Direct Synthesis of Heterometallic Europium/Barium Complexes: $H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ and $EuBa_2(OC_6H_4Me\text{-}4)_7(diglyme)_2(DME)$

William J. Evans,*[a] Dimitrios G. Giarikos,[a] Michael A. Greci,[a] and Joseph W. Ziller[a]

Keywords: Europium / Barium / Heterometallic complexes / Isopropoxide complexes

Convenient syntheses of mixed-metal Eu/Ba complexes starting from the elemental metals have been explored. A mixture of europium and barium ingots reacts in boiling 2-propanol to form a product which crystallizes from THF as the heterometallic complex formulated as $H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ (**1**). An analogous reaction in the presence of *p*-cresol (HOC_6H_4Me-4) forms trimetallic $EuBa_2(OC_6H_4Me_4)_7(diglyme)_2(DME)$ (**2**), after recrystallization from THF/DME/diglyme (DME = 1,2-dimethoxyethane). Complex **1** exhibits an octametallic geometry comprised of two square pyramids with coplanar bases which share a basal edge and have apices on opposite sides. The six barium atoms occupy the basal positions and the two europium atoms are at the apices. Complex **2** exhibits a triangular arrangement of metal atoms with both terminal and bridging aryloxide ligands coordinated to the europium atom and bridging aryloxide and terminal ether ligands coordinated to the barium atoms.

Introduction

One approach to improve the performance of multi-metallic solid-state materials is to construct them from molecular precursors which have the metal components mixed with a predetermined stoichiometry at the molecular level.[1] To use this method to improve phosphors[2,3] that depend on the special fluorescent properties of europium,[4] convenient syntheses of heterometallic europium complexes are needed. Alkoxide or aryloxide complexes are desirable since they could be converted into oxide materials by sol-gel and thermal methods.[5] Preparation of such complexes directly from the metals is preferable, since it avoids the problems of drying and potential anion contamination which accompany the use of metal salts as precursors.

Although several routes to well-defined homometallic europium alkoxide complexes have been reported,[6−15] heterometallic species have remained elusive. For example, attempts to produce heterometallic Eu/alkaline earth species by direct reaction of the metal ingots with aryl alcohols in liquid ammonia were unsuccessful and produced only mixtures of homometallic species.[16]

We report here the direct synthesis of well-defined heterometallic europium alkoxide complexes by reaction of mixtures of europium and barium metal ingots with 2-propanol at reflux. Barium was chosen since it is a frequent heterocomponent in europium-based phosphors.[17−19] We also describe the variation in structure and metal stoichiometry induced in the isolated products by addition of *p*-cresol to the reaction mixture.

Results and Discussion

Synthesis

Mixtures of metallic europium and barium react with 2-propanol at reflux to form an ether-soluble product. Structural details could not be elucidated from the NMR spectra of the product due to the broadness and shifts in resonances caused by the paramagnetism of europium in this product. To unambiguously determine the nature of reaction products, crystallization was attempted from a variety of coordinating solvents and mixtures of solvents.

Single crystals of **1** could only be obtained from THF. Crystallization of the europium/barium/2-propanol reaction product from THF yielded single crystals which were found by X-ray diffraction to be $H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ (**1**), see Figure 1. The magnetic moment of

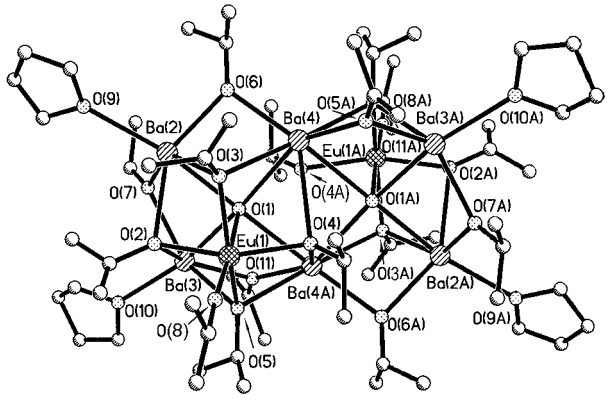

Figure 1. Ball-and-stick diagram of $H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ (**1**); hydrogen atoms are omitted for the sake of clarity

[a] Department of Chemistry, University of California, Irvine, California 92697-2025, USA

this complex was consistent with the presence of trivalent, rather than divalent, europium.[20]

Reactions containing aryl alcohols were also examined, since they had previously been shown to be effective in generating crystalline polymetallic lanthanide complexes.[6,7,11−13,21] After heating a mixture of *p*-cresol and europium and barium metals in 2-propanol at reflux, removal of solvent resulted in a yellow solid. The solid failed to crystallize from THF, diglyme, diethyl ether, and DME, but formed crystals from a mixture of ethers (THF, DME, diglyme, 6:1:1). The fact that **2** crystallized only from a mixture of ethers, but not from any single ether suggested that there may be more than one type of ether in the product. IR data indicated that the product contained arlyoxide ligands. The effective magnetic moment of **2** was also consistent with the presence of Eu^{III}.[20] Elemental analysis was consistent with a 2:1 ratio of Ba/Eu. The structure was determined by X-ray diffraction to be $EuBa_2(OC_6H_4Me\text{-}4)_7(diglyme)_2(DME)$ (**2**), Figure 2.

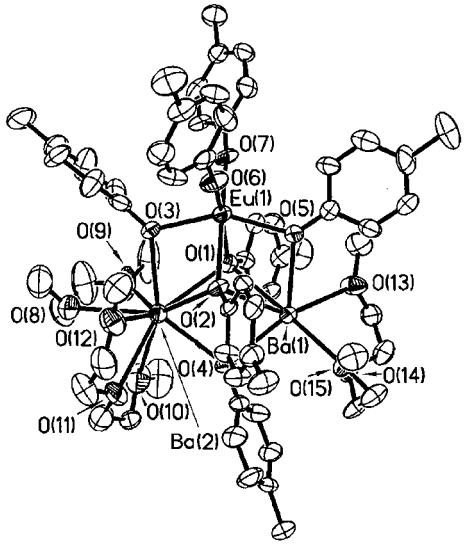

Figure 2. ORTEP diagram of the molecular structure of $EuBa_2(OC_6H_4Me\text{-}4)_7(diglyme)_2(DME)$ (**2**); thermal ellipsoids are drawn at the 30% probability level; hydrogen atoms are omitted for the sake of clarity

Structure of $H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ (1)

Due to the limited quality of the data, only the atomic connectivity in this structure can be described. The metal atoms in **1** do not adopt a conventional eight-coordinate geometry, but rather form the vertices of two square pyramids which share an edge and have their apices on the opposite sides of the basal plane (Figure 3). This geometry

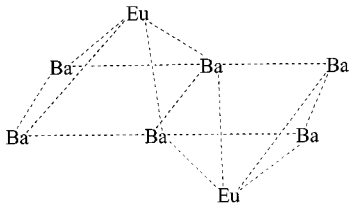

Figure 3. Metal framework in $H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ (**1**)

is not unique to **1** and has been observed in $H_2[Ba_8O_2(OC_6H_5)_{14}(HMPA)_6]$ (**3**), and $H_2[Ba_2Sr_6O_2(OC_6H_5)_{14}(HMPA)_6]$ (**4**), both of which have the same general formula as **1**, namely $H_2[M_8O_2(ligand)_{20}]$.[22]

The two apical positions of the square pyramids in **1** are occupied by europium atoms and the six basal positions are occupied by barium atoms. Complex **4** also has a 3:1 ratio of metals (Sr/Ba) in the same geometry as **1**, but the set of two Ba atoms occupy the shared basal edge positions in **4** instead of the apical positions occupied by the set of two europium atoms in **1**. Both square-pyramidal units in **1** are symmetry-related due to a center of symmetry located between the two europium atoms. The metal···metal distances are given in Table 1.

Table 1. Metal−metal bond lengths [Å] in $H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ (**1**)

Bond	**1**
Eu(1)···Ba(3)	3.737(1)
Eu(1)···Ba(2)	3.738(1)
Eu(1)···Ba(4A)	3.895(1)
Eu(1)···Ba(4)	3.896(1)
Ba(2)···Ba(3)	3.836(1)
Ba(2)···Ba(4)	3.892(1)
Ba(3)···Ba(4A)	3.886(1)
Ba(4)···Ba(3A)	3.886(1)
Ba(4)···Eu(1A)	3.895(1)

The five metal atoms of each square pyramid are connected by one μ_5-oxygen, four μ_3-O*i*Pr ligands bridging the triangular faces, and three μ-O*i*Pr ligands bridging the unshared basal edges of the square pyramid. In addition, there is one terminal isopropoxide ligand on each of the two europium atoms and there is one THF ligand attached to each of the four unshared basal corners of the square pyramids. This generates a six-coordinate europium atom and six- and eight-coordinate barium atoms. Two THF ligands also co-crystallize with each molecule of **1**, but do not interact with the metal centers. In addition to the components described so far, the presence of two protons is required to balance the charge between the observed cations and anions. Hydrogen atoms were not located in the X-ray study and there are no structural anomalies in **1** that would indicate their exact position, in contrast to the situation in **3** and **4**.[22]

Structure of $EuBa_2(OC_6H_4Me\text{-}4)_7(diglyme)_2(DME)$ (2)

The three metal atoms in **2** occupy a triangular arrangement with 4.1316(14) Å Ba(1)···Ba(2) nonbonding distances and 3.8440(13) and 3.8934(13) Å Eu(1)···Ba nonbonding distances. The metal atoms in **2** are connected by two μ_3-aryloxide ligands above and below the triangular plane and three μ_2-aryloxide ligands, each bridging one edge of the triangle. The europium atom has two additional terminal aryloxide ligands, which lead to a formal coordination number of six. The barium atoms have dissimilar coordination environments: each atom has one tridentate diglyme coordinated to it, but Ba(2) also has a bidentate DME. This

gives a formal coordination number of seven for Ba(1) and nine for Ba(2), with respect to the oxygen donor atoms, but further ligation is present, as described below. Bond lengths in **2** are shown in Table 2.

Table 2. Bond lengths [Å] in $EuBa_2(OC_6H_4Me\text{-}4)_7(diglyme)_2(DME)$ (**2**)

Eu(1)−O(1)	2.432(9)	Ba(1)−O(15)	2.815(10)
Eu(1)−O(2)	2.412(9)	Ba(2)−O(1)	2.822(9)
Eu(1)−O(3)	2.299(10)	Ba(2)−O(2)	2.829(9)
Eu(1)−O(5)	2.343(9)	Ba(2)−O(3)	2.751(9)
Eu(1)−O(6)	2.161(10)	Ba(2)−O(4)	2.675(9)
Eu(1)−O(7)	2.193(9)	Ba(2)−O(8)	2.918(11)
Ba(1)−O(1)	2.770(9)	Ba(2)−O(9)	2.909(11)
Ba(1)−O(2)	2.780(9)	Ba(2)−O(10)	2.893(12)
Ba(1)−O(4)	2.630(10)	Ba(2)−O(11)	2.943(11)
Ba(1)−O(5)	2.672(9)	Ba(2)−O(12)	2.815(11)
Ba(1)−O(13)	2.849(10)	Eu(1)···Ba(1)	3.844(1)
Ba(1)−O(14)	2.837(10)	Eu(1)···Ba(2)	3.893(1)

The 2.412(9) and 2.432(9) Å Eu−μ_3-O (OAr) (OAr = OC_6H_4Me-4) distances and the 2.161(10) and 2.193(9) Å Eu−O (terminal OAr) distances in **2** are in the range of those in the trivalent lanthanum 4-methylphenoxide complex $[Me_4N][La_2Na_2(\mu_4\text{-}OAr)(\mu_3\text{-}OAr)_2(\mu\text{-}OAr)_4(OAr)_2(THF)_5]$ [2.284(3) and 2.296(3) Å],[21] considering the differences in Shannon radii,[23] but they are shorter than the corresponding 2.350(5) Å distance in divalent $Eu_2(OC_6H_3Me_2\text{-}2,6)_4(DME)_3$.[6] The 2.299(10) and 2.343(9) Å Eu−μ-O (OAr) distances in **2** are also reasonable compared to those in trivalent $K_3Nd_2(\mu\text{-}OAr)_6(\mu_4\text{-}OAr)_3(THF)_7$ [24] and $\{[La_2Na_2(\mu_4\text{-}OAr)_3(\mu\text{-}OAr)_6(dioxane)_5](dioxane)\}_n$,[17] but they are shorter than the 2.479(3)−2.632(3), 2.447(5)−2.597(5), and 2.444(13)−2.581(12) Å Eu−O (μ-$OC_6H_3Me_2$-2,6) distances in the divalent complexes $Eu_2(OC_6H_3Me_2\text{-}2,6)_4$(*N*-methylimidazole)$_5$,[12] $Eu_2(OC_6H_3Me_2\text{-}2,6)_4(DME)_3$,[6] and $Eu_3(OC_6H_3Me_2\text{-}2,6)_6(THF)_6$,[14] respectively. In general, the differences in Eu−O bond lengths between **2** and divalent europium aryloxides in the literature correspond to the difference in Shannon radii between Eu^{III} and Eu^{II}.[23] This is in agreement with the magnetic data on **2** which indicate that the europium atom is trivalent.

The 2.630(10)−2.751(9) Å Ba−O (μ-OAr) and 2.770(9)−2.829(9) Å Ba−O (μ_3-OAr) distances in **2** are also similar to the corresponding average distances in $HBa_5(O)(OC_6H_5)_9(THF)_8$ [2.65(3) and 2.75(2) Å],[25] **3** [2.65(6) and 2.76(9) Å],[22] and those in $Ba_5(OH)(OC_6H_3Me_2\text{-}3,5)_9(THF)_5$ [26] [2.61(5) and 2.70(3) Å]. The 2.815(11)−2.943(11) Å Ba−O (ether) distances in **2** are in good agreement with the 2.814(6)−2.900(6) Å and 2.826(7)−2.919(8) Å distances in Ba(tetramethylheptanedionate)$_2$(triglyme)[27] and $KBa_2(OSiPh_3)_5(DME)_2$.[28]

In addition to coordination from oxygen atoms, Ba(1) exhibits close contacts with the *ipso*-carbon atoms, C(8) and C(1), from both μ_3-aryloxide ligands, with 3.229(13) and 3.254(14) Å Ba−C (*ipso*-Ar) distances, respectively. These distances are in the range of similar 2.981(6)−3.193(7) Å Ba−C (Ar) contacts in $[Ph_2P(4\text{-methylbenzylide})_2]_2Ba$.[29] The Ba−O−C (Ar) angles in **2** involving these two ligands also suggest that both phenyl rings are canted towards Ba(1): the angles involving Ba(1) [97.0(7) and 98.7(8)°] are more acute than those involving Ba(2) [127.5(8) and 128.3(8)]. Consideration of these two interactions increases the coordination number of Ba(1) to nine, the same as Ba(2).

Conclusion

Mixed metal complexes of europium and barium can be readily synthesized directly from the metals in 2-propanol at reflux. Varying Eu/Ba stoichiometries have been identified in crystalline systems depending on the crystallization conditions.

Experimental Section

General: All reactions were performed in a glovebox under nitrogen or by using standard Schlenk and vacuum line techniques under nitrogen. Europium and barium ingots were washed with hexanes, dried, and cut to appropriate size before use. 2-Propanol was dried by addition of 0.02 equiv. of sodium per equivalent of 2-propanol at 20° C, followed by vacuum transfer of the alcohol from this mixture into the reaction flasks. 4-Methylphenol (Aldrich) was dried and vacuum-distilled from molecular sieves (3 Å). Other solvents were dried and physical measurements were made as previously described.[15] Magnetic moments were measured by the method of Evans[30] with a General Electric QE300 NMR spectrometer. Elemental analyses were performed by Desert Analytics, Tucson, AZ with metal analyses done by atomic absorption spectroscopy.

$H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ (1): Mixtures of europium (0.166 g, 1.1 mmol) and barium (0.408 g, 3 mmol) ingots, typically 0.5 mm in diameter, were combined in a round-bottom flask equipped with a stir bar and a Schlenk adapter. 2-Propanol (25 mL) was vacuum-transferred into the flask. The mixture was heated at reflux for 4 h and the solvent was removed under vacuum with slight heating to give an orange-brown solid (0.51 g, 50% yield based on Eu). A portion of this material (110 mg) was then dissolved in hot THF and centrifuged. Yellow crystals formed overnight at −31 °C (75 mg, 68%). $C_{64}H_{146}Ba_6Eu_2O_{22}$ (2395.74): calcd. C 32.08, H 6.14, Ba 34.39, Eu 12.69; found C 31.86, H 6.28, Ba 34.25, Eu 12.45. Magnetic susceptibility: $\chi_g^{298K} = 5.4 \times 10^{-6}$, $\mu_{eff}^{298K} = 4.2\ \mu_B$. IR (KBr): $\tilde{\nu}$ = 2948 s, 2858 m, 2770 m, 2670 w, 2581 m, 2353 w, 2104 w, 1933 w, 1731 w, 1457 m, 1368 m, 1348 m, 1239 w, 1150 s, 1040 w, 966 s, 902 w, 812 m, 763 w, 728 w, 510 m cm^{-1}. Space group: *C*2/*c*. Unit cell: *a* = 27.853(5), *b* = 24.263(3), *c* = 17.097(4) Å, β = 108.496(12)°, *V* = 10958(4) $Å^3$, *Z* = 4.

X-ray Data Collection and Solution and Refinement for $H_2[Eu_2Ba_6O_2(OiPr)_{16}(THF)_4]$ (1): A yellow crystal of approximate dimensions 0.30 × 0.23 × 0.23 mm was mounted on a glass fiber and transferred to the Siemens P4 diffractometer. The determination of symmetry, crystal class, unit cell parameters and the crystal's orientation matrix were carried out according to standard procedures.[31] Intensity data were collected at 163 K using the 2θ/ω scan technique with Mo-K_α radiation. The raw data were processed with a local version of CARESS[32] which employs a modified version of the Lehman−Larsen algorithm to obtain intensities and standard deviations from the measured 96-step peak profiles. All 7818 data were corrected for absorption and Lorentz and polarization effects and were placed on an approximately absolute scale. The diffrac-

tion symmetry was 2/*m* and the systematic absences were consistent with the centrosymmetric monoclinic space group *C*2/*c*. All calculations were carried out using the SHELXL program.[33] The analytical scattering factors for neutral atoms were used throughout the analysis.[34] The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. Hydrogen atoms were included using a riding model. Two molecules of THF were located per octametallic molecule of **1**. Only heteroatoms were refined anisotropically because of unacceptable thermal parameters for several carbon atoms after anisotropic refinement was attempted. Hence, only connectivity could be determined from these data.

$EuBa_2(OC_6H_4Me\text{-}4)_7(diglyme)_2(DME)$ (2): Europium (117 mg, 0.77 mmol) and barium (210 mg, 1.53 mmol) ingots and *p*-cresol (592 mg, 5.47 mmol) were combined in a round-bottom flask equipped with a stir bar and a Schlenk adapter. 2-Propanol (15 mL) was vacuum-transferred into the flask and the mixture was heated at reflux for 24 h. After the solvent was removed under vacuum with slight heating, 30 mL of THF, 5 mL of DME, and 5 mL of diglyme were added to the flask. After heating for 30 min, the entire product was soluble. Reduction of the solution volume to 5 mL by rotary evaporation led, over a period of 12 h, to the formation of crystals of **2** suitable for single-crystal X-ray diffraction (910 mg, 80%). $C_{65}H_{87}Ba_2EuO_{15}$ (1534.99): calcd. C 50.9, H 5.7, Eu 9.9; found C 50.8, H 5.9, Eu 10.4. Magnetic susceptibility: $\chi_g^{298K} = 3.5 \times 10^{-6}$, $\mu_{eff}^{298K} = 3.5\ \mu_B$. IR (KBr): $\tilde{\nu}$ = 3010 w, 2916 m, 2860 w, 1604 m, 1557 w, 1501 s, 1454 m, 1318 m, 1266 s, 1201 w, 1167 m, 1097 w, 1065 m, 1013 m, 933 w, 858 m, 824 s, 753 m, 580 w cm^{-1}. Temperature: 163 K. Crystal system: monoclinic. Space group: $P2_1/n$. Unit cell: a = 12.269(3), b = 24.750(5), c = 23.570(4) Å, β = 98.685(10)°, V = 7076(2) $Å^3$, Z = 4, $\rho_{calcd.}$ = 1.441 Mg/m^3, μ = 2.035 mm^{-1}.

X-ray Data Collection and Solution and Refinement for 2: A yellow crystal of approximate dimensions 0.20 × 0.10 × 0.10 mm was handled and raw data were processed as described above for **1**. All 9756 data were corrected for absorption and Lorentz and polarization effects and were placed on an approximately absolute scale. The diffraction symmetry was 2/*m* and the systematic absences were consistent with the centrosymmetric monoclinic space group $P2_1/n$. All calculations were as described for **1** above. The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. Minor disorder in the diglyme molecules was modeled by assigning partial occupancy to components of the disordered groups. Hydrogen atoms were included using a riding model. At convergence, $wR2$ = 0.1705 and GOF = 1.066 for 748 variables refined against all 9248 unique data [for refinement on F, $R1$ = 0.0631 for those 5757 data with $F > 4.0\sigma(F)$].

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-171956 (**1**) and -171957 (**2**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

(Diene)rhodium and -iridium Complexes of Pyridinophane Ligands

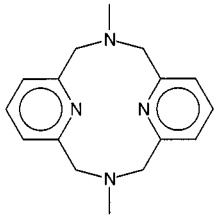
Timo Sciarone,[a,b] Johan Hoogboom,[a] Paul P. J. Schlebos,[a] Peter H. M. Budzelaar,[a] René de Gelder,[a] Jan M. M. Smits,[a] and Anton W. Gal*[a]

Keywords: Diene ligands / Fluxionality / Iridium / Oxidations / Rhodium

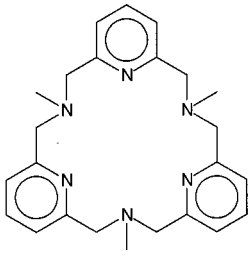
(Diene)rhodium(I) and -iridium(I) derivatives of the pyridinophane ligand L^4 and the analogous macrocycle L^6 have been prepared and characterized [diene = cyclooctadiene (COD) or norbornadiene (NBD)]. In all of the complexes, the ligand is coordinated in a κ^3-(amine)(pyridine)$_2$ fashion; a dynamic process, believed to be concerted, exchanges free and coordinated amine groups. $[L^4Ir(COD)]^+$ can be protonated at the amine nitrogen atom. It reacts with H_2O_2, but *only* in the presence of acid, to give an oxocyclooctenyl complex, formally a 4-e$^-$ oxidation product. X-ray structures of $[L^4Rh(COD)]PF_6$, $[L^6Rh(COD)]PF_6$, $[L^6Rh(NBD)]PF_6$, $[(L^4H)Ir(COD)](BF_4)_2$, and $[L^4Ir(C_8H_{11}O)](PF_6)_2$ are presented.

Introduction

Olefin oxidation at a transition metal center constitutes an important method for functionalizing hydrocarbons. Recent work by Klemperer,[1] Flood,[2] and ourselves[3–8] has shown that hard N- and O-donor ligands can be used to "trap" primary oxidation products such as metallaoxetanes and metalladioxolanes. The oxidation reactions have been found to be very sensitive to ligand variation. In order to explore these ligand effects further, we decided to investigate the (diene)rhodium and -iridium [diene = COD (cyclooctadiene), NBD (norbornadiene)] complexes of pyridinophane ligands L^4 and L^6.



L^4



L^6

These ligands contain the same donor groups as the dipicolylamine (DPA) and tripicolylamine (TPA) ligands that we have studied previously,[5,6] but obviously have very different geometric constraints. Diene complexes are usually rather stable and thus provide a convenient starting point for further studies using more labile olefins. One Rh complex of L^4 has been reported,[9] but no Ir complexes. The coordination chemistry of L^6 appears to be relatively unexplored, and only complexes of two cryptand-like derivatives have been described.[10,11]

thesis always produces a mixture of bis- and tris(pyridine) ligands. The most convenient preparation of pure L^4 involves crystallization at the NH stage.[13] For the preparation of pure L^6, we separated the two components by chromatography at the *N*-tosyl stage; this was much less convenient and required large amounts of solvent.

Complexes of L^4 and L^6 were prepared by adding the ligand to a suspension of $[M(COD)Cl]_2$ (M = Rh, Ir) or $[Rh(NBD)Cl]_2$ in methanol. The products can be isolated as the PF_6, BF_4 or BPh_4 salts by precipitation, or as the chlorides by evaporation of the solvent.

Structure and Fluxionality

In all complexes the metal atom is coordinated to one amine nitrogen atom, two pyridine nitrogen atoms and the diene ligand. X-ray structures of $[L^4Rh(COD)]^+$, $[L^6Rh(COD)]^+$, and $[L^6Rh(NBD)]^+$ are shown in Figures 1, 2, and 3, respectively. The structures are all roughly square-pyramidal, with N_{amine} occupying the apical position. In $[L^4Rh(COD)]^+$, the methyl group at the noncoordinated amine group points away from the Rh atom. This is somewhat surprising, since in the only other complex of a κ^3-coordinated L^4 ligand reported to date $[L^4Mo(CO)_3]$[14] the methyl group points in the opposite direction.[15]

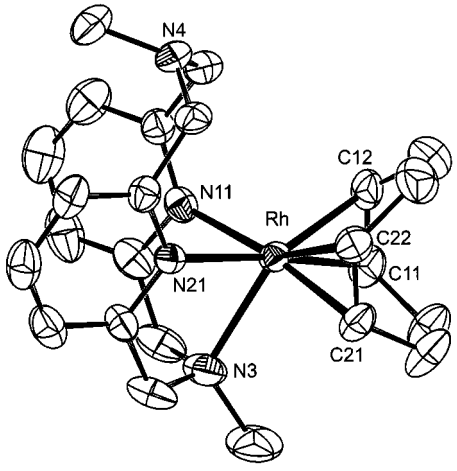

Figure 1. X-ray structure [40% TME (Thermal Motion Ellipsoids)] of $[L^4Rh(COD)]PF_6$; all hydrogen atoms and the counterion have been omitted; selected bond lengths [Å] and angles [°]: Rh−C11 2.105(7), Rh−C12 2.123(7), Rh−C21 2.119(8), Rh−C22 2.137(8), Rh−N11 2.183(6), Rh−N21 2.171(5), Rh−N3 2.336(7); N11−Rh−N21 75.9(2), N11−Rh−N3 77.0(2), N21−Rh−N3 77.0(2)

It is interesting to compare the structures of the L^4 and L^6 complexes with those of other tridentate N-donor ligands. We have recently reported the structures of several $Rh^I(COD)$ complexes of DPA-type ligands.[5] With one exception,[16] these all have $N_{py}-Rh-N_{py}$ angles of 87−92°. The $N_{py}-Rh-N_{py}$ angle in $[L^4Rh(COD)]^+$ is small (76°), undoubtedly because of steric constraints; in fact, it is close to the $N_{amine}-Rh-N_{py}$ angles (75−77° in our L^4 and L^6 complexes), and to the $N_{amine}-Rh-N_{amine}$ angles in $[Cn^*Rh(COD)]^+$ (77−80°) (Cn* = 1,4,7-trimethyl-1,4,7-triazacyclononane).[5] In contrast, the $N_{py}-Rh-N_{py}$ angles in the two L^6 complexes are normal (91° and 95°), showing that steric constraints are much less important there.

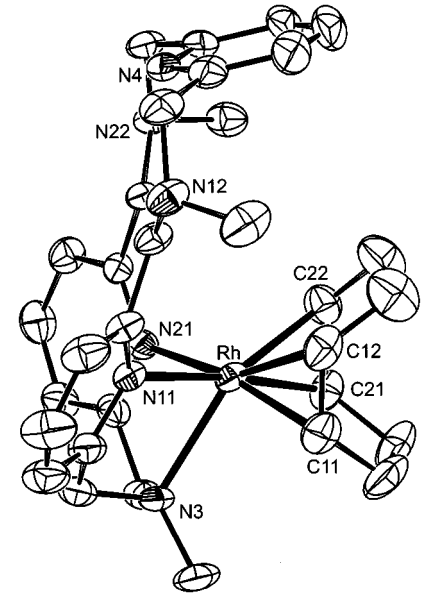

Figure 2. X-ray structure (40% TME) of $[L^6Rh(COD)]PF_6$; all hydrogen atoms and the counterion have been omitted; selected bond lengths [Å] and angles [°]: Rh−C11 2.124(5), Rh−C12 2.165(5), Rh−C21 2.101(5), Rh−C22 2.183(5), Rh−N11 2.311(4), Rh−N21 2.176(4), Rh−N3 2.343(4); N11−Rh−N21 91.48(14), N11−Rh−N3 75.86(14), N21−Rh−N3 75.15(15)

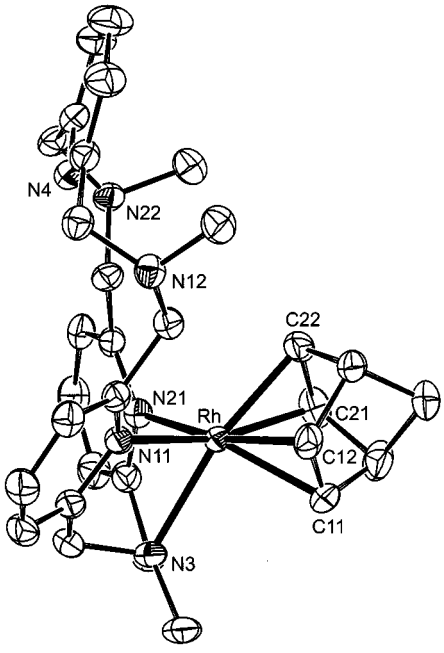

Figure 3. X-ray structure (40% TME) of $[L^6Rh(NBD)]PF_6$(acetone); all hydrogen atoms, the counterion and the acetone molecule of crystallization have been omitted; selected bond lengths [Å] and angles [°]: Rh−C11 2.152(4), Rh−C12 2.148(4), Rh−C21 2.054(4), Rh−C22 2.079(4), Rh−N11 2.310(3), Rh−N21 2.154(3), Rh−N3 2.278(3); N11−Rh−N21 94.71(12), N11−Rh−N3 75.95(12), N21−Rh−N3 74.84(12)

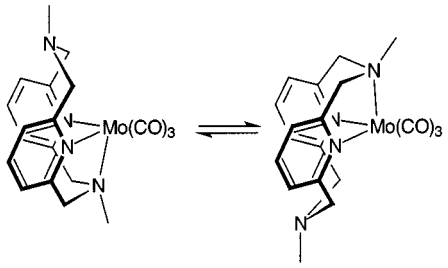
Ligand L^4 seems to be preorganized for κ^4 coordination. The κ^3-coordinated Mo complex mentioned above displays fluxional behaviour involving exchange of the two amine nitrogen atoms (Scheme 2) with activation parameters $\Delta H^{\ddagger} = 13.9$ kcal/mol, $\Delta S^{\ddagger} = -0.8$ cal/mol·K.



Scheme 2

The strongly broadened 1D ^{1}H NMR spectra and the negative cross-peaks in the NOESY spectra of our diene complexes indicate a similar fluxionality. The situation is complicated here by the occurrence of another fluxional process, namely diene rotation (Scheme 3). Diene rotation is common in five-coordinate complexes and would therefore be expected here; it exchanges the "top" and "bottom" halves of the diene ligand. Amine exchange would also exchange the diene halves; thus, the rate of diene rotation as determined by NMR includes a contribution from amine exchange. Variable-temperature NMR studies and full-spectrum NMR fits[17] were used to determine rate constants for $[L^4Rh(COD)]^+$, $[L^4Ir(COD)]^+$, and $[L^6Rh(COD)]^+$; the resulting activation parameters are shown in Table 1.

For the L^4 complexes, the total rate of COD rotation is significantly faster than the amine exchange in the temperature range of 0 to 100 °C, demonstrating that both processes indeed contribute. Interestingly, amine exchange has a lower activation *enthalpy*, but is still the slower process because of its more negative activation *entropy*. Since COD rotation is unlikely to be a dissociative process, these results

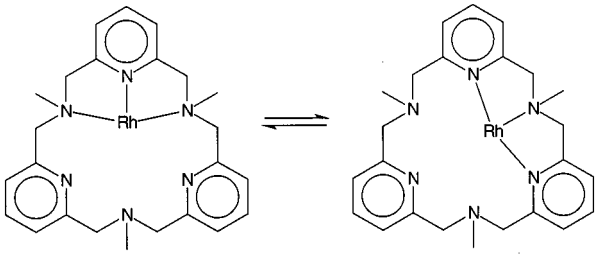
Table 1. Activation parameters for fluxionality of $LM(COD)^+$ complexes

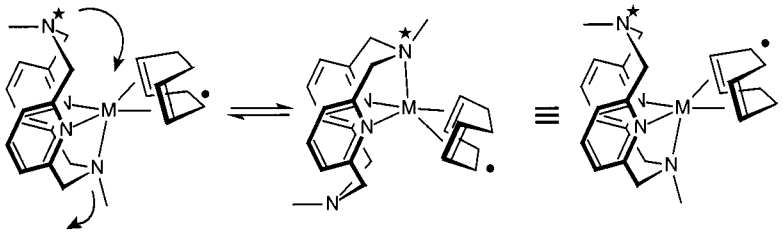
Complex	Amine exchange[a] [b]		COD rotation[a] [b]	
	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$
$[L^4Rh(COD)]PF_6$	12.0±0.3	−11.0±1.0	15.7±1.0	3.2±3.1
$[L^4Ir(COD)]PF_6$	14.0±0.2	−6.7±0.7	22.8±1.5	18.2±4.4
$[L^6Rh(COD)]PF_6$	11.8±0.3	−10.3±0.9		

[a] $\Delta H^{\ddagger}$ [kcal/mol], $\Delta S^{\ddagger}$ [cal/mol·K]. [b] Error margins are 1σ limits from Eyring fits.

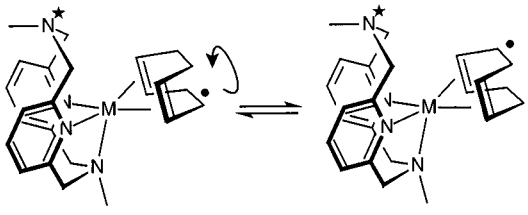
suggest that metal−amine bond dissociation and formation occur simultaneously. Amine exchange is only slightly slower for Ir than for Rh, which agrees with this interpretation; for a dissociative process, the Ir analogue should have a much higher barrier.

For $[L^6Rh(COD)]^+$, COD rotation is always fast on the NMR timescale. The activation parameters for movement of the metal atom around the ring are similar to those found for amine exchange in $[L^4Rh(COD)]^+$, suggesting a similar mechanism involving repeated amine/pyridine exchange at Rh. The metal atom thus presumably moves between κ^3-(amine)(pyridine)$_2$ and κ^3-(amine)$_2$(pyridine) compartments of the macrocycle; the observed preference for the κ^3-(amine)(pyridine)$_2$ compartment suggests that this is the stronger donor site. Even at 100 °C, the two faces of the ring remain inequivalent, implying that the Rh(COD) fragment cannot move *through* the ring.





amine exchange



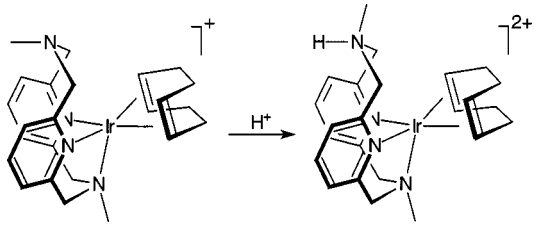
COD rotation

Scheme 3

Since L^6 has six N-donor atoms, one might wonder whether dinuclear complexes could be formed, in which one metal atom would occupy a κ^3-(amine)(pyridine)$_2$ compartment and the other a (less favourable) κ^3-(amine)$_2$(pyridine) compartment. However, treatment of L^6 with excess [Rh(diene)Cl]$_2$ produces the mononuclear complex as the only product. Possibly, there would be too much repulsion between the two diene fragments in a dinuclear complex. Also, the nitrogen lone pairs in the X-ray structures of [L^6Rh(COD)]$^+$ and [L^6Rh(NBD)]$^+$ are oriented in an unfavourable manner for coordination to the κ^3-(amine)$_2$(pyridine) compartment, as shown in Figures 2 and 3. We therefore conclude that formation of dinuclear complexes of L^6 is unlikely.

Protonation and Oxidation

Surprisingly, [L^4Ir(COD)]$^+$ reacts with H_2O_2 *only* in the presence of acid. Therefore, protonation was also investigated separately. Addition of a diethyl ether solution of HBF_4 to a solution of [L^4Ir(COD)]$^+PF_6$ in methanol produced a colourless solution. Evaporation of the solvent and dissolution of the product in methanol gave a yellow solution, from which red crystals precipitated overnight. The X-ray structure (Figure 4) shows these crystals to have the composition [(L^4H)Ir(COD)]$^+(BF_4)_2$; evidently, the lower solubility of the BF_4 salt resulted in selective precipitation of the complex with this counterion. Protonation has occurred on the dangling amine nitrogen atom. The hydrogen atom was located and refined; additional proof for protonation at the nitrogen atom comes from the C−N−C angles at the nitrogen atom (av. 110.2°), which are similar to those of the metal-coordinated nitrogen atoms in [(L^4H)Ir(COD)]$^+(BF_4)_2$ (av. 110.1°) and [L^4Rh(COD)]PF_6 (av. 109.9°) and definitely smaller than those around the dangling nitrogen atom in [L^4Rh(COD)]PF_6 (av. 115.6°). The methyl group on the ammonium nitrogen atom is now in the expected position, pointing towards the Ir atom; the ammonium proton forms a hydrogen bond with a fluorine atom of a BF_4 group. Apart from this, the structure of the dication is fairly similar to that of the unprotonated monocation [L^4Rh(COD)]$^+$.



Addition of excess H_2O_2 to a solution of [L^4Ir(COD)]$^+$ and 1 equiv. of acid results in a fast reaction to give an oxocyclooctenyl complex [L^4Ir($C_8H_{11}O$)]$^{2+}$. This is a net 4-e$^-$ oxidation and we were unable to detect any intermediates by NMR; 1 equiv. of acid is consumed, but if only 0.5 equiv. of acid is used, half of the starting material is recovered unchanged. Crystals suitable for X-ray diffraction were obtained from acetone; they were found to contain

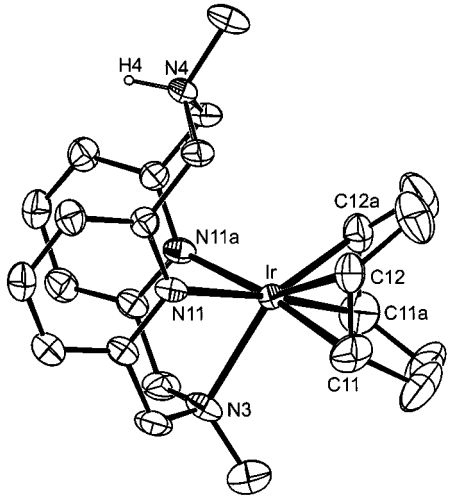


Figure 4. X-ray structure (50% TME) of [(L^4H)Ir(COD)]$(BF_4)_2$; all hydrogen atoms (except 4) and the counterion have been omitted; selected bond lengths [Å] and angles [°]: Ir−C11 2.091(7), Ir−C12 2.112(7), Ir−N11 2.169(5), Ir−N3 2.301(7); N11−Ir−N11a 74.6(3), N11−Ir−N3 77.9(2)

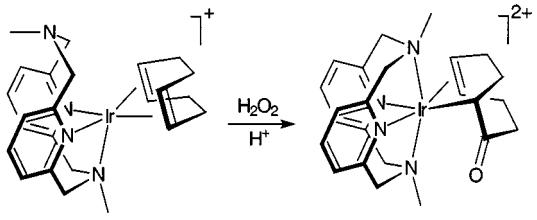
one molecule of diacetone alcohol of crystallization. The structure (Figure 5) shows that the ligand is now κ^4-coordinated. Compared with those in the Rh^I(COD) and Ir^I(COD) complexes described above, the Ir−N distances in this Ir^{III} derivative are shorter and the Ir−olefin distances longer, as expected. Perhaps somewhat surprisingly, all Ir−N distances are significantly shorter (by ca. 0.1 Å) than the corresponding Rh−N distances in [L^4RhCl_2]$^+$.[9]



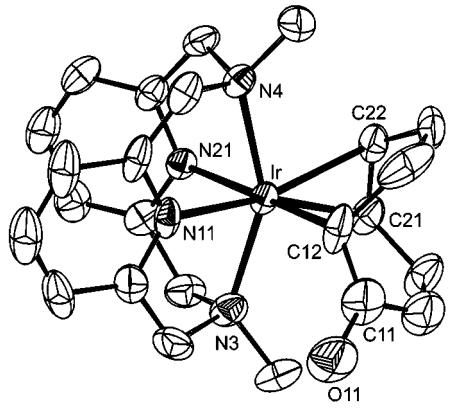


Figure 5. X-ray structure (30% TME) of [L^4Ir($C_8H_{11}O$)]$(PF_6)_2$(diacetone alcohol); all hydrogen atoms, the counterion and the molecule diacetone alcohol of crystallization have been omitted; selected bond lengths [Å] and angles [°]: Ir−C12 2.124(11), Ir−C21 2.242(10), Ir−C22 2.247(10), Ir−N11 2.031(8), Ir−N21 2.093(7), Ir−N3 2.213(10), Ir−N4 2.211(8), C11−O11 1.275(17); N11−Ir−N21 79.1(3), N11−Ir−N3 79.6(4), N21−Ir−N3 78.7(3), N11−Ir−N4 79.2(4), N21−Ir−N4 79.3(3), N3−Ir−N4 151.8(3)

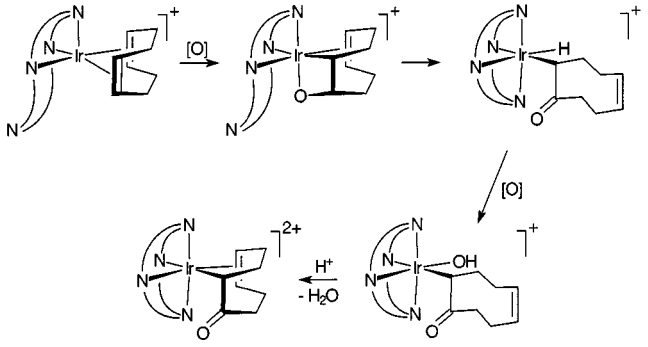
Oxocyclooctadiene and oxoalkyl-allyl ligands somewhat similar to ours were obtained by Klemperer in the O_2 oxidation of Cp*Ir(COD).[18] He attributed their formation to a radical (autoxidation) mechanism; the reaction required rather drastic conditions. Since ligands, conditions and oxidants are different in our case, it is difficult to draw parallels between the two systems.

We have found that COD coordinated to Rh can be oxidized to an 9-oxabicyclo[4.2.1]nona-2,5-diyl fragment, presumably via a metallaoxetane intermediate.[3,5] (COD)Ir complexes can also be oxidized to oxetanes.[1,2,19] In both cases, the products rearrange to hydroxycyclooctenediyl complexes. In addition, we have observed that unsubstituted oxetanes can decompose to aldehydes, and can be oxidized to formylmethyl complexes.[8] On the basis of analogy, one possible mechanism for the formation of the oxocyclooctenyl complex could involve further oxidation of an initially formed metallaoxetane, represented schematically in Scheme 4.



Scheme 4

The change in ligand coordination mode from κ^3 to κ^4 might be important here; it could result in displacement of the unchanged C=C bond from the metal atom, thus facilitating further reaction of the oxetane by relieving geometric constraints. Since we have not been able to observe any intermediates, we feel that further speculation on details of this reaction is not warranted.

The most interesting aspect of the H_2O_2 oxidation chemistry is probably the role of acid. Activation of H_2O_2 by acid is relatively common, but the H_2O_2 oxidation of $[(DPA)Rh(COD)]^+$ and $[(N\text{-Bu-DPA})Rh(COD)]^+$ does not require the addition of acid.[5] It might be that for the L^4 ligand, with substituents in the 6-positions of the pyridine rings, the increased steric hindrance prevents or slows down direct oxidation by H_2O_2. The isolation of the amine-protonated Ir complex makes it tempting to suggest that such a protonated species might also might also play a role in the oxidation by, for example, activating H_2O_2 near the metal centre, assisting in the first step of Scheme 4.

Conclusions

(Diene)rhodium and -iridium complexes of L^4 and L^6 pyridinophane ligands have five-coordinate structures in which the ligand is bound in a κ^3-(amine)(pyridine)$_2$ fashion. All Rh and Ir complexes are fluxional and show movement of the (diene)metal fragment over the ligand. Oxidation of $[L^4Ir(COD)]^+$ by H_2O_2 requires addition of acid, and then gives the oxocyclooctenyl complex in a net 4-e$^-$ oxidation reaction. In the absence of H_2O_2, acid protonates the dangling amine ligand; an amine-protonated species *might* also play a role in the oxidation reaction.

Experimental Section

General: All synthesis involving air-sensitive compounds were carried out by using standard Schlenk techniques. All solvents were distilled under nitrogen prior to use. Starting materials were prepared by literature methods: L^4/L^6,[12] $[Rh(COD)Cl]_2$,[20] $[Rh(NBD)Cl]_2$,[21] $[Ir(COD)Cl]_2$.[22] All other reagents were commercial products.

$[L^4Rh(COD)]PF_6$: $[Rh(COD)Cl]_2$ (13 mg, 0.026 mmol) was added to a solution of L^4 (14 mg, 0.052 mmol) in methanol (6 mL). The mixture turned yellow. After stirring for 1 h, the solution was filtered, and a solution of KPF_6 (40 mg, 0.22 mmol) in methanol (4 mL) was added. The mixture was concentrated to half its volume in vacuo, after which a yellow solid precipitated. The supernatant was removed with a Pasteur pipette. The resulting solid was washed with methanol (3 × 3 mL) and dried in vacuo. Yield: 0.35 g (75%). $[L^4Rh(COD)]PF_6$ is a yellow, air-stable solid. ^{1}H NMR (500 MHz, [D$_6$]acetone, 213 K): δ = 7.71 (t, J = 7.7 Hz, 2 H, py H_4), 7.36 (d, J = 7.7 Hz, 2 H, py H_3), 7.23 (d, J = 7.7 Hz, 2 H, py H_5), 6.22 (d, J = 14.0 Hz, 2 H, NCH_2), 4.97 (d, J = 17.0 Hz, 2 H, NCH_2), 4.49 (d, J = 14.0 Hz, 2 H, NCH_2), 4.30 (d, J = 17.0 Hz, 2 H, NCH_2), 3.79 (s, 3 H, CH_3), 2.89 (br, 2 H, C=CH), 2.59 (br, 2 H, C=CH), 2.44 (m, 2 H, =CCH_2), 2.27 (s, 3 H, CH_3), 1.94 (m, 2 H, =CCH_2), 1.76 (m, 2 H, =CCH_2), 1.61 (m, 2 H, =CCH_2). ^{1}H NOESY (200 MHz, [D$_6$]acetone, 298 K, exchange cross-peaks): δ = (7.23⇄7.36, Py-$H_{3,5}$), (4.97⇄6.22, NCH_2), (4.30⇄4.49, NCH_2), (3.5⇄4.1, C=CH), (2.27⇄3.79, CH_3). At this temperature all ligand signals except that of py-H_4 are severely broadened. ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone, 297 K): δ = 159 (2 C, py C_6), 158 (2 C, py C_2), 138 (2 C, py C_4), 126 (2 C, py C_5), 122 (2 C, py C_3), 80.7 (br, 2 C, =CH), 67.1 (2 C, NCH$_2$), 66.2 (br, 2 C, =CH), 65.0 (2 C, NCH_2), 51.8 (1 C, CH$_3$), 38.7 (1 C, CH$_3$), 32.6 (br, 2 C, = CHCH$_2$−), second =CHCH$_2$ obscured by acetone signal. FAB$^+$ MS (BPh$_4$ salt): m/z = 370 $[L^4Rh - H]^+$, 479 $[L^4Rh(COD)]^+$. IR (KBr): $\tilde{\nu}$ = 2976, 2943, 2906, 2895, 2852, 1603, 1463, 1450, 1105, 1035, 989, 874, 839, 771 cm^{-1}. $C_{24}H_{32}F_6N_4PRh$ (624.41): calcd. C 46.17, H 5.17, N 8.97; found C 46.42, H 4.91, N 8.61.

$[L^4Rh(NBD)]PF_6$: $[Rh(NBD)Cl]_2$ (107 mg, 0.23 mmol) was added to a solution of L^4 (125 mg, 0.47 mmol) in methanol (3 mL). The resulting yellow solution was stirred for 1 h. Upon addition of a solution of KPF_6 (343 mg, 1.86 mmol) in methanol (4 mL), a yellow solid precipitated. The solid was filtered off, washed with methanol (3 × 5 mL) and dried in vacuo. Yield: 215 mg (76%). ^{1}H NMR (500 MHz, [D$_6$]acetone, 273 K): δ = 7.60 (t, J = 7.8 Hz, 2 H, Py-H_4), 7.25 (d, J = 7.8 Hz, 2 H, Py-H_3), 7.15 (d, J = 7.8 Hz, 2 H, Py-H_5), 6.26 (d, J =14 Hz, 2 H, NCH_2), 4.96 (d, J = 16.0 Hz, 2 H, NCH_2), 4.47 (d, J = 14.0 Hz, 2 H, NCH_2), 4.34 (d, J = 16.0 Hz, 2 H, NCH_2), 4.11 (s, 3 H, CH_3), 3.99 (s, 2 H, NBD CH$_2$), 3.54 (m, 4 H, NBD =CH), 2.38 (s, 3 H, CH_3), 1.19 (s, 2 H, NBD =CCH). ^{1}H NOESY (200 MHz, [D$_6$]acetone, 298 K, exchange cross-peaks): δ = (7.15⇄7.19, Py-$H_{3,5}$), (5.02⇄6.23, NCH_2), (2.43⇄4.15, CH_3).

$^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone, 297 K): δ = 159 (2 C, py C_2), 158 (2 C, py C_6), 137 (2 C, py C_4), 125 (2 C, py C_3), 121 (2 C, py C_5), 67.2 (2 C, NCH_2), 65.6 (2 C, NCH_2), 58.3 (4 C, NBD =C), 52.8 (1 C, NBD CH_2), 47.5 (1 C, CH_3), 39.4 (1 C, CH_3), 39.3 (2 C, NBD =CCH). FAB$^+$-MS: m/z = 370 [L^{4}Rh − H]$^+$, 463 [L^{4}Rh(NBD)]$^+$. IR (KBr): ṽ = 3004, 2941, 2892, 2861, 2813, 1601, 1573, 1464, 1449, 1430, 1305, 1168, 1101, 1034, 990, 968, 885, 839, 772, 557 cm^{-1}. We did not obtain a satisfactory elemental analysis for this complex: $C_{23}H_{28}F_6N_4PRh$ (608.37): calcd. C 45.41, H 4.64, N 9.21; found C 43.67, H 4.74, N 8.78.

[L^{6}Rh(COD)]PF$_6$: [Rh(COD)Cl]$_2$ (62 mg, 0.13 mmol) was added to a solution of L^6 (100 mg, 0.25 mmol) in methanol (10 mL). After the mixture had been stirred for 1 h, a solution of KPF_6 (184 mg, 1.0 mmol) in methanol (4 mL) was added. The reaction mixture was concentrated to half its volume in vacuo, after which a yellow solid precipitated. The product was filtered off, washed with methanol (3 × 2 mL) and dried in vacuo. Yield: 150 mg (79%). ^1H NMR (500 MHz, [D$_6$]acetone, 273 K): δ = 7.95 (t, J = 7.4 Hz, 1 H, py H_4), 7.92 (t, J = 7.4 Hz, 2 H, py H_4), 7.86 (d, J = 7.4 Hz, 2 H, py H_3), 7.50 (d, J = 7.4 Hz, 2 H, py H_5), 7.38 (d, J = 7.4 Hz, 2 H, py $H_{3,5}$), 5.07 (d, J = 17.0 Hz, 2 H, NCH_2), 4.96 (d, J = 17.0 Hz, 2 H, NCH_2), 4.57 (d, J = 15.0 Hz, 2 H, NCH_2), 4.24 (s, 4 H, NCH_2), 3.92 (d, J = 15.0 Hz, 2 H, NCH_2), 3.38 (s, 3 H, CH_3), 3.07 (br, 4 H, =CH), 2.49 (s, 6 H, CH_3), 2.35 (br, 4 H, =CCH_2), 1.55 (br, 4 H, =CCH_2). ^1H NMR (500 MHz, [D$_6$]acetone, 203 K): δ = 8.09 (t, J = 7.4 Hz, 1 H, py H_4), 7.97 (t, J = 7.4 Hz, 2 H, py H_4), 7.89 (d, J = 7.4 Hz, 2 H, py H_3), 7.63 (d, J = 7.4 Hz, 2 H, py H_5), 7.43 (d, J = 7.4 Hz, 2 H, py $H_{3,5}$), 4.78 (d, J = 17.0 Hz, 2 H, NCH_2), 4.72 (d, J = 17.0 Hz, 2 H, NCH_2), 4.52 (d, J = 15.0 Hz, 2 H, NCH_2), 4.26 (d, J = 13.0 Hz, 2 H, NCH_2), 4.19 (d, J = 13.0 Hz, 2 H, NCH_2), 3.88 (d, J = 15.0 Hz, 2 H, NCH_2), 3.42 (s, 3 H, CH_3), 3.15 (br, 2 H, =CH), 2.68 (br, 2 H, =CH), 2.59 (s, 6 H, CH_3), 2.30 (br, 2 H, =CCH_2), 1.97 (br, 2 H, =CCH_2), 1.51 (d, br, J = 8.1 Hz, 2 H, =CCH_2), 1.33 (d, br, J = 8.1 Hz, 2 H, =CCH_2). ^1H NOESY (chloride salt, 200 MHz, [D$_6$]acetone, 298 K, exchange cross-peaks): δ = (7.38⇄7.86, Py-$H_{3,5}$), (4.24⇄4.96, CH_2), (3.92⇄5.07), CH_2), (3.92⇄4.24, CH_2), (3.92⇄5.07, CH_2), (3.92⇄4.24, CH_2), (3.38⇄2.49, CH_3). $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone, 297 K): δ = 164 (2 C, py C_2), 160 (2 C, py C_6), 156 (2 C, py $C_{2,6}$), 139 (2 C, py C_4), 137 (1 C, py C_4), 124 (2 C, py C_3), 123 (2 C, py C_5), 122 (1 C, py $C_{3,5}$), 75.3 (br, 4 C, =CH), 64.5 (2 C, NCH_2), 63.7 (2 C, NCH_2), 63.0 (2 C, NCH_2), 47.7 (1 C, CH_3), 40.7 (2 C, NCH_3), 30.6 (4 C, =CCH_2), second =$CHCH_2$ signal obscured by acetone signal. FAB$^+$-MS (chloride salt): m/z = 403 [L^6 + H]$^+$, 425 [L^6 + Na]$^+$, 613 [L^{6}Rh(COD)]$^+$. IR (KBr): ṽ = 2931, 2884, 2866, 2844, 2796, 1602, 1584, 1572, 1455, 1427, 1159, 1116, 1094, 1040, 976, 877, 843, 800, 771, 558 cm^{-1}. $C_{32}H_{42}F_6N_6PRh$ (758.59): calcd. C 50.67, H 5.58, N 11.08; found C 49.84, H 6.05, N 10.38.

[L^{6}Rh(NBD)]PF$_6$: [Rh(NBD)Cl]$_2$ (57.2 mg, 0.12 mmol) was added to a solution of L^6 (100 mg, 0.25 mmol) and KPF_6 (184 mg, 1.0 mmol) in methanol (7.5 mL). The yellow reaction mixture was stirred for 1 h, after which the volume was concentrated to half its volume in vacuo. The product was precipitated by addition of water, filtered off, washed with diethyl ether (3 × 3 mL) and dried in vacuo. Yield: 140 mg (76%). ^1H NMR (500 MHz, [D$_6$]acetone, 273 K): δ = 7.94 (t, J = 7.6 Hz, 2 H, py H_4), 7.85 (t, J = 7.3 Hz, 1 H, py H_4), 7.79 (d, J = 7.6 Hz, 2 H, py H_3), 7.41 (d, J = 7.6 Hz, 2 H, py H_5), 7.38 (d, J = 7.3 Hz, 2 H, py $H_{3,5}$), 5.04 (d, J = 17.0 Hz, 2 H, NCH_2), 4.54 (d, J = 15.0 Hz, 2 H, NCH_2), 4.49 (d, J = 17.0 Hz, 2 H, NCH_2), 4.12 (s, 4 H, NCH_2), 3.95 (d, J = 15.0 Hz, 2 H, NCH_2), 3.58 (2 H, NBD CH_2), 3.08 (4 H, NBD = CH), 2.94 (s, 3 H, CH_3), 2.41 (s, 6 H, CH_3), 1.00 (2 H, NBD = CCH). ^1H NOESY (chloride salt, 200 MHz, [D$_6$]acetone, 298 K, exchange cross-peaks): δ = (7.52⇄7.70, py $H_{3,5}$), (7.36⇄7.81, py $H_{3,5}$ and py H_4), (4.48⇄5.08, NCH_2), (4.24⇄4.36, NCH_2), (4.14⇄5.08, NCH_2), (4.14⇄4.50, NCH_2), (2.46⇄2.95, CH_3). At this temperature all ligand signals are severely broadened. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone, 297 K): δ = 168 (2 C, py $C_{2,6}$), 163 (2 C, py $C_{2,6}$), 162 (2 C, py $C_{2,6}$), 144 (2 C, py C_4), 142 (1 C, py C_4), 2 × 128 (4 C, py $C_{3,5}$), 126 (2 C, py $C_{3,5}$), 70 (2 C, NCH_2), 67 (2 C, NCH_2), 67 (2 C, NCH_2), 63 (2 C, NBD CH_2), 53 (2 C, NBD =CH), 52 (1 C, CH_3), 46 (4 C, NBD =CCH), 43 (2 C, CH_3). FAB$^+$-MS: m/z = 597 [L^{6}Rh(NBD)]$^+$. IR (KBr): ṽ = 2932, 2917, 2863, 2841, 1604, 1588, 1574, 1462, 1450, 1427, 1160, 1096, 1051, 875, 842, 793, 777, 558 cm^{-1}. We did not obtain a satisfactory elemental analysis for this complex: $C_{31}H_{38}F_6N_6PRh$ (742.55): calcd. C 50.14, H 5.16, N 11.32; found C 46.99, H 4.74, N 10.38.

[L^{4}Ir(COD)]PF$_6$: [Ir(COD)Cl]$_2$ (25 mg, 0.037 mmol) was added to a solution of L^4 (20 mg, 0.075 mmol) in methanol. After addition of KPF_6 (14 mg), a yellow precipitate was collected by filtration. This was dissolved in dichloromethane, KCl was filtered off, and the solvent was evaporated in vacuo. Yield: 46 mg (85%). ^1H NMR (400 MHz, [D$_6$]acetone, 298 K): δ = 7.73 (t, J = 7.7 Hz, 2 H, py H_4), 7.39 (d, J = 7.6 Hz, 2 H, py H_3), 7.33 (d, J = 7.8 Hz, 2 H, py H_5), 6.03 (d, J = 14.0 Hz, 2 H, NCH_2), 4.87 (d, J = 16.8 Hz, 2 H, NCH_2), 4.61 (d, J = 16.9 Hz, 2 H, NCH_2), 4.48 (d, J = 14.1 Hz, 2 H, NCH_2), 3.84 (s, 3 H, CH_3), 3.79 (br, 2 H, =CH), 2.98 (br, 2 H, =CH), 2.75, (br, 2 H, =CCH_2), 2.39 (br, 2 H, =CCH_2), 2.29 (s, 3 H, CH_3), 1.76 (d, J = 7.9 Hz, 2 H, =CCH_2), 1.30 (d, J = 8.9 Hz, 2 H, =CCH_2). ^1H NOESY (400 MHz, [D$_6$]acetone, 298 K, exchange peaks): δ = (3.84⇄2.29, CH_3). $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone, 298 K): δ = 162 (2 C, py C_2), 160 (2 C, py C_6), 139 (2 C, py C_3), 127 (2 C, py C_4), 122 (2 C, py C_5), 70 (2 C, NCH_2), 66 (2 C, NCH_2), 65 (2 C, =CH), 55 (1 C, CH_3), 46 (2 C, =CH), 39 (1 C, CH_3), 35 (2 C, =CCH_2), 30 (2 C, =CCH_2). FAB$^+$-MS: m/z = 569 [L^{4}Ir(COD)]$^+$, 192 [Ir]$^+$. $C_{24}H_{32}F_6IrN_4P$ (713.73): calcd. C 40.39, H 4.52, N 7.85; found C 39.99, H 4.18, N 7.64.

[(L^{4}H)Ir(COD)](BF$_4$)$_2$: A solution of HBF_4 in ether (54 wt%, 3.86 mL) was added at 0 °C to a suspension of [L^{4}Ir(COD)]PF$_6$ (20 mg, 0.028 mmol) in methanol. The solvents were removed in vacuo. Treatment of the residue with methanol gave a yellow solution, from which a yellow solid [(L^{4}H)Ir(COD)](BF$_4$)$_2$ could be isolated by addition of 5 mL of diethyl ether. Overnight, the solution deposited further red crystals, suitable for X-ray diffraction. The complex is only poorly soluble in most solvents, while solutions in acetonitrile and methanol slowly decompose. We could therefore only partially interpret the ^1H NMR spectrum and did not obtain useful ^{13}C NMR spectroscopic data. ^1H NMR (200 MHz, CD_3OD, 298 K): δ = 7.73 (t, J = 7.7 Hz, 2 H, py H_4), 7.60 (d, J = 7.3 Hz, 2 H, py H_3), 7.36 (d, J = 7.5 Hz, 2 H, py H_5), 6.39 (d, J = 12.9 Hz, 2 H, NCH_2), 5.16 (d, J = 13.1 Hz, 2 H, NCH_2), 4.71 (d, J = 16.7 Hz, 2 H, NCH_2), 4.48 (d, J = 16.9 Hz, 2 H, NCH_2), 3.70 (s, 3 H, CH_3), 2.70 (br, 2 H, =CH), 2.37 (br, 2 H, =CCH_2), 2.04 (br, 2 H, =CCH_2), 1.74 (br, 2 H, =CCH_2), 1.28 (br, 2 H, =CCH_2).

[L^{4}Ir(C$_8$H$_{11}$O)](PF$_6$)$_2$: H(OEt$_2$)$_2^+$B(Ar^F)$_4^-$ (28.4 mg, 0.028 mmol) was added to a solution of [L^{4}Ir(COD)]PF$_6$ (20 mg, 0.028 mmol) in acetonitrile. After 5 min, aqueous hydrogen peroxide (1%, 0.08 mL) was added, after which the mixture was stirred vigorously for 15 min. Removal of the solvent in vacuo gave a yellow solid, which could be dissolved in methanol. Addition of KPF_6 (14 mg) yielded a yellow solid, which could be "crystallised" as droplets from acetonitrile by slow diffusion of diethyl ether into the solution. Yield: 22 mg (90%). When the reaction was attempted with only 0.5 equiv. of H(OEt$_2$)$_2^+$B(Ar^F)$_4^-$, a 1:1 mixture of [L^{4}Ir(COD)]PF$_6$ and

$[L^4Ir(C_8H_{11}O)](PF_6)_2$ was isolated. $[L^4Ir(C_8H_{11}O)](PF_6)_2$ is an air-stable, yellow solid. ^1H NMR (600 MHz, [D$_6$]acetone, 298 K): δ = 8.15 (t, J = 8.16 Hz, 1 H, py H_4), 8.02 (t, J = 7.7 Hz, 1 H, py H_4), 7.70 (d, J = 8.1 Hz, 1 H, py H_3), 7.67 (d, J = 7.4 Hz, 1 H, py H_3), 7.65 (d, J = 7.8 Hz, 1 H, py H_5), 7.61 (d, J = 7.4 Hz, 1 H, py H_5), 6.94 (br, 1 H, =C*H*), 6.75 (br, 1 H, =C*H*), 5.47 (d, J = 16.7 Hz, 1 H, NCH_2), 5.31 (d, J = 16.3 Hz, 2 H, NCH_2), 4.79 (d, J = 16.8 Hz, 1 H, NCH_2), 4.75 (d, J = 16.7 Hz, 1 H, NCH_2), 4.64 (d, J = 16.3 Hz, 1 H, NCH_2), 4.62 (d, J = 15.9 Hz, 1 H, NCH_2), 4.31 (d, J = 16.3 Hz, 1 H, NCH_2), 3.76 (br, 1 H, COD CH_2), 3.51 (s, 3 H, CH_3), 3.22 (br, 1 H, COD CH_2), 3.14 (s, 3 H, CH_3), 3.12 (br, 1 H, COD CH_2), 2.99 (br, 1 H, COD CH_2), 2.67 (br, 1 H, COD CH_2), 2.53 (br, 1 H, COD CH_2), 2.38 (br, 1 H, COD CH_2), 1.83 (dd, J_1 = 9.7 Hz, J_2 = 15.9 Hz, 1 H, Ir-C*H*). One COD CH_2 proton signal is probably obscured by a solvent signal. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]acetone, 298 K): δ = 220.8 (1 C, *C*=O), 157.5 (1 C, py C_2), 157.0 (1 C, py C_2), 156.9 (1 C, py C_6), 156.5 (1 C, py C_6), 142.5 (1 C, py C_4), 142.2 (1 C, py C_4), 123.2 (1 C, py C_3), 123.1 (1 C, py C_3), 123.0 (1 C, py C_5), 122.7 (1 C, py C_5), 100.4 (1 C, =*C*H), 88.2 (1 C, =*C*H), 80.4 (1 C, N*C*H$_2$), 78.9 (1 C, N*C*H$_2$), 77.9 (1 C, N*C*H$_2$), 76.4 (1C, N*C*H$_2$), 57.1 (1 C, *C*H$_3$), 53.5 (1 C, *C*H$_3$), 38.1 (1 C, =C*C*H$_2$), 36.1 (1 C, O=C*C*H$_2$), 28.7 (1 C, =C*C*H$_2$), 28.6 (1 C, =C*C*H$_2$), 25.3 (1 C, Ir-*C*). ^1H NOESY (600 MHz, [D$_6$]acetone, 298 K, cross peaks): δ = (6.94/5.31, =C*H*/CH_2), (6.75/5.47, =C*H*/CH_2), (6.94/3.51, =C*H*/CH_3), (6.75/3.14 (=C*H*/CH_3). MALDI-TOF-MS: m/z = 583 $[L^4Ir(C_8H_{11}O)]^+$, 556 $[L^4Ir(C_8H_{11}O) - HCN]^+$, 493 [?]$^+$, 459 $[L^4Ir]^+$, 269 $[L^4H]^+$. $C_{24}H_{31}F_{12}IrN_4OP_2$ (873.68): calcd. C 32.99, H 3.58, N 6.41; found C 32.80, H 3.63, N 6.38. X-ray quality crystals were obtained by crystallization from acetone, and were found to contain one molecule of diacetone alcohol of crystallization (see below).

X-ray Structure Determinations: Single crystals were mounted in air on glass fibres. Intensity data were collected at room temperature with an Enraf−Nonius CAD4 single-crystal diffractometer. Unit-cell dimensions were determined from the angular setting of a limited number of reference reflections. Intensity data were corrected for Lorentz and polarization effects, and for absorption using a semiempirical ψ-scan correction.[23] Structures were solved by the DIRDIF[24] program system, using the PATTY[25] program to locate the heavy atom (Rh or Ir), and refined with standard methods (refinement against F^2 of all reflections) with SHELXL97.[26] All

non-hydrogen atoms were refined anisotropically; hydrogen atoms were refined isotropically in riding mode, unless otherwise noted. Geometrical calculations (PLATON[27]) revealed neither unusual geometric features, nor unusual short intermolecular contacts, no higher symmetry and no (further) solvent-accessible areas. Details of the data collection and structure determinations are collected in Table 2. − **[L^{4}Rh(COD)]PF$_6$:** Hydrogen atoms attached to C11, C12, C21, and C22 were freely refined. − **[L^{6}Rh(NBD)]PF$_6$·C$_3$H$_6$O:** The hydrogen atoms of the acetone methyl groups were refined as rigid rotors with idealized sp^3 hybridization and a C−H bond length of 0.97 Å to match maximum electron density in a difference Fourier map. All other hydrogen atoms were initially placed at calculated positions and were subsequently freely refined. − **[(L^{4}H)Ir(COD)](BF$_4$)$_2$:** The normal least-squares refinement procedure failed to give acceptable anisotropic displacement parameters for a number of atoms. Refinement in space group *Pna*21, although possible and resulting in an even lower *R* value (0.1118 vs. 0.1161 isotropic, 0.0607 vs. 0.0638 anisotropic), produced even worse displacement parameters. Because the irregular crystal shape prevented adequate analytic absorption correction, the DIFABS procedure[28] was applied after all atoms, including hydrogen atoms, had been refined isotropically in *Pnma*. After this correction, refinement in *Pnma* lowered the isotropic *R* value from 0.1161 to 0.0530, and the anisotropic *R* value from 0.0638 to 0.0410, with perfectly acceptable anisotropic displacement parameters. Further refinement in *Pna*21, however, again gave nonpositive definite values for most atoms. Besides this, there is no significant change/improvement in the geometry in those parts of the structure (esp. the COD moiety) that are possibly constrained most by the imposed symmetry. The statistical distribution of *E* values favours the centrosymmetric space group *Pnma*. However, all the structures containing cyclooctadiene that we have solved so far showed a twist in the COD moiety, through which an eclipsed conformation of the CH_2CH_2 groups is avoided. The mirror symmetry imposed on the COD moiety in space group *Pnma* does not conform with this convincing observation, and the refinement in *Pna*21 clearly shows the expected torsion in the COD moiety. Therefore, we believe that the average structure shows an overall centrosymmetric arrangement in which mainly the COD moiety is disordered to a certain extent, although there will also be some effect on the remainder of the structure. Unfortunately, if this is the case then the deviations from a centrosymmetric structure are not large enough to allow for a disorder refinement. The bond lengths in the COD fragment should be treated with caution. − **[L^{4}Ir(C$_8$H$_{11}$O)](PF$_6$)$_2$·C$_6$H$_{12}$O$_2$:** The diacetone alcohol molecule of crystallization shows large displacement parameters and is probably disordered. The assignments of O77 and O78 as oxygen atoms is based on bond lengths only, and that of O77 is not certain. The hydrogen bond involving H77 must therefore be regarded as tentative. − Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-166291−166295. New Helical Complexes with a Bis(bidentate) Schiff Base Ligand Containing a Flexible Spacer

Miguel Vázquez,[a] Manuel R. Bermejo,*[a] Matilde Fondo,[a] Ana García-Deibe,[a] Ana M. González,[a] and Rosa Pedrido[a]

Keywords: Supramolecular chemistry / Helical structures / Schiff bases / Electrochemistry

Neutral complexes with the general empirical formula M(PTs) [M: Mn, Fe, Co, Cu, Zn, and Cd; H_2PTs: *N*,*N*′-bis(2-tosylaminobenzylidene)-1,3-diaminopropane] were obtained by means of an electrochemical procedure. All complexes were characterised by elemental analyses, mass spectrometry, IR and ^{1}H NMR spectroscopy, and magnetic measurements, where appropriate. Recrystallisation of the cobalt, copper, and zinc complexes yielded single crystals of [Co(PTs)] (**1**), [Cu(PTs)]·1.5CH_3CN (**2**) and [Zn(PTs)]$_2$·1.5H_2O·CH_3CN (**3**). Their X-ray characterisation shows that **1** and **2** are mononuclear tetrahedral single-stranded helical complexes in the solid state, while **3** is a double-helical compound containing a major and a minor groove, with the Schiff base acting as a bis(bidentate) N_4 donor.

Introduction

The study of supramolecular helical complexes has been the subject of considerable interest recently, in order to clarify the mechanisms of self-assembly processes.[1−5] From these studies, it was concluded that metal helicates are generated by the combination of appropriate ligands and metal ions with specific preferences for particular coordination geometries.

Interesting studies have been devoted to the development of synthetic procedures, in order to prepare new multidentate ligands with the potential ability of forming bridged polynuclear species.[6−11] A key parameter in the assembly of helicates is how a flexible polydentate ligand becomes partitioned into distinct metal binding sites. In many cases ligands have been constructed that contain several bidentate or terdentate domains separated by rigid or bulky groups. Thus, the domains are arranged such that each site will definitely bind to different metal ions rather than chelating to a single metal centre. Furthermore, the spacer groups usually contain aromatic moieties, which provoke π···π and/or CH···π non-covalent interactions that control the self-assembly process.

The supramolecular chemistry involving ligands containing flexible spacers has not been extensively investigated. In this case, the way in which the ligand is partitioned into binding sites mainly depends on the stereoelectronic preferences of the metal ion, and this type of ligand often leads to the isolation of mononuclear helical species.[12−14]

Our recent investigations on Schiff bases allowed us to isolate the bis(bidentate) N_4 ligand H_2PTs [IUPAC name: *N*,*N*′-bis(2-tosylaminobenzylidene)-1,3-diaminopropane] (Scheme 1), which contains a flexible spacer. Its X-ray structure[15] shows that it adopts an *anti*-opened conformation[16] in the solid state that should do it suitable to span two metal centres, generating double-helical complexes. This is the situation found in the related [Ni(PTs)]$_2$ complex.[17] In an attempt to know the role of the metal atom in the disposition of this type of ligand, we extended our investigations to the behaviour of H_2PTs. In order to check if the arrangement of the ligand is the same as that found for nickel,[17] its electrochemical interaction with manganese, iron, cobalt, copper, zinc and cadmium was studied and the results obtained are described here.

Results and Discussion

The Schiff base H_2PTs has been prepared as previously described and satisfactorily characterised by elemental analysis, FAB mass spectrometry, IR and ^{1}H NMR spectroscopy,[17] and X-ray diffraction studies.[15]

Synthesis of the Complexes

All the complexes were prepared by an electrochemical method previously described.[17,18] The electrochemical efficiency of the cell E_f was approximately 0.5 mol·F^{-1} in all cases, which is compatible with the reaction mechanism shown in Scheme 2.

Elemental analyses (Table 1) show that all metal ions react with the ligand in a 1:1 molar ratio affording complexes

of the bis(deprotonated) ligand $[PTs]^{2-}$ in high purity. These neutral metal complexes are obtained in high yields and appear to be stable in the solid state and in solution. Most of them are insoluble or sparingly soluble in water and common organic solvents, but soluble in polar coordinating organic solvents such as DMF, DMSO, and pyridine.

Crystal Structures

[Co(PTs)] (1) and [Cu(PTs)]·1.5CH$_3$CN (2)

The crystal structures of **1** and **2** are shown in Figures 1 and 2, respectively. Selected bond lengths and angles are displayed in Table 2.

Both compounds consist of discrete molecules of M(PTs) and show quite similar structures. In complex **2**, two acetonitrile solvates per complex molecule are present in the unit cell, one of them at 0.5 occupancy.

In both complexes, the ligand uses all its N-donor atoms to bind to the same metal centre. One oxygen atom of each

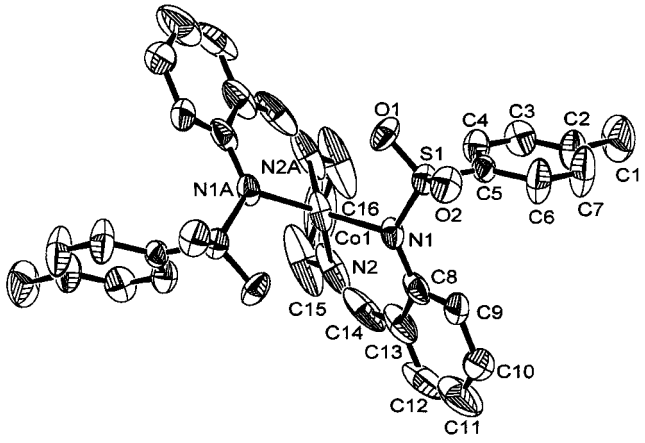

Figure 1. ORTEP view of complex **1** (thermal ellipsoids are drawn at 30% of probability level)

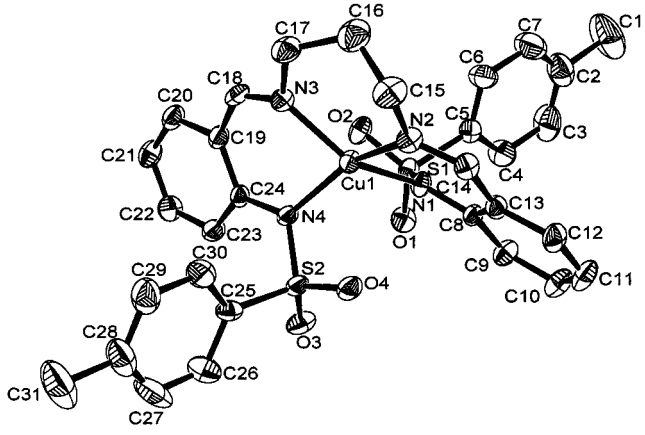

Figure 2. ORTEP view of complex **2** (thermal ellipsoids are drawn at 30% of probability level; hydrogen atoms and solvent molecules have been omitted for clarity)

tosyl group seems to weakly interact with the metal atom, the M···O distances (about 2.6 Å for **1** and 2.8 Å for **2**) are too long to be considered as true coordinated bonds, and therefore are best described as secondary intramolecular interactions. Thus, the metal centres are tetracoordinated, with the cobalt atom located in a twofold crystallographic axis in **1**. The geometry about the metal ions could be described as pseudo-tetrahedral, although the two terminal bidentate fragments are not mutually perpendicular. The dihedral angle θ between the two MNN terminal planes is 69.38° for **1** and 44.37° for **2**. This shows that the deviation

Table 2. Selected bond lengths [Å] and angles [°] for **1**−**3**

from tetrahedral to square-planar geometry is higher for the copper complex ($\theta = 0$ for square-planar geometry and $\theta = 90$ for tetrahedral geometry). The wide range of angles observed around the metal centres [from 89.0(4) to 128.1(3)° for **1** and from 89.2(2) to 149.7(2)° for **2**] also shows the deviation from the ideal tetrahedral geometry. The M−N distances are typical of cobalt and copper complexes with this type of ligand,[19−20] although it should be noted that all the Cu−N bonds are very similar while the $Co-N_{amide}$ bonds are significantly shorter than the $Co-N_{imine}$ bonds (Table 2).

The tetradentate dianionic Schiff base PTs^{2-} wraps around the metal ions affording helical molecules in both cases. The screwed disposition of the ligand seems to be favoured by the presence of the two terminal bulky tosyl groups. The steric hindrance induced by these tosyl groups appears to provoke a twisting of the Schiff base, in order to minimise the steric interactions. Therefore, the torsion of the flexible spacer allows a remarkable shortening of the $N_{imine}\cdots N_{imine}$ distances relative to the free ligand (ca. 2.9 Å for **1** and **2**, and ca. 4.4 Å for free H_2PTs[15]). This permits the four nitrogen atoms to bind to the same metal centre, leading to the isolation of mononuclear, tetrahedral, single-stranded helical complexes. These compounds can be also classified as saturated,[4] as the Schiff base fulfil the stereochemical requirements of the cobalt and copper atoms. Both right- (*P*) and left-handed (*M*) helixes[4] can be simultaneously observed (in 50% yields) in the unit cell of **1** and **2**.

The PTs^{2-} ligand forms three six-membered chelate rings. The angles between adjacent calculated chelate planes show the screwing of the thread. The degree of twisting is much smaller for the copper complex than for the cobalt complex (the angles between adjacent chelates for **1** is 55.67° and for **2** are 29.78 and 12.68°). Besides, in the crystal structure it can be clearly seen that when the tosyl groups are excluded, the wrapping angle is smaller than 360°. This angle is significantly higher for the copper complex than for the cobalt complex (264° for **1** and 305° for **2**), and this trend correlates with the ionic radius, as expected.

Finally, no specific π-stacking interactions (face-face or face-edge π-π) can be identified, either between the benzylidene binding moieties or between terminal tosyl aromatic rings, which probably appear to be separated in order to minimise the steric hindrance.

[Zn(PTs)]$_2$·1.5H$_2$O·CH$_3$CN (3)

An ORTEP view of **3** is shown in Figure 3. Main bond lengths are shown in Table 2.

The unit cell of complex **3** consists of $[Zn(PTs)]_2$ discrete molecules, with lattice acetonitrile and disordered water. The complex is dinuclear and adopts an *anti*-opened conformation, with the Schiff bases acting as bis(bidentate) donors.[16] Its structure is quite similar to that of the related $[Ni(PTs)]_2$ complex.[17] Each Schiff base uses the amide and imine nitrogen atoms corresponding to one of its arms [N(1), N(2); N(5), N(6)] to bind to Zn(1), and the nitrogen donor atoms of the remaining arm [N(3), N(4); N(7), N(8)] to bind to the second zinc atom [Zn(2)]. One oxygen atom of each tosyl group weakly interacts with the metal centre [the Zn(1)···O(1), Zn(1)···O(6), Zn(2)···O(4) and Zn(2)···O(7) distances are ca. 2.6 Å]. These distances could be secondary intramolecular interactions, as seen in **1** and **2**, as well as in $[Ni(PTs)]_2$.[17] Therefore, each zinc centre has a four-coordinated pseudo-tetrahedral environment, bound to two imine and two amide nitrogen atoms.

The two ligands wrap around the metal−metal axis giving rise to a double-stranded dinuclear helical compound with a Zn···Zn separation of ca. 6.031 Å. This distance compares fairly well with that observed in its analogue nickel complex,[17] but is clearly shorter than that found for dizinc complexes with bis(bidentate) ligands containing a propylene spacer (11.29 Å).[21] The wrapping angle of both strands is ca. 240°, and shows less helical coiling of the ligand than for mononuclear complexes. Both (*P*,*P*) and (*M*,*M*) isomers are present in the unit cell in 50% yields.

The ligands form two six-membered chelate rings, one around each metal atom, which are nearly planar. The dihedral angles between the two ZnNN planes around the same zinc centre are 84.77° for Zn(1) and 82.51° for Zn(2), indicating the deviation of the coordination polyhedron from the ideal geometry. All the distances and angles are in the expected range for distorted tetrahedral zinc(II) complexes with Schiff bases.[22−23] The variety of angles [ranging from 92.7(2) to 144.6(2)° for Zn(1) and from 93.8(2)

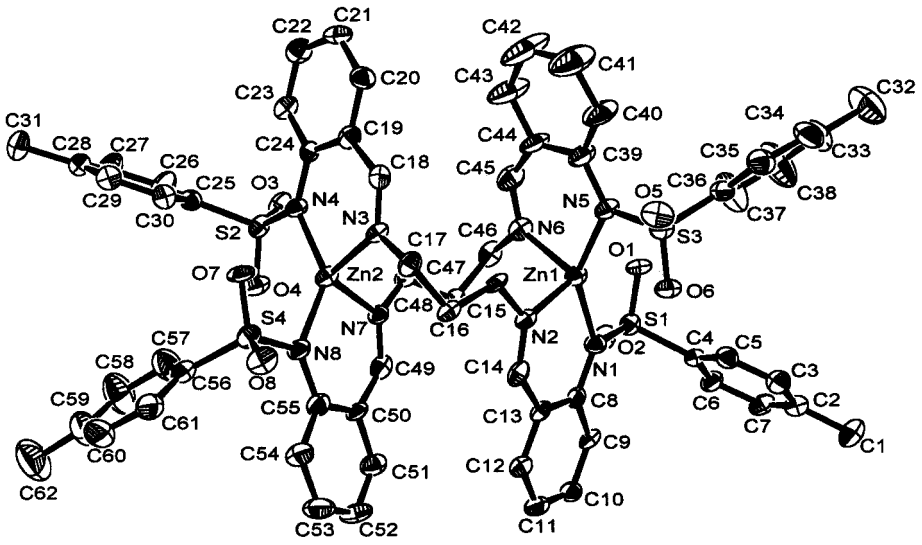

Figure 3. ORTEP view of complex **3** (thermal ellipsoids are drawn at 50% of probability level; hydrogen atoms and solvent molecules have been omitted for clarity)

to 139.7(2)° for Zn(2)] also show the distortion of the tetrahedral environment and that both metal atoms are not equivalent. All these features resemble those in the nickel analogue.[17] Besides, no symmetry elements relate the two ligands or the two halves of the same ligand. This leads to a certain degree of asymmetry in the complex, which gives rise to the formation of two different grooves (major and minor) (Figure 4), as seen in $[Ni(PTs)]_2$.[17] In addition, no π-interactions are observed between the aromatic rings.

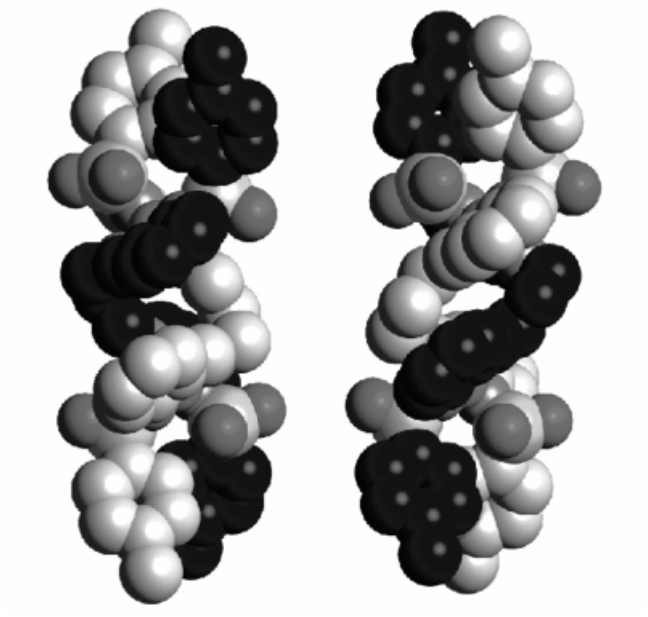

Figure 4. Space-filling representation of complex **1**, showing the minor (left) and major (right) grooves; both representations correspond to the same enantiomer, turned 180°

In spite of the detailed NMR spectroscopic studies of van Koten on dinuclear zinc complexes with diimine ligands,[24] not many complexes of this kind have been reported. There are some structurally characterised dizinc helical complexes described in the literature,[7,21,23–31] but only two helicates (one triple-stranded and one double-stranded) contain Schiff bases.[7,23] In these cases, the two bidentate domains are separated by a rigid spacer, which is the most general situation.[7,23,25–31] In fact, the structurally characterised zinc complexes derived from bis(bidentate) ligands containing flexible spacers are usually monohelical in the solid state,[13–14] and to the best of our knowledge, there are only two examples of bis(dipyrromethane)dizinc complexes with aliphatic spacers, where the extent of helicity is really small.[21] Therefore, the isolation of complex **3** further substantiates the NMR spectroscopic studies of van Koten and unequivocally demonstrates that Schiff bases with flexible spacers can generate zinc double-helical species.

IR Spectroscopy and FAB Mass Spectrometry

The IR spectra of all complexes show a strong band between 1641 and 1612 cm^{-1} due to the imine ν(C=N) group (Table 3). This is a negative shift of 4–23 cm^{-1} relative to the free ligand for all complexes except **3**. In the case of the zinc complex, the ν(C=N) band is shifted to higher wavenumbers (6 cm^{-1}), indicating a slight shift of charge towards the CN group on coordination. However, the ν(C–N) stretching frequency is shifted to lower wave-

Table 3. Selected IR data for the complexes (ṽ, cm^{-1})

Compound	ν(C=N)	ν(C–N)	$\nu_{as}(SO_2)$	$\nu_{s}(SO_2)$
H_2PTs	1635	1340	1287	1164
Mn(PTs)	1624	1304	1272	1158
Fe(PTs)	1612	1298	1260	1158
Co(PTs)	1630	1296	1264	1134
Cu(PTs)	1617	1297	1267	1137
Zn(PTs)	1641	1296	1264	1137
Cd(PTs)	1631	1294	1259	1128

Table 4. Selected ^{1}H NMR chemical shifts (δ values)

	H^1	H^2	H^3	H^5	H^4	H^7	H^6	H^9	H^{10}	H^8
H_2PTs	2.07 (q, 2 H)	3.80 (t, 4 H)	8.55 (s, 2 H)	7.08 (t, 2 H)	7.48 (m, 4 H)		7.37 (t, 2 H)	7.27 (d, 2 H)	2.25 (s, 6 H)	7.65 (d, 2 H)
Zn(PTs)	2.17 (st, 2 H)	4.20, 3.88 (m, 4 H)	8.67 (s, 2 H)	6.93 (t, 2 H)	7.34 (d, 2 H)	7.50 (d, 2 H)	7.27 (m, 4 H)		2.32 (s, 6 H)	7.77 (d, 2 H)
Cd(PTs)	2.03 (b, 2 H)	3.80 (b, 4 H)	8.48 (s, 2 H)	6.86 (t, 2 H)	7.20 (d, 2 H)	7.38 (d, 2 H)	7.15 (m, 4 H)		2.27 (s, 6 H)	7.84 (d, 2 H)

numbers (36−46 cm^{-1}) in all the complexes. This behaviour is compatible with the participation of both imine and amide nitrogen atoms in the coordination to the metal centres. In addition, two bands in the ranges 1259−1272 cm^{-1} and 1128−1158 cm^{-1} are assigned to the asymmetric and symmetric vibration modes of the SO_2 group.[32−33] Finally, no bands above 2500 cm^{-1} were detected for the complexes, indicating the deprotonation of the NH groups, and therefore the dianionic character of the ligand.

The FAB mass spectra show peaks assigned to the $[M(PTs)]^+$ fragments (Table 1) for all the complexes, indicating the coordination of the ligand to the metal centre. However, no other information about the nuclearity of the complexes can be drawn in this case study.

^{1}H NMR Spectroscopy

The ^{1}H NMR spectra of the zinc and cadmium complexes were recorded in [D_6]DMSO as the solvent at room temperature (Table 4), and in CD_3CN at low temperatures (273 and 233 K). The spectra do not change significantly with temperature. In fact, the spectra of the zinc complex recorded at the three different temperatures are identical. All spectra show a singlet set of proton resonances that could be fully assigned. This seems to indicate that there is a single species in solution. In all cases, the disappearance of the NH protons present in the free ligand is observed, which is in agreement with the bis(deprotonation) of the Schiff base. When the ^{1}H NMR spectra of the free ligand is compared with those of the complexes at room temperature, some clear differences are observed (Figure 5):

1. The imine hydrogen atom (3-H) shows a downfield shift for the zinc complex, whilst it is displaced upfield in the spectrum of the cadmium complex, indicating that the coordination of the imine group to the metal centre induces opposite shielding effects on this hydrogen atom. Only one signal is observed for the H-imine atom in **3** at different temperatures suggesting that only symmetric species exist in solution. The imine protons of the cadmium complex are flanked by satellites arising from spin-spin coupling to $^{111/113}$Cd, indicating that the complex is kinetically inert on the NMR timescale.

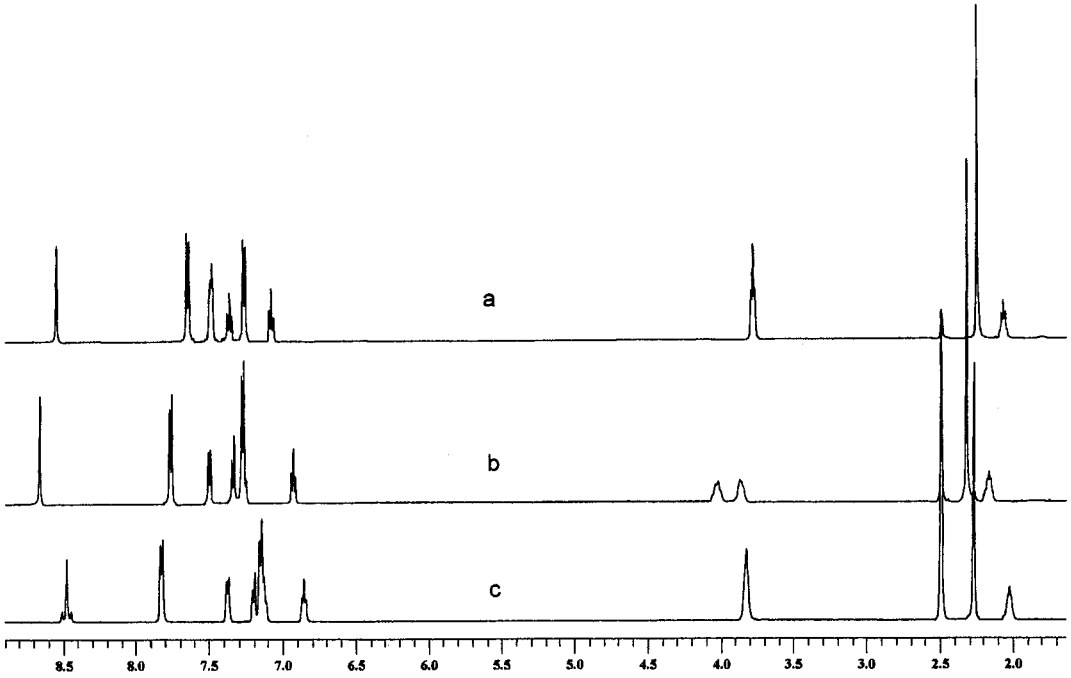

Figure 5. ^{1}H NMR spectra in [D_6]DMSO at room temperature for a) H_2PTS, b) Zn(PTs), and c) Cd(PTs)

2. The signals of the aromatic protons of the benzylidene ring are shifted upfield and the displacements are higher for the cadmium complex. The spectra show that complexation clearly affect the environments of 7-H and 4-H. In the spectra of the free ligand the signals are overlapped, while two sharp doublets are observed in the spectra of the complexes.

3. The signals of the aromatic protons of the tosyl groups also appear to be shifted on complexation, and the displacement is similar for the zinc and cadmium complexes.

4. Finally, the methylene protons of the cadmium and zinc complexes show different chiral behaviour in solution. The 2-H protons are equivalent in the free ligand and appear as a triplet at $\delta = 3.80$. However, for complex **3**, the 2-H protons appear as two multiplets at $\delta = 3.88$ and 4.20. This implies that the strong coordination of the hard imine nitrogen atom to the zinc atom removes the erstwhile enantiotopic nature of the protons making them diastereotopic, and the complex chiral. This is also supported by the central methylene 1-H protons, which in the free ligand appear as a quintuplet at $\delta = 2.07$, while in **3** they appear as a septuplet at $\delta = 2.17$ as a result of the coupling with two pairs of different protons. However, these central methylene hydrogen atoms seem to rotate freely as they are enantiotopic.

The spectrum of the cadmium complex is clearly different. Only one broad signal can be observed for the 2-H protons at room temperature, at $\delta = 3.80$. The 1-H protons also appear as a unique broad signal at $\delta = 2.03$. These signals get sharper on lowering the temperature, and a triplet (4 H) and a quintuplet (2 H) can clearly be observed for 2-H and 1-H, respectively. However, no splitting of the signal assigned to 2-H ($\delta = 3.80$) is observed. This indicates that all 2-H protons are equivalent, in contrast to that found in **3**, and therefore that the cadmium complex is not chiral in solution.

Magnetic Characterisation

Magnetic measurements at room temperature of all the paramagnetic compounds give similar values for the magnetic moments to those expected for magnetically diluted M^{II} ions. The magnetic moment of the manganese and copper complexes only allows for the confirmation of the +2 oxidation state for the central atom, indicating the deprotonation of the Schiff base ligand. The magnetic moments of Fe(PTs) and Co(PTs) are in agreement with high-spin M^{II} complexes. In both cases the magnetic moment is in the normal range for Fe^{II} (5.0−5.4 BM) and Co^{II} (4.3−4.8 BM) tetrahedral complexes. Thus, in view of the formulation of the complexes and their magnetic moments, it seems quite reasonable to propose a tetrahedral environment around the metal atom for all the paramagnetic complexes, as confirmed by the crystal structures of **1** and **2**.

Comparison of all the data obtained from the characterisation techniques employed herein with related complexes[17] leads us to conclude that zinc and nickel[17] form dinuclear double-stranded helicates, and Co and Cu yield mononuclear complexes with H_2PTs in the solid state. In addition, comparison of the ^{1}H NMR spectroscopic data of the Zn and Cd complexes seem to indicate that the tosyl groups behave in a similar way in both complexes and are not directly linked to the central atom, suggesting a tetrahedral environment for the metal centre in both cases. This tetrahedral environment can also be proposed for the other complexes on the basis of the magnetic measurements and X-ray results. Thus, the coordination preferences of the metal ion do not seem to have a profound effect on the disposition of the ligand and the nuclearity of the helix in this case study.

Experimental Section

General: Elemental analysis was performed with a Carlo Erba EA 1108 analyser. The NMR spectra were recorded with a Bruker AMX-500 spectrometer using [D_6]DMSO (296 K) and CD_3CN (273 and 233 K) as solvents. Infrared spectra were recorded as KBr pellets with a Bio-Rad FTS 135 spectrophotometer in the range 4000−600 cm^{-1}. Fast atom bombardment mass spectra (FAB) were obtained with a Kratos MS-50 mass spectrometer in *m*-nitrobenzyl alcohol as a matrix. Room-temperature magnetic measurements were performed using a Sherwood Scientific Magnetic Susceptibility Balance, calibrated using mercury tetrakis(isothiocyanato)cobaltate(II).

Syntheses: All the starting materials were purchased from Aldrich and used without further purification. 2-(Tosylamino)benzaldehyde was prepared according to literature methods[34] and was fully characterised.[35] *N*,*N*′-Bis(2-tosylaminobenzylidene)-1,3-diaminopropane (H_2PTs) was synthesised as previously reported by us and characterised by elemental analyses, melting point, IR, ^{1}H NMR spectroscopy and FAB mass spectroscopy and X-ray diffraction.[15,17]

Synthesis of the Metal Complexes: All complexes were prepared in a similar way, that can be exemplified by the isolation of [Co(PTs)] (**1**). A solution of H_2PTs (0.1 g, 0.15 mmol) in acetonitrile (80 mL), containing ca. 10 mg of tetramethylammonium perchlorate as the supporting electrolyte, was electrolysed for 1.8 h using a current of 5 mA. Concentration of the resultant solution to a third of its initial volume yielded a garnet solid that was washed with diethyl ether and dried in vacuo. Recrystallisation of the powder obtained in acetonitrile yielded single crystals of [Co(PTs)] (**1**), suitable for X-ray diffraction studies. The other complexes were obtained by the same method, using the appropriate metal anode. In the case of the manganese complex, the synthesis was performed in an inert gas under an argon stream. Recrystallisation of [Cu(PTs)] in acetonitrile and of [Zn(PTs)] by diffusion of ether into an acetonitrile solution, yielded crystals suitable for single X-ray analyses of [Cu(PTs)]·1.5CH_3CN (**2**) and [Zn(PTs)]$_2$·1.5H_2O·CH_3CN (**3**), respectively.

CAUTION: Perchlorate salts are potentially explosive and should therefore be handled with the appropriate care.

X-ray Crystallography: Crystals of **1** and **2**, suitable for X-ray diffraction studies, were grown as previously described. Data were collected at 298 K using a Siemens CCD diffractometer employing graphite-monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation, using the ω-scan mode. The structures were solved by direct methods[36] and refined by full-matrix least squares on F^2.[37] Absorption and incident beam corrections were applied (Sadabs). All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were in-

Compared Behaviours of Dawson-Type Tungstodiarsenates and -diphosphates

Bineta Keita,[a] Israel Martyr Mbomekalle,[a] Louis Nadjo,*[a] and Roland Contant[b]

Keywords: Polyanions / Tungsten / Arsenic / Phosphorus / Electrochemistry

The lacunary α_2-$[As_2W_{17}O_{61}]^{10-}$ derived from the Dawson molecule α-$[As_2W_{18}O_{62}]^{6-}$ was used as a ligand for the following metal cations: Mn^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+}. The cyclic voltammograms of this lacunary precursor species, as well as those of the substituted complexes were run in a medium at pH = 3. A systematic comparison was carried out with the electrochemical characteristics of the corresponding complexes derived from α-$[P_2W_{18}O_{62}]^{6-}$, with the aim of highlighting the differences in their behaviour, which could be ascribed to the identity of the central atoms. The study was also extended to the Fe^{3+} species of the α_1 series. The comparisons reveal that whatever the series, the first several voltammetric waves are driven in the positive potential direction by the presence of As as the central atom in the heteropolyanions. These results agree with those from crystallographic evaluations, and with the knowledge of the stability constants of the complexes, indirectly reveal a coherent picture of the behaviour of the vacant sites in the diarsenates and diphosphates. In particular, the influence of the central heteroatom on the redox and/or acid-base properties could be assessed and compared. Steric effects, expected on geometrical grounds, and already reflected in the values of the stability constants of the metal ion substituted compounds, also influence the cyclic voltammograms.

1. Introduction

Much work has been devoted to Dawson-type tungstodiphosphates. In particular, their ability to generate lacunary species, and hence metal cation substituted derivatives has received extensive attention.[1−10] The impetus was triggered by the pioneering remark that monosubstituted heteropolyanions can be considered as the analogues of metallated porphyrins, and can be used in catalytic processes with the advantage, over their organic counterparts, of their thermal stability, robustness and inertness toward oxidising environments.[11] In contrast, the corresponding diarsenates have been the subject of very few papers,[12−14] presumably owing to the assumption that a complete analogy should be expected between the two series of species. Actually, such an assumption would ignore the possibility that the change in the central heteroatom might bring about new physical, and correlatively, electronic, chemical and redox behaviours. Several papers[2,4] have shown the linear dependence of the first one-electron reduction potentials (under conditions of no protonation) on the overall negative charge of the heteropolyanions, in conjunction with the charge on the central heteroatom. Further, the influence of the central heteroatom (Si^{IV}, Ge^{IV}, P^{V}, As^{V}) on the stabilities of the metal(II) and alkaline ion complexes of selected heteropolytungstates[12,15] was published. However, most of these studies were performed in the Keggin series.

In our systematic study of the parameters which could modify the redox properties of heteropolyanions, and hence their electrocatalytic behaviour, several possibilities were identified. The pH of the solution is one obvious parameter. A rich series of possibilities is opened up by the substituent effect; the location of the heterometal in the framework, the nature, and the number of substituents may influence the interactions between the electroactive centres within the molecule.[6,9,16] Furthermore, a recent paper from our group[17] has stressed the change in symmetry of the charge distribution in lacunary species and in their first transition metal ion substituted derivatives, thus justifying the comparison between these two series of compounds, and not with the saturated precursors.[6,9,16,17]

Until now the influence of the central heteroatom in Dawson-type anions on their cyclic voltammograms was not explored. In this context, we are interested in comparing saturated and metal ion monosubstituted diarsenates with diphosphates. Particular attention will be paid to the location of the vacant site in the framework, to steric effects (in other words the ability of the vacant site to accommodate the substituent metal cation), and the physical and chemical behaviour.

2. Results

2.1. The Selection of Relevant Heteropolyanions

All the polyanions studied here can be considered as being primarily derived from α-$[P_2W_{18}O_{62}]^{6-}$ (abbreviated as

α-P_2W_{18} in the following) and α-$[As_2W_{18}O_{62}]^{6-}$ (abbreviated as α-As_2W_{18}). Although it has become classical, Figure 1 is shown for clarity. The tungsten atoms are numbered according to the IUPAC recommendations. The two P atoms are numbered 1 and 2 for the upper and the lower halves of the molecule, respectively. For example, considering the upper half of the molecule, and taking into account the numbering, the metal atoms in the "cap" occupy what will be termed the α_2 positions and those in the "belt" the α_1 positions. In the lacunary species, the vacancies (missing W atoms) are numbered in the same way and represented, when necessary, by □ in the formula of the anion. Any metal atom occupying the vacancy will keep the same index.

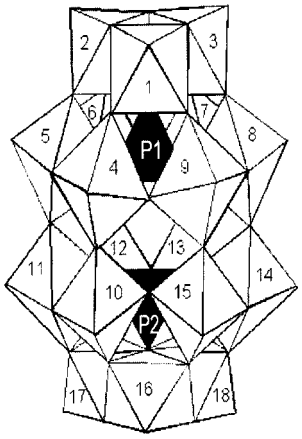

Figure 1. Idealised structure of α-$[P_2W_{18}O_{62}]^{6-}$ and its substitution derivatives

The following heteropolyanions were used: α-$[As_2W_{18}O_{62}]^{6-}$ (abbreviated as α-As_2W_{18}), α_1- and α_2-$[As_2W_{17}O_{61}]^{10-}$ (α_1- and α_2-As_2W_{17}), α_2-$[Mn(H_2O)(As_2W_{17}O_{61})]^{8-}$ (α_2-$As_2W_{17}Mn$), α_1- and α_2-$[Fe(H_2O)(As_2W_{17}O_{61})]^{7-}$ (α_1- and α_2-$As_2W_{17}Fe$), α_2-$[Co(H_2O)(As_2W_{17}O_{61})]^{8-}$ (α_2-$As_2W_{17}Co$), α_2-$[Ni(H_2O)(As_2W_{17}O_{61})]^{8-}$ (α_2-$As_2W_{17}Ni$), α_2-$[Cu(H_2O)(As_2W_{17}O_{61})]^{8-}$ (α_2-$As_2W_{17}Cu$), α_2-$[Zn(H_2O)(As_2W_{17}O_{61})]^{8-}$ (α_2-$As_2W_{17}Zn$), α-$[P_2W_{18}O_{62}]^{6-}$ (abbreviated as α-P_2W_{18}), α_1- and α_2-$[P_2W_{17}O_{61}]^{10-}$ (α_1- and α_2-P_2W_{17}), α_2-$[Mn(H_2O)(P_2W_{17}O_{61})]^{8-}$ (α_2-$P_2W_{17}Mn$), α_1- and α_2-$[Fe(H_2O)(P_2W_{17}O_{61})]^{7-}$ (α_1- and α_2-$P_2W_{17}Fe$), α_2-$[Co(H_2O)(P_2W_{17}O_{61})]^{8-}$ (α_2-$P_2W_{17}Co$), α_2-$[Ni(H_2O)(P_2W_{17}O_{61})]^{8-}$ (α_2-$P_2W_{17}Ni$), α_2-$[Cu(H_2O)(P_2W_{17}O_{61})]^{8-}$ (α_2-$P_2W_{17}Cu$), α_2-$[Zn(H_2O)(P_2W_{17}O_{61})]^{8-}$ (α_2-$P_2W_{17}Zn$). Their preparation and characterisation have already been described in detail.[6,8,9,12−15,18,19]

2.2. Electrochemistry

The main features of the electrochemical data are presented in Table 1, which allows a pertinent comparison of the reduction peak potentials pertaining to the first W wave for the As and P derivatives. The ΔE_p values can be considered as a self-consistent parameter, using the appropriate precursor lacunary species as a reference. Most of our study is devoted to derivatives that are substituted in the α_2 position. Strictly, the changes in acid-base properties from the lacunary precursor to the substituted species preclude the direct use of the ΔE_p values in obtaining reliable values for the stability constants of the complexes. As previously with tungstodiphosphates, the location of the vacant site, and subsequently of the substituent metal cation, is revealed by the characteristic fingerprint associated with the α_2 compounds in a medium with pH = 3,[10] where the first two two-electron W-centred processes are followed by two one-electron processes. From the two pH values studied (pH = 3 and 5), the first W wave is shifted roughly by 74 mV/pH, irrespective of the type of substituted tungstodiarsenate.

Table 1. Reduction peak potential vs. SCE for the first tungsten wave in α_2-$X_2W_{17}M$ complexes (X = As or P; M represents the substituent metal cation) and comparison with the appropriate lacunary species; supporting electrolyte: 0.2 M Na_2SO_4 + H_2SO_4 (pH = 3); scan rate 10 mV·s^{-1}; the results for the diphosphates were published previously in ref.[10], but here, for composite waves in this series, only the most negative peak potential was retained for clarity

Compound	$-E_p$ [mV] vs. SCE	$\delta\Delta E_p$ [mV][a]
α-As_2W_{18}	−18	−
α-P_2W_{18}	22	−
α_2-As_2W_{17} o	298	0
α_2-P_2W_{17} o	320	0
α_2-$As_2W_{17}Mn$	324	26
α_2-$P_2W_{17}Mn$	394	74
α_2-$As_2W_{17}Fe$	360	62
α_2-$P_2W_{17}Fe$	402	82
α_2-$As_2W_{17}Co$	346	48
α_2-$P_2W_{17}Co$	392	72
α_2-$As_2W_{17}Ni$	358	60
α_2-$P_2W_{17}Ni$	406	86
α_2-$As_2W_{17}Cu$	288	−10
α_2-$P_2W_{17}Cu$	306 (composite W/Cu wave)	−14
α_2-$As_2W_{17}Zn$	360	62
α_2-$P_2W_{17}Zn$	386	66

[a] $\Delta E_p = E_{p,lacunary} - E_{p,substituted}$.

At pH = 3, the first W wave for α-As_2W_{18} and α-P_2W_{18} features a one-electron process, as confirmed by controlled potential coulometry. Otherwise, throughout Table 1, the first redox process associated with the W centres involves two electrons. Examination of the values in this table underscores the previously demonstrated fact[9,10,16] that the appropriate comparison among the present compounds must be made between the precursor lacunary species and their metal ion substituted derivatives. In this series of "unsaturated" species, it can be seen that the first W wave is shifted in the positive potential direction in all the As compounds relative to the P derivatives. This trend appears even in the lacunary species and can be ascribed to the larger basicity of the reduced forms of the As derivatives. However, it is worth noting that these W peak potentials in the substituted As derivatives are rather close from one compound to

the next, except in the case of the Cu-substituted species. This observation would indicate, even in the case of the Fe derivative in which the reduction of the iron centre occurs prior to the W centres, that a roughly constant change in basicity exists between the precursor lacunary species and its metal ion complexes.

Several complementary results characteristic of the diarsenates are worth noting and are presented in Table 2. The influence of pH is obvious, except for the $Co^{2+/3+}$ redox couple. The pH dependence of the $Mn^{2+/3+}$ redox couple in α_2-$As_2W_{17}Mn$ is very apparent. The significance of this observation will be studied in conjunction with the electrocatalytic properties of this system. In the α_2 series it is found that the reduction peaks for the substituent cations, that are reduced in a potential domain close to that of the W centres, are observed at more positive potentials in the As than in the P derivatives; in the As compounds, the reduction peak potentials are located at −66 mV vs. SCE for Fe^{3+} and −212 mV vs. SCE for Cu^{2+}, compared with −130 mV and −306 mV, respectively for the P derivatives.

Table 2. Oxidation or reduction peak potentials for the electroactive substituent cations within the α_2-$As_2W_{17}M$ species (M represents the substituent metal cation) at pH = 3 and 5; scan rate 10 mV·s^{-1}

	$Mn^{2+/3+}$	$Mn^{3+/4+}$	$Fe^{3+/2+}$	$Co^{2+/3+}$	$Cu^{2+/0}$
E_p [mV] (pH = 3)	1040	1186	−66	1130	−212
E_p [mV] (pH = 5)	624	950	−134	1124	−270

A short comparison is made in Table 3, between some compounds of the α_1 series. The corresponding results of the α_2 series are added to facilitate further comments. The location of the vacant site has no influence (for As), or only a small influence (for P), on the reduction peak potential of the lacunary species, irrespective of the identity of the central atom. Even so, a small positive shift is observed for the diarsenates relative to the diphosphates. Substantially larger shifts in the same direction are seen for the first reduction process of W centres in the iron-substituted species. The same trend can be seen for the reduction of the Fe^{3+} centre within the heteropolyanions with regard to the comparison between the diarsenates and the diphosphates. It must be noted that the influence of the pH on the $Fe^{3+/2+}$ redox couple in the α_1 derivatives is rather small. In contrast, the maximum shift in the negative potential direction for the α_2 species is 68 mV for the As derivative and 46 mV for the P compound. It is also worth noting that the iron centre is less easily reduced in the α_1 than in the α_2 derivatives. Such an observation should be related to a more general problem; it has been proposed[20,21] that α-P_2W_{18} is first reduced at one of the twelve equivalent tungsten atoms in the "belt". Experimental evidence supports this fact.[22] This behaviour still holds for the α_1-substituted species, the first observed wave depends on the relative reducibility of the substituent cation and W. It is then conceivable that the reduction potential of this hetero-cation is influenced by the neighbouring W atoms.[6] This point is being elaborated and will be published in a forthcoming paper.[23]

Tables 1−3 are complemented by Figure 2, which displays cyclic voltammograms of selected representative heteropolyanions that show more specific descriptions of their behaviour. Figure 2A compares the cyclic voltammograms of the α_1- and α_2-$As_2W_{17}Fe$ derivatives at pH = 3, and Figure 2B compares those of the corresponding P derivatives. Provisionally, it must be pointed out that the characteristic fingerprint for the α_2-type derivatives is present, as expected. Although the assignment of the observed first wave might appear straightforward, the novelty of the compounds prompted us to carry out several complementary coulometric determinations. Controlled potential coulometric experiments at pH = 3, and at the relevant peak potential or just negative of this value, suggest that one electron per molecule of α_1- or α_2-$As_2W_{17}Fe$ is involved. The characteristic blue colour of the reduced W centres was not observed, thus confirming that only the Fe^{3+} centre was reduced. Complete reoxidation to the Fe^{3+} state was achieved, and this indicated the stability of the $Fe^{3+/2+}$ system within the heteropolyanions, at least on the coulometric

Table 3. Reduction peak potential vs. SCE for $Fe^{3+/2+}$ redox couple and first tungsten wave in complexes of the α_1 and α_2 series; electrolytes: pH = 3 and 5; scan rate 10 mV·s^{-1}; for further details, see text

[a] The combined 1st and 2nd W waves are split into three components, the peaks of which are located at the potentials indicated in the table (see Figure 2A). [b] The number in parentheses corresponds to the first part of a composite wave.

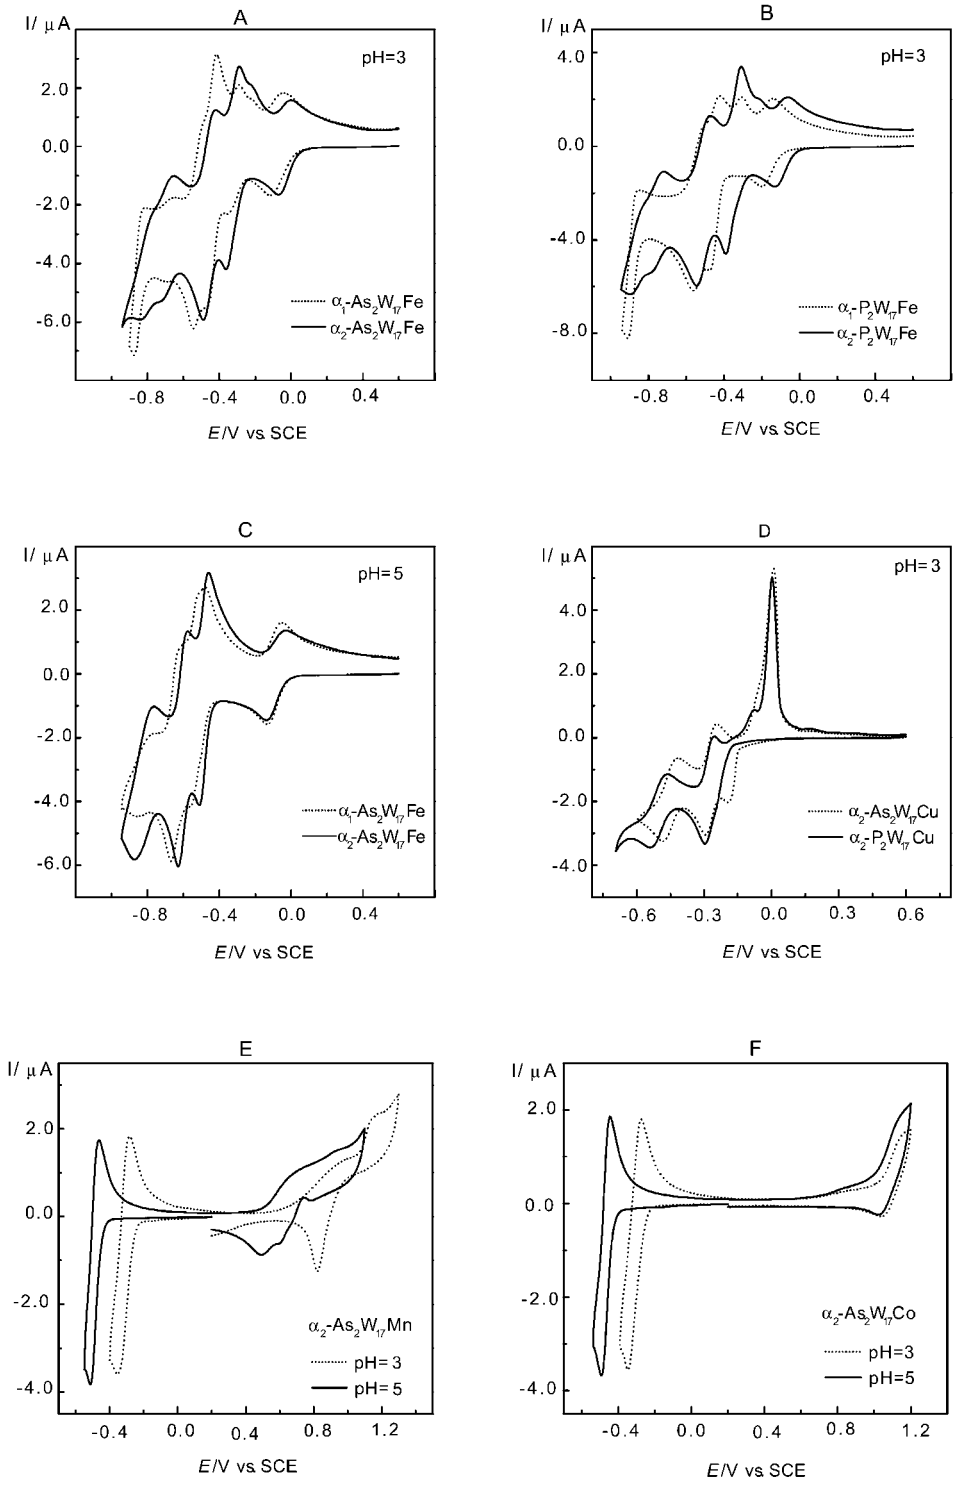

Figure 2. Cyclic voltammograms of a 5×10^{-4} M solution of the relevant heteropolyanion; working electrode glassy carbon; scan rate 10 $mV \cdot s^{-1}$, unless otherwise stated: A and B: 0.2 M Na_2SO_4 + H_2SO_4 (pH = 3); C: 0.4 M CH_3COONa + CH_3COOH (pH = 5); D: 0.2 M Na_2SO_4 + H_2SO_4 (pH = 3); scan rate 2 $mV \cdot s^{-1}$: E and F: 0.2 M Na_2SO_4 + H_2SO_4 (pH = 3) and 0.4 M CH_3COONa + CH_3COOH (pH = 5)

timescale. Under the same experimental conditions, a parallel behaviour was obtained for α_1- and α_2-$P_2W_{17}Fe$.[10,16] In Figure 2A, the Fe^{3+} reduction wave for α_2-$As_2W_{17}Fe$ is followed by two two-electron W waves. The same observation is seen for α_2-$P_2W_{17}Fe$ in Figure 2B, with a slight splitting of the first W wave in the P derivative. In contrast, for the α_1-$As_2W_{17}Fe$ derivative in Figure 2A, the expected two two-electron tungsten waves are separated into three components, with a remarkable reduction in the current of the first W wave and an enhancement of the intermediate part. A

different behaviour is displayed by α_1-$P_2W_{17}Fe$ in Figure 2B. An important negative shift of the first W wave, and a large enhancement of the first wave relative to the second wave is seen. Comparison of these two Figures indicates a sharp difference in the acid-base behaviour between the α_1 and α_2 derivatives in each series, and also between the α_1 derivatives of the two series. Such a difference between α_1-$As_2W_{17}Fe$ and α_2-$As_2W_{17}Fe$ is less striking at pH = 5, as can be seen in Figure 2C. The last example selected for comparison can be seen in Figure 2D, and involves α_2-$As_2W_{17}Cu$ and α_2-$P_2W_{17}Cu$. The cyclic voltammograms were run at pH = 3, and clearly show the good separation between the Cu^{2+}- and W^{6+}-centred processes in α_2-$As_2W_{17}Cu$, in contrast to the almost complete merging of the corresponding processes in α_2-$P_2W_{17}Cu$. Coulometry at the peak potential of the Cu^{2+} reduction wave in α_2-$As_2W_{17}Cu$ clearly showed the involvement of two electrons per molecule of heteropolyanion. No blue colour was observed, which would have indicated the concomitant reduction of the W centres. Using the same experimental conditions, it was necessary to use spectroelectrochemistry to appreciate the degree of separation of these two processes in α_2-$P_2W_{17}Cu$[24] Finally, Figure 2E,F illustrates the behaviour of the Mn^{2+} and Co^{2+} diarsenate derivatives at the two pH values studied. Two oxidation-reduction steps are easily observed for Mn^{2+} and one for Co^{2+}.

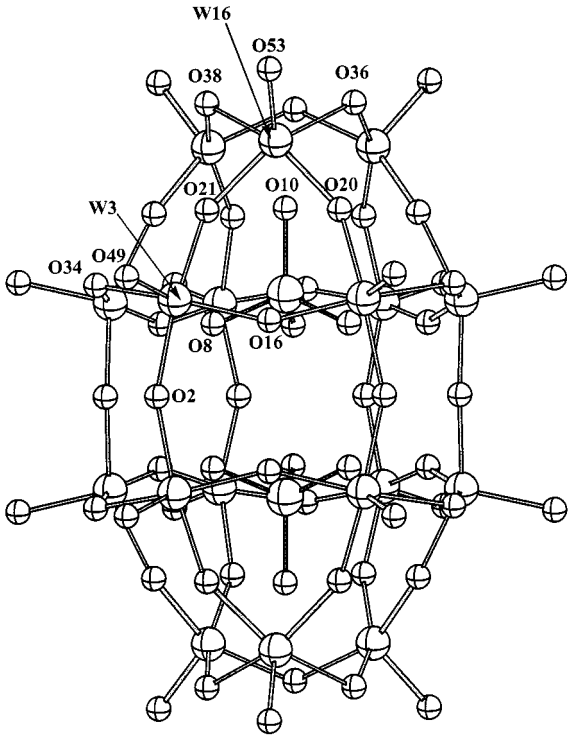

Figure 3. Numbering of atoms in the idealised structure of α-$[P_2W_{18}O_{62}]^{6-}$, used in the working out of crystallographic distances in Table 4

3. Discussion

We attempted to rationalise the experimental results by considering the interplay between several influences that ultimately determine the physical properties of the vacant site and hence, the behaviour of the substituted species. A crude evaluation of the size of the vacant site can be obtained by measuring the W−O distances around a selected W atom in the Dawson-type structure, with special attention being paid to the W−O terminal bond, which disappears when the vacancy is created. It is assumed during this process that the bond lengths or bond angles do not change on creating the vacant site. In this context, the numbering of atoms in the idealised structure in Figure 3 is based directly on the crystallographic results of D'Amour[25] and are used for the evaluation of the energies of molecular orbitals,[23] and more specifically here, for the determination of bond lengths. Table 4 shows the bond lengths recalculated from this idealised structure of P_2W_{18}. This evaluation of the sizes of vacant sites is primarily useful when comparing the behaviours of the derivatives of α_1- and α_2-P_2W_{18}.

Table 4. Mean W−O distances in Å in an idealised structure of $[P_2W_{18}O_{62}]^{6-}$

W3−O2	1.9220	W16−O10 (W−O−P)	2.3010
W3−O8 (W−O−P)	2.3196	W16−O20	1.9235
W3−O49	1.8986	W16−O21	1.9235
W3−O21	1.9401	W16−O36	1.9917
W3−O16	1.9575	W16−O38	1.9917
W3−O34 (W−O_t)	1.9147	W16−O53 (W−O_t)	1.8230

The two possible nonequivalent locations for a monovacant site are outlined by the W3−O and the W16−O distances; extraction of a W−O_t moiety from the appropriate position will create a vacant site in the so-called α_1 position for W3−O, or α_2 position for W16−O. Examination of the bond lengths would then suggest that the vacant site in the α_2 position is slightly larger than that in the α_1 position. However, this evaluation does not take into account the influence of the bond angles, which could minimise the difference in size between the two sites, whether the volume or the entrance surface is considered. In any case, a direct study of the size of the vacant site is severely plagued by the lack of precise crystallographic data on the lacunary species. As a matter of fact, it was pointed out that the vacancy in such species is statistically distributed over several or all of the equivalent positions.[26,27] Therefore, although the same kind of derivation as above could have been carried out using the crystallographic determinations on As_2W_{18} by Neubert and Fuchs,[28] we found that the following complementary qualitative observations might prove more useful. From a general point of view in the Dawson-type tungstodiphosphates and tungstodiarsenates, the physical behaviour of a vacancy depends on its location in the polyoxometalate frame. The greater rigidity of the α_1 sites compared with the relative fluidity of the α_2 sites might be explained as follows: a WO_6 octahedron in an α_1 position is once edge-shared and three times corner-shared, while in an α_2 position it is twice corner-shared and twice edge-

shared. Such an explanation clearly predicts the influence of the degree of matching between the size of the vacant site and the radius of the substituent cation on the stability constants of the complexes. Incidentally, it is worth noting that such a reasoning suggests a parallel behaviour for monolacunary Keggin species and α_2 Dawson-type lacunary compounds that possess the same kind of vacancy. Thus, the variations in the stability constants of the metal(II) and alkaline ion complexes of lacunary heteropolytungstates can be explained.[12,15] In contrast, it also justifies that the stability constants for the divalent metal ion complexes of α_1-P_2W_{17} □ and α_1-As_2W_{17} □ are not really affected by the nature of the central heteroatom.[12] Such an observation is important to propose a tentative explanation for some of the results in Table 3. The following suggestion can be made: the first W wave is driven in the positive potential direction in α_1-$As_2W_{17}Fe$ relative to the corresponding wave in α_1-$P_2W_{17}Fe$, due to the electronic effects of the central heteroatom, which ultimately is reflected in the relative basicity of the reduced species. The same influence holds for the compounds substituted in the α_2 position. Turning then to the general comparison between Dawson-type tungstodiphosphates and diarsenates, it can be assumed that, all things being equal, the size of the central atoms becomes the main relevant parameter. Considering the ionic radii of As^{5+} (0.46 Å) and P^{5+} (0.35 Å)[29] the larger space-filling ability of As should decrease the size of vacancies in the tungstodiarsenates relative to the -diphosphates. On this basis it is expected that the substituent cations would be attached less tightly in As than in the P derivatives. Stability constant values confirm this reasoning.[12] The only two examples of complexes in the present series in which the substituent cations are reduced in the vicinity of the W centres are the Fe^{III}- and Cu^{II}-substituted derivatives. The reduction potentials of these heterometal centres are substantially less negative in the As than in the P species, thus corroborating the expectations from the aforementioned reasoning.

4. Concluding Remarks

In the present work, Dawson-type tungstodiarsenates were synthesised, as well as their mono-lacunary species and several corresponding metal ion substituted derivatives. Attention was focused mainly on α_2-type derivatives, however, the Fe^{3+} derivatives of the α_1-, as well as the α_2-lacunary precursors were used. Systematic comparisons of the cyclic voltammograms of these compounds with those of tungstodiphosphates reveal that the first several voltammetric waves are driven in the positive potential direction by the presence of As as the central atom in the heteropolyanions. Precise crystallographic data are lacking for such compounds, in the diarsenate or in the diphosphate series. In spite of this situation, the present electrochemical results agree with the rough geometrical considerations, and with the knowledge of the stability constants of the metal ion substituted compounds indirectly reveal a coherent picture of the behaviour of the vacant sites in diarsenates and diphosphates. In particular, the influence of the central heteroatom on the redox and/or acid-base properties could be assessed and compared. Steric effects, expected on geometrical grounds, and already reflected in the values of the stability constants of the metal ion substituted compounds, also influence the cyclic voltammogram.

In conclusion, the identity of the central heteroatom substantially influences the redox behaviour of heteropolyanions, and must therefore be taken into account in our study of the parameters, which could modify electrocatalytic properties of this class of chemicals. It is rewarding to note that indirect methods can be used when evaluating the influence of changing the central atom in heteropolyanions. The study of multi-substitutions in the diarsenates and diphosphates is currently in progress.

5. Experimental Section

Pure water from a Milli-RO_4 unit, followed by a Millipore Q purification set was used throughout. All the chemicals were of high-purity grade and were used as received. H_2SO_4, Li_2SO_4, Na_2SO_4, CH_3COOH, CH_3COONa (Prolabo Normapur) were commercial products. In the present study, the medium of pH = 3 was made up with 0.2 M Na_2SO_4 + H_2SO_4 and that of pH = 5 with 0.4 M CH_3COONa + CH_3COOH. The heteropolyanions used in this work have been cited previously, along with appropriate abbreviations and preparations. Their stability was checked in a 0.2 M Na_2SO_4 + H_2SO_4 medium (pH = 3) using UV/Vis spectroscopy over a period of at least 24 h. The solutions were deaerated thoroughly for at least 30 min with pure argon and kept under argon during the electrochemical experiments**.** The source, mounting and polishing of the glassy carbon electrode (GC, Le Carbone Lorraine, France, 3 mm diameter) have been described.[5,6] The electrochemical setup was an EG & G 273 A driven by a PC with the 270 software. Potentials are quoted against the saturated calomel electrode (SCE), in a compartment separated from the test solution by a fine porosity glass frit. The counter electrode was platinum gauze with a large surface area in a separated compartment with a medium porosity glass frit. The UV/Vis spectra were recorded with a Perkin−Elmer Lambda 19 spectrophotometer. Experiments were performed at 23 ± 1 °C.

Acknowledgments

This work was supported by the CNRS (Laboratoire de Chimie Physique, UMR 8000, CNRS) and the University Paris XI. The help of Y. Jean, B. Levy and S. Blasco (Laboratoire de Chimie Physique) in the extraction of distances from crystallographic data and the numbering of the atoms in Figure 3 is gratefully acknowledged.

Synthesis, Characterization and Structural Studies on the First Rhenium Complex with Di(2-pyridyl) Ketone 2,4-Dinitrophenylhydrazone (dpkdnph), *fac*-[Re(CO)$_3$(dpkdnph)Cl]

Mohammed Bakir[a]

Keywords: Rhenium / Carbonyl ligands / Hydrazones

When di(2-pyridyl) ketone 2,4-dinitrophenylhydrazone (dpkdnph) was allowed to react with [Re(CO)$_5$Cl] in refluxing toluene *fac*-[Re(CO)$_3$(dpkdnph)Cl] was formed in good yield. Spectroscopic measurements on *fac*-[Re(CO)$_3$(dpkdnph)Cl] revealed strong solvent dependence as manifested by the high sensitivity of its electronic absorption spectra to solvent variation. Electrochemical measurements on *fac*-[Re(CO)$_3$(dpkdnph)Cl] in DMF show electrochemical properties with quasi-reversible reductions following an irreversible one-electron transfer. Structural studies on a brown crystal of *fac*-[Re(CO)$_3$(dpkdnph)Cl]·CH$_3$CN grown from an acetonitrile solution of *fac*-[Re(CO)$_3$(dpkdnph)Cl] show well separated linear CH$_3$CN and pseudo-octahedral *fac*-[Re(CO)$_3$(dpkdnph)Cl], with the major distortion about rhenium being due to the bidentate binding of dpkdnph to form a six-membered Re–N–C–C–C–N metallacyclic ring in a boat conformation. The molecular packing shows a web of *fac*-[Re(CO)$_3$(dpkdnph)Cl]·CH$_3$CN units interlocked via a network of intra- and intermolecular non-covalent interactions that include donor/acceptor and hydrogen bonds.

Introduction

Hydrazones and their compounds have been extensively studied for their rich physicochemical properties, reactivity patterns and applications in many important chemical processes that include non-linear optics, medicine, molecular sensing and separations.[1−16] The synthesis and characterization of rhenium carbonyl compounds of di(2-pyridyl) ketone (dpk), di(2-pyridyl)amine (dpa), di(2-pyridyl) ketone oxime (dpk·oxime), and di(2-pyridyl) ketone *p*-nitrophenyl hydrazone (dpknph) were described by us previously.[17−20] Electrochemical measurements on *fac*-[Re(CO)$_3$(dpk)Cl] and *fac*-[Re(CO)$_3$(dpk.oxime)Cl] revealed strong solvent dependence and the possible use of *fac*-[Re(CO)$_3$(dpk)Cl] as an electrochemical sensor for electrophiles that include metal ions.[17−19] Optical and thermodynamic measurements in polar solvents on dpknph and *fac*-[Re(CO)$_3$(dpknph)Cl] show the presence of two charge-transfer bands for the free ligand and its metal compound; the electronic/charge transfer in *fac*-[Re(CO)$_3$(dpknph)Cl] is faster than that in dpknph, and therefore *fac*-[Re(CO)$_3$(dpknph)Cl] can be used as a spectrophotometric sensor for metal ions.[20,21] These results prompted us to explore how a variation in the ligand backbone affects the electrochemical and optical properties of the complex, and here I report the synthesis, characterization and solid-state structure of the first metal compound of di(2-pyridyl) ketone 2,4-dinitrophenyl hydrazone (dpkdnph). Although a variety of 2,4-dinitrophenylhydrazones have been reported, to the best of my knowledge there has been no report on the isolation of dpkdnph.[1]

Results and Discussion

The reaction between [Re(CO)$_5$Cl] and dpkdnph in toluene under reflux gave *fac*-[Re(CO)$_3$(dpkdnph)Cl] in good yield. This reaction is similar to those reported for the synthesis of *fac*-[Re(CO)$_3$(L-L)Cl] (L-L = dpk, dpk.oxime, dpknph) from [Re(CO)$_5$Cl] and L-L in refluxing toluene.[17−20] The formulation of the isolated rhenium-carbonyl as *fac*-[Re(CO)$_3$(dpkdnph)Cl] is based on the results of a number of spectroscopic measurements and a comparison of these results with those reported for *fac*-[Re(CO)$_3$(L-L)Cl].[17−20] In the IR spectrum of *fac*-[Re(CO)$_3$(dpkdnph)Cl] three strong bands appeared in the ν(C=O) stretching region similar to those observed for *fac*-[Re(CO)$_3$(dpknph)Cl] and other tricarbonylhalorhenium(I) compounds with polypyridyl-like ligands, thus confirming the assigned *fac* geometry.[17−20] The ν(C=N) absorption of the hydrazone moiety and the combined ν(C=C) and ν(C=N) of the pyridine vibrations are normal and in the same region as in *fac*-[Re(CO)$_3$(dpknph)Cl].[20] A single absorption band was observed for the ν(NH) stretching mode signalling a free N−H in the solid state.[22] The ^{1}H NMR spectrum of *fac*-[Re(CO)$_3$(dpkdnph)Cl] (see Exp. Sect.) is solvent dependent, indicating a solvent-solute interaction. No evidence of paramagnetic line broadening or unusual shifts of resonances appeared in the spectra of this compound, thus confirming its diamagnetic character.

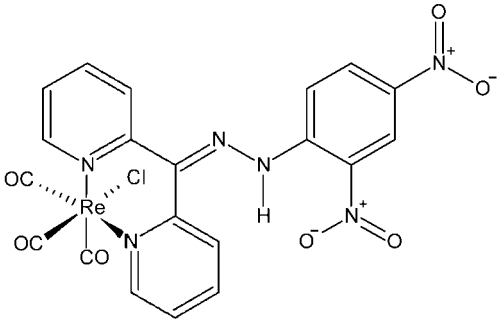
dpkdnph



fac-Re(CO)$_3$(dpkdnph)Cl

The electronic absorption spectra of *fac*-[Re(CO)$_3$(dpkdnph)Cl] show spectral features similar to those reported for *fac*-[Re(CO)$_3$(dpknph)Cl], although subtle differences are apparent.[20,21] The charge-transfer bands in *fac*-[Re(CO)$_3$(dpkdnph)Cl] shift to high-energy relative to *fac*-[Re(CO)$_3$(dpknph)Cl] due to a decrease in the electron-withdrawing ability of dpkdnph compared to dpknph. In non-polar solvents such as CH_2Cl_2 a highly intense high-energy charge-transfer band appeared (Figure1a), in polar solvents such as CH_3CN two charge-transfer bands appeared (Figure 1b), and in highly polar solvents such as DMF a low-energy charge-transfer band appeared (Figure 1c). The intensity and location of these bands are solvent dependent. The gradual addition of a physical or chemical stimulus to a solution of *fac*-[Re(CO)$_3$(dpkdnph)Cl] causes an interconversion between the low- and high-energy intra-ligand charge-transfer bands of *fac*-[Re(CO)$_3$(dpkdnph)Cl]. For example, when a DMF solution of *fac*-[Re(CO)$_3$(dpkdnph)Cl] was exposed to sunlight, the intensity of the low-energy charge-transfer band decreased and the intensity of the high-energy band increased (Figure 2). The spectrophotometric response of *fac*-[Re(CO)$_3$(dpkdnph)Cl] towards physical and chemical stimuli is similar to that reported for *fac*-[Re(CO)$_3$(dpknph)Cl] and studies are in progress to explore the thermodynamics and kinetics of the interconversion between the high- and low-energy forms of *fac*-[Re(CO)$_3$(dpkdnph)Cl] and its use as a spectrophotometric sensor.

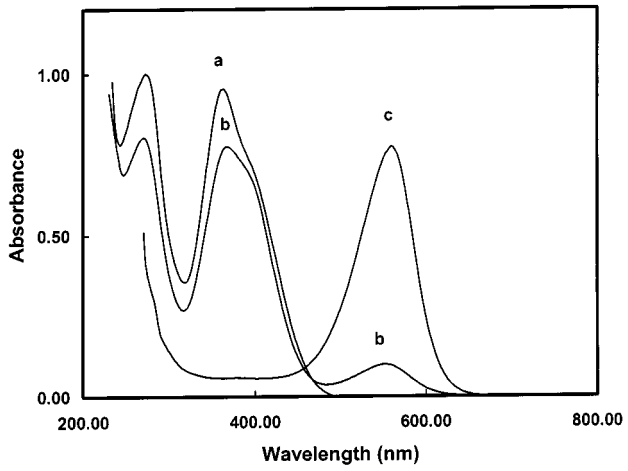


Figure 1. Electronic absorption spectrum of *fac*-[Re(CO)$_3$(dpkdnph)Cl] in: (a) CH_2Cl_2 (3.00×10^{-5} M); (b) CH_3CN (3.00×10^{-5} M); (c) DMF (1.00×10^{-5} M)

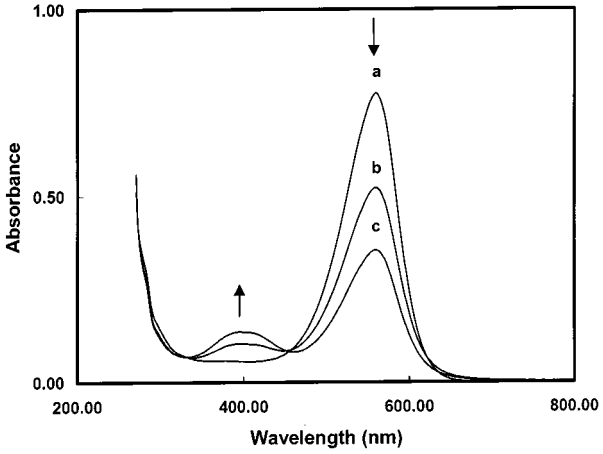

Figure 2. Electronic absorption spectrum of *fac*-[Re(CO)$_3$(dpkdnph)Cl] in DMF (1.00×10^{-5} M) (a) in the absence of sunlight, (b) after 3 h of sunlight exposure and (c) after 6 h of sunlight exposure

The electrochemical properties of *fac*-[Re(CO)$_3$(dpkdnph)Cl] in non-aqueous media were investigated using voltammetric techniques. Cyclic voltammograms of *fac*-Re(CO)$_3$(dpkdnph) in DMF are shown in Figure 3. In these voltammograms rich redox processes appeared. The first reduction wave at $E_{p,c} = -0.76$ V is one-electron and irreversible. Scan rate variations on this wave from 100−2000 mV/s revealed no sign of reversibility pointing to structural/chemical modification following the first electronic transfer. Two quasi-reversible reduction waves appeared at $E_p = -1.24$ V ($E_{p,c} = -1.29$ and $E_{p,a} = -1.18$ V) and -1.62 V ($E_{p,c} = -1.75$ and $E_{p,a} = -1.48$ V) pointing to the stability of the electrochemically generated species following the second and third electron transfer. The quasi-reversible reduction wave at -1.62 V is assigned to the $Re^{I/0}$ couple as it

falls in the potential range observed for such a couple in a variety of rhenium compounds of polypyridyl-like ligands of the type *fac*-[Re(CO)$_3$(L-L)Cl], where L-L = dpk, dpk.oxime, dpknph and others.[17−20] The irreversible oxidation wave at $E_{p,a}$ = +1.74 V carries a peak current larger than that observed for the first irreversible reduction wave and points to its multi-electron character. The peak potential of this wave and its multi-electron character is similar to that reported for *fac*-[Re(CO)$_3$(dpk.oxime)Cl] and suggests a metal-mediated oxidation of coordinated dpkdnph.[19] Electrochemically generated product waves appeared at $E_{p,a}$ = −1.62, +0.15, +0.55 and +0.98 V pointing to structural modifications following electron transfer(s). Their appearance, coupled with the reversibility of the reduction waves, points to the formation of electrochemically generated transient intermediates sensitive to their surroundings that can be used to explore the electrochemical behaviour of various substrates toward *fac*-[Re(CO)$_3$(dpkdnph)Cl] in a procedure similar to that reported for *fac*-[Re(CO)$_3$(dpk)Cl].[17,18]

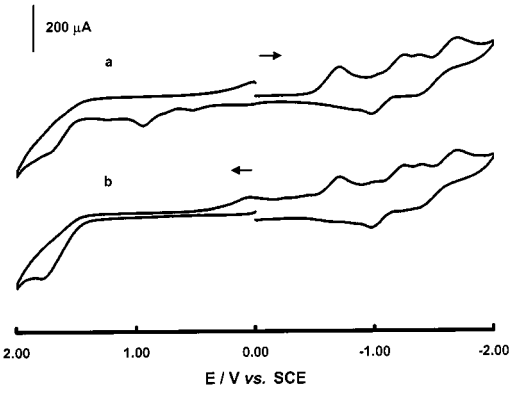

Figure 3. Cyclic voltammograms of *fac*-[Re(CO)$_3$(dpkdnph)Cl] in DMF solutions 0.1 M in [N(nBu)$_4$](PF$_6$)) at a glassy carbon working electrode at a scan rate of 400 mVs^{-1} vs. SCE

Single crystals of *fac*-[Re(CO)$_3$(dpkdnph)Cl]·CH$_3$CN were grown from an acetonitrile solution of *fac*-[Re(CO)$_3$-(dpkdnph)Cl] and the structure was determined using X-ray crystallography. An ORTEP drawing of *fac*-[Re(CO)$_3$(dpkdnph)Cl]·CH$_3$CN (Figure 4) shows well separated linear CH$_3$CN and pseudo-octahedral *fac*-[Re-(CO)$_3$(dpkdnph)Cl]. The distortion from an octahedral geometry about rhenium is due to the *N*,*N*-bidentate binding of dpkdnph and the formation of a six-membered metallacyclic ring (Re1−N1−C15−C00−C25−N5) in a boat conformation with the pyridine rings in a butterfly (Λ) formation. The N−N bite angle [N(1)−Re1−N(2)] of 83.03(11)° is of the same order as the 84.6° bite angles observed for the dpkO,OH in [ReOCl$_2$(dpkO,OH)],[23] and is larger than the 74.3° reported for bipy in *fac*-[Re(CO)$_3$-(bipy)(OPOF$_2$)].[24] These results reveal that the six-membered metallacyclic ring in rhenium compounds with polypyridyl-like ligands is less constrained than the five-membered metallacyclic ring in rhenium compounds with α-diimine ligands. The 2,4-dinitrophenylhydrazone moiety is planar with all nitrogen and carbon atoms sp^2 hybridized. The bond lengths and angles (Table 1) of the coordinated atoms are normal and similar to those reported for a variety of rhenium compounds of the type *fac*-[Re(CO)$_3$(N-N)X], where N-N = α-diimine ligand and X = anion.[24−26]

The packing of molecules (Figure 5) shows *anti*-parallel *fac*-[Re(CO)$_3$(dpkdnph)Cl]·CH$_3$CN units interlocked via a network of non-covalent interactions that include hydrogen bonding of the type X···H−C, where X = O, N or Cl and oxygen-nitrogen charge-transfer between the *ortho*-nitro groups of adjacent molecules. Selected views of the non-covalent interactions are shown in Figure 6 and their bond angles and distances are listed in Table 2. The amide (NH) proton of the hydrazone backbone forms an intramolecular classical hydrogen bond of the type N−H···O with the oxygen atom (O4) of the *ortho*-nitro group. The acetonitrile

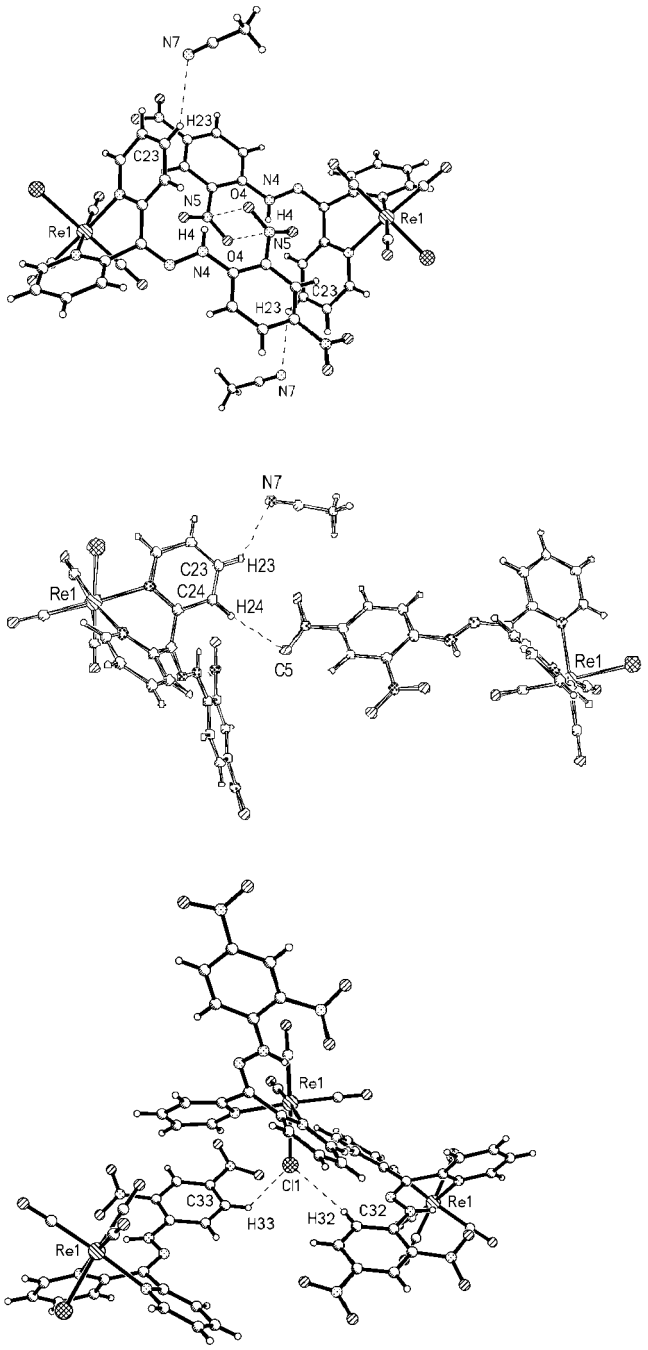

Figure 6. Selected views of the non-covalent bonding in the packed structure of *fac*-[$Re(CO)_3$(dpknph)Cl]·CH_3CN; non-covalent bonds are indicated by dashed lines

molecule binds to the adjacent proton (Figure 6b), whereas the *p*-nitro group binds to an adjacent *fac*-[$Re(CO)_3$-(dpkdnph)Cl] unit and the axial chloride doubly bridges two adjacent phenyl rings in a [C(32)−H(32)···Cl(1)···H(33)−C(33)] bonding form (Figure 6c). The bond lengths and angles of the non-covalent interactions are of the same order as those reported for a variety of compounds containing such bonds.[27−29] The difference in the oxygen−nitrogen bond length (Table 1) of the *para*-nitro group hints to an increase in electron density around the oxygen atom participating in the non-covalent C(24)−H(24)···O(6) interaction.

Owing to their convenient synthesis, rich physicochemical properties and potential use as molecular sensors, work is in progress to explore the electro-optical properties, solid state structures and solution conformations of a variety of di(2-pyridyl) ketone derivatives and their rhenium compounds.

Experimental Section

Reagents and Reaction Procedures: Solvents were reagent grade and thoroughly deoxygenated prior to use. All other reagents were obtained from commercial sources and used without further purification. All reactions were performed under a nitrogen atmosphere.

Physical Measurements: Electronic absorption spectra were recorded on a Perkin−Elmer Lambda 19 UV/Vis/NIR spectrometer. Solution ^{1}H NMR spectra were recorded on a Bruker ACE 200-MHz Fourier transform spectrometer and referenced to the residual protons in the deuterated solvent. Infrared spectra were recorded as KBr pellets on a Perkin−Elmer Spectrum 1000 FT-IR Spectrometer. Photochemical measurements were conducted on deoxygenated solutions before and after exposure to sunlight. Electrochemical measurements were performed with the use of a Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat and Model 276 interface in conjunction with a 286 PC. Data were acquired with the EG&G PARC Headstart program and manipulated using Microsoft Excel Program. Measurements were performed in solutions that were 0.1 M in $[N(n\text{Bu})_4](PF_6)$.The $E_{p,a}$, $E_{p,c}$ and $E_p = (E_{p,a} + E_{p,c})/2$ values were referenced to the potassium chloride saturated calomel electrode, SCE, at room temperature and are uncorrected for junction potentials. The number of electrons in the redox waves was determined using the oxidative peak current of the reversible one electron $FeCp_2/FeCp_2^+$ couple as an internal standard. Electrochemical cells were of conventional design based on scintillation vials or H-cells. A glassy-carbon disc was used as the working electrode and Pt-wire as a counter electrode.

Analytical Procedures: Microanalyses were performed by MEDAC Ltd., Department of Chemistry, Brunel University, Uxbridge, United Kingdom.

Preparation of dpkdnph: A mixture of dpk (200 mg, 1.09 mmol), 2,4-dinitrophenylhydrazine (220 mg, 1.12 mmol), ethanol (100 mL) and conc. HCL (0.25 mL) was refluxed for 5 h. The resulting reaction mixture was allowed to stand at room temperature for 3 h. A yellow solid was filtered off, washed with diethyl ether, hexane and dried; yield 350 mg, 0.96 mmol (88%). $C_{17}H_{12}N_6O_4$ (364.3): calcd. C 56.04, H 3.33, N 23.06; found C 55.86, H 3.32, N 22.98. IR (KBr disk): ν(N−H) 3320 cm^{-1}. The low solubility of dpkdnph in polar and non-polar solvents prevented any solution measurements on this compound.

Preparation of *fac*-[Re(dpkdnph)(CO)$_3$Cl]: A mixture of $[Re(CO)_5Cl]$ (200 mg, 0.55 mmol), dpkdnph (250 mg, 0.67 mmol) and toluene (50 mL) was refluxed for 20 h. The resulting mixture was allowed to cool to room temperature and reduced in volume to ≈ 25 mL. A yellow solid was filtered off, washed with hexane and diethyl ether, and dried; yield 300 mg, 0.45 mmol (82%). $C_{20}H_{12}ClN_6O_7Re$ (670.0): calcd. C, 35.87, H 1.80, N 12.54; found C 35.91, H 1.91, N 12.48. IR (KBr disk): ν(C=O) 2020, 1900, 1890 cm^{-1}, ν(NO_2) 1340, ν(N−H) 3273. ^{1}H NMR ([D$_6$]DMSO): δ = 11.80 (s, 1 H, NH), 9.15 (d, 1 H, dnph), 8.95 (d, 1 H, dnph), 8.85 (s, 1H dnph), 8.50−8.00 (closely spaced overlapped triplets and doublets, 6 H, dpk), 7.8 (overlapped triplets, 2 H, dpk). In $CDCl_3$: δ = 11.98 (s, 1 H, NH), 9.40 (d, 1 H, dnph), 9.16 (s, 1 H, dnph), 9.14 (d, 1 H, dnph), 8.45 (d, 1 H, dpk), 8.25−8.10 {overlapped triplet (8.16) and doublet (8.15), 2 H, dpk}, 8.04 (t, 1 H, dpk), 7.85 (d, 2 H, dpk), 7.65 (t, 1 H, dpk), and 7.55 (t, 1 H, dpk). UV/Vis {CH_2Cl_2, nm(ε)}: 396 sh (28,700); 358 (37,600), 268 (39,400).

X-ray Crystallography: When *fac*-[Re(CO)$_3$(dpkdnph)Cl] was allowed to stand in acetonitrile solution for several days brown cubic crystals of *fac*-[Re(CO)$_3$(dpkdnph)Cl]·CH_3CN were obtained. A single crystal was selected and mounted on a glass fibre with epoxy cement. A Bruker diffractometer equipped with a Mo-K_α radiation source and a graphite monochromator was used for data collection, and the SHELXTL software package version 5.1 was used for structure solution. Cell parameters and other crystallographic information are given in Table 3 along with additional details concerning data collection.[30−32] The location of the rhenium atom was determined from a Patterson map, and the remaining non-hydrogen atoms were located in subsequent difference Fourier maps. All non-hydrogen atoms were refined with anisotropic thermal parameters. In the final least-squares cycle, 344 parameters were fitted to 4095 observations, for a data to parameters ratio of 11.90:1. The least-squares residuals and other relevant parameters are given in Table 3.

Table 3. Crystal data and structure refinement for *fac*-[Re(CO)$_3$(dpkdnph)Cl]·CH_3CN

Empirical formula	$C_{22}H_{15}ClN_7O_7Re$
Formula mass	711.06
Temperature	298(2) K
Wavelength	0.71073 Å
Crystal system	Monoclinic
Space group	$P2_1/n$
Unit cell dimensions	a = 12.1221(19) Å, α = 90°
	b = 14.226(2) Å, β = 98.691(13)°
	c = 14.6170(19) Å, γ = 90°
V	2491.7(7) Å^3
Z	4
Density (calculated)	1.895 mg/m^3
Absorption coefficient	5.042 mm^{-1}
F(000)	1376
Theta range for data collection	2.01 to 25.00 °
Reflections collected/unique	8326/4095 [R(int) = 0.0417]
Completeness to theta: 25.00	93.2%
Absorption correction	Empirical
Max. and min. transmission	0.3158 and 0.2749
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	4095/0/344
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0227, $wR2$ = 0.0547
R indices (all data)	$R1$ = 0.0294, $wR2$ = 0.0568
Largest diff. peak and hole	0.646 and −0.695 e·A^{-3}

Investigation of Sugar-Binding Sites in Ternary Ligand−Copper(II)−Carbohydrate Complexes

Susanne Striegler*[a] and Elfi Tewes[a]

Keywords: Carbohydrates / Copper / Molecular imprinting / N ligands / UV/Vis spectroscopy

Evaluation of the binding interactions between a template (such as a carbohydrate) and a functional monomer (such as a metal complex) is one of the key steps during the design of molecularly imprinted polymers. Since we are interested in the development of carbohydrate-imprinted polymers as functional enzyme mimics, we have evaluated the binding interactions of several carbohydrates with [(diethylenetriamine)copper(II)] dinitrate (**1**), [*N*-{(2-hydroxyethyl)ethylenediamine}copper(II)] dichloride (**8**), and [{4-(*N*-vinylbenzyl)-diethylenetriamine}copper(II)] diformate (**13**) in aqueous solution. The binding sites of epimeric carbohydrates in complex formation with different copper(II) complexes have been investigated for the first time. The ternary ligand–copper(II)–carbohydrate complexes produced have been characterized by determination of their stoichiometry and their binding strength, by UV/Vis spectroscopy at alkaline pH.

Introduction

The mimicking of carbohydrate recognition by synthetic receptors has attracted much attention, especially in supramolecular chemistry.[1−5] Several attempts to recognize carbohydrates selectively by means of synthetic receptors based on hydrogen bonding, charged interactions, or boronic acids have been made, and the progress achieved was recently reviewed in detail by Davis and Shinkai.[1,6] Hydrogen bonding interactions, which provide the major driving force for sugar binding in apolar organic media, become far less effective in aqueous media.[7] The binding interactions of synthetic receptors with carbohydrates in water should therefore rely on other forces, such as metal coordination.

Functional enzyme mimics can be engineered by the molecular imprinting technique, which is suitable for the development of robust, inexpensive, but highly selective polymers.[8−10] Molecular imprinting involves the preorganization of polymerizable functional monomers around a targeted template (such as a carbohydrate) in solution, forming a monomer−template assembly, followed by cross-linking polymerization to stabilize this arrangement in the three-dimensional polymeric material. The solvent serves as a porogen during the imprinting process and is responsible for the microporosity of the later polymer. During the imprinting process the functional monomers are placed complementarily to the functionality of the template (such as a carbohydrate) inside the polymer matrix. Functional cavities remain after removal of the template, and these enable the matrix to rebind its original template specifically. The preparation of these polymers can only be rationalised with precise knowledge of the binding interaction between the functional monomer and the targeted template (carbohydrate) prior to polymerization.[11,12]

Binding forces applied during the self-organization of functional monomers and carbohydrates as templates include covalent, noncovalent, and coordinative binding interactions. Wulff and co-workers introduced a covalent approach for the separation of racemates of glycosides and free carbohydrates.[13−15] The reversible formation of boronate esters between pairs of hydroxyl groups of the sugar molecule and *p*-vinylphenylboronic acid was used for preorganization of the functional monomer and the carbohydrate. The esters were characterized by common methods, such as ^{1}H and ^{13}C NMR spectroscopy, prior to polymerization. Mosbach and co-workers introduced a noncovalent approach for the investigation of sugar-imprinted polymers. Their study demonstrates the feasibility of noncovalent binding interactions for the preparation of sugar binding polymers, and the binding specificity of the resulting polymer sites.[16] Prior to polymerization, derivatized carbohydrates (templates) were prearranged through hydrogen bonding to methacrylic acid (functional monomer). The complex formation was assumed to be similar to that investigated for the previously reported self-organization of amino acids with methacrylic acid.[17] However, binding sites with high affinity and excellent anomeric and epimeric selectivity suitable for the separation of racemic mixtures were obtained. Arnold and co-workers have also developed a sensing device for glucose, based on an α-methyl-D-glucose-imprinted polymer.[18] Metal coordination was used as the

binding force between functional monomer and carbohydrate to generate a glucose-specific cavity inside the polymer. Isothermal titration calorimetry was applied in order to study the formation of a ternary triazacyclononane−Cu^{II}−glucose complex in solution at pH = 11.25 [K_{app} = 2.6 (±0.2) × 10^3 M^{-1}] and to study the binding interactions between the triazacyclononane−Cu^{2+} complex and *cis*-1,2- or *trans*-1,2-diols, such as 1,4-anhydroerythritol or 1,4-anhydro-L-threitol. Upon binding of *cis*-diols at high pH (> 9), the metal complex releases protons, which can be easily detected by a pH electrode. However, this sensing device is limited by its operation range, which is not suitable for sensing carbohydrates at physiological pH values.[19]

Taking advantage of the demonstrated recognition capability for *cis*-1,2-diols over *trans*-1,2-diols of metal-coordinated molecularly imprinted polymers, we are aiming to prepare molecularly imprinted polymers as enzyme mimics, that are operational at physiological pH. We have therefore investigated suitable binding interactions and binding sites prior to the imprinting of carbohydrates by metal coordination into polymeric materials. Accordingly, we now report for the first time on the evaluation of the binding sites of several closely related carbohydrates upon chelation to selected copper(II) complexes. We have also characterized the ternary ligand−Cu^{II}−carbohydrate complexes produced in terms of stoichiometry and binding strength.

Results and Discussion

Determination of the Stoichiometry of the Ternary Ligand−Copper(II)−Carbohydrate Complexes

Binding events in light-absorbing metal complexes can easily be observed by UV/Vis spectroscopy, while the application of NMR spectroscopy to the observation and characterization of binding events is widely used only for diamagnetic complexes. Therefore, a direct line of arguments relying on NMR spectroscopy does not appear to be applicable for systems containing paramagnetic copper(II) complexes. Accordingly, the following chain of indirect evidence is given.

The determination of the number of spectroscopic states in an equilibrium gives an insight into the number of complexes formed, and influences the choice of a suitable method to evaluate the binding constant, which strongly depends on the number of absorbing species. The association of a metal complex (M) with a carbohydrate (C) resulting in a ternary ligand−Cu^{II}−carbohydrate complex (MC) is described by Equation (1), its apparent binding constant $pK_{11} = -\log(K_{11}^{-1})$, whereas K_{11} is defined by Equation (2).[20] The number of spectroscopic states does not characterize intramolecular equilibria within ternary metal complexes.

$$M + C \leftrightharpoons MC \quad (1)$$

$$K_{11} = [MC]/([M] \times [C]) \quad (2)$$

When no complex formation between C and M takes place, M remains the only absorbing species in a one-state system, although the number of species (i.e., C and M) in this solution is two. Accordingly, a system containing two absorbing species (i.e., M and MC), refers to a two-state system and also to 1:1 complex formation if the carbohydrate C does not absorb within the selected wavelength range.[20]

If additivity of absorbances is assumed for two solutions k and n at any wavelength pair 1 and 2, Beer's law can be rewritten, resulting in Equations 3:

$$A_{1k} = \varepsilon_{1k}^{M}[M]_k + \varepsilon_{1k}^{MC}[MC]_k \quad (3a)$$

$$A_{1n} = \varepsilon_{1n}^{M}[M]_n + \varepsilon_{1n}^{MC}[MC]_n \quad (3b)$$

$$A_{2k} = \varepsilon_{2k}^{M}[M]_k + \varepsilon_{2k}^{MC}[MC]_k \quad (3c)$$

$$A_{2n} = \varepsilon_{2n}^{M}[M]_n + \varepsilon_{2n}^{MC}[MC]_n \quad (3d)$$

When $[M]_k + [MC]_k = [M]_n + [MC]_n = M_t$ (t = total; M_t is kept constant) and medium-independent spectra can be assumed, then $\varepsilon_{1k}^{M} = \varepsilon_{1n}^{M}$ and $\varepsilon_{1k}^{MC} = \varepsilon_{1n}^{MC}$. It also follows that the ratio of differences of the absorbances is a constant. Plots of $(A_{1k} - A_{1n})$ versus $(A_{2k} - A_{2n})$, $k \neq n$, give straight lines passing through the origin [Equation (4)]. The corresponding system has two spectroscopic states and refers to 1:1 complex formation.[20]

$$(A_{1k} - A_{1n}) = [(\varepsilon_{1k}^{MC} - \varepsilon_{1k}^{M}) \times (\varepsilon_{2k}^{MC} - \varepsilon_{2k}^{M})^{-1}] \times (A_{2k} - A_{2n}) \quad (4)$$

[(Diethylenetriamine)copper(II)] dinitrate — [CuDIEN]-$(NO_3)_2$ (**1**) — and glucose (**2**), galactose (**3**), mannose (**4**), or maltose (**5**) assemble at pH > 10.4 to give 1:1 complexes, resulting in two-state systems. This conclusion is based: (1) on the evaluation of the number of spectroscopic states, and (2) on the method of continuous variation (Job's method).[20] As a representative example for other calculations of numbers of spectroscopic states reported in this

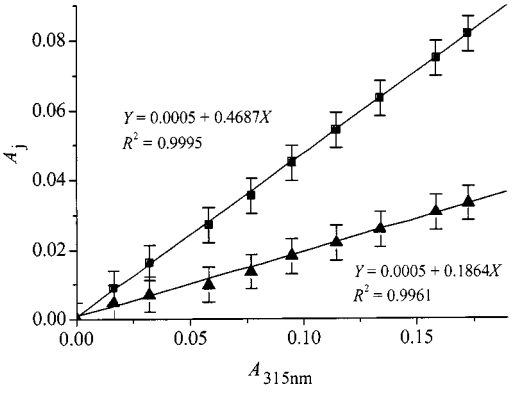

Figure 1. Plot of selected absorbances A_j [j = 325 nm (■) and 335 nm (▲)] over A_{315nm} from titration of [CuDIEN]$(NO_3)_2$ (**1**) with water at pH 12.4, 25 °C (calibration curve)

paper, the stoichiometry of the ternary complex formed from **1** and glucose (**2**) is determined by Equation (4) according to the plots shown in Figure 1 and Figure 2.

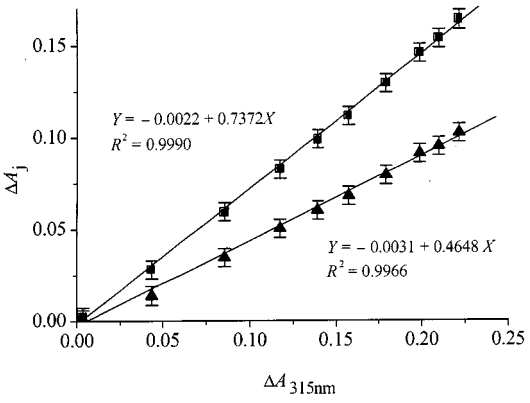

Figure 2. Plot of selected differences in absorbances $\Delta A_j = (A_{j,k} - A_{j,n})$ over $\Delta A_{315nm} = (A_{315nm,k} - A_{315nm,n})$ from titration of $[CuDIEN](NO_3)_2$ (**1**) with glucose (**2**) at j = 325 nm (■) and 335 nm (▲) for solution k containing **1** and **2** and solution n containing **1** at V_t = 2 mL, $[\mathbf{1}]_t$ = 2 mM, t = total, $A_{315nm,\mathbf{1}}$ = 0.0657, $A_{325nm,\mathbf{1}}$ = 0.0354, $A_{335nm,\mathbf{1}}$ = 0.0109, pH = 12.4, 25 °C

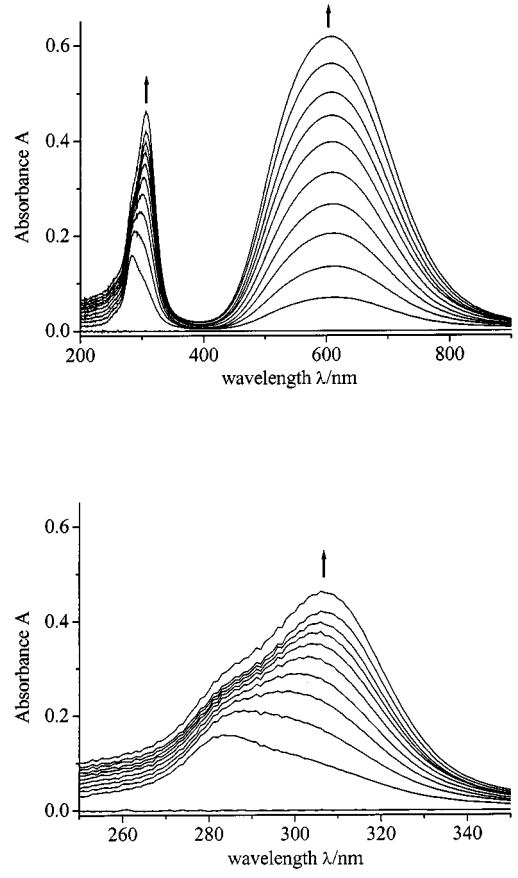

Figure 3. UV/Vis spectra observed during titration of $[CuDIEN](NO_3)_2$ (**1**) with glucose (**2**) at 25 °C in unbuffered, aqueous solution at pH = 12.4 according to Job's method; the concentrations of **1** and **2** were varied from 0−10 mM, while the sums of the total concentrations ($M_t + C_t$ = 10 mM) and the total volume of the solution (V_t = 2 mL) were kept constant

If the system contains only one absorbing species (i.e., M), no complex formation takes place and the slopes of the linearly fitted data for corresponding wavelength pairs in systems containing **1** or **1** and **2** would be identical. This is not observed here; therefore, association between **1** and **2** takes place and at least one ternary ligand−copper(II)−carbohydrate complex is formed (Figures 1 and 2). From the linear fit of the data, the current system can be described as a two-state system, based on 1:1 complex formation.[20]

The method of continuous variation (Job's method) was also applied to demonstrate association between **1** and **2**−**5**. Accordingly, the concentrations of **1** and the carbohydrates were varied, keeping the total concentration of the sugars and the metal complex constant. The titration data of **1** and **2** obtained by Job's method are shown as representative examples in Figures 3−5 and discussed below (for others, see Supporting Information).

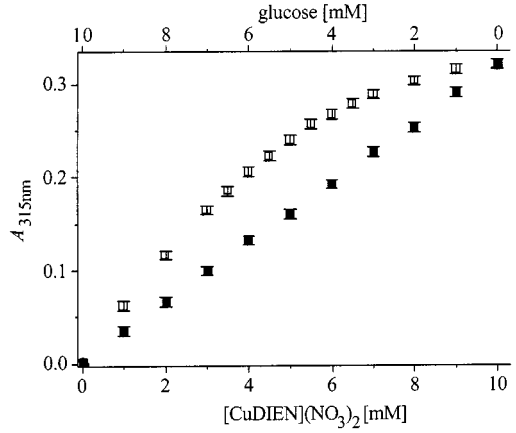

Figure 4. Plot of the absorbance A at 315 nm versus concentration of $[CuDIEN](NO_3)_2$ (**1**), observed during titration of **1** with glucose (**2**) (□) and during titration of **1** with water (■) according to Job's method at pH 12.4, 25 °C

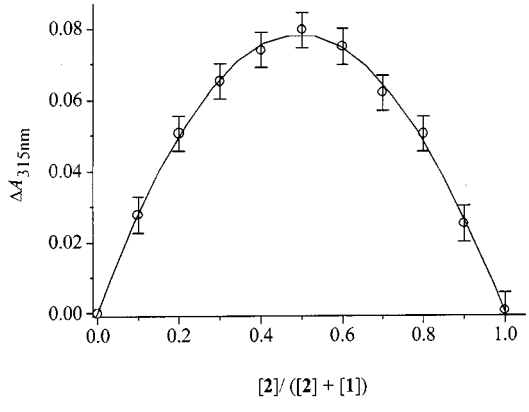

Figure 5. Plot of differences in absorbances ΔA at 315 nm between solutions containing $[CuDIEN](NO_3)_2$ (**1**) and glucose (**2**) and solutions containing pure **1** versus the molar ratio **2**/(**2** + **1**); the maximum is related to the molecular ratio of n and m in $n\mathbf{M} + m\mathbf{C} = \mathbf{M}_n\mathbf{C}_m$ and is defined by $n/(n + m)$; the ratio of $n/(n + m)$ = 0.5 corresponds to n = 1 and m = 1 and refers to 1:1 complex formation of **1** and **2** (Job plot)

There is no evidence for the occurrence of multiple equilibria or other complex formation if a 1:1 molar ratio of the compounds or an excess of ligand is applied. The complex formation is not observable by UV/Vis spectroscopy when the pH value is less than 10.4. In contrast, multiple equilibria are present for the association of glucuronic acid (**6**) with **1** (Figure 6).

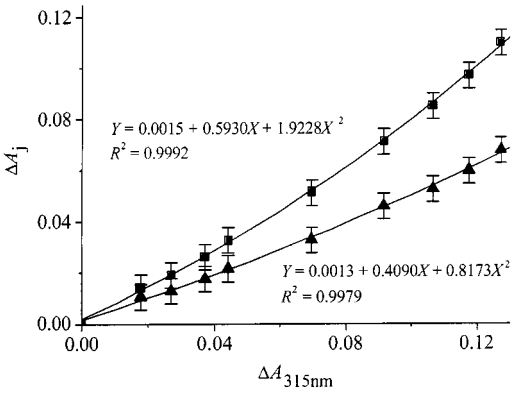

Figure 6. Plot of selected differences in absorbances $\Delta A_j = (A_{j,k} - A_{j,n})$ over $\Delta A_{315nm} = (A_{315nm,k} - A_{315nm,n})$ from titration of $[CuDIEN](NO_3)_2$ (**1**) with glucuronic acid (**6**) at j = 325 nm (■) and 335 nm (▲) for solutions k containing **1** and **6** and solution n containing **1**, V_t = 2 mL, $[\mathbf{1}]_t$ = 2 mM, t = total, $A_{315nm,\mathbf{1}} = 0.0657$, $A_{325nm,\mathbf{1}} = 0.0354$, $A_{335nm,\mathbf{1}} = 0.0109$, pH = 12.4, 25 °C

The nonlinear plot shows complex formation between **1** and **6** and accounts for the presence of more than two spectroscopic states due to multiple equilibria. The carboxylic group at the carbon C^6 of **6**, in contrast to **2**−**5**, offers an additional binding site to copper(II) complexes, which can be used for coordination or, in combination with the hydroxyl group at C^4, chelation to a copper(II) complex.

Evaluation of Suitable Ligand−Cu^{II} Complexes for Association with Carbohydrates

We also evaluated whether the reported binding constants of binary, nonpolymerizable Cu^{II}−ligand complexes can be used to interpret their association behavior with carbohydrates. Our idea behind this was: (1) to achieve fast accessibility and screening of potentially useful and structurally different Cu^{II}−ligand complexes, (2) to achieve increased stability of the Cu^{II} complex during the UV/Vis measurement, avoiding polymerization reactions, and (3) to demonstrate the similar association capabilities of structurally related Cu^{II} complexes with and without polymerizable ligands. Accordingly, we picked several tri- and bidentate Cu^{II} complexes with reported binding constants, in order to evaluate their complexation behavior with **2**−**5** (Figure 7).

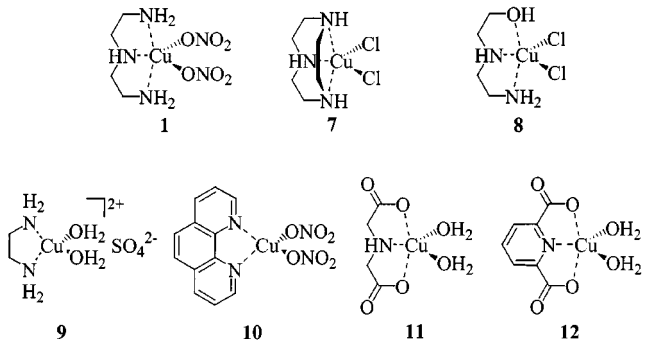

Figure 7. Structures of the copper(II) complexes **1**, **7**−**12**

The Cu^{II} complexes formed from tridentate N- and N,O-ligands **1**, [(triazacyclononane)copper(II)] dichloride $[Cu(TACN)]Cl_2$ (**7**),[18] and *N*-[{(2-hydroxyethyl)ethylenediamine}copper(II)] dichloride CuHEN (**8**), each associate with **2**−**5** with identical stoichiometries (see Supporting Information). In contrast, decomposition of [(ethylenediamine)copper(II)]sulfate (**9**), [(phenanthroline)copper(II)] dinitrate (**10**), copper(II)iminodiacetic acid (**11**), and copper(II)pyridinedicarboxylic acid (**12**) occurs in alkaline solution (pH > 10.4), which prevents the observation of complex formation with **2**−**5**. The formation of a precipitate, which was identified as copper(II) hydroxide, is due to the low chelating ability of the ligands ethylenediamine (EN), iminodiacetic acid (IDA), pyridinedicarboxylic acid (pdca), or phenanthroline (phen), to copper(II) in alkaline solution. Since strong binding of carbohydrates during molecular imprinting requires highly alkaline pHs, only copper(II) complexes stable under these conditions are useful. Surprisingly, *N*-(2-hydroxyethyl)ethylenediamine (HEN) is a suitable ligand for chelating copper(II) in alkaline solution according to our UV measurements, although the reported binding strength of HEN to copper(II) (pK^{Cu} = 10.09) is of the same order of magnitude as those reported for the tridentate IDA (pK^{Cu} = 10.56) or pdca (pK^{Cu} = 9.1), and the bidentate EN (pK^{Cu} = 10.49) or phen (pK^{Cu} = 9.12), while those for copper(II) complexes with tridentate N-ligands — TACN (pK^{Cu} = 15.5) or DIEN (pK^{Cu} = 15.9) — are much higher.[21] The advantage of the copper(II) complex **1** over **7** lies in the low cost of the diethylenetriamine ligand compared to triazacyclononane (1 g of TACN can be purchased from Aldrich for about US $350, whereas 1 g of DIEN costs only about US $0.02), while the binding strength to copper(II) is almost the same (pK^{Cu}_{TACN} = 15.5, pK^{Cu}_{DIEN} = 15.9).[21,22] Accordingly, we chose [{4-(*N*-vinylbenzyl)-diethylenetriamine}copper(II)] diformate $[Cu(styDIEN)](HCOO)_2$ (**13**) as a functional monomer for the preparation of molecularly imprinted polymers after characterization of the stoichiometry of the targeted ternary ligand−Cu^{II}−carbohydrate complexes from **13** and **2**−**5** (see Supporting Information).[23]

As demonstrated for CuHEN, the binding constants of known binary nonpolymerizable Cu^{II}−ligand complexes do not allow a generally valid interpretation of their association behavior with carbohydrates. In contrast, the complexation behavior of the polymerizable Cu^{II} complex **13** can be estimated from the known binding behavior of the corresponding nonpolymerizable Cu^{II} complex **1**.

Investigation of the Binding Sites of Selected Carbohydrates upon Interaction with Copper(II) Complexes

Carbohydrates exist in several equilibrium structures (i.e., α- and β-pyranoses, α- and β-furanoses, and an acyclic

form) and conformers. It is known that both *cis*- and *trans*-diols in six-membered rings can complex to metal ions, but that only *cis*-diols in five-membered rings do.[24] It is also generally accepted that the effectiveness of complexing sites can be listed in descending order: *cis*-diol on a five-membered ring > *cis*-diol on a six-membered ring > *trans*-diol on a six-membered ring.[25] The pyranoses of **2**−**4**, which are the main equilibrium structures in aqueous solution of the saccharides under investigation here,[30] are shown in Figure 8.

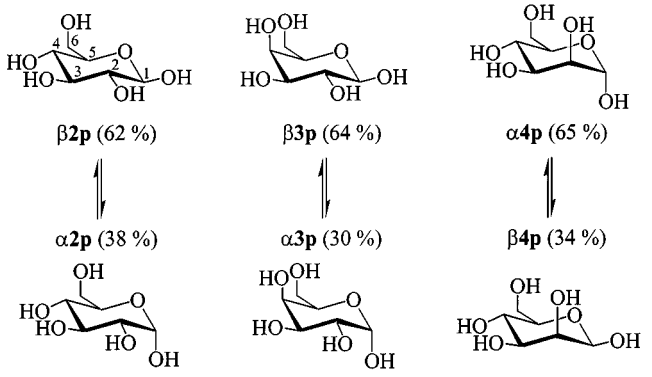

Figure 8. Percentage values of the main equilibria structures of glucose (**2**), galactose (**3**), and mannose (**4**) in aqueous solution at pH = 7 at 31 °C (**2**, **3**) and 44 °C (**4**);[30] missing percentage values refer to the furanose and the acyclic carbonyl forms; **p** = pyranose

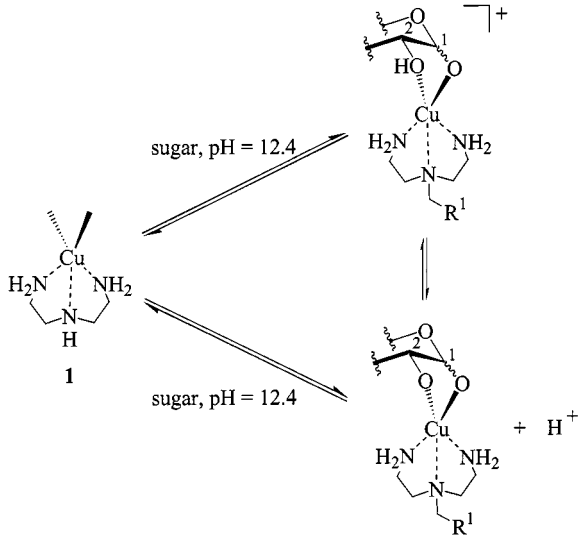
Subsequently, we firstly determined whether multiple deprotonation of the carbohydrate occurs upon complexation with **1**, **7**, and **8** under the conditions applied, and secondly, which 1,2-diol groups of the carbohydrates **2**−**6** are involved in chelation to **1**, **7**, and **8**.

Multiple deprotonation of metal-bound carbohydrates is a well-known phenomenon in the solid state, particularly when pH values close to 14 are considered. Klüfers et al. reported on a crystal structure of fivefold deprotonated D-mannose as a ligand in homoleptic dinuclear metalates of trivalent iron, vanadium, chromium, aluminium, and gallium.[26] However, the systems under investigation here are clearly different in terms of concentration of the compounds, the kind and charge of the metal ion, and the identity of the metal atom-binding ligand. When the solutions both of the metal complex and of the sugar are adjusted to pH 12.4 prior to mixing, proton release during complex formation is directly related to the single or multiple deprotonation of the carbohydrate in a ternary ligand−copper(II)−carbohydrate complex and observable by a drop in the pH value of the solution.

Since ternary complexes formed both from singly deprotonated and from doubly deprotonated carbohydrate can coexist in equilibrium (Scheme 1), titration experiments were performed at 2, 5 and 10 mM concentrations of **1** with fortyfold, sixteenfold, and eightfold molar excesses of **2** to distinguish both possible binding modes (Figure 9).



Scheme 1. Complex formation of $[Cu(DIEN)](NO_3)_2$ (**1**) with singly and doubly deprotonated carbohydrates at pH 12.4

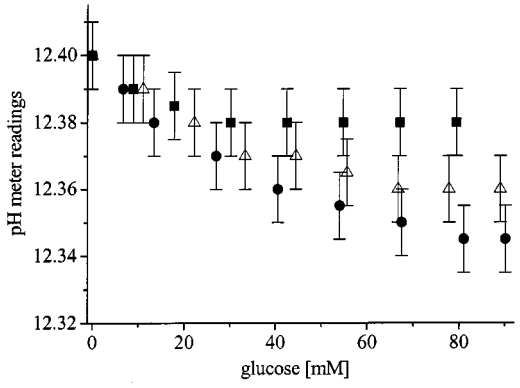


Figure 9. Plot of average pH meter readings from titration experiments of 2 mM (■), 5 mM (▲), and 10 mM (circle) $[CuDIEN](NO_3)_2$ (**1**) solution with up to fortyfold molar excesses of glucose (**2**) at 25 °C; each set of titration was performed three times and the error in the pH reading was within 0.01 units; total concentration of **1** and the total volume of the solution (V_t = 1 mL) were kept constant; nanopure water was sonicated and purged with argon prior to use; stock solutions were separately adjusted to pH 12.4 with $NaOH_{(aq)}$ and kept under argon prior to use

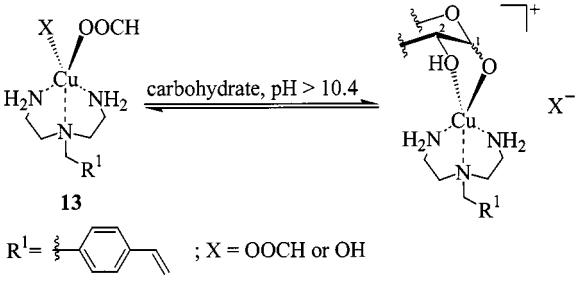
By using the Hendersson−Hasselbach equation and the reported first deprotonation constants of the carbohydrates,[21] we calculated the ratio of singly deprotonated and nondeprotonated sugars in the saccharide stock solution.[27] We further estimated the maximum amount of proton release during the formation of the ternary ligand−copper(II)−carbohydrate complexes for 2, 5, and 10 mM metal ion solution for complete dissociation of **2** into a singly deprotonated saccharide upon binding to the copper(II) complex. The pH value would be expected to drop from 12.40 to 12.38 for 2 mM, from 12.40 to 12.36 for 5 mM, and from 12.40 to 12.32 for 10 mM copper(II) ion solution. In contrast, the pH value of the solution for doubly deprotonated **2** should drop from 12.40 down to 12.34 for 2 mM, from 12.40 to 12.25 for 5 mM, and from 12.40 to 12.03 for 10 mM copper(II) solution. This larger drop is caused by

further dissociation of **2** and additional release of 1 mol proton/mol carbohydrate upon binding to the copper(II) ion. However, the observed changes in pH for the overall solutions of both 5 mM and 10 mM Cu^{II} concentrations correspond to singly deprotonated **2** as the main species in solution in the ternary ligand−copper(II)−carbohydrate complex (Figure 9). The drop in the pH value for the 2 mM solution is close to the experimental error and was not considered.

We therefore propose that complex formation between **1**, **7**, and **8** with **2** at pH = 12.40 takes place with singly deprotonated α-D-glucopyranose (pK_2^H = 12.28)[21] chelating the copper(II) complex through the hydroxyl groups at C^1 and C^2, this being the only equilibrium structure of glucose with a 1,2-*cis* arrangement of hydroxyl groups. The proposed complex formation between **13** and **2**−**5** for aqueous solution at alkaline pH is indicated in Scheme 2.



Scheme 2. Complex formation of [Cu(styDIEN)]$(HCOO)_2$ (**13**) with **2**−**5** at pH =12.40

If this assumption is valid, then the derivatizing carbon atoms C^1 and C^2 should have a strong influence on the binding behavior of glucose to **1**, **7**, and **8**. To obtain confirmation of this, we performed several experiments at pH = 12.40 with **1** as a model for the similar copper(II) complexes **7** and **8**. Firstly, blocking of the hydroxyl group of the anomeric carbon atom C^1 of **2** by using α-D-methylglucopyranoside or β-D-methylglucopyranoside resulted in no detectable binding interactions with **1**. Secondly, removal of the hydroxyl group at C^2 of **2** by using 2-desoxyglucose as ligand resulted in no ternary complex formation. Thirdly, blocking of the hydroxyl group at C^3 by using 3-*O*-methyl-D-glucose (**2a**) as ligand permitted the formation of a 1:1 complex with **1**. These experiments demonstrate that the free hydroxyl groups at carbon atoms C^1 and C^2 of **2** are essential for chelating the copper(II) complex **1** in alkaline solution, while the hydroxyl group at C^3 is not involved in complex formation of **1** and **2** under the provided conditions.

Galactose (**3**) differs from its epimer **2** in the configuration at carbon atom C^4, while the arrangement of the hydroxyl groups at C^1 and C^2 is identical. Complex formation with **3** and **1** can in principle occur through the hydroxyl groups at C^1 and C^2, at C^3 and C^4, or at C^4 and C^6. At pH = 12.40, deprotonation of the hydroxyl group at C^1 takes place (pK_3^H = 12.35)[21] in analogy to **2**, which would be expected to provide stronger and therefore preferable binding interactions with a copper(II) complex than those arising by chelation through the protonated hydroxyl groups at C^3 and C^4, or C^4 and C^6. Under the given conditions, the number of spectroscopic states corresponds to a two-state system and a 1:1 assembly of **3** with **1**. No evidence for multiple equilibria is given by the experimental data when a 1:1 molar ratio between **1** and **3**, or an excess of **3**, is provided during the experiments. Since no binding interactions between **1** and α-methyl-D-galactopyranoside or β-methyl-D-galactopyranoside are detectable, only the hydroxyl groups at the anomeric carbon C^1 and at C^2 of **3** are considered to chelate **1**, in agreement with the observations made for ternary complex formation of **1** with **2**.

Mannose (**4**) differs from its epimer **2** in the configuration at C^2. Chelation of **1** should preferentially be through the *cis*-diol groups at C^1, C^2, and C^3 of **4**. The binding interaction between **4** and **1** at pH = 12.40 was characterized as a two-state system corresponding to a 1:1 molar ratio during complex formation. A protonated hydroxyl group at C^2 of **4** is less likely to act as a donor group for two molecules of **1** at the same time, which is attributable to steric constraints during complexation. Since deprotonation of the hydroxyl group at C^1 of **4** occurs at pH = 12.40 (pK_4^H = 12.08),[21] analogously with **2** and **3**, participation of the deprotonated hydroxyl group at C^1 in chelation has the strongest influence on the complex formation between **1** and **4**. No binding interactions between α-methyl-D-mannopyranoside and **1** were observed even at pH = 12.40. This demonstrates that the deprotonated hydroxyl group at C^1 is necessary for strong binding, and suggests that the hydroxyl groups at C^2 and C^3 of **4** do not contribute significantly to the binding interactions with **1** under the given conditions.

Determination of the Binding Constant of Selected Copper(II) Complexes with Different Carbohydrates

The method of Rose and Drago was applied in order to determine the binding constants of the 1:1 complexes formed from **1**, **8**, and **13** with **2**−**5**.[20] This graphical tech-

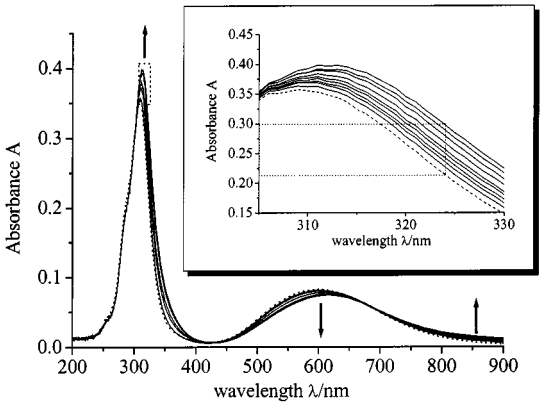


Figure 10. UV/Vis spectra obtained during titration of [Cu(styDIEN)]$(HCOO)_2$ (**13**) with glucose (**2**) at 25 °C in unbuffered, aqueous solution at pH = 12.40; ····· UV/Vis spectrum of **13** (1 mM); —— UV spectra of **13** after addition of **2** (2, 3, 4, 5, 6, 7, 8, 9, and 10 mol equivalents); the total concentration of **13** (M_t = 1 mM) and the total volume of the solution (V_t = 2 mL) were kept constant

nique does not require the assumption that $C = C_t$ made in the Scatchard plot analysis and is only applicable when the total concentration of the copper complex (C_t = 1 mM) and the total volume of the resulting solution (V_t = 2 mL) are kept constant.[28] As representative examples, the UV/Vis spectra obtained during titration of **13** with **2** at 25 °C in unbuffered, aqueous solution at pH 12.4 are depicted in Figure 10.

The binding strengths of the complexes formed from **1** and **6** were determined by nonlinear regression. The obtained apparent binding constants (pK_{11}) from the titration of **1**, **8**, and **13** with **2**−**6** are summarized in Table 1.

Table 1. Apparent binding constants (pK_{11}) for ternary complexes formed from [CuDIEN]$(NO_3)_2$ (**1**), CuHEN (**8**), and [Cu(styDIEN)]$(HCOO)_2$ (**13**) with the carbohydrates **2**−**6** at pH = 12.40

Compd.	pK_{11} [1]	pK_{11} [13]	pK_{11} [8]
2	3.73 ± 0.12	3.37 ± 0.31	3.61 ± 0.17
2a	3.71 ± 0.09	n.d.[a]	n.d.[a]
3	3.70 ± 0.09	3.41 ± 0.43	3.64 ± 0.12
4	3.68 ± 0.12	3.05 ± 0.41	3.38 ± 0.19
5	3.75 ± 0.12	3.41 ± 0.26	3.62 ± 0.09
6	3.48 ± 0.14	n.d.[a]	n.d.[a]
	1.36 ± 0.15	n.d.[a]	n.d.[a]

[a] n.d. = not determined.

The pK values for the complexes formed from **1**, **8**, and **13** with **2**−**5** are of the same order of magnitude. The ternary complexes formed from **2**, **3**, and **5** with **1**, **8**, or **13** show similar apparent binding constants, while those formed with **4** are smaller in each case. We attribute this to a rearrangement of the ligand−copper(II)−mannose complex when complex formation with the *cis*-1,2-diol at C^2 and C^3 occurs despite the preferential chelation through the hydroxyl groups at C^1 and C^2. Unfortunately, no binding interaction with α-methyl-D-mannopyranoside, which could have provided evidence for complex formation with the hydroxyl groups at C^2 and C^3, was observed by UV spectroscopy at alkaline pH values (see above and Supporting Information).

Since a carbohydrate is mostly deprotonated at a pH value larger than its pK (i.e., pK_2^H = 12.28), the binding strength of the coordinative bond to a metal complex increases with pH.[21] Therefore, the determined binding constants of the ternary complexes formed from **1** and **2** (pK_{11} = 3.73 ± 0.12 at pH = 12.40) or **13** and **2** (pK_{11} = 3.37 ± 0.31 at pH = 12.40) are of the same order of magnitude as those reported by Arnold for **7** and **2**, which were determined by isothermal titration calorimetry (pK_{11} = 2.6 ± 0.1 at pH = 11.25).[18]

In agreement with the number of spectroscopic states, two binding interactions are observed between **1** and **6**. The stronger (pK_{11} = 3.38 ± 0.14) is of the same order of magnitude as that observable between **1** and **2** (pK_{11} = 3.73 ± 0.12) and is due to chelation of **1** through the hydroxyl groups at C^1 and C^2 of **6**. The weaker binding interaction (pK_{11} = 1.36 ± 0.15) is caused by coordination of **1** by the carboxylic group of **6**, which is comparable to that observed for coordination of free copper(II) ions to **6** at neutral pH (pK_{11} = 1.44),[29] in which coordination of **6** is reported to be through the carboxylic group only. A detailed investigation of binding interactions between copper(II) complexes and disaccharides and other carbohydrates providing multiple points of interactions during complex formation is currently underway.

The binding strength of the ternary ligand−copper(II)−carbohydrate complex decreases to some extent when the secondary amino group in the DIEN ligand of **1** is alkylated with a styryl group to yield **13**, but it decreases only slightly when the HEN-based functional monomer **8** is used. Accordingly, the replacement of one amino group by a more weakly electron-donating hydroxyl group influences the stability of complexes formed with carbohydrates less than the alkylation of the secondary amino group in the DIEN-based functional monomer **1**. However, the determined binding strength for a ternary complex consisting of **13** and **2**−**5** [e.g., pK_{11} = 3.37 for complex formation of **13** with **2** (Table 1)] seems to be suitable for imprinting carbohydrates into a polymer matrix.

Determination of the Distribution of Species Participating in Complex Formation

Since different coordinating compounds (species) usually exist in equilibrium structures in aqueous solution, it is important, prior to a planned imprinting process, to examine the total amount of copper(II) bound in the formed ternary ligand−copper(II)−carbohydrate complex. We therefore evaluated the species distribution during complexation of **13** with **2**−**5** from their binding constants, with the SPE computer program.[22] The calculations suggested that only up to 80% of **13** (the overall concentration of which is kept at 2 mM) are bound in a 1:1 complex with **2**−**5** at pH = 12.4. This is not favorable for the planned imprinting process, since about 20% of the functional monomer would remain unbound and would therefore not be able to create specific cavities during polymerization, but would generate randomly distributed, nonspecific binding sites inside the polymer instead. Up to 100% complexation of the copper-containing functional monomer can be achieved by using an excess of carbohydrate, which does not interfere with the 1:1 ratio of complex formation as determined and described earlier.

Investigation of Carbohydrate Stability at Alkaline pH Values

It is known that a Lobry de Bruyn−van Ekenstein rearrangement as well as base-catalyzed fragmentation of aldoses and ketoses may occur under alkaline conditions.[30] Treatment of D-glucose with a 0.035% aqueous sodium hydroxide solution at 35 °C for 100 h results in a mixture containing D-fructose (28%), D-mannose (3%), and unchanged D-glucose (57%).[30] This behavior is not favorable either for carbohydrate chelation to copper(II) complexes, or for a planned imprinting process in which the original template has to be maintained during polymerization. Since we use

even more strongly alkaline conditions (pH = 12.40; i.e., about 0.1% aqueous sodium hydroxide) at 25 °C for strong carbohydrate binding to copper(II) complexes, we investigated the stability of **2**−**4** under these conditions by ^{1}H NMR spectroscopy. A set of ^{1}H NMR spectra recorded for **2** after its exposure to base is depicted in Figure 11 and Figure 12 (for others, see Supporting Information).

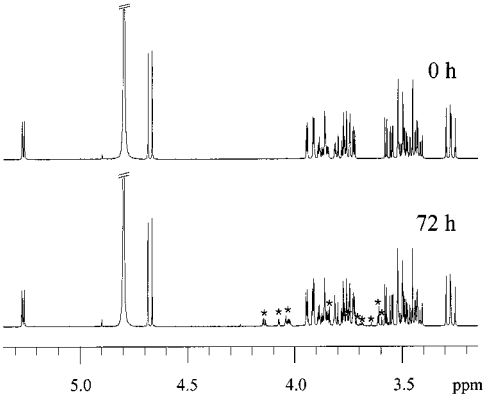

Figure 11. 400.1 MHz ^{1}H NMR spectra (303 K) of glucose (**2**) after exposure to pH = 12.40 at 25 °C for 0 and 72 h

The ^{1}H NMR spectra demonstrate the stability of **2**−**4** at pH = 12.40 for at least 1 h. Additional signals in the recorded ^{1}H NMR spectra occur for the first time only after 3 h. The original carbohydrates **2**, **3**, or **4** are maintained during the UV experiments, which are usually complete in under 20 minutes.

Polymerization methods commonly used during an imprinting process proceed for about 72 h at 60 °C and so, according to our results, are not applicable to the system described here, especially since even faster decomposition of the carbohydrate at the elevated temperature would be expected. A fast polymerization technique has been developed to prevent the carbohydrates from epimerization, isomerization, or fragmentation during the imprinting process under our conditions. The investigation of the obtained molecularly imprinted polymers is reported elsewhere.[23]

Conclusion

Careful characterization of the binding interactions between functional monomers (such as copper complexes) and targeted templates (such as carbohydrates) prior to polymerization is one of the key steps in the molecular imprinting technique. We therefore report here for the first time on the naturally accessible binding sites in several sugars — namely glucose (**2**), galactose (**3**), mannose (**4**), and maltose (**5**) — upon chelation to copper(II) complexes at alkaline pH values. Under these conditions, only the hydroxyl groups at C^1 and C^2 of the carbohydrates **2**−**5** are involved in formation of ternary ligand−copper(II)−carbohydrate complexes, which were characterized in terms of stoichiometry and binding strength at alkaline pH.

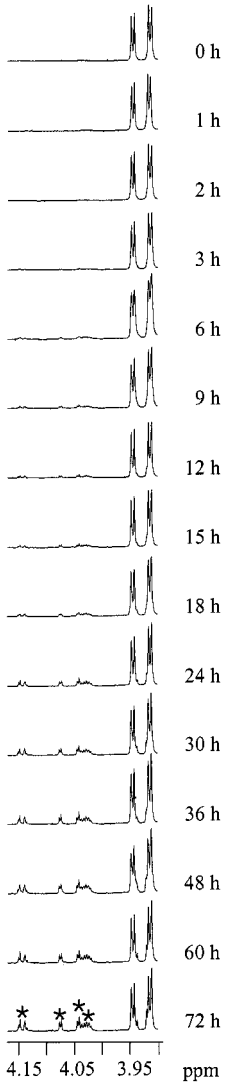

Figure 12. 400.1 MHz ^{1}H NMR signals (303 K) of protons 6a-H and 6b-H of **2** at 303 K after exposure of **2** to pH = 12.4 at 25 °C for 0, 1, 2, 3, 6, 9, 12, 15, 18, 24, 30, 36, 48, 60, and 72 h; the asterisks indicate the formation of new signals

Experimental Section

General Remarks: Methyl β-D-galactopyranoside, β-D-(+)-glucose (**2**), and maltose (**5**) were obtained from Sigma; sodium hydroxide, D-mannose (**4**), methyl α-D-galactopyranoside, methyl α-D-mannopyranoside, methyl β-D-glucopyranoside, and methyl α-D-glucopyranoside were obtained from Fluka; diethylenetriamine, 2-(2-aminoethylamino)ethanol, 3-*O*-methyl-D-glucose (**2a**), and 2-desoxy-D-glucose were obtained from Aldrich; nanopure water, cupric chloride dihydrate, cupric nitrate trihydrate, and D-(+)-galactose (**3**) were obtained from Merck Eurolab. Diethylenetriamine and 2-(2-aminoethylamino)ethanol were distilled prior to use. The nanopure water was sonicated and purged with argon prior to use. All other commercially available reagents were used as received from the supplier.

(Diethylenetriamine)copper(II) dinitrate (**1**),[31] [(1,4,7-triazacyclononane)copper(II)] dichloride (**7**),[32] [{4-(*N*-vinylbenzyl)-diethylenetriamine}copper(II)] diformate (**13**),[23] and [{*N*-(2-

hydroxyethyl)ethylenediamine}copper(II)] dichloride (**8**)[33] were prepared as described.

UV Experiments: All experiments described here were performed on a J & M TIDAS UV spectrophotometer (software SPECTRALYS Version 1.55) with Suprasil® standard cells (200−2000 nm) of 10 mm thickness and 700 μL volume at 25 °C. All experiments were done in unbuffered, degassed, nanopure water, the pH of which was freshly adjusted to pH 12.40 with NaOH for each set of titrations. Typically, 10 mM stock solutions of the appropriate copper complex and 25 mM stock solutions of the carbohydrates were prepared separately and kept at 25 °C. The total concentration of the absorbing copper complex (M_t = 1 mM in the case of **13**; M_t = 2 mM in the case of **1**, **7**, **8**) and the total volume of the resulting solutions (V_t = 2 mL) were kept constant during the titration experiments by addition of an appropriate amount of water. The UV/Vis absorbances of the resulting mixtures were measured immediately, over a range of 200−900 nm. The pH of the resulting solutions did not differ from the solutions prepared initially.

NMR Experiments: All NMR experiments were performed on a Bruker DRX 400 (^{1}H: 400.1 MHz; ^{13}C: 100.6 MHz), D_2O was used as solvent, and residual HDO was used as internal standard [δ = 4.80]. Chemical shifts (δ values) downfield from tetramethylsilane refer to the residual nondeuterated solvent signal.

Typically, **2**−**4** (1 g) was dissolved in H_2O (25 mL) at pH 12.4. The resulting solution was kept for 72 h at 25 °C. After 0, 1, 2, 3, 6, 9, 12, 15, 18, 24, 30, 36, 48, 60, and 72 h, 1 mL of the solution was removed and neutralized with HCl_{aq} (1 N, 30 μL), and the solvents were evaporated to dryness. The residue was taken up in 0.7 mL D_2O and the ^{1}H NMR spectra were recorded at 303 K.

Supporting Information (see footnote, page one) includes Job plots for the demonstration of association of the copper(II) complexes **1**, **13**, and **8** with the carbohydrates **2**−**5** at pH 12.4, 25 °C, and sets of time-dependent ^{1}H NMR spectra (400.1 MHz, D_2O, 303 K) of **3** and **4**.

Acknowledgments

A fellowship from the Margarete von Wrangell habilitation program from the state of Baden-Württemberg (S. S.) and financial support from the University of Ulm are gratefully acknowledged. The authors also thank Prof. Dr. G. Wulff, Düsseldorf, Germany and Prof. Dr. P. Klüfers, Munich, Germany for helpful discussions during the preparation of this manuscript.

COVER PICTURE

The cover picture shows an electrospray mass spectrum obtained with a time of flight instrument of a mixture of Cu^{II} coordination polymers in solution. For these artificial nanostructures, electrospray mass spectrometry (ESMS) is the only analytical tool allowing an unambiguous characterisation. The largest polymer clearly identified consists of 47 units and has a molecular weight of 32901.4 D. Details are discussed in the article by E. Leize et al. on p. 573 ff.

The Coordination of Cu^{II} in Zeolites − Structure and Spectroscopic Properties

Annelies Delabie,[a] Kristine Pierloot,*[a] Marijke H. Groothaert,[b] Robert A. Schoonheydt,[b] and Luc G. Vanquickenborne[a]

Keywords: Zeolites / Copper / Ab initio calculations / Density functional calculations / ESR spectroscopy / UV/Vis spectroscopy / Heterogeneous catalysis

Zeolites loaded with transition metal ions are promising heterogeneous catalysts. Knowledge about the location and structure of the metal centers is of paramount importance for the understanding of the catalytic potential of these materials. In this work, the spectroscopic studies of the coordination of Cu^{II} in zeolite A, ZK4, X, Y and mordenite are reviewed. Experimentally, diffuse reflectance spectroscopy (DRS) and electron spin resonance (ESR) spectroscopy have been applied to study the coordination of Cu^{II} in zeolites. Ab initio calculations on model clusters, representing the Cu^{II} sites in zeolites, are used for the interpretation of the experimental data. The combination of experimental spectroscopic information with theoretical results leads to a new and profound insight into the Cu^{II}–zeolite interaction.

1. Introduction

Zeolites are inorganic crystalline materials characterized by a regular structure of channels and cages of molecular dimensions. Their structure is built from tetrahedral units (TO_4), consisting of a central atom (T) − mostly Si^{IV} − coordinated to four oxygen atoms. Other atoms, especially

Annelies Delabie (left top) completed her PhD study with the thesis "Computational study of transition metal ions in zeolites: structure, spectroscopy and reactivity" at the division of Quantum Chemistry, University of Leuven, Belgium, in May 2001 under the supervision of Professor Kristine Pierloot. Presently, she is a postdoctoral research fellow of the Flemish Fund of Scientific Research at the University of Leuven. She is the author of 12 scientific papers.

Kristine Pierloot (right top) is a Professor at the Department of Chemistry, University of Leuven. She received her PhD in Leuven in 1985 under the supervision of Professor Luc Vanquickenborne. She teaches general chemistry and computational chemistry. Her main research interest is the application of ab initio methods for the study of spectroscopic and magnetic properties of systems containing transition metals.

Marijke H. Groothaert (left center) was born in Neerpelt, Belgium in 1975. In 1998 she received her M. S. degree from the Faculty of Agricultural and Applied Biological Sciences, Catholic University of Leuven, Belgium. Since 1998 she is a PhD student at the Center for Surface Chemistry and Catalysis under the supervision of Professor Robert A. Schoonheydt. Her research is concentrated on the coordination of transition metal ions in zeolites and combines spectroscopic techniques with computational methods.

Robert A. Schoonheydt (left bottom) received his M. S. degree in 1966 and his PhD in 1970, both under the supervision of Professor Jan B. Uytterhoeven at the Catholic University of Leuven, Belgium. After one year as a postdoc with Professor Jack H. Lunsford in the Chemistry Department of Texas A&M University, USA, he returned to the Catholic University of Leuven as a National Fund of Scientific Research researcher. He became full professor in 1989. His teaching responsibilities include physical chemistry, analytical chemistry, and general thermodynamics for engineering students at the Faculty of Agricultural and Applied Biological Sciences. His research is concentrated in three areas: (1) spectroscopy and chemistry of surface transition metal ions, (2) molecular organization on clay surfaces, (3) theoretical modeling of molecule-surface interactions. He has authored more than 170 scientific papers, and is the editor of the book "Developments in the theory of chemical reactivity and heterogeneous catalysis". Presently, he is secretary-general of AIPEA and dean of the Faculty of Agricultural and Applied Biological Sciences. He also serves on the editorial board of Microporous and Mesoporous Materials, Applied Clay Science and European Journal of Inorganic Chemistry.

Luc G. Vanquickenborne (right bottom) is a Professor of theoretical chemistry at the Department of Chemistry, University of Leuven. He received his PhD and Dr. Hab. in Leuven, where he teaches quantum chemistry, computational chemistry, and inorganic chemistry. His main research interests are in the application of computational methods in different areas of chemistry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Al^{III}, but also P^{V}, Ga^{III} and even transition metal ions can replace the central Si^{IV}. The tetrahedral units are linked by sharing all the oxygen atoms, leading to a wide variety of materials, differing in framework structure and chemical composition.[1] In the case of microporous solids (with aperture diameters from ca. 3 to 14 Å) the largest two subclasses are the aluminosilicates and aluminophosphates (the latter also known as ALPOs). This review will only deal with aluminosilicate zeolites. Other recent reviews focus on transition metal ions in aluminophosphate molecular sieves.[2,3]

As each Al^{III} incorporated in the silicate framework leads to one excess negative charge, an equivalent amount of extra-framework cations must be introduced to neutralize the structure. These cations, mostly Na^{I}, K^{I} and Ca^{II}, are present inside the cages and channels of the zeolite together with intrazeolitic water. They are not covalently bound to the zeolite framework and can therefore easily be replaced by transition metal ions by conventional aqueous ion exchange. After dehydration, these transition metal ions become localized. They are dispersed over the large internal surface of the zeolite, coordinating to the framework oxygen atoms. The obtained metal coordination environment is often not saturated, which means that these ions can act as coordination centers for adsorbed molecules or as catalytically active sites. The microporous character of the zeolite material puts limits on the size and shape of the interacting molecules, and hence enables shape selective reactions. Alternatively, transition metal ions can also be encountered at framework positions (the T atoms) in zeolites. In this case, the transition metal ions are already incorporated during the synthesis of the zeolite by so-called isomorphous substitution.

This review deals with studies of Cu^{II} in the zeolite channels, acting as a charge-compensating ion. These Cu−zeolites have been studied extensively because they display high activities for the catalytic and photocatalytic decomposition of NO and N_2O forming N_2 and O_2.[4−15] Also the selective reduction of NO by NH_3 or hydrocarbons is catalyzed by Cu−zeolites.[16−19]

A prerequisite for a fundamental understanding of the catalytic potential of Cu−zeolites is the knowledge of the location (and accessibility), coordination and electronic structure of the Cu ions. However, the location and coordination of transition metal ions inside zeolites are still a matter of debate. For aluminum-rich zeolites, one usually assigns the cations to well-defined rings or cages in the zeolite structure. The preference of the cation for occupation of these specific extra-framework sites can be thought of as arising from favorable interactions between the cation and the framework structure. The study of the distribution of the transition metal ions throughout the zeolite is usually referred to as cation siting.[20−21] On the other hand, it has also been suggested that the location of cations, especially divalent cations, is determined by the distribution of aluminum in the zeolite lattice.[22−25] Indeed, it can be expected, on the basis of simple electrostatic considerations, that divalent cations are preferentially located in the proximity of two framework aluminum atoms. The importance of charge compensation by aluminum must be emphasized in particular in the case of Si-rich zeolites. Unfortunately, the exact positions of aluminum ions in the zeolite lattice are unknown, and there is no general agreement on whether the distribution of aluminium is random or ordered.

We intend to give an overview of the studies on the siting and coordination of Cu^{II} in zeolites by means of spectroscopic and theoretical methods. Especially diffuse reflectance spectroscopy (DRS) and electron spin resonance (ESR) spectroscopy have been applied extensively in the study of the coordination of Cu^{II} in zeolites. We will focus on Cu^{II} in zeolite A, ZK4, X, Y and mordenite because of their well-documented literature. The spectroscopic fingerprints of the Cu^{II} species in these zeolites are now firmly established, as shown in a previous review[20] in 1993. However, there is still a good deal of disagreement on the interpretation of the spectroscopic data. At the time of the 1993 review, the spectroscopic fingerprints were mainly interpreted from XRD results or by means of semi-empirical calculations. Recently, however, it has become possible to study the coordination and spectroscopic features of Cu^{II} in zeolites by means of ab initio calculations.[26−32] Large model clusters were constructed, representing the possible Cu^{II} sites in the different zeolites. The structure of the Cu^{II} coordination environment was obtained from geometry optimizations based on density functional theory (DFT). Multiconfigurational perturbation theory (CASPT2) was used for the calculation of the spectroscopic features of these clusters. As will be shown in the present review, the combination of these ab initio results with the available experimental spectroscopic information is a powerful research tool, and leads to new and detailed information on the interaction of Cu^{II} with zeolites. We therefore present a summary of the new ab initio results and compare them with the older methods and interpretations.

We note that the present review will be limited to "model materials", i.e. with high Al contents (Si/Al ratio between 1 and 5) and with low Cu^{II} contents. Isolated and bare Cu^{II} sites are then present in the fully dehydrated state. Spectroscopic techniques clearly point to a limited number of well-defined Cu^{II} coordination modes in these zeolites, and the fingerprints can often be individually resolved, thereby facilitating the comparison with the ab initio results. On the other hand, several zeolites studied for catalytic processes contain Cu^{II} in larger than stoichiometric amounts. These so-called "overexchanged" zeolites do not only contain isolated Cu^{II} ions, but also Cu dimers or oxides. We have also incorporated some ab initio results for zeolite Y where the adsorption of one molecule (H_2O or NH_3) on the Cu^{II} site is studied.

The text is organized as follows: First, we recall the framework structures of zeolite A, faujasite and mordenite, together with a description of their most important cation sites. Next, we describe some of the major advantages and drawbacks of the spectroscopic techniques frequently used for the study of Cu^{II} in zeolites, mainly X-ray diffraction (XRD), diffuse reflectance spectroscopy and electron spin

resonance spectroscopy. We also discuss why theoretical calculations can be useful for the interpretation of the spectroscopic information. Finally, we present a critical overview of both experimental and theoretical spectroscopic studies of Cu^{II}−zeolites.

2. Overview of Zeolite Structures and Cation Sites

2.1 Zeolite A, ZK4, X and Y

The structure of zeolites with LTA (e.g. zeolite A, ZK4) or FAU topology (e.g. zeolite X, Y) can be visualized as a regular stacking of sodalite cages. The sodalite unit comprises 24 T atoms that make up a truncated octahedron, and 36 bridging oxygen atoms. Usually, the structure of a zeolite framework is represented in a schematic way. As shown in Figure 1, the vertices give the position of the T atoms, while the lines connecting the vertices represent the oxygen atoms.

One can see in Figure 1A that in zeolite A, the sodalite cages are connected through the oxygen four-membered rings. They enclose a larger volume, the supercage, with eight-membered ring apertures. The contours of this supercage are indicated in Figure 1A by dashed lines. The Si/Al ratio of zeolite A is 1, implying a strict alternation of Si and Al tetrahedra according to the Loewenstein rule.[33] ZK4 has the same topology as zeolite A, but a higher Si/Al ratio.

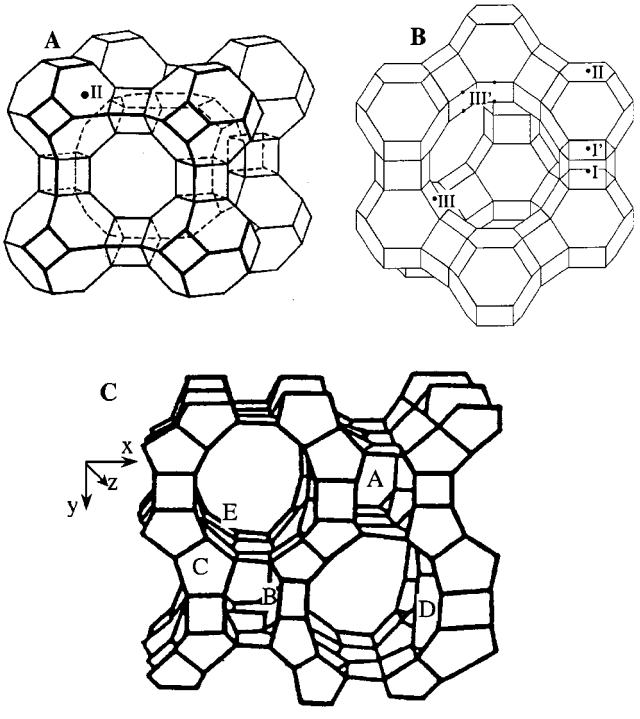

Figure 1. Schematic framework structure of zeolite A, ZK4 (A), zeolite X, Y (B) and mordenite (C); only the T atoms are shown on the vertices of the structure, the oxygen atoms are arranged in between; the location of the exchangeable cation sites is also indicated; the contours of the supercage in zeolite A are shown by dashed lines

For zeolite A and ZK4, only one site for Cu^{II} has been proposed: It is indicated as site II in Figure 1, at the oxygen six-membered ring between sodalite and supercage. The atomic structure of this six-membered ring is shown in Figure 2. This cation site has C_{3v} symmetry. One can see that there are six oxygen atoms available for coordination with the Cu^{II} ion. Three of them (indicated with O_A) are bent slightly inwards, and are therefore favorably located for coordination with a cation in the ring. The other three oxygen atoms (O_B) are bent outwards and therefore seem less accessible.

On the other hand, the sodalite cages can also be linked via the six-membered rings to form hexagonal prisms, as for the faujasite (FAU) topology (see Figure 1B). The interior supercage can be entered via twelve-membered rings, and is therefore much larger than the supercage of zeolite A. Zeolite X and Y are both members of the faujasite topology;

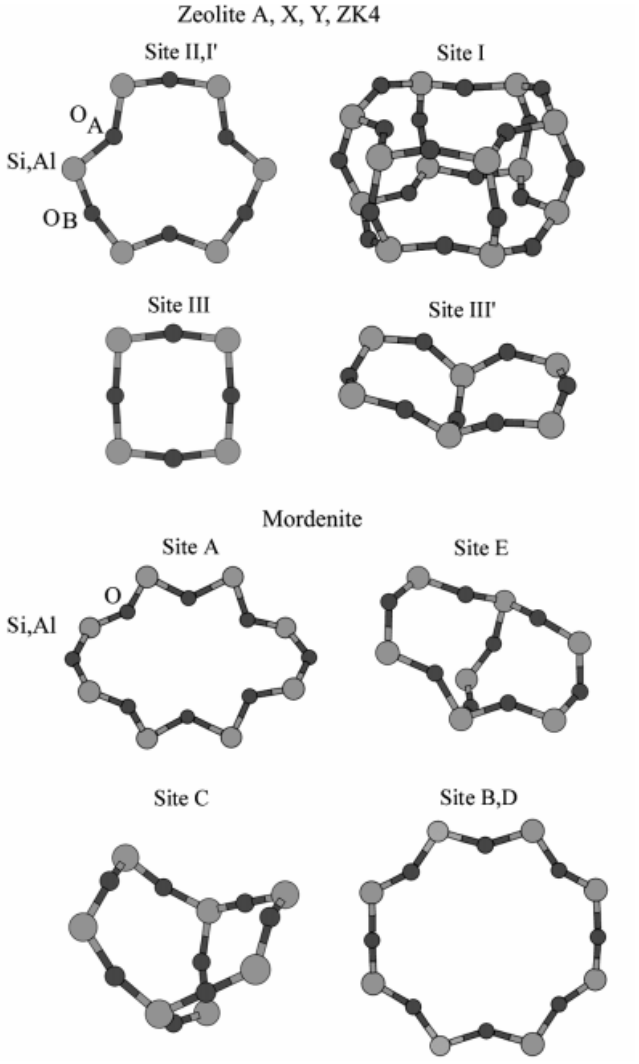

Figure 2. The common cation exchange sites of zeolite A and ZK4 (site II), X and Y (sites II, I′, I, III, III′) and mordenite (site A, E, C, B and D); the two types of oxygen atoms in sites II and I′ are labeled as O_A and O_B

they differ only by the aluminum content. Zeolite X has an Si/Al ratio between 1 and 1.25; faujasites with an Si/Al ratio higher than about 2 are generally referred to as zeolite Y.

As shown in Figures 1 and 2, many possible cation sites are present in the faujasite structure. Due to the tetragonal stacking of the sodalite cages, one can distinguish two distinct types of six-membered ring sites in faujasite. In Figure 2, these two types of six-membered rings are represented in the same picture, as they differ only by the zeolite surroundings extending beyond the atoms on display. One can, however, clearly see in Figure 1 that site II is the hexagonal window between the sodalite cage and the supercage, and it is therefore similar to site II in zeolite A. On the other hand, site I′ is one of the base planes of the hexagonal prism. A completely different cation site is the center of the hexagonal prism (site I), where the cations may obtain a sixfold coordination by binding with the three O_A oxygen atoms of the two six-membered ring base planes. Finally, cations may coordinate to oxygen atoms of the four-membered ring structures III and III′, located at the walls of the supercage.

2.2 Mordenite

Mordenite (MOR) is one of the pentasil zeolites. In these zeolites, five-membered ring building units (the pentasil units) are linked to form parallel columns. In the complex framework of mordenite (see Figure 1C), these columns are arranged along the *z* direction, so that they enclose a large, straight twelve-membered ring channel along the *z* direction, often referred to as the main channel, and eight-membered ring side-pockets. There is also an eight-membered ring zigzag channel, but as it runs in a direction perpendicular to the main channel, this channel is not visible in Figure 1C. The Si/Al ratio in the pentasil zeolites is usually considerably higher than in zeolite A and faujasite. The typical Si/Al ratio of mordenite is 5, but structures with higher Si/Al ratios can be synthesized.

The location of the cation sites in the mordenite structure is also indicated in Figure 1C, while the detailed structures of the sites can be seen in Figure 2. A first cation site in mordenite is site A, a twisted eight-membered ring located in the eight-membered ring side-pockets. The symmetry of this site is C_{2h}. The six most central oxygen atoms can coordinate with cations in this site. The E site is the planar six-membered ring in the twelve-membered ring channel. This six-membered ring is significantly different from the trigonal six-membered ring sites encountered in zeolite A and Y because it is formed by connecting two (bent) five-membered rings (see Figure 2). As a consequence, even an ideal E site in mordenite shows only C_s symmetry, whereas the highest possible symmetry of the six-membered ring sites in zeolite A and Y is C_{3v}. Cations in site E usually coordinate to the four central oxygen atoms of the six-membered ring. Other cation sites in mordenite are site D, the circular eight-membered rings situated at the walls of the large twelve-membered ring channel, and site B, a similar eight-membered ring in the side-pockets. There is also a boat-shaped site in the eight-membered ring channel of the zeolite; the latter site is composed of a non-planar six-membered ring (site C) in between two five-membered rings. As one can see from Figure 2, this six-membered ring also contains, like site E, an O−T−O bridge. The corresponding planar five-membered ring leads to the main channel of mordenite. It is not known which cation coordination environments can be achieved in site C. One can see from Figure 2 that site E and site C have the same topology, but a different shape.

3. Experimental and Theoretical Tools

3.1 Electron Spin Resonance

The first studies of the coordination of Cu^{II} in zeolites, starting from the year 1959, were based on ESR.[34,35] The ESR spectrum is very sensitive to the surroundings of the Cu^{II} ion, as manifested by the *g* tensor and the hyperfine splitting. The number of ESR signals present in the spectrum therefore indicates the number of different coordination environments of Cu^{II}. The initial goal of the ESR studies of Cu^{II}−zeolites was to draw conclusions concerning the coordination environment of Cu^{II} in unknown zeolite surroundings by comparing ESR spectroscopy data with that of Cu^{II} in crystals of known structure. However, since the ESR spectra turn out to be very sensitive to the degree of hydration, the temperature of the heat treatment during dehydration and the nature of other cations in the zeolite, the early reported ESR spectral parameters varied strongly from one report to another.[34−42] Over the years, a consensus emerged in the literature on the ESR parameters of the fully dehydrated Cu^{II}−zeolites, which are by now firmly established.[20] On the other hand, the interpretation of this spectroscopic information is not straightforward. One has attempted to obtain more information about the accessibility of the Cu^{II} species by studying the dependence of the ESR signal on the adsorption of small molecules on the Cu^{II} sites and on the degree of dehydration of the Cu^{II}−zeolite.

Additionally, the pulsed electron spin resonance technique called electron spin-echo (ESE) spectroscopy can measure the superhyperfine interaction between the Cu^{II} ion and nearby magnetic nuclei (for example ^{27}Al).[43] These very weak hyperfine interactions cannot be observed in a conventional ESR spectroscopy experiment, but they show up as a modulation of the decay of the time domain ESE spectrum. By proper analysis of this modulation one can determine the types, number and distances of magnetic nuclei surrounding the Cu^{II} ion.

In order to avoid magnetic dipole interactions between different Cu^{II} centers, the ESR spectra are recorded at low Cu^{II} exchange levels.[44]

3.2 Diffuse Reflectance Spectroscopy

Diffuse reflectance spectroscopy (DRS) allows the measurement of the electronic transitions in the UV/Vis/NIR region from a powdered zeolite sample. As the excitation en-

ergies of the transitions within the 3d shell depend on the ligand field surrounding of the transition metal ion, these spectra provide a "fingerprint" of the local Cu^{II} coordination environment in the considered zeolite. In many cases, however, not one but several different coordination environments are present inside the zeolite. Hence overlapping spectra are obtained, and the spectrum must be deconvoluted into its individual components.[45−48] DRS spectra are therefore often measured at low exchange levels, as it is assumed that under low load conditions only the preferential coordination sites are occupied.

ESR and DRS both have the advantage that, although their spectra may represent a superposition of several Cu^{II} coordinations, the local atomic environments of Cu^{II} can often be extracted from progressive loading and preferential site occupations.

3.3 X-ray Diffraction

X-ray diffraction (XRD) is the most direct method of obtaining the location of the exchangeable cations in the zeolite unit cell. However, a major limitation of XRD in the study of transition metal exchanged zeolites is that no distinction can be made between Si and Al in the lattice. The apparent symmetry of the coordination environment of cations obtained with XRD is therefore often too high. This means that the local effect of Al on the coordination environment of the cation cannot be investigated with XRD. Another disadvantage is that in the case of partial site occupancy XRD visualizes only an average structure for the given crystallographic site, whether it is occupied or empty. Hence, XRD as such provides only average information, pertaining to the overall structural integrity, as opposed to ESR and DRS, which reveal the local atomic environment of the transition metal ion.

Apart from these disadvantages, there are also limits in the preparation of suitable samples. With high-alumina zeolites (such as zeolite A, X and Y), it is usually possible to obtain concentrations of divalent cations in the zeolite matrix which are sufficiently high to allow determination of their location in the zeolite unit cell. However, with siliceous zeolites, levels of exchange are low. Since the unit cell of such zeolites is often large and has low symmetry, the limited number of available metal ions is distributed among several crystallographically different positions.

Ever since the first XRD study of Cu^{II} zeolite Y, the XRD structures of Cu^{II}−zeolites have been used to interpret the ESR signals and DRS spectra.[49] One should, however, be careful with such a comparison, not only because XRD reports only average Cu^{II} coordination environments, but also because the XRD results are reported for highly loaded Cu^{II} samples (close to complete exchange), while in ESR and DRS often zeolites with low Cu^{II} contents are studied.

3.4 Theoretical Calculations

Even the combination of complementary experimental techniques cannot always provide a conclusive picture of the siting of Cu^{II} ions in zeolites. As one will see from the literature overview in sections 4 and 5, different authors have proposed different sites for Cu^{II} in zeolites. In order to obtain a sound interpretation of the spectroscopic data, at the end of the 1970s Klier started to perform theoretical calculations.[50−52] He carried out semi-empirical calculations on a simple CuO_3 model to study the electronic structure of Cu^{II} in the trigonal six-membered ring site of zeolite Y, and proposed the first assignment of the ligand field bands measured by DRS. The group of Schoonheydt soon followed this example and studied the spectroscopic properties of Cu^{II} at several exchange sites (in zeolite Y, mordenite), with calculations based on the angular overlap model (AOM).[20,53−55] These theoretical results were used to provide an interpretation for the available ESR and DRS data. One disadvantage was that the only structural information available was obtained from XRD. These calculations were therefore performed at the average XRD structures.

Thanks to the rapid development of computer power, today it has become possible to perform ab initio calculations on model clusters large enough to represent the cation exchange sites in zeolites. Pierloot et al. have studied the coordination of Cu^{II} in various zeolites (zeolite A, Y, ZK4 and mordenite) with a cluster model approach.[26−32] The considered clusters include the Cu^{II} ion surrounded by a zeolite ring (or a combination of rings), terminated by either OH groups or hydrogen atoms. The structures of the cluster models were obtained from partial geometry optimizations, based on density functional theory (DFT). The spectroscopic features (ligand field excitation energies and ESR g factors) were calculated by means of the CASPT2 method, i.e. multiconfigurational perturbation theory. The calculated results were compared with the experimental DRS and ESR spectra. This comparison allowed detailed information about the Cu^{II} coordination in zeolites to be obtained. The present approach was also applied to study the coordination of Co^{II} in the six-membered ring sites in zeolites.[26,56] The main features of the electronic spectrum of Co^{II} in zeolite A and Y are successfully described.

We note that very recently Larsen et al. used DFT to calculate both ESR g values and A values of several vanadyl model complexes, in which H_2O molecules were used to represent the framework oxygen atoms.[57] Theory and experimental results were also combined here, but this time to interpret the ESR spectra of VO^{2+}-exchanged zeolites.

Another theoretical approach has been followed by Sauer and co-workers.[58−60] A combined quantum mechanics/interatomic potential function technique was developed, in which the cation exchange site is treated by quantum mechanical methods, while the periodic lattice is treated by an ion pair shell model potential. Using this method, the location, structure and coordination of isolated Cu^{I} ions in ZSM-5 were studied.[61,62] Photoluminescence energies of Cu^{I} sites were also calculated, and could help in assigning the observed bands of the Cu^{I} luminescence spectra.

We have also noted that during the last years, many other ab initio studies have concentrated on the catalytic potential of Cu-containing zeolites.[59,61−77] Various kinds of cluster

models have been constructed in order to represent the Cu^{II} coordination in the zeolite. There is, however, still no agreement about the active site and reaction mechanism of − for instance − the decomposition reactions of NO and N_2O.

3.5 Additional Observations

Although the previous techniques are most often used in order to probe the coordination environment of Cu^{II} in zeolites, other experimental techniques provide complementary information. Infrared spectroscopy of adsorption complexes in Cu−zeolites (mostly of NO and CO) is often used as a selective probe for Cu ions because there is a shift in the vibration frequencies depending on the copper oxidation state and its coordination environment. The technique can therefore be used to discriminate between different Cu sites.[23,78] Secondly, IR measurements have shown that cations induce local perturbations of the T−O−T bonds adjacent to the cation, reflected in a shift of the skeletal T−O−T vibrations.[79,80]

Determination of the Cu oxidation state, coordination number and Cu−O bond lengths can be achieved by X-ray absorption fine structure (XAFS) techniques.[81,82] However, for isolated Cu^{II} sites the EXAFS (extended X-ray absorption fine structure) spectrum only yields average Cu−O bond lengths and coordination numbers. Hence, this technique is not well suited to offer detailed information on the different Cu^{II} sites and is more often used to distinguish between isolated versus clustered Cu ions in over-exchanged zeolites.

The photoluminescence spectra of Cu^{I} ions are highly sensitive to their coordination environment. The $Cu^{I}(3d^{9}4s^{1})-Cu^{I}(3d^{10})$ transition energies have been measured by several groups for several zeolites. The group of Wichterlová started from the assumption that the Cu ions do not migrate upon reduction of Cu^{II} to Cu^{I}. Therefore they use the various bands in the luminescence spectra of Cu^{I} zeolites to distinguish between different types of Cu^{II}.[23−25]

Few NMR spectroscopic studies have been reported for studying the coordination of cations inside zeolites. They are based on ^{65}Cu NMR[83] or ^{129}Xe NMR spectra of Xenon adsorbed in various Cu−zeolite samples. Due to the large polarizability of the latter ion, its chemical shift is very sensitive to its environment.[84−86]

4. Cu^{II} in Zeolites A, ZK4, X and Y

Below, we present a literature overview of the spectroscopic and theoretical studies of Cu^{II} zeolites. Because of their related framework structures, zeolite A, ZK4, X and Y are treated together. The XRD results of Cu^{II}−zeolites will be discussed before the results of the spectroscopic studies (ESR and DRS), since they may give a first indication of the possible Cu^{II} sites in the zeolites. Next, the results of the ab initio calculations are summarized and compared with the earlier interpretations.

4.1 Diffraction Studies

The structure of fully exchanged Cu^{II} zeolite A was determined by single-crystal XRD in the cubic space group *Pm3m*.[87] All Cu^{II} ions are located in site II, on the threefold axes in the hexagonal six-membered rings. The coordination environment of Cu^{II} in this site is shown in Figure 3. The Cu^{II} ion is coordinated to three close-by oxygen atoms (O_A), at a distance of 2.14 Å. A second shell of three oxygen atoms is found at a distance of 2.85 Å from Cu^{II}. The Cu^{II} ion extends slightly into the large cavity, giving rise to an O_A-Cu-O_A angle of 119°.

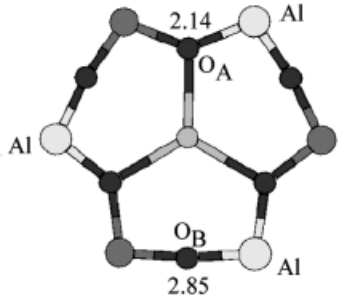

Figure 3. Trigonal coordination environment of Cu^{II} in the six-membered ring site II of zeolite A, as obtained from XRD;[87] Cu−O distances are given in Å; the labeling of the two types of oxygen atoms (O_A and O_B) is also indicated

On the other hand, XRD reveals several exchange sites for Cu^{II} in zeolite Y. Two XRD studies on $Cu^{II}-Y$ have indicated that the six-membered rings are the favored, although not the only possible cation sites for Cu^{II}. First, an X-ray powder diffraction study of a 50% exchanged $Cu^{II}-Y$,[49] reported that Cu^{II} ions are, for the most part, present in six-membered ring site I′. The large affinity of Cu^{II} for site I′ was ascribed to the opportunity to be firmly bound to three O_A atoms of the zeolite framework. The remaining Cu^{II} ions were located at the center of the hexagonal prism (site I) in an octahedral coordination environment.

Secondly, a single-crystal XRD experiment on a 90% exchanged $Cu^{II}-Y$ by Maxwell and de Boer[88] pointed to the presence of Cu^{II} ions in both six-membered rings I′ and II. The coordination environment is trigonal; the Cu−O distances are compared with the other XRD structures in Table 1. Only a very small fraction of the Cu^{II} ions were found in the hexagonal prism I, in a sixfold coordination environment. Finally, Cu^{II} ions were also found in the four-membered ring sites III and III′.

Table 1. Cu−O distances (given in Å) in the trigonal six-membered ring sites, obtained from X-ray diffraction studies on $Cu^{II}-A$ and $Cu^{II}-Y$

Zeolite	Site	$Cu-O_A$	$Cu-O_B$
$Cu^{II}-A$[87]	II	2.14	2.85
$Cu^{II}-Y$[49]	I′	2.00	2.91
$Cu^{II}-Y$[88]	II	2.22	2.92
	I′	2.12	2.95

Recently, a pulsed-neutron diffraction study of solid-state copper(II)-exchanged zeolite Y (with a Cu-exchange level of 87%) was also reported.[89] This study indicated that Cu^{II} occupies three sites. About half of the Cu^{II} ions were found in site III′, each coordinated in a near square-planar manner to four framework oxygen atoms. However, an undetected fifth ligand (H_2O, OH^- or Cl^-) may be present, coordinating axially to Cu^{II} so as to give a distorted square pyramid. 31% of Cu^{II} are placed at site I′ in a trigonal coordination with Cu−O distances of 2.17 Å. The remaining Cu^{II} ions are present in site I.

4.2 ESR Spectroscopic Results

Zeolite A and ZK4

In the first ESR studies of Cu^{II} in zeolite A no agreement was reached on the number of Cu^{II} species or the characteristic ESR parameters of these species.[90−92] Most of the later studies agree that only one axially symmetric signal is present in the ESR spectrum of fully dehydrated Cu^{II} zeolite A, described by $g_{//}$ = 2.37−2.41 (see Table 2).[20,28,53−55,93,94] The presence of one ESR signal is in good agreement with the XRD study, pointing to Cu^{II} at only one site, the trigonal six-membered ring II.[87] Kevan et al.[93−96] monitored the coordination of Cu^{II} in zeolite A during the process of dehydration by electron spin echo spectrometry. After complete dehydration, they described the Cu^{II} coordination as close to the plane of the six-membered ring site II, in a position displaced 0.2 Å into the supercage, where it is trigonally coordinated to three of the six lattice oxygen atoms. This coordination environment is very similar to that obtained by XRD (see Figure 3).

The coordination of Cu^{II} in ZK4 has also been studied. Two Cu^{II} species were detected by ESR spectroscopy, characterized by $g_{//}$ = 2.357 and 2.321.[97] The former signal was assigned to Cu^{II} in the six-membered ring site II, moved inside the sodalite cage, while the latter signal was attributed to Cu^{II} ions at the same site, but extended into the supercage. The presence of these two ESR signals in Cu^{II}−ZK4 was recently confirmed.[28] However, a totally different interpretation based on ab initio calculations was given, as will be detailed in section 4.4.

Table 2. An overview of the ESR parameters found in literature of Cu^{II} in various zeolites; for references, see text

Zeolite	$g_{//}$	$g_{\perp}$
Cu^{II}−zeolite A	2.37−2.41	2.06−2.07
Cu^{II}−ZK4	2.36	2.07
	2.32	2.07
Cu^{II}−zeolite Y	2.36−2.41	2.07−2.08
	2.30−2.34	2.05−2.07
Cu^{II}−zeolite X	2.37−2.38	2.06
	2.35	2.06
Cu^{II}−mordenite	2.32−2.34	2.05−2.06
	2.27−2.29	2.05−2.06

Zeolite Y and X

Most authors report at least two overlapping axial signals in Cu^{II}−zeolite Y.[20,28,36−42,53−55,86,92−94,98−103] Generally, there is agreement about the parameters describing these ESR spectra (see Table 2). One of the signals conforms to the one observed in zeolite A with $g_{//}^{(1)}$ = 2.36−2.41. The second signal is characterized by a much smaller $g_{//}$ value, $g_{//}^{(2)}$ = 2.30−2.34. It was suggested that these ESR signals are, within experimental accuracy, independent of the Si/Al ratio, the Si−Al ordering and the type of co-exchanged cation.[20,53] As such, they only reflect the type of coordination of Cu^{II} in the structure. However, the relative intensities of the two ESR signals vary with the Si/Al ratio, the type of co-cation and the Cu^{II} loading, and are indicative of the site preference of Cu^{II}.[20,53]

Interpretations of the two ESR signals of Cu^{II} in zeolite Y in terms of specific coordination environments at cation sites were published only after the first XRD study of Cu^{II}−Y became available. Almost all groups assign the two ESR signals to Cu^{II} at two different cation sites. However, different research groups have proposed different sites for Cu^{II}. Conesa and Soria[102,104−106] suggested that Cu^{II} remains mainly in the two types of trigonal six-membered rings in the final dehydrated state, at positions I′ and II. This interpretation is in agreement with subsequent studies by Herman[92] and Schoonheydt,[20] and was also confirmed by O_2 line-broadening experiments. The O_2 molecule can only enter the large supercage of zeolite Y, but it cannot access the smaller sodalite cages and hexagonal prisms (see also Figure 1B). One can therefore expect that the ESR signals of Cu^{II} in the supercage (site II, III, III′) will be broadened by the dipolar interaction between the O_2 molecule and Cu^{II} (the resolution and signal intensity decrease), while the ESR signals of Cu^{II} in the sodalite cage and hexagonal prism (site I, I′) are not affected. Since the ESR signal with $g_{//}^{(1)}$ = 2.38 disappears upon admission of oxygen, it was assigned to Cu^{II} in six-membered ring site II in the supercage, with Cu^{II} in a distorted trigonal coordination environment. This assignment also seems very reasonable, because of the similarity of the parameters of this signal with those of the Cu^{II} ions encountered in zeolite A, where the Cu^{II} ions are also present in site II. On the other hand, the signal with $g_{//}^{(2)}$ = 2.33 is insensitive to the presence of oxygen molecules and was assigned to Cu^{II} ions in site I′. As the latter ESR parameters are characteristic for a square-pyramidal coordination, Conesa and Soria suggested that the Cu^{II} ions in site I′ should remain coordinated to two water molecules in order to realize such a coordination.[106] On the other hand, Schoonheydt assigned this signal to naked Cu^{II} ions in site I′ in a trigonal coordination environment.[20] We will come back to this point in section 4.4.

In the Cu^{II}−zeolite X, two axial ESR signals are also observed.[20,36,42,107−110] A first signal conforms to the one observed in both zeolite A and Y, and is characterized by $g_{//}^{(1)}$ = 2.37−2.38. The second is described by a somewhat higher $g_{//}^{(2)}$ value than the second signal in zeolite Y, 2.35

instead of 2.30−2.34. Schoonheydt assigned the signal with $g_{//}^{(1)} = 2.37-2.38$ in zeolite X to Cu^{II} ions in site II, in line with the assignments of Cu^{II} zeolite A and Y. On the other hand, the second signal in Cu^{II}−X was assigned to a different site; since this ESR signal is also broadened by O_2, it was assigned to the Cu^{II} ions in the supercage at site III′.

A different site-dependent interpretation of the ESR signals in zeolite Y and X was provided by the group of Kevan, who used ESR spectroscopy in combination with electron spin echo (ESE) spectrometry.[21,97,103,109−113] These authors propose the same sites for Cu^{II} in zeolite X and Y. The ESR signal with $g_{//}^{(1)} = 2.39$ was attributed to an almost planar trigonal Cu^{II} coordination in the six-membered ring site I′ of zeolites X and Y. On the other hand, the signals with $g_{//}^{(2)} = 2.33$ and $g_{//}^{(2)} = 2.35$ in zeolite Y and X, respectively, were suggested to both correspond to Cu^{II} in the hexagonal prism I. This assignment is in agreement with the earliest XRD results[49] and with the findings of Iwamoto,[114] who studied the oxygen adsorption in Cu^{II}−zeolites Y by temperature-programmed desorption (TPD).

Matar and Goldfarb studied the interactions of the Cu^{II} cations with framework Al in zeolites A, X and Y in various stages of dehydration and after methanol adsorption by electron spin echo envelope modulation (ESEEM).[115−117] The spectra show contributions from two types of ^{27}Al nuclei. One type includes first-shell Al, bound to the oxygen atoms to which the Cu^{II} ion is coordinated; they are at about 3.1−3.4 Å from the Cu^{II} ion and exhibit relatively large isotropic hyperfine constants which indicate strong interaction with the framework oxygen atoms. The second type consists of distant Al nuclei, situated at distances larger than 5 Å. Orientation-selective ESEEM experiments provide additional structural information: The modulation of the first-shell Al in some cases showed strong orientation dependence. Based on these results, a link was proposed between the ESR $g_{//}$ values of the coordinated Cu^{II} and the position of this ion with respect to the aluminum atoms in the trigonal six-membered ring. The Cu^{II} ions situated close to a plane of Al nuclei are held responsible for the $g_{//}$ value of 2.33, whereas the larger $g_{//}$ value (2.38) is supposed to originate from Cu^{II} ions located away from the plane of Al nuclei. This interpretation is original in its suggestion that the different ESR signals might actually be due to Cu^{II} at one and the same site, but surrounded by different Al distributions. A somewhat similar idea will be backed by ab initio calculations (section 4.4), where it is shown that the ESR signals can indeed be explained by Cu^{II} in the six-membered ring site with different Al surroundings.

4.3 DRS and Ligand Field Theory

Klier was the first to interpret the diffuse reflectance spectrum of dehydrated Cu^{II}−zeolite Y.[50−52] This spectrum is composed of a narrow peak centered at 10900 cm^{-1} and two broader bands centered at 12700 and 14650 cm^{-1}. He studied the electronic structure of Cu^{II} positioned in the six-membered ring site, represented by a CuO_3 model. The presence of one hole in its 3d shell corresponds to the free $Cu^{II}(d^9)$ ion in a ^2D ground state. The C_{3v} symmetry of the oxygen environment imposes a splitting on the Cu^{II} ^2D ion term as shown in Figure 4A. The ground state is a degenerate ^2E, with the one hole in the 3d shell located in the e shell, consisting (to a first approximation) of the $3d_{x^2-y^2}$, $3d_{xy}$ orbitals. The Jahn−Teller effect was invoked, inducing an off-axial distortion to remove this degeneracy, as also shown in Figure 4A. Furthermore, the effect of spin-orbit coupling was considered. By fitting the energy of the three highest transitions to the experimental band positions, the Jahn−Teller coupling constant *b*, the spin-orbit coupling constant λ, and β, a structural parameter, were determined. As such, an O−Cu−O angle of 117° was determined, in (somewhat fortuitous) agreement with the angle found by XRD (of 115°). This means that the Cu^{II} ion would obtain an almost planar coordination in the six-membered ring. Klier's assignment of the ligand field transitions is presented in Table 3.

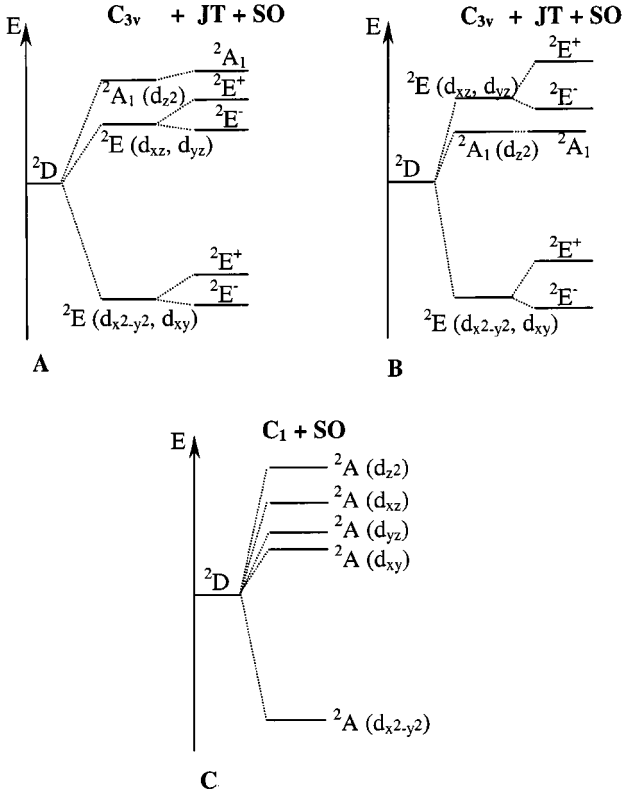

Figure 4. Energy term diagram for Cu^{II} in the trigonal six-membered ring site of zeolite A, ZK4, X, Y by Klier (A),[51] Schoonheydt (B)[53] and Pierloot (C)[28]

Table 3. Assignments of the ligand field bands of Cu^{II} in the trigonal six-membered ring site by various authors

Band maximum [cm^{-1}]	Assignments		
	Klier	Schoonheydt	Pierloot
10900	$^2E_1 \rightarrow {}^2E_2^-$	$^2E_1 \rightarrow {}^2A_1$	$X^2A \rightarrow b^2A$ $X^2A \rightarrow c^2A$
12700	$^2E_1 \rightarrow {}^2E_2^+$	$^2E_1 \rightarrow {}^2E_2^-$	$X^2A \rightarrow d^2A$
14650	$^2E_1 \rightarrow {}^2A_1$	$^2E_1 \rightarrow {}^2E_2^+$	$X^2A \rightarrow e^2A$

Packet and Schoonheydt[20,53−55] studied the coordination of Cu^{II} in various zeolites by combined DRS/ESR experiments. The ligand field band positions for Cu^{II} in zeolite A, X and Y are summarized in Table 4. As one can see, these spectra all show ligand field transitions at similar energies. In contrast to the ESR results, no pronounced difference is found between the DRS spectra of Cu^{II}−A on the one hand and Cu^{II}−X and −Y on the other hand. As already explained in section 4.2, the Cu^{II} ions were assigned to site II and I′ for zeolite Y, while sites II and III were proposed for Cu^{II} in zeolite X. These assignments were supported by calculations based on the angular overlap model (AOM).[20,53−55] Schoonheydt et al. further extended the work on the CuO_3 complex of Klier by also including the three more distant oxygen atoms of the six-membered ring. The two types of six-membered ring sites of zeolite Y, site I′ and II, were both considered. Not only were the three ligand field bands calculated but also the ESR parameters $g_{//}$, $A_{//}$ and $g_{\perp}$. In agreement with Klier, a distortion of the trigonal geometry of the six-membered rings was proposed, due to a Jahn−Teller effect. Spin-orbit coupling was taken into account. By the least-squares procedure, the values of six adjustable parameters were then optimized, the AOM spectroscopic parameters σ and π, a geometrical parameter, the Jahn−Teller parameter, the spin-orbit coupling constant and the Fermi contact parameter. The resulting assignment of the ligand field spectrum is compared to that of Klier in Figure 4 and Table 3. As one can see, the sequence of the $^2A_1$ and ^2E terms is reversed. The reason can be traced back to a different value for the π/σ ratio from both authors. The ligand field stabilization energy of Cu^{II} in site I′ and II was calculated. From these calculations, no site preference between type I′ and II six-membered rings could be predicted.

Both Klier and Packet obtained rather unusual values for the spectroscopic parameters from their ligand field calculations. The spectra of Klier were calculated at an extremely high π/σ ratio, while Packet reports a very large σ value. The origin of these unrealistic parameters may be because the semi-empirical calculations started from the average XRD structures of Cu^{II} sites and are therefore performed in fictitious high symmetry coordination environments. The possibility of symmetry reduction, for example by an asymmetric aluminum surrounding, was not considered. As was suggested by Goldfarb[115−117] and will also be shown in the following section, this factor does play a crucial role in the Cu^{II}−zeolite interaction.

Table 4. Overview of DRS band positions of Cu^{II} in various zeolites by Schoonheydt et al.[20]

Zeolite	Band I	Band II	Band III
Cu^{II}−zeolite A	10400	12200−12800	15000−15400
Cu^{II}−zeolite Y	10400−10800	12400−13000	14700−15100
Cu^{II}−zeolite X	10400−11100	12400−13000	14700−15100
Cu^{II}−mordenite	12500	13700	14800

4.4 Ab initio Studies of Cu^{II} in Trigonal Six-Membered Ring Sites

Recently, more advanced quantum chemical calculations have been performed in order to investigate the coordination and spectroscopic properties of Cu^{II} in the trigonal six-membered ring site.[27−29] The results point to a new interpretation of the ESR signals in zeolite A and Y. Ab initio calculations were performed on the cluster models shown in Figure 5. They consist of the Cu^{II} ion in the six-membered ring, with OH groups (Figure 5A, denoted as "large models") or hydrogen atoms (Figure 5B, denoted as "small models") inserted in order to saturate the dangling bonds of Si, Al. The cluster models are thus represented by the structural formula $CuO_6Si_{6-x}Al_x(OH)_{12}^{(2-x)+}$ and $CuO_6Si_{6-x}Al_xH_{12}^{(2-x)+}$. Different aluminum contents and distributions were studied in order to examine the local effect of aluminum on the coordination environment and the spectroscopic properties of Cu^{II} in the six-membered ring.

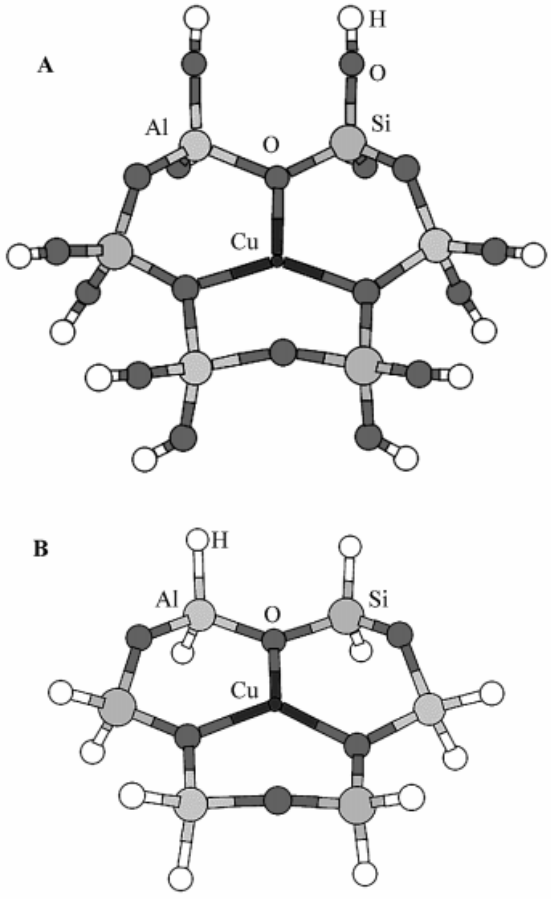

Figure 5. Cluster models for the ab initio calculations of Cu^{II} in the trigonal six-membered ring site in zeolites A, ZK4, X and Y: (A) the dangling bonds of the silicon or aluminum atoms are terminated by OH groups ("large models"); (B) the dangling bonds of the silicon or aluminum atoms are terminated by hydrogen atoms ("small models"); the clusters are depicted at the XRD starting geometry as obtained from the literature[77]

The coordination environment of Cu^{II} in the six-membered ring was obtained by partial geometry optimizations of the large clusters (Figure 5A). The starting geometry of

the cluster models is based on XRD data of Cu^{II}−zeolite A.[87] Partial geometry optimizations of these cluster compounds were performed; restrictions were applied to mimic the rigidity of the zeolite framework. The geometry optimizations were based on density functional theory (DFT) with the B3LYP functional in combination with basis sets from Schäfer et al.[118] The accuracy of the obtained B3LYP-DFT structures was checked by performing additional restricted CASPT2 geometry optimizations for a few clusters.[28] Significant corrections were only obtained for the negatively charged $CuO_6Si_3Al_3(OH)_{12}^-$ cluster model.

As for the calculation of the electronic spectra and the *g* factors, calculations based on multiconfigurational perturbation theory (CASPT2) were performed. Since these CASPT2 calculations demand a considerably larger computational effort than the DFT geometry optimizations, slightly smaller models were used, obtained by replacing the terminal OH groups in the optimized cluster models by hydrogen atoms. It was shown that this reduction of the cluster size does not affect the spectroscopic features of the central Cu^{II} ion to any significant extent.[26,28] In the CASPT2 calculations, the basis sets are atomic natural orbitals.[119] The reference active space consists of the Cu(3d) orbitals, an additional d-shell (to take into account the 3d-double shell effect) and one bonding oxygen valence orbital. The effect of spin-orbit coupling was taken into account by means of an effective one-electron operator.[120] Finally, the *g* tensors were calculated using second-order perturbation theory, introducing spin-orbit coupling and the magnetic field as simultaneous perturbations. More information about the details of the calculations can be found in the original papers.[27−29]

First, it was checked whether the ligand field spectrum of Cu^{II}−zeolite A can be explained by assuming Cu^{II} to be coordinated in the high-symmetric (C_{3v}) oxygen six-membered ring structure as reported on the basis of XRD (see Figure 3). However, the CASPT2 excitation energies of a six-membered ring cluster at the XRD geometry did not exceed 8500 cm^{-1} for the ligand field transitions. Even after invoking a Jahn−Teller distortion, the calculated excitation energies remained much too low to offer an explanation of the experimental DRS spectra of Cu^{II}−A, −Y.

In a next step, the DFT-optimized structures of model clusters with all possible aluminum distributions in the six-membered ring were considered. All structures were optimized without applying any symmetry restrictions. The optimized coordination environments are shown in Figure 6. Only one Al is present in ring A, while rings B and C contain two, and ring D three Al. As one can see, the calculated structures reveal strong local deformations of the six-membered rings; as a matter of fact, no symmetry whatsoever is retained. The distortions are due to the tendency of the Cu^{II} ion to obtain a fourfold coordination environment in the six-membered ring. One of the more distant O_B oxygen atoms (O_{B1}) is bent inwards in order to provide an additional short Cu−O bond. This fourfold coordination environment gives rise to a much higher ligand field as compared to the trigonal coordination; the CASPT2 excitation

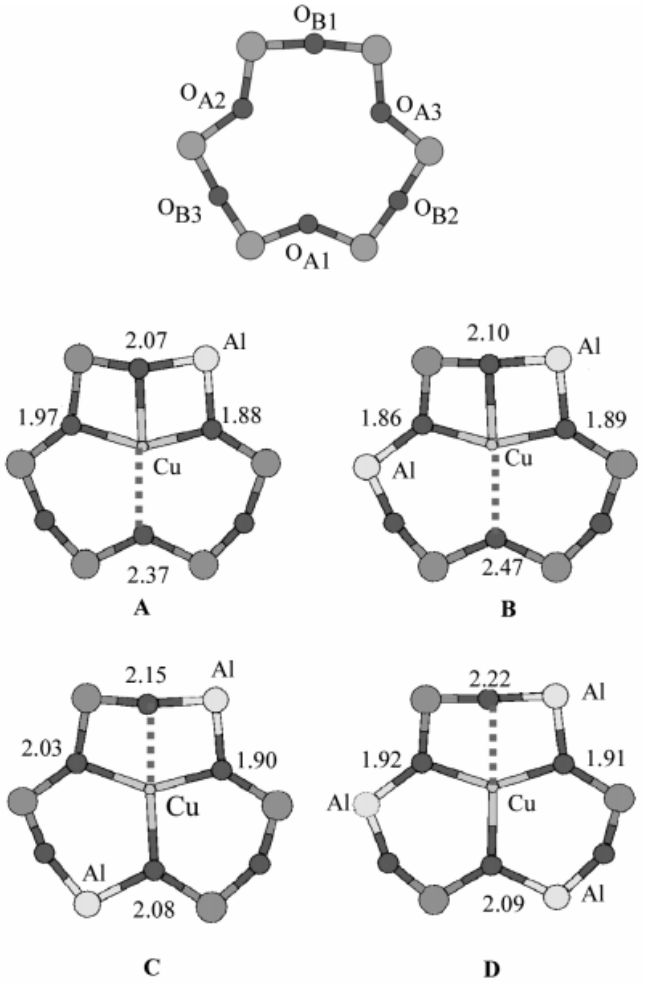

Figure 6. Calculated structures of Cu^{II} in the trigonal six-membered ring site; Cu−O distances are given in Å; cluster A contains only one Al, clusters B, C contain two Al, while three Al are present in cluster D; the coordination geometry of Cu^{II} is fourfold planar; one can clearly distinguish the two coordination modes in the six-membered ring: clusters A, B on the one hand and clusters C, D on the other hand; clusters A, B represent B3LYP-DFT structures, while cluster C, D contain a CASPT2-optimized Cu−O_{B1} bond

energies are calculated between 9500 and 15400 cm^{-1}, in good agreement with the experimental ligand field bands. The energy term diagram is shown in Figure 4C. A new assignment of the experimental ligand field bands is proposed, as shown in Table 3.

One can also see from Figure 6 that the cation shows a strong preference for coordination to oxygen atoms bound to Al rather than Si. This also means that the aluminum distribution may thoroughly influence the coordination environment of Cu^{II}. Two distinct fourfold coordination modes could be distinguished, depending on the number and relative positions of Al in the six-membered ring. In clusters A and B, the Cu−O_{B1} distance is much shorter than Cu−O_{A1}. On the other hand, Cu−O_{A1} is shorter than Cu−O_{B1} in rings C and D, due to the introduction of a second Al next to O_{A1}. The two coordination modes can also clearly be distinguished by looking at the calculated *g* factors. The $g_{//}$ value is systematically lower (2.31−2.33) for

the clusters A and B, than for the other group with clusters C and D (2.39−2.41). Based on the close correspondence between the calculated *g* factors and the experimental ESR signals of zeolite A and Y, a new interpretation of these signals is proposed. The occurrence of two ESR signals in zeolite Y as opposed to only one signal in zeolite A can be attributed to the higher Si/Al ratio in the former zeolite. In zeolite A, with an Si/Al ratio of 1, only the ring shown in Figure 6D can occur, explaining the single ESR signal with $g_{//} = 2.38$. On the other hand, rings with 1, 2 or 3 Al (all structures in Figure 6) can occur in zeolite Y, which leads to the two ESR signals. This new interpretation is corroborated by the experimental ESR signals obtained for Cu^{II}−ZK4 (with Si/Al > 1).[28,97] Also here, two ESR signals are observed, while only one six-membered ring site is present. On the other hand, the rather high $g_{//}^{(2)}$ value observed in the Cu^{II}−zeolite X remains puzzling.

Finally, we should remark that for clusters with more than 1 Al, there are different structural minima for Cu^{II} in the six-membered ring. The energy barriers for going from one minimum to another are low, which indicates that at room temperature Cu^{II} is likely to undergo a hopping process between the different minima. This also explains why the actual minima are not detected on the time-scale of an XRD measurement.

As a next step, the DFT/CASPT2 approach was applied to investigate how the coordination of Cu^{II} in the six-membered ring is influenced when an external ligand is adsorbed at the Cu^{II} ion.[29] The structures of the six-membered rings were reoptimized with B3LYP-DFT in the presence of one NH_3 or H_2O ligand. Adsorption on Cu^{II} in the two coordination modes in the six-membered ring may be compared by considering clusters B and D in Figure 6. For both clusters, it is found that the weakest of the four Cu−O bonds is partially given up upon adsorption of NH_3 or H_2O, and a new strong bond is formed with the extra-lattice ligand instead. This means that for cluster B, the $Cu-O_{A1}$ bond is partially relaxed, while in cluster D, the CuO_{B1} bond is relaxed. When the binding energies were calculated, it was found that adsorbed NH_3 systematically gives a stronger bond than H_2O.

The ligand field spectra of the clusters with external ligands were compared to those of the naked Cu^{II} clusters. The CASPT2 excitation energies of the adsorption complexes are calculated at a lower energy than that of the Cu^{II} clusters without adsorbent. This is in agreement with experimental observations; it is known that the partially hydrated or ammoniated Cu^{II}−Y samples are characterized by a ligand field band in the range 10500−12500 cm^{-1}, somewhat lower than the ligand field band for fully dehydrated Cu^{II}−Y.[29,121] It has indeed been proposed in the literature that the Cu^{II} species in these partially saturated samples are complexes with Cu^{II} coordinated to three lattice oxygen atoms of the six-membered ring site and one external ligand.[41,121] On the other hand, a trigonal bipyramidal complex with Cu^{II} coordinating to three oxygen atoms of the six-membered ring and two axial H_2O or NH_3 molecules has also been suggested.[101] So far, clusters with more than one external ligand have not been studied with the ab initio approach.

5. The Siting of Cu^{II} Ions in Mordenite

5.1 XRD

According to the best of our knowledge, XRD data on fully dehydrated Cu^{II}−mordenite are not available yet. Therefore, other XRD data are often consulted to obtain a first indication of possible coordination sites of Cu^{II}. In partially dehydrated Cu^{II}−mordenite,[122] three sites for Cu^{II} were determined. In site A (see Figure 1C) the Cu^{II} ions are not only coordinated to six lattice oxygen atoms of the eight-membered ring, but also to two water molecules. A second occupied site is the six-membered ring in the twelve-membered ring channel (site E), where the Cu^{II} ion is coordinated to four lattice oxygen atoms of the six-membered ring. The last and least occupied site is site D, where Cu^{II} is bound to three oxygen atoms of the circular eight-membered ring. It can, however, not be excluded that the Cu^{II} ion further migrates to other cation sites upon complete dehydration.

Most of the interpretations of the siting of Cu^{II} in mordenite are based on the much earlier XRD results of dehydrated Ca^{II} mordenite.[123] Four sites are occupied by Ca^{II}. Ca^{II} ions are first found in site A, where this ion is coordinated to six lattice oxygen atoms in C_{2h} symmetry. The second exchange site which is occupied by Ca^{II} is site E, where Ca^{II} is coordinated to four lattice oxygen atoms. A smaller portion of the Ca^{II} ions is located in the boat-shaped site in the eight-membered ring channel of the zeolite. This site is composed of a non-planar six-membered ring (site C) in between two bent five-membered rings. Finally, Ca^{II} ions were also found in site D. It should, however, be noted that the ion radius for Cu^{II} is much smaller than that of Ca^{II}, which can result in different preferential sites for dehydrated Cu^{II}− and Ca^{II}−mordenite. Moreover, it can also be expected that transition metal cations react differently with the zeolite than the closed shell alkaline-earth cations. Any interpretation of the spectroscopic signals in Cu^{II}−mordenite on the basis of these two available XRD studies is therefore speculative.

5.2 ESR and DRS Studies

In the first ESR studies of Cu^{II}-exchanged mordenite, two types of Cu^{II} cations, both in an axial environment, were detected, with $g_{//}^{(1)} = 2.32$ and $g_{//}^{(2)} = 2.27$ (as also reported in Table 2).[124,125] The two coordination environments were described as either four-coordinated square-planar (characterized by $g_{//}^{(2)} = 2.27$) or five-coordinated square-pyramidal (characterized by $g_{//}^{(1)} = 2.32$). An investigation of the Cu^{II} reducibility provided additional information on the coordination of these ions. The Cu^{II} ions in the close to square-planar coordination are readily reduced by CO at 400 °C, while the five-coordinated Cu^{II} ions are more stable to reduction by CO. It was therefore suggested that

the five-coordinated Cu^{II} ion compensates for the two elemental charges of the mordenite lattice and has no additional link to extra-lattice oxygen ligands. The reduction process for the latter species must involve the abstraction of an O^{2-} anion from the zeolitic framework and should prove difficult. Finally, the accessibility of the Cu^{II} species was examined. It was shown that both types of Cu^{II} ions interact with cation-radicals of large molecules such as benzene and *o*-xylene via a dipole−dipole interaction, implying that they must be located in sites that are accessible from the main channel.

Sass and Kevan[126] studied the coordination of Cu^{II} in mordenite in the presence of adsorbed molecules. Due to the very low Cu^{II} loadings (1 Cu^{II} per 30 unit cells), they observed only one ESR signal in CuNa−, CuK− and CuCa−mordenite, with $g_{//}^{(1)} = 2.32-2.33$. This Cu^{II} species was assigned to Cu^{II} in site A.

De Tavernier and Schoonheydt observed the same two Cu^{II} signals with ESR as Kucherov, and found that their relative intensities are dependent on the Cu^{II} loading, the Si/Al ratio and co-exchanged cations.[20,30,31,127] At small Cu^{II} loadings, only the ESR signal with $g_{//}^{(1)} = 2.33$ is detected. In the DRS spectrum of these samples, a ligand field band with maximum intensity at 13700 cm^{-1} is observed. In contrast with the DRS spectra of zeolite Y, the individual transitions of this band are not resolved. When the Cu^{II} loading is increased, the second signal ($g_{//}^{(2)} = 2.27$) also becomes apparent in the ESR spectrum. This goes along with a broadening of the DRS ligand field band. An interpretation of these combined DRS/ESR data of Cu^{II}−mordenite was provided on the basis of AOM calculations.[127] According to this interpretation only site A is occupied at low Cu^{II} exchange levels, in agreement with the assignment of Kevan. The weak coordination with six oxygen atoms at this site gives rise to the ESR signal with a $g_{//}^{(1)}$ value of 2.32. At higher copper loadings, a second exchange site, i.e. site E, becomes occupied. The fourfold Cu−oxygen coordination at this site was held responsible for the second ESR signal with $g_{//}^{(2)} = 2.27$.

Carl and Larsen[128,129] also decomposed the ESR spectrum of CuNa−mordenite into two axial signals, but with different parameters $g_{//} = 2.33$, $A_{//} = 164\ 10^{-4}\ cm^{-1}$ and $g_{//} = 2.34$, $A_{//} = 121\ 10^{-4}\ cm^{-1}$. While the first signal is in good correspondence with that found by de Tavernier, the second signal has an exceptionally low value of $A_{//}$ ($121\ 10^{-4}\ cm^{-1}$). A third ESR signal was also present, but its parameters could not be resolved.

The siting of Cu^{II} in various Si-rich zeolite matrices, including mordenite, has been studied extensively by Wichterlová et al.[23−25] They combined conventional ESR measurements with Cu^{I} luminescence and IR studies of adsorbed NO on Cu^{II} and also studied the reducibility of the Cu^{II} ions. It was assumed that the Cu^{I} siting and distribution reflect those of the Cu^{II} ion. As shown in Table 5, four main coordinations of the Cu ions, common in ZSM-5, mordenite, erionite, and zeolite beta, were distinguished. These authors concluded that the Cu^{II} siting in high silica zeolites is essentially controlled by the local Si−Al sequences in the framework, in agreement with the earlier suggestions of Kucherov.[124,125] Cu^{II} characterized by $g_{//}^{(1)} = 2.32$ is preferentially located in the close vicinity of two framework aluminum atoms. Here it obtains the square-pyramidal oxygen coordination. The Cu^{II} ions are strongly bound to the zeolite lattice and they are not easily reduced. A second type of Cu^{II}, characterized by a $g_{//}^{(2)}$ value of 2.27, has a square-planar oxygen coordination and is adjacent to a single aluminum atom. This site is easily reduced and was suggested to be responsible for the high and stable activity of Cu−zeolites in NO decomposition.[130,131] The possibility of an extra-framework oxygen ligand (O^- or OH^-) was, for the latter site, also considered.

From an FTIR study of the framework T−O−T vibrations, Wichterlová et al. also showed that the bonding of Cu^{II} (or other divalent cations) to the framework oxygen atoms causes local deformations in the zeolite framework.[79] Upon reduction of Cu^{II} to Cu^{I} or the adsorption of a ligand on the Cu^{II} ion, the band shifted to higher wavenumbers, indicating some relaxation of the framework.

5.3 Ab initio Studies of the Siting of Cu^{II} in Mordenite

Pierloot et al.[30,31] also performed ab initio calculations in order to interpret the two ESR signals of Cu^{II} in mordenite. Cluster models of several cation exchange sites in mordenite were constructed, based on the XRD structure of Ca^{II}−mordenite. These clusters consist of the ring systems in Figure 2 terminated by OH groups or hydrogen atoms. The considered sites were site A, as a representative of an oxygen eight-membered ring site, and sites E and C (see Figures 1C and 2).

The structure and spectroscopic features of Cu^{II} on these cation exchange sites were calculated with the DFT/CASPT2 approach, using a similar strategy as described in section 4.4. The effect of the aluminum distribution on the coordination environment, spectroscopic features and siting

Table 5. Spectroscopic signatures of Cu^{II} as established by Wichterlová et al.:[23−25] Cu^{+} emission wavelengths, IR frequencies of Cu^{2+}−NO, and ESR parameters of Cu^{2+}

Cu site	Cu^{+} emmision [nm]	Cu^{2+}−NO [cm^{-1}]	$g_{//}$	Al	Cu^{2+} coordination
Cu-I	450	1921 (1909)	2.31	Al pairs	square-pyramidal
Cu-II	480	1912	2.33	Al pairs	square-pyramidal
Cu-III	510	1906	−		
Cu-IV	540	1896	2.28	single Al	square-planar

of Cu^{II} was examined in detail. The calculated spectroscopic features were confronted with the experimental DRS and ESR data in order to understand the siting of Cu^{II} in mordenite.

The geometry optimizations of site-A clusters indicate that the Cu^{II} ion cannot acquire a fourfold coordination environment in this site. The distortions induced by Cu^{II} are insufficient to realize an optimal fourfold oxygen coordination. Eight-membered rings are simply too large to supply Cu^{II} with the desired planar oxygen four-coordination. This was also shown by a molecular modeling study of the coordination of Cu^{II} in mordenite.[132] As a consequence of the weak coordination, the obtained ligand field is not strong enough to explain the observed spectroscopic features of Cu^{II}−mordenite (the CASPT2 excitation energies remain below 10000 cm^{-1}). Therefore, the eight-membered ring sites in mordenite will be excluded from the following considerations.

As a next step, the coordination of Cu^{II} in the cluster models of site E and site C was studied. The geometry optimizations show that Cu^{II} can obtain a strong fourfold coordination environment in the planar rings of these sites, i.e. in the six-membered ring of site E and in the planar five-membered ring of site C. Let us first look at the results for site E. As for the trigonal six-membered ring site, two coordination modes can be distinguished in the six-membered ring of site E, depending on the relative positions of Al. A representative cluster of each of these two coordination modes is represented in Figure 7. Coordination mode I is realized if Al is present at the central positions in the six-membered ring. Then, an almost perfect square-planar coordination is obtained (see Figure 7), with four Cu−O distances of around 2 Å. This strong coordination gives rise to a ligand field spectrum at high energy (and is in agreement with experimental results), and axial g factors with a $g_{//}$ value around 2.27. On the other hand, more distorted coordination environments are present if Al is placed at less central positions, mode II in Figure 7. Cu^{II} forms a bond with one of the less central oxygen atoms due to the preference of Cu^{II} for coordination with oxygen atoms bound to Al. As can be seen from Figure 7, this results in a planar four-coordination with one rather large O−Cu−O angle. This distortion of the coordination environment slightly weakens the strength of the ligand field, resulting in higher characteristic $g_{//}$ values ($g_{//}$ = 2.30−2.32) for coordination mode II as compared with mode I.

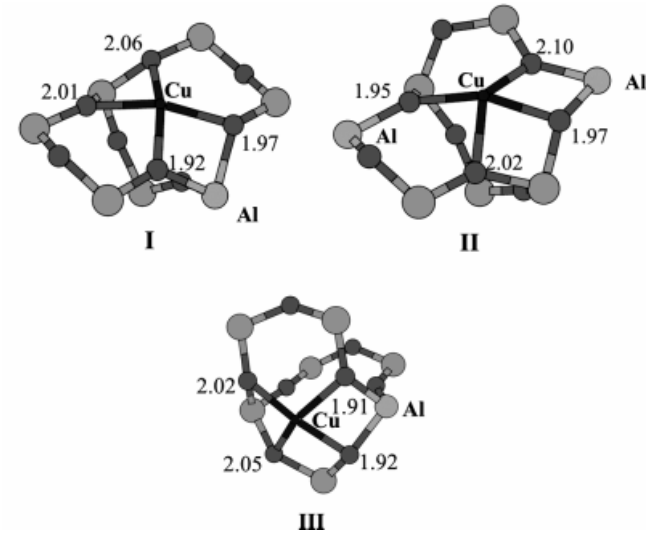

Figure 7. The representative coordination modes for Cu^{II} in mordenite; cluster I represents Cu^{II} in site E where one Al is present at a central position; the Cu^{II} ion obtains a planar fourfold coordination environment; cluster II represents Cu^{II} in site E with two Al at non-central positions; Cu^{II} is present in an irregular fourfold coordination environment; cluster III represents Cu^{II} in the planar five-membered ring in the main channel, where this ion obtains a fourfold pyramidal coordination; the Cu−O distances are given in Å

At site C, it was found that Cu^{II} acquires a pyramidal four-coordination in the planar five-membered rings, coordination mode III in Figure 7. Due to the small size of the five-membered ring, the Cu^{II} ion is located slightly above the plane of the oxygen atoms, in the main channel of mordenite. This pyramidal coordination is also characterized by $g_{//}$ = 2.27, and this third coordination mode can therefore not be distinguished from mode I in site E.

As one can see, the calculated g factors characterizing coordination mode I, II and III are in good agreement with the experimental ESR spectra. The ESR signal with $g_{//}^{(1)}$ = 2.33 is assigned to Cu^{II} in coordination mode II, while the second signal with $g_{//}^{(2)}$ = 2.27 can be assigned to Cu^{II} ions in coordination mode I and/or III. Additional considerations must be taken into account in order to explain the order in which the two ESR signals appear; first, it may be expected that the Cu^{II} ions prefer rings in which two Al are present above rings containing only one Al, due to electrostatic effects. Second, the rule of Takaishi for the ordered aluminum distribution in mordenite was invoked.[133][134] According to this rule, the five-membered rings in mordenite can never contain more than one Al. This also implies that not all six-membered rings with two Al in site E and C can occur (as linking five-membered rings forms them). Six-membered rings with 2 Al at central positions cannot be formed in mordenite; 2 Al must be placed at the non-central positions.

The following interpretation of the siting of Cu^{II} ions in mordenite is then proposed: at low Cu^{II} loadings, the Cu^{II} ions are found at the preferential sites, that is in rings with two aluminum atoms. Takaishi's rule excludes those aluminum distributions that might have provided Cu^{II} with a regular square-planar coordination in a ring containing 2 Al. As such, only coordination mode II (see Figure 7) is realized at the lowest Cu^{II} loadings, leading to only one ESR signal with $g_{//}$ = 2.33. The number of vacant six-membered rings decreases when the Cu^{II} loading increases. Therefore, rings with 1 Al also become occupied at higher Cu^{II} loadings, so that the more regular square-planar or square-pyramidal coordination modes in the planar five- and six-membered ring in the main channel are also formed. This gives rise to the second ESR signal, characterized by $g_{//}$ = 2.27. We remark that the Cu^{II} ions are located in the main channel of mordenite, and as such they are

well accessible for adsorbing molecules, in agreement with ESR results.[124]

Finally, the charge compensation of Cu^{II} in rings with only 1 Al was examined. In the literature, it is often suggested that Cu^{II} ions in the vicinity of only 1 Al are coordinated to an extra-lattice OH^- ligand in order to compensate for the local positive charge.[23,70,128,135] To test this hypothesis, additional calculations were performed for clusters with 1 Al, where Cu^{II} is also coordinated to OH^-. The optimized structures show that the Cu^{II} ion is in a planar threefold coordination environment. The Cu^{II} ion is moved outside the plane of the zeolite ring and remains coordinated to only two of the lattice oxygen atoms (the ones bound to Al) and the OH^- group. The latter bond has an unusually short Cu−O distance. This trigonal coordination is very unusual in the inorganic coordination chemistry of Cu^{II}. The $g_{//}$ factors characterizing this coordination (around 2.40) are much higher than the experimentally observed ESR signals. It is concluded that the $(Cu-OH)^+$ species are not present in the Cu^{II}−mordenite samples considered here. Charge compensation therefore only proceeds via Al in the lattice. In the case of Cu^{II} in rings with only 1 Al, this implies that charge compensation is also realized by Al in a next shell of the zeolite structure.

6. Concluding Remarks

The present work demonstrates that the structure and spectroscopic properties of transition metal ions in zeolites can successfully be explained by means of cluster model calculations using a combined DFT/CASPT2 treatment. Accurate structural information about the coordination of the transition metal ion and the distortions of the zeolite framework due to the metal adsorption is obtained from the partial geometry optimizations based on DFT. The spectroscopic features of the cluster models were calculated by means of the CASPT2 method. The ligand field excitation energies were predicted with an accuracy of less than 1000 cm^{-1}, while the ESR g factors were calculated with an accuracy of 0.03.

The DFT/CASPT2 approach allows a thorough investigation of the role of the Al distribution on the coordination environment and siting of the transition metal ion, which turns out, plays a crucial role in the cation−zeolite interaction. The main disadvantage of the cluster model approach could be the neglect of the effect of the rest of the zeolite crystal on the coordination environment of the transition metal ion. One may wonder whether restricted model clusters can correctly describe the cation exchange sites in the real zeolite matrix. However, the excitation energies and g factors crucially depend on the structure of the cluster model. The close correspondence between the experimental and calculated spectroscopic features therefore indirectly confirms the high quality of the DFT structures. The fact that the coordination environment and spectroscopic properties of transition metal ions in the considered zeolites can be described by the relatively small cluster models used in this work is an indication that they are essentially only dependent on the nearest neighbors of the cation. It would be interesting to examine the effect of the wider zeolite environment by using a QM/MM embedding procedure. In this method, the quantum mechanical (QM) description of the cluster is coupled with a classical description (with molecular modeling, MM) of the interactions between the cluster and its further environment.[58−60]

The study of the coordination of Cu^{II} in zeolite A, Y, ZK4 and mordenite has led to a new and profound insight in the Cu^{II}−zeolite interaction, which can be summarized by the following three rules:

(1) The presence of Cu^{II} in cation exchange sites in zeolites causes local distortions of the zeolite framework. The driving force for these structural deformations is the tendency of Cu^{II} to attain a four-coordinate square-planar coordination to the lattice oxygen atoms. This can be rationalized by means of molecular orbital theory; in a square-planar environment, Cu^{II} can maximize the σ interaction between the $Cu(3d_{x^2-y^2})$ orbital and the oxygen ligands. The Cu−O binding thus has a partially covalent character.

(2) Framework aluminum atoms strongly influence the coordination environment of Cu^{II}, since the cation preferentially coordinates to lattice oxygen atoms bound to Al. As there are different possible Al distributions in one site (for zeolites with Si/Al > 1), this can lead to different coordination modes for Cu^{II} in one site.

(3) Planar five- and six-membered rings are the ideal sites to accommodate the Cu^{II} ion, as the planar fourfold coordination is most easily achieved in these rings. Larger or twisted rings are avoided.

In the future, it will be interesting to examine and compare the reaction mechanism and reactivity of these transition metal ion centers for the N_2O and NO_x decomposition reactions.

Finally, the performance of the DFT/CASPT2 approach can also be compared to previous theoretical calculations of transition metal ions in zeolites, which were based on crystal or ligand field theory.[20,50−55] Whereas the crystal/ligand field calculations essentially had a rationalizing role, the current DFT/CASPT2 approach has proven to have a predictive value. As a first example, the DFT/CASPT2 calculations have revealed large local distortions of the zeolite structure due to the presence of the transition metal ion. These local deformations of the zeolite in the presence of divalent cations were already decided from IR spectroscopy experiments, where a shift of the framework T−O−T stretching vibrations is observed upon complexation with the cations,[79,80] and from ESEEM and ^{27}Al NMR spectroscopy experiments.[115] In this respect, the DFT structures offer detailed structural information about these distortions which has, so far, been inaccessible to experiment. Secondly, our new interpretation of the ESR signals of Cu^{II} in zeolite A and Y suggested the presence of two ESR signals in a related zeolite, namely Cu^{II}−ZK4. The subsequent ESR experiments on this zeolite indeed confirmed this prediction.

The new ab initio interpretations differ quite significantly from many previous ligand field results on the coordination

of Cu^{II} in zeolites. On the other hand, some of the main ideas of ligand field theory apparently survive. The predominant orbitals that constitute the complete basis of the whole ligand field framework are the metal d orbitals. And these very same orbitals play a crucial role in the construction of the complete active space of the ab initio work. The unique role of the $d_{x^2-y^2}$ orbital in the stabilization of the four-coordinate square-planar coordination is completely in line with simple ligand-field predictions.

Mesoscopic Globular Self-assemblies of Platinum(II) Complexes Containing Porphyrins

Mariangela Castriciano,[a] Andrea Romeo,[a] Raffaello Romeo,[a] and Luigi Monsu′ Scolaro*[a,b]

Keywords: Platinum / Porphyrins / Nanostructures / Aggregation / Scanning probe microscopy

Slow evaporation of an acetone or chloroform solution of the novel tetranuclear platinum(II) complex $[Pt(Lau_2dim)Me]_4$-$(TpyP)(CF_3SO_3)_4$ [Lau_2dim = didodecyldiimine; TpyP = 5,10,15,20-tetrakis(4-pyridyl)-21*H*,23*H*-porphyrin] on a glass surface affords globular micrometric sized aggregates.

Introduction

The formation of organized supramolecular structures of chromophores with well-defined shapes and sizes is a topic of relevant interest.[1] Their potential application in energy storage and conversion, supramolecular catalysis, optics and electronics can be easily recognized. In this respect, porphyrins and their metal derivatives are important compounds due to their favorable photophysical, electronic and catalytic properties. These features are strictly related to their aggregation state and strongly depend on the microstructural environment.[2] Specifically tailored porphyrins can be easily dissolved in micelles or liposomes[3] obtaining systems that assume the required stability, rigidity and orientation to perform specific functions, for example to mimic cytochrome P-450.[4] Amphiphilic porphyrins have been exploited in the preparation of simple micelles,[5] fibers[6] and vesicles,[7] while "octopus" porphyrins have shown their tendency to self-assemble in vesicles[8] or fibers[9] able to bind oxygen in an aqueous medium. The formation of porphyrin wheels or rings in the mesoscopic range has been achieved by simple solvent evaporation.[10]

Metal complexes can be conveniently exploited to synthesize properly modified porphyrins[11] or linked porphyrin arrays using the self-assembly idea.[12] We have recently reported on the application of platinum(II) organometallic complexes to the synthesis of tetrasubstituted porphyrins that are soluble in micellar phases.[13] We knew from a detailed kinetic investigation on cationic complexes of the type $[Pt(N\text{-}N)Me(Me_2SO)]^+$ (N-N = a series of diamines or diimines)[14] that the coordinated Me_2SO becomes very labile when N-N is a diimine. Therefore, we used the complex $[Pt(Cy_2dim)Me(Me_2SO)]^+$ (Cy_2dim = dicyclohexyldiimine) as a monofunctional building block for introducing the platinum molecular fragment and for accessing a specifically tailored porphyrin.[13]

This paper describes the formation of globular mesoscopic aggregates by simple evaporation of solutions containing a novel 5,10,15,20-tetrakis(4-pyridyl)-21*H*,23*H*-porphyrin (TpyP) derivative functionalized with a platinum(II) complex bearing long alkyl chains.

Results and Discussion

The synthetic route to the porphyrin platinum(II) complex $[Pt(Lau_2dim)Me]_4(TpyP)(CF_3SO_3)_4$ (**1**) (Lau_2dim = didodecyldiimine) can be summarized as follows (Scheme 1): (i) the diimine ligand Lau_2dim is readily prepared, according to a literature method,[15] by reacting dodecylamine and glyoxal in methanol; (ii) in analogy with a well-established procedure,[14] the diimine ligand is reacted with the complex *trans*-$[Pt(Me_2SO)_2MeCl]$ in methanol, in the presence of a stoichiometric amount of $AgCF_3SO_3$; separation of solid AgCl and cautious evaporation of the excess solvent affords the sulfoxide complex $[Pt(Lau_2dim)Me(Me_2SO)](CF_3SO_3)$; (iii) this latter compound is reacted with a stoichiometric amount of the TpyP porphyrin in chloroform leading almost quantitatively to the tetranuclear complex **1**. The gradual platination of the porphyrin can be monitored easily in situ by ^1H NMR spectroscopy, by titrating a solution of TpyP with the sulfoxide complex. The aromatic region of the spectrum shows a decrease of the signals for TpyP and a matching increase of the peaks due to intermediate mono-, di- and trisubstituted species, af-

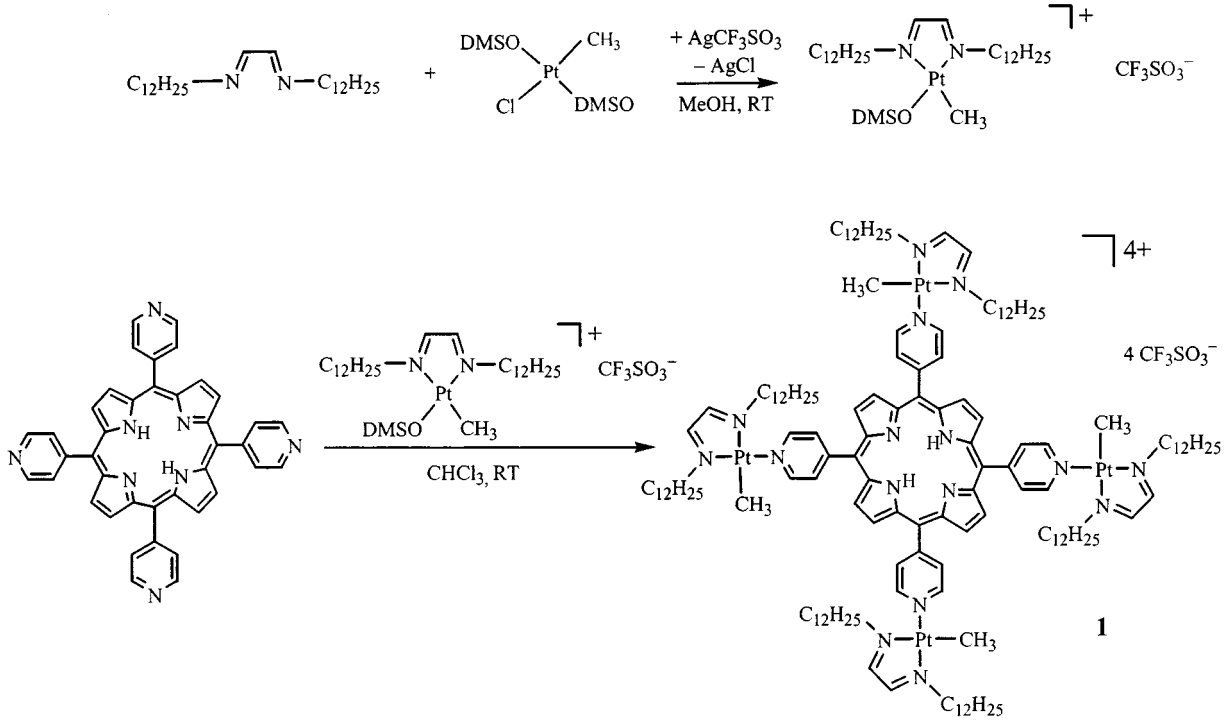

Scheme 1

fording eventually the required tetrasubstituted complex with a metal to porphyrin ratio of 4:1.

The UV/Vis electronic spectrum of **1** in acetone exhibits an intense Soret band at 422 nm ($\varepsilon = 2.76 \times 10^5$ м$^{-1}$cm^{-1}), which is bathochromically shifted with respect to the free TpyP porphyrin ($\Delta\lambda = +9$ nm, Figure 1). A series of four Q-bands are present at longer wavelengths. The resonance light-scattering[17] spectrum of the acetone solution of **1** exhibits a rather low intensity with respect to the neat solvent, and is strongly modulated by the absorbance of the sample, suggesting the monomeric nature of this complex in acetone. The platinated porphyrin is still emissive in acetone solutions. The fluorescence spectra display the typical two-band emission at 654 and 716 nm, very similar (even if partially quenched by the heavy atom effect) to those of the parent porphyrin and of other tetraaryl-substituted porphyrins (inset of Figure 1).[18] The excitation spectra match the absorption spectra.

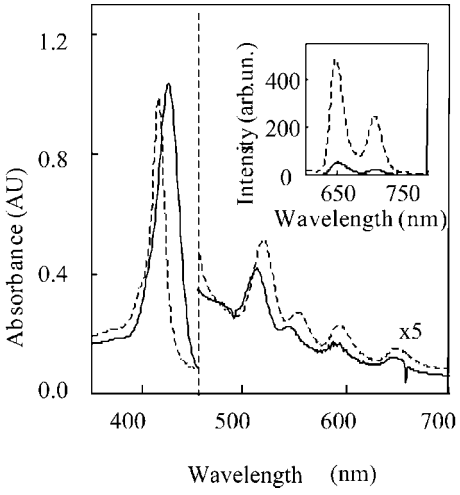

Figure 1. UV/Vis spectra of 5 μм solutions of TpyP (dashed line) and complex **1** (solid line) in acetone [the inset shows the fluorescence emission spectra of TpyP (dashed line) and complex **1** (solid line) in acetone ($\lambda_{exc} = 420$ nm; emissions are corrected for absorption)]

Chloroform or acetone solutions of complex **1** have been evaporated on glass cover slides. The resulting films exhibit an intense and sharp Soret band at 431 nm and the typical two-band emission fluorescence at 662 and 720 nm. Both the Soret and the emission features are bathochromically shifted with respect to the organic solution phase. These observations suggest a well-defined geometrical arrangement of porphyrins in the solid state, which could be accounted for by the occurrence of porphyrin−porphyrin interactions, in spite of the presence of the bulky alkyl side chains. These latter could be responsible for a further stabilization of the structure through hydrophobic interactions, which help to orientate the chromophore planes (Figure 2). Optical microscopy on these samples revealed a distribution of apparently globular objects, which are stable at 298 K for at least a week. After this period, the aggregates collapse in continuum unstructured layers. Scanning Electron Microscopy (SEM) has been exploited to investigate the morphology of this system. The SEM images (Figure 3) show a population of almost spherical aggregates with sizes spanning from 1000 up to 2000 nm. The presence of platinum in the aggregates is confirmed by Energy Dispersion Spectrometry (EDS), which shows the typical pattern of this element. The clear-cut evidence that compound **1** retains its identity in the globular aggregates has been proved by strip-

ping the compound from the glass with acetone and comparing the UV/Vis absorption and fluorescence emission of these solutions with those of **1** in the same solvent prior to deposition. Analogous experiments performed using solutions of [Pt(Lau$_2$dim)Me(Me$_2$SO)](CF$_3$SO$_3$) or of the platinated porphyrin compound [Pt(Cy$_2$dim)Me]$_4$(TpyP)(CF$_3$SO$_3$)$_4$ [13] resulted only in the formation of unstructured films, resembling a waxy layer.

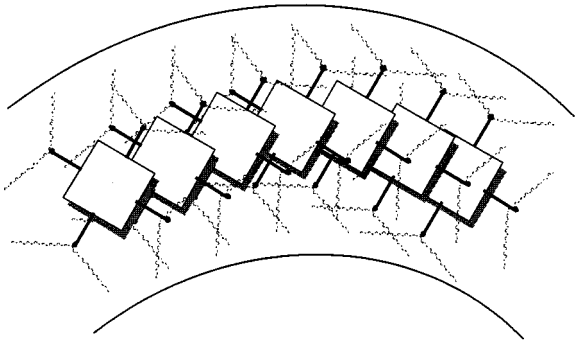

Figure 2. Schematic model for the arrangement of porphyrins in the aggregates

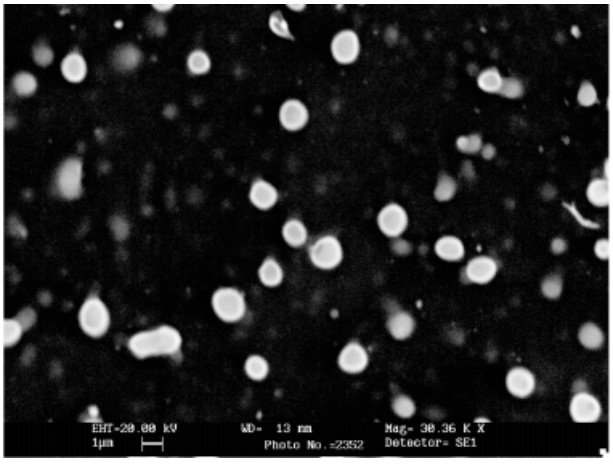

Figure 3. SEM image acquired on a sample of **1** deposited on glass from an acetone solution; the slide has been coated with graphite for EDS analysis

The growth of porphyrin wheels[10c] and of other well-defined patterns[19] of chromophores on different solid substrates has been explained on the basis of surface forces acting at the interface between the solid, the liquid and the gas phase. A similar mechanism could well apply to the growth of objects of spherical shape, even if a complete understanding deserves further investigations. The nature of the solvent does not allow a complete wettability of the glass substrate, leading to an increase of the contact angle. The droplets are pinned at the glass surface by the roughness of the surface or by defects present in the film. On evaporation the hydrophobic porphyrin concentrates in the droplet which tends to assume a spherical shape. The resulting structure should be stabilized by included solvent molecules. Further studies are in progress to test the catalytic ability of aggregated manganese(III) porphyrin derivatives in oxidative processes.

Experimental Section

General Procedures and Chemicals: All solvents were dried according to standard procedures by distillation under an oxygen-free nitrogen atmosphere from appropriate drying agents (i.e. dichloromethane from barium oxide and diethyl ether from sodium benzophenone ketyl). $CDCl_3$ was purchased from Cambridge Isotopes Laboratories (D, 99.8%). 5,10,15,20-tetrakis(4-pyridyl)-21*H*,23*H*-porphyrin (TpyP) was purchased from Aldrich. K_2PtCl_4 (Strem Chemical Co.) was purified from metallic Pt and K_2PtCl_6 by dissolving it in water and filtering. Tetramethyltin was received from Aldrich and its purity was checked by ^{1}H NMR spectroscopy. All the other reagents were of the highest commercial grade available and were used as received or were purified by distillation or recrystallization where necessary.

Instrumentation: ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded at 298 K on a Bruker AMX R-300 spectrometer operating with a broad-band probe at 300.13 and 75.7 MHz for ^{1}H and ^{13}C nuclei, respectively. Chemical shifts (δ, ppm) are referred to $SiMe_4$. UV/Vis spectra were measured on a Hewlett Packard mod. HP 8453 diode array spectrophotometer. Fluorescence and resonance light scattering experiments were performed on a Jasco mod. FP-750 spectrofluorimeter equipped with a Hamamatsu R928 PMT using, in this latter case, a synchronous scan protocol with a right-angle geometry.[17] Microanalysis was performed by Redox Analytical Laboratories, Milan, Italy. SEM was performed on a LEO S420 Cambridge instrument operating with an accelerating potential of 20 kV. The samples were prepared by graphite coating for the EDS analysis.

Lau$_2$dim: Didodecyldiimine (Lau$_2$dim) was prepared following a literature method used for other dialkyl diimines.[15] The solid compound was crystallized from methanol. Yield 75%. $C_{26}H_{52}N_2$ (392.7): calcd. C 79.51, H 13.36, N 7.14; found C 79.3, H 13.5, N 7.10. ^{1}H NMR ($CDCl_3$): δ = 7.9 (s, 2 H), 3.55 (t, $^3J_{H-H}$ = 6.9 Hz, 4 H), 1.65 (m, 4 H), 1.24 (m, 36 H), 0.85 (t, $^3J_{H-H}$ = 6.6 Hz, 6 H). ^{13}C NMR ($CDCl_3$): δ = 162 (CH), 61 (C_1-N), 32 (C_2-N), 30 (C_3-N), 29 (2C), 27 (3C), 22 (3C), 15 (CH_3). MS-EI: *m*/*z* = 391 [M − H$^+$]. M.p. 63 °C.

[Pt(Lau$_2$dim)Me(Me$_2$SO)](CF$_3$SO$_3$): The precursor [Pt(Lau$_2$dim)-Me(Me$_2$SO)](CF$_3$SO$_3$) was prepared using a slightly modified literature method.[14] A weighed amount of *trans*-[Pt(Me$_2$SO)$_2$MeCl][16] (40.2 mg, 0.1 mmol) was reacted in methanol (70 mL) with an equimolar amount of $AgCF_3SO_3$ and the ligand Lau$_2$dim. After stirring for 30 min, AgCl was removed by centrifugation. The solvents were then evaporated under reduced pressure, and the resulting yellow-orange solid was dissolved in dichloromethane and filtered through a cellulose column to remove residual AgCl. The compound was precipitated by adding diethyl ether and cooling to −30 °C. 58 mg of the complex were recovered. Yield 70%. $C_{30}H_{61}F_3N_2O_4PtS_2$ (830.0): calcd. C 43.41, H 7.41, N 3.37; found C 43.2, H 7.2, N 3.5. ^{1}H NMR ($CDCl_3$): δ = 8.87 (s, $^3J_{Pt-H}$ = 46 Hz, 1 H), 8.84 (s, $^3J_{Pt-H}$ = 83 Hz, 1 H), 3.99 (t, 2 H), 3.77 (m, 2 H), 3.36 (s, $^3J_{Pt-H}$ = 32 Hz, 6 H), 1.67 (m, 4 H), 1.24 (m, 36 H), 0.87 (t, $^3J_{H-H}$ = 6 Hz, 6 H), 0.79 (s, $^2J_{Pt-H}$ = 70.2 Hz, 3 H). ^{13}C NMR ($CDCl_3$): δ = 173 (CH), 166 (CH′), 120.4 ($^2J_{F-C}$ = 320 Hz, CF_3), 62.3, 59.3 (C_2 + $C_{2'}$), 45.5 ($^2J_{Pt-C}$ = 84 Hz, Me_2SO), 41,

40.5 (C_3 + $C_{3'}$), 32−26.22 (18 C), 14 (C_{12} + $C_{12'}$), −9.6 ($^1J_{Pt-C}$ = 700 Hz, CH_3). MS-FAB: *m/z* = 680 [$M^+ - CF_3SO_3$].

[Pt(Lau$_2$dim)Me]$_4$(TpyP)(CF$_3$SO$_3$)$_4$ (1): [Pt(Lau$_2$dim)Me(Me$_2$SO)](CF$_3$SO$_3$) (54 mg, 0.064 mmol) was added to a stirred solution of TpyP (10 mg, 0.016 mmol) in 25 mL of freshly distilled chloroform. The solution was allowed to react for 2 hours, and the solvent was then removed under reduced pressure. The resulting deep purple compound was dissolved in acetone and precipitated by adding diethyl ether and cooling to −30 °C (46 mg). Yield 80%. $C_{152}H_{246}F_{12}N_{16}O_{12}Pt_4S_4$ (3626.3): calcd. C 50.35, H 6.84, N 6.18; found C 50.01, H 6.50, N5.98. ^{1}H NMR ($CDCl_3$): δ = 9.14 (m, $^3J_{H-H}$ = 5.5 Hz, 8 H), 8.97 (s, 8 H), 8.85 (s, 4 H), 8.71 (s, 4 H), 8.45 (m, $^3J_{H-H}$ = 5.5 Hz, 8 H), 3.99 (m, 8 H), 3.85 (m, 8 H), 1.85−1.05 (m, 160 H), 0.86 (m, $^3J_{H-H}$ = 6 Hz, 24 H), 0.60 (s, 12 H), −3.00 (s, 2 H). MS (MALDI-TOF): *m/z* = 1972 [M − 2Pt − $CF_3SO_3^+$], 1220.8 [M − 3Pt − $CF_3SO_3^+$]. UV/Vis (acetone): λ_{max} (ε) = 422 (276000), 514, 550, 592, 648 nm. UV/Vis (on glass): λ_{max} = 431, 521, 555, 598, 650 nm. Fluorescence emission (acetone): λ_{exc} = 420 nm; λ_{em} = 654, 716 nm. Fluorescence emission (on glass): λ_{exc} = 420 nm; λ_{em} = 662, 720 nm.

Deposition on Glass: Microscope slides, cleaned prior to use by immersion in a 1:1 mixture of concentrated NH_3 solution and 30+% H_2O_2, then rinsed with Milli-Q water and dried under a steam of N_2, were used as film substrates. A droplet of a 10^{-5}−10^{-4} M solution of **1** in acetone or chloroform (Aldrich, Spectral grade) was placed on the substrate and evaporation was achieved by gentle spinning at 298 K.

Supporting Information Available (see footnote on the first page of this article): ^{1}H NMR titration of TpyP with the precursor platinum(II) complex (Figure S1), UV/Vis and fluorescence emission of **1** in acetone solution and on glass surface (Figure S2 and S3), optical images (1000× magnification) of different porphyrin complexes (Figure S4) and Energy Dispersion Spectrometry (EDS) profile on samples of **1** deposited on glass (Figure S5).

A Dinuclear Zinc(II) Complex of 2,6-bis{[(2-hydroxybenzyl)(2-pyridylmethyl)amino]methyl}-4-methylphenol Bearing an Exogenous Hydroxo Bridge

Harry Adams,[a] Darren Bradshaw,[a] and David E. Fenton*[a]

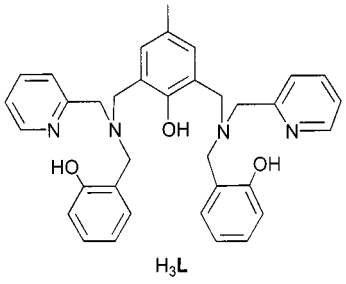
Keywords: N ligands / O ligands / Bridging ligands / Zinc

Reaction of the symmetrical proligand H_3L with zinc(II) perchlorate gives a product from which the cationic complex $[Zn_2L(OH_2)_3]ClO_4$ and the neutral complex $[Zn_2L(OH)]$ co-crystallise in the triclinic space group $P\bar{1}$, with unit cell parameters a = 14.7647(13), b = 16.9376(14), c = 17.8089(15) Å, α = 68.634(2)°, β = 71.356(2)°, γ = 87.526(2)°. The dinuclear zinc centre in $[Zn_2L(OH_2)_3]^+$ is endogenously bridged by a cresolato-O atom; in $[Zn_2L(OH)]$ this bridging mode is enhanced by an exogenous hydroxo bridge.

Introduction

The symmetric "end-off" compartmental proligand 2,6-bis{[(2-hydroxybenzyl)(2-pyridylmethyl)amino]methyl}-4-methylphenol (H_3L) has been used to generate homodinuclear donor asymmetric nickel(II) ethanoato- and coordination number asymmetric zinc(II) ethanoato complexes.[1] The crystal structures revealed the presence of a (μ-cresolato)(μ-ethanoato)-bridged dinuclear core in each complex with the (μ-cresolato) bridge endogenous and the (μ-ethanoato) bridge exogenous in nature. Noncoordinated ethanoic acid molecules were tightly hydrogen-bonded to the pendant phenols of the ligand generating a double acid salt of the type $[CH_3COO\cdots H\cdots L\cdots H\cdots OOCCH_3]^{3-}$ in the dinickel complex and a single acid salt of the type $[CH_3COO\cdots H\cdots L]^{3-}$ in the dizinc complex. In both cases the ligand periphery has been extended to provide a supraligand in which the donor potential of the original ligand has been enhanced.

The presence of a noncoordinating anion, rather than ethanoate, should inhibit the formation of an anion-based exogenous bridge and encourage interaction of the dinuclear core with the solvent. The reaction of H_3L with zinc perchlorate was therefore investigated and herein we report the effect of a noncoordinating anion on product formation together with the crystal structure of the product.



H_3L

Results and Discussion

H_3L was synthesized by modification of the method of Krebs et al.[2] and reacted with zinc(II) perchlorate in acetonitrile. Colourless crystals, suitable for X-ray structural determination, were obtained on standing. The crystal structure revealed that the cationic complex $[Zn_2L(OH_2)_3]ClO_4$ (**1**) and the neutral complex $[Zn_2L(OH)]$ (**2**) had co-crystallised. The molecular structures of the complexes are shown in Figures 1 and 2 with selected bond lengths and angles given in the captions to the figures. In addition to the complexes two disordered water molecules and a disordered acetonitrile molecule were present in the asymmetric unit.

The structure of complex **1** shows that the complex is coordination number asymmetric[3] with one zinc atom [Zn(1)] six-coordinate and the second [Zn(2)] five-coordinate. There is an endogenous cresolato bridge at the dinuclear centre but no exogenous bridge. Zn(1) is in a slightly distorted octahedral geometry with an N_2O_4 donor set derived from two ligand cresolato-O and pendant phenolato-O donor atoms [O(1) and O(2)], an articular tertiary aminic-N atom [N(1)], the pyridinyl-N atom [N(2)] and two *cis*-coordinated water molecules [O(4) and O(5)]. One water molecule is *trans* to the cresolato bridge and the other is *trans* to the articular tertiary amine as found at the six-coordinated metal atoms in the structure of the related dinickel(II) complex $[Ni_2L_A(OH_2)_4]\cdot CH_3COO^-\cdot C_3H_7NO\cdot 0.75H_2O$.[4] The three *trans*-axial angles at Zn(1) are 171.8

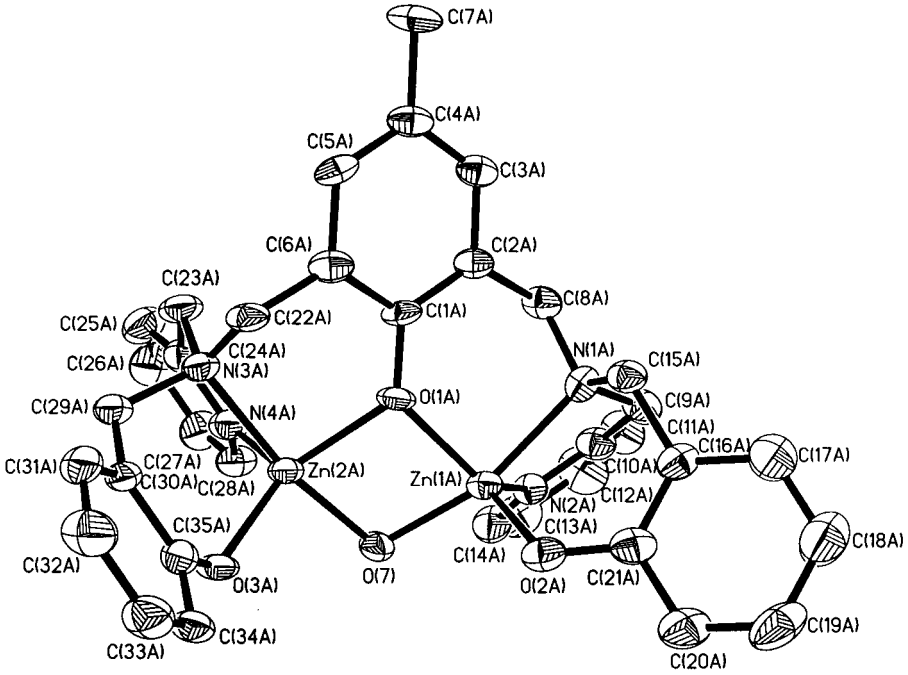

Figure 2. An ORTEP drawing of the molecular structure of $[Zn_2LOH]$ (**2**) showing the atom labelling; thermal ellipsoids for the non-hydrogen atoms are drawn at the 50% probability level; selected bond lengths (Å) and angles (°) at the zinc(II) atom: Zn(1A)−O(1A) 2.048(5), Zn(1A)−O(2A) 1.967(5), Zn(1A)−O(7) 1.990(5), Zn(1A)−N(1A) 2.179(6), Zn(1A)−N(2A) 2.107(6), Zn(2A)−O(1A) 2.066(5), Zn(2A)−O(3A) 1.989(5), Zn(2A)−O(7) 1.975(5), Zn(2A)−N(3A) 2.209(6), Zn(2A)−N(4A) 2.060(7), Zn(1A)−Zn(2A) 3.0696(13); O(7)−Zn(1A)−N(1A) 159.6(2), N(2A)−Zn(1A)−O(1A) 128.2(2), O(1A)−Zn(1A)−O(2A) 109.4(2), O(2A)−Zn(1A)−N(2A) 121.0(2), O(7)−Zn(2A)−N(3A) 169.3(2), O(1A)−Zn(2A)−O(3A) 130.4(2), O(3A)−Zn(2A)−N(4A) 115.8(2), N(4A)−Zn(2A)−O(1A) 112.8(2), Zn(1A)−O(1)−Zn(2A) 96.54(19), Zn(1A)−O(7)−Zn(2A) 101.5(2)

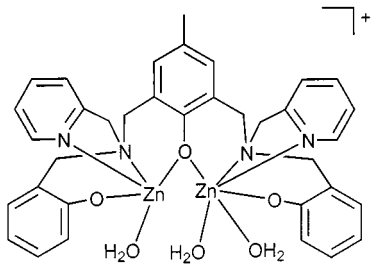
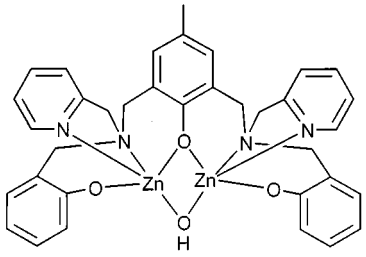
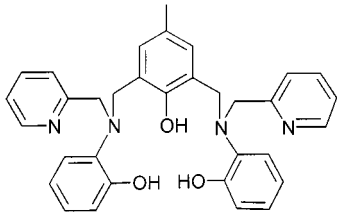


$[Zn_2L(OH_2)_3]^+$



$[Zn_2L(OH)]$



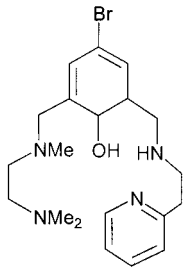
H_3L_A

[O(2)−Zn(1)−N(2)], 177.9 [O(5)−Zn(1)−N(1)] and 172.5° [O(4)−Zn(1)−O(1)].

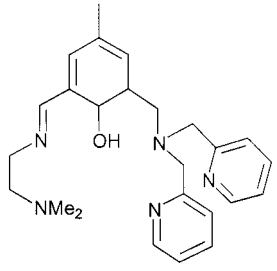
The second zinc atom, Zn(2), is five-coordinate with an N_2O_3 donor set derived from the bridging cresolato-O and pendant phenolato-O donor atoms [O(1) and O(3)], an articular tertiary aminic-N atom [N(3)], the pendant pyridinyl-N atom [(N4)] and one coordinated water molecule [O(6)]. The degree of trigonality (τ) at Zn(2) is 0.60 signifying a distortion towards a trigonal bipyramidal geometry [a perfect trigonal bipyramidal geometry has τ = 1 and a perfect square pyramidal geometry has τ = 0.5].[5] The largest angle at Zn(2) is O(6)−Zn(2)−N(3) (167.9°) indicating that the water molecule and the articular aminic-N atom occupy the axial positions.

The second complex in the asymmetric unit, $[Zn_2L(OH)]$ (**2**), is a neutral dinuclear species with a (μ-cresolato)(μ-hydroxo) core. Both zinc atoms are five-coordinate with N_2O_3 donor sets made up of a bridging cresolato-O atom, a pendant phenolato-O atom, a pyridinyl-N atom, an articular tertiary aminic-N atom and a bridging hydroxo-O atom. The τ values of 0.52 [Zn(1A)] and 0.65 [Zn(2A)] show that the geometries at the metals are intermediate between trigonal bipyramidal and square pyramidal geometry. The largest angles at the metals are 159.6° [O(7)−Zn(1A)−N(1A)] and 169.3° [O(7)−Zn(2A)−N(3A)] showing that the O atom of the exogenous hydroxo bridge is *trans* to the articular tertiary aminic-N atom in each case.

The absence of an exogenous bridge in the complex cation from **1** promotes an intermetallic separation, Zn(1)−Zn(2), of 3.62 Å which is longer than that generally found in complexes bearing a (μ-cresolato)(μ-ethanoato)-bridged dinuclear core (≈3.41 Å)[1,6] and this is mirrored by the open Zn(1)−O(1)−Zn(2) angle of 116.5°. The separation Zn(1A)−Zn(2A) in complex **2** is 3.07 Å which is considerably shorter than those found in complexes with exogenously bridged bidentate bridges.[7] This is accompanied by a narrowing of the cresolato bridging angle [Zn(1A)−O(1A)−Zn(2A): 96.5°] *cf.* 116.5° in complex **1**. The Zn−OH−Zn bridge is slightly asymmetric with Zn−O distances of 1.975(5) and 1.990(5) Å. The bond lengths and angles at the dinuclear centre in complex **2** are similar to those found in the structure of $[Zn_2L_BOH(NO_3)_2]$ derived from the unsymmetrical compartmental ligand HL_B and used in the functional mimicking of metallo-β-lactams.[6] In this molecule the bridging bond angles at the phenolate- and hydroxo-O atoms are 98.2° and 105.7° respectively and the inter-zinc separation is 3.11 Å.



HL_B



HL_C

In the crystal structures of dizinc(II)-containing metalloenzymes a water molecule or hydroxide anion shared by the zinc atoms frequently gives rise to a μ-hydroxo(*aqua*)-dizinc(II) motif[8,9] and the following metalloenzymes serve as representative examples: the metallo-β-lactamases from *Bacteriodes fragilis*[10,11] and *Stenotrophonomonas maltophilia*,[12] phospholipase C from *Bacillus cereus*,[13] P1 nuclease from *Penicillium citrium*[14] and bovine lens leucine aminopeptidase.[15,16] The first two examples have an unsupported water bridge and the Zn···Zn separation is approx. 3.5 Å, the next two examples are doubly bridged, by a water molecule and a bidentate carboxylato group, closing the Zn···Zn separation to approx. 3.3 Å. In the final example there is a triple bridge arising from a water molecule, a monodentate aspartate residue and a bidentate glutamate residue leading to a Zn···Zn separation of approx. 3.0 Å. Complex **2** has a double bridge constituted from two single oxygen atoms [(μ-cresolato)(μ-hydroxo)] and a Zn···Zn separation of 3.07 Å, and is thus similar to that found in bovine lens leucine aminopeptidase.

It is intriguing that the two complexes **1** and **2** co-crystallise and it is possible that conversion of **1** to **2** can occur if one of the polarisable water molecules on one Zn atom[17]

attacks the second Zn atom to displace bound water, thus forming the exogenous hydroxo bridge. Such an opportunity might also arise in the formation of μ-hydroxo bridges in dizinc(II)-containing metalloenzymes. A comparable co-crystallisation has been reported for the related complex $[Zn_2L_C(NCS)_3]$, derived from the phenol-based Schiff base compartmental ligand HL_C, in which one molecule has an exogenously bridging thiocyanate and two terminal thiocyanates, whereas the second molecule has no exogenous bridge and all three thiocyanates are terminal.[18]

Experimental Section

The Bulk Sample of $[ZnL]ClO_4 \cdot 3H_2O$: The proligand H_3L (133 mg, 0.24 mmol) was dissolved in warm CH_3CN (20cm^3) and $Zn(ClO_4)_2 \cdot 6H_2O$ (177 mg, 0. 48 mmol) added. The solution was refluxed gently for 1 h and then cooled to room temperature. Colourless crystals, suitable for X-ray structural analysis, were recovered on standing for one week. Yield: 154 mg (90%). MS (ES): *m*/*z* (%) = 687 (100) $[Zn_2L]^+$. IR (KBr disc): $\tilde{\nu}$ = 1609 cm^{-1} (C=N-pyr), 1572 (C=C-Ar), 1081 (ClO_4). $C_{35}H_{39}ClN_4O_{10}Zn_2$ (841.9): calcd. C 49.6, H 4.7, N 6.9, Cl 4.1; found C 49.9, H 4.7, N 6.7, Cl 4.1.

Caution! Although we have experienced no difficulties with the perchlorate salts they should nevertheless be regarded as hazardous and treated with care.

Crystal Data: $C_{72}H_{80}ClN_9O_{16}Zn_4$: M = 1624.38. Crystallises from CH_3CN as colourless blocks; crystal dimensions 0.28 × 0.15 × 0.06 mm^3. Triclinic, space group $P\bar{1}$, a = 14.7647(13), b = 16.9376(14), c = 17.8089(15) Å, α = 68.634(2)°, β = 71.356(2)°, γ = 87.526(2)°, U = 3916.3(6) Å^3, Z = 2, D_c = 1.377 Mg/m^3, Mo-K_α radiation (λ = 0.71073 Å), μ(Mo-K_α) = 1.312 mm^{-1}, F(000) = 1680. Data collected were measured on a Bruker Smart CCD area detector with an Oxford Cryosystems low temperature system at 150 K. Cell parameters were refined from the setting angles of 54 reflections (1.46 < θ < 28.32°). Reflections were measured from a hemisphere of data collected of frames each covering 0.3 degrees in omega. Of the 24262 reflections measured, all of which were corrected for Lorentz and polarisation effects and for absorption by semi-empirical methods based on symmetry-equivalent and repeated reflections (minimum and maximum transmission coefficients 0.7102 and 0.9254), 8804 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically, except those on O1W, and refined with a riding model (including torsional freedom for methyl groups) and with U_{iso} constrained to be 1.2 (1.5 for methyl groups) times U_{eq} of the carrier atom. Refinement converged at a final R_1 = 0.0822 ($wR2$ = 0.2186, for all 17770 data, 913 parameters, mean and maximum δ/σ 0.004, 0.175) with allowance for the thermal anisotropy of all non-hydrogen atoms. The $[ClO_4]^-$ anion was disordered and refined to an occupancy of 41.0:59.0%; two disordered water molecules [O(2W) and O(3W)] were refined to occupancies of 52.0:48.0 and 51.0:49.0% respectively, and a disordered CH_3CN molecule was refined to an occupancy of 54.0:46.0%. Minimum and maximum final electron density: −1.176 and 2.371 e·Å^{-3}. A weighting scheme $w = 1/[\sigma^2(F_0^2) + (0.1212P)^2 + 0.00P]$ where $P = (F_0^2 + 2F_c^2)/3$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXTL as implemented on a Viglen Pentium computer.[19]

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data centre as supplementary publication no. CCDC-171737. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Olefin-Metal π-Interactions of Mercury and Zinc Ions in Complexes of Neutral Quinolylcyclopentadiene Derivatives

Markus Enders,*[a] Gunter Ludwig,[a] and Hans Pritzkow[a]

Dedicated to Professor Walter Siebert on the occasion of his 65th birthday

Keywords: Mercury / Zinc / N ligands / π interactions

The donor-functionalised cyclopentadiene derivative **1** acts as a neutral chelate ligand and forms the zinc and mercury complexes **2** and **3** upon treatment with $HgCl_2$ or $ZnCl_2$. Due to the predefined geometry of **1**, the MCl_2 moieties are found in close proximity to the π-system of the cyclopentadiene. In the mercury compound **3** there is some evidence for a bond between the d^{10}-ion and the ring carbon atoms, although this is not conclusive. The zinc compound **2**, however, clearly shows an interaction between the metal atom and the cyclopentadiene fragment. At the same time the bond between the Cp ring and the Me_3Si group is weakened.

Introduction

Coordination compounds of d^{10}-metals with olefins are very common for Ni, Pd and Pt. The metal-olefin interaction is strengthened by back bonding of d-electrons into the anti-bonding olefin-π-orbitals. In d^{10}-metal ions with one or two positive charges, the d-orbitals are contracted and therefore the electrons in these orbitals are much less accessible for back bonding to π-acceptor ligands such as carbon monoxide or olefins. Therefore metal carbonyl or olefin complexes of group 11 cations or group 12 dications are much less common and are less stable than similar neutral group 10 compounds.[1] However, Hg^{2+} is known to interact with arenes and a few examples have been studied by X-ray diffraction.[2]

A metal ion can be fixed in proximity to an olefinic system by the judicious choice of rigid chelating ligands. With such ligands it is possible to study weak interactions between metal atoms and π-electrons. We report here the use of quinoline-functionalised cyclopentadiene derivatives for such investigations, as these ligands possess an adequate rigid geometry.

Results and Discussion

Previously we have found that quinoline-functionalised cyclopentadiene derivatives can bind transition metal atoms through the nitrogen donor and two carbon atoms of the cyclopentadiene ring.[3] Attempts to isolate similar compounds with d^{10}-metal cations have been unsuccessful. In order to increase the donor ability of the pentadiene system, the trimethylsilyl derivative **1** was used as a ligand. Compound **1** was described by us some time ago and it reacts with $TiCl_4$ or $ZrCl_4$ with elimination of Me_3SiCl and formation of η^5-cyclopentadienyl complexes.[4] The solid state structure of **1** has now been investigated and is shown in Figure 1. The Me_3Si group lies in the 3-position relative to the quinoline substituent. The bond C12−Si1 is relatively long [1.924(2) Å] compared to the same distance in other cyclopentadiene derivatives with a Me_3Si substituent [average value 1.88 Å].[5]

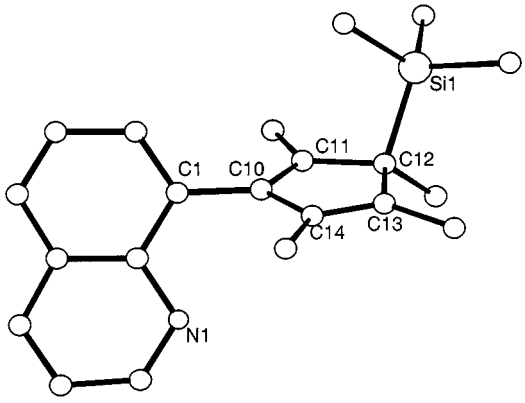

Figure 1. Solid-state structure of **1**; hydrogen atoms are omitted for clarity; selected bond lengths [Å]: C1−C10 1.482(2), C10−C11 1.357(2), C11−C12 1.504(2), C12−C13 1.508(2), C13−C14 1.352(2), C14−C10 1.464(2), C12−Si1 1.924(2), Si1−C_{Me} 1.863−1.869(2)

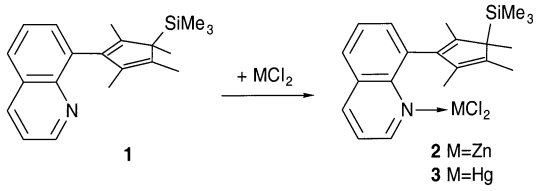
Compound **1** was treated with zinc dichloride and with mercury dichloride (Scheme 1). In analogy to the synthesis of titanium or zirconium complexes, the elimination of trimethylsilyl chloride was expected with formation of cyclopentadienyl half-sandwich complexes. In fact anhydrous $ZnCl_2$, which is insoluble in toluene, slowly dissolves in the presence of a solution of **1** in toluene. After stirring for 16 h a yellow precipitate was obtained in 75% yield. Addition of hexane to a dichloromethane solution of this new compound led to the formation of yellow crystals suitable for X-ray diffraction. However, the structure analysis showed that an addition product of $ZnCl_2$ and **1** had been formed rather than the expected half-sandwich compound (Figure 2).



Scheme 1. Formation of **2** and **3**

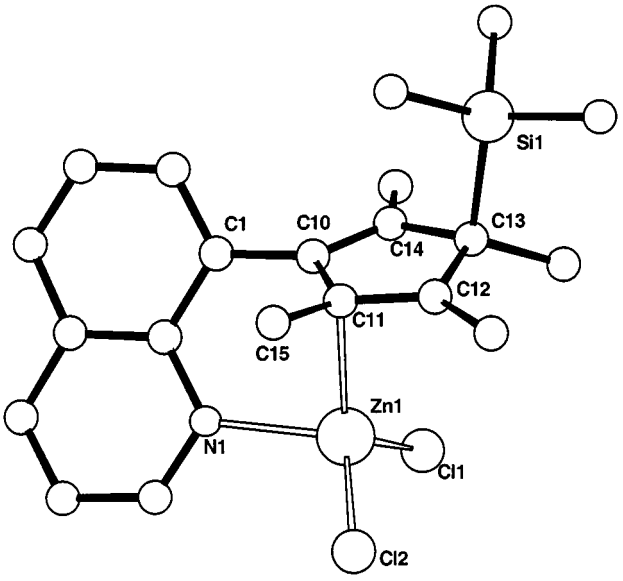


Figure 2. Solid-state structure of **2**; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: C1−C10 1.475(3), C10−C11 1.467(3), C11−C12 1.376(3), C12−C13 1.486(3), C13−C14 1.486(3), C14−C10 1.358(3), C13−Si1 1.985(3), Si1−C_{Me} 1.856−1.867(3) Zn1−N1 2.080(2), Zn1−C11 2.316(2), Zn1−C12 2.735(2), Zn1−C10 2.639(2), Zn1−Cl1 2.216(1), Zn1−Cl2 2.219(1); C11−Zn1−Cl1 123.6(1), C11−Zn1−Cl2, 106.7(1), C11−Zn1−N1 89.4(1), Cl1−Zn1−Cl2 117.9(1), C10−C11−C15 123.8(2), C10−C11−C12 108.2(2), C12−C11−C15 126.3(2).

The zinc atom is coordinated in a distorted tetrahedral manner by two chlorine atoms, the nitrogen donor and one sp^2-carbon atom of the cyclopentadiene ring. The coordination of the neutral carbocyclic ring to the zinc atom is confirmed not only by a carbon-zinc distance of 2.316(2) Å but also by the strong pyramidalisation of the $ZnLCl_2$ fragment (L = nitrogen donor). The ligand framework in **2** shows some differences from the solid state structure of the free ligand **1**. Due to the interaction of the carbon atom C11 with the zinc atom, the bonding vector C11−C15 does not lie in the plane defined by the cyclopentadiene system but forms an angle of 15°. The Si1−C13 bonding vector approaches an orthogonal orientation (76°) to the best plane of the cyclopentadiene ring. In addition, the Si1−C13 bond length [1.985(3) Å] is considerably longer than the respective silicon-carbon bonds in **1**. To the best of our knowledge, the interaction of a zinc atom with a neutral olefinic π-system has not been observed previously in the solid state.[5] Many compounds are known where anionic $C_5R_5^-$ ligands bind to Zn^{2+} ions. In $[Zn(\eta^2\text{-}C_5H_5)_2]_n$ one zinc atom is coordinated by three cyclopentadienyl ligands in an η^2 binding mode with one short (2.04−2.19 Å) and one long (2.42−2.48 Å) metal-carbon bond.[6]

The NMR spectra of **2** show a higher symmetry than in the solid state. The four methyl substituents of the five-membered ring give only two signals in the ^1H and ^{13}C NMR spectrum. This can only be explained by a dynamic process where the zinc atom and the Me_3Si group are changing their positions at the five-membered ring. We were not able to freeze out this process by cooling to lower temperatures (down to 170 K in the ^1H NMR spectrum at 200 MHz). The ^1H NMR spectrum of the ligand **1** exhibits four broad resonances at room temperature for the four methyl groups of the ring. A fast exchange occurs at higher temperatures.[4] The higher fluxionality of **2** compared to that of **1** shows the influence of the zinc-carbon interaction, which weakens the bond between the $SiMe_3$ group and the five-remembered ring.

The reaction between **1** and $HgCl_2$ leads to an orange yellow solution, from which yellow needles of the new compound **3** were obtained by addition of hexane. The NMR spectra of redissolved crystals showed signals indicating the presence of several different species in solution. The elemental analysis proves that **3** is an adduct of **1** with one equivalent of $HgCl_2$. The X-ray analysis reveals that two isomers — a monomer and a dimer — are present in the solid state. The molecular structure of the monomeric complex is shown in Figure 3.

The mercury atom is surrounded by one nitrogen, two chlorine and two carbon atoms of the cyclopentadiene ring. The coordinated sp^2-carbon atoms are interconnected by a single bond [C31−C35: 1.479(6) Å]. The interaction between the metal and the two carbon atoms, with distances of 2.957(4) and 3.000(5) Å, seems to be weak. The N2−Hg2−Cl3−Cl4 unit remains nearly trigonal planar, in contrast to the geometry in the zinc compound **2**. In the dimeric isomer shown in Figure 4, the coordination number at mercury is higher. Three chlorine ligands, the nitrogen donor and two carbon atoms of the cyclopentadiene are connected to the metal atom. The two sp^2-carbon atoms are part of an olefinic C−C double bond [C10−C11: 1.359(5) Å]. This double bond is not lengthened by the interaction with the Hg^{2+} ions and is practically equal to the corresponding C−C double bond in **1** [1.357(2)]. The dis-

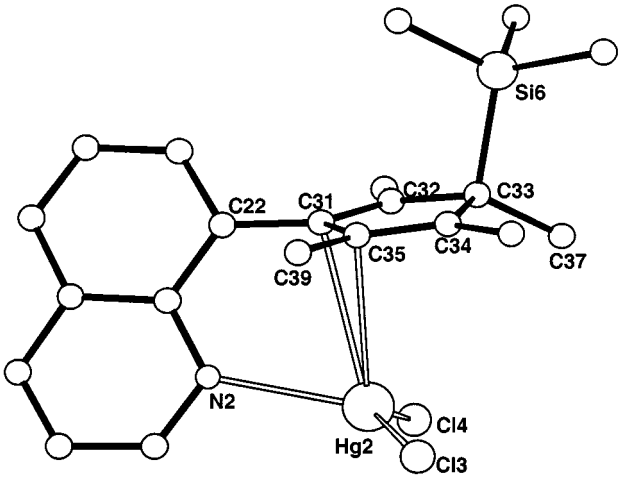

Figure 3. Part of the solid-state structure of **3** (monomeric Hg complex); hydrogen atoms are omitted for clarity; selected bond lengths[Å] and angles [°]: C22−C31 1.480(6), C31−C32 1.359(6), C32−C33 1.503(6), C33−C34 1.501(7), C34−C35 1.345(7), C35−C31 1.479(6), C33−Si6 1.956(5), Hg2−N2 2.391(4), Hg2−Cl3 2.356(1), Hg2−Cl4 2.358(1), Hg2−C31 2.957(4), Hg2−C35 3.000(5); N2−Hg2−Cl3 108.5(1), N2−Hg2−Cl4 110.5(1), Cl3−Hg2−Cl4 137.3(1)

tances between the mercury atoms and the linked carbon atoms are shorter in the dimeric compound (2.81 and 2.88 Å) than in the monomeric one (2.96 and 3.00 Å). In known Hg^{II}-arene complexes, the mercury-carbon distances vary considerably, from 2.56 Å[2a][2b] to 3.11 Å[2c][2d] and 3.33 Å.[2e]

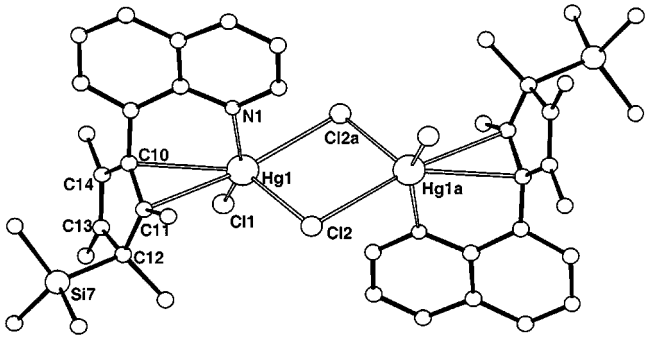

Figure 4. Part of the solid-state structure of **3** (dimeric Hg complex); hydrogen atoms are omitted for clarity; selected bond lengths[Å] and angles [°]: C10−C11 1.359(5), C11−C12 1.498(5), C12−C13 1.498(6), C13−C14 1.356(6), C14−C10 1.464(6), C12−Si7 1.949(4), Hg1−Cl1 2.365(1), Hg1−Cl2 2.549(1), Hg1−Cl2a 2.946(1), Hg1−Hg1a 3.985(1), Hg1−C10 2.813(4), Hg1−C11 2.879(4); Cl1−Hg1−Cl2 113.1(1), Cl1−Hg1−Cl2a 88.9(1), Hg1−Cl2−Hg1a 92.70, N1−Hg1−Cl1 151.1(1)

A comparison of the positions of the $SiMe_3$ groups in the solid-state structures of **1**, **2** and **3** shows significant differences. The C_{Cp}−Si bond lengths become longer when going from **1** to **3** and to **2** [1.924(2), 1.949(4), 1.985(3), respectively]. The value for the zinc compound **2** is much larger than for a normal Si−C bond. In addition, the angles between the Si−C_{Cp} bonding vectors and the corresponding planes of the five-membered rings become larger in the same order (**1**: 62°, **3**: 71°, **2**: 76°). As other Lewis acids such as $TiCl_4$ react with **1** with substitution of the $SiMe_3$ group, the compounds **3** and **2** may be described as snapshots of this electrophilic substitution reaction where the metal fragment attacks from one face of the five-membered ring and the $SiMe_3$ group is released at the other face.

Experimental Section

All reactions were carried out under a nitrogen or argon atmosphere. Compound **1** was prepared by the reported procedure.[4]

2: A total of 300 mg (0.93 mmol) of the trimethylsilyl derivative **1** was added to a suspension of zinc(II)chloride (130 mg, 0.95 mmol) in 30 mL of toluene. The solution was stirred for 16 hours. The resulting yellow precipitate was separated by filtration and dried in vacuum. The solid was dissolved in dichloromethane and layered with 10 mL of hexane. Compound **2** crystallised from the hexane phase at −30 °C as yellow cubes, which were suitable for X-ray analysis. Dichloromethane, which is present in the single crystals, was removed by pulverising the solid and evaporation under vacuum. Yield 310 mg (0.68 mmol, 72%). ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 0.12 [s, 18 H, $Si(CH_3)_3$], 1.83 (s, 6 H, Cp-CH_3), 1.99 (s, 6 H, Cp-CH_3), 7.66−7.75 (m, 3 H), 7.80−8.02 (m, 1 H), 8.57 (d, $J_{H,H}$ = 6.0 Hz, 1 H), 8.96 (d, $J_{H,H}$ = 3.2 Hz, 1 H). ^{13}C {^{1}H} NMR (75 MHz, CD_2Cl_2): δ = −2.53 [$Si(CH_3)_3$], 13.6 (Cp-CH_3), 14.0 (Cp-CH_3), 122.6, 128.5, 128.6, 133.0, 141.5, 151.3 ($CH_{quinoline}$). MS (EI): *m*/*z* (%) =322 (2) [$Cp^QSiMe_3^+$], 306 (5) [$Cp^QSiMe_2^+$], 249 (41) [Cp^QH^+], 108 (51) [$ClSiMe_3^+$], 93 (100) [$ClSiMe_2^+$], 74 (84) [$SiMe_3^+$], 65 (64) [Zn^+].

3: A total of 360 mg (1.12 mmol) of the trimethylsily-derivative **1** was added to a suspension of mercury(II)chloride (320 mg, 1.19 mmol) in 20 mL of toluene. The solution was stirred for 48 hours and the resulting orange solid was separated by filtration. The yellow solution was concentrated and layered with 10 mL of hexane. Compound **3** crystallised as bright yellow needles from the hexane phase, which were suitable for X-ray analysis; yield 320 mg (0.54 mmol, 48%). MS (FAB): *m*/*z* (%) = 558 (6) [M^+ − Cl], 322 (100) [$Cp^QSiMe_3H^+$], 248 (80) [Cp^{Q+}], 147 (55). $C_{21}H_{27}Cl_2HgNSi$ (593.03): calcd. C 42.53, H 4.59, N 2.36; found C 42.76, H 4.60, N 2.37.

Crystal Structure Determinations:

1: $C_{21}H_{27}NSi$, monoclinic, $P2_1/c$, a = 13.5835(9), b 16.3449(11), c = 8.6546(6) Å, β = 101.0150(10)°, V = 1886.1(2) Å^3, Z = 4, $d_{calcd.}$ = 1.132 g cm^{-3}, 4491 reflections, 316 parameters, $R1$ = 0.0445, $wR2$= 0.129.

2·1/2CH_2Cl_2: $C_{21.5}H_{28}Cl_3NSiZn$, monoclinic, $C2/c$, a = 34.954(17), b = 8.414(4), c = 17.501(9) Å, β = 113.07(2)°, V = 4735(4) Å^3, Z = 8, $d_{calcd.}$ = 1.403 g cm^{-3}, 4163 reflections, 361 parameters, $R1$ = 0.0285, $wR2$ = 0.0656.

3: $C_{21}H_{27}Cl_2HgNSi$, triclinic, $P\bar{1}$, a = 10.5069(2), b = 13.9186(2), c = 15.7285(3) Å, α= 85.213(1), β = 78.735(1), γ = 88.288(1)°, V = 2247.76(7) Å^3, $d_{calcd.}$ = 1.752 g cm^{-3}, 10594 reflections, 486 parameters, $R1$ = 0.0305, $wR2$ = 0.0791.

Data were collected on a Siemens Stoe AED2 (−70 °C, **2**) or on a Bruker AXS SMART1000 (−85 °C **1**, −100 °C **3**) diffractometer equipped with Mo-K_α radiation and in the ω-scan mode. An empirical absorption correction was applied. The structures were solved by direct methods (SHELXS-86 [7]) and refined by full-matrix least-squares techniques (SHELXL-93 [7]) based on F^2 using all

measured reflections and with anisotropic temperature factors for all non-hydrogen atoms. The hydrogen atoms were located and refined isotropically for **1** and **2**, for **3** they were inserted in their calculated positions.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-168388 (**1**), -16389 (**2·1/2CH_2Cl_2**) and -168390 (**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank Professor W. Siebert for his generous support over the years.

Self-Assembly of a Chiral Three Dimensional Architecture Composed of Two Different Silver(I) Helical Chains Connected by Bitopic Tris(pyrazolyl)methane Ligands

Daniel L. Reger,*[a] Radu F. Semeniuc,[a] and Mark D. Smith[a]

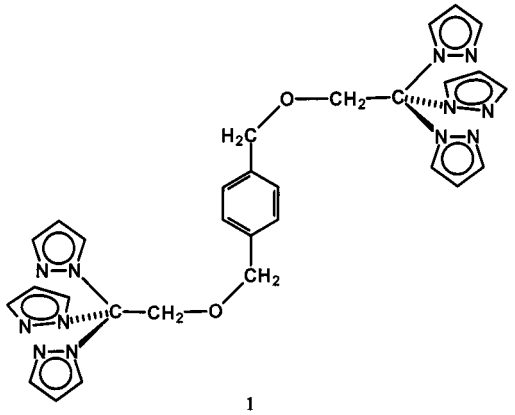
Keywords: Helical structures / Ligand design / Silver / Self-assembly

The coordination polymer $\{p\text{-}C_6H_4[CH_2OCH_2C(pz)_3]_2\text{-}Ag_2(BF_4)_2\}_n$ contains two opposite chirality metallohelicates, formed by a κ^2, κ^1 bonding arrangement of each tris(pyrazolyl)methane unit, that are linked with the bitopic ligand into 2D sheets. The 3D supramolecular structure is formed by C–H···F weak hydrogen bonds that also order the solvent molecules.

Helical structures have received increasing attention because of their structural similarities to nucleic acids and proteins. Potential applications, such as asymmetric catalysis and nonlinear optical materials,[1] have also increased the interest in the synthesis and characterization of these types of structures. Helical organization has been driven by the formation of covalent bonds in metal complexes[1a,2] and intermolecular forces, mainly hydrogen bonding.[3] Most known structures consist of discrete molecules or ions,[1a,1b,4] although examples of coordination polymers with helical structures are also known.[2,5] We report here a unique supramolecular architecture formed by using a new bitopic ligand to link two different metallohelicates having opposite chirality.

We are developing supramolecular chemistry using a new class of multitopic ligands, formed from linking two or more tris(pyrazolyl)methane units[6] in a single molecule, a study made possible by our recent progress on the preparation and reaction chemistry of tris(pyrazolyl)methane ligands.[7] Our first example is $p\text{-}C_6H_4[CH_2OCH_2C(pz)_3]_2$ (**1**, Scheme 1). This ligand was designed to have the unique capability of linking metals into chiral polymer chains with a κ^2, κ^1 bonding arrangement while also linking these chains with the flexible side arms of a 1,4-bis(ethoxymethyl)benzene bridge.

The reaction of $p\text{-}C_6H_4[CH_2OCH_2C(pz)_3]_2$ with $AgBF_4$ in a 1:2 ratio in THF yields $\{p\text{-}C_6H_4[CH_2OCH_2C(pz)_3]_2Ag_2(BF_4)_2\}_n$ (**2**), a coordination polymer that contains two types of bridged helical chains. Crystals of **2** suitable for X-ray diffraction[8] were grown by vapor-phase diffusion of Et_2O into an acetonitrile solution. The left side of Figure 1 shows a drawing of one of the two polymer chains. Each Ag(1) is three-coordinate, κ^2-bonded to a tris(pyrazolyl)methane unit in one ligand and κ^1-bonded to a second from a different ligand, forming polymer chain **1**. The polyhedron involving the Ag(1) atom is a flattened trigonal pyramid [sum of the N–Ag(1)–N bond angles = 347°], with a significant distortion caused by the restricted angle [83.43(11)°] of the κ^2-bonded ligand.



1

Scheme 1. 1,4-Bis[tris(pyrazolyl)ethoxymethyl]benzene

The right side of Figure 1 shows a drawing of the polymer chain formed by Ag(2). Each Ag(2) is four-coordinate. As with Ag(1), each silver(I) is κ^2-bonded to one tris(pyrazolyl)methane unit and κ^1-bonded to a second, forming polymer chain **2**. In addition, there is an acetonitrile molecule bonded to each Ag(2). The polyhedron involving the Ag(2) atom is a distorted tetrahedron with a large distortion caused by the restricted angle [77.40(11)°] of the κ^2-bonded ligand. The CH_3CN molecules bonded to the Ag(2) atoms are alternatively above and below the chain, as pictured (see also Figure 3b).

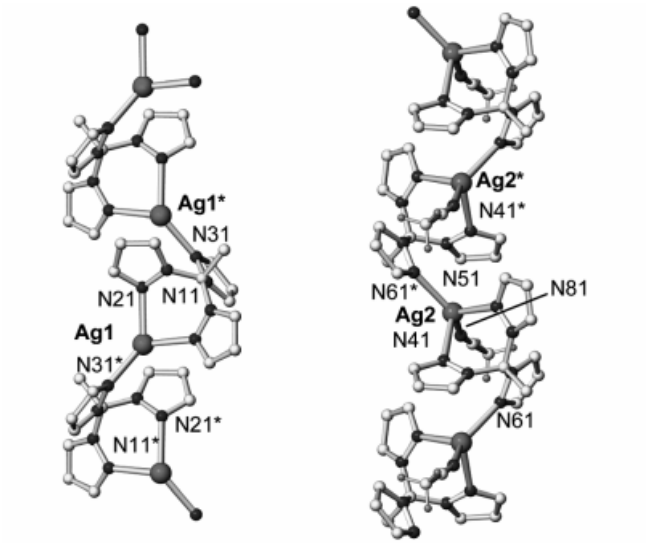

Figure 1. (a) Partial structure of **2** showing the polymeric chain formed by Ag(1); selected bonds (Å) and angles (deg.) are as follows: Ag(1)−N(11) 2.269(3), Ag(1)−N(21) 2.283(3), Ag(1)−N(31*) 2.196(4), N(11)−Ag(1)−N(21) 83.43(11), N(11)−Ag(1)−N(31*) 127.50(13), N(21)−Ag(1)−N(31*) 136.16(12); (b) the polymeric chain formed by Ag(2); selected bonds (Å) and angles (deg.) are as follows: Ag(2)−N(41) 2.405(3), Ag(2)−N(51) 2.380(3), Ag(2)−N(61*) 2.292(3), Ag(2)−N(81) 2.206(4), N(41)−Ag(2)−N(51) 77.40(11), N(41)−Ag(2)−N(61*) 107.07(11), N(41)−Ag(2)−N(81) 103.48(12), N(51)−Ag(2)−N(61*) 102.77(11), N(51)−Ag(2)−N(81) 124.19(13), N(61*)−Ag(2)−N(81) 128.28(12)

Figure 2 shows a space filling model of the backbone of both silver chains. In both cases the arrangement of the backbone is helical, but the chirality of each is opposite. Both helices are generated around crystallographic 2_1 screw axes along the *a* axis of the unit cell. For both, the distance between every other silver atom is equal and identical to the length of the *a* axis of the unit cell, 10.282 Å, making the pitches of both helicates identical.

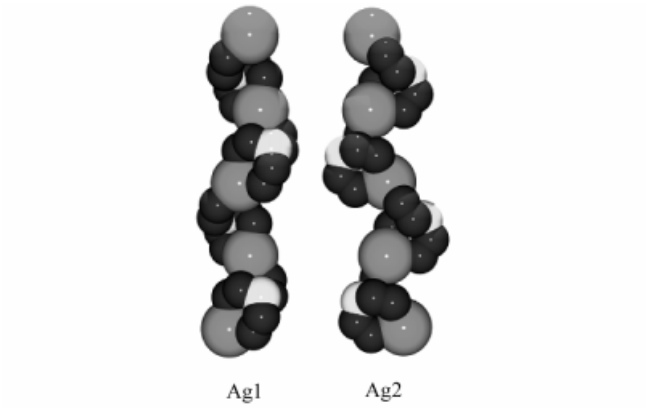

Figure 2. Space filling representation of the backbone of both silver chains, showing the helical arrangement; for the sake of clarity all atoms not directly related to the backbone chains have been omitted; the acetonitrile molecule is also excluded in the Ag(2) case

Figure 3a is a view perpendicular to the network formed by the alternating helical chains. The helical chains are connected by the 1,4-bis(ethoxymethyl)benzene bridging units with the ether groups in each ligand oriented on opposite sides of the aromatic ring. Although this part of the network is two dimensional, the structure has thickness. Figure 3b is the view in the same alignment of chains as in Figure 3a, viewed parallel to the network, showing two U-shape channels formed between the silver strands by the 1,4-bis(ethoxymethyl)benzene bridge. The dimensions of the channels are 5.8 × 3.6 Å, measured between the two methylene groups directly bonded to the phenyl ring and between these methylene groups and the central methine carbon atoms from the tris(pyrazolyl)methane units. There is also a cavity formed along the strand formed by the three-coordinate Ag(1) because of the parallel orientation of the flattened trigonal pyramids.

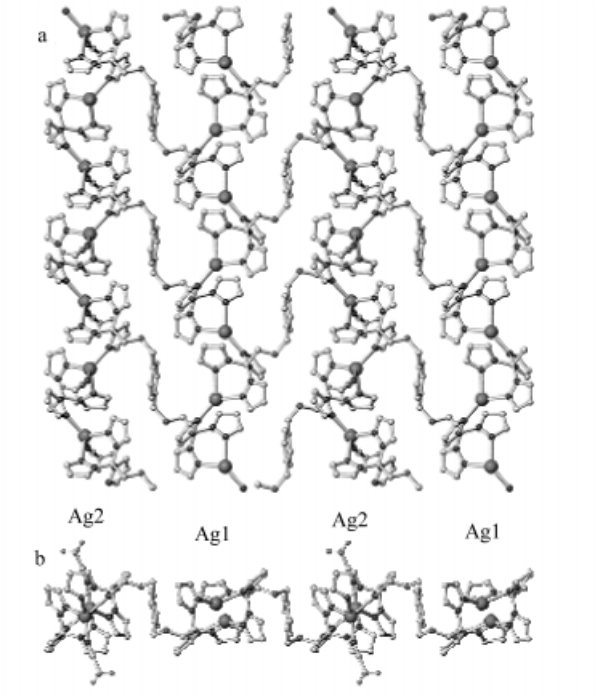

Figure 3. View perpendicular (a) and parallel (b) to the sheets formed by the alternating silver chains

Figure 4 shows that the 2D network (viewed as in Figure 3b) formed by the helical chains and the connecting organic bridges is arranged into a 3D supramolecular structure by weak C−H···F hydrogen bonds. One of the two nonequivalent BF_4^- ions makes four hydrogen bonds with two of the 2D sheets forming the 3D architecture. Two of the bonds, one to each sheet, are very short at 2.262 and 2.290 Å. The average C−H···F bond length of 2.326 Å is significantly shorter than the sum of the van der Waals radii for H and F atoms (2.54 Å)[9] and other known cases of this type of interaction,[10] where the reported values are close to 2.5 Å. The second BF_4^- ion makes two hydrogen bonds, one to each of two sheets, at a distance of 2.302 and 2.353 Å.

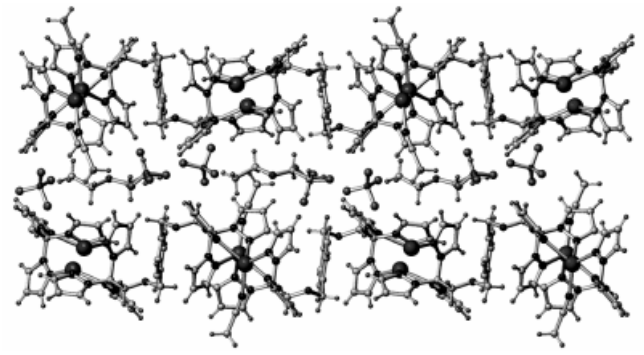

Figure 4. Two sheets held together through C−H···F bonds, forming a 3D architecture

An additional important structural feature is that the solvent molecules are held between the helical layers in a very ordered fashion by weak hydrogen bonds, an unusual observation for helical superstructures.[1a] As pictured in Figure 4, each diethyl ether molecule is bonded through one terminal methyl group to the BF_4 counter-ion that makes four hydrogen bonds (C−H···F separation is 2.362 Å, with the corresponding angle of 142.48°) and also through the ether oxygen atom to a coordinated acetonitrile (C−H···O separation is 2.557 Å with corresponding angle = 150.05°).

We plan to develop these chiral polymers as useful materials in the field of stereospecific synthesis or asymmetric catalysis.[11] The dual chiral material reported here is made using inexpensive and readily available materials. The potential applications of our compounds are increased by the observation of the ordered solvent molecules. Future work will determine the influence of the solvent and the counter-ion on the overall structure. We are also studying the diversity of the supramolecular structures that arise from small changes in the structure of the ligand (for example, by using *ortho*-xylene in the bridge instead of *para*-xylene).

Experimental Section

p-$C_6H_4[CH_2OCH_2C(pz)_3]_2$ (1): α,α′-Dibromo-*p*-xylene, *p*-$(BrCH_2)_2$-C_6H_4, (2.64 g, 0.010 mol) and tris-2,2,2-(1-pyrazoyl)ethanol,[7] HO-CH_2-$C(pz)_3$, (4.88 g, 0.020 mol) were dissolved in dry THF (125 mL). This solution was added dropwise to a suspension of NaH (1.5 g) in dry THF (300 mL) under an inert atmosphere. The mixture was stirred under reflux for 24 h and then allowed to cool at room temperature. Enough water (150 mL) was added dropwise to consume the excess NaH and dissolve the resulting NaBr and NaOH. The THF/water mixture was extracted with ethyl ether (3 × 100 mL), the combined organic extracts were washed with 100 mL saturated $NaHCO_3$ solution, with 100 mL saturated NaCl solution and finally with 100 mL water. The organic layer was dried over anhydrous Na_2SO_4, filtered and the solvent removed under vacuum to afford the desired compound as a white-yellow powder (5.38 g, 0.0091 mol, 91%). M.p. 128−129 °C. ^{1}H NMR (300 MHz, [D$_6$]acetone): δ = 7.59, 7.49 (m, 3,3 H, 3,5-H *pz*), 7.18 (s, 2 H, *C_6H_4*), 6.35 (m, 3 H, 4-H pz), 5.11 (s, 2 H, O*CH_2*Ph), 4.54 [s, 2 H, O*CH_2*C(pz)$_3$]. $C_{30}H_{30}N_{12}O_2$ (590.6): calcd. C 60.96, H 5.08; found C 61.06, H 4.98.

{p-$C_6H_4[CH_2OCH_2C(pz)_3]_2Ag_2(BF_4)_2$}$_n$ (2) $AgBF_4$ (0.195 g, 1.0 mmol) was dissolved in THF (15 mL) under an inert atmosphere. With vigorous stirring, a solution of *p*-$C_6H_4[CH_2OCH_2C(pz)_3]_2$ (0.295 g, 0.50 mmol) in THF (15 mL) was added dropwise during a 10 min period. A white precipitate appeared as the mixture was stirred for 3 h. The THF was removed by cannula filtration, the white precipitate washed with THF (2 × 10 mL) and then vacuum dried to afford 0.475 g of solid identified as {p-$C_6H_4[CH_2OCH_2C(pz)_3]_2Ag_2(BF_4)_2(THF)$}$_n$, m.p. 163−166 °C with decomposition. ^{1}H NMR ([D$_6$]acetone): δ = 7.82, 7.77 (m, 3,3 H, 3,5-H *pz*), 7.09 (s, 2 H, *C_6H_4*), 6.57 (m, 3 H, 4-H *pz*), 5.02 (s, 2 H, O*CH_2*Ph), 4.67 [s, 2 H, O*CH_2*C(pz)$_3$], 3.62 (m, 2 H, *CH_2*O THF), 1.92 (m, 2 H, *CH_2* THF). $C_{30}H_{30}Ag_2B_2F_8N_{12}O_2{\cdot}C_4H_8O$ (1051.1): calcd. C 38.81, H 3.64; found C 38.86, H 3.55. ES$^+$/MS: calcd. for $[C_{30}H_{30}N_{12}O_2Ag]^+$ 697.1666; found 697.1683.

A New Family of Supramolecular Complexes with 3D Cationic Hg/Z Frameworks, SnX_3^- Guest Anions (Z = P, As, Sb; X = Cl, Br, I): Crystal Structures and Host−Guest Interactions

Andrei V. Olenev,[a] Alexei I. Baranov,[b] Andrei V. Shevelkov,*[a] and Boris A. Popovkin[a]

Keywords: Host-guest systems / Tin / Supramolecular chemistry / Mercury / Ab initio calculations / Pnicogens

Five new inorganic supramolecular complexes, $[Hg_6P_4Cl_3](SnCl_3)$ (**I**), $[Hg_6As_4Cl_3](SnCl_3)Hg_{0.13}$ (**II**), $[Hg_6As_4Br_3](SnBr_3)$ (**III**), $[Hg_6Sb_4I_3](SnI_3)Hg_{0.16}$ (**IV**), and $[Hg_7P_4Br_3](SnBr_3)$ (**V**), have been prepared and their structures determined by X-ray single crystal experiments. They all crystallize in the cubic space group $P2_13$ (No 198) with $Z = 4$, and unit cell parameters $a = 11.865(1)$ (**I**), 12.233(1) (**II**), 12.383(1) (**III**), 13.285(2) (**IV**), and 12.490(1) Å (**V**). The crystal structures of these compounds are composed of the 3D positively charged frameworks $[Hg_6Z_4X_3]^+$ (**I**–**IV**) or $[Hg_7P_4Br_3]^+$ (**V**), with SnX_3^- anions trapped in the larger cavities of the frameworks (X = Cl, Br, I; Z = P, As, Sb). In the structures of **II** and **IV** the smaller cavities are partly filled by mercury atoms. The structures of **I**–**V** and of previously reported $[Hg_7As_4I_3](SnI_3)$ (**VI**) are discussed with respect to the matching and mutual adjusting of the host frameworks and guest anions. A comparison of the observed and calculated (ab initio, RHF level) geometry of the SnX_3^- anions is used to analyze the weak host–guest interactions.

Introduction

Supramolecular inorganic compounds possess a huge variety of crystal structures and physical properties.[1] Among them a group of phases can be distinguished in which the three dimensional (3D) positively charged host framework is built up of linearly coordinated mercury and tetrahedrally coordinated pnicogen atoms.[2] Halometallate anions — guests of different shapes and sizes — reside in the cavities of the frameworks. These compounds may be exploited as convenient systems for the investigation of the role of the host-guest interactions in the formation and crystal structure organization of inorganic supramolecular architectures in which both host and guest fragments are electrically charged. For this purpose, a group of related phases with similar crystal structures should be used. In our previous work[2e] we reported on a novel supramolecular complex $[Hg_7As_4I_3](SnI_3)$ in which the cationic framework encapsulates the SnI_3^- anion. It therefore seemed obvious that different SnX_3^- anions (X = Cl, Br and I) may serve as templates for the formation of new Hg−Z (Z = P, As, Sb) cationic frameworks. We have performed a systematic search for such compounds, and here we report on the crystal structures of five new supramolecular phases: $[Hg_6P_4Cl_3](SnCl_3)$ (**I**), $[Hg_6As_4Cl_3](SnCl_3)Hg_{0.13}$ (**II**), $[Hg_6As_4Br_3](SnBr_3)$ (**III**), $[Hg_6Sb_4I_3](SnI_3)Hg_{0.16}$ (**IV**) and $[Hg_7P_4Br_3](SnBr_3)$ (**V**). The significant amounts of the materials isolated makes it possible to discuss the relationship between the structural organization of the title compounds and the host-guest complementarity.

Results and Discussion

The new compounds were obtained by a standard ampoule technique (see Exp. Sect. for details) exploiting the synthetic conditions previously reported for a similar compound.[2e] As a result of a systematic search for new phases in the Hg−Z−Sn−X systems performed in this and our previous[2e] work, six supramolecular compounds have been prepared (Table 1).

Table 1. Host-guest phases in the Hg−Z−Sn−X systems (cubic cell parameter a in Å, space group $P2_13$)

	Cl	Br	I
P	$[Hg_6P_4Cl_3](SnCl_3)$ (**I**), Type 1[a] $a = 11.865(1)$	$[Hg_7P_4Br_3](SnBr_3)$ (**V**), Type 2[b] $a = 12.490(1)$	not found
As	$[Hg_6As_4Cl_3](SnCl_3)Hg_{0.13}$ (**II**), Type 1 $a = 12.233(1)$	$[Hg_6As_4Br_3](SnBr_3)$ (**III**), Type 1 $a = 12.383(1)$	$[Hg_7As_4I_3](SnI_3)$ (**VI**), Type 2 $a = 13.110(1)$
Sb	not found	not found	$[Hg_6Sb_4I_3](SnI_3)Hg_{0.16}$ (**IV**), Type 1 $a = 13.285(2)$

[a] Type 1 framework: $[Hg_6Z_4X_3]^+$. [b] Type 2 framework: $[Hg_7Z_4X_3]^+$.

The crystal structures of the five new phases prepared in this work were determined by means of single crystal X-ray diffraction (Table 2). Selected interatomic distances and bond angles are given in Table 3−7. All the reported compounds have a similar structural organization. Their crystal structures are composed of a 3D cationic host framework, built up of linearly coordinated mercury and tetrahedrally coordinated pnicogen atoms, and additional halogen atoms, and have two types of closed cavities of different sizes. The SnX_3^- guest anions are encapsulated in the larger cavities of the host framework (Figure 1). In all cases the separation between the halogen atoms of the guest anion and the mercury atoms of the host framework is much larger than the sum of the covalent radii of the respective elements — a feature that is characteristic of host-guest compounds. In the structures of **II** and **IV** the smaller cavities are partly filled by mercury atoms.

Despite the similarity of the reported compounds (the same $P2_13$ space group and the same type of guest anion) they possess two types of host frameworks with the general formulae $[Hg_6Z_4X_3]^+$ (**I**−**IV**) and $[Hg_7Z_4X_3]^+$ (**V**). The latter has the same structure as in the earlier reported compound $[Hg_7As_4I_3](SnI_3)$ (**VI**).[2e] The cationic framework of **V** contains two types of phosphorus atoms. While P(1) and P(2) are tetrahedrally coordinated by mercury atoms, P(3) and P(4) are joined into P_2^{4-} dumbbells, such that their nearest neighbors are one phosphorus and three mercury atoms. Compounds **I**−**IV** have frameworks of a different type, where all the pnicogen atoms are joined into Z_2^{4-} dumbbells. The structure of the host framework is closely related to that found in $[Hg_6As_4](HgBr_6)Hg_{0.4}$ [2b] and $[Hg_6As_4](M^{III}X_6)X$ (X = Cl, Br),[2f,2g] the only difference being that in the compounds reported here the additional halogen atoms modify the framework. The Hg−Z and Z−Z interatomic distances within the frameworks [d(Hg−P) = 2.37−2.45 Å; d(Hg−As) = 2.50−2.52 Å; d(Hg−Sb) = 2.67−2.69 Å; d(P−P) = 2.18 Å; d(As−As) 2.38−2.42 Å; d(Sb−Sb) = 2.76−2.80 Å] are in good agreement with those found in numerous mercury pnictide halides.[2,3]

Table 3. Selected interatomic distances and bond angles for **I**

Distances [Å]	
Sn−Cl(2)	2.615(10) ×3

Hg(2)−P(2)−Hg(2)	110.1(4) ×3
P(2)−P(3)−Hg(1)	111.5(4) ×3
Hg(1)−P(3)−Hg(1)	107.3(4) ×3
P(1)−P(4)−Hg(2)	110.4(4) ×3
Hg(2)−P(4)−Hg(2)	108.5(4) ×3

The SnX_3^- anions residing in the larger cavities of the frameworks are formed by the unique tin and X(2) atoms and have the shape of a trigonal pyramid with the tin atom at the vertex. Such a geometry of the anions is in an agreement with the Gillespie−Nyholm rules:[4] the three halogen atoms and the lone electron pair of the Sn^{2+} cation form a pseudo-tetrahedron around the tin atom, the X−Sn−X angles being smaller than regular tetrahedral.

Table 2. Data collection and structure refinement parameters for **I**−**V**; space group $P2_13$, $Z = 4$, $\lambda = 0.71073$ (Mo-K_α)

The interesting feature of **II** and **IV** is that the additional mercury atoms partly occupy small cavities of the host framework. The coordination sphere of such a guest consists of 10 neighbors [3X(1), 1Z, 3Hg, and 3X(2) atoms]. The high coordination number of these mercury atoms, together with the large distances in their first coordination sphere (3.11−3.79 Å), indicate their low oxidation state. Mercury atoms serving as clathrated guests have already been observed in $[Hg_6As_4](HgCl_6)Hg_{0.4}$ [2a] where a zero oxidation state of the guest mercury was confirmed by means of solid state ^{199}Hg NMR spectroscopy.[5] It is not yet clear what factors control the population of mercury atoms in the smaller cavities of different frameworks. The results of this research suggest that the occupancies are only slightly different for **II** and **IV** (13 and 16%, respectively), the composition being confirmed by the stoichiometric synthesis of the phase-pure sample only in the former case, and differ significantly from the 40% population in $[Hg_6As_4](HgCl_6)Hg_{0.4}$ [2a] and 60% population in $[Hg_6As_4](FeBr_6)Hg_{0.6}$.[6] It could be that the population is sensitive both to the synthetic conditions and to the extent of the host-guest mismatch; this is currently being investigated.

As was described above, the SnX_3^- anions encapsulated in the framework cavities are not covalently bonded to the host structure (Figure 2), the host-guest interactions being limited to very weak electrostatic forces. Having a family of phases with similar crystal structures, we can now estimate

how these weak interactions influence the structural organization and formation of these compounds. As a first step, we shall discuss the problem of size matching between the cavity of the cationic framework and the guest anion, as well as the slight structural changes in the host structure that this mismatch may cause. Then we shall show how the cavity configuration influences the geometry of the guest anion through weak electrostatic forces. It should be noted that the quality of the structural data differs from one compound to another — as can be seen from Table 2 — the structures of the compounds **I** and **V** being less accurate. However, since the discussion of the host-guest interaction is semi-quantitative, the achieved accuracy of the structural data seems to be sufficient.

In the structures of **I** and **II**, the same $SnCl_3^-$ ion occupies the cavities of the $[Hg_6P_4Cl_3]^{1+}$ and $[Hg_6As_4Cl_3]^{1+}$ host frameworks. Evidently, the two frameworks possess cavities of different size (smaller in **I** than in **II**) to trap the same anion. This means that the size of the cavity may vary within a certain range, whilst still remaining appropriate for anions of the same size. Comparing **III** and **V**, one can see that the $SnBr_3^-$ anion fits into the cavity of the $[Hg_6As_4Br_3]^{1+}$ framework of **III**, but is too large if arsenic is replaced by phosphorus in the host structure (**V**). In the latter case the $SnBr_3^-$ anion requires a larger cavity in the host framework. Similarly, the SnI_3^- anion fits into the cavity of the $[Hg_6Sb_4I_3]^{1+}$ framework (**IV**), but becomes too large if antimony is replaced by arsenic in the framework (**VI**) and requires an expansion of the host structure. The

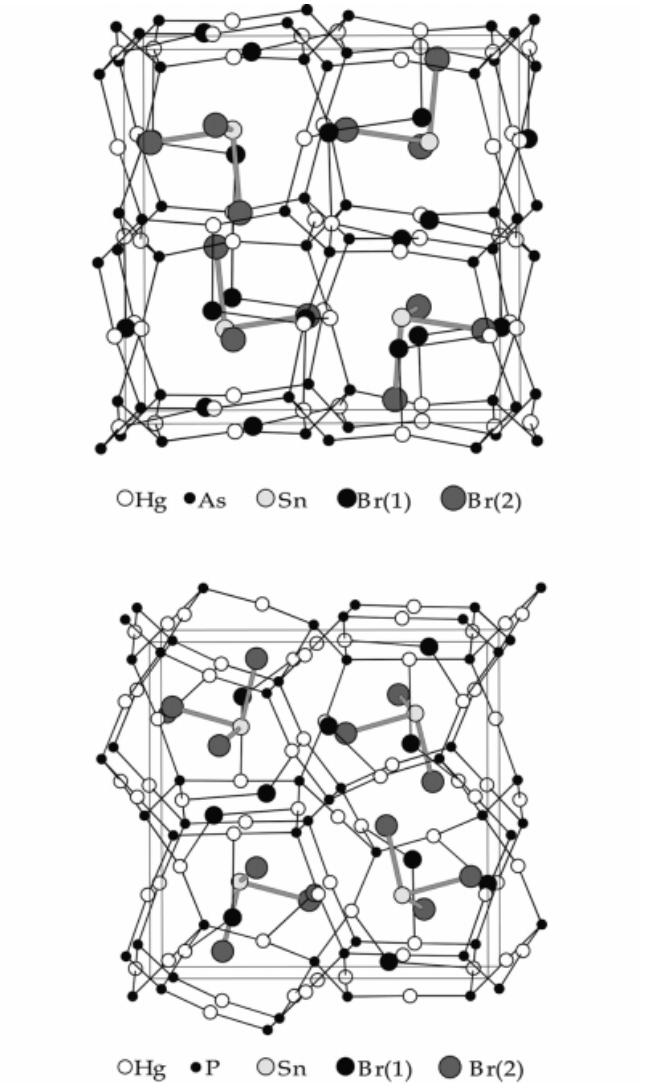

Figure 1. Unit cells of the crystal structures of $[Hg_6As_4Br_3](SnBr_3)$ (top) and $[Hg_7P_4Br_3](SnBr_3)$ (bottom)

expansion of the framework in **V** and **VI** occurs by the addition of an extra Hg^{2+} atom which "breaks" every second Z_2^{4-} dumbbell into two discrete Z^{3-} atoms (Figure 3). This leads to the formation of another type of host framework with larger cavities, $[Hg_7Z_4X_3]^{1+}$, and keeps the framework charge unchanged. Due to the severe size mismatch no SnX_3^--containing compounds have been found in the Hg/P/Sn/I, Hg/Sb/Sn/Cl, and Hg/Sb/Sn/Br systems. As is clear from Table 1, the $SnCl_3^-$ and $SnBr_3^-$ anions are too small for the antimony-containing frameworks, whereas the SnI_3^- anion is too large for the phosphorus-containing frameworks, be they of type 1 or 2 (Table 1). The above discussion leads to the following conclusion: the condition of the size matching of the guest anion and the host framework cavity is not too strict but is still important for the formation of the phases under consideration.

As has already been shown for **VI**,[2e] weak host-guest interactions influence the geometry of the SnI_3^- anion, and the calculated equilibrium geometry of the SnI_3^- anion appeared to differ from that observed in the crystal structure.

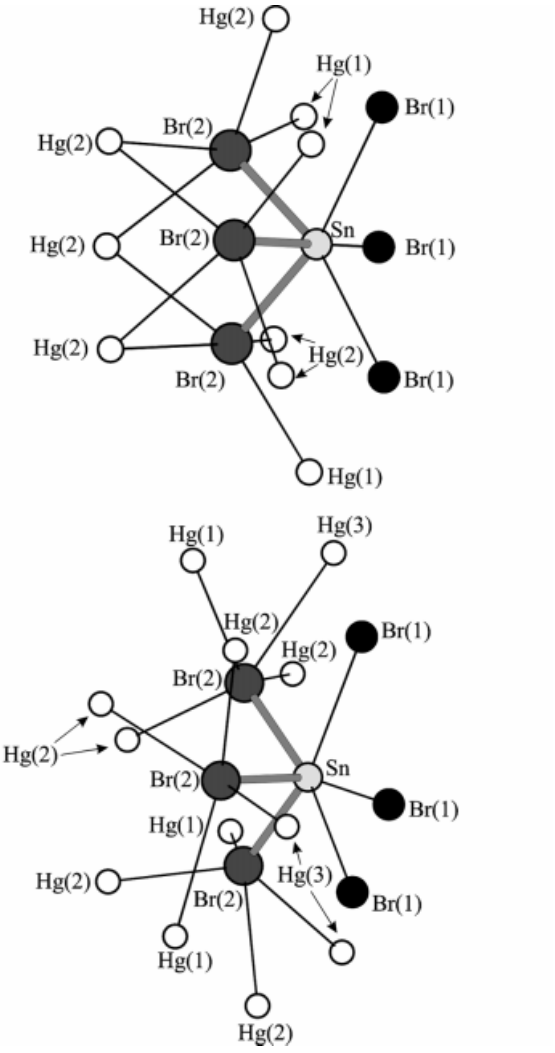

Figure 2. Coordination of the SnX_3^- anion by distant atoms of the host framework in **III** (top) and **V** (bottom)

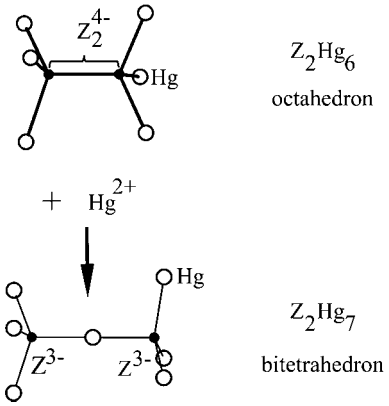

Figure 3. A scheme of the transition from the $[Hg_6Z_4X_3]^+$ framework to the $[Hg_7Z_4X_3]^+$ framework by breaking a Z_2^{4-} dumbbell with a Hg^{2+} cation

In this work we have performed the same level of ab initio calculations for the $SnCl_3^-$ and $SnBr_3^-$ guest anions (see Exp. Sect. for details). The geometry of the SnX_3^- anions found in the crystal structures of **I**−**V** and **VI**,[2e] and the corresponding calculated equilibrium values, are given in Table 8. It is clear that in all crystal structures the Sn−X separations are longer and the X−Sn−X angles are lower than the equilibrium values. A comparison of the observed geometry of the $SnBr_3^-$ guest anion in the structures of **III** and **V**, and of the SnI_3^- anion in **IV** and **VI** with the calculated ones shows that the same guest anion appears to be more distorted in **III** than in **V**, and in **IV** than in **VI**. The reason for such differences is quite apparent. The positive charge of the host cationic framework is "smeared" over the inner surface of the cavities. In **V** and **VI** the cavity has one additional mercury atom which expands its surface. Consequently, the "specific charge" of the cavity is smaller in **V** and **VI** than in the other four phases, and this is why the electrostatic interaction between the host and guest is weaker in **V** and **VI**. In turn, the weaker host-guest interaction causes a less-pronounced departure of the observed geometry from the equilibrium. A comparison of **I** and **II** shows that they possess an identical type of framework, and although the size of these frameworks is different, the observed geometry of the $SnCl_3^-$ anion they trap exhibits the same deviation from equilibrium in both structures. The above discussion leads to the conclusion that the weak electrostatic host-guest interactions primarily control the geometry of the guest SnX_3^- anion and the type of the host framework, provided that the size matching, which is not very strict, is achieved.

The nature of the weak electrostatic host-guest interaction is not discussed in this article. Recently[7] we showed that for similar supramolecular complexes containing d-metals as the centers of guest anions a host-guest charge transfer takes place.

Concluding Remarks

The above-described family of compounds illustrates features important for understanding the principles of the formation of solid state supramolecular complexes. Evidently, new compounds in the Hg/Z/Sn/X systems form only if the host-guest complementarity, which includes the geometry/topology matching and charge balance, is achieved. More important is that the mutual adjustment of the host and guest is possible. The supramolecular complexes discussed in this article show that the guest serves as a template for the construction of a host framework of the appropriate size, and changes its own geometry according to the "requirements" of the host. Weak electrostatic forces that exist between charged host and guest control their mutual adjustment.

Experimental Section

Starting Materials: Hg_2Cl_2, Hg_2Br_2, $HgBr_2$, HgI_2, red phosphorus, gray arsenic, antimony, tin powder, and mercury were used for the synthesis and single crystal growth of the reported compounds. All reagents were of high purity (> 99.99%), except for phosphorus (97%), which was purified as described elsewhere.[2e]

Table 8. Geometry of SnX_3^- as found and calculated

Anion	in compound		d(Sn−X)/Å and (X−Sn−X)/deg. from structure	calculated
$SnCl_3^-$	$[Hg_6P_4Cl_3]SnCl_3$	**(I)**	2.62 Å, 86.9°	2.49 Å, 96.6°
	$[Hg_6As_4Cl_3](SnCl_3)Hg_{0.13}$	**(II)**	2.63 Å, 87.7°	
$SnBr_3^-$	$[Hg_7P_4Br_3]SnBr_3$	**(V)**	2.71 Å, 91.5°	2.66 Å, 97.8°
	$[Hg_6As_4Br_3]SnBr_3$	**(III)**	2.77 Å, 87.5°	
SnI_3^-	$[Hg_7As_4I_3]SnI_3$	**(VI)**	2.95 Å, 90.9°	2.90 Å, 99.2°
	$[Hg_6Sb_4I_3](SnI_3)Hg_{0.16}$	**(IV)**	2.99 Å, 88.1°	

Synthesis: Compounds **I**, **II** and **III** were prepared from stoichiometric mixtures (approx. 1 g.) of the respective mercury(I) halide, pnicogen, and tin powder, which were heated for five days at 400 °C in vacuum-sealed silica tubes. The samples formed as yellow (**I**) or dark-red (**II** and **III**) air-stable polycrystalline powders, but did not contain single crystals suitable for a structure determination. A profile analysis of the diffraction patterns of the samples [STADI-P (STOE), Cu-$K_{\alpha 1}$ radiation] confirmed that they were phase-pure. For the X-ray crystal structure analysis, single crystals of **I**, **II**, and **III** were selected from the samples prepared from the mixtures of the respective mercury(I) halide, phosphorus (arsenic), tin powder, and mercury in a 3:4:1:1 molar ratio. The mixtures (total weight approx. 1 g) were vacuum-sealed in silica ampoules and heated at 400 °C for five days.

For the preparation of **IV**, mercury(II) iodide, antimony, tin powder, and mercury were mixed in a 3:4:1:4 ratio. Approximately 1 g of this mixture was heated for five days at 500 °C in an evacuated silica ampoule. The product formed as a mixture of a new black phase and liquid mercury, and contained single crystals suitable for a structure determination.

Compound **V** was prepared by heating a stoichiometric mixture of mercury(II) bromide, red phosphorus, tin powder, and mercury in a vacuum-sealed silica tube for two days at 400 °C. The sample appeared as a crop of yellow crystals of different shapes and sizes. Only a small admixture of unchanged starting materials was detected by X-ray powder diffraction.

No new compounds were obtained from the Hg/P/Sn/I, Hg/Sb/Sn/Cl and Hg/Sb/Sn/Br systems upon annealing samples with the composition $3HgI_2$:4P:1Sn, $3Hg_2Cl_2$:4Sb:1Sn, and $3Hg_2Br_2$:4Sb:1Sn for five days, and varying the temperature from 400 to 500 °C.

Crystal Structure Determinations: Suitable single crystals of **I**−**V** were mounted on a CAD-4 (Nonius) goniometer head. The cubic unit cell parameters were refined based on 24 well-centered reflections in the angular range $12° < \theta < 17°$. All data sets were collected at ambient temperature with the data collection parameters listed in Table 2. A semiempirical absorption correction was introduced based on azimuthal scans of not less than six reflections with χ angles close to 90°. Analysis of the systematic absences in the data sets revealed two possible space groups $P2_13$ (no. 198) and $P4_232$ (no. 208). For the structure solution, following the presumed analogy with the synthesized earlier compound $[Hg_7As_4I_3](SnI_3)$, the space group of lower symmetry was chosen in all cases. The atomic positions of mercury, iodine, antimony, tin, bromine and arsenic atoms in all the structures were estimated by direct methods (SHELXS-97).[8] The phosphorus and chlorine atoms were localized by a sequence of $\Delta\rho$(xyz) syntheses and least-squares cycles (SHELXL-97).[9] During the refinement of the crystal structures of **II** and **IV** an electron density peak was observed residing in the smaller cavity of the host framework. The position of this peak was refined as being partly occupied by mercury. Final anisotropic full-matrix refinement on F^2 led to satisfactory R_1 and wR_2 values as listed in Table 2. Attempts to solve the structures in the space group $P4_232$ did not lead to reasonable solutions.

It should be noted that the quality of the reflections that were used for the absorption correction procedure in the case of **I** was rather low. We consider this to be the reason why one of the phosphorus atoms has abnormally weak thermal displacement parameters. Unfortunately, due to the irregular shape of the crystal, the numerical absorption correction was unsuccessful.

Further details of the crystal structure determination may be obtained from Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-411863 (**I**), -411862 (**II**), -411861 (**III**), -411859 (**IV**), and -411860 (**V**).

Computational Aspects: Ab initio RHF calculations were performed using the GAMESS-US[10] program. SBKJC effective core potentials were applied to all atoms and the SBKJC basis set[11] implemented in GAMESS was used. The starting geometry of the $SnCl_3^-$ and $SnBr_3^-$ anions was taken from the crystal structure refinement of **I** and **III**, respectively. The geometry of the SnX_3^- anions was optimized without any constraints (C_{3v} and C_s symmetries). Geometry optimizations were performed by the quasi-Newton algorithm[12] implemented in GAMESS. In all cases the optimized geometries did not depend on the point symmetry group applied to the SnX_3^- ion. The hessian computations and normal vibration analyses showed all stationary points located to be minima.

Probing the Nature of the Redox Products and Lowest Excited State of $[(bpy)_2Ru(\mu\text{-}bptz)Ru(bpy)_2]^{4+}$: A Resonance Raman Study

Keith C. Gordon,*[a] Anthony K. Burrell,[b] Timothy J. Simpson,[a] Simon E. Page,[a] Geoffrey Kelso,[a] Matthew I. J. Polson,[a] and Amar Flood[a]

Keywords: Raman spectroscopy / Mixed-valent compounds / Ab initio calculations / Ruthenium(II) / Tetrazines

The resonance Raman and infrared spectra of the bridging ligand 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine (bptz) have been studied. Ab initio calculations on bptz and the radical anion $bptz^{\cdot-}$ are able to predict the frequencies and intensities of the vibrational spectra. This analysis is used to interpret the vibrational spectroscopy of the bridged binuclear complexes $[(bpy)_2Ru(\mu\text{-}bptz)Ru(bpy)_2]^{4+}$ (**1**) and $[(PPh_3)_2Cu(\mu\text{-}bptz)Cu(PPh_3)_2]^{2+}$ (**2**) and their redox products. The resonance Raman spectroscopy of **1** reveals the bichromophoric nature of the complex, with bpy and bptz ligand modes being enhanced selectively as a function of excitation wavelength. The UV/Vis spectrum of $\mathbf{1}^+$ reveals a strong IVCT band suggesting the mixed-valent species is Class III in nature. This is consistent with findings for other metal moieties with the bptz ligand. The resonance Raman spectrum of $\mathbf{1}^+$ is also consistent with a Class III formulation. The resonance Raman spectrum of $\mathbf{2}^-$ is used to model $bptz^{\cdot-}$ and the ab initio calculations show some correlation with the observed spectrum. The excited-state resonance Raman spectra of **1**, generated with 532 and 633 nm excitation, show spectral features that are not strongly characteristic of $bptz^{\cdot-}$. This appears to be a consequence of the delocalised nature of the molecular orbitals involved in the excited-state of **1**.

Introduction

The extent to which different bridging ligands (BL) can facilitate coupling between adjacent metal-based moieties is an area of intense interest.[1−3] Mixed-valence complexes in which such metal coupling may occur are classified as Class I, II, or III. In a complex in which the BL provides no or little communication the resulting mixed-valent species would show Class I behaviour but when the communication is effective, Class II or III states may be formed.[4−8] Class III systems are completely delocalised such that the mixed-valence is equally shared by both metal centres. The Class II classification is intermediate between I and III, in which a barrier exists to moving charge between the adjacent centres. Studies of mixed-valence complexes may focus on the bridging ligand, by observing the properties of the π* MO.[9] The metal communication may be probed by creating mixed-valent species and observing inter-valence charge-transfer (IVCT) transitions, or by measuring the separation between metal-based oxidation for identical moieties such as $\{Fe(CN)_4\}^{2-}$ or $\{Ru(bpy)_2\}^{2+}$.[10−14] The electrochemical methods have been widely used to measure the comproportionation constant (K_c) for the mixed-valent species. Generally the mixed-valent species of interest is formed through chemical or electrochemical redox reactions.[15,16] However, it is possible to form mixed-valence species through photoexcitation of a binuclear metal complex:[17]

$$M-BL-M + h\nu \rightarrow M^+-BL^{\cdot-}-M \quad (1)$$

Fewer studies have addressed the nature of the mixed-valent state formed upon such excitation. Vibrational spectroscopy is a very powerful tool in this regard as reporter ligands may be used to provide vibrational signatures that are oxidation-state sensitive. The mixed-valent state may be accessed through electrochemistry[18−20] or photoexcitation.[17,21−26]

The aims of the present study are to probe the nature of the lowest excited state and the redox states of $[(bpy)_2Ru(\mu\text{-}bptz)Ru(bpy)_2]^{4+}$ (**1**) using resonance Raman spectroscopy. The structure of the bridging ligand, 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine (bptz) is shown in Figure 1. The advantage of studying **1** is that the compound has a well-defined redox behaviour.[27,28] Thus the spectroscopic data obtained may

be related to a specific type of mixed-valent system, in this case Class III. The mixed-valent species formed by electrochemical oxidation is delocalised.[29] Furthermore the MO structure of the bridging ligand, bptz, has been studied experimentally[27] and through computational calculations.[30] These have found the redox MO for the reduced ligand and **1** to be strongly localised on the tetrazine portion of the bptz ligand. Complex **1** therefore provides a system in which each of the redox states that constitute an idealized model of the MLCT excited-state are known.

One of the disadvantages of using resonance Raman spectroscopy to probe the redox states and the lowest excited state of **1** is the presence of a number of overlapping chromophores in the visible region. In studying complexes with the $\{Ru(bpy)_2\}^{2+}$ moiety the strong enhancement of the bpy modes through the $Ru^{II} \rightarrow$ bpy MLCT transitions often conspire to obscure the resonance Raman spectral features from the other ligand present.[31–34] In order to obtain uncontaminated spectral signatures for bptz and bptz$^{\cdot-}$ the resonance Raman spectra of $[(PPh_3)_2Cu(\mu\text{-}bptz)Cu(PPh_3)_2]^{2+}$ (**2**) and **2**$^-$ were obtained. The $\{Cu(PPh_3)_2\}^+$ moiety possesses no additional chromophores in the visible region other than the $Cu^I \rightarrow$ bptz MLCT transition. Furthermore the $\{Cu(PPh_3)_2\}^+$ moiety causes only modest changes in the ligand structure and complexes with $\{Cu(PPh_3)_2\}^+$ may be used to obtain the radical anion spectra of ligands.[35–37] The crystal structures of **2**, reported herein, and **2**$^-$, previously published,[38] permit an analysis of the changes in the vibrational spectra in terms of the changes in bond lengths attendant upon reduction.

Results and Discussion

Electronic Spectroelectrochemistry

The electronic spectroscopic data for **1**, **2**, bptz, and their redox products are summarized in Table 1.

Table 1. Electronic absorption data for bptz, complexes, and their redox products

Compound	λ [nm] (ε [10^3 M^{-1}·cm^{-1}])				
bptz[a]	294 (19.6)				
bptz$^{\cdot-}$ [a]		368 (6.4)			
1[b]	281 (64.1)		404 (7.5)	688 (13.6)	
1$^+$ [b]			478 (4.6)	604 (12.2)	1483 (2.8)
1$^-$ [b]			434 (14.6)	491 (14.7)	
2[a]	258 (32.6)			707 (4.5)	
2$^-$ [a]			430 (3.7)		

[a] CH_2Cl_2 solution. [b] MeCN solution.

Reduction results in the depletion of ground state bands and the grow in of bptz$^{\cdot-}$ bands at approximately 400 to 450 nm. The spectra of **1**$^-$ and **2**$^-$ contain a bptz$^{\cdot-}$ band at ca. 430 nm. The spectrum of **1**$^-$ is also complicated by the red-shifting of $Ru^{II} \rightarrow$ bpy MLCT transitions as a consequence of the raising of dπ orbitals' energies because of the bptz reduction.[11] The spectrum of bptz$^{\cdot-}$ in solution shows a band at 368 nm. Recent studies of the spectroelectrochemistry for the mononuclear complex $[(bptz)Re(CO)_3Cl]^{\cdot-}$ reveals a band at 390 nm attributed to the bptz$^{\cdot-}$ species.[45a]

The absorption spectrum of **2** shows a strong MLCT transition at 707 nm. Reduction of **2** → **2**$^-$ results in the depletion of this band with the grow in of transitions at 430 and a shoulder at 520 nm, attributed to the radical anion of bptz. This is in good agreement with the reported UV/Vis spectrum of **2**$^-$ formed through comproportionation reaction,[38] which shows bands at 427 and 510 nm, and that observed for $[Cp^*ClIr(\mu\text{-}bptz)IrClCp^*]^+$ [39] which shows a band attributed to bptz$^{\cdot-}$ at 428 nm with ε = 4500 M^{-1} cm^{-1}.

The electrochemical oxidation of **1** → **1**$^+$ shows a reduction in the intensity of the MLCT band at 688 nm concomitant with the appearance of bands at 604 nm and 1483 nm (Figure 2). The intensity of the band in the NIR region is significantly greater than that observed for the related $[(NH_3)_4Ru(\mu\text{-}bptz)Ru(NH_3)_4]^{5+}$ (**3**$^+$).[30] In that case a band observed at 1453 nm (ε ≈ 500 M^{-1} cm^{-1}) was assigned as the IVCT transition. We propose that the feature observed at 1483 nm in **1**$^+$ is also of IVCT origin; however this band is more intense than that for the related **3**$^+$ complex. For both **1**$^+$ and **3**$^+$ the mixed-valent species formed are Class III in nature.[1,9] This may be established from the electrochemistry, the separation between metal-based oxidations being > 400 mV, and from the band shape of the IVCT band. In Class III systems the bandwidth ($\Delta\nu_{1/2}$) is less than that predicted by Hush theory.[7,8] In the Hush analysis the bandwidth is related to the transition wavenumber (ν) by $\Delta\nu_{1/2} = (2310\nu)^{1/2}$ cm^{-1}.

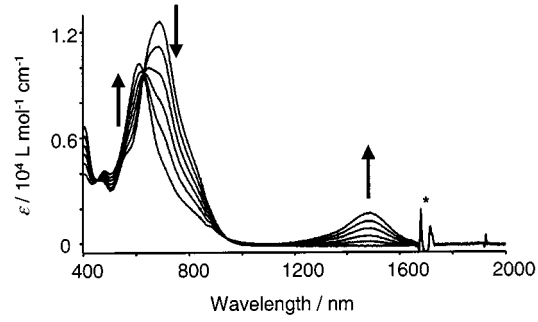

Figure 2. UV/Vis absorption spectra for **1** → **1**$^+$ (MeCN) electrochemical oxidation; arrows indicate the spectral changes occurring as the sample is oxidized; the asterisk * indicates overtone absorption bands of solvent (MeCN)

Compounds that show IVCT bands that fit this model are Class II in nature, whereas those which show much narrower transitions are Class III.[40]

For **1**$^+$ and **3**$^+$ the experimental values of $\Delta\nu_{1/2}$ are 1000 and 1600 cm^{-1},respectively, the values predicted through Hush theory would be 3960 and 3990 cm^{-1} for **1**$^+$ and **3**$^+$. They are therefore Class III systems. As **1**$^+$ and **3**$^+$ are Class III mixed-valence systems the amount of coupling may be parameterised by H_{ad}. This parameter represents the bonding interactions between the two identical Ru sites

directly and/or through superexchange pathways.[1,7,8] H_{ad} is related to the wavenumber of the IVCT transition (E_{op}) by $E_{op} = 2H_{ad}$.

In $\mathbf{1}^+$ and $\mathbf{3}^+$ H_{ad} is 3300 and 3440 cm^{-1}, respectively.

The upshot of this is that the μ-bptz ligand is allowing a similar level of coupling in the two complexes. The question arises as to why in $\mathbf{1}^+$ the IVCT transition is 5 times more intense than in $\mathbf{3}^+$. A similar phenomenon has been observed in mixed-valence complexes with 1,4-dicyanoamidobenzene.[41] In this case the peripheral ligands could tune the system between Class II and Class III behavior. The magnitude of the transition dipole moment (M) for the IVCT transition is dependent upon the overlap integral between the donor and acceptor wavefunctions (S_{ad}) and the dipole moment length (R).[40]

In the case of $\mathbf{3}^+$ the highly delocalised donor and acceptor wavefunction mean that R will be very small. This would result in a low ε for the IVCT band as is observed. In the case of $\mathbf{1}^+$ the dipole length is greater because of the inclusion of the bpy ligands in the donor and acceptor wavefunctions. Calculations on related Ru^{II} mononuclear complexes reveal that NH_3 ligands show less potential to mix with the dπ Ru^{II}-based HOMO than if bpy ligands are present.[42] In the case of $[Ru(bpy)_2L]^{2+}$ complexes the HOMO has ca. 70% dπ Ru character. In the case of $\mathbf{1}^+$ it is therefore reasonable to assume that the nature of the donor and acceptor MOs of the IVCT transition produce a greater dipole length than for $\mathbf{3}^+$.

Calculations of Structure and Crystal Structure Determination

The geometry of bptz was calculated by using HF and DFT (B3LYP) methods. In each case the ligand geometry was planar. Bond lengths and angles for the calculated and crystal structures are shown in Table 2. The notation is given in Figure 1. The result is surprising in view of the previously reported geometry optimization of bptz,[43] which reports a dihedral angle [as defined by N(1)−C(5)−C(6)−N(2)] of 19°. Furthermore, the crystal structure of the bptz contains a dihedral angle of 19°. In order to test our calculations we delibrately started the optimization with the structure having a significant dihedral angle. An analysis of the geometry optimization reveals that the major structural modification is in the dihedral angle − no other parameters show greater than 5% variation. Other than this discrepancy the bond lengths and angles we calculate are in good agreement with the crystal structure. Importantly the frequency calculations from these optimised structures show no imaginary frequencies, suggesting the geometries are at minimum energy.

An analysis of the bond lengths and angles reveals that the structure predicted at HF/6-31G(d) corresponds less closely to the crystal structure than the DFT (B3LYP) method. The average discrepancy in bond length for the HF calculation is 0.005 Å whereas for B3LYP it is 0.002 Å, for both basis sets used. The HF calculation generally does a poorer job with the C−N bond lengths and the N−N linkage is also too short. The increase in basis set in the B3LYP calculation does little to improve the predicted geometry.

Calculations were also carried out by using DFT methods on the radical anion of bptz. The spin expectation value, $<s^2>$, for the radical anion was 0.7501. This is very close to that for a pure doublet. We did not use HF methods to model the radical anion because they often give very poor $<s^2>$ values.[44] The calculated structure shows a lengthening of the N=N bond of the tetrazine. This is consistent with the population of a LUMO by the reducing electron that is based on the tetrazine and is antibonding with respect to the N=N bonds. It is consistent with the crystallographic data, vide infra.

The structure of **2** is similar to the previously described complexes, with the bptz acting as a linear bidentate ligand.[39,45] The structure confirms the presence of two $\{Cu(PPh_3)_2\}^+$ groups bound at a Cu−Cu distance of 6.78

Å, Figure 3. The bond length and angles for the bptz moiety are presented in Table 2. The geometry about the copper is not completely tetrahedral with the small bite-angle of the bptz ligand and an axial-equatorial displacement of the PPh_3 groups. This displacement is not unusual in complexes of this type[46] and is driven by the π−π interactions between the tetrazine ring and one of the phenyl rings on each PPh_3. The distance from the tetrazine to the phenyl range from 3.3−3.7 Å.

The structure of the reduced complex has been previously reported and it is useful to compare the two structures in some detail. The structural details for bptz in **2** and $\mathbf{2}^-$ are given in Table 2.[38] The most important area for comparison is the bond lengths in the tetrazine ring. The study by Kaim and co-workers indicated that the reducing electron was located in the π* orbital of the N=N bond. The structure of **2** helps support this proposal; the N=N distance [1.329(2) Å] is significantly shorter than that observed in $\mathbf{2}^-$ [1.394(5) Å]. The other distances in the tetrazine ring of **2** do not vary significantly from those described in $\mathbf{2}^-$ (see Table 2). The bptz ligand in **2** is slightly more distorted than its anion radical form $\mathbf{2}^-$. The twist angle between the pyridyl groups and the tetrazine ring in **2** is 7.69°, whereas it is only 5.8° in $\mathbf{2}^-$. Another notable distortion is caused by the coordination of Cu^I. The ligand gains a slight distortion which can be seen in the relative distances between N1−N2 (2.66 Å) and N4−C4 (2.98 Å). The Cu−N distances show the same trend for **2** as noted for $\mathbf{2}^-$ with the Cu−N(1) pyridyl bond [2.0957(17) Å] being longer than the Cu−N(2) tetrazine [2.0666(15) Å] bond. The Cu−P distances in **2** at 2.2469(5) and 2.2760(5) Å are relatively similar, whereas in $\mathbf{2}^-$ they differ significantly [2.0297(12) and 2.2873(12) Å].

Frequency Calculations and Resonance Raman Spectroscopy

The frequency calculations were performed on bptz within a C_{2h} point group. The energy difference between the bptz with no symmetry and that with C_{2h} is less than $1.2\cdot10^{-7}$ Hartrees ($3.1\cdot10^{-1}$ J·mol^{-1}). Essentially the structures are equivalent.[47]

The frequencies calculated at HF/6-31G(d) were empirically scaled by 0.87 according to the findings of Radom et al.[48] The IR intensities and Raman activites were also obtained. Frequencies were also calculated using the DF hybrid method [B3LYP with a 6-31G(d) basis set, frequencies were scaled by 0.96].[48] The IR and Raman intensities were also calculated.

The HF and DFT calculations show reasonably good agreement with the IR data. The difference between the frequency calculations at HF and DFT/B3LYP level in the 1100 to 1700 cm^{-1} region are that the HF calculation poorly predicts the intensities of the Raman spectrum. It also places more a_g modes above 1500 cm^{-1} than the DFT calculation and has only two modes in the 1400 to 1500 cm^{-1} region. The Raman spectrum of bptz clearly shows 3 bands in the 1400 to 1500 cm^{-1} region. Furthermore the intensities calculated from HF predict strong Raman bands in the 1530 and 1600 cm^{-1}. This is not observed in the experimental spectra. For these reasons the HF calculations are not used in our subsequent analyses.

A listing of modes, their symmetries and wavenumbers for the DFT calculation and experimental data are given in Table 3.

The measured IR spectrum of bptz shows strong transitions at 1586, 1387, and 1130 cm^{-1} (Table 3). These correspond to modes 64, 54, and 45, respectively, from the DFT calculation. These modes are depicted in Figure 4 and can be best described as being pyridine ring (mode 64) and tetrazine ring (modes 54 and 45) stretches.

The Raman activity is related to the intensity of Raman bands as a function of the excitation wavelength and the wavenumber of the Raman photon.[49] It should be noted that the spectrum of bptz is a resonance Raman spectrum and this affords enhancement of band intensities not simply related to the Raman scattering cross section as calculated in the simulated spectrum. A detailed quantitative analysis is therefore inappropriate. It should, however, be noted that a_g modes are enhanced in resonance Raman spectra.[50] The predicted modes that should show large Raman scattering cross section are at 1599 (mode number 63), 1461 (mode 57), 1322 (mode 52), and 1278 cm^{-1} (mode 49). Modes 57 and 52 are almost exclusively tetrazine based stretches (Figure 4).

The calculated spectra of $bptz^{\cdot-}$ were only run using DFT methods. The predicted frequencies and intensities for $bptz^{\cdot-}$ are presented in Table 4. The Raman spectrum in the 1100 to 1700 cm^{-1} is dominated by mode 56 at 1380 cm^{-1}. This mode corresponds to mode 57 for the neutral ligand. A number of other weak a_g modes are also Raman-active in the 1100 to 1700 cm^{-1} region. It is interesting to note that those bands that are associated with normal modes of pyridine-ring character, such as modes 64 and 63, are predicted not to shift much upon reduction. However, the tetrazine modes, such as 57, 54, and 52, are predicted to shift significantly. Mode 57 (1461 cm^{-1} for bptz) is pre-

[a] Relative intensities of IR and Raman bands, respectively, are given in parentheses. The band intensities are normalized so that the strongest band in the reported region has an intensity of 100. [b] Relative intensities given in parentheses; normalized to 100 for the strongest band in the region. [c] These data pertain to a resonance Raman spectrum. The intensities are modulated by the resonance effect, hence they are not comparable to the predicted spectra and are not given.

dicted to shift to 1380 cm^{-1} in $bptz^{\cdot -}$ (corresponding to mode 56). Mode 54 shifts from 1388 to 1328 cm^{-1} and mode 52 from 1322 to 1280 cm^{-1}. These shifts are consistent with population of a tetrazine-based MO in $bptz^{\cdot -}$ and the concomitant weakening of the N−N linkages.

The resonance Raman spectra (RRS) of the complexes are presented in Figure 5.

The Raman spectrum of the bptz ligand (Figure 5, bptz) shows strong bands at around 1447 cm^{-1} and at 1591 and 1576 cm^{-1}. The 1447 cm^{-1} group of modes are assigned as predominantly tetrazine ring stretch, those at higher frequency are pyridyl ring stretches. If the excitation wavelength is changed from 457.9 nm to 514.5 nm the relative intensity of the 1447 cm^{-1} is diminished suggesting resonance enhancement of these spectra. All of the observed bands are polarised and are thus from modes of a_g symmetry.

The binding of the two $\{Ru(bpy)_2\}^{2+}$ moieties results in more complex resonance Raman spectra (Figure 5; **1**). The complex has two sets of chromophores in the visible region; these are Ru(dπ) → bpy(π*) MLCT transitions and Ru(dπ) → bptz(π*) MLCT transitions. From electrochemical studies the bptz-terminated MLCT transition should lie at lower energy than the bpy-based MLCT band. This is borne out in the resonance Raman spectra where bpy modes at 1605, 1566, 1499, 1317, and 1172 cm^{-1} are very strong with 457.9 nm excitation (Figure 5; **1**, 457 nm).[33] Modes associated with the bptz ligand lie at 1503 and 1366 cm^{-1} and are attributed to modes 60 and 53. The intensity of the 1366 cm^{-1} is convoluted with the solvent band; it is therefore difficult to assign. The observed bptz bands of **1** are significantly shifted from the bands in the free ligand. This may be due to the electronic effect of the $\{Ru(bpy)_2\}^{2+}$ distorting the ligand, or its steric effect. The relative intensity of the bpy modes is depleted as the excitation wavelength is tuned from 488.0 to 514.5 to 632.8 nm. With the red excitation wavelength no bpy modes are observed suggesting the Ru → bpy MLCT transition has negligible intensity at this wavelength.

The RRS of **2** (Figure 5) shows the enhancement of modes at 1488, 1459, 1437, 1305, and 1290 cm^{-1} assigned as modes 60, 57, 55, 52, and 51. For bptz they are shifted slightly from the Raman bands of the free ligand.

The RRS of **1** and **2** are generally similar with 632.8 nm excitation; they both show a strong band at about 1490 cm^{-1}, 1488 for **2** and 1503 cm^{-1} for **1**, and a group of vibrations at about 1300 cm^{-1}. The wavenumbers are shifted significantly for each. Structural data are not available for **1** but recent detailed calculations on related Pt^{II} complexes reveal significant perturbation of the electronic structure of bptz by the bound metals.[43] It is known that the $\{Ru(bpy)_2\}^{2+}$ moiety is a stronger π-acid than $\{Cu(PPh_3)_2\}^{+}$ and this may lead to perturbations of the ring structure and thus the vibrational spectra of the ligand.

Resonance Raman Spectroelectrochemistry

Resonance Raman spectroelectrochemistry offers a vibrational spectroscopic probe of the mixed-valent state, with oxidation, and of the bptz radical anion species, with reduction. The latter has already been thoroughly studied using ESR spectroscopy.[51] Such studies revealed that most of the electron density in the MO populated in the reduced species is localised at the tetrazine ring.

The resonance Raman spectrum of $\mathbf{1}^{+}$ was measured using 457.9, 488.0, 514.5, and 632.8 nm excitation wavelengths (Figure 5). In ascertaining the electron density changes about a metal upon oxidation, reporter groups are often utilised. These may be CO or CN^{-} ligands; both show a sensitivity of wavenumber of the stretch vibration to the oxidation state of the metal atom.[17,21−23] However, the bpy vibrations are also frequency dependent on the oxidation state of the metal atom.[33,34] For $[Ru(bpy)_3]^{3+}$ the bpy modes lie approximately 3−5 cm^{-1} higher in frequency than observed in the vibrational spectrum of $[Ru(bpy)_3]^{2+}$.[52] The spectra observed for $\mathbf{1}^{+}$ show bpy bands that are slightly shifted from that of **1**. This is most readily observed in the spectrum generated with 457.9 nm excitation; the bpy band at 1605 cm^{-1} in **1** is shifted to 1608 cm^{-1} in $\mathbf{1}^{+}$. Although this is a small shift it is not negligible

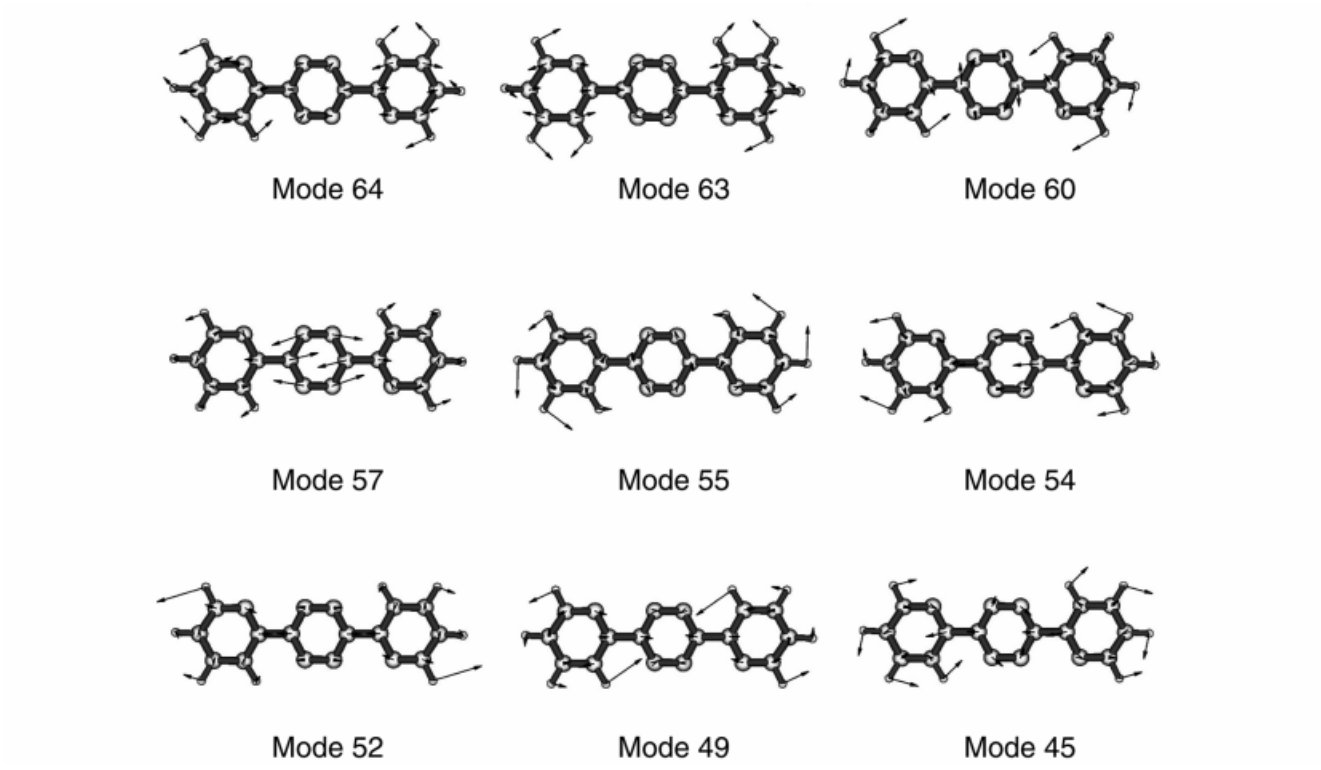

Figure 4. Selected normal modes calculated for bptz. Modes 64 and 63 are pyridine-based, 57, 54, and 52 are tetrazine-based

and is consistent with oxidation of a metal site or sites. The largest frequency shift observed in comparing **1** and $\mathbf{1}^+$ is the bptz band at 1503 and 1513 cm^{-1} respectively. This is most readily seen in the spectra generated with 632.8 nm excitation. The significance of these data are as follows: (1) The larger shift for the bptz vibrational transition is consistent with significant perturbation at the bridging ligand relative to the peripheral bpy ligands. (2) The shift of the bpy mode upon oxidation is consistent with a perturbation of electron density at *both metal sites*; an unperturbed Ru^{II} centre would retain bpy signatures at 1605 cm^{-1}. This is perhaps unsurprising in view of the strong coupling between the metal sites.[45a] Oxidation is likely to create an $\{Ru^{+2.5}(\mu\text{-bptz})Ru^{+2.5}\}$ species; thus the electron density change on the metal atoms is delocalised and changes in the bonding of the bpy ligands is delocalised over both metal centres.

The 10 cm^{-1} frequency shift of the bptz band, in relation to point (1) above, provides support for the presence of a superexchange contribution to the production of a Class III species. Consequently, the HOMO has some bptz π-character, in which the $\mathbf{1}^+$ formulation $\{Ru^{+2.4}(bptz^{+0.2})Ru^{+2.4}\}$ may be more truthfully representative. That is, the 10 cm^{-1} frequency shift of the bptz band is a direct result of the depopulation of the HOMO which is constituted by some% of bptz π-character.

In summary, the resonance Raman spectroscopy of $\mathbf{1}^+$ is consistent with a Class III species.

The electrochemical reduction of $\mathbf{2} \rightarrow \mathbf{2}^-$ results in significant spectral changes; firstly, the RRS of $\mathbf{2}^-$ is much more intense than that of **2** generated with 457.9 nm excitation. A new set of bands are observed at 1406, 1313, 1274, 1027, and 1002 cm^{-1}. These may be assigned to modes 56, 53, 51 43, and 40, respectively. The correlation is based on: (1) the fact that this is a resonance Raman spectrum, thus a_g modes will be enhanced; (2) the calculation predicts some intensity for each. The strongest of these bands lie at 1406 and 1274 cm^{-1}. The crystal structure of $\mathbf{2}^-$, and calculations on $bptz^{\cdot -}$, reveal that the N=N bond is 1.39 Å in $\mathbf{2}^-$ and 1.32 Å in **2**. The shift to lower frequencies is most prevalent for the tetrazine modes as predicted by calculation.

The resonance Raman spectra of $\mathbf{1}^-$ show significant changes to those of the parent complex at all 4 excitation wavelengths (Figure 5). The spectrum of $\mathbf{1}^-$ generated with 457.9 nm excitation shows bands at 1506 cm^{-1} that may be assigned as a $bptz^{\cdot -}$ feature; other bands at 1605, 1486 and 1317 cm^{-1} are bpy modes. Complete conversion from the parent species is confirmed by the absence of any residual 1494 cm^{-1} band. The band at 1559 cm^{-1} (mode 62, Table 4) is rather interesting; it appears to be composed of bpy and $bptz^{\cdot -}$ vibrations. The spectrum at 488.0 nm excitation shows similar bands with the bpy-modes reduced in intensity. However, their relative intensity is greater in the spectrum of $\mathbf{1}^-$ than in that of **1** at the same excitation wavelength. This is consistent with a destabilisation of the metal t_{2g} MOs upon reduction at the ligand site. This effect redshifts the $Ru(d\pi) \rightarrow bpy(\pi^*)$ MLCT transitions causing them to become resonant at 488.0 and 514.5 nm.[33,34,53]

The resonance Raman spectrum of $\mathbf{1}^-$ observed with 632.8 nm excitation shows a very different intensity pattern than that observed at the other excitation wavelengths. Firstly, no bpy modes are observed. This is consistent with

Table 4. Wavenumbers [cm^{-1}] of calculated bands for bptz$^{\cdot-}$, and experimental bands of $\mathbf{2}^-$ in the 1000 to 1650 cm^{-1} region

[a] Relative intensities of IR and Raman bands, respectively, are given in parentheses. The band intensities are normalized so that the strongest band in the reported region has an intensity of 100 for IR and 1000 for Raman. [b] These data pertain to a resonance Raman spectrum. The intensities are modulated by the resonance effect, hence they are not comparable to the predicted spectra and are not given.

the fact that at 632.8 nm there are no electronic transitions involving the bpy ligands. Secondly, the bptz$^{\cdot-}$ mode at 1559 cm^{-1} is absent and bands appear at 1005, 1257, and 1308 cm^{-1} in a pattern completely different from that observed at the other excitation wavelengths. The frequency calculation predicts modes at 996, 1280, and 1303 cm^{-1} which correspond to modes 40, 51, and 53, respectively. The enhancement of these modes is quite different from that observed for $\mathbf{2}^-$ (Figure 5; $\mathbf{2}^-$, 457 nm) and this suggests that the bptz$^{\cdot-}$ species has a number of transitions in the visible region that involve quite different portions of the bptz$^{\cdot-}$ radical anion ligand. This is also supported by the fact that the resonance Raman spectra of **2** show strong variations in intensity for bands at 1488 and 1305 cm^{-1} with λ_{exc} (Figure 5).

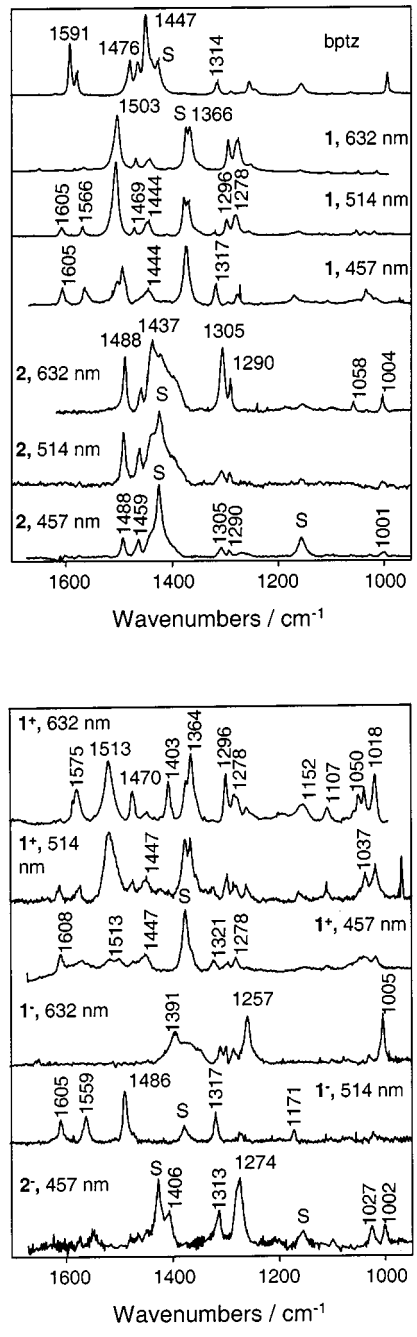

Figure 5. Resonance Raman spectra of **1** (3 mM MeCN), **2** (3 mM CH_2Cl_2), $\mathbf{1}^+$ (3 mM MeCN), $\mathbf{2}^-$ (3 mM CH_2Cl_2), $\mathbf{1}^-$ (3 mM MeCN); **S** represents a solvent band; all λ_{exc} = 15 mW at sample

Excited-State Resonance Raman Spectra

The excited-state lifetime of **1** has not been reported; the lack of any emission in fluid media suggests it is < 5 ns. It is possible to probe such short-lived species using nanosecond pulsed laser excitation at sufficient pump powers.[37,54–56] The RRS of **1** generated using 532 and 633 nm pulsed excitation are shown in Figure 6. As the pulse energy is increased a number of bands become stronger; these are assigned to the excited state (**1***). They lie at 988, 1100, 1120, 1161, 1568, and 1608 cm^{-1}. In a simple fashion the spectrum of **1*** can be thought of as a combination of the spectra of $\mathbf{1}^+$ and $\mathbf{1}^-$. The 1568 and 1608 cm^{-1} bands may be attributed to bpy vibrational bands of a Ru→bpy MLCT transition from an Ru centre. None of the other excited-state features present are bptz-associated marker bands for $\mathbf{1}^+$ or bptz$^{\cdot-}$ as probed in $\mathbf{1}^-$ or even $\mathbf{2}^-$.[57] This is in contrast to what is normally observed in the spectra of mononuclear polypyridylmetal complexes.[21,22] A plausible explanation for this discrepancy is that there is strong mixing

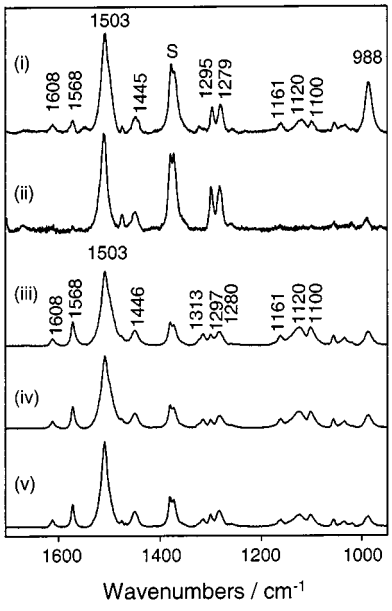

Figure 6. Resonance Raman spectra of **1** (2 mM MeCN) with pulsed laser excitation: (i) λ_{exc} = 633 nm, pulse energy 2 mJ; (ii) λ_{exc} = 633 nm, pulse energy 0.4 mJ; (iii) λ_{exc} = 532 nm, pulse energy 4 mJ; (iv) λ_{exc} = 532 nm, pulse energy 2 mJ; (v) λ_{exc} = 532 nm, pulse energy 0.5 mJ

(superexchange pathway) between the dπ and bptz π* MOs such that both the acceptor and donor orbital in the excited state are delocalised over the two Ru centres and bptz. Consequently, the bptz vibrational band positions will reflect the bonding changes due to the acceptor *and* donor orbitals and not solely the acceptor orbital as is the case for mononuclear metal polypyridyl complexes or Class I/II binuclear polypyridylmetal complexes. Therefore, the excited-state resonance Raman spectra of **1** are not inconsistent with a Class III formulation of the $\mathbf{1}^+$ mixed-valent state in which the Class III state is produced from a superexchange pathway via bptz.

Conclusion

Ab initio calculations can provide useful insight into the structure and vibrational spectra of ligands and their radical anions. In this case DFT calculations modelled the IR spectrum of bptz very well. The frequency calculation also allowed for a clear picture of the resonance Raman spectra of **1** and **2**.

The calculations on the $bptz^{\cdot-}$ predict a significant lengthening of the N=N linkage from 1.31 to 1.40 Å. This is the largest structural change predicted from the calculations. The crystal structure of $\mathbf{2}^-$ shows this predicted effect. The frequencies calculated for $bptz^{\cdot-}$ predict significant shifting of tetrazine modes from 1461 cm^{-1} in bptz (mode 57) to 1380 cm^{-1} in $bptz^{\cdot-}$ (mode 56). This may be correlated with bands of **2** at 1462 cm^{-1} shifting to 1406 cm^{-1} in $\mathbf{2}^-$.

The UV/Visible spectra of the oxidised complex, $\mathbf{1}^+$, shows a distinct and narrow IVCT transition at 1483 nm. This is somewhat more intense than that observed for other mixed-valent species with the bptz bridging ligand. We attribute the increased intensity to the ability of the $\{Ru(bpy)_2\}^{2+}$ moiety to mix bpy character into the wavefunction of the donor MO in the IVCT transition. This has the effect of increasing the dipole length of the transition and thus its intensity. The resonance Raman spectra of $\mathbf{1}^+$ reveal small shifts in the bpy bands consistent with metal oxidation. The absence of a discrete set of bpy bands for Ru^{II} and Ru^{III} centres suggests a Class III mixed-valent formulation for $\mathbf{1}^+$; consistent with previous findings.

The resonance Raman spectra of the complexes **1** and **2** are consistent with the UV/Vis spectral assignments. The resonance Raman spectra of **1** show enhancement of bpy modes at blue excitation wavelengths with bptz modes being enhanced with red excitation. This is consistent with Ru→bpy MLCT and Ru→bptz MLCT transitions. For **2** only bptz modes are enhanced with visible excitation. The change in relative intensities for the bptz bands suggest the presence of two Cu→bptz MLCT transitions in the visible region. This is exemplified by the increased resonance enhancement of the 1305 cm^{-1} band relative to 1488 cm^{-1} on going from 457.9 to 632.8 nm excitation.

The UV/Vis spectrum of $\mathbf{1}^-$ shows chromophores associated with the Ru→bpy MLCT and $bptz^{\cdot-}$ π→π* transitions. The spectra generated with 457.9, 488.0, and 514.5 nm excitation are dominated by bpy bands but at 632.8 nm excitation $bptz^{\cdot-}$ bands are evident. The signature for the $bptz^{\cdot-}$ comes from the spectrum of $\mathbf{2}^-$ which shows the vibrational signature of $bptz^{\cdot-}$ and reveals the π→π* transition to lie at ca. 430 nm.

The excited-state resonance Raman spectra of **1*** show spectral features that are not a simple linear combination of the oxidised metal centre and ligand radical anion. This is consistent with a pair of acceptor and donor orbitals that are delocalised over the two Ru centres and the bptz ligand. A delocalised donor orbital is consistent with a Class III mixed-valent species. It may also be due to the differing probe wavelengths employed in the excited-state spectra of **1** over the spectroelectochemical spectra of $\mathbf{2}^-$.

Experimental Section

Complex Synthesis: $[(bpy)_2Ru(\mu\text{-bptz})Ru(bpy)_2](PF_6)_4$ [**1**·$(PF_6)_4$] and $[(PPh_3)_2Cu(\mu\text{-bptz})Cu(PPh_3)_2](BF_4)_2$ [**2**·$(BF_4)_2$] were prepared by literature procedures.[58−60] Purity was confirmed by microanalysis. **1** can exist in a number of diastereoisomers; no attempt was made to separate them.

Physical Measurements: Electronic absorption spectra were measured using a Perkin−Elmer λ-19 spectrometer. Electrochemical and spectroscopic measurements used solvents of spectroscopic grade. These were further purified by distillation and were stored over 5-Å molecular sieves. The supporting electrolytes used in the electrochemical measurements were tetrabutylammonium perchlorate (TBAP) and tetrabutylammonium hexafluorophosphate (TBAH). These were purified by repeated recrystallizations from ethanol/water, for TBAP, or ethyl acetate/ether, for TBAH.[61] Cyclic voltammograms (CVs) were obtained from argon-purged degassed so-

lutions of compound (ca. 1 mM) with 0.1 M concentration of TBAP or TBAH present. The electrochemical cell consisted of a 1.6 mm diameter platinum working electrode embedded in a Kel-F cylinder with a platinum auxiliary electrode and a saturated potassium chloride calomel reference electrode. The CV was calibrated against ferrocene/ferrocenium couple by addition of ferrocene to the sample cell and the running of a calibration CV. The potential of the cell was controlled by an EG&G PAR 273A potentiostat with Model 270 software. Resonance Raman spectra, generated with continuous wave excitation, were obtained using an air-cooled argon ion laser (Melles−Griot Omnichrome 543-MAP) or helium-neon laser (Oplectra). Plasma emission lines were removed from the exciting beam using bandpass filters or a wavelength-specific holographic laser bandpass filter (Kaiser Optical Systems, Inc.). Spectra were analysed by using GRAMS 5.0 (Galactic Industries). The cell used for Raman spectroelectrochemistry was an OTTLE cell.[62] The sample was held in a spinning NMR tube or OTTLE cell and Raman photons were imaged into the spectrograph (SPEX 750M) with a 135° backscattering arrangement. The spectrograph was equipped with an 1800 g/mm holographic grating; detection was achieved using a CCD (Princeton Instruments 1152 EUV LN_2 cooled with CSMA version 2.3 software). Calibration of Raman spectra were achieved with neon or argon ion emission lines. Spectral calibrations were checked against solvent spectra.[63] This revealed that peak reproducibility was accurate to 1.5 cm^{-1} across differing excitation wavelengths. For electronic absorption spectroelectrochemistry spectra were acquired at a series of applied potentials stepping through the oxidation or reduction of interest. For Raman studies the applied potential was set beyond the $E^{0\prime}$ value of the electrochemical process, and data were collected after sufficient time that the probed volume contained only the reduced or oxidised product. The frequency-doubled output from an Nd:YAG (Continuum Surelite I-10) pulsed laser (5−7 ns pulse width, operating at 10 Hz) was used to generate excited-state resonance Raman (ESRR) spectra at 532 nm, it was also used to provide stimulated Raman scattering[64,65] for the ESRR experiments with 633 nm excitation. The 532 nm output from the Nd:YAG laser was focused into a 10-cm cell filled with spectrophotometric grade acetonitrile. A quartz Pellin−Broca prism was used to separate the co-linear partially depleted pump beam and four Stokes orders of stimulated Raman scattering. The first Stokes output from the Raman shifter was directed onto the sample in the same manner as the continuous-wave Raman experiments. Typically a 532 nm, 7−40 mJ pump pulse was used, generating 0.5−4.5 mJ of the second Stokes-shifted line at 633 nm. Beam diameter at sample was 300 μm. The geometry and vibrational frequencies of the bptz ligand and its radical anion were obtained using HF and DFT-HF hybrid calculations implemented with the Gaussian98 and -94 program packages.[66,67] Visualization of the MOs and vibrational modes was provided by the Molden package.[68]

X-ray Crystallographic Study: Crystal data for **2**·$(BF_4)_2$·CH_2Cl_2: $C_{85}H_{68}B_2Cl_2Cu_2F_8N_6P4$, M = 1668.93, triclinic, a = 13.2173(2), b = 13.2183(2), c = 14.70050(10) Å, α = 87.8200(10), β = 69.1300(10), γ = 64.0130(10)°, V = 2135.72(5) $Å^3$, T = 175 K, space group $P\bar{1}$, Z = 1, μ(Mo-K_α) = 0.699 mm^{-1}, d = 1.298 Mg/m^3. Data collection: Siemens SMART CCD area detector, graphite monochromator, 0.38 × 0.22 × 0.14 mm, 20511 reflections measured, 9168 unique (R_{int} = 0.0173) which were used in all calculations. The final $Rw(F_o^2)$ = 0.0983 [$R(F_o)$ = 0.0383] $Rw(F_o^2)$ = $[\{w(F_o^2 - F_c^2)^2\}]/\{w(F_o^2)^2\}]^{1/2}$ where w^{-1} = $[\sigma^2(F_o^2) + (aP)^2 + bP]$ (a = 0.0498; b = 1.20) and P = $[\max(F_o^2,0) + 2F_c^2]/3$. All other aspects of data collection, reduction, solution and refinement were performed as previously described.[62][69] Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-166062. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[57] One pragmatic possibility for the absence of $bptz^{\cdot-}$ features is that the bands observed in **1*** are $bptz^{\cdot-}$ in nature but differ from those seen in $\mathbf{2}^-$ because of the differing λ_{exc} used. The UV/Vis spectroelectrochemistry of $\mathbf{2} \rightarrow \mathbf{2}^-$ reveals that $bptz^{\cdot-}$ is not highly absorbing at 532 or 633 nm.

Trichlorohydroxyphosphonium Hexafluorometallate — Synthesis, Spectroscopic Characterization and Crystal Structure of $Cl_3POH^+AsF_6^-$

Rolf Minkwitz*[a] and Markus Dzyk[a]

Keywords: Phosphonium salts / Superacidic systems / Structure elucidation / Vibrational spectroscopy

The reaction of trichlorophosphane oxide with the superacidic systems XF/MF_5 (X = H, D; M = As, Sb) leads to trichlorophosphonium hexafluorometallates. The structure of trichlorophosphonium hexafluoroarsenate was successfully determined. $Cl_3POH^+AsF_6^-$ crystallises in the orthorhombic space group *Pnma* (No. 53) with four formula units per unit cell with the dimensions a = 1286.7(1) pm, b = 842.2(1)pm and c = 822.2(1) pm. The Raman, IR, ^1H and ^{31}P NMR spectra of $Cl_3POX^+MF_6^-$ (X = H, D; M = As, Sb) are reported.

Introduction

The behaviour of trichlorophosphane oxide in strongly acidic solvents has been studied by various techniques since 1966.[1−8] Gillespie et al. found $POCl_3$ to be a non-electrolyte in 100% H_2SO_4, while Paul and co-workers, using mainly cryoscopy and conductance techniques, concluded that $POCl_3$ is incompletely protonated in HSO_3F, but completely protonated by $H_2S_2O_7$ to Cl_3POH^+.[1−4] Partial protonation of $POCl_3$ by chlorosulfuric acid has been reported by Zaidi et al.[5] Dillon et al. and Hibbert et al. used ^{31}P NMR spectroscopy to investigate the behaviour of $POCl_3$ in different acidic media.[6,7] Their studies suggested that an increase of the acidic strength leads to an increase in the degree of protonation of $POCl_3$ in the different acids. Dillon et al. observed the formation of the Cl_3POH^+ cation as an intermediate in the reaction of PCl_3 or PCl_5 with acidic solvents like H_2SO_4 (100%), oleum or HSO_3Cl.[6,8] No attempts were made to isolate the Cl_3POH^+ cation in the form of a phosphonium salt.

In recent years our research group has been successful in the isolation and characterisation of such unstable onium salts by protonation of various precursors at low temperature in the superacidic system HF/MF_5 (M = As, Sb).[9−11] Within the scope of our investigations of the behaviour of phosphorus compounds in the superacidic systems HF/MF_5 (M = As, Sb) we isolated a series of $Cl_3POX^+MF_6^-$ salts (X = H, D; M = As, Sb) and characterised them by X-ray diffraction, and vibrational and NMR spectroscopy.[12−14]

Results and Discussion

Formation of $Cl_3POX^+MF_6^-$ Salts (X = H, D; M = As, Sb)

The salts are prepared by protonation of trichlorophosphane oxide in superacidic media XF/MF_5 (X = H, D; M = As, Sb) [Equation (1)].

$$Cl_3PO + XF + MF_5 \rightarrow Cl_3POX^+MF_6^- \quad (X = H, D; M = As, Sb) \qquad (1)$$

The colourless solids are stable for several months at −70 °C under nitrogen atmosphere, decomposing at −30 °C in the case of the hexafluoroarsenates and at −5 °C in the case of the hexafluoroantimonates. The salts are slightly soluble in sulfur dioxide at −60 °C and HF at −78 °C.

X-ray Crystal Structure of $Cl_3POH^+AsF_6^-$

Trichlorohydroxyphosphonium hexafluoroarsenate crystallises in the orthorhombic space group *Pnma* (No. 53) with a = 1286.7(1) pm, b = 842.2(1) pm, c = 822.2(1) pm and four formula units per unit cell. The crystal structure was solved by applying the Patterson method and successive difference Fourier syntheses. For refinement full-matrix least-square methods were applied. The hydrogen atom was taken from Fourier maps and refined with isotropic displacement parameters; all non-hydrogen atoms were refined with anisotropic displacement parameters. For the data reduction, structure solution, and refinement, programs in the SHELXTL package, PLATON, MISSYM, and PARST were used.[16−18] The crystal data are summarised in Table 1.[19] The cation has C_s symmetry and the anion a distorted octahedral structure. Bond lengths and selected angles are shown in Table 2. The structure of the trichlorohydroxyphosponium cation with a hydrogen bond

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434−1948/02/0303−0564 $ 17.50+.50/0 *Eur. J. Inorg. Chem.* **2002**, 564−568

[O···F(2): 249.5(9) pm] and weak interionic contacts to the nearest fluorine atoms of the anions is shown in Figure 1. Figure 2 shows a section of the crystal structure. The hydrogen bond and the strongest interionic Cl···F contact result in the formation of chains parallel to the *ac* plane, and the other weaker Cl···F contacts lead to a linkage of these chains. One of the chlorine atoms [Cl(1)] forms more contacts to fluorine atoms than the others. This different environment of the Cl atoms correlates with more vibrational modes for the PCl_3 group in the IR and Raman spectra (see below). The PO bond length of 150.6(7) pm is lengthened relative to the precursor [$POCl_3$: 145.6(1) pm] and lies in the range between typical single and double bonds.[20,21] In comparison to the precursor the phosphorus-chlorine bond lengths are equal and shortened [$POCl_3$: 196.6(1) pm to 199.0(1) pm].[20] The phosphorus has a distorted tetrahedral environment with angles between 107.4(2)° and 111.9(3)°.

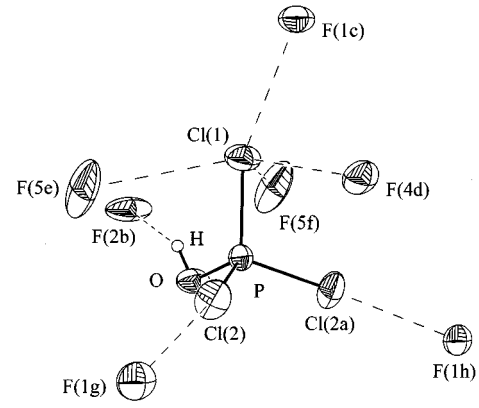

Figure 1. Fragment of the structure of $Cl_3POH^+AsF_6^-$, showing the Cl_3POH^+ cation with interionic contacts (50% probability ellipsoids for the non hydrogen atoms); symmetry operations: a = $x, -0.5 - y, 1 + z$; b = $-0.5 + x, y, -0.5 - z$; c = $-0.5 + x, y, 1.5 - z$; d = $x, +y, 1 + z$; e = $0.5 - x, y, 0.5 + z$; f = $0.5 - x, 0.5 + y, 0.5 + z$

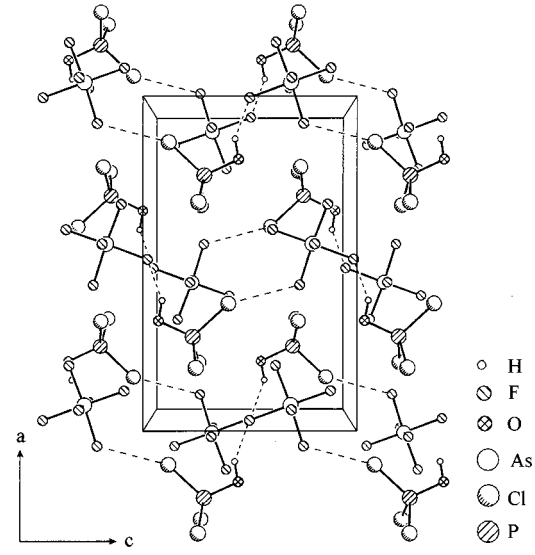

Figure 2. Structure of $Cl_3POH^+AsF_6^-$, showing the arrangement in the crystal lattice

The As−F bond lengths of the anion that is involved in the hydrogen bond and the short Cl···F contacts are longer than the other As−F lengths. A distorted octahedral structure is found for the AsF_6^- anions in the $Cl_3POH^+AsF_6^-$ salt, with deviations from an ideal octahedron of up to 3.3°.

Vibrational Spectra

The Raman and IR spectra of $Cl_3POD^+AsF_6^-$ are shown in Figure 3 and all observed wavenumbers of the salts are summarised in Table 3. The vibrational spectra are assigned according to C_s symmetry for the Cl_3POX^+ cation (X = H, D) and by comparison with the precursor and IR matrix spectra of the isoelectronic trichlorohydroxysilane.[22−24] The cation has twelve fundamental modes consisting of eight A_1 vibrations and four A_2 vibrations. All vibration modes are active in both the Raman

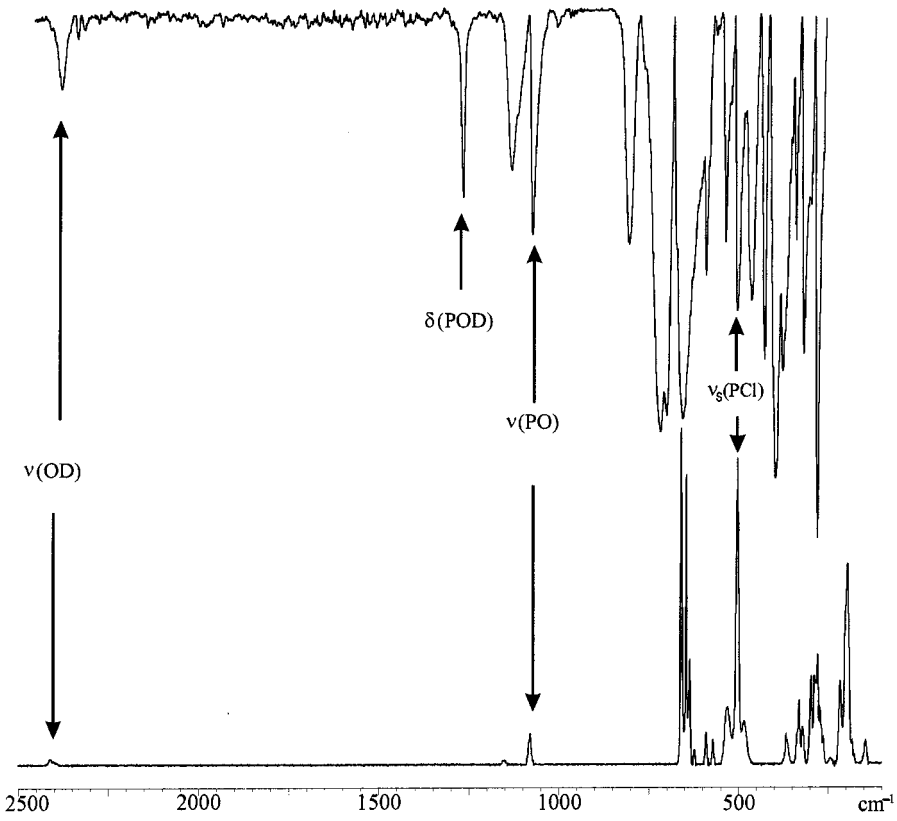

Figure 3. IR and Raman spectra of $Cl_3POD^+AsF_6^-$

and IR spectra. Due to the different interactions between the chlorine and fluorine atoms (see above) we observed more vibrational modes for the PCl_3 group than would have been expected without the X-ray studies. Altogether fifteen vibrational modes for the Cl_3POX^+ cation (X = H, D) were detected. Vibrational modes below 220 cm^{-1} were not detectable on account of the window material used in the low temperature cuvette for IR measurements (CsBr). The fifteen detected modes can be divided into four modes which are associated with the OH and PO modes, with the remaining modes being considered as motions of the PCl_3 group.

The OH and OD stretching modes are found at 3135 cm^{-1} and 2410 cm^{-1}, respectively. The corresponding POX (X = H, D) deformation modes were only observed by IR spectroscopy (at 1280 cm^{-1}) due to their low Raman intensity. The position of the PO stretching mode is important for the spectroscopic confirmation of the Cl_3POX^+ cation. The PO stretching mode is shifted to lower wavenumbers by 200 cm^{-1}, relative to the precursor, corresponding to protonation of Cl_3PO at the O atom.[22] The PCl stretching modes are observed in the range of 501 to 667 cm^{-1}. They are shifted by up to 80 cm^{-1} to higher wavenumbers relative to the analogous vibrations in trichlorophosphane oxide.[22] The PCl_3 deformation modes are found between 193 and 430 cm^{-1}. Two OPCl deformation modes are detected at 800 cm^{-1} and 1150 cm^{-1}, respectively, due to the interionic interactions between the Cl atoms and the F atoms of the anions.

Because of cation−anion interactions, the MF_6^- ions (M = As, Sb) do not show ideal O_h symmetry. This lowered symmetry causes a splitting of the anion vibrational modes.[25]

^1H and ^{31}P NMR Spectra of $Cl_3POH^+MF_6^-$ (M = As, Sb)

The ^1H NMR spectra of freshly prepared $Cl_3POH^+MF_6^-$ (M = As, Sb) dissolved in SO_2 with TMS as external standard at −60 °C show a singlet at δ = 10.7 (AsF_6^-) and δ = 10.8 (SbF_6^-) for the hydroxyl group. In the ^{31}P NMR spectra a singlet at δ = 55.5 for the arsenate and δ = 55.2 for the antimonate are observed. These signals are shifted to lower field by more than 51 ppm relative to the precursor. This result is similar to the results of Dillon and Hibbert (Table 4).[6,7]

Experimental Section

Caution: *Avoid contact with these compounds and note that the hydrolysis of AsF_6^- and SbF_6^- salts forms HF, which burns the skin and causes irreparable damage. Safety precautions should be taken when using and handling these materials!*

General: All synthetic work and sample handling was conducted by standard Schlenk techniques on a standard vacuum line (stainless steel or glass). Drying of HF was carried out with Fluorine (1.5 bar) in a stainless steel bomb. AsF_5 was synthesised from As and F_2.[26] SbF_5 (Merck) and $POCl_3$ (Merck) were distilled repeat-

edly before use. Reactions in HF were carried out in a KEL-F reactor fitted with a KEL-F valve. The Raman spectra were recorded on a Jobin Yvon T64000 spectrometer using an Ar^+ laser (514.5 nm) from Spectra Physics. The spectra were obtained in a glass cell cooled with solid CO_2.[27] Infrared spectra were recorded on a Bruker ifs 113v spectrophotometer. Spectra were obtained from a coated CsBr plate in a low-temperature cuvette.[28] NMR spectra were recorded with a Bruker DPX spectrometer and referenced to either TMS (^1H) or 85% H_3PO_4 (^{31}P) in SO_2 at −60 °C. Single crystals for the crystallographic studies were placed in Lindemann capilllaries in a cooled stream of dry nitrogen, and an X-ray diffraction study was carried out at −100 °C using a Nonius Kappa CCD (1152 × 1242 Pixel) diffractometer.

Preparation of $Cl_3POX^+MF_6^-$ (X = H, D; M = As, Sb): In a typical reaction, 5 mL of XF (X = H, D) was distilled into the Kel-F reactor at −196 °C, followed by 0.2 mmol of MF_5 (M = As, Sb). The mixture was warmed to 20 °C to form the superacid. The reactor was then cooled to −196 °C, and $POCl_3$ (0.2 mmol) was added. The mixture was warmed to −78 °C. After removing the volatile compounds at −78 °C during 7 days colourless solids, stable up to −30 °C (arsenate) and −5 °C (antimonate) were obtained.

$Cl_3POH^+AsF_6^-$: ^1H NMR: δ = 10.7 (s). ^{31}P NMR: δ = 55.5(s).

$Cl_3POH^+SbF_6^-$: ^1H NMR: δ = 10.8 (s). ^{31}P NMR: δ = 55.2(s).

The Crystal Structures of the Trihalogenphosphonium Salts $X_3PH^+As_2F_{11}^-$ (X = Cl, Br)

Rolf Minkwitz*[a] and Markus Dzyk[a]

Keywords: Phosphonium salts / Protonation / X-ray diffraction / Phosphorus / Main group elements

The X_3PH^+ ions (X = Cl, Br) were prepared as their $X_3PH^+As_2F_{11}^-$ salts by protonation of PX_3 with HF/AsF_5 at low temperature in anhydrous HF. Single crystals were obtained directly from this solvent. $Cl_3PH^+As_2F_{11}^-$ crystallises in the orthorhombic space group *Pnma* (No. 53) with a = 2350.6(1) pm, b = 837.7(1) pm, c = 1179.9(1) pm and eight formula units per cell. $Br_3PH^+As_2F_{11}^-$ crystallises in the monoclinic space group $P2_1/m$ (no. 14) with a = 617.7(1) pm, b = 872.4(2) pm, c = 1182.5(2) pm, β = 94.68(3)° and two formula units per cell.

Introduction

Salts with the phosphonium ion PR_4^+ are very well known, and R can be an organic or an inorganic group like hydrogen or halogen, amongst others. In contrast to phosphonium ions with organic groups relatively little is known about halogenated phosphonium salts. Only the fluorinated salts $F_{4-n}PH_n^+A^-$ (n = 0−3, A^- = anion) have been characterised by NMR and vibrational spectroscopy.[1−5] Recently Seppelt at al. prepared the salt $F_3PH^+SbF_5^-$ from a $PF_3/HF/SbF_5$ solution and determined its crystal structure by X-ray diffraction.[6]

Most of the corresponding chlorine and bromine compounds are not yet known. A few years ago our research group prepared a series of $X_3PH^+AsF_6^-$ salts (X = Cl, Br; M = As, Sb) by protonation of phosphorus trihalides with HF/MF_5.[7] The compounds were characterised by vibrational and NMR spectroscopy. Due to the negligible solubility no single crystals of these compounds were available. Within the scope of further investigations of the behaviour of phosphorus trihalides in the superacidic system HF/AsF_5 we have isolated single crystals of $X_3PH^+As_2F_{11}^-$ salts (X = Cl, Br) and determined their structures by X-ray diffraction.

Results and Discussion

Formation of $X_3PH^+As_2F_{11}^-$ (X = Cl, Br)

Protonation of phosphorus trichloride or phosphorus tribromide by the superacidic system HF/AsF_5 gives the corresponding phosphonium undecafluorodiarsenates [Equation (1)]:

$$X_3P + HF + 2AsF_5 \rightarrow X_3PH^+As_2F_{11}^- \quad (X = Cl, Br) \qquad (1)$$

The resulting colourless, moisture-sensitive salts decompose in the case of the trichlorophosphonium salt above −25 °C, and in the case of the bromine compound above −45 °C. They can be stored for several months without decomposition under inert conditions at −70 °C.

X-ray Crystal structure of $Cl_3PH^+As_2F_{11}^-$

Trichlorophosphonium undecafluorodiarsenate crystallises in the orthorhombic space group *Pnma* (no. 53) with eight units per cell (see Table 1).[8] For data collection and reduction, a semi-empirical correction determined from single ψ-scan data, and programs in the SHELXL package, PLATON, MISSYM and PARST, were used.[9−12] The solution of the crystal structure was done by the Patterson method with a subsequent difference Fourier synthesis. A final refinement with anisotropic (except H atoms) thermal parameters gave a value of R = 0.0314.

The orthorhombic unit cell contents two crystallographically independent anions and cations. Table 2 lists important bond lengths and angles. Figure 1 shows a trichlorophosphonium cation with weak interionic contacts to the nearest atoms of the anions and Figure 2 a section of the crystal structure. The cation has the shape of a trigonal pyramid and the anion has a distorted edge-linked dioctahedral structure. The P−Cl bond lengths [192.9(1)−193.6(1) pm] show no significant differences and they are shortened by about 10 pm relative to the precursor PCl_3 [PCl_3: P−Cl = 203.9(1) pm].[13] The Cl−P−Cl angles of 109.5(1)° to 110.1(5)° are wider than in phosphorus trichloride [PCl_3: Cl−P−Cl = 100.07(7)−100.19(7)°].[13]

The two independent cations form the same kind of interionic contacts to the fluorine atoms of neighbouring an-

[a] Symmetry operation: a = x, $-y$, 0.5 + z.

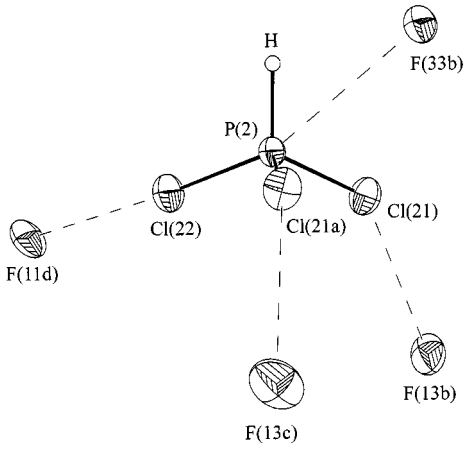

Figure 1. Fragment of the structure of $Cl_3PH^+As_2F_{11}^-$, showing the Cl_3PH^+ cation of the crystallographically independent unit 2 with interionic contacts (50% probability ellipsoids for the non-hydrogen atoms); symmetry operations: a = x, 0.5 − y, z; b = 0.5 − x, $-y$, $-0.5 + z$; c = 0.5 − x, 0.5 + y, $-0.5 + z$; d = $-0.5 + x$, y, 2.5 + z

ions, but with different strengths. There are chlorine-fluorine contacts of between 280.4(3) and 312.5(3) pm and P−F contacts of 300.4(2) pm and 321.9(2) pm, respectively. There are no contacts between hydrogen and fluorine atoms that are significantly below the sum of the van der Waals radii of 267 pm. The interionic contacts result in the formation of a three-dimensional linkage of anions and cations.

The anion consists of two distorted octahedra which are linked at one corner. The As−F bond lengths involving the "bridging" fluorine atom are 205.9(2) pm and are thus significantly longer than the other As−F bond lengths of between 167.7(2) and 170.5(2) pm, which are in the normal range of As−F bond lengths of hexafluoroarsenate anions.[14−16] These unusually long As−F bonds are in the same range as in the other known $As_2F_{11}^-$ salts.[14−16] In both anions the two octahedral AsF_6 units are in a gauche arrangement. The average torsion angles F−As−As−F of

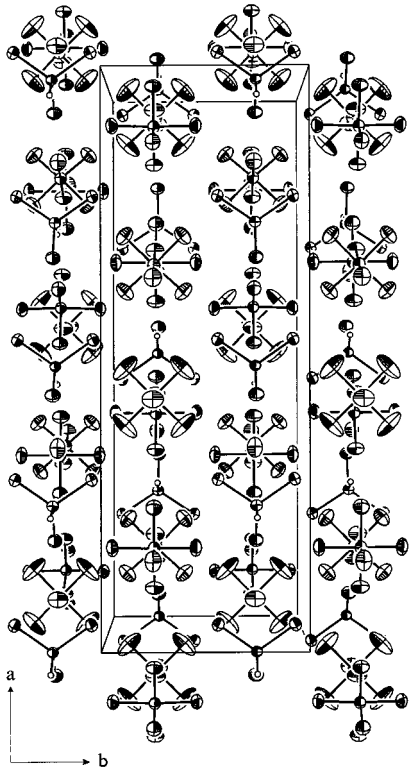

Figure 2. Projection of the $Cl_3PH^+As_2F_{11}^-$ salt

45.3° and 45.6° and the As−F−As bridge angles of 145.6(2)° and 148.3(2)° are similar to those found in other $As_2F_{11}^-$ salts.[14−16]

X-ray Crystal structure of $Br_3PH^+As_2F_{11}^-$

$Br_3PH^+As_2F_{11}^-$ crystallises in the monoclinic space group $P2_1/m$ (No. 14) with a = 617.7(1) pm, b = 872.4(2) pm, c = 1182.5(2) pm, β = 94.68(3)° and two formula units per unit cell.[17] The crystal structure was solved by direct methods and successive difference Fourier syntheses. For refinement full-matrix least-squares methods were applied. A final refinement with anisotropic (except H atoms) thermal parameters gave a value of R = 0.0504. For data reduction, structure solution, and refinement the same programs were used as for the structure solution of $Cl_3PH^+As_2F_{11}^-$.[9−12]

The crystal data are summarised in Table 1 and bond lengths and selected angles are shown in Table 3.

Table 3. Bond lengths [pm], selected angles [°] and contacts [pm] for $Br_3PH^+As_2F_{11}^-$[a]

Br(1)−P	211.1(2)	Br(1)−P−Br(2)	110.8(1)
Br(2)−P	211.1(4)	Br(1a)−P−Br(1)	110.3(2)
As(1)−F(11)	170.1(5)		
As(1)−F(12)	170.0(7)	As(1)−F(15)−As(2)	145.9(4)
As(1)−F(13)	171.0(6)	F(11)−As(1)−F(12)	89.8(2)
As(1)−F(14)	172.9(6)	F(13)−As(1)−F(14)	174.9(4)
As(1)−F(15)	183.6(6)		
As(2)−F(21)	168.5(5)	Br(1)·····F(13)	306.1(3)
As(2)−F(22)	168.5(7)	Br(1)·····F(21)	325.1(2)
As(2)−F(23)	167.8(6)	Br(2)·····F(22)	300.8(7)
As(2)−F(15)	202.0(6)		

[a] Symmetry operation: a = x, y − 1.5, z.

The phosphorus−bromine bond lengths are equal and shorter by about 10 pm than in the precursor [PBr_3: P−Br = 221.2(3) pm].[18] The Br−P−Br angles of 110.3(2)° and 110.8(1)° are wider than in phosphorus tribromide [PBr_3: Br−P−Br = 99.0(2)−101.3(2)°].[18]

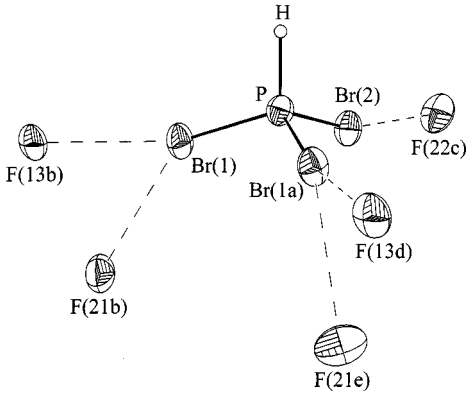

Figure 3. Fragment of the structure of $Br_3PH^+As_2F_{11}^-$, showing the Br_3PH^+ cation with interionic contacts (50% probability ellipsoids for the non-hydrogen atoms); symmetry operations: a = x, y − 1.5, z; b = 1 + x, 1 + y, z; c = −x, 1 − y, 1 − z; d = 1 − x, −y, −z; e = 1 + x, 0.5 − y, z

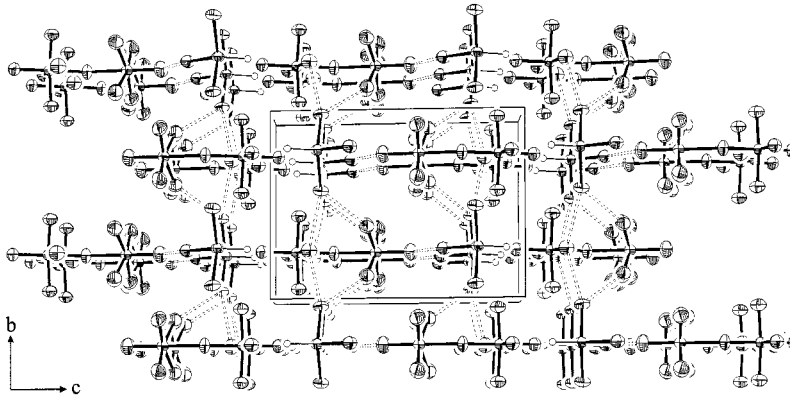

Figure 4. Projection of the $Br_3PH^+As_2F_{11}^-$ salt with interionic contacts

The cations form interionic contacts of different strengths to fluorine atoms of neighbouring anions (Figure 3). Two weak fluorine−bromine contacts of 300.8(7) pm and 325.1(2) pm result in the formation of chains in the *bc* plane. The chains of different *bc* planes are connected along the *c* axes by further weak fluorine−bromine contacts of 321.8(7) pm (Figure 4).

The undecafluorodiarsenate anion has the same distorted edge-linked dioctahedral structure as the anion in the $Cl_3PH^+As_2F_{11}^-$ salt. All bond lengths and angles of the anion (Table 3) are of the same order as the previous salt and similar to the other known $As_2F_{11}^-$ salts.[14−16]

Experimental Section

All synthetic work and sample handling was conducted by standard Schlenk techniques on a standard vacuum line (stainless steel or glass). Drying of HF was carried out with Fluorine (1.5 bar) in a stainless steel bomb. AsF_5 was synthesised from As and F_2.[19] The synthesis of PBr_3 was carried out by a known literature method from Br_2 (Riedel de Haen) and red phosphorous (Fluka).[20] PBr_3 and PCl_3 (Riedel de Haen) were distilled repeatedly before use. Reactions in HF were carried out in a KEL-F reactor fitted with a KEL-F valve. Single crystals were placed in Lindemann capillaries in a cooled stream of dry nitrogen, and an X-ray diffraction study was carried out at −100 °C using a Nonius Kappa CCD-(1152 × 1242 Pixel) diffractometer.

Preparation of $X_3PH^+As_2F_{11}^-$ (X = Cl, Br):

Caution! Avoid contact with these compounds and note that hydrolysis of $As_2F_{11}^-$salts forms HF, which burns the skin and causes irreparable damage. Safety precautions should be taken when using and handling these materials!

In a typical experiment AsF_5 (1 g, 5.9 mmol) was dissolved in HF (10 g) in a 50 mL KEL-F reactor. The solution was frozen at −196 °C and PX_3 (X = Cl, Br; 0.01 mmol) was added under an inert atmosphere (N_2). The mixture was warmed to −78 °C and kept for 30 minutes. The excess HF and AsF_5 were very slowly removed during 5 days under dynamic vacuum at −78 °C. The remaining colourless salts contained crystals suitable for X-ray diffraction studies and can be stored under inert conditions at −70 °C without decomposition.

High Molecular Weight Cu^{II} Coordination Polymers and Their Characterisation by Electrospray Mass Spectrometry (ESMS)

Hélène Nierengarten,[a] Javier Rojo,[b] Emmanuelle Leize,*[a] Jean-Marie Lehn,[b] and Alain Van Dorsselaer[a]

Keywords: Supramolecular chemistry / Copper / Polymers / Mass spectrometry / Self-assembly

The ligands L and ligand L* self-assemble with Cu^{II} in different solvents to give a mixture of coordination polymers. These artificial nanostructures have been characterised with the help of ESMS, the only analytical tool that allows their unambiguous characterisation. Kinetic and thermodynamic ESMS studies have excluded the possibility that these compounds form aggregates during the ES process.

Introduction

The self-assembly of suitably designed organic ligands with transition-metal ions allows the generation of a wide range of polymetallic complexes possessing a variety of well-defined architectures (racks, ladders, grids, rings, etc.).[1,2] These organised entities, and especially coordination polymers, may present interesting physical and chemical properties and are of much current interest within metallosupramolecular chemistry due to their potential applications in materials science.[3] One of the challenges in this field resides in the preparation of high molecular weight coordination polymers that may possess good solubilities in order to characterise their properties in solution as well as in the solid state. Unfortunately, an unequivocal structural analysis of these metallosupramolecular compounds is often missing. Indeed, because of the complexity of the NMR spectra and because of the recurrent presence of paramagnetic metals, NMR spectroscopy is often unusable. In the same way, X-ray suitable crystals of sufficient quality are often difficult to obtain; the use of X-ray crystallography is therefore limited. The other classical analytical tools able to give any information are in most cases inconclusive with respect to the formulation (e.g., UV/Vis absorption and emission spectroscopy, infrared, etc.). An unambiguous characterisation is therefore highly compromised. Despite the problems and difficulties that often occur during the development of this chemistry (especially due to the increasing size of such molecules), encouraging perspectives are offered by the use of electrospray mass spectrometry (ESMS)[4] for an unequivocal characterisation. ESMS has been proven to be a very useful technique for the characterisation of biological[5] and chemical[6] assemblies. Moreover, this analytical method is particularly suitable for large, noncovalent species with high molecular masses. Indeed, when several parameters are carefully controlled, ESMS is a mild method, which causes minimum fragmentation and therefore allows molecular mass determination.

We describe here the characterisation in solution by ESMS of the largest reported Cu^{II} coordination polymers stable in solution up to a concentration of 10^{-4} M and soluble in common organic solvents (acetonitrile, methanol, nitromethane). In this present case, ESMS was the only analytical tool allowing an unambiguous characterisation. Therefore, kinetic and thermodynamic studies have been undertaken in order to exclude the possibility that these coordination polymers are aggregates resulting from the ES process.[7]

Results and Discussion

The ligand **L** was synthesised following the procedure outlined in Scheme 1. The self-assembly reaction to obtain the Cu^{II} coordination polymers was carried out as follows: an equimolar amount of the ligand **L** and $Cu(CF_3SO_3)_2$ were mixed together in anhydrous acetonitrile (ca. 10^{-4} M), the mixture was stirred at room temperature for five minutes and a clear blue solution was obtained.

The analysis of this solution by ESMS immediately after preparation has shown the presence of coordination complexes of general formula $[LCu(CF_3SO_3)_2]_n$, M_n, in equilibrium in solution (Figure 1). Ions observed in the ES mass spectrum (M_n^{x+}; $1 \leq n \leq 47$ and $1 \leq x \leq 4$) are interpreted

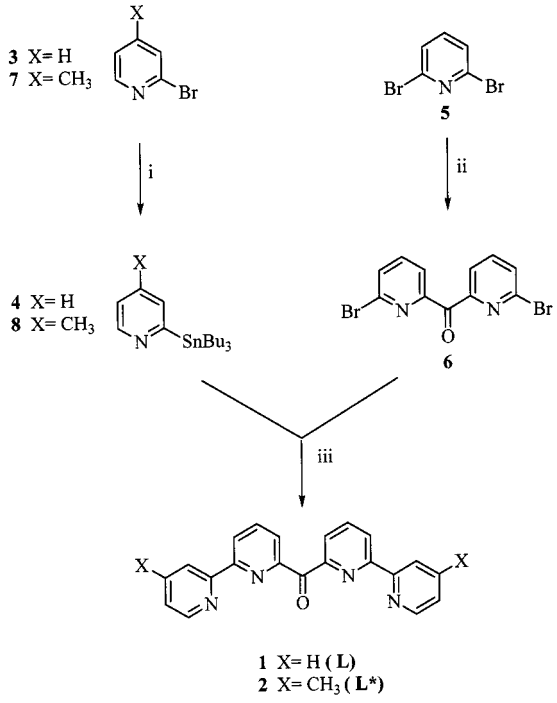

Scheme 1. i, *n*BuLi, THF, −78 °C; Bu_3SnCl, −78 °C, 96%; ii, *n*BuLi, ether, −90 °C; $ClCO_2Et$, 47%; iii, $Pd(PPh_3)_4$, toluene, 110 °C, 50−76%

as the successive loss of *x* counter anions $CF_3SO_3^-$ ($^-$OTf), leading to multiply charged ions, and correspond to molecular masses up to 32901.4 Da ($n = 47$).

The charge states of these ions were unambiguously determined owing to the high-resolution capability of a time of flight analyser (Figure 2). Charge states of these ions range from $x = 1+$ to $x = 4+$. The largest polymer ($n = 47$) has been identified owing to its 4+ charged ion at $m/z = 8076.0$ (see the ES mass spectra, Figure 1). The ES mass spectra obtained were reproducible (±10%) and identical in terms of relative intensities of the different peaks on four different instruments [Quattro II, LC-Tof, Q-Tof (Micromass, Altrincham, UK) and ESQUIRE-LC (Bruker-Franzen Analytik GmbH, Bremen, Germany)]. All the ions observed were interpreted and are summarised with their *m*/*z* values and their charge states in Table 1.

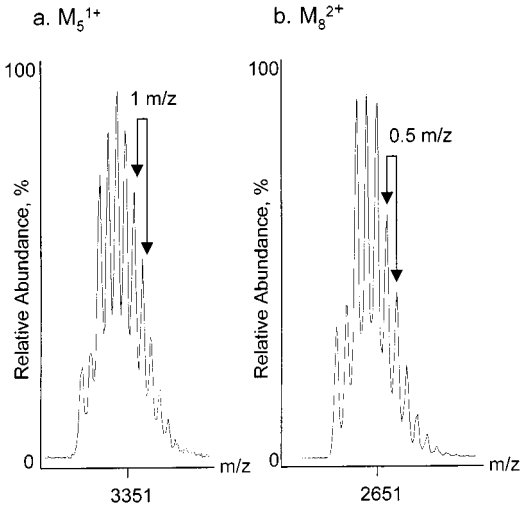

Figure 2. High resolution spectrum, obtained on an LC-Tof spectrometer

These ESMS results in acetonitrile and the stoichiometries determined suggest that in all complexes four nitrogen donor atoms coordinate one Cu^{II}. The IR analysis showed only a slight change in the C=O vibration frequency between the ligand and the mixture of complexes — from 1686 cm^{-1} to 1679 cm^{-1} — suggesting that the carbonyl group does not participate in the coordination with Cu^{II}. Since Cu^{II} is normally pentacoordinated, if we assume

[a] Measured *m/z* (charge state) and calculated *m/z* in italics.

that four nitrogen donor atoms coordinate one Cu^{II}, the fifth coordination position is probably occupied by a molecule of solvent in order to complete the metal coordination sphere. In fact an acetonitrile molecule is probably coordinated to the Cu^{II} in solution but is lost in the gas phase.

To confirm this possible coordination cell, ESMS studies in anhydrous MeOH have been undertaken. Indeed, it has already been observed in the case of metallic complexes that MeOH is a better coordinating solvent than acetonitrile in the gas phase.[8] The ES mass spectrum (Figure 3) obtained in [D_4]MeOH has confirmed the presence of solvent molecules attached to these high-molecular-weight complexes. [D_4]MeOH was used in this case instead of MeOH to facilitate the resolution of the different adducts. In these conditions, for small oligomers (M_n, $n = 1$ to $n = 5$), the addition of one molecule of [D_4]MeOH to each Cu^{II} atom is observed from the *m/z* difference of 36 for singly charged peaks and 18 for doubly charged peaks. Unfortunately, for higher oligomers (M_n, $n > 5$) the ES mass spectrum is too complex at the resolution available (R = 8000) and no information could be obtained on the number of molecules of solvent attached to these large ions.

Slow crystallisation of these oligomers was unsuccessful and only crystals corresponding to the monomer (M_1) structure were found. Thanks to the ESMS and IR data a possible structure was deduced for these polymers in solution (Figure 4). Obviously, a cyclic form cannot be distinguished from a linear structure by mass measurement in our case. However, the 1:1:1 (L:Cu^{II}:MeOH) stoichiometry obtained for small oligomers (M_n, $n = 1$ to $n = 5$), suggests the formation of cyclic compounds in solution. On the other hand, considering the number of units, high polymers (M_n, $n > 5$) should be present as open structures (linear polymers). At both extremities the coordination sphere of Cu^{II} would be completed in solution by acetonitrile molecules, which are lost in the gas phase and not detected in the ESMS.

Considering that ESMS is the only analytical tool allowing an unambiguous characterisation in this case, kin-

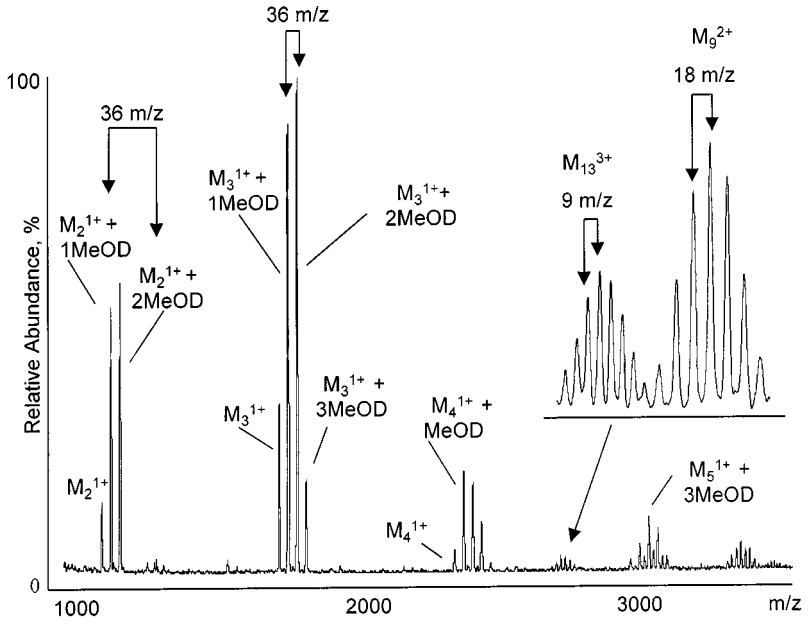

Figure 3. ES mass spectrum of an equimolar mixture of L and $Cu(CF_3SO_3)_2$ in $[D_4]MeOH$

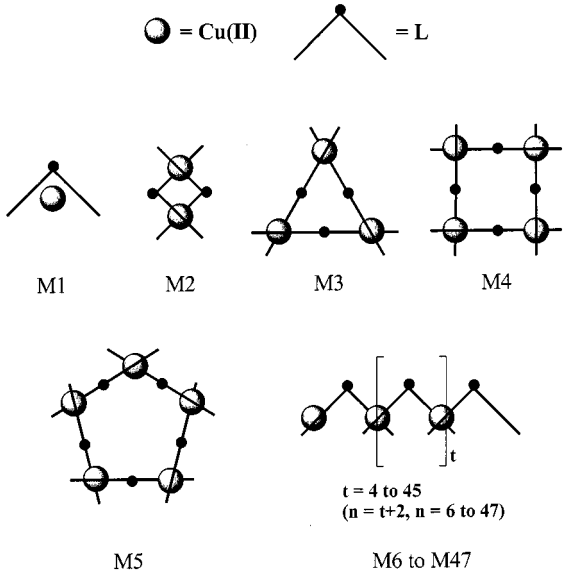

Figure 4. Possible structure of the coordination polymers $[LCu(CF_3SO_3)_2]_n$ deduced from ESMS and IR data (solvent adducts are omitted for clarity)

etic and thermodynamic studies were necessary in order to exclude the possibility of these oligomers being artefacts resulting from the ES process.

Kinetic Studies

The stability of the polymers in solution was tested during 40 days in several anhydrous solvents (acetonitrile, nitromethane, and methanol). ES mass spectra obtained from the same sample immediately after mixing (5 minutes) and after 40 days were found to be the same, showing the high stability of these compounds in solution. In the same way, when 5% water was added to one of these solutions, the ES analysis after 5 minutes was unchanged. Later, peaks corresponding to the higher oligomers progressively disappeared and after 24 hours only one peak corresponding to the monomer complex (M_1^{1+}) was observed in the ES mass spectrum (Figure 5a, b, c).

The observation of this progressive dissociation is the definitive piece of evidence which shows that these high molecular weight coordination complexes are formed in solution and not during the ES process. Hence, the possibility for these polymers of being artefacts of the ES process can be definitely rejected.

Thermodynamic Studies

Attempts to isolate some of the oligomers using size exclusion sephadex chromatography (by classical column or by HPLC) were fruitless and unfortunately only the monomer (M_1) was obtained. This result indicates that all these components are in equilibrium in solution. In order to determine if ligand exchange took place in this high-molecular-weight system, the ligand L was first mixed with a stoichiometric amount of $Cu(OTf)_2$ in anhydrous acetonitrile (ca. 10^{-4} M). Then, after stirring for 5 minutes, one equivalent of the methylated ligand L* (Scheme 1) was added to this mixture. The resulting solution was stirred for 5 minutes at room temperature and analysed immediately. The ES mass spectrum (Figure 6) showed that all possible combinations of oligomers M_aM_b* ($0 < a, b < 9$) of general formula L_aL_b*$[Cu(CF_3SO_3)_2]_{a+b}$ were obtained statistically in solution. This observation clearly indicates that ligand exchange occurred in solution, and confirms that these coordination polymers are in equilibrium in solution. Interestingly, the methylated ligand L* yielded a mixture of oligomers with $Cu(OTf)_2$ in anhydrous acetonitrile in the same manner as obtained with the ligand L.

To complete the study of these compounds, other thermodynamic experiments were carried out. In order to obtain more information about the stability of the complexes in solution, five solutions containing an equimolar amount of $Cu(OTf)_2$ and the ligand L in anhydrous acetonitrile at different concentrations (10^{-3}, 10^{-4}, 10^{-5}, 10^{-6} and 10^{-7} M) were analysed by ESMS. The ES mass spectra obtained showed the presence of the oligomeric mixture for a concentration down to 10^{-4} M. For lower concentrations, these high-molecular-weight complexes disappear and only the monomer ion (M_1^{1+}) is detected, indicating that dissociation processes occur below a concentration of 10^{-4} M (Figure 7a, b).

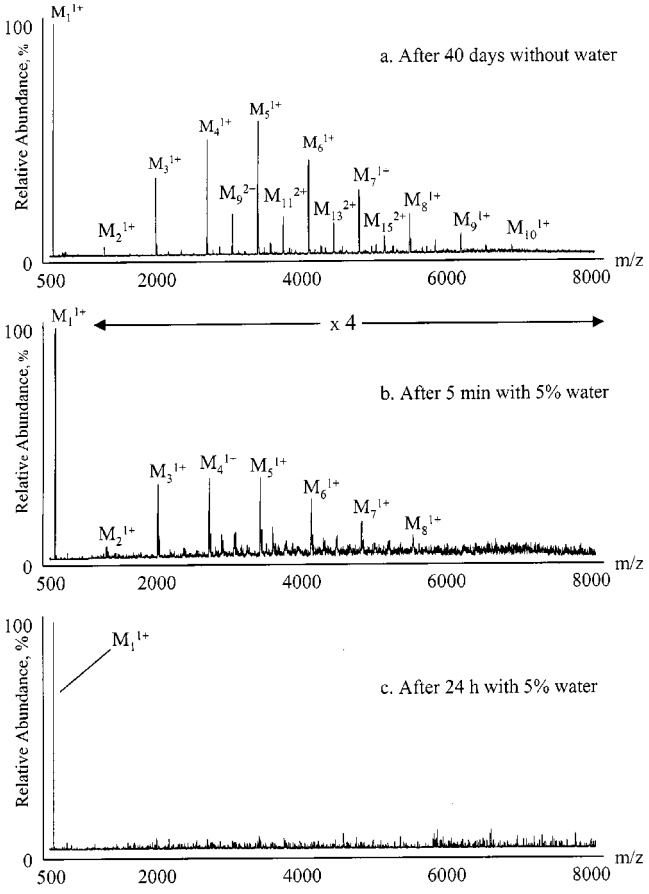

Figure 5a, b, c. Kinetic study: a. in anhydrous acetonitrile after 40 days; b. in acetonitrile with 5% water after 5 min; c. in acetonitrile with 5% water after 24 h; this study addresses the possibility that the compounds are ES process artefacts

Conclusion

We have shown that ligand L and $Cu(CF_3SO_3)_2$ in a 1:1 ratio in anhydrous solvents generate a mixture of high molecular weight coordination polymers of general formula $[LCu(CF_3SO_3)_2]_n$ by self-assembly. The largest oligomer clearly identified contains 47 units and weighs 32901.4 Da. The structure (cyclic for small oligomers and linear for the highest one) has been deduced from the IR and the ESMS data.

The kinetic decomplexation observed in the presence of 5% water shows that these self-assembled polymeric species are formed in solution and are not artefacts due to the ES process. To complete this study, ESMS thermodynamic experiments have been carried out and have demonstrated that these oligomers are in equilibrium in solution, are stable over time and can be observed down to a concentration of 10^{-4} M.

ESMS may therefore be regarded as an extremely valuable tool to prove the existence of very large polynuclear transition metal complexes in solution, and encouraging perspectives are offered for the characterisation of species of nanometric dimensions.

Experimental Section

Materials: Unless otherwise noted, ^{1}H NMR spectra were measured at 200 MHz with a Bruker AC 200 spectrometer in $CDCl_3$ and referenced to the residual solvent peak. Melting points were obtained with a digital Thomas Hoover (Electrotherma) apparatus. Infrared absorption spectra were recorded on a Perkin−Elmer 1600 series FTIR spectrometer in KBr, and electronic absorption spectra on a Cary 219 spectrometer in $CHCl_3$ with λ_{max} in nm and ε ($\times 10^4$) in M^{-1} cm^{-1}. Fast atom bombardment mass spectrometry (FAB-MS) was performed on a ZAB-HF VG spectrometer with *m*-nitrobenzyl alcohol as the matrix. Spectroscopic studies were performed in spectroscopic-grade solvents. All solvents were reagent-grade and used without further purification. The Cu^{II} triflate was purchased from Fluka (Buchs, Switzerland).

ESMS: Positive ES mass spectra were mainly obtained on an ES triple quadrupole mass spectrometer Quattro II with an *m*/*z* range extended to 8000 (Micromass, Altrincham, UK). The electrospray source was heated to 70 °C. The sampling cone voltage (V_c) was set to 70 V and the skimmer Lens Offset to 0 V to allow the transmission of ions with $m/z > 4000$ without fragmentation processes. Sample solutions were introduced into the mass spectrometer source with a syringe pump (Harvard type 55 1111: Harvard Apparatus Inc., South Natick, MA, USA) with a flow rate of 5 $\mu L \cdot min^{-1}$. Calibration was performed using protonated horse myoglobin. Scanning was performed from $m/z = 500$ to 8000 in 20 s, and several scans were summed to obtain the final spectrum. ES mass spectra at higher resolution were obtained on an LC-Tof mass spectrometer (Micromass, Altrincham, UK).

Samples for ESMS were prepared by mixing the corresponding ligand and $Cu(CF_3SO_3)_2$ in a 1:1 ratio to achieve a concentration of 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6} or 10^{-7} M in anhydrous acetonitrile and a concentration of 10^{-4} M in $[D_4]$MeOH. After stirring at room temperature for 1 min, the clear blue solution was analysed directly by ESMS.

Synthesis of the Ligands L and L*: The ligands were prepared as shown in Scheme 1. The stannylation of 2-bromopyridine (**3**) with butyllithium and tributylstannyl chloride gave 2-tributylstannylpyridine (**4**).[9] The ketone **6** was prepared from 2,6-dibromopyridine (**5**) by monolithiation and reaction with ethylchloroformate as previously described.[10] The cross coupling reaction between **4** and **6** or **8** and **6** in the presence of $Pd(PPh_3)_4$ yielded ligand **1 (L)** or ligand **2 (L*)** which were completely characterised.

2-Tributylstannylpyridine (4): A 1.6 M solution of *n*-butyllithium in hexane (39.2 mL, 0.062 mol) was slowly added to a solution of 2-bromopyridine (**3**; 6 mL, 0.062 mol) in THF (120 mL) cooled to −78 °C under argon. After 30 min, Bu_3SnCl (16.8 mL, 0.062 mol) was added to give a dark solution which was stirred at −78 °C for one more hour. The solution was allowed to warm to room temperature and a saturated aqueous solution of NH_4Cl (60 mL) was added. The aqueous phase was extracted with ether (3 × 100 mL) and the combined organic layers were washed with brine (100 mL) and dried (Na_2SO_4). The solvent was removed under reduced pressure to give a yellow oil. The crude product was purified by chromatography on alumina (EtOAc/hexane 1:20) to obtain a pale yellow oil (22.1 g, 96%).[9] ^{1}H NMR: δ = 8.73 (ddd, *J* = 4.9, 1.9, 1.0 Hz, 1 H, H_6), 7.48 (dt, *J* = 7.4, 1.8 Hz, 1 H, H_5), 7.39 (dt, *J* = 7.4, 1.6 Hz, 1 H, H_3), 7.10 (ddd, *J* = 6.9, 4.9, 1.7 Hz, 1 H, H_4), 1.70−1.05 (m, 18 H, CH_2), 0.85 (t, 9 H, *J* = 7.3 Hz, CH_3).

Bis(6-bromo-2-pyridyl)ketone (6): 1.1 Equiv. of *n*-butyllithium in hexane (29 mL, 0.046 mol) was added dropwise under argon to a solution of 2,6-dibromopyridine (**5**; 10 g, 0.042 mol) in diethyl ether (200 mL) cooled to −90 °C. After stirring vigorously for 20 min, a solution of ethyl chloroformate (2.02 mL, 0.021 mol) in diethyl ether (50 mL) was added. The deep blue solution was stirred for one hour and warmed to −40 °C for 30 min. Then, the reaction was quenched successively with methanol (50 mL) and water (50 mL). The organic phase was removed under vacuum and the aqueous layer was extracted with chloroform (3 × 50 mL). The combined organic layers were dried (Na_2SO_4) and the solvent was removed under low pressure. The residue was purified by flash chromatography on silica gel using EtOAc/hexane (1:6) as eluent to give a white solid (3.4 g, 47%). M.p. 159−160 °C (ref.[10] 155−156.5 °C). ^{1}H NMR: δ = 8.08 (dd, *J* = 7.1, 1.4 Hz, 2 H, H_3), 7.76 (dd, *J* = 8.0, 7.2 Hz, 2 H, H_4), 7.69 (dd, *J* = 8.0, 1.5 Hz, 2 H, H_5). ^{13}C NMR: δ = 189.5, 154.0, 141.5, 138.9, 131.4, 124.3.

2-Tributylstannyl-4-picoline (8): 1 Equiv. of a 1.6 M solution of *n*-butyllithium in hexane (18.15 mL, 29.066 mmol) was added at −78 °C under argon to a solution of 2-bromopicoline (**7**; 5 g, 29.066 mmol) in tetrahydrofuran (100 mL). After 30 min, Bu_3SnCl (7.9 mL, 29.066 mmol) was added and the reaction was monitored by TLC. The reaction was allowed to rise to room temperature and after 30 min a saturated aqueous solution of NH_4Cl was added (100 mL). The organic layer was separated and the aqueous layer was extracted with diethyl ether (3 × 100 mL). The combined organic layers were dried (Na_2SO_4) and the solvent was removed under low pressure. The residue was purified by chromatography on alumina using EtOAc/hexane (1:20) as eluent to obtain a pale yellow oil (11.1 g, 78%). B.p. 144 °C (0.6 Torr). ^{1}H NMR: δ = 8.58 (d, *J* = 5.0 Hz, 1 H, H_6), 7.22 (s, 1 H, H_3), 6.94 (d, *J* = 5.0 Hz, 1 H, H_5), 2.32 (s, 3 H, CH_3), 1.70−1.05 (m, 18 H, CH_2), 0.85 (t, *J* = 7.2 Hz, 9 H, CH_3). ^{13}C NMR: δ = 173.1, 150.2, 143.9, 133.4, 123.0, 29.1, 27.3, 13.7, 9.7, 8.7. EI-MS: *m*/*z* (%) = 383 (5) [M + 1], 326 (85) [M − Bu], 268 (45) [M − 2Bu], 212 (100) [M − 3Bu].

L [Bis(2,2′-bipyrid-6′-yl)ketone]: Toluene (20 mL) was added to a mixture of compound **4** (2.15 g, 5.84 mmol), the dibromo com-

pound **6** (0.50 g, 1.46 mmol) and tetrakis(triphenylphosphane)palladium (0.34 g, 20% mol) and the resulting mixture was stirred at 110 °C under argon for 24 hours. The toluene was then evaporated and the residue was chromatographed on silica gel eluting with acetone/hexane (2:5). The pale yellow solid was triturated with hexane to afford a white solid (0.38 g, 77%). M.p. 171−172 °C. ^{1}H NMR: δ = 8.68 (m, 2 H, H_3), 8.66 (dd, J = 7.8, 1.3 Hz, 2 H, $H_{3'}$), 8.33 (dt, J = 7.9, 1.0 Hz, 2 H, H_6), 8.16 (dd, J = 7.6, 1.3 Hz, 2 H, $H_{5'}$), 8.04 (t, J = 7.7 Hz, 2 H, $H_{4'}$), 7.70 (dt, J = 7.7, 1.8 Hz, 2 H, H_5), 7.30 (ddd, J = 7.5, 4.8, 1.2 Hz, 2 H, H_4). ^{13}C NMR: δ = 192.8, 144.4 (2C), 153.7, 149.1, 137.3, 136.9, 125.0, 124.0, 123.4, 121.4. FAB-MS: *m*/*z* (%) = 339.1 (100) [M + 1], 155 (7) [M − 183 (bipy)]. $C_{21}H_{14}N_4O$ (338.4): calcd. C 74.53, H 4.17, N 16.57; found C 74.45, H 4.41, N 16.68. IR (KBr): $\tilde{\nu}$ = 1686, 1581, 1430, 1320, 1258, 1097, 992, 752, 667 cm^{-1}. UV/Vis: λ (ε_{max}) = 230 (1.0), 279 (0.9).

L* [Bis(2,2′-bipyrid-4-methyl-6′-yl)ketone]: Toluene (5 mL) was added to a mixture of compound **8** (0.17 g, 0.442 mmol), dibromo compound **6** (0.063 g, 0.184 mmol) and tetrakis(triphenylphosphane)palladium (0.043 g, 20% mol) and the resulting mixture was stirred at 110 °C under argon for 17 hours. The toluene was then evaporated and the residue was chromatographed on silica gel eluting with acetone/hexane (2:5). The pale yellow solid was triturated with hexane to afford a white solid (0.040 g, 59%). M.p. 149−150 °C. ^{1}H NMR: δ = 8.64 (dd, J = 1.2, 7.8 Hz, 2 H), 8.54 (d, J = 4.7 Hz, 2 H), 8.20−8.15 (m, 4 H), 8.03 (t, J = 7.8 Hz, 2 H), 7.12 (dq, J = 0.6, 6.1 Hz, 2 H), 2.25 (s, 3 H). FAB-MS: *m*/*z* (%)= 367.1 (100) [M + 1]. $C_{23}H_{18}N_4O$ (366.4): calcd. C 75.39, H 4.95, N 15.29; found C 74.3, H 4.95, N 15.5.

Synthesis of the Cu^{II} Coordination Polymers: The Cu^{II} coordination polymers were obtained by mixing the ligand **L** or **L*** and Cu^{II} triflate [$Cu(CF_3SO_3)_2$] in a 1:1 ratio in anhydrous acetonitrile or in [D_4]MeOH. The resulting clear blue solution was stirred at room temperature for 1 min.

Five-Coordination and Adduct Formation in Co^{III}−Corrinoids Dissecting Ligand Substitution into Its Component Steps

Mohamed S. A. Hamza,[a,c] Rudi van Eldik,*[a] Pascal L. S. Harper,[b] John M. Pratt,*[b] and Eric A. Betterton[d]

Keywords: Adduct formation / Reaction mechanisms / Cobalt / Equilibrium / Ligand substitution / High-pressure chemistry / Kinetics

The equilibria between the five- and six-coordinate species of alkylcobinamide and cobalamin (base-off) have been studied using high-pressure spectroscopic techniques. The addition of a water molecule to the five-coordinate complex is accompanied by a volume decrease of 12 $cm^3 \cdot mol^{-1}$.

Introduction

The mechanisms of ligand substitution reactions can be divided into the two extremes of limiting dissociative (D) and associative (A) mechanisms, linked by a broad range of interchange (I) mechanisms involving the formation of some weak, non-bonded "outer-sphere" (OS) adduct or intermediate between the entering and/or leaving ligand and the complex,[1] but few such adducts have been reported.[2] Good evidence for several such OS intermediates has recently been obtained from kinetic studies of both ligand substitution[3] in the six-coordinate Co^{III}−corrinoids (derivatives of vitamin B_{12})[4] and of the methylation of five-coordinate Co^{II}−corrinoids by MeI in the presence of thiols.[5] As will be shown here, the Co^{III}−corrinoids also offer an unusual opportunity to observe analogues of the five-coordinate intermediate of the limiting D mechanism, and of adducts with both five- and six-coordinate forms under equilibrium (i.e. non-reacting) conditions. In addition they offer the opportunity to establish a link between kinetically deduced transient intermediates and directly observable stable species.

Co−corrinoids with only amide side-chains are termed *cobinamides* (Cbi), those with the attached nucleotide (as in B_{12} itself) *cobalamins* (Cbl), and those where the amides have been esterified (usually as the Me ester) *cobesters* (Cbs); protonation and displacement of the coordinated nucleotide base in a Cbl gives a coordination sphere identical to that of a Cbi. UV/Vis spectrophotometry provides the main tool for kinetic and other studies.[4b] Both axial sites are surrounded by a hydrophobic cylinder of the exocyclic substituents, projecting roughly normal to the corrin ring, and an outer ring of hydrophilic amide groups. Comparing a Cbi with the analogous Cbs provides a test for possible involvement of the side-chains in, e.g. adduct formation. Co^{III}−corrinoids with the more typical axial ligands used in kinetic studies are red and six-coordinate. There is, however, good evidence that Cbi's (and protonated Cbl's) with stronger donor ligands (e.g. vinyl, methyl, sulfite, or dialkyl phosphite) exist as temperature-dependent mixtures of yellow five-coordinate and red six-coordinate aqua (solvato) forms based on UV/Vis, EXAFS, and NMR measurements.[4a,6] No other explanation for the available data has been put forward. Increasing temperature favours the yellow five-coordinate form, and with diethyl phosphite[7] as ligand it has also been shown qualitatively that increasing pressure favours the red six-coordinate form. No structural data on the yellow forms have yet been reported and more evidence for the reversible coordination of H_2O is clearly desirable.

We have now quantitatively studied the pressure dependence (up to 150 MPa) of the spectra of both vinyl-Cbi (VCbi, $4 \cdot 10^{-5}$ M, pH = 7, unbuffered solution) and protonated methyl-Cbl ($3 \cdot 10^{-5}$ M MeCbl/0.5 M $HClO_4$) in aqueous solution, which contain 70 and 90%, respectively, of the yellow form at ambient pressure and 20 °C,[6a] in order to determine the reaction volumes for conversion of the yellow to red forms according to Equation (1).

Calculations[8] suggest a volume of activation ($\Delta V^{\#}$) of $+13.1$ cm^3·mol^{-1} for a limiting D mechanism of ligand substitution involving the loss of coordinated H_2O in an octahedral complex and such a value may be taken as diagnostic of the loss of coordinated H_2O in the conversion of the red to yellow forms. In addition, possible adduct formation has been studied with the five-coordinate VCbi and vinyl-Cbs (VCbs), and the six-coordinate dicyano-Cbi (DCCbi) and dicyano-Cbs (DCCbs).

Results and Discussion

Increasing pressure p displaces the observed equilibrium from the yellow (Y) towards the red (R) form both for VCbi and MeCbl/H^+, as shown in Figures 1 and 2. Figure 1 shows distinct isosbestic points at 372, 447, and 536 nm, and a significant absorbance increase at the shoulder at 482 nm in the case of Vcbi. In addition, distinct isosbestic points at 385, 473, and 584 nm, and a significant increase in the absorbance at 490 nm were observed in the case of MeCbl/H^+ (Figure 2). The effect of pressure on the UV/Vis spectra suggests the formation of a six-coordinate species, since it is known that these (assumed) five-coordinate corrinoids exhibit maxima at 451 and 458 nm, respectively, and their six-coordinate corrinoid forms at ca. 495 and 503 nm, respectively.[6a] Values of the equilibrium constant (K = [R]/[Y]) as a function of p were calculated from the increase in absorbance at 490 nm using the optical density ratio of the two bands for the fully formed R and Y derived from the temperature-dependence studies as described in the literature.[6a] The slopes of the plots of ln K versus p (see Figures 3 and 4) gave values (in duplicate experiments) for the reaction volume $\Delta V = -12.4 \pm 1.0$ and -12.5 ± 1.2 cm^3·mol^{-1} for the conversion of Y to R in VCbi and MeCbl/H^+, respectively. Their identical values underline the close parallel between Cbi's and protonated Cbl's, and their agreement with the theoretical value of -13.1 cm^3·mol^{-1} (see above) confirms that conversion of the Y to R form involves the coordination of one molecule of H_2O by the five-coordinate Y form. Formation of the R form is therefore favoured both by increasing pressure ($\Delta V \approx -12.5$ cm^3·mol^{-1}) and by decreasing temperature ($\Delta S = -22 \pm 2$ e.u. reported for (diethyl phosphito)Cbl in aqueous acidic solution).[7]

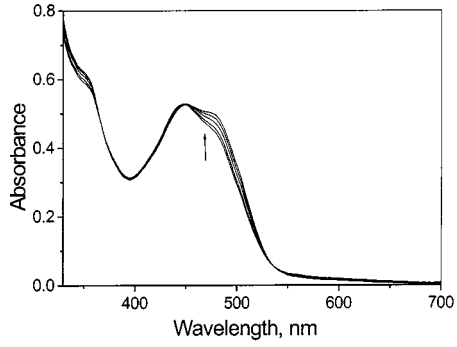

Figure 1. UV/Vis spectra of vinylcobinamide, recorded as a function of pressure (0.1, 30, 70, 110, and 150 MPa, accompanied by an increase in absorbance around 490 nm)

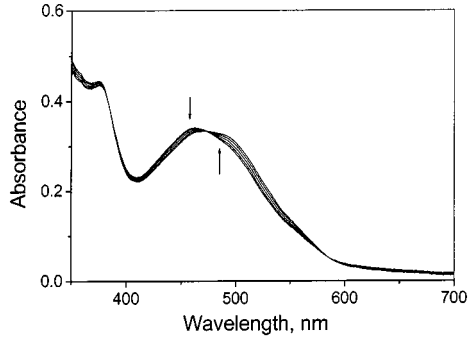

Figure 2. UV/Vis spectra of methylcobalamin (base-off form), recorded as a function of pressure (0.1, 30, 70, 110, and 150 MPa, accompanied by an increase in absorbance around 500 nm)

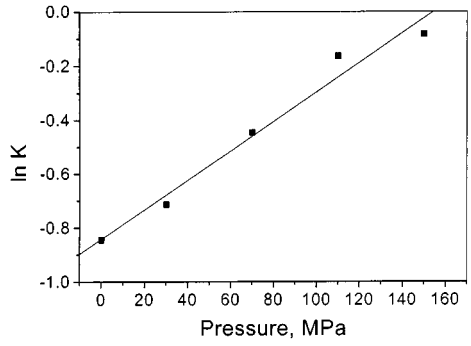

Figure 3. ln K versus pressure for the equilibrium between the five- and six-coordinate species of vinylcobinamide according to Equation (1); the best fit of the data (solid line) gives $\Delta V = -12.4 \pm 1.0$ cm^3·mol^{-1}

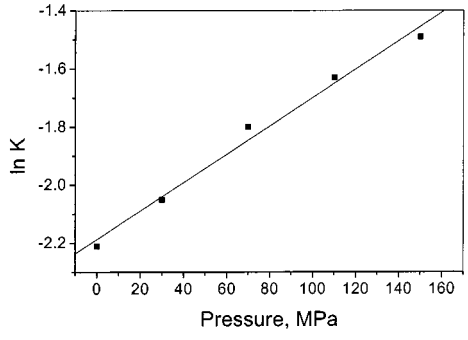

Figure 4. ln K versus pressure for the equilibrium between the five- and six-coordinate species of methylcobalamin (base-off) according to Equation (1); the best fit of the data (solid line) gives $\Delta V = -12.5 \pm 1.2$ cm^3·mol^{-1}

Initial experiments on adduct formation by VCbi showed that the addition of the structure-breakers[9] KI and $NaClO_4$ (but not the structure-makers[9] NaCl and NaF), of sodium iodoacetate (but not sodium acetate), and of MeI all caused an immediate and significant change in the spectrum, indicating a shift from the R to the Y form, with distinct isosbestic points observed at least in the case of $NaClO_4$. A similar positive result was obtained for VCbs with KI and $NaClO_4$ (a negative result was obtained with NaCl). All these observations suggest that the solute (as adduct or ion-pair) binds in the hydrophobic cavity close enough to the Co metal centre to destabilise the coordinated H_2O and favour the five-coordinate form. By contrast, hydroxide (as well as imidazole, etc.) forms a red six-coordinate complex.[10] Binding constants of $K = 3.0 \pm 0.4$ M^{-1} and 1.5 ± 0.5 M^{-1} were obtained for VCbi with iodide (phosphate buffer pH = 7.25, up to 0.4 M KI) and perchlorate (unbuffered solution, up to 2 M $NaClO_4$), respectively.

Comparison of the spectrum of DCCbi (with a slight excess of cyanide to suppress ligand substitution) in 1 M solutions of a range of solutes showed no detectable difference (from that in water alone) with urea, NH_2OH, ethylene glycol (i.e. very hydrophilic compounds), NaOH, NaF, and sodium acetate (structure-making anions), KF or Me_4NF. Differences, however, were observed in the presence of imidazole, pyridine, 2,6-dimethylpyridine, NaBr and NaI (structure-breaking anions), sodium iodoacetate, and MeI. These changes were not reversed by adding more cyanide (i.e. do not involve displacement of coordinated cyanide) and, at least with iodide, did not vary with the Co concentration (i.e. not due to aggregation). All the observed changes were characterised by a similar broadening of both the α, β and γ bands (at 580, 540, and 367 nm, respectively) with a decrease in absorbance but no significant shift in λ_{max}, an increase in the 400−450 nm region and a cross-over (or even an isosbestic point) at ca. 460 and 600 nm; cf. the so-called Ham effect.[11] Similar experiments with DCCbs showed changes with both pyridine and KI in aqueous solution but no change with urea or ethylene glycol, while no changes were observed even with pyridine or KI in methanol or with pyridine in chloroform. The tests for solute, solvent and side-chains all suggest that the solute interacts with some hydrophobic part of the corrin structure, which is probably (as with VCbi) the cavity around one or both of the axial coordination sites, but interaction with its external walls cannot be excluded. Binding constants could not reliably be determined from the small changes in spectra. On re-examining the reported failure of cyano-Cbl (vitamin B_{12} itself) and dicyano-Cbl (nucleotide base displaced from coordination by cyanide) to fluoresce,[12] however, it was found that DCCbi in methanol fluoresces in the visible region with a maximum at 603 nm (when excited at 500 nm) but that this is quenched by adding imidazole or benziminazole (modelling the 3,5-dimethylbenzimidazole present in the Cbl's) and not restored by adding more cyanide (i.e. quenching does not involve displacement of coordinated cyanide). A binding constant K of ca. 14 M^{-1} for DCCbi with imidazole was calculated from the decreasing emission at 603 nm with increasing imidazole concentration in unbuffered methanol (containing ca 10^{-3} M KCN). This is comparable to the value of $K = 12$ to 16 M^{-1} for aquapentaammineruthenium(II) with the incoming methylpyrazinium ion.[2]

The close agreement between our experimentally determined volumes of reaction and the calculated value provides strong evidence that the equilibrium of interest involves the simple coordination of H_2O by the yellow five-coordinate corrinoid to produce the red six-coordinate form. Conversely, it provides the first experimental value for (and support for the calculated value of) the limiting volume of activation required in discussing D and I_d mechanisms of ligand substitution. Our results also demonstrate that both the five-coordinate VCbi and the six-coordinate DCCbi can form directly observable stable adducts and ion-pairs; the solutes are probably located within the hydrophobic cylinder surrounding the Co ion which, in effect, acts like a calixarene. The qualitatively similar behaviour of iodide, iodoacetate, and MeI demonstrates that the corrin ring can promote the formation of adducts as potential intermediates in reactions ranging from nucleophiles with Co^{III} to electrophiles (such as MeI) with Co^{II} and Co^{I}. The Co^{III}−corrinoids offer a unique opportunity to see how, as the donor power of one axial ligand is increased in the established order of the *trans* effect [e.g. H_2O < DMB (nucleotide base) < OH^- < CN^- < acetylide < vinyl < methyl < ethyl],[4a] the unstable five-coordinate intermediate for ligand substitution in the other axial position will become the stable yellow five-coordinate form, a transient OS intermediate will become a stable adduct, and the observed low volumes of activation ($\Delta V^{\#} = +4$ to $+8$ cm^3 mol^{-1}),[3c−3d,13] typical of an I_d mechanism, will increase to the reaction volume ($\Delta V = +12.5$ cm^3·mol^{-1}), denoting a limiting D mechanism.

Experimental Section

The pH of the solutions was measured using a Mettler Delta 350 pH meter. It was calibrated with standard buffer solutions at pH = 4 and 7. UV/Vis spectra were recorded with Shimadzu UV-2101 or Cary 5 spectrophotometers. UV/Vis spectra under high pressure were recorded with the Shimadzu spectrophotometer utilizing a home-made high-pressure unit.[14] Emission spectra of degassed methanolic solutions were recorded with a Spex Fluorimax 2. All the instruments used in this work were thermostated to 25 °C. Values of ΔV were calculated from the slope (= $-\Delta V/RT$) of plots of ln K versus pressure. Methylcobalamin was purchased from Sigma. Dicyanocobinamide was prepared as described in the literature[15] by treating cyanocobalamin with trifluoromethanesulfonic acid and then adding cyanide. Dicyanocobester was prepared by heating cyanocobalamin under reflux in a solution of methanol containing 1 M H_2SO_4 under N_2 for 4 d, and then adding cyanide.[16] Vinylcobinamide was prepared by treating Co^{I}−cobinamide with acetylene and vinylcobester by an analogous reaction.[17] The purity of the prepared complexes was checked by UV/Vis spectroscopy and thin layer chromatography, and the results were found to be in excellent agreement with data reported in the literature. The preparation of solutions and measurements were carried out

in diffuse light since all the alkylcobalamins are known to be very light-sensitive.

Synthesis and Structure of Novel Complexes of Gallium

Eva Leiner,[a] Oliver Hampe,[b] and Manfred Scheer*[a]

Dedicated to Prof. G. Schmid on the occasion of his 60th birthday

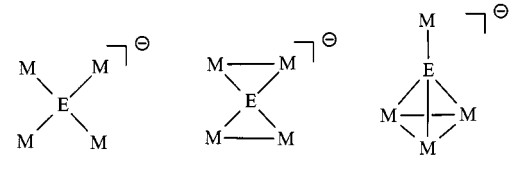
Keywords: Metathesis / Iron / Gallium / Cobalt / Cyclopentadienyl ligands

$[Cp^*GaCl_2]$ ($Cp^* = \eta^1$-C_5Me_5) reacts with $K[Co(CO)_4]$ with elimination of KCp^* and KCl to form the novel ionic complexes $[K(toluene)_2][Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]$ (**1**) and $K[GaCl\{Co_2(CO)_6(\mu\text{-}CO)\}\{Co(CO)_4\}]$ (**2**), where the gallium atoms possess the coordination number four. The reaction of $[\{Co(CO)_4\}_2GaCl(THF)]$ with $LiCp^*$ leads to the ionic product $[Li(THF)][Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]$ (**3**). The $[Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]^-$ anions of **1** and **3** represent the first homoleptic spirocyclic coordination mode of gallium. The reaction of $GaCl_3$ with $Na_2[Fe(CO)_4]$ leads to the ionic compound $[Na(OEt_2)_2][Fe(CO)_4(GaCl_3)_2]$ (**4**). Complexes **1**, **2**, **3** and **4** were characterised by X-ray structure analysis and IR spectroscopy. Additionally, ESI mass spectra of **1** were recorded at different cone voltages, where the molecular ion peak of the anion $[Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]^-$ as well as the peaks resulting from sequential loss of CO ligands until the formation of the naked $[Co_4Ga]^-$ cluster are observed. The ionic complexes **1**, **2**, **3** and **4** form polymeric networks through coordination of their cations. In **2** a three-dimensional polymeric network is formed by coordination of the Co_3Ga units and their K counterions, whereas in **1** the K ions are additionally coordinated by toluene molecules to form dimeric macrocyclic motifs by coordination of two of the anionic Co_4Ga units. In **3** a zigzag chain is formed by coordination of the Co_4Ga units through their Li cations. In the crystal packing of complex **4** the $FeGa_2$ moieties form zigzag chains, coordinating through their Na counterions.

Introduction

Metathesis reactions of group 13 element halides with carbonyl metalates represent a useful method to synthesise compounds with covalent transition metal-main group bonds. The majority of complexes thereby obtained possesses coordination numbers (CN) of three and four with exclusively trigonal planar and tetrahedral coordination modes, respectively. Depending on the reaction conditions competing reactions occur, for example the formation of anionic complexes of CN 4.[1] Among complexes of CN 4 of the general type $E(ML_n)_4^-$ (E = Al, Ga, In, Tl; ML_n = transition metal fragment), which can alternatively be regarded as Lewis base adducts of the type $E(ML_n)_3$, the coordination modes **A**, **B** and **C** are possible.

For complexes of type **A**, examples exist for E = In and Tl, such as $[In\{Co(CO)_4\}_4]^-$,[2] whereas for **B** the indium complexes $[In\{Fe_2(CO)_8\}_2]^-$,[3] $[\{(\mu\text{-}H)Mn_3(CO)_{12}\}_2(\mu_4\text{-}In)]$[4] and $[\{Re(CO)_3(\mu\text{-}I)_2Re(CO)_3\}In\{Re(CO)_4(\mu\text{-}I)Re(CO)_4\}]$[5] are the only known representatives. For gallium only $[Re_3(CO)_9(Ph_3P)_3(\mu\text{-}Cl)_3(\mu_3\text{-}\{GaRe(CO)_4(Ph_3P)\})]$ and the Re_4Ga_4 cluster $[Re_4(CO)_{12}\{\mu_3\text{-}\{GaRe(CO)_5\}_4]$[6] are known for type **C**; examples of the coordination modes **A** and **B** are as yet unknown for gallium. We report herein on the synthesis of the first examples for gallium with the coordination mode **B**.



Results and Discussion

The reaction of Cp^*GaCl_2 ($Cp^* = \eta^1$-C_5Me_5) with $K[Co(CO)_4]$ in Et_2O or THF results in the formation of the ionic heteronuclear clusters $[K(toluene)_2][Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]$ (**1**) and $K[GaCl\{Co_2(CO)_6\}(\mu\text{-}CO)\}\{Co(CO)_4\}]$ (**2**), respectively, in high yields [Equation (1) and (2)]. Although the workup of **2** was carried out by extraction with toluene, as was the case for **1**, no solvated toluene was found in the crystal lattice of **2**. The results show that besides the KCl elimination, Cp* removal also occurs as a competing reac-

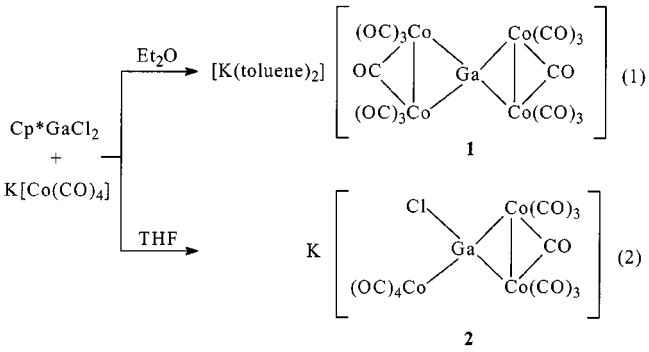
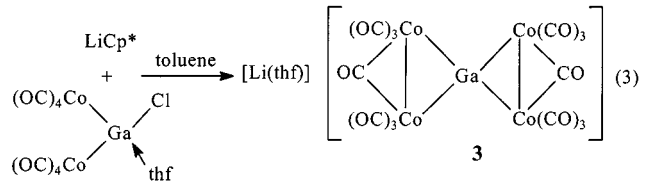
tion. Furthermore, the reaction in donor solvents seems to favour the formation of ionic complexes. Complex **2** can be regarded as a formal precursor molecule of **1**, from which Cl substitution by $Co(CO)_4^-$ leads to the formation of the spirocyclic complex **2**.



Surprisingly, we found that the reaction of $[\{Co(CO)_4\}_2GaCl(THF)]$ with LiCp* in toluene at −78 °C leads to the ionic product $[Li(THF)][Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]$ **3** [Equation (3)].



Complexes **1** and **3** represent the first examples of the coordination mode **B** where the Ga atom is additionally homoleptically coordinated by metal atoms.

Complexes **1** and **3** are orange and **2** red-brown crystalline compounds, which are readily soluble in toluene, THF and CH_2Cl_2. In their IR spectra, CO stretching frequencies for terminal and bridging CO ligands are observed.

The ionic complex **1** crystallises in the triclinic space group $P\bar{1}$ with two independent molecules (A and B) in the asymmetric unit, which reveal similar structural features.[7] Each of the K counterions possesses two coordinated toluene molecules. Figure 1 shows the molecular structure of the anion $[Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]^-$ of one of the independent molecules (molecule A) of **1**. The gallium atom is bound side-on to two $[\{Co(CO)_3\}_2\{\mu\text{-}CO\}]$ groups to form a spirocyclic compound containing two Co−Ga−Co three membered rings. These rings are bent by 82.55(4)° (molecule A) and 87.58(4)° (molecule B). Alternatively, the structure of **1** can be described as a distorted Co_4 tetrahedron centred by a Ga atom.

The Co−Co bond lengths in both independent molecules [2.560(1) to 2.588(1) Å] are similar to the Co−Co bond length in $Co_2(CO)_8$ [2.528(1)−2.530(1) Å];[8] the Co−Ga bonds [2.395(1)−2.454(1) Å] are in the range of known Co−Ga bond lengths as in, for example, $[(CO)_3Co\{\mu\text{-}(\eta^5\text{-}Cp^*Ga)\}_2Co(CO)_3]$ [2.3784(5)−2.3959(5) Å].[9] In addition to the molecular structure of anion **1** described above, the location of the K atom and its coordinated toluene molecules are depicted in the crystal lattice in Figure 2. Both independent $GaCo_4$ units of **1** are bridged through their K counterions to form a dimer in which each K atom is coordinated by four CO ligands (a terminal and a bridging CO moiety of each anion of **1**) and two molecules of toluene. The macrocycle thus formed contains eight heavier atoms (gallium, cobalt and potassium), and two such macrocycles form the unit cell. The formation of the macrocyclic dimer of **1** in the crystal leads to the small structural

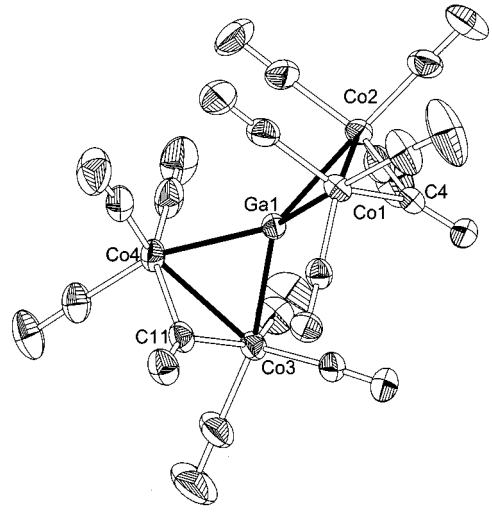


Figure 1. Molecular structure of the $[Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]^-$ anion of one of the independent molecules (molecule A) of **1** in the crystal (showing 30% probability ellipsoids); selected bond lengths [Å] and angles [°]: Ga1−Co1 2.442(1), Ga1−Co2 2.397(1), Ga1−Co3 2.396(1), Ga1−Co4 2.451(1), Co1−Co2 2.588(1), Co3−Co4 2.562(1), Co1−C4 1.907(4), Co2−C4 1.925(4), Co3−C11 1.925(4), Co4−C11 1.904(4); Co1−Ga1−Co2 64.66(3), Co3−Ga1−Co4 63.78(3)

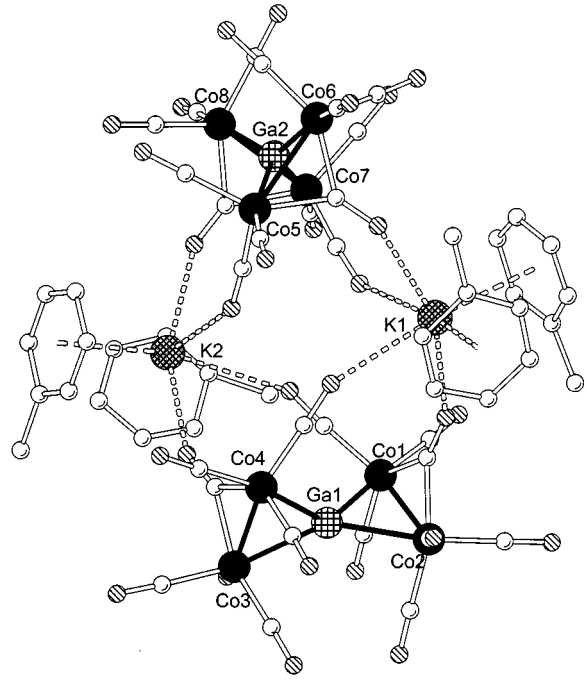

Figure 2. Formation of macrocyclic dimers in the crystal lattice of **1** (H atoms of the toluene molecules are omitted for clarity)

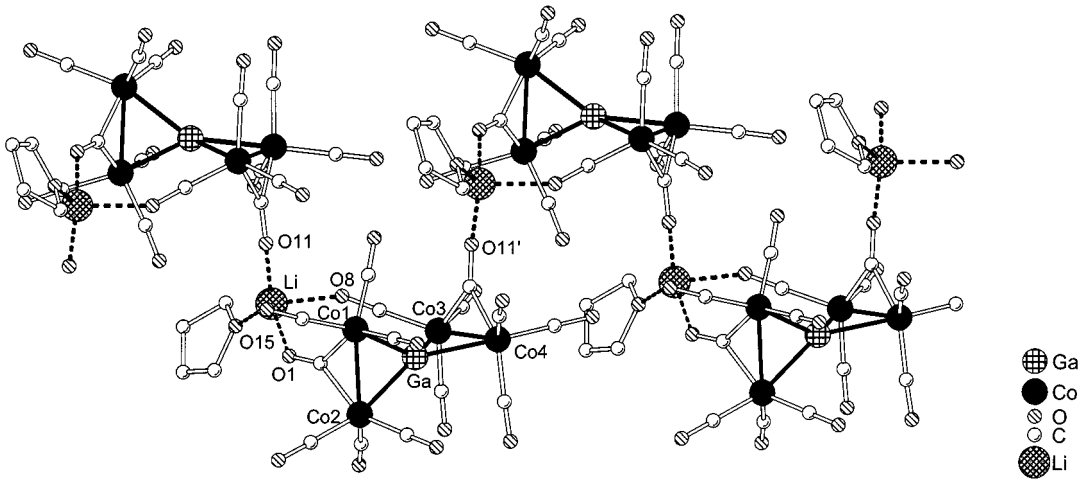

Figure 3. Structure of **3** in the crystal lattice; selected bond lengths [Å] (H atoms of the toluene molecules are omitted for clarity): Ga−Co1 2.439(1), Ga−Co2 2.398(1), Ga−Co3 2.453(1), Ga−Co4 2.398(1), Co1−Co2 2.557(1), Co3−Co4 2.576(1), Li−O1 1.946(13), Li−O8 2.17(2), Li−O11 1.904(13), Li−O15 1.807(13)

differences between the independent molecules of **1**. Thus, the Co−Ga−Co bond angles in molecule B are very similar [63.72(4)° and 63.96°], whereas those in molecule A differ slightly more [64.66(3)° and 63.78(3)°].

Complex **3** crystallises as one enantiomer in the orthorhombic space group $P2_12_12_1$, with four formula units in the asymmetric unit cell. The molecular structure of the anion of **3** is similar to the structure of the anion of **1** (Figure 1), where similar bond lengths and angles are observed. In contrast to **1**, **3** possesses Li counterions, which are coordinated by THF molecules. A view of the packing of **3** in the crystal lattice is shown in Figure 3, and is clearly different to that of **1**. Each of the $GaCo_4$ moieties in **3** is connected by two Li cations to the next molecular units establishing an overall zigzag chain forming a chiral helix. The Li counterions are fourfold coordinated by three O atoms of the CO ligands and the O atom of a THF molecule.

The existence of the $[Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]^-$ anions of **1** and **3** in solution was further proved by Electrospray-Ionisation (ESI) mass spectrometry using a high resolution FT-ICR mass spectrometer.[10] Figure 4a shows the observed molecular ion peak of the anion $[Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]^-$ of **1** (cone voltage = 20 V), which, as can clearly be seen from Figure 4b, is in good agreement with the simulated mass distribution at m/z = 696 $[^{69}Ga(^{12}CO)_{14}Co_4]$. The mass spectrum of the cation of **1** shows only the peak for the K^+ cation. In further experiments the fragmentation behaviour of the anion of **1** at continuously increasing cone voltages was investigated. A stepwise elimination of CO was found with a steadily increasing voltage, and all the fragments up to the naked $[Co_4Ga]^-$ cluster (cone voltage of 240 V) were detected. This result shows the exceptional stability of the $GaCo_4$ cluster core.

The ionic complex **2** crystallises in the monoclinic space group $P2_1/n$ with four molecules in the unit cell. The molecular structure of the $[GaCl\{Co_2(CO)_6\}(\mu\text{-}CO)\}\{Co(CO)_4\}]^-$ anion of **2** is depicted in Figure 5. The gallium atom is in a distorted tetrahedral geometry surrounded by one Cl and three Co atoms. The metal-metal bond between the Co1 and Co2 atoms is bridged by a CO ligand. The Co−Co [2.595(1) Å] and the Co−Ga bond lengths [2.419(1), 2.441(1) and 2.448(1) Å] of **2** are similar to those observed in **1** [2.396(1)−2.451(1) Å]. The angle between the planes formed by the atoms Co1−Ga−Co2 and Cl−Ga−Co3 is 83.96(3)°. In contrast to the macrocyclic

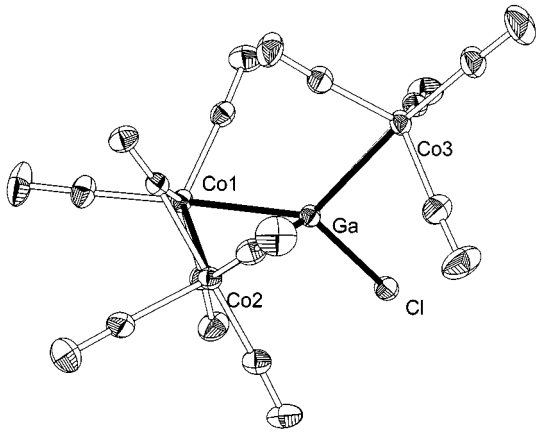

Figure 5. Molecular structure of the $[GaCl\{Co_2(CO)_6\}(\mu\text{-}CO)\}\{Co(CO)_4\}]^-$ anion of **2** in the crystal (showing 30% probability ellipsoids); selected bond lengths [Å] and angles [°]: Ga−Co1 2.441(1), Ga−Co2 2.419(1), Ga−Co3 2.448(1), Co1−Co2 2.595(1), Ga−Cl 2.304(1); Co1−Ga−Co2 64.54(2), Cl−Ga−Co2 118.66(3), Cl−Ga−Co1 112.34(3), Cl−Ga−Co3 102.30(3), Co2−Ga−Co3 125.71(2), Co1−Ga−Co3 131.00(3)

dimeric structure in the crystal lattice of **1** and the zigzag-chain of **3**, the $GaCo_3$ clusters of **2** coordinate to the unsolvated K atoms to form a three-dimensional network. A view of a layer along the crystallographic *c* axis of the crystal packing structure of **2** is depicted in Figure 6. The $GaCo_3$ units of **2** are similarly oriented along the crystallographic *a* axis, whereas they are alternately twisted along the *b* axis. Each of the K atoms is ninefold coordinated by seven O atoms of the CO ligands (terminal as well bridging CO) and by two Cl atoms. The K atoms along the *a* axis are oriented above and below the presented plane, and each are coordinated by five $GaCo_3$ moieties, three of which are shown in Figure 6.

The reaction of $GaCl_3$ with $Na_2[Fe(CO)_4]$ in Et_2O at 0 °C leads to the ionic addition product $[Na(OEt_2)]_2[Fe(CO)_4(GaCl_3)_2]$ **4** [Equation (4)], which was isolated as colourless crystals. Complex **4** is readily soluble in donor solvents like Et_2O and THF. In the IR spectrum of **4**, only bands for terminal CO groups are found.

$$2\ GaCl_3 + Na_2[Fe(CO)_4] \xrightarrow{Et_2O} [Na(OEt)]_2\left[\begin{array}{c} Cl_3Ga \quad GaCl_3 \\ \diagdown \quad \diagup \\ Fe(CO)_4 \end{array}\right] \quad (4)$$

4

Complex **4** crystallises in the monoclinic space group $P2_1/c$ with four formulae units in the asymmetric unit cell. The molecular structure of the anion of **4** is depicted in Figure 7. The central Fe atom is octahedrally surrounded by four CO ligands and two *cis*-oriented $GaCl_3$ moieties. The axial carbonyl ligands of the $Fe(CO)_4$ unit are unexpectedly strongly bent towards the $GaCl_3$ groups, probably due to the Lewis acid character of the group 13 atoms. The Ga−Fe bond lengths [2.409(1) and 2.411(1) Å, respectively] are slightly longer than in $[(CO)_4FeGaCl_2(tmeda)]$ [2.338(1) Å].[11]

A view of the packing of **4** in the crystal lattice is shown in Figure 8. Each of the $GaCl_3$ moieties in **4** is connected via two Na cations to the next molecular unit establishing

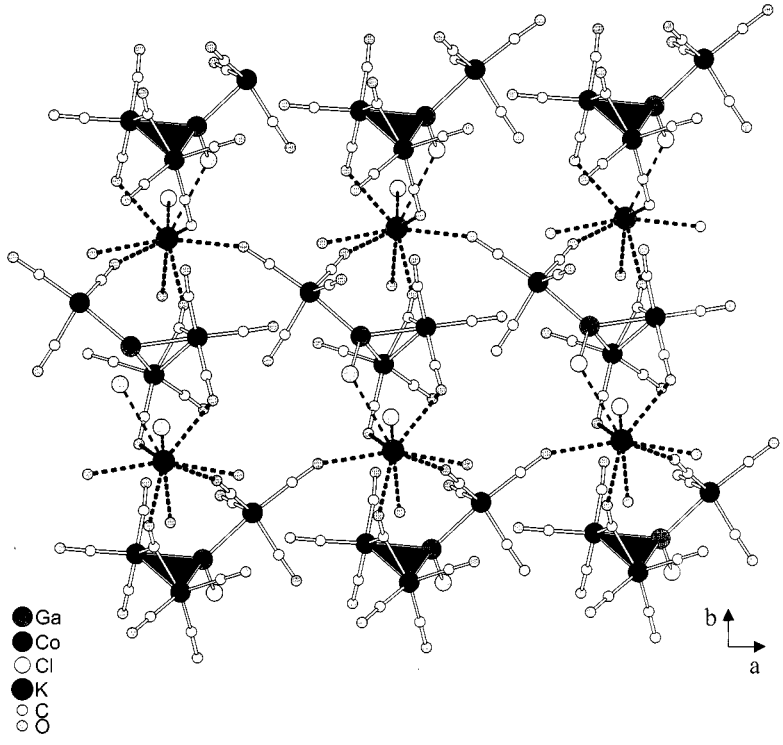

Figure 6. View along the crystallographic *c* axis in the crystal lattice of **2** (the Co_2Ga planes are marked); the coordinating O and Cl atoms of the K atoms above and below the *a*,*b* plane are depicted without their connecting cluster units for clarity

out identically, the coordination of the toluene molecules in **1** seems to be the determining factor for the formation of macrocycle **1**.

Experimental Section

General Techniques: All manipulations were performed under an atmosphere of dry N_2 using standard Schlenk techniques. All solvents were dried by common methods and freshly distilled prior to use. Gallium trichloride was obtained commercially and used without further purification. The starting materials Cp^*GaCl_2 [12] and the compounds $K[Co(CO)_4]$[13] and $Na_2[Fe(CO)_4]$[14] were prepared according to literature methods. The ESI mass spectra were recorded on a Bruker APEX II Fourier-Transform-ICR mass spectrometer and the IR spectra on a Bruker IFS 28.

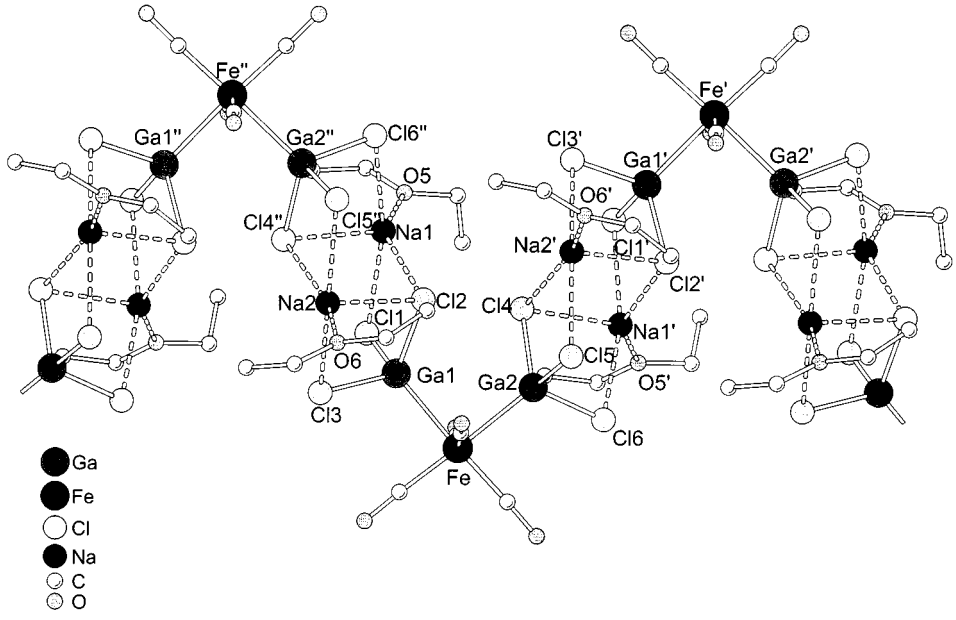

Figure 8. Structure of **4** in the crystal lattice; selected bond lengths [Å] and angles [°] (H atoms of the toluene molecules are omitted for clarity): Na1···Cl1 2.789(2), Na1···Cl2 2.818(2), Na1···Cl4 2.883(2), Na1···Cl6 2.799(2), Na2···Cl2 2.853(2), Na2···Cl3 2.779(2), Na2···Cl4 2.877(2); Cl5···Na2···C12 95.19(6), Cl3···Na2···Cl4 95.19(6).

an overall zigzag chain. The Na ions are fivefold coordinated by four Cl atoms and an O atom of the coordinated ether molecule.

Conclusions

We have shown that the reaction of Cp^*GaCl_2 and $GaCl_3$ with transition metal metalates leads to the formation of ionic compounds forming polymeric structures in the crystal lattice. Whereas the solvation of the K counterion in **1** by toluene leads to a macrocyclic dimer, the Li counterion in **3**, due to its lower coordination number, leads to a chiral zigzag chain-like structure. The absence of solvent molecules in **2** leads to the formation of a 3D polymeric network. The degree of aggregation is strongly determined by the coordination of the counterions and the coordinated solvent molecules. Since the workup of **1** and **2** was carried

$[K(toluene)_2][Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]$ (1): A solution of Cp^*GaCl_2 (0.138 g, 0.5 mmol) in Et_2O (10 mL) was slowly added at −78 °C to a solution of $K[Co(CO)_4]$ (0.231 g, 1.1 mmol) in 10 mL Et_2O. The reaction mixture was stirred for 14 h and was then allowed to warm to room temperature. The resulting yellow solution was filtered through silica and all of the solvent was removed in vacuum. The yellow residue was extracted with 20 mL toluene and the solution was reduced to 2 mL. At −30 °C orange crystals of $[K(toluene)_2][Ga\{Co_2(CO)_6(\mu\text{-}CO)\}_2]$ (**1**) were formed (244 mg, 70%). IR (KBr): $\tilde{\nu}$ = 1968(s) cm^{-1}, 1764(m) ν(CO). MS (ESI): *m*/*z* = 696 $[M^-]$.

$K[GaCl\{Co_2(CO)_6\}(\mu\text{-}CO)\}\{Co(CO)_4\}]$ (2): A solution of Cp^*GaCl_2 (0.138 g, 0.5 mmol) in 15 mL THF was slowly added at −78 °C to a solution of $K[Co(CO)_4]$ (0.231 g, 1.1 mmol) in 15 mL THF. The solution was stirred for 14 h and was then allowed to warm to room temperature. Et_2O (2 mL) was added, and after two hours stirring the colour of the solution turned to red-brown and a white precipitate appeared. All volatiles were removed in vacuum, and

the oily residue was extracted with about 50 mL toluene. After filtration over silica gel, the volume of the solution was reduced to 2 mL and at −20 °C red-brown crystals of K[GaCl{$Co_2(CO)_6$}(μ-CO)}{$Co(CO)_4$}] (**2**) were obtained (177 mg, 60%). IR (KBr): $\tilde{\nu}$ = 2062(s) cm^{-1}, 2039(s), 1987(s), 1969(s), 1765(m) ν(CO).

[Li(THF)][Ga{$Co_2(CO)_6$(μ-CO)}$_2$] (3): A solution of [{$Co(CO)_4$}$_2$GaCl(THF)] (0.154 g, 0.3 mmol) in 5 mL toluene was slowly added at −78 °C to a slurry of LiCp* (0.063 g, 0.3 mmol) in 5 mL toluene. The reaction mixture was allowed to warm to room temperature and stirred for three days. After filtration over silica gel, the volume of the orange solution was reduced to 2 mL and at −30 °C orange crystals of [Li(THF)][Ga{$Co_2(CO)_6$(μ-CO)}$_2$] (**3**) were obtained (0.167 g, 70%). IR (KBr): $\tilde{\nu}$ = 1968(s) cm^{-1}, 1764(m) ν(CO). MS (ESI): m/z = 696 [M^-].

[Na(OEt$_2$)]$_2$[Fe(CO)$_4$(GaCl$_3$)$_2$] (4): A solution of $GaCl_3$ (0.088 g, 0.5 mmol) in 5 mL Et_2O at 0 °C was slowly added to a suspension of $Na_2[Fe(CO)_4]$ (0.216 g, 1 mmol) in 20 mL Et_2O. The colour changed to yellow, and after stirring for 3 h at room temperature, the colour changed again to yellow-red. Addition of *n*-hexane led to colourless crystals of [Na(OEt$_2$)]$_2$[Fe(CO)$_4$(GaCl$_3$)$_2$] (**4**) (126 mg, 70%, based on $GaCl_3$). IR (KBr): 2082(s, br) cm^{-1}, 2042(s), 2035(s), 2025(s), 2000(m), 1978(s, br) ν(CO).

X-ray Structure Determination and Details of Refinement. Data were collected on a STOE IPDS area-detector diffractometer using Ag-K_α radiation (λ = 0.56087 Å) for complex **1** and Mo-K_α radiation (λ = 0.71069 Å) for **2**, **3** and **4**. Machine parameters, crystal data and data collection parameters are summarised in Table 1. The structures were solved by direct methods using SHELXS-86,[15a] and refined by full-matrix least-squares methods on F^2 in SHELXL-97[15b] with anisotropic displacement for non-H atoms (except for atom C50 of **1**, due to the limited crystal quality of this complex). Hydrogen atoms were placed in idealised positions and refined isotropically according to the riding model. The Flack-parameter of the chiral space group of **3** comes to −0.01(3).

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-170990 (**1**), -170991 (**2**), -170992 (**3**) and -170993 (**4**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Structure, and Thermoelectric Properties of the New Antimonide Sulfide $MoSb_2S$

Chi-Shen Lee[a] and Holger Kleinke*[a]

Keywords: Antimony / Sulfur / Materials science / Chalcogens / Molybdenum

The structure of a new ternary compound, $MoSb_2S$, was identified by single-crystal X-ray diffraction. The title compound was synthesized by heating the elements in stoichiometric ratios in sealed silica tubes at 600–800 °C using small amounts of I_2 as a mineralizator. The compound crystallizes in a new structure type in the monoclinic space group *C*2/*m* [*a* = 36.157(3) Å, *b* = 6.3823(5) Å, *c* = 6.5379(5) Å, β = 95.093(2)°, *Z* = 16, *R*1/*wR*2 = 0.035/0.059]. Its crystal structure contains CdI_2-related layers (MoSbS) and Sb columns, namely a zigzag (*cis-trans*) chain and an equidistant ladder, both of which are located between the MoSbS layers. The results of thermoelectric measurements and electronic structure calculations indicate metallic properties.

Introduction

Thermoelectric materials exhibit a unique property, namely the conversion of heat into electrical energy and vice versa. Such materials, which are usually small-gap semiconductors, have been utilized in applications like refrigerators and power generators. Commercial materials include semiconductors based on Bi_2Te_3, $Si_{0.7}Ge_{0.3}$, and PbTe.[1] Extensive research activities were carried out with investigations of new thermoelectric materials, including the filled skutterudites LnM_4Sb_{12} (Ln = lanthanoid; M = Fe, Co, Ni, ...) and most recently the ternary telluride $CsBi_4Te_6$.[2–5] Good thermoelectric materials have a high *figure-of-merit* that combines a high Seebeck coefficient, low thermal conductivity, and high electrical conductivity. To approach the goal of preparing new thermoelectrics, heavy main group metalloid elements such as antimony, selenium or tellurium may be used as the common element.

Our group has focused on the syntheses and characterizations of new materials in the ternary M–Sb–Q systems (M = transition metal atoms; Q = S, Se, Te). During the course of this study, a new ternary compound, $MoSb_2Se$, was identified.[6] The structure of $MoSb_2Se$ can be treated as the combination of a CdI_2-related layer structure (MoSbSe layer) with interstitial Sb chains binding the Sb atoms of MoSbSe layers. A similar structure is realized in the Mo–Sb–S system; the structure of $MoSb_2S$ exhibits topologically equivalent MoSbS layers, yet significant differences in the Sb atom substructure. With this contribution, the synthesis, characterization and electronic structure studies of $MoSb_2S$ are presented.

Results and Discussion

Structure

$MoSb_2S$ crystallizes in the space group *C*2/*m*, with six independent positions for Sb, three for Mo, and three for S atoms. The perspective view of the $MoSb_2S$ crystal structure along [010] is illustrated in Figure 1. In general, the structure of $MoSb_2S$ contains a CdI_2-related layer of the composition MoSbS and two types of columnar Sb atom substructures, which bind the Sb atoms of the two surrounding MoSbS layers. Pseudo-octahedral voids remain present in the interlayer Sb atom substructure.

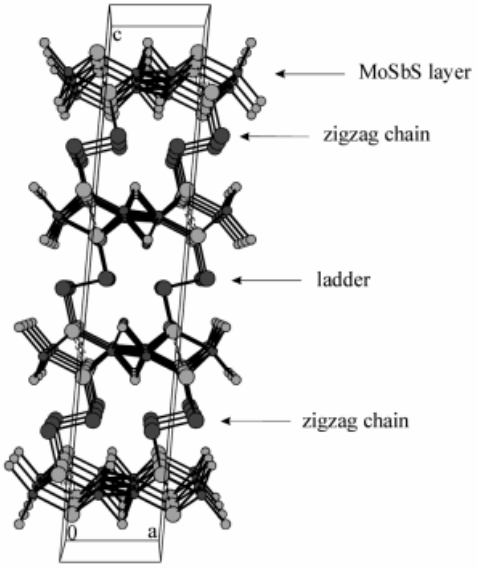

Figure 1. The three-dimensional structure of $MoSb_2S$ projected along [010]; dark circles: Mo; small gray circles: S; large circles: Sb, with dark circles representing interlayer and bright circles intralayer atoms

The Mo atoms are sandwiched between the approximately closed packed Sb and S atom layers, forming MoSbS layers that are reminiscent of the $MoTe_2$ layers of the monoclinic β-$MoTe_2$ [7] structure. Each Mo is coordinated by three Sb and three S atoms in a distorted octahedral coordination. The averaged Mo−Sb and Mo−S distances are 2.83 and 2.38 Å, respectively. This may be compared to the corresponding interatomic distances in Mo_3Sb_7 (d_{Mo-Sb} = 2.77 and 2.85 Å)[8] and MoS_2 (d_{Mo-S} = 2.41 Å).[9]

The Mo atoms in $MoSb_2S$ are connected to form zigzag chains along the *b* axis, as is the case for the β-$MoTe_2$ structure. The shortest Mo−Mo distances are 2.76−2.77 Å, shorter than that of the topologically equivalent chains of $MoSb_2Se$ (2.81 Å) and β-$MoTe_2$ (2.89−2.90 Å). The Mo−Mo bonds in elemental molybdenum (cubic body-centered packing, W type) are 8 × 2.73 and 6 × 3.15 Å per Mo atom. Thus, the Mo−Mo interactions in $MoSb_2S$ have significant bonding character.

The Sb−Sb distances within the MoSbS layer are between 3.18 and 3.33 Å. While these distances are larger than a typical Sb−Sb single bond (2.80−2.90 Å), they are shorter than the weak bond in elemental antimony (d = 3.35 Å). Interactions like these are typically weakly bonding.[10] The averaged S−S and S−Sb distances are 3.19 and 3.64 Å, respectively. These presumably nonbonding contacts are much longer than the sums of the covalent radii (r_S = 1.02, r_{Sb} = 1.40 Å).[11] A detailed discussion of the bonding character of these interactions will be given in the electronic structure section.

Chains comprising Sb atoms are running along the *b* axis between the MoSbS layers. Two types of interlayer Sb−Sb chains exist in the structure of $MoSb_2S$. The first type (located at *x* close to 1/4 and 3/4 as shown in Figure 2a) is a zigzag chain with Sb−Sb bonds of 2.84 (parallel to *b*) and 2.88 Å (approximately parallel to *c*), which are both in the range of the Sb−Sb single bond lengths, as comparisons with KSb (2.83 and 2.85 Å),[12] *cyclo*-Sb_5^{5-} (2.81−2.91 Å),[13] and Sb_{11}^{3-} (2.76−2.85 Å) reveal.[14] Short (2.84 Å) and long (3.54 Å) Sb−Sb distances alternate along [010]. This type of *cis-trans* chain is also found in the structure of $MoSb_2Se$ (Figure 2b). Furthermore, each Sb atom of the zigzag chain binds an Sb atom of the MoSbS layer (d = 2.84 Å). Thus, each Sb atom of the zigzag chain takes part in three Sb−Sb interactions described best as single bonds.

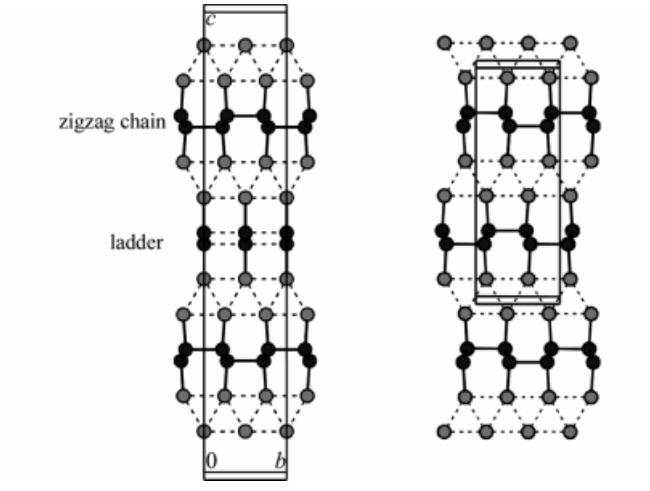

Figure 2. The pseudo two-dimensional Sb atom network of a) $MoSb_2S$ and b) $MoSb_2Se$; solid lines: short Sb−Sb contacts (2.8−2.9 Å); dash lines: long Sb−Sb contact (3.1−3.4 Å)

The second type is an Sb ladder at *x* close to 1/2. Each ladder contains two parallel Sb atom columns with equidistant Sb−Sb contacts of 3.19 Å parallel to the *b* axis. These two columns are interconnected to form the ladder by Sb−Sb bonds of 2.85 Å, and to the Sb atoms of the MoSbS layer by a second Sb−Sb single bond of 2.84 Å. This particular Sb atom substructure is not observed in the $MoSb_2Se$ structure, but the Sb atom ladder compares well to that found in $FeSb_2$ with Sb−Sb distances of 3.20 Å in the columns and 2.89 Å for the bonds connecting the columns to the ladder.[15] Figure 3 illustrates the different columnar Sb atom substructures of $MoSb_2S$, namely the *cis-trans* chain and the ladder.

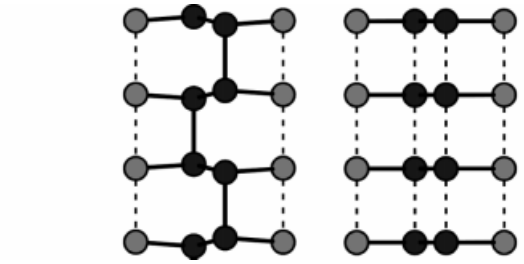

Figure 3. The columnar Sb atom substructure of $MoSb_2S$: a) zigzag chain; b) ladder

Sb−Sb bonds of 3.0−3.2 Å are usually identified as half bonds.[16−21] Instead of forming three full Sb−Sb bonds like the Sb atoms of the zigzag chain, each Sb atom of the ladder forms two full and two half Sb−Sb bonds. This bonding situation resembles those of the $FeSb_2$ structure and of the Li_2Sb structure. In the latter, two different linear Sb atom chains occur; one comprises equidistant Sb−Sb distances of 3.26 Å, and the second one has alternating short and long distances of 2.97 and 3.56 Å.[22]

The question remains, why two different columnar Sb atom substructures occur in $MoSb_2S$, but not in $MoSb_2Se$. In general, the presence of one full bond is preferred over two half bonds (Peierls distortion). However, the Li_2Sb structure proves that the energetic differences may be very small, since both alternatives exist in this same structure − as they do in $MoSb_2S$. Also, the differences between $MoSb_2S$ (one linear equidistant, thus an undistorted chain is present) and $MoSb_2Se$ are reminiscent of those between the high- and low-temperature form of $LaSiAs_3$.[23] In this arsenide, an almost square-planar, i.e. undistorted, As layer (with intermediate As−As bonds of 3.01 and 3.05 Å) is present in the high-temperature modification, resembling the $MoSb_2S$ case. This As layer is transformed into zigzag chains in the low-temperature modification (thus resembling the $MoSb_2Se$ case), with short and long As−As distances of alternating 2.56 and 3.52 Å along [100] and 2.76

and 3.29 Å along [010]. In analogy, one can consider $MoSb_2Se$ as the distorted variant of $MoSb_2S$.

However, even if the differences are subtle, why is there no undistorted Sb chain in $MoSb_2Se$, but one in $MoSb_2S$? We speculate that this is due to the matrix effect imposed by the larger chalcogen atom Se, which would make the half bonds longer than in $MoSb_2S$ as reflected in the longer *b* axis of $MoSb_2Se$, namely 3.25 Å compared to 3.19 Å.

The formal charges of each atom in $MoSb_2S$ may be assigned qualitatively based on the Zintl−Klemm concept.[24,25] Among these elements, the electronegativity of sulfur is the largest on any electronegativity scale, and the distances between two nearest S atoms fall in the range of 3.2−3.5 Å, which are normal van der Waals distances. Then, the S atom can be treated as S^{2-} ions. The short Mo−Mo contacts in the Mo zigzag chain suggest a d^2 configuration, that is Mo^{4+}, which is the preferred valence-electron configuration for the transition metal atom zigzag chain. The analogous assignments for MoS_2 and $MoTe_2$ result in $(Mo^{4+})(S^{2-})_2$ and $(Mo^{4+})(Te^{2-})_2$, respectively. The formal charge of each Sb atom is assigned based on the $(8 - N)$ rule, with N = number of full Sb−Sb bonds. Therefore, the Sb atom on the MoSbS layer is Sb^{2-} (one full bond, thus $N = 1$, ergo $8 - N = 7$ valence electrons), and the Sb atom of the zigzag chain is Sb^0 (three full bonds, $N = 3$). The Sb atom from the ladder carries the same charge (i.e. 0), since it comprises two full and two half bonds. We therefore arrive at an electron-precise formula, that is $Mo^{4+}Sb^0Sb^{2-}S^{2-}$, which in general implies that semiconducting properties are possible. In this case, however, semiconducting properties are unlikely due to the presence of other intermediate Sb−Sb interactions (3.18−3.20 Å) within the MoSbS layer. These increase N of the intralayer Sb atom, and thus decrease the formal charge to $(2 - x)-$ with $x < 1$, resulting in the more accurate formulation $Mo^{4+}Sb^0Sb^{(2-x)-}S^{2-}(e^-)_x$ that hints towards metallic properties.

Electronic Structure

Theoretical band calculations using the LMTO method were carried out to study the electronic structure of $MoSb_2S$. The band structure of $MoSb_2S$ is illustrated in Figure 4. Bands cross the Fermi level along each direction, which strongly suggests three-dimensional metallic property. The different orbital contributions can be evaluated by the *fat band* analyses.[26] The results indicate that the orbital contributions near the Fermi level stem mostly from Mo $d_{x^2-y^2}$ and Sb p orbitals from the interlayer Sb atoms (Sb1, Sb5 and Sb6, as emphasized by the fat band representations). The contributions from the S atom are near zero at the Fermi level. Thus, the Mo−Mo and Sb−Sb interactions are likely responsible for the metallic behavior of $MoSb_2S$.

Density of states (DOS) curves for $MoSb_2S$ and the partial projections onto the Mo and Sb atoms are illustrated in Figure 5. The s block of sulfur occurs in the energy window of −13 to −15 eV, and the broad peak between −13 eV and the Fermi level at 0 eV mainly comprises S p, Sb p and Mo d orbitals. There is no band gap, but a pronounced local minimum in the densities of states at the Fermi level.

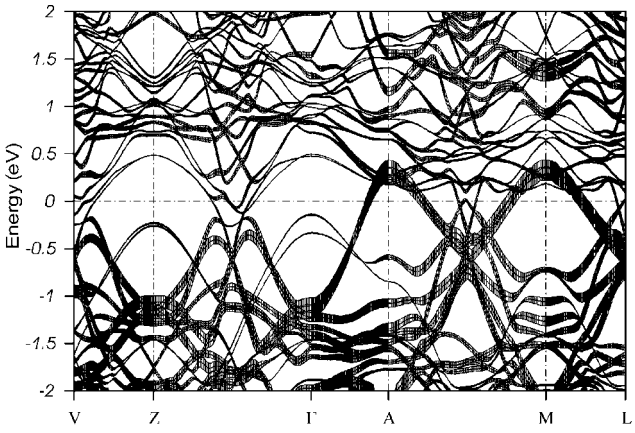

Figure 4. Band structure of $MoSb_2S$; the dashed line denotes the Fermi energy; the interlayer Sb contributions are emphasized

The interatomic interactions in $MoSb_2S$ were analyzed by integrating the area of the COHP curves, resulting in ICOHP values. This is a similar procedure to obtaining the widely used Mulliken overlap populations (MOPs)[27] from the Crystal Orbital Overlap Population (COOP) curves[28] calculated with the Extended Hückel method.[29,30] In contrast to the MOPs, bonding character is reflected in negative ICOHPs. Mo−Mo COHP curves (solid line in Figure 5b) are nearly optimized at the Fermi level E_F (ICOHP = −1.16 eV per bond). A small gap at E_F separates weak antibonding from strong antibonding Mo−Mo states, which suggests that the Mo−Mo bonding will be destabilized by small changes in the valence-electron concentration. The COHP curves of the Mo−S (dotted) and Mo−Sb (dashed) interactions also exhibit a nearly maximized bonding interaction at the Fermi level (ICOHP: Mo−Sb = −1.69; Mo−S = −2.93 eV per bond). All three kinds of interactions shown in Figure 5b comprise zero contributions directly at the Fermi level.

The Sb−Sb interactions are illustrated in Figure 5c for two kinds of Sb−Sb contacts. The first COHP curve (solid line, I) represents the shorter Sb−Sb contacts < 2.9 Å. Almost no antibonding states are filled, the interactions are almost optimized at the Fermi level with an averaged ICOHP value of −1.66 eV per bond. The second COHP curve (dotted line, II) represents Sb−Sb contacts within the MoSbS layer ($3.18 < d_{Sb-Sb} < 3.33$ Å). These interactions exhibit antibonding characters at the Fermi level. The average ICOHP value for these Sb−Sb bonds is −0.31, indicating weaker yet still bonding character. The longer bond of the equidistant ladder of 319 Å (curve III, dashed line) was considered as a half bond, which is reflected in an intermediate ICOHP value of −0.63 eV per bond. These ICOHPs may be compared to those of the two different bonds in elemental antimony, which are −1.63 for the short one of 2.91 and −0.23 eV for the longer one (3.35 Å). For the Sb−Sb bonds of 2.91 and 3.10 Å in Mo_3Sb_7,[31] we calculated similar ICOHPs of −0.79 and −0.40, respectively.

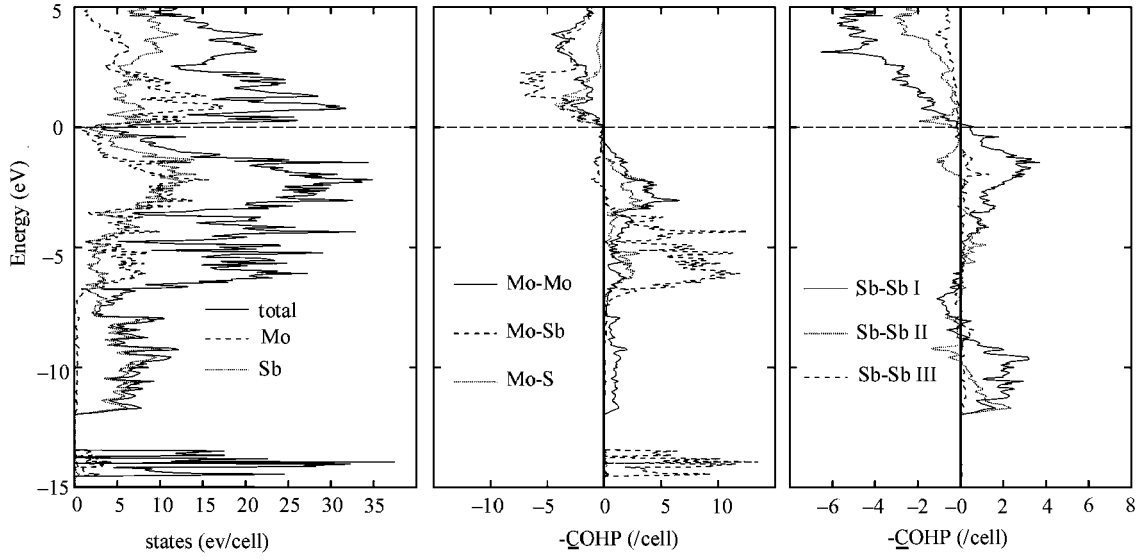

Figure 5. DOS and COHP curves for the $MoSb_2S$; the horizontal dashed line denotes the Fermi energy: a) total DOS (solid line), PDOS from Mo (dashed), Sb (dotted); b) COHP curves for Mo−Mo (solid line), Mo−Sb (dotted), Mo−S (dashed) interactions; c) Sb−Sb contacts (solid line: I, 2.83 < d_{Sb-Sb} < 2.88 Å; dotted line: II, intralayer 3.18 < d_{Sb-Sb} < 3.33 Å, dashed line: III, interlayer 3.19 Å)

Correspondingly, the half bond (3.11 Å) in $Zr_{11}Sb_{18}$ exhibits an ICOHP of −0.49, while the full bonds in KSb have larger ICOHPs of −2.29 and −1.87 eV per bond.[32]

Physical Properties

The temperature-dependent Seebeck coefficient measurement is shown in Figure 6. The Seebeck coefficient drops from −17 μV/K at 300 K to −30 μV/K at 600 K. The negative sign indicates that electrons are the main charge carriers. Typical magnitudes of Seebeck coefficients at 300 K range from a few μV/K for most metals to 10−20 μV/K for some transition metal elements.[1] The observed Seebeck coefficient of $MoSb_2S$ is at the upper end for metallic materials.

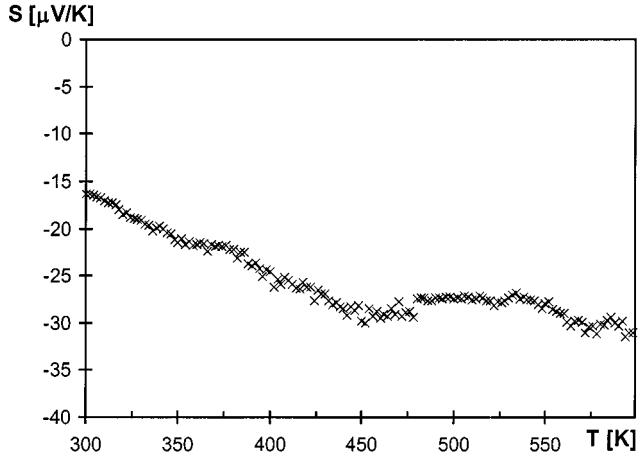

Figure 6. Temperature-dependent Seebeck coefficients of $MoSb_2S$

Conclusion

In summary, the synthesis and characterization of a new ternary compound, $MoSb_2S$, were presented. $MoSb_2S$ crystallizes in a new three-dimensional structure type exhibiting CdI_2-related layers (MoSbS) and Sb columns (*cis-trans* chains and equidistant ladders). The structure comprises strong heteronuclear Mo−S and Mo−Sb bonds, and additional Mo−Mo and Sb−Sb bonds. The Sb atom substructure of $MoSb_2S$ may be considered to be a partly undistorted variant of $MoSb_2Se$. Both antimonide chalcogenides can be formally derived from MoSbS layers topologically equivalent to the β-$MoTe_2$ layers, with additional interlayer Sb atoms. The (formal) intercalation of anionic Sb atoms actually enlarges the octahedral voids between the sheets, thereby rendering an additional intercalation of cations more facile.

$MoSb_2S$ exhibits metallic behavior as predicted by electron counting, electronic structure calculations and confirmed by physical property measurements (Seebeck coefficients). The results from the electronic structure calculations show the smallest number of states directly at the Fermi level; thus, changing the valence-electron concentration is likely to further increase the number of itinerant valence electrons, a disadvantage when looking for thermoelectric materials.

Experimental Section

Synthesis: All starting materials were stored in an Argon-filled glove box. The starting materials were molybdenum (Aldrich, 99.9%), antimony powder (Aldrich, 99.8%, melting point 903 K,

99.5%), sulfur (Aldrich, 99.98%), Mo_3Sb_7 and Sb_2S_3. Mo_3Sb_7 was synthesized by starting from the stoichiometric ratio of Mo/Sb = 3:7 and heating at 973 K for 3 d in an evacuated fused silica tube, whereas Sb_2S_3 was prepared at 773 K within 3 d in an evacuated fused silica tube. Initial reactions were carried out by preparing mixtures in stoichiometric ratios of the elements with a small amount of I_2 as the transport reagent, in a silica tube, sealed under vacuum ($< 10^{-3}$ mbar), and heated at 1073 K for 3 d. Black, needle-shaped crystals of $MoSb_2S$ and mixtures of Sb and binary phases (Mo_3Sb_7, MoS_2) were observed from these reactions. Pure $MoSb_2S$ can be synthesized either by heating stoichiometric amounts of the elements at 873 K for 3 d or annealing binary compounds Mo_3Sb_7 and Sb_2S_3 in a 1:1 ratio at 973 K for 2 d. The purity of $MoSb_2S$ was checked by powder X-ray diffraction and elemental analyses (EDS, see below). The second reaction route (Mo_3Sb_7 + Sb_2S_3) yielded $MoSb_2S$ and elemental antimony, that crystallized on different sides of the reaction container. Higher reaction temperatures (> 1123 K) for both reaction routes led to the disproportionation of $MoSb_2S$ into MoS_2, Mo and Sb. $MoSb_2S$ is stable in air for at least two weeks.

Structure Determination: Needle-shaped crystals for single-crystal X-ray diffraction experiments were selected under an optical microscope and then mounted on glass fibers. Single-crystal X-ray diffraction data were collected with the use of graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) at 298(2) K with a Bruker APEX CCD diffractometer. The crystal-to-detector distance was 4.550 cm. Data were collected by a scan of 0.3° in ω groups of 606 frames each at φ settings of 0°, 60°, 120°. The exposure time was 120 s/frame. The 2θ values varied between 3° and 70°. The data were corrected for Lorentz and polarization effects. Absorption corrections were based on fitting a function to the empirical transmission surface as sampled by multiple equivalent measurements.[33] Diffraction peaks obtained from all frames of reciprocal space images were used to determine the unit cell parameters. Initially, the data revealed a primitive unit cell similar to the one of $MoSb_2Se$ and additional weak reflections, which suggested a supercell. The unit cell parameters of $MoSb_2S$ indicated monoclinic symmetry, as later proven by a comparison of symmetry-equivalent reflections (R_{int} = 0.043). The systematic absences revealed *C*-centering. Therefore, the space group *C*2/*m* was chosen for subsequent structural analyses. The structure model was obtained by direct methods and refined by full-matrix least-squares refinement based on F^2 with the SHELXTL5.12 package.[34] Table 1 summarizes the crystallographic data of $MoSb_2S$. Table 2 lists selected interatomic distances. Further details of the crystal-structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-412092. All Mo and S atoms exhibit reasonable thermal displacement parameters. However, the Sb5 and Sb6 atoms show 2−3 times higher thermal displacement parameters along each main direction, which might suggest an even higher order of supercell or lower symmetry. However, lowering the symmetry, for example by refining in C_2 or *Cm*, did not result in any improvements. Also, we found no evidence for the existence of a higher superstructure.

Elemental Analysis: Energy dispersive spectroscopy (EDS, LEO 1050) was performed on the crystalline and powdered samples. The Mo/S ratio could not be determined due to the severe overlap of the peaks of Mo (L_α = 2.293 eV) and S (K_α = 2.307 eV). No impurities of other elements (like iodine, silicon or oxygen) were detected.

Thermopower Measurements: Seebeck coefficients were determined on a cold-pressed bar by a commercial thermopower measurement apparatus (MMR Technologies) in the temperature range of 300 to 600 K, using Constantan as an internal standard. Silver paint (AMI DODUCO Technology) was used to create electric contacts.

Electronic Structure Calculations: The tight-binding LMTO (Linear Muffin Tin Orbitals)[35−37] band calculations were carried out in order to understand the electronic structure of $MoSb_2S$. The integration in *k* space was performed by an improved tetrahedron method[38] on a grid of 16 × 16 × 8 irreducible *k* points of the first Brillouin zone (i.e. 554 of 2048 *k* points). We analyzed the electronic structure by extracting information from the band structure, Densities of states (DOS), and Crystal Orbital Hamiltonian Population curves (COHP).[39]

The Cationic Rearrangement of (3-Hydroxy-1-propenyl)tris(trimethylsilyl)-silanes into (1-Trimethylsilyl-2-propenyl)bis(trimethylsilyl)silanols – Experimental and Theoretical Studies

Kathleen Schmohl,[a] Dirk Wandschneider,[a][‡] Helmut Reinke,[a] Andreas Heintz,*[a] and Hartmut Oehme*[a]

Keywords: Alcohols / Rearrangements / Silanes / Silicon

(3-Hydroxy-1-propenyl)tris(trimethylsilyl)silanes $(Me_3Si)_3SiCH{=}CHCR_2OH$ (**8b,c**) (**b:** R = Me; **c:** R = Ph) undergo a rapid rearrangement involving a 1,2-Si,C migration of one trimethylsilyl group from the central silicon atom to a cationic neighboring carbon atom and a shift of the olefinic double bond, in the presence of acid, to afford (1-trimethylsilyl-2-propenyl)bis(trimethylsilyl)silanols $(Me_3Si)_2Si(OH)CH(SiMe_3)CH{=}CR_2$ (**13b,c**). Treatment of **8b,c** with sulfuric acid in methanol gives the methoxysilanes $(Me_3Si)_2Si(OMe)CH(SiMe_3)CH{=}CR_2$ (**14b,c**). In a related reaction, **8b,c** are converted by boron trifluoride into the fluorosilanes $(Me_3Si)_2SiFCH(SiMe_3)CH{=}CR_2$ (**15b,c**). A possible mechanism of the isomerization reaction, involving the rearrangement of the silylcarbenium ions $[(Me_3Si)_3SiCH{=}CHCR_2]^+$ into the silylium ions $[(Me_3Si)_2SiCH(SiMe_3)CH{=}CR_2]^+$, is proposed. This is supported by calculations, which indicate the higher stability of the silylium ion **10b** compared with the isomeric silylcarbenium cation **9b**. For **14c** the results of an X-ray structural analysis are given.

Introduction

Recently we found that 1-hydroxyalkyltris(trimethylsilyl)-silanes (**1**) undergo a rapid isomerization in the presence of strong acids into 1-trimethylsilylalkylbis(trimethylsilyl)silanols (**6**) (Scheme 1).[1] The reaction path was interpreted in terms of a cationic rearrangement initiated by an acid-catalyzed elimination of water from the alcohol **1** and formation of the carbenium ion **2**. The subsequent 1,2-Si,C migration of one trimethylsilyl group, and attack of X^-, the conjugate base of the acid used as the catalyst, at the central silicon atom produces the intermediate **5**, which after hydrolytic workup affords the silanol **6**. A decision as to whether the reaction involves a synchronous nucleophilic attack by X^- on the central silicon atom and migration of one trimethylsilyl group from silicon to carbon (**3**) or, alternatively, proceeds through a silylium ion intermediate **4**, could not be made. It is very likely that the isomerization is facilitated by the greater stability of the silylium ion **4** than the carbenium cation **2**, and we consider the crucial step of the conversion **1**→**6** to be the isomerization of the silyl-substituted carbenium ion into the silylium ion by 1,2-migration of one $SiMe_3$ group from the tetracoordinated silicon center to the neighboring carbon atom. Some reactions of this type have recently been described,[2,3] and confirm expectations from theoretical work, according to which α-silyl carbenium ions should generally be less stable than the isomeric silylium ions.[4]

Continuing these studies we extended our experiments to vinylogous derivatives of the alcohols **1**, and in the present paper we report on the related behavior of (3-hydroxy-1-propenyl)tris(trimethylsilyl)silanes **8**, which rearrange in the presence of acid to give the (1-trimethylsilyl-2-propenyl)bis-(trimethylsilyl)silanols **13**.

Results and Discussion

The aim of the studies described in this paper was to examine whether tris(trimethylsilyl)silyl-substituted carbenium ions with a delocalized positive charge also undergo 1,2-Si,C trimethylsilyl migrations as discussed above for the isomerization of **2** into **5**. As model compounds we have chosen tris(trimethylsilyl)silylcarbocations, which were intended to be generated by the acid-induced elimination of water from the respective 3-hydroxy-1-propenylsilanes. For that purpose we prepared the alcohols **8a–c** by addition of tris(trimethylsilyl)silane (**7**) across the triple bonds of propargylic alcohol, 2-methyl-3-butyn-2-ol and 1,1-diphenyl-2-propyn-1-ol (Scheme 2). This method, and its application to the synthesis of **8a**, has already been described,[5] and proved to be suitable also for the reaction of **7** with the above-mentioned propynols.

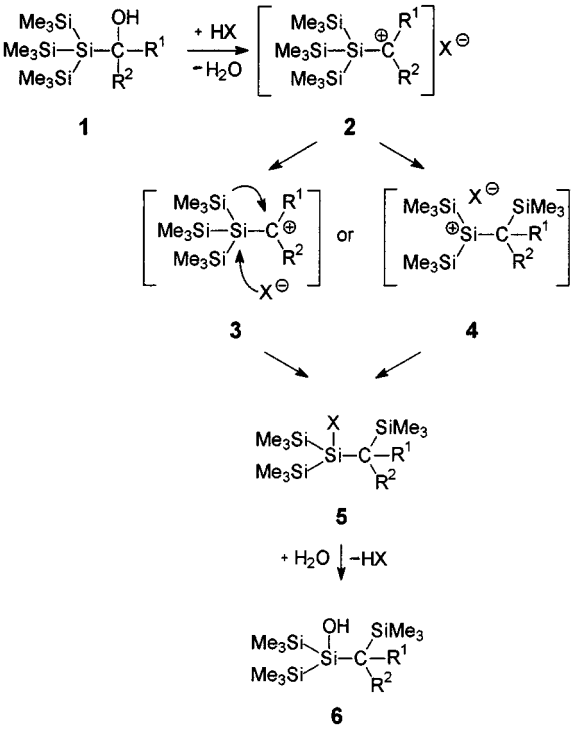
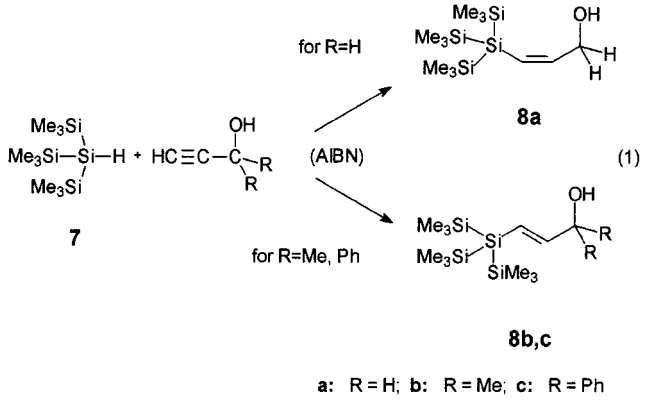


Scheme 1. The acid-induced rearrangement of 1-hydroxyalkyltris-(trimethylsilyl)silanes **1** into bis(trimethylsilyl)-1-trimethylsilylalkylsilanols **6**



Scheme 2

In agreement with the literature data, the addition of **7** to the triple bond of propargylic alcohol led to the *Z*-olefin **8a**.[5] In contrast, the coupling constants of the olefinic protons in **8b** and **8c** unambiguously revealed an *E*-configuration for both olefins. This difference is due to the different space filling properties of the $C(OH)R_2$ substituents (R = Me, Ph) in **8b,c**.

The Acid-Induced Isomerization of the (3-Hydroxy-1-propenyl)tris(trimethylsilyl)silanes into (1-Trimethylsilyl-2-propenyl)bis(trimethylsilyl)silanols

The alcohols **8a−c**, dissolved in ether, were treated with hydrochloric acid or, alternatively, pentane solutions of **8a−c** were stirred with a few drops of sulfuric acid at room temperature. In all experiments with **8a** the alcohol was always recovered unchanged. Under the same conditions, however, **8b** and **8c** underwent rapid rearrangements and after aqueous workup of the reaction mixtures we obtained the silanols **13b** and **13c**, respectively. Sulfuric acid proved to be most effective for the acid-catalyzed isomerization of 1-hydroxyalkyl-tris(trimethylsilyl)silanes (**1**).[1] Therefore — and also because of the convenient experimental procedure — we used only this catalyst in all the studies described below.

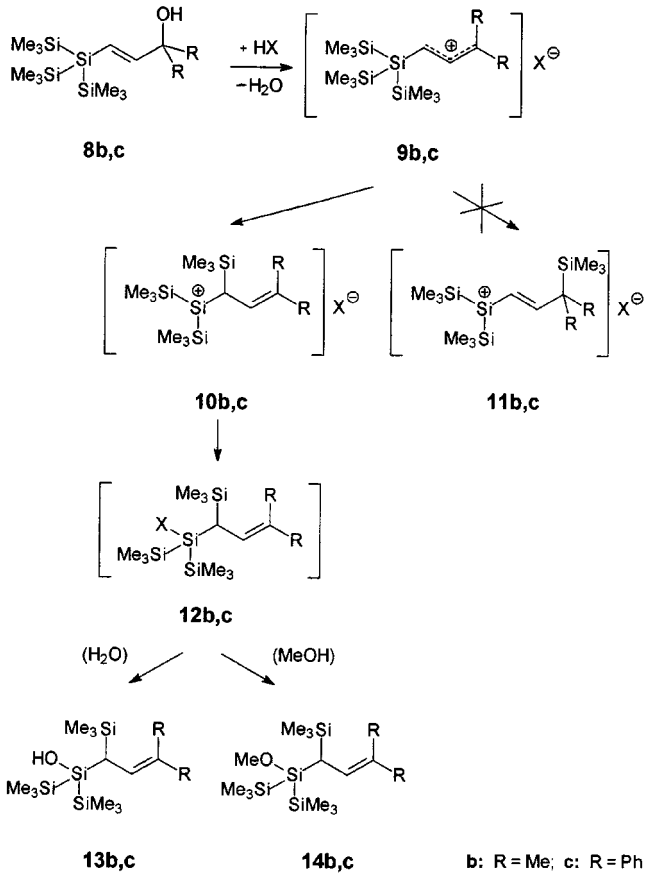
The suggested mechanism of the reaction is outlined in Scheme 3. Protonation of **8b,c** and elimination of water leads to the carbenium ions **9b,c**. (3-Hydroxy-1-propenyl)-tris(trimethylsilyl)silane (**8a**) is reluctant to undergo the rearrangement. Obviously, elimination of water from the primary alcohol failed under our conditions and therefore no reaction occurs. Despite delocalization of the positive charge in **9b,c**, which is expected to enhance the stability of the carbocations, one trimethylsilyl group migrates from the central silicon atom to the adjacent carbon atom generating the transient silylium ions **10b,c**. As already mentioned, Apeloig et al. found that α-silyl-substituted carbenium ions are generally less stable than the isomeric silylium ions.[3,4] This is confirmed by ab initio calculations, described below, which indicate a significantly higher stability of the silylium ion **10b** than the carbenium ion **9b**; this energy difference is supposed to be the driving force of the rearrangement **9b,c→10b,c**. Addition of X^- to the silylium silicon atoms results in formation of the silanes **12b,c**, which during the aqueous workup hydrolyse to give the silanols **13b,c**. Of course, a synchronous process involving an attack of X^- at the central silicon atom of **9b,c** and a simultaneous shift of one Me_3Si group to the α-carbon atom of the alkyl substituent affording **12b,c** cannot be excluded.

For the reaction of **8c** with ethereal HCl the intermediate chlorosilane **12c** (R = Cl) was isolated; this compound can easily be converted into the silanol **13c** by addition of water. Attempts to isolate the silyl sulfates **12b,c** ($R = OSO_3H$) after reaction of **8b,c** with sulfuric acid failed. Due to rapid hydrolysis, the products obtained always contained considerable amounts of the silanols **13b,c**. When the isomerization of **8b,c** was carried out with sulfuric acid in methanol, solvolysis of the silylsulfates **12b,c** ($X = OSO_3H$) afforded the methoxysilanes **14b,c** (Scheme 3).

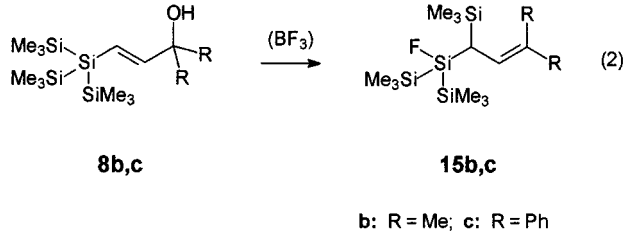
Of course, a 1,4-migration of one trimethylsilyl group of **9b,c** producing the silylium ions **11b,c** may be possible (Scheme 3), although products originating from conversions of **11b,c** were not observed. This is in agreement with the results of the calculations described below.

According to a related mechanism, treatment of **8b,c** with boron trifluoride produced the fluorosilanes **15b,c** (Scheme 4).

The structures of **8b,c** and **13b,c−15b,c** were elucidated by a full spectral analysis (^1H, ^{13}C and ^{29}Si NMR spectroscopy, IR spectroscopy, MS and elemental analysis). For the methoxysilane **14c** an X-ray structural analysis was performed, which confirmed the compound as a crowded silane (Figure 1). Thus, the Si1−C1 bond in **14c** is slightly elongated (1.906 Å) and the angle C1−Si1−Si3 (112.53 °)



Scheme 3. The acid-induced conversion of the 3-hydroxy-1-propenyltris(trimethylsilyl)silanes **8b,c** into the silanols **13b,c** or the methoxysilanes **14b,c**



Scheme 4

is widened. The other bond lengths and angles are in the expected range.

The reaction sequence **8**→**10** can be considered to be possibly a useful method for the generation of sterically congested silylium ions just by operating in the unprotected periphery of the molecule.

Theoretical Studies

Since there is no direct experimental evidence that the rearrangement of **8b,c** → **13b,c** proceeds through the intermediates **9b,c** and **10b,c**, we have used ab initio calculations to predict the relative stabilities of the carbenium ion **9b** and the isomeric silylium ion **10b**. To estimate the probability of a 1,4-trimethylsilyl migration in **9b**, we also included the silylium ion **11b** in these studies (Scheme 3). The calculations were performed for isolated species using the Gaussian 98 program package.[6] The following procedure was applied. First, we made a geometry optimization of **9b, 10b** and **11b** at the HF/6-31G(d) level. Based on these geometric structures single point energy calculations were performed at the HF/6-31G(d) and MP2/6-31G(d) levels. Secondly, geometry optimizations with single point energy calculations were performed at the HF/6-31++G(d,p) level.[7] The values of the absolute energies obtained by these procedures are shown in Table 1. Table 2 shows the energy differences in kcal/mol. The differences of the absolute energies obtained at the different levels indicate a stabilization of **10b** of between 9.9 and 22.7 kcal·mol^{-1} compared with **9b** depending on the method indicated in Table 2. The values obtained are close to the stabilization energies of other silylium ions over their isomeric α-silyl-substituted carbenium ions reported by Apeloig.[4] The other possible intermediate **11b** is energetically disfavoured by between 3.6

Experimental Section

General: All reactions involving organometallic reagents were carried out under purified argon. NMR: Bruker AC 250 or Bruker ARX 300, tetramethylsilane as internal standard. IR: Nicolet 205 FT-IR. MS: Intectra AMD 402. $(Me_3Si)_3SiH$ (**7**) was prepared using the method described by Marschner;[8] **8a** was synthesized following the procedure given by Utimoto,[5] but the reaction was induced by AIBN instead of triethylborane. Due to the formation of SiC, the results of the elemental analyses of some compounds were unsatisfactory. In these cases HRMS data are given.

(3-Hydroxy-3-methyl-1-butenyl)tris(trimethylsilyl)silane (8b): 2-Methyl-3-butyn-2-ol (1.2 g, 14.0 mmol) and AIBN (0.2 g) were gradually added at room temperature to a solution of **7** (3.0 g, 12.1 mmol) in toluene (30 mL). The mixture was heated under reflux for 5 h, and then water was added and the organic phase separated, dried and the solvents evaporated. The residue was purified by kugelrohr distillation at 75−100 °C/7·10^{-3} mbar to afford 3.0 g (74.7%) of **8b**. Colorless crystals, m.p. 58−63 °C. IR (nujol): $\tilde{\nu}$ = 3407 cm^{-1} (OH). ^{1}H NMR ([D$_6$]benzene): δ = 0.27 (s, 27 H, $SiCH_3$), 0.98 (s, 1 H, OH), 1.15 (s, 6 H, CCH_3), 5.92 (d, ^3J = 18.6 Hz, 1 H, CH), 6.29 (d, ^3J = 18.6 Hz, 1 H, CH). ^{13}C NMR ([D$_6$]benzene): δ = 0.9 ($SiCH_3$), 29.7 (CCH_3), 71.9 (COH), 115.4 and 156.9 (olef. C). ^{29}Si NMR ([D$_6$]benzene): δ = −85.5 (SiSiMe$_3$), −13.1 ($SiMe_3$). MS (70 eV): *m*/*z* (%) = 317 (3) [M − CH_3]$^+$, 315 (3) [M − OH]$^+$, 259 (12) [M − $SiMe_3$]$^+$, 73 (100) [$SiMe_3$]$^+$. $C_{14}H_{36}OSi_4$ (332.8): calcd. C 50.53, H 10.90; found C 50.79, H 10.85.

(3-Hydroxy-3,3-diphenyl-1-propenyl)tris(trimethylsilyl)silane (8c): Following the procedure given for **8b**, 3.0 g (12.1 mmol) of **7**, 2.50 g (12.1 mmol) of 1,1-diphenyl-2-propyn-1-ol and 0.2 g of AIBN gave 2.7 g (49%) of **8c** after kugelrohr distillation (200 °C/3·10^{-2} mbar). Colorless oil. IR (cap.): $\tilde{\nu}$ = 3462 cm^{-1} ($OH_{ass.}$), 3556 and 3601 cm^{-1} (OH_{free}). ^{1}H NMR ([D$_6$]benzene): δ = 0.23 (s, 27 H, $SiCH_3$), 1.84 (s, 1 H, OH), 6.12 (d, ^3J = 18.6 Hz, 1 H, CH), 6.82 (d, ^3J = 18.6 Hz, 1 H, CH), 7.03−7.49 (m, arom. 10 H, CH). ^{13}C NMR ([D$_6$]benzene): δ = 1.0 ($SiCH_3$), 81.0 (COH), 119.6 and 153.3 (olef. C), 127.3, 127.5 and 128.3 (arom. CH), 146.8 (arom. C). ^{29}Si NMR ([D$_6$]benzene): δ = −85.0 (SiSiMe$_3$), −12.8 ($SiMe_3$). MS (70 eV): *m*/*z* (%) = 456 (2) [M]$^+$, 441 (2) [M − CH_3]$^+$, 439 (2) [M − OH]$^+$, 383 (7) [M − $SiMe_3$], 73 (100) [$SiMe_3$]$^+$. $C_{24}H_{40}OSi_4$ (456.9): calcd. C 63.09, H 8.82; found 63.47, H 8.86.

Chloro(3,3-diphenyl-2-propenyl-1-trimethylsilyl)bis(trimethylsilyl)-silane (12c): Compound **8c** (0.5 g, 1.1 mmol) was dissolved in 30 mL of ether containing excess hydrogen chloride, and the solution was stirred at room temperature for 8 h. After addition of solid $NaHCO_3$ and filtration, the solution was evaporated. Chromatographic separation of the residue (silica gel, heptane/ethyl acetate 20:1) gave 0.14 g (26%) of the chlorosilane **12c** and 0.15 g (30%) of the silanol **13c**.

12c: Colorless oil. ^{1}H NMR ([D$_6$]benzene): δ = 0.18, 0.22 and 0.27 (3s, 3 × 9 H, $SiCH_3$). 2.51 (d, ^3J = 13.4 Hz, 1 H, SiCH), 6.43 (d, ^3J = 13.4 Hz, 1 H, olef. CH), 6.98−7.48 (m, arom. 10 H, CH). ^{13}C NMR ([D$_6$]benzene): δ = −0.9, −0.6 and 0.3 ($SiCH_3$), 22.8 (CH), 126.9, 127.1, 127.2, 127.4, 128.6, 128.7, 130.7, 139.4, 140.3 and 143.5 (arom. and olef. C). ^{29}Si NMR ([D$_6$]benzene): δ = −14.3 and −13.7 (SiSiMe$_3$), 3.3 ($CSiMe_3$), 9.6 (SiCl). MS (70 eV): *m*/*z* (%) = 474 (5) [M]$^+$, 459 (4) [M − CH_3]$^+$, 439 (1) [M − Cl]$^+$, 401 (2) [M − $SiMe_3$]$^+$, 73 (100) [$SiMe_3$]$^+$. $C_{24}H_{39}ClSi_4$ (475.4): calcd. C 60.64, H 8.27, Cl 7.46; found C 61.18, H 8.24, Cl 8.07. HRMS: calcd. 474.18173; found 474.18510.

(3-Methyl-1-trimethylsilyl-2-butenyl)bis(trimethylsilyl)silanol (13b): Concentrated sulfuric acid (0.15 g, 1.5 mmol) was added gradually to a solution of **8b** (0.5 g, 1.5 mmol) in pentane (30 mL) and the mixture was stirred at room temperature for 8 h. After neutralization with aqueous $NaHCO_3$ solution, washing with water and drying, the solvent was removed in vacuo and the residue purified by column chromatography (silica gel, heptane/ethyl acetate 20:1) to give 0.09 g (18%) of **13b**. Colorless oil. IR (nujol): $\tilde{\nu}$ = 3454 cm^{-1} ($SiOH_{ass.}$), 3649 cm^{-1} and 3677 cm^{-1} ($SiOH_{free}$). ^{1}H NMR ([D$_6$]benzene): δ = 0.19 (s, 18 H, $SiSiCH_3$), 0.24 (s, 9 H, $SCSiCH_3$), 0.52 (s, 1 H, OH), 1.54 and 1.70 (2d, ^4J = 1.2 Hz, 2 × 3 H, CCH_3), 1.97 (d, ^3J = 12.8 Hz, 1 H, SiCH), 5.24 (dpseudoquart, ^3J = 12.8, ^4J = 1.2 Hz, 1 H, olef.CH). ^{13}C NMR ([D$_6$]benzene): δ = −1.1, −0.3 and −0.1 ($SiCH_3$), 17.9 and 26.0 (CCH_3), 22.8 (CH), 121.6 and 127.8 (olef. C). ^{29}Si NMR ([D$_6$]benzene): δ = −19.4 and −19.6 (SiSiMe$_3$), 2.0 ($CSiMe_3$), 8.4 (SiSiMe$_3$). MS (70 eV): *m*/*z* (%) = 332 (2) [M]$^+$, 317 (4) [M − CH_3]$^+$, 259 (19) [M − $SiMe_3$]$^+$, 73 (100) [$SiMe_3$]$^+$. HRMS: calcd. 332.18433; found 332.18365.

(3,3-Diphenyl-1-trimethylsilyl-2-propenyl)bis(trimethylsilyl)silanol (13c): Following the procedure described above but using ether instead of pentane as the solvent, 0.5 g (1.1 mmol) of **8c** and 0.3 g (0.3 mmol) of sulfuric acid afforded 0.22 g (45%) of **13c**. Colorless crystals from heptane/ethyl acetate, m.p 96−98 °C. IR (nujol): $\tilde{\nu}$ = 3463 cm^{-1} ($SiOH_{ass.}$), 3646 and 3677 cm^{-1} ($SiOH_{free}$). ^{1}H NMR ([D$_6$]benzene): δ = 0.12, 0.21 and 0.23 (3s, 3 × 9 H, $SiCH_3$), 0.57 (s, 1 H, OH), 2.47 (d, ^3J = 13.4 Hz, 1 H, CH), 6.52 (d, ^3J = 13.4 Hz, 1 H, CH), 6.98−7.41 (m, arom. 10 H, CH). ^{13}C NMR ([D$_6$]acetone): δ = −1.0, −0.5 and 0.0 ($SiCH_3$), 25.8 (CH), 126.5, 127.0, 127.2, 128.6, 128.8, 129.7, 130.9, 137.2, 140.8 and 144.0 (arom. and olef. C). ^{29}Si NMR ([D$_6$]benzene): δ = −19.1 and −18.8 (SiSiMe$_3$), 2.1 ($CSiMe_3$), 8.8 (SiSiMe$_3$). MS (70 eV): *m*/*z* (%) = 456 (2) [M]$^+$, 441 (5) [M − CH_3]$^+$, 338 (20) [M − $SiMe_3$]$^+$, 73 (100) [$SiMe_3$]$^+$. $C_{24}H_{40}OSi_4$ (456.9): calcd. C 63.09, H 8.82; found C 62.92, H 8.88.

Methoxy(3-methyl-1-trimethylsilyl-2-butenyl)bis(trimethylsilyl)-silane (14b): Compound **8b** (0.5 g, 1.5 mmol) and sulfuric acid (0.4 g, 3.6 mmol) were dissolved in 30 mL of methanol. The solution was stirred at room temperature for 8 h, neutralized with solid $NaHCO_3$ and washed with cold water. The product was extracted with ether, the solution evaporated and the residue purified by chromatography (silica gel, heptane/ethyl acetate 20:1) to afford 0.21 g (40%) of **14b**. Colorless crystals, m.p. 54−58 °C. IR (nujol): $\tilde{\nu}$ = 1087 cm^{-1} (SiOC). ^{1}H NMR ([D$_6$]benzene): δ = 0.22, 0.24 and 0.29 (3s, 3 × 9 H, $SiCH_3$), 1.56 and 1.70 (2d, ^4J = 1.2 Hz, 2 × 3 H, CCH_3), 2.01 (d, ^3J = 12.8 Hz, 1 H, SiCH), 3.31 (s, 3 H, OCH_3), 5.25 (dpseudoquart, ^3J = 12.8, ^4J = 1.2 Hz, 1 H, olef.

CH). ^{13}C NMR ([D$_6$]benzene): δ = −0.2, −0.1 and 0.6 ($SiCH_3$), 17.9 and 26.0 (CCH_3), 21.3 (CH), 53.6 (OCH_3), 121.7 and 127.7 (olef. C). ^{29}Si NMR ([D$_6$]benzene): δ = −19.6 and −19.8 (Si*Si*Me$_3$), 2.4 ($CSiMe_3$), 12.2 (SiOMe). MS (70 eV): *m*/*z* (%) = 346 (2) $[M]^+$, 331 (7) $[M - CH_3]^+$, 273 (15) $[M - SiMe_3]^+$, 73 (100) $[SiMe_3]^+$. $C_{15}H_{38}OSi_4$ (346.8): calcd. C 51.95, H 11.04; found C 51.82, H 10.89. HRMS: calcd. 346.19998; found 346.19792.

Methoxy(3,3-diphenyl-1-trimethylsilyl-2-propenyl)bis(trimethylsilyl)silane (14c): As described for **14b**, 0.5 g (1.1 mmol) of **8c** gave 0.4 g (78%) of **14c** after treatment with H_2SO_4 in methanol. The purification was performed by chromatography (silica gel, heptane); single crystals were obtained by recrystallization from heptane, m.p. 83−87 °C. IR (nujol): $\tilde{\nu}$ = 1090 cm^{-1} (SiOC). ^{1}H NMR ([D$_6$]benzene): δ = 0.17, 0.24 and 0.29 (3s, 3 × 9 H, $SiCH_3$), 2.52 (d, ^3J = 13.4 Hz, 1 H, SiCH), 3.28 (s, OCH_3, 1 H), 6.54 (d, ^3J = 13.4 Hz, 1 H, olef. CH), 7.01−7.42 (m, 10 H, arom. CH). ^{13}C NMR ([D$_6$]benzene): δ = 0.1, 0.2 and 0.7 ($SiCH_3$), 24.9 (CH), 53.6 (OCH_3), 126.6, 127.0, 127.2, 128.5, 128.6, 128.9, 130.9, 137.9, 140.6 and 144.0 (arom. and olef. C). ^{29}Si NMR ([D$_6$]benzene): δ = −19.26 and −19.31 (Si*Si*Me$_3$), 2.7 ($CSiMe_3$), 13.2 (SiOMe). MS (70 eV): *m*/*z* (%) = 470 (2) $[M]^+$, 450 (10) $[M - CH_3]^+$, 397 (15) $[M - SiMe_3]^+$, 73 (100) $[SiMe_3]^+$. $C_{25}H_{42}OSi_4$ (471.0): calcd. C 63.76, H 8.99; found C 63.75, H 8.78.

Fluoro(3-methyl-1-trimethylsilyl-2-butenyl)bis(trimethylsilyl)silane (15b): Boron trifluoride diethyl ether complex (0.22 g, 1.6 mmol) was added gradually at −78 °C to a solution of **8b** (0.50 g, 1.5 mmol) in diethyl ether (30 mL) and the mixture was stirred for 2 h. After warming to room temperature stirring was continued for 4 h, water was added and the organic phase was separated, dried and the solvents evaporated. Column chromatography (silica gel, heptane) of the residue gave 0.40 g (79.5%) of **15b**. Colorless oil. IR (nujol): $\tilde{\nu}$ = 1011 cm^{-1} (SiF). ^{1}H NMR ([D$_6$]benzene): δ = 0.21 (s, 18 H, Si*Si*Me$_3$), 0.25 (s, 9 H, $CSiMe_3$), 1.51 and 1.67 (2d, ^4J = 1.53 Hz, 2 × 3 H, CCH_3), 2.18 (dd, ^3J = 5.8, ^3J = 12.8 Hz, 1 H, CH), 5.27 (dpseudoquart, ^3J = 12.8, ^4J = 1.53 Hz, olef. CH, 1 H). ^{13}C NMR ([D$_6$]benzene): δ = −1.5, −0.6 and −0.5 ($SiCH_3$), 17.8 and 25.9 (CCH_3), 22.9 (d, ^2J = 15.0 Hz, SiCH), 120.3 (d, ^3J = 4.7 Hz, olef. CH), 128.3 (olef. C). ^{29}Si NMR ([D$_6$]benzene): δ = −19.0 and −19.4 (Si*Si*Me$_3$), 2.6 ($CSiMe_3$), 33.5 (d, ^1J = 334 Hz, SiF). ^{19}F NMR ([D$_6$]benzene): δ = −198.1 (SiF). MS (70 eV): *m*/*z* (%) = 335 (5) $[M + H]^+$, 319 (5) $[M - CH_3]^+$, 261 (15) $[M - SiMe_3]^+$, 73 (100) $[SiMe_3]^+$. Due to the ease of fragmentation an HRMS could not be obtained.

Fluoro(3,3-diphenyl-1-trimethylsilyl-2-propenyl)bis(trimethylsilyl)-silane (15c): As described above, treatment of 0.50 g (1.1 mmol) of **8c** with 0.16 g (1.1 mmol) of boron trifluoride diethyl ether complex in ether (30 mL) afforded 0.22 g (43%) of colorless crystals, m.p. 76−79 °C. IR (nujol): $\tilde{\nu}$ = 1021 cm^{-1} (SiF). ^{1}H NMR ([D$_6$]benzene): δ = 0.13, 0.23 and 0.27 (3s, 3 × 9 H, $SiCH_3$), 2.57 (dd, ^3J = 8.8, ^3J = 13.4 Hz, 1 H, SiCH), 6.57 (d, ^3J = 13.4 Hz, 1 H, olef. CH), 7.01−7.39 (m, 10 H, arom. CH). ^{13}C NMR ([D$_6$]benzene): δ = −1.3, −0.7 and −0.3 ($SiCH_3$), 26.2 (d, ^2J = 15.9 Hz, CH), 126.8, 126.9, 127.2, 128.3, 128.7, 130.6, 138.8, 140.6, 143.3 and 148.7 (arom. and olef. C). ^{29}Si NMR ([D$_6$]benzene): δ = −18.6 (Si*Si*Me$_3$), 3.0 ($CSiMe_3$), 34.7 (d, ^1J = 334 Hz, SiF). ^{19}F NMR ([D$_6$]benzene): δ = −197.5 (SiF). MS (70 eV): *m*/*z* (%) = 458 (5) $[M]^+$, 443 (2) $[M - CH_3]^+$, 385 (2) $[M - SiMe_3]^+$, 73 (100) $[SiMe_3]^+$. $C_{24}H_{39}FSi_4$ (458.9): calcd. C 62.81, H 8.57; found C 62.82, H 8.50.

X-ray Structure Determination of 14c: X-ray diffraction data were collected with a Bruker P4 four-circle diffractometer, Mo-*Ka* radiation, graphite monochromator, crystal size 0.48 × 0.44 × 0.41 mm^3, *T* = 293(2)K, $C_{25}H_{42}OSi_4$, *M* = 470.95, colorless prism, monoclinic, *a* = 9.205(2), *b* = 12.684(7), *c* = 13.226(4) Å, β = 94.78(3)°, *V* = 1538.8(10) Å^3, *Z* = 2, space group *Pn*, ρ_{ber} = 1.016 Mg m^{-3}, μ = 0.206 mm^{-1}, *F*(000) = 512, data collection range: 4.46≤ 2Θ ≤ 44.00, −9 ≤ *h* ≤ 9, −13 ≤ *k* ≤ 13, −13 ≤ *l* ≤ 13, 4054 reflections collected, 3776 independent and 3156 observed [$I > 2\sigma(I)$], R_1 = 0.0452 (obs.), wR_2 = 0.1073 (obs.), GOF(F^2) = 1.033; max./min. residual electron density: +0.122/−0.105 e·Å^{-3}. The weighting scheme was calculated according to $w^{-1} = \sigma^2(F_0^2) + (0.0485P)^2 + 0.000\,P$ with $P = (F_0^2 + 2F_c^2)/3$. The structure was solved by direct methods (Bruker SHELXTL). All non-hydrogen atoms were refined anisotropically, with the hydrogen atoms introduced into theoretical positions and refined using a riding model.

Crystallographic data (excluding structure factors) for the structure in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-156379. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Hydrazino Derivatives of Gallanes and Indanes − Synthesis and Structures

Heinrich Nöth*[a] and Thomas Seifert[a]

Dedicated to Prof. Dr. Marianne Baudler on the occasion of her 80th birthday

Keywords: Gallium / Indium / Cage compounds / Cleavage reactions / Hydrolysis

The reaction of Me_2GaCl with *t*BuHN–NH_2 proceeds with ligand exchange at the gallium atom leading to $MeCl_2Ga{\cdot}H_2N$–NH*t*Bu (**1**). On the other hand, only one methyl group of the trimethylgallium molecule reacts in refluxing toluene with anhydrous hydrazine in a 4:3 ratio to produce the bicyclic dimethylgallium hydrazide **3**. *N*-Lithio-*N*-trimethylsilyl-*N*′-2-naphthylhydrazine reacts with dimethylgallium chloride, not only by introducing a gallium atom into the hydrazine unit, but also by inducing CH activation at the 1-position of the naphthyl group with methane evolution. The main product isolated is the 2,3-dihydro-1*H*-naphtho[1,2-*d*][1,2,3]diazagallol **4** which proved to be dimeric. A 1:1 $GaMe_3$ adduct of Li(Me_3Si)N–NH*t*Bu (**5**) is the unexpected compound in the reaction of Me_2GaCl with Li(Me_3Si)N–NH*t*Bu. The expected substitution product $Me_2Ga(Me_3Si)$N–NH*t*Bu is not formed. Compound **5** is a dimer in the solid state. The products obtained from reactions of Li(Me_3Si)N–NH*t*Bu with Me_2InCl depend on the solvent. With hexane as a solvent the dimeric trimethylindium adduct of Li(Me_3Si)N–NH*t*Bu (**7**), is produced as the main species. In diethyl ether the cage compound **8** is isolated which can be regarded as an $(Me_3SiN{=}InMe)_2$ adduct with $[Li(Me_3Si)N–NHtBu]_2$. Moreover, the reaction of Me_2InCl in diethyl ether with the bulky lithium hydrazide $Li[Me_3SiN–N(SiMe_3)_2]$ leads not to the substitution product, but to the dimeric adduct **9** of a diindoxane, $Me_2In–O–InMe_2$ with Li(Me_3Si)N–N($SiMe_3$)$_2$. The formation of this product indicates that ether cleavage or hydrolysis (during crystallization) has occurred.

Introduction

Metal amides have not only become important reagents in synthesis,[1−3] but have also attracted interest due to unique structural patterns.[4−6] More recently, alkali metal hydrazides have been used in the synthesis of new non-metal hydrazides[7−13] and metal hydrazides.[14−16] Amongst the latter, those of group 13 are considered as being good single-source precursors in MOCVD processes (Metal Organic Chemical Vapor Deposition) for the preparation of AlN, GaN, and InN thin films, which are useful for the production of optoelectronic devices, particularly for light-emitting diodes.[17−23] In comparison to alkali metal organylamides, the molecular structure of the alkali metal hydrazides show additional features, particularly the *side-on* coordination of Li centers to the N−N bond.[13,24−26] The best studied class of group 13 hydrazides are the hydrazinoboranes that feature non-cyclic, cyclic, and cage arrangements as the molecular units.[27−30] Aluminum hydrazides have been reported only recently.[14,24,31−36] Information on hydrazides of gallium and indium is, so far, comparatively scanty.[37−40]

Results

Gallium Hydrazides

Synthesis

Several routes to metallated hydrazines are known, and in this study only two have been employed, the reaction of dimethylgallium and dimethylindium chloride with monolithium hydrazides, and the reaction of trimethylgallium with anhydrous hydrazine.

It was expected that the reaction of dimethylgallium chloride with *tert*-butylhydrazine would first produce a 1:1 addition product followed by methane elimination either to give MeClGa−NH−NH*t*Bu or $(ClGa–NH–NtBu)_n$. However, in toluene solution no gas evolution was observed at ambient temperature. However, this gas evolution set in at 70 °C, and became rapid on heating the solution to reflux. Under these conditions a sparingly soluble product was formed, which showed two signals in the ^{1}H NMR spectrum in a 1:3 ratio, suggesting the formation of oligomeric $(MeGa–NH–NtBu)_n$ (**2**). From the solution the adduct $MeCl_2Ga{\cdot}H_2N$−NH*t*Bu (**1**) was isolated. This result suggests that under the conditions of the experiment Me_2-GaCl is subject to substituent exchange as shown in Equation (1). The Lewis acid $MeGaCl_2$ so formed added to the hydrazine [Equation (2)] while $GaMe_3$ reacted with the hy-

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434−1948/02/0303−0602 $ 17.50+.50/0 *Eur. J. Inorg. Chem.* **2002**, 602−612

drazine $H_2N-NHtBu$ to produce methane and **2** [Equation (3)].

$$2\,Me_2GaCl \rightarrow Me_3Ga + MeGaCl_2 \quad (1)$$

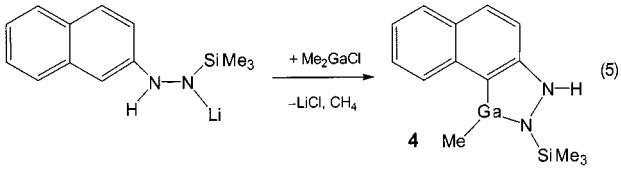
$$MeGaCl_2 + H_2N{-}NHtBu \rightarrow \underset{\mathbf{1}}{MeCl_2Ga{-}NH_2{-}NHtBu} \quad (2)$$

$$Me_3Ga + H_2N{-}NHtBu \rightarrow {}^{1}/_{n}\,\underset{\mathbf{2}}{[MeGa{-}NH{-}NtBu]_n} + 2\,CH_4 \quad (3)$$

$$4\,GaMe_3 + 3\,H_2N{-}NH_2 \xrightarrow{\Delta} \underset{\mathbf{3}}{(Me_2Ga)_4(N_2H_2)(NH{-}NH_2)_2} + 4\,MeH \quad (4)$$

This result demonstrates the high reactivity of $GaMe_3$. Therefore, hydrazine was allowed to react with $GaMe_3$. In refluxing toluene, practically only compound **3** was formed, containing Me_2Ga and hydrazino units in a ratio of 4:3, irrespective of the molar ratio employed. In **3** there are two different hydrazino groups, one that is doubly metallated, and two hydrazino groups that are singly metallated [see Equation (4)].

Although one might expect that the reaction of Me_2GaCl with a lithiated disubstituted hydrazine would proceed in a more straightforward manner, a surprising reaction occurred between Me_2GaCl and *N*-lithio-*N′*-(2-naphthyl)-*N*-(trimethylsilyl)hydrazine in refluxing toluene, as depicted in Equation (5). The product was the 2,3-dihydro-1*H*-naphtho[1,2-*d*][1,2,3]diazagallol **4**.



(5)

In the solid state **4** is present as a dimer (vide infra). Obviously, the hydrogen atom in position 1 of the 2-naphthyl group is more reactive than the hydrogen atom of the NH group of the hydrazide. Taking these results into account it was expected that a more bulky lithium hydrazide such as $Li(Me_3Si)N-NHtBu$ might react with Me_2GaCl by simple substitution as shown in Equation (6).

$$Me_2GaCl + LiNSiMe_3{-}NHtBu \rightarrow Me_2Ga{-}N(SiMe_3){-}NHtBu + LiCl \quad (6)$$

$$2\,Me_2GaCl + 2\,LiN(SiMe_3){-}NHtBu \rightarrow$$

$$\underset{\mathbf{5}}{LiN(SiMe_3){-}NHtBu{\cdot}GaMe_3} + \underset{\mathbf{6}}{MeClGa{-}N(SiMe_3){-}NHtBu} + LiCl \quad (7)$$

However, only a small amount of LiCl precipitated, and the product obtained was **5**. Obviously, Me_2GaCl again suffers substituent exchange as described by Equation (1), and $GaMe_3$ adds to the lithium hydrazide to form **5**. The second product of the reaction was expected to be $MeClGa-N(SiMe_3)-NHtBu$ (**6**), but this compound could not be isolated.

In summary, none of the reactions described above led to the anticipated product.

X-ray Structure Determinations

Compounds **1** and **3**−**5** were obtained as single crystals. This allowed the determination of their molecular structures in the solid state, and this knowledge was helpful for the assignment of signals obtained by NMR experiments.

The $MeGaCl_2$ adduct **1** crystallized in the tetragonal system, space group $I4_1/a$ with $Z = 16$. Figure 1 depicts the molecular structure of **1** ascertaining that the compound is the $MeGaCl_2$ adduct of the hydrazine $H_2N-NHtBu$. Its Ga−N distance [2.023(7) Å] correlates well with those found for $Cl_3Ga-NMe_2SiMe_2NMe_2$ [2.002(9) Å][41]or the dimeric gallium amides $[Me_2Ga-N(Ph)SiMe_3]_2$,[42] $[Me(Cl)Ga-NHSiMe_3]_2$,[43] and $(iPr_2Ga-NHNMe_2)_2$[44] [2.071(2), 2.012(8), and 2.031(2) Å, respectively]. The Ga−C bond in **1** [1.933(7) Å] lies in the range found for several amino(methyl)gallanes having tetracoordinated Ga atoms[33,42,43]. Both N atoms are in a non-planar situation, the coordination site at N1 corresponds with a distorted tetrahedral array (bond angles ranging from 104.3 to 113.8°) and a sum of bond angles of 656.6°, while that of the tricoordinated atom N2 is 320.1° slightly smaller than calculated for a pseudo-tetrahedral array (328.5°). Taking this into account, the N−N bond length of 1.446(9) Å in **1** corresponds with the N−N bond length of hydrazine (1.47 Å)[44] and of the methylhydrazinium cations $MeNH_2NH_2^+$ [1.445(1) Å][45] and $Me_3N-NH_2^+$ [1.457(1) Å].[46] The two amino groups are present in a staggered conformation. A *trans* conformation results for the Ga−N−N−C unit (τ = 175.5°).

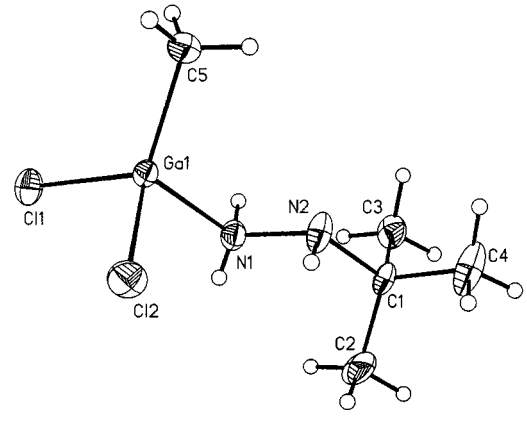


Figure 1. ORTEP representation of **1**; selected bond lengths [Å] and bond angles [°], esd values in parentheses: Ga1−N1 2.023(7), N1−N2 1.446(9), Ga1−C5 1.933(7), Ga1−Cl1 2.202(2), Ga1−Cl2 2.175(2), N1−H1A 0.72, N1−H1B 0.97; N1−Ga1−Cl2 100.8(2), N1−Ga1−C5 112.0(4), Cl1−Ga1−Cl2 105.62(8), Cl1−Ga1−C5 116.4(3), Cl2−Ga1−C5 118.9(3), Ga1−N1−N2 108.3(5), N1−N2−Cl 115.4(6), N1−N2−H2 115.4, Cll···H−N 2.5475(1), Cl2···H−N 2.88(1); angles at hydrogen bonds: N1−H1−Cl2A 160.7, N1−H1B−Cl1B 167.4; Cl···Cl contact: Cl1···Cl1B 3.556

The two Ga−Cl bond lengths differ significantly with Δ = 0.027 Å, and on first sight there is no reason why this should be so. One might suspect that the different Ga−Cl

bond lengths arise from different N−H···Cl hydrogen bonding. Hydrogen bonds indeed connect the molecules of **1** in the solid state, and only the H atoms of the NH_2 groups, which have ammonium-type character, are involved in hydrogen bonding, in contrast to the NH group. Bond angles at the H atoms of the bridging N−H···Cl units span a range from 160.7 to 167.4° with H···Cl distances between 2.547 to 2.878 Å. Tetrameric units result by these hydrogen bonds. Figure 2 depicts the association of four molecules of **1** in the crystal.

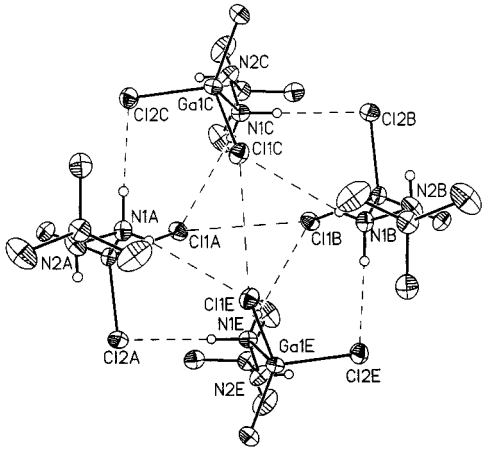

Figure 2. Tetrameric association of **1** formed by hydrogen bonds

The molecular structure of compound **3** is represented in Figure 3, showing a bicyclo[3.3.0]octane skeleton. Compound **3** crystallizes in the triclinic system in space group $P\bar{1}$.[47] The unit cell contains two independent molecules each having a crystallographically imposed center of symmetry lying at the midpoint of the central N−N vector, but these two N atoms are site-disordered with an SOF of 0.5. Therefore, the bicyclic system shows two conformations. In addition, there is a disordered toluene molecule in the unit cell with a center of inversion in the midpoint of the benzene unit. A consequence of this disorder is that the standard deviations particularly for the central N−N bond is fairly large, and this is also true for the *R* indices.

The structure of compound **3** can be considered to be composed of one dimetallated hydrazine unit, $Me_2Ga-NH-NH-GaMe_2$, and two $Me_2Ga-NH-NH_2$ units, which allows all Ga atoms to become tetracoordinated by two Me groups and two N atoms. Because the Ga atoms are part of a five-membered heterocycle the N−Ga−N angles are only 92.8(3) and 92.9(4)° while the C−Ga−C bond angles are 124.1(4)° at Ga1 and 123.8(4)° at Ga2. The Ga1−N2−Ga2 bond angle [107.7(3)°] is closer to the tetrahedral angle than the Ga1−N1−N1A and N1−N1A−Ga2 bond angles [111.7(11) and 111.5(11)°]. The two N−N bond lengths in the molecules with atoms Ga1 and Ga2 are 1.38(2) Å (N−N bridge of the bicycle) and 1.48(8) Å (for the exocyclic N−N bonds). However, these bonds are significantly different in the second independent molecule with 1.51(8) and 1.48(8) Å.

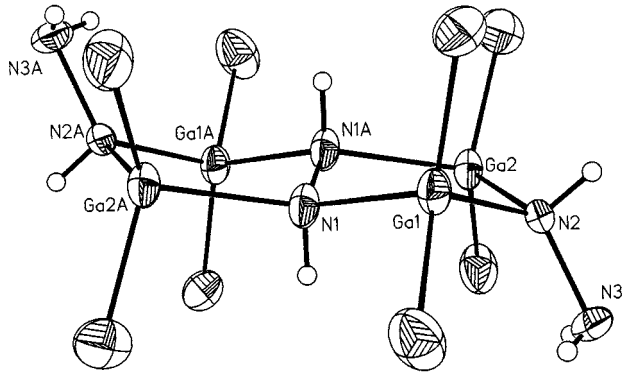

Figure 3. Molecular structure of one of the two independent molecules of **3** in ORTEP representation; *C*-bonded hydrogen atoms omitted; selected bond lengths [Å] and bond angles [°], esd values in parentheses: Ga1−C1 1.947(8), Ga1−C2 1.9478(8), Ga1−C2 1.947(7), Ga2−C3, 1.959(7), Ga1−C4 1.943(8), Ga1−N1 2.03(1), Ga1−N2 1.985(5), Ga2−N1A 2.05(1), Ga2−N2 2.000(5), N1−N1A 1.49(1), N2−N3 1.487(7); C1−Ga1−C2 124.1(4), C3−Ga2−C4 123.8(4), N1−Ga1−N2 92.9(4), N1A−Ga2−N2 96.4(4), Ga1−N2−Ga2 107.7(3), Ga1−N1−N1A 1112(1), Ga2−N1A−N1 112(1), H−N1−N2 104(2), H−N2−N3 106(2); sum of bond angles at N1 655.7, at N2 657.1, at N1A 655.1

While atoms Ga1, N2, Ga2, Ga1A, N2A, Ga2A lie almost in a plane, atom N1 is 0.65 Å apart from the Ga1−N2−Ga2−N1A plane (τ = 8.5°), e.g. the five-membered rings have an envelope conformation. Figure 4 shows the two conformations that result from the site disorder of the central N−N unit. These conformations result in an "up-and-down" arrangement for the central N−N groups.

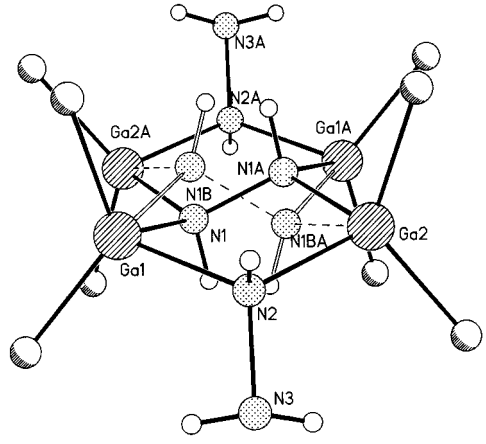

Figure 4. Representation of the disorder of the molecule **3**; methyl hydrogen atoms are removed for clarity

All N atoms in **3** are in a non-planar environment. They can be considered to be sp^3-hybridized. In the solid state, the molecules of **3** are interconnected by NH···N hydrogen bonding. These bridges are formed with the H atoms of the central N_2H_2 units, which bridge to NH_2 groups. This results in chains of interconnected molecules of **3** that extend parallel to the *c* axis of the crystal (Figure 5).

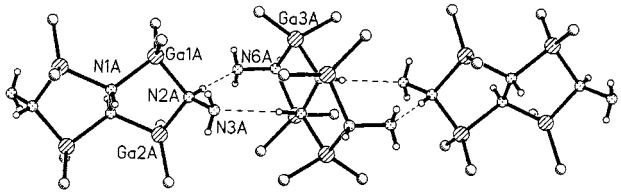

Figure 5. Association of the molecules of **3** in the solid; the chains extend parallel to the *z* axis; note that only N−H···NH_2 bridges are formed; the H atoms of the NH_2 groups are not involved in hydrogen bonds

Table 2. Population analysis and Wiberg bond orders

	Charges	Wiberg bond order	
Ga1	+0.66	N1−N1A	0.99
Ga2	+0.68	N2−N3	1.01
N1	−0.68	Ga1−N1	0.35
N2	−0.72	Ga1−N2	0.36
N3	−0.58	Ga2−N1A	0.35
C1−C4	−0.69	Ga−C	0.69

As indicated, the N−N bond and the corresponding bond angles of **3** could be determined only with large standard deviation and are, therefore, not very accurate due to the indicated disorder.[47] For this reason geometrical data for the molecule were calculated on the B3LYP/6-31* level.[48] The data for the geometry-optimized molecular structure of **3** and frequency analysis are compiled in Table 1 together with the data found in the X-ray structure determination. The calculated data correspond to the energy minimum.

Table 1 shows that the Ga−C distances comply well with the calculated bond lengths, while the calculated Ga−N bond lengths are shorter than the experimental values. More importantly, the calculated central N−N bond length is noticeably longer than the exocyclic N−N bonds. The average experimental value corresponds with the calculated bond length. On the other hand, the experimental bond angles differ by −2.5 to 3.4° from those calculated.

Data for the population analysis and the Wiberg bond orders are summarized in Table 2. These show that the N−N bonds are single bonds. A *trans* conformation for the central N−N unit also results for the calculated structure. In contrast to the experimental structure with its eclipsed conformation for the exocyclic hydrazino moiety (torsion angle Ga−N−N−H 3.9°), a *gauche* conformation results from the calculation as is well known for hydrazine itself[44] (torsion angle 34.7°). This discrepancy, however, can be easily resolved by considering the N−H···N hydrogen bonds that are present in the solid sate.

Yellow crystals of **4** are monoclinic, space group $P2_1/c$ with $Z = 4$ monomeric units; actually, $Z = 2$ because two molecules form a dimer via Ga−N coordinative bonds. The center of the Ga−Ga vector of the four-membered Ga_2N_2 ring coincides with a crystallographic inversion center. The molecular structure of $(\mathbf{4})_2$ is depicted in Figure 6.

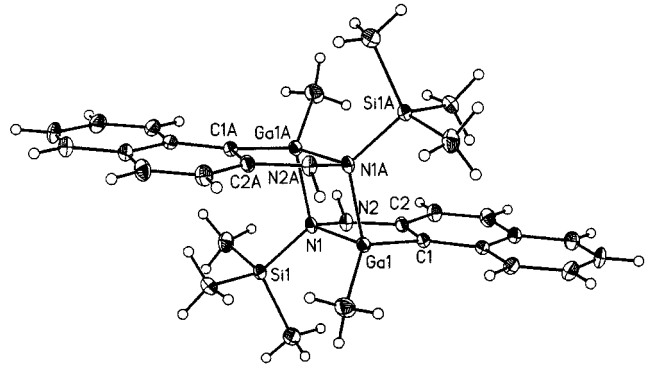

Figure 6. Molecular structure of dimeric **4** in the crystal; selected bond lengths [Å] and bond angles [°], esd values in parentheses: Ga1−C1 1.947(3), Ga1−C14 1.949(3), Ga1−N1 2.051(2), Ga1−N1A 2.031(2), N1−Si1 1.780(2), N1−N2 1.482(3), N2−C2 1.414(3), C1−C2 1.333(4), C1−C10 1.430(4), C2−C3 1.420(4), C3−C4 1.365(4), C4−C5 1.414(4), C5−C10 1.423(4); C1−Ga1−N1 110.98(9), C1−Ga1−C14 129.2(1), C1−Ga1−N1A 89.25(8), N2−N1−Si1 103.8(2), N2−N1−Ga1 112.5(2), Si1−N1−Ga1 123.5(1); interplanar angles: Ga1,N1,Ga1a,N1a/N1,N2,C1,C2,Ga1 110.1, N1,N2,C1,C2,Ga1/C1−C5,C10 6.5

Table 1. Experimental and calculated structural data for compound **3**

	Exp. values				Calcd. values
Ga1−C	1.947(8) C1	Ga3−C	1.95(1) C5	C1	1.997
	1.947(7) C2		1.960(1) C6	C2	1.997
Ga2−C	1.959(7) C3	Ga4−C	1.95(1) C7	C3	1.995
	1.943(8) C4		1.95(1) C8	C4	1.995
Ga1−N	2.03(1) N1	Ga3−N	1.96(1) N4A	N1	1.985
	1.985(5) N2		1.997(8) N5	N2	1.972

	2.000(5) N2		1.992(7) N5	N2	1.984
N−N	1.49(1) N1	N−N	1.51(3) N4	N1	1.522
	1.481(7) N2		1.476(9)	N2	1.489
N1−Ga1−N2	92.8(3)	N5−Ga3−N4a	96.2(4)		95.3
Ga1−N2−Ga2	107.7(2)	Ga3−N5−Ga4	107.4((3)		108.3
N1−N1A−Ga2	107.3(9)	N4A−N4−Ga4	102(1)		110.7
N1A−N1−Ga1	109.7(9)				107.5

The two Ga−N bond lengths are significantly different, the shorter bond, Ga1−N1 [2.031(2) Å], is found in the five-membered ring, the longer one, Ga1−N1A [2.051(2) Å], in the four-membered ring. Inspection of the Ga−C bond lengths reveals an interesting and somewhat unusual feature, both are of equal lengths [Ga1−C1 1.949(3), Ga1−C14 1.947(3) Å] although C1 is of sp^2-type hybridization, and this should result in a shorter Ga−C distance as compared to the Ga1−C14 bond with an sp^3-C atom. Due to the situation that the Ga atom is both part of a four- and a five-membered ring system, the tetracoordinated Ga atom shows strong deviations from the tetrahedral bond angle. Even the C1−Ga1−N1 bond angle of the five-membered ring is only 87.4°, a consequence of the longer Ga1−C1 and Ga1−N1 bonds.

The molecular structure of **4** was of importance to unequivocally demonstrate that the Ga metallation of the naphthyl group occurred at the 1-position. An almost planar Ga−N−N−C−C five-membered ring is present with atoms N2 and C2 being 0.064 and −0.082 Å away from the best plane. The ring is almost coplanar with the naphthalene moiety, the angle between the two planes being only 7.2°. The Ga_2N_2 four-membered ring forms an angle of 113.6° with the five-membered GaN_2C_2 ring. Because both N atoms of the hydrazine moiety in compound **5** are sp^3-hybridized (sum of bond angles at N2 338.4°), a comparatively long N−N bond can be expected. The distance [1.482(3) Å], however, is typical for a simple hydrazine unit.

The needles of **5** proved to be monoclinic, space group $P2_1/n$ with $Z = 2$. Figure 7 shows that the molecule is dimeric. There is a crystallographic inversion center situated in the center of the six-membered Li_2N_4 ring. The $GaMe_3$ units are attached at the deprotonated side of the hydrazide units. Moreover, it can be noted that the hydrazine *t*BuNH−NHSiMe$_3$ is metallated at the silyl-group-carrying nitrogen atom. Both Li atoms of the Li_2N_4 ring are coordinated to two nitrogen atoms and, in addition, each one shows Li···H−C contacts with CH hydrogen atoms of the $GaMe_3$ units that add to the steric shielding of the Li centers [Li−H 2.20(1), 2.21(1) Å]. The Li−N bond lengths are found in the expected ranges,[49] actually both can be considered to be of equal length. Moreover, it should be noted that the Ga−N bond length is shorter than the Li−N distances.

It can be seen from Figure 7 that the Me groups are arranged in such a manner that a staggered orientation results, minimizing intramolecular repulsion of the methyl groups. Although the ring adopts no true chair conformation, the ring is, nevertheless, not planar. Bond angles for the ring atoms are: Li1−N2−N1 98.1(2), N1−N2−Li1A 108.6(2), and N2−Li1−N1A 124.8(2)°. The bond angles N2−N1−Si1 and N2−N1−Ga1 [119.5(1)° and 116.6(1)°, respectively] are wider than expected for a tetrahedral moiety at nitrogen atoms N1 and N2, and the angle Ga1−N1−Li1A is sharp with 80.5(1)°.

Two of the Ga−C bond lengths are almost of equal lengths considering the 3σ criterion. However, the Ga1−C9 distance is noticeably elongated; it is this atom of the CH_3 group that is involved in Li···H−C interactions. Consequently, the Li−C distance is short, 2.234(4) Å, a distance that is typical for organolithium compounds.[49,50] The N−N bond in **5** is fairly long, 1.496(2) Å. All N atoms are tetracoordinated.

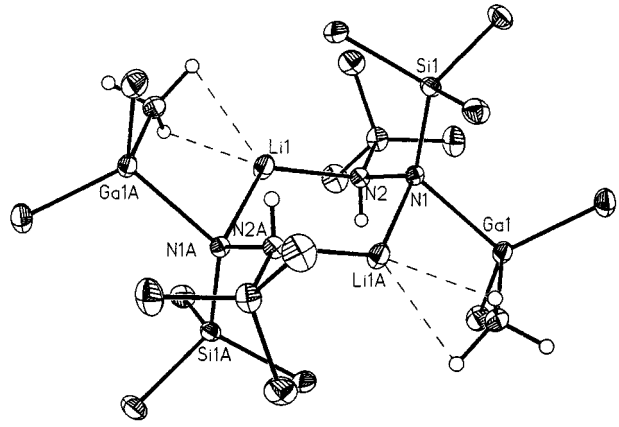

Figure 7. Molecular structure of **5** in the crystal; CH hydrogen atoms are omitted; selected atom distances [Å] and bond angles [°], esd values in parentheses: Ga1−N1 2.053(2), Ga1−C8 1.998(3), Ga1−C9 2.084(3), Ga1−C10 1.985(3), Li1−N1 2.093(4), Li1−N2 2.010(4), Li1···C9 2.234(4), N1−N2 1.496(2), N2−C4 1.514(3), N1−Si1 1.743(2), Li1···H9A 2.20(1); Li1···H9B 2.21(1); N1−Ga1−C8 108.7(1), N1−Ga1−C9 102.83(9), N1−Ga1−C10 113.0(1), N1A−Li1−C9 95.5(2), N2−Li1−N1A 124.8(2), N2−N1−Ga1 116.6(1), N2−N1−Si1 119.5(1), N2−N1−Li1A 108.6(2), N1−N2−Li1 98.1(2), Ga1−N1−Li1A 80.5(19); torsion angles: Li1A−N1−Ga1−C9 16.0, Li1−N2−N1−Li1A 49.0; sum of bond angles at N1 331.8, at N2 324.9

NMR Spectra

As expected, the ^{1}H and ^{13}C NMR spectra of the adduct **1** is simple. There are three signals of each kind. Those of the ^{1}H resonances are observed at δ = 0.33 (GaMe), 0.65 (CMe), and 4.15 (broad, NH) in a 1:3:1 ratio, while the ^{13}C signals are located at δ = −3.1 (GaMe), 25.6 (C*Me*), and 55.3 (*C*Me$_3$). It is well known that the shielding of the Ga*Me* group resonances depends on the nature of the substituents, the more electronegative the substituents the stronger the deshielding. For example, while the ^{1}H signal of $(Me_2GaCl)_2$ is found at δ = 0.12, it is observed for $(Me_2Ga{-}NMe_2)_2$ at δ = −0.4. The NH resonance signal is broad and not resolved, indicating rapid exchange of these protons.

In contrast, the signal for the *N*-bonded hydrogen atoms in the bicyclic compound **3** are well resolved. There are three signals at δ = 2.24, 2.35, and 2.72 in the correct intensity ratio. On the other hand, seven signals were observed in the region from δ = −0.4 to −0.1 for the Me groups attached to the Ga atoms. Complementary results were obtained in the ^{13}C NMR spectrum, which reveals 7 signals in the range δ = −11.2 to −7.1. The double envelope conformation of compound **3** should lead to four pairs of chemically equivalent methyl groups. In case of inversion at the N atoms two sets of four signals may results. That inversion takes place is ascertained by coalescence of the ^{13}C resonances at 80 °C. Using the Eyring equation[51] the

calculated activation energy is $\Delta G^* = 72.3$ kJ/mol. This corresponds with the activation energy of 73.9 kJ/mol[52] found for the six-membered hydrazinoalane $[Me_2Al-NSiMe_3-NCMe_3]_2$.[16]

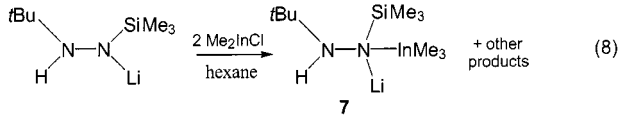
Knowing the structure of compound **4**, only a single ^{29}Si resonance was expected and found at $\delta = -0.17$, apart from the ^1H and ^{13}C resonances of the $SiMe_3$ group. On the other hand, six ^1H signals for the naphthyl group were found, and this corresponds with a metallation of the naphthyl group at the 1-position, excluding the possibility of metallation at the 3-position. For this latter case, only three signals should be observable.

The ^1H and ^{13}C NMR spectra of compound **5** are in agreement with the X-ray structure. The GaMe protons are fairly well shielded with $\delta^1H = -0.08$. With $\delta = 7.00$ the ^{29}Si nucleus is better shielded compared with $\delta^{29}Si = 13.6$ for compound **4**, and this is most likely due to the negative charge at the Si bearing nitrogen atom of compound **5**.

Indium Hydrazides

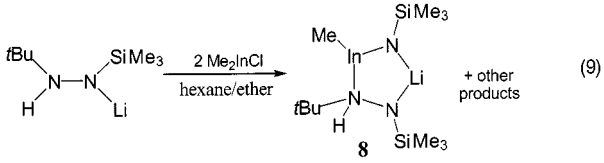
Synthesis

In order to test whether Me_2InCl is also liable to substituent exchange on reactions with lithium hydrazides this indium chloride was allowed to react with $Li(Me_3Si)N-NHtBu$ in a 1:1 molar ratio in hexane. The indium homologue **7** of the gallium complex **5** was indeed formed as indicated in Equation (8).



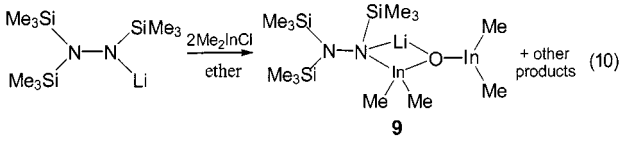
(8)

7



(9)

8



(10)

9

However, when the same reaction was performed in an ether/hexane mixture the reaction took a different course, as depicted in Equation (9). Only compound **8** and no by-products could be isolated and characterized. This would have been important to obtain an idea on the course of the redox reaction involved in the formation of compound **8**, which can be considered to be composed of the iminoindane $MeIn=NSiMe_3$ added to the lithium hydrazide used as a starting material. Assuming that the first step in the reaction is the expected substitution to give $Me_2In-N(SiMe_3)-NHtBu$, a methyl transfer to produce the amine $NHMe(tBu)$ may formally lead to the iminoindane. A similar reaction has not been observed in our experiments with gallium.

One might expect that by employing a sterically better shielded lithium hydrazide than $Li(Me_3Si)N-NHtBu$ could lead to anticipated products. For this reason Me_2InCl was treated with $Li(Me_3Si)N-N(SiMe_3)_2$. In nonpolar solvents such as hexane or toluene, the NMR spectra pointed to a very complex reaction, e.g. fifteen ^{29}Si NMR signals were detected in the range $\delta = 5.0-19.5$. However, when ether was employed as a solvent the situation changed drastically because compound **9** was formed as the main product. This compound was isolated and fully characterized. Nevertheless, it is once again an unexpected product, as shown in Equation (10). Compound **9** can be regarded as the adduct of a bis(dimethylindium) oxide (diindoxane) with lithium tris(trimethylsilyl)hydrazide. The X-ray structure determination shows that **9** is actually a dimer in the solid state.

Structures

Compound **7** crystallizes, like the trimethylgallane adduct **5**, in the monoclinic system, space group $P2_1/n$ (no figure is given because the structure of **7** is very similar to the structure of **5**). The molecular parameters for both compounds are listed in Table 3. The unit cells differ particularly with respect to the angle β. As far as the molecular parameters are concerned, there are no great differences except, of course, for the In−N and In−C bond lengths. The molecular symmetry is C_i. The equatorial positions of the chair-type six-membered ring are occupied by the *tert*-butyl and Me_3In groups while the Me_3Si groups are in axial positions. Li··H contacts complete the coordination sphere of the Li atom by two H atoms. The Li···C contact of Li1 to C10A [2.278(8) Å] is 0.04 Å longer than in compound **5**. This difference is probably due to the fact that there is only one Li···H contact while there are two Li···H contacts in compound **5**. The bond angles N2−N1−Si1 (120.4°) and N2−N1−In1 (116.0°) are quite open. This indicates that the Li−N bonds are highly polar.

Compound **8** is present as a dimer in the monoclinic crystal, space group $C2/m$. The molecular symmetry is, crystallographically imposed, C_2. Figure 8 shows the molecular structure with its cage-like arrangement of the core atoms. While we have previously discussed the compound as a formal adduct of an iminoindane with a lithium hydrazide, we now see that it is an adduct of a dimeric, tub-shaped six-membered lithium hydrazide with a four-membered 1,3,2,4-diazadiindetidine. The NH hydrogen atoms are present in axial positions, while the Me_3Si and MeIn groups are in equatorial positions. The four-membered In_2N_2 ring is only slightly bent (folding angle 13°) with endocyclic angles close to 90°. Due to the different atomic radii, one observes trapezoidal InN_2Li fragments. All indium atoms are tetracoordinated while the Li atoms are tricoordinated. The N atoms reside in a distorted tetrahedral environment.

The most interesting structural features are the In−N distances. These are short for the four-membered In_2N_2 ring [2.145, 2.178(4) Å], while those to the lithium hydrazide units are 2.223(3) Å. This latter bond length compares well with those found for $(Me_2N-InMe_2)_2$ (2.255 Å),[53]

Table 3. Structural parameters of the Me_3E adducts of Li(Me$_3$Si)N−NH*t*Bu (E = Ga, In); atom distances in Å, bond angles in °; standard deviations in parentheses

	E = Ga (**5**)	E = In (**7**)		E = Ga (**5**)	E = In (**7**)
E−N	2.053(2)	2.281(3)	N1−E−C10	102.83(9)	97.3(1)
E−C	1.998(3) C8	2.189(4) C8	N1−E−C8	113.0(1)	105.4(2)
	1.985(3) C10	2.242(3) C10	N1−E−C9	108.7(1)	112.9(1)
	2.048(3) C9	2.169(4) C9	N2−N1−E	116.6(1)	116.0(2)
N−N	1.492(2)	1.495(4)	N1−N2−Si	119.5(1)	120.4(2)

	2.010(4) N2	2.008(6)	N1−Li1A−C10	95.5(3)	102.0(3)
N−Si	1.743(2)	1.744(3)			

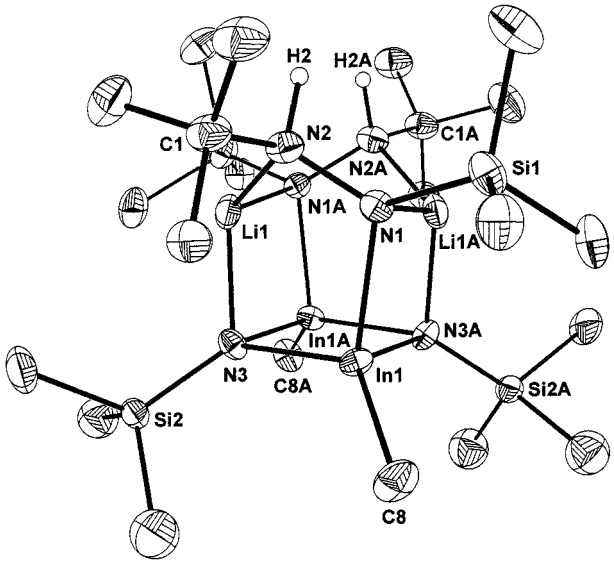

Figure 8. Molecular structure of **8**; hydrogen atoms are removed for clarity; selected atom distances [Å] and bond angles [°], esd values in parentheses: In1−N1 2.323(3), In1−N3 2.145(4), In1−N3A 2.178(3), Li1−N1A 2.165(8), Li1−N2 1.983(9), N1−N2 1.472(5), In1−C8 2.157(4), N1−Si1 1.752(7), N3−Si3 1.733(5); N3−In1−N3A 88.1(1), N3−In1−N1 99.8(1), In1−N1−Li1A 79.3(2), In1−N1−N2 1135.5(2), N2−N1−Li1A 107.3(3), N2−Li1−N3 114.1(4), N2−Li1−N1A 112.9(4), N3−Li1−N1A 101.9(3), N1−N2−Li1 103.0(3), Li1−N2−In1A 84.9(2), In1−N3−In1A 91.9(1), Li1−N3−In1 95.1(3); sum of bond angle at Li1 328.9, at N2 333.2

(*i*Pr$_2$In−NH*t*Bu)$_2$ (2.231 Å),[54] and various other aryl or Me$_3$Si substituted dimeric aminoindanes (up to 2.305 Å).[55,56] Shorter In−N bonds are observed for [Me$_2$In−N=CMe$_3$]$_2$ (2.195 Å)[57] or [Cl$_2$In−N=CPh$_2$]$_2$ (2.112 Å).[58] These latter distances fall into the range for the In$_2$N$_2$ unit of **8**.

The monoclinic compound **9**, which crystallizes in space group $P2_1/c$, displays a spirocyclic system (as depicted in Figure 9) featuring a central four-membered In$_2$O$_2$ ring. Its center coincides with a crystallographic inversion center. The interplanar angle between this ring and the neighboring LiN$_2$In ring is 67.1°, the latter ring is almost planar as demonstrated by an Li−N−In−N torsion angle of 4.3°. Both In atoms are tetra-coordinated with a very open C−In−C angle of 126.6(2)° at In1 and 131.4(2)° at In2.

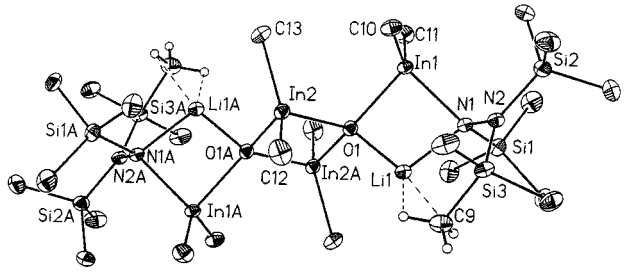

Figure 9. ORTEP plot of the molecular structure of **9**; selected atom distances [Å] and bond angles [°], esd values in parentheses: In1−N1 2.201(3), N1−N2 1.508(4), In1−O1 2.168(3), In2−O1 2.144(3), In2−O1A 2.162(3), N1−Si1 1.738(3), N2−Si2 1.738(4), N2−Si3 1.742(4), In1−C12 2.143(5), In1−C13 2.166(5), Li1−N1 2.036(9), Li1−O1 1.837(8), Li···H 2.03(1), 2.23(1);− O1−In1−N1 87.98(1), O1−In2−O1A 84.8(1), C11−In1−C12 126.6(2), C1−In2−C13 131.4(2), O1−Li1−N1 102.9(4), N1−Li1−C9 90.6(3), In2−O1In1 112.4(1)

The Li ions are formally two-coordinated with bonds to one O and one N atom, but the next shortest distances (2.03 and 2.23 Å) are found to H atoms of the Me$_3$Si groups. The N−N bond length is 1.508(4) Å. The sum of bond angles at atom N2 is 360°, and from this point of view, one has to regard the N−N bond as comparatively long. Once again, we take this as evidence for polar Li−N interactions due to a high negative charge at N2. The compound can be regarded an addition product of lithium tris(trimethylsilyl)hydrazide with bis(dimethylindium) oxide.

NMR Spectra

NMR spectroscopic data recorded for compound **7** are similar to those found for compound **5**. However, the ^{1}H and ^{13}C resonances for **7** are at slightly higher field due to the lower electronegativity of In. The ^{29}Si resonance is found at $\delta = 6.4$, shifted only by 0.6 ppm to higher field compared to **5**. On the other hand, the ^{7}Li chemical shift at $\delta = -1.0$ is the same as found for **5**.

Knowing the structure of compound **8**, it is not surprising to find its NMR spectroscopic data are close to those of **7**. Even δ^7Li = −0.9 is almost the same. As expected,

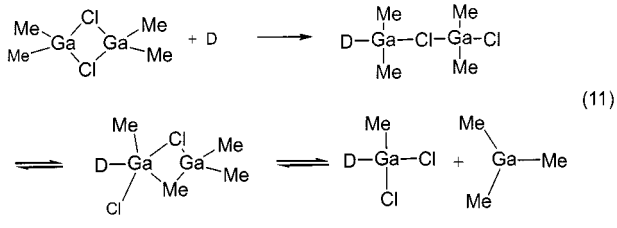
there are two ^{29}Si NMR signals, while the NH protons result in a broad signal.

In agreement with the structure of **9** there are four ^{1}H and ^{13}C signals in the NMR spectra for the MeIn groups and two signals each for the Me_3Si group in the ^{1}H, ^{13}C, and ^{29}Si NMR spectra. However, not having had available the X-ray structure result it would have been difficult to guess the presence of a bis(dimethylindium) oxide unit in the molecule.

Discussion

This study demonstrates that the reactions of Me_2GaCl with organylhydrazines and lithium organylhydrazides are characterized by a substituent exchange at Me_2GaCl, leading to $MeGaCl_2$ and $GaMe_3$. Most likely, the substituent exchange is induced by the base as depicted in Equation (11). Such exchange reactions are well know in the chemistry of organyl compounds of the heavier group 13 elements.[59] Nevertheless, reactions of lithium amides with dialkylaluminium chlorides or dialkylgallium chlorides lead to the expected dialkylmetal amides without ligand exchange.[60] However, reaction of tBu$_2$AlCl with $Li_2N_2(SiMe_3)_2$ produced $[t\text{BuAl}-N(SiMe_3)-N(SiMe_3)]_2$, indicating a similar ligand exchange at the metal atom as reported here.[14] Moreover, Uhl et al. found that the reaction of tBu$_2$AlCl with $H_2NNHSiMe_3$ produced $t\text{BuCl}_2\text{Al}\cdot NH_2-NHSiMe_3$, a compound that is analogous to compound **1**.[61]

It is interesting that the *tert*-butylhydrazine removes $MeGaCl_2$ from the equilibrium in Equation (1) while the lithium hydrazide $Li(Me_3Si)N-NH-t$Bu adds to trimethylgallium and not to a methylgallium chloride molecule. This can be rationalized as follows. The hydrazide is expected to be a stronger base than the hydrazine, and binds, therefore, to Me_3Ga because one can expect that $MeGaCl_2$ formed in the ligand exchange reaction has (most likely) reacted rapidly with the hydrazide by substitution as indicated in Equation (7).



Trimethylgallium reacts with hydrazine (N_2H_4) readily with CH_4 evolution to produce a bicyclic compound **3** that may be a precursor for MOCVD of GaN. As far as we are aware, no such structure has been observed so far for group 13 hydrazides. So, in contrast, the reaction of tBu$_2$AlH with N_2H_4 leads, in a first step, to the six-membered $(t\text{Bu}_2\text{Al}-NH-NH_2)_2$, and in a second step to $(t\text{Bu}_2\text{Al}-NH-NH-\text{Al}t\text{Bu}_2)_2$ with retention of the six-membered ring structure.[62]

C-Metallation by Ga results when the reaction of Me_2GaCl with $Li(Me_3Si)N-NH$(naphth) is performed in refluxing toluene. The product **4** is a 2,3-dihydro-1*H*-naphtho[1,2-*d*][1,2,3]diazagallol, which dimerizes via Ga−N bonds generating a centrosymmetric Ga_2N_2 ring system. As far as we know, this is the first example of the gallation of a naphthalene ring.

Interestingly, Me_2InCl behaves in a manner similar to Me_2GaCl in its reactions with lithium organylhydrazides. However, the solvent seems to play a more important role than in the reactions with Me_2GaCl. Therefore, an unprecedented type of redox reaction occurs in the formation of compound **8**. And even the reaction shown in Equation (10) is unusual in the sense that the bulky $Li(Me_3Si)N-N(SiMe_3)_2$ is retained if the reaction is performed in ether. Whether dimethylindium chloride induces double ether cleavage or the formation of the diindoxane unit is a result of unintended slow hydrolyses during the crystallization process was not investigated. Ether cleavage by strong Lewis acidic group 13 halides is not unusual, but the cleavage reaction usually stops after the first step leading to alkoxides X_2EOR of group 13 compounds.[63] In−O−In structural units are well known e.g. in organylindium alkoxide or OH-bridged diorganylindium carboxylates.[64−66]

Experimental Section

General: All experiments were conducted using Schlenk techniques under a blanket of nitrogen or argon. Solvents used were rendered anhydrous by conventional methods and stored under nitrogen. NMR spectra were recorded using JEOL 270 and 400 instruments. X-ray diffraction data were obtained with a Siemens P4 instrument equipped with a CCD area detector and a low-temperature device LT2. Data collection was performed using Mo-K_α radiation. Commercial products were Me_2GaCl (1 M in hexane, checked for purity by NMR), $GaMe_3$ (neat), BuLi (1.5 M in hexane). Hydrazine hydrate was made anhydrous with activated BaO. The trimethylsilylhydrazines were prepared according to the literature.[67] Reaction with BuLi in hexane afforded the *N*-lithio derivatives. Me_2InCl was prepared from $InCl_3$ by methylation with an ether solution of MeLi in a 1:2 ratio. The sublimed product had a m.p. of 221−222 °C (ref. 222−225 °C[68]). ^{1}H NMR (C_6D_6): $\delta = 0.23$.

***tert*-Butylhydrazine−Dichloro(methyl)gallane (1):** To a stirred solution of $t\text{BuHN}-NH_2$ (1.24 g, 14.1 mmol), dissolved in toluene (30 mL), was added a solution of Me_2GaCl (1.91 g, 14.1 mmol) in 5 mL of toluene. No gas evolution occurred, which set in slowly at 70 °C and became rapid on heating the mixture to reflux for 3 h. A solid had formed that was removed by filtration and the filtrate was cooled to −20 °C. Within a few days crystals of **1** separated from the filtrate. These crystals were suitable for X-ray crystallography. Yield: 0.83 g (24%), m.p. 51−53 °C. The solid on dissolving in hot toluene showed ^{1}H NMR resonances in a 1:3 ratio for MeGa and tBu protons. This product, assumed to be **2**, was not further characterized. Yield: 0.84 g. NMR of **1** (C_6D_6): $\delta^{1}H = 0.33$ (s, 3 H, GaMe), 0.65 (s, 9 H, tBu), 4.15 (br., NH); $\delta^{13}C = -3.1$ (Ga*Me*), 25.6, 55.3 (tBu). $C_5H_{15}Cl_2GaN_2$ (243.81): calcd. C 24.63, H 6.20, N 11.49; found C 24.21, H 6.12, N 11.51.

3,7-Diamino-2,2,4,4,6,6,8,8-octamethyl-1,3,5,7-tetrazonia-2,4,6,8-tetragallatabicyclo[3.3.0]octane (3): $GaMe_3$ (5.85 g, 50.9 mmol) was condensed into a three-necked flask at −78 °C. It was diluted with toluene (40 mL). While stirring a solution of toluene (20 mL) containing N_2H_4 (1.63 g, 50.8 mmol), was added droppwise at −50 °C to the $GaMe_3$ solution. After slowly warming the reaction mixture to room temperature, gas evolution set in quickly and was rapid on heating the resulting suspension to reflux (2 h). The solid (5.68 g) that had formed was isolated by filtration and proved to be principally compound **3** (NMR). Single crystals separated from the filtrate kept at −20 °C. Yield after crystallization from toluene: 4.86 g of **3** (65% calcd. for $GaMe_3$), m.p. 62−63 °C. No explosive decomposition was observed on heating, but one should be careful in handling this compound because methylaluminium hydrazides are reported to be explosive. NMR (C_6D_6): δ^1H = 0.38 to −0.09 (7 signals, 24 H, Ga*Me*), 2.24 (br., 2 H, NH), 2.34 (br., 4 H, NH), 2.74 (br., 2 H, NH); at 80 °C: δ^1H = −0.32 (br. s, 24 H, Ga*Me*), 2.40 (br. s, 6 H, NH), 2.64 (br. s, 2 H, NH); $\delta^{13}C$ = −11.5, −10.6, −9.4, −7.3, −6.4, −5.9, −7.1 (Ga*Me*); at 80 °C: $\delta^{13}C$ = −9.0 (br., Ga*Me*). IR (hostaflon): $\tilde{\nu}$ = 3161 (br., νNH), 1613, 1601 cm^{-1} (δNH_2). $C_{15}H_{40}Ga_4N_6$ (583.40): calcd. C 30.88, H 6.91, N 14.41; found C 30.73, H 6.87, N 14.28.

1-Methyl-2-trimethylsilyl-2,3-dihydro-1*H*-naphtho[1,2-*d*]-[1,2,3]diazagallol (4): A stirred solution of naphth(H)N−$NHSiMe_3$ (2.01 g, 8.7 mmol) in toluene (40 mL) was metallated with a hexane solution of butyllithium (5.6 mL, 1.56 M, 8.7 mmol). After heating to reflux for 2 h, the solution was cooled to −30 °C. Then, a solution of Me_2GaCl (1.18 g, 8.7 mmol) in toluene (20 mL) was added dropwise. After addition, the suspension was allowed to attain room temperature. On heating to reflux for 2 h some gas evolution was noted. The solid that had formed was removed by filtration and the solvents evaporated in vacuo. The remaining oil was treated with hexane (10 mL) and the solution stored at −20 °C. Light yellow crystals separated within a few weeks. Yield: 1.56 g of **4** (57%), m.p. 113−115 °C. NMR (C_6D_6): δ^1H = −0.17 (s, 3 H, Ga*Me*), 0.30 (s, 9 H, *Me*Si), 5.71 (s, 1 H, NH), 6.7−7.8 (m, 6 H, naph*H*); $\delta^{13}C$ = −8.6 (Ga*Me*), 1.4 (Si*Me*), 114.8, 123.1, 126.9, 128.8, 130.0, 130.5, 130.8, 135.7, 139.9, 155.3 (arom. C); $\delta^{29}Si$ = 13.6. $C_{14}H_{19}GaN_2Si$ (313.12): calcd. C 53.70, H 6.12, N 8.95; found C 53.55, H 6.09, N 8.89.

Lithium *N*′-*tert*-Butyl-*N*-trimethylsilylhydrazide−Trimethylgallium (5): $Me_3Si(H)N-NHtBu$ (1.76 g, 11.0 mmol), dissolved in hexane (40 mL), was metallated by adding to the stirred solution BuLi in hexane (7.05 mL, 1.56 M, 11 mmol). The metallation was completed by heating to reflux for 2 h, followed by cooling to −40 °C. Addition of Me_2GaCl (1.54 g, 11.0 mmol), dissolved in hexane (20 mL), led to the formation of a precipitate that was removed by filtration after the suspension had been stirred for 12 h at ambient temperature. Cooling the filtrate to −78 °C yielded colorless needles of **5**, which separated within three weeks. Yield: 1.05 g (34%), m.p. 64−65 °C (dec.). NMR (C_6D_6): δ^1H = −0.08 (s, 9 H, Ga*Me*), 0.21 (s, 9 H, Si*Me*), 1.05 (br. s, 9 H, CMe_3), 3.6 (br. s, 1 H, NH); $\delta^{13}C$ = −2.7 (GaMe), 2.7 (SiMe), 29.0 (CMe_3); $\delta^{29}Si$ = 7.0; δ^7Li = −1.0 ($h_{1/2}$ = 19 Hz). $C_{10}H_{28}GaLiN_2Si$ (281.09): calcd. C 42.73, H 10.04, N 9.97; found C 41.85, H 9.87, N 9.73.

Lithium *N*′-*tert*-Butyl-*N*-trimethylsilylhydrazide−Trimethylindium (7): A stirred solution of $Me_3Si(H)N-NHtBu$ (1.68 g, 10.5 mmol) in 30 mL of toluene was treated with a 1.56 M solution of BuLi (6.7 mL, 10.5 mmol) in hexane. After heating to reflux for 4 h and cooling to ambient temperature, the solution was added dropwise to a stirred suspension of Me_2InCl (1.89 g, 10.5 mmol) in toluene (40 mL), kept at −60 °C. After addition, the mixture was allowed to attain room temperature followed by heating the orange mixture to reflux for 2.5 h. Then, the solids (0.15 g) were removed by filtration and the filtrate stored at −20 °C. Within three weeks small crystals had settled, suitable for X-ray diffraction analysis. Yield: 1.33 g of **6** (39%), m.p. 70−71 °C (dec.). NMR ([D_8]toluene): δ^1H = −0.18 (s, 9 H, InMe), 0.22 (s, 9 H, $SiMe_3$), 0.98 (s, 9 H, *t*Bu),3.4 (s br., 1 H, NH); $\delta^{13}C$ = −5.9 (InMe), 3.3 ($SiMe_3$), 28.3 (*t*Bu), 55.1 (*t*Bu); $\delta^{29}Si$ = 6.4; δ^7Li = −1.0 ($h_{1/2}$ = 18 Hz). $C_{10}H_{28}InLiN_2Si$ (326.19): calcd. C 36.82, H 8.65; N 8.59; found C 35.45, H 8.12, N 8.43.

Dimeric Lithium *N*′-*tert*-Butyl-*N*-trimethylsilylhydrazide−(Methylindyl)(trimethylsilyl)imide (8): A stirred solution of $Me_3Si(H)N-NHtBu$ (1.75 g, 10.9 mmol) in diethyl ether (40 mL) was deprotonated by adding a hexane solution of BuLi (1.56 M, 7.0 mL, 10.9 mmol). To complete the reaction the mixture was kept at reflux for 2 h. After cooling to ambient temperature, Me_2InCl (1.97 g, 10.9 mmol), dissolved in 40 mL of diethyl ether, was added. Small amounts of a solid were filtered off after 12 h. Then the solvents were removed from the filtrate in vacuo and the solid residue treated with hexane (40 mL). The solution was stored at −25 °C. Crystals of **8** separated within four weeks. Yield: 0.92 g of **8** (55%), m.p. 104−105 °C (dec.). NMR (C_6D_6 or [D_8]toluene): δ^1H = −0.10 (s, 3 H, InMe), 0.21 (s, 9 H, $SiMe_3$), 0.25 (s, 9 H, $SiMe_3$), 1.03 (s, 9 H, *t*Bu), 3.3 (br. s, 1 H, NH); $\delta^{13}C$ = −6.0 (InMe), 3.2 ($SiMe_3$), 4.4 ($SiMe_3$), 28.8 (*t*Bu), 55.2 (*t*Bu); $\delta^{29}Si$ = 3.5 ($NSiMe_3$), 6.5 ($NNSiMe_3$); δ^7Li = −0.9 ($\Delta h_{1/2}$ = 18 Hz). $C_{11}H_{31}InLiN_3Si_2$ (383.33): calcd. C 34.46, H 8.15, N 10.96; found C 33.98, H 7.85, N 11.21.

Lithium Tris(trimethylsilyl)hydrazide−Bis(dimethylindium) Oxide Dimer (9): To a stirred solution of Me_2InCl (0.83 g, 4.6 mmol) in ether (40 mL) was added a solution of $(Me_3Si)_2N-NLi(SiMe_3)$ (1.16 g, 4.6 mmol) in diethyl ether (20 mL). After 12 h, the insoluble material (0.10 g, 2.4 mmol LiCl) was removed by filtration. After all volatile components had been stripped off from the filtrate in vacuo, recrystallization of the residue from toluene produced colorless crystals of **9** within 2 weeks. Yield: 0.73 g (57%), m.p. 165 °C. NMR (C_6D_6): δ^1H = −0.03 (s, 3 H, InMe), 0.03 (s, 3 H, $SiMe_3$), 0.04 (s, 3 H, InMe), 0.08 (s, 3 H, InMe), 0.10 (s, 9 H, $SiMe_3$), 0.13 (s, 18 H, $SiMe_3$); $\delta^{13}C$ = −5.4, −3.4, −2.9, −0.6 (InMe), 0.9, 1.4 ($SiMe_3$); $\delta^{29}Si$ = 6.6, 12.1. $C_{13}H_{39}In_2Li-N_2OSi_3$(560.30): calcd. C 27.87, H 7.02, N 5.00; found C 27.79, H 7.05, N 4.98.

Crystal Structure Determinations: Single crystals were covered with a perfluoroether oil and a specimen selected, placed on the tip of a glass fiber and then mounted on the goniometer head. The crystal was then cooled to −80 °C. After alignment, the dimensions of the unit cell were determined from reflections on 5 sets of 15 frames each. Data were collected with the SMART program[69] in the hemisphere mode. An exposure time of 5 s/frames was chosen. Δφ was changed by 0.3° between two frames. Data on a total of 1240 frames were collected and reduced with the program SAINT[70] Absorption correction was employed (SADABS[71]). The structures were solved by direct methods and refined by using the programs SHELXTL and SHELX97.[72] Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were placed in calculated position and included in the final cycles of refinement as riding on the respective carbon atom. Table 4 contains relevant crystallographic data and data related to structure solution and refinement.[73] Thermal ellipsoids in the figures are depicted on a 25% probability level.

[47] The structural data are given for the triclinic unit cell, space group "$P\bar{1}$", The structure of **3** could also be solved in the monoclinic system, space group *C2/m.* In this case, two independent molecules were also found. However, the central N atom occupies a special position. This results in planar heterocycles. The model could be better refined by choosing split positions for this atom, however, the disorder for the toluene molecule could not be refined. Therefore the data are given here for a triclinic space group.

Keywords: C−H activation / Palladium / S ligands / Schiff bases

Treatment of the thiosemicarbazone ligands 4-$MeC_6H_4C(Me)$=NN(H)C(=S)NHMe (**a**), 4-$MeC_6H_4C(Me)$=NN(H)C(=S)NHEt (**b**), and 4-$MeC_6H_4C(Me)$=NN(H)C(=S)NHPh (**c**) with $K_2[PdCl_4]$ produced the tetranuclear palladium(II) compounds [Pd{4-$MeC_6H_3C(Me)$=NNC(=S)-NHMe}]$_4$ (**1a**), [Pd{4-$MeC_6H_3C(Me)$=NNC(=S)NHEt}]$_4$ (**1b**), and [Pd{4-$MeC_6H_3C(Me)$=NNC(=S)NHPh}]$_4$ (**1c**) with deprotonation of the NH group. Treatment of thiosemicarbazones 4-$MeOC_6H_4C(H)$=NN(Me)C(=S)NH_2 (**d**) and 3-$MeOC_6H_4C(H)$=NN(Me)C(=S)NH_2 (**e**) with $K_2[PdCl_4]$ gave the mononuclear palladium(II) compounds [Pd{4-$MeOC_6H_3$-C(H)=NN(Me)C(=S)NH_2}(Cl)] (**1d**) and [Pd{3-$MeOC_6H_3$-C(H)=NN(Me)C(=S)NH_2}(Cl)] (**1e**). Treatment of the Schiff base 4-$MeOC_6H_4C(H)$=N[2-$(SMe)C_6H_4$] (**f**) with $Li_2[PdCl_4]$ afforded [Pd{4-$MeOC_6H_3C(H)$=N[2-$(SMe)C_6H_4$]}(Cl)] (**1f**). All the ligands are terdentate through the [C,N,S] atoms and the Pd–S bond formed is sufficiently strong to tolerate treatment with nucleophiles without bond cleavage. Treatment of **1a**, **1b**, and **1c** with triphenylphosphane gave the mononuclear species **2a**, **2b**, and **2c**, which upon treatment with hydrochloric acid resulted in the 1:1 electrolytes **3a**, **3b**, and **3c**, with NH and C=S groups. Coordination of PPh_3 to Pd in **1f** was achieved by treatment of the compound with sodium perchlorate, followed by the nucleophile in a 1:1 molar ratio, to yield **2f**. The crystal structures of compounds **2a** and **1f** are described.

Introduction

Cyclometallated compounds, as a class within the organometallic family, are quite numerous and they have been intensively studied.[1−7] This is due especially to the wide variety of organic ligands bearing an appropriate donor atom that may sustain metallation with formation of the stable five-membered ring. When the ligand to be metallated has more than one donor atom, a second ring, bonded to the metal ion through the corresponding non-carbon donor atoms, may be created, thus giving compounds with two fused rings at the metal center. We have previously met with this situation with terdentate [C,N,N] Schiff bases,[8−10] terdentate [C,N,O] semicarbazones,[11] and terdentate [C,N,S] thiosemicarbazones.[12] The last case is clearly distinct from the former two, in that the sulfur atom strongly binds to the metal ion, palladium(II) and platinum(II) in our case, thus making the ligands excellent pincer species that powerfully secure three of the four coordination positions of the metal ion, allowing only the fourth coordination site to undergo further reaction with nucleophiles such as tertiary phosphanes. Even with the use of strongly chelating diphosphanes, the palladium− or platinum−sulfur bond remains uncleaved, in contrast to the breakage of the oxygen− or nitrogen−metal bonds of the chelate ring found in the cases of semicarbazone or Schiff base ligands, respectively. Another interesting issue relating to these ligands is the tetrameric nature of the compounds obtained upon treatment of the ligand with the corresponding metal salt; these are cyclometallated thiosemicarbazone Pd_4 or Pt_4 clusters, which also form polymers through hydrogen bonds.[12] The outstanding question still to be answered is whether these findings are dependent on the structure of the −C(R)=N−X(R′)−C(S)−NH(R′′) chain (X = C, N; R, R′, R′′ = H, alkyl, aryl) that supports the rings at the metal atom and how modification of this chain may alter the nature of the resulting products and their properties. That is the purpose of this paper, and here we report results concerning ligands with three different chain se-

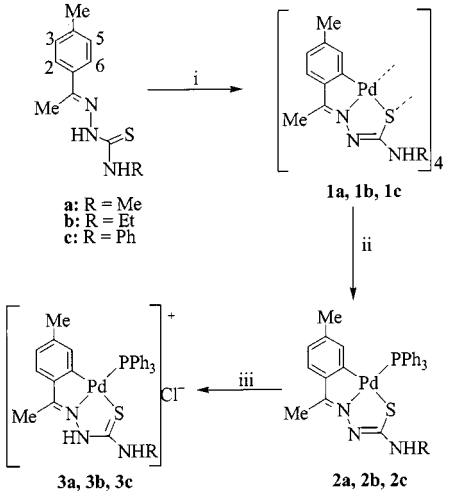
quences, −C(Me)=N−N(H)−C(NHR)−S (R = Me, Et, Ph), −C(H)=N−N(Me)−C(NH_2)−S, and −C(H)=N−C−C−SMe, in order to undertake a comparative study of the complexes.

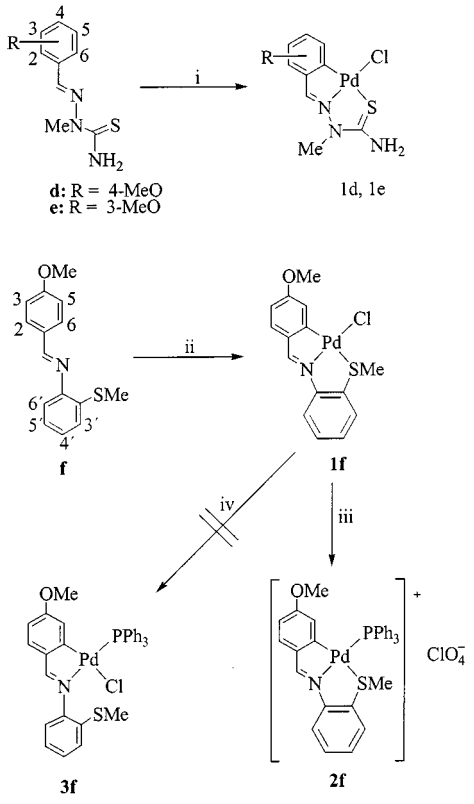
Results and Discussion

The thiosemicarbazones **a**, **b**, **c**, **d**, and **e** were prepared by treatment of 4-methylthiosemicarbazide, 4-ethylthiosemicarbazide, 4-phenylthiosemicarbazide, or 2-methylthiosemicarbazide with 4-methylacetophenone, 4-methoxybenzaldehyde, or 3-methoxybenzaldehyde as appropriate, whilst ligand **f** was prepared by treatment of 4-methoxybenzaldehyde with 2-(methylthio)aniline (see Exp. Sect.). All the ligands showed the characteristic ν(C=N) stretch in their IR spectra, and ligands **a**−**e** also showed the ν(C=S) band (Exp. Sect.); although bands involving the C=S group are often difficult to assign, we have located the ν(C=S) mode in the free ligands in the 850−820 cm^{-1} range [for a more detailed study concerning the ν(C=S) mode, see ref.[12]]. The NH protons in **a**, **b**, and **c** showed signals at δ ≈ 8−9.5. From these ligands, new cyclometallated compounds were obtained, and these are shown in Schemes 1 and 2. In a typical experiment, a suspension of potassium tetrachloropalladate in ethanol/water was treated with the corresponding thiosemicarbazone ligand to give complexes [Pd{4-$MeC_6H_3C(Me)$=NNC(=S)NHMe}]$_4$ (**1a**), [Pd{4-$MeC_6H_3C(Me)$=NNC(=S)NHEt}]$_4$ (**1b**), and [Pd{4-$MeC_6H_3C(Me)$=NNC(=S)NHPh}]$_4$ (**1c**) as yellow, air-stable solids, with the ligand in the (*E*,*Z*) configuration.



Scheme 1. (i) $K_2[PdCl_4]$/EtOH or $Pd(AcO)_2$/glacial acetic acid; (ii) PPh_3/Me_2CO (1:4); (iii) HCl(aq)

The products were characterized by elemental analysis (C, H, N) and IR and ^1H and ^{13}C {^1H} NMR spectroscopy. For complexes **1a**, **1b**, and **1c**, the mass spectra (FAB) showed peaks at *m*/*z* = 1302.9, 1359.0, and 1551.2, respectively, suggesting tetranuclear complexes similar to others obtained by us[12] and by others.[13−15] In addition, the absence of signals for the NH groups in the ^1H NMR spectra attested to deprotonation, as observed previously.[13,14,16,17]



Scheme 2. (i) $K_2[PdCl_4]$/EtOH; (ii) $Li_2[PdCl_4]$/NaAcO/MeOH; (iii) $AgClO_4/PPh_3/Me_2CO$; (iv) PPh_3/Me_2CO

The metallation of the ligand was clear, from the absence of the AA′XX′ systems of the *para*-substituted phenyl rings, and the three remaining proton resonances were unequivocally assigned (see Exp. Sect.). The ^{13}C-{^1H} data confirmed metallation of the phenyl ring:[18] the C=N, C(1), and C(6) resonances were shifted to low field relative to those of the free ligands, whilst the N*C*S resonance was shifted upfield. The ν(C=N) band shifted to lower wavenumbers on complex formation,[19] contrary to the trend observed for other thiosemicarbazone complexes, which show a shift to higher wavenumbers.[20] The ν(C=S) band disappeared, in agreement with loss of the double bond character upon deprotonation of the NH group, which is necessary in order to preserve the electroneutrality of the tetranuclear complexes. In view of these results, we reasoned that, if deprotonation of the NH group could be hindered, then the N(H)−C=S moiety would not be able to adopt the N···C···S character needed for the tetrameric species. In order to achieve this, we synthesized ligands **d** and **e**, in which the chain sequence on the metallated aromatic ring was −C(H)=N−N(Me)−C(NH_2)−S. The stronger N−Me bond, in place of the N−H bond, should keep the −N(Me)−C=S moiety unaltered, providing a mononuclear compound. Thus, treatment of ligands **d** or **e** with potassium tetrachloropalladate in ethanol/water gave the complexes [Pd{4-$MeOC_6H_3C(H)$=NN(Me)C(=S)NH_2}(Cl)] (**1d**) and [Pd{3-$MeOC_6H_3C(H)$=NN(Me)C(=S)NH_2}(Cl)] (**1e**), as yellow, air-stable solids, which were fully characterized (see Exp. Sect.).

The ^{1}H and ^{13}C-{^{1}H} data showed metallation of the aromatic ring (vide supra). The mass spectra (FAB) in each case showed a peak at *m*/*z* = 364.2. The IR spectra showed ν(C=S) bands (absent in **1a**, **1b**, and **1c**) at 831 and 837 cm^{-1} for **1d** and **1e**, respectively, and ν(Pd−Cl) bands (also absent in **1a**, **1b**, and **1c**, in accordance with the absence of the chloride ligand in the palladium coordination environment) at 310 and 306 cm^{-1} for **1d** and **1e**, respectively. These findings are in good agreement with mononuclear species and establish that the −N(Me)−C=S group remains unchanged, confirming our initial assumption. Having established how modification of the chain alters the nature of the compounds synthesized, another issue to be considered was the reactivity of the complexes; that is, whether similar variations would influence the excellent pincer properties of the terdentate [C,N,S] ligands so far studied by us, the thiosemicarbazones, which strongly retain three metal coordination positions. For this purpose we included the sequence −C(H)=N−C=C−SMe (ligand **f**, in which the −C−C− group is part of an aryl ring) and synthesized compound **1f** for more detailed comparative study. Thus, treatment of 4-MeOC$_6$H$_4$C(H)=N[2-(SMe)C$_6$H$_4$] with lithium tetrachloropalladate in methanol gave compound [Pd{4-MeOC$_6$H$_3$C(H)=N[2-(SMe)C$_6$H$_4$]}(Cl)] as an air-stable, fully characterized solid (see Exp. Sect.). The shift of the ν(C=N) stretch towards lower wavenumbers[21] and the upfield shift of the HC=N resonance in the ^{1}H NMR spectrum supported nitrogen coordination to the metal center.[22] The metallated ligand showed the absence of the AA′XX′ system of the *para*-substituted phenyl ring (vide supra). The C=N, C(1), and C(6) resonances in the ^{13}C-{^{1}H} NMR spectrum were shifted downfield from those of the free ligand, in accordance with metallation and Pd−N coordination.[18] The S*Me* resonance was shifted downfield in both the ^{1}H and the ^{13}C-{^{1}H} NMR spectra, in agreement with Pd−S coordination. The crystal and the molecular structure of **1f** are described below.

Reactivity of the Complexes

For **1a**, **1b**, and **1c**, a reactivity pattern similar to that observed by us earlier[12] was found. Thus, treatment of **1a**, **1b**, and **1c** with triphenylphosphane in a 1:4 molar ratio gave compounds [Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHMe}(PPh$_3$)] (**2a**), [Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHEt}(PPh$_3$)] (**2b**), and [Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHPh}(PPh$_3$)] (**2c**), which were fully characterized (see Exp. Sect.). The ^{1}H NMR spectra showed the H(5) resonance shifted upfield and coupled to the phosphorus nucleus. The C=S, C=N, C(1), and C(6) signals in the ^{13}C-{^{1}H} spectra appeared shifted as shown above. The ^{31}P resonance was a singlet and the chemical shift values were consistent with a geometry with the phosphorus atom *trans* to the nitrogen atom.[23−26] Treatment of complexes **1a**, **1b**, and **1c** with hydrochloric acid gave compounds [Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHMe}(PPh$_3$)]$^+$Cl$^-$ (**3a**), [Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHEt}(PPh$_3$)]$^+$Cl$^-$ (**3b**), and [Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHPh}(PPh$_3$)]$^+$Cl$^-$ (**3c**) as fully characterized 1:1 electrolytes, as shown by electric conductivity measurements[27] (see Exp. Sect.). The most noticeable feature of these compounds is the protonation of their NC(=S) nitrogen atoms, as shown by the resonances at δ ≈ 9.0 in their ^{1}H NMR spectra, and bands attributable to ν(C=S) in the 840−820 cm^{-1} range. We then treated complex **1f** with triphenylphosphane to compare its behavior with that of the thiosemicarbazone complexes **1a**−**1c**, which did not show cleavage of the Pd−S bond even with a large excess of the triphenylphosphane ligand and use of prolonged reaction times (compounds **1d** and **1e** displayed similar behavior, and neither the Pd−S bond nor the Pd−Cl bond were cleaved). Under similar reaction conditions, the Pd−S bond in **1f** remained uncleaved and compound **3f** was not formed (Scheme 2). Triphenylphosphane could be coordinated to the metal atom only after abstraction of the chlorine ligand; this was achieved by treatment of compound **1f** with silver perchlorate, followed by addition of the phosphane ligand to give compound [Pd{4-MeOC$_6$H$_3$C(H)=N[2-(SMe)C$_6$H$_4$]}(PPh$_3$)](ClO$_4$) (**2f**) as a fully characterized (see Exp. Sect. and Scheme 2) 1:1 electrolyte. The removal of the chlorine ligand was confirmed by the absence of the ν(Pd−Cl) band. The H(5) resonance in the ^{1}H NMR spectrum showed an upfield shift and appeared as a multiplet, due to coupling to the ^{31}P nucleus, whilst the MeO resonance was shifted to lower frequency by 0.20 ppm, due to shielding by the phosphane phenyl ring.

Crystal and Molecular Structures of 2a and 1f

Suitable crystals were grown by slow concentration of chloroform solutions of complexes **2a** and **1f**. The labelling schemes for the complexes are shown in Figures 1 and 2, respectively. Both crystals consist of discrete molecules separated by normal van der Waals distances. Crystallographic data and selected interatomic distances and angles are listed in Tables 1 and 2.

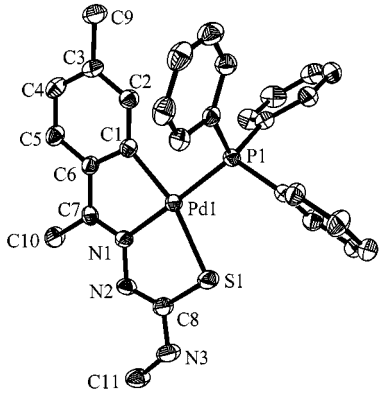


Figure 1. Molecular structure of complex [Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHMe}(PPh$_3$)] (**2a**), with labelling scheme; hydrogen atoms have been omitted for clarity

In compound **2a**, the structure comprises a molecule with the palladium(II) atom bonded in a slightly distorted square-planar environment to four different donor atoms, a terdentate thiosemicarbazone through the aryl C(1) carbon, the imine N(1) nitrogen, the thioamide S(1) sulfur atom,

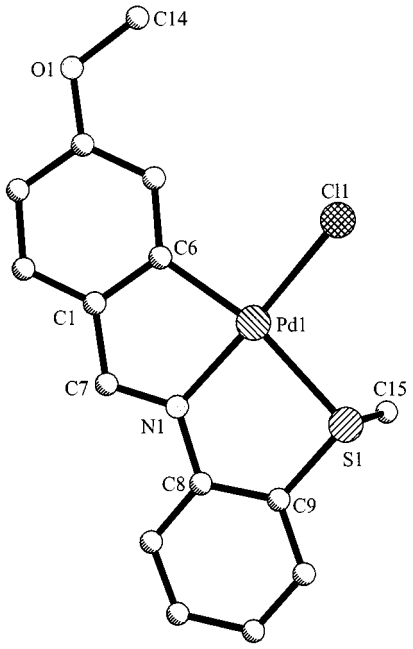

Figure 2. Molecular structure of complex [Pd{4-MeOC$_6$H$_3$C(H)=N[2-(SMe)C$_6$H$_4$]}(Cl)] (**1f**), with labelling scheme; hydrogen atoms have been omitted for clarity

Table 2. Selected bond lengths [Å] and angles [°] for complexes **2a** and **1f**

zone ligand. The angles N(1)−Pd(1)−C(1), at 81.03(3)°, and N(1)−Pd(1)−S(1), at 82.77(9)°, are less than 90°, whilst C(1)−Pd(1)−P(1), at 97.05(10)°, and S(1)−Pd(1)−C(1), at 99.19(4)°, are thus greater than 90°; the sum of angles at the palladium center in the equatorial plane is 360.04°. All and the phosphorus atom P(1) of the triphenylphosphane ligand.

The deviations from the mean plane are as follows: Pd −0.0096, C(1) −0.0320, N(1) 0.0403, P(1) 0.0282, S(1) −0.0269 Å. The angles between adjacent atoms in the coordination geometry of the metal atom are close to the expected value of 90°, in the 99.19(4) to 81.03(13)° range, with the most noticeable distortions being in the thiosemicarba-bond lengths are within the expected range, with allowance for the strong *trans* influence of the phosphorus donor ligand,[28] which is reflected in the Pd(1)−N(1) distance of 2.024(3) Å [a value larger than the sum of the covalent radii for Pd and N: 2.01 Å]. The Pd(1)−C(1) length, at 2.044(4) Å, and the Pd(1)−P(1) length, at 2.2519(9) Å, are shorter than the expected values of 2.081 Å and 2.41 Å,[29] respectively; this suggests some degree of multiple bond character

in the Pd−C(aryl)[30−32] and Pd−P linkages.[33] The S(1)−C(8) bond length, at 1.757(4) Å, and the N(2)−C(8) length, at 1.306(5) Å, are consistent with increased single- and double-bond character, respectively; the former is similar to that found for the Pd−S single bond in compound **1f** (vide infra). The metallacycle Pd, C(1), C(6) C(7), N(1) is planar, with mean deviations from the plane in the ±0.0113 Å range.

The crystal structure of **1f** consists of molecules with the palladium(II) atom bonded to a terdentate Schiff base system through the aryl C(6) carbon, the imine N(1) nitrogen, and the S(1) sulfur atoms, and also to the chlorine Cl(1) atom, thus yielding the palladium ion bonded to four different atoms.

The deviations from the mean plane are as follows: Pd −0.0088, C(6) −0.0162, N(1) 0.0218, S(1) −0.0127, and Cl(1) 0.0160 Å. The angles between adjacent atoms in the palladium coordination sphere show deviations from the ideal 90° similar to those described above for compound **2a**, with the most noticeable distortion in the N(1)−Pd(1)−C(6) angle of 81.7(2)°, a consequence of chelation; the sum of angles around the palladium atom is 360.03°. All bond lengths are within the expected ranges, with a shorter Pd(1)−C(aryl) linkage than in compound **2a** (vide supra). The Pd(1)−N(1) distance is also shorter in **1f** than in **2a**, reflecting the smaller *trans* influence of the chlorine atom in comparison with that of the phosphorus atom of the phosphane ligand. The metallacycle Pd, C(1), C(6), C(7), N(1) and the coordination ring Pd(1), N(1), C(8), C(9), S(1) are planar, with mean deviations from the plane in the ±0.0236 Å and ±0.0097 Å ranges, respectively, and they form angles with the Pd(1), C(6), N(1), S(1), Cl(1) palladium coordination plane of 2.63 and 0.72°, respectively.

Conclusion

We have shown that cyclometallation of organic ligands may be controlled, to provide different species through the introduction of appropriate changes in the chain bonded to the metallated aryl ring, and which contains the donor atoms that afford the metallated and coordination rings at the metal center. Thus, polynuclear metal compounds or mononuclear complexes may be synthesized by impeding cleavage of the N−H linkage on the hydrazine nitrogen atom. Furthermore, we have also demonstrated that the ligands discussed in this paper are good terdentate [C,N,S] pincer species that firmly sustain three metal coordination sites, allowing only one remaining position to undergo further reactions with nucleophiles, and they are therefore most suitable for providing a means to protect the metal ion against undesirable side reactions. Our goal now is to extend these findings to related ligands and also to examine their behavior in six-coordinate metals.

Experimental Section

General Remarks: Solvents were purified by standard methods.[34] Chemicals were reagent grade. Lithium tetrachloropalladate was prepared in situ by treatment of palladium(II) chloride with lithium chloride in methanol or ethanol. Palladium(II) acetate, potassium tetrachloropalladate, and palladium(II) chloride were purchased from Alfa Products, triphenylphosphane from Aldrich-Chemie. Microanalyses were carried out at the Servicio de Análisis Elemental at the University of Santiago, with a Carlo Erba Elemental Analyzer Model 1108. IR spectra were recorded as Nujol mulls or KBr discs with a Perkin−Elmer 1330 and with a Mattson spectrophotometer. NMR spectra were obtained as $CDCl_3$ solutions and referenced to $SiMe_4$ (^1H, ^{13}C) or 85% H_3PO_4 (^{31}P-{^1H}) and were recorded with Bruker WM250 and AMX 300 spectrometers. All chemical shifts are reported downfield from standards. The FAB mass spectra were recorded with a Fisons Quatro mass spectrometer with a Cs ion gun; 3-nitrobenzyl alcohol was used as the matrix.

CAUTION: Perchlorate salts of metal complexes are potentially explosive. Extreme caution should be exercised when handling these materials.

Synthesis of 4-$MeC_6H_4C(Me)$=NN(H)C(=S)NHMe (a): 4′-Methylacetophenone (650 mg, 4.84 mmol) and hydrochloric acid (35%, 0.65 mL) were added to a suspension of 4-methyl-3-thiosemicarbazide (510 mg, 4.84 mmol) in water (25 mL) to give a clear solution, which was stirred at room temperature for 4 h. The white solid that precipitated was filtered off, washed with cold water, and dried in air. Yield: 858 mg, 80%. $C_{11}H_{15}N_3S$ (221.3): calcd. C 59.7, H 6.8, N 19.0, S 14.5; found C 59.5, H 6.6, N 18.6, S 13.9. IR: $\tilde{\nu}$ = 1620 [s, ν(C=N)], 849 [m, ν(C=S)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.61 (s, 1 H, NH), 7.63 (br, 1 H, N*H*Me), 7.59 (d, 2 H, H2, H6, *N* = 8.3 Hz), 7.21 (d, 2 H, H3, H5, *N* = 8.3 Hz), 3.27 (d, 3 H, NMe, $^3J_{HH}$ = 4.9 Hz), 2.38 (s, 3 H, C4−Me), 2.25 (s, 3 H, =C−Me). ^{13}C-{^1H} NMR (62.46 MHz, $CDCl_3$): δ = 179.3 (C=S), 147.3 (C=N), 140.3 (C1), 135.0 (C4), 129.7 (C2, C6), 126.6 (C3, C5), 31.7 (NHMe), 21.7 (C4−Me), 13.9 (*Me*C=N).

Thiosemicarbazones b−e: These were prepared by similar procedures.

4-$MeC_6H_4C(Me)$=NN(H)C(=S)NHEt (b): Yield: 992 mg, 87%. $C_{12}H_{17}N_3S$ (235.4): calcd. C 61.2, H 7.3, N 17.9, S 13.6; found C 61.0, H 7.2, N 17.8, S 13.2. IR: $\tilde{\nu}$ = 1617 [m, ν(C=N)], 835 [m, ν(C=S)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.56 (s, 1 H, NH), 7.57 (d, 2 H, H2, H6, *N* = 8.5 Hz), 7.50 (br, N*H*Et), 7.21 (d, 2 H, H3, H5, *N* = 8.5 Hz), 3.77 (m, 2 H, N*CH*$_2$CH$_3$), 2.37 (s, 3 H, C4−Me), 2.24 (s, 3 H, =C−Me), 1.30 (t, 3 H, NCH$_2$*CH*$_3$, $^3J_{HH}$ = 7.1 Hz). ^{13}C {^1H} NMR (62.46 MHz, $CDCl_3$): δ = 178.1 (C=S), 147.3 (C=N), 140.3 (C1), 135.1 (C4), 129.7 (C2, C6), 126.6 (C3, C5), 39.8 (N*CH*$_2$CH$_3$), 21.7 (C4−Me), 14.9 (NCH$_2$*CH*$_3$), 14.0 (*Me*C=N).

4-$MeC_6H_4C(Me)$=NN(H)C(=S)NHPh (c): Yield: 1263 mg, 92%. $C_{16}H_{17}N_3S$ (283.4): calcd. C 67.8, H 6.0, N 14.8, S 11.3; found C 68.0, H 6.2, N 14.8, S 11.0. IR: $\tilde{\nu}$ = 1611 [s, ν(C=N)], 828 [m, ν(C=S)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 9.41 (s, 1 H, NH), 8.77 (br, N*H*Me), 7.63 (d, 2 H, H2, H6, *N* = 8.2 Hz), 7.23 (d, 2 H, H3, H5, *N* = 8.2 Hz), 2.39 (s, 3 H, C4−Me), 2.32 (s, 3 H, =C−Me).^{13}C-{^1H} NMR (62.46 MHz, $CDCl_3$): δ = 176.6 (C=S), 147.9 (C=N), 140.7 (C1), 138.4 (C4), 129.2 (C2, C6), 124.6 (C3, C5), 21.8 (C4−Me), 14.2 (*Me*C=N).

4-$MeOC_6H_4C(H)$=NN(Me)C(=S)NH_2 (d): Yield: 906 mg, 85%. $C_{10}H_{13}N_3OS$ (223.3): calcd. C 53.8, H 5.9, N 18.8, S 14.4; found C 53.4, H 6.0, N 18.5, S 15.3. IR: $\tilde{\nu}$ = 1619 [m, ν(C=N)], 836 [m, ν(C=S)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.27(s, 1 H, NH_2), 8.22 (s, 1 H, NH_2), 7.84 (s, 1 H, HC=N), 7.86 (d, 2 H, H2, H6, *N* = 8.6 Hz), 6.96 (d, 2 H, H3, H5, *N* = 8.6 Hz), 3.78 (s, 3 H, MeO),

3.74 (s, 1 H, NMe). ^{13}C {^1H} NMR (62.46 MHz, $CDCl_3$): δ = 180.5 (C=S), 161.0 (C4), 141.4 (C=N), 129.8 (C2, C6), 127.4 (C1), 114.4 (C3, C5), 55.6 (MeO), 33.1 (NMe).

3-MeOC$_6$H$_4$C(H)=NN(Me)C(=S)NH$_2$ (e): Yield: 906 mg, 85%. $C_{10}H_{13}N_3OS$ (223.3): calcd. C 53.8, H 5.9, N 18.8, S 14.4; found C 53.6, H 6.0, N 18.6, S 15.0. IR: $\tilde{\nu}$ = 1615 [m, ν(C=N)], 840 [m, ν(C=S)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.38 (s, 1 H, NH_2), 8.31 (s, 1 H, NH_2), 7.85 (s, 1 H, HC=N), 7.50 (s, 1 H, H2), 7.45 [d, 1 H, H6, ^3J(H5H6) = 7.5 Hz], 7.32 (t, 1 H, H5, $^3J_{H4H5}$ = 7.5 Hz), 6.96 (d, 1 H, H4), 3.79 (s, 3 H, MeO), 3.76 (s, 3 H, NMe). ^{13}C {^1H} NMR (62.46 MHz, $CDCl_3$): δ = 180.9 (C=S), 159.9 (C3), 141.5 (C=N), 136.2 (C1), 130.0, 121.2, 116.3, 112.4 (C2, C4, C5, C6), 55.6 (MeO), 33.2 (NMe).

Preparation of 4-MeOC$_6$H$_4$C(H)=N[2-(SMe)C$_6$H$_4$] (f): 4-Methoxybenzaldehyde (500 mg, 3.67 mmol) and 2-methylthioaniline (518 mg, 3.72 mmol) were heated together under reflux in a Dean−Stark apparatus. After the mixture had cooled to room temperature, the solvent was evaporated to dryness, and the residue was dried under vacuum to give an oily yellow product from which the desired ligand was obtained as a yellow solid. Yield: 785 mg, 83%. $C_{15}H_{15}NOS$ (257.4): calcd. C 70.0, H 5.9, N 5.4, S 12.5; found C 70.1, H 6.0, N 5.7, S 12.3. IR: $\tilde{\nu}$ = 1626 [s, ν(C=N)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 8.44 (s, 1 H, HC=N), 7.88 (d, 2 H, H2, H6, *N* = 8.0 Hz), 7.2 (m, 4 H), 7.07 (d, 2 H, H3, H5, *N* = 8.0 Hz), 3.82 (s, 3 H, MeO), 2.37 (s, 3 H, SMe). ^{13}C {^1H} NMR (62.46 MHz, $CDCl_3$): δ = 165.1 (C−SMe), 162.4 (C=N), 151.5 (C4), 137.0 (C−N), 133.6 (C2, C6), 132.0 (C1), 129.2, 128.0, 127.0, 120.4 (N-ring C atoms), 117.4 (C3, C5), 58.5 (MeO), 16.7 (SMe).

Preparation of [Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHMe}]$_4$ (1a). − Method 1: Ethanol (40 mL) was added to a stirred solution of potassium tetrachloropalladate (200 mg, 0.61 mmol) in water (6 mL). The obtained fine, yellow suspension of potassium tetrachloropalladate was treated with 4-MeOC$_6$H$_4$C(Me)=N(H)C(=S)NHMe (**a**) (148 mg, 0.67 mmol). The mixture was stirred for 48 h at room temperature. The yellow precipitate was filtered off, washed with ethanol, and dried. Yield: 178 mg, 89%. $C_{44}H_{52}N_{12}Pd_4S_4$ (1302.9): calcd. C 40.6, H 4.0, N 12.9, S 9.8; found C 40.1, H 3.8, N 12.3, S 9.5. IR: $\tilde{\nu}$ = 1590 [m, ν(C=N)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 7.27 (d, 1 H, H5, $^4J_{H3H5}$ = 1.3 Hz), 6.71 (dd, 1 H, H3, $^3J_{H2H3}$ = 7.8 Hz), 6.65 (d, 1 H, H2), 5.03 (q, 1 H, N*H*Me, $^3J_{HH}$ = 5.0 Hz), 2.98 (d, 3 H, NH*Me*), 2.30 (s, 3 H, C4−Me), 1.65 (s, 3 H, =C−Me). ^{13}C {^1H} NMR (62.46 MHz, $CDCl_3$): δ = 169.6 (C=S), 165.9 (C=N), 165.1 (C1), 147.2 (C6), 138.0 (C4), 134.2 (C2), 125.8, 125.0 (C3, C5), 33.1 (NHMe), 22.3 (C4−Me), 13.0 (*Me*C=N). − **Method 2:** Ligand **a** (201 mg, 0.91 mmol) and palladium(II) acetate (204 mg, 0.91 mmol) were added to glacial acetic acid (45 mL) to give a clear solution, which was heated to 60° C for 8 h. After this had cooled to room temperature, the yellow precipitate was filtered off, washed with ethanol, and dried. Yield: 169 mg, 57%.

[Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHEt}]$_4$ (1b). − Method 1: Analogous to **1a**. Yield: 181 mg, 87%. $C_{48}H_{60}N_{12}Pd_4S_4$ (1359.0): calcd. C 42.4, H 4.5, N 12.4, S 9.4; found C 41.9, H 3.6, N 11.8, S 8.7. IR: $\tilde{\nu}$ = 1586 [m, ν(C=N)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 7.30 (s, 1 H, H5), 6.71 (d, 1 H, H3, $^3J_{H2H3}$ = 7.4 Hz), 6.64 (d, 1 H, H2), 5.03 (m, 1 H, N*H*Et), 3.44 (m, 2 H, N*CH$_2$*CH$_3$), 2.29 (s, 3 H, C4−Me), 1.65 (s, 3 H, =C−Me), 1.26 (t, 3 H, NCH$_2$*CH$_3$*, $^3J_{HH}$ = 7.1 Hz). ^{13}C {^1H} NMR (62.46 MHz, $CDCl_3$): δ = 169.1 (C=S), 165.8 (C=N), 165.0 (C1), 147.5 (C6), 137.5 (C4), 134.3 (C2), 125.8, 125.0 (C3, C5), 41.4 (N*CH$_2$*CH$_3$), 22.2 (C4−Me), 15.0 (NCH$_2$*CH$_3$*), 13.0 (*Me*C=N). − **Method 2:** Ligand **b** (186 mg, 0.79 mmol) and palladium(II) acetate (177 mg, 0.79 mmol) were added to glacial acetic acid (40 mL) to give a clear solution, which was heated to 60° C for 8 h. After this had cooled to room temperature, the acetic acid was removed under vacuum. The residue was diluted with water and extracted with dichloromethane. The combined extracts were dried with anhydrous sodium sulfate, filtered, and concentrated in vacuo to give a yellow solid. This was chromatographed on a column packed with silica gel. Elution with dichloromethane/ethanol (1%) afforded product **1b** as a yellow solid after concentration. Yield: 169 mg, 63%.

[Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHPh}]$_4$ (1c): Compound **1c** was obtained through a similar procedure to that used for **1a** (method 1). Yield: 226 mg, 95%. $C_{64}H_{60}N_{12}Pd_4S_4$ (1551.2): calcd. C 49.6, H 3.9, N 10.8, S 8.3; found C 49.9, H 3.6, N 10.2, S 7.9. IR: $\tilde{\nu}$ = 1574 [m, ν(C=N)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 7.24 (br, 1 H, H5), 6.94 (s, 1 H, NHPh), 6.78 (br, 2 H, H2, H3), 2.16 (s, 3 H, C4−Me), 1.74 (s, 3 H, =C−Me).^{13}C {^1H} NMR (62.46 MHz, $CDCl_3$): δ = 172.1 (C=S), 166.5 (C=N), 161.0 (C1), 147.0 (C6), 139.4 (C4), 134.5 (C2), 126.5, 125.4 (C3, C5), 22.1 (C4−Me), 13.7 (*Me*C=N).

[Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHMe}(PPh$_3$)] (2a): Triphenylphosphane (40 mg, 0.152 mmol) was added to a suspension of complex **1a** (50 mg, 0.038 mmol) in acetone (15 mL). The mixture was stirred for 3 h and the resulting yellow solid was filtered off and dried. Yield: 55 mg, 61%. $C_{29}H_{28}N_3PPdS$ (588.0): calcd. C 59.2, H 4.8, N 7.1, S 5.5; found C 59.1, H 4.7, N 7.0, S 5.4. IR: $\tilde{\nu}$ = 1588 [m, ν(C=N)] cm^{-1}. ^{31}P {^1H} NMR ($CDCl_3$): δ = 36.7 (s). ^1H NMR ($CDCl_3$): δ = 6.95 (d, 1 H, H2, $^3J_{H2H3}$ = 7.7 Hz), 6.64 (d, 1 H, H3), 6.05 (d, 1 H, H5, $^4J_{PH5}$ = 4.3 Hz), 4.63 (m, 1 H, N*H*Me), 2.90 (d, 3 H, NH*Me*, $^3J_{HH}$ = 4.5 Hz), 2.35 (s, 3 H, C4−Me), 1.73 (s, 3 H, =C−Me).

Compounds 2b and 2c: These were synthesized by a similar procedure.

[Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHEt}(PPh$_3$)] (2b): Yield: 47 mg, 53%. $C_{30}H_{30}N_3PPdS$ (602.1): calcd. C 59.9, H 5.0, N 7.0, S 5.3; found C 59.8, H 4.9, N 6.9, S 5.1. IR: $\tilde{\nu}$ = 1588 [m, ν(C=N)] cm^{-1}. ^{31}P {^1H} NMR ($CDCl_3$): δ = 36.8 (s). ^1H NMR ($CDCl_3$): δ = 6.96 (d, 1 H, H2, $^3J_{H2H3}$ = 7.5 Hz), 6.65 (dd, 1 H, H3, $^4J_{H3H5}$ = 1.1 Hz), 6.07 (dd, 1 H, H5, $^4J_{PH5}$ = 3.5 Hz), 4.63 (m, 1 H, N*H*Et), 3.35 (m, 2 H, N*CH$_2$*CH$_3$), 2.35 (s, 3 H, C4−Me), 1.71 (s, 3 H, =C−Me), 1.12 (t, 3 H, NCH$_2$*CH$_3$*, $^3J_{HH}$ = 7.2 Hz).

[Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHPh}(PPh$_3$)] (2c): Yield: 48 mg, 57%. $C_{34}H_{30}N_3PPdS$ (650.1): calcd. C, 62.8, H 4.7, N 6.5, S 4.9; found C 62.5, H 4.6, N 6.3, S 4.7. IR: ν(C=N) 1577m, cm^{-1}. ^{31}P {^1H} NMR ($CDCl_3$): δ = 36.7 (s). ^1H NMR ($CDCl_3$): δ = 7.02 (d, 1 H, H2, $^3J_{H2H3}$ = 7.2 Hz), 6.68 (d, 1 H, H3), 6.63 (s, 1 H, NHPh), 6.10 (d, 1 H, H5, $^4J_{PH5}$ = 3.1 Hz), 2.46 (s, 3 H, C4−Me), 1.73 (s, 3 H, =C−Me).

[Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHMe}(PPh$_3$)]$^+$Cl$^-$ (3a): A suspension of complex **2a** (50 mg, 0.085 mmol) in ethanol (15 mL) was treated with three drops of concentrated hydrochloric acid (35%). The resulting mixture was stirred for 3 h and the yellow solid formed was filtered off and dried. Yield: 49 mg, 92%. $C_{29}H_{29}ClN_3PPdS$ (624.5): calcd. C 55.8, H 4.7, N 6.7, S 5.1; found C 55.6, H 4.6, N 6.7, S 4.9. IR: $\tilde{\nu}$ = 1574 [m, ν(C=N)], 840 [m, ν(C=S)] cm^{-1}. Λ_M (acetonitrile, 3×10^{-3} mol L^{-1}) = 97 Ω^{-1} cm^2 mol^{-1}. ^{31}P {^1H} NMR ($CDCl_3$): δ = 38.4 (s). ^1H NMR ($CDCl_3$): δ = 9.05 (s, 1 H, NH), 7.05 (d, 1 H, H2, $^3J_{H2H3}$ = 7.6 Hz), 6.68 (d, 1 H, H3), 6.09 (d, 1 H, H5, $^4J_{PH5}$ = 4.5 Hz), 5.9 (m, 1 H, N*H*Me), 3.05 (d, 3 H, NH*Me*, $^3J_{HH}$ = 4.0 Hz), 2.33 (s, 3 H, C4−Me), 1.93 (s, 3 H, =C−Me).

Compounds 3b and 3c: These were synthesized by a similar procedure.

[Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHEt}(PPh$_3$)]$^+$Cl$^-$ (3b): Yield: 49 mg, 93%. $C_{30}H_{31}ClN_3PPdS$ (638.5): calcd. C 56.4, H 4.9, N 6.6, S 5.0; found C 56.2, H 4.7, N 6.5, S 4.9. IR: $\tilde{\nu}$ = 1576 [m, ν(C=N)], 832 [m, ν(C=S)] cm^{-1}. Λ_M (acetonitrile, 3×10^{-3} mol L^{-1}) = 92 Ω^{-1} cm^2 mol^{-1}. ^{31}P {^{1}H} NMR ($CDCl_3$): δ = 38.5 (s). ^{1}H NMR ($CDCl_3$): δ = 9.07 (s, 1 H, NH), 7.03 (d, 1 H, H2, $^3J_{H2H3}$ = 7.1 Hz), 6.80 (dd, 1 H, H3, $^4J_{H3H5}$ = 7.0 Hz), 6.10 (dd, 1 H, H5, $^4J_{PH5}$ = 3.6 Hz), 6.12 (m, 1 H, N*H*Et), 3.45 (m, 2 H, N*CH$_2$*CH$_3$), 2.36 (s, 3 H, C4−Me), 1.91 (s, 3 H, =C−Me), 1.29 (t, 3 H, NCH$_2$*CH$_3$*, $^3J_{HH}$ = 7.0 Hz).

[Pd{4-MeC$_6$H$_3$C(Me)=NNC(=S)NHPh}(PPh$_3$)]$^+$Cl$^-$ (3c): Yield: 48 mg, 91%. $C_{34}H_{31}ClN_3PPdS$ (686.6): calcd. C, 59.5, H 4.6, N 6.1, S 4.7; found C 59.2, H 4.5, N 6.0, S 4.4. IR: $\tilde{\nu}$ = 1570 [m, ν(C=N)], 825 [m, ν(C=S)] cm^{-1}. Λ_M (acetonitrile, 3×10^{-3} mol L^{-1}) = 95 Ω^{-1} cm^2 mol^{-1}. ^{31}P {^{1}H} NMR ($CDCl_3$): δ = 38.6 (s). ^{1}H NMR ($CDCl_3$): δ = 9.04 (s, 1 H, NH), 7.6 (s, 1 H, NHPh), 7.18 (d, 1 H, H2, $^3J_{H2H3}$ = 7.0 Hz), 7.02 (d, 1 H, H3), 6.17 (d, 1 H, H5, $^4J_{PH5}$ = 3.4 Hz), 2.53 (s, 3 H, C4−Me), 1.92 (s, 3 H, =C−Me).

Compounds 1d and 1e: These were prepared in a similar fashion to **1a** (Method 1).

[Pd{4-MeOC$_6$H$_3$C(H)=NN(Me)C(=S)NH$_2$}(Cl)] (1d): Yield: 185 mg, 83%. $C_{10}H_{12}ClN_3OPdS$ (364.2): calcd. C 33.0, H 3.3, N 11.5, S 8.8; found C 31.9, H 3.3, N 11.1, S 9.2. IR: $\tilde{\nu}$ = 1589 [m, ν(C=N)], 309 [m, ν(Pd−Cl)], 834 [m, ν(C=S)] cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 8.14 (s, 1 H, HC=N), 7.24 (d, 1 H, H2, $^3J_{H2H3}$ = 8.4 Hz), 6.93 (d, 1 H, H5, $^4J_{H3H5}$ = 2.2 Hz), 6.53 (dd, 1 H, H3), 3.72 (s, 3 H, MeO), 3.46 (s, 3 H, NMe). ^{13}C {^{1}H} NMR (62.46 MHz, $CDCl_3$): δ = 189.1 (C=S), 163.5 (C4), 160.1 (C6), 157.6 (C=N), 139.6 (C1), 130.1 (C2), 118.6 (C3), 109.7 (C5), 55.4 (MeO), 35.4 (NMe).

[Pd{3-MeOC$_6$H$_3$C(H)=NN(Me)C(=S)NH$_2$}(Cl)] (1e): Yield: 185 mg, 83%. $C_{10}H_{12}ClN_3OPdS$ (364.2): calcd. C 33.0, H 3.3, N 11.5, S 8.8; found C 32.9, H 3.2, N 11.3, S 9.1. IR: $\tilde{\nu}$ = 1591 [m, ν(C=N)], 315 [m, ν(Pd-Cl)], 842 [m, ν(C=S)] cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 9.47 (s, 1 H, NH$_2$), 8.74 (s, 1 H, NH$_2$), 8.18 (s, 1 H, HC=N), 7.23 (d, 1 H, H5, $^3J_{H4H5}$ = 8.4 Hz), 6.94 (d, 1 H, H2, $^4J_{H2H4}$ = 2.7 Hz), 6.67 (dd, 1 H, H4), 3.68 (s, 3 H, MeO), 3.47 (s, 3 H, NMe). ^{13}C {^{1}H} NMR (62.46 MHz, $CDCl_3$): δ = 174.6 (C=S), 160.1 (C6), 157.8 (C=N), 157.1 (C3), 146.7 (C1), 133.2 (C2), 114.1 (C5), 113.4 (C4), 55.4 (MeO), 35.5 (NMe).

[Pd{4-MeOC$_6$H$_3$C(H)=N[2-(SMe)C$_6$H$_4$]}(Cl)] (1f): 4-MeOC$_6$H$_4$C(H)=N[2-(SMe)C$_6$H$_4$] (**f**) (217 mg, 0.84 mmol) and sodium acetate (500 mg, 6.1 mmol) were added to a stirred solution of palladium(II) chloride (135 mg, 0.76 mmol) and lithium chloride (65 mg, 1.53 mmol) in methanol (40 mL). The mixture was stirred for 48 h at room temperature under nitrogen. The yellow precipitate was filtered off, washed with ethanol, and dried. Yield: 252 mg, 83%. $C_{15}H_{14}ClNOPdS$ (398.18): calcd. C 45.2, H 3.5, N 3.5, S 8.1; found C 45.0, H 3.4, N 3.4, S 8.0. IR: $\tilde{\nu}$ = 1603 [m, ν(C=N)], 310 [m, ν(Pd−Cl)] cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 9.12 (s, 1 H, HC=N), 7.98 (d, 1 H, H6′, $^3J_{H5'H6'}$ = 8.4 Hz), 7.83 (d, 1 H, H3′, $^3J_{H3'H4'}$ = 7.9 Hz), 7.55 (t, 1 H, H4′, $^3J_{H4'H5'}$ = 8.0 Hz), 7.53 (d, 1 H, H2, $^3J_{H2H3}$ = 8.8 Hz), 7.44 (t, 1 H, H5′), 7.11 (d, 1 H, H5, $^4J_{H3H5}$ = 2.7 Hz), 6.71 (dd, 1 H, H3), 3.80 (s, 3 H, MeO), 2.75 (s, 3 H, SMe). ^{13}C {^{1}H} NMR (62.46 MHz, $CDCl_3$): δ = 169.7 (C=N), 168.0 (C−S), 167.1 (C4), 147.5 (C−N), 143.1 (C6), 133.2 (C1), 133.0 (C2), 135.3, 131.6, 129.9, 119.5 (N-ring C atoms), 118.3, 111.4 (C3, C5), 55.8 (MeO), 24.8 (SMe).

Synthesis of [Pd{4-MeOC$_6$H$_3$C(H)=N[2-(SMe)C$_6$H$_4$]}(PPh$_3$)](ClO$_4$) (2f): $AgClO_4$ (29 mg, 0.14 mmol) was added to compound **1f** (56 mg, 0.14 mmol) in acetone (15 mL). The resulting suspension was stirred for 3 h and filtered through Celite to remove the silver chloride precipitate. PPh_3 (37 mg, 0.14 mmol) was added to the filtrate and the solution was stirred for 3 h. The solvent was removed and the product was recrystallized from dichloromethane/hexane as a yellow solid. Yield: 84 mg, 83%. $C_{33}H_{29}ClNO_5PPdS$ (724.5): calcd. C 54.7, H 4.0, N 1.9, S 4.4; found C 54.2, H 3.9, N 1.8, S 4.7. IR: $\tilde{\nu}$ = 1607 [m, ν(C=N)] cm^{-1}. Λ_M (acetonitrile, 3×10^{-3} mol L^{-1}) = 91 Ω^{-1} cm^2 mol^{-1}.^{1}H NMR ($CDCl_3$): δ = 9.18 (d, 1 H, HC=N, $^4J_{PH}$ = 8.4 Hz), 8.06 (d, 1 H, H6′, $^3J_{H5'H6'}$ = 8.0 Hz), 7.86 [d, 1 H, H3′, $^3J_{H3'H4'}$ = 8.4 Hz), H4′, H2, H5′ (signals hidden by the phosphane resonances)], 6.57 (d, 1 H, H3, $^4J_{H3H5}$ = 2.7 Hz), 6.71 (dd, 1 H, H5, $^4J_{PH}$ = 5.5 Hz), 3.60 (s, 3 H, MeO), 2.75 (s, 3 H, SMe).

X-ray Crystallographic Study:[35] Crystals of complexes **2a** and **1f** were mounted on a glass fiber and transferred to the diffractometer. Three-dimensional, room-temperature X-ray data were collected with Siemens (**2a**) and Bruker (**1f**) SMART CCD diffractometers by the ω-scan method, using graphite-monochromated Mo-K_α radiation. All the measured reflections were corrected for Lorentz and polarization effects and for absorption by semiempirical methods based on symmetry-equivalent and repeated reflections [T_{max}/T_{min} = 0.9573/0.8437 (**2a**) and 0.7356/0.6194 (**1f**)]. The structure was solved by direct methods and refined by full-matrix, least squares on F^2. Hydrogen atoms were included in calculated positions (except H3 in **2a**, which was located from a Fourier-difference map) and refined in the riding mode. Refinement converged at a final R = 0.0447 (**2a**) and 0.0349 (**1f**) (observed data, F) and wR_2 = 0.1038 (**2a**) and 0.0811 (**1f**) (all unique data, F^2), with allowance for thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron densities: −0.475 and 0.542 e Å^{-3} (**2a**), 0.726 and −0.839 e Å^{-3} (**1f**). The structure solutions and refinements were carried out with the SHELX-97 program package.[36]

New Neutral and Cationic Dialkylaluminium Complexes Bearing Imino-Amide or Imino-Phenoxide Ligands: Synthesis, Characterization and Reactivity With Olefins

Daniela Pappalardo,*[b] Consiglia Tedesco,[a] and Claudio Pellecchia[a]

Keywords: Alkenes / N ligands / N,O ligands / Polymerization / Aluminum

The synthesis and the characterization of some new aluminium complexes carrying bidentate monoanionic imino-amide or imino-phenoxide ligands are described. Reaction of 1-(*o*,*o*′-diisopropylphenylamino)-6-(*o*,*o*′-diisopropylphenylimino)cyclohexene with $AlMe_3$ proceeded by methane elimination to produce the yellow compound dimethylaluminium *N*-(*o*,*o*′-diisopropylphenyl)-6-[*N*-(*o*,*o*′-diisopropylphenyl)-imido]-1-cyclohexen-1-amide (**1**). In contrast, reaction of the same ligand with $AlEt_3$ under the same experimental conditions involved the 1,4-addition of $AlEt_3$ to the α,β-unsaturated imine, and led to the highly crystalline diethylaluminium *N*-(*o*,*o*′-diisopropylphenyl)-2-[(*o*,*o*′-diisopropylphenyl)amino]-3-ethyl-1-cyclohexen-1-amide (**2**). The structures of compounds **1** and **2** were determined by single-crystal X-ray diffraction. Thermolysis of **2** gave rise to ethane elimination, and led to the oily bis(amido) monoethyl derivative. Treatment of the salicylaldimine ligands 3-*t*Bu-2-(OH)C_6H_3CH=N–R with $AlMe_3$ yielded the dimethylaluminium compounds {3-*t*Bu-2-(O)C_6H_3CH=N–R}$AlMe_2$ [R = C_6H_5 (**3**); 2,6-*i*$Pr_2C_6H_3$ (**4**); and C_6F_5 (**5**)]. Compounds **1**, **3**, and **5** underwent methyl abstraction reactions with $B(C_6F_5)_3$; trapping of the cationic species was accomplished in the presence of THF in dichloromethane solution. Preliminary polymerization tests were carried out for the synthesized Al complexes. Toluene solutions of **3**, **4**, and **5**, when activated with 1 equiv. of $B(C_6F_5)_3$, polymerised ethylene (1 atm) to solid polyethylene with low activity.

Introduction

Since the disclosure by Ziegler of the "aufbau" reaction, alkylaluminium compounds have been known as olefin oligomerization catalysts, because of the displacement reaction competing with a "smooth stepwise addition of ethylene".[1] In 1992 Martin demonstrated that the growth reaction of ethylene at bis(dichloroaluminium)ethane and trialkylaluminium produces, with low activity, polyethylene of high molecular weight and thermoplastic character.[2] More recently, Sen et al. reported that simple alkylaluminium compounds, after reaction with the activators commonly used in the homogeneous olefin polymerization catalysis {i.e. $B(C_6F_5)_3$, $[(C_6H_5)_3C][B(C_6F_5)_4]$ or $[(C_6H_5)N(CH_3)_2H][B(C_6F_5)_4]$} are able to catalyse the polymerization of ethylene and propene, although with low activity.[3] The authors hypothesize that neutral aluminium species, such as $[(R)(C_6F_5)_2Al]_x$, are the active catalysts operating in these systems.[3] Actually, the reaction of $AlMe_3$ with $[(C_6H_5)_3C][B(C_6F_5)_4]$ gives the transient species $[AlMe_2]^+[B(C_6F_5)_4]^-$ which immediately decomposes by ligand exchange to $Al(C_6F_5)_3$ and BMe_3.[4,5] Trapping of the cationic alkylaluminium species was achieved in the presence of bases,[6] or using coordinating solvents such as diethyl ether and THF.[7] Base-free cationic species are expected to be highly electrophilic, and therefore more active as olefin polymerization catalysts.

The stability of base-free group-13 alkyl cations seems to be strongly dependent on the ancillary ligand and the kind of counter-anion. Bochmann described the bis(cyclopentadienyl)aluminium cation as an initiator for the carbocationic polymerization of isobutylene,[8] and Jordan reported the synthesis and characterization of several cationic aluminium complexes incorporating chelating nitrogen-based ligands, able to polymerise ethylene.[9] According to Jordan's results, a few related aluminium derivatives carrying chelating monoanionic ligands have also been shown to polymerise ethylene with comparably low activity.[10]

In this paper we report on the synthesis and the characterization of some new aluminium complexes carrying bidentate monoanionic imino-amide or imino-phenoxide ligands (Scheme 1) and some preliminary data on their reactivity with ion-generating activators and the subsequent reactivity in ethylene polymerization.[11]

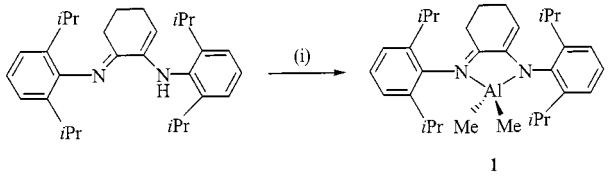
Results and Discussion

Treatment of 1-(*o*,*o*′-diisopropylphenylamino)-6-(*o*,*o*′-diisopropylphenylimino)cyclohexene[12] with $AlMe_3$ in heptane at room temperature afforded the dimethyl complex **1** as a yellow solid in high yield. The disappearance of the N−*H* signal of the ligand in the ^1H NMR spectrum of **1** ([D_6]benzene, room temperature), and the appearance of a high-field signal (δ = −0.37, 6 H) compatible with Al*Me*$_2$ protons, reveal that the reaction proceeds by protodealumination of the Al−CH_3 bond with concomitant elimination of methane (Scheme 2). Although the molecule belongs to the C_1 symmetry group, the presence of only one signal for the Al*Me*$_2$ protons in the ^1H NMR spectrum, and the signals pattern in the ^{13}C NMR spectrum (i.e. 4 signals for the methyl groups of the isopropyl groups, 2 signals for C*H*Me$_2$) are compatible with the presence of a "pseudo" mirror symmetry passing through the Al and the two nitrogen atoms. This therefore indicates that, under the analysis conditions (i.e. room temperature, benzene solution), the change in conformation of the cyclohexene ring is fast on the NMR time scale.



Scheme 2. Reaction conditions: (i) $AlMe_3$, heptane, room temperature

Crystals of **1** suitable for an X-ray structure determination were grown from toluene at −20 °C. The compound crystallized as prismatic crystals in the monoclinic space group $P2_1/n$, the asymmetric unit containing one discrete molecule of **1** and half of a centrosymmetric disordered toluene molecule. The molecular structure of **1** is shown in Figure 1; selected bond lengths and angles are given in Table 1. The coordination environment about the Al atom is approximately tetrahedral, with Al−CH_3 distances comparable to those observed in analogous β-diketiminato[13] and imino-amide complexes.[14] The Al−N distances differ slightly from each other [1.968(11) and 1.897(10) Å], suggesting a dative and a sigma bond, respectively, as already observed in the just cited imino-amide compounds.[14] Inspection of the bond lengths within the −N1−C1(C6)−C2(C3)−N2− moiety suggests the presence of a partial delocalization.[14,15] The puckering of the cyclohexene ring is described by the deviations of the atoms C3, C4, C5, and C6 from the least-square plane defined by N1, C1, C2, and N2 atoms (rmsd 0.005); these deviations are 0.01(2) Å, 0.45(3) Å, 0.25(3), and 0.02(2) Å, respectively. The Al atom lies under the previously defined plane and deviates by −0.22(2) Å. The aromatic rings C7···C12 and C19···C24 are planar with rmsd of 0.027 and 0.017, respectively, and are almost perpendicular to the Al−N1−C1−C2−N2 ring. The dihedral angles between the five-atom Al−N1−C1−C2−N2 plane and each aromatic ring are 87.8(4)° and 86.6(4)°.

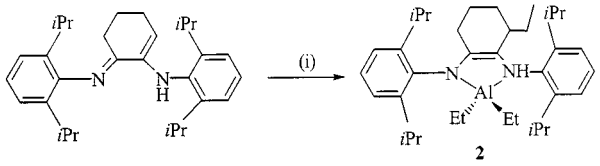
C32−Al−N1 114.5(5)	C35−Al−N2 119.8(2)

Interestingly, the reaction of the same ligand with $AlEt_3$ under identical conditions did not afford the expected di-

ethylaluminium imino-amide derivative analogous to **1**, but an orange crystalline solid, characterized by X-ray diffraction and NMR spectroscopy as the diethylaluminium complex **2**, featuring a *C*-alkylated amino-amido ligand (Scheme 3). Particularly diagnostic in the ^{1}H NMR spectrum of **2** ([D$_6$]benzene, 25 °C) (Figure 2) is the broad singlet at δ = 6.55 (1 H, N*H*), indicating that the amine function is not deprotonated, while the signal of the unsaturation on the six-membered carbon ring of the ligand is absent, as a consequence of the ethyl addition. The ethyl groups bound to the aluminium atom are not equivalent, thus resulting in two well-defined patterns of signals at high field; in particular the methylene hydrogen atoms in each ethyl group are diastereotopic and appear as a double quadruplet (δ = 0.18, 2 H, AlCH_2CH$_3$) and two multiplets (δ = 0.52−0.28, 2 H, AlCH'_2CH$_3$).



Scheme 3. Reaction conditions: (i) AlEt$_3$, heptane, room temperature

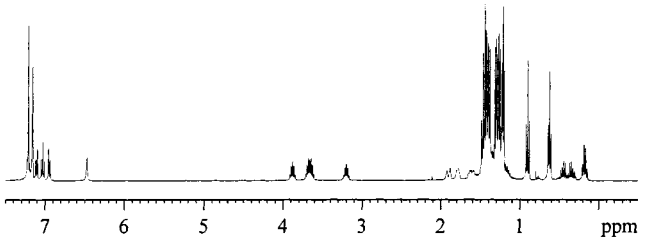


Figure 2. ^{1}H NMR spectrum of **2** (C$_6$D$_6$, room temperature)

This picture is consistent with a C_1 symmetry, that is confirmed by the number of signals in the ^{13}C NMR spectrum [i.e. 4 signals for *C*H(CH$_3$)$_2$, 8 signals for CH(*C*H$_3$)$_2$, 2 signals for AlCH$_2$*C*H$_3$ (δ = 9.6 and 9.0), and 2 broad signals for Al*C*H$_2$CH$_3$ (δ = 0.95 and −0.5)].

Complex **2** was crystallized from toluene at −20 °C. The molecular structure of **2** is shown in Figure 3; selected bond lengths and angles are given in Table 1. The coordination environment about the Al atom is almost tetrahedral with Al−Et bond lengths displaying usual values. The distances Al−N1 and Al−N2 are 2.045(4) Å and 1.856(4) Å, respectively, as observed in analogous aluminium compounds bearing a monoanionic chelating secondary amine-amido ligand.[16] The ligand bite angle N2−Al−N1 measures 85.9(2)° and differs significantly from the values previously observed in analogous secondary amine-amido compounds[16] [88.4(1)−93.6(3)°]. This feature can be ascribed to the different nature of the −N−C−C−N− backbone in compound **2**, which is the only one showing a central double bond. The five atom Al−N1−C1−C2−N2 ring is planar with rmsd = 0.034. The C3 and C6 atoms deviate from the plane by −0.025 and 0.190 Å, respectively. The aromatic rings C9···C14 and C21···C26 are planar with rmsd of 0.004 and 0.007, respectively. The C21···C26 ring lies perpendicularly to the five-atom Al−N1−C1−C2−N2 plane with a dihedral angle between the two mentioned planes of 89.3(1)°. The other aromatic ring cannot assume the same conformation with respect to the five-atom plane because of the steric hindrance of the ethyl group on the cyclohexene ring, thus resulting in a dihedral angle of 83.6(1)°.

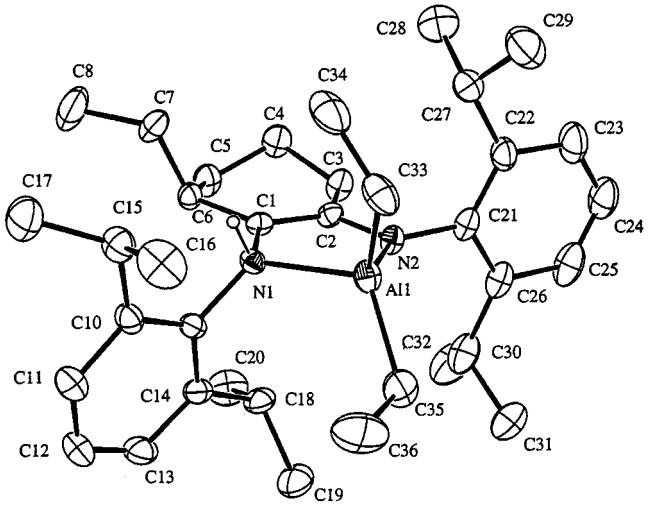

Figure 3. Molecular structure of **2**; thermal ellipsoids are drawn at 20% probability level; hydrogen atoms have been omitted for clarity, with the exception of the amine hydrogen atom

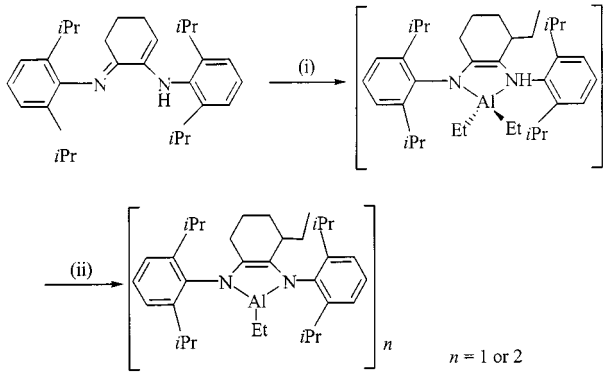
A reasonable reaction pathway leading to compound **2** involves 1,4-addition of AlEt$_3$ to the α,β-unsaturated imine, resulting in alkylation of the cyclohexene moiety of the ligand to give the diethylaluminium amido-amino complex **2**. Although we are not aware of similar reactions for α,β-unsaturated imines, there are many examples of this kind for α,β-unsaturated carbonyl derivatives. Addition of AlR$_2$I to enones, or addition of AlPh$_3$ to chalcone, for example, occurs in this manner almost quantitatively; with α,β-unsaturated ketones, in general, the 1,4-addition of AlR$_3$ can become the principal mode of reaction, and proceeds via initial coordination of the aluminium reagent at the carbonyl group.[17] We hypothesize that, also in our case, the coordination of the AlEt$_3$ is required prior to nucleophilic attack of the ethyl group to the ligand. Actually, the *pre*-coordination of the alkylaluminium compound to the iminic nitrogen atom should increase the electrophilic character of the β-unsaturated carbon atom on the cyclohexene ring, thus supporting the 1,4-addition. Moreover, it is well established that N,N-bidentate ligands, such as the closely related α-diimines, form initial complexes with trialkylaluminium in which only one N-atom is bonded to the aluminium centre.[18]

It is an open question why such a different behaviour is observed by just changing the alkyl group bound to Al from methyl to ethyl. It is, however, evident that the ligand can behave both as a Lewis acid and as a Brønsted acid, and actually nucleophilic addition is observed with AlEt$_3$, while AlMe$_3$ serves as a deprotonating agent.

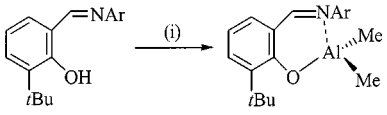
With the aim of obtaining the protodealumination product analogous to **1**, we performed the reaction of the ligand with $AlEt_3$ in refluxing toluene. Removal of volatiles in vacuo left a red oil, that, on the basis of ^1H and ^{13}C NMR analysis, was identified as the bis(amido)monoethylaluminium derivative, possibly derived by thermolysis of **2** by ethane elimination (Scheme 4). Comparing the ^1H NMR spectrum ([D_6]benzene, 25 °C) of the thermolysis product with the ligand spectrum, we noticed the lack of both the resonances of N*H* and =C*H* of the cyclohexene ring. On the other hand, diagnostic signals are a quadruplet at $\delta = 0.33$ (2 H) and a triplet at $\delta = 0.85$ (3 H) attributable to one ethyl group bound to the aluminium atom, and a triplet at $\delta = 0.57$ (3 H) for the CH_3CH$_2$− on the cyclohexene ring. We suppose that, at higher temperatures, the reaction generates first the 1,4-addition product **2**, which rapidly decomposes by ethane elimination resulting in the monoethyl derivative. We cannot determine if the compound is a monomer or a dimer; unfortunately, ^{27}Al NMR experiments were precluded by the probe signal noise.



Scheme 4. Reaction conditions: (i) $AlEt_3$, refluxing toluene; (ii) − C_2H_6

While the five-coordinate alkyl(Salen)group-13 complexes have been largely studied and used in many catalytic reactions,[19] only a few reports concerning the related lower coordinate dialkyl(salicylaldiminato)aluminium compounds have appeared in the literature.[10b,11] We have synthesized the dimethyl(salicylaldiminato)aluminium compounds **3** and **4**, and the perfluoro derivative **5** with the aim to test their reactivity in olefin polymerization. Actually, recent reports by Coates[20a] and by Fujita[20b] described titanium complexes carrying salicylaldiminato ligands with electron-withdrawing substituents that show increased activity in the polymerization of olefins.

Compounds **3**−**5** were prepared in good yields as yellow solids by treating the related ligand with $AlMe_3$ (1:1 ratio) in heptane at room temperature (Scheme 5). Reactions cleanly proceed by protodealumination of the Al−CH_3 bond with concomitant elimination of methane. Products were characterized by ^1H and ^{13}C NMR (room temperature, C_6D_6 solution), revealing similar features. The methyl groups bound to the aluminium atom show characteristic resonances at $\delta \approx -0.30$ in the ^1H NMR spectrum, and between $\delta = -8$ and -9 in the ^{13}C NMR spectrum. No differences were observed for the resonances of the *tert*-butyl substituent on the phenoxy group; for all the complexes the C(CH_3)$_3$ signal appeared at $\delta \approx 1.5$ in ^1H NMR spectrum, while the ^{13}C NMR resonances for *C*Me$_3$ and C*Me*$_3$ are shown at $\delta = 35.7$ and 29.8, respectively. Diagnostic signals for the imine function appear at $\delta \approx 7.5$ in the ^1H NMR spectrum, and between $\delta = 170$ and 180 in the ^{13}C NMR spectrum. Interestingly, in the ^1H NMR spectrum of **5**, the Al*Me* resonance appears as a triplet ($J = 1.4$ Hz), which is probably due to the coupling with the α-fluorine atoms of the C_6F_5 group.

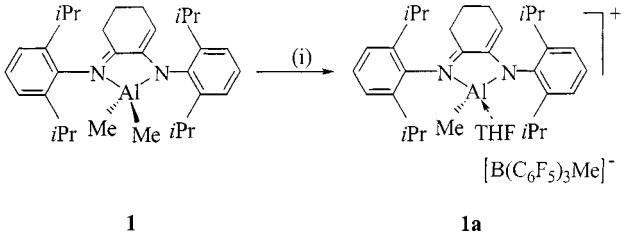


Scheme 5. Reaction conditions: (i) $AlMe_3$, heptane, room temperature

We have explored the generation of cationic complexes from the synthesized aluminium compounds by NMR tube reactions with $B(C_6F_5)_3$.

When **1** and $B(C_6F_5)_3$ are mixed in C_6D_6 at room temperature, a red oil precipitated, thus preventing NMR solution analysis. The reaction was consequently studied in CD_2Cl_2 solution. After in situ treatment of **1** with 0.5 equiv. of $B(C_6F_5)_3$, the ^1H NMR spectrum showed, in addition to the signals of the neutral dimethylaluminium starting compound, new resonances attributable to a mixture of organometallic species. Although the ^1H NMR spectrum's region relative to the ligand is quite complicated, the high-field region can be easily interpreted in terms of methyl abstraction by $B(C_6F_5)_3$. Diagnostic resonances are two singlets at $\delta = +0.45$ and -0.42, attributable, by comparison with the data reported in the literature, to the free anion $[MeB(C_6F_5)_3]^-$ [21] and to the methyl group bound to the aluminium cation $AlMe^+$, respectively.[9] Formation of $[MeB(C_6F_5)_3]^-$ was further confirmed by a resonance at $\delta = -15.4$ in the ^{11}B NMR spectrum. After addition of a further amount (0.5 equiv.) of $B(C_6F_5)_3$, the resonances of the neutral starting compound disappeared. Subsequently, ethylene was added to the NMR tube; monitoring of the reaction showed that ethylene was consumed. Attempts to isolate and better characterize the cationic species in the absence of bases were unsuccessful. Trapping of the cationic species was instead achieved in the presence of THF. When $B(C_6F_5)_3$ (1 equiv.) was added to a CD_2Cl_2 solution of **1** containing 1 equiv. of THF, the THF-coordinated methyl cation **1a** was formed (Scheme 6). Characteristic resonances are the signals at $\delta = -0.41$ for AlMe^+ (3 H) and at $\delta = 0.48$ (3 H) for B*Me* in the ^1H NMR spectrum; the corresponding ^{13}C NMR resonances appear at $\delta = -13.6$ and 10.3, respectively. As a consequence of the positive charge on the aluminium atom, the resonances of the ligand in the cationic species are shifted to lower field compared to the resonances of the neutral compound in the same solvent (CD_2Cl_2). For instance, the triplet of C*H*= in the cyclohex-

ene ring of the ligand moves from δ = 4.76 for compound **1** to δ = 5.61 for the cation **1a**. Moreover, a C_1 symmetry can be deduced by the number of signals relative to the isopropyl substituents on the aryl groups (i.e. four signals for C*H*Me$_2$ and eight doublets for CH*Me*$_2$). Ethylene (ca. 1.3 equiv.) was added in the NMR tube; reaction of the olefin with the cationic species did not take place under these conditions, as shown by the ^{1}H NMR spectrum. Further investigation is in progress to determine if polymerization of ethylene occurs under more severe conditions.



1 **1a**

Scheme 6. Reaction conditions: (i) B(C_6F_5)$_3$, THF in CD_2Cl_2

Attempts to generate clean cationic species from the amino-amide diethylaluminium compound **2** with B(C_6F_5)$_3$ were in vain; reactions always led to a mixture of species, even in the presence of THF.

Similar experiments were performed with the imino-phenoxide compounds **3** and **5**, giving analogous results. Thus, while reaction of **3** with B(C_6F_5)$_3$ in C_6D_6 gives a mixture of species, the cationic species {3-*t*Bu-2-(O)C_6H_3CH=N−C_6H_5}AlMe(THF)$^+$[MeB(C_6F_5)$_3$]$^-$ (**3a**) and {3-*t*Bu-2-(O)C_6H_3CH=N−C_6F_5}AlMe(THF)$^+$[MeB(C_6F_5)$_3$]$^-$ (**5a**) were instead obtained in the presence of THF in CD_2Cl_2 solution. The ^{1}H NMR spectrum of **3a** (CD_2Cl_2, room temperature) shows the Al*Me*$^+$ resonance at lower field in comparison with the resonance of the neutral one in the same solvent (δ = −0.15 vs. −0.82, respectively), as a consequence of the positive charge on the aluminium atom. Resonances relative to the imino-phenoxide ligand show an analogous shift; particularly, the C*H*=N signal moves from δ = 8.35 to 8.72. In addition, the aromatic hydrogen atom signals on the phenoxy group are split in a wider range (δ = 7.82−6.80). Signals for the THF coordinated to the aluminium atom appear at δ = 4.22 and 2.14 (OC*H*$_2$ and OCH$_2$C*H*$_2$, respectively). Our results parallel those of Gibson[11] for closely related (salicylaldiminato)aluminium compounds. As observed for the cationic complex **1a** (vide supra), ethylene does not polymerise appreciably under these conditions; aluminium species **3a** and **5a** are quite stable in CD_2Cl_2 solution.

It is worth noting that in all the examined cases, the broad ^{1}H NMR resonances for *Me*B(C_6F_5)$_3^-$ were observed in the range δ = 0.40−0.48, characteristic of the free anion,[21] thus suggesting that there are no relevant interactions between cation and anion, at least under the conditions used (this remark is further supported by the observed poor solubility of the cationic species in C_6D_6, compared to the high solubility of **1a**, **3a**, and **5a** in dichloromethane).

Preliminary polymerization tests were carried out for all the synthesized Al complexes. Toluene solutions of **3**, **4**, and **5**, when activated with 1 equiv. of B(C_6F_5)$_3$, polymerised ethylene (1 atm) to solid polyethylene with low activity [**3**: 400 g (PE) mol^{-1} h^{-1} atm^{-1}; **4**: 75 g (PE) mol^{-1} h^{-1} atm^{-1}; **5**: 200 g (PE) mol^{-1} h^{-1} atm^{-1}].

Compounds **1** and **2** were considerably less active; some solid polyethylene was obtained only in the presence of some added $AlMe_3$. A more detailed investigation of the polymerization activity of these Al derivatives after activation with different co-catalysts under more severe conditions is in progress.

Experimental Section

General: Manipulations of sensitive materials were carried out under dry nitrogen using Schlenk or glove-box techniques. Toluene, heptane, and THF were dried by reflux over sodium and benzophenone and distilled under nitrogen prior to use. $AlMe_3$ and $AlEt_3$ were purchased from Aldrich and used as received. The 1-(*o*,*o*′-diisopropylphenylamino)-6-(*o*,*o*′-diisopropylphenylimino)-cyclohexene,[12] the imino-phenoxide ligands,[22] and B(C_6F_5)$_3$ [21] were synthesized according to literature procedures. NMR spectra were recorded with a Bruker Advance 400 MHz spectrometer; chemical shifts were referenced to the residual protio impurities of the deuterated solvents. EI MS data were obtained with a Finnigan Thermoquest GCQ Plus 2000 spectrometer, using a direct exposure probe for compound **1** and **2**, and a direct insertion probe for compounds **3**, **4**, and **5**.

Preparation of Complexes

Complex 1: $AlMe_3$ (10.0 mL, 0.62 M in heptane, 6.2 mmol) was slowly added to a solution of 1-(*o*,*o*′-diisopropylphenylamino)-6-(*o*,*o*′-diisopropylphenylimino)cyclohexene (2.5 g, 6.8 mmol) in 20 mL of heptane at 0 °C with stirring. The orange solution was stirred at 0 °C for 1 h, at room temperature for additional 2 h and then was concentrated to 10 mL. Light orange crystals deposited overnight at −20 °C. Further crops were obtained by concentration and cooling of the mother liquor. Overall yield: 2.7 g (90%). Crystals of **1** suitable for an X-ray crystal structure determination were grown from toluene at −20 °C. ^{1}H NMR (400 MHz, C_6D_6, 293 K): δ = −0.37 [s, 6 H, Al(C*H*$_3$)$_2$], 0.96 [d, 6 H, CH(C*H*$_3$)$_3$], 1.27−1.28 [m, 14 H, CH(C*H*$_3$)$_2$ and N=C−CH$_2$C*H*$_2$CH$_2$)], 1.41 [d, 6 H, CH(C*H*$_3$)$_2$], 1.86 (q, 2 H, N=C−CH$_2$CH$_2$C*H*$_2$), 2.00 (t, 2 H, N=C−C*H*$_2$CH$_2$CH$_2$), 3.08 [sept, 2 H, C*H*(CH$_3$)$_2$], 3.68 [sept, 2 H, C*H*(CH$_3$)$_2$], 4.86 (t, 1 H, =C*H*), 7.03−7.28 (m, 6 H, Ar-*H*). ^{13}C NMR (C_6D_6, 293 K): δ = −8.0 [Al(*C*H$_3$)$_2$], 23.9 (N=C−CH$_2$*C*H$_2$CH$_2$), 25.4 (N=C−CH$_2$CH$_2$*C*H$_2$); 24.8, 25.3, 25.4, 26.2 [CH(*C*H$_3$)$_2$], 28.6, 28.8, [*C*H(CH$_3$)$_2$], 30.6 (N=C-*C*H$_2$CH$_2$CH$_2$); 113.8 (*C*H=C−N); 124.7, 125.2, 126.2, 128.4 (*meta* and *para* Ar), 146.8 (CH=*C*−N), 138.0, 141.5, 142.2, 147.6, (*ipso* and *ortho* Ar), 181.1 (*C*=N). Assignments were made using HMQC long-range experiments. EI MS (35 eV): *m*/*z* = 486, 487, 489 [M]$^+$, 471, 472, 473 [M − CH$_3$]$^+$.

Complex 2: $AlEt_3$ (6.0 mL, 1.1 M in heptane, 6.6 mmol) was slowly added to a solution of 1-(*o*,*o*′-diisopropylphenylamino)-6-(*o*,*o*′-diisopropylphenylimino)cyclohexene (2.5 g, 5.8 mmol) in 25 mL of heptane at 0 °C with stirring. The solution was stirred at 0 °C for 1 h and at room temperature for additional 3 h. The solvent was removed in vacuo, and the orange-red oil residue was dissolved in toluene (5 mL). Orange crystals deposited overnight at 0 °C. Yield: 2.4 g (75%). ^{1}H NMR (400 MHz, C_6D_6, 293 K): δ = 0.18 (dq, 2 H, $^3J_{H,H}$ = 8.1 Hz, CH$_3$C*H*$_2$Al), 0.28−0.52 (m, 2 H, CH′$_3$C*H*′$_2$Al),

0.62 (t, 3 H, $CHCH_2CH_3$), 0.90 (t, $^3J_{H,H}$ = 8.1 Hz, 3 H, CH_3CH_2Al), 1.2−1.6 [m, $CH(CH_3)_2$, $CH_2CH_2CH_2CHEt$, $CH_2CH_2CH_2CHEt$, $CHCH_2CH_3$ and $CH'_3CH'_2Al$ overlapping], 1.62−2.02 (m, br, 3 H, CHEt and $CH_2CH_2CH_2CHEt$), 3.27 [sept, 1 H, $CH(CH_3)_2$], 3.74 [sept, 2 H, $CH(CH_3)_2$], 3.96 [sept, 1 H, $CH(CH)_3$], 6.55 (s, 1 H, NH), 7.01−7.29 (m, 6 H, Ar-H). ^{13}C NMR (C_6D_6, 293 K): δ = −0.5 (br, $CH'_3CH'_2Al$ or CH_3CH_2Al), 0.9 (br, CH_3CH_2Al or $CH'_3CH'_2Al$), 9.0 ($CH'_3CH'_2Al$ or CH_3CH_2Al), 9.6 (CH_3CH_2Al or $CH'_3CH'_2Al$), 11.0 ($CHCH_2CH_3$), 18.9 ($CHCH_2CH_3$), 23.2, 24.3, 24.7, 25.0, 25.5, 25.6, 25.7, 26.1, $[CH(CH_3)_2]$, 26.0, 26.1, 26.4, (−CH_2− of cyclohexene), 26.9, 27.1, 27.9, 28.6, $[CH(CH_3)_3]$, 34.5 (CHEt), 108.9 (NC=CNH), 134.6 (NC=CNH), 123.8, 123.86, 123.91, 125.5, 126.0, 126.4 (*meta* and *para* Ar), 140.3, 140.8, 142.9, 147.4, 147.6, 147.8 (*ipso* and *ortho* Ar). Assignments were made using HMQC long-range experiments. EI MS (35 eV): *m*/*z* = 544, 545 $[M]^+$, 543, 544 $[M - H]^+$, 515, 516, 517 $[M - CH_3CH_2]^+$, 514, 515, 516 $[M - CH_3CH_3]^+$.

{[3-*t*Bu-2-(O)C_6H_3]CH=NC_6H_5}$AlMe_2$ (3): $AlMe_3$ solution (15.0 mL, 0.26 M in heptane, 4.0 mmol) was slowly added to a solution of 0.98 g of [3-*t*Bu-2-(OH)C_6H_3]CH=NC_6H_5 (3.9 mmol) in heptane (20 mL) at 0 °C. The reaction was allowed to warm to room temperature and stirred for 1 h. The solution was concentrated and stored at 0 °C, providing **3** as a yellow crystalline solid. Yield: 0. 85 g (71%). ^{1}H NMR (400 MHz, [D_8]toluene, 293 K): δ = −0.30 (s, 6 H, $AlCH_3$), 1.51 [(s, 9 H, $C(CH_3)_3$], 6.58 (t, 1 H, OAr-H), 6.62 (d, 1 H, OAr-H), 6.90−6.98 (m, 5 H, NAr-H), 7.38 (d, 1 H, OAr-H), 7.48 (s, 1 H, CH=N). ^{13}C NMR (C_6D_6, 293 K): δ = −8.4 (br, $AlCH_3$), 29.8 $[C(CH_3)_3]$, 35.7 $[C(CH_3)_3]$, 117.7, 120.4, 122.7, 130.1, 134.5, 135.3, 142.1, 147.4, 165.1, (Ar-C), 170.7 (CH=N). EI MS (35 eV): *m*/*z* = 294, 295 $[M - CH_3]^+$.

{[3-*t*Bu-2-(O)C_6H_3]CH=N(2,6-*i*$Pr_2C_6H_3$)}$AlMe_2$ (4): An $AlMe_3$ solution (10.0 mL, 0.25 M in heptane, 2.5 mmol) was slowly added to a solution of 0.75 g of [3-*t*Bu-2-(OH)C_6H_3]CH=N(2,6-*i*$Pr_2C_6H_3$) (2.2 mmol) in heptane (20 mL) at 0 °C. The reaction was allowed to warm to room temperature and stirred for 2 h. The volatiles were removed in vacuo affording a yellow oil that solidified upon standing one night at room temperature. Yield: 0.78 g (90%). ^{1}H NMR (400 MHz, C_6D_6, 293 K): δ = −0.27 (s, 6 H, $AlCH_3$), 0.81 [d, 6 H, $CH(CH_3)_2$], 1.19 [d, 6 H, $CH(CH_3)_2$], 1.54 [(s, 9 H, $C(CH_3)_3$], 3.13 [(sept, 2 H, $CH(CH_3)_2$], 6.60 (t, 1 H, OAr-H), 6.72 (d, 1 H, OAr-H), 7.00−7.12 (m, 3 H, NAr-H), 7.42 (d, 1 H, OAr-H), 7.82 (s, 1 H, CH=N). ^{13}C NMR (C_6D_6, 293 K): δ = −8.7 (br, $AlCH_3$), 23.0 and 26.2 $[CH(CH_3)_2]$, 28.8 $[CH(CH_3)_2]$, 29.8 $[C(CH_3)_3]$, 35.7 $[C(CH_3)_3]$, 118.1, 119.8, 124.9, 128.8, 134.1, 135.6, 142.4, 142.9, 143.1, 165.3, (Ar-C), 174.5 (CH=N). EI MS (35 eV): *m*/*z* = 393 $[M]^+$, 378, 379 $[M - CH_3]^+$.

{[3-*t*Bu-2-(O)C_6H_3]CH=NC_6F_5}$AlMe_2$ (5): This compound was prepared as above, using an $AlMe_3$ solution (10.0 mL, 0.25 M in heptane, 2.5 mmol) and 0.795 g of [3-*t*Bu-2-(OH)C_6H_3]CH=NC_6F_5 (2.3 mmol) in heptane (20 mL) at 0 °C. Yield: 0.79 g (86%). ^{1}H NMR (400 MHz, C_6D_6, 293 K): δ = −0.27 [t, 6 H, *J*(HF) = 1.4 Hz, $AlCH_3$], 1.46 [(s, 9 H, $C(CH_3)_3$], 6.53 (t, 1 H, OAr-H), 6.64 (d, 1 H, OAr-H), 7.28 (s, 1 H, CH=N), 7.40 (d, 1 H, OAr-H). ^{13}C NMR (C_6D_6, 293 K): δ = −9.74 (br, $AlCH_3$), 29.7 $[C(CH_3)_3]$, 35.7 $[C(CH_3)_3]$, 118.4, 119.7, 135.1, 137.5, 142.8, 166.8 (OAr-C), 177.3 (CH=N). EI MS (35 eV): *m*/*z* = 384 $[M - CH_3]^+$.

Thermolysis of Compound 2: $AlEt_3$ (10 mL, 0.22 M in heptane, 2.2 mmol) was quickly added to a solution of 1-(*o*,*o*′-diisopropylphenylamino)-6-(*o*,*o*′-diisopropylphenylimino)cyclohexene (0.800 g, 1.9 mmol) in 10 mL of toluene at room temperature and then heated under reflux for 2 h. Solvent and volatiles were removed in vacuo, leaving a red oil. ^{1}H NMR (400 MHz, C_6D_6, 293 K): δ = 0.33 (m, 2 H, CH_3CH_2Al), 0.57 (t, 3 H, CH_3CH_2−C), 0.84 (t, 3 H, CH_3CH_2Al), 1.10−1.30 [complex multiplet, $CH(CH_3)_2$ and CH_3CH_2C, overlapping, 26 H], 1.30−1.80 and 1.84−2.01 (three multiplets, CH_2 in the cyclohexene ring), 3.22 [sept, 1 H, $CH(CH_3)_2$], 3.48 [sept, 2 H, $CH(CH_3)_2$], 3.82 [sept, 1 H, $CH(CH_3)_2$], 7.16−7.18 (m, 6 H, Ar-H). ^{13}C NMR (C_6D_6, 293 K), selected resonances: δ = −0.4 (br, CH_3CH_2Al), 8.7 (CH_3CH_2Al), 12.8 ($CHCH_2CH_3$), 19.1 ($CHCH_2CH_3$), 22.7, 23.3, 23.4, 23.8, 25.8, 26.0, 26.9, 27.2 $[CH(CH_3)_2]$, 25.7, 26.4, 26.8 (−CH_2− of cyclohexene), 28.5, 28.8 $[CH(CH_3)_3]$, 34.1 (CHEt), 123.6, 123.9, 126.0, 126.3 (*meta* and *para* Ar), 140.2, 140.9 (NC=CN and NC=CN), 145.9, 146.6, 146.7, 147.2 (*ipso* and *ortho* Ar).

Generation of Cations

Complex 1a: Compound **1** (24 mg, 0.05 mmol) was dissolved in CD_2Cl_2 (0.5 mL). Dry THF (4.0 μL, 0.05 mmol) and $B(C_6F_5)_3$ (26 mg, 0.05 mmol) were sequentially added, and the resulting orange solution was analyzed by NMR spectroscopy at room temperature. ^{1}H NMR (400 MHz, 293 K): δ = −0.41 (s, 3 H, $AlCH_3$), 0.48 (br. s, 3 H, CH_3B), 0.83−1.38 [m, 24 H, $CH(CH_3)_2$], 1.72 −1.98 (m, 2 H, N=C−$CH_2CH_2CH_2$), 2.17 (m, br, 4 H, OCH_2CH_2), 2.50−2.60 [m, 5 H, N=C−$CH_2CH_2CH_2$, N=C−$CH_2CH_2CH_2$, $CH(CH_3)_2$, overlapping], 2.91 [sept, 1 H, $CH(CH_3)_2$], 3.11 [sept, 1 H, $CH(CH_3)_2$], 3.28 [sept, 1 H, $CH(CH_3)_2$], 4.25 (m, br, 4 H, OCH_2CH_2), 5.61 (t, 1 H, =CH), 7.15−7.50 (m, 6 H, Ar-H). ^{13}C NMR (293 K), selected resonances; cation: δ = −13.6 (br, $AlCH_3$), 23.6, 25.7, 30.7 (CH_2 of the cyclohexene ring), 23.7, 24.3, 24.5, 25.5, 25.9, 26.0 $[CH(CH_3)_2]$, 24.9, (OCH_2CH_2), 29.2, 29.6, 30.2 $[CH(CH_3)_2]$, 75.0 (OCH_2), 128.3 (CH=C−N), 123.9, 125.8, 126.0, 126.2, 127.6, 130.3 (*meta* and *para* Ar), 145.0 (CH=C−N), 134.7, 141.6, 142.3, 146.2, 147.0 (*ipso* and *ortho* Ar), 186.8 (C=N); anion: δ = 10.3 (br, BCH_3). Assignments were made using HMQC long-range experiments.

{[3-*t*Bu-2-(O)C_6H_3]CH=NC_6H_5}$AlMe(THF)^+[MeB(C_6F_5)_3]^-$ (3a): This compound was prepared as above by dissolving 15 mg of **5** (0.05 mmol) in CD_2Cl_2 (0.5 mL). Dry THF (4.0 μL, 0.05 mmol) and $B(C_6F_5)_3$ (26 mg, 0.05 mmol) were sequentially added, and the resulting yellow solution was analyzed by NMR spectroscopy at room temperature. ^{1}H NMR (400 MHz, 293 K): δ = −0.15 (s, 3 H, $AlCH_3$), 0.47 (br. s, 3 H, CH_3B), 1.51 [(s, 9 H, $C(CH_3)_3$], 2.14 (m, br, 4 H, OCH_2CH_2), 4.21 (m, br, 4 H, OCH_2CH_2), 7.06 (t, 1 H, OAr-H), 7.28 (d, 2 H, NAr-H), 7.45 (d, 1 H, OAr-H), 7.55−7.61 (m, 3 H, NAr-H), 7.81 (d, 1 H, OAr-H), 8.72 (s, 1 H, CH=N). ^{13}C NMR (293 K); cation: δ = −13.5 (br, $AlCH_3$), 25.9 (OCH_2CH_2), 29.6 $[C(CH_3)_3]$, 35.7 $[C(CH_3)_3]$, 75.8 (OCH_2), 120.0, 121.7, 122.3, 130.5, 131.7, 136.0, 139.1, 142.1, 144.3, 162.6 (all Ar-C), 175.8 (CH=N); anion: δ = 10.8 (br, BCH_3).

{[3-*t*Bu-2-(O)C_6H_3]CH=NC_6F_5}$AlMe(THF)^+[MeB(C_6F_5)_3]^-$ (5a): This compound was prepared as above by dissolving 20 mg of **5** (0.05 mmol) in CD_2Cl_2 (0.5 mL). Dry THF (4.0 μL, 0.05 mmol) and $B(C_6F_5)_3$ (26 mg, 0.05 mmol) were sequentially added, and the resulting yellow solution was analyzed by NMR spectroscopy at room temperature. ^{1}H NMR (400 MHz, 293 K): δ = −0.31 (s, 3 H, $AlCH_3$), 0.40 (br. s, 3 H, CH_3B), 1.45 [(s, 9 H, $C(CH_3)_3$], 2.21 (m, br, 4 H, OCH_2CH_2), 4.28 (m, br, 4 H, OCH_2CH_2), 7.12 (t, 1 H, OAr-H), 7.41 (d, 1 H, OAr-H), 7.93 (d, 1 H, OAr-H), 8.63 (s, 1 H, CH=N). ^{13}C NMR (293 K); cation: δ = −15.5 (br, $AlCH_3$), 25.8 (OCH_2CH_2), 29.7 $[C(CH_3)_3]$, 35.7 $[C(CH_3)_3]$, 76.0 (OCH_2), 118.4, 119.7, 135.1, 137.5, 142.8, 166.8, (OAr-C), 177.3 (CH=N); anion: δ = 10.2 (br, BCH_3).

Polymerization Tests: A typical polymerization test was carried out in a 100-mL glass flask charged under nitrogen with 20 mL of toluene and thermostated at 50 °C. The inert gas was replaced by ethylene at 1 atm, then 0.1 mmol of the proper aluminium complex and 0.1 mmol of $B(C_6F_5)_3$ (each dissolved in 2.0 mL of toluene) were injected into the flask. The flask was fed with constant monomer pressure, and after 15 min the reaction was stopped by injecting methanol. The mixture was poured into acidified methanol, and the polymer was recovered by filtration, washed with fresh methanol, and dried under vacuum.

X-ray Crystallography: Suitable crystals were selected and mounted in Lindemann capillaries under an inert gas. Diffraction data were measured at room temperature with a Rigaku AFC7S diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). Data reduction was performed with the crystallographic package TEXSAN.[23] No absorption correction was applied to the data. The structures were solved by direct methods using the program SIR92[24] and refined by means of full-matrix least squares based on F^2 using the program SHELXL93.[25] For compound **1**, half a molecule of toluene was located on an inversion centre. A rigid-body refinement was performed for the solvent molecule, assuming that two distinct molecules equally share the same site with opposite orientation, methyl group hydrogen atoms were assumed to be disordered over two sites rotated by 60° to each other. All non-hydrogen atoms excluding those belonging to the solvent molecule were refined anisotropically. For the disordered toluene molecule a unique displacement parameter was considered. Hydrogen atoms were positioned geometrically and included in structure factor calculations but not refined. Restraints were applied to the $CH-CH_3$ distance of the isopropyl groups. The presence of the disordered solvent molecule accounts for the low-quality structure refinements. For compound **2** all non-hydrogen atoms were refined anisotropically, hydrogen atoms were positioned geometrically and included in structure factor calculations but not refined. Crystal structures were drawn by means of the program ORTEP32.[26] Crystal data and refinement details for both compounds are reported in Table 2. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-168133 (**1**) and -168132 (**2**). Copies of data may be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 2. Crystal data and structure refinement details for compounds **1** and **2**

	1	**2**
Empirical formula	$C_{32}H_{47}N_2Al{\cdot}0.5C_7H_8$	$C_{36}H_{57}N_2Al$

Ring Closure Kinetics of Bidentate Hemilabile P,N and P,S Ligands on a Platinum(II) Complex

Raffaello Romeo,*[a] Luigi Monsu' Scolaro,[a,b] Maria Rosaria Plutino,[a] Andrea Romeo,[a] Francesco Nicolo',[a] and Alessandro Del Zotto[c]

Keywords: N,P ligands / Kinetics / Platinum / Hydrogen bonds / Chelate effect

Complexes of the type *cis*-[$PtPh_2(CO)(\eta^1$-P–N)] and *cis*-[$PtPh_2(CO)(\eta^1$-P–S)], where bidentate phosphorus–nitrogen and phosphorus–sulfur ligands are bound to the metal centre in a monodentate fashion [P–N = $Ph_2PC_5H_4N$ (Ph_2PPy), $Ph_2P(CH_2)_2C_5H_4N$ (ppye), $Ph_2P(o\text{-}C_6H_4)NMe_2$ ($PNMe_2$), $Ph_2P(CH_2)_nNMe_2$ (n = 2, 3, i.e., $peNMe_2$ and $ppNMe_2$) and P–S = $Ph_2P(CH_2)_2SEt$ (P–SEt), $Ph_2P(CH_2)_nSPh$ (n = 1, 2, i.e., P–CH_2SPh and P–SPh)], were prepared in situ by reaction of the hybrid ligands with *cis*-[$PtPh_2(CO)(SEt_2)$]. In each case, the first observed process was the fast substitution of diethyl sulfide by the phosphanyl group leading to the monosubstituted ring-open *cis*-[$PtPh_2(CO)(\eta^1$-P–X)] (X = N or S) complexes, which were characterised in solution by ^{1}H and $^{31}P\{^1H\}$ NMR spectroscopy. These initially formed species undergo a slow ring closure process with extrusion of carbon monoxide and formation of the chelate [$PtPh_2$(P–X)] products, except in the case of the short-bite Ph_2PPy and P–CH_2SPh ligands and of $ppNMe_2$, where ring closure was not observed. The chelate complexes were isolated as solids from the reaction of the ligands with *cis*-[$PtPh_2(Me_2SO)_2$]. A single-crystal X-ray diffractometric study of *cis*-[$PtPh_2$(P–SEt)] (**18**) was performed. The crystal packing showed linear chains originated by weak intermolecular Pt···H–C hydrogen bonding interactions. The chelation kinetics of P–X in the *cis*-[$PtPh_2(CO)(\eta^1$-P–X)] complexes have been monitored in [D]chloroform by ^{1}H and $^{31}P\{^1H\}$ NMR. The rates of ring closure were found to be strongly dependent on the nature (S or N) and steric hindrance of the chelating end of the monocoordinated bidentate P–X ligand, and on the size of the ring formed. In contrast, ring size plays a negligible role, if any, in the dechelation reactions of *cis*-[$PtPh_2$(S–S)] [S–S = 1,2-bis(phenylthio)ethane, dpte and 1,3-bis(phenylthio)propane, dptp] using diphosphanes (dppm and dppp) as reagents. These kinetic data, together with those of previous work, give useful insight into the factors controlling cyclisation reactions and the stability of the rings in square planar platinum(II) complexes.

Introduction

Factors affecting the ease of cyclisation of bifunctional organic chains, such as ring strain and the probability of end-to-end joining, have been well understood and recognised in physical organic chemistry, through detailed kinetic studies. At this stage they are at the basis of synthetic procedures in making rings of all sizes as well as macrocycles.[1,2] By contrast, in coordination or organometallic chemistry, kinetic studies on the formation of chelated rings are relatively scarce because of the difficulty of monitoring the rate of ring closure that, usually, is much faster than the rate of attack of the first end of the bidentate ligand on the metal centre. An old practice of overcoming this difficulty is to render the uncoordinated end of the ligand inactive by steric hindrance or protonation. This latter approach has been used with the formation of certain five- and six-membered chelated rings involving amino acids,[3] amino alcohols,[4] amino sulfides,[5] or diamines,[6−12] in platinum(II) complexes. The rate of ring closure can be modulated through an appropriate control of the acidity of the solution but, in most cases, it is not possible to separate the rate constant for ring closure from the acid dissociation constant of the protonated end of the ligand.

An alternative approach involves the generation in solution of coordinatively unsaturated species by photolysis, in the presence of a bidentate ligand L−L, as for $M(CO)_6$ (M = Cr, Mo, W) complexes.[13−18] The reaction involves photodissociation of one CO ligand to yield an extremely reactive $M(CO)_5$ species which captures L−L, leading to an $M(CO)_5(\eta^1$-L−L) intermediate with a monocoordinate bidentate ligand. Thereby, ring closure follows with loss of

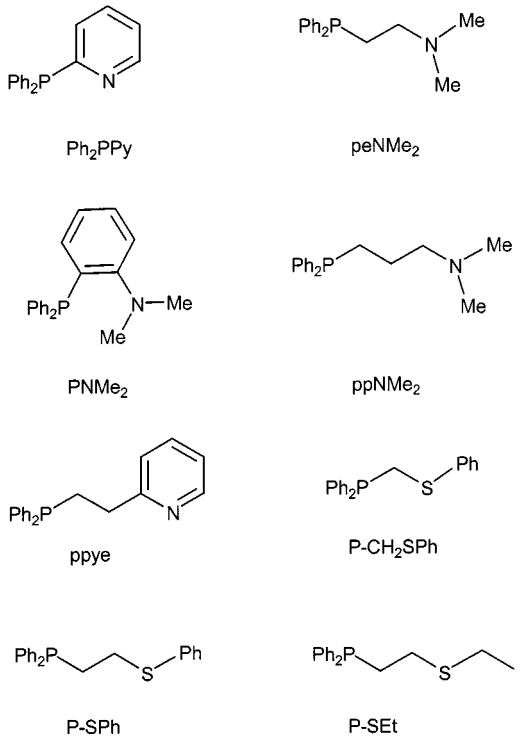
another CO ligand. If this latter process is too rapid, it is necessary to use flash photolysis techniques to initiate the kinetics.[19−24] In some cases the intimate nature of the thermal process was revealed by the determination of the volumes of activation.[20−24]

In the study of the reactivity of the complex *cis*-[$PtPh_2(CO)(SEt_2)$] (**1**) with pyridines[25] and amines[26] we became aware that this substrate contains a labile SEt_2 and a relatively inert CO ligand in the *trans* positions to the firmly bonded phenyl groups. The substrate showed a remarkable selectivity between the two nucleophilic ends of an unsymmetrical bidentate ligand, with a clear preference for the most basic and the less hindered end. Thus, we have exploited this property to prepare stable ring-open species such as *cis*-[$PtPh_2(CO)(\eta^1\text{-}NH_2(CH_2)_4NH_2)$] and *cis*-[$PtPh_2(CO)(\eta^1\text{-}NH_2(CH_2)_2NHPh)$] in solution, to intercept and characterise monocoordinate reaction intermediates of the type *cis*-[$PtPh_2(CO)(\eta^1\text{-}N-N)$] or *cis*-[$PtPh_2(CO)(\eta^1\text{-}P-P)$] in the reactions of this complex with diamines,[27] aminopyridines,[27] or diphosphanes,[28] and to identify the factors controlling the rates of their final conversion into the chelate products with extrusion of CO.

In this paper we have extended the study to so-called "hemilabile" ligands. New classes of unsymmetrical bidentate ligands (P−X) were recently developed and used in organometallic chemistry, which associate the phosphorus atom with donor atoms such as oxygen,[29] nitrogen[30] or sulfur.[31] Indeed it was expected, and it has often been observed, that the non-phosphorus donor X of the ligand is weakly coordinated in solution to the metal centre, generating potential catalytically active systems, by providing, under mild conditions, a vacant site for the coordination and activation of organic substrates. To complete the outline of reactivity of **1** we have chosen a series of hybrid ligands P−X of different chain length, bearing a diphenylphosphanyl group and a substituted sulfur or nitrogen atom of variable electronic and steric properties. The high lability of the SEt_2 group in the starting substrate, combined with the very high nucleophilic power of the phosphorus donor of the bidentate ligands, leads ineluctably to the rapid formation of *cis*-[$PtPh_2(CO)(\eta^1\text{-}P-X)$] and to a subsequent relatively slow ring closure to the final product [$PtPh_2(P-X)$]. The kinetics of ring closure of P−X ligands, together with those of dinitrogen and diphosphane ligands studied previously,[27,28] give a useful insight into the factors controlling these cyclization reactions and the stability of the rings in square-planar complexes.

thioether, a dimethylamino or a pyridyl function, characterised by different steric and electronic properties, and separated from the phosphorus atom by a backbone of variable length. The reaction takes place very rapidly at room temperature and produces the monosubstituted species in quantitative yield. The most interesting feature of this reaction concerns the selectivity of the nucleophilic site of attack of the unsymmetrical ligand that is invariably the phosphanyl group. The phosphorus atom enters the coordination sphere of the metal centre leaving the remaining nitrogen or sulfur atoms free. This is in line with the sequence of reactivity, phosphane[32] >> amine[26] > pyridine[25] of a monodentate ligand replacing SEt_2 from **1**, while the subsequent substitution of the carbonyl group takes place very slowly. Thus, the pattern of behaviour of the P−X ligands reflects the different nucleophilicity of the two donors (P and S or N) of the ligand. This peculiar selectivity of the substrate between the two ends of an unsymmetrical ligand was already shown in the reactions with dinitrogen ligands such as 2-(aminomethyl)pyridine and 2-(2-aminoethyl)-pyridine.[27]



Scheme 1

Results and Discussion

Synthesis and Structural Characterisation of the Complexes

Complexes *cis*-[$Pt(Ph)_2(CO)(\eta^1\text{-}P-X)$] (**4−11**), in which P−X acts as a *P*-bound monodentate ligand, were prepared in situ by treating equimolar amounts of ligand and complex **1**. Sketches of the heteronuclear ligands used are given in Scheme 1. The P−X unsymmetrical species contain on one side a diphenylphosphanyl group and on the other a

The complexes [$PtPh_2(SEt_2)]_2$ (**2**) and *cis*-[$PtPh_2(Me_2SO)_2$] (**3**) proved to be very useful synthons for the synthesis of chelate complexes. The addition of an equimolar amount of a P−X ligand to a dichloromethane solution of **3**, according to Equation (1) leads to the rapid substitution of both sulfoxide ligands, yielding chelate compounds in a pure crystalline form and in almost quantitative yield.

$$cis\text{-}[PtPh_2(Me_2SO)_2] + P{-}X \rightarrow cis\text{-}[PtPh_2(P{-}X)] + 2\ Me_2SO \quad (1)$$

In a similar fashion, these compounds were formed starting from the dinuclear complex **2**, in the presence of a moderate excess of SEt_2.The cyclization reaction failed in the case of the short-bite Ph_2PPy and $P{-}CH_2SPh$ ligands and also $ppNMe_2$, but was successful for the formation of the chelate *cis*-$[PtPh_2(S{-}S)]$ complexes, containing the dithioether ligands dpte (**12**) and dptp (**13**). The isolation of the chelate complexes as solid compounds allowed for their complete characterisation through ^1H and $^{31}P\{^1H\}$ NMR spectroscopy. The complexes **14**–**18** are characterised by the presence, on the coordination plane, of two phenyl groups in the mutual *cis* position and of a 5- or 6-membered ring, arising from the coordination of the hybrid chelating ligand.

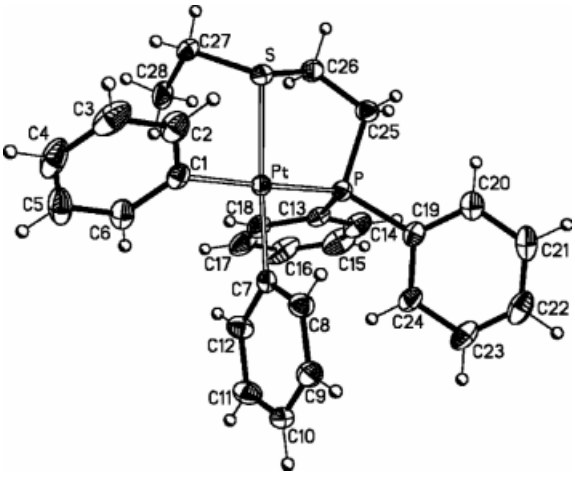


Figure 1. Perspective view and atom numbering scheme of one of the two equal complex units of compound **18**; thermal ellipsoids are drawn at 30% probability, while the H size is arbitrary

X-ray Structure of 18

The crystallographic asymmetric unit contains two independent molecules which are related by a pseudo two-fold screw axis 2_1 parallel to cell edge *a*. However, both are essentially identical structurally (Table 1) and one of them is illustrated in Figure 1. The main differences concern the arrangement of the phenyl groups. The η^1-phenyl rings are almost equally oriented with respect to the Pt coordination plane in the two complexes [53.1(2) vs. 52.8(2)° and 99.0(4) vs. 95.2(4)° for $C1_{Ph}$ and $C7_{Ph}$ planes, respectively] forming a reciprocal dihedral angle of 71.0(4) vs. 63.9(3)°. The same behaviour is exhibited by the phenyl groups of the diphenylphosphane fragment, with the $C13_{Ph}$ ring forming a dihedral angle of 79.2(2) vs. 66.1(3)° with the other $C19_{Ph}$ plane. The square-planar coordination around the two platinum atoms is almost identical and the geometric values are in agreement with those of other arylplatinum[26,33] and 1-(ethylthio)-2-(diphenylphosphanyl)ethane complexes.[31d,34] Both the two Pt–P and Pt–S bonds [mean length 2.280(3) and 2.352(2) Å, respectively] show a significant elongation caused by the strong *trans* influence of the η^1-phenyl acting as a powerful σ-donor, as already reported for the compound *cis*-$[PtPh_2(SMe_2)_2]$.[35] The chelating ligand forms a five-membered puckered ring with a bite angle of 85.97(7) vs. 86.30(8)°. The sulfur atoms display a tetrahedral arrangement acting as a stereogenic akyrotopic centre, but the solid state is a racemic mixture due to centrosymmetric space group.

The most interesting feature of the solid state is the presence of a weak nonconventional intermolecular hydrogen-bonding interaction between each platinum atom and the terminal methyl group of the diphenylphosphanyl ligand of the adjacent complexes (Figure 2). This interaction corresponds to a 3-centre-4-electron (3c-4e) model, the three centres being the C, H and Pt atoms and the four electrons belonging two each to the C–H bond and to the platinum d_z^2 orbital.[36] The two C–H···Pt interactions are almost equal [C(28)H···Pt = 2.94 vs. 2.88Å, C(28)···Pt = 3.68(1) vs. 3.680(8) Å, C(28)–H···Pt = 135 vs. 141°]. Despite the fairly high electron density available on the metal ion,[37] it seems that the Pt···H interaction is weak owing to the low electropositive character of the interacting hydrogen atom. This hydrogen interaction alternatively connects the two independent complexes of adjacent asymmetric units along the crystallographic axis *a*. The crystal packing is constituted by infinite columns parallel to *a* and interconnected by van der Waals interactions as a monodimensional polymer. The weakness of the hydrogen bond in the solid state precludes its existence in solution, as evidenced by the absence in the ^1H NMR spectrum of **18,** in $CDCl_3$, of upfield or downfield chemical shifts or of scalar ^1H-^{195}Pt couplings.

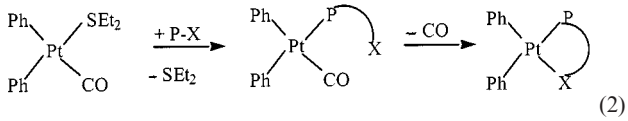
NMR Characterisation

Selected ^{1}H and ^{31}P{^{1}H} NMR resonances for ring-open and chelate compounds are given in Table 2. Within the chelate compounds **14−18** the average value of $^1J_{PtP}$ for the ^{31}P{^{1}H} signal is found at 1885 Hz, typical for a phosphorus atom *trans* to a σ-Pt−C bond.[28,32] A remarkable decrease of the $^1J_{PtP}$ coupling constant is found for the ring-open derivatives **4−11** ($^1J_{PtP}$ average value 1603 Hz). For those ligands (peNMe$_2$, PNMe$_2$, P−SPh and P−SEt) which form a 5-membered ring upon chelation, the coordination of the N or S donor is confirmed by the marked downfield shift of the δ^{31}P values. In fact, an increase of ca. 20 ppm is observed for the P−N ligands (in complexes **15** and **16**), while a higher Δδ (ca. 30 ppm) is found for the P−S ligands (in complexes **17** and **18**). These features are in accordance with the criterion proposed by Garrou for assessing chelation in the case of P-containing potentially chelating ligands.[38] Furthermore, the chemical shift values reported here for the P−S species are very close to that found for other Pt^{II} derivatives with the same ligands.[31e] Finally, chelation in compound **14** (where the ligand ppye forms a six-membered ring) is proved on the basis of the existence of a ^{195}Pt-^{1}H scalar coupling between the metal and a proton of the "far-from-P" side of the ligand. In fact, the H^6 nucleus of the pyridine ring at δ = 8.55 exhibits a $^3J_{PtH}$ coupling of 23 Hz, while conversely the same proton in the corresponding ring-open complex **5** exhibits no coupling.

Ring Closure Reactions

As described above, the formation of the chelate complexes occurs in two steps, according to Equation (2): (i) a fast formation of the ring-open species, on mixing equivalent amounts of complex and ligand, (ii) a subsequent slow ring closure. The course of the reaction can be effectively monitored in [D]chloroform by ^{1}H or ^{31}P{^{1}H} NMR spectroscopy, through the changes in intensity of appropriate signals.



(2)

Typical time-resolved NMR spectra for a kinetic run with ppye are shown in Figure 3. The mol fraction F = [**A**]/([**A**] + [**B**]) of the unchanged complex **A** was obtained by integration of the signals and the first-order rate constant k_c [s^{-1}] for ring closure was obtained from a nonlinear least-squares fit of the experimental data to $F = c_1 + c_2 \exp(-k_c t)$, with c_1, c_2, and k_c as the parameters to be optimised. A similar analysis can be performed using the mol fraction of the chelate product **B**. In order to account for the possible re-entry of carbon monoxide into the coordina-

Table 2. Selected ^{1}H and ^{31}P NMR spectroscopic data for ring-open *cis*-[Pt(Ph)$_2$(CO){η^1-(P−X)}] (numbers in square brackets) and chelate [PtPh$_2$(P−X)] complexes[a]

Dechelation Reactions

Complexes of the type [$PtPh_2$(S−S)] [S−S = dpte (**12**), dptp (**13**)] were easily prepared in high yield by reaction of **2** with the appropriate dithioether ligand S−S in dichloromethane at room temperature. Any attempt to prepare platinum(II) derivatives with shorter or longer S−S ligands [i.e. bis(phenylthio)methane and 1,4-bis(phenylthio)butane] failed, due to the instability of four- and seven-membered chelate rings. The analysis of the ^1H NMR spectral changes during the course of the reaction with diphosphane ligands (P−P = dppm, dppe, dppp) showed a single-stage conversion from the starting complex to the final chelate compound, according to Equation (3).

$$[PtPh_2(S\text{-}S)] \xrightarrow[+\ (P\text{-}P)]{k_{obs}} cis\text{-}[PtPh_2(\eta^1\text{-}S\text{-}S)(\eta^1\text{-}P\text{-}P)] \xrightarrow[-\ (S\text{-}S)]{fast} [PtPh_2(P\text{-}P)] \quad (3)$$

For example, the ^1H NMR spectrum of [$PtPh_2$(dpte)] in $CDCl_3$ at 298 K showed a broad singlet for the methylene protons (at $\delta = 3.03$; $^3J_{PtH} = 16.6$ Hz) and a doublet ($\delta = 7.38$; $^3J_{PtH} = 76$ Hz) in the aromatic region, relative to the *ortho*-protons of the coordinated phenyl rings. By addition of dppm, in an 1:1 ratio, these peaks begin to decrease in intensity and new signals appear which belong to [$PtPh_2$(dppm)] (methylene proton signals at $\delta = 4.36$), together with a sharp singlet at $\delta = 3.10$ of free dpte. The $^{31}P\{^1H\}$ NMR spectrum of the reaction product shows a singlet at $\delta = -37.6$ with platinum satellites of 1392 Hz, typical of the four-membered diphosphane chelate ring. The ^1H and $^{31}P\{^1H\}$ NMR spectra of the compound agree

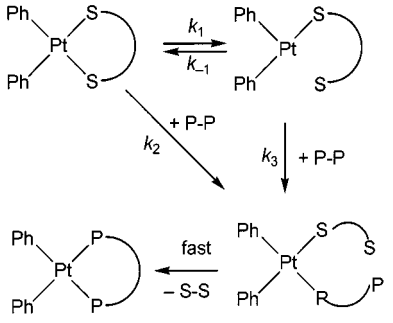
with its formulation as a diaryl(phosphanyl)platinum chelate complex.[28] No intermediate species were detected in solution during the reaction and addition of excess dppm does not significantly affect the reaction. The same behaviour was observed using dppe or dppp as reagents, with formation of the phosphane-chelated derivatives [$PtPh_2$(dppe)] and [$PtPh_2$(dppp)], respectively.

Reaction according to Equation (3) (P−P = dppm, dppp) was carried out under pseudo-first-order conditions in dichloromethane at 298.2 K, using spectrophotometric techniques. The kinetics were monitored by repetitive scanning of the spectrum at suitable times in the wavelength range 315−350 nm, where the absorbance of the free diphosphane ligand is negligible. The reactions went to completion, the final spectra being identical to those of authentic samples of [$PtPh_2$(P−P)] complexes.[28] Abstract factor analysis[40] of the spectral changes confirmed the presence of only two absorbing species in solution, i.e. the starting complex [$PtPh_2$(S−S)] and the final diphosphane product [$PtPh_2$(P−P)]. The pseudo-first-order rate constants k_{obs} calculated from the kinetic traces, are listed in the Supporting Information (Table SI1, see footnote on the first page of this article). On plotting k_{obs} as a function of the entering diphosphane concentration straight lines were obtained with a y axis intercept different from zero. Linear regression analysis applied to the rate data and fitted with the simple two-term Equation (4) gave the following values of the rate constants for the two systems: (i) for [$PtPh_2$(dpte)], $k_1 = (0.004 \pm 0.0008)\ s^{-1}$, $k_2 = (1.04 \pm 0.03)\ M^{-1}s^{-1}$ in the reaction with dppm, and $k_1 = (0.007 \pm 0.0001)\ s^{-1}$, $k_2 = (1.86 \pm 0.05)\ M^{-1}s^{-1}$ with dppp; (ii) for [$PtPh_2$(dptp)] $k_1 = (0.004 \pm 0.0008)\ s^{-1}$, $k_2 = (1.00 \pm 0.03)\ M^{-1}s^{-1}$ in the reaction with dppm.

$$k_{obs} = k_1 + k_2\,[\text{P-P}] \quad (4)$$

We know from previous studies[37] that complexes containing ligands with an array of donor atoms of the type *cis*-[Pt(C,C)(S,S)] (C = alkyl or aryl; S = thioether or sulfoxide) show a great propensity to undergo substitution of one sulfur ligand through a dissociative mechanism. The reasons for the observed behaviour are a combination of (i) ground-state destabilisation (lengthening of the Pt−S bond), (ii) increase of electron density at the metal centre preventing the approach of weak nucleophiles, and (iii) stabilisation of the coordinatively unsaturated three-coordinated intermediate. The most likely mechanism that can be envisaged for substitution reactions of the chelated [$PtPh_2$(S−S)] complexes, on the basis of the behaviour of strictly similar substrates containing monodentate thioethers,[41] is depicted in Scheme 2, and involves: (i) dissociative opening of the chelate S−S ring (k_1 path) to yield a ring-open three-coordinated 14-electron intermediate, (ii) competition for it between ring closure (k_{-1} path) and the attack of one end of the diphosphane ligand (via k_3) to form a doubly ring-open species and, (iii) final fast ring closure of P−P to yield the observed products. The pathway via k_2 represents the usual direct bimolecular attack of the nucleophile on the substrate. The rate law derived for this mechanism obeys Equation (5) which reduces to $k_{obs} = k_1 + k_2\,[\text{P−P}]$, when $k_{-1} << k_3\,[\text{P−P}]$.

$$k_{obs} = k_1 k_3\,[\text{P−P}]/(k_{-1} + k_3\,[\text{P−P}]) + k_2\,[\text{P-P}] \quad (5)$$



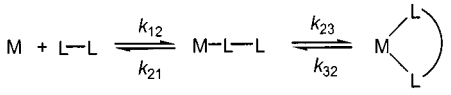
Scheme 2

Thus, the values derived for k_1 and k_2 represent the rate constants for ring opening upon dissociation of the Pt−S bond (k_1 [s^{-1}]) and upon bimolecular attack of the nucleophile (k_2 [$M^{-1}s^{-1}$]). The values of k_1 and k_2 derived for the two complexes do not show appreciable differences, indicating that both the pathways for dechelation (dissociative and associative) are hardly affected by the length of the ring (five- or six-membered).

The Chelate Effect

The formation constant of a metal−chelate complex is related to the rate constants of the separate bond-making and bond-breaking steps in Scheme 3 by the expression $K_f = k_1k_3/k_2k_4$. For octahedral systems, such as Co^{III} and Ni^{II} chelates, there is increasing evidence indicating that the processes of metal−ligand bond formation (k_1 and k_3) and loss of a monodentate ligand (k_2) hardly affect the stability of the chelate. An unexpected slowness of the ring-opening reaction (k_4) accounts for the high formation constant of the chelates,[42] while the effect has traditionally been associated with a high chelate ring-closing rate constant (k_3). Two different explanations have been given to account for the slowness of this dissociatively activated pathway (k_4). For ethylendiamine complexes of relatively small ions, Funahashi et al.[43] have proposed that the elongation of the M−N separation, along the coordinate reaction, forces the metal−nitrogen−carbon (M−N−C) angle to decrease, thus increasing the energy involved in the formation of the transition state. In the case of a monodentate amine such angular distortion around the leaving nitrogen donor is absent. Very recently, Blackman, Clark et al.[44] have given an alternative explanation for the much slower rate of chelate ring-opening in $[Co(cyclen)(diamine)]^{3+}$ compared to the loss of NH_3 from $[Co(cyclen)(NH_3)_2]^{3+}$, based on the reduced ability of the former system to allow the bond angle expansion required to produce the S_N1CB trigonal-bipyramidal intermediate. Formation of the latter from the conjugated base $[Co(cyclen\text{-}H)(diamine)]^{2+}$ requires expansion

of the bond angles in the equatorial plane from ca. 90° to 120°, and the in-plane bidentate ligand will hinder this expansion, while the loss of NH_3 from $[Co(cyclen-H)(NH_3)_2]^{2+}$ is not restricted in this way. Clearly, the energy barrier for the rate-determining Co−N bond cleavage and the formation of the dissociative five-coordinate intermediate is increased by the structural restriction imposed by the retention of the diamine chelate character.



Scheme 3

The mechanistic picture for ring opening and closure in a square-planar complex appears to be much simpler than that of an octhaedral complex, since both processes (k_3 and k_4) are characterised by an associative mode of activation. We have shown above that the rates of dechelation of 5- and 6-membered rings in the complexes $[PtPh_2(S-S)]$ (S−S = dpte, dptp) have very similar values. This is in line with the results of previous studies showing that the rate constants for ring opening of complexes of the type $[Pt(Me_2SO)(N-N)Cl]^+$ (N−N = en, tn, bn) do not differ significantly from one complex to another.[10] The same complexes, in their ring-open $[Pt(Me_2SO)(N-NH)Cl_2]^+$ protonated forms, showed a marked dependence of the rate of ring closure on the ring size. The same strong dependence on ring size characterises the ring-closing kinetics of *trans*-$[PtCl_2(NH_3)(N-NH)]^+$.[12] Therefore, as for the relationships between the formation constant of square-planar complexes and the size of the chelate ring, it is possible to conclude that the rates of ring closure (k_3) have a dominant effect while ring opening (k_4) makes a relatively small contribution. The formation of 4-membered rings is hindered by ring strain and the formation of large rings (7- or 8-membered rings) must compete with other reaction pathways, in particular with the possibility of obtaining dinuclear or polynuclear species. In this context, it is interesting to mention the results of a recent work on chelation kinetics of bidentate phosphane ligands on five-coordinate $[Ru(CO)_4(\eta^1\text{-}P-P)]$ complexes, where the rates of ring closing (10^4 k_{obs}/s^{-1} at 60 °C, in *n*-heptane) are as follows: dppm (11.2), dppe (4.44), dppp (6.73), dppb (5.75). This stands in striking contrast with the strong dependence of the rates on ring size observed for the square-planar $[PtPh_2(CO)(\eta^1\text{-}P-P)]$ complexes (Table 3 and ref.[28]).

The nucleophilic power of the uncoordinated end of the chelating ligand is also a factor of major importance in controlling the rates of ring closure (k_3), as suggested by the data collected in Table 3. The differences in reactivity are the same as those found in the n^0_{Pt} nucleophilicity scale which controls the rates of bimolecular substitution reactions on platinum(II).[45] An attractive example comes from the comparison of the rates of ring closure by dppp, ppye, and $ppNMe_2$ with a 6-membered ring. As a matter of fact, the difference of velocity between dppp and ppye encompasses at least five orders of magnitude, in line with the much greater nucleophilicity of PPh_2 compared to pyridine. In the case of $ppNMe_2$, steric congestion brought about by alkyl substitution on the donor nitrogen atom impedes ring closure.

The opposite role of k_3 and k_4 in octahedral and square-planar complexes stems from the different mode of activation (dissociative vs. associative). In light of the above considerations, elongation of the ring combined with the use of a weak donor atom at one end of the chelating ligand, would be a way of increasing the "hemilability" of hybrid ligands in square-planar complexes and their possible efficiency as catalysts.

Experimental Section

General Procedures and Chemicals: All solvents were dried according to standard procedures by distillation under oxygen-free nitrogen from appropriate drying agents (i.e. dichloromethane from barium oxide and diethyl ether from sodium benzophenone ketyl). Spectrophotometric grade dichloromethane was dried by distillation, degassed by several freeze-pump-thaw cycles and then stored over activated 4-Å molecular sieves. $CDCl_3$ was purchased from Cambridge Isotopes Laboratories (D 99.8%). Solid phosphane ligands (Aldrich Chemical Co) triphenylphosphane (PPh_3), bis(diphenylphosphanyl)methane (dppm), and 1,3-bis(diphenylphosphanyl)propane (dppp) were recrystallized from ethanol. 1,2-Bis(phenylthio)ethane (dpte), and 1,3-bis(phenylthio)propane (dptp) were recrystallized from toluene before use. 2-(Diphenylphosphanyl)pyridine (PPh_2Py) was purchased from Aldrich. The other bidentate hybrid ligands P−X {1-(diphenylphosphanyl)-2-(pyrid-2-yl)ethane (ppye),[46] 1-(dimethylamino)-2-(diphenylphosphanyl)-ethane ($peNMe_2$),[47] 1-(dimethylamino)-3-(diphenylphosphanyl)-propane ($ppNMe_2$),[47] [*o*-(dimethylamino)phenyl]diphenylphosphane ($PNMe_2$),[48] 1-(diphenylphosphanyl)-2-(thioethyl)-ethane (P−SEt),[49] 1-(diphenylphosphanyl)-2-(thiophenyl)-ethane (P−SPh),[49] (diphenylphosphanyl)(thiophenyl)methane ($P-CH_2SPh$)[50]} were prepared according to published methods.

Instrumentation: ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded at 298 K with a Bruker AMX R-300 spectrometer operating with a broad-band probe at 300.13 and 121.50 MHz for ^1H and ^{31}P nuclei, respectively. Chemical shifts (δ) refer to $SiMe_4$ for ^1H and to external H_3PO_4 (85%) for $^{31}P\{^1H\}$ NMR. The temperature within the NMR tube was calibrated by use of the ethylene glycole method.[51] UV/Vis data were collected with a rapid-scanning Hewlett−Packard Model 8452 A spectrophotometer. Infrared spectra were recorded in dichloromethane solution using a Perkin−Elmer FT-IR model 1730 spectrometer. Microanalysis was performed by Redox Analytical Laboratories, Milan, Italy.

X-ray Data Collection and Structure Refinement of 18: Crystal data: $C_{28}H_{29}PPtS$ (623.63), monoclinic, $P2_1/c$ (no. 14), a = 12.230(3), b = 24.911(3), c = 16.493(2) Å, β = 90.789(15)°, V = 5025(1) $Å^3$, Z = 8, $D_{calcd.}$ = 1.649 Mg/m^3, $F(000)$ = 2448, μ (Mo-K_α) = 5.745 mm^{-1}, $R1$ = 0.044/0.070 and $wR2$ = 0.098/0.112 for 7123/9763 observed [$I > 2\sigma(I)$]/all independent reflections, GOF = 1.024. Air-stable, pale yellow crystals of **18** were obtained by slow diffusion of *n*-hexane into a concentrated dichloromethane solution of the complex. For the data collection, a prismatic single crystal (0.33 × 0.25 × 0.10 mm) was mounted on a Siemens P4 automated four-circle single-crystal diffractometer and measured with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). 12164

reflections were collected using the ω/2θ scan technique up to 2θ = 52°. No crystal decay was detected from the check reflections monitored every 197 measurements. Intensities were evaluated by profile fitting of a 96-steps peak scan among 2θ shells procedure[52] and then corrected for Lorentz polarisation effects. Absorption correction was applied by fitting a pseudo-ellipsoid to the azimuthal scan data of 20 suitable reflections with high χ angles.[53] Data collection and reduction were performed by XSCANS[54] and SHELXTL[55] packages. The accurate evaluation of the data set excluded the orthorhombic crystal system. The structure was solved by a combination of standard Direct Methods[56] and Fourier synthesis, and refined by minimising the function $\Sigma w(F_o^2 - F_c^2)^2$ with the full-matrix least-squares technique based on all 9763 independent F^2 [R(int) = 0.0284], by using SHELXL97.[57] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the model refinement among the "riding model" method with the X−H bond geometry and isotropic displacement parameter depending on the parent atom X. An empirical extinction parameter was included in the last refinement cycles. The last difference map showed the largest electron density residuals within 1 Å from the platinum atoms (max/min values 1.657/−1.437 eÅ^{-3}). The final geometrical calculations and drawings were carried out with the PARST program[58] and the XPW utility of the Siemens package, respectively.[59]

Synthesis of Complexes: The complexes *cis*-[$PtPh_2(CO)(SEt_2)$] (**1**),[60] [$PtPh_2(SEt_2)]_2$ (**2**),[60] and *cis*-[$PtPh_2(dmso)_2$] (**3**),[61] were synthesised according to literature methods. Complexes in which the heteronuclear P−X ligands are bound to the metal ion in a monodentate fashion were formed upon mixing equimolar amounts of complex **1** and of the appropriate ligand in $CDCl_3$ solution, taking advantage of the slow rate of ring closure. These reaction intermediates have been characterised in situ by ^{1}H and $^{31}P\{^1H\}$ NMR spectroscopy (T = 298 K).

***cis*-[$PtPh_2(\eta^1$-$Ph_2PPy)$(CO)] (4):** ^{1}H NMR($CDCl_3$): δ = 6.57 (m, 1 H), 6.65 (m, 2 H), 6.83 (m, 1 H, H^3-py), 6.90 (m, 1 H), 7.04 (m, 2 H), 7.13 (m, 1 H, H^5-py), 7.27 (m, 1 H, H^4-py), 7.53−7.44 (m, 14 H), 8.83 (m, 1 H, H^6-py).$^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 20.1 ($^1J_{PtP}$ = 1636 Hz). Chelate complexes with both dithioethers and hybrid P−X ligands were prepared by adding a stoichiometric amount of the ligand to compound **2** or **3** in dichloromethane solution. The compounds were precipitated in an almost quantitative yield by adding diethyl ether or *n*-hexane (1:1, v/v) and cooling to −30 °C. The off-white solids were washed with cold *n*-hexane and air-dried.

[$PtPh_2$(dpte)] (12): ^{1}H NMR ($CDCl_3$): δ = 3.03 (br. s, $^3J_{PtH}$ = 16.6 Hz, 4 H, CH_2−S), 6.81 (m, 2 H, H^4), 6.90 (dd, $^3J_{av}$ = 6.6, $^4J_{PtH}$ = 12.0 Hz, 4 H, $H^{3,5}$), 7.38 (d, $^3J_{H,H}$ = 6.6, $^3J_{PtH}$ = 76.0 Hz, 4 H, $H^{2,6}$), 7.41 (m, 6 H, $H^{m,m'}$ + H^p Ph−S), 8.00 (m, $^3J_{H,H}$ = 6.6, $^4J_{H,H}$ = 2.2 Hz, 4 H, $H_{o,o'}$ Ph−S). Kinetics

NMR Measurements: The ring-closure reactions were initiated as follows: $6{\cdot}10^{-3}$ mmol of the hemilabile ligand was dissolved in $CDCl_3$ (0.3 mL) in a 5-mm NMR tube which was immersed in a liquid nitrogen bath. After a few minutes, a [D]chloroform solution of *cis*-[$PtPh_2(CO)(SEt_2)$] ($6{\cdot}10^{-3}$ mmol, 0.2 mL) was added over the frozen solution of the ligand and the NMR tube was cooled again to allow the complex solution to freeze over that of the ligand. Then, the NMR tube was rapidly inserted into the probe of the spectrometer thermostated at 298 K. ^1H or $^{31}P\{^1H\}$ NMR spectra were recorded, immediately after the sample temperature reached an equilibrium value (i.e. stable lock signal), and at subsequent appropriate time intervals. The first recorded spectrum only showed signals relative to free sulfide at $\delta = 2.57$ and 1.27 and to the ring-open *cis*-[$Pt(Ph)_2(CO)(\eta^1$-P−X)] complex, indicating that the displacement of SEt_2 from **1** by the phosphorus end of all the bidentate ligands is too fast at 298 K to be monitored by ^1H NMR spectroscopy. The ring-closure process was followed by monitoring the decrease in intensity of the ^1H or $^{31}P\{^1H\}$ signals associated with the amount of unchanged *cis*-[$PtPh_2(CO)(\eta^1$-P−X)] and the matching increase of the signals due to the final chelate [$PtPh_2$(P−X)] product. Care was taken to choose well-defined and not overlapping resonances for the kinetic analysis (selected values of the chemical shifts and of the ^{195}Pt coupling constants for ring-open and chelate complexes are reported in Table 2. The peaks monitored during the kinetic runs are marked in bold).

UV/Vis Measurements: The reactions of ring opening of the chelate complexes *cis*-[$Pt(Ph)_2$(S−S)] (S−S = dpte and dptb) by dppm and dppp were carried out in CH_2Cl_2 at 298 K, with various concentrations of diphosphane. The kinetics were started by mixing known pre-thermostated volumes of complex and diphosphane solutions, located in a tandem quartz cell (1 cm path length), in the cell compartment of the spectrophotometer. The use of at least a tenfold excess of nucleophile over the complex ensured pseudo-first-order kinetics in all runs. The kinetics were usually followed over four half-lives by monitoring the spectral changes at suitable times. Rate constants were determined using ProFit (Cherwell Scientific Publishing Limited) data analysis software by fitting absorbance data to $A_t = A_\infty + (A_0 - A_\infty)\exp(-k_{obs}\,t)$ with A_0, A_∞, and k_{obs} as the parameters to be optimized (A_0 = absorbance after mixing of reagents, A_∞ = absorbance at completion of the reaction).

Acknowledgments

We are grateful to the Ministero dell'Universitá e della Ricerca Scientifica e Tecnologica (MURST), Programmi di Ricerca Scientifica di Rilevante Interesse Nazionale, Cofinanziamento 2000−2002, to Messina and Udine Universities and CNR for funding this work.

Activation and Functionalization of Vinylic C−F Bonds by Transition Metal Compounds: The Factors Determining Reactions between Nucleophiles and a (Perfluorovinyl)diiron(I) Complex; Syntheses of Diiron Derivatives Containing New C−N, C−S, C−H and C−O Bonds

Karine Guennou de Cadenet,[a] René Rumin,[a] François Y. Pétillon,*[a] Dmitri S. Yufit,[b] and Kenneth W. Muir*[b]

Keywords: C−F activation / C−N, C−S coupling / Carbenes / Nucleophiles / Vinyl complexes

The reactions between alcohols ROH (R = Me, Et) and $RR(OH)_2$ (RR = CH_2–CH_2) and the [perfluoro(sulfanyl)vinyl]-diiron complex [{$Fe(CO)_3$}$_2${μ-C(SMe)(CF_3)$C_\beta C_\alpha F_2$}] (**1**) in THF at room temperature involve substitution at the C_α atom to give new (alkoxymethylene)thiaferracyclobutadiene compounds [{$Fe(CO)_3$}$_2${μ-S(Me)C(CF_3)$C_\beta C_\alpha$(OR)$_2$}] [R = Me (**2a**), Et (**2b**); RR = CH_2CH_2 (**2c**)]. Treatment of **1** with aniline and (methoxycarbonyl)hydrazine, bases of intermediate strength according to Pearson, produces α,β-substituted thiaferracyclopentadiene [{$Fe(CO)_3$}$_2${μ-S(Me)C(CF_3)C_β(NHR)C_α-(NHR)}] [R = Ph (**5a**), NHC(O)OMe (**5b**)] complexes. It is suggested that these compounds form through initial nucleophilic attack at C_α to give the zwitterionic intermediate [{$Fe(CO)_3$}$_2${μ-S(Me)C(CF_3)CC(NRH)$_2$}] (**f**). Thermally induced C–F bond activation is a feature of these reactions. When **1** reacts with thioamides containing three "hard" competitive primary and secondary amine functions and one "soft" thione function, the nucleophile first attacks at C_α through a secondary amine and, in a second step, at C_β through the thiol function to give α,β adducts [{$Fe(CO)_3$}$_2${μ-S(Me)C(CF_3)C_βSC(=NR^2)N(R^1)C_α(C_β–C_α)}] [R^1 = NH_2, R^2 = CH_3 (**6a**); R^1 = CH_3, R^2 = H (**6b**); R^1 = R^2 = CH_3 (**6c**)] possessing novel iminothiazolidine systems fused to the five-membered metallacyclic ring. Treatment of **1** with acetylhydrazine, which has three "hard" nucleophilic functions, results in the formation of the compound [{$Fe(CO)_3$}$_2${μ-S(Me)C(CF_3)C(H)$C_{(10)}$NNC(Me)O($C_{(10)}$–O)}] (**7a**), in which an oxadiazole function is fused to the thiaazaferracyclohexene ring. The position of the fluorine substituent on the $C_\alpha C_\beta C_\gamma$($CF_3$)S(Me) ring of ferracyclopentadiene complexes has been found to be the essential factor determining the specific activation of the C–F bond. A single fluoro substituent attached to the β-carbon atom of the chain can be activated by nucleophiles to give α,β adducts [{$Fe(CO)_3$}$_2${μ-S(Me)C(CF_3)C_β(X)C_α(NRR′)}] [X = OR″, R = R′ = R″ = Me (**3a**); X = OR″, R = R″ = Me, R′ = C(O)NMe_2 (**3b**); X = SR″ (**4**)]. In contrast, complexes in which a single fluorine atom is linked to the α-carbon atom do not undergo C–F bond cleavage reactions. X-ray structures of compounds **2a**, **3b**, **5a**, **5b**, **6a** and **7a** are reported.

Introduction

C−F activation reactions induced by transition metal compounds are of salient importance in organometallic chemistry. They are involved in many of the catalytic transformations that result in the formation of new carbon−heteroatom bonds and they are an essential feature of the synthesis of partially fluorinated molecules.[1] The recent upsurge of interest in (perfluorovinyl)metal complexes also stems from the observation that the chemical properties of these compounds differ substantially from those of their hydrocarbon analogues.[2] Although vinyl fluorides are normally inert, in some cases they undergo unexpected C−F cleavage reactions with nucleophilic agents to give either substituted vinyl derivatives[2] or new organofluorine compounds with unusual functional groups.[3,4]

In this context we have previously described the reaction between the [perfluoro(sulfanyl)vinyl]diiron(I) compound [{$Fe(CO)_3$}$_2${μ-C(SMe)(CF_3)$C_\beta C_\alpha F_2$}] (**1**) and primary and secondary amines, thiols, phosphanes and tertiary phosphanes. Analysis of the reaction products showed that soft nucleophiles (phosphanes, tertiary phosphanes, thiols) react at C_β to give thiaferracyclopentadiene compounds of types **D**, **E** or **F**[4b,4c] (Scheme 1), whereas hard nucleophiles (primary and secondary amines) react at C_α to give either monofluorothiaferracyclopentadiene complexes of type **A** when stoichiometric amounts of nucleophile are used, or thiaferracyclobutene compounds of type **C** when excess nucleophile is employed[4a,4d] (Scheme 1). These results imply

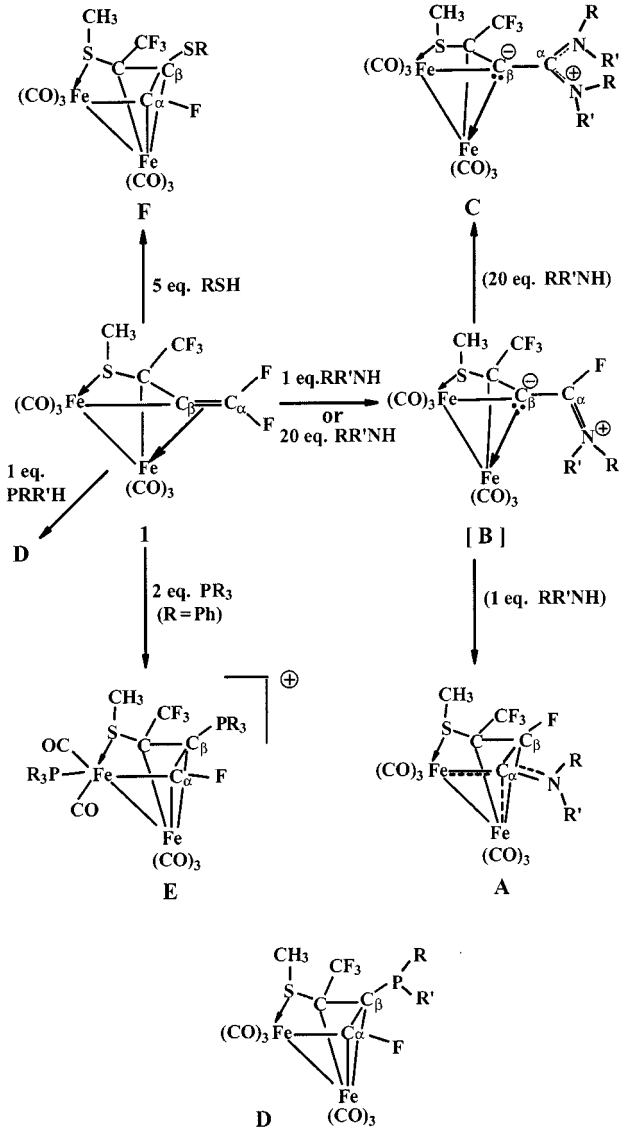
that soft nucleophiles activate only one C−F bond whereas hard bases activate both C−F bonds, resulting either in a 1,2-transfer of F onto C_β or in further addition of nucleophile.



Scheme 1

Perhaps our most striking result from these earlier studies of the reactions of nucleophiles with **1** was that the C−F activation step depended on whether the attacking nucleophile was hard or soft.[4] We have therefore become interested in reactions between **1** and such nucleophiles as alcohols and aniline. These are still hard bases according to Pearson's concept,[5] but are nevertheless thought to be softer than most aliphatic amines. We have also investigated the addition of multifunctional amines to **1**, in order to see whether the reaction of the iron compound with one function influences the reactivity of the others. Moreover, as an extension of our earlier studies of the reactions between nucleophiles and **1**,[4] we have investigated the dependence of the C−F bond activation on the position of the fluorine atoms in the carbon chain of the vinylic ligand.[6] Here we report these various reactions and the characterisation of the resulting products.

Results and Discussion

Analytical data and mass, infrared and multinuclear (^{1}H, ^{19}F and ^{13}C) NMR spectroscopic data for all new compounds discussed in this paper are given in Table 1. Selected bond lengths for **2a**, **3b**, **5a**, **5b**, **6a** and **7a** are compared in Table 2. All these structures contain rather similar $Fe_2(CO)_6$ units, in which the single Fe−Fe bond is bridged in various ways by a six-electron donor $MeSC(CF_3)C_\beta C_\alpha$ ligand. Apart from **7a**, the Fe−Fe distances are in the narrow 2.60−2.65 Å range, with a mean of 2.634 Å. Further spectroscopic and structural details are presented in the Exp. Sect. and in figure captions.

1. Reactions between [{Fe(CO)$_3$}$_2${μ-C(SMe)(CF$_3$)C−CF$_2$}] (1) and Alcohols ROH (R = CH$_3$, C$_2$H$_5$) and RR(OH)$_2$ (RR = CH$_2$−CH$_2$)

Synthesis and Spectroscopic Characterisation

The reactions between **1** and alcohols depend markedly on the solvent. Treatment of **1** with a large excess of alcohol in THF at room temperature results in the quantitative formation of the (alkoxymethylene)thiaferracyclobutene compounds **2** (Scheme 2). When the reaction is carried out in CH_2Cl_2, it is necessary to heat the solution to 60 °C to obtain the same products. The regiochemistry observed in the reaction is consistent with the known hard base character of alcohols: they are expected to react at C_α like amines,[4d] which are even harder nucleophiles than alcohols.

The molecular structure of **2a** was established by X-ray diffraction (see below). It is clearly apparent from the NMR spectroscopic data in Table 1 that complexes **2a** and **2b** have the same basic structure. Both mass spectra have molecular ions corresponding to replacement of the two fluorine atoms of **1** by two alkoxide groups. The ^{13}C NMR spectra of **2a**, **2b** and the parent complex **1** are very similar, each showing two resonances at $\delta \approx 120$ and 160 in the range expected for vinylic carbon atoms σ- and π-bonded to metal atoms. The mass spectrum of **2c** shows a molecular ion peak corresponding to a complex in which two fluorine atoms have been replaced by one molecule of ethylene glycol. The most significant difference between **2c** and **2a** or **2b** occurs in the ^{13}C NMR spectra, and particularly in the region associated with the carbon atom (C_β) directly bound to the two iron atoms. The $^{13}C_\beta$ signal of **2c** appears at $\delta = 85.6$, whereas those of **2a** and **2b** occur at $\delta = 124.0$ and 116.2, respectively, indicating a difference in the bridging mode of the vinyl ligand. However, the ^{13}C NMR spectra of **2c** and **C**[4d] (Table 1) are very similar, strongly suggesting that **2c** in solution adopts mainly the zwitterionic form depicted in Scheme 2, whereas **2a** and **2b** adopt a neutral structure closely related to that of the parent compound **1**. The highfield shifting of the C_β resonance of **2c**

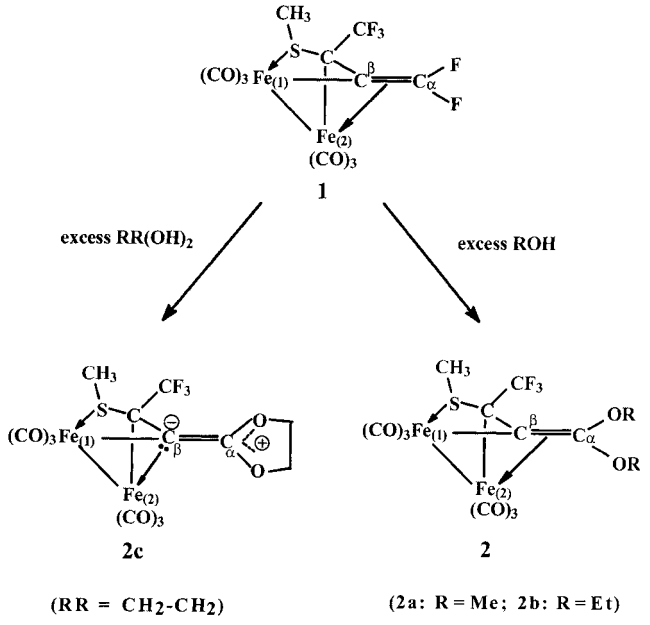

Scheme 2. Synthesis and proposed structures of complexes **2**

relative to that of **2a** and **2b** may be a consequence of the presence of negative charge on this carbon in **2c**.

Single-Crystal X-ray Analysis of 2a

Crystals suitable for X-ray diffraction were grown from a solution of **2a** in dichloromethane and hexane at −20 °C. The molecular structure of **2a** (Figure 1, Table 2) is broadly consistent with that deduced from the spectra (Scheme 2, Table 1). It is formally derived from **1** by replacement of both fluoro substituents by methoxide groups to give a six-electron donor $MeSC_\gamma(CF_3)C_\beta C_\alpha(OMe)_2$ ligand. This process obviously involves the cleavage of two C−F bonds. Iron atom Fe(1) is incorporated in an $Fe(1)S(1)C_\gamma C_\beta$ thiaferracyclobutene ring, linking to Fe(2) through a normal Fe−Fe bond. Fe(2) interacts weakly with C_α [Fe(2)−C(10) 2.347(2) Å], strongly with C_β [Fe(2)−C(9) 1.973(2) Å] and slightly less strongly with C_γ [Fe(2)−C(8) 2.039(2) Å]. Atom Fe(2) and the $C_\gamma-C_\beta-C_\alpha$ chain define a rather distorted (π-allyl)Fe substructure; this view is consistent with the $C_\delta-C_\gamma-C_\beta-C_\alpha$ and other torsion angles (Figure 1, caption) and with the $C_\alpha-C_\beta$ and $C_\beta-C_\gamma$ distances [1.384(3) and 1.441(3) Å], which may reflect the asymmetry in the Fe(2)−C distances [for comparison, average Fe−C(allyl) and C−C(allyl) distances are 2.07 and 1.404 Å and C−C bond lengths of 1.369(9) − 1.391(4) Å have been reported in μ_2-η^1:η^2-vinyl derivatives[7a,8]]. The Fe−C distances in **2a** are also broadly in agreement with those that we found in the C=C=CN*t*Bu derivative [{Fe(CO)$_3$}$_2$-{μ-C_β[C(CF$_3$)(SMe)]C_α(N*t*Bu)}] [Fe(2)−C_β 2.004(4), Fe(1)−C_β 1.970(3), Fe(2)−C_α 2.465(4) Å[4a]]. Finally, we note that C_β is nearly equidistant from the two metal atoms and that both Fe−C_β distances are within the range typical of iron−carbene bonds.[4b,4c,7b] The ^{13}C NMR spectrum of **2a** in solution shows a highfield resonance for the C_β carbon atom at δ = 124.0, in sharp contrast with the bridging C_α carbon atoms of thiaferracyclopentadiene compounds, which have carbene-like character and which give rise to lowfield resonances at δ ≈ 224.[4b,4c]

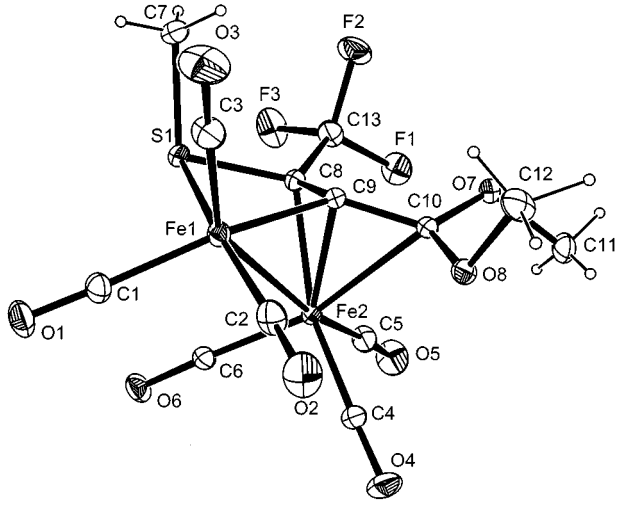

Figure 1. Molecular structure and numbering scheme of compound **2a** in the crystal; here and elsewhere 20% probability ellipsoids are shown for non-hydrogen atoms; selected bond lengths [Å] and angles [°]: O(7)−C(10) 1.352(3), O(7)−C(11) 1.437(3), O(8)−C(10) 1.356(3), O(8)−C(12) 1.446(3); C(8)−C(9)−C(10)−O(7) 38.8, C(8)−C(9)−C(10)−O(8) −161.7(2), and C(13)−C(8)−C(9)−C(10) −43.9(3)

Fluxional Behaviour of Compound 2 and Mechanistic Considerations

Spectroscopic data indicate that **2** is present as a single species in solution (Table 1 and Exp. Sect.). The fluxional solution behaviour of the ligands in **2a** and **2c** was examined by variable temperature $^{13}C\{^1H\}$ NMR studies, and typical results for **2a** in the OMe region between 195 and 270 K are presented in Figure 2. Limiting ^{13}C NMR spectra in the methyl or methylene regions consistent with structures **2a** and **2c** were obtained at 195 and 183 K, respectively. Two resonances in each spectrum are visible at these temperatures, indicating that the two OCH_3 (**2a**) and the two OCH_2 groups (**2c**) are inequivalent. As the temperature is raised from 183 to 270 K, these two signals broaden and coalesce into a single resonance, at 230 K (δ ≈ 59.3) for **2a** and 270 K (δ ≈ 68.9) for **2c**, the chemical shift of which is the weighted average of those of the two methyl or methylene groups in the limiting spectra. The activation barriers of the observed dynamic processes, estimated from the chemical shift difference ($\Delta\nu$) and coalescence temperature (T_c [9]) of the OCH_3 and CH_2 signals, are presented in Table 3. The most obvious route to high-temperature equivalence of the two OCH_3 or OCH_2 groups is rotary motion around the $C_\alpha-C_\beta$ axis. However, rotation about such a multiple bond [$C_\alpha-C_\beta$ 1.384(3) Å in **2a**] would seem at first sight to require an activation energy higher than those estimated for **2a** and **2c** (Table 3). A more elaborate explanation for the fluxionality involves a flip of the π-allyl system from Fe(2) to Fe(1). This would require simultaneous transfer of the Fe(1)−S bond to Fe(2) and of the Fe(2)−C_α and

Fe(2)−C_γ bonds to Fe(1). Both Fe−C_β bonds are conserved, so that C_β momentarily has sp^3 hybridisation (Scheme 3), which permits free rotation about C_α−C_β and averaging of the OR groups attached to C_α, as well as of the CO environments at Fe(1) and Fe(2).

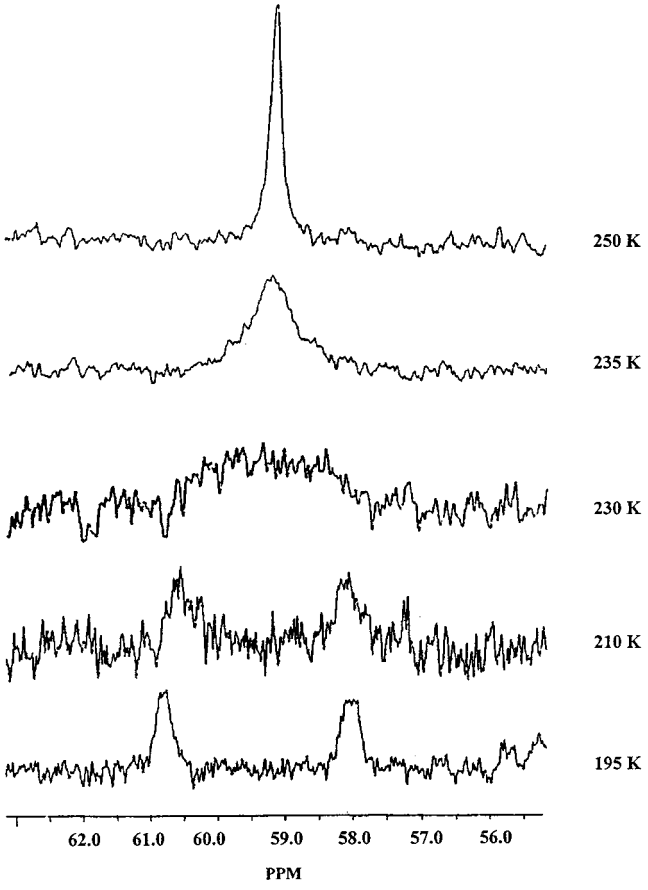

Figure 2. Variable-temperature $^{13}C\{^1H\}$ NMR spectra in the methyl region of **2a** in CD_2Cl_2

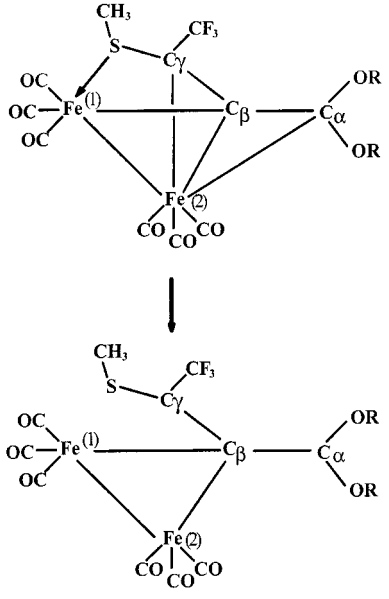
The $^{13}C\{^1H\}$ NMR spectra of **2a** and **2c** in the carbonyl region are also temperature-dependent; the low-temperature resonances are averaged as the temperature is increased. The spectrum of **2c** in the CO region between 183 and 298 K is presented in Figure 3 as an example. At 183 K, the spectra of **2a** and **2c** both show six singlets of equal intensity, but three of them are broad. On the basis of previous data for the parent fluorovinyl complex **1**,[6] we tentatively assign the broad resonances to the CO groups coordinated to Fe(1) and the three sharper singlets to the carbonyl groups attached to Fe(2). As the temperature is increased, the three signals assigned to the carbonyl groups bound to Fe(1) broaden still further and finally collapse at 213 and 250 K for **2c** and **2a**, respectively. At still higher temperatures, the signals for the three Fe(2)-bound carbonyl groups broaden and collapse, at about 240 K for **2a** and 270 K for **2c**, to a single broad resonance. Above 270 K the lines again sharpen, producing high-temperature spectra that consist of two singlets at 298 K. All these changes were found to be reversible. These observations indicate that all the carbonyl ligands take part in local CO exchange processes on the two iron atoms. The low values of the energy barriers associated with these site exchanges (Table 3) are roughly of the order expected for localised scrambling of the carbonyl groups on metal atoms.[10] The observed exchange of carbonyl groups at Fe(1) involves scission of only two bonds, whereas localised exchange at Fe(2) requires the rupture of at least three. Since Fe(2) is bonded to both C_α and C_β, it is perhaps to be expected that the energy barriers associated with scrambling of the R substituents in C_β−$C_\alpha(OR)_2$ and those associated with carbonyl exchange at Fe(2) are very similar (Table 3). It is also worth noting



Scheme 3

Table 3. Dynamic $^{13}C\{^1H\}$ NMR spectroscopic data

Compd.	Resonance	T_c [K][a]	Δν [Hz][b]	$\Delta G^{\ddagger}_{T_c}$ [kJ mol^{-1}][c]

that the higher-energy process concerns CO movement at Fe(1) in **2a** but at Fe(2) in **2c**, which may indicate that the coordination modes of the $C_\beta-C_\alpha(OR)_2$ ligands to the iron atoms differ in **2a** and **2c**.

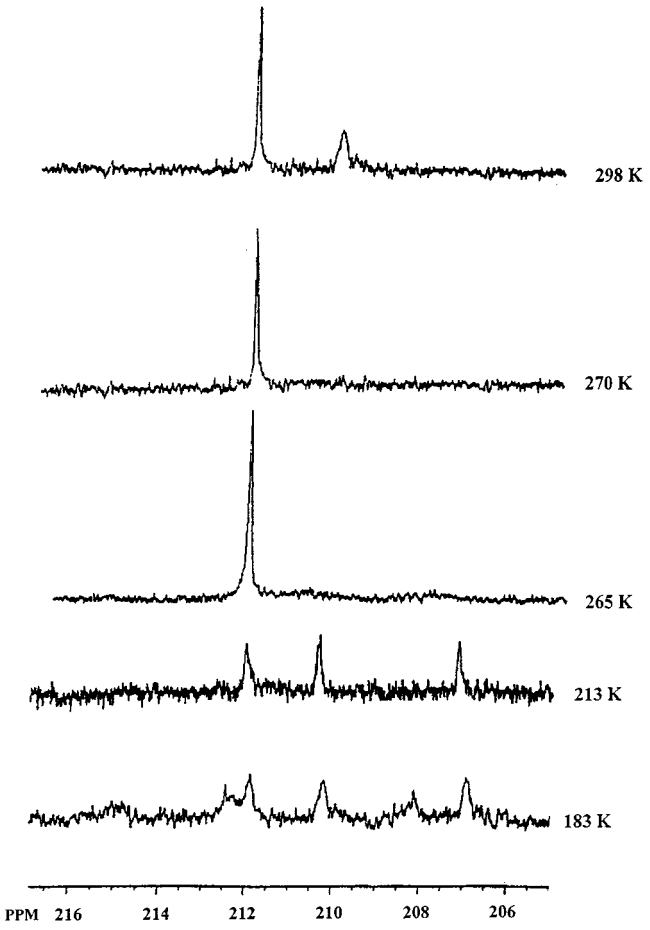

Figure 3. Variable-temperature $^{13}C\{^1H\}$ NMR spectra in the carbonyl region of **2c**, in CD_2C1_2

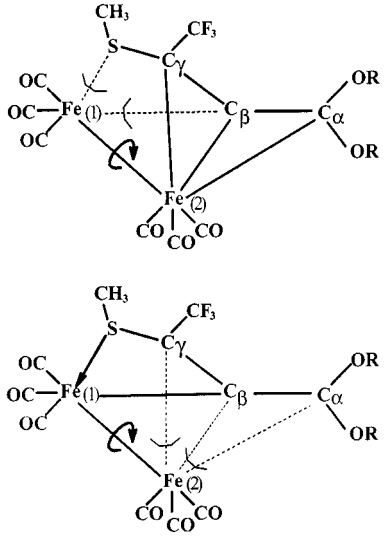


As mentioned above, the reactions between **1** and excess alcohol depend critically on the conditions; both the nature of the alcohol and that of the solvent greatly influence the reaction rates. Thus, in THF at room temperature, the reactions of **1** with methanol, ethanol and ethylene glycol were complete in 2, 3 and 5 h, respectively. The same reactions in dichloromethane were very slow at room temperature and heating was necessary to provide acceptable yields of **2**. Evidently, the solvent is involved in the mechanism of the reaction between **1** and a large excess of alcohol. Monitoring of the reaction of **1** with 40 equiv. of methanol in $[D_8]$THF by ^{19}F NMR at room temperature showed the gradual disappearance of **1** and the formation of several fluoro intermediates, **2a** being the last in this sequence. As the reaction proceeded, several fluoro complexes were present together in solution, giving rise to complicated ^{19}F NMR patterns from which it was difficult to identify the intermediates. Since the reaction depends markedly upon the nature of the solvent, it probably involves a transient, THF-containing intermediate. There is evidence that such a species plays a role in the reaction between **1** and Me_2NH.[4d]

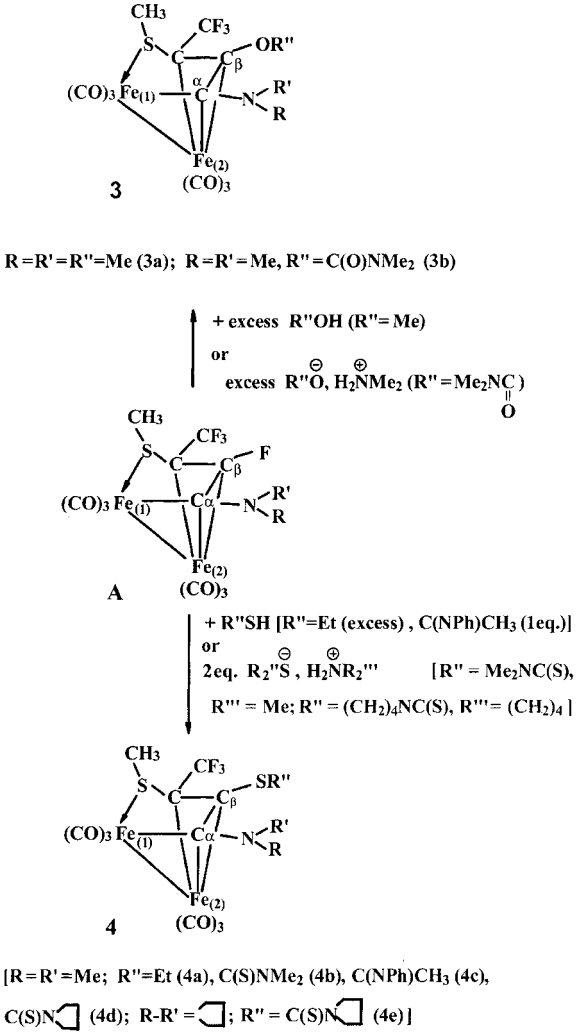
2. Reactions between Monofluorothiaferracyclopentadiene Compounds of Types A, D and F and Nucleophiles

Synthesis and Spectroscopic Characterisation of Complexes 3 and 4

We have previously shown that hard nucleophiles (Nu) such as amines react with the (perfluorovinyl)diiron complex **1**, $[\{Fe(CO)_3\}_2\{\mu\text{-}CC(SMe)(CF_3)C_\beta C_\alpha F_2\}]$, by attack at C_α, activating both vinylic C−F bonds, to give only α adducts containing either a thiaferracyclopentadiene $Fe(1)C_\alpha(Nu)C_\beta(F)C(CF_3)S(Me)$ ring (compounds of type **A**) or a thiaferracyclobutene $Fe(1)S(Me)C(CF_3)C_\beta\text{-}\{C_\alpha(NRR')_2\}$ ring.[4d] In contrast, soft nucleophiles (Nu) (phosphanes, tertiary phosphanes, thiols) react only at C_β, activating only one vinylic C−F bond to give β adducts containing a thiaferracyclopentadiene $Fe(1)C_\alpha(F)C_\beta(Nu)\text{-}CCF_3)S(Me)$ ring (compounds of type **D** or **F**).[4c] It was therefore of interest to see how hard and soft nucleophiles activate the C−F bonds in monofluoro complexes of types **A**, **D** and **F**.

Accordingly, the aminofluorothiaferracyclopentadiene complex **A** (R = R′ = Me) in dichloromethane was treated with large excesses of either methanol or dimethylammonium dimethylcarbamate. The alkoxythiaferracyclopentadiene complexes **3a** and **3b** were formed quantitatively as red or orange microcrystalline solids, respectively (Scheme 4). Soft nucleophiles, such as thiols and dialkylammonium dialkyldithiocarbamates, also react with **A** in dichloromethane to afford high yields of new complexes **4a**−**4e** as orange or red crystalline solids (Scheme 4). Evidently, addition of both hard and soft nucleophiles to **A** results in activation and cleavage of the $C_\beta-F$ bond.

However, treatment of **D** and **F** with nucleophiles, both soft (thiols, phosphanes) and hard (methanol, primary and secondary amines), in dichloromethane produced no reac-



Scheme 4. Synthesis and proposed structures of complexes **3**−**4**

tion (Scheme 5). It thus appears that the vinylic C−F bond is unreactive towards nucleophiles when the fluorine atom is bound to C_α of a *mono*fluorothiaferracyclopentadiene derivative.

It is clearly apparent from the NMR spectroscopic data in Table 1 that the product compounds **3** have the same basic structure as their parent complex **A**. The ^{19}F and ^{13}C NMR spectra are consistent with the formation of **3** from **A** by rupture of the C_β−F bond and replacement of the fluorine atom by an alkoxy group. The $^{13}C\{^1H\}$ NMR spectra contain quadruplets indicative of coupling to a CF_3 group at δ = 189.1 (**3a**) and 198.6 (**3b**); these chemical shifts and the very small $^{13}C-^{19}F$ coupling constant, $^4J_{C,F}$ = 2 Hz, are consistent with the carbon atom responsible being positioned α to Fe(1) in the Fe(1)$C_\alpha C_\beta C_\gamma(CF_3)$S(Me) ring. The assignments of the other quaternary carbon atoms of the thiaferracyclopentadiene ring were then made on the basis of their observed $^{13}C-^{19}F$ coupling constants and chemical shifts. In the highfield regions of **3a** and **3b**, quadruplets at δ = 54.0 ($^2J_{C,F}$ = 34 Hz) and 51.9 ($^2J_{C,F}$ = 35 Hz) were found for the carbon atoms of the $C(CF_3)$ unit. The singlet resonances at δ = 122.5 (**3a**) and 102.0 (**3b**) are attributable to C_β, since a similar chemical shift was observed for the C_β atom (δ = 120.0) in the parent complex **A**. Signals due to the methoxide group were observed at δ = 59.9 in the ^{13}C NMR spectrum and δ = 3.66 in the ^1H NMR spectrum of **3a**. A lowfield resonance at δ = 154.7 in the ^{13}C NMR spectrum of **3b** was assigned to the carbonyl group of the dimethylcarbamoyl unit; the medium band at $\tilde{\nu}$ = 1725 cm^{-1} in the IR spectrum of **3b** is consistent with this attribution.

All compounds **4** may easily be identified from their mass and NMR spectra and elemental analyses. The upper parts of their mass spectra are characterised by the molecular ion peak $[M]^+$ and ion peaks of the sequence $[M^+ - nCO]$ (n = 1−6). The close similarities between the NMR spectra of **4** and those of complex **F**[4c] (Table 1) strongly suggest that all six compounds contain the same Fe(1)C(X)C(SR)$C(CF_3)$S(Me) ring (X = F or NRR′) π-bonded to an $Fe(CO)_3$. It is worth noting that in the ^{13}C NMR spectra the signals of the β-carbon atoms of the thiolato complexes **4** appeared at higher field ($\Delta\bar{\delta}$ = 37) than the corresponding signals from the alkoxo compounds **3**. This highfield shift is consistent with linkage of C_β to the "soft" polarizable sulfur atom rather than the "hard" oxygen nucleophile. In the lowfield part of the $^{13}C\{^1H\}$ NMR spectra of **4b**, **4d** and **4e**, resonances typical of the thiocarbamate groups occur at δ = 197.3, 192.6 and 194.9, respectively.

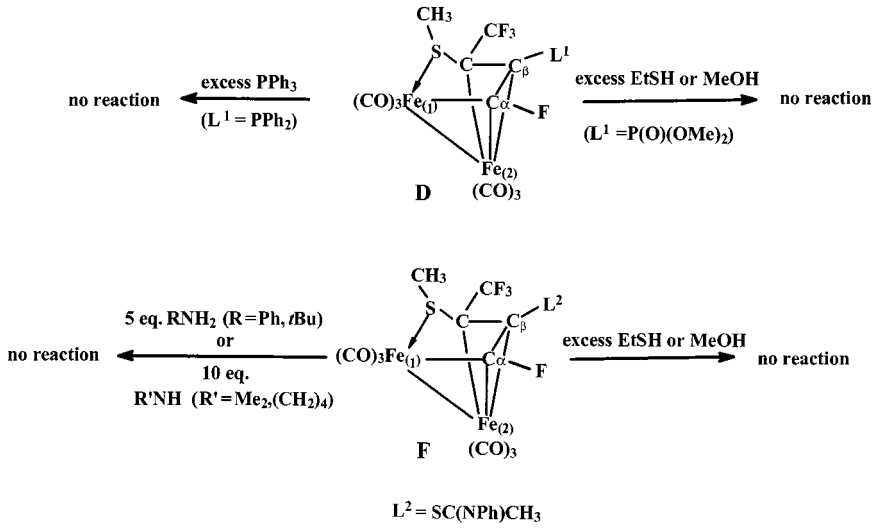
Single-Crystal X-ray Analysis of 3b

The solid-state structure of **3b** (Table 2, Figure 4) fully confirms the conclusions drawn from the solution spectra and is qualitatively similar to that of the parent complex **A**[4a] in that it contains a metallated, butadiene-like Fe(1)=C_α(11)−C_β(10)=C_γ(8) unit π-bonded to Fe(2), the Fe(2)−C_α bond being especially weak. However, as in the parent complex, there is extensive electron delocalization along the Fe(1)=C_α−C_β=C_γ chain, as shown by the sequence of distances [2.000(6), 1.415(8) and 1.431(8)/1.997(6), 1.428(8) and 1.469(8) Å] in the two independent molecules. The Fe(1)−C_α bonds in **3b** are the longest in Table 2, suggesting that C_α here has only a small amount of carbene-like character;[4b,4c,7] this is consistent with the comparatively highfield resonance (δ = 198.6) attributable to this carbon atom in the $^{13}C\{^1H\}$ NMR spectrum. The $C_\alpha-C_\beta-C_\gamma-C_\delta$ torsion angles in **3b** [−171.0(6) and −168.9(6)°] are typical of the values in thiaferracyclopentadiene complexes and contrast with that in **2a** [−43.9(3)°], which presumably resembles the value in the parent complex **1.**

3. Reactions between Compound 1 and Primary Aromatic and Multifunctional Amines

Synthesis of Complexes 5

We have shown that C−F bonds in **1** can be activated by primary[4a] and secondary[4b] monoamines, which have similar basicities according to Pearson.[5] These reactions



Scheme 5. Reaction of **D** and **F** species with nucleophiles

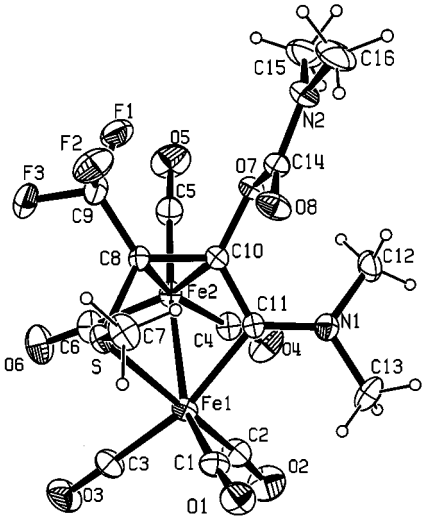


Figure 4. The structure of one of the two independent molecules of **3b** in the crystal; throughout this paper a common atom numbering system has been used for crystallographically independent molecules; selected bond lengths [Å] and angles [°]: O(7)−C(14) 1.369(8)/1.377(7), O(7)−C(10) 1.418(7)/1.405(6), O(8)−C(14) 1.217(8)/1.198(7), N(1)−C(11) 1.356(8)/1.345(7), N(1)−C(13) 1.448(8)/1.450(9), N(1)−C(12) 1.477(9)/1.478(8), N(2)−C(14) 1.332(9)/1.341(8), N(2)−C(15) 1.469(11)/1.441(9), N(2)−C(16) 1.462(10)/1.453(9); C(14)−O(7)−C(10)−C(11) 80.3(8)/75.2(8), C(12)−N(1)−C(11)−C(10) 20.8(10)/19.0(9), C(11)−C(10)−C(8)−C(9) −171.0(6)/−168.9(6)

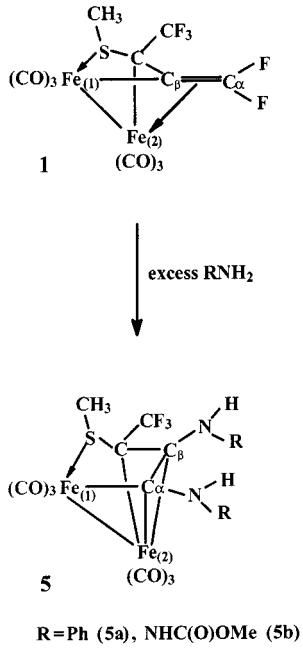

Scheme 6. Synthesis and proposed structures of complexes **5b**

give rise to substitution patterns that markedly depend on the strength of the attacking nucleophile in the carbon chain of the complex. We therefore decided to investigate the reaction between **1** and both aniline, a base of medium strength according to Pearson,[5] and also (methoxycarbonyl)hydrazine, $H_2NNHC(=O)OMe$, which contains potentially competitive primary and secondary amine functions. Compound **1** was treated with excess quantities (3−4 equiv.) of either aniline or (methoxycarbonyl)hydrazine in dichloromethane at room temperature. The α,β adducts **5a** and **5b** were formed as orange, microcrystalline solids in high yields (Scheme 6).

Elemental analysis, together with mass and NMR spectroscopy, indicated that the reaction of **1** with (methoxycarbonyl)hydrazine paralleled that with aniline. Both reactions gave thiaferracyclopentadiene products of the type $[\{Fe(CO)_3\}_2\{\mu\text{-}C(SMe)(CF_3)C(NHR)C(NHR)\}]$. Thus, in these reactions the (methoxycarbonyl)hydrazine behaves as a primary amine.

Single-crystal X-ray Analyses of Compounds 5a and 5b

The structures of **5a** and **5b** (Figures 5 and 6, Table 2) are based on an $Fe(1)S(1)C_\gamma C_\beta C_\alpha$ thiaferracyclopentadiene ring. The butadiene-like $Fe(1)=C_\alpha-C_\beta=C_\gamma$ unit π-bonds to

the $Fe(2)(CO)_3$ group. The bridging organic group is thus derived formally from the vinylic ligand in **1** through the loss of two fluorine atoms from C_α and the addition of a single NHR group to both C_α and C_β. Several diiron complexes containing the same $[\{(OC)_3Fe(1)S(Me)C_\gamma(CF_3)C_\beta(R^2)C_\alpha(R^1)\}Fe(2)(CO)_3]$ skeleton have now been characterised; they include **3b**, **6a**, and $[\{Fe(CO)_3\}_2\{\mu\text{-}C(SMe)(CF_3)C(PPh_2)CF\}]$ (**D**),[4c] as well as **5a** and **5b**. Some structural features characteristic of this group (see Table 2) are worth noting:

(a) The $Fe(1)S(Me)C_\gamma(CF_3)C_\beta C_\alpha$ rings are distorted envelopes with S at the flap, the S−Me bond axial, and the $C-CF_3$ bond equatorial, so that the $C_\alpha-C_\beta-C_\gamma-CF_3$ torsion angle is close to 180° (range 169−176°).

(b) Where possible, conjugation is maximised across $C_\alpha-R^1$ but minimised across $C_\beta-R^2$; in **5a**, for example, the C−C−N−Ph torsion angles are close to 180° across C7−N1, permitting π-overlap, but close to 90° across C8−N2, precluding it. This is consistent with the shortness of the C7−N1 bonds (1.35 Å) compared those across C8−N2 (1.41 Å). It can be argued that similar effects operate in **3b** and **5b**.

(c) Corresponding bond lengths are remarkably constant, except for the $Fe(1)-C_\alpha$ and $Fe(2)-C_\alpha$ distances (Table 2). Both of these bonds shorten as the substituent at C_α becomes more electron-withdrawing along the series NMe_2 (**3b**) < NHPh (**5a**) < $NHNHCO_2Me$ (**5b**) < $N(NH_2)R$ (**6a**) < F [**D**: $Fe(1)-C_\alpha$ = 1.918(3), $Fe(2)-C_\alpha$ = 2.073(3) Å]. The weak $Fe(2)-C_\alpha$ bonds shorten by 0.28 Å across this series. This can be explained in terms of the occurrence of two alternative structures, shown for **5a** in Scheme 7. Electron release by the substituent at C_α should stabilise the zwitterionic form **II** at the expense of the thiaferracyclopentadiene structure **I**, weakening $Fe(2)-C_\alpha$ but also discouraging $Fe(1)\rightarrow C_\alpha$ back-donation.

The structural features of the recently reported σ-η^3-allylic complex $[\{Fe(CO)_3\}(\mu\text{-}PPh_2)\{\mu\text{-}\eta^1(P):\eta^3(C)\text{-}(C)(Ph)C(Ph)C(H)C(=CH_2)PPh_2\}]$[11] are similar to those of the compounds discussed here.

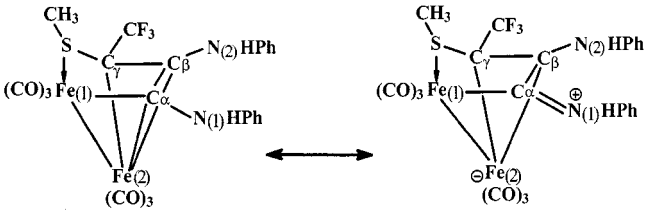
Spectroscopic Characterisation of Complexes 5 and Mechanistic Considerations

The solid-state structures of **5a** and **5b** have definitively been shown to persist in solution by IR and NMR spectroscopy (see Table 1 and Exp. Sect.). The IR spectra in CH_2Cl_2 show four ν(CO) bands in the 2075−1950 cm^{-1} range, corresponding to the Fe-bound terminal carbonyl groups, along with a characteristic band at 1720 cm^{-1} (**5b**), which confirms the presence of the $NHNHC(O)OCH_3$ group. The ^{19}F and ^{13}C NMR spectra are also consistent with the structures proposed for **5a** and **5b**. In particular, the ^{19}F NMR spectra of **5a** and **5b** no longer contain the vinylic CF resonances typical of **1**, but do retain the peaks due to the CF_3 group. In the $^{13}C\{^1H\}$ NMR spectra, the quadruplets assigned to the metallated carbon atoms (C_α) appear at δ = 202.0 (**5a**) and 210.7 (**5b**), with C−F coupling constants (^4J) of about 2 Hz. These resonances are shifted to high field relative to that seen for the closely related phosphanyl complex $[\{Fe(CO)_3\}_2\{\mu\text{-}C_\alpha(F)C_\beta(PPh_2)\text{-}C_\gamma(CF_3)S(CH_3)\}]$ (**D**),[4c] indicating that C_α possesses a less carbene-like character in **5a** and **5b** than in the phosphanyl complex, in conformity with the trends in $Fe-C_\alpha$ bond lengths discussed in the preceding section. Atom C_β gives rise to singlets at δ = 91.6 for **5a** and δ = 93.5 for **5b**, and atom C_γ to quadruplets at δ = 53.4 for **5a** and δ = 52.5 for



Scheme 7

5b, with C−F coupling constants (^2J) of about 33 Hz. The ^{1}H NMR spectra show lowfield resonances at δ = 8.50 (**5a**) and 9.46 (**5b**), characteristic of iminium protons, along with peaks at δ = 4.60 (**5a**) and 4.64 (**5b**), corresponding to the amino protons. In addition, the ^{1}H NMR spectrum of **5b** contains two broad singlets at δ = 6.55 and 6.85, attributable to the amino protons α to the methoxycarbonyl group. Thus, the ^{1}H NMR spectroscopic data clearly indicate that there is an iminium group at $C_α$ but an amino group at $C_β$ in **5a** and **5b**; in solution it is possible that there is an increased contribution from **II** to the overall structure (Scheme 7).

The reactions producing **5a** and **5b** were carried out at low temperature in order to detect possible intermediates. In the event, only one intermediate was found when either aniline or methyl hydrazinocarboxylate reacted with **1**. The reaction between **1** and aliphatic amines[4d] involves the initial formation of a stable fluoro−zwitterionic intermediate [**B**] (see Scheme 1). However, when **1** reacts with excess aniline (3 equiv.) or methyl hydrazinocarboxylate (4 equiv.), instead of [**B**] the only intermediate detected was the doubly substituted species [**f**] (Scheme 8). After 5 h, the relative amounts of [**f**], **1** and **5** were 47, 29 and 24%, respectively. The ^{19}F and ^{13}C{^{1}H} patterns of [**f**] are similar to those of neutral (alkoxymethylene)thiaferracyclobutene compounds (such as **2a**, **2b**; see Table 1) and to those of zwitterionic (diaminomethylene)thiaferracyclobutene derivatives such as **C**. Now, these species are mainly differentiated from one another by the $C_β$ atom resonances, which occur at δ = 70.0−90.0 for the zwitterionic complexes and at δ = 115.0−130.0 for neutral species (see Table 1). In view of this, a zwitterionic structure is proposed for [**f**], which has a chemical shift of δ = 95.6 for the $C_β$ atom (Scheme 8). Conversion of **f** into the final product requires the transfer of one amido group from $C_α$ to $C_β$. This probably occurs through a double intramolecular migration, from $C_α$ to the metal ion and from there to $C_β$, as postulated in Scheme 8.

4. Reactions between Compound 1 and Multifunctional Thioamines

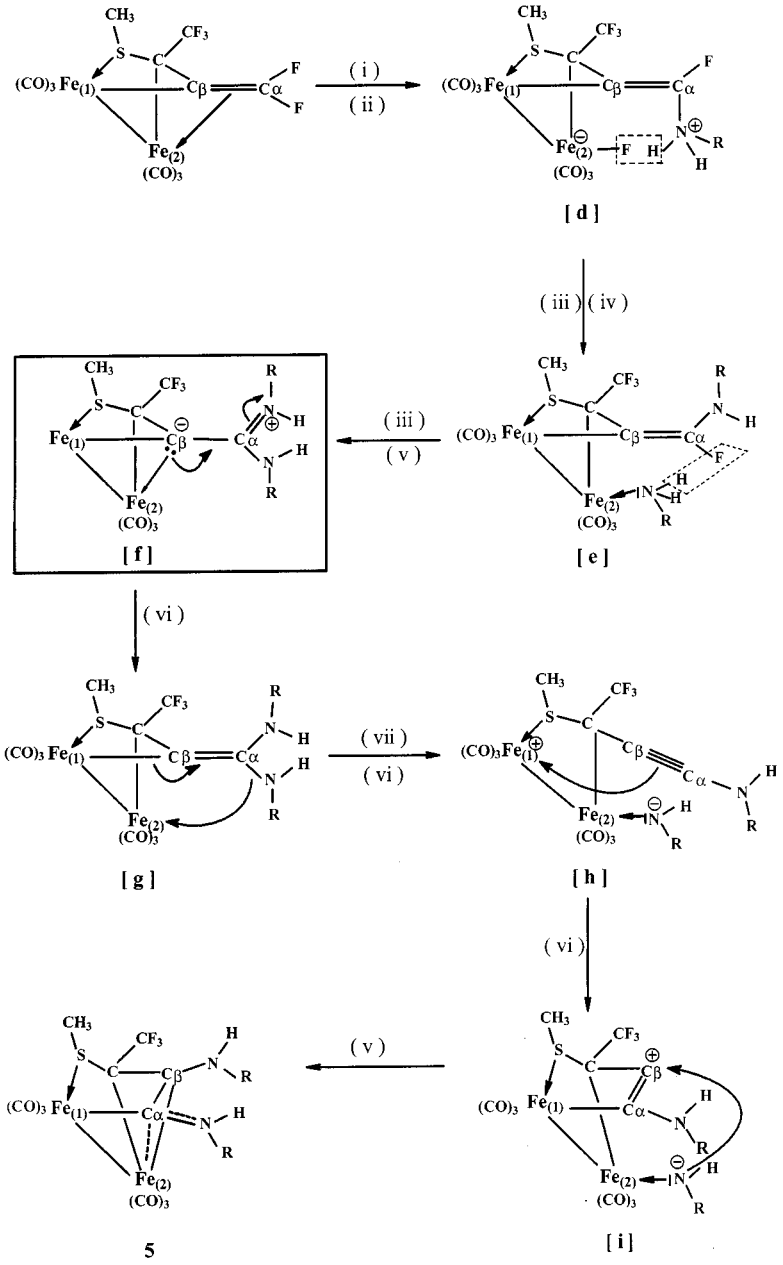
Synthesis and Characterisation of Complexes 6

In the preceding section it was shown that methoxycarbonylhydrazine, although it contains three "hard" and potentially competitive base functions (carbonyl, primary amine and secondary amine), acts only as a primary amine to cleave both C−F bonds of **1**. We speculated that the choice of the nucleophile might be pivotal to the regiochemistry of the C−F activation. We therefore treated **1** with three thioamines containing competitive "hard" amine and "soft" thione functions, namely, MeNHC(S)NHR, R = NH_2, H and Me.

Treatment of **1** with equimolar amounts of 4-methyl-3-thiosemicarbazide in tetrahydrofuran at room temperature resulted in the formation, in high yields, of the N-α,S-β adduct **6a** (Scheme 9). Similar results were obtained with methyl- and dimethylthioureas; complexes **6b** and **6c** were isolated as orange powders (Scheme 9). All the complexes have been characterised by ^{1}H NMR, ^{19}F NMR, ^{13}C NMR and IR spectroscopy and by mass spectrometry and microanalysis (see Table 1 and Exp. Sect.) and, in addition, complex **6a** has been the subject of a single-crystal X-ray diffraction study.

It is immediately apparent from examination of the spectroscopic data that all the complexes **6** have the same basic structure. The close similarity of their ^{13}C NMR spectra with those of compounds **4** (see Table 1) strongly suggests that **4** and **6** contain similar five-membered rings [$FeC_α(NR)C_β(SR)C(CF_3)S(CH_3)$]. The ^{19}F NMR spectra showed only single trifluoromethyl resonances at δ ≈ − 59.0, confirming that the two vinylic C−F bonds had been cleaved. The ^{1}H NMR spectrum of **6a** displayed three singlets in a 2:3:3 ratio, two at δ = 4.67 and 3.18 corresponding to the amino[12] and the methylimino[13] groups, respectively, and the more upfield line (δ = 1.87) to the SMe ligand.[4d] The ^{1}H NMR spectrum of **6b** differs from that of **6c** only by the presence, in a 1:3 ratio, of a lowfield signal at δ = 7.59 for the C=NH imino group in **6b** versus a higher field peak at δ = 3.15 assignable to the methylimino function in **6c**.[14] Otherwise, complexes **6b** and **6c** showed similar ^{1}H NMR patterns, in particular they displayed two signals at δ ≈ 3.7 and 1.9, which were assigned to the methylamino[14] and SMe[4d] groups, respectively. The ^{1}H NMR spectroscopic data clearly indicated the presence in **6** of a $R^1NC(=NR^2)S$ unit (R^1 = NH_2 or CH_3, and R^2 = H or CH_3) derived from the parent thioamine, as depicted in Scheme 9. This was confirmed by the ^{13}C NMR spectra, in which typical C=N resonances were observed at δ ≈ 160, and by the IR spectra in which strong C=N stretching bands were seen at ca. 1625 cm^{-1}. To complete the characterisation, an X-ray diffraction study of **6a** was undertaken.

The structure of **6a** (Figure 7) is derived from **1** through the loss of two fluorine atoms from $C_α$; a new ring is formed by attachment of a hard N-donor function of the thioamide to $C_α$ and of the softer thione S atom to $C_β$. As in **3** and **5**, the Fe(1) atom is now bound to $C_α$, completing a $Fe(1)C_αC_βC(CF_3)S(CH_3)$ metallacycle. The short Fe(1)−$C_α$ bonds [1.947(7) and 1.936(7) Å] imply that $C_α$ has some carbene-like character,[4b,4c,7] and this conclusion is confirmed by the highfield resonance (δ = 205.3) attributable to this carbon atom in the ^{13}C{^{1}H} NMR spectrum. The C(4)N(1)C(5)S(2)C(3) heterocycle formed by coupling

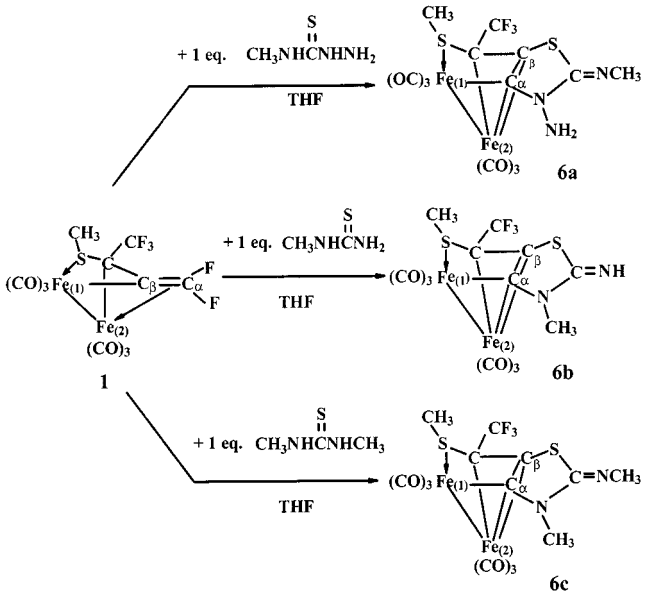


Scheme 8. Possible pathway to the formation of diaminothiaferracyclopentadiene derivatives **5**: (i) α-elimination of F; (ii) nucleophilic attack of RNH_2 at C_α; (iii) − HF; (iv) + RNH_2; (v) amino migration; (vi) internal rearrangement; (vii) α-elimination of NHR

of the 4-methyl-3-thiosemicarbazide to the coordinated $CCC(CF_3)SMe$ ligand is coplanar within ±0.03Å. The shortness of the C(5)−N(3) bonds [1.268(8) and 1.242(8) Å] compared to the C(13)−N(3) distances [1.471(9) and 1.469(9) Å] is consistent with the presence of a localised C(5)=N(3) double bond. The S(2)−C bond lengths (Figure 7, caption) suggest bonds of unit order, while the C_α−N(1) distances [1.382(8) and 1.361(8) Å], though longer than corresponding bonds in **5a** or **5b**, imply some multiple character.

Similar structural examples of diiron or diruthenium thiametallacyclic μ-C(R)C(R)C(R)S(R′) or phosphametallacyclic μ-C(R)C(R)C(R)P(R′)$_2$ ligands include [{$Fe(CO)_3$}$_2$-{μ-C(OEt)C(H)C(Ph)S(*t*Bu)}] (**I**)[15], [{$Fe(CO)_3$}$_2$(μ-C(Ph)-C(R)C(R′)P(Ph)$_2$}] (**J**)[16], [{$Ru_2(CO)_5X_2$}{μ-C(C_2H_5)-C(R)C(R′)S(C_2H_5)} (**K**)[17], as well as the complexes **3**−**5** and **A**, **D**−**F** that we have described previously.[4] The conformations of the μ-C(R)−C(R)−C(R)−X′(R_n) ligands [X′ = S (n = 1), P (n = 2)] in the complexes described by other authors[15−17] are very similar to those we have found in **6** and its close relatives.

Although two isomers, **6a$_1$** and **6a$_2$** (Scheme 10), could result from the reaction between 4-methyl-3-thiosemicarbazide and **1**, depending on whether the $NH(NH_2)$ or NHMe secondary amine function attacked the C_α atom, only one isomer is actually observed.



Scheme 9. Synthesis and proposed structures of complexes **6**

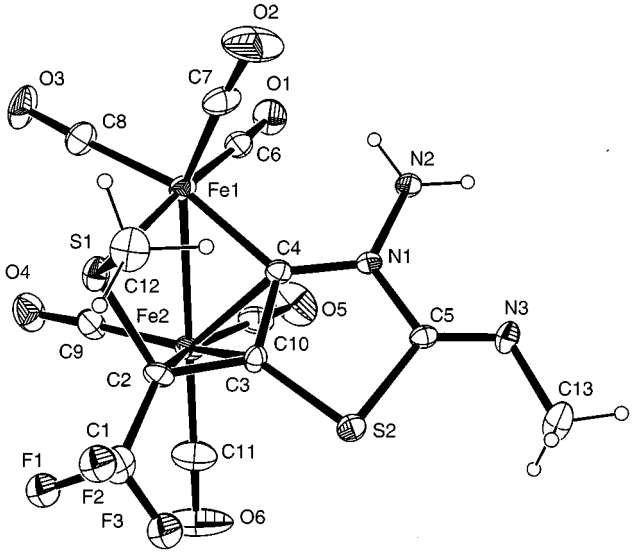


Figure 7. Molecular structure and numbering scheme of compound **6a** in the crystal; only one of the two independent molecules is shown; selected bond lengths [Å] and angles[°]: S(2)−C(3) 1.768(7)/1.762(7), S(2)−C(5) 1.776(7)/1.785(7), N(1)−C(4) 1.382(8)/1.361(8), N(1)−N(2) 1.397(7)/1.404(7), N(1)−C(5) 1.399(8)/1.407(8), N(3)−C(5) 1.268(8)/1.242(8), N(3)−C(13) 1.471(9)/1.469(9); C(4)−C(3)−C(2)−C(1) −176.3(7)/−175.9(7)

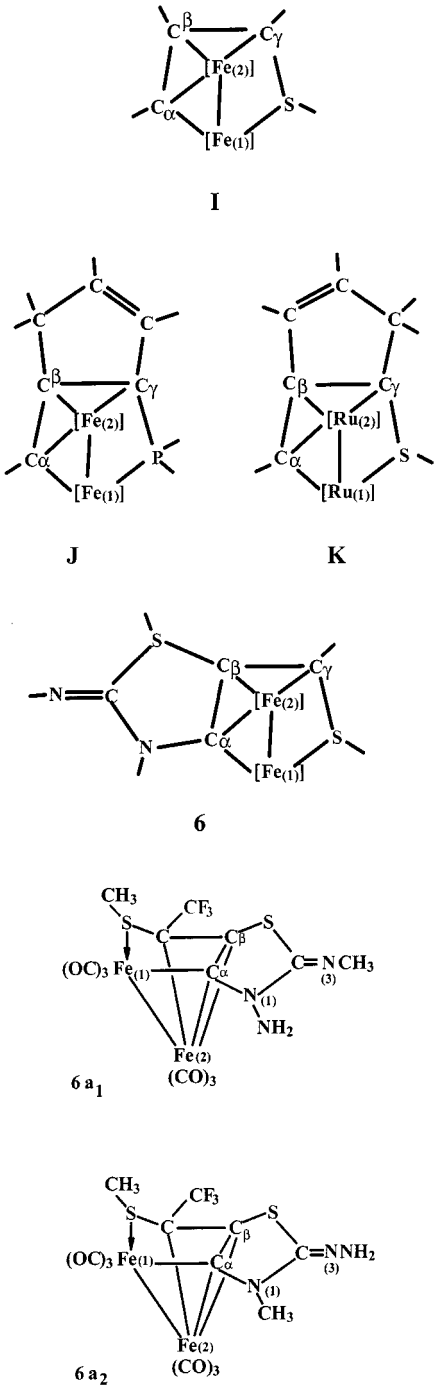
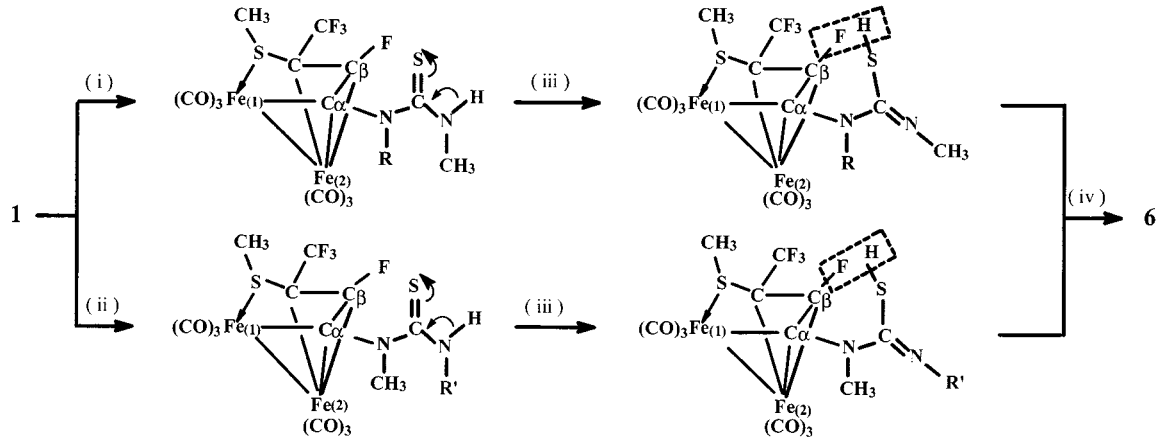


Scheme 10

The crystallographic study favours structure **6a$_1$**, but supporting evidence is desirable at this point, since **6a$_1$** and **6a$_2$** differ only in the positions of isoelectronic CH_3 and NH_2 groups. Accordingly, a ^{1}H-^{13}C 2D HMBC experiment was performed at room temperature. The carbon atom (δ = 159.4) of the imino group correlated ($^3J_{CH}$) with the hydrogen atoms of the methyl group (δ = 3.18), whereas the C_α atom (δ = 184.0) showed a correlation ($^3J_{CH}$) with the low-field resonance (δ = 4.61) due to the protons of the NH_2 group. This coupling pattern clearly showed that the amino group was attached to the nitrogen atom [N(1)], which was bound to C_α (**6a$_1$**). Similar experiments were undertaken for **6b** and revealed that the methyl group (δ = 3.71) correlated ($^3J_{CH}$) with both C_α (δ = 183.2) and the carbon atom of the imino group (δ = 166.0), thereby confirming the structure depicted in Scheme 9.

Mechanistic Considerations

It is likely that similar mechanisms are involved in the formation of **6a**−**6c**, and so we shall give only an illustrative



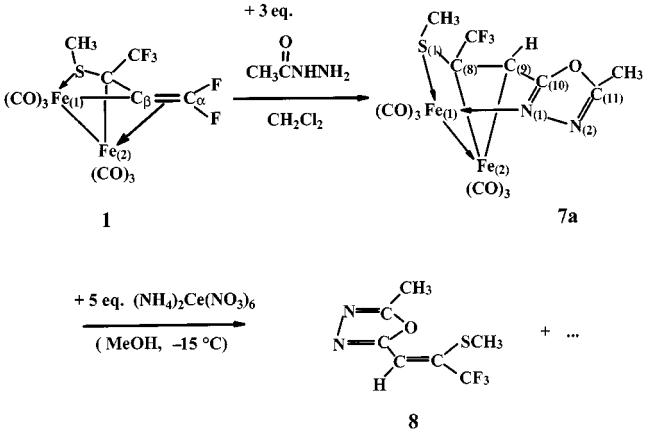
Scheme 11. Possible pathway to the formation of aminothiothiaferracyclopentadiene derivatives **6**: (i) nucleophilic attack of $CH_3-NH-C(S)-NHR$ at C_α; (ii) nucleophilic attack of $CH_3-NH-C(S)-NHR'$ (R′ = H, CH_3) at C_α; (iii) tautomerisation reaction; (iv) HF elimination

discussion of the pathway to **6a** (Scheme 11). Investigation of the reaction between **1** and 1 equiv. of thiosemicarbazide by NMR spectroscopy at low temperature did not result in the characterisation of any intermediate. However, the formation of **6a** is likely to resemble the well-established processes that produce the related thiaferracyclopentadiene derivatives of types **A**[4d] and **F**.[4c] Compound **6a** has some features in common with **A** and **F**, and all three complex types are obtained from the same parent compound **1**. The NH_2 function is preserved unchanged in **6a**, while the secondary amine and thiol functions of the thiosemicarbazide bind to the C_α and C_β atoms of **1**, respectively. If the thiol function initiated the attack, the expected product would be a ferracyclopentadiene intermediate of type **F**,[4c] which we have shown to be totally unreactive towards nucleophiles in Section 2 above. It is more likely then that **1** first reacts through a secondary amine function of the thiosemicarbazide to form a thiaferracyclopentadiene adduct of type **A**,[4d] which, as shown in Section 2, can give rise to intramolecular $C_\beta-F$ activation through a thione function tautomer of the coordinated 4-methyl-3-thiosemicarbazide, ultimately to afford complex **6a** (Scheme 11). A similar pathway to **6b** and **6c** is also summarized in Scheme 11. The main feature of these reactions is the successive activation of two C−F bonds by a nucleophile with both "hard" and "soft" functional groups, resulting in the formation of a five-membered heteroorganic ring fused to the cycloferrathiopentadiene unit.

5. Reactions between Compound 1 and Multifunctional Amides

Reaction between Compound 1 and Acetylhydrazine: Synthesis and Characterisation of Complex 7a

Since the perfluorovinyl complex **1** reacts with thioamides containing both "hard" and "soft" nucleophilic functions to give **6**, we also decided to investigate the behaviour of **1** toward multifunctional reagents containing only "hard" nucleophilic groups. On treatment of **1** with 3 equiv. of acetylhydrazine in CH_2Cl_2 at room temperature, the α,β adduct **7a** was formed (Scheme 12). It was isolated as red solid in 98% yield and has been characterised by ^1H NMR, ^{19}F NMR, ^{13}C NMR and IR spectroscopy and by mass spectrometry and microanalysis (see Table 1 and Exp. Sect.), as well as by a single-crystal X-ray diffraction study.



Scheme 12. Synthesis and proposed structures of compounds **7a** and **8**

Though the nucleophiles involved in the formation of **6a** and of **7a** are exact analogues, the molecular structure of **7a** (Figure 8, Table 2) is novel, differing significantly from that of **6a**. It consists of a dinuclear $Fe_2(CO)_6$ unit stabilized by an Fe−Fe bond and by a bridging organic group. This is derived *formally* from the vinylic ligand in **1** through the substitution of two fluorine atoms at C_α by O and N atoms of the deprotonated nucleophile and protonation of C_β. The result is a *six*-membered $Fe(1)-N(1)=C_\alpha(10)-C_\beta(9)=C(8)-S(1)$ metallacycle. There is extensive electron delocalization along the $Fe(1)-N(1)-C(10)-C(9)-C(8)$ chains, as shown by the bond length sequences [1.974(2), 1.288(3), 1.440(4) and 1.455(4) Å in molecule I and 1.964(2), 1.297(3), 1.424(4) and 1.463(4) Å in molecule II]. The

$Fe(2)(CO)_3$ unit is attached to the metallacycle through a π-interaction with the C(9)−C(8) double bond and through a direct bond to Fe(1). The Fe(1)−Fe(2) distances are long [2.794(1) and 2.799(1) Å], not unexpectedly since Fe(2) bridges across the six-membered Fe(1)-metalla ligand; shorter Fe−Fe distances of 2.591(1) and 2.643(1) Å are found in $[\{Fe(CO)_3\}_2\{\mu\text{-}S(Me)C(CF_3)C(CN\textit{t}Bu)\}]$ and $[\{Fe(CO)_3\}_2\{\mu\text{-}S(Me)C(CF_3)C(F)C(NMe_2)\}]$,[4a] in which the second $Fe(CO)_3$ group is attached to four- and five-membered ferracyclic bridging groups, respectively.

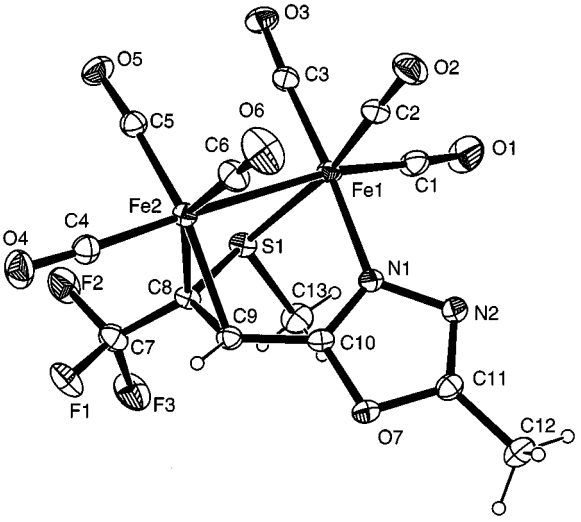


Figure 8. Molecular structure and numbering scheme of compound **7a** in the crystal; only one of the two independent molecules is shown; selected bond lengths [Å] and angles [°]: O(7)−C(10) 1.351(3)/1.359(3), O(7)−C(11) 1.368(3)/1.377(3), N(1)−C(10) 1.288(3)/1.297(3), N(1)−N(2) 1.401(3)/1.403(3), N(2)−C(11) 1.290(4)/1.282(4); C(4)−C(3)−C(2)−C(1) 140.3(3)/142.4(3)

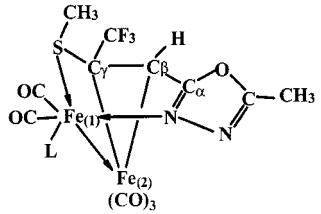
Compound **7a** contains a planar 1,3,4-oxadiazole ring formed by cyclisation of the amide nucleophile with the vinylic C_α carbon atom of **1**. The shortness of the C(10)−N(1) and C(11)−N(2) bonds [1.282(4)−1.297(3) Å] indicates some multiple character.

The solution spectra of **7a** are consistent with the solid-state structure. Four strong to medium IR bands between 2072 and 1950 cm^{-1} can be attributed to carbonyl ν(CO) stretching vibrations. A single highfield signal (δ = −66.65) in the ^{19}F NMR spectrum, typical of a trifluoromethyl resonance, provided the first indication that both C−F bonds in **1** had been cleaved. In the $^{13}C\{^1H\}$NMR spectrum, the carbon atom of the trifluoromethyl group appeared as a quadruplet at δ = 128.6 ($^1J_{C,F}$ = 274 Hz). The assignments of the three carbon atoms of the thiaazaferracyclohexene ring were made on the basis of the observed ^{13}C-^{19}F coupling constants and chemical shifts. The highfield resonances at δ = 44.6 (quadruplet; $^2J_{C-F}$ = 36.5 Hz) and 24.4 (singlet) are attributable to C(8) and C(9). The chemical shifts of these two carbon atoms suggest that they form a $C(sp^3)-C(sp^3)$ single bond rather than a $C(sp^2)=C(sp^2)$ double bond; the C(8)−C(9) distances [1.455(4) and 1.463(4) Å] lie at the upper end of the range for alkenes π-bonded to transition metal ions. The lowfield signals at δ = 175.9 and 163.0 are typical of imino-substituted carbon atoms and are attributable to C(10) and C(11). The carbonyl region contains three singlets at δ = 198.3, 211.1 and 215.6 and three broader singlets at δ = 207.6, 211.0 and 219.4, which correspond to the $Fe(1)(CO)_3$ and $Fe(2)(CO)_3$ fragments, respectively. In the ^1H NMR spectrum there are three singlets at δ = 1.87, 2.49 and 2.86 with intensities in an integral ratio of 3:3:1. The first two resonances can be assigned to the C(12) oxadiazole and S−C(13) methyl groups and the third to the methine proton attached to C(9) of the bridging heteropolycarbon fragment.

Reactions between Compound 7a and Phosphanes and between Compound 7a and Oxidants

An attempt to liberate the bridging heteropolycarbon ligand of **7a** by treatment with an excess of either phosphane (PPh_2Me) or phosphite [$P(OMe)_3$] in CH_2Cl_2 at 60 °C was unsuccessful. However, it resulted in a carbonyl substitution reaction that gave high yields of the complexes $[\{Fe(CO)_2L\}\{\mu S(Me)C(CF_3)CHC_\alpha NNC(CH_3)O(C_\alpha\text{−}O)\}\text{-}\{Fe(CO)_3\}]$ [**7b**: L = PPh_2Me; **7c**: L = $P(OMe)_3$] as red solids. All complexes other than **7a** described in this work showed marked reluctance to undergo carbonyl substitution reactions. Microanalyses of **7b** and **7c** indicated that the two complexes had similar compositions. The mass spectrum of **7c** revealed a single molecular ion peak and fragmentation peaks corresponding to the sequential loss of five carbonyl ligands.

On the basis of the close similarity of their spectroscopic data (see Table 1), structures similar to **7a** are postulated for **7b** and **7c**, with phosphane bound to the iron atom Fe(1) as shown in Scheme 13. The ^{31}P NMR spectra each display only one signal, at δ = 29.12 (**7b**) and at 157.73 (**7c**), corresponding to the terminal PPh_2Me and $P(OMe)_3$ ligands, respectively.[16] The $^{13}C\{^1H\}$ NMR spectra of **7b** and **7c** contain only five distinct resonances in the carbonyl region, two doublets at δ ≈ 215.5 and 220.0, and three broad singlets at δ = 208.2−222.8. The singlets are associated with the $Fe(2)(CO)_3$ group and the two doublets with the carbonyl groups of the $Fe(1)L(CO)_2$ unit. The magnitude of $^2J_{C,P}$ (7.5−2.0 Hz) is consistent with a *cis* arrangement of the phosphane and carbonyl groups. In other respects, the magnitude of the splitting of the methyl resonance of the thiolato group ($^3J_{C,P}$ = 8 and 6.5 Hz) confirms that the phosphane ligand is located at Fe(1) and is *trans* to the SMe



7b (L = PPh_2Me)

7c (L = $P(OMe)_3$)

Scheme 13

groups. The replacement of one carbonyl group in **7a** by an electron-releasing phosphane ligand to give **7b** or **7c** is accompanied by a shift of the resonances of the remaining carbonyl groups attached to Fe(1) to lower field compared with those attached to Fe(2). This observation confirms that the substitution reaction operated at Fe(1).

In a further attempt to decoordinate the bridging heteropolycarbon ligand, **7a** was treated at low temperature with excess ceric salt in methanol. The reaction resulted in the formation of **8** as a white solid in high yields (Scheme 12). The product was fully characterised by mass spectrometry and NMR spectroscopy (see Exp. Sect.). The mass spectrum exhibited a molecular ion, and sequential losses of methyl and oxadiazole fragments. The characterising NMR spectroscopic data of **8** were closely related to those of the parent heteropolycarbon ligand of **7a** and the ^{1}H, ^{19}F and ^{13}C NMR spectra showed the expected pattern of peaks for a 2-methyl-5-(3,3,3-trifluoro-2-methylthio-2-propenyl)-1,3,4-oxadiazole compound. Though unsubstituted and 2,5-dialkyl-1,3,4-oxadiazoles have long been known,[17] compound **8** has not previously been reported.

Conclusion

These investigations have shown that the (perfluorovinyl)-diiron complex [{$Fe(CO)_3$}$_2${μ-C(SMe)(CF_3)$C_\beta C_\alpha F_2$}] (**1**) reacts readily and cleanly with nucleophiles to give novel organometallic compounds through unusual C−F cleavage processes. This work confirms and extends our previous conclusion[4] that the pattern of reactivity depends strongly on the "hardness" or softness" of the nucleophile used in the reactions. Reactions between **1** and "hard" amines involve two C−F cleavages and migration of a fluorine atom from C_α to C_β to give exclusively α adducts with formation of Fe(1)−C_α(NR_2)−C_β(F)−C(CF_3)−S(Me) rings,[4d] while nucleophiles such as alcohol and aniline, thought to be less hard than aliphatic amines, afford either μ_2-η^1:η^2-vinyl complexes, [{Fe $(CO)_3$}$_2${μ-C(SMe)(CF_3)$C_\beta C_\alpha$($OR)_2$}] (**2**), or α,β adducts **5**, containing Fe(1)−C_α(NHR)−C_β-(NHR)−C(CF_3)−S(Me) rings. X-ray analysis of **2a** (R = Me) indicates that the μ_2-η^1:η^2-vinyl ligand [C(SMe)(CF_3)$C_\alpha C_\beta F_2$] present in **1** is maintained in **2** in the form of a dialkoxyvinyl ligand [C(SMe)(CF_3)$C_\beta C_\alpha$($OR)_2$], whereas X-ray analysis of **5** (R = Ph) demonstrates the transformation of the ligand in **1** into a new polycarbon [C(SMe)(CF_3)C_β(NHR)C_α(NHR)] chain by the action of aniline. The mechanisms proposed to account for the formation of complexes **2** and **5** both imply a double C−F bond cleavage. When **1** reacts with a thioamide containing three "hard" primary and secondary amine functions and one "soft" thiol function, the nucleophile attacks first at C_α with its secondary amine, while its primary amine function takes no part in the reaction. In a second step, the thiol function of the nucleophile attacks at C_β to give α,β adducts **6**, each containing a novel iminothiazolidine ring [C(SMe)(CF_3)C_βSC(=NR)N(R′)C_α(C_β−C_α)] fused to the five-membered metallacycle. Formation of the imino-thiazolidine ligand in **6** implies C−N and C−S couplings. When the nucleophile reacting with **1** contains only "hard" functions, namely a primary and secondary amine and a carbonyl group, the reaction involves attack by the primary amine and the carbonyl functions at C_α; two C−F bond cleavages and a 1,3-hydrogen shift from the nitrogen atom to the β-carbon atom of the vinyl ligand gives **7**. Compound **7** contains a thiaazaferracyclohexene ring to which is fused an oxadiazole fragment formed through a cyclisation reaction. Finally, it should be remarked that, while β-fluoro substituents on the $C_\alpha C_\beta C_\gamma$($CF_3$)S(Me) chain of thiaferracyclopentadiene (type **A**) complexes are readily activated by nucleophiles, α-fluoro substituents in compounds of type **D** and **F** are not cleaved by nucleophiles under the same conditions.

Experimental Section

General: All reactions were performed by Schlenk techniques under argon or nitrogen, and solvents were deoxygenated and dried by standard methods. Column chromatography was carried out with silica gel purchased from SDS and deoxygenated before use. The starting materials **1**,[18] **A**,[4d] **D**[4c] and **F**[4c] were prepared as described in the literature. All other reagents were purchased commercially. Yields are with respect to the starting clusters for the preparation of all the products. Infrared spectra were recorded with a Perkin−Elmer 1430 spectrophotometer on dichloromethane or hexane solutions. The mass spectra were measured with a GC/MS Hewlett−Packard 5595C or a GC/MS Ribermag R10−10 spectrometer at the "Laboratoire de Biochimie", Faculté de Médecine (Brest, France). Chemical analyses were performed by the "Centre de Microanalyses du CNRS de Lyon" or the "Laboratoire de Spectroscopie Atomique" at the University of Brest. The NMR spectra (^{1}H, ^{13}C, ^{19}F, ^{31}P), in $CDCl_3$ solutions, were recorded at room temperature with a Bruker AC 300 or DRX 400 spectrometer and were referenced to $SiMe_4$ (^{1}H, ^{13}C), $CFCl_3$ (^{19}F) and H_3PO_4 (^{31}P). Part of the NMR spectroscopic data for **2**−**7** and [**f**] are compared in Table 1; the remaining spectroscopic data of these complexes are reported in this section.

Synthesis of [{$Fe(CO)_3$}$_2${μ-S(Me)C(CF_3)CC($OR)_2$}] (2): A tetrahydrofuran (10 mL) solution of **1** (94.0 mg, 0.20 mmol) was treated at room temperature with 40 equiv. of alcohol (CH_3OH: 256.0 mg, 324 μL; C_2H_5OH: 369.0 mg, 542 μL). After it had been stirred for 3 h, the reaction mixture was filtered through Celite and the volatiles were removed under vacuum. The residue was then washed at −50 °C with pentane (10 mL) to give either **2a** (with CH_3OH) as an analytical pure red solid in 98% yield (97.0 mg) or **2b** (with C_2H_5OH) as an orange solid in 99% yield (103.0 mg). **2a:** $C_{13}H_9F_3Fe_2O_8S$ (493.96): calcd. C 31.6, H 1.8; found C 31.4, H 1.8. MS: *m*/*z* = 494 $[M]^+$, 466, 438, 410, 382, 354, 326 [M − *n* CO (*n* = 1−6)]$^+$, 232 [M − 6 CO − $FeFe_2$]$^+$. IR (hexane): ṽ =2077 m, 2062 w, 2032 s, 2004 s, 1983 m [ν(CO)] cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 2.2 (s, 3 H, SCH_3), 3.7 (s, 6 H, 2OCH_3). $^{13}C\{^{1}H\}$ NMR ($CDCl_3$): δ = 65.2 (q, $^{2}J_{C,F}$ = 38.0 Hz, CCF_3), 123.1 (q, $J_{C,F}$ = 278.0 Hz, CF_3). **2b:** $C_{15}H_{13}F_3Fe_2O_8S$ (522.01): calcd. C 34.5, H 2.5; found C 34.3, H 2.4. MS: *m*/*z* = 522 $[M]^+$, 507 $[M - CH_3]^+$, 466, 438, 410, 382, 354 [M − *n* CO (*n* = 2−6)]$^+$, 260 [M, 6 CO − FeF_2]$^+$. IR (CH_2Cl_2): ṽ = 2070 m, 1995 s, 1955 w, 1925 s [ν(CO)] cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 1.32 (t, 6 H, $^{3}J_{H,H}$ = 7.0 Hz, 2CH_3), 2.40 (s, 3 H, SCH_3), 3.98 (q, 2 H,^{3} $J_{H,H}$ = 7.0 Hz, CH_2), 4.02 (q,

$^3J_{H,H}$ = 7.0 Hz, 2 H, CH_2). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 14.2 (s, 2CH_2), 62.2 (q, $^2J_{C,F}$ = 38.5 Hz, CCF_3), 123.4 (q, $J_{C,F}$ = 277.5 Hz, CF_3). Similarly, a tetrahydrofuran (10 mL) solution of ethylene glycol (497.0 mg, 448 μL) and **1** (94.0 mg, 0.20 mmol) was stirred at room temperature for 5 h. After evaporation of the solvent, the residue was chromatographed on a silica gel column. Elution with hexane/CH_2Cl_2 (1:0.66) gave an orange band. After evaporation of the volatiles, **2c** was obtained as an analytical pure orange solid in 90% yield (88.5 mg). $C_{13}H_7F_3Fe_2O_8S$ (491.95): calcd. C 31.7, H 1.4; found C 31.5, H 1.3. MS: *m*/*z* = 492 $[M]^+$, 477 $[M - CH_3]^+$, 464, 436, 408, 380, 352, 324 $[M - n\ CO\ (n = 1-6)]^+$, 230 $[M - 6\ CO - FeF_2]^+$. IR (CH_2Cl_2): ν̃ =2070 m, 1995 s, 1960 w, 1928 s [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.3 (s, 3 H, SCH_3), 4.5 (s, 4 H, 2 CH_2). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 61.1 (q, $^2J_{C,F}$ = 39.0 Hz, CCF_3), 68.2 (s br, 2 CH_2), 123.5 (q, $J_{C,F}$ = 277.0 Hz, CF_3).

Synthesis of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C(OMe)C(NMe$_2$)}] (3a): A dichloromethane (5 mL) solution of methanol (128.0 mg, 162 μL, 0.4 mmol) and [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C(F)C (NMe$_2$)}] (**A**: R = R′ = Me) (49.5 mg, 0.10 mmol) was stirred at 60 °C for 4 h. After evaporation of the solvent, column chromatography of the residue produced a red band of **3a** (49.7 mg, 98%) eluted with hexane/CH_2Cl_2 (1:0.2). $C_{14}H_{12}F_3Fe_2NO_7S$ (507.00): calcd. C 33.2, H 2.4, N 2.8; found C 33.3, H 2.4, N 2.7. MS: *m*/*z* = 507 $[M]^+$, 479, 451, 423, 395, 367, 339 $[M - n\ CO\ (n = 1-6)]^+$, 245 $[M - 6\ CO - FeF_2]^+$. IR (CH_2Cl_2): ν̃ =2065 m, 2025 s, 1995 s, 1966 sh [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.90 (s, 3 H, SCH_3), 3.10 [s, 6 H, N(CH_3)$_2$], 3.66 (s, 3 H, OCH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 47.1 [s, N(CH_3)$_2$], 54.0 (q, $^2J_{C,F}$ = 34.0 Hz, CCF_3), 59.9 (s, OCH_3), 126.6 (q, $J_{C,F}$ = 274.0 Hz, CF_3).

Synthesis of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C[OC(O)NMe$_2$]-C(NMe$_2$)}] (3b): Carbon dioxide was bubbled at −50 °C for 5 min through a dichloromethane (10 mL) solution containing 49.5 mg (0.10 mmol) of **A** (R = R′ = Me). At −50 °C, 20 equiv. (90.0 mg, 132 μL) of Me_2NH was added. The mixture was warmed to 60 °C and stirred for 1 h. After evaporation of the solvent, the residue was chromatographed on deoxygenated silica gel. Elution with CH_2Cl_2/hexane (1:0.66) afforded an orange band, which gave **3b** as orange solid (98% yield). $C_{16}H_{15}F_3Fe_2N_2O_8S$ (564.04): calcd. C 34.1, H 2.7, N 5.0; found C 34.2, H 2.7, N 5.1. MS: *m*/*z* = 536, 508, 480, 452, 424, 396 $[M - n\ CO\ (n = 1-6)]^+$. IR (hexane): ν̃ =2066 m, 2020 s, 1998 m, 1990 sh, 1965 sh, 1725 m [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.18 (s, 3 H, SCH_3), 2.96 [s, 3 H, C(O)NCH_3], 2.99 (s, 3 H, C(O)NCH_3), 3.28 [s, 6 H, N(CH_3)$_2$]. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 36.15 [s, C(O)NCH$_3$], 36.8 [s, C(O)NCH$_3$)], 48.5 [s, N(CH_3)$_2$], 51.9 (q, $^2J_{C,F}$ = 35.0 Hz, CCF_3), 126.7 (q, $J_{C,F}$ = 274.0 Hz), 154.7 (s, *C*=O).

Synthesis of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C(SEt)C(NMe$_2$)}] (4a): Complex **A** (R = R′ = Me) (49.5 mg, 0.10 mmol) and 20 equiv. of ethanethiol were stirred in CH_2Cl_2 (5 mL) at 60 °C for 6 h. Compound **4a** was isolated as red solid (80% yield) by column chromatography on deoxygenated silica gel with hexane/dichloromethane (4:1). $C_{15}H_{14}F_3Fe_2NO_6S_2$ (537.08): calcd. C 33.5, H 2.6, N 2.6; found C 33.6, H 2.4, N 2.5. MS: *m*/*z* = 537 $[M]^+$, 509, 481, 453, 425, 397, 369 $[M - n\ CO\ (n = 1-6)]^+$. IR (CH_2Cl_2): ν̃ = 2065 s, 2022 s, 1988 sh, 1968 sh [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ =1.30 (t, $^3J_{H,H}$ = 7.5 Hz, 3 H, CH_3), 1.85 (s, 3 H, SCH_3), 2.60 (m, ABX_3, $^2J_{AB}$ = 11.5, $^3J_{H,H}$ = 7.5 Hz, CH_2), 3.00 (m, ABX_3, $^2J_{AB}$ = 11.5, $^3J_{H,H}$ = 7.5 Hz, CH_2), 3.19 [s, 6 H, N(CH_3)$_2$]. $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 14.05 (s, CH_2CH_3), 30.2 (s, CH_2CH_3), 48.4 [s, N(CH_3)$_2$], 59.15 (q, $^2J_{C,F}$ = 32.0 Hz, CCF_3), 126.8 (q, $J_{C,F}$ = 274.0 Hz, CF_3).

Synthesis of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C[SC(S)NMe$_2$]C(NMe$_2$)}] (4b): Complex **A** (R = R′ = Me) (49.5 mg, 0.10 mmol) and 1 equiv. of dimethylammonium dimethylthiocarbamate were stirred in CH_2Cl_2 (5 mL) at room temperature for 1 h. The solution was then concentrated and chromatographed on a silica gel column. Elution with hexane/$CHCl_2$ (1:0.4) removed an orange band, which gave orange crystals of **4b** (53.5 mg, 90% yield). $C_{16}H_{15}F_3Fe_2N_2\ O_6S_3$ (596.16): calcd. C 33.2, H 2.5, Fe 18.7, N 4.8; found C 33.4, H 2.5, Fe 18.8, N 4.8. MS: *m*/*z* = 596 $[M]^+$, 568, 540, 512, 484, 456, 428 $[M - n\ CO\ (n = 1-6)]^+$, 334$[M - 6\ CO - FeF_2]^+$. IR (CH_2Cl_2): ν̃ = 2064 s, 2022 s, 1998 sh, 1970 sh [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.3 (s, 3 H, SCH_3), 3.4 (s, 9 H, 3 CH_3), 3.5 (s, 3 H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 42.0 (s, C(S)NCH_3), 45.3 (s, C(S)NCH_3), 49.8 [s, N(CH_3)$_2$], 59.7 (q, $^2J_{C,F}$ = 33.0 Hz, CCF_3), 127.0 (q, $J_{C,F}$ = 274.0 Hz, CF_3), 197.3 (s, *C*=S).

Synthesis of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C[SCMeNPh]C(NMe$_2$)}] (4c): This compound was prepared as described for **2a**, by using **A** (R = R′ = Me) (49.5 mg, 0.10 mmol) and *N*-phenylthioacetamide (15.2 mg, 0.10 mmol) as starting materials. Treatment of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C(L1)C(F)}] [D: L$_1$ = PPh$_2$, P(O)(OMe)$_2$] and [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C(L$_2$)C(F)}]

[F: L_2 = SC(NPh)CH_3] with Nucleophiles: Dichloromethane solutions of **D** (0.10 mmol) or **F** (0.10 mmol) and an excess of nucleophile {5 equiv. of RNH_2 (R = Ph, *t*Bu), 10 equiv. of R′NH [R′ = Me_2, $(CH_2)_4$], 10 equiv. of EtSH, 40 equiv. of MeOH, 5 equiv. of PPh_3} were stirred at 60 °C for 18 h. After this time the starting materials were wholly recovered. This was checked by IR analysis.

Synthesis of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C(NHPh)C(NHPh)}] (5a): A dichloromethane (10 mL) solution of **1** (94.0 mg, 0.20 mmol) and 3 equiv. of aniline (55.8 mg, 54.6 μL) was stirred at room temperature for 2 h. The reaction mixture was then filtered through deoxygenated silica gel. After evaporation of the solvent, the residue was crystallized from pentane (5 mL) at −60 °C to give **5a** as orange crystals in 95% yield (111.0 mg). $C_{23}H_{15}F_3N_2O_6S$ (616.11): calcd. C 44.8, H 2.45, Fe 18.1, N 4.5; found C 44.5, H 2.4, Fe 18.3, N 4.3. MS: *m*/*z* = 616 $[M]^+$, 588, 560, 532, 504, 476, 448 $[M - n\ CO\ (n = 1-6)]^+$, 354 $[M - 6\ CO - FeF_2]^+$. IR (CH_2Cl_2): $\tilde{\nu}$ = 2070 m, 2022 s, 2002 m, 1965 sh [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 2.0 (s, 3 H, SC*H*$_3$), 4.6 (s, 1 H, PhN*H*), 6.9−7.4 (m, 10 H, 2 C$_6$*H*$_5$), 8.5 (s, 1 H, PhN*H*). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 53.4 (q, $^2J_{C,F}$ = 33.0 Hz, *C*CF$_3$), 127.0 (q, $J_{C,F}$ = 273.5 Hz, *C*F$_3$), 110.0−150.0 (8 s, *C*$_6$H$_5$).

Synthesis of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)C[NHNHC(O)OMe]C-[NHNHC(O)OMe)}] (5b): This compound was prepared as described for **5a**, by using **1** (94.0 mg, 0.20 mmol) and (methoxycarbonyl)hydrazine (72.0 mg, 0.80 mmol) as starting materials. Orange crystals: yield 112.3 mg (97%). $C_{15}H_{13}F_3Fe_2N_4O_{10}S$ (610.01): calcd. C 29.5, H 2.15, N 9.2; found C 29.8, H 2.2, N 9.1. IR (CH_2Cl_2): $\tilde{\nu}$ =2075 m, 2030 s, 1980 sh, 1950 sh, 1720 s [ν(CO)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.90 (s, 3 H, SC*H*$_3$), 3.78 (s, 3 H, OC*H*$_3$), 3.79 (s, 3 H, OC*H*$_3$), 4.74s (s br, 1 H, N*H*), 6.55 (s br, 1 H, N*H*), 6.85 (s br, 1 H, N*H*), 9.46 (s br, 1 H, N*H*). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 52.5 (m, *C*CF$_3$), 53.1 (s, OC*H*$_3$), 53.3 (s, OC*H*$_3$), 127.7 (q, $J_{C,F}$ = 273.5 Hz, *C*F$_3$), 156.8 (s, *C*(O)OMe), 158.8 (s, *C*(O)OMe).

Synthesis of [{Fe(CO)$_3$}$_2${μ-S(Me)C(CF$_3$)CC(NHPh)$_2$}] ([f]): The intermediate [**f**] was formed rapidly in the NMR tube on mixing **1** (23.5 mg, 0.05 mmol) with 3 equiv. of aniline (13.9 mg, 13.6μL) in $CDCl_3$ solution (at −10 °C). The reaction was monitored by ^{19}F NMR spectroscopy. When the yield of product [**f**] reached about 50%, a $^{13}C\{^1H\}$ (and ^1H) NMR analysis was undertaken at −40 °C in order to characterise this intermediate (see Table 1).

Synthesis of 6a: A tetrahydrofuran solution (10 mL) of **1** (94.0 mg, 0.20 mmol) and 1 equiv. of 4-methyl-3-thiosemicarbazide (21 mg) was stirred at room temperature for 3 h. After evaporation of the solvent, the residue was chromatographed on a deoxygenated silica gel column. Elution with ether/CH_2Cl_2 (1:4) gave an orange band. After evaporation of the volatiles, **6a** was obtained as an analytical pure orange solid in 86% yield (89.2 mg). $C_{13}H_8F_3Fe_2N_3O_6S_2$ (535.01): calcd. C 29.2, H 1.5, N 7.85; found C 29.5, H 1.5, N 7.7. MS: *m*/*z* = 535 $[M]^+$, 520 $[M - CH_3]^+$, 507, 479, 451, 423, 395, 367 $[M - n\ CO\ (n = 1-6)]^+$, 352 $[M - 6\ CO - CH_3]^+$, 273 $[M - 6\ CO - FeF_2]^+$, 258 $[M - 6\ CO - FeF_2 - CH_3]^+$. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2055 s, 2010 s, 1994 s, 1970 sh [ν(CO)], 1650 s [ν(C=N)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.87 (s, 3 H, SC*H*$_3$), 3.18 (s, 3 H, C*H*$_3$), 4.67 (s, 2 H, N*H*$_2$). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 40.9 (s, *C*H$_3$), 49.8 (q, $^2J_{C,F}$ = 37.0 Hz, *C*CF$_3$), 126.7 (q, $J_{C,F}$ = 274.0 Hz, *C*F$_3$), 159.4 (s, *C*=N).

Synthesis of 6b: This compound was prepared as described for **6a**, by using **1** (94.0 mg, 0.20 mmol) and 1 equiv. of *N*-methylthiourea (18.0 mg) as starting materials. The elution of product **6b** was performed with ether/dichloromethane (1:19) to give an orange solid in 88% yield (86.9 mg). $C_{13}H_7F_3Fe_2N_2O_6S_2$ (520.00): calcd. C 30.0, H 1.35, N 5.4; found C 30.2, H 1.4, N 5.7. MS: *m*/*z* = 520 $[M]^+$, 505 $[M - CH_3]^+$, 492, 464, 436, 408, 380, 352 $[M - n\ CO\ (n = 1-6)]^+$, 258 $[M - 6\ CO - FeF_2]^+$. IR (CH_2Cl_2): $\tilde{\nu}$ = 2075 s, 2035 s, 2005 s, 1998 sh [νCO), 1595 s [ν (C=N)] cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.90 (s, 3 H, SC*H*$_3$), 3.71 (s, 3 H, C$_α$N*H*$_3$), 7.59 (s br, 1 H, N*H*). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 35.7 (s, C$_α$NCH$_3$), 49.1 (q, $^2J_{C,F}$ = 37.5 Hz, *C*CF$_3$), 126.5 (q, $J_{C,F}$ = 27**1.0** Hz, *C*F$_3$), 166.0 (s, *C*=N).

Synthesis of 6c: A tetrahydrofuran solution (10 mL) of **1** (94.0 mg, 0.20 mmol) and 1 equiv. of *N*,*N*′-dimethylthiourea (20.8 mg) was stirred at room temperature for 2 h. The solvent was then removed under vacuum and **6c** was extracted with CH_2Cl_2/pentane (1:9) (10 mL) and then recrystallized at −60 °C in pentane (91.3 mg, 90% yield). $C_{14}H_9F_3Fe_2N_2O_6S_2$ (534.03): calcd. C 31.5, H 1.7, N 5.2; found C 31.9, H 1.8, N 5.2. MS: *m*/*z* = 534 $[M]^+$, 519 $[M - CH_3]^+$, 506, 478, 450, 422, 394, 366 $[M - n\ CO\ (n = 1-6)]^+$, 272 $[M - 6\ CO - FeF_2]^+$. 9.0 Hz, $P(OCH_3)_3$], 128.9 (q, $J_{C,F}$ = 274.0 Hz, CF_3), 160.9 (s, CCH_3).

Synthesis of 8: A solution of **7a** (50.4 mg, 0.10 mmol) in dichloromethane (2 mL) was added to a chilled solution (−15 °C) of $(NH_4)_2Ce(NO_3)_6$ (274 mg, 0.50 mmol) in methanol (2 mL). The reaction mixture was stirred at −15 °C for 45 min and was then slowly warmed to room temperature The volatiles were removed under vacuum and the product **8** was extracted with pentane (5 mL) and then recrystallized at −80 °C. White crystals were formed and filtered off to give 19.0 mg (85%) of **8**; m.p. 44 °C. $C_7H_7F_3N_2OS$ (224.18). MS: m/z = 224 $[M]^+$, 209 $[M - CH_3]^+$, 141 $[HCC(CF_3)SMe]^+$, 83 $[NNC(CH_3)OC]^+$. ^{1}H NMR ($CDCl_3$): δ = 2.54 (s, 3 H, CH_3), 2.60 (s, 3 H, SCH_3), 7.02 (s, 1 H, CH). ^{19}F NMR ($CDCl_3$): δ = −62.5 (s, CF_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 11.1 (s, CH_3), 15.9 (q, $^4J_{C,F}$ = 3.0 Hz, SCH_3), 111.5 (q, $^3J_{C,F}$ = 7.0 Hz, CH), 121.9 (q, $J_{C,F}$ = 276.0 Hz, CF_3), 137.5 (q, $^2J_{C,F}$ = 32.0 Hz, CCF_3), 161.7 (s, $NCCH$), 163.9 (s, $NCCH_3$).

Single-Crystal X-ray Analyses of 2a, 3b, 5a, 5b, 6a and 7a: Measurements were made with a Nonius CAD4 diffractometer. Subsequent calculations were performed with the WINGX system, the structures being refined with SHELXL97.[19] Crystallographic data for **2a**, **3b**, **5a**, **5b**, **6a** and **7a** are presented in Table 4. Full details of each structure have been deposited.[20] All the structures apart from **2a** involve asymmetric units that contain two independent molecules. Differences between these molecules are insignificant and are easily accounted for by packing forces. Crystals of **3b**, **5a** and **6a** are metrically triclinic. The collection of high-angle data for **5a** had to be abandoned when the crystal decomposed. The structure has two independent sites which contain disordered CH_2Cl_2 at about 20% occupancy. The scattering of the disordered CH_2Cl_2 was included by back-transformation of the difference map using the SQUEEZE facility of the PLATON program.[19] In **6a**, the CF_3 fluorine atoms are disordered equally over two sites. The structure of **5b** has several unusual features. It appears to be a distortion from space group $P2_1/n$ in that the two independent molecules are *roughly* related by the pseudo-screw operation $-x$, $-0.28 + y$, $-z$. The Laue symmetry is undoubtedly $2/m$, although it is possible to choose a centred orthorhombic cell. Four small residual peaks of 1.8−1.0 e/Å^3 suggest a very minor disorder of the O and OMe groups attached to C(8), but attempts to derive a satisfactory model of the disorder were unsuccessful. Compound **7a** is *metrically C*-centred monoclinic, although its Laue symmetry is that of a triclinic crystal.

Transformations of Hydrazines $RNHNH_2$ (R = Me, Ph) at a Sulfur-Rich Bimetallic Site: Diazene−Diazenido−Isodiazene/Hydrazido(2−) Interconversions

Philippe Schollhammer,[a] Béatrice Didier,[a] Nathalie Le Grand,[a] François Y. Pétillon,*[a] Jean Talarmin,[a] Kenneth W. Muir,*[b] and Simon J. Teat[c]

Keywords: N ligands / S ligands / X-ray diffraction / Metal-metal interactions / Molybdenum

The bis(nitrile) compound $[Mo_2Cp_2(\mu\text{-}SMe)_3(MeCN)_2](BF_4)$ (**1**) (Cp = C_5H_5) reacted with substituted hydrazines $RNHNH_2$ (R = Me, Ph) in acetonitrile at room temperature to give the stable diazene species $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}HN{=}NR)](BF_4)$ [R= Me (**2**), Ph (**3**)]. Compounds **2** and **3** could be readily deprotonated with BuLi to produce neutral diazenido species $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NR)]$ [R = Me (**4**), Ph (**5**)]. Photolysis of **4** in THF induced isomerization of the diazenide bridge, affording the complex $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NMe)]$ (**8**). This species underwent protonation at the outer nitrogen atom (N_β) to give the stable isodiazene/hydrazido(2–) complex $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NHMe)](BF_4)$ (**9**) which isomerised slowly back into **2** on warming. The molecular structure of the $\mu\text{-}\eta^2$-methyldiazenido complex **4** was established by an X-ray diffraction study.

Introduction

Transition metal complexes containing sulfur ligands have aroused much attention because of their biological and industrial potential.[1] We have been interested in making sulfur-rich dimolybdenum systems in order to relate their reactivity and electrochemical behaviour to their molecular structure.[2] Recently, we have investigated the chemistry of complexes with a tris-thiolato-bridged dimolybdenum(III) core $\{Mo_2Cp_2(\mu\text{-}SMe)_3\}^+$ (Cp = C_5H_5), and have shown that they are extremely suitable candidates for molecular activation.[3−5] In particular, the chloro-bridged complex $[Mo_2Cp_2(\mu\text{-}Cl)(\mu\text{-}SMe)_3]$ reacts with hydrazine and phenylhydrazine to give compounds containing nitrogenous functional groups: hydrazine yields the amido (NH_2)[4] group, while phenylhydrazine leads to the formation of diazenido ($N{=}N{-}Ph$)[5] ligands.

The mechanisms that give rise to these products are only poorly understood, but the products themselves are useful structural and chemical models of key intermediates in the reduction of dinitrogenous substrates to ammonia at a binuclear core.[6] In addition, we have demonstrated that the complex $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N_\alpha N_\beta Ph)]$ unexpectedly undergoes protonation at the outer nitrogen atom (N_β) to give the $\mu\text{-}\eta^1$-isodiazene derivative $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}NNHPh)](BF_4)$, which, upon warming, readily isomerises into the more thermodynamically favoured $\mu\text{-}\eta^2$-diazene $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}HN{=}NPh)](BF_4)$ species.[5] The molecular structure of this derivative showed that the *cis*-diazene Ph−N=N−H unit is stabilized by the $\{Mo_2Cp_2(\mu\text{-}SMe)_3^+\}$ dimolybdenum core.

In order to obtain more information on the interaction of hydrazines with Mo_2 systems we investigated the reactions of $RNHNH_2$ (R = Me, Ph) with another tris-thiolato-bridged compound, namely the bis-nitrile derivative $[Mo_2Cp_2(\mu\text{-}SMe)_3(MeCN)_2](BF_4)$ (**1**), in which the labile nitrile groups conferred a reactivity that was quite different from that of the chloride-bridged complex.[3a] We report here the ready formation of *cis*-diazene species $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}HN{=}NR)](BF_4)$ [R= Me (**2**), Ph (**3**)] and their relationships with their η^1-, η^2-diazenido and η^1-isodiazene/hydrazido(2−) parent molecules. Moreover, we show multiple transformations of methyldiazene and methyldiazenido substrates at a bimetallic site and describe the solid-state structure of a rare η^2-methyldiazenido bridged complex.[7−9]

Results

Syntheses and Spectroscopic Characterisation of $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}HN{=}NR)](BF_4)$ [R= Me (2), Ph (3)] and $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NR)]$ [R= Me (4), Ph (5)]

A red solution of $[Mo_2Cp_2(\mu\text{-}SMe)_3(MeCN)_2](BF_4)$ (**1**) in acetonitrile reacted with an excess of $MeNHNH_2$ at

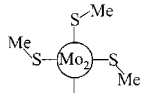
room temperature within 1 h to give a mixture of the two compounds $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}HN{=}NMe)](BF_4)$ (**2a**) and $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH_2)]$ (**6**) [Equation (1)]. Precipitation of **6** from the cooled acetonitrile solution and subsequent workup permitted **2a** to be isolated as a spectroscopically and analytically pure brownish powder in 50−60% yields. Under the same conditions, $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}HN{=}NPh)](BF_4)$ (**3a**) was the only product obtained with $PhNHNH_2$. The yields of **2a** and **3a** were occasionally lowered by the formation of a deactivated paramagnetic derivative of the bis-nitrile complex, namely $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}NHCO(Me)](BF_4)$ (**7**), which was formed in low and varying yields and could also be detected in cyclic voltammetry experiments.[3b]

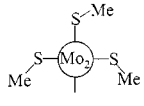
$$\underset{\mathbf{1}}{Mo_2Cp_2(\mu\text{-}SMe)_3(MeCN)_2](BF_4)} \xrightarrow[CH_3CN]{MeNHNH_2\ (excess)} \underset{\mathbf{2a}}{[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH{=}NMe)](BF_4)} + \underset{\mathbf{6}}{[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH_2)]} \quad (1)$$

Complexes **2a** and **3a** were unambiguously formulated as dimolybdenum species $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}HN{=}NR)](BF_4)$ with R = Me and R = Ph, respectively. Their ^1H NMR ($CDCl_3$) spectra exhibit two inequivalent cyclopentadienyl resonances and three SMe resonances, indicating that the $\{Mo_2Cp_2(\mu\text{-}SMe)_3\}$ moiety has been retained. The presence of a H−N=N−R ligand is supported by the observation of a low-field signal (at about δ = 12) typical for the proton of the NH group and of the peaks expected for the R substituent.[7] Two-dimensional heteronuclear ^1H-^{15}N inverse-correlation experiments completed the characterisation of **2a**. The ^{15}N chemical shifts (relative to nitromethane) of the NH and NMe groups could be unambiguously assigned to peaks at δ = −18.5 and δ = −31.0, respectively.

On heating, **2a** and **3a** underwent a change in the orientation of the methyl group of one thiolate bridge [Equation (2)]. This isomerization reaction was complete within 24 h and afforded compounds **2b** and **3b**. Complex **2b** is new but it gives rise to ^1H NMR patterns that resemble those of **2a**, suggesting strongly that the two compounds have very similar structures. In particular, the ^1H NMR spectrum of **2b** shows a resonance at δ = 12.3 attributed to the NH group of the diazo bridge. Compound **3b** was identified by comparison of its ^1H NMR spectroscopic data with that of an authentic sample of the species obtained by protonation of the $\mu\text{-}\eta^2$-diazenido derivative $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NPh]$. X-ray analysis has established a *syn* orientation of the methyl groups borne by the two sulfur atoms that lie in the equatorial plane of this molecule.[5]

$$\underset{\text{R = Me 2a, Ph 3a}}{[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH{=}NR)](BF_4)} \xrightarrow{MeCN/\Delta} \underset{\text{R = Me 2b, Ph 3b}}{[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH{=}NR)](BF_4)} \quad (2)$$





Deprotonation of **2a**−**b** and **3a**−**b** could readily be carried out with Et_3N or BuLi, and gave the η^2-diazenido species $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NR)]$ [R = Me (**4a**−**b**), R = Ph (**5a**−**b**)] [Equation (3)]. Likewise, complexes **4**−**5** could readily be protonated to regenerate **2**−**3**. The absence of a resonance at about δ = 12 in the ^1H NMR spectra of **4a**−**b** and **5a**−**b** indicates loss of the NH proton. Complexes **5a**−**b** have been identified as a pair of isomers, which differ in the orientation of the *S*-methyl substituents, by comparison of their ^1H NMR spectra with those of a mixture of the two isomers of the compound $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NPh)]$, previously obtained from the reaction of the chloro-bridged derivative $[Mo_2Cp_2(\mu\text{-}Cl)(\mu\text{-}SMe)_3]$ with $PhNHNH_2$.[5]

$$\underset{\mathbf{2\text{-}3}}{[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH{=}NR)](BF_4)} \underset{HBF_4}{\overset{BuLi}{\rightleftharpoons}} \underset{\mathbf{4\text{-}5}}{[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NR)]} \quad (3)$$

Molecular Structure of $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NMe)]$ (4b)

Various bonding modes have been observed for the diazenido ligand.[7,8,10] Sutton et al have recently given a helpful summary of these, and we use their terminology in the following discussion.[8] However, very few of the available structural examples relate to the methyldiazenido ligand.[7−9,11−14]

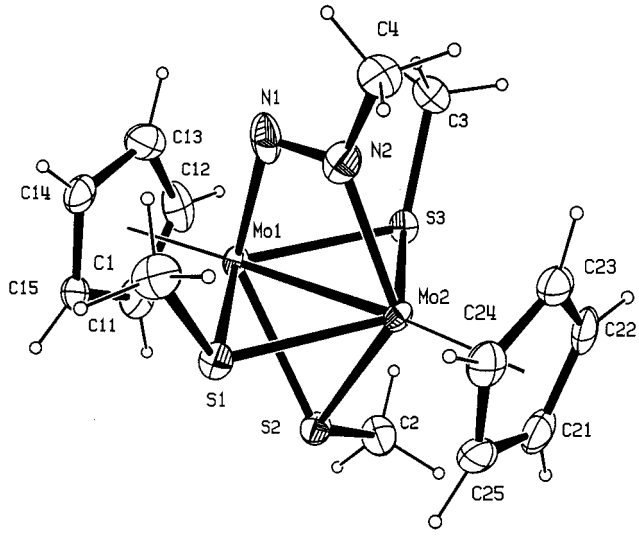


Figure 1. Molecular structure of $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NMe)]$ **4b** showing 20% probability ellipsoids; selected bond lengths [Å] and angles [°]: Mo(1)−Mo(2) 2.613(1), Mo(1)−N(1) 2.058(5), Mo(2)−N(2) 2.096(4), N(1)−N(2) 1.202(5), N(2)−C(4) 1.490(6), Mo(1)−S(1) 2.419(1), Mo(1)−S(2) 2.453(1), Mo(1)−S(3) 2.406(1), Mo(2)−S(1) 2.429(1), Mo(2)−S(2) 2.451(1), Mo(2)−S(3) 2.423(1); Mo(1)−S(1)−Mo(2) 65.2(1), Mo(2)−S(2)−Mo(1) 64.4(1), Mo(1)−S(3)−Mo(2) 65.5(1), N(2)−Mo(2)−Mo(1) 68.1(1), N(1)−Mo(1)−Mo(2) 72.2(1), N(2)−N(1)−Mo(1) 107.1(4), N(1)−N(2)−Mo(2) 112.5(4), N(1)−N(2)−C(4) 115.4(4), C(4)−N(2)−Mo(2) 132.0(3)

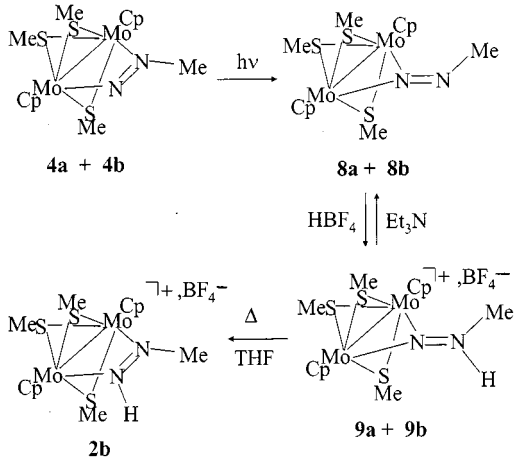
The structure of **4b** (Figure 1) consists of a tris(μ-thiolato)dimolybdenum unit $\{Mo_2Cp_2(\mu\text{-}SMe)_3\}$ bridged by a

bidentate, doubly bent N=N−Me group, which is σ-bonded to the Mo_2 unit through both nitrogen atoms [Mo(1)−N(1) = 2.058(5), Mo(2)−N(2) = 2.096(4) Å]. These Mo−N distances differ only slightly from one another. They are shorter than the Mo−NH_2 bonds in the amido complex [$Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH_2)$] (**6**) [2.151(2) Å],[4] but not nearly as short as the terminal Mo−NNMe distance of 1.809(3) Å in [Mo{$N(CH_2CH_2S)_3$}(NNMe)], where the Mo−N=N angle is nearly linear.[14] In **4b** the N−N and Mo−Mo bonds are virtually coplanar [N(1)−Mo(1)−Mo(2)−N(2) = 0.1(2)°] and the N(1)−N(2) bond length of 1.202(5) Å is nearly equal to the corresponding value of 1.213(4) Å in [Mo{$N(CH_2CH_2S)_3$}(NNMe)], where the metal-bound N atom is *sp* rather than sp^2-hybridised. The N=N bond lengths in N_2Me ligands in general seem insensitive to the bonding mode of the diazenide: a value of 1.224(11) Å was found in the triply bridging diazenido compound [{$Mn(CO)_4$}$_3$(μ_3-N_2Me)],[11] 1.247(4) Å in the bridging singly bent diazo complex [$CpW(CO)_2(\mu_2\text{-}\eta^2\text{-}N_2Me)Cr(CO)_5$],[12] and values of 1.215(5) and 1.199(4) Å in the singly bent N_2Me mononuclear complexes [$CpW(CO)_2(N_2Me)$][13] and [$ReCl(N_2Me)(MeNHNH_2)${$PPh(OEt)_2$}$_3$][BPh_4], respectively.[9]

The endocyclic angles in the Mo_2N_2 ring [72.2(1) and 68.1(1)° at Mo, 107.1(4) and 112.5(4)° at N(1) and N(2)] resemble those in related strained four-membered M_2N_2 ring derivatives such as [{$C_5Me_5Ir(CO)$}$_2$($\mu\text{-}\eta^2$-*p*-$N_2C_6H_4OMe$)][8] and [$Os_3(CO)_{10}(\mu\text{-}H)(\mu\text{-}\eta^2\text{-}N_2C_6H_5)$].[10] The Mo(1)−Mo(2) distance [2.613(1) Å] is typical for a quadruply bridged {$Mo_2Cp_2(\mu\text{-}SMe)_3$} dimolybdenum(III) compound and indicates the bond of unit order required by electron counting rules.[2]

Synthesis and Spectroscopic Characterisation of [$Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NMe)$] (8) and [$Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NHMe)$]($BF_4$) (9)

Photolysis of a red solution of **4** in THF afforded an orange solution of the complex [$Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NMe)$] (**8**) (Scheme 1). Conversion of **4** into **8** was complete within 48 h. ^{1}H NMR analysis of **8** revealed the presence of two isomeric species, which are believed to differ only in the orientation of a single SMe group. The ^{1}H NMR spectrum shows two similar sets of resonances: two peaks between δ = 6 and δ = 5, a single signal at about δ = 3.4 and three peaks between δ = 2 and δ = 1, which can be assigned to inequivalent cyclopentadienyl ligands, the NMe end of the diazo bridge, and the three SMe groups, respectively.



Scheme 1

The mode of coordination of the diazenido bridge in **8** is preserved in the orange cationic complex **9**, which is formed by addition of HBF_4 to a solution of **8** (Scheme 1). Compound **9** could be identified without any ambiguity by ^{1}H NMR spectroscopy. Its ^{1}H NMR spectrum displays two sets of characteristic resonances assigned to the {$Mo_2Cp_2(\mu\text{-}SMe)_3$} cores of two isomers. In addition, two similar patterns consisting of a doublet ($J_{H,H}$ = 4.0 Hz) at δ = 3.56 and 3.64, and a single broad resonance at δ = 11.98 and 12.64 can be attributed to an H−N−CH_3 group. Irradiation of the signals at δ = 11.98 and 12.64 gave two singlets at δ = 3.56 and 3.64, which confirms the $^3J_{H,H}$ coupling. Furthermore, variable-temperature ^{1}H NMR experiments (between 293 and 340 K) show that the line shape is temperature dependent, suggesting that isomer **9a** is fluxional. On warming to 330 K in CD_3CN, broadening and coalescence of the cyclopentadienyl signals of **9a** occurred. The activation barrier of the resulting dynamic process, estimated from the chemical shift difference Δν and the coalescence temperature of the Cp signals in the ^{1}H NMR spectrum [$\Delta G^{\neq} = 4.575T_c(9.972 + \log_{10}T_c - \log_{10}\Delta\nu)$], is 71 ± 1 kJ·mol^{-1}.[15] A similar behaviour ($\Delta G^{\neq}$ = 61 ± 1 kJ·mol^{-1}) has previously been reported for the analogous phenyl derivative [$Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NHPh)$]($BF_4$) (**10**), in which the methyl groups of the equatorial thiolate bridges are in an *anti* configuration.[5] The dynamic behaviour of **9** and **10** is attributable to rotation of the NHR group around the N=N bond axis.

Compound **9** was easily deprotonated to regenerate **8** (Scheme 1), and thermolysis of a mixture of **9a** and **9b** afforded complex **2b** exclusively (Scheme 1).

Discussion

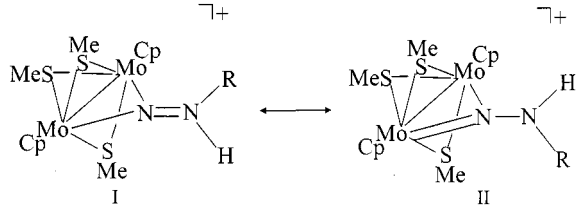
Protic diazenes, RN=NH, are reactive species that readily decompose into RH by an N_2 extrusion process.[7,16] Such molecules may be stabilized through coordination to one or two metal centres. There are several reports of the formation of protic diazene complexes by insertion of aryldiazonium reagents ArN_2^+ into a metal-hydride bond or by oxidation of a suitable hydrazine $RNHNH_2$ (R = aryl, alkyl or H), previously coordinated to a metal centre.[7,9,17−19] The latter route has been used to effect the synthesis of methyldiazene derivatives.[9,19] However, it remains unclear precisely how substituted hydrazines $RNHNH_2$ (R = Me, Ph) undergo dehydrogenation upon treatment with [$Mo_2Cp_2(\mu\text{-}SMe)_3(MeCN)_2$]($BF_4$) (**1**). It has not been possible to detect the loss of H_2 or the formation of any other side products arising from the eventual disproportionation

or deprotonation of hydrazines.[20] The formation of the amido derivative $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH_2)]$ (**6**) from methylhydrazine indicates that the reagent does undergo disproportionation, but **6** has not been isolated from the analogous reaction with phenylhydrazine. We assume that **6** can be formed by reaction of **1** with ammonia at room temperature, but that has no bearing on the formation of **2**−**3** through a disproportionation mechanism.[21] However, the hydrido complex $[HOs(CO)_{10}(\mu\text{-}\eta^2\text{-}N_2Ph)]$ was formed by reaction of phenylhydrazine with the triosmium derivative $[Os_3(CO)_{10}(MeCN)_2]$.[10] This suggests that the protons of the hydrazine can add to a metal centre and that subsequent elimination of H_2 or deprotonation may afford diazenido or diazene species.

The deprotonation of the diazene species **2a** allowed us to compare the behaviour of methyldiazene and methyldiazenido substrates at a bimetallic site with that of the related phenyl ligands that we have described previously.[5,6] $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}N{=}NMe)]$ (**4**) was completely transformed by photolysis into its η^1 isomer $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NMe)]$ (**8**). It is worth noting that **8** was readily protonated at the outer nitrogen (N_β) atom and that the protonated product $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NHMe)](BF_4)$ (**9**) was easily isolated as a powder that could be stored for several weeks under a nitrogen atmosphere without isomerizing into **2**. Compound **9** is reasonably stable in solution, and its isomerization into the $\{\mu\text{-}\eta^2\text{-}HN{=}NMe\}$ species **2** was observed only after it had been kept for long periods in solution at ambient temperature (for example, during attempts at recrystallization) or when the solution had been heated. This contrasts with the behaviour of the phenyl analogue **10**, which isomerizes readily at room temperature, and which can be stored in solution only after cooling. The methyl group is evidently more effective than the phenyl group at stabilizing the $\{\mu\text{-}\eta^1\text{-}N{=}NHR\}$ system, and the outer nitrogen atom in $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NR)]$ complexes is obviously more basic when R = Me. Attempted protonation of the outer nitrogen atom in a doubly bent η^1-N=NR bridge has usually been unsuccessful.[8,10]

In mononuclear complexes containing a terminal doubly bent diazenido ligand it has been shown that the inner nitrogen atom (N_α) is more basic than the N_β atom, and is therefore more easily protonated to give diazene groups.[8] In complexes like $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^1\text{-}N{=}NR)]$ the inner nitrogen atom is coordinated to both metal atoms and only the outer nitrogen can be protonated.

The facile $\mu\text{-}\eta^1 \rightarrow \mu\text{-}\eta^2$ rearrangement process observed in $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}N_2HR)]^+$ species, with concomitant migration of the proton from the outer to the inner nitrogen atom to give an η^2-NH=NR species, reveals the flexible nature of the ($\mu\text{-}\eta^1\text{-}N_2HR$) bridge, especially when R= phenyl. The values of the energy barrier for rotation of the NHR group about the N−N axis in **9** and **10** are in agreement with a greater lability of the diazo bridge when R = Ph than when R = Me. Indeed, replacement of a phenyl by a methyl group increases the energy barrier ($\Delta G^{\neq}$) by about 10 kJ/mol. This suggests that the η^1-N_2HR bridging ligand is better described as an hydrazido(2−) limiting form when R = Ph (II in Scheme 2) and as an isodiazene form when R = Me (I in Scheme 2). The greater electron-withdrawing ability of Ph than Me is consistent with this suggestion. In addition, preliminary electrochemical experiments on the protonated diazenido complexes[22] show that oxidation, which can be compared with the electronic effect of replacing Me by Ph, favours the $\mu\text{-}\eta^1 \rightarrow \mu\text{-}\eta^2$ isomerisation. Moreover, in reactions with bases the cation $[Mo_2Cp_2(\mu\text{-}SMe)_3(MeCN)_2]^+$, (**1**$^+$), releases both of its terminal nitrile ligands more easily than $[Mo_2Cp_2(\mu\text{-}Cl)(\mu\text{-}SMe)_3]$ loses its bridging chloride group, thus explaining the formation of different products, η^2-diazene derivatives from **1**$^+$, but η^1-diazenido species from the μ-chloro complex.



Scheme 2

Experimental Section

General Procedures: All the reactions were performed under nitrogen using standard Schlenk techniques. Solvents were deoxygenated and dried by standard methods. IR spectra were recorded on a Perkin−Elmer 1430 spectrophotometer from KBr pellets. Chemical analyses were performed by the Centre de Microanalyses du CNRS, Vernaison, France. ^{1}H NMR spectra were recorded on either a Bruker AC300 or AMX3 400 spectrometer and were referenced to $SiMe_4$. ^{1}H-^{15}N HMBC NMR spectra were recorded on a Bruker 500 and AMX3 400 spectrometer by R. Pichon and N. Kervarec. Literature methods were used for the preparation of $[Cp_2Mo_2(\mu\text{-}SMe)_3(CH_3CN)_2](BF_4)$ (**1**).[23]

Preparation of $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}HN{=}NMe)](BF_4)$ (2a): An excess of methylhydrazine (72 μL, 1.36 mmol) was added to a solution of **1** (0.32 mmol, 200 mg) in 15 mL of acetonitrile. The mixture was stirred at room temperature for one hour, whereupon the colour of the mixture changed from red to orange and then a brown solid of $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}NH_2)]$ (**6**) precipitated. Precipitation of **6** was completed by concentration and cooling of the solution (yields: 54 mg, 35%). The solution was then filtered off and the solvents evaporated under vacuum to afford a brown residue that was washed with pentane (2 × 10 mL). Complex **2a** was obtained as a brown powder (yield: 104 mg, 55%). $C_{14}H_{24}BF_4N_2Mo_2S_3$ (595.2): calcd. C 28.3, H 3.9, N 4.7; found C 28.1, H 4.3, N 5.3. Selected spectroscopic data for **2a**: ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.54 (s, 3 H, SCH_3), 1.63 (s, 3 H, SCH_3), 1.77 (s, 3 H, SCH_3), 3.69 (s, 3 H, HN=NCH_3), 5.70 (s, 5 H, C_5H_5), 5.88 (s, 5 H, C_5H_5), 12.30 (s, 1 H, HN=NCH$_3$). IR (KBr): $\tilde{\nu}$ = 3160 cm^{-1} (w), [ν(N−H)], 1150−950 (s) [ν(B−F)].

Preparation of $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}\eta^2\text{-}HN{=}NPh)](BF_4)$ (3a): An excess of phenylhydrazine (54 μL, 0.48 mmol) was added at room temperature to an acetonitrile (10 mL) solution of **1** (0.16 mmol, 100 mg). The mixture was stirred for one hour and the solution turned orange. The volume of the mixture was then reduced under vacuum and diethyl ether was added to precipitate the brown-or-

ange product **3a** (yield: 73 mg, 70%). $C_{19}H_{25}BF_4N_2Mo_2S_3$ (656.3): calcd. C 34.8, H 3.8, N 4.3; found C 35.3, H 4.2, N 4.3. Selected spectroscopic data for **3a**: ^{1}H NMR (CD_2Cl_2, 298 K): δ = 1.71 (s, 3 H, SCH_3), 1.73 (s, 3 H, SCH_3), 1.81 (s, 3 H, SCH_3), 5.85 (s, 5 H, C_5H_5), 6.03 (s, 5 H, C_5H_5), 7.32−6.79 (m, 5 H, HN=NC$_6H_5$), 12.0 (s, 1 H, HN=NC$_6$H$_5$). IR (KBr): ṽ = 3200 cm^{-1} (w) [ν(N−H)], 1200−900 (s), [ν(B−F)].

Preparation of [Mo_2Cp_2(μ-SMe)$_3$(μ-η^2-HN=NR)](BF$_4$) [R = Me (2b), R = Ph (3b)]: A solution of **2a** (0.17 mmol, 100 mg) in 10 mL of acetonitrile was warmed to 70 °C for 24 h. The solution turned green. The solution was then concentrated and addition of diethyl ether precipitated a green powder, which was washed twice with pentane (2 × 10 mL). Complex **2b** was obtained as a green powder (yield: 96 mg, 95%). $C_{14}H_{24}BF_4N_2Mo_2S_3$ (595.2): calcd. C 28.2, H 3.9, N 4.7; found C 28.0, H 4.2, N 5.3. Selected spectroscopic data for **2b**: ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.45 (s, 3 H, SCH_3), 1.58 (s, 3 H, SCH_3), 1.63 (s, 3 H, SCH_3), 3.79 (s, 3 H, HN=NCH_3), 5.77 (s, 5 H, C_5H_5), 5.91 (s, 5 H, C_5H_5), 12.58 (s, 1 H, HN=NCH$_3$). IR (KBr): 3080 cm^{-1} (w), ṽ = [ν(N−H)], 1200−950 (s), [ν(B−F)].

In a similar manner, the complex **3b** was obtained as an orange powder (yield: 88 mg, 90%) upon warming **3a** (0.15 mmol, 98 mg). Selected spectroscopic data for **3b**:[5] ^{1}H NMR (CD_3CN, 298 K): δ = 1.52 (s, 3 H, SCH_3), 1.65 (s, 3 H, SCH_3), 1.72 (s, 3 H, SCH_3), 5.79 (s, 5 H, C_5H_5), 6.11 (s, 5 H, C_5H_5), 7.42−6.93 (m, 5 H, HN=NC$_6H_5$), 12.6 (s, 1 H, HN=NC$_6$H$_5$).

Preparation of [Mo_2Cp_2(μ-SMe)$_3$(μ-η^2-N=NMe)](BF$_4$) (4a−b): 100 μL of a 2.5 M solution of butyllithium in hexane (0.25 mmol) was added to a dichloromethane (10 mL) solution of **2a** or **2b** (100 mg, 0.17 mmol). The solution rapidly turned red. After stirring for a few minutes at ambient temperature, the solvent was evaporated. The residue was extracted with diethyl ether and the extract was purified by chromatography on a silica gel column. Elution with a mixture of THF/Et_3N (90:10) afforded compounds **4a** (yield: 60 mg, 70%) and **4b** (yield: 56 mg, 65%).
4a: ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.29 (s, 3 H, SCH_3), 1.44 (s, 3 H, SCH_3), 1.69 (s, 3 H, SCH_3), 3.41 (s, 3 H, N=NCH_3), 5.44 (s, 5 H, C_5H_5), 5.67 (s, 5 H, C_5H_5).
4b: ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.31 (s, 3 H, SCH_3), 1.38 (s, 3 H, SCH_3), 1.48 (s, 3 H, SCH_3), 3.45 (s, 3 H, N=NCH_3), 5.45 (s, 5 H, C_5H_5), 5.68 (s, 5 H, C_5H_5).

In similar manner, complexes **5a−b** were obtained as green powders (yield: **5a**: 55 mg, 65%; **5b**: 60 mg 70%) by reacting BuLi with **3a** or **3b** (0.15 mmol, 100 mg).
5a:[5] ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.49 (s, 3 H, SCH_3), 1.50 (s, 3 H, SCH_3), 1.68 (s, 3 H, SCH_3), 5.31 (s, 5 H, C_5H_5), 5.85 (s, 5 H, C_5H_5), 7.13−6.59 (m, 5 H, HN=NC$_6H_5$).
5b:[5] ^{1}H NMR ($CDCl_3$, 298 K): 1.37 (s, 3 H, SCH_3), 1.45 (s, 3 H, SCH_3), 1.53 (s, 3 H, SCH_3), 5.44 (s, 5 H, C_5H_5), 5.89 (s, 5 H, C_5H_5), 7.20−6.61 (m, 5 H, HN=NC$_6H_5$).

Photolysis of [Mo_2Cp_2(μ-SMe)$_3$(μ-η^2-N=NMe)](BF$_4$) (4a−b): A mixture of **4a** and **4b** (100 mg, 0.20 mmol) was dissolved in 20 mL of THF and irradiated with UV light [Hanau TQ 150 mercury-vapour lamp (300−600 nm)] for 48 h at room temperature. The solution changed from red to orange during this time. THF was removed under vacuum and the residue was purified by chromatography on a silica gel column. Elution with THF/Et_3N (90:10) afforded an orange band containing **8a−b** (yields: 60 mg, 60%).
8a: (80%). ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.20 (s, 3 H, SCH_3), 1.27 (s, 3 H, SCH_3), 1.90 (s, 3 H, SCH_3), 3.41 (s, 3 H, N=NCH_3), 5.35 (s, 5 H, C_5H_5), 5.53 (s, 5 H, C_5H_5).
8b: (20%). ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.18 (s, 3 H, SCH_3), 1.46 (s, 3 H, SCH_3), 1.83 (s, 3 H, SCH_3), 3.43 (s, 3 H, N=NCH_3), 5.44 (s, 5 H, C_5H_5), 5.62 (s, 5 H, C_5H_5).

Preparation of Complexes [Mo_2Cp_2(μ-SMe)$_3$(μ-η^1-N=NHMe)](BF$_4$) (9a−b): 1 Equiv. of HBF_4·Et_2O was added to a solution of **8** (100 mg, 0.20 mmol) in Et_2O (10 mL). Orange solids of [Mo_2Cp_2(μ-SMe)$_3$(μ-η^1-N=NHMe)](BF$_4$) (**9**) precipitated from the solution and were collected by filtration and then washed with pentane (yields: 112 mg, 85%). $C_{14}H_{24}BF_4N_2Mo_2S_3$ (595.2): calcd. C 28.3, H 3.9, N 4.7; found C 29.0, H 4.1, N 4.7. Selected spectroscopic data for **9a**: ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.51 (s, 3 H, SCH_3), 1.64 (s, 3 H, SCH_3), 2.08 (s, 3 H, SCH_3), 3.64 (d, $J_{H,H}$ = 4 Hz, 3 H, N=NHCH_3), 5.88 (s, 5 H, C_5H_5), 5.97 (s, 5 H, C_5H_5), 12.40 (s, 1 H, N=NHCH$_3$). Selected spectroscopic data for **9b**: ^{1}H NMR ($CDCl_3$, 298 K): δ = 1.47 (s, 3 H, SCH_3), 1.49 (s, 3 H, SCH_3), 1.98 (s, 3 H, SCH_3), 3.56 (d, $J_{H,H}$ = 4 Hz, 3 H, N=NHCH_3), 5.96 (s, 5 H, C_5H_5), 6.03 (s, 5 H, C_5H_5), 11.97 (s, 1 H, N=NHCH$_3$). IR (KBr): ṽ = 3220 cm^{-1} (w), [ν(N−H)], 1200−900 (s), [ν(B−F)].

Structure Analysis: Details of the structure analysis of **4b** are summarised in Table 1.[25] The crystals were very thin plates and it was necessary to use synchrotron radiation in conjunction with a Bruker SMART diffractometer to get measurable diffraction patterns. The structure was solved and refined by standard methods.[24] The cyclopentadienyl rings were treated as variable metric rigid groups.

New Fluorenyl-Substituted Dioxotetraamine Ligands and Their Copper(II) Complexes − Crystal Structure and Fluorescent Sensing Properties in Aqueous Solution

Li-Jian Jiang,[a,b] Qin-Hui Luo,*[a] Qing-Xiang Li,[a] Meng-Chang Shen,[a] and Hong-Wen Hu[a]

Keywords: Copper / Dioxotetraamines / Fluorescence / N ligands

Two new ligands consisting of a fluorenyl and dioxotetraaza unit, namely, 2,10-diamino-6-(9*H*-fluoren-9-yl)-4,8-diazaundecane-5,7-dione (L^1) and 1-(9*H*-fluoren-9-yl)-1,4,7,10-tetraazadecane-5,6-dione (L^2) along with their copper(II) complexes have been synthesized. Their properties were examined by ES-MS and CV in aqueous solution and the crystal structure of the copper(II) complex of L^1 has also been determined. The recognition of the transition metal ions (Cu^{2+}, Ni^{2+}, etc.) by receptors has been studied in aqueous solutions using pH-potentiometric and fluorimetric titrations. The results show that the binding of Cu^{2+} or Ni^{2+} ion with L^1 leads to quenching of the fluorescence of the fluorenyl group, but on the contrary the fluorescence of L^2 is enhanced. The mechanisms are discussed.

Introduction

The phenomena of luminescence quenching and enhancement resulting from metal−ligand interactions have attracted much attention with regards to its application in sensing metal ions in solution.[1,2] The dioxotetraamine ligands are interesting because they coordinate metal ions with the release of two protons on the amide nitrogen atoms and are able to stabilize a +3 oxidation state of transition metal ions.[3] Recently, chemists have been devoted to append a luminophore to the framework of the dioxotetraamine ligands and to explore new fluorescent signaling systems.[4−6] Although many luminescent signaling systems have been presented,[7−9] to date, hydrophilic luminescent ligands used as receptors are still rarely reported.[1,10] In view of the high quantum yield and long fluorescent lifetime of fluorene, we linked it as a luminophore to the dioxotetraamine units and obtained two new water-soluble ligands, 2,10-diamino-6-(9*H*-fluoren-9-yl)-4,8-diazaundecane-5,7-dione (L^1) and 1-(9*H*-fluoren-9-yl)-1,4,7,10-tetraazadecane-5,6-dione (L^2) and synthesized their complexes $[Cu(H_{-2}L^1)]\cdot 2H_2O$ and $[Cu(H_{-2}L^2)]\cdot 4H_2O$ by the route shown in Scheme 1.

It is interesting that L^1 and L^2 exhibit different fluorescent properties. The fluorescence of fluorenyl in L^1 is quenched by transfer of electrons from the metal center to the photoexcited state of fluorenyl during coordination of Cu^{II} or Ni^{II}. Conversely, fluorescence of L^2 is enhanced by coordination of transition metal ions. Their different fluorescent properties result from different positions of fluorenyl in the ligands. Because both ligands and complexes are water-soluble, they might have an application in biological analysis. To the best of our knowledge, the studies on enhancement of fluorescence of ligands by transition metal ions in aqueous solution are limited.[8]

Results and Discussion

Characterization

The values of molar conductivities of $[Cu(H_{-2}L^1)]\cdot 2H_2O$ and $[Cu(H_{-2}L^2)]\cdot 4H_2O$ in aqueous solution indicate that the amide protons are lost during coordination of the Cu^{2+} ion. In the IR spectra, both ligands exhibit two bands at about 760 and 740 cm^{-1} which are assigned to skeleton stretching vibration of the fluorene ring. The bands at 1660 cm^{-1} are assigned to the vibration of the carbonyl groups of L^1 or L^2 shifted by about 90 cm^{-1} during the coordination of Cu^{2+} ions. In the ^1H NMR spectrum of L^2 there are four groups of peaks at $\delta = 7.46-7.88$ assigned to the resonance absorption of protons of the fluorene ring, confirming linkage of the fluorenyl group to the dioxotetraamine unit. At $\delta = 2.96-3.62$ there are four groups of triple peaks assigned to the four methylene groups. The resonance absorption of protons on the nitrogen atoms disappeared due to exchange with heavy water. The ^1H NMR spectrum of the ligand L^1 is similar to that of L^2.

The ES-MS spectrum of L^2 that coexisted with the Cu^{2+} ion in methanol solution at pH = 9 is shown in Figure 1. The simplicity of the spectrum is attributed to the thermodynamic stability and kinetic inertness of the ligand. No obvious ligand fragmentation peaks were observed, showing that the ligand is quite stable under the ES-MS spectrum conditions.

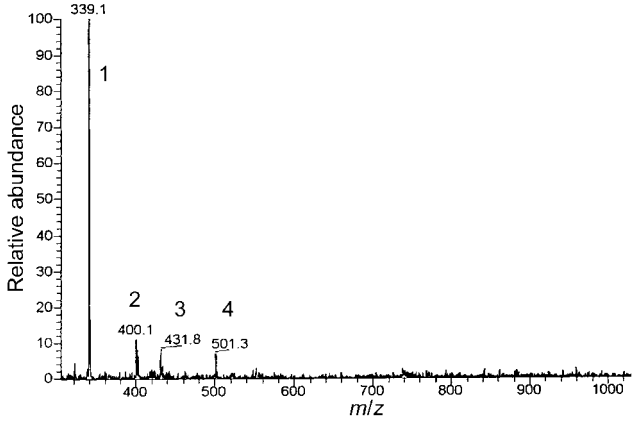

Figure 1. ES-MS spectrum of $L^2 + Cu^{2+}$ (1:1) system at pH = 9: 1. $[HL^2]^+$, 2. $[Cu(H_{-1}L^2)]^+$, 3. $[Cu(H_{-2}L^2)\cdot MeOH]^+$, 4. $[CuL^2(ClO_4)]^+$

Crystal Structure of $[Cu(H_{-2}L^1)]\cdot 2H_2O$

In Figure 2 the crystal structure of the copper(II) complex $[Cu(H_{-2}L^1)]\cdot 2H_2O$ is shown. Selected bond lengths and angles are listed in Table 1. From Figure 3 and Table 1 it can been seen that the copper(II) atom is situated in the center of a slightly distorted square composed of four nitrogen atoms. The distance between the plane and copper atom is 0.1628(4) Å. The distances of Cu−N are 1.941−2.022 Å. Two methyl groups are situated on the same side of the plane composed of four nitrogen atoms, and the carbon atoms (C-1, C-9) of the methyl groups deviate from the plane by 1.705(9) and 1.751(6) Å, respectively. The six-membered ring composed of N-2, Cu-1, N-3, C-6, C-5 and C-4 has a chair conformation. The fluorene ring is linked to the six-membered ring by the C-5 atom and forms a dihedral angle of 45.7 ° with the plane composed of N-2, N-3, C-6 and C-4. The complex was linked to the water molecules by the hydrogen bonds and formed a two-dimensional network structure.

Electrochemistry

The cyclic voltammetrical diagrams of $[Cu(H_{-2}L^1)]$ and $[Cu(H_{-2}L^2)]$ have similar features. During anodic scanning from 0−1.0 V, the ligands L^1 and L^2 do not show redox processes, but the two complexes display a pair of redox peaks. The separation between the anodic and cathodic peaks was 78−88 mV and the peak height ratio is near unit. A variation of the peak potential separation with scan rates (from 40 to 400 mVs^{-1}) was also observed. Furthermore, peak heights for the two complexes are proportional to the square roots of scan rates. The electron numbers of electrode oxidation reactions for $[Cu(H_{-2}L^1)]$ and $[Cu(H_{-2}L^2)]$ are 0.98 and 0.96 respectively, obtained by controlled potential analysis. These features are indicative of a one-electron quasi-reversible electrode process. Their values of $E_{1/2}$ are listed in Table 2.

Table 2. Half-wave potential $E_{1/2}$ (vs. SCE) for Cu^{III}/Cu^{II} redox process of $[Cu(H_{-2}L)]$ (L = L^1, L^2), pH = 9.8, scan rate 16 $mV{\cdot}s^{-1}$, Na_2SO_4 concentration = 0.5 $mol{\cdot}dm^{-3}$

	$[Cu(H_{-2}L^1)]$	$[Cu(H_{-2}L^2)]$
E_{pa} [V]	0.743	0.500
E_{Pc} [V]	0.655	0.422
ΔE [mV]	88	78
$E_{1/2}$ [V]	0.699	0.461

Stability of the Complexes

The pH-potentiometric titration curves of ligand L^1 and $L^2{\cdot}2HBr$ and that of the ligands plus metal ions(Cu^{2+}, Ni^{2+}, Co^{2+}, Zn^{2+}) are shown in Figure 3. In Figure 3 (a) all the curves 1−5 have two steps with defined inflection points. The first steps of all the curves are at $a = 2$ (a denotes the number of equivalents of base per mol of ligand), corresponding to free acid to be neutralized. The second step for the ligand L^1 (curve 1) is at $a \approx 4$, corresponding to protons of the amino cations to be neutralized. For the system of L^1 coexisting with the metal ions (curves 2−5), the second steps are at $a \approx 6$, corresponding to the formation of the predominant species $[M(H_{-2}L^1)]$.

The curves 6−8 in Figure 3 (b) are the titration curves of ligands L^2 and L^2 with the metal ions. At $a > 2$, the curves of the L^2 system are obviously different from those of the L^1 system. Curve 6 has two steps at $a = 3$ and $a = 4$, showing that the two amino nitrogen atoms have different abilities to bind protons. Two indistinct inflection points on curve 7 ($Cu^{2+} + L^2$) at $a = 4$ and $a = 5$ correspond to the formation of the dominant species $[CuL^2]^{2+}$ and $[Cu(H_{-1}L^2)]^{+}$, respectively. The obvious step of curve 8 at $a \approx 6$ shows that in the alkaline region $[Ni(H_{-2}L^2)]$ is the dominant species. Assuming that the above-mentioned species are formed, logarithms of the equilibrium constants, listed in Table 3, were obtained by curve fitting.

From Table 3 it can be seen that the stability sequence of the species [ML] and $[M(H_{-2}L)]$ (L = L^1 or L^2) is $Cu^{II} > Ni^{II} > Zn^{II} > Co^{II}$, being consistent with the Irving−Williams sequence. Stabilities of the complexes of L^2 in which an amino nitrogen atom is linked to a large fluorenyl group are lower than that of L^1. The species distribution curves of $L^1 + Cu^{2+}$ and $L^2 + Cu^{2+}$ systems are shown in Figure 4 and Figure 5, respectively.

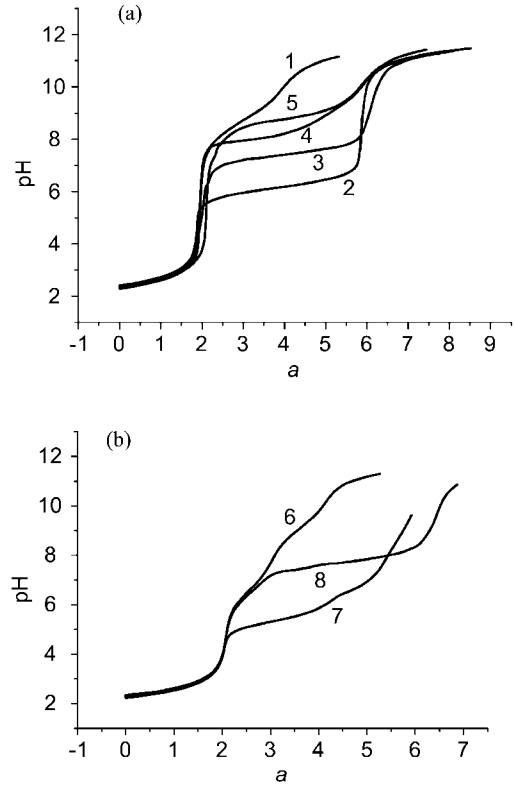

Figure 3. pH-potentiometric titration curves: (a) L^1 system, $L^1/M(NO_3)_2/HNO_3$ = 1:1:4; $L^1 = 1.8 \times 10^{-3}$ $mol{\cdot}dm^{-3}$: 1. M = none, 2. M = Cu^{2+}, 3. M = Ni^{2+}, 4. M = Zn^{2+}, 5. M = Co^{2+}; $L^2{\cdot}2HBr$ system, $L^2{\cdot}2HBr/HNO_3$ = 1:2; $L^2{\cdot}2HBr = 1.86 \times 10^{-3}$ $mol{\cdot}dm^{-3}$: 6. M = none, 7. $Cu^{2+} = 2.05 \times 10^{-3}$, 8. $Ni^{2+} = 2.08 \times 10^{-3}$ $mol{\cdot}dm^{-3}$

Fluorescent Properties of the Ligands in Aqueous Solution

The maximum fluorescence emission of L^1 in aqueous solution is located at 312 nm (pH = 9.0) by excitation of 280 nm. The intensity and position of the maximum emission remains constant at pH = 3−8. Figure 6 shows the dependence of the fluorescence intensity I_F (312 nm) and absorbance A (508 nm) of L^1 on the pH in the presence of Cu^{2+} ions. Both curves 1 and 2 show a typical sigmoidal shape. The dependence of the absorbance A on the pH is contrary to that of the fluorescence intensity. The curve of A vs. pH can be conveniently superimposed on the distribution diagram of $[Cu(H_{-2}L^1)]$ (Figure 4, curve 2), indicating that the formation of species $[Cu(H_{-2}L^1)]$ leads to quenching of the fluorescence by an electron transfer from the Cu^{II} center to the photoexcited state of the fluorenyl group Fl*. The fluorescent mechanism is similar to that of its analogs.[4,6] The electron-transfer process is described by Equation (1). The variation of potential of the electron transfer (ΔE_T) can be calculated by Equation (2).

Table 3. Logarithm of equilibrium constants of the ligands and complexes, 30±0.1 °C, KNO_3 concentration = 0.10 mol·dm^{-3}

Reaction[a]	H	Cu	Ni	Co	Zn[b]

$M^{2+} + L^2 \leftrightarrows [M(H_{-2}L^2)] + 2\,H^+$		−6.48±0.03[b]	−11.09±0.03[b]		

[a] For each system, two titrations were performed; during each titration more than 60 points were recorded. [b] At 25±0.1 °C.

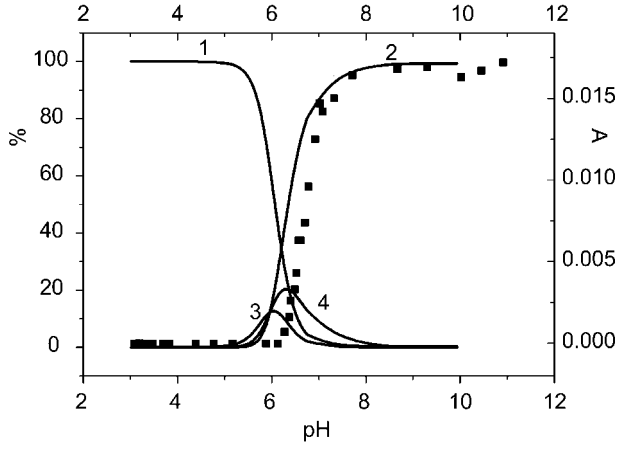

Figure 4. Species distribution curves and dependence of the absorbance A (■) on the pH for the $L^1 + Cu^{2+}$ system ($Cu^{2+} = L^1 = 2.6 \times 10^{-4}$ mol·dm^{-3}): 1. Cu^{2+}, 2. $[Cu(H_{-2}L^1)]$, 3. $[CuL^1]^{2+}$, 4. $[Cu(H_{-1}L^1)]^+$

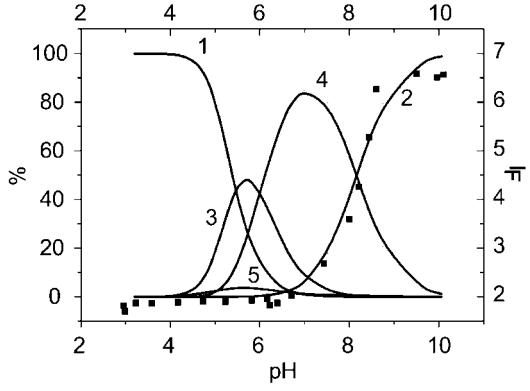

Figure 5. Species distribution curves and the dependence of the fluorescence intensity I_F (■) on the pH for the $L^2 + Cu^{2+}$ system ($Cu^{2+} = L^2 = 6.8 \times 10^{-5}$ mol·dm^{-3}): 1. Cu^{2+}, 2. $[Cu(H_{-2}L^2)]$, 3. $[CuL^2]^{2+}$, 4. $[Cu(H_{-1}L^2)]^+$, 5. $[HL^2]^+$

$$*Fl + [Cu^{II}(H_{-2}L^1)] \xrightarrow{\Delta E_T} Fl^- + [Cu^{III}(H_{-2}L^1)]^+ \quad (1)$$

$$\Delta E_T = E°(*Fl_{CT}) - E°(Cu^{III}/Cu^{II}) + E°(Fl/Fl^-) = 0.63\ V \quad (2)$$

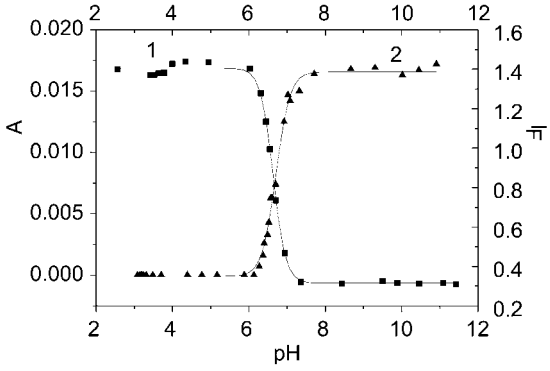

Figure 6. Dependence of fluorescence intensity I_F (1) and absorbance A (2) on the pH for an aqueous solution containing L^1 plus 1 equiv. Cu^{2+} ions

In Equation (2), the redox potential $E°(Fl/Fl^-)$ of the fluorenyl group linked to the dioxotetraaza moiety is −2.65 V, $E°(Cu^{III}/Cu^{II})$ is the redox potential obtained from cyclic voltammetrical experiments (0.699 V), and $E°(*Fl_{CT})$, the potential of the excited state, is 3.92 V, an approximation calculated from the energy of the emission band of the ligand.

The ΔE_T value of $[Cu(H_{-2}L^1)]$ is higher than that of $[Cu(H_{-2}L^3)]$[10b] (0.57 V) (L^3 denotes 6-(9*H*-fluoren-9-yl)-1,4,8,11-tetraazaundecane-5,7-dione), because in the former, two methyl groups that substituted two hydrogen atoms on the carbon atom of the ethylenediamine decreases the redox potential $E(Cu^{III}/Cu^{II})$ and increases the excited fluorescent potential of $[Cu(H_{-2}L^1)]$, thus favoring transfer of an electron from Cu^{II} to the fluorenyl group. The electron transfer behavior of L^1 in the presence of Ni^{2+} is similar to that in the presence of Cu^{2+}. For $[Ni(H_{-2}L^1)]$, ΔE_T (+0.57 V) was obtained by the same calculated method as that for $[Cu(H_{-2}L^1)]$. It is shown from Table 3 that the stability constants of the complexes of L^1 with Co^{II} and Zn^{II} are quite low, and the complexes $[M(H_{-2}L^1)]$ (M = Co, Zn) cannot be formed at pH ≤ 8.0, therefore the electron transfer cannot proceed. When the solution of ligand L^1 was adjusted to pH = 7.0 with NaOH and Ni^{2+} ions

were gradually added to it, no obvious decrease of I_F was observed (Figure 7). When Cu^{2+} ions were added to the same solution, I_F decreased linearly to a minimum value, corresponding to $n_{Cu}/n_L = 1$. Based on the above-mentioned results, L^1 could be employed as a fluorescent sensor to discriminate between Cu^{2+} and Ni^{2+}, as well as Cu^{2+} and Ni^{2+} ions from other divalent 3d metal ions.

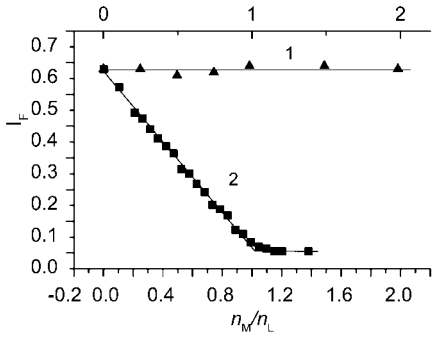

Figure 7. Plotting of I_F of H_2L^1 aqueous solution vs. n_M/n_L (M = Cu, Ni): 1. Ni^{2+} was added to a solution of H_2L^1 at pH = 7.0, 2. Cu^{2+} was added to the solution of 1.

Fluorescent properties of L^2 are different from L^1 and the fluorescent intensity of L^2 is low. A plot of I_F vs. pH in the presence of 1 equiv. of Cu^{2+} or Ni^{2+} ions is shown in Figure 8. In Figure 8, two systems display a similar fluorescent feature, when pH values of solutions are higher than 5.5. Fluorescence intensities increase with an increase of pH and reach a maximum value at pH $\approx$ 10. The curve of I_F vs. pH for systems of L^2 plus the Cu^{2+} ion can be superimposed on the distribution curve of $[Cu(H_{-2}L^2)]$ (Figure 5, curve 2), indicating that the formation of species $[Cu(H_{-2}L^2)]$ leads to an enhancement of the fluorescence. The distinction of the fluorescent properties between L^1 and of L^2 results from the difference of the structures. In L^2, a fluorenyl group substitutes a hydrogen atom of an amino group in the ligand and forms an imido group. The nitrogen atom of the imido group linked to the fluorenyl group can transfer its lone electron pair to a proximate excited fluorenyl group, quenching its fluorescence. When solutions of L^2 in the presence of metal ions were titrated with NaOH, an increase in the pH value led to binding of the metal ions. The electron transfer from the nitrogen atom to the fluorenyl group is suppressed, resulting in an enhancement of the fluorescence. The analogous mechanism has been reported by previous authors.[1,8,12] The detailed study on the fluorescence mechanism is in progress. Quantum yields of the ligand in the absence and presence of metal ions are listed in Table 4. From Table 4 it can be seen that L^2 has much lower quantum yields than L^1 in the absence of metal ions and the quantum yield of L^2 increases by about one order of magnitude upon binding of metal ions.

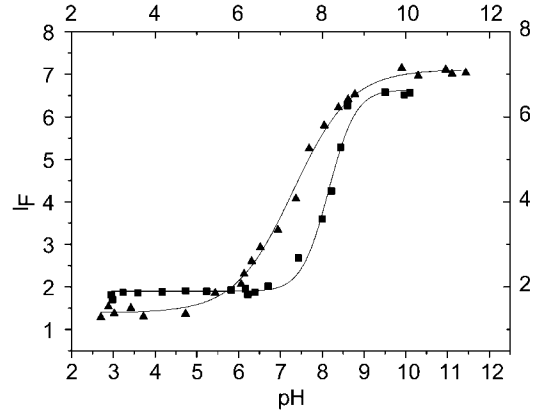

Figure 8. pH dependence of I_F for aqueous solutions containing L^2 plus metal ions; Cu^{2+} (■), Ni^{2+} (▲); $L^2 = Cu^{2+} = Ni^{2+} = 6.8 \times 10^{-5}$ mol·dm^{-3}

Table 4. Quantum yields of L^2 and L^2 plus metal ions (1:1) in aqueous solutions at 25 °C; $L^2 = Cu^{2+} = Ni^{2+} = 5 \times 10^{-5}$ mol·dm^{-3}

Sample	pH	Φ_u [a]
L^1	9.2	1.3×10^{-3}
L^2	9.2	2.0×10^{-4}
$Cu^{2+} + L^2$	5.0	5.2×10^{-4}
$Cu^{2+} + L^2$	9.2	2.7×10^{-3}
$Ni^{2+} + L^2$	5.0	2.6×10^{-4}
$Ni^{2+} + L^2$	9.2	3.4×10^{-3}
Trytophan[b]	7.2	0.14

[a] Deviation of measurement is ±15%. [b] Concentration of trytophan is 6.6×10^{-6} mol dm^{-3}.

It has been known for a long time that transition metal ions (especially Cu^{2+}) effectively quench the fluorescence of the systems by an electron transfer mechanism. Recently, Bharadwaj and co-workers[8] reported for the first time that Cu^{2+} and Ni^{2+} could enhance the fluorescence intensity of a ligand in THF/H_2O (9:1). In our systems, the enhancement of the fluorescence by Cu^{2+} and Ni^{2+} is carried out in aqueous solution. To the best of our knowledge, there are few reports[7] on enhancement of the fluorescence by transition metal ions in aqueous solution.

Experimental Section

Materials: Reagents and organic solvents were of reagent grade and purified prior to use. 9-Bromofluorene was prepared by literature methods.[13] Diethyl 2-(9*H*-fluoren-9-yl)malonate and *N*,*N*′-bis(2-aminoethyl)oxamide were synthesized by a method reported previously.[10b] Carbonate-free NaOH for pH titration was prepared by Powell's method.[14] $M(NO_3)_2 \cdot 6H_2O$ (M = Cu, Ni, Co, Zn) (reagent grade) were recrystallized from doubly distilled water and their stock solutions were standardized by titration with EDTA.

Spectral Measurements: IR spectra were measured as KBr discs with a Nicolet 5DX FT IR spectrophotometer. UV spectra were measured with an UV-3100 spectrophotometer. Luminescence spectra were recorded with an AB2 luminescence spectrometer.

Concentrations of metal ions and equivalent ligands in spectrophotometric titrations and in fluorimetric titrations were $2.6-4.3 \times 10^{-4}$ and $5.4-6.6 \times 10^{-5}$ mol·dm^{-3}, respectively. The solutions were deaerated for ca. 15 min before measurements. Quantum yields Φ of fluorescence were calculated by literature methods[15] using tryptophan as a standard. The quantum yield Φ_s of tryptophan is 0.14 in aqueous solution at 25 °C. Electrospray mass spectra (ES-MS) were obtained in positive mode with a Finnigan LCQ mass spectrograph. The diluted solutions were electrosprayed at a flow-rate of 2×10^{-4} dm^3·min^{-1} with a needle voltage of 4.5 kV. The mobile phase was a methanol solution. ^{1}H NMR spectroscopy was carried out with a Bruker AM500 spectrometer (TMS as internal reference).

Electrochemical Measurements: Cyclic voltammetry was carried out with a Model-270 electrochemical analysis system. A glassy carbon electrode was employed as working electrode, a saturated calomel electrode (SCE) as reference electrode and a platinum plate as auxiliary electrode. Experiments were performed under purified argon at 25 °C. Concentrations of the complexes were 1.0×10^{-3} to 1.0×10^{-4} mol·dm^{-3} in 0.2 mol·dm^{-3} potassium nitrate or in 0.5 mol·dm^{-3} sodium sulfate. The solutions were deaerated for ca. 15 min before applying the voltage. The half wave potentials $E_{1/2}$ were approximately calculated from $(E_{Pa} + E_{Pc})/2$. In a controlled potential coulometer, a platinum web electrode was employed as a working electrode instead of a glassy carbon.

pH Titration: The aqueous solutions containing L^1, $M(NO_3)_2$ and HNO_3 (1:1:4; M = Cu, Ni, Co, Zn) or L^2·2HBr, $M(NO_3)_2$ and HNO_3 (1:1:2; M = Cu, Ni) were titrated with carbonate-free 0.1598 mol·dm^{-3} NaOH using a microsyringe with a precision of ±2 μL in a sealed jacketed vessel at 30 °C under nitrogen. The pH values were measured with a Corning pH meter equipped with a glass/silver/silver chloride combination electrode with a precision of ±0.001 pH units. The combination electrode was standardized with buffer solutions of potassium hydrogen phthalate and sodium borate. The ionic strength was kept at 0.10 mol·dm^{-3} with KNO_3. The protonation constants of ligands were determined under the same conditions. The equilibrium constants were obtained by pH-potentiometric titrations. The protonation constants of the ligands were calculated by the PKAS program.[16] The equilibrium constants of complexes were calculated by using the program LEMIT,[17] which is based on the Newton−Raphson and Gauss−Newton method for minimizing U in Equation (3), where $C_{Hi}^{calcd.}$ and $C_{Hi}^{exp.}$ denote the calculated and experimental values of H^+ concentration at the ith point.

$$U = \sum_{i=1}^{n} (C_{Hi}^{\text{calcd.}} - C_{Hi}^{\text{exp.}})^2 \quad (3)$$

Preparation of Compounds

2,10-Diamino-6-(9*H*-fluoren-9-yl)-4,8-diazaundecane-5,7-dione (L^1): A mixture of diethyl 2-(9*H*-fluoren-9-yl)malonate (6.48 g, 0.02 mol) and freshly distilled propylenediamine (30 mL) was stirred at room temperature for two weeks. Excess propylenediamine was distilled off under reduced pressure. After cooling, the yellow residue was washed with ethanol and diethyl ether successively; L^1 (5.8 g, 76%) was obtained as a white solid. IR (KBr): ν_{max} = 3250 m (NH), 3030 w and 2930 w (CH), 1660 s (CO), 1540 s (NH), 760 m and 742 m cm^{-1} (C−C). UV (MeOH): λ_{max} (ε [dm^3·mol^{-1}·cm^{-1}]) = 266 (18700), 291 (4300) and 302 nm (4600). ^{1}H NMR (500 MHz, [D$_6$]DMSO, standard SiMe$_4$): δ = 0.92 (q, 6 H, *k*-CH$_3$), 2.91 (m, 2 H, *i*-CH), 2.98 (t, 4 H, *j*-NH$_2$), 3.06 (m, 7 H, *h*-CH$_2$, *f*-CH, *g*-CONH), 4.35 (d, 1 H, *e*-CH-Ar), 7.24 (m, 2 H, *c*-Ar-H), 7.39 (t, 2 H, *b*-Ar-H), 7.43 (d, 2 H, *d*-Ar-H), 7.86 (d, 2 H, *a*-Ar-H). $C_{22}H_{28}N_4O_2$ (380.5): calcd. C 69.45, H 7.42, N 14.72; found C 69.23, H 7.28, N 14.54.

1-(9*H*-Fluoren-9-yl)-1,4,7,10-tetraazadecane-5,6-dione Hydrogen Bromide (L^2·2HBr): To a solution of *N*,*N*′-bis(2-aminoethyl)oxamide (1.4 g, 0.008 mol) in DMF (30 mL), a solution of 9-bromofluorene (1.97 g, 0.008 mol) in DMF(20 mL) was added dropwise whilst stirring at 80 °C. After heating for 5 h at 80 °C, the mixture was cooled and filtered. The filtrate was added dropwise ice-cold water (400 mL). After filtering, the filtrate was concentrated to almost dryness and 30 mL of diethyl ether was added. The resultant product was separated and washed with diethyl ether, and 0.5 g of white solid was obtained. The white solid was recrystallized from 95% ethanol, and L^2·2HBr (0.4 g, 10.0%) was obtained. IR (KBr): ν_{max} = 3500 m to 2500 b (NH_3^+), 1660 s (CO), 1580 s (NH), 1520 s, 1440 s, 1070 m, 765 m and 745 m cm^{-1} (C−C). UV (MeOH): λ_{max} (ε [dm^3·mol^{-1}·cm^{-1}]) = 268 (15000), 294 (4130) and 304 (3730). ^{1}H NMR(500 MHz, D$_2$O, standard SiMe$_4$): δ = 2.96 (2 H, t, *j*′-CH$_2$NCO), 3.21 (2 H, t, *g*′-CH$_2$NCO), 3.51 (2 H, t, *h*′-CH$_2$-NAr), 3.62 (2 H, t, *k*′-CH$_2$N$^+$), 5.56 (1 H, s, *e*′-CH), 7.46 (2 H, t, *c*′-Ar-H), 7.59 (2 H, t, *b*′-Ar-H), 7.74 (2 H, d, *d*′-Ar-H), 7.88 (2 H, d, *a*′-Ar-H). $C_{19}H_{24}Br_2N_4O_2$ (500.2): calcd. C 45.62, H 4.84, N 11.20; found C 45.96, H 5.11, N 11.45.

[Cu(H$_{-2}$L^1)]·2H$_2$O: To a solution of L^1 (1.14 g, 3.0 mmol) in water (50 mL), $CuSO_4$·5H$_2$O (0.75 g, 3.0 mmol) was added. Whilst stirring, the mixture was adjusted to pH = 10 with dilute $Ba(OH)_2$ solution. After heating at 80 °C for 2 h, the mixture was filtered. The filtrate was concentrated and cooled; purple-red crystals of [Cu(H$_{-2}$L^1)]·2H$_2$O (0.32 g, 22.3%) were obtained. IR: ν_{max} = 3350 m (OH), 3200 m (NH), 3100 m, 2950 w and 2900 w (CH), 1570 vs (C=O), 760 w and 730 w cm^{-1}(C−C). UV (H$_2$O): λ_{max} (ε [dm^3·mol^{-1}·cm^{-1}]) = 265 (4280), 274 (3440), 291 (1210), 302 (1120) and 504 (69) nm. Λ_m (H$_2$O, 25 °C) = 68.75 S·cm^2·mol^{-1}. $C_{22}H_{30}CuN_4O_4$ (478.1): calcd. C 55.27, H 6.33, N 11.72, Cu 13.27; found C 55.61, H 6.25, N 11.57, Cu 13.13.

[Cu(H$_{-2}$L^2)]·4H$_2$O: L^2·2HBr (0.25 g, 0.5 mmol) and $CuSO_4$·5H$_2$O (0.125 g, 0.5 mmol) were dissolved in water (20 mL). The solution was adjusted to pH = 10 with a dilute solution of $Ba(OH)_2$ whilst stirring. After stirring for 1 h at 80 °C, the solution was cooled and filtered. The filtrate was concentrated and a purple solid of [Cu(H$_{-2}$L^2)]·4H$_2$O (0.12 g, 50.9%) was obtained. IR (KBr): ν_{max} = 3350 m (OH), 3200 m (NH), 2900 w (CH), 1651 s (CO), 1600 s (CO), 1100 m, 745 m and 620 cm^{-1} (C−C). UV (H$_2$O): λ_{max} (ε [dm^3·mol^{-1}·cm^{-1}]) = 268 (15000), 294 (4130), 304 (3730) and 536 (154). Λ_m (H$_2$O, 25 °C) = 69.10 S·cm^2·mol^{-1}. $C_{19}H_{28}CuN_4O_6$ (472.0): calcd. C 48.36, H 5.98, N 11.87; found C 48.54, H 6.08, N 11.57.

X-ray Structure Determination of [Cu(H$_{-2}$L^1)]·2H$_2$O: Crystal data: $C_{22}H_{30}CuN_4O_4$, M = 478.04, monoclinic, space group $P2_1/n$, a = 17.264(4) Å, b = 7.6627(16) Å, c =19.559(4) Å, β = 114.582(15) °, V = 2352.9(8) Å^3, $D_{calcd.}$ = 1.349 Mg·m^{-3}, F(000) = 1004, Z = 4, graphite-monochromated Mo-K radiation (λ = 0.71073 Å), μ = 0.962 mm^{-1}, T = 293(2) K. Data collection and processing: A crystal of [Cu(H$_{-2}$L)]·2H$_2$O with dimensions 0.40 × 0.30 × 0.30 mm, wrapped with resin, was mounted on a glass fiber and used for structure determination. The intensities were collected at 293 K with a Siemens *P*4 four-circle diffractometer with θ/2θ scan mode with a variable scan speed of 4.0−60.0 min^{-1} in ω. A total of 5316 reflections (4129 unique) were collected in the range of

$2.06° < \theta < 25.0°$. The data were corrected for Lorentz and polarization effects during data reduction using XSCANS.[18] Structure analysis and refinement: The structure was solved by direct methods. All non-hydrogen atoms were refinedanisotropically on F^2 by full-matrix least-squares methods. The hydrogen atoms were placed in calculated positions assigned fixed isotropic thermal parameters at 1.2 times the equivalent isotropic U of the atoms to which they are attached and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were included in the structure-factor calculations. The final least-squares cycle gave $R = 0.0542$, $Rw = 0.1280$ and $GOF = 1.075$. The maximum and minimum peaks corresponded to $+0.665$ and -0.290 eÅ^{-3}, respectively. All computations were carried out using the SHELXTL PC program package.[19] Crystallographic data for the the crystal structure of $[Cu(H_{-2}L^1)]\cdot 2H_2O$ have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-163292. Copies of the data can be obtained free of charge on applicaton to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Bis(pyrazol-1-yl)acetato Ligands in Ruthenium Chemistry: Syntheses and Structures of Ruthenium(II) and Ruthenium(III) Complexes with bpza and bdmpza

Alberto López-Hernández,[a] Rainer Müller,[a] Henning Kopf,[a] and Nicolai Burzlaff*[a]

Keywords: Ruthenium / N ligands / Scorpionates / Tripodal ligands / Structural chemistry

New ruthenium(II) and ruthenium(III) complexes with the ligands bis(pyrazol-1-yl)acetate (bpza) and bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza) are reported. The reaction of ruthenium trichloride hydrate, H[bpza], and excess PPh_3 yielded $[Ru(bpza)Cl(PPh_3)_2]$ as a racemic mixture of an unsymmetrical isomer with traces of a symmetrical isomer. Similar reaction conditions using the more bulky H[bdmpza] yielded $[Ru(bdmpza)Cl_2(PPh_3)]$. Reaction of K[bpza] with $[RuCl_2(PPh_3)_3]$ offered a second route to $[Ru(bpza)Cl(PPh_3)_2]$. Also, $[Ru(bdmpza)Cl(PPh_3)_2]$ was accessed by this synthetic approach. All three new complexes were characterized by X-ray structure determination.

Introduction

The cyclopentadienylruthenium(II) complex $[Ru(Cp)Cl(PPh_3)_2]$ has been used for more than 30 years as a versatile starting material in thousands of reactions in organometallics.[1−6] In the last ten years this chemistry has been extended to $[Ru(Cp^*)Cl(PPh_3)_2]$[7−9] and, due to the firmly established analogy between the cyclopentadienyl ligand and the hydrotris(pyrazol-1-yl)borato ligand (Tp), also to $[Ru(Tp)Cl(PPh_3)_2]$.[10,11] It is thought that the differences in the reactivity of these complexes are essentially determined by the cone angle of triphenylphosphane (145°) as well as the cone angles of the Cp (150°), Cp* (182°), and Tp (199°) ligands.[10−14] Structural data of the complexes, confirming these steric effects, have been available for a long time.[4−6,8−10] Therefore, these bulky ligands are an important factor in the chemistry of these complexes by inducing lability of one of the triphenylphosphane ligands.

Recently, bis(pyrazol-1-yl)acetato ligands, a new class of scorpionate ligands with binding properties similar to those of the cyclopentadienyl or the hydrotris(pyrazol-1-yl)borato ligand (Figure 1), have been introduced to organometallic and coordination chemistry.[15−20] The binding properties as well as the steric hindrance of the two new ligands bis(pyrazol-1-yl)acetate (bpza) and bis(3,5-dimethylpyrazol-1-yl)acetate (bdmpza) are between those of a Cp ligand and a Cp* ligand.

Recently, we studied iron(II) complexes with these ligands − although with our main focus on bioinorganic model complexes for iron enzymes.[17] Now we report on a route to ruthenium(II) and ruthenium(III) complexes with these new bis(pyrazol-1-yl)acetato ligands.

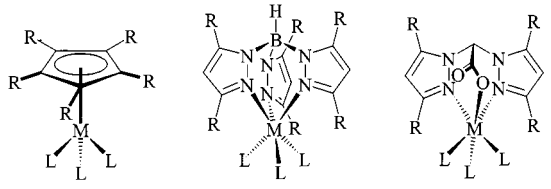

Figure 1. Metal complexes with Cp, Cp*, Tp, $Tp^{Me}{}_2$, bpza, and bdmpza ligands

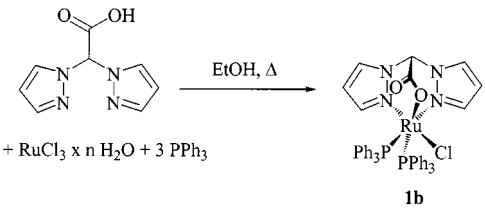
Results and Discussion

First we investigated a one-step synthesis analogous to the synthesis of $[Ru(Cp)Cl(PPh_3)_2]$ reported by Bruce et al.[3] Reaction of $RuCl_3 \times nH_2O$ with bis(pyrazol-1-yl)acetic acid (H[bpza]) and an excess of PPh_3 in ethanol under refluxing conditions yielded $[Ru(bpza)Cl(PPh_3)_2]$ as the unsymmetrical isomer **1b** [Equation (1)].



(1)

There are two possible isomeric products: (a) a symmetrical one (**1a**) with the chloride ion in *trans* position to the

[a] Fachbereich Chemie, Universität Konstanz, Fach M728, 78457 Konstanz, Germany
Fax: (internat.) + 49-(0)7531/88-3136
E-mail: nicolai@chemie.uni-konstanz.de

carboxylate group of the ligand and (b) an unsymmetrical one (**1b**) with the carboxylate group *trans* to a PPh_3 ligand. The main isomer **1b** obtained in this one-step synthesis is a racemic mixture of two enantiomers. The ^1H NMR spectra of the crude reaction product showed only traces of the symmetrical **1a**. Pure product **1b** could be obtained by column chromatography over silica followed by recrystallization in methanol. The solubility of **1b** in methanol is much lower than that of **1a**.

The coordination of the bpza ligand follows from the IR signal in KBr matrix $\nu_{asym}(CO_2^-) = 1653\ cm^{-1}$. The observation of two doublets in the ^{31}P NMR spectra [$\delta = 43.8$ ($^2J_{PP} = 31.0$ Hz), 49.5 ($^2J_{PP} = 31.0$ Hz)] and of two sets of signals for the pyrazolyl groups in the ^1H and ^{13}C NMR spectra indicates an unsymmetrical coordination of the triphenylphosphane ligands in **1b**. Finally, the molecular structure was proven by CHN analysis, mass spectra, and an X-ray structure determination (Figure 2) of crystals of **1b** obtained from a solution of **1b** in ethanol layered with diethyl ether. Selected bond lengths and angles are summarized in Tables 1 and 2.

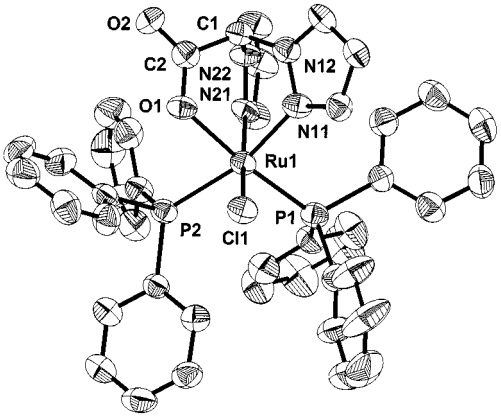


Figure 2. Molecular structure of [Ru(bpza)Cl(PPh_3)$_2$] (**1b**); thermal ellipsoids are shown at a 50% probability level; hydrogen atoms and co-crystallised solvent are omitted for clarity

Table 1. Selected distances of the complexes **1b**, **2**, and **3**

C(1)−C(2)	1.566(10)	1.562(4)	1.539(6)

The molecular structure shows one PPh_3 ligand positioned *trans* to the carboxylate group of the bpza ligand and the other phosphane ligand *trans* to a pyrazolyl group. The distances of the bonds in the *cis* geometry [P(1)−Ru = 2.360(3) Å and N(21)−Ru = 2.100(6) Å] are slightly shorter than those in a *trans* geometry [P(2)−Ru = 2.378(4) Å and N(11)−Ru = 2.157(6) Å]. This might be due to the *trans* influence of the triphenylphosphane ligand and the pyrazolyl group.

Table 2. Selected angles of the complexes **1b**, **2**, and **3**

Angle [°]	**1b**	**2**	**3**

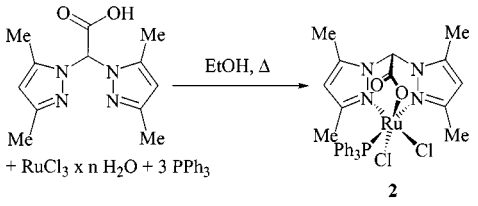
An analogous reaction of $RuCl_3$ with excess PPh_3 and bis(3,5-dimethylpyrazol-1-yl)acetic acid (H[bdmpza]) yielded [Ru(bdmpza)Cl_2(PPh_3)] (**2**) as an orange, air-sensitive complex [Equation (2)].



(2)

Complex **2** is paramagnetic, and therefore was only characterized by mass spectrometry, CHN analysis, and infrared spectroscopy (KBr matrix). The $\nu_{asym}(CO_2^-)$ at 1682 cm^{-1} established the coordination of bdmpza to the ruthenium ion. An X-ray structural analysis of **2** finally confirmed a constitution with the PPh_3 ligand *trans* to one of the pyrazolyl groups (Figure 3). Selected bond lengths and bond angles are summarised in Tables 1 and 2.

Apart from the distances Ru−N(21) [2.184(3) Å] and Ru−P(1) [2.3715(18) Å], all other distances Ru−O, Ru−N, and Ru−Cl are significantly shorter compared to those of **1b**. This is caused by the ruthenium(III) centre in **2** instead of ruthenium(II) in **1b**. These two significantly longer distances again imply a *trans* influence between the PPh_3 ligand and the pyrazolyl group of the bdmpza ligand.

In a second attempt to obtain the target molecule [Ru(bdmpza)Cl(PPh_3)$_2$], potassium bis(3,5-dimethylpyrazol-1-yl)acetate was allowed to react with [$RuCl_2$(PPh_3)$_3$] [Equation (3)].

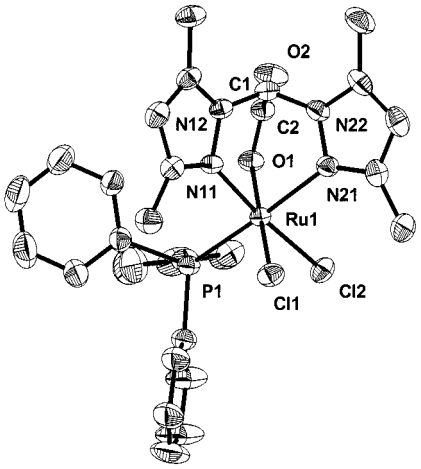


Figure 3. Molecular structure of $[Ru(bdmpza)Cl_2(PPh_3)]$ (**2**); thermal ellipsoids are shown at a 50% probability level; hydrogen atoms and co-crystallised solvent are omitted for clarity

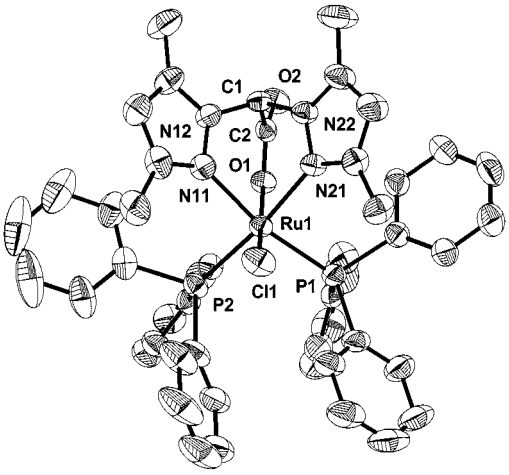

Figure 4. Molecular structure of $[Ru(bdmpza)Cl(PPh_3)_2]$ (**3**); thermal ellipsoids are shown at a 50% probability level; hydrogen atoms and co-crystallised solvent are omitted for clarity

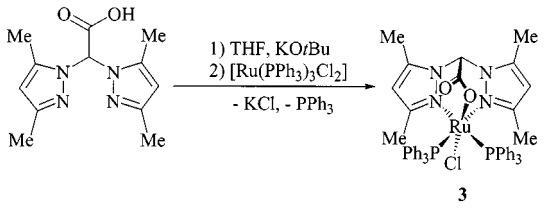


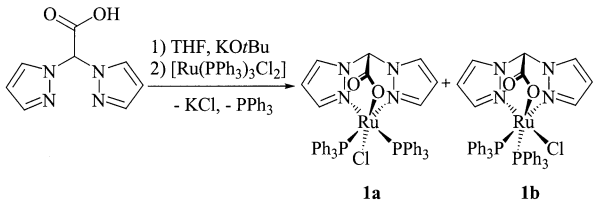
(3)

In an analogous reaction with potassium hydrotris(pyrazol-1-yl)borate and $[RuCl_2(PPh_3)_3]$ the complex $[Ru(Tp)Cl(PPh_3)_2]$ was obtained by Hill et al.[10] Very recently the complex $[RuCl(PPh_3)_2(TPM)]Cl$ was synthesized from tris(pyrazol-1-yl)methane (TPM) and $[RuCl_2(PPh_3)_3]$ by Field and Messerle.[21] $[Ru(bdmpza)Cl(PPh_3)_2]$ (**3**) was obtained in good yield after simply washing with degassed water and diethyl ether and was fully characterized. A single signal in the ^{31}P NMR spectrum as well as one set of signals for the pyrazolyl groups in the ^1H and ^{13}C NMR spectra indicate a symmetric geometry for **3**. Proton signals of **3** were assigned on the basis of cross-peaks observed in a rotating frame Overhauser spectroscopy (ROESY) experiment. The ^{13}C NMR resonances of the methyl groups were assigned by correlating them to the assigned proton resonances using a heteronuclear multiple quantum coherence (HMQC) experiment. The methyl group at position 3 of the pyrazolyl groups (Me^3) was found in the ^1H NMR spectra at $\delta = 1.72$ [^{13}C NMR: $\delta = 15.5$], the methyl group at position 5 (Me^5) at $\delta = 2.35$ [^{13}C NMR: $\delta = 11.1$]. A distinction of the quaternary pyrazolyl carbon resonances was possible with a heteronuclear multiple bond correlation (HMBC) experiment [^{13}C NMR: $\delta = 140.6$ (C^5), 157.3 (C^3)]. The assignment of the NMR signals is in good agreement with those reported by Otero for similar niobium complexes.[16] The symmetric structure was also proven by a single-crystal X-ray structure analysis of **3** (Figure 4). Selected bond lengths and bond angles of **3** are summarized in Tables 1 and 2.

The IR spectrum of **3** shows bands at 1668 and 1570 cm^{-1} [$\nu_{asym}(CO_2^-)$ and $\nu(C{=}N)$]. For all three complexes **1a/1b**, **2**, and **3** we were not able to assign $\nu_{sym}(CO_2^-)$ properly to one of the resonances in the region between 1400 and 1500 cm^{-1}. This was due to the weakness of the signals and several resonances of the PPh_3 ligand in that region.

Complex **3** is rather sensitive to oxygen (especially compared to the almost air-stable complexes **1a** or **1b**). This is caused by the bigger steric hindrance of **3**, causing a labilisation of the PPh_3 ligands. This hindrance is indicated by a much smaller angle N(11)−Ru−N(21) of 78.40(15)° compared to 86.5(2)° in **1b**. Another explanation might be, that bdmpza is a better donor ligand compared to bpza due to the four methyl groups in the pyrazolyl rings.

Also $[Ru(bpza)Cl(PPh_3)_2]$ could be obtained in good yield by reaction of potassium bis(pyrazol-1-yl)acetate with $[RuCl_2(PPh_3)_3]$. Both isomers **1a** and **1b** were formed [Equation (4)].



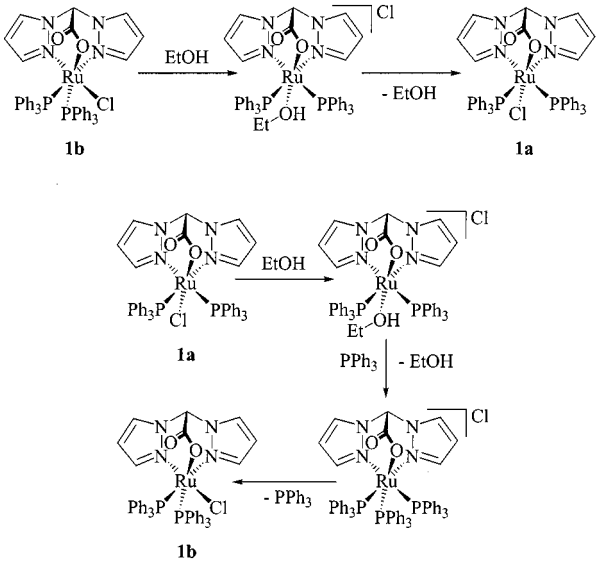
(4)

Due to the simple workup and high yield, we now favour this second synthetic route to **1a/1b**. Potassium chloride and traces of excess base are removed by washing with degassed water. Thus, ruthenium complexes with bis(pyrazol-1-yl)-

acetato ligands are stable against hydrolysis, an imminent advantage compared to hydrotris(pyrazolyl)borato ligands. In contrast to unsymmetrical **1b**, only a single ^{31}P NMR signal at $\delta = 40.4$ and one set of ^{1}H NMR signals is found for **1a**. Both isomers of **1a/1b** are rather stable and can be stored under air as a solid. Assignment of the proton signals of **1a/1b** was accomplished from the cross-peaks observed in correlation spectroscopy (COSY) experiments and ROESY experiments. HMQC experiments were used for correlation of these assigned proton resonances with ^{13}C NMR resonances. In the NMR spectra of the symmetrical isomer **1a** only three proton resonances [$\delta = 5.89$ (H^4), 6.87 (H^3), 7.55 (H^5)] and three carbon resonances [$\delta = 107.6$ (C^4), 132.6 (C^5), 146.6 (C^3)] were detected for the pyrazolyl groups. The pyrazolyl groups in **1b** are no longer spectroscopically equivalent causing six ^{1}H NMR signals [$\delta = 5.20$ (H^3), 5.46 (H^4), 5.97 ($H^{4'}$), 7.44 ($H^{3'}$), 7.79 ($H^{5'}$), 7.79 (H^5)] and six ^{13}C NMR signals [$\delta = 106.5$ (C^4), 107.4 ($C^{4'}$), 131.9 (C^5 or $C^{5'}$), 132.0 (C^5 or $C^{5'}$), 145.7 ($C^{3'}$), 147.9 (C^3)]. In the ROESY experiment of **1b** an NOE correlation was observed between a signal at $\delta = 7.84$ (six *ortho*-H of the PPh_3 ligand *trans* to the carboxylate donor group) and H^3 indicating a close spherical contact.

From the fact that the unsymmetrical isomer could be isolated by recrystallization, it follows that it is stable against conversion into **1a** at ambient temperature for a reasonable time. To investigate whether one of the isomers is thermodynamically favoured, a mixture of the isomers and PPh_3 in ethanol was heated under reflux. After 4 h in ethanol under refluxing conditions, surprisingly only traces of **1b** were detected by ^{1}H NMR spectroscopy besides **1a**. Since this formation of the symmetrical isomer **1a** seemed to be incompatible with the one-step synthesis of **1b**, a solution of **1a** with traces of **1b** and PPh_3 in ethanol was heated under reflux for 5 h. After this time **1b** was the main product and only traces of **1a** were left. Obviously, the ratio **1a/1b** depends on whether excess PPh_3 is present in the reaction mixture or not. Very likely, this is due to the intermediate formation of a cationic solvent complex. For alcoholic solutions of $[Ru(Cp)Cl(PPh_3)_2]$ dissociation of a chloride ligand and formation of a cationic alcohol complex is well known.[1,3] The most likely position of the ethanol ligand is the position *trans* to the carboxylate donor group. Exchange of the ethanol ligand by a chloride ion will therefore result in the symmetrical isomer **1a** (Scheme 1). With excess PPh_3 an intermediate cationic complex $[Ru(bpza)(PPh_3)_3]Cl$ might be formed. Similar complexes $[Ru(Cp)(dppm)(PPh_3)]PF_6$ and $[Ru(Cp^*)(PHPh_2)_3]Cl$ were recently reported.[22,23] Both PPh_3 ligands *trans* to pyrazolyl groups are more labile than the one *trans* to the carboxylate donor group because of the *trans* influence of the pyrazolyl groups. Therefore, in this case substitution for a chloride ion will result in formation of the unsymmetrical isomer **1b** (Scheme 1).

Finally, we observed that traces of alcohols or THF in NMR samples caused significant changes in the NMR spectra again indicating an interaction between **1a/1b** and traces of these donor solvents. In protic solvents the carboxylate group might also interact with protons and therefore be a less efficient donor, causing this behaviour. In future experiments we will concentrate on the question of whether such interactions of the carboxylate donor and protons, or even Lewis acids, could be used for changing the reactivity of the complexes.



Scheme 1. Proposed mechanism for the conversion of **1b** in **1a** in ethanol and of **1a** in **1b** in ethanol with excess PPh_3

Conclusions

A simple synthetic route to the ruthenium(II) complexes $[Ru(bpza)Cl(PPh_3)_2]$ (**1a/1b**) and $[Ru(bdmpza)Cl(PPh_3)_2]$ (**3**) was established by reaction of the potassium bis(pyrazol-1-yl)acetates with $[RuCl_2(PPh_3)_3]$. Complex **3** seemed to be more active towards exchange of a PPh_3 ligand by another donor, whereas in **1a/1b** the ratio of the symmetrical isomer **1a** to the unsymmetrical isomer **1b** could be influenced by adding PPh_3 during heating under reflux. Thus, both complexes are promising starting complexes for future organometallic experiments.

Experimental Section

All experiments were carried out in Schlenk tubes under argon. The solvents were dried by standard procedures, distilled, and stored under argon. Microcrystalline precipitates were separated by filtration or centrifugation with a Hettich Rotina 46 R Schlenk tube centrifuge. IR: Biorad FTS 60, CaF_2 cuvettes (0.5 mm) or KBr matrix. ^{1}H NMR and ^{13}C NMR: Bruker WM 250, Bruker AC 250, δ values relative to TMS. ^{31}P NMR: JEOL GX 400. Two-dimensional NMR experiments: Bruker DRX 600 (Avance). EI-MS and FAB-MS: modified Finnigan MAT 312. Elemental analyses: Analytical Laboratory of the Fachbereich Chemie. A modified Siemens P4 diffractometer was used for X-ray structure determinations. Bis(pyrazol-1-yl)acetic acid and bis(3,5-dimethylpyra-

zol-1-yl)acetic acid were synthesised from pyrazole and 3,5-dimethylpyrazole as reported recently.[17,18] $[RuCl_2(PPh_3)_3]$ was prepared according to the literature.[24] Hydrated ruthenium trichloride (35−40% Ru) was used as purchased from Merck.

Synthesis of $[Ru(bpza)Cl(PPh_3)_2]$ (1a/1b). − Method A: A solution of $RuCl_3 \times n\ H_2O$ (670 mg, 2.65 mmol) and bis(pyrazol-1-yl)acetic acid (578 mg, 3.00 mmol) in EtOH (40 mL) was added over a period of 10 min to a refluxing solution of PPh_3 (2.09 g, 7.95 mmol) in EtOH (80 mL). The mixture was maintained under reflux for 3 h, cooled to ambient temperature and the solvent was evaporated. The crude product was loaded with CH_2Cl_2 on a short column of silica (length 6 cm, i.d. 4 cm). The column was washed with CH_2Cl_2 (150 mL). Finally, the pure product was recovered with MeOH. The dark yellow MeOH solution was concentrated in vacuo to 20 mL. The precipitated yellow product was filtered off and dried in vacuo. It was dissolved in CH_2Cl_2, precipitated with *n*-pentane, filtered off, and dried in vacuo. The unsymmetrical isomer **1b** was obtained as a yellow crystal powder. Suitable crystals of **1b** for X-ray structure analysis were obtained from a solution in EtOH layered with diethyl ether. Yield 1.23 g (1.44 mmol, 54%), m.p. 194−196 °C. − **Method B:** To a solution of bis(pyrazol-1-yl)acetic acid (200 mg, 1.04 mmol) in THF (25 mL) potassium *tert*-butoxide (117 mg, 1.04 mmol) was added and the mixture stirred for 1 h at ambient temperature. A white precipitate formed during this time indicated the formation of the potassium carboxylate. $[RuCl_2(PPh_3)_3]$ (1.00 g, 1.04 mmol) was added and the mixture was stirred at ambient temperature for 30 min, during which time the colour of the brown suspension changed to orange. The solvent was removed in vacuo and the residue was washed with degassed water (2 × 20 mL) and diethyl ether (2 × 20 mL) and dried in vacuo to yield a mixture of **1a/1b** as an orange crystal powder. Yield 760 mg (0.89 mmol, 86%), m.p. 188−192 °C. FAB-MS (NBOH matrix): *m/z* (%) = 853 (2) $[MH^+]$, 817 (4) $[(MH - Cl)^+]$, 590 (11) $[MH^+ - PPh_3]$, 555 (5) $[(MH - PPh_3 - Cl)^+]$. $C_{44}H_{37}ClN_4O_2P_2Ru \times H_2O \times EtOH$ (916.36): calcd. C 60.29, H 4.95, N 6.11; found C 60.58, H 4.73, N 6.00. − **1a:** ^1H NMR ($CDCl_3$, 250 MHz): δ = 5.89 (vt, $^3J_{H,H}$ = 2.3 Hz, 2 H, H^4), 6.61 (s, 1 H, CH), 6.87 (d, $^3J_{H,H}$ = 1.9 Hz, 2 H, H^3), 7.04 (m, 12 H, *m*-PPh_3), 7.21 (m, 6 H, *p*-PPh_3), 7.43(m, 12 H, *o*-PPh_3), 7.55 (d, $^3J_{H,H}$ = 2.5 Hz, 2 H, H^5). ^{13}C NMR ($CDCl_3$, 62.9 MHz): δ = 75.5 (CH), 107.6 (C^4), 127.1 (vt, $J_{C,P}$ = 3.7 Hz, *m*-PPh_3), 128.8 (*p*-PPh_3), 132.6 (C^5), 134.9 (vt, $J_{C,P}$ = 4.5 Hz, *o*-PPh_3), 135.0 (d, $J_{C,P}$ = 40.1 Hz, *i*-PPh_3), 146.6 (C^3), 166.1 (CO_2^-). ^{31}P NMR ($CDCl_3$, 161.8 MHz): δ = 40.4. IR (THF): $\tilde{\nu}$ = 1670 s (CO_2^-), 1653 m, 1507 w cm^{-1}. IR (KBr): $\tilde{\nu}$ = 1653 s (CO_2^-), 1482 w, 1433 m, 1408 w cm^{-1}. − **1b:** ^1H NMR ($CDCl_3$, 250 MHz): δ = 5.20 (s, 1 H, H^3), 5.46 (s, 1 H, H^4), 5.97 (s, 1 H, $H^{4'}$), 6.84 (s br, 6 H, *o*-PPh_3), 7.07 (m, 16 H, CH and *p*-PPh_3 and *m*-PPh_3), 7.26 (m, 3 H, *p*-PPh_3), 7.44 (s, 1 H, $H^{3'}$), 7.84(m, 8 H, *o*-PPh_3 and H^5 and $H^{5'}$). ^{13}C NMR ($CDCl_3$, 62.9 MHz): δ = 74.2 (CH), 106.5 (C^4), 107.4 ($C^{4'}$), 127.3 (d, $J_{C,P}$ = 9.1 Hz, *m*-PPh_3), 127.6 (d, $J_{C,P}$ = 9.0 Hz, *m*-PPh_3), 128.7 (*p*-PPh_3), 129.2 (*p*-PPh_3), 131.9 (C^5 or $C^{5'}$), 132.0 (C^5 or $C^{5'}$), 133.9 (d, $J_{C,P}$ = 9.0 Hz, *o*-PPh_3), 134.4 (d, $J_{C,P}$ = 9.4 Hz, *o*-PPh_3), 134.5 (d, $J_{C,P}$ = 40.4 Hz, *i*-PPh_3), 135.3 (d, $J_{C,P}$ = 40.5 Hz, *i*-PPh_3), 145.7 ($C^{3'}$), 147.9 (C^3), 166.6 (CO_2^-). ^{31}P NMR ($CDCl_3$, 161.8 MHz): δ = 43.8 ($^2J_{PP}$ = 31.0 Hz), 49.5 ($^2J_{PP}$ = 31.0 Hz). IR (CH_2Cl_2): $\tilde{\nu}$ = 1661 s (CO_2^-), 1481 w cm^{-1}. IR (KBr): $\tilde{\nu}$ = 1653 s (CO_2^-), 1482 w, 1433 m cm^{-1}.

Synthesis of $[Ru(bdmpza)Cl_2(PPh_3)]$ (2): A solution of $RuCl_3 \times n\ H_2O$ (383 mg, 1.52 mmol) in EtOH (20 mL) was added over a period of 10 min to a solution of bis(3,5-dimethylpyrazol-1-yl)-acetic acid (376 mg, 1.51 mmol) and PPh_3 (1.20 g, 4.57 mmol) in EtOH (30 mL). The mixture was heated under reflux for 1 h, cooled in an ice bath and the precipitate was collected by filtration. The brownish residue was washed with CH_2Cl_2 (30 mL) and the now orange residue was dried in vacuo. Crystals suitable for a X-ray structure determination were obtained from a solution of **2** in acetonitrile and also from a solution in $CHCl_3$. Yield 660 mg (0.97 mmol, 64%), m.p. 260−265 °C (dec.). FAB MS (NBOH matrix): *m/z* (%) = 722 (4) $[M^+ + CH_3CN]$, 681 (4) $[M^+]$, 646 (18) $[(M - Cl)^+]$, 611 (6) $[(M - Cl_2)^+]$, 566 (6) $[(M - Cl_2 - CO_2)^+]$. IR (KBr): $\tilde{\nu}$ = 1682 s (CO_2^-), 1560 w (C=N), 1482 w, 1458 w, 1436 w cm^{-1}. $C_{30}H_{30}Cl_2N_4O_2PRu \times CH_3CN$ (722.60): calcd. C 53.19, H 4.60, N 9.69; found C 53.32, H 4.23, N 9.83.

Synthesis of $[Ru(bdmpza)Cl(PPh_3)_2]$ (3): Reaction of bis(3,5-dimethylpyrazol-1-yl)acetic acid (248 mg, 1.00 mmol) in THF (25 mL) with potassium *tert*-butoxide (112 mg, 1.00 mmol) and $[RuCl_2(PPh_3)_3]$ (953 mg, 0.99 mmol) according to Method B yielded **3** as an orange crystal powder. Suitable crystals of **3** for X-ray structure analysis were obtained from a solution in $CHCl_3$. Yield 815 mg (0.90 mmol, 91%), m.p. 201−205 °C (dec.). ^1H NMR ($CDCl_3$, 250 MHz): δ = 1.72 (s, 3 H, Me^3), 2.35 (s, 3 H, Me^5), 5.42 (s, 2 H, H^4), 6.45 (s, 1 H, CH), 6.90 (m, 12 H, PPh_3), 7.04 (m, 6 H, PPh_3), 7.31 (m, 12 H, PPh_3). ^{13}C NMR ($CDCl_3$, 62.9 MHz): δ = 11.1 (Me^5), 15.5 (Me^3), 69.1 (CH), 109.3 (C^4), 126.5 (vt, $J_{C,P}$ = 4.2 Hz, *m*-PPh_3), 128.0 (*p*-PPh_3), 134.5 (vt, $J_{C,P}$ = 4.2 Hz, *o*-PPh_3), 136.2 (d, $J_{C,P}$ = 39.1 Hz, *i*-PPh_3), 140.6 (C^5), 157.3 (C^3), 168.2 (CO_2^-). ^{31}P NMR ($CDCl_3$, 161.8 MHz): δ = 35.3. FAB-MS (NBOH-matrix): *m/z* (%) = 908 (0.5) $[M^+]$, 873 (1) $[(M - Cl)^+]$, 648 (3) $[MH^+ - PPh_3]$, 611 (2) $[(MH - PPh_3 - Cl)^+]$. IR (THF): $\tilde{\nu}$ = 1672 s (CO_2^-), 1571 w (C=N) cm^{-1}. IR (CH_2Cl_2): $\tilde{\nu}$ = 1662 s (CO_2^-), 1571 w (C=N) cm^{-1}. IR (KBr): $\tilde{\nu}$ = 1668 s (CO_2^-), 1570 w (C=N), 1482 w, 1458 w, 1432 m cm^{-1}. $C_{48}H_{45}ClN_4O_2P_2Ru \times 3CHCl_3$ (1266.52): calcd. C 48.37, H 3.82, N 4.42; found C 48.50, H 3.98, N 4.21.

X-ray Structure Determinations: Single crystals of **1b**, **2**, and **3** were sealed in glass capillaries at room temperature. A modified Siemens P4-diffractometer was used for data collection (Wyckhoff technique, graphite monochromator, Mo-K_α radiation, λ = 0.71073 Å, scan rate 4−30 °min^{-1} in ω). The structures were solved and refined using the SHELX-97 program package (refined with full-matrix least squares against F^2).[25] A weighting scheme was applied in the last steps of the refinement with $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ and $P = [2F_c^2 + \max(F_o^2,0)]/3$. Hydrogen atoms were included in their calculated positions and refined in a "riding model". One molecule of ethanol and water co-crystallised per asymmetric unit in **1b**, one molecule of $CHCl_3$ in **2**, and three molecules of $CHCl_3$ in **3**. The co-crystallised water in the structure of **1b** can be explained as being due to the crystallisation of **1b** in an open flask. Crystals of **2** were also obtained from a solution in acetonitrile. The X-ray structure determination of these crystals resulted in an almost identical structure model but with higher *R* factors. Therefore, this structure $\mathbf{2} \times CH_3CN$ is not discussed here although the data were deposited with CCDC (see below). Two of the $CHCl_3$ molecules in the structure of **3** are severely disordered causing relatively high *R* factors. All details and parameters of the measurements are summarised in Table 3. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-168912 ($\mathbf{1b} \times H_2O \times EtOH$), -168913 ($\mathbf{2} \times CHCl_3$), -168914 ($\mathbf{2} \times CH_3CN$) and -168915 ($\mathbf{3} \times 3CHCl_3$). Copies of the data can be obtained free

Alkyl(amino)- and Alkyl(chloro)phosphanyl-Substituted Cyclopentadienyl Complexes of Titanium and Zirconium

Vasily V. Kotov,*[a][‡] Evgeni V. Avtomonov,*[b][‡‡] Jörg Sundermeyer,[c] Klaus Harms,[c] and Dmitry A. Lemenovskii[a]

Dedicated to Prof. Dr. J. Lorberth on the occasion of his 65th birthday

Keywords: Titanium / Zirconium / Cyclopentadienyl ligands / P ligands / Polymerisation

Phosphanyl-substituted cyclopentadienes of the type [R_nCp–PR(NR^1R^2/Cl)] (**1**–**22**) (R = Alk, Ar; R^1, R^2 = H, Alk, Ar, SiR_3; R_nCp = *t*BuCp, Me_4Cp, Ind, Me_6Ind, Flu) can be synthesised by reaction of alkyldichlorophosphanes and alkyl(amino)chlorophosphanes with alkali metal cyclopentadienides. The method used is a general one and provides high isolated yields of the target compounds. The phosphanylcyclopentadienes can easily be deprotonated by strong bases (e.g. *n*BuLi, $PhCH_2K$, Ph_2CHK) and the potassium salts [R_nCp–PR(NR^1R^2)]K (**25**–**28**) are efficiently transmetallated by Me_3SnCl. A subsequent reaction with $TiCl_4(L)_2$ and $ZrCl_4(L)_2$ (L = THF, tetrahydrothiophene, Me_3P) affords new half-sandwich complexes [{Me_4Cp–P*t*Bu(NEt_2)}$TiCl_3$] (**36**), [{Me_4Cp–P*t*Bu(NEt_2)}$TiCl_3$] (**37**) and [{*t*BuCp–P*t*Bu(NEt_2)}$TiCl_3$] (**38**) in moderate yields. The reaction of [*t*BuCp–P*t*Bu(Cl)] (**6**) with $TiCl_4$ in the presence of Et_3N at low temperature yields the half-sandwich complex [{*t*BuCp–P*t*Bu(Cl)}$TiCl_3$] (**39**) quantitatively; [(Cp–P*t*Bu(Cl)]$_2$-CMe_2] (**11**) reacts similarly and gives, dependent on the reagent ratio, either the homobimetallic derivative [{(Cp–P*t*Bu(Cl)$_2$$CMe_2$}{$TiCl_3$}$_2$] (**40**) (1:2 ratio) or the *ansa* complex [{(Cp–P*t*Bu(Cl)]$_2$$CMe_2$}$TiCl_2$] (**41**) (1:1 ratio). The scope of this reaction could not be extended to sterically more demanding cyclopentadienyl derivatives. Treatment of [{*t*BuCp–P*t*Bu(Cl)}$TiCl_3$] (**39**) by LiN(H)*t*Bu in the presence of Et_3N leads to the formation of the constrained geometry complex [{*t*BuCp–P*t*Bu(N*t*Bu)}$TiCl_2$] (**42**) in a high yield. All synthesised compounds were characterised by NMR spectroscopy, mass spectrometry and elemental analyses. The crystal structures of the ligand precursor [Me_6Ind–P*t*Bu(NH*t*Bu)] (**15**) and that of [{Me_4Cp–P*t*Bu(NEt_2)}$TiCl_3$] (**36**) have been determined by X-ray diffractometry. The complexes described in this work are active in the MAO-mediated polymerisation of ethylene.

Introduction

In the past three decades a variety of transition metal complexes have been developed and applied as catalysts for homogeneous polymerisation of α-olefins to form a wide number of polymers with unique properties.[1−3] The most famous of them are *ansa*-metallocenes **I**[4] and *C*onstrained *G*eometry *C*atalysts (CGC) **II** with ancillary cyclopentadienyl ligands first described by Bercaw,[5] Okuda[6] and later developed by researchers of Dow and Exxon.[7] At the same time other systems, having no cyclopentadienyl-type ligands at all[8−11] were successfully applied for the homogeneous polymerisation of alkenes and have promoted extensive studies focussed on the catalyst geometry,[12−20] and investigation of the relationship between the catalyst's structure and properties of the polymer produced.[21,22] As a consequence, a huge number of theoretical[23,24] and experimental studies of the mechanism of polymerisation have been reported to date.[25−29] There is still growing interest in substituted cyclopentadienylmetal compounds containing a terminal donor group in the side chain.[11−19] Due to the Lewis acidity of the metal centre in the postulated active species in the polymerisation reaction a coordination of the "pendant" donor functionality to the transition metal centre might be anticipated.

We were interested in novel ligand models and the synthesis of transition metal complexes on their basis. Recently,

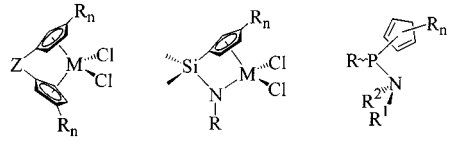
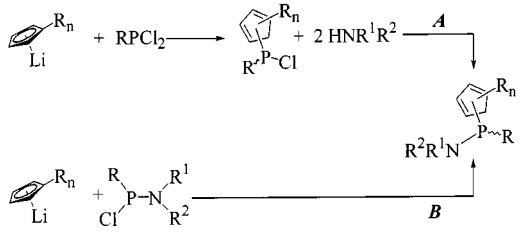
we have been exploring the synthesis of the ligands derived from phosphanyl-substituted cyclopentadienes [$R_nCp-PR(NR^1R^2)$] (**III**) (R_nCp = Cp, Ind, Flu; R, R^1, R^2 = Alk, Ar or H) in an attempt to probe this class of compounds in the organotransition metal chemistry. The choice of the [$R_nCp-PR(NR^1R^2)$] system was stimulated by the expectation that the presence of a σ-donating aminophosphanyl group in the periphery of the cyclopentadienyl ligand would have an impact on the catalytic properties of target complexes.



I **II** **III**

Z = carbon or silicon bridge; R_nCp = Cp, Ind, Flu; R, R^1, R^2 = Alk or Ar; M = Ti (IV), Zr (IV), Hf (IV).

There are two main synthetic approaches to these ligands of type **III** (Scheme 1) containing a three-coordinate phosphorus atom: ***A***) a stepwise nucleophilic substitution of the halogen atoms at the phosphorus centre of $RPCl_2$ by cyclopentadienyl-type carbanions [R_nCp]M (M = Li, Na, K) and amines HNR^1R^2 and ***B***) the reaction of cyclopentadienyl anions with (alkyl or aryl)chloro(dialkylamino)-phosphanes.



R_nCp = Cp, Ind, Flu; R = Alk, Ar; R^1 = H or R^2; R^2 = Alk or Ar.

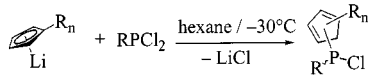
Scheme 1

Route ***A*** is a common route to prepare alkyl(amino)-cyclopentadienylphosphanes and has been described previously in the literature for pentamethylcyclopentadienes.[30] The second approach ***B*** for which alkyl(or aryl)chloro(dialkylamino)phosphanes $RP(Cl)NR^1R^2$ are key starting compounds has recently been developed.[31] They could be advantageously used for the preparation of sterically less encumbered derivatives. Here we wish to report the synthesis of the new phosphanylcyclopentadienes **III**, using route ***A*** as a synthetic strategy, their transformations to group-4 transition metal complexes and our results of the polymerisation of ethylene by the catalysts obtained from the complexes and methylalumoxane (MAO).

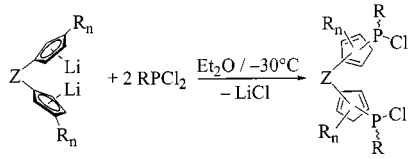
Results and Discussion

Synthesis of the Ligand Precursors

Phosphanylcyclopentadienes of the type [$R_nCp-PR(Cl)$] can be prepared by nucleophilic substitution of a chlorine atom in dichlorophosphanes $RPCl_2$ (Scheme 1, route ***A***). In the 1980s this synthetic approach was applied for a variety of pentamethylcyclopentadienylphosphanes [$Me_4C_5-PR^3R^4$] (R^3, R^4 = C_5Me_5(Cp*), Alk, Ar, Cl, F, I, NMe_2) with the aim of studying isomerisation of the phosphanyl substituent around the Cp* ring.[32−36] Sterically crowded cyclopentadienes, indenes, fluorenes, or bulky phosphanes can also be utilised while cyclopentadienylphosphanes having less demanding substituents, e.g. Cp or MeCp, are a thermally labile class of compounds and readily undergo Diels−Alder reaction.[37] The most recent examples were reported by Alt and co-workers[38] and by researchers at Shell[39] as intermediate compounds in the synthesis of symmetrical and unsymmetrical *ansa*-metallocenes with the phenylphosphanylidene bridge. In both cases subsequent nucleophilic substitutions by different cyclopentadienyl-, indenyl- and fluorenyllithium salts have been carried out. According to a similar methodology we synthesised a number of alkylchloro(cyclopentadienyl-, indenyl- and fluorenyl)phosphanes [$R_nCp-PR(Cl)$] (**1**−**6**) and their bridged analogues [{$R_nCp-PR(Cl)$}$_2$Z] (**7**−**11**) (Scheme 2).



[R_nCp-PR(Cl)] = **1** [Ind-P*t*Bu(Cl)] 66%
2 [Flu-P*t*Bu(Cl)] 94%[40]
3 [Ind-PMes(Cl)] 82%
4 [Me_6Ind-P*t*Bu(Cl)] 85%
5 [Me_4Cp-P*t*Bu(Cl)] 73%
6 [*t*BuCp-P*t*Bu(Cl)] 95%



[{R_nCp-PR(Cl)}$_2$Z] = **7** [{Ind-P*t*Bu(Cl)}$_2$(CH_2)$_2$] 64%
8 [{Ind-P*t*Bu(Cl)}$_2$$CMe_2$] >95%
9 [{Ind-P*t*Bu(Cl)}$_2$$CEt_2$] 92%
10 [{Ind-P*t*Bu(Cl)}CMe_2{Cp-P*t*Bu(Cl)}] 50%
11 [{Cp-P*t*Bu(Cl)}$_2$$CMe_2$] 80%

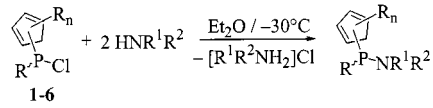
Scheme 2

This method, however, has some drawbacks. In the case of monocyclopentadienyl-type carbanions the formation of by-products is observed, e.g. alkylbis(cyclopentadienyl)phosphane [$(R_nCp)_2PR$], as a result of the double substitution of the chlorine atoms at the phosphorus centre, when Et_2O was used as solvent. By-products can be avoided by the use of a nonpolar aliphatic solvent, e.g. hexane. Since many compounds derived from phosphanylcyclopentadienes [$R_nCp-PR(Cl)$] or [$R_nCp-PR(NR^1R^2)$] cannot be purified

by standard methods such as distillation or chromatography, pure starting materials have to be used in all stages of the preparation. The substances synthesised are highly soluble in aliphatic solvents and exist as expected as mixtures of isomers (see NMR spectroscopic data in the Exp. Sect.).

On the contrary, bis[*tert*-butylchloro(indenyl)phosphanes] [{Ind−P*t*Bu(Cl)}$_2$Z] (**7**−**9**) exist exclusively as allylic regioisomers. These compounds possess four stereogenic centres and hence consist of a complex set of stereoisomers. Eight diastereomeric pairs are theoretically possible. Four of them would exhibit an identical chemical environment around the phosphorus substituents and only four diastereomers could therefore be observed by conventional NMR techniques (three enantiomeric pairs and one *meso* form).[31] The ^{31}P NMR spectroscopic data confirm this assumption and demonstrate seven resonances, i.e. three pairs of nonequivalent phosphorus atoms in the racemic forms and one signal of the *meso* form, each part having different integral intensity (compare ref.[31]). For this reason we were not able to make a detailed assignment of the proton and carbon NMR spectra for compounds **6**,**7**−**11**. The structures of **10** and **11** were deduced solely on the basis of C,H,N analyses and ^{31}P NMR spectra.

The second step of method ***A*** is the reaction of [R$_n$Cp−PR(Cl)] (**1**−**11**) with amines. This transformation proceeds smoothly for **1**−**6** and affords aminophosphanyl derivatives **12**−**22** in high yields (Scheme 3). The structure of [Me$_6$Ind−P(*t*Bu)N(H)*t*Bu] (**15**) was determined by an X-ray analysis (Figure 1).



1-6

[R$_n$Cp-PR(NR^{1}R^2)] =
12 [Ind-P*t*Bu(NEt$_2$)] >95%
13 [Ind-P*t*Bu(NH*t*Bu)] >95%
14 [Ind-P*t*BuP(NHPh)] >95%
15 [Me$_6$Ind-P*t*Bu(NH*t*Bu)] 75%
16 [Ind-PMes(NH*t*Bu)] >95%
17 [Flu-P*t*Bu(NEt$_2$)] >95%
18 [Flu-P*t*Bu(NH*t*Bu)] >95%
19 [Me$_4$Cp-P*t*Bu(NH*t*Bu)] 78%
20 [Me$_4$Cp-P*t*Bu(NEt$_2$)] >95%
21 [*t*BuCp-P*t*Bu(NEt$_2$)] >95%
22 [*t*BuCp-P*t*Bu(NH*t*Bu)] >95%

Scheme 3

The geometry at the phosphorus atom that occupies the allylic position of the Me$_6$Ind group is trigonal-pyramidal. The bond angles range from 103 to 108°, indicating certain steric strain in the molecule. The P(1)−N(1) bond of 1.701(5) Å and the bond P(1)−C(11) of 1.899(5) Å are somewhat longer than typical P^{III}−N (ca. 1.65 Å) and P^{III}−C (1.83−1.87 Å) bond lengths for most substituted organophosphorus compounds,[41] which again confirms the steric congestion in **15**. All other structural fragments reveal no peculiarities.

To our surprise, for the bridged ligand precursors [{R$_n$Cp−P*t*Bu(Cl)}$_2$Z] (**7**−**10**), no nucleophilic substitution by secondary amines HNR^{1}R^2 takes place. The reaction affords oligomeric products which are difficult to analyse,

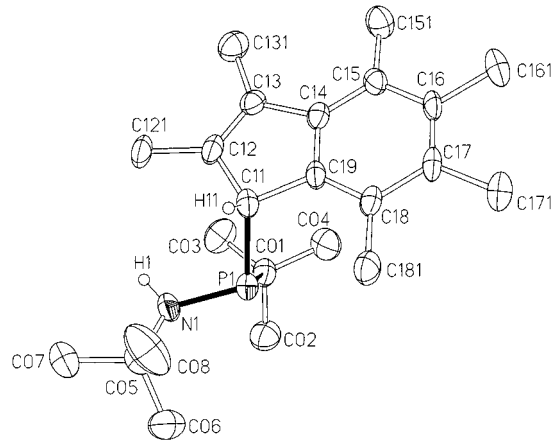


Figure 1. ORTEP diagram of the molecule of [Me$_6$Ind−P*t*Bu(NH*t*Bu)] (**15**); thermal ellipsoids are drawn at 50% probability level; hydrogen atoms except for H(1) and H(11) are omitted for the sake of clarity; selected bond lengths [Å]: P(1)−N(1) 1.701(5), P(1)−C(01) 1.880(6), P(1)−C(11) 1.899(5), C(11)−C(12) 1.504(8), C(11)−C(19) 1.518(7), C(12)−C(13) 1.350(8); selected bond angles [°]: N(1)−P(1)−C(01) 102.5(2), N(1)−P(1)−C(11) 103.3(2), C(01)−P(1)−C(11) 108.0(2), C(19)−C(11)−P(1) 112.7(3), C(13)−C(12)−C(11) 110.9(5)

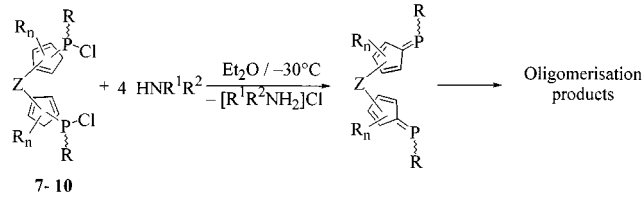
probably stemming from the very reactive phosphafulvenes generated in situ by β-"HCl" elimination.[42] Thus, the elimination of HCl takes place faster than a nucleophilic substitution reaction (Scheme 4).



7- 10

HNR^{1}R^2 = HNMe$_2$, HNEt$_2$, HN(*i*Pr)$_2$, H$_2$N(*t*Bu); Z = -(CH$_2$)$_2$-, CMe$_2$.

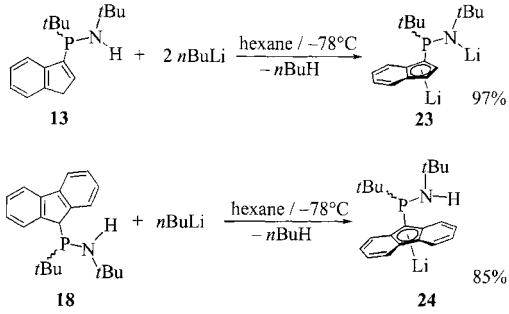
Scheme 4

The result of the reaction is independent of the length of the bridge Z and the size of alkyl groups R^1 and R^2, which might be attributed to an exclusively allylic structure of the bis[alkylchloro(indenyl)phosphanes] [{R$_n$Cp−P*t*Bu(Cl)}$_2$Z] (**7**−**10**) and/or higher steric hindrance in these encumbered substrates. Bis[alkylchloro(indenyl)phosphane] **11**, isolated as a mixture of allylic and vinylic isomers, gave, after the addition of the amine HNR^{1}R^2 a mixture of the desired products formed from the vinylic isomer and oligomers derived from the allylic isomer. The attempts to separate these substances were unsuccessful. Luckily, such ligand precursors are available by synthetic route ***B*** and can readily be obtained in high yield.[31]

Syntheses of the Complexes

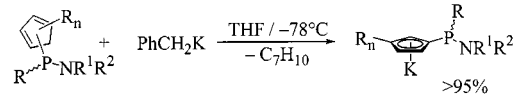
Taking into account the geometry of the prepared ligand precursors several types of transition metal complexes might be synthesised: half-sandwich, sandwich, CGC (**II**) and *ansa*-type (**I**) metallocenes. To date, a variety of methods for the preparation of such early transition metal complexes has been described in the literature.[43] The most

common synthetic approach to the desired compounds is the transmetallation reaction between transition metal halides and alkali metal derivatives of the ligands. The lithium salts **23** and **24** were prepared in order to be further treated with transition metal halides. After **13** and **18** have been treated with *n*BuLi in 2:1 and 1:1 ratios, respectively, the corresponding di- and monolithium salts are formed (Scheme 5).



Scheme 5

The compounds **23** and **24** are soluble in aliphatic solvents, thus making purification difficult. Potassium salts are expected to be less soluble and a series was synthesised by the use of Ph_2CHK or $PhCH_2K$ as deprotonating agents in THF (Scheme 6).



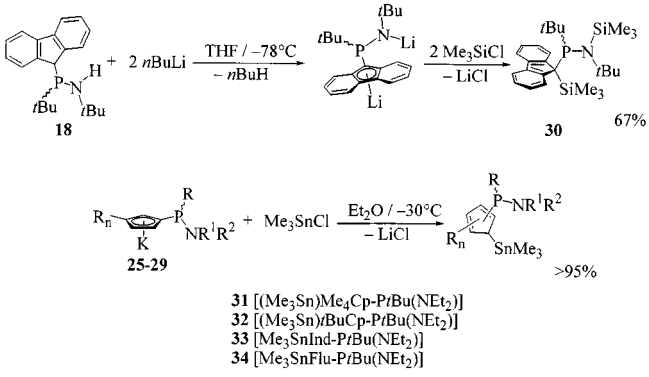
12, **17**, **18**, **20**, **21**

$[R_nCp\text{-}PR(NR^1R^2)]K$ = **25** [Me_4Cp-P*t*Bu(NEt_2)]K
26 [*t*BuCp-P*t*Bu(NEt_2)]K
27 [Ind-P*t*Bu(NEt_2)]K
28 [Flu-P*t*Bu(NEt_2)]K

$[\{R_nCp\text{-}PR(NR^1R^2)\}_2Z]K_2$ = **29** [$\{$Ind-P*t*Bu(NEt_2)$\}_2CEt_2]K_2(THF)_2$ 81%

Scheme 6

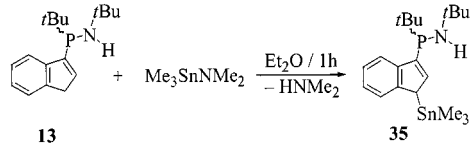
The salts **25**−**28** do not contain THF as a ligand and can be obtained free of any THF by washing with an aliphatic solvent. The alkali metal derivatives can then be transformed into the corresponding Me_3Si or Me_3Sn derivatives **30**−**34** (Scheme 7).



31 [(Me_3Sn)Me_4Cp-P*t*Bu(NEt_2)]
32 [(Me_3Sn)*t*BuCp-P*t*Bu(NEt_2)]
33 [Me_3SnInd-P*t*Bu(NEt_2)]
34 [Me_3SnFlu-P*t*Bu(NEt_2)]

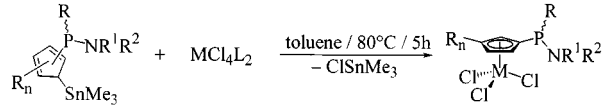
Scheme 7

The reaction of the ligand precursors with trialkyltin amides proceeds smoothly and results in *C*-stannylated products, e.g. when **13** is treated with 1 equiv. of Me_3SnNMe_2, **35** is formed quantitatively (Scheme 8). At room temperature Me_3Si and Me_3Sn groups occupy allylic positions of the cyclopentadienyl ring.



Scheme 8

Our numerous efforts to isolate desired complexes [half-sandwich, sandwich, CGC (**II**) and *ansa*-type (**I**)] of Ti^{IV} and Zr^{IV} from the reactions of homoleptic alkylmetal compounds (Alk = CH_2Ph), metal amides (NR_2 = NMe_2) of Ti^{IV}, Zr^{IV} and neutral ligand precursors **12**−**22** analogously to $R_nCpSiMe_2(NHtBu)$ (R_nCp = C_5H_5, Me_4C_5),[44] or between disilylated (**30**), dilithium/dipotassium (**23** and **29**), lithium/potassium (**24** and **25**−**28**) derivatives of the ligands and THF, THT (THT = tetrahydrothiophene) and Me_3P adducts of $TiCl_4$ and $ZrCl_4$, were unsuccessful. Either no reaction took place over rational periods of time, or complex mixtures of products were formed, which were difficult to separate and identify. The method of choice is the reaction of trimethyltin derivatives with $TiCl_4$ and $ZrCl_4$. Several substituted alkyl(amino)cyclopentadienylphosphanes [(Me_3Sn)R_nCp−P*t*Bu(NR^1R^2)] (**31**, **32**) and several Ti^{IV} (**36**, **38**) and Zr^{IV} (**37**) complexes have been synthesised in moderate yields (Scheme 9).



$[\{R_nCp\text{-}PR(NR^1R^2)\}MCl_3]$ = **36** [$\{Me_4Cp$-P*t*Bu(NEt_2)$\}TiCl_3$] 38%
37 [$\{Me_4Cp$-P*t*Bu(NEt_2)$\}ZrCl_3$] 25%
38 [$\{$*t*BuCp-P*t*Bu(NEt_2)$\}TiCl_3$] 30%
L = THF, THT, Me_3P.

Scheme 9

The main product of these reactions is a coordination polymer and the yield of the desired compound is not affected by donor molecules coordinated to the metal centre (THF, THT, Me_3P). In the case of indenyl- (**33**) and fluorenyltin (**34**) derivatives only ill-defined oligomeric products could be isolated. According to NMR spectroscopic data the oligomeric substance still contains the π-bound cyclopentadienyl ligand. The oligomeric products obtained from indenyl- and fluorenyl-containing phosphanes are soluble in polar solvents, e.g. CH_2Cl_2, toluene or THF, and decompose to $TiCl_3$ and presumably also the dimeric organic species formed from the ligand upon storage. Such behaviour is documented for situations when fluorenyltitanium complexes were attempted to be synthesised.[45] The complexes **36**−**38** are in turn very soluble in pentane and could be separated from the oligomers by extraction. Again, when a pentane solution of **36**−**38** was stored for several weeks at room temperature a precipitate containing decomposition products was formed.

Diffraction-quality crystals of [{$Me_4Cp-PtBu(NEt_2)$}$TiCl_3$] (**36**) and [{tBuCp−PtBu(NEt_2)}$TiCl_3$] (**38**) could be obtained from saturated *n*-pentane solutions at −80 °C, and a single-crystal X-ray structure of [{$Me_4Cp-PtBu(NEt_2)$}$TiCl_3$] (**36**) has been determined (Figure 2). The structure of **38** could not be solved due to twinning problems.

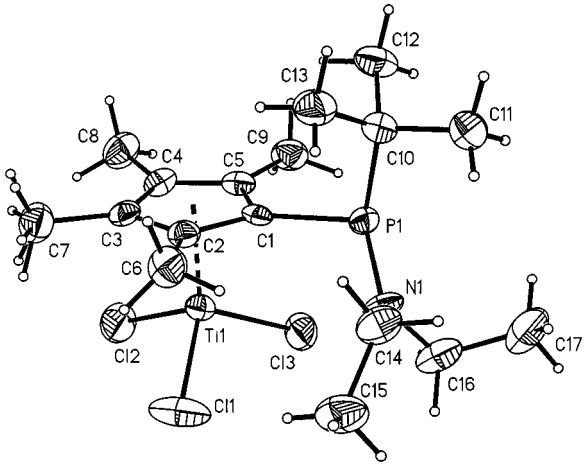


Figure 2. ORTEP diagram of the molecular structure of [{$Me_4Cp-PtBu(NEt_2)$}$TiCl_3$] (**36**); thermal ellipsoids are drawn at 50% probability level; selected bond lengths [Å]: Ti(1)−Cl(3) 2.232(2), Ti(1)−Cl(2) 2.235(2), Ti(1)−Cl(1) 2.235(2), Ti(1)−C(1) 2.328(5), Ti(1)−C(2) 2.352(5), Ti(1)−C(3) 2.368(5), Ti(1)−C(4) 2.379(5), Ti(1)−C(5) 2.339(5), P(1)−N(1) 1.691(4), P(1)−C(1) 1.862(6), P(1)−C(10) 1.897(6), N(1)−C(16) 1.465(7), N(1)−C(14) 1.479(7); selected bond angles [°]: Cl(1)−Ti(1)−Cl(2) 101.91(8), Cl(3)−Ti(1)−Cl(1) 104.47(8), Cl(3)−Ti(1)−Cl(2) 100.74(8), C(1)−P(1)−C(10) 100.3(2), N(1)−P(1)−C(1) 108.6(2), N(1)−P(1)−C(10) 110.4(2), C(16)−N(1)−C(14) 113.9(4), C(14)−N(1)−P(1) 128.7(4), C(16)−N(1)−P(1) 112.7(4); non-bonding distance [Å]: Ti(1)−N(1) 4.03

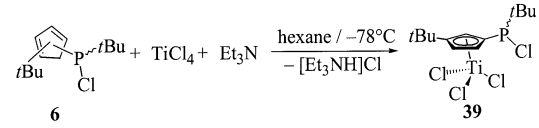
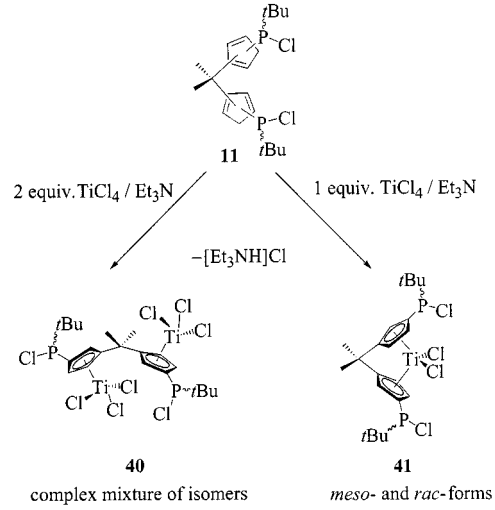
The racemic mixture of the chiral complex **36** crystallises in the centrosymmetric space group $P2_1/c$ building up non-chiral crystals. The coordination geometry at the titanium atom can be described as a piano-stool configuration typical for half-sandwich complexes, e.g. [$CpTiCl_3$].[46] The η^5-bound cyclopentadienyl ligand is practically planar with Ti−C bond lengths ranging from 2.332(2) to 2.379(5) Å and with C−C bond lengths of 1.407(8) to 1.438(8) Å. The deviations in the Ti−C distances indicate that the titanium atom is bonded somewhat more strongly to C(1), C(2) and C(5) atoms with average distances of 2.34 Å than to C(3) and C(4) atoms (2.37 Å), but the cyclopentadienyl fragment can be still regarded as η^5-coordinated. A different situation has been observed for the [$Ph_2PCpTiCl_3$] complex[47] in which the distance between the titanium atom and the phosphorus-substituted carbon atom is slightly elongated in comparison to the other carbon atoms of the cyclopentadienyl ligand. The bond angle C(1)−P(1)−C(10) at the phosphorus atom of 100.3(2)° is smaller than N(1)−P(1)−C(1) of 108.6(2)° and N(1)−P(1)−C(10) 110.4(2)°. This phenomenon may be attributed to a higher steric demand of a shorter bound nitrogen substituent at the phosphorus atom [1.691(4) Å], while the electronegative character of the Et_2N group should work in an absolutely opposite direction. This leads to a greater contribution of the 3p orbital of the phosphorus atom to the P−N bond and as a consequence more 3s character in the P−C bond according to the well-known "rehybridisation" effect, also referred to as Bent's rule.[48] Introduction of an electronegative substituent X (e.g. NR_2) in a compound X−EY_n (e.g. $R_2N-PR'_2$) develops more p-orbital character of the E−X (e.g. P−N) bond, leaving more s character for the bonds E−Y (e.g. P−C), thus shortening them and enhancing Y−E−Y angles. The Ti−Cl distances as well as Cl−Ti−Cl angles have values typical of other related cyclopentadienyltitanium trichlorides.[49−51] Although the Et_2N group is oriented towards the metal centre, the Ti(1)−N(1) distance of 4.03 Å is considerably longer than the sum of the van der Waals radii of 3.82 Å.[52]

When [tBuCp−PtBu(Cl)] (**6**) is treated with $TiCl_4$ in hexane at a low temperature in the presence of Et_3N [{tBuCp−PtBu(Cl)}$TiCl_3$] (**39**) is obtained in almost quantitative yield as estimated by ^1H and ^{31}P NMR spectroscopy(Scheme 10). Complex **39** is, however, very soluble in aliphatic solvents so that an analytically pure sample could be isolated with 40% yield.



Scheme 10

Attempts to extend this synthetic strategy to other derivatives [$R_nCp-PtBu(Cl)$] (**1**−**3** and **5**) and [{$R_nCp-PtBu(Cl)$}$_2Z$] (**7**−**10**) failed. Only the sterically less encumbered [{$Cp-PtBu(Cl)$}$_2CMe_2$] (**11**) was successfully transformed into target complexes by the reaction with 1 and 2 equiv. of $TiCl_4$ to form complex isomeric mixtures of corresponding homobimetalic [{$(Cp-PtBu(Cl)]_2$-CMe_2}{$TiCl_3$}$_2$] (**40**) and *ansa*-[{$(Cp-PtBu(Cl)]_2$-CMe_2}$TiCl_2$] (**41**) compounds (Scheme 11).

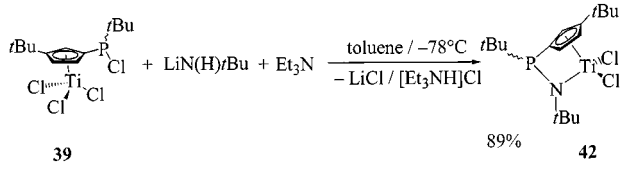


Scheme 11

According to ^1H and ^{31}P NMR spectroscopic data both complexes are formed in a high (ca. 90%) yield. The physical properties of **40** and **41** are totally different. **40** is only soluble in polar solvents, e.g. toluene, CH_2Cl_2, THF, and insoluble in aliphatic solvents, whereas the *ansa* complex **41** is practically unlimitedly soluble in aliphatic solvents. All of our efforts to purify these compounds by standard methods such as sublimation, liquid chromatography or recrystallisation have failed so far.

The fact that only sterically less demanding and more CH-acidic alkyl(chloro)cyclopentadienylphosphanes react with $TiCl_4$ in the presence of Et_3N to give complexes similar to **39** leads us to the hypothesis that in the mechanism of the reaction the key-step should be controlled by the acidity of the Cp protons. An analogous methodology has been used for the synthesis of [{Cp(CH$_2$)$_2$NR$_2$}TiCl$_3$] complexes by direct reaction of Cp ligand precursors and $TiCl_4$ in the presence of Et_3N as a base.[53,54]

The complex [{*t*BuCp−P*t*Bu(Cl)}TiCl$_3$] (**39**) is structurally related to [{R$_n$CpSiMe$_2$(Cl)}TiCl$_3$] derivatives bearing a reactive chlorine atom at the dimethylsilyl group that were then transformed into [{R$_n$CpSiMe$_2$(N*t*Bu)}TiCl$_2$] CGC-type of complexes.[55−58] Awarding all of our previous unsuccessful attempts to access this class of compounds with a phosphorus bridging group, the transformation of **39** (half-sandwich) into complex **42** of CGC-type proceeded in good yield (Scheme 12).



39 **42**

Scheme 12

The complex **42** is formed as a mixture of two diastereomers with respect to *syn* and *anti* orientation of the *t*Bu groups at the phosphorus atom and Cp ligand. Compound **42** was characterised by ^1H, ^{13}C, ^{31}P NMR spectroscopy and C,H,N elemental analyses.

Polymerisation of Ethylene

The preparative organotitanium chemistry described in the preceding sections was undertaken in part to provide precursors for an investigation of the catalytic polymerisation of ethylene in the presence of methylalumoxane (MAO), being suitable to roughly estimate the primary catalytic properties of the complexes.

Complexes **39** and **42** show moderate activities in the ethylene polymerisation at 20 and 80 °C (800 for **39** and 100 kg PE·mol^{-1}[Ti]·h^{-1}·bar^{-1} for **42**, MAO/[Ti] = 2000, T = 80 °C, p = 3 bar), while MAO-activated compounds **36**−**38** produce polyethylene with performances lower than 20 kg PE·mol^{-1}[M]·h^{-1}·bar^{-1} under the same polymerisation conditions. Related complexes [CpTiCl$_3$] (60), [Cp*TiCl$_3$] (600), [{Me$_4$CpCH$_2$CH$_2$NMe$_2$}TiCl$_3$] (200)[59] and [{Me$_4$CpSiMe$_2$N(*t*Bu)}TiCl$_2$] (950 kg PE·mol^{-1}·[Ti]·h^{-1}·bar^{-1})[60] show comparable and, under our experimental conditions, reproducible activities. The product is in all cases a highly linear polyethylene of high molecular weight ($10^5 < M_w < 1.4 \cdot 10^6$, determined viscosimetrically) having a melting point (DSC) in the range from 123 to 132 °C. Our main objective, however, was to compare the polymerisation activity of various organotitanium compounds and we have not investigated the morphology and the molecular weight distribution in detail. An investigation of the influence of the aminophosphanyl group attached to the cyclopentadienyl ligand on the catalytic behaviours of the complexes and the polymer properties is underway.

Conclusion

We have developed a new facile route to a class of P−N-functionalised phosphorylated cyclopentadienes, indenes and fluorenes **12**−**22**. Many attempts to obtain complexes **12**−**22** with group-4 transition metals Ti^{IV} and Zr^{IV} using classical procedures were, however, unsuccessful. We believe that the limiting factor is the high Lewis acidity of the Ti^{IV} and Zr^{IV} halides when they are treated with lithium and potassium salts of the ligand precursors giving complex mixtures of products. On the other hand, less Lewis-acidic Ti^{IV} and Zr^{IV} derivatives, e.g. Ti(NMe$_2$)$_4$, Zr(NMe$_2$)$_4$, do not react with the cyclopentadienylphosphanes under mild conditions due to a low CH acidity of these cyclopentadienes, while in the case of Ti(CH$_2$Ph)$_4$ or Zr(CH$_2$Ph)$_4$, again mixtures of products difficult to separate were formed at elevated temperatures. Several complexes could be synthesised only when trimethyltin-substituted amino(cyclopentadienyl)phosphane derivatives **31** and **32** were used as cyclopentadienylating agents. Surprising results have been obtained in the reaction of [*t*BuCp−P*t*Bu(Cl)] (**6**) with $TiCl_4$ in the presence of Et_3N at low temperature; the half-sandwich complex [{*t*BuCp−P*t*Bu(Cl)}TiCl$_3$] (**39**) was formed in a high yield. Compound **39** could be transformed into a CGC complex [{*t*BuCp−P*t*Bu(N*t*Bu)}TiCl$_2$] (**42**) by treatment with LiN(H)*t*Bu/Et_3N mixture in toluene. The isolated half-sandwich complexes [{R$_n$Cp−P*t*Bu(NEt$_2$)}TiCl$_3$] (**36**−**39** and **42**) were tested in the polymerisation of ethylene, some of them having activities comparable to known systems.[59][60]

Experimental Section

General Remarks: All manipulations involving air- and moisture-sensitive materials were carried out by standard Schlenk techniques under dry argon. Solvents were dried and distilled prior to use and stored under an inert gas. ^1H, ^{13}C and ^{31}P NMR spectra were recorded at 25 °C with Bruker AC250P, Bruker ARX300 and Varian VXR-400 spectrometers. Mass spectra (EI-MS) were recorded with a Varian CH-7a device using electron impact with an ionisation energy of 70 eV; all assignments were made with reference to the most abundant isotopes. C,H,N elemental analyses were carried out by the Microanalytical Division of Philipps-Universität Marburg. IR spectra were recorded with a Nicolet 510 FT-IR spectro-

meter. $[Cp_2CMe_2]$,[61] $[Ind_2CEt_2]$,[62] $[Ind_2(CH_2)_2]$ and $[IndCMe_2Cp]$,[63] $MesPCl_2$ (Mes = 2,4,6-$Me_3C_6H_2$) and $tBuPCl_2$,[64] Me_6IndH,[65] were prepared according to literature methods. Li salts of the cyclopentadienyl ligand precursors, indene and fluorene were obtained by deprotonation with a 1.6 M solution of *n*BuLi (purchased from Merck); $PhCH_2K$,[66] Ph_2CHK[67] by a standard procedure. MAO was used as 10% solution in toluene as received from Witco GmbH.

General Procedure for the Preparation of [$R_nCp-PR(Cl)$] (1−11): The total amount of dichlorophosphane ($RPCl_2$) (1 mol-equiv.; R = Alk or Ar) was added at once to a suspension of [R_nCp]Li (R_nCp = *t*BuCp, Me_4Cp, Ind, Flu) in hexane [in the case of bis(cyclopentadienyl) or bis(indenyl) diethyl ether had to be used] at −30 °C and the reaction mixture was stirred for 8 h, after warming to room temperature (1 h). Then the precipitated LiCl was removed by filtration. The filtrate was concentrated under vacuum (3 mbar) at room temperature to yield a product of an oily yellow liquid. Yield: 66−98%.

General Procedure for the Preparation of [$R_nCp-PR(NR^1R^2)$] (12−22): The total amount of HNR^1R^2 (2 mol) was immediately added to a solution of [$R_nCp-PR(Cl)$] (**1**−**6**) (1 mol) in diethyl ether at −20 °C and the reaction mixture was stirred for an additional 5 h at room temperature. Then the precipitated ammonium salt was removed by filtration. The filtrate was concentrated under vacuum at room temperature to yield a product of an oily yellow or red-yellow liquid. The yield, in all cases, was nearly quantitative.

General Procedure for the Preparation of [$R_nCp-PR(NR^1R^2)$]K (25−29): A solution of Ph_2CHK/$PhCH_2K$ (1 mol) was added slowly at −78 °C to a solution of [$R_nCp-PR(NR^1R^2)$] (**12**, **17**, **20** and **21**) (1 mol) in THF. The reaction mixture was stirred for 8 h, while warming to room temperature. The reaction mixture had a red colour except for the monoindenyl ligand derivatives that were green. Then the solvent was removed by evaporation under vacuum to give an oil. The oil solidified in pentane after several minutes to 2 d. Solvent-free potassium salts were isolated by filtration, washed twice with pentane and dried under vacuum. The yields, in all cases, were nearly quantitative.

General Procedure for the Preparation of [(Me_3Sn)-$R_nCp-PR(NR^1R^2)$] (31−34): A solution of Me_3SnCl (1 mol) in diethyl ether was added dropwise at −30 °C to a suspension of potassium salt [$R_nCp-PR(NR^1R^2)$]K (**25**−**28**) (1 mol) in diethyl ether. The reaction mixture was stirred for 8 h, while warming to room temperature. Then the precipitated KCl was removed by filtration. The filtrate was concentrated under vacuum at room temperature to yield a product of a white or pale yellow oil. The yield, in all cases, was nearly quantitative.

[Ind−P*t*Bu(Cl)] (1): Obtained from IndLi (3.54 g, 29.0 mmol) and $tBuPCl_2$ (4.77 g, 30.0 mmol). Isolated 4.61 g (19.3 mmol), yield 66%. *Isomer 1: tert*-Butylchloro(1*H*-inden-1-yl)phosphane (60%). ^1H NMR (300 MHz, [D_6]benzene): δ = 0.89 (d, 9 H, *t*Bu, $^3J_{HP}$ = 12.6 Hz), 3.99 (m, 1 H, Ind), 6.31−6.28 (dt, 1 H, Ind, $^3J_{H,H}$ = 4.2, $^3J_{HP}$ = 2.1 Hz), 6.66−6.64 (dt, 1 H, Ind, $^3J_{H,H}$ = 4.2 Hz), 7.13−7.01 (m, 2 H, Ind), 7.20−7.18 (d, 1 H, Ind), 7.81−7.78 (d, 1 H, Ind). $^{31}P\{^1H\}$ NMR (162 MHz, [D_6]benzene): δ = 132.0. *Isomer 2: tert*-Butylchloro(1*H*-inden-2-yl)phosphane (25%). ^1H NMR (300 MHz, [D_6]benzene): δ = 0.98 (d, $^3J_{HP}$ = 13.3 Hz, 9 H, *t*Bu), 3.62 (dt, 1 H, Ind), 6.42−6.38 (m, 1 H, Ind), 6.72−6.68 (m, $^3J_{H,H}$ = 8.1, $^3J_{HP}$ = 1.9 Hz, 1 H, Ind), 7.18−7.00 (m, 3 H, Ind), 7.59−7.57 (m, 1 H, Ind). *Isomers 1 and 2:* $^{13}C\{^1H\}$ NMR (75 MHz, [D_6]benzene): δ = 26.7 (d, $^2J_{C,P}$ = 9 Hz, CH_3, *t*BuP), 26.8 (d, $^2J_{C,P}$ = 9.3 Hz, CH_3, *t*BuP), 34.5 (d, $^1J_{C,P}$ = 35.9 Hz, C, *t*BuP), 35.3 (d, $^1J_{C,P}$ = 38.1 Hz, C, *t*BuP), 51.4 (d, $^1J_{C,P}$ = 47.2 Hz, CH, Ind), 54.8 (d, $^1J_{C,P}$ = 44.3 Hz, CH, Ind), 121.8 (CH, Ind), 121.9 (CH, Ind), 124.4 (d, $J_{C,P}$ = 9 Hz, CH, Ind), 125.2, 125.3, 125.4, 127.3, 127.4 (CH, Ind), 132.5 (d, $J_{C,P}$ = 5.2 Hz, CH, Ind), 132.8 (d, $J_{C,P}$ = 2.2 Hz, CH, Ind), 133.5 (d, $J_{C,P}$ = 3.7 Hz, CH, Ind), 133.6 (d, $J_{C,P}$ = 3.2 Hz, CH, Ind), 143.7 (d, $J_{C,P}$ = 11.3 Hz, C, Ind), 144.4 (d, $J_{C,P}$ = 22.5 Hz, C, Ind). $^{31}P\{^1H\}$ NMR (162 MHz, [D_6]benzene): δ = 127.2. *Isomer 3: tert*-Butylchloro(1*H*-inden-3-yl)phosphane (15%). ^1H NMR (300 MHz, [D_6]benzene): δ = 1.08 (d, $^3J_{HP}$ = 17.9 Hz, 9 H, *t*Bu), 3.00 (d, $^3J_{H,H}$ = 2 Hz, 2 H, Ind), 7.70−7.64 (m, 1 H, Ind), 6.79 (dt, $^3J_{H,H}$ = 2, $^3J_{HP}$ = 4.1 Hz, 1 H, Ind), 7.28−7.15 (m, 3 H, Ind). $^{13}C\{^1H\}$ NMR (75 MHz, [D_6]benzene): δ = 26.3 (d, $^2J_{C,P}$ = 18.1 Hz, CH_3), 35.3 (d, $^1J_{C,P}$ = 27.8 Hz, C, *t*Bu), 39.9 (CH, Ind), 122.3 (d, $J_{C,P}$ = 6 Hz, CH, Ind), 124.2, 125.4, 126.5 (CH, Ind), 141.0 (d, $^1J_{C,P}$ = 46.5 Hz, C, Ind), 144.2 (d, $^2J_{C,P}$ = 12.1 Hz, CH, Ind), 144.4 (d, $J_{C,P}$ = 3.7 Hz, C, Ind), 145.8 (d, $J_{C,P}$ = 21.3 Hz, C, Ind). $^{31}P\{^1H\}$ NMR (162 MHz, [D_6]benzene): δ = 102.4. EI-MS: *m*/*z* (%) = 238 (8) [M^+], 182 (9) [M^+ − *t*Bu], 115 (26) [Ind], 57 (100) [*t*Bu]. $C_{13}H_{16}PCl$ (238.70): calcd. C 65.41, H 6.76; found C 65.02, H 6.37.

[Flu−P*t*Bu(Cl)] (2):[40] Obtained from FluLi (2.61 g, 15.2 mmol) and $tBuPCl_2$ (2.41 g, 15.2 mmol). Isolated 4.13 g (14.3 mmol), yield 94%. ^1H NMR (300 MHz, [D_6]benzene): δ = 0.41 (d, $^3J_{HP}$ = 12.9 Hz, 9 H, *t*Bu), 7.98−7.90 (m, 1 H, Flu), 4.41 (s, 1 H, Flu), 7.18−6.95 (m, 4 H, Flu), 7.45−7.40 (m, 3 H, Flu). $^{13}C\{^1H\}$ NMR (75 MHz, [D_6]benzene): δ = 26.8 (d, $^2J_{C,P}$ = 16.7 Hz, CH_3, *t*BuP), 36.3 (d, $^1J_{C,P}$ = 40.7 Hz, C, *t*BuP), 51.2 (d, $^1J_{C,P}$ = 49.4 Hz, CH, Flu), 120.4, 120.5, 125.9, 126.1, 126.7, 126.8, 127.3, 127.8 (CH, Flu), 141.2 (d, $J_{C,P}$ = 15 Hz, C, Flu), 141.3 (C, Flu), 142.4 (d, $J_{C,P}$ = 15 Hz, C, Flu), 144.1 (C, Flu). $^{31}P\{^1H\}$ NMR (162 MHz, [D_6]benzene): δ = 132.0. EI-MS: *m*/*z* (%) = 288 (3) [M^+], 231 (1) [M^+ − *t*Bu], 165 (100) [Flu]. $C_{17}H_{18}ClP$ (288.76): calcd. C 70.71, H 6.28; found C 70.14, H 6.40.

[Ind−PMes(Cl)] (3): Obtained from IndLi (2.5 g, 20.5 mmol) and $MesPCl_2$ (4.53 g, 20.5 mmol). Isolated 5.07 g (16.9 mmol), yield 82%. *Mixture of Isomers:* ^1H NMR (300 MHz, [D_6]benzene): δ = 2.5−1.8 (several s and d, 9 H, CH_3), 5.3−4.5 (several m, 1 H, Ind), 7.5−6.2 (several m, 7 H, Ind and Mes). $^{13}C\{^1H\}$ NMR (75 MHz, [D_6]benzene): δ = 25.0−21.0 (10 resonances, CH_3), 56.0−39.0 (3 d, Ind), 126.0−120.0 (22 resonances, CH, Ind/Mes), 127.7 (CH, Ind/Mes), 131.0−129.0 (6 d, CH, Ind/Mes), 132.0 (3 d, C, Ind/Mes), 132.5 (2 d, C, Ind/Mes), 134 (d, C, Ind/Mes), 137.0−136.0 (2 d and 1 s, C, Ind/Mes), 142.0−141.0 (3 s, C, Ind/Mes), 145.0−144.5 (3 d, C, Ind/Mes). $^{31}P\{^1H\}$ NMR (162 MHz, [D_6]benzene): δ = 70.7, 83.5, 84.3. EI-MS: *m*/*z* (%) = 300 (25) [M^+], 265 (10), [M^+ − Cl], 185 (100), [M^+ − Ind], 119 (42) [Mes], 115 (56) [Ind]. $C_{18}H_{18}ClP$ (300.77): calcd. C 71.88, H 6.03; found C 71.21, H 5.87.

[Me_6C_9H−P*t*Bu(Cl)] (4): Obtained from [Me_6C_9H]Li (3.0 g, 14.5 mmol) and $tBuPCl_2$ (2.32 g, 14.5 mmol). Isolated 3.98 g (12.3 mmol), yield 85%. ^1H NMR (300 MHz, [D_6]benzene): δ = 0.81 (d, $^3J_{HP}$ = 12.9 Hz, 9 H, *t*Bu), 2.04 (s, 3 H, CH_3), 2.06 (s, 6 H, 2 CH_3), 2.20 (s, 3 H, CH_3), 2.32 (s, 3 H, CH_3), 2.45 (d, $^4J_{HP}$ = 2 Hz, 3 H, CH_3), 4.14 (s, 1 H, Me_6C_9H). $^{13}C\{^1H\}$ NMR (75 MHz, [D_6]benzene): δ = 15.1, 16.0 (CH_3), 16.2 (d, $^3J_{C,P}$ = 7.5 Hz, CH_3, Me_6C_9H), 16.3 (CH_3, Me_6C_9H), 18.9 (d, $^4J_{C,P}$ = 19.6 Hz, CH_3, Me_6C_9H), 24.5 (CH_3, Me_6C_9H), 26.6 (d, $^2J_{C,P}$ = 17.3 Hz, CH_3, *t*BuP), 36.2 (d, $^1J_{C,P}$ = 40.8 Hz, C, *t*BuP), 57.7 (d, $^1J_{C,P}$ = 52.1 Hz, C, Me_6C_9H), 126.7, 129.3, 131.4, 134.7, 135.2 (C, Me_6C_9H), 138.1 (d, $J_{C,P}$ = 8.5 Hz, C, Me_6C_9H), 140.0, 141.7 (C, Me_6C_9H). $^{31}P\{^1H\}$ NMR (162 MHz, [D_6]benzene): δ = 45.3. [{Me$_4$C$_5$−P*t*Bu(NEt$_2$)}ZrCl$_3$] (37): Obtained from [(Me_3Sn)-Me_4C_5−P*t*Bu(NEt_2)] (**31**) (0.57 g, 1.3 mmol) and $ZrCl_4(THF)_2$ (0.49 g, 1.3 mmol), using the same procedure as for the preparation of [{Me_4C_5−P*t*Bu(NEt_2)}$TiCl_3$] (**36**). Isolated 0.15 g (0.32 mmol), yellow solid (yield 25%). ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 1.10 (t, $^3J_{H,H}$ = 7 Hz, 6 H, $-NCH_2CH_3$), 1.16 (d, $^3J_{HP}$ = 14.2 Hz, 9 H, *t*BuP), 2.15 (s, 3 H, CH_3, Me_4C_5), 2.16 (s, 3 H, CH_3, Me_4C_5), 2.45 (s, 3 H, CH_3, Me_4C_5), 2.52 (s, 3 H, CH_3, Me_4C_5), 3.19 (m, 4 H, $-NCH_2CH_3$). ^{13}C{^{1}H} NMR (50 MHz, CD_2Cl_2): δ = 12.8 ($-NCH_2CH_3$), 13.9, 15.7, 16.1, 17.5 (CH_3, Me_4C_5), 29.5 (d, $J_{C,P}$ = 18.9 Hz, CH_3, *t*BuP), 37.0, 37.5 ($-NCH_2CH_3$), 47.6 (d, $J_{C,P}$ = 17 Hz, C, *t*BuP), 128.4, 128.2 (C, Me_4C_5), 129.0 (br. resonance, C, Me_4C_5), 132.5 (d, $J_{C,P}$ = 3.8 Hz, Me_4C_5), 132.7 (br. resonance, C, Me_4C_5). ^{31}P{^{1}H} NMR (162 MHz, CD_2Cl_2): δ = 73.2. EI-MS: *m*/*z* (%) = 346 (1) [M$^+$ − $C_8H_{19}N$], 224 (27) [M$^+$ − $C_{12}H_{27}N$], 153 (40) [Me_4C_5P], 121 (100) [Me_4C_5H], 106 (7) [Me_4C_5H − Me], 73 (5) [$HNEt_2$] 57 (56) [*t*Bu]. $C_{17}H_{31}Cl_3NPZr$ (475.03): calcd. C 42.72, H 6.54, N 2.93; found C 42.57, H 6.33, N 2.81.

[{*t*BuC$_5$H$_3$−P*t*Bu(NEt$_2$)}TiCl$_3$] (38): Obtained from [(Me_3Sn)*t*BuC$_5$H$_3$−P*t*Bu(NEt_2)] (**32**) (0.57 g, 1.28 mmol) and

$TiCl_4(THF)_2$ (0.42 g, 1.28 mmol) using the same procedure as for the preparation of [{Me_4C_5−P*t*Bu(NEt$_2$)}$TiCl_3$] (**36**). Isolated 0.16 g (0.37 mmol), deep red solid (yield 30%). ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 1.22 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, −NCH$_2$*CH$_3$*), 1.14 (d, $^3J_{HP}$ = 13.7 Hz, 9 H, *t*BuP), 1.40 (d, J_{HP} = 1 Hz, 9 H, CH_3, *t*BuC_3H_5), 3.16 (m, 4 H, −N*CH$_2$*CH$_3$), 6.93−7.30 (several m, 3 H, *t*BuC_3H_5). ^{13}C{^{1}H} NMR (50 MHz, CD_2Cl_2): δ = 15.5 (CH_3, −NCH$_2$*CH$_3$*), 15.7 (CH_3, *t*BuC_3H_5), 28.6 (d, $J_{C,P}$ = 17 Hz, CH_3, *t*BuP), 35.2, 35.3 (−N*CH$_2$*CH$_3$), 43.6 (C, *t*BuC_3H_5), 47.2 (d, $J_{C,P}$ = 15.5 Hz, C, *t*BuP), 125.1, 128.4, 129.2 (CH, *t*BuC_3H_5), 151.0 (d, $J_{C,P}$ = 21 Hz, C, *t*BuC_3H_5) 159.5 (C, *t*BuC_3H_5). ^{31}P{^{1}H} NMR (162 MHz, CD_2Cl_2): δ = 88.4, 88.5. EI-MS: *m*/*z* (%) = 361 (2) [M^+ − NEt_2], 304 (12) [M^+ − $C_8H_{19}N$], 281 (35) [$C_{15}H_{32}N$], 160 (4) [*t*BuPNEt$_2$], 121 (100) [*t*BuC_5H_3], 72 (54) [NEt_2], 57 (73) [*t*Bu]. $C_{17}H_{31}Cl_3NPTi$ (433.07): calcd. C 46.98, H 7.19, N 3.22; found C 47.11, H 7.29, N 3.05.

[{*t*BuC_5H_3−P*t*Bu(Cl)}$TiCl_3$] (39): $TiCl_4$ (0.45 mL, 4.09 mmol) was slowly added at −80°C to a solution of [*t*BuC_5H_3−P*t*Bu(Cl)] (**6**) (1.0 g, 4.1 mmol) in 30 mL of hexane; after 1 min of stirring, Et_3N (0.57 mL, 4.1 mmol) was added. The reaction mixture was stirred for 4 h, while warming to room temperature. The ammonium salt precipitate was removed by filtration. All volatiles were removed under vacuum to give the crude product. Yield according to ^{1}H and ^{31}P NMR spectra was 98%. An analytically pure product was obtained, after two times of washing with cold (−50 °C) pentane, as an orange solid with 40% yield. ^{1}H NMR (250 MHz, CD_2Cl_2): δ = 1.09, 1.05 (2 d, J_{HP} = 14.3 Hz, J_{HP} = 14.4 Hz, 9 H, *t*BuP), 1.4 (s, 9 H, *t*Bu), 7.0 (m, 6 H, *t*BuC_3H_5), 7.02−7.1 (2 m, CH, *t*BuC_3H_5), 7.25 (m, CH, *t*BuC_3H_5), 7.32 (m, CH, *t*BuC_3H_5). ^{13}C NMR (50 MHz, CD_2Cl_2): δ = 25.2 (CH_3, *t*BuC_3H_5), 30.8 (d, $^2J_{C,P}$ = 12.9 Hz, CH_3, *t*BuP), 35.2 (d, $^4J_{C,P}$ = 2.6 Hz, C, *t*Bu), 36.3 (d, $J_{C,P}$ = 25.4 Hz, C, *t*BuP), 122.3 (d, $^2J_{C,P}$ = 2.9 Hz, CH, *t*BuC_3H_5), 122.3 (d, $^2J_{C,P}$ = 2.9 Hz, CH, *t*BuC_3H_5), 125.4 (d, $J_{C,P}$ = 4.8 Hz, C, *t*BuC_3H_5), 125.9 (CH, *t*BuC_3H_5), 123.4 (d, $^2J_{C,P}$ = 3.3 Hz, CH, *t*BuC_3H_5), 126.3 (C, *t*BuC_3H_5). ^{31}P{^{1}H} NMR (162 MHz, CD_2Cl_2): δ = 105.4, 106.4. EI-MS: *m*/*z* (%) = 362 (1) [M^+ − Cl], 270 (2) [$C_9H_{13}Cl_2TiP$], 244 (3) [*t*BuC_5H_3(*t*Bu)PCl], 121 (10) [*t*BuC_5H_3], 57 (100) [*t*Bu]. $C_{13}H_{21}Cl_4PTi$ (397.37): calcd. C 39.23, H 5.32; found C 39.05, H 5.09.

[{(C_5H_4−P*t*Bu(Cl)]$_2$CMe$_2$}{$TiCl_3$}$_2$] (40): Obtained from [{C_5H_4−P*t*Bu(Cl)}$_2$CMe$_2$] (**11**) (3.98 g, 9.5 mmol), $TiCl_4$ (2.09 mL, 19.1 mmol) and Et_3N (2.66 mL, 19.1 mmol), using the same procedure as for the preparation of [{*t*BuC_5H_3−P*t*Bu(Cl)}$TiCl_3$] (**39**). According to ^{1}H and ^{31}P NMR spectra the yield was 90%. A product was isolated as a deep green solid. *Mixture of Isomers:* ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 0.87−1.0 (several d, 9 H, *t*BuP),

Table 1. Crystal data and structure refinement for **15**

Empirical formula[a]	$C_{23}H_{38}NP$
Formula mass	359.51
Crystal size [mm]	0.40 × 0.20 × 0.15
Temperature [K]	223(2)
Wavelength [Å]	0.71073
Crystal system	monoclinic
Space group	$P2_1/c$
Unit cell dimensions [Å, °]	a = 7.768(1), b = 22.196(1), c = 12.8267(10), β = 91.14(1)
Volume [Å^3]	2211.2(3)
Z	4
Calculated density [g/cm^3]	1.080
Absorption coefficient [mm^{-1}]	0.130
F(000)	792
Θ-range for data collection [°]	2.43 to 23.41
Index ranges	$-8 \le h \le 0$, $-24 \le k \le 0$, $-14 \le l \le 14$
Reflections collected/unique	3502/3235, [R(int) = 0.0682]
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	3235/0/280
Goodness-of-fit on F^2	1.100
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0754, $wR2$ = 0.2332
R indices (all data)	$R1$ = 0.1357, $wR2$ = 0.2678
Largest diff. peak and hole [e/Å^3]	0.454 and −0.489

[a] Data collection and cell refinement has been carried out with an Enraf Nonius CAD4 four-circle diffractometer using CAD4-EXPRESS software. Data reduction and Lorentz and polarisation corrections were undertaken using the XCAD4 programme (K. Harms, **1993**). For structure solution SHELXS-96 and structure refinement SHELXL-96 (both G. M. Sheldrick, **1996**) were used. Molecular graphics: ORTEP III. After data reduction the data set has been checked for systematic absence violations. Due to weak absence violations *h0l*: $l \neq 2n$ for compound **15** two space groups should be taken into account, $P2_1$ and $P2_1/c$. The structure was first solved by direct methods in the chiral space group $P2_1$ and a structural model including all non-hydrogen atoms was refined isotropically. A search for additional symmetry elements (PLATON: A. Speck, **1990**) showed that a slide mirror plane parallel to the crystallographic axis c exists. The "zero point" was placed in the centre of inversion and the structure was refined in the centrosymmetric space group $P2_1/c$, after all symmetrically dependent atoms had been eliminated. The hydrogen atoms were placed at a calculated position and refined in a riding model.

Table 2. Crystal data and structure refinement for **36**

Empirical formula[a]	$C_{17}H_{31}Cl_3NPTi$
Formula mass	434.65
Crystal size [mm]	0.36 × 0.21 × 0.12
Temperature [K]	203(2)
Wavelength [Å]	0.71073
Crystal system	monoclinic
Space group	$P2_1/c$
Unit cell dimensions [Å, °]	a = 9.351(2), b = 15.637(2), c = 14.732(1), β = 91.39(1)
Volume [Å^3]	2153.5(5)
Z	4
Calculated density [g/cm^3]	1.341
Absorption coefficient [mm^{-1}]	0.843

Θ-range for data collection [°]	2.54 to 22.55
Index ranges	$0 \le h \le 10$, $-16 \le k \le 0$, $-15 \le l \le 15$
Reflections collected/unique	3007/2807, [R(int) = 0.0488]
Refinement method	Full-matrix least squares on F^2
Data/restraints/parameters	2807/0/217
Goodness-of-fit on F^2	1.022
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0550, $wR2$ = 0.1168
R indices (all data)	$R1$ = 0.1007, $wR2$ = 0.1365
Largest diff. peak and hole [e/Å^3]	0.906 and −0.751

[a] Data collection and cell refinement has been carried out with an Enraf−Nonius CAD4 four-circle diffractometer using CAD4-EXPRESS software. Data reduction and Lorentz and polarisation corrections were undertaken using the XCAD4 programme (K. Harms, **1997**). For the structure solution SHELXS-97 and structure refinement SHELXL-97 (both G. M. Sheldrick, **1997**) were used. Molecular graphics: ORTEP III. An analytical absorption correction based on face indexing was applied to the data set. Hydrogen atoms were placed at calculated positions and refined in a riding model.

2.1 (s, 3 H, CH_3, CMe_2), 6.99−7.04 (several m, 1 H, Cp), 7.09−7.15 (several m, 1 H, Cp). $^{31}P\{^1H\}$ NMR (162 MHz, CD_2Cl_2): δ = 95.3, 94.4, 95.8, 101.3, 102.4, 102.5 (2 signals), 102.7, 103.0, 103.3(2 signals), 103.4, 103.5, 103.6, 104.0, 104.3. EI-MS: *m*/*z* (%) = 534 (12) [$M^+ - TiCl_4$], 442 (22) [$M^+ - TiCl_3 - t$BuPCl], 386 (30) [$M^+ - Cp(t\text{Bu})PTiCl_4$], 318 (92) [$Cp(t\text{Bu})PTiCl_3 - H$], 57 (100) [*t*Bu].

[{(C_5H_3−P*t*Bu(Cl)]$_2$$CMe_2$}$TiCl_2$] (41): Obtained from [{$C_5H_4$−P*t*Bu(Cl)}$_2$$CMe_2$] (**11**) (4.79 g, 11.5 mmol), $TiCl_4$ (1.25 mL, 11.5 mmol) and Et_3N (3.2 mL, 23.0 mmol) using the same procedure as for the preparation of [{*t*BuC_5H_3−P*t*Bu(Cl)}$TiCl_3$] (**39**). According to ^1H and ^{31}P NMR spectra the yield was 90%. A product was isolated as a deep red solid. *Mixture of Isomers:* ^1H NMR (400 MHz, CD_2Cl_2): δ = 0.85−1.5 (several m, *t*BuP), 1.7−1.9 (several m, CH_3, CMe_2), 5.3−5.92 (several m, Cp), 7.14−7.24 (several m, Cp). $^{31}P\{^1H\}$ NMR (162 MHz, CD_2Cl_2): δ = 96.2, 96.6, 96.8, 97.5, 101.7, 103.0, 103.2, 103.7.

[{*t*BuC_5H_3−P*t*Bu(N*t*Bu)}$TiCl_2$] (42): A suspension of Li[NH*t*Bu] (0.03 g, 0.37 mmol) and Et_3N (0.052 mL, 0.37 mmol) were immediately added, −78 °C, to a solution of [{*t*BuC_5H_3−P*t*Bu(Cl)}$TiCl_3$] (**39**) (0.15 g, 0.37 mmol) in 20 mL of toluene. The reaction mixture was stirred for 12 h, while warming to room temperature. Then the precipitated LiCl and Et_3NHCl were removed by filtration. The filtrate was concentrated under vacuum. The product was taken up in pentane. Isolated 0.13 g (0.33 mmol), deep red solid (yield 89%). *Mixture of 2 Isomers (1:3):* ^1H NMR (200 MHz, CD_2Cl_2): δ = 1.24 (*major*), 1.20 (*minor*) [2 d, $^3J_{HP}$ = 14.4 Hz (*both isomers*), 9 H, *t*BuP], 1.30 (*major*), 1.27 (*minor*) [2 d, $^6J_{HP}$ = 3.7 Hz (*major*), 3.5 Hz (*minor*), 9 H, CH_3, *t*BuC_5H_3], 1.45 (*minor*), 1.42 (*major*) [2 d, $^4J_{HP}$ = 0.7 Hz (*both isomers*), 9 H, *t*BuN], 6.95−7.85 (6 m, total 3 H, *t*BuC_5H_3). *Both Isomers:* $^{13}C\{^1H\}$ NMR (50 MHz, [D_6]benzene): δ = 15.0, 15.1, 15.2, 15.3 (CH_3, *t*BuN and *t*Bu), 29.0 (d, $J_{C,P}$ = 17 Hz, CH_3, *t*BuP), 29.6 (d, $J_{C,P}$ = 18.5 Hz, CH_3, *t*BuP), 47.0 (d, $J_{C,P}$ = 17 Hz, C, *t*BuP), 47.5 (d, $J_{C,P}$ = 16.1 Hz, C, *t*BuP), 53.1, 53.2 (C, *t*Bu), 61.9, 62.8 (C, *t*BuN), 134.6 (d, $J_{C,P}$ = 1.5 Hz, CH, *t*BuC_5H_3), 135.7 (d, $J_{C,P}$ = 1.5 Hz, CH, *t*BuC_5H_3), 135.8 (d, $J_{C,P}$ = 4.5 Hz, CH, *t*BuC_5H_3), 135.9 (d, $J_{C,P}$ = 4 Hz, CH, *t*BuC_5H_3), 141.7 (d, $J_{C,P}$ = 36 Hz, CH, *t*BuC_5H_3), 142.4 (d, $J_{C,P}$ = 34 Hz, CH, *t*BuC_5H_3), 145.1 (d, $J_{C,P}$ = 1.5 Hz, C, *t*BuC_5H_3), 145.3 (C, *t*BuC_5H_3), 150.5 (d, $J_{C,P}$ = 30 Hz, C, *t*BuC_5H_3), 151.5 (d, $J_{C,P}$ = 29 Hz, C, *t*BuC_5H_3). $^{31}P\{^1H\}$ NMR (162 MHz, CD_2Cl_2): δ = 45.9 (*major*), 51.1 (*minor*). EI-MS: *m*/*z* (%) = 340 (4) [$M^+ - t$Bu], 283 (15) [$M^+ - 2\ t$Bu], 226 (35) [$M^+ - 3\ t$Bu], 121 (100) [*t*BuC_5H_3], 57 (100) [*t*Bu]. $C_{17}H_{30}Cl_2NPTi$ (397.09): calcd. C 51.28, H 7.59, N 3.52; found C 51.13, H 7.68, N 3.44.

Polymerisation of Ethylene: A glass autoclave was charged with 50 mL of toluene and 0.5 mL of triisobutylaluminium, then thermostatted for 30 min and saturated with ethylene (3 bar) for another 30 min. The catalyst was generated by treatment of the corresponding complex with MAO [10% solution in toluene, Al/(Ti or Zr) ratio was either 500 or 2000] and preformed over 1 h in an ultrasonic bath. This toluene solution was injected into the autoclave. The reaction mixture was placed under 3 bar of ethylene for 30 min with rapid stirring. The polymerisation was stopped by quenching with 50 mL of aqueous HCl/methanol (1:5, v/v). The polymer was isolated by filtration, washed subsequently with HCl solution, water, methanol, acetone and dried at 60 °C to a constant weight. All polymerisation experiments were repeated at least twice, whereby no large deviations have been observed.

X-ray Crystallographic Study: Crystallographic data for the structures reported (Tables 1 and 2) in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications nos. CCDC-162747 (**15**) and -162746 (**36**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We appreciate the help of, and many fruitful discussions with Prof. Dr. H.-H. Brintzinger (University of Konstanz) during the stay of K. V. V. in his research group. Financial support by the Deutscher Akademischer Austauschdienst (DAAD, research stay at the University of Konstanz) and the Deutsche Forschungsgemeinschaft (DFG, SFB 260, Graduiertenkolleg "Metallorganische Chemie", research stay at the University of Marburg) to K. V. V. is gratefully acknowledged.

Electrochemical and Complexation Studies of Ferrocenyl Complexes Bearing Terpyridine or Phenanthroline Ligands

Jean-Claude Moutet,*[a] Eric Saint-Aman,[a] Guy Royal,[a] Sophie Tingry,[a][‡] and Raymond Ziessel[b]

Keywords: N ligands / Sandwich complexes / Receptors / Cyclic voltammetry

The coordinative properties of 1,1′-bis(phen)- and bis(terpy)-carboxyester-bridged derivatives of ferrocene L^1 and L^2 (phen refers to 2,9-substituted-1,10-phenanthroline; terpy refers to 4′-substituted-2,2′:6′,2"-terpyridine) towards various transition metal cations have been investigated by a combination of cyclic voltammetry, mass spectrometry and ^1H NMR spectroscopy. These novel redox receptors form 1:1 ligand:metal complexes with all the surveyed metal cations (L^1: M = Cu^I, Ni^{II}, Fe^{II}, Hg^{II}; L^2: M = Ni^{II}, Fe^{II}, Hg^{II}). Particular attention was paid to the recognition properties of these redox-active ligands, as monitored by the modulation of the potential of the ferrocene/ferricinium (Fc/Fc^+) couple upon complexation. Complexation of L^1 gives rise to a new emerging Fc/Fc^+ redox peak system. In contrast, complexation of L^2 does not alter this redox process appreciably. In addition, decomposition of free L^2 occurs upon oxidation and causes the growth of a film of an Fe-bis(terpy) complex onto the electrode surface.

Introduction

Molecular structures comprising two or more coordinated metal cations are useful models for studying electronic coupling between metal centers in different oxidation states and for the coupling of a remote active metal centre to a putative catalytic site.[1] Ferrocenyl units are frequently employed as redox-active sites in supramolecular assemblies,[2] owing to their well-behaved redox activity as well as their synthetic versatility. A number of ferrocenyl-functionalized bipyridines,[3] terpyridines,[3c,4] quinquepyridines,[5] and sexipyridines[6] have been synthesized for these reasons.

In previous studies,[7] we reported that mono(bipy)- and bis(bipy)ester- and -carboxamide-bridged derivatives of ferrocene (bipy = 2,2′-bipyridine) present a very rich coordination chemistry and electrochemistry in the presence of various transition metal cations. The resultant di-, tri-,or tetranuclear complexes displayed significant levels of electronic coupling between the metal sites. Additionally, it was demonstrated that these redox ligands can be used for the electrochemical recognition of certain transition metal cations in both homogeneous[7a][7d] and polymeric[7b] phases by way of a large shift in the ferrocene/ferricinium (Fc/Fc^+) redox couple following the binding of a guest cation at the coordination site. Here we report on the electrochemical response of novel 1,1′-bis(phenanthroline) and bis(terpyridine) derivatives of ferrocene L^1 and L^2 (Figure 1) to various transition metal cations. Some particular spectral properties (^1H NMR, FT IR and electronic absorption spectra) of certain complexes are also described.

versible, one-electron wave corresponding to the Fc/Fc^+ couple ($E_{1/2}$ = 0.58 V; labeled I in Figure 2A and 2C, curves a). We have examined how complexation of L^1 by various transition metal cations (Cu^I, Ni^{II}, Fe^{II}, and Hg^{II}) affects the electrochemical features of the ferrocene centre. Metal cations were added as the salts $[Cu(CH_3CN)_4]ClO_4$, $[Ni(ClO_4)_2]$, $[Fe(ClO_4)_2]$ or $[Hg(CF_3SO_3)_2]$. The electrochemical data for L^1 and its metal complexes are summarized in Table 1.

Cu^IL^1 and $Ni^{II}L^1$ Complexes

The electrochemical behavior of L^1 in the presence of Cu^I and Ni^{II} ions is similar to that already observed with ferrocenyl receptors containing 2,2′-bipyridine ligands.[7] The progressive complexation of L^1 causes the emergence of a new redox peak system corresponding to the complexed Fc/Fc^+ redox couple (labeled II on Figure 2) at the expense of the original Fc/Fc^+ wave for the free ligand. It should be emphasized that oxidation of the ferrocene group occurs in the $[Cu^{II}L^1]^{2+}$ complex (see below). The new wave reaches full development at a metal cation:L^1 ratio of 1 (Figure 2A and 2C, curves c). These observations are in keeping with

Figure 2. Metal	Fc/Fc^+	Metal−centered redox systems
Free L^1	0.58	
Cu^I	0.74[b]	0.33($Cu^{I/II}$)
Ni^{II}	0.86	−0.96($Ni^{II/I}$),[c] −1.39($Ni^{I/0}$)[c] [d]
Fe^{II}	0.85	1.31($Fe^{II/III}$),[e] −1.33($Fe^{II/I}$)[c,e]
Hg^{II}	0.68	−0.75($Hg^{II/I}$)[c,e]

[a] $E_{1/2}$, V vs. $Ag/AgNO_3$ 0.01 M in CH_3CN + TBAP 0.1 M, determined by CV on Pt in CH_3CN + TBAP 0.1 M; ν = 0.1 Vs^{-1}. [b] Ferrocene oxidation occurs after copper oxidation, i.e. in the $[Cu^{II}L^1]^{2+}$ complex.[c] Formal oxidation states. [d] Poorly reversible system. [e] E_p; irreversible peak.

the formation of 1:1 $[CuL^1]^+$ and $[NiL^1]^{2+}$ complexes. This result is corroborated by electrochemical studies carried out with genuine samples of pure $[CuL^1](ClO_4)$ (Figure 2B) and $[NiL^1](ClO_4)_2$ (Figure 2D) complexes: when solubilized in CH_3CN + TBAP solution they display the same CV features as obtained by in situ complexation of L^1 with one mol equivalent of Cu^I (Figure 2A, curve c) or Ni^{II} (Figure 2C, curve c).

Complexation of L^1 with Cu^I causes the rise of a new redox peak system ($E_{1/2}$ = 0.33 V) attributed to the complexed Cu^I/Cu^{II} couple (labeled III on Figure 2A and 2B). The relatively high redox potential of the $Cu^{I/II}$ redox system is in good agreement with those previously reported for various polypyridyl copper complexes.[7a,8] The electrochemical behavior of $[CuL^1]^+$ is summarized in Equation (1):

$$[Cu^I\mathbf{L^1}]^+ \underset{+e}{\overset{0.33\ V\ -e}{\rightleftharpoons}} [Cu^{II}\mathbf{L^1}]^{2+} \underset{+e}{\overset{0.74\ V\ -e}{\rightleftharpoons}} [Cu^{II}(\mathbf{L^1})^+]^{3+} \quad (1)$$

Complexation of L^1 with Ni^{II} ions is also revealed by the appearance of two reversible one-electron reduction waves at −0.96 V and −1.39 V (Figure 2C and 2D). This behavior is reminiscent of that of the Ni^{II} complex of the 2,9-di-*p*-anisyl-1,10-phenanthroline.[8] However, the reduced $[NiL^1]^+$ complex is less stable, since the $Ni^{II/I}$ redox couple was found at a notably less negative potential in the nickel bis-(anisylphenanthroline) complex ($E_{1/2}$ = −0.18 V vs. SCE).[8] Furthermore, the second reduction of the nickel complex down to its $[NiL^1]^0$ form leads to some decomplexation, as shown by the appearance on the reverse scan of a weak Fc/Fc^+ peak system corresponding to the free ligand (Figure 2D, curve b). The redox behavior of $[NiL^1]^{2+}$ is summarized in Equation (2).

$$[Ni^0\mathbf{L^1}]^0 \underset{+e}{\overset{-1.39\ V\ -e}{\rightleftharpoons}} [Ni^I\mathbf{L^1}]^+ \underset{+e}{\overset{-0.96\ V\ -e}{\rightleftharpoons}} [Ni^{II}\mathbf{L^{1\bullet}}]^{2+} \underset{+e}{\overset{0.86\ V\ -e}{\rightleftharpoons}} [Ni^{II}(\mathbf{L^1})^+]^{3+} \quad (2)$$

Complexation of L^1 by Cu^I was further investigated by ^1H NMR titration. Addition of Cu^I cation to a solution of L^1 in CD_3CN produced significant perturbations in all ^1H

NMR resonances recorded at 273 K. Signals for both free and complexed ligand were observed at a substoichiometric level of copper salt. This fact reveals the inertness of this complex, i.e. intramolecular exchange is restricted on the NMR time scale. The ^{1}H NMR spectrum shows only resonances for the copper complex after the addition of one mol equivalent of Cu^I ions. In the copper complex, all the resonances of protons at the phenanthroline rings are shifted downfield (see the Experimental Section). As noticed in copper complexes of 1,1′-(bispyridyl) ferrocenes,[7a] ferrocene-proton pairs become nonequivalent in the $[CuL^1]^+$ complex; the α′-Cp resonances at δ = 4.91 in the free ligand are shifted upfield to δ = 4.72, whereas the α-Cp signal is found at δ = 3.66. The signal of the methylene protons changes from a singlet (δ = 5.52 in free L^1) to an AB system (H-exo: δ = 5.47, J = 12.0 Hz; H-endo: δ = 4.88, J = 12.0 Hz). The prochirality of the methylene protons is consistent with the fact that the 1,10-phenanthroline arms become more rigid upon coordination.

$Fe^{II}L^1$ Complex

Very recently,[7c] we found that L^1 forms a high spin 1:1 complex $[FeL^1]^{2+}$ with Fe^{II} ions. This unusual stoichiometry (two phen ligands per iron centre) was unambiguously established by FAB-MS data and X-ray structure analysis. The crystal structure of the complex revealed that the iron(II) coordination environment consists of four nitrogen atoms provided by the phenanthroline units and two oxygen atoms of the carbonyl groups, forming a distorted octahedral environment.

CV experiments show that the progressive complexation of L^1 with Fe^{II} ions leads to the growth of a new Fc/Fc^+ redox wave ($E_{1/2}$ = 0.85 V) at the expense of the original wave for free L^1 (Figure 3). However a weak oxidation peak for the uncomplexed ligand (labeled with an asterisk in Figure 3) is always seen even in the presence of an excess (e.g. 1.2 equivalent) of Fe^{II} ions. Obviously, the $[FeL^1]^{2+}$ complex is weaker than the copper and nickel complexes. Furthermore, oxidation of the ferrocene centre in the iron complex leads to partial decomplexation, as shown by the appearance on the reverse scan of a large reduction peak corresponding to the Fc/Fc^+ redox system in the free ligand (labeled with a double asterisk in Figure 3). Complexation of L^1 with Fe^{II} also gives rise to an irreversible oxidation wave (E_p = 1.31 V) at more positive potentials corresponding to the $Fe^{II/III}$ redox process in the $[FeL^1]^{2+}$ complex (Figure 3, curve b). The redox behavior of $[FeL^1]^{2+}$ is summarized in Equation (3).

$$[Fe^{II}(\mathbf{L^1})^-]^+ \xleftarrow[+e]{-1.33\ V} [Fe^{II}\mathbf{L^1}]^{2+} \underset{+e}{\overset{0.85\ V\ -e}{\rightleftharpoons}} [Fe^{II}(\mathbf{L^1})^+]^{3+} \xrightarrow[-e]{1.31\ V} [Fe^{III}(\mathbf{L^1})^+]^{4+} \quad (3)$$

The $Fe^{II/III}$ redox process in the $[FeL^1]^{2+}$ complex occurs at a potential close to that of free Fe^{2+} cations. In the presence of an excess of Fe^{II}, this last process (E_p = 1.44 V) is seen on the CV curve as a shoulder that appears at the positive foot of the complexed $Fe^{II/III}$ redox peak (Figure 3, curve b). The abnormally high intensity of the oxidation peak corresponding to the $Fe^{II/III}$ redox process in the $[FeL^1]^{2+}$ complex is probably due to its overlapping with the background current corresponding to some electrolyte oxidation that occurs at this potential. By comparing $[Fe^{II}L^1]^{2+}$ to a regular $[Fe(phen)_3]^{2+}$ complex (phen = 5,6-dimethyl-1,10-phenanthroline, for example; $E_{1/2}[Fe^{II/III}]$ = 0.62 V), it is obvious that the unusual coordination environment in the $[FeL^1]^{2+}$ complex strongly stabilizes the divalent state of the iron centre. It should be noted that stabilization of the Fe^{II} state in the $[Fe^{II}L^1]^{2+}$ complex based on phen binding sites is larger than in the corresponding Fe-bis(bipy) derivative of ferrocene ($E_{1/2}$ = 0.99 V).[7c]

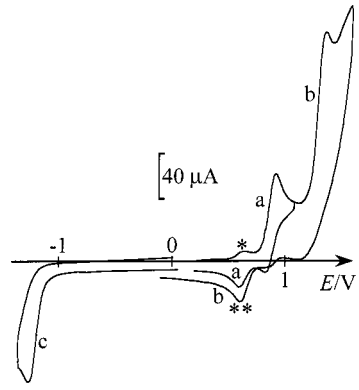

Figure 3. Cyclic voltammograms in CH_3CN + TBAP 0.1 M at a Pt disk electrode (5 mm diameter) of L^1 (2 mM) + 1.2 $Fe(ClO_4)_2$: (a) scan between 0 and 1 V; (b) scan between 0 and 1.5 V; (c) scan between 0 and −1.2 V; scan rate 0.1 Vs^{-1}

Oxidation of the iron centre in the $[Fe^{II}(L^1)^+]^{3+}$ complex (Figure 3, curve b) leads to an important degradation; on the reverse scan the complexed Fc/Fc^+ redox couple becomes less reversible and the intensity of the free Fc^+ reduction wave is twice that observed when the CV scan is restricted to the 0 to 1 V potential range. Since the iron-centered oxidation occurs after that of the ferrocenyl unit, decomplexation probably results from strong repulsive electrostatic forces between the Fc^+ and Fe^{III} centers in the fully oxidized $[Fe^{III}(L^1)^+]^{4+}$ complex.

CV curves recorded in the negative-potential region show a number of ill-behaved, irreversible reduction peaks between −1 V and −2 V; the first one appears at E_p = −1.33 V (Figure 3, curve c). Once again, the behavior of $[FeL^1]^{2+}$ contrasts with that for a regular Fe-tri(phen) complex, which is characterized by three ligand-centered, reversible reduction waves ($E_{1/2}$ = −1.85, −2.03, −2.25 V; phen = 5,6-dimethyl-1,10-phenanthroline).

$Hg^{II}L^1$ Complex

A mercury(II) complex was obtained from L^1 upon treatment with $Hg(CF_3SO_3)_2$. The FAB-mass spectra were identical when the complex was prepared using one or two molar equivalents of mercury salt and clearly show a 1:1 stoichiometry.

When investigated by NMR spectrometry, the progressive addition of Hg^{II} cations to a solution of L^1 in CD_3CN produces significant perturbations in all ^1H NMR resonances recorded at room temperature. The spectra are characterized by broad, unstructured peaks until one mol equivalent of metal cation had been added. The NMR spectra remained unresolved over the −20 °C to 40 °C temperature range and the solutions were EPR silent. These observations reveal that the intermolecular exchange is fast on the NMR time scale at substoichiometric levels of mercury salt. After the addition of more than one mol equivalent of Hg^{II} cations, well-behaved NMR signals for the Hg^{II} complex develop. As already noticed for the $[CuL^1]^+$ complex, the ferrocene-proton pairs become nonequivalent. The α-Cp and α′-Cp resonances are shifted downfield and upfield, respectively. The NMR signal of the methylene protons changes from a singlet to an AB system (see Figure 4 and the Exp. Sect.).

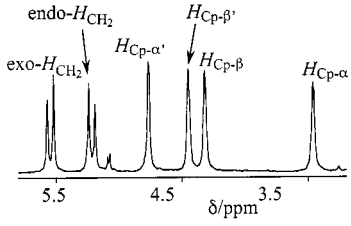

Figure 4. Methylene and cyclopentadienyl region of the ^1H NMR spectrum of $[HgL^1](CF_3SO_3)_2$ at room temperature in CD_3CN

CV experiments have confirmed that one Hg^{II} ion is complexed with one L^1 ligand. The addition of increasing amounts of $Hg(CF_3SO_3)_2$ to a solution of L^1 in acetonitrile results in the growth of a new Fc/Fc^+ wave ($E_{1/2}$ = 0.68 V) weakly separated from the original Fc/Fc^+ wave. This wave reaches full development after the addition of one mol equivalent of mercury salt and replaces the original Fc/Fc^+ wave in free L^1 (Figure 5A). In addition, the $[HgL^1]^{2+}$ complex presents an irreversible one-electron reduction wave (E_p = −0.75 V; Figure 5B), followed by several ill-behaved reduction peaks around −1.6 V. Reduction of the complex down to −2 V led to dissociation with formation of mercury metal, as evidenced on the reverse scan by the rise of a sharp mercury metal stripping peak (E_p = 0.42 V). The electrochemical behavior of $[HgL^1]^{2+}$ is summarized in Equation (4).

$$[Hg^{I}\mathbf{L^1}]^{+} \underset{+e}{\overset{-0.75\ V}{\rightleftharpoons}} [Hg^{II}\mathbf{L^1}]^{2+} \underset{+e}{\overset{0.68\ V}{\rightleftharpoons}} [Hg^{II}(\mathbf{L^1})^{+}]^{3-} \quad (4)$$

Electrochemical Behavior and Complexation of L^2 with Fe^{II}, Ni^{II} and Hg^{II}

Electrochemical Behavior and Polymerization of L^2

The CV behavior of L^2 in acetonitrile presents complex features. Repeated scans over the 0 to 1 V potential range (Figure 6A) leads to the progressive decrease of the Fc/Fc^+ redox wave ($E_{1/2}$ = 0.56 V) and to the rise of a large reversible peaks system ($E_{1/2}$ = 0.77 V; ΔE_p = 40 mV at ν = 0.1 Vs^{-1}). The new wave reaches full development when the original Fc/Fc^+ peak system has totally vanished (Figure 6A). This electroactivity is maintained after transfer of the electrode to clean CH_3CN + TBAP electrolyte and remains stable upon repeated scans (Figure 6B). This behavior is in accordance with the growth of an insoluble film of Fe-bis(terpyridine) complex onto the electrode surface. Indeed, the half wave potential of immobilized species is the same as that found for the $Fe^{II/III}$ couple in the $[Fe(L^2)]^{2+}$ complex ($E_{1/2}$ = 0.77 V; see Figure 6C and the discussion below) and is similar to that measured with the $[Fe(L^3)_2]^{2+}$ model complex ($E_{1/2}$ = 0.76 V) containing no ferrocenyl groups. The latter was obtained by in situ complexation of L^3 (Figure 1) with a half mol equivalent of Fe^{II}. Two broad, reversible waves (not shown in Figure 6) were also seen at −1.63 V and −1.82 V on the CV curve of the film, corresponding to ligand-localized reductions in the Fe-bis(terpyridine) moieties. These redox processes occur at −1.65 V and −1.80 V in the $[Fe(L^3)_2]^{2+}$ model complex.

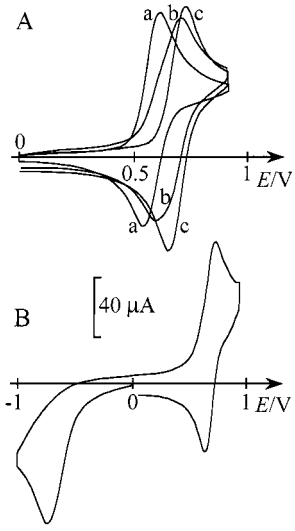

Figure 5. Cyclic voltammograms at a Pt disk electrode (5 mm diameter) in CH_3CN + TBAP 0.1 M: (A) (a) free L^1 (1.5 mM), (b) L^1 + 0.3 $Hg(CF_3SO_3)_2$, (c) L^1 + 1.0 $Hg(CF_3SO_3)_2$; (B) $[HgL^1](CF_3SO_3)_2$ 1.5 mM; scan rate 0.1 Vs^{-1}

The formation of Fe-bis(terpyridine) species upon oxidation of L^2 was corroborated by UV/Vis and FT-IR experiments. Around 40 scans have been performed in the 0 to 1 V potential range on a 1 cm^2 Pt electrode. The solution turned from orange to pink-violet and a dark-pink film covered the electrode surface. The visible spectrum of the electrolysis solution showed a new absorption peak at 557 nm, very close to that observed with the isolated $[FeL^2](ClO_4)_2$ complex (λ_{max} = 558 nm). Furthermore, the infrared spectrum of the film was characterized by strong bands at 1707 cm^{-1} (C=O stretching vibration) and 1628 cm^{-1} (terpyridine ring stretching vibration). These bands appear at 1708 and 1621 cm^{-1} in the $[FeL^2](ClO_4)_2$ complex.

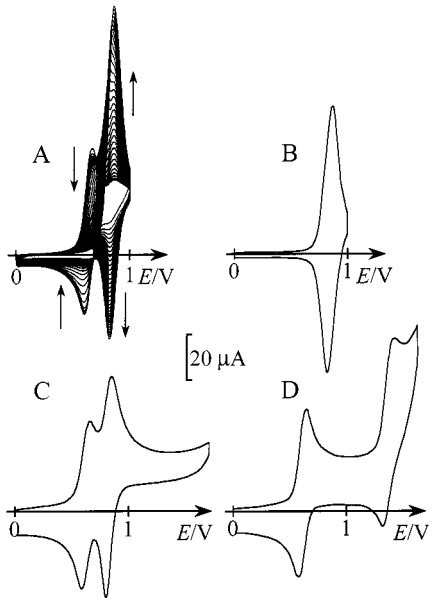

Figure 6. (A) Oxidative coating of a Pt disk electrode (5 mm diameter) with an Fe-bis(terpy) film, by repeated scans in a solution of L^2 (2.5 mM) in CH_3CN + TBAP 0.1 M; (B) modified electrode prepared in (A) and transferred to L^2-free CH_3CN + TBAP 0.1 M; (C) L^2 (2.5 mM) + 1 equiv. $Fe(ClO_4)_2$; (D) L^2 + 1 equiv. $Ni(ClO_4)_2$; scan rate 0.1 V

A similar behavior has already been observed with a ferrocenyl-substituted terpyridine containing an olefinic linkage.[4f] The formation of a polymer film containing iron centers in a terpyridine environment was attributed to the oxidative electropolymerization of the vinyl or vinyl-cyclopentadienyl backbone, followed by rupture of the ferrocenyl groups and complexation of iron cations. Since L^2 does not contain any olefinic group, the formation of a stable Fe-bis(terpyridine) material must be explained in a different way. Fe-bis(terpyridine) films are also obtained when the scan range is restricted to the Fc/Fc^+ redox couple. However, the films formed in these experimental conditions are of smaller size than those obtained when the potential scan range is extended up to 1 V. Electrode coating can thus be explained by considering the decomposition of the ferricinium groups in the presence of terpyridine ligands, to form poorly soluble Fe-bis(terpyridine) species, which precipitate onto the electrode surface. The high stability of the films upon cycling and their better growth when the scan range is increased up to 1 V could be due to some oxidative polymerization of free cyclopentadienyl groups released by decomposition of the ferricinium species.

The effect of added metal cations on film growth confirmed that this process is mainly due to the decomplexation of ferricinium groups by terpyridine ligands. The addition of small amounts (e.g. 0.2 mol equivalent) of Fe^{II}, Ni^{II} and Hg^{II} cations led to stabilization of the Fc/Fc^+ redox couple and slowed down the growth of the Fe-bis(terpyridine) films. This last process was fully inhibited in the presence of one mol equivalent of metal cation, suggesting the formation of 1:1 L^2 + M^{II} complexes (M = Fe, Ni, Hg).

The CV curves recorded in L^2 solutions containing one mol equivalent of metal cation show stable Fc/Fc^+ redox peak systems (Figure 6C and 6D). Complexation of L^2 with Fe^{II} ions is also revealed by the appearance of a $Fe^{II/III}$ redox wave ($E_{1/2}$ = 0.77 V; Figure 6C). The sharp and symmetrical shape of the Fe^{III} Fe^{II} reduction peak indicates that the oxidized form of the iron complex ($[FeL^2]^{4+}$) is poorly soluble in CH_3CN, adsorbs at the electrode surface during the scan towards positive potentials and dissolves upon reduction. No accumulation of complex onto the electrode surface was observed upon repeated scans. This observation confirms that the polymerization of free cyclopentadienyl groups is involved in the growth of films by oxidation of L^2.

Complexation of L^2 with Ni^{II} ions is also evidenced by the rise of a $Ni^{II/III}$ redox wave at 1.31 V (Figure 6D). This wave was found at 1.33 V for the $[Ni(L^3)_2]^{2+}$ model complex. No redox system concerning the metal centre could be found with the $[HgL^2]^{2+}$ complex. As already observed for other complexes of ferrocene-functionalized terpyridines,[4a,4f,4g] the potential of the Fc/Fc^+ process is slightly or not changed upon complexation of L^2 (+10 mV, +5 mV and 0 mV for Hg^{II}, Ni^{II} and Fe^{II} complexes, respectively). This behavior contrasts with that obtained upon complexation of the phen-based ligand L^1. As already found with iron,[7c] nickel and mercury complexes of L^1, the drop in the ν(CO) stretching vibration in L^2-based complexes (see the Exp. Sect.) indicates a coordination between the metal center and the oxygen atoms of the carbonyl groups. However, this interaction is not sufficient to produce an appreciable electronic coupling between the ferrocene group and the metal center in complexes of L^2. Although we have no clear explanation at the present time, this different behavior could be due to a structural effect, since the ferrocenyl group is linked to very different positions with regard to the complexing site in L^1 (2-position) and in L^2 (4′-position). Complexation of L^1 may lead to a non-coplanarity of the Cp rings in the complexes, which is known to result in marked positive potential shifts in strained ferrocene derivatives.[9,10]

Finally, the formation of 1:1 L^2 + M complexes (M = Fe, Ni, Hg) was confirmed by FAB-MS measurements. The spectra of the isolated complexes only displayed peaks corresponding to $[\{ML^2\}X]^+$ entities (Fe and Ni: X = ClO_4^-; Hg: X = $CF_3SO_3^-$), without any evidence for the presence of oligomeric species.

Conclusion

This study confirms the remarkable complexation and electrochemical properties of polypyridyl-ferrocene metallosynthons towards various transition metal cations. Complexation of the 1,1′-bis(phen) derivative of ferrocene (L^1) with Cu^I, Ni^{II}, Fe^{II} and Hg^{II} cations results in large potential shifts of the ferrocenyl-centered redox process. This redox ligand could thus be used for the electrochemical recognition of selected metal cations. In contrast, complexation of the ferrocene-bis(terpy) derivative L^2 does not

alter appreciably the electron density on the ferrocenyl groups. Additionally, we found that the oxidative decomposition of L^2 is a simple way to tailor stable polymer films of Fe-bis(terpyridine) complexes.

Experimental Section

Reagents, Instrumentation and Procedure: Acetonitrile (Rathburn, HPLC grade) was used as received. Dichloromethane was dried over neutral alumina (activity I) for at least six days before use. Tetra-*n*-butylammonium perchlorate (TBAP) was purchased from Fluka and dried under vacuum for three days at 80 °C. Electrochemical experiments were conducted in a conventional three-electrode cell under an argon atmosphere at 20 °C. The reference electrode was $Ag/AgNO_3$ (10 mM in CH_3CN containing 0.1 M TBAP). The ferrocene/ferricinium (Fc/Fc^+) redox couple was used as internal standard. FAB (positive mode) mass spectra were recorded with an AEI Kratos MS 50 spectrometer fitted with an Ion Tech Ltd. gun and using *m*-nitrobenzyl alcohol as matrix. Elemental analysis were performed by the Service Central d'Analyses, CNRS, Lyon.

Ligands: L^1 was synthesized as previously reported.[7c] ^1H NMR (250 MHz, CD_3CN): δ = 2.76 (s, 6 H, CH_3), 4.52 (t, 4 H, $H_{\beta\beta'}$), 4.91 (t, 4 H, $H_{\alpha\alpha'}$), 5.52 (s, 4 H, CH_2), 7.49 (d, J = 7.9 Hz, 2 H, H_8), 7.60−7.83 (m, 6 H, $H_{5,6,3}$), 8.13 (d, J = 7.9 Hz, 2 H, H_7), 8.23 (d, J = 7.9 Hz, 2 H, H_4). FAB-MS: m/z = 687 $[L^1 + H]^+$. UV/Vis (d-d band; CH_3CN): λ_{max} (ε/M^{-1} cm^{-1}) = 450 nm (300). FT-IR (KBr): ν(CO) = 1713 cm^{-1}. $C_{40}H_{30}FeN_4O_4$ (686.16): C 69.88, H 4.40, N 8.16; found C 69.26, H 4.89, N 8.36.

L^2 was prepared by the stoichiometric reaction of 4′-(hydroxymethyl)-2,2′:6′,2"-terpyridine[11] with 1 mmol of 1,1′-bis(chlorocarbonyl)ferrocene[12] in 10 mL of dried toluene containing 4 mmol of freshly distilled triethylamine. The reaction mixture was stirred overnight under an inert atmosphere, then filtered and the solvents evaporated to dryness. The crude product was extracted with CH_2Cl_2 and the organic phase was washed with H_2O. The solvent was removed in vacuo and the crude product was purified by column chromatography on neutral alumina eluting with CH_2Cl_2, to yield L^2 (70%) as an orange solid. ^1H NMR (250 MHz, CD_3CN): δ = 4.52 (t, 4 H, $H_{\beta\beta'}$), 5.08 (t, 4 H, $H_{\alpha\alpha'}$), 5.40 (s, 4 H, CH_2), 7.30 (dd, J = 7.5, 4.8 Hz, 4 H, $H_{5,5''}$), 7.79 (td, J = 7.7, 1.6 Hz, 4 H, $H_{4,4''}$), 8.45 (s, 4 H, $H_{3',5'}$), 8.55 (d, J = 7.9 Hz, 4 H, $H_{3,3''}$), 8.65 (m, 4 H, $H_{6,6''}$). FAB-MS: m/z = 765 $[L^2 + H]^+$. UV/Vis (d-d band; CH_2Cl_2): λ_{max} (ε/M^{-1} cm^{-1}) = 453 nm (310). FT-IR (KBr): ν(CO) = 1718 cm^{-1}. $C_{44}H_{32}FeN_6O_4{\cdot}H_2O$ (782.65): C 67.53, H 4.38, N 10.74; found C 67.51, H 4.34, N 10.24.

Complexes: The quantitative synthesis of metal complexes (yield 90%) was performed by the reaction of stoichiometric amounts of L^1 or L^2 and a metal salt {$[Cu(CH_3CN)_4]ClO_4$, $[Ni(ClO_4)_2{\cdot}xH_2O]$, $[Fe(ClO_4)_2{\cdot}6H_2O]$ and $[Hg(CF_3SO_3)_2]$} at room temperature in CH_2Cl_2. Products were precipitated by the addition of diethyl ether and collected by suction filtration. **Warning**! *Perchlorate salts are hazardous because of the possibility of explosion*. Characterization of the $[FeL^1](ClO_4)_2$ complex has already been reported.[7c]

$[CuL^1]ClO_4$: ^1H NMR (250 MHz, CD_3CN): δ = 2.56 (s, 6 H, CH_3), 3.66 (s, 2 H, H_α), 4.37 (s, 2 H, H_β), 4.43 (s, 2 H, $H_{\beta'}$), 4.72 (s, 2 H, $H_{\alpha'}$), 4.88 (d, J = 12.0 Hz, 2 H, CH_2-endo), 5.47 (d, J = 12.0 Hz, 2 H, CH_2-exo), 7.90 (d, J = 7.9 Hz, 2 H, H_8), 8.17 (d, J = 2.4 Hz, 4 H, $H_{5,6}$), 8.28 (d, J = 7.9 Hz, 2 H, H_3), 8.63 (d, J = 7.9 Hz, 2 H, H_7), 8.73 (d, J = 7.9 Hz, 2 H, H_4). FAB-MS: m/z = 749 $[CuL^1]^+$. UV/Vis (CH_3CN): λ_{max} (ε/M^{-1} cm^{-1}) = 444 nm (6975). FT-IR (KBr): ν(CO) = 1713 cm^{-1}. $C_{40}H_{30}ClCuFeN_4O_8{\cdot}H_2O$ (867.57): C 55.38, H 3.72, N 6.46; found C 55.45, H 3.54, N 6.76.

$[HgL^1](CF_3SO_3)_2$: ^1H NMR (250 MHz, CD_3CN): δ = 3.01 (s, 6 H, CH_3), 3.47 (s, 2 H, H_α), 4.32 (s, 2 H, H_β), 4.45 (s, 2 H, $H_{\beta'}$), 4.77 (s, 2 H, $H_{\alpha'}$), 5.22 (d, J = 12.0 Hz, 2 H, CH_2-endo), 5.54 (d, J = 12.0 Hz, 2 H, CH_2-exo), 8.21 (d, J = 7.9 Hz, 2 H, H_8), 8.35 (d, J = 2.2 Hz, 4 H, $H_{5,6}$), 8.46 (d, J = 7.9 Hz, 2 H, H_3), 8.92 (d, J = 7.9 Hz, 2 H, H_7), 9.06 (d, J = 7.9 Hz, 2 H, H_4). FAB-MS: m/z = 1037 $[\{HgL^1\}CF_3SO_3]^+$. UV/Vis (CH_3CN): λ_{max} (ε/M^{-1} cm^{-1}) = 454 nm (360). FT-IR (KBr): ν(CO) = 1710 cm^{-1}. $C_{42}H_{30}F_6FeHgN_4O_{10}S_2$ (1185.3): C 42.56, H 2.55, N 4.73; found C 42.43, H 2.37, N 4.33.

$[NiL^1](ClO_4)_2$: FAB-MS: m/z = 843 $[\{NiL^1\}ClO_4]^+$. UV/Vis (CH_3CN): λ_{max} (ε/M^{-1} cm^{-1}) = 454 nm (450). FT-IR (KBr): ν(CO) = 1664 cm^{-1}. $C_{40}H_{30}Cl_2FeN_4NiO_{12}{\cdot}H_2O$ (962.17): C 49.93, H 3.35, N 5.82; found C 49.23, H 3.28, N 6.06.

$[HgL^2](CF_3SO_3)_2$: FAB-MS: m/z = 1115 $[\{HgL^2\}CF_3SO_3]^+$. No correct elemental analysis for this compound could be obtained.

$[NiL^2](ClO_4)_2$: FAB-MS: m/z = 921 $[\{NiL^2\}ClO_4]^+$. UV/Vis (CH_3CN): λ_{max} (ε/M^{-1} cm^{-1}) = 452 nm (496). FT-IR (KBr): ν(CO) = 1666 cm^{-1}. $C_{44}H_{32}Cl_2FeN_6NiO_{12}{\cdot}H_2O$ (1040.2): C 50.08, H 3.29, N 8.08; found C 49.82, H 3.23, N 7.73.

$[FeL^2](ClO_4)_2$: FAB-MS: m/z = 919 $[\{FeL^2\}ClO_4]^+$. UV/Vis (CH_3CN): λ_{max} (ε/M^{-1} cm^{-1}) = 558 nm (2150), 510 (1050, sh). FT-IR (KBr): ν(CO) = 1708, 1621 cm^{-1}. $C_{44}H_{32}Cl_2Fe_2N_6O_{12}{\cdot}H_2O$ (1037.4): C 50.94, H 3.30, N 8.10; found C 50.75, H 3.25, N 8.01.

Two Ferromagnetic One-Dimensional Nickel(II) Complexes Containing the Diamagnetic $[Ni(CN)_4]^{2-}$ Group

Hui-Zhong Kou,[a][‡] Shu-Feng Si,[a] Song Gao,[b] Dai-Zheng Liao,*[a] Zong-Hui Jiang,[a] Shi-Ping Yan,[a] Yu-Guo Fan,[c] and Geng-Lin Wang[a]

Keywords: Cyanides / Bridging ligands / Nickel / Magnetic properties / Crystal structure

A cyano-bridged nickel(II) compound, $[NiL][Ni(CN)_4]\cdot 4H_2O$ (L = 3,10-diethyl-1,3,5,8,10,12-hexaazacyclotetradecane), was prepared and characterized. Single crystal X-ray analysis reveals that the compound assumes a cyano-bridged chain structure in which one nickel(II) ion is coordinated by four cyanide ligands and the other is coordinated by four nitrogen atoms of the macrocyclic ligand and two nitrogen atoms of the bridging cyanide ligands. The six-coordinate nickel(II) centres display an axially elongated octahedron, whereas the four-coordinate nickel(II) centres assume planar geometry. Magnetic investigations on $[NiL][Ni(CN)_4]\cdot 4H_2O$ and a similar chain-like compound $[Ni(TIM)][Ni(CN)_4]$ show the presence of weak intrachain ferromagnetic interactions between the paramagnetic nickel(II) ions through the diamagnetic $[Ni(CN)_4]^{2-}$ anions.

Introduction

During the last two decades, much attention has been directed to the synthesis of molecule-based magnets, especially to Prussian Blue analogues.[1] Prussian Blue, with the formula $Fe_4^{III}[Fe^{II}(CN)_6]_3\cdot 15H_2O$ is a ferromagnet with T_c = 5.6 K, in which the paramagnetic iron(III) ions are bridged in three-dimensions by the diamagnetic hexacyanoferrate(II) anion, with a shortest intermetallic $Fe^{III}\cdots Fe^{III}$ separation of 10.6 Å.[2] Recently, a series of three-dimensional bimetallic compounds $[Ni(L)_2]_3[Fe^{II}(CN)_6]X_2$ (L = en or tn, X = PF_6^- or ClO_4^-) and one two-dimensional copper(II)-iron(II) compound $[Cu(dmen)_2]_2[Fe^{II}(CN)_6]$ (dmen = dimethylaminoethylamine) were prepared and found to exhibit ferromagnetic interactions between the nearest nickel(II) or copper(II) ions through the diamagnetic $[Fe(CN)_6]^{4-}$ anions.[3] Nevertheless, antiferromagnetic coupling between paramagnetic transition metal ions is more often operative via diamagnetic building blocks, such as $[Co(CN)_6]^{3-}$, $[Ni(CN)_4]^{2-}$, $[Mo(CN)_8]^{4-}$ and $[W(CN)_8]^{4-}$.[4–6] In addition, the diamagnetic $[CrO_4]^{2-}$ group can mediate either ferromagnetic[7] or, in most cases, antiferromagnetic interactions.[8] We have been interested in magnetic interactions via cyanide-containing diamagnetic building blocks, and have found that the nitroprusside anion $[Fe(CN)_5(NO)]^{2-}$ can transmit weak antiferromagnetic interactions in $[Cu(en)][Fe(CN)_5(NO)]$,[9] as is also observed in $[Ni(en)_2][Fe(CN)_5(NO)]$.[10] Using the diamagnetic $[Ni(CN)_4]^{2-}$ building block, we prepared two one-dimensional chain complexes $[NiL][Ni(CN)_4]\cdot nH_2O$ [L = 2,3,9,10-tetramethyl-1,4,8,11-tetraazacyclotetradeca-1,3,8,10-tetraene abbreviated as TIM, n = 0 (**1**);[11] L = 3,10-diethyl-1,3,5,8,10,12-hexaazacyclotetradecane, n = 4 (**2**)]. Interestingly, a ferromagnetic interaction is observed in the two complexes. In the present paper, we report the synthesis, crystal structure and magnetic properties of **2** together with the magnetic behaviour of **1**.

Results and Discussion

The IR spectrum of **2** exhibits two strong bands at 2150 and 2120 cm^{-1}, which can be attributed to the C≡N stretching vibration. It is well-known that the formation of a cyanide bridge shifts ν(CN) towards higher frequencies.[1] The strong band at 2150 cm^{-1} may therefore be attributed to ν(CN) of the bridging cyanides and that at 2120 cm^{-1} to the terminal ones. The strong absorption at 1650 cm^{-1} indicates the presence of water in the molecule, which is consistent with the structural studies.

It has been shown that the four-coordinate nickel(II) macrocyclic complexes can accept donor atoms yielding six-coordinate nickel(II) geometries.[11,12] The cyano nitrogen

atom is a strong donor and easily coordinates to the nickel(II) ion to give rise to cyano-bridged complexes.

Crystal Structure

The structure of **2** consists of one *trans*-$[NiL]^{2+}$ cation and one $[Ni(CN)_4]^{2-}$ anion as illustrated in Figure 1. Selected bond lengths and angles are listed in Table 1. The coordination geometry about Ni(1) is nearly octahedral, with four secondary amine nitrogen atoms of the macrocyclic ligand L [$Ni-N_{eq}$ = 2.072(4) Å] occupying the equatorial plane and two nitrogen atoms of two bridging cyanide ligands situated at the axial sites [$Ni-N_{ax}$ = 2.137(2) Å]. The bridging cyanides coordinate to Ni(1) in a linear fashion [Ni(1)−N(1)−C(1) = 175.0(5)°], significantly different from the situation found in **1**[158.0(2)°].[11] The bond lengths and angles of [NiL] are similar to those in $[NiL]_3[Fe(CN)_6]_2\cdot 12H_2O$:[12a] each $[Ni(CN)_4]^{2-}$ unit uses two *trans* C≡N groups to connect to two *trans*-$[NiL]^{2+}$ moieties giving rise to one-dimensional Ni−C≡N−Ni linkages, whereas the two remaining *trans* CN^- groups are monodentate. The adjacent Ni···Ni distance is 5.094 Å, and the nearest interchain Ni(1)···Ni(1) distance is 9.337 Å. The water molecules are positioned in the vicinity of the chain and hydrogen-bonded to the nitrogen atoms of the nonbridging cyanides within the chain and to each other (Figure 2 top and bottom). No hydrogen-bonded two- or three-dimensional network is formed.

Magnetic Properties

The magnetic susceptibilities of **1** and **2** have been measured in the temperature range 1.8−200 K. Plots of $\chi_m T$ and χ_m^{-1} vs. T for **1** and **2**, where χ_m is the magnetic susceptibility per Ni_2 unit, are shown below.

Complex 1

At 200 K, the $\chi_m T$ value is ca. 1.06 emu K mol^{-1} (2.91 μ_B), close to that (1.0 emu K mol^{-1}, 2.83 μ_B) of an isolated Ni^{II} ion ($S = 1$, $g = 2.0$) interacting with a diamagnetic Ni^{II} ion ($S = 0$). As the temperature decreases the $\chi_m T$ value increases slowly reaching a maximum value of 1.16 emu K mol^{-1} (3.05 μ_B) at 20.8 K and then decreases sharply reaching a minimum value of 0.53 emu K mol^{-1} (2.06 μ_B) at 1.8 K. Such a magnetic behaviour is characteristic of a dominant ferromagnetic interaction to which weak antiferromagnetic interactions are superimposed.[13] The lack of interchain intermolecular contacts in **1**[11] suggests the through-space magnetic coupling is weaker than that through the -NC−Ni−CN- pathway. Therefore, the dominant ferromagnetic interaction is due to the intrachain interaction, and the interchain interaction is antiferromagnetic. The magnetic susceptibility above 10 K obeys the Curie−Weiss law with a positive Weiss constant $\theta = +2.9$ K (Figure 3); this also proves the presence of ferromagnetic coupling within the Ni_2 chain of **1**.

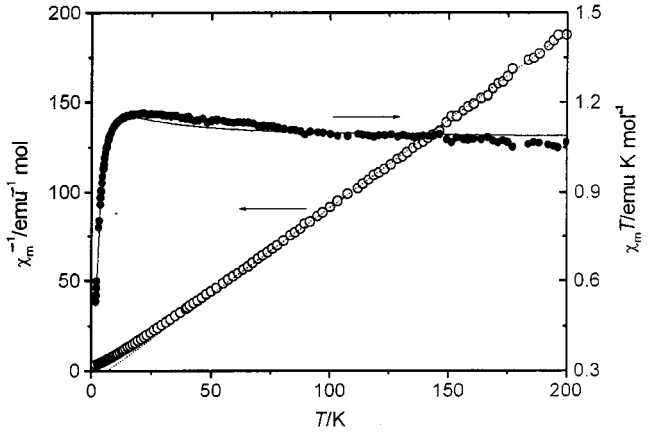

Figure 3. Temperature dependence of $\chi_m T$ and χ_m^{-1} for **1**; the solid line represents the theoretical values and the dotted line the fit to the Curie−Weiss law

We attempted to interpret the magnetic data using Fisher's model[14] for the classical spin chain system ($S = 1$ and $\boldsymbol{H}_{chain} = -J\Sigma \mathbf{S}_i\mathbf{S}_{i+1}$) neglecting zero-field splitting and the Haldane gap effect[15] and taking into consideration a mean-field correlation term.[7a,16] The magnetic susceptibility can be expressed by Equation (1), where N is Avogadro's number, β is the Bohr magneton, k is the Boltzmann constant and z is the number of nearest neighbours (two in this case). The least-squares fitting to the experimental data led to $J = +2.88$ cm^{-1}, $J' = -0.94$ cm^{-1} and $g = 2.08$. This result ($J = +2.88$ cm^{-1}) shows the presence of weak ferromagnetic interaction between the paramagnetic nickel ions within each chain through the diamagnetic $[Ni(CN)_4]^{2-}$ ions.

$$\chi_{chain} = \frac{Ng^2\beta^2}{3kT}\frac{1+u}{1-u} \times S(S+1)$$
$$u = \coth K - 1/K \text{ and } K = JS(S+1)/kT \quad (1)$$
$$\chi_m = \chi_{chain}/[1-\chi_{chain}(zJ'/Ng^2\beta^2)]$$

Complex 2

Complex **2** has a magnetic behaviour similar to that of **1** (Figure 4). At 200 K, the $\chi_m T$ value is ca. 1.25 emu K mol^{-1} (3.16 μ_B), larger than that (1.0 emu K mol^{-1}, 2.83 μ_B) of an isolated Ni^{II} ion ($S = 1$, g = 2.0) interacting with a diamagnetic Ni^{II} ion ($S = 0$). As the temperature decreases, the $\chi_m T$ value increases slightly reaching a maximum value of 1.29 emu K mol^{-1} (3.21 μ_B) at 16.6 K and then decreases sharply reaching a minimum value of 0.60 emu K mol^{-1} (2.2 μ_B) at 1.6 K. The magnetic susceptibility above 11 K obeys the Curie−Weiss law with a positive Weiss constant $\theta = +1.5$ K (Figure 4), which confirms the presence of ferromagnetic coupling within the Ni_2 chain of **2**. Similarly, the magnetic data can be analysed by Equation (1) giving the parameters $J = +2.19$ cm^{-1}, $J' = -0.92$ cm^{-1} and $g = 2.23$.

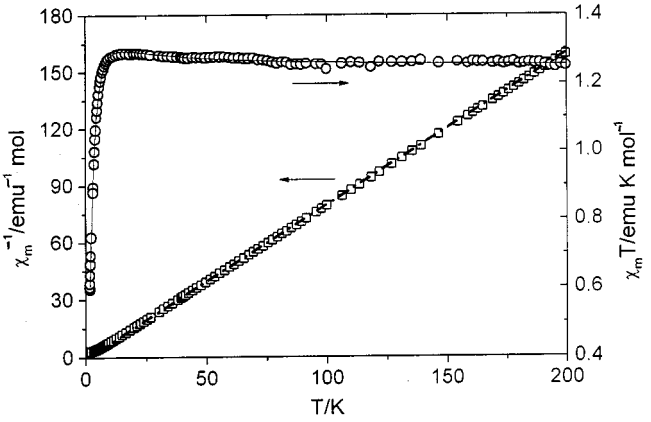

Figure 4. Plot of $\chi_m T$ and χ_m^{-1} vs. temperature for **2**; the solid line represents the theoretical values and the dashed line the fit to the Curie−Weiss law

The increase in $\chi_m T$ is due to a substantial contribution of ferromagnetic coupling, although the origin of this is not clear at this stage. Apparently, the ferromagnetic nature is not due to the orthogonality of the magnetic orbitals. One possibility is that it is due to a long-range interaction mediated through the empty d_σ orbital of the diamagnetic Ni^{II} ion. According to the Goodenogh−Kanamori rules for magnetic superexchange,[17] if a magnetic orbital overlaps an empty orbital the interaction between the two ions is ferromagnetic. This mechanism has recently been used to explain the ferromagnetic interaction between the nearest paramagnetic metal ions through the diamagnetic $[Fe(CN)_6]^{4-}$ or $[Co(CN)_6]^{3-}$ anions in $[Ni(en)]_3[Fe(CN)_6]PF_6$, $[NiL_2]_3[Fe(CN)_6]X_2$ (X = PF_6^- or ClO_4^-) and $[Ni(tn)_2]_2[Co(CN)_6]NO_3{\cdot}2H_2O$.[3a,18] For the present complexes, an electron spin of the same sign as that of the unpaired electron in the $d_{x^2-y^2}$ (paramagnetic Ni^{II}) orbital

(x axis is taken along the Ni−C≡N−Ni linkage) is polarized on the empty $d_{x^2-y^2}$ (diamagnetic Ni^{II}) orbital (x axis is taken perpendicular to the NiC_4 plane) through the filled orbital of the cyanide bridges, giving rise to a ferromagnetic coupling between the nearest intrachain paramagnetic nickel(II) ions.

If we compare the θ and J values of the two complexes, we see that the values for **1** are slightly larger indicating a stronger magnetic coupling in **1**. This is in good agreement with the increasing order of the Ni(2)−C(1) and Ni(1)−N(1) bond lengths (1.858, 2.123 Å for **1**, 1.871, 2.137 Å for **2**). Such an elongation indicates a decreasing overlap of the d_σ orbitals and is unfavourable for the magnetic interaction between paramagnetic Ni^{II} ions.

Experimental Section

Physical Measurements: Elemental analyses of carbon, hydrogen and nitrogen were carried out with a Perkin−Elmer analyzer model 240. Infrared spectroscopy on KBr pellets was performed on a Shimadzu IR-408 infrared spectrophotometer in the 4000−600 cm^{-1} region. Variable-temperature magnetic susceptibility measurements (1.8−200 K) of powder samples were performed in a field of 1 T on a model Maglab System^{2000} magnetometer. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal's Tables).

Preparations: All reagents used in the syntheses were of analytical grade and were used without further purification. [Ni(TIM)][Ni(CN)$_4$] (**1**),[11] [Ni(TIM)](ClO$_4$)$_2$,[19] and [NiL](ClO$_4$)$_2$,[20] were prepared as described previously.

[NiL][Ni(CN)$_4$]·4H$_2$O (2): Two aqueous solutions of [NiL](ClO$_4$)$_2$ (0.25 mmol) and K$_2$[Ni(CN)$_4$] (0.25 mmol) were mixed to produce immediately a brown fine powder which was collected by suction filtration, washed with water and dried under vacuum over P_2O_5. Yield 125 mg (90%). $C_{16}H_{42}N_{10}Ni_2O_4$ (556.0): calcd. C 34.71, H 6.66, N 28.92; found C 34.87, H 6.48, N 28.95. IR: $\tilde{\nu}_{max}$ = 2150, 2130 and 2110 (C≡N) cm^{-1}. Well-shaped light-grey crystals suitable for an X-ray structure analysis were grown at room temperature by the slow mixing of an orange acetonitrile solution of [NiL](ClO$_4$)$_2$ and a colourless aqueous solution of K$_2$[Ni(CN)$_4$] in an H-tube.

Crystal Data for 2: $C_{16}H_{42}N_{10}Ni_2O_4$, M = 556.02, monoclinic, $P2_1/n$, a = 11.0104(8), b = 10.1878(4), c = 11.5099(10) Å, β = 91.980(10)°, U = 1290.3(2) Å^3, Z = 2, μ(Mo-K_α) = 1.500 mm^{-1}. F(000) = 592, 2263 unique reflections, 1265 observations ($I > 2.00\sigma(I)$] considered unique (R_{int} = 0.0295). The final R_{wF} was 0.129, with conventional R_F = 0.0401 for 148 parameters.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-152642. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Electrochemical Synthesis and X-ray Characterisation of Cadmium Complexes Containing 2,6-Bis(1-salicyloylhydrazonoethyl)pyridine − the Influence of the Supporting Electrolyte on the Nature of the Isolated Compounds

Matilde Fondo,[a] Antonio Sousa,*[a] Manuel R. Bermejo,[a] Ana García-Deibe,[a] Antonio Sousa-Pedrares,[a] Olga L. Hoyos,[b] and Madeleine Helliwell[c]

Keywords: N ligands / Cadmium / Electrochemistry

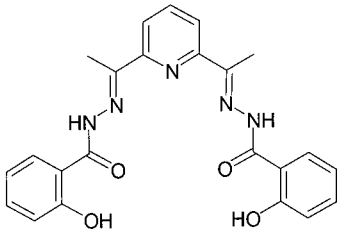
The influence of the supporting electrolyte and the solvent of crystallisation on the nature of cadmium complexes of 2,6-bis(1-salicyloylhydrazonoethyl)pyridine (H_4daps), obtained by an electrochemical procedure, has been investigated. [Cd(H_2daps)(H_2O)$_2$] (**1**), [Cd(H_2daps)(H_2O){(CH_3)$_2$CHOH}] (**2**), [Cd(H_3daps)Cl]·CH_3CN·0.25H_2O (**3**), [Cd(H_3daps)Cl-(CH_3OH)]·2H_2O·CH_3OH (**4**), and [Cd(H_2daps)Cl(H_2O)]N-(CH_3)$_4$ (**5**), have all been isolated and crystallographically characterised. X-ray diffraction studies show that the cadmium atom in **3** is in an unusual pentagonal pyramidal [CdN_3O_2Cl] geometry, while in the other compounds the cadmium atom is in a bipyramidal pentagonal environment. The organic ligand acts as a pentadentate dianionic ligand in **1**, **2**, and **5**, and as a pentadentate monoanionic ligand in **3** and **4**.

Introduction

The coordination chemistry of hydrazones has been extensively studied. The diversity seen in the structures of their metal complexes,[1−6] their pharmacological activity,[7−9] and magnetic properties[10−12] make these compounds of special interest.

Earlier studies of the coordination chemistry of hydrazone ligands have revealed some interesting aspects, such as their tendency to act as approximately planar pentadentate ligands in most complexes,[1−5,13,14] although an example of tridentate behaviour has recently been reported.[13] Furthermore, these ligands can coordinate in either the neutral,[2b−2d,14] monoanionic,[5,15] dianionic,[2a,16] or tetraanionic[17] form, giving rise to mononuclear or binuclear species. The type of complex obtained seems to be critically dependent on the reaction conditions employed.

We have recently reported that an electrochemical procedure can be used for the isolation of neutral hydrazone complexes that apparently cannot be prepared by other chemical methods.[18] For example, most nickel complexes with hydrazone ligands are mononuclear, while electrochemical synthesis yields a binuclear complex. As a continuation of this work, we have turned our attention to other metals such as cadmium. Although one chemical method for the synthesis of [Cd(H_2daps)(H_2O)] has been described,[2b] we were interested in studying the interaction of cadmium with H_4daps (Scheme 1) under an electrical current in the presence of different supporting electrolytes. The results of this study are described herein.



H_4daps

Scheme 1

Results and Discussion

The reaction of H_4daps with cadmium in an electrochemical cell in the presence of different electrolyte species yields a variety of complexes, as illustrated in Scheme 2. Thus, when a suspension of H_4daps in acetonitrile is electrolysed using [$N(CH_3CH_2)_4$]ClO_4 as the supporting electrolyte, the

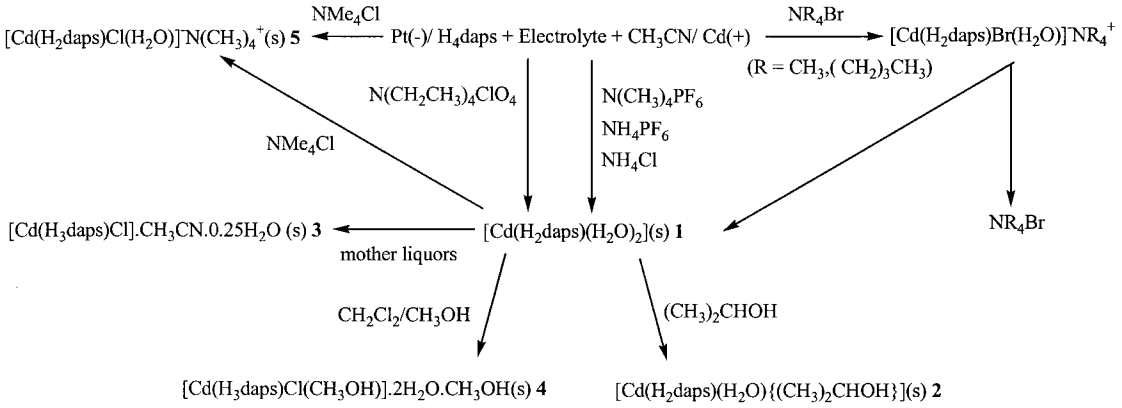


Scheme 2. Routes for the isolation of the metal complexes

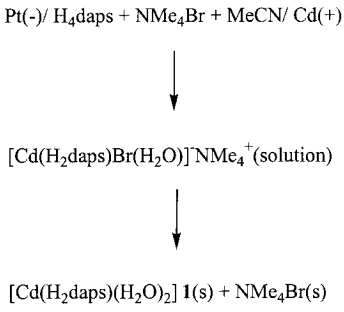
insoluble complex $[Cd(H_2daps)(H_2O)_2]$ (**1**) is isolated as the main product. A similar complex, $[Cd(H_2daps)(H_2O)\{(CH_3)_2CHOH\}]$ (**2**), has been isolated and crystallographically characterised by recrystallisation of **1** from 2-propanol. Complex **1** is stable in air and thermally stable, melting above 300 °C without decomposition. The compound is insoluble or sparingly soluble in water and common organic solvents, but soluble in polar coordinating solvents such as DMF, DMSO, and pyridine.

Slow evaporation of the solvents from the mother liquors obtained following this electrochemical reaction allows the isolation of $[Cd(H_3daps)Cl]\cdot CH_3CN\cdot 0.25H_2O$ (**3**) as a secondary product, which has also been crystallographically characterised. It is clear that the chlorine ligand could only have come from the electrochemical reduction of the tetraethylammonium perchlorate used as the supporting electrolyte, as there is no other chlorine source in the reaction medium. This type of behaviour has been reported previously.[19]

Recrystallisation of **1** from CH_2Cl_2/CH_3OH yields a complex with the molecular formula $[Cd(H_3daps)Cl(CH_3OH)]\cdot 2H_2O\cdot CH_3OH$ (**4**). In this case, there are two possible sources of the chlorine ligand: (a) a slight impurity in **1**, arising from the reduction of the perchlorate electrolyte, or (b) the chlorine could have come from the dichloromethane used as solvent.

In an attempt to discern between these two possibilities, the perchlorate was replaced by a chlorine-free electrolyte, such as $[N(CH_3CH_2)_4]PF_6$. The electrochemical synthesis performed under these conditions again yielded complex **1**. Recrystallisation of the resulting powder from purified CH_2Cl_2/CH_3OH led to compound **4**, which was crystallographically characterised. This result demonstrates that the dichloromethane is the chlorine source. In view of this evidence, it was envisaged that electrolytes such as NH_4Cl or $N(CH_3)_4Cl$ might produce the same result. Therefore, the electrochemical synthesis in the presence of these chloride salts was investigated. Surprisingly, it was found that these two electrolytes play different roles in the reactions. NH_4Cl acts as a simple current carrier and leads to the isolation of the insoluble complex **1**, while the use of $N(CH_3)_4Cl$ produces the soluble complex $[Cd(H_2daps)Cl(H_2O)]N(CH_3)_4$ (**5**). Compound **5** was also obtained when a suspension of **1** in acetonitrile was treated with a stoichiometric amount of $N(CH_3)_4Cl$.

These results indicate that the cadmium centre is susceptible to nucleophilic attack, yielding ionic complexes. To verify this, the aforementioned electrochemical reaction was performed in the presence of other electrolytes, such as NH_4PF_6, $N(CH_3)_4Br$, or $N(CH_2CH_2CH_2CH_3)_4Br$. In the case of NH_4PF_6, the reaction yielded **1**, as one would expect in view of the poor nucleophilicity of PF_6^-. The use of the bromide electrolytes led to transparent yellow acetonitrile solutions, rather than to the insoluble complex **1**. When the solutions were left to stand, two different compounds could be identified. Thus, when $N(CH_3)_4Br$ was used, **1** and $N(CH_3)_4Br$ were identified by X-ray diffraction studies. A possible explanation for this could be the formation of $[Cd(H_2daps)Br(H_2O)]NR_4$, which reorganises when the solution is concentrated to give the final products **1** and NR_4Br, as shown in Scheme 3.



Scheme 3

Complexes **1** and **4** show very low conductivities in DMF (5.46 and 10.97 Ω^{-1} cm^2 mol^{-1}, respectively), in agreement with their nonelectrolyte natures.[20] This indicates that the chlorine ligand is coordinated to the metal in complex **4** and that it remains coordinated even after dissolution in a donor solvent. The conductivity of complex **5** in DMF (84.1 Ω^1 cm^2 mol^{-1}) is in the expected range for 1:1 electrolytes, in accordance with the proposed formulation.

X-ray Diffraction Studies

Pentagonal Bipyramidal Complexes $[Cd(H_2daps)(H_2O)_2]$ (1), $[Cd(H_2daps)(H_2O)\{(CH_3)_2CHOH\}]$ (2), $[Cd(H_3daps)Cl(CH_3OH)]\cdot 2H_2O\cdot CH_3OH$ (4), and $[Cd(H_2daps)Cl(H_2O)]N(CH_3)_4$ (5)

ORTEP views of **1**, **2**, **4**, and **5** are shown in Figures 1 to 4. Experimental details are given in Table 1 and selected bond lengths and angles are shown in Table 2.

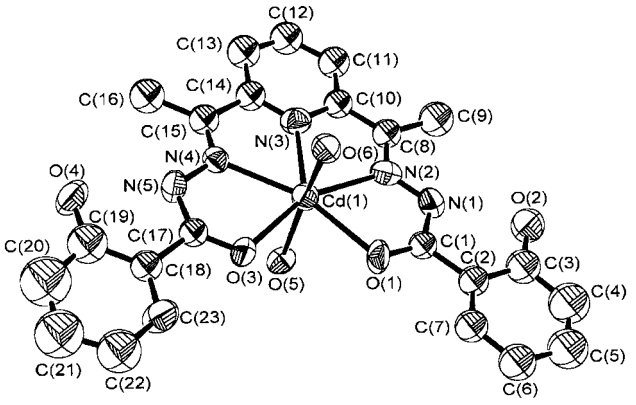


Figure 1. An ORTEP view of $[Cd(H_2daps)(H_2O)_2]$ (**1**) showing the atomic numbering scheme; ellipsoids are drawn at a 50% probability level

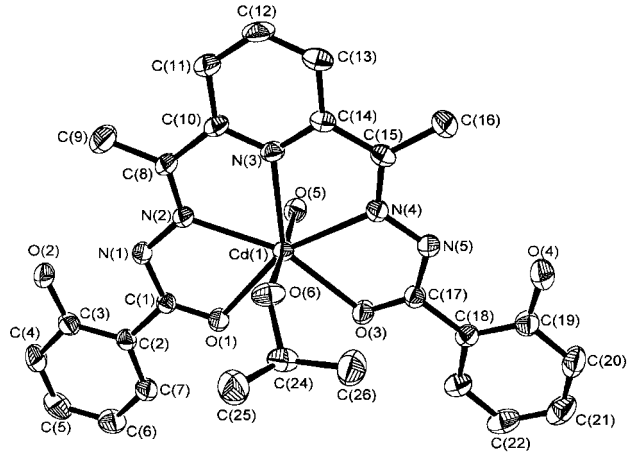

Figure 2. An ORTEP view of $[Cd(H_2daps)(H_2O)\{(CH_3)_2CHOH\}]$ (**2**) showing the atomic numbering scheme; ellipsoids are drawn at a 50% probability level

X-ray quality crystals of complex **4** proved to be extremely unstable under X-ray irradiation and we were unable to prevent them from decomposing (standard decay = 38%). This is the reason for the rather poor resolution of the structure. Therefore, only the general structural aspects will be discussed.

All the compounds are noncentrosymmetric, with the exception of **5**, which has a twofold crystallographic axis and hence the two halves of the hydrazone ligand are symmetry related. Complexes **1**, **2**, and **4** are neutral, while **5**, containing the $[Cd(H_2daps)Cl(H_2O)]^-$ anion, is ionic. This is remarkable, as all the previously reported ionic complexes

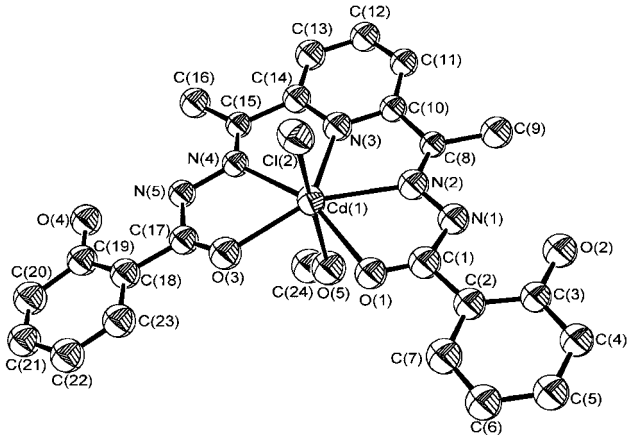

Figure 3. Molecular structure of $[Cd(H_3daps)Cl(CH_3OH)]\cdot 2H_2O\cdot CH_3OH$ (**4**) showing the atomic numbering scheme; solvent molecules are omitted for clarity; ellipsoids are drawn at a 30% probability level

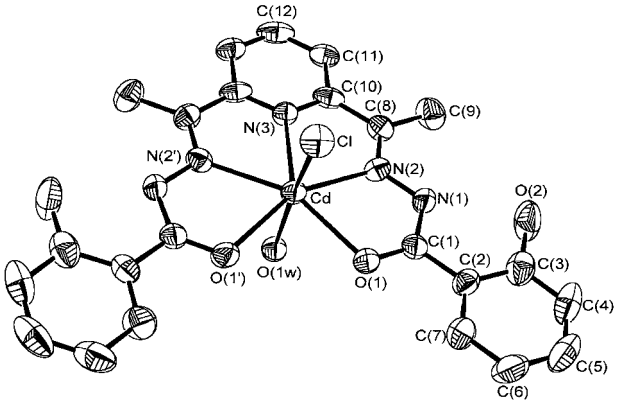

Figure 4. An ORTEP view of $[Cd(H_2daps)Cl(OH_2)]N(CH_3)_4$ (**5**) showing the complex anion; the $N(CH_3)_4^+$ cation is omitted for clarity; ellipsoids are drawn at a 50% probability level

derived from H_4daps or similar hydrazones contain a positively charged metallic fragment.

All the compounds exhibit a distorted pentagonal-bipyramidal environment around the Cd atom, with the hydrazone ligand being pentadentate. The N_3O_2 donor set of the dianionic (**1**, **2**, and **5**) or monoanionic (**4**) hydrazone occupies the equatorial plane of the bipyramid, while solvent molecules and/or chlorine atoms occupy the apical positions. All the distances around the cadmium atom are in the expected ranges for heptacoordinated cadmium,[21,22] although the interaxial and equatorial angles around the metal (Table 2) differ from the ideal values of 180° and 72°, respectively, for a pentagonal bipyramidal arrangement. Four of the five equatorial angles are smaller than the ideal value and the fifth $O_{carbonyl}-Cd-O_{carbonyl}$ angle is greater. These angles show the degree of distortion from the ideal polyhedron.

The N_3O_2 donor set is nearly planar in all cases, with the ionic complex **5** showing the least deviation from the N_3O_2 least-squares calculated plane (maximum deviation of any atom in **5**: 0.014 Å, with the cadmium atom lying 0.2251 Å below the plane).

[a] For **5**: O(5) = O(1w), O(3) = O(1′), and N(4) = N(2′).

In **1**, **2**, and **4**, the C−O_{phenol} distances are noticeably shorter than the ideal value of 1.36 Å, indicating some double character for this bond. This is consistent with the participation of the phenol oxygen atom in hydrogen-bonding interactions. In the case of complexes **1** and **4**, the hydrogen atoms bonded to oxygen were not included as they could not be unequivocally defined; they could not be located by difference Fourier methods and have more than one possibility for hydrogen bonding. However, the hydrogen atoms attached to oxygen could be located for **2** and **5**. Both complexes feature two types of hydrogen bond: intramolecular between the phenol oxygen and the hydrazide nitrogen atoms [O(2)···N(1) = 2.509(3) Å and O(4)···N(5) = 2.538(3) Å in **2**; O(2)···N(1) ≈ 2.516 Å in **5**], and intermolecular, involving solvent molecules. Thus, in complex **2**, the water molecule establishes two hydrogen bonds with the carbonyl oxygen atoms of another unit [O(5)···O(1′) = 2.781(3) Å and O(5)·O(3′) = 2.753(3) Å] and vice versa. The 2-propanol molecule also interacts through hydrogen bonding with a phenol oxygen atom of another unit [O(6)···O(2″) = 2.815(3) Å]. These contacts lead to shorter and longer Cd···Cd distances [Cd(1)···Cd(1′) = 5.1125(5) Å and Cd(1)···Cd(1″) = 8.981(5) Å].

In complex **5**, the water molecule of one unit establishes hydrogen bonds with the two carbonyl oxygen atoms of a neighbouring unit [O(1w)···O(1) distance ≈ 2.758 Å] and vice versa. Thus, two complex molecules interact through four hydrogen bonds, the shortest Cd···Cd distance being ca. 5.264 Å, with the structure resembling a weakly joined dimer (Figure 5).

Pentagonal Pyramidal Complex [Cd(H_3daps)Cl]·CH_3CN·0.25H_2O (3)

The X-ray crystal structure of **3** is shown in Figure 6 and selected bond lengths and angles are given in Table 3.

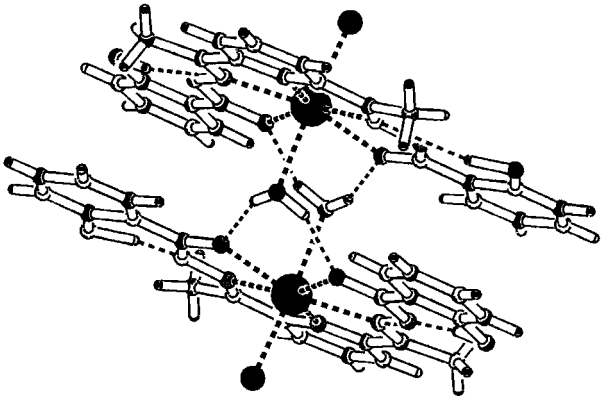

Figure 5. Part of the unit cell of **5** showing the association between two [Cd(H_2daps)Cl(H_2O)]$^-$ anions through hydrogen bonding

The crystal structure consists of discrete [Cd(H_3daps)Cl] molecules with acetonitrile and disordered water in the unit

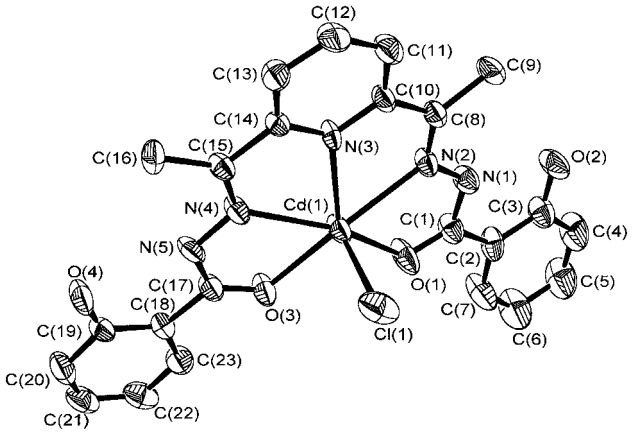

Figure 6. Molecular structure of $[Cd(H_3daps)Cl]\cdot CH_3CN\cdot 0.25H_2O$ (**3**); solvent molecules are omitted for clarity; ellipsoids are drawn at a 50% probability level

cell, these having occupancies of 0.25. The terminal carbon atom of the acetonitrile molecule is disordered over two sites with occupancies of 0.65 and 0.35.

The metal atom is in a hexacoordinate environment $[CdN_3O_2Cl]$. The seventh position is unoccupied, despite of the presence of acetonitrile in the unit cell. The Cd···N(6) distance, 2.739(10) Å, is too long to be considered a true coordinated bond and may be viewed as a secondary intramolecular interaction. Thus, the environment of the metal atom can be described as distorted pentagonal pyramidal, with the chlorine atom at the apex and the base formed by the N_3O_2 donor set of the pentadentate monoanionic $[H_3daps]^-$ ligand. The distortion from ideal geometry is clearly shown by the angles between chlorine, cadmium, and the donor set of the hydrazone ligand (Table 3). Moreover, four of the five angles subtended at Cd by adjacent equatorial atoms are slightly smaller than the value for an ideal pentagonal pyramidal arrangement, ranging from 65.1(2)° to 68.0(2)°, while the fifth angle, O(1)−Cd−O(3), is 89.2(2)°. The distortion of the polyhedron is further reinforced by the deviation of the donor set of the hydrazone ligand and the Cd atom from planarity. The maximum deviation from the N_3O_2 least-squares calculated plane is 0.044 Å, with the Cd atom lying 0.348 Å above this plane, giving rise to an "umbrella-like" distortion.

All the cadmium−donor distances are similar to those found in **1**−**3** and **5**, and the $C-O_{phenol}$ bond lengths (ca. 1.32 Å) also suggest hydrogen-bonding interactions. The short distances between phenol oxygen atoms of adjacent units [O(2)O(2′) = 2.446(9) Å and O(4)···O(4") = 2.505(9) Å] and the disposition of the molecules in the unit cell seem to indicate that every molecule establishes two intermolecular hydrogen bonds with neighbouring units. Thus, the unit cell shows a zigzag chain disposition of the molecules, with wide channels between layers of these chains (Figure 7).

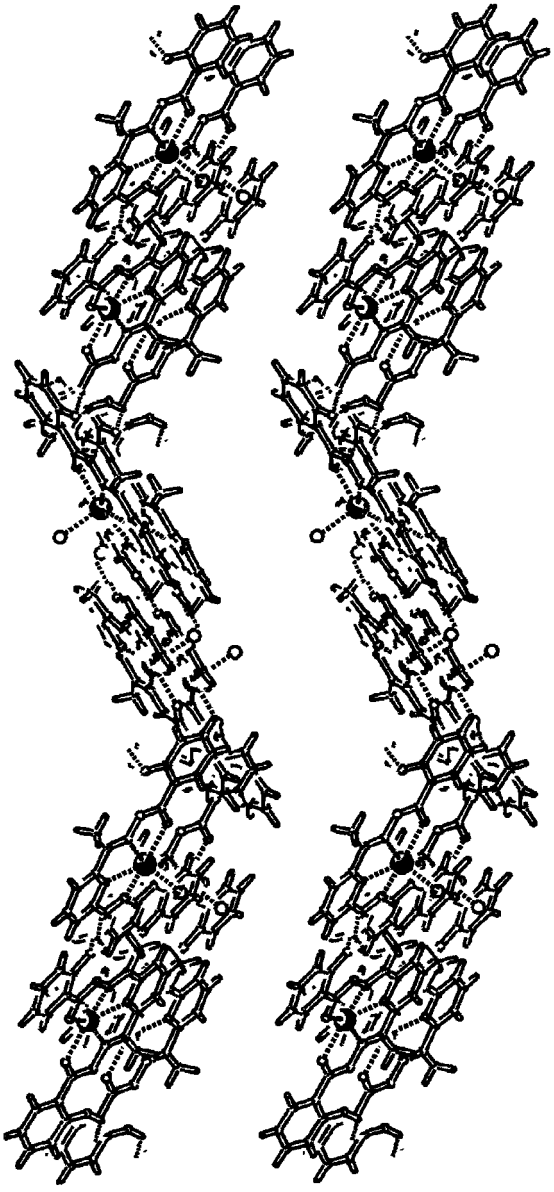

Figure 7. The unit cell of **3** showing the channels between the chains

It should be noted that the crystal structure of $[Cd(H_4daps)Cl_2]$, containing H_4daps as a neutral ligand, has been described previously.[2b] In this case, the complex has a pentagonal-bipyramidal geometry, characteristic of mononuclear compounds containing pentadentate hy-

[a] See ref.[2b]

drazone ligands, as observed for **1**, **2**, **4**, and **5**. However, the geometry of **3** is quite unexpected, especially considering the presence of a possible donor molecule (acetonitrile) in the unit cell. The pentagonal pyramidal geometry is very unusual and, to the best of our knowledge, no other complexes containing hydrazone ligands have been reported with this structure. Some hydrazone complexes having the metal atom in a hexacoordinate environment have been published.[3,6,18,23–25] In all these cases, the metal atom resides in a distorted octahedral environment. On the other hand, although some examples of complexes with a pentagonal pyramidal geometry have been reported, mainly for metals of the s- or p-blocks,[26,27] to the best of our knowledge no cadmium complexes showing this type of geometry have hitherto been reported.

A comparison of the cadmium complexes described herein with [Cd(H_4daps)Cl_2] reveals some general trends (Table 4):

(i) Cadmium complexes with H_4daps contain the hydrazone ligand acting in a pentadentate manner and show a high preference for pentagonal-bipyramidal geometry.

(ii) The Cd–$O_{carbonyl}$ distances are more symmetric in those complexes in which the ligand is dianionic (**1**, **2**, **5**) or neutral {[Cd(H_4daps)Cl_2]} than in those in which the ligand is monoanionic (**3**, **4**).

(iii) The Cd–Cl distance in **3** is significantly shorter than those in **4**, **5**, and [Cd(H_4daps)Cl_2]. This reflects the lower coordination number for **3**.

(iv) The Cd–O_{water} distances in **1** and **2** are markedly shorter than those in **4**. This may be attributed to the stronger "*trans* effect" of the chlorine ligand. This pattern was also observed in previously reported pentagonal-bipyramidal cadmium complexes.[22]

(v) The C–O_{phenol} distances seem to reflect the deprotonation of the ligand in neutral complexes. Thus, complexes **1** to **4** show C–O_{phenol} distances that are shorter than the ideal value. However, anionic complexes do not seem to follow this pattern, as the C–O_{phenol} distance in **5** [1.367(8) Å] is typical of a single C–O bond.

(vi) A comparison of complexes **1** to **5** shows that when cadmium is coordinated by water, the shortest Cd···Cd distances have a lower value (ca. 5.26 Å for **1** and **5**; 5.11 Å for **2**) than in the remaining cases (ca. 8.2 Å for **3** and **4**).

IR and ^{1}H NMR Spectroscopy and Mass Spectrometry

The IR spectra of **1**, **4**, and **5** show a negative shift of the amide I and amide II bands, by 39–52 cm^{-1} and 59–64 cm^{-1}, respectively, compared with the values found in free H_4daps (see Exp. Sect.). This behaviour is indicative of the coordination of the ligand to the metal through the oxygen atoms of both carbonyl groups in all cases.[2] The spectra also show the absence of the ν(N–H) band for **1** and **5**, which appears at 3208 cm^{-1} in the free ligand. This situation is in accordance with the dianionic nature of the ligand in these cases. However, the IR spectrum of complex **4** features bands at 3200 and 3060 cm^{-1}, indicating that the hydrazide nitrogen atoms are not fully deprotonated.

The ^{1}H NMR spectra of **1** and **5** in [D_6]DMSO (see Exp. Sect.) show the absence of a resonance due to the NH protons, which appears at δ = 11.8 in the free ligand.[2] This is in agreement with the bis-deprotonation of the ligand. In the case of complex **4**, the resonance of the NH group is not observed either, in spite of the monoanionic nature of the ligand. This can be attributed to the fact that the hydrogen atom is in rapid exchange between the two nitrogen atoms. The signal due to the OH groups is strongly downfield shifted in each case (from δ = 11.51 to ca. δ = 14.5). This behaviour has been observed previously and was attributed to the participation of the OH groups in strong hydrogen bonds.[2b]

The ES mass spectra of **1**, **4**, and **5** are consistent with the isotopic simulated pattern, with peaks of maximum intensity at *m*/*z* = 544 attributable to the fragment $[CdL]^+$,

confirming the coordination of the ligand to the metal. In addition, it was possible to observe peaks at $m/z = 579$ for **4** and **5**, corresponding to the binding of the chlorine to the cadmium atom.

Conclusion

Electrolysis of a suspension of H_4daps in acetonitrile using a cadmium anode yields $[Cd(H_2daps)(H_2O)_2]$ (**1**) as the major product. Recrystallisation of this complex from 2-propanol gives $[Cd(H_2daps)(H_2O)\{(CH_3)_2CHOH\}]$ (**2**). Concomitant reduction of the perchlorate electrolyte during the electrochemical process produces $[Cd(H_3daps)Cl]\cdot CH_3CN\cdot 0.25H_2O$ (**3**) as a by-product. $[Cd(H_3daps)Cl(CH_3OH)]\cdot 2H_2O\cdot CH_3OH$ (**4**) and $[Cd(H_2daps)Cl(H_2O)]N(CH_3)_4$ (**5**) show that dichloromethane and tetramethylammonium chloride can also act as sources of chlorine. The five compounds are all monomers, but have different geometries. Complexes **1**, **2**, **4**, and **5** have pentagonal-bipyramidal environments, but **3** is a pentagonal-pyramidal complex and is, to the best of our knowledge, the first characterised example of an H_4daps metal complex showing this type of geometry. Therefore, this work further emphasises the variety of molecular structures that hydrazone ligands can produce. Moreover, the ability of H_4daps to behave as an anionic ligand has been demonstrated: monoanionic and dianionic forms are found in different complexes containing the same metal atom.

Experimental Section

General Remarks: Elemental analyses (C, H N) were performed on a Carlo Erba EA 1108 analyser. NMR spectra were recorded on a Bruker WM-250 spectrometer with samples in $[D_6]$DMSO solution. Infrared spectra were recorded from samples in KBr pellets on a Bio-Rad FTS 135 spectrophotometer in the range 4000−600 cm^{-1}. Electrospray mass spectra were obtained on a Hewlett−Packard LC/MS spectrometer, using methanol as solvent. Conductivities of 10^{-3} M solutions in DMF were measured using a Crison microCM 2200 conductivimeter.

Syntheses: All solvents, 2,6-diacetylpyridine, and salicyl hydrazide are commercially available and were used without further purification. Cadmium (Ega Chemie) was used in the form of ca. 2 × 2 cm^2 plates.

2,6-Bis(1-salicyloylhydrazonoethyl)pyridine (H_4daps) was synthesized as described previously[2a] and was satisfactorily characterised by elemental analysis, IR and ^{1}H NMR spectroscopy.

Syntheses of the Complexes: $[Cd(H_2daps)(H_2O)_2]$ (**1**) was obtained by electrochemical synthesis. A suspension of H_4daps (0.108 g, 2.5 × 10^{-4} mol) in acetonitrile (80 mL) containing tetraethylammonium perchlorate (ca. 10 mg) as a current carrier was electrolysed at 10 mA, 12 V for 1 h 20 min, using a platinum wire as the cathode and a cadmium plate as the anode. The cell system can be represented as Pt(−)/MeCN + H_4daps/Cd(+). At the end of the experiment, the insoluble yellow powder deposited was collected by filtration, washed with diethyl ether, and dried in air. Recrystallisation of the compound from CH_3CN and 2-propanol yielded crystals of $[Cd(H_2daps)(H_2O)_2]$ (**1**) and $[Cd(H_2daps)(H_2O)\{(CH_3)_2CHOH\}]$ (**2**), respectively, which were both suitable for X-ray diffraction studies.

$Cd(H_2daps)(H_2O)_2$: Yield: 85%. $C_{23}H_{23}N_5O_6Cd$ (577.4): calcd. C 47.8, H 4.0, N 12.1; found C 48.0, H 3.9, N 12.1. ES-MS (amu): $m/z = 544$ $[ML]^+$. Λ (Ω^{-1} cm^2 mol^{-1}) = 5.46. IR (KBr): $\tilde{\nu}$ = 1617 $\nu(am_1)$, 1530 $\nu(am_2)$, 3400 cm^{-1} ν(OH). ^{1}H NMR (250 MHz, $[D_6]$DMSO): δ = 14.65 (s, 2 H, OH), 6.83−8.15 (m, 11 H, H_{arom}), 2.45 (s, 6 H, CH_3).

Slow evaporation of the solvent from the mother liquor obtained following the electrochemical experiment led to the isolation of yellow crystals of $[Cd(H_3daps)Cl]CH_3CN\cdot 0.25H_2O$ (**3**), which were also suitable for X-ray diffraction analysis.

Slow recrystallisation of **1**, by diffusion of diethyl ether into a solution in dichloromethane/methanol, yielded crystals of $[Cd(H_3daps)Cl(CH_3OH)]\cdot 2H_2O\cdot CH_3OH$ (**4**), which loses solvent to generate $Cd(H_3daps)Cl(H_2O)_2$. Yield: 42%. $C_{23}H_{24}N_5O_6ClCd$ (613.9): calcd. C 44.9, H 3.9, N 11.4; found C 44.9, H 3.3, N 11.2. − ES-MS (amu): m/z = 544 $[ML]^+$, 579 $[MLCl]^+$. Λ (Ω^{-1} cm^2 mol^{-1}) = 10.97. IR (KBr): $\tilde{\nu}$ = 1595 $\nu(am_1)$, 1530 $\nu(am_2)$, 3417 cm^{-1} ν(OH). ^{1}H NMR (250 MHz, $[D_6]$DMSO): δ = 14.45 (s, 2 H, OH), 6.60−8.10 (m, 11 H, H_{arom}), 2.47 (s, 6 H, CH_3).

Compound **1** was also obtained when $[N(CH_2CH_3)_4]PF_6$, NH_4PF_6, or NH_4Cl was used as the supporting electrolyte instead of $[N(CH_2CH_3)_4]ClO_4$.

$[Cd(H_2daps)Cl(H_2O)]N(CH_3)_4$ (**5**) was obtained by two different methods:

Method A. Electrochemical Method: A suspension of H_4daps (0.108 g, 2.5 × 10^{-4} mol) in acetonitrile containing tetramethylammonium chloride (27.4 mg) was electrolysed at 10 mA, 9 V for 1 h 20 min, using a platinum wire as the cathode and a cadmium plate as the anode. Slow evaporation of the solvent from the resultant yellow solution yielded crystals of $[Cd(H_2daps)Cl(H_2O)]N(CH_3)_4$ (**5**), which proved suitable for X-ray diffraction studies. Yield: 76%. $C_{27}H_{33}N_6O_5ClCd$ (669.44): calcd. C 48.4, H 4.9, N 12.5; found C 47.2, H 4.0, N 12.1. ES-MS (amu): m/z = 544 $[ML]^+$, 579 $[MLCl]^+$. − Λ (Ω^{-1} cm^2 mol^{-1}) = 84.1. IR (KBr): $\tilde{\nu}$ = 1598 $\nu(am_1)$, 1530 $\nu(am_2)$, 3321 cm^{-1} ν(OH). ^{1}H NMR (250 MHz, $[D_6]$DMSO): δ = 14.63 (s, 2 H, OH), 6.78−8.20 (m, 11 H, H_{arom}), 2.45 (s, 6 H, CH_3), 3.36 [s, 12 H, $N(CH_3)_4$].

Method B. Chemical Method: Tetramethylammonium chloride (0.025 g, 2.3 × 10^{-4} mol) was added to a suspension of H_4daps (0.1 g, 2.3 × 10^{-4} mol) in acetonitrile. The suspension was stirred at room temperature until a yellow solution was obtained (ca. 1 h). The volume of the solution was reduced to ca. 10 mL, whereupon a yellow solid precipitated. This solid was collected by filtration, washed with diethyl ether, and dried in air.

X-ray Crystallographic Study: Crystal data and details of the refinement are given in Table 1.

$[Cd(H_2daps)(H_2O)_2]$ (1), $[Cd(H_3daps)Cl]\cdot'CH_3CN\cdot 0.25H_2O$ (3), and $[Cd(H_3daps)Cl(CH_3OH)]\cdot 2H_2O\cdot CH_3OH$ (4): Orange plate, orange prismatic, and yellow tabular crystals of **1**, **3**, and **4**, respectively, suitable for single-crystal X-ray studies, were obtained as described previously. The crystals were mounted on a glass fibre. Data were collected at 296 K on a Rigaku AFC5R diffractometer, employing graphite-monochromated Cu-K_α radiation (λ = 1.54178 Å) and a rotating anode generator. The structures were solved by and expanded using Fourier techniques.[28] An empirical absorption cor-

rection based on azimuthal scans of several reflections was applied for **1** and **3**. The data were corrected for Lorentz and polarisation effects. Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically. The data for **1** and **4** were of rather low quality, hence only the Cd, N and O atoms were refined anisotropically in order to maintain a reasonable data-to-parameter ratio. Hydrogen atoms bonded to carbon were included in the structure factor calculation in idealised positions, but were not refined. Hydrogens attached to oxygen could not be located in the Fourier map and were not included (**1** and **4**) or were included with occupancies of 0.5 and refined isotropically (**3**), with the bond lengths restrained to 0.82 Å. All calculations were performed using the teXsan crystallographic software package from Molecular Structure Corporation.[29]

[Cd(H_2daps)(H_2O){(CH_3)$_2$CHOH}] (2) and [Cd(H_2daps)Cl(H_2O)]-N(CH_3)$_4$ (5): Yellow block and plate crystals of **2** and **5**, respectively, were obtained as detailed above. Data were collected using a CAD4 diffractometer or a Rigaku RAXIS diffractometer at 293(2) K employing Mo-K_α radiation (λ = 0.71073 Å). An absorption correction based on φ-scans was applied for **5**. Non-hydrogen atoms were refined anisotropically. Hydrogens attached to carbon atoms were included in idealised positions, but were not refined. Hydrogens bonded to oxygen atoms were located in the Fourier map and were refined isotropically. Data processing and computation were carried out using the SHELX-97 (**2** and **5**) program package[28] and the teXsan crystallographic software package (**2**).[29]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-159081 (**1**), -159082 (**2**, -15983 (**3**), -15984 (**4**), -15985 (**5**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44-(0)1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Rhodium(I), Palladium(II), and Platinum(II) Complexes Containing New Mixed Phosphane−Phosphite Ligands − Effect of the Catalytic System Stability on the Enantioselective Hydroformylation of Styrene

Carmela G. Arena,[a] Felice Faraone,*[a] Claudia Graiff,[b] and Antonio Tiripicchio[b]

Keywords: Rhodium / Palladium / Platinum / Chirality / P ligands / Hydroformylation

The new mixed phosphane–phosphite ligands **1** and **2**, derived from 3,3′-di-*tert*-butyl-2,2′-dihydroxy-5,5′-dimethoxybiphenyl and (*S*)-binaphthol, respectively, reacted with $[Rh(COD)(THF)_2]CF_3SO_3$ to give the compounds $[Rh(COD)(\mathbf{1})]CF_3SO_3$ and $[Rh(COD)(\mathbf{2})]CF_3SO_3$ in which the ligands **1** and (*S*)-**2** are chelated to the rhodium centre. The reaction with $[Rh(CO)_2Cl]_2$ gave two different products, $[Rh(CO)_2(L)Cl]$ and [Rh(CO)(L)Cl] [L = **1** and (*S*)-**2**], containing L as a chelate. On the basis of the IR and NMR spectroscopic data, the proposed structure of the pentacoordinate species is a trigonal bipyramide in which the phosphane–phosphite ligand assumes an equatorial-axial coordination. The reactions of **1** and **2** with $[Pd(C_6H_5CN)_2Cl_2]$ and $[Pt(COD)I_2]$ gave the corresponding compounds $[Pd(L)Cl_2]$ and $[Pt(L)I_2]$ in which the ligands are chelated to the metal centre. The crystal structure of the chloroform solvate of $[Pd(L)Cl_2]$ was fully characterised by an X-ray study. The chiral ligands (*S*)-**2** and (*S*)-**3** [derived from the *ortho*-bis(trimethylsilyl)-substituted (*S*)-binaphthol] were tested in the hydroformylation of styrene. The results obtained were discussed in light of the catalytic system stability.

Introduction

In the last twenty years great efforts have been made in the design of chiral ligands due to their role in enantioselective catalysis.[1] Attempts have been made to correlate structural and electronic characteristics of the coordinated chiral ligands with catalytic regio- and enantioselectivity. The structural features of the coordinated ligands, viz. the geometry, rigidity, asymmetry, natural bite angle, presence of sterically hindered groups, type of chirality and distance of the chiral centre from the metal centre have been considered to be factors determining the asymmetric induction.[2] However, in spite of the number of works produced, the crucial factors in designing ligands able to induce high enantioselectivity are not clear. As concerns the electronic characteristics of bidentate ligands, the presence of donor atoms with different properties seems to afford an advantageous effect on the regio- and enantioselectivity of the catalytic process. For example, Takaya et al.[3] have reported excellent chemo- and regioselectivities in the rhodium(I)-catalysed hydroformylation of vinylarenes using the phosphane−phosphito mixed chiral ligand binaphos. Some of us,[4] using (R_a,S_C)-quinaphos, a phosphane−phosphoramidite ligand derived from quinoline, in the rhodium(I)-catalysed hydroformylation of styrene, obtained the branched aldehyde with 74% *ee* in the (*S*) form. Using the same ligand, in the (R_a,R_C) configuration, in the rhodium(I)-catalysed enantioselective hydrogenation of dimethyl itaconate and methyl 2-acetamidoacrylate the products have been obtained with a conversion higher than 99% and 98.8 and 97.8% of *ee*, respectively.

Recently we reported[5] on the synthesis of the new phosphane−phosphite ligands **1**−**3** and on their applications in the Pd-catalysed enantioselective allylic alkylation of 1,3-diphenyl-2-propen-1-yl acetate by dimethyl malonate. Using the complexes $[Pd(\eta^3\text{-}C_3H_5)(\mathbf{2})]CF_3SO_3$ and $[Pd(\eta^3\text{-}C_3H_5)(\mathbf{3})]CF_3SO_3$ as catalyst precursors, the allylic substitution product was obtained with up to 71% *ee*.

R = $SiMe_3$ (*S*)-**3**

Here we describe the synthesis of rhodium(I), palladium(II) and platinum(II) complexes containing the ligands **1** and (*S*)-**2**, together with the X-ray structure of the compound $[Pd(\mathbf{1})Cl_2]$. The results obtained in the hydroformyl-

ation of styrene using ligands (*S*)-**2** and (*S*)-**3** are also briefly reported. This study stems from our interest in developing the synthesis of d^8-metal complexes able to act as efficient catalyst precursors in homogeneous catalysis.

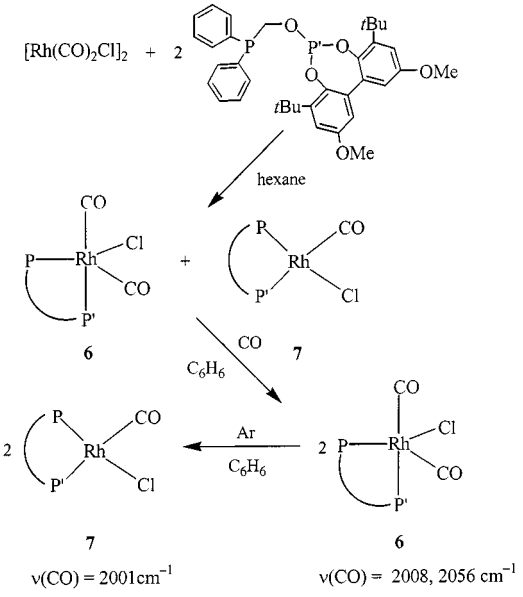
Results and Discussion

As previously reported,[5] the ligands **1** and (*S*)-**2** have been easily prepared by treating (hydroxymethyl)diphenylphosphane (Ph_2PCH_2OH)[6] with 1 equiv. of 4,8-di-*tert*-butyl-6-chloro-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo[*a*,*c*]cycloheptene and (*S*)-4-chloro-3,5-dioxa-4-phosphacyclohepta[2,1-*a*:3,4-*a*′]dinaphthalene, respectively, in the presence of NEt_3 in toluene at 0 °C. They were obtained as white solids and are air-sensitive in both the solid state and in solution. The ligand (*S*)-**3** was used only in the hydroformylation.

Rhodium(I) Complexes

The addition of an equimolar THF solution of **1** or (*S*)-**2** to a solution of $[Rh(COD)(THF)_2]CF_3SO_3$ {prepared in situ by treating $[Rh(COD)Cl]_2$ in THF solution with $AgCF_3SO_3$ in a 1:2 molar ratio and filtration of AgCl precipitate} affords a yellow solution. Addition of hexane leads to the compounds $[Rh(COD)(\mathbf{1})]CF_3SO_3$ (**4**) and $[Rh(COD)(\mathbf{2})]CF_3SO_3$ (**5**). They are yellow solids that are soluble in chlorinated solvents, acetone, benzene and methanol; conductivity measurements performed on methanol solutions of **4** or **5** ($5\cdot10^{-4}$ to 10^{-3} M) are in accordance with their formulation as 1:1 electrolytes. As expected, the $^{31}P\{^1H\}$ NMR spectrum of **4** (C_6D_6 solution) shows two doublets of doublets at δ = 162.29 [J(RhP′) = 256.0 Hz; J(PP′) = 37.0 Hz] and δ = 63.89 [J_{RhP} = 148.0 Hz; J(PP′) = 37.0 Hz]. Analogously, compound **5** exhibits two doublets of doublets at δ = 167.0 [J(RhP′) = 260.0 Hz; J(PP′) = 41.3 Hz] and δ = 64.77 [J_{RhP} = 149.0 Hz; J(PP′) = 41.3 Hz]. The signals at higher frequencies are due to the phosphite moiety.[3] Of interest is that the phosphorus−phosphorus coupling constant appears in the $^{31}P\{^1H\}$ NMR spectra of **4** and **5**, but was not observed in the free ligands **1** and (*S*)-**2**. In the complexes containing **1** and **2**, the rigidity of the five-membered ring formed by chelation of the ligand to the rhodium centre promotes the coupling between the phosphorus atoms that are now only separated by the metal atom.

The slow addition of a hexane solution of the ligand **1** to a solution of $[Rh(CO)_2Cl]_2$ in the same solvent, in a 1:2 molar ratio, affords a yellow precipitate; its $^{31}P\{^1H\}$ NMR spectrum in $CDCl_3$ solution shows two signals as doublets of doublets of different intensity, centred at δ = 62.25 [J(RhP′) = 195 Hz, J(PP′) = 53.1 Hz] and δ = 84.5 [J_{RhP} = 133.5 Hz, J(PP′) = 49.1 Hz] for the phosphane group and two signals as doublets of doublets, centred at δ = 163.76 [J(RhP′) = 266.7 Hz, $J_{P'P}$ = 49.1 Hz] and 167.97 [J(RhP′) = 325.9 Hz, $J_{P'P}$ = 53.1 Hz] for the phosphite moiety. The IR spectrum of the solid in Nujol mull exhibits in the CO stretching region bands at 2001, 2008 and 2056 cm^{-1}. These spectroscopic data support the presence, in the crude product, of both the five-coordinated $[Rh(CO)_2(\mathbf{1})Cl]$ (**6**) and tetra-coordinated $[Rh(CO)(\mathbf{1})Cl]$ (**7**) species, containing ligand **1** as the chelate. When CO was bubbled for 10 min into a benzene solution of the yellow crude product, the $^{31}P\{^1H\}$ NMR spectrum only showed the signals centred at δ = 62.25 and 167.97. In the IR spectrum of the solution the ν(CO) bands occur at 2056 and 2008 cm^{-1}. This supports the presence in solution, under these conditions, of only the five-coordinated species **6** (Scheme 1). When argon was bubbled into the benzene solution containing **6**, the tetracoordinated square-planar species **7** was almost quantitatively formed; the ν(CO) at 2001 cm^{-1} is a high wave number value for a neutral rhodium(I) species and supports a structure in which the CO ligand is in the *trans* position to the phosphite moiety of **1**, with the phosphite group having a greater *trans* influence than the phosphane one.



Scheme 1

The reaction of the ligand **1** with $[Rh(CO)_2Cl]_2$, in the molar ratio 2:1, was also undertaken in toluene solution; under these conditions the precipitate formed contained only the five-coordinated species **6**, while in solution both the tetra-coordinated **7** and five-coordinated species (the latter as minor product) were detected. By adding a solution of the ligand (*S*)-**2** in hexane dropwise to a solution of $[Rh(CO)_2Cl]_2$ in the same solvent, in a 2:1 molar ratio, a yellow precipitate was formed and the solution turned yellow. The solid, separated by filtration, on the basis of analytical data and spectroscopic properties, was formulated as the five-coordinated $[Rh(CO)_2(\mathbf{2})Cl]$ (**8**).

In accordance, the $^{31}P\{^1H\}$ NMR spectrum in C_6D_6 solution shows two signals as doublets of doublets at δ = 61.27 [J_{RhP} = 133 Hz, J(PP′) = 49.1 Hz] and δ = 177.34 [J(RhP′) = 266.7 Hz, $J_{P'P}$ = 49.1 Hz] and the IR spectrum (Nujol) exhibits two bands in the ν(CO) stretching region at 1998 and 2064 cm^{-1}. A yellow solid was recovered from

the mother liquor, the square-planar rhodium(I) species [Rh(CO)(**2**)Cl] (**9**). In accordance with its formulation the $^{31}P\{^{1}H\}$ NMR spectrum shows two signals as doublets of doublets at δ = 84.2 [J_{RhP} = 190 Hz, $J(PP')$ = 54.2 Hz] and δ = 170.75 [$J(RhP')$ = 325 Hz, $J_{P'P}$ = 54.2 Hz] and the IR spectrum (Nujol) exhibits a ν(CO) band at 2003 cm^{-1}. The ν(CO) value results are high for a neutral square-planar rhodium(I) species and supports a structure in which the CO ligand is in the *trans* position to a group with a high *trans* influence, such as the phosphite group.

For compounds **6** and **8**, the high values of the ν(CO) allows a trigonal bipyramide structure containing the CO and Cl ligands in the *trans* position to be ruled out and supports a structure in which the phosphite moiety of **1** or (*S*)-**2** and CO occupy the axial positions. The ligands **1** and (*S*)-**2** assume an equatorial-axial coordination as expected if their natural bite angle is nearly 90°.[3a] Moreover, the presence of two ν(CO) bands allowed us to rule out structures with both the CO ligands in the equatorial position.

The reactions of [Rh(acac)$(CO)_2$] with the ligands **1** and (*S*)-**2** in hexane afforded the complexes [Rh(acac)(**1**)] (**10**) and [Rh(acac)(**2**)] (**11**) as yellow solids. Compound **11** was not obtained in a pure form owing to the presence of a very minor unidentified carbonyl product. However, the IR spectra indicate that the reactions occur by displacement of the CO ligands. The $^{31}P\{^{1}H\}$ NMR spectra of **10** and **11** show the phosphorus resonances as two doublets of doublets. The observed $J(PP')$ coupling value supports for **10** and **11** structures in which the ligands **1** and **2** are chelated to the rhodium atom.

Palladium(II) and Platinum(II) Complexes

The reactions of [Pd$(C_6H_5CN)_2Cl_2$] with **1** and (*S*)-**2** in toluene solution afford the corresponding compounds [Pd(**1**)Cl_2] (**12**) and [Pd(**2**)Cl_2] (**13**) as pale yellow crystals, soluble in acetone and chlorinated solvents and slightly soluble in benzene. As expected the $^{31}P\{^{1}H\}$ NMR spectra of **12** and **13** in $CDCl_3$ solution show the phosphorus resonances as doublets at very different δ values [138.2 and 74.88, $J(PP')$ = 23.7 Hz for **12**; 134.48 and 74.71, $J(PP')$ = 25.0 Hz for **13**]. The crystal structure of the chloroform solvate of **12** was fully characterized by an X-ray study.

The reactions of [Pt(COD)I_2] with **1** and (*S*)-**2** in toluene solution afford the compounds [Pt(**1**)I_2] (**14**) and [Pt(**2**)I_2] (**15**), respectively, as white solids that are stable in air. In the $^{31}P\{^{1}H\}$ NMR spectra of **14** and **15** in $CDCl_3$ solution the phosphorus resonances appear as singlets at higher fields than those of **12** and **13** along with peaks due to $^{195}Pt-P$ coupling.

Description of the Crystal Structure of [Pd(1)Cl_2]·$CHCl_3$ (**12**·$CHCl_3$)

Chloroform molecules of solvation were found in the crystals. A view of the structure of complex **12** together with the atomic numbering system is shown in Figure 1. Selected bond lengths and angles are given in Table 1.

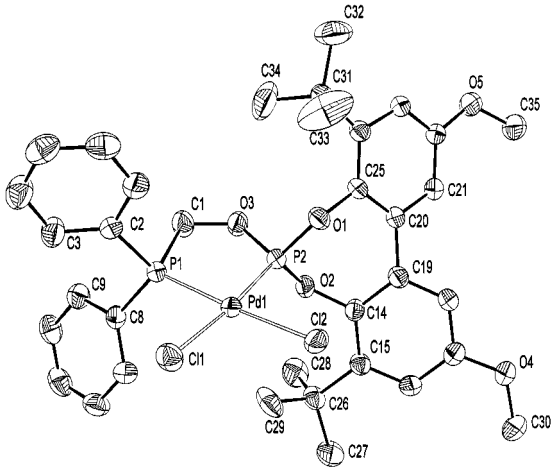


Figure 1. View of the molecular structure of complex **12** with the atomic numbering system; the ellipsoids are drawn at the 30% probability level

Table 1. Selected bond lengths [Å] and angles [°] for **12**·$CHCl_3$

Bond lengths

O(3)−P(2)−Pd(1) 111.6(1)	

The metal ion is square-planarly coordinated by two Cl atoms and two P atoms from the phosphane−phosphite chelating ligand **1** [maximum deviation from the mean plane through the five atoms 0.026(1) Å for Cl2]. The five-membered Pd1P1C1O3P2 ring [the P1−Pd1−P2 bite angle is 85.95(5)°] is roughly planar with only the Pd1 atom being significantly displaced from the mean plane [0.114(1) Å]. The two Pd1−P1 and Pd1−P2 bond lengths [2.227(1) and 2.192(1) Å] are comparable, as well as the two Pd1−Cl1 and Pd1−Cl2 ones [2.341(2) and 2.354(1) Å], as expected. The P and the N atoms are in the *trans* position.

In ligand **1** the P−O bond lengths are practically equal, in the range 1.573(4)−1.590(4) Å, whereas the O−P−O angles are in the range 96.2(2)−107.3(2)°. In the diphenyl moiety the C14−C19−C20−C25 torsion angle is +47.1(1)° with a C19−C20 bond length of 1.501(7) Å.

Catalysis

The catalytic systems formed by [Rh(acac)(CO)$_2$] and ligands (*S*)-**2** and (*S*)-**3** at variable ligand/metal ratios were used in the hydroformylation of styrene: The catalytic runs were carried out in benzene solution using an equimolar hydrogen/carbon monoxide mixture. The catalytic system with ligand (*S*)-**3** turned out to be the most efficient. Indeed, almost quantitative conversion (> 99%) of styrene could be attained within 66 h at 100 atm and 40 °C with a 1:4 Rh/ligand molar ratio. Also the chemo- and regioselectivity results are very high with the linear (L) and branched (B) aldehydes being about 99.9% of the reaction products with a B/L ratio of 32.3. Under these experimental conditions only a 20% *ee* of the branched aldehyde in the (*S*) form was obtained. No influence of the ligand/Rh ratio on the enantioselectivity was found. The stability of the catalytic system [Rh(acac)(CO)$_2$]/(*S*)-**2** was very low under the same experimental conditions.

The poor hydroformylation results are surprising in view of the high enantioselectivity reached by catalytic rhodium systems containing chiral diphosphites[2f] or phosphane−phosphite[3] mixed ligands in the styrene hydroformylation. However, in the literature examples of catalytic rhodium systems containing good ligands affording high conversion and chemo- and regioselectivity, but low or zero values of enantioselectivity from the styrene hydroformylation, have been reported.[7] Generally, these situations have been found when the chelate ligand is not strongly bonded to the rhodium centre. Thus, under elevated CO/H_2 pressure displacement of the chelate ligand by CO can take place to give [RhH(CO)$_4$] or [RhH(CO)$_3$L] (L = bidentate ligand acting as monodentate) as the catalytic species.[8] The use of a high ligand/Rh ratio can also modify the hydride−rhodium catalyst affording species containing two bidentate ligands which are monodentate or bridging (in a binuclear species) coordinated.

We attempted to obtain information about the catalytic system on leaving [Rh(acac){(*S*)-**3**}] to stand for36 h under CO/H_2 of 50 atm at 40 °C in C_6D_6. The resulting solution, transferred under H_2/CO to an NMR tube showed two doublets centred at δ = 120.1 (J_{RhP} = 193.6 Hz) and at δ = 11.7 in the $^{31}P\{^1H\}$ NMR spectrum along with some signals of low intensity in the δ = 12−18 region due to the presence of phosphane oxide.

The lack of the phosphorus−phosphorus coupling in the signal at δ = 120.1 supports the presence of a monodentate ligand coordinated to the rhodium(I) centre; the shift in the δ value from 169.7 as dd, to 120.1 is indicative of a modification at the phosphite group. Moreover the ^{31}P NMR ^1H-coupled spectrum showed the signal at δ = 11.7 as a doublet; the J_{PH} value of 729 Hz and the chemical shift values support the presence of a P−H bond of a phosphonate group.[9] This can be formed by hydrolysis of the ligand (*S*)-**3** in a tautomeric equilibrium, shifted towards the phosphonate, with the corresponding phosphite form. A similar process[9] was observed by hydrolysis of phosphite **15**.

Thus, considering the spectroscopic data and our previously reported results,[9] coordination of the hydrolysis product to the rhodium ion could occur in both phosphite and phosphonate forms affording a rhodium−phosphonate complex. This is further supported by the presence of the phosphorus signal at δ = 120.1 (J_{RhP} = 205 Hz) and of two ν(CO) bands at 2095 and 2050 cm^{-1}. We suggest that species **16** is prevalent in solution. This species can participate in a catalytic process affording the aldehydes but, since only monodentate ligands are present in the catalyst, it cannot bring about an asymmetric induction.

16

Experimental Section

General: All reagents were purchased and used as supplied. Solvents were dried by standard procedures. All experiments were performed under purified nitrogen. IR spectra were obtained as Nujol mulls on KBr plates using a Perkin−Elmer FT-IR 1720 spectrophotometer. ^1H, and $^{31}P\{^1H\}$ NMR spectra were recorded with a Bruker AMX R300. ^1H NMR spectra were referenced to internal tetramethylsilane and $^{31}P\{^1H\}$ spectra to external 85% H_3PO_4; positive chemical shifts for all nuclei are at higher frequencies. Elemental analyses were performed by Redox s.n.c., Cologno Monzese, Milano.

[Rh(COD)(1)]CF$_3$SO$_3$ (4): Solid AgCF$_3$SO$_3$ (0.063 g, 0.249 mmol) was added to a stirred solution of [Rh(COD)Cl$_2$]$_2$ (0.061 g, 0.124 mmol) in tetrahydrofuran (10 mL). After 10 min, the precipitate of AgCl was separated by filtration and ligand **1** (0.149 g, 0.248 mmol) was added to the filtrate. The yellow-orange solution

was stirred for 30 min and was then reduced to ca. 2 mL. On addition of 30 mL of hexane a yellow solid separated. It was removed by filtration, washed with hexane and vacuum-dried. Yield 85% (0.203 g, 0.211 mmol). $C_{44}H_{52}F_3O_8P_2RhS$ (962.8): calcd. C 54.89, H 5.44; found C 54.78, H 5.37. ^1H NMR ($CDCl_3$): δ = 1.58 [s, 18 H, $C(CH_3)_3$], 3.44 (s, 6 H, OCH_3), 4.35 [d, 2 H, $J_{P'H}$ = 22.4, CH_2], 5.35 (br. s, 2 H, CH), 5.62 (br. s, 2 H, CH), 6.76 [d, 2 H, J = 3.0 Hz, CH], 7.10 [d, 2 H, J = 3.0 Hz, CH], 7.25−7.62 (m, 10 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 162.29 [dd, J(RhP′) = 256 Hz, $J_{P'P}$ = 37 Hz], 63.89 [dd, J_{RhP} = 148 Hz, J(PP′) = 37 Hz].

[Rh(COD)(2)]CF_3SO_3 (5): The yellow compound **5** was prepared from $[Rh(COD)Cl_2]_2$ (0.070 g, 0.142 mmol) and the ligand (*S*)-**2** (0.154 g, 0.284 mmol) as described above for the compound **4**. Yield 80% (0.202 g, 0.227 mmol). $C_{42}H_{36}F_3O_6P_2RhS$ (890.6): calcd. C 56.64, H 4.07; found C 56.49, H 4.15. ^1H NMR ($CDCl_3$): δ = 4.30 [d, 2 H, $J_{P'H}$ = 21, CH_2], 5.30 (br. s, 2 H, CH), 5.59 (br. s, 1 H, CH), 6.76 [d, 2 H, J = 3 Hz, CH], 7.01−7.95 (m, 22 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 167 [dd, J(RhP′) = 260 Hz, $J_{P'P}$ = 41.3 Hz], 64.77 [dd, J_{RhP} = 149 Hz, J(PP′) = 41.3 Hz].

[$Rh(CO)_2$(1)Cl] (6) and [Rh(CO)(1)Cl] (7): To a stirred solution of $[Rh(CO)_2Cl]_2$ (0.080 g, 0.205 mmol) in hexane (30 mL) was added ligand **1** (0.247 g, 0.41 mmol). Immediately a yellow solid, containing both the products $[Rh(CO)_2$(**1**)Cl] and [Rh(CO)(**1**)Cl], precipitated. The solid was filtered, washed with hexane, and dried. Attempts to separate compounds **6** and **7** failed. Data for **7**: IR (KBr, Nujol): ν_{CO} = 2001 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.65 [s, 18 H, $C(CH_3)_3$], 3.27 (s, 6 H, OCH_3), 4.12 [d, 2 H, $J_{P'H}$ = 20 Hz, CH_2], 6.67 [d, 2 H, J = 3.0 Hz, CH], 7.05 (m, 2 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 163.76 [dd, J(RhP′) = 266.7 Hz, $J_{P'P}$ = 49.1], 84.5 [dd, J_{RhP} = 133.5 Hz, J(PP′) = 49.1 Hz].

[$Rh(CO)_2$(1)Cl] (6): Compound **6** was obtained by the following procedure: To a stirred solution of $[Rh(CO)_2Cl]_2$ (0.040 g, 0.103 mmol) in toluene (10 mL) was added dropwise a solution of **1** (0.124 g, 0.206 mmol) in the same solvent (2 mL). A yellow precipitate was deposited during the course of the addition. This was collected, washed with toluene (1 mL) and hexane, and then dried. Yield 87% (0.143 g, 0.179 mmol). $C_{37}H_{40}ClO_7P_2Rh$ (797.0): calcd. C 55.76, H 5.06, Cl 4.45; found C 55.69, H 5.10, Cl 4.39. IR (KBr, Nujol): ν_{CO} = 2033, 2072 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 1.49 [s, 18 H, $C(CH_3)_3$], 3.30 (s, 6 H, OCH_3), 4.24 [d, 2 H, J(PH) = 20 Hz, CH_2], 6.71 [d, 2 H, J = 3.0 Hz, CH], 7.09 [d, 2 H, J = 3.0 Hz, CH], 7.83−7.90 (m, 10 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 167.97 [dd, J(RhP′) = 325.9 Hz, $J_{P'P}$ = 53.1 Hz], 62.25 [dd, J_{RhP} = 195 Hz, J(PP′) = 53.1 Hz].

[$Rh(CO)_2$(2)Cl] (8) and [Rh(CO)(2)Cl] (9): A solution of ligand **2** (0.318 g, 0.6 mmol) in toluene (6 mL) was added dropwise to a stirred solution of $[Rh(CO)_2Cl]_2$ (0.120 g, 0.3 mmol) in hexane (30 mL). A yellow solid immediately precipitated. This was collected washed with toluene (1 × 1 mL) and hexane, and then dried. By IR and NMR spectroscopy the yellow solid was identified as $[Rh(CO)_2$(2)Cl] (**8**). Data of **8**: $C_{35}H_{24}ClO_5P_2Rh$ (724.8): calcd. C 57.99, H 3.34, Cl, 4.89; found C 57.78, H 3.29, Cl 4.93. IR (KBr, Nujol): ν_{CO} = 1995, 2064 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 4.24 [d, 2 H, $J_{P'H}$ = 21 Hz, CH_2], 7.65−7.95 (m, 22 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 177.34 [dd, J(RhP′) = 266.7 Hz, $J_{P'P}$ = 49.1 Hz], 61.27 [dd, J_{RhP} = 133 Hz, J(PP′) = 49.1 Hz]. Compound **9** was recovered, as a yellow powder, from the mother liquor by addition of hexane. Data of **9**: $C_{34}H_{24}ClO_4P_2Rh$ (708.9): calcd. C 58.60, H 3.47, Cl 5.09; found C 58.71, H 3.51; Cl 5.02. IR (KBr, Nujol): ν_{CO} = 2003 cm^{-1}. ^1H NMR ($CDCl_3$): δ = 4.20 [d, 2 H, $J_{P'H}$ = 21 Hz, CH_2], 7.62−7.94 (m, 22 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 170.75 [dd, J(RhP′) = 325 Hz, $J_{P'P}$ = 54.2 Hz], 84.2 [dd, J_{RhP} = 190 Hz, J(PP′) = 54.2 Hz].

[Rh(acac)(1)] (10): A stirred solution of $[Rh(acac)(CO)_2]$ (0.050 g, 0.194 mmol) in hexane (15 mL) was added dropwise to a solution of **1** (0.117 g, 0.194 mmol) in the same solvent (10 mL). During the addition, a colour change from yellow to orange was observed. Monitoring the reaction by IR spectroscopy, a gradual disappearance of starting ν_{CO} bands was observed. After ca. 1 h, the solvent was removed to give an orange solid. It was washed twice with hexane and vacuum-dried. Yield 85% (0.133 g, 0.165 mmol). $C_{40}H_{47}O_7P_2Rh$ (801.7): C 59.71, H 5.89; found C 60.03, H 5.94. ^1H NMR (C_6D_6): δ = 1.25 (s, 3 H, acac-CH_3), 1.39 [s, 18 H, $C(CH_3)_3$], 1.60 (s, 3 H, acac-CH_3), 3.29 (s, 6 H, OCH_3), 4.22 (d, 2 H, $J_{P'H}$ = 20 Hz, CH_2), 5.03 (s, 1 H, acac-H), 6.61 (d, 2 H, J = 3.0 Hz, CH), 6.82 (d, 2 H, J = 3.0 Hz, CH), 7.04−7.99 (m, 10 H, CH). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 168.1 [dd, J(RhP′) = 308 Hz, $J_{P'P}$ = 77 Hz], 78.8 [dd, J_{RhP} = 188 Hz, J(PP′) = 77 Hz].

[Rh(acac)(2)] (11): This compound was obtained by an analogous procedure to **10** as yellow solid starting from $[Rh(acac)(CO)_2]$ (0.080 g, 0.310 mmol) and **2** (0.164 g, 0.310 mmol). Yield 80% (0.182 g, 0.248 mmol). $C_{38}H_{31}O_5P_2Rh$ (732.5): C 62.31, H 4.27; found C 62.81, H 4.29. ^1H NMR (C_6D_6): δ = 1.60 (s, 3 H, acac-CH_3), 4.22 [d, 2 H, $J_{P'H}$ = 20 Hz, CH_2], 5.03 (s, 1 H, acac-H), 7.04−7.99 (m, 10 H, CH). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 168.1 [dd, J(RhP′) = 308 Hz, $J_{P'P}$ = 77 Hz], 78.8 [dd, J_{RhP} = 188 Hz, J(PP′) = 77 Hz].

[$Pd(1)Cl_2$] (12): Solid ligand **1** (0.094 g, 0.156 mmol) was added to a stirred solution of $[Pd(PhCN)_2Cl_2]$ (0.060 g, 0.156 mmol) in toluene (10 mL). The resulting solution was stirred for ca. 30 min during which a colour change from red-orange to pale yellow occurred. The solution was reduced in volume (5 mL), and upon addition of hexane, compound **12** separated as a yellow solid. This was removed by filtration, washed with hexane and vacuum-dried. Yield 88% (0.107 g, 0.137 mmol). $C_{35}H_{40}Cl_2O_5P_2Pd$ (779.9): C 53.90, H 5.17, Cl 9.09; found C 53.65, H 5.22, Cl 9.23. ^1H NMR ($CDCl_3$): δ = 1.39 [s, 18 H, $C(CH_3)_3$], 3.81 (s, 6 H, OCH_3), 4.60 [dd, 2 H, $J_{P'H}$ = 26 Hz, J(PH) = 1 Hz, CH_2], 6.71 [d, 2 H, J = 3.0 Hz, CH], 6.99 [d, 2 H, J = 3.0 Hz, CH], 7.55−7.90 (m, 10 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 138.2 [d, $J_{P'P}$ = 23.7 Hz], 74.88 [d, $J_{P'P}$ = 23.7 Hz].

[$Pd(2)Cl_2$] (13): This compound was obtained similarly to **12** as a yellow-orange solid by starting from $[Pd(PhCN)_2Cl_2]$ (0.070 g, 0.182 mmol) and ligand **2** (0.096 g, 0.182 mmol). Yield 83% (0.107 g, 0.151 mmol). $C_{33}H_{24}Cl_2O_3P_2Pd$ (707.8): C 56.00, H 3.42, Cl, 10.02; found C 56.15, H 3.46, Cl 10.16. ^1H NMR ($CDCl_3$): δ = 4.45 (m, 1 H, CH_2), 4.71 (m, 1 H, CH_2), 7.0−7.96 (m, 22 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 144.4 [d, $J_{P'P}$ = 25 Hz], 74.71 [d, $J_{P'P}$ = 25 Hz].

[$Pt(1)I_2$] (14): Solid ligand **1** (0.064 g, 0.107 mmol) was added to a stirred solution of $[Pt(COD)I_2]$ (0.060 g, 0.107 mmol) in toluene (10 mL). Upon addition of **1** a white solid precipitated. This was removed by filtration, washed with toluene and hexane, and then vacuum-dried. Yield 90% (0.101 g, 0.096 mmol). $C_{35}H_{40}I_2O_5P_2Pt$ (1051): C 39.98, H 3.83, I 24.14; found C 39.89, H 3.87, I 24.20. ^1H NMR ($CDCl_3$): δ = 1.37 [s, 18 H, $C(CH_3)_3$], 3.82 (s, 6 H, OCH_3), 4.48 [dd, 2 H, $J_{P'H}$ = 22 Hz, J(PH) = 1 Hz, CH_2], 6.73 [d, 2 H, J = 3.0 Hz, CH], 6.99 [d, 2 H, J = 3.0 Hz, CH], 7.65−7.99 (m, 10 H, CH). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 123 [s, J(PtP′) = 5682 Hz], 52.28 [d, J_{PtP} = 3180 Hz].

[$Pt(2)I_2$] (15): This compound was obtained similarly to **14** as a yellow-orange solid by starting from $[Pt(COD)I_2]$ (0.100 g,

0.178 mmol) and ligand **2** (0.095 g, 0.178 mmol).Yield 89% (0.155 g, 0.158 mmol). $C_{33}H_{24}I_2O_3P_2Pt$ (979.4): C 40.47, H 2.47, I 25.92; found C 40.52, H 2.49, I 25.85. ^{1}H NMR ($CDCl_3$): δ = 4.37 (m, 1 H, CH_2), 4.55 (m, 1 H, CH_2), 7.1−7.95 (m, 22 H, CH). ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 128.42 [s, J(PtP′) = 5621 Hz], 54.26 [d, J_{PtP} = 3180 Hz].

Crystal Structure Determination of [Pd(1)Cl$_2$]·CHCl$_3$ (12·CHCl$_3$): The intensity data of the complex was collected at room temperature with an Enraf Nonius CAD 4 single-crystal diffractometer using a graphite-monochromated Cu-K_α radiation and the θ/2θ scan technique. Crystallographic and experimental details for the structure are summarized in Table 2. A correction for absorption was made for the complex [maximum/minimum value for the transmission coefficient was 1.000/0.677].[10] The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares procedures (based on F_o^2) with anisotropic thermal parameters in the last cycles of refinement for all the non-hydrogen atoms. The hydrogen atoms were introduced into the geometrically calculated positions and refined *riding* on the corresponding parent atoms. In the final cycles of refinement a weighting scheme $w = 1/[\sigma^2F_o^2 + (0.1416\ P)^2]$, where $P = (F_o^2 + 2F_o^2)/3$, was used. All calculations were carried out with the DIGITAL AlphaStation 255 computers of the Centro di Studio per la Strutturistica Diffrattometrica del CNR, Parma, using the SHELX-97 systems of crystallographic computer programs.[11] Details of the crystal structure investigations are deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-166947. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Table 2. Crystal data and structure refinement for **12**·$CHCl_3$; $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$

Empirical formula	$C_{35}H_{40}Cl_2O_5P_2Pd{\cdot}CHCl_3$
Formula mass	899.28
Wavelength	1.54184 Å
Crystal system	triclinic
Space group	$P\bar{1}$
Unit cell dimensions	a = 13.474(4) Å
	b = 14.214(5) Å
	c = 10.424(3) Å
	α = 93.79(3)°
	β = 91.45(2)°
	γ = 97.27(3)°
V	1974.9(11) Å^3
Z	4
Density (calculated)	1.512 Mg/m^3
Absorption coefficient	79.95 cm^{-1}
F(000)	916
Crystal size	0.21 × 0.27 × 0.39 mm
θ range [°]	3−70
Index ranges	$-16 \le h \le 16$, $-17 \le k \le 17$, $0 \le l \le 12$
Reflections collected	7415
Independent reflections	7415 [R(int) = 0.0]
Observed reflections [$I > 2\sigma(I)$]	5953
Data/restraints/parameter	7415/0/451
Goodness-of-fit on F^2	1.067
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0567, $wR2$ = 0.1777
R indices (all data)	$R1$ = 0.0676, $wR2$ = 0.1969

Hydroformylation Procedure: The air was evacuated from a 30-mL stainless steel autoclave and a benzene solution of [Rh(acac)(CO)$_2$], the ligand and the olefin were introduced by suction. The vessel was pressurised with CO/H$_2$ (1:1) at the required pressure at room temperature and thermostated. The conversion and the composition of the reaction products were determined by GLC with a Carlo Erba HRGC 5160 Mega Series apparatus (split/splitless injector, MEGA OV1 25-m column, film thickness 2 μm, carrier gas He, flame ionization detector). The enantiomeric excess was determined by the shift reagent Eu(hfc)$_3$.[12]

2,5-Bis(di-*tert*-butylhydroxysilyl)furan as a Host Molecule for Potassium Fluoride, H_2O, NH_3 and $MeNH_2$

Uwe Klingebiel,*[a] Peter Neugebauer,[a] Ilka Müller,[a] Mathias Noltemeyer,[a] and Isabel Usón[a]

Keywords: Silicon / Furan / Host-guest complexes / Structure elucidation

2,5-Bis(di-*tert*-butylfluorosilyl)furan reacts with potassium hydroxide in a 1:2 molar ratio to give 2,5-bis(di-*tert*-butylhydroxysilyl)furan, $O(CRCH)_2$ [R = $SiOH(CMe_3)_2$ (**1**)]. Compound **1** is very selective in its adduct formation and forms host-guest complexes in the presence of KF [**1**·1/2KF (**2**)], H_2O [**1**·H_2O (**3**)], NH_3 [**1**·NH_3 (**4**)] and $MeNH_2$ [**1**·2$MeNH_2$ (**5**)]. The host-guest complexes are stable at room temperature. Compound **4** is the first neutral ammonia cage that is stable up to 100 °C. The crystal structures of **2**, **3**, **4** and **5** have been determined.

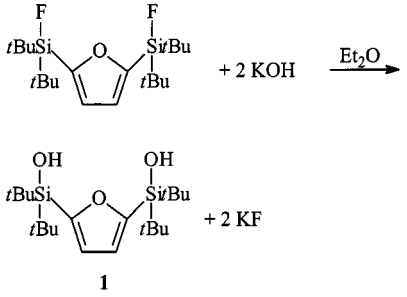
Introduction

Heterocycles such as furan undergo electrophilic aromatic substitution reactions very readily and regioselectively, with the 2-position being more reactive than the 3-position. On particular such reaction is metallation, particularly lithiation of a C−H group next to the oxygen atom. These lithium compounds are very reactive and combine with electrophiles such as fluorosilanes.[1] Recently, 2,5-bis(di-*tert*-butylfluorosilyl)furan was obtained from the reaction of dilithiated furan and $F_2Si(CMe_3)_2$ in a 1:2 molar ratio.[1] Fluorosilyl compounds are, like other halosilanes, excellent precursors for the synthesis of silylamines or silanols.[2] In view of the high acidity and the relatively high basicity of silanols[2] is to be expected that they will form strong hydrogen bonds both with themselves[2−5] and with other suitable species.[2] The association of silanols in solution has been discussed previously and a wide range of hydrogen-bonded structures has been found in the solid state.[2−5] The crystal structure of triphenylsilanol, for example, has 16 molecules in the unit cell, arranged as two sets of two independent tetrameric hydrogen-bonded units.[2,6] This tetrameric structure is retained in the adduct with ethanol, $(Ph_3SiOH)_4$·EtOH, which has a cyclic network of hydrogen bonds. Silanol is very selective in its adduct formation and also forms adducts with MeOH, DMSO and ethers.[2,7,8] Host-guest complexes between silanols and many organic liquids and solids are nicely summarized in ref. 2.

In this paper we describe the preparation of 2,5-bis(di-*tert*-butylhydroxysilyl)furan and its application as a host molecule for the gases NH_3 and $MeNH_2$, the liquid H_2O and the salt KF.

Results and Discussion

2,5-Bis(di-*tert*-butylfluorosilyl)furan[1] reacts with KOH in a 1:2 molar ratio to give 2,5-bis(di-*tert*-butylhydroxysilyl)furan.[1]



1

The reaction progress can be followed by ^{19}F NMR spectroscopy. Unreacted KF was separated by filtration and condensation of **1** into a cooled trap in vacuo (10^{-2} mbar) above 100 °C.

Attempts to crystallize **1** from the reaction mixture led to the isolation of the host-guest complex **2**, where two molecules of **1** coordinate one of KF.

Heating **2** in vacuo (10^{-2} mbar) above 100 °C leads to the condensation of **1** into the cold trap. The reaction is not reversible: we didn't succeed in preparing **2** from **1** and KF, perhaps because of the insolubility of KF in organic solvents.

2

Crystal Structure of 2

Compound **2** crystallizes in the monoclinic space group $P2_1/c$ with one molecule of **1** and half a molecule of potassium fluoride in the asymmetric unit i.e. the potassium atom is coordinated by two disilanol molecules. In this dimer, the coordination sphere of the potassium is quite unusual: six oxygen atoms and one fluorine atom coordinate to the cation to form a distorted hexagonal pyramid with the fluorine atom, which forms hydrogen bonds with two hydroxyl groups, at the axial position (Figure 1).

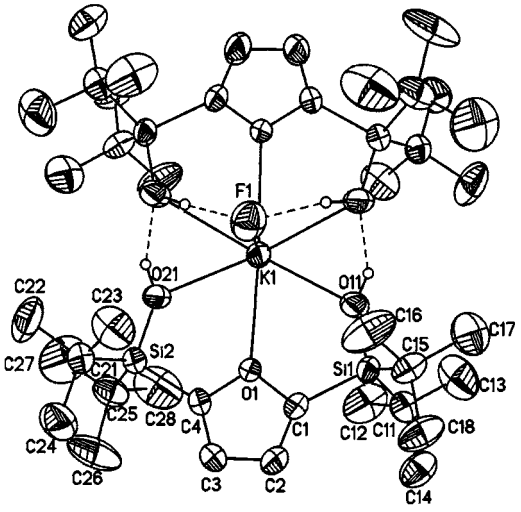

Figure 1. Structure of **2**

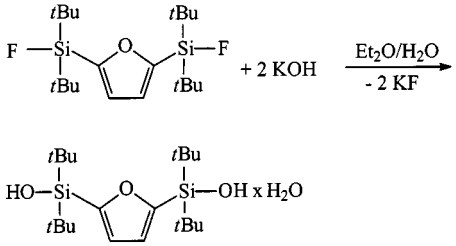
The potassium atom lies out of the base of the pyramid. This could be a result of the limited space in the dimer which does not allow the potassium and the fluoride atom to lie in the plane of the hydroxyl group. Another reason for the special arrangement of the potassium atom above the pyramid base could be the conflict between the attempts of the fluorine atom to build up hydrogen bonds and the minimum distance between the fluorine and potassium atoms.

As all oxygen atoms of the disilanol are coordinated to the potassium, the Si(1)−O(11) [Si(2)−O(21)] and the C(1)−O(1) [C(4)−O(1)] bonds are eclipsed. This induces stronger steric interactions between the methylene group C(2) and the *tert*-butyl substituents so that the Si(1)−C(1) and the Si(2)−C(4) bonds are lengthened.

Attempts to accelerate the formation of **1** by addition of water or to dissolve KF in order to purify **1** led to the formation of the host-guest complex **3**. Warming **3** in vacuo (10^{-2} mbar) up to 130 °C leads to the loss of water and reisolation of **1**. This process is reversible.



3

Crystal Structure of 3

In compound **3**, which crystallizes in the orthorhombic space group *F*dd2, one water molecule per disilanol molecule is incorporated in the crystal. One 2,5-bis(di-*tert*-butylsilyl)furan molecule and one water molecule form the asymmetric unit.

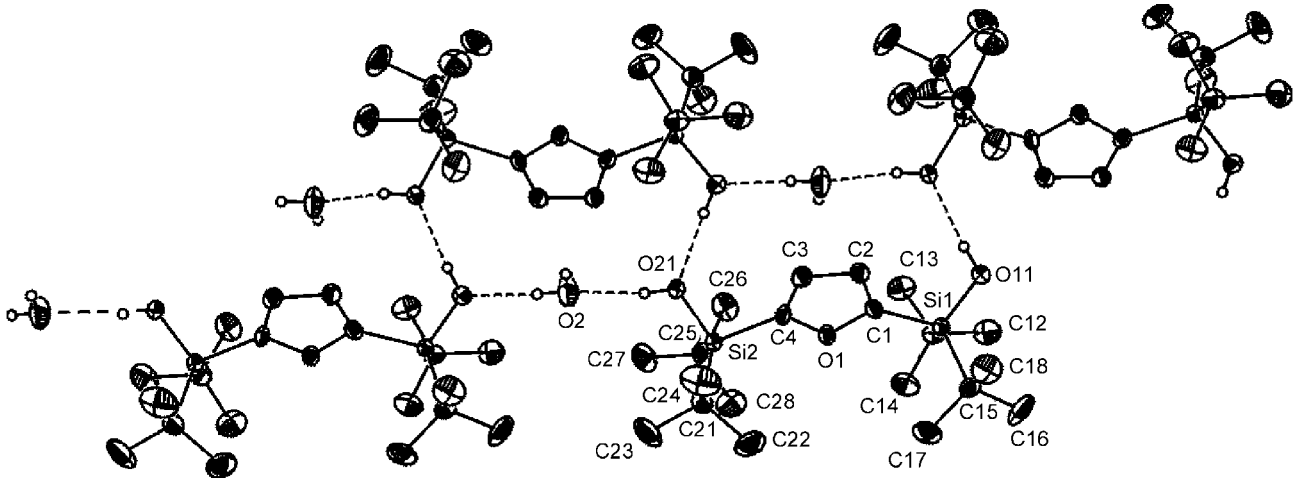


Figure 2. Structure of **3**

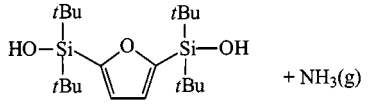
The disilanol molecules are arranged in zig-zag chains with hydrogen bonds between the hydroxyl groups. In these chains, a water molecule connects a monomer N, with monomer (N + 2), acting once as a hydrogen donor and once as an acceptor (Figure 2). One of the water hydrogen atoms is not involved in hydrogen bonding.

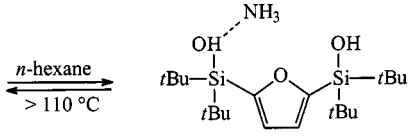
In order to minimize steric constraints, the distance between the *tert*-butyl groups at the silicon and the methylene groups of the furan is maximized. As a result, the Si(1)−O(11) [Si(2)−C(21)] and the C(1)−C(2) [C(4)−C(3)] bonds are arranged eclipsed. Due to this conformation, the oxygen atom that is part of the furan ring lies on the outer side of the zig-zag chain, and it does not form hydrogen bonds because of the shielding effect of the *tert*-butyl groups. In this way, the chains form tubes along the crystallographic *c*-axis with the hydrophobic groups on the outside and hydrophilic ones inside.

Ammonia and amines are well-known as ligands in complexes, where they generally undergo a formal Lewis acid-base interaction, with the nitrogen bound to the central metal atom or ion through its free electron pair.[10] The inclusion of gas molecules in salts or clathrates prepared under gas pressure or at low temperature has been reported,[11] although only one inclusion compound of dihydroxybinaphthyl containing ammonia and methanol as guest molecules is known.[12]

Having succeeded in isolating host-guest complexes of the bis(hydroxysilyl)furan **1** with the KF and water, we considered the possibility of the inclusion of gaseous amines such as NH_3 and $MeNH_2$. A solution of **1** in *n*-hexane was saturated with ammonia or methylamine at room temperature to give the host-guest compounds **4** or **5**, respectively. Compound **4** was obtained as colourless prisms with a melting point of 90 °C. TG and DTA studies show that **4** loses NH_3 above its melting point (90 °C), in two steps (at 100 °C and 110 °C), with reconversion of **1**.



1



4

Crystal Structure of 4

Compound **4** crystallizes in the monoclinic space group $P2_1/c$ with one disilanol molecule and two ammonia molecules in the asymmetric unit. The hydroxyl groups of the disilanol monomers form hydrogen bonds with each other and with the ammonia molecules. Only two of the hydrogen atoms of each ammonia molecule participate in this hydrogen bonding (Figure 3). As in compound **2**, the Si1−O11 (Si2−O21) and the C1−O1 (C4−O1) bonds are eclipsed thus permitting formation of the dimer and causing the lengthening of the Si1−C1 (Si2−C4) bond.

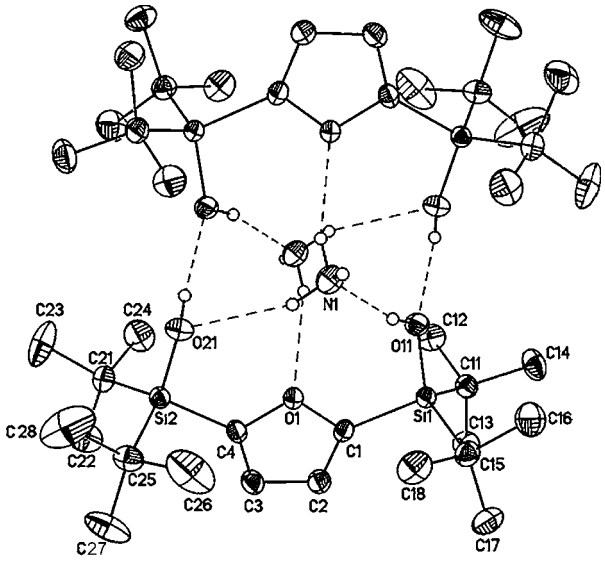


Figure 3. Structure of **4**

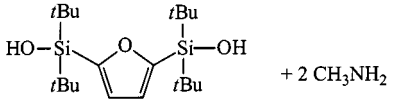
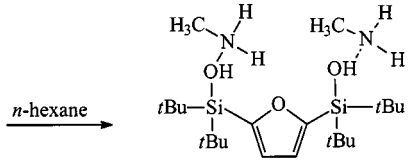
The host-guest complex **5**, obtained at room temperature, incorporates $MeNH_2$ in a molar ratio 1:2. It is far less stable than **4** and loses $MeNH_2$ when isolated from solution at room temperature.



1



5

Crystal Structure of 5

Crystals of compound **5**, which were not stable out of the mother liquor at room temperature, belong to the triclinic space group $P\bar{1}$. They contain one 2,5-bis(di-*tert*-butylsilyl)-furan molecule and two methylamine molecules in the asymmetric unit (Figure). The disilanol monomers are connected to each other and the guest molecules through hydrogen bonds, forming a double chain. One of the methylamine molecules [$CH_3-N(1)H_2$] in the asymmetric unit connects opposite disilanol molecules through hydrogen bonds. The other one [$CH_3-N(2)H_2$] establishes these same contacts and an additional hydrogen bond to the next disilanol molecule along the chain. The hydrogen bonds

formed by the first methylamine are longer than those formed by the4 ammonia molecule in compound **4**. The second methylamine molecule interacts more strongly with the disilanol than with the ammonia molecule (Table 2). The instability of the crystals of compound **5** could be a consequence of the formation of only two hydrogen bonds by one of the methylamine moieties instead of the three that are possible.

As in compound **2**, the Si(1)−O(11) and Si(2)−O(21) bonds are eclipsed to the C(1)−C(2) and C(4)−C(3) bonds, respectively, to avoid steric hindrance between the furan methylene groups and the *tert*-butyl groups. The difference between the Si(1)−O(11) and Si(2)−O(21) bond lengths is 0.01 Å, whereas the same bonds in compounds **2**−**4** are equal within the experimental error. As the oxygen atom O(11) is part of three hydrogen bonds and O(21) partici-

pates only in two hydrogen bonds, the Si(2)−O(21) bond is shorter than the corresponding Si(1)−O(11) bond.

Comparison of the Crystal structures of 2, 3, 4, and 5

The crystallographic data of compounds **2** to **5** are summarized in Table 1 and selected bond lengths and angles are given in Table 2.

The X-ray analyses of **2**, **3**, **4**, and **5** show that the arrangement of the 2,5-bis(di-*tert*-butylhydroxysilyl)furan, which is the central structural element of all four structures, is mainly influenced by the guest molecule. In the case of compounds **2** and **4** the molecules form dimers that are held together by hydrogen bonds. Additionally, ionic interactions occur between potassium and the oxygen atoms of the disilanol in compound **2**. Again, hydrogen bonds between the guest molecules and the disilanol connect the monomers in compounds **3** and **5** to form long chains. Due to the arrangement of the silane molecules either as chains or as dimers in the crystals, the conformations of the silanol groups are different depending on the guest molecule.

Nevertheless, the bond lengths and angles of the disilanol molecules are very similar. The angles between the *tert*-butyl substituents at the silicon atoms are not tetrahedral but about 118° (**2:**118.34°; **3:** 116.88°; **4:** 118.41°; **5:** 116.33°) in all four structures to minimize steric hindrance. The geometry of the furan ring in these structures is identical within experimental error. As the four structures are not isostructural and the fixation of the different guest molecules is unique. Interatomic distances concerning hydrogen bonds between the monomers and guest molecules of **2** to **5** are given in Table 3.

Table 3. Interatomic distances concerning hydrogen bonds between the monomers and the guest molecules of compounds **2** to **5**

Experimental Section

All experiments were performed under N_2. The NMR spectra were recorded in $CDCl_3$ with $SiMe_4$ as internal references. The mass spectrum of **1** was obtained with a Finnigan MAT 8200.

2,5-Bis(di-*tert*-butylhydroxysilyl)furan (1): 2,5-Bis(di-*tert*-butylfluorosilyl)furan (3.9 g, 0.01 mol) was added to a suspension of KOH (1.1 g, 0.02 mol) in Et_2O (200 mL) and the resulting mixture was stirred for 24 h. Separation of KF by filtration and condensation of the raw product into a cooled trap in vacuo (10^{-2} mbar) gave **1**. Yield: 98% (3.8 g), m.p. 95 °C. ^{1}H NMR ($CDCl_3$): δ = 1.04 (s, 36 H, CH_3), 1.63 (br. s, 2 H, OH), 6.78 (s, 2 H, 3-H, 4-H). ^{13}C NMR: δ = 20.00 [s, $C(CH_3)_3$], 27.29 [s, $C(CH_3)_3$], 121.16 (s, 3-H, 4-C), 161.0 (s, 2-C, 5-C). ^{29}Si NMR: δ = 1.08 (s). MS (EI): *m*/*z* (%) = 384 (15) $[M]^+$, 327 (100) $[M - C_4H_9]^+$. $C_{20}H_{40}O_3Si_2$ (384.70): calcd. C 62.96, H 10.48; found C 63.15, H 10.64.

2,5-Bis(di-*tert*-butylhydroxysilyl)furan Potassium Fluoride Adduct (2): The synthesis of **2** was performed analogously to the synthesis of **1**. Compound **2** crystallized out of the reaction mixture at room

temperature. Yield: 35% (1.4 g), m.p. > 260 °C (decomposition). $C_{40}H_{80}FKOSi_4$ (827.51): calcd. C 58.54, H 9.74; found C 59.02, H 10.05.

2,5-Bis(di-*tert*-butylhydroxysilyl)furan-hydrate (3): The synthesis of **3** was performed analogously to the synthesis of **2** in aqueous KOH solvent (5% H_2O in Et_2O). Compound **3** crystallized from the reaction solvent. Yield: 61% (2.5 g), m.p. 90 °C. $C_{20}H_{42}O_2Si_2$ (402.72): calcd. C 61.15, H 10.51; found C 61.02, H 10.38.

2,5-Bis(di-*tert*-butylhydroxysilyl)furan-ammoniate (4): A solution of **1** (1.9 g, 0.005 mol) in *n*-hexane (150 mL) was saturated with ammonia. Compound **4** crystallized as colourless prisms from the reaction mixture. Yield: 65% (2.6 g), m.p. 90 °C. $C_{20}H_{43}NO_3Si_2$ (401.73): calcd. C 60.29, H 10.79; found C 60.51, H 11.02.

2,5-Bis(di-*tert*-butylbutylhydroxysilyl)furan-methylamine (5): The synthesis of **5** was performed similarly to the synthesis of **4**, with $MeNH_2$ instead of NH_3. Yield: 20% (0.9 g). $C_{22}H_{50}N_2O_3Si_2$ (446.82): calcd. 59.14, H 11.28; found C 58.85, H 11.01.

X-ray Crystallographic Study: Crystals were mounted on a glass fibre in a rapidly cooled perfluoropolyether.[12] Data for compounds **3** and **4** were collected at 150(2) K, and data for compound **2** were collected at 210(2) K. The diffraction data of compounds **3** and **4** were collected on a Stoe AED2 four circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å).

The diffraction data of compound **5** were collected on a Stoe−Siemens−Huber four-circle diffractometer coupled to a Siemens CCD area-detector at 133(2) K, with graphite-monochromated Mo-K_α radiation. The small, air-sensitive, plate-shaped crystals of **5** showed weaker diffraction than those of compounds **2**−**4**. This accounts for the somewhat higher values of the *R* factors obtained.

The structures were solved by direct methods using SHELXS-97[14] and refined against F^2 on all data by full-matrix least-squares with SHELXL-97.[15] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms on the methyl groups of the *tert*-butyl ligands and the hydrogen atoms on the methylene groups of the furan ring were included in the model at geometrically calculated positions and refined using a riding model. The positions of the hydrogen atoms of the hydroxyl groups were located in the difference electron density map and the O−H bond lengths were restrained to be about 0.84 Å for compounds **3**, **4** and **5** and about 0.83 Å for compound **2**.

The structure of compound **3** is racemically twinned in the space group *Fdd*2.

In compound **2**, the position of the host molecule KF is only half occupied. Because of that the potassium fluoride molecule in the dimer is allowed to occupy one of two symmetry-related positions. As the formation of the hydrogen bonds depends on the orientation of the KF in the dimer, two half-occupied positions for the hydrogen atoms were refined as described above with an occupancy of 50%.

The unusual coordination sphere of the potassium atom (coordinated to the disilanol molecule and the fluorine atom, with the potassium above the base of a hexagonal pyramid) indicated the presence of a solvent molecule coordinated to the cation. However, residual electron density was not found near the cation and the packing of the dimers in the crystal does not allow enough space for additional ligands at the potassium.

CCDC-166872 (**2**), CCDC-166871 (**3**), CCDC-166873 (**4**) and CCDC-166874 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Interactions of Remote Alkyl Groups with Lanthanide Metal Centers: Synthesis, Characterization and Ligand Redistribution Reactions of Heterobimetallic Species Containing Trialkylaluminum Fragments

Garth R. Giesbrecht,[a] John C. Gordon,*[b] John T. Brady,[b] David L. Clark,[c] D. Webster Keogh,[b] Ryszard Michalczyk,[d] Brian L. Scott,[b] and John G. Watkin[b]

Keywords: Lanthanides / Samarium / Aluminum / O ligands / Agostic interactions

The reaction of $[Ln(OAr)_3]_2$ with four equivalents of trialkylaluminum leads to the formation of the bis-trialkylaluminum adducts $(ArO)Ln[(\mu\text{-}OAr)(\mu\text{-}R)AlR_2]_2$ [Ln = La, R = Me (**1**); Ln = La, R = Et (**3**); Ln = Sm, R = Et (**4**)]. The X-ray crystal structure of **1** reveals short La–C(bridging) distances of 2.800(5) and 2.759(5) Å. A reduced $^1J_{C\text{-}H}$ coupling constant of 110 Hz and a low energy ν(C–H) stretch in the solution and solid state IR spectra are consistent with a strong agostic La···H–C interaction in solution. Crystal data for **1**: a = 11.708(2) Å; b = 18.416(4) Å; c = 20.949(4) Å; α = 90°; β = 90°; γ = 90°; V = 4516.8(15) Å^3; Z = 4; $R1$ = 4.69%. The solid-state structure of the samarium ethyl derivative **4** reveals close contacts of 2.627(4) and 2.649(4) Å between the samarium center and the methylene carbons of the triethylaluminum groups. The room temperature ^{13}C NMR spectrum of **4** exhibits a $^1J_{C\text{-}H}$ coupling constant of 102 Hz; additionally, the fluxional process that exchanges methyl groups in **1** and **2** is slow enough on the NMR time scale to allow distinct methylene groups in **4** to be observed. Crystal data for **4**: a = 19.318(1) Å; b = 20.150(1) Å; c = 26.280(1) Å; α = 90°; β = 90°; γ = 90°; V = 10229.8(9) Å^3; Z = 8; $R1$ = 3.53%. Thermolysis of **1**–**4** results in ligand redistribution to form $[R_2Al(OAr)]_2$ [R = Me, Et (**5**)] and other unidentified species. Crystal data for **5**: a = 9.496(4) Å; b = 10.183(4) Å; c = 18.794(7) Å; α = 90.06(1)°; β = 92.394(7)°; γ = 114.976(6)°; V = 1645.6(11) Å^3; Z = 2; $R1$ = 10.13%.

Introduction

Aryloxide groups have proven to be suitable ancillary ligands in organolanthanide chemistry due in part to their ability to participate in π-bonding with electron-deficient metal centers.[1−3] Additionally, the coordination number and degree of oligomerization may be controlled through the use of bulky substituents on the arene ring. For example, use of the sterically demanding aryloxide ligand 2,6-di-*tert*-butyl-4-MeC_6H_2 leads to the formation of mononuclear complexes $Ln(OAr)_3$ for the entire lanthanide series.[4] Although these complexes are three-coordinate, they are essentially inert, with their reaction chemistry being limited to adduct formation with Lewis bases [i.e. $Ln(OAr)_3L$].[5] Previously, we demonstrated that the smaller 2,6-diisopropylphenoxide ligand bridges between metal centers in an unusual η^6-bridging mode to alleviate the steric unsaturation at the metal center.[1] Addition of a Lewis base to these complexes (e.g. THF, NH_3) leads to the formation of five-, six- or seven-coordinate species,[2] illustrating the large effect that a relatively small change in the steric bulk of the ancillary ligand may have upon a simple process such as adduct formation.

Recent studies of lanthanide alkoxide and aryloxide complexes have revealed that heterobimetallic complexes can often be obtained by utilizing the tendency of $^-$OR and $^-$OAr ligands to bridge two different metals.[6−10] Heterobimetallic complexes of the lanthanide metals (particularly when aluminum is one component) are of interest with respect to a) catalysis[11−13] and b) in the production of mixed-metal solid-state materials (e.g. lanthanide-doped ceramics) which may exhibit unusual and interesting physical properties.[14−18] In light of these reports, we were interested in exploring the reaction of these π-arene-bridged dimers with Lewis acids such as $AlMe_3$. Recently, we reported the solid state and solution properties of the mixed-metal complex $(ArO)Sm[(\mu\text{-}OAr)(\mu\text{-}Me)AlMe_2]_2$ (Ar = 2,6-*i*$Pr_2C_6H_3$) which maintains a strong agostic Sm···H−C interaction

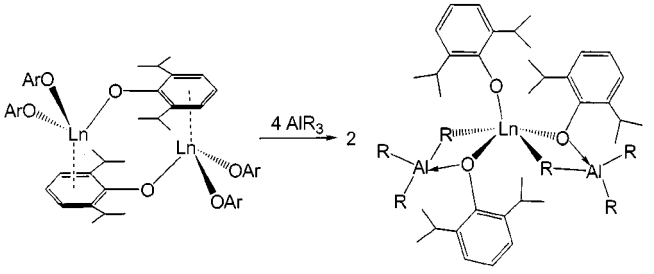
in solution.[19] However, the paramagnetism of trivalent samarium precluded a detailed study of this compound by ^1H and ^{13}C NMR spectroscopy. Thus, we sought to synthesize the diamagnetic lanthanum derivative in order to further investigate the nature of any fluxional processes that may be occurring in solution. Additionally, we were interested in the effect of introducing a larger Lewis acid into the coordination sphere (i.e. $AlEt_3$). Here we describe the synthesis and characterization of heterobimetallic complexes of lanthanum and samarium, and suggest that the solid-state structures of these agostic complexes may be viewed as potential "snapshots" of the intermediates present in the alkylation reaction of a lanthanide metal with trialkylaluminum reagents.

Results and Discussion

The addition of four equivalents of trimethyl- or triethylaluminum to a toluene solution of the π-arene bridged dimers $[Ln(OAr)_3]_2$ (Ar = 2,6-*i*$Pr_2C_6H_3$) (Ln = La, Sm)[1,2] yields the bis-trialkylaluminum adducts (ArO)Ln[(μ-OAr)(μ-R)$AlR_2]_2$ [Ln = La, R = Me (**1**); Ln = Sm, R = Me (**2**); Ln = La, R = Et (**3**); Ln = Sm, R = Et (**4**)] [Equation (1)].



(1)

The trimethylaluminum adducts were isolated as colorless (La) and orange (Sm) solids in good yield. Complexes **1**−**4** are soluble in common organic solvents such as hexane and toluene. A measure of the crowding around the lanthanide center is given by the complexation of only two molecules of $AlMe_3$ or $AlEt_3$ per metal. In the reaction of $[Ln(OAr)_3]_2$ with six equivalents of AlR_3 only the bis-aluminum complex was isolated {and not Ln[(μ-OAr)(μ-R)-$AlR_2]_3$ as is observed for smaller alkoxide groups such as O*t*Bu (M = Y, Pr, Nd).[8,9]}

Single crystals of (ArO)La[(μ-OAr)(μ-Me)$AlMe_2]_2$ (**1**) were obtained by slow evaporation of a saturated toluene solution. An ORTEP view of the molecular structure is given in Figure 1; selected bond lengths and angles are given in Table 1. Complete details of the structural analyses of compounds **1**, **4** and $[Et_2Al(OAr)]_2$ (**5**) are presented in Table 4.

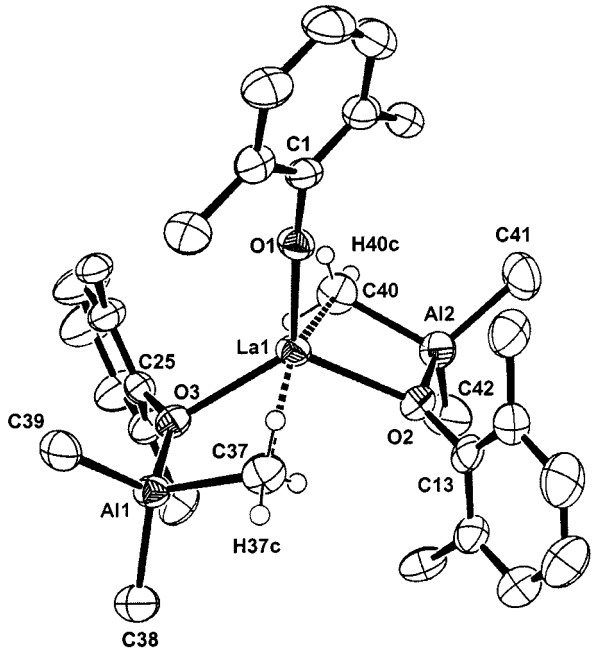


Figure 1. ORTEP view of (ArO)La[(μ-OAr)(μ-Me)$AlMe_2]_2$ (**1**) drawn with 30% probability ellipsoids; isopropyl methyl groups have been omitted for clarity

The structure of **1** is isomorphous with that previously reported for the samarium derivative **2**. Both trimethylaluminum adducts crystallize in the orthorhombic space group $P2_12_12_1$ with equivalent unit cell parameters. As found for **2**, the geometry about the metal center is square-based pyramidal, with a terminal aryloxide ligand occupying the apical site and two [(μ-OAr)(μ-Me)$AlMe_2$] units in the basal plane of the molecule. The La−C distances of 2.800(5) and 2.759(5) Å are slightly longer than the Sm−C distances observed in **2** [2.620(5) and 2.632(5) Å] and reflect both the larger size of lanthanum and a weaker agostic Ln···H−C interaction.[20] By comparison, these bond lengths are longer than the La−C σ bonds in La[$CH(SiMe_3)_2]_3$

[2.515(9) Å][21] or (η^5-C_5Me_5)La[$CH(SiMe_3)_2$]$_2$ [2.537(5) and 2.588(4) Å][22] but similar to the Nd−C(bridging) distance reported in Nd[(μ-O*t*Bu)(μ-Me)$AlMe_2$]$_3$ (2.784 (11) Å].[9] A feature common to the crystal structures of **1**, **2** and **4** is the presence of two distinct types of lanthanide-oxygen bonds; the two longer bonds [2.387(3) and 2.367(3) Å in **1**] are a result of the interaction of the AlR_3 groups with the phenoxide oxygen atoms (i.e. there is a competition between two Lewis acid centers for the oxygen electron density). The third unique phenoxide ligand "compensates" for the electron-deficient nature of the lanthanide center by engaging in O→M π-bonding, as evidenced by the very short Ln−O distance [2.136(3) Å] and the almost linear La−O−C angle [175.2(3)°]. The hydrogen atoms on C37 and C40 were located and refined and define a trigonal bipyramidal geometry for these carbon atoms. The lanthanum center and H37c and H40c occupy the axial positions [La1−C37−H37c = 172(3)°, La1−C40−H40c = 177(4)°] with the aluminum center and the remaining hydrogen atoms in the equatorial positions. As was found for **2**, the hydrogen atoms do not point directly towards the lanthanide center, which supports a β-Al−C···La type of interaction in which electron density from the aluminum-carbon bond is donated to the metal center.[23,24] Consistent with this postulate is the observation of elongated $Al-C_{agostic}$ bonds [2.040(5) and 2.053(6) Å]; these bond lengths are about 0.1 Å longer than the remaining Al−C bonds in **1** [1.969(5) to 1.964(6) Å]. Overall, the metrical parameters of **1** are similar to those determined for the samarium derivative **2**, with the significant features of an agostic Ln···H−C interaction being present in both.

Orange crystals of (ArO)Sm[(μ-OAr)(μ-Et)$AlEt_2$]$_2$ (**4**) that were amenable to X-ray crystal diffraction were obtained by slow evaporation of a saturated hexamethydisiloxane solution. The molecular structure of **4** is shown in Figure 2 with a list of important bond lengths and angles available in Table 2.

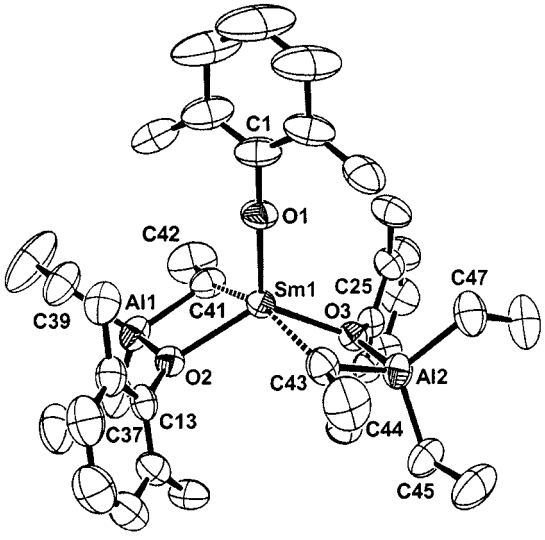

Figure 2. ORTEP view of (ArO)Sm[(μ-OAr)(μ-Et)$AlEt_2$]$_2$ (**4**) drawn with 30% probability ellipsoids; isopropyl methyl groups have been omitted for clarity

Table 2. Selected bond lengths (Å) and angles (deg) for (ArO)Sm[(μ−OAr)(μ-Et)$AlEt_2$]$_2$ (**4**)

Sm1−O1	2.060(2)	Sm1−O2	2.292(2)

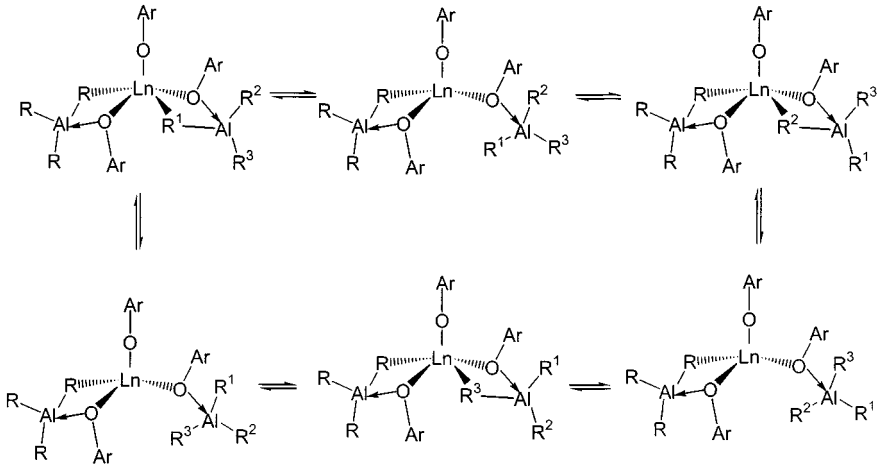
O3−Sm1−C43	71.80(10)	C41−Sm1−C43	160.14(12)
Sm1−O1−C1	178.0(2)	Sm1−O2−C13	124.81(17)
Sm1−O3−C25	126.12(17)	Sm1−O2−Al1	103.60(9)
Sm1−O3−Al2	103.88(10)	Sm1−C41−C42	166.8(3)
Sm1−C43−C44	165.9(3)		

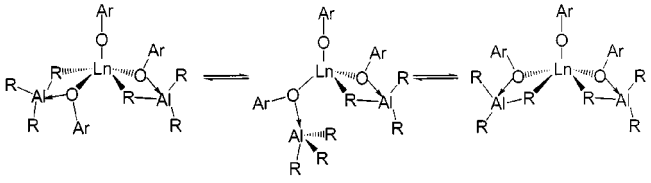
The structure of **4** is similar to that determined for **1** and **2**; however, in the case of **4**, the samarium center engages in agostic interactions with the methylene carbons of the triethylaluminum groups. The $Sm-C_{methylene}$ distances of 2.627(4) and 2.649(4) Å are similar to the Sm−C bond lengths to the bridging alkyl groups in **2** [2.620(5) and 2.632(5) Å]. The geometry about the agostic carbon atoms (C41, C43) is best described as trigonal bipyramidal, as are the agostic methyl carbons in **1** and **2**. In this case, the Sm−C−C bond angles are 166.8(3)° and 165.9(3)° (Sm1−C41−C42 and Sm1−C43−C44, respectively). The bond lengths and angles determined for the triethylaluminum derivative **4** are virtually identical to those observed for the trimethylaluminum analogue **2**. From this metric data, one would conclude that the substitution of a triethylaluminum group for a trimethylaluminum moiety has a negligible effect on steric congestion about the metal center. While the use of triethylaluminum does not result in longer $Sm-C_{agostic}$ bonds, the effect of using a larger Lewis acid on ligand dynamics in these complexes can be directly observed by ^{1}H NMR spectroscopy (vide supra).

We previously reported the ^{1}H and ^{13}C NMR spectra of (ArO)Sm[(μ-OAr)(μ-Me)$AlMe_2$]$_2$ (**2**); although the spectra were broadened by fluxional processes and the paramagnetism of Sm^{III}, we were able to extract a $^1J_{C\text{-}H}$ coupling constant of 106 Hz for the agostic methyl groups. Lowering the temperature to −90 °C did not result in decoalescence into separate methyl resonances as would be expected for a static structure. Thus, the coupling constant of 106 Hz may be viewed as an average of agostic and nonagostic coupling constants, indicating that the true $^1J_{C\text{-}H}$ coupling determined for the agostic methyl group would be significantly lower. This suggests a strong "classical" Sm···H−C agostic interaction, in which electron density from the C−H bond is donated to the electrophilic metal center.[25,26] This is supported by the infrared spectrum of **2**, which shows a weak intensity ν(C−H) stretch in the solid state and in solution (2728 cm^{-1}). It is possible that a number of different fluxional processes may give rise to the single aluminum-methyl

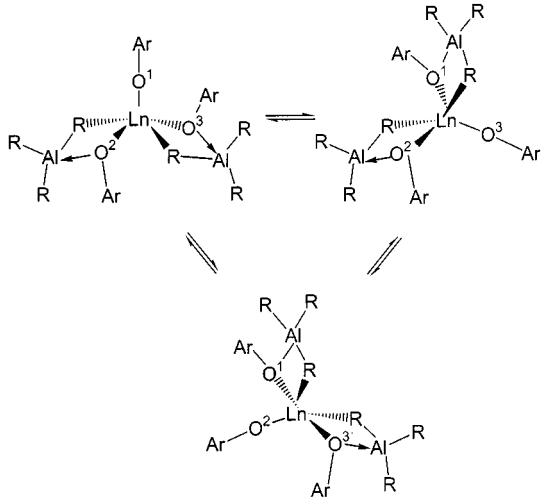


Scheme 1

resonance observed in the variable temperature NMR spectra of **2**: a) rotation about the O−Al bond may serve to average the three aluminum-methyl groups (Scheme 1), b) the trimethylaluminum units may remain fixed to their respective oxygen atoms, but flip between sides of the molecule, roughly defined by the three oxygens (Scheme 2), and c) the two trialkylaluminum moieties may rotate between the three oxygen sites (Scheme 3). In order to potentially distinguish between these three processes, we synthesized the diamagnetic lanthanum analogue in the hope of obtaining spectra that were not broadened by the presence of a paramagnetic metal center.



Scheme 2



Scheme 3

The ambient temperature ^{1}H NMR spectrum of **1** exhibits a single sharp resonance for the aluminum-methyl groups ($\delta = -0.31$) consistent with rapid bridge-terminal exchange at room temperature (Scheme 1). Lowering the temperature to −90 °C ([D_8]toluene) causes a broadening of the resonance, but decoalescence into separate methyl signals was not observed. The isopropyl methine protons appear as septets in a 2:1 ratio at all temperatures ($\delta = 3.49$ and 3.36). This is consistent with a solution structure that retains the integrity of the aluminum-oxygen bonds at all temperatures, i.e. the trimethylaluminum groups do not exchange between all three aryloxides since this would result in an averaging of the methine proton signals into a single septet (Scheme 3). However, the observation of two methine signals does not allow one to assess whether the fluxional process detailed in Scheme 2 makes a significant contribution to the averaging of the aluminum methyl resonances in solution. In the solid state structure outlined in Figure 1, the four methine protons on the aryloxide ligands associated with the two coordinated trialkylaluminum groups are rendered equivalent both by symmetry (C_2) and by free rotation about the O−C_{ipso} bond; additionally, the two methine protons on the remaining aryloxide ligand are equivalent by symmetry. We note that the operation of a fluxional process such as that described in Scheme 2 would also result in the observation of two methine peaks in a 2:1 ratio, and therefore this piece of data alone does not allow us to determine whether the processes in Scheme 1, Scheme 2, or both, are operating. However, a study of the isopropyl group methyl resonances does allow a distinction to be made. The isopropyl methyl groups in **1** give rise to two doublets in a 2:1 ratio ($\delta = 1.29$ and 1.21); this is consistent with the fluxional process in Scheme 2 being operative at room temperature. Since the isopropyl methyl groups in **1** are diastereotopic in the case of a rigid solution structure, one would expect this region of the ^{1}H NMR spectrum to be more complicated. For example, the methyl groups of the uncomplexed aryloxide unit would result in two doublets of equal intensity. However, dissociation, rotation of the

[(μ-OAr)(μ-Me)AlMe$_2$] fragments about the La−O bonds, and reattachment to the other side of the molecule would generate two pseudo mirror planes (one roughly defined by the three oxygen atoms, and a second plane perpendicular to the first, containing La1, O1 and C1), allowing the four isopropyl methyl groups to appear as a single doublet. Cooling the sample to the low temperature limit (−90 °C) resulted in a loss of resolution such that only a single broad resonance was observed.

The room temperature $^{13}C\{^1H\}$ NMR spectrum of **1** displays a single resonance corresponding to the aluminum-bound methyl groups ($\delta = -0.6$). When the ^{13}C NMR spectrum is collected with proton coupling, a quadruplet is observed with a $^1J_{C\text{-}H}$ coupling constant of 110 Hz. This compares to a coupling constant of 106 Hz determined for the samarium analogue, (ArO)Sm[(μ-OAr)(μ-Me)AlMe$_2$]$_2$ (**2**). As for **2**, a single resonance was evident at all temperatures; thus the value of 110 Hz represents an average of agostic and nonagostic methyl groups. The slightly larger $^1J_{C\text{-}H}$ coupling constant for **1** is consistent with a weaker Ln···H−C agostic interaction and is reflected in the slightly longer Ln−C$_{agostic}$ bond lengths determined for **1**.

As observed previously for **2**, the ^1H NMR spectrum of the samarium triethylaluminum derivative, (ArO)Sm[(μ-OAr)(μ-Et)AlEt$_2$]$_2$ (**4**) consisted of broad, unassignable resonances due to the paramagnetism of samarium. However, in the $^{13}C\{^1H\}$ NMR spectrum, the aluminum-methylene resonances were upfield of the remaining resonances and could be identified by comparison with the spectrum of **2**. In contrast to **2**, the bridge-terminal exchange process is arrested at room temperature; the proton-coupled ^{13}C NMR spectrum displays two triplets in a 2:1 ratio ($\delta = 7.2$ and -5.3). The downfield resonance is twice the intensity of the upfield resonance, and exhibits a normal $^1J_{C\text{-}H}$ coupling constant of 126 Hz. Additionally, this resonance is only slightly broadened, indicating a limited direct contact with the paramagnetic metal center. Conversely, the upfield resonance is significantly broadened ($\Delta\nu_{1/2} = 150$ Hz vs. 50 Hz for **2**) suggesting a carbon atom that resides in a highly relaxed environment. The $^1J_{C\text{-}H}$ coupling constant of 102 Hz is lower than that determined for the agostic methyl groups in **1** or **2**; however, it should be noted that the coupling constant in **4** arises from a static structure, and indicates a weaker interaction than in **1** or **2**, where the $^1J_{C\text{-}H}$ coupling constants of 106 and 110 Hz, respectively, are the averaged values arising from agostic and nonagostic methyl groups. The infrared spectrum of **4** shows a low energy ν(C−H) stretch at 2727 cm^{-1}, which we have previously shown to be consistent with the presence of agostic Ln···C−H interactions in the solid state.[27] In the case of **4**, ^{13}C NMR spectroscopy provides direct evidence for the effect that small changes in sterics can have upon dynamic processes that occur in solution. Whereas X-ray crystallography suggests that the coordination sphere about the samarium center remains virtually unchanged upon going from trimethylaluminum to triethylaluminum, NMR spectroscopy indicates that the triethylaluminum group is sufficiently bulky to retard the fluxional processes postulated to be present in **1** and **2**.

In contrast to **1**, the ^1H and $^{13}C\{^1H\}$ NMR spectra of material isolated in an attempt to prepare (ArO)La[(μ-OAr)(μ-Et)AlEt$_2$]$_2$ (**3**) consist of a large number of resonances that are difficult to assign. From this data, it is evident that **3** is unstable and readily converts to other species in solution or in the solid state. If samples of **3** were left to stand at room temperature for several days, the formation of a dark brown oil and colorless crystals were observed. An X-ray crystallographic study of the crystals determined them to be the aluminum aryloxide species, [Et$_2$Al(OAr)]$_2$ (**5**). An ORTEP representation of the molecular structure of **5** is given in Figure 3. A partial list of bond lengths and angles is available in Table 3.

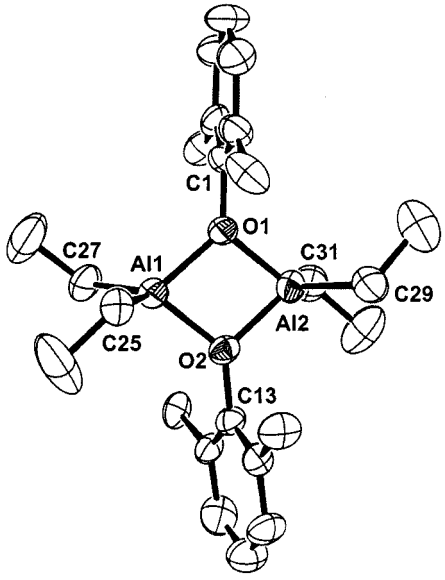


Figure 3. ORTEP view of [Et$_2$Al(OAr)]$_2$ (**5**) drawn with 30% probability ellipsoids; isopropyl methyl groups have been omitted for clarity

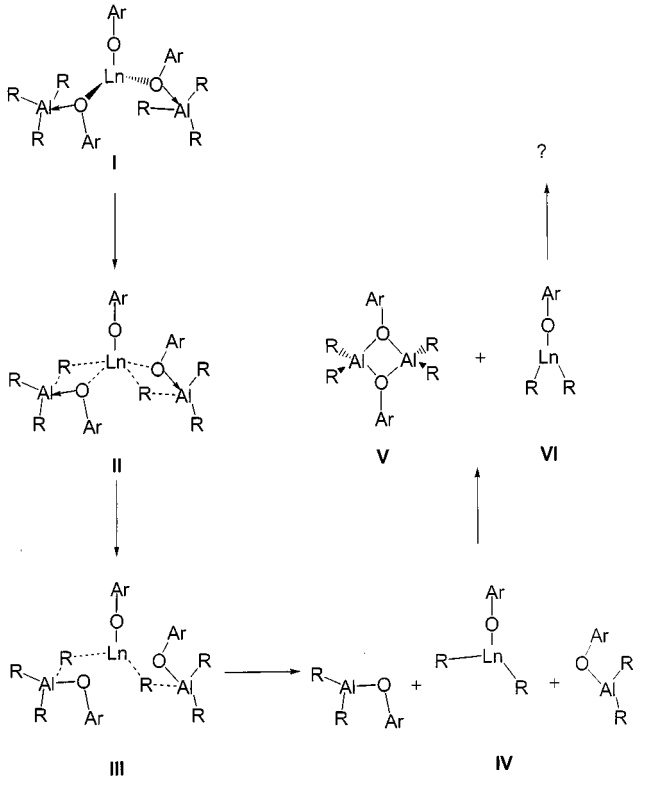
The crystallographic analysis confirmed the dimeric nature of **5**, in which two aluminum centers are bridged by two phenoxide oxygen atoms. The structure of **5** is analogous to those determined for $[Me_2Al(\mu\text{-}O\text{-}2,6\text{-}i\text{Pr}_2C_6H_3)]_2$ [28] and $[Me_2Al(\mu\text{-}O\text{-}2,4,6\text{-}t\text{Bu}_3C_6H_2)]_2$ [29] and the Al−O and Al−C distances are similar in all three structures. Compound **5** was prepared independently and isolated as colorless crystals from the treatment of $AlEt_3$ with one equivalent of 2,6-diisopropylphenol in toluene after evaporation of the solvent. The isolation of the aluminum-aryloxide dimer **5** from a reaction mixture thought to contain the heterobimetallic species $(ArO)La[(\mu\text{-}OAr)(\mu\text{-}Et)AlEt_2]_2$ implies that aryloxide group transfer is relatively facile in these systems. Samples of $(ArO)La[(\mu\text{-}OAr)(\mu\text{-}Me)AlMe_2]_2$ (**1**) and $(ArO)Sm[(\mu\text{-}OAr)(\mu\text{-}Me)AlMe_2]_2$ (**2**) were re-examined by NMR spectroscopy and found to contain small amounts ($< 5\%$) of the previously reported aluminum phenoxide species, $[Me_2Al(\mu\text{-}O\text{-}2,6\text{-}i\text{Pr}_2C_6H_3)]_2$. Heating samples of **1** or **2** to 80 °C overnight resulted in an increase in the intensity of the signals due to $[Me_2Al(\mu\text{-}O\text{-}2,6\text{-}i\text{Pr}_2C_6H_3)]_2$, and the formation of a third, unidentified species (presumably a Ln dialkyl derivative). We suggest that a ligand redistribution reaction such as that detailed in Scheme 4 is occurring: original addition of four equivalents of trialkylaluminum to the π-arene-bridged dimers $[Ln(OAr)_3]_2$ results in the monomeric bis-trialkylaluminum adducts $(ArO)Ln[(\mu\text{-}OAr)(\mu\text{-}R)AlR_2]_2$ which are held together by dative O→Al bonds (I). Due to the steric constraints of the bulky aryloxide groups, only two trialkylaluminum groups per metal center are complexed. The electrophilic lanthanide center engages in further interactions to satisfy its Lewis acidity in the form of a π-bonding interaction with the remaining uncomplexed aryloxide group, and two agostic interactions with the methyl or methylene carbons of the trialkylaluminum units (II). Due to the oxophilicity of aluminum, and the weakened $Al-C_{agostic}$ bonds in II, an alkyl group from each aluminum atom is transferred to the lanthanide center as two formal aluminum-oxygen bonds are formed (III). The bis-trialkylaluminum adduct then separates into three discrete species (IV) which then recombine to form one equivalent of the dimeric aluminum-aryloxide species $[R_2Al(OAr)]_2$ (V) and a lanthanide dialkyl species (VI), which is most likely unstable and reacts further to form other unidentified decomposition products.

In the sense that II is an intermediate in the ligand redistribution reaction of $(ArO)Ln[(\mu\text{-}OAr)(\mu\text{-}R)AlR_2]_2$ to form $[R_2Al(OAr)]_2$ and "R_2LnOAr", the crystal structures of $(ArO)La[(\mu\text{-}OAr)(\mu\text{-}Me)AlMe_2]_2$ (**1**), $(ArO)Sm[(\mu\text{-}OAr)(\mu\text{-}Me)AlMe_2]_2$ (**2**) and $(ArO)Sm[(\mu\text{-}OAr)(\mu\text{-}Et)AlEt_2]_2$ (**4**) may be viewed as "snapshots" of these intermediates, where the migration of the methyl and/or ethyl groups from the aluminum to the metal center has been arrested.[30]



Scheme 4

Conclusions

The synthesis of heterobimetallic complexes of the lanthanides is easily achieved by the addition of trialkylaluminum reagents to the dimeric starting materials, $[Ln(OAr)_3]_2$. By utilizing the bulky 2,6-ddiisopropylphenoxide ligand, adduct formation stops after the addition of two trialkylaluminum units per metal center, which contrasts with trialkylaluminum adducts of the smaller alkoxide, $Ln[(\mu\text{-}Ot\text{Bu})(\mu\text{-}Me)AlMe_2]_3$. These heterobimetallic complexes appear to lie somewhere on a continuum between classical Ln···H−C interactions and Ln···C−X bonding modes which have recently been described. The staggered hydrogens on the five-coordinate agostic carbons and the elongated Al−C bonds in the crystal structures of **1** and **4** support the donation of electron density from the aluminum-carbon bond to the lanthanide center; however, the reduced C−H coupling constants and the lowered infrared stretching frequencies are consistent with a more conventional γ-C−H···Ln interaction. The averaging of the trialkylaluminum methyl groups in the ambient temperature NMR spectra of **1** is likely a result of two separate processes: 1) rotation about the O−Al bond, and 2) the flipping of trialkylaluminum units to opposite sides of the molecule while remaining bound to the aryloxide oxygen atoms. The effect of the larger trialkylaluminum group in **4** is evidenced by ^{13}C NMR spectroscopy, where the bridging and terminal methylene groups give rise to distinct resonances. These adducts readily undergo alkyl/aryloxide group transfer upon thermolysis; thus the crystals structures of **1** and **4** may not only be viewed as examples of lanthanide centers engaging in agostic interactions with remote alkyl groups, but also as intermediates in the transfer of alkyl groups from an aluminum atom to a highly electrophilic lanthanide center.

Experimental Section

General Remarks: All manipulations were carried out under an inert atmosphere of oxygen-free UHP grade argon using standard Schlenk techniques or under oxygen-free helium in a Vacuum Atmospheres glovebox. $AlMe_3$ (2.0 M hexane solution) and $AlEt_3$ (1.9 M toluene solution) were purchased from Aldrich and used as received. 2,6-diisopropylphenol was purchased from Aldrich, distilled over sodium and crystallized at −40 °C prior to use. $[Sm(OAr)_3]_2$,[1] $[La(OAr)_3]_2$ [2] and $[Me_2Al(OAr)]_2$ [28] were prepared according to literature procedures. Hexane and toluene were deoxygenated by passage through a column of supported copper redox catalyst (Cu-0226 S) and dried by passing through a second column of activated alumina. Hexamethyldisiloxane was distilled over sodium benzophenone and degassed prior to use. $[D_6]$benzene and $[D_8]$toluene were degassed, dried over Na-K alloy, and trap-to-trap distilled before use. ^{1}H NMR spectra were recorded on a Bruker AMX 500 spectrometer at ambient temperature; chemical shifts are given relative to residual $[D_5H]$benzene (δ = 7.15) or $[D_7H]$toluene (δ = 2.09). ^{13}C NMR chemical shifts are given relative to $[D_6]$benzene (δ = 128.39) or $[D_8]$toluene (δ = 20.4). Infrared spectra were recorded on a Nicolet Avatar 360 FT-IR spectrometer; solid-state spectra were taken as Nujol mulls between KBr plates, while solution spectra were recorded as benzene solutions vs. a solvent blank in KBr cells. Elemental analyses were performed on a Perkin−Elmer 2400 CHN analyzer. Elemental analysis samples were prepared and sealed in tin capsules in a glovebox prior to combustion.

(ArO)La[(μ-OAr)(μ-Me)AlMe$_2$]$_2$ (1): $AlMe_3$ (0.75 mL of a 2.0 M solution in hexane, 1.50 mmol) was added to a toluene solution of $[La(OAr)_3]_2$ (500 mg, 0.37 mmol). The mixture was stirred at room temperature for 30 minutes and then filtered through a Celite pad. The solvent was removed under vacuum and the sticky residue was washed with a minimum of hexane. Slow evaporation of a saturated toluene solution yielded waxy, colorless crystals (420 mg, 68% yield). ^{1}H NMR (500 MHz, $[D_8]$toluene): δ = −0.31 (s, 18 H, Al*Me$_3$*), 1.21 and 1.29 (2:1 d, $^3J_{H\text{-}H}$ = 6.6 Hz, 36 H, CH*Me$_2$*), 3.36 and 3.49 (1:2 sept, $^3J_{H\text{-}H}$ = 6.6 Hz, 6 H, C*H*Me$_2$), 6.70−7.20 (overlapping m, 9 H, *m,p*-H). ^{13}C{^{1}H} NMR (125 MHz, $[D_8]$toluene): δ = −0.6 (Al*Me$_3$*), 24.5, 24.8 and 24.9 (isopropyl methyl), 27.6 and 28.2 (isopropyl methine), 121.2, 123.0, 123.8 and 124.2 (phenyl *C*H), 136.7, 139.8, 147.0 and 159.1 (tertiary phenyl). Selected ^{13}C NMR spectroscopic data (125 MHz, $[D_8]$toluene): δ = −0.6 (q, $^1J_{C\text{-}H}$ = 110 Hz, Al*Me$_3$*). IR (Nujol): $\tilde{\nu}$ = 2783 cm^{-1} (m), 2725 (m), 1588 (m), 1364 (s), 1322 (s), 1252 (s), 1197 (s), 1097 (s), 1054 (m), 1041 (s), 933 (s), 886 (s), 835 (s), 797 (s), 758 (s), 703 (s), 628 (s). $C_{42}H_{69}Al_2LaO_3$ (814.9): calcd. C 61.91, H 8.53; found C 60.97, H 8.24.

(ArO)La[(μ-OAr)(μ-Et)AlEt$_2$]$_2$ (3): $AlEt_3$ (0.75 mL of a 1.9 M solution in toluene, 1.50 mmol) was added to a toluene solution of $[La(OAr)_3]_2$ (500 mg, 0.37 mmol). The mixture was stirred at room temperature for 90 minutes. The solvent was removed under vacuum and the residue was washed with a minimum of hexane to yield a colorless oil. Over a period of several days, the residue changed into a mixture of a dark red oil and large colorless crystals. X-ray crystallography indicated that the crystals consisted of $[Et_2Al(OAr)]_2$ (**5**). No discrete lanthanum-containing species were identified.

(ArO)Sm[(μ-OAr)(μ-Et)AlEt$_2$]$_2$ (4): $AlEt_3$ (0.47 mL of a 1.9 M solution in toluene, 0.91 mmol) was added to a toluene solution of $[Sm(OAr)_3]_2$ (310 mg, 0.23 mmol), causing an immediate color change from yellow to orange. The mixture was stirred at room temperature for 90 minutes. The solvent was removed under vacuum and the sticky residue was washed with a minimum of hexane. Slow evaporation of a saturated hexamethyldisiloxane solution yielded small orange crystals (340 mg, 80% yield). Selected ^{13}C NMR spectroscopic data (125 MHz, $[D_6]$benzene): δ = 7.2 (t, $^1J_{C\text{-}H}$ = 126 Hz, 4C, nonagostic Al*C*H$_2$), −5.3 (t, $^1J_{C\text{-}H}$ = 102 Hz, $\Delta\nu_{1/2}$ = 150 Hz, 2C, agostic Al*C*H$_2$). IR (Nujol): $\tilde{\nu}$ = 2785 cm^{-1} (w), 2727 (w), 1588 (m), 1424 (s), 1391 (s), 1317 (m), 1243 (m), 1186 (m), 1181 (m), 1088 (m), 1047 (w), 1030 (m), 965 (w), 948 (m), 924 (w), 883 (m), 855 (m), 825 (m), 785 (s), 735 (s), 686 (w), 673 (m), 654 (w). $C_{48}H_{81}Al_2O_3Sm$ (910.5): calcd. C 63.32, H 8.97; found C 61.69, H 9.36.

[Et$_2$Al(OAr)]$_2$ (5): $AlEt_3$ (1.00 mL of a 1.9 M solution in toluene, 1.90 mmol) was added to a toluene solution of 2,6-diisopropylphenol (340 mg, 1.90 mmol). Gas evolution was apparent immediately. The reaction mixture was stirred for 1 h, and the solvent removed under vacuum to yield a white, crystalline solid (420 mg, 84% yield). ^{1}H NMR (500 MHz, $[D_6]$benzene): δ = 0.41 (q, $^3J_{H\text{-}H}$ = 8.2 Hz, 8 H, CH$_3$C*H$_2$*Al), 1.01 (t, $^3J_{H\text{-}H}$ = 8.2 Hz, 12 H, C*H$_3$*CH$_2$Al), 1.30 (d, $^3J_{H\text{-}H}$ = 6.8 Hz, 24 H, CH*Me$_2$*), 3.72 (sept, $^3J_{H\text{-}H}$ = 6.8 Hz, 4 H, C*H*Me$_2$), 6.95−7.04 (overlapping m, 6 H, *m,p*-H). ^{13}C{^{1}H} NMR (125 MHz, $[D_6]$benzene): δ = 0.8 (CH$_3$*C*H$_2$Al), 10.6 (*C*H$_3$CH$_2$Al), 25.9 (*C*HMe$_2$), 27.2 (CH*Me$_2$*), 125.7 and 125.9 (phenyl *C*H), 141.0 (*o*-phenyl), 145.8 (*ipso*-phenyl). IR (Nujol): $\tilde{\nu}$ = 1445 cm^{-1} (s), 1411 (m), 1383 (m), 1377 (m), 1344 (w), 1320 (w), 1260 (m), 1245 (w), 1189 (m), 1162 (s), 1097 (s), 1054 (m), 1041 (w), 972 (m), 949 (m), 933 (m), 884 (m), 833 (s), 800 (m), 758 (s), 693 (s), 668 (s), 633 (s), 610 (s). $C_{32}H_{54}Al_2O_2$ (524.7): calcd. C 73.25, H 10.37; found C 72.31, H 11.04.

X-ray Crystallographic Studies: Crystals of **1**, **4**, and **5** were mounted on a thin glass fiber using a small dot of silicone grease. The crystals were then immediately placed on a Bruker P4/CCD/PC diffractometer, and cooled to 203 K using a Bruker LT-2 temperature device. The data were collected using a sealed, graphite monochromatized Mo-K_α X-ray source. A hemisphere of data was collected using a combination of and ω scans, with 30-second frame exposures and 0.3° frame widths. Data collection and initial indexing and cell refinement was handled using SMART[31] software. Frame integration and final cell parameter calculations were carried out using SAINT[32] software. The data were corrected for absorption using the SADABS[33] program. Decay of reflection intensity was not observed.

The structures were solved using Direct methods and difference Fourier techniques. The initial solution revealed all non-hydrogen atom positions. The methyl hydrogen atom positions for C37 and C40 (**1**) were found on the difference map and refined with their isotropic temperature factors set to 0.08 Å^2. The methylene hydrogen atom positions for C41 and C43 (**4**) were also found and refined as described above. All other hydrogen atoms positions were idealized, C−H = 0.93 Å (aromatic), 0.96 Å (methyl), 0.98 Å (methine) and 0.97 Å (methylene). The hydrogen atoms were refined using a riding model, with isotropic temperature factors fixed at 1.5 (methyl) or 1.2 (all others) times the equivalent isotropic U of the atom they are bonded to. The final refinement[34] included anisotropic temperature factors on all atoms. Structure solution, refinement, graphics, and creation of publication materials were performed using SHELXTL NT.[35] Additional details of data collection and structure refinement are listed in Table 4. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-171086 (**1**), CCDC-171087 (**4**) and CCDC-171088 (**5**). Cop-

Keywords: P,N ligands / Chelates / Diaminophosphanes / Imines / Palladium

The coordination behaviour of the readily prepared, potentially ambidentate, bis(α,α′-phosphanyl)imine (iPr_2N)$_2$-PCH_2C(=N*i*Pr)$CH_2P(NiPr_2)_2$ (**1**, **PNP**) has been investigated. Treatment of palladium(II), platinum(II), chromium(0), and molybdenum(0) sources with ligand **1** afforded complexes in which **1** was coordinated solely in a bidentate *P,N*-chelating fashion with a non-coordinating bis(diisopropylamino)phosphanyl-substituted pendant arm. Ligand **1** and complexes [$PdCl_2$(**PNP**-κ^2*P,N*)] (**2**) and [$Mo(CO)_4$(**PNP**-κ^2*P,N*)] (**10**) were characterised in the solid state by X-ray crystallography. The preparation of cationic Pd^{II} derivatives of **PNP** is discussed.

Introduction

There is continued interest in hetero-bifunctional "hybrid" ligands, which possess two chemically distinct donor sites that are each able to interact to a different extent with a chelated metal centre (e.g. one soft and one hard donor).[1] The asymmetry present in systems of this type offers a degree of selectivity in reactions occurring at the metal centre, due to the electronic and steric disparity between the two different donor groups. In addition, it has been suggested that ligands of this type confer a "flexible" coordination environment at the metal centre, such that a vacant coordination site can be generated reversibly, without complete dissociation of the ligand (so-called "hemilability"). This feature is of considerable importance in catalysis and, since phosphanes are essential components in numerous industrially relevant catalytic processes, it is perhaps not surprising that many of the best-studied "hybrid" systems contain a *P*-donor constituent.

Currently there is a considerable resurgence in the use of heteroatom substituents at phosphorus to "tune" the steric demands and basicity of phosphane ligands.[2] This is due, in part, to the ease with which phosphorus−heteroatom bonds can be formed, as exemplified by *P*−*O* and *P*−*N* moieties. Diaminophosphanes have been targeted for study as they exhibit enhanced σ-donor strength (basicity) when compared with arylphosphanes and even triaminophosphanes, yet are often more easily prepared than strongly basic alkylphosphanes.[2h]

As the number of stoichiometric and catalytic applications involving hetero-bifunctional ligands increases,[3,4] simple, high-yielding syntheses of such species are of particular interest. Recently, we have reported the simple, "one-pot" synthesis of the bis(α,α′-phosphanyl)-substituted imines, e.g. **PNP** (**1**; Figure 1).[5] These compounds are rare examples of a potentially chelating diaminophosphane-containing "hybrid" ligand. However, the presence of one imino- and two phosphanyl-donor sites permits **1** to potentially adopt a number of different coordination modes, examples of which are outlined in Figure 1. Here we report preliminary studies of the coordination chemistry of this ligand, with particular emphasis placed on investigating its mode of binding.

Results and Discussion

Neutral Palladium(II) Derivatives

The dichloro complex [$PdCl_2$(**PNP**-κ^2*P,N*)] (**2**) is readily prepared through addition of **PNP** (**1**), prepared as reported previously,[5] to a dichloromethane solution of [$PdCl_2(NCPh)_2$] at ambient temperature, the reaction reaching completion within 1 h according to $^{31}P\{^1H\}$ NMR spectroscopy (Scheme 1). in vacuo, followed by washing with dry hexane affords **2** as a yellow, air-stable, analytically pure powder in 90% yield, which exhibits a fragment ion at *m*/*z* = 702 {[PdCl(**PNP**)]$^+$} by mass spectrometry.

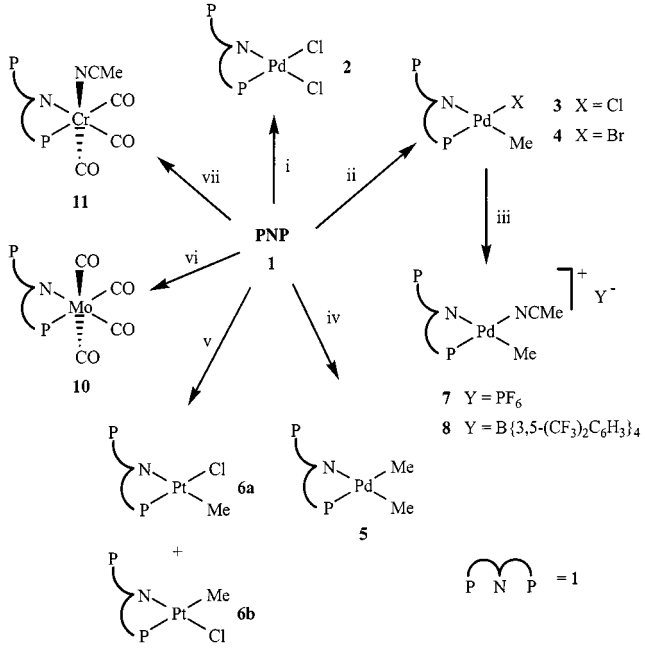

Scheme 1. Reagents and conditions: i: *trans*-[PdCl$_2$(NCPh)$_2$], CH$_2$Cl$_2$, room temp., 2 h; ii: [PdX(Me)(cod)] (X = Cl, Br), CH$_2$Cl$_2$, room temp., 1 h; iii: NaY {Y = PF$_6$, [B{3,5-(CF$_3$)$_2$C$_6$H$_3$}$_4$]}, CH$_3$CN, room temp., 3 d; iv: [PdMe$_2$(tmeda)], CH$_2$Cl$_2$, room temp., 2 d; v: [PtCl(Me)(cod)], CDCl$_3$, room temp., 3 d; vi: *cis*-[Mo(CO)$_4$(pip)$_2$], CH$_2$Cl$_2$, room temp., 18 h; vii: *fac*-[Cr(CO)$_3$(NCMe)$_3$], toluene, room temp., 2 d

The ^{31}P{^{1}H} NMR spectrum of complex **2** exhibits two sharp resonances at δ = +100.9 (s) and +51.9 (s). The considerable downfield shift of only one of the two resonances associated with **1** (Table 1) upon coordination (Δδ ≈ 50 ppm) suggests that in **2** the **PNP** ligand (**1**) is coordinated in a bidentate *P*,*N*-chelating bonding mode (**I**; Figure 1), with a pendant bis(diisopropylamino)phosphane arm.[6] The lack of any detectable $^4J_{PP}$ coupling constant for **2** could result either from an alteration in the angle between the two phosphorus centres or from the change in hybridization of the phosphorus atom upon coordination.[7] There is no evidence by NMR of any exchange between the free and bound phosphane components of **2** over the temperature regime −80 to +40 °C. The ^{1}H NMR spectroscopic data for the **PNP** moiety are little changed following its coordination to the palladium centre with the two methylene resonances being obtained at δ = 2.94 (s) and δ = 3.61 (d, $^2J_{PH}$ = 11.6, endocyclic C*H*$_2$), although the latter clearly exhibits a coupling to the phosphorus atom; both CH$_2$ groups appear as singlets in the ^{1}H NMR spectrum of **1**.[5] Similarly, ^{13}C NMR spectroscopy clearly distinguishes the two different CH$_2$ environments: δ = 54.4 (dd, $^1J_{PC}$ = 35.6, $^3J_{PC}$ = 10.8 Hz) and 38.5 (dd, $^1J_{PC}$ = 20.6, $^3J_{PC}$ = 9.8 Hz). The former has been assigned to the endocyclic methylene group based on its coordination chemical shift change (Δδ ≈ 10 ppm). As expected, the imine carbon atom appears as a doublet of doublets at δ = 176.6 ($^2J_{PC}$ = 16.5, 8.3 Hz), exhibiting a downfield shift compared with uncoordinated **1** [δ = 166.0 (dd, $^2J_{PC}$ = 15.0, 9.5 Hz)].

[a] 81.0 MHz. [b] 122.0 MHz. [c] 101.3 MHz. [d] 109.4 MHz.

Preparation of **2** through reaction of **1** with [PdCl$_2$(cod)] (cod = 1,5-cyclooctadiene) was considerably slower (ca. 2 d) than with [PdCl$_2$(NCPh)$_2$]. This observation is presumed to reflect the higher barrier to dissociation of the chelating cod ligand, compared with that for benzonitrile, and is consistent with the observation that [PdCl$_2$(tmeda)] does not react with **PNP**.

In contrast, **1** reacted rapidly at room temperature with dichloromethane solutions of [PdX(Me)(cod)] to afford [PdX(Me)(**PNP**-κ^2*P*,*N*)] [X = Cl (**3**), Br (**4**)] quantitatively within 1 h, according to ^{31}P NMR spectroscopy (Scheme 1). Complexes **3** and **4** could be isolated as air-stable, cream solids in 85 and 72% yields, respectively. The ^{31}P{^{1}H} NMR spectra suggest that ligand **1** again adopts a *P*,*N*-chelating bonding mode (**I**; Figure 1), with the formation of a single isomer in each case [e.g. **3**: δ: +112.6 (s), +49.3 (s)] (Table 1). In contrast with **2**, the endocyclic CH$_2$ resonance from **3** now displays both $^2J_{PH}$ and $^4J_{PH}$ couplings (overlapping resonances obscure the signal for **4**). The presence of one methyl ligand environment was confirmed

by both ^{1}H [e.g. **3**: δ = 0.71 (s)] and ^{13}C [e.g. **3**: δ = 0.8 (d)] NMR spectroscopy. The ^{1}H NMR chemical shifts associated with the methyl ligand are comparable to those observed for related [PdCl(Me)(*P′*,*N′*)] complexes (ca. 0.7 ppm).[8,9] Resonances corresponding to the exo- and endocyclic CH_2 groups are readily detected by ^{13}C NMR spectroscopy for **3** and **4**. Again, neither **3** nor **4** showed any evidence for exchange of the free and bound phosphane moieties.

The small magnitudes of the $^2J_{P-Pd-C}$ coupling constants associated with the methyl ligands (**3**: 7.3 Hz; **4**: 9.0 Hz) suggest that both complexes **3** and **4** adopt a structure in which the strongly *trans*-influencing methyl group lies *trans* to the weakly *trans*-influencing imine *N*-atom, i.e. the thermodynamically favoured form.[10] This is consistent with data from other palladium complexes possessing a *P*,*N*-ligand.[11] However, Boersma has indicated that caution must be used when spectroscopic methods are employed to assign *cis*/*trans* configurations about Pd for these types of complex.[8] The geometric assignment for complex **3** is strongly supported by a combination of COSY and NOE NMR experiments.

Attempts were made to prepare the corresponding dimethyl complex, [$PdMe_2$(**PNP**-κ^2*P*,*N*)], by methylation of complexes **2**, **3**, and **4** with Me_2LiCu, MeLi, or MeMgBr at low temperatures by analogy with previous work.[12] In each case, an inseparable mixture of products, including some resulting from deprotonation of the coordinated **PNP** ligand methylene backbone, was obtained on warming to room temperature. There was no evidence for the generation of any Pd−Me species.

In contrast, treating a dichloromethane solution of the known [$PdMe_2$(tmeda)] complex with 1 equiv. of ligand **1** cleanly afforded a single new product, which has tentatively been assigned as [$PdMe_2$(**PNP**-κ^2*P*,*N*)] (**5**), according to ^{31}P{^{1}H} NMR spectroscopy [δ = +113.2 (s), +48.9 (s)] in 77% yield (Scheme 1).[9] Complete displacement of tmeda by **PNP** occurred within 2 d at room temperature. The exchange is presumably aided by the strong *trans* influence of the two methyl groups that facilitate dissociation of the diamine.

Problems were encountered, however, with the ^{1}H and ^{13}C NMR spectra associated with **5**. In both cases, only a single resonance attributable to a palladium-bound methyl ligand could be detected [^{1}H: δ = 0.73 (d, $^3J_{PH}$ 0.9 Hz); ^{13}C: δ = −0.6 (d, $^2J_{PC}$ 7.8 Hz)]. Variable-temperature, T_1, and correlated ^{1}H/^{13}C NMR spectra were obtained but did not aid identification.

The correct formulation of **5** as [$PdMe_2$(**PNP**-κ^2*P*,*N*)] was suggested by mass spectrometry, which exhibited ions at *m*/*z* = 681 and 695 corresponding to the species [PdH(Me)(**PNP**)]$^+$ and [$PdMe_2$(**PNP**)]$^+$, respectively. Elemental analyses were irreproducible and inconclusive, possibly as a result of the lack of long-term thermal stability of the dimethyl complex. However, further support for the formation of the desired species was obtained by treating a sample of **5** with 1 equiv. of dppe in dichloromethane. This cleanly afforded the known [$PdMe_2$(dppe)] complex (δ = +55.7) with concomitant liberation of ligand **1**, according to ^{31}P{^{1}H} NMR spectroscopy.[12]

Neutral Platinum(II) Derivatives

Attempts were made to prepare the analogous platinum(II) complexes of **PNP**. Somewhat surprisingly, no reaction was observed between either [$PtCl_2$(cod)] or [$PtCl_2(NCR)_2$] (R = Me, Ph) and ligand **1** in chlorinated solvents even at elevated temperatures (under rigorously dry and anaerobic conditions). In each case, **1** could be recovered unchanged. However, displacement of cod from unsymmetrical [PtCl(Me)(cod)] by **1** proved more facile (vide supra). After 3 d at room temp., [PtCl(Me)(**PNP**-κ^2*P*,*N*)] (**6a**,**b**) was obtained as a mixture of *trans* and *cis* isomers according to ^{31}P NMR spectroscopy (20:1) in $CDCl_3$, the product in which the phosphorus atom lies *trans* to the chloride ion (**6a**) being the major species ($^1J_{PtP}$ = 6007.0 Hz). No interconversion of isomers was observed on prolonged heating.

Cationic Palladium(II) Derivatives

Part of our interest in group 10 complexes of the sterically demanding ligand **PNP**, arises from their potential to serve as precursors to the corresponding cationic Pd^{II} salts for application in olefin oligomerisation and polymerisation.[14,15] Initial, unsuccessful attempts to prepare the desired alkyl cations focussed on halide abstraction from acetonitrile solutions of the dichloro and chloro(methyl) complexes **2** and **3**, respectively, using a variety of silver salts. In each case, oxidation and subsequent decomposition of the *P*,*N*-ligand accompanied by precipitation of colloidal palladium was observed.

In contrast, halide abstraction from **3** using 1 equiv. of NaY (Y = PF_6, [B{3,5-$(CF_3)_2C_6H_3$}$_4$]) proceeded cleanly in acetonitrile at room temperature to afford the monocationic acetonitrile adducts [PdMe($NCCH_3$)(**PNP**-κ^2*P*,*N*)]Y {Y = PF_6 (**7**); Y = [B{3,5-$(CF_3)_2C_6H_3$}$_4$] (**8**)} (Table 1, Scheme 1), which could be isolated as moisture-sensitive, yellow/brown solids. Elemental analyses and variable-temperature ^{1}H NMR spectroscopy confirmed the presence of acetonitrile in both complexes. At 300 K complex **7** presents a broadened resonance at δ = 2.33 ($\nu_{1/2}$ = 11 Hz), which is replaced by two singlets (δ = 2.45 and 2.04) in a 50:1 ratio at 243 K, corresponding to bound and a trace of residual free CH_3CN, respectively. [Pure acetonitrile displays a single resonance at δ = 2.04 by ^{1}H NMR spectroscopy (400.1 MHz, $CDCl_3$) at 243 K.] This behaviour has been attributed to the CH_3CN ligand of **7** undergoing slow exchange with any residual CH_3CN at 300 K, a process that no longer occurs at lower temperatures. Similarly, complex **8** exhibits a single resonance at δ = 2.23 (300 K), which is resolved into two signals at 243 K (δ = 2.30 and 2.04) corresponding to bound and free CH_3CN, respectively.

Surprisingly, treatment of **3** with $NaBPh_4$ under identical reaction conditions resulted in the formation of the acetonitrile-free salt [PdMe($NCCH_3$)(**PNP**-κ^2*P*,*N*)][BPh_4] (**9**), as confirmed by both elemental analyses and variable-temper-

ature ^{1}H NMR spectroscopy. Indeed, the room-temperature ^{1}H NMR spectrum of a freshly prepared $CDCl_3$ solution of **9** shows no evidence of free or bound acetonitrile. On lowering the temperature to 243 K, a small resonance corresponding to a trace of residual unbound CH_3CN was detected (δ = 2.04), despite extended drying of the solid sample of **9** under high vacuum. There was no indication of bound acetonitrile. Addition of 1.1 equiv. of CH_3CN to this sample, followed by cooling to 243 K, merely increased the intensity of the signal corresponding to unbound CH_3CN.

The coordination of the tetraphenylborate anion to electron-deficient metal centres is now well documented.[16] Thus, it seems reasonable to suggest that the formation of complex **9** as a base-free species has to be attributed to the presence of the $[BPh_4]^-$ anion presumably as a result of ion pairing. However, variable-temperature ^{1}H NMR spectroscopy, over the temperature regime 243−300 K, could not establish the nature of the cation−anion interaction for **9**. The possibility of intermolecular coordination of the pendant diaminophosphane arm or a monomer/dimer equilibrium was, however, clearly ruled out by ^{31}P NMR spectroscopy (243−300 K).

Salts **7** and **8** are stable in acetonitrile solution and in the solid state under nitrogen (months). Complex **8** is also stable in $CDCl_3$ solution, but both **7** and **9** decompose slowly in dry chlorinated solvents (24 h at room temp.). Despite the differences in structure, complexes **7**−**9** exhibit virtually identical ^{31}P NMR spectra, in both CD_3CN and $CDCl_3$. As for the neutral Pd^{II} derivatives, ^{13}C NMR spectroscopy readily distinguishes two CH_2 environments for the cationic derivatives **7**−**9**. Just as was observed for **3** the ^{1}H NMR spectra of these complexes display both $^2J_{PH}$ and $^4J_{PH}$ couplings to the endocyclic CH_2 resonance.

In the olefin polymerisation arena, high catalytic activities have been achieved by combining sterically encumbered metal alkyl cations with a noncoordinating anion such as the perfluorinated analogue of BPh_4, $[B(C_6F_5)_4]^-$.[17] Hence, a number of attempts were made to prepare the palladium **PNP** salts of this anion. Both halide elimination from **3**, using $Li[B(C_6F_5)_4]$, and alkyl abstraction from the proposed dimethyl complex **5** by $[Ph_3C][B(C_6F_5)_4]$, led to intractable mixtures of largely unidentifiable but similar products according to NMR spectroscopy, when performed under rigorously dry and anaerobic conditions. However, for the latter reaction, the formation of Ph_3CH was evident presumably as a result of hydride abstraction by the trityl cation. There was no evidence of C_6F_5-group transfer to the metal centre.

Carbonylmetal Coordination Chemistry

The potential for ligand **1** to adopt a number of different coordination modes is readily apparent (Figure 1). Thus, in order to probe the coordination behaviour of **PNP** (**1**), substitution reactions between **1** and a number of group 6 carbonyl complexes were undertaken. Subsequently, examination of the metal−carbonyl stretching frequencies from the resulting complexes can be used to assess the relative basicity of the chelating ligand **1**, although some caution must be observed when comparing carbonyl stretching frequencies of unsymmetrical chelate complexes.[2c,2h]

Treating a dichloromethane solution of $[Mo(CO)_4(pip)_2]$ (pip = piperidine) with an equimolar amount of chelate **1** cleanly afforded the six-coordinate carbonylmolybdenum complex [*cis*-$Mo(CO)_4$(**PNP**-κ^2*P,N*)] (**10**) in 64% yield after 18 h at room temperature. The complex was isolated, after workup, as an air-stable crystalline solid. Data from both $^{31}P\{^1H\}$ NMR and infrared spectroscopy are consistent with ligand **1** being coordinated in a bidentate, *P,N* fashion [δ = +132.1 (s), +51.4 (s)] (mode **I**; Figure 1). A compound which possesses identical spectroscopic data to those obtained for **10** was isolated in low yield (28%) from the reaction of **1** with $[Mo(CO)_3(cht)]$ (cht = η^6-cycloheptatriene). In the latter case, the formation of **10** is believed to result from carbon monoxide scrambling.

As was observed for the palladium−**PNP** derivatives, complex **10** is rigid on the NMR timescale, with no interconversion of the free and bound phosphane components being detectable. The infrared spectroscopic data from complex **10** reveal that the presence of the diisopropylamino substituents on the phosphane component does render ligand **1** slightly more basic when compared with the values of the range of carbonyl stretching frequencies observed for similar *P,N*-ligands bearing a diphenylphosphane moiety bound to the $Mo(CO)_4$ fragment (Table 2). However, ligand **1** remains considerably less basic than the strongly σ-donating bis(pyrrolyl)-substituted diphosphane, $(pyrrolyl)_2P(CH_2)_2P(pyrrolyl)_2$ [$\tilde{\nu}_{CO}$ = 2044, 1970, 1916 cm^{-1}], which possesses related diaminophosphane components, as a result of aromatic delocalisation of the nitrogen lone pair in the latter.[2b]

Table 2. Representative metal−carbonyl stretching frequencies observed for $[Mo(CO)_4(\kappa^2P,N)]$ complexes

κ^2 ligand	$\tilde{\nu}_{CO}$	Ref.
1	2009, 1897, 1882, 1822	This work
 R = Me	2014, 1905, 1887, 1853	[18]
 R = H	2020, 1910, 1870, 1843	[19]
	2018, 1911, 1897, 1850	[20]
	2020, 1905, 1850	[21]
	2013, 1909, 1878, 1820	[22]

Treatment of a toluene solution of *fac*-$[Cr(CO)_3(NCCH_3)_3]$ with 1 mol-equiv. of **1** afforded a single phosphorus-containing product according to $^{31}P\{^1H\}$ NMR spectroscopy [δ = +158.3 (s) and +50.3 (s)] after 2 d at room temp. Cooling (−30 °C, 12 h) of a concentrated

toluene/pentane solution of the crude mixture produced yellow/orange microcrystals in a low yield (23%).

The ^{31}P, ^{1}H, and ^{13}C NMR spectroscopic data are consistent with the formulation of this product as the mono(acetonitrile) adduct, *fac*-[$Cr(CO)_3(NCCH_3)$(**PNP**-κ^2*P*,*N*)] (**11**), with **1** again adopting a mode **I** coordination (Figure 1).

In the IR spectrum of **11**, recorded under rigorously dry, anaerobic conditions (KBr, Nujol), no C−N absorption corresponding to bound CH_3CN could be detected. For comparison, an IR spectrum of an authentic sample of *fac*-[$Cr(CO)_3(NCMe)_3$] [$C_9H_9N_3O_3Cr$ (259.18): calcd. C 41.71, H 3.50, N 16.21; found C 41.79, H 3.39, N 16.09] was recorded under identical conditions. In contrast to the original work,[40] no CN absorption was detectable at 2280 cm^{-1}, despite the carbonyl regions being identical [experimentally observed IR (Nujol): $\tilde{\nu}$ = 1915, 1782 cm^{-1}]. Neither decomposition nor the appearance of free CH_3CN was observed over a period of approximately 30 min.

The isolation of an octahedral group 6, tricarbonyl/mono(acetonitrile) complex bearing a bidentate ligand is not without precedent.[23] The formation of a bridged species of the type [{$Cr(CO)_5$}$_2$(**PNP**-κ^2*P*,*P*)], resulting from CO scrambling, is clearly ruled out by ^{31}P NMR spectroscopy.[24] Both the ^{1}H and ^{13}C NMR spectra show some line broadening, which appears temperature-independent (−45 to +40 °C). This suggests the presence of traces of a paramagnetic chromium species rather than any fluxionality associated with **11**. Such an explanation is reinforced by the broadened signals observed for the residual protio impurities of the deuterated NMR solvents. All attempts to further purify **11** were unsuccessful and resulted in decomposition. Prolonged cooling of the reaction mixture containing **11** eventually yielded inseparable mixtures of $Cr(CO)_6$ and **11**. Simply heating a toluene solution containing equimolar amounts of **1** and hexacarbonylchromium resulted in the formation of an intractable mixture of unidentified products with no evidence consistent with the formation of **11**.

Investigation of the Reactivity of the Pendant Diaminophosphane Arm

Since complexes **2**−**11** all possess a pendant, non-coordinating diaminophosphane moiety, it was of interest to investigate the reactivity of this group. Preliminary studies employing [$PdCl_2$(**PNP**-κ^2*P*,*N*)] (**2**) are somewhat surprising. In dry dichloromethane solution, no reaction was observed at either of the two phosphorus centres with molecular oxygen, sulfur, BH_3(THF), Me_3SiN_3, or [Mo(CO)$_5$(THF)]. In contrast, **1** reacted rapidly with elemental sulfur.[5] A similar lack of reactivity towards boranes or chalcogens was noted for the free phosphane arm of **10**.

It is noteworthy that despite the well-documented reactivity of P−N bonds towards protic reagents, complexes **2**, **3**, and **4** were found stable to alcoholysis, even in neat anhydrous methanol.[25] However, when solutions of complex **2** were treated with 1 equiv. of either methyl iodide or benzyl bromide (CH_2Cl_2, −30 °C), many unidentifiable products were observed by $^{31}P\{^{1}H\}$ NMR spectroscopy. Similar reactivity is observed when the oxidative addition of alkyl halides is attempted with **1**.

Molecular Structure Determinations

Surprisingly few metal complexes of chelating ligands bearing a diaminophosphane unit rather than a dialkyl- or diarylphosphane have been structurally characterised.[2c,26,27] This prompted an investigation of the molecular structures of ligand **1** and complexes **2** and **10** in the solid state.

The crystal structure of **1** revealed that the geometric parameters associated with the imine moiety [C=N 1.268(4) Å, C(3)−N(1)−C(4) 122.8(2)°, sum of angles about C(3) = 360.0°] are typical of this functionality (Figure 2, Table 3).[2c] A staggered conformation is adopted such that the lone pair of phosphorus atom P(1) is directed away from those on both the imine nitrogen N(1) and the second phosphorus atom P(2). As is observed for many aminophosphanes, the four P−N bond lengths are significantly shorter than that associated with a true P−N single bond, the sums of angles about nitrogen atoms N(2) to N(5) [358.4, 359.9, 360.0, 360.0°, respectively] indicating significant sp^2 character;[28] together this suggests there is a degree of lone pair donation from the nitrogen atom to the phosphorus atoms.

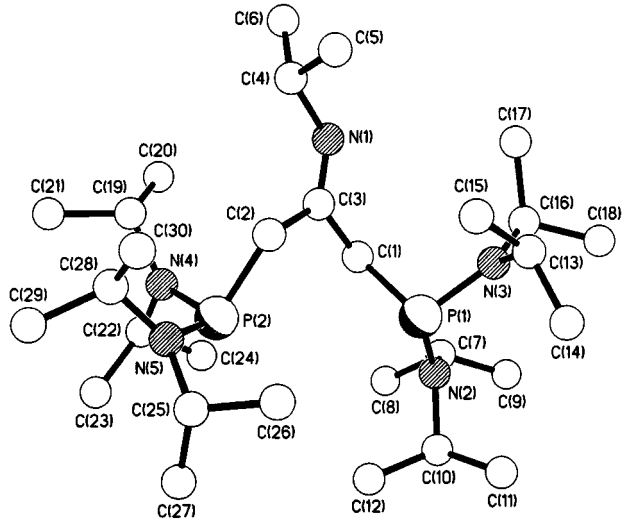

Figure 2. Molecular structure of **PNP** (**1**)

Table 3. Selected bond lengths [Å] and angles [°] for ligand **PNP** (**1**)

P(1)−N(3)	1.691(2)	P(1)−N(2)	1.698(2)
P(1)−C(1)	1.870(3)	P(2)−N(5)	1.703(2)
P(2)−N(4)	1.687(2)	P(2)−C(2)	1.857(3)
N(1)−C(3)	1.268(4)	C(1)−C(3)	1.502(4)
C(2)−C(3)	1.509(4)		
N(3)−P(1)−N(2)	110.0(1)	N(3)−P(1)−C(1)	102.6(1)
N(2)−P(1)−C(1)	99.5(1)	N(5)−P(2)−N(4)	109.7(1)
N(5)−P(2)−C(2)	100.7(1)	N(4)−P(2)−C(2)	102.3(1)
C(3)−N(1)−C(4)	122.8(2)	C(3)−C(1)−P(1)	114.8(2)
C(3)−C(2)−P(2)	117.1(2)	N(1)−C(3)−C(2)	126.9(2)
N(1)−C(3)−C(1)	117.0(2)	C(2)−C(3)−C(1)	116.1(2)

The molecular structure determination of complex **2** (Figure 3, Table 4) revealed a near square-planar geometry, the palladium centre and its four coordinated atoms being co-planar to within 0.049 Å, with a *cis*-$PdCl_2$ arrangement. No inter- or intramolecular interaction of the pendant phosphane P(2) was observed, the closest intermolecular contact being 4.93 Å to Cl(2). The P(1)−Pd and N(1)−Pd bond lengths of 2.197(2) and 2.112(7) Å, respectively, and the P(1)−Pd−N(1) angle of 81.7(2)° are entirely consistent with those reported for similar Pd^{II} complexes.[11,29] The non-equivalence observed for the two palladium−chlorine bond lengths Pd−Cl(1) and Pd−Cl(2) of 2.412(2) and 2.306(3) Å, respectively, reflects the larger *trans* influence of phosphorus compared to nitrogen.[30]

N(2)−P(1)−C(1)	104.1(4)	N(3)−P(1)−Pd	111.7(3)
N(2)−P(1)−Pd	121.7(3)	C(1)−P(1)−Pd	99.4(3)
N(5)−P(2)−N(4)	111.3(4)	N(5)−P(2)−C(2)	102.8(4)
N(4)−P(2)−C(2)	98.2(4)	C(3)−N(1)−C(4)	119.2(7)
C(3)−N(1)−Pd	119.6(5)	C(4)−N(1)−Pd	121.1(5)
C(3)−C(1)−P(1)	107.5(6)	C(3)−C(2)−P(2)	113.1(6)
N(1)−C(3)−C(2)	127.0(7)	N(1)−C(3)−C(1)	117.9(7)
C(2)−C(3)−C(1)	115.1(7)		

Following its complexation to the $PdCl_2$ fragment, ligand **1** adopts a folded envelope conformation with C(3) and C(1) lying 0.37 and 0.88 Å, respectively, "above" the coordination plane a geometry that results from the presence of the planar C=N moiety. There is little perturbation of the metrical parameters for the imine fragment [C(3)−N(1) 1.293(11) Å, C(3)−N(1)−C(4) 119.2(7)°, sums of angles at C(3) and N(1) 360.0 and 359.9°, respectively]. Similarly, the geometry around each of the four amino nitrogen atoms N(2) to N(5) remains essentially planar (sum of angles 359.4, 359.9, 359.5, and 359.3°, respectively). The P−N bond lengths in the non-coordinated aminophosphane moiety [P(2)−N(4) 1.697(8); P(2)−N(5) 1.690(8) Å] are both marginally longer than their counterparts [P(1)−N(2) 1.669(6), P(1)−N(3) 1.647(7) Å] in the metal-bound component. As in the free ligand **1**, these distances are significantly shorter than the values quoted for a P−N single bond,[28] but are in line with those of other structurally characterised coordinated aminophosphanes.[2c,26,27,31]

For comparison, the crystal structure of **10** was also determined and is presented in Figure 4 with selected bond lengths and angles given in Table 5. The comparatively small P−N "bite angle" [P(1)−Mo−N(1) 75.96(9)°] of ligand **1** results in a distorted octahedral geometry about the molybdenum centre. The metal atom lies only 0.011 Å from the equatorial plane formed by atoms P(1), N(1), and the two carbonyl ligands C(31) and C(32), which are coplanar to within 0.042 Å. The contracted geometry at the molybdenum centre caused by the small bite angle of the chelating ligand is compensated in the equatorial plane by an increase in both the adjacent angles P(1)−Mo−C(32) and N(1)−Mo−C(31) to 95.8(2) and 100.4(2)°, respectively. The two pseudo-axial carbonyl ligands bend slightly away from the chelating ligand [C(33)−Mo−C(34) 171.8(2)°]. As was observed for the palladium complex **2**, the P−N-metallacycle adopts a folded envelope conformation with C(3) and C(1) lying 0.25 and 0.77 Å, respectively, "above" the coordination plane. Again the metric parameters of the imine fragment [N(1)−C(3) of 1.287(5) Å, C(3)−N(1)−C(4) 117.9(4)°] differ little from those for the free ligand **1**, with both N(1) and C(3) remaining essentially planar (sums of angles around both atoms 360°). Similarly, the P(1)−N bond lengths, and the geometries about N(2) and N(3), show little alteration from those of the free ligand. The Mo−N(1) bond length [2.356(4) Å] is comparable with other Mo−N σ-donor bonds.[29,31] The greater *trans* influence of phosphorus over nitrogen is reflected in the molybdenum−carbonyl bond lengths of the equatorial carbonyl ligands with that to C(31) being significantly longer than that to C(32) [Mo−C(31) 1.987(6) Å, Mo−C(32) 1.940(6) Å]. The molybdenum−phosphorus bond length of 2.5367(11) Å [P(1)−Mo] is unremarkable.[22,29,33] There are no short inter- or intramolecular interactions involving the pendant phosphane P(2), the closest intermolecular contact being 5.46 Å to O(32).

Conclusion

Together, these observations suggest that the easily prepared, chelating *P,N*-ligand **1** makes an interesting partner for a range of metals. The straightforward synthesis and now predictable coordination geometry of bis(phosphanyl)-imine **1** offers considerable scope for further "tuning" the chemistry of **PNP**-containing complexes. The incorporation of amino rather than alkyl or aryl groups at the phosphorus atoms considerably facilitates greater variation of the steric and electronic properties of the ligand. X-ray crystallography clearly demonstrates the considerable steric demands of ligand **1**, the isopropyl substituents dominating the molecular structures of complexes **2** and **10**. Furthermore, the amino substituents at the phosphorus atoms that are simultaneously σ-electron-withdrawing but π-electron-donating, render the phosphane comparatively electron-rich. This is something that is likely to have a profound effect on the nature of the metal−phosphorus interaction and hence on the chemistry of the metal complexes.[2c][2h]

The apparent lack of reactivity of the pendant, non-coordinated, diaminophosphane unit warrants additional study. If the reactions at this site can be controlled, then this "arm" could be exploited as a means of "immobilising" these complexes on insoluble support materials such as silica or cross-linked polystyrenes. Further coordination chemistry and catalysis studies are on-going.

Experimental Section

All manipulations were performed under nitrogen using standard Schlenk and cannula techniques or in a conventional nitrogen-filled glove box. Solvents were freshly distilled under nitrogen from sodium/benzophenone (tetrahydrofuran, diethyl ether, toluene), from calcium hydride (dichloromethane, acetonitrile), from sodium (hexane, pentane), or from P_2O_5 (C_6D_6, CD_3CN, and $CDCl_3$) and degassed prior to use. Elemental analyses were performed by the microanalytical services of Imperial College or by S. Boyer at the University of North London. NMR spectra were recorded with a Bruker AC200, AM 250, AMX 300, AMX 400, or JEOL 270; chemical shifts were referenced to residual protio impurities in the deuterated solvent (^1H), to the deuterated solvent (^{13}C), external $CFCl_3$ (^{19}F), or to external aqueous 85% H_3PO_4 (^{31}P). All spectra were obtained at ambient probe temperatures unless stated otherwise. Infrared spectra were recorded [Nujol mulls (KBr windows), KBr discs, or in solution (KBr windows)] with either Perkin−Elmer 1600 or Mattson Research Series 1 spectrophotometers; Nujol was dried over sodium wire. Mass spectra were recorded with either Kratos Concept 1H or AutospecQ instruments and are reported in (*m/z*). **PNP (1)**,[5] *cis*-$[Mo(CO)_4(pip)_2]$,[34] *fac*-$[Cr(CO)_3(NCCH_3)_3]$,[35] *trans*-$[PdCl_2(NCPh)_2]$,[36] $[PdCl_2(cod)]$,[37] $[PdCl_2(tmeda)]$, $[PdMe_2(tmeda)]$,[9] [PdCl(Me)(cod)],[38] [PtCl(Me)-(cod)],[11b] and $Na[B\{3,5\text{-}(CF_3)_2C_6H_3\}_4]$[39] were prepared according to literature procedures. [PdBr(Me)(cod)] was prepared using a procedure based on that used for the preparation of [PdCl(Me)-(cod)] but starting with $[PdBr_2(cod)]$. All other chemicals were obtained commercially and used as received. Melting points were obtained in sealed glass tubes under nitrogen, using a Gallenkamp melting point apparatus and are uncorrected. A variable-temperature ^1H NMR study of the various cationic palladium systems reported is recorded in the electronic Supporting Information in addition to ORTEP views for each of the molecular structures determined by X-ray crystallography.

Synthesis of $[PdCl_2(PNP\text{-}\kappa^2P,N)]$ (2): A dichloromethane (10 mL) solution of **1** (0.32 g, 0.57 mmol) was added to a solution of $[PdCl_2(NCPh)_2]$ (0.22 g, 0.57 mmol) in dichloromethane (10 mL) at −30 °C. The mixture was allowed to warm to room temp. and

stirred for 2 h, affording a red-orange solution. Removal of solvent under reduced pressure gave a yellow-orange solid that was washed with Et_2O (3 × 10 mL) yielding a pale yellow analytically pure sample of **2** (0.38 g, 90% yield). Single crystals suitable for study by X-ray diffraction were obtained following prolonged cooling (−30 °C) of a concentrated CH_2Cl_2/Et_2O solution, m.p. > 225 °C (dec.). $C_{30}H_{67}Cl_2N_5P_2Pd$ (737.16): calcd. C 48.88, H 9.18, N 9.50; found C 49.02, H 9.02, N 9.48. MS (FAB$^+$, NBA matrix): *m*/*z* = 702 [M − Cl]. ^{1}H NMR (270.1 MHz, $CDCl_3$): δ = 1.08 [d, 12 H, $^3J_{H,H}$ = 6.7, PNCH(C*H*$_3$)$_2$], 1.16 [d, 12 H, $^3J_{H,H}$ = 6.7, PNCH(C*H*$_3$)$_2$], 1.28 [d, 12 H, $^3J_{H,H}$ = 6.9, PNCH(C*H*$_3$)$_2$], 1.45 [d, 12 H, $^3J_{H,H}$ = 6.9, PNCH(C*H*$_3$)$_2$], 1.65 [d, 6 H, $^3J_{H,H}$ = 6.7, C=NCH(C*H*$_3$)$_2$], 2.94 (s, 2 H, C*H*$_2$), 3.35 (m, 4 H, PNC*H*), 3.61 (d, 2 H, $^2J_{PH}$ = 11.6, C*H*$_2$), 4.07 (sept, 4 H, $^3J_{H,H}$ = 6.9, PNC*H*), 4.28 (sept, 1 H, $^3J_{H,H}$ = 6.7, C=NC*H*). ^{13}C {^{1}H} NMR (68.0 MHz, $CDCl_3$): δ = 23.1 [s, C=NCH(*C*H$_3$)$_2$], 24.4 [d, $^3J_{CP}$ = 6.2, PNCH(*C*H$_3$)$_2$], 25.2 [d, $^3J_{CP}$ = 7.2, PNCH(*C*H$_3$)$_2$], 25.7 [s, PNCH(*C*H$_3$)$_2$], 38.5 (dd, $^1J_{CP}$ = 20.6, $^3J_{CP}$ = 9.8, exocyclic P*C*H$_2$), 47.7 (d, $^2J_{CP}$ = 10.3, PN*C*H), 50.0 (d, $^2J_{CP}$ = 7.2, PN*C*H), 54.4 (dd, $^1J_{CP}$ = 35.6, $^3J_{PC}$ = 10.8, endocyclic P*C*H$_2$), 59.0 (s, C=N*C*H), 176.6 (dd, $^2J_{CP}$ = 8.3, 16.5, *C*=N).

Synthesis of [PdCl(Me)(PNP-κ^2*P*,*N*)] (3): A dichloromethane solution (10 mL) of **1** (0.72 g, 1.28 mmol) was added to a solution of [PdCl(Me)(cod)] (0.34 g, 1.28 mmol) in dichloromethane (10 mL) at −30 °C. The mixture was allowed to warm to room temp. and stirred for 1 h, affording a red solution. Removal of solvent under reduced pressure gave a yellow-orange solid that was washed with Et_2O (3 × 10 mL) yielding **3** as a cream powder that was used without further purification (0.78 g, 85% yield), m.p. > 200 °C (dec.). $C_{31}H_{70}ClN_5P_2Pd$ (716.74): calcd. C 54.64, H 10.38, N 10.28; found C 55.01, H 10.10, N 10.20. MS (FAB$^+$, NBA matrix): *m*/*z* = 717 [M$^+$], 702 [M$^+$ − Me], 681 [M$^+$ − Cl]. ^{1}H NMR (400.1 MHz, $CDCl_3$): δ = 0.71 (s, 3 H, Pd−C*H*$_3$), 1.11 [d, 12 H, $^3J_{H,H}$ = 6.6, PNCH(C*H*$_3$)$_2$], 1.20 [d, 12 H, $^3J_{H,H}$ = 6.7, PNCH(C*H*$_3$)$_2$], 1.30 [24 H, overlapping d, $^3J_{H,H}$ = 6.7, PNCH(C*H*$_3$)$_2$], 1.60 [d, 6 H, $^3J_{H,H}$ = 6.5, C=NCH(C*H*$_3$)$_2$], 2.85 (s, 2 H, C*H*$_2$), 3.31 (dd, 2 H, $^2J_{PH}$ = 10.0, $^4J_{PH}$ = 1.5, C*H*$_2$), 3.39 (septd, 4 H, $^3J_{H,H}$ = 6.7, $^3J_{PH}$ = 11.1, PNC*H*), 3.92 (sept, 4 H, $^3J_{H,H}$ = 6.7, PNC*H*), 4.10 (sept, 1 H, $^3J_{H,H}$ = 6.5, C=NC*H*). ^{13}C {^{1}H} NMR (100.6 MHz, $CDCl_3$): δ = 0.75 (d, $^2J_{CP}$ = 7.3, Pd-*C*H$_3$), 22.9 [s, C=NCH(*C*H$_3$)$_2$], 24.9 [d, $^3J_{CP}$ = 7.1, PNCH(*C*H$_3$)$_2$], 24.4 [d, $^3J_{CP}$ = 6.4, PNCH(*C*H$_3$)$_2$], 24.6 [d, $^3J_{CP}$ = 2.4, PNCH(*C*H$_3$)$_2$], 26.1 [d, $^3J_{CP}$ = 2.1, PNCH(*C*H$_3$)$_2$], 37.3 (dd, $^1J_{CP}$ = 19.7, $^3J_{CP}$ = 5.7, exocyclic P*C*H$_2$), 46.9 (d, $^2J_{CP}$ = 10.9, PN*C*H), 47.8 (d, $^2J_{CP}$ = 9.3, PN*C*H), 50.6 (dd, $^1J_{CP}$ = 26.5, $^3J_{CP}$ = 7.3, endocyclic P*C*H$_2$), 56.0 (s, C=N*C*H), 171.2 (dd, $^2J_{CP}$ = 5.7, 16.1, *C*=N).

Synthesis of [PdBr(Me)(PNP-κ^2*P*,*N*)] (4): In a similar manner to the above, reaction of **1** (0.132 g, 0.24 mmol) in dichloromethane (25 mL) with a solution of [PdBrMe(cod)] (0.073 g, 0.24 mmol) in dichloromethane (15 mL) at −30 °C afforded **4**. Recrystallisation from a mixture of ether and dichloromethane (1:1) and prolonged cooling to −30 °C afforded **4** as yellow-orange microcrystals (0.14 g, 72% yield). A small (50 mg) sample of **4** was recrystallised a second time using the same combination to afford a microcrystalline material that afforded correct elemental analyses, m.p. > 195 °C (dec.). $C_{31}H_{70}BrN_5P_2Pd$ (761.32): calcd. C 48.92, H 9.27, N 9.20; found C 48.95, H 9.20, N 9.19. Preparation of 10 from [Mo(cht)(CO)$_3$]: Toluene (10 mL) was added to a mixture of **1** (0.20 g, 0.36 mmol) and [Mo(cht)(CO)$_3$] (0.08 g, 0.36 mmol) at room temp. After stirring at room temp. for 2 d, the reaction mixture was heated to 70 °C for a further 3 d. Complex **10** was observed as the only phosphorus-containing product by ^{31}P NMR spectroscopy. Subsequent removal of all volatile components under reduced pressure afforded a brown waxy solid. Washing with ether (3 × 10 mL) afforded **10** as an orange-brown solid (0.08 g, 28% yield).

Synthesis of *fac*-[Cr(CO)$_3$(NCMe)(PNP-κ^2*P*,*N*)] (11): To a solution of *fac*-[Cr(CO)$_3$(NCMe)$_3$] (0.2 g, 0.8 mmol) in toluene (10 mL) was added a toluene (10 mL) solution of **1** (0.44 g, 0.8 mmol) at −30 °C. The solution slowly darkened from yellow to orange/brown upon stirring at room temp. for 2 d. Removal of solvent in vacuo afforded a dark brown waxy solid. The product was extracted into toluene (3 mL) and pentane (ca. 2 mL) added. After cooling at −30 °C for 12 h, yellow-orange microcrystals of **11** were isolated by filtration and dried in vacuo for 4 d, at room temp. (0.12 g, 23% yield). No reliable analyses could be obtained presumably due to subsequent decomposition. MS (FAB$^+$, NBA matrix): *m*/*z* = 639 [M$^+$ − CH_3CN − 2 CO], 611 [M$^+$ − CH_3CN − 3 CO]. IR (Nujol): $\tilde{\nu}$ = 1941 (w, CO), 1885 (s, CO), 1821 (s, CO). ^{1}H NMR (270.1 MHz, $CDCl_3$): δ = 1.25 (54H br. m), 2.28 (3 H, br. s, C*H*$_3$CN), 2.90 (2 H, br. s, CH$_2$), 3.39 (9 H, br. m, PNC*H*, C*H*$_2$, and C*H*$_3$CN), 3.97 (4 H, br. m, PNC*H*), 4.22 (1 H, br. m, C=

NC*H*). ^{13}C NMR (75.8 MHz, $CDCl_3$): δ = 22.6 (br, s, *C*H_3CN), 24.0 [br, C=NCH(*C*H_3)$_2$], 24.2 [br. d, $^3J_{PC}$ = 6.6, PNCH(*C*H_3)$_2$], 24.6 [br. d, $^3J_{PC}$ = 6.6, PNCH(*C*H_3)$_2$], 24.9 (br. s), 25.9 (br. s), 39.6 (br. d, $^1J_{PC}$ = 21.1, exocyclic *C*H_2), 47.3 (br. d, $^2J_{PC}$ = 10.8, PN*C*H), 49.4 (br. d, $^2J_{PC}$ = 9.0, PN*C*H), 52.8 (br. m, endocyclic P*C*H_2), 57.3 (br. s, C=N*C*H), 127.8 (br. s, CH_3*C*N), 176.3 (br. m, *C*=N*i*Pr), 219.5 (br. d, $^2J_{PC}$ = 14.5, *C*O), 227.9 (br. s, *C*O), 229.0 (br. d, $^2J_{PC}$ = 18.1, *C*O).

Reaction of [$PdMe_2$(PNP-κ^2*P*,*N*)] (5) with dppe: An NMR tube was charged under nitrogen with **5** (0.01 g, 0.01 mmol), dppe (0.005 g, 0.01 mmol), and dry $CDCl_3$ (0.5 mL). The reaction mixture was shaken and left to stand at room temp. for 30 min. ^{31}P NMR (101.3 MHz, $CDCl_3$): δ = +55.7 ($PdMe_2${dppe}), +53.1 (d, $^4J_{PP}$ = 14.5 Hz, [**PNP**]), +46.2 (d, $^4J_{PP}$ = 14.5 Hz, [**PNP**]).

X-ray Crystallographic Study: Crystal Data for **1**: $C_{30}H_{67}N_5P_2$, *M* = 559.8, orthorhombic, *Pbca* (no. 61), *a* = 17.888(1), *b* = 18.586(2), *c* = 21.924(2) Å, *V* = 7289(1) Å^3, *Z* = 8, D_c = 1.020 g·cm^{-3}, μ(Mo-$K_α$) = 1.40 cm^{-1}, *T* = 293 K, yellow/white blocks; 6404 independent measured reflections, *F* refinement, R_1 = 0.028, *Rw* = 0.029, 2743 independent observed absorption corrected reflections [$|F_o| > 4σ(|F_o|)$, 2θ ≤ 50°], 334 parameters. Crystal Data for **2**: $C_{30}H_{67}Cl_2N_5P_2Pd$, *M* = 737.1, monoclinic, $P2_1/c$ (no. 14), *a* = 14.617(1), *b* = 15.998(3), *c* = 18.323(3) Å, β = 109.44(1)°, *V* = 4040(1) Å^3, *Z* = 4, D_c = 1.212 g·cm^{-3}, μ(Cu-$K_α$) = 58.5 cm^{-1}, *T* = 293 K, yellow platy needles; 5989 independent reflections, F^2 refinement, R_1 = 0.066, wR_2 = 0.164, 4241 independent observed absorption corrected reflections [$|F_o| > 4σ(|F_o|)$, 2θ ≤ 120°], 362 parameters. Crystal Data for **10**: $C_{34}H_{67}MoN_5O_4P_2$, *M* = 767.8, monoclinic, $P2_1/n$ (no. 14), *a* = 13.722(1), *b* = 17.284(1), *c* = 19.098(2) Å, β = 109.19(1)°, *V* = 4278.0(6) Å^3, *Z* = 4, D_c = 1.192 g·cm^{-3}, μ(Mo-$K_α$) = 4.19 cm^{-1}, *T* = 293 K, yellow blocks; 7494 independent reflections, F^2 refinement, R_1 = 0.050, wR_2 = 0.106, 5006 independent observed reflections [$|F_o| > 4σ(|F_o|)$, 2θ ≤ 50°], 415 parameters. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-165966 to -165968. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Electronic Supporting Information: Variable-temperature ^1H NMR spectra for complexes **7**–**9** together with ORTEP views of the molecular structures of ligand **1** and complexes **2** and **10** have been deposited (see also footnote on the first page of this article).

Acknowledgments

The Nuffield Foundation (Award to Newly Appointed Science Lecturers), The Royal Society, the Chemistry Departments of the Imperial College and the University of Leicester, the EPSRC and Lubrizol Ltd. (CASE award to M. J. H.) are gratefully acknowledged for funding. Johnson Matthey is thanked for a loan of palladium salts while Asahi Glass Corporation is thanked for gifts of $B(C_6H_5)_3$. Drs. G. Griffiths (Leicester), R. N. Shepherd (Imperial College), and P. Hammerton (Imperial College) are thanked for their help with NMR spectroscopy.

Reduced Molybdovanadophosphates[‡]

Anna Selling,*[a] Ingegärd Andersson,[a] John H. Grate,[b] and Lage Pettersson[a]

Keywords: Polyoxometalates / NMR spectroscopy / Redox chemistry / Speciation / Formation constants

The equilibrium speciation in the aqueous $H^+/MoO_4^{2-}/HVO_4^{2-}/HPO_4^{2-}/e^-$ system, 0.600 M Na(Cl) medium at 25 °C, was characterised by potentiometric [H^+] (glass electrode) and {e^-} (platinum electrode) titration techniques as fundamental tools, complemented by $^{51}V^V$ NMR (131.6 MHz) and V^{IV} ESR spectroscopy. The study has been focused on solutions with the Keggin ratio, (Mo + V)/P = 12:1 and Mo/V > 5, in the pH range 1.4–4.5, where anions having the formula $[H_zMo_{12-x-y}V^V_xV^{IV}_yPO_{40}]^{(3+x+2y-z)-}$ are predominant species. Added numbers of electrons per vanadium(V) (e^-/V^V) have been kept less than one to exclude reduction of molybdenum(VI). Six reduced molybdovanadophosphate species have been identified. The $[Mo_{11}V^{IV}PO_{40}]^{5-}$ species [logβ = 154.15 ± 0.03 (3σ)] and the mixed-valence species $[Mo_{10}V^VV^{IV}PO_{40}]^{6-}$ (logβ = 155.84 ± 0.02) can both be monoprotonated. These species have pK_a values of 0.93 and 3.68, respectively. A "fully" reduced Keggin species, $[H_2Mo_{10}V^{IV}_2PO_{40}]^{5-}$ (logβ = 171.27 ± 0.06), and a lacunary $[H_4Mo_{10}V^{IV}PO_{39}]^{5-}$ species (logβ = 142.0 ± 0.2) were found as well. Except for the molybdovanadophosphate species, the only reduced species formed, in the present investigation, is the vanadyl ion, VO^{2+}. logK_{red} ($2H^+ + VO_2^+ + e \rightleftarrows VO^{2+} + H_2O$) was determined to 17.15 ± 0.01 (E^0 = 1014.5 ± 0.6 mV).

Introduction

Polyoxoanions are of considerable interest as redox catalysts, for they are easily reduced and can often be reoxidised by O_2. Molybdovanadophosphate complexes have for example been used as catalysts in the selective oxidation of olefins to carbonyl groups.[1] Studies of solutions containing vanadium(IV), tungsten, and phosphorus[2–7] or vanadium(IV), molybdenum, and phosphorus[3,8–12] are frequently reported in the literature. In both cases so-called mixed addenda Keggin species are formed. In most of these studies the experimental techniques used have been cyclic voltammetry, NMR, and ESR. Recently, results from investigations of solutions containing vanadium(IV), tungsten, molybdenum, and phosphorus, forming Keggin anions with three addenda atoms, have been reported.[13,14]

As a part of our studies of the equilibrium speciation in the aqueous molybdovanadophosphate system, the electron has been included as the fifth component. A complete study of this system can only be done when all the oxidised and reduced subsystems are known at the same experimental conditions. The oxidised subsystems are the three binary systems H^+/MoO_4^{2-},[15] H^+/HVO_4^{2-},[16–18] and H^+/HPO_4^{2-},[19] the three ternary systems $H^+/MoO_4^{2-}/HVO_4^{2-}$,[20,21] $H^+/MoO_4^{2-}/HPO_4^{2-}$,[22,23] and $H^+/HVO_4^{2-}/HPO_4^{2-}$,[19] and the quaternary system $H^+/MoO_4^{2-}/HVO_4^{2-}/HPO_4^{2-}$.[24,25] Within the concentration ranges of this study, it was found that the only reduced species, except for those with five components, was the vanadyl cation, VO^{2+}. The formation constant for VO^{2+} has already been determined,[17] but is redetermined here with more advanced equipment.

The present system has, like all the subsystems, been studied in 0.600 M Na(Cl) medium at 25 °C. Species and formation constants have been determined by using potentiometric [H^+] (glass electrode) and {e^-} (platinum electrode) titration techniques as fundamental tools, complemented by NMR and ESR spectroscopy. One prerequisite of working with complicated systems is to have access to a computer program, which can treat all kinds of data simultaneously. Therefore, all calculations for determining the formation constants were made with the calculation program LAKE,[26] which can treat both potentiometric (EMF) and NMR spectroscopic data simultaneously.

Notations and Designations

The formation constants are reported with H^+, MoO_4^{2-}, HVO_4^{2-}, HPO_4^{2-}, and e^- as components. The equilibria are written according to Equation (1).

$$p\,H^+ + q\,MoO_4^{2-} + r\,HVO_4^{2-} + s\,HPO_4^{2-} + t\,e^- \rightleftarrows [(H^+)_p(MoO_4^{2-})_q(HVO_4^{2-})_r(HPO_4^{2-})_s(e^-)_t]^{p-2(q+r+s)-t} \quad (1)$$

A species formed will, for brevity, sometimes be denoted by its (*p*,*q*,*r*,*s*,*t*) integers. The potentiometric data can only establish the composition and charge of the species formed, as water may be gained or lost relative to the components. However, when complementary structural information is available, the formula can be given. For example, since in the present study (23,11,1,1,1) is known to have the Keggin composition it can be written $[HMo_{11}V^{IV}PO_{40}]^{4-}$. The charge and number of oxygen atoms and protons are often omitted below, and species are instead written in the compact forms $Mo_{11}VP$ and $Mo_{10}V_2P$. Our definition of the degree of reduction, denoted z_e, is equivalents of electrons added per mol of vanadium(V). Thus, a z_e value of 0.25, means that 25% of the vanadium, initially of valence V, is reduced.

A 0.600 M Na(Cl) ionic medium is 0.600 M Na^+ with Cl^- providing counteranion balance not provided by the oxometalate anions. The acidity measurements are on the concentration scale, where pH = $-\log[H^+]$, and *not* on the activity scale, pH = $-\log\{a_{H+}\}$. For brevity, the total concentrations of molybdenum, vanadium, and phosphorus will be denoted Mo, V, and P.

Results and Discussion

To fully understand the reduced molybdovanadophosphate system, all subsystems, both oxidised and reduced, must be known at the same experimental conditions. All oxidised subsystems have already been determined and the only reduced non-Keggin vanadium species present in this study is VO^{2+}. It is formed when the $H_zMo_{12-x-y}V^V{}_xV^{IV}{}_yP$ species decompose in acidic solutions. In the decamolybdodivanadophosphate system it was found that the ^{51}V NMR signal disappears as soon as one electron is added to the complex. One would expect that the vanadium atom, well separated from the reduced vanadium atom, should not be affected, but due to an electron tunnelling effect even this signal disappears. Similar observations have been made in studies on the reduced molybdotungstohosphate system showing that tungsten atoms, not adjacent to the reduced molybdenum atom, are affected of the reduction.[27,28]

The Reduced Vanadate System

The $H^+/HVO_4^{2-}/e^-$ system had been studied earlier in acidic solutions and in the same medium [0.600 M Na(Cl)], but with rather simple equipment.[17] Therefore, a redetermination using more advanced equipment and a more sophisticated technique for working with air-sensitive solutions was found worthwhile. Since VO^{2+} is the only reduced non-Keggin vanadium species present, only one reaction and one equilibrium constant ($\log K_{red}$) has to be determined; $2\,H^+ + VO_2^+ + e^- \rightleftarrows VO^{2+} + H_2O$, $\log K_{red}$ = 17.15 ± 0.01 (E^0 = 1014.5 ± 0.6 mV), can be compared with the old result of 17.37. When the redox equilibrium is written with the components used in the study of the five component system, $5\,H^+ + HVO_4^{2-} + e^- \rightleftarrows VO^{2+} + 3\,H_2O$, the $\log\beta_{5,0,1,0,1}$ value is 32.03 ± 0.01. NMR and ESR spectra were recorded to establish that VO_2^+ and VO^{2+} are the only species formed in acidic solutions (pH < 2). ESR spectra of VO^{2+} reveal a typical vanadium(IV) signal, with 8 hyperfine lines arising from the unpaired electron (S = 1/2) with the nuclear spin (I = 7/2). ESR and NMR spectra recorded on the same solutions showed the 8-line ESR pattern for VO^{2+} increasing in proportion to the decrease of the VO_2^+ resonance in the NMR spectrum.

The Reduced Molybdovanadophosphate System

In the determination of formation constants of reduced molybdovanadophosphate species, both EMF and ^{51}V integral data were included. Calculations have been made stepwise by gradually decreasing the Mo/V ratio and expanding the pH range. Starting with different rather high Mo/V ratios (11−22), where only $Mo_{11}VP$ species and some MoP species are present, constants for the reduced $Mo_{11}V^{IV}P$ species could be determined. Once these constants were known, data from lower Mo/V ratios, down to 5.67, where also $Mo_{10}V_2P$ species are present in oxidised solutions, were included in the calculations. Different formulations for reduced species were systematically tested using LAKE. Table 1 shows the model that gave the best (lowest sum of squared errors) fit of data. Of the reduced species found, $[Mo_{11}V^{IV}PO_{40}]^{5-}$ can be monoprotonated (pK_a = 0.93), in contrast to the oxidised $[Mo_{11}V^{V}PO_{40}]^{4-}$ species.[25] The $Mo_{10}V_2P$ species with mixed valence states of vanadium, $Mo_{10}V^VV^{IV}P$, can also be monoprotonated, having a pK_a value of 3.68. A diprotonated doubly reduced species, $[H_2Mo_{10}V^{IV}{}_2PO_{40}]^{5-}$, is also found. An X-ray structure study on deep blue tabular crystals obtained when concentrating a fully reduced molybdovanadophosphate solution (Mo/V = 5.67; pH ≈ 4.8; z_e = 1.0), showed that the doubly reduced species have an α-Keggin structure.[29] One incomplete Keggin species, (20,10,1,1,1), an $Mo_{10}V^{IV}P$ species, is required in the model to explain data. Incomplete Keggin species (often called lacunary species e.g. with tungsten and Si,[30] B,[31] or P[32] as heteroatoms) are well known

Table 1. The equilibrium model obtained from calculations on data in the pH range 1.4 < pH < 4.5 and at Mo/V>5

(*p*,*q*,*r*,*s*,*t*)	Formula	$\log\beta \pm 3\sigma$	pK_a
22,11,1,1,1	$[Mo_{11}V^{IV}PO_{40}]^{5-}$	154.15 ± 0.03	
23,11,1,1,1	$[HMo_{11}V^{IV}PO_{40}]^{4-}$	155.08 ± 0.15	0.93
21,10,2,1,1	$[Mo_{10}V^VV^{IV}PO_{40}]^{6-}$	155.84 ± 0.02	
22,10,2,1,1	$[HMo_{10}V^VV^{IV}PO_{40}]^{5-}$	159.52 ± 0.04	3.68
23,10,2,1,2	$[H_2Mo_{10}V^{IV}{}_2PO_{40}]^{5-}$	171.27 ± 0.06	
20,10,1,1,1	$[H_4Mo_{10}V^{IV}PO_{39}]^{5-}$	142.04 ± 0.20	

in heteropoly anion systems. Such a lacunary species of a generalised polyhedral structure is shown in Figure 1. Accordingly, (20,10,1,1,1) most probably has the lacunary Keggin formula $[H_4Mo_{10}V^{IV}PO_{39}]^{5-}$. This lacunary species is most likely formed by dissociation of VO^{2+} from the double reduced divanadium Keggin species.

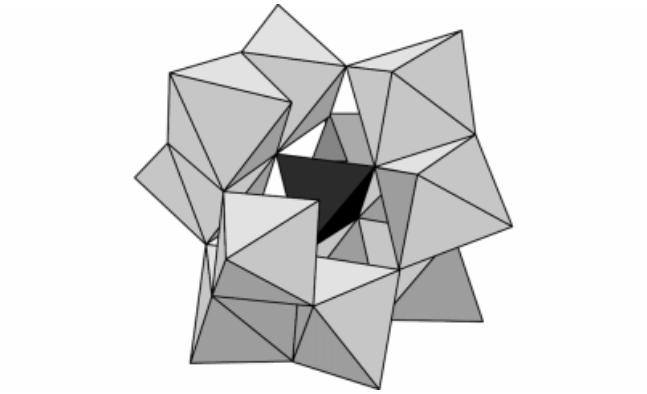

Figure 1. Polyhedral structure of an incomplete Keggin anion, a so-called lacunary species

Figure 2 shows distribution diagrams of a) vanadium and b) phosphorus for a solution where 50% of the vanadium(V) atoms are reduced to vanadium(IV). The fully oxidised solution had a composition of 20% $Mo_{11}VP$ and 80% $Mo_{10}V_2P$. The $(\alpha_i)_{V(P)}$ coordinate quantitates the fraction of every species *i* relative to the total V(P). Each species has its own region in the cumulative diagram, so that the fraction of the species is the region's vertical extent, at a given pH. A bold line separates reduced and oxidised species. In this figure, each protonation step is plotted individually with a dotted line and the solid line shows the sum of them. The symbols (O) in Figure 2 (a) represent experimental points (integral values) and show how the experimental NMR spectroscopic data fit the proposed model. The fit is within the evaluation error of the integrals.

In acidic solutions (pH < 2.5) there is considerable decomposition of reduced $Mo_{10}V_2P$ species to VO^{2+} and $Mo_{11}V^{IV}P$ species. Where VO^{2+} is the predominant reduced species, most of the phosphorus atoms are bound in oxidised species or present as phosphoric acid.

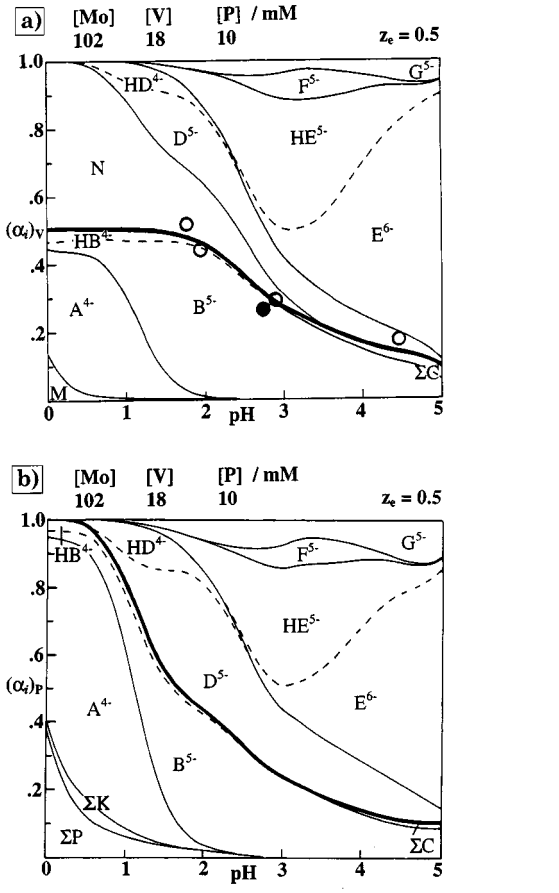

Figure 2. Distribution diagrams of a) vanadium and b) phosphorus at z_e = 0.5 and (Mo + V)/P = (102 + 18)/10 mM; oxidised and reduced species are separated with a bold line; each protonation step is plotted individually with a dotted line and the solid line shows the sum of them; symbols (O) represent ^{51}V integral data, and (●) is the integral value from the equilibrated, "aged", solution in Figure 5; A^{4-} = $Mo_{11}VP^{4-}$; B^{5-} = $Mo_{10}V_2P^{5-}$; HB^{4-} = $HMo_{10}V_2P^{4-}$; ΣC = ΣMo_9V_3P; M = VO_2^+; D^{5-} = $Mo_{11}V^{IV}P^{5-}$; HD^{4-} = $HMo_{11}V^{IV}P^{4-}$; E^{6-} = $Mo_{10}V^{V}V^{IV}P^{6-}$; HE^{5-} = $HMo_{10}V^{V}V^{IV}P^{5-}$; F^{5-} = $H_2Mo_{10}V^{IV}_2P^{5-}$; G^{5-} = $H_4Mo_{10}V^{IV}P^{5-}$; N = VO^{2+}; ΣP = ΣH_3PO_4; ΣK = ΣMo_xP_y

Comparison between Distribution Diagrams and NMR Spectra

^{51}V NMR spectra of acidic solutions (pH ≈ 2) containing 20% $Mo_{11}VP$ and 80% $Mo_{10}V_2P$ at different z_e values have been recorded on an absolute intensity mode, as shown in Figure 3. At this rather low pH value, the resonance arising from $Mo_{11}VP$ (a) decreases first when electrons are added, cf. spectra at z_e = 0 and 0.10. When almost all of the $Mo_{11}VP$ species has been reduced, the positional isomers of the $Mo_{10}V_2P$ (b−e) species start to reduce. In more acidic solutions (pH ≈ 1.5) the behaviour is different, the $Mo_{10}V_2P$ isomers are the first to be reduced. The redox reactions are thus very dependent upon the pH of the solutions. The simplified distribution diagram in Figure 4 shows the difference between the oxidised $Mo_{11}VP$ and $Mo_{10}V_2P$ species in solutions with z_e = 0.0 (full-drawn lines) and z_e = 0.10 (dashed lines). The $Mo_{11}VP$ species is present with approximately the same amount in oxidised and reduced solutions at pH ≈ 1.5, while it is almost completely reduced at pH ≈ 2.1. This was also experimentally observed in the NMR spectra recorded from such solutions.

To examine which one of the five positional $Mo_{10}V_2P$ isomers[24] is the first to be reduced, a ^{51}V NMR spectrum was recorded immediately after the electrons had been added from a potentiostat to z_e = 0.50 (fresh) and then at equilibrium 2 d later (aged), Figure 5. A comparison between the two spectra shows that the resonance from the α-1,4-$Mo_{10}V_2P$ isomer (b), where two vanadium octahedra share edges, decreases more than the others in fresh solution; but after equilibrium, the ratio between all the isomers

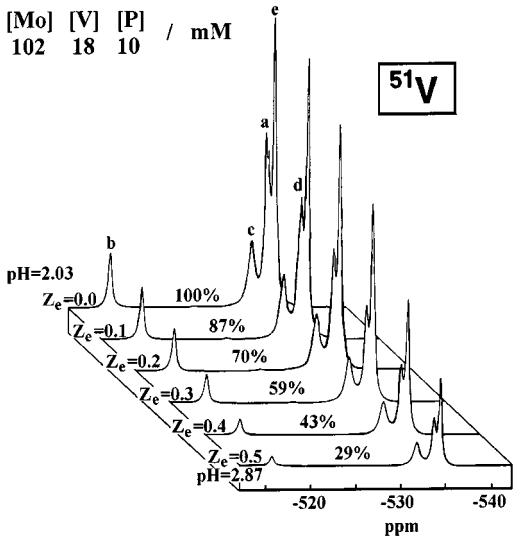

Figure 3. A set of ^{51}V NMR spectra of a solution containing 80% $Mo_{10}V_2P$ and 20% $Mo_{11}VP$ at different degrees of reduction recorded on an absolute intensity mode; resonance labelled **a** arise from the $Mo_{11}VP$ species and resonances **b**−**e** from the $Mo_{10}V_2P$ isomers; **b** = α-1,4; **c** = α-1,2; **d** = α-1,5; **e** = α-1,6 + α-1,11

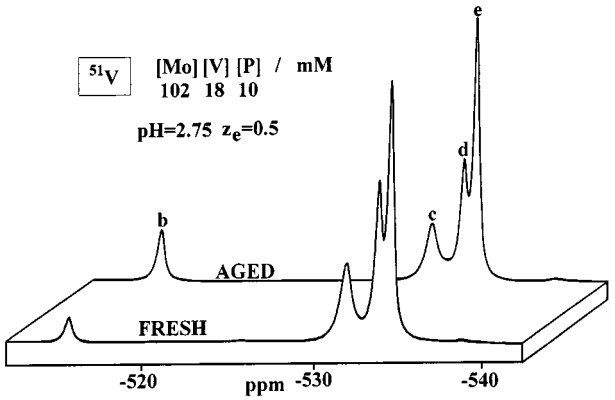

Figure 5. Two ^{51}V spectra recorded on the same $Mo_{10}V_2P$ solution; the front spectrum was recorded only a few minutes after the electrons were added with a potentiostat, and the rear spectrum after equilibration; resonances arising from the $Mo_{10}V_2P$ isomers are labelled **b**−**e**; **b** = α-1,4; **c** = α-1,2; **d** = α-1,5; **e** = α-1,6 + α-1,11

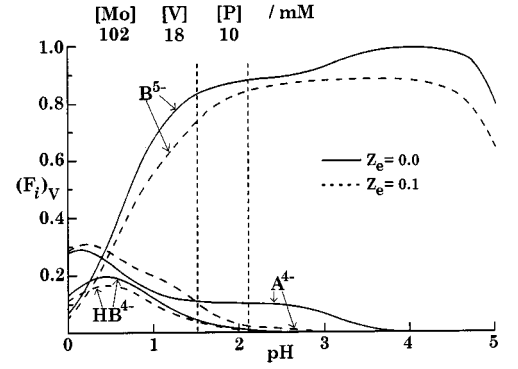

Figure 4. A simplified distribution diagram for a solution with (Mo + V)/P = (102 + 18)/10 mM, where only some oxidised species are shown at two different z_e values; full-drawn lines represent the distribution at z_e = 0.0 and dashed lines at z_e = 0.1; A^{4-} = $Mo_{11}VP^{4-}$; B^{5-} = $Mo_{10}V_2P^{5-}$; HB^{4-} = $HMo_{10}V_2P^{4-}$

are the same as in a fully oxidised solution. This means that the α-1,4-$Mo_{10}V_2P$ isomer (b) takes care of most of the added electrons in the start, but at equilibrium all isomers have the same amount of reduction. In non-aqueous solutions, a similar reduction pattern has been observed. The isomers with vicinal vanadium atoms seem to be the first to be reduced.[33] The distribution diagram in Figure 2 (a) shows that an equilibrated solution at z_e = 0.5 and pH = 2.75, should have 71% of the total vanadium in fully or partially reduced species. Experimentally, the equilibrated solution in Figure 5 has an integral value showing that 27% of the total vanadium is present in nonreduced species [marked with ● in Figure 2 (a)].

Comparison between Distribution Diagrams and ESR Spectra

In a solution with pH ≈ 2, containing both $Mo_{11}VP$ and $Mo_{10}V_2P$ species, the first species to be reduced when electrons are added is $Mo_{11}VP$, since its resonance disappears first, cf. Figure 3. A distribution diagram of a solution, where 10% of the total amount of vanadium is reduced is shown in Figure 6 (a). At pH = 2.1 the only reduced species is $[Mo_{11}V^{IV}PO_{40}]^{5-}$. An ESR spectrum [Figure 6 (b)] of the same solution indeed corresponds to the feature of $[Mo_{11}V^{IV}PO_{40}]^{5-}$ alone. The ESR spectrum of a solution with the ratio (Mo + V)/P = (110 + 10)/10 mM, reduced to z_e = 1.0 at pH = 1.0 is shown in Figure 7 (a). From our model, three reduced species should be present in such a solution, 42% $[Mo_{11}V^{IV}PO_{40}]^{5-}$, 40% $[HMo_{11}V^{IV}PO_{40}]^{4-}$, and 18% $[V^{IV}O]^{2+}$ [Figure 7 (b)]. Arrows in Figure 7 (a) mark peaks arising from VO^{2+}. Subtracting VO^{2+} from this spectrum gives the same pattern as in Figure 6 (b), which means that both the protonated and deprotonated $Mo_{11}V^{IV}P$ have the same ESR spectrum. Similar checks of the proposed model against ESR spectra were also made at different pH values and different Mo/V ratios and the agreement was good.

ESR spectra of the present system should be virtually the same as for the corresponding vanadotungstates, reported by Pope et al.[2] Five positional isomers of $W_{10}V_2P$ and $Mo_{10}V_2P$ occur in both systems. Two isomers have neighbouring vanadium atoms and in the remaining three isomers one or more tungsten/molybdenum atoms separate the two vanadium atoms. The relative statistical abundances are 12 + 12 = 24 and 12 + 24 + 6 = 42, respectively. These have been verified in solution by ^{31}P NMR for both $W_{10}V_2P$[2] and $Mo_{10}V_2P$.[24] The unpaired electron in the

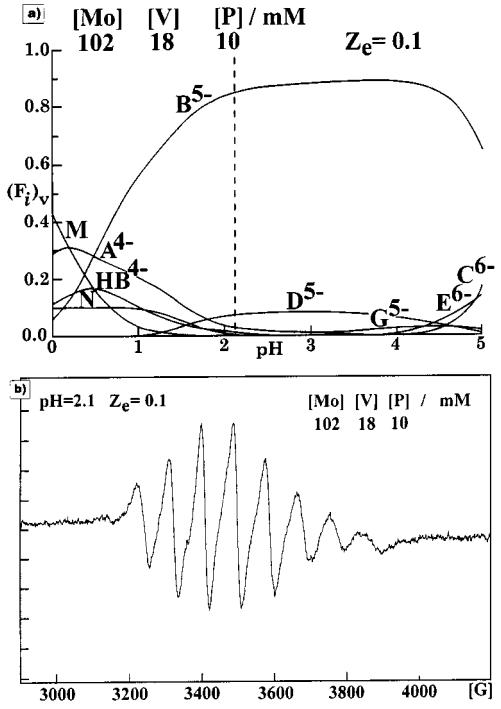

Figure 6. a) Distribution diagram of vanadium at z_e = 0.1 and (Mo + V)/P = (102 + 18)/10 mM; A^{4-} = $Mo_{11}VP^{4-}$; B^{5-} = $Mo_{10}V_2P^{5-}$; HB^{4-} = $HMo_{10}V_2P^{4-}$; C^{6-} = $Mo_9V_3P^{6-}$; M = VO_2^+; D^{5-} = $Mo_{11}V^{IV}P^{5-}$; E^{6-} = $Mo_{10}V^{V}V^{IV}P^{6-}$; G^{5-} = $H_4Mo_{10}V^{IV}P^{5-}$; N = VO^{2+}; b) ESR spectrum of the solution marked with a dashed line in a), showing the 8-line feature for $[Mo_{11}V^{IV}PO_{40}]^{5-}$

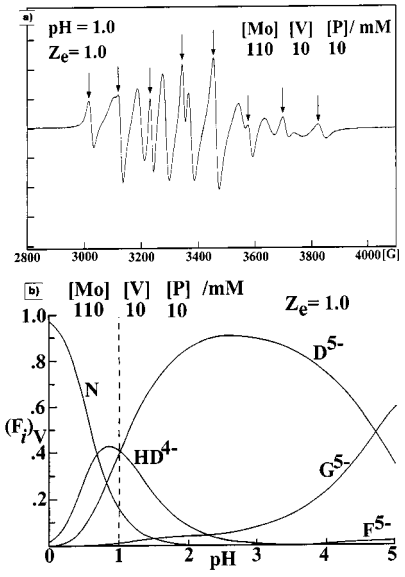

Figure 7. a) ESR spectrum of a solution with (Mo + V)/P = (110 + 10)/10 mM reduced to z_e = 1.0; arrows mark peaks arising from VO^{2+}; b) distribution diagram of vanadium for the same concentrations; dashed line marks the solution recorded on ESR in a); D^{5-} = $Mo_{11}V^{IV}P^{5-}$; HD^{4-} = $HMo_{11}V^{IV}P^{4-}$; F^{5-} = $H_2Mo_{10}V^{IV}{}_2P^{5-}$; G^{5-} = $H_4Mo_{10}V^{IV}P^{5-}$; N = VO^{2+}

two isomers with vicinal vanadium atoms, interacts with both vanadium nuclei through rapid intramolecular hopping to give a 15-line spectrum. In the remaining three isomers, where vanadium atoms are separated, the electron is effectively trapped by a single vanadium atom, thus giving an 8-line spectrum.[2] The relative intensity of the overlapping 15- and 8-line spectra in a mixed-valence vanadium solution should be 24:42 = 4:7. From our model, a solution with the ratio Mo/V = 102:18 = 5.7 and pH = 4.5 contains predominantly $Mo_{10}V^{V}V^{IV}P$ when z_e = 0.5. As expected, an ESR spectrum of the $Mo_{10}V^{V}V^{IV}P$ solution (Figure 8, bottom spectrum) shows a mixed 8- and 15-line pattern. The 8-line feature in the figure has, however, higher intensity than the 15-line, which means that the abundance observed by ESR is in accordance with the statistical prediction. In contrast, the doubly reduced $W_{10}V_2P$ species gives a spectrum with 15 equal lines, expected for the interaction of the unpaired electrons with two vanadium nuclei.[2] In the present work, a solution with the ratio Mo/V = 200:40 = 5 and pH = 4.5, which should contain 50% $Mo_{10}V^{V}V^{IV}P$ and 50% $Mo_{10}V^{IV}{}_2P$ species when z_e = 0.75, gave rise to the top 15-line spectrum shown in Figure 8. It has both the previous (8 + 15)-line component feature arising from $Mo_{10}V^{V}V^{IV}P$ species and also a 15-line component feature from $Mo_{10}V^{IV}{}_2P$ species, with an increase for the latter compared with the lower spectrum in Figure 8. This shows again that the proposed model is in good agreement with the experimental data.

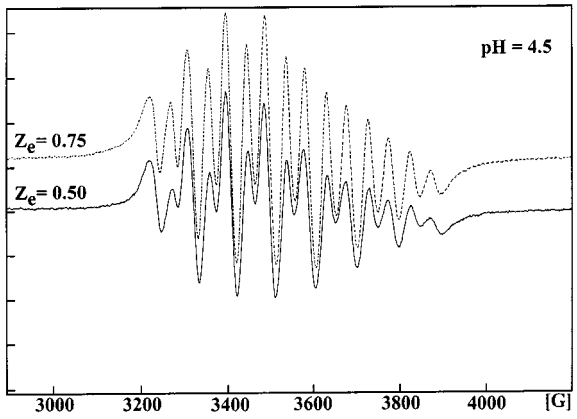

Figure 8. The bottom spectrum (z_e = 0.5) shows the (8 + 15)-line feature for the mixed valence state of the $Mo_{10}V^{V}V^{IV}P$ isomers; the top dashed spectrum (z_e = 0.75) shows how the 15-line pattern has increased when $Mo_{10}V^{IV}{}_2P$ also is present in the solution

Pourbaix Diagrams

The redox speciation in systems with few components is often illustrated in the literature by means of predominance diagrams, so-called Pourbaix diagrams [showing areas of predominant species as a function of *E* (or *pe*) and pH]. Numerous diagrams are needed to illustrate the speciation in the present 5-component system. The reason is that the speciation is not only dependent on the total concentrations, but also on the Mo/V/P ratios. Figure 9 shows a diagram of vanadium containing species at (Mo + V)/P = (105 + 15)/10 mM (equal amounts of $Mo_{11}VP$ and $Mo_{10}V_2P$). At high *E* values (oxidised solutions), $Mo_{11}VP$ is the predominant species at the pH range 0.2−1.3. In less acidic

solutions at this high E value, the deprotonated $Mo_{10}V_2P$ isomers are predominant. When the E value is lowered, i.e. electrons have been added, these species are reduced to VO^{2+} and the monoprotonated $Mo_{11}V^{IV}P$, respectively. As can be seen from the figure, additional reduced species appear as predominant species at pH values higher than 3.4.

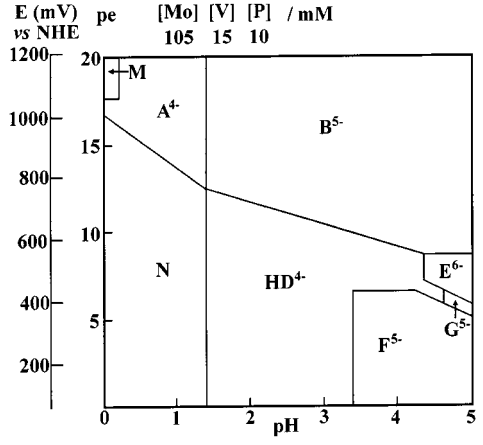

Figure 9. Predominance (Pourbaix) diagram of vanadium at (Mo + V)/P = (105 + 15)/10 mM; $A^{4-} = Mo_{11}VP^{4-}$; $B^{5-} = Mo_{10}V_2P^{5-}$; M = VO_2^+; $HD^{4-} = HMo_{11}V^{IV}P^{4-}$; $E^{6-} = Mo_{10}V^{V}V^{IV}P^{6-}$; $F^{5-} = H_2Mo_{10}V^{IV}{}_2P^{5-}$; $G^{5-} = H_4Mo_{10}V^{IV}P^{5-}$; N = VO^{2+}

Experimental Section

Solutions for Potentiometric, NMR, and ESR Studies: The oxidised solutions for potentiometric, NMR, and ESR studies were prepared as previously described.[24,25] Stock solutions of vanadium(IV) were prepared from vanadium(IV) oxide, V_2O_4 (Aldrich Chemical 99.9%), which was dried at 100 °C and then used without any further purification. V_2O_4 was dissolved in diluted hydrochloric acid and the absence of vanadium(V) as VO_2^+ was checked by ^{51}V NMR. The dissolution process is very slow, but can be speeded up in an ultrasound bath. To make sure that no reoxidation will occur, all glassware was filled with argon and all solutions bubbled with argon for at least 30−40 min before mixing.

Equilibria: Equilibria in the reduced molybdovanadophosphate system were attained within 2−48 h, and in the reduced vanadium system within 2−24 hours. No matter how the electrons were added, coulometrically or with a vanadium(IV) stock solution, the same results were obtained. Equilibrium was, however, reached more rapidly using a vanadium(IV) solution. The redox reactions of Keggin species were shown to be reversible.

EMF Measurements: EMF titrations were conducted at 25.0 ± 0.1 °C using an automated potentiometric titrator. Free H^+ concentrations were determined by measuring the EMF of the following cell, using an Ingold type 201-NS glass electrode, an Ag/AgCl reference electrode, prepared according to Brown,[34] and a Wilhelm bridge.[35]

− Ag, AgCl | 0.600 M NaCl ‖ equilibrium solution | measuring electrode +

The redox potential was measured between a small foil or spiral of platinum metal in the solution and the same reference electrode as for the measurements of free [H^+]. The free H^+ concentration and the electron activity were calculated from the measured EMF values E [mV] by Equation (2) and Equation (3), where the last term is the liquid junction potential for 0.6 M NaCl medium and the type of bridge used.

$$E = E_{0a} + 59.157\cdot\log[H^+] - 76\cdot[H^+] \quad (2)$$

$$E = E_{0b} - 59.157\cdot\log\{e^-\} - 76\cdot[H^+] \quad (3)$$

The electrons were added coulometrically at 800−250 mV vs. NHE using an automated potentiostat (developed at our department), or with a solution containing vanadium(IV) of known concentration. All titrations were performed under pure argon to prevent contamination by oxygen from the air. The argon was sparged through 10% NaOH solution to remove any acid impurities, 10% H_2SO_4 solution to remove any alkaline impurities, and, finally, 0.6 M NaCl medium before introduction to the titration vessel. Before each titration, the platinum electrode was rinsed in distilled water and heated in an ethanol flame. The constant E_{0a} was determined before and after each titration, using a separate solution of known [H^+]. In separate experiments, E_{0b} was determined to −250 mV in solutions with known {e^-}. Several experiments were performed and the variation in E_{0b} was negligible. The value −250 mV could thus be used for all titrations. Reduction constants are often reported with E^0 instead of $\log K_{red}$ values. The relation between them is described in Equation (4), where $g = (R\cdot T\cdot\ln 10)/F$ and n_e is the number of electrons in the redox reaction; at 25 °C, g = 59.157 mV.

$$E^0 = g/n_e\cdot\log K_{red} \quad (4)$$

EMF Data: In the determination of the formation constant of the vanadyl cation, VO^{2+}, 118 data points were collected from 12 different titrations in the concentration ranges 1.5 < pH < 2.1 and 4 < [V] < 10 mM. To ensure that no other species than the vanadyl ion was formed, the upper limit of the z_e value was 0.92. In the reduced molybdovanadophosphate system 44 titrations were performed on Keggin ratio solutions, (Mo + V)/P = 12, with 5 < Mo/V < 22 and 10 < Mo/P < 11. The concentration ranges 1.38 < pH < 5.49, 100 < [Mo] < 200 mM, 5 < [V] < 40 mM, and 10 < [P] < 20 mM have been covered. In the calculations, data were restricted to the pH and z_e ranges 1.38 < pH < 4.5 and 0.0 < z_e < 0.9 giving in total 322 data points. To confirm that the same result is achieved both when electrons are added to an oxidised solution and when an oxidised solution is added to a reduced, titrations were made in both directions and they coincide. Since the present study has been focused on $Mo_{11}VP$ and $Mo_{10}V_2P$ species and to avoid the formation of Mo_9V_3P species, no Mo/V ratio lower than 5 was allowed. The upper limit of z_e was set at 0.9 to avoid the reduction of molybdenum(VI).

NMR Measurements: The ^{51}V and ^{31}P NMR measurements were obtained by using a Bruker AM500 spectrometer at 131.6 and 202.5 MHz, respectively. The probe temperature was thermostatted at 25.0 ± 0.5 °C. The field frequency stabilisation was locked to deuterium by placing the 8-mm sample tubes into 10-mm tubes containing D_2O. The samples were spinning in all experiments. All NMR samples were transferred from the titration solution to the sample tubes with a Hamilton® gas syringe. Commercial stainless steel needles could not be used since the steel was found to reduce oxidised MoVP solutions. Instead, specially prepared titanium needles were used. The NMR tubes used were of septa type and were "rinsed" with argon for about 45 min, to avoid oxidation of

the reduced solutions by oxygen in the air. The spin-lattice relaxation time (T_1) was just a few ms for ^{51}V, so by having a relaxation delay of 1 s the spectra were quantitatively recorded. The free induction decay (FID) was multiplied by an exponential line-broadening function (LB = 1), using the Bruker software, to improve the signal/noise ratio. A Gaussian−Lorentzian double apodization was sometimes applied to the FID, also by using the Bruker software, to enhance resolution to obtain more accurate chemical shifts of overlapping resonances. $VOCl_3$ and 85% H_3PO_4 were used as external shift standards. Positive chemical shifts (δ) correspond to higher frequency. For an exact shift scale, a solution of α-$[Mo_{11}VPO_{40}]^{4-}$ = 10 mM in 0.600 M Na(Cl) medium was used as external ^{51}V and ^{31}P chemical shift standards.[24] When studying reduced solutions, the absolute intensity (AI) mode was used and spectra recorded with exactly the same experimental parameters as for a spectrum of a fully oxidised solution with known concentration of vanadium(V) and phosphorus.

NMR Spectroscopic Data: Integral values from 42 different ^{51}V spectra in the pH range 1.51−4.42 were included in the calculations. By working in an AI mode, it was possible from the total integral value to determine how much of the total vanadium is bound in oxidised and reduced species, since species containing vanadium(IV) are NMR-silent. A set of ^{51}V NMR spectra recorded in AI mode is shown in Figure 3, and the total integral values (sum of vanadium in oxidised species) of each spectrum decreases when z_e increases. ^{31}P NMR spectroscopic data have not been included in any of the calculations. Spectra were recorded only to find out if the resonances of oxidised species decrease at the same rate as for vanadium when electrons were added. When this was shown to be the case, only ^{51}V NMR spectroscopic data were recorded, since quantitative data of high quality could be obtained in much shorter time.

ESR Measurements and Data: ESR measurements on vanadium(IV) were carried out with a Bruker ESP 300E X-band spectrometer. Aqueous samples were contained in 115 μL sealed capillary tubes, and spectra scanned from 2800 G to 4200 G. The microwave power was 5 mW. No ESR data have been included in the calculations. ESR was used to (i) obtain "fingerprints" of reduced species and (ii) verify that the proposed model fitted to experimental reduced data.

Computer Programs: Resonance intensities were computed by integration using the Bruker software. By using the least-square program LAKE,[26] mathematical analysis of combined $[H^+]$ and $\{e^-\}$ data, and ^{51}V NMR integral data was accomplished. Multimethod data can be treated simultaneously in LAKE, which considerably refines the equilibrium analysis. This is the greatest advantage of the program. Calculation and plotting of distribution and predominance diagrams were performed using the program SOLGASWATER.[36]

A Study of the Interactions in an Extended Unsupported Gold-Silver Chain

Eduardo J. Fernández,[a] Antonio Laguna,*[b] José M. López-de-Luzuriaga,[a] Miguel Monge,[a] Pekka Pyykkö,*[c] and Nino Runeberg[c]

Keywords: Gold / Silver / Ab initio calculations / N ligands

The complex $[Ag(Py)_3][Au(C_6F_5)_2]\cdot Py$ (**1**) (Py = pyridine) has been prepared by the reaction of $NBu_4[Au(C_6F_5)_2]$ with $AgClO_4$ in the presence of pyridine. The crystallographic measurements indicate the presence of an extended unsupported one-dimensional chain of alternating gold and silver atoms. This arrangement is due to the formation of molecular Au–Ag ion pairs, to the π-stacking of C_6F_5 and pyridine arene ligands and to the packing effects that lead to molecular ion pairs at short distance. Theoretical calculations based on approximate experimental distances and angles reveal the presence of both metallophilic Au^I–Ag^I and aromatic C_6F_5-pyridine interactions. From a theoretical point of view the nature of the intermetallic attraction arises from both an ionic contribution and from dispersion-type correlation effects; the aromatic interaction is mainly due to dispersion-type correlation effects.

Introduction

The tendency of gold centers to aggregate has been termed "aurophilicity" by Schmidbaur.[1] Many research groups have been involved in an exhaustive search for structural information concerning such systems. The results have encouraged the theorists to construct theoretical models whose results could be compared with the experimental data. These models lead one to conclude that these interactions arise from correlation and relativistic effects.[2,3] The attraction due to electron correlation is dominated by dispersion, with a significant contribution from the recently identified ionic-type excitations.[4] These studies are nowadays being extended to other metals with closed shell configurations in theoretical models of systems with the same or different centers. Previous studies carried out in our group of heteropolynuclear metallacycles of the type $[AuM(HSCH_2PH_2)_2]^{2+}$ (M = Ag, Cu) concluded that the presence of only one gold atom is enough to induce metallophilic attractions in the group congeners and that this effect could be modulated depending on the gold ligand.[5] We also performed a detailed analysis of the d^8-d^{10} interaction between Pd^{II} and Au^I in the model complex $[AuPdCl_3(HSCH_2PH_2)_2]$ showing a dominant dispersion effect, some ionic contributions and no net charge transfer between the metals.[6] In both cases a bidentate ligand acts as a bridge between the metallic centers and its contribution to the close approach of the metal atoms cannot be neglected.

In contrast, the anionic complex $[Au(C_6F_5)_2]^-$ has been found to be a very valuable agent in the preparation of heteropolynuclear complexes in which the metal-metal interactions are not imposed by the ligand architecture.[7–10] Accordingly, we report here the synthesis, characterization and theoretical study of the complex $[Ag(Py)_3][Au(C_6F_5)_2]\cdot Py$ (**1**) (Py = pyridine), which shows an extended unsupported one-dimensional chain formed by repetition of gold-silver ion pairs that, in addition, displays π-stacking interactions[11–14] between C_6F_5 and pyridine arene ligands supporting the formation of the infinite chains.

Results and Discussion

Compound **1** was synthesized according to Equation (1). An ionic formulation could be proposed in solution based on the molar conductivity measurement in acetone solution (Λ_M = 110 Ω^{-1} cm^2 mol^{-1}, $5\cdot10^{-4}$ M) assigned to a 1:1 electrolyte. The IR spectrum shows, amongst others, the absorptions of the C_6F_5 ligands at 783, 963 and 1500 cm^{-1} [15] and pyridine ligands in the range 617–651 cm^{-1}.[16] Moreover, the ^{19}F NMR chemical shifts of δ = −114.60, −162.07 and −163.87 are similar to the values observed for the $[Au(C_6F_5)_2]^-$ fragment in solution. The separation of compound **1** into ionic components in solution is also confirmed by the mass spectrometry measurements (electrospray) in which we observe, depending on the experiment, the $[Au(C_6F_5)_2]^-$ anion at m/z = 541 (ES^-) and the

$[Ag(Py)_2]^+$ cation at $m/z = 266$ or the $[Ag(Py)]^+$ cation at $m/z = 187$ (ES^+).

$$NBu_4[Au(C_6F_5)_2] + AgClO_4 + C_5H_5N_{(excess)} \xrightarrow[-\,NBu_4ClO_4]{CH_2Cl_2} [Ag(C_5H_5N)_3][Au(C_6F_5)_2]\cdot C_5H_5N \quad (1)$$

A single-crystal X-ray diffraction study has been carried out for compound **1**. The silver atom is found to be disordered over two positions (50% each one), which makes the results of this study not completely valid. Despite this, the molecular structure can be described as being formed by $[Au(C_6F_5)_2]^-$ units and tricoordinate $[Ag(Py)_3]^+$ cations giving rise to a molecular ion-pair model (Figure 1). The molecular Au−Ag ion pairs are repeated in one dimension forming a chain due to the presence of π-stacking interactions between C_6F_5 and pyridine rings and packing effects,. Because of the disorder, any comment about bond lengths and angles is inappropriate, but nevertheless, the singular structural disposition could be used as a basis for a theoretical study.

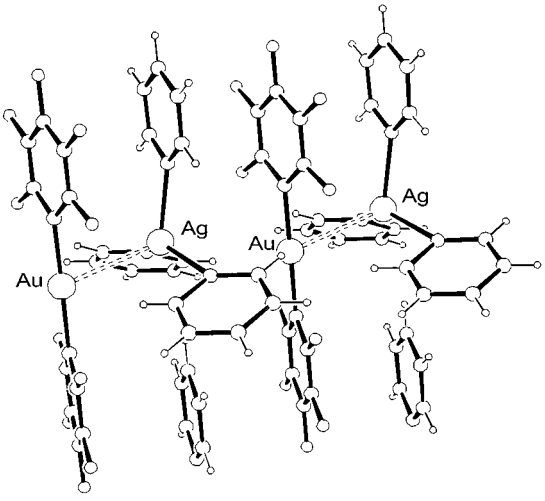

Figure 1. Structure of complex **1**; two molecular Au−Ag ion pairs and C_6F_5-pyridine π-stacking are shown

The structural arrangement of complex **1** shows some interesting features from a theoretical point of view. First, a short distance between the Au^I and Ag^I atoms is observed. Secondly, two C_6F_5···Py aromatic interactions could be proposed in the formula unit $[Ag(Py)_3][Au(C_6F_5)_2]\cdot Py$, one between a free pyridine molecule and one of the C_6F_5 rings and the other between a pyridine ligand bonded to silver and the other C_6F_5 ring. A theoretical study of these secondary interactions has been carried out separately on three different model systems (Figure 2) using two levels of theory based on Hartree−Fock (HF) and Local second order Møller−Plesset perturbation (LMP2) theory. The LMP2 approach, which is the simplest of the local correlation methods,[17−19] is analogous to the traditional MP2 but is performed using localized occupied and local virtual orbitals. The virtual space is spanned by nonorthogonal atomic orbitals (AOs), which are projected against the occupied space in order to ensure orthogonality between the occupied and virtual spaces. These nonorthogonal projected orbitals are inherently localized. The *orbital domain* [i] is that part of the virtual space assigned to an individual LMO (i), consisting only of those basis functions that are centered on the atoms involved in that particular LMO. The orbital domains [i] are kept orthogonal to the occupied space by projecting out the LMOs. Double excitations from an orbital pair (ij) are only allowed into the *pair domain* [ij], which is spanned by the union of the corresponding orbital domains [i] and [j]. The introduction of this physically appealing restriction in which electron pairs are only interacting in the vicinity of either electron, gives rise to the significant reduction of the computational cost as well as a diminished basis-set supposition error (BSSE). On the other hand the use of localized orbitals makes it possible to decompose the correlation contribution into the interaction energy of a complex according to different classes of double excitations. The two most important contributions arise from the dispersion class, in which one electron is excited from each subsystem into its own virtual space, and the ionic class, in which one of the electrons is excited from one of the subsystems to the virtual space of the other subsystem. In addition to the partition of the correlation contribution of the interaction energy, we can assume that the major part of the electrostatic interaction is already described at the uncorrelated HF level. Hence, we can theoretically study in great detail the forces that are responsible for the one dimensional disposition of complex **1** in the solid state.

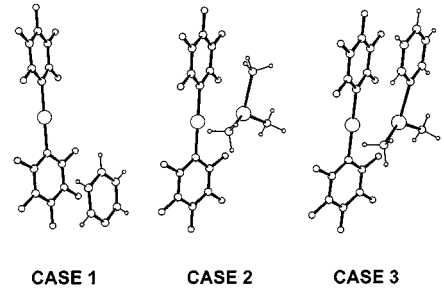

Figure 2. The assumed structures of the theoretical models, (a): $[Au(C_6F_5)_2]$···Py **CASE 1**; (b): $[Ag(NH_3)_3]$···$[Au(C_6F_5)_2]$ **CASE 2**; (c): $[Ag(NH_3)_2(Py)]$···$[Au(C_6F_5)_2]$ **CASE 3**

Finally, we emphasize that the role of dynamic correlation effects in transition-metal chemistry is well-known. The particular correlation effects leading to the R^{-6} dispersion forces involve dipole-allowed virtual excitations at the two centers involved ($A \rightarrow A'$, $B \rightarrow B'$). The "ionic correlation" mentioned above means ($A \rightarrow A'$, $B \rightarrow A'$). These interaction can only be reproduced by explicitly correlated methods.

One advantage of the LMP2 method is that it has almost no BSSE. Thus, no counterpoise corrections are needed.

In principle one should simulate the entire crystal structure but we have only considered particular contributions using cluster models.

In case 1 (Figure 2a) we have studied the interaction between $[Au(C_6F_5)_2]^-$ and a free pyridine molecule present in the crystal structure. The results of this interaction are given in Table 1 and the calculated interaction energy curves are shown in Figure 3. The HF curve is repulsive, whereas the LMP2 curve is attractive. The calculated $[Au(C_6F_5)_2]\cdots$Py distance, defined as the distance between the virtually parallel Py and C_6F_5 units, is 344.7 pm for our simplified model system and the interaction energy is 36.5 kJ/mol at the equilibrium distance. Thus, we can assume that the aromatic interaction between a C_6F_5 group from the $[Au(C_6F_5)_2]^-$ unit and the free pyridine molecule is due to dispersion-type correlation effects, since a stabilization energy is observed when these effects are included at the LMP2 level of theory and a repulsion between the rings at HF level is found.

Table 1. Optimized distance (R_e) and interaction energy (E_e) for the three model systems at HF and LMP2 levels (distances in pm and energy in kJ/mol)

CASE 1	REPULSIVE	−0.44[a]	317.8[b]	36.5
CASE 2	312.3	160	284.3	234
CASE 3	323.2	143	289.4	239

[a] At the LMP2 optimized distance. [b] Referred to the Au−Ag distance.

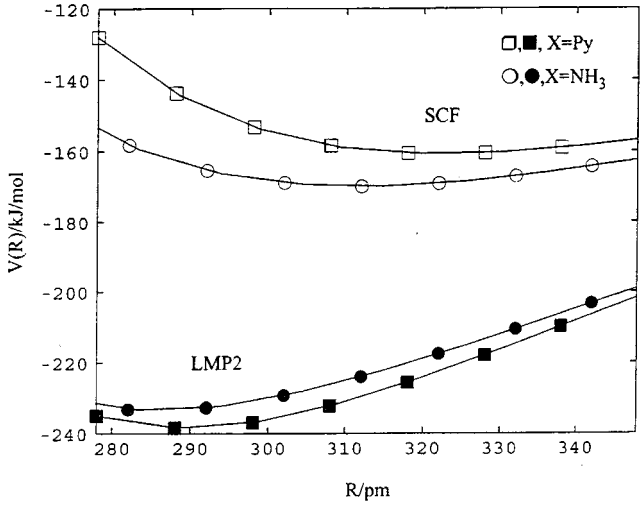

Figure 3. Interaction energy curves for the $[Au(C_6F_5)_2]\cdots[XAg(NH_3)_2]$ (X = NH_3, Py) interaction calculated at the SCF and LMP2 levels

Many earlier examples of coplanar "π-stacks" between aromatic rings are known. A typical ring-ring distance is 350 pm.[13] If the two rings have opposite electric quadrupole moments, like C_6H_6 and C_6F_6, the electric quadrupole-quadrupole interactions already yield an attraction of about 6 kJ/mol.[20] Examples of π-stacks in organometallic chemistry are also known.[14] For further information on this subject see ref.[21]

In case 2 (Figure 2b) we have proposed a model system $[Ag(NH_3)_3]\cdots[Au(C_6F_5)_2]$ in order to study only the intermetallic Au−Ag interaction. The results of the interaction energies at the theoretically predicted equilibrium distance are given in Table 1 and the calculated interaction energy curves are shown in Figure 3. In this case, the HF curve is attractive with a minimum corresponding to the equilibrium distance at 312.3 pm and an attractive interaction energy of 160 kJ/mol compared to the ionic dissociation limit. Regarding the LMP2 curve we also obtain an attractive behavior with an interaction energy at the equilibrium distance (284.3 pm) of 234 kJ/mol. In this case, in which only the Au···Ag interaction is studied, both electrostatic attraction and dispersion-type correlation effects are responsible for this interaction. The electrostatic interaction is responsible for the attractive behavior obtained at the HF level since dispersion-type correlation effects are not included. The additional stabilization obtained at the LMP2 level is due to the introduction of these correlation effects, which include dispersion.

Going from case 2 to case 3, we exchange one of the NH_3 ligands bonded to silver for one pyridine ligand that is parallel and at a short distance from one of the C_6F_5 rings bonded to gold (Figure 2c). In this case we study the influence of the presence of two interactions, the intermetallic Au−Ag and the aromatic $C_6F_5\cdots$Py (Ag-bonded), at the equilibrium distances and at the interaction energy values. For this case we obtain an $Au^I\cdots Ag^I$ equilibrium distance at the HF level of 323.2 pm and of 289.4 pm at the LMP2 level. The equilibrium distance at both levels of theory is accompanied by interaction energy values of 143 kJ/mol at the HF level and 239 kJ/mol at the LMP2 level (see Table 2 and Figure 3). Thus, this comparison allows us, if we make the simplified conclusion that HF covers electrostatic interactions and the correlation energy (the difference between LMP2 and HF) covers the dispersion contribution, to establish that the overall interaction is very similar for both cases 2 and 3, in terms of the LMP2 equilibrium distance and the interaction energy (284.3 pm and 234 kJ/mol for case 2 and 289.4 pm and 239 kJ/mol for case 3). However, the contributions are different. The pyridine ligand in case 3 introduces electrostatic repulsion since the electrostatic interaction diminishes from 160 kJ/mol in case 2 to 143 kJ/mol in case 3, but it also introduces attractive dispersion interactions (74 kJ/mol in case 2 to 96 kJ/mol in case 3), as occurs in case 1. In Table 2 we compare the results for cases 2 and 3 at the LMP2 optimized distances, which are quite similar in both cases (284 vs. 289 pm respectively).

Table 2. Electrostatic (HF) and dispersion (LMP2) contributions to the intermetallic Au−Ag interaction (kJ/mol) at the LMP2 optimized distance

	Electrostatic	Correlation Energy	Total
CASE 2	160	74	234
CASE 3	143	96	239

The partitioning of the correlation contribution to the $[Ag(NH_3)_3]\cdots[Au(C_6F_5)_2]$ (case 2) and $[Ag(NH_3)_2(Py)]\cdots[Au(C_6F_5)_2]$ (case 3) interaction energies based on the obtained experimental distances are given in Table 3. The introduction of the pyridine ring into the model system in case 3 gives, as we have commented above, a net enhancement of the correlation energy and, looking at the partition of this correlation energy, the dispersion (van der Waals) contribution increases with respect to the ionic correlation contribution seen as the charge transfer.

Table 3. LMP2 correlation energy partitioning at the experimental geometry (kJ/mol)

	Ex-dispersion	Dispersion	Ionic	Ag→Au	Au→Ag
CASE 2	0.0	29	16	4	12
CASE 3	−0.1	45	20	6	14

Conclusions

1) An ionic, Coulomb attraction obviously exists between the $[Au(C_6F_5)_2]^-$ anions and the $[Ag(Py)_3]^+$ cations. This is an important contribution behind the infinite chains.

2) In addition, dispersion-type correlation effects lead to attractions both between Ag^I and Au^I and between C_6F_5 and pyridine moieties.

3) Looking at the detailed correlation energy partitioning, the most important contributions are the normal dispersion (van der Waals) terms. Charge-transfer-type contributions are about one third as important and, of them, the Au→Ag virtual excitation is more important than the Ag→Au one.

Experimental Section

General: All experiments were performed under argon by using standard Schlenk techniques. Solvents were dried and distilled under argon. ^1H and ^{19}F NMR spectra were recorded on a Bruker ARX 300. Elemental analyses were carried out with a C.E. instrument EA-1110 CHNS-O microanalyzer. Infrared spectrum was recorded in the 4000−200 cm^{-1} range on a Perkin−Elmer FT-IR Spectrum 1000 spectrophotometer as nujol mulls between polyethylene sheets. Mass spectra were recorded on a HP-5989B Mass Spectrometer API-Electrospray with interface 59987A.

$[Ag(Py)_3][Au(C_6F_5)_2]\cdot Py$ (1): The reaction between $NBu_4[Au(C_6F_5)_2]$ (200 mg, 0.258 mmol), $AgClO_4$ (54 mg, 0.258 mmol) and an excess of pyridine in CH_2Cl_2 leads, after a slow crystallization process (24 h) at low temperature, to compound **1** as colorless crystals. Yield: 47%. ^1H NMR [$(CD_3)_2CO$]: δ = 7.52 (dd, 2 H, -CH-), 7.96 (t, 1 H, -CH-), 8.67 (d, 2 H, -CH-). $C_{32}H_{20}AgAuF_{10}N_4$ (955.4): calcd. C 40.23, H 2.18, N 5.86; found C 39.92, H 2.25, N 5.41.

Computational Details: All calculations were performed as implemented in the MOLPRO program package. For the metals, the 19 valence electron pseudopotentials from Stuttgart and the corresponding basis sets[22a] augmented with two f polarization functions were used.[22b] For the lighter atoms the cc-pVDZ basis sets were used.[22c] The LMOs were obtained through a Pipek−Mezey localization procedure.[22d]

Anionic Poly(pyrazolyl)borate Ligands Obtained from 3,5-Dimethylpyrazole and 3,5-Diphenylpyrazole and Their Cobalt(II) Complexes − X-ray Crystallographic and ^{1}H NMR Studies[‡]

Tomasz Ruman,[a] Zbigniew Ciunik,[b] Jaroslaw Mazurek,[b] and Stanislaw Wolowiec*[a]

Keywords: Cobalt / Borates / X-ray diffraction / NMR spectroscopy / N ligands

Synthesis of poly(pyrazolyl)borate anionic ligands composed of 3,5-dimethyl- and 3,5-diphenylpyrazoles and their bis(ligand) high-spin cobalt(II) complexes are described. The molecular structures of [dihydrobis(3,5-diphenylpyrazolyl)borato][hydrobis(3,5-dimethylpyrazolyl)(3,5-diphenylpyrazolyl)borato]cobalt(II) and bis[dihydro(3,5-dimethylpyrazolyl)(3,5-diphenylpyrazolyl)borato]cobalt(II) complexes were established by X-ray crystallography. The cobalt center is hexacoordinate in the former with five Co–N_2(pyrazolyl) bonds and short Co–H [attached to the boron atom of bis(pyrazolyl)borate] bond (2.03 Å), whereas a distorted tetrahedral geometry was found for the latter due to four Co–N_2(pyrazolyl) bonds. Additionally, the pentacoordinate homoscorpionate [tris(3,5-diphenylpyrazolyl)borato]cobalt(II) nitrate side product was obtained from the reaction and characterized structurally. It contains a κ^3-coordinated Tp′ ligand and a κ^2-bound nitrate anion.

Introduction

Heteroscorpionate tris(pyrazolyl)borate anions (Tp′) − tripodal ligands containing two or more substituted pyrazol-1-yl moieties − provide a unique opportunity to construct transition metal complexes of low symmetry. Early work by Trofimenko demonstrated that some homoscorpionate Tp′ ligands undergo intramolecular rearrangement into heteroscorpionate ones in their transition metal complexes by borotropic rearrangement of the 3-R-pyrazolyl residue of Tp′ into the 5-R-pyrazolyl one (R = isopropyl or neopentyl).[1,2] Recently, we reported that 3(5)-methyl-5(3)-phenylpyrazole (Ph,MepzH) gave two Tp′ ligands upon condensation of Ph,MepzH with borohydride anion: the homoscorpionate [hydrotris(5-methyl-3-phenylpyrazolyl)borate]$^-$ and the heteroscorpionate [hydrobis(5-methyl-3-phenylpyrazolyl)(3-methyl-5-phenylpyrazolyl)-borate]$^-$, which were characterized structurally in the solid state by X-ray crystallography and in solution by ^{1}H NMR spectroscopy as high-spin cobalt(II) complexes of the general formula Tp′Co(NCS).[3,4]

Continuing our efforts to synthesize a chiral Tp′ ligand with boron-centered chirality we have applied two independent routes to reach the target: a stepwise synthetic approach, in which dihydro(3,5-dimethylpyrazolyl)(3,5-diphenylpyrazolyl)borate was synthesized in the first step, dihydrobis(pyrazolyl)borate (Bp′) being a convenient substrate for conversion into chiral Tp′ by condensation of NaBp′ with another substituted pyrazole, and a more promising and less laborious method based on a one-step condensation of 2 equiv. of Ph,MepzH and 1 equiv. of 3,5-diMepzH with sodium borohydride.[4] This first-step condensation led to the isolation of a mixture of Tp′ and Bp′ products, some of which were converted into high-spin cobalt(II) complexes, characterized structurally by X-ray crystallography in the solid state and ^{1}H NMR spectroscopy in solution.

Chiral Tp ligands of C_3 symmetry based on pyrazoles derived from camphor and menthone[5] and potentially hexacoordinate hydrotris[3-{2-(pinene[4,5]pyridyl)}pyrazolyl]borate[6] were synthesized recently and used to construct metal complexes of catalytic activity.

Results and Discussion

Synthetic Procedures and Distribution of Products

The synthesis of poly(pyrazolyl)borate anions by condensation of sodium (or potassium) borohydride with pyrazoles in the melt can be controlled exclusively by the appropriate choice of stoichiometry of substrates and often leads to a nonstatistical distribution of products due to inhomogeneity of the reaction mixture. A typical example of this phenomenon is represented by synthetic route (1) (see Exp. Sect.), in which the condensation of KBH_4 (or $NaBH_4$)

[‡] Complexes of Heteroscorpionate Tris(pyrazolyl)borate Anionic Ligands, IV. − Part III: Ref.[4]

with 1 equiv. of 3,5-diphenylpyrazole and 1 equiv. of 3,5-dimethylpyrazole led to the formation of a mixture of potassium (or sodium) dihydrobis(pyrazolyl)borates (Bp′) and hydrotris(pyrazolyl)borates (Tp′), i.e. dihydro(3,5-diphenylpyrazolyl)(3,5-dimethylpyrazolyl)borate, dihydrobis(3,5-diphenylpyrazolyl)borate, dihydrobis(3,5-dimethylpyrazolyl)borate, hydrobis(3,5-dimethylpyrazolyl)(3,5-diphenylpyrazolyl)borate, hydrobis(3,5-diphenylpyrazolyl)-(3,5-dimethylpyrazolyl)borate, and hydrotris(3,5-diphenylpyrazolyl)borate. The anionic products were identified as their high-spin cobalt(II) complexes. This method was proven to be particularly useful[1−4,7] because it allows for both the isolation of the anionic poly(pyrazolyl)borate ligands and their identification by ^{1}H NMR spectroscopy. This method is effective in the case of tris(pyrazolyl)borate ligands (Tp′) with large or intermediate steric hindrance imposed by substituents placed at the 3- and/or 5-positions on the pyrazolyl moiety, which can be isolated as Tp′Co(X) complexes, where X = NCS^-, Cl^-, or CO_2^-. The Bp′ and Tp′ ligands obtained in the synthesis described here gave bis(ligand) complexes of the type Bp′$_2$Co, Bp′CoTp′, and Tp′$_2$Co along with Tp′Co(X). We have isolated three complexes, containing different Bp′ and Tp′ ligands and found other ligands coordinated to the cobalt(II) ion in the mixture of products. The pyrazoles used for the construction of the Bp′ and Tp′ ligands have small (3,5-dimethylpyrazole) and intermediate (3,5-diphenylpyrazole) steric hindrance. The isolation procedure applied for the separation of cobalt(II) complexes was based on fractional crystallization from THF/hexane solvent mixtures: the least soluble product, the hydrotris(3,5-diphenylpyrazolyl)boratocobalt(II) nitrate complex [$Tp^{Ph_2}Co(NO_3)$, **1**], was isolated as a pure crystalline product in the first instance, although the synthetic yield of the ligand was only 1%. Deliberate synthesis of this ligand and conversion into the $Tp^{Ph_2}Co(NCS)$ complex **1′** gave the analytically pure product, which was completely insoluble in all common organic solvents, analogously to **1**. Similar $Tp^{Ph_2}Zn(OOCCH_3)$ and $Tp^{Ph_2}NiCl$ complexes have been synthesized before and characterized crystallographically.[8] The purple $Tp^{Ph_2}NiCl$ complex with the ligand κ^3-bound in the solid state was found to be diamagnetic in [D$_6$]DMSO solution as was concluded from its ^{1}H NMR spectrum.

Even though we observed the formation of only two of the three expected Bp′ ligands in the synthetic route (1) (Exp. Sect.), the conversion of the mixture of anionic ligands into cobalt(II) complexes gave the pink crystalline product Bp′CoTp′ (**2**) in 12% yield. Surprisingly, the Tp′ ligand trapped in this heteroleptic complex is the hydrobis(3,5-dimethylpyrazolyl)(3,5-diphenylpyrazolyl)borate {[HB(3,5-diMepz)$_2$(3,5-diPhpz)]$^-$} with intermediate steric hindrance, while the Bp′ ligand turned out to be the symmetrical dihydrobis(3,5-diphenylpyrazolyl)borate {[H_2B-(3,5-diPhpz)$_2$]$^-$) instead of the statistically more probable [H_2B(3,5-diMepz)(3,5-diPhpz)]$^-$ ligand. Although the new heteroscorpionate Tp′ ligand was itself interesting for us from a structural point of view, the synthetic procedure, which was designed to synthesize [H_2B(3,5-diMepz)(3,5-diPhpz)]$^-$, had to be modified. We therefore performed the condensation of $NaBH_4$ with one equivalent each of 3,5-diMepzH and 3,5-diPhpzH in refluxing tetradecane. The reaction at 254° C allowed for better control and thus optimization of the reaction conditions for the desired unsymmetrical Bp′ ligand. The [H_2B(3,5-diMepz)(3,5-diPhpz)]$^-$ ligand was thus isolated as the complex Bp′$_2$Co (**3**) and characterized structurally in the solid state by single-crystal X-ray diffraction measurements. The isolated yields of **2** and **3** are rather low, although we observed the formation of other Tp′Co(NO_3) and Bp′CoTp′ complexes containing other heteroscorpionate Tp′ and unsymmetrical Bp′ ligands, which were later identified. We were therefore able to determine the composition of the crude reaction mixture obtained in the synthesis of KBp′ (NaBp′) and KTp′ (NaTp′) salts on the basis of the integration of the corresponding resonances in the ^{1}H NMR spectrum of a mixture composed of Tp′Co(NO_3), Bp′CoTp′, and Bp′CoBp′′ complexes.

X-ray Crystallographic Studies of the Co Complexes

Structure of $Tp^{Ph_2}Co(NO_3)$ (1)

A view of the molecule of **1** is presented in Figure 1, along with selected bond lengths and angles. The cobalt-centered bite angle is 133.1°, which is much lower than those found in tetracoordinate $Tp^{Ph_2}Cu(CO)$ (145.5°)[9] and pentacoordinate $Tp^{Ph_2}Fe(OOCC(O)Ph)$ (139.6°).[10] It is noteworthy that an increasing steric hindrance at *C*-5(pyrazole) in the order H < CH_3 < Ph causes a tightening of the bite angle from 142.0° [5-H in $Tp^{Ph}Co(NCS)(pzH)$],[7] through 140.3° [5-CH_3 in $Tp^{PhMe}Co(NCS)(THF)$][4] to

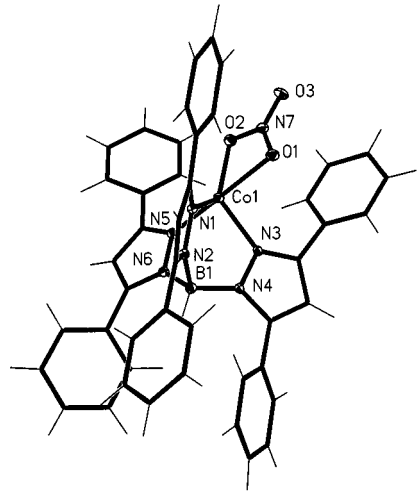

Figure 1. Molecular structure of **1** with crystallographic numbering; selected bond lengths (Å) and angles (°): Co(1)−N(1) 2.038(2), Co(1)−N(3) 2.030(2), Co(1)−N(5) 2.059(2), Co(1)−O(1) 2.230(2), Co(1)−O(2) 2.008(2); N(1)−Co(1)−N(3) 96.18(7), N(1)−Co(1)−N(5) 93.23(7), N(3)−Co(1)−N(5) 89.83(8), O(2)−Co(1)−O(1) 60.67(6), O(1)−N(7)−O(2) 114.15(17), O(1)−N(7)−O(3) 124.2(2), O(2)−N(7)−O(3) 121.68(19)

Structure of [Dihydrobis(3,5-diphenylpyrazolyl)borato]-[hydrobis(3,5-dimethylpyrazolyl)(3,5-diphenylpyrazolyl)-borato]cobalt(II) (2)

The cobalt(II) center in **2** is surrounded by five nitrogen donors from the pyrazolyl moieties of the Tp′ and Bp′ ligands (Figure 2). The sixth coordination site is occupied by the boron-bonded hydrogen of the Bp′ ligand. The two shortest Co−N(pz) bonds were found for the 3,5-di-Mepz(Tp′) moieties, whereas the longest Co−N(Tp′) bond was observed for the 3,5-diPhpz moiety, presumably because of steric clashes between 3,5-diPhpz(Tp′) and one of the 3,5-diPhpz(Bp′) ligands. The distance between the cobalt center and hydrogen (Bp′) (2.03 Å) is the shortest amongst this type of complexes. This distance was found to be equal to 2.26 Å in $[H_2B(3\text{-}Phpz)_2]Co[HB(3\text{-}i\text{Pr},4\text{-}Brpz)_3]$,[1] 2.69 Å in $[H_2B(3,5\text{-}diMepz)_2]Cd[HB(3\text{-}Phpz)_3]$,[11] 2.84 Å in BpSmTp,[12] and 2.26 Å and 2.17 Å in hexacoordinate $[\kappa^3\text{-}H,N,N(Tp')]$ $[(\kappa^3\text{-}N,N,N(Tp''))]Co^{II}$ complexes, where Tp′ = Tp^{Ph}, $Tp^{iPr,4Br}$ [1] and Tp′ = Tp′′ = Tp^{Ph}.[13]

Structure of $[H_2B(3,5\text{-}diMepz)(3,5\text{-}diPhpz)]_2Co$ (3)

A view of the molecule of **3** is presented in Figure 3 with selected bond lengths and angles. An almost isostructural complex (Bp'_2Zn) has been synthesized previously.[14] In both complexes the M−N(3,5-diMepz) distances are shorter (1.98−1.99 Å) than the M−N(3,5-diPhpz) ones (2.01−2.02 Å). The Co−N(pz) distances are slightly shorter in the Bp_2Co complex (1.93−1.98 Å).[15] In all cases there is no Co−H(Bp′) contact; the Co−H distances increase from 2.93 Å (2.96 Å) for **3** through 3.00 Å (3.06 Å) for Bp_2Co up to 3.26 Å (3.28 Å) for Bp'_2Zn. The closest distance between the metal ion and the boron-bound hydrogen in tetracoordinate complexes with Bp′ ligands was found in the complex $Bp^{tBu}Zn(t\text{Bu})$ (2.47 Å)[16] whereas in other cases it falls in the range 2.9−3.1 Å.[17−23]

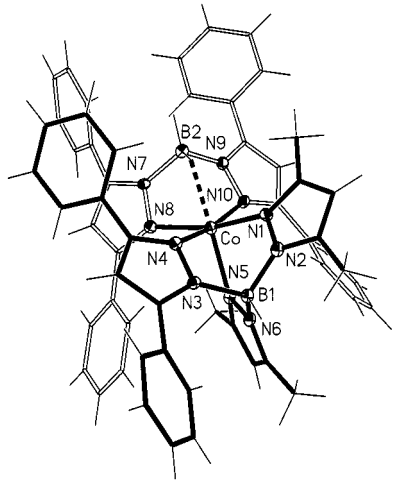

Figure 2. Molecular structure of **2** with crystallographic numbering; selected bond lengths (Å) and angles (°): Co(1)−N(1) 2.091(3), Co−N(4) 2.153(3), Co−N(5) 2.103(3), Co−N(8) 2.113(3), Co−N(10) 2.140(3); N(1)−Co−N(5) 91.00(13), N(1)−Co−N(4) 81.91(12), N(5)−Co−N(4) 90.03(12), N(8)−Co−N(10) 89.91(12)

Spectral Studies

The pink color of **2** is characteristic of pentacoordinate complexes of Tp′Co(XY), which can be produced either by coordination of a neutral ligand, such as a methanol solvent molecule, to Tp′CoX (X = NCS^-, N_3^-, Cl^-), or by chelation of an anionic carboxylate with an additional donor atom (lactate). The most characteristic feature of the ^1H NMR spectra of the high-spin Tp′Co(XY) complexes is the chemical shift of the B−H proton, which depends on the coordination number of the cobalt ion center. Thus, the B−*H* resonances can be found between δ = 0 and −20 for tetracoordinate Tp′Co(X) complexes,[1−3,7,24] between δ = 83 and 130 for hexacoordinate complexes,[1,3,7,24−28] and between δ = 40 and 90 for pentacoordinate complexes, the latter depending on the nature of the fifth donor.[3,7]

There are two interesting features in the ^1H NMR spectrum of **2**: i) the low symmetry of the complex found in the solid state is preserved in solution at room temperature; consequently all the pyrazole proton resonances can be distinguished, and ii) the chemical shift of B−*H* from the Tp′ ligand (δ = 61.3) is rather low in comparison with other typical pentacoordinate Tp′Co(XY) complexes (XY = lactate).[3,7] This low symmetry is even preserved at 383 K (in $[D_8]$toluene) indicating that the mutual rotation of the Tp′ and Bp′ ligands at this temperature is still slow on the timescale of this method. The 2-D ^1H COSY spectrum of **2** taken at 372 K (Figure 4) allowed us to unambiguously identify the *o*-, *m*-, and *p*-H resonances from the three 5-Ph

substituents of the Bp′ and Tp′ ligands due to the presence of scalar cross-peaks (lower left inset at Figure 4). These resonances are paramagnetically shifted downfield, as was observed previously for [HB(3-Ph,5-Mepz)2(3-Me,5-Phpz)]Co(NCS)(CD_3OD) and [HB(3-Ph,5-Mepz)(3-Me,5-Phpz)2]Co(NCS)(CD_3OD) complexes.[4,7] Three cross-peaks between the *m*- and *p*-H of the 3-Ph substituents of the Tp′ and Bp′ ligands were also observed, although the scalar connectivity pattern within the 3-Ph substituents was broken due to the short relaxation times of the *ortho* hydrogens (right inset of Figure 4). We were also unable to observe the appropriate NOE cross-peaks between 3-CH_3(Tp′) and *o*-H(Bp′) which would have allowed us to assign all the resonances. Nevertheless, the resonances for *o*-H(3-Ph,Bp′) are shifted upfield considerably less than those of *o*-H(3-Ph,Tp′) which is consistent with the static geometry of the molecule (see above). Very broad resonances at $\delta = 9$ and 10, which can be tentatively assigned to the H-B(Bp′) protons, were observed in the spectrum. One of the resonances for 5-CH_3 (Tp′) is also extremely broad and is placed within the diamagnetic envelope.

The UV/Vis spectra of **2** and **3** are characteristic of high-spin cobalt(II) in octahedral and tetrahedral environments, respectively.[29] Two bands centered at 498 and 538 nm for **2**, which can be assigned to a $^4T_{1g}(P) \leftarrow {}^4T_{1g}$ transition, have extinction coefficients near 60 mol^{-1} dm^3 cm^{-1}. This slightly higher than the corresponding band observed for Tp_2Co,[30] and is probably due to the higher coordination geometry in **2**. In the case of **3** the position and extinction coefficient of the three observed bands are close to those found for Bp_2Co,[30] and can be assigned to a $^4T_1(P) \leftarrow {}^4A_2$ transition.[29]

Experimental Section

Methods: ^{1}H NMR spectra were obtained with a Bruker AMX300 spectrometer operating in the quadrature mode at 300 MHz. The residual peaks of the deuterated solvents were used as internal standards. The 2-D ^{1}H COSY spectrum was obtained with a repetition time of 0.2 s. The magnetic moments of **2** and **3** were measured on the same instrument in $CDCl_3$ at 298 K. The IR and UV/Vis spectra were recorded on a Perkin−Elmer 1725X and a HP 8453 diode-array spectrophotometer, respectively. Elemental analyses were performed with an EA 1108 apparatus (Carbo Erba) at Department of Organic Chemistry, Faculty of Chemistry, Rzeszów University of Technology.

Crystal data for **1**−**3** are given in Table 1, together with refinement details. All measurements were performed on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo-K_α radiation. The crystals were positioned 65 mm from the KM4CCD camera. 612 frames were measured at 0.75° intervals with a counting time of 20 sec. The data were corrected for Lorentz and polarization effects. An absorption correction based on least-squares fitted against $|F_c| - |F_o|$ differences was also applied for **1**.[31] No absorption corrections were applied for **2** and **3**. Data reduction and analysis were carried out with the Kuma Diffraction (Wroclaw) programs. Structures were solved by direct methods (program SHELXS-97)[32] and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97[33] program suite. Non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included from the geometry of the molecules and Δρ maps, and refined with isotropic thermal parameters for **1** only.

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-160912 (**1**), CCDC-160913 (**2**), and CCDC-160914 (**3**). Copies of the data can be obtained free of charge on applicaton to The Director, CCDC, 12 Union Road,m Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Condensation of 3,5-Dimethylpyrazole and 3,5-Diphenylpyrazole with Potassium Borohydride. Route (1): The one-step condensation of KBH_4 (0.818 g, 15.2 mmol) with 3,5-diphenylpyrazole (3.304 g, 15.0 mmol) and 3,5-dimethylpyrazole (1.35 g, 14.1 mmol) was done by heating the reagents in melted pyrazoles at 165−225° C until 725 cm^3 hydrogen had been evolved. The crude reaction mixture was washed with hot heptane (100 cm^3), then petroleum ether (50 cm^3) and dried in air to give 3.131 g of crude product [as a mixture of potassium poly(pyrazolyl)borate salts] in approximately 56% yield.

Route (2): The one-step condensation of $NaBH_4$ (0.352 g, 9.31 mmol) with 3,5-diphenylpyrazole (1.640 g, 7.45 mmol) and 3,5-dimethylpyrazole (0.716 g, 7.45 mmol) was performed by heating the mixture in tetradecane 50 (cm^3) under reflux (254 °C) until 340 cm^3 hydrogen had been evolved. The crude reaction mixture was cooled to about 80° C, filtered to remove unchanged pyrazoles, washed with hot heptane (100 cm^3) and petroleum ether (50 cm^3). The solid residue was dried, crushed into pieces, suspended in 50 cm^3 heptane, boiled, filtered and washed with petroleum ether. A dry mixture of sodium salts of anionic poly(pyrazolyl)borates (1.85 g) was obtained (approximately 57% yield).

Synthesis of Cobalt(II) Complexes with Poly(pyrazolyl)borate Ligands: 1.21 g of potassium salts [approx. 3.3 mmol of crude reac-

tion mixture obtained in route (1), vide supra] was dissolved in tetrahydrofuran (THF, 150 cm^3) and into this solution a stock solution of cobalt(II) nitrate in THF [1.5 equivalents of cobalt(II) calculated for potassium dihydro(3,5-dimethylpyrazolyl)(3,5-diphenylpyrazolyl)borate] was added dropwise, with vigorous stirring. The resulting pink-violet solution was concentrated to a volume of 30 cm^3, then 150 cm^3 of methylene dichloride was added and the organic phase was twice extracted rapidly with 150 cm^3 of water. The organic phase was separated and the solvents removed on a rotary evaporator. The solid obtained was dissolved in THF, passed through a short bed of celite and the solution layered with heptane. After two days, 25 mg of deep-violet crystals deposited from the mixture. These crystals were separated and their composition was determined by elemental analysis and X-ray diffraction as hydrotris(3,5-diphenylpyrazolyl)boratocobalt(II) nitrate [Tp^{Ph_2}-$Co(NO_3)$ (**1**)]. The complex was totally insoluble in most organic solvents and water. Yield: approx. 1%.

For comparison we also synthesized potassium hydrotris(3,5-diphenylpyrazolyl)borate KTp^{Ph_2} by the standard procedure[8] and $Tp^{Ph_2}Co(NCS)$ complex (**1′**) by addition of KTp^{Ph_2} in THF to an excess of cobalt(II) thiocyanate, as described previously.[7]

After separation of **1**, crystallization of the cobalt(II) complexes was continued and the mixture of products was examined by ^1H NMR spectroscopy. The major product in the mixture was finally separated after four recrystallizations from THF/heptane as pink crystals (160 mg) and identified by elemental analysis, ^1H NMR spectroscopy, and X-ray crystallography as [dihydrobis(3,5-diphenylpyrazolyl)borato][hydrobis(3,5-dimethylpyrazolyl)(3,5-diphenylpyrazolyl)borato]cobalt(II) (**2**). Yield: approx. 12%.

In a separate synthesis, 1.85 g (approx. 5.3 mmol) of the mixture of poly(pyrazolyl)borate sodium salts obtained from route (2) (vide supra) was converted into a mixture of bis(ligand) cobalt(II) complexes as described above. Fractional crystallization of the complexes from THF/hexane mixture gave pink crystals of a mixture of Bp′CoTp′ compounds and another Tp′$Co(NO_3)$ complex in the first instance (220 mg), whereas the desired Bp′CoBp′′ complexes remained in solution. The complex [H_2B(3,5-diMepz)(3,5-diPhpz)]$_2$Co (**3**; 385 mg, 0.54 mmol, yield approx. 18%) was obtained from the filtrate as burgundy red crystals and identified by means of an X-ray crystallographic analysis.

Dipeptides Made up Solely from Histidine: Solution Behaviour and Zinc Complexation[‡]

Raphael Vogler[a] and Heinrich Vahrenkamp*[a]

Keywords: Zinc / Peptides / Histidine / Complex stabilities

The acid/base chemistry and the zinc complexation of the four dipeptides H-HisHis-OH, H-HisHis-OEt, Ac-HisHis-OH and Ac-HisHis-OEt were investigated by potentiometric methods. 1:1 (zinc:dipeptide) complexes prevail in solution, and those complexes that could be isolated on a preparative scale also have 1:1 compositions. The stability data confirm that exclusive zinc-imidazole(histidine) coordination is weak, and additional effects are essential to effect the high preference of zinc for histidine in proteins. A comparison of the stability data for zinc complexes of all dipeptides made up solely from histidine and/or cysteine reveals systematic trends and allows a parameterization of the log β values.

Introduction

Both catalytic and structural zinc in enzymes are always coordinated by at least one cysteine or histidine donor, and specifically in hydrolytic zinc enzymes a $(histidine)_3Zn-X$ coordination is typical.[2,3] This is the reason why we have focused heavily on peptides containing cysteine or histidine in our series of studies on zinc peptide complexes. Prior and parallel to our investigations there were relatively few reports in the literature on the zinc coordination of small peptides dominated by these two amino acids. The main reason for this is the great effort which is necessary for the synthesis of peptides that are rich in cysteine or histidine.

This paper completes our work on the zinc complexation of peptides containing two cysteine and/or histidine units. Previously we have reported on HisCys[4] and CysCys[1] dipeptides, on cyclic dipeptides,[5] and on tri- and tetrapeptides with cysteine and/or histidine at both termini and referenced the related literature.[6−8] The missing part — the HisHis dipeptides — is reported here.

In principle simple unprotected peptides are not suitable as representatives of the related proteins. They offer additional donor functions by their amino and carboxylate termini, and they lack the geometrical effects resulting from folding and helix formation. This disadvantage is compensated, however, by the basic information obtainable from them. When they have unprotected termini, the effect of those on complex formation can be quantified; when they offer only their side-chain donors the strength of the zinc−side-chain interactions can be evaluated free from the influences of protein preorganization. Being inorganic and not protein chemists we see our justification in providing this basic information.

For the present study the four possible HisHis dipeptides listed below were chosen. They represent the various stages of reduction of the donor functionality to exclusive imidazole donation. They were subjected to potentiometric titrations in the absence and presence of zinc nitrate, and they were treated with zinc salts on a preparative scale. The data obtained from them have enabled a comprehensive comparison of zinc complex stabilities for all small peptides with two closely spaced histidine and/or cysteine units.

H-HisHis-OH H-HisHis-OEt
Ac-HisHis-OH Ac-HisHis-OEt

Results and Discussion

Synthesis of the Peptides

The preparation of HisHis dipeptides requires the heavy use of protective groups due to the trifunctional nature of histidine itself. Such dipeptides have been reported in the literature,[9] and H-HisHis-OH is commercially available. We chose to prepare the four dipeptides by the methods used in our laboratory. As outlined in the Exp. Sect., Boc protection of the amino terminus and ethyl ester protection of the carboxylate terminus were used. The imidazole function was protected either by the Boc or the Trt groups. Peptide coupling was effected either by the CAIBE or by the DCC methods, and the standard procedures were applied to remove the protective groups as necessary. Final purification by preparative HPLC yielded the TFA adducts of the

four peptides in gram quantities as analytically pure solids which are very hygroscopic.

Isolated Zinc Complexes

All four peptides were treated in a 1:1 and a 2:1 ratio with zinc perchlorate, nitrate, trifluoroacetate, chloride and iodide. Solid products containing zinc and the peptide could be obtained in all cases, but only some of the 1:1 reactions yielded complexes with simple compositions. It must be concluded that the formation of coordination polymers prevails. As observed by us before[1,4,5] the odd zinc:peptide ratios of these compounds make it difficult to assign constitutions or structures to them.

Those 1:1 reactions that were successful yielded 1:1 complexes in water or ethanol/water. The fully unprotected peptide could be combined with zinc trifluoroacetate to form **1**. Likewise, Ac-HisHis-OH yielded the trifluoroacetate **2**. Zinc chloride could be combined with Ac-HisHis-OH to form **3**, and with the fully protected peptide to form **4**. After slow crystallization these complexes were analytically pure but not suited for crystal structure determinations. Once crystallized they were not soluble enough for NMR measurements. Thus, although they seem to be mononuclear in solution (as is also evident from potentiometry, see below) they must be coordination polymers in the solid state. Counting the number of donor functions available for the zinc ions in the observed compositions allows the conclusion that zinc is tetrahedrally coordinated both in the monomers and the polymers. While none of our zinc complexes of bis(histidine) oligopeptides[1,6,8] has formed crystals suitable for X-ray analysis, we could confirm the tetrahedral coordination by an EXAFS analysis for $Zn(Ac\text{-}His\text{-}GlyGlyHis\text{-}NH_2)_2Zn(ClO_4)_2$.[6]

(Ac-HisHis-OEt)ZnCl$_2$ **4**

Potentiometric Titrations

The acid/base titrations of the peptides themselves initially determined the amount of trifluoroacetic acid contained in them, as given in the Exp. Sect. Then they yielded the pK_a values which are listed in Table 1.

Table 1. Acid dissociation constants (pK_a) of the peptides (standard deviations in parentheses)

	COOH	ImH$^+$(1)	ImH$^+$(2)	NH_3^+
H-HisHis-OH	2.58(9)	5.72(1)	6.83(1)	8.04(4)
H-HisHis-OEt		5.47(1)	6.63(2)	7.86(3)
Ac-HisHis-OH	2.68(8)	6.40(6)	7.60(7)	
Ac-HisHis-OEt		5.96(11)	6.89(17)	

The carboxylate and amine pK_a's of the dipeptides can simply be referenced against those of histidine itself [pK(COOH) = 1.77, pK(NH_3^+) = 9.24].[9] The insertion of the second histidine unit between the carboxylate and ammonium functions, i.e. increasing their distance, eliminates completely their mutual influence. As a result the carboxylic pK_a rises and the ammonium pK_a decreases by about one unit. For histidine itself the imidazole pK_a (6.14) rises when the amino function is blocked and decreases when the carboxylate function is blocked;[10] these are basically charge effects. This can also be seen when comparing H-HisHis-OH with both H-HisHis-OEt and Ac-HisHis-OH in terms of the first imidazole pK_a. It seems that a mutual compensation of these two effects moves the first imidazole pK_a of Ac-HisHis-OEt back to the value of H-HisHis-OH.

In terms of exclusive histidine coordination, like in the proteins themselves the imidazole pK_a's of the fully protected histidine peptides are relevant. While the fully protected histidine Ac-His-NH_2 (pK = 7.07)[11] and isolated histidine in the peptide Ac-HisVal-OH (pK = 6.84)[12] have the typical pK_a for histidine near 7, the first histidine pK_a for all four dipeptides in this study is roughly one unit lower. This again is a charge effect: the positive charge on the second imidazolium function makes the deprotonation of the first one easier. The two pK_a values for Ac-HisHis-OEt are almost identical to those for the two histidine units in fully protected His-X-His tripeptides with X = Gly, Pro, Val and Apa.[8] This indicates that the distances between the two imidazolium functions has no pronounced effect. On the other hand, cyclo-HisHis shows pK_a's of 5.53 and 6.61[5] which are significantly lower than the others, and which may be correlated with the highly polar nature of this diketopiperazine derivative. One feature is common for all the bis(histidine) peptides mentioned here: their two imidazole pK_a's are all 1.1 ± 0.1 units apart.

The titrations in the presence of zinc nitrate did not suffer from the problem of precipitation which is a common one for cysteine-containing peptides. The rich species distributions exemplified by Figures 1 and 2 could be analyzed and correlated with the complex stabilities listed in Table 2.

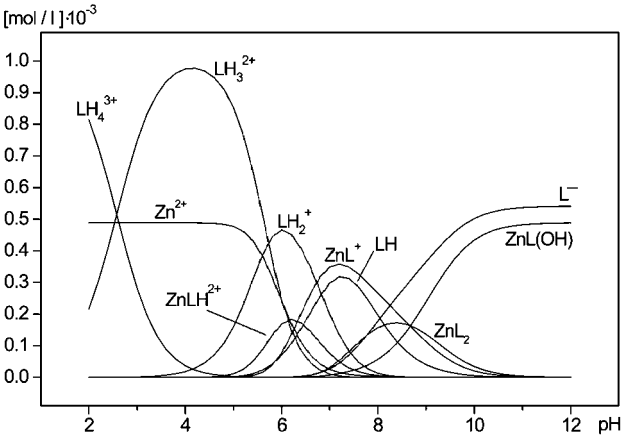

Figure 1. Species distribution in a solution of H-HisHis-OH and $Zn(NO_3)_2$ in a ratio of 2.1:1

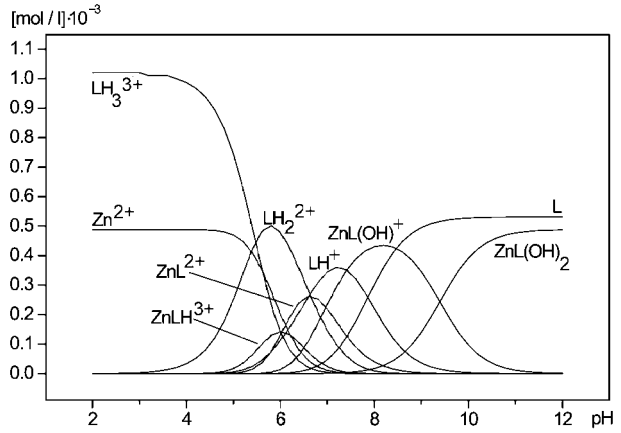

Figure 2. Species distribution in a solution of H-HisHis-OEt and $Zn(NO_3)_2$ in a ratio of 2:1

Table 2. Stability constants for the zinc complexes (log β) in solutions of the peptides (σ values in parentheses)

	ZnLH	ZnL	ZnL(OH)	$ZnL(OH)_2$	ZnL_2
H-HisHis-OH	12.02(6)	5.79(13)	−3.18(18)	−	9.18(6)
H-HisHis-OEt	11.70(2)	5.70(6)	−1.20(9)	−10.62(8)	−
Ac-HisHis-OH	−	3.35(15)	−3.74(18)	−	−
Ac-HisHis-OEt	10.05(4)	4.19(11)	−2.31(11)	−	−

As a rule only three complex species were necessary to fit the data: ZnLH, ZnL and ZnLOH, which are all 1:1 complexes. Of these, ZnLH represents a complex with a protonated peptide ligand, and ZnLOH represents a complex with a deprotonated water ligand, and hence ZnL is the only relevant species. Only in the case of H-HisHis-OH is a ZnL_2 complex observed, which must have to do with the fact that this ZnL_2 complex is uncharged and there is good chelation involving the imidazole and amino nitrogen donors.[10]

The stability constants for the four ZnL species have characteristic and very informative values. First and most important, they underline that the complex stability provided by exclusive Zn-imidazole(histidine) coordination is unusually small. Even two such interactions, as for Ac-HisHis-OEt, yield only a moderate stability of the ZnL species. This is also evident from the data for ZnL complexes of fully protected His-X-His peptides (X = Gly, Val, Apa), whose log β values are 3.4 ± 0.1.[8] Even the presumed preorganization of the two imidazole donors in cyclo-HisHis yields the very poor log β for ZnL of 2.55.[5] Reference compounds with a single and exclusive imidazole(histidine) donor are Ac-His-NH_2 (log β for ZnL = 1.96)[11] and cyclo-GlyHis (log β for ZnL = 1.71).[5]

This situation only gets better when additional donors of the dipeptides are involved. The best combination is that with the amino function, which forms a six-membered chelate ring. As Table 2 shows by the comparison of the H-HisHis with the Ac-HisHis dipeptides, this combination accounts for 2−2.5 log units in stability. This increase of stability is larger than the one resulting from the combination of one imidazole(histidine) donor with a second, neighbouring one (see above). The same observation also results from a comparison of the mono-histidine reference compounds H-His-OMe/Ac-His-NH_2 (log β = 4.45/1.96)[10] or H-ValHis-OEt/Ac-HisVal-OH (log β = 4.20/2.89).[12]

The effect of using the carboxylate function as an additional donor is small. The log β values for ZnL of H-HisHis-OH and H-HisHis-OEt are virtually identical, and that of Ac-HisHis-OH is even smaller than that of Ac-HisHis-OEt. For the simpler reference compounds the effect is noticeable: ZnL of Ac-His-OH (log β = 2.91)[10] is more stable than that of Ac-His-NH_2 (log β = 1.96),[11] and that of H-HisCys-OEt (log β = 8.36) is more stable than that of Ac-HisCys-OEt (log β = 6.17).[4]

The latter two values are again reminiscent of the low donor strength of the histidine-imidazole function relative to that of the cysteine-thiolate function. For all pairs of peptide derivatives X-His-Y/X-Cys-Y that form ZnL complexes in solution, the Cys compound is more stable than

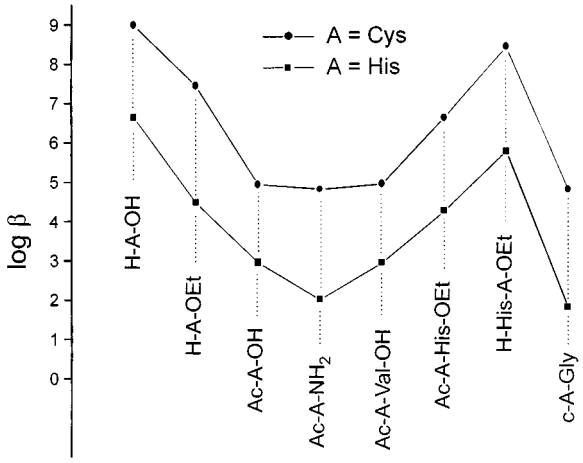

Figure 3. Stabilities of ZnL complexes for amino acid and peptide derivatives with one histidine (A = His) or cysteine (A = Cys) unit

the His compound by roughly 2.5 log β units. Figure 3 visualizes this for all available data for ZnL complexes. A similar relation holds for ZnL complexes of peptide ligands representing pairs of comparable His_2 and Cys_2 derivatives. As Figure 4 shows, the difference of the stabilities amounts to roughly six log β units, i.e. twice the amount of the mono-His/mono-Cys pairs.

This latter observation points to a further generalization, namely the possibility of expressing the stabilities of all ZnL complexes mentioned in this paper by parameters for the donors involved. It seems that this can be done with a satisfactory degree of precision in the ± 0.2 log β range of total stabilities for ZnL complexes with exclusive Cys or His coordination. Table 3 demonstrates this in section (a), based on log β parameters of 4.7 for Cys and 2.1 for His. Serious deviations from this approximation occur only for cyclo-HisHis, the unusually low log β value of which has already been discussed before,[5] and for Ac-CysCys-OEt for which the calculated log β is 0.8 units off.

[a] Estimated value from ref.[5]

The parameterization works less satisfactorily for the amine and carboxylate donors, cf. parts (b) and (c) of Table 3. As mentioned above the effect of chelation involving the amino function is strong, accounting for a log β contribution of more than two units. However, it is obviously variable, depending on whether the amino group is part of histidine or cysteine and on the number of amino acid building blocks. Likewise the contribution of the carboxylate function cannot be accounted for by a fixed parameter. Thus the agreement between observed and calculated log β values is not so good in section (b) of Table 3, and in section (c), where four parameters are involved, the disagreement amounts to 0.1−1.8 log β units. Nevertheless the given parameters should be good enough to estimate the stabilities of ZnL complexes of peptides containing two cysteine and/or histidine units, either in adjacent positions or separated by one or two nonligating amino acid constituents.

Conclusions

This paper has completed our studies of the acid/base chemistry and zinc complexation of small peptides rich in cysteine and histidine. The four possible His-His dipeptides (unprotected, partly and fully protected) were employed. Their 1:1 zinc complexes are of moderate stability. Even for two imidazole(histidine) donor functions there is no stabilization which could compete with that of a single thiolate-(cysteine) donor, and the complex stability for a chelating coordination of the imidazole and a terminal amino function surpasses that for a bis(imidazole) coordination. Furthermore, conformational effects due to the position of histidine in a peptide are not evident: compared to the ZnL complex of Ac-HisHis-OEt both the ZnL complexes of cyclo-HisHis or Ac-HisApaHis-NH_2, whose imidazole donors should be positioned more favourably, are less stable. All this underlines the notion that the frequent occurrence of Zn-histidine coordination in proteins reflects a very efficient tuning of preorganization of the donors by the polypeptide backbone.

Our accumulated data for zinc complexes of peptides with one or two cysteine and/or histidine constituents has allowed a comparative discussion of their stabilities. As Table 3 shows, this has enabled a parameterization of the contributions of the individual donors to the stability of 1:1 complexes in terms of log β increments. The agreement between calculated and observed complex stabilities is quite satisfying for the systems with exclusive histidine and/or cysteine coordination. When additional carboxylate or amine coordination is involved the parameterization for these donors works less satisfactorily. However, as cysteine and histidine are the natural donors and terminal amino or carboxylate functions do not coordinate in proteins, the stability parameters should be valuable for estimating the strength of zinc-peptide interactions for new or hitherto uninvestigated peptides containing cysteine and/or histidine.

Experimental Section

General: For general working and measuring procedures, see ref.[13] The histidine derivatives Boc-His(Boc)-OH, H-His-OEt, Ac-His-OH and Ac-His(Trt)-OH were obtained commercially. The detailed procedures of peptide coupling by the CAIBE and the DCC method as well as for the removal of the protective groups Boc and

Trt[8] have been described by us before. Purifications by HPLC were performed with a Merck−Hitachi system using Nucleosil 7C18 from Macherey−Nagel. The flow rate was 6 mL/min. The eluents always contained 0.1% of trifluoroacetic acid which thereby became a constituent of the isolated peptides. The specific HTFA content of each peptide was determined by potentiometric titration.

H-HisHis-OH: Boc-His(Boc)-OH (10.00 g, 28.14 mmol) and H-His-OEt·3*p*-TosOH (19.69 g, 28.14 mmol) were coupled by the CAIBE method resulting in 4.42 g (30%) of Boc-His(Boc)-His-OEt as a colourless solid. 2.15 g (4.13 mmol) of this in a mixture of 25 mL of methanol and 25 mL of 1 M NaOH was stirred at 50 °C for 30 min. After cooling to room temp. the solution was brought to pH 2 with 1 M HCl. All volatiles were removed in vacuo, the residue was suspended in 30 mL of dry methanol, filtered, and the filtrate evaporated to dryness again. The residue was washed three times with 15 mL of diethyl ether and dried in vacuo to give of Boc-His(Boc)-His-OH (1.99 g, 98%) as a pale yellow solid. This solid was treated with trifluoroacetic acid as described previously[8] to remove the Boc groups, giving H-HisHis-OH·4HTFA (2.10 g, 82%) as a yellow oil. Preparative HPLC with water and freeze-drying yielded the analytically pure product as a colourless, very hygroscopic solid, m.p. 63 °C. $C_{12}H_{16}N_6O_3·4C_2HF_3O_2$ (292.30 + 456.09): calcd. C 32.10, H 2.69, N 11.23; found C 31.82, H 2.71, N 11.27. IR (KBr): $\tilde{\nu}$ = 3436 bs, (OH), 3156 bs, (NH), 1676 vs (amide I), 1559 m, 1540 m (amide II), 1205 vs (CF). ^{1}H NMR: ([D$_6$]DMSO): δ = 2.92−3.31 (m, 4 H, H$_\beta$), 4.19−4.25 (m, 1 H, H$_\alpha$), 4.59−4.69 (m, 1 H, H$_\alpha$), 4.91−5.58 (m, 3 H, NH_3^+), 7.40 (s, 1 H, im), 7.42 (s, 1 H, im), 8.92−9.00 (m, 1 H, amide), 8.98 (s, 1 H, im), 8.99 (s, 1 H, im).

H-HisHis-OEt: Boc-His(Boc)-His-OEt (2.17 g, 4.17 mmol; see above) was treated with trifluoroacetic acid as described previously[8] to remove the Boc groups, giving H-HisHis-OEt·4HTFA (2.57 g, 93%) as a yellow oil. Preparative HPLC with water/acetonitrile (98:2) and subsequent freeze-drying yielded the analytically pure product as a colourless, very hygroscopic solid, m.p. 59 °C. $C_{14}H_{20}N_6O_3·4C_2HF_3O_2·2H_2O$ (320.35 + 456.09 + 36.03): calcd. C 32.52, H 3.47, N 10.34; found C 32.69, H 3.07, N 10.60. IR (KBr): $\tilde{\nu}$ = 3442 m, 3385 m (NH), 1672 vs (amide I), 1559 m (amide II), 1203 vs (CF). ^{1}H NMR ([D$_6$]DMSO): δ = 1.14 (t, *J* = 7.4 Hz, 3 H, Et), 3.00−3.29 (m, 4 H, H$_\beta$), 4.09 (q, *J* = 7.4 Hz, 2 H, Et), 4.20−4.26 (m, 1 H, H$_\alpha$), 4.65−4.76 (m, 1 H, H$_\alpha$), 7.40 (s, 1 H, im), 7.44 (s, 1 H, im), 8.99 (s, 1 H, im), 9.00 (s, 1 H, im), 9.12 (d, *J* = 6.3 Hz, 1 H, amide).

Ac-HisHis-OEt: Ac-His(Trt)-OH (8.79 g, 20.0 mmol) and H-His-OEt·3*p*-TosOH (14.00 g, 20.0 mmol) were coupled by the DCC method to give Ac-His(Trt)-His-OEtr (9.89 g, 82%) as a colourless solid. 3.98 g of this were treated with ethanethiol as described previously[8] to remove the Trt group, yielding Ac-HisHis-OEt·2.4HTFA (1.63 g, 42%) as a colourless solid. Preparative HPLC with water which was gradually replaced by acetonitrile, and subsequent freeze-drying, yielded the analytically pure product as a colourless, very hygroscopic solid, m.p. 48 °C. $C_{16}H_{22}N_6O_4·2.4C_2HF_3O_2$ (362.39 + 273.65): calcd. C 39.28, H 3.87, N 13.21; found C 39.18, H 3.85, N 13.41. IR (KBr): $\tilde{\nu}$ = 3424 bs, 3148 m (NH), 1672 vs (amide I), 1541 m (amide II), 1204 vs (CF). ^{1}H NMR ([D$_6$]DMSO): δ = 1.14 (t, *J* = 7.0 Hz, 3 H, Et), 1.82 (s, 3 H, Ac), 2.78−3.23 (m, 4 H, H$_\beta$), 4.08 (q, *J* = 7.0 Hz, 2 H, Et), 4.48−4.65 (m, 2 H, H$_\alpha$), 7.31 (s, 1 H, im), 7.38 (s, 1 H, im), 8.25 (d, *J* = 8.0 Hz, 1 H, amide), 8.58 (d, *J* = 7.6 Hz, 1 H, amide), 8.95 (s, 1 H, im), 8.97 (s, 1 H, im).

Ac-HisHis-OH: Ac-HisHis-OEt·2.4HTFA (2.01 g, 3.40 mmol; see above) was treated with NaOH as described above for H-HisHis-OH to remove the ethyl group, giving Ac-HisHis-OH·2HCl (1.28 g, 93%) as a colourless solid. Preparative HPLC with water/acetonitrile (95:5) and subsequent freeze-drying yielded the analytically pure product as a colourless, very hygroscopic solid, m.p. 144 °C. $C_{14}H_{18}N_6O_4·4C_2HF_3O_2·5H_2O$ (334.33 + 456.09 + 90.08): calcd. C 30.01, H 3.66, N 9.54; found C 29.63, H 3.72, N 9.87. IR (KBr): $\tilde{\nu}$ = 3437 vs, b (OH), 1659 s (amide I), 1641 s, 1548 s (amide II), 1206 s (CF). ^{1}H NMR ([D$_6$]DMSO): δ = 1.83 (s, 3 H, Ac), 2.76−3.33 (m, 4 H, H$_\beta$), 4.42−4.62 (m, 2 H, H$_\alpha$), 7.33 (s, 1 H, im), 7.43 (s, 1 H, im), 8.38 (d, *J* = 8.0 Hz, 1 H, amide), 8.61 (d, *J* = 7.8 Hz, 1 H, amide), 8.99 (s, 1 H, im), 9.01 (s, 1 H, im).

1: A solution of $Zn(TFA)_2$ (13.2 mg, 0.045 mmol) in 10 mL of water was added to a solution of H-HisHis-OH·4HTFA (34.0 mg, 0.045 mmol) in 10 mL of ethanol. Triethylamine (31.7 μL, 23.0 mg, 0.23 mmol) was then added with vigorous stirring, and the solution was reduced in vacuo to 5 mL. The resulting precipitate was filtered off, washed twice with 5 mL of dry ethanol and dried in vacuo to give **1**·EtOH (11.0 mg, 47%) as a colourless solid, m.p. 270 °C (dec.). $C_{16}H_{21}F_3N_6O_6Zn$ (515.76): calcd. C 37.26, H 4.10, N 16.29, Zn 12.68; found C 37.23, H 3.99, N 17.04, Zn 12.09. IR (KBr): $\tilde{\nu}$ = 3415 vs, b (OH), 3274 vs, b, 3133 s (NH), 1669 vs (amide I), 1507 s (amide II), 1204 s (CF).

2: A solution of $Zn(TFA)_2$ (55.0 mg, 0.19 mmol) in 10 mL of water was added to a solution of Ac-HisHis-OH·4HTFA·5H$_2$O (166 mg, 0.19 mmol) in 10 mL of water. The reaction flask was attached to a second flask containing triethylamine (132 μL, 96 mg, 0.95 mmol) which diffused into the reaction solution. After two days the resulting precipitate was filtered off, washed three times with 5 mL of dry ethanol and dried in vacuo to give **2**·2H$_2$O (22.5 mg, 43%) as a colourless solid, m.p. 280 °C (dec.). $C_{16}H_{21}F_3N_6O_8Zn$ (547.76): calcd. C 35.08, H 3.86, N 15.34, Zn 11.94; found C 35.21, H 3.61, N16.31, Zn 12.50. IR (KBr): $\tilde{\nu}$ = 3416 vs, b (OH), 3282 s, 3135 s (NH), 1646 vs (amide I), 1540 s (amide II), 1203 s (CF).

3: Prepared as for **2** from of $ZnCl_2$ (38.5 mg, 0.28 mmol), Ac-HisHis-OH·4HTFA·5H$_2$O (249 mg, 0.28 mmol) and triethylamine (197 μL, 143 mg, 1.41 mmol). Yield 81.0 mg (63%) of **3**·H$_2$O as a colourless solid, m.p. 280 °C (dec.). $C_{14}H_{19}ClN_6O_5Zn$ (452.18): calcd. C 37.19, H 4.24, N 18.59, Zn 14.46; found C 36.90, H 3.74, N 17.72, Zn 14.12. IR (KBr): $\tilde{\nu}$ = 3291 vs, b (OH), 3131 s (NH), 1650 vs (amide I), 1536 s (amide II).

4: Prepared as for **2** from $ZnCl_2$ (23.2 mg, 0.17 mmol), Ac-HisHis-OEt·2.4HTFA (108 mg, 0.17 mmol) and triethylamine (119 μL, 0.85 mmol). Yield 46.3 mg (55%) of **4** as a colourless solid, m.p. 260 °C (dec.). $C_{16}H_{22}Cl_2N_6O_4Zn$ (498.68): calcd. C 38.54, H 4.45, N 16.85, Zn 13.11; found C 38.82, H 4.23, N 17.21, Zn 13.65. IR (KBr): $\tilde{\nu}$ = 3378 bs, 3285 bs, 3134 s (NH), 1654 vs (amide I), 1539 s (amide II).

Potentiometric Titrations: The apparatus used, the experimental details, the calibration techniques and the titration procedure were as described before.[8,10] The common anion in all solutions was ni-

Table 4. Starting concentrations (× 10^{-3} M) of the regents for the potentiometric titrations

Peptide	c(peptide)	c(acid)	c(Zn)
H-HisHis-OH	0.890−1.030	0.602−1.082	0.235−0.940
H-HisHis-OEt	1.001−1.020	1.331−1.405	0.240−0.977
Ac-HisHis-OH	0.860−1.741	0.013−1.716	0.250−1.038
Ac-HisHis-OEt	0.707−0.778	0.827−1.573	0.309−0.865

trate [KNO_3, $Zn(NO_3)_2$, HNO_3]. Zuberbühler's TITFIT program[14] was used for the computations. The ionic strength was 0.1. All measurements were done at 25.0 ± 0.1 °C. The starting concentrations of peptides, acid and zinc nitrate are given in Table 4.

COVER PICTURE

The cover picture shows the electron diffraction pattern, high resolution electron microscopy and a structural model of $Ba_9Rh_{7.92}O_{24}$, the $\alpha = 3$, $\beta = 6$ member of the one-dimensional $(A_3B_2O_6)_\alpha(A_3B_3O_9)_\beta$ homologous series. Seven octahedra sharing faces alternate with a trigonal prism defining chains of Rh atoms running parallel to the *c* axis of a rhombohedral unit cell ($R\bar{3}c$), separated by Ba atoms. Electron diffraction allows the direct observation of the α and β structural blocks forming such a commensurate modulated structure as well as the superstructure direction. Details are discussed in the article by J. M. González-Calbet et al. on p. 805 ff.

Electrophilic Half-Sandwich (Carbene)metal (Metal = Fe, Ru, Os) Complexes: Recent Developments in Synthesis and Applications

Véronique Guerchais[a]

Keywords: Carbene complexes / Catalysis / C−C bond formation / Diazo compounds

This review covers synthetic and structural aspects of electrophilic half-sandwich (carbene)metal complexes of Group-8 metals as well as the use of these complexes in transformations of organic molecules. These species, including chelate complexes, are involved in C–C bond-forming reactions in stoichiometric or catalytic processes.

5. Concluding Remarks

1. Introduction

The chemistry of electrophilic (carbene)metal complexes is an area of current interest because of the wide applications in organic synthesis.[1,2] Their potential to mediate novel C−C bond-forming reactions has generated the development of new synthetic methodologies. In this context, the (carbene)ruthenium complexes, that are highly active metathesis catalysts able to generate polymeric materials and five-, six-, seven-, and eight-membered carbocycles or heterocycles, have seen rapid developments.[3] In addition, (carbene)metal complexes attract considerable attention since they offer the possibility of the development of new types of organometallic intermediates that may have unusual reactivity.

This review deals with electrophilic half-sandwich complexes of iron, ruthenium, and osmium containing the C_5R_5 (R = H, Me, Ph), $C_9H_4R_3$ (R = H, Me), or Tp [Tp = hydrotris(pyrazolyl)borate] ligand and covers the literature from January 1995 up to June 2001. We will focus our attention on the synthesis, the structural features, and the role of these carbene complexes in C−C bond-forming reactions. The discussion will emphasise our ongoing research on chelate (carbene)iron derivatives that are involved in bond-activation reactions. We are interested in investigating the chemistry of electrophilic (carbene)iron complexes containing a labile or hemi-labile ligand. The presence of a potential vacant coordination site allows the introduction of a substrate capable of reacting with the carbene ligand within the coordination sphere of the metal centre. Finally,

Véronique Guerchais is a CNRS researcher at the Institut de Chimie de Rennes, unit "Organometallics and Catalysis". She received her PhD under the supervision of Prof. D. Astruc on "electron reservoir" complexes. She carried out postdoctoral studies on the activation of alkynes at diruthenium centres at the University of Bristol (U. K.) with Prof. S. A. R. Knox. Her current research interests are focused on iron complexes, including carbene species, for bond activation and C−C bond formation.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

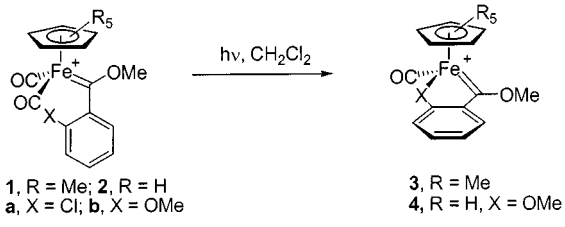
we will describe the catalytic reactions of (carbene)-ruthenium complexes.[4] Cyclopentadienyl complexes $[Ru(C_5R_5)(L)_2Cl]$ and related species were found to be effective catalyst precursors in C−C coupling reactions involving diazo compounds,[5] including insertion, carbene dimerisation, and carbene transfer reactions to alkenes and alkynes.

2. Preparation and Structural Characterisation

2.1. Iron Complexes

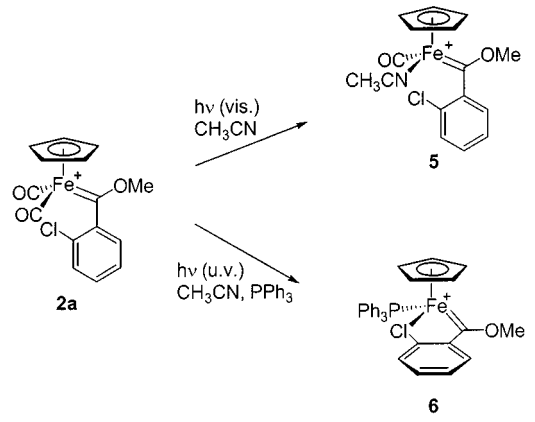
The reaction of an acyl complex with an electrophile is a common route to alkoxycarbene complexes of iron $[Fe(C_5R_5)(CO)_2\{C(OR^2)R^1\}]^+$ (R = H, Me). The required alkyl- and aryl-substituted acyl derivatives $[Fe(C_5R_5)(CO)_2\{C(O)R^1\}]$ are in turn accessible by the reaction of the ferrate complex $[M][Fe(C_5R_5)(CO)_2]$ (M = Na, K) with the appropriate acyl chloride.[6]

ortho-Substituted arylcarbene complexes are good precursors of chelate carbene species.[7] Thus, the cationic κ^2-(*C*,*X*) chelate complexes $[Fe(C_5R_5)(CO)\{C(OMe)C_6H_4$-*o*-$X\}(Fe-X)][OTf]$ (**3**) (R = Me; **a**: X = Cl; **b**: X = OMe)[7a] and **4** (R = H; X = OMe)[7b] are obtained upon irradiation of the corresponding dicarbonyl species in a non-coordinating solvent such as CH_2Cl_2 (Scheme 1). In contrast with the C_5Me_5 analogue, coordination of the chlorine atom of **2a** does not take place. When irradiation of **2a** is performed in CH_3CN, the stable acetonitrile complex $[Fe(C_5H_5)(CO)(CH_3CN)\{C(OMe)C_6H_4$-*o*-$Cl\}][OTf]$ (**5**) is obtained (Scheme 2). Substitution of one carbonyl ligand by PPh_3 allows the isolation of the κ^2-(*C*,*Cl*) chelated derivative **6** (Scheme 2).[7b] The phosphane ligand has the same effect on the nature of the product as the permethylation of the C_5 ring. The formation of the chelate structure can easily be established by ^{13}C NMR spectroscopy. The signal of the aryl carbon atom which bears the heteroatom is shifted downfield upon coordination of the *ortho* substituent X. There is a marked shift difference of 20 ppm in both the C_5H_5 and C_5Me_5 series, in agreement with a decrease in electronic density. The chlorine and the oxygen atoms act as neutral two-electron donor ligands allowing the formation of a five-membered metallacycle. This has been confirmed by the crystallographic analyses of **3a** and **4**.

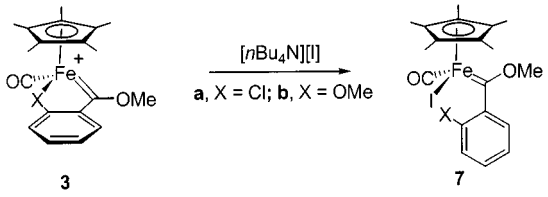


Scheme 1. Synthesis of chelate arylcarbene complexes

The neutral iodo derivatives **7a**,**b** are obtained on treating **3a**,**b** with $[nBu_4N][I]$, due to the lability of the chelating group X (Scheme 3). In contrast with the dicarbonyl species, the competitive *O*-demethylation reaction that leads to the acyl complex and methyl iodide does not take place.[8]

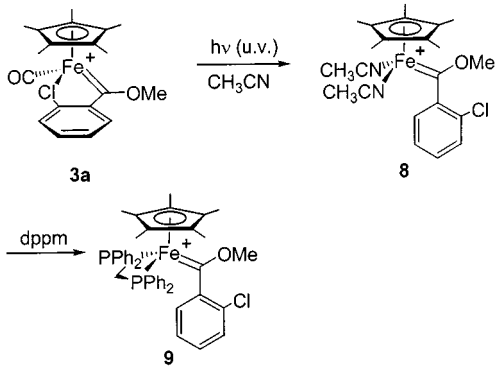


Scheme 2. Synthesis of (chloroaryl)carbene complexes containing a labile or hemi-labile ligand



Scheme 3. Synthesis of iodo carbene complexes **7**

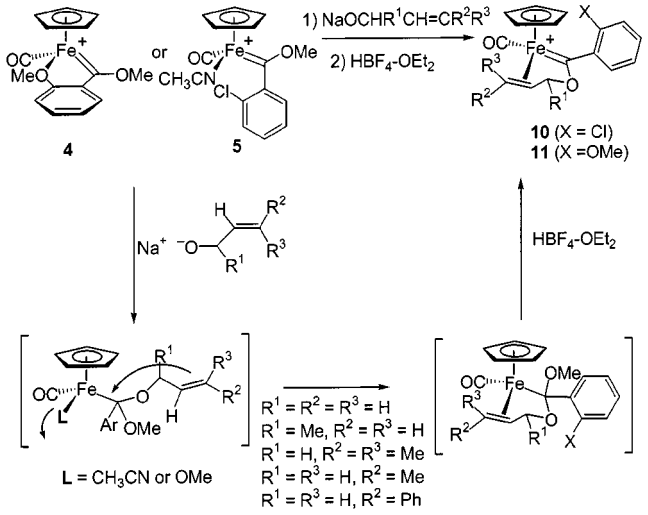
Carbene complexes containing two labile ligands can also be obtained. For example, UV irradiation of **3a** gives **8**, and then addition of dppm [dppm = bis(diphenylphosphanyl)-methane] provides **9** (Scheme 4).



Scheme 4. Ligand exchange reactions of **3a**

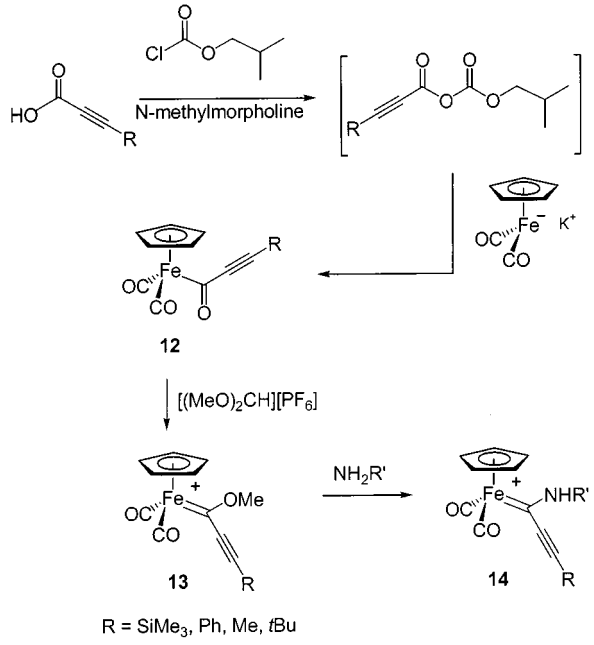
The presence of a labile or hemi-labile ligand in carbene complexes **4** and **5** allows the chelation of the C−C double bond of an allyloxy group, and the chelate (allyloxy)carbene complexes **10** and **11** are thus accessible (Scheme 5).[9] They are prepared in a two-step one pot procedure, by treating **4** or **5** with the appropriate allyl oxide followed by protonation. This sequence conveniently gives access to various substituted complexes. The iron moiety, which is sterically not encumbered, is able to coordinate a di- and trisubstituted C−C double bond. We found that this preparation

requires pre-coordination of the allyloxy group, otherwise the synthesis fails.

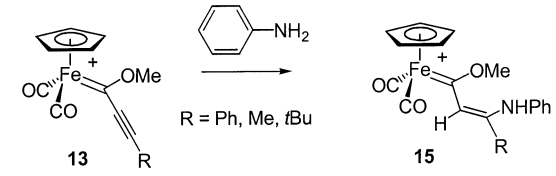


Scheme 5. Synthesis of chelate (allyloxy)carbene complexes **10** and **11**

The preparation of the alkynyl-substituted acyl complexes **12** has been achieved by using mixed anhydrides [*i*PrCH$_2$OC(O)OC(O)C≡CR] (Scheme 6).[10] Compounds **12** are obtained in high yields and can be converted into the respective methoxy- and aminocarbene complexes **13** and **14** (Scheme 6). Some of the methoxycarbene complexes **13** undergo a Michael-type addition of aniline at room temperature to give the (2-aminoethenyl)methoxycarbene complexes **15** (Scheme 7).[10d]

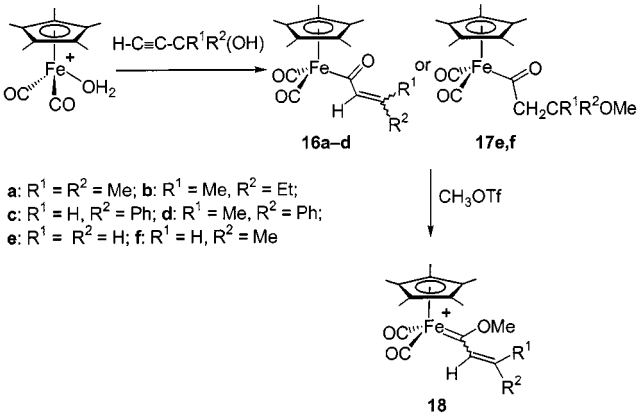


Scheme 6. Synthesis of (alkynyl)acyl complexes and the corresponding methoxy- and aminocarbene complexes



Scheme 7. Synthesis of (2-aminoethenyl)methoxycarbene complexes **15**

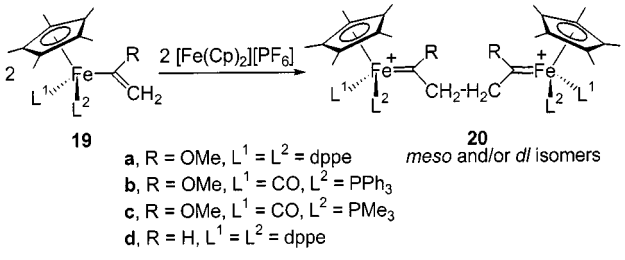
We have found that the activation of propargylic alcohols by [Fe(C$_5$Me$_5$)(CO)$_2$(H$_2$O)][BF$_4$] in the presence of methanol leads to the isolation of the α,β-unsaturated acyl complexes **16** or the Michael adducts **17** (Scheme 8).[11] The expected methoxycarbene complexes [Fe(C$_5$Me$_5$)(CO)$_2${=C(OMe)CH=CR^{1}R^2}] (**18**) are not obtained directly, and *O*-alkylation of **16** or **17** with methyl triflate generates **18**. This may be due to a spontaneous demethylation reaction of methoxycarbene complexes in solution, a feature already described.[8]



Scheme 8. Synthesis of (alkenyl)carbene complexes **18** by activation of propargylic alcohols

Alkylation of formyl transition metal complexes constitutes a route to secondary alkoxycarbene complexes. Thus, methylation of the stable formyl complex [Fe(C$_5$Ph$_5$)(CO)(PMe$_3$)(CHO)] and addition of [NH$_4$][PF$_6$] afford the secondary methoxycarbene complex [Fe(C$_5$Ph$_5$)(CO)(PMe$_3$)(=CHOMe)][PF$_6$] in high yield.[12]

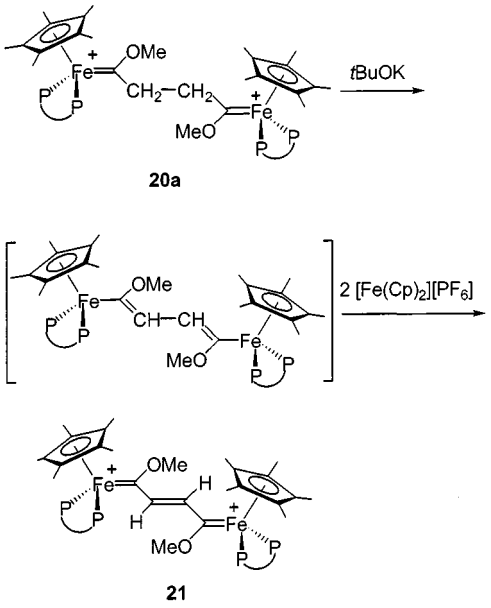
Dinuclear bis(carbene) complexes have been synthesised from mononuclear species through a carbon−carbon ligand coupling.[13] The 18-electron (vinyl)iron(II) derivatives **19** undergo oxidative coupling via 17-electron **19**$^+$ (Fe^{III}) to produce [μ-bis(methoxycarbene) or μ-bis(ethylidene)]diiron



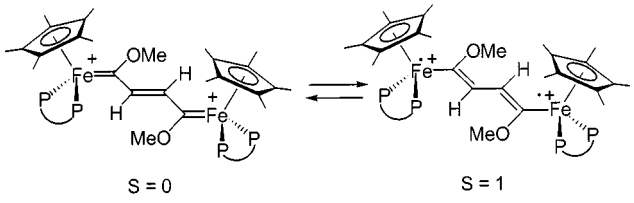
Scheme 9. Synthesis of bridged bis(carbene) complexes

complexes **20** in good yields (Scheme 9). The coupling reaction is sensitive to steric effects of the ancillary ligands at the metal centre, and the *meso* and *dl* couples of the bis(carbene) dimers are formed with good diastereoselectivities.

The dinuclear butadienediyl-bridged bis(carbene) complex **21** is then accessible through deprotonation of **20a**, followed by a two-electron oxidation with 2 equiv. of ferricenium (Scheme 10).[14] Complex **21** is diamagnetic in solution. However, variable-temperature Mössbauer spectroscopy allows the observation of the singlet and triplet spin isomers and their interconversion (Scheme 11).[14,15]



Scheme 10. Synthesis of the butadienediyl-bridged bis(carbene) complex **21**

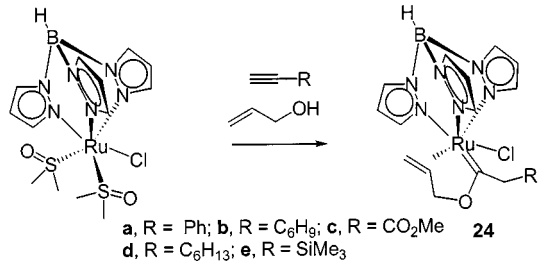


Scheme 11. Interconversion of the singlet and triplet spin isomers of **21**

2.2. Ruthenium and Osmium Complexes

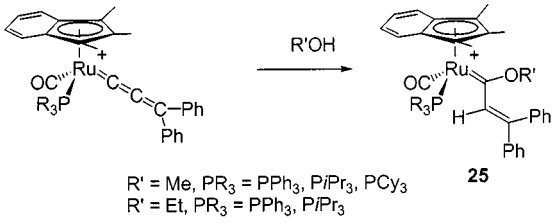
(Carbene)ruthenium complexes are accessible from vinylidene and allenylidene precursors but the formation of the carbene ligand depends on both the ligand sphere of the metal centre and on the nature of the substituents of the unsaturated ligand.[16]

For instance, the methoxycarbene complex [Ru(Tp)(dippe){=C(OMe)CH_2CO_2Me}][BPh_4] (**22**) [dippe = bis(diisopropylphosphane)ethane] is formed by the addition of MeOH to the corresponding vinylidene complex [Ru(Tp)(dippe)(=C=$CHCO_2$Me)][BPh_4].[17] Similar alkoxycarbene complexes have not been obtained from [Ru(Tp)(dippe)(=C=CHR)][BPh_4] when R is different from CO_2Me. Complex [Ru(Tp)(Haapy)(Cl)] (Haapy = 2-acetamido-4-methylpyridine) reacts with HC≡CR to give the cyclic amidocarbene complexes [Ru(Tp)(Cl)(=CCH_2R-aapy)] (**23**) (**a**: R = Ph; **b**: R = *n*Bu).[18] The formation of **23** presumably proceeds via vinylidene intermediates. Although such intermediates could not be isolated or detected spectroscopically, such a process would be facile when the nucleophilic attack occurs in an intramolecular, chelate-assisted fashion. This can explain the addition of the weakly nucleophilic nitrogen atom of the amide. Similarly, addition of allyl alcohol to terminal alkynes mediated by [Ru(Tp)$(dmso)_2$(Cl)] gives the (allyloxy)carbene complexes **24** (Scheme 12).[19]



Scheme 12. Synthesis of (allyloxy)carbene complexes **24**

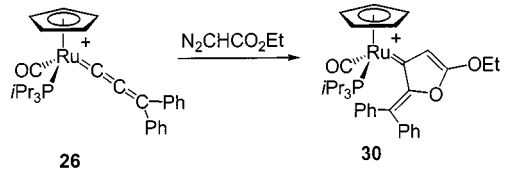
Addition of nucleophiles to allenylidene complexes is a general route to Fischer-type α,β-unsaturated carbene complexes of ruthenium. The reactivity of allenylidene complexes has recently been reviewed.[20] For example, the addition of methanol or ethanol to the trimethylindenyl complex [Ru(η^5-1,2,3-$Me_3C_9H_4$)(L^1)(L^2){=C=C=CPh_2}][BF_4] (L^1 = CO and L^2 = PPh_3, P*i*Pr_3, PCy_3) takes place to afford the corresponding alkoxy derivatives **25** (Scheme 13).[20,21] Unstable allenylidene derivatives can be trapped in situ by methanol, and this allows the complexes [Ru(η^5-C_9H_7)(L^1)(L^2){=C(OMe)−CH=CHR}][PF_6] (R = Ph, L^1 = L^2 = dppe, dppm; R = H, L^1 = L^2 = dppm) to be isolated.[22] By contrast, the bis(triphenylphosphane)-substituted carbene derivatives are not formed, presumably because the PPh_3 ligands offer a steric protection of the allenylidene group towards nucleophilic addition.



Scheme 13. Synthesis of alkoxy(alkenyl)carbene complexes **25**

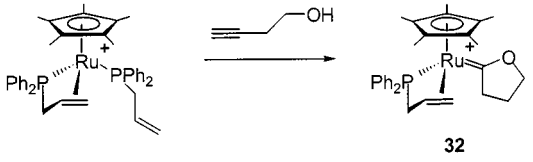
The acetone complex [Ru(C_5H_5)(CO)(P*i*Pr_3){OC-$(CH_3)_2$}][BF_4] reacts with 1,1-diphenyl-2-propyn-1-ol to afford the allenylidene derivative [Ru(C_5H_5)(CO)(P*i*Pr_3){C=C=CPh_2}][BF_4] (**26**) which adds water, alcohols, and thiols, at the $C_\alpha-C_\beta$ double bond of the allenylidene group to afford diphenyl-α,β-unsaturated-hydroxycarbene, -alkoxycar-

bene, and -(alkylthio)carbene complexes, respectively.[23] Complex **26** reacts with alcohols such as allyl alcohol (without pre-coordination of the olefinic moiety) and propargyl alcohol affording $[Ru(C_5H_5)(CO)(P\mathit{i}Pr_3)\{C(OCH_2CH{=}CH_2)CH{=}CPh_2\}][BF_4]$ (**27**)[24] and $[Ru(C_5H_5)(CO)(P\mathit{i}Pr_3)\{C(OCH_2C{\equiv}CH)CH{=}CPh_2\}][BF_4]$ (**28**),[25] respectively. Treatment of **26** with secondary and primary amines affords azoniabutadienyl derivatives $[Ru(C_5H_5)(CO)(P\mathit{i}Pr_3)\{C(CH{=}CPh_2){=}NR^1R^2\}][BF_4]$ (**29**).[26] Addition of ethyl diazoacetate to **26** affords the cyclic carbene complex $[Ru(C_5H_5)(CO)(P\mathit{i}Pr_3)\{{=}[-CCH{=}C(OEt)-O-C(=CPh_2)-]\}][BF_4]$ (**30**), which results from a formal 1,3-addition of the organic reagent at the $C_\alpha-C_\beta$ double bond (Scheme 14).[27]



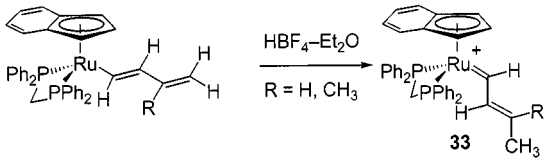
Scheme 14. Synthesis of the cyclic carbene complex **30**

The common approach to cyclic Fischer-type carbene complexes is the metal-assisted cycloisomerisation of ω-alkynols to oxacycloalkylidenes.[28] Such a reaction has been used for the preparation of $[Ru(C_5Me_5)(\kappa^1\text{-DPVP})_2\{{=}C^a(CH_2)_3O(C^a{-}O)\}][PF_6]$ (DPVP = diphenylvinylphosphane) starting from $[Ru(C_5Me_5)(\kappa^1\text{-DPVP})(\kappa^3\text{-DPVP})][PF_6]$.[29] In contrast, the formation of $[Ru(C_5Me_5)(\kappa^3\text{-ADPP})\{{=}C^a(CH_2)_3O(C^a{-}O)\}][PF_6]$ (**32**) (ADPP = allyldiphenylphosphane) from $[Ru(C_5Me_5)(\kappa^1\text{-ADPP})(\kappa^3\text{-ADPP})][PF_6]$ is accompanied by the loss of one phosphane ligand (Scheme 15).[30]



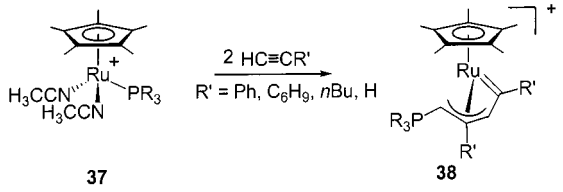
Scheme 15. Synthesis of cyclic oxycarbene complex **32**

The synthesis of (alkenyl)carbene complexes **33** has been achieved by protonation of the readily available (vinyl)alkenyl derivatives $[Ru(\eta^5\text{-}C_9H_7)(dppm)\{CHCH{=}CR^1R^2\}]$ (Scheme 16).[31] The formation of these α,β-unsaturated alkylidene complexes proceeds through regioselective protonation at either the C_γ or C_δ atom revealing the high electron density on these positions of the vinylalkenyl ligand.



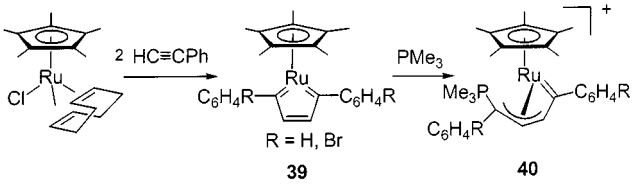
Scheme 16. Synthesis of vinylcarbene complexes **33**

(Allyl)carbene complexes are accessible through alkyne coupling reactions. The labile complexes $[Ru(C_5H_5)(PR_3)(CH_3CN)_2][PF_6]$ (**37**) (R = Me, Ph, Cy) react with alkynes HC≡CR′ and 1,6-heptadiyne to afford the (allyl)carbene complexes **38** and $[Ru(C_5H_5)\{{=}CH\text{-}\kappa^3\text{-}C(CH_2)_3CCHPR_3\}][PF_6]$ in high yields.[32] For the substituted derivatives, the substituents are exclusively in the 1- and 3-positions (Scheme 17).



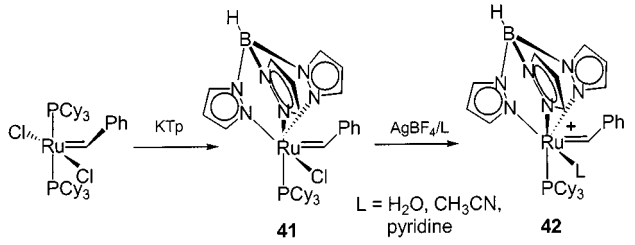
Scheme 17. Synthesis of the (allyl)carbene complexes **38** from **37**

A possible mechanism may involve a metallacyclopentatriene intermediate, from which subsequent migration of the phosphane to one of the electrophilic carbene carbon atoms occurs to give the observed carbene complex. This proposal is supported by the formation of **40** by treating the isolated ruthenacyclopentatriene **39** with PMe_3.[33] Addition of the phosphane occurs at the electrophilic α-carbon atom. Note that the substituents of **40** are located on the 1,4-positions due to a head-to-head coupling of the alkynes (Scheme 18). The ruthenacyclopentatriene complexes are prepared from $[Ru(C_5Me_5)(Cl)(TMEDA)]$ [34] or $[Ru(C_5Me_5)(cod)(Cl)]$ [33] in the presence of alkynes.



Scheme 18. Synthesis of (allyl)carbene complex **40** via **39**

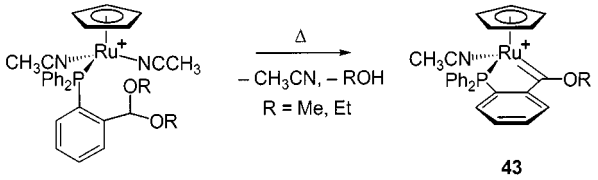
The complex $[Ru(Tp)(PCy_3)(Cl)(=CHPh)]$ (**41**) has been synthesised by the reaction of $[Ru(PCy_3)_2(Cl)_2(=CHPh)]$ and KTp (Scheme 19).[35] The cationic species **42** are then obtained by treatment of **41** with $AgBF_4$ or $AgSbF_6$ in the presence of various coordinating solvents L (L = H_2O, CH_3CN, pyridine).



Scheme 19. Synthesis of benzylidene complexes **41** and **42**

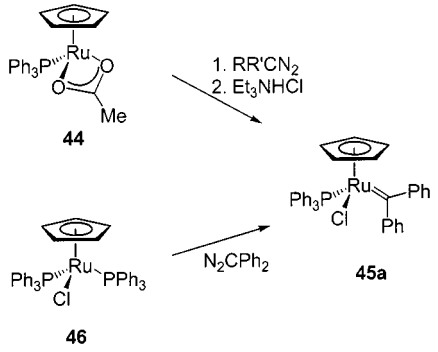
The synthesis of alkoxycarbenes **43** from an acetal derivative has been described.[36] Heating the acetal complexes

$[Ru(C_5H_5)(CH_3CN)_2\{\kappa^1\text{-}Ph_2PCH(OR)_2C_6H_4\}][OTf]$ (R = Me, Et) at 60−95 °C results in loss of one CH_3CN ligand and the alcohol ROH resulting from C−O bond cleavage, leading to carbene complex **43** in high yield (Scheme 20).



Scheme 20. Synthesis of alkoxycarbene complexes **43** from an acetal derivative

The diarylcarbene complexes $[Ru(C_5H_5)(PPh_3)(Cl)(=CRR')]$ (**45**) (**a**: R = Ph, R′= Ph; **b**: R = Ph, R′= *p*-C_6H_4Me; **c**: R = *p*-C_6H_4Cl, R′= *p*-C_6H_4Cl; **d**: R = *p*-C_6H_4OMe, R′= *p*-C_6H_4OMe) can be readily prepared by reaction of the acetato complex $[Ru(C_5H_5)(\kappa^2\text{-}O_2CMe)(PPh_3)]$ (**44**) with diaryldiazomethanes N_2CRR', followed by treatment with Et_3NHCl (Scheme 21).[37]

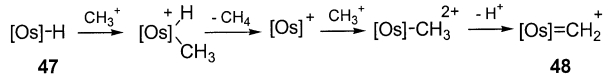


Scheme 21. Synthesis of the (diphenylcarbene)Ru complex **45a**

Complex **45a** is also obtained from $[Ru(C_5H_5)(PPh_3)_2(Cl)]$ (**46**) by direct reaction with diphenyldiazomethane. The dissociation of one triphenylphosphane ligand from **46** occurs at 65 °C in a non-polar solvent such as toluene (Scheme 21).[38] An excess of N_2CPh_2 has to be added during the reaction to obtain complete conversion of **46** into **45a**, because of the slow decomposition of N_2CPh_2. Similarly, facile displacement of one phosphane ligand in $[Ru(C_5H_5)\{PPh_2(2\text{-}MeC_6H_4)\}_2(Cl)]$ leads to the formation of $[Ru(C_5H_5)\{PPh_2(2\text{-}MeC_6H_4)\}(Cl)(=CPh_2)]$.[38] The (methyl-substituted aryl)phosphane appears to be more weakly bound to the ruthenium centre compared to PPh_3 and therefore more prone to dissociation. Complex **46** is also a good precursor for the aminocarbene complex $[Ru(C_5H_5)(PPh_3)_2(=CNHPh-CH_2Ph)]$ via the vinylidene complex $[Ru(C_5H_5)(PPh_3)_2(=C=CHPh)]$[40] by addition of benzylamine.[39]

Well-characterised examples of methylidene complexes remain relatively rare. One example has recently been described; complex **48** is obtained by treatment of the osmium hydride **47** with 2 equiv. of methyl triflate (Scheme 22).[41] The mechanism depicted in Scheme 23 is proposed to account for the formation of **48**. Methylation of the hydride precursor **47** generates the methyl/hydride intermediate, which then undergoes reductive elimination of methane. Attack of a second molecule of methyl triflate would give a methyl dication that provides **48** by loss of a proton.

Scheme 22. Synthesis of the (methylidene)osmium complex **48**



Scheme 23. Proposed mechanism for the formation of **48**

2.3. Conformational and Structural Features

Table 1 lists the M=C and C−X (X = O, N) bond lengths of structurally characterised (carbene)metal complexes (M = Fe, Ru, Os). These piano-stool complexes adopt a classical pseudo-octahedral geometry around the metal centre. The carbene ligand of such piano-stool complexes is generally oriented perpendicular to the plane of the C_5 ligand, the so-called "upright" conformation. This is for example the case for the ethylidene complex $[Fe(C_5Me_5)(dppe)(=CHMe)][CF_3SO_3]$ (**49**) in which the hydrogen atom is directed towards the C_5 ring.[13] The aminocarbene complex **14a** was found to exist in an "upright" conformation, whereas the related derivative **14b** shows an "orthogonal" conformation.[10b] Moreover, it has been shown that **14a** and **14b** exist in the solid state as *anti* isomers with respect to the C−N bond.

In solution, dynamic studies show that the arylcarbene complex **50** exists as two isomers in solution at −80 °C. Since the rotation around the Fe−C_α bond usually cannot be frozen out in such complexes, this feature most likely arises from restricted rotation about the C_α−C_{ipso} bond. Therefore, these two geometric isomers differ from each other in the orientation of the anisyl group [$\Delta G^{\ddagger}$ = 9.7 kcal·mol^{-1}, T_C(300 MHz) = 211 K].[7a] The conformation in which the aryl group is aligned with the Fe−C_α−C_{ipso} plane (rotamer **A**) provides the better electronic delocalisation of the positive charge (Scheme 24). On the basis of the NMR spectroscopic data of the carbonyl ligands, we assume that conformation **B** is preferred for the methoxycarbene derivatives **1**, **2**, and **9**; steric interactions appear to govern the carbene conformation. A twisted orientation of the carbene ligand is expected for the unsymmetrically substituted carbene complex **2a**.

X-ray structures of (alkylidene)iron complexes are scarce. The only complex that has been structurally characterised is the ethylidene complex **49**. The Fe−C_α bond length [1.787(8) Å] reflects the double-bond character of the iron−carbon bond.[13] The Fe−C bond lengths of het-

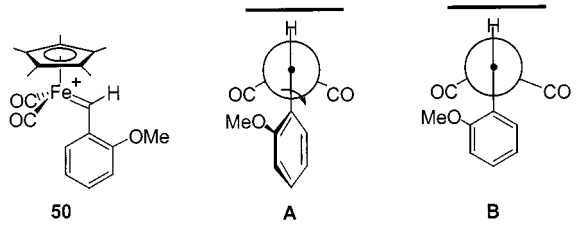
[a] Three independent molecules per unit cell.



Scheme 24. Conformers of complex **50**

eroatom-stabilised carbene complexes are typically in the range 1.83−1.97 Å. We can note that the Fe−C bond lengths are shorter in the case of chelated structures (Table 1, complexes **3a** and **4**). The $C_{carbene}-O$ bond length ranges from 1.30 to 1.36 Å. In the case of chelated complexes, the C−O bond lengths are shortened. Similarly, the C−N bond lengths of aminocarbene complexes of iron reflect the π-bonding between the amino substituent and the carbene carbon atom.

The chelate κ^2-(*C*,*Cl*) complex **3a** is characterised by an Fe−Cl bond length of 2.310(2) Å.[7a] The Fe−O bonds [2.045(5), 2.043(4), 2.043(4) Å, three independent molecules][7b] in κ^2-(*C*,*O*) complex **4** are similar to those found for other oxygen-containing iron complexes,[42] such as $[Fe(C_5Me_5)(dppe)(O{=}CMe_2)][OTf]$[42a] [2.031(4) Å] and $[Fe(C_5Me_4Et)(CO)_2(H_2O)][BF_4]$ [2.022(8), 2.043(9) Å, two independent molecules].[42c]

For ruthenium complexes, the bond lengths Ru−C(carbene) are typically in the range 1.90−1.97 Å. The $Ru-C_\alpha$ bond length in **22** is rather short,[17] compared with that of other (alkoxycarbene)Ru complexes, and found to be even shorter than that of the benzylidene complex **42**.[35] The longest bond length was found in the cyclic carbene complexes $[Ru(C_5H_5)(CO)(PiPr_3)\{{=}C^aCH{=}C(R)\text{-}OC^b(=CPh_2)(C^\alpha\text{-}C^b)\}][BF_4]$ (R = OEt, Me),[27] for which the Ru−C bond order is between that of a single and double bond. This suggests a significant contribution of the alkenyl resonance form.

X-ray diffraction studies and calculations on $[Ru(C_5H_5)(CO)(PiPr_3)\{C(CH{=}CPh_2){=}NEt_2\}][BF_4]$ (**29a**) show that the contribution of the carbene form is not relevant.[26] The $Ru-C_\alpha$ [2.063(6) Å] and the $C_\alpha-N$ [1.306(7) Å] bond lengths correspond rather to an Ru−C single bond and a C=N double bond, respectively. Complexes **29** can be considered as azoniabutadienyl rather than carbene complexes.

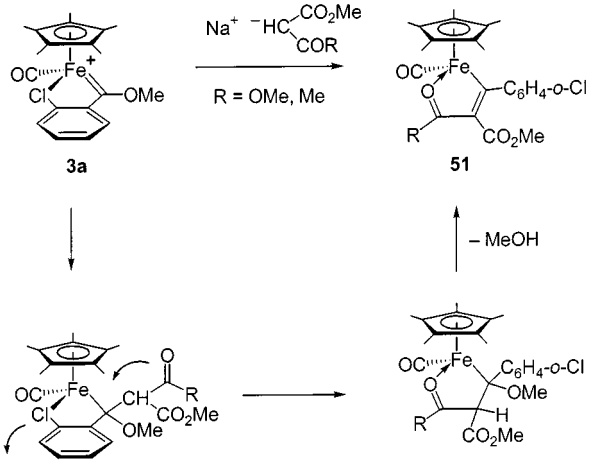
3. Reactivity of Carbene Complexes in Stoichiometric Reactions

3.1. Chelated Carbene Complexes: Bond-Activation and -Formation Reactions

Hemilabile ligands in carbene complexes may stabilize reactive intermediates or influence catalytic activity. For instance, the importance of chelated carbene complexes has been pointed out for diastereoselective cyclopropanation reactions of electronically neutral alkenes with chromium

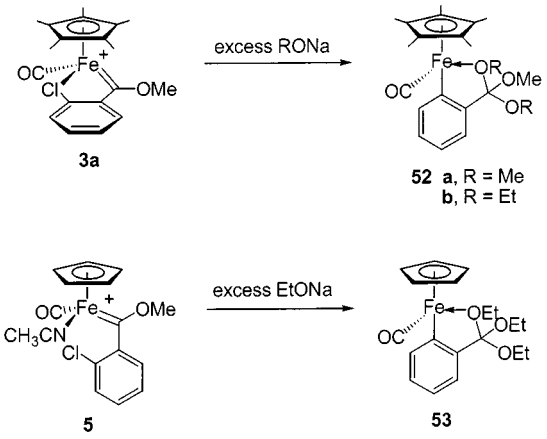
complexes.[43] The chelate isopropoxy derivative $[Ru(Cl)_2(PCy_3)(\kappa^2\text{-CH-}o\text{-}C_6H_4OiPr)]$ was found to be efficient in Ring Closing Metatheses (RCM) reactions for the formation of five- to eight-membered carbo- and heterocycles and it can be recovered through simple chromatography in high yield.[44] The importance of the chelated structure was also found for arylcarbene complexes **3a**,**b** which are involved in bond-activation and -formation reactions.

Nucleophilic attack of Lewis bases at the halocarbon atom gives rise to substitution reactions.[45] However, addition of stabilized carbanions $NaCH(CO_2Me)(COR)$ (R = OMe, Me) to **3a** affords oxametallacycles **51** (Scheme 25).[46] The substitution of the chlorine atom does not take place in these cases. The formation of **51** results from an α-attack by the nucleophile to give the C−C-bonded adduct, followed by displacement of the chlorine ligand by the coordinating carbonyl group to form a new five-membered ring. Eventually, spontaneous elimination of MeOH produces a more stable conjugated ring in the final product.



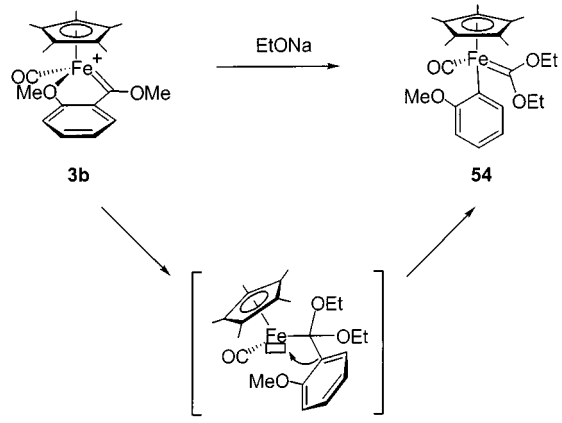
Scheme 25. Formation of oxametallacycles **51**

The chelated chloro derivative **3a** cleanly reacts with ethoxide or methoxide affording **52** which contains a chelated orthoester group (Scheme 26).[47] Similarly, complex **53** is formed upon treatment of **5** with EtONa (Scheme).[7b] The formation of **52**−**53** involves the cleavage of the Ar−Cl bond, which can be promoted by the coordination of the chlorine atom or the presence of a vacant coordination site. In contrast, the Ar−Cl bond cleavage does not occur for the dicarbonyl(carbene) complex **1a**. The reaction with RO^- affords the ketal derivatives $[Fe(C_5Me_5)(CO)_2\{C(OMe)(OR)(C_6H_4\text{-}o\text{-Cl}\}]$ by addition at the electrophilic carbene centre. Although the formation of an orthoester group from a carbene species has already been reported,[27] such a rearrangement process is without precedent.



Scheme 26. Activation of the Ar−Cl bond of (chloroaryl)carbene complexes

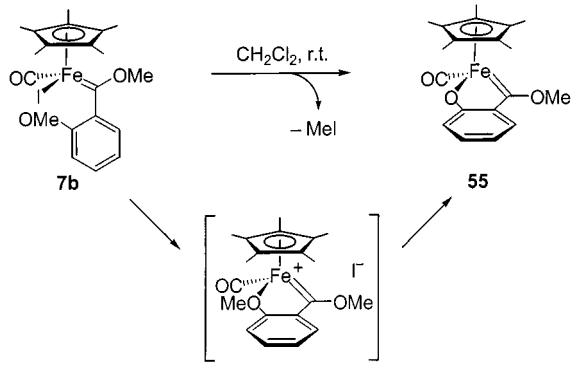
The related anisyl derivative $[Fe(C_5Me_5)(CO)\{\kappa^2\text{-C-}(OMe)C_6H_4\text{-}o\text{-}O^aMe\}(Fe-O^a)][OTf]$ (**3b**) affords the bis-(ethoxy)carbene complex **54** upon treatment with ethoxide (Scheme 27).[47] The Lewis base interaction in **3b** appears not to weaken the Ar−OMe bond to the same extent as the Ar−Cl bond in the chloroaryl derivative **3a**. Therefore, a different rearrangement process takes place. We assume that the formation of **54** results from an initial formation of the chelate ketal intermediate $[Fe(C_5Me_5)(CO)\{C(OMe)(OEt)\text{-}(C_6H_4\text{-}o\text{-}O^aMe)\}(Fe-O^a)]$ followed by deinsertion/migration of the anisyl substituent to the metal centre. This final step is promoted by the presence of a labile ligand. Such migrations of alkyl or aryl groups to give carbenes are rare,[48,49] and are relevant to C−C bond activation. The C−C bond formation corresponds to the insertion/migration of an alkyl or aryl group to a carbene ligand (Scheme 28).



Scheme 27. C−C bond cleavage of complex **3b**

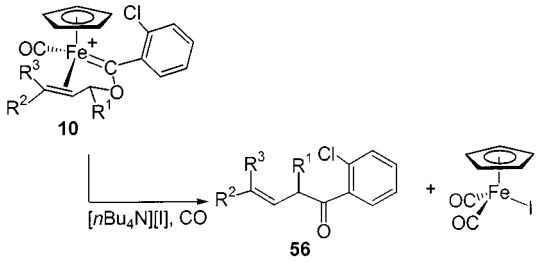
Scheme 28. Alkyl migration in carbene complexes

In this system, the Me−O bond is cleaved in the presence of halide anions.[7a] The (anisylcarbene)iodo complex **7b** spontaneously rearranges in dichloromethane or chloroform solution into the chelate aryloxy complex **55** along with the formation of methyl iodide (Scheme 29). We assume that the neutral iodo complex **7b** is in equilibrium with the cationic chelated form. The iodide counter-anion reacts as a demethylation reagent. The organometallic fragment plays the role of a Lewis acid to activate the C−O bond. Related sp^3-sp^3 C−O bond cleavage has previously been reported in the case of a palladium complex.[50]



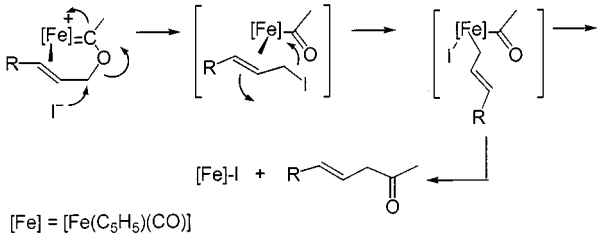
Scheme 29. Formation of the (aryloxy)carbene complex **55**

We found that chelate [(allyloxy)carbene]iron complexes **10** are involved in regioselective C−C bond-coupling reactions. Complex **10** reacts with [*n*Bu$_4$N][I] to give the corresponding β,γ-unsaturated ketones **56** (Scheme 30).[51] The organometallic fragment is recovered as the iodo derivative [Fe(C$_5$H$_5$)(CO)$_2$(I)] when the reaction is carried out under CO. Remarkably, no rearrangement of the initial allyl substituent is observed. Moreover, the C−C coupling is regioselective, since the carbon atom that is involved in the C−O bond cleavage recombines to form the new C−C bond.



Scheme 30. Formation of β,γ-unsaturated ketones **56** from (allyloxy)carbene complexes **10**

We propose that the formation of **56** results from an initial nucleophilic attack of the iodide, the rupture of the C−O bond thus leads to a coordinated η^2-(*C*,*C*)-allyl iodide. Oxidative addition of the latter and decoordination of the olefinic unit provide a transient Fe^{IV} species. Reductive elimination of the acyl and allyl ligands affords the observed ketone (Scheme 31).

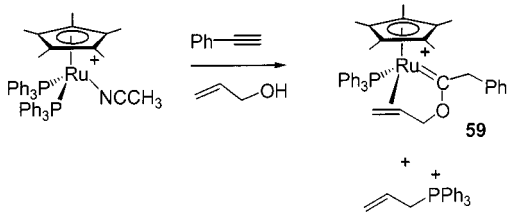


Scheme 31. Postulated mechanism for the formation of **56** showing the participation of the iodide anion

This study provides the direct evidence of the formation of unsaturated ketones from *chelate* (allyloxy)carbene complexes by an intramolecular regioselective C−C coupling reaction. Such (allyloxy)carbene complex intermediates have been postulated in the Ru-catalysed synthesis of β,γ-unsaturated ketones from terminal alkynes and allyl alcohols.[52,53]

The β,γ-unsaturated ketone complex [Ru(Tp)(Cl)(κ^3-C$_7$H$_{15}$C(O)CH$_2$CH=CH$_2$)] (**57**) as well as the free ketone 4-dodec-1-enone (**58**) are formed during the synthesis of the chelate carbene complex [Ru(Tp)(Cl){κ^3-C(OCH$_2$CH=CH$_2$)(C$_7$H$_{15}$)}] (**24d**).[19] Although this result is also in agreement with the proposed intermediary of chelate (allyloxy)carbene complexes, it is only observed for **58**, and the yields of **57** and **58** are low.

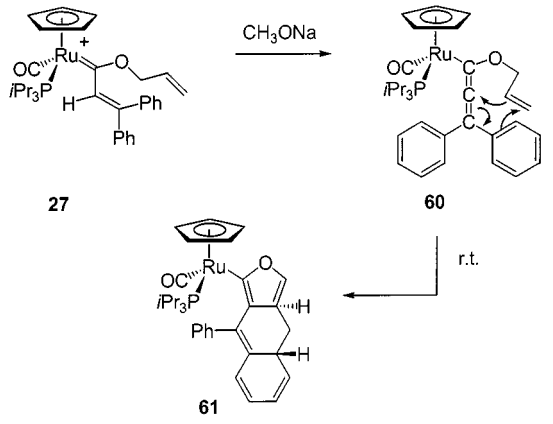
We attempted to synthesise the parent (carbene)(C$_5$Me$_5$)Ru complex **59** from the acetonitrile derivative [Ru(C$_5$Me$_5$)(PPh$_3$)$_2$(CH$_3$CN)][PF$_6$] in the presence of PhC≡CH and CH$_2$=CH−CH$_2$OH, but a mixture of the expected (allyloxy)carbene complex **59** [Ru(C$_5$Me$_5$)(PPh$_3$){(κ^3-*C*,*C*,*C*)-C(OCH$_2$CH=CH$_2$)CH$_2$Ph}][PF$_6$] and the allylphosphonium salt [CH$_2$=CH−CH$_2$PPh$_3$][PF$_6$] was obtained (Scheme 32).[54] The formation of the latter results from nucleophilic attack of free PPh$_3$ at the terminal carbon atom of the coordinated olefinic fragment, precluding the isolation of the pure carbene complex.



Scheme 32. Synthesis of the [(allyloxy)carbene]ruthenium complex **59**

When the allyloxy group is not coordinated to the metal fragment such as in **27**, it can be involved in an intramolecular reaction. The phenylallene fragment of the deprotonated complex [Ru(C$_5$H$_5$)(CO)(P*i*Pr$_3$){C(OCH$_2$CH=CH$_2$)=C=CPh$_2$}] (**60**) reacts with the free C=C double bond (Scheme 33).[25] In solution at room temperature, **60** isomerised into the tricyclic tetraenyl complex **61** by an intramolecular Diels−Alder reaction where the C$_\beta$−C$_\gamma$ double bond and one of the two phenyl groups of the al-

lenyl unit acts as an inner-outer sphere diene and the CH=CH_2 double bond of the alkoxy fragment act as a dienophile.

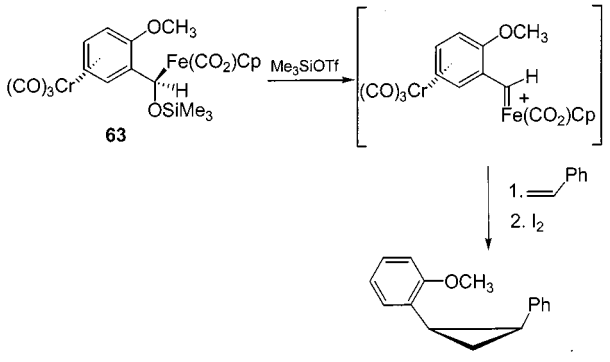


Scheme 33. Intramolecular Diels–Alder reaction involving a free allyloxy group

3.2. Transient Carbene Species: Cyclopropanation and Intramolecular C–H Bond-Insertion Reactions

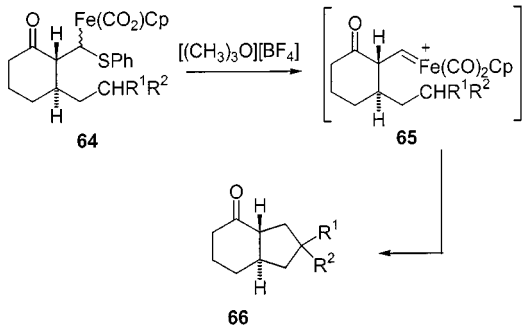
Non-heteroatom-stabilised carbene complexes of iron are good cyclopropanating agents of alkenes.[55,56] These transient species can be generated from (α-siloxyalkyl)iron derivatives [Fe(η^5-ligand)$(CO)_2${CH(OSiMe)R}] (η^5-ligand = C_5H_5, C_9H_7). They are readily accessible from saturated or unsaturated aldehydes RCHO (R = Ph, CH_3, *p*-C_6H_4OMe, *p*-C_6H_4Cl, *p*-C_6H_4Me, *p*-$C_6H_4CF_3$, *o*-C_6H_4OMe, CH=CMe_2) by addition to the iron metallate [Na][Fe(η^5-ligand)$(CO)_2$] and subsequent capture with $ClSiMe_3$.[57]

Asymmetric cyclopropanation reactions involving a chiral carbene ligand have been performed using the dimetallic Fe/Cr complex **63** (Scheme 34).[58] Reaction with styrene affords the corresponding cyclopropanes in a 10:1 *cis*/*trans* ratio. The origin of diastereoselectivity has been investigated. The Cr participation that stabilises the (carbene)iron was expected to induce a *trans* selectivity. However, when aromatic alkenes are used, a π-stacking effect leads to *cis* selectivity.[59]

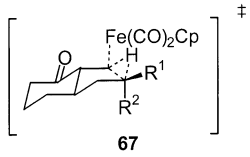


Scheme 34. Cyclopropanation of styrene by **63**

(Carbene)metal complexes are also known to insert into X–H bonds (X = Si, C). Examples of Si–H insertion reactions from alkylidene and benzylidene complexes [Fe(C_5H_5)(CO)(PR_3)(=CHR′)]$^+$ (R = Ph, Et) have been described.[60] With regards to the C–H bond, an intramolecular procedure from (carbene)iron complexes has been developed as a highly stereoselective route to cyclopentanes (Scheme 35).[61] The carbene complexes **65** are generated by *S*-methylation of thiophenyl derivatives **64** and loss of thioanisole. Intramolecular C–H insertion affords the fused cyclopentanes **66**. The main stereochemical features of the cyclisation have been investigated. In agreement with the observed diastereoselectivities, the reaction may proceed through a one-step, concerted insertion of a (carbene)iron complex into a properly situated C–H bond, namely via the chair-like cyclic transition state **67** (Scheme 36).



Scheme 35. Intramolecular C–H insertion reactions involving transient (carbene)iron complexes

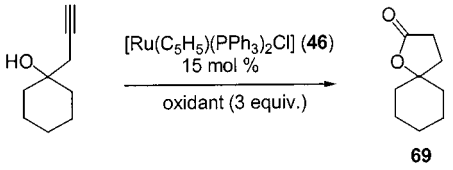


Scheme 36. Chair-like cyclic transition state

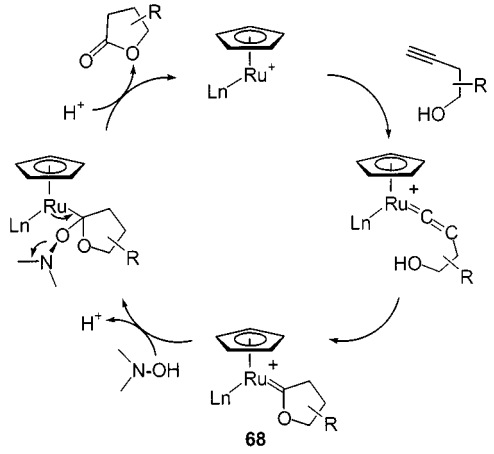
4. Carbene Complexes as Intermediates in Catalysis

4.1. Oxidative Cycloisomerisation of Homopropargyl Alcohols

Homopropargyl alcohols react with Ru complexes to form oxycarbene species via hydroxyvinylidenes.[28] This approach was used to convert homopropargyl alcohols into γ-butyrolactones through a mild oxidative cycloisomerisation process catalysed by **46** (Scheme 37).[62] *N*-Hydroxyimides are used as oxidants which do not affect the catalytic activity. The proposed mechanism involves initial formation of the (oxycarbene)metal intermediate **68** followed by nucleophilic attack of *N*-hydroxyimide (Scheme 38). Eventually, the lactone **69** is released along with the imide.



Scheme 37. Ru-catalysed synthesis of γ-butyrolactones **69**

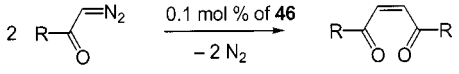


Scheme 38. Proposed catalytic cycle for oxidative cycloisomerisation of homopropargyl alcohols

4.2. Reactions Involving Diazo Compounds

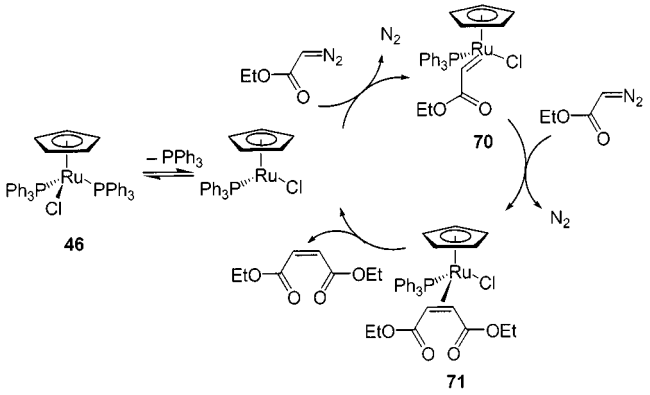
It is generally agreed that carbene species are key intermediates in transition-metal-catalysed C−C bond-forming reactions involving diazo compounds. However, the catalytically active (carbene)Ru species have rarely been isolated or detected during these processes.[3,63] Complex **46** was found to be a catalyst for carbene−carbene coupling, insertion reactions into X−H bonds (X = N, S), cyclopropanation of olefins, and carbene transfer reactions. The formation of neutral carbene intermediates from the 16-electron species $[Ru(C_5H_5)(PR_3)(Cl)]$ is a key step in all these catalytic reactions involving diazo compounds and **46** as a catalyst.

Stereoselective decomposition of α-diazo carbonyl compounds N_2CHCOR [R= Me, *n*Pr, *i*Pr, $(CH_2)_{10}CH_3$] catalysed by **46** affords the corresponding ene-diones RCOCH=CHCOR, the *cis* isomers being formed in 95−97% yield (Scheme 39).[64]

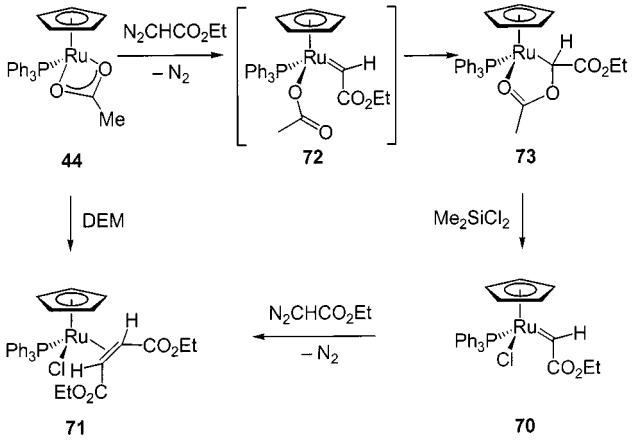


Scheme 39. Formation of *cis*-enediones from α-diazo carbonyl compounds

Under the same conditions, ethyl diazoacetate (EDA) is converted into diethyl maleate (DEM). The observed stereoselectivity (95−99%) may be due to steric factors. A detailed study suggests that the less crowded (*cis*-π-olefin)metal intermediate **71** is formed (Scheme 40). The proposed mechanism involves the carbene complex $[Ru(C_5H_5)(PR_3)(Cl)\{=CHCO_2Et\}]$ (**70**) (Scheme 39). The latter would be formed by dissociation of a PPh_3 ligand from **46**, a key step of the catalytic process. The highly reactive species **70** was spectroscopically not detected in the reaction mixture but has been independently prepared from the Ru acetate precursor **44** and characterised in solution (Scheme 41). Addition of equimolar amounts of EDA to **44** gives the metallacycle derivative **73**. Its formation arises from nucleophilic addition of the κ^1-acetate group at the electrophilic carbene carbon atom. Complex **73** is then converted at −40 °C to the expected carbene derivative **70** by displacement of the acetato group using Me_2SiCl_2. Finally, the DEM complex **71** is formed upon addition of another equivalent of EDA. The reactions have been monitored by NMR spectroscopy allowing all of the intermediates to be characterised.



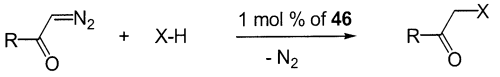
Scheme 40. Proposed mechanism for EDA dimerisation



Scheme 41. Independent synthesis of the carbene intermediate **70** and the DEM complex **71**

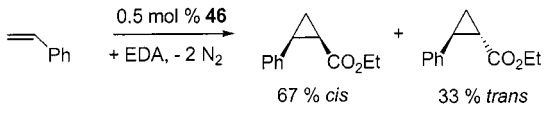
Complex **46** also catalyses chemoselective insertion reactions of α-diazo carbonyl compounds $N_2CHC(O)R$ [R = CH_3, *n*Pr, *i*Pr, $(CH_2)_{10}CH_3$, $(CH_2)_{14}CH_3$, Ph] into N−H and S−H bonds.[65] This procedure affords α-oxo amines and α-oxo thioethers in very good yields (Scheme 42). As proposed for the synthesis of *cis*-enediones, a (carbene)ruthenium complex $[Ru(C_5H_5)(PR_3)(Cl)\{=CHC(O)R\}]$ is in-

volved in the catalytic process. Nucleophilic attack by amine or thiol (X−H) gives the product $RC(O)CH_2X$.

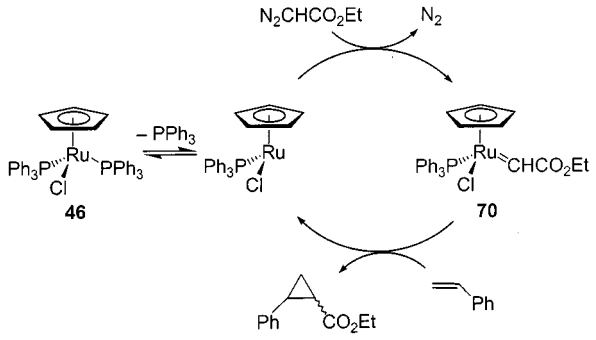


Scheme 42. Insertion reactions of diazo carbonyl compounds into X−H (X = N, S) bonds catalysed by **46**

Selective catalytic carbene transfer reactions from diazo compounds to terminal alkenes have been reported. Complex **46** is an efficient catalyst for cyclopropanation of styrene with EDA (Scheme 43).[38] The catalytic activity of Ru derivatives of general formula $[Ru(\eta^5\text{-ligand})(PR_3)_2(X)]$ have also been investigated. The reaction is performed in pure alkene solvent, in order to avoid dimerisation of EDA. The cyclopropane products are readily obtained in high yields and with significant *cis* stereoselectivity. For instance, in the case of **46**, optimum conditions gave rise to a 95% yield of ethyl 2-phenylcyclopropanecarboxylate with a stereoselectivity of 67% *cis* versus 33% *trans*. As above, the reaction is likely to proceed via the carbene derivative **70** that would account for the observed stereoselectivity (Scheme 44). However, no spectroscopic evidence for the formation of this intermediate in the reaction mixture was obtained.

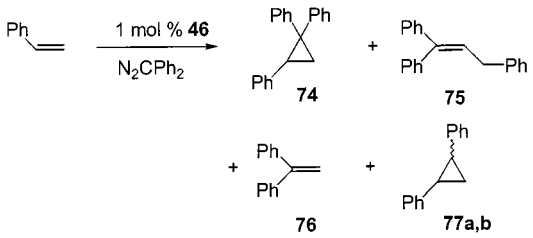


Scheme 43. Ru-catalysed cyclopropanation of styrene with EDA



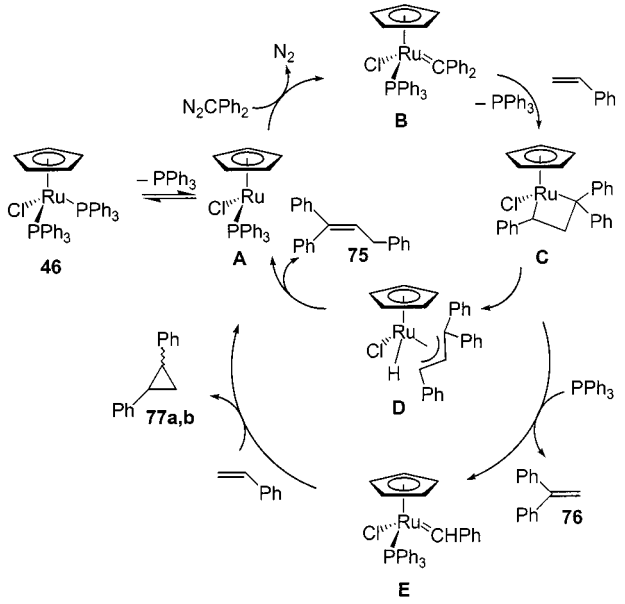
Scheme 44. Proposed mechanism of cyclopropanation of styrene with EDA catalysed by **46**

When diphenyldiazomethane is used, an unusual C−C coupling reaction takes place (Scheme 45).[38] The reaction with styrene in the presence of **46** (1 mol %), affords mainly 1,1,3-triphenylpropene (**75**) (58%), together with a 1:1 mixture of 1,1-diphenylethene (**76**) (17%), and 1,2-diphenylcyclopropanes **77a**,**b** (16%). Only 9% of the expected cyclopropyl derivative **74** is present, the product is actually formed in a thermal side reaction from styrene and diphenyldiazomethane without involvement of **46**. The carbene intermediate **45a** has been spectroscopically identified during catalysis. In a stoichiometric reaction, complex **45a** can transfer its carbene ligand to styrene to give the compounds **75**, **76**, and **77**, formed with a distribution comparable to that of the catalytic reaction.



Scheme 45. Ru-catalysed C−C bond-forming reactions from styrene and diphenyldiazomethane

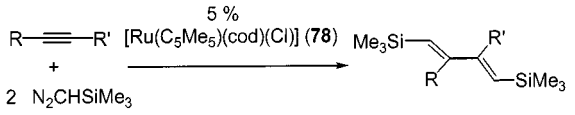
On the basis of the mechanism suggested for (sulfonato)rhodium complexes,[66] the formation of compound **75** results from a formal $:CPh_2$ and $:CHCH_2Ph$ coupling (Scheme 46). In the first stage, the carbene derivative **B** is generated from **A**. Coordination of styrene and coupling with the carbene ligand affords a metallacyclobutane intermediate **C**. Then, **C** rearranges into the π-allyl complex **D** by a β-H elimination. Reductive elimination affords the observed propene derivative **75**. Note that the metallacycle **C** is postulated in olefin metathesis reactions and can account for the formation, in a side reaction, of 1,1-diphenylethene (**76**). Thus, this second competitive reaction would lead to the formation of a benzylidene complex **E**. Carbene transfer to styrene provides the cyclopropanes **77** and regenerates **A**.



Scheme 46. Proposed mechanism for the formation of **75**, **76**, and **77**

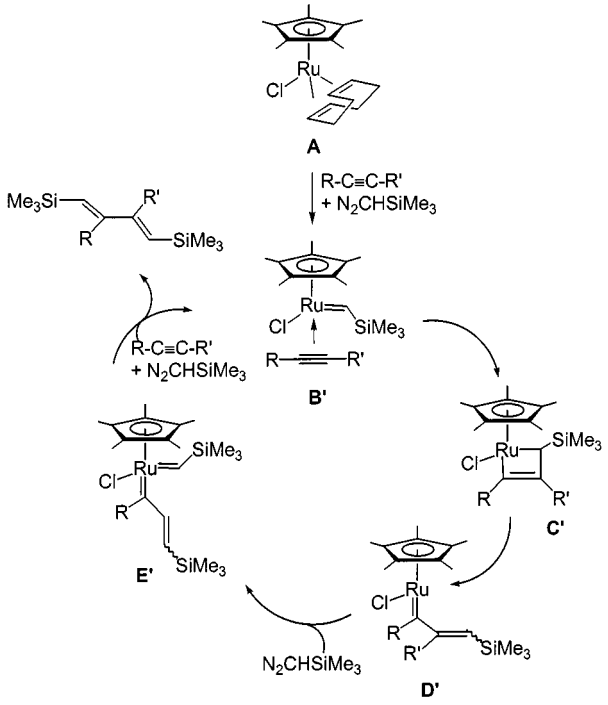
The above results suggest that complex **46** and related complexes constitute a promising class of catalysts for chemo-, regio-, and stereoselective processes involving diazo compounds. A wide range of synthetically useful trans-

formations have been developed. In another example, the ruthenium-catalysed addition of diazo compounds to alkynes has been reported.[67] This double addition is catalysed by [Ru(C_5Me_5)(cod)(Cl)] (**78**) allowing, for example, the access to 1,4-bis(trimethylsilyl)buta-1,3-dienes, by combination of two molecules of trimethylsilyldiazomethane and one of alkyne (Scheme 47).



Scheme 47. Synthesis of 1,4-bis(trimethylsilyl)butadiene catalysed by **78**

A plausible mechanism for this selective process has been proposed (Scheme 48). Displacement of the cod ligand by one molecule of alkyne and trimethyldiazomethane to the ruthenium centre provides the (carbene)ruthenium intermediate **B′**. The intramolecular C−C coupling leads to **C′** which then rearranges into the unsaturated vinylcarbene derivative **D′**. Addition of a second molecule of diazomethane leads to the bis(carbene) **E′**. Finally, coupling of the two carbene ligands affords the observed diene. This reaction constitutes an unusual 2:1 coupling between diazoalkanes and a wide range of alkynes, demonstrating that it is possible to selectively create two C=C double bonds.



Scheme 48. Proposed mechanism for the catalytic formation of functional conjugated dienes

5. Concluding Remarks

The importance of the carbene complexes is reflected by their widespread use in synthesis. In stoichiometric reactions, electrophilic iron complexes are involved in diastereoselective syntheses of fused cyclopentanes. The development of enantioselective methodologies is an important challenge in organic synthesis. In catalysis, most of the (carbene)ruthenium complexes are generated from diazo compounds. An alternative pathway is via vinylidene complexes. The intermediary of allenylidene complexes is still rare. Condensation of the Ru=C double bond with unsaturated substrates appears to be a promising new field. The search for new catalysts is highly desirable, and then carbene complexes could become standard tools in synthesis provided that these species are readily accessible and easily handled.

Acknowledgments

I would like to thank my co-workers who have contributed to this project. Their names are mentioned in the references. I am indebted to the CNRS and the University of Rennes 1 for generous support of this work.

Keywords: Hydrothermal synthesis / Nanostructures / Materials science / Europium / Organic-inorganic hybrid composites

The open framework of $[Eu_2(btc)(H_2btc)(H_2O)]\cdot 4H_2O$ (**1**), prepared by hydrothermal reaction of $EuCl_3$ with 1,2,4,5-benzenetetracarboxylic anhydride in acidified aqueous solution, is built up from two types of polymeric layers with $[EuO_6(H_2O)]_n$ units as tethers, resulting in nanoporous channels that host water molecules through complex hydrogen bonding. Crystallographic data for **1**: monoclinic, $P2_1/n$, with a = 10.7562(2) Å, b = 7.2075(2) Å, c = 17.2180(5) Å, β = 97.072(2)° and Z = 2. A study of the temperature dependence of the magnetic susceptibility data reveals that the paramagnetic behavior of **1** is mainly due to the effective spin-orbital coupling between the ground and exited states through the Zeeman perturbation; the magnetic interaction between europium(III) centers is very weak. A study of the electronic properties demonstrates that compound **1** is a semiconductor. A TGA analysis between 30 and 600 °C for **1** suggests that when the lattice water molecules are removed from the network, the skeleton of the network still remains stable up to 150 °C; this is also confirmed by XRPD.

Introduction

In the past few years, the construction of inorganic coordination networks, especially of zeolite-like microporous materials, has attracted much attention[1−4] not only because of their intriguing architectures, but also because of their promising potential applications.[5−7] The design and synthesis of new frameworks containing large pores that can facilitate the removal/adsorption of guest molecules is a continuing challenge.

We are currently interested in pursuing synthetic strategies that use lanthanide ions as nodes for the construction of three-dimensional microporous frameworks. Such structures are more difficult to control than those of d-block transition metal analogues due to the higher coordination numbers of lanthanide ions and the inherent flexibility of their coordination geometries, which could lead to unprecedented topological architectures. Recent reports have demonstrated that some organic ligands have a dramatic impact on structures, and consequently on their properties, and are therefore very useful for the control of the architectures of coordinated polymers.[8−11] The 1,2,4,5-Benzenetetracarboxylic (pyromellitic) acid (H_4btc) ligand,[12] which has eight (btc) or four (H_2btc) potential donor oxygen atoms, is a rather versatile ligand for the synthesis of polymeric complexes with metal cations.[13] However, examples of H_4btc-bridged metal-organic frameworks that can maintain their structural integrity upon the removal of guest molecules are still rare. In the course of our investigations on the synthesis of btc- and/or H_2btc-bridged f-block lanthanide metal-based materials, we realized that the unique lanthanide nature, the H_4btc ligand and the reaction conditions could work synergistically to produce new 3D porous open frameworks. Here we report the synthesis and crystal structure of $[Eu_2(btc)(H_2btc)(H_2O)]\cdot 4H_2O$ (**1**), as well as some new phenomena observed during the course of investigations of its physical properties.

Results and Discussion

The hydrothermal reaction of an acidified aqueous solution of $EuCl_3$ with 1,2,4,5-benzenetetracarboxylic anhydride gives rise to **1** as colorless crystals. A single crystal X-ray analysis revealed that the three-dimensional microporous framework of compound **1** is built by linking one crystallographically independent nine-coordinate Eu^{III} subunit through its btc and H_2btc ligands. Each nine-coordinated Eu^{III} unit is a distorted tricapped trigonal prism, of which eight oxygen atoms belong to six different carboxylate groups of btc or H_2btc and the other one to a water molec-

ule, with the $Eu^{III}-O$ bond lengths ranging from 2.353(4) to 2.581(4) Å.

Interestingly, there are two types of coordination modes for the H_4btc ligands in compound **1** (I and II). In mode I, each H_4btc unit acts as a dodecadentate ligand coordinating six europium(III) atoms, that is, each of the four carboxylate groups chelates to one Eu^{III} center, while every two adjacent oxygen atoms of the nearest carboxylate groups coordinate to one more europium(III) atom (Figure 1). In mode II, only two of the four carboxylate groups of an H_4btc ligand coordinate to europium(III) centers and each carboxylate group coordinates to two different Eu^{III}, thus, each ligand coordinates to four europium(III) centers (Figure 2). The H_4btc ligand links europium(III) atoms in very different ways to produce two different infinite network layers. The layers of these two types interlock with each other with a fold of about 60° to form a unique three-dimensional microporous framework with channels (dimensions about 10.331 × 11.201 Å). The zigzag $[EuO_6(H_2O)]_n$ tethers, which are built up from nine-coordinate europium(III) atoms with Eu−Eu distances of about 3.950(1) Å, are bridged by carboxyl oxygen atoms and the carboxylate groups of H_4btc. The channels are filled with eight water molecules per unit cell, which can be replaced by other suitable molecules under certain conditions (Figure 3). Finally, it should also be pointed out that the distances between guest water oxygen atoms are about 2.83(1) Å, while those between the water oxygen atoms and the oxygen atoms of the carboxylate groups range from 2.65(1) to 3.08(1) Å. Additionally, the distances between the oxygen atoms of coordinated water molecules and guest water molecules or carboxylate groups are also within the hydrogen bonding ranges [2.75(1) to 2.97(1) Å], indicating a complex hydrogen bonding network in the packing of compound **1**.

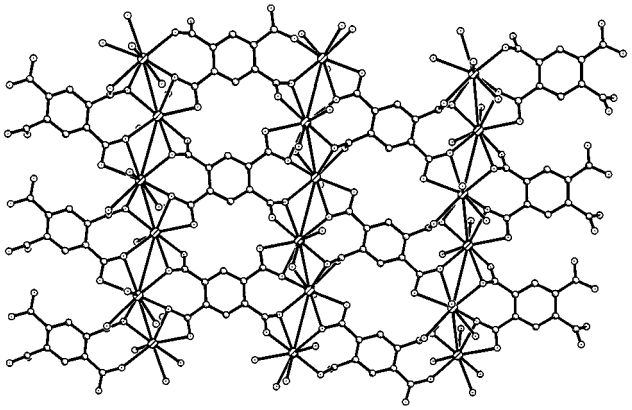

Figure 1. View of an intralamellar structure down the *a* axis for **1**, showing the environments of Eu^{III} atoms and one of the coordination modes for H_4btc

The variation of the molar magnetic susceptibility χ_M was investigated for compound **1** in the temperature range from 5.0 to 300 K in a 10 KG applied field. Figure 4 shows

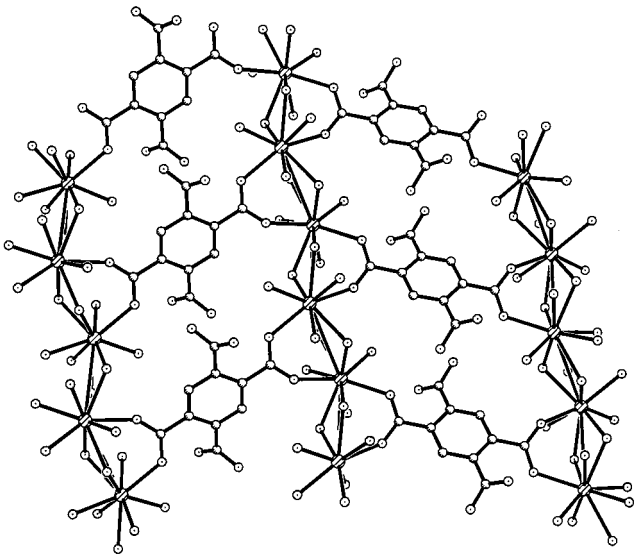

Figure 2. Side view of another intralamellar structure of **1**, showing the environments of the Eu^{III} atoms and the second coordination mode for H_4btc

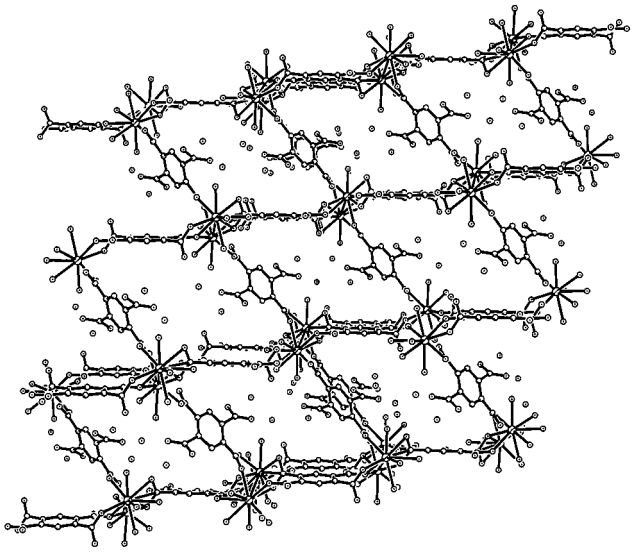

Figure 3. View down the *b* axis showing the channels that are occupied by water molecules in **1**

the magnetic behavior of **1** in the form of $\chi_M T$ vs. T and χ_M vs. T plots. At 299.2 K, the $\chi_M T$ value is 1.262 emu·K·mol^{-1} per Eu^{III}, and upon cooling to 5.0 K the $\chi_M T$ values decrease gradually to 0.0288 emu·K·mol^{-1}, indicating the presence of a strong paramagnetic coupling in compound **1**.

In contrast with transition metal compounds, the magnetic properties of rare earth metal compounds, even of mononuclear species, have not yet been fully understood. According to the literature,[14] the effect of the crystal field is not easily calculated, while the angular momentum often plays a key role in the magnetic susceptibilities of rare earth metal compounds. For the trivalent europium ion, the ^7F ground term is split by the spin orbit coupling into seven

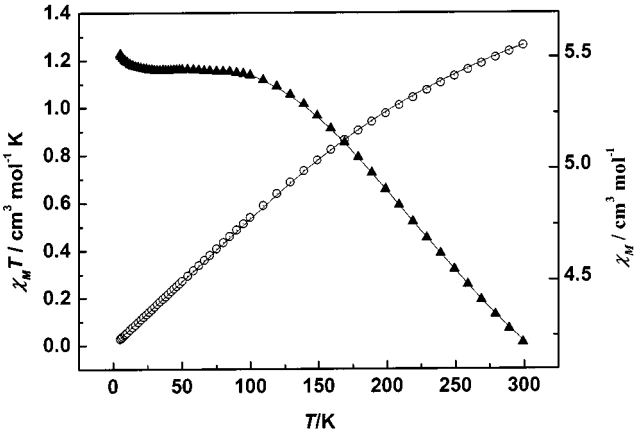

Figure 4. The $\chi_M T$ vs. T and χ_M vs. T plots for compound **1**

states, ^7F_J ($J = 0, 1, 2, \ldots 6$). Thus, the removal of the $2J + 1$ degeneracy of the ground state at zero field and the thermal population of the free-ion exited states must be considered in this case for Eu^{III}; these factors obviously cause the deviation from normal Curie−Weiss behavior. Based upon the above discussion, the magnetic susceptibility data were quantitatively analyzed using Equation (1):

$$\chi_M = N\beta^2/3k(T-\theta)x[24 + (27x/2 - 3/2)e^{-x} + (135x/2 - 5/2)e^{-3x} + (189x - 7/2)e^{-6x} + (405x - 9/2)e^{-10x} + (1485x/2 - 11/2)e^{15x} + (2457x/2 - 13/2)e^{-21x}]/[1 + 3e^{-x} + 5e^{-3x} + 7e^{-6x} + 9e^{-10x} + 11e^{-15x} + 13e^{-21x}] \quad (1)$$
with $x = \lambda/kT$

In this case, λ is the spin-orbit coupling parameter between ground and exited states through the Zeeman perturbation, while θ is the Curie−Weiss temperature. A least-squares fitting of all experimental data leads to λ and θ values of 393.99 cm^{-1} and 0.897 K with an agreement factor R of 2.0×10^{-5} ($R = \Sigma[(\chi_M)_{obs} - (\chi_M)_{calcd}]^2/\Sigma[(\chi_M)^2_{obs}]$). These results demonstrate that all of the europium(III) ions are well isolated from each other in the magnetic molecular field, even if the Eu−Eu distance is rather short [3.950(1) Å]. The paramagnetic behavior is mainly due to the spin-orbital coupling and weak ferromagnetic interactions between Eu^{III} centers transferred through oxygen atoms and the ligands.

Determination of the conductivity (powder sample from ground crystals) gives a value of 3.01×10^{-7} Scm^{-1} at 303 K for **1**, and it increases as the temperature rises, indicating that **1** is a semiconductor. This semiconducting behavior of **1**, which demonstrates the existence of either Eu−Eu or Eu−L−Eu interactions, is probably due to the unique structural feature whereby the arrays of Eu^{III} atoms are coordinated by bridging oxygen atoms, and to the short Eu−Eu distance [3.950(1) Å].

The overall neutral three-dimensional framework of **1** shows clearly the presence of large channels, which are occupied by water molecules. These guest molecules can be removed to generate nanoporous solids with retention of the framework skeleton. The thermogravimetric analysis (TGA) data graph shows a four-stage weight loss for compound **1**. The first stage, which occurs from 30−190 °C, is attributed to the loss of the four crystal water molecules per formula unit. The observed weight loss (7.3%) is in agreement with the calculated value (7.0%). The second stage occurs between 190−230 °C, with a weight loss corresponding to one aqua ligand per empirical formula (calcd. 2.0%; found 1.7%). The weight of the molecule remains almost unchanged in the third stage (230−410 °C). At 410 °C, the product begins to lose btc and H_2btc ligands and then to decompose.

A sample of **1** was ground and heated at 150 °C for 24 h at 10^{-2} Torr and then an XRPD spectrum was recorded of the remains. The characteristic peaks are almost identical to those of freshly prepared sample of **1**, which suggests that the hybrid organic-inorganic skeleton is retained. This result demonstrates clearly that the unique framework of **1** is rather stable and its application as a nanoporous material is very promising.

Conclusion

In summary, it is well-known that hydrothermal reactions often produce unprecedented complexes with interesting properties.[15] However, to produce novel complexes with desirable properties under mild reaction conditions is still the preferred option for most chemists. The successful isolation of complex **1** is an example of how to carry out hydrothermal reactions at relatively low temperatures (100 °C). Our strategy not only yields a novel architecture, but also allows us to understand more about whether the reactions are controlled by thermodynamic or by kinetic factors. Although the Eu−Eu distance in the $[EuO_6(H_2O)]_n$ chain is rather short [3.950(3) Å], the magnetic study reveals that the paramagnetic behavior of **1** is mainly due to the coupling among the populated free-ion states, which causes the magnetic behavior to deviate from the Curie−Weiss law. This work provides very important evidence that shows that the free-ion approximation is also appropriate for the interpretation of the magnetic properties of polynuclear rare earth metal species, while the contribution from the overlap of the magnetic orbitals can be almost ignored. The semiconducting behavior of **1** demonstrates the existence of metal-metal interactions. Based upon the TGA and XRPD analyses, the structure is rather stable, and this is undoubtedly due to the multidentate ligands forming a rigid framework for **1**. Moreover, from these studies, compound **1** is one of the few compounds that maintains its structural integrity after the removal of guest molecules. We have reasons to believe that it has potential applications for shape-selective reactions[16] or solvent-exchange process,[17] and these are now under investigation.

Experimental Section

Synthesis of 1: The pH of a mixture of $EuCl_3$ (0.68 mmol) (prepared from Eu_2O_3 dissolved in 35% HCl) and 1,2,4,5-benzenetetra-

carboxylic anhydride (0.22 g, 1.0 mmol) in H_2O (18 mL) was adjusted to 1.22 whilst stirring vigorously and the resulting mixture was then heated at 100 °C for twelve days under autogenous pressure in a sealed 30 mL Teflon-lined stainless steel vessel. Colorless crystals were isolated after the reaction solution was cooled down gradually and washed with water and ethanol. Yield: 0.239 g (76.8%, based on Eu). $C_{20}H_{18}Eu_2O_{22}$ (914.26): calcd. C 26.27, H 1.98; found C 26.19, H 1.96. IR (KBr pellet): $\tilde{\nu}$ = 1878w cm^{-1}, 1659s, 1610s, 1579s, 1554s, 1498s, 1429sh, 1387s, 1336m, 1323m, 1294s, 1269s, 1142w, 1124s, 849m, 933m, 881s, 849m, 835s, 816m, 775m, 754m, 658m, 590s, 521s, 442m. FT-Raman (solid, λ = 1064 nm): $\tilde{\nu}$ = 1677m cm^{-1}, 1633sh, 1594s, 1579s, 1459s, 1440sh, 1419sh, 1390sh, 1278m, 1253m, 1187s, 973s, 898s, 848s, 825m, 794s, 682s, 597w, 489m, 478m, 456m, 399m, 331m, 304w, 250m, 215m, 179m, 165m, 138m, 119m.

X-ray Crystallography: The determination of the unit cell and the data collection for a colorless crystal of compound **1** were performed on a Siemens SMART CCD, and the data were collected using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 293 K in the range of $2.12 < \theta < 25.05°$. The data set was corrected with the SADABS program.[18] The structure was solved by direct methods and refined by full-matrix least-squares methods, which were performed using the SHELXL-97 software package.[19] All non-hydrogen atoms were refined anisotropically. Crystal data: $C_{20}H_{18}Eu_2O_{22}$, M_r = 914.26, monoclinic, space group $P2_1/n$, a = 10.7562(2), b = 7.2075(2), c = 17.2180(5) Å, β = 97.072(2)°, U = 1324.68(6) $Å^3$, Z = 2, D_c = 2.292 gcm^{-3}, μ = 4.795 mm^{-1}, $F(000)$ = 880, crystal size = 0.30 × 0.06 × 0.04 mm^3. $R1$ = 0.0289, $wR2$ = 0.0613 and S =1.077 for 1943 reflections with $F_o > 4\sigma(F_o)$ and 216 parameters ($R1$ = 0.0414 and $wR2$ = 0.0681 for all 2316 data). CCDC-160794 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

From *P*-Metalated *trans*-Iminodiphosphanes to *N*-Metalated *cis*-Iminodiphosphanes: An Unprecedented Rearrangement

Maria Zablocka,[a] Krzysztof Owsianik,[a] Alain Igau,[b] Aleksandra Skowronska,[a] and Jean-Pierre Majoral*[b]

Keywords: Phosphanes / Zirconium / N ligands

The reaction of chlorophosphanes with azazirconacyclopentenes provides an unique way to cyclic *P*-metalated *trans*-iminodiphosphanes, which rearrange to give unprecedented *N*-metalated *cis*-iminodiphosphanes.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The search for new derivatives incorporating phosphorus and nitrogen continues to receive considerable attention due to the versatility of these ligands (combination of hard and soft donor atoms) towards complexation. Classical nitrogen ligands (amine, pyridine, oxazoline, quinoline, pyrazole etc.) and classical phosphanes constitute the coordinating skeleton of the majority of these P,N species.[1] Similarly, β- or γ-iminophosphanes in which the imine acts as a weak π-acceptor and the phosphane as a good σ-donor are also being used more and more frequently. Palladium(II) complexes of these phosphorus-nitrogen mixed donors ligands have been found, for example, to be efficient catalysts for the Heck reaction,[2] for the carbostannylation of alkynes,[3] for the copolymerisation of CO/ethylene and CO/norbornylene[4] or for allylic alkylation.[5]

In contrast, very few iminodiphosphanes, namely the linear *trans*-*C*-phosphanyl, *N*-phosphanyl imines **I**, are known[6] and no complexes of this potential ligand or free or complexed *trans* or *cis* cyclic analogs of these derivatives have been described.

We report herein a powerful and versatile one-pot synthesis of cyclic *P*-metalated *trans*-iminodiphosphanes from azazirconacyclopentenes and chlorophosphanes and the quite unusual rearrangement of the former derivatives to cyclic *N*-metalated *cis*-iminodiphosphanes.

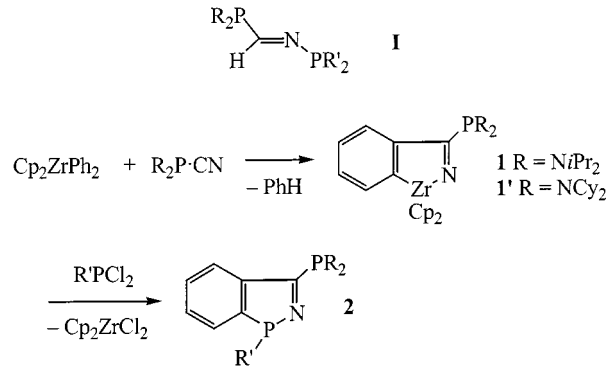
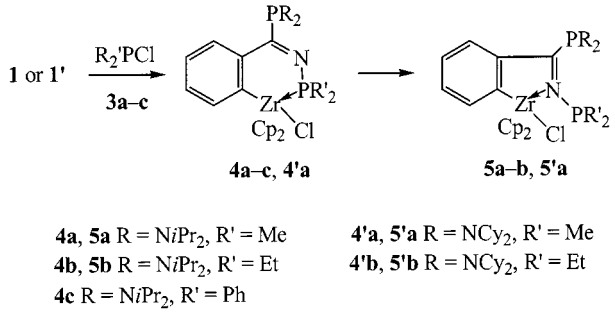
Results and Discussion

We have already reported that the thermolysis of diphenylzirconocene in the presence of bis(amino)cyanophosphane leads to the formation of the azazirconacyclopentenes **1** and **1′**. These complexes can then be reacted with various dichlorophosphanes to give the 1,2-azaphosphindoles **2** and Cp_2ZrCl_2 (Scheme 1).[7] The same reaction performed with chlorophosphanes R'_2PCl (**3a−c: a** R′ = Me, **b** R′ = Et, **c** R′ = Ph) instead of dichlorophosphanes proceeds differently. In this case no exchange reaction takes place. Indeed, the addition of chlorophosphanes **3a−c** to **1** (R = N*i*Pr$_2$) in toluene at −20 °C affords the unexpected cyclic *P*-metalated *trans* (the two phosphanyl groups) iminodiphosphanes **4a−c** (Scheme 2). The reaction can be monitored by ^{31}P NMR spectroscopy which shows the disappearance of the signal due to **1** (δ = 45) and the appearance of two doublets at δ = 74.0 [P(NiPr$_2$)$_2$] and 67.5 (PMe$_2$) ($J_{P,P}$ = 6.9 Hz) for **4a**, δ = 78.4 (PEt$_2$) and 74.1 [P(NiPr$_2$)$_2$] ($J_{P,P}$ = 8 Hz) for **4b** and δ = 78.8 [P(NiPr$_2$)$_2$] and 63.3 (PPh$_2$) ($J_{P,P}$ = 8.6 Hz) for **4c**. The direct complexation of the R$_2$P phosphanyl group to the 16e$^-$ zirconium moiety is shown in the ^{1}H NMR spectrum by the presence of two doublets for the Cp groups due to the coupling between phosphorus and the Cp protons ($1.9 < J_{H,P} < 2.2$ Hz). Such $J_{H,P}$ values are characteristic of compounds with a P→ZrCp$_2$ dative bond.[8] The formation of **4a−c** can be viewed as the 1,2-addition of the chlorophosphane to the zirconium-nitrogen covalent bond of **1** initiated by the halophilicity of the zirconium moiety and the nucleophilicity of the cyclic imino-nitrogen bond, followed by direct complexation of the phosphanyl group at zirconium. However, the resulting *P*-metalated *trans*-iminodiphosphanes appear to be the kinetic products of the reaction. In solution at room temperature, **4a−b** afford the thermodynamically favored complexes **5a−b** (Scheme 2). Such an evolution de-

pends strongly on the nature of the phosphanyl group linked to zirconium: it takes 24 h for the transformation **4a** → **5a** and 24 days for **4b** → **5b**. The evolution of **4c** gave numerous unidentified products.



Scheme 1



Scheme 2

These transformations can be monitored by ^{31}P NMR spectroscopy. As an example, the two doublets for **4a** disappeared and two new doublets appeared at δ = 74.0 (PMe_2) and 41.7 [$P(NiPr_2)_2$] ($J_{P,P}$ = 6.2 Hz) for **5a**. As expected, only a singlet is detected for the Cp groups in the ^1H NMR spectrum, strongly indicating that the phosphanyl group is not linked to the Cp_2Zr unit. A similar observation can be made for the evolution of **4b** into **5b**, with an analogous characteristic shielding effect in the ^{31}P NMR spectrum for the $P(NiPr_2)_2$ group (Δδ = 30.1 ppm).

The stability of *P*-metalated *trans*-iminodiphosphanes and their transformation to the corresponding *N*-metalated *cis*-iminodiphosphanes depends also on the nature of the substituents directly linked to the exocyclic phosphorus atom. Thus, treatment of the azazirconacyclopentene **1′** with chlorodimethylphosphane **3a** at −20 °C leads to the unstable *P*-metalated *trans*-iminodiphosphane **4′a** which was only characterized by ^{31}P NMR spectroscopy {doublets at δ = 81.3 [$P(N(Cy)_2$] and 64.9 (PMe_2) with $J_{P,P}$ = 7.0 Hz}. The evolution of **4′a** is fast (a few hours at room temperature) and leads to the thermodynamically stable complex **5′a** which was fully characterized by NMR spectroscopy, mass spectrometry and elemental analysis. In marked contrast the same reaction performed with **1′** and **3b** allowed us to isolate the *P*-metalated iminodiphosphane **4′b** {$\delta^{31}P$ = 80.7 [$P(N(Cy)_2]_2$ and 77.1 (PEt_2) ($J_{P,P}$ = 8.5 Hz)}. The formation of a dative bond between the Et_2P group and Zr is again confirmed by the presence in the ^1H NMR spectrum of the characteristic two doublets for the Cp groups at δ = 5.87 and 6.25 with $J_{H,P}$ = 2.0 and 1.9 Hz. The full transformation of **4′b** to **5′b** occurs at room temperature after 6 h (Scheme 2). Here again a typical shielding effect is observed for the $P[N(Cy)_2]_2$ group when moving from the six- to the five-membered ring (Δδ = 34.6 ppm).

Attempts to grow suitable crystals for an X-ray diffraction study have so far been unsuccessful.

Conclusion

The treatment of cyanophosphanes successively with diphenylzirconocene and then a chlorophosphane allows the clean reduction of the cyano group to an imino group, the formation of cyclic *P*-metalated *trans*-iminodiphosphanes and their unprecedented rearrangement to cyclic *N*-metalated *cis*-iminodiphosphanes. Such a sequence of reactions can be performed as a one-pot process.

Investigations concerning the generality of this unique synthetic methodology, studies concerning the complexation of the *N*-metalated *cis*-iminodisphosphanes and the use of the resulting complexes in catalytic processes are currently underway.

Experimental Section

General: All reactions were carried out under argon using standard Schlenk techniques and vacuum-line manipulations. All solvents were dried degassed and distilled before use. A Perkin−Elmer 1725X spectrometer was used to record the FT-IR spectra. NMR spectra were recorded on Bruker AC80, AC200, or AM250 spectrometers for ^1H, ^{13}C and ^{31}P NMR, with $SiMe_4$ and H_3PO_4, as references. The assignment of the signals in the ^{13}C NMR spectrum was done using Jmod, two dimensional HMBC and HMQC, broad band or CW ^{31}P decoupling experiments when necessary.

Compound 4a: Chlorodimethylphosphane (0.079 g, 64.8 μL, 0.82 mmol) was added to a solution of azazirconacyclopentene **1** (0.455 g, 0.82 mmol) in toluene at −20 °C. The mixture was stirred at room temperature for 30 min, and then evaporated to dryness. The resulting solid residue was extracted with pentane (2 × 20 mL) and filtered. The volatiles were removed from the solution to give **4a** as a yellow solid in 92% yield (0.491 g). ^1H NMR (C_6D_6): δ = 0.62 (d, $J_{H,P}$ = 5.7 Hz, 3 H, CH_3), 1.01 (d, $J_{H,H}$ = 6.7 Hz, 12 H, CH_3), 1.14 (d, $J_{H,H}$ = 6.7 Hz, 12 H, CH_3), 1.31 (d, $J_{H,P}$ = 4.2 Hz, 3 H, CH_3), 3.4 (sept, $J_{H,H}$ = 6.7 Hz, 4 H, CH), 5.74 (d, $J_{H,P}$ = 2.0 Hz, 5 H, CH_{Cp}), 6.09 (d, $J_{H,P}$ = 1.9 Hz, 5 H, CH_{Cp}), 7.14 (m, 1 H, CH_{arom}), 7.53 (m, 1 H, CH_{arom}), 7.89 (d, $J_{H,P}$ = 1.1 Hz, $J_{H,H}$ = 7.7 Hz, CH_{arom}), 8.5 (d, $J_{H,H}$ = 7.7 Hz, CH_{arom}). $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 15.4 (d, $J_{C,P}$ = 16.7 Hz, CH_3P), 17.7 (d, $J_{C,P}$ = 16.6 Hz, CH_3P), 25.4 (d, $J_{C,P}$ = 11.1 Hz, CH_3), 26.6 (d, $J_{C,P}$ = 8.5 Hz, CH_3), 26.8 (d, $J_{C,P}$ = 10.6 Hz, CH_3), 51.4 (d, $J_{C,P}$ = 8 Hz, CH), 58.4 (d, $J_{C,P}$ = 11.9 Hz, CH), 109.8 (s, CH_{Cp}), 109.9 (s, CH_{Cp}), 124.1, 125.2, 137.6 (s, CH_{arom}), 156.1 (dd, $J_{C,P}$ = 7.5 Hz, $J_{C,P}$ = 20.9 Hz, C_{arom}), 172.9 (dd, $J_{C,P}$ = 26.9 Hz, C_{arom}), 204.3 (dd, $J_{C,P}$ = 12.2 Hz, $J_{C,P}$ = 8.9 Hz, C=N). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 74.0 [d, $J_{P,P}$ = 6.9 Hz, $P(NiPr_2)_2$], 67.5 (d, $J_{P,P}$ = 6.9 Hz,

PMe_2). $C_{31}H_{48}ClN_3P_2Zr$ (651.36): calcd. C 57.16, H 7.42, N 6.45; found C 57.01, H 7.38, N 6.39.

Compound 4b: Same experimental procedure as for **4a** starting from **1** (0.416 g, 0.75 mmol) and chlorodiethylphosphane (0.094 g. 91 μL, 0.75 mmol); **4b** was obtained in 88% yield (0.484 mg). ^1H NMR (C_6D_6): δ = 0.65 (dt, $J_{H,H}$ = 7.5 Hz, $J_{H,P}$ = 18.8 Hz, 3 H, CH_3, Et), 0.68 (dt, $J_{H,H}$ = 7.7 Hz, $J_{H,P}$ = 13.3 Hz, 3 H, CH_3, Et), 1.10 (d, $J_{H,H}$ = 6.7 Hz, 12 H, CH_3), 1.20 (d, $J_{H,H}$ = 6.7 Hz, 12 H, CH_3), 2.20 (m, 4 H, CH_2), 3.50 (sept, $J_{H,H}$ = 6.7 Hz, 4 H, CH), 5.94 (d, $J_{H,P}$ = 2.0 Hz, 5 H, $CH_{C,P}$), 6.17 (d, $J_{C,P}$ = 2.2 Hz, 5 H, CH_{Cp}), 7.30 (m, 1 H, CH_{arom}), 8.00 (dd, $J_{H,P}$ = 1.2 Hz, $J_{H,H}$ = 7.7 Hz, 1 H, CH_{arom}), 8.21 (d, $J_{H,H}$ = 7.9 Hz, 1 H, CH_{arom}), 8.64 (d, $J_{H,H}$ = 7.6 Hz, 1 H, CH_{arom}). $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 8.2 (d, $J_{C,P}$ = 8.1 Hz, CH_2CH_3), 18.5 (d, $J_{C,P}$ = 8.8 Hz, CH_2CH_3), 25.5 (d, $J_{C,P}$ = 12.1 Hz, CH_3), 27.6 (d, $J_{C,P}$ = 12.1 Hz, CH_3), 51.5 (d, $J_{C,P}$ = 8.9 Hz, CH), 58.7 (d, $J_{C,P}$ = 12.6 Hz, CH), 110.5 (s, CH_{Cp}), 109.8 (s, CH_{Cp}), 124.2, 126.6, 128, 146.5 (s, CH_{arom}), 146.2 (d, $J_{C,P}$ = 3.5 Hz, CH), 173.7 (d, $J_{C,P}$ = 27.1 Hz, C_{arom}), 205.1 (dd, $J_{C,P}$ = 10.0 Hz, $J_{C,P}$ = 9.8 Hz, C=N). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 78.4 (d, $J_{P,P}$ = 8.0 Hz, PEt_2), 74.1 [d, $J_{P,P}$ = 8.0 Hz, $P(NiPr_2)_2$]. $C_{33}H_{52}ClN_3P_2Zr$ (679.4): calcd. C 58.34, H 7.71, N 6.18; found C 58.16, H 7.60, N 6.04.

4c: ^1H NMR (C_6D_6): δ = 1.09 (d, $J_{H,H}$ = 6.7 Hz, 12 H, CH_3), 1.20 (d, $J_{H,H}$ = 6.7 Hz, 12 H, CH_3), 3.40 (sept $J_{H,H}$ = 6.7 Hz, 4 H, CH), 6.12 (d, $J_{H,P}$ = 1.9 Hz, 5 H, Cp), 6.17 (d, $J_{H,P}$ = 2.1 Hz, 5 H, Cp), 7.1−7.6 (m, 12 H, CH_{arom}), 8.22 (m, 1 H, CH_{arom}), 8.83 (d, $J_{H,H}$ = 6.9 Hz, 1 H, CH_{arom}). $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 23.4 (d, $J_{C,P}$ = 5.7 Hz, CH_3), 24.2 (d, $J_{C,P}$ = 5.8 Hz, CH_3), 49.5 (d, $J_{C,P}$ = 12.0 Hz, CH), 111.6 (s, CH, Cp), 124.4 (d, $J_{C,P}$ = 24.3 Hz, C_{ipso}), 124.9 (d, $J_{C,P}$ = 23.8 Hz, C_{ipso}), 127.6, 127.8, 128.0, 128.4 (s, CH_{arom}, PPh), 124.1, 126.7, 138.6 (s, CH_{arom}), 178.9 (s, *C*−C=N), 199.9 (dd, $J_{C,P}$ = 12 Hz, $J_{C,P}$ = 9 Hz, C=N). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 78.8 [d, $J_{P,P}$ = 8.6 Hz, $P(NiPr_2)_2$], 63.3 (d, $J_{P,P}$ = 8.6 Hz, PPh_2). $C_{41}H_{52}ClN_3P_2Zr$ (775.50): calcd. C 63.50, H 6.76, N 5.42; found C 63.31, H 6.51, N 5.34.

Compound 5a: Evolution of **4a** at room temperature in toluene for 24 h gave rise quantitatively to **5a**. ^1H NMR (C_6D_6): δ = 1.20 (d, $J_{H,H}$ = 6.6 Hz, 12 H, CH_3), 1.24 (d, $J_{H,H}$ = 6.6 Hz, 12 H, CH_3), 1.27 (d, $J_{H,P}$ = 3.0 Hz, 6 H, CH_3P), 3.30 (m, 4 H, CH), 5.80 (s, 10 H, CH_{Cp}), 7.0−7.2 (m, 2 H, CH_{arom}), 7.52 (m, 1 H, CH_{arom}), 8.41 (dd, $J_{H,H}$ = 7.8 Hz, $J_{H,P}$ = 0.9 Hz, 1 H, CH_{arom}). $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 14.0 (dd, $J_{C,P}$ = 5 Hz, $J_{C,P}$ = 23.0 Hz, CH_3), 24.3 (d, $J_{C,P}$ = 5.4 Hz, CH_3), 24.5 (d, $J_{C,P}$ = 5.8 Hz, CH_3), 48.1 (d, $J_{C,P}$ = 10.4 Hz, CH), 112.2 (s, CH_{Cp}), 112.6 (s, CH_{Cp}), 124.9, 125.7, 126.8, 139.0 (s, CH_{arom}), 145.1 (dd, $J_{C,P}$ = 41.9 Hz, $J_{C,P}$ = 17.8 Hz, *C*−C=N), 156.1 (dd, $J_{C,P}$ = 4.6 Hz, $J_{C,P}$ = 17.8 Hz, C-Zr), 185.8 (dd, $J_{C,P}$ = 15.7 Hz, $J_{C,P}$ = 15.7 Hz, C=N). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 74.0 (d, $J_{P,P}$ = 6.2 Hz, PMe_2), 41.7 [d, $J_{P,P}$ = 6.2 Hz $P(NiPr_2)_2$]. $C_{31}H_{48}ClN_3P_2Zr$ (651.4): calcd. C 57.16, H 7.42, N 6.45; found C 56.97, H 7.35, N 6.31.

Compound 5b: The evolution of **4b** to **5b** was very slow (24 days) and the formation of **5b** (NMR yield: 60%) was accompanied by that of numerous unidentified by-products. **5b** was only characterized by ^{31}P NMR [δ = 86.9 (d, $J_{P,P}$ = 6.5 Hz), 43.9 (d, $J_{P,P}$ = 6.5 Hz)].

Compounds 4′a and 5′a: Chlorodimethylphosphane (0.068 g, 56 μL, 0.7 mmol) was added to a solution of azazirconacyclopentene **1′** (0.364 g, 0.7 mmol) in toluene at −20 °C. The mixture was stirred at room temperature for 15 min and then evaporated to dryness. The resulting solid residue was extracted with pentane (20 mL) and filtered. The volatiles were removed from the solution to give a mixture of **4′a** and **5′a** in a 4:1 ratio. Compound **4′a** was only characterized by ^{31}P NMR: δ = 81.3 (d, $J_{P,P}$ = 7.0 Hz, $P(NCy_2)_2$, 64.9 (d, $J_{P,P}$ = 7.0 Hz, PMe_2). Evolution of **4′a** to **5′a** is fast and complete within 24 h at room temperature.

5′a: ^1H NMR (C_6D_6): δ = 1.06 (d, $J_{H,P}$ = 3.2 Hz, 3 H, CH_3), 1.29 (d, $J_{H,P}$ = 3.2 Hz, 3 H, CH_3), 1.39−2.11 (m, 40 H, CH_2), 3.21−3.30 (m, 4 H, CHN), 6.00 (s, 10 H, CH_{Cp}), 6.45−7.20 (m, 2 H, CH_{arom}), 7.51 (d, $J_{H,H}$ = 6.5 Hz, 1 H, CH_{arom}), 8.51 (d, $J_{H,H}$ = 5.5 Hz, 1 H, CH_{arom}). $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 13.6 (d, $J_{C,P}$ = 23.6 Hz, CH_3), 13.7 (d, $J_{C,P}$ = 23.6 Hz, CH_3), 26.0, 26.8, 27.0 (s, CH_2), 35.0 (br. s, CH_2), 57.6 (d, $J_{C,P}$ = 9.4 Hz, CH), 57.9 (d, $J_{C,P}$ = 8.5 Hz, CH), 113.8 (s, CH, C_{Cp}), 125.6, 125.8, 126.7, 138.6 (s, CH_{arom}), 145.3 (dd, $J_{C,P}$ = 43.4 Hz, $J_{C,P}$ = 21.8 Hz, CCN), 155.5 (dd, $J_{C,P}$ = 3.7 Hz, $J_{C,P}$ = 17.7 Hz, C-Zr), 185.6 (dd, $J_{C,P}$ = 17.4 Hz, $J_{C,P}$ = 17.4 Hz, C=N). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 70.2 (d, $J_{P,P}$ = 8.4 Hz, PMe_2), 40.3 [d, $J_{P,P}$ = 8.4 Hz, $P(NCy_2)_2$]. $C_{43}H_{64}ClN_3P_2Zr$ (811.6): calcd. C 63.63, H 7.95, N 5.18; found C 63.41, H 7.89, N 5.09.

Compound 4′b: Chlorodiethylphosphane (0.077 g, 76 μL, 0.62 mmol) was added to a solution of azazirconacyclopentene **1′** (0.323 g, 0.62 mmol) in toluene at −20 °C. The mixture was stirred at room temperature for 20 min and then the solvents evaporated to dryness. The resulting solid residue was extracted with pentane (2 × 20 mL) and filtered. The volatiles were removed from the solution to give **4′b** as an orange-yellow solid in 68% yield (0.272 mg). ^1H NMR (C_6D_6): δ = 1.57 (t, $J_{H,H}$ = 3.1 Hz, 3 H, CH_3), 1.64 (t, $J_{H,H}$ = 3.1 Hz, 3 H, CH_3), 2.15 (dq, $J_{H,P}$ = $J_{H,H}$ = 3.1 Hz, 4 H, CH_2), 1.20−2.10 (m, 40 H, CH_2), 2.95 (br. s, 4 H, CHN)5.87 (d, $J_{H,P}$ = 2.0 Hz, 5 H, CH_{Cp}), 6.25 (d, $J_{H,P}$ = 1.9 Hz, 5 H, CH_{Cp}), 7.02−7.40 (m, 2 H, CH_{arom}), 7.70 (m, 1 H, CH_{arom}), 8.50 (d, $J_{H,H}$ = 9.2 Hz, 1 H, CH). $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 10.3 (s, CH_3), 10.6 (s, CH_3), 20.9 (d, $J_{C,P}$ = 11.7 Hz, CH_2), 26.4, 27.5, 27.7 (s, CH_2), 35.7 (br. s, CH_2), 56.6 (d, $J_{C,P}$ = 9.2 Hz, CHN), 58.5 (d, $J_{C,P}$ = 8.2 Hz, CHN), 59.6 (d, $J_{C,P}$ = 8.3 Hz, CHN), 62.0 (d, $J_{C,P}$ = 8.4 Hz, CHN), 110.2 (s, CH_{Cp}), 110.4 (s, CH_{Cp}), 124.7, 125.6, 126.0, 137.4 (s, CH_{arom}), 147.1 (s, C_{arom}), 172.8 (d, $J_{C,P}$ = 25.7 Hz, C_{arom}), 205.0 (dd, $J_{C,P}$ = 12.73 Hz, $J_{C,P}$ = 9 Hz, C=N). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 80.7 (d, $J_{P,P}$ = 8.5 Hz, PEt_2), 77.1 [d, $J_{P,P}$ = 8.5 Hz, $P(NCy_2)_2$]. $C_{45}H_{68}ClN_3P_2Zr$ (839.67): calcd. C 64.37, H 8.16, N 5.00; found C 64.21, H 7.98, N 4.92.

Compound 5′b: Compound **4′b** evolves quickly (6 h, room temperature) to give **5′b**. ^1H NMR (C_6D_6): δ = 0.92 (t, $J_{H,H}$ = 7.5 Hz, 3 H, CH_3), 0.99 (t, $J_{H,H}$ = 7.4 Hz, 3 H, CH_3), 1.31−1.95 (m, 40 H, CH_2), 3.25 (q, $J_{H,H}$ = 7.0 Hz, 4 H, CH_2), 3.15−3.35 (m, 4 H, CH), 5.81 (s, 10 H, CH_{Cp}), 7.02−7.20 (m, 2 H, CH_{arom}), 7.60 (d, $J_{H,H}$ = 6.8 Hz, 1 H, CH_{arom}), 8.55 (d, $J_{H,H}$ = 8.7 Hz, 1 H, CH_{arom}). $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 10.1 (d, $J_{C,P}$ = 14.0 Hz, CH_3), 21.0 (d, $J_{C,P}$ = 12.7, CH_2), 26.7, 27.5, 27.7, 35.7 (s, CH_2), 58.5 (br. s, CH), 114.6 (s, CH_{Cp}), 125.4, 125.6, 126.4, 138.2, (s, CH_{arom}), 146.0 (dd, $J_{C,PN}$ = 41.6 Hz, $J_{C,PEt}$ = 21.4 Hz, C_{arom}), 154.1 (dd, $J_{C,P}$ = 5.3 Hz, $J_{C,P}$ = 19.2 Hz, C_{arom}), 186.8 (dd, $J_{C,P}$ = 17.4 Hz, C=N). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 83.2 (d, $J_{P,P}$ = 6.9 Hz, PEt_2), 42.5 (d, $J_{P,P}$ = 6.9 Hz, $P(NCy_2)_2$. $C_{45}H_{68}ClN_3P_2Zr$ (839.67): calcd. C 64.37, H 8.16, N 5.00; found C 64.17, H 7.82, N 4.86.

Structure Determination of the α = 3, β = 6 Term of the $(A_3B_2O_6)_\alpha(A_3B_3O_9)_\beta$ Homologous Series (A = Ba, B = Rh) by a Combination of Powder X-ray Diffraction and Electron Microscopy

Keywords: One-dimensional oxides / X-ray diffraction / Electron diffraction / Electron microscopy

The α = 3, β = 6 term of the series $(A_3B_2O_6)_\alpha$ $(A_3B_3O_9)_\beta$ has been synthesized in polycrystalline form. The structural characterization by powder X-ray diffraction, electron diffraction and high-resolution electron microscopy indicates that this material is isostructural with $Ba_9Co_8O_{24}$. In the structure, seven face-sharing octahedra alternate with a trigonal prism defining chains running parallel to the *c* axis of a rhombohedral unit cell ($R\bar{3}c$), with parameters a = 1.00766(4) nm and c = 4.1571(2) nm. The structural refinement shows the presence of a small percentage of Rh vacancies leading to the composition $Ba_9Rh_{7.92}O_{24}$. Pauli paramagnetic behaviour is observed.

Introduction

Recently, a great deal of interest has been devoted to a family of pseudo-monodimensional oxides structurally related to the 2H-hexagonal perovskite ABO_3.[1] This structure and the K_4CdCl_6 structure type[2] constitute the two end-members of this family. The main feature of both structures is that they are formed by a hexagonal array of isolated chains of face-sharing polyhedra running parallel to the *c* axis. In the hexagonal 2H-ABO_3 perovskite, the polyhedral rows are built up by $[BO_6]$ octahedra (O_h), while in the K_4CdCl_6 halide, or $A_3A'BO_6$ oxide,[3] one $[BO_6]$ octahedron and one $[A'O_6]$ trigonal prism (TP) alternate in an ordered 1:1 sequence. An unlimited number of closely related structures can be generated by varying the ratio of the octahedral and trigonal prisms.

There are several ways to describe this family of materials. Darriet et al.[4] provide a structural systematisation of these phases based on the stacking of $[A_3O_9]$ and $[A_3A'O_6]$ layers. The B and A′ cations fill the generated O_h and TP sites, respectively. Different sequences of both layer types lead to different stoichiometries that can be expressed by the general formula $A_{3n+3m}A'_nB_{3m+n}O_{9m+6n}$. Besides this generic formulation, several general formulas have been proposed to denote this homologous series, and different approaches to describe their structures have been reported.[5−7] A very useful approach is to consider these structures as formed by the ordered intergrowth of the structural units building up the two end-members. This building principle gives rise to the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ general formula,[8] where α and β denote the number of $A_3A'BO_6$ and 2H-ABO_3 structural blocks in each member, respectively.

A large number of one-dimensional oxides have been obtained by varying the chemical nature of A, A′ and B cations in the above family, due to the ability of these structures to accommodate any value of α and β blocks. So far, when A′ = B, few oxides have been reported and members belonging to this family have been only described in the A-(A′ = B)-O (A = Ca, Sr, Ba; B = Co, Ni, Rh) systems. Among them, the A-Co-O system has proven to be the most fruitful one: at least twelve members of the above series have been stabilized by varying the chemical nature of the alkaline-earth metal between the two limiting structures $Ca_3Co_2O_6$ (α = 3,β = 0)[9] and 2H-$BaCoO_3$ [10] (α = 0, β = 3).[8,11,12] In all of them, cobalt atoms occupy both the TP and the O_h sites. It is worth mentioning that $Ba_9Co_8O_{24}$,[11] the α = 3, β = 6 member, is, apart from the end-member of this series, the largest member of this one-dimensional family stabilized until now. In this phase, seven octahedra and one trigonal prism constitute the polyhedral chains by sharing faces.

When Ni occupies the polyhedral chains, the stabilized phases are much less numerous. The α = 3, β = 1 term $Sr_4Ni_3O_9$,[13] the α = 2, β = 1 term $Sr_9Ni_7O_{21}$,[14] and the

$\alpha = 3$, $\beta = 3$ term $Ba_6Ni_5O_{15}$ [15] have been synthesised and structurally characterized.

Finally, when $A' = B = Rh$, only a 1D-oxide has been described: Zur Loye et al.[16] reported the stabilization of the $Sr_6Rh_5O_{15}$ phase, closely related to $Sr_6Co_5O_{15}$,[17] the $\alpha = 3$, $\beta = 3$ member of the above series. In fact, the main structural features of the latter are maintained in the Sr-Rh oxide, i.e. the polyhedral rows are also constituted by four face-sharing RhO_6 octahedra linked by one RhO_6 trigonal prism. However, when Rh occupies these polyhedra, the authors propose, from X-ray diffraction data, a new unit cell doubling the basal plane with respect to the $Sr_6Co_5O_{15}$ oxide. This superstructure seems to originate from a distortion of the strontium chains. The microstructural characterization[18] of such a member shows that it actually presents a complex stoichiometry, $Sr_{30}Rh_{23}O_{75}$, which results from the presence of empty Rh sites in the polyhedral chains. This feature leads to a fivefold superstructure along the *c* axis with respect to the $Sr_6Co_5O_{15}$ unit cell.

In the Ba-Rh-O system, several well-known ABO_3-hexagonal polytypes have been described. The hexagonal 4H[19] and 18R-$BaRhO_3$ [20] phases can be stabilized under oxidising conditions. These hexagonal phases, which always present the Ba/Rh = 1:1 cationic ratio, can be structurally considered as intermediates between the cubic-ABO_3 perovskite and the 2H-type, hexagonal-ABO_3 perovskite. The latter structure therefore provides the link between these phases and the monodimensional oxides belonging to the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ family. Much less information on these rhodium-containing phases is available, since only the synthesis of a non-commensurate $Ba_{1.06}RhO_3$ single crystal has been reported, and no structural data were provided.[21]

In a systematic characterization of powdered samples in the A-Rh-O system (A = Sr, Ba),[22,23] preliminary data from selective area electron diffraction (SAED) and high-resolution electron microscopy (HREM) give evidence of a commensurate one-dimensional Ba-Rh oxide belonging to the $(A_3A'BO_6)_\alpha(A_3B_3O_9)_\beta$ family with the composition $Ba_9Rh_8O_{24}$. We describe in this paper its synthesis and structural characterization by means of X-ray and electron diffraction and HREM. This study reveals that this new oxide adopts the structure corresponding to the $\alpha = 3$, $\beta = 6$ member of the series and, therefore, that it is isostructural to $Ba_9Co_8O_{24}$. $Ba_9Rh_8O_{24}$ is therefore the second such example reported, expanding the range of elements that can be incorporated into this structure. (NB During the writing of this paper, Slitzer et al.[24] reported the structure determination of a $Ba_9Rh_8O_{24}$ single crystal. Both powder and single crystal X-ray diffraction data provide structural models that are coincident in the main features.)

Results and Discussion

Chemical and Structural Characterization

The sample of nominal composition $Ba_9Rh_8O_{24}$ was confirmed to be a single phase by X-ray diffraction (XRD). The average Ba:Rh ratio, as determined by ICP, is close to 0.90(5) along the whole sample, in good agreement with the nominal metallic ratio. It is worth emphasizing that energy dispersive spectroscopy (EDS) analyses performed on numerous crystallites suggest that the sample is very homogeneous, since all of them exhibit the same Ba/Rh ratio of close to 0.9, confirming the ICP results. The anionic composition, as determined from TGA data, is in agreement with 24 oxygen atoms per formula unit, indicating that the anionic sublattice is complete.

The whole XRD pattern of $Ba_9Rh_8O_{24}$ (Figure 1) can be indexed within a hexagonal unit cell of parameters $a = 1.00755(7)$ nm and $c = 4.1572(3)$ nm, corresponding to the $\alpha = 3$, $\beta = 6$ member of the $(A_3B_2O_6)_\alpha(A_3B_3O_9)_\beta$ family.

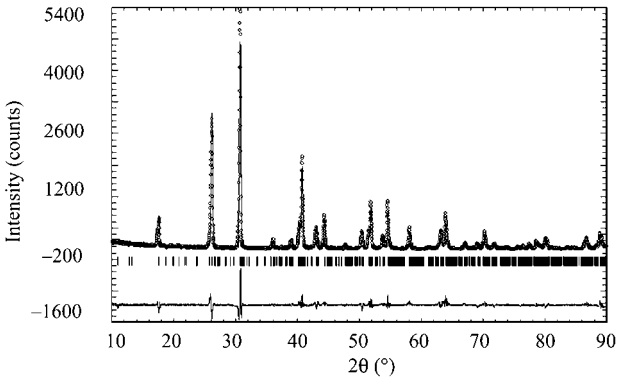

Figure 1. Results of the fitting of the powder XRD data of $Ba_9Rh_{7.92}O_{24}$: experimental (points), calculated (solid line) and difference (bottom)

Microstructural characterization by SAED and HREM confirms the XRD results. The most relevant SAED patterns, taken along the $[\bar{2}110]$, [0001] and $[1\bar{1}00]$ zone axes are shown in Figure 2a, 2b and 2c, respectively. Among them, the $[\bar{2}110]$ reciprocal plane provides the most valuable structural information. In fact, this SAED pattern allows us to obtain directly the values of α and β structural blocks forming the corresponding structure, and, thus, to identify the different members of the $(A_3B_2O_6)_\alpha(A_3B_3O_9)_\beta$ series. For this purpose, it is useful to describe this SAED pattern on the basis of the 2H-hexagonal subcell by differencing two sets of maxima. The more intense spots (referred to as subindex 2H in Figure 2a) correspond to the hexagonal 2H planes, while the least intense ones can be considered as satellite reflections with a modulation vector $\mathbf{k} = (a^*_{2H} + b^*_{2H})/3 + m\,2c^*_{2H}$. The *z* component (*m*) of this vector is related to the α and β values according to the expression $m = \alpha/(3\alpha + 3\beta)$. Besides, and taking into account that such a modulation is commensurate, the studied $Ba_9Rh_8O_{24}$ phase can also be regarded as a 2H superstructure, the 2H superstructure direction being $[\alpha+\beta\ \alpha+\beta\ i\ 2\alpha]^*_{2H}$. In this case, as can be observed in Figure 2a, this direction corresponds to $[33\bar{6}2]_{2H}$, and the *m* value is 1/9, therefore the $\alpha = 3$, $\beta = 6$ values are obtained, which indicates the stabilization of such a member in the Ba-Rh-O system. Furthermore, the observed reflection conditions, (*hkl*), $-h+k+l = 3n$, (000*l*) $l = 6n$ and (*h*00) $h = 3n$, are in agreement with

the rhombohedral $R\bar{3}c$ space group previously proposed for the $Ba_9Co_8O_{24}$ oxide.[11]

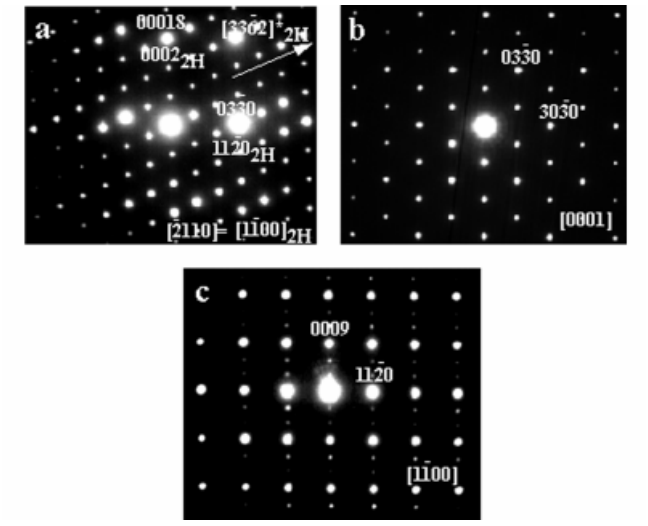

Figure 2. SAED patterns corresponding to $Ba_9Rh_{7.92}O_{24}$ along the [$\bar{2}$110] (a), [0001] (b) and [1$\bar{1}$00] (c) zone axes

The SAED patterns shown in Figure 2b and 2c confirm this result. In the first one, along the [0001] reciprocal plane, the reflections are distributed in a hexagonal array corresponding to a lattice parameter close to 1.0 nm. Only the (*h00*), *h* = *3n* reflections are visible according to the $R\bar{3}c$ space group. Furthermore, the [1$\bar{1}$00] reciprocal plane is also in agreement with the rhombohedral unit cell of this phase, although (*000l*), *l* = 3n reflections appear due to the dynamical diffraction effect.

The polyhedral sequence along the *c* axis, i.e. the arrangement of the blocks building the structure, can be deduced from the contrast variation observed in the experimental HREM. Figure 3 shows the high-resolution micrograph of the $Ba_9Rh_8O_{24}$ compound along the [$\bar{2}$110] zone axis. An apparently well-ordered material is observed with d-spacings close to 2.05 and 0.87 nm, corresponding to d_{002} and d_{100} of the hexagonal unit cell obtained by XRD. The image features are very close to those found in $Ba_9Co_8O_{24}$ and can be interpreted in a similar way. The sequence of bright dots of different contrast is due to rhodium columns. The two brightest dots correspond to the Rh prisms that are aligned following the diagonal cell, according to the rhombohedral symmetry proposed for this phase. The less intense dots could be due to Rh in an octahedral environment, leading to the -1TP-7O_h- polyhedra sequence characteristic of this structure. From this ideal model, the image has been calculated using the MacTempas package. The simulated image (inset in Figure 3) fits well with the experimental one for Δf = −95 nm and a sample thickness of 6 nm.

These results when taken together allow us to conclude that $Ba_9Rh_8O_{24}$ is isostructural to $Ba_9Co_8O_{24}$ and, therefore, that rhodium metal can also be incorporated into the metal-oxygen structure framework of the α = 3, β = 6 member of the one-dimensional $(A_3B_2O_6)_\alpha(A_3B_3O_9)_\beta$ family.

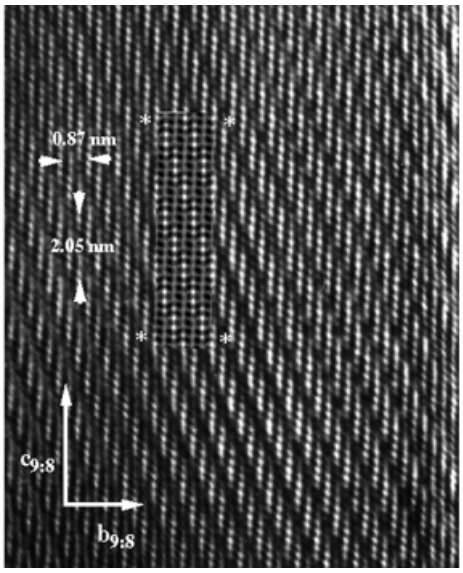

Figure 3. HREM image of $Ba_9Rh_{7.92}O_{24}$ along the [$\bar{2}$110] axis; the simulated image (Δf = −95 nm, Δf = 6 nm) is shown at the inset

Structural Refinement

Since the previous structural results obtained from SAED and HREM data suggested that the title compound is isostructural to $Ba_9Co_8O_{24}$, the structure of the latter was used as the starting model for the refinement of the XRD data of $Ba_9Rh_8O_{24}$. Figure 1 shows the graphic result of the fitting of the experimental X-ray diffraction pattern for $Ba_9Rh_8O_{24}$ and the difference between observed and calculated data. The final structural parameters are collected in Table 1; Table 2 shows some selected interatomic distances. A schematic representation of the structure is depicted in Figure 4a.

one-dimensional materials, a strong preferred orientation effect is usually present because of the pronounced hexagonal shape of the crystallites. This is an additional problem when it comes to solving and refining the structure of these materials from powder diffraction data. In spite of this, the refinement was stable and it was possible to refine the positions of the oxygen atoms, provided an overall temperature factor was used. Any attempt to use individual temperature factors yielded unstable refinements, probably due to the very large volume of the cell and the limited number of observed reflections. Thus, the metal−oxygen distances in Table 2 should be considered with some care, although the metallic coordination, i.e. the polyhedron defined by the closest oxygen atoms around a given metal, is undoubtedly correct. According to that, both Ba atoms are coordinated to eight oxygen atoms at distances in the range 2.36−3.02 Å. Rh(1) occupies a regular trigonal prism, while the other Rh atoms (2, 3, 4 and 5) are octahedrally coordinated by nearby oxygen atoms at the distances reported in Table 2. The obtained values for all M−O distances are reasonable and consistent with previously reported bond lengths in comparable Ba/Rh oxides.[20,21]

Inside the chains, the inter-octahedral Rh(2)−Rh(3) and Rh(4)−Rh(5) distances are very close to those found in 4H or 18H-$BaRhO_3$ (2.5−2.6 Å). However, the Rh(3)−Rh(4) distance (2.45 Å) is significantly shorter and this could be due to the presence of some Rh vacancies in the Rh(4) octahedral site. On the other hand, the distance between Rh(1) in a trigonal prism and Rh(2) in a neighbouring octahedron sharing a triangular face is larger than the other Rh−Rh distances (2.81 Å). Although there is no comparable data for Rh ions in a similar oxygen environment, the enlargement of the distance between TP-O_h metals compared to that shown by O_h-O_h metals is also observed in other similar one-dimensional oxides such as $Ba_6Ni_5O_{15}$ [16] and $Sr_6Co_5O_{15}$.[17]

It is worth mentioning that we found some degree of metal vacancies (4%) in one of the rhodium positions. According to this, the actual composition of the title material

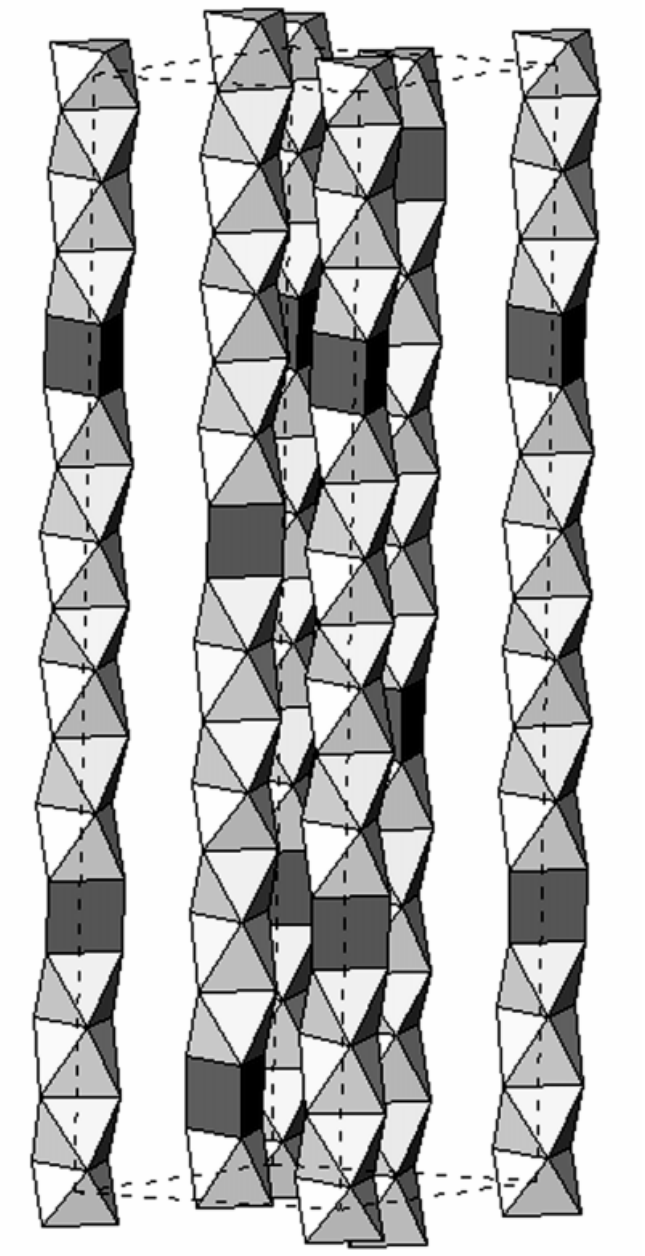

Figure 4. Schematic representation of the $Ba_9Rh_{7.92}O_{24}$ structure; Ba atoms have been omitted for clarity

obtained from the refinement of XRD data is $Ba_9Rh_{7.92(2)}O_{24}$. Assuming the usual valences for Ba and O, then the average Rh oxidation state is +3.78, indicating the presence of both Rh^{IV} and Rh^{III} in the polyhedra chains. However, Bond Valence Sums (BVS) calculations[25] give inappropriate values of the actual oxidation states of rhodium atoms.

The presence of vacancies at rhodium positions seems to play an important role in the stabilisation of the structures. In fact, as we have mentioned above, the $\alpha = 3$, $\beta = 3$ member of this series, stabilised when Sr fully occupies the A-sublattice, is characterized by the presence of one empty position every ten Rh sites in the polyhedra rows. The or-

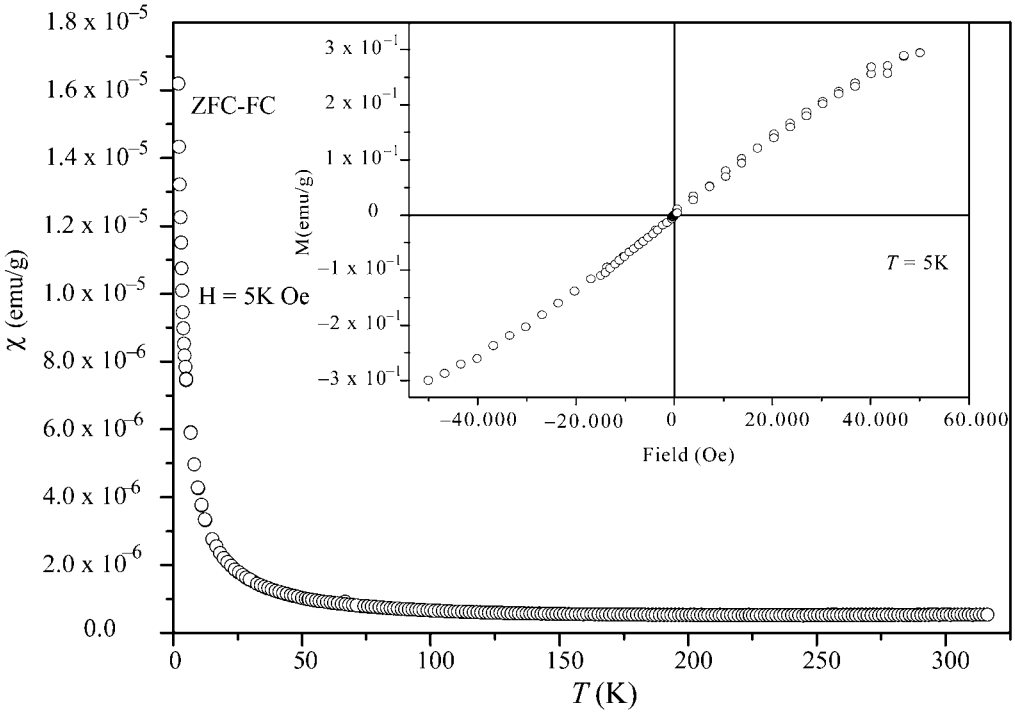

Figure 5. Magnetic susceptibility versus temperature plot for polycrystalline $Ba_9Rh_{7.92}O_{24}$; the susceptibility variation as a function of the applied field is shown as the inset

dered distribution of empty and full sites along the crystal is clearly seen in both the SAED patterns and the HREM study. Interestingly enough, the Rh vacancy concentration in $Ba_9Rh_{7.92}O_{24}$ is considerably lower, and it is not detected either by SAED or HREM. Apparently, the substitution of Sr by Ba causes an increase of the polyhedra average volume in such a way that Rh^{III} can also be accommodated into the structure and, therefore, the number of empty sites decreases considerably.

Magnetic Behaviour

Figure 5 shows the variation of the magnetic susceptibility versus temperature for $Ba_9Rh_{7.92}O_{24}$. The magnetic susceptibility of this oxide presents a Pauli-type behaviour, with an almost temperature independent susceptibility in a wide temperature range from 100 K to 350 K. At low temperature, the susceptibility shows a Curie tail which may be due to a small paramagnetic contribution. A low temperature isotherm until 5T (inset of Figure 5) shows an almost linear behaviour as expected for a Pauli-like system. From the magnetic point of view the system appears to be a linear chain of Rh^{IV} atoms with uncoupled electrons.

Experimental Section

Polycrystalline $Ba_9Rh_8O_{24}$ was prepared by a solid-state reaction with stoichiometric amounts of $BaCO_3$ (Merck, 99.9%) and RhO_2 (Aldrich, 99.8%). The mixture was initially calcined at 900 °C for 12 hours, and then heated at 1050 °C for three days.

The average cationic composition was determined by Inductively Coupled Plasma (ICP) while the local composition in every crystal was analysed by X-ray Energy Dispersive Spectroscopy (EDS). For this purpose, a JEOL 2000 FX electron microscope equipped with a LINK ISIS 300 analyser system was employed. The oxygen content was determined by thermogravimetric analysis (TGA) by using a thermobalance based on a CAHN D-200 electrobalance. The sample (about 100 mg) was reduced in a platinum crucible at 700 °C under $0.2H_2/0.3He$ atmosphere.

Powder X-ray diffraction (XRD) patterns were collected at room temperature on a PHILIPS X′PERT diffractometer equipped with a graphite monochromator and Cu-K_α radiation. The diffraction data were analysed by the Rietveld method[26] using the Fullprof program.[27]

Selected Area Electron Diffraction (SAED) was carried out using a JEOL 2000FX electron microscope fitted with a double-tilting goniometer stage (±45°). High Resolution Electron Microscopy (HREM) was performed on a JEOL 4000EX electron microscope fitted with a double-tilting goniometer stage (±25°). Simulated HREM images were calculated by the multi-slice method using the MacTempas software package.

Magnetic behaviour was measured by a SQUID magnetometer in a temperature range from 5 to 350 K, with a maximum applied magnetic field of 5T.

Structurally Different Dinuclear Copper(II) Complexes with the Same Triazolopyrimidine Bridging Ligand

Mohammad Abul Haj,[a] Miguel Quirós,*[a] Juan M. Salas,[a] José A. Dobado,[b] José Molina Molina,[b][†] Manuel G. Basallote,[c] and M. Ángeles Máñez[c]

Keywords: Copper / N,O ligands / Metal-metal interactions / Structure elucidation

Four binuclear copper(II) compounds with the anionic form of the ligand 4,5-dihydro-5-oxo[1,2,4]triazolo[1,5-*a*]pyrimidine ($5tpO^-$) have been isolated, their formulae being $[Cu_2(5tpO)_4(H_2O)_2]\cdot 2H_2O$ (**1**), $[Cu_2(phen)_2(5tpO)_2(H_2O)_2](NO_3)_2\cdot 4H_2O$ (**2**), $[Cu_2(biim)_2(5tpO)_2(H_2O)](ClO_4)_2\cdot 5.5H_2O$ (**3**), and $[Cu_2(CH_3CO_2)_2(5tpO)_2(H_2O)_2]$ (**4**) (phen = 1,10-phenanthroline, biim = bisimidazole). A related mononuclear complex, $[Cu(phen)_2(5HtpO)_2](NO_3)_2$ (**5**), has also been prepared. The crystal structure of compounds **1**–**3** has been determined by X-ray diffraction, showing their binuclear nature with four (**1**) or two (**2**, **3**) bridging $5tpO^-$ moieties. The triazolopyrimidine ligand binds the copper atoms through N3 and N4 in compounds **1** and **3**, whereas a novel binding mode through N3 and the exocyclic oxygen atom has been found in **2**. The study of the solution behaviour of **2** and **5** shows the important role of the solvent in the formation of the mono or binuclear complex. The reduction of the metal centres to Cu^I has been observed by electrochemical methods, demonstrating that this ligand stabilizes this oxidation state. Magnetic susceptibility measurements and electronic paramagnetic resonance (EPR) spectra seem to indicate a dimeric nature also for compound **4**. The antiferromagnetic interaction between the copper atoms inside the dimer is very strong for **4** ($2J = -221.3\ cm^{-1}$) and **1** ($2J = -104.9\ cm^{-1}$), fairly strong for **3** ($2J = -21.6\ cm^{-1}$), and very weak or non-existent for **2**. The nature of the copper–copper interaction in compound **1** has been analyzed by using molecular orbital calculations.

Introduction

The study of dinuclear complexes of copper(II) is a very active research field and more than nine hundred of such complexes have been structurally characterized, according to a recent review.[1] The interaction between the spins of both metal atoms leads to the existence of two states with different energy, one with a total spin of zero (singlet) and the other with a total spin of one (triplet). This difference of energy ($2J$) is experimentally observable by means of magnetic susceptibility measurements. The value of $2J$ depends on many structural features and the Cu−Cu distance does not seem to be the key parameter. This dependence is far from being fully understood in the general case, but useful correlations, more empirical than theoretical, have been formulated for a few types of bridging ligands: hydroxo,[2] halides,[3,4] carboxylates,[5] azide and thiocyanate,[6] or even purine bases.[7]

The work presented here follows the research line that has been carried out in the last few years by our group on the interaction of 1,2,4-triazolo[1,5-*a*]pyrimidine ligands with metal ions; a review about the subject has been recently published by us.[8] These compounds present several positions in their molecules for binding metal ions making them suitable for building dinuclear or polynuclear compounds. The interactions between the metal centres have been studied by means of molecular orbital (MO) calculations in dimeric compounds of silver(I)[9] and platinum(II),[10] but dinuclear copper(II) complexes with bridging triazolopyrimidine ligands have not been described previously to this article, despite the structural and theoretical interest of copper dinuclear compounds and their magnetic properties.

We describe here the synthesis and characterization of several copper(II) dinuclear complexes with the ligand 4,5-dihydro-5-oxo[1,2,4]triazolo[1,5-*a*]pyrimidine in its anionic form ($5tpO^-$) bridging the metal centres. The aim of this work is to characterize the bridging coordination behaviour of the ligand towards Cu^{II}, studying the relationship between the structure and the experimental properties of the isolated compounds. The role of the ligand has been determined by X-ray diffraction, an unexpected binding mode having been found in the compound with phenanthroline as

an auxiliary ligand. The way in which the structural features influence the redox properties (observed by electrochemical measurements) and the intermetallic interaction (observed by magnetic susceptibility and EPR measurements) has been studied. The nature of this interaction has been theoretically analyzed by means of MO calculations for the compound with a quadruple bridge. The study of the formation process in solution of the related mono- and dinuclear complexes containing phenanthroline as an auxiliary ligand has revealed the role of the solvent.

Results and Discussion

The compounds described in this work are the following: $[Cu_2(5tpO)_4(H_2O)_2]\cdot 2H_2O$, (**1**) $[Cu_2(phen)_2(5tpO)_2(H_2O)_2](NO_3)_2\cdot 4H_2O$ (**2**), $[Cu_2(biim)_2(5tpO)_2(H_2O)](ClO_4)_2\cdot 5.5H_2O$ (**3**), $[Cu_2(CH_3CO_2)_2(5tpO)_2\ (H_2O)_2]$ (**4**), and $[Cu(phen)(5HtpO)_2](NO_3)_2$ (**5**), 5HtpO being the ligand 4,5-dihydro-5-oxo[1,2,4]triazolo[1,5-*a*]pyrimidine and phen and biim representing respectively the auxiliary chelating ligands 1,10-phenanthroline and bisimidazole.

Description of the Structures

The crystal structures of compounds **1**, **2**, and **3** have been determined from single-crystal X-ray diffractometry. The molecular structure of these compounds is depicted in Figures 1, 2, and 3. The three complexes are dinuclear with the anionic form of ($5tpO^-$) acting as the bridging ligand; four such bridges are present in compound **1** and two in compounds **2** and **3**. Attached to each copper atom in the two latter compounds, there is a bidentate aromatic amine (1,10-phenanthroline or 2,2′-bisimidazole) acting as an auxiliary ligand. A typical 4+1 square pyramidal environment (not considering the other copper atom) is completed by a water molecule at a longer distance (see Table 1) at the apical position, except for one of the metal atoms (Cu2) in compound **3**, which is square planar. Copper atoms are, in all cases, deviated from the corresponding basal planes

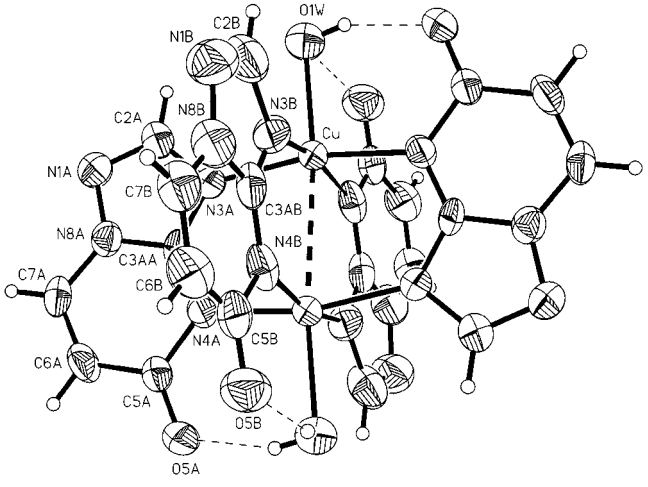

Figure 1. View of the molecular structure of compound **1**; atoms are represented as 50% probability thermal ellipsoids

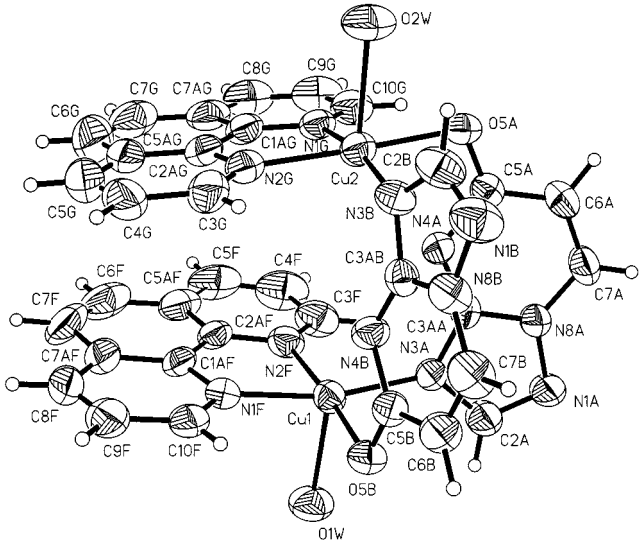

Figure 2. View of the molecular structure of compound **2**; atoms are represented as 50% probability thermal ellipsoids

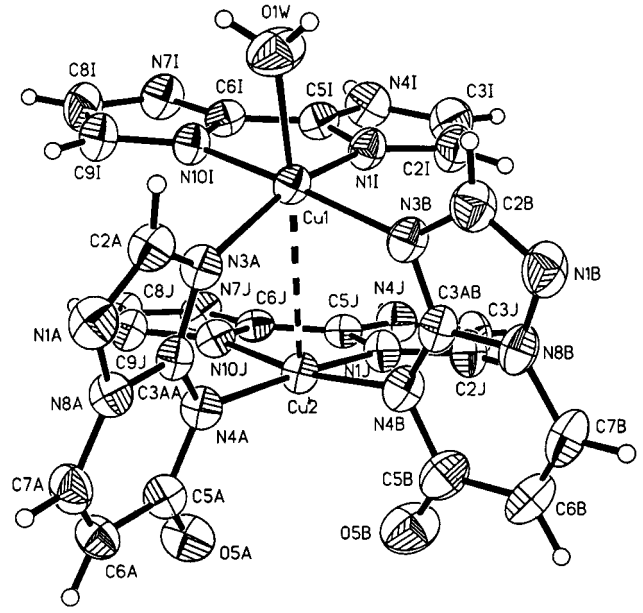

Figure 3. View of the molecular structure of compound **3**; atoms are represented as 50% probability thermal ellipsoids

away from their counterparts: the corresponding distances (also included in Table 1) seem to be influenced both by the presence of the water molecule in the fifth position (the deviation is almost zero for the square planar Cu atom and is higher when the $Cu-OH_2$ distance is shorter) and also by the proximity of the other metal atom. Nitrate **2** or perchlorate **3** ions balance the charge and non-coordinated water molecules complete the crystal structures.

The most outstanding feature of these structures is the different coordinating behaviour of the ligand. In **1** and **3**, the $5tpO^-$ entities bridge the metal atoms through the nitrogen atoms at positions 3 and 4; such a binding mode is

common for triazolopyrimidine ligands and has been observed for Cu^{I},[11] Ag^{I},[9,12] Pd^{II},[13] Pt^{II} [10] and heterometallic $Pt^{II}-Pd^{II}$ compounds,[14] but it was observed first for Cu^{II}, although other ligands such as purines interact with Cu^{II} in a similar fashion.[15] The coordination behaviour of the ligand in **2**, is much more unusual, however, in using the exocyclic oxygen atom (instead of N4) together with N3 to bridge the metal atoms (Figure 2). We have not found any other example in the bibliography of this binding mode for any metal and any bicyclic aromatic heterocycle containing an exocyclic oxygen atom, apart from a compound with a single xanthinato ion bridging three titanium atoms in a disposition that is, however, rather different to that in our compound.[16]

The versatility of triazolopyrimidine ligands for binding metal ions has been well established in previous works[8] and the possible involvement of the exocyclic oxygen atom in coordination was predicted for $5tpO^{-}$ from theoretical calculations.[17] However, it is quite unexpected to find such different ligand binding modes for compounds that are otherwise so similar, and we cannot see a clear reason for this behaviour. Perhaps it is just a matter of crystal packing optimization or small differences between the stacking properties (or even just the steric demands) of both auxiliary ligands. These are not parallel but convergent in **2** and divergent in **3** as we move away from the metal atoms (angles between the average planes are 10.7 and 11.7°, respectively). Stacking interactions are possibly responsible for this, since the optimum stacking distance between parallel aromatic rings is around 3.4 Å,[18] intermediate between the intermetallic distance in compounds **2** and **3**.

There are also differences in the relative disposition of the ligands: it is head-head-tail-tail for **1**, head-tail for **2**, and head-head for **3**. The molecular symmetry is then C_{2h} for **1**, C_2 for **2**, and C_s for **3**. This symmetry is only local, however: the only exact crystallographic symmetry present in the dimers is the inversion centre in **1**. The relative disposition of the ligands in **1** is stabilized by the presence of the coordinated water molecule (see Figure 1) which forms strong hydrogen bonds with the carbonyl oxygen atoms of the ligands [distances O1W···O5, 2.651(10) and 2.689(12) Å] and is the same as that found in the analogous Pt^{II} compound with 4,7-dihydro-5-methyl-7-oxopyrimidine.[10] Compounds analogous to **1** have been reported with purine ligands[15,19,20] and 7-azaindolate[21] and all of them present the C_{2h} atropisomer. We have not found any example of a copper(II) compound similar to **3,** but the analogous Pd^{II} complexes with 4,7-dihydro-5-methyl-7-oxopyrimidine[13] display head-tail geometry.

Bond lengths within the ligands are not significantly different from those in free 5HtpO,[17] except for the C5−O5 bond in **2**, which is somewhat longer as a consequence of O5 binding to the metal [1.236(3) Å for 5HtpO]. The bond angles within the ligands are very similar in the three compounds and differ from the values in free 5HtpO mainly in the angles around N4, C3A−N4−C5 being closed and N4−C3A−N8 being open [the angles in the free ligand are 122.6(2) and 118.8(2)° respectively].

The structures are stabilized by extensive hydrogen bonding, with water molecules being the donors towards carbonyl oxygen atoms, oxygen atoms of the anions and other water molecules. The nitrogen atoms of bisimidazole away from the copper atoms in **3** remain protonated and form hydrogen bonds in a "chelating" way towards the oxygen atom of a water molecule (N4I and N7I) and a neighbouring carbonyl oxygen (N4J and N7J). This suggests that these couples of atoms, if deprotonated, could act as new chelating binding sites for metal atoms.

Infrared Spectra

The infrared spectrum of **5**, with the ligand in neutral form, is almost identical to that of the free ligand, displaying an intense band in the C=O region at 1684 cm^{-1}, with two shoulders at 1711 and 1738 cm^{-1}. The spectra of the other compounds, with the ligand in anionic form, display the expected shift of this band to lower wavenumber. The spectrum shows a single narrow band at 1649 cm^{-1} for **1** and **3** and 1637 cm^{-1} for **2**, this extra shift being perhaps due to the involvement of O5 in coordination. For compound **4**, the C=O band seems to overlap with a band of the acetate anion, giving rise to a broader band centred at 1640 cm^{-1}. The presence of the anions is indicated by the typical stretching vibrations of nitrate (**2** and **5**) and perchlorate (**3**) at 1385 and 1107 cm^{-1} respectively. Assignment of other bands is quite uncertain.

Studies in Solution of Compounds 2 and 5

The behaviour in solution of compound **2** and the related mononuclear compound **5** has been studied. Compound **2** has been chosen because of its greater solubility in water and the possibility of making useful comparisons with **5**. The visible spectrum of a 10^{-3} M aqueous solution of **2** presents a band centred at 670 nm ($\varepsilon = 72$) whereas for **5** the maximum appears at 710 nm ($\varepsilon = 38$). The spectra of the latter are identical to those of solutions containing Cu^{II}, 5HtpO, and phen in 1:1:1 molar ratio. These results seem to indicate that the dimeric structure of **2** is kept in solution or, at least, that **5** is not its decomposition product.

In order to explore the formation process of compounds **2** and **5**, kinetic studies were carried out using a stopped-flow apparatus. In these studies two solutions were mixed, one containing Cu^{II} and phenanthroline at 10^{-3} M concentration each, and the other containing 5HtpO in concentrations ranging from $5\cdot10^{-3}$ to 10^{-2} M. When water or acetonitrile were used as the solvent, the mononuclear complex $[Cu(5HtpO)_2(phen)]^{2+}$ was generated within the stopped-flow mixing time without further spectral changes. Formation of the binuclear complex **2** was only observed if a mixed solvent (water/acetonitrile, 1:1) was used; in that case, the absorbance changes last for ca. 2 seconds. These results reveal an important effect of the solvent on the course of the reaction, in agreement with the synthetic procedures of **2** and **5** (see below), despite the fact that compound **2**, once obtained, seems to be stable in solution (see above). Unfortunately, a more detailed kinetic study of the formation of **2** was not possible because of the small absorbance changes and the overlap with the deviations of the stopped-flow baseline caused by the use of the mixed solvent.

Electrochemical Studies

The electrochemical properties of complexes **1**, **2**, **3**, and **5** were studied by measuring their cyclic voltammograms (CV) and square-wave voltammograms (SWV) in aqueous solution. Solubility of compounds **1** and **3** in water is quite low, just enough to record the voltammograms; the even lower solubility of compound **4** precluded reliable measurements. Despite their binuclear nature, a single reduction signal is observed in the CV of **1**, **2**, and **3**. The corresponding reduction potentials are 0.49 V (**1**), 0.24 V (**2**), 0.20 V (**3**), and 0.27 V (**5**). The same is observed in the SWV of **1** and **3**, a single signal at the same potentials as the CV. On the other hand, the SWV of **2** shows two overlapping peaks at 0.239 and 0.293 V, which can be considered as indicative of the presence of two copper centres and as evidence that the binuclear structure is maintained in solution, as was also suggested by visible spectroscopy. In contrast, both the mononuclear compound **5** and the solution containing Cu^{II}, 5HtpO, and phen (1:1:1) show a single reduction peak close to 0.28 V. Controlled-potential coulometry confirmed that this signal corresponds to a single electron process. The possibility of a breakage of the dimeric compound to generate a mononuclear compound analogous to the cationic complex of **5** and a species of the type $[Cu(phen)(H_2O)_n]^{2+}$ can be ruled out by the absence of a reduction peak around 0.174 V in the voltammograms of **2**, which is what is observed in solutions containing only Cu^{II} and phenanthroline.[22]

A comparison of the redox potential of the complexes $[Cu_2(5tpO)_2(phen)_2]$ or $[Cu(5HtpO)_2(phen)]^{2+}$ with those found for binary copper–phenanthroline complexes[22] indicates that the triazolopyrimidine ligand stabilizes Cu^{I}, probably by the generation of dimeric species analogous to the very stable ones formed by Ag^{I} with these types of ligands.[12] This stabilization is corroborated by the quite high potential value obtained for **1** and for solutions containing Cu^{II} and a great excess of 5HtpO (also 0.49 V).

Magnetic Susceptibility Measurements and EPR Spectra

The magnetic susceptibility of the four compounds has been measured in the range 5–300 K. In this range, **2** behaves as a magnetically diluted compound obeying the Curie law with a constant effective magnetic moment of 1.86 BM. Thus, no interaction between the two copper atoms in the dimer is observed. As expected, the same happens for the mononuclear compound **5** with $\mu_{eff} = 1.95$ BM.

On the other hand, **1**, **3**, and **4** present a χ vs. T curve with a maximum (Figure 4), indicative of antiferromagnetic interactions between the metal atoms. In the three cases, the data fit very well to the Bleaney–Bowers equation for copper(II) dimers.[23] The values of g and $2J$ (energy gap between the singlet and the triplet state) obtained from this fit are shown in Table 2. The interaction is very strong for compounds **1** and **4** and fairly strong for **3**. The trend in the strength of the interaction **1** >> **3** >> **2** is the expected one according to the number of bridging ligands, the length of the path across the ligand and the Cu–Cu distance.

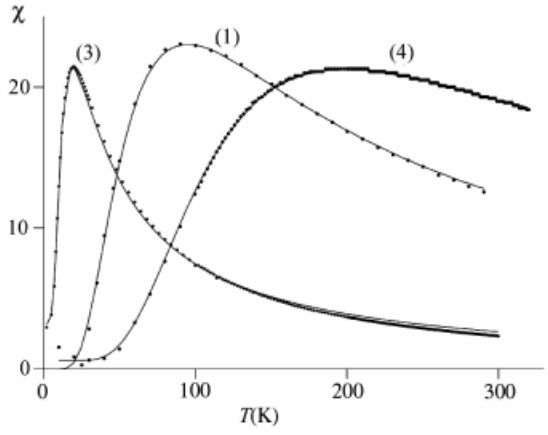

Figure 4. Magnetic susceptibility of compounds **1**, **3**, and **4** as a function of temperature; data (in emu/mol) have been multiplied by $5\cdot10^3$ (**1**), by 10^3 (**3**), or by 10^4 (**4**); solid lines represent the Bleaney–Bowers equation with the parameters indicated in Table 2

Table 2. Data from magnetic susceptibility measurements and EPR spectra

	1	3	**4**
From χ measurements			
g	2.148	2.081	2.117
$2J$ [cm^{-1}]	−104.9	−21.6	−221.3
From EPR spectra:			
$g_{\|}$	2.28	ca. 2.3	2.36
$g_{\perp}$	2.05	2.05	2.06
D [cm^{-1}]	0.161	0.095	0.247

The value of $2J$ in **1** is, however, considerably smaller than those found in compounds with quadruple purine bridges,[7] including that with the adeninate anion,[24] which is the most similar one. The wide range of values found for these compounds indicate how sensitive $2J$ is to subtle changes in the structure. We have not been able to find a clear and unambiguous relationship between $2J$ and any structural parameter.

The interaction in **4** is even stronger than in **1**, the value of $2J$ being intermediate between that of the latter and that of the copper acetate dimer ($2J = -305$ cm^{-1}).[25] We have not been able to grow crystals of compound **4** large enough to undergo X-ray determination, but these data allow us to propose a molecular dimeric structure with two acetate and two $5tpO^-$ bridging ligands, with the two water molecules occupying apical positions.

X-band EPR spectra have been recorded for the polycrystalline powdered samples at room temperature. Compound **2** presents a spectrum made up by a single very broad asymmetric band with an average g value of 2.11, which could be attributed to an unresolved anisotropic triplet or doublet spectrum. No half-field transition is detected for this compound. The mononuclear compound **5** presents a normal axial spectrum with $g_{\|} = 2.25$ and $g_{\perp} = 2.08$.

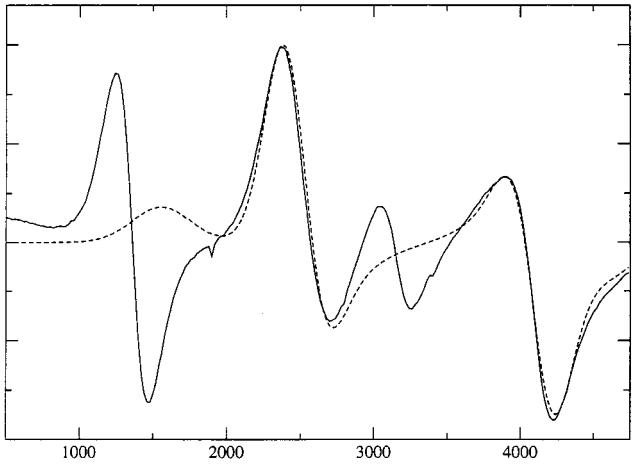

Figure 5. Experimental (− − −) and simulated (- - -) X-band EPR spectra of **1**; the simulation does not include the $S = 1/2$ and the half-field transitions (features at 3200 and 1400 G); simulation parameters, collected in Table 2, also reproduce well the Q-band spectrum; the spectrum of compound **4** is analogous to this

The other three spectra are quite complex and their main features have been assigned to ($S = 1$, $\Delta M_S = 1$) transitions with axial symmetry, although the parallel components in the spectrum of **3** are quite broad and difficult to identify. Together with these, strong signals also appear assignable to $S = 1/2$ transitions and, in the case of **1** and **4**, there is also a quite strong half-field ($S = 1$, $\Delta M_S = 2$ transition) band. As all these features overlap, the Q-band spectrum was also recorded for **1** to help in the assignments. Using computer simulation by means of the WINEPR program,[26] the values in Table 2 were finally obtained. Figure 5 displays the experimental and the calculated X-band spectra for **1**, only the ($S = 1$, $\Delta M_S = 1$) transitions are included in the simulation, which easily explains the differences between both. It is noteworthy that, comparing the zero-field splitting parameters of these compounds, we find the same trend as when comparing the $2J$ values.

Theoretical Studies

In order to analyze the Cu···Cu interaction in **1**, theoretical calculations have been performed for the singlet state of this compound. Its geometry was optimized and constrained to C_{2h} symmetry (thus, keeping a mirror plane that relates "head" with "head" and "tail" with "tail" and a binary axis perpendicular to it, so that the four ligands are equivalent). A very good agreement between the experimental and theoretical geometries was obtained; in particular, the theoretical Cu···Cu distance obtained was 2.893 Å. As in previous work by our group,[27] the hybrid density functional method with a large basis set (B3LYP/6-311G*) has been demonstrated to be accurate for describing large transition-metal complexes.

The topology of the electron charge density $\rho(r)$ was analyzed by means of the "Atoms in Molecules" (AIM) theory.[28,29] This analysis revealed the presence of a bond critical point (BCP) between the metal atoms, showing that the corresponding atomic basins share a common surface, and thus supporting the existence of a direct metal−metal interaction. As a consequence, four ring critical points (RCP) also appear at the middle of the Cu−Cu−C−N−C irregular pentagons. The $\rho(r)$ value at the Cu−Cu BCP is 0.012 ea_o^{-3}, only about one eighth of the corresponding values at the Cu−N bonds (0.085 and 0.081 ea_o^{-3}); this value may be taken as a rough estimation of the strength of the interaction. The Laplacian of the electron density [$\nabla^2(\rho)$] is positive at both Cu−Cu and Cu−N BCP (with values 0.054, 0.344, and 0.302 ea_o^{-5} for Cu−Cu, Cu−N3, and Cu−N4 respectively), as expected for closed-shell types of interactions, which are always found in coordination bonds and metal-metal interactions.

It is interesting to have a look at the shape of the calculated MO of the compound, particularly the HOMO and the LUMO, which are displayed in Figure 6. Looking only at one half of these orbitals, they resemble the antibonding combination of the $d_{x^2-y^2}$ orbital of the metal atom and the proper symmetry adapted combination of the orbitals of the ligands, as expected from textbook simple MO theory for metal complexes. These two halves mix with each other

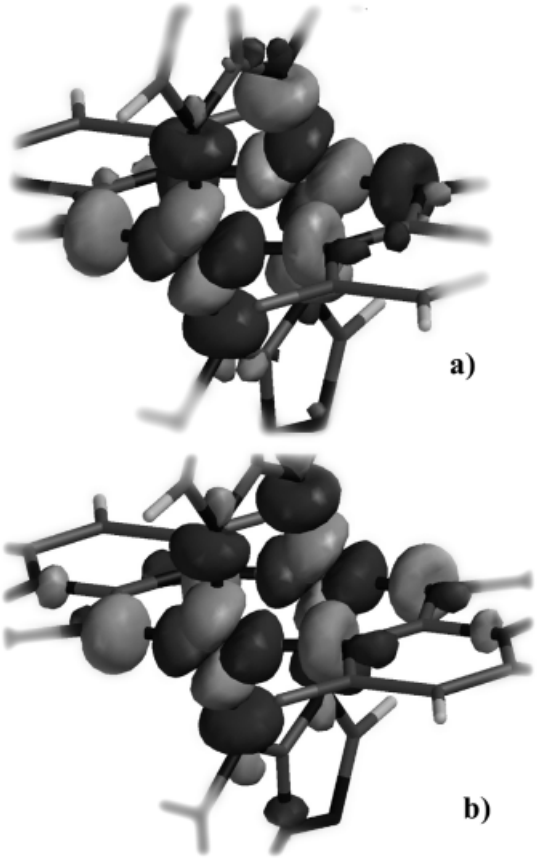

Figure 6. Calculated (B3LYP/6-311G*) HOMO (a) and LUMO (b) of **1**

giving rise to a "same-phase" (b_g) and to a "opposite-phase" (a_u) combination, the latter (HOMO) with less energy than the former (LUMO). The fact that the lobes of the HOMO on one copper atom have opposite signs to those on the other copper atom indicates that this orbital is antibonding (Δ antibonding) for the Cu−Cu union. This result, surprising at first sight, indicates that the stabilization of the HOMO with respect to the LUMO does not come from the direct intermetallic interaction, but from energetically more favourable electronic distribution within the ligands.

The calculated energy gap between these two orbitals is 1.095 eV, which of course cannot be regarded, not even as a first approximation, as the energy difference between the singlet and the triplet state. This latter value (2*J*) can only be theoretically obtained by performing separate calculations for both states (singlet and triplet) and subtracting the corresponding total energies. Extremely accurate methods must be applied for this since the goal is to get a small number by subtracting another two, very similar to each other and several orders of magnitude larger. Nevertheless, a method for calculating 2*J* in copper(II) dimers has been developed by Ruiz et al.,[30] which implies performing a so-called "broken-symmetry" calculation for the singlet state without geometry optimization (that is, keeping the geometry observed by X-ray data). This method has yielded good results for some systems[31] but the assumption that the energy of the singlet is well represented by the broken-symmetry model has been criticized by several authors.[32,33] Nevertheless, we have tested the method with our compound but the results do not reproduce, even qualitatively, the experimental data.

Conclusions

In this work, we have demonstrated the ability of the ligand 4,5-dihydro-5-oxo[1,2,4]triazolo[1,5-*a*]pyrimidinate ($5tpO^-$) to bridge copper(II) atoms to form dimeric species. Four such compounds have been isolated, three of them having been structurally characterized by single-crystal X-ray diffraction: compound **1** with a quadruple bridge and compounds **2** and **3** with a double bridge, and containing phenanthroline or bisimidazole, respectively, as auxiliary ligands. The bridging mode of the ligand in **1** and **3** is the one most usually found in the triazolopyrimidine ligand through the nitrogen atoms in positions 3 and 4, whereas compound **2** displays an unprecedented binding mode trough N3 and the exocyclic oxygen atom. The dimeric nature of compound **4**, for which X-ray structural data are not available, is indicated by its magnetic behaviour and EPR spectrum, which allow us to tentatively propose the presence of two $5tpO^-$ and two acetate bridges.

The structural features of these compounds clearly influence their electrochemical, magnetic and EPR properties. Thus, the ligand ability for stabilizing lower oxidation states is indicated by the reduction potentials, which increase with the number of $5tpO^-$ ligands attached to the metal. The dimeric nature of **1**, **3**, and **4** is shown by their strong antiferromagnetic behaviour as well as by their triplet EPR spectra, these methods not showing clearly the interaction for the compound with the longer bite (**2**). Opposite to this, the SWV of **2** display a double peak, probably revealing its dimeric nature in solution, whereas the reduction of Cu^{II} to Cu^{I} seems to be simultaneous for both metal atoms in **1** and **3**.

The strength of the intermetallic interaction, measured as the 2*J* parameter, is clearly correlated with the number and nature of bridging ligands and with the length of the bite, following the order: **4** > **1** > **3** > **2**. For compound **1**, an unsuccessful attempt has been made for calculating this parameter theoretically. The zero-field splitting of the triplet state, as deduced from the EPR spectra, follows the same trend as 2*J*.

A theoretical analysis has been performed by means of MO calculations for compound **1**. The calculated geometry fits well with the experimental one and the Bader analysis indicates the existence of a direct contact between the metal basins (the BCP). The topology of the HOMO of the compound indicates that its stabilization with respect to the LUMO comes from the electronic structure within the ligands rather than from the direct intermetallic interaction.

Lastly, it is interesting to note the need for a mixed solvent for the formation of compound **2**, revealed by kinetic measurements, in agreement with the synthetic procedure.

Experimental Section

Synthesis of the Compounds

4,5-dihydro-5-oxo[1,2,4]triazolo[1,5-*a*]pyrimidine (5HtpO) was synthesized as indicated in a previous work.[17] Bisimidazole was also synthesized according to the literature.[34] Copper salts, other reagents and solvents were obtained from standard commercial suppliers.

$[Cu_2(5tpO)_4(H_2O)_2]\cdot 2H_2O$ (1): A suspension was made with 80 mg (0.24 mmol) of copper basic carbonate and 200 mg (1.47 mmol) of 5HtpO in 20 mL of water, the mixture being stirred at room temperature for 30 min. After this, a dark blue precipitate was obtained, which was dissolved by adding 10 mL of acetonitrile to the mixture. Unchanged copper carbonate was then filtered off and, after two days of keeping the solution at room temperature, dark blue crystals of **1** were obtained. Yield: 40 mg (7.4%). $C_{20}H_{20}Cu_2N_{16}O_8$: calcd. C 32.48, H 2.71, N 30.31; found C 32.68, H 2.79, N 30.52%.

$[Cu_2(phen)_2(5tpO)_2(H_2O)_2](NO_3)_2\cdot 4H_2O$ (2): 240 mg (1 mmol) of copper(II) nitrate trihydrate and 180 mg (1 mmol) of 1,10-phenanthroline (phen) were dissolved in 20 mL of methanol. This solution was mixed with another one containing 136 mg (1 mmol) of 5HtpO in 20 mL of water/acetonitrile 2:1. After one week, blue crystals of the compound appeared. Yield: 300 mg (30%). $C_{34}H_{34}Cu_2N_{14}O_{14}$: calcd. C 41.25, H 3.43, N 19.82; found C 41.45, H 3.23, N 19.96%.

$[Cu_2(biim)_2(5tpO)_2(H_2O)](ClO_4)_2\cdot 5.5H_2O$ (3): The same procedure was followed as for compound **2**, using copper(II) perchlorate hexahydrate instead of copper(II) nitrate and 2,2′-bisimidazole (biim) instead of 1,10-phenanthroline. Yield: 50 mg (5.2%). $C_{22}H_{29}Cl_2Cu_2N_{16}O_{15.5}$: calcd. C 27.47, H 3.04, N 23.31; found C 27.66, H 3.09, N 23.50%.

$[Cu_2(CH_3CO_2)_2(5tpO)_2(H_2O)_2]$ (4): The procedure starts as for compound **1**, but the dark blue solid initially obtained is treated with 20 mL of a 10% solution of acetic acid in ethanol instead of acetonitrile, which dissolves it completely. After two days, a blue microcrystalline solid was obtained. Yield: 50 mg (12.5%). $C_{14}H_{16}Cu_2N_8O_8$: calcd. C 30.49, H 2.92, N 20.32; found C 30.62, H 3.13, N 20.21%.

$[Cu(phen)(5HtpO)_2](NO_3)_2$ (5): 240 mg (1 mmol) of copper(II) nitrate trihydrate and 180 mg (1 mmol) of 1,10-phenanthroline (phen) were dissolved in 20 mL of acetonitrile. 272 mg (2 mmol) of 5HtpO were then added and the suspension was refluxed for 30 min, after which the product was obtained as a blue powder. Yield: 500 mg (78%). $C_{22}H_{16}CuN_{12}O_8$: calcd. C 41.31, H 2.52, N 26.29; found C 41.34, H 2.44, N 26.54%.

Instrumental Work: Microanalysis of C, H and N were performed in a Fisons Instruments EA-1008 analyzer, X-band EPR spectra were recorded in a X-band Bruker ESP-300 apparatus (all this equipment sited at the Centre of Scientific Instrumentation of the University of Granada). The Q-band spectrum of **1** was recorded on a Q-band Bruker ESP-300 apparatus. IR spectra were obtained using a FT MIDAC Prospect 1 spectrophotometer with samples dispersed in KBr pellets. Magnetic susceptibility measurements were made in a SQUID MPMS-XL Quantum Design magnetometer. Solution electronic spectra were obtained using a Perkin−Elmer Lambda 3B spectrophotometer, whereas the stopped-flow experiments were carried out using an Applied Photophysics SX 17MV instrument.

X-ray Crystallography: X-ray work was carried out at room temperature on a Stoe Stadi4 (**1** and **2**) or Siemens P4 (**3**) diffractometer with Mo-K_α radiation. The dimensions of the chosen crystals were (in mm) 0.6 × 0.3 × 0.1 (**1**), 0.45 × 0.3 × 0.15 (**2**), and 0.5 × 0.4 × 0.3 (**3**). Data collections were performed in 2Θ/ω scan mode. The number of independent reflections collected were, after averaging, 3908, 7333, and 4640 for **1**, **2**, and **3**, respectively. Data were corrected for Lorentz and polarization effects and empirically (psi-scans) for absorption (transmission ranges: 0.5888−0.6927 for **1**, 0.6456−0.7601 for **2**, and 0.6471−0.7750 for **3**). The structures were solved by standard Patterson methods and refined by full-matrix least-squares using the SHELXL-93[35] (**1**, **2**) or SHELXL-97[36] (**3**) programs. One of the nitrate ions and two water molecules in **2** were found to be disordered over two positions, as well as two water molecules in compound **3**; another water molecule in this compound was refined with an occupancy of 1/2. Fixed N−O distances (1.19 Å) were imposed to the disordered nitrate. Atoms with an occupancy of less than one were refined isotropically, all other non-hydrogen atoms were refined anisotropically. Hydrogen atoms of the organic residues were introduced in their ideal positions, those of water molecules were found and refined with a fixed O−H distance (0.86 Å) in

compounds **1** and **3** and were not found in compound **2**. An isotropic thermal parameter was applied to all hydrogen atoms 1.2 times those of their parent atoms. The full sets of crystal data (excluding structure factors) for these compounds have been deposited with the Cambridge Crystallographic Data Centre (CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, E-mail: deposit@ccdc.cam.ac.uk), the corresponding deposition numbers are indicated in Table 3, together with selected crystal data.

Electrochemical Measurements: The electrochemical measurements were carried out using an EG&G PARC model 163A potentiostat provided with a Pt disk working electrode and a Pt wire auxiliary electrode. A Ag/AgCl electrode was used as reference for the measurements in water and the measured potentials were referenced to the normal hydrogen electrode by adding 0.222 V.[37] The complex solutions for electrochemical measurements (1−2 mM) contained 0.10 M KNO_3 and were purged with N_2 and thermostated at 25.01°C before measurement. The CVs were recorded at a scan rate of 50 mV/s and the SWVs with a frequency of 5 Hz.

MO and Electronic Charge Density Calculations: Density functional theory (B3LYP) calculations were performed with the Gaussian 98 package of programs.[38] The singlet state of structure **1** was fully optimized at the B3LYP/6-311G* level, with constrained C_{2h} symmetry and tested with frequency calculations (no imaginary frequencies). The Bader analysis was made by using the AIMPAC series of programs,[39] with the DFT density as input as described in the AIM theory.[28,29]

Calculations at the B3LYP/6-31G* level without geometry optimization have also been performed for both the singlet and the triplet state, including for the singlet state the "broken-symmetry" procedure that has been described elsewhere[30] in order to get an estimate for the 2*J* value.

Acknowledgments

This work was supported by a DGES project (PB 97-0786-CO3) from Ministerio de Educación y Cultura. Computing time was provided by the Universidad de Granada. We are grateful to Professor R. F. W. Bader for a copy of the AIMPAC package of programs. We acknowledge Professors T. Rojo and J. L. Lezama (Universidad del País Vasco) for collecting the Q-band spectrum of compound **1** and help with its assignment. We are also grateful to Professor R. Sáez (Universidad Autónoma de Madrid) for the magnetic measurements. M. Abul Haj acknowledges UNESCO for a PEACE grant.

^{139}La NMR Kinetic Study of Lanthanum(III) Complexation with Acetohydroxamic Acid

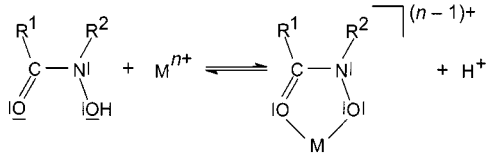
Mladen Biruš,*[a] Rudi van Eldik,*[b] Mario Gabričević,[a] and Achim Zahl[b]

Keywords: Lanthanum / NMR spectroscopy / Kinetics / Reaction mechanisms

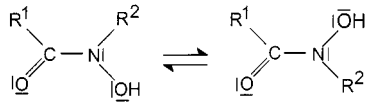
The application of ^{139}La NMR spectroscopy to kinetic and equilibrium studies of the substitution of coordinated water by acetohydroxamic acid (HA) is described. The reaction of La^{3+} with HA can be represented by the following equation (with equilibrium constant K_1): $La^{3+} + HA \rightleftarrows La(A)^{2+} + H^+$ (1). The following equilibrium parameters were calculated from the ^{139}La NMR chemical shift of the equimolar reactants measured as a function of acidity and temperature: $K_1(298) = 2.36(8)\cdot10^{-4}$, $\Delta_rH_1 = -28(1)$ kJ·mol^{-1}, $\Delta_rS_1 = -162(4)$ J·K^{-1}·mol^{-1}. The kinetics of the reaction between La^{3+} and HA can be represented by the following equations: $La^{3+} + HA \rightleftarrows La(A)^{2+} + H^+$ (11) and $La^{3+} + A^- \rightleftarrows La(A)^{2+}$ (12). The complexation rate constants were calculated from the line widths of the corresponding signals as a function of acidity and temperature: $k_{11}(298\ K) = 1.54(4)\cdot10^6$ M^{-1}·s^{-1}, $\Delta H^{\ddagger}_{11} = 70(14)$ kJ·mol^{-1} and $\Delta S^{\ddagger}_{11} = +108(47)$ J·K^{-1}·mol^{-1}, k_{12} (298 K) = 1.6 10^{10} M^{-1}·s^{-1}, $\Delta H^{\ddagger}_{12} = 35(6)$ kJ·mol^{-1} and $\Delta S^{\ddagger}_{12} = +68(20)$ J·K^{-1}·mol^{-1}. The spin-spin relaxation times of La^{III} in the aqua ion and the hydroxamato complex are 4.36(4) ms and 54(1) μs at 298 K, respectively.

Introduction

The rare earth metal cations are widely used in industry[1] and medicine.[2] Due to the "hard" character of the lanthanum(III) ion, it is capable of forming stable complexes with "hard" ligands that contain oxygen electron-donor atom(s) within their functional groups. It also forms stable complexes with hydroxamic acids [$R^1C(=O)N(OH)R^2$], coordinating in a bidentate manner through the two oxygen atoms of the hydroxamate group.[3] Hydroxamic acids are weak organic acids with $pK_a \approx 9$, which release one proton per coordinated hydroxamato group as shown in the following reaction.

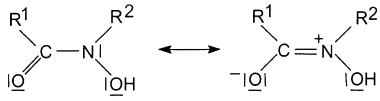


Hydroxamic acids are believed to exist in the two forms shown below, evidence for the presence of these forms and their isomerization is confirmed by NMR spectroscopic data.[4–6]



cis *trans*

The room-temperature isomerization of *N*-methylacetohydroxamic acid (≡ NMHA; $R^1 = R^2 = CH_3$) from the *trans* to the (chelation kinetically appropriate) *cis* form is characterized by a rate constant of ca. 3 s^{-1}. The magnitude of this rate constant indicates a partial double bond character of the hydroxamate C–N bonds, which can be explained by the two extreme resonance structures of the hydroxamic acids shown by structures **Ia** and **Ib**.[7–9]



Ia **Ib**

As the electron-donor capability of R^2 increases, the form **Ib** predominates. This form bears a partial negative charge on the carbonyl oxygen atom, which results in an increased stability of the formed metal complex. The crystallographic data show that the more stable the ferric hydroxamate complex, the shorter the Fe–O(C) bond in the complex, probably due to the emerging negative charge on the carbonyl oxygen atom.[10]

Supporting information for this article is available on the WWW under http://www.eurjic.com or from the author.

To date, only two papers (from our laboratories) have been devoted to the kinetics of the complexation of La^{III} with hydroxamic acids.[5,6] We have recently proposed that a slow *trans*→*cis* isomerization of *N*-alkylhydroxamic acids is the rate-determining step for their chelation to La^{3+} ions. The observed complexation processes were followed on the same time scale as was the isomerization of the free ligands. On the other hand, when R^2 is an H atom, as in HA, the complexation rate was found to be extremely fast, exceeding the limits of the stopped-flow mixing time. In order to investigate the complexation of La^{3+} with HA, it was necessary to utilize a kinetic technique that is not limited to such a long time-scale. ^{139}La NMR has already been successfully used as a tool for determining rate constants in kinetic studies involving complex-formation reactions.[11] In this study, we extend our previous investigations by presenting kinetic and equilibrium studies of the complexation of La^{3+} with HA ($R^1 = CH_3$; $R^2 = H$) in aqueous medium. The study was accomplished by observing ^{139}La NMR line-broadening and the chemical-shift change as a function of temperature, acidity and concentration of the reactants.

Results and Discussion

Figure 1(a) shows the ^{139}La NMR spectra of 0.2 M solutions of $La(ClO_4)_3$ and acetohydroxamic acid at 298 K as a function of $p[H^+]$. The recorded spectra are characterized by a one-resonance peak, which broadens as the $p[H^+]$ increases.[12] The spectra also exhibit a temperature dependence, which is shown for the same reactants at $p[H^+] = 3.71$ in Figure 1(b).

Since the UV-spectroscopic data under the employed conditions indicate a complexation reaction, the occurrence of only one peak in the recorded spectra reveals that lanthanum nuclei exchange fast on the NMR time-scale between two different environments, i.e. the aqualanthanum(III) ion and mono(acetohydroxamato)lanthanum(III) complex. In other words, reaction (1) lies in the so-called "fast-exchange region".

In the acidity range used, neither the hydrated La^{3+} ions nor HA deprotonate considerably in aqueous solutions; for both reactants $pK_a \geq 9$.[13,14] In equimolar solutions of the reactants, the only expected species formed is a monohydroxamato complex in which acetohydroxamate is chelated in a bidentate manner through two oxygen atoms of hydroxamate.[3] The formation of such a complex is represented by Equation (1), which is related to the equilibrium constant, $K_1 = [La(A)^{2+}]\cdot[H^+]\cdot[La^{3+}]^{-1}\cdot[HA]^{-1}$, where the terms in brackets represent the molar concentrations, HA is $CH_3C(=O)N(H)OH$ and $La(A)^{2+}$ is $La[CH_3C(=O)N(H)O]^{2+}$ (coordinated water molecules are omitted for clarity).

$$La^{3+} + HA \rightleftarrows La(A)^{2+} + H^+ \quad (1)$$

The modified Bloch equation for a two-site exchange has been solved by Leigh[15], and for the reaction system

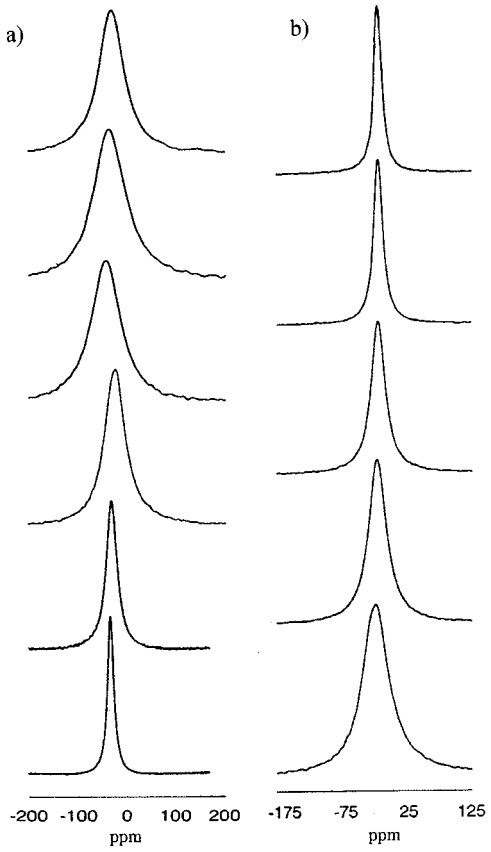

Figure 1. (a) ^{139}La NMR spectra of 0.2 M $La(ClO_4)_3$ and 0.2 M acetohydroxamic acid in 20% (w/w) D_2O at 298 K at $p[H^+] = 2.48$ (bottom), 3.49, 3.99, 4.47, 4.89, and 5.46 (top); (b) ^{139}La NMR spectra of 0.2 M $La(ClO_4)_3$ and 0.2 M acetohydroxamic acid in 20% (w/w) D_2O ($p[H^+] = 3.71$) at 278 K (bottom), 288 K, 298 K, 328 K, and 338 K (top)

studied, the relaxation rate ($1/T_2$) is described by Equations (2) to (9).

$$1/T_2 = A_2 \pm \{[G + (G^2 + H^2)^{1/2}]/2\}^{1/2} \quad (2)$$

$$A_2 = (1/\tau_{2a} + 1/\tau_{2b})/2 \quad (3)$$

$$G = (1/\tau_{2a} - 1/\tau_{2b})^2/4 + 1/\tau_A\tau_B - (\Delta\omega_{AB}/2)^2 \quad (4)$$

$$H = 0.5\cdot(1/\tau_{2a} - 1/\tau_{2b})\,\Delta\omega_{AB} \quad (5)$$

$$1/\tau_{2a} = 1/T_{2A} + 1/\tau_A \quad (6)$$

$$1/\tau_{2b} = 1/T_{2B} + 1/\tau_B \quad (7)$$

$$\Delta\omega_{AB} = \Delta\nu_{La^{3+}} - \Delta\nu_{La(A)^{2+}} \quad (8)$$

$$p_A = \tau_A/(\tau_A + \tau_B) = p_{La^{3+}}; p_B = \tau_B/(\tau_A + \tau_B) = p_{La(A)^{2+}} \quad (9)$$

In these equations, A and B are the above-mentioned two different environments, $1/T_{2A}$ and $1/T_{2B}$ are the intrinsic relaxation rates in the absence of the exchange, τ_A and τ_B are the residence times and p_A and p_B are the molar fractions

of lanthanum in the sites A and B, respectively; $\Delta\omega_{AB}$ is the difference in chemical shift of the two sites in the absence of exchange, i.e. $\Delta\nu_A - \Delta\nu_B$. Since the observed relaxation rate ($1/T_2$) was found to depend linearly on the "free" ligand concentration, as shown in Figure 2, Equation (6) had to be modified to include the first-order term with respect to the concentration of HA, $\tau_A^{-1} = k$ [HA].

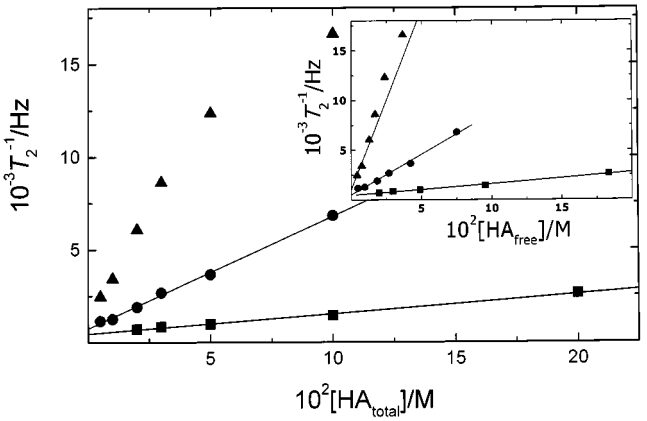

Figure 2. The observed ($1/T_2$) as a function of the total HA concentration at: − solid squares − p[H$^+$] = 3.74(2), − solid circles − p[H$^+$] = 4.85(2), − solid triangles − p[H$^+$] = 5.74(1); conditions: temperature 298 K, ionic strength 1.2 M (perchlorate), equimolar [La(ClO$_4$)$_3$]$_{total}$ and [HA]$_{total}$ = 0.005−0.2 M; the inset shows the observed ($1/T_2$) as a function of the calculated "free" HA concentration, under the same experimental conditions

The above equations show that in order to calculate the kinetic parameters for the La^{III} complexation reaction, it is necessary to accurately estimate p_A, p_B, and the concentration of free HA under the experimental conditions employed. The estimates were made using the equilibrium parameters for reaction (1) obtained from the experimentally determined temperature and p[H$^+$] dependent ^{139}La chemical shift, seen in Figure 3. The chemical shift of the ^{139}La NMR resonance for equimolar solutions containing lanthanum perchlorate and acetohydroxamic acid is mainly determined by temperature and by the composition of the La^{III} inner coordination sphere, which depends on p[H$^+$]. The observed chemical shift in the reaction mixture can be regarded as a weighted average of the shifts related to the La^{3+} and $La(A)^{2+}$ species, using the mol fractions as a weighting factor for each species.

$$\Delta\nu_{obs.} = \Delta\nu_{La}{}^{3+}\cdot p_{La}{}^{3+} + \Delta\nu_{La(A)}{}^{2+}\cdot p_{La(A)}{}^{2+} \quad (10)$$

For each experimental data point the species concentrations were calculated from the known total concentration of each reactant and the value of K_1 in the temperature range used. A nonlinear least-square fitting procedure[16] was applied for the optimization of the parameters defined in Equation (10) to the experimental data points shown in Figure 3, taking into account the temperature dependent behavior of both the chemical shifts and the equilibrium constant. The following equation $K_1(T) = K_1(298) \times \exp[\Delta_r H_1(T - 298)/298RT]$ describes the relationship between temperature and the equilibrium constant, where

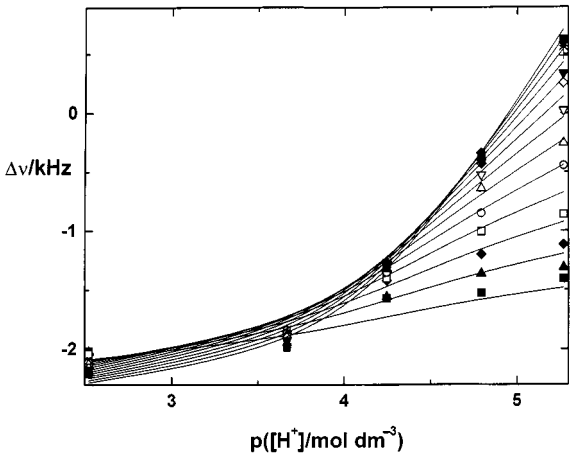

Figure 3. The temperature and p[H$^+$] dependencies of the ^{139}La chemical shift of 0.2 M La(ClO$_4$)$_3$ and 0.2 M acetohydroxamic acid in 20% (w/w) D$_2$O; the lines drawn are the theoretical ones calculated using the optimized parameters of Equation (10); the temperature increment between the experimental series is 5 K, the solid squares corresponding to the lowest temperature, 278 K

$\Delta_r H_1$ is the reaction enthalpy for reaction (1). During the fitting procedure, the distribution of species was calculated simultaneously for each experimental point by a Newton−Raphson algorithm[17] used for solving a set of homogeneous differential equations. The temperature dependence of the chemical shift for the La^{3+} ion was found to be concentration-independent. Within the temperature range used, the experimentally determined $\Delta\nu_{La}{}^{3+}$ is found to be satisfactorily described by the linear relationship $\Delta\nu_{La}{}^{3+}(T)$ Hz = $-2.18(2)\cdot10^3$ Hz − 3.3(3) Hz·K^{-1} × (T − 298) K (see Supporting Information, Figure S1).[18] Under the experimental conditions used, full complexation could not be achieved (see Supporting Information, Figure S2), hence, the experimental determination of the temperature-dependent nature of $\Delta\nu_{La(A)}{}^{2+}$ is impossible.[19] Therefore, the parameters describing the dependence had to be adjusted during the fitting procedure. For the La^{3+} ion, a linear temperature dependence of $\Delta\nu_{La(A)}{}^{2+}$ within the temperature range used, is proposed,. Fitting Equation (10) to 87 data points collected at various temperatures and proton concentrations resulted in the following parameters: $\Delta\nu_{La(A)}{}^{2+}(T)$ Hz = $2.5(3)\cdot10^2$ Hz + $7.9(2)\cdot10^1$·Hz·K^{-1} × (T − 298) K, $K_1(298) = 2.36(8)\cdot10^{-4}$, $\Delta_r H_1 = -28(1)$ kJ·mol^{-1}, and $\Delta_r S_1 = -162(4)$ J·K^{-1}·mol^{-1}.

From these parameters a chemical shift of $\delta = 44$ is calculated for ^{139}La in the $La(A)^{2+}$ complex relative to the aqua ion at 298 K. This is within the range expected for the coordination of the hydroxamate oxygen atoms to the central lanthanum ion.[20] The $K_1(298)$ value obtained, which was confirmed by potentiometric titration under the same experimental conditions, differs from the reported value of $6.17\cdot10^{-5}$ determined at 20 °C and $I = 0.1$.[3] The observed discrepancy can be attributed to the difference between the reactant concentrations and activities used in our and the reported study. For the same reason our calculated values of the thermodynamic functions do not represent the standard

values, and possibly a larger negative value of the reaction entropy than expected is calculated. As expected, the K_1 value obtained is slightly smaller than that reported for the complexation of La^{III} with *N*-methylacetohydroxamic acid.[6]

The ^{139}La ($I = {}^{7}/_{2}$) nuclear spin-spin relaxation is governed by the quadrupolar interaction, for which it was shown that the extreme narrowing is valid above 278 K.[11] The intrinsic relaxation time in the absence of the exchange for the aqualanthanum(III) ion (T_{2A}) was determined from the NMR spectra of 0.2 M $La(ClO_4)_3$ in 20% D_2O (w/w), collected as a function of concentration and temperature. Figure S3 shows that in the temperature range 278−338 K, the observed relaxation time of the $La(ClO_4)_3$ solution, which was found to be concentration-independent, depends almost linearly on the temperature according to the following equation: $T_{2La}{}^{3+}(T) = -0.00758$ (s) + $3.009 \cdot 10^{-5}$ ($s \cdot K^{-1}$) × T (K). At 298 K, the spin-spin relaxation time $T_{2La}{}^{3+} = 4.36(4)$ ms compares reasonably well with the reported values,[11,20] taking into account the slightly different experimental conditions employed in these studies. Since full complexation of La^{3+} was impossible to achieve under our experimental conditions, T_{2B} and its temperature dependence were refined during the fitting procedure (vide infra). The optimized spin-spin relaxation times of lanthanum in the hydroxamato complex at 298 K, $T_{2B}(298) = 54(1)$ μs, is within the range reported for other complexes.[20] For a quadrupolar nucleus such as ^{139}La, besides the exchange broadening effect, the line-width variation should result essentially from two factors, a change in the symmetry of the first coordination shell, and a change in the size of the La^{III} species. The larger the size and the lower the species symmetry, the broader the resonance will be. The substitution of two coordinated water molecules by one acetohydroxamato ligand in the inner sphere of La^{III} should slightly increase the size of the complex, as expected from the reaction molar volume determined for the complexation of iron with HA.[21] This, along with the lower symmetry of the monohydroxamato complex, accounts for a much broader resonance observed for the complex than for the aqua species.

Two essentially different reaction models could be considered as the operative reaction mechanism for the complexation of the lanthanum ion by acetohydroxamic acid. The rate-determining step should be characterized by the energetics of either (*i*) the water exchange on the aquated lanthanum ions, or (*ii*) the ring-closure reaction of the mono-coordinated ligand. For the former process either a dissociative or an associative mode of activation can be proposed, whereas for the latter one the rate-determining step may involve a slow proton transfer from the −NO*H* group or a slow *trans*→*cis* isomerization of the attached hydroxamato ligand.

Besides the proton, four different reactants can be considered to participate in the complexation kinetics, i.e. La^{3+}, $La(OH)^{2+}$, HA, and A^-. Accordingly, the studied reaction can be plausibly represented by Equations (11) to (14).

$$La^{3+} + HA \rightleftarrows La(A)^{2+} + H^+ \quad (11)$$

$$La^{3+} + A^- \rightleftarrows La(A)^{2+} \quad (12)$$

$$La(OH)^{2+} + HA \rightleftarrows La(A)^{2+} \quad (13)$$

$$La(OH)^{2+} + A^- \rightleftarrows La(A)(OH)^+ \quad (14)$$

Since the pK_a values of both reactants are > 9,[13,22] reaction path (14) results in a calculated microscopic rate constant for the complexation, that would greatly exceed the rate of the diffusion-controlled processes. The reaction paths (12) and (13) are kinetically indistinguishable from each other, but the contribution of the latter path could be excluded for the following reasons. Due to the difference in electric charge of La^{3+} and $La(OH)^{2+}$, the ion−dipole attractive coulombic force between the reactants of path (11) must be more than doubled in comparison with path (13). Furthermore, even at the lowest acidity used, the concentration of La^{3+} was more than 10^3 times that of $La(OH)^{2+}$. Therefore, for a notable contribution of path (13) HA would have to react at least 10^3 times faster with $La(OH)^{2+}$ than with La^{3+}. However, the latter ion exchanges water on a time-scale shorter than 10 ns.[23]

Taking into account the above arguments, Equations (2) to (9) were fitted to the experimental data, but k in Equation (6) was substituted by $k_{11} + k_{12}K_a[H^+]^{-1}$ (the subscripts of the rate constants are related to the equation numbers, whereas K_a stands for the ionization constant of HA). Figure 4 shows the experimentally determined $\Delta\nu_{1/2}$ of 0.2 M reactants plotted as a function of p[H^+] at various temperatures. The lines drawn are the theoretical ones calculated using the optimized parameters of Equations (2) to (9), obtained by a non-linear least-squares fit[16] in which

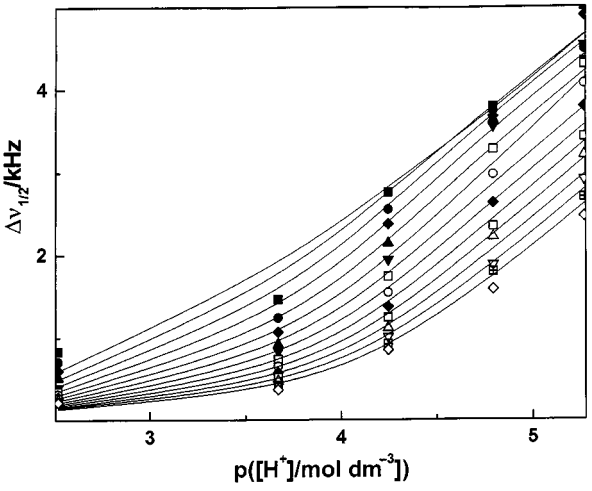

Figure 4. The observed $\Delta\nu_{1/2}$ of 0.2 M $La(ClO_4)_3$ and 0.2 M acetohydroxamic acid in 20% (w/w) D_2O plotted vs. p[H^+] at various temperatures; the lines drawn are the theoretical ones calculated using the optimized parameters of Equations (2) to (9); the temperature increment between the experimental series is 5 K, the open diamonds corresponding to lowest temperature, 278 K

τ_B was substituted for $\tau_A p_B/p_A$ in order to reduce the number of variables. The theoretical values follow a general trend delineated by the observed values. A slight disagreement seems acceptable considering the complexity of the expression describing $\Delta\nu_{1/2}$ and the number of parameters that had to be adjusted during the fitting procedure. The necessary equilibrium concentration of free HA for each data point was calculated simultaneously during the iteration procedure, as well as the difference in chemical shift of the two sites in the absence of exchange, $\Delta\omega_{AB}(T) = \Delta\nu_{La}{}^{3+}(T) - \Delta\nu_{La(A)}{}^{2+}(T)$. The values of the kinetic parameters for the formation of $La(A)^{2+}$ are calculated as: $k_{11}(298\ K) = 1.54(4)\cdot10^6\ M^{-1}\cdot s^{-1}$, $\Delta H^{\ddagger}_{11} = 70(14)\ kJ\cdot mol^{-1}$ and $\Delta S^{\ddagger}_{11} = +108(47)\ J\cdot K^{-1}\cdot mol^{-1}$, $k_{12}K_a(298\ K) = 1.5(5)\cdot10^1\ s^{-1}$, $(\Delta H^{\ddagger}_{12} + \Delta_r H_a) = 53(5)\ kJ\cdot mol^{-1}$ and $(\Delta S^{\ddagger}_{12} + \Delta_r S_a) = -45(17)\ J\cdot K^{-1}\cdot mol^{-1}$. From the calculated values and the published thermodynamic parameters for the ionization of HA,[23] the following values can be calculated: $k_{12}(298\ K) = 1.5\cdot10^1/K_a = 1.6\cdot10^{10}\ M^{-1}\cdot s^{-1}$, $\Delta H^{\ddagger}_{12} = 53 - \Delta_r H_a = 35(6)\ kJ\cdot mol^{-1}$ and $\Delta S^{\ddagger}_{12} = -45 - \Delta_r S_a = +68(20)\ J\cdot K^{-1}\cdot mol^{-1}$. The kinetic parameters for the backward reaction are calculated from the forward reaction and the equilibrium parameters: $k_{-11}(298\ K) = 6.75\cdot10^9\ M^{-1}\cdot s^{-1}$, $\Delta H^{\ddagger}_{-11} = 98(14)\ kJ\cdot mol^{-1}$, $\Delta S^{\ddagger}_{-11} = +270(47)\ J\cdot K^{-1}\cdot mol^{-1}$, $k_{-12}(298\ K) = 6.48\cdot10^4\ s^{-1}$, $\Delta H^{\ddagger}_{-12} = 82(8)\ kJ\cdot mol^{-1}$, and $\Delta S^{\ddagger}_{-12} = +121(24)\ J\cdot K^{-1}\cdot mol^{-1}$.

From the calculated values of k_{11} and k_{12}, and the estimated outer-sphere association constants for $\{La^{3+}\cdots AH\}$ and $\{La^{3+}\cdots A^-\}$ with concentrations of ca. 10^{-1} M^{-1} and ca. $5\cdot10^2$ M^{-1},[24] respectively, the inner-sphere reorganization rate constants for reactions (11) and (12) can be calculated as $1.5\cdot10^7\ s^{-1}$ ($= 1.54\cdot10^6\ M^{-1}\cdot s^{-1}/10^{-1}\ M^{-1}$) and $3\cdot10^7\ s^{-1}$ ($= 1.6\cdot10^{10}\ M^{-1}\cdot s^{-1}/5\cdot10^2\ M^{-1}$), respectively. Both constants appear to be an order of magnitude smaller than the water exchange rate constants for the La^{3+} and $La(OH)^{2+}$ ions.[25] However, two factors could easily increase these rate constants to values similar to that of the water exchange rate constant. Participation of the *trans* isomer in free HA increases their values, as well as the inner-sphere reorganization rate constants by a factor of ca. 10, as a statistical correction for the outer-sphere water molecules.

A value of k_{-11} that is larger than the estimated water exchange rate constant by an order of magnitude indicates that this rate constant is not strictly related to the inner-sphere reorganization of the complex, but possibly encompasses protonation of the coordinated hydroxamate according to Equations (15) and (16).[26]

$$La(CH_3C(=O)N(H)O)^{2+} + H^+ \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} La(CH_3C(=O)N(H)OH)^{3+} \quad K_2 \tag{15}$$

$$La(CH_3C(=O)N(H)OH)^{3+} \xrightarrow{k_{-HA}} La^{3+} + CH_3C(=O)N(H)OH \tag{16}$$

A lack of spectroscopic evidence for $La(AH)^{3+}$, even at the highest proton concentration used (0.003 M), indicates that $K_2 \leq 3\cdot10^1\ M^{-1}$. This results in a decreased protonation constant of $La(A)^{2+}$, by ca. 7 orders of magnitude, in comparison with free A^-. This favorably compares with a decreased protonation constant of the hydroxo ligand coordinated to La^{3+} by ca. $6^1/_2$ orders of magnitude compared with free OH^-. Assuming that $La(AH)^{3+}$ is formed by a fast pre-equilibrium protonation of $La(A)^{2+}$, the inverse of the mean residence time of lanthanum in the mono complexes can be expressed by Equation (17).

$$1/\tau_B = k_{-11}[H^+] + k_{-12} = \frac{k_{-HA}K_2[H^+]}{1+K_2[H^+]} + k_{-12} \tag{17}$$

For $K_2[H^+] << 1$, the equation reduces to a simpler form: $\tau_B{}^{-1} = k_{-HA}K_2[H^+] + k_{-12}$ (the plots of calculated $\tau_B{}^{-1}$ vs. $[H^+]$ at various temperatures show linearity with significant intercepts, Figure S4). Therefore, k_{-11} could be considered as a product of the equilibrium constant for the protonation of $La(A)^{2+}$ and the first order dissociation rate constant of HA from the $La(AH)^{3+}$ complex, and a minimum value of k_{-HA} can be estimated as $7\cdot10^8\ s^{-1}$. The closeness of this value to the water-exchange rate constant seems reasonable considering that both ligands are uncharged, i.e. H_2O and HA molecules, and considering the electrostatic nature of the ligand−La^{III} bond,[27] which also accounts for a much smaller value calculated for k_{-12} than k_{-11}.

Despite the uncertainty in its determination from a far-removed intercept in the Eyring plot, the activation entropy has frequently been used as a useful criterion for distinction between possible mechanisms. The value $\Delta S^{\ddagger} = -100\ J\cdot K^{-1}\cdot mol^{-1}$ reported for the second-order complexation of Fe^{3+} with HA[7] was taken as evidence for an associative mechanism for this reaction. Similarly, the negative activation entropies determined for water exchange on a series of lanthanide ions were interpreted in terms of an associative mechanism.[23] Therefore, considering an associative mechanism for the studied reaction, negative activation entropies would be expected. The reliability of the activation entropies is made more dubious when obtained by such a complex iterative procedure as presented in this study, since mutual compensations between the activation parameters and the natural line broadening for the observed temperature effects are possible. Nevertheless, we believe that for the deduction of the reaction mechanism at least the signs of calculated entropies could be used. Therefore, the positive signs obtained could be indicative of a dissociative mode of activation for the studied reaction. The activation entropies for the backward reactions show that the dechelation of $La(A)^{2+}$ is also accompanied by a large increase in disorder. The proton assisted aquation exhibits an additional 149 $J\cdot K^{-1}\cdot mol^{-1}$ increase in entropy compared with the spontaneous aquation. The additional increase in activation entropy is very similar to the reaction entropy for the proton dehydration in water, viz. $\Delta S = +130\ J\cdot K^{-1}\ mol^{-1}$.[28]

All the above arguments speak in favor of a dissociative reaction mechanism and indeed no other mechanism is necessary to be invoked to rationalize the results obtained.

Furthermore, Crumbliss and Garrison[29] have shown that for Fe^{3+} and Al^{3+} ions, the ring-closure step is fast enough not to interfere with the complexation rate, but the water-exchange rate constants for those metal ions are much smaller than for the La^{3+} ion.

Nevertheless, it must also be mentioned that the chelation of HA was indeed proposed as the rate-determining step for its complexation to Fe^{2+}, Co^{2+}, and Ni^{2+}. Ring closure was assumed to be sufficiently retarded by slow proton dissociation from mono-coordinated hydroxamic acid to become the rate-limiting step. However, the value for k_{11} we obtained is more than three orders of magnitude larger than the rate constant for the proton dissociation from free HA in 55 M water at 25 °C, which was estimated as $1.4 \cdot 10^3$ $M^{-1} \cdot s^{-1}$.[30] The metal ion−proton repulsion and the inductive electron flow into the electron-deficient metal ion center could enhance the proton loss from $La(AH)^{3+}$ relative to the free acid, but for the above-mentioned ions the metal ion−proton repulsion was not the dominant factor.

Obviously, the proton exchange limited chelation could not be the rate-determining step for the reaction according to Equation (12) since the entering ligand had already been deprotonated. On the other hand, if the rate-determining chelation step was limited by the *trans*→*cis* isomerization of mono-coordinated HA, approximately equal rates would be expected for paths (11) and (12), which is not the case based on our results. These arguments indicate that the isomerization rate constant for HA exceeds the reported isomerization rate constant for *N*-alkyl derivatives by at least a factor of ca. 10^5 [$= 1.54 \cdot 10^6$ $M^{-1} \cdot s^{-1} \times 0.3$ M (HA)/($\approx$ 3) s^{-1}].

Experimental Section

General Remarks: A stock solution of $La(ClO_4)_3$ was prepared by mixing equivalent amounts of $Ba(ClO_4)_2$ (Merck) and $La_2(SO_4)_3$ (Fluka), dissolved in distilled water, followed by the centrifugation of precipitated $BaSO_4$. The concentration of La^{3+} was determined by titration with EDTA. Acetohydroxamic acid (98%) from Aldrich was used without further purification. Doubly distilled water was used in the preparation of all solutions. The ionic strength was 1.2 M in all the experiments, maintained by the addition of La/Na/H/ClO_4 ions. The pH of the solutions was adjusted with 2 M NaOH. The ^{139}La NMR measurements were performed at 56.52 MHz with a Bruker Avance 400 DRX spectrometer equipped with an 89-mm wide-bore magnet. The temperature was kept constant within ±0.1 K by means of a Bruker BVT 3000 digital temperature control unit, which was tested for the absolute temperature-scale reading. The spectral width of the spectra varied between $\delta = 200$ and 800, according to the changing La linewidth (11.3−45.2 kHz), and 128 up to 8000 data points were collected with a 90° pulse duration of about 18 μs. The half width ($\Delta\nu_{1/2}$), related to the relaxation times T_2 ($= 1/\pi\Delta\nu_{1/2}$), were calculated by fitting a single Lorentzian function to the recorded spectroscopic data. Chemical shifts were measured relative to external 0.2 M $La(ClO_4)_3$ in 20% (w/w) D_2O keeping the frequency of the external lanthanum fixed at 298 K, i.e. $\Delta\nu_{La^{3+}}(298) = -2187$ Hz. The observed temperature dependence of the ^{139}La NMR line widths were within the experimental error limits. A Mettler Toledo MP230 research digital pH meter equipped with a Schott N 6480 combination electrode, containing saturated NaCl solution, was used for pH measurements. The pH readings in H_2O/D_2O = 4:1 (w/w) solutions were converted into the $p[H^+]$ ($\equiv -\log([H^+]/mol \cdot dm^{-3})$ values by means of a linear function experimentally determined by the titration of $HClO_4$ with NaOH in the same solvent mixture at an ionic strength of 1.2 M (H/Na perchlorate) and at various temperatures. The results revealed that the slope and intercept of the function are temperature-independent within the experimental error limits. In order to exclude hydrolysis of lanthanum ions, experiments were performed in solutions of $p[H^+] < 6$.

[12] Above 293 K, as the $p[H^+]$ increases the peak strongly shifts to the lower fields, but below that temperature the $p[H^+]$ increase above 5.27 reverses the direction of the shift towards the upper field. However, since at the latter acidity a weak opalescence appears slowly, the spectra were collected only at $p[H^+] \leq 5.27$. The same $p[H^+]$ increase at the lowest used temperature does not reverse the direction of the peak shift of 0.2 M $La(ClO_4)_3$.

[25] It should be noted that the calculated value of an outer-sphere association equilibrium constant remarkably depends on the arbitrary choice of the ion-pair radius. An experimentally determined value of the ion-pair equilibrium constant for association of aquapentaamminecobalt(III) with azide at 25 °C and 3.5 M ionic strength was reported as low as 0.18 M^{-1} in: T. W. Swaddle, G. Guastalla, *Inorg. Chem.* **1969**, *8*, 1604.
[26] In the protonated complex species, $La(CH_3C(=O)N(H)OH)^{3+} \equiv La(AH)^{3+}$, a molecule of hydroxamic acid could be coordinated to the La^{3+} ion either bidentately through carbonyl and hydroxy oxygen atoms, or monodentately through the carbonyl oxygen atom alone. In any case this species is expected to be much more reactive than the $La(A)^{2+}$ species.

Keywords: Nickel / Palladium / P ligands / S ligands

The phosphanylthiol $PPh(2\text{-}C_6H_4SH)_2$ reacts with the Ni^{II} and Pd^{II} complexes $[MCl_2L_2]$ in the presence of NaOEt to give the mononuclear derivatives $[M\{PPh(C_6H_4S)_2\}L]$ [M = Ni, L = PPh_3 (**1**), PPh_2Me (**2**); M = Pd, L = PPh_3 (**3**)]. The analogous reaction starting with complexes containing bidentate ligands $[MX_2(L\text{-}L)]$ produces different results depending on the ligand used. The complexes $[M\{PPh(C_6H_4S)_2\}(dppm)]$ [M = Ni (**4**), Pd (**5**)], with an unligated phosphorus atom in the diphosphane are obtained with bis(diphenylphosphanyl)methane (dppm), while the dinuclear complexes $[M_2(\mu\text{-dppe})\{PPh(C_6H_4S)_2\}]$ [M = Ni (**6**), Pd (**7**)] are isolated in the case of 1,2-bis(diphenylphosphanyl)-ethane (dppe). With 1,10-phenanthroline (phen), the complexes $[M\{PPh(C_6H_4S)_2\}(phen)]$ [M = Ni (**8**), Pd (**9**)] are obtained, but when 2,2′-bipyridine is used the dinuclear compounds $[M\{PPh(C_6H_4S)_2\}]_2$ [M = Ni (**10**), Pd (**11**)] are isolated instead. Complexes **10** and **11**, which can be obtained starting from $NiCl_2$ or $[PdCl_2(NCPh)_2]$ respectively, afford complexes **1**–**7** when treated with the respective phosphanes in the appropriate stoichiometries. The structures of **2**, **7** and **10** have been confirmed by X-ray analysis.

Introduction

Transition metal chemistry involving sulfur donor groups is of current interest because of its relevance in biology, because of its many industrial applications, and because of its importance in the area of novel complex synthesis.[1] Thus, sulfur-ligated transition metal complexes form the inorganic parts of the biologically active centres of some metalloproteins and enzymes. Consequently, some of these have found applications in pharmacology,[2−4] and industrial chemistry.[5−7] As for synthetic chemistry as such, transition metal thiolate complexes have received special interest because of their ability to adopt different structures and nuclearities.[8]

It is fairly common that these thiolate complexes contain phosphane moieties which, operating as ancillary ligands, are able to enhance the properties of interest. For this reason the chemistry of polydentate ligands with sulfur and phosphorus donor atoms in their frameworks has attracted increasing interest, augmented by the observation of unusual structures and reactivities in the resulting transition metal complexes.[9] In this regard, the systems most studied have been the proligands $PR_2(CH_2SH)$, $PR_2(CH_2CH_2SH)$ and $PR_2(C_6H_4SH)$.[10−16]

Species with more than two donor atoms — $PR(CH_2CH_2SH)_2$, $PR(C_6H_4SH)_2$, $P(CH_2CH_2SH)_3$ and $P(C_6H_4SH)_3$ — have received much less attention,[17−20] although they possess intrinsic interest in as much as they stably occupy three or more coordination sites, thus permitting more specific chemistry to be performed at the remaining sites. Such is the case for $PPh(C_6H_4S)_2^{2-}$, which possesses a three-donor set "PS_2" and can be described as a pincer ligand similar to van Koten's[21] $[C_6H_3(CH_2NMe_2)_2]^-$ and $[2,6\text{-}(Ph_2PCH_2)_2C_6H_3)]^-$, Milstein's[22] $[C_6H_3(CH_2PBu_2)_2]^-$ and $[C_6H_4(CH_2PPr_2)_2]$ or to Sellmann's [bis(2-mercaptophenyl)sulfide^{2-}].[23]

In this paper we describe some mono- and dinuclear complexes of Ni^{II} and Pd^{II}, with $PPh(C_6H_4S)_2^{2-}$ acting as a pincer ligand in an *S,S′,P* coordination mode, as confirmed by the X-ray structures of $[Ni\{PPh(C_6H_4S)_2\}(PPh_2Me)]$, $[Pd_2(\mu\text{-dppe})\{PPh(C_6H_4S)_2\}_2]$ and $[Ni\{PPh(C_6H_4S)_2\}]_2$.

Results and Discussion

The reaction of a solution of $PPh(C_6H_4SH)_2$ and sodium ethoxide with the nickel(II) and palladium(II) species MCl_2L_2 (L = monodentate phosphane; step *i,* Scheme 1), yields the mononuclear derivatives $[M\{PPh(C_6H_4S)_2\}(L)]$

Scheme 1. Synthesis of complexes **1−11**

[M = Ni, L = PPh_3 (**1**), PPh_2Me (**2**); M = Pd, L = PPh_3 (**3**)]. This process can be described as the result of deprotonation of the starting phosphanylthiol ligand at room temperature, followed by coordination to the metal centre with the concomitant dissociation of one monodentate phosphane. To date the most common synthetic routes to complexes with these ligands have involved electrochemical procedures[24] or reflux conditions in the presence of NEt_3 as a base. The preparation of **1−3** occurs under milder conditions than those reported for related complexes.

The IR spectra of complexes **1−3** do not show the ν(S−H) band, which appears at 2495 cm^{-1} in the free ligand. This fact, and the absence of the S−*H* signal in the ^1H NMR spectrum, indicates the presence of the anionic form of the ligand. The ^1H NMR spectra exhibit multiplets in the aromatic region and, for **2**, a doublet at δ = 1.93 due to the methyl group of the PPh_2Me ligand. The ^{31}P NMR spectra of the complexes show two doublets due to the two nonequivalent phosphorus atoms. The phosphanylthiolate resonance, which appears at δ = −19.4 in the free ligand, is shifted to about δ = 85 in complexes **1−3**. This downfield shift could be considered as being due to the coordination of the phosphorus atom to the metal. The second doublet appears at higher field: δ = 26.0 (**1**), 9.4 (**2**) and 22.6 (**3**). The $LSIMS^+$ mass spectra show the parent peak at *m/z* = 644 (**1**), 582 (**2**) and 692 (**3**), with appropriate isotope distributions, in agreement with the mononuclear description of the three products. Electrovoltammetry studies show a nonreversible one-electron oxidation at 0.412 V only in the case of $[Ni\{PPh(C_6H_4S)_2\}(L)]$ (**1**).

When the same reaction as described in *i)* is carried out in the presence of a nickel or palladium complex with a bidentate phosphane $[MCl_2(L\text{-}L)]$ (steps *ii* and *iii*, Scheme 1), the results obtained are different depending on the diphosphane used. Thus, in the case of bis(diphenylphosphanyl)methane (dppm) the mononuclear complexes **4** and **5** are isolated, whereas the dinuclear species **6** and **7** are formed when 1,2-bis(diphenylphosphanyl)ethane (dppe) is used instead.

The complexes $[M\{PPh(C_6H_4S)_2\}dppm]$ [M = Ni (**4**), Pd (**5**)] show IR spectra similar to those of compounds **1−3**, with the S−H vibration absent and the phosphane bands present. The ^1H NMR spectra show multiplets in the aromatic region, and broad signals centred at δ = 3.17 (**4**) and 3.33 (**5**), even at low temperature, due to the -CH_2- group of dppm. The room temperature ^{31}P NMR spectrum of **4** shows a triplet at δ = 85 assignable to the P atom of the phosphanylthiolate, although no signal was observed for the phosphorus atoms of dppm. A new broad signal appears in the negative region upon lowering the sample temperature that could be attributed to the dppm ligand. Decoalescence occurs at 283 K and a pattern corresponding to an AMX spin system becomes well-resolved at 223 K with the parameters δ_A = 85.9 (d, J_{AM} = 284 Hz), δ_M = 18.6 (dd, J_{MX} = 77.4 Hz) and δ_X = −27.1 (d). The high-field signal at δ = −27 is indicative of a free P-atom in the diphosphane. At 283 K $\Delta G^{\neq}$ has a value of 12.18 kcal/mol.[25] Complex **5** exhibits a similar three-resonance pattern at room temperature. The $LSIMS^+$ spectra show the parent peaks at *m/z* = 766 (**4**) and 813 (**5**) with the appropriate isotope distribution, again in agreement with the proposed formulation.

When the diphosphane 1,2-bis(diphenylphosphanyl)-ethane (dppe) is used instead of dppm, the dinuclear derivatives $[Pd_2(\mu\text{-}dppe)\{PPh(C_6H_4S)_2\}_2]$ [M = Ni (**6**), Pd (**7**)] can be isolated as air stable solids (step *iii*, Scheme 1). The ^1H NMR spectra in $CDCl_3$ solution display the resonances characteristic of the phosphanyldithiolate ligand in the aro-

matic region, as well as those of the dppe. The ^{31}P NMR spectra reveal AA′XX′ systems for both complexes: **6** (δ_A = 87.46, δ_X = 22.47, $J_{AA'}$ = 21.32, J_{AX} = 234.13, $J_{XX'}$ = 21.60 Hz), **7** (δ_A = 84.8, δ_X = 20.85, $J_{AA'}$ = 23.7, J_{AX} = 414.2, $J_{XX'}$ = 25.1 Hz). This is consistent with a dinuclear formulation. The mass spectrum (LSIMS$^+$) does not show the molecular peak for **6** and shows only weak intensity for **7** (*m*/*z* = 1258, 5%).

The reaction of [MCl_2(N-N)] [N-N = 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen)] with $PPh(C_6H_4SH)_2$ in the presence of sodium ethoxide, depends on the N-containing ligand. This ligand remains bound to the metal only in the case of 1,10-phenanthroline, yielding [M{$PPh(C_6H_4S)_2$}(phen)] [M = Ni (**8**), Pd (**9**); process *iv*, Scheme 1]. Curiously, the nickel complex is soluble in conventional solvents, while the palladium-containing product is not soluble enough, so that no solution data could be measured for complex **9**. The ^{31}P NMR spectrum of **8** shows a singlet at δ = 75.4, as a consequence of the coordination of the P atom to the metal centre, meaning that complex **8** is in all likelihood pentacoordinated. With bipy present as the auxiliary ligand, the reaction proceeds with the formation of the dinuclear species [M{$PPh(C_6H_4S)_2$}]$_2$ [M = Ni (**10**) and Pd (**11**)].

The dinuclear derivatives **10** and **11** can also be obtained from the reaction between $PPh(C_6H_4SH)_2$ in NaOEt, and $NiCl_2{\cdot}6H_2O$ or [$PdCl_2(PhCN)_2$], in which PhCN serves as a leaving group (step *v*, Scheme 1). The ^1H NMR spectra show only signals in the aromatic region, while the ^{31}P NMR spectra display the expected singlets at δ = 72.7 and 76.9, respectively, due to the equivalent phosphorus donors in each complex. The mass spectra show the molecular peaks at *m*/*z* = 764 (45%) (**10**) and 861 (12%) (**11**), in agreement with a dinuclear formulation.

Complexes **10** and **11** react readily with mono- and bidentate phosphanes in dichloromethane in the appropriate stoichiometries, to give mixtures of products in which complexes **1**−**9** are the major products, as shown by ^1H and ^{31}P NMR spectroscopic data. This fact is in agreement with the dinuclear formulation of **10** and **11**. [M{$PPh(C_6H_4S)_2$}(bipy)] complexes are again inaccessible by this route, and when the corresponding reaction was attempted the starting materials were recovered unchanged.

Crystal Structures of [Ni{$PPh(C_6H_4S)_2$}(PPh_2Me)] (2), [Pd_2(μ-dppe){$PPh(C_6H_4S)_2$}$_2$] (7) and [Ni{$PPh(C_6H_4S)_2$}]$_2$ (10)

Zubieta et al.[20] have previously reported a complex similar to **1**, and described it as a dinuclear derivative. Because the data for complexes **1**−**5**, and particularly the mass spectra, point more to them being mononuclear, we undertook the X-ray analysis of one of these complexes, namely [Ni{$PPh(C_6H_4S)_2$}(PPh_2Me)] (**2**), which yielded the most suitable crystals for X-ray studies. Figure 1 shows a view of the molecule, a mononuclear, distorted square planar *trans*-P,P and *trans*-S,S nickel complex with the Ni atom 0.031 Å out of the plane formed by S(1), P(1), S(2) and P(2) (planar within 0.208 Å). The main distortion from square-planar geometry arises from closure of the S(2)−Ni−S(1) angle [166.22(4)°], and to a much lesser extent, of the angles S(1)−Ni−P(2) and S(2)−Ni−P(2) [87.05(3)° and 88.66(3)°, respectively] most likely imposed by the rigidity of the phosphanyldithiolate ligand. The two Ni−P distances are quite different from each other. The Ni−P(1) distance of 2.2054(8) Å is similar to that found for Ni−PPh_3 bonds such as that found in [Ni(S_3)PPh_3] [S_3^{2-} = bis(2-mercaptophenyl)sulfide, 2.197(1) Å].[23] However, the Ni−P(2) bond

C(1)−P(1)−C(10)	103.21(15)		

length of 2.1186(8) Å is shorter than the former and shorter than other Ni-phosphanylthiolate complexes:[26] [$Ni(PS)_2$] with PS = $PPh_2(C_6H_4S)$ and $PPh_2[C_6H_3(SiMe_3)S]$, 2.181(2) and 2.172(3) Å, respectively. The Ni−P(2) bond is similar to that found in the binuclear compound [$Ni_2\{P(C_6H_4S)_3\}_2$][27] [2.109(4) Å]. This short distance is again consistent with the constraints imposed by the PS_2 ligand. The Ni−S distances, which average 2.1693(8) Å, are in the range reported for terminal nickel-thiolate bonds[23] and lie in the range found for [$Ni(PS)_2$]:[25,26] PS = $PPh_2(C_6H_4S)$, 2.180(2); $PPh_2(C_6H_3(SiMe_3)S)$, 2.151(3) Å. Moreover, the Ni−S distances are similar to those found for other phosphanylthiolate derivatives.[28−30] Complexes **1**, **3**, **4** and **5** presumably adopt similar mononuclear dispositions.

The crystal structure of **7**, which includes an interstitial molecule of CH_2Cl_2, was also determined by X-ray diffraction. The structure (Figure 2) displays two Pd-phosphanylthiolate units connected to each other by the dppe ligand. The geometry around each palladium centre, *trans*-P,P and -S,S, is close to square planar, as was the case in **2**, and

P(2)−Ni(2)−Ni(1)	124.3(3)	Ni(2)−S(4)−Ni(1)	75.8(3)

the Pd atom lies out of the plane by 0.167 Å, with the main deviations due to contraction of the S(2)−Pd−S(1) [164.93(3)°], S(1)−Pd−P(1) [86.78(4)°], and S(2)−Pd−P(1) [84.24(4)°] angles. The two Pd−P distances are different from each other, as in **2**. The Pd−P(phosphanylthiolate) bond [Pd(1)−P(1) = 2.2265(10) Å] is shorter than that in Pd−P(dppe) [Pd(1)−P(2) = 2.3402(10) Å]. This reinforces the notion that the shorter bond distance from Pd to the phosphanylthiolate phosphorus atom results from constraints imposed by the ligand. Accordingly, several systems with palladium coordinated by less restrictive P,S ligands show larger Pd−P distances, such as in $[Pd\{PPh_2(CH_2CH_2S)\}Cl(PPh_3)]$ [2.280(2) Å],[31] *trans*-$[Pd\{PPh_2(C_6H_4S)\}_2]$ [2.291(1) Å][32] or *cis*-$[Pd\{PPh_2(C_6H_4S)\}_2]$ [2.2845(8) and 2.2802(8) Å].[33] The Pd−P bonds involving the dppe ligand are slightly longer [2.3402(11) Å] than in other derivatives with this diphosphane.[34] The Pd−S bond lengths [average value 2.3227(10) Å] are similar to those found in the complexes mentioned above and in other bisdithiolene derivatives.[35−37]

The structure determination of **10** was undertaken in order to establish the chemical connectivity, although it was clear from the outset that the data would not be of high quality. The analysis reveals (Figure 3) a dinuclear complex consisting of two Ni-phosphanyldithiolate units linked by a double sulfur bridge. Although the accuracy of the structure determination does not permit a systematic comparison of distances, the Ni−P and Ni−S(terminal) distances are similar to those found in complex **2**; the Ni−S(bridging) distances are greater than those for Ni−S(terminal) as is the case in other systems with terminal and bridging sulfur atoms, such as $[Ni(S_3)]_3$ [S_3^{2-} = bis(2-mercaptophenyl)sulfide][23] and $[Ni_2\{P(C_6H_4S)_3\}_2]$.[27] It is worth noting that the Ni−Ni distance of 2.714(6) Å is rather short, which could be indicative of some degree of metal-metal interaction.[27,38,39]

Experimental Section

General Procedures: All reactions were performed under argon using standard Schlenk techniques, although the products are air stable. $[MCl_2L_2]$ (M = Ni, Pd; L = PPh_3, PPh_2Me),[40,41] and $[MCl_2(L\text{-}L)]$ (M = Ni, Pd; L-L = dppm, dppe,[42,43] bipy, phen[44]) were prepared by established procedures. All other reagents were used as supplied. The synthesis of $PPh(2\text{-}C_6H_4SH)_2$ was carried out using the standard literature procedure.[45] IR spectra were recorded on a Perkin−Elmer 883 spectrophotometer, over the range 4000−200 cm^{-1}, using Nujol mulls between polyethylene sheets. ^1H and ^{31}P NMR spectra were measured on a Varian UNITY 300 or Bruker 300 spectrometer in $CDCl_3$ or CD_2Cl_2 solution; chemical shifts are quoted relative to $SiMe_4$ (^1H) or H_3PO_4 (external, ^{31}P). The C, H N and S analyses were performed with a Perkin−Elmer 2400 microanalyser. Mass spectra were recorded on a VG Autospec, by liquid secondary ion mass spectrometry (LSIMS+) using nitrobenzyl alcohol as matrix and a cesium gun.

Preparation of the Phosphanyldithiolate Complexes [Ni{PPh($C_6H_4S)_2$}PPh_3] (1), [Ni{PPh($C_6H_4S)_2$}PPh_2Me] (2), and [Pd{PPh($C_6H_4S)_2$}PPh_3] (3): A solution of 0.1 M NaOEt (3 mL, 0.3 mmol) and $[NiCl_2(PPh_3)_2]$ (0.098 g, 0.15 mmol), $[NiCl_2(PPh_2Me)_2]$ (0.079 g, 0.15 mmol) or $[PdCl_2(PPh_3)_2]$ (0.105 g, 0.15 mmol) was added, over a period of 10 minutes, to a suspension of $PPh(C_6H_4SH)_2$ (0.048 g, 0.15 mmol) in 10 mL of ethanol. After 5 h of stirring, green (**1,2**) or brown (**3**) solids precipitated; these were filtered off, washed with ethanol and dried in vacuo.

1: Yield: 73 mg (75%). $C_{36}H_{28}NiP_2S_2$ (645.4): calcd. C 66.99, H 4.37, S 9.93; found C 66.45, H 4.20, S 9.50. ^1H NMR ($CDCl_3$): δ = 6.69 (m, 2 H, Ph), 7.18 (m, 2 H, Ph), 7.62−7.26 (m, 24 H, Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 86.2 (d, $J_{P\text{-}P}$ = 270 Hz), 26 (d). MS: *m*/*z* (%) = 644 (100) $[M]^+$.

2: Yield: 62 mg (70%). $C_{31}H_{26}NiP_2S_2$ (583.3): calcd. C 63.83, H 4.49, S 10.99; found C 63.42, H 4.21, S 10.38. ^1H NMR ($CDCl_3$): δ = 1.93 (d, $^2J_{P\text{-}H}$ = 8.3 Hz, 3 H, Me), 7.0 (m, 2 H), 7.64−7.22 (m, 21 H, Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 87.4 (d, $J_{P\text{-}P}$ = 280 Hz), 9.4 (d). MS: *m*/*z* (%) = 582 (100) $[M]^+$, 382 (60) $[M - PPh_2Me]^+$.

3: Yield: 94 mg (90%). $C_{36}H_{28}P_2PdS_2$ (693.1): calcd. C 62.38, H 4.07, S 9.25; found C 61.95, H 4.21, S 8.69. ^1H NMR ($CDCl_3$): δ = 6.99 (m, 2 H, Ph), 7.21 (m, 2 H, Ph), 7.62−7.27 (m, 24 H, Ph).

$^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 85.2 (d, $J_{P\text{-}P}$ = 406 Hz), 22.6 (d). MS: *m/z* (%) = 692 (100) $[M]^+$, 430 (55) $[M - PPh_3]^+$.

[Ni{PPh($C_6H_4S)_2$}(dppm)] (4) and [Pd{PPh($C_6H_4S)_2$}(dppm)] (5): A solution of 0.1 M NaOEt (3 mL, 0.3 mmol) and either [$NiCl_2$dppm] (0.077 g, 0.15 mmol) or [$PdCl_2$dppm] (0.084 g, 0.15 mmol) was added, over a period of 10 minutes, to a suspension of PPh($C_6H_4SH)_2$ (0.048 g, 0.15 mmol) in 10 mL of ethanol. Green (**4**) or orange (**5**) solids precipitated immediately, and were filtered off, washed with ethanol and dried in vacuo.

4: Yield: 80 mg (70%). $C_{43}H_{35}NiP_3S_2$ (767.5): calcd. C 67.29, H 4.59, S 8.35; found C 66.96, H 4.35, S 7.85. ^1H NMR ($CDCl_3$): δ = 3.17 (br. s, 2 H, CH_2), 6.95 (m, 2 H), 7.45−7.14 (m, 29 H, Ph), 7.54 (m, 2 H, Ph). $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = (−50 °C): δ_A = 85.9 (d, J_{AM} = 284 Hz), δ_M = 18.6 (dd, J_{MX} = 77.4 Hz), δ_X = −27.1 (d). MS: *m/z* (%) = 766 (100) $[M]^+$, 383 (70) $[M - dppm]^+$.

5: Yield: 107 mg (88%). $C_{43}H_{35}P_3PdS_2$ (815.2): calcd. 63.35, H 4.3, S 7.85; found C 62.94, H 3.92, S 7.71. ^1H NMR ($CDCl_3$): δ = 3.33 (br. s, 2 H, CH_2), 6.95 (m, 2 H, Ph), 7.71−7.15 (m, 31 H, Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 83.2 (d, $J_{P\text{-}P}$ = 399 Hz), 11.3 (d), −26.1 (br. s,). MS: *m/z* (%) = 813 (100) $[M]^+$, 430 (70) $[M - dppm]^+$.

[Ni_2(μ-dppe){PPh($C_6H_4S)_2$}$_2$] (6) and [Pd_2(μ-dppe){PPh($C_6H_4S)_2$}$_2$] (7): The procedure followed was similar to that described for **4** and **5**, using [$NiCl_2$dppe] (0.078 g, 0.15 mmol) or [$PdCl_2$dppe] (0.085 g, 0.15 mmol). Green (**6**) or brown (**7**) solids precipitated from the reaction media, and were filtered off and washed with EtOH.

6: Yield: 123 mg (70%). $C_{62}H_{50}Ni_2P_4S_4$ (1164.6): calcd. C 63.94, H 4.32, S 11.01; found C 63.55, H 4.15, S 10.52. ^1H NMR ($CDCl_3$): δ = 2.74 (br. s, 4 H, CH_2-CH_2), 7.61−6.66 (m, 46 H, Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$): AA′XX′: $\delta_A = \delta_{A'}$ = 87.46, $\delta_X = \delta_{X'}$ = 22.47, $J_{AA'}$ = 21.32 Hz, J_{AX} = 234.13 Hz, $J_{AX'} = J_{A'X}$ = 0 Hz, $J_{XX'}$ = 21.60 Hz. MS: *m/z* (%) = 780 (30) $[M - Ni(PPh(C_6H_4S)_2]^+$.

7: Yield: 123 mg (65%). $C_{62}H_{50}P_4Pd_2S_4$ (1260.0): calcd. C 59.09, H 3.99, S 10.17; found C 58.82, H 3.81, S 9.85. ^1H NMR ($CDCl_3$): δ = 3.33 (br. s, 4 H, CH_2-CH_2), 7.0 (m, 4 H), 7.61−7.17 (m, 42 H, Ph). $^{31}P\{^1H\}$ NMR ($CDCl_3$): AA′XX′: $\delta_A = \delta_{A'}$ = 84.8, $\delta_X = \delta_{X'}$ = 20.85, $J_{AA'}$ = 23.7 Hz, J_{AX} = 414.2 Hz, $J_{AX'} = J_{A'X}$ = 0 Hz, $J_{XX'}$ = 25.1 Hz. MS: *m/z* (%) = 1258 (5) $[M]^+$, 780 (30) $[M - Ni(PPh(C_6H_4S)_2]^+$.

[Ni{PPh($C_6H_4S)_2$}(phen)] (8) and [Pd{PPh($C_6H_4S)_2$}(phen)] (9): A 0.1 M solution of NaOEt (3 mL, 0.3 mmol) was added over a period of 10 minutes to a suspension of PPh($C_6H_4SH)_2$ (0.048 g, 0.15 mmol) in 10 mL of ethanol, and then [$NiCl_2$phen] (0.046 g, 0.15 mmol) or [$PdCl_2$phen] (0.054 g, 0.15 mmol) was added. After stirring overnight brown solids precipitated, which were filtered off, washed with ethanol and dried in vacuo.

8: Yield: 55 mg (65%). $C_{30}H_{21}N_2NiPS_2$ (563.3): calcd. C 64.06, H 3.76, N 4.98, S 11.40; found C 63.65, H 3.35, N 4.52, S 10.98. ^1H NMR ($CDCl_3$): δ = 7.58−6.79 (m, 14 H, Ph), 7.62 (m, 2 H, phen), 7.78 (s, 2 H, phen), 8.23 (m, 2 H, phen), 9.72 (m, 1 H, phen). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 4.5(s). MS: *m/z* (%) = 562 (5) $[M]^+$, 780 (30) $[M - Ni(PPh(C_6H_4S)_2]^+$.

9: Yield: 64 mg (70%). $C_{30}H_{21}PPdN_2S_2$ (611.0): calcd. C 58.97, H 3.46, N 4.58, S 10.49; found C 58.75, H 3.5, N 4.35, S 11.05.

[Ni{PPh($C_6H_4S)_2$}]$_2$ (10) and [Pd{PPh($C_6H_4S)_2$}]$_2$ (11): a) Following the same procedure as described for the previous complexes, using $NiCl_2{\cdot}6H_2O$ (0.036 g, 0.15 mmol) or [$PdCl_2$(PhCN)$_2$] (0.057 g, 0.15 mmol), afforded green or brown solids which precipitated from their respective reaction media and were filtered off and washed with EtOH.

10: Yield: 40 mg (70%). $C_{36}H_{26}Ni_2P_2S_4$ (766.2): calcd. C 56.43, H 3.42, S 16.73; found C 56.10, H 3.21, S, 16.25. ^1H NMR (CD_2Cl_2): δ = 6.99 (m, 4 H), 7.22 (m, 4 H), 7.49−7.19 (m, 10 H), 7.56 (m, 4 H), 7.76 (m, 4 H, Ph). $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 72.7 (s). MS: *m/z* (%) = 764 (65) $[M]^+$.

11: Yield: 56 mg (87%). $C_{36}H_{26}P_2Pd_2S_4$ (861.6): calcd. C 50.18, H 3.04, S 14.88; found 50.45, H 3.14, S 15.26. ^1H NMR (CD_2Cl_2): δ = 7.61−7.17 (m). $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 76.9 (s). MS: *m/z* (%) = 861 (15) $[M]^+$.

b) A 0.1 M solution of NaOEt (3 mL, 0.3 mmol) was added, over a period of 10 minutes, to a suspension of PPh($C_6H_4SH)_2$ (0.048 g, 0.15 mmol) in 10 mL of ethanol. Then, [$NiCl_2$·bipy] (0.042 g, 0.15 mmol) or [$PdCl_2$·bipy] (0.050 g, 0.15 mmol) was added. After stirring overnight green (**10**) or brown (**11**) solids precipitated, which were filtered off, washed with ethanol and dried in vacuo. Yields: **10:** 42 mg (73%); **11:** 55 mg (85%).

Reaction of [Ni{PPh($C_6H_4S)_2$}]$_2$ (10) and [Pd{PPh($C_6H_4S)_2$}]$_2$ (11) with Ligands: 0.1 mmol of L (L= PPh_3, PPh_2Me, dppm, or phen), or 0.05 mmol of dppe was added to a suspension of [Ni{PPh($C_6H_4S)_2$}]$_2$ (**10**; 0.076 g, 0.05 mmol) or [Pd{PPh($C_6H_4S)_2$}]$_2$ (**11**; 0.086 g, 0.05 mmol) in dichloromethane (30 mL) and stirred for 6 hours to give clear solutions. Partial evaporation of the solvents and addition of ethanol (20 mL) afford complexes **1**−**8**. Complex [Pd{PPh($C_6H_4S)_2$}(phen)] (**9**) was obtained as a brown insoluble solid from dichloromethane.

X-ray Crystallography: Single crystals of [Ni{PPh-($C_6H_4S)_2$}(PPh_2Me)] (**2**) and of [Pd_2(μ-dppe){PPh($C_6H_4S)_2$}$_2$] CH_2Cl_2 (**7**) were grown by slow diffusion of hexane into dichloromethane solutions of the complexes. Data collection[46] at low temperature was carried out on a Bruker SMART diffractometer for **2** and on a Nonius−KappaCCD diffractometer for **7**. Crystal parameters and experimental details are summarised in Table 1. The structures were solved by direct methods for **2**[47] and for **7**,[48] and refined on F_0^2 by full-matrix least-squares using the program SHELXL-97.[49] Data were corrected for absorption using SADABS[50] for **2** and SORTAV[51] for **7**. All hydrogen atoms were included at idealised positions. Selected bond lengths and angles are given in Table 2 and 3. The details of the crystal structures have been deposited at the Cambridge Crystallographic Data Center as supplementary publication nos. CCDC-162696, CCDC-162697 and CCDC-162698 for complexes **2**, **7** and **10** respectively. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge UK CB2 1EZ [E-mail: deposit@ccdc.cam.ac.uk, Fax: (internat.) +44-1223/336-033].

A very thin plate-like crystal of **10**, suffering from severe anisotropic mosaicity, was used for X-ray measurements. An initial, slow reflection search yielded 12 reflections, which were indexed to a primitive monoclinic cell.[52] Preliminary data collection between 26 and 32° (2θ) was used in an attempt to obtain better reflections for cell determination and for ψ-scans, but the results were not satisfactory. The positions of 13 reflections with lower values of 2θ were used to calculate the unit cell parameters reported. Accurate centring of reflections in the higher 2θ range was rendered difficult because of the mosaic spread of the crystal. As for the ψ-scans, in addition to producing low signal-to-noise ratios, they also suffered from the effects of mosaicity; this compromises the validity of the absorption corrections so obtained, and so absorption corrections were not applied.

Intensity data were gathered in the 2θ range of 4.0−46.0°. Omega-scans were used, with the ω scan speed set for each reflection on the basis of a preliminary measurement made at a speed of 4°/min. The weakest data were gathered at the slowest speed; no reflection was skipped on the basis of a poor showing on the initial scan. The

maximum scan time for any reflection was limited to 270 sec, and most reflections were measured for that amount of time. The photon count for the preliminary scan was added to that of the final scan to give the datum. A single monitor reflection was measured after every 30 min of accumulated beam time, as a check on experimental stability. An orientation check was made after every 1000 intensity measurements. In all, 5630 intensity measurements were made, in a single quadrant of reciprocal space.

Following data reduction,[53] the structure was solved by direct methods, which yielded the positions of all of the non-hydrogen atoms in the asymmetric unit. The hydrogen atoms, all of which are in phenyl groups, were placed at calculated positions and refined as riders, with isotropic displacement parameters set to 1.2-times the equivalent isotropic displacement parameters of their respective parent carbon atoms. All non-hydrogen atoms were refined anisotropically, but it was necessary to apply both rigid bond restraints and restraints to isotropic behavior to the anisotropic displacement parameters of the carbon atoms. The isotropic restraints had one-quarter the relative weight of the rigid bond restraints. The heavier atoms were refined freely.

In all, 397 parameters were adjusted to all 4437 unique data (used as F_0^2) and to 288 restraints in the full-matrix least-squares calculation, giving an observation-to-parameter ratio of 11.9:1. The final residuals are shown in Table 1.

The diffraction data were weak, with mean $I/\sigma(I) = 1.45$ in the data set before averaging of equivalents. Only 16% of the data had $I > 3\sigma(I)$. Consequently, the standard uncertainties in the derived bond distances and angles are high, and we emphasize that it would not be useful to try to derive conclusions beyond the connectivity from this structure determination.

As already mentioned, the results reported here are based on data without correction for absorption. We also performed a separate refinement of the structure with data that had been treated with an *a posteriori* calculated absorption correction.[54] The residual $R1$ was found to be lowered by only slightly more than 0.01, and it was still necessary to apply restraints to the anisotropic displacement parameters of the carbon atoms to avoid having the large majority of them emerge nonpositive definite. The results of this second refinement are available from the authors upon request. Selected bond lengths and angles are given in Table 4.

Salts of 5,5′-Azotetrazolate

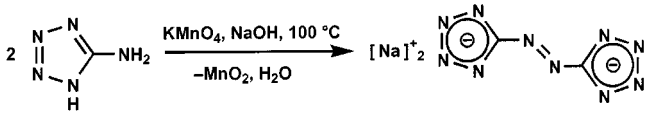
Anton Hammerl,[a] Gerhard Holl,[b] Thomas M. Klapötke,*[a] Peter Mayer,[a] Heinrich Nöth,[a] Holger Piotrowski,[a] and Marcus Warchhold[a]

Keywords: Azo compounds / Hydrates / Nitrogen heterocycles / Tetrazoles / Highly energetic materials

Salts of 5,5′-azotetrazolate with alkali metal, alkaline earth metal and several trivalent cations were synthesized as potential initial explosives. The synthesis in water yields hydrates of these salts that were studied by NMR and vibrational spectroscopy as well as X-ray diffraction. Their thermal properties were studied by DSC and TG.

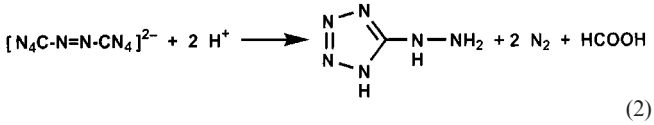
Introduction

Thiele first prepared sodium 5,5′-azotetrazolate (**2**), which is the starting material for all other 5,5′-azotetrazolate compounds, from the oxidation of aminotetrazole with potassium permanganate [Equation (1)].[1]



(1)

He prepared several salts with metal cations (K^+, Ca^{2+}, Ba^{2+}, Ag^+, Hg^+, Pb^{2+}) and salts of protonated nitrogen bases (NH_4^+, NH_3OH^+, $N_2H_6^+$). 5,5′-Azotetrazolate salts decompose in mineral acid solution to form hydrazinotetrazole, dinitrogen and formic acid [Equation (2)].



(2)

Azidotetrazole,[2] 5-azo(diazomethano)tetrazole hydrate[3] and other compounds[4] were recovered as intermediates from the decomposition reaction of 5,5′-azotetrazolate salts in acidic media. Salts of 5,5′-azotetrazolate with protonated nitrogen bases (e.g. guanidinium, triaminoguanidinium and hydrazinium 5,5′-azotetrazolate) are powerful gas generation agents and can be used in gas generators for airbags and fire extinguishing systems.[5] Heavy metal salts of 5,5′-azotetrazolate, especially $Pb_2(OH)_2C_2N_{10}$, which consists of PbO ladders with a pyramidal coordination of the lead atom,[6] have been used as initiators.[7] Anhydrous sodium and potassium 5,5′-azotetrazolate are very sensitive to shock and friction.[5e,7f] 1,1′-Dimethyl-5,5′-azotetrazole, first studied by Stolle,[8] has been used as an additive in solid rocket propellants.[9] Although some of the alkali- and alkaline earth metal salts of 5,5′-azotetrazolate have been known since 1898, no data on these compounds have been reported. We therefore investigated these salts as potential initiators. We also investigated the 5,5′-azotetrazolate salts of trivalent and tetravalent cations. All 5,5′-azotetrazolate salts include water of crystallisation. We also examined the thermal properties of the compounds and determined the temperatures of water loss. For a better understanding of the decomposition of 5,5′-azotetrazolate we synthesized the free acid 5,5′-azotetrazole. The tetraphenylarsonium salt and the covalent 2,2′-dimethyl-5,5′-azotetrazolate were synthesized to investigate 5,5′-azotetrazolate units that have no interactions with cations in the solid state. The quality of all elemental analyses suffers because of the difficulty of obtaining correct values for compounds with extremely high nitrogen content.[9]

Results and Discussion

Syntheses and properties

Sodium 5,5′-azotetrazolate (**2**) was used as starting material and was synthesized according to Thiele [see Equation (1)].[1d] Strontium (**8**) and barium 5,5′-azotetrazolate (**9**) were prepared from solutions of **2** and the respective

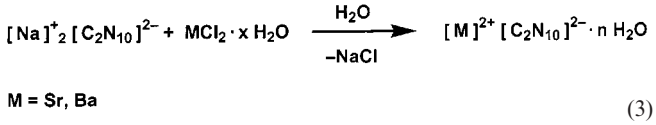
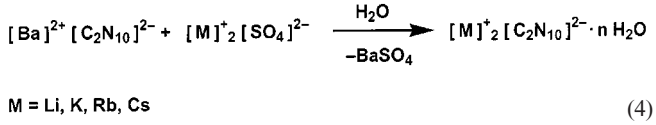
metal chlorides [Equation (3)]. Both compounds are almost insoluble in water and precipitated after the solutions were mixed.

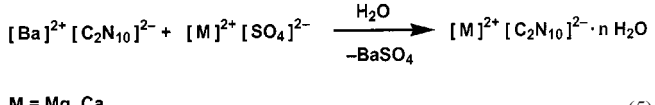


(3)

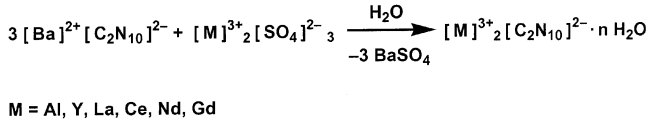
All other metal salts were obtained from the respective metal sulfates and barium 5,5-azotetrazolate [Equation (4)−(6)]. After barium sulfate had been filtered off and the water evaporated, yellow crystals of the salts were obtained. During the reaction of $Ce(SO_4)_2$ with barium 5,5′-azotetrazolate (**9**) a gas was evolved and no 5,5′-azotetrazolate salt of Ce^{IV} could be isolated. The Ce^{III} salt **13** does not show this decomposition.



(4)



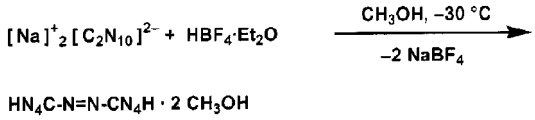
(5)



(6)

All compounds contain water of crystallisation (see Table 1). For the heavier elements the deviation of the elemental analysis is too big to calculate the exact number of water molecules present. During storage all compounds lose water; this takes place over a period of hours for the lithium **1** and potassium salt **3** as well as the salts of the trivalent cations **10**−**15**. The water loss from the other compounds takes between days and weeks. Upon loss of water, the salts of the trivalent cation **10**−**15** decompose to colourless substances. The magnesium salt **6** shows a similar behaviour. This decomposition is the reason for the low yields in the syntheses of these compounds, and it occurs due to the acidity of the metal-water complexes of the trivalent cations [cf. the decomposition of 5,5′-azotetrazolate in acidic medium, Equation (1)].

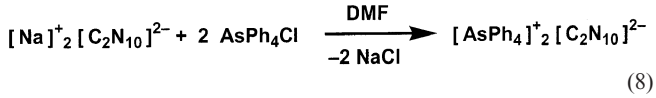
The free acid 5,5′-azotetrazole **16** was synthesized from the sodium salt **1** and $HBF_4{\cdot}Et_2O$ at −30 °C in methanol [Equation (7)] in order to gain an insight into its decomposition.



(7)

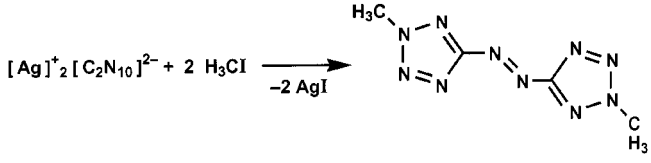
A crystal structure analysis showed the presence of two methanol molecules. The free acid is a yellow solid that can be stored for several months at −80 °C without decomposition.[10] At 0 °C, however, it decomposes in an hour to form tetrazolhydrazine, and at room temperature this decomposition takes only a few seconds.

Tetraphenylarsonium 5,5′-azotetrazolate (**17**) was synthesized from the sodium salt **2** and tetraphenylarsonium chloride [Equation (8)]. The cations in this compound do not interact with the 5,5′-azotetrazole units.



(8)

We also synthesized 2,2′-dimethyl-5,5′azotetrazolate from silver 5,5′-azotetrazolate and iodomethane [Equation (9)].



(9)

NMR Properties

The ^1H NMR spectrum of **1** shows water at δ = 4.1; the carbon atom of the 5,5′-azotetrazolate ion appears in the ^{13}C NMR spectrum at δ = 173.1. The ^{14}N NMR spectrum of **1** in [D_6]DMSO displays no absorptions: only very concentrated solutions in D_2O (sample amount 3.5 g) show absorptions. The same sample was used for the recording of a ^{15}N NMR spectrum. Figure 1 shows the broad ^{14}N NMR

Table 1. Numbering scheme for metal salt hydrates of 5,5′-azotetrazolate

1	**2**	**3**	**4**	**5**
$Li_2[C_2N_{10}](H_2O)_6$	$Na_2[C_2N_{10}](H_2O)_5$	$K_2[C_2N_{10}](H_2O)_5$	$Rb_2[C_2N_{10}](H_2O)$	$Cs_2[C_2N_{10}](H_2O)_2$
6	**7**	**8**	**9**	**10**
$Mg[C_2N_{10}](H_2O)_8$	$Ca[C_2N_{10}](H_2O)_8$	$Sr[C_2N_{10}](H_2O)_6$	$Ba[C_2N_{10}](H_2O)_5$	$Al_2[C_2N_{10}]_3(H_2O)_x$
11	**12**	**13**	**14**	**15**
$Y_2[C_2N_{10}]_3(H_2O)_{22}$	$La_2[C_2N_{10}]_3(H_2O)_x$	$Ce_2[C_2N_{10}]_3(H_2O)_x$	$Nd_2[C_2N_{10}]_3(H_2O)_x$	$Gd_2[C_2N_{10}]_3(H_2O)_x$

signals (due to the quadrupole moment of ^{14}N)[11] in comparison to the sharp signals in the ^{15}N NMR spectrum.

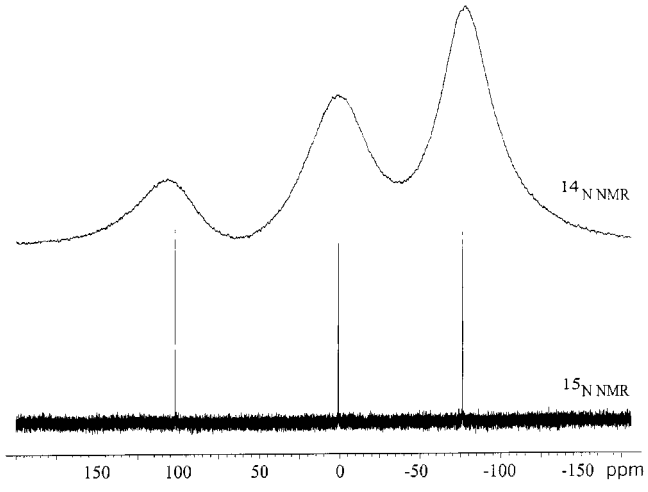


Figure 1. $^{14/15}N$ NMR spectra of **2**

The signal of the C−N nitrogen atoms of the tetrazole ring system appears at δ = 2/0.6 ($^{14}N/^{15}N$), and the signal of the other two tetrazole nitrogen atoms at δ = −77/−76.2 ($^{14}N/^{15}N$). The diazo nitrogen signal appears at δ = 105/102.0 ($^{14}N/^{15}N$). Since the ^{1}H and ^{13}C NMR spectrum are the same for all 5,5′-azotetrazolate salts and the sample amount needed to record a ^{14}N NMR spectrum is very high, the NMR spectra of the other salts were not recorded. The signals of the tetraphenylarsonium salt **17** in the ^{1}H and ^{13}C NMR spectra have the same chemical shifts as for the starting material. The signal of the methyl group of dimethylated **18** in the ^{1}H NMR is found at δ = 4.47 (^{13}C: δ = 40.5), with the NH signal of the acid **16** at δ = 5.68. The signals of the azotetrazolate carbon atoms of **16** and **18** are shifted to higher field than in the ionic compounds [δ = 168.6 (**16**) and 171.5 (**18**)]. No absorptions were detected in the ^{14}N NMR spectra of **16** and **18**, the same as for the ionic compounds.

Vibrational Spectra

The most intense absorptions in the IR spectra (see Table 2) are an asymmetrical $C-N_3$ stretching mode around 1390 cm^{-1} and an asymmetrical $C-N_2$ stretching mode around 735 cm^{-1}. For several compounds two bands are detected in this region. In the Raman spectra the most intense bands are a symmetrical $C-N_{azo}$ stretching mode around 1384 cm^{-1} and the N−N stretching mode of the diazo group around 1480 cm^{-1}. Again, for several compounds two signals are observed for these modes. The $C-N_{azo}$ stretching mode and the N−N stretching mode of the covalent compounds **16** and **18** are shifted slightly to higher wavenumbers relative to the 5,5′-azotetrazolate salts. Some absorptions were assigned according to a calculation of the 5,5-azotetrazolate dianion at the B3LYP level of theory,[5d] although, due to the large number of combination modes, especially in the IR spectra, not all modes could be assigned.

Table 2. Characteristic data for 5,5′-azotetrazolate salts (wavenumbers in cm^{-1}, Temperatures and DSC peaks in °C)

18	1375	1503, 1393	170	–

Thermal Properties

The temperature for the loss of different water molecules depends on their coordination. DSC measurements (Table 2) show endotherms at temperatures between 41 °C and 144 °C. Compounds that have water molecules bound by hydrogen bonds lose these water molecules faster than those with the water molecules included in the coordination sphere of the cation. Slow heating (1 °C/min) of the alkali- and alkaline earth metal salt hydrates results in an explosion at a specific decomposition temperature. The lithium salt **1** has the highest decomposition temperature of 335 °C. The other alkali and alkaline earth metal salts have decomposition temperatures in the range between 211 °C and 248 °C, with the barium salt **9** having the lowest decomposition temperature. The salts of the trivalent cations decompose slowly at temperatures higher than room temperature: the tetraphenylarsonium salt **17** decomposes slowly at temperatures higher than 180 °C and the dimethylated **18** explodes at170 °C. It is not possible to dry the compounds at higher temperatures in vacuo. All attempts resulted in explosions.

Crystal Structures

The bonding parameters of the 5,5′-azotetrazolate anions in **1**, **2**, **4**, **7**, **9**, **11** and **15** are very similar (see Table 3) and are in agreement with the theoretical values calculated at the B3LYP/6-31+G(2df) level of theory. In the reported

structure of dihydroxylead 5,5′-azotetrazolate[6] the N−N bond length of the diazo group is 1.20(3) Å shorter, otherwise the bonding parameters agree with the new structures.

The 5,5′-azotetrazolate ions of the lithium salt **1** are connected to water molecules through seven hydrogen bonds (see Figure 2). N(21) and N(12) are not connected to other molecules; N(52) is coordinated to a lithium ion. All other nitrogen atoms take part in hydrogen bonding to the water molecules. The hydrogen bonds to the ring nitrogen atoms have O−N distances of between 2.783(2) and 2.830(3) Å. The hydrogen bond to the N(11) nitrogen atom of the diazo group is, at 3.188(3) Å, longer. There are also hydrogen bonds between water molecules, with O−O distances of between 2.700(2) and 2.778(2) Å.

Compound **1** contains two different lithium atoms with tetrahedral coordination (Figure 3). The Li(2) atom is surrounded only by water molecules, whereas the Li(1) atom is coordinated to three water molecules and the N(52) nitrogen atom. Lithium has been reported to show tetrahedral, octahedral and sometimes fivefold coordination when surrounded by oxygen atoms.[12] The lithium-oxygen distances [1.910(4) to 1.980(4) Å] compare well with the reported values of 1.94−1.99 Å for tetrahedrally coordinated lithium ions. The lithium-nitrogen distance [2.077(4) Å] is also in the expected range (2.06−2.08 Å).[13] The coordination tetrahedra of two Li(2) atoms share an edge with each other and a corner with the coordination tetrahedron of Li(1) atom. The O(96) oxygen atom is not coordinated to a lithium ion, although it is bound by hydrogen bonds. The weak bonding of the O(96) oxygen atom explains the rapid loss of water from **1**.

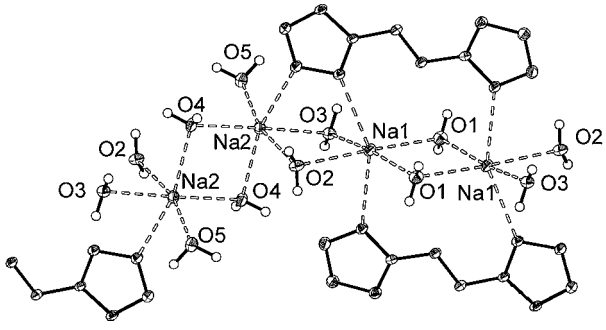

Figure 5. Coordination of the sodium ions in **2** (thermal ellipsoids represent 25% probability); parts of the 5,5′-azotetrazolate ions have been omitted for clarity

The 5,5′-azotetrazolate ions of **2** are coordinated to three sodium ions and eight water molecules (4). The hydrogen bonds have O−N distances of between 2.776(3) and 3.342(3) Å, the longest distances belonging to the bridging hydrogen bonds of the hydrogen atoms of O(3) with N(21) and N(31). The O−N distance to the N(12) nitrogen atom of the diazo group is also longer, and there is only one hydrogen bond between water molecules [O−O distance 2.826(3) Å].

The sodium ions in **2** have different surroundings (Figure 5). They all have a distorted octahedral coordination geometry, with the Na(1) atom connected to four water molecules and the N(22) and N(51) nitrogen atoms, and the Na(2) atom to five water molecules and the N(32) nitrogen atom. The Na−O distances [2.369(2) and 2.483(2) Å][14] as well as the Na−N distances [2.456(2) to 2.556(3) Å][15] are in the expected range. The coordination octahedra of the sodium ions are connected edgewise. The aquated sodium ions form chains, and the 5,5′-azotetrazolate ions form stacks between these chains.

Compound **4** has an inversion centre (Figure 6) and the water molecules are hydrogen bonded to the N(3) and N(4)

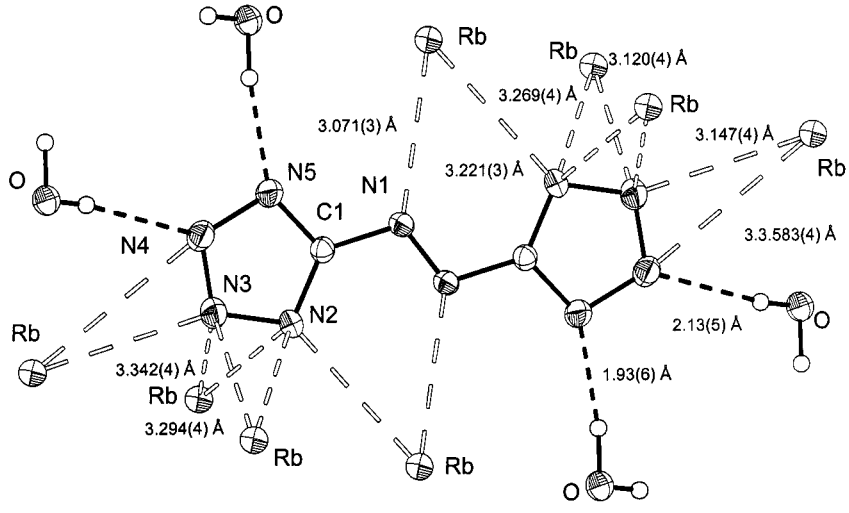

Figure 6. Coordination of the 5,5′-azotetrazolate ions in **4** (thermal ellipsoids represent 25% probability); selected bond lengths [Å]: Rb−O 2.964(3), Rb−O(B) 3.080(3), Rb−O(D) 3.125(3), Rb−O(F) 3.080(3), Rb−N(1A) 3.071(3), Rb−N(2) 3.221(3), Rb−N(2B) 3.294(4), Rb−N(2C) 3.269(4), N(2)−Rb(F) 3.294(3), Rb−N(3B) 3.342(4), Rb−N(3C) 3.120(4), Rb−N(3E) 3.147(4), N(3)−Rb(F) 3.342(4), Rb−N(4E) 3.583(4); symmetry operations for equivalent atoms: A: $-x + 1, -y + 1, -z + 1$; B: $x + 1, y, z$; C: $-x + 1, -y + 1, -z + 2$; D: $-x + 1, -y, -z + 2$; E: $-x, -y + 1; -z + 2$; F: $x - 1, y, z$; hydrogen bonds: O−N distances [Å] (OHN angles [°]), N···H distances are given in the figure: O−H(1)···N(5) 2.875(4) [161(5)], O−H(2)···N(4) 2.823(5) [172(6)]

nitrogen atoms [O−N distances 2.875(4) and 2.823(5) Å]. The 5,5′-azotetrazolate ions are coordinated to eight rubidium ions, with every nitrogen atom either being hydrogen bonded to a water molecule or coordinated to rubidium.

The rubidium ions in **4** are tenfold coordinated to three oxygen atoms and seven nitrogen atoms (Figure 7). The coordination polyhedra of the rubidium ions form face-sharing layers that are separated by layers of 5,5′-azotetrazolate ions. The Rb−O distances [2.964(3) to 3.125(3) Å][16] and the Rb−N distances [3.071(3) to 3.583(4) Å][17] agree with literature values.

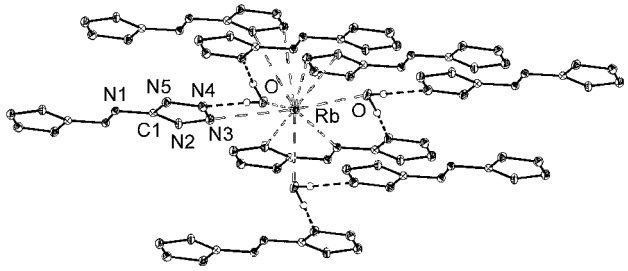

Figure 7. Coordination of the rubidium ions in **4** (thermal ellipsoids represent 25% probability); parts of the 5,5′-azotetrazolate ions have been omitted for clarity

The calcium ions of **7** are not coordinated to any nitrogen atoms (Figure 8). They are surrounded by eight water molecules in the form of a slightly distorted, bi-capped trigonal prism. Two coordination polyhedra share an edge. The bridging water molecules have longer Ca−O distances [2.613(2) and 2.639(2) Å] than the other water molecules [2.369(2) to 2.480(2) Å]. Calcium coordinated by eight water molecules is well-known in the literature, and the distances of the bridging and nonbridging oxygen atoms found here agree well with the previously reported values.[18] One water molecule is not connected to calcium but is hydrogen bonded to the other water molecules and to the 5,5′-azotetrazolate ions. The 5,5′-azotetrazolate ions have hydrogen bonds to eleven water molecules [O−N distances 2.787(3) to 3.226(3) Å].

The 5,5′-azotetrazolate ions of **9** are connected to six water molecules with hydrogen bonds to the N(2) and N(3) nitrogen atoms [Figure 9; O−N distances 2.791(4) to 3.158(5) Å]. The N(4) and N(5) nitrogen atoms are coordin-

Figure 8. Figure 9. Structure of **9** (thermal ellipsoids represent 25% probability); selected bond lengths [Å]: Ba−O(92) 2.799(6), Ba−O(93) 2.840(3), Ba−O(93) 2.867(3), Ba−N(4) 3.046(4), Ba−N(5) 2.935(4); hydrogen bonds: O−N and O−O distances [Å] (OHN/OHO angles [°]), N···H distances are given in the figure: O(91)−H(911)−N(3) 2.834(6) [162(6)], O(91)−H(912)−N(2) 3.158(5) [124(5)], O(93)−H(932)−N(2) 2.791(4) [171(6)], O(92)−H(92)−O(91) 2.823(6) [167(10)], O(93)−H(931)−O(91) 2.873(4) [168(7)]

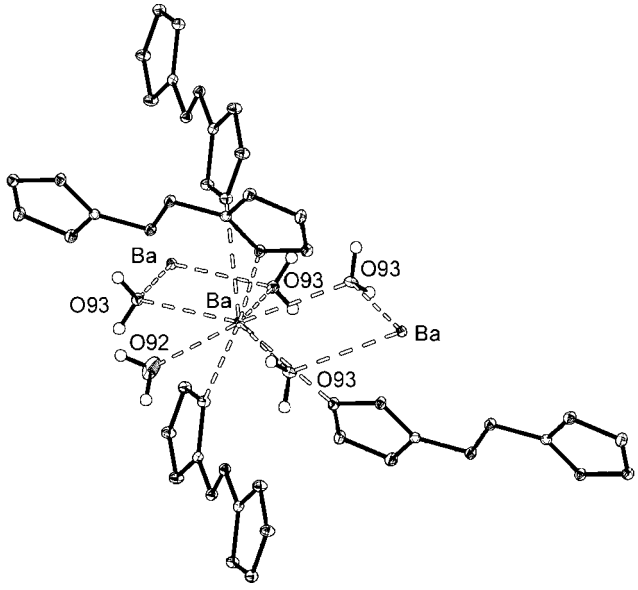

Figure 10. Coordination of the barium ions in **9** (thermal ellipsoids represent 25% probability); parts of the 5,5′-azotetrazolate ions have been omitted for clarity

ated to barium. The O(91) water molecule is not coordinated to barium, but has hydrogen bonds to the O(93) and O(92) oxygen atoms [O−O distances 2.283(6) to 2.873(4) Å], which are themselves coordinated to barium.

The barium atoms of **9** are coordinated to five water molecules and four nitrogen atoms to form a distorted, capped quadratic antiprism (Figure 10). The coordination polyhedra share faces. The Ba−O [2.799(6) to 2.867(3) Å] and Ba−N [2.935(4) and 3.046(4) Å] bond lengths agree with the values for barium azide hydrate.[19] The structure consists of layers of hydrated barium atoms and a layer of stacks of 5,5′-azotetrazolate ions. The layers are connected by Ba−N interactions, explaining the greater insolubility of this compound compared to the calcium salt **7**. The insolubility of the strontium salt is probably also due to Sr−N interactions.

Compound **11** contains two different 5,5′-azotetrazolate ions, one with and one without an inversion centre (Figure 11). The bonding parameters of the two ions are identical within the standard deviation (see Table 3, **11a** and **11b**). The yttrium ions of **11**, like the calcium ions of **7**, are coordinated to eight water molecules in the form of a threefold capped, trigonal prism. In contrast to **7**, however, the coordination polyhedra are not connected. The Y−O distances [2.322(2) to 2.450(2) Å] agree with those of known compounds.[20] Three further water molecules are bound with hydrogen bonds. The O−N distances of the hydrogen bonds between the water molecules and the ring nitrogen atoms of the 5,5′-azotetrazolate ions [2.722(3) and 2.973(3) Å] are shorter than the hydrogen bonds to the diazo nitrogen atoms [3.323(3) and 3.376(3) Å]. The hydrogen bonds between the water molecules have O−O distances of between 2.683(3) and 2.975(3) Å.

The bonding parameters of the tetraphenylarsonium ions of **17** agree with the literature data.[21] The cations have no interactions with the 5,5′-azotetrazolate ions. Figure 12 shows stacks of 5,5′-azotetrazolate ions between the tetraphenylarsonium ions. The orange colour of **17** and **18**, in contrast to the yellow colour of all the other compounds, is probably due to the lack of interactions with the 5,5′-azotetrazolate unit.

Figure 11. Figure 12. Stacks of 5,5′-azotetrazolate ions in **17**

The bonding parameters of **18** are in good agreement with the bonding parameters of 2-methyl-5-aminotetrazole.[22] As in **17**, the 5,5′-azotetrazole units form stacks (Figure 13).

Conclusion

Salts of the 5,5′-azotetrazole dianion with different metal cations were examined. These salts include different amounts of water molecules that are either in the coordination sphere of the cation or bound by hydrogen bonds. The azotetrazolate ion is not connected to harder cations (calcium, yttrium), and these salts decompose, due to their acidity in water, to form tetrazolhydrazine, with evolution of nitrogen. The free acid 5,5′-azotetrazole, which was synthesized from sodium 5,5′-azotetrazolate and HBF_4 decomposes within seconds at room temperature, but can be handled at −30 °C. The loss of water from the 5,5′-azotetrazolate salts occurs at different temperatures depending on how the water molecule is bound in the compound. Upon loss of water, the sensitivity of the compounds toward shock and friction increase drastically. During drying under dynamic vacuum many explosions occurred.

Experimental Section

CAUTION: While all hydrates of 5,5′-azotetrazolate salts are insensitive to shock and friction, the anhydrous 5,5′-azotetrazolate salts and silver 5,5′-azotetrazolate are very sensitive. Safety equipment such as leather gloves, face shields and ear plugs are necessary.

General Remarks: All chemicals were used as provided from the chemical store of the Department of Chemistry. Silver 5,5′-azotetrazolate was prepared from sodium 5,5′azotetrazolate (**2**) and silver nitrate.[1d] NMR: Jeol EX 400, ^{1}H (400.0 MHz), ^{13}C (100.0 MHz): chemical shifts referenced to TMS δ = 0.00; ^{14}N (28.6 MHz), ^{15}N (40.5 MHz): shifts referenced to external CH_3NO_2. IR: Nicolet 520 FT−IR (as KBr pellets). Raman: Perkin−Elmer FTIR−2000 spectrometer (Nd−Yag Laser:

1064 nm, Laser power: 100 mW). CHN analyses: Elementar Vario EL analysator. DSC: Setaram DSC 141. TG: Setaram DTA−TG 92. MS: Balzers QMS 420.

General Procedure: Sodium 5,5′-azotetrazolate (**2**) was prepared following a literature synthesis.[1d] Barium (**9**) and strontium 5,5′-azotetrazolate (**8**) were synthesized by adding the respective chloride to a solution of sodium 5,5′-azotetrazolate (**2**). After stirring for 30 minutes a yellow precipitate was separated and recrystallized from water. All other 5,5′-azotetrazolate salts were obtained from the reaction of barium 5,5′-azotetrazolate (**9**) with the respective metal sulfates in water. After stirring for 30 minutes a yellow solution was obtained after filtration. The water was allowed to evaporate from this solution to give respective 5,5′-azotetrazolate salts as yellow crystals that were then recrystallized from water.

Lithium 5,5′-Azotetrazolate Hexahydrate (1): Yield: 92%. $T_{Dec.}$ = 335 °C. DSC: 64.0 °C (44.0 J/g), 109.2 °C (25.0 J/g), 133.9 °C (581.9 J/g). IR: $\tilde{\nu}$ = 3425 cm^{-1} m, 3183 m, 1625 w, 1399 s, 1211 m, 1180 m, 1096 m, 1046 m, 891 m, 760 m, 733 s, 693 m, 602 w, 564 w. Raman: $\tilde{\nu}$ = 1484 cm^{-1} m, 1420 w, 1387 s, 1108 m, 1080 w, 926 w, 111 w. $C_2H_{12}Li_2N_{10}O_6$ (286.06): calcd. C 8.4, H 4.2, N 49.0; found C 11.6, H 4.1, N 82.6.

Sodium 5,5′-Azotetrazolate Pentahydrate (2): $T_{Dec.}$ = 248 °C. DSC: 115.6 °C (355.5 J/g), 159.3 °C (306.1 J/g). ^1H NMR ([D$_6$]DMSO): δ = 4.1 (H_2O). ^{13}C NMR ([D$_6$]DMSO): δ = 173.1 ([$N_4C-N=N-CN_4$]$^{2-}$). ^{14}N NMR (D_2O): δ = −77 (CN_β), 2 (CN_α), 105(-*N*=*N*-). ^{15}N NMR (D_2O): δ = −76.2 (CN_β), 0.6 (CN_α), 101.8 (-*N*=*N*-). IR: = $\tilde{\nu}$ = 3612 cm^{-1} s, 3544 s, 3435 s, 3389 s, 3248 s, 2443 w, 2257 w, 2216 w, 2152 w, 2106 m, 1685 m, 1628 s, 1401 s, 1165 m, 1096 w, 1082 w, 1065 m, 1044 m, 776 s, 741 s, 732 s, 566 s, 526 s, 398 s. Raman: $\tilde{\nu}$ = 1480 cm^{-1} m, 1420 w, 1386 s, 1088 m, 1058 m, 926 w, 383 w, 223 w, 123 w. $C_2H_{10}N_{10}Na_2O_5$ (300.14): calcd. C 8.0, H 3.4, N 46.7; found C 8.1, H 3.3, N 46.6.

Potassium 5,5′-Azotetrazolate Pentahydrate (3): Yield: 93%. $T_{Dec.}$ = 243 °C. DSC: 40.5 °C (49.1 J/g), 107.5 °C (70.1 J/g), 144.1 °C (326.3 J/g). IR: $\tilde{\nu}$ = 3647 cm^{-1} m, 3265 w, 2921 m, 2851 w, 2415 m, 2355 m, 2319 m, 2097 m, 1960 w, 1668 w, 1488 w, 1447 m, 1390 m, 1380 m, 1185 m, 1153 m, 1058 w, 1033 w, 866 m, 846 m, 822 m, 772 m, 727 s, 667 m. Raman: $\tilde{\nu}$ = 1482 cm^{-1} m, 1416 w, 1378 s, 1189 w, 1155 w, 1079 w, 1065 w, 1053 w, 1041 w, 925 w, 736 w, 340 w, 104 w. $C_2H_{10}K_2N_{10}O_5$ (278.32): calcd. C 7.2, H 3.0, N 42.1; found C 7.5, H 2.6, N 42.8.

Rubidium 5,5′-Azotetrazolate Dihydrate (4): Yield: 90%. $T_{Dec.}$ = 239 °C. DSC: 96.9 °C (200.5 J/g). IR: $\tilde{\nu}$ = 3440 cm^{-1} s. 3281 s, 2550 w, 2509 w, 2442 w, 2103 w, 2062 w, 1981 w, 1887 w, 1791 w, 1710 m, 1519 w, 1453 w, 1395 m, 1292 w, 1199 w, 1156 m, 1073 w, 1056 w, 1033 m, 933 w, 847 w, 773 w, 736 m, 666 m, 565 m. Raman: $\tilde{\nu}$ = 1494 cm^{-1} s, 1418 w, 1386 s, 1361 w, 1200 w, 1155 w, 1082 m, 1059 m, 1036 w, 924 w, 348 w, 104 w. $C_2H_4N_{10}O_2Rb_2$ (371.05): calcd. C 6.4, H 1.1, N 37.7; found C 6.4, H 0.9, N 38.0.

Caesium 5,5′-Azotetrazolate Dihydrate (5): Yield: 91%. $T_{Dec.}$ = 237 °C. DSC: 40.3 °C. IR: $\tilde{\nu}$ = 3314 cm^{-1} m, 3244 m, 2924 s, 2853 m, 1742 w, 1593 w, 1463 w, 1389 m, 1382 m, 1195 w, 1179 w, 1146 w, 1064 w, 1052 w, 1039 w, 773 w, 728 s, 661 w, 559 w. Raman: $\tilde{\nu}$ = 1494 cm^{-1} s, 1467 w, 1413 w, 1381 s, 1356 w, 1313 w, 1197 w, 1154 w, 1080 w, 1068 m, 1057 m, 1035 w, 923 w, 340 w, 98 w. $C_2H_4Cs_2N_{10}O_2$ (465.93): calcd. C 5.2, H 0.9, N 30.1; found C 5.3, H 0.8, N 29.9.

Magnesium 5,5′-Azotetrazolate Octahydrate (6): Yield: 15%. $T_{Dec.}$ = 231 °C. IR: $\tilde{\nu}$ = 3256 cm^{-1} s, 2881 w, 2832 w, 1668 m, 1639 m, 1529 w, 1428 w, 1393 m, 1386 m, 1323 w, 1199 w, 1053 w, 767 w, 736 m, 657 m. Raman: $\tilde{\nu}$ = 1499 cm^{-1} m, 1452 w, 1416 w, 1375 s, 1200 w, 1086 w, 1062 m, 932 w, 112 w. $C_2H_{16}MgN_{10}O_8$ (332.5): calcd. C 7.2, H 4.8, N 42.1; found C 7.5, H 4.4, N 34.3.

Calcium 5,5′-Azotetrazolate Octahydrate (7): Yield: 74%. $T_{Dec.}$ = 221 °C. IR: $\tilde{\nu}$ = 3513 cm^{-1} s, 3425 s, 3250 s, 2950 s, 2925 s, 2850 s, 2251 w, 2093 w, 1659 m, 1619 m, 1510 w, 1463 w, 1398 s, 1375 m, 1201 m, 1193 w, 1063 m, 1042 w, 943 w, 821 w, 772 w, 734 m, 672 w, 614 w, 563 w, 444 w. Raman: $\tilde{\nu}$ = 1496 cm^{-1} m, 1479 w, 1435 w, 1416 w, 1394 s, 1377 s, 1202 w, 1089 w, 1070 s, 1051 w, 929 w, 336 w, 143 w. $C_2H_{16}CaN_{10}O_8$ (348.29): calcd. C 6.9, H 4.6, N 40.2; found C 6.6, H 4.4, N 40.2.

Strontium 5,5′-Azotetrazolate Hexahydrate (8): Yield: 80%. $T_{Dec.}$ = 238 °C. DSC: 76.2 °C (51.7 J/g), 130.3 °C (132.7 J/g), 139.3 °C (285.6 J/g). IR: $\tilde{\nu}$ = 3378 cm^{-1} s, 3225 s, 2967 m, 2926 m, 2844 m, 2439 m, 1651 m, 1468 wm 1396 m, 1384 s, 1258 w, 1203 w, 1161 w, 1083 w, 1068 w, 1039 w, 855 w, 802 w, 760 w, 734 w, 662 w, 554 w. Raman: $\tilde{\nu}$ = 1488 cm^{-1} m, 1420 w, 1382 s, 1203 w, 1165 w, 1094 m, 1071 m, 1042 w, 918 w, 336 w. $C_2H_{12}N_{10}O_6Sr$ (359.80): calcd. C 6.7, H 3.4, N 38.9; found C 6.7, H 3.2, N 38.6.

Barium 5,5′-Azotetrazolate Pentahydrate (9): Yield: 90%. $T_{Dec.}$ = 211 °C. DSC: 129.1 °C (265.2 J/g). IR: $\tilde{\nu}$ = 3401 cm^{-1} m, 3276 m, 3142 m, 2954 m, 2926 m, 2446 w, 2220 w, 2037 w, 1609 m, 1504 w, 1450 w, 1399 s, 1199 m, 1161 m, 1061 w, 1039 w, 805 m, 774 w, 735 m, 675 w, 562 m. Raman: $\tilde{\nu}$ = 1488 cm^{-1} m, 1428 w, 1391 s, 1365 w, 1163 w, 1090 w, 1068 m, 1044 w, 922 w, 357 w, 206 w, 111 w. $C_2H_{10}BaN_{10}O_5$ (391.49): calcd. C 6.1, H 2.6, 35.8 N; found C 6.3, H 3.0, N 35.3.

Aluminium 5,5′-Azotetrazolate Hydrate (10): IR: $\tilde{\nu}$ = 2956 cm^{-1} s, 2845 s, 2405 m, 2400 m, 2321 m, 1601 m, 1505 w, 1489 w, 1464 w, 1442 w, 1409 m, 1398 s, 1381 w, 1228 w, 1213 w, 1190 w, 1121 w, 1085 w, 950 w, 869 w, 797 m, 738 s, 725 m, 667 w, 613 w, 553 m. Raman: $\tilde{\nu}$ = 1488 cm^{-1} m, 1399 s, 1385 s, 1124 m, 1110 m, 1089 m, 931 w. $C_6Al_2N_{30}\cdot(16-18)H_2O$: found C 8.8, H 3.7, N 46.1.

Yttrium 5,5′-Azotetrazolate Docosahydrate (11): Yield: 24%. IR: $\tilde{\nu}$ = 3598 cm^{-1} m, 3542 m, 3191 s, 2391 m, 1649 m, 1629 m, 1448 w, 1403 s, 1207 m, 1172 w, 1083 w, 1061 w, 1043 w, 951 w, 770 s, 727 s, 667 s, 575 m. Raman: $\tilde{\nu}$ = 1487 cm^{-1} m, 1453 w, 1424 w, 1388 s, 1365 w, 1209 w, 1177 w, 1103 w, 1085 w, 1076 w, 1062 w, 926 w, 734 w, 356 w, 206 w, 124 w. $C_6H_{44}N_{30}O_{22}Y_2$ (1066.53): calcd. C 6.8, H 4.2, 40.2 N; found C 8.1, H 4.2, N 40.2.

Lanthanum 5,5′-Azotetrazolate Hydrate (12): IR: $\tilde{\nu}$ = 2954 cm^{-1} m, 2925 s, 2854 m, 2148 w, 1623 w, 1535 w, 1512 w, 1459 m, 1398 m, 1384 m, 1259 w, 1228 w, 1096 w, 1032 w, 968 w, 879 w, 799 w, 730 m, 630 w, 563 w. Raman: $\tilde{\nu}$ = 1479 cm^{-1} m, 1429 w, 1390 s, 1109 w, 1088 w, 1074 w, 931 w. $C_6N_{30}La_2\cdot(20-24)H_2O$: found C 6.1, H 3.8, N 34.7.

Cerium 5,5′-Azotetrazolate Hydrate (13): IR: $\tilde{\nu}$ = 3129 cm^{-1} m, 1624 m, 1550 w, 1529 w, 1452 w, 1408 m, 1394 m, 1361 m, 1208 w, 1184 w, 1169 w, 1048 m, 768 s, 743 s, 650 s, 627 s, 570 s. Raman: $\tilde{\nu}$ = 1478 cm^{-1} m, 1437 w, 1396 s, 1388 m, 1110 w, 1090 w, 1073 m, 1053 w, 934 w. $C_6N_{30}Ce_2\cdot(14-18)H_2O$: found C 6.8, H 2.8, N 36.6.

Neodymium 5,5′-Azotetrazolate Hydrate (14): IR: $\tilde{\nu}$ = 3138 cm^{-1} s, 2946 m, 2880 m, 2811 m, 2346 w, 2148 w, 1626 w, 1498 w, 1442 w, 1404 s, 1396 m, 1332 w, 1203 w, 1182 w, 1064 w, 771 m, 743 s, 730 m, 673 m. Raman: $\tilde{\nu}$ = 1477 cm^{-1} m, 1426 w, 1394 s, 1111 w, 1091 w, 1067 m, 929 w.

Gadolinium 5,5′-Azotetrazolate Hydrate (15): IR: $\tilde{\nu}$ = 3173 cm^{-1} m, 2894 w, 2146 w, 1656 w, 1541 s, 1454 s, 1416 m, 1345 m, 1221

w, 1049 w, 1022 w, 962 w, 941 w, 730 w, 681 m. Raman: $\tilde{\nu}$ = 2935 cm^{-1} w, 1488 m, 1477m, 1424 w, 1390 s, 1084 w, 1066 m, 967 w, 943 w, 680 w.

Reaction of $Ce(SO_4)_2$ with Barium 5,5′-Azotetrazolate: $Ce(SO_4)_2$ (1.00 g, 3.0 mmol) and barium 5,5′-azotetrazolate (1.81 g, 6.0 mmol) were stirred in 30 mL of water. During stirring gas evolved and a brown precipitate was formed.

5,5′-Azotetrazole-dimethanol (16): $HBF_4{\cdot}Et_2O$ (0.26 g, 1.6 mmol) was added to a suspension of sodium 5,5′-azotetrazolate (**2**; 0.17 g, 0.8 mmol) in methanol. After stirring for 2 h a yellow solution was formed. The solvent was then removed in vacuo at −30 °C to give yellow needles of **16**, which were dried under oil-pump vacuum at −30 °C. ^{1}H NMR (CD_3CN, −30 °C): δ = 3.34 (s, 6 H, CH_3), 5.68 (s, 4 H, NH, OH). ^{13}C NMR (CD_3CN, −30 °C): δ = 49.9 (CH_3), 168.6 ($[N_4C{-}N{=}N{-}CN_4]^{2-}$). IR: $\tilde{\nu}$ = 3518 cm^{-1} m, 3224 m, 2956 m, 2923 m, 2852 m, 1687 w, 1630 w, 1467 w, 1436 w, 1383 m, 1056 s, 735 m, 666 w. Raman (100 mW, −30 °C): $\tilde{\nu}$ = 2970 cm^{-1} w, 1542 m, 1483 s, 1463 w, 1361 m, 1208 m, 1122 w, 1061 w, 1003 w, 913 w, 785 w, 330 w, 180 w, 141 w, 101 w.

Bis-tetraphenylarsonium 5,5′-Azotetrazolate (17): Sodium 5,5′-azotetrazolate (**2**; 0.13 g (0.62 mmol) and tetraphenylarsonium chloride (0.52 g, 1.24 mmol) were stirred in 20 mL DMF for two weeks. The resulting orange solution was isolated by filtration, the DMF removed in vacuo, and the remaining orange crystals recrystallized from DMF. Yield: 435 mg (76%). ^{1}H NMR ([D$_6$]DMSO): δ = 7.77−7.92 (m, PhH). ^{13}C NMR ([D$_6$]DMSO): δ = 121.0 (C-As), 130.9 (C_α), 133.1 (C_β), 134.3 (C_γ). IR: $\tilde{\nu}$ = 3421 cm^{-1} m, 3158 m, 3085 m, 3047 m, 3011 m, 2228 m, 2189 w, 2158 w, 2130 s, 2101 w, 2037 m, 1998 s, 1660 m, 1578 m, 1480 s, 1438 s, 1373 m, 1338 m, 1308 m, 1282 w, 1184 m, 1171 w, 1162 w, 1081 s, 1022 w, 997 s, 931 w, 855 w, 752 s, 742 s, 723 m, 690 s, 612 w, 557 w, 521 w, 478 s, 467 s, 363 m, 351 m. Raman: $\tilde{\nu}$ = 3061 cm^{-1} m, 1578 m, 1466 m, 1397 m, 1361 s, 1019 m, 1001 m, 913 w, 672 m, 240 w, 108 w. $C_{50}H_{40}As_2N_{10}$ (930.76): calcd. C 64.52, H 4.3, N 15.0; found C 65.8, H 4.6, N 11.1.

2,2′-Dimethyl-5,5′-azotetrazole (18): Iodomethane (6.05 g, 4.1 mmol) was added to a suspension of silver 5,5′-azotetrazolate (0.50 g, 1.3 mmol) in 20 mL water. The reaction mixture was stirred for three days in a closed vessel. The unreacted iodomethane was then removed in vacuo, and the reaction mixture was extracted three times with chloroform and dried with magnesium sulfate. Recrystallisation from chloroform gave 89 mg (34%) of an orange solid. $T_{Dec.}$: 170 °C. ^{1}H NMR (CD_3CN): δ = 4.47 (s, 6 H, CH_3). ^{13}C NMR (CD_3CN): δ = 40.5 (CH_3), 171.5 ($[N_4C{-}N{=}N{-}CN_4]^{2-}$). IR: $\tilde{\nu}$ = 2928 cm^{-1} m, 2857 m, 2356 w, 2347 w, 1745 w, 1457 w, 1420 w, 1375 m, 1346 m, 1316 m, 1266 w, 1189 w, 1157 w, 1094 w, 1036 w, 831 w, 774 s, 701 w, 649 w, 569 m, 556 w, 532 w, 349 m, 326 w. Raman: $\tilde{\nu}$ = 2961 cm^{-1} w, 1503 s, 1433 m, 1393 s, 1354 s, 1277 w, 1235 w, 1196 m, 1102 w, 1014 m, 914 w, 713 w. $C_4H_6N_{10}$ (374.33): calcd. C 24.7, H 3.1, N 72.1; found C 25.0, H 3.0, 70.9 N.

X-ray Structure Determination: Data were collected with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). Data collection for **2** was performed on a Siemens P4 diffractometer, for **1**, **16** and **17** on a Stoe IPDS diffractometer equipped with an image-plate area detector and for **4**, **7**, **9** and **11** on a Nonius Kappa CCD diffractometer. All data refinement was performed using SIR97[23] and SHELXL-97.[24] Acquisition and refinement data are shown in Table 4.

Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-169910 (**1**), -169906 (**2**), -169907 (**4**), -169908 (**7**), -169911 (**9**), -169909 (**11**), -169912 (**17**), -169913 (**18**). Copies of the data can be obtained free of charge on application to CCDC, 12

Rhodium Mediated N−O Bond Formation

Helen M. Burke,[a] John F. Gallagher,[b] Maria T. Indelli,[c] Franco Scandola,[c] and Johannes G. Vos*[a]

Keywords: Rhodium / N ligands / Oxygen / Insertion / Crystal structure

Reaction of $[Rh(phen)_2Cl_2]Cl$ (phen = 1,10-phenanthroline) with the ligand 3,5-bis(pyridin-2-yl)-1,2,4-triazole (Hbpt) in H_2O at pH 9 gives rise to the formation of a single stable compound. Single-crystal X-ray analysis of this material reveals that in the product obtained an oxygen atom has been inserted between the $Rh(phen)_2$ moiety and the triazole ring of the bpt ligand yielding a compound of the type $[Rh(phen)_2(Obpt)](PF_6)_2 \cdot 0.767CH_3CN \cdot 0.28H_2O$. Insertion of oxygen in this manner has not been reported previously.

Introduction

A considerable amount of research has been dedicated to the study of ligand-bridged polynuclear transition metal complexes.[1] This particular class of complexes has been used as a basis for studying electron transfer processes with the aim of creating multicomponent systems (supramolecular systems) capable of effecting useful light- and/or redox-induced functions. Most of the initial systems developed incorporated ruthenium(II) polypyridine compounds, although systems incorporating other transition metals such as rhodium(III), osmium(II) and iridium(III) have also been investigated.[2−5]

We have recently started a systematic investigation into the photophysical properties of mixed ligand rhodium(III) complexes. These studies are aimed at achieving a better understanding of the way in which the excited states of rhodium(III) complexes are affected by the introduction of ligands other than polypyridyl ligands. In these studies the ligands investigated are based on substituted 1,2,4-triazole moieties. Through well-established synthetic routes both π accepting and σ donating groupings can be introduced and these triazole based ligands have been shown to promote interactions between metal centres in dinuclear structures via deprotonation of the triazole ring. As a result a wide range of both mononuclear and dinuclear complexes of ruthenium(II) and osmium(II) incorporating these ligands has been reported.[6] An additional interest in these ligands is due to their asymmetry, which allows for different coordination modes. Of particular interest are ligands such as 3,5-bis(pyridin-2-yl)-1,2,4-triazole (Hbpt) (for structure see Figure 1) for which mononuclear and dinuclear Ru^{II} and Os^{II} complexes have been reported.[5] Orthometallated Rh^{III} complexes with Hbpt and the related ligand 4-amino-3,5-bis(2-pyridyl)-4*H*-1,2,4-triazole ($bptNH_2$) have also been reported,[7−9] as have Rh^{I} complexes with the ligands Hbpt and $bptNH_2$.[10−11] In this paper we wish to report on a very unusual reaction product obtained when a rhodium(III) precursor is reacted with Hbpt. In the compound obtained an oxygen atom has inserted into the Rh^{III}-nitrogen bond. To the best of our knowledge this is the first time that such an insertion reaction has been observed.

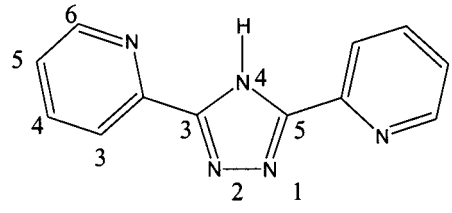

Figure 1. 3,5-bis(pyridin-2-yl)-1,2,4-triazole (Hbpt)

Results and Discussion

$[Rh^{III}$ bis(1,10-phenanthroline)$Cl_2]Cl$ was reacted with Hbpt in aqueous solution at pH 9. The product obtained was purified by column chromatography and precipitated

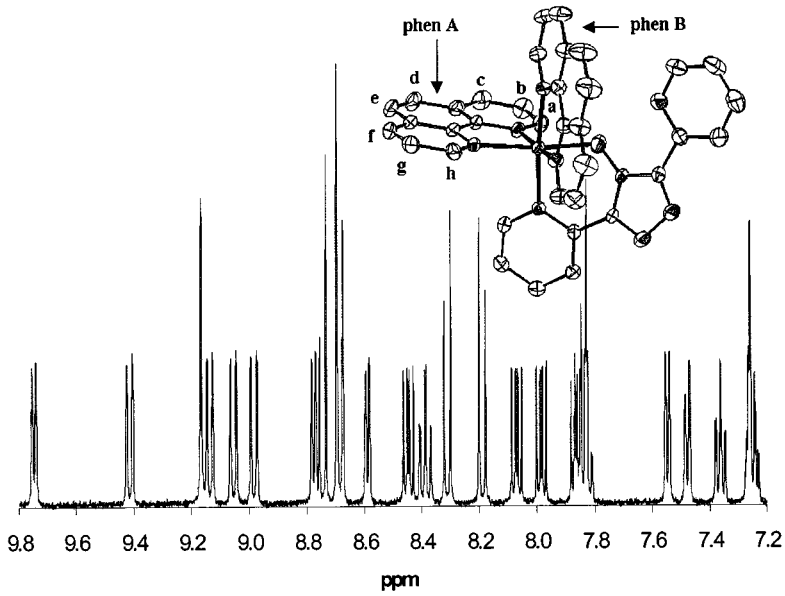

Figure 2. ^{1}H NMR spectrum $[Rh(phen)_2(Obpt)](PF_6)_2$ in $[D_6]$DMSO

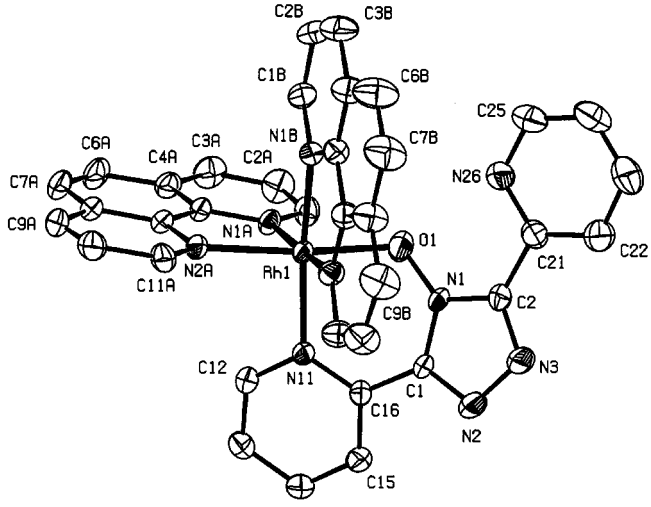

Figure 3. Molecular structure of the cation in $[Rh(phen)_2(Obpt)](PF_6)_2$; hydrogen atoms, counterions and the solvent molecules have been omitted for clarity

as a PF_6^- salt. NMR spectroscopy shows the presence of a single product (see Figure 2). Upon further recrystallisation of the product from acetonitrile/toluene (7:3) yellow needles were obtained. A single crystal X-ray investigation yielded the molecular structure, the cation of which is depicted in Figure 3. X-ray collection parameters are listed in Table 1 and selected bond lengths and angles are given in Table 2 and Table 3, respectively.

The most striking feature of the molecular structure is the presence of an oxygen atom between the metal centre and the triazole nitrogen atom. The rhodium centre is further surrounded by the two 1,10-phenanthroline ligands and the sixth coordination site is taken up by a pyridine ring of the bpt ligand. Two disordered PF_6^- counterions

and partial site occupancy acetonitrile (0.767) and water solvent molecules (0.28) complete the crystal structure (not depicted). The Rh−O bond length is 2.016(4) Å, in the range expected for Rh−O bond lengths. For example, in the diacetyl monooxime Rh^{III} complex reported by Moszner et. al., typical Rh−O bond lengths are 2.028Å and 2.023Å.[12] The N−O bond length is 1.406(6) Å and typical of an N−O single bond. The presence of the oxygen atom causes a substantial *trans* effect. The Rh−N distance *trans* to the oxygen atom is 2.105(4) Å, which is about 0.07 Å longer than the other three rhodium-nitrogen distances. A number of other rhodium polypyridyl crystal structures have been reported. Paul et al. have reported Rh−N bond lengths of 1.990(5), 2.059(5) and 2.036(5) Å in a rhodium(II) complex with the ligand 2,4,6-tris(2-pyridyl)-1,3,5-triazine and bond lengths of 2.027(10), 2.031(10), 2.083(9) and 2.071(9) Å were found by Brewer et al. in the case of the rhodium(III) complex with the ligand 2,3-bis(2-pyridyl)quinoxaline.[13,14] The X-ray structure of a ruthenium(II) complex with the ligand Hbpt has also been reported.[15]

The NMR spectrum shown in Figure 2 clearly indicates the presence of only one species, indicative of the absence of linkage isomers. This is in contrast with the behaviour of most common triazole complexes.[16,17] 2-D COSY spectroscopic techniques were used to assign the ^1H resonances where possible. The doublets observed at $\delta = 9.75$ and 9.42 can be attributed to the protons at positions **a** and **c** of the phenanthroline ring **A** respectively. These resonances are downfield with respect to the resonances observed for the equivalent protons in the $[Rh(phen)_3]^{3+}$ complex and this can be attributed to the influence of the oxygen in the rhodium complex.[18] The source of the singlet at $\delta = 9.17$ has yet to be determined. Deuteration of the $[Rh(phen)_2(Obpt)](PF_6)_2$ is currently being undertaken in order to unambiguously assign all of the resonances.

The emission spectrum obtained at 77 K in a 4:1 ethanol/methanol glass for $[Rh(phen)_2(Obpt)](PF_6)_2$ can be seen in Figure 4. This structured emission, with maxima at 453 nm, 482 nm and 513 nm, is typical of ligand-centred (LC) phosphorescence of rhodium(III) phenanthroline complexes.[19] This indicates that the lowest LC excited state in this heteroleptic complex lies on the phen ligands.

An insertion of oxygen, as observed in this case, has not been reported previously. The only slightly related compound reported in the literature is a Rh^I complex with the ligand $bptNH_2$.[11] In the complex [Rh(NHbpt)(diolefin)], where the diolefin is for example 2,2,2-octatriene, NMR spectroscopy and elemental analysis suggest that an isoelectronic Rh−NH−N-triazole bond is formed. The mechanism responsible for the formation of $[Rh(phen)_2(Obpt)](PF_6)_2$ can at present only be tentatively formulated. The fact that the reaction described here is carried out in basic solution may indicate that a rhodium hydroxy intermediate is formed by replacement of the chloride atom by water and subsequent deprotonation [Equation (1)]. Interaction between the OH group and the triazole ring may then result in the formation of the N−O bond. In order to account for the oxidative nature of this step, a likely mechanism is the formation of an intermediate Rh^I complex [Equation (2)] which is subsequently reoxidised by oxygen [Equation (3)]. The overall reaction would then amount to a rhodium-mediated oxidation of the ligand by molecular oxygen [Equation (4)].

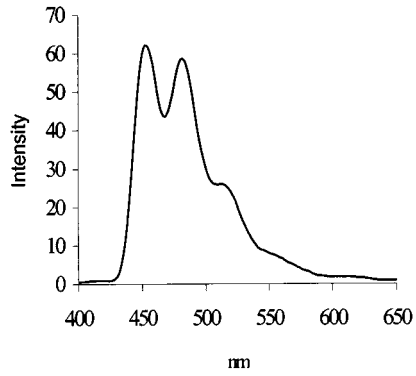

Figure 4. Emission spectra of $[Rh(phen)_2(Obpt)](PF_6)_2$ obtained in an ethanol/methanol 4:1 glass at 77 K

$$[Rh^{III}(phen)_2Cl_2]^+ + Hbpt + H_2O \rightarrow [Rh^{III}(phen)_2(OH)bpt]^+ + 2H^+ + 2Cl^- \quad (1)$$

$$[Rh^{III}(phen)_2(OH)bpt]^+ \rightarrow [Rh^{I}(phen)_2(Obpt)] + H^+ \quad (2)$$

$$[Rh^{I}(phen)_2(Obpt)] + 2H^+ + 1/2O_2 \rightarrow [Rh^{III}(phen)_2(Obpt)]^{2+} + H_2O \quad (3)$$

$$[Rh^{III}(phen)_2Cl_2]^+ + Hbpt + 1/2O_2 \rightarrow [Rh^{III}(phen)_2(Obpt)]^{2+} + 2Cl^- + H^+ \quad (4)$$

Interestingly no *N*-hydroxytriazoles have been reported in the literature. The formation of this N−O bond is therefore clearly dependent on the presence of the rhodium centre. Recently the formation of Rh^I−O−C bond via a Rh-hydroxy intermediate has been reported for the compound $[C_5(CH_3)_5]RhO(C_6F_4)CF_2]$.[20]

Conclusion

The reaction product reported upon reaction of $[Rh(phen)_2Cl_2]Cl$ and Hbpt is a very unusual one. In the complex obtained an oxygen atom has been inserted between the rhodium centre and the triazole ring. We are at present engaged in a systematic study of the interaction be-

tween rhodium polypyridyl centres and triazole type ligands. In this investigation we aim to further develop this chemistry and to determine the factors that control this unusual behaviour.

Experimental Section

Materials: Rhodium(III) chloride hydrate and 1,10-phenanthroline were purchased from Aldrich. $[Rh(1,10\text{-phenthroline})_2Cl_2]Cl$ and 3,5-bis(pyridin-2-yl)-1,2,4-triazole (Figure1) were prepared by previously reported procedures.[21,22]

Instrumentation: NMR spectra were obtained on a Bruker AC 400 MHz spectrometer. The peak positions are relative to TMS and the spectra were converted from their FID profiles using a Bruker WINNMR software package. Low temperature emission spectra were obtained at 77 K in a 4:1 ethanol/methanol glass using a Perkin−Elmer LS50B instrument. Elemental analysis on C, H and N was carried out at the Microanalytical Laboratory at University College Dublin (UCD) using an Exador analytical CE440.

Preparation of the Complex: Hbpt (0.3 mmol) was dissolved in H_2O at pH 9. $[Rh(phen)_2Cl_2]Cl$ (0.1 mmol) was then added and the reaction mixture was refluxed for 8 hours. Purification was carried out using a Sephadex C-25 column. Unreacted ligand was removed with distilled water and the product was eluted using 0.1 M NaCl. The complex was precipitated by the addition of a saturated aqueous solution of NH_4PF_6 to the required fraction. Yield: 0.033 g, 32%. Crystals were obtained by recrystallisation from a minimum amount of acetonitrile/toluene (7:3). ^1H NMR spectroscopy was carried in $[(CD_3)_2SO]$ and the resonances observed have been tentatively assigned as follows: **phenanthroline A:** δ = 9.75 (d, 1Ha), 8.45 (dd, 1Hb), 9.41 (d, 1Hc), 8.74 (d, 1Hd), 8.68 (d, 1He), 9.13 (d, 1Hf), 7.98 (dd, 1Hg), 8.59 (d, 1Hh); **phenanthroline B:** δ = 8.98 (d, 1Ha), 8.07 (dd, 1Hb), 8.78 (d, 1Hc), 8.31 (d, 1Hd), 8.19 (d, 1He); **bpt:** δ = 8.68 (d, 1H6), 8.39 (dd, 1H5), 7.36 (dd, 1H4), 7.48 (d, 1H3). It was not possible to assign the resonances at δ = 9.17 (s, 1 H), 9.05 (d, 1 H), 7.9−7.8 (m, 3 H), 7.55 (d, 1 H), 7.26 (m, 2 H) unambiguously. $[Rh(phen)_2(Obpt)](PF_6)_2{\cdot}H_2O$: calcd. C 42.83, H 2.60, N 12.49; found C 42.24, H 2.63, N 12.97. It should be noted that the sample for elemental analysis was recrystallised from ethanol/water.

CCDC-168699 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of Organouranium(IV) Triflates from $U(OTf)_4$ or from Alkyl or Amide Precursors

Jean Claude Berthet,*[a] Martine Nierlich,[a] and Michel Ephritikhine[a]

Keywords: Uranium / Triflate complexes / Cyclopentadienyl complexes / Cyclooctatetraenyl complexes

The uranium(IV) triflate $[U(OTf)_4]$ (**1**) (OTf = OSO_2CF_3) gives stable adducts with Lewis bases, such as $[U(OTf)_4(py)]$ (**2**) (py = pyridine). The crystal structure of a solvate of $[U(OTf)_4(OPPh_3)_3]$ (**3**), which exhibits a bidentate OTf group, has been determined. Substitution of the triflate ligands of **1** with $LiNEt_2$, Kacac (acac = MeCOCHCOMe), KCp (Cp = η-C_5H_5), and K_2COT (COT = η-C_8H_8) has led to the formation of $[U(NEt_2)_4]$, $[U(acac)_4]$, $[U(Cp)_3(OTf)]$ (**4**), and $[U(COT)(OTf)_2(py)]$ (**5**), respectively. However, the bis(cyclopentadienyl) compounds $[U(Cp^*)_2(OTf)_2]$ (**6**) (Cp^* = η-C_5Me_5) and $[U(Cp)_2(OTf)_2(py)]$ (**7**) could not be prepared from **1**. Complexes **4**–**7** have been isolated in good yields from the protonolysis reactions of the corresponding alkyl or amide precursors by means of pyridinium triflate. Compound **5** has also been prepared by treating $[U(COT)_2]$ with either [pyH][OTf] or **1** in pyridine. The crystal structures of $[U(Cp)_2(OTf)_2(py)_2]$ (**8**) and $[U(COT)(OTf)_2(OPPh_3)_2]\cdot0.5py$ (**9**) have been determined.

Introduction

The growing interest in metal triflates (trifluoromethanesulfonates), which proved to be effective Lewis acid catalysts in a number of organic reactions[1] and valuable precursors in inorganic and organometallic syntheses,[2] prompted us to study the preparation and properties of such complexes of uranium. In a preliminary communication,[3] we described the synthesis of $[U(OTf)_4(py)]$ (OTf = OSO_2CF_3; py = pyridine) and some organouranium(IV) triflates using the pyridinium salt [pyH][OTf] as a novel reagent for the protonolysis of U−C and U−N bonds. Following these initial results, we found that the base-free uranium(IV) triflate $[U(OTf)_4]$ (**1**) could be prepared in a more expeditious and simple way by treatment of U, UH_3, UCl_3, or UCl_4 with pure triflic acid.[4] The uranium(III) triflate $[U(OTf)_3]$ has also been obtained in a good yield by performing the reactions with U, UH_3, or UCl_3 at a lower temperature. These large-scale preparations of **1** allowed us to consider it as a possible good precursor for the syntheses of the derivatives. Here we present some reactions of $[U(OTf)_4]$, with special attention to those leading to organouranium(IV) triflate complexes. These preparations are compared with the alternative synthetic routes starting from the parent chloride, alkyl or amide compounds. The X-ray crystal structures of $[U(OTf)_4(OPPh_3)_3]\cdot0.5py\cdot0.5Et_2O$, $[U(Cp)_2(OTf)_2(py)_2]$ (Cp = η-C_5H_5), and $[U(COT)(OTf)_2(OPPh_3)_2]\cdot0.5py$ (COT = η-C_8H_8) are also described.

Results and Discussion

Reactions of $[U(OTf)_4]$ − X-ray Crystal Structure of $[U(OTf)_4(OPPh_3)_3]\cdot0.5py\cdot0.5Et_2O$

The uranium(IV) triflate $[U(OTf)_4]$ (**1**) is a strong Lewis acid and is quite soluble in coordinating solvents giving stable adducts. Thus, $[U(OTf)_4(py)]$ (**2**) was isolated from the reaction of the metallacycle $[U(N\{SiMe_3\}\{CH_2SiMe_2\})(N\{SiMe_3\}_2)_2]$ with [pyH][OTf] in pyridine [Equation (1)]. It is worth noting that similar treatment of $[U(NEt_2)_4]$ gave a mixture of unidentified amide products; this difference is not understood as the NEt_2 group, which is sterically less demanding and has a more basic character than $N(SiMe_3)_2$, is expected to be more easily protonated.[5]

$$[U(N\{SiMe_3\}\{CH_2SiMe_2\})(N\{SiMe_3\}_2)_2] + 4\,[pyH][OTf] \xrightarrow{py} [U(OTf)_4(py)]\ (\mathbf{2}) + 3\,HN(SiMe_3)_2 \quad (1)$$

In the presence of 2 equiv. of $OPPh_3$, **1** was transformed into $[U(OTf)_4(OPPh_3)_2]$ in pyridine or dimethoxyethane,[4] while green crystals of a solvate of $[U(OTf)_4(OPPh_3)_3]$ (**3**) were obtained by slow diffusion of diethyl ether into a pyridine solution of **1** and excess $OPPh_3$. Complex **3** is the first actinide tetratriflate to have been crystallographically characterized. Such metal complexes with four coordinated OTf ligands are not common and to the best of our knowledge, only the crystal structures of the neutral chromium compound $[Cr(OTf)_4(C_6H_4\{NH_2\}_2)]$,[6] and of the anionic species $[Fe(OTf)_4]^{2-}$ [7] and $[Na(OTf)_4]^{3-}$ [8] have been determined. The crystal structure of **3** is shown in Figure 1; selected bond lengths and angles are listed in Table 1. The

 © WILEY-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002 1434−1948/02/0404−0850 $ 17.50+.50/0 *Eur. J. Inorg. Chem.* **2002**, 850−858

uranium atom is surrounded by eight oxygen atoms in a dodecahedral arrangement defined by the two trapezia O(1)O(2)O(13)O(14) and O(3)O(4)O(7)O(10) intersecting at an angle of 90.4(4)°. The most salient feature of the structure is the presence of the η^2-O,O′ triflate ligand. This mode of ligation of the OTf group remains rare in d-transition metal complexes,[9] as well as in the f-block element compounds where only the two trivalent lanthanum and uranium complexes $[La(OTf)_2(HMPA)_4][OTf]$ (HMPA = hexamethylphosphoramide)[10] and $[U(OTf)_2(OPPh_3)_4][OTf]$[4] exhibit such a bidentate triflate ligand in their crystal structure. The U−O(η^2-OTf) bond lengths of 2.563(3) and 2.593(3) Å are ca 0.2 Å longer than the three U−O(η^1-OTf) distances which average 2.39(2) Å. Such a difference between the metal−oxygen bond lengths of the mono- and bidentate OTf ligands has been previously observed, in particular in the aforementioned uranium(III) compound.[4] The lengths of the U−O($OPPh_3$) bonds have an average value of 2.26(7) Å.

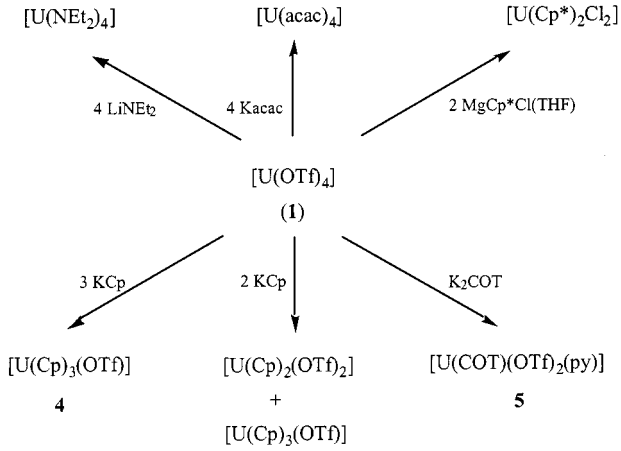
Homoleptic triflate complexes, like their halide counterparts, have been commonly used as starting materials for the synthesis of inorganic and organometallic derivatives;[2] in this context, it was of interest to evaluate the potential of **1**. The triflate groups of **1** can easily be substituted with anionic ligands (Scheme 1). For example, treatment of **1** with a slight excess of $LiNEt_2$ or Kacac (acac = MeCOCHCOMe) in tetrahydrofuran (THF) gave $[U(NEt_2)_4]$ or $[U(acac)_4]$ in almost quantitative yields (NMR experiments). In these syntheses, **1** proved to be as good a starting material as UCl_4.



Scheme 1. Reactions of $[U(OTf)_4]$

Attempts to prepare new organouranium(IV) triflates from **1** have been moderately successful. Reaction of **1** with 2 equiv. of KCp* in THF, pyridine, or toluene gave some unidentified products, while its treatment with MgCp*Cl(THF) in refluxing toluene afforded only the dichloride $[U(Cp^*)_2Cl_2]$ ($Cp^* = \eta$-C_5Me_5).[11] Tris(cyclopentadienyl)-uranium(IV) triflate $[U(Cp)_3(OTf)]$ (**4**) was synthesized in an almost quantitative yield by treatment of **1** with 3 equiv. of KCp in THF, followed by extraction with diethyl ether. However, a similar reaction of **1** with 2 equiv. of KCp afforded a mixture of $[U(Cp)_3(OTf)]$ and $[U(Cp)_2(OTf)_2]$ in a ratio of 73:27. Thus, pure bis(cyclopentadienyl)uranium(IV) compounds $[U(Cp^*)_2(OTf)_2]$ and $[U(Cp)_2(OTf)_2]$ could not be obtained by substitution of the triflate ligands of **1**.

Addition of 1 equiv. of $K_2C_8H_8$ to **1** in pyridine led to the immediate precipitation of a green powder, presumably $[U(COT)_2]$. The reaction mixture was heated under reflux for 15 h affording the (cyclooctatetraenyl)uranium(IV) triflate $[U(COT)(OTf)_2(py)]$ (**5**). In agreement with this observation, compound **5** was synthesized in an almost quantitative yield by direct comproportionation of **1** and $[U(COT)_2]$ in pyridine [Equation (2)]. Most notably, this ligand exchange reaction proceeded much less rapidly in THF. Such a remarkable solvent effect was also observed in the synthesis of $[U(COT)(BH_4)_2]$ from $[U(COT)_2]$ and $[U(BH_4)_4]$, which was effective in toluene but not in THF.[12] These results led us to re-examine the comproportionation reaction of UCl_4 and $[U(COT)_2]$ which, in refluxing pyridine, was found to readily afford the (cyclooctatetraenyl)uranium(IV) dichloride $[U(COT)Cl_2(py)_2]$ [Equation (3)].[13] It is ironical that this complex could so easily be obtained in pyridine whilst its synthesis in THF was difficult. This was a major obstacle in the development of the chemistry of mono(cyclooctatetraenyl) uranium compounds for a long time.[13] However, this situation favored the design of several $[U(COT)X_2]$ complexes (X = I,[14] BH_4,[12] NEt_2[15]) which were useful precursors for the synthesis of alkyl,[14b] alkoxide,[16] or thiolate[17] derivatives.

$$[U(OTf)_4] + [U(COT)_2] \xrightarrow{py} 2\,[U(COT)(OTf)_2(py)] \quad (2)$$

Synthesis of Organouranium(IV) Triflates from Alkyl or Amide Precursors − X-ray Crystal Structures of $[U(Cp)_2(OTf)_2(py)_2]$ and $[U(COT)(OTf)_2(OPPh_3)_2]\cdot 0.5py$

The lack of success in the preparation of $[U(Cp^*)_2(OTf)_2]$ and $[U(Cp)_2(OTf)_2]$ from **1** forced us to envisage other synthetic routes. We first tried to prepare these complexes by treating chloride, alkyl or amide precursors with classical reagents like AgOTf, Me_3SiOTf, or TfOH that proved to be effective in the synthesis of main-group and d-transition metal triflates.[2] While reaction of $[U(Cp)_3X]$ (X = Cl, *n*Bu) with AgOTf in THF or toluene cleanly afforded **4**, similar treatment of $[U(Cp^*)_2X_2]$ (X = Cl, Me, NMe_2) failed to give any tractable product, and polymerization of THF was sometimes observed. Compounds **4** and **5** were prepared in quantitative yields by immersing the parent chlorides in pure Me_3SiOTf at 110 °C, but the same reaction with $[U(Cp^*)_2Cl_2]$ gave a mixture of unidentified products. Reactions of $[U(Cp)_3(NEt_2)]$ or $[U(Cp^*)_2Me_2]$ with stoichiometric amounts of triflic acid in benzene effectively produced the expected compounds **4** and $[U(Cp^*)_2(OTf)_2]$ (**6**). The X-ray crystal structures of the Lewis base adducts $[U(Cp)_3(OTf)(CN\textit{t}Bu)]$ and $[U(Cp^*)_2(OTf)_2(H_2O)]$ have been described in the preliminary communication.[3] However, difficulties were encountered when the above reactions were performed on a preparative scale; products resulting from protonation of the cyclopentadienyl ligands were also formed in variable yields, apparently depending on the concentration of the acid. Similar observations have previously been seen in the reaction of $[Zr(Cp)_4]$ and triflic acid.[2e]

The pyridinium triflate was then considered as a milder and more selective acidic reagent than triflic acid. Its use in the synthesis of uranium triflates was inspired by our previous studies on the protonolysis reactions of U−C and U−N bonds by means of the ammonium salt $[NHEt_3][BPh_4]$, which constitute an efficient route to cationic complexes.[18] Treatment of $[U(Cp)_3(NEt_2)]$ with [pyH][OTf] afforded **4** which was isolated with a 93% yield; **4** was similarly obtained from the alkyl precursor $[U(Cp)_3\textit{n}Bu]$. This synthetic method was found to have a general applicability, since **5** was prepared in a 92% yield from $[U(COT)(NR_2)_2]$ (R = Et, $SiMe_3$) and, most notably, the bis(cyclopentadienyl) complexes **6** and $[U(Cp)_2(OTf)_2(py)]$ (**7**) were obtained from $[U(Cp^*)_2X_2]$ (X = Me, NMe_2) and $[U(Cp)_2(NEt_2)_2]$ in a 78 and 60% yield, respectively. These syntheses, depicted in Equations (4) to (7), were reproducible.

$$[U(Cp)_3(NEt_2)] + [pyH][OTf] \xrightarrow{THF} [U(Cp)_3(OTf)] + HNEt_2 + py \quad (4)$$
(4)

$$[U(COT)(NR_2)_2] + 2\,[pyH][OTf] \xrightarrow{THF} [U(COT)(OTf)_2(py)] + 2\,HNR_2 + py \quad (5)$$
R = Et, $SiMe_3$ (5)

$$[U(Cp^*)_2Me_2] + 2\,[pyH][OTf] \xrightarrow{THF} [U(Cp^*)_2(OTf)_2] + 2\,CH_4 + 2\,py \quad (6)$$
(6)

$$[U(Cp)_2(NEt_2)_2] + 2\,[pyH][OTf] \xrightarrow{THF} [U(Cp)_2(OTf)_2(py)] + 2\,HNEt_2 + py \quad (7)$$
(7)

The synthesis of **7** from $[U(Cp)_2(NEt_2)_2]$ [Equation (7)] indicates that the formation of the tris(cyclopentadienyl) compound **4** as the major product in the reaction of **1** with 2 equiv. of KCp most likely occurs as a result of kinetic factors, and is not due to the decomposition of **7**, which is stable in coordinating solvents. This behavior of **7** is in contrast with that of the Lewis base adducts of $[U(Cp)_2Cl_2]$, which could not be isolated because of their rapid rearrangement into the equimolar mixture of $[U(Cp)_3Cl]$ and $[U(Cp)Cl_3L_2]$ (L = Lewis base or solvent).[19] As this disproportionation reaction was explained in terms of the great electron-rich nature of $[U(Cp)_2Cl_2L_x]$,[20] the stability of **7**, like that of the cationic complex $[U(Cp)_2(NEt_2)(THF)_x]^+$,[18a][18c] can clearly be related to the greater Lewis acidity of the metal center.

The acidic reagent [pyH][OTf] was also effective in the protonation of the aromatic ligand in $[U(COT)_2]$, since **5** was quantitatively obtained in refluxing THF or pyridine [Equation (8)]. Such syntheses of mono(cyclooctatetraenyl)-uranium complexes by protonolysis of uranocene are not common; they are limited to the preparation of $[U(COT)(acac)_2]$ by reaction of $[U(COT)_2]$ with Hacac,[21] and to the non-selective formation of $[U(COT)Cl_2(THF)_x]$ by treatment of $[U(COT)_2]$ with HCl.[13] It is likely that the driving force of reaction (8) is the formation of a uranium−oxygen σ-bond, since $[U(COT)_2]$ failed to react with $[pyH][BPh_4]$ to give the dication $[U(COT)(THF)_x]^{2+}$.[22] A reaction was not observed between $[U(COT)_2]$ and NaOTf, while the uranocene was easily transformed into the anion $[U(COT)(O\textit{i}Pr)_3]^-$ in the presence of NaO*i*Pr;[23] this difference would simply reflect the weaker nucleophilic character of the triflate ligand.

$$[U(COT)_2] + 2\,[pyH][OTf] \xrightarrow{py\ or\ THF} [U(COT)(OTf)_2(py)] + C_8H_{10} \quad (8)$$
(5)

The pyridinium triflate thus proved to be very useful in the synthesis of organouranium(IV) triflates by protonolysis of alkyl or amide precursors. In addition to its selectivity and efficiency, this commercial reagent presents many advantages over triflic acid since it can be used in a greater variety of organic solvents, is not corrosive, can be stored for a long time and is easy to handle. Trialkylammonium triflates can also be used in such protonolysis reactions, as shown recently by the synthesis of (cyclopentadienyl)zirconium triflates by treatment of $[Zr(Cp)_4]$ with $[NBu_3H][OTf]$.[2e]

Compounds **2**−**7** were characterized by elemental analyses and ^1H NMR spectroscopy. Brown crystals of $[U(Cp)_2(OTf)_2(py)_2]$ (**8**) and orange crystals of a pyridine solvate of $[U(COT)(OTf)_2(OPPh_3)_2]$ (**9**) were obtained by slow diffusion of diethyl ether into a pyridine solution of **7**, or into a pyridine solution of **5** and excess $OPPh_3$. These crystals were suitable for X-ray diffraction analysis.

Other than the uranium borohydride $[U(Cp)_2(BH_4)_2]$[24] and the thorium complexes $[Th(Cp)_2X_2(DMPE)]$ (X = Cl, Me,[25a] CH_2Ph;[25b] DMPE = $Me_2PCH_2CH_2PMe_2$), **8** is one of the few mononuclear bis(cyclopentadienyl)actinide(IV) compounds to have been crystallographically characterized. The crystal structure is shown in Figure 2 and selected bond lengths and angles are listed in Table 2. The stereochemistry of this six-coordinate complex (if the Cp ring centroid is considered as occupying a single coordination site) strongly resembles that of the thorium derivatives $[Th(Cp)_2X_2(DMPE)]$; the two *cis* pyridine ligands can be thought of as replacing the bidentate phosphane ligand and the two *trans* monodentate triflate ligands can be thought of as replacing the X groups. The geometrical parameters of the $U(Cp)_2(py)_2$ and $Th(Cp)_2(DMPE)$ fragments are very similar, with the ring centroid−metal−ring centroid angles equal to 113.8(1) and 115(1)° (mean value) and the N(1)−U−N(2) and P−Th−P angles equal to 65.5(1) and 64.3(2)° (mean value), respectively. However, the O(1)−U−O(4) angle of 153.1(1)° is much greater than the C−Th−C or Cl−Th−Cl angles which average 140(1)°; this difference most likely reflects the greater steric size of the triflate ligands. The U−C bond lengths are unexceptional, with an average value of 2.73(4) Å, and the U−N bond lengths of 2.614(5) and 2.685(5) Å compare with those in $[U(SiPr)_2I_2(py)_3]$[26] and $[U(COT)Cl_2(py)_2]$[13] [2.56(9) and 2.64(1) Å, respectively]. The U−O(1) and U−O(4) distances [2.395(4) and 2.385(4) Å, respectively] are similar to those found in the other uranium(IV) triflate compounds (vide infra).

Table 2. Selected bond lengths [Å] and angles [°] for $[U(Cp)_2(OTf)_2(py)_2]$

U−O(1)	2.395(4)	U−O(4)	2.385(4)
U−N(2)	2.685(5)	U−Cp(1)[a]	2.454(5)
U−N(1)	2.614(5)	U−Cp(2)[a]	2.466(5)
O(1)−U−O(4)	153.1(1)	N(1)−U−N(2)	65.5(1)
Cp(1)−U−Cp(2)	113.8(1)	Cp(1)−U−N(1)	155.5(1)
Cp(2)−U−N(2)	155.3(1)	Cp(1)−U−O(1)	94.1(1)
Cp(2)−U−O(1)	99.3(1)	Cp(1)−U−O(4)	98.5(1)
Cp(2)−U−O(4)	97.1(1)		

[a] Cp(1) and Cp(2) are the centroids of the C(1)−C(5) and C(6)−C(10) cyclopentadienyl rings.

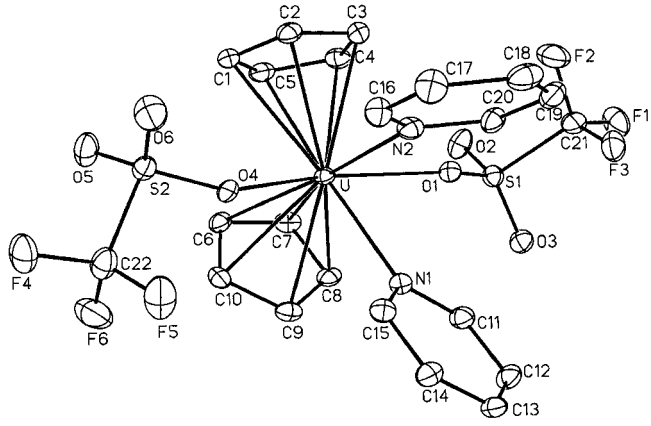

Figure 2. X-ray crystal structure of $[U(Cp)_2(OTf)_2(py)_2]$ with displacement ellipsoids at the 30% probability level

The crystal structure of one of the two independent and identical molecules of **9** is shown in Figure 3, and selected bond lengths and angles are listed in Table 3. The complex adopts a perfect square-pyramidal configuration, if the COT ligand is considered to be monodentate. The square base is defined by the oxygen atoms of the two $OPPh_3$ and the two monodentate OTf ligands, which are mutually in the *trans* positions; in the quadrilateral O(1)O(4)O(1′)O(4′), the O(1)−O(4) and O(1)−O(4′) distances are 2.923(4) and 2.763(4) Å, respectively, and the angles O(4)−O(1)−O(4′) and O(1)−O(4)−O(1′) have a value of 88.3(4) and 91.6(4)°, respectively. The square base is almost parallel to the planar COT ring, with a dihedral angle of 1.8(4)°, and the two planes are perpendicular to the two-fold axis. The U atom is 1.202(4) and 1.957(4) Å away from the square base and the COT ring, respectively. The COT ligation is similar to that found in uranocene and other mono(cyclooctatetraenyl)uranium(IV) compounds, with an average U−C bond length of 2.66(2) Å.[5a,13,27] The U−O($OPPh_3$) distances of 2.304(4) Å are unexceptional and the U−O(OTf) distances of 2.433(4) Å are within the range of the U−O bond lengths found in uranium(IV) monodentate triflates. These distances, which are equal to 2.371(3), 2.404(3) and 2.418(3) Å in $[U(OTf)_4(OPPh_3)_3]$ (vide supra), 2.36(1) and 2.40(1) Å in $[U(Cp^*)_2(OTf)_2(H_2O)]$,[3] 2.395(4) and 2.385(4) Å in $[U(Cp)_2(OTf)_2(py)_2]$ (vide supra), and 2.485(9) Å in $[U(Cp)_3(OTf)(NCtBu)]$,[3] are significantly longer than the typical U−O bond length of the alkoxide ligand (2.0−2.3 Å),[28] thus indicating the much lower nucleophilic character of the OTf group. However, no dissociation and substitution of the triflate ligands were found to occur in these uranium(IV) compounds, even in the presence of strongly coordinating ligands like $OPPh_3$. In particular, it is worth noting that such a dissociation was not observed in $[U(OTf)_4(OPPh_3)_3]$, in contrast to the U^{III} derivative $[U(OTf)_2(OPPh_3)_4][OTf]$ which is composed of discrete

cation−anion pairs in the solid state.[4] These features indicate that the uranium triflate bond is not as weak as is expected.

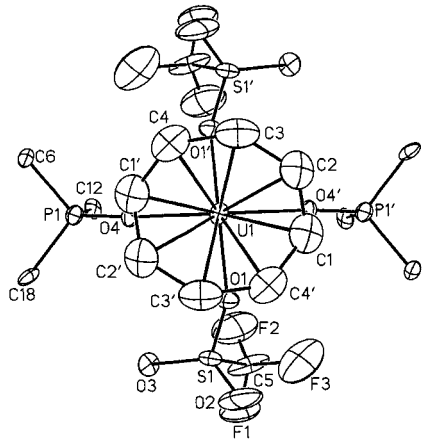

Figure 3. X-ray crystal structure of one of the two independent molecules of $[U(COT)(OTf)_2(OPPh_3)_2]$ with displacement ellipsoids at the 30% probability level; view along the two-fold axis; for clarity, only the *ipso*-carbon atoms of the phenyl rings are represented; atoms labeled prime are related to the non-labeled ones by the two-fold axis (symmetry code: 0.75 − *x*, 1.75 − *y*, *z*)

Table 3. Selected bond lengths [Å] and angles [°] for $[U(COT)(OTf)_2(OPPh_3)_2]$

U(1)−O(1)[a]	2.382(4)	U(2)−O(5)[a]	2.433(4)
U(1)−O(4)	2.304(4)	U(2)−O(8)	2.296(4)
U(1)−COT[b]	1.957(4)	U(2)−COT	1.938(4)
O(1)−U(1)−O(1′)[c]	117.8(2)	O(5)−U(2)−O(5′)	117.4(2)
O(4)−U(1)−O(4′)	118.7(2)	O(8)−U(2)−O(8′)	116.5(2)
COT−U(1)−O(1)	121.2(2)	COT−U(2)−O(5)	121.3(2)
COT−U(1)−O(4)	120.7(2)	COT−U(2)−O(8)	121.7(2)

[a] The corresponding values in the two independent molecules [U(1) and U(2)] are given. [b] COT is the centroid of the cyclooctatetraenyl ring. [c] Atoms labeled prime are related to the non-labeled ones by the two-fold axis.

Conclusion

The uranium(IV) triflate $[U(OTf)_4]$ (**1**) can be considered, like UCl_4, as a useful starting material for the synthesis of uranium complexes. We think that the preparation of **1**, although requiring the use of triflic acid, is more convenient and less hazardous than that of UCl_4 which necessitates the handling of harmful and volatile chlorinating agents.[29] However, there are some limitations associated with the use of **1** for the synthesis of organometallic compounds since the bis(cyclopentadienyl) complexes $[U(Cp^*)_2(OTf)_2]$ (**6**) and $[U(Cp)_2(OTf)_2(py)]$ (**7**) could not be obtained by substitution of the triflate ligands. These compounds, as well as $[U(Cp)_3(OTf)]$ (**4**) and $[U(COT)(OTf)_2(py)]$ (**5**), the most representative examples of organouranium(IV) triflates, were prepared in good yields by protonolysis of the corresponding alkyl or amide precursors by means of pyridinium triflate. This synthetic method appears to have a general applicability, and [pyH][OTf] is a practical, effective and selective reagent which can be favorably used in place of TfOH or AgOTf. Of special interest is the synthesis of **5**, which was alternatively prepared by treatment of $[U(COT)_2]$ with either [pyH][OTf] or $[U(OTf)_4]$; the solvent plays a major role in the comproportionation reactions of $[U(COT)_2]$ and UX_4 (X = OTf, Cl), which were found to occur easily in pyridine. These results provide new and convenient findings for the chemistry of monocyclooctatetraenyl uranium compounds.

Experimental Section

General: All preparations were carried out under argon (less than 2 ppm of oxygen and water) using standard Schlenk vessel and vacuum-line techniques or in a glove box. Solvents were thoroughly dried and deoxygenated by standard methods and distilled before use. $[D]_8$THF was dried with Na/K alloy. The ^{1}H NMR spectra were recorded with a Bruker DPX 200 instrument and were referenced internally using the residual protio solvent resonances relative to tetramethylsilane (δ = 0). Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany). TfOH and Me_3SiOTf (Aldrich) were distilled before use, AgOTf (Aldrich) was used without purification, and the white powder of [pyH][OTf] was obtained by addition of pyridine to a solution of TfOH in diethyl ether. The uranium compounds UCl_4,[29] $[U(OTf)_4]$,[4] $[U(NEt_2)_4]$,[30] $[U(N\{SiMe_3\}\{CH_2SiMe_2\})(N\{SiMe_3\}_2)_2]$,[31] $[U(Cp)_3X]$ (X = Cl,[32] *n*Bu,[33] NEt_2[34]), $[U(Cp^*)_2X_2]$ (X = Cl,[11] Me,[35] NMe_2[36]), $[U(Cp)_2(NEt_2)_2]$,[37] $[U(COT)_2]$,[38] and $[U(COT)(NR_2)_2]$ (R = Et,[18c] $SiMe_3$[39]) were synthesized as previously reported.

Syntheses of the Complexes

$[U(OTf)_4(py)]$ (2): A 100-mL round-bottom flask was charged with $[U(N\{SiMe_3\}\{CH_2SiMe_2\})(N\{SiMe_3\}_2)_2]$ (250 mg, 0.35 mmol) and [pyH][OTf] (319.1 mg, 1.39 mmol), and pyridine (20 mL) was condensed into it under vacuum at −78 °C. The reaction mixture was heated for 20 h at 110 °C. After filtration, the volume of the green solution was reduced to 10 mL, and addition of pentane or diethyl ether (30 mL) led to the precipitation of a green powder of **2** which was filtered off, washed with diethyl ether and dried under vacuum (244 mg, 76%). ^{1}H NMR (200 MHz, $[D_8]$THF): δ = 7.3, 7.85, and 8.8 (py). $C_9H_5F_{12}NO_{12}S_4U$ (913): calcd. C 11.83, H 0.55, N 1.55; found C 12.07, H 0.72, N 1.59.

$[U(NEt_2)_4]$: An NMR tube was charged with $[U(OTf)_4]$ (10.0 mg, 0.012 mmol) and $LiNEt_2$ (3.9 mg, 0.049 mmol) in $[D_8]$THF (0.4 mL). The tube was immersed in an ultrasound bath (80 W, 40 kHz) for 1.5 h, and the spectrum showed the quantitative formation of $[U(NEt_2)_4]$.

$[U(acac)_4]$: An NMR tube was charged with $[U(OTf)_4]$ (10.0 mg, 0.012 mmol) and Kacac (6.6 mg, 0.048 mmol) in $[D_8]$THF (0.4 mL). The tube was immersed in an ultrasound bath (80 W, 40 kHz) for 30 min, and the spectrum showed the quantitative formation of $[U(acac)_4]$.

$[U(Cp)_3(OTf)]$ (4)

From $[U(Cp)_3(NEt_2)]$ and [pyH][OTf]: A 50-mL round-bottom flask was charged with $[U(Cp)_3(NEt_2)]$ (209 mg, 0.41 mmol), and THF (20 mL) was condensed into it under vacuum at −78 °C. At 20 °C, a solution of [pyH][OTf] (95 mg, 0.41 mmol) in THF (15 mL) was

slowly added to the red solution of the uranium complex, which rapidly turned orange. After 45 min, the solution was filtered and its volume was reduced to 10 mL. Addition of pentane (20 mL) led to the precipitation of a brown powder of **4** which was filtered off, washed with pentane and dried under vacuum (225 mg, 93%). ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −2.45 (s, Cp). $C_{16}H_{15}F_3O_3SU$ (582): calcd. C 32.99, H 2.60; found C 32.86, H 2.70.

From [U(Cp)$_3$*n*Bu] and [pyH][OTf]: An NMR tube was charged with [U(Cp)$_3$*n*Bu] (10.0 mg, 0.02 mmol) and [pyH][OTf] (4.7 mg, 0.02 mmol) in [D$_8$]THF. After 15 h at 20 °C, the spectrum showed the quantitative formation of **4**.

From [U(Cp)$_3$X] (X = Cl, *n*Bu) and AgOTf: An NMR tube was charged with [U(Cp)$_3$Cl] (10.0 mg, 0.021 mmol) and AgOTf (6.6 mg, 0.025 mmol) in [D$_8$]THF (0.4 mL). The tube was immersed in an ultrasound bath for 10 min; the color of the solution turned brown and precipitation of AgCl was observed. The spectrum showed the quantitative formation of **4**. The same reaction with [U(Cp)$_3$*n*Bu] also gave **4** in a quantitative yield, with the precipitation of metallic silver.

From [U(Cp)$_3$Cl] and Me$_3$SiOTf: An NMR tube was charged with [U(Cp)$_3$Cl] (10.0 mg, 0.021 mmol) and Me$_3$SiOTf (0.1 mL, 0.55 mmol). The tube was immersed in an ultrasound bath for 1 h and left at 20 °C for 15 h. After concentration to dryness, the brown residue was washed with diethyl ether, dried under vacuum and dissolved in [D$_8$]THF. The spectrum showed the quantitative formation of **4**.

From [U(Cp)$_3$(NEt$_2$)] and TfOH: An NMR tube was charged with [U(Cp)$_3$(NEt$_2$)] (10.0 mg, 0.021 mmol) in benzene (0.4 mL), and TfOH (1.7 μL, 0.02 mmol) was added via a microsyringe. After vigorous shaking by hand, a brown powder was deposited from the red solution. After concentration to dryness, the residue was dissolved in [D$_8$]THF and the spectrum showed the formation of the unique product **4**.

From [U(OTf)$_4$] and KCp: An NMR tube was charged with [U(OTf)$_4$] (10.0 mg, 0.012 mmol) and KCp (3.8 mg, 0.036 mmol) in [D$_8$]THF (0.4 mL). After 1 h at 20 °C, the spectrum showed a large signal at δ = −4.7. The solvent was evaporated and the residue extracted with diethyl ether. After concentration to dryness, the spectrum of the brown powder in [D$_8$]THF showed the formation of the unique product **4**.

[U(COT)(OTf)$_2$(py)] (5)

From [U(COT)(N{SiMe$_3$}$_2$)$_2$] and [pyH][OTf]: A 50-mL round-bottom flask was charged with [U(COT)(N{SiMe$_3$}$_2$)$_2$] (250 mg, 0.38 mmol), and THF (20 mL) was condensed into it under vacuum at −78 °C. At 20 °C, a solution of [pyH][OTf] (174 mg, 0.76 mmol) in THF (15 mL) was introduced and the resulting dark red solution was stirred for 30 min. After filtration and concentration to dryness, the residue was extracted with diethyl ether or toluene (30 mL). The solvent was evaporated and the brown powder of **5** was dried under vacuum (250 mg, 92%). ^{1}H NMR (200 MHz, [D$_8$]THF): δ = −37.5 (s, 8 H, COT), 6.9, 7.4 and 7.6 (s, 5 H, py). $C_{15}H_{13}F_6NO_6S_2U$ (719): calcd. C 25.04, H 1.82, N 1.94; found C 24.98, H 1.92, N 2.08. Complex **5** was similarly prepared in an almost quantitative yield from [U(COT)(NEt$_2$)$_2$] (10.0 mg, 0.02 mmol) and [pyH][OTf] (9.3 mg, 0.04 mmol).

From [U(COT)$_2$] and [pyH][OTf]: An NMR tube was charged with [U(COT)$_2$] (10.0 mg, 0.022 mmol) and [pyH][OTf] (10.3 mg, 0.45 mmol) in [D$_8$]THF (0.4 mL). After 15 min at 80 °C, the spectrum of the red solution showed the quantitative formation of **5**. The same reaction in refluxing pyridine required 15 h to go to completion.

From [U(COT)Cl$_2$(py)$_2$] and Me$_3$SiOTf: An NMR tube was charged with [U(COT)Cl$_2$(py)$_2$] (25 mg, 0.044 mmol) (prepared from [U(COT)$_2$] and UCl$_4$, see below) and Me$_3$SiOTf (0.4 mL, 2.2 mmol). The suspension was heated for 15 h at 110 °C, and after concentration to dryness, the brown residue was dissolved in [D$_8$]THF. The spectrum showed the formation of [U(COT)(OTf)$_2$(THF)$_x$] (δ = 37.3) and [PySiMe$_3$][OTf].

From [U(OTf)$_4$] and K$_2$C$_8$H$_8$: An NMR tube was charged with [U(OTf)$_4$] (10.0 mg, 0.012 mmol) and K$_2$C$_8$H$_8$ (2.2 mg, 0.012 mmol) in pyridine. Precipitation of a green powder of [U(COT)$_2$] was immediately observed. After heating at 110 °C for 15 h, the dark green solution was concentrated to dryness and the residue dissolved in [D$_8$]THF. The spectrum showed the formation of **5** as a unique product.

From [U(OTf)$_4$] and [U(COT)$_2$]: A 50-mL round-bottom flask was charged with [U(OTf)$_4$] (100 mg, 0.12 mmol) and [U(COT)$_2$] (53.5 mg, 0.12 mmol), and pyridine (20 mL) was condensed into it under vacuum at −78 °C. The mixture was heated at 110 °C for 20 h and the resulting dark green solution was concentrated to dryness. The residue was extracted with diethyl ether and the brown powder of **5** was obtained after evaporation of the solvent (155 mg, 90%). Under the same conditions, reaction of **2** and [U(COT)$_2$] in [D$_8$]THF did not reach completion, as only ca. 20% of the green crystalline powder of uranocene was transformed into **5**.

[U(COT)Cl$_2$(py)$_2$]: A 25-mL round-bottom flask was charged with [U(COT)$_2$] (50 mg, 0.11 mmol) and UCl$_4$ (42.5 mg, 0.11 mmol) in pyridine (10 mL). The mixture was heated for 24 h at 110 °C; the color of the solution turned from green to red. The solvent was evaporated and the residue extracted with THF (10 mL). After concentration to dryness, the product was dissolved in pyridine (5 mL) and was then precipitated on addition of diethyl ether (10 mL). The red powder was filtered, washed with toluene (10 mL) and dried under vacuum (88 mg, 70%).

[U(Cp*)$_2$(OTf)$_2$] (6)

From [U(Cp*)$_2$X$_2$] (X = Me, NMe$_2$) and [pyH][OTf]: A 100-mL round-bottom flask was charged with [U(Cp*)$_2$Me$_2$] (257 mg, 0.47 mmol), and THF (20 mL) was condensed into it under vacuum at −78 °C. A solution of [pyH][OTf] (219 mg, 0.95 mmol) in THF (20 mL) was slowly added to the solution of the uranium complex at −70 °C; vigorous evolution of gas was observed. After 1 h at 20 °C, the brown solution was concentrated to dryness and the residue extracted with toluene (30 mL). The solvent was evaporated and a red brown powder of **6** was washed with pentane and dried under vacuum (300 mg, 78%). ^{1}H NMR (200 MHz, [D$_8$]THF): δ = 20.1 (s, Cp*). $C_{22}H_{30}F_6O_6S_2U$ (806): calcd. C 32.75, H 3.75, S 7.95; found C 32.81, H 3.73, N 7.84. An NMR tube was charged with [U(Cp*)$_2$(NMe$_2$)$_2$] (10.0 mg, 0.017 mmol) and [pyH][OTf] (7.7 mg, 0.034 mmol) in [D$_8$]THF (0.4 mL). The tube was immersed in an ultrasound bath and after 30 min, the spectrum showed that **6** was formed in an almost quantitative yield.

From [U(Cp*)$_2$Me$_2$] and TfOH: An NMR tube was charged with [U(Cp*)$_2$Me$_2$] (10.0 mg, 0.018 mmol) in [D$_8$]toluene (0.4 mL), and TfOH (1.6 μL, 0.018 mmol) was introduced via a microsyringe. Evolution of gas was immediately observed and the spectrum showed the formation of **6** with variable amounts of side products.

[U(Cp*)$_2$Cl$_2$]: An NMR tube was charged with **1** (10.0 mg, 0.012 mmol) and MgCp*Cl(THF) (6.4 mg, 0.024 mmol) in [D$_8$]tol-

uene (0.4 mL). After 3 h at 110 °C, the spectrum of the red solution showed the formation of $[U(Cp^*)_2Cl_2]$ as the unique product.

$[U(Cp)_2(OTf)_2(py)]$ (7)

From $[U(Cp)_2(NEt_2)_2]$ and [pyH][OTf]: A 100-mL round-bottom flask was charged with $[U(Cp)_2(NEt_2)_2]$ (300 mg, 0.58 mmol), and THF (20 mL) was condensed into it under vacuum at −78 °C. A solution of [pyH][OTf] (268 mg, 1.17 mmol) in THF (20 mL) was slowly added into the solution of the uranium compound at −40 °C. After stirring for 1 h at −30 °C and 3 h at 20 °C, the orange solution was filtered, concentrated to dryness and the orange powder of **7** was washed with diethyl ether and dried under vacuum (260 mg, 60%). Compound **7** may be contaminated with traces (2−3%) of **4**. ^{1}H NMR (200 MHz, $[D_8]$THF): δ = 6.9, 8.8 and 8.85 (s, 5 H, py), 11.2 (s, 10 H, Cp). $C_{17}H_{15}F_6NO_6S_2U$ (745): calcd. C 27.39, H 2.02, N 1.88; found C 26.66, H 1.99, N 2.05.

From $[U(OTf)_4]$ and KCp: An NMR tube was charged with $[U(OTf)_4]$ (10.0 mg, 0.012 mmol) and KCp (2.5 mg, 0.024 mmol) in $[D_8]$THF (0.4 mL). After 12 h at 20 °C, the spectrum of the yellow solution showed the formation of **4** and **7** in a ratio of 73:27.

X-ray Crystallography of $[U(OTf)_4(OPPh_3)_3]\cdot 0.5py\cdot 0.5Et_2O$: Diffraction data collection was carried out with a Nonius diffractometer equipped with a CCD detector. The lattice parameters were determined from ten images recorded with 2° Φ-scans and later refined on all data. A 180° Φ-range was scanned with 2° steps with a crystal-to-detector distance fixed at 30 mm. Data were corrected for Lorentz polarization and absorption[40] effects. The structure was solved by the heavy-atom method and refined by full-matrix least squares on F^2 with anisotropic thermal parameters for all non-solvent atoms. H atoms were introduced at calculated positions and constrained to ride on their parent C atom with an isotropic displacement parameter equal to 1.2 (CH, CH_2) or 1.5 (CH_3) times that of the parent atom. One pyridine and one diethyl ether solvent molecules were found on the same position and were refined disordered on two positions with 0.5 occupation factor. All calculations were performed with an O2 Silicon Graphics Station using the SHELXTL package.[41] Crystal data and summary of data collection and refinement are given in Table 4. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-171474. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Spin States and Stability of Fe^{III} Complexes of Ligands with Carboxamido Nitrogen and Phenolato Oxygen Donors

Dana S. Marlin,[a] Marilyn M. Olmstead,[b] and Pradip K. Mascharak*[a]

Keywords: Iron / N ligands / O ligands / Spin states

As part of our attempts to prepare Fe^{III} complexes with "tunable" spin states, we have synthesized three novel six-coordinate Fe^{III} complexes containing both carboxamido nitrogen (N_{amido}) and phenolato oxygen (O_{phen}) donors in their ligand framework. Since it has already been shown that carboxamido nitrogen donors usually stabilize Fe^{III} in a low spin configuration, while phenolato oxygens tend to stabilize Fe^{III} in a high spin state, we have incorporated both donor groups in our designed ligands. The syntheses and structures of Fe^{III} complexes with either one or two N_{amido} and O_{phen} donors are reported in this paper. The properties of these complexes have been compared with the properties of analogous Fe^{III} complexes. The competing effects of N_{amido} and O_{phen} on the spin state of the Fe^{III} center are discussed in terms of the stabilities of the overall complexes.

(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

Monomeric complexes with stable Fe^{III} centers are attractive synthetic targets to inorganic chemists for their use, among other things, as catalysts, enzyme mimics, or as model complexes that allow for detailed study of the electronic properties of the Fe^{III} center.[1−4] Recent work from this laboratory in conjunction with the work of others has shown that coordination of a carboxamido nitrogen (N_{amido}) to an Fe^{III} center makes it resistant toward hydrolytic decomposition.[5] Furthermore, the reduction potential of the Fe^{III} center is shifted toward more negative values by approximately −0.5 V per N_{amido} to a maximum of about −1.10 V.[5,6] In addition, the majority of the six-coordinate Fe^{III} complexes with one, two, and four N_{amido} donors possess low spin (LS) ground states.[3,5,6] Wieghardt and coworkers have performed extensive studies to evaluate the electronic and physical properties of mononuclear Fe^{III} complexes with $Fe^{III}-O_{phen}$ (O_{phen} = phenolato O) bonds.[7−8] They have pointed out that the majority of these complexes tend to have high spin (HS) Fe^{III} centers (with a $t_{2g}^3e_g^2$ electronic configuration) and that $Fe^{III}-O_{phen}$ bonds are often short, indicating considerable double bond character with ligand-to-metal d_π-p_π back bonding.[9] We decided to combine both $Fe^{III}-N_{amido}$ and $Fe^{III}-O_{phen}$ interactions within the same Fe^{III} complex with the intention of obtaining Fe^{III} complexes with "tunable" spin states. In the long term, we intend to gain control over (a) the redox potential, (b) stability and (c) the spin state of the Fe^{III} center, all of which influence its reactivity. Here we report the results of our initial effort toward this goal.

Previously, we have described the structure and chemistry of Fe^{III} complexes of the pentadentate ligand *N*,*N*′-bis(2-hydroxyphenyl)-pyridine-2,6-dicarboxamide ($POPYH_4$) (Figure 1).[10] When deprotonated, this ligand becomes planar and coordinates to the Fe^{III} center in the basal plane of a pentagonal bipyramid. The HS Fe^{III} complexes of this ligand namely, $[Fe(POPY)(L)_2]^{n-}$ (L = SCN^-, *N*-methylimidazole), were the first examples of structurally characterized species in which both N_{amido} and O_{phen} donors are coordinated to the Fe^{III} center in the same complex. We have now prepared additional six-coordinate complexes with similar ligands in order to explore the properties of these types of complexes in more detail. The two designed ligands that have been employed in this study are the tridentate ligand *N*-(2-hydroxyphenyl)-2-pyridinecarboxamide ($PypepOH_2$) and the pentadentate ligand *N*,*N*-bis(2-pyridylmethyl)amine-*N*-ethyl-2-hydroxyphenyl-2-carboxamide ($Papy_2OH_2$) (Figure 1). In both $PypepOH_2$ and $Papy_2OH_2$, the H's represent dissociable phenolic and carboxamide hydrogens. In the deprotonated forms, these ligands coordinate to Fe^{III} to afford stable HS six-coordinate complexes $Na[Fe(PypepO)_2]$ (**1**), and $[Fe(Papy_2O)(L)]$ (**2** L = Cl^-; **3** L = SCN^-). These complexes represent only the second and third set of examples of structurally characterized complexes with Fe^{III} centers coordinated to both N_{amido} and O_{phen} donors. They are also the first such examples of six-coordinate Fe^{III} complexes. The structural and spectro-

scopic properties of these complexes (with both $Fe^{III}-N_{amido}$ and $Fe^{III}-O_{phen}$ bonds) have been compared with Fe^{III} complexes with either $Fe^{III}-O_{phen}$ or $Fe^{III}-N_{amido}$ bonds.

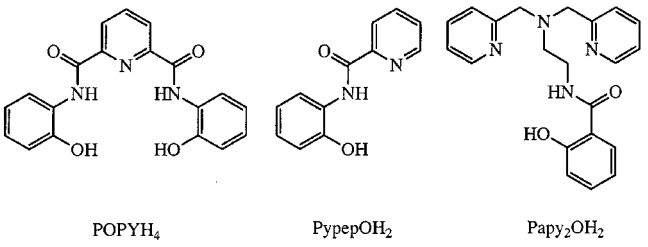

Figure 1. Ligands that contain both N_{amido} and O_{phen} donors used in previous ($POPYH_4$) and the present study ($PypepOH_2$ and $Papy_2OH_2$); the H's in $POPYH_4$, $PypepOH_2$ and $Papy_2OH_2$ represent dissociable phenolate and carboxamide hydrogens

Results and Discussion

The tridentate ligand $PypepOH_2$ was prepared by reacting 2-aminophenol with 2-pyridinecarbonyl chloride (the latter prepared from 2-picolinic acid and thionyl chloride) in tetrahydrofuran (THF). The acetate-protected derivative of the pentadentate ligand $Papy_2OH_2$, namely $Papy_2OCOCH_3$, was synthesized from (2-aminoethyl)bis(2-pyridylmethyl)amine and 2-acetylphenylcarbonyl chloride (the latter prepared from 2-acetylsalicylic acid and oxalyl chloride). Pure $Papy_2OH_2$ was obtained in good yield following deprotection of $Papy_2OCOCH_3$ with NaOH and neutralization with HCl. For ease of handling, $Papy_2OH_2$ was converted into the mono-sodium salt $NaPapy_2OH$ by reaction of $Papy_2OH_2$ with NaOMe in MeOH. Reaction of $[Fe(DMF)_6](ClO_4)_3$ with two equiv. of $PypepOH_2$ and four equiv. of NaH (both relative to iron) in DMF afforded the Fe^{III} complex $Na[Fe(PypepO)_2]$ (**1**). The dark red complex $[Fe(Papy_2O)(Cl)]$ (**2**) was synthesized by reacting $(Et_4N)[FeCl_4]$ with $NaPapy_2OH$ plus one equiv. of NaH in DMF. Reaction of $[Fe(DMF)_6](ClO_4)_3$ with one equiv. of $Papy_2O^{2-}$ in DMF followed by one equiv. of NaSCN resulted in the formation of $[Fe(Papy_2O)(NCS)]$ (**3**) in high yield.

Molecular Structure of Na[Fe(PypepO)2] (1)

X-ray quality crystals of **1**·2.5CH_3CN were grown from a saturated solution of **1** in CH_3CN, upon cooling to −20 °C. The structure of the complex shows two deprotonated $PypepO^{2-}$ ligands coordinated to an Fe^{III} center in a *mer* geometry (Figure 2a). In the solid state, **1**·2.5CH_3CN forms an elaborate network of $[Fe(Pypep)_2]^-$ and Na^+ ions bridged through carbonyl and phenolato oxygens with additional coordination of CH_3CN to the Na^+ center. The lattice structure is built up of dimeric $[Fe(PypepO)_2]^-\cdots Na^+\cdots[Fe(PypepO)_2]^-\cdots Na^+$ units which in turn are connected together into an extended network with large pockets formed by four such dimeric units (Figure 2b). This arrangement creates small pockets at the center of each dimer and large pockets by the four-dimer clusters. Some of the large pockets are occupied by uncoordinated CH_3CN molecules (Figure 2b).

It is interesting to note that like complex **1**, $Na[Fe(POPY)(N\text{-}MeIm)_2]\cdot 3CH_3CN$ also forms an extended structure in the solid state with Na^+ bonded to phenolate and carbonyl oxygen donors from the $POPY^{4-}$ ligand and lattice CH_3CN molecules.[10] However, in the case of $Na[Fe(POPY)(N\text{-}MeIm)_2]\cdot 3CH_3CN$, polymeric chains form between monomeric $Na^+\cdots[Fe(POPY)(N\text{-}MeIm)_2]^-$ units in the lattice, which differs considerably from the elaborate porous network seen in **1**·2.5CH_3CN. Also, the bond lengths for **1** $Fe^{III}-N_{amido}$ [av. 2.064(4) Å] and $Fe^{III}-O_{phen}$ [av. 1.962(4) Å] as well as $Fe^{III}-N_{py}$ [av. 2.178(5) Å] (py = pyridine) are substantially shorter than analogous bond lengths in $Na[Fe(POPY)(N\text{-}MeIm)_2]$ (av. 2.228 Å, 2.045 Å, and 2.221 Å respectively) due to the ligand strain imposed by the pentadentate planar $POPY^{4-}$ ligand in the latter complex.

Molecular Structures of [Fe(Papy2O)(Cl)] (2) and [Fe(Papy2O)(SCN)] (3)

X-ray quality crystals of **2**·2CH_3CN were grown from CH_3CN at −20 °C while a toluene/CH_2Cl_2 (3:1) mixture was used to obtain single crystals of **3**·toluene. Both **2** and **3** are monomeric and the coordination geometry is octahedral with the deprotonated $Papy_2O^{2-}$ ligand coordinated to five of the six sites of the Fe^{III} center in both complexes. In **2**, a Cl^- ion occupies the sixth site (Figure 3) while in **3**, the sixth site is occupied by a SCN^- ion (Figure 4).

Since these complexes are neutral, there is no extended structure in solid state. The bond lengths of **2** and **3** are similar (Table 1). The $Fe^{III}-N_{amido}$ [av. 2.0157(14) Å] and $Fe^{III}-N_{py}$ [av. 2.1511(15) Å] bond lengths of **2** and **3** compare well with those noted for **1** while the $Fe^{III}-O_{phen}$ distance [av. 1.8781(12) Å] is slightly shorter. The $N_{amido}-Fe-O_{phen}$ angles in both **2** and **3** are larger (91°, six-membered rings) than the same angles in **1** (av. 80°, five-membered rings, Table 1).

Stability and Spectroscopic Properties

The EPR spectra of **1**, **2**, and **3** in DMF glass clearly indicate that the Fe^{III} centers in these complexes exist as HS. During the past few years, we have synthesized several similar Fe^{III} complexes that contain one, two or four $Fe^{III}-N_{amido}$ bonds in addition to $Fe^{III}-N_{py}$ and/or $Fe^{III}-S_{thio}$ (thio = thiophenolato) bonds.[5,11−14] All these complexes are consistently LS (Table 2). The obvious difference between the present set of complexes (**1**, **2**, and **3**) and the rest of the entries in Table 2 is the fact that complexes **1**, **2**, and **3** contain $Fe^{III}-O_{phen}$ bonds. In general, mononuclear Fe^{III} complexes with either one,[7,15,16] two,[17] three[8,18] or four[10,19] $Fe^{III}-O_{phen}$ bonds all tend to possess HS ($t_{2g}^3e_g^2$) Fe^{III} centers. The $Fe^{III}-O_{phen}$ bond in the majority of these complexes has been described as more than a single bond with additional d_π-p_π back-bonding.[9] Wiegh-

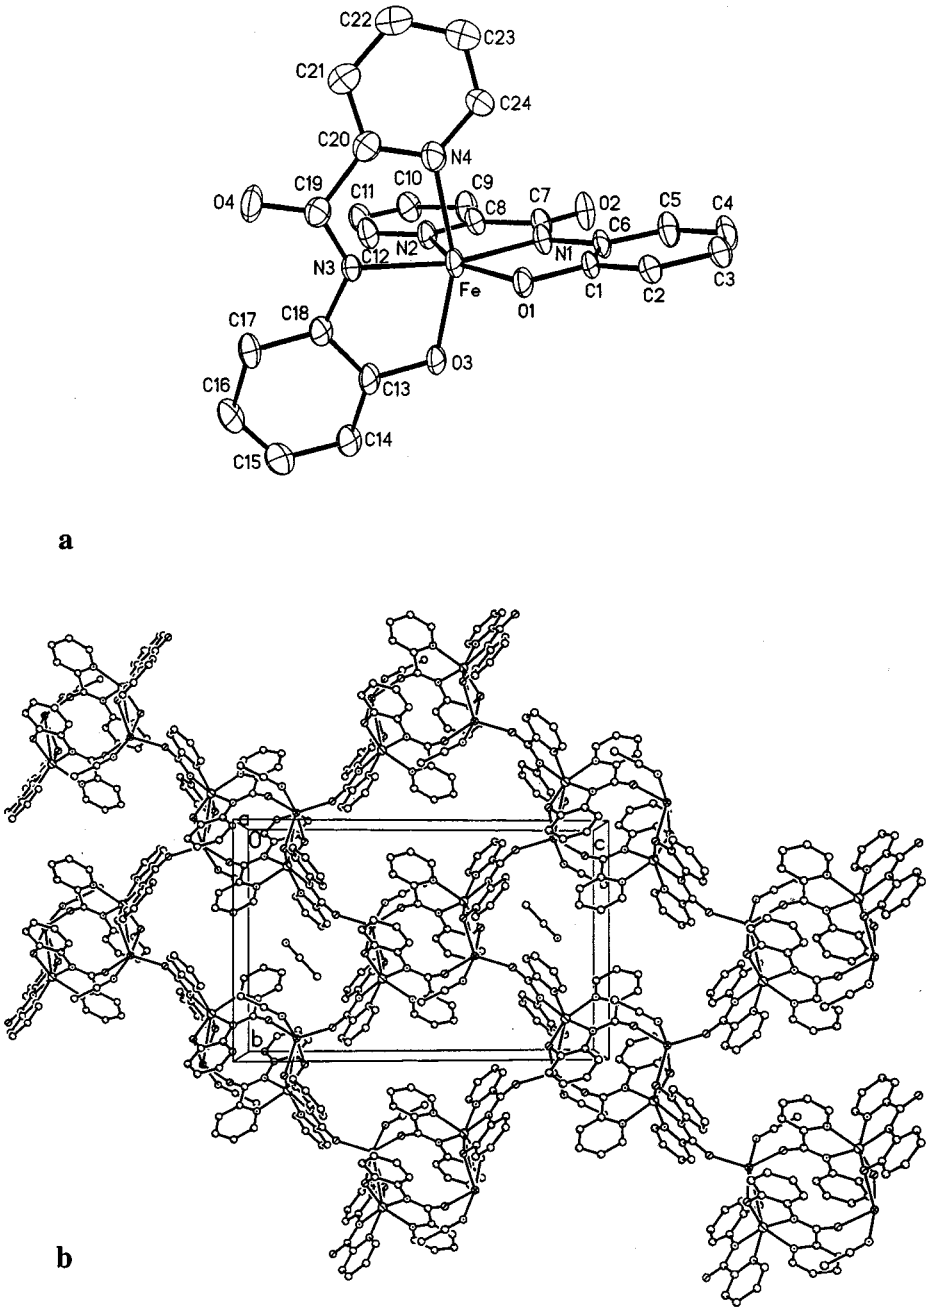

Figure 2. (a) Thermal ellipsoid plot of $[Fe(PypepO)_2]^+$ (at the 35% probability level); (b) extended structure of $Na[Fe(PypepO)_2]\cdot 2.5CH_3CN$ showing the small and large pockets formed in the solid state

ardt and co-workers have suggested that the HS configuration of the Fe^{III} center facilitates such a d_π-p_π interaction.[9] Since the $Fe^{III}-O_{phen}$ distances in complexes **1**, **2**, and **3** (Table 1) compare well with the "short" $Fe^{III}-O_{phen}$ distances reported so far (range = 1.85−1.97 Å),[7−10,15−19] it is evident that the $Fe^{III}-O_{phen}$ bonds in **1**, **2**, and **3** are of a similar nature, and hence these complexes prefer a HS configuration. Taken together, these facts indicate that when the Fe^{III} center is coordinated to both carboxamido nitrogen(s) and phenolato oxygen(s) (like **1**, **2**, and **3**), the $Fe^{III}-O_{phen}$ interaction dominates and the resultant complexes are HS.

A change in spin state occurs when the Cl^- ligand of $[Fe(Papy_2O)(Cl)]$ (**2**) is replaced with CN^-. The HS complex **2** is converted into a LS cyanide adduct $[Fe(Papy_2O)(CN)]$ upon addition of one equiv. of $(Et_4N)(CN)$ to a solution of **2** in DMF (EPR data, Figure 5). This change in spin state on going from **2** to $[Fe(Papy_2O)(CN)]$ supports the notion that the spin state of the Fe^{III} center is controlled by the $Fe^{III}-N_{amido}$ and $Fe^{III}-O_{phen}$ interactions *which*

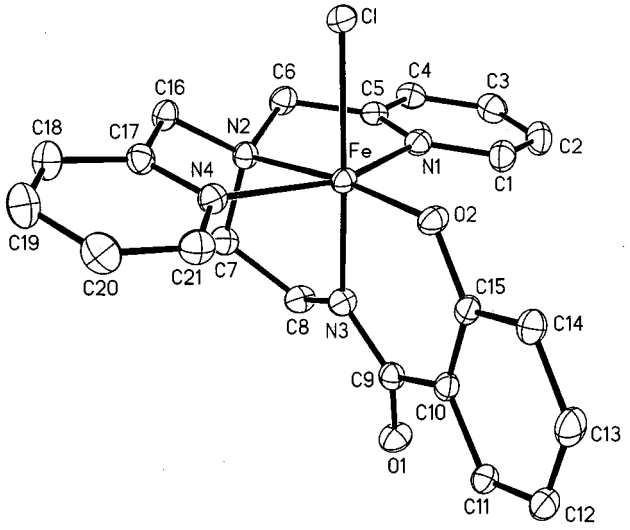

Figure 3. Thermal ellipsoid plot of **2** (at the 50% probability level)

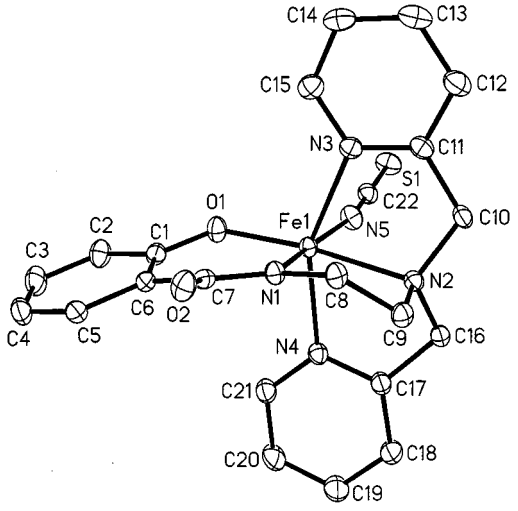

Figure 4. Thermal ellipsoid plot of **3** (at the 50% probability level)

compete against each other. The competing effect of these two interactions appears to be similar enough so that addition of a strong sixth ligand like CN^- results in a switch in the spin state during the [Fe(Papy$_2$O)(Cl)] → [Fe(Papy$_2$O)(CN)] transformation.

At this point it is also important to note that the LS species [Fe(Papy$_2$O)(CN)] is quite unstable and can only be studied by low temperature spectroscopy. All attempts to isolate this complex as a solid product have failed so far. In contrast, the analogous CN^- adduct $[Fe(Papy_3)(CN)]^+$ (a similar complex with *no* $Fe^{III}-O_{phen}$ bond) is LS and very stable.[6] Clearly, the change in spin state converts a stable complex **2** into an unstable species [Fe(Papy$_2$O)(CN)]. Since HS complexes with $Fe^{III}-O_{phen}$ bonds are usually very stable, it is quite evident that forcing the HS complex **2** (with $Fe^{III}-O_{phen}$ bond) into a LS ($t_{2g}^5e_g^0$) configuration in [Fe(Papy$_2$O)(CN)] reduces its stability, presumably by minimizing the d_π-p_π bonding interaction. Reduction of the $M^{III}-O_{phen}$ bonding interaction has been noted for Co^{III} complexes with phenolate ligands in which the t_{2g}^6 configuration of the Co^{III} center eliminates any d_π-p_π bonding.[9] Our work thus far indicates that LS complexes with $Fe^{III}-N_{amido}$ and $Fe^{III}-O_{phen}$ bonds are inherently unstable. We must comment here that our conclusion regarding weakening of the $Fe^{III}-O_{phen}$ interaction in LS complexes is preliminary and the final word on the stability of LS versus HS Fe^{III} complexes with both $Fe^{III}-N_{amido}$ and $Fe^{III}-O_{phen}$ coordination will require more in-depth studies. Such studies are in progress in this laboratory at the present time.

Finally, we like to point out that complexes **2** and **3** are quite stable toward hydrolysis and do not give rise to species with a (μ-oxo)diiron(III) core. For some time now we have maintained that the presence of an $Fe^{III}-N_{amido}$ bond stabilizes the Fe^{III} center to a great extent and prevents both

hydrolytic decomposition and formation of oxo- or hydroxo-bridged iron species which are often the thermodynamic end products in iron chemistry.[10,13] Since the complexes with the $Papy_2O^{2-}$ ligand contain only one $Fe^{III}-N_{amido}$ bond, we have attempted to synthesize directly the corresponding (μ-oxo)diiron(III) complex. However, addition of 2 equiv. of $Papy_2O^{2-}$ to $(Et_4N)_2[Fe_2OCl_6]$ [a pre-formed (μ-oxo)diiron(III) synthon] resulted in the isolation of complex **2** rather than the expected μ-oxo species $[\{Fe(Papy_2O)\}_2O]$. This further supports our previous remarks that complexes with $Fe^{III}-N_{amido}$ bonds do not form oxo-bridged dimers (or polymers), which translates into an enhanced stability of these complexes towards hydrolytic decomposition.

Conclusion

In conclusion, we have prepared and structurally characterized three stable complexes that contain both $Fe^{III}-N_{amido}$ and $Fe^{III}-O_{phen}$ bonds. In previous studies, it has been shown that carboxamido nitrogens (N_{amido}) are strong donors and their coordination to iron usually results in LS Fe^{III} complexes. Previous studies have also shown that complexes with O_{phen} comprise HS Fe^{III} centers. The complexes reported herein now indicate that these two donor atoms in the same molecule influence the spin state of the Fe^{III} center in the opposite sense. Overall, the resulting complexes are HS and so far, no LS complex with both $Fe^{III}-N_{amido}$ and $Fe^{III}-O_{phen}$ bonds has been isolated. It thus appears that the effect of the phenolato oxygen to afford HS Fe^{III} species overrides the spin-pairing trend of the carboxamido nitrogen in Fe^{III} complexes. In the case of Fe^{III} complexes of the $Papy_2O^{2-}$ ligand (which has one N_{amido} and one O_{phen} donor), the overriding effect of O_{phen} can just be compensated by adding a strong sixth ligand (like CN^-). The resulting LS complex $[Fe(Papy_2O)(CN)]$ is, however, unstable. Since similar LS Fe^{III} complexes with no $Fe^{III}-O_{phen}$ bond(s) are stable entities, it now appears that $Fe^{III}-O_{phen}$ bonds impart instability to LS Fe^{III} complexes.

Experimental Section

Physical Measurements: A Perkin−Elmer 1600 FTIR spectrophotometer was used to monitor the IR spectra. ^1H NMR spectra were recorded on a Bruker 250 MHz spectrometer. EPR spectra were monitored at X-band frequencies on a Bruker ESP-300 spectrometer. Electrochemical measurements were performed with standard Princeton Applied Research instrumentation and a Pt inlay electrode. Potentials were measured at 25 °C versus an aqueous saturated calomel electrode (SCE) as reference.

Materials and Methods: All manipulations were carried out in air. (2-Aminoethyl)bis(2-pyridylmethyl)amine was prepared following a published procedure.[20] 2-Aminophenol, 2-picolinic acid, 2-acetylsalicyclic acid, thionyl chloride ($SOCl_2$), oxalyl chloride, sodium hydroxide (NaOH), sodium hydride (NaH), and sodium thiocyanate (NaSCN) were purchased from Aldrich Chemical Company

and used without further purification. $(Et_4N)[FeCl_4]$[21] and $[Fe(DMF)_6](ClO_4)_3$ [22] were prepared by following published procedures. *N*,*N*′-dimethylformamide (DMF) was distilled from BaO while tetrahydrofuran (THF) and toluene were distilled from Na/benzophenone prior to use. Dichloromethane (CH_2Cl_2) and acetonitrile (CH_3CN) were distilled from CaH_2 prior to use.

Preparation of $PypepOH_2$: 2-picolinic acid (5.00 g, 41 mmol) was dissolved in neat $SOCl_2$ (10−20 mL) and warmed to 50 °C until a clear deep purple solution remained (approx. 1 h). The excess $SOCl_2$ was removed under vacuum and the purple residue was triturated twice with THF to remove traces of HCl. The purple solid was then redissolved in THF (30 mL) and added to a solution of 2-aminophenol (4.40 g, 41 mmol) and Et_3N (6.30 g, 62 mmol) in THF (50 mL) at 0 °C. The mixture was then heated to reflux for 5 h. Following a brief cooling period, triethylamine hydrochloride was filtered off, and the volatiles were removed by rotary evaporation. The remaining residue was triturated twice with THF and recrystallized from $MeOH/H_2O$ (1:10 v/v) (6.90 g, 78% yield). ^1H NMR (250 MHz, $CDCl_3$): δ = 6.85 (t, 1 H, ArH), 7.00 (d, 1 H, ArH), 7.08 (t, 2 H, ArH), 7.47 (t, 1 H, ArH), 7.87 (t, 1 H, ArH), 8.23 (d, 1 H, ArH), 8.58 (d, 1 H, ArH), 10.16 (s, 1 H, NH). Selected FTIR absorption bands (KBr pellet): $\tilde{\nu}$ = 3308 (m, N−H), 3072 (m, O−H), 1653 (s, C=O), 1593 (s), 1543 (s), 1458 (s), 1434 (m), 1370 (m), 1284 (m), 1230 (m), 1098 (w), 1038 (w), 932 (w), 852 (w), 757 (s), 738 (s), 691 (s), 618 (w), 594 (w) cm^{-1}.

$NaPapy_2OH$: 2-Acetylsalicyclic acid (1.40 g, 7.5 mmol) was dissolved in neat oxalyl chloride (10−20 mL) and warmed to 40 °C until a clear solution remained (approx. 1 h). Excess oxalyl chloride was removed under vacuum and the clear oil was triturated twice with THF to remove traces of HCl. The residue was then redissolved in THF (10 mL) and added dropwise to a solution of (2-aminoethyl)bis(2-pyridylmethyl)amine (1.80 g, 7.5 mmol) and triethylamine (0.90 g, 9.0 mmol) in THF (25 mL) at 0 °C. The mixture was warmed to room temperature and allowed to stir for 12 h, at which point 6 M NaOH (20 mL) was added. Volatiles were removed by rotary evaporation, the residue was made neutral with 12 M HCl, and extracted with CH_2Cl_2 (3 × 20 mL). The combined extracts were dried over $MgSO_4$ and volatiles were removed under vacuum to yield a gummy yellow residue (crude $Papy_2OH_2$: 2.30 g, 6.2 mmol). Sodium metal (0.14 g, 6.2 mmol) was dissolved in methanol (10 mL) and added to the residue. The solution was stirred for 1 h and then the solvent was removed under vacuum. The remaining yellow solid, $NaPapy_2OH$, was used without further purification (2.40 g, 83% yield). ^1H NMR (250 MHz, $[D_6]DMSO$): δ = 2.56 (t, 2 H, CH_2), 3.40 (m, 2 H, CH_2), 3.78 (s, 4 H, CH_2), 6.08 (t, 1 H, ArH), 6.36 (d, 1 H, ArH), 6.87 (t, 1 H, ArH), 7.19 (t, 2 H, ArH), 7.63 (m, 5 H, ArH), 8.44 (d, 2 H, ArH). Selected FTIR absorption bands (KBr pellet): $\tilde{\nu}$ = 3051 (w), 2933 (w), 1625 (s), 1594 (s), 1466 (s), 1438 (s), 1390 (m), 1342 (m), 1256 (m), 1150 (m), 860 (w), 758 (s), 704 (m), 567 (w), 543 (w) cm^{-1}.

$Na[Fe(PypepO)_2]$ (1): $PypepOH_2$ (0.24 g, 1.1 mmol) was dissolved in DMF (25 mL) and to this was added solid NaH (0.05 g, 2.2 mmol). The mixture was stirred for 2 h and then a batch of $[Fe(DMF)_6](ClO_4)_3$ (0.43 g, 0.55 mmol) dissolved in DMF (5 mL) was added to it. The resultant deep green solution was allowed to stir for 2 h at 25 °C. Next, the solvent was removed under vacuum and the residue was dissolved in CH_3CN (10 mL). The solution was then stored at −20 °C for 3 days. The dark green microcrystalline solid thus obtained was collected by filtration (0.27 g, 42% yield). $C_{29}H_{23.5}FeN_{6.5}NaO_4$ (605.58 for $Na[Fe(PypepO)_2]\cdot 2.5\,CH_3CN$): calcd. C 57.47, H 3.91, N 15.03; found C 57.21, H 3.85, N 15.21. Selected FTIR absorption bands (KBr pellet): $\tilde{\nu}$ = 1670 (s), 1614 (s), 1593 (s, C=O), 1567 (s), 1464 (s), 1388 (m), 1274 (s), 1248 (m), 1098 (m), 1020 (w), 937 (w), 863 (w), 803 (w), 754 (m), 742 (m), 692 (w), 642 (w), 611 (w), 575 (w), 562 (w), 501 (w) cm^{-1}.

$[Fe(Papy_2O)(Cl)]$ (2): A portion of solid NaH (0.01 g, 0.43 mmol) was added to $NaPapy_2OH$ (0.16 g, 0.43 mmol) dissolved in DMF (10 mL) and the mixture was stirred for 2 h. To this solution was added a solution of $(Et_4N)[FeCl_4]$ (0.14 g, 0.43 mmol) dissolved in DMF (5 mL) and the resultant deep red solution was allowed to stir for an additional 1 h. The DMF solvent was then removed under vacuum and the residue was dissolved in CH_3CN (20 mL). The red solution was stored at −20 °C overnight. The resultant deep red microcrystalline solid was then filtered off and dried under

vacuum (0.16 g, 70% yield). $C_{25}H_{26}ClFeN_6O_2$ (533.55 for [Fe(Papy$_2$O)(Cl)]·2CH_3CN): calcd. C 56.23, H 4.91, N 15.75; found C 56.19, H 4.96, N 15.28. Selected FTIR absorption bands (KBr pellet): $\tilde{\nu}$ = 1597 (m, C=O), 1571 (s), 1533 (s), 1444 (s), 1360 (s), 1290 (w), 1244 (w), 1102 (w), 1024 (w), 895 (w), 768 (s,), 704 (w), 658 (w) cm^{-1}.

[Fe(Papy$_2$O)(NCS)] (3): To a solution of NaPapy$_2$OH (0.21 g, 0.55 mmol) in DMF (10 mL) was added a batch of solid NaH (0.013 g, 0.55 mmol) and the mixture was allowed to stir for 2 h. To this solution was then added a batch of $[Fe(DMF)_6](ClO_4)_3$ (0.43 g, 0.55 mmol) dissolved in DMF (5 mL) and the purple/red solution was stirred for an additional 1 h. At this point, a solution of NaSCN (0.067 g, 0.83 mmol) in DMF (1 mL) was added and the color of the solution changed to red/brown. The DMF solvent was removed under vacuum and the residue was dissolved in THF (30 mL). The solution was stored at −20 °C overnight. The deep red needles were collected by filtration (0.15 g, 50% yield). $C_{26}H_{28}FeN_5O_3S$ (546.17 for [Fe(Papy$_2$O)(NCS)]·THF): calcd. C 57.13, H 5.17, N 12.82; found C 57.27, H 5.19, N 12.74. Selected FTIR absorption bands (KBr pellet): $\tilde{\nu}$ = 2046 (s, SCN), 1594 (m, C=O), 1570 (m), 1534 (m), 1445 (m), 1352 (m), 1103 (w), 1024 (w), 763 (m,) cm^{-1}.

Crystal Structure Analysis: Deep black/green crystals of Na[Fe(PypepO)$_2$]·2.5CH_3CN (**1**·2.5CH_3CN) and dark red crystals of [Fe(Papy$_2$O)(Cl)]·2CH_3CN (**2**·2CH_3CN) were each grown from CH_3CN at −20 °C. Black/red X-ray quality plates of [Fe(Papy$_2$O)(NCS)]·toluene (**3**·toluene) were grown from toluene/CH_2Cl_2 (3:1). Diffraction data for all complexes were collected at 90 K on Bruker SMART 1000 diffractometer. Mo-K_α (0.71073 Å) radiation was used in all cases and the data were corrected for absorption. The structures were solved using the standard SHELXS-97 package. Machine parameters, crystal data, and data collection parameters for **1**·2.5CH_3CN, **2**·2CH_3CN, and **3**·toluene are summarized in Table 3, while selected bond lengths and angles are listed in Table 1.

CCDC-166560, -166561 and -166552 contain the supplementary crystallographic data for complexes **1**·2.5CH_3CN, **2**·2CH_3CN, and **3**·toluene, respectively. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support from NSF (CHE-9818492) and NIH (GM 61636) is gratefully acknowledged. The Bruker SMART 1000 diffractometer was funded in part by an NSF Instrumentation Grant CHE-9808259.

Difunctionalised Chemosensors Containing Electroactive and Fluorescent Signalling Subunits

Félix Sancenon,[a] Angel Benito,[a] Francisco J. Hernández,[a] José M. Lloris,[a] Ramón Martínez-Máñez,*[a] Teresa Pardo,[a] and Juan Soto[a]

Keywords: Ferrocene / Anthracene / Fluorescence / Chemosensors

The new ligands 13-anthrylmethyl-7-ferrocenylmethyl-1,4,10-trioxa-7,13-diaza-cyclopentadecane (L^1) and 1-anthrylmethyl-4,8,11-ferrocenylmethyl-1,4,8,11-tetraaza-cyclotetradecane (L^2) have been synthesised, characterised, and their potential activity as chemosensors towards the metal cations Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+} studied in 1,4-dioxane/water (70:30, v/v). Both ligands L^1 and L^2 are difunctionalised receptors containing redox-active (ferrocene) and fluorescent (anthracene) signalling subunits. The crystal structures of $[H_2L^1][PF_6]_2$ and $[CuL^2][PF_6]_2$ were determined by single-crystal X-ray procedures. Potentiometric experiments in dioxane/water (70:30, v/v; 0.1 M KNO_3; 25.0 ± 0.1 °C) for L^1 and L^2 allowed the determination of protonation constants and complex stability constants with the Cu^{2+} and Pb^{2+} metal ions. They form stable complexes with both ligands and show stability constants with values close to those reported for similar complexes. The electrochemical and fluorescence behaviour of L^1 and L^2 was studied as a function of the pH and in the presence of the Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+} metal cations. The fluorescence and electrochemical response of L^1 and L^2 is pH-dependent. Ligand L^1 was able to electrochemically and selectively sense Pb^{2+} whereas L^2 sensed Cu^{2+}, Zn^{2+}, and Cd^{2+} using electrochemical techniques. The maximum electrochemical shift (ca. 57 mV) was found for L^2 in the presence of Cu^{2+} at pH = 8. Fluorescence studies showed that the emission intensities of L^1 and L^2 were selectively enhanced in the presence of Cu^{2+}. Additionally, the $[Cu(L^2)]^{2+}$complex acted as anion-sensing receptor in acetonitrile. The oxidation potential of the ferrocenyl group of the $[Cu(L^2)]^{2+}$complex was cathodically shifted upon addition of anions. The largest electrochemical shift was observed in the presence of fluoride (210 mV). The fluorescence emission of the anthracene groups in $[Cu(L^2)]^{2+}$ was enhanced in the presence of fluoride, nitrate, and dihydrogenophosphate.

Introduction

The design of functionalised receptors for the development of potential chemosensors is a field of active research. Of especial interest is the synthesis of molecules capable of amplifying microscopic events (for instance the presence of a target guest in a certain solution) to macroscopic levels.[1] This sensing function is generally achieved by the coupling of two well-defined parts, (i) selective binding sites and (ii) signalling subunits. This second component can be classified by the type of signal output; colour changes,[2] redox shifts,[3] and fluorescence quenching or enhancement[4] are among some commonly observed signals. Sensing molecules showing those changes can be built by attaching chromogenic units,[5] redox-active groups,[6] or fluorescent signalling subunits,[7] respectively, near the binding sites. Whereas the ligand−guest interaction is controlled by well-known binding rules (this is particularly true for ligand−cation interactions) the communication with the signalling subunit is more subtle. In some cases this is even unpredictable due to the competition of several processes, namely changes in photoelectron transfer or energy transfer paths, changes in redox properties of the receptor, etc. These new molecules are important because they will surely be the chemical active part of new sensing devices. For instance, receptors able to change spectroscopic properties (colour or fluorescence) in the presence of target substrates are of application in optical fibre devices,[8] whereas changes in redox potential upon addition of certain guests could be of application in the development of amperometric sensing devices.[9]

Despite the development of these individual areas, there are very few examples of molecules containing more than one type of signalling unit.[10] These systems can be important in the development of a new family of ion chemosensors that can either be able to sense different guests or display two or more macroscopic observable events upon addition of a certain analyte. Towards this goal, we have synthesised macrocyclic polyaza or oxaaza components and have functionalised them with both ferrocenyl and anthryl groups. Ferrocene is a well-known electro-active signalling subunit. Anthracene can act as either an electro- or photo-active

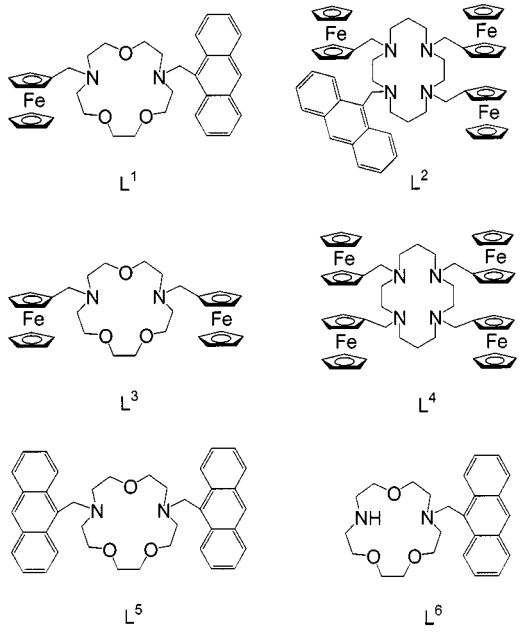
group. Moreover, we have used the anthracene group because of its photophysical properties, and therefore we will refer to it as a fluorescent signalling subunit.

Results and Discussion

The new ligands L^1 and L^2 (Scheme 1) were synthesised according to a two-step reaction. Thus, reaction of 9-(chloromethyl)anthracene and the corresponding macrocycle (1:1 molar ratio) allowed isolation of the anthrylmethyl-functionalised derivatives that were further treated with an excess of (ferrocenylmethyl)trimethylammonium iodide in acetonitrile to give L^1 and L^2 in rather good yield. ^1H and ^{13}C NMR and mass spectra of L^1 and L^2 were consistent with the proposed formulation. Additionally, the crystal structures of the protonated form of L^1 and the Cu^{2+} complex of L^2 were determined using single-crystal X-ray procedures (see below).



Scheme 1

L^1 and L^2 are rare examples of molecules containing redox-active and fluorescence signalling subunits. The following work has been devoted to characterise the ligands, their solution behaviour and their electrochemical and emission properties in the presence of transition metal ions and anions.

Crystal Structure of $[H_2L^1][PF_6]_2$

Addition of aqueous $[NH_4][PF_6]$ to acetonitrile solutions of L^1 allowed us to isolate the $[H_2L^1][PF_6]_2$ salt as a yellow solid. Suitable crystals of this compound for single-crystal X-ray diffraction techniques were obtained by slow diffusion of ether into dichloromethane solutions of $[H_2L^1][PF_6]_2$. The molecular structure consists of $[H_2L^1]^{2+}$ cations and PF_6^- anions linked ionically. The anthryl and cyclopentadienyl groups are planar within the experimental error and the ferrocenyl moiety adopts a nearly eclipsed conformation. The Fc−Cp(centroid) distances are 1.631 and 1.639 Å. A view of the $[H_2L^1]^{2+}$ cation and selected bond lengths and angles have been included as Supporting Information (see footnote on the first page of this article).

Crystal Structure of $[CuL^2][PF_6]_2 \cdot CH_2Cl_2$

The $[CuL^2][PF_6]_2$ complex was obtained by reaction of L^2 with copper(II) nitrate in acetonitrile and further addition of aqueous $[NH_4][PF_6]$. Suitable crystals for X-ray diffraction were obtained by diffusion of ether into dichloromethane solutions of the complex. Table 1 gives selected bond lengths and angles. Figure 1 shows a view of the compound. The molecular structure consists of cationic $[CuL^2]^{2+}$ and PF_6^- anions as counterions. Molecules of dichloromethane complete the packing. The Cu^{2+} atom is coordinated by the four nitrogen atoms of the macrocycle, giving a distorted square-planar geometry. Three nitrogen atoms are also covalently bonded to three ferrocenylmethyl centres, whereas one nitrogen atom is attached to an anthrylmethyl group. The Cu−N distances range from 2.116(7) to 2.152(7), averaging 2.127 Å. Some bond angles around Cu^{2+} are far from the ideal square-planar geometry, for instance N(3)−Cu(1)−N(2), N(3)−Cu(1)−N(1), and N(4)−Cu(1)−N(1) are 86.8(3), 151.2(3), and 85.7(3), respectively. The four nitrogen atoms define a plane within ±

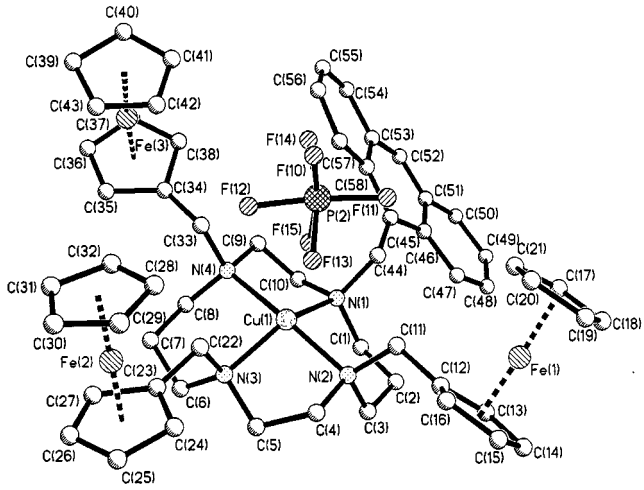

Figure 1. Molecular structure of the $[CuL^2]^{2+}$ cation

0.23 Å and the copper atom is out-of-plane by ± 0.30 Å. The deviation from the ideal geometry is mainly induced by the cyclam unit that adopts a configuration with the four nitrogen atoms pointing above the N4 plane. This has been reported to be the thermodynamically less favourable isomer.[11] However, the conformation of tetrafunctionalised cyclam derivatives containing the four groups above the N4 plane is not unusual and has also been found in complexes such as $[Ni(Me_4cyclam)]^{2+}$, Me_4cyclam = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane, and in the nickel(II) complex of L^4.

It is remarkable that the molecular assembly of Cu^{2+} and the ligand L^2 leads to the formation of a host molecule containing a cavity built with three ferrocenylmethyl groups and one anthrylmethyl group. In the crystal structure this cavity is filled by one PF_6^- counterion. In fact, there is a very close contact between the Cu^{2+} and the F(15) atom [Cu^{2+}···F(15) 2.47 Å]. Figure 2 also shows as an alternative view, with the space-filling representation emphasising the electro-photo-active cavity and the host−guest association.[12] No significant distortions were found in the ferrocenylmethyl and anthrylmethyl groups. The ferrocenyl units adopt the usual sandwich conformation with the cyclopentadienyl rings parallel within the experimental error. Fe-Cp(centroid) distances range from 1.621 to 1.659, averaging 1.637 Å.

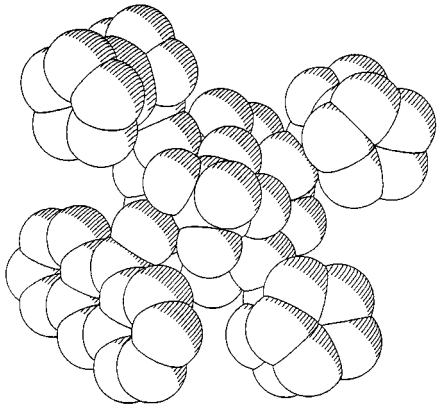

Figure 2. the space-filling representationof the $[CuL^2]^{2+}$ cation

Potentiometric Studies

Protonation constants determined potentiometrically in 1,4-dioxane/water (70:30 v/v; 25 °C; 0.1 M potassium nitrate) are shown in Table 2. As expected, L^1 and L^2 show two and four protonation processes, respectively. Ligand L^1 displays stepwise protonation constants close to those reported[13] for L^3. Ligand L^4 is a cyclam derivative, and it shows the two first protonations being much more basic than the last two. A similar behaviour was found for cyclam itself and other cyclam derivatives.[14] Figure 3 shows the distribution diagram of the L^1/H^+ and L^2/H^+ systems.

Table 2. Stepwise protonation constants for L^1 and L^2 in dioxane/water (70:30 v/v; 25 °C; 0.1 M potassium nitrate)

Reaction	L^1	L^2
$L + H^+ = [HL]^+$	8.14(2)	8.91(2)
$[HL]^+ + H^+ = [H_2L]^{2+}$	5.80(2)	6.56(1)
$[H_2L]^{2+} + H^+ = [H_3L]^{3+}$		2.71(3)
$[H_3L]^{3+} + H^+ = [H_4L]^{4+}$		2.36(1)

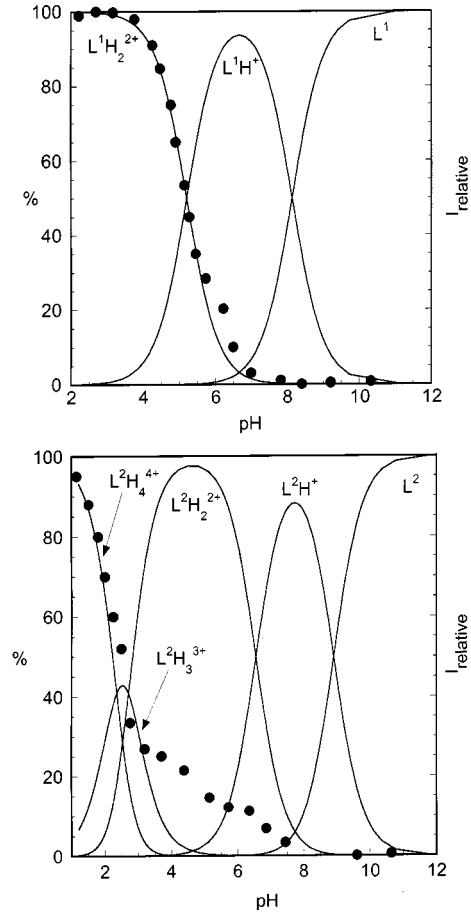

Figure 3. Distribution diagrams of the species for a) L^1/H^+ and b) L^2/H^+ (full line) and the fluorescence emission titration curves (•) for those systems

Stability constants for the formation of complexes of L^1 and L^2 with Cu^{2+}, Pb^{2+} in dioxane/water (70:30, v/v) mixtures are shown in Table 3. Both metal ions form with the receptors here considered stable $[ML]^{2+}$ complexes. Figures 4 and 5 show the distribution diagram of the $L/Cu^{2+}/H^+$ and $L/Pb^{2+}/H^+$ systems (L = L^1 or L^2). In general, the formation stability constants obtained are in line with those reported for related complexes.[14] Receptor L^2 is a tetraaza macrocycle, and displays larger stability constants with Cu^{2+} than with Pb^{2+}. In fact, the stability constant of the $L^2 + M^{2+} = [M(L^2)]^{2+}$ process is 10^3 times larger for Cu^{2+} than for Pb^{2+}. In contrast, when the N-donor atoms are partially replaced with O-donor atoms the affinity for Cu^{2+} is considerably reduced and the stability constants for the formation of the $[M(L^1)]^{2+}$ complexes are similar for Cu^{2+} and Pb^{2+} (log$K$ = 5.23 for copper and log$K$ = 5.12 for lead). These stability constants are not very different to those found for L^3 with the same metal ions {log$K$ = 6.27 and log$K$ = 6.43, for the formation of the $[M(L^3)]^{2+}$ complexes with Cu^{2+} and Pb^{2+}, respectively}.[13]

Table 3. Stability constants (log K) for the formation of Cu^{2+} and Pb^{2+} complexes of L^1 and L^2 in dioxane/water (70:30, v/v; 25 °C; 0.1 M potassium nitrate)

Reaction	L^1	L^2
$Cu^{2+} + L + H^+ = [Cu(HL)]^{3+}$	12.85(4)	14.05(4)
$Cu^{2+} + L = [Cu(L)]^{2+}$	5.23(2)	9.67(1)
$Cu^{2+} + L + H_2O = [Cu(L)(OH)]^+ + H^+$	−1.84(2)	0.56(4)
$Cu^{2+} + L + 2H_2O = [Cu(L)(OH)_2] + 2H^+$	−13.13(3)	−9.34(3)
$Pb^{2+} + L + H^+ = [Pb(HL)]^{3+}$	11.15(3)	13.45(4)
$Pb^{2+} + L = [Pb(L)]^{2+}$	5.12(1)	6.31(3)
$Pb^{2+} + L + H_2O = [Pb(L)(OH)]^+ + H^+$	−2.72(1)	−0.70(3)
$Pb^{2+} + L + 2H_2O = [Pb(L)(OH)_2] + 2H^+$	−12.81(3)	−10.12(4)

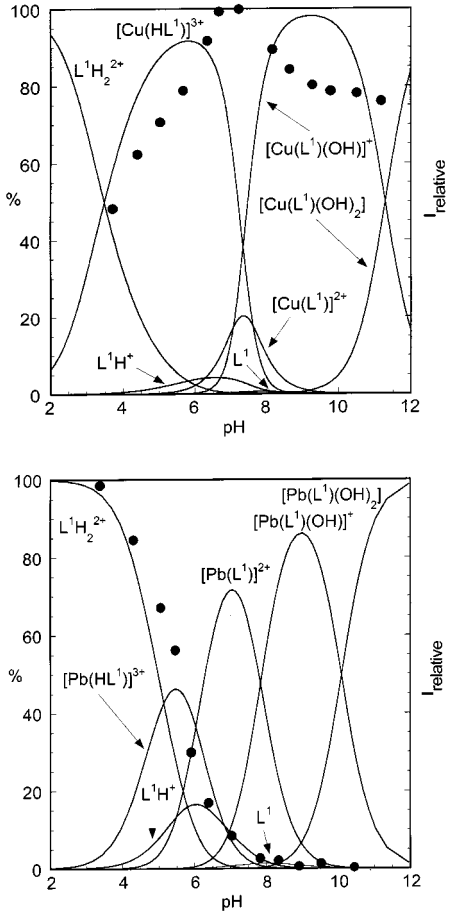

Figure 4. Distribution diagrams of the species for a) $L^1/Cu^{2+}/H^+$ and b) $L^1/Pb^{2+}/H^+$ (full line) and the fluorescence emission titration curves (•) for those systems

Cation Sensing

Electrochemical Behaviour

The redox potentials of both L^1 and L^2 are pH-dependent. When basic solutions of L^1 and L^2 are acidified a steady displacement of $E_{1/2}$ ($E_{1/2}$ = half-wave potential) to more anodic potentials was observed. This is a known behaviour, attributed to the protonation of the amino groups and therefore to the formation of positively charged species that are more difficult to be oxidised.[15] The difference found between the oxidation potential under basic (pH ≈ 12) and acidic (pH ≈ 2) conditions was 140 and 110 mV for L^1 and L^2, respectively. We have also electrochemically

studied the variation of $E_{1/2}$ versus pH for the $L/H^+/M^{2+}$ systems (L = L^1 or L^2; M = Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} or Pb^{2+}; M^{2+}/L molar ratio = 1). In order to rationalise those data the difference between $E_{1/2}$ for the receptor/metal system and that for the free receptor [$\Delta E_{1/2}$ = $E_{1/2}$(receptor/metal) − $E_{1/2}$(receptor)] was monitored at different pH values from 2 to 12. Figure 6 (top) shows $\Delta E_{1/2}$ versus pH for L^1 in the presence of Pb^{2+}. For other metal ions (Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Hg^{2+}) $\Delta E_{1/2}$ is less than 5 mV (not shown). Ligand L^1 was able to electrochemically recognise Pb^{2+} over other common, typically present (in water samples) metal ions in the pH range of 5 to 7.5, although the maximum shift found of 25 mV at pH = 6.5 is rather small. Figure 6 (bottom) displays the electrochemical response found for L^2 as a function of the pH in the presence of Cu^{2+}, Zn^{2+}, and Cd^{2+}. No electrochemical shift was induced for Ni^{2+}, Hg^{2+}, and Pb^{2+}. The Cu^{2+}, Cd^{2+}, and Zn^{2+} ions change the oxidation potential of the L^2 ligand in a wide pH range, the maximum shift being observed for Cu^{2+} at pH = 8 (ca. 57 mV).

Comparison between the electrochemical response in Figure 6 and the distribution diagrams in Figures 4 and 5 allows a determination of the species responsible for the electrochemical shift. Thus, the $[Pb(L^1)]^{2+}$ complex exists in the pH range 6−8, at which the redox potential of the ferrocenyl groups suffer an anodic shift of ca. 25 mV with respect to that of the L^1 ligand. Comparison between Figure 5 (top) and Figure 6 (bottom) also suggests that it is the existence in solution of the $[Cu(L^2)]^{2+}$ complex that induces anodic shifts of up to 60 mV. It seems that there is a correlation between the presence, in solution, of the $[M(L)]^{2+}$ species and the electrochemical response. In this sense the absence of an electrochemical signal for the L^1/Cu^{2+} and L^2/Pb^{2+} systems might be related to the appearance of the $[Cu(L^1)]^{2+}$ and $[Pb(L^2)]^{2+}$ complexes as minor species [see Figure 4 (top) and Figure 5 (bottom)].

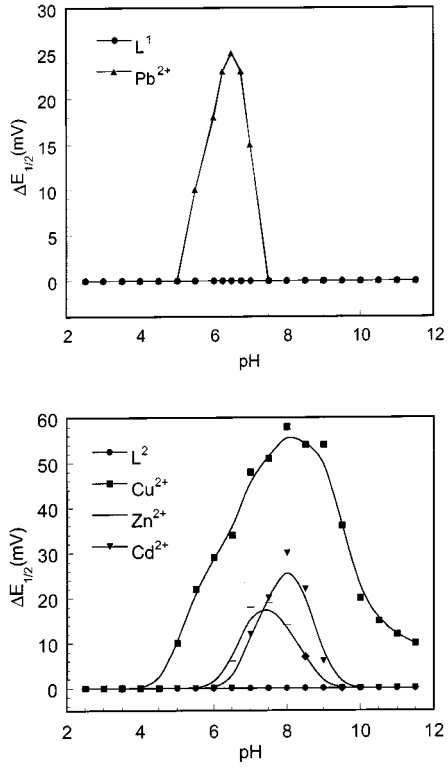

Figure 6. Oxidation potential shift ΔE [defined as $E_{1/2}$(receptor + metal ion) − $E_{1/2}$(receptor)] of a) L^1 and b) L^2 as a function of the pH in the presence of certain metal ions

At this point, it might be interesting to compare the electrochemical response of L^1 and L^2 with that previously reported for the L^3 and L^4 ferrocene-functionalised ligands. L^3 displays a large electrochemical recognition for Pb^{2+} (ca. −60 mV), although other heavy metal ions such as Cd^{2+} and Hg^{2+} also produce significant shifts (ca. −35 mV).[13] Additionally, the electrochemical shift in the presence of Pb^{2+} for L^1 is anodic but was reported to be cathodic for L^3. We have recently pointed out that in these systems, where there is no electronic communication through the bond between the metal centre and the signalling subunits, the electrochemical shift is mainly controlled by the nature of the complex formed at a certain pH and the distance between the positively charged metal centre and the ferrocenyl unit. The significant difference between the electrochemical response of L^1 and L^3 shows how subtle differences in the receptor (one or two ferrocenyl units) have significant influence in the electrochemical response. The receptor L^4 is able to electrochemically detect Cu^{2+}, Zn^{2+}, and Cd^{2+} in a wide pH range over Ni^{2+} and Pb^{2+}. This is a similar response to that observed for L^2. However, the maximum shift for L^2 in the presence of Cu^{2+} is ca. 60 mV at pH = 8, whereas for L^4 the maximum electrochemical shift was ca. 100 mV for Cu^{2+} at the same pH.[14] In conclusion, L^1 and L^2 are redox-active functionalised molecules that can electrochemically sense Pb^{2+} (L^1) and Cu^{2+}, Zn^{2+}, and Cd^{2+} (L^2) using electrochemical methods.

Fluorescence Behaviour

The study of the fluorescence behaviour of the L^1 and L^2 ligands was also carried out in dioxane/water (70:30) mixtures and with modulation of the pH. The ligands L^1 and L^2 show typical structured anthracene-like absorption and emission spectra with a maximum in the absorption band at 366 nm for L^1 and 367 nm for L^2, and with maximum emission wavelengths at 412 and 414 nm, respectively (see photophysical data in Table 4). The fluorescence intensity of L^1 and L^2 shows the typical behaviour of anthrylmethyl-substituted polyamines with maximum fluorescence at acidic pH and decrease of fluorescence at basic pH (see Figure 3 for the fluorescence emission titration curves of L^1 and L^2). This pH-dependent emission behaviour is well

Table 4. Photophysical parameters

	λ_{exc}	λ_{emi}	φ[a]
L^1	366	412	0.0030
L^5	366	410	0.0080
L^6	366	411	0.0055

[a] Quantum yield relative to anthracene in acetonitrile (φ = 0.36).

known and attributed to the existence of electron-transfer paths from the lone pair of the amine to the photo-excited state of the anthracene at basic pH that is not operative upon amine protonation.[16] From Figure 3 it can be observed that the fully protonated species of H_2L^1 are fluorescent, whereas deprotonation of at least one nitrogen atom gave species showing a much weaker emission intensity. In line with this behaviour, the species L^2 and L^2H^+ display low fluorescence; $L^2H_2^{2+}$ and $L^2H_3^{3+}$ induce some fluorescence enhancement, but the emission enhancement is at a maximum with the fully protonated $L^2H_4^{4+}$ species.

Figures 4 and 5 show the fluorescent emission titration curves for L^1 and L^2 in the presence of Cu^{2+} and Pb^{2+} (1:1 metal/ligand ratio). In both cases, Cu^{2+} is the only metal ion able to produce a considerable modification of the emission intensity versus pH profile of the free ligand. In contrast, Pb^{2+} [shown in Figure 4 (bottom) and Figure 5 (bottom)] and the cations Ni^{2+}, Zn^{2+}, Cd^{2+}, and Hg^{2+} (not shown) do not change significantly the fluorescence emission versus pH curves of the free receptors. Figure 4 (top) shows that all four complexes $[Cu(HL^1)]^{3+}$, $[Cu(L^1)]^{2+}$, $[Cu(L^1)(OH)]^+$, and $[Cu(L^1)(OH)_2]$ induce enhancement of the emission fluorescence intensity. The quantum yield of L^1 at pH = 7 is 0.050, whereas in the presence of Cu^{2+} the quantum yield at the same pH is 0.10. Figure 5 (top) also shows that all the Cu^{2+} complexes induce fluorescence emission enhancement.

The fluorescence curve in the presence of Pb^{2+} is very close to that found for the free receptors. At this point it has to be noted that a similar effect has been observed for instance in zinc(II) complexes of *N*,*N*-dibenzylated- or *N*-(anthrylmethyl)polyazaalkanes; that is, despite the formation of stable complexes the fluorescence behaviour versus pH of the free ligand and in the presence of Zn^{2+} is very similar.[17] From Figure 4 (bottom) and Figure 5 (bottom) it can be deduced that, except for the $[Pb(HL)]^{3+}$ complex (L = L^1 or L^2), that slightly enhances the fluorescence, the remaining species, $[Pb(L)]^{2+}$, $[Pb(L)(OH)]^+$, and $[Pb(L)(OH)_2]$, do not increase the emission intensity of the free L^1 receptor. This indicates that the coordination of Pb^{2+} to the nitrogen atoms is less effective than protonation in preventing photo-induced electron-transfer processes, and that the Pb^{2+} cation has little effect on the fluorescence behaviour despite the formation of stable complexes. One possible explanation of this observed behaviour could be related to the strength of the coordination between the nitrogen atoms and the Pb^{2+} cation, a poor coordination with at least one nitrogen atom will not hinder the photo-electron transfer from the lone pair of the nitrogen atom to the excited fluorophore. In this sense the effect is similar to that observed with protons; only when the L^1 or L^2 molecules are fully protonated there is an emission enhancement, whereas partial protonations have a lesser effect or no effect at all.

The fluorescent response of L^1 and L^2 in the presence of Cu^{2+} is remarkably different to the response observed for Cu^{2+} for similar receptors. The usual behaviour observed with anthrylaza macrocycles in the presence of Cu^{2+} is a fluorescence quenching upon complexation.[18] The chelation-enhanced quenching (CHEQ) has been reported to occur with copper and also with other open-shell paramagnetic or easily reducible metal cations. In fact, for the receptor 1,4,8,11-tetrakis(naphthylmethyl)-1,4,8,11-tetraazacyclotetradecane (containing four naphthylmethyl groups attached to the four N-donor atoms of the cyclam unit) the presence of Cu^{2+} (and also Hg^{2+}) produces a noticeable quenching of the emission fluorescent intensity at acidic pH.[19] A similar effect, the quenching of the emission fluorescence, is observed for cyclam functionalised with $Ru(tpy)_2^{2+}$ groups in the presence of Cu^{2+}.[20] All these reported data contrast with the fluorescence enhancement observed for L^1 and L^2 upon complexation of Cu^{2+}. This result could be of interest because in sensing processes fluorescence enhancement rather than quenching is usually preferred in order to observe a high signal output. However, it has to be pointed out that there are a few papers reporting enhancement of the fluorescence upon copper(II) complexation.[21] This has been achieved for instance by controlling either the interaction of the metal ion with the receptor in order to reduce the metal−fluorophore interaction or acting directly modifying the nature of the fluorophore. Thus, Bharadwaj has reported that the use of preorganised cryptands can induce unusual geometries that suppress the redox activity of the coordinated Cu^{II} cation, inhibiting the interaction between the copper(II) and the photo-excited state of anthryl fluorescent groups.[21a] In a recent paper Samanta reports the development of a receptor that suffers enhancement upon addition of metal ions by simply using electron-deficient fluorophores.[21b]

In our case we believe that the anomalous behaviour observed for Cu^{2+} could be ascribed to the presence of the ferrocenyl groups (see below). It is well known that ferrocene is an efficient fluorescence quencher via both energy-transfer and reductive quenching processes.[10d] In our case, the occurrence of an electron-transfer mechanism is thermodynamically favourable as it can be demonstrated from electrochemical and photophysical data. The free energy of the process (anthracene + Fc = anthracene$^-$ + Fc$^+$) in which the ferrocene is acting as reductive quencher can be calculated by the equation of Rehm-Weller, where $E^0_{Fc^+/Fc}$ and E^0_{fl/fl^-} are the redox potentials of the processes $Fc^+ + 1e^- \rightarrow Fc$ and $fl + 1e^- \rightarrow fl^-$ (fl = fluorophore), respectively, and λ can be obtained from the emission fluorescence spectrum.[22]

$$\Delta G = -\frac{hcN_A}{\lambda} + F\left[E^o_{Fc^+/Fc} - E^o_{fl/fl^-}\right]$$

Redox potentials were measured in dry acetonitrile (0.1 M tetrabutylammonium perchlorate; 25 °C). The ligand L^2 shows a reversible oxidation process at 450 mV and a reduction irreversible wave at −2.2 V versus SCE, which have been ascribed to the oxidation of the ferrocenyl and to the reduction of the anthryl groups, respectively. Taking into account these data, ΔG is −33.6 kJ/mol indicating that photo-induced electron transfer from the ferrocene to the anthryl fluorophore can occur. Additionally, an energy-

transfer quenching mechanism could also be possible.[10d] The quenching induced by the ferrocenyl group is supported by experimental data, thus the quantum yield of the ferrocene-containing ligand L^1 in acetonitrile ($\varphi = 0.0030$) is lower than that of L^6 ($\varphi = 0.0055$) or L^5 ($\varphi = 0.0080$). This difference in quantum yield is ascribed to the presence of ferrocenylmethyl groups in L^1. In fact, when stoichiometric amounts of H_2O_2 were added to L^1, the solution turned green-blue (due to the oxidation of ferrocene) and there was a fluorescence enhancement (quantum yield of ca. 0.0042).

As stated above, Cu^{2+} is also a well-known quencher. From a thermodynamic point of view both energy-transfer or electron-transfer processes are possible when Cu^{2+} ions are added to L^1 or L^2 solutions. Bearing this in mind, one would expect that the presence of Cu^{2+} would reduce even more the emission intensity of the receptors. In contrast, an enhancement of the fluorescence is observed. However, it has to be taken into account that, although the presence of Cu^{2+} gives new quenching routes, it might also inhibit some. Namely, strong coordination to nitrogen atoms can inhibit the photo-electron transfer from the lone pair of the amine to the fluorophore. Additionally, it might also happen that the presence of Cu^{2+} hinders the energy-transfer quenching process from the ferrocene to the anthracene due to the increase of the rigidity of the receptor upon coordination, thereby disfavouring the nonradiative decay processes. Furthermore, and especially for L^2, the cation Cu^{2+} induces a significant cathodic electrochemical shift of the ferrocenyl redox potential of ca. 60 mV in dioxane/water and of ca. 100 mV in acetonitrile making electron transfer from the ferrocene to the anthracene thermodynamically less favourable. In resume, although Cu^{2+} itself might introduce energy- and electron-transfer quenching paths it also inhibits other quenching mechanisms, the overall effect being an emission fluorescence enhancement.

Anion Sensing

The free receptors L^1 and L^2 are anion-insensitive. Thus, addition of different anions such as phosphate, sulfate, nitrate, fluoride, chloride, bromide, etc. to solutions of these receptors in acetonitrile or dioxane/water resulted in no variation of either electrochemical or photochemical properties. This contrasts with the anion-sensing ability found for the $[Cu(L^2)]^{2+}$complex (see below). In this sense it is noticeable that one of the most interesting features in the crystallographic characterisation of the $[Cu(L^2)]^{2+}$ complex is the formation of a host molecule containing a Cu^{2+} ion surrounded by a cavity built with three ferrocenylmethyl and one anthrylmethyl group. This is a peculiar topology. The interaction (either covalent or electrostatic) of anions with the Cu^{2+} charged cation might allow a close proximity between the guest (anion) and the electro-active ferrocenyl or the photo-active anthryl signalling units. In order to check this possible co-operative effect, the anion-sensing properties of the $[Cu(L^2)]^{2+}$complex was investigated electrochemically and by fluorescence studies. Table 5 summarises the electrochemical data in acetonitrile. The most remarkable effect is the very large cathodic shift of 210 mV observed upon fluoride addition. Other halide anions such as chloride and bromide gave much lower cathodic shifts (ca. 20 mV). Thus, the $[Cu(L^2)]^{2+}$complex is able to selectively and electrochemically sense fluoride over other halide anions.[23] The $H_2PO_4^-$ anion also induces an important electrochemical cathodic shift of 150 mV whereas the response in the presence of HSO_4^-, and NO_3^- is remarkably lower.[24] Fluorescence studies on the $[Cu(L^2)]^{2+}$complex upon addition of anions in acetonitrile were also carried out. Table 5 summarises the anion response. The addition of Cl^-, Br^-, I^-, and HSO_4^- had no effect, whereas nitrate, fluoride and $H_2PO_4^-$ induced an enhancement of the fluorescence intensity of the $[Cu(L^2)]^{2+}$ complex of 26%, 20%, and 17%, respectively. From fluorimetric/spectroscopic titration well-defined isosbestic points were observed indicating the formation of 1:1 complexes. The logarithms of the stability constants obtained by least-squares analysis of the titration curves were 4.5 ± 0.2; 4.2 ± 0.1, and 4.4 ± 0.3 for nitrate, fluoride, and dihydrogenophosphate, respectively.[25]

Table 5. Photophysical and electrochemical anion response of $[Cu(L^2)]^{2+}$ upon addition of 10 equiv. of the corresponding anion in acetonitrile

Conclusions

We can conclude that L^1 and L^2 are rare receptors, containing two signalling subunits whose response against metal cations can be controlled by the type of output signal (electrochemical shift or changes in fluorescence emission) used to trace information from the solution. This is resumed in Table 6 that shows the selective response obtained by the oxaaza ring 1,4,10-trioxa-7,13-diazacyclopentadecane or the polyaza ring 1,4,8,11-tetraazacyclotetradecane depending on their functionalisation. Difunctionalised systems could have advantages over monofunctionalised ones because the former might act as multiple-sensing receptors. Thus, L^1 responds to Pb^{2+} using electrochemical methods, but is a Cu^{2+} chemosensor if emission intensity is used as output signal. In a similar way, L^2 electrochemically responds to Cu^{2+}, Zn^{2+}, and Cd^{2+} but it only gives emission response against Cu^{2+}. A similar control effect on the sens-

Table 6. Electrochemical and photophysical response against certain transition metal ions by the functionalised binding domains 1,4,10-trioxa-7,13-diazacyclopentadecane and 1,4,8,11-tetraazacyclotetradecane functionalised with ferrocene and anthracene

	Ferrocene	Anthracene	Ferrocene and Anthracene
1,4,10-Trioxa-7,13-diazacyclopentadecane	Pb^{2+}, Cd^{2+}, Hg^{2+}	Hg^{2+}	Electrochemical: Pb^{2+} Photophysical: Cu^{2+}
1,4,8,11-Tetraazacyclotetradecane	Cu^{2+}, Zn^{2+}, Cd^{2+}	–	Electrochemical: Cu^{2+}, Zn^{2+}, Cd^{2+} Photophysical: Cu^{2+}

ing process depending on the output signal, is observed for the $[Cu(L^2)]^{2+}$complex in its interaction with anions. Thus, the maximum electrochemical shift is observed in the presence of fluoride, whereas the largest emission fluorescence enhancement was observed upon addition of the poorly coordinating anion nitrate.

Experimental Section

General Remarks: All commercially available reagents were used without further purification. Air/water-sensitive reactions were performed in flame-dried glassware under argon. Dioxane and acetonitrile were dried with CaH_2 and distilled prior to use.

L^1: The free base 1,4,10-trioxa-7,13-diazacyclopentadecane (400 mg, 1.832 mmol) was heated under reflux in dry dichloromethane with 9-(chloromethyl)anthracene (410 mg, 1.805 mmol) in the presence of triethylamine (560 mg, 5.5 mmol). After 6 h, the mixture was cooled to room temperature, basic water was added and the organic phase separated, dried with anhydrous magnesium sulfate, filtered, and concentrated to dryness. The resulting oil was dissolved in dichloromethane and purified by chromatography on alumina using dichloromethane/ethanol (100:1, v/v) as eluent. This allowed us to isolate the compound 7-anthracenylmethyl-1,4,10-trioxa-7,13-diazacyclopentadecane. Yield 450 mg, 56%. This compound (415 mg, 1.015 mmol) was heated under reflux in dry acetonitrile with (ferrocenylmethyl)trimethylammonium iodide (508 mg, 1.32 mmol) in the presence of potassium carbonate. After 24 h, the reaction mixture was filtered and the orange solution concentrated to dryness. The product L^1 was obtained after chromatography on alumina using dichloromethane/ethanol (100:1, v/v) as eluent. Yield 615 mg, 67%. ^{1}H NMR ($CDCl_3$): δ = 2.65 (dt, 4 H, CH_2), 2.81 (t, 2 H, CH_2), 2.96 (t, 2 H, NCH_2), 3.55 (m, 14 H, CH_2), 4.09 (t, 2 H, C_5H_4), 4.10 (s, 5 H, C_5H_5), 4.14 (t, 2 H, C_5H_4), 4.55 (s, 2 H, CH_2), 7.48 (m, 4 H, CH_{anthr}), 8.00 (d, 2 H, CH), 8.40 (s, 1 H, CH), 8.55 (d, 2 H, CH_{anthr}). ^{13}C {^{1}H} NMR ($CDCl_3$): δ = 52.1, 53.2, 53.5, 53.6, 54.2, 55.5 (CH_2), 67.9, 68.4, 69.1 (CH, Cp), 70.1, 70.3, 70.4 (CH_2O), 124.7, 125.2, 125.5, 127.3, 128.8, 130.3, 131.3, 131.3 (CH_{anthr}). MS (FAB): *m*/*z* = 607 [M^+]. $C_{36}H_{42}FeN_2O_3{\cdot}3H_2O$ (660): calcd. C 65.5, H 6.4, N 4.3; found C 65.5, H 6.3, N 4.2.

L^2: The polyazacycloalkane 1,4,8,11-tetraazacyclotetradecane (520 mg, 2.6 mmol) was heated under reflux in absolute ethanol with 9-(chloromethyl)anthracene (560 mg, 2.6 mmol) in the presence of triethylamine. After 16 h, the mixture was cooled to room temperature and the solvent was removed. To the residue basic water and dichloromethane were added and the organic phase was separated, dried with anhydrous magnesium sulfate, filtered, and concentrated to dryness. The resulting oil was dissolved in dichloromethane and purified by chromatography on alumina using dichloromethane/ethanol (100:3, v/v) as eluent. This allowed us to isolate the compound 1-anthrylmethyl-1,4,8,11-tetraazacyclotetradecane. Yield 280 mg, 28%. This compound (280 mg, 0.717 mmol) was heated under reflux in dry acetonitrile with (ferrocenylmethyl)trimethylammonium iodide (1103 mg, 2.868 mmol) in the presence of potassium carbonate. After 24 h, the reaction mixture was filtered and the orange solution concentrated to dryness. The product L^2 was obtained after column chromatography on alumina using dichloromethane/ethanol (100:1, v/v) as eluent. Yield 565 mg, 80%. ^{1}H NMR ($CDCl_3$): δ = 1.55 (q, 2 H, $CH_2CH_2CH_2$), 1.75 (q, 2 H, $CH_2CH_2CH_2$), 2.00 (t, 4 H, N$CH_2CH_2CH_2$N), 2.28−2.70 (m, 12 H, NCH_2CH_2N), 3.36, 3.28, 3.15 (s, 6 H, CH_2), 3.84 (t, 2 H, C_5H_4), 3.90 (t, 2 H, C_5H_4), 3.93 (s, 5 H, C_5H_5), 3.99 (t, 2 H, C_5H_4), 4.01 (s, 5 H, C_5H_5), 4.02 (t, 4 H, C_5H_4), 4.05 (s, 5 H, C_5H_5), 4.07 (t, 2 H, C_5H_4), 4.31 (s, 2 H, CH_2), 7.48 (m, 4 H, CH_{anthr}), 8.00 (d, 2 H, CH), 8.40 (s, 1 H, CH), 8.55 (d, 2 H, CH_{anthr}).^{13}C {^{1}H} NMR ($CDCl_3$): δ = 24.1, 24.8 ($CH_2CH_2CH_2$), 47.0, 49.0, 49.6, 49.7, 50.3, 50.4, 51.0, 51.3, 51.4, 53.3, 53.4, 54.1 (CH_2N), 67.6, 67.7, 68.2, 68.3, 68.4, 70.1, 70.2, 70.3 (CH, Cp), 124.8, 125.1, 126.1, 127.0, 128.7, 131.2, 131.4, 131.5 (CH_{anthr}). MS (FAB): 985 [M^+]. $C_{56}H_{64}Fe_3N_4{\cdot}3H_2O$ (1014): calcd. C 67.0, H 6.6, N 5.2; found C 67.1, H 6.7, N 5.4.

Structure Determination of $[H_2L^1][PF_6]_2{\cdot}0.5CH_2Cl_2{\cdot}H_2O$: $C_{36.5}H_{44}ClF_{12}FeN_2O_4P_2$, M = 955.98, triclinic, space group $P\bar{1}$, a = 12.176(2), b = 12.787(2), c = 15.589(2) Å, α = 95.716(11), β = 110.088(12), γ = 106.236(12) °, Z = 2, V = 2136.1(5) Å^3, $D_{calcd.}$ = 1.486 g cm^{-3}, λ(Mo-K_α) = 0.71069 Å, T = 293(2) K, μ(Mo-K_α) = 0.583 mm^{-1}. Measurements were carried out using a Siemens P4 diffractometer with graphite-monochromated Mo-K_α radiation on a yellow crystal of dimensions 0.10 × 0.20 × 0.27 mm. A total of 5844 reflections was collected of which 5532 were independent (R_{int} = 0.0143). Lorentz, polarisation and absorption (ψ-scan, max. and min. transmission 0.541 and 0.014) corrections were applied. The structure was solved by direct methods (SHELXTL)[26] and refined by full-matrix least-squares analysis on F^2 (SHELXTL). The refinement converged at $R1$ = 0.084 [$F > 4\sigma(F)$] and $wR2$ = 0.249 (all data). Largest peak and hole in the final difference map +0.75 and −0.41 e Å^{-3}.

Structure Determination of $[CuL^2][PF_6]_2{\cdot}CH_2Cl_2$: $C_{59}H_{66}Cl_2CuF_{12}Fe_3N_4P_2$, M = 1423.09, monoclinic, space group $P2_1/c$, a = 14.419(5), b = 35.644(9), c = 13.282(4) Å, β = 104.20(3) °, Z = 4, V = 6618(3) Å^3, $D_{calcd.}$ = 1.428 g cm^{-3}, λ(Mo-K_α) = 0.71069 Å, T = 293(2) K, μ(Mo-K_α) = 1.163 mm^{-1}. Measurements were carried out using a Siemens P4 diffractometer with graphite-monochromated Mo-K_α radiation on a yellow crystal of dimensions 0.15 × 0.15 × 0.23 mm. A total of 9086 reflections was collected of which 8645 were independent (R_{int} = 0.0985). Lorentz, polarisation and absorption (ψ-scan, max. and min. transmission 0.3133 and 0.2912) corrections were applied. The structure was solved by direct methods (SHELXTL) [26] and refined by full-matrix least-squares analysis on F^2 (SHELXTL). The refinement converged at $R1$ = 0.1008 [$F > 4\sigma(F)$] and $wR2$ = 0.3609 (all data). Largest peak and hole in the final difference map +0.78 and −0.63 e Å^{-3}.

Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-158668 ($[H_2L^1][PF_6]_2 \cdot 0.5CH_2Cl_2 \cdot H_2O$) and -158669 ($[CuL^2][PF_6]_2 \cdot CH_2Cl_2$). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Physical Measurements: The fluorescence behaviour was studied with a FS900CDT Steady State T-Geometry Fluorimeter, Edinburgh Analytical Instruments. All solutions for photophysical studies were previously degassed. The concentration of ligands and metal ions were ca. 1.0×10^{-4} M in dioxane/water (the metal ions were perchlorate or nitrate salts of Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, and Pb^{2+}). The fluorescence quantum yield of anthracene [27] in acetonitrile was used as standard and taken to be 0.36. In order to obtain the quantum yield of the new ligands, those were dissolved in acetonitrile, their absorbance adjusted to ca. 0.15 and then compared to the standard. The ^1H NMR spectra were recorded with a Varian Gemini spectrometer. Chemical shifts are reported in ppm downfield from the TMS signal. Spectra taken in $CDCl_3$ were referenced to residual $CHCl_3$. Potentiometric titrations were carried out in 1,4-dioxane/water (70:30, v/v; 0.1 M KNO_3) using a reaction vessel that was thermostatically controlled using water at 25.0 ± 0.1 °C under nitrogen. The titrant was added by a Crison microburete 2031. The potentiometric measurements were made using a Crison 2002 pH-meter and a combined glass electrode. The titration system was automatically controlled using a PC. The electrode was calibrated as a hydrogen concentration prove by titration of well-known amounts of HCl with CO_2-free KOH solution and determining the equivalent point by the Gran's method which gives the standard potential E'° and the ionic product of water ($K'_w = [H^+][OH^-]$). The concentration of the metal ions was determined using standard methods. The computer program SUPERQUAD [28] was used to calculate the protonation and stability constants. The titration curves for each system (ca. 250 experimental points corresponding to at least three titration curves, pH = −log [H] range investigated 2.2−10.3, concentration of the ligand and metal ion being ca. 1.2×10^{-3} M) were treated either as a single set or as separated entities without significant variations in the values of the stability constant. Finally, the data sets were merged and treated simultaneously to give the stability constant. Electrochemical data were carried out in 1,4-dioxane/water (70:30, v/v) and in dry acetonitrile, with a programmable function generator Tacussel IMT-1, connected to a Tacussel PJT 120−1 potentiostat. The concentration of ligands and metal ions were ca. 1.0×10^{-3} M in dioxane/water (the metal ions were perchlorate or nitrate salts of Cu^{2+} and Pb^{2+}; metal-to-ligand ratio 1:1). The working electrode was platinum with a saturated calomel reference electrode separated from the test solution by a salt bridge containing the solvent/supporting electrolyte. The auxiliary electrode was platinum wire. $E_{1/2}$ values were measured by rotating-disc electrode experiments (scan speed 10 mVs^{-1}, rotating speed 7000 revolutions min^{-1}).

Acknowledgments

We thank the DGICYT (proyectos PB98−1430-C02−02, 1FD97−0508-C03−01 and AMB99−0504-C02−01) for support. F. S. also thanks the Ministerio de Ciencia y Tecnología for a Doctoral Fellowship.

Thermal Isomerisation of Tris(silyl)hydroxylamines to Silylaminodisiloxanes – Experimental and Quantum Chemical Results

Stefan Schmatz,*[a] Friedhelm Diedrich,[b] Christina Ebker,[b] and Uwe Klingebiel*[b]

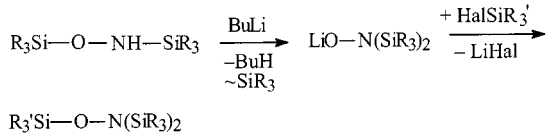
Keywords: Silicon / Hydroxylamines / Isomerisation / Ab initio calculations / Transition states

O-Lithio-*N*,*N*-bis(trimethylsilyl)hydroxylamide, LiO–N-$(SiMe_3)_2$, reacts with $ClSiMe_2H$ to give $HMe_2Si–O–N(SiMe_3)_2$ (**1**), while $LiO–N(SiMe_2CMe_3)_2$ reacts with $C_6H_5SiF_3$ to give $C_6H_5SiF_2–O–N(SiMe_2CMe_3)_2$ (**2**). **2** isomerises in solution to give *N*,*O*-bis(*tert*-butyldimethylsilyl)-*N*-[difluoro(phenyl)silyl]hydroxylamine (**3**). Boiling of **1** leads to the structurally isomeric silylaminodisiloxane, $Me_3Si–O–SiMe_2–NH–SiMe_3$ (**4**), while boiling of **3** leads to the isomeric $Me_3CSiMe_2–O–Si(Me)CMe_3–NMe–SiF_2C_6H_5$ (**5**). Quantum chemical calculations (B3LYP) on the thermal rearrangement of tris(silyl)hydroxylamines to silylaminodisiloxanes for the model compounds $H_3Si–O–N(SiMe_3)_2$ (**A**), $Me_3Si–O–N(SiH_3)_2$ (**B**), $Me_3Si–O–N(SiH_3)SiMe_2F$ (**C**), and $Me_3Si–O–N(SiMe_2F)SiMeF_2$ (**D**) demonstrate that *N*-bonded silyl units, e.g. SiH_2 in model compound **B** or SiFMe in model compound **D**, preferentially insert into the N–O bond. The reaction mechanisms and the structures of the transition states are discussed in detail.
(© Wiley-VCH Verlag GmbH, 69451 Weinheim, Germany, 2002)

Introduction

The most dramatic difference between the chemistry of silylhydroxylamines and that of organylhydroxylamines is the ability of the former to undergo anionic, radical, and thermal intramolecular rearrangements.[1–7] The first example of a 1,2-anionic rearrangement of a silyl group from an oxygen atom to a nitrogen atom was observed for lithiated *N*,*O*-bis(silyl)hydroxylamines.[1,2,8] Although lithiobis(silyl)hydroxylamines have been successfully used in the synthesis of tris(silyl)hydroxylamines since the end of the 1960s, the first crystal structures of these compounds were described only two years ago.[6,7] It was found that lithium derivatives of *N*,*O*-bis(silyl)hydroxylamines form *O*-lithio-*N*,*N*-bis(silyl)hydroxylamides in the solid state.

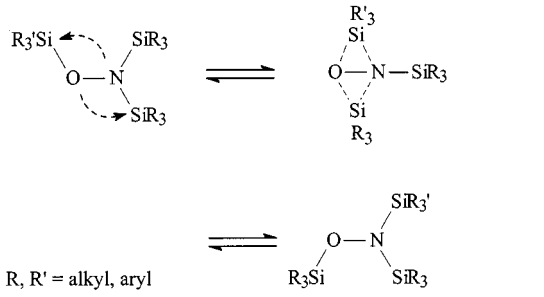
Depending on the bulkiness of the silyl groups and on the solvent used, $(Li–O)_{2,3,4}$ four-, six-, or eight-membered rings were formed,[6,7] and dimeric, trimeric, or tetrameric *O*-lithio-*N*,*N*-bis(silyl)hydroxylamides could be isolated. This indicated that silyl group migration from the oxygen atom to the nitrogen atom had occurred. In the reactions of halosilanes with these lithium salts, the new silyl group is attached to the oxygen atom in each case [Equation (1)].



(1)

R, R' = alkyl, aryl

1,2-Silyl shifts in *neutral* organosilylhydroxylamines have been known since 1973,[1,2,9] when Frainnet and Nowakowski described an exchange of trialkylsilyl groups in bis(organosilyl)hydroxylamines.[9] Later, West and co-workers found a reversible rearrangement involving positional exchange between the organosilicon groups on the oxygen and the nitrogen atom in tris(silyl)hydroxylamines, which they suggested to proceed via a dyotropic transition state[1,2,10,11] [Equation (2)].



(2)

R, R' = alkyl, aryl

In 1998, we studied the rearrangement of *O*-(fluorosilyl)-*N*,*N*-bis(trimethylsilyl)hydroxylamines to the isomeric *N*-
