(4-CH_3C_6H_4)\}_3Sn-Cu-$



Scheme 9. Synthesis of the coinage metal/tin compounds **28** and **29**

$(PPh_3)]$ (**28**)[37] and $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn-Au(PPh_3)]$ (**29**) (Scheme 9).[40] The formation of Sn−Cu and Sn−Au bonds in these complexes is supported by the observation of $^{117/119}Sn$ satellites in their ^{31}P NMR spectra. Neither compound apparently undergoes detectable redistribution reactions in solution.

The crystal structure of **29** confirms the conclusions drawn from the spectroscopic data. In its molecular structure (Figure 12), the triamidostannate cage is directly bonded to the Ph_3PAu unit [d(Au−Sn) = 2.5651(13) Å], the gold atom adopting an essentially linear geometry [<(Sn−Au−P(1) = 179.9(1)°], as expected for monovalent gold. This Sn−Au distance is slightly shorter than that found for $[Au_8(PPh_3)_7(SnCl_3)][SnCl_6]$ [2.625(3) Å],[41] and considerably shorter than those in the tricoordinate Au^I complex $[(PMe_2Ph)_2AuSnCl_3]$ [2.881(1) Å][42] and in the polynuclear compound $[Au_4(PPh_3)_4(\mu_2\text{-}SnCl_3)_2]$ [2.8150(7), 2.9725(8) Å], for which a weak Sn−Au interaction was proposed.[43]

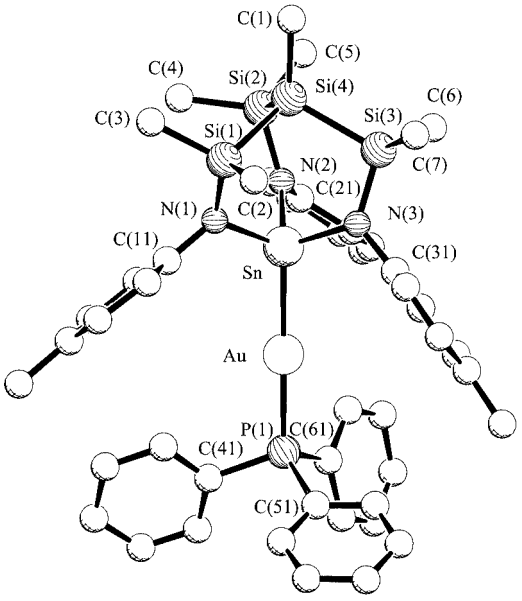


Figure 12. Molecular structure of $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn-Au(PPh_3)]$ (**29**)

The stannate **27** reacts with various other gold halide complexes by salt metathesis and formation of the metal−metal bond to afford the respective tin−gold heteronuclear compounds. By this approach, gold(I−III) complexes **30**−**34** have been obtained upon treatment of the stannate with $[PPN][AuCl_2]$, $[PPN][AuCl(R)]$ (R = C_6F_5, mesityl), $[Au_2(CH_2PPh_2CH_2)_2Cl_2]$ and $[PPN][AuCl(C_6F_5)_3]$, respectively (Scheme 10).[40]

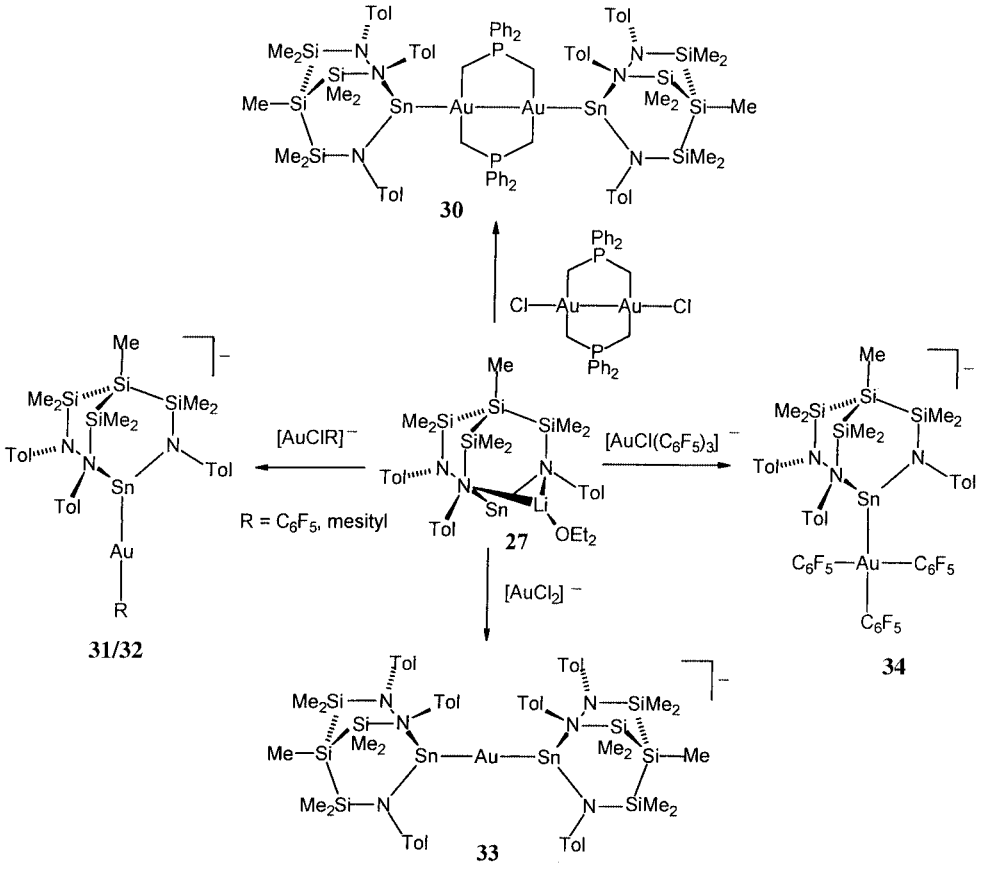
An X-ray diffraction study of the first example of an $Sn-Au^{II}$ complex **30** established the details of its molecular structure (Figure 13). The Sn−Au bond length is 2.6804(13) Å, and thus significantly longer than the Sn−Au distance in the gold(I) derivative $[MeSi\{Me_2SiN(p\text{Tol})\}_3SnAu(PPh_3)]$ (**29**) discussed above [2.5651(13) Å]. This may be a consequence of the steric repulsion between the periphery of the tripodal amido ligand and the bis(ylide) ligands coordinated to the Au_2 unit. The coordination geometry of the gold(II) centres is square-planar, as usually exhibited in gold(II) derivatives with gold−gold bonds. The $Au^{II}-Au^{II}$ distance is 2.7492(13) Å, one of the longest found in these type of gold(II) complexes, the only species with a longer Au−Au bond being $[\{(C_6F_5)Au(CH_2PPh_2CH_2)_2Au\}Au(C_6F_5)_2][Au(C_6F_5)_4]$ [2.755(1) Å].[44]

Ag−Sn heterobimetallic compounds are particularly rare, the only known molecular species containing an Ag−Sn bond prior to our studies being $[(Ph_3P)_3AgSnCl_3]$.[44] While this compound has been the object of several spectroscopic studies, there was no direct structural proof for an Sn−Ag bond. Since stannous chloride finds applications in photography as a reduction sensitizer for silver halide emulsions,[46] a more detailed investigation of such Ag^ISn^{II} systems was of general interest.

Upon treatment of **27** with 0.25 mol-equiv. of $[(Ph_3P)AgCl]_4$, the two Ag−Sn-bonded phosphane-containing products together with $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn-Ag(PPh_3)]$ (**35**) and $[MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn-Ag(PPh_3)_2]$ (**36**) were detected in solution, the latter being directly accessible by treatment of the stannate with $[Ag(PPh_3)_2][CF_3SO_3]$ (Scheme 11). The phosphane-free component **37** in this equilibrium mixture could be isolated by fractional crystallization. While the analytical data were consistent with a formulation of **37** as $[MeSi\{SiMe_2N(p\text{Tol})\}_3Sn-Ag]_n$, a single-crystal X-ray structure analysis established a dimeric structure corresponding to $[MeSi\{SiMe_2N(p\text{Tol})\}_3Sn-Ag]_2$ (Figure 14).[47]

The molecular structure of **37** is based on a centrosymmetric dimeric molecular unit featuring two Sn atoms, each coordinated by a tripod-triamido ligand. Each Sn atom links to an Ag atom through an Sn−Ag bond [d(Sn−Ag) = 2.6567(7) Å]. The two Ag centres in the complex are in close proximity; the d(Ag−Ag′) distance [= 2.6544(11) Å] is among the shortest ever observed in Ag^I aggregates and may indicate a significant $d^{10}-d^{10}$ attraction. In **37**, the ligand periphery plays an "active" role and facilitates the dimerization of the silver stannate units. These monomer units are linked by η^2-coordination of one tolyl group of each tripodal amido ligand to the silver atom of the opposite unit [d(Ag−C25′) = 2.604(5); d(Ag−C26′) = 2.374(4) Å], the asymmetry of the η^2-coordination in the complex being typical of arene−Ag^I interactions.[48]

The presence of a ligand redistribution equilibrium of the Ag−Sn complexes is a manifestation of the propensity of Ag^I species to attain coordination numbers higher than two. The displacement of the phosphane ligand may additionally be favoured by the possibility of "arene solvation" of the Ag centres. This study provided the first direct structural evidence for an Ag−Sn bond. More recently, however, Lappert and co-workers have reported another structurally characterized Ag−Sn heterodimetallic complex.[49]



Scheme 10. Synthesis of $Au^{I}-Sn$, $Au^{II}-Sn$ and $Au^{III}-Sn$ complexes

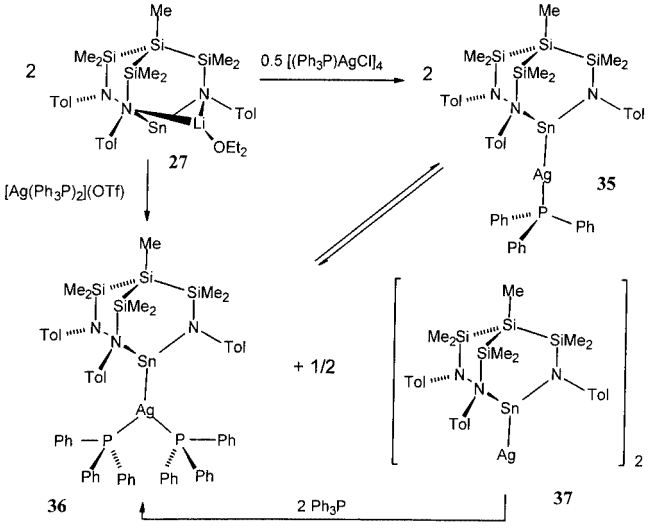

Scheme 11. Ag−Sn complexes **35−37**, which are in equilibrium in solution, upon treatment of the lithium stannate **27** with $[AgCl(PPh_3)]_4$

Group 12 Metal/Tin Complexes

Complexes containing bonds between group 12 metals and a group 14 element are versatile reagents in synthetic chemistry. The most prominent examples are cyclopropanation reactions with (α-halomethyl)mercury compounds,[50] the reductive replacement of mercury by hydrogen, the use of $Hg(SiMe_3)_2$ as a silylating reagent[51] and the photolytic cleavage of $Hg(SiMe_3)_2$ to yield silyl radicals.[52] Although a few examples of structurally characterized complexes with the lighter group 14 metals (Si, Ge)[53] have been reported, and compounds such as $R_3Sn-Hg-SnR_3$ have been spectroscopically studied in detail,[54] there was, at the time we began our studies, no direct structural characterization of

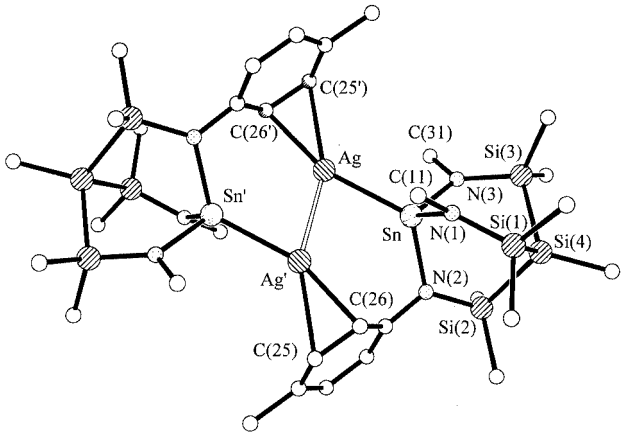

Figure 14. Molecular structure of the first crystallographically characterized Ag−Sn complex; the two molecular units are linked by attractive Ag−arene and Ag−Ag interactions; the peripheral tolyl groups not coordinated to Ag are omitted in this representation for clarity

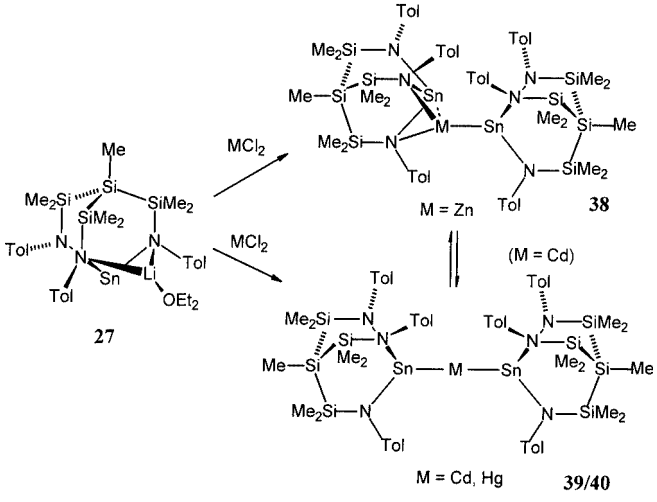
either Sn−Hg or Sn−Cd bonds and only a single example of a crystallographically authenticated Sn−Zn complex[55] to be found in the literature.

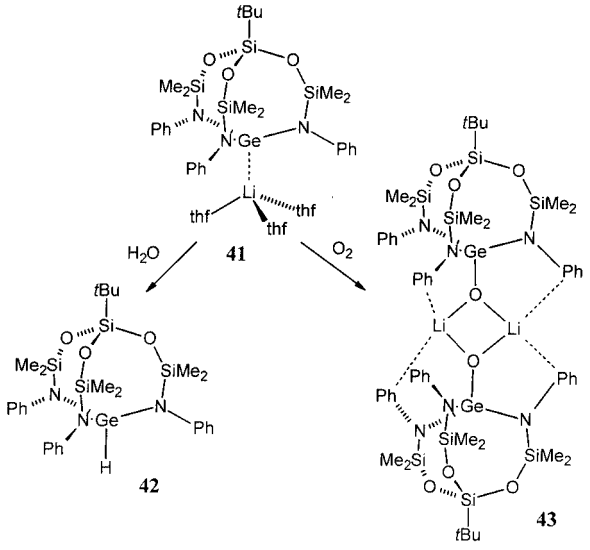
Treatment of the lithium stannate **27** with MCl_2 (M = Zn, Cd, Hg) cleanly gave the corresponding Sn−M−Sn complexes **38**−**40** (Scheme 12).[56] Whereas the linear Sn−Hg−Sn complex is stable in solution, the cadmium compound **39** − while also linear in the crystal − is in equilibrium with a second, less symmetrical isomer, as became evident from NMR studies carried out in solution. This second structural arrangement is the most stable form of the Sn−Zn−Sn complex **38** and is also found in its crystal structure.[56] Here the tendency of the "dication" Zn^{2+} to adopt coordination numbers greater than two and ligands containing hard donor atoms becomes readily apparent.



Scheme 12

Beyond the Rigid [2.2.2]Bicyclooctane Cage

Recent work from Veith's group indicates that the principles outlined in this overview might possibly be extendable to systems with less rigid structures. Those workers synthesized the tripodal amido ligand $[t\text{BuSi(OSiMe}_2\text{NPh)}_3]^{3-}$,[57] which was coordinated to divalent germanium, to give a lithium triamidogermanate with a direct Ge−Li bond $[t\text{BuSi(OSiMe}_2\text{NPh)}_3\text{Ge−Li(THF)}_3]$ (**41**). This compound was in turn hydrolysed to give the corresponding Ge−H germane **42** and oxidized to yield the lithium oxogermanate(IV) **43** (Scheme 13).[58]



Scheme 13

The different orientation of the N-donor functions imposed by the expanded ligand framework allows for structural motifs somewhat different to those that we found for the systems discussed above. It will be interesting to learn more about the "ligand" properties of these systems.

Conclusions and Outlook

The combination of thermodynamic stabilization of the triamidometallates by their integration into a rigid molecular cage structure, along with the well-defined orientation and high variability of the peripheral N-substituents, has established tripodal triamidometallates as a versatile new class of ligands in the coordination chemistry of the transition metals. The electronegative N-substituents at the divalent metal atoms render them less oxidizable than would be expected for alkyl- or aryl-substituted derivatives.

The first results of our attempts to stabilize low-coordinate late transition metal complexes with catalytically relevant metals such as rhodium or palladium suggests that the monoanionic group 14 metallates, apart from being objects of study in their own right, may find applications in the development of novel homogeneous catalysts.

Acknowledgments

I thank my dedicated co-workers for their contributions to this chemistry. The field was opened up for us by Konrad Hellmann and then further developed by Bernd Findeis. Uta Kauper and Claudia Bott also provided significant input at this early stage.

Most recently, Matthias Lutz, who has been delocalized between our laboratory and the University of Joesuu in Finland, has made important advances. The fruitful collaboration with Tapani Pakkanen (Joensuu), Mary McPartlin (London), Dietmar Stalke (Würzburg) and Mariano Laguna (Zaragoza) has been a significant factor in developing the research programme. The author acknowledges funding by the Deutsche Forschungsgemeinschaft, the European Commission (TMR network MECATSYN) and the CNRS (France).

cine and *tele* Nucleophilic Substitutions in (η^6-Arene)tricarbonylchromium and Tricarbonyl(η^5-cyclohexadienyl)manganese Complexes

Françoise Rose-Munch*[a] and Eric Rose*[a]

Keywords: Arene ligands / Carbonyl ligands / Chromium / Manganese / Nucleophilic substitution

Addition of a nucleophile to an (η^6-arene)tricarbonylchromium or a tricarbonyl(η^5-cyclohexadienyl)manganese complex substituted with a leaving group X (X = F, Cl, OMe, OPh, NR_2) affords (after treatment with acid) new complexes with the same η^6 or η^5 hapticity. The overall reaction involves addition of the nucleophile *ortho*, *meta*, or *para* with respect to the leaving group and HX elimination.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

I. Introduction

Coordination of a transition metal atom to the π-system of an arene **1** and a cyclohexadienyl ring **3** activates the ring towards addition of nucleophiles to give (η^5-cyclohexadienyl)- and (η^4-cyclohexadiene)metal complexes **2** and **4**, respectively (Scheme 1). The (η^6-arene)tricarbonylchromium complexes **1** [M = $Cr(CO)_3$] undergo a number of very useful reactions, and have found significant applications in organic and organometallic syntheses.[1−4] Moreover, their preparation is very easy and they are usually air-stable, crystalline solids and, furthermore, the free arene may readily be released from complexation by mild oxidation of the metal atom. The neutral (η^5-cyclohexadienyl)manganese complexes **3** [M = $Mn(CO)_3$] are beginning to receive more and more attention because they are easily handled in nonpolar solvents and so may be purified very conveniently by silica gel chromatography. They are also easily obtained from the corresponding, highly electrophilic, cationic manganese complexes **1** [M = $Mn^+(CO)_3$] by addition of a wide range of nucleophiles. It has been shown that these neutral manganese complexes **3** display reactivity similar to some extent to that of the (η^6-arene)chromium complexes; thus *cine* and *tele* nucleophilic substitutions and − recently − Pd-mediated reactions[5] have been reported to occur under mild conditions.

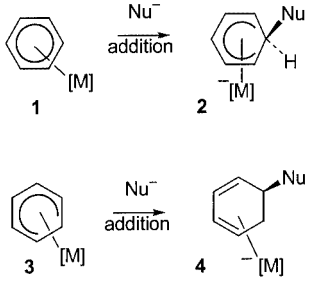
Françoise Rose-Munch was born in Metz, France. She entered the CNRS in 1975 and received her "Doctorat d'Etat" in 1976 from the University Pierre et Marie Curie, Paris, working under the supervision of Prof. Jacques Levisalles. After a postdoctoral period in 1976 and 1977 at the University of Stanford, California, USA with Prof. Jim Collman, she returned to Paris and was promoted to "Directrice de Recherche" in 1992. Her research interests concern the organometallic chemistry of Pd, Fe, Cr, and Mn complexes, nucleophilic substitutions in (arene)metal complexes, and their application in nonlinear optics.

Eric Rose was born in Nancy, France. He entered the CNRS in 1970 and received his "Doctorat d'Etat" in 1975 from the University Pierre et Marie Curie, Paris, working under the supervision of Prof. Jacques Levisalles. After a postdoctoral period in 1976 and 1977 at the University of Stanford, California, USA, with Prof. Jim Collman, he then moved back to Paris and was promoted to "Directeur de Recherche" in 1985. His research interests focus on the preparation of models of hemoproteins (Mb, Hb, cyt P450) and of new chiral porphyrins as catalysts for the epoxidation of terminal olefins, as well as nucleophilic substitutions in (arene)metal complexes.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.



Scheme 1

In this review we focus on recent work investigating nucleophilic substitutions on (η^6-ligand)chromium complexes and (η^5-ligand)manganese complexes. After a brief description of the preparation of these complexes (Cr, Mn), some general reactivity patterns mostly related to the nucleophilic substitutions of (arene)$Cr(CO)_3$ are outlined. Later sections concern *cine* and *tele* nucleophilic substitution in chromium and manganese complexes, with up-to-date examples from current literature.

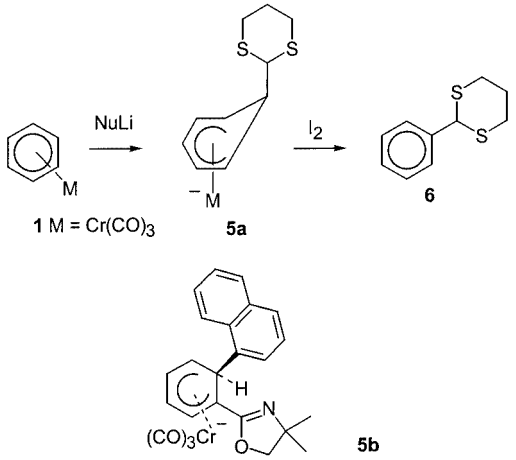
II. Complexation Methods

(Arene)tricarbonylchromium complexes[6] are usually prepared in good yields by heating the free arene with $Cr(CO)_6$ in a high-boiling solvent. The most popular method, described by Mahaffy and Pauson, uses a mixture of di-*n*-butyl ether and THF in a 9:1 ratio.[6c] These complexes are usually yellow, but can be orange or even dark red if the arene is conjugated to an aldehyde, a ketone, or a withdrawing group. They may also be prepared by use of $Cr(CO)_3L_3$,[6b,6e] where L is a two-electron ligand (L = NH_3, CH_3CN, pyridine) or L_3 = naphthalene.[6d] These complexes are decoordinated easily under mild conditions by treatment with I_2, CAN, CO, PPh_3, or Py,[6d] or simply by exposure to air or light.[1c−1e] (Arene)tricarbonylmanganese complexes can be prepared in good yield by treatment of the free arene with $BrMn(CO)_5$ [7a−7c] and $AgBF_4$ in CH_2Cl_2.[7d] Similarly, arene complexes are accessible by treatment of the arene with $Mn(CO)_5ClO_4$, $(acetone)_3Mn(CO)_3^+$ in CH_2Cl_2,[7e] $BrMn(CO)_5$ in the presence of $AlCl_3$,[7f] or $Mn_2(CO)_{10}$, or by transferring $Mn(CO)_3^+$ from cationic (polyarene)$Mn(CO)_3^+$ complexes.[7b,7c] A recent preparation involves a two-step methodology, starting from (η^5-1-halocyclohexadienyl)-$Mn(CO)_3^+$ and involving a Pd-catalyzed carbonylation followed by an easy η^5/η^6 rearomatization with Ph_3CBF_4. This gives a route to the previously unknown (η^6-RCO-arene)$Mn(CO)_3^+$ derivatives (RCO = ester, ketone, amide).[5a]

III. General Reactivity Patterns of (η^6-Arene)tricarbonylchromium Complexes

(Arene)tricarbonylchromium complexes are known to have unprecedented reactivities. It is now well established that η^6-coordinated arenes are susceptible to many manipulations thanks to the electron-withdrawing properties of the $Cr(CO)_3$ entity, which have been compared to the electron removal of a nitro group of nitrobenzene.[1c] It has been reported by Semmelhack et al.[8b] and by Card and Trahanowsky[8c] that carbanion addition occurs under very mild conditions.[8] It has been shown that benzylic and, in certain cases, homobenzylic carbanions are easily formed by deprotonation,[1,9] that benzylic carbocations are stabilized,[1d,9b,10a−10h] and recently that benzylic radicals are interesting intermediates.[11] The $Cr(CO)_3$ residue is also known to play a "stereodirecting" effect in reactions occurring at the periphery of the ring.[1c] The ring hydrogen atoms have increased acidity and are easily deprotonated with organolithium reagents.[1d,10a] In the context of this microreview, we focus, as mentioned, only on the nucleophilic addition reactions on the ring. Thus, before description of *cine* and *tele* S_N reactions, some general information on the reactivity of addition of a nucleophile to an (arene)$Cr(CO)_3$ complex is presented.

2-Lithio-1,3-dithiane reacts with (benzene)tricarbonylchromium [**1**, M = $Cr(CO)_3$] to give an anionic η^5-cyclohexadienyl complex **5a** (Scheme 2). This air-sensitive intermediate can be observed spectroscopically and has been characterized by X-ray diffraction analysis by Semmelhack et al.[8a] Another study of a similar η^5-structure (**5b**) has recently been reported.[8a] Oxidation of **5a** at −78 °C with at least 2.5 mol-equiv. of I_2 gives the substituted arene **6**, together with HI, Cr^{III} and CO.



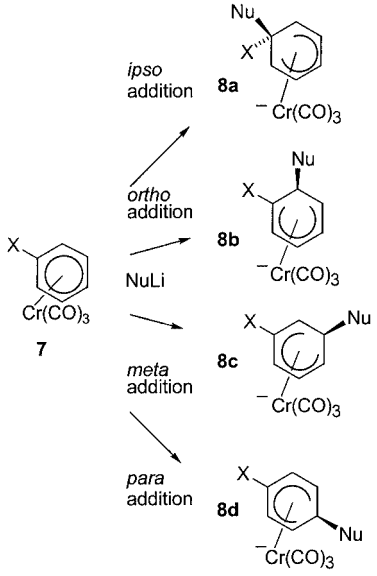
Scheme 2

This reaction has been generalized to other nucleophiles. Table 1 provides a representative sample of the carbanions tested.[8b,8c,12] The regioselectivity of carbon nucleophile addition to a substituted complex **7** is of interest because there are four possible ways to functionalize the ring. The nucleophile can react at the *ipso* carbon atom, bearing the X group, or at the positions *ortho*, *meta*, or *para* to the X group, to yield anionic intermediates **8a**, **8b**, **8c**, or **8d** (Scheme 3).

Table 1. Representative sample of carbanions tested with benzene tricarbonyl chromium

Unreactive carbanions	Successful carbanions	Other reaction[a]
	$LiCH_2CO_2tBu$[b]	
$LiCH_2CO_2tBu$	$LiCH_2CN$[b]	*n*BuLi
MeMgBr	$LiCH_2SPh$[b]	MeLi
Me_2CuLi	2-Li-1,3-dithiane[b]	*s*BuLi
	LiCH=CHR[b]	
	LiPh[b]	
	$LiCMe_3$ [c]	

[a] Metallation of the ring occurs. [b] Ref.[8b] [c] First addition of a carbanion to a (non-halogenated arene)$Cr(CO)_3$ unit.[8c]



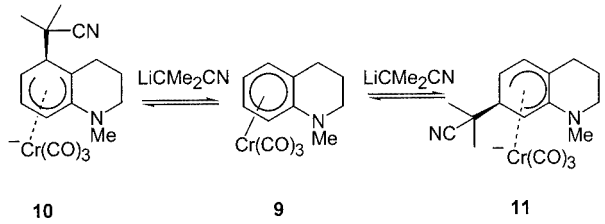
Scheme 3

Table 2. Regioselectivity of the addition of a carbon nucleophile to $C_6H_5XCr(CO)_3$, [8b]

Entry	X	LiNu	*m*/*p* ratio	Yield (%)
1	OMe	$LiCMe_2CN$	3:97:0	93
2	OMe	$LiCMe_2CO_2tBu$	0:100:0	76
3	NMe_2	$LiCMe_2CN$	1:99:0:	92
4	Me	$LiCMe_2CN$	1:97:2	95
5	Me	$LiCMe_2CO_2tBu$	3:97:0	96
6	Cl	$LiCMe_2CO_2tBu$	5:95:0	84
7	Cl	$LiCMe_2CN$	10:89:1	84
8	Me	$LiCH_2CN$	35:63:2	88
9	Cl	$LiCH_2CO_2tBu$	28:72:0	89

Addition of these carbanions can be reversible, but it is not so simple to know whether the addition occurs under kinetic or thermodynamic control.[12,13] In fact, the difference between the kinetic and thermodynamic selectivity is small in most cases, even if some exceptions are known. Thus, it is well precedented that arenes substituted with a donor substituent (**7**, X = OR, NR_2, Scheme 3) are attacked by the nucleophile at a *meta* position (Table 2, Entries 1, 3). The selectivity is also excellent with toluene or chlorobenzene complex in the case of tertiary stabilized carbanions (Table 2, Entries 4−7), but is not so high with primary carbanions (Table 2, Entries 8, 9).

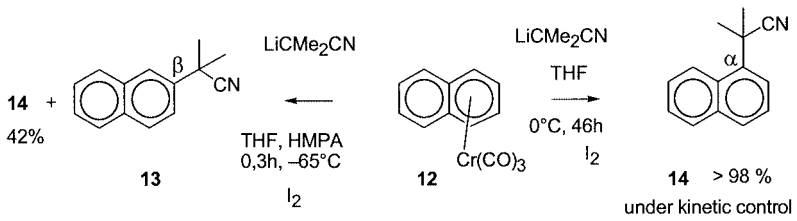
Ullenius et al. presented an interesting example in which the kinetic and the thermodynamic products are not the same, in the particular case of tricarbonyl(*N*-methyltetrahydroquinoline)chromium (**9**, Scheme 4).[13c] Indeed, the ratio of **11/10** changes from 2:1 at −78 °C after 1 min reaction time to 96:4 after 8.6 h at −78 °C, changes being observed with time, temperature, and solvent (THF or THF and 4 equiv. HMPA).



Scheme 4

Kündig et al. also reported interesting results in the case of the tricarbonyl(naphthalene)chromium complex **12**. On addition of $LiCMe_2CN$, a mixture of C_α and C_β complexes **14** and **13** was obtained in the ratio 42:58. Equilibration was avoided because a mixture of THF and HMPA was used. In THF, however, the only product was the α-substituted naphthalene **14** (Scheme 5).[13a] The same study has been undertaken with 1,4-dimethoxynaphthalene, the authors elegantly showing that the rate of equilibration could be slowed down by a factor of 50.000 by an appropriate choice of solvent mixture: THF, THF/HMPT (3:1).[13a] Replacement of lithium with the potassium counterion can slow the reaction down by a factor of 500.

The selectivity of the addition of a carbanion in polar solvents has been discussed in terms of charge control and orbital control. Thus, analysis of orbital control has been proposed by determination of the interaction of the frontier molecular orbitals [HOMO for the nucleophile and LUMO for the (arene)tricarbonylchromium complex].[12,13b] This picture does not explain the differences in selectivity between toluene and anisole complexes, because the LUMOs of these two arenes show the same pattern. Thus, charge control could be very important. This is the reason why the conformation of the complex should be considered. Indeed, in the case of the anisole complex, for example, it is well precedented that the methoxy group is eclipsed by a chromium−carbonyl bond. It is also well known that, in the case of the free anisole, the carbon atom bearing the OMe group is more electrophilic. There is therefore a synergic effect between the role of the methoxy group and that of the conformation of the $Cr(CO)_3$ entity. In solution, in fact, the percentage of the conformer eclipsing the methoxy group of (anisole)tricarbonylchromium should be higher than that of the conformer eclipsing the methyl group of (toluene)tricarbonylchromium. Thus, it might be predicted



Scheme 5

that *meta* selectivity should be better with anisole than with toluene. The percentage of the major conformer takes into account the nature of the substituents attached to the arene ring. Indeed, it has been reported that in solution a substituted arene complex can be considered to be in equilibrium between two conformations: the *syn*-eclipsed conformation SE and the *anti*-eclipsed conformation AE (Figure 1).[3a,14] Thus, if D is an electron donor substituent, the major conformer is the SE one, and if X is an electron-withdrawing group, the major conformer is AE.

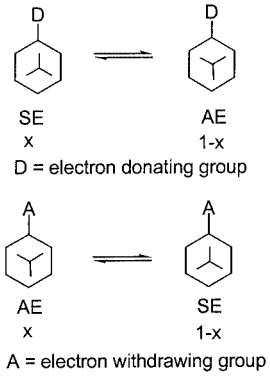


Figure 1. Conformation of the $Cr(CO)_3$ tripod

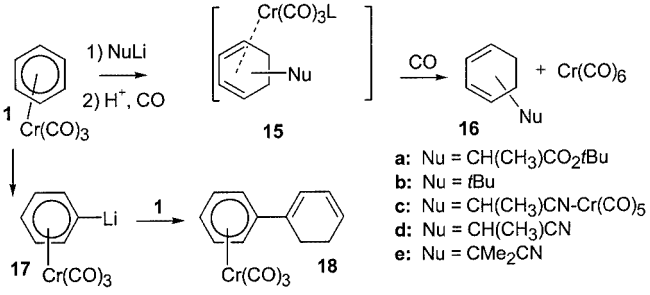
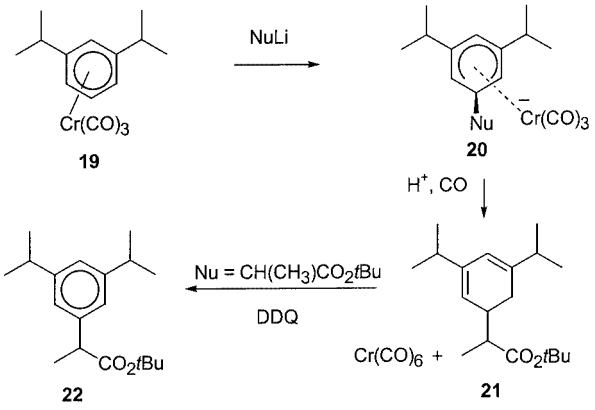
Addition of different nucleophiles to (benzene)tricarbonylchromium under carbon monoxide (the reaction medium being treated with CF_3CO_2H at −78 °C) has also been reported to give firstly the η^4 complexes **15a** and then the free substituted cyclohexadienes **16a** in 83% yield and $Cr(CO)_6$ in 75% yield [**16b** in 72% yield and $Cr(CO)_6$ in 78% yield] (Scheme 6). With the propionitrile carbanion, under CO, the cyclohexadiene **16c** is recovered and a 30 atm pressure of CO is necessary to obtain the decoordinated cyclohexadiene **16d** in 85% yield and $Cr(CO)_6$ in 85% yield.[15] Determination of the proportion of the cyclohexadienes **16e** (Nu = CMe_2CN) showed that the major isomer is the 1-substituted 1,3-cyclohexadiene (78%). The 2- and 5-sustituted 1,3-cyclohexadienes are obtained in 9 and 13% yields, respectively (Nu = CMe_2CN). A minor complex $[C_6H_5Cr(CO)_3(C_6H_7)]$ has been isolated as a single isomer; it is (1-η^6-phenyl)$Cr(CO)_3$(1,3-cyclohexadiene) (**18**), the formation of which can easily be interpreted in terms of addition of (phenyllithium)$Cr(CO)_3$ (**17**) to (benzene)$Cr(CO)_3$, followed by acid treatment and decoordination of the $Cr(CO)_3$ unit attached to the cyclohexadiene.



Scheme 6

Addition of the nucleophile to tricarbonyl(*meta*-diisopropylbenzene)chromium (**19**) occurs *meta* with respect to the isopropyl groups and, on treatment of the anionic complex **20** with acid under CO, the cyclohexadienes **21** are obtained in 83% yield, together with $Cr(CO)_6$ in 78% yield. The product can be aromatized by treatment with DDQ, giving the free 1,3,5-trisubstituted arene **22** (Scheme 7).[15]



Scheme 7

An examination of the regioselectivity of the addition of a stabilized carbanion LiCHMeCN to a tricarbonyl(spiroindane)chromium complex **23**, giving complex **24** after I_2 oxidation, is interesting. We observed an 81% selectivity at the C-5 carbon atom (Scheme 8).[3c] In the solid state, the C-5 carbon atom is eclipsed by a chromium−carbon bond, and in solution the conformer with the major population (x = 72%) is the one eclipsing the C-5 carbon atom (Figure 2). Thus, the $Cr(CO)_3$ unit adopts a preferred conformation for steric reasons. The regioselectivity of the addition of $LiCH(CH_3)CN$ is the same at −78 °C and at 0

°C, both with THF and with a mixture of THF and HMPA, and involves the eclipsed C-5 carbon atom of the major conformer. This is the conclusion that we have reached in many examples using a stabilized carbanion at low temperature.

Scheme 8

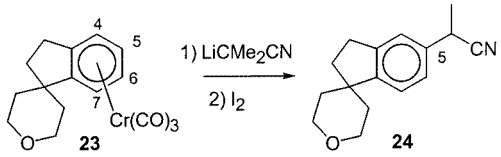


Figure 2. Population of the major conformer

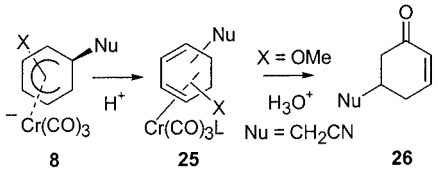
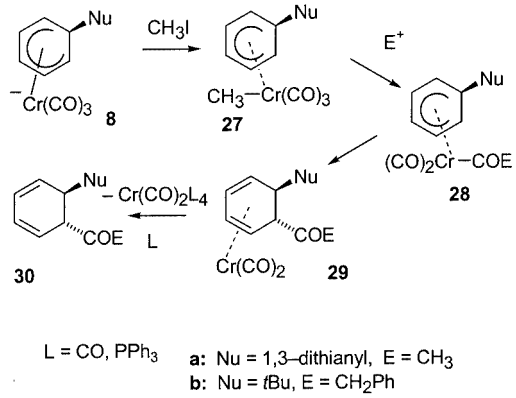
In summary, the regioselectivity of the nucleophilic addition under kinetic control can be explained in terms of charge control and (or) orbital control. The substituents on the arene and the conformation of the $Cr(CO)_3$ tripod play important roles. Under thermodynamic control, the equilibrium can be interpreted in terms of steric and electronic interactions in the intermediate anions, such as **8b**−**d** (Scheme 3).

The anionic η^5-cyclohexadienyl intermediate **8**, obtained by addition of a carbon nucleophile to an arene complex, has been treated with electrophiles. Protonation, for example, occurs at low temperature, giving the η^4-coordinated cyclohexadienes **25** (Scheme 9), with L being (for example) a THF molecule in order to respect the 18-electron rule.[16b] In the case of anisole, the resulting η^4-methoxycyclohexadiene complex **25** has been hydrolyzed to give an enone **26**.[16]



Scheme 9

The anionic intermediate **8** (Nu = 1,3-dithian-2-yl) has also been trapped with a limited set of electrophiles when the nucleophile addition is irreversible. It has been shown that addition of 2-lithio-1,3-dithiane to (η^6-benzene)tricarbonylchromium followed by addition of CH_3I yields a *trans*-disubstituted cyclohexadiene **30a** if the reaction medium is oxidized or treated with a two-electron ligand L (Scheme 10).[17b] CO inserted into the metal−alkyl bond of complex **27** to give the metal−acyl bond of complex **28a**. A reductive elimination can afford the η^4-cyclohexadiene complex **29a** and then the organic compound **30** and $Cr(CO)_2L_4$ through use of a ligand L (L = CO, PPh_3).[1b]



Scheme 10

If *t*BuLi is used as a nucleophile under CO pressure, the anionic intermediate can be trapped in order to recover $Cr(CO)_6$ necessary for the preparation of the starting complex. By addition of *t*BuLi to (benzene)$Cr(CO)_3$ and then benzyl iodide, for example, we obtain the *trans*-cyclohexadiene **30b** (Nu = *t*Bu, E = $CH_2C_6H_5$), but even under 100 atm CO, we recover only a small amount of $Cr(CO)_6$.[18]

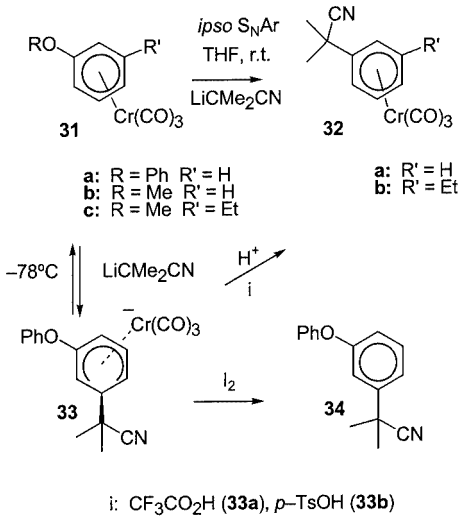
IV. *cine* and *tele* Nucleophilic Aromatic Substitutions: (η^6-Arene)$Cr(CO)_3$ Complexes

IV. a. Organic Carbanions: C−O, C−Cl, C−F Cleavage

One of the first nucleophilic aromatic substitutions described in the literature concerns the addition of sodium methoxide to tricarbonyl(chlorobenzene)chromium (**7**, X = Cl), which gives (anisole)tricarbonylchromium complex (**7**, X = OMe) via the η^5-cyclohexadienyl intermediate **8a** (X = Cl, Nu = OMe). This is the classical *ipso* substitution of the methoxy group at the carbon atom bearing the chloro atom.[19] Usually, however, the kinetic site of addition is at a position bearing a hydrogen substituent, which yields anionic η^5-ligand complexes **8b**, **8c**, and **8d** (Scheme 3).[8b] If equilibration occurs, complexes **8b**−**d** give **8a** and then anisole complex with the irreversible departure of the leaving group X.[1g] It has been shown that the fluorobenzene complex **7** (X = F) is almost 2000 times more reactive than the chlorobenzene complex **7** (X = Cl), in good agreement with a rate-limiting addition of the methoxide anion on the arene ring followed by fast departure of halide. We will not describe these *ipso* reactions in detail − they have been well reported in different reviews[1g] − but will instead consider carbanion addition to carbon atoms *ortho*, *meta*, and *para* with respect to the carbon atom bearing the leaving group.

Whereas direct displacement of oxygen leaving group is not effective, we have shown that treatment of 2-lithio-2-methyl-1,3-dithiane with tricarbonyl(diphenyl ether)chro-

mium (**31a**) at room temperature gives the *ipso*-monosubstituted complex **32a** (Scheme 11).[20]

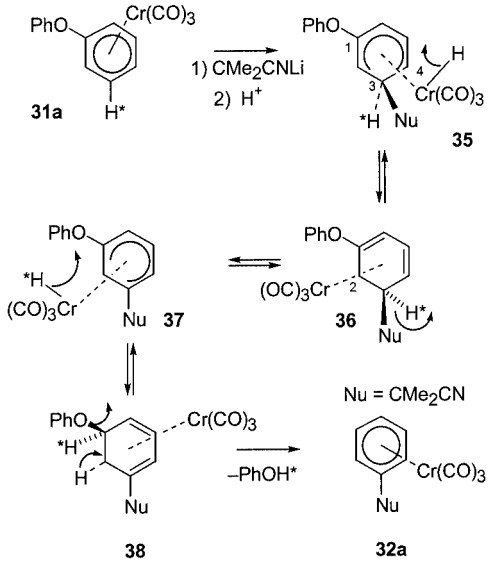


Scheme 11

More interestingly, addition of the same nucleophile at −78 °C affords the anionic intermediate **33**, which is quenched with I_2 at −78 °C to yield the *meta*-disubstituted arene **34** (Scheme 11). Addition occurs *meta* with respect to the PhO group, the overall reaction consisting of a *meta* substitution of a hydrogen atom by the nucleophile.[21]

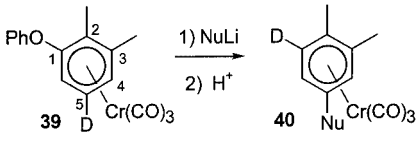
If the anionic intermediate **33** is treated with CF_3CO_2H at −78 °C, complex **32** is again unexpectedly obtained (Scheme 11). The same study with (anisole)$Cr(CO)_3$ (**31b**) and isobutyronitrile carbanion and acid gives phenylisobutyronitrile complex **32a**, but the yield is very low. With *p*TsOH, elimination of MeOH is easier, and complex **32a** is formed in 62% yield. Similarly, treatment of (*meta*-ethylanisole)$Cr(CO)_3$ (**31c**) with $LiCMe_2CN$ and *p*-TsOH affords complex **32b** in 62% yield.[22b]

Taking into account that *ipso* reaction does not occur at −78 °C, we have to consider a new mechanism to explain these unusual results. Addition of $LiCMe_2CN$ to diphenyl ether complex **31a** (Scheme 12) gives (after CF_3CO_2H treatment) the chromium hydride **35**, which can undergo a reductive elimination on the C-4 and C-2 carbon atoms. The new η^4 intermediate **36**, for example, which is a dienol ether, cannot be hydrolyzed in the absence of water. An oxidative addition of the allylic hydrogen atom can give another η^5-cyclohexadienyl complex **37**. Again, a reductive elimination can give the η^4-cyclohexadiene **38**. By elimination of the *anti*-parallel hydrogen atom and the PhO group, a new η^6-arene **32a** is formed. The driving force of the reaction is the rearomatization of the ring, which corresponds to a 1,5-hydrogen shift of the proton located at the C-3 carbon atom (Scheme 12).[21] The nucleophiles that have been tested are the carbanions of CH_3CO_2Me (pK_a = 24.5), $CH_3CH_2CO_2Me$, $(CH_3)_2CHCO_2Me$, CH_3CN (pK_a = 25), CH_3CH_2CN, $(CH_3)_2CHCN$, and 2-phenyl-1,3-dithiane.



Scheme 12

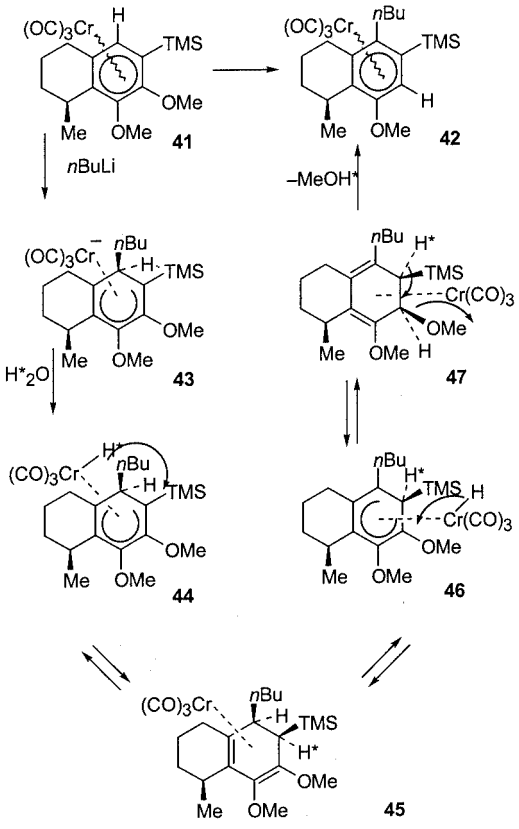
In order to understand the mechanism of this reaction, we undertook the same experiment starting from the labeled tricarbonyl(5-deuterio-2,3-dimethylphenyl phenyl ether)chromium (**39**). We obtained the deuterated complex **40** after treatment with a nucleophile NuLi (Nu = CMe_2CN, CMe_2CO_2tBu, ...) and CF_3CO_2H or CF_3CO_2D (Scheme 13).[21a] This reaction involves a 1,5-deuteride migration from the C-5 carbon atom to the C-1 carbon atom.[21,22] With CF_3CO_2D, we recovered PhOD, showing that the deuterium of the acid is not incorporated into the arene ring. For precision, we called this reaction a *tele-meta* nucleophilic aromatic substitution, in accordance with IUPAC naming schemes. The term *tele* is used to denote reactions in which the entering group takes up a position further than one atom away from the atom to which the leaving group is attached.[23]



Scheme 13

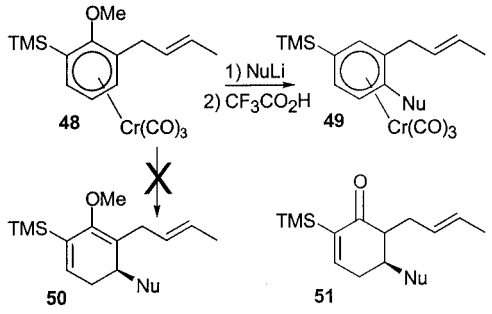
Schmalz et al.[24] reported that addition of *n*BuLi to tetralin derivative complex **41** in THF/HMPA gives a high yield of complex **42**.[24f] This reaction is a *tele* substitution with methoxide as the leaving group. To be more precise, it is a *tele-meta* S_NAr reaction, detailed in Scheme 14. The mechanism should not involve incorporation of deuterium in the ring if the anionic species **43** is trapped with a deuterium source. It is worth noting the ease with which *n*BuLi adds to a carbon atom of the arene ring under conditions that should result in smooth benzylic deprotonation, which according to the authors is disfavored for stereoelectronic reasons. The selective formation of complex **42** is remark-

able because the methoxide expulsion is regioselective: no *tele-para* substitution is observed.



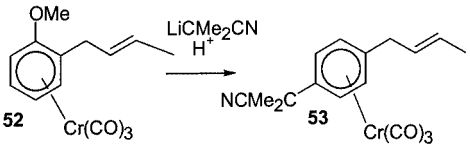
Scheme 14

The same group showed that *tele* substitution is the major pathway in S_NAr reactions of (*ortho*-alkylated η^6-anisole)$Cr(CO)_3$ derivatives such as **48** (Scheme 15).[24c,24e] Treatment of **48** with NuLi (Nu = 2-lithio-1,3-dithiane or *n*BuLi) followed by protonation with CF_3CO_2H does not give the expected enones **51** after hydrolysis of the dienol ethers **50** but, rather, complex **49** by way of a *tele-meta* S_NAr substitution of the MeO group by the nucleophile.



Scheme 15

In close analogy, desilylated complex **52**, when treated with 2-lithioisobutyronitrile and then with CF_3CO_2H, affords the *tele-meta* complex **53** as the major product (Scheme 16).[24e]



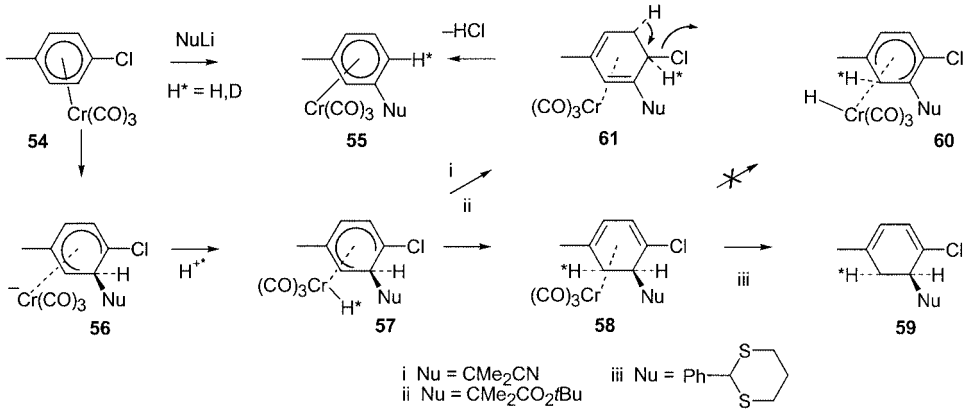
Scheme 16

The addition of stabilized carbanions to tricarbonyl(*para*-chlorotoluene)chromium complex **54** (NuLi and CF_3CO_2H) gives a *meta*-disubstituted complex **55**[25,26] (Nu = CMe_2CN, CMe_2CO_2tBu, p-$CH_3C_6H_4SO_2CHCH_3$. This is termed a *cine* nucleophilic aromatic substitution in accordance with IUPAC recommendations. Indeed a *cine* S_NAr is a reaction in which the incoming group (Nu) takes up a position at the carbon atom *ortho* to the leaving group.[23] With use of CF_3CO_2D, incorporation of deuterium takes place on the carbon atom that bore the leaving group (Scheme 17). If this reaction is performed with 2-lithio-2-methyl-1,3-dithiane, the η^4-cyclohexadiene **58** is obtained by a reductive elimination of the η^5-cyclohexadienyl complex **57**. It is likely that, the nucleophile being too bulky, the *endo*-hydrogen atom cannot be extracted from the carbon atom bearing this nucleophile and the isomerization process is therefore stopped. Instead, decoordination takes place, giving the cyclohexadiene **59**, X-ray analysis of which confirmed the proposed structure.[26b]

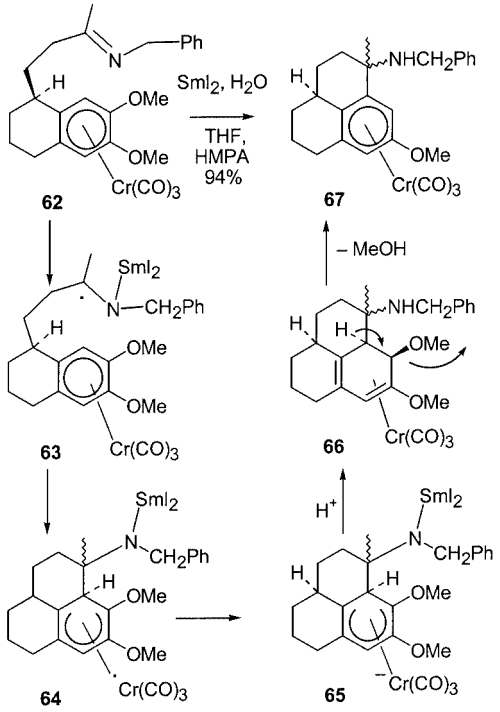
A *cine* S_NAr has been observed by Schmalz et al. in the case of an SmI_2-mediated radical cyclization of ketimines **62** (Scheme 18).[24a] The cyclization product is obtained from addition of azaketyl-type radical **63** to the complexed arene to form intermediate **64**, converted by a single electron transfer to the corresponding anionic complex **65**. Addition of acid affords a hydride, which gives rise to the formation of an η^4 intermediate **66**, which in turn yields complex **67** after a reductive elimination of MeOH. Another *cine* S_NAr with methoxide as a leaving group has been described for the synthesis of hydrophenalene complex **69**, starting from complex **68** (Scheme 19).[24d]

Another impressive example has been found in the case of tricarbonyl(1-chloro-2,6-dimethylbenzene)chromium complex **70** (Scheme 20).[27] In order to avoid addition *ortho* to the chloro atom, we protected the two positions *ortho* and *ortho'* of tricarbonyl(η^6-chlorobenzene)chromium. We thus forced the addition of the nucleophile *para* to the leaving chloride ion. By addition of $LiCMe_2CN$ and CF_3CO_2H, we observed the formation of the 1,3,5-trisubstituted complex **71** in 89% yield. This is a *tele-para* nucleophilic aromatic substitution.[28] Use of CF_3CO_2D results in complex **71** being labeled by a deuterium atom at the carbon atom that bore the leaving group. Thus, we completed the discovery of a trilogy: *cine*, *tele-meta*, and *tele-para* S_NAr.

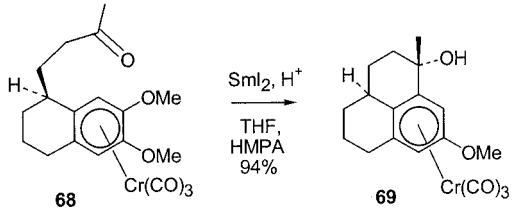
We achieved an analogous reaction with tricarbonyl(η^6-1-fluoro-2,6-dimethylbenzene)chromium complex **72**, by using the reversible addition of $LiCMe_2CN$ in THF at −78 °C and CF_3CO_2H at −78 °C. A mixture of *tele-meta* and *tele-para* substitution products **73** and **74** was isolated in 26



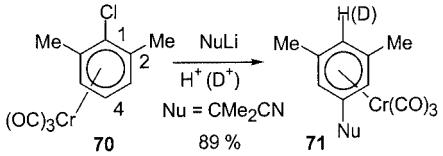
Scheme 17



Scheme 18

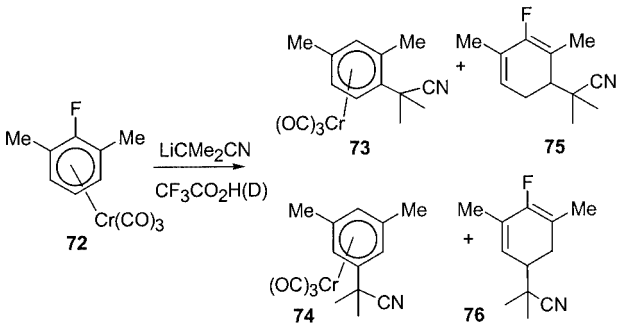


Scheme 19



Scheme 20

and 16% yield, together with a mixture of isomeric cyclohexadienes **75** and **76** in low yield (Scheme 21).[29] In the presence of HMPA, the addition of the nucleophile was irreversible and regioselective, and we recovered mostly the 1,3,5-trisubstituted *tele-meta* complex **74**.

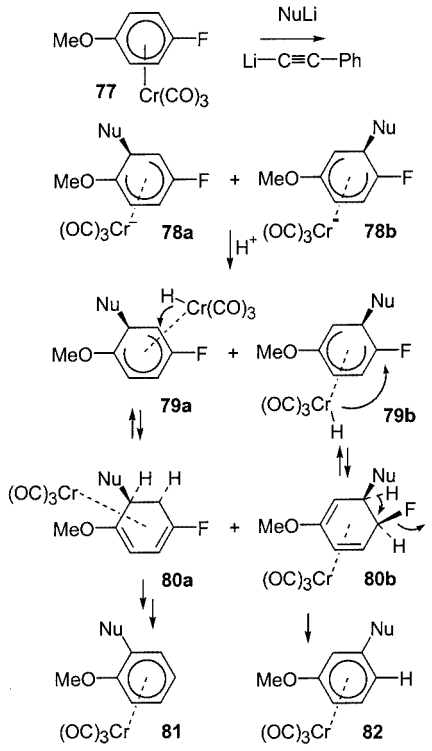


Scheme 21

It is worth noting the difference in the regioselectivities of addition of the nucleophile to the complexes **70** and **72**. In the first case, complex **70**, there is a weak effect from the chloro atom but an important effect from the methyl groups at the C-4 carbon atom. In the second case, that of complex **72**, the directing effect of the fluoro atom (strong *meta* effect) dominates over the effect of the two methyl groups. This study underlines the possibility of controlling the sites of *cine*, *tele-meta*, or *tele-para* substitutions: depending on the nature of the carbanion and on the nature of the leaving group, it is possible to obtain addition of the nucleophile *meta* or *para* to the halogenated atom.

If the *tele-meta* and *cine* substitution mechanisms are applied to the reaction studied by F. E. Hung et al. (Scheme 22), an easy explanation for the formation of the final products may be found. Tricarbonyl(*para*-fluoroanisole)chromium complex **77** was treated with lithium phenylacetylide in THF and HMPA at −78 °C for 1 h and then at −50 °C for 12 h to form two interesting compounds **81** and **82** in a 2:1 ratio and an overall yield of 41% after silica gel column chromatography.[30] We can predict competition between the addition of the nucleophile *meta* to the fluoro atom (strong *meta* effect) and *meta* to the methoxy group (strong mesomeric effect). The following mechanism, invol-

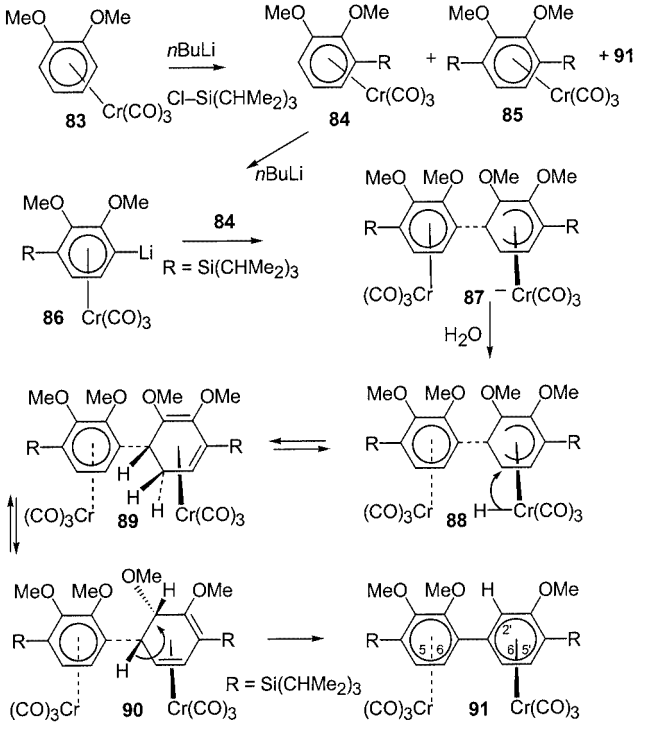
ving an irreversible addition of LiC≡CPh to give anionic intermediates **78a** and **78b**, can be suggested (Scheme 22), with these affording cyclohexadienes **80a** and **80b** on protic workup or on silica gel, via η^5-cyclohexadienyl complexes **79a** and **79b**. After isomerization (for **80a**) and elimination of HF, complexes **81** and **82** are obtained.



Scheme 22

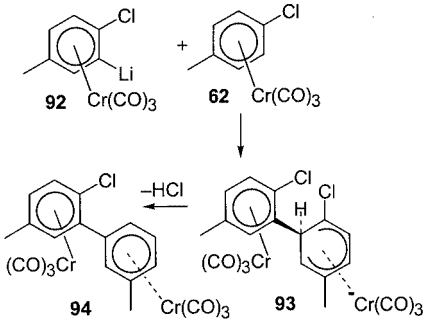
IV. b. Organometallic Carbanions: C−O, C−F, C−Cl Cleavage

When performing the lithiation/silylation of tricarbonyl(-veratrole)chromium (**83**) with *n*BuLi and $ClSi(CHMe_2)_3$, we recovered not only the expected (3-triisopropylsilylveratrole)$Cr(CO)_3$ (**84**) in 17% yield and [3,6-bis(triisopropylsilyl)-veratrole]$Cr(CO)_3$ **85** in 14% yield, but also an unexpected dinuclear complex **91**.[31] Its formation is interpreted as a *cine* S_NAr substitution of one methoxy group of **84** by the lithiated derivative **86**, as depicted in Scheme 23. It is noteworthy that the formation of **91** does not require acid treatment. Thus, the irreversibly formed anionic complex **87** can deliver a chromium hydride **88** on protic workup. Migration of the hydride ion can afford the cyclohexadiene **89**, which is in equilibrium with another cyclohexadiene **90**. Elimination of MeOH finally yields complex **91** in 16% yield. The X-ray structure of this complex shows, as should be expected, the conformations of the two $Cr(CO)_3$ units *anti*-eclipsed with respect to the bulky triisopropylsilyl groups.



Scheme 23

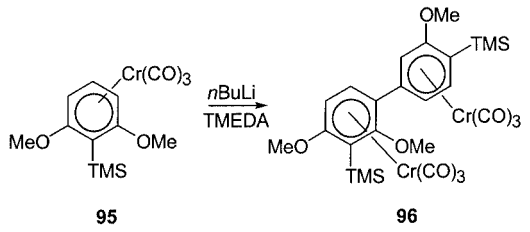
We extended this reaction to (*para*-chlorotoluene)$Cr(CO)_3$ (**62**) (1 equiv.) and treatment with *n*BuLi (0.5 equiv.). Again, without any acid treatment, the dinuclear complex **94** is formed anyway, through a *cine* S_NAr reaction (Scheme 24). The mechanism of this reaction involves lithiation of *para*-chlorotoluene complex **62**, *ortho* to the chloro atom, and then addition of this aryllithium compound **92** *ortho* to the chloro atom of another molecule of **62**. After protonation and rearrangement of the hydride intermediate, elimination of HCl affords the dinuclear complex **94**.[32]



Scheme 24

Another dimetallic compound has been described to be formed by treatment of complex **95** with *n*BuLi and TMEDA at −20 °C followed by addition of TMSCl at 0 °C. The expected silylated complexes are not formed, but the dinuclear complex **96** is obtained instead in high yield

by a *tele-meta* substitution of one of the methoxy groups (Scheme 25).[24b]

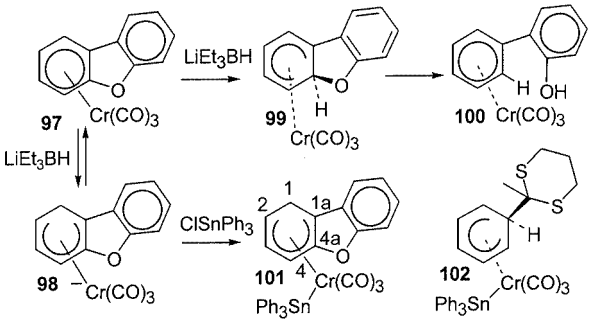


95 96

Scheme 25

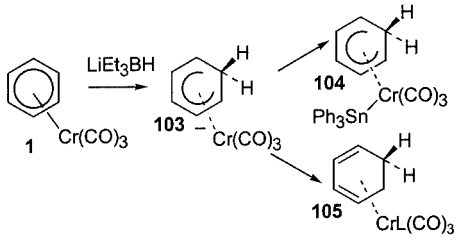
IV. c. Hydrides as Nucleophiles: C−F, C−Cl, C−O, C−N Cleavage

We then investigated the regioselectivity and the reversibility of hydride addition such as that of $LiEt_3BH$ to dibenzofuran complex **97** (Scheme 26).[33,34a] If the reaction is performed at room temperature in a sealed NMR tube in $[D_8]$THF, an unstable anionic complex **98** is obtained. This is pyrophoric under air! If, however, the reaction is performed at 67 °C, complex **100** is isolated in 55% yield as a yellow powder. Many attempts to isolate the anionic intermediate failed, the starting dibenzofuran complex **97** being recovered. However, triphenyltin chloride reacts at the metal center to give the binuclear red complex **101**, the X-ray structure of which definitively corroborates not only the regioselectivity of the addition of the hydride ion but also the η^5-cyclohexadienyl structure, which looks more or less like an unprecedented η^4-cyclohexadiene complex. Indeed, the Cr−C-1a bond was unexpectedly longer (2.41 Å) than the other Cr−C_{ar} bonds: Cr−C-2 2.228 Å, Cr−C-3 2.19 Å, Cr−C-4 2.19 Å, Cr−C-4a 2.25 Å. Another structure **102** has been obtained treating triphenyltin chloride with the anionic adduct of the reaction between (benzene)tricarbonylchromium and 2-lithio-2-methyl-1,3-dithiane.[35] In this case, the bond lengths of the chromium atom to the η^5-cyclohexadienyl framework are not so different, at 2.28, 2.19, 2.18, 2.20, and 2.30 Å.



Scheme 26

We successfully performed an analogous reaction with (benzene)tricarbonylchromium (**1**) and obtained a new binuclear Sn−Cr complex **104** by addition of $LiEt_3BH$ and $ClSnPh_3$. The X-ray structure confirms the η^5 structure (Scheme 27).[34] In solution, the NMR spectra of these η^5 complexes are characteristic, and their data are listed in Table 3. The hydrogen atom 1-H_{exo} in all cases resonates at the highest field as a doublet resulting (for **98**) from a ^1J (11 Hz) geminal coupling with 1-H_{endo}. The latter appears as a doublet of triplets from combined ^1J (11 Hz) and ^3J (6 Hz) coupling of 1-H_{endo} with 1-H_{exo} and 2- ,6-H, respectively. It is noteworthy that treatment of the anionic complex **103** with CF_3CO_2H in $[D_8]$THF in a sealed NMR tube at −78 °C affords a deep red solution, which turns orange-yellow at room temp. The ^{1}H NMR spectrum indicates the formation of an unstable η^4-cyclohexadiene complex **105**, the ^{1}H NMR spectroscopic data of which show peaks at δ = 5.80, 3.80, and 2.10, in good agreement with the spectra of carbonyl(1,3-cyclohexadiene)chromium derivatives.[36]



Scheme 27

Table 3. Selected ^{1}H and ^{13}C NMR spectroscopic data of (η^5-cyclohexadienyl)$Cr(CO)_3$

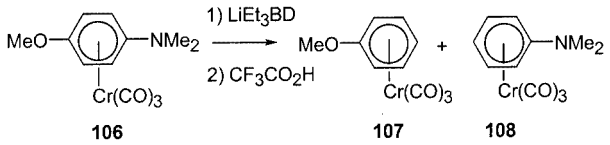
[a] $[D_8]$THF. [b] Under a multiplet at δ = 1.4−3.1. [c] C_6D_6. [d] Signal of 5-H at δ = 4.41, of 6-H at δ = 4.76.[e] $CDCl_3$.

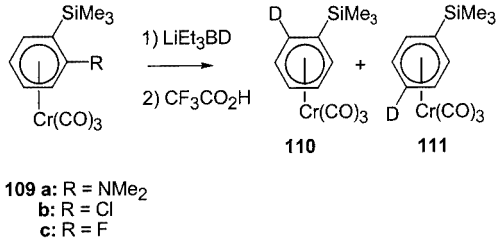
We then investigated the cleavage of a carbon−nitrogen bond. Addition of $LiEt_3BH$ to *para*-methoxydimethylaniline complex **106** at room temp., followed by treatment with CF_3CO_2H, affords two complexes, the anisole and aniline complexes **107** and **108** in 34% and 24% yields, respectively, showing competition between carbon−oxygen cleavage and carbon−nitrogen cleavage (Scheme 28).[34,37] Addition of an excess of $LiEt_3BH$ to **108** is necessary to obtain (after CF_3CO_2H treatment at room temp.) a red solution (which

rapidly becomes yellow) of (benzene)$Cr(CO)_3$ and the starting material.



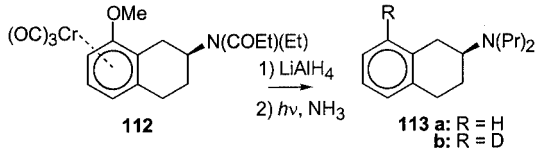
Scheme 28

We carried out a similar experiment with a complex possessing a well-defined $Cr(CO)_3$ conformation. We chose an [η^6-1-(dimethylamino)-2-(trimethylsilyl)benzene]$Cr(CO)_3$ (**109a**), which gave a mixture of 2- and 4-deuterio derivatives of [η^6-2-(trimethylsilyl)benzene]$Cr(CO)_3$ **110** and **111** in 56% yield in the ratio 84:16 (Scheme 29) after treatment with $LiEt_3BD$ and CF_3CO_2H. With *ortho*-chloro and *ortho*-fluoro(trimethylsilyl)benzene complexes **109b** and **109c**, however, we observed the almost quantitative formation of a single compound **111** through a *tele-meta* S_NAr.[34b]



Scheme 29

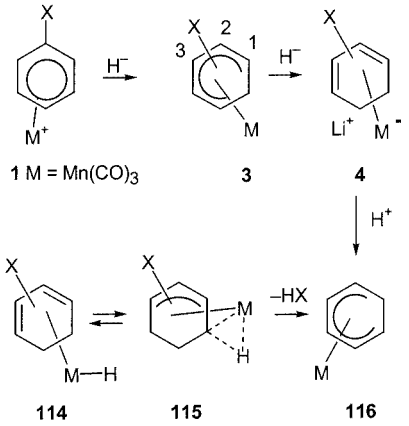
Another example of C−O cleavage by a hydride ion is described by Hacksel et al., who obtained an interesting arene **113a**, with loss of an OMe group, after addition of $LiAlH_4$ to tetrahydronaphthalene complex **112**, and decoordination of $Cr(CO)_3$[38] (Scheme 30). Two kinds of substitution − a *tele-meta* S_NAr or an *ipso* substitution − seem likely at this stage and could explain the formation of the observed product. However, the authors, when performing the reaction with $LiAlD_4$, obtained the compound **113b**, deuterated at the carbon atom that bore the methoxy group, in good agreement with an *ipso* S_NAr. If a *tele-meta* S_NAr had occurred, a deuterio complex labeled at the position *meta* to the carbon atom that bore the methoxy group should have been obtained.



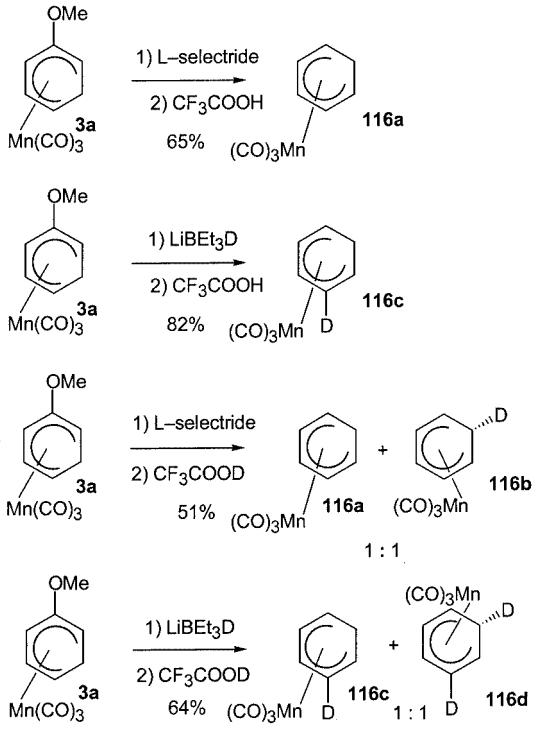
Scheme 30

V. *cine* and *tele* Nucleophilic Substitutions: (η^5-Cyclohexadienyl)$Mn(CO)_3$ Complexes

It is now well established that tricarbonyl[phenoxy-, methoxy-, chloro-, fluoro-, (dimethylamino)-substituted η^6-arene]chromium complexes undergo cleavage of aromatic C−O, C−Cl, C−F, C−NMe_2 bonds upon treatment first with a nucleophile or a hydride ion and then with acids. The first step of these reactions is the formation of anionic η^5 intermediates, which can undergo different isomerizations once protonated. We were interested in transposing this study to manganese complexes, encouraged by the convincing demonstration by Brookhart et al. of the facile isomerization of cyclohexenyl isomers **115** involving manganese−hydrogen−carbon agostic bonds (Scheme 31).[39] Indeed, these authors reported that treatment of the neutral complexes **3**, obtained by hydride addition to cationic tricarbonyl(X-substituted η^6-arene)manganese complexes **1**, resulted in the formation of anionic complexes **4** and, on addition of water, a stable complex **115**



Scheme 31



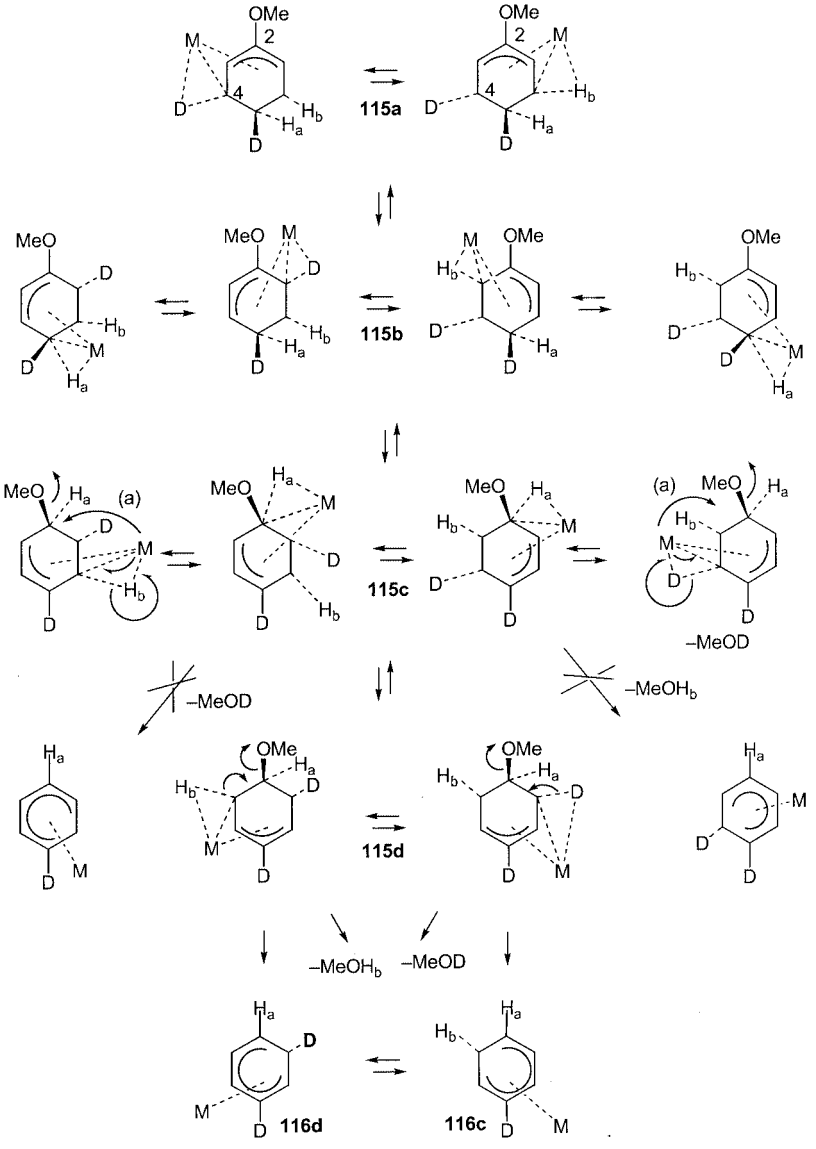
Scheme 32

with a three-center Mn−H−C agostic bond (X = OMe, for example) (Scheme 31). We therefore repeated this reaction, starting from various (η^5-cyclohexadienyl)manganese complexes substituted with a leaving group X, in order to eliminate HX after H^-, H^+ treatment. We obtained a new complex **116**, again with an η^5 structure.

V. a. C−O Cleavage

Addition of L-selectride to the η^5 complex **3a**, followed by protonation with MeOH or CF_3CO_2H, gives the known η^5-cyclohexadienyl complex **116a** in 65% yield if the reaction mixture is heated in THF for 3 h. With $LiEt_3BD$ and CF_3CO_2H, complex **116c** is recovered in 82% yield (Scheme 32). If $LiEt_3BH$ and CF_3CO_2D are used, a mixture of complexes **116a** and **116b**, deuterated at the *endo* position, is recovered in a ratio of 1:1 and in 51% yield. When complex **3a** is treated with $LiEt_3BD$ and MeOH, a single deuterated complex **116c** is obtained in 82% yield. Similarly, treatment of complex **3a** with $LiEt_3BD$ and CF_3CO_2D results in a mixture of complexes **116c** and **116d** being recovered in a 1:1 ratio and in 64% yield. These data are consistent with a four-step mechanism involving hydride addition, protonation, isomerization, and elimination. We will focus only on the last step. The formation of the various labeled products obtained has been explained in terms of the easy isomerization of different η^3-cyclohexenyl intermediates such as **115** in an acidic medium. We thus considered all the possible hydrogen migrations giving the mono- and the dideuterated complexes **116c** and **116d** in order to understand the elimination of MeOH(D) (Scheme 33).

The exact mechanism of this reaction is not yet known precisely, because the π-allyl complexes **115a**, **115b**, **115c**, and **115d**, which are in equilibrium, can be represented by two different agostic bonds in the cases of the symmetrical derivatives **115a** and **115d** and by four different agostic bonds in the cases of the unsymmetrical derivatives **115b** and **115c**. Thus, in the last elimination step, complex **115d**



Scheme 33

could eliminate either $MeOH_b$ or MeOD, giving complexes **116c** and **116d**. In fact, we arrived at the conclusion that 1,5-elimination could occur between the OMe group and an agostic hydrogen atom, and we never observed a 1,2-elimination of OMe and a non-agostic hydrogen atom. Thus, the hydrido-demethoxylation of complex **3a** occurred by hydride ion addition at the C-5 carbon atom and elimination of the methoxy group at the C-2 carbon atom (Figure 3). By analogy with the chromium complexes, this is a *tele-para* nucleophilic substitution.[40]

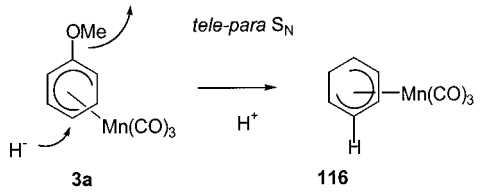


Figure 3. *tele-para* S_N

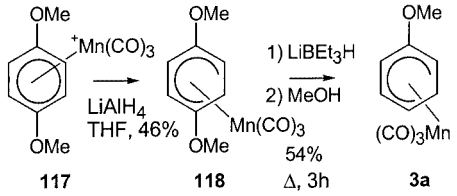
In the case of the tricarbonyl(*para*-dimethoxybenzene)manganese complex **117**, addition of $LiAlH_4$ in THF at −78 °C affords complex **118** in 46% yield (Scheme 34).



Scheme 34

The addition of L-selectride (4 equiv.) to complex **118**, followed by protonation with MeOH (6 equiv.) and heating of the solution for 3 h, resulted in the formation of a single isomer tricarbonyl(η^5-2-methoxycyclohexadienyl)manganese complex **3a** in 54% yield. The formation of this can be interpreted in terms of a *cine* or a *tele-meta* nucleophilic substitution (Figure 4). We extended these reactions to other examples showing the possibility of C−N, C−Cl and C−S bond cleavage.

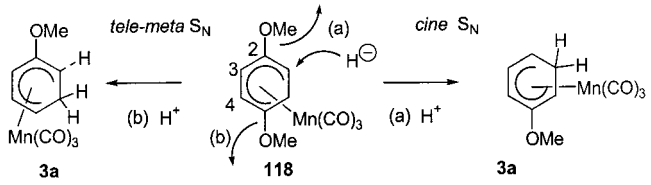


Figure 4. *cine* or *tele-meta* S_N

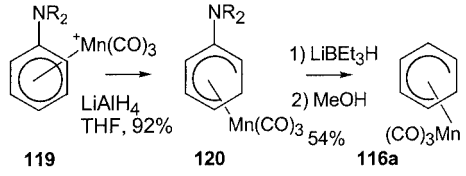
V.b. C−N Cleavage

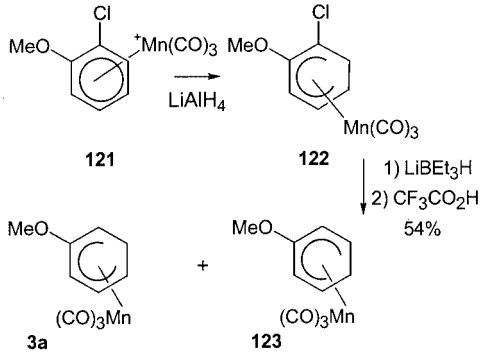
Addition of $LiAlH_4$ to [(diethylamino)benzene]-$Mn^+(CO)_3$ (**119**) exclusively yields the expected *meta*-addition product **120** in 92% yield. Addition of L-selectride followed by protonation with CF_3CO_2H at −78 °C gives, after warming to room temp., the η^5-cyclohexadienyl complex **116a** in 54% yield (Scheme 35).[40]



Scheme 35

V. c. C−X Cleavage (X = F,Cl)

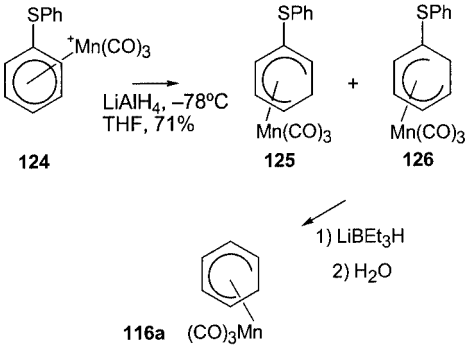
Complex **122** (obtained in 57% yield from addition of $LiAlH_4$ to (*ortho*-chloroanisole)$Mn^+(CO)_3$ complex **121** behaves similarly, reacting with L-selectride and then CF_3CO_2H to afford the 2- and 3-methoxycyclohexadienyl complexes **3a** and **123** in a 45:55 ratio (Scheme 36). Cleavage of the C−Cl bond occurs very quickly even at low temperature, contrary to the C−O bond cleavage, which requires higher temperature.



Scheme 36

V. d. C−S Cleavage

Addition of $LiAlH_4$ to (η^6-phenylthiobenzene)-$Mn^+(CO)_3$ complex **124** gives two neutral complexes **125** and **126** in 71% yield and in a 30:70 ratio. Complex **126**, if treated with L-selectride and water and heated in refluxing THF for 20 h, affords complex **116a** in 38% yield (Scheme 37). We have never succeeded in cleaving the C−S bond in the case of the corresponding (arene)$Cr(CO)_3$ complexes (Scheme 37).[40]



Scheme 37

VI. Concluding Remarks

The reactivity of (arene)tricarbonylchromium and -manganese complexes involved in *cine* and *tele* nucleophilic substitutions has been described. The use of chromium complexes provides rapid routes to compounds that are difficult to obtain in organic chemistry. Thus, addition at low temperature of a stabilized carbanion to an (arene)tricarbonylchromium complex substituted with a leaving group X, followed by addition of CF_3CO_2H, yields new arene complexes and HX through the cleavage of carbon−oxygen, carbon−halogen, and carbon−nitrogen bonds. The addition of the nucleophile occurs *ortho*, *meta*, or *para* to the leaving group, depending mainly on the nature and on the relative positions of the substituents on the arene ring. There is no doubt that development in this area will be extended in our laboratory and also elsewhere, not only in the cases of chromium or manganese complexes such as we have already discovered, but also in the case of other metals. These *cine* and *tele* S_N processes appear to be efficient organometallic reactions and represent a new tool for organic chemists. By taking advantage of the presence of the tripod $Cr(CO)_3$, which remains coordinated to the arene ring of the final product, a further functionalisation is possible and so broadens the scope of potential applications.[41]

Isomerization of η^4-cyclohexadiene intermediates occurs through 1,5-hydrogen shifts. The driving force of these reactions is the elimination of HX, with aromatization of the η^4 complexes into the η^6-arenes in the case of (η^6-ligand)Cr complexes.

In the case of Mn complexes, we extended these reactions and found that carbon−oxygen, carbon−halogen, carbon−nitrogen, and even carbon−sulfur bonds can be cleaved by *cine* and *tele* S_N processes if the starting neutral (substituted η^5-cyclohexadienyl)$Mn(CO)_3$ is treated with a hydride ion and a proton source, yielding (η^5-cyclohexadienyl)$Mn(CO)_3$ complex and HX. The driving force of these reactions is again the elimination of HX, transforming an η^3 complex into an η^5-cyclohexadienyl complex.

VII. Abbreviations

CAN: ceric ammonium nitrate; DDQ: 2,3-dichloro-5,6-dicyanobenzoquinone; HMPA: hexamethylphosphoramide; L: $2e^-$ ligand; LDA: lithium diisopropylamide; S_N: nucleophilic substitution; S_NAr: nucleophilic aromatic substitution; THF: tetrahydrofuran; TMEDA: tetramethylethylenediamine; TMSCl: trimethylsilyl chloride.

Acknowledgments

We thank the CNRS (Scientific National Research Center) for the support of our laboratory research for the published and unpublished work from our group. Grateful acknowledgment is given to an enthusiastic group of Ph.D. students − A. Auffrant, R. Chavignon, and S. Schouteeten − and to our collaborators B. Andrioletti (CNRS researcher) and J. P. Tranchier (Assistant Professor).

Copper(II) and Palladium(II) Complexes of the Reducing Sugar Lyxose[‡]

Peter Klüfers*[a] and Thomas Kunte[a]

Keywords: Lyxose / Copper / Palladium / Aldose−metal complexes

The reaction of the reducing aldopentose lyxose towards the metal centres in the copper-based cellulose solvents Schweizer's reagent (cupric hydroxide in aqueous ammonia) and Cu-en (cupric hydroxide in aqueous ethylenediamine) was investigated. Crystals of the trinuclear complexes $[(NH_3)_4Cu^{II}_3(\beta\text{-D-Lyx}p1,2,3H_{-3})_2(H_2O)_2]\cdot 4H_2O$ (**1**) and $[(en)_2Cu^{II}_3(\beta\text{-D-Lyx}p1,2,3H_{-3})_2(H_2O)_2]\cdot 4H_2O$ (**2**) (Lyx*p* = lyxopyranose) were grown upon preventing Fehling-type aldose oxidation. One of the three cupric centres is coordinated by two chelating diolato ligands only, hence both ammonia and ethylenediamine are displaced from Cu^{II} by a carbohydrate ligand. A binuclear lyxose-palladium(II) complex is formed on reaction of lyxose with Pd-en ($[(en)Pd(OH)_2]$ in water), which is another cellulose solvent of the coordinating type. From racemic mixtures of the lyxose enantiomers, crystals of $[(en)_2Pd^{II}_2(\beta\text{-}rac\text{-Lyx}pH_{-4})]\cdot 7H_2O$ (**3**) were obtained. ^{13}C NMR spectra reveal the bimetallated lyxose tetraanions to be the main species in palladium-rich solutions.

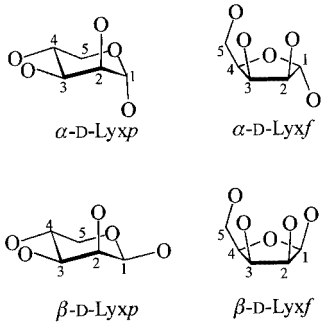
Introduction

Reducing Sugars as Ligands

Metal complexation of reducing sugars is a particularly challenging field of carbohydrate-metal complexation because of the characteristic reactivity of aldoses and ketoses. While nonreducing sugars and sugar derivatives such as sugar alcohols, on- and ar-acids or glycosides have fixed configurations and hence a limited capability to match their oxygen-atom pattern with the binding sites of a metal ion, reducing sugars can isomerize to the various furanose and pyranose anomers. For the aldopentose D-lyxose, for example, Scheme 1 depicts the O-atom patterns of the anomeric α- and β-forms of D-lyxofuranose and -pyranose, the latter as the $^4C_1$ conformers. Structural information concerning how a reducing sugar is bound to a particular transition metal in a specified oxidation state is rare. The few structural analyses available are due to the pioneering work of Taylor and Waters on a binuclear molybdenum(VI) complex of D-lyxose in its β-furanose form,[1] a series of binuclear β-D-mannofuranose complexes of trivalent metals (V, Cr, Fe, Mn),[2a,2b] and a palladium(II) complex of the most important aldose, D-glucose, in its α-pyranose form.[3] Despite its significance as a metal for catalysis, there is no structural information on any copper complex of a reducing sugar. The main experimental difficulty when investigating



Scheme 1. Oxygen-atom patterns of the anomeric D-lyxofuranoses (right) and -pyranoses (left), the IUPAC-recommended abbreviations, and the atom numbering used throughout the text; NB the β anomers (bottom) provide two diol moieties of suitable torsion angle for metal complexation each, but not the α forms (top)

complexes of this kind is the ease of the Fehling reaction. However, the oxidation of a carbohydrate may be suppressed for prolonged periods of time by cooling to about 5 °C and avoidance of local or short-term temperature increases when preparing the solutions. We report here the first structural analyses of crystals obtained from lyxose solutions in the well-known cellulose solvents Schweizer's reagent (ammonia as a co-ligand) and Cu-en (ethylenediamine as the additional ligand).

Results and Discussion

Lyxose Complexes in Schweizer's Reagent and Cu-en

Blue, monoclinic crystals of $[(NH_3)_4Cu^{II}_3(\beta\text{-D-Lyx}p1,2,3H_{-3})_2(H_2O)_2]\cdot 4H_2O$ (**1**) were obtained from D-lyxose solutions in ice-cold Schweizer's reagent (cupric hy-

droxide dissolved in aqueous ammonia) in a large range of molar ratios of the components (Cu:Lyx from 0.5:1 to 2:1). To inhibit progress of the autocatalytic sugar oxidation in the course of crystallization, the solutions were filtered after preparation to remove small amounts of cuprous oxide. In the crystals of **1**, two bridging lyxose ligands adopt the β-pyranose form in C_2 symmetrical, trinuclear molecules; they are each threefold deprotonated along the *cis-cis* sequence of the hydroxy groups with C1, C2, and C3 (Figure 1). The coordination chemistry of the cupric centres is normal i.e. the bis-diolato-bonded Cu1 atom is square-planar coordinated with no further ligands, whereas Cu2, which is coordinated by a diolato ligand derived from the anomeric and the epimeric hydroxy groups, is surrounded by a square pyramid consisting of the two alkoxy oxygens, two ammine ligands and a water ligand at a longer distance. Intramolecular hydrogen bonds are established from N2−H donors and O3 acceptors. Also as usual in polyolato-metal compounds, the alkoxo atoms O1 and O3 are acceptors of two hydrogen bonds each; the acceptor capability of the bridging O2 atoms is weakened by an almost planar arrangement of its substituents (angle sum: 359.2°).

The capability of a polyolato ligand to replace ammine ligands is a prerequisite for the formation of **1**. To gain more insight into whether the molecular arrangement in **1** is unique to Schweizer's reagent, attempts were made to crystallize an analogous lyxose-copper complex in the related $Cu(OH)_2$/en/D-lyxose system with ethylenediamine instead of ammonia. Again, the stoichiometry was varied between half- and bimetallation of the saccharide. Blue, monoclinic crystals of $[(en)_2Cu^{II}_3(\beta\text{-D-Lyx}p1,2,3H_{-3})_2(H_2O)_2]\cdot 4H_2O$ (**2**) were obtained by the same procedure as with **1**, and also in all the Cu:Lyx ratios chosen. The molecular structure (Figure 2) resembles that in the ammine complex, including the detail of intramolecular hydrogen bonding from amine donors to alkoxide acceptors. The structure determination demonstrates that the stronger ethylenediamine ligand is also replaced by the lyxose anions. Both **1** and **2** crystallize in space group *C*2; however, despite the similarities in the lattice constants, the packing of the molecules is different. The lattice constants are therefore related according to $a_1 = 2c_2$, $b_1 = -b_2$, $2c_1 = a_2$, $\beta_1 = \beta_2$.

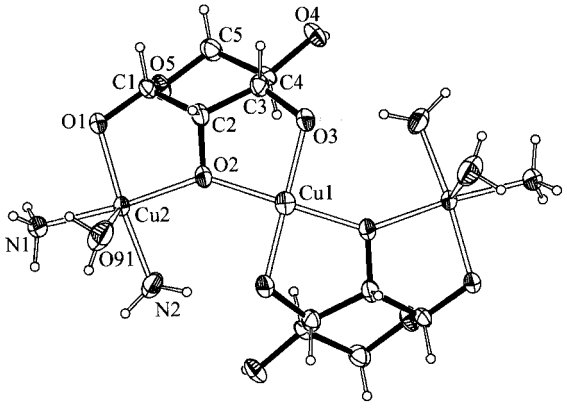

Figure 1. The structure of the $[(NH_3)_4Cu_3(\beta\text{-D-Lyx}p1,2,3H_{-3})_2(H_2O)_2]$ molecules in **1** projected down the twofold axis of space group *C*2; thermal ellipsoids are drawn at 60% probability; distances (Å) from Cu1 to: O3 1.932(3), O2 1.970(3); from Cu2 to: O1 1.930(2), N2 1.972(4), O2 1.983(3), N1 2.002(3), O91 2.427(4); O1−C1 1.372(5), O2−C2 1.417(5), O3−C3 1.410(5), O4−C4 1.430(5), O5−C5 1.429(5), O5−C1 1.459(6), C1−C2 1.526(6), C2−C3 1.523(6), C3−C4 1.521(6), C4−C5 1.527(6); torsion angles (°): O1−C1−C2−O2 48.2(5), O2−C2−C3−O3 −47.3(4), O3−C3−C4−O4 −71.9(4); puckering parameters of the lyxopyranose ring: Q = 0.555(4) Å, θ = 11.9(4)°, φ = 349(2)°

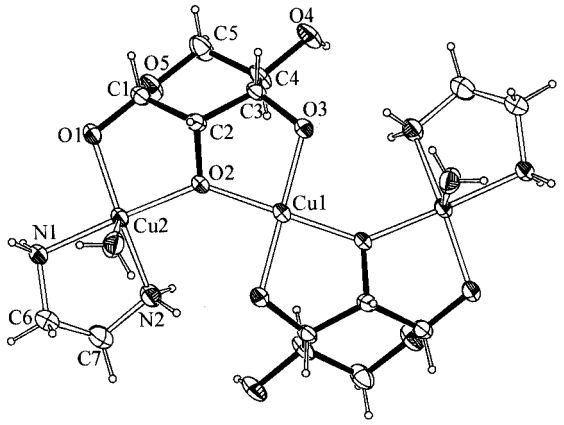

Figure 2. The structure of the $[(en)_2Cu_3(\beta\text{-D-Lyx}p1,2,3H_{-3})_2(H_2O)_2]$ molecules in **2** projected down the twofold axis of space group *C*2; thermal ellipsoids are drawn at 40% probability; distances (Å) from Cu1 to: O3 1.936(2), O2 1.940(2); from Cu2 to: O2 1.943(2), O1 1.946(2), N2 1.998(3), N1 2.004(3), O91 2.350(3); C1−O1 1.378(4), C1−O5 1.437(5), C2−O2 1.430(4), C3−O3 1.412(4), C4−O4 1.436(4), C5−O5 1.425(5), C1−C2 1.523(5), C2−C3 1.527(4), C3−C4 1.522(5), C4−C5 1.522(6); bond angles (°): O3−Cu1−O2 86.53(9), O2−Cu2−O1 86.07(9); torsion angles (°): O1−C1−C2−O2 47.5(4), O5−C1−C2−O2 −71.6(3), O2−C2−C3−O3 −47.1(4), O3−C3−C4−O4 −71.0(4), C2−C3−C4−O4 167.4(3), O4−C4−C5−O5 179.1(3); puckering parameters of the lyxopyranose ring: Q = 0.546(4) Å, θ = 11.7(4)°, φ = 327(2)°

The structures of the copper-lyxose complexes show that the retardation of Fehling-type reactions is not caused by a lack of contacts between the central copper atoms and the hemiacetal function of the monosaccharide. As should be expected from the acidities of the lyxose hydroxy groups, the OH group at C1 (as the most acidic one) is deprotonated and bonded to a copper ion. The high tendency of formation of **1** and **2** shows the difficulty in deriving rules for copper complexation in these ternary systems. Neither simple monometallated species of the kind $[(\text{N-ligand})_m\text{Cu(D-LyxH}_{-2})]$ nor bimetallated complexes of the type $[(\text{N-ligand})_n\text{Cu}_2\text{(D-LyxH}_{-4})]$ have been isolated despite the use of suitable molar ratios. One of the reasons for the formation of the more complicated structures of **1** and **2** is the higher stability of polyolato over am(m)ine complexes in solutions of sufficiently high pH, as has been shown for simple diolates,[4] possibly together with a particular stability of Cu_2-μ-triolate(3−) assemblies, which are known for glycerol complexes.[5]

Lyxose Complexes of Palladium(II)

The experiments with the copper-based cellulose solvents suggest that monosaccharide complexation should follow simpler rules if the spectator ligand is chosen such that the stabilities of the competing complexes are not in the same order of magnitude. Maintaining lyxose as the sugar component, this may be demonstrated by replacing Cu-en with Pd-en {as an aqueous solution of $[(en)Pd^{II}(OH)_2]$}, which is also a cellulose solvent.[6] The ethylenediamine ligand at the central palladium atoms is not prone to substitution by polyolato ligands. Thus Pd-en can only act as a diol-coordinating agent (the typical reactions following hydroxide addition to cellulose solutions in Schweizer's reagent — in particular cross-linking of polysaccharide strands due to bis-diolato-cuprate formation — are therefore missing with Pd-en.) On reaction with lyxose, the lowest number of species was found for Pd/lyxose molar ratios of 2:1 and higher. ^{13}C NMR spectra of the diamagnetic complexes reveal bimetallated lyxopyranose ligands by the typical "coordination induced shift" (CIS) of the carbon atoms 1−4. Crystals of the complex formed from D-lyxose and Pd-en could not be isolated, although yellow, centrosymmetric, triclinic crystals of $[(en)_2Pd^{II}_2(\beta\text{-}rac\text{-}Lyxp\mathrm{H}_{-4})]\cdot 7H_2O$ (**3**) were obtained from *rac*-lyxose solutions, which can be prepared easily due to the availability of both D- and L-lyxose. The structure of the complex molecules agrees well with the expectation that: (1) only diol moieties are bound to palladium, and (2) due to the high thermodynamic stability of the complexes, the maximum number of palladium atoms should be bonded to the monosaccharide. Scheme 1 shows that only two isomers are able to bind two palladium atoms for steric reasons: the β-pyranose form in its $^4C_1$ conformation, and the β-furanose form when 1,3-diolato complex formation is taken into consideration as well as 1,2-bonding. Figure 3 shows the actual structure with the lyxose ligands in the β-pyranose form. In agreement with the NMR spectra, O1−4 are deprotonated and bonded to the central palladium atoms. Hydrogen bonding is as usual with polyolato-metallates: each alkoxide O atom accepts two hydrogen bonds, mostly from water donors (2 N−H···O- and 14 O−H···O- contacts are established by the 16 lone pairs of the eight alkoxo ligands of the asymmetric unit). The water donors are incorporated in cooperative hydrogen bond sequences, which often start with an N−H donor.

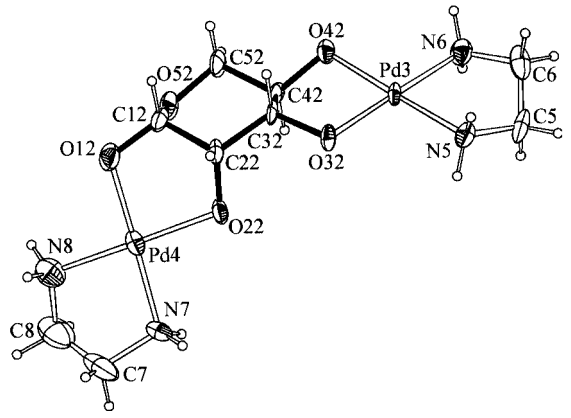

Figure 3. The structure of the $[(en)_2Pd_2(\beta\text{-D-}Lyxp\mathrm{H}_{-4})]$ isomer from the racemic mixture in **3** projected with almost the same view of the carbohydrate ligand as in the copper complexes; thermal ellipsoids are drawn at 60% probability; distances (Å) and angles (°) (the first entry is the specified distance, the second entry is the corresponding distance in the L-configured isomer): Pd3−O42 2.004(4), 2.006(4), Pd3−O32 2.024(4), 2.027(4), Pd4−O22 2.011(4), 1.990(4), Pd4−O12 1.993(5), 2.004(4), C12−O12 1.374(8), 1.372(7), C12−O52 1.434(9), 1.432(8), C22−O22 1.418(8), 1.414(8), C32−O32 1.421(7), 1.427(6), C42−O42 1.424(7), 1.414(8), C52−O52 1.424(8), 1.425(8), C12−C22 1.542(8), 1.551(8), C22−C32 1.529(8), 1.527(9), C32−C42 1.514(9), 1.509(9), C42−C52 1.517(8), 1.525(8); mean of eight Pd−N distances: 2.034 Å, standard deviation of the mean: 0.007 Å, mean standard deviation: 0.006 Å; torsion angles: O12−C12−C22−O22 49.8(7), −47.2(7), O22−C22−C32−O32 −55.6(8), 52.8(8), O32−C32−C42−O42 −55.9(6), 58.0(6); puckering parameters of the lyxopyranose ring: Q = 0.574(7), 0.579(7) Å, θ = 6.2(7), 173.0(7)° (the conformation is close to an ideal chair, hence no φ value is given)

In the ^{13}C NMR spectra, the aforementioned CIS is a maximum for C2. Though data on aldoses are scarce, this seems to be biased towards the axial substitution of the epimeric carbon atom to some extent.[7] At the concentrations given in Table 1, the binuclear $[(en)_2Pd^{II}_2(\beta\text{-D-}Lyxp\mathrm{H}_{-4})]$ complex is the main species at high palladium:lyxose ratios. Monometallated species occur in only small amounts, although they become the main species at a

Table 1. Signal positions in the ^{13}C NMR spectrum of solutions of D-lyxose in 1 M Pd-en; in addition to the chemical shift the "coordination induced shift" ("CIS", defined as $\delta_{complex} - \delta_{reference}$) is tabulated; the reference is an approx. 0.6 M solution of D-lyxose in D_2O;[a] signals of the en ligand are omitted; Δδ values that indicate a CIS are printed in **boldface**; in the last two columns, a rough estimate of the species distribution as derived from ^{13}C signal heights is given for different molar ratios: a "+" sign represents about one fifth of the tetraol, whereas a "−" sign accounts for less than about 10%; an unidentified form of lyxose (abundance: "−" at 2:1, "+" at 1:1 molar ratio) exhibits signals at δ = 90.6, 71.3, 68.7, 66.8, 56.6; from the fact that signal height closely corresponds to that of the monometallated form on Pd/Lyx ratio variation, the unidentified species may be another monometallated derivative, possibly with a lyxofuranose ligand

molar ratio of 1:1. Their concentration is governed by the relative acidities of the hydroxy groups of lyxose. The main species is the mononuclear [(en)Pd^{II}(β-D-Lyx*p*1,2H_{-2})] complex with the most acidic hydroxy group at O1 being deprotonated, although almost the same concentration is reached by the [(en)Pd^{II}(β-D-Lyx*p*2,3H_{-2})] species. A minor species in the 1:1 solutions has not been identified (cf. Table 1).

Attempts to synthesize a heteronuclear Pd_2Cu complex by reacting the [(en)Pd^{II}(β-D-Lyx*p*H_{-2})] complexes with $Cu(OH)_2$ failed according to NMR spectroscopy. Instead of increasing signal widths at the suggested copper-binding site (C2, C3), the signals of the binuclear [$(en)_2Pd^{II}_2$(β-D-Lyx*p*H_{-4})] complex emerge. Obviously, the dissolved cupric hydroxide forms homonuclear species of unknown composition that do not give rise to observable NMR signals and also consume lyxose.

Conclusion

Prior to undergoing redox chemistry, the aldose lyxose forms coordination compounds with copper atoms in alkaline aqueous solution. The compounds are prevented from Fehling-type reactions by cooling to 5 °C and removal of autocatalytically acting seeds of cuprous oxide. The most acidic hydroxy group at the anomeric carbon atom is involved in copper chelation. However, the prediction of a particular structure is complicated by the ability of diolato ligands to substitute nitrogen ligands at the cupric centres.

[a] C- and N-bonded H atoms fixed; O−H and H−H distance fixed for water-H atoms at 0.83 and 1.31, respectively; one common *U* for all H atoms. [b] C- and N-bonded H atoms fixed; one common O−H distance refined for water-H atoms (0.94), H−H distance fixed to the 1.57-times that of O−H thus forcing a 105° bonding angle; one common *U* for all H atoms.

The latter characteristic does not hold for palladium(II) centres, to which nitrogen ligation is clearly favoured over alkoxide bonding. (en)Pd fragments thus bind to diol groups without loss of the ethylenediamine ligand. Hence the rules of carbohydrate-metal coordination appear to be less complicated in the palladium(II) case. For this metal, the maximum number of palladium atoms is bonded to as many diol groups as are needed for chelation in terms of the torsion angle (i.e. no axial-axial diols in pyranoses and no *trans*-diols in furanoses).

Experimental Section

D- and L-lyxose were purchased from the Institute of Chemistry, Bratislava. Ethylenediamine, ammonia and sodium hydroxide were purchased from Fluka. Cupric hydroxide was synthesized from cupric sulfate pentahydrate (Merck). Pd-en was stored under nitrogen at 4 °C before use. All experiments with Pd-en were carried out under nitrogen. NMR measurements were performed either with a Jeol EX 400 or a Jeol GSX 270 NMR spectrometer.

1: D-Lyxose (450 mg, 3.00 mmol) and cupric hydroxide (195 mg, 2.00 mmol) were stirred in 5 mL aqueous ammonia (25%) at 4 °C for 2 h. The dark blue solution was filtered off from excess cupric hydroxide. Blue platelets of **1** formed during the course of one week upon diffusing acetone vapours into the solution. Solutions kept at room temperature had decomposed after two days.

2: The entire procedure was conducted at a temperature of 4 °C: D-lyxose (300 mg, 2.00 mmol) and cupric hydroxide (195 mg, 2.00 mmol) were stirred in 5 mL water for 5 min. Sodium hydroxide (8 mg, 0.2 mmol) was then added and stirring was continued for a further 5 min, after which time ethylenediamine (120 mg, 2.00 mmol) was added. After stirring for 1 h, the dark blue solution was filtered. Blue platelets of **1** formed during the course of one week upon diffusing acetone vapours into the solution. Decomposition of the solutions at room temperature proceeds in the same way as with **1**.

3: Pd-en was prepared as described earlier.[6] *rac*-Lyxose (74 mg, 0.50 mmol) was dissolved in 5 mL of an aqueous 0.2 M Pd-en solution (1.0 mmol) and stirred for 24 h at 0 °C. Diffusion of acetone−water vapours (4:1) caused the formation of yellow platelets within one week.

X-ray Structure Determinations: Details of the structure analyses are summarized in Table 2. Disordered positions for hydrogen attached to two (**1**) or one (**2**) water-oxygen atoms were allowed for to account for hydrogen bonding between symmetry-related oxygen atoms.

CCDC-170697 (**1**), -170696 (**2**) and -170960 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Pressure Variations in Closed Sonochemical Reactors

Nicolas Segebarth*[a] and Jacques Reisse[a]

Keywords: Sonochemistry / Pressure / Gas effect / Water chemistry / Radicals

The pressure inside a closed sonochemical reactor evolves during sonication of a gas-saturated solution. The pressure evolution is dependent on the nature of the dissolved gas: after a common increase during the first 30 minutes, the pressure keeps increasing under argon, stays constant under dinitrogen and decreases under dioxygen and air. The reasons for these observed pressure variations and their implications on physico-sonochemical experiments are discussed in terms of gas solubility and gas reactivity of solutions submitted to intense pressure waves.

Introduction

Acoustic cavitation is the phenomenon by which intense ultrasonic waves induce the formation, oscillation, and implosion of gas bubbles in liquids. Chemical reactions (sonochemistry) and the emission of light (sonoluminescence) often accompany this process.[1] The light emission mechanism is due to the bubble interior achieving high temperatures and pressures during its quasi-adiabatic collapse.[2] These conditions also cause chemical reactions. For instance, in water, the bubble collapse leads to the homolysis of the water molecules into OH and H radicals and to the re-formation of water but also of H_2O_2 and H_2 after recombination of these radicals.[3]

Several studies on the influence of the hydrostatic pressure on sonochemistry and/or sonoluminescence have been published[3−7] and have shown the importance of this parameter. On the one hand, an increase of the pressure affects the bubble's dynamics, increasing, for instance, the cavitation threshold and the velocity of the bubble wall during the implosion.[6,7] On the other hand, a pressure increase affects indirectly the cavitation through a change of the acoustic impedance of the liquid, which itself induces changes in the transducer characteristics, including its resonance frequency.[4] Obviously, the concentration of the dissolved gas, which is known to have an effect on the chemical yields[8−10] of sonochemical reactions (whether they involve the dissolved gas or not) and which differs under sonication[11] from that predicted by Henry's law, is also a function of the gas partial pressure. Considering the broad range of parameters that depends on variations of the hydrostatic pressure above the sonicated solution, it was of interest to investigate the pressure evolution in a closed sonochemical reactor under sonication.

Results and Discussion

The typical evolution of the pressure in the closed sonochemical reactor during sonication of water saturated with air, argon, dinitrogen and dioxygen is represented in Figure 1. For each saturating gas, at least three experiments have been conducted and all show qualitatively the same evolution, although small differences of less than 5 mbar can be observed between two sets of data. Starting with an initial pressure equal to the atmospheric pressure, the same evolution is observed for the four gases during the first 30 minutes: a pressure increase of 10 to 15 mbar is observed. After this first phase (phase 1), and depending upon the gas, three different kinds of evolution are observed (phase

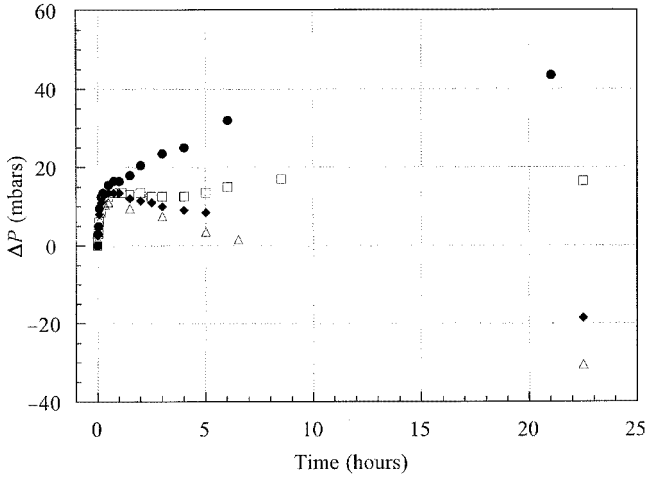

Figure 1. Evolution of the pressure in a closed reactor during sonication of water saturated with (●) argon, (□) N_2, (◆) O_2 and (△) air

2). Under argon, the pressure increases slowly during phase 2 (<1 mbar/hour) and experiments conducted over very long sonication times (> 70 hours) have not shown any plateau. When the experiment is conducted under dinitrogen, the pressure remains constant during phase 2. The evolution of the pressure under air is similar to that observed under dioxygen: phase 2 is characterized by a linear pressure decrease, at a rate of about 2 mbar/hour, leading to a reduction in pressure in the reactor.

Fluctuations in the temperature are insufficient to explain the observed pressure evolutions. Indeed, the experimental set-up (see Exp. Sect.) allows for a control of the temperature to within ±1 °C, in the liquid phase as well as in the gas phase, leading to pressure fluctuations in the reactor of a maximum of ±3.5 mbar, i.e. much smaller than the observed variations. Furthermore, the consistency observed between repeated experiments is incompatible with random temperature fluctuations.

The pressure increase during phase 1 is likely to be due to the well-known degassing effect of ultrasound: cavitation bubbles grow by rectified diffusion, pumping gas out of the liquid, and are pushed out of the liquid by buoyancy, leading to a lowering of the gas concentration in the solution.[11−15] In the case of open reactors, the resulting stationary gas concentration in the liquid is lower than that predicted by Henry's law. In our case, with a closed reactor, the decrease of the gas concentration in the solution will inevitably lead to an increase of the pressure in the gas phase.

In order to explain the differences that are observed during phase 2, it is necessary to resort to the chemical effects of ultrasound on water solutions of argon, dioxygen, dinitrogen and air. As the experimental set-up does not allow a continuous monitoring of the concentration of the different reaction products in the reactor, and as it is not possible to withdraw samples from it either, the discussion of the experimental results is based on the analysis of the final reaction products and also on what is known concerning the reactivity of water and water solutions when they are insonified.

In the case of dioxygen, the pressure decreases linearly during phase 2. This is due to the reactivity of dioxygen.[16] In addition to the sonochemical reactions that occur in cavitation bubbles filled with water vapour and an inert gas like argon (reactions 1−7), dioxygen-consuming reactions also take place (reaction 8−9).[3] This explains the linear pressure decrease that is observed as soon as a stationary concentration of dissolved dioxygen is reached, i.e. at the end of phase 1.

$$H_2O \rightarrow OH^{\cdot} + H^{\cdot} \quad (1)$$

$$H_2O \rightarrow H_2 + O \quad (2)$$

$$O + H_2O \rightarrow OH^{\cdot} + OH^{\cdot} \quad (3)$$

$$H^{\cdot} + H_2O \rightarrow H_2 + OH^{\cdot} \quad (4)$$

$$OH^{\cdot} + H^{\cdot} \rightarrow H_2O \quad (5)$$

$$OH^{\cdot} + OH^{\cdot} \rightarrow H_2O_2 \quad (6)$$

$$H^{\cdot} + H^{\cdot} \rightarrow H_2 \quad (7)$$

$$O_2 \rightarrow O + O \quad (8)$$

$$H^{\cdot} + O_2 \rightarrow OH^{\cdot} + O \quad (9)$$

In the case of argon, phase 2 is characterized by a weak pressure increase. As argon is inert, this increase probably reflects the production of H_2 (reactions 2 and 7) and, perhaps, the production of a small amount of dioxygen (reactions 10−12, or via another mechanism involving the dissociation of $HO_2^{\cdot}$ but leading to the same net result).[3]

$$OH^{\cdot} + H_2O_2 \rightarrow H_2O + HO_2^{\cdot} \quad (10)$$

$$OH^{\cdot} + HO_2^{\cdot} \rightarrow H_2O + O_2 \quad (11)$$

$$HO_2^{\cdot} + HO_2^{\cdot} \rightarrow H_2O_2 + O_2 \quad (12)$$

Dinitrogen is also usually considered as an inert gas, although this is usually not true in sonochemical reactions. As the dissociation energy of N_2 ($\Delta H_{D,N_2}$ = 944 kJ/mol) is much higher than that of O_2 ($\Delta H_{D,O_2}$ = 496 kJ/mol), thermal dissociation in the cavitation bubbles is not expected to be important. However, N_2 is reactive towards the products of the sonolysis of water, O and $OH^{\cdot}$. Indeed, dinitrogen is oxidised through a series of reactions to form eventually NO_2^- and NO_3^-.[17−19] The presence of nitrogen oxides in the solution at the end of the sonication was confirmed by the observation of strong absorption bands in the UV spectrum. The reactivity of N_2 towards O also explains why the pressure evolution under air, although composed of 80% N_2, is similar to the evolution under O_2. The increase of the concentration of the oxygen atoms, from thermal dissociation of the dioxygen present in air, will strongly favour the consumption of N_2, compared to a situation where the only oxygen atoms come from water sonolysis.

As pointed out earlier, the degassing effect of ultrasound leads to a gas stationary concentration lower than that predicted by Henry's law. The value of this stationary concentration is gas- and solvent-dependant and is generally situated between 60% and 90% of the saturation concentration.[11−15] Using Henry's law ($k_{H,Ar}$ = 714 atm/M) and the perfect gas law, it is easy to calculate the total amount of argon in the reactor and then to estimate its stationary concentration in the solution under sonication. The result of this calculation shows that the concentration of argon decreases to about 30% of the concentration predicted by Henry's law. In the case of air, the measure of [O_2] in water has shown that the concentration drops from 8.5 mg/L to 3.5 mg/L while the pressure drops from 1015 to 987 mbar (corresponding to an O_2 consumption of approximately 1 μmol/h, which is typical for a sonochemical reaction rate). Similar calculations, with the hypothesis that the ratio N_2/O_2 remains constant throughout sonication, lead to the conclusion that the stationary concentration of O_2 in sonicated water is only 40% of the equilibrium concentration, in the absence of sonication. In both cases, the stationary concentration under sonication is therefore significantly lower than what has been measured previously.

Conclusion

We have shown that the pressure inside a closed sonochemical reactor evolves during sonication and that the evolution is gas dependant. The differences that have been observed result from phenomena already described in the literature, namely the degassing effect of ultrasound and the reactivity of any gas other than the rare gases inside the cavitation bubbles.

These pressure variations, although relatively weak, might have a non-negligible impact on some sonochemical studies performed in closed reactors. For instance, in the case of studies in the literature concerning gas effects, it is common to find differences which are fairly small and which, generally, are never explained by pressure effects.[20,21] In this work we have shown that, starting from the same initial pressure, differences of 70 mbar can exist between a sonochemical experiment conducted under argon and the same sonochemical experiment conducted under air. In a similar manner, von Sonntag has shown that a pressure change above a water solution can modify the sonochemical yields of H_2O_2 production by up to 20%.[3] Under these conditions, if the pressure inside the reactor has not been carefully measured as a function of time, how can one assess what are, and in which proportions, the real causes for a gas effect: the gas itself, the hydrostatic pressure or, for instance, the gas concentration?

Experimental Section

General Remarks: The experiments were conducted in an Undatim Ultrasonics D-Reactor operating at 518 kHz, at a power, estimated by calorimetry, of 17 Watts. The hermetically closed reactor had a gas inlet and a gas outlet (equipped with a precision valve) and was connected to an Eirelec manometer (model MP 340A), allowing precise measurement (±1 mbar) of the reactor's internal pressure. The reactor was also equipped with a cooling jacket in order to keep the temperature constant at 23 ± 1 °C. All experiments were performed in a thermostatted room at 23 ± 1 °C, assuring the control of the gas phase temperature above the solution. The hermeticity of the reactor was tested by checking that a pressure of 1200 mbar could be maintained for 48 hours.

The experiments were conducted under air, argon (Air Liquide, N57), dinitrogen (Messer, 4.0) and dioxygen (Air Liquide, N48). The "Milli-Q" water was saturated with gas by bubbling the gas through it for 2 hours. It was then transferred into the reactor (under gas flux) and a second bubbling of 30 minutes was performed. Closing the reactor resulted in an overpressure that was adjusted, with the precision valve, to 1015 mbar. The water volume was 100 mL while the gas-phase volume was 165 mL. The concentration of dioxygen was measured with an Oxi 323-A/Set WTW Oxymeter.

1,1,1-Trisborylalkanes as Precursors for Dicarbapentaboranes(5) − Synthesis, Reactivity, and Structures of *closo*-1,5-Bis(neopentyl)-2,3,4-trichloro-1,5-dicarbapentaborane and Its Derivatives

Michael J. Bayer,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

Dedicated to Prof. Armin Berndt on the occasion of his 65th birthday

Keywords: Alkynes / Boranes / Boron / Catechol / Hydroboration

The treatment of 3,3-dimethyl-1-butynyllithium with boron trichloride followed by double hydroboration with $HBCl_2$ afforded 1,1,1-tris(dichloroboryl)-3,3-dimethylbutane (**1a**), characterized as its catechol derivative **1b**. Analogously, three isomers (**3a**, **4a**, and **5a**) were obtained with trimethylsilylacetylide and identified as catechol derivatives **3b**, **4b**, and **5b**. On heating, **1a** formed 2,3,4-trichloro-1,5-dicarba-*closo*-pentaborane(5) (**6a**) with elimination of boron trichloride. Compound **6a** reacted with methyllithium and trimethylaluminium, and also with pentamethylsilazane and acetylides, to give the corresponding carborane derivatives **6c**, **6d**, **6e**, and **6f**. The compositions of the products followed from analytical data and X-ray structure analyses of **1b**, **4b**, **5b**, **6a**, and **6f**.

Introduction

The first synthesis of triborylmethane derivatives was reported in 1968, by Matteson and Castle,[1,2] who obtained methanetriboronic esters by treatment of dimethoxychloroborane and carbon tetrachloride with lithium in tetrahydrofuran. Subsequently, tris(dichloroboryl)methane was synthesized.[3] Köster et al.[4] described the preparation of pentaalkyl-1,5-dicarba-*closo*-pentaboranes(5) by hydroboration of dialkyl(1-alkynyl)boranes $R_2BC{\equiv}CR^1$ with tetraalkyldiboranes $(R_2BH)_2$. They obtained 1,1-bis(dialkylboryl)-1-alkenes, although detection of 1,1,1-tris(dialkylboryl)alkanes as precursors for the carboranes was unsuccessful.[4] In 1995 a new route to pentaethyl-1,5-dicarba-*closo*-pentaborane(5) was established, through the use of a large excess of $(Et_2BH)_2$ as a "hydride bath" to give a 1-carba-*arachno*-pentaborane(10) derivative[5] as precursor.[6] Its formation most probably occurred through [BH]-catalyzed condensation of two molecules of undetectable 1,1,1-tris(diethylboryl)propane.[6]

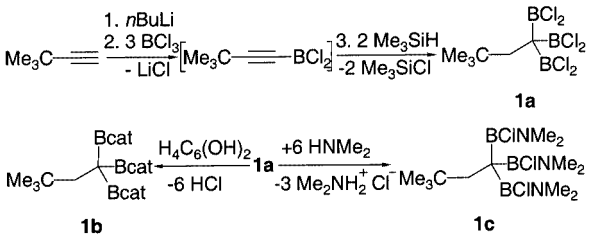
The *closo*-C_2B_3-carboranes warrant particular interest because their structure and bonding may be described as midway between classical and nonclassical. In the last decade, the structures of these smallest *closo*-carboranes have been elucidated by X-ray diffraction analyses of amino-substituted derivatives[7,8] and pentaethyl-1,5-dicarba-*closo*-pentaborane(5),[6,9] by electron density distribution,[9] and by ab initio computations.[10]

We report here on the synthesis and the characterization of 1,1,1-tris(dichloroboryl)-3,3-dimethylbutane and its transformation into 2,3,4-trichloro-1,5-dicarba-*closo*-pentaborane(5) (**6a**). Substitution reactions of **6a** and the syntheses of other tris(dichloroboryl)alkanes are also described.

Results and Discussion

1,1,1-Tris(dichloroboryl)-3,3-dimethylbutane (1a)

The synthesis of **1a** started with lithiation of 3,3-dimethyl-1-butyne by *n*-butyllithium, followed by boron/metal exchange with BCl_3 and a double hydroboration of the boryl alkyne with dichloroborane prepared in situ[11] (Scheme 1). This reaction sequence afforded a 42% yield of **1a**, a colorless and extremely air- and moisture-sensitive liquid. Its ^{11}B NMR spectrum showed a signal at $\delta = 58.7$,



Scheme 1

[a] Anorganisch-Chemisches Institut der Universität Heidelberg, Im Neuenheimer Feld 270, 69120 Heidelberg, Germany
Fax: (internat.) +49-(0)6221-545-609
E-mail: ci5@ix.urz.uni-heidelberg.de

and in the ^{1}H NMR spectrum signals for the *tert*-butyl group (δ = 0.94) and the methylene group (δ = 2.77) were observed. The ^{13}C NMR spectrum exhibited four resonances: at δ = 31.9 (CH_3), 33.8 (CMe_3), 55.2 (CH_2), and 59 (broad, CB_3). A NICI mass spectrum showed the molecular ion peak [M^+] at *m*/*z* = 328 as the base peak.

On treatment of **1a** with three equivalents of catechol in dichloromethane at −78 °C, compound **1b** was synthesized in 95% yield (Scheme 1). Compound **1b** is a colorless solid, soluble in dichloromethane, toluene, and THF. Its composition was determined by NMR spectroscopy, MS spectrometry, and an X-ray structure analysis, single crystals of **1b** being grown from a solution in dichloromethane at room temperature. The molecular structure of **1b** in the crystal is shown in Figure 1. The heterocycles are planar and the boron-bound carbon atom C1 is almost tetrahedral. For all distances and bonding angles, no significant differences from those in similar compounds[12] are observed.

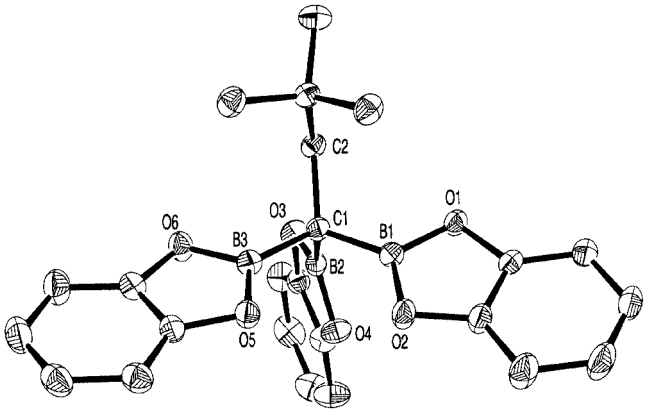


Figure 1. Molecular structure of **1b** in the crystal; selected bond lengths [Å] and angles [°]: B1-C1 1.569(2), B2−C1 1.573(2), B3−C1 1.575(2), B1−O1 1.395(1), B1−O2 1.383(1), B2−O3 1.386(1), B2−O4 1.388 (1), B3−O5 1.388(1), B3−O6 1.391(1), C1−C2 1.570(1), B1−C1−B2 103.51(8), B2−C1−B3 102.44(9), B1−C1−B3 114.79(9), B1−C1−C2 113.27(9), B2−C1−C2 108.72(8), B3−C1−C2 112.86(9)

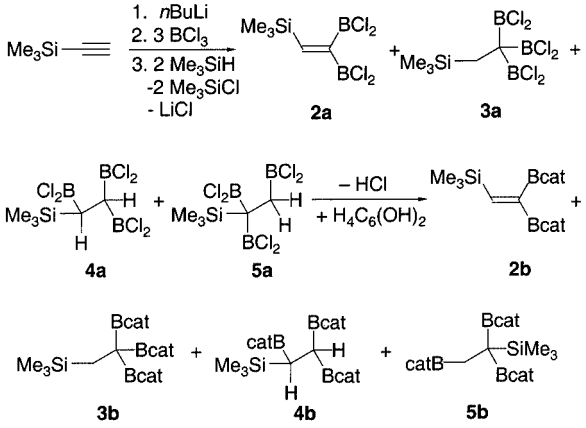
To obtain information on its reactivity, **1a** was treated with six equivalents of dimethylamine to form **1c** as a colorless, viscous liquid in 88% yield (Scheme 1). Its ^{11}B NMR spectrum showed a signal at δ = 38.5, confirming that each boryl group had one dimethylamino and one chlorine substituent. In the ^{1}H and ^{13}C NMR spectra, the signals of the *tert*-butyl group, the dimethylamino groups, and the methylene group were found in the expected regions. As in **1a** and **1b**, the resonance of the quaternary CB_3 carbon atom was broad (δ = 42). The EI mass spectrum of **1c** exhibited the molecular ion peak [M^+] at *m*/*z* = 353.

1,1-Bis(dichloroboryl)-2-trimethylsilylethene (2a), 1,1,1-Tris(dichloroboryl)-2-trimethylsilylethane (3a), 1,1,2-Tris(dichloroboryl)-2-trimethylsilylethane (4a), and 1,1,2-Tris(dichloroboryl)-1-trimethylsilylethane (5a)

Treatment of trimethylsilylacetylene with *n*-butyllithium, BCl_3, and two equivalents of $HBCl_2$ in the same manner as described above provided isomeric products (Scheme 2). On distillation of the reaction mixture, two fractions were obtained, these containing 1,1-bis(dichloroboryl)-2-trimethylsilylethene (**2a**), and a mixture of **3a**, **4a**, and **5a**.



Scheme 2

The ^{11}B NMR spectrum of **2a** showed signals at δ = 57.4 and 60.5, indicating two inequivalent boron atoms, while the ^{29}Si NMR spectrum exhibited a signal at δ = −3.2, in the range for trimethylalkenylsilanes.[13] In the ^{1}H NMR spectrum, the signals for the $SiMe_3$ group and the olefinic proton were detectable at δ = 0.22 and 7.12, respectively. The EI mass spectrum of **2a** showed the molecular ion peak [M^+] at *m*/*z* = 260. Treatment of **2a** with catechol gave the corresponding catechol derivative **2b** in 85% yield, and this was characterized by ^{1}H and ^{11}B NMR spectroscopy and EI mass spectrometry. The NMR spectroscopic data of the second fraction could not be interpreted; its ^{29}Si NMR spectrum indicated the presence of three saturated compounds. However, the NICI mass spectrum showed only one molecular ion peak [M^+] at *m*/*z* = 342, indicating the presence of constitutional isomers. In order to obtain evidence regarding the product mixture and to characterize the components, the mixture was treated with an excess of catechol. The NMR spectroscopic data of the catechol derivatives indicated the presence of **3b**, **4b**, and **5b** in the ratio 15:8.5:1. In the EI mass spectrum, the molecular ion peak [M^+] of the isomers **3b**, **4b**, and **5b** was found at *m*/*z* = 456.

Crystals of compounds **4b** and **5b** suitable for X-ray structure analysis were obtained from solutions of the catecholboryl isomers in dichloromethane at 4 °C. The structures are shown in Figure 2 and 3, respectively. All bond lengths and angles are normal, and the coordination of the boron atoms is almost trigonal planar.

For the formation of three isomeric compounds **3a**, **4a**, and **5a**, we propose the following mechanism. In the first step, hydroboration of [$Me_3Si-C\equiv C-BCl_2$] occurs regioselectively to give product **2a**. $HBCl_2$ then hydroborates **2a** in both directions, giving rise to the compounds **3a** and **4a**, with the former being favored. Moreover, the trimethylsilyl group has the tendency to migrate,[14] and the trimethylsilyl and one dichloroboryl group in **3a** change their positions, with formation of **5a** (Scheme 3).

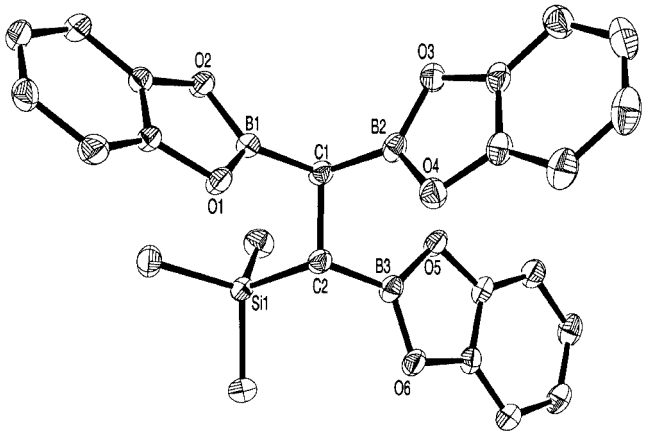


Figure 2. Molecular structure of **4b** in the crystal; selected bond lengths [Å] and angles [°]: B1−C1 1.564(3), B2−C1 1.560(3), B3−C2 1.548(3), B1−O1 1.388(3), B1−O2 1.392(2), B2−O3 1.391(3), B2−O4 1.393(3), B3−O5 1.395(3), B3−O6 1.393(3), C1−C2 1.579(3), C2−Si1 1.913(2), B1−C1−B2 109.5(2), B3−C2−C1 113.1(2), B1−C1−C2 111.8(2), B2−C1−C2 111.1(2), C1−C2−Si1 112.37(13), B3−C2−Si1 106.10(14)

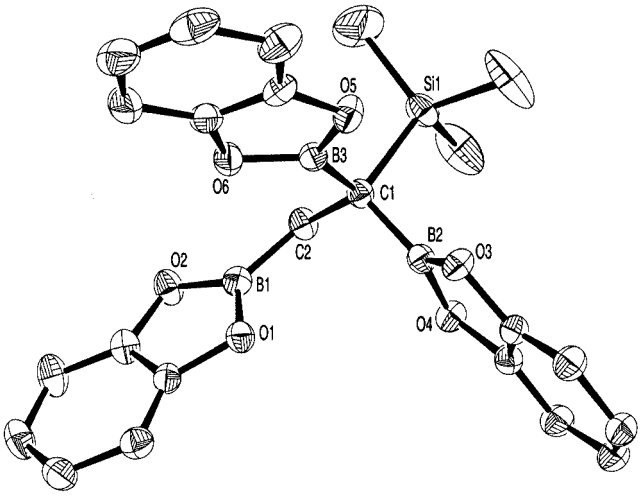

Figure 3. Molecular structure of **5b** in the crystal; selected bond lengths [Å] and angles [°]: B1−C2 1.555(3), B2−C1 1.556(3), B3−C1 1.551(3), B1−O1 1.388(3), B1−O2 1.383(2), B2−O3 1.392(2), B2−O4 1.395(2), B3−O5 1.391(2), B3−O6 1.389(2), C1−C2 1.566(2), C1−Si1 1.925(2), B2−C1−B3 110.98(15), B2−C1−C2 112.88(15), B3−C1−C2 111.30(15), B1−C2−C1 115.75(15), B2−C1−Si1 105.89(12), B3−C1−Si1 108.18(12)

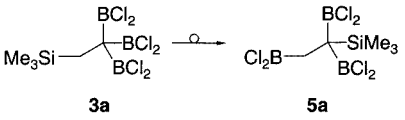
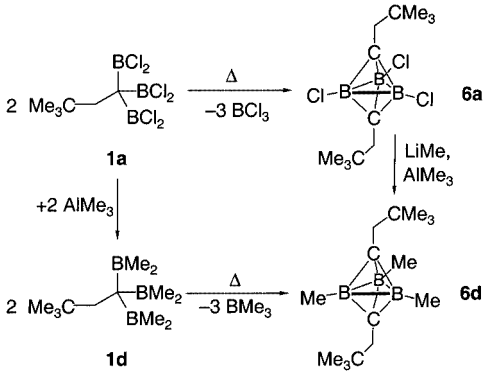


Scheme 3

2,3,4-Trichloro-1,5-dicarba-*closo*-pentaborane(5) (6a) and Its Substitution

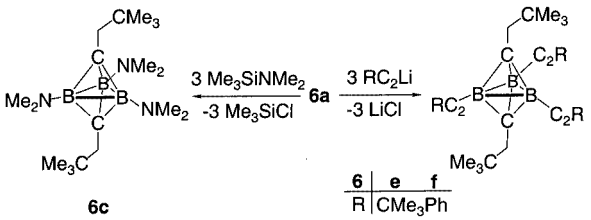
On heating neat **1a** at 170 °C for two hours, elimination of BCl_3 occurred with formation of the *closo*-C_2B_3 carborane **6a**, which was obtained by distillation as a colorless, air-sensitive solid in 25% yield (Scheme 4). A signal at δ = 22.1 in its ^{11}B NMR spectrum supported the carborane structure. The ^1H NMR spectrum showed two singlets for the methyl and the methylene protons, at δ = 1.02 and 2.09, respectively, and the ^{13}C NMR spectrum exhibited four signals for CH_3 (δ = 29.7), the quaternary carbon atom (δ = 31.6), CH_2 (δ = 38.5), and the apical carbon atoms of the cluster (δ = 94, br.). The highest peak observed in an EI mass spectrum of **6a** was found at *m*/*z* = 289 [$M^+ - CH_3$], but the PICI mass spectrum showed [M^+] at *m*/*z* = 303 as the base peak. The composition of **6a** was confirmed by an X-ray structure analysis. The trimethyl derivative **6d** may be obtained by two routes (Scheme 4). Firstly, methylation of **1a** gave **1d**, which on heating was transformed into **6d** with elimination of trimethylborane. Compound **1d** was characterized by ^1H, ^{11}B and ^{13}C NMR spectroscopy and by PICI mass spectrometry.



Scheme 4

The second route is of general interest, because **6d** was formed by direct methylation of **6a** with MeLi or $AlMe_3$ at low temperature. Substitution reactions of *closo*-C_2B_3 carboranes have not previously been investigated. In general, substitution reactions at boron atoms in carboranes are difficult[15] and not as developed as those at carbon atoms. The first successes were achieved with *closo*-C_2B_{10} carboranes.[15,16] The ^{11}B NMR signal for **6d** was shifted to higher field (δ = 17.3) relative to that of **6a**. In the ^1H NMR spectrum, the expected signals for *tert*-butyl (δ = 0.99) and the methylene group (δ = 2.17) were observed, whilst the signal of the methyl group at boron was located at δ = 1.23. The ^{13}C NMR spectrum exhibited the resonances of the *tert*-butyl substituent at δ = 29.7 for the methyl groups and at δ = 31.6 for the quaternary carbon atom. The signal of the methylene carbon atom appeared at δ = 39.6, while the signal for the methylboron group was broad at δ = 14. No signal was found for the apical carbon atoms. An EI mass spectrum of **6d** showed the molecular ion peak [M^+] at *m*/*z* = 244. When **6a** was treated with pentamethylsilazane at −30 °C (Scheme 5), colorless **6c** was formed as a solid in good yields. Its ^{11}B NMR spectrum showed a signal at δ = 21.3, in agreement with the reported[7,8] amino-substituted *closo*-$(RC)_2(BN\mathit{i}Pr_2)_3$. In the ^1H and ^{13}C NMR spectra, the expected signals for the *tert*-butyl, dimethylamino, and methylene groups were found, although no resonance was detected for the quaternary CB_3 carbon atom. The EI mass

spectrum of **6c** showed the molecular ion peak [M^+] at *m*/*z* = 331.



Scheme 5

Treatment of **6a** with 3,3-dimethyl-1-butynyllithium and 2-phenylethynyllithium afforded **6e** and **6f**, respectively (Scheme 5). Compound **6e** is a colorless solid and **6f** a yellow solid. Their compositions were determined by NMR spectroscopy, MS spectrometry, and X-ray structure analysis.

With sterically demanding lithium reagents (*t*BuLi, LiN*i*Pr$_2$, *n*BuLi, PhLi), only product mixtures were obtained. NMR spectroscopic and MS spectrometric data indicated the presence of the expected products; isolation of them failed, however. Attempts to substitute the chloro atoms with OH, OMe, O*t*Bu, and catechol were unsuccessful. In all cases the ^{11}B NMR spectra showed low-field signals at about δ = 32, indicating the decomposition of the carborane framework and the formation of dialkoxyboranes.

Discussion of the Structure of 6

The structure of **6a** was obtained by performing a single-crystal X-ray analysis. Colorless crystals of **6a** were grown from a solution in pentane at 4 °C; its molecular structure is shown in Figure 4. In the C_2B_3 framework, the B−B [1.842(3)−1.855(3) Å] and B−C distances [1.541(3)−1.586(3) Å] are in the range of the corresponding values for the parent *closo*-$C_2B_3H_5$, determined by electron diffraction.[17] The B−B bond lengths are substantially shorter than the structure data [1.965(8) Å] published by Meller et al.,[7,8] who classified their molecules as bicycles. The B−B distances in **6a** are somewhat shorter than those in the carborane $C_2B_3Et_5$ reported by Köster et al.[6] [1.876(4) Å]. Nevertheless, the B−B bond in **6a** is long and the B−C bond short in comparison with data relating to octahedral carboranes [B−B: 1.72 Å, C−B: 1.62 Å in 1,6-$C_2B_4H_6$].[17] The C_2B_3 carborane may be described as a classically bonded structure in which the trigonal bipyramid is bonded through 2c,2e C−B bonds, but involves no strong B−B overlap.[17,18] This was confirmed by measurements of the electron density distribution of the *closo*-cluster $C_2B_3Et_5$, which gave no electron density in the B−B−B plane of the molecule;[9] electron density was, however, found above each triangular CB_2 face. This indicates that the contribution of nonclassical multicenter bonds is as important as that of the conventional 2c,2e bonds.[9]

As far as the X-ray data are concerned, the classification of the C_2B_3 framework is ambiguous. In the light of ^{11}B NMR spectra of several dialkylchloroboranes in cyclic or

Figure 4. Figure 5. Molecular structure of **6f** in the crystal; selected bond lengths [Å] and angles [°]: C1−B1 1.536(3), C1−B2 1.567(3), C1−B3 1.594(3), C2−B1 1.596(3), C2−B2 1.557(3), C2−B3 1.539(3), B1−B2 1.855(3), B1−B3 1.852(3), B2−B3 1.849(3), B1−C13 1.511(3), B2−C21 1.508(3), B3−C29 1.509(3), C13−C14 1.208(3), C21−C22 1.206(3), C29−C30 1.206(3), C1−B1−C2 93.7(2), C1−B2−C2 94.1(2), C1−B3−C2 93.7(2), B2−B1−B3 59.83(12), B1−B2−B3 59.99(13), B1−B3−B2 60.19(13), B1−C1−B2 73.4(2), B1−C1−B3 72.5(2), B2−C1−B3 71.6(2), B1−C2−B2 72.1(2), B1−C2−B3 72.4(2), B2−C2−B3 73.3(2)

acyclic organoboranes, one would expect a signal at about δ = 74 for **6a** as a bicycle.[19] In fact, the resonance for **6a** is at higher field (δ = 22.1), which is compatible with a nonclassical description of the bonding situation and supports the carborane character of **6a**.

Crystals of compounds **6e** and **6f** suitable for X-ray structure analyses were obtained from toluene at 4 °C. As **6e** is disordered in the crystal, only the structure of **6f** is discussed here, because of its better crystallographic data. The molecular structure is shown in Figure 5. The B−B [1.848(3)−1.855(3) Å] and B−C [1.536(3)−1.596(3) Å] distances are in the same range as those in the chloro-substituted compound **6a**. As no elongations of the B−B bond lengths relative to those in **6a** are observed and the ^{11}B NMR spectra of **6e** and **6f** showed signals at δ = 11.4 (expected resonances for dialkylalkynylboranes lie at about δ = 72[20]) both compounds are regarded as carboranes.

Conclusion

In this paper we report on the treatment of alkynyllithium with boron trichloride, followed by double hydroboration with $HBCl_2$. 3,3-Dimethyl-1-butynyllithium as starting material afforded 1,1,1-tris(dichloroboryl)-3,3-dimethylbutane (**1a**), which was transformed into the chloro-substituted 1,5-dicarba-*closo*-pentaborane(5) **6a**. Furthermore, it was shown that substitution reactions at **6a** occurred in good yields. Substitution of **6a** with small groups (methyl in **6d**, dimethylamino in **6c**, or rod-like acetylides in **6e** and **6f**) was successful, while bulky substituents produced inseparable product mixtures of unknown composition. Treatment with oxygen-containing reagents decomposed the carborane framework. In the case of lithium trimethylsilylacetylide as starting material, a mixture of three constitutional isomers was formed.

Experimental Section

General: Reactions were carried out under dry argon or nitrogen, by standard Schlenk techniques. Solvents were dried, distilled, and saturated with nitrogen. Glassware was dried with a heat gun under high vacuum. ^1H, ^{11}B, and ^{13}C NMR: Bruker DRX 200 spectrometer, $Et_2O{\cdot}BF_3$ was used as the external standard for ^{11}B NMR. The signals of the deuterated solvents were used as internal references for ^1H and ^{13}C NMR spectra, and calculated relative to TMS. The mass spectra were measured on a ZAB-2F VH Micromass CTD spectrometer (EI and HR-EI techniques) and on a Jeol MS station JMS 700 (NICI, PICI, EI, and HR-EI techniques). Melting points (uncorrected) were measured with a Büchi apparatus in capillaries that were filled under argon or nitrogen, and sealed.

1,1,1-Tris(dichloroboryl)-3,3-dimethylbutane (1a): 3,3-Dimethyl-1-butyne (8.22 g, 0.1 mol) was added at −15 °C to a solution of *n*BuLi (0.1 mol) in 230 mL of pentane. The mixture was allowed to warm to room temp. and stirred for 2 h. The suspension was then cooled to −78 °C and added at −78 °C to a solution of BCl_3 (37.5 g, 0.32 mol) in 50 mL of pentane. After the mixture had stirred for 1 h, a solution of Me_3SiH (14.9 g, 0.2 mol) in 20 mL of pentane was added over 30 min from a dropping funnel cooled to − 30 °C. The reaction mixture was allowed to warm slowly to room temp. and was stirred for 10 h. After separation of the solution from the precipitate, the solvent was evaporated and the residue was distilled at 63 °C/0.057 mbar to yield **1a** (13.67 g, 41.6% yield) as a colorless and extremely air-sensitive liquid. ^1H NMR ($CDCl_3$, 200 MHz): δ = 0.94 [s, 9 H, $C(CH_3)_3$], 2.77 (s, 2 H, CH_2). ^{11}B NMR ($CDCl_3$, 64 MHz): δ = 58.7. ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 31.9 [$C(CH_3)_3$], 33.8 [$C(CH_3)_3$], 55.2 (CH_2), 59 [br., $C(BCl_2)_3$]. EI-MS: *m*/*z* (%) = 313 (1) [$M^+ - CH_3$], 246 (1) [$M^+ - BCl_2$], 231 (4) [$M^+ - CH_3 - BCl_2$], 195 (1) [$M^+ - CH_3 - BCl_2 - HCl$], 128 (15) [$M^+ - 2BCl_2 - HCl$], 115 (51) [$M^+ - 2BCl_2 - HCl - CH_3$], 81 (63) [$BCl_2^+$], 57 (100) [$C_4H_9^+$], 41 (62) [$C_3H_5^+$]. NICI-MS: *m*/*z* (%) = 328 (100) [M^+].

1,1,1-Tris(catecholboryl)-3,3-dimethylbutane (1b): Catechol (660 mg, 6 mmol) was dissolved in CH_2Cl_2 (40 mL), and the solution was cooled to −60 °C. Compound **1a** (660 mg, 2 mmol) was then added dropwise to the reaction mixture, and the solution was allowed to warm to room temp. The CH_2Cl_2 was removed under vacuum to give colorless **1b** (840 mg, 95.0%, m.p. 163 °C). ^1H NMR ($CDCl_3$, 200 MHz): δ = 0.83 [s, 9 H, $C(CH_3)_3$], 2.62 (s, 2 H, CH_2), 7.03−7.27 (m, 12 H, C_6H_4). ^{11}B NMR ($CDCl_3$, 64 MHz): δ = 34.7. ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 30.0 [$C(CH_3)_3$], 32.6 [$C(CH_3)_3$], 43.3 (CH_2), 112.7, 122.7, 148.2 (C_6H_4). EI-MS: *m*/*z* (%) = 440 (21) [M^+], 425 (5) [$M^+ - CH_3$], 383 (42) [$M^+ - C_4H_9$], 320 (4) [$M^+ - C_6H_4O_2BH$], 305 (1) [$M^+ - CH_3 - C_6H_4O_2BH$], 120 (4) [$C_6H_4O_2BH^+$], 57 (100) [$C_4H_9^+$]. HR-MS (EI): *m*/*z* = 440.1797 [M^+]; calcd. for $^{12}C_{24}{}^1H_{23}{}^{11}B_3{}^{16}O_6$: 440.1820 (Δ = 2.3 mmu).

1,1,1-Tris[chloro(dimethylamino)boryl]-3,3-dimethylbutane (1c): Compound **1a** (2.38 g, 7.25 mmol) was added to a solution of dimethylamine (1.96 g, 43.5 mmol) in 40 mL of hexane at −60 °C. The mixture was allowed to warm to room temp., the solution was separated from the precipitate, the solvent was evaporated, and the colorless oil **1c** was dried under vacuum. Yield: 2.27 g (88.4%). ^1H NMR ($CDCl_3$, 200 MHz): δ = 0.93 [s, 9 H, $C(CH_3)_3$], 2.20 (s, 2 H, CH_2), 2.86 [s, 9 H, $N(CH_3)_2$], 2.87 [s, 9 H, $N(CH_3)_2$]. ^{11}B NMR ($CDCl_3$, 64 MHz): δ = 38.5. ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 31.0 [$C(CH_3)_3$], 33.0 [$C(CH_3)_3$], 40.0, 40.6 [$N(CH_3)_2$], 42 (br., CB_3), 48.3 (CH_2). EI-MS: *m*/*z* (%) = 353 (2) [M^+], 296 (10) [$M^+ - C_4H_9$], 262 (2) [$M^+ - HBClN(CH_3)_2$], 251 (4) [$M^+ - C_4H_9 - HN(CH_3)_2$], 228 (11) [$M^+ - BClN(CH_3)_2 - Cl$], 207 (9) [$M^+ - C_4H_8 - BClN(CH_3)_2$], 171 (100) [$M^+ - 2HBClN(CH_3)_2$], 90 (61) [$BClN(CH_3)_2^+$], 57 (48) [$C_4H_9^+$]. 2,3,4-Trichloro-1,5-dicarba-*closo*-pentaborane(5) (6a): Neat **1a** (5.30 g, 11.8 mmol) was heated for 2 h at 170 °C and elimination of BCl_3 was observed. The brown product mixture was distilled at 54 °C/0.02 mbar to give colorless, air-sensitive **6a** (606 mg, 24.6%), m.p. 61 °C. ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.02 [s, 9 H, $C(CH_3)_3$], 2.09 (s, 2 H, CH_2). ^{11}B NMR ($CDCl_3$, 64 MHz): δ = 22.1. ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 29.7 [$C(CH_3)_3$], 31.6 [$C(CH_3)_3$], 38.5 (CH_2), 94 (br., CB_3). EI-MS: *m*/*z* (%) = 289 (87) [$M^+ - CH_3$], 247 (21) [$M^+ - C_4H_9$], 57 (100) [$C_4H_9{}^+$]. PICI-MS: *m*/*z* (%) = 303 (100) [$M^+ - H$], 289 (11) [$M^+ - CH_3$], 261 (5) [$M^+ - C_3H_7{}^+$]. HR-MS (EI): *m*/*z* = 304.1034 [M^+]; calcd. for $^{12}C_{12}{}^1H_{22}{}^{11}B_3{}^{35}Cl_3$: 304.1001 ($\Delta$ = 3.3 mmu).

2,3,4-Tris(dimethylamino)-1,5-dicarba-*closo*-pentaborane(5) (6c): Pentamethylsilazane (310 mg, 2.20 mmol) was added at −30 °C to a solution of **6a** (224 mg, 0.73 mmol) in 15 mL of pentane. The solution was allowed to warm to room temp. and after 4 h stirring all volatile components were removed. Compound **6c** was obtained as a colorless oil. Yield: 193 mg (79.4%). ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 1.00 [s, 18 H, $C(CH_3)_3$], 2.16 (s, 4 H, CH_2), 2.77 [s, 18 H, $N(CH_3)_2$]. ^{11}B NMR ($CDCl_3$, 64 MHz): δ = 21.3. ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 32.1 [$C(CH_3)_3$], 34.9 [$C(CH_3)_3$], 38.9 (CH_2), 42.5 [$N(CH_3)_2$]. EI-MS: *m*/*z* (%) = 331 (45) [M^+], 316 (1) [$M^+ - CH_3$], 260 (1) [$M^+ - C_5H_{11}$], 57 (100) [$C_4H_9{}^+$], 44 (73) [$N(CH_3)_2{}^+$]. HR-MS (EI): *m*/*z* = 331.3499 [M^+]; calcd. for $^{12}C_{18}{}^1H_{40}{}^{11}B_3{}^{14}N_3$: 331.3497 ($\Delta$ = 0.2 mmu).

2,3,4-Trimethyl-1,5-dicarba-*closo*-pentaborane(5) (6d):
a) Compound **1d** (500 mg, 2.43 mmol) was dissolved in 5 mL of toluene, and this was heated under reflux for 2 h. The solvent and volatile compounds were removed under vacuum to yield a brown, viscous residue, consisting of **6d** and some by-products.
b) Compound **6a** (124 mg, 0.4 mmol) was dissolved in 10 mL of hexane and treated at −78 °C with a solution of $AlMe_3$ (0.4 mL, 4 mmol) in 5 mL of hexane. The reaction mixture was allowed to warm slowly to room temp. After filtration of a solid, the solvent was removed and **6d** was dried under vacuum to afford a pale yellow, viscous oil. Yield: 71 mg (71.6%).

c) Compound **6a** (170 mg, 0.56 mmol) was dissolved in 15 mL of diethyl ether and treated at −70 °C with a solution of methyllithium in diethyl ether (1.6 M, 1.1 mL, 1.7 mmol). The reaction mixture was allowed to warm slowly to room temp. After the solution had been separated from the precipitate, the solvent was removed and the pale yellow, viscous oil **6d** was dried under vacuum. Yield: 101 mg (74.3%). ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 0.99 [s, 18 H, $C(CH_3)_3$], 1.23 (s, 9 H, BCH_3), 2.17 (s, 4 H, CH_2). ^{11}B NMR ($CDCl_3$, 64 MHz): δ = 17.3. ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 14.1 (BCH_3), 29.7 [$C(CH_3)_3$], 31.6 [$C(CH_3)_3$], 39.6 (CH_2). EI-MS: *m*/*z* (%) = 244 (7) [M^+], 229 (7) [$M^+ - CH_3$], 187 (17) [$M^+ - C_4H_9$], 173 (8) [$M^+ - C_5H_{11}$], 131 (23) [$M^+ - C_4H_9 - C_4H_8$], 57 (100) [$C_4H_9{}^+$], 41 (80) [$C_3H_5{}^+$]. HR-MS (EI): *m*/*z* = 244.2715 [M^+]; calcd. for $^{12}C_{15}{}^1H_{31}{}^{11}B_3$: 244.2725 ($\Delta$ = 1.0 mmu).

2,3,4-Tris(3,3-dimethyl-1-butynyl)-1,5-dicarba-*closo*-pentaborane(5) (6e): 3,3-Dimethyl-1-butyne (172 mg, 2 mmol) was added at −15 °C to a solution of *n*BuLi (2 mmol) in 20 mL of hexane. The mixture was allowed to warm to room temp. and stirred for 30 min. The suspension was then cooled to −78 °C and added to a solution of **6a** (212 mg, 0.69 mmol) in 5 mL of hexane. The reaction mixture was allowed to warm slowly to room temp. After the solution had been separated from the precipitate, the solvent was removed, and the yellow, solid **6e** was dried under vacuum. Yield: 236 mg

Crystal Structure Determinations of 1b, 4b, 5b, 6a, and 6f: A summary of the crystal data and details of the structure determinations is given in Table 1. Data were collected on a Bruker AXS Smart 1000 area detector (Mo-K_α radiation, λ = 0.71073 Å, ω-scans) at low temperature. Data were corrected for Lorentz polarisation and absorption effects (semiempirical, SADABS[21]). The structures were solved by direct methods and refined by full-matrix, least-squares methods based on F^2 (SHELXTL).[22] Non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were located in difference Fourier syntheses and refined with isotropic displacement parameters [with the exception of the methyl groups in **5b** and those at the disordered $CH_2C(CH_3)_3$ group in **6a**, which were inserted in calculated positions and refined using a riding model].

CCDC-175653 (**1b**), -175654 (**4b**), -175655 (**5b**), -175656 (**6a**) and -175656 (**6f**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Dinuclear Triple-Stranded Helicates from Rigid Oligo-*p*-phenylene Ligands: Self-Assembly and Ligand Self-Recognition

Markus Albrecht*[a] and Matthias Schneider[a]

Keywords: Catechol / Titanium / Self-assembly / Helical structures / Molecular recognition

The rigid rod oligo-*p*-phenylene type dicatechol ligands **1-3**-H_4 form dinuclear triple-stranded helicates $M_4[(\mathbf{1}–\mathbf{3})_3Ti_2]$ in the presence of appropriate counterions (M = Li, Na, K, or NH_4). Studies on the self-recognition ability of the ligands show that self-recognition takes place if mixtures of ligands with significantly different sizes (**1/2**) are used in coordination studies, or if ligands are used which do not match for geometric reasons (**1/4**). Mixtures of ligands with a similar geometric preference (**2/5**) do not lead to self-recognition, but instead give mixtures of hetero- and homoleptic complexes.

Introduction

Supramolecular aggregates are formed from molecular components by non-covalent interactions. The geometrical and electronic information contained in the single building blocks controls the success of the formation of a supermolecule. For a rational design of non-covalently linked structures it is important to understand the factors that control self-assembly processes such as, for example, supramolecular stereochemistry, regiochemistry or templating effects.[1,2]

We are interested in the chemistry of helicates[3–7] and of related complexes[8–12] because those simple supramolecular coordination compounds allow the study of a variety of mechanistic aspects of self-assembly processes. In this context, we have found a way to control the diastereoselectivity[13] and the regioselectivity of complex formation.[14] In addition we have investigated the ligand self-recognition during helicate or meso-helicate formation and found a template control of this process.[15] This is an option for "ligand self-recognition" in addition to the examples described by Lehn,[16] Raymond[17] or Stack,[18,19] where different numbers of metal binding sites, preferred coordination geometry at the metal centers, different ligand length, or chirality is used to control the self-recognition.

The formation of the titanium(IV) complex $K_4[(\mathbf{2})_3Ti_2]$ has already been discussed and its X-ray structural analysis communicated.[20] In this paper, we report the titanium(IV) coordination chemistry of the rigid oligo-*p*-phenylene derivatives **1-3**-H_4, with two catechol binding sites, in the presence of different cations (Li^+, Na^+, K^+) and we introduce them into ligand self-recognition experiments.

Results and Discussion

Coordination Studies

The rigid ligands **1**-H_4, **2**-H_4, and **3**-H_4 (Figure 1) were prepared by use of a Suzuki coupling as a key step in the synthetic procedure. The linear oligo-*p*-phenylene derivatives **1-3**-H_4 have different lengths [9.2 (**1**-H_4), 13.5 (**2**-H_4), and 17.8 Å (**3**-H_4)] and the metal binding sites (catechol units) are fixed at defined distances to each other.[21] However, there is some flexibility at the C(aryl)–C(aryl) single bonds.

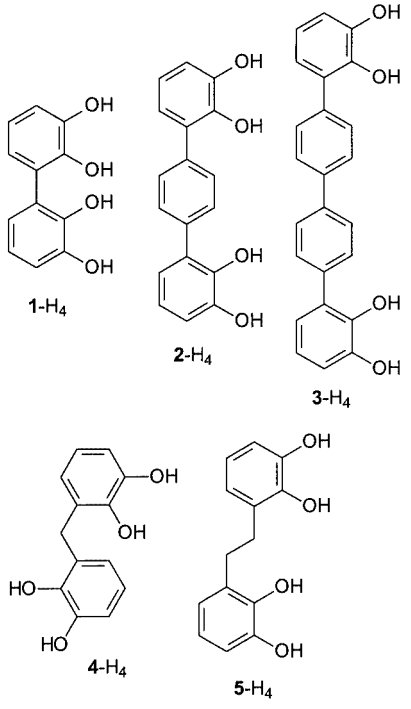

Figure 1. Ligands discussed in this study

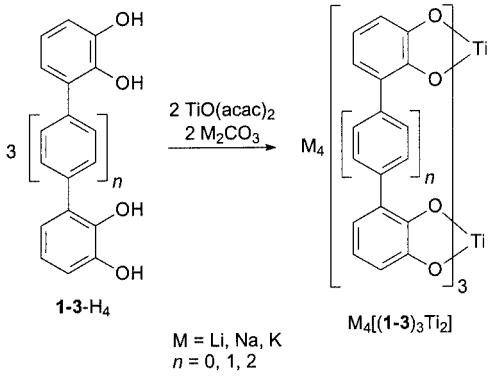
Dinuclear titanium(IV) complexes $M_4[(\mathbf{1}-\mathbf{3})_3Ti_2]$ (M = Li, Na, K) of the ligands **1**-H_4, **2**-H_4, and **3**-H_4 were obtained upon stirring a mixture of the ligand (3 equiv.), $TiO(acac)_2$ (2 equiv.) and the corresponding alkali metal carbonate (2 equiv.) in methanol (Scheme 1). After removal of the solvent a red solid material was obtained, which was purified by filtration through Sephadex LH 20.



Scheme 1. Formation of triple-stranded helicates $M_4[(\mathbf{1}-\mathbf{3})_3Ti_2]$

The smallest ligand **1**-H_4, with a direct connection of the two catechol moieties, affords dinuclear triple-stranded helicates $M_4[(\mathbf{1})_3Ti_2]$ (M = Li, Na, K) in 61% to quantitative yield. The positive FAB MS spectra show peaks at *m/z* = 766 $[Li_4\{(\mathbf{1})_3Ti_2\}]^+$ and 760 $[Li_3\{(\mathbf{1})_3Ti_2\}H]^+$, *m/z* = 809 $[Na_3\{(\mathbf{1})_3Ti_2\}H_2]^+$ and 787 $[Na_2\{(\mathbf{1})_3Ti_2\}H_3]^+$, and *m/z* = 895 $[K_4(\{(\mathbf{1})_3Ti_2\}H]^+$, 857 $[K_3\{(\mathbf{1})_3Ti_2\}H_2]^+$ and 818 $[K_2\{(\mathbf{1})_3Ti_2\}H_3]^+$ revealing that the helicates are made up from three ligands and two titanium(IV) ions. To our surprise the ^1H NMR spectra of all three compounds were significantly different. The lithium and sodium compounds show a pattern of two doublets of doublets and one (pseudo)triplet at δ = 6.57 (dd), 6.47 (pt), and 6.28 (dd) ($Li_4[(\mathbf{1})_3Ti_2]$) and at δ = 6.62 (dd), 6.56 (pt), and 6.35 (dd) ($Na_4[(\mathbf{1})_3Ti_2]$). For the potassium salt $K_4[(\mathbf{1})_3Ti_2]$ two multiplets are observed at δ = 6.53 (12 H) and 6.34 (6 H).

The different ^1H NMR spectra indicate that the different countercations bind to the triple-stranded dinuclear titanium complex anion $[(\mathbf{1})_3Ti_2]^{4-}$ and thus lead to different anisotropic effects at the ligand protons. However, in contrast to earlier observations, this binding cannot proceed by encapsulation of the cation. The interior of the anion $[(\mathbf{1})_3Ti_2]^{4-}$, which is formed from three ligands **1**, is too small for the binding of an alkali metal cation. Binding has to occur from the outside of the cavity as was observed for the titanium(IV) complexes of ligand **4**. However, in the case of the titanium complex of ligand **4** a dinuclear species $[(\mathbf{4})_3Ti_2]^{4-}$ can only be stabilized by sodium and lithium cations; potassium destabilizes this complex and leads to a mixture of oligomeric coordination compounds.[22,23] In contrast to the flexible methylene-bridged ligand **4** the rigid derivative **1** seems to be more preorganized for the formation of dinuclear helicate-type complexes $[(\mathbf{1})_3Ti_2]^{4-}$, and therefore the formation of the dinuclear species does not depend on the countercation which is present. Due to the fixed geometry of the ligand the dinuclear complexes seem to be favored over oligonuclear complexes. $[(\mathbf{1})_3Ti_2]^{4-}$ can even be formed in the presence of ammonium cations, although this cation does not seem to be able to stabilize the dinuclear complex very well and therefore no pure compound which shows a correct elemental analysis could be isolated. Characteristic ^1H NMR signals can be observed at δ = 6.83 (dd), 6.69 (pt), and 6.40 (dd).

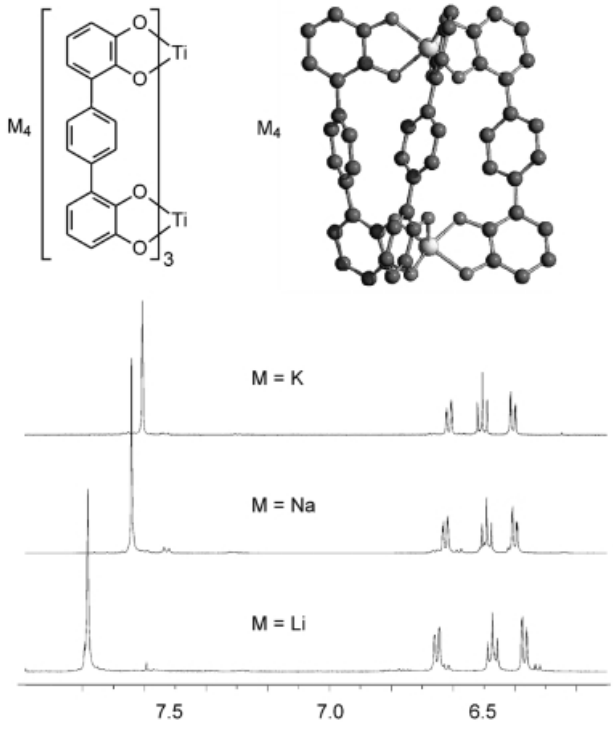


Figure 2. Dinuclear helicates $M_4[(\mathbf{2})_3Ti_2]$, a representation of the X-ray structure of $K_4[(\mathbf{2})_3Ti_2]$[20] and ^1H NMR spectra in [D_4]methanol

The formation and the X-ray structure (Figure 2, top) of the potassium salt $K_4[(\mathbf{2})_3Ti_2]$ of the *p*-phenylene bridged ligand **2**-H_4 was already been communicated by us.[20] A triple-stranded helicate structure $[(\mathbf{2})_3Ti_2]^{4-}$ was found which encapsulates two of the potassium counterions and which forms a dimer by DMF bridges between two potassium cations in the solid state. The two triple-stranded helicates of this dimer possess opposite helicity resulting in a *meso* configuration.[20]

The sodium and lithium salts $M_4[(\mathbf{2})_3Ti_2]$ can also be obtained. Figure 2 (bottom) shows a comparison of the ^1H NMR spectra of the three salts $M_4[(\mathbf{2})_3Ti_2]$ (M = Li, Na, K) in [D_4]methanol. At relatively high field two doublets of doublets [δ = 6.37 (Li), 6.40 (Na), 6.41 (K) and δ = 6.65 (Li), 6.63 (Na), 6.61 (K)] and a pseudo triplet [δ = 6.47 (Li), 6.49 (Na), and 6.50 (K)] are observed which show no significant shift differences for the three different alkali metal salts. However, the shift of the protons at the bridging *p*-phenylene moiety depends highly on the countercation which is present. Singlets are observed at δ = 7.78 (Li), 7.64 (Na), and 7.60 (K) for this proton. The observed NMR spectroscopic features indicate that one (or maybe two) of the cations of $M_4[(\mathbf{2})_3Ti_2]$ are bound in the interior of the

cavity formed by the three ligand strands **2** and the two titanium(IV) ions. Thus, they are located close to the protons of the spacer and lead to different shifts for the corresponding ^{1}H NMR resonances. The aromatic catechol hydrogen atoms are far away and experience the presence of the cations only in a very moderate way.

Due to the low solubility of the complexes $M_4[(\mathbf{2})_3Ti_2]$ (as well as $M_4[(\mathbf{3})_3Ti_2]$) in the FAB MS matrix (e.g., glycerine, 3-NBA) only poorly resolved positive FAB MS spectra could be obtained. Signals of the dinuclear complexes can be detected but show an extremely low intensity.

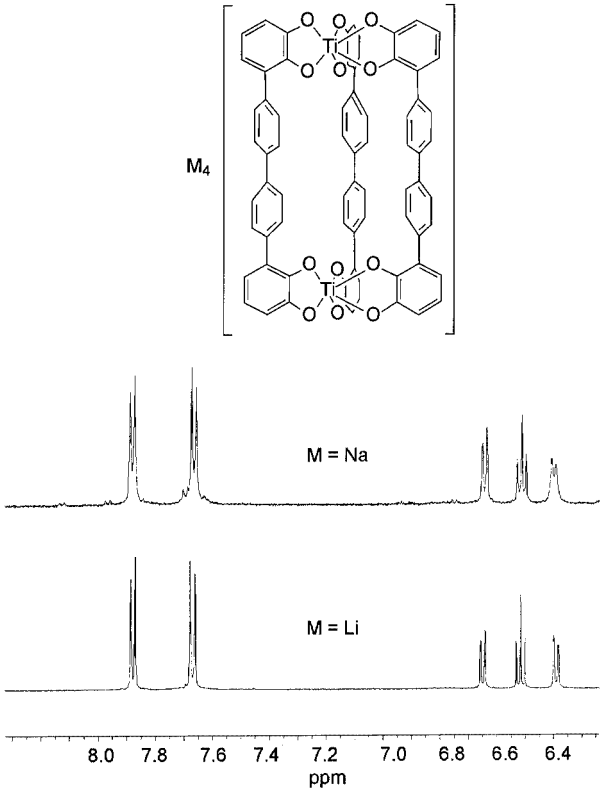

Figure 3. ^{1}H NMR spectra of $M_4[(\mathbf{3})_3Ti_2]$ in [D$_4$]methanol

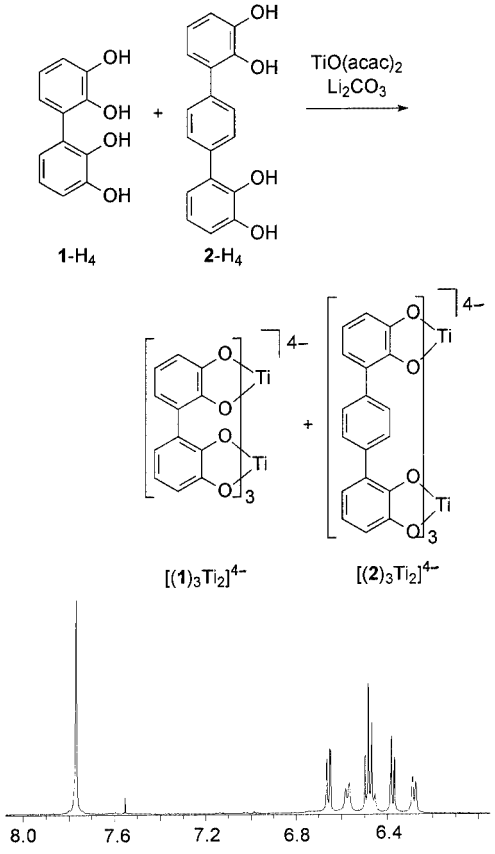
Dinuclear complexes $M_4[(\mathbf{3})_3Ti_2]$ of ligand **3** (Figure 3) are formed only with sodium or lithium as countercations. With potassium as a cation we rather surprisingly could not obtain a well-defined titanium(IV) complex. The ^{1}H NMR spectra of the two salts $Li_4[(\mathbf{3})_3Ti_2]$ and $Na_4[(\mathbf{3})_3Ti_2]$ in [D$_4$]methanol (Figure 3) are very similar with signals at δ = 7.88 (d), 7.67/7.66 (d, Li/Na), 6.65/6.64 (dd), 6.52/6.51 (pt), and 6.39 (dd). The tetraanion $[(\mathbf{3})_3Ti_2]^{4-}$ possesses a huge internal cavity where it is supposed that lithium or sodium cations can be weakly bound in the interior but can be exchanged very fast.

Self-Recognition Studies

Raymond showed in 1997 that amide-bridged rigid linear dicatechol ligands with significantly different distances between metal binding sites can be introduced into self-recognition experiments and that, upon complex formation with gallium(III) ions, self-sorting of the ligands takes place and only homoleptic complexes (every metal complex contains only one kind of ligand) could be observed.[17] We showed that with alkyl-bridged dicatechol ligands (**4**-H$_4$, **5**-H$_4$) the formation of specific dinuclear titanium(IV) complexes is highly dependent on the templating alkali metal countercation.[15]

In a first investigation we mixed the two ligands **1**-H$_4$ and **2**-H$_4$ (ratio 1:1) and performed coordination studies with titanium(IV) ions in the presence of lithium carbonate (Na_2CO_3 and K_2CO_3 as base lead to essentially the same results).

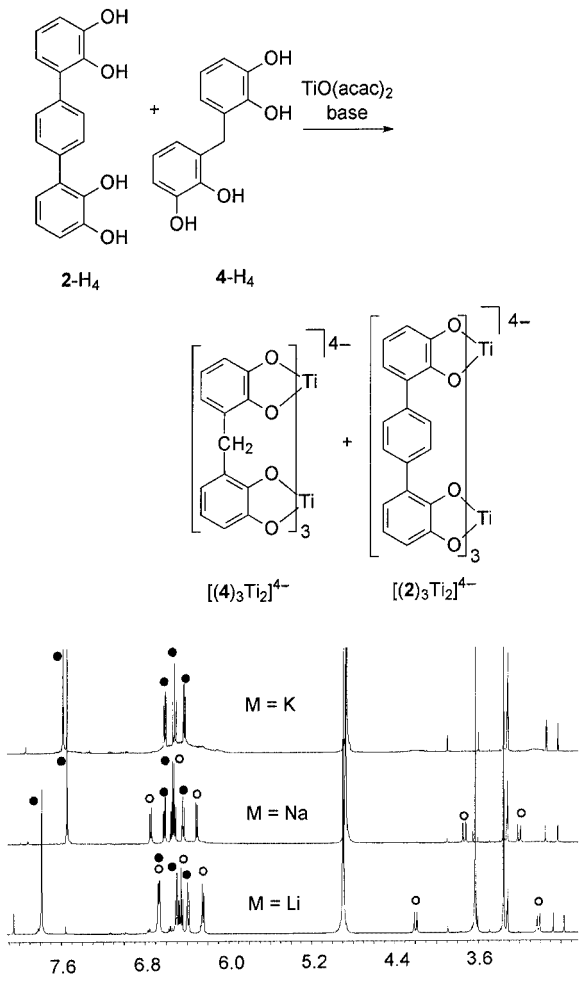


Scheme 2. Self-recognition experiment with a mixture of ligands **1**-H$_4$ and **2**-H$_4$ leading to homoleptic complexes by self-sorting

In Scheme 2 (bottom) the ^{1}H NMR spectrum of the self-recognition experiment with ligands **1** and **2** is presented, showing that only the two homoleptic complexes $Li_4[(\mathbf{1})_3Ti_2]$ and $Li_4[(\mathbf{2})_3Ti_2]$ are present. The signals of $Li_4[(\mathbf{1})_3Ti_2]$ appear at δ = 6.57 (d), 6.47 (pt), and 6.28 (d) while those of $Li_4[(\mathbf{2})_3Ti_2]$ are observed at δ = 7.77 (s), 6.66 (dd), 6.48 (pt), and 6.37 (dd). The ^{13}C NMR spectra also show only the signals of the two homoleptic coordination compounds. In this experiment we observed the same control mechanism as was described earlier by Raymond:[17] rigid linear ligands self-sort in self-recognition experiments due to the match (or mismatch) of the separation of the metal coordination sites.

In an additional experiment we mixed the rigid derivative **2**-H$_4$ with the more flexible ligands **4**-H$_4$ or **5**-H$_4$. The result of the coordination studies with a **2**-H$_4$/**4**-H$_4$ mixture (1:1)

depends strongly on the templating cation which is present. It was shown earlier that the dinuclear complex $[(\mathbf{4})_3Ti_2]^{4-}$ only assembles in the presence of lithium or sodium cations, while the larger potassium cation leads to the formation of a mixture of oligomeric complexes. This has to be taken into account when the self-recognition studies are performed.



Scheme 3. Alkali metal cation dependant self-recognition of the ligands **2**-H_4 and **4**-H_4. ($[(\mathbf{2})_3Ti_2]^{4-}$: •; $[(\mathbf{4})_3Ti_2]^{4-}$: ○)

Scheme 3 shows the NMR spectra of the crude product of the reaction of a mixture of **2**- and **4**-H_4 (1:1) with titanium(IV) ions in the presence of alkali metal carbonates. If the experiment is performed with potassium carbonate the dinuclear helicate complex $K_4[(\mathbf{2})_3Ti_2]$ can be observed in the ^1H NMR spectrum ([D_4]methanol) at $\delta = 7.58$, 6.61, 6.52, and 6.42. (The shifts differ slightly from those observed for the pure complex due to the presence of several different species in solution.) No resolved resonances can be assigned to a titanium complex of ligand **4**. However, according to our earlier results,[22] broad signals of oligomeric material $\{K_4[(\mathbf{4})_3Ti_2]\}_n$ are detected at $\delta = 4.20$, 3.03 and in the region of aromatic signals. With lithium or sodium carbonate, however, nicely resolved NMR spectra are obtained showing the formation of only homoleptic complexes $M_4[(\mathbf{2})_3Ti_2]$ and $M_4[(\mathbf{4})_3Ti_2]$ by self-recognition of the dicatecholates. In Scheme 3 the signals of the dinuclear complex $[(\mathbf{2})_3Ti_2]^{4-}$ are marked with a•• and those of $[(\mathbf{4})_3Ti_2]^{4-}$ with a ○. No significant amounts of additional metal complexes were observed.

If a similar self-recognition experiment is performed with a mixture of ligands **2**-H_4 and **5**-H_4, no specific titanium(IV) complexes could be observed by NMR spectroscopy. An unspecific complex formation takes place.

The discrepancy in the results obtained in the self-recognition experiments of ligand **2** and **4** or **2** and **5** shows that subtle changes in the system can be important for observing selectivity in self-assembly processes. The ligand **5**-H_4 possesses only one methylene unit more in the spacer than **4**-H_4. This results in a somewhat larger separation of the binding sites and, maybe even more importantly, also results in a dramatic difference in the geometry of the compound.

Due to the rigidity of ligand **2**-H_4 only helical structures can be obtained in the dinuclear coordination compounds $[(\mathbf{2})_3Ti_2]^{4-}$ (for a non-helical complex the ligand has to adopt a very strained "C" type conformation). The ligand **4**-H_4, on the other hand, is predisposed to form the *meso*-helicate $[(\mathbf{4})_3Ti_2]^{4-}$ with two oppositely configured complex units. Therefore the geometries of the two ligands **2** and **4** do not match and only homoleptic complexes can be formed. Ligand **5**, like **2**, is predisposed for the formation of dinuclear helicates, so that for geometric reasons a matched situation results between those two ligands. No specificity is found in the coordination study.

Here the self-recognition in the formation of $[(\mathbf{2})_3Ti_2]^{4-}$ and $[(\mathbf{4})_3Ti_2]^{4-}$ from a mixture of the two ligands seems to be due to a geometric mismatch of the ligand strands. Thus, molecular recognition of the matching strands during complex formation leads to self-sorting and formation of the homoleptic complexes.

Conclusion

In this paper we have described the formation of dinuclear triple-stranded titanium(IV) helicates from rigid rod-type dicatechol ligands **1-3**-H_4 with two binding sites for metals. The formation of these coordination compounds seems not to be templated by the countercation, although interaction of the cations with the tetraanionic complexes $[(\mathbf{1/2})_3Ti_2]^{4-}$ can be deduced from the ^1H NMR spectra. Obviously the linear rigid ligand systems are suitably preorganized for the formation of dinuclear helicates.

In self-recognition studies with titanium(IV) ions a mixture of the derivatives **1**-H_4 and **2**-H_4 leads to the formation of only homoleptic complexes $[(\mathbf{1})_3Ti_2]^{4-}$ and $[(\mathbf{2})_3Ti_2]^{4-}$. This complex formation is controlled by the different length of the ligands.

Self recognition also takes place if a mixture of derivatives **2**-H_4 and **4**-H_4 is used, although not with a mixture of **2**-H_4 and **5**-H_4. Here a mismatch of the ligand geometries of **2** and **4** is supposed which leads to the formation of dinuclear complexes with only one kind of ligand. In the

case of **2** and **5**, however, both ligands possess a geometry that is ideal for the formation of helical complexes and therefore the geometric match of the derivatives prevents self-recognition.

Experimental Section

General Remarks: ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DRX 500 spectrometer using DEPT techniques for the assignment of the multiplicity of carbon atoms. FT-IR spectra were recorded by diffuse reflection (KBr) on a Bruker IFS spectrometer. UV/Vis spectra were recorded on a Perkin−Elmer Lambda 2 spectrometer. Mass spectra (EI, 70 eV) were recorded on a Finnigan MAT 90 mass spectrometer. Elemental analyses were obtained with a Heraeus CHN-O-Rapid analyzer. All commercial reagents were purchased from Aldrich or Fluka. The ligands **1-3**-H_4 and **4/5**-H_4 were prepared as described previously.[21,24,25]

General Procedure for the Preparation of Dinuclear Titanium(IV) Complexes: A mixture of ligand (3 equiv.), $TiO(acac)_2$ (2 equiv.) and alkali metal carbonate (2 equiv.) in methanol was stirred overnight until a clear red solution had formed. The solvent was then removed under vacuum and the residue purified by filtration through Sephadex LH 20.

$Li_4[(1)_3Ti_2]$: Yield: 56 mg (100%), orange solid. ^{1}H NMR ([D$_4$]methanol): δ = 6.28 (dd, *J* = 7.7, 1.4 Hz, 6 H), 6.47 (pt, *J* = 7.7 Hz, 6 H), 6.57 (dd, *J* = 7.7, 1.4 Hz, 6 H). ^{13}C NMR ([D$_4$]methanol): δ = 111.0 (CH), 118.8 (CH), 122.1 (CH), 126.1 (C), 157.3 (C), 157.5 (C). IR (KBr): $\tilde{\nu}$ = 3371, 3057, 1602, 1519, 1420, 1250, 1181, 1135, 1059, 996, 871, 777, 742, 711 cm^{-1}. Positive FAB MS (3-NBA): *m*/*z* = 766 $[Li_4\{(\mathbf{1})_3Ti_2\}]^+$, 760 $[Li_3\{(\mathbf{1})_3Ti_2H\}]^+$. UV/Vis (methanol): λ = 214, 352 nm. $C_{36}H_{18}Li_4O_{12}Ti_2{\cdot}12H_2O$ (982.28): calcd. C 44.02, H 4.31; found C 43.74, H 4.13.

$Na_4[(1)_3Ti_2]$: Yield: 31 mg (61%), red solid. ^{1}H NMR ([D$_4$]methanol): δ = 6.35 (dd, *J* = 7.7, 1.4 Hz, 6 H), 6.56 (pt, *J* = 7.7 Hz, 6 H), 6.62 (dd, *J* = 7.7, 1.4 Hz, 6 H). ^{13}C NMR ([D$_4$]methanol): δ = 111.9 (CH), 120.4 (CH), 121.0 (CH), 123.8 (C), 155.4 (C), 157.7 (C). IR (KBr): $\tilde{\nu}$ = 3421, 3053, 1700, 1420, 1251, 1056, 998, 871, 778, 698, 647, 617 cm^{-1}. Positive FAB MS (3-NBA): *m*/*z* = 809 $[Na_3\{(\mathbf{1})_3Ti_2\}H_2]^+$, 787 $[Na_2\{(\mathbf{1})_3Ti_2\}H_3]^+$. UV/Vis (methanol): λ = 215, 354 nm. $C_{36}H_{18}Na_4O_{12}Ti_2{\cdot}8H_2O$ (974.41): calcd. C 44.37, H 3.52; found C 44.54, H 3.97.

$K_4[(1)_3Ti_2]$: Yield: 42 mg (84%), red solid. ^{1}H NMR ([D$_4$]methanol): δ = 6.34 (m, 6 H), 6.53 (m, 12 H). ^{13}C NMR ([D$_4$]methanol): δ = 111.9 (CH), 119.6 (CH), 119.9 (CH), 123.7 (C), 156.8 (C), 157.5 (C). IR (KBr): $\tilde{\nu}$ = 3403, 3051, 1421, 1251, 1055, 999, 871, 774, 646, 615 cm^{-1}. Positive FAB MS (3-NBA): *m*/*z* = 895 $[K_4\{(\mathbf{1})_3Ti_2\}H]^+$, 857 $[K_3\{(\mathbf{1})_3Ti_2\}H_2]^+$, 818 $[K_2\{(\mathbf{1})_3Ti_2\}H_3]^+$. UV/Vis (methanol): λ = 214, 360 nm. $C_{36}H_{18}K_4O_{12}Ti_2{\cdot}9H_2O$ (1056.86): calcd. C 40.91, H 3.43; found C 41.25, H 3.50.

$(NH_4)_4[(1)_3Ti_2]$: A red solid is obtained by use of ammonium acetate as base. ^{1}H NMR ([D$_4$]methanol): δ = 6.40 (dd, *J* = 7.8, 1.1 Hz, 6 H), 6.69 (pt, *J* = 7.8 Hz, 6 H), 6.83 (dd, *J* = 7.8, 1.1 Hz, 6 H). IR (KBr): $\tilde{\nu}$ = 3237, 3061, 1558, 1420, 1251, 1114, 1057, 993, 871, 773, 713 cm^{-1}. UV/Vis (methanol): λ = 214, 355 nm.

$Li_4[(2)_3Ti_2]$: Yield: 28 mg (100%), red solid. ^{1}H NMR ([D$_4$]methanol): δ = 6.37 (dd, *J* = 7.7, 1.2 Hz, 6 H), 6.47 (pt, *J* = 7.7 Hz, 6 H), 6.65 (dd, *J* = 7.7, 1.2 Hz, 6 H),7.78 (s, 12 H). ^{13}C NMR ([D$_4$]methanol): δ = 111.2 (CH), 117.3 (CH), 118.3 (CH), 125.8 (C), 129.4 (CH, double intensity), 138.6 (C), 158.4 (C), 160.6 (C). IR (KBr): $\tilde{\nu}$ = 3528, 3056, 1617, 1520, 1448, 1392, 1329, 1255, 1218, 1170, 1093, 1058, 918, 893, 782, 737, 688, 640 cm^{-1}. UV/Vis: λ = 206, 278 nm. $C_{54}H_{30}Li_4O_{12}Ti_2{\cdot}8H_2O$ (1138.51): calcd. C 56.97, H 4.07; found C 57.27, H 4.53.

$Na_4[(2)_3Ti_2]$: Yield: 84 mg (100%), orange solid. ^{1}H NMR ([D$_4$]methanol): δ = 6.40 (dd, *J* = 7.7, 1.4 Hz, 6 H), 6.49 (pt, *J* = 7.7 Hz, 6 H), 6.63 (dd, *J* = 7.7, 1.4 Hz, 6 H), 7.64 (s, 12 H). ^{13}C NMR ([D$_4$]methanol): δ = 111.5 (CH), 118.1 (CH), 118.3 (CH), 125.8 (C), 129.5 (CH, double intensity), 138.9 (C), 158.4 (C), 160.6 (C). IR (KBr): $\tilde{\nu}$ = 3567, 3422, 3054, 1635, 1559, 1517, 1447, 1390, 1330, 1252, 1220, 1092, 1058, 917, 839, 783, 735, 683, 636 cm^{-1}. UV/Vis (methanol): λ = 205, 273 nm. $C_{54}H_{30}Na_4O_{12}Ti_2{\cdot}10H_2O$ (1238.74): calcd. C 52.36, H 4.07; found C 52.39, H 4.03.

$K_4[(2)_3Ti_2]$: Yield: 50 mg (100%), red solid. ^{1}H NMR ([D$_4$]methanol): δ = 6.41 (dd, *J* = 7.7, 1.4 Hz, 6 H), 6.50 (pt, *J* = 7.7 Hz, 6 H), 6.61 (dd, *J* = 7.7, 1.4 Hz, 6 H), 7.60 (s, 12 H). ^{13}C NMR ([D$_4$]methanol): δ = 111.6 (CH), 118.1 (CH), 118.5 (CH), 125.5 (C), 129.7 (CH, double intensity), 139.3 (C), 158.3 (C), 160.7 (C). IR (KBr): $\tilde{\nu}$ = 3404, 3052, 1630, 1517, 1446, 1390, 1333, 1252, 1093, 1057, 917, 838, 783, 735, 635 cm^{-1}. UV/Vis (methanol): λ = 205, 270 nm. $C_{54}H_{30}K_4O_{12}Ti_2{\cdot}8H_2O$ (1267.14): calcd. C 51.19, H 3.66; found C 51.10, H 3.58.

$Li_4[(3)_3Ti_2]$: Yield: 26 mg (48%), orange solid. ^{1}H NMR ([D$_4$]methanol): δ = 6.39 (dd, *J* = 7.7, 1.2 Hz, 6 H), 6.52 (pt, *J* = 7.7 Hz, 6 H), 6.65 (dd, *J* = 7.7, 1.2 Hz, 6 H), 7.67 (d, *J* = 8.3 Hz, 12 H), 7.88 (d, *J* = 8.3 Hz, 12 H). ^{13}C NMR ([D$_4$]methanol): δ = 111.5 (CH), 118.5 (CH), 118.7 (CH), 125.4 (C), 127.0 (CH, double intensity), 130.7 (CH, double intensity), 139.5 (C), 140.1 (C), 158.1 (C), 160.8 (C). IR (KBr): $\tilde{\nu}$ = 3617, 3055, 3026, 1609, 1444, 1391, 1333, 1252, 1219, 1102, 1059, 1005, 916, 849, 828, 782, 765, 738, 678, 628 cm^{-1}. Synthesis and Structure of Monomeric and Platinum-Bonded (1,10-Phenanthroline)thallium Complexes

Guibin Ma,*[b] Andreas Fischer,[a] and Julius Glaser*[a]

Keywords: Metal−metal interactions / Platinum / Thallium / N ligands / NMR spectroscopy

Oxidative addition of (1,10-phenanthroline)thallium(III) complexes $[Tl(phen)_n(solv)]^{3+}$ (n = 1–2) (phen = 1,10-phenanthroline) to $[Pt(CN)_4]^{2-}$ in DMSO, in the presence of cyanide ions and in the absence of cyanide ions yielded heterodinuclear metal–metal-bonded complexes, $[(NC)_5Pt–Tl(phen)_n(solv)]$ and $[(NC)_4Pt–Tl(phen)_n(solv)]^+$ (n = 0, 1, and 2), respectively. The presence of a direct Pt–Tl bond in the complex is evident by a very strong one-bond $^{195}Pt–^{205}Tl$ spin-spin coupling detected by ^{205}Tl NMR: ^1J = 94.0 kHz (**1a**), 84.2 kHz (**2a**), and 77.1 kHz (**3a**) corresponding to n = 0, 1, and 2 in $[(NC)_4Pt–Tl(phen)_n(solv)]^+$, and ^1J = 65.4 kHz (**2b**) and 62.5 kHz (**3b**) for n = 1 and 2, respectively, in $[(NC)_5Pt–Tl(phen)_n(solv)]$. The crystal structures of $[(NC)_5Pt–Tl(phen)(DMSO)_3]\cdot(DMSO)$ (**2b**), $[(NC)_5Pt–Tl(phen)_2]\cdot(DMSO)_3$ (**3b**), and $[Tl(phen)_2Cl_2](ClO_4)$ (**4**) complexes were determined. Very short Pt–Tl bonds, 2.6296(3) and 2.6375(5) Å, are present in structures **2b** and **3b**, respectively. The corresponding force constants in the molecules in the solid state, 1.84 and 1.74 N/cm for **2b** and **3b**, respectively, were calculated using Raman stretching frequencies of the Pt–Tl vibrations, and are characteristic for a single, strong metal–metal bond. Electronic absorption spectra were recorded for selected compounds and the optical transition attributed to the metal–metal bond was assigned.

Introduction

Square-planar complexes of d^8 transition metal ions comply with the 16-electron rule, the occupied d_{z^2} orbital can act as a potential donor to another metal ion (M), resulting in a dative $M(d^8)\rightarrow M$ bond. Many $Pt^{II}-M$ dative-bond complexes have been reported.[1a] A direct metal−metal bond between platinum(II) and thallium(I) in the solid state was first described by Nagle et al.[1b] Recently, several compounds containing a Pt−Tl bond have been prepared.[2] In this laboratory, a family of four dinuclear platinum−thallium cyano compounds with the formula $[(NC)_5Pt-Tl(CN)_{n-1}(aq)]^{(1-n)}$ (n = 1−4 for compound **I**, **II**, **III** and **IV**, respectively), which contain a direct metal−metal bond unsupported by ligands, have been synthesized and characterized in aqueous solutions.[3] Due to the light sensitivity of the Pt−Tl metal−metal bond in these compounds, they are of principal interest. A study was initiated of the effects of modifications of these compounds with nitrogen donor and chromophore organic ligands, e.g. 2,2′-bipyridine and porphyrin (tpp, thpp).[4] When the compounds were exposed to daylight, two-electron transfer was induced between the metal ions. Thus, possible applications in photovoltaic devices, for example in a "wet" solar cell of Grätzel-type,[5] can be envisaged. In the search for suitable compounds for future applications, we report here the synthesis and structural characteristics of new complexes containing a direct metal−metal bond, $[(NC)_4Pt-Tl(phen)_n(solv)]^+$ with n = 0 (**1a**), 1 (**2a**), 2 (**3a**) and $[(NC)_5Pt-Tl(phen)_n(solv)]$ with n = 1 (**2b**), 2 (**3b**). For the first time, a naked Pt−Tl bond with the formal oxidation states Pt^{II} and Tl^{III} and the composition $[(NC)_4Pt-TlX]^+$ was synthesised and structurally characterised [X = $(phen)_n(solv)$, n = 0,1,2; solv = DMSO].

Results and Discussion

Characterization in Solution by ^{205}Tl NMR Spectroscopy

The preparation of Pt−Tl complexes with the N-donor ligand ethylenediamine was described in our previous paper.[4a] In a similar way, two new Pt−Tl complexes $[(NC)_4Pt-Tl(solv)]^+$ (**1a**) and $[(NC)_5Pt-Tl(solv)]$ (**1b**) could be prepared; these two species were then treated with 1,10-phenanthroline, whereby the complexes $[(NC)_4Pt-Tl(phen)(solv)]^+$ (**2a**), $[(NC)_5Pt-Tl(phen)(solv)]$ (**2b**), $[(NC)_4Pt-Tl(phen)_2(solv)]$ (**3a**), and $[(NC)_5Pt-Tl(phen)_2]$ (**3b**) in DMSO solution (Scheme 1) were prepared.

In the reaction between the solid compound $[Tl(DMSO)_6](ClO_4)_3$ and $[Pt(CN)_4{}^{2-}]$ in DMSO (cf. Scheme 1, lower part), it is clear from the ^{205}Tl NMR spectrum that only

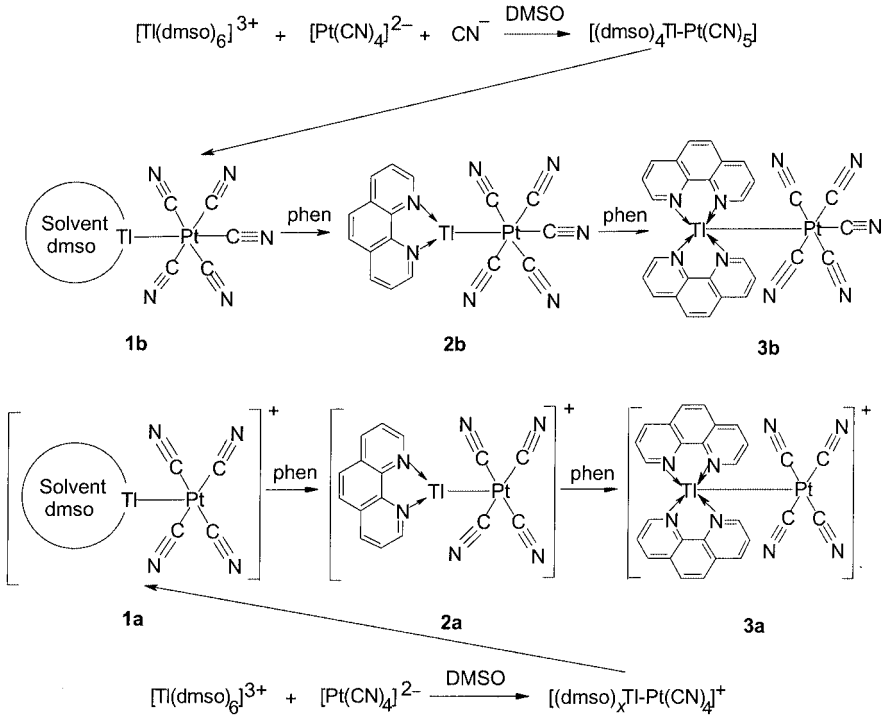

Scheme 1

one Pt−Tl dinuclear complex forms (**1a**); a 1:3.9:1 triplet peak appears centred at δ = 82 with a large spin-spin coupling constant (94000 Hz), this is characteristic for a non-buttressed Pt−Tl bond.[3] The ^{205}Tl NMR signal splits into a doublet by nuclear spin-spin coupling to the NMR-active isotope ^{195}Pt (natural abundance 33.8%, I = 1/2) and, together with the NMR-inactive Pt isotopes (natural abundance 66.2%), it shows a triplet pattern with the expected intensity ratio 1:3.9:1 (cf. Figure 1). Then, upon stepwise addition of 1,10-phenanthroline, two Pt−Tl species showed up in the spectra as typical triplet signals at δ = 472 (**2a**) and δ = 775 (**3a**) with the spin-spin coupling constants 84200 Hz and 77120 Hz, respectively.

The preparation and characterization of [(NC)$_5$Pt−Tl(solv)] (**1b**) was studied earlier[4a] and crystalline [(NC)$_5$Pt−Tl(DMSO)$_4$] was obtained. When the solid [(NC)$_5$Pt−Tl(DMSO)$_4$] was treated with 1,10-phenanthroline at different molar ratios (cf. Scheme 1, top part), it dissolved completely, and the complexes [(NC)$_5$Pt−Tl(phen)$_n$] (n = 1−2 for compounds **2b** and **3b**, respectively) formed in solution. The ^{205}Tl NMR chemical shifts for the two new phenanthroline species are δ = 992 and 1162, and spin-spin coupling constants ^1J(^{195}Pt-^{205}Tl) are 65440 and 62490 Hz for **2b** and **3b** in DMSO, respectively. Similar to the ^{205}Tl NMR spectrum discussed above, the signals are triplets with the expected intensity ratio 1:3.9:1 (Figure 2).

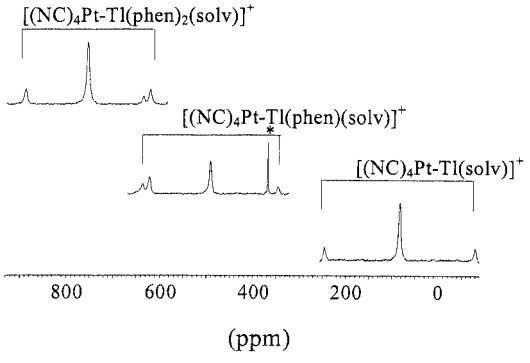

Figure 1. 288 MHz ^{205}Tl NMR spectra of Pt−Tl compounds in DMSO: [(NC)$_4$Pt−Tl(solv)]$^+$ (**1a**), [(NC)$_4$Pt−Tl(phen)(solv)]$^+$ (**2a**), and [(NC)$_4$Pt−Tl(phen)$_2$(solv)]$^+$ (**3a**); * represents Tl^I signal at δ = 363

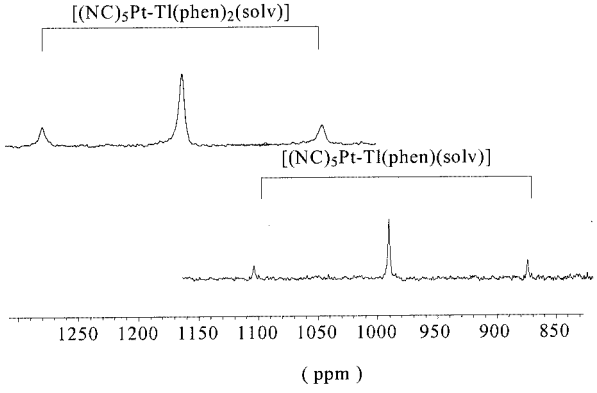

Figure 2. 288 MHz ^{205}Tl NMR spectra of the Pt−Tl compounds [(NC)$_5$Pt−Tl(phen)(DMSO)$_y$] (**2b**) and [(NC)$_5$Pt−Tl(phen)$_2$] (**3b**) in DMSO

The large spin-spin coupling constants show that a Pt−Tl bond is formed; the appearance of peaks with different and hitherto unreported chemical shifts and coupling constants suggests that new complexes $[(NC)_4Pt-Tl(phen)_n]^+$ (n = 1 and 2 for **2a** and **3a**, respectively) and $[(NC)_5Pt-Tl(phen)_n]$ (n = 1 and 2 for **2b** and **3b**, respectively) formed in solution (Scheme 1). Upon coordination of the second phen molecule to the thallium atom in all the studied Pt−Tl dinuclear complexes in DMSO, the spin-spin coupling constant $^1J(^{195}Pt\text{-}^{205}Tl)$ decreased. This strong coupling is a characteristic feature of the bonding between the two metal ions with the formal oxidation states $Pt^{II}-Tl^{III}$, and is an indication of a significant contribution of thallium 6s orbitals to the metal−metal bonding.[3b] Owing to the relativistic effects, the thallium 6s orbital is stabilized and contracted; this results in an increased electron density at the nucleus, which contributes to the Fermi contact term for spin-spin coupling.[2j,23] It was found that there is a correlation between the spin-spin coupling constant and the metal−metal separation/bond strength in the series of complexes $[(NC)_5Pt-Tl(CN)_n]^{n-}$ (n = 1−3). The stronger Pt−Tl bonding, the shorter Pt−Tl bond length and the larger spin-spin coupling constant.[6]

NMR chemical shifts for heavy metals with large chemical shift ranges are very sensitive to the oxidation state of the metal ion.[7] Thus, ^{205}Tl NMR chemical shifts of Tl^I species are in the range δ = −200 to +200 and those of Tl^{III} complexes are usually at δ = 2000 to 3000.[3d] In DMSO, ^{205}Tl NMR chemical shifts of $[Tl(DMSO)_6]^{3+}$ and Tl^+ are δ = 1886 and 361, respectively.[11] For the currently studied compounds, $[(NC)_4Pt-Tl(solv)]^+$, $[(NC)_4Pt-Tl(phen)_n]^+$ (n = 1−2), and $[(NC)_5Pt-Tl(phen)_n]$ (n = 1−2), ^{205}Tl NMR chemical shifts are in the Tl^+ region for $[(NC)_4Pt-Tl(solv)]^+$ and between Tl^I and Tl^{III} for all the others. Consequently, the thallium oxidation state in these compounds is between Tl^I and Tl^{III}.[6a] It could be of interest to compare the differences between the spin-spin coupling constants $^1J(^{195}Pt\text{-}^{205}Tl)$ for the two types of complexes prepared in this work in which the only difference between the compounds **a** and **b** is one extra cyanide ligand bound to the platinum atom. Still, the differences in coupling constants are very large: 28100 Hz [between ^1J(**1a**) and ^1J(**1b**)], 18800 Hz [between ^1J(**2a**) and ^1J(**2b**)], and 15600 Hz [between ^1J(**3a**) and ^1J(**3b**)].

Crystal Structures of Pt-Bonded and Monomeric Tl(phen) Compounds

$[(NC)_5Pt-Tl(phen)(DMSO)_3]$ (DMSO) (2b)

Single crystals of the dinuclear compound **2b** were obtained from the studied solution and the structure determined by X-ray diffraction method. The ORTEP perspective view of the molecular structure and the selected bond lengths of **2b** are shown in Figure 3. The Pt−Tl bond length is short, 2.6296(3) Å, significantly shorter than for other reported Pt−Tl bond lengths.[2] In the $Pt(CN)_5$ moiety the Pt−C bonds range between 2.005 and 2.053 Å; the axial cyanide has a slightly longer Pt−C distance than the equatorial ones. The Tl atom coordinates one phen ligand and three DMSO molecules forming a distorted octahedral geometry around the thallium atom. Atoms O1, O4, O5, and N2 define an equatorial plane, from which the Tl atom is displaced 0.57(1) Å towards the Pt atom. The four equatorial ligand atoms around Tl are in a staggered conformation to the adjacent square-planar $Pt(CN)_4$ unit. The angle between the Tl1−N1 bond and the plane formed by the atoms O1, O4, and O5 is 91.6°, close to perpendicular, whereas the angle N1−Tl1−Pt1 is 176.1°, close to 180°. In this compound, two kinds of DMSO molecules are present in the structure; three molecules coordinated to the thallium atom and one remains uncoordinated. The bond lengths of the coordinated DMSO molecules are altered compared to the uncoordinated one. The strong coordination gives a short Tl−O and a long S−O bond length [for coordinated DMSO: Tl1−O1 = 2.448(4) Å, S2−O1 = 1.527(5) Å; Tl1−O4 = 2.471(4) Å, S1−O4 = 1.511(5) Å; Tl1−O5 = 2.495(5) Å, S4−O5 = 1.499(6) Å; for free DMSO: S3−O6 = 1.483(8) Å]. The S−O bond order is diminished by coordination, and it is due to electrons of the oxygen atom moving toward the thallium atom upon coordination. Comparing these data to our previous structural data of $[Tl(DMSO)_6]^{3+}$ [Tl−O = 2.224(3) Å, S−O = 1.544(4) Å],[11] the Tl−DMSO coordination is much weaker in compound **2b**. It is probably due to the decreased positive charge of thallium in the dinuclear complex.

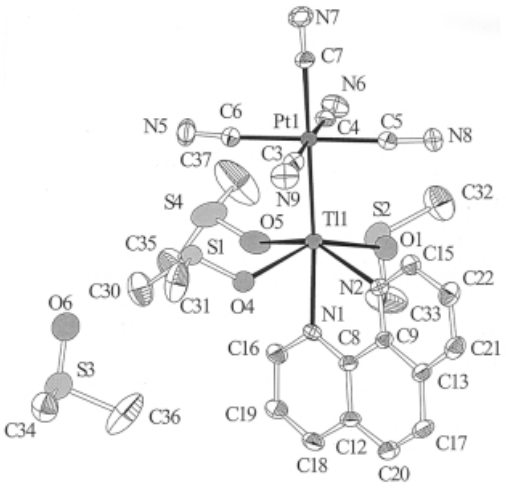

Figure 3. ORTEP view of the species $[(NC)_5Pt-Tl(phen)(DMSO)_3]$ found in the crystal structure of $[(NC)_5Pt-Tl(phen)(DMSO)_3]\cdot(DMSO)$ (**2b**), thermal ellipsoids are drawn at 30% probability level; selected bond lengths [Å] and angles [°]: Pt(1)−Tl(1) 2.6296(3), Pt(1)−C(3) 2.030(6), Pt(1)−C(4) 2.007(6), Pt(1)−C(5) 2.011(6), Pt(1)−C(6) 2.005(6), Pt(1)−C(7) 2.053(6), Tl(1)−N(1) 2.322(4), Tl(1)−N(2) 2.434(4), Tl(1)−O(1) 2.448(4), Tl(1)−O(4) 2.471(4), Tl(1)−O(5) 2.495(5), S(1)−O(4) 1.511(5), S(2)−O(1) 1.527(5), S(4)−O(5) 1.499(6); C(6)−Pt(1)−C(5) 177.4(2), C(3)−Pt(1)−C(4) 177.4(2), C(7)−Pt(1)−Tl(1) 177.58(18), N(1)−Tl(1)−Pt(1) 176.21(12)

$[(NC)_5Pt-Tl(phen)_2]$ 3(DMSO) (3b)

The ORTEP perspective view of the molecular structure and the selected bond lengths of **3b** are shown in Figure 4. Similar to compound **2b**, the main structural feature of **3b**

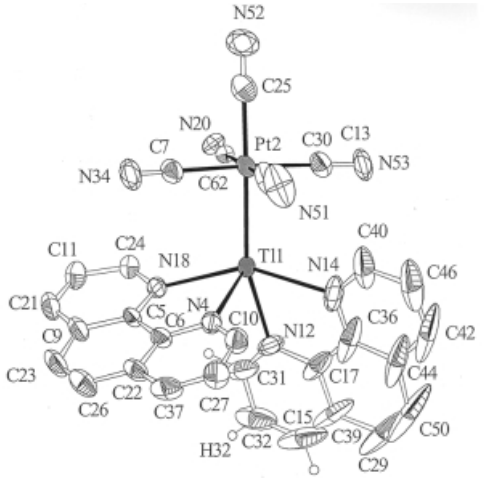

Figure 4. ORTEP view of the species $[(NC)_5Pt-Tl(phen)_2]$ found in the crystal structure of $[(NC)_5Pt-Tl(phen)_2]\cdot(3dmso)$ (**3b**); thermal ellipsoids are drawn at 30% probability level; selected bond lengths [Å] and angles [°]: Pt(1)−Tl(1) 2.6375(5), Pt(2)−C(7) 2.029(10), Pt(2)−C(13) 2.022(11), Pt(2)−C(25) 2.025(14), Pt(2)−C(30) 2.002(14), Pt(2)−C(62) 1.990(9), Tl(1)−N(4) 2.428(7), Tl(1)−N(12) 2.291(10), Tl(1)−N(14) 2.524(10), Tl(1)−N(18) 2.445(7); C(25)−Pt(2)−Tl(1) 178.3(4), N(4)−Tl(1)−Pt(2) 118.2(2), N(14)−Tl(1)−Pt(2) 103.1(4), N(18)−Tl(1)−Pt(2) 103.55(17), N(12)−Tl(1)−Pt(2) 158.6(2), C(30)−Pt(2)−C(13) 90.8(5), C(13)−Pt(2)−C(7) 177.6(4)

is the short and non-buttressed Pt−Tl bond [Pt−Tl = 2.6375(5) Å]. In addition to the Pt−Tl linkage, the platinum atom of **3b** is bonded to five carbon atoms of the cyanide ligands. Four carbon atoms constitute an almost square plane around the platinum atom, while the fifth carbon atom occupies an axial position in the pseudo-octahedron. The Tl atom is linked to four N atoms (two phen molecules), which together with the bond to Pt form irregular five-coordinated surroundings (Figure 4). The two coordination planes of the phenanthroline ligands around Tl are skewed relative to each other (torsion angle 60.8°), reminding one of butterfly wings. All carbon atoms located in the phenanthroline planes including N12 and N14 exhibit very large atomic displacement parameters; this is probably due to the relatively large free space around them.

The main structural feature of these dimetallic compounds is the short and unsupported Pt−Tl bond with the bond lengths 2.6296(3) and 2.6375(5) Å in **2b** and **3b**, respectively. These Pt−Tl distances fall into the range of values obtained previously in this laboratory for the family of related compounds: $[(NC)_5Pt-Tl(CN)_n(H_2O)_m]^{3-n}$ (n = 0−3; 2.598−2.638 Å),[6] $[(NC)_5Pt-Tl(DMSO)_4]$ (2.6131 Å),[4] $[(NC)_5Pt-Tl(en)_2]$ (2.6348 Å),[4] and $[(NC)_5Pt-Tl(bipy)_n]$ [n = 1−2; 2.6186(8) Å and 2.6117(5) Å, respectively]. The bond lengths of the hitherto characterized Pt−Tl compounds are related to the formal oxidation states of the metal ions $[Pt^0-Tl^I]$ (2.860−3.047 Å);[2a,2b] $Pt^{II}-Tl^I$ (2.876−3.152 Å);[1,2f−2i] $Pt^{II}-Tl^{II}$ (2.698−2.708);[2c,2d] and $Pt^{II}-Tl^{III}$ (2.598−2.638 Å) (refs.[3,4] and present work) Considering only the compounds of divalent platinum, it appears that the Pt−Tl bond becomes shorter when the formal oxidation state of thallium increases from Tl^I to Tl^{III}. This is consistent with both the decreasing size of the thallium cation and with the strengthening of the metal−metal interaction due to participation of the thallium 6s orbitals in the bonding.[3]

Raman vibration bands for the crystalline compounds $[(NC)_5Pt-Tl(phen)(DMSO)_3]$ and $[(NC)_5Pt-Tl(phen)_2]\cdot(DMSO)_3$ were detected at 177 and 172 cm^{-1}, respectively. The Pt−Tl force constants in the title molecules, 1.84 and 1.74 N/cm for **2b** and **3b**, were estimated using the diatomic oscillator approximation model.[8,9] These values are larger than those of the previously studied Pt−Tl cyano complexes (about 1.6 N/cm for the diatomic approximation).[3b,6] It shows that the phenanthroline ligand coordination stabilizes the Pt−Tl metal−metal bonding. The relation between the force constant and the Pt−Tl bond length was observed in the previously studied compounds $[(NC)_5Pt-Tl(CN)_n]^{n-}$ (n = 1−3) [the bond lengths are 2.598(3), 2.618(4), and 2.638(4) Å, which corresponds to force constants of 1.736, 1.693, and 1.563 N/cm, respectively).[6] A correlation seems to exist between the force constant and the Pt−Tl bond length within this series of compounds. In the present case, the ligand coordinated to the thallium atom is different, so the results are not expected to fit into the series of cyano compounds. A similar trend is, however, observed in **2b** and **3b**; the bond lengths are 2.6296(3) and 2.6375(5) Å, and the corresponding force constants are 1.85 and 1.74 N/cm, respectively. Even if the force constants increase when the cyano ligands are replaced by phenanthroline in the Tl sphere of the dinuclear Pt−Tl complex, the constants are still compatible with a single metal−metal bond.[10] The C≡N stretching region of the dinuclear species is also informative and can provide an additional support for the structure of the compounds. We assigned the two sharp bands at $\tilde{\nu}$ = 2174 and 2161 cm^{-1} for **2b** and at 2178 and 2160 cm^{-1} for **3b** to the symmetric (A_{1g}) and antisymmetric (B_{1g}) stretching vibrations of the four equivalent cyanide ligands of the $Pt(CN)_4$ unit in D_{4h} symmetry.[18] These bands shift to high frequency and are very close to the stretching bands at 2153 cm^{-1} (s) and 2137 cm^{-1}(m) for $[Pt(CN)_4]^{2-}$ in the solid state. The higher frequency bands at 2184 cm^{-1} and 2189 cm^{-1} were assigned to the axial cyanide in compounds **2b** and **3b**, respectively.

$[Tl(phen)_2Cl_2](ClO_4)$ (4)

The molecular structure of the cation $[Tl(phen)_2Cl_2]^+$ is shown in Figure 5. The thallium atom is six-coordinated and is bonded to four nitrogen atoms of two 1,10-phenanthroline ligands and to two chloride ions. Interestingly, the two phen planes are almost perpendicular to each other (torsion angle = 90.1°). The atoms within the phenanthroline ligands are almost within its molecular plane. The thallium complex can be viewed as consisting of two equivalent Tl(phen)Cl units, each located in its own hemisphere of the coordination shell of Tl. In **4**, thallium is *cis*-coordinated by two Cl ligands similarly to the *cis*-dichlorobis(2,2′-bipyridyl)gallium(III) cation.[24] Four N atoms and two chloride ions form a distorted octahedral geometry around Tl. The

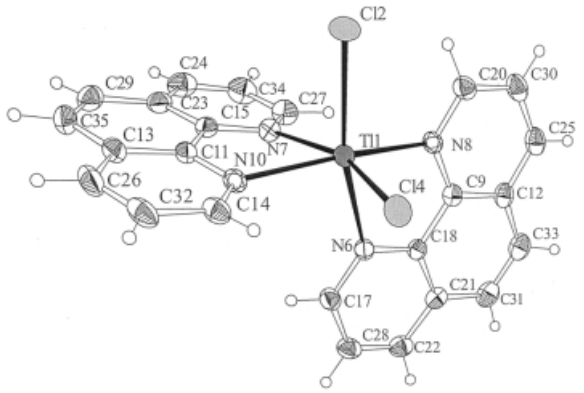

Figure 5. ORTEP view of the $[Tl(phen)_2Cl_2]^+$ cation found in the crystal structure of $[Tl(phen)_2Cl_2](ClO_4)$ (**4**); thermal ellipsoids are drawn at the 30% probability level; selected bond lengths [Å] and angles [°]: Tl(1)−N(8) 2.357(3), Tl(1)−N(7) 2.362(3), Tl(1)−N(10) 2.372(3), Tl(1)−N(6) 2.384(3), Tl(1)−Cl(4) 2.4655(9), Tl(1)−Cl(2) 2.4789(9); N(8)−Tl(1)−N(7) 96.81(10), N(7)−Tl(1)−N(10) 70.64(19), N(10)−Tl(1)−N(6) 98.95(10), N(8)−Tl(1)−Cl(4) 100.05(7), N(7)−Tl(1)−Cl(4) 160.29(8), N(10)−Tl(1)−Cl(2) 98.15(8), N(6)−Tl(1)−Cl(2) 159.35(7), Cl(4)−Tl(1)−Cl(2) 100.02(4)

mean Tl−N distance, 2.369(3) Å (2.357−2.384 Å), is similar to that in $[Tl(bipy)_3(DMSO)]^{3+}$ (2.356−2.372 Å), and the atomic arrangement is almost exactly the same as in the complex $[Tl(phen)Cl_3]$.[12] The mean Tl−Cl distance, 2.4722(9) Å (2.4655−2.4789 Å), is similar to the previously studied complex {$[Tl(phen)Cl_3]$: 2.467(3) Å}, but they are longer than those in tetrahedral $[TlCl_4]^-$ and shorter than those in $[TlCl_5(DMSO)]^{2-}$ [2.506(6)−2.636(6) Å][13] and $[TlCl_6]^{3-}$ (2.59 Å).[14]

Comparison of the Structures and Optical Properties

Apart from the previously discussed ^{205}Tl NMR chemical shift, the change in the actual oxidation state of the metal ions in the heterodinuclear compounds is also reflected by the bond lengths Tl−O and Tl−N. The bonds Tl−O [average 2.471(5) Å in **1**] and Tl−N [average 2.422(8) Å in **2**] are significantly longer than the corresponding distances in the mononuclear Tl^{III} complexes $[Tl(DMSO)_6]^{3+}$ [2.224(3) Å][11] and $[Tl(phen)_2Cl_2]^+$ [average 2.369(3) Å] (**4**). The increase in the Tl−O and Tl−N bond lengths in the studied Pt−Tl compounds is compatible with the decrease of the thallium oxidation state upon formation of the Pt−Tl bond. It confirms that the reaction of $[Tl^{III}(phen)_n]^{3+}$ (n = 1−2) with $[Pt^{II}(CN)_4]^{2-}$ to form heterodinuclear Pt−Tl metal−metal-bonded compounds $[(NC)_4Pt-Tl(phen)_n(solv)]^+$ and $[(NC)_5Pt-Tl(phen)_n(solv)]$ (n = 1,2) can be considered as an oxidative addition.

The optical properties of the dinuclear complexes $[(NC)_5Pt-Tl(CN)_n(aq)]^{n-}$ (n = 0−3) in aqueous solution are dominated by the metal−metal interaction. A very intensive electronic absorption band appears in the UV region, with the maximum in the range 238−259 nm (ε = $2.9-6.9\cdot10^4$ $L\cdot mol^{-1}\cdot cm^{-1}$) depending on the number of cyanide ligands in the compound.[3] The metal-to-metal charge-transfer band (MMCT) of the dinuclear complex $[(NC)_5Pt-Tl(solv)]$ in DMSO is found at 294 nm (ε = $2.1\cdot10^4$ $L\cdot mol^{-1}\cdot cm^{-1}$). Interestingly, the maximum MMCT band of $[(NC)_4Pt-Tl(solv)]^+$ in DMSO is found at 350 nm, which is a dramatic shift to the red compared to $[(NC)_5Pt-Tl(solv)]$. For all the dinuclear complexes studied, it seems that the maximum of the MMCT band is approximately proportional to the corresponding Pt−Tl spin-spin coupling constant. This phenomenon was also found for the dinuclear Pt−Tl cyano complexes. By comparing the electronic absorption spectra of $[(NC)_5Pt-Tl(phen)_2]$ and the parent complex $[Tl(phen)_3]^{3+}$, both in DMSO, the maximum for the former compound, at 274 nm (ε = $4.41\cdot10^4$ $L\cdot mol^{-1}\cdot cm^{-1}$), was assigned to the metal-to-metal charge transfer transition (MMCT). This corresponds to a shift by 15 nm to longer wavelength relative to the M−M transition in the complex $[(NC)_5Pt-Tl(H_2O)_5]$ in water. This shift is attributed to the change of thallium coordination (two phen ligands replace five water molecules). It can be concluded that there is no dramatic effect of the coordinated phenanthroline ligand on the MMCT transition.

^{195}Pt-^{205}Tl Spin-Spin Coupling Constants and ^{205}Tl NMR Chemical Shifts

Until now, ^{205}Tl NMR chemical shifts and Pt−Tl spin-spin coupling constants have been recorded for fifteen Pt−Tl heterodinuclear complexes in DMSO (cf. Supporting Information). Interestingly, the values of δ_{Tl} and $^1J(^{195}Pt-^{205}Tl)$ for all these complexes fall onto a straight line (Figure 6). This cannot be accidental, considering the very large intervals for both parameters, about 57000 Hz and 2140 ppm, respectively. As has been discussed previously,[20,21] the very large chemical shift variation is related to the oxidation state (large variation of the electron density) of the ^{205}Tl nucleus via the paramagnetic term of the Ramsey equation.[22] Also, the spin-spin coupling is related to the electron density: in the present case, the Pt−Tl coupling is transmitted via the s-electrons participating in the Pt−Tl bond.[23] The relation can be explained as follows: The Tl-coordinated ligands induce transfer of electrons from the Tl nucleus towards Pt. In this way, Tl becomes more deshielded, which leads to larger values of the Tl NMR chemical shift.

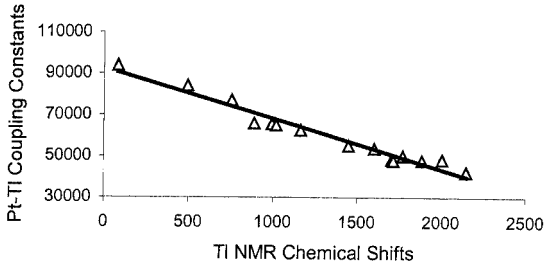

Figure 6. A correlation between the ^{205}Tl NMR chemical shifts (in ppm) and spin-spin coupling constants (in Hz) for all measured Pt−Tl bonded compounds in DMSO; the straight line follows the equation ^1J [Hz] = $-24.6\cdot\delta_{Tl}$ [ppm] + 92740

At the same time, the total electron density (and the density of the s electrons that contribute to the Fermi contact term)[23] of the Pt−Tl bond decreases, which leads to a decrease in the spin-spin coupling constant $^1J(^{195}Pt-^{205}Tl)$ and to a weakening of the Pt−Tl bond.

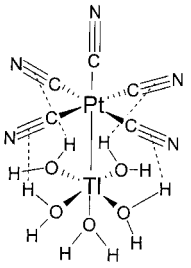
It would be interesting to compare the spin-spin coupling and chemical shifts of the two studied types of complexes $[(NC)_4Pt-Tl(phen)_n(solv)]^+$ and $[(NC)_5Pt-Tl(phen)_n(solv)]$ (n = 0, 1, and 2). A single cyanide ligand coordinated to the platinum atom in the axial position decreases the Pt−Tl coupling and increases the Tl chemical shifts dramatically. What could be the reason? It is probable that after the axial cyanide ligand has been coordinated, the electron-donating ability of the orbital d_{z^2} towards the Tl 6s orbital decreases, the electron density around Tl decreases and the Fermi contact term becomes small, so the real oxidation state increases. Meanwhile, the spin-spin coupling becomes small and the chemical shift increases.

It is also interesting to compare the Pt−Tl spin-spin coupling of the complex $[(NC)_5Pt-Tl]$ in two different solvents, water and DMSO. It is reasonable to consider that five molecules of H_2O or DMSO are coordinated to the thallium atom in the Pt−Tl dinuclear complex, in the same way as in the solid state.[6] In agreement with the stronger ability of DMSO to donate electron density to Tl^{III}, ^{205}Tl NMR chemical shift in solution of $[Tl(DMSO)_6]^{3+}$ (δ = 1886)[11] is smaller than that of $[Tl(H_2O)_6]^{3+}$ (δ = 2093).[19] Accordingly, the ^{205}Tl NMR chemical shift of the $[(NC)_5Pt-Tl]$ complex in DMSO should be smaller than for the same complex in aqueous solution. Also, the Pt−Tl coupling constant of $[(NC)_5Pt-Tl(DMSO)_5]$ should be larger than that of $[(NC)_5Pt-Tl(H_2O)_5]$. Surprisingly, both the ^{205}Tl NMR shifts and the coupling constants of the two complexes follow just the opposite trend, $[(NC)_5Pt-Tl(DMSO)_5]$ (δ = 887 and 65.9 kHz) and $[(NC)_5Pt-Tl(H_2O)_5]$ (δ = 786 and 71.1 kHz).

What could be the reason for this behaviour? One explanation is that the stronger electron donation from DMSO to the thallium atom would induce a partial transfer of electrons from Tl towards Pt, thus causing the observed trend for the chemical shifts and the spin-spin coupling constant Pt−Tl. An alternative explanation goes as follows: Very recently, theoretical calculations (DFT calculation considering relativistic effects)[23] led to a suggestion that short C≡N···H hydrogen bonds (N···H approximately 2.2 Å, see Scheme 2) are formed between the thallium-coordinated water molecules and the platinum-bonded cyanide ligands. This would lead to a strengthening of the Pt−Tl bond; indeed, the Pt−Tl distance would become quite short (Pt−Tl approximately 2.600 Å).[23] This type of hydrogen bond cannot form in DMSO solution; hence, it would be compatible with the (opposite to the expected) trend of the chemical shifts and the coupling constant.

Conclusions

Five novel Pt−Tl(phen) complexes in DMSO, $[(NC)_4Pt-Tl(solv)]^+$ (**1a**), $[(NC)_4Pt-Tl(phen)(solv)]^+$ (**2a**),



Scheme 2

$[(NC)_4Pt-Tl(phen)_2(solv)]^+$ (**3a**), $[(NC)_5Pt-Tl(phen)(solv)]$ (**2b**), and $[(NC)_5Pt-Tl(phen)_2(solv)]$ (**3b**) have been prepared and their formation shown by means of ^{205}Tl NMR. The very large ^{195}Pt-^{205}Tl spin-spin coupling constants, 94.0, 84.2, and 77.1 kHz for complex **1a**, **2a**, and **3a**, and 65.4 and 62.5 kHz for complex **2b** and **3b**, respectively, unambiguously demonstrate the presence of a direct metal−metal bond in the complexes. For the first time in Pt−Tl-bonded complexes, the species $[(NC)_4Pt-TlX]$ [where X = $(phen)_n(solv)$, n = 1 and 2] comply with the 16-electron rule, with respect to platinum. The results show that the complexes with 16 electrons are stable in solution, long enough for the study on the ^{205}Tl NMR time scale. Three solid compounds, $[(NC)_5Pt-Tl(phen)(DMSO)_3]$ (**2b**), $[(NC)_5Pt-Tl(phen)_2]$ (**3b**), and $[Tl(phen)_2Cl_2](ClO_4)$ (**4**), were crystallised from solution and their structures determined by X-ray diffraction. In compounds **2b** and **3b** unsupported metal−metal bonds are present. The Pt−Tl distances, 2.6296(3) and 2.6375(5) Å for **2b** and **3b**, respectively, are among the shortest reported separations between these two metals. The Pt−Tl force constants in the molecules **2b** and **3b**, 1.84 and 1.74 N/cm, respectively, calculated from Raman frequencies of the metal−metal stretching vibrations, are compatible with the intermetallic Pt−Tl separations; the values of the force constants are characteristic for a strong, single metal−metal bond. Attachment of phenanthroline to the thallium part of the dimetallic platinum−thallium(cyano) compounds resulted in a red shift of the metal-to-metal charge transfer band.

Experimental Section

Synthesis: The solid $[Tl(DMSO)_6](ClO_4)_3$ was prepared as described in a recent paper.[11] The complex $[(NC)_4Pt-Tl(solv)]^+$ (**1a**) was obtained by the reaction between solid compounds $[Tl(DMSO)_6](ClO_4)_3$ (49 mg, 0.05 mmol) and $K_2Pt(CN)_4$ (19 mg, 0.05 mmol), concentration 50 mM in 1 mL of DMSO. Upon addition of 1,10-phenanthroline to the solution of complex **1a**, the complexes **2a** and **3a** were prepared in solution. The reactions were monitored by ^{205}Tl NMR spectroscopy. The solid compound $[(NC)_5Pt-Tl(DMSO)_4](DMSO)$ was obtained as described previously.[4a] Two different routes were used to prepare compounds **2b** and **3b**: i) 49 mg of $[Tl(DMSO)_6](ClO_4)_3$ (0.05 mmol), 19 mg of $K_2Pt(CN)_4$ (0.05 mmol), and 9 mg or 18 mg of 1,10-phenanthroline (0.05 mmol or 0.1 mmol) for **2b** and **3b**, respectively, were added to 1 mL of DMSO in the presence of 50 mM NaCN. After stirring the

solutions for 5 h, compounds **2b** and **3b** formed in solution (see Scheme 1). ii) 46 mg (0.05 mmol) of solid $[(NC)_5Pt-Tl(DMSO)_4](DMSO)$ was dissolved in 1 mL of DMSO, then 11 mg (0.06 mmol) of 1,10-phenanthroline was added for compound **2b** and 20 mg (0.1 mmol) for compound **3b**. After stirring for half an hour, compounds **2b** and **3b** formed in solution. Crystals containing **2b** and **3b** suitable for X-ray analysis were crystallised by putting the resulting solutions inside a dark vacuum desiccator and slowly evaporating the solvent by degassing. Small round transparent white crystals formed at the bottom of the flask after several days. Raman spectra of the solid compounds **2b** and **3b** were recorded with a Renishaw System 1000 spectrometer equipped with a microscope (Leica DMLM). The abbreviations are: vs = very strong, s = strong, m = medium, w = weak. The band positions and assignments are as follows. **2b:** $\tilde{\nu}$ = 2995 m, 2915 s (CH_3 str.), 2184 s (axial C≡N str.), 2174 m, 2161 m (equatorial C≡N str.), 1206 w, 1102 m, 1002 m, 952 m (CH_3 bend), 712 s, 672 vs (CS str.), 452 s (TlO str.), 378 m, 308 m (CSC or OSC bend), 177 vs (Pt−Tl str.). $\tilde{\nu}$ (of coordinated phen) = 1621 w, 1603 w, 1588 w, 1516 m, 1446 m, 1412 vs, 1341 w, 1311 m, 1255 w, 1206 w, 1052 m, 862 w, 727 m, 552 s, 452 s 422 s, 402 m, 332 s 282 m, 257 w.

3b: $\tilde{\nu}$ = 2189 s (axial C≡N str.), 2178 m, 2160 m (equatorial C≡N str.), 172 vs (Pt−Tl str.). $\tilde{\nu}$ (of coordinated phen) = 1626 w, 1604 w, 1590 w, 1521 w, 1455 s, 1417 vs, 1344 w, 1306 s, 1252 w, 1207 w, 1139 w, 1103 m, 1060 m, 867 m, 728 s, 558 s, 463 s, 423 vs, 408 m, 332 s, 288 s, 261 m (for free phen: 1585 m, 1499 m, 1444 s, 1402 vs, 1341 m, 1291 s, 1094 m, 1032 s, 707 vs, 407 s, 242 m).

4: Colourless cubic crystals of compound **4** were obtained from a DMSO solution with the following composition: 50 mM $Tl(ClO_4)_3$, 100 mM 1,10-phenanthroline, and 200 mM Cl^- by slowly evaporating the solvent. Raman vibration bands of solid compound **4:** $\tilde{\nu}$ (of coordinated phen) = 1623 w, 1601 w, 1581 w, 1514 w, 1448 s, 1418 vs, 1336 w, 1306 s, 1248 w, 1198 w, 1144 w, 1102 m, 1052 m, 857 w, 726 s, 554 s, 437 s, 420 vs, 402 m, 280 m, 268 s. $\tilde{\nu}$ (of ClO_4^-) = 929 s.

^{205}Tl NMR Measurements: All ^{205}Tl NMR measurements were performed with a Bruker DMX500 spectrometer at a probe temperature of 25 (±0.5) °C. DMSO was used as solvent. The spectra were recorded at SF = 288.5 MHz; typical NMR parameters: flip angle about 30°; spectral window 86 kHz; pulse repetition time 0.5 s. The chemical shifts are reported in ppm toward higher frequency with respect to an external aqueous solution of $TlClO_4$ extrapolated to infinite dilution.

X-ray Crystal Structure Analysis: Suitable crystals of **2b**, **3b**, and **4** were selected under a polarizing microscope and mounted on a glass fibre. The data were collected with a Nonius Kappa CCD area detector, λ(Mo-K_α) = 0.71073 Å, using a graphite monochromator. Numerical absorption correction was applied.[15] The structures were solved by direct methods[16] and refined using full-matrix least squares on F^2 (SHELXL-97).[17] All the non-hydrogen atoms in compounds **2b**, **3b**, and **4** were refined with anisotropic displacement parameters. Hydrogen atoms were located at calculated positions and refined riding on their carrier atoms. In **3b**, one of the three non-coordinated DMSO molecules is disordered. Selected crystal data for compounds **2b**, **3b**, and **4** are listed in Table 1. CCDC-157362 (**2b**), -157363 (**3b**) and -157364 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[8] Force constants in N/cm were calculated from $k = (5.889 \cdot 10^{-7}) \cdot \tilde{\nu}^2 \cdot \mu$, where $\tilde{\nu}$ is wavenumber in cm^{-1} and $\mu = M_{Pt} \cdot M_{Tl}/(M_{Pt} + M_{Tl})$, with atomic masses of the metals in Daltons.

[9] Recently completed calculations of the metal−metal stretching force constants in the complexes $[(NC)_5Pt-Tl(CN)_n]^{n-}$ (n = 0−3) show that in a full model, taking into account all vibrational modes (both metal−metal and metal−ligands), about 92% is attributed to purely diatomic Pt−Tl stretch (see ref.[6a]).

Bis(η-*tert*-butylcyclopentadienyl)hydridoniobium Ditelluride, a Convenient Reagent for the Synthesis of Polynuclear Metal Telluride Complexes

Henri Brunner,[a] Helene Cattey,[b] David Evrard,[b] Marek M. Kubicki,[b] Yves Mugnier,[b] Estelle Vigier,[b] Joachim Wachter,*[a] Robert Wanninger,[a] and Manfred Zabel[a]

Keywords: Niobium / Tellurium / Polynuclear complexes / Cyclopentadienyl complexes / Electrochemistry

Reaction of $[Cp'_2NbH_3]$ ($Cp' = tBuC_5H_4$) with Te powder in THF gives $[Cp'_2Nb(Te_2)H]$ (**1**) and $[Cp'_6Nb_4Te_4O]$ (**2**). The yield of **1** varies between 10 and 81% depending on the degree of oxygen contamination of the reagents. Complexes **1** and **2** react with $[Cr(CO)_5THF]$ to give $[Cp'_2Nb(Te_2)H{\cdot}Cr(CO)_5]$ (**3**) and $[Cp'_6Nb_4Te_4O{\cdot}2Cr(CO)_5]$ (**4**), respectively. The crystal structures of **2**–**4** have been determined. In **3** a Te_2 unit and an H ligand are coordinated to a bent niobocene moiety; the $Cr(CO)_5$ group is attached to the lateral Te atom. The molecular cores of **2** and **4** are practically identical in that they contain two planar Nb_2Te_2 rings connected by a nearly linear oxygen bridge. Each of the "outer" Nb atoms bears two Cp′ ligands, whereas the "inner" Nb atom only has one such ligand. An additional structural feature in **4** is two $Cr(CO)_5$ groups, attached to one Te bridge of each Nb_2Te_2 ring. Thermolysis of **3** leads to the formation of diamagnetic $[Cp'_4Nb_2Te_2]$ (**5**), which also contains a planar Nb_2Te_2 core. The relatively long transannular Nb–Nb distance (3.647 Å) is consistent, according to DFT calculations, with a through-space Nb–Nb coupling. Complex **5** reacts with CH_3I with successive methylation of both Te bridges to give $[Cp'_4Nb_2Te(CH_3Te)]I$ (**[6]I**) and $[Cp'_4Nb_2(CH_3Te)_2]I_2$ (**[7]I_2**). The crystal structure of **[7]I_2** may be derived from that of **5**, the incoming CH_3 groups being fixed at the Te bridges in a *trans* position. ^1H NMR spectroscopic investigations reveal a restricted rotation around the Cp′–Nb bonds in **2** and **5** at –90 °C and in **4** and **[7]I_2** at ambient temperature. Electrochemical studies have been carried out on **5**, **[6]I**, and **[7]I_2**, showing that all compounds undergo two reversible one-electron reduction steps. The reduction potential decreases by ca. 1.6 V when going from **5** to **[7]I_2**. There is also a clear linear correlation between the reduction potentials measured for **5** to **[7]I_2** and the energies of the corresponding LUMO's calculated at the DFT/B3LYP level. These LUMO's bear some 70% contribution from both Nb atoms and, consequently, the reduction processes mainly operate at both metallic centers.

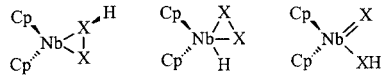
Introduction

Group 4 and 5 metallocene derivatives of the heavier chalcogens Se and Te are an attractive target for reactivity studies.[1−3] Recent examples include ligand rearrangements[4−6] and the stabilization of labile seleno- and telluroorganic ligands.[3,4] Niobocene or tantalocene dichalcogenides exist in the isomeric forms **A**−**C**, and depending on the nature of the cyclopentadienyl ligand (Cp) and the chalcogen X (X = Se or Te) the additional hydrogen is found in different bonding modes.[6] The only known example of isomer **A** is $[Cp^*_2Nb(\eta^2\text{-}Te_2H)]$ in which the Nb center bears electron-rich peralkylated C_5Me_5 (Cp^*) ligands along with a hydrogenditelluride ligand.[7] Its reactivity is characterized by an easy loss of Te^0 [7] or Te^{2-} [8−11] in the presence of reactive transition metal fragments, which finally leads to a series of homo- and heterometallic telluride clusters.



A **B** **C**

It has already been established that the formation of related niobocene sulfides strongly depends on the substituents at the Cp ligand.[12] Therefore, we decided to investigate the reaction of $[Cp'_2NbH_3]$ ($Cp' = tBuC_5H_4$) with tellurium. Our investigations show that the replacement of the electron-rich C_5Me_5 ligand by Cp′ exerts considerable influence on the electronic and steric parameters as well as on the subsequent formation of polynuclear metal telluride complexes.

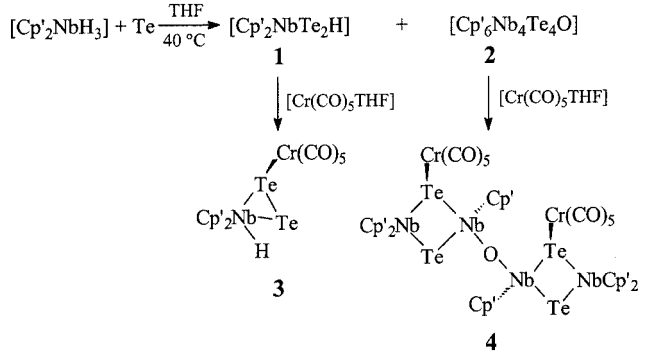
Results and Discussion

Preparation and Characterization of Complexes 1−4

Reaction of $[Cp'_2NbH_3]$ with 2.5 equivalents of carefully degassed tellurium powder in freshly distilled THF at 40 °C

[a] Institut für Anorganische Chemie, Universität Regensburg, 93040 Regensburg, Germany
[b] Laboratoire de Synthèse et d'Electrosynthèse Organométalliques (UMR 5632), Université de Bourgogne, 21100 Dijon, France

gave dark orange $[Cp'_2Nb(Te_2)H]$ (**1**) in 81% yield. However, in the presence of traces of air complex **1** was obtained in yields of between 10 and 32% and red-violet $[Cp'_6Nb_4Te_4O]$ (**2**) formed in yields from 9−53% as an additional product (Scheme 1). Similar results were obtained in toluene at 80 °C. Solutions of **1** are very sensitive towards air and even the solid decomposes slowly when stored at −20 °C. In boiling toluene **1** slowly converts into **2**. In a typical example 18% of **2** was formed after 24 h. This behavior is in contrast with that of the structurally related $[Cp^*_2Ta(Te_2)H]$, which transforms into $[Cp^*_2Ta(=Te)H]$ under similar conditions.[4]



Scheme 1

The composition of complexes **1** and **2** was determined from FD mass spectra and confirmed by elemental analyses. The latter, however, gives good results only for **2** as the values obtained for **1** are always a little bit too low. Correct analytical data have been obtained for the $Cr(CO)_5$ adduct **3** (see below), which has successfully been subjected to an X-ray crystallographic investigation.

The ^1H NMR spectrum of **1** at room temperature as well as at −90 °C shows four multiplets of equal intensities for the aromatic protons and one singlet at $\delta = 1.39$ for the *t*Bu groups. An additional signal at $\delta = -3.50$ is observed with $^2J(H\text{-}^{125}Te) = 86.7$ Hz. One Te resonance was found by means of $^1H\text{-}^{125}Te$ polarization transfer techniques and this was confirmed in the ^{125}Te NMR spectrum, which revealed only one broad resonance ($h_{1/2} \approx 300$ Hz) at $\delta = -749.4$. The second resonance cannot be detected, probably due to partially relaxed scalar $^{125}Te\text{-}^{93}Nb$ interactions. Unfortunately, similar problems prevented the observation of ^{125}Te NMR spectra for the other compounds. An X-ray diffraction analysis carried out on $[Cp'_2Nb(Te_2)H{\cdot}Cr(CO)_5]$ (**3**) (see below) provides evidence for the presence of a $\mu,\eta^{1:2}\text{-}Te_2$ ligand. Localization of a hydride directly bonded to the Nb center and lying in the $NbTe_2$ plane allows for the determination of **3**, and very likely **1**, from the structural form **B**. Structural analogs of **1** are $[Cp^*_2Ta(Te_2)H]$,[4] $[Cp'_2Ta(S_2)H]$,[13] and $[Cp^*_2Nb(S_2)H]$.[12a] There is no evidence for the existence of any other isomeric form.

An X-ray diffraction analysis of a single crystal of **2** shows two planar Nb_2Te_2 rings (Figure 1) connected by an oxygen bridge. Each of the "outer" Nb atoms [Nb(1), Nb(4)] bears two Cp′ ligands, whereas the coordination sphere of the "inner" Nb atoms [Nb(2), Nb(3)] is completed by only one Cp′ ligand, thus forming two $Cp'_3Nb_2Te_2$ units. The linearity of the Nb−O−Nb bridge [angle (Nb−O−Nb) = 177.1(1)°] evokes a contribution of p_π oxygen orbitals as has been suggested for other linearly O-bridged bimetallic complexes.[14] The fact that the observed Nb−O distances [mean 1.909(2) Å] are longer than Nb=O bonds in oxoniobocene complexes (1.63−1.741 Å)[15] is not in contradiction with the above argument.[14] Within the Nb_2Te_2 rings there are two different Nb−Te distances. The Nb−Te bonds around Nb(2) and Nb(3) are shorter than the bonds around Nb(1) and Nb(4), by 0.18 Å (Table 1). They are also slightly shorter than typical Nb−Te single bonds.[16] Striking differences are found for the Te−Nb−Te angles, they range from 96.4(1)° [Te(3)−Nb(4)−Te(4)] to 107.1(1)° [Te(1)−Nb(2)−Te(2)], thus reflecting the different coordination spheres around both niobium centers. A similar structure has been found in $[Cp'_6V_4S_4O]$.[17]

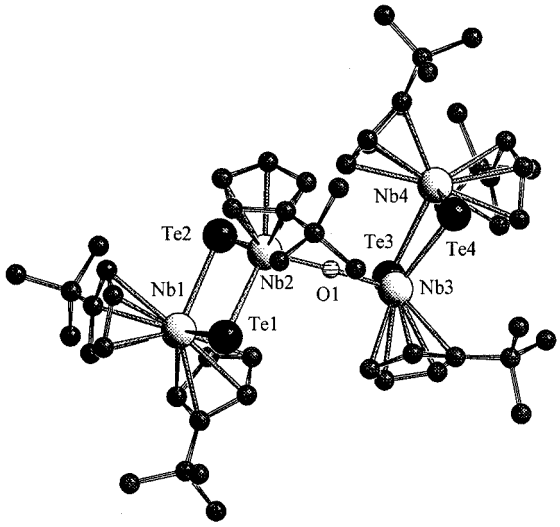


Figure 1. Molecular structure of $[Cp'_6Nb_4Te_4O]$ (**2**) (Schakal)

The diamagnetic nature of the molecule is deduced from its ^1H NMR spectrum (see below) and it may be explained by the presence of direct Nb−Nb interactions: Whereas the Te−Te distances (4.236 Å) approximately correspond to the sum of the van der Waals radii[18] the Nb−Nb distances (3.43 Å) are only slightly longer than those in $[(C_5H_5)_2Nb(\mu\text{-}S)]_2$ [*d*(Nb−Nb) 3.2340(8) Å][19] or in $[C_5H_5(C_5H_4)NbH]_2$ (3.105 Å),[20] for which Nb−Nb bonds have been postulated. The possibility of through-space Nb−Nb coupling in complexes containing Nb_2Te_2 rings has been investigated for compounds **5**, **[6]I**, and **[7]I_2** (see below).

The crystal structure of **2** also reveals that the bulky *t*Bu groups in the niobocene units "Nb(1)" and "Nb(4)" are oriented in a staggered conformation. The concerned $t\text{Bu}-Cp_{center}/t\text{Bu}-Cp'_{center}$ torsional angles are about 122°. Recently it has been shown that for bent group 4 metallocenes like $[(t\text{Bu}C_5H_4)_2ZrX_2]$ (X = halogen, alkyl, aryl), chiral ground-state geometries are able to epimerize upon rotation around the Cp′−metal bond.[21] The activation barrier for this rotation depends on the interaction of

the Cp′-bonded substituent with the ligands X. In our case the ^{1}H NMR spectrum of **2** shows five signals of intensity 4:4:4:8:4 between δ = 4.18 and 5.75 for the C_5H_4 protons, at room temperature. Three singlets of equal intensities are observed for the six *t*Bu groups. Upon cooling to −90 °C the diastereotopic cyclopentadienyl protons split into several broad multiplets, while the *t*Bu groups give a set of not very well resolved signals (Figure 2). A much better resolution into distinct resonances is achieved in the sterically crowded $Cr(CO)_5$ adduct **4** (see below, Figure 2) even at room temperature.

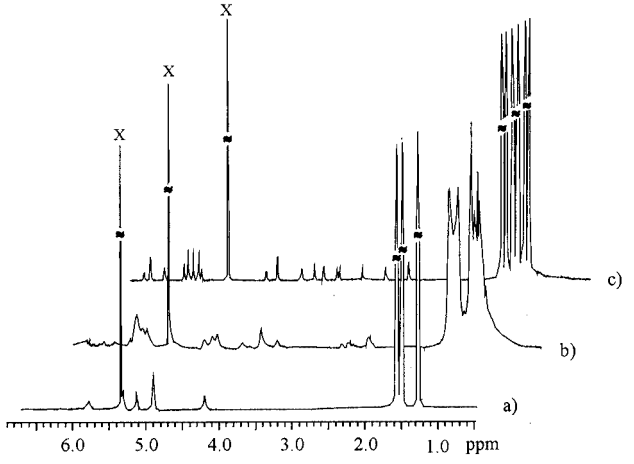

Figure 2. ^{1}H NMR spectra (*t*BuC_5H_4 signals) of **2** at 24 °C (a) and −90 °C (b), and of **4** at 24 °C (c) (X: CH_2Cl_2)

Reaction of $[Cp'_2NbTe_2H]$ with an excess of $[Cr(CO)_5THF]$ gave $[Cp'_2NbTe_2H{\cdot}Cr(CO)_5]$ (**3**) in 90% yield. An FD mass spectrum, elemental analysis and X-ray diffraction studies confirmed the composition of **3**. The IR spectrum of **3** contains absorptions at 2050, 1945, and 1895 cm^{-1} typical of the $Cr(CO)_5$ fragment, while the ν(Nb−H) frequency is too weak to be detected. The ^{1}H NMR spectrum in CD_2Cl_2 solution exhibits eight broad multiplets of equal intensity between δ = 4.64 and 6.58 at room temperature, which then sharpen at −20 °C. The observed pattern agrees with the presence of nonequivalent Cp′ rings. However, the singlet at δ = 1.31, which is characteristic for the *t*Bu groups, does not split even at low temperatures. The Nb−H resonance at δ = −2.95 is only slightly affected by coordination of the $Cr(CO)_5$ fragment compared to that of **1** (δ = −3.50). The ^2J(H-Te) coupling has disappeared. As **3** is thermally labile in solution (see below) heating of the solution in order to simplify the spectrum was not tried.

A single crystal of **3** was obtained from toluene/pentane (1:1) and studied by X-ray diffraction analysis. A bent metallocene structure with nearly eclipsed *t*Bu substituents is observed as the main structural feature (Figure 3). The Nb atom bears a Te_2 unit and an H atom both located in the plane bisecting the niobocene moiety. The Nb-coordinated hydride follows directly from the difference Fourier synthesis after refinement of all the other atoms. Thus, complex **3** is one of the few structurally characterized complexes containing a $\mu,\eta^{1:2}$-Te_2 ligand. Consequently, the structural type **B** may be assumed for precursor **1**. The Te−Te distance of 2.695(1) Å is similar to those in complexes containing side-on coordinated η^2-Te_2.[22] The coordination of the $Cr(CO)_5$ fragment at Te(2) may be responsible for two slightly different Nb−Te bonds, which are in turn in the

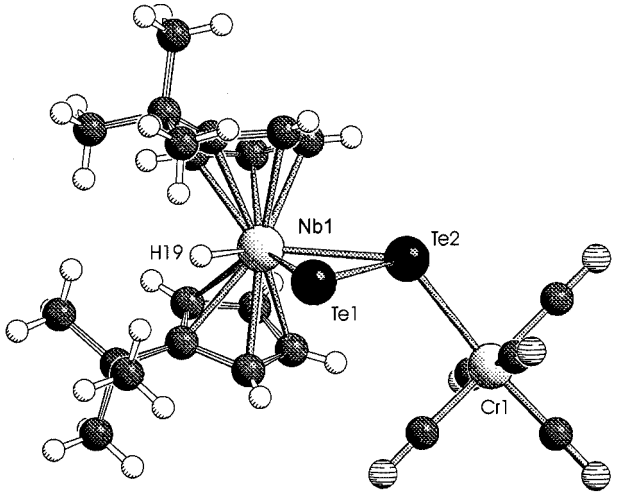

Figure 3. Molecular structure of $[Cp'_2NbTe_2H{\cdot}Cr(CO)_5]$ (**3**) (Schakal); selected distances [Å] and angles [°]: Te(1)−Te(2) 2.695(1), Te(1)−Nb(1) 2.846(1), Te(2)−Nb(1) 2.950(1), Te(2)−Cr(1) 2.712(1), Nb(1)−H(19) 1.60(5); Te(1)−Te(2)−Nb(1) 60.3(1), Te(2)−Te(1)−Nb(1) 64.3(1), Te(1)−Te(2)−Cr(1) 113.3(1), Nb(1)−Te(2)−Cr(1) 128.1(1), Te(1)−Nb(1)−H(19) 68.2(2), $C(1-5)_{center}$−Nb−$C(10-14)_{center}$ 134.1(1)

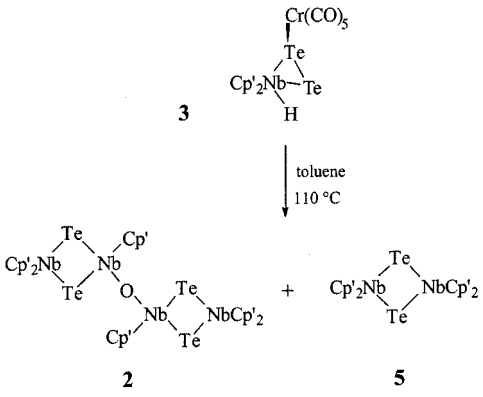
same range as Nb−Te single bonds (see complex **2**). The Te(2)−Cr distance is similar to those in other molecular chromium tellurides.[23]

The solid state structure of **2** has shown the niobocene components to be rather space filling. Therefore it was of interest to see whether the Te bridges were still sufficiently accessible for the addition of bulky Lewis acid complex fragments such as $[Cr(CO)_5]$. Indeed, reaction of THF solutions of **2** with excess $[Cr(CO)_5THF]$ gave $[Cp'_6Nb_4Te_4O{\cdot}2Cr(CO)_5]$ (**4**). Its composition follows from elemental analyses and X-ray crystallography, whereas FD mass spectra only showed the mass peak of the precursor complex **2**. The IR spectrum of **4** exhibits a CO absorption pattern typical for coordinated $Cr(CO)_5$ fragments. The ^1H NMR spectrum of **4** (Figure 2) shows six singlets for the *t*Bu groups between $\delta = 1.24$ and 1.59 and 18 multiplets for the C_5H_4 hydrogens between $\delta = 2.89$ and 6.50 at room temperature, as would be expected from the solid state structure. This result indicates that coordination of the $Cr(CO)_5$ groups gives rise to restricted rotation around the Cp′−Nb bonds in **4** at room temperature, whereas in the precursor complex **2** cooling to −90 °C is required in order to distinguish between the diastereotopic ring protons.

A crystallographic study shows **4** to possess the same structural framework as its precursor **2**. In addition, one Te bridge of each of the two four-membered Nb_2Te_2 rings bears a $Cr(CO)_5$ group (Figure 4). Upon comparing the bonding parameters of **2** and **4** (Table 1) it is evident that coordination of the $Cr(CO)_5$ fragments does not cause significant differences within the inorganic core of both molecules. Differences may only be noted for the conformations of the *t*Bu groups of the niobocene units "Nb(2)" and "Nb(4)" with respect to those of the Cp′ ligands attached at Nb(1) and Nb(3). Steric reasons may be responsible for the coordination of only two $Cr(CO)_5$ fragments at **2**. The Cr−Te−Nb angles in the range of 130° along with the acute dihedral angles (34.4°) formed by the Cr−Te bonds and the Nb_2Te_2 planes are indicative of strong steric interactions in **4** between the $Cr(CO)_5$ groups and the Cp′ ligands.

Preparation, Characterization, and Methylation of $[Cp'_4Nb_2Te_2]$ (5)

In contrast to $[Cp^*_2Nb(Te_2H)]$, which easily eliminates Te^0 units upon reaction with $[Cr(CO)_5THF]$ affording *cyclo*-$Te_4[Cr(CO)_5]_4$,[7] **1** gives the $Cr(CO)_5$ adduct **3**, whose solutions are surprisingly stable at room temperature. However, one may expect a thermal lability of **3** similar to that observed for the isostructural sulfur homologues $[Cp'_2Ta(S_2)H{\cdot}Cr(CO)_5]$[24] and $[Cp^*_2Nb(S_2)H{\cdot}Cr(CO)_5]$.[25] Solutions of these compounds readily lose CO upon heating, forming the heterotrimetallic complexes $[(Cp'_2TaS_2)_2Cr]$ and $[(Cp^*_2NbS_2)_2Cr]$, respectively.[8,9]



(1)

A solution of $[Cp'_2Nb(Te_2)H{\cdot}Cr(CO)_5]$ (**3**) in toluene gave green-black $[Cp'_4Nb_2Te_2]$ (**5**) upon heating, along with small amounts of **2** [Equation (1)]. Complex **5** has been obtained in still better yield from the reaction of **1** with $[Cr(CO)_6]$ in refluxing toluene.[25] The analytical and spectroscopic data of **5** are in agreement with the independently synthesized compound, the solid state structure of which has been described briefly. In this study direct bonding interactions between opposite atoms of the Nb_2Te_2 core were excluded.[25] The central feature of the structure is two niobocene units held together by two Te bridges, thus forming a planar Nb_2Te_2 core (Figure 5). As in compounds **2** and **4** the niobocene units are chiral, but the conformation found in the crystal structure of **5** corresponds to the achiral *meso* form. Although C_{2h} symmetry has been found in

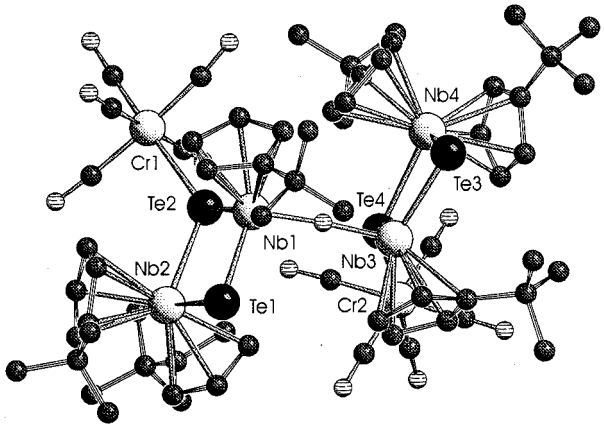


Figure 4. Molecular structure of $[Cp'_6Nb_4Te_4O{\cdot}2Cr(CO)_5]$ (**4**)

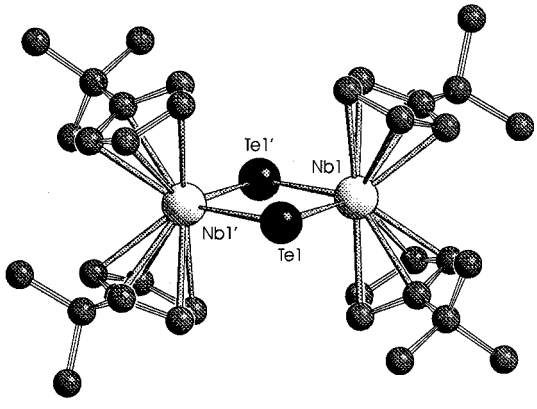

Figure 5. Molecular structure of $[Cp'_4Nb_2Te_2]$ (**5**)[25]

the related complex $[Cp'_4Zr_2Te_2]$ as well, in this complex the ^1H NMR spectra could not provide evidence for a restricted rotation around the Cp′−Zr axis.[21] In our case, examination of CD_2Cl_2 solutions reveals two signals for the C_5H_4 protons and one resonance for the *t*Bu group at ambient temperature, with splitting of the aromatic resonances into four multiplets at δ = 3.24, 4.79, 5.47, and 5.61 upon cooling to −90 °C. As expected the *t*Bu resonance remains unaffected.

Of particular interest is an analysis of the bonding system within the four-membered Nb_2Te_2 ring. In complex **5** each Nb center is surrounded by two Cp′ anions and two Te^{2-} bridges. A bonding interaction between opposite atoms Te(1) and Te(1′) [*d* = 4.262(1) Å] was excluded[25] in agreement with literature values given for planar M_2Te_2 rings: Whereas in the Ni_2Te_2 cycle of $[(iPr_4C_5H)_2Ni_2(\mu\text{-}Te)_2]$ the observed Te···Te distance of 3.052(5) Å has been ascribed to a bond order of nearly one,[26] a clearly nonbonding situation has been found in $[Cp'_4Zr_2Te_2]$ [*d*(Te···Te) = 4.006(1) Å].[21] Less evident is the interpretation of the Nb(1)···Nb(1′) distance in **5**. The found value of 3.647(1) Å is about 0.22 Å longer than that in compounds **2** and **4**. As a possibility to explain the observed diamagnetism of the molecule a through-space metal−metal coupling of both $Nb(d^1)$ centers was suggested[25] as has been recently established in the isoelectronic $[(C_5H_5)_4Zr_2(\mu\text{-}I)_2]$.[27] This direct Nb−Nb interaction has now been confirmed by DFT calculations (see below).

In order to get a better insight into the bonding system and the reactivity of **5** we decided to study methylation reactions and to carry out electrochemical studies on **5** and the reaction products. The methylation of μ_2-Te bridges in organometallic complexes has been reported recently.[28]
